Abstract

Two novel heptanuclear trigonal prismatic $LnNi_6$ clusters, $[SmNi_6(Gly)_6(Ac)(\mu_3\text{-}OH)_3(\mu_2\text{-}H_2O)_2(im)_6]\cdot(ClO_4)_5\cdot(H_2O)_5$ (**1**) and $[GdNi_6(Gly)_6Cl_3(OH)_3(py)_6]\cdot Cl\cdot(ClO_4)_2\cdot(H_2O)_5$ (**2**), were synthesized through self-assembly, and were characterized by X-ray structure analyses. Complex **1** crystallizes in the monoclinic *Cc* space group ($a = 17.9722(3)$ Å, $b = 16.3906(2)$ Å, $c = 25.3463(3)$ Å, $\beta = 99.832(1)°$ and $Z = 4$). Complex **2** attributes to the monoclinic $P2(1)/c$ space group ($a = 15.5408(2)$ Å, $b = 20.0516(4)$ Å, $c = 23.8204(4)$ Å, $\beta = 100.096(1)°$ and $Z = 4$). **1** has six terminal imidazole ligands, while **2** has six terminal pyridine ligands. The two complexes both have a $[LnNi_6(Gly)_6(\mu_3\text{-}OH)_3]^{6+}$ core. The magnetic measurements reveal that **1** exhibits an overall antiferromagnetic interaction, while **2** exhibits a ferromagnetic interaction.

1. Introduction

Polynuclear mixed-metal clusters are of considerable interest owning to their special physicochemical properties arising from the close proximity of dissimilar metal ions. For about three decades, the design and characterization of molecular complexes comprising simultaneously of 3d and 4f metal ions have been one of the interesting research areas [1,2]. Up until now most of the studies were focused on low-nuclearity 3d–4f compounds [2], and similar research about high-nuclearity compounds is still very limited [3–7]. Therefore the design and syntheses of high-nuclearity 3d–4f clusters are still significant.

In order to synthesize 3d–4f heteronuclear compounds, it is necessary to find suitable ligands that can associate the two different metal ions. Many chelating ligands such as pyridones [8] , Schiff-base [9], oxalato [10], oximates [11] or oxamides [12], cyano groups [13] and carboxylic acids [14] have been used to construct heterometallic compounds. Recently we found amino acid, one of the most important biological ligands, is also a good candidate for such a purpose [3c,7]. The ligand can use its amino and carboxylate groups to coordinate to 3d and 4f metal ions simultaneously. But of course, during the synthetic process it is very necessary to choose a suitable pH window so that the unprotonated amino group can take part in coordination. As the ligand has a variety of coordinated modes, its use for the synthesis of 3d–4f heteronuclear compounds may lead to much more complex and intriguing structures than using a simple carboxylic acid [3c,7].

doi:10.1016/j.poly.2005.04.030

Up until now several heptanuclear 3d–4f clusters with the general formula of LnM_6 (M means transition metal) have been reported [3]. They have the structure motif of an octahedron ($LnNi_6$) [3a,b], trigonal prism ($LnNi_6$, $LnCu_6$) [3c,d] and wheel ($LnCu_6$) [3e]. We have reported a series of novel heptanuclear $LnNi_6$ trigonal prismatic clusters with different edge ligands [3c]. The complexes all have a $[LnNi_6(Gly)_6(\mu_3\text{-}OH)_3(H_2O)_6]^{6+}$ core, but different edge ligands. In this paper we report two new heptanuclear $LnNi_6$ clusters which have the same $[LnNi_6(Gly)_6(\mu_3\text{-}OH)_3]^{6+}$ core but different terminal ligands: $[SmNi_6(Gly)_6(Ac)(\mu_3\text{-}OH)_3(\mu_2\text{-}H_2O)_2(im)_6]\cdot(ClO_4)_5\cdot(H_2O)_6$ (**1**), with imidazole (im) as terminal ligands, and $[GdNi_6(Gly)_6Cl_3(OH)_3(py)_6]\cdot Cl\cdot(ClO_4)_2\cdot(H_2O)_5$ (**2**) with pyridine (py) as terminal ligands. The crystal structures of these clusters are reported and their magnetic properties are investigated.

2. Experimental

2.1. Materials and instrumentation

$Ln(ClO_4)_3\cdot 6H_2O$ was synthesized by dissolving Ln_2O_3 in an excess amount of perchloric acid. Other starting materials were of reagent grade and used without further purification. Elemental analyses were carried out by the Elemental Analysis Lab of our Institute. Magnetic measurements were carried out with a Quantum Design PPMS model 6000 magnetometer.

2.2. Synthesis of the complexes

2.2.1. $[SmNi_6(Gly)_6(Ac)(\mu_3\text{-}OH)_3(\mu_2\text{-}H_2O)_2(im)_6]\cdot(ClO_4)_5\cdot(H_2O)_5$ (**1**)

To an aqueous solution (10 ml) of $Sm(ClO_4)_3\cdot 6H_2O$ (0.556 g, 1 mmol), $Ni(Ac)_2\cdot 4H_2O$ (1.493 g, 6 mmol) and glycine (0.45 g, 6 mmol) were added. Then the pH value of the reaction mixture was carefully adjusted to about 6.6 by slow addition of 0.1 M NaOH solution. After 2 h of stirring, 6 mmol imidazole were added and the solution was stirred for half an hour. Then it was filtrated to remove the precipitate and placed in a desiccator filled with phosphorus pentaoxide. Green crystals were obtained about a month later. Yield: 0.41 g, 19.6%. *Anal.* Calc. for $C_{32}H_{68}Cl_5N_{18}Ni_6O_{44}Sm$: C, 18.40; H, 3.28; N, 12.07. Found: C, 18.16; H, 3.13; N, 11.88%.

2.2.2. $[GdNi_6(Gly)_6Cl_3(OH)_3(py)_6]\cdot Cl\cdot(ClO_4)_2\cdot(H_2O)_5$ (**2**)

The above procedure was repeated except that $Gd(ClO_4)_3\cdot 6H_2O$, $NiCl_2\cdot 6H_2O$ and pyridine were used. Yield: 0.37 g, 19.4%. *Anal.* Calc. for $C_{42}H_{67}Cl_6GdN_{12}Ni_6O_{28}$: C, 26.41; H, 3.54; N, 8.80. Found: C, 26.12; H, 3.24; N, 8.50%.

[a] $R = \sum(||F_o| - |F_c||)/\sum|F_o|$.

[b] $R_w = \{\sum w[(F_o^2 - F_c^2)^2]/\sum w[(F_o^2)^2]\}^{1/2}$, $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, $P = (F_o^2 + F_c^2)/3]$.

2.3. X-ray crystallography

Intensity data for the complexes were collected at 293(2) K on a Siemens Smart/CCD area-detector diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å). Data reduction and unit cell refinement were performed with Smart-CCD software [15]. The structures were solved by direct methods using SHELXS-97 [16] and were refined by full-matrix least squares methods using SHELXL-97. Anisotropic displacement parameters were refined for all non-hydrogen atoms. Final $R\sum||F_o| - F_c||)/\sum|F_o|$, $R_w = \{\sum w[(F_o^2 - F_c^2)^2]/\sum w[(F_o^2)^2]\}^{1/2}$, with $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ [where $P = (F_o^2 + F_c^2)/3$]. The crystallographic data are summarized in Table 1.

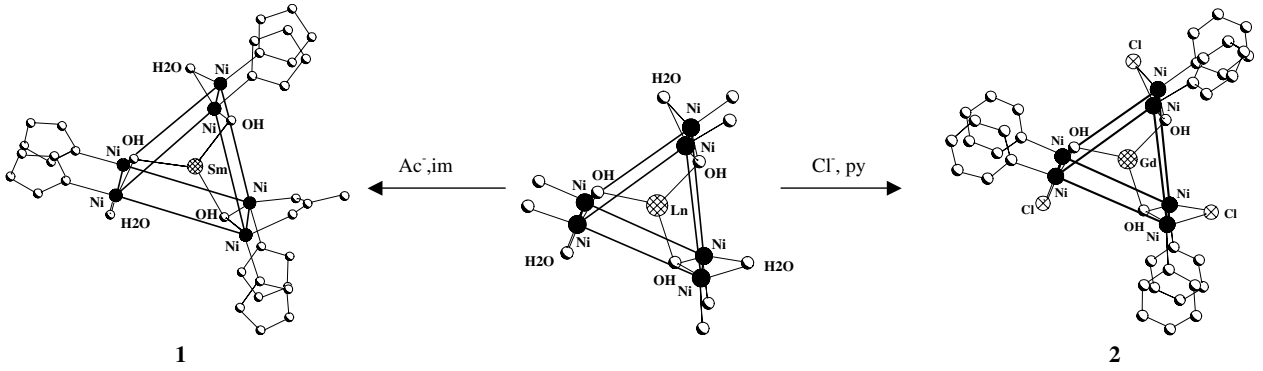
3. Results and discussion

3.1. Syntheses of the complexes

We have reported that the three μ_2-OH_2 edge ligands of the $[LnNi_6(Gly)_6(\mu_3\text{-}OH)_3(H_2O)_6(\mu_2\text{-}OH_2)_3]^{6+}$ species can be partly or wholly replaced by glycine or Cl^- and a series of novel heptanuclear $LnNi_6$ trigonal prismatic clusters can be obtained [3c]. In this paper, complex **1** has one acetate and two μ_2-OH_2 edge ligands, while **2** has three μ_2-Cl edge ligands.

Complexes **1** and **2** also have six im and py terminal ligands, respectively. Although further evidences is

lacking, the strong structural relationships between **1**, **2** and $[LnNi_6(Gly)_6(\mu_3\text{-}OH)_3(H_2O)_6(\mu_2\text{-}OH_2)_3]^{6+}$ suggests a possible terminal ligand substitution reaction, as shown in Scheme 1. This is reminiscent of other famous poly-nuclear clusters whose terminal sites are occupied by solvent molecules and could be substituted by pyridine, carboxylic acid or other ligands, such as trinuclear clusters of the type $[M_3(\mu_3\text{-}O)(\mu\text{-}RCO_2)_6L_3]^{n+}$ (L = neutral monodentate ligand) which widely occur in a variety of first-, second- and third-row transition-metal ions [17], and polynuclear manganese clusters [18]. However, we notice a similar reaction is still very rare in 3d–4f



Scheme 1. The syntheses of **1** and **2** through the possible substitution reaction of the species $[LnNi_6(Gly)_6(\mu_3\text{-}OH)_3(H_2O)_6(\mu_2\text{-}OH_2)_3]^{6+}$.

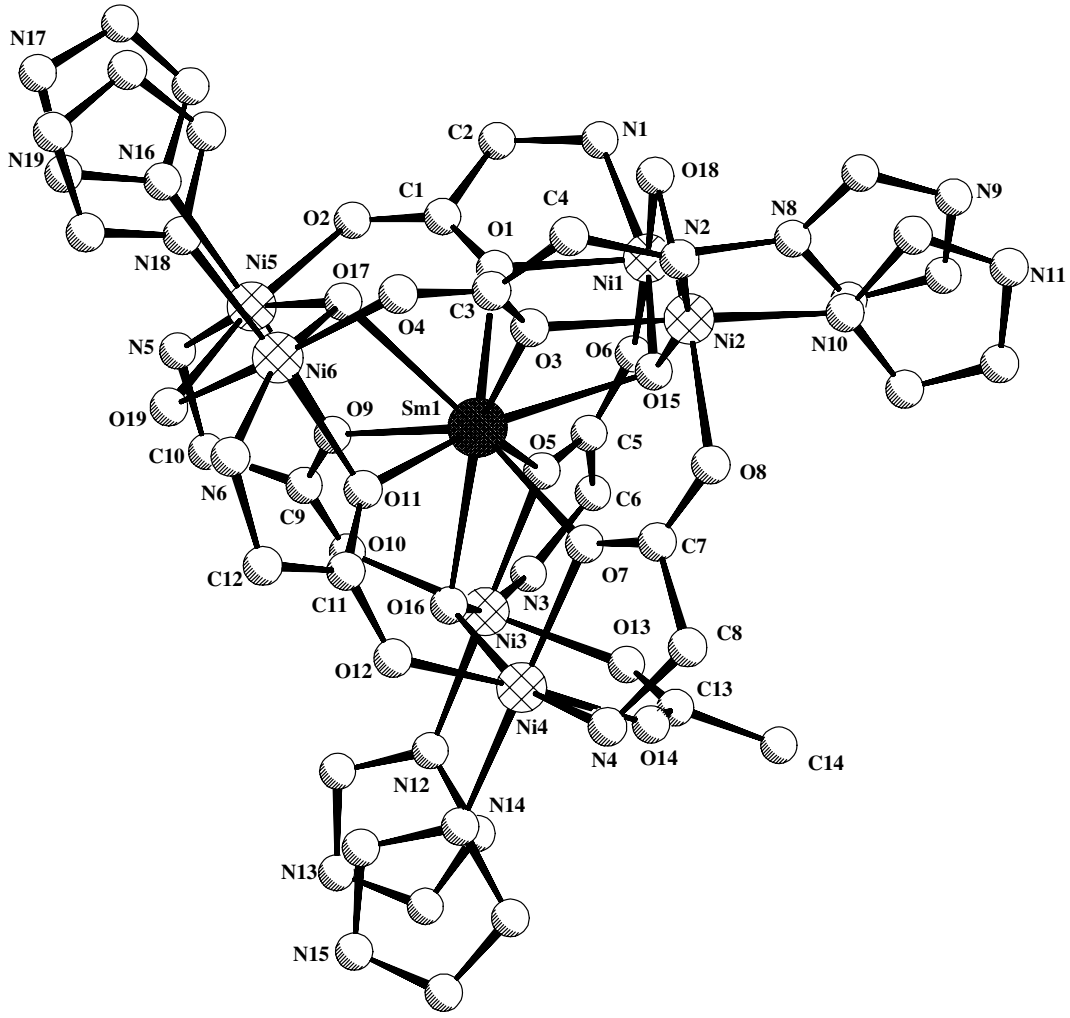


Fig. 1. A view of the cation of complex **1** with the atom numbering scheme.

heteronuclear clusters. This strategy may help us to design and synthesize a large variety of 3d–4f clusters.

3.2. The structure of complex *1*

The structure of the cation is shown in Fig. 1. Selected bond distances and bond angles are shown in Table 2. Fig. 1 shows that in **1** six Ni^{2+} ions form a large trigonal prism and a Sm^{3+} ion is situated at the center. The Sm···Ni distance is about 3.52 Å, longer than the Tb···Cu distance (3.45 Å) in another trigonal prismatic $TbCu_6$ cluster [12] with iminodiacetic acid as a ligand, and close to the Ln···Ni distances in the former reported series of trigonal prismatic $LnNi_6$ clusters [3c]. The six nickel ions belong to two bases (Ni1, Ni3, Ni5 and Ni2, Ni4, Ni6). In each base, with the help of three $[3.1_12_{23}1_3]$-coordinated glycinato ligands, the three Ni^{2+} ions are connected to form an equilateral triangle with a side distance of about 5.3 Å (Ni···Ni distance). The two bases are connected by one acetate (Ni3 and Ni4) and two μ_2-H_2O ligands (Ni1 and Ni2, Ni5 and Ni6). The Ni3···Ni4 distance is about 3.581 Å, while those of Ni1···Ni2, and Ni5···Ni6 are 3.345 and 3.335 Å, respectively. This causes a slight distortion of the metal skeleton. In other words, a 3.0° torsion angle may be formed between the two bases. This value is comparable with those (4.5°) in other heptanuclear trigonal prismatic $LnNi_6$ clusters [3c].

As shown in Fig. 2, the centered Sm^{3+} ion is nine-coordinated in a tricapped trigonal prismatic geometry and has an O_9 donor set. The six carboxyl oxygen atoms from six glycinato ligands form six apexes, and the three oxygen atoms from three μ_3-OH^- groups form three caps. The Sm–O bond lengths are all about 2.45 Å.

Ni(1), Ni(2), Ni(5) and Ni(6) all have N_2O_4 donor sets which consist of two nitrogen atoms from a glycinato and an im ligand, respectively, two carboxyl

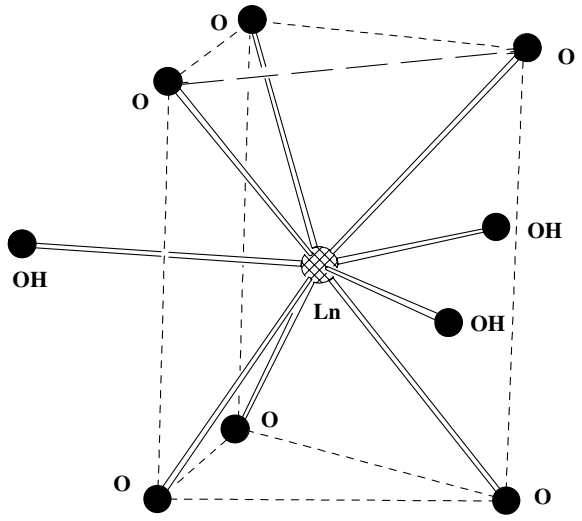

Fig. 2. Coordination polyhedron of the Ln^{3+} ion in the heptanuclear clusters.

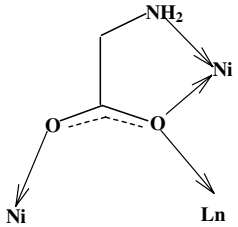

$[3.1_12_{23}1_3]$

Scheme 2. The $[3.1_12_{23}1_3]$-coordinate mode of the glycinato ligand indicated by the Harris notation [19].

oxygen atoms from two glycinato ligands, one μ_2-H_2O and one μ_3-OH^- group. The distances of Ni^{2+} to the μ_2-H_2O are about 2.3 Å, slightly longer than other Ni–O and Ni–N distances (all about 2.0 Å). To Ni(1), small deviations of bond angles from the value of 180° of the idealized octahedral geometry are found for angles N(8)–Ni(1)–O(1) [176.0(4)°], O(15)–Ni(1)–N(1) [162.5(5)°] and O(6)–Ni(1)–O(18) [168.7(4)°], implying it has a slightly distorted octahedral configuration. Ni(2), Ni(5) and Ni(6) show similar configurations. Ni(3) and Ni(4) also have N_2O_4 donor sets which are almost the same as the above-mentioned four Ni^{2+} ions, except a carboxylate oxygen atom was used instead the μ_2-H_2O. They also have slightly distorted octahedral configurations.

There are two μ_2-H_2O edge ligands (O18 and O19) in the cluster. Each of them coordinates to two corresponding Ni^{2+} ions from the two bases with a distance of about 2.3 Å. The ∠Ni(2)–O(18)–Ni(1) and ∠Ni(6)–O(19)–Ni(5) are about 94.8° and 92.8°, respectively. Each cation also has three μ_3-OH^- groups (O15, O16 and O17). They are located in almost the same plane with the Sm^{3+} ion. Each coordinates to the central Sm^{3+} ion and the two corresponding Ni^{2+} ions from different bases.

In the complex the glycinato ligand adopts a $[3.1_12_{23}1_3]$-coordinated mode, each coordinates to the central Sm^{3+} ion and two Ni^{2+} ions in the same base, as shown in Scheme 2. The five-membered chelate rings (N–Ni–O) formed in the $[3.1_12_{23}1_3]$-coordinated mode are all about 80°. The acetate edge ligand coordinates to Ni(3) and Ni(4), adopting a bidentate coordination mode. Six im terminal ligands, each coordinating to one Ni^{2+} ion, were used to construct the cluster. The five-membered rings of two neighboring im ligands are almost parallel, with a face-to-face distance of about 3.4 Å, which falls within the limit for strong offset π–π aromatic stacking interactions.

3.3. The structure of complex **2**

The structure of the cation of **2** is shown in Fig. 3. Selected bond distances and bond angles are shown in Table 3. The skeleton of **2** is almost the same as that

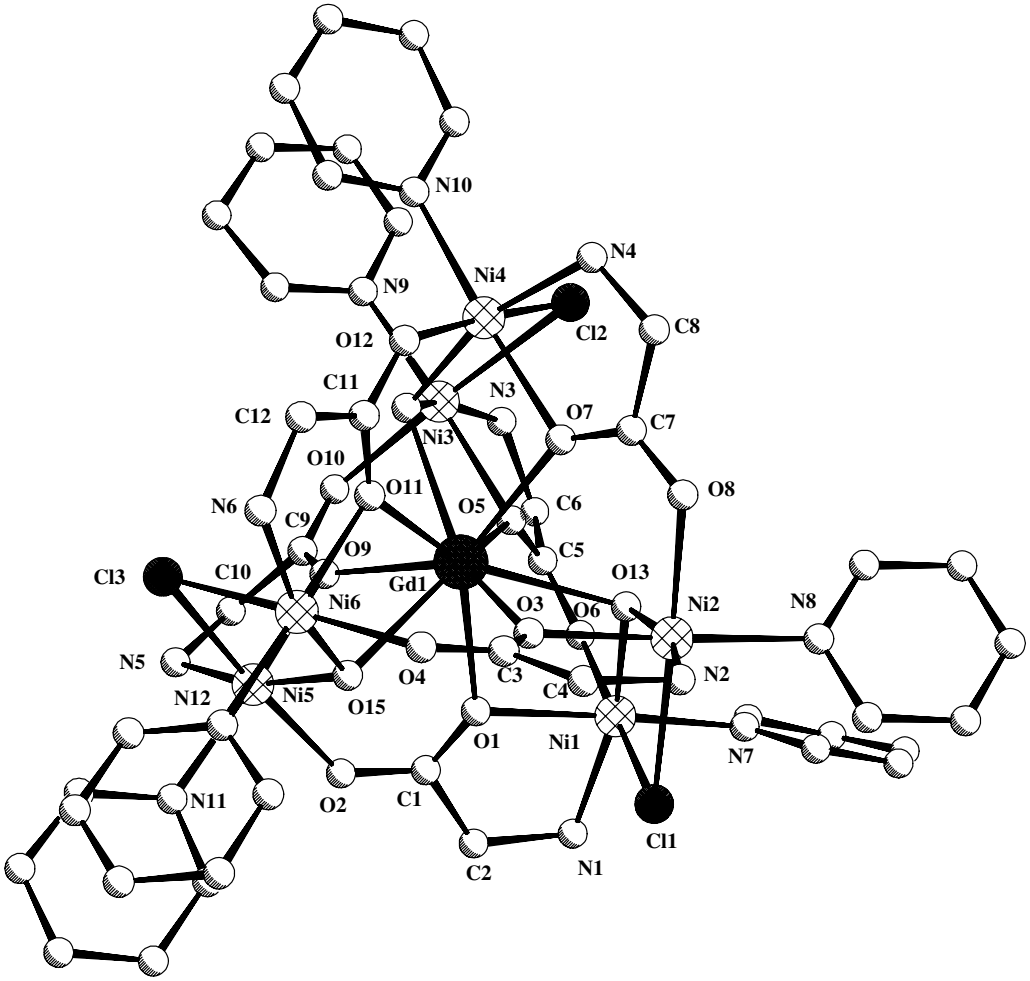

Fig. 3. A view of the cation of complex **2** with the atom numbering scheme.

Ni(5)–Cl(3)–Ni(6)	83.2(1)

of complex **1** except three μ_2-Cl edge ligands and six pyridine terminal ligands were used to construct the structure. The upper and down bases (Ni1, Ni3, Ni5 and Ni2, Ni4, Ni6) are almost parallel, which may be compared with that of **1** (3.0°).

Another interesting structural feature of **2** is the abnormal behavior of one of the py ligands. Four of the six py ligands, N9, N10 and N11, N12 are all stacked with strong offset aromatic stacking interactions, with a face-to-face distance of about 3.4 Å, just as the im ligands observed in **1**. The other two py ligands, N7 and N8, are not parallel, a 63.6° torsion angle is observed between the two six-membered rings. It is not suitable to say there is a face-to-face π–π stacking interaction, but a weak edge-to-face C–H···π interaction exists between the two py rings. This phenomenon is somewhat strange considering the behaviors of the other py ligands, as well as the im ligands of complex **1**.

In complex **2**, each Ni ion has a N_2O_3Cl slightly distorted octahedral configuration. The Ni–O and Ni–N distances are about 2.00–2.11 Å, while the Ni–Cl distances are much longer (2.52–2.56 Å). Two neighboring Ni^{2+} ions from different bases are bridged by one μ_3-OH^- and one Cl^- ion. The average value of ∠Ni–Cl–Ni is about 83.083, which is compared with the ∠Ni–H_2O–Ni (about 93°) in **1**. It is also an intermediate value between those found in polynuclear nickel complexes with Cl^- as bridge. (81.8–85.6°) [20].

3.4. Magnetic properties

Temperature dependent magnetic susceptibilities of complexes **1** and **2** were measured in the range 5–300 K at 10 kOe. Fig. 4 shows the $\chi_M T$ versus T curves for them. At 300 K, the $\chi_M T$ values per $GdNi_6$ unit are 14.68 $cm^3\,mol^{-1}\,K$ for **2**, slightly smaller than the expected values (15.33 $cm^3\,mol^{-1}\,K$) for one Gd^{III} with free-ion state and six spin only Ni^{II} ions ($S = 1$, $g = 2.23$). On decreasing the temperature, $\chi_M T$ remains almost constant down to ca. 90 K, where it begins to increase smoothly until it reaches a maximum of 20.89 $cm^3\,mol^{-1}\,K$ around 7 K and then it decreases. This phenomenon corresponds to an overall ferromagnetic interaction. This ferromagnetic interaction is also confirmed by the positive Weiss constants (3.87 K), determined by data in the temperature range 50–300 K.

The Gd^{3+} ion has an f^7 electron configuration. The contributions of spin-orbit coupling and zero-field splitting do not need to be taken into consideration, which makes it simple to interpret the nature of the Gd–M interaction (M = 3d metal ion). Up until now most of the studies on the magnetic properties of 3d–4f compounds have been limited to the Gd(III)–Cu(II) system and many attempts have been made to rationalize the relationship between the structure and the nature of the Gd···Cu interaction in Gd–Cu heterometallic compounds [2]. It has been suggested that the dihedral angle of the GdOOCu bridging network plays an important role in affecting the magnetic interaction between the metal ions [9a]. Generally the smaller the dihedral angle, the larger the magnitude of the ferromagnetic interaction, and a large dihedral angle means a small ferromagnetic or even an antiferromagnetic interaction. In **2**, a carboxylate oxygen atom and a μ_3-OH^- were used to bridge the central Gd^{3+} ion and Ni^{2+} ion. The average dihedral angle of 12.6° is an intermediate value between those found in the three Gd–Ni heterometallic compounds (4.2–62.6°) with Gd–Ni ferromagnetic interactions [21]. So we may deduce in this compound the Gd–Ni interaction is also ferromagnetic.

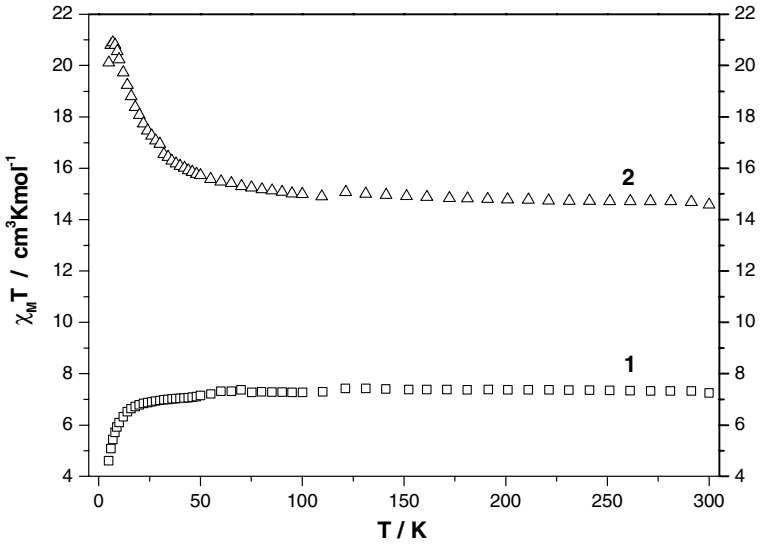

Fig. 4. Temperature dependence of the magnetic susceptibilities of **1** and **2** (5–300 K at 10000 G).

1 shows an overall antiferromagnetic interaction. The free-ion approximation for Sm(III) is not valid because of the presence of thermally populated excited states. The $\chi_M T$ value at room temperature is about 7.25 $cm^3\,mol^{-1}\,K$, which is compared with the calculated value 7.49 $cm^3\,mol^{-1}\,K$ (a $\chi_M T$ value of 0.32 $cm^3\,mol^{-1}\,K$ is used for the Sm^{3+} ion [22]).

4. Conclusion

Two novel heptanuclear trigonal prismatic $LnNi_6$ clusters with different terminal aromatic ligands were synthesized. The magnetic measurements reveal the Gd–Ni interaction is ferromagnetic in the $\{GdNi_6\}$ cluster. Future work will be aimed at using bifunctional bridging ligands containing O-donors or N-donors, such as bipyridine or polycarboxylates, to replace the edge or terminal ligands to synthesize polydimensional coordination polymers with the heptanuclear cluster as nodes.

5. Supplementary data

CCDC 262010–262011 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033, or deposit@ccdc.cam.ac.uk.

Abstract

A new ruthenium complex series of type $Ru(NBD)Cl_2L$ (with L = 2,2′-biquinoline derivative) was prepared. Their spectroscopic properties were analysed by RMN ^1H, UV–Vis and Infrared and their electrochemical potentials were obtained by cyclic voltammetry technique. The structure for a complex of this series was established by X-ray analysis. This structure shows a planarity distortion of biquinoline ligand on the complex. The coplanarity distortion degree through the complex series is modulated by the 3,3′-substitued position on the 2,2′-biquinoline ligand, and show correlation with the differences observed on their spectroscopic properties.

Keywords: Ruthenium complexes; Heterocyclic nitrogen ligand; Biquinoline ligand

1. Introduction

The ruthenium compounds have been intensively used in different studies. For example, charge and energy transfer, excited state properties and catalyst in thermal and photochemical reaction [1]. Numerous thermal reactions of industrial interest [2], for example, hydrogenation and hydrogen transfer are actively catalyzed by ruthenium coordination compounds using polypyridine ligands [3]. In general, the mechanism for this thermally catalyzed reaction considers a generation of the free coordination site. The labile diolefin norbornadiene (NBD) ligand is a good precursor for catalyst in many reactions due to substitution may easily allow the coordination of the substrate to metal center in the $Ru^{(II)}$(diolefine)(polypyridine) compound. Consequently, we have reported the preparation of the $Ru(NBD)Cl_2L$ (L = bipyridine and substituted phenanthroline) and their application to hydrogen transfer reaction with adequate results [4].

The modulation of the complex properties through the electronic and conformational effect generated by the ligand constitutes an interesting route to prepare compounds with enhanced catalytic properties. In previous works [5], we observed that the distortion degree of biquinoline ligand induces variation on the spectroscopic and electrochemical properties of the rhenium and manganese complexes. The modulation of this

doi:10.1016/j.poly.2005.05.009

distortion may be defined through substitution on 3,3′-position of the biquinoline ligand.

Our main purpose is obtains biquinoline ruthenium complexes to evaluate the conformational effect on the catalytic properties. Consequently, we have prepared and analysed the spectroscopical properties of a new series of ruthenium complexes as a function of the conformational characteristics of the annealed 3,3′-substituted-2,2′-biquinoline ligand. The general formulation of complexes is $Ru^{(II)}(NBD)Cl_2L$, where NBD is norbornadiene and L is 2,2′-biquinoline (0,2N), 3,3′-dimethylene-2,2′-biquinoline (2,2N) or 3,3′-trimethylene-2,2′-biquinoline (3,2N).

2. Experimental

2.1. Physical measurements

Microanalyses were performed at the Departamento de Química Orgánica, Facultad de Química y Farmacia, Universidad de Chile. IR spectra were obtained in solid state (KBr cell of 0.2 mm) using a Bruker IFS-66 V FT-IR spectrophotometer. ^1H NMR and COSY spectra were recorded at 400.13 MHz in a Bruker Avance 400 NMR spectrometer gradient enhanced. Absorption spectra were recorded in quartz cells at room temperature in a Shimadzu UV-160 spectrophotometer, using solvents of different polarity previously purified. Molar conductivities were determined from 10^{-3} mol dm^{-3} solutions of complexes in CH_3CN at 25 °C using a conductivitymeter Cole-Parmer 01481.

Electrochemical data were acquired by cyclic voltammetry following the procedure already reported [6]. The measurements were carried out with a PAR 173 potentiostat coupled to a PAR 175 universal programmer. Deaerated solutions, 10^{-4} M complex and 10^{-2} M tetraethylammonium perchlorate in acetonitrile, were placed in a three-electrode cell with a glassy carbon working electrode, a Pt wire counter electrode, and a Ag/AgCl reference electrode. Solvents and supporting electrolyte for the electrochemical measurements were dried according to the literature procedures [7]. Potentials were reported as $E_{1/2}$ values versus SCE and they were determined from the following relationship $E_{1/2} = 1/2(E_{pa} + E_{pc})$, where E_{pa} and E_{pc} are the anodic and cathodic peak potentials, respectively. The cyclic voltammograms were recorded at a sweep rate of 250–1000 mV s^{-1} range for all the scans, at room temperature and in a nitrogen atmosphere.

For the crystalline structure determination, a highly redundant diffractometer data set was collected at room temperature ($T = 295$ K) up to 2θ maximum of ca. 58°, with a Bruker AXS SMART APEX CCD diffractometer using monochromatic Mo Kα radiation, $\lambda = 0.71069$ Å, and a 0.3° separation between frames. Integration was performed using SAINT, and a semi-empirical absorption correction was applied using SADABS, both programs being included in the diffractometer package. The structure resolution was achieved routinely by direct methods and difference Fourier. The structure was refined by least squares on F^2, with anisotropic displacement parameters for non-H atoms. Hydrogen atoms were placed at their calculated positions and allowed to ride onto their host carbons both in coordinates as well as in thermal parameters. The tetrahydrofurane (THF) solvato molecule appears riding onto a symmetry center, a place with a site of symmetry higher than the one of the molecule itself. The molecule is thus forced to split into two equally populated, centro-symmetrically related halves ($Z' = 0.5$), giving to the final local electron density map an intriguing S_6 look.

All calculations to solve the structures, refine the proposed models and obtain derived results were carried out with the computer programs SHELXS-97, SHELXL-97 [8], and SHELXTL/PC [9]. Full use of the CCDC package was also made for searching in the CSD Database [10]. Pertinent results are given in Tables 1–3 and Figs. 1 and 2, respectively.

2.2. Chemical

All the operations were carried out under purified nitrogen atmosphere by standard Schlenk and vacuum-line techniques using freshly distilled, dried and degassed solvents. The solvents used in preparations,

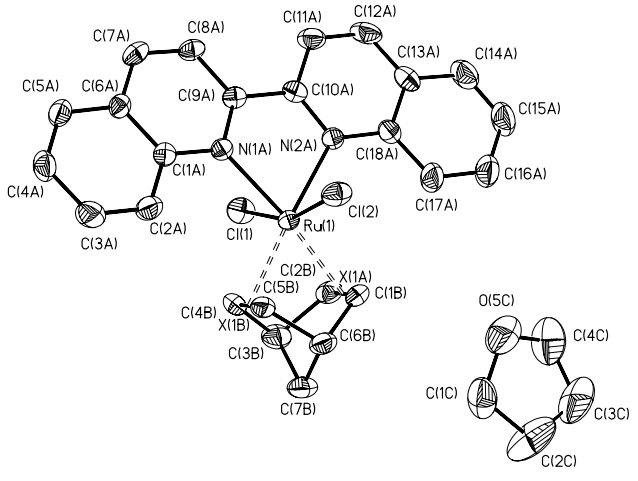

Fig. 1. Ellipsoid plot of the molecule showing the numbering scheme used. The π interaction between the Ru atom and the NBD ligand has been represented by double dashed lines joining the cation and the mid points (X(1), X(2)) of the corresponding double bonds involved (C(1B)=C(2B), C(4B)=C(5B), respectively). Only one out of the two disordered THF moieties is shown, for clarity.

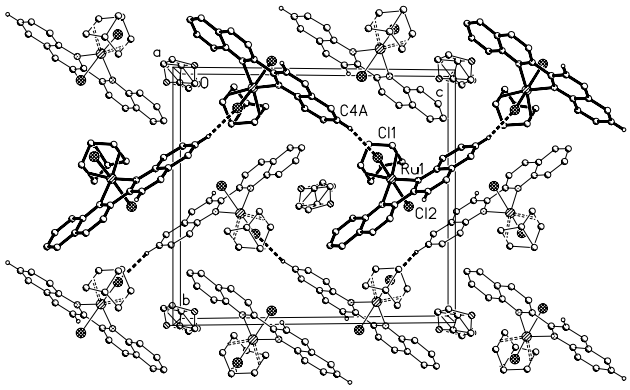

Fig. 2. Packing view of the structure along *a*, where the zig-zag chains formed by C(4A)–H(4A)···Cl(1) are clearly seen (one of them has been highlighted, for clarity). The second hydrogen bond (C(8A)–H(8A)···Cl(2)) linking chains together along the vertical a axis, is not drawn. The THF is shown in its two disordered parts.

crystallizations and spectroscopic analysis (Mallinckrodt, grade HPLC) were treated and distilled from the appropriate drying prior to use. In electrochemical studies, anhydrous acetonitrile was dried using CaH_2 under nitrogen atmosphere at reflux for a period of 2 h and freshly distilled prior to use. Commercially available 2,2′-biquinoline (0,2N), $AgCF_3SO_3$, $RuCl_3(H_2O)$ (Aldrich) compounds were used without further purification. The synthesis of the 3,3′-dimethylene-2,2′-biquinoline ligand (2,2N), 3,3′-trimethylene-2,2′-biquinoline ligand (3,2N) and precursor complexes $[Ru(NBD)Cl_2]_x$ has been previously described [11].

2.3. General synthesis procedure for the complexes

The new complexes were prepared at 60 °C under inert atmosphere. A stoichiometric amount of the biquinoline ligand was added to an emulsion of $[Ru(NBD)Cl_2]_x$ polymer in a THF/water (70:30) solvent mixture. The mixture was vigorous stirred for 6 h until the formation of a microcrystalline dark red precipitate that then was filtered. The product was purified dissolving the crystals in methylene chloride/THF solvent mixture and then it was filtered through celite. The resulting red solution was concentrated and the fine dark red crystals were isolated after crystallization. The mono crystal for a X-ray analysis, was obtained of the THF solution for the $[Ru(NBD)Cl_2(0,2N)]$ complex.

3. Results and discussion

The complexes are sparingly soluble in most common organic solvents, e.g., methyl alcohol, acetonitrile, acetone, methylenechloride. The elemental analysis, conductivity measurements and spectroscopic results are in accord with the Ru(NBD)Cl$_2$L formulation for all the complexes and with the X-ray analysis for a Ru(NBD)Cl$_2$(0,2N).

The structure for the Ru(NBD)Cl$_2$(0,2N) is conformed by the mononuclear complex units and disordered tetrahydrofurane molecules, in a (2:1) ratio. The ruthenium cation is octahedrally surrounded (Fig. 1). The basal plane of the polyhedron being defined by the two active nitrogen from a bidentate biquinoline ligand and a double π interaction mediated by the two parallel double bonds (C1B=C2B, C4B=C5B) of a NBD unit, to be represented in that follows (Tables 2 and 3) by their midpoints X(1) and X(2). The apical sites, in turn, are occupied by two chlorine anions, thus providing for the required charge balance.

The coordination geometry is basically a regular octahedral. The only exception is the restraint imposed by chelation, which turns the expected basal square into a rectangle-like form (opposite chelation angles: 77.4° and 67.6° for expected values of 90°). The main plane through the four basal atoms has an esd of 0.017Å, and leaves the ruthenium atom 0.07 Å away, towards the Cl(2) site.

The protruding hydrogens in the structure force numerous situations of steric hindrance which the system avoids through further departures from a regular geometry.

Thus, the hydrogen pairs H(2B), H(4B) and H(1B), H(5B) in NBD push Cl(1) and Cl(2) by 9.7° and 8.7° away from the apical line (Mean Cl(1)–H: 2.775 Å; mean Cl(2)–H: 2.893 Å) in such a way that the angle subtended by the chlorine atoms to the cation center is 161.6° [12].

The biquinoline group is in turn rotated some 20° away from the basal plane of the Ru coordination polyhedron by way of a couple of Cl$\cdots$H$_{biq}$ interactions (to be described below) to end up with its H(2A) and H(17A) hydrogens at a colliding distance from H(5B) and H(1B) in NBD, viz.: H(2A)$\cdots$H(5B): 2.016 Å; H(17A)$\cdots$H(1B): 1.921 Å. This fact forces a rotation of the NBD group in order to oppose the effect, with a concomitant lengthening of some C$_{NBD}$–Ru bond lengths and the shortening of some others. This fact renders the coordination to the cation notoriously asymmetric (Ru–C(2B): 2.188 Å; Ru–C(4B): 2.191 Å against Ru–C(1B): 2.237 Å; Ru–C5B): 2.238 Å).

As a consequence of this process the biquinoline ligand adopts a sort of "butterfly" look with the individual quinolinic moieties (planar to within 0.02 Å) subtending a dihedral angle of 8.3° to each other, which seems to be the main distortion of the ligand.

The monomers interact with each other through two mild C–H$\cdots$Cl hydrogen bonds involving both chlorine atoms (Table 3). The first one, in which Cl(1) takes part defines "zig-zag" chains running along *c*; the second, in which Cl(2) is involved, links these chains together along the *a*-axis into some sort of 2D "corrugated" structures expanding normal to (0 1 0) and fitting into each other in a zip-like fashion (Fig. 2).

The link of these 2D structures is mainly due to the π–π interaction arising between symmetry related biquinoline groups. The symmetry centers which relate contiguous 2D structures also end up positioning one of the lateral wings of the 0,2N ligand at a graphitic distance (ca. 3.30 Å) of its (parallel) symmetry related image, with an overlap of ca. 80% of a whole aromatic ring and a slippage of ca. 1.5 Å.

The structure is stabilized by the inclusion of half of a tetrahydrofurane molecule like a solvato, which appears disordered as it was described in Section 2.

The infrared spectra of the ruthenium complexes do not show a notorious effect of the metal–nitrogen coordination on the characteristic bands of the biquinoline or NBD ligands. The assignation of the Ru–Cl frequency values expected into IR distant region is difficult due to this appear overlapped with another ligand bands. Therefore, it is expected that the structural differences into biquinoline ligand produce only negligible changes in the ruthenium electronic density.

Proton NMR data for the ruthenium complexes and free ligands are shown in Table 4. The ^{1}H assignments for the both NBD and biquinoline free ligands are previously reported (Fig. 3) [11a].

The ^{1}H NMR spectra in solution of the complexes exhibit in the high field region, the characteristic set of signal for NBD ligand. The shielding of the H$_{1'}$ in the complexes related to uncoordinated NBD agrees with the electron density shifting towards the metal due to π coordination. However, the π coordination to Ru(II) causes a shift to upfield of the signal of the H$_{1'}$ with respect to this proton in the free NBD. The set of three signals observed for NBD indicates that this ligand has high symmetry in the complexes. This is only possible if the NBD is placed in the same plane than the biquinoline ligand (X-ray structure).

The ^{1}H NMR spectra in the aromatic region correspond to the expected biquinoline signals (Fig. 4). Due

to the fact that all the biquinoline aromatic protons are coupled between themselves (similar J values), the assignation to each proton was made using COSY correlation and differences in their coupling pattern (Table 4).

The ^{1}H NMR spectra of the coordinated biquinoline exhibit same set of signals when compared to that of free biquinoline and coordinated biquinoline in other complexes [5]. However, the difference in the chemical shift with respect to the free biquinoline and coordinated biquinoline in other complexes reveals a marked effect of coordination and the complexes structure.

In general, all aromatic proton signals for the biquinoline ligand in the complex appear shifted toward lower field with respect to the free ligand. This deshielding effect is due to the electron density of the metal in the coordinated quinoline. However, the H_8 proton shifted to high field in all complexes. This could be due to the double bond diamagnetic effect of the NBD ligand placed in the same plane, which affords a more protected environment.

The shifting to high field of the H_3 proton in $RuCl_2$(NBD)(2,2′-biquinoline), relative to the uncoordinated 0,2N ligand, has been generally observed in 2,2′-biquinoline complexes [5]. This effect was explained for a "peri" interaction with nitrogen into *trans* preferential free ligand conformation [11a] (see Figs. 4 and 5).

The restriction to coplanarity of two halves of biquinoline ligand, due to 3,3′ substitution and coordinate

requirement to metal for this ligand, determinates geometrical restriction on the complexes. Therefore, the geometric differences through the series of biquinoline complexes can be spectroscopically analyzed.

The proton shift differences for the analogous proton in different biquinoline ligand were observed in all complexes (Table 4). Mainly, ^1H NMR chemical shift data of H_4, H_8 and $H_{1'}$ protons are informative of the disposition of the ligand geometries in the complexes. The chemical shift difference between the complexes and the corresponding free ligand ($\Delta\delta$) of the H_4 and H_8 protons were greater. These $\Delta\delta$ values decrease in the next ligands order: (0,2N), (2,2N), (3,2N).

These chemical shift differences were also observed for the $H_{1'}$ in all series of complexes. However, correlation with biquinoline ligands was not observed.

In the structure of the complexes, the H_4 chemical shift is notoriously influenced by electronic effects associated with the coordination of nitrogen in *para*-position. On the other hand, the H_8 chemical shift is influenced by the diamagnetic effect of NBD. For $H_{1'}$, the chemical shifts are the result of the paramagnetic effect of aromatic ring of biquinoline. From the previous information, it appears that the chemical shifts of these protons are influenced by the non-planarity grade of substituted-biquinoline in the structure of complexes [5a,5j,11a].

The UV–Vis spectroscopical data for the complexes are shown in Table 5. The $Ru(NBD)Cl_2L$ complexes show one band placed up on 430 nm, that has been assigned to a ruthenium-to-biquinoline-charge-transfer (MLCT) transition, in accord with electron acceptor biquinoline ligand characteristic and assignments previously reported for related complexes [1,5]. Consequently, this band shows a slight solvent polarity dependence.

The energy for the MLCT band increases in the order of (0,2N), (2,2N), (3,2N) showing a slight dependence with the deviation of the quinoline halves from planarity in the coordinated biquinoline ligand. A similar trend is exhibited by the biquinoline rhenium and manganese complexes previously reported [5]. In previous work [5a], we explain the shift of the MLCT band through complex series with changes in the electronic repulsion between the d-orbital metal and the biquinoline orbitals. The HOMO stabilization and the LUMO destabilization usually result from the increase in this conformational distortion.

The most intense bands below 400 nm correspond to biquinoline intraligand transitions. These bands may overlap the Ru to NBD MLCT bands expected in this same region.

The electrochemical data were obtained with cyclic voltammetry in 250 and 1000 mV s^{-1} scan rates range. The voltammograms for the all complexes exhibited similar features, i.e., one oxidation pick and two reduction pick on the −2.0 to 2.0 V potential range (Table 6). The pick separation between the cathodic and anodic waves, of all the redox couples, increase with the scan rates increase, that suggest a quasireversible process.

The only oxidation wave is a quasireversible process, and it is found close to +1.12 V. This process has been observed in several related polypyridine Ru(II) com-

pounds [1b,1e,1f,13] and correspond to the typical one electron Ru(III)/Ru(II) couple.

The two electrochemical reductions on the first scan occur in the $E_{1/2} = -0.85$ to -1.04 V range and $E_{1/2} = -1.06$ to -1.24 V range, respectively. According to previous studies, the first reduction wave could be attributed to a ligand-centered process that involves the addition of an electron to the π* orbital on the biquinoline ligand. The another reduction peak may be assigned to the second reduction of the biquinoline ligand. This assumption is unclear due to the small difference between the two reduction peak is not consistent with the differences reported previously (roughly 500 mV) found for related complexes showing similar electrochemical behavior [1h,1e,5a,14].

4. Conclusions

The X-ray studies for a ruthenium complex revealed that the structure of the complexes is a quasi perfect octahedron. However, spectroscopic and electrochemical results already discussed showed differences through the series that only are attributed to conformational differences in the complexes. In previous works, we established that the structural restriction in the biquinoline derivative ligands remove to quinoline halves from a perfect plane in the octahedral complexes and also it influence their spectroscopical properties. Our presumption is that these differences may determinate interesting catalytic properties.

5. Supplementary materials

Crystallographic data (excluding structure factors) have been deposited in the Cambridge Crystallographic Data Centre like Supplementary Publication No. CCDC_212516. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1233 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Abstract

The cobalt(II), nickel(II), copper(II) and zinc(II) complexes of *N*-phthaloylglycinato (Nphgly) ligands have been synthesised and characterised. The cobalt and zinc complexes have the composition $[M(Nphgly)_2(H_2O)_4]2H_2O$ with an octahedral geometry around the metal ion. In these two complexes, the phthaloylglycinato groups are monodentate and have four coordinated water molecules and two molecules of lattice water. The lattice water molecules are held through hydrogen bonding with one carbonyl group of the phthalimide part and the carbonyl group of glycinato part. Such water molecules are further held by hydrogen bonding to two coordinated water molecules. There are also two other coordinated water molecules having a different hydrogen-bonding environment. These two water molecules attached to the metal are stabilised by hydrogen bonding through two carbonyl groups from the glycinato part and the phthalimide part. Distinctions of these two sets of water environment are reflected in thermogravimetry and DSC of the complexes. In the thermogram of these two complexes there is loss of four water molecules at a relatively lower temperature than the other two water molecules. The copper complex containing *N*-phthaloylglycinato and pyridine ligands, having the composition $[Cu(Nphgly)_2(py)_3]$, is prepared. This complex has a square pyramidal structure with one pyridine molecule at the axial position. The complex on thermal degradation leads to the formation of CuO at 380 °C. The similar nickel complex has the composition $[Ni(Nphgly)_2(py)_3 1.3H_2O]$, having a trimeric H-bonded structure with a distorted octahedral environment around nickel(II).

1. Introduction

Amino acid complexes are important in biology [1,2]. The *N*-protected amino acids are used for the synthesis of peptide bonds in solid phase syntheses [3–5]. The phthalimide group acts as a protecting group for amines and amino acids [6–10]. The *N*-phthaloylamino acids undergo photochemical reactions to give rearranged products [11]. Several such phthalimide derivatives have importance in medicinal chemistry [12] and are used as antimicrobial reagents [13]. The silver(I) complex of *N*-phthaloylglycinato has an interesting three-dimensional network [14]. Several other studies on the transition metal complexes of *N*-phthaloylglycine are reported but these studies lack structural details [15–17]. *N*-hydroxyphthalimide along with the cobalt(II) complexes in the presence of oxygen acts as a catalyst for selective oxidation of primary alcohols to the corresponding aldehydes [18,19]. Palladium complexes are known to catalyses amido-carbonylation of *N*-phthalimide derivatives [20]. We have earlier discussed that in adducts of *N*-substituted phthalimide with polyhydroxy aromatics supramolecular features play an important role in the structure [21]. Thus, the structural features of these molecules are important and we report here characteristic features of *N*-phthaloylglycinato complexes of cobalt (II), zinc(II), copper(II) and nickel (II).

2. Experimental

2.1. Material and methodology

All the chemicals used in this study were analytical grade and used as procured. The solvents were distilled and dried prior to use. For example, acetonitrile was distilled over calcium hydride, pyridine was distilled over potassium hydroxide. The IR spectra were recorded as KBr pellets on a Nicolet Impact 410 FT-IR spectrometer. Magnetic moments were measured on a Sherwood Scientific Magnetic susceptibility balance. The conductance and pH were measured by a digital conductivity bridge and pH metre of Systronics. For molar conductance, the cell constants were determined by standard KCl, and for pH measurements the pH-metre was calibrated with a solution prepared from standard pH tablets. The thermal analyses were performed on a Metler Toledo TGA/SDTA 851^e and Metler Toledo 821^e thermal analyzer. Thermogravimetry studies were done in an aluminium crucible under pure nitrogen gas. DSCs were done under ordinary conditions in a platinum crucible. The visible spectra were recorded on a Hitachi U-2001 UV–Vis spectrometer.

X-ray diffraction data were collected on a Bruker 3-circle diffractometer with CCD area detectors ProteumM APEX or SMART 6000, using graphite monochromated Mo Kα radiation from a 60 W microfocus Bede Microsource® with glass polycapillary optics. The low temperature was maintained using an Oxford cryosystem open flow N_2 cryostat. The structures were solved by direct methods and refined by full-matrix least squares against F^2 of all data, using SHELXTL software.

2.2. Synthesis of tetra-aqua-bis-N-phthaloylglycinatocobalt(II) dihydrate

A finely ground mixture of phthalic anhydride (0.74 g, 5 mmol) and glycine (0.38 g, 5 mmol) was heated at 80 °C for 30 min; the solid mass was then dissolved in methanol (10 ml) and filtered; the filtrate was taken and evaporated. Water (10 ml) was added to the residue obtained from the filtrate after evaporation; this was followed by addition of a solution of cobalt(II)acetate tetrahydrate (0.5 g, 2 mmol, in 5 ml water). The reaction mixture was stirred at room temperature (4 h), which led to the precipitation of pink coloured tetra-aqua-bis-*N*-phthaloylglycinatocobalt(II) dehydrate (Yield: 0.32 g, 31%). Recrystallisation of the complex was done from an aqueous solution of the complex by diffusing acetone. Elemental *Anal*. Calc. for $C_{20}H_{24}CoN_2O_{14}$: C, 41.45; H, 4.15; N, 4.84. Found: C, 41.39; H, 4.12; N, 4.90%. IR (KBr, cm^{-1}): 3476(s), 3263(bs), 2925(m), 1772(w), 1701(s), 1598(s), 1470(w), 1429(s), 1383(s), 1312(s), 1194(w), 1117(s), 968(s), 743(s), 717(s), 630(s) cm^{-1}. Vis (λ_{max}, acetonitrile), 540 nm ($\varepsilon = 30\ mol^{-1}\ dm^3\ cm^{-1}$).

2.3. Synthesis of tetra-aqua-bis-N-phthaloylglycinatozinc(II) dihydrate

An aqueous solution of zinc acetate dihydrate (0.219 g, 1 mmol in 10 ml) was added dropwise to a well-stirred solution of *N*-phthaloylglycine (0.410 g, 2 mmol) in ethanol (10 ml) at room temperature. After half an hour of stirring a gelatinous precipitate was formed. The stirring was continued for another 3 h and the precipitate obtained was redissolved in water (10 ml). After redissolving the precipitate the solvent was slowly evaporated to give colourless crystals after three days (Yield: 0.36 g, 66%). Elemental *Anal*. Calc. for $C_{20}H_{24}N_2O_{14}Zn$: C, 41.25; H, 4.13; N, 4.81. Found: C, 41.30; H, 4.11; N, 4.78%. IR (KBr, cm^{-1}): 3486(b), 3288(b), 1776(s), 1706(s), 1610(b), 1428(s), 1390(s), 1314(s), 1120(s), 966(s), 750(s), 720(s).

2.4. Synthesis of tri-pyridine-di-phthaloylglycinato copper(II)

An ethanolic solution of copper acetate monohydrate (0.199 g, 1 mmol, 10 ml ethanol) was added dropwise to a well-stirred solution of *N*-phthaloylglycine (0.410 g, 2 mmol) in ethanol (10 ml) at room temperature. A light blue precipitate appeared instantaneously. The reaction was allowed to proceed for 3 h with constant stirring. The blue precipitate was collected through filtration and the residue obtained was washed with water followed by ethanol and dried in air. The precipitate was redissolved in pyridine (5 ml) and slow evaporation gave a complex having composition the $Cu(py)_3(Nphgly)_2$ (Yield: 0.24 g, 34%). Elemental *Anal*. Calc. for $C_{35}H_{27}CuN_5O_8$: C, 59.22; H, 3.81; N, 9.87. Found: C, 59.20; H, 3.79; N, 9.85%. Vis (λ_{max}, pyridine) 662 nm ($\varepsilon = 156\ dm^3\ mol^{-1}\ cm^{-1}$). IR (KBr, cm^{-1}): 3462(w), 3083(w), 2950(w), 1772(s), 1721(s), 1655(s), 1598(s), 1455(s), 1419(s), 1368(s), 1291(s), 1194(s), 1117(s), 963(s), 743(s), 712(s), 649(s).

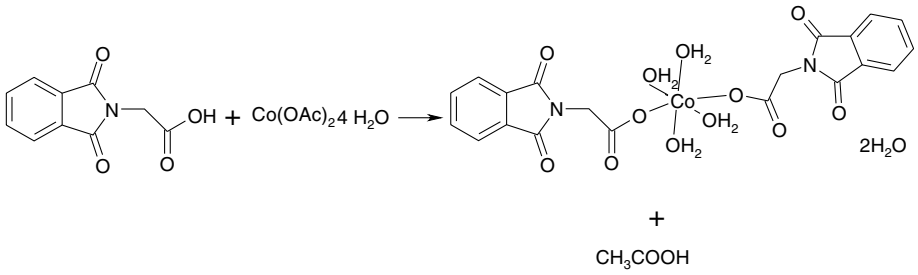
2.5. Synthesis of the phthaloylglycinato complex of nickel(II)

An ethanolic solution (10 ml) of nickel(II)acetate tetrahydrate (0.248 g, 1 mmol) was added dropwise to a stirred solution of *N*-phthaloylglycine (0.410 g, 2 mmol) in ethanol (10 ml) at room temperature. The resulting light green solution was stirred at room temperature for 2 h and left undisturbed. A light green precipitate was obtained after seven days by slow evaporation of the solution. The precipitate was filtered, washed with ethanol and dried in air. Finally, it was dissolved in pyridine (10 ml) to obtain a light blue solution. Light blue crystals were obtained after three weeks by slow evaporation of the solvent (Yield: 0.25 g, 35%). Elemental *Anal*. Calc. for $C_{35}H_{27}NiN_5O_8 \cdot 1.3H_2O$: C, 57.03; H,

4.02; N, 9.31. Found: C, 57.09; H, 4.09; N, 9.52%. IR (KBr,cm^{-1}): 3568(bw), 3472(bw), 3260(w), 3106(w), 3072(w), 2948(w), 1770(s), 1711(s), 1602(b), 1418(s), 1376(s), 1314(s), 1113(s), 963(s), 744(s), 714(s). Vis (λ_{max}, pyridine)610 nm ($\varepsilon = 34\ dm^3\ mol^{-1}\ cm^{-1}$).

3. Results and discussion

A cobalt complex having the composition [Co(Nphgly)$_2$(H_2O)$_4$]2H_2O can be prepared by the reaction of *N*-phthaloylglycine (NphglyH) with cobalt(II)acetate tetrahydrate (Eq. (1)). This complex is prepared by reaction of cobalt(II)acetate tetrahydrate with in situ generated *N*-phthaloylglycine. The reaction is carried out in one pot by the condensation of phthalic anhydride and glycine followed by the reaction with cobalt(II)acetate. In this reaction, cobalt(II)acetate itself causes the deprotonation of *N*-phthalolylglycine to form the desired complex and thus no buffer or external reagent needs be added to maintain a pH for making a basic medium. It is also to be noted that the pK_a of *N*-phthalolylglycine is 3.48 whereas acetic acid has pK_a 4.76 at 25 °C, thus, the cobalt acetate can get protonated by *N*-phthalolylglycine to release acetic acid which allows the formation of the desired complex



(1)

results are in accordance with a distorted octahedral geometry around cobalt(II). The structure of [Co(Nphgly$_2$)(H_2O)$_4$]2H_2O in the solid state shows that all the four coordinating water molecules have extensive hydrogen bonding. Two water molecules are linked to carbonyl groups of the carboxylato ligand through hydrogen bonding; this provides a chelate like structure. The other two coordinated water molecules are attached to the lattice water molecules by hydrogen bonding, which in turn are held in between the carbonyl groups of the phthalimide part. Thus, a cyclic structure including the cobalt centre and coordinated water molecules along with the lattice water through intermolecular hydrogen bonding is formed. The hydrogen atom of the coordinated water molecules are also associated with the carbonyl group (for example H11W···O5) of the phthalimide ring of another phthaloylglycinato ligand bound to another cobalt centre through intermolecular hydrogen bonding. All water molecules in the complex are involved in extensive hydrogen bonding to form a self assembled structure (Fig. 1). There are both intra- and intermolecular hydrogen bonds.

The structure of the complex has been determined by X-ray crystallography and it is observed that cobalt(II) has a distorted octahedral environment with four aqua ligands occupying one plane of the octahedron. There are two monodentate carboxylate groups at the axial positions (Fig. 1). In the coordination chemistry of cobalt(II), the monodentate carboxylato group is a common phenomenon, for example cobalt(II)acetate itself has monodentate carboxylate groups linked to the cobalt atom [22]. However, in the case of [Co(Nphgly)$_2$(H_2O)$_4$]2H_2O, we have observed interesting supramolecular features that are not present in ordinary cobalt(II)acetate. The bond distance between Co1–O3, Co1–O2 and Co1–O1 are 2.1165(14), 2.0833(16) and 2.0694(16) Å, respectively, whereas the O3–Co1–O2, O2–Co1–O1 and O1–Co1–O3 bond angles are 88.98(6)°, 88.04(7)° and 90.72(6)°, respectively. These

The intramolecular H-bonds are:

	D–H	H···A	D···A	DHA
O1–H12W···O4	0.84(3)	1.88(3)	2.640(2)	150(3)
O2–H22W···O7	0.83(4)	1.87(4)	2.663(3)	159(4)
O7–H71W···O6	0.873(10)	1.93(3)	2.732(3)	151(5)

There are also intermolecular H-bonds involving the remaining H atoms of the water molecules not involved in intramolecular H-bonds:

	D–H	H···A	D···A	DHA
O1 H11W O5B	0.75(3)	2.02(3)	2.772(2)	173(3)
O2AA H21W O4	0.88(3)	1.83(3)	2.710(2)	172(3)

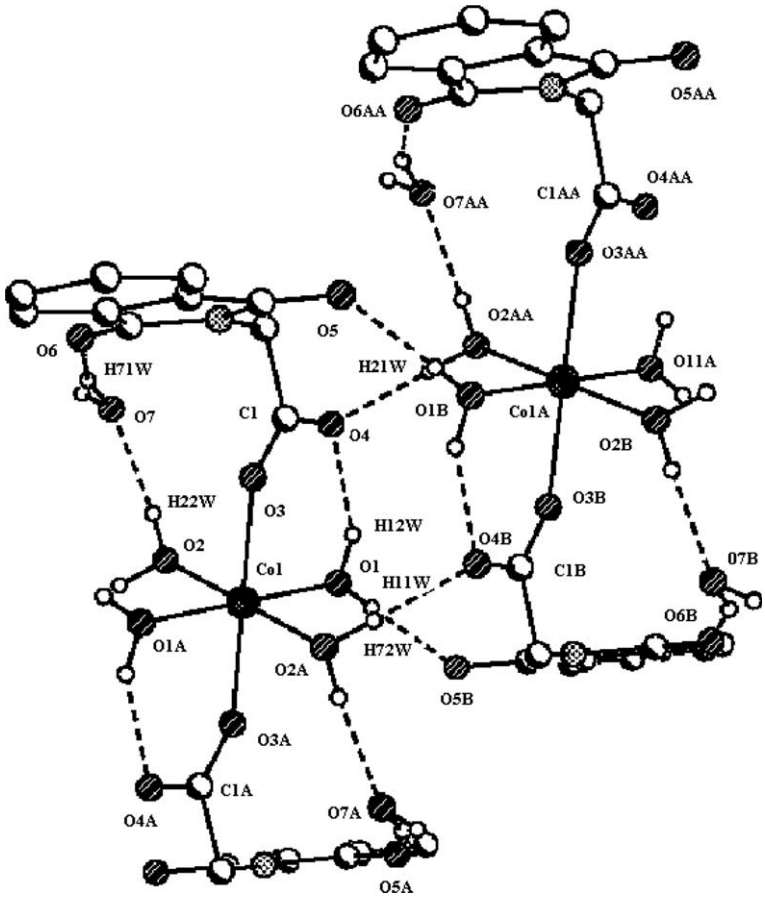


Fig. 1. Crystal structure showing two units of tetra-aqua-bis-*N*-phthaloylglycinato cobalt(II)dihydrate (the H-atoms of the phthaloyl part are not shown for clarity).

In the structure shown in Fig. 1 the hydrogen-bonds have a twofold effect on the crystal packing. Firstly, the hydrogen-bonds involving the coordinated molecules make a chain of molecular units. Secondly, the intermolecular H-bond involving the loose water molecule joins these chains along one direction, producing layers of molecular units on the plane containing the two directions of the chain linkages. This effect along with the bipolar arrangement of phthalimide makes two types of environments for water molecules. Two different environments around coordinated water molecules are represented in Fig. 2. Two types of environments around the coordinated water molecules are shown by taking segments from Fig. 1 (segment A and B in Fig. 2). These fragments are created by the H-bonding between the ligands that are bonded in an intermolecular fashion with the ligands that are associated to two cobalt centres. The two environments for the coordinated water molecules are also reflected in the bond lengths. Namely, there is a bond length difference of 0.0139 Å between the two types of Co–O bonds in the two types of coordinated water molecules as depicted in A and B of Fig. 2. Since the cobalt complex is coordinated through the carboxylate group, it's coordination may be compared with the supramolecular construction that is made from the analogous carboxy-phosphonate complex reported in the literature [23]. We have found that water molecules are involved in a tight packed structure in our cobalt complex, in contrast to the supramolecular assembly reported for the carboxylate phosphate that has interesting S-shaped voids filled with water molecules [23]. In their case they observed hexa coordinated cobalt with two water molecules occupying coordination sites and had observed it to be a cluster containing three cobalt centres. But in our case four water molecules are coordinated to cobalt(II), which are in two different environments with a three-dimensional network. The crystallographic parameters of the complex are listed in Table 1.

The two types of water environment, as shown in A and B (Fig. 2), are also reflected in the thermogravimetric study. The cobalt complex on heating shows that it loses four water molecules in the region 35–104 °C (experimental loss 11.82%, theoretical 12.5%). In the temperature range 104–146 °C the complex loses two molecules of water (experimental loss 18.16%, theoretical 18.76%). In DSC these two losses are also reflected as endothermic processes occurring at 104.37 and

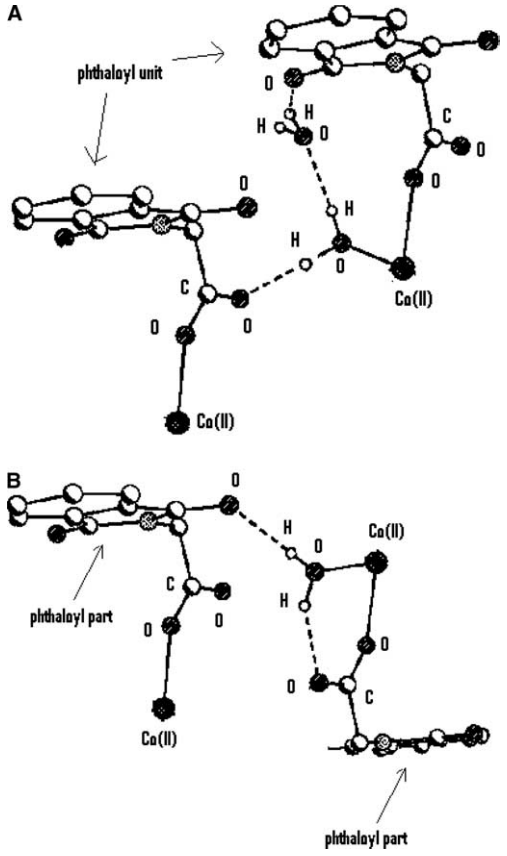

Fig. 2. Two different types of environment for coordinated water molecules in tetra-aqua-bis-*N*-phthaloylglycinato cobalt(II)dihydrate (segment from Fig. 1 is drawn omitting the H-atoms on the ring).

143.72 °C. This clearly indicates that the water molecules present in the complex are not in equivalent environments. Generally, a lattice water molecule is expected to be lost at a lower temperature and one would anticipate a loss of two water molecules of crystallisation at a lower temperature than the coordinated water molecules in our cobalt complex. But the experimental observation shows that there are four water molecules lost at a lower temperature. This can be interpreted in terms of the two different molecular environments around the coordinated water due to hydrogen-bonding. Thus, the loss of four water molecules at a low temperature relative to the two other molecules implies that these are water molecules that are held through weak hydrogen bonding between the metal and one carbonyl group of the phthalimide unit, providing the H-bonding scheme as shown in motif A of Fig. 2. The other two water molecules that are lost at 144 °C are tightly bound by coordination to the metal and held by the carbonyl group of the glycinato part as well as by a carbonyl group of the phthalimide part, as shown as motif B in Fig. 2. The molecule on further heating shows a third weight loss in the region of 302–680 °C, to form cobalt oxide (experimental loss 89.2%, theoretical 87.5%).

The cobalt complex is non-ionic and has a molar conductance of 4.6 S cm^2 mol^{-1} in acetonitrile. The magnetic moment of the complex is 5.22BM at room temperature, which is usual for high spin cobalt (II) octahedral complexes.

The reaction of zinc acetate with *N*-phthaloylglycine also results in the formation of a *N*-phthaloylglycinato complex, having the composition $[Zn(Nphgly)_2(H_2O)_4]$-$2H_2O$. In this complex, the zinc atom is held in a distorted octahedral environment with a similar coordination to that observed for the analogous cobalt(II) complex. The selected bond distances in the complex for Zn–O3, Zn–O5 and Zn–O6 are 2.095, 2.094 and 2.075 Å, respectively. The O6–Zn–O5, O6–Zn–O3 and O6–Zn–O3′ bond angles are 92.07°, 88.71° and 91.29°, respectively. The solid state structure of the complex is shown in Fig. 3. It is clear that the *N*-phthaloylglycinato complexes of cobalt(II) and zinc(II) are isostructural.

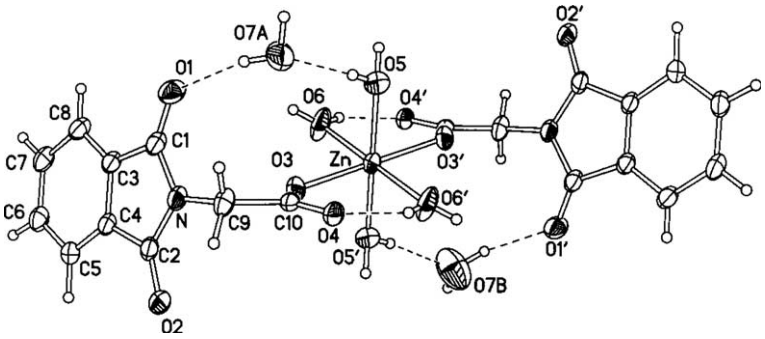

Fig. 3. Crystal structure of tetra-aqua-bis-*N*-phthaloylglycinato zinc(II)dihydrate.

Zinc complexes generally show six-coordination [21], however, due to the presence of extensive hydrogen bonding, this complex shows a distorted octahedral geometry around the zinc. The ^{1}H NMR of the complex shows signals from the aromatic protons (7.9 ppm, multiplet) and the CH_2– protons (4.25 ppm, singlet) only. Due to solubility problems, we have measured the ^{1}H NMR in deuterated dimethylsulfoxide. It is observed that in the solution state the two types of coordinated water molecules cannot be distinguished and their signals merges as one and appear with the signals of water present in DMSO-d^6 at 3.4 ppm. The complex formation is confirmed in solution from the fact that the carboxylic proton that is observed at 13.2 ppm for the ligand is not present in the complex.

In the thermogram of the zinc complex it is observed that heating at a rate of 5 °C/min, the complex loses weight in three steps. In the first step the loss occurs at 80–100 °C; which corresponds to15.5% of the total weight. This loss of weight can be accounted for by the loss of four water molecules; theoretically loss of four water molecules would amount to 13.2% weight loss. At 160–184 °C the molecule loses the other two coordinated water molecules, totaling to a loss of weight of 18.71%, for the loss of all the six water molecules, the calculated loss would be 18.75%. Our observations on the cobalt–phthaloylglycinato complex also tallies with this observation. Thus, a similar explanation can be put forward for the loss of weight from two types of environment around coordinated water, as already illustrated. The third weight loss occurs at 342–363 °C which corresponds to 44.0% and this is due to formation of Zn(Nphgly)(OAc). The calculated weight loss for this transformation is 43.54%. The TG-plot of the zinc-complex is shown in Fig. 4.

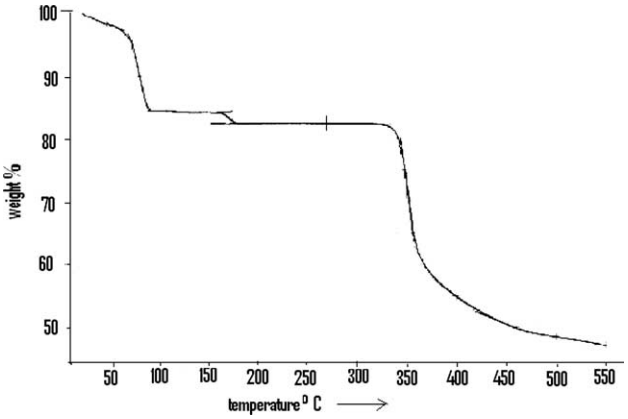

Fig. 4. Thermogram of tetra-aqua-bis-*N*-phthaloylglycinatozinc(II) dihydrate (heating rate 5 °C per minute).

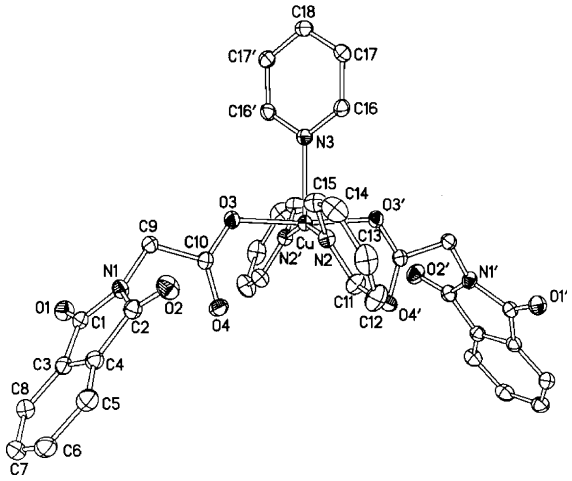

Fig. 5. Structure of $[Cu(py)_3(Nphgly)_2]$.

While attempting to crystallise analogous copper complex from various solvents such as methanol, acetonitrile, DMF, etc., was not successful. However, the compound could be crystallised from pyridine and the crystallised product has the composition $[Cu(py)_3(Nphgly)_2]$. The crystal structure, represented in Fig. 5, shows that this copper complex has a square pyramidal geometry around the copper atom. In this complex, the *N*-phthalolylglycinato ligand also coordinates to the copper in a monodentate fashion. Two of the pyridine ligands and two monodentate carboxylate ligands occupy the basal plane of the square pyramid in which the other pyridine occupies the axial position. In this arrangement, the carboxylate parts are *trans* to each

other and the two pyridines are also *trans* to each other. The bond angles between different atoms attached to the copper ion are N3–Cu–N2, 100.75°; N3–Cu–N2′, 100.75°; N3-Cu–O3, 87.25°; N3–Cu–O3′, 87.25°; N2–Cu–O3, 90.92°; N2′–Cu–O3, 90.10°. Selected bond distances are N2–Cu, 2.303 Å; O3–Cu, 1.956 Å; O3′–Cu, 1.956 Å; N2–Cu, 2.030 Å; N2′–Cu, 2.030 Å; N3–Cu, 2.235 Å. This shows that the molecule has a distorted square pyramidal geometry. It is also interesting to note that the pyridine molecules in the basal plane are twisted such that they are inclined at an angle of 27.51° from a common plane. This puckering brings the carbonyl group of the carboxylic acid group to the proximity of a hydrogen atom present at the 3-position of a coordinated pyridine molecule, resulting in a weak C–H···O interaction in the lattice. The copper(II) complex can be compared to the corresponding copper(II) acetate [21] rather than the bis-glycinato copper(II) complexes as the coordination is restricted to the carboxylate group of the glycine derivative [1f]. In the copper(II) acetate a dimeric structure through a bidentate carboxylate is observed, but in our case we have observed a monodentate carboxy linkage and it is obvious that the pyridine, being a strong ligand, occupies three coordination sites to complete the five coordination.

In the thermogram of the copper complex there is 20.49% weight loss at 90–150 °C corresponding to the weight of two pyridine molecules (theoretical loss 22.23%). These two pyridine molecules are positioned at the base of the square pyramid. As in the complex, the two pyridines have a slightly shorter bond length than the third pyridine ($\Delta R = 0.205$ Å). At 190–240 °C the molecule loses another molecule of pyridine, this amounts to 31.70% of loss (theoretical 33.35%). However, looking at the bond distances determined at 120 K there should have been a weight loss in the reverse manner, that is the loss of axial pyridine first rather than the loss of the other two pyridine ligands from the base of the square pyramid. However, a careful look at the structure suggests that loss of two pyridines would release the steric congestion, which is a thermodynamically favourable process. In fact due to steric crowding the two pyridines in the basal plane do not remain in one plane (Fig. 5). Thus, it may be possible that on heating the system adopts a triangular bipyramidal geometry to release the steric effect and there is loss of two axial pyridine ligands, leaving the equatorial one to be lost at a later stage. In the temperature range 270–380 °C, the molecule transforms to CuO by losing 88.8% of its weight (theoretical 88.39%).

The reaction of *N*-phthaloylglycine with nickel acetate tetrahydrate, followed by crystallisation of the complex from pyridine, gave a nickel complex having the composition $[Ni(py)_3(Nphgly)_2 1.3H_2O]$. Although, we could not refine the X-ray diffraction data for this complex to our satisfaction, we can predict that the molecule has octahedral geometry and remains as a trimeric cluster through involvement of coordinated water and the carbonyl groups of the glycinato and phthalolyl part. The evidence for the presence of water in the complex also comes from the IR absorptions at 3568 and 3472 cm^{-1}, as well as being reflected in the elemental analysis. Further quantification could be determined from the weight loss at low temperature in the thermogram. In the thermogram of this compound, we have found that on heating at a rate of 10 °C per minute it loses 16.13% of its weight between 83 and 140 °C. This corresponds to the loss of water and a pyridine molecule from the complex (theory 14.24%). There is a further loss of weight of 32.19% in the region 140–320 °C, corresponding to the formation of $Ni(Nphgly)_2$ (theoretical 36.09%). The compound loses a further 75.62% of its weight from the parent composition in the region of 340–487 °C. This weight loss corresponds to loss of the phthalimide units and formation of $Ni(OAc)_2$ (theoretical 75.66%).

4. Conclusion

In conclusion, the phthaloylglycinato complexes of Cu(II), Co(II), Zn(II), Ni(II) possess monodentate *N*-phthaloylglycinato ligand. The carbonyl groups in the phthaloyl moiety as well as in the glycinato part provide the anchor to form two distinguishable sets of hydrogen-bonded motifs in the cobalt and zinc complexes. From the crystallographic and thermal studies two hydrogen-bonded environments for coordinated water could be unambiguously established. A square pyramidal copper(II) complex having phthaloylglycinato and pyridine as ligands, has been synthesised and characterised.

5. Supplementary materials

Supplementary data on the crystal structures are available from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk) on request, quoting the Deposition Nos. 268833, 268834 and 204520. ^{1}H NMR spectra of tetra-aqua-bis-*N*-phthaloylglycinato zinc(II)dihydrate.

Abstract

Complexes of the general formula $[Ni_2L_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ have been synthesised in good yields by reacting $Ni(NO_3)_2 \cdot 6H_2O$ with L in the presence of excess of sodium azide in methanol at room temperature. Here L is *N*,*N*-bis(2-pyridylmethyl)amine (L^1) and *N*-(2-pyridylmethyl)-*N*′,*N*′-diethylethylenediamine (L^2). The X-ray structures of both compounds reveal that the *N*,*N*,*N* coordinating reduced Schiff bases are ligated facially. The Ni–N_{azido}–Ni angle is ∼100° and the Ni···Ni separation is ∼3.2 Å. The variable temperature magnetic susceptibility measurements of the two complexes show ferromagnetic behavior.

1. Introduction

Nickel enzymes are involved in various biological reactions [1–4] and consequently the study of the coordination chemistry of nickel has been of significant interest in recent years [5–7]. It has been demonstrated that the azido group inhibits enzymatic reactions [8,9]. Thus, the investigation of nickel–azido complexes has become a field of recent interest to understand the role of the metal ion in biological reactions. In addition, the study of such complexes has also received great deal of attention in the context of enhancement of the knowledge about magnetic interactions as well as development of magnetic materials [10–12].

Although a sizeable number of azido-bridged nickel(II) complexes have so far been reported [13–15], such complexes with reduced Schiff base ligands are rare. Herein, we describe the synthesis and characterization of two neutral end-on diazido-bridged nickel(II) complexes incorporating conformationally labile *N*,*N*,*N*-coordinating reduced Schiff bases. The single crystal X-ray structures, IR and UV–Vis spectroscopic and redox properties are discussed. The variable temperature magnetic susceptibility measurements of the complexes confirm the ferromagnetic behavior in the solid state.

2. Experimental

Materials. All the starting chemicals were analytically pure and used without further purification. The ligands were prepared according to the literature procedure [16].

Caution! Azido complexes of metal ions are potentially explosive, and should be handled with care and in small amounts.

2.1. Physical measurements

The UV–Vis spectra were recorded on a Perkin–Elmer LAMBDA EZ-301 spectrophotometer and IR spectra were measured with a Perkin–Elmer L-0100 spectrometer. Electrochemical measurements were performed (acetonitrile solution) on a CH 620A electrochemical analyzer using a platinum electrode. Tetraethylammonium perchlorate (TEAP) [17] was used as a supporting electrolyte and the potentials are referenced to the standard calomel electrode (SCE) without junction correction. Magnetic measurements were carried out on polycrystalline samples with a Quantum Design MPMS XL SQUID susceptometer operating at a magnetic field of 0.1 T between 2 and 300 K. The diamagnetic corrections were evaluated from Pascal's constants. Elemental analyses (C, H, N) were performed on a Perkin–Elmer 2400 Series II elemental analyzer.

2.2. Synthesis of the complexes

The complexes were prepared by the same general methods. Details are given here for a representative case.

$[Ni_2(L^1)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ (**1**). To a methanolic solution (10 mL) of nickel(II) nitrate hexahydrate (0.146 g, 0.5 mmol) was added L^1 (0.100 g, 0.5 mmol), followed by an aqueous solution of sodium azide (0.065 g, 0.10 mmol). The resulting pale green solution was stirred for 0.5 h at room temperature. Slow evaporation of the solution yielded a light green coloured crystalline product. Yield: 0.09 g, 68%. *Anal*. Calc. for $C_{24}H_{26}N_{18}Ni_2$: C, 42.1; H, 3.8; N, 36.84. Found: C, 41.9; H, 3.6; N, 36.6%. UV–Vis (λ_{max}/nm (ε/M^{-1} cm^{-1}) CH_2Cl_2 solution): 625(12); 1010(32). IR (KBr)/cm^{-1}: ν(NH) 3010; $\nu(N_3^-)$ 2065, 2040. $E_{pa}(Ni^{III}/Ni^{II})$: 1.7 V.

$[Ni_2(L^2)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ (**2**). Yield: 0.12 g, 68%. *Anal*. Calc. for $C_{24}H_{42}N_{18}Ni_2$: C, 41.1; H, 5.99; N, 35.99. Found: C, 41.4; H, 5.7; N, 36.2%. UV–Vis (λ_{max}/nm (ε/M^{-1} cm^{-1}) CH_2Cl_2 solution): 632(12); 1015(26). IR (KBr)/cm^{-1}: ν (NH) 3005; $\nu(N_3^-)$ 2070, 2045. $E_{pa}(Ni^{III}/Ni^{II})$: 1.6 V.

2.3. Crystallographic studies

Suitable crystals of complexes **1** and **2** were grown by slow evaporation of their methanolic solutions. In the case of **1**, the X-ray intensity data were measured at 293 K on a Bruker AXS SMART APEX CCD diffractometer (Mo Kα, $\lambda = 0.71073$ Å). The detector was placed at a distance of 6.03 cm from the crystal. A total 606 frames were collected with a scan width of 0.3° in different settings of φ. The data were reduced in SAINTPLUS [18] and empirical absorption correction was applied using the SADABS package [18]. It was found that there was limited resolution of X-ray data in the case of **1**. For complex **2**, the intensity data were collected at 153 K on a Stoe Mark II-Image Plate Diffraction System [19] equipped with a two-circle goniometer and using Mo Kα graphite monochromated radiation. The image plate distance was 135 mm, ω rotation scans 0–180° at ϕ 0°, and 0–42° at ϕ 90°, step $\Delta\omega = 1.0°$, 2θ range 2.7–51.2°, d_{min}–d_{max} = 15.03–0.82 Å. An empirical absorption correction was applied using the DELrefABS routine in PLATON [20]. The structures were solved by direct methods using the program SHELXS-97 [21]. The refinement and all further calculations were carried out using SHELXL97 [22]. In complex **1**, the N(8) and N(9) atoms of the terminal azide group are distorted and these two were refined isotropically. The remaining non-hydrogen atoms of **1** and all the non-hydrogen atoms of **2** were refined anisotropically, using full-matrix least-squares procedures on F^2. The hydrogen atoms were included in calculated positions. Molecular structure plots were drawn using ORTEP [23]. Relevant crystal data are given in Table 1.

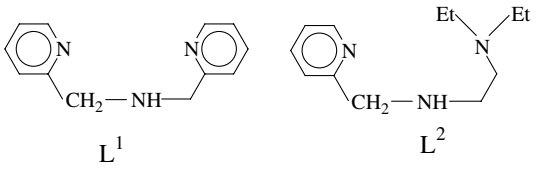
3. Results and discussion

Two reduced Schiff bases L^1 and L^2 (general abbreviation L) are used in this present work and these are synthesized by $NaBH_4$ reduction of their respective Schiff bases [16].



The stoichiometric reaction of $Ni(NO_3)_2 \cdot 6H_2O$ with L in methanol in the presence of excess of sodium azide at room temperature furnishing the pale green coloured

$$Ni(NO_3)_2 \cdot 6H_2O + L \xrightarrow[MeOH]{NaN_3} Ni_2L_2(\mu_{1,1} - N_3)_2(N_3)_2 \quad (1)$$

complexes of type $[Ni_2L_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ Eq. (1).

The complexes display asymmetric azide stretches near 2040 and 2070 cm^{-1}. The stretching frequency of NH group occurs as a broad band near 3000 cm^{-1}. The complexes display an irreversible peak near 1.6 V that may be assigned as a $Ni^{II} \rightarrow Ni^{III}$ oxidation couple.

Both the complexes show two bands in CH_2Cl_2 solution and the bands near 1000 and 630 nm are believed to be of ligand field origin [24].

4. Crystal structure

The crystal structures of $[Ni_2(L^1)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ (**1**), and $[Ni_2(L^2)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ (**2**) have been determined and the ORTEP diagrams are given in Figs. 1 and 2. Selected bond distances and angles are given in Tables 2 and 3. The asymmetric unit of **1** consists of one molecule while that of complex **2** contains one non-centrosymmetric and one half of a centrosymmetric molecule. In both cases, in each half of the dinuclear complexes, the tridentate ligand, L (L^1–L^2) is ligated facially and the other two equatorial sites are occupied by one terminal and one bridging azide group. The remaining axial site of one half of the molecule is fulfilled by the equatorially coordinated azide nitrogen atom of the other half and vice versa, thus, forming a double end-on azido-bridged entity.

In the distorted NiN_6 octahedral environment, the Ni–N bonds span the range 2.043(2)–2.264(2) Å. The Ni–N_{azido}(terminal) and the Ni–N_{azido}(end-on) bonds are usual [15a]. The Ni–N_{azido}–Ni–N_{azido} rings are planar [md < 0.05 Å] and the Ni–N_{azido}–Ni bond angles are ~99° and ~100° in complexes **1** and **2**, respectively. The dihedral angle between the two bridging azido groups is ~30° for **1** and ~25° for **2** and the $\mu_{1,1}$-N_3 groups form an angle of ~50° for **1** and ~40° for **2** with

the Ni–N_{azido}–Ni–N_{azido} plane. The terminal azide groups are quasilinear and coordinate *trans* to each other, the N–Ni···Ni–N torsion angles being 180° for **1** and 177.52(8)° and 179.47(9)° for **2**. The Ni···Ni distances in the dinuclear entities are 3.191(4) Å for complex **1** and 3.296(2) and 3.222(3) Å for **2**.

5. Magnetic studies

The variable temperature magnetic susceptibility measurements were carried out in the temperature range 2–300 K. The $\chi_M T$ versus T plot for complexes **1** and **2** are given in Figs. 3 and 4. The experimental $\chi_M T$ value is 2.6 $cm^3\ mol^{-1}$ K for **1** and 2.96 $cm^3\ mol^{-1}$ K for **2** at 300 K [a characteristic feature for a Ni^{II} ion with g close to 2.30]. This value increases to 3.4 $cm^3\ mol^{-1}$ K at 30 K and to 3.94 $cm^3\ mol^{-1}$ K at 10 K for complexes **1** and **2**, respectively. Below 30 K (for **1**) and 10 K (for **2**) the $\chi_M T$ values decreases abruptly to 2.4 and ~3 $cm^3\ mol^{-1}$ K at 2 K. The shape of the curve is typical of intramolecular ferromagnetic coupling with the presence of either zero-field splitting (D parameter) and/or intermolecular antiferromagnetic interactions (J'). Both D and J' are strongly correlated and show same results at low temperature. Thus, it was not possible to separate them in any attempt to fit the experimental data [25]. So two different approaches have been used to fit the experimental data for **1** and **2**: the first one was a full diagonalisation formalism introducing the single-ion D parameter employing, thus, the spin-Hamiltonian $H = -JS_1S_1 + D[S_z^2 - 1/3S(S+1)] + g\beta HS_z$, and the second one using the molecular field approximation, with the intermolecular J' parameter, according to the method given by Kahn with the Hamiltomian $H = -JS_1S_1 + g\beta HS_z - zJ'\langle S_z\rangle S_z$ [26]. In both the approaches, the best J values were obtained by minimizing the function $R = \sum(\chi_M^{calc} - \chi_M^{obs})^2 / \sum(\chi_M^{obs})^2$. By using the molecular field approach (neglecting the D parameter), the best-fit parameters obtained were as follows: complex **1**; $J = 34.19 \pm 0.7\ cm^{-1}$, $z'J' =$

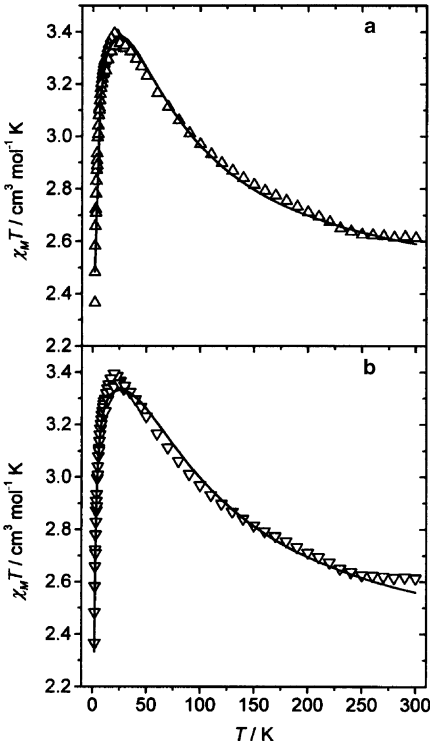

Fig. 3. Plot of $\chi_M T$ vs. T for complex **1** (a) assuming the J' parameter without the D parameter and (b) assuming the D parameter without the J' interaction. Solid line represents the best-fit curve.

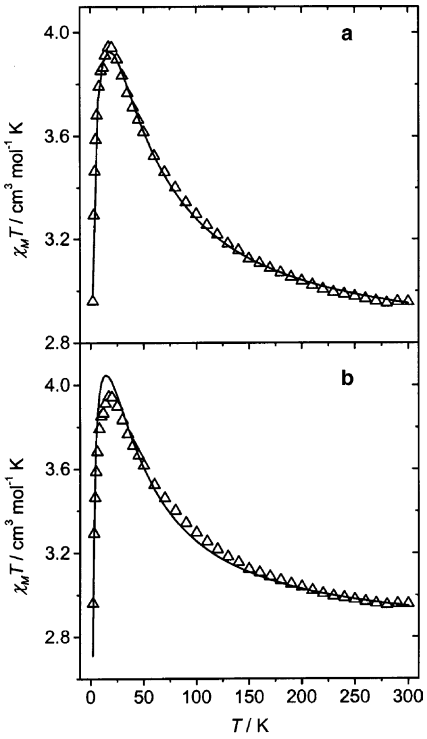

Fig. 4. Plot of $\chi_M T$ vs. T for complex **2** (a) without considering the D parameter and with the $z'J'$ parameter (intermolecular interactions) and (b) assuming the D parameter without the J' interaction. Solid line represents the best-fit curve.

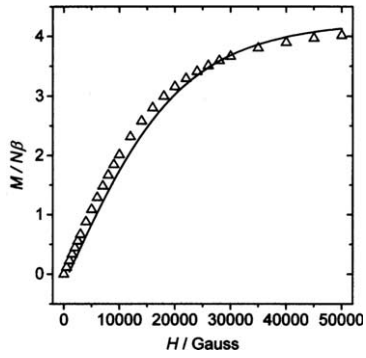

Fig. 5. Plot of the reduced magnetization (M/Nβ) vs. H at 2 K for **1**. Solid line represents the Brillouin function for two isolated Ni^{2+} ions with $g = 2.13$.

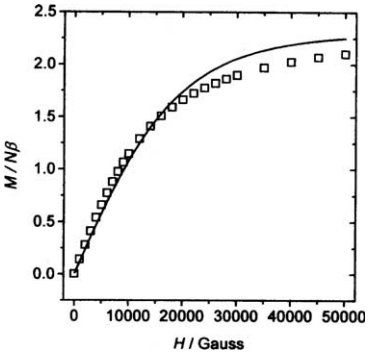

Fig. 6. Plot of the reduced magnetization (M/Nβ) vs. H at 2 K for **2**. Solid line represents the Brillouin formula for $g = 2.35$.

$-0.29\ cm^{-1}$, $g = 2.17 \pm 0.01$ and $R = 6 \times 10^{-4}$ and complex **2**; $J = 22.7\ cm^{-1}$, $z'J' = -0.27\ cm^{-1}$, $g = 2.35$ and $R = 1.5 \times 10^{-4}$ (Figs. 3(a) and 4(a)). By using a full diagonalization method with the D parameter (Figs. 3(b) and 4(b)), the best-fit was obtained with the following parameters: $J = 47.6 \pm 1\ cm^{-1}$, $D = 8.4 \pm 0.5\ cm^{-1}$, $g = 2.12 \pm 0.01$ and $R = 3 \times 10^{-3}$ for complex **1** and $J = 23.2\ cm^{-1}$, $D = 5.27\ cm^{-1}$, $g = 2.25$ and $R = 1.2 \times 10^{-3}$ for complex **2**. The zero-field splitting parameters of isolated Ni(II) ions are usually large and lie in the range 4–8 cm^{-1} [27]. The plot of the reduced magnetization (M/Nβ) is shown in Figs. 5 and 6 for complexes **1** and **2**, respectively. For complex **1**, this curve is in good agreement with the theoretical Brillouin function for two isolated nickel(II) ions assuming $g = 2.13$ (average of the two different fits). The coincidence of the curve can be attributed to the positive J value and the negative J' and D parameters having an opposite effect. The curve of reduced magnetization does not follow the Brillouin formula in the case of **2**. At low fields, the experimental points are above the theoretical ones but at high fields, the experimental points lie below the theoretical curve. This feature is indicative of the complication due to the D parameter and the presence of ferromagnetic and antiferromagnetic interactions.

It is stated in the literature [12,28] that for a bis ($\mu_{1,1}$-N_3) bridged dinuclear nickel(II) system the strength of ferromagnetic coupling between two paramagnetic centers mainly depends on the Ni–N_{azido}–Ni angle, the average angle being close to 101°. With this and similar angles the coupling is ferromagnetic. In **1**, this angle is ~99° and in **2** it is ~100°. The Ni–N_{azido} and Ni···Ni distances are ~2.085 and ~3.191 Å for **1** and ~2.12 and ~3.22 Å for **2**, respectively. Thus the structural parameters corroborate the observed ferromagnetic interactions in the two complexes.

In the solid state, in complex **2** the N(14)–H(14) and N(17)–H(17) groups are involved in intramolecular hydrogen bonding with N(12) and N(7) atoms, respectively. The intramolecular hydrogen bonding could originate a small but not negligible coupling into the magnetic exchange interaction. Hence, the weak coupling generated by such hydrogen bonding may modify the overall Ni–N_{azido}–Ni coupling in case of complex **2**.

6. Conclusion

Two new complexes of the formula $[Ni_2(L^1)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ (**1**) and $[Ni_2(L^2)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ (**2**) have been synthesized and characterized. These species represent the first examples of an end-on azido bridged dinuclear entity incorporating conformationally flexible reduced Schiff base ligands. Variable temperature magnetic

moment measurements of the two complexes confirm the ferromagnetic behavior in the solid state and in the case of **2**, the intramolecular hydrogen bonding modulates the overall Ni–N_{azido}–Ni coupling. Our search for new nickel(II) complexes with different reduced Schiff base ligands and the study of their solid state behavior is in progress.

7. Supporting Information

Crystallographic data for structural analysis have been deposited with the Cambridge Crystallographic Data Centre with CCDC numbers 272898 and 246819 for **1** and **2**, respectively. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033, or e-mail: deposite@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk.

Acknowledgments

Financial support from the Council of Scientific and Industrial Research, New Delhi, India and from the Department of Science and Technology, New Delhi, India are gratefully acknowledged. We are also thankful to DST for the data collection on the CCD facility setup (Indian Institute of Science, Bangalore, India) under the IRHPA-DST program. Joan Ribas acknowledges the financial support from the Spanish Government (Grant BQU2000/0791).

Abstract

The ligand *N*,*N*,*N*′,*N*′-tetraethylpyridine-2,6-dicarboxamide (L^1 and abbreviated as deap) reacts with CoX_2 ($X = PF_6^-, BF_4^-, ClO_4^-$ and NO_3^-) salts to give the octahedral complexes, $[Co(L^1)_2(CH_3CN)](PF_6)_2$ (**1**) and $[Co(L^1)_2(H_2O)_2](X)_2 \cdot H_2O$ ($X = PF_6^-$ (**2**), BF_4^- (**3**), ClO_4^- (**4**) and NO_3^- (**5**). The compounds have been characterised by elemental analysis, IR spectroscopy and X-ray crystallography. The composition of the product is dependant upon the nature of the reaction medium. Compound **1** contains ON and ONO bonded deap ligands in bidentate and tridentate coordinating modes, in which the coordination sphere of the Co^{2+} ion is completed by attachment of an acetonitrile molecule. Compounds **2** and **4** have identical cationic species $[Co(L^1)_2(H_2O)]^{2+}$ in which Co^{2+} is bonded by deap ligands in a bidentate ON mode. As deap is coordinating in a bidentate mode, the two coordinating water molecules are placed *cis* to each other in the octahedral arrangement.

The similarity of the molecular structure of compounds **2** and **4** is, interestingly, also reflected in their crystal structures, both are structurally similar with a *C*2/*c* space group in the monoclinic crystal system. In the crystal lattice, due to the symmetrical disposition of the complex on a twofold axis, there is an interesting chain of molecules formed through hydrogen bonding. The lattice water has a crucial role in the formation of this chain, in fact it acts as a connecting link between the complex molecules running almost perpendicular to the '*ac*' plane.

1. Introduction

Pyridine-2,6-dicarboxamide ligands, like their precursor pyridine-2,6-dicarboxylic acid, are versatile ONO donors capable of forming stable chelates with metal ions [1–8]. These ligands have been widely used to prepare metal complexes exhibiting a range of coordination numbers, geometries and nuclearities. Complexes of divalent transition metal [1,5] and lanthanide ions [2] with these ligands have been investigated to study the effects of steric and electronic factors brought about by peripheral modifications in the tertiary amide side arms at the 2- and 6-positions of the central pyridine ring.

Apart from the general interest reported above, there has been a report on the preparation and spectral characterisation of bis-complexes of cobalt(II), nickel(II)

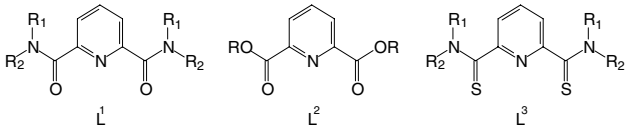
and copper(II) with *N*,*N*,*N*′,*N*′-tetraethylpyridinedicarboxamide (L^1, deap) with particular reference to the two cobalt compounds, $[Co(L^1)_2](X)_2 \cdot 3H_2O$ ($X = PF_6^-, ClO_4^-$) [3]. Based on IR and electronic spectral data, it was proposed that the cobalt ion had distorted octahedral stereochemistry bonded by the *N*,*N*,*N*′,*N*′-tetraethylpyridinedicarboxamide ligand in a tridentate mode and containing ionic PF_6^- and ClO_4^- groups [3]. Continuing our work on the ligational behaviour of a number of tridentate ligands containing ONO(L^1), [9,10] (L^2) [11,12] and *SNS*(L^3) [13,14] sets of donor atoms towards cobalt, nickel and copper, we have now synthesized cobalt complexes of deap (L^1) with PF_6^- (**1**) and (**2**), BF_4^- (**3**), ClO_4^- (**4**), and NO_3^- (**5**), and report the X-ray crystal structures of **1**, **2** and **4**. These anions have different coordinating abilities, i.e., from virtually 'non-coordinating' (PF_6^-, BF_4^- and ClO_4^-) to strongly coordinating (NO_3^-). The present work is also aimed at finding out the role of the counter ions in determining the flexibility of the network created by the arrangement of the cationic species.



Interestingly, formulations of **2** and **4** are the same as had been reported earlier [3], but the compounds show significant structural differences to that which had been proposed on the basis of spectral data. Our crystallographic studies show that the deap ligands are coordinating in a bidentate mode and to the best of our knowledge these are the only examples of this structural type. Possibly, the nature of the anions and lattice effects may be responsible for the variation in coordination mode observed for deap in the complexes isolated.

2. Experimental

2.1. Preparation of complexes

N,*N*,*N*′,*N*′-tetraethylpyridinedicarboxamide (L^1) was prepared as reported [12]. Solvents were dried using standard techniques [15]. $Co(NO_3)_2 \cdot 6H_2O$ (s.d. fine chemicals) and $CoCl_2 \cdot 6H_2O$(BDH) were used as such.

2.1.1. Syntheses

$[Co(L^1)_2(CH_3CN)](PF_6)_2$ (1). To a dark blue coloured solution of $Co(NO_3)_2 \cdot 6H_2O$ (0.567 g, 1.95 mmol, in 10 mL) in acetonitrile was added, with stirring, a solution of deap (1.080 g, 3.90 mmol in 10 mL) in the same solvent. An aqueous solution of KPF_6 in a minimum amount of water (0.714 g, 3.90 mmol) was added to the dark purple solution. The solution was stirred for 24 h, which subsequently on cooling to 0 °C yielded a pink crystalline solid. It was filtered, washed with ether and dried in vacuo. *Anal.* Calc. for $C_{32}H_{49}CoO_4N_7P_2F_{12}$: C, 40.68; H, 5.19; N, 10.38. Found: C, 40.24; H, 4.98; N, 10.16%. M.p., 260 °C. Λ_M ($ohm^{-1}\,cm^2\,mol^{-1}$) = 210 (CH_3CN) and 136 (CH_3NO_2) [expected range for 1:1 and 1:2 electrolytes in these solvents are 120–160 and 220–380 (CH_3CN) and 75–95 and 150–180 (CH_3NO_2) $ohm^{-1}\,cm^2\,mol^{-1}$. ^{19}F NMR ($CDCl_3$/DMSO-d_6, ppm): δ, −70.93 and −73.45; J_{PF} 712 Hz. Absorption spectrum [λ_{max}, nm]: 506(sh), 530 (CH_3OH). Selected IR bands(cm^{-1}): 3586m, 3185m,br, 2324w, 1608s, 845s,br, 558m. Magnetic moment (BM, 300 K): 5.01.

$[Co(L^1)_2(H_2O)_2](PF_6)_2 \cdot H_2O$ (2). This was prepared by following the above procedure except that the reaction was now performed in an aqueous acetonitrile medium. It has been noted that irrespective of whether the metal–ligand ratio is 1:1 or 1:2 the product is always complex **2**. *Anal.* Calc. for $C_{30}H_{52}CoO_7N_6P_2F_{12}$: C, 37.62; H, 5.43; N, 8.78. Found: C, 37.26; H, 5.08; N, 8.60%. M.p., 162–165 °C. Λ_M ($ohm^{-1}\,cm^2\,mol^{-1}$) = 228 (CH_3CN) and 144 (CH_3NO_2). ^{19}F NMR ($CDCl_3$/DMSO-d_6, ppm):δ, −69.50 and −72.02; J_{PF} = 711 Hz. Absorption spectrum [λ_{max}, nm]: 490(sh), 534 (CH_3OH). Selected IR bands (cm^{-1}): 3584m, 3190m, br, 1614s, 845s,br, 558m. Magnetic moment (BM, 300 K): 4.68.

$[Co(L^1)_2(H_2O)_2](BF_4)_2 \cdot H_2O$ (3). This complex was prepared by the procedure described for **1** using $NaBF_4$ instead of KPF_6. A pink crystalline solid of **3** was obtained (ca. 78% yield based on L^1). *Anal.* Calc. for $C_{30}H_{52}CoO_7N_6B_2F_8$: C, 42.80; H, 6.18; N, 9.98. Found: C, 42.56; H, 5.88; N, 10.24%. M.p., 105 °C. Λ_M ($ohm^{-1}\,cm^2\,mol^{-1}$) = 208 (CH_3CN) and 165 (CH_3NO_2). Absorption spectrum [λ_{max}, nm]: 490(sh), 530 (CH_3OH). Selected IR bands (cm^{-1}): 3474m, 3190m,br, 1609s, 1080s. Magnetic moment (BM, 300 K): 4.68.

$[Co(L^1)_2(H_2O)_2](ClO_4)_2 \cdot H_2O$ (4). To a deep blue solution of $CoCl_2$ in ethanol (0.447 g, 3.44 mmol in 10 mL) was added an aqueous solution of $NaClO_4$ (0.842 g, 6.88 mmol). After stirring for 4 h at r.t., NaCl was removed by filtration. A solution of deap in ethanol (0.953 g, 3.44 mmol) was added with stirring to the solution of cobalt perchlorate. The contents were stirred for 8 h, and on vacuum drying yielded a purple solid. It was recrystallised from ethanol solution on keeping it at 0 °C. *Anal.* Calc. for $C_{30}H_{52}Cl_2CoO_{15}N_6$: C, 41.57; H, 6.00; N, 9.70. Found: C, 41.24; H, 6.38; N, 9.56%. M.p., 110 °C. Λ_M ($ohm^{-1}\,cm^2\,mol^{-1}$) = 184 (CH_3CN) and 160 (CH_3NO_2). Absorption spectrum [λ_{max}, nm]: 490(sh), 515 (CH_3OH). Selected IR bands (cm^{-1}): 3400m, 3189m,br, 1609s, 1112s,br, 624m. Magnetic moment (BM, 300 K): 4.75.

$[Co(L^1)_2(H_2O)_2](NO_3)_2 \cdot H_2O$ (5). A solution of $Co(NO_3)_2 \cdot 6H_2O$ in CH_3CN was stirred with a solution of deap in the same solvent for about 8 h. On addition of diethylether, a pink crystalline solid separated out of the solution. It was filtered, washed with diethylether and acetonitrile mixture and dried under vacuo. *Anal*. Calc. for $C_{30}H_{52}CoO_{13}N_8$: C, 45.51; H, 6.57; N, 14.15. Found: C, 45.14; H, 6.18; N, 14.01%. M.p., 140 °C. Λ_M ($ohm^{-1}\,cm^2\,mol^{-1}$) = 215 (CH_3CN) and 158 (CH_3NO_2). Absorption spectrum [λ_{max}, nm]: 490(sh), 515 (CH_3OH). Selected IR bands (cm^{-1}): 3400m, 3189m,br, 1609s, 1112s,br, 624m. Magnetic moment (BM, 300 K): 4.75.

Caution! Perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled with care.

2.2. Physical measurements

Elemental analyses (C, H, N) were carried out using a Perkin–Elmer model 2400 CHN elemental analyzer at the SAIF, Panjab University. Cobalt was determined gravimetrically as $[Co(C_5H_5N)_4](SCN)_2$. IR spectra were recorded as KBr pellets on a Perkin–Elmer RX-1 FTIR spectrophotometer. The UV–Vis spectra (200–1000 nm) were recorded on a JASCO V-530 UV–VIS spectrophotometer in 1 cm matched quartz cells. Molar conductances were measured using a Digital conductivity bridge, Model CC601. Magnetic susceptibilities were measured on a Gouy balance at 300 K using solid $Hg[Co(NCS)_4]$ as calibrant.

2.3. X-ray crystallography

Crystallization of **1**, **2** and **4** at room temperature by slow evaporation of their saturated solutions in CH_3CN, slightly aqueous CH_3CN and C_2H_5OH respectively yielded good single crystals. Intensity data were collected on a Siemens P4 single-crystal diffractometer equipped with a molybdenum sealed tube (λ = 0.7173 Å) and highly oriented graphite monochromator at 293(2) K. The lattice parameters and standard deviations were obtained by a least-squares fit to 40 reflections [$10.27 < 2\Theta < 28.08°$] for **1**. The data were collected by the $2\Theta-\Theta$ scan mode with a variable scan speed ranging from 2.0 to a maximum of $60° \,min^{-1}$. Three reflections were used to monitor the stability and orientation of the crystal and were measured after every 97 reflections. Their intensities showed only statistical fluctuations during 74.92 h of X-ray exposure time. The data were collected for Lorentz and polarisation factors and an empirical absorption correction based on the Psi scan method was applied. The structures were solved by direct methods using SHELX-97 [16] and also refined on F^2. All the non-hydrogen atoms were refined anisotropically. During the refinement, the difference Fourier clearly showed the twofold disordered positions of the PF_6^- anions in **1** and one of the ethyl moieties [C(14)–C(15)] of the side arms of **2** and **4**. These disordered atoms were refined with partial occupancy factors. Similarly, the twofold disordered oxygen atoms of ClO_4^- (in **4**) through the [Cl(1)–O(5)] axis were refined to a major occupancy factor of 0.89%. The minor

positions of all these disordered atoms were assigned an occupancy of $1 - x$ (where $x =$ major occupancy). The hydrogen atoms were included in ideal positions with fixed isotropic U values and riding with their respective non-hydrogen atoms. A weighting scheme of the form $w = 1/[(\sigma 2F_o^2) + (ap)^2 + bp]$ with $a = 0.0980$ and $b = 5.60$ was used. The refinement converged to a final R value of 0.0648 ($wR_2 = 0.1723$ for 4823 reflections) [$I > 2\sigma(I)$]. The final difference map was featureless. The data collection procedure, structure solution and refinement for compounds **2** and **4** were essentially the same as for **1**. The parameters associated with their structures are as follows: **2**. 40 reflections ($10.13 < 2\theta < 28.27°$) for an accurate cell parameter determination, $R = 0.0555$ ($wR_2 = 0.1431$ for 2475 reflections) [$I > 2\sigma(I)$] with $a = 0.0934$ and $b = 3.89$ in the weighting scheme. **4** 40 reflections ($9.52 < 2\theta < 30.04°$) for an accurate cell parameter determination, $R = 0.0474$ ($wR_2 = 0.1285$ for 2551 reflections) [$I > 2\sigma(I)$] with $a = 0.0739$ and $b = 5.10$ in the above mentioned weighting scheme. A summary of the crystal parameters, experimental details and refinement results are listed in Table 1.

3. Results and discussion

Complexes **1**–**5** are isolated in good yield by stirring $Co(NO_3)_2 \cdot 6H_2O$ or $CoCl_2 \cdot 6H_2O$ with two equivalents of the alkali metal salt of the appropriate anion containing 2 moles of deap. The final composition of the product is dependant on the solvent used. The complexes are sensitive to moisture and were identified and characterised through melting points, elemental analyses, IR and visible spectral data, conductivity measurements, X-ray crystallography and magnetic measurements. The complexes are practically insoluble in CH_2Cl_2, $CHCl_3$, CCl_4 and C_6H_6 but easily dissolve in polar organic solvents such as CH_3OH, CH_3CN and CH_3NO_2. Their conductivities were measured in CH_3CN and/or CH_3NO_2 and the molar conductances are slightly below the expected ranges for 1:2 electrolytes in these solvents [17]. The magnetic moment of the complexes at room temperature falls in the range 4.60–4.80u_B, consistent with the presence of three unpaired d electrons, suggesting a high-spin octahedral structure [18]. The visible spectra of complexes **1**–**4** show a weak absorption band near 530 nm which is due to the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transition. The shoulder band on the high frequency side is attributed to spin–orbit coupling in the $^4T_{1g}(P)$ state [18]. The other two transitions, i.e., $^4T_{1g}(F) \rightarrow {}^4A_{2g}$ and $^4T_{1g}(F) \rightarrow {}^4T_{2g}$ expected for an octahedrally coordinated Co^{II} ion are not observed [18].

Vibrational spectroscopy is also in agreement with the present structures. The IR spectra of compounds **1**–**5** show absorptions characteristic of the coordinated ligand. In the free ligand, the carbonyl stretching frequency appears as a strong band at 1625 cm^{-1}, and this is lowered by about 15–20 cm^{-1} on coordination to the metal ion in the complexes. In these compounds, we were expecting two bands in this region, one band near 1625 cm^{-1} due to a free carbonyl group and the second peak near 1600 cm^{-1} due to a coordinated carbonyl group. In fact only a single broad peak was observed around 1600 cm^{-1}. Probably, due to strong hydrogen bonding between the free carbonyl oxygen and the lattice water, the $\nu_{C=O}$ peak is lowered to an extent that only a single peak is observed. Participation of the pyridine ring nitrogen in all the complexes is indicated by the upward movement in the absorption and ring breathing mode of pyridine. Compounds **2**–**5** show a broad band centred around 3200 cm^{-1} and a sharper absorption near 3460 cm^{-1}. These bands are indicative of the presence of hydrogen-bonded lattice water and coordinated water. The IR spectra of **2**–**5** are essentially similar to each other except for the vibrations of the respective counteranion (PF_6^-, 845 and 560 cm^{-1} in **1** and **2** [19]; BF_4^-, 1072 cm^{-1} in **3** [20]; ClO_4^-, 1090 and 630 cm^{-1} in **4** [21] and NO_3^-, 1390 cm^{-1} in **5**) [20].

In order to prepare mixed ligand complexes, **1**, **2** and **4** were treated with HMPA. However, deap was eliminated resulting in the isolation of $MX_2 \cdot 2$ HMPA ($X = PF_6^-$ and ClO_4^-). It suggests that HMPA is a stronger nucleophile than deap.

3.1. Crystal structure of $[Co(deap)_2CH_3CN](PF_6)_2$ (1)

Selected bond angles and bond distances for complex **1** are given in Table 2. A perspective view of complex **1** is depicted in Fig. 1. The complex consists of discrete $[Co(deap)_2CH_3CN]^{2+}$ cations and PF_6^- anions. The cobalt atom in the complex cation is hexacoordinated (CoN_3O_3 chromophore), one deap ligand is acting as a tridentate ligand [bonding through two carboxamide oxygen atoms O(1), O(2) and the pyridilic N(1) atom] while the second deap ligand is coordinated in a bidentate mode [bonding through O(3) and N(4) atoms]. The carboxamide oxygen O(4) of the other side arm moves away from the cobalt center, $Co(1)\cdots O(4) = 3.67$ Å, indicating no bonding interaction. The sixth coordination site is occupied by an acetonitrile molecule bonded to Co(1) through the N(7) atom. The bond angle involving the axial atoms, N(7)–Co(1)–N(4) is 161.37(17)°, giving a severely distorted octahedral arrangement. The four atoms O(2), O(1), N(1) and O(3) define a mean plane from which these atoms are deviated by −0.097, −0.117, +0.133 and +0.081 Å. The cobalt atom is displaced by +0.031 Å from the mean plane formed by these four atoms. The distortion exhibited by the complex may be attributed to the steric hindrance caused by the ethyl groups of the carboxamide moiety. Due

Symmetry transformations used to generate equivalent atoms #1 $-x+2, y, -z+3/2$; #2 $-x, y, -z+3/2$.

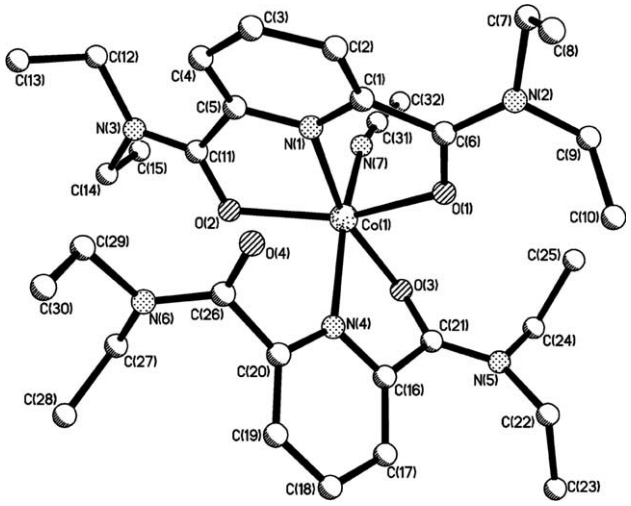

Fig. 1. A perspective view of complex **1** with the atom numbering scheme. The hydrogen atoms and anions are omitted for clarity.

to the difference in coordination mode, the conformation of the two deap ligands is also different in the crystal lattice. To maximize the electron donation through coordination, both the carbonyl moieties of the tridentate deap are almost in the meridional plane of the ligand, the torsion angle with respect to the C(1)–C(6) and C(5)–C(11) bonds being −18.4° and 22.0°, respectively. On the other hand, in the bidentate deap, as this restriction does not apply, the torsional angles are much more varied [at the C(16)–C(21) bond −28.8°, and at the C(20)–C(28) bond −65.7°]. In fact it is the non-coordinating carbonyl moiety [C(26)–O(4)], that is quite out of plane from the aromatic pyridyl ring [N(4)–C(20)–C(26)–O(4) = −65.7°]. In the crystal lattice both the PF_6^- anions are disordered and placed in the cavities formed by the metal ligand complex cations. Such disordered PF_6^- anions are common in other similar structures containing PF_6^- anions [22].

3.2. Crystal structures of $[Co(deap)_2(H_2O)_2](X)_2$ [X = PF_6^- (2); ClO_4^- (4)]

The crystal structures of **2** and **4** comprise of $[Co(deap)_2(H_2O)_2]^{2+}$ cations and PF_6^- or ClO_4^- anions. The structure of the cation involves a hexa-coordinated CoO_4N_2 chromophore with the metal center presenting a nearly perfect octahedral geometry. The molecules of **2** and **4**

occupy the twofold axis of the $C2/c$ space group, resulting in an interesting network of hydrogen bonds. The deap ligands are coordinated in a bidentate mode bonded by the pyridilic N atom and an oxygen atom of the carboxamide moiety. The oxygen atom of the non-coordinating part of the side arm moves away from the metal center [Co(1)···O(2) = 4.114 Å]. The fifth and sixth coordination sites are occupied by water molecules. The four atoms O(3), N(1), O(3)$^{\#}$ and N(1)$^{\#}$ (# = $-x$, $-y$, $1.5 - z$) define a mean plane from which these atoms are deviated by −0.284, −0.249, 0.284 and 0.249 Å for **2** and −0.257, −0.225, 0.257 and 0.225 Å for **4**, respectively. Interestingly, the cobalt atom resides exactly on this plane, deviation = 0.00 Å. The bite angles around the cobalt atom range from 76.89(9) to 104.37(10)°, summing up the in-plane angles to be 359.98°.

The similarity in the molecular structure of compounds **2** and **4** is, interestingly, reflected in their crystal structures also, both are structurally similar with a $C2/c$ space group in the monoclinic crystal system. However, to accommodate a larger PF_6^- anion (in **2**) than ClO_4^- (in **4**), the cell volume has increased by ca. 334 Å^3 in **2** compared to **4**. In effect, the monoclinic 'box' has enlarged significantly in the '*a*' and '*c*' directions (1.604 and 0.586 Å increase) and only slightly in the '*b*' direction (0.014 Å increase) to accommodate the larger counteranion, but the structural features are strikingly similar (vide infra). Firstly, both anions in these complexes are disordered in the lattice, probably due to their high symmetry, as the walls of the cavity from the cations have similar stabilizing interactions even if the anion is positioned in a different orientation. Secondly, even the disordered nature of one of the coordinating 'arms' is preserved in both the crystal lattices. Thus, this family of cations may adjust to the topological demand of the varying nature of the anions by showing larger flexibility in their cavity size for anion accommodation. Structure determination of a series of complexes with different counter ions may validate this point.

In the crystal lattice, the cobalt cation sits on a twofold axis, and two deap ligands and two water molecules together complete the octahedral geometry around the metal ion (due to the structural similarity between **2** and **4**, the structural description regarding **2** is equally valid for **4** and relevant parameters are recorded in brackets for **4**). As deap is only acting as a bidentate ligand, the two coordinating water molecules are placed *cis* to each other in the octahedral arrangement (Figs. 2 and 3). It is also interesting to note that deap is not utilizing all of its coordinating abilities (it can act as a tridentate ligand [12]) but only binds to the metal atom in a bidentate mode with one of its carbonyl oxygen atoms and its pyridyl nitrogen atom. The free carbonyl group is in fact strongly hydrogen bonded to the lattice water molecule (Fig. 4). As observed in **1** the non-coordinating

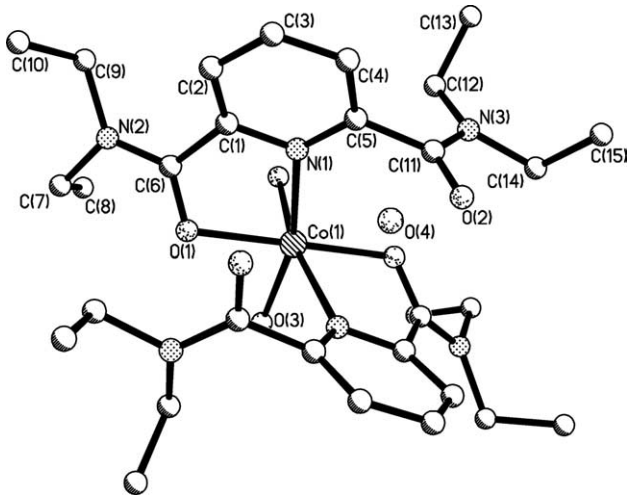

Fig. 2. A perspective view of complex **2** with the atom numbering scheme. The hydrogen atoms and anions are omitted for clarity.

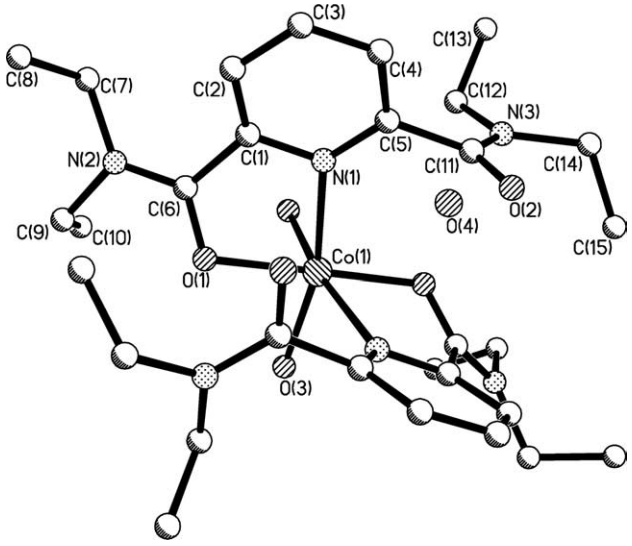

Fig. 3. A perspective view of complex **3** with the atom numbering scheme. The hydrogen atoms and anions are omitted for clarity.

carbonyl moiety is almost orthogonal to the pyridyl ring, the relevant torsional angle being −103.3° (**2**) and 99.8° (**4**). The coordinating carbonyl group is also deviated to an extent of 30.0° from the aromatic plane [N(1)–C(1)–C(6)–O(1)].

In the crystal lattice, due to the symmetrical disposition of the complex on the twofold axis, there is an interesting chain of molecules formed through hydrogen bonding (Fig. 4). The lattice water has a crucial role in the formation of this chain, in fact it acts as a connecting link between the complex molecules running almost perpendicular to the '*ac*' plane. The relevant hydrogen bonding parameters are given in Table 3. This water molecule is saturated in terms of its hydrogen bonding capabilities and, as expected, the four hydrogen bonds are almost tetrahedrally oriented and they are strong

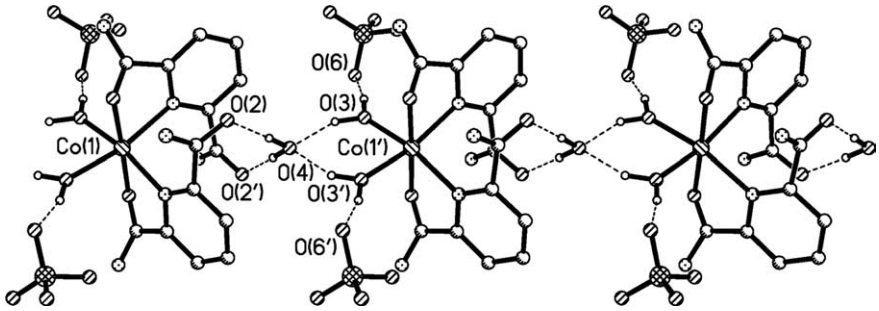

Fig. 4. Interlinkage of complex molecules of **4** through the lattice water leading to the formation of a molecular chain. Note that the water is saturated in its hydrogen bonding capability. Due to crystallographic symmetry O(2) and O(2′) are identical and similarly so are O(3) and O(3′).

O–H···O hydrogen bonds $d(H\cdots A < 1.9$ Å). Such a strong holding of the water molecule to the ligand moiety has its physical consequences. Our deliberate attempt to remove this water by warming the complex to 60 °C for 12 h or applying vacuum (10^{-3} Torr) for 12 h or both did not remove this water molecule. The IR spectra before and after these experiments remained virtually identical.

The hydrogen bonded chains of the complex generate flexible linear columns in which either PF_6^- (**2**) or ClO_4^- (**4**) reside and stabilize the lattice (Fig. 5). These anions are topologically locked in their place through either O–H···F (**2**) or O–H···O (**4**) hydrogen bonds (Table 3). It is noteworthy that it is the lattice water that anchors these anions through multiple interactions. Even the disordered positions of the anions are stabilized through hydrogen bonds. One such typical example is shown in Table 3. Thus, in this family of complexes, the columnar cavity is flexible to accommodate anions of different sizes and the cavity surface can also provide multiple interaction sites with the anions that can provide overall stability to the lattice. If these cavities are capable of exchanging the anions at different rates and stabilities, they can even act as specific receptors for these anions. A careful combination of kinetic and spectroscopic studies on these systems may validate this aspect. Preliminary experiments show anion exchange of $[Co(deap)_2(H_2O)_2](BF_4)_2 \cdot H_2O$ with PF_6^- in acetonitrile solution.

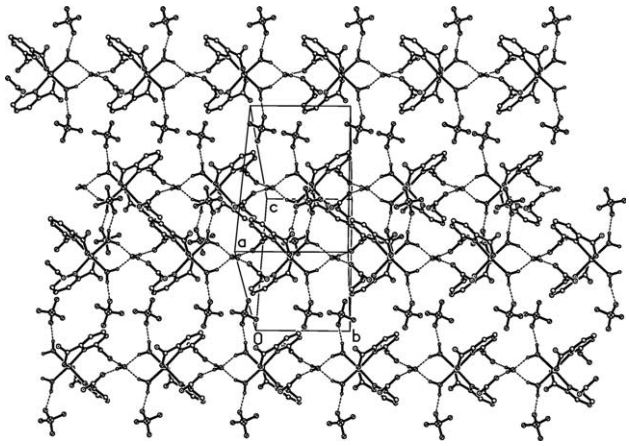

Fig. 5. Formation of channels out of the molecular chains shown in Fig. 4. The anions are disordered (only the major positions are shown here) and are stabilized through hydrogen bonding. Due to the similarity of structure, the packing of complex **2** is exactly the same as **4** except for a change of the counterion to PF_6^-.

Appendix A. Supplementary data

Phthalocyanines with rigid carboxylic acid containing pendant arms

Ayfer Kalkan, Zehra Altuntaş Bayır *

Department of Chemistry, Technical University of Istanbul, TR34469 Maslak, Istanbul, Turkey

Received 6 June 2005; accepted 25 June 2005
Available online 18 August 2005

Abstract

Metal-free and metallophthalocyanines (Zn, Co) substituted with four carboxybiphenyloxy groups on the peripheral positions were prepared from 4-(4′-carboxybiphenyloxy)phthalonitrile. Esterification of all of the biphenylcarboxylic acid groups of metal-free phthalocyanine with hexanol afforded 2,9,16,23-tetrakis(4′-carbhexyloxybiphenyloxy) phthalocyanine. These new compounds have been characterised by ^{1}H NMR, ^{13}C NMR, FT-IR, UV–Vis and mass spectroscopies.

Keywords: Phthalocyanine; Biphenylcarboxylic acid; Zinc; Cobalt

1. Introduction

Phthalocyanine is a close relative of the porphyrin macrocycle and is the parent compound of one of the most studied class of functional organic materials. The most important and extensive application of phthalocyanines is to be used as colorants. Furthermore, phthalocyanine and its derivatives displaying interesting photophysical properties, electron transfer ability and reduction–oxidation behaviour are studied for applications in electrophotography, photovoltaic cells, fuel cells and electrochromic displays [1,2].

Recent years, remarkable progress has been made in the use of phthalocyanine derivatives as sensitisers for photodynamic therapy (PDT) of cancer [3,4]. PDT employs the combination of light and photosensitiser. Photosensitiser is getting excited after the absorption of light of proper wavelength. It is followed by a singlet oxygen production by energy transfer from activated photosensitiser. Phthalocyanines display cytotoxic effects when activated by light. Especially, water soluble zinc and aluminium phthalocyanine complexes have good photosensitising properties for PDT [5–7].

The main restricting factor of phthalocyanines is a rather low solubility in organic solvents. Periferal substitution of phthalocyanines with alkyl, alkoxy, alkythio chains or bulky groups enhances their solubility drastically [8–18]. The introduction of carboxy or amino groups gives water-soluble products. The synthesis of soluble phthalocyanines should provide them new optical, electronic, redox and magnetic properties which could increase the field of possible applications [19–21].

Recently, we have reported on the synthesis, separation and characterisation of unsymmetrical and symmetrical phthalocyanines [22–25]. This paper describes metal-free and metallo phthalocyanines (Zn, Co) carrying biphenylcarboxylic acid substituents on the periphery. Also, all of the biphenylcarboxylic acid substituents of the metal-free phthalocyanine were esterified with hexanol.

2. Experimental

IR spectra were recorded on a Perkin–Elmer Spectrum One FT-IR (ATR sampling accessory)

spectrophotometer, electronic spectra on a Unicam UV2 spectrophotometer. ^{1}H NMR spectra were recorded on Bruker 250 MHz and Inova 500 spectrometers using TMS as internal reference. Mass spectra were performed on Ultima Fourier Transform and Varian 711 mass spectrometer. All reagents and solvents were of reagent grade quality obtained from commercial suppliers. The homogeneity of the products was tested in each step by TLC. All solvents were dried and purified as described by Perrin and Armarego [26]. The solvents were stored over molecular sieves. 4-Nitrophthalonitrile (**1**) [27] was synthesised according to published methods.

2.1. 4-(4′-Carboxybiphenyloxy)phthalonitrile (*2*)

4-Nitrophthalonitrile (0.5, 2.89 mmol) and an excess of 4′-hydroxy-4-biphenylcarboxylic acid (1.24 g, 5.78 mmol) were dissolved in 10 ml dry DMF. Anhydrous K_2CO_3 (1.59 g, 11.56 mmol) was added portion wise over 2 h and the mixture was stirred vigorously at room temperature under N_2 for 48 h. The reaction mixture was poured into water (100 ml) and the pH of solution was adjusted to 1 by addition of aqueous hydrochloric acid. The precipitated solid was filtered, washed with water until the filtrate was neutral, and then dried. Finally, a pale beige product was crystallised from methanol–water. Yield: 0.54 g, 55%. M.p. >200 °C. IR $\nu_{max}/(cm^{-1})$: 3055 (Ar–H), 2238 (C≡N), 1681 (C=O), 1588, 1522, 1489, 1268, 1242 (C–O–C), 1183, 1007, 839, 776, ^{1}H NMR (*d*-DMSO): 13.03 (s, 1H, OH), 8.14 (d, 2H, Ar–H), 8.05 (d, 1H, Ar–H), 7.85 (m, 4H, Ar–H), 7.49 (d, 1H, Ar–H), 7.46 (d, 1H, Ar–H), 7.34 (d, 2H, Ar–H); ^{13}C NMR (*d*-DMSO, APT): 167.58 (C=O), 161.24 (aromatic C), 154.57 (biphenyl C), 143.66 (biphenyl C), 136.85 (biphenyl C), 136.81 (aromatic CH), 130.48 (biphenyl CH), 130.17 (biphenyl C), 129.66 (biphenyl CH), 127.22 (biphenyl CH), 123.45 (aromatic CH), 122.82 (aromatic CH), 121.26 (biphenyl CH), 117.22 (aromatic C), 116.37 (C≡N), 115.85 (C≡N), 108.93 (aromatic C); UV–Vis λ_{max} (nm) (log ε) in THF: 291 (4.63). *Anal.* Calc. for $C_{21}H_{12}N_2O_3$: C, 74.11; H, 3.55; N, 8.23. Found: C, 74.10; H, 3.52; N, 8.22%.

2.2. 2,9,16,23-Tetrakis(4′-carboxybiphenyloxy)-phthalocyanine (*3*)

4-(4′-Carboxybiphenyloxy)phthalonitrile (0.50 g, 1.47 mmol) was dissolved in 6 ml dry 1-pentanol and heated at 140 °C under N_2. After addition of elemental lithium (0.07 g, 10.3 mmol) a green colour appeared in a few seconds. The suspension was stirred under reflux for 1 h. Then, the mixture was cooled to room temperature. The reaction mixture was acidified with HCl and the resulting precipitate was centrifuged off. The precipitated blue-green coloured solid was filtered and washed first with water, then with ethanol and acetone finally dried in vacuo. Yield: 0.34 g, 17%. M.p. >200 °C. IR $\nu_{max}/(cm^{-1})$: 3310 (N–H), 3050 (Ar–H), 1683 (C=O), 1598, 1522, 1470, 1250, 1181, 1091, 1003, 926, 825, 771; ^{1}H NMR (*d*-DMSO): 8.01–7.38 (m, 44H, Ar–H); UV–Vis λ_{max} (nm) (log ε) in DMSO: 288 (4.77), 340 (4.36), 668 (4.41), 700 (4.40); MS (MALDI-TOF): *m*/*z* 1363.4 [M^+], 1317.4 [$M^+ - COOH - H$]. *Anal.* Calc. for $C_{84}H_{50}N_8O_{12}$: C, 74.01; H, 3.67; N, 8.22. Found: C, 73.99; H, 3.65; N, 8.19%.

2.3. 2,9,16,23-Tetrakis(4′-carboxybiphenyloxy)-phthalocyaninatozinc(II) (*4*)

The metal-free phthalocyanine **3** (0.20 g, 0.14 mmol) was dissolved in 20 ml dry DMF and anhydrous zinc acetate (0.27 g, 1.46 mmol) was added and the mixture was heated under stirring for 24 h at 80 °C. After cooling to room temperature, the suspension was added to diethyl ether (100 ml) and the precipitated green solid was filtered. The crude product was treated with CH_3COOH (10 ml) for 2 h then filtered off and washed with ethanol, acetone and then dried in vacuo. Yield: 0.10 g, 48%. M.p. >200 °C. IR $\nu_{max}/(cm^{-1})$: 3050 (Ar–H), 1688 (C=O), 1600, 1522, 1472, 1250, 1184, 1092, 1004, 928, 827, 773; ^{1}H NMR (*d*-DMSO): 12. 78 (br s, 4H, OH), 8.01–7.31 (m, 44H, Ar–H); UV–Vis λ_{max} (nm) (log ε) in DMSO: 289 (4.78), 347 (4.47), 679 (4.51); MS (FAB): *m*/*z* 1426.3 [M^+]. *Anal.* Calc. for $C_{84}H_{48}N_8O_{12}Zn$: C, 70.72; H, 3.37; N, 7.85. Found: C, 70.70; H, 3.34; N, 7.83%.

2.4. 2,9,16,23-Tetrakis(4′-carboxybiphenyloxy)-phthalocyaninatocobalt(II) (*5*)

A mixture of **3** (0.25 g, 0.18 mmol) and anhydrous cobalt(II)chloride (0.24 g, 1.84 mmol) was heated in dry DMF (20 ml) at 80 °C under N_2 with stirring for 18 h. The resulting green suspension was cooled and then added drop wise to diethyl ether (100 ml). The precipitate was stirred with CH_3COOH for 2 h and then filtered off. The green product was washed several times with hot ethanol and acetone to remove unreacted materials and then dried in vacuo. Yield: 0.13 g, 51%. M.p. >200 °C. IR $\nu_{max}/(cm^{-1})$: 3050 (Ar–H), 1687 (C=O), 1598, 1522, 1470, 1250, 1182, 1090, 1004, 927, 826, 771; UV–Vis λ_{max} (nm) (log ε) in DMSO: 289 (4.68), 343 (4.40), 664 (4.41); MS (MALDI-TOF): *m*/*z* 1420.3 [M^+]. *Anal.* Calc. for $C_{84}H_{48}N_8O_{12}Co$: C, 71.04; H, 3.38; N, 7.89. Found: C, 71.02; H, 3.37; N, 7.86%.

2.5. 2,9,16,23-Tetrakis(4′-carbhexyloxybiphenyloxy)-phthalocyanine (*6*)

A mixture of **3** (0.20 g, 0.14 mmol), dicyclohexylcarbodiimide (DCCI) (0.36 g, 1.76 mmol), toluene-*p*-sulfonic

acid (0.03 g, 0.14 mmol) and 1-hexanol (0.22 ml, 1.76 mmol) was stirred in dry pyridine (15 ml) under N_2 for 72 h. The suspension was filtered and the solvent was evaporated in vacuum. The residue was dissolved in chloroform (10 ml) and washed first with a solution of 10% Na_2CO_3 (50 ml) and then with water. The chloroform phase was dried over anhydrous Na_2SO_4 and finally the solvent was evaporated in vacuo. The green product was washed with 20 ml of ethanol–cyclohexane (1:1) mixture and then purified by column chromatography with silica gel using THF as eluent. Yield: 0.05 g, 21%. IR $\nu_{max}/(cm^{-1})$: 3310 (N–H), 3080 (Ar–H), 2927–2870 (alkyl CH), 1689 (C=O), 1599, 1522, 1470, 1250, 1180, 1091, 1004, 927, 825, 771; ^1H NMR (d-chloroform): 8.10–7.36 (m, 44H, Ar–H), 4.33 (t, 8H, OCH_2), 1.78–1.65 (m, 32H, CCH_2C), 0.93 (t, 12H, CH_3); UV–Vis λ_{max} (nm) (log ε): 287 (4.75), 338 (4.55), 668 (4.66), 699 (4.68); MS (FAB): *m*/*z* 1698.8 [M]. *Anal*. Calc. for $C_{108}H_{98}N_8O_{12}$: C, 76.34; H, 5.76; N, 6.59. Found: C, 76.31; H, 5.75; N, 6.59%.

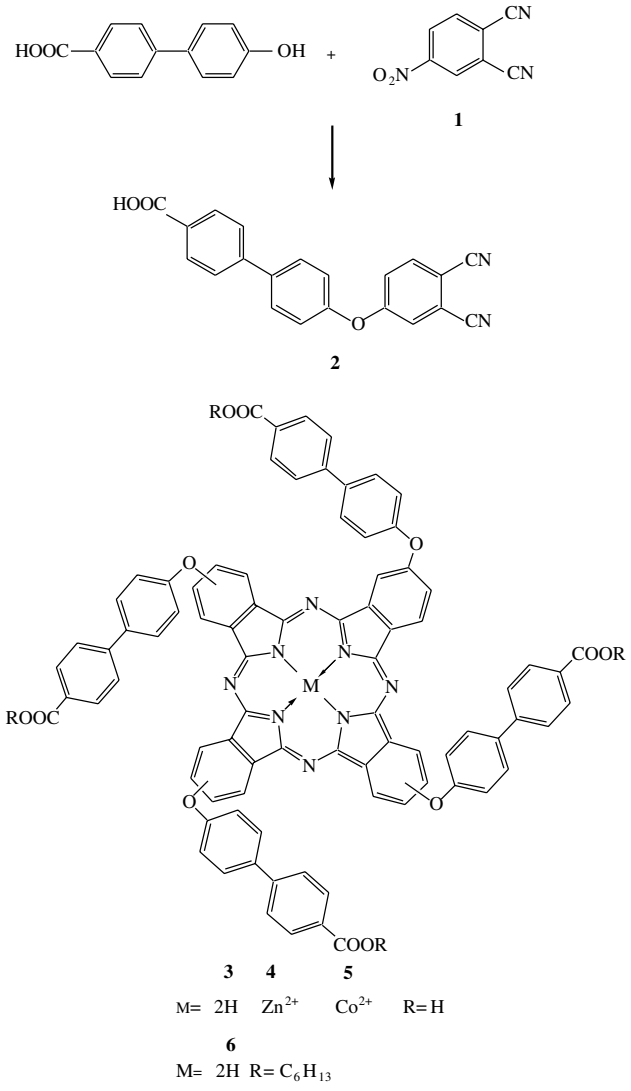
3. Results and discussion

Scheme 1 shows the synthesis of the target phthalocyanines **3**–**6**. The first step in the synthetic procedure was to obtain 4-(4′-carboxybiphenyloxy)phthalonitrile (**2**). **2** was prepared from 4-nitrophthalonitrile and 4′-hydroxy-4-biphenylcarboxylic acid in DMF. K_2CO_3 was used as the base for this nucleophilic aromatic displacement [28].

The most usual method to prepare metal-free phthalocyanines is the cyclotetramerisation of a phthalic acid derivative such as phthalonitrile or diiminoisoindoline. A practical way of achieving this goal is the treatment of a phthalonitrile with lithium alkoxide, giving rise to the corresponding alkali metal phthalocyanine and it can be subsequently demetallated to the metal-free phthalocyanine with a mineral acid. In the present work, the latter was chosen for synthesising the metal-free phthalocyanine **3**; i.e., cyclisation of **2** by using lithium in 1-pentanol, and then acidification with HCl resulted with the formation of **3**.

The crude product obtained by metallation of metal-free phthalocyanine **3** with zinc acetate in dry DMF was insoluble in all common solvents. Such insoluble products were encountered frequently as a result of complexation between the COOH groups and the zinc(II) ions [4]. After treatment of the product with acetic acid, desired zinc phthalocyanine **4** with free carboxy groups are obtained. The same route was also applied for synthesising cobalt phthalocyanine **5**.

As expected, all the phthalocyanines synthesised during this work are a mixture of positional isomers starting with the phthalonitrile precursor **2** with a single substituent [2]. However, our attempts to separate these isomers by column chromatography and, also by HPLC methods using different solvents were not successful.



Scheme 1.

The phthalocyanines **3**–**5** are only soluble in DMSO and DMF. The biphenylcarboxylic acid substituents on the phthalocyanine core bring out a vast number of possibilities for binding with different groups. To achieve a better solubility of **3**, hexyl substituents were introduced into the biphenyl units. Esterification of all the COOH groups in **3** with hexanol to give tetrakis(4′-carbhexyloxybiphenyloxy)phthalocyanine **6** was accomplished in pyridine in the presence dicyclohexylcarbodiimide and 4-toluenesulfonic acid as catalyst for 72 h at room temperature. **6** shows good solubility in organic solvents such as $CHCl_3$, THF, $CHCl_2$.

Characterisation of the products involved a combination of methods including elemental analysis, ^1H and ^{13}C NMR, UV/Vis, IR and mass spectroscopy. The

spectroscopic data of the new compounds were in accordance with the structures. When IR spectrum of **1** is compared with that of **2**, a distinct difference is the disappearance of the aromatic $-NO_2$ band at 1548 cm^{-1} and the appearance of a new absorption at 1242 cm^{-1} attributable to aromatic (C–O–C) [29].

In the IR spectrum of **2** the presence of C≡N and C=O groups is indicated by the intense stretching bands at 2238 and 1681 cm^{-1}. ^1H NMR spectrum of **2** exhibited the aromatic protons around 7.34–8.14 ppm and the COOH proton at 13.03 ppm. The ^{13}C NMR spectral data are in accord with expected structure. The ^{13}C APT (Attached Proton Test) NMR spectrum of **2** indicated the nitrile carbons at 116.37 and 115.85 ppm as expected [30]. Protonated aromatic and unsaturated carbon atoms appeared in the range at δ 161.24–108.93 ppm. Also the carbon atom of carboxylic acid was observed at the lowest field at δ 167.58 ppm.

A diagnostic feature of the phthalocyanine formation from **2** is the disappearance of the C≡N peak of the reactant. The IR spectra of metal-free **3** and metallo phthalocyanines (**4**, **5**) are very similar. The significant difference is the presence of NH vibrations of the inner phthalocyanine core which are assigned to a weak band at 3310 cm^{-1} in the metal-free molecule. In the ^1H NMR spectrum of **3** aromatic protons appeared at 8.01–7.38 ppm. COOH protons and inner core NH protons could not be observed probably due to the broad nature of these peaks in the presence of intense resonances of phthalocyanine ring and the biphenyl group [31]. ^1H NMR spectrum of **4** showed the aromatic protons at 8.01–7.31 ppm and COOH protons at 12.78 ppm. In the IR spectrum of **6** indicated the presence of alkyl groups by the intense stretching bands at 2927–2870 cm^{-1}. Chemical shifts due to the alkyl protons of **6** were observed between 4.33 and 0.93 ppm as expected.

A close investigation of the mass spectra of the phthalocyanines confirmed the proposed structure. In the mass spectrum of **3** in addition to the $[M^+]$ peak at 1363.4 a fragment ion corresponding to the loss of COOH–H $[M^+ - 46]$ is easily identified.

The phthalocyanines show typical electronic spectra with two absorption regions, the Q band around 600–700 nm and the B band in the near UV region around 300–350 nm, both correlate to π–π* transitions [32–34]. The split form of Q band in **3**, which is characteristic for metal-free phthalocyanines, is observed at λ_{max} 700 and 668 nm. The presence of absorption band in **3** in the near UV region at λ_{max} 340 nm also show B band. The Q band absorption of metallophthalocyanines is observed as a single band of high intensity in the visible region. The metallophthalocyanines **4** and **5** showed the expected absorptions of the Q and B bands appearing at 679, 664 nm and 347, 343 nm, respectively.

Abstract

Two new structural isomeric ligands, 2-(indazol-1-yl)-2-thiazoline (TnInA) (**1**) and 2-(indazol-2-yl)-2-thiazoline (TnInL) (**2**), have been prepared and characterized by a variety of physico-chemical techniques. Likewise, the cadmium (II) complexes $[Cd(NO_3)_2(TnInA)_2]$ (**3**) and $[Cd(NO_3)_2(TnInL)_2]$ (**4**) have been isolated and characterized through elemental analysis, IR and UV–Vis spectroscopy. Moreover, the structures have been determined by X-ray diffraction. Both ligands act as bidentate ligands through thiazoline nitrogen atom and indazole nitrogen atom, making a five-membered chelate ring. The environment around the cadmium (II) atom in both complexes may be described as a triangulated dodecahedral geometry.

Keywords: Cadmium (II) complex; Crystal structures; Thiazoline; Indazole

1. Introduction

The indazole subunit is a frequently found motif in drug substances with important biological activities such as anti-inflammatory, anti-tumor and anti-HIV activities [1–3]. Moreover, several indazoles are found to exhibit significant levels of activity as serototonin 5-$HT_{1\alpha}$, 5-HT_2 and 5-HT_3 receptor antagonists and aldol reductase inhibitors [4–7]. On the other hand, some thiazoline derivatives are of interest due to their potential activity as antibiotic and antitumoral agents [8–10].

Interestingly, coordination makes bioactive ligands improve their bioactivity profiles, while inactive ligands may acquire pharmacological properties [11–13]. Thus, there is a ruthenium complex with indazole as ligand which has inhibitory activity against colon carcinomas and other tumor types [14]. In addition, metal coordination is one of the most efficient strategies in the design of repository, slow release or long-acting drugs [15].

Because of the importance of these heterocycles in pharmaceutical development, we are initiating a line of investigation on the coordination chemistry of compounds containing thiazoline and indazole rings. In this paper, we report the synthesis of two structural isomeric ligands 2-(indazol-1-yl)-2-thiazoline (TnInA) and 2-(indazol-2-yl)-2-thiazoline (TnInL). The characterization of these ligands has been carried out by means of ultraviolet and visible spectroscopy (UV–Vis), proton nuclear magnetic resonance (^{1}H NMR), carbon nuclear magnetic resonance (^{13}C NMR), single crystal X-ray diffraction, elemental analysis and infrared spectroscopy (IR). Likewise, two cadmium complexes were obtained through reaction of cadmium (II) nitrate with these ligands and their characterization has been carried out by means of ultraviolet and visible spectroscopy (UV–Vis), elemental analysis, single crystal X-ray diffraction and infrared spectroscopy (IR).

2. Experimental

2.1. Preparation of 2-(indazol-1-yl)-2-thiazoline (TnInA) (1) and 2-(indazol-1-yl)-2-thiazoline (TnInL) (2)

TnInA (**1**) and TnInL (**2**) were prepared according to modifications of the procedure reported by Haugwitz et al. [16]. To a solution of 6.02 g (50 mmol) of indazole in dry glyme (500 mL) was added 4 g sodium hydride (100 mmol; 60%) and the mixture was stirred at room temperature for 6 h. Then a solution of 13.36 g of 3-chloroethylisothiocyanate [17] (110 mmol) in dry glyme (10 mL) was added and the reaction mixture was refluxed for 24 h and cooled. After the addition of methanol (5 mL), the solvent was removed in vacuo. Water was added to the residue and the resulting oily solid was extracted once with 25 mL of chloroform. The organic layer was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to give an oil. This oil was flash chromatographed using 1:1 v/v ether/ether petroleum as eluent. The early fraction contained **1** and the last fraction contained **2**. Colourless crystals of **1** were obtained after a slow evaporation of the ethanol solution at room temperature (3.63 g, 25%). ^{1}H NMR ($CDCl_3$): δ 8.43 (d, $J = 8.14$ Hz, 1H), 8.12 (s, 1H), 7.71 (d, $J = 7.99$ Hz, 1H), 7.52 (t, $J = 7.49$ Hz, 1H), 7.29 (t, $J = 7.57$ Hz, 1H), 4.45 (t, $J = 8.07$ Hz, 2H), 3.45 (t, $J = 8.08$ Hz, 2H); ^{13}C NMR ($CDCl_3$): δ 158.84, 138.87, 137.99, 128.68, 125.89, 123.55, 120.87, 114.29, 62.02, 33.26. *Anal.* Calc. for $C_{10}H_9N_3S$: C, 59.09; H, 4.46; N, 20.67; S, 15.77. Found: C, 59.45; H, 4.83; N, 20.22; S, 15.43%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 232 (26 000), 295 (9248), 306 (9585). Colourless crystals of **2** were obtained after a slow evaporation of the acetone solution at room temperature (2.54 g, 25%). ^{1}H NMR ($CDCl_3$): δ 8.73 (s, 1H), 7.71 (d, $J = 8{,}84$ Hz, 1H), 7.64 (d, $J = 8.76$ Hz, 1H), 7.31 (t, $J = 6.52$ Hz, 1H), 7.10 (t, $J = 6.75$ Hz, 1H), 4.45 (t, $J = 4.12$ Hz, 2H), 3.59 (t, $J = 4.12$ Hz, 2H); ^{13}C NMR ($CDCl_3$): δ 159.99, 150.13, 128.14, 123.59, 122.16, 121.54, 120.86, 118.31, 61.50, 34.27. *Anal.* Calc. for $C_{10}H_9N_3S$: C, 59.09; H, 4.46; N, 20.67; S, 15.77. Found: C, 58.86; H, 4.69; N, 20.53; S, 15.53%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 225 (26 728), 293 (12 193), 300 (12 246).

2.2. Preparation of [Cd(NO$_3$)$_2$(TnInA)$_2$] (3)

This complex was prepared by reacting an ethanol solution (1 mL) of $Cd(NO_3)_2 \cdot 4H_2O$ (151.8 mg, 0.5 mmol) with an ethanol solution (15 mL) of TnInA (100 mg, 0.5 mmol). By means of slow evaporation of the solution at room temperature, colourless crystals were isolated (127.4 mg, 40.3%). The crystals were filtered and washed with cold ether and air-dried. *Anal.* Calc. for $C_{20}H_{18}CdN_8S_2O_6$: C, 37.36; H, 2.82; N, 17.43; S, 9.97. Found: C, 37.20; H, 2.97; N, 17.20; S, 10.21%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 232 (53 794), 295 (18 192), 306 (18 744).

2.3. Preparation of [Cd(NO$_3$)$_2$(TnInL)$_2$] (4)

This complex was prepared by reacting an ethanol solution (10 mL) of $Cd(NO_3)_2 \cdot 4H_2O$ (151.8 mg, 0.5 mmol) with an ethanol solution (15 mL) of TnInL (100 mg, 0.5 mmol), giving colourless crystals after a slow evaporation of the solution at room temperature (153.7 mg, 48.6%). The crystals were filtered and washed with cold ether and air-dried. *Anal.* Calc. for $C_{20}H_{18}CdN_8S_2O_6$: C, 37.36; H, 2.82; N, 17.43; S, 9.97. Found: C, 37.16; H, 2.74; N, 17.18; S, 9.85%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 224 (81 795), 292 (34 093), 301 (34 231).

2.4. Instrumental procedures

Chemical analyses of carbon, hydrogen, nitrogen and sulphur were performed by microanalytical methods using a Leco CHNS-932 microanalyser. IR spectra were recorded on a Perkin–Elmer FT-IR 1720 spectrophotometer, from KBr pellets in the 4000–370 cm^{-1} range and on a Perkin–Elmer FT-IR 1700X spectrophotometer, from polyethylene pellets in the 500–150 cm^{-1} range. Electronic spectra in solution were measured on a Shimadzu UV-3101 PC using a 10-mm quartz cell. ^{1}H and ^{13}C NMR spectra were obtained with a Bruker AM 400 instrument at 400 and 100 MHz, respectively, in $CDCl_3$ using Me_4Si as internal standard.

2.5. Crystal structure determinations

Experimental details of crystal structure determinations including crystal data, data collection, structure determinations and refinement parameters for **1**–**4** are listed in Table 1. X-ray diffraction measurements were performed at room temperature (298 K) using a Bruker SMART CCD diffractometer equipped with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) using the ϕ–ω scan technique. The first 50 frames were recollected at the end of data collection to monitor for decay. Empirical absorption corrections were applied using the program SADABS [18]. The structures of **1**, **2** and **4** were solved by direct methods and subsequent Fourier differences, whereas the structure of **3** was solved by Patterson methods and subsequent Fourier differences using, in all cases, the WINGX package [19] and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms attached to carbon and nitrogen atoms were positioned geometrically, with U_{iso} values derived from U_{eq} values of the corresponding

carbon and nitrogen atoms. The final electron density map for compound **3** contained various electron density peaks, clustered in one region of the unit cell. These could not sensibly be resolved into a molecule and presumably represent a severely disordered solvent molecule. Despite exhaustive attempts at modelling this severely disordered solvent molecule, satisfactory solutions were not obtained and a diffuse solvent correction was applied using the SQUEEZE routine in PLATON [20]. The unit cell contains a symmetry-unique cavity centered at (1, 1/10, 1/2), filled with disordered solvent, probably ethanol. The volume of cavity is 254.8 Å^3 with a total of 82 electrons calculated, compared to 78 electrons predicted for the presence three ethanol molecules.

3. Results and discussion

3.1. Crystal structures of the ligands

ORTEP diagrams of the molecular structure of **1** and **2** are shown in Figs. 1 and 2, respectively. Bond lengths and angles are listed in Table 2.

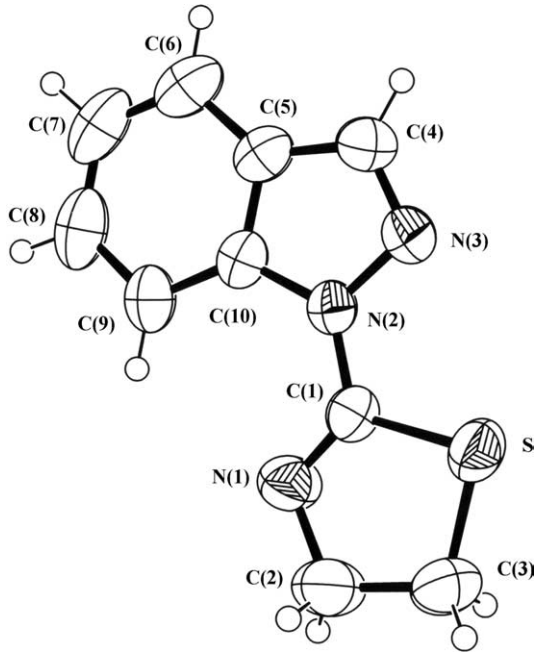

Fig. 1. Crystal structure of **1**, showing the atom-numbering scheme. The thermal ellipsoids are plotted at the 50% probability level.

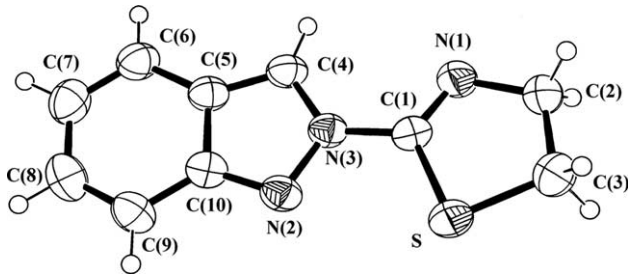

Fig. 2. Crystal structure of **2**, showing the atom-numbering scheme used for better comparison with **1**. The thermal ellipsoids are plotted at the 50% probability level.

N(3)–C(4)–C(5)	112.4(2)	105.6(2)

In the S–C(1)–N(1)–C(2)–C(3) rings of the ligands, the short endocyclic C=N bonds [C(1)–N(1) = 1.256(2) Å for **1**; 1.252(2) Å for **2**] are accompanied by high N–C–S angles [N(1)–C(1)–S = 119.9(1)° for **1**; 121.4(2)° for **2**] and relatively long S^{II}–C(sp^2) bonds [S–C(1) = 1.764(2) Å for **1**; 1.752(2) Å for **2**], which are characteristic of a thiazoline ring [21]. Likewise, bond lengths and angles in indazole rings are in good accord with literature [22].

The thiazoline ring in **1** shows a conformation near to envelope with the C(3) atom deviating 0.309 Å above the plane formed by S, C(1), N(1) and C(2). This geometry is proved by the puckering parameters $q = 0.203$ Å and $\phi = 138.5°$, calculated according to Cremer and Pople [23]. However, the thiazoline ring in **2** is essentially planar [$q = 0.019$ Å, $\phi = 68.6°$].

As was to be expected, the indazole rings in both compounds are essentially planar with maximum least square plane deviations for C(9) [0.009 Å] in **1** and C(6) [0.007 Å] in **2**. Likewise, the planarity of indazole systems is shown by the dihedral angles between the mean planes of the six- and five-membered rings, being 0.4° in **1** and 0.6° in **2** (maximum least square plane deviation of N(2), N(3), C(4), C(5), C(10) for C(10) = 0.005 Å in **1** and C(10) = 0.003 Å in **2**).

3.2. Crystal structures of the cadmium complexes

The structure of the complex **3** consists of discrete neutral monomeric units in which the metal is eight-coordinate, being bound to four oxygen atoms from two bidentate nitrate ligands, two thiazoline nitrogen atoms and two indazole nitrogen atoms. A diagram of the molecular structure and the atom numbering system used is shown in Fig. 3. The most relevant bond lengths and angles are given in Table 3.

Eight-coordinate systems are found to adopt either a cube, a square antiprism or a triangulated dodecahedron (TD) arrangement [24]. On the basis of the observed angles, complex **3** adopts a slightly distorted TD geometry with N(3) as the lone capping atom whereas O(4) and O(5) are the shared capping atoms (see Fig. 4). Likewise, the two interpenetrating trapezoids, which characterize [25] the dodecahedron, are defined by the positions of the atoms O(1), O(2), N(6), N(4) and O(4), O(5), N(3), N(1). The angle between the mean planes of these trapezoidal planes is 89.1°, very close to the ideal one (90°). As indicated by Drew [26], the values of δ angles (δ_1, δ_2, δ_3 and δ_4), are too a good test for the determination of the shape of the coordination polyhedron. The δ angles calculated by using the hard sphere model (HSM) shape characteristics, are $\delta_1 = 29.5$, $\delta_2 = 29.5$, $\delta_3 = 29.5$ and $\delta_4 = 29.5$ for the ideal dodecahedron and $\delta_1 = 0.0$, $\delta_2 = 0.0$, $\delta_3 = 52.4$ and $\delta_4 = 52.4$ for the ideal squared antiprism. In this case, the δ values (Table 4) indicate that the coordination polyhedron is best described as a distorted TD geometry.

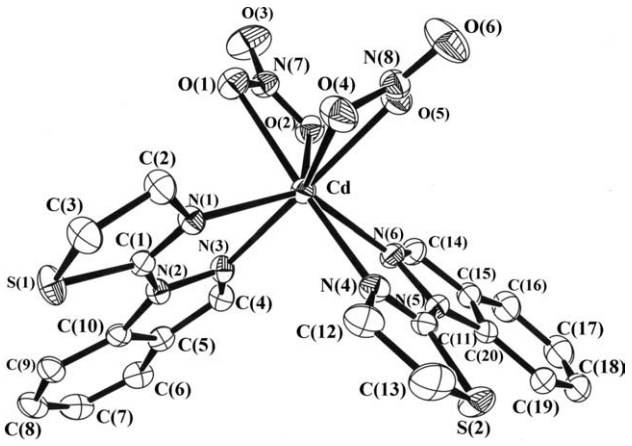

Fig. 3. Molecular structure of **3**, showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 30% probability level.

[a] This complex presents a C_2 symmetry, therefore only half angles and distances are shown.

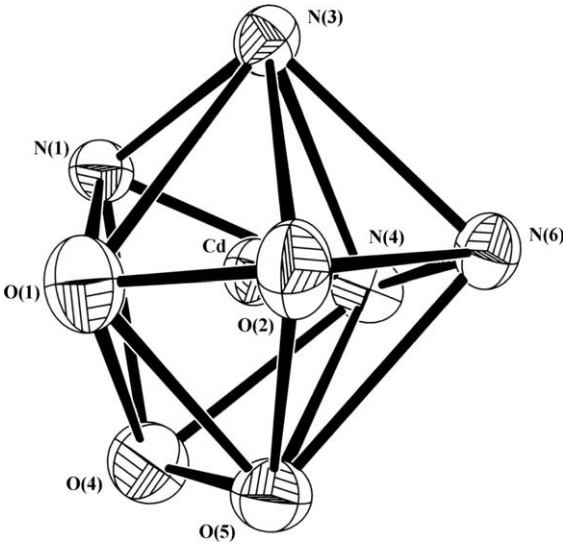

Fig. 4. View of the dodecahedral coordination polyhedron for **3**.

Table 4
Quantification of the geometry of the cadmium (II) polyhedra

	Triangulated dodecahedral	Square antiprism	**3**	**4**
δ_1	29.5	0.0	31.27	15.53
δ_2	29.5	0.0	21.71	19.89
δ_3	29.5	52.4	36.59	28.73
δ_4	29.5	52.4	35.83	15.53

One nitrate group may be considered as a symmetric one, while the other nitrate group presents a high asymmetry [{Cd–O(4)}–{Cd–O(5)} = δ = 0.352 Å], which is similar to those found in $[Cd(NO_3)_2L_2]$ (L = 1,6,7-trimethyllumazine) (δ = 0.395 Å) [27] and $[Cd(NO_3)_2L]$ (L = 1,4,7-tris(cyanomethyl)-1,4,7-triaza-10,13-dioxacyclopentadecane) (δ = 0.365 Å) [28].

The Cd–O distances for symmetric bidentate nitrate group (av. 2.492 Å) and asymmetric bidentate nitrate group (av. 2.508 Å) are comparable with the calculated mean value [2.482(144) Å] for 28 eight-coordinate cadmium (II) complexes obtained from CONQUEST software [29] from the Cambridge Structural Database (CSD) [30]. Finally, the Cd–$N_{thiazoline}$ bond lengths (av. 2.360 Å) are closer to that found in $[Cd(NO_3)_2(PyTT)(H_2O)]$ (2.351 Å) [31], but somewhat longer than that observed in $[CdCl_2\{(\mu\text{-}Cl)_2CdCl(\mu\text{-}Cl)(\mu\text{- PyTT})Cd\}_2]_n$ (2.271 Å) [31] and $[CdCl_2(HzTz)]\cdot H_2O$ (2.241 Å) [32].

The chelate rings Cd–N(1)–C(1)–N(2)–N(3) and Cd–N(4)–C(11)–N(5)–N(6) are essentially planar with maximum mean plane deviation for N(2) (0.024 Å) and N(6) (0.036 Å), respectively.

The thiazoline ring S(1)–C(1)–N(1)–C(2)–C(3) shows a conformation near to half-chair [q = 0.197 Å, ϕ = −45.2°] [23] with C(2) and C(3) deviating by −0.112 and 0.209 Å of the plane formed by S(1), C(1) and N(1). However, the other thiazoline ring S(2)–C(11)–N(4)–C(12)–C(13) shows a conformation near

to envelope [$q = 0.141$ Å, $\phi = -39.1°$] [23] with the apex at C(13). This atom is 0.222 Å out of the mean plane formed by S(2), C(11), N(4) and C(12).

The X-ray structure of **4** shows a eight-coordinated environment around cadmium (II) with four oxygen atoms from two bidentate nitrate ligands, two thiazoline nitrogen atoms and two indazole nitrogen atoms. The overall view and labelling of the atoms of complex are displayed in Fig. 5. Table 3 lists the selected bond lengths and angles.

The disposition of the eight donor atoms is adequately best described as a distorted triangulated dodecahedron (Fig. 6), with approximate C_2 symmetry, with the twofold axis placed at the bisector of the angle formed by the two four-membered chelate rings present in the molecule. In the dodecahedral geometry O(1) is the lone capping atom whereas N(1) and N(2) are the shared capping atoms (see Fig. 6). Likewise, the two interpenetrating trapezoids are defined by the positions

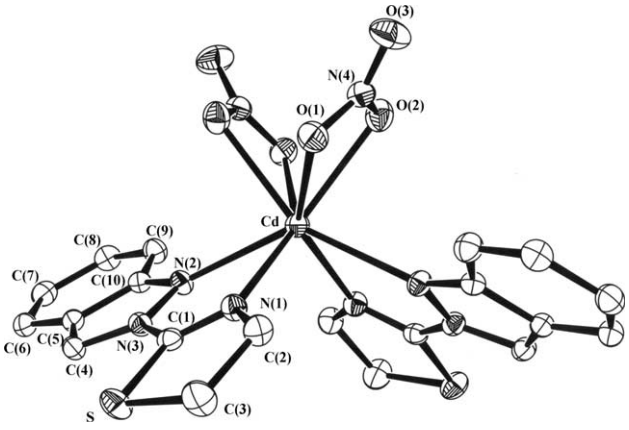

Fig. 5. Molecular structure of **4**, showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 30% probability level.

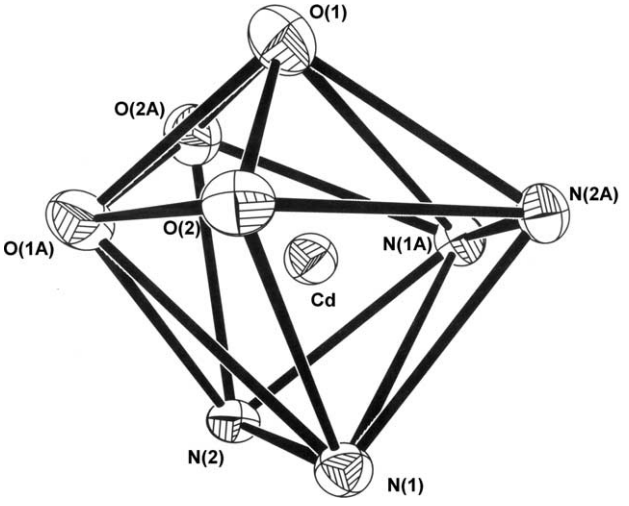

Fig. 6. View of the dodecahedral coordination polyhedron for **4**.

of the atoms O(1), O(2A), N(2), N(1) and O(1A), O(2), N(2A), N(1A). The angle between the mean planes of these trapezoidal planes is 79.9°, whereas the ideal one is 90°. The δ values for this complex (Table 4) indicates that the coordination polyhedron is best described as a distorted TD geometry.

The nitrate group show a slight but significant asymmetry [{Cd–O(2)}–{Cd–O(1)} = $\delta = 0.153$ Å], which is similar to those found in [$Cd(NO_3)_2(H_2O)_2$(μ-adeninium)$_2$] ($\delta = 0.155$ Å) [33] and [$Cd(NO_3)$L] (L = 1-aza-4,10-dithia-7-oxacyclododecane) ($\delta = 0.149$ Å) [34].

The Cd–O bond lengths are similar to those collected from the CSD used during discussion of complex **3**. The Cd–$N_{thiazoline}$ and the Cd–$N_{indazole}$ bond distances are similar, and slightly longer, respectively, than those observed in **3**.

The chelate ring Cd–N(1)–C(1)–N(3)–N(2) shows a conformation near to envelope [$q = 0.086$ Å, $\phi = -26.7°$] [23] with the apex at N(2), deviating 0.135 Å from the mean plane formed by Cd, N(1), C(1) and N(3).

For the thiazoline ring, the puckering parameters $q = 0.106$ Å, $\phi = -34.9°$ [23] indicate a conformation near to envelope with the C(3) atom deviating 0.173 Å above the mean plane formed by S, C(1), N(1) and C(2).

Finally, it should be pointed out that the main difference in both complexes with respect to the structure of free TnInA (**1**) and TnInL (**2**) is due to the different degree of rotation of the thiazoline ring around the C(1)–N(2) [or C(11)–N(5)] and C(1)–N(3) bond, respectively, which permits the coordination through N(1) (torsion angle N(1)–C(1)–N(2)–N(3) = −4.0° and [N(4)–C(11)–N(5)–N(6) = −4.4° in **3**; −176.9° in **1**; torsion angle N(1)–C(1)–N(3)–N(2) = 5.7° in **4**; 178.8° in **2**].

3.3. IR spectra

The IR spectra of **1** and **2** in the 4000–370 cm^{-1} region show the presence of bands due to thiazoline ring vibrations at 1632 (W_1), 921 (W_3), 752 (W_5), 671 (W_6), 586 (W_8), 553 (W_7), and 430 cm^{-1} (Γ_1) for **1**, and at 1641 (W_1), 985 (W_2), 919 (W_3), 785 (W_4), 757 (W_5), 676 (W_6), 586 (W_8), 555 (W_7) and 438 cm^{-1} (Γ_1) for **2** [35,36].

Likewise, the spectra of **1** and **2** exhibit bands assignable to the indazole ring vibrations at 1614, 1583, 1503, 1451, 1427, 1391, 1352, 1314, 1276 and 1250 cm^{-1} for stretching skeletal vibrations (ν); at 1004, 890, 768 and 624 cm^{-1} for bending skeletal in-plane vibrations (δ); and at 478 and 430 cm^{-1} for bending skeletal out-of-plane vibrations (τ), for compound **1**, and at 1637, 1652, 1517, 1455, 1441, 1387, 1376, 1361, 1338, 1270 and 1234 cm^{-1} for stretching skeletal vibrations (ν); at 1010, 945, 893, 640, 610 and 538 cm^{-1} for bending skeletal in-plane vibrations (δ); and at 573, 497 and

438 cm^{-1} for bending skeletal out-of-plane vibrations (τ), for compound **2** [37].

The IR spectra of **3** and **4** in the 4000–370 cm^{-1} region show the presence of bands due to the organic moiety ring vibrations as is shown in Table 5. On the other hand, bands due to nitrate ligands are registered at 689 and 709 (ν_4), 1386 and 1319 (ν_3), 818 (ν_2) and 1036 (ν_1) cm^{-1} for **3** and at 691 and 701 (ν_4), 1387 and 1321 (ν_3), 809 (ν_2) and 1057 (ν_1) cm^{-1} for **4** [38].

Methods to discriminate between bidentate and monodentate bonded nitrate groups have been reported and have been proved reliable. They are based on the ($\nu_1 + \nu_4$) combination bands pattern or on the splitting [39–42]. The bands registered at 1749 and 1718 cm^{-1} for **3** are assigned to ($\nu_1 + \nu_4$) combination bands. The value of the splitting ($\Delta = 31$ cm^{-1}) reveals the presence of a bidentate nitrate group in agreement with Lever's criteria [40]. In the same way, the bands observed at 1763 and 1736 cm^{-1} for (**4**) ($\Delta = 27$ cm^{-1}) can be assigned to one bidentate nitrate group.

In both complexes, the bands assigned to ν(C=N) vibration and the in-plane stretching vibrations corresponding to ν(C=N) skeletal vibrations of the heterocyclic rings (W_1), suffering a negative shift when compared with that for the uncoordinated respective ligand (Table 4). From all this can be deduced a coordination via these nitrogen atoms of the ligands [43–46].

Only three bands assignable to metal–ligand stretching vibrations are observed in the low frequency range for **3** and **4** spectra. Thus, in the **3** and **4** spectra, the bands at 227 and 232 cm^{-1}, respectively, are tentatively assigned to $\nu(Cd–N_{thiazoline})$ vibration in agreement with the values of complexes containing thiazoline derivative ligands [31,47]. The bands at 206 cm^{-1} for **3** and at 195 cm^{-1} for **4**, have been attributed to $\nu(Cd–ONO_2)$ vibration [31,38]. Finally, because of bibliography for cadmium–indazole unions has not been reported to the best of our knowledge, the bands at 176 cm^{-1}, in the case of **3** complex, and at 169 cm^{-1}, in the case of **4** complex, could be tentatively assigned to $\nu(Cd–N_{indazole})$, according to the consulted bibli-

Table 5

4. Conclusion

In summary, the reaction between indazole and 3-chloroethylisothiocyanate (ClEtNCS) produces two structural isomers: 2-(indazol-1-yl)-2-thiazoline (TnInA) and 2-(indazol-2-yl)-2-thiazoline (TnInL). This synthesis involves the generation of the anion I, in equilibrium with the resonant form II (Scheme 1). The reaction of the resonant forms I and II with 3-chloroethylisothiocyanate gives the isomers **1** and **2**. A comparison of cadmium (II) nitrate complexes containing TnInA and TnInL shows some similarities in the coordination behaviour of ligands. The structural studies reveals that both ligands act as bidentate. Likewise, cadmium complexes exhibits a triangulated dodecahedral geometry, however in case of complex **4** is a more distorted than in complex **3**. It can be due to packing effects on molecular geometry because of the different arrangement of heterocycles in ligands: angular in TnInA and linear in TnInL. Although this is notoriously difficult to estimate, a high percentage of molecules have imposed crystallographic symmetry where packing effects may well have tipped the balance towards one geometry rather than another.

Abstract

A new ligand *N*-(5,6-dihydro-4H-1,3-thiazin-2-yl)indazole (InTz) and its metal complexes $[Co(NO_3)_2(InTz)_2]$ and $[Cd(NO_3)_2(InTz)_2]$ have been prepared and characterized by a variety of physico-chemical techniques. Likewise, the structures have been determined by X-ray diffraction. Metal complexes have C_2 symmetry. The environment around the cobalt atom may be described as a distorted octahedral geometry with the metallic atom coordinated to two oxygen atoms from two monodentate nitrate groups, two thiazine nitrogen atoms and two indazole nitrogen atoms. The cadmium complex consists of molecules in which the cadmium atom is eight coordinated, with two bidentate nitrate groups and two bidentate InTz ligands, each of the latter having one thiazine and one indazole nitrogen atom involved in coordination. The geometry around the cadmium atom is adequately described as a distorted dodecahedron.

1. Introduction

Heterocycles containing nitrogen or sulphur atoms (or both) are common features incorporated in the structures of numerous natural products and pharmaceutical compounds. Besides, they form part of multidentate ligands extensively used in coordination chemistry with the aim of obtaining new frameworks having potential bioactivity [1]. Among these ligands are thiazine and indazol derivatives due to their biological importance as constituents of many biomolecules and drugs. Thiazines possess an N–C–S linkage that is believed to account for the anticonvulsant, fungicidal and antiviral activities [2,3]. Thus, some thiazine derivatives present antitumoral, antihistaminic, antiinflammatory, analgesic and antibiotic properties [4–9].

In the same way, indazole and its derivatives have gained considerable importance in recent year in view of their promising pharmacological properties [10]. Several indazoles are found to exhibit significant levels of activity as HIV protease inhibitors, serototonin $5\text{-}HT_{1\alpha}$, $5\text{-}HT_2$ and $5\text{-}HT_3$ receptor antagonists and aldol reductase inhibitors [11–16].

In some cases, the structural and biological properties of the organic ligands can be modified or even improved when coordinate to a metal ion [17].

Taking into account the aforementioned, recently we have been investigating the coordination chemistry of compounds containing these heterocycles [18–20]. As

doi:10.1016/j.poly.2005.07.003

part of these investigations, we now report the synthesis and the characterization by elemental analysis, infrared spectra (IR), ultraviolet and visible spectra (UV–Vis), single crystal X-ray diffraction, proton nuclear magnetic resonance (^{1}H NMR) and carbon nuclear magnetic resonance (^{13}C NMR) of *N*-(5,6-dihydro-4H-1,3-thiazin-2-yl)indazole (InTz). The Cd(II) and Co(II) complexes have been isolated and their characterization has been carried out by means of elemental analysis, IR and X-ray diffraction. The cobalt complex has also been characterized through UV–Vis–NIR diffuse reflectance and magnetic susceptibility measurement.

2. Experimental

2.1. Preparation of N-(5,6-dihydro-4H-1,3-thiazin-2-yl)-indazole (InTz)

InTz was prepared according to a modifications of the procedure reported by Haugwitz and Narayanan [21]. To a solution of 1.20 g (10 mmol) of indazole in dry glyme (50 ml) was added 0.4 g sodium hydride (10 mmol; 60%) and the mixture was stirred at room temperature for 3 h. Then a solution of 1.49 g of 3-chloropropylisothiocyanate [22] (11 mmol) in dry glyme (3 ml) was added and the reaction mixture was refluxed for 4 h and cooled. After the addition of methanol (5 ml), the solvent was removed in vacuo. Water was added to the residue and the resulting oil solid was extracted with chloroform. The organic layer was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to give an oil. This oil was flash chromatographed using 1:1 v/v ether/ether petroleum as eluent. Early fraction contained InTz. The resulting solution was allowed to evaporate slowly at room temperature and after a few days, colourless crystals were isolated from solution (1.00 g, 46%). ^{1}H NMR (CD_2Cl_2): δ 8.48 (d, $J = 8.52$ Hz, 1H), 8.06 (s, 1H), 7.68 (d, $J = 7.94$ Hz, 1H), 7.44 (t, $J = 7.37$ Hz, 1H), 7.23 (t, $J = 7.51$ Hz, 1H), 3.94 (t, $J = 5.62$ Hz, 2H), 3.15 (t, $J = 5.87$ Hz, 2H), 1.97 (m, 2H); ^{13}C NMR (CD_2Cl_2): δ 147.71, 138.20, 135.90, 128.10, 125.70, 122.90, 120.60, 114.94, 46.00, 26.70, 19.80. Found: C, 60.58; H, 5.09; N, 19.37; S, 14.45%. *Anal*. Calc. for $C_{11}H_{11}N_3S$: C, 60.81; H, 5.10; N, 19.33; S, 14.75%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 234 (22 100), 295 (8860), 306 (8118). FT-IR (cm^{-1}): 1632, 1610, 1578, 1497, 1373, 1350, 1314, 1288, 1250, 1005, 954, 907, 877, 768, 752, 624, 585, 552, 515, 467, 431, 405.

2.2. Preparation of $[Co(NO_3)_2(InTz)_2]$

This complex was prepared by reacting a methanol solution (1 mL) of $Co(NO_3)_2 \cdot 6H_2O$ (134 mg, 0.461 mmol) with a methanol solution (15 mL) of InTz (100 mg, 0.461 mmol). By means of liquid–vapor diffusion of ether over this solution, red crystals were isolated (123 mg, 43.3%). The crystals were filtered and washed with cold ether and air-dried. This complex is soluble in EtOH and MeOH, sparingly in acetonitrile and insoluble in H_2O, ether, acetone and $CHCl_3$. Found: C, 42.95; H, 3.89; N, 18.18; S, 10.04%. *Anal*. Calc. for $C_{22}H_{22}CoN_8S_2O_6$: C, 42.78; H, 3.59; N, 18.15; S, 10.39%. FT-IR (cm^{-1}): 1599, 1577, 1515, 1436, 1385, 1364, 1294, 1035, 1020, 958, 914, 900, 817, 782, 753, 729, 707, 629, 592, 558, 500, 491, 426, 298, 266, 227. $\mu_{eff} = 4.7$ BM. Diffuse reflectance spectrum (cm^{-1}): 9653, 11 211, 20 000, 32 895.

2.3. Preparation of $[Cd(NO_3)_2(InTz)_2]$

This complex was prepared by reacting an ethanol solution (1 mL) of $Cd(NO_3)_2 \cdot 4H_2O$ (142 mg, 0.461 mmol) with an ethanol solution (15 mL) of InTz (100 mg, 0.461 mmol), being obtained colourless crystals after a slow evaporation of the solution at room temperature (102 mg, 56.5%). The crystals were filtered and washed with cold ether and air-dried. This complex is soluble in EtOH and MeOH, sparingly in acetone and insoluble in H_2O, ether, acetonitrile and $CHCl_3$. Found: C, 39.32; H, 3.33; N, 16.50; S, 9.86%. *Anal*. Calc. for $C_{22}H_{22}CdN_8S_2O_6$: C, 39.38; H, 3.30; N, 16.70; S, 9.56%. FT-IR (cm^{-1}): 1607, 1577, 1514, 1434, 1385, 1363, 1299, 1034, 1017, 945, 911, 895, 820, 779, 753, 730, 707, 625, 587, 559, 499, 481, 423, 203, 193, 173.

2.4. Instrumental procedures

Chemical analyses of carbon, hydrogen, nitrogen and sulphur were performed by microanalytical methods using a Leco CHNS-932 microanalyser. IR spectra were recorded on a Perkin–Elmer FT-IR 1720 spectrophotometer, from KBr pellets in the 4000–370 cm^{-1} range and on a Perkin–Elmer FT-IR 1700X spectrophotometer, from polyethylene pellets in the 500–150 cm^{-1} range. Electronic spectra in solution of ligand were measured on a Shimadzu UV-3101 PC using a 10 mm quartz cell. The UV–Vis–NIR reflectance spectra for the cobalt complex in the 200–1600 nm range was registered from a pellet of the sample, using a Shimadzu UV-3101 PC spectrophotometer and $BaSO_4$ as a reference. Magnetic measurement was made at room temperature on a magnetometer with pendulum MANICS DSM8, equipped with helium continuous-flow cryostat and an electromagnetometer DRUSCH EAF 16 UE. Data were corrected for temperature-independent paramagnetism and diamagnetic contributions, which were estimated from the Pascal constants. ^{1}H and ^{13}C NMR spectra were obtained with a Bruker AM 400 instrument at 400 and 100 MHz, respectively, in CD_2Cl_2 using Me_4Si as internal standard.

2.5. Crystal structure determinations

Experimental details of crystal structure determinations including crystal data, data collection, structure determination and refinement parameters for InTz, $[Co(NO_3)_2(InTz)_2]$ and $[Cd(NO_3)_2(InTz)_2]$ are listed in Table 1. X-ray diffraction measurements were performed at room temperature (298 K) using a Bruker SMART CCD diffractometer equipped with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) using the ϕ–ω scan technique. The first fifty frames were recollected at the end of data collection to monitor for decay. Empirical absorption corrections were applied using program SADABS. The structures were solved by direct methods and subsequent Fourier differences using the WINGX package [23] and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters, except C(3A) and C(14A) disordered atoms with isotropic displacement parameters. In the structure of InTz, the thiazine ring of both independent molecules show a disorder affecting C(3) and C(14) atoms, being the value of the refined occupancy 0.93(1) for C(3) and 0.07(1) for C(3A) in first independent molecule and 0.87(1) for C(14) and 0.13(1) for C(14A) in second one. Hydrogen atoms attached to carbon and nitrogen atoms were positioned geometrically, with U_{iso} values derived from U_{eq} values of the corresponding carbon and nitrogen atoms.

3. Results and discussion

3.1. Description of the structures

The single crystal X-ray diffraction analysis has revealed that InTz crystallizes in the triclinic system with two independent molecules in the asymmetric unit cell. The overall view and labelling of the atoms in two independent molecules are displayed in Fig. 1. Table 2 lists the selected bond lengths and angles.

In the S(1)–C(1)–N(1)–C(2)–C(3)–C(4) and S(2)–C(12)–N(4)–C(13)–C(14)–C(15) rings, the short endocyclic C=N bonds [C(1)–N(1) = 1.250(3) Å; C(12)–N(4) = 1.260(3) Å] are accompanied by high N–C–S

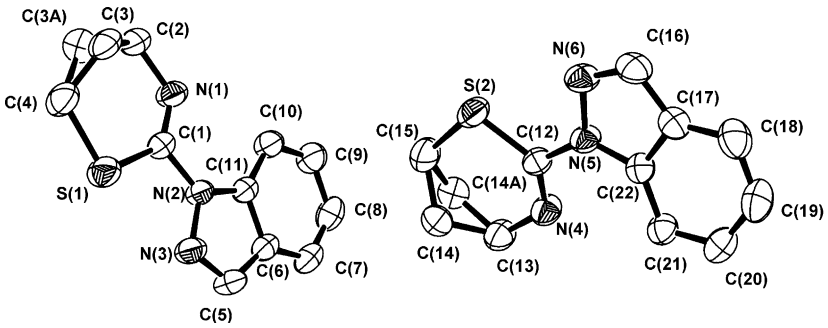

Fig. 1. The atom numbering scheme for two molecules on InTz constituting the asymmetric unit of the structure. The thermal ellipsoids are plotted at the 50% probability level.

angles [N(1)–C(1)–S(1) = 131.1(2)°; N(4)–C(12)–S(2) = 130.9(2)°] and relatively long S^{II}-C(sp^2) bonds [S(1)–C(1) = 1.753(2) Å; S(2)–C(12) = 1.757(2) Å], which are characteristic of a 5,6-dihydro-4-H-1,3-thiazine ring [24]. Likewise, bond lengths and angles in indazole rings are in good accord with the literature [25].

According to the X-ray results, the corresponding bond lengths in both independent molecules show small differences (±0.019 Å), except for bond lengths involving C(3A) and C(14A) atoms (±0.150 Å). In the same way, the corresponding bond angles are very similar (±1.4°), except for angles involving C(3A) and C(14A) atoms (±6.8°). These differences could be attributed to the disorder present in thiazine rings affecting C(3) and C(14) atoms. Finally, in first independent molecule, the thiazoline ring is in the same plane that indazole ring [torsion angle N(1)–C(1)–N(2)–N(3) = 179.7°], whereas, in second independent molecule, the thiazoline ring is slightly rotated with respect the indazole ring [torsion angle N(4)–C(12)–N(5)–N(6) = 167.2°].

In the first molecule of InTz, thiazine ring displays two conformations due to disorder. Both conformations show a half-boat form, with the C(3) and C(3A) atoms deviating −0.665 and 0.234 Å, respectively, from the plane formed by S(1), C(1), N(1), C(2) and C(4). These geometries are proved by the puckering parameters calculated according to Cremer and Pople [26], $Q = 0.492$ Å, $\phi = 66.9°$ and $\theta = 128.2°$ for S(1)–C(1)–N(1)–C(2)–C(3)–C(4) and $Q = 0.171$ Å, $\phi = 234.6°$ and $\theta = 53.2°$ for S(1)–C(1)–N(1)–C(2)–C(3A)–C(4). In the same way, the thiazine ring in second molecule of InTz presents two conformations near to half-boat form, with the C(14) and C(14A) atoms deviating 0.639 and −0.470 Å, respectively, from the plane formed by S(2), C(12), N(4), C(13) and C(15) [$Q = 0.453$ Å, $\phi = 232.8°$ and $\theta = 62.8°$ for S(2)–C(12)–N(4)–C(13)–C(14)–C(15) and $Q = 0.397$ Å, $\phi = 25.3°$ and $\theta = 122.8°$ for S(2)–C(12)–N(4)–C(13)–C(14A)–C(15)]. As was to be expected, the indazole rings are essentially planar with maximum least square plane deviations for C(8) [0.010 Å] and C(22) [0.026 Å].

The X-ray study of $[Co(NO_3)_2(InTz)_2]$ reveals that crystals are made up of orthorhombic cells, each one containing four complex molecules. A diagram of the molecular structure is shown in Fig. 2, and selected bond lengths and angles are given in Table 3.

The complex molecule possesses a crystallographic C_2 symmetry, with the twofold axis being coincident with the bisectrix of the O(1)–Co–O(1A) angle.

The environment around the cobalt (II) atom may be described as a distorted octahedral geometry with the metal coordinated to two oxygen atoms from two monodentate nitrate groups [Co–O(1) = 2.122(2) Å], two thiazine nitrogen atoms [Co–N(1) = 2.122(2) Å] and two indazole nitrogen atoms [Co–N(3) = 2.109(2) Å]. The ligand–metal–ligand bite angles differ from the ideal value of 90°, varying between 74.9(1)° and 101.2(1)°. This compound is the second structurally characterized compound having a 1,3-thiazine link to cobalt (II) [18], being, moreover, the first with an octahedral geometry.

The Co–O bond distance of monodentate nitrate group is comparable with the calculated average value [2.108(43) Å] for 46 six-coordinate cobalt (II) complexes obtained from CONQUEST software [27] from the Cambridge Structural Database (CSD) [28]. Likewise, the Co–$N_{indazole}$ bond length is similar to those found in bis(hydrotris(indazol-1-yl)borato)-cobalt (II) chloroform solvate (1/3.5) (average 2.116 Å) [29]. The Co–$N_{thiazine}$ bond distance is longer to this found in $[CoCl_2(TdTz)]$ (1.946 Å) [18].

The chelate ring Co–N(3)–N(2)–C(1)–N(1) shows a intermediate form between envelope and half-chair [$q = 0.213$ Å; $\phi = 12.4°$] [26] with the atoms Co and N(3) deviating by −0.293 and 0.128 Å, respectively, above the plane formed by N(2), C(1) and N(1).

The thiazine ring shows a conformation near to half-boat with the C(3) atom deviating 0.671 Å above the plane formed by S(1), C(1), N(1), C(2) and C(4). This geometry is proved by the puckering parameters $Q = 0.499$ Å, $\phi = 63.2°$ and $\theta = 121.9°$ [26].

The structure of the cadmium (II) complex consists of discrete neutral monomeric units in which the geometry

of the metal is eight coordinate, being bound to four oxygen atoms from two bidentate nitrate ligands [Cd–O(1) = 2.432(4) Å; Cd–O(2) = 2.585(3) Å], two thiazine nitrogen atom [Cd–N(1) = 2.385(3) Å] and two indazole nitrogen atom [Cd–N(3) = 2.332(2) Å]. To the best of our knowledge, this compound is the first structurally characterized compound having a 1,3-thiazine link to cadmium (II) and is, likewise, the first with indazole nitrogen bound to cadmium (II). A diagram of the molecular structure and the atom numbering system used is shown in Fig. 3. The most relevant bond lengths and angles are given in Table 4.

The disposition of the eight donor atoms is adequately best described as a distorted dodecahedron (Fig. 4), with approximate C_2 symmetry, with the two-fold axis placed at the bisector of the angle formed by the two four-membered chelate rings present in the molecule. In the dodecahedral geometry N(1) is the lone capping atom whereas O(1) and O(2) are the shared capping atoms (see Fig. 4). Likewise, the two interpenetrating trapezoids, which characterize [30] the dodecahedron, are defined by the positions of the atoms O(1), O(2), N(3), N(1) and O(1A), O(2A), N(3A), N(1A). The angle between the mean planes of these trapezoidal planes is 84.4°, very close to the ideal one (90°).

The Cd–O distances of bidentate nitrate groups are comparable with the calculated average value [2.476 (136) Å] for 26 eight-coordinate cadmium (II) complexes collected in CSD.

The nitrate group show a small asymmetry [{Cd–O(2)}–{Cd–O(1)} = δ = 0.153 Å], which is similar to those found in [$Cd(NO_3)_2(H_2O)_2$(μ-adeninium)$_2$] (δ = 0.155 Å) [31] and [$Cd(NO_3)$L] (L = 1-Aza-4,10-dithia-7-oxacyclododecane) (δ = 0.149 Å) [32].

The chelate ring Cd–N(3)–N(2)–C(1)–N(1) shows a conformation near to envelope [q = 0.200 Å; ϕ = 40.5°] [26] with the apex at Cd, deviating 0.415 Å from the plane formed by N(3), N(2), C(1) and N(1).

For the thiazine ring, the puckering parameters Q = 0.459 Å, ϕ = 234.0° and θ = 58.2° [26] indicate a conformation near to half-boat with the C(3) atom deviating by 0.614 Å above the plane formed by S(1), C(1), N(1), C(2) and C(4).

Finally, it should be pointed out that the aim difference in both complexes with respect to the structure of free InTz is due to the different degree of rotation of the thiazine ring around the C(1)–N(2) bond, which permit the coordination through N(1) [torsion angle N(1)–C(1)–N(2)–N(3) = −5.9° in [$Co(NO_3)_2$(InTz)$_2$]; 1.6° in [$Cd(NO_3)_2$(InTz)$_2$]; average value 173.5° in InTz].

3.2. Physical measurements

The observed molar magnetic susceptibility for [$Co(NO_3)_2$(InTz)$_2$] was corrected for diamagnetism and temperature-independent paramagnetism to provide the fully corrected magnetic moment at room temperature (μ_{eff} = 4.7 BM). This value is consistent with an octahedral environment around cobalt (II) [33].

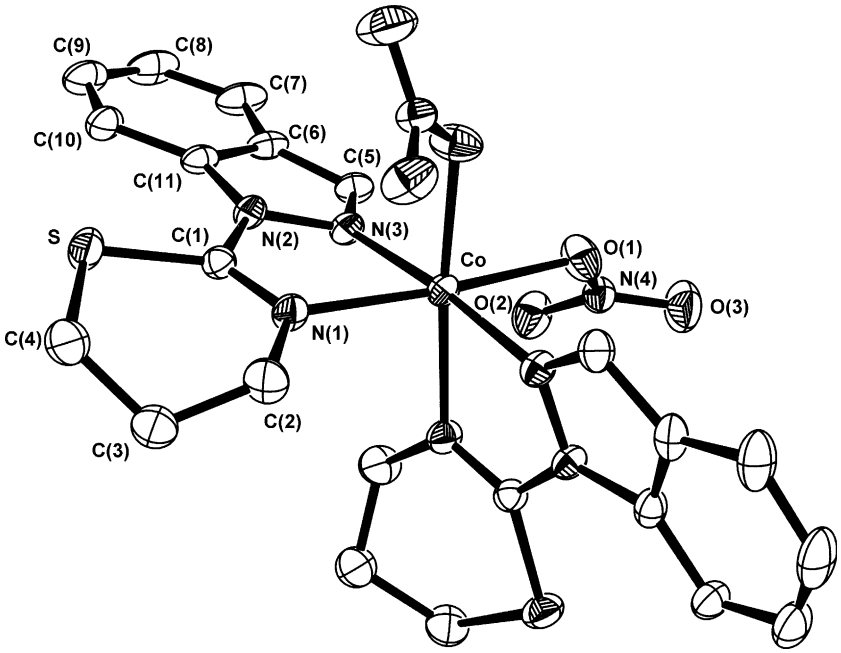

Fig. 2. Molecular structure of $[Co(NO_3)_2(InTz)_2]$, showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 40% probability level.

The diffuse reflectance spectrum shows one intense band at 32 895 cm^{-1} (304 nm), which is assigned to transitions of the organic ligand. Moreover, the spectrum exhibits two main bands that have intensities consistent with spin-allowed d–d transitions. These bands may be assigned as: $\nu_1[^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)]$ (10 361 cm^{-1}) and $\nu_3[^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)]$ (20 000 cm^{-1}) transitions, in an idealized O_h symmetry. It must be pointed out that the ν_1 assignment has been made by calculating the baricenter of two bands (11 211, 9653 cm^{-1}) of approximately equal intensity in the solid-state spectrum [34]. The ligand field parameters, 10 Dq and B, were calculated using the following known relationships [35] for octahedral d^7 complexes:

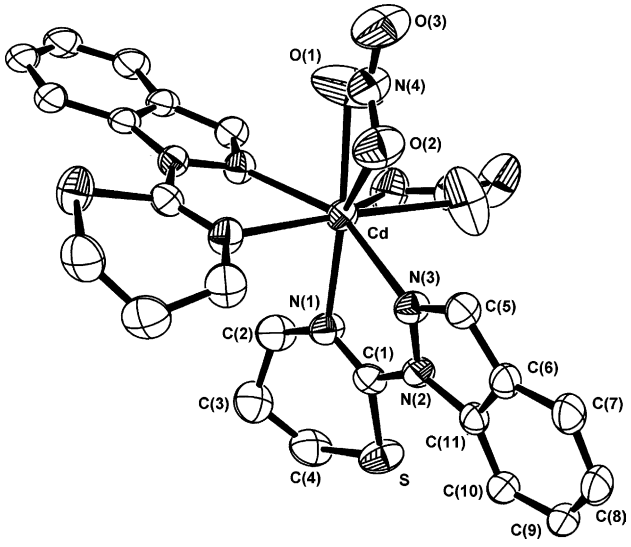

Fig. 3. Molecular structure of $[Cd(NO_3)_2(InTz)_2]$, showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 40% probability level.

$$\nu_1[^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)] = 1/2(10Dq - 15B) + 1/2[(10Dq + 15B)^2 - 12B \cdot 10Dq]^{1/2},$$

$$\nu_3[^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)] = [(10Dq + 15B)^2 - 12B \cdot 10Dq]^{1/2}.$$

The calculated values of the ligand field parameters $10Dq = 12\,257\ cm^{-1}$ and $B = 769\ cm^{-1}$ are in fair agreement with the predicted values for octahedral complexes and are consistent with the presence of a cromophere group $[CoN_4O_2]$ [36–39].

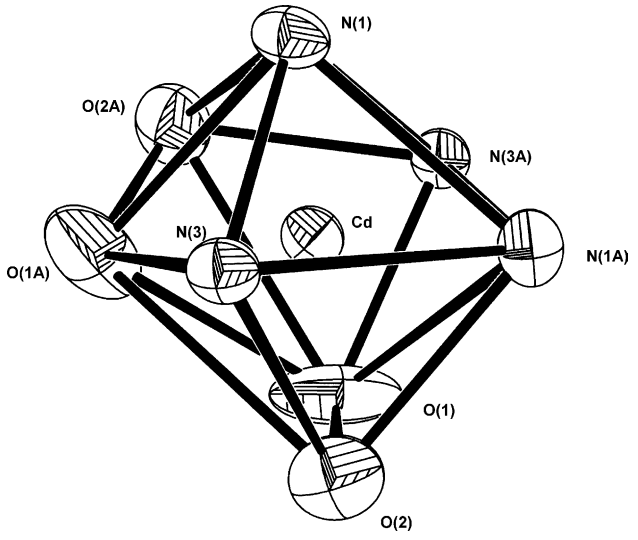

Fig. 4. View of the dodecahedral coordination polyhedron for $[Cd(NO_3)_2(InTz)_2]$.

The IR spectrum of InTz in the 4000–370 cm^{-1} region shows the presence of bands due to thiazine ring at 1632 (Ψ_1), 954 (Ψ_2), 907 (Ψ_3), 877 (Ψ_4), 768 (Ψ_5), 752 (Ψ_6), 624 (Ψ_7), 585 (Ψ_8), 515 (ϕ_1) and 467 (ϕ_2) cm^{-1} [18–20,40,41].

Likewise, the spectrum of InTz exhibits bands assignable to the indazole ring vibrations at 1610, 1578, 1497, 1373, 1350, 1314, 1288 and 1250 cm^{-1} for stretching skeletal vibrations (ν); at 1005, 954, 768 and 552 cm^{-1} for bending skeletal in-plane vibrations (δ); and at 431 and 405 cm^{-1} for bending skeletal out-of-plane vibrations (τ) [42].

The IR spectra of $[Co(NO_3)_2(InTz)_2]$ and $[Cd(NO_3)_2(InTz)_2]$ in the 4000–370 cm^{-1} region show the presence of bands due to the organic moiety ring vibrations as is shown in Table 5. On the other hand, bands due to nitrate ligands are registered at 729 and 707 (ν_4), 1436 and 1294 (ν_3), 817 (ν_2) and 1035 (ν_1) cm^{-1} for $[Co(NO_3)_2(InTz)_2]$ and at 730 and 707 (ν_4), 1435 and 1299 (ν_3), 820 (ν_2) and 1034 (ν_1) cm^{-1} for $[Cd(NO_3)_2(InTz)_2]$ [43].

Methods to discriminate between bidentate and monodentate bonded nitrate groups have been reported and have been proved reliable. They are based on the ($\nu_1 + \nu_4$) combination bands pattern or on the splitting [44–47]. The bands registered at 1748 and 1735 cm^{-1} for $[Co(NO_3)_2(InTz)_2]$ are assigned to ($\nu_1 + \nu_4$) combination bands. The value of the splitting ($\Delta = 13$ cm^{-1}) reveals the presence of one monodentate nitrate group in agreement with Lever's criteria [45]. In the same way, the bands observed at 1763 and 1737 cm^{-1} for $[Cd(NO_3)_2(InTz)_2]$ ($\Delta = 26$ cm^{-1}) can be assigned to one bidentate nitrate group.

Only three bands assignable to metal–ligand stretching vibrations are observed in the low frequency range for $[Co(NO_3)_2(InTz)_2]$ and $[Co(NO_3)_2(InTz)_2]$ spectra. Thus, the Co(II) spectrum shows the first band at 298 cm^{-1}, corresponding to ν(Co–ONO_2) vibration in

accord with the literature data for this type of bonds [39,48], whereas the band at 266 cm^{-1} is tentatively attributed to $\nu(Co–N_{indazole})$ vibration [49]. Finally, the band at 227 cm^{-1} is assigned to $\nu(Co–N_{thiazine})$ vibration [18]. In the Cd(II) spectrum, the band at 203 cm^{-1} is tentatively assigned to $\nu(Cd–N_{thiazine})$ vibration in agreement with the values of complexes containing thiazoline derivative ligands [50,51]. The second band at 193 cm^{-1} has been attributed to $\nu(Cd–ONO_2)$ vibration [43,50]. Finally, the band at 173 cm^{-1} could be tentatively assigned to $\nu(Cd–N_{indazole})$, according to the consulted bibliography for cadmium complexes containing pyrazole derivative ligands [52].

4. Supplementary material

CCDC 262540, 262541 and 262542 corresponding to InTz, $[Cd(NO_3)_2(InTz)_2]$ and $[Co(NO_3)_2(InTz)_2]$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk).

Abstract

Reaction of 2-benzoylpyridine *N*(4)-phenyl thiosemicarbazone (HL) with a variety of copper salts yielded a series of copper(II) complexes of the type [CuLX] where X = Cl (**1**), Br (**2**), NO_3 (**3**), NCS (**4**), N_3 (**5**) excluding the perchlorate complex. In the perchlorate complex (**6**), one molecule each of the neutral and deprotonated ligand is found to be coordinated to the metal. The complexes are characterized by molar conductivity measurements, magnetic studies, electronic, infrared and EPR spectral studies. The crystal structures of two copper complexes, **1** and **4** have been resolved using single crystal X-ray studies. The crystal structure of compound **1** revealed chlorine bridged dimer having monoclinic lattice with space group symmetry $P2_1/c$. The compound **4** adopts a distorted square planar geometry with N_3S core as the base. The antimicrobial activity of the ligand and the copper complexes were tested against five types of bacteria isolated from clinical samples. The ligand (HL) was found to be active against *Staphylococcus aureus*. The copper(II) complexes were found to be active against *Vibrio cholerae* O1 and *Salmonella paratyphi*.

1. Introduction

Thiosemicarbazones and their metal complexes exhibit a wide range of medicinal applications. Owing to the interest they generate in pharmacology [1,2], thiosemicarbazones and their metal complexes have been extensively studied. The biological activity of thiosemicarbazones is related to its chelating ability with transition metal ions. Earlier studies on the biological properties of thiosemicarbazones and their metal complexes have concluded that the biologically active thiosemicarbazone molecules are planar and contain a pyridine ring or derivatives giving rise to NNS tridentate system [3]. In some cases, changing the point of attachment of the thiosemicarbazone chain from the 2-position in the pyridine ring to the 3- or 4-position causes a decrease in activity, presumably due to lower coordination ability but the presence of a bulky group at the terminal nitrogen considerably increases the activity. Earlier reports on *N*(4)-substituted thiosemicarbazones have concluded that, an additional potential bonding site together with the presence of bulky groups at the *N*(4) position of the thiosemicarbazone moiety greatly enhances biological activity [4–6]. Recently, we have reported diverse transition metal complexes of a variety of substituted thiosemicarbazones [7–13]. In the present work, our objective is to study the variation in

antimicrobial activity by changing the *N*(4) substituent from cyclohexyl [14] in 2-benzoylpyridine thiosemicarbazone to phenyl group. This paper describes the synthesis, UV–visible, infrared, EPR spectral studies and antimicrobial activities of Cu(II) complexes of 2-benzoylpyridine *N*(4)-phenyl thiosemicarbazone (HL).

2. Experimental

2.1. Materials

Phenyl isothiocyanate (Fluka), hydrazine hydrate (Lancaster), 2-benzoylpyridine (Lancaster), and the different Cu(II) salts were used as received. Solvents were purified by distillation.

2.2. Synthesis of ligand and complexes

The ligand 2-benzoylpyridine *N*(4)-phenyl thiosemicarbazone (HL) was prepared by adapting a reported method [15]. Phenyl isothiocyanate (6.759 g, 50 mmol) and hydrazine hydrate (2.4 ml, 50 mmol), each dissolved in 50 ml methanol were mixed with constant stirring. The stirring was continued for 30 min and the white product, *N*(4)-phenylthiosemicarbazide formed was washed with methanol and dried. A methanolic solution of 2-benzoylpyridine (9.16 g, 50 mmol) was added to a solution of *N*(4)-phenylthiosemicarbazide (8.35 g, 50 mmol) dissolved in 100 ml of methanol. The resulting solution was refluxed for 5 h after adding 2–3 drops of acetic acid. Yellow crystals separated on cooling were washed with methanol, recrystallised from ethanol and dried over P_4O_{10} in vacuo, m.p. 135 °C.

Complexes of copper(II) **1**, **2**, **3** and **6** were prepared by refluxing the respective methanolic solutions of the metal salts and the ligand HL in 1:1 molar ratio for 4–6 h. The resulting solution, on cooling yielded respective solids, which were filtered, washed with methanol and ether and dried over P_4O_{10} in vacuo. Compounds **4** and **5** were prepared by a metathetical displacement of the acetate anion of the copper acetate by the addition of 1 mmol each of the methanolic solutions of KSCN and NaN_3, respectively, to the reaction mixture of the ligand and copper acetate in methanol. The resulting solution was refluxed for 3 h and left overnight. The solids separated were filtered, washed with methanol and ether and dried over P_4O_{10} in vacuo. The colours, stoichiometries, elemental analyses, and magnetic moments of the copper(II) complexes are given in Table 1.

Caution! Azide and perchlorate salts of metal complexes with organic ligands are potentially explosive. So they should be prepared and handled carefully.

2.3. Physical measurements

Elemental analyses of the ligand and the complexes were done on a Heracus elemental analyzer at CDRI, Lucknow. The IR spectra were recorded on a Shimadzu DR 8001 series FTIR instrument using KBr pellets. The solid state reflectance spectra of the ligand and the complexes were recorded on Ocean Optics, Inc.SD2000 Fibre Optic Spectrometer. The EPR spectra of the complexes were recorded in a Varian E-112 Spectrometer using TCNE as the standard at SAIF, IIT, Bombay, India.

The magnetic susceptibility measurements were carried out at Indian Institute of Technology, Roorkee, at room temperature in the polycrystalline state on a PAR model 155 Vibrating sample magnetometer at 5 K Oersted field strength. The molar conductances of the complexes in dimethylformamide solutions (10^{-3}M) at room temperature were measured using a direct reading conductivity meter.

2.4. X-ray crystallography

Single crystals of compounds **1** and **4**, suitable for diffraction were grown by slow evaporation of 1:2 mixtures of methanol and DMF. Compound **1** crystallized with one molecule of water of crystallization. Selected crystal data and data collection parameters are presented in Table 2. Data were collected using a Bruker Smart Apex CCD diffractometer equipped with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation at 273 K. The trial structure was solved using SHELXS-97 and refinement was carried out by full-matrix least squares on F^2 (SHELXTL) [16]. Molecular graphics employed was

PLATON [17]. The hkl ranges are $-19 \leqslant h \leqslant 18$, $-10 \leqslant k \leqslant 9$, $-20 \leqslant l \leqslant 17$ and $-13 \leqslant h \leqslant 14$, $-20 \leqslant k \leqslant 20$, $-14 \leqslant l \leqslant 9$ for compounds **1** and **4**, respectively.

2.5. Antimicrobial activity

The ligand and the complexes were tested for antimicrobial activity, at the Department of Biotechnology, Cochin University of Science and Technology. The test organisms chosen for antimicrobial activity were two Gram positive and three Gram negative bacteria. The MIC (minimum inhibitory concentration) determination and screening of antimicrobial property was done by the disc diffusion method.

3. Results and discussion

3.1. Synthesis of ligand and complexes

Reaction of methanolic solutions of the ligand and the corresponding copper salts in 1:1 molar ratio yielded compounds **1**, **2**, **3** and **6** whereas compounds **4** and **5** were prepared by the metathetical displacement of acetate in $Cu(OAc)_2 \cdot H_2O$ by either the thiocyanate or azide ion. The thiosemicarbazone deprotonates and chelates in thiolate form as evidenced by the IR spectra. The elemental analyses suggest the general formula as $[CuLX] \cdot xH_2O$ for complexes **1**–**5** but the perchlorate complex turned out to be $[Cu(HL)L]ClO_4$ with the perchlorate ion out of the coordination sphere. The complexes are appreciably soluble in alcohol and DMF. The molar conductance values of the compounds **1**, **2**, **3**, **4** and **5** in 10^{-3} M solution in DMF are found to be less than $20\ \Omega^{-1}\ mol^{-1}\ cm^{-1}$, showing that they are nonconductors [18] which indicate that the anion and the ligand are coordinated to the central copper(II). But the molar conductance value of compound **6** is $72\ \Omega^{-1}\ mol^{-1}\ cm^{-1}$ which is consistent with the value of 1:1 electrolyte as suggested by the formula. The effective magnetic moment values in the range 1.5–1.9 B.M. indicate a typical $S = 1/2$ Cu(II) system.

3.2. Crystal structures

The molecular structures of the compounds **1** and **4** along with atom numbering scheme are given in Figs. 1 and 2, respectively. Table 3 depicts a list of selected bond parameters of the ligand HL and complexes. While the present work was in progress, the molecular structure of HL was reported [19]. However we include here the various structural parameters of HL for comparison with the structures of the two complexes. Single crystal X-ray

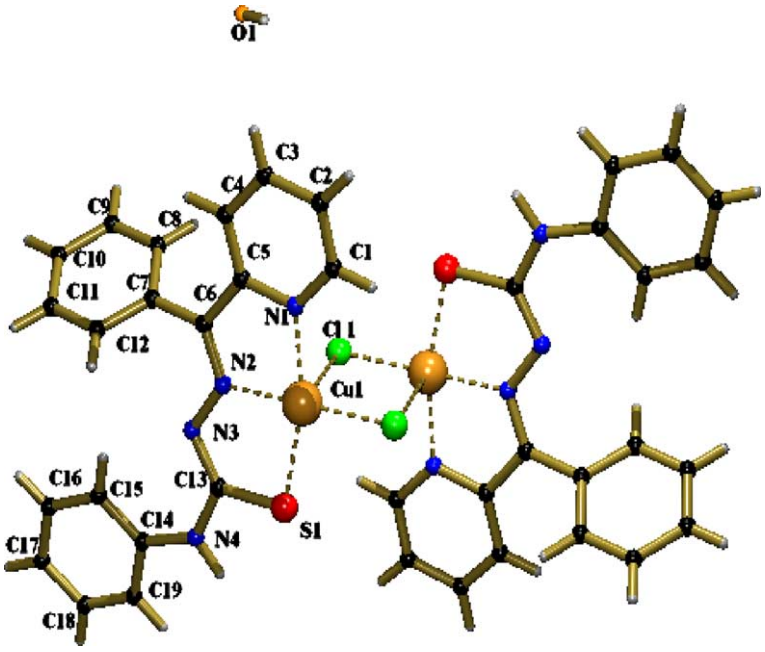

Fig. 1. Molecular structure for compound **1**.

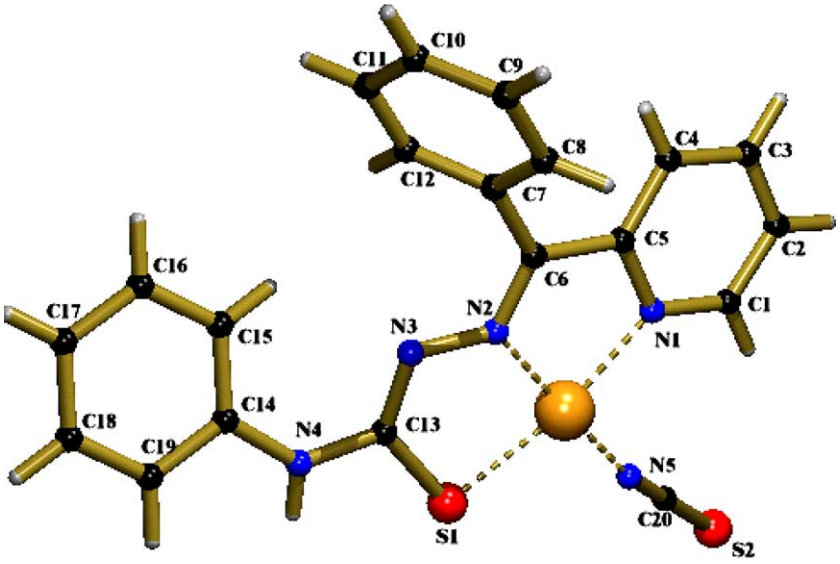

Fig. 2. Molecular structure for compound **4**.

studies of compound (**1**) show that the compound exists as a chlorine bridged dimer. The centrosymmetric nature of the molecule is revealed by a C_2 axis perpendicular to the Cu(1)–Cl(1)–Cu(2)–Cl(2) plane. The lattice nature is monoclinic with space group symmetry $P2_1/c$. Earlier, we have reported a similar chlorine bridged dimeric copper complex with the ligand 2-benzoylpyridine *N*(4), *N*(4)-(butane-1,4-diyl) thiosemicarbazone [20]. The thiosemicarbazone ligand coordinates in a tridentate manner with the metal atom using its azomethine nitrogen, thiolate sulfur and pyridyl nitrogen resulting in two five membered chelate rings. The compound exhibits a distorted square pyramidal geometry with the basal plane occupied by the thiosemicarbazone ligand and the chlorine atom. The chlorine atom of the adjacent monomer plugs into the axial position resulting in a dimer with a Cu–Cu separation of approximately 3.550 Å. The distortion from square pyramid geometry is evident from the bond angles Cl(1)–Cu(1)–S(1) 95.44(3), Cl(1)–Cu(1)–N(1) 98.70(7), N(2)–Cu(1)–N(1) 81.10(8) and N(2)–Cu(1)–S(1) 84.68(6). The basal plane defined by the atoms Cu(1), N(1), N(2), S(1), and Cl(1) deviates

significantly from planarity with a mean deviation of 0.0488 Å. A distance of 3.986 Å between the Cu(II) metal and the centroid Cg(6) defined by C(14),C(15),C(16), C(17),C(18) and C(19) leads to a ring metal interaction. The significant distance of 2.8613 Å between the centroids Cg(5) and Cg(2) consisting of Cu(1), N(1), C(5), C(6), N(2) and Cu(1), Cl(1), Cu(1a), Cl(1a) makes the crystal packing effective.

The compound **(4)** crystallizes into monoclinic lattice having $P2_1/n$ space symmetry with four molecules per unit cell. The ligand HL together with the thiocyanate group coordinate with Cu(II) resulting in a distorted square planar geometry. The bonding parameters agree with the coordinating pattern of thiosemicarbazone via the thiolate form. Upon complexation, the C(13)–S(1) bond and C(6)–N(2) bonds shift to 1.750(2) and 1.297(2) compared to 1.6661(16) and 1.3002(18), respectively in the ligand. There are also remarkable variations in C(13)–N(3) bond lengths of ligand and complex. The bond angles N(2)–Cu–N(1) 81.06(6), N(2)–Cu–S(1) 84.19(4), N(5)–Cu(1)–N(1) 96.66(7) and N(5)–Cu(1)–S(1) 98.19(6) illustrate that the complex is slightly distorted from the square planar geometry. Liu et al. [21] have synthesized a tetranuclear thiocyanato-copper complex from 2-benzoylpyridine thiosemicarbazone with *N*(4) position unsubstituted. The geometry of copper-ligand-thiocyanato moiety is distorted square planar as in the present complex. However, there is similarity in the N(2)–Cu(1)–N(5) bond angle, while the other bond angles and bond lengths differ significantly. Formation of the chelate ring Cu(1)–N(2)–N(3)–C(13)–S(1) is facilitated by change in configuration of C(13)–N(3) bond from Z in ligand to E in complex, the dihedral angle being 178.51(17) with respect to N(2) and N(4) substituents. Thus with Cu–N2 as the main frame, two chelate

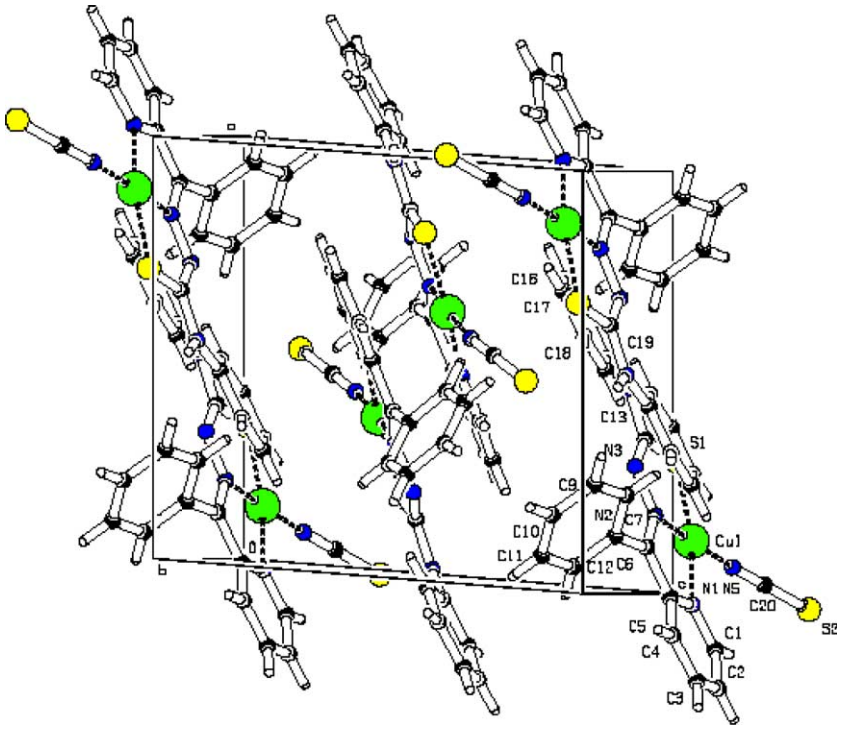

Fig. 3. Packing diagram of compound **4**.

rings are formed which are almost planar with a dihedral angle separation of 0.88°, the second chelate ring being Cu(1)–N(2)–C(6)–C(5)–N(1). Comparing compound **4** with a similar compound in which the *N*(4) substituent is cyclohexyl [12], there exists appreciable variation in C(13)–N(4) bond length. It is seen that in compound **4**, the C(13)–N(4) bond length, 1.364(2) is increased when compared to the value of 1.339(3) in the compound where the *N* (4) substituent is cyclohexyl. This may be due to the delocalization of lone pair electrons of *N*(4) with the phenyl ring. The bond angle C(20)–N(5)–Cu(1) 165.5(2) reveals that the Cu–NCS coordination is not linear while the linearity of N(5)–C(20)–S(2) bond angle, 179.5(2) is almost retained. In the unit cell, the molecules are arranged in a zig-zag manner, where the NCS tails on neighbouring molecules are pointing towards opposite sides (Fig. 3). Table 4 features the H-bonding interactions of HL and two complexes **1** and **4**.

3.3. IR and electronic spectra

The tentative assignments of the significant IR spectral bands of HL and its copper(II) complexes are presented in Table 5. The *ν*(C=N) band of the thiosemicarbazone at 1591 cm^{-1} undergoes a negative shift of wavenumber in the complexes indicating coordination via the azomethine nitrogen. This is confirmed by the bands in the range 440–475 cm^{-1}, which have been assigned to the *ν*(Cu–N) band [22]. A strong band found at 1102 cm^{-1} is assigned to the *ν*(N–N) band of the thiosemicarbazone. The increase in the frequency of this band in the spectra of complexes is due to the increase in the bond strength, again confirms the coordination via the azomethine nitrogen. In the uncomplexed thiosemicarbazone the two bands appearing at the frequencies at 1369 and 835 cm^{-1} have been assigned to *ν*(C=S). In the complexes these two bands are found to be shifted to lower frequencies in the ranges 1280–1320 and 745–785 cm^{-1}, respectively. Thus due to coordination via the thiolate sulfur atom a negative shift occurs in the *ν*(C=S) band in all complexes [23]. In all the copper complexes, a strong band is observed in the region 270–295 cm^{-1}. This is consistent with the *ν*(Cu–N) of pyridine as suggested by Clark and Williams [24]. Based on the above spectral evidences, it is confirmed that the ligand HL is tridentate, coordinating via the azomethine nitrogen, the pyridyl nitrogen and thione/thiolate sulfur. In the chloro complex the strong band observed at 310 together with a band at 150 cm^{-1} has been assigned to the *ν*(Cu–Cl) which is in a bridging mode [20]. The *ν*(Cu–Br) frequency is observed at 255 cm^{-1} in the bromo complex. The *ν*(Cu–Br) frequency is consistent with the terminal bromo ligand. In the nitrato complex the three bands observed at 1431, 1302 and 1014 cm^{-1} indicates the ν_4, ν_1 and ν_2 modes of the nitrato group. The fact that the nitrato group is terminally bonded is understood from the separation of 129 cm^{-1} between the two highest frequency bands just mentioned above [22]. Besides, in the far IR spectrum of the complex, the band observed at 271 cm^{-1} can be assigned to *ν*(Cu–ONO_2)

Table 5

in consistence with the bands at 253–280 cm^{-1}, reported earlier for Cu–ONO_2 in metal complexes [25].

In the azido complex, the strong band observed at 2046 cm^{-1} is assigned to ν_a of the azide group indicative of azide coordination [26]. In the thiocyanato complex, a very strong band at 2098 cm^{-1}, a medium band at 869 cm^{-1} and a strong band at 480 cm^{-1} are assigned to ν(CN), ν(CS), and δ(NCS) modes of the NCS group, respectively. The intensity and position of these bands indicate the unidentate coordination of the thiocyanate group through the nitrogen [20,27]. For the perchlorate complex **6**, the bonding of the neutral ligand needs to be considered because the perchlorate group is not coordinated to the metal ion. The perchlorate complex contains a single broad band at 1123 cm^{-1} and an unsplit band at 644 cm^{-1}, indicating the presence of ionic perchlorate. The bands at 1123 and 644 cm^{-1} can be assigned to $\nu_3(ClO_4)$ and $\nu_4(ClO_4)$, respectively. The presence of these bands and the absence of a band near 930 cm^{-1} assignable to $\nu_1(ClO_4)$ suggest ionic perchlorate [28]. The IR spectrum of compound **6** contains a strong band at 785 cm^{-1} which has been assigned to ν(C–S) indicating coordination via the thiolate sulfur. In addition to this band, the spectrum also contains a band at 830 cm^{-1} indicating the presence of the ligand in the thione form. The presence of a weak shoulder at ~622 cm^{-1} indicates that the neutral ligand does not coordinate through pyridyl nitrogen. However, bands corresponding to azomethine groups of both HL and L are shifted indicating that the neutral ligand coordinates through azomethine nitrogen while the ligand in thiolate form coordinates via azomethine nitrogen, pyridyl nitrogen and thiolate sulfur resulting in a four coordinate structure. Based on the elemental analyses and IR spectral data a tentative structure is proposed for compound **6** and is given in Fig. 4. Attempts to isolate single crystals of compound **6** were unsuccessful.

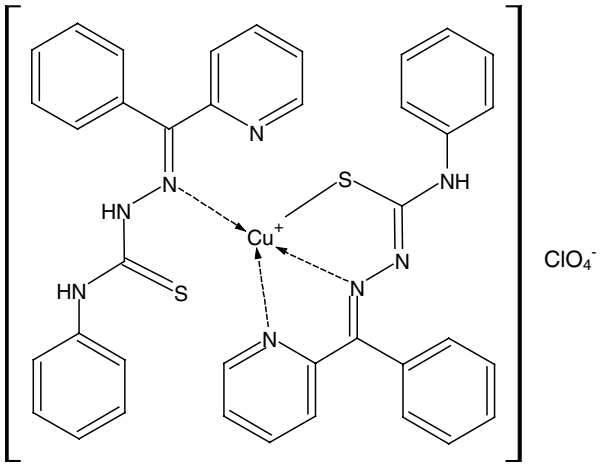

Fig. 4. Tentative structure for compound **6**.

The solid state electronic spectrum of HL consists of a broad band at ca. 29410 cm^{-1} which is n → π* band of the pyridine ring. An absorption band observed at ca. 37313 cm^{-1} in the solid state spectrum of the ligand may be due to π → π* transition. The electronic spectra of Cu(II) complexes (Table 6) consist of bands in the region 27000–33000 cm^{-1} which are assigned to n → π* band of pyridine ring. A strong band in the range 22500–24500 cm^{-1} observed in the spectra of all Cu(II) complexes which are assigned to S → Cu and py → Cu charge-transfer bands [29,30]. In the chloro complex a shoulder observed at 31446 cm^{-1} is assigned as Cl → Cu charge-transfer transitions. The solid state spectra of all compounds exhibit d → d bands in the range 19000–16000 cm^{-1} which are consistent with a broad structured band suggested for square planar complexes in the range 13000–20000 cm^{-1} [31]. In the electronic spectra of Cu(II) complexes in DMF, the bands corresponding to electronic transitions are found to be shifted from that of the solid state.

3.4. EPR spectra

The EPR spectra of the complexes in the polycrystalline sample at 298 K, in solution at 298 and 77 K were recorded in the X band, using 100 kHz field modulation and the g factors were quoted relative to the standard marker TCNE ($g = 2.0277$). The EPR parameters of the copper(II) complexes obtained for the polycrystalline state at 298 K and in DMF at 298 and 77 K are presented in Table 7. In the case of a $3d^9$ copper(II) ion the appropriate spin Hamiltonian assuming a B_{1g} ground state is given by [32].

$$\hat{H} = \beta[g_{\parallel}H_zS_z + g_{\perp}(H_xS_x + H_yS_y)] + AI_zS_z + B(I_xS_x + I_yS_y).$$

The EPR spectrum of compound **5** in the polycrystalline state (298 K) show only one broad signal at $g = 2.07$. The spectra of the compounds **2**, **3** and **4** show typical axial spectra with well-defined $g_{\parallel}$ and $g_{\perp}$ values at ≈2.21 and 2.05, respectively. The spectra of compounds **1** and **6** give three g values viz. g_1, g_2 and g_3 which indicate rhombic distortions in their geometry. The geometric parameter G, which is a measure of the exchange interaction between the copper centres in the polycrystalline compound, is calculated using the equation:

$G = (g_{\parallel} - 2.0023)/(g_{\perp} - 2.0023)$ for axial spectra and for rhombic spectra, $g_{\perp} = (g_1 + g_2)/2$. If $G > 4$, exchange interaction is negligible and if it is less than 4, considerable exchange interaction is indicated in the solid complex [33,34]. In all the copper(II) complexes $g_{\parallel} > g_{\perp} > 2.0023$ and G value within the range 2.5–3.5 are consistent with a $d_{x^2-y^2}$ ground state. In the EPR spectra of the complexes in DMF solution at 298 K, four hyperfine lines are observed which arise from the coupling of the odd electron with the copper nuclei (^{65}Cu, $I = 3/2$). The spectrum of compound **1** at 77 K is a typical axial one with well-resolved hyperfine lines with no superhyperfine lines. However, the half field signal corresponding to the dimer was not observed for compound **1**. The spectrum of compound **2**, is isotropic without any hyperfine lines due to poor glass formation. The spectrum of compound **6** is a typical rhombic one without any hyperfine and superhyperfine lines.

The EPR parameters $g_{\parallel}$, $g_{\perp}$, g_{av}, $A_{\parallel}$(Cu) and $A_{\perp}$(Cu) and the energies of d–d transition were used to evaluate the bonding parameters α^2, β^2 and γ^2, which may be regarded as measures of the covalency of the in-plane σ bonds, in-plane π bonds, and out-of-plane π bonds, respectively. In all the copper(II) complexes, it is observed that $K_{\parallel} < K_{\perp}$ (Table 8) which indicates the presence of significant in-plane π bonding. This is further

Table 7

confirmed by the bonding parameters α^2, β^2 and γ^2 which are less than 1.0, expected for 100% ionic character of the bonds, and decrease on increasing the covalent character of the bonding. This observation supports the argument that there is significant in-plane π bonding and in-plane σ bonding in the copper(II) complexes of HL.

3.5. Antimicrobial activity

The ligand and its five Cu(II) complexes were tested for their antimicrobial activity. Two Gram positive bacteria and three Gram negative bacteria were used as test organisms: (1) *Staphylococcus aureus*, (2) *Bacillus* sp. (Gram positive), (3) *Escherichia coli*, (4) *Salmonella paratyphi*, (5) *Vibrio cholerae* O1 (Gram negative). Table 9 depicts the antimicrobial activity of the complexes using the disc diffusion method [35]. The effectiveness of an antimicrobial agent in sensitivity testing is based on the size of the zones of inhibition. The diameter of the zone is measured to the nearest millimeter. Test substances which produce the zone of inhibition with diameters 9 mm or more are regarded as positive, i.e. having antimicrobial activity; while those cases where the diameter is below 9 mm, the bacteria are resistant to the sample tested and the sample is said to have no antimicrobial activity. The MIC (minimum inhibitory concentration) expressed in micrograms, of the compounds showing positive antimicrobial property was determined using the disc diffusion method and is given in Table 10.

It was observed that the ligand HL was active against *Staphylococcus aureus* while it was inactive against the other four test organisms. But all its Cu(II) complexes were found to be inactive against this particular bacteria. Out of the five Cu(II) complexes, four complexes were found to be active against only one type of microorganism under study, i.e. *Vibrio cholerae* O1. The complex $[CuLN_3]$ was found to be active against *Vibrio cholerae* and *Salmonella paratyphi*. The ligand and the Cu(II) complexes are found to be inactive against *Bacillus* sp. and *Escherichia coli*. It was surprising to find that *N*(4)-phenyl substituted thiosemicarbazone was active whereas the more bulky cyclohexyl substituted thiosemicarbazone ligand was inactive. But the activity of Cu(II) complexes were found to be reversed as expected, where the more bulky *N*(4) substituent leads to more activity.

Acknowledgements

The authors are thankful to Sophisticated Analytical Instruments Facilities at CDRI, Lucknow and IIT, Bombay, India for the elemental analyses and EPR spectral studies, respectively. M.R.P. Kurup would like to thank the Department of Science and Technology, New Delhi for financial assistance (SR/S1/IC-31/2002) and M. Joseph acknowledges Kerala State Council for Science, Technology and Environment, Govt. of Kerala for financial support.

Appendix A. Supplementary data

Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic

Data center, CCDC reference numbers are 251896, 254305 and 254304 for HL, compounds **1** and **4**, respectively. Copies of this information may be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html or from the Director, CCDC, 12 Union Road, Cambridge, CB2, IEZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk. Abstract

The use of a ligand directed strategy in the assembly of discrete cluster, 2D layers and 3D networks, using *N*-substituted glycine derivatives with *o*-iodobenzoyl (a bulky substituent) or pyrimidyl, create a new possibility in the design of coordination networks. According to the nature of the substituent, 2D layers (with *o*-iodobenzoyl) or 3D networks (with pyrimidyl), with tubular cavities and Ag···Ag short contacts, are obtained. The synthesis and crystalline structure of the ligand *N*-(pyrimidyl)glycine (**1**), its silver derivative [Ag(pyr-gly)] · $0.5H_20$ (**2**) and the silver derivative of *o*-iodohippuric acid [Ag(I-hip)] · $1.25H_2O$ (**3**) are described. The structures of **2** and **3** present tubular cavities being, in complex **2** a 3D structure with cycles and clusters Ag_4O_4 that retains water inside the tubular channels. In the other hand, the compound 3 presents a 2D structure generated by macrocyclic rings formed between the ligand and the metal ion; these bi-dimensional networks are piled in the *c*-direction, and the different layers are detached by water molecules as an intercalation compound; in addition, each layer interacts with the others by stacking (distance, 3.38 Å) between series of two aryl rings inside of the channel and preserving it along the *c*-axis. Finally, short Ag···I contacts are also present as recognition factors in compound **3**.

1. Introduction

The control of the self-assembly process between labile metal ions and flexible polydentate ligands is a key objective in the development of supramolecular coordination chemistry [1]. Obviously, this process will be related with the number, type and spatial disposition of the binding sites of ligands, the steric plasticity of metal ions, the coordinative versatility of the ligands, the solvent effect and the nature of counter anions [2,3]. The combination of all of these factors leads to numerous metallosupramolecular complexes with various structural topologies [2–12].

In this context, Ag(I) is a profitable metal ion choice because of presents suitable coordination geometries such as linear, T-shaped, trigonal, distorted tetrahedral, or octahedral [7].

The aim to obtain highly specific materials can be tackled with the properties of Ag(I) to produce nanomaterials [8], porous open channels structures with properties like zeolites [5,9,10], polymers with controlled chirality [11], frameworks with luminescence and special conductivity properties [12].

The choice of particular ligands has generated different type of structures: 3D [3,13,14], 2D [15,16], 1D [11,17,18] or discrete polynuclear complexes [19]. The

doi:10.1016/j.poly.2005.07.014

ligands designed for self-assembly of silver are normally rigid or with a degree of preorganization as for example polypyridyl [20,21], diphosphine [22], pyridine substituted [23], pyrimidine derivatives [24], hexamethylenetetramine [25], aliphatic amines [26], aryl iodine or alkyl iodine derivatives [27–33] or [2,2]-paracyclophane (that produces a 2D polymer with reversible guest-driven solid state transformation) [34].

Recently the topic is boosting and a great number of references appear in the literature, between them the importance of Ag–Ag short contacts are emerging as a relevant factor to self-assembly [35–37].

Previously, we have studied the coordination chemistry of hippuric and *o*-iodohippuric acids [38,39] with 3d metals. Some aspects are of interest, the N peptide of these hippuric derivatives do not coordinate with the metal ions except for the case of Pd [40] whereas the terminal carboxylic group is the main target. Moreover, in the *o*-iodohippuric compound should be mentioned that the plane of the aryl group is strictly perpendicular to the peptide bond producing a steric restriction that could prevent the formation of well defined 3D structures. On the other hand, the coordination behaviour of pyrimidine-substituted derivatives was also known [41].

For these reason, we have obtained the ligand *N*-(pyrimidyl)glycine (pyr-gly), where this steric restriction of the bulky iodo-aryl is not present in order to compare the coordination chemistry of the two ligands whereas the ligands have a similar distance between the coordination atoms (Scheme 1). Due to the lack of coordination with metal ions of the N amide bond [38,39] the terminal carboxylic group and the O atom of the peptidic bond (I-hip) or the N atom of the pyrimidine ring (pyr-gly) were considered the coordination targets of silver.

In this study we report results related to the coordination chemistry of two *N*-substituted glycine derivatives, *o*-iodobenzoylglycine (*o*-iodohippuric acid; I-hipH) and pyr-gly (Scheme 1), with silver nitrate. We have prepared this last ligand, pyr-gly, by means of a modification of a previously described methodology [42]. In this context, the two ligands have an interesting angular geometry, which leads to build multidimensional architectures forming tri- (pyr-gly) and bi-dimensional (I-hip) macrocyclic open networks that could be added to previous examples. Also, the capability of iodine residues to form short interactions with metal ions is also of the maximum interest owing to the presence of this recognition factor in thyroid hormones, which are iodinated derivatives of the tyrosine residues from thyroglobin [43].

2. Experimental

Elemental microanalyses were carried out using a Carlo Erba model 1108 microanalyzer and a Thermo Finnigan model Flash 1112 microanalyzer. IR spectra in the solid state (KBr pellets) were measured in the 4000–400 cm^{-1} range on a Bruker IFS 66 spectrometer. ^1H NMR spectra were recorded at room temperature on a Bruker AMX 300 (300 MHz). Proton chemical shifts in deuterated dimethylsulfoxide ([D_6] DMSO) were referenced to [D_6] DMSO (δ[D_6] DMSO: 2.47 ppm). Thermogravimetric data in the temperature range from 30 to 900 °C were recorded in a flowing oxygen atmosphere (heating rate 2 °C/min) on a TA Instruments SDT 2960 Simultaneous DSC-TGA thermobalance.

Reagents were used as received from Sigma, Merck or Aldrich. *o*-Iodohippuric acid (*o*-iodobenzoylglycine) was prepared according to the literature procedure [44,45] or supplied by Aldrich. *N*-(pyrimidyl)glycine was synthesized by reaction between 2-chloropyrimidine and glycine (see below).

2.1. Synthesis of N-(pyrimidyl)glycine (pyr-gly) (1)

Glycine (16 mmol), 2-chloropyrimidine (8 mmol) and Na_2CO_3 (9 mmol) in water (20 ml) were refluxed during 3 h. The resulting solution was cooled. The pH was adjusted to 3.75 with formic acid and the product precipitates (55% yield). White crystals, suitable for X-ray studies, appeared by slow evaporation at room temperature of the filtered final solution (6–7 days). *Anal.* Calc. for $C_6H_7N_3O_2$: C, 47.06; H, 4.61; N, 27.44. Found: C, 46.87; H, 4.60; N, 27.00%. IR (cm^{-1}): 445w, 551w, 577w, 611w, 651m, 699m, 798m, 883m, 927m, 1050m, 1151m, 1326m, 1388m, 1457m, 1522s, 1540s, 1560s, 1576vs, 1601vs, 1718m, 3426vs. ^1H NMR ([D_6] DMSO): δ 8.24 [d, 2H, H(7), $J = 4.8$ Hz], 7.27 [t, 1H, N(4)–H, $J = 6.3$ Hz], 6.57 [t, 1H, H(8), $J = 4.8$ Hz], 3.86 [d, 2H, H(3), $J = 6.3$ Hz].

2.2. [Ag(pyr-gly)] · 0.5H_2O (2)

Ag(I) nitrate (1 mmol) in water (5 ml) was added dropwise to a solution of pyr-gly (1 mmol) in 30 ml of

HNO_3 0.16 M. These conditions were designed to ensure the lack of coordination of the NH moiety. The resulting colourless solution was refluxed during 2 h and left to cool. Small white crystals (75% yield), diamond type, suitable for X-ray diffraction studies, appeared on standing the final solution at room temperature (3–4 days). *Anal.* Calc. for $AgC_6H_6N_3O_2 \cdot 0.5H_2O$: C, 26.79; H, 2.62; N, 15.62. Found: C, 27.50; H, 2.62; N, 15.64%. TG: The decomposition of the complex takes place in two steps. The water was loosed smoothly between 100 and 180 °C [calc.: 3.3; found: 3.0%]. The first overall step takes place in the 100–250 °C temperature range implying a higher decomposition of the molecule at 200 °C, whereas the second overall step occurs in the 350–500 °C temperature range with a higher loss about 450 °C. The weight loss associated with these two steps is in accordance with the expected value for the total decomposition of the complex [calc.: 59.96; found: 60.54% (1st step 24.66; 2nd step 35.94)], leading to the final residue Ag [calc.: 40.04; found: 39.39%]. There is no loss of water molecules before 100 °C. IR (cm^{-1}): 416vw, 520w, 585m, 648m, 700m, 799s, 907w, 985w, 993w, 1005w, 1077w, 1136w, 1180w, 1237w, 1305s, 1360m, 1384s, 1414s, 1452m, 1583vs, 1596vs, 1684w, 3298vs, 3438vs. ^{1}H NMR: This product is insoluble in the most common NMR solvents ([D_6] DMSO, CD_3OD, D_2O and $CDCl_3$).

2.3. [Ag(I-hip)] · 1.25H_2O (3)

Ag(I) nitrate (1 mmol) in water (5 ml) was added dropwise to a solution at neutral pH obtained dissolving *o*-iodohippuric acid (1 mmol) in 30 ml of NaOH 0.03 M. The resulting solution was refluxed during 2 h, filtered off to eliminate white precipitate of silver hydroxide, and left to cool. White needles (60% yield), suitable for X-ray studies, were obtained by slow evaporation at room temperature of the final solution (4–5 days). *Anal.* Calc. for $AgC_9H_7INO_3 \cdot 1.25H_2O$: C, 24.88; H, 2.20; N, 3.22. Found: C, 24.90; H, 1.97; N, 3.15%. TG: The complex exhibits a weight loss between 50 and 150 °C corresponding to 1.25 water molecules per formula unit [calc.: 5.18; found: 4.93%]. A subsequent decomposition corresponding to one I-hip molecule occurs between 180 and 320 °C [calc. for $C_9H_7NO_3$:

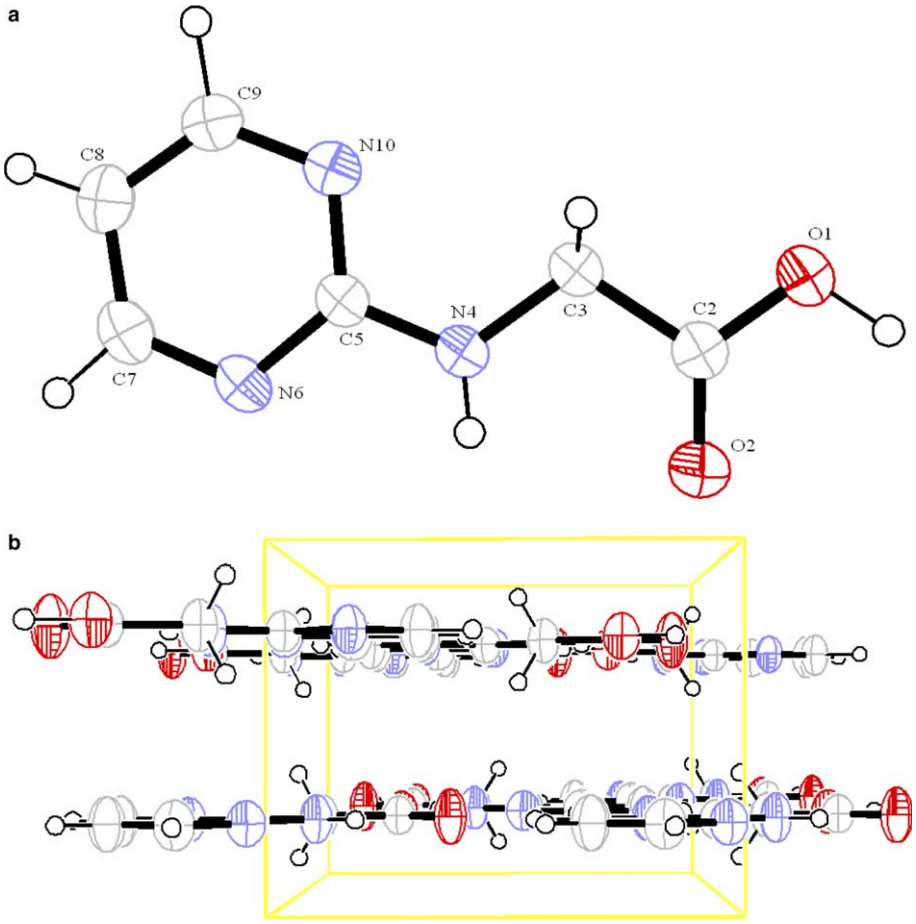

Fig. 1. ORTEP representation of the ligand *N*-(pyrimidyl)glycine (pyr-gly) (**1**). (a) Top: asymmetrical unit. (b) Bottom: view showing the planarity of the compound.

40.78; found: 40.01%] leading to AgI [calc.: 54.04; found: 55.00%] that decomposes at 556 °C in I_2 and metallic Ag, generally with projections of the analyzed material. The third weight loss takes place between 450 and 750 °C, leading to the final residue Ag. IR (cm^{-1}): 435w, 510w, 559w, 603w, 641w, 684w, 722m, 755m, 913vw, 947vw, 998m, 1016w, 1062vw, 1165vw, 1235w, 1258w, 1302m, 1328vw, 1392m, 1429m, 1460w, 1541m, 1597vs, 1642s, 3320m. ^{1}H NMR ([D_6] DMSO): δ 8.10 [t, 1H, N(4)–H, $J = 5.4$ Hz], 7.84 [d, 1 H, H(11), $J = 7.8$ Hz], 7.41 [t, 1H, H(9), $J = 7.2$ Hz], 7.35 [dd, 1H, H(8), $J = 7.4$ and 1.7 Hz], 7.13 [dt, 1H, H(10), $J = 7.5$ and 2.1 Hz], 3.73 [d, 2H, H(3), $J = 5.4$ Hz].

2.4. X-ray crystallographic study

Suitable crystals of **1**, **2** and **3** were selected for X-ray single crystal diffraction experiments and mounted at the tips of glass fibres on an Enraf-Nonius CAD4 diffractometer producing graphite monochromated Mo Kα radiation. After the random search of 25 reflections, the indexation procedure gave rise to the cell parameters (see Table 2 for a summary of the crystal data of the three compounds). Data were collected in the $\omega-2\vartheta$ scan mode. Absorption correction was performed following the PSI-scan semi-empirical (**1**) and the empirical DIFABS (**2**, **3**) methods. The structural resolution procedure was made using the WINGX package [46]. Solving for structure factor phases was performed by SIR2002 [47] and the full-matrix refinement, by SHELXL97 [48]. Noticeably, all the non-hydrogen atoms in **1** lay on m planes. Non-H atoms were refined anisotropically and H-atoms were introduced in calculated positions and refined riding on their parent atoms. A summary of the refinement parameters can be also seen in Table 2. The ORTEP [49] representations of the three complexes were made at 50% probability.

3. Results and discussion

3.1. Crystal structure of N-(pyrimidyl)glycine (*1*)

The molecular structure of *N*-(pyrimidyl)glycine (**1**) is depicted in Fig. 1(a). Selected bond lengths and angles are collected in Table 1. The bond lengths and angles are similar to pyrimidine related molecules [17,23,24,41] and hippuric acid derivatives in the glycine moiety [38,39]. This compound presents a perfectly planar disposition (Fig. 1(b)). The molecular structure is formed by different planes were molecules interact via intermolecular H-bonds (in the same plane) [dist. COO(1)···N(6), 2.62 Å; angle COO(1)–H···N(6), 173.5°] and via stacking (among parallel planes) [ca. 3.41 Å between N(4)–C(5)–N(6)–C(7) moieties; dihedral angle between planes, 180°].

and 2.34(5) Å] and a nitrogen atom of other pyr-gly molecule [Ag–N(6), 2.19(5) Å]. The coordination sphere is completed by means of a long Ag–Ag interaction [Ag–Ag, 3.099(11) Å], which must be considered, at least, as a short contact interaction. Thus, the value for distance Ag–Ag in metallic silver is 2.89 Å [35]. Short contacts present in coordination complexes are comprised between 2.86–3.07 Å in salicylic acid derivates [35]. Values of 2.85 are described for Ag–Ag metal bonds in di- and tetranuclear silver (I) saccharinate complexes [36]. In other tetranuclear silver units, values comprised between 2.93–3.13 Å are described [50,51]. In polymer structures, distances of 2.92–2.97 Å for 1D, and 2.89 Å and 2.88 Å for 2D polymers are presented [27,37]. Distances of 3.02, 3.12, 3.13 and 3.09 Å are described as short intermetallic contacts [7,26]. Finally a value of 3.30 Å is considered the upper limit for an Ag···Ag contact in coordination chemistry [52], whereas other authors stated that an actual Ag–Ag bond requires a distance of 2.89 Å or lower similar to the distance in metallic silver [35]. Between the five hundred references deposited in the CCDC, distances from 2.65 to 3.36 Å are considered Ag–Ag single bonds.

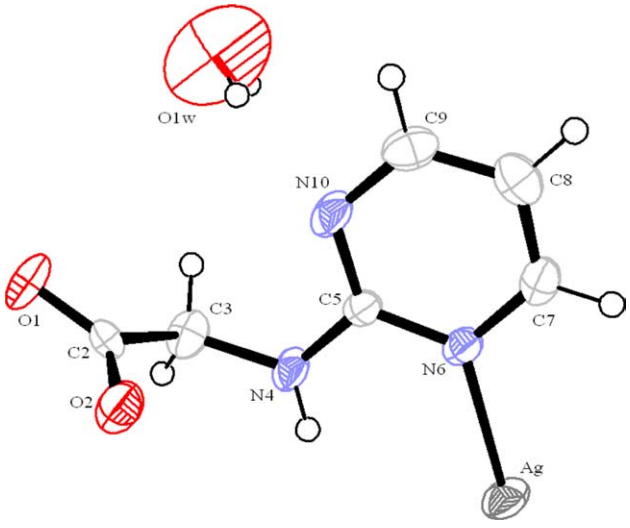

Fig. 2. ORTEP representation of [Ag(pyr-gly)] · 0.5H_2O (**2**).

A strong distortion in the coordination environment of the metal is indicated by the observed bond angles, which vary from 81.7° [O–Ag–O] to approximately 140.0° [O–Ag–N] in the basal plane, and from 63.4° to 98.1° with the apical Ag–Ag bond. The ORTEP

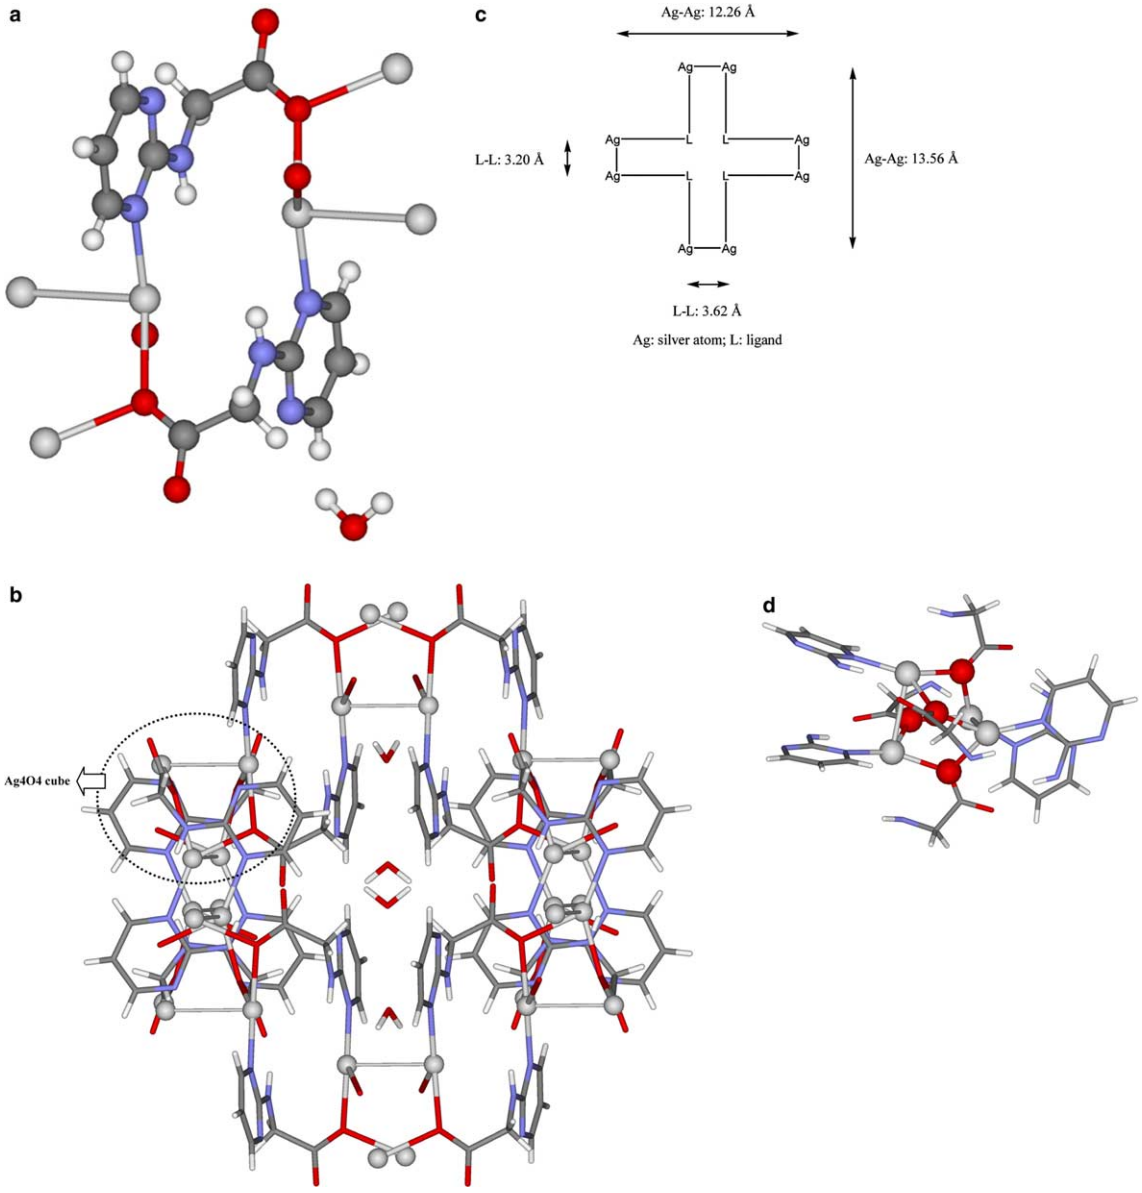

Fig. 3. Representation of the complex [Ag(pyr-gly)] · 0.5H_2O (**2**): (a) rectangular-shaped small holes; (b) bigger cross-type holes; (c) scheme of the hole; (d) cluster Ag_4O_4 very distorted cube.

representation of minimal asymmetric unit is depicted in Fig. 2. Selected bond lengths and angles are summarized in Table 1.

Two different holes, connecting among them are present in the structure (Fig. 3): (i) rectangular-shaped small holes, formed by two pyr-gly molecules and two silver atoms [C(2)–C(2′), 8.31; O(1)–C(3′), 6.92; Ag–N(6′), 3.74; Ag–N(4′), 2.91; and O(1)–C(3), 2.39 Å] (Fig. 3(a)), and (ii) bigger cross-type holes where several water molecules are present inside the channels, formed by four coplanar holes of the first type (Figs. 3(b) and 3(c)). Moreover, the water molecule present in the crystal structure is symmetrically distributed inside the hole, forming two hydrogen bonds with two non coordinated nitrogen of pyrimidine rings of two ligands [dist. N(10)···O(1w) and N(10′)···O(1w), 3.17 and 3.17 Å; angle N(10)···H–O(1w) and N(10′)···H–O(1w), 164.8 and 164.8°] forming a bridge between two pyr-gly molecules. In addition, the perfectly planar structure of the ligand changes to a quasi orthogonal disposition (dihedral angle between pyrimidine and –CH_2–COO– moieties, 80.4°). The three-dimensional network of this structure yields very distorted Ag_4O_4 cube (Fig. 3(d)).

A view of the three-dimensional network according to *a*-axis is depicted in Fig. 4. Four Ag_4O_4 cubes (with an Ag atom or an oxygen atom alternatively occupy the vertices of the distorted hexahedron) nucleate the 3D structure. The framework generates five tubular

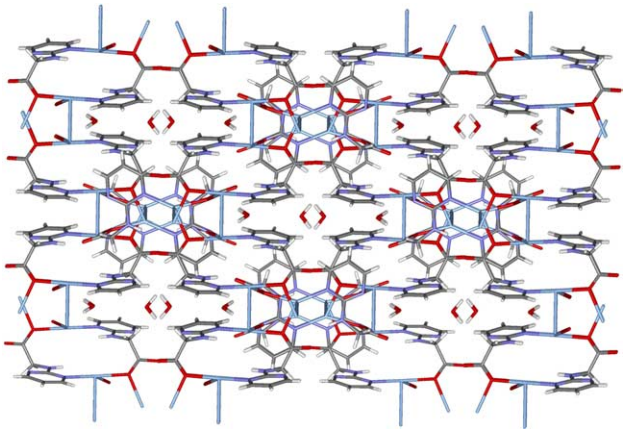

Fig. 4. View of the 3D network in [Ag(pyr-gly)] · 0.5H_2O (**2**) along the *a*-axis.

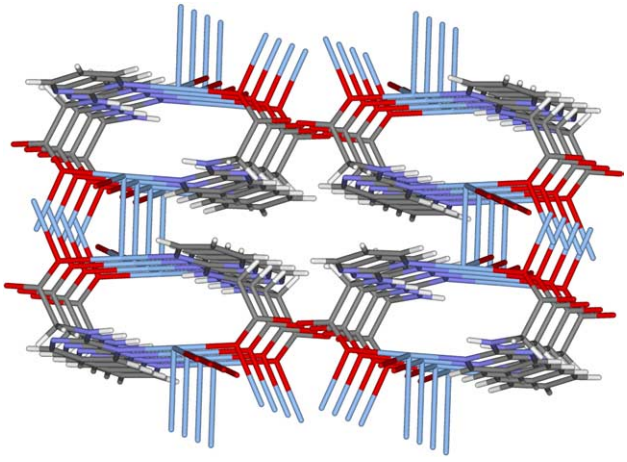

Fig. 5. Simplified structure of **2** showing the tubular cross holes. Different pseudo-layers are showed along the *a*-axis.

cross type holes were four water molecules are retained. One cross is showed in the centre of the figure, and four near the four corners of the picture. Interacting with this cross type holes, without any water molecule, four narrow channels encircled each cross type hole. The pseudo-layer depicted in Fig. 4 is repeated along the *a*-axis, being the Ag_4O_4 cubes the responsible of the 3D character of the structure connecting the apparent 2D planes formed by axis *b* and *c*. The connection between the cube unities is made with ligand cross-links. Each Ag atom is bound to an oxygen and a nitrogen atoms, another Ag atom and to an oxygen atom (from the carboxylic group) alternatively from upper or lower pseudo-layers.

A more clear vision of the channels is depicted in the Fig. 5, were the water molecules are not depicted for clarity. The pseudo layers are shown along the *a*-axis, perpendicular from the frontal *b*–*c* plane.

3.3. Crystal structure of [Ag(I-hip)] · 1.25H_2O (**3**)

The structure of [Ag(I-hip)] · 1.25H_2O (**3**), is shown in Fig. 6(a). This compound present two types of Ag(I) atoms, Ag1 and Ag2.[1] Thus, Ag1 corresponds to a distorted trigonal bipyramid geometry (3 + 2) [three shorter bond distances of Ag–O(carboxylate moiety): Ag–O(1), 2.167(9) Å, Ag–O(2), 2.222(8) Å and Ag–O(2′), 2.490(8) Å; a larger distance Ag1–Ag1, 2.955 Å; and a short contact Ag–I(7′), 3.15 Å]. Moreover, Ag2 possess a distorted octahedral environment (2 + 4) [shorter bond distances Ag–O(carboxylate): Ag–O(1′), 2.217(9) Å and Ag–O(2′), 2.253(9) Å, and larger distances Ag–O(2)(carboxylate), 2.688 Å, Ag–O(5′) (peptide moiety), 2.607 Å and Ag2–Ag2, 3.047 Å. The coordination sphere is completed with a short contact: Ag–I(7′), 3.36 Å].

These distance are in agreement with other carboxylato complexes, for instance [31] Powell refers values comprised between 2.22 and 2.51 Å for the short bonds. A typical value for longer coordination carboxylato bond is 2.757 Å [35]. As we have discussed in the previous complex distances for Ag–Ag are comprised between 2.72 and 3.36 Å [7,26,27,35–37,50–52]. Distances of magnitude like 2.955 and 3.047 Å, present in the compound **3**, are best described as short intermetallic contacts [7,26,50,51].

The number of references about silver–iodine bonds when the iodine is bound to an aryl or alkyl group is very limited in the literature [27–33]. Typical values are comprised between 2.812 and 3.309 Å [27–33]. The distances are longer for iodo-aryl derivatives, as for example 3.138 and 3.229 Å (aryl group: 1,2-diiodobenzene) and 3.309 Å (aryl group: iodobenzene) [31] or 3.053 Å (2,3,5-triiodobenzoato) [27]. Our distance values for Ag–I are 3.15 and 3.36 Å (aryl group: *o*-iodobenzoyl) which implies, in agreement with Powell and Ino [27,31], a weak interaction.

In the crystal packing it is possible to observe bi-dimensional networks build up by overlapped chains of 4 and 8 atoms links (Fig. 6(b)), which are connected between them through I-hip molecules bounded to Ag2 atoms across the peptide moieties. The lateral view of this network (Fig. 6(c)) shows the presence of rectangular-shaped holes along the *c*-axis [7.66 (vertically) and 11.31 Å (horizontally in the figure)], with an aryl ring of I-hip in the front and the top of every hole. The Fig. 6(c) depicts clearly one sheet perpendicular to the *c*-axis that is repeated along.

These bi-dimensional networks are piled in the *c*-direction. The interaction between two layers is made by van der Waals interactions and staking between aryl rings. Water molecules detach the different layers as an intercalation compound. In addition, each layer is

[1] In the crystallographic data we use Ag for Ag1 and Ag′ for Ag2.

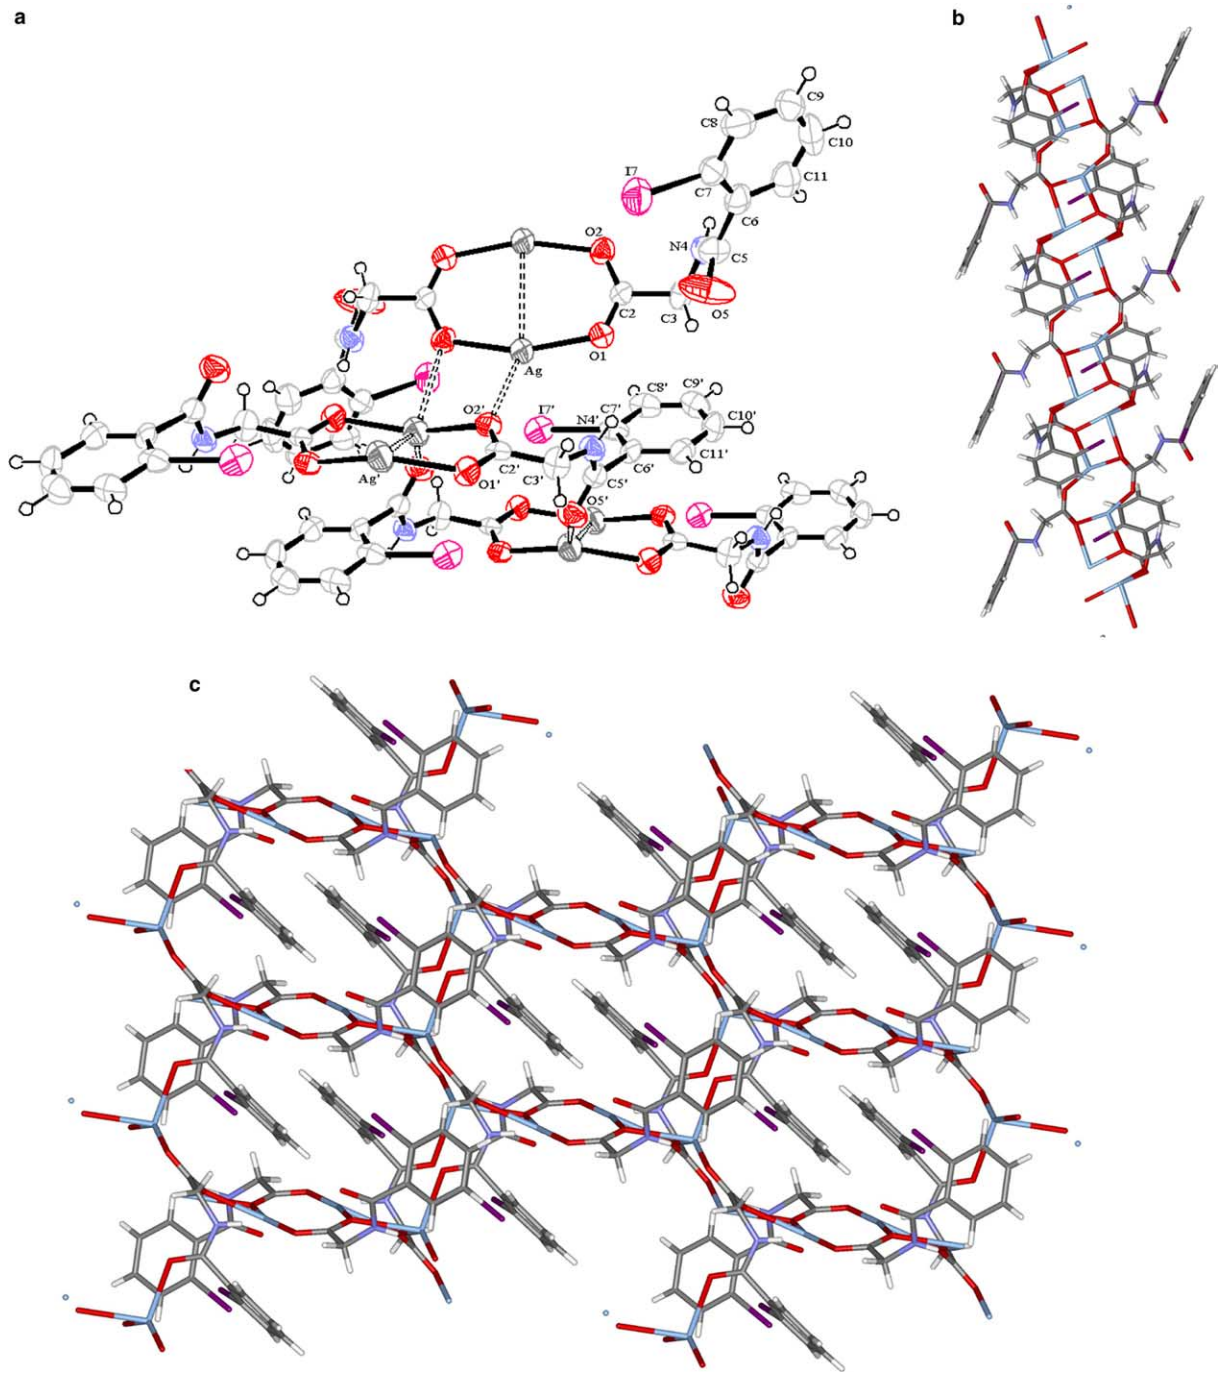

Fig. 6. Representation of the complex [Ag(I-hip)] · 1.25H_2O (**3**): (a) ORTEP; (b) bi-dimensional network builds up by overlapped chains of 4 and 8 atoms links; (c) macrocyclic holes along the *c*-axis.

connected with the next one by stacking (distance, 3.38 Å) [39,53] between series of two aryl rings inside of the channel and preserving it along the *c*-axis (Fig. 7). Selected bond lengths and angles are summarized in Table 1.

It must be mentioned other short contact interactions between iodine atoms and the entourage. Distances I(7)···H of 3.10 and 3.08 Å are distinctly shorter than the van der Waals distance of 3.18 Å determined by Bondi [54]. I(7′)···O(peptide) of 3.47 Å are also observed (van der Waals distance: 3.50 Å). The two interactions can be considered short contacts as it occurs in some described structures [43,55–57]. This ligand shows similar contacts that other related binary and ternary complexes previously described: Thus, binary complex $Zn(I\text{-}hip)_2$ shows a I···C(aromatic ring) contact of 3.56 Å (similar to a C–H···π interaction) shorter than the corresponding van der Waals distance (3.68 Å). On the other hand, ternary derivatives (Zn, Co or Ni)

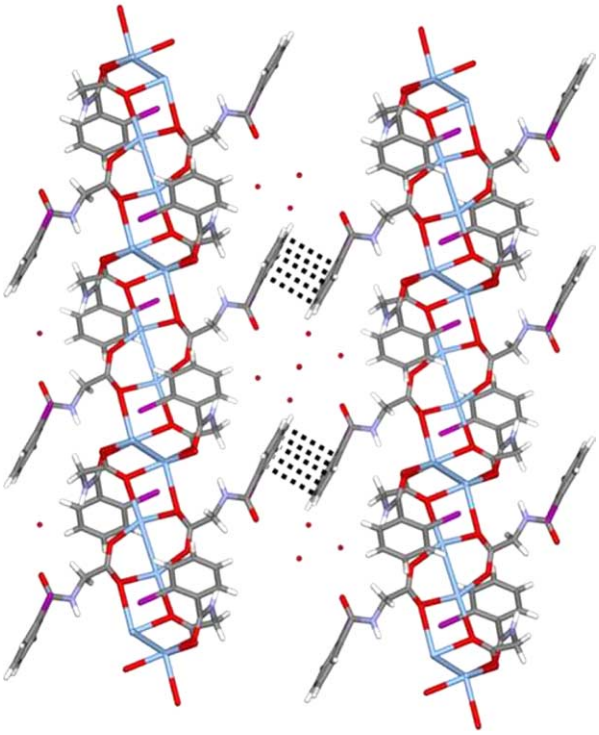

Fig. 7. Two bi-dimensional networks, in complex **3**, connected by stacking (dotted lines). The water molecules detach the different layers.

$(I\text{-hip})_2(ACV)$ with I···I distances of 3.80 and 3.79 Å (van der Waals distance: 3.96 Å) and I···H of 3.15 Å should be mentioned [39].

4. Conclusion

Using relatively flexible *N*-substituted glycine derivatives with *o*-iodobenzoyl or pyrimidyl substituents creates a new possibility in the design of coordination networks. The lack of reactivity of the nitrogen atom of the peptidic bond of I-Hip, the planarity of peptidic bond and the fact that the conformation of the iodo-aryl group is perpendicular to the peptidic group provides an unique ligand with a capability to produce 2D networks with silver(I). Comparison was made with a similar glycine derivative as ligand, with less steric restrictions of bulky susbstituents, but with the same "bite" for coordination (pyr-gly). This ligand instead produces 3D structures.

5. Supplementary material

CCDC Nos. 269071, 269072 and 269073 contains the supplementary crystallographic data for this paper, corresponding to the compounds **1**, **2** and **3**, respectively. These data can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or www.ccdc.cam.ac.uk/conts/retrieving.html.

Acknowledgements

Abstract

The dinuclear compound, $Cu_2(SL)(\mu\text{-}Cl)(Cl)_2(CH_3OH)$ (in which HSL is the chiral ligand *S*-1,2-bis(benzimidazol-2-yl)-1-hydroxyethane), has been synthesized and characterized by X-ray crystallography and infrared spectroscopy. In addition, EPR and magnetic measurements have been performed, and related to the dinuclear structural details. The compound crystallizes in the orthorhombic space group $P2_12_12_1$, with $a = 6.1240(12)$ Å, $b = 15.780(3)$ Å, $c = 20.316(4)$ Å, $V = 1963.3(7)$ Å^3 and $Z = 4$.

The Cu1 ion has a distorted square-pyramidal geometry with the basal plane consisting of a nitrogen atom from the ligand with a Cu–N distance of 1.995(8) Å, a bridging oxygen atom of the ligand with a Cu–O distance of 1.943(8) Å and two chloride anions (of which one is bridging to Cu2) with Cu–Cl distances of 2.259(3) and 2.351(3) Å. The apical position is occupied by a third chloride atom (Cl3), which is also connected to Cu2 from a neighbouring unit, at a semi-coordinating distance of 3.114(3) Å.

The second copper atom, Cu2, has also a distorted square-pyramidal geometry with the basal plane also consisting of a nitrogen atom from the ligand with a Cu–N distance of 1.960(8) Å, a bridging oxygen atom of the ligand with a Cu–O distance of 1.934(8) Å and two chloride atoms (of which one is bridging to Cu1) with Cu–Cl distances of 2.258(3) and 2.309(3) Å. The apical position is occupied by an oxygen atom of a coordinating methanol molecule at a distance of 2.392(3) Å. The bridging Cl3 atom, forms a zig-zag chain between Cu1 and Cu2 from different units forming an extended chain with a Cu···Cu distance of 4.2114(19) Å. The intramolecular Cu···Cu distance is 3.2301(18) Å.

At room temperature the title compound displays an EPR silent behaviour and magnetic susceptibility measurements, down to 5 K, agree with a strong overall antiferromagnetic interaction having a large singlet-triplet splitting ($J = -348$ cm^{-1}).

1. Introduction

The coordination chemistry of azoles acting as ligands in copper(II) compounds in the context of modelling biological systems has gained much interest in the past decades [1–4]. In this respect bis(2-benzimidazoles) have received much attention for their wide-ranging antivirus activity [5,6], their importance in selective ion-exchange resins [7,8] and the possibility to form supramolecular aggregates with d^{10} metal ions [9].

Previously, spectroscopic and magnetic properties, as well as some structures of copper(II) coordination compounds with bis(2-benzimidazolyl)alkanes and

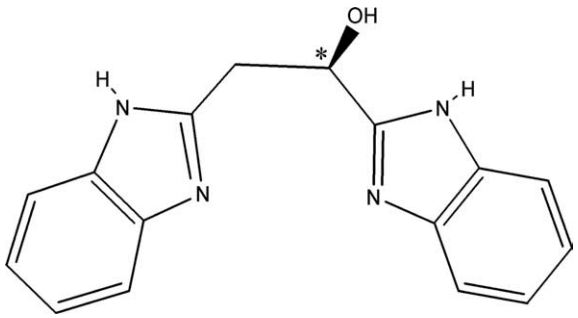

Scheme 1. 1,2-bis(benzimidazol-2-yl)-1-hydroxyethane (* = chiral atom).

zsome substituted bis(2-benzimidazolyl)alkanes have been reported [10–20] by others and us. In one of the earlier studies, we synthesized racemic mixture of a chiral, chelating ligand, i.e., 1,2-bis(benzimidazol-2-yl)-1-hydroxyethane (abbreviated HRSL) (see Scheme 1) [19]. The chiral centre is present at C*, allowing also the study of the (*R*) and (*S*) isomers of this ligand, apart from the (*RS*) mixture. In this earlier study, a number of transition metal compounds were synthesized from the racemic ligand. Also two X-ray crystal structures were reported, one of a tetranuclear copper(II) compound and one of a mononuclear Ni(II) compound. In both cases, the ligand acts as a tridentate chelating ligand with dehydronation of the alcohol oxygen.

The present study describes a new Cu(II) dinuclear compound, using the *S* isomer of the ligand. The compound $Cu_2(SL)(\mu\text{-}Cl)(Cl)_2(CH_3OH)$ contains a bridging chloride ion in addition to the trinuclear chelating ligand. This compound was characterised by X-ray structure analysis, ligand-field and EPR. Also the magnetic susceptibility was investigated and discussed.

2. Experimental

2.1. General

C,H,N determinations were performed on a Perkin–Elmer 2400 Series II analyzer. Ligand field spectra were obtained on a Perkin–Elmer Lambda900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. X-band powder EPR spectra were obtained on a Jeol RE2x electron spin resonance spectrometer using DPPH ($g = 2.0036$) as a standard. FTIR spectra were obtained on a Perkin–Elmer Paragon 1000 FTIR spectrophotometer equipped with a Golden Gate ATR device, using the reflectance technique (4000–300 cm^{-1}, res. 4 cm^{-1}). Magnetic susceptibility measurement (5–300 K) were carried out (at 0.1 T) using a Quantum Design MPMS-5S SQUID magnetometer. Data were corrected for the magnetisation of the sample holder and for diamagnetic contributions, which were estimated from Pascal constants.

2.2. Synthesis

The ligands HRSL and HSL (the racemic mixture and the *S* form, respectively, of 1,2-bis(benzimidazol-2-yl)-1-hydroxyethane) and the coordination compounds were synthesized as described in the literature [19]. After dehydronation the abbreviations RSL and SL, respectively, are being used. The Cu(II) chloride compound with the ligand HRSL (the racemic mixture) only provides a powder and no crystalline material could be obtained. Fortunately, very small green crystals were obtained when the ligand HSL and methanol as a solvent were used and these crystals were characterized by elemental analysis, Yield: 82%, Elemental *Anal*. Calc. for $C_{17}H_{17}Cl_3Cu_2N_4O_2$: C, 38.0; H, 3.1; N, 10.4. Found: C, 37.6; H, 3.2; N, 10.3%.

2.3. X-ray crystallography

A crystal was selected and mounted to the glass fiber using the oil-drop method; data were collected on a Nonius KappaCCD diffractometer (graphite-monochromated Mo Kα radiation). The intensity data were corrected for Lorentz and polarization effects, for absorption and extinction. The structures were solved by direct methods. The programs COLLECT [21], SHELXS-97 [22], SHELXL-97 [23] were used for data reduction, structure solution and structure refinement,

3. Results and discussion

3.1. Crystal structure of $Cu_2(SL)(\mu\text{-}Cl)(Cl)_2(CH_3OH)$

The structure of the title compound is depicted in Fig. 1, with relevant bond length and bond angle information given in Table 2. Both Cu ions have both a slightly different five-coordination geometry. The Cu1 atom has the basal plane consisting of a nitrogen atom from the ligand with a Cu–N distance of 1.995(8) Å, a bridging oxygen atom of the ligand with a Cu–O distance of 1.943(8) Å and two chloride atoms (of which one is bridging to Cu2) with Cu–Cl distances of 2.259(3) and 2.351(3) Å. The angles of the basal plane are 167.1(2)° and 167.8(2)°. The apical position is occupied by a third chloride atom (Cl3), which is also connected to Cu2 ion from a neighbouring unit, at a semi-coordinating distance of 3.114(3) Å. The intermolecular Cu···Cu distance is 4.2114(19), while the intramolecular Cu···Cu distance is 3.2301(18) Å.

The second copper atom, Cu2, has the basal plane also consisting of a nitrogen atom from the ligand with a Cu–N distance of 1.960(8) Å, a bridging oxygen atom of the ligand with a Cu–O distance of 1.934(8) Å and two chloride atoms (of which one is bridging to Cu1) with Cu–Cl distances of 2.258(3) and 2.309(3) Å. The trans angles of the basal plane are 161.7(2)° and 166.3(3)°. The apical position is occupied by an oxygen atom of a coordinating methanol molecule at a distance of 2.392(3) Å.

The degree of distortion in five-coordinated compounds can be described by the structural parameter τ (τ describes the relative amount of trigonality; $\tau = 0$ for square pyramidal and $\tau = 1$ for trigonal bipyramidal) [24]. This value is only 0.01 and 0.08 for Cu1 and Cu2, respectively, providing for both copper compounds almost a perfect square pyramidal geometry. The bridging Cl3 atom, forms a zig-zag chain between Cu1 and Cu2 from different units forming a extended chain (see Fig. 2).

The crystal lattice is further stabilised by an extensive H-bonding system between an imidazole nitrogen atom and the methoxo oxygen atom (N18···O1 2.8917 Å), between an imidazole nitrogen atom and a chloride anion (N26···Cl2 3.295(8) Å) and between the methoxo oxygen atom and a chloride anion (O1···Cl3 3.2518 Å). More details are given in Table 2.

3.2. Ligand field spectroscopy and EPR

The ligand-field transition band measured as a solid with the diffuse reflectance technique is not quite informative and is observed as a very broad tail-shaped band with a maximum at 14.1×10^3 cm^{-1}, which is a normal ligand field transition for distorted square pyramidal geometries [25].

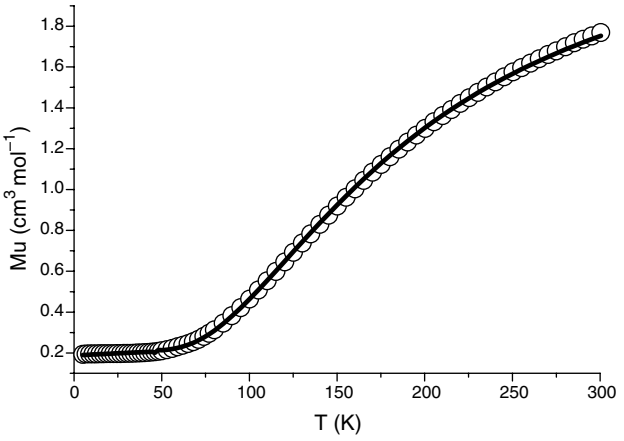

Fig. 3. A plot of the temperature dependence of μ_{eff} vs. T for $Cu_2(SL)(\mu\text{-}Cl)(Cl)_2(CH_3OH)$. The solid line represents the calculated curve for the parameters $J = -348$ cm^{-1}, $g = 2.04$, $zJ' = -0.015$ cm^{-1} (see text).

[b] Two crystallographic independent dinuclear units present in the unitcell.

The EPR of the title compound, measured as a polycrystalline powder at RT is weak and very broad and almost EPR silent, while at 77 K only a very weak mononuclear signal is observed with $g_\perp = 2.06$, $g_\parallel = 2.28$ and $A_\parallel = 12.7$ mT. The absence of an EPR signal indicates a strong AF interaction (vide infra), while the weak signal at 77 K most probably originates from a small mononuclear impurity, which is usually present in dinuclear compounds, as has been also observed earlier [19]. No triplet signals are visible, indicating that the zero-field splitting is larger then the EPR frequency.

3.3. Magnetic properties

The magnetic susceptibility of a powdered sample was measured from 5 to 300 K. The magnetic properties of the complex are depicted in Fig. 3 in the form of μ_{eff} versus T for two Cu(II) ions. At 300 K, the μ_{eff} starts at a value of about 1.76 BM (much below the spin only value for two Cu ions of 2.83 BM) and the μ_{eff} gradually decreases at 50 K to about 0.10 BM and stays then constant till 5 K. This behaviour agrees with a strong antiferromagnetic interaction.

The theoretical expression for the magnetic susceptibility for two interacting $S = 1/2$ centres, which is based on the general Hamiltonian [26] is: $H_{ex} = -JS_1S_2$, in which the exchange parameter J, is negative for antiferromagnetic and positive for ferromagnetic interaction. The magnetic data were fitted to the equation given in the literature for dinuclear copper compounds [26]:

$$\chi_m = (2N\mathrm{g}^2\beta^2)[kT - (2zJ'/(3 + \exp(-J/kT)))]^{-1} \times [3 + \exp(-J/kT)]^{-1}(1 - p) + \chi_p p,$$

in which N, g, β, k and T have their usual meanings [26]. The parameter p denotes the fraction of paramagnetic impurity in the sample and zJ' the interaction between neighbouring dinuclear identities. The fit was accomplished by minimisation of $R = (\chi_m T_{calc} - \chi_m T_{obs})^2/(\chi_m T_{obs})^2$ by a least-squares procedure. The best fit, depicted in Fig. 3 as a solid line, was obtained for $J = -348$ cm^{-1}, $g = 2.04$, $zJ' = -0.015$ cm^{-1}, $p = 0.006$, with a final R of 3.0×10^{-2}.

The magnitude of the antiferromagnetic interaction also corresponds very nicely with the preliminary results for the compound $Cu_2(RSL)Cl(Cl)_2(H_2O)$, a compound for which no X-ray crystal structure could be obtained in our earlier study [19].

4. Concluding remarks

A new dinuclear chloride-bridged Cu(II) compound prepared from the tridentate chelating ligand HSL is described. The dinuclear unit contains two Cu(II) ions with different geometries and a third chloride anion, which is bridging between two Cu ions from different units forming a polymeric zig-zag chain.

The magnetic interaction between the two Cu ions in the dinuclear unit is strongly antiferromagnetic ($J = -348$ cm^{-1}). In the literature much research has been undertaken to describe the relationship between the Cu–X–Cu (where X = OH, MeO, Cl, etc.) angle and the magnetic interaction [27–36]. A number of Cu(II) dinuclear compounds which have the same bridge and which are structurally and magnetically characterised are summarised in Table 3. As can be seen from Table 3 the Cu–Cl–Cu bridge is in all cases <90°, which contribution should be weakly ferromagnetic [36], while the Cu–O–Cu angle is in all cases >110° and this contribution should be the strongly antiferromagnetic [35]. In total the "overall" magnetic exchange interaction is then strong antiferromagnetic, which is in fact observed in all five compounds.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as Supplementary Publication No. CCDC-273762. Copies of available material can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk.

Abstract

The reactions of diorganotin oxides with *o*-diphenylphosphinobenzoic acid ([PPh_2(*o*-C_6H_4COOH)], LH) in 1:1 stoichiometry afforded tetraorganodistannoxanes [{$R_2Sn(OOC\text{-}C_6H_4PPh_2)$}$_2O$]$_2$ (R = Me, Et, Pr^n, Bu^n). *o*-(Diphenylphosphino)benzoic acid complexes of palladium (II) and platinum (II) with the formulae [$MCl_2(LH)_2$], [$MCl_2(PR_3)(LH)$] (PR_3 = PEt_3, PBu_3, $PMePh_2$; M = Pd, Pt) have been prepared. Reactions of [{$Bu_2Sn(OOC\text{-}C_6H_4PPh_2)$}$_2O$]$_2$ with $PtCl_2(PhCN)_2$ in 1:1 and 1:2 ratio gave a complex mixture of products from which [$Pt(O_2CC_6H_4PPh_2)_2$] was isolated. All the complexes have been characterized by elemental analyses, IR, NMR (^{1}H, ^{13}C{^{1}H}, ^{31}P{^{1}H} and ^{119}Sn{^{1}H}) and UV–Vis spectroscopy. The stereochemistry of these complexes has been deduced from spectroscopic data. The structures of [{$Bu_2Sn(OOC\text{-}C_6H_4PPh_2)$}$_2O$]$_2$ and [$Pt(O_2CC_6H_4PPh_2)_2$] have been established by X-ray crystallography.

1. Introduction

Functionalized phosphines, such as *o*-(diphenylphosphino)phenol [1–4], *o*-(diphenylphosphino)benzaldehyde [5–10], *o*-(diphenylphosphino)benzoic acid [11–16] and several other related molecules [17–21], represent a versatile family of ligands. They are capable of forming complexes of variable stoichiometries and in stabilizing hetero-metallic complexes containing metals of different reactivities. Classical and organometallic complexes derived from these ligands display several interesting and useful properties [22,23]. *o*-(Diphenylphosphino)benzoic acid (**1**) is of particular interest as the hydrophilic carboxylate group would give water soluble complexes which can be employed in phase-transfer catalysis. The mixed donor set would permit isolation of hetero-bi and -poly-nuclear complexes. Dicarboxylato tetraorganodistannoxanes, obtained readily by the reaction of R_2SnO with carboxylic acids in 1:1 ratio [24–26], as well as palladium phosphine complexes have been employed as homogeneous catalysts [27–30]. With this objective reactions of **1** with diorganotin oxides and palladium/platinum complexes have been investigated and the results are reported herein.

2. Experimental

2.1. Materials and methods

o-(Diphenylphosphino)benzoic acid [11], Na_2PdCl_4, $[PdCl_2(MeCN)_2]$, $[PtCl_2(PhCN)_2]$ were prepared by the literature procedures [31]. All the reactions were carried out under a nitrogen atmosphere in dry and distilled analytical grade solvents. Microanalyses were carried out in the Analytical Chemistry Division, BARC. The ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ and $^{119}Sn\{^1H\}$ NMR spectra were recorded on a Bruker DPX-300 spectrometer operating at 300, 75.47, 121.49 and 111.82 MHz, respectively. Chemical shifts are relative to the internal chloroform peak ($\delta = 7.26$ ppm for ^1H; $\delta = 77.0$ ppm for ^{13}C) external Me_4Sn in C_6D_6 for $^{119}Sn\{^1H\}$ and external H_3PO_4 (85%) for $^{31}P\{^1H\}$ NMR. IR spectra were recorded as Nujol mulls using CsI plates on a Bomen-102 FT IR spectrometer in the range 200–4000 cm^{-1}. UV–Vis absorption spectra were recorded on a JASCO V-530 spectrophotometer.

2.2. Synthesis of ligand and complexes

2.2.1. *o*-(Diphenylphosphino)benzoic acid [$PPh_2(o\text{-}C_6H_4COOH)$] (**1**)

Sodium metal (6.02 g, 261.79 mmol) in a three necked round bottom flask was dissolved in liq. NH_3 resulting in a blue solution (~100 cm^3) and the solution was cooled to −78 °C. To this PPh_3 (34.3 g, 130.91 mmol) was added in portions with stirring resulting in the formation of orange-red $NaPPh_2$ solution. To this *o*-chlorobenzoic acid (20.65 g, 131.93 mmol) was added in portions followed by addition of dry THF (150 cm^3). The reaction mixture was brought to room temperature whereupon ammonia evaporates and the reaction mixture turned golden yellow. The solid residue was dissolved in distilled water (~500 cm^3) which was washed with diethylether (3×100 cm^3). pH of the aqueous phase was adjusted to 2 by addition of conc. HCl (~20 cm^3). From this, the desired compound was extracted with dichloromethane (4×75 cm^3), which was evaporated and from the residue **1** was precipitated by addition of methanol. The precipitate was filtered through G-3 filter and then dried in vacuo. This was recrystallized from hot methanol as pale yellow needle shaped crystals in 38% (15.26 g) yield [11]. Melting point 166 °C. *Anal.* Calc. for $C_{19}H_{15}O_2P$: C, 74.5; H, 4.9. Found: C, 75.1; H, 5.1%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 237 (10085), 257 (6228), 324 (1762). $^{13}C\{^1H\}$ NMR in $CDCl_3$: 128.3 (br, C-3, 5 (Ph), C-4, 6 (C_6H_4)), 131.6 (br, C-5, C_6H_4); 131.8 (d, 66 Hz, C-1, Ph); 133.8 (d, 21 Hz, C-2, 6 (Ph), C-3 (C_6H_4)); 134.1 (s, C-4, Ph); 141.4 (d, 28 Hz, C-2, C_6H_4); 170.3 (CO).

2.2.2. [{$R_2Sn(OOC\text{-}C_6H_4PPh_2)$}$_2O$]$_2$

To a benzene solution (50 cm^3) of $PPh_2(C_6H_4COOH)$ (1.057 g, 3.45 mmol), Bu^n_2SnO (869 mg, 3.49 mmol) was added and the whole was refluxed for 8 h on a Dean and Stark assembly. A clear pale yellow solution was obtained. The solvent was evaporated and the compound was recrystallized twice from CH_2Cl_2–hexane mixture to give a white cubic crystalline compound in 43% yield. Melting point 115 °C. *Anal.* Calc. for $C_{108}H_{128}O_{10}P_4Sn_4$: C, 59.2; H, 6.0. Found: C, 58.5; H, 5.8%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 238 (47388), 330 (10064), 378 (2975). $^{13}C\{^1H\}$ NMR in $CDCl_3$ δ: 13.6 (s, Sn–CCCMe); 26.7, 26.9 (each s, Sn–$CCCH_2$); 27.3, 27.7 (each s, Sn–CCH_2); 28.4, 30.1 ($SnCH_2$); 130.9 (d, 10 Hz); 133.8 (d, 20 Hz); 134.3 (s); 138.2 (2-C of C_6H_4); 139.5 (d, 12 Hz); 173.3 (s, CO).

2.2.3. [{$Pr^n_2Sn(OOC\text{-}C_6H_4PPh_2)$}$_2O$]$_2$

Prepared similar to Section 2.2.2 and recrystallized from CH_2Cl_2–hexane in 37% yield. Melting point 205 °C. *Anal.* Calc. for $C_{100}H_{112}O_{10}P_4Sn_4$: C, 57.8; H, 5.6. Found: C, 57.3; H, 5.6%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 237 (41479), 270 (sh), 322 (sh).

2.2.4. [{$Et_2Sn(OOC\text{-}C_6H_4PPh_2)$}$_2O$]$_2$

Prepared similar to Section 2.2.2 and recrystallized from toluene–hexane in 34% yield. Melting point 173 °C. *Anal.* Calc. for $C_{92}H_{96}O_{10}P_4Sn_4$: C, 56.2; H, 5.1. Found: C, 56.3; H, 5.5%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 236 (32230), 271 (sh), 334 (sh).

2.2.5. [{$Me_2Sn(OOC\text{-}C_6H_4PPh_2)$}$_2O$]$_2$

To facilitate dissociation of Me_2SnO, methanol (~5 cm^3) was also added in the reaction. Product was recrystallized twice from benzene–hexane as colorless crystals in 36% yield. Melting point 239 °C. *Anal.* Calc. for $C_{84}H_{80}O_{10}P_4Sn_4$: C, 54.5; H, 4.6. Found: C, 53.2; H, 4.9%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 236 (29644), 267 (sh), 324 (sh). $^{13}C\{^1H\}$ NMR in $CDCl_3$ δ: 6.6 (s, Sn–Me; $^1J(^{119/117}Sn–^{13}C) = 721$ Hz), 11.3 (s, Sn–Me; $^1J(^{119/117}Sn–^{13}C) = 846$ Hz); 128.2, 128.4, 131.2 (d, 27 Hz); 134.0 (d, 21 Hz); 137.2 (d, 12 Hz); 139.2 (d, 12 Hz); 140.1 (d, 24 Hz, C-2, C_6H_4); 173.5 (s, CO).

2.2.6. [$PdCl_2${$PPh_2(C_6H_4COOH)$}$_2$]

To a stirred acetone solution of $[PdCl_2(MeCN)_2]$ (342 mg, 1.32 mmol), a solution of $PPh_2(C_6H_4\text{-}COOH)$ (808 mg, 2.64 mmol) was added, whereupon a yellow precipitate formed. The whole was stirred for 3 h. The precipitate was filtered out using a G-3 fritz, washed with hexane and dried in vacuo. The product was recrystallized from DMF–ether mixture to give yellowish orange solid in 84% (879 mg) yield. Melting point 182 °C (dec). *Anal.* Calc. for $C_{38}H_{30}Cl_2O_4P_2Pd$: C, 57.8; H, 3.8. Found: C, 58.3; H, 4.3%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 240 (15929), 292 (sh), 349 (13590).

2.2.7. $[PtCl_2\{PPh_2(C_6H_4COOH)\}_2]$

Prepared from $PtCl_2(PhCN)_2$ and $Ph_2P(C_6H_4COOH)$ in 81% yield. Melting point 225 °C. *Anal.* Calc. for $C_{38}H_{30}Cl_2O_4P_2Pt$: C, 52.0; H, 3.4. Found: C, 52.3; H, 3.6%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 232 (6673), 290 (3575).

2.2.8. $[PdCl_2(PEt_3)\{PPh_2(C_6H_4COOH)\}]$

To a CH_2Cl_2 stirred solution of $[Pd_2Cl_2(\mu\text{-}Cl)_2(PEt_3)_2]$ (34 mg, 0.057 mmol), $PPh_2(C_6H_4\text{-}COOH)$ (36 mg, 0.12 mmol) was added with stirring. Orange solution changed instantly to yellow. The whole was stirred for 2 h. The solvent was evaporated in vacuo and the residue was recrystallized from CH_2Cl_2–hexane mixture in 87% (61 mg) yield. Melting point 148 °C (dec). *Anal.* Calc. for $C_{25}H_{30}Cl_2O_2P_2Pd$: C, 49.9; H, 5.0. Found: C, 50.5; H, 5.4%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 238 (21 616), 293 (sh), 320 (22 055), 337 (sh). $^{13}C\{^1H\}$ NMR in $CDCl_3$ δ: 8.0 (s, $PCCH_3$); 14.2 (d, 29 Hz, PCH_2); 128.0 (d, 10 Hz), 130.0 (d, 13 Hz); 131.1 (s); 131.2 (d, 5 Hz), 131.4 (br), 132.4 (d, 6 Hz); 133.2 (d, 7 Hz), 134.4 (s), 135.2 (d, 11 Hz); 170.0 (s, CO).

2.2.9. $[PdCl_2(PMePh_2)\{PPh_2(C_6H_4COOH)\}]$

Prepared similar to Section 2.2.8 in 80% yield as yellow powder. Melting point 128 °C (dec). *Anal.* Calc. for $C_{32}H_{28}Cl_2O_2P_2Pd$: C, 56.2; H, 4.1. Found: C, 55.5; H, 4.6%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 237 (18 798), 270 (10 244), 345 (8364).

2.2.10. $[PtCl_2(PBu_3)\{PPh_2(C_6H_4COOH)\}]$

Prepared similar to Section 2.2.8 in 85% yield as yellow powder. Melting point 168 °C (dec). *Anal.* Calc. for $C_{31}H_{42}Cl_2O_2P_2Pt$: C, 48.1; H, 5.5. Found: C, 48.8; H, 5.7%. UV–Vis λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$): 238 (14 678), 268 (13 365).

2.2.11. Reactions of $[\{Bu_2Sn(OOC\text{-}C_6H_4PPh_2)\}_2O]_2$ with $PtCl_2(PhCN)_2$

To a stirred CH_2Cl_2 solution (10 cm^3) of $PtCl_2(PhCN)_2$ (53 mg, 0.11 mmol), a solution of $[\{Bu_2Sn(OOC\text{-}C_6H_4PPh_2)\}_2O]_2$ (249 mg, 0.11 mmol) was added slowly at room temperature. The solvent was evaporated under vacuum and the pale yellow residue was investigated by NMR spectroscopy. After three recrystallizations, $[Pt(O_2CC_6H_4PPh_2)_2]$ was isolated, which was coordinated with two water molecules. Melting point 220 °C (dec). *Anal.* Calc. for $C_{38}H_{32}O_6P_2Pt$: C, 54.2; H, 3.8. Found: C, 52.1; H, 3.6%. $^{13}C\{^1H\}$ NMR: 125.2 (d, 70 Hz); 127.0 (d, 64 Hz); 128.8 (d, 5 Hz); 128.9 (d, 5 Hz), 130.6 (d, 82 Hz), 132.0 (s), 134.1 (m, three peeks); 166.9 (CO). Similarly reaction between $PtCl_2(PhCN)_2$ (63 mg, 0.13 mmol) and $[\{Bu_2Sn(OOC\text{-}C_6H_4PPh_2)\}_2O]_2$ (148 mg, 0.07 mmol) in 2:1 molar ratio was carried out.

2.3. Crystallography

X-ray data of a colorless single crystal of $[\{Bu_2Sn(O_2CC_6H_4PPh_2)\}_2O]_2\cdot 2CH_2Cl_2$ were collected on a Rigaku AFC-6S diffractometer (at 103(2) K) using graphite monochromated Mo-Kα radiation. The intensity data were corrected for Lorentz and polarization effects [32]. Semi-empirical absorptions correction was based on ψ scan of several reflections. The structure was solved by direct methods and refined by full-matrix least squares on F^2. All calculations were performed using the TEXSAN [33] crystallographic software package of the Molecular Structure Corporation.

The unit cell parameters and the intensity data for a colorless single crystal of $[Pt(O_2CC_6H_4PPh_2)_2]\cdot 2H_2O$ were collected at −170 °C on a Bruker Smart 1K CCD diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), employing the ω scan technique. The intensity data were corrected for Lorentz, polarization and absorption effects. The structure was solved and refined with SHELX program [34]. The non-hydrogen atoms were refined anisotropically. One water molecule is disordered so the site occupancy was shared. Selected crystallographic data are given in Table 1.

3. Results and discussion

3.1. Synthesis and spectroscopy

Reactions of diorganotin oxides with *o*-(diphenylphosphino)benzoic acid in 1:1 stoichiometry afforded complexes of composition $[\{R_2Sn(O_2CC_6H_4PPh_2)\}_2O]_2$ as colorless crystalline solids. The IR spectra exhibited absorption due to $\nu_{C=O}$ in the region 1644–1590 cm^{-1}. Stretching vibrations associated with the Sn–O and Sn–C are tentatively assigned in the regions 490–650 and 570–650 cm^{-1}, respectively. The Et, Pr^n and Bu^n groups attached to the tin atom exhibited multiplet or broad resonances in their ^1H NMR spectra (Table 2). For the dimethyl tin derivative, two methyl tin resonances were observed both in the ^1H and $^{13}C\{^1H\}$ NMR spectra as expected for dicarboxylato tetraorganostannoxanes. The ^{119}Sn NMR spectra of $[\{R_2Sn(OOC\text{-}C_6H_4PPh_2)\}_2O]_2$ (R = Me; $\delta = -174$, -200 ppm; R = Bu; $\delta = -201$, -208 ppm) displayed two well separated resonances. The NMR data clearly favor the formation of familiar dicarboxylato tetraorganodistannoxanes [25,26,35] and was unambiguously established by X-ray diffraction analysis of $[\{Bu_2Sn(O_2CC_6H_4PPh_2)\}_2O]_2$ (see later).

Treatment of $[MCl_2(RCN)_2]$ (M = Pd or Pt; R = Me or Ph) with two equivalents of *o*-diphenylphosphinobenzoic acid readily yields poorly soluble $[MCl_2(PPh_2C_6H_4\text{-}COOH)_2]$. The IR spectrum of $[PtCl_2(PPh_2C_6H_4\text{-}COOH)_2]$ showed an absorption at 346 cm^{-1} attributable

[b] NMR in dmso-d_6.

to υ(Pt–Cl) indicating a *trans* configuration. This is further substantiated by the ^1J(Pt–P) coupling constant of 2911 Hz. It is worthnoting that the complex was isolated exclusively as the *trans* isomer. The reaction of $PtCl_2$(COD) with **1**, however, has been reported to afford *cis* isomer with an unusually small ^1J(Pt–P) of 3305 Hz as compared to other analogous derivatives (~3650 Hz) [16]. Isomerization of $MCl_2(PR_3)_2$ (M = Pd or Pt) in the presence of catalytic amounts of free phosphine is well established. Thus $^{31}P\{^1H\}$ NMR spectrum of

trans-[$PtCl_2(PPh_2C_6H_4$-$COOH)_2$] was monitored in the presence of catalytic amounts of $PPh_2C_6H_4$-COOH. The spectrum recorded immediately after mixing of phosphinobenzoic acid, besides parent complex and free phosphine, exhibited an additional resonance due to $Pt(O_2CC_6H_4PPh_2)_2$. An equilibrium was established after a few hours which did not change the concentration of the later complex on prolong standing (48 h) at room temperature. The palladium complex [$PdCl_2(Ph_2$-$PC_6H_4COOH)_2$] displayed three IR absorptions at $\sim$350 cm^{-1} due to ν_{Pd-Cl} suggesting the formation of a mixture of *cis* and *trans* isomers. The $^{31}P\{^1H\}$ NMR spectrum of [$PdCl_2(PPh_2C_6H_4$-$COOH)_2$] exhibited peaks at δ 21.2, 25.7 ppm substantiating the presence of *cis* and *trans* isomers. The ^1H NMR spectra in DMSO-d_6 exhibited multiplets for aromatic protons in the region 6.48–8.11 ppm (Table 2). The CO absorptions are little influenced as compared to the absorptions for free ligand.

The UV–Vis spectra in CH_2Cl_2 exhibited absorption due to π–π* charge transfer transitions in case of $PPh_2C_6H_4$-COOH and in the palladium and platinum complexes the mixed metal-to-ligand charge transfer (MLCT) and π–π* are observed. The representative spectra are shown in Fig. 1.

To assess suitability of $[\{Bu_2Sn(O_2CC_6H_4PPh_2)\}_2O]_2$ (**2**) as a metallo-ligand by coordinating dangling free phosphine, its reactions with $PtCl_2(PhCN)_2$ in different stoichiometries were investigated. The reactions of **2** with $PtCl_2(PhCN)_2$ in 1:1 and 1:2 molar ratios were monitored by NMR spectroscopy. $^{31}P\{^1H\}$ and $^{119}Sn\{^1H\}$ NMR spectra of both the reactions showed the formation of a complex mixture of products. In this mixture, at least three products are readily identifiable – $Pt(O_2CC_6H_4PPh_2)_2$, *trans*-$PtCl_2(PPh_2C_6H_4COOH)_2$ and a product showing ^{31}P resonance at δ 11.5 ppm (^1J(Pt–P) 2865 Hz) which can be assigned tentatively for *trans*-[$PtCl_2(\{Bu_2Sn(O_2CC_6H_4PPh_2)\}_2O)_2$]. The latter product dominates in the reaction carried out in 1:2 molar ratio. The former complex could be isolated by repeated recrystallization and its structure was established by X-ray crystallography (see later). The ^{119}Sn NMR spectra of these reactions did not show peaks due to **2**, but resonances attributable to asymmetric tetraorganodistannoxanes as well as for $[(Bu_2SnCl)_2O\}_2$-$O]_2$ (^{119}Sn −89, −138 ppm) can be identified. The ^{119}Sn resonances at −118 and −163 ppm may be assigned tentatively to $[Bu_2SnClOSn(O_2CC_6H_4PPh_2)Bu_2]_2$. From these reactions, it is evident that ligand scrambling from tetraorganodistannoxane (**2**) and "$PtCl_2$" fragment takes place. Ligand scrambling in tetraorganodistannoxanes has been reported by us earlier [36].

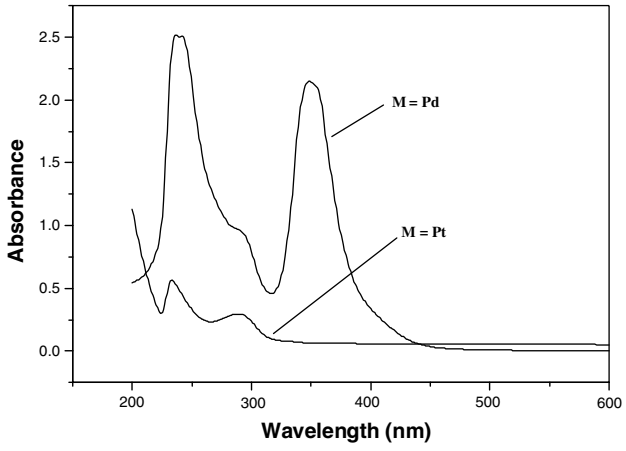

Fig. 1. UV–Vis spectra of $[MCl_2(Ph_2PC_6H_4$-$COOH)_2]$ in CH_2Cl_2.

3.2. X-ray crystallography

3.2.1. Crystal structure of $[\{Bu_2Sn(O_2CC_6H_4PPh_2)\}_2O]_2$

The X-ray structural analysis of [$\{Bu_2Sn(O_2CC_6H_4P$-$Ph_2)\}_2O]_2$ revealed the dicarboxylato tetraorganodistannoxane formulation. The structure, shown in Fig. 2 with crystallographic numbering scheme, is similar to related complexes [25,26,37–42]. The molecule consists of a centrosymmetric (crystallographically imposed) planar four-membered Sn_2O_2 ring with the bridging oxygens further bonded to two "$Bu_2Sn(O_2CC_6H_4PPh_2)$" fragments. There are two distinct carboxylate groups. One of the carboxylate ligands functions essentially in a monodentate fashion, i.e., bonded to exocyclic tin atom through O1B atom only. The second carboxylate ligand bridges both exo and endocyclic tin centers through O1A and O2A atoms.

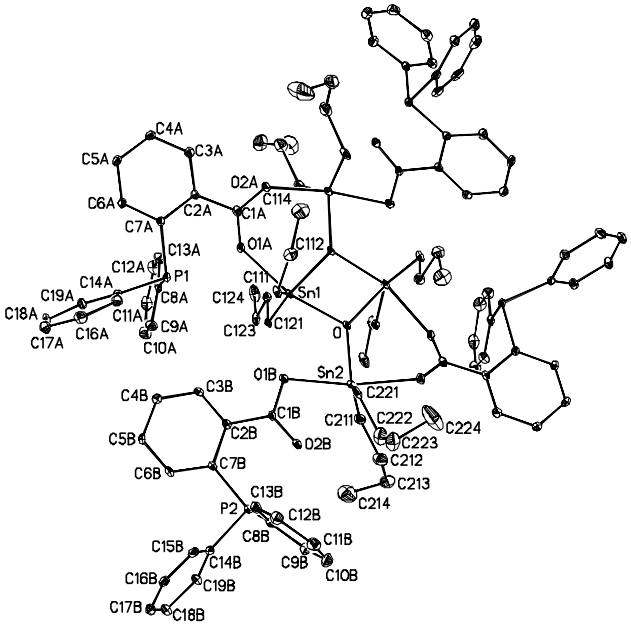

Fig. 2. Molecular structure of $[\{Bu_2Sn(O_2CC_6H_4PPh_2)\}_2O]_2 \cdot 2CH_2Cl_2$.

Both endo (Sn1) and exo (Sn2) cyclic tin atoms adopt a distorted trigonal bipyramidal geometry with each tin atom bonded two butyl groups and three oxygen atoms. The trigonal plane of *endo*-cyclic tin atom is defined by large C–Sn–C angle (139.01(12)°) and two compressed C–Sn–O#1 angles of 108.51(10)° and 112.25(10)° (Table 3). The apical angle, O–Sn–O(1A), of 162.88(8)° deviates significantly from linearity. A similar situation exists for exocyclic tin atom with apical angle O(1B)–Sn(2)–O(2A)# 169.72(8)° and trigonal angles, C(211)–Sn–C(221) 138.2(2)°; O–Sn(2)–C(211) 107.53(17)° and O–Sn(2)–C(221) 113.06(13)°. Various Sn–C and Sn–O distances are normal and can be compared with the distances reported in related complexes [37–42].

There is no significant contact between the tin atoms and P atom of the carboxylate ligand. The P–C (av. 1.84 Å) and C–P–C angles ranging from 99.36(14)° to 103.13(15)° are as expected for uncoordinated phosphines.

3.2.2. Crystal structure of $[Pt(O_2CC_6H_4PPh_2)_2]$

The structure of $[Pt(O_2CC_6H_4PPh_2)_2]$, which crystallizes with two water molecules, was unambiguously established by X-ray diffraction analysis. The structure (ORTEP [43], Fig. 3) consists of discrete molecule with the platinum atom acquiring distorted square planar geometry defined by two oxygen atoms of the carboxylate groups and two P atoms of the chelated phosphine ligand. The neutral P atoms are mutually *cis* disposed. The two Pt–O distances are essentially identical so are the two Pt–P distances (Table 4). These distances (Pt–O ~2.1 Å) [44,45] and Pt–P ~2.21 Å [46] are in agreement with the values reported for platinum complexes. The six-membered chelate rings, "PC_3O" are non-planar. The P(1)–Pt(1)–P(2) angle has opened up to 102.87° from the ideal value of 90° owing to relieve steric crowding of the phenyl groups on two P atoms. Consequently P(2)–Pt(1)–O(3), P(1)–Pt(1)–O(1) and O(1)–Pt(1)–O(3) angles are acute.

Abstract

Treatment of $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OMe})]$ (**1**) with dppm {dppm = bis(diphenylphosphino)methane} at 110 °C gave the known compound $[Os_3(CO)_{10}(\mu_2\text{-}\eta^2\text{-dppm})]$ (**2**) and the new compound $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppm})]$ (**3**). A similar reaction of **1** with dppe {dppe = bis(diphenylphosphino)ethane} afforded two products, $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_1\text{-}\eta^2\text{-dppe})]$ (**5**) and $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppe})]$ (**6**) which differ in the mode of bonding of the dppe ligand. The reaction of **1** with dppp {dppp = bis(diphenylphosphino)propane} at 110 °C gave exclusively $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppp})]$ (**7**) which exists as two isomers in solution. Compounds **2**, **3**, and **5**–**7** are also obtained in almost similar yields from reactions of $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(MeCN)]$ (**4**) with the appropriate diphosphine at ambient temperature. The reaction of **1** with PPh_2H at 110 °C gave the new compounds $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(PPh_2H)]$ (**8**) and $[(\mu\text{-H})_2Os_3(CO)_7(\mu\text{-}PPh_2)_2(PPh_2H)]$ (**10**) and the previously reported compound $[(\mu\text{-H})_2Os_3(CO)_8(\mu\text{-}PPh_2)_2]$ (**9**). The molecular structures of **3** and **8** were determined by single crystal X-ray diffraction. In compound **3**, the dppm ligand bridges the same Os–Os edge as the hydride and the methoxide ligand. In **8**, the PPh_2H ligand occupies a 'pseudo' axial site on one of the osmium atoms bearing the bridging hydride and methoxide ligand.

1. Introduction

In recent years bridging diphosphine groups have been used in metal cluster chemistry because of their ability to maintain the integrity of the metal core during chemical reactions, to act as templates for the synthesis of metal–metal bonds by bridge assisted reactions [1–5] and in applications in homogeneous catalysis [6–8]. The chemistry of dodecacarbonyltriosmium with diphosphine ligands is well established [9–17]; $[Os_3(CO)_{12}]$ derivatives containing one and two diphosphine ligands have been synthesized and fully characterized. The structures of a substantial number of derivatives have been reported over the past two decades: $[Os_3(CO)_{10}(dppm)]$ [12], $[Os_3(CO)_9(dppm)(dppm)]$

[13], $[Os_3(CO)_8(dppm)_2]$ [15], $[Os_3(CO)_{10}(dppe)]$ [16,17], $[Os_3(CO)_{10}(dppp)]$ [15], and $[Os_3(CO)_{10}(dppb)]$ [15]. From these studies it has been found that the diphosphine groups adopt a variety of bonding modes on the cluster surface including monodentate, chelating and edge bridging.

In polynuclear complexes dppm can chelate but the four membered rings are strained and the ligand has a greater tendency to act either as a monodentate ligand or as a bridging bidentate ligand. Dppe has been widely used as a chelating ligand. Although less common, it is also known to bridge metal–metal bonds [18]. Both the chelating and bridging coordination modes have been structurally characterized in the cluster $[Os_3(CO)_{10}$-(dppe)] [16,17]. The chelating tendency decreases as the chain length increases, so for the ligand dppb {dppb = $Ph_2P(CH_2)_4PPh_2$} only the bridging isomer of $[Os_3(CO)_{10}(dppb)]$ was isolated and structurally characterized [15]. It is likely that steric effects will have a major influence on the bridging vs. chelating behaviour of these ligands.

Although a large number of diphosphine derivatives of $[Os_3(CO)_{12}]$ have been described, only a few examples of such derivatives of hydrido-triosmium compounds of the type $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-X})]$ are known. Lewis et al. [19] investigated the reaction of $[(\mu\text{-H})Os_3(CO)_{10}(\mu$-OH)] with dppm at 80 °C and obtained the bridging dppm compound $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OH})(\mu_2\text{-}\eta^2\text{-dppm})]$. Recently, Leong and co-workers have reported reactions of $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OH})]$ with glycols and naphthol affording compounds of the type $[(\mu\text{-H})Os_3(CO)_{10}(\mu$-O-OH)] [20] and $[(\mu\text{-H})_2Os_3(CO)_9(\mu_3\text{-1-}C_{10}H_6)]$, [21], respectively. As a part of our ongoing studies of the reactivity of triosmium clusters with mono and diphosphine ligands, we have now investigated the chemistry of $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OMe})]$ (**1**) and its acetonitrile derivative $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(\mu\text{-MeCN})]$ (**4**) with dppm, dppe, and dppp, in order to make a comparison of the structural variation that can arise from lengthening of the methylene chain of the organic backbone of the diphosphine ligands. We have also investigated the reaction of **1** with PPh_2H in order to synthesize triosmium clusters containing bridging methoxy and phosphido ligands. These results are reported here.

2. Experimental

All reactions and manipulations were routinely performed under a nitrogen atmosphere by using standard Schlenk techniques. Reagent grade solvents were dried and distilled prior to use by standard methods. Infrared spectra were recorded on a Shimadzu FT-IR 8101 spectrophotometer. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian Unity Plus 400 spectrometer. Chemical shifts for the $^{31}P\{^1H\}$ NMR spectra are relative to 85% H_3PO_4. Bis(diphenylphosphino)methane (dppm), bis(diphenylphosphino)ethane) (dppe) and bis(diphenylphosphino)propane) (dppp) were purchased from Strem and PPh_2H from Sigma–Aldrich Chemical Company and used as received. Reagent grade solvents were dried and distilled prior to use by standard procedures. The products were purified by thin-layer chromatography (TLC) on 20 × 20 cm glass plates coated with Merck GF254 silica gel. Fast atom bombardment mass spectra were obtained on a JEOL SX-102 spectrometer using 3-nitrobenzyl alcohol as matrix and CsI as calibrant. The starting clusters $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OMe})]$ (**1**) [22] and $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(MeCN)]$ (**4**) [23] were prepared according to the literature methods.

2.1. Reaction of $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OMe})]$ (1) with dppm

To a toluene solution (20 mL) of $[(\mu\text{-H})Os_3(CO)_{10}(\mu$-OMe)] (**1**) (0.100 g, 0.113 mmol) was added dppm (0.043 g, 0.113 mmol) and the reaction mixture was heated to reflux for 8 h. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with hexane/CH_2Cl_2 (3:2, v/v) developed three bands. The first band gave a small quantity of an uncharacterized compound. The second band afforded $[Os_3(CO)_{10}(\mu_2\text{-}\eta^2\text{-dppm})]$ (**2**) (0.032 g, 23%) while the third band gave $[(\mu\text{-H})Os_3(CO)_8(\mu$-OMe)$(\mu_2\text{-}\eta^2\text{-dppm})]$ (**3**) (0.055 g, 40%) as yellow crystals after recrystallization from hexane/CH_2Cl_2 at −20 °C (*Anal*. Calc. for $C_{34}H_{26}O_9Os_3P_2$: C, 33.72; H, 2.17. Found: C, 33.95; H, 2.38%). IR [ν(CO), CH_2Cl_2]: 2070 s, 1998 vs, 1993 s, 1956 w, 1931 m cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.37 (m, 20H), 3.41 (s, 3H), 3.07 (m, 1H), 2.86 (m, 1H), −11.2 (t, 1H, J = 12.0 Hz). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ −7.9 (s). Mass spectrum: m/z 1210 (M^+).

2.2. Reaction of $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(MeCN)]$ (4) with dppm

To a dichloromethane solution (15 mL) of **4** (0.086 g, 0.096 mmol) was added dppm (0.037 g, 0.096 mmol) and the reaction mixture was stirred for 1 h. Work up and chromatographic separation as above gave **2** (0.030 g, 25%) and **3** (0.053 g, 45%).

2.3. Reaction of 1 with dppe

A toluene solution (15 mL) of **1** (0.075 g, 0.085 mmol) and dppe (0.034 g, 0.085 mmol) was heated to reflux for 8 h. The solvent was rotary evaporated and the residue chromatographed by TLC on silica gel. Elution with hexane/CH_2Cl_2 (7:3, v/v) developed two bands. The faster moving band gave $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})$-$(\mu_1\text{-}\eta^2\text{-dppe})]$ (**5**) (0.030 g, 29%) as yellow crystals after

recrystallization from hexane/CH_2Cl_2 at −20 °C (*Anal.* Calc. for $C_{35}H_{28}O_9Os_3P_2$: C, 34.31; H, 2.31. Found: C, 34.53; H, 2.56%). IR [ν(CO), CH_2Cl_2]: 2078 s, 2053 vs, 2005 vs, 1975 w, 1939 m cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.35 (m, 20H), 2.93 (s, 3H), 2.86 (m, 1H), 2.71 (m, 1H), 2.62 (m, 1H), 2.52 (m, 1H), −11.91 (t, 1H, $J = 3.6$ Hz). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 7.3 (s). Mass spectrum: m/z 1224 (M^+). The second band gave [(μ-H)$Os_3(CO)_8$(μ-OMe)(μ_2-η^2-dppe)] (**6**) (0.039 g, 38%) as yellow crystals after recrystallization from hexane/CH_2Cl_2 at 20 °C (*Anal.* Calc. for $C_{35}H_{28}O_9Os_3P_2$: C, 34.31; H, 2.31. Found: C, 34.65; H, 2.66%). IR [ν(CO), CH_2Cl_2]: 2067 vs, 2001 vs, 1984 s, 1950 w, 1932 m cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.51 (m, 20H), 3.39 (s, 3H), 2.80 (m, 2H), 2.30 (m, 2H), −11.54 (t, 1H, $J = 10.4$ Hz). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 8.0 (s). Mass spectrum: m/z 1224 (M^+).

2.4. Reaction of *4* with dppe

To a dichloromethane solution (15 mL) of **4** (0.085 g, 0.095 mmol) was added dppe (0.038 g, 0.095 mmol) and the reaction mixture was stirred for 1 h. The solvent was removed under reduced pressure and the residue chromatographed as above to give **5** (0.031 g, 30%) and **6** (0.046 g, 44%).

2.5. Reaction of *1* with dppp

To a toluene solution (15 mL) of **1** (0.098 g, 0.111 mmol) was added dppp (0.046 g, 0.112 mmol) and the reaction mixture was refluxed for 4 h. The solvent was removed in vacuo and the residue chromatographed by TLC on silica gel. Elution with hexane/CH_2Cl_2 (4:1, v/v) developed two bands. The faster moving band gave [(μ-H)$Os_3(CO)_8$(μ-OMe)(μ_2-η^2-dppp)] (**7**) (0.090 g, 66%) as yellow crystals after recrystallization from hexane/CH_2Cl_2 at 20 °C (*Anal.* Calc. for $C_{36}H_{30}O_9Os_3P_2$: C, 34.89; H, 2.44. Found: C, 35.25; H, 2.66%). IR [ν(CO), CH_2Cl_2]: 2072 s, 2065 m, 2005 vs, 2000 sh, 1996 s, 1986 w, 1965 sh, 1935 w cm^{-1}. ^1H NMR ($CDCl_3$): *major isomer*, δ 7.45 (m, 20H), 3.62 (s, 3H), 2.62 (m, 2H), 2.49 (m, 2H), 2.20 (m, 2H), −14.22 (t, $J = 10.0$ Hz, 1H); *minor isomer*, 7.45 (m, 20H), 3.26, (s, 3H), 2.75 (m, 2H), 2.35 (m, 2H), 2.05 (m, 2H), −10.94 (t, $J = 10.2$ Hz, 1H), $^{31}P\{^1H\}$ NMR ($CDCl_3$): *major isomer*, δ 7.0 (s); *minor isomer*, δ 11.0 (s). Mass spectrum: m/z 1238 (M^+).

2.6. Reaction of *4* with dppp

A dichloromethane solution (15 mL) of **4** (0.045 g, 0.051 mmol) and dppp (0.038 g, 0.092 mmol) was stirred at room temperature for 1 h. The solvent was removed under reduced pressure and the residue chromatographed as above to give **7** (0.034 g, 54%).

2.7. Reaction of *1* with PPh_2H

A toluene solution (20 mL) of **1** (0.100 g, 0.113 mmol) and PPh_2H (0.042 g, 0.224 mmol) was heated to reflux for 4 h. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with hexane/CH_2Cl_2 (9:1, v/v) developed three bands. The first band gave [(μ-H)$Os_3(CO)_8$(μ-OMe)(PPh_2H)] (**8**) (0.046 g, 35%) as yellow crystals after recrystallization from hexane/CH_2Cl_2 at 20 °C (*Anal.* Calc. for $C_{22}H_{15}O_{10}Os_3P_2$: C, 25.38; H, 1.46. Found: C, 25.65; H, 1.63%). IR [ν(CO), CH_2Cl_2]: 2091 m, 2053 s, 2016 vs, 1991 m, 1968 m, 1946 m cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.57 (m, 10H), 7.33(d, 1H, $J = 384.0$ Hz), 3.45(m, 3H), −12.51(d, 1H, $J = 34.8$ Hz). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ −38.5 (s). Mass spectrum: m/z 1040 (M^+). The second band gave the known compound [(μ-H)$_2Os_3(CO)_9$(μ-PPh_2)$_2$] (**9**) (0.036 g, 30%) while the third band afforded [(μ-H)$_2Os_3(CO)_7$(μ-PPh_2)$_2$($PHPh_2$)] (**10**) (0.021 g, 15%) as yellow crystals after recrystallization from hexane/CH_2Cl_2 at 20 °C (*Anal.* Calc. for $C_{43}H_{33}O_7Os_3P_3$: C, 38.97; H, 2.51. Found: C, 39.25; H, 2.70%). IR [ν(CO), C_6H_{12}]: 2054 vs, 2014 vs, 1999 m, 1991 m, 1979 m, 1954 w cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.40 (m, 30H), 6.74 (d, 1H, $J = 74.8$ Hz), −16.23 (dd, 1H, $J = 7.5$, 5.0 Hz), −17.74 (ddd, 1H, $J = 3.5$, 7.5, 15.0 Hz); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 99.5 (d, $J = 65.5$ Hz), 66.9 (dd, $J = 65.5$, 40.5 Hz), −14.27 (d, $J = 40.5$ Hz). Mass spectrum: m/z 1324 (M^+).

2.8. X-ray crystallography

Yellow crystals of compounds **3** and **8** were grown by slow diffusion of a layered hexane/methylene chloride solution at −4 °C. Crystallographic data were collected at 293 K, using a Bruker-Nonius CCD area detector diffractometer and Mo Kα radiation ($\lambda = 0.71073$ Å). The crystal-to detector distance was 32 mm, and ϕ and ω scans (1.2° increments, 15 s exposure time) were carried out to fill the Ewald sphere. Data collection and processing were carried out using the program COLLECT [24] and DENZO [25]. Empirical absorption corrections were applied to the data set using multiple and symmetry-related data measurements via the program SORTAV [26,27]. The unit cell was indexed on low angle reflections and refined from 25 reflections in a range of 12°–13°. The structure was solved by direct methods (SHELXS-96) [28] and refined on F^2 by full matrix lest squares (SHELXS-97) [29] using all unique data. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions (riding model) with U_{iso} set at 1.2 times the U_{eq} of the parent atom. Atoms O(2) and C(12) C(22) in **3** were refined with an ISOR = 0.015 restraint and C(6) in **8** with an ISOR = 0.02 restraint. Details of crystal parameters,

data collection parameters, and refinement data are summarized in Table 1. Selected bond lengths and angles for **3** and **8** are given in Tables 2 and 3, respectively.

3. Results and discussion

The reaction of [(μ-H)Os_3(CO)$_{10}$(μ-OMe)] (**1**) with dppm in refluxing toluene at 110 °C gives the new compound [(μ-H)Os_3(CO)$_8$(μ-OMe)(μ$_2$-η^2-dppm] (**3**) and the previously reported cluster [Os_3(CO)$_{10}$(μ$_2$-η^2-dppm] (**2**) in 40% and 23% yields, respectively (Scheme 1). Compound **2** has been characterized by a combination of elemental analysis, IR, ^{1}H, and ^{31}P{^{1}H} NMR spectroscopies, FAB mass spectrometry and a single crystal X-ray diffraction study. The pattern of the infrared spectrum of **2** is similar to that of [(μ-H)Os_3(CO)$_8$(μ-OH)-(μ$_2$-η^2-dppm] [19] indicating that they a have similar distribution of the carbonyl ligands. The hydride region of the ^{1}H NMR spectrum contains a triplet at δ −11.2 with an H–P coupling constant of 12.0 Hz indicating that the hydride is coupled to two equivalent phosphorus atoms. The aliphatic region of the spectrum exhibits two multiplets at δ 3.07 and 2.86 due to the methylene protons of the dppm ligand and a singlet at δ 3.41 attributed to the methoxy protons. The ^{31}P{^{1}H} NMR spectrum of **3** shows a singlet at δ −7.9 indicating that the phosphorus atoms of the dppm ligand are equivalent. The FAB mass spectrum of **3** confirms the formula [(μ-H)Os_3(CO)$_8$(μ-OMe)(μ$_2$-η^2-dppm)], exhibiting the molecular ion peak at *m*/*z* 1210 and peaks due to the sequential loss of eight carbonyl groups. In order to confirm the coordination mode of the dppm ligand, an X-ray diffraction study was undertaken on compound **3**. The molecular structure of **3** is shown in Fig. 1, crystallographic data are given in Table 1 and selected bond distances and angles are collected in Table 2. The molecule consists of an approximate isosceles triangle of osmium atoms with one bridging dppm ligand, one bridging methoxy ligand, a bridging hydride and eight terminal carbonyl ligands. The osmium–osmium distances in **3** {Os(1)–Os(2) = 2.8329(9) Å, Os(1)–Os(3) = 2.8365(10) Å, and Os(2)–Os(3) = 2.8143(9) Å}, are somewhat shorter than the average Os–Os distances of {2.877(3) Å} in [Os_3(CO)$_{12}$] {2.877(3)} [30]. Two CO ligands are bound to Os(2) and Os(3) atoms while Os(1) bears four CO groups. An interesting feature of the structure of **3** is that the OMe group and the hydride bridge the same Os–Os vector as the dppm ligand. The bridging hydride ligand was located along the Os(2)–

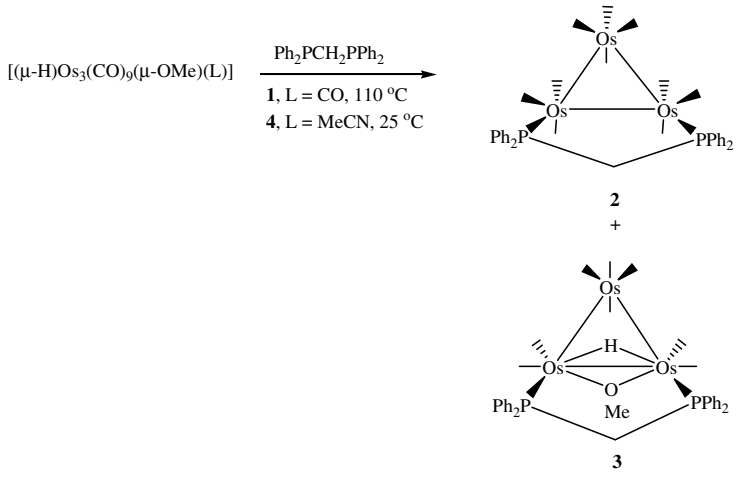
Os(3) edge but not refined. The Os–O bond distances and angles associated with the bridging OMe unit {Os(2)–O(9) = 2.126(8), Os(3)–O(9) = 2.099(9) Å, Os(3)–O(9)–Os(2) = 83.5(3)°} are comparable to those found in **1** {Os–O = 2.112–2.093 Å, Os–O–Os = 83.9°} [31]. As expected the dppm ligand is equatorially coordinated; the Os–P bond distances {Os(2)–P(1) = 2.382(4), Os(3)–P(2) = 2.362(3) Å} are somewhat longer than those found in [Os_3(CO)$_{10}$(μ$_2$-η^2-dppm)] {2.332(3) and 2.312(3) Å} [32]. To synthesize compound **3** selectively in high yield and to stop the formation of the known compound **2** we decided to react the labile acetonitrile compound [(μ-H)Os_3(CO)$_9$(μ-OMe)(MeCN)] (**4**) with dppm at ambient temperature. However, compound **4** reacts with dppm at ambient temperature to give **2** and **3** in 25% and 45% yields, respectively.

In contrast, the reaction of **1** with dppe at 110 °C gives both the chelating and bridging isomers, [(μ-H)Os_3-(CO)$_8$(μ-OMe)(μ$_1$-η^2-dppe)] (**5**) and [(μ-H)Os_3(CO)$_8$-(μ-OMe)(μ$_2$-η^2-dppe)] (**6**) in 29% and 38% yields, respectively (Scheme 2). The two isomers have different colors (the chelating isomer **5** is pale yellow and the bridging isomer **6** is orange). This reaction can be compared to that of [Os_3(CO)$_{10}$(η^4-*cis*-C_4H_6)] which



Scheme 1.

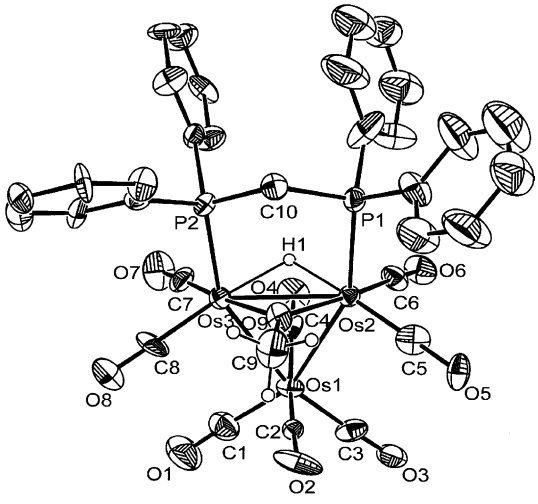


Fig. 1. Molecular structure of $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppm})]$ (**3**) showing the atom-labeling scheme. Thermal ellipsoids are drawn at the 35% probability level.

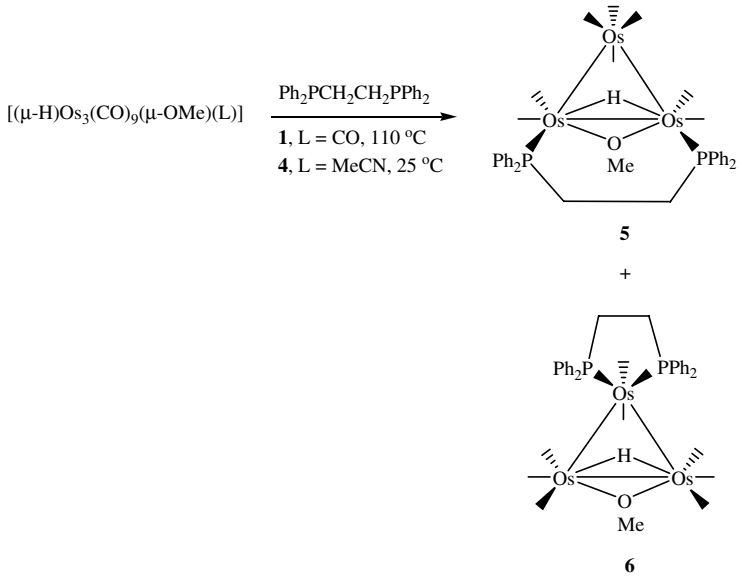
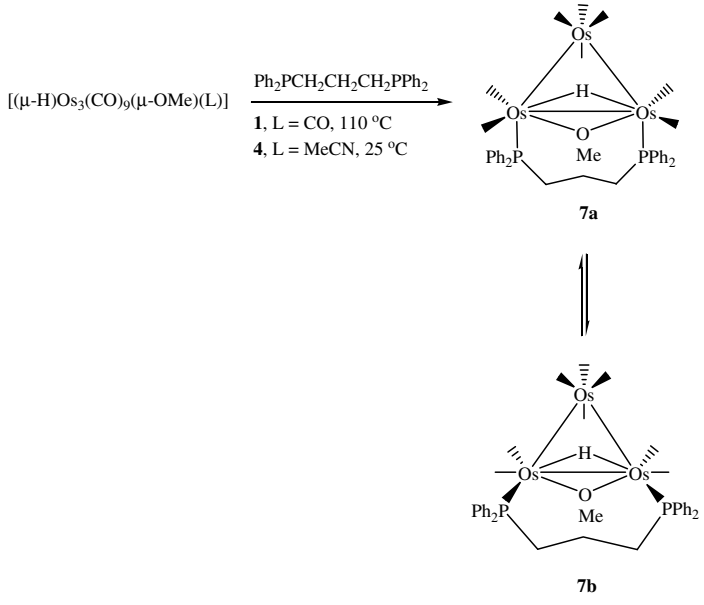
led to the formation of $[Os_3(CO)_{10}(\mu_1\text{-}\eta^2\text{-dppe})]$ and $[Os_3(CO)_{10}(\mu_2\text{-}\eta^2\text{-dppe})]$ [10,16]. We were unable to obtain X-ray quality crystals of compounds **5** and **6**, therefore, their characterization was based on elemental analysis, infrared, ^{1}H NMR, ^{31}P{^{1}H} NMR and mass spectroscopic data. The mass spectra of both **5** and **6** exhibit the molecular ion peak at m/z 1224 corresponding to the formulation $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(dppe)]$ and fragment ions due to the sequential loss of eight carbonyl ligands. The infrared spectrum of **6** is similar to that of **3** but quite different from that of **5**, indicating that the distribution of the carbonyl groups in **5** is different from that of **3** and **6**. The hydride region of the ^{1}H NMR spectrum of **5** contains a triplet at δ −11.91 with a H–P coupling constant of 3.6 Hz. The phosphorus–hydrogen coupling constant observed in this spectrum is typical of a three bond P–H coupling [33] indicating that the dppe ligand is coordinated to the osmium atom not bridged by the hydride and the methoxide group. In addition to usual phenyl resonances, the aliphatic region of the spectrum exhibits four equally intense multiplets at δ 2.86, 2.71, 2.62 and 2.52 due to the methylene protons of the dppe ligand and a singlet at δ 2.93 attributable to the methy1 protons of OMe group. The ^{31}P{^{1}H} NMR spectrum of **5** shows a singlet at δ 7.3 indicating that the phosphorus nuclei are equivalent. The spectroscopic data of **5** are thus consistent with the structure with the hydride and the methoxide ligand bridging one edge of the Os_3 triangle and the dppe ligand coordinated to the third osmium atom. This is the only possible structure and conformation where the two phosphorus atoms are magnetically equivalent. The aliphatic region of the ^{1}H NMR spectrum of **6** exhibits two equally intense multiplets at δ 2.30 and 2.80 due to the methylene protons of dppe ligand and a singlet at δ 3.39 due to the methyl protons of the methoxide group. The hydride region of the spectrum contains a triplet at δ −11.54 with a phosphorus–hydrogen coupling constant of 10.4 Hz, which is consistent with the hydride being coupled to two equivalent phosphorus atoms. The ^{31}P{^{1}H} NMR spectrum of **5** exhibits a single peak at δ 8.0 for the two equivalent phosphorus atoms of the dppe ligand. The similarities of the spectroscopic data of **6** to those of **3** points to a structure for the former with the dppe, hydride and OMe group bridging the same Os–Os edge of the Os_3 triangle (Scheme 2). Compounds **5** and **6** have also been obtained in 30% and 44% yields, respectively from the room temperature reaction of **4** with dppe.

The reaction of **1** with dppp at 110 °C gave exclusively $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppp}]$ (**7**) in 66% yield, which exists as a mixture of two isomers in a 3:2 ratio. These two isomers could not be separated by using either chromatography or crystallization techniques. The pattern of the infrared spectrum of **7**, in the carbonyl-stretching region, is similar to those of **3** and **6** but contains two additional bands at 2065 and



Scheme 2.

1996 cm^{-1}. The hydride region of the ^1H NMR spectrum of **7** exhibits two triplets at δ −14.22 and −10.94 with a relative intensity of 3:2 indicating that in each isomer the hydride is coupled to two equivalent ^{31}P nuclei. The aliphatic region of the spectrum shows two singlets at δ 3.62 and 3.26 for the methyl protons of the methoxide ligand and two sets of the three multiplets (see Section 2) for the methylene protons of the dppp ligand. The $^{31}P\{^1H\}$ NMR spectrum of **7** contains two singlets at δ 11.0 and 7.0 with a relative intensity of 3:2 (one singlet for each isomer). Thus the spectroscopic data clearly indicate that compound **7** exists as two isomers in solution in a 3:2 ratio. The probable structures for the two isomers are shown in Scheme 3. A comparison may be made between **7** and the previously reported compound $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OPh})P(OMe)_{32}]$ which also exists as two isomers in solution [33]. In the latter complex the major isomer has both the $P(OMe)_3$ ligands at equatorial sites on the bridgehead Os atoms whereas in the minor isomer one $P(OMe)_3$ ligand coordinated at equatorial site and the other at an axial site of the bridged Os atoms. The structure of **7** with one phosphorus atom coordinating at an axial position and another at an equatorial site can be ruled out since one would expect a hydride double doublet and two ^{31}P signals for such a structure. Therefore, in this case the second isomer must be one in which both phosphorous atoms occupy axial positions (Scheme 3). Due to lack of X-ray quality



crystals and the similarity of the ratio of the two isomers we cannot be certain which of the two would be present in the solid state. However, the two isomers of **7** are the analogs of compounds **5** and **6**. Compound **4** also reacts with dppp at room temperature to give **7** (54%).

The reaction of **1** with $PHPh_2$ in refluxing toluene at 110 °C gave two new compounds $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(PHPh_2)]$ (**8**), and $[(\mu\text{-H})_2Os_3(CO)_7(\mu\text{-PPh}_2)_2(PHPh_2)]$ (**10**) in 35% and 15% yields, respectively together with the known compound $[(\mu\text{-H})_2\ Os_3(CO)_8(\mu\text{-PPh}_2)_2]$ (**9**) in 30% yield. Compound **9** was previously reported by Carty et al. [34] from the phosphine compound $[Os_3(CO)_{10}(\mu\text{-PPh}_2H)_2]$ via oxidative addition of P–H bond. Compound **8** has been characterized by a combination of spectroscopic data and single crystal X-ray diffraction studies. The pattern of the IR spectrum of **8** is similar to that of $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-SPh})(PEt_3)]$ in which the PEt_3 ligand is coordinated to one of the bridgehead osmium atoms [33]. In addition to the usual phenyl resonances, the ^1H NMR spectrum of **8** shows a singlet at δ 3.45 due to the methyl protons of the OMe group and a strongly coupled doublet at δ 7.33 ($J = 384.0$ Hz) attributed to the P–H proton of the $PHPh_2$ ligand. The magnitude of the P–H coupling constant of the doublet at δ 7.33 is similar to those observed for other terminally coordinated PPh_2H compounds [35,36]. The hydride region of the spectrum contains a doublet at δ −12.51 with a P–H coupling constant of 34.8 Hz. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at δ −38.5. The mass spectrum of **8** exhibits a molecular ion peak at m/z 1040, which undergoes fragmentation by sequential loss of nine carbonyl groups. The spectroscopic data, therefore, suggest that **8** has a structure similar to that of $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-SPh})(PEt_3)]$ [33] as shown in Scheme 4.

A single crystal X-ray diffraction analysis of compound **8** confirmed the proposed structure. The molecular structure of **8** is depicted in Fig. 2, crystallographic data are collected in Table 1 and selected bond distances and angles are listed in Table 3. The structure is derived from $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OMe})]$ by replacement of one CO group from one of the bridgehead osmium atoms. The overall structure is similar to that of $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-SPh})(PEt_3)]$. The bridging hydride ligand was located along the Os(2)–Os(3) edge but not refined. This edge is also bridged by the methoxide ligand. The Os–O bond distances and angles associated with the bridging OMe unit {Os(2)–O(10) = 2.088 (13), Os(3)–O(10) = 2.125(12) Å, Os(3)–O(10)–Os(2) = 83.3(4)°} are comparable to those found in **3**. The nine carbonyl groups are in terminal positions with four bonded to Os(1), three bonded to Os (2) and two attached to Os(3). The doubly bridged Os(2)–Os(3) edge {2.7993(11) Å} is shorter than the two non-bridged Os–Os bonds {Os(1)–Os(2) = 2.8273(13), Os(1)–Os(3) = 2.8492(11) Å}. It is possible that the usual bond lengthening effect produced

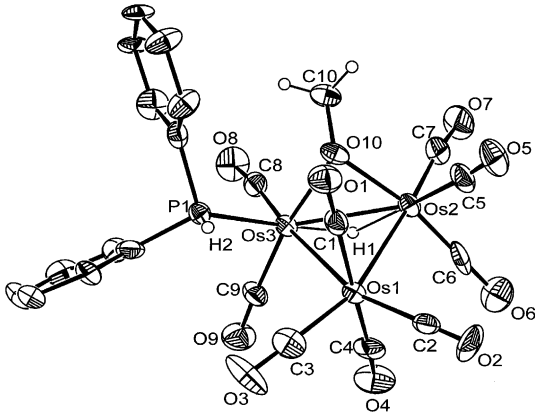


Fig. 2. Molecular structure of $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(PPh_2H)]$ (**8**) showing the atom-labeling scheme. Thermal ellipsoids are drawn at the 35% probability level.

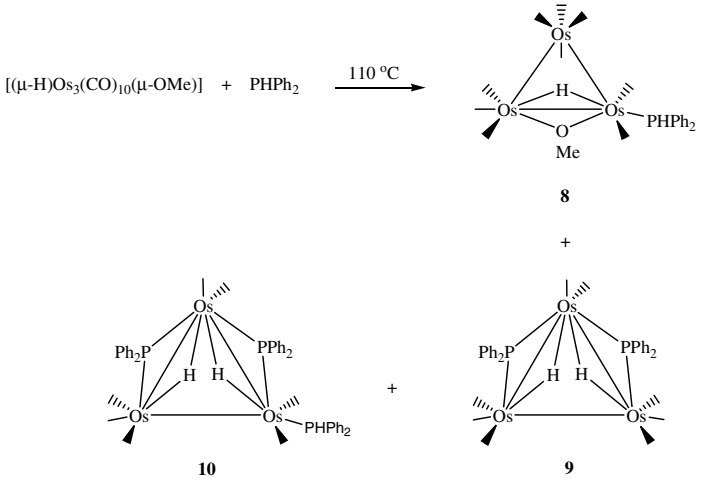

by the hydride ligand may be counterbalanced by the bridging methoxide ligand. The two unbridged Os–Os edges differ by ca. 0.002 Å, but the average value is somewhat shorter than the average Os–Os distance of 2.877(3) Å in $[Os_3(CO)_{12}]$ [30]. The longer Os(1)–Os(3) bond has the 'pseudo axial' phosphine *cis* to it and the increase in length may be consistent with the greater steric bulk of this group. The Os(3)–P(1) bond distance of 2.309(5) Å is comparable to that observed in $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OH})(PMe_2Ph)]$ (2.329(2) Å} [19].

The elemental analysis, infrared, ^{1}H NMR, $^{31}P\{^1H\}$ NMR and mass spectroscopic data for compound **10** are consistent with the proposed structure. The infrared spectrum of **10** indicates that the carbonyl groups are terminal. The mass spectrum shows molecular ion peak at *m/z* 1324, which is consistent with the proposed formulation. The $^{31}P\{^1H\}$ NMR spectrum of **10** shows two doublets at δ 99.5 ($J = 65.5$ Hz) and −14.3 ($J = 40.5$ Hz) and a double doublets at δ 66.9 ($J = 40.5$, 65.5 Hz) consistent with the proposed structure. The strongly deshielded resonances at δ 99.49 and 66.9 are due to the bridging phenylphosphido ligands while the doublet at δ −14.27 is attributed to the phosphorus atom of the terminal PPh_2H ligand. The hydride region of the ^{1}H NMR spectrum of **10** contains two equally intense signals, a doublet of doublets at δ −16.23 ($J = 7.5$, 15.0 Hz) and a doublet of a double doublets at δ −17.74 ($J = 3.5$, 7.5, 15.0 Hz) indicating that the compound has two non-equivalent bridging hydride ligands. The hydride and ^{31}P chemical shifts and coupling constants are in agreement with the proposed structure for **10** (Scheme 4).

4. Conclusions

In summary, the present work demonstrates that the reactivity of both $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OMe})]$ (**1**) and $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(MeCN)]$ (**4**) toward diphosphines depends on the methylene chain length of the organic back bone of the diphosphine ligands. Two compounds, $[Os_3(CO)_{10}(\mu_2\text{-}\eta^2\text{-dppm})]$ (**2**) and $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppm})]$ (**3**) have been obtained from the reaction of dppm with **1**. Compound **2** results from reductive elimination of methanol followed by addition of dppm and **3** by substitution of one CO ligand from each of the bridgehead osmium atom by a PPh_2 group of the dppm ligand. The single crystal structure analysis of **3** reveals that the dppm ligand spans the same Os–Os vector as the methoxide and hydride ligands. In contrast, dppe reacts with both **1** giving two isomeric compounds, $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_1\text{-}\eta^2\text{-dppe})]$ (**5**) and $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppe})]$ (**6**), which differ in the mode of bonding of the dppe ligand. In **5**, the dppe ligand is coordinated at the unbridged Os atom (chelating mode) whereas in **6** the ligand is coordinated at the bridgehead Os atoms (edge-bridging mode) as in **3**. Treatment of **1** with dppp produces only $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-OMe})(\mu_2\text{-}\eta^2\text{-dppp})]$ (**7**) which exists as two isomers in solution (Scheme 3). Similar products were obtained from the reactions of dppm, dppe, and dppp with **4**. The attempted preparation of bridging methoxide and phosphido compounds from the reaction of **1** with PPh_2H at 110 °C gave the new compounds $[(\mu\text{-H})Os_3(CO)_9(\mu\text{-OMe})(PPh_2\mathit{H})]$ (**8**) and $[(\mu\text{-H})_2Os_3(CO)_7(\mu\text{-}PPh_2)_2$ $(PPh_2H)]$ (**10**) and previously reported compound $[(\mu\text{-H})_2Os_3(CO)_8(\mu\text{-}PPh_2)_2]$ (**9**). In **8**, the PPh_2H ligand occupies a 'pseudo' axial site on one of the osmium atoms bearing the bridging hydride and methoxide ligand. The formation of the μ-phosphido complexes is directly related to the elimination of methanol and points out the lability of this moiety as a cluster ligand. This may provide a general synthetic route, using **1**, for the formation of cluster derivatives with compounds containing active hydrogen atoms but where no additional hydride is desired in the final product.

Abstract

The phosphazene copolymers $\{[NP(O_2C_{12}H_8)]_{0.5}[NP(O–C_6H_4–CO_2Pr^n)(O–C_6H_4–L)]_{0.5}\}_n$ [L = CN (**1**), PPh_2 (**2**)] and $\{[NP(O_2C_{12}H_8)]_{0.6}[NP(O–C_6H_4–CO_2Pr^n)(O–C_5H_4N)]_{0.4}\}_n$ (**3**) have been synthesized by sequential substitution from $[NPCl_2]_n$. Their reactions with $[W(MeOH)(CO)_5]$ gives the corresponding tungsten carbonyl complexes $\{[NP(O_2C_{12}H_8)]_{0.5}[NP(O–C_6H_4–CO_2Pr^n)(O–C_6H_4–CN)(W(CO)_5)_{0.4}]_{0.5}\}_n$ (**4**), $\{[NP(O_2C_{12}H_8)]_{0.5}[NP(O\text{-}C_6H_4–CO_2Pr^n)(O–C_6H_4–PPh_2)(W(CO)_5)_{0.7}]_{0.5}\}_n$ (**5**), $\{[NP(O_2C_{12}H_8)]_{0.6}[NP(O–C_6H_4–CO_2Pr^n)(O–C_5H_4N–W(CO)_5)]_{0.4}\}_n$ (**6a**), and $\{[NP(O_2C_{12}H_8)]_{0.6}[NP(O–C_6H_4–CO_2Pr^n)(O–C_5H_4N)(W(CO)_5)_{0.4}]_{0.4}\}_n$ (**6b**), that have been fully characterized by IR and NMR spectroscopies. The thermal properties (TGA and DSC) of the polymeric complexes showed that they are high glass transition materials that undergo a complete decarbonylation below 300 °C forming metal containing species that have a stabilizing effect on the polymeric matrices. The final residues up to 800 °C are of the order of30–50%.

Keywords: Polyphosphazenes; Tungsten; Carbonyl complexes

1. Introduction

The polyphosphazenes, that are inorganic–organic polymers with $[–N=PR_2–]$ repeating units, continue attracting a great deal of interest in both basic and applied material science [1]. In particular, they can be used to support a variety of transition metal carbonyl and organometallic complexes [2,3]. In earlier papers we reported [4] that the polydichlorophosphazene reacts directly first with 2,2′-(HO)–C_6H_4–C_6H_4(OH) and subsequently with para-substituted phenols OH–C_6H_4–R in THF in the in the presence of K_2CO_3, affording a new type of phosphazene copolymers $\{[NP(O_2C_{12}H_8)]_x[NP(O–C_6H_4–R)_2]_{1-x}\}_n$ with high thermal stability and elevated transition temperatures.

This sequential substitution, using also Cs_2CO_3 as proton abstractor, allowed the facile synthesis of a wide range of functionalized random copolymers systematically designed to carry chemical functions including ligands for transition metal fragments [3], useful in catalysis [5–7]. Therefore, we have extended this synthetic route to the preparation of new polyphosphazene random copolymers incorporating nitrile, phosphine or pyridine ligands in the vicinity of a carboxylate group

doi:10.1016/j.poly.2005.07.016

(CO_2Pr), that, as we have shown recently, are very helpful in determining the composition of the polymers, to modify their physical properties [8] and that may be easily transformed into other groups, including the useful carboxylic acids COOH [9].

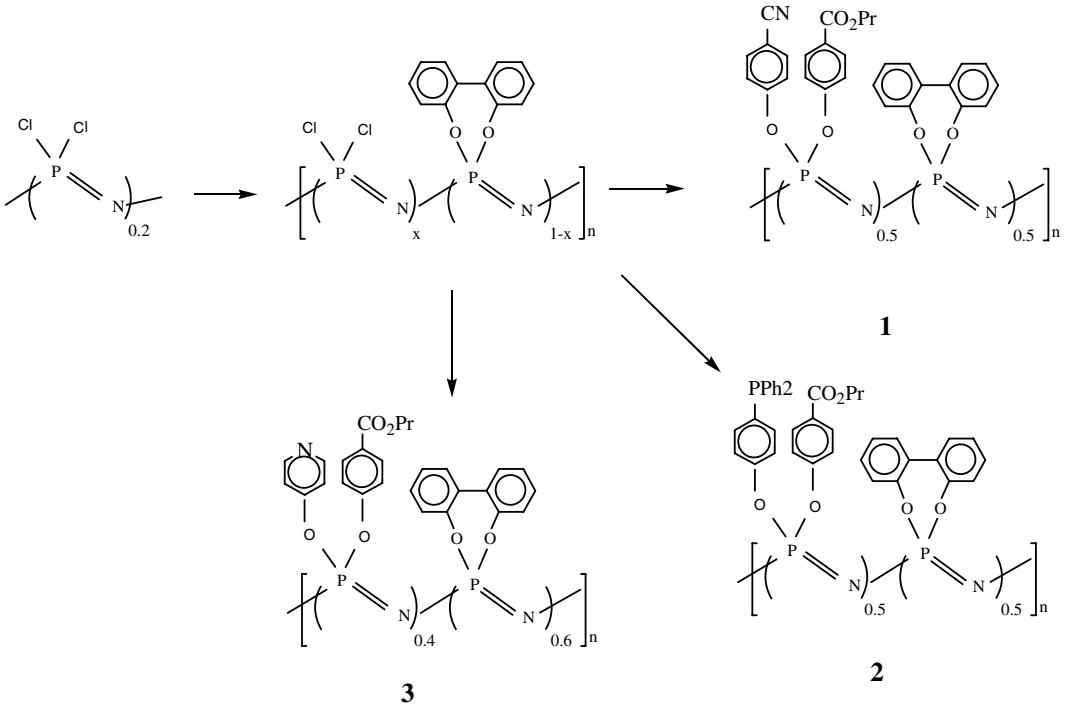
In this paper we report the synthesis and the study of the thermal properties of new polymers of this type, and the formation of their complexes with $W(CO)_5$. We have found that these complexes undergo a fast decarbonylation below 300 °C that, depending on the electronic characteristics of the ligand, specially its labilizing effect to CO dissociation, may give carbide-oxide or metallic tungsten particles that, in the latter cases, appear to have an stabilizing effect on the polymeric matrices. Therefore, those observations could be useful to understand the characteristics of the residues generated by thermal treatments of polymeric complexes, and to the design of precursor complexes in order to control the nature of the metal containing particles resulting within the polymeric matrices, which is a topic of current interest [10].

2. Results and discussion

The reaction of $[NPCl_2]_n$ in THF first with 0.5 equivalents of 2,2′-dihydroxybiphenyl $(HO)_2(C_{12}H_8)$ and K_2CO_3, followed by 0.5 equivalents of $HO–C_6H_4–CO_2Pr_n$ and Cs_2CO_3, and finally with ca. 0.6 equivalents (see Section 3) of $HO–C_6H_4–L$ (L = CN or PPh_2), gave the random phosphazene copolymers $\{[NP(O_2C_{12}H_8)]_{0.5}[NP(O–C_6H_4–CO_2Pr^n)(O–C_6H_4–L)]_{0.5}\}_n$ [L = CN (**1**), PPh_2 (**2**)]. A similar sequential substitution but using 4-hydroxypyridine in the third step afforded the polymer $\{[NP(O_2C_{12}H_8)]_{0.6}[NP(O–C_6H_4–CO_2Pr^n)(O–C_5H_4N)]_{0.4}\}_n$ (**3**) (Scheme 1).

The average M_w (of the order of 1.210^6 with polydispersities in the range 2–5) and the glass transition temperatures (around 70 °C) were not far from the values observed for the related polymer $\{[NP(O_2C_{12}H_8)]_{0.5}[NP(O–C_6H_4\text{-}CO_2Pr^n)_2]_{0.5}\}_n$ published recently [8].

All the analytical and spectroscopic data (Section 3) were in accord with the chemical composition (calculated values are for the idealized formulas and some deviation from the experimental data is frequently found in polymers of this type) and the structure of the new polymers. Most significantly, the ^{31}P NMR spectra exhibited two broad signals, one for the $[NP(O_2C_{12}H_8)]$ units (ca. −4 ppm) and other for the $[NP(O–C_6H_4–CO_2Pr^n)(O–C_6H_4\text{-}L)]$ units (ca. −22 ppm). No signals of [NPCl(OR)] units were detected, indicating that the unreacted Cl is negligible. The relative intensities (that were more accurately measured in DMSO at 110 °C where the spectra were much sharper) indicated the actual composition of the copolymers, that also agreed with the calculated from the ^1H NMR spectra. In the ^{31}P NMR spectrum of **2** a singlet at −6.4 ppm (chloroform) or −4.5 ppm (DMSO) confirmed the presence of the PPh_2 ligands (in DMSO at 110 °C a conspicuous inversion of the relative positions of the



Scheme 1.

[$NP(O_2C_{12}H_8)$] and (PPh_2) signals were observed). However, another peak at 29 ppm (chloroform) indicated that some of the phosphines were oxidized to –P(O)Ph_2 groups. From the relative intensity of this signal (also measured in the spectrum in DMSO at 110 °C, where it appears at 24 ppm) the degree of oxidation was found to be ca. 8%.

Among other useful NMR spectral data were the small peak at 112 ppm in the ^{13}CNMR of **1** clearly attributable to the C_4 carbon of the O–C_6H_4–CN group (the expected very weak CN signal around 120 ppm was obscured by the abundant signals in that region).

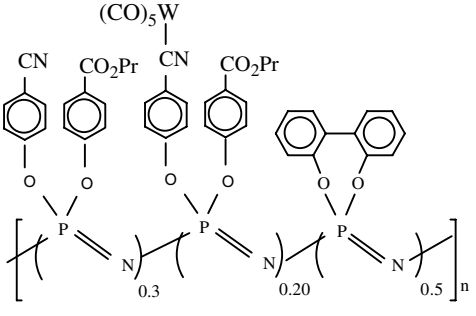
The IR clearly evidenced the presence of the (O–C_6H_4–CO_2Pr^n) groups (carbonyl stretching at 1717 cm^{-1}), and the ligand supported in the lateral groups, namely: the *v*-CN stretching at 2228 cm^{-1} (polymer **1**) or the characteristic pyridine ring stretching band [3] at 1585 cm^{-1} (polymer **3**). The presence of the phosphine ligand is best detected in the IR spectrum of **2** by the medium intensity band at 696 cm^{-1}, typical of the mono-substituted arene ring [11] (in the spectrum of the related compound without phosphine {[$NP(O_2C_{12}H_8)]_{0.5}$[NP-($O–C_6H_4–CO_2Pr^n)_2]_{0.5}\}_n$, only a very weak absorption at 694 cm^{-1} could be observed).

Although it cannot be shown experimentally, it should be noted that, because of the essentially random nature [8] of the substitution reactions that lead to **1**, **2** and **3** from $[NPCl_2]_n$, only mixed units of the type [$NP(O–C_6H_4–CO_2Pr^n)$(O–R–L)] are present in the chains of the copolymers, and, therefore, most of the pendant ligands L are in the vicinity of the (O–C_6H_4–CO_2Pr^n) groups (see Scheme 1).

The reaction of the polymeric ligands **1**, **2** and **3** with the corresponding stoichiometric or substoichiometric amounts of [$W(MeOH)(CO)_5$] in a mixture of dichloromethane–methanol gave the complexes (Scheme 2) {[NP-($O_2C_{12}H_8$)]$_{0.5}$[NP(O–C_6H_4–CO_2Pr^n)(O–C_6H_4–CN)(W-$(CO)_5)_{0.4}]_{0.5}\}_n$ (**4**), {[$NP(O_2C_{12}H_8)]_{0.5}$[NP(O–C_6H_4–CO_2-Pr^n)(O–C_6H_4–PPh_2)($W(CO)_5)_{0.7}]_{0.5}\}_n$ (**5**), {[$NP(O_2C_{12}$-$H_8)]_{0.6}$[NP(O–C_6H_4–CO_2Pr^n)(O–C_5H_4N–$W(CO)_5)]_{0.4}\}_n$ (**6a**), and {[$NP(O_2C_{12}H_8)]_{0.6}$[NP(O–C_6H_4–CO_2Pr^n)(O–C_5H_4N)($W(CO)_5)_{0.4}]_{0.4}\}_n$ (**6b**). The relative quantities of the polymeric ligand and the precursor complex were calculated using the functionalization degree of the ligands FD (in mmol of ligating group per gram of polymer) given in the experimental part. In the case of the phosphine the calculation took into account the 8% of the oxidized PPh_2 groups.

All the analytical and spectroscopic data (Section 3) confirmed that the composition of the new complexes were not too far from the intended one (50–100% coordination of the available ligands).

Most significant were the changes in the IR spectra evidencing the incorporation of the $W(CO)_5$ fragment. The absence of $W(CO)_6$ was guaranteed by the constancy of the spectra after several purifications. Apart from the expected *v*(CO) stretching absorbances of the pentacarbonyl moiety, the spectrum of **6a** showed the absence of the strong absorption at 1585 cm^{-1} (present in the spectrum of the free ligand **3**, and with



4

6a(y=1), **6b**(y=0.4)

Scheme 2.

less intensity also in the incompletely charged complex **6b**) that is a good diagnosis of the coordination of a MLn fragment to the pyridine [3]. In all cases, the carbonyl stretching frequency of the CO_2Pr group was unaffected by the presence of the tungsten carbonyl units, indicating that the electronic interaction between this group and the ligand attached to the vicinal aryloxy group is very small. The ^{31}P NMR spectrum (measured in NMP) showed the two phosphazene units at chemical shifts only 1 ppm lower than those of the free ligands. This limited sensibility of the PN groups to the coordination of metals to the ligands supported on them has been frequently observed [3].

In the case of the phosphine ligand **2** the composition of the products obtained in the reactions with $[W(HOMe)(CO)_5]$ were not reproducible and always contained ca. 70% of the maximum $W(CO)_5$ fragments. The isolated products were not completely soluble and gave rather cloudy solutions (the NMR spectral signals were extremely broad, preventing the observation of the ^{183}W satellites). This, and the presence of a shoulder at 1890 cm^{-1} in the IR spectrum, strongly suggest that, as found in similar reactions [12], some interchain substitution of CO by phosphine groups might take place during the formation of **5**. It should be noticed that a very few of such cross-linking points would transform the polymer into an insoluble gel-forming material [13].

The thermal properties of the new complexes were studied by TGA and DSC calorimetry (Tables 1 and 2). In all cases the TGA curves exhibited a distinct first weight loss step between 100 and 300 °C, and a main loss between 300 and 800 °C. It was clearly noted that the weight loss produced by further heating the complexes for 1/2 h at 800 °C were almost negligible, while the free polymeric ligands underwent another weight loss of the order of 7%. Therefore, unlike the precursor ligand, the residues left by the complexes are already stabilized at 800 °C.

The first weight loss could be unambiguously assigned to a decarbonylation process. Thus, the IR spectra of the samples heated in this range of temperatures under N_2 atmosphere (Fig. 1), evidenced the total disappearance of the initial ν(CO) absorptions (that changed gradually to lower CO frequency patterns clearly attributable to intermediate tetra, tri or dicarbonyls units [14] and the final spectra were identical to those of the free ligands. In the cases of **6a** and **6b**, the disappearance of the tungsten carbonyl complex was also noted by the re-appearance of the absorption at 1585 cm^{-1} of the free pyridine ligand. However, although in all the cases all the CO ligands had disappeared at 300 °C, the weight losses measured in the TGA thermograms below this temperature range (Table 1) were slightly lower than the expected from the $W(CO)_5$ contents in the original complexes (Table 2). The difference (C/O res. in Table 2) was small for the complexes **4**, **6a** and **6b** (ca. 2%), but more significant for **5** (3.4%). Although not very pronounced, this effect might be indicating that,

Table 1

[c] Carbon and oxygen not lost in the decarbonylation (%CO content − weight loss below 350 °C).
[d] W content + RL + C/O res.
[e] Residue found (Table 1) – expected residue.

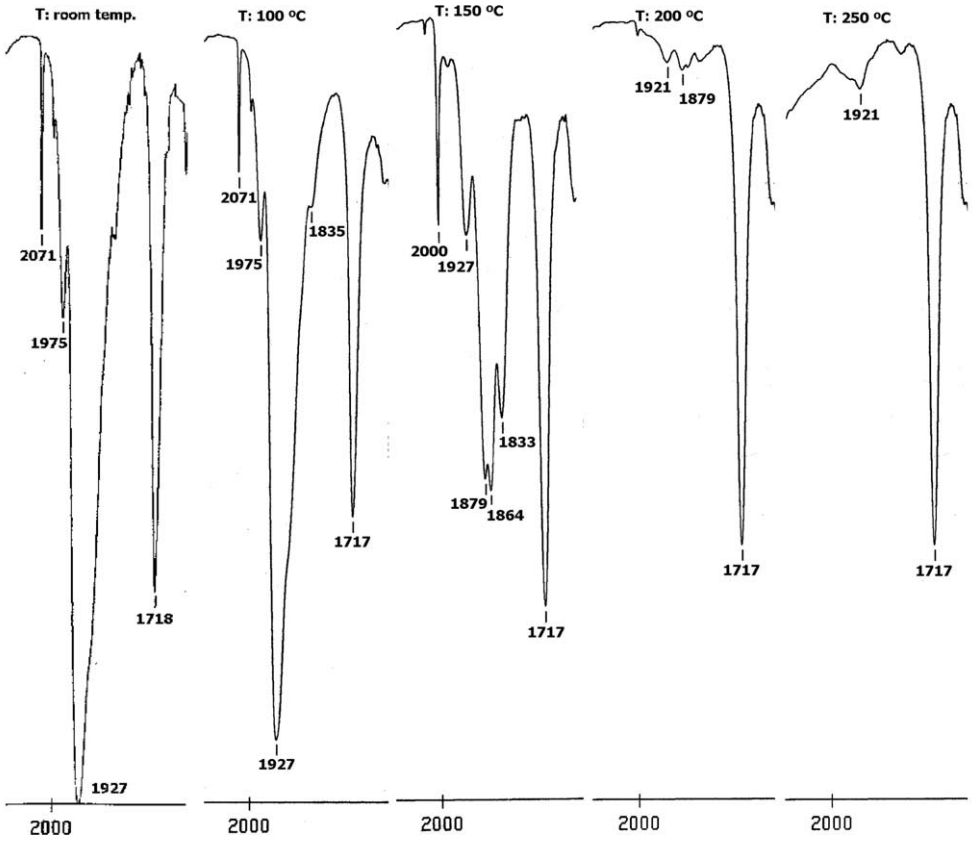

Fig. 1. Monitoring by IR spectrum (ν_{CO} region) of the decarbonylation of $\{[NP(O_2C_{12}H_8)]_{0.6}[NP(O–C_6H_4–CO_2Pr^n)(O–C_5H_4N)(W(CO)_5)_{0.4}]_{0.4}\}_n$ (**6b**), below 300 °C.

as it has been well established [15] the decarbonylation of tungsten carbonyls below 300 °C give residues that consist on tungsten oxide carbides, formed by the dissociation of a fraction of the CO ligands on the metal surface. Therefore, it is possible that, with the more *cis*-labilizing [16] N-donor ligands, the decarbonylation is more favoured minimizing the secondary CO scission process, forming mainly tungsten particles trapped in the residual polymeric matrix. This observation could be useful in designing polymeric complexes in order to control the nature of the metal containing particles resulting in the thermal decomposition.

On the other hand, the thermograms also indicated that, in the case of **4**, and **6b** and, even more conspicuously, in the case of **6a**, the final residues left by the complexes after an stabilization step at 800 °C for 1/2 hour, (Table 1) were higher than those expected by adding the metallic residues to the residues left (under the same conditions) by the free polymeric ligands (Table 1). For complex **5** the difference was much smaller. This suggests that the tungsten particles might have a greater stabilizing effect on the polymeric matrices (yielding less proportion of volatiles at higher temperatures) than the carbide-oxide richer particles.

The decarbonylation of the tungsten carbonyl fragments also accounted for the DSC thermograms of the complexes, that showed a distinct glass transition with a T_g that depended on the metal content and also on the temperature range chosen for the running cycles (Table 1). It has been established that the T_g of a polyphosphazene bearing a complex should be higher than that of the corresponding polyphosphazene free ligand [17]. Thus, although the T_g of the complex **4** is only 5 °C higher than that of the polymeric ligand **1**, the T_g observed for **5** and **6** (Table 1) were ca. 25 °C higher than those of **2** and **3**. However, taking into account that the complexes undergo a decarbonylation in this range of temperatures, the effect of the T_g must be due to the formation of the resulting metallic or metal-carbide-oxide residues rather than to the present of the original $W(CO)_5$ fragments. It was also noted that, in those cases were a heat capacity jump attributable to a glass transition could be detected in the first heating runs of the DSC experiments (i.e., before extensive decarbonylation had taken place) the measured T_g were approximately (but not well reproducible) 20–30 °C higher than the observed in the second heating run. It is to be expected that the final residues are heavily cross-linked polymeric matrices and it is known that, as found for polystyrene [18], the cross-linking increases the glass transition temperatures of the polymers.

3. Experimental part

K_2CO_3 and Cs_2CO_3 were dried at 140 °C prior to use. The THF was treated with KOH and distilled twice from Na in the presence of benzophenone. The 2,2′-dihydroxibiphenyl HO–C_6H_4–C_6H_4–OH, the phenols HO–C_6H_4–R (R = CO_2Pr or CN), and the pyridone HO–C_5H_4N were used as purchased (Aldrich). The phosphine HO–C_6H_4–R was obtained as described elsewhere [19]. The starting polymer $[NPCl_2]_n$ was prepared as described previously [20]. The complexes $[W(MeOH)(CO)_5]$ were obtained by the literature methods [21].

The IR spectra were recorded with a Perkin–Elmer FT Paragon 1000 spectrometer. NMR spectra were recorded on Bruker AC-200, AC-300 and Avance 300 instruments, using $CDCl_3$, DMSO (dimethylsulfoxide) or NMP (*N*-methyl-pyrrolidone) as solvents. ^1H and $^{13}C\{^1H\}$ NMR are given in δ relative to TMS. $^{31}P\{^1H\}$ NMR are given in δ relative to external 85% aqueous H_3PO_4. Coupling constants are in Hz. C, H, N analyses were performed with a Perkin–Elmer 240 microanalyzer. Chlorine analyses were performed by Galbraith Laboratories. GPC were measured with a Perkin–Elmer equipment with a Model LC 250 pump, a Model LC 290 UV, and a Model LC 30 refractive index detector. The samples were eluted with a 0.1% by weight solution of tetra-*n*-butylammonium bromide in THF through Perkin–Elmer PLGel (Guard, 10^5, 10^4 and 10^3 Å) at 30 °C. Approximate molecular weight calibration was obtained using narrow molecular weight distribution polystyrene standards. T_g values were measured with a Mettler DSC 300 differential scanning calorimeter equipped with a TA 1100 computer. Thermal gravimetric analyses were performed on a Mettler TA 4000 instrument. The polymer samples were heated at a rate of 10 °C/min from ambient temperature to 800 °C under constant flow of nitrogen, and further heated at 800 °C for 1/2 h for stabilization of the residue.

3.1. {[NP($O_2C_{12}H_8$)]$_{0.5}$[NP(O–C_6H_4–CO_2Pr^n)-(O–C_6H_4–CN)]$_{0.5}$}$_n$ (1)

To a THF solution of $[NPCl_2]_n$ (200 mL, 2.08 g, 17.9 mmol), 2,2′-(HO)–C_6H_4–C_6H_4(OH) (1.67 g, 8.97 mmol) and solid K_2CO_3(2.48 g, 17.9 mmol) were added and the mixture was refluxed with mechanical stirring for 15 h. Then, HO–C_6H_4–CO_2Pr (1.61 g, 8.97 mmol) and Cs_2CO_3 (8.8 g, 27 mmol) were added, and refluxing was continued for another 6.5 h. To the mixture HO–C_6H_4–CN (1.18 g, 9.9 mmol) were added, and refluxing was continued for another 24 h. The reaction mixture was poured into water (2 L) to give a precipitate that was filtered, washed with water (2 × 100 mL), isopropanol and hexane, and dried. The purification was performed by dissolving the product in THF (600 mL) to give a clear solution that was concentred at reduced pressure until the formation of a viscous liquid that was poured portion-wise (Pasteur pipette) into water (1 L), followed by two further reprecipitations from THF/isopropyl-alcohol and THF/hexane. The final white material was dried 72 h in vacuo at 50 °C. Yield: 3.67 g (71.7%). *Anal.* Calc. for $C_{14.5}H_{11.5}N_{1.5}O_3P$ (285.7): C, 60.9; H, 4.06; N, 7.35. 3.4. Synthesis of the polymeric complexes 4, 5 and 6

The following preparation for complex **6a** is representative of all the other complexes using the data given below, calculated with the corresponding functionalization degrees of the polymeric ligands (FD in mmol(Ligand)/g (polymer)), and aiming to coordinate $W(CO)_5$ to ca. 50% or 100% of the available ligands.

3.4.1. {[NP(O$_2$C$_{12}$H$_8$)]$_{0.6}$[NP(O–C$_6$H$_4$–CO$_2$Pr^n)-(O–C$_5$H$_4$N–W(CO)$_5$)]$_{0.4}$}$_n$ (6a)

A solution of $[W(CO)_6]$ (0.06 g, 0.17 mmol) in methanol (75 mL) was stirred under UV irradiation until the disappearance of the 1977 cm^{-1} IR absorption (ca. 1 h), to give an orange solution of $[W(HOMe)(CO)_5]$ (IR: 2075w, 1932 s, 1887m,br.). To this solution, another solution of the polymeric ligand **3**(FD = 1.5) (0.09 g, 0.34 mmol ≡ 0.135 mmol OC_5H_4N) in CH_2Cl_2 (250 mL) was added and the mixture was stirred at room temperature for 2.5 h. The volatiles were evaporated and the resulting solid was washed with hexane (4 × 50 mL) and CH_2Cl_2, and dried in vacuum for 24 h to give complex **6a** as yellow solid. Yield: 0.114 g (85%). *Anal.* Calc. for $C_{15.2}H_{10.8}N_{1.4}O_{4.8}PW_{0.4}$ (394.4): C, 46.3; H, 2.76; N, 4.97; W, 18.65. Found: C, 41.7; H, 2.67; N, 4.5; W, 19.2%. IR (KBr): $\nu = 3068$m, br. Abstract

Studies of the known single-molecule magnet $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)\}Br \cdot 8H_2O$ complex, tacn = 1,4,7-triazacyclononane, in an aqueous solution and in the powder state have been carried out with the aim of characterizing the stability of the Fe_8 cluster in an aqueous solution. The characterization involves IR, UV–Vis, NMR (Evans method) and Mössbauer spectroscopies, as well as dc-magnetic susceptibility and magnetization studies. Both spectroscopic and magnetic measurements clearly show the lack of stability of the Fe_8 cluster in an aqueous solution.

1. Introduction

Molecular chemistry is presently having a great impact on the field of nanoscale magnetism by providing new magnetic clusters based on either metallic ions or organic radicals [1–3]. Molecular clusters are unique objects, which are useful in studying the magnetic behaviour of organized matter of a few nanometres in size. In contrast to conventional metallic magnets, in which exchange interactions that couple localized magnetic moments are mediated by conduction electrons, magnetic interactions between metallic centres in molecular magnets occur via diamagnetic bridges, such as oxygen or carboxylate groups, i.e., by a mechanism known as superexchange.

Single-molecule magnets (SMM) are a broad, emerging class of magnetic nanomaterials based on metal ions bridged by O^{2-}, OH^-, OR^- and RCO_2^-. The main characteristics of SMM are a large-spin ground state and stepwise magnetization hysteresis loops at low temperatures resulting from transitions between quantized states of individual molecules rather than long-range order effects [4,5]. Molecular clusters containing metal ions, mostly $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)\}Br \cdot 8H_2O$, Fe_8, and $[Mn_{12}O_{12}(O_2CCH_3)_{16}(H_2O)_4]$, Mn_{12}, have been widely studied and special emphasis has been given to the observation of quantum effects, such as tunnelling of the magnetic moment [6]. $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)\}Br \cdot 8H_2O$ is characterized by an $S = 10$ spin ground state [7]. In fact, for this cluster pure quantum tunnelling relaxation of the magnetization

has been observed below 0.4 K, thanks to a relatively large transverse intrinsic magnetic field [8].

Potential medical applications of magnetic molecular clusters are nowadays of high interest in the fields of active targets for medical therapy [9,10]; aqueous solutions of $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)\}Br \cdot 8H_2O$ have been checked as contrast agents in magnetic resonance imaging obtaining fruitful results [11]. From this point of view, their stability in biological solutions and their overall magnetic properties are basic features of these metallo-organic compounds.

Here, we have undertaken the study of the structural stability and magnetic properties of $[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]^{8+}$ clusters (where tacn = 1,4,7-triazacyclononane) in an aqueous solution, hereafter referred to as $Fe_{8(aq)}$. Water was chosen as the solvent mainly due to its importance as a biological medium. In fact, Fe_8 presents very low solubility in other solvents, with the exception of methanol in which it is slightly soluble. For the comparison study, the magnetic behaviour of a powder sample ($Fe_{8(s)}$) (the precursor for the aqueous solution) has also been examined. Considering that intermolecular interactions between Fe_8 clusters are negligible [12] in the solid, we believe possible to compare the magnetic results for the powder sample with those for the aqueous solution. The results obtained by all the techniques indicate a lack of stability of Fe_8 clusters in aqueous solution, although further studies should be undertaken to assess the kinetics of the hydrolisation process.

2. Results and discussion

2.1. Spectroscopic characterization

The crystal structure of $[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]^{8+}$, reported by Wieghardt et al. [7], is shown in Fig. 1. An octameric Fe^{III} cation is formed, in which six of the eight Fe^{III} atoms are bonded to an amine ligand. The iron ions are coupled by 12 hydroxo-bridges and by two oxo-bridges. The center of the cluster is formed by two central irons coupled by two μ_3-oxo bridges. The oxygens are bonded to two other irons completing a $\{Fe_4O_2\}^{8+}$ unit, known as 'butterfly core'.

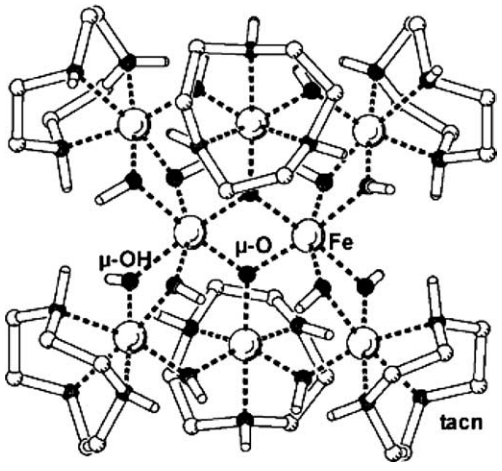

Fig. 1. Crystal structure of $[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]^{8+}$, tacn = 1,4,7-triazacyclononane molecule cluster.

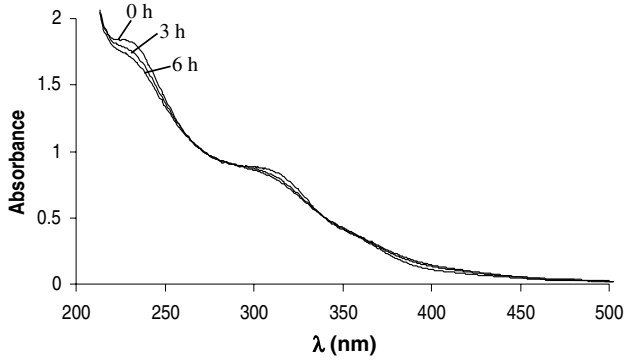

Fig. 2. Repetitive scan UV–Vis spectra of $Fe_{8(aq)}$ at 25 °C. Spectra were recorded at three-hourly intervals.

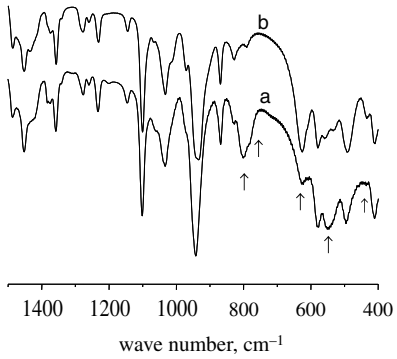

Fig. 3. Infrared absorption spectra: (a) $Fe_{8(aq)}$; and (b) $Fe_{8(s)}$, with arrows indicating significant differences between two spectra.

The UV–Vis spectra of $Fe_{8(aq)}$ are displayed in Fig. 2, they were recorded at different times: 0 h, 3 h and 6 h, where 0 h means right after the aqueous dissolution was made. The three spectra consist of three main weak bands at 230, 300 and 410 nm. Oxo-bridged Fe(III) complexes exhibit intense absorption in the visible and near-UV region, these include two very strong bands in the near-UV region (320–380 nm) and several less intense bands in the visible region (430–550 nm) [13]. Several related complexes present the $\{Fe_4(\mu\text{-}O)_2\}^{8+}$ unit [14–16]; these tetranuclear species may arise by dimerization of the $\{Fe_2O\}^{4+}$ binuclear species, which are very stable in solution due to Fe–O–Fe unit [17,18]. Gorun et al. [15] reported that the 'butterfly core' presents bands at ~465–475 and 565–575 nm, which provides a useful tool for discriminating between the $\{Fe_4O_2\}^{8+}$ unit and its $\{Fe_3O\}^{7+}$ and $\{Fe_2O\}^{4+}$ subsets. The UV–Vis spectrum of $Fe_{8(aq)}$ is similar to those obtained for other, already reported, complexes containing the 'butterfly core'. This

could indicate that the 'butterfly core' remains stable in solution. Nevertheless, a slight diminution of the intensity of the bands is detected for increasing times, better seen for $t = 6$ h, which would indicate the dissociation of the Fe_8 complex in an aqueous solution, even though no precipitate was observed.

Fig. 3 shows the infrared spectra (the region from 1500 to 400 cm^{-1}) of $Fe_{8(aq)}$ freeze-dried (spectrum a) and of $Fe_{8(s)}$ (spectrum b). Most of the peaks above 800 cm^{-1} are due to vibrations in the organic ligands. In this region, there is a strong similarity between the two spectra. However between 800 and 400 cm^{-1} there are some small differences. In this region the symmetric stretch of the Fe–O–Fe unit occurs between 540 and 340 cm^{-1} for (μ-oxo)diiron (III) complexes and the asymmetric stretch occurs between 885 and 725 cm^{-1} [17], but a clear band assignment for Fe_8 spectrum has not been done. Moreover, Spool et al. [19] have studied the integrity of the $[Fe_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(tacn)_2]^{2+}$ core in water by comparing the infrared spectra of the as-prepared powder and the dry powder, after dissolution in water and removal of the solvent in vacuum, showing that both spectra were identical. However, after a few hours, the standing aqueous solution of $[Fe_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(tacn)_2]^{2+}$ became cloudy and developed a precipitate if left overnight, which seems to indicate a lack of integrity of their complex. Drüke et al. [20] have interpreted such observations by pointing out that μ-carboxylate bridges are relatively labile, and that this lability depends on the cyclic amine attached to the core, since in the complex $[(L)_2Fe_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2](ClO_4)_2 \cdot H_2O$, where L = 1,4,7-trimethyl-1,4,7-triazacyclononane, no significant dissociation of the (μ-oxo)(μ-carboxylate)diiron occurs. They argued that the methylated capping ligand is sterically more demanding than its unmethylated analogue, thereby providing an increased stability of the methylated species in water. We propose then a hypothetic mechanism of the decomposition pathway of the Fe_8 cluster in aqueous solution based on the low sterically demand from the tacn which provide a poor protection to our iron-cluster.

2.2. Magnetic characterization

Room-temperature magnetic susceptibility of Fe_8 in an aqueous solution was obtained from NMR measurements with the Evans method, as described in the literature for similar compounds [21]. A value for μ_{Fe8} of $11.7 \pm 2\mu_B$ at 300 K was calculated for $Fe_{8(aq)}$, which is ~10% smaller than that for $Fe_{8(s)}$ complexes, as shown below.

In view of the non-conclusive findings obtained by the spectroscopic techniques and the Evans method, more in-depth magnetic studies were performed.

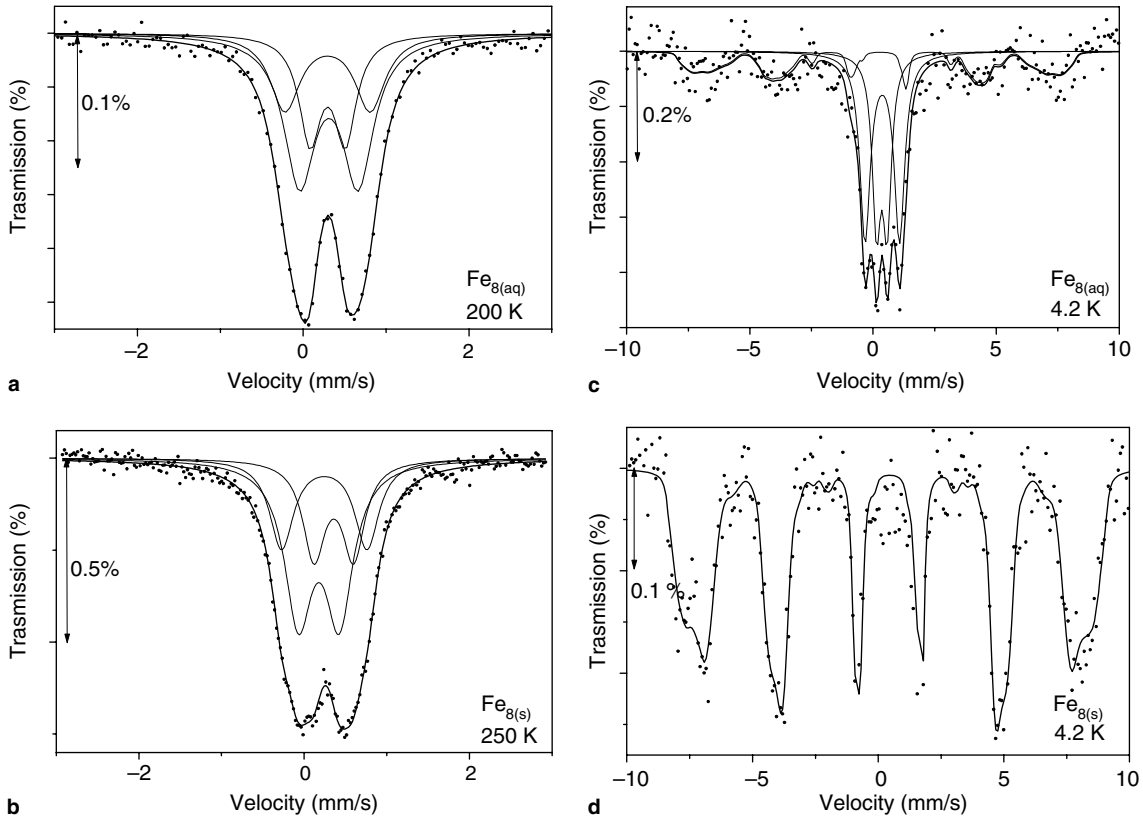

Fig. 4. Mössbauer spectra for $Fe_{8(aq)}$ and $Fe_{8(s)}$; (a) and (c) correspond to $Fe_{8(aq)}$ at 200 and 4.2 K, respectively; (b) and (d) correspond to $Fe_{8(s)}$ at 250 and 4.2 K, respectively.

Mössbauer spectra and the hyperfine parameters, resulting from the fitting of the spectra, for the powder sample (Fig. 4(b) and (d)) are the same to those previously reported [12]. The fit was done in the basis of the three different iron sites within the molecule, $[FeO_2(OH)_4]_2$, $[FeO(OH)_2N_3]_2$, $[Fe(OH)_3N_3]_4$ with area ratios of 1:1:2. The Mössbauer spectrum of $Fe_{8(aq)}$ at 200 K (see Fig. 4(a)) consists of a very broad, almost symmetrical, doublet that could be also fitted using three subspectra since its overall appearance is somehow similar to that of $Fe_{8(s)}$ at 250 K (see Fig. 4(b)). However, the hyperfine parameters of the three subspectra are very different (see Table 1). Only at 4 K the differences between $Fe_{8(aq)}$ (see Fig. 4(c)) and $Fe_{8(s)}$ (see Fig. 4(d)) are evident. The $Fe_{8(aq)}$ spectrum could be fit using three subspectra; two symmetric doublets and a magnetically split component accounting for a 25% of the total area (that sub-spectra was fitted using a distribution of hyperfine fields). On the other hand, the $Fe_{8(s)}$ spectrum shows a magnetically split broad sextet that was fit using three six-line subpectra with 1:1:2 area ratios. In this sample the spectrum is completely resolved indicating that all the spins are frozen in a collective state and no paramagnetic component are detected for the $Fe_{8(s)}$ sample which would lead to a central doublet or singlet. From the low temperature Mössbauer spectrum of the $Fe_{8(aq)}$ we can suggest the presence of several iron sites in the solution: (i) two very different paramagnetic Fe ion centres and (ii) and a minor phase, magnetically split, that we have tentatively assigned to iron hydroxide colloidal particles of the gel–type $Fe(OH)_3 \cdot 0.9H_2O$ [22]. Such phase shows superparamagnetic behaviour at higher temperature, namely at 250 K where the magnetically split component is not visible.

The substantial differences between $Fe_{8(s)}$ and $Fe_{8(aq)}$ are also seen in the dc magnetization results. The temperature dependence of $\chi_g T$ for $Fe_{8(aq)}$ and $Fe_{8(s)}$ samples obtained in a field of 90 kOe are shown in Fig. 5(a) and (b), respectively. For the powdered sample the $\chi_g T(T)$ curve measured at 10 kOe is also presented in Fig. 5(b). The $\chi_g T(T)$ dependence of the $Fe_{8(s)}$ sample exhibits a plateau at elevated temperatures, then a steady increase for decreasing temperatures, up to a certain maximum followed by a rapid decrease. The maximum strongly depends on the measuring field and corresponds to: (i) $\chi_g T = 0.029$ emu K g^{-1} Oe^{-1}, at 12.5 K for 10 kOe and (ii) $\chi_g T = 0.0175$ emu K g^{-1} Oe^{-1}, at 62 K for 90 kOe. The peak is stronger and better pronounced for 10 kOe, which is due to saturation effects in the field, and shows a much higher susceptibility at lower fields than that at high fields. The dependence obtained at 10 kOe is very similar to that published by Delfs et al. [23]. The $\chi_g T(T)$ curve obtained for powder $Fe_{8(s)}$ is indicative of the presence of ferrimagnetic interactions between the Fe ions. This is seen even better from the

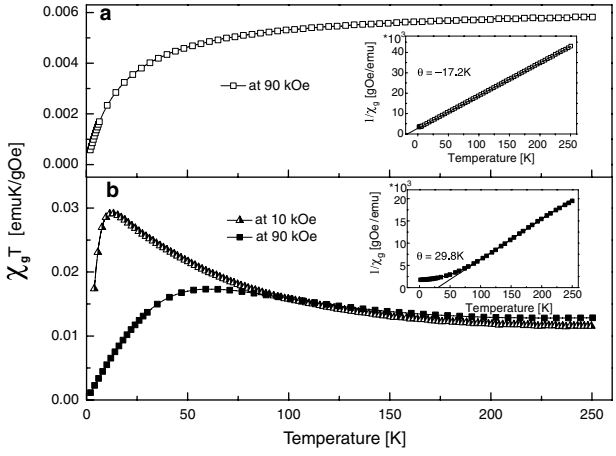

Fig. 5. Temperature dependence of the susceptibility measured at H = 90 kOe – $\chi_g T$ vs. T for: (a) $Fe_{8(aq)}$ and (b) $Fe_{8(s)}$. Inverse susceptibility vs. T is shown in the insets.

Table 1
Hyperfine parameters for the fitting of the Mössbauer spectra

Sample	Iron site	δ_{Fe} (mm/s)	ΔE (mm/s)	Γ (mm/s)	B_{HF} (T)	Area (%)
Fe_8(aq) 200 K	Site 1	0.39(2)	0.43(4)	0.32(4)		25
	Site 2	0.39(2)	1.03(8)	0.43(6)		25
	Site 3	0.41(2)	0.71(5)	0.45(6)		50
Fe_8(s) 250 K	$[FeO_2(OH)_4]_2$	0.46(1)	0.47(2)	0.32(4)		25
	$[FeO(OH)_2N_3]_2$	0.34(1)	1.05(2)	0.35(2)		25
	$[Fe(OH)_3N_3]_4$	0.28(1)	0.50(2)	0.40(2)		50
Fe_8(aq) 4.2 K	Site 1	0.48(2)	1.45(4)	0.41(6)		32
	Site 2	0.46(2)	0.48(4)	0.53(6)		43
	Site 3	0.38(8)			44 (2)	26
Fe_8(s) 4.2 K	$[FeO_2(OH)_4]_2$	0.49(2)		0.37(8)	46.3(1)	25
	$[FeO(OH)_2N_3]_2$	0.44(2)		0.34(4)	43.9(1)	25
	$[Fe(OH)_3N_3]_4$	0.40(2)		0.65(8)	50.1(1)	50

δ_{Fe}, ΔE and Γ are the isomer shift (relative to metallic iron), quadrupolar splitting and the full-width at half-maximum, respectively (in mm/s) $\langle B_{HF} \rangle$ is the mean hyperfine field in Tesla. The area represents the Mössbauer fraction of each sub-spectra in relative percentage. The errors are given within brackets and correspond to the last digit.

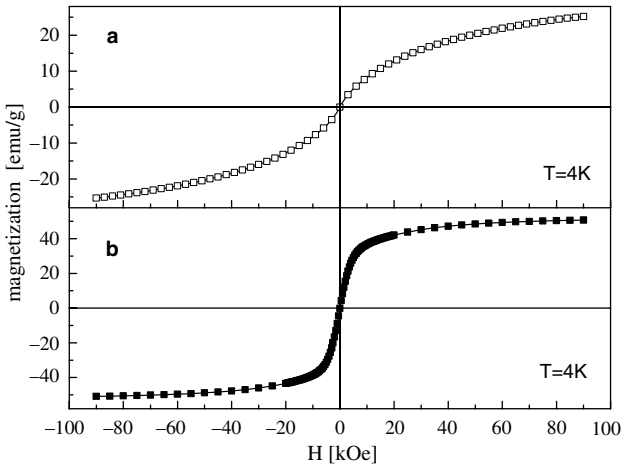

Fig. 6. Magnetization curves at 4 K: (a) for $Fe_{8(aq)}$; and (b) for $Fe_{8(s)}$.

temperature dependence of the inverse susceptibility, shown in the inset in Fig. 5(b), which reveals Curie–Weiss behaviour at $T > 100$ K with a positive Weiss constant $\theta = 29.8$ K and a magnetic moment of $13.5 \pm 0.5\mu_B$. For the $Fe_{8(aq)}$ sample, the $\chi_g T(T)$ dependence (Fig. 6(a)) presents completely different behaviour – $\chi_g T$ remains almost constant (at a value of $\sim$0.006 emu K g^{-1} Oe^{-1}) down to 100 K, and then decreases slowly with temperature, suggesting the presence of dominant antiferromagnetic coupling between Fe ions. The $\chi_g{}^{-1}(T)$ obeys the Curie–Weiss law (see the inset in Fig. 6(a)) with a negative Weiss constant $\theta = -17.2$ K and a magnetic moment of $10.6 \pm 0.5\ \mu_B$ (i.e., similar to that estimated from the Evans method).

The magnetization curves of $Fe_{8(aq)}$ and $Fe_{8(s)}$ samples are also very different, as shown in Fig. 6(a) and (b) in the loops recorded at 4 K. The $Fe_{8(s)}$ sample exhibit superparamagnetic behaviour at low temperatures, for the time scale used in the magnetic measures, and the magnetization curve at 4 K for $Fe_{8(s)}$ can be fitted to a Langevin function with a saturation magnetization of $\sim 20\ \mu_B$, which corresponds to an $S = 10$ ground state. On the other hand, the corresponding magnetization curve of the $Fe_{8(aq)}$ sample cannot be described by a simple Langevin function, which indicates a change in structure of the initially unisize iron clusters. Moreover, the saturation magnetization cannot be estimated. Thus, the magnetic results demonstrate that the Fe_8 clusters do not remain stable in the aqueous solution and this conclusion is additionally supported in [24], where NMR studies show indication of partial decomposition of Fe_8 in aqueous solution.

3. Conclusions

Studies of the large $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]^{8+}$ cluster in the powder state and in the aqueous solution have been performed aimed at characterizing the stability of this 3d-metal magnetic cluster in solution. The IR spectra of the powder and aqueous samples do not show significant differences. The UV–Vis spectrum of $Fe_{8(aq)}$ shows bands that could be assigned to the $\{Fe_4O_2\}^{8+}$ core. However, these bands decrease with time which indicates a slow kinetic decomposition. The NMR Evans method, routinely used to assess the magnetic moment of complexes in solution, yielded a value for the magnetic moment only slightly lower than that found for the solid sample, although fluctuations of this value were observed. The clearest evidence for the decomposition of the core of the Fe_8 cluster in solution is provided by Mössbauer spectroscopy and dc magnetization studies.

At low temperatures, all the Fe ions are in a collective magnetic state in Fe_8 powder and are coupled by the predominantly ferrimagnetic interactions. In turn, when Fe_8 molecules are in an aqueous solution, most of the superexchange bonds between Fe ions are broken, a majority of Fe(III) ions appears in the paramagnetic state, whereas the remaining 30% of Fe(III) ions are coupled by preferential antiferromagnetic interactions, we suppose that are in a form of small iron oxide hydroxide colloidal clusters. The results presented in this paper are in agreement with those presented in previous studies [25], which suggested that tacn does not provide stability to the core and hydroxo and oxo bridges can be hydrolyzed in an aqueous solution.

4. Experimental

4.1. Synthesis of $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]\text{-}Br_7(H_2O)\}Br \cdot 8H_2O$

Reagents were obtained from commercial sources and used as received without further purification. Fe_8 synthesis was performed in two steps, as described by Wieghardt et al. [7,26]; first, the complex (tacn)$FeCl_3$ was formed by mixing $FeCl_3$ and tacn in an ethanolic solution, then the complex (tacn)$FeCl_3$ was dissolved in H_2O/pyridine and NaBr was added. Brown crystals of Fe_8 appeared after 24 h. A special batch enriched with ^{57}Fe isotope was prepared to be used for Mössbauer characterization. The aqueous solution was prepared by mixing the Fe_8 powder with distilled water at a concentration of 5 mM of Fe_8; the pH of the solutions was not adjusted.

4.2. Physical methods

4.2.1. Spectroscopy measurements

UV–Vis spectral measurements for $Fe_{8(aq)}$ were performed using a Varian Cary 5 E Spectrophotometer. IR spectra (4000–400 cm^{-1}) from KBr discs of $Fe_{8(aq)}$ (after freeze-drying the aqueous solution) and $Fe_{8(s)}$

were recorded on a Fourier transform Perkin–Elmer spectrometer.

Evans susceptibility measurements, based on the Evan's method [20], were carried out using a Bruker AMX-400-WB spectrometer. 5-mm-diameter NMR tubes containing an aqueous solution of 5 mM Fe_8 and a capillary tube filled with deuterated water were used. 5% of *t*-BuOH was added to both solutions.

Mössbauer spectra of $Fe_{8(aq)}$ and $Fe_{8(s)}$ both enriched with Fe^{57} were recorded at 200 and 4.2 K with a conventional transmission spectrometer using a ^{57}Co source in a Rh matrix. The source was moved via triangular velocity wave and the γ-counts were collected in a 512 multichannel analyzer. The data were folded, plotted and fitted by a computer procedure NORMOS [27]. Velocity calibration was done using a 25 μm thick metallic Fe foil, and the Mössbauer spectral parameters are given relative to this standard at room temperature. $Fe_{8(aq)}$ spectra were obtained from a frozen solution in water.

4.2.2. Magnetic characterization

The dc magnetization temperature dependence for the powder and frozen aqueous Fe_8 samples were measured with a VSM (Oxford Instruments Ltd.) and a PPMS magnetometer (Quantum Design) over the temperature range 2–250 K in the applied field up to 90 KOe. Hysteresis loops for both samples were measured at selected temperatures. The experimental results were corrected for the holder contribution and for a temperature-independent diamagnetic contribution. All the magnetization data are presented in emu per gram of Fe_8. The measurements for $Fe_{8(aq)}$ were performed at high field since $Fe_{8(aq)}$ shows very large high field susceptibility. This allowed to enhance the signal (which is low because the content of the magnetic phase in the solution is small) even though this is associated with an increase of the diamagnetic contribution. For $Fe_{8(s)}$ sample, which saturates at lower fields the susceptibility measurements were performed both at high field, and low fields.

Synthesis and X-ray structural characterization of M(3,5-^{t}Bu$_2$-salophen) (M = Cu, V=O)

Michael P. Weberski Jr., Craig C. McLauchlan *, Christopher G. Hamaker *

Department of Chemistry, Illinois State University, Campus Box 4160, Normal, IL 61790-4160, USA

Received 13 May 2005; accepted 8 July 2005
Available online 29 August 2005

Abstract

The synthesis and characterization of Cu(3,5-^{t}Bu$_2$-salophen) (**4**) and VO(3,5-^{t}Bu$_2$-salophen) (**5**) as well as the crystallographic elucidation of the structures are reported. X-ray analyses show the expected approximately square planar geometry of copper (II) and the square pyramidal geometry of vanadium in structures **4** and **5**, respectively. Both discrete molecular structures are well defined with no obvious hydrogen bonding present. The EPR spectra of **4** and **5** are typical of complexes of this type. 3,5-^{t}Bu$_2$-salophen = *N*,*N*′–phenylenebis(3,5-di-*tert*-butylsalicylideneimine).

Keywords: Copper; Vanadium; Vanadyl; Crystal structures; EPR

1. Introduction

Schiff bases are common ligands in coordination chemistry because of their ease of preparation. Many Schiff base complexes are efficient catalysts for industrially important reactions. For example, chiral manganese (III) salen complexes have been shown by both Jacobsen and Katsuki and their co-workers to catalyze the asymmetric epoxidation of olefins [1–4]. Recently, Zolezzi et al. [5] have shown that copper (II) Schiff base complexes catalyze the epoxidation of styrene. Scheme 1 illustrates the Schiff bases H_2salen (**1**), H_2salophen (**2**), and H_2[3,5-^{t}Bu$_2$-salophen] (**3**).

Use of the Schiff base H_2[3,5-^{t}Bu$_2$-salophen] (**3**) as a ligand has been previously reported [6,7]. Crystal structures of **3** complexed with many elements including Sr, Sn, Ga, Mo, Al, Zn, In, and Rh have been reported [8–15]. The preparations of these complexes were, in many cases, quite straightforward and employed the reaction of metal salts with **3** that had been generated in situ. In our efforts to prepare a model complex to model a structurally more complex copper (II) porphyrin for EPR study [16], we synthesized the complex Cu(3,5-^{t}Bu$_2$-salophen) (**4**). Also prepared was vanadyl(3,5-^{t}Bu$_2$-salophen) (**5**), which is known to catalyze the electroreduction of O_2 to H_2O [17]. The metal–ligand bond distances of some of the previously reported [3,5-^{t}Bu$_2$-salophen] compounds are similar to the metrics for **4** and **5** [10,12,13,15].

The synthesis, characterization, and crystallographic elucidation of the structures of **4** and **5** are presented here.

2. Experimental

2.1. General considerations

All materials were obtained from commercial sources and used as received. Infrared spectra were collected on a Nicolet 5SXC FT-IR spectrometer as KBr mulls. Electronic absorption (UV–Vis) spectra were collected on a

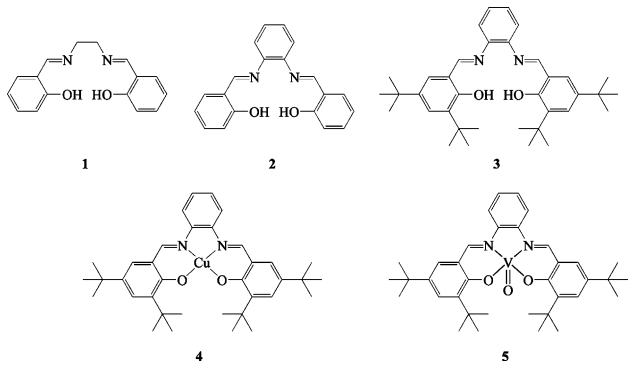

Scheme 1.

Cary 500 UV–Vis–NIR spectrophotometer. ^{1}H NMR spectra were collected on a 400-MHz Bruker spectrometer and were referenced to residual $CHCl_3$. EPR spectra were collected at 290 K on a Bruker EMX-080 spectrometer. Magnetic susceptibility measurements were carried out using a Johnson Matthey magnetic susceptibility balance. Microanalyses were conducted by the Microanalytical Laboratory, School of Chemical Sciences, University of Illinois, Urbana-Champaign.

2.2. Synthesis of H_2[3,5-^{t}Bu$_2$-salophen] (3)

This compound has been previously reported [6,7]. To a solution of 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde (4.74 g, 20.2 mmol) in 100 ml of absolute ethanol was added 1.09 g (10.1 mmol) of 1,2-phenylenediamine. The resulting solution was refluxed for 2 h, cooled to room temperature, and then placed into a freezer at −40 °C for 16 h. The solution was filtered and the solid was washed with cold ethanol and air dried giving 1.04 g of **3** as a fluffy yellow solid. The volume of the filtrate liquid was reduced to approximately 50 ml and placed into the freezer. The resulting solid was filtered to produce an additional 2.95 g of product. Total yield was 3.99 g (7.38 mmol, 73%). IR (KBr cm^{-1}): 3125 (OH), 1617 (C=N). ^{1}H ($CDCl_3$, δ) 11.64 (s, 2H, O*H*); 8.66 (s, 2H, C*H*=N); 7.44 (d, 2H, $C_6H_2(^t$Bu$)_2$(OH)); 7.32 (m, 2H, *o*-$C_6H_4N_2$); 7.24 (m, 2H, *o*-$C_6H_4N_2$); 7.21 (d, 2H, $C_6H_2(^t$Bu$)_2$(OH)); 1.43 (s, 18H, C(CH_3)$_3$); 1.32 ppm (s, 18H, C(CH_3)$_3$).

2.3. Synthesis of Cu(3,5-^{t}Bu$_2$-salophen) (4)

To a solution of H_2[3,5-^{t}Bu$_2$-salophen] (**3**) (0.2024 g, 0.3740 mmol) in ethanol(15 ml) was added Cu$(NO_3)_2 \cdot 2.5H_2O$(0.0870 g, 0.374 mmol) in ethanol (8 ml). The reaction mixture was heated gently to 50 °C and 1.5 ml of 0.5 M NaOH was added. The resulting brown crystals were filtered off and washed with cold ethanol. Total yield was 0.1837 g (0.3050 mmol, 82%). IR (KBr cm^{-1}): 1601(C=N). UV–Vis (toluene λ, nm (ε, M^{-1} cm^{-1})): 317 (20 300), 334 (18 100), 352 (14 500), 408 (11 000), 453 (14 800), 711 (3011). Elemental *Anal.* Calc. for $C_{36}H_{46}N_2O_2Cu$: C, 71.79; H, 7.70; N, 4.65. Found: C, 70.20; H, 7.26; N, 4.56%. Magnetic susceptibility χ_m (erg G^{-2} mol^{-1}): 1.73×10^{-3} μ_{eff} (μ_B): 2.04 ($\chi_m T = 0.520$). This compound was further characterized by X-ray crystallography.

2.4. Synthesis of VO(3,5-^{t}Bu$_2$-salophen) (5)

Vanadyl sulphate dihydrate (0.421 g, 2.12 mmol) and H_2[3,5-^{t}Bu$_2$-salophen] **3** (1.084 g, 2.01 mmol) were dissolved in 50 ml of methanol. To the resulting solution was added 0.60 ml (4.3 mmol) of triethylamine and the reaction was refluxed for 45 min. The reaction was cooled to room temperature and placed into a freezer at −40 °C for 4 h. The resulting precipitate was filtered, washed with cold methanol and hexanes and air dried to yield 1.063 g (1.76 mmol, 88%) of the product as an olive green microcrystalline solid. IR (KBr cm^{-1}): 1609(C=N), 982(V=O). UV–Vis (toluene λ, nm (ε, M^{-1} cm^{-1})): 333 (24 678), 427 (17 386), 713 (3365). Elemental *Anal.* Calc. for $C_{36}H_{46}N_2O_3V$: C, 71.39; H, 7.65; N, 4.62. Found: C, 71.33; H, 7.70; N, 4.82%. Magnetic susceptibility χ_m (erg G^{-2} mol^{-1}): 1.99×10^{-3} μ_{eff} (μ_B): 2.18 ($\chi_m T =$ 0.594). This compound, as its ethanol solvate, was further characterized by X-ray crystallography.

2.5. X-ray structure determinations

Single crystals of **4** and **5** · EtOH suitable for X-ray were obtained by slow growth in ethanol. Intensity data were collected at Johns Hopkins University, Baltimore, MD at −173 °C on an Oxford Xcaliber3 diffractometer equipped with a CCD area detector. Graphite monochromated Mo Kα radiation from an Enhance source was used. Data were reduced and corrected for absorption using the Crysalis Software Suite [18]. Structure solutions were obtained by direct methods and were refined on F^2 with the use of full-matrix least-squares techniques [19]. Except where noted, all non-hydrogen atoms were refined anisotropically and hydrogen atoms were refined with a riding model. All compounds solved and refined routinely. The crystallographic results are summarized in Table 1. Further details are available in Supporting Information.

3. Results and discussion

3.1. Electronic and magnetic properties

Compound **4** has a calculated μ_{eff} value of 2.04μ_B ($\chi_m T = 0.520$) representative of a d^9 metal corresponding to the one unpaired electron of copper in the 2+

[a] $R_1(F) = \sum(||F_o| - |F_c||)/\sum|F_o|$.
[b] $wR_2(F_o^2) = [\sum[w(F_o^2 - F_c^2)^2]/\sum wF_o^4]^{1/2}$; $w_4 = 1/[\sigma^2(F_o^2)+(0.0487P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$; $w_{5\cdot EtOH} = 1/[\sigma^2(F_o^2)+(0.0348P)^2 + 3.0757P]$ where $P = (F_o^2 + 2F_c^2)/3$.

oxidation state. Magnetic susceptibility measurements for **4** are consistent with published μ_{eff} values for copper (II) systems [20].

Compound **5** has a calculated μ_{eff} value of $1.30\mu_B$ ($\chi_m T = 0.594$). This value is lower than expected μ_b values for V^{4+} of 1.7–1.8 [20]. Other reported oxovanadium (IV) salen complexes have low magnetic susceptibilities [21,22].

The EPR spectrum for **4** was collected at room temperature in toluene and was consistent with previously reported copper (II) salen complexes [23,24]. Complex **4** is expected to have a single unpaired electron, consistent with a formulation of Cu(II), d^9 (vide supra). Four peaks centered around $g = 2.015$ are also consistent with the expected hyperfine splitting from the copper center ($I = 3/2$).

EPR spectral data for **5** have been previously reported by Liu and Anson [17]. The EPR spectrum for **5** collected at room temperature in acetonitrile showed an octet of peaks ($I_V = 7/2$) centered at $g = 1.988$. This study agrees with the previously reported g-factor value [17].

UV–Vis absorptions for **4** are also consistent with similar compounds that have been previously reported [24]. A similar copper (II) salen complex with a methyl in lieu of a *tert*-butyl gives visible absorptions (nm) at 405 and 444, whereas **4** gives absorptions 408 and 452. Similar electronic spectra were obtained for **5**. The character of the absorptions are similar to previously reported assignments [24], i.e., an intense absorption between 316 and 333 nm for both compounds is due to metal-to-ligand charge transfer; weak d–d transitions were observed around 711 nm.

3.2. X-ray structures

The crystal structure of Cu[3,5-^{t}Bu$_2$-salophen] (**4**) consists of one molecule in the asymmetric unit. The compound **4** crystallizes in the triclinic space group $P\bar{1}$. Selected geometric parameters are shown in Table 2. A displacement ellipsoid plot of **4** is shown in Fig. 1. The structure consists of discrete molecules with no obvious hydrogen bonding between adjacent molecules. The molecular structure is roughly planar with a curving of the plane of the Cu and 3 phenyl rings – the Cu atom sits 0.0266 Å below the mean O/O/N/N plane, but 0.2479 Å above the mean plane of the centroids of the three phenyl rings of the ligand. The Cu—N and Cu—O bond distances are typical of compounds of this type [24,25]. In the three-dimensional structure, the molecule packs in what appears to be dimers. The central phenyl ring of one molecule resides above the Cu atom of the adjacent molecule at a distance of 3.350 Å. The idealized H on a methyl group from the adjacent dimer forms a short contact (~2.78 Å) with Cu to "complete" a distorted octahedral geometry.

Table 2
Selected bond lengths (Å) and angles (°) for **4**

Cu–N(1)	1.940 (3)
Cu–N(2)	1.944 (2)
Cu–O(1)	1.896 (2)
Cu–O(2)	1.897 (2)
C(1)–O(1)–Cu	129.12 (17)
C(12)–O(2)–Cu	128.16 (17)
O(1)–Cu–O(2)	90.28 (9)
O(1)–Cu–N(1)	92.74 (10)
O(2)–Cu–N(1)	176.90 (8)
O(1)–Cu–N(2)	175.71 (9)
O(2)–Cu–N(2)	93.14 (10)
N(1)–Cu–N(2)	83.81 (10)

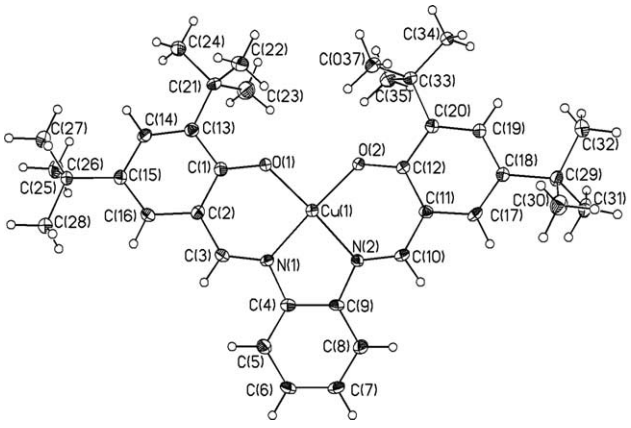

Fig. 1. Displacement ellipsoid plot of **4**. Here and in Fig. 2 displacement ellipsoids are drawn at the 50% probability level. Hydrogen atoms are drawn as arbitrarily small circles.

Compound **5** co-crystallizes with one equivalent of ethanol solvent molecule in the monoclinic space group $P2_1/c$. A displacement ellipsoid plot of **5** is shown in Fig. 2. Selected geometric parameters are shown in Table 3. Crystals of the compound effloresce when removed from the mother liquor. The molecular structure is well-defined and consists of a well-separated moiety and one solvent molecule per asymmetric unit, with four asymmetric units per unit cell. No hydrogen bonding is obvious in the molecular structure, however, π–π stacking of adjacent molecules is present. **5** packs in typical herringbone fashion when viewed along [1 0 0] with ethanol filling structural voids. The centroid of the central phenyl ring and the centroid of the π–π stacked outer phenyl ring of an adjacent molecule are separated by 3.832 Å (closest contact 3.52 Å C9···C11). The strength of π–π stacking interactions leads to several close contacts and disrupts any V=O···solvent hydrogen bonding that may have otherwise occurred. The metrics of the molecule are similar to the current 73 vanadyl salen complexes in the Cambridge Structural Database with V–N bonds of 2.051(2) Å, V–O bonds of 1.9133(18) Å, and a V=O bond of 1.5991(18) Å [26]. Average literature values for these types of bonds are 2.07, 1.88, and 1.60 Å, respectively [26]. The vanadium has the expected square pyramidal geometry and lies 0.611 Å above the O/O/N/N plane. A 21° angle exists between the *tert*-butyl substituted aromatic rings. This curvature of the salophen ligand is most likely due to steric hindrance between the *tert*-butyl groups in the 3 position.

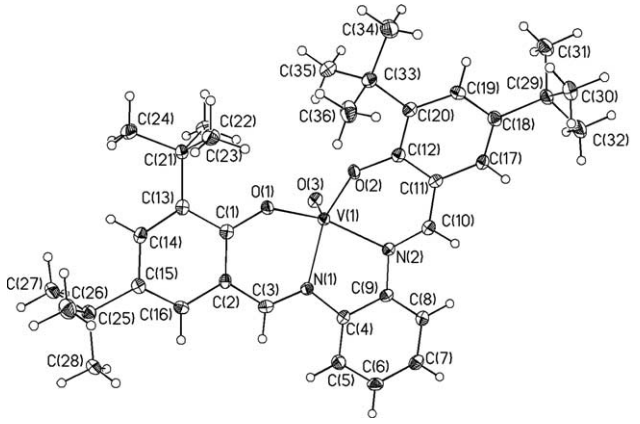

Fig. 2. Displacement ellipsoid plot of **5**. The O in V=O is projected into the plane of the page.

3.3. Reactivity

Reactivity studies were also attempted on compound **4**. Initial attempts were made to bind pyridine to **4**. An amount of **4** was dissolved in toluene and titrated with pyridine while being monitored using UV–Vis spectroscopy. No changes in the UV–Vis spectrum were observed. An amount of **4** was also dissolved in neat pyridine, but again no change in the UV–Vis spectrum was observed. Initially it was believed that **4** existed as an ethanol solvated molecule, but X-ray structural information was not consistent with this theory, at least in the solid state. Pyridine may not bind to **4** due to the 18-electron rule. The central copper atom in **4** has an electron count of 17, so it is unlikely that the two electron donor pyridine could bind to the copper without the dissociation of a portion of the salophen ligand.

4. Supporting information available

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 271743 and 271742 for **4** and **5**, respectively. Copies of this information maybe obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk.

Abstract

Copper(I) acylpyrazolonate derivatives of formula $[Cu(Q)(PPh_3)_2]$ (HQ = HQ^{C2F5} = 1-phenyl-3-methyl-4-pentafluoropropanoyl-pyrazol-5-one, $HQ^{CF3,CF3}$ = 1-(4-trifluoromethyl)phenyl-3-methyl-4-trifluoroacetylpyrazol-5-one, HQ^{naph} = 1-phenyl-3-methyl-4-(1-naphthoyl)pyrazol-5-one, HQ^{fur} = 1-phenyl-3-methyl-4-furylpyrazol-5-one, HQ^{thi} = 1-phenyl-3-methyl-4-thienoylpyrazol-5-one, $HQ^{CF3,py}$ = 1-(2-pyridyl)-3-methyl-4-trifluoromethylpyrazol-5-one) have been synthesized and characterized, both in the solid state and in solution. The isomorphous crystal structures of $[Cu(Q^{fur})(PPh_3)_2]$ and $[Cu(Q^{thi})(PPh_3)_2]$ and of $[Cu(Q^{C2F5})(PPh_3)_2]$ show their copper atoms in distorted tetrahedral environments. Apart from the derivative $[Cu(Q^{naph})(PPh_3)_2]$, they are fluxional in chloroform solution, dissociating partially to the $[Cu(Q)(PR_3)]$ fragment and free PR_3, or existing in solution as $[Cu(O_2–Q)(PR_3)_2]$ or $[Cu(O–Q)(PR_3)_2]$ species, with CuO_2P_2 or $CuOP_2$ metal environments, in equilibrium with each other. By contrast, in $[Cu(Q^{CF3,py})(PPh_3)_2]$ the $Q^{CF3,py}$ ligand is coordinated to copper through the nitrogen atoms of the pyrazole and pyridine rings. The latter compound reacts with $Zn(BF_4)_2 \cdot xH_2O$ and $[Ru(p\text{-cymene})Cl_2]_2$ affording ionic heterobimetallic adducts.

1. Introduction

In the last decade we have been involved in elucidating the coordinative properties of a class of β-diketones, namely 4-acyl-5-pyrazolones [1], here indicated as HQ, having a pyrazole fused to the chelating moiety, well-known mainly for their selective extraction properties toward several metal ions [2,3]. They generally chelate metal centers in an unsymmetrical fashion because of the different donor capabilities of their oxygen atoms [4,5]. Furthermore they have been shown capable of binding also to soft metal acceptors through the nitrogen of the pyrazole [6]. These ligands can be easily functionalized in the acyl fragment and several examples can be found in the literature, in which the substituents range from electron-withdrawing groups to electron-donating ones [1].

We have also investigated the coordination chemistry of some acylpyrazolone-type ligands with copper(I) and copper(II) acceptors, due to potential applications in the microelectronic industry of some recent copper–β-diketonate compounds as promising molecular precursors for CVD techniques [7]. When heated in vacuo, copper(II) adducts of the type $Cu(Q)_2(L)$ (where L = dipy or phen

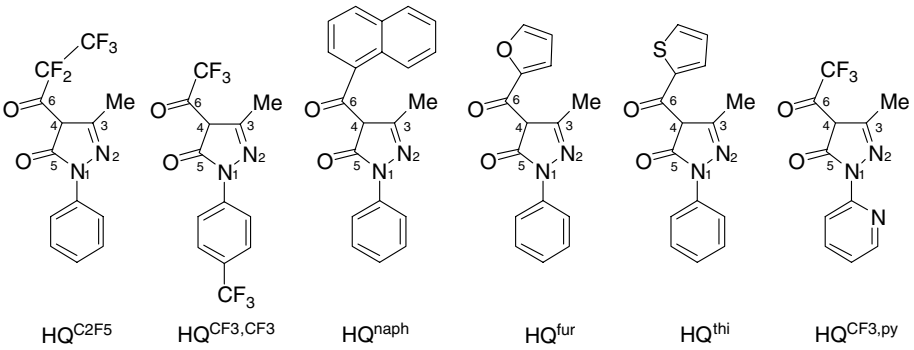

Fig. 1. Proligands HQ used in this work.

and Q = 1-phenyl-3-methyl-4-trifluoromethyl-pyrazolon-5-ato) eliminate the ancillary L ligand and convert into $Cu(Q)_2$, which have lower volatilities than their corresponding classical β-diketonato copper(II) complexes [8]. Cu(I) derivatives of the form $Cu(Q)(PR_3)_2$ (R = Ph, Cy, Bn, *p*-tolyl) show higher volatility, and during sublimation form a thin film of metallic copper, according to the disproportionation: $2\ Cu(Q)(PR_3)_2 \rightarrow Cu + Cu(Q)_2 + 4PR_3$ [8].

Here we extend previous studies on the interaction of copper(I) and silver(I) phosphino acceptors [6a,6b,9] with some selected acylpyrazolones, two containing fluorinated substituents, others with aromatic groups such as naphthyl, furanyl or thienyl in the acyl moiety and, finally, a ligand containing a pyridine ring bonded to N1 of the pyrazolone moiety (Fig. 1), recently reported as an N_2-chelating donor in the synthesis of new silver compounds [10]. A detailed structural and spectroscopic study of the derivatives obtained is reported, and comparison made with the features of the previously studied silver(I) phosphino acylpyrazolonates [6a,6b,9,10]. Possible further interactions through any additional N-, S- or O-donor atoms in $Q^{CF3,py}$, Q^{thi} or Q^{fur}, respectively, with additional metal acceptors, such as zinc(II) and (arene)ruthenium(II), have also been investigated.

2. Experimental section

2.1. General remarks

Solvents were used as supplied or distilled using standard methods. All chemicals were purchased from Aldrich (Milwaukee) and used as received. The samples for microanalyses were dried in vacuum to constant weight (20 °C, ca. 0.1 Torr). Elemental analyses (C, H, N, S) were performed in-house with Fisons Instruments 1108 CHNS–O Elemental Analyser. IR spectra were recorded from 4000 to 100 cm^{-1} using CsI pellets and a Perkin Elmer System 2000 FT-IT instrument. ^1H, ^{13}C, ^{19}F and ^{31}P NMR spectra were recorded on a VXR-300 Varian spectrometer operating at room temperature (300 MHz for ^1H, 75 MHz for ^{13}C, 282.3 MHz for ^{19}F and 121.4 MHz for ^{31}P) and are referred to TMS, 85% H_3PO_4 and $CFCl_3$, respectively; signals are indicated as s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet). The electrical conductances of the acetonitrile solutions were measured with a Crison CDTM 522 conductimeter at room temperature.

2.2. Syntheses of the proligands

The proligands HQ^{C2F5}, $HQ^{CF3,CF3}$, HQ^{naph}, HQ^{fur}, HQ^{thi} and $HQ^{CF3,py}$ were synthesized according to the procedures previously described [6b,9–13].

2.3. Syntheses of the complexes

2.3.1. *[Cu(Q^{C2F5})(PPh$_3$)$_2$] (1)*

$CuNO_3(PPh_3)_2$ (650 mg, 1.0 mmol) was added to a toluene solution/suspension (30 ml) of HQ^{C2F5} (320 mg, 1.0 mmol) and $NaOCH_3$ (54 mg, 1.0 mmol). The clear solution was stirred for 1 h. Solvent was then removed on a rotary evaporator and chloroform (20 ml) was added to the crude of the mixture reaction. The solution was filtered and, after addition of light petroleum (20 ml), a yellow precipitate was afforded, which was filtered off, washed with light petroleum and shown to be compound **1**. Crystals suitable for the X-ray work were deposited from chloroform/diethyl ether solution. It is soluble in most organic solvents, except petroleum ether. Yield: 84%. M.p. 142–144 °C. *Anal.* Calc. for $C_{49}H_{38}CuF_5N_2O_2P_2$: C, 64.86; H, 4.22; N, 3.09. Found: C, 63.95; H, 4.09; N, 3.01%. IR (nujol, cm^{-1}): 1636vs, 1597s, 1584s and 1542m *ν*(C=O, C=N, N=N), 517vs, 503vs, 497vs, 443m, 430m and 426m *ν*(*y*- and *t*-mode of PPh_3), 397w and 345m *ν*(Cu–O). ^1H ($CDCl_3$) NMR: *δ* 2.25s (3H, C3–C*H*$_3$); 7.20–7.50m, 7.90d (35H, H_{arom} of Q^{C2F5} and PPh_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): *δ*, 17.4s (C3–*C*H$_3$), 120.0s, 124.2s, 128.5s, 148.1s (C_{arom} of Q^{C2F5}), 129.5d ($^3J_{(P-C)}$: 14.1 Hz, *m*-*C* of PPh_3), 129.9s (*p*-*C* of PPh_3), 133.2d ($^1J_{(P-C)}$: 36.1 Hz, *C*–P of PPh_3), 134.0d ($^2J_{(P-C)}$: 21.7 Hz, *o*-*C* of PPh_3), 104.6s (*C*4),

2.3.3. [Cu(Q^{naph})(PPh_3)$_2$] (3)

Compound **3** has been synthesized similarly to **1.** It is soluble in dmso, acetonitrile, acetone and chlorinated solvents. Yield: 88%. M.p. 204–207 °C. *Anal.* Calc. for $C_{57}H_{46}CuN_2O_2P_2$: C, 74.70; H, 5.06; N, 3.06. Found: C, 74.45; H, 5.10; N, 3.11%. IR (nujol, cm^{-1}): 1621vs, 1592s, 1578m, 1532m and 1500m ν(C=O), 528s, 515vs, 500vs, 437m and 420m ν(*y*- and *t*-mode of PPh_3), 343m ν(Cu–O). ^1H ($CDCl_3$) NMR: δ 1.21s (3H, C3–CH_3), 7.05–7.45m, 7.54d, 7.83dd, 7.97dd (37H, H_{arom} of Q^{naft} and PPh_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ, 16.1s (C3–CH_3), 119.5s, 123.5s, 123.9s, 125.3s, 125.9s, 126.1s, 126.6s, 128.1s, 130.4s, 140.0s (C_{arom} of Q^{naph}), 128.5d ($^3J_{(P–C)}$: 17.6 Hz, *m*-*C* of PPh_3), 129.6s (*p*-*C* of PPh_3), 133.4d ($^1J_{(P–C)}$: 34.4 Hz, *C*–P of PPh_3), 133.6d ($^2J_{(P–C)}$: 22.3 Hz, *o*-*C* of PPh_3), 106.3s (*C*4), 140.4s (*C*3), 165.9s (*C*5), 189.9s (*C*6). $^{31}P\{^1H\}$ NMR ($CDCl_3$, $T = 293$ K): δ −3.43s [$Cu(O_2–Q^{naph})(PPh_3)_2$]. $^{31}P\{^1H\}$ NMR ($CDCl_3$, $T = 218$ K): δ −4.15s.

2.3.4. [Cu(Q^{fur})(PPh_3)$_2$] (4)

Compound **4** has been synthesized similarly to **1**, crystals suitable for the X-ray work being deposited from chloroform/diethyl ether solution. Yield: 88%. M.p. 168–170 °C. *Anal.* Calc. for $C_{51}H_{41}CuN_2O_3P_2$: C, 71.70; H, 4.72; N, 3.28. Found: C, 71.53; H, 4.66; N, 3.24%. IR (nujol, cm^{-1}): 1610vs, 1592s, 1581s, 1557m and 1526m ν(C=O), 516s, 505vs, 494s, 440m and 426m ν(*y*- and *t*-mode of PPh_3), 408m and 356m ν(Cu–O). ^1H ($CDCl_3$) NMR: δ 2.61s (3H, C3–CH_3), 6.64m, 6.88m, 7.10–7.45m, 7.49dd, 7.65dd, 7.73d (38H, H_{arom} of Q^{fur} and PPh_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ, 16.7s (C3–CH_3), 111.4s, 114.4s, 119.9s, 123.5s, 143.6s, 154.0s (C_{arom} of Q^{fur}), 128.5d ($^3J_{(P–C)}$: 6.9 Hz, *m*-*C* of PPh_3), 129.6s (*p*-*C* of PPh_3), 132.4d ($^1J_{(P–C)}$: 27.1 Hz, *C*–P of PPh_3), 134.1d ($^2J_{(P–C)}$: 14.8 Hz, *o*-*C* of PPh_3), 104.8s (*C*4), 140.0s (*C*3), 167.2s (*C*5), 176.5s (*C*6). $^{31}P\{^1H\}$ NMR ($CDCl_3$, $T = 293$ K): δ −2.20s. $^{31}P\{^1H\}$ NMR ($CDCl_3$, $T = 218$ K): δ −2.68s [$Cu(O–Q^{fur})(PPh_3)_2$], −4.04s [$Cu(O_2–Q^{fur})(PPh_3)_2$].

2.3.5. [Cu(Q^{thi})(PPh_3)$_2$] (5)

Compound **5** has been synthesized similarly to **1**, crystals suitable for the X-ray work being deposited from chloroform/diethyl ether solution. Yield: 79%. M.p. 159–161 °C. *Anal.* Calc. for $C_{51}H_{41}CuN_2O_2P_2S$: C, 70.29; H, 4.74; N, 3.21; S, 3.68. Found: C, 69.87; H, 4.79; N, 3.22; S, 3.55%. IR (nujol, cm^{-1}): 1609vs, 1592s, 1579s, 1554m and 1516m ν(C=O), 515vs, 504vs, 498vs, 440m, 431m and 424m ν(*y*- and *t*-mode of PPh_3), 405w and 353m ν(Cu–O). ^1H ($CDCl_3$) NMR: δ 1.91s (3H, C3–CH_3); 6.97t, 7.05t, 7.15t, 7.22–7.40m, 7.88d (38H, H_{arom} of Q^{thi} and PPh_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ, 16.9s (C3–CH_3), 119.7s, 123.4s, 126.3s, 145.1s, 148.2s (C_{arom} of Q^{thi}), 128.2d ($^3J_{(P–C)}$: 7.1 Hz, *m*-*C* of PPh_3), 129.4s (*p*-*C* of PPh_3), 133.2d ($^1J_{(P–C)}$: 27.3 Hz, *C*–P of PPh_3), 133.8d ($^2J_{(P–C)}$: 14.1 Hz, *o*-*C* of PPh_3), 104.9s (*C*4), 139.9s (*C*3), 166.2s (*C*5), 181.4s (*C*6). $^{31}P\{^1H\}$ NMR ($CDCl_3$, $T = 293$ K): δ −2.62s. $^{31}P\{^1H\}$ NMR ($CDCl_3$, $T = 218$ K): δ −2.64s [$Cu(O–Q^{thi})(PPh_3)_2$], −4.17s [$Cu(O_2–Q^{thi})(PPh_3)_2$].

2.3.6. [Cu($Q^{CF3,py}$)(PPh_3)$_2$] (6)

Compound **6** has been synthesized similarly to **1**, but using a mixture of acetonitrile/methanol (1:1) because of the very low solubility of $HQ^{CF3,py}$ in toluene. Crystals suitable for the X-ray work were deposited from chloroform/diethyl ether solution. Yield: 67%. M.p. 180–183 °C. *Anal.* Calc. for $C_{47}H_{37}CuF_3N_3O_2P_2$: C, 65.77; H, 4.35; N, 4.90. Found: C, 65.43; H, 4.54; N, 4.88%. 2.4. Structure determinations

Full spheres of 'low-temperature' CCD diffractometer data were measured (Bruker AXS instrument, monochromatic Mo Kα radiation ($\lambda = 0.7107_3$ Å), ω-scans; T ca. 153 K), yielding $N_{t(otal)}$ reflections, merging to N unique after 'empirical'/multiscan absorption correction (proprietary software), N_o with $F > 4$ (F) considered 'observed' and used in the full matrix least squares refinements, refining anisotropic displacement parameter forms for the non-hydrogen atoms, $(x, y, z, U_{iso})_H$ being included constrained at estimates. Conventional residuals R, R_w (weights: $(\sigma^2(F) + 0.000n_wF^2)^{-1}$) are cited at convergence. Neutral atom complex scattering factors were employed, computation using the XTAL 3.4 program system [14]. Pertinent results are given below and in the Tables and Figures, the latter showing non-hydrogen atoms with 50% probability amplitude displacement ellipsoids, hydrogen atoms having arbitrary radii of 0.1 Å.

2.4.1. Crystal/refinement data

$[Cu(Q^{C2F5})(PPh_3)_2]$ (**1**). $C_{49}H_{38}CuF_5N_2O_2P_2$, $M = 907.4$. Triclinic, space group $P\bar{1}$ (C_i^1, No. 2), $a = 14.169(1)$, $b = 19.140(2)$, $c = 19.252(2)$ Å, $\alpha = 118.414(2)$, $\beta = 103.092(2)$, $\gamma = 99.222(2)°$, $V = 4248$ Å^3. D_c ($Z = 4$) $= 1.41_9$ g cm^{-3}. $\mu_{Mo} = 6.5$ cm^{-1}; specimen:

$0.26 \times 0.22 \times 0.18$ mm; $'T'_{min/max} = 0.65$. $2\theta_{max} = 60°$; $N_t = 87869$, $N = 24407$ ($R_{int} = 0.12$), $N_o = 14682$; $R = 0.075$; $R_w = 0.14$ ($n_w = 850$ (refinement on F^2)). $|\Delta\rho_{max}| = 2.2(2)$ eÅ^{-3}.

Variata. The ligand on molecule **2** was modelled as disordered over two sets of sites, occupancies refining to 0.680(1) and complement, the geometries of the two C_2F_5 components being constrained. P(22) and associated ring 223 were modelled as disordered over two sets of sites, occupancies refining to 0.743(3) and complement.

[Cu(Q^{fur})(PPh$_3$)$_2$] (**4**). $C_{51}H_{41}CuN_2O_3P_2$, $M = 855.4$. Orthorhombic, space group $P2_12_12_1$ (D_2^4, No. 19), $a = 10.778(1)$, $b = 18.872(2)$, $c = 20.829(2)$ Å, $V = 4237$ Å^3. D_c ($Z = 4$) $= 1.34_1$ g cm^{-3}. $\mu_{Mo} = 6.4$ cm^{-1}; specimen: $0.15 \times 0.12 \times 0.10$ mm; $'T'_{min/max} = 0.70$. $2\theta_{max} = 58°$; $N_t = 42477$, $N = 5987$ ($R_{int} = 0.071$), $N_o = 4264$; $R = 0.048$; $R_w = 0.052$ ($n_w = 4$). $|\Delta\rho_{max}| = 0.8(2)$ eÅ^{-3}. $x_{abs} = 0.02(2)$.

[Cu(Q^{thi})(PPh$_3$)$_2$] (**5**). $C_{51}H_{41}CuN_2O_2P_2S$, $M = 871.5$ is isomorphous with **4**, the specimen chosen being of opposite chirality. $a = 10.764(1)$, $b = 19.015(2)$, $c = 21.034(3)$ Å, $V = 4305$ Å^3. $D_c = 1.34_4$ g cm^{-3}. $\mu_{Mo} = 6.7$ cm^{-1}; specimen: $0.38 \times 0.35 \times 0.20$ mm; $'T'_{min/max} = 0.83$. $2\theta_{max} = 58°$; $N_t = 43413$, $N = 6148$ ($R_{int} = 0.051$), $N_o = 4722$; $R = 0.039$; $R_w = 0.037$ ($n_w = 4$). $|\Delta\rho_{max}| = 0.6(1)$ eÅ^{-3}. $x_{abs} = -0.03(1)$.

[Cu(Q^{CF3,py})(PPh$_3$)$_2$] (**6**). 1/4MeOH≡$C_{47}H_{38}CuF_3N_3O_2P_2$. 1/4 MeOH, $M = 867.3$. Monoclinic, space group $P2_1/n$ (C_{2h}^5, No. 14), $a = 23.771(2)$, $b = 15.797(2)$, $c = 24.585(3)$ Å, $\beta = 115.657(2)°$, $V = 8322$ Å^3. D_c ($Z = 8$) $= 1.38_4$ g cm^{-3}. $\mu_{Mo} = 0.66$ cm^{-1}; specimen: $0.33 \times 0.19 \times 0.16$ mm; $'T'_{min/max} = 0.89$. $2\theta_{max} = 55°$; $N_t = 119048$, $N = 19109$ ($R_{int} = 0.078$), $N_o = 13181$; $R = 0.052$; $R_w = 0.070$. $|\Delta\rho_{max}| = 0.70(5)$ eÅ^{-3}.

Variata. Difference map residues in a lattice void were modelled in terms of disordered methanol solvent C, O fragments (H not located), site occupancies set at 0.25 after trial refinement. Neighbouring ligand substituent residues also exhibit exalted displacement parameters, possibly encompassing unresolved (concerted?) disorder.

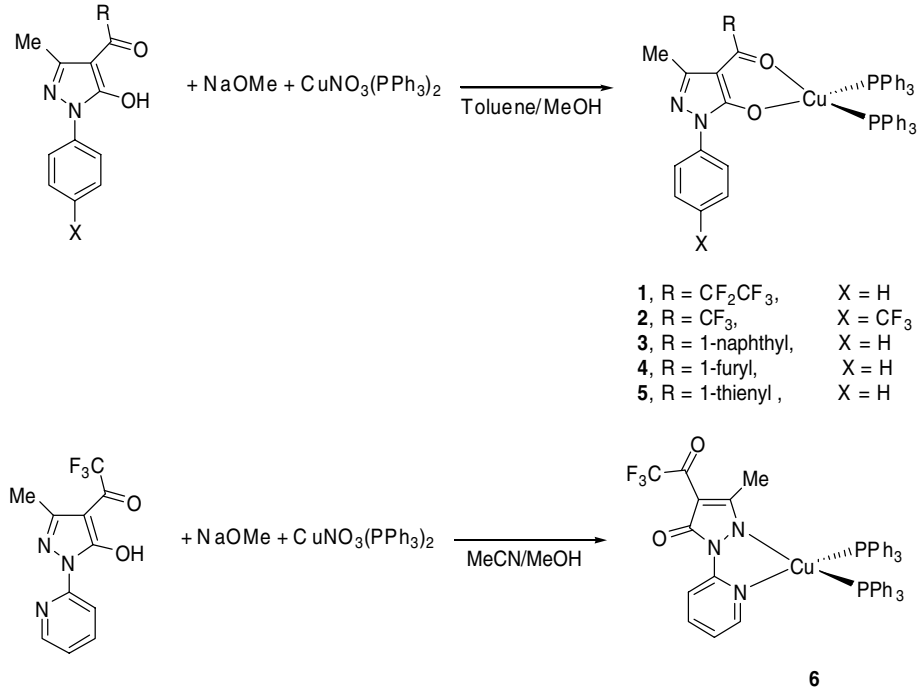
3. Results and discussion

3.1. Synthesis and spectroscopic characterization of the derivatives

The new copper(I) derivatives **1**–**6** have been obtained according to synthetic methods previously reported (Scheme 1) [7].

The choice of a mixture of acetonitrile/methanol in the synthesis of derivative **6** being dictated by the solubility of the proligand HQ^{CF3,py}. They are air-stable solid compounds with sharp melting points, very soluble in most organic solvents, as dmso, acetone, acetonitrile aromatic and chlorinated solvents, in which they are non-electrolytes.

The IR spectra of derivatives **1**–**5** show the typical strong bands in the range 1500–1650 cm^{-1}, due to the stretching modes of C=O, C=N and N=N of pyrazolo-



Scheme 1.

nate ligands, slightly shifted upon coordination to lower frequencies, the broad band between 2300 and 2800 cm^{-1} in free HQ donors due to the O–H···O moiety having disappeared, in accordance with deprotonation of the pyrazolonate [1,7]. In the low-frequency region the typical bands due to the *y*- and *t*-modes of vibration of triphenylphosphine have been detected at 400–530 cm^{-1} [15], partially overlapped with two medium Cu–O bands at ca 405 and 355 cm^{-1} [16]. The IR spectrum of **6** shows *ν*(C=O) to be unchanged, in accordance with coordination to copper through the two N atoms of the pyrazole and pyridine rings, with the Cu–N absorption bands at 310 and 244 cm^{-1} [17].

Proton, fluorine, phosphorus and carbon NMR spectra of **1**–**6** recorded at room temperature show a unique broad set of resonances. The integration of the signals in the proton spectra are in accordance with the formulation proposed, i.e. with a 1:2 Q:PPh_3 ratio. The low temperature (218 K) ^{31}P NMR spectrum of **1** exhibits three resonances, one of them being the free phosphine, the others, located at higher frequencies, being attributed to copper–phosphino species of the type $Cu(O_2–Q^{C2F5})(PPh_3)_2$ and $Cu(O_2–Q^{C2F5})(PPh_3)$, the latter arising from dissociation of one PPh_3 in solution, as previously found for similar copper derivatives [7a,7d].

The ^{31}P NMR spectra of **2**, **4** and **5** measured at low temperature (218 K), show two resonances, consistent with the presence of two different species, having CuO_2P_2 and a $CuOP_2$ metal environment, respectively, the latter containing a Q ligand which seemingly acts in an O-monodentate fashion [7c]. Finally the ^{31}P NMR spectra of **3** and **6** remains essentially unchanged with respect to cooling of the samples at 218 K.

The ^{13}C NMR spectra of **1**–**6** exhibit one set of carbon resonances, and the presence of further doublets due to C–P coupling assists in the assignment of signals arising from the C atoms of the phosphine ligand.

3.2. Structural studies

The results of structural characterisations by single crystal X-ray studies of **4** and **5** are consistent in terms of stoichiometry and connectivity with the above representations, unsolvated (Fig. 2). The two complexes are isomorphous with each other (single neutral molecules comprising their asymmetric units), but not with their silver(I) analogue [6b], the latter being modelled as a disordered array in which the pair of coordinated oxygen sites may be interchanged. In none of the three adducts is the substituent heterocycle chalcogen (O or S) found to interact with any metal component of the structure, and differences in the coordination environments of the two complexes are trivial. Because of the irrelevance of the substituent in this respect and the disorder in the immediate silver–furyl counterpart, we adopt the phenyl-substituted ligand analogue of the latter as a comparator. (The geometries of other relevant similar silver(I) systems are also tabulated comparatively in [9].) In that compound [6a], Ag–P are 2.475(3), 2.465(3) and Ag–O 2.498(6) and 2.349(7) Å; P–Ag–P is 120.9(1)°, O–Ag–O 73.0(2)° with O–Ag–P ranging between 92.1(2)–124.3(2)°, Ag–O exhibiting a much greater disparity (the Ag–pyrazolone–O distance being the longer) than the barely perceptible differences found in the present copper complexes (Table 1). In the latter, both P–M–P and O–M–O are enlarged relative to their silver counterpart. In **4**, **5**, the pair of PPh_3 ligands, of the quasi-3 conformation, are of opposite chiralities within each molecule, with the $Q^{fur,thi}$ non-hydrogen skeletons approximately planar, except for a slight twist

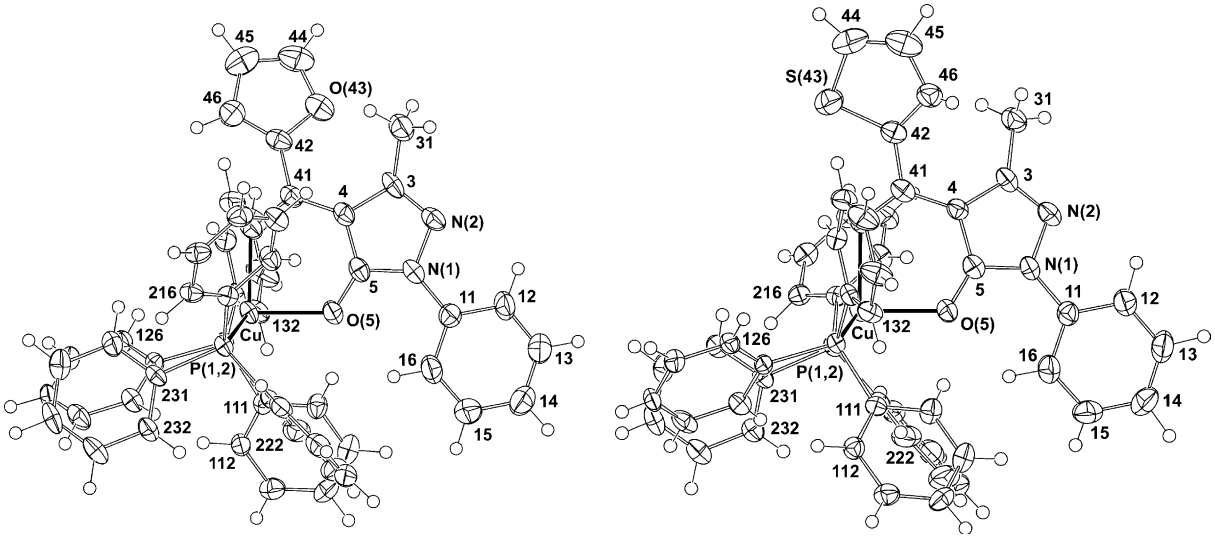


Fig. 2. Projections of **4** and **5**, normal to the Q skeletal planes, showing the reorientation of the heterocycle substituent within the pair of isomorphous structures.

of the fur/thi ring planes, presumably in consequence of the methyl proximity; interestingly, the substituent planes adopt alternate dispositions in the two complexes (Fig. 2): O(43)···C(31) is 2.83(1) Å, while in the Q^{thi} derivative C(46)···C(31) is 3.159(8) Å, the determinant of the twist presumably being the bulk of the sulphur atom. They are thus *not* isostructural.

Complex **1** is also of the above type (Fig. 3); the determination, although derivative of CCD data at low temperature, shows two molecules in the asymmetric unit, one having the ligand disordered by oxygen interchange in the manner described above for the previously disordered silver derivative [6b]. Nevertheless the non-disordered molecule provides useful data for a complex derivative of a ligand with a fluorinated substituent (Table 1), the Cu–O(4) distance adjoining the substituent being appreciably lengthened while Cu–O(5) is slightly shortened, in keeping with the expectations incumbent on the fluorinated substituent.

In **6**, although the formulation is again confirmed to be of the form $[CuQ(PPh_3)_2]$, the nature of the complex is quite different, presumably a consequence of the more potent donor capability of the py substituent. In $[Cu(Q^{CF3,py})(PPh_3)_2]$, **6**, two independent neutral molecules, accompanied by diverse solvent fragments in a lattice void, comprise the asymmetric unit of the structure; again the complex is not isomorphous with the recorded unsolvated structure of its silver(I) analogue [10] which is monoclinic, but with one independent molecule in the asymmetric unit. In both copper and silver complexes, the ligand $Q^{CF3,py}$ now behaves as an *N*,*N*′- rather than an *O*,*O*′-chelate, the *N*,*N*′-chelate ring being five-membered rather than six, with the extended ligand skeleton again quasi-planar (Fig. 4). In the silver(I) adduct Ag–P are 2.4585(7), 2.4494(7) Å, only slightly diminished cf. those of the Q^{fur} analogue; Ag–N are 2.400(2), 2.349(1) Å (the latter shorter distance associated with the py donor) and P–Ag–P and N–Ag–N are 119.36(2)° and 68.59(6)°, respectively. In **6** (Table 2), Cu–P are seen to be similar to the counterpart distances in **4**, **5**; Cu–N distances are inequivalent with Cu–N(py) the longer. The two molecules of **6** differ very significantly in terms of their P–Cu–P angles and in a manner which it is difficult to ascribe to anything other than a considerable and unexpected sensitivity to 'packing forces'. The other significant difference between the

two molecules is found in the PPh_3 conformations – opposite chiralities are found within each molecule, but in only one PPh_3 group (molecule 2, ligand 1) is the symmetry at all a close approach to the usual three-fold norm.

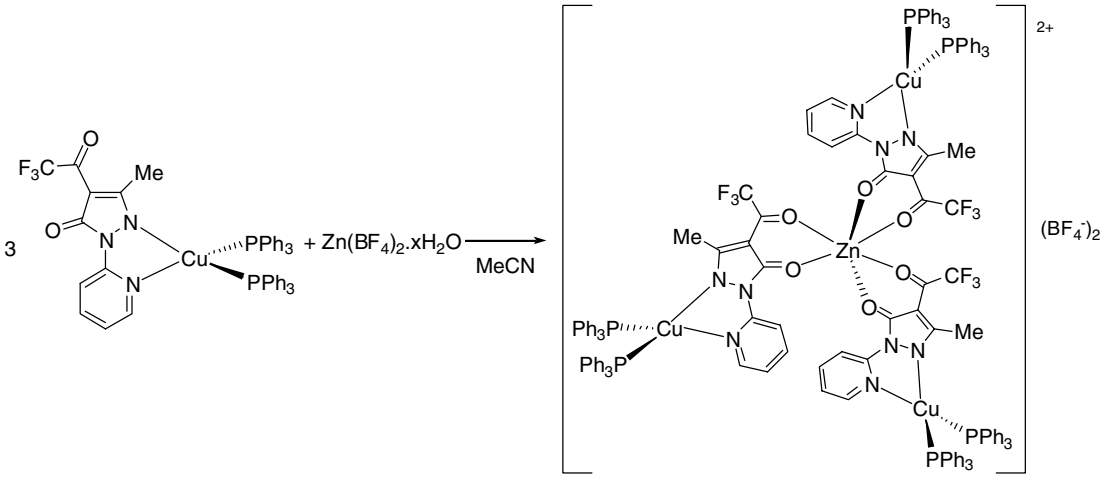
3.3. Reactivity of derivative $[Cu(Q^{py})(PPh_3)_2]$

Because the Q ligands of derivatives **4**–**6** contain additional heterocyclic groups with different donor atoms, we planned to investigate their potential as multidentate donors by exploring their reactivity toward Lewis acids. Attempted reactions between derivatives **4** or **5** with a Lewis acid such as $Zn(BF_4)_2 \cdot xH_2O$ in acetonitrile were always unsuccessful, whereas with derivative **6** the same reaction takes place, affording the ionic adduct **7** in high yield (Scheme 2), the difference in behaviour being clearly due to the position of the additional heteroaromatic rings, in the acyl fragment for furyl and thienyl in derivatives **4** and **5**, and at N1 of the pyrazole for 2-pyridyl in derivative **6**, where the N_2-chelating face is involved in the coordination of the $\{Cu(PPh_3)_2\}$ fragment, leaving both the carbonyl arms un-coordinated and able to give additional interactions with new metal acceptors.

Adduct **7** is a yellow solid with a sharp melting point. The conductivity value of 288 Ω^{-1} cm^2 mol^{-1} in acetonitrile is typical of 2:1 ionic species [18]. Moreover the strong band at 1057 cm^{-1} and a sharp one at 966 cm^{-1} in the IR spectrum of **7**, due to ν_4 and ν_3 of BF_4, shows no splitting or fine structure of the degenerate asymmetric vibrations, consistent with an ionic BF_4 [19]. The most significant spectral feature in the IR of adduct **7** is related to the red shift of ν(C=O) with respect to that found in derivative **6**, in accordance with the coordination of $Q^{CF3,py}$ to the zinc through both carbonyl arms. Finally, the resonances in the proton and carbon NMR spectra of **7** show downfield shifts due to the electron density flow toward the zinc centre.

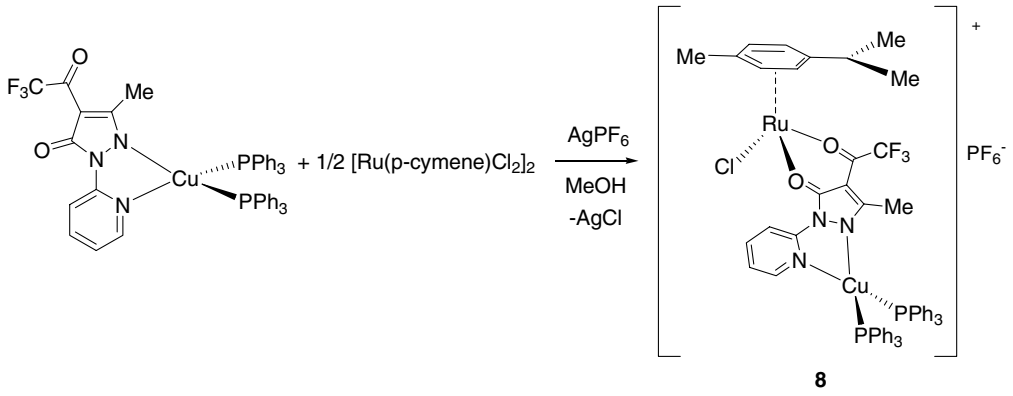
We decided to investigate also the reactivity of derivative **6** toward an organometallic Lewis acid such as $[Ru(p\text{-cymene})Cl_2]_2$. The reaction between **6** and $[Ru(p\text{-cymene})Cl_2]_2$ was performed in acetonitrile and, after 24 h refluxing, $AgPF_6$ was added to effect the chloride exchange, the ionic adduct **8** resulting (Scheme 3).

It is a brown solid with a sharp melting point. The conductivity value of 136 Ω^{-1} cm^2 mol^{-1} in acetonitrile is typical of 1:1 ionic species [18]. In the IR spectrum of **8** the strong bands at 840 and 695 cm^{-1} are typical of ν_{as} and ν_s of PF_6, typical of ionic PF_6 [20]. ν(C=O)



7

Scheme 2.



Scheme 3.

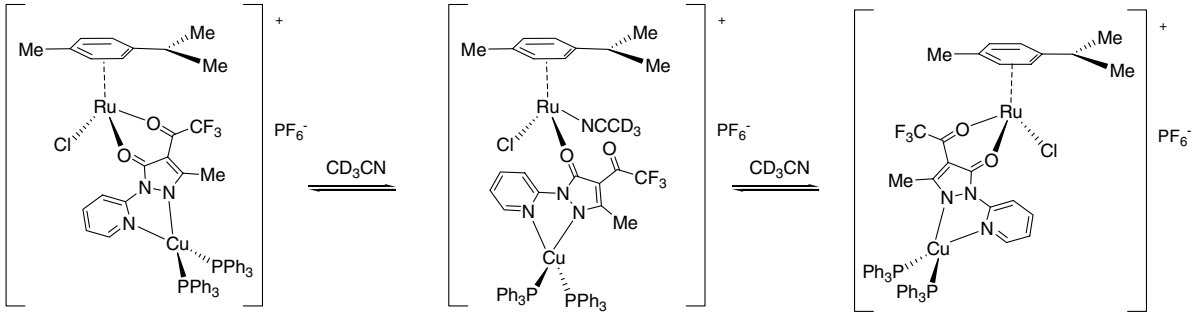


Fig. 5. Species in equilibrium with each other (hypothesized from NMR spectra of CD_3CN solution of derivative **8**).

is shifted to lower frequency with respect to that found in the IR of derivative **6**, in accordance with the coordination of $Q^{CF3,py}$ to the ruthenium through both carbonyl arms. In the far-IR region the bands due to PPh_3 [14] and to *ν*(Ru-Cl) have been detected [21]. The proton and carbon NMR spectra of **8** show three set of resonances for both the {Ru(*p*-cymene)} and $\{(Q^{CF3,py})Cu(PPh_3)_2\}$ fragments. This feature could be explained by the presence of three different species in equilibrium with each other, as suggested in Fig. 5.

The presence of two resonances in the ^{19}F NMR spectrum at −73 and −76 ppm, the former due to $CF_3C{=}O$ of a $Q^{CF3,py}$ coordinated through C=O and the second coincident with that found in the ^{19}F NMR spectrum of derivative **6**, further supports our previous hypothesis.

4. Supplementary material

X-ray crystallographic files, in *.cif* format, for the structure determinations of derivatives **1**, **4**, **5** and **6** have been deposited with the Cambridge Crystallographic Data Centre, CCDC 268466–268468, 269315. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam. ac.uk).

The coordination chemistry of pyridyl oximes

Constantinos J. Milios, Theocharis C. Stamatatos, Spyros P. Perlepes *

Department of Chemistry, University of Patras, GR-265 04 Patras, Greece

Received 14 July 2005
Available online 24 August 2005

Abstract

The coordination chemistry of pyridyl oximes is reviewed. Simple pyridyl oximes have the general formula (py)C(R)NOH, where py is a pyridyl group (2-, 3- or 4-) attached to the oxime carbon atom and R can be a donor or a non-donor group. There are also ligands containing more pyridyl and/or oxime groups. The coordination chemistry of twenty-three such ligands is described, including 2-acetylpyridine *N*-oxide oxime (which strictly speaking is not a pyridyl oxime) and of four polydentate ligands containing pyridyl groups that are not directly attached to the oxime carbon. References are given to methods for the synthesis of the ligands that are not available in the market. The coordination chemistry of each ligand with all metals is detailed, with emphasis being placed on structural features and physical properties (mainly magnetic) of the resulting metal complexes. This report shows that the anions of pyridyl oximes are versatile ligands for a variety of objectives/advantages, including μ_2 and μ_3 behavior, preparation of polynuclear complexes (clusters) and coordination polymers, mixed-metal chemistry and interesting magnetic characteristics. The activation of 2-pyridyl oximes by 3d-metal centers towards further reactions seems to be an emergent area of synthetic chemistry.

1. Introduction and information for the organization of this report

Simple pyridyl oximes have the general structures depicted in Fig. 1 and consist of a pyridyl group (2-, 3- or 4-) attached to the oxime carbon atom. R can be a donor or a non-donor group. There are also pyridyl oximes containing more pyridyl and/or oxime groups.

The anionic forms of these molecules are versatile ligands for a variety of objectives, including μ_2 and μ_3 behavior, formation of polynuclear complexes (clusters), isolation of coordination polymers, mixed-metal chemistry and significant magnetic characteristics. The activation of 2-pyridyl oximes by 3d-metal centers towards further reactions is also becoming a fruitful area of research. The majority of the metal complexes of these ligands have been prepared only in the last 15 years and much of their chemistry remains to be explored in more detail.

This report presents a review of the chemistry of pyridyl oxime ligands. It aims not to be comprehensive in terms of a discussion of every known complex containing a pyridyl oxime ligand (such a task would create a monograph for the complexes of di-2-pyridyl ketone oxime alone!); rather, it aims to provide the reader some idea of the range of chemistry that has been carried out (and indeed remains still to do) with these ligands. This review will also deal with the coordination chemistry of 2-acetylpyridine *N*-oxide oxime (which is not a pyridyl oxime) and of some polydentate oxime ligands containing pyridyl groups that are not directly attached to the oxime carbon (Sections 5.6 and 7.3, respectively).

The report contains 10 sections. The first four are introductory. Section 2 briefly describes the already published reviews on metal oxime and oximato complexes. In Sections 3 and 4, the reader can find information on the organic, supramolecular and coordination chem-

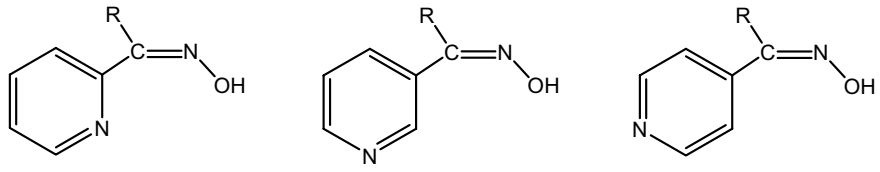

Fig. 1. General structures of simple pyridyl oximes.

istry of the simple oxime group. Sections 5–9 describe the chemistry of metal complexes that have neutral and anionic pyridyl oximes as ligands. The ligands' classification is based both on the nature of R and the number of pyridyl or oxime groups per molecule. Section 10 gives some conclusions and areas for further investigation. Most sections are divided into parts. Each part, devoted to the coordination chemistry of a particular pyridyl oxime, gives its structural formula, systematic name and abbreviation, details the synthesis of the free ligand, and discusses some of its important metal complexes, with particular emphasis being placed on structural aspects of these.

As in the case of many organic ligands, most pyridyl oxime ligands are known by an abbreviation, usually of three or four letters, nominally derived from the full name of the ligand. For example, the systematically named ligand pyridine-2-carbaldehyde oxime (Fig. 1, R = H; Section 5.2) is better known as paOH, the abbreviation being derived from the non-systematic names pyridine-2-aldoxime or 2-pyridinaldoxime; other abbreviations used for this ligand are HPOX and PyAH. The abbreviations of other pyridyl oximes are somewhat haphazard and confusing. Obviously, this is an unsatisfactory situation and ideally a systematic abbreviation system should be developed. In what follows, we adopt a common abbreviation system based on the use of the constituent py for a 2-pyridyl group, 3-py for a 3-pyridyl and 4-py for a 4-pyridyl group; the oxime group(s) and the nature of R (Fig. 1) will complete the abbreviation. For example, the abbreviation of pyridine-2-carbaldehyde oxime (Fig. 1, R = H; Section 5.2) will be (py)CHNOH, while the anionic ligand will be abbreviated as (py)CHNO. The abbreviation of 1-pyridine-2-yl-ethanone oxime (Fig. 1, $R = CH_3$; Section 5.4) will be (py)C(Me)NOH, etc. We hope that this abbreviation system is more convenient for the reader than abbreviations with letters derived from the name of the ligand.

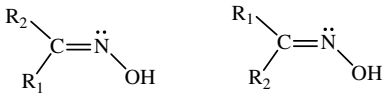
2. Background

A review article on the coordination chemistry of pyridyl oximes has never appeared. However, metal complexes of pyridyl oximes have been incorporated into more general reviews on the chemistry of metal oxime/oximate complexes. This chemistry has been actively investigated since 1890, when Tschugaeff [1] first introduced dimethylglyoxime as a reagent for the gravimetric determination of Ni(II). Oximes as ligands have played a significant role in the development of transition metal chemistry. This development has been documented in a number of review articles and we refer the readers to some of these excellent treatises [2–9]. An early treatise by Chakravorty [2] is a comprehensive review on the structural chemistry of simple oximes, *vic*-dioximes, quinonemonoximes, and carbonyl-, imine-, pyridine-, azo-, hydroxy- and amidoximes. A review by Bertrand and Eller [3] covers oxime-bridged complexes of transition metals, while a concise review by Mehrotra [4] deals with the syntheses, structures and reactivity of complexes containing "simple" and *vic*-dioximes. In more recent years five excellent reviews have been published [5–9]. The survey by Tasker and co-workers [5] describes the rich coordination chemistry of phenolic oxime ligands. The strategy of using "metal oximate" building blocks as ligands to synthesize various homo- and heterometallic paramagnetic complexes has been reviewed by Chaudhuri [6]. This review is an important contribution to the field of Molecular Magnetism; the oximato groups ($>C{=}N{-}O^-$) can mediate exchange interactions of varying range, from moderate ferromagnetic to strong antiferromagnetic. Metal-ion mediated reactions of oximes, and reactivity of oxime-containing and oximate metal complexes have been described and classified by Kukushkin and Pombeiro [7–9]; the three reviews illustrate the fact that the chemistry of oxime/oximato metal complexes is rich since these species display an amazing variety of reactivity modes.

3. Brief information on the organic and supramolecular chemistry of the oxime group

3.1. Isomerism

The oxime group ($>C{=}N{-}OH$) is a well-explored group in organic chemistry. The type of isomerism about a C=C double bond [10] is also possible with the C=N bond, though in this case only three groups are connected to the double-bond atoms. The method, which can be applied, is based on the Cahn–Ingold–Prelog system [10]. The two groups at the carbon atom are ranked by the sequence rules. Then that isomer with the



Z or *syn* *E* or *anti*

Fig. 2. The *Z*–*E* isomerism of the oxime group assuming that R_1 takes precedence over R_2 according to the Cahn–Ingold–Prelog system.

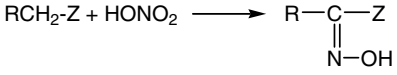
higher ranking group and the –OH group on the same side of the double bond is called *Z* (for the German word *zusammen* meaning *together*); the other is called *E* (for *entgegen* meaning *opposite*). In the case of oximes, the *Z* isomer may be called *syn* and the *E* isomer *anti* [11]. The isomerism of the oxime group is illustrated in Fig. 2 for the case in which the substituent R_1 is a higher ranking group than R_2. If there is more than one oxime group in a molecule, the number of isomers can be increased, e.g., *Z*, *Z*, *Z*, *E* and *E*, *E*.

3.2. Formation of the oxime group

Some synthetic schemes that lead to the oxime group may be useful for coordination chemists. These are briefly mentioned below [10].

3.2.1. Nitrosation at a carbon bearing an active hydrogen

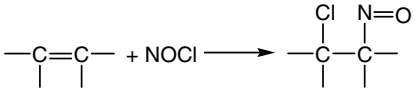
Carbon atoms adjacent to a Z group (Z may be CO-OR′, CHO, COR′, $CONR'_2$, COO^-, CN, NO_2, SOR′, SO_2R', SO_2OR', $SO_2NR'_2$ or similar groups) can be nitrosated with nitrous acid or alkyl nitrates. The initial product is the C-nitroso compound, but these are stable only when there is no tautomerizable hydrogen. When there is, the product is the most stable oxime (Eq. (1)).



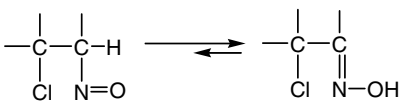
(1)

3.2.2. Addition of NOCl to olefins

The initial product is always the β-halo nitroso compound, but these are stable only if the carbon bearing the nitrogen has no hydrogen (Eq. (2a)). If it has, the nitroso compound tautomerizes to the oxime (Eq. (2b)).



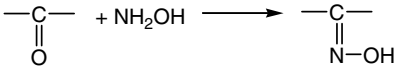
(2a)



(2b)

3.2.3. Addition of hydroxylamine to aldehydes or ketones

This is the commonly used method for the synthesis of new oxime ligands by coordination chemists (Eq. 3). It has been shown that the rate of formation of oximes is maximum at a pH which depends on the substrate but is usually 4, and that the rate decreases as the pH is either raised or lowered from this point.



(3)

3.2.4. Addition of Grignard reagents to the conjugate bases of nitro compounds

The conjugate bases of nitro compounds (formed by treatment of the nitro compound with BuLi) react with Grignard reagents in the presence of $ClCH{=}NMe_2^+Cl^-$ to give oximes (Eq. (4)).

$$RCH{=}N(O)OLi + R'MgX \rightarrow RR'C{=}NOH \quad (4)$$

3.2.5. Oxidation of primary aliphatic amines

Primary aliphatic amines can be oxidized to nitroso compounds by Caro's acid (H_2SO_5) or with H_2O_2 in $MeCO_2H$. Hydroxylamines, which are probably intermediates in most cases, can sometimes be isolated, but under the reaction conditions are generally oxidized to the nitroso compounds. The nitroso compound is stable only if there is no α hydrogen; if there is an α hydrogen, the compound tautomerizes to the oxime.

3.2.6. Reduction of aliphatic nitro compounds

Nitro compounds that contain an α hydrogen can be reduced to oximes with Zn dust in acetic acid (Eq. (5)) or with other reagents, among them Co–Cu(II) salts in alkanediamines, CS_2–Et_3N and $CrCl_2$.

$$RCH_2NO_2 \xrightarrow[HOAc]{Zn} RCH{=}N\text{–}OH \quad (5)$$

3.3. The oxime group in supramolecular chemistry

In supramolecular chemistry a major goal is to control the aggregation of molecules via intermolecular interactions [12,13]. This is most readily achieved when such interactions are strong and directional. For this reason hydrogen bonds are often employed. More specifically, molecular building blocks can be designed to carry particular functional groups that are capable of recognition of other groups or self-recognition through the formation of one or more hydrogen bonds. By such a synthetic approach even quite complex molecular aggregates (supermolecules) can be prepared in a designed manner [14–16]. Where infinite assemblies are formed, the opportunity arises to construct crystalline solids in which 1D, 2D or 3D networks are propagated by hydrogen bonds [17,18].

Despite earlier studies establishing its capability to form hydrogen bonds [19–21], the oxime group has received far less attention in supramolecular chemistry and crystal engineering [22] than have other groups as carboxyl [23], amide [24] and alcohol [25]. Oximes are

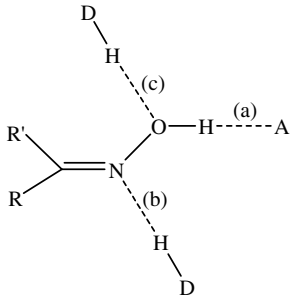


Fig. 3. Formation of hydrogen bonds by oxime groups [22]. A, hydrogen bond acceptor; D, hydrogen bond donor.

able to form three types of hydrogen bond (Fig. 3). Formation of only an O–H···A hydrogen bond is typical of the situation in which another strong hydrogen bond acceptor group is present, as is illustrated by the structures of pyridyl oximes [26]. The situation in which both O–H···A and D–H···N hydrogen bonds form is typified by the absence of other hydrogen bonding functional groups, or at least ones strong enough to compete with the oxime. Thus, O–H···N hydrogen bonds form between oxime groups, most often as either an $R_2^2(6)$ [27] dimeric arrangement (**I**) or a C(3) catemer (**II**) [22], resembling the $R_2^2(8)$ (**III**) and C(4) arrangements (**IV**,**V**) that are well established [13] for carboxyl groups (Fig. 4).

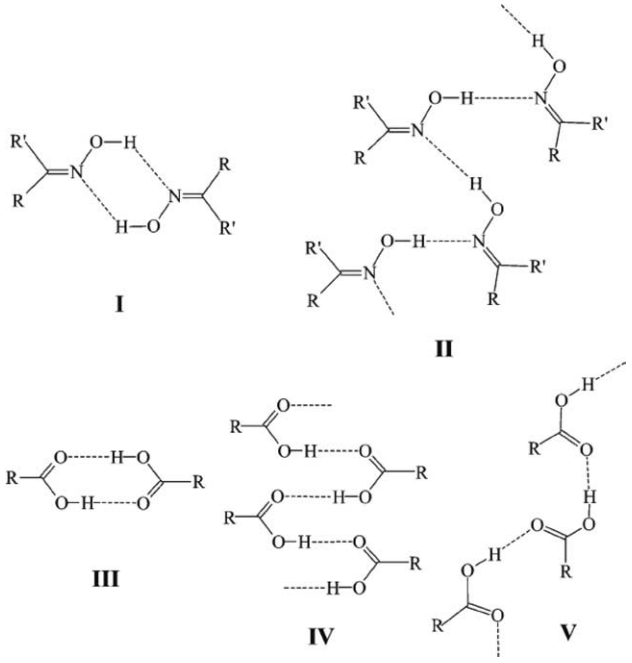

Fig. 4. Common hydrogen bonding arrangements [22] for oxime (**I**, **II**) and carboxyl (**III**–**V**) groups.

Less common, crystallographically established hydrogen bond patterns in oximes are presented in Fig. 5. One potential advantage [22] to the use of oximes is the possibility of greater tunability by facile variation of the substituent R′ (Fig. 3), which is not present in carboxylic acids or primary amides. Careful choice of this substituent also permits the solubility of the oxime ligand to be modified, facilitating supramolecular synthesis in a wider range of solvent systems.

4. The importance of oxime and oximate groups in coordination chemistry

4.1. General information

There is currently a renewed interest in the coordination chemistry of oximes [6,9]. The research efforts are driven by a number of considerations. These include the solution of pure chemical problems [28–34], the desire to provide useful bioinorganic models (oximes may be considered to be reasonable models for the biologically significant imidazole donor group of the amino acid histidine) [35], the design of Ca^{2+}- and Ba^{2+}-selective receptors based on site-selective transmetalation of multinuclear polyoxime–zinc(II) complexes [36], the development of new oxygen activation catalysis based on nickel(II)–polyoximate complexes [37], the application of metal ion/oxime systems as simple and efficient catalysts for the hydrolysis

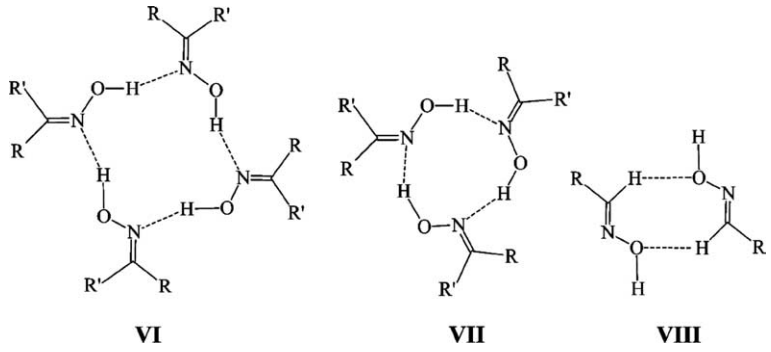

Fig. 5. Less common hydrogen bonding arrangements [22] for oxime groups: $R_4^4(12)$ oxime tetramer (**VI**), related $R_3^3(9)$ oxime trimer (**VII**) and aldoxime $R_2^2(8)$ C–H···O dimer (**VIII**).

of organonitriles [38] (metal ions can behave as extremely strong activators of RCN toward nucleophilic attack by OH^-/H_2O), the mechanistic study of corrosion inhibition by Acorga P5000 (a modern corrosion inhibitor comprising 5-nonylsalicylaldoxime as a mixture of carbon-chain isomers) on iron surfaces [39] and the employment of oximate ligands in the synthesis of homometallic [6,32,40,42] and heterometallic [6,29,41] clusters [6,29,32,40–42] and coordination polymers [43] with interesting magnetic properties including single-molecule magnetism [42] and single-chain magnetism [43] behaviors.

For example, the pure chemical interest in the coordination chemistry of oximes arises from the ability of the oximate(−1) group to stabilize higher oxidation states of metals, e.g., Ni(III) or Ni(IV) [33,34] and the fact that the activation of oximes by transition metal centers towards further reactions seems to be an emergent area of modern synthetic chemistry (Section 4.3). Another example of the importance of metal oximate complexes are the excellent studies on surface coordination chemistry by Collison, Garner, Tasker and co-workers; they have postulated (based on synthetic models) that the corrosion inhibition by P5000 on an iron surface is due to the generation of a tetranuclear iron(III) cluster complex [39]. Iron ions must be available for the formation of such species, and the efficiency of the inhibitor is therefore enhanced by treatment of an oxidized iron surface with a mild acid. The polyfunctional P5000 oxime ligand tends to produce compact polymetallic assemblies, and when formed at the surface of a metal, such species can form a protective barrier which inhibits further corrosion [39].

4.2. Coordination modes of oxime and oximato groups

Oxime and oximato groups can bind a metal ion in different modes [9]; these coordination modes are shown in Fig. 6. The numbers below each bonding mode refer to the Harris notation [44]. Harris notation describes the binding mode as $X{\cdot}Y_1Y_2Y_3{\cdots}Y_n$, where X is the overall number of metals bound by the whole ligand, and each value of Y refers to the number of metal atoms (ions) attached to the different donor atoms. The ordering of Y is listed by Cahn–Ingold–Prelog priority rules, hence (for most of the ligands included in this report) O before N. In the case of chelating/bridging ligands, to distinguish between several alternatives, a subscript number is included to show to which metal ion the donor is attached. In the following, the binding mode of the ligands will be often described using Harris notation. Since the reader will always have recourse to diagrams, we shall avoid using subscript numbers. Occasionally we shall use the currently approved notation based on Greek letters μ and η. We do believe that Harris notation

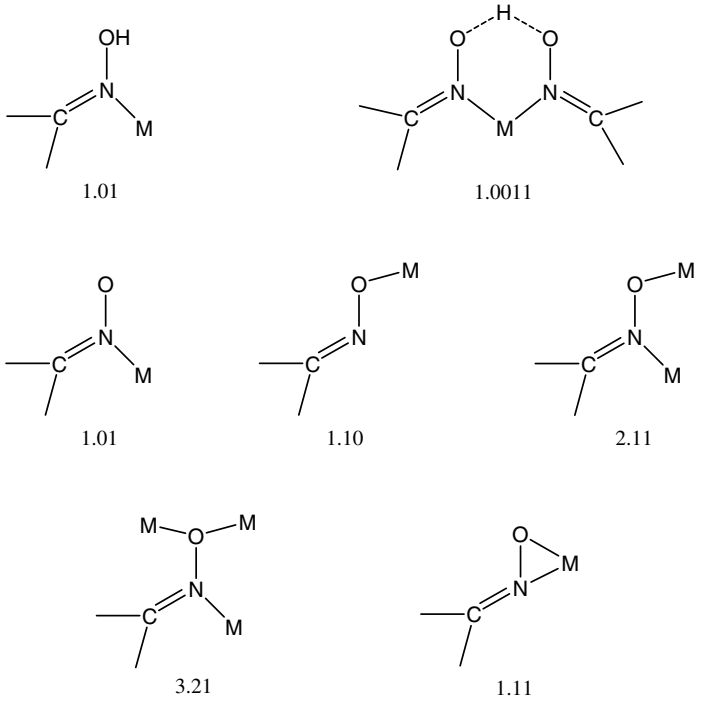

Fig. 6. The crystallographically established coordination modes of oxime and oximato groups, and the Harris notation [44] that describes these modes. Note that the upper right mode combines one formally neutral oxime group and one formally anionic oximato group.

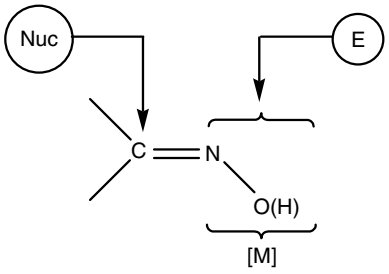
is, at least for pyridyl oximes, more convenient than the notation based on Greek letters.

4.3. Reactivity of coordinated oximes

4.3.1. A brief introduction

As said in Section 2, oxime and oximato metal species exhibit versatile reactivity. Their reactions can be classified according to the extent of involvement of the {C=NO} moiety and to the bond at which the reaction is centered (see below). The reviews by Pombeiro and Kukushkin [7–9] are excellent sources on this topic.

The general modes of reactivity concerning nucleophilic or electrophilic additions to the polarized C=N bond are illustrated in Scheme 1. Nucleophilic reagents can add to the carbon atom of the azomethine linkage (a reaction that is promoted by coordination of the oxime, in particular via the N-atom), whereas electrophilic reagents can attack the O- or the N-sites.



Scheme 1. General reactivity modes of the coordinated oxime group [9]. Nuc = nucleophile; E = electrophile.

4.3.2. Reactions with preservation of the {CNO} fragment [9]

The reactions can either be centered at any of the atoms of the {CNO} moiety, leading to oxime (or oximato), imine or other types of complexes, or occur at another part of the oxime molecule.

On account of the nucleophilic character of the oxime O-atom, the oximes can add, via this atom, to unsaturated species such as organonitriles, anhydrides, ketones, isocyanates, aldehydes, olefins and the olefinic group of an α,β-unsaturated oxime. Few examples of oxime coupling via the N-atom acting as the nucleophile, are known. These include reactions of oximes with allene-Pt^{II} complexes to produce metallacycles and reactions of Cu(II) or Ni(II) complexes of *o*-quinone monoxime with electrophilic acetylenes to give N-containing heterocycles. The electrophilicity of the C-atom of the NCO group of an oxime is expected to be promoted by oxidation and formal two-electron oxidations promote not only H^+ loss from the NOH group, but also addition of a nucleophile to that C-atom to yield nitrosoalkyl species.

4.3.3. Reactions with rupture of the {CNO} fragment

Several N–O bond rupture reactions are known (Fig. 7); these reactions usually involve the formation

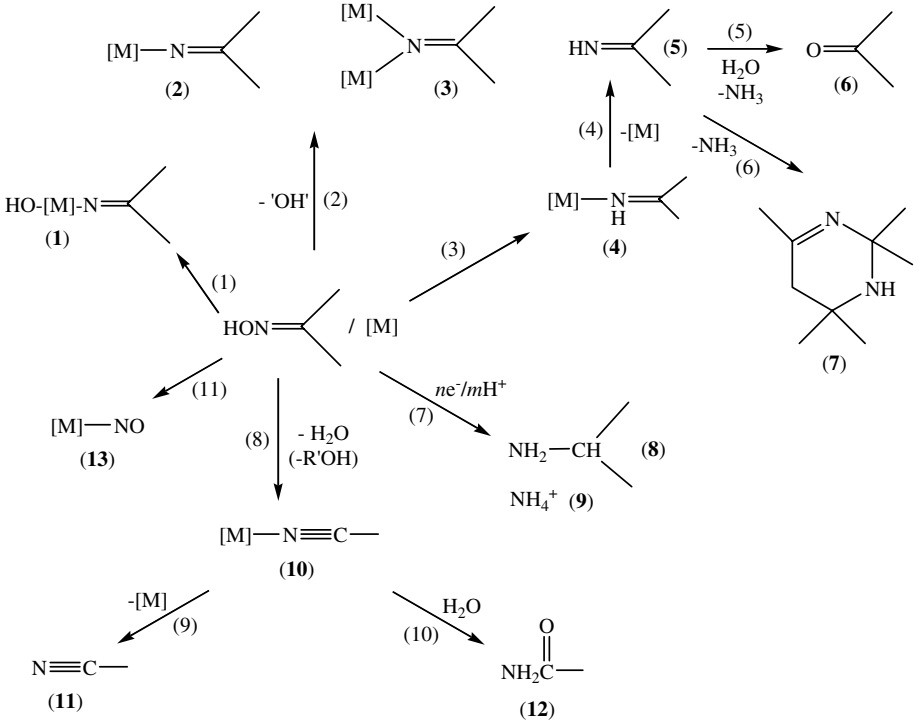


Fig. 7. Reactions of coordinated oximes that lead to N–O and N=C bond cleavage [9].

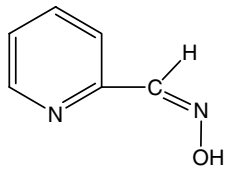
of an N–metal bond. The reactions include [9] oxidative addition of oximes to an electron-rich metal center (Reaction (1)), dehydroxygenation of oximes by a hydride metal center (Reaction (2)), deoxygenation of oximes (Reactions (3)–(7)), dehydration or alcohol elimination (Reactions (8) and (9)) and the Beckmann rearrangement of aldoximes into amides (Reactions (8) and (10)). Reactions with complete N=C bond cleavage are also known [9], for example, Reactions (3)–(5), (7) and (11) in Fig. 7.

5. Ligands containing one oxime group, one pyridyl group and no other donor atoms

5.1. Coordination modes

Ligands containing one oxime group, one pyridyl group and no other donor atoms are popular. Most of these ligands contain a 2-pyridyl group. The crystallographically established coordination modes of these 2-pyridyl oximes are shown in Fig. 8. Their anions can bridge two or three metal ions.

5.2. Pyridine-2-carbaldehyde oxime, (py)CHNOH



(py)CHNOH

The free ligand is commercially available. Its crystal structure has been determined [45]. There are two unique molecules in the asymmetric unit; the molecules related by a 2_1 screw axis, form infinite 1D chains held together by hydrogen bonds. The predominant hydrogen bond

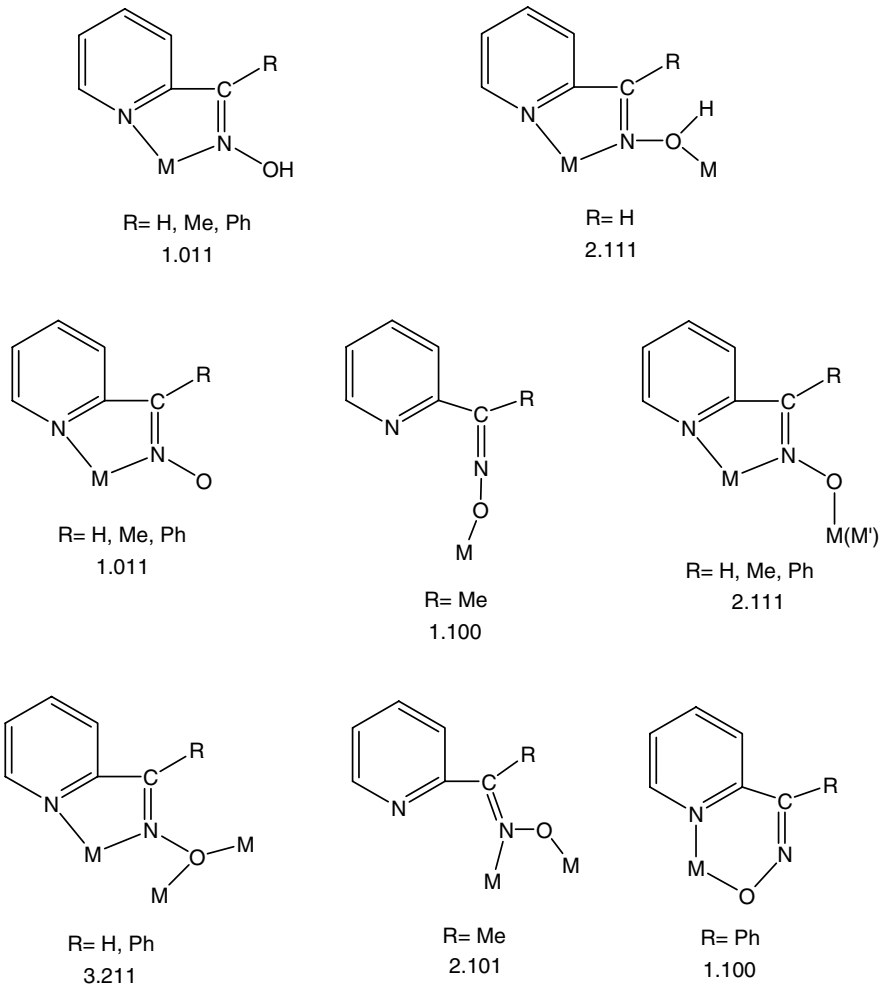


Fig. 8. The crystallographically established coordination modes of the neutral and anionic forms of simple 2-pyridyl oximes, and the Harris notation [44] that describes these modes.

interaction assembling the chains is a head-to-tail O–H···N hydrogen bond involving the oxime O–H and the 2-pyridyl nitrogen atom. There is also a C–H···N hydrogen bond involving the oxime C–H and the oxime nitrogen atom (C···N 3.274, 3.283 Å). The chains are arranged in an *anti*-parallel fashion and pack in a typical herringbone motif.

Potentiometric titrations at 25 °C in aqueous 0.1 M NaCl solution have provided the values of the logarithm of the protonation constant, $\log\beta$, of the 2-pyridyl nitrogen and the acid dissociation constant, pK_a, of the oxime group [46]; these values are 3.59 and 10.01, respectively.

The first studies on the coordination chemistry of (py)CHNOH were reported in the late 50s and early 60s [47–54]. No single-crystal X-ray structures were available at that time. Investigations based on physical and spectroscopic data showed [49,51,53] that square planar cationic complexes of divalent transition metals were capable of intramolecular hydrogen bonding in the type of structure shown in Fig. 9. However, this structural type has never been proven by crystallography. The groups of Busch [48] and Liu [50,54] were the first to suggest that the deprotonated oxygen atom of coordinated (py)CHNO$^-$ can act as donor giving homo- and heteropolynuclear complexes.

The first structurally characterized metal complex of pyridine-2-carbaldehyde oxime was $[Cu_3(OH)(SO_4)\{(py)CHNO\}_3]$ [55]. The Cu^{II} atoms fall at the corners of an exact equilateral triangle of side 3.22 Å due to the presence of a threefold crystallographic axis. The metal ions are held together by three distinct bridging systems: (i) the μ_3-hydroxo group, (ii) the sulfato group, lying on the threefold axis but below the plane containing the metal ions, and acting as a tripod bridge bonding to all three Cu^{II} atoms through three of its oxygen atoms ($\eta^1{:}\eta^1{:}\eta^1{:}\mu_3$), and (iii) the three symmetry-related (py)CHNO$^-$ ligands each of which functions as a bidentate chelate to one of the Cu^{II} atoms, through its two nitrogen atoms, and as a $Cu^{II}\cdots Cu^{II}$ bridging group through the nitrogen and oxygen atoms of the oximato moiety (Fig. 10). Thus, the (py)CHNO$^-$ ligands adopt

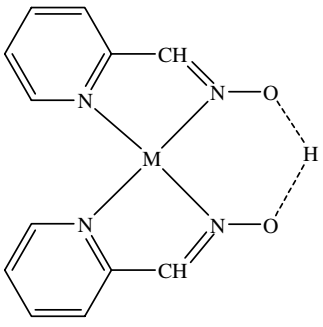

Fig. 9. The square planar structural type proposed [49,51,53] for the complex cations $[M\{(py)CHNO\}\{(py)CHNOH\}]^+$ (M = Ni, Cu, Pd).

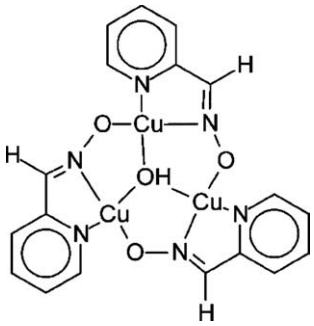

Fig. 10. A drawing of the trinuclear molecule $[Cu_3(OH)(SO_4)\{(py)CHNO\}_3]$ down its threefold axis; the SO_4^{2-} group has been omitted for clarity [6].

the coordination mode 2.111, see Fig. 8. Two of the three electrons of the Cu_3^{II} core are completely paired and only the doublet spin state ($S_T = 1/2$) is populated at room temperature ($\mu_{eff} = 1.0$ BM per Cu^{II} in the 80–300 K range) [6], which is evidence for strong antiferromagnetic coupling.

Addition of I^- to a solution of Cu^{2+} normally leads to reduction to CuI, but in the presence of nitrogen donors reduction is inhibited. Chaudhuri and co-workers [56] have synthesized the complex $[LCu^{II}\{(py)CHNO\}_2Cu^{II}I](ClO_4)$ [56], where L is the capping tridentate ligand 1,4,7-trimethyl-1,4,7-triazacyclononane. The molecular structure consists of dinuclear cations (Fig. 11). The Cu^{II} atoms are bridged by 2.111 oximato ligands. Both metal ions have a distorted square pyramidal (spy) geometry with a $Cu^{II}\cdots Cu^{II}$ separation of 3.45 Å; the Cu^{II}–I bond length is 2.74 Å. The chloro and acetato analogues of the iodo complex have also been prepared and structurally characterized [6]. The chloro complex has a very similar structure to that of the iodo compound. On the other hand, the acetate ion bridges the copper centers and, thus, one metal ion is five-coordinate and the other is six-coordinate. The magnitude of the exchange parameter J ($2J$ being the singlet-triplet splitting) depends on the nature of the axial ligand: $MeCO_2^-$ ($J = -358$ cm^{-1}), Cl^- ($J = -390$ cm^{-1}) and I^- ($J = -460$ cm^{-1}). Interestingly, the strength of the spin interaction is not related to the N–O and C=N bond distances, suggesting that a π exchange mechanism via the ring system is not the major pathway.

The coordination chemistry of (py)CHNOH with Fe and Co is practically unknown. Early aqueous solution studies by Hanania and Irvine [47,52] have shown that when Fe^{II} forms a complex with (py)CHNOH the acid strength of the oxime group increases considerably. The localized mixed-valence cation $[LFe^{III}\{(py)CHNO\}_3Fe^{II}]^{2+}$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane) contains a low-spin Fe^{II} atom [6], the complex behaves magnetically as a mononuclear high-spin Fe(III) species, with a μ_{eff} value of 5.83 ± 0.02 BM at 10–290 K.

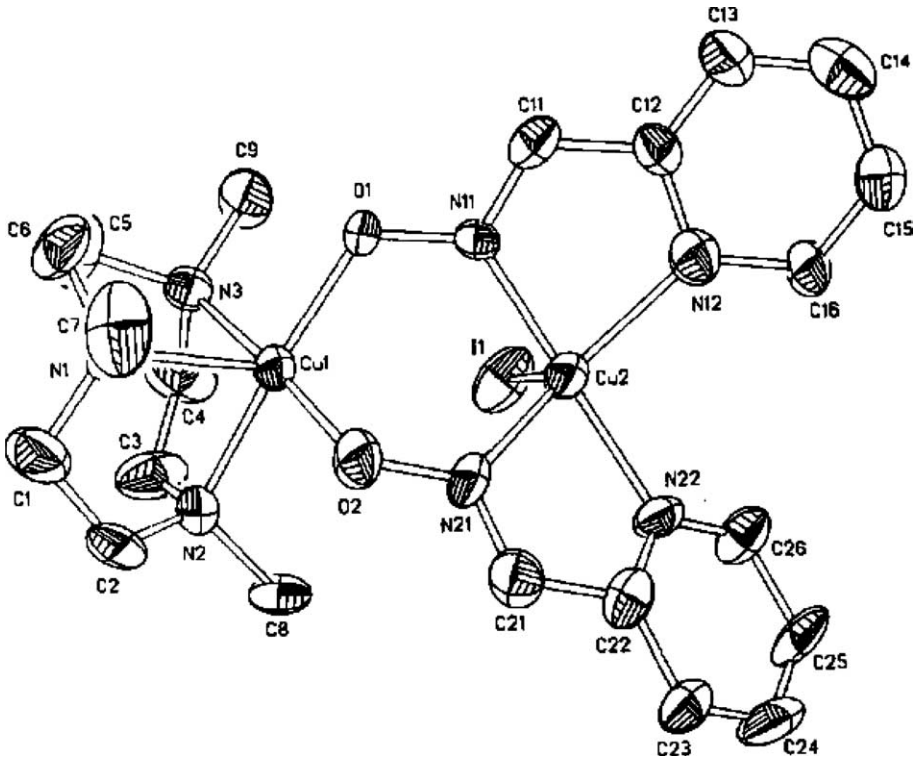

Fig. 11. X-ray molecular structure of the $[LCu^{II}\{(py)CHNO\}_2Cu^{II}I]^+$ cation [56].

A structurally impressive dodecanuclear Fe(III) cluster was recently reported by Christou's group [57]. The complex $[Fe_{12}(\mu_3\text{-}O)_8(\mu\text{-}OMe)_2(O_2CPh)_{12}\{(py)CHNO\}_6]$ was obtained from the reaction of $[Fe_3O(O_2CPh)_6(H_2O)_3](O_2CPh)$, (py)CHNOH and NaOMe in MeCN. The complicated core of the complex contains a central Fe_6 unit that can be described in various ways, one of which is as four edge-sharing $\{Fe_3(\mu_3\text{-}O)\}^{7+}$ triangular units and two additional $\{Fe_3(\mu_3\text{-}O)\}^{7+}$ units attached to the flanks. Variable-temperature solid-state susceptibility studies on the cluster in the temperature range 5.0–300 K reveal that this possesses an $S = 0$ ground state; this behavior is not suprising given the dominance of antiferromagnetic interactions in high-spin Fe(III) chemistry.

Blackmore and Magee [58a] reported a slow reaction between Co(II) and (py)CHNOH; their explanation was that the low rate is due to the slowness of the interconversion of the *syn* and *anti* forms of the ligand. A later photometric and pHmetric solution study by Beck's group [58b] showed that this reaction is complicated. The complex formation reaction itself is very fast, in contrast to the data by Blackmore and Magee [58a], and is followed by a slow redox process where the metal ion is oxidised by the ligand to yield an inert cobalt(III) complex. Recently, our group investigated the solid-state coordination chemistry of (py)CHNOH with Co [59]. The refluxing reaction mixtures $Co(O_2CMe)_2 \cdot 4H_2O$/(py)CHNOH/$NaClO_4$ (1:2:1) in MeOH, $CoCl_2 \cdot 6H_2O$/(py)CHNOH/LiOH/$NaClO_4$ (1:2:2:1) in H_2O or $Co(ClO_4)_2 \cdot 6H_2O$/(py)CHNOH/Me_4NOH (1:2:2) in MeOH led (under aerobic conditions) to the clean preparation of dark red complex $[Co_2^{III}Co^{II}\{(py)CHNO\}_6](ClO_4)_2$ (Fig. 12). The central Co^{II} atom, Co(2), which sits on a threefold axis of symmetry, is octahedrally coordinated by six oxygen atoms belonging to six crystallographically equivalent 2.111 $(py)CHNO^-$ ligands. The six sites on each of the distorted octahedral, terminal Co^{III} atoms, Co(1), which sit on a threefold axis of symmetry, are occupied by the nitrogen atoms that belong to the "chelating" part of three $(py)CHNO^-$ ligands, with the three oximato N atoms in the *fac* (or *cis*) configuration.

The fact that the two mononuclear neutral *fac*-$Co^{III}\{(py)CHNO\}_3$ units of the above mentioned mixed-valence, trinuclear cluster can be considered as acting as tridentate chelating "ligands" to the central Co^{II} center, Co(2), led us to suspect that the mononuclear 1:3 Co(III) complex would be capable of existence. Our suspicion was both correct and incorrect. It proved correct because the desired product has been, indeed, prepared and, simultaneously, it proved incorrect because the discrete mononuclear complex, $[Co^{III}\{(py)CHNO\}_3]$, that we managed to isolate and structurally characterize is the "wrong", i.e., the *mer* (or *trans*) isomer. The Co^{III} atom is coordinated by three *N*,*N*′-bidentate chelating (or 1.011 [44], Fig. 8) ligands.

The mononuclear distorted octahedral Co(III) complexes $[Co\{(py)CHNO\}_2(L\text{–}L)]Cl$ (L–L = bpy, phen) and $[Co(acac)_2\{(py)CHNO\}]$ have been recently

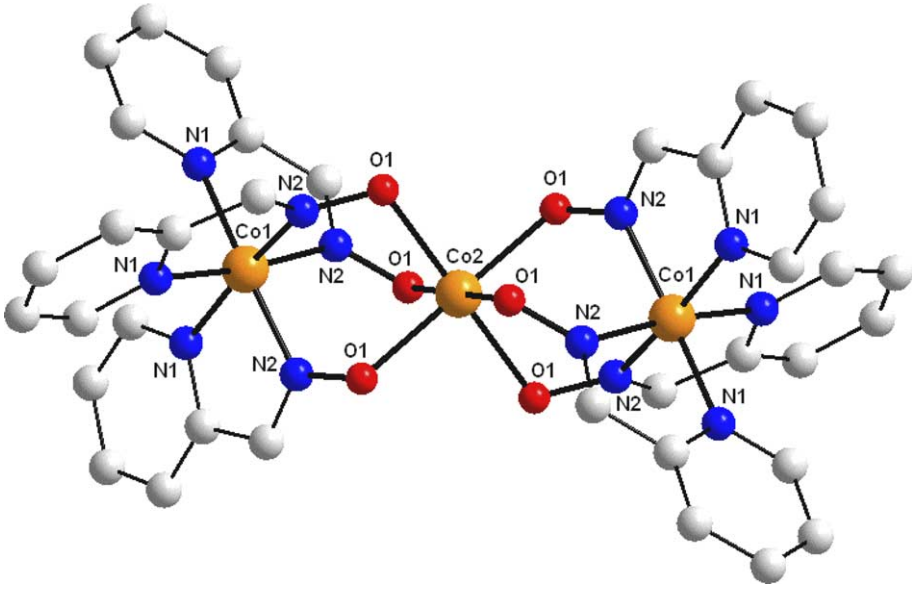

Fig. 12. The molecular structure of the mixed-valence (III/II/III) cation $[Co_3\{(py)CHNO\}_6]^{2+}$; identical atoms are used for atoms generated by symmetry [59].

prepared by our group; single-crystal X-ray crystallography revealed that $(py)CHNO^-$ behaves as an 1.011 ligand [60].

Few homometallic Ni(II) complexes containing the neutral and/or anionic ligand have been published [61–63]. All are mononuclear: $[Ni\{(py)CHNO\}_2\{(py)CHNOH\}]$ [61], $[Ni\{(py)CHNO\}_2L_2]$ (L = pyridine, 4-picoline, 4-ethylpyridine) [62] and $[Ni\{(py)CHNO\}_2(L–L)]$ (L–L = bpy, phen) [63]. Representative drawings are shown in Figs. 13 and 14. The deprotonated ligands are *N*,*N*′-bidentate (or 1.011). All compounds containing monodentate aromatic N-ligands have the same structural motif with *trans* coordination fashion for the identical donor groups [62], while those containing bpy or phen are racemic [63]. Polynuclear Ni(II) complexes comprise [64] several salts of the enneanuclear cation $[Ni_9(OH)_6\{(py)CHNO\}_{10}(H_2O)_6]^{2+}$ and $[Ni_3(acac)\{(py)CHNO\}_2\{(py)CHNOH\}_3](ClO_4)_3$.

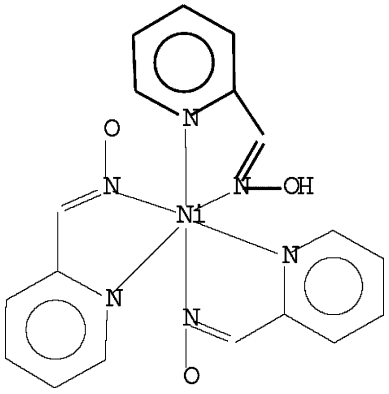

Fig. 13. A drawing of $[Ni\{(py)CHNO\}_2\{(py)CHNOH\}]$.

The latter (Fig. 15) contains two 2.111 neutral ligands, one 1.011 neutral ligand and two 3.211 deprotonated ligands (Fig. 8).

Although complex formation equilibria involving (py)CHNOH and Zn^{II} were studied [65], only one structurally characterized $Zn(II)/(py)CHNO^-$ complex has been reported [66]; this is $[Zn_4(OH)_2Cl_2\{(py)CHNO\}_4]$ (Fig. 16). The molecule of this complex features an inverse 12-metallacrown-4 motif [67] with the oximato ligand adopting the 2.111 coordination mode.

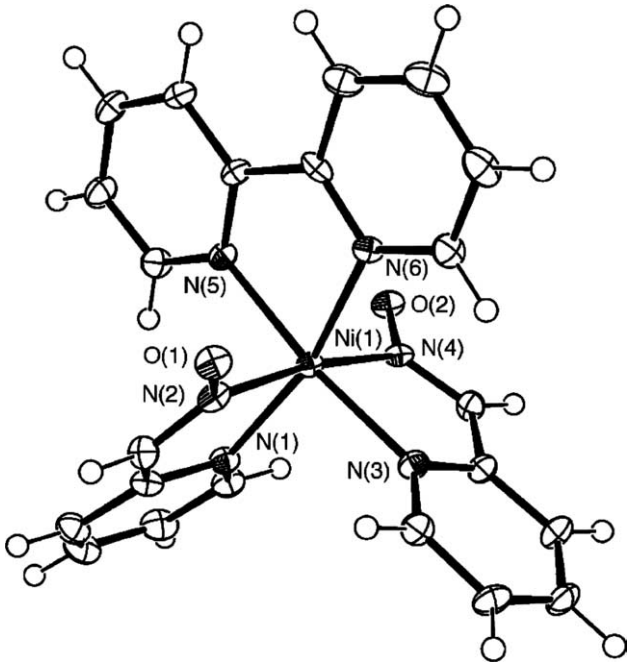

Fig. 14. The molecular structure of $[Ni\{(py)CHNO\}_2(bpy)]$ [63].

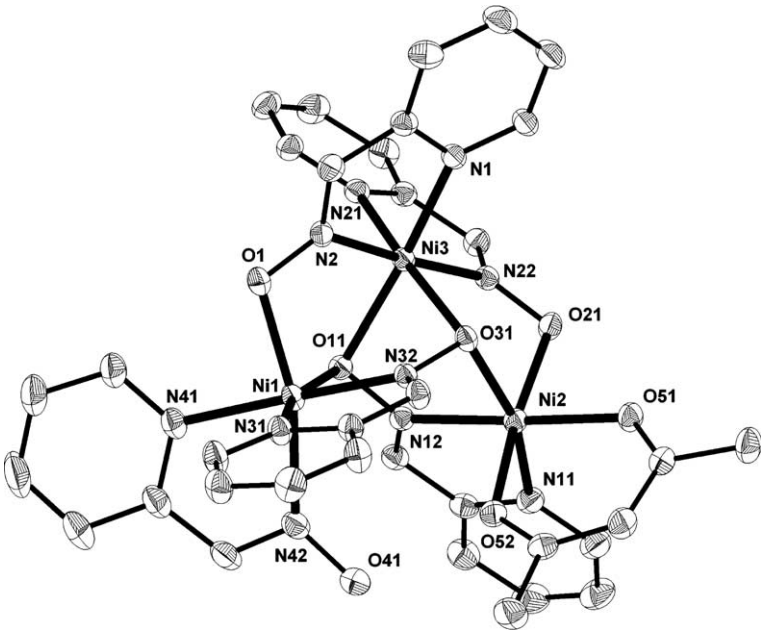

Fig. 15. The structure of the trinuclear cation $[Ni_3(acac)\{(py)CHNO\}_2\{(py)CHNOH\}_3]^{3+}$ [64].

A dinuclear mixed-valence d^3/d^4 complex $[LCr^{III}\{(py)CHNO\}_3Cr^{II}](ClO_4)_2$ has been prepared [68], in which the Cr^{III} and Cr^{II} centers are antiferromagnetically coupled ($J = -7.9$ cm^{-1}) [68]; L = 1,4,7-trimethyl-1,4,7-triazacyclononane. No structural data are available for this compound.

The Mn/(py)CHNOH chemistry is better developed. A modular approach (vide infra) using tris(pyridine-2-aldoximato)manganate(II), $[Mn^{II}\{(py)CHNO\}_3]^-$, and $[Mn^{III}L]$-units (L = 1,4,7-trimethyl-1,4,7-triazacyclononane) yielded the localized mixed-valence complex $[LMn^{III}\{(py)CHNO\}_3Mn^{II}]^{2+}$ [6]. The two manganese centers are bridged by the –NO oximato linkages of the three 2.111 $(py)CHNO^-$ ligands. The interaction between the two metal ions was found to be ferromagnetic ($J = +1.8$ cm^{-1}, $S_T = 9/2$).

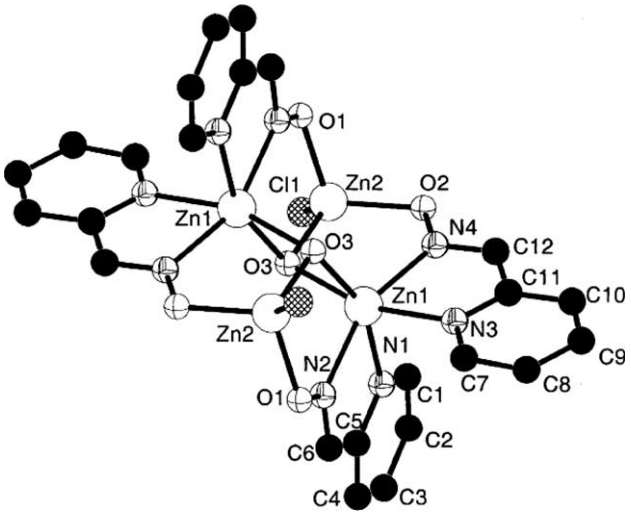

Fig. 16. X-ray structure of $[Zn_4(OH)_2Cl_2\{(py)CHNO\}_4]$; atoms O(3) are the hydroxo oxygen atoms [66].

The structure of the 1D polymer $[Mn(SO_4)\{(py)CHNOH\}(H_2O)]_n$ (Fig. 17) consists of double chains, in which the Mn^{II} ions are bridged by $\eta^1{:}\eta^1{:}\eta^1{:}\mu_3$ sulfato ligands [66]; the neutral oxime ligand behaves as *N*,*N*′-bidentate chelate (1.011, Fig. 8).

The preparation and crystal structures of four Mn(II) carboxylate complexes containing neutral (py)CHNOH were recently reported [69]. The 1:1 reaction between $Mn(O_2CPh)_2 \cdot 2H_2O$ and the ligand in MeCN led to isolation of $[Mn_4(O_2CPh)_6\{(py)CO_2\}_2\{(py)CHNOH\}_2]$ (Fig. 18). The most interesting synthetic feature of this reaction is the in situ formation of the picolinate(−1) ligand, $(py)CO_2^-$. The centrosymmetric tetranuclear cluster consists of an exactly planar zig-zag array of Mn^{II} atoms and is held together by four *syn*, *syn* $\eta^1{:}\eta^2{:}\mu_2$ and two $\eta^1{:}\eta^2{:}\mu_3$ $PhCO_2^-$ groups, two $\eta^1{:}\eta^2{:}\mu_2(py)CO_2^-$ ligands and two *N*,*N*′-bidentate chelating (py)CHNOH molecules.

The 1:4:7 $[Mn_3^{II,III,III}O(O_2CPh)_6(py)_2(H_2O)]$/$Me_3SiCl$/(py)CHNOH reaction mixture in MeCN (py = pyridine) yielded the 1D coordination polymer $[Mn(O_2CPh)\{(py)CO_2\}\{(py)CHNOH\}]_n$, in which the partial (py)CHNOH → $(py)CO_2^-$ transformation has again occurred. Its structure is shown in Fig. 19. The 1:3 reaction between $Mn(O_2CMe)_2 \cdot 4H_2O$ and (py)CHNOH in EtOH led to the isolation of the dinuclear complex $[Mn_2(O_2CMe)_2\{(py)CO_2\}_2\{(py)CHNO\}_2]$; crystallography again revealed the partial (py)CHNOH → $(py)CO_2^-$ transformation. A simplified scheme for this transformation was proposed (Fig. 20). Reaction of $Mn(hfac)_2 \cdot 3H_2O$ (hfacH = hexafluoroacet-

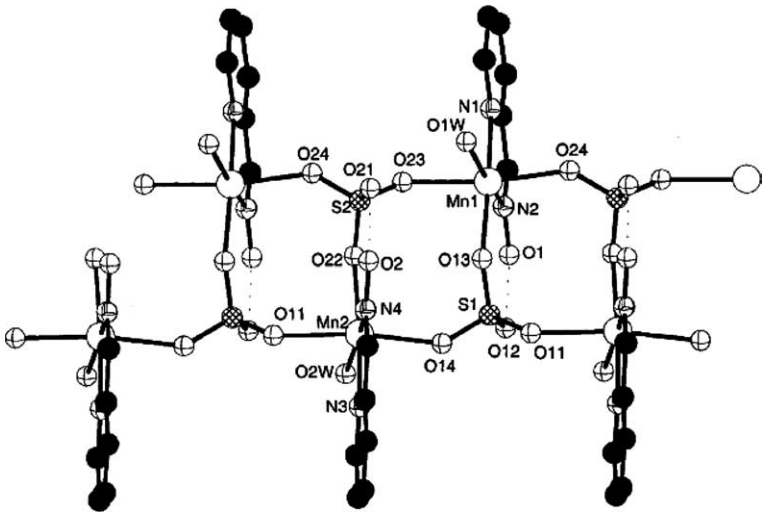

Fig. 17. A small portion of the 1D double chain present in complex $[Mn(SO_4)\{(py)CHNOH\}(H_2O)]_n$ [66].

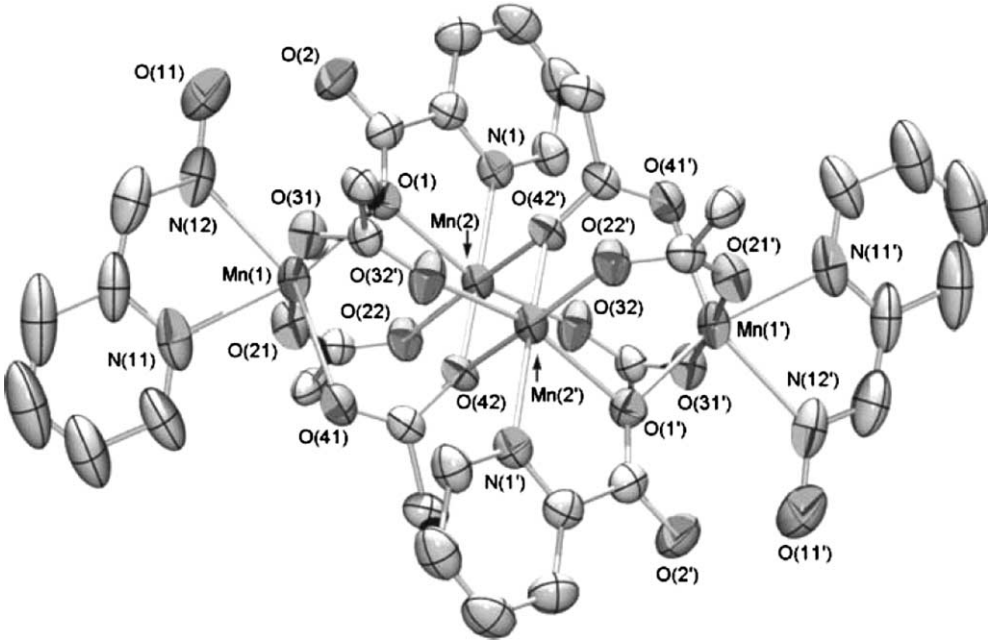

Fig. 18. The molecular structure [69] of the complex $[Mn_4(O_2CPh)_6\{(py)CO_2\}_2\{(py)CHNOH\}_2]$. Only the *ipso* carbon atoms of the phenyl groups of the benzoate ligands are shown.

ylacetone) with one equivalent of (py)CHNOH in CH_2Cl_2 yields complex $[Mn(O_2CCF_3)_2\{(py)CHNOH\}_2]$; the $CF_3CO_2^-$ ligand is one of the decomposition products of the hfac$^-$ ligand. The Mn^{II} ion is coordinated by two $CF_3CO_2^-$ groups and two 1.011 neutral oxime ligands.

$[Pt\{(py)CHNO\}_2]\cdot 2H_2O$ is the only structurally characterized (py)CHNOH- or (py)CHNO$^-$-based complex with 4d or 5d metals [70]. The coordination around the Pt^{II} center is roughly *trans* square planar, the ligating atoms being the two nitrogen atoms from each of two deprotonated ligands. The planar units form a chain parallel to the crystallographic *c*-axis (Pt$\cdots$Pt = 3.245 Å). A powdered sample of the complex shows enhanced electrical conductivity which is in the same range as that observed for Magnus's Green salt, $[Pt(NH_3)_4][PtCl_4]$.

The main-group metal chemistry of (py)CHNOH is virtually non-existent. The only exception is the organometallic complex $[In_2Me_4\{(py)CHNO\}_2]$ (Fig. 21), in which the In^{III} atoms are five-coordinate adopting a distorted trigonal bipyramidal geometry [71].

Up to now, we have discussed *homometal* complexes of (py)CHNOH/(py)CHNO$^-$. We now continue our discussion with the description of *heterometal* complexes that

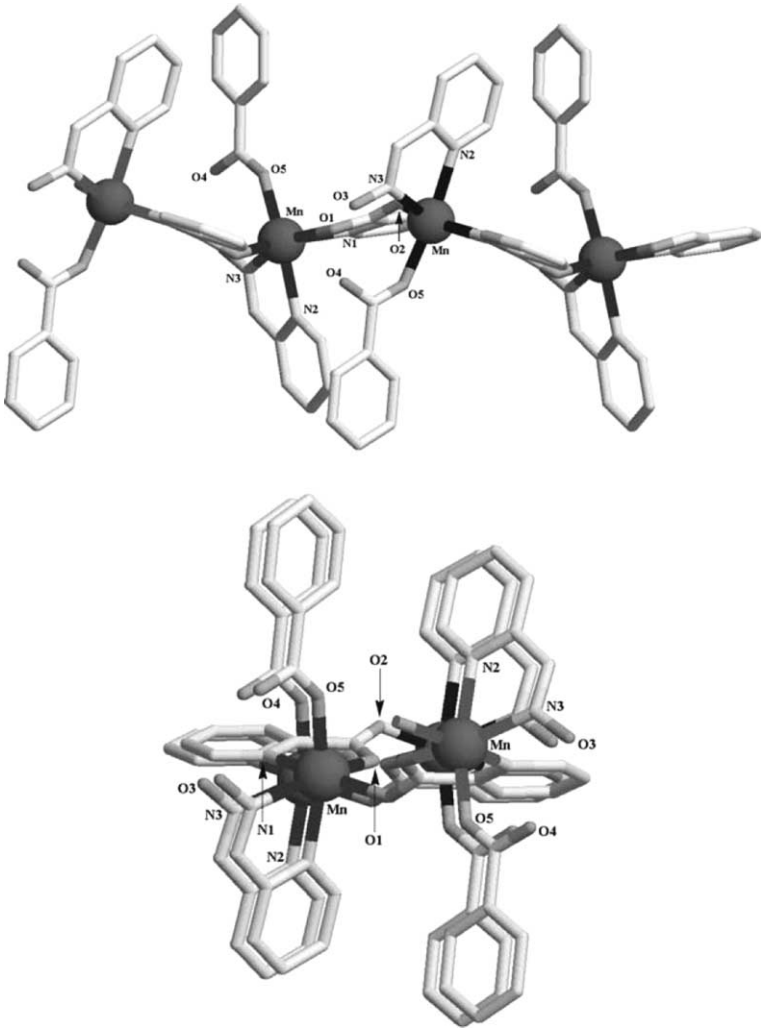

Fig. 19. Views of the complex $[Mn(O_2CPh)\{(py)CO_2\}\{(py)CHNOH\}]_n$ along *b*-axis (up) and *c*-axis (down) [69].

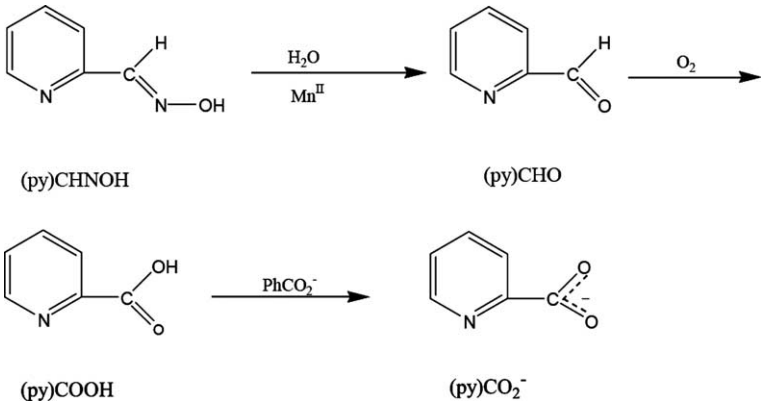

Fig. 20. A simplified view for the transformation of an account of (py)CHNOH to picolinate(−1) during the preparation of some Mn(II) carboxylate complexes.

are (exclusively or partially) based on bridging $(py)CHNO^-$ ligands. All these complexes have aesthetically beautiful structures, while some of them present interesting magnetic properties. Magnetic investigations of heteronuclear complexes are more informative than those of homonuclear complexes as new exchange pathways can be expected for two different spin carriers within a molecular unit, because unusual sets of magnetic orbitals are brought in close proximity [6]. Thus, oximato-bridged heterometal complexes are central players in the

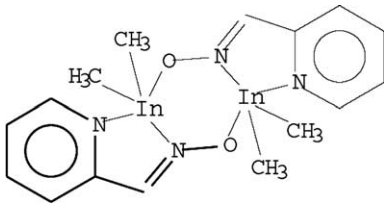

Fig. 21. A drawing of the molecule of $[In_2Me_4\{(py)CHNO\}_2]$.

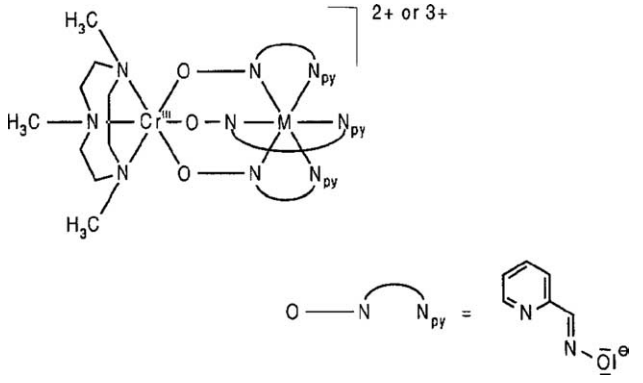
field of molecular magnetism [72]. Most of these species are prepared by the so-named "modular" synthesis [6]; other names of this approach are "complexes as ligands" or "complexes as ligands and complexes as metals" strategies [73]. Different "modules", i.e., complexes containing one or more metal centers, are able to react further with other modules (different metal centers or metal complexes) through available appropriate donor atoms.

In an excellent paper [68], Chaudhuri, Wieghardt and co-workers reported that tris(pyridine-2-aldoximato)metalates(II), $[M^{II}\{(py)CHNO\}_3]^-$, are capable of acting as "ligands" reacting with $[LCr^{III}(MeOH)_3]^{3+}$ ("metals") to give various asymmetric dinuclear complexes of the general type $[LCr^{III}\{(py)CHNO\}_3M^{II}]^{2+}$ ($M^{II} = Mn^{II}$, Fe^{II}, Ni^{II}, Cu^{II}, Zn^{II}; L is the "end-cap" 1,4,7-trimethyl-1,4,7-triazacyclononane), see Scheme 2. In the case of cobalt(II), oxidation occurs and the resulting complex is $[LCr^{III}\{(py)CHNO\}_3Co^{III}](ClO_4)_3$. These compounds contain three 2.111 $(py)CHNO^-$ ions as bridging ligands. The complexes are isostructural in the sense that they all contain a terminal Cr^{III} atom in a distorted octahedral $Cr^{III}N_3O_3$ environment and a second six-coordinate metal ion M in a mostly trigonal prismatic MN_6 geometry. Analysis of the variable-temperature magnetic susceptibility data indicates the presence of weak ferro- or antiferromagnetic exchange interactions between the paramagnetic centers. A qualitative rationale on the basis of Goodenough–Kanamori rules [74,75] was provided to explain the differences in magnetic behavior.

Using the "complexes as ligands and complexes as metals" strategy Clérac, Miyasaka and co-workers [62] per-

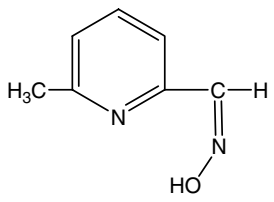


Scheme 2. General structural type of the $[LCr^{III}\{(py)CHNO\}_3M]^{2+\text{ or }3+}$ cations (L = 1,4,7-trimethyl-1,4,7-triazacyclononane); the metal ion M is Cr^{II}, Mn^{II}, Fe^{II}, Co^{III}, Ni^{II}, Cu^{II}, Zn^{II} [68].

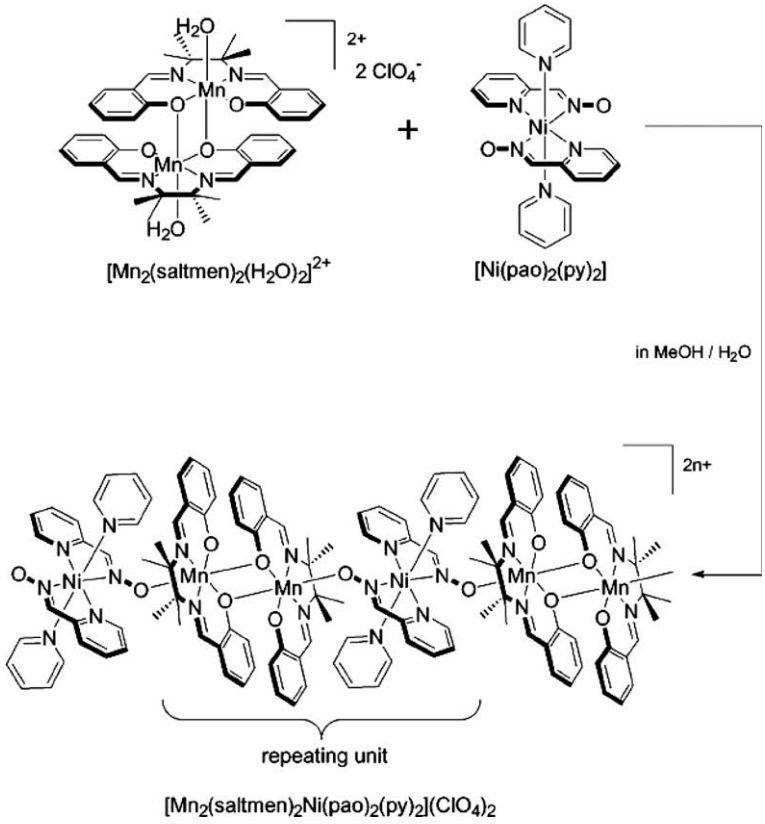
formed the reaction between $[Mn_2^{III,III}(saltmen)_2(H_2O)_2](ClO_4)_2$ (the "metal") and $[Ni\{(py)CHNO\}_2(py)_2]$ (the "bridging ligand"), where saltmen^{2-} is *N*,*N*′-(1,1,2,2-tetramethylethylene)bis(salicylideneiminate), see Scheme 3. The product [43] consists of two fragments, the out-of-plane dimer $[Mn_2(saltmen)_2]^{2+}$ as a coordination acceptor building block and the neutral mononuclear unit $[Ni\{(py)CHNO\}_2(py)_2]$ as a coordination donor building block, forming an alternating chain having the $[-Mn^{III}-(O)_2-Mn^{III}-(ON)-Ni-(NO)-]$ repeating unit. The chains are well isolated and there are no interchain π–π overlaps between organic ligands; these features ensure a good magnetic isolation of the chains. The $Ni^{II}\cdots Mn^{III}$ exchange is antiferromagnetic ($J = -21$ K) and much stronger than the ferromagnetic intrachain $Mn^{III}\cdots Mn^{III}$ interaction ($J' = +0.67$ K). Hysteresis loops are observed below 3.5 K, indicating a magnet-type behavior. Combined ac (Fig. 22) and dc measurements show a slow relaxation of the magnetization. The material constitutes an elegant design of a heterometallic chain with $S_T = 3$ magnetic units showing a "single-chain magnet" behavior predicted in 1963 by Glauber [76] for an Ising 1D system and first experimentally documented by Gatteschi's group [77,78]. Complexes $\{[Mn_2^{III,III}(saltmen)_2Ni^{II}\{(py)CHNO\}_2(L)_2](A)_2\}_n$ (L = *N*-methylimidazole, A = ClO_4; L = py, A = PF_6; L = py, A = ReO_4) were also structurally characterized, and found to have similar structures and properties [79] with those of the L = py, A = ClO_4 archetype described above.

Employing $[Ni\{(py)CHNO\}(bpy)_2]^+$ as "terminal ligand", the groups of Miyasaka and Clérac characterized [80] the heterometallic linear tetramers $[Mn(5\text{-}R\text{-}saltmen)Ni\{(py)CHNO\}(bpy)_2]_2(ClO_4)_2$ (R = H, Cl, Br, MeO; Scheme 4). These tetramers can be seen as oligomeric units (components) of the aforementioned "single-chain magnets". Magnetic studies on the former [80] confirm the nature of the magnetic interactions reported for the latter [43,79]; a strong antiferromagnetic $Mn^{III}\cdots Ni^{II}$ coupling via the oximato bridge ($J_{Mn\cdots Ni}$ ranges from −23.7 to −26.1 K) and a weak ferromagnetic $Mn^{III}\cdots Mn^{III}$ coupling through the bis(phenolato) bridge ($J_{Mn\cdots Mn}$ ranges from +0.4 to +0.9 K). These magnetic interactions lead to tetramers with an $S = 2$ ground state.

5.3. 6-Methylpyridine-2-carbaldehyde oxime, (6-Mepy)CHNOH



(6-Mepy)CHNOH



Scheme 3. Synthesis of the "single-chain magnet" $\{[Mn_2^{III,III}(saltmen)_2Ni^{II}\{(py)CHNO\}_2(py)_2](ClO_4)_2\}_n$; paO is another abbreviation for the anion of pyridine-2-carbaldehyde oxime (see Section 2).

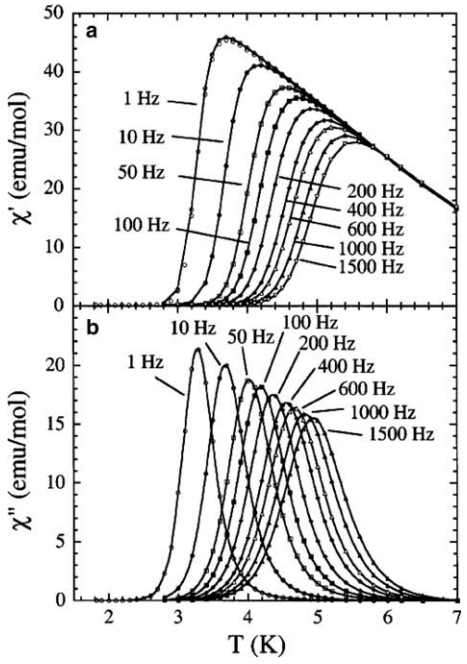


Fig. 22. Temperature and frequency dependence of (a) the real (χ') and (b) the imaginary (χ'') parts of the ac susceptibility; the solid lines are guides for the eye [43].

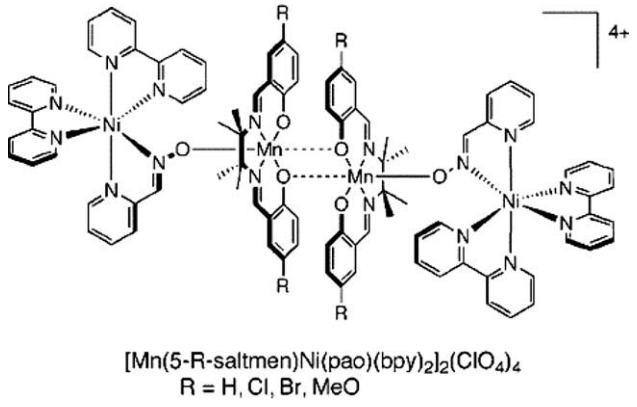
The free ligand is synthesized [46] by the reaction of 6-methylpyridine-2-carbaldehyde, (6-Mepy)CHO, with an equimolar amount of H_2NOH in MeOH under reflux. The values of the logarithm of the protonation constant of the 2-pyridyl nitrogen and pK_a of the oxime group are [46] 4.26 and 9.94, respectively. The coordination chemistry of this ligand is practically unknown. Complex formation equilibria involving (6-Mepy)CHNOH and Cu(II) [46], Zn(II) [65] and Cd(II) [65] have

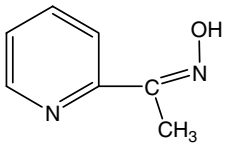


Scheme 4. A drawing of the cations $[Mn^{III}(5\text{-R-saltmen})Ni^{II}\{(py)CHNO\}(bpy)_2]_2^{4+}$ which are the tetrameric components of the "single-chain magnets" depicted in Scheme 3.

been studied by Saarinen's group. Only one complex has been structurally characterized [81]. This is the enneanuclear Ni(II) cluster $[Ni_9(\mu_3\text{-}OH)_2(\mu_2\text{-}OH)_4\{\mu_3\text{-}(6\text{-Mepy})CHNO\}_4\{\mu_2\text{-}(6\text{-Mepy})CHNO\}_6(H_2O)_6](ClO_4)_2$, prepared by the reaction between $NiCl_2 \cdot 6H_2O$ and the ligand in H_2O at pH 8 (Eq. (6)). The chromophores in the structure are NiO_6, NiN_2O_4 and NiN_4O_2. The nine Ni^{II} atoms are held together via $\mu_3\text{-}OH^-$, $\mu_2\text{-}OH^-$, 2.111 and 3.211 (6-Mepy)$CHNO^-$ ligands.

$$9NiCl_2 \cdot 6H_2O + 10(6\text{-Mepy})CHNOH + 16NaOH + 2NaClO_4 \xrightarrow[\text{pH 8}]{H_2O} [Ni_9(OH)_6\{(6\text{-Mepy})CHNO\}_{10}(H_2O)_6](ClO_4)_2 + 18NaCl + 58H_2O \quad (6)$$

5.4. 1-Pyridin-2-yl-ethanone oxime, (py)C(Me)NOH



(py)C(Me)NOH

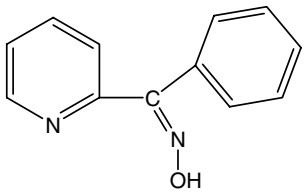
The free ligand can be synthesized [46] by the reaction of equimolar quantities of 1-pyridin-2-yl-ethanone (2-acetylpyridine), (py)C(Me)O, $H_2NOH \cdot HCl$ and NaOMe in EtOH. The values of $\log\beta$ of the 2-pyridyl nitrogen (β is the protonation constant) and pK_a of the oxime group are [46] 3.97 and 10.87, respectively. The acidity of the oxime group of (py)C(Me)NOH is lower than that of (py)CHNOH ($pK_a = 10.01$) due to the adjacent methyl group in the former. Complex formation equilibria involving the neutral and/or the deprotonated ligand and Cu(II) [46], Zn(II) [65] and Cd(II) [65] have been studied in aqueous solution by potentiometic methods.

The published coordination chemistry of (py)C(Me)NOH is limited compared with (py)CHNOH. The structurally characterized metal complexes of (py)C(Me)NOH and/or (py)C(Me)NO^- [82–91] are listed in Table 1, along with the coordination modes of the ligands and few structural details. Of particular note are the coordination modes 1.100 and 2.101 observed in organometallic compounds of Sb(V) and Sn(IV) [89–91], which are unique for the (py)C(R)NO^- ligands (R = H, Me, Ph).

Molecular structures of representative complexes are shown in Figs. 23–27. In general terms, the comparison of the coordination chemistry of (py)C(Me)NOH with that of (py)C(H)NOH is not possible because of the different nature of the reaction systems studied. However, three metal/(py)C(Me)NO^- complexes, i.e., $[Co\{(py)C(Me)NO\}_3]$ [59], $[Zn_4(OH)_2Cl_2\{(py)C(Me)NO\}_4]$ [84] and $[Pt\{(py)C(Me)NO\}_2]$ [88], have rather similar molecular structures to their (py)$CHNO^-$ counterparts, i.e., $[Co\{(py)CHNO\}_3]$ [59], $[Zn_4(OH)_2Cl_2\{(py)CHNO\}_4]$ [66] and $[Pt\{(py)CHNO\}_2]$ [70]. It should be mentioned that the Co(III)/(py)C(Me)NO^- complex is the *fac* isomer, whereas the Co(III)/(py)C(H)NO^- complex is the *mer* isomer. The nature of R affects the structural identity of the organometallic complexes $[R_8Sn_4O_2\{(py)C(Me)NO\}_4]$ [90,91], see Table 1.

The crystal structure of the free ligand consists of chains of molecules arising from intermolecular hydrogen bonding with the ring nitrogen atom as acceptor [90].

5.5. Phenyl-pyridin-2-yl-methanone oxime, (py)C(ph)NOH



(py)C(ph)NOH

The free ligand can be synthesized [92] by the reaction of 2-benzoylpyridine, (py)C(ph)O, with an excess of NH_2OH ($NH_2OH \cdot HCl + NaOH$) in $EtOH/H_2O$. The first structurally characterized metal complexes of (py)C(ph)NOH were the carbonyl compounds [93] $[Os_3(CO)_8\{(py)C(ph)NO\}_2]$, $[Os_3(CO)_8\{(py)C(ph)NO\}\{(py)C(ph)HNH\}]$, $[Os_3H(CO)_9\{(py)C(ph)NO\}]$ and $[Os_3H(CO)_{11}\{(py)C(ph)NO\}]$, which exhibit interesting structural features. The structurally characterized, non-organometallic metal complexes of the neutral or anionic ligand are listed in Table 2.

The comproportionation reaction between $Mn(O_2CPh)_2 \cdot 2H_2O$ and $^nBu_4MnO_4$ (3:1) in the presence of (py)C(ph)NOH in $MeCN/EtOH/CH_2Cl_2$ leads to the isolation of the mixed-valent cluster $[Mn_4^{II}Mn_4^{III}O_2(OH)_2(O_2CPh)_{10}\{(py)C(ph)NO\}_4]$. The centrosymmetric octanuclear molecule (Fig. 28) contains four Mn^{II} and four Mn^{III} ions held together by two $\mu_4\text{-}O^{2-}$ ligands and two $\mu_3\text{-}OH^-$ ions to give the $\{Mn_8(\mu_4\text{-}O)_2(\mu_3\text{-}OH)_2\}^{14+}$ core (Fig. 29), with peripheral ligation provided by 10 $PhCO_2^-$ ligands that exhibit three different coordination modes and four 2.111 (py)C(ph)NO^- ions [94,95]. The molecular structure of this complex is very similar with that of $[Mn_4^{II}Mn_4^{III}O_2(OH)_2(O_2CPh)_{10}\{(py)C(Me)NO\}_4]$ [82].

Table 1
Structurally characterized metal complexes containing (py)C(Me)NOH and/or (py)C(Me)NO$^-$ ligands

Complex[a]	Coordination mode of the oxime/oximate ligand	Coordination spheres; coordination geometries	Reference
$[Mn(O_2CPh)_2\{(py)C(Me)NOH\}_2]$	1.011	*cis*,*cis*,*trans*-$Mn^{II}O_2(N_{py})_2(N_{ox})_2$; oct	[82]

$[^nBu_8Sn_4O_2\{(py)C(Me)NO\}_4]$	1.100, 2.101	$Sn^{IV}C_2(\mu_3\text{-}O)(O_{ox})(N_{ox})$, $Sn^{IV}C_2(\mu_3\text{-}O)_2(O_{ox})$; spy, tbp	[90]
$[Et_8Sn_4O_2\{(py)C(Me)NO\}_4]$	1.100, 2.101	$Sn^{IV}C_2(\mu_3\text{-}O)(O_{ox})_2$, $Sn^{IV}C_2(\mu_3\text{-}O)_2(N_{ox})$; tbp, spy	[90]
$[Me_8Sn_4O_2\{(py)C(Me)NO\}_4]$	1.100, 2.111	$Sn^{IV}C_2(\mu_3\text{-}O)(O_{ox})_2$, $Sn^{IV}C_2(\mu_3\text{-}O)_2(N_{py})(N_{ox})$; tbp, oct	[91]

Abbreviations: N_{ox}, oxime or oximato nitrogen; N_{py}, 2-pyridyl nitrogen; O_{carb}, carboxylate oxygen; O_{ox}, oximate oxygen; O_{sulf}, sulfate oxygen; oct, octahedral; sp, square planar; spy, square pyramidal; tbp, trigonal bipyramidal; tet, tetrahedral.

[a] Solvate and other lattice molecules have been omitted.

[b] The crystal structure of this coordination polymer consists of single and double chains.

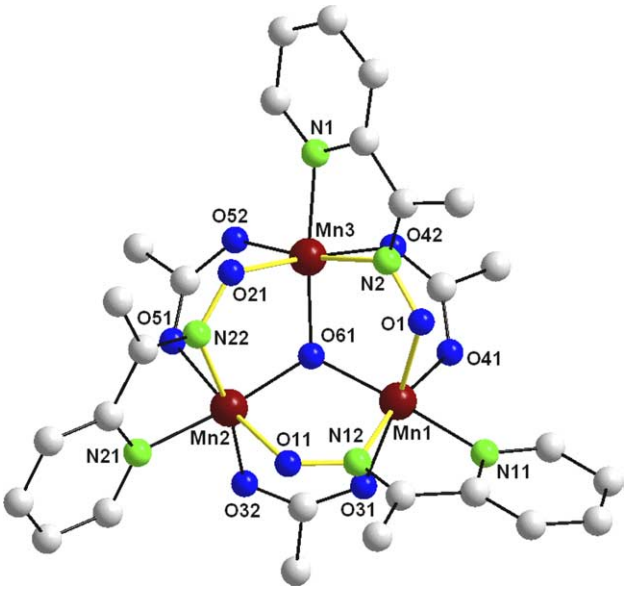

Fig. 23. X-ray structure of the $[Mn_3O(O_2CMe)_3\{(py)C(Me)NO\}_3]^+$ cation [82].

The reaction of $Mn(O_2CPh)_2 \cdot 2H_2O$ with the sodium salt of (py)C(ph)CNOH and NaN_3 in MeOH gives a tetranuclear cage (Fig. 30) with a $\{Mn_3^{II}Mn^{IV}(\mu_4\text{-}O)(\eta^1{:}\mu_2\text{-}N_3)\}^{7+}$ core; the four oximate anions behave as 2.111 ligands [96]. Magnetic and EPR (Fig. 31) studies show the cage has an $S = 6$ ground state.

Complexes $[Co_2^{III,III}Co^{II}\{(py)C(ph)NO\}_6](PF_6)_2$ and $[Co\{(py)C(ph)NO\}_3]$ are structurally similar to their $(py)CHNO^-$ partners. The use of $(py)C(ph)NO^-/MeCO_2^-$ and $(py)C(ph)NO^-/SO_4^{2-}$ "blends" in Ni(II) chemistry leads to a variety of structurally interesting clusters [84,97]. Of particular note are the complexes $[Ni_3\{(py)C(ph)NO\}_6]$ and $[Ni_6(OH)(SO_4)_4\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(MeOH)_3]$; both complexes have been isolated from the $NiSO_4 \cdot 6H_2O/(py)C(ph)NOH/NaOMe$ reaction mixtures. In the former [84], the oximate ligands adopt four different coordination modes, including the unique 1.110 mode (Fig. 8) which gives rise to a six-membered chelating ring. The molecular structure of the latter consists of two parallel triangles (Fig. 32). The metal ions in the "small" triangle (defined by Ni(2), Ni(5) and Ni(6)) are held together by the μ_3-OH^-, the $\eta^1{:}\eta^1{:}\eta^1{:}\mu_3$-$SO_4^{2-}$ and the deprotonated oximate groups of the three 3.211 $(py)C(ph)NO^-$ ligands; this triangle can be viewed as an inverse 9-MC-3-subunit [67]. The metal ions in the "large" triangle (defined by Ni(1), Ni(3), Ni(4)) are held together by the three $\eta^1{:}\eta^2{:}\mu_3$-SO_4^{2-} groups. Monoatomic oxygen bridges from the

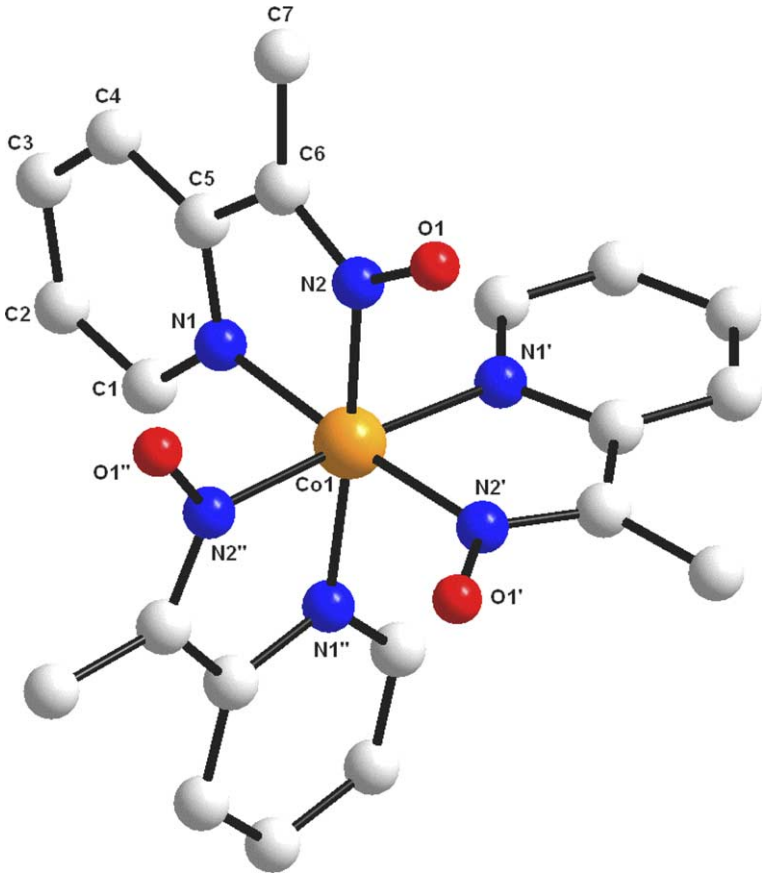

Fig. 24. Molecular structure of complex $[Co\{(py)C(Me)NO\}_3]$; the Co^{III} atom sits on a threefold axis of symmetry [59].

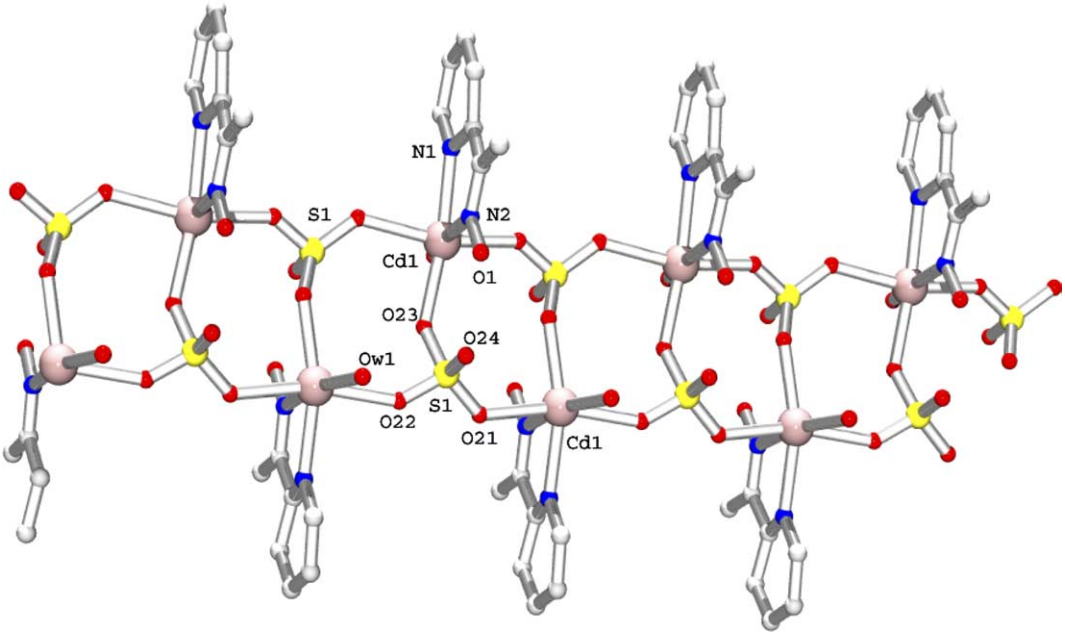

Fig. 25. A small portion of the double chain $[Cd(SO_4)\{(py)C(Me)NOH\}(H_2O)]_n$ present in the complex $\{[Cd(SO_4)\{(py)C(Me)NOH\}(H_2O)]\cdot[Cd(SO_4)\{(py)C(Me)NOH\}(H_2O)_2]\}_n$ [84].

$\eta^1:\eta^2:\mu_3$-SO_4^{2-} and the 3.211 (py)C(ph)NO$^-$ ligands link up the two triangles.

Despite the four complexes listed in Table 2, the Cu(II), Zn(II) and Cd(II) chemistry of (py)C(ph)NOH is virtually non-existent. In the dinuclear complex $[Cu_2(hfac)_2\{(py)C(ph)NO\}_2]$ (Fig. 33) [97], the two bridges are the oximato groups of the two 2.111 (py)C(ph)NO$^-$ ligands, whereas complexes $[M_2(SO_4)_2\{(py)C(ph)NOH\}_4]$ (M = Zn, Cd) contain neutral 1.011 oxime ligands and $\eta^1:\eta^1:\mu_2$ sulfato groups (Fig. 34) [84]. Complex $[Zn_4(OH)_2(N_3)_2\{(py)C(ph)NO\}_4]$ features [84] an inverse 12-metallacrown-4 motif,

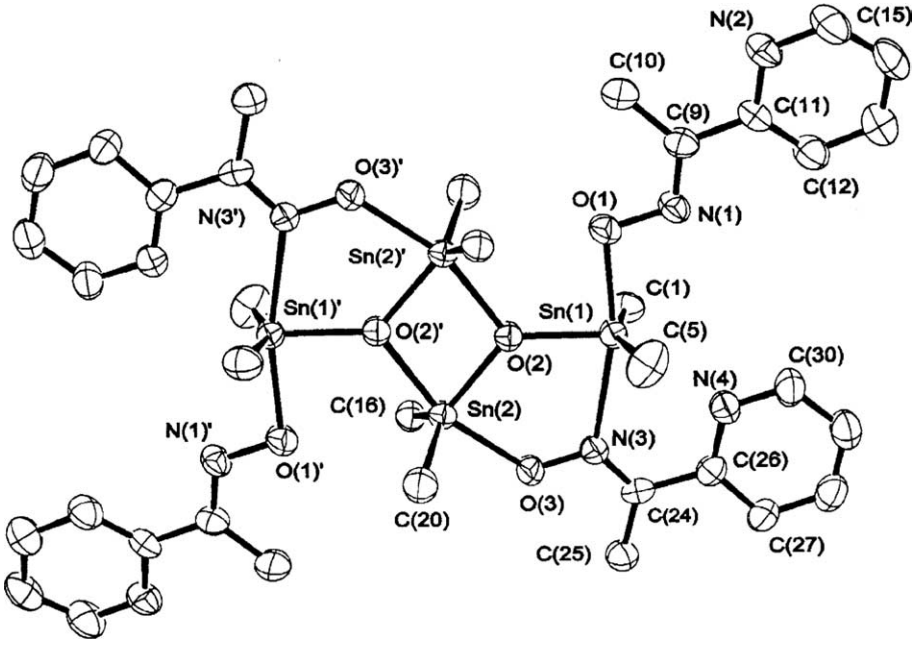

Fig. 26. X-ray structure of $[^nBu_8Sn_4O_2\{(py)C(Me)NO\}_4]$ [90].

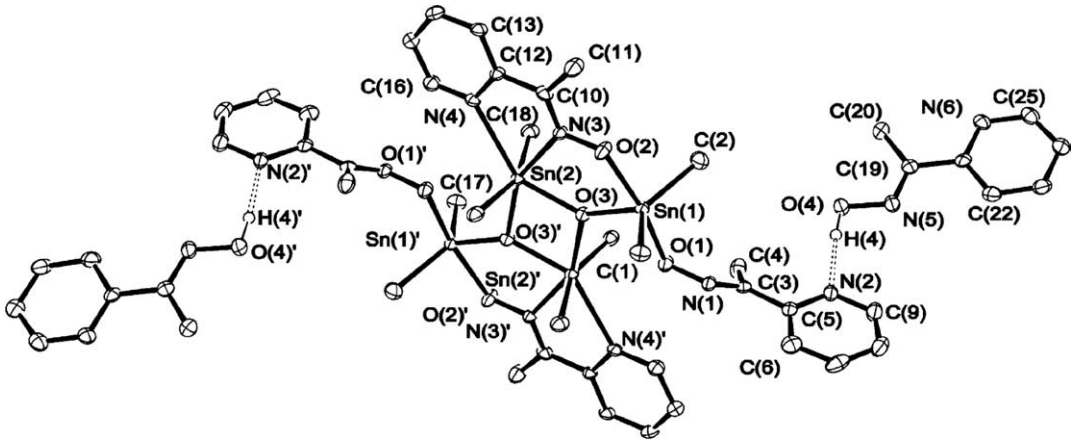

Fig. 27. X-ray structure of $[Me_8Sn_4O_2\{(py)C(Me)NO\}_4]\cdot 2(py)C(Me)CNOH$ [91].

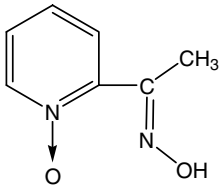
like its $(py)CHNO^-$ [66] and $(py)C(Me)NO^-$ [84] chloro analogs.

5.6. Metal complexes of 2-acetylpyridine N-oxide oxime, (Opy)C(Me)NOH

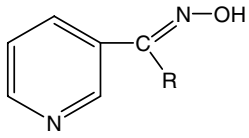


(Opy)C(Me)NOH

Strictly speaking this ligand is not a pyridyl oxime. The (Opy)C(Me)NOH ligand was first mentioned in the literature in 1977 in a paper describing Co(II) and Ni(II) complexes of 2-substituted pyridine *N*-oxides, although the synthesis of (Opy)C(Me)NOH was not detailed [98]. The detailed synthesis was reported in 1982 and involves the reaction of $NH_2OH\cdot HCl$ with 2-acetylpyridine *N*-oxide in warm H_2O in the presence of $NaO_2CMe\cdot 3H_2O$ [99].

The only metal complexes of (Opy)C(Me)NOH that have been structurally characterized are $[CoBr_2\{(Opy)C(Me)NOH\}_2]$ [100] and $[Co_2Cl_4\{(Opy)C(Me)NOH\}_2(MeOH)_2]$ [101]. The Co^{II} ion in the mononuclear complex is coordinated by two bromo ions and two $O_{N\text{-oxide}}$, N_{oxime}-bidentate chelating (Opy)C(Me)NOH ligands (1.101, Fig. 35) in a *cis–cis–trans* fashion (the *trans* donor atoms are the N_{oxime} atoms) [100]. The ligand adopts the 2.201 coordination mode (Fig. 35) in the centrosymmetric dinuclear complex [101]. Each Co^{II} ion has a six-coordinate O_3NCl_2 environment, produced by *O*,*N*-coordination from one ligand, bridging *N*-oxide bonding from the second ligand, two terminal chlorides and one coordinated MeOH.

5.7. Pyridine-3-carbaldehyde oxime, (3-py)CHNOH, and 1-pyridin-3-yl-ethanone oxime, (3-py)C(Me)NOH



(3-py)CHNOH (R= H)

(3-py)C(Me)NOH (R= Me)

Compounds (3-py)CHNOH and (3-py)C(Me)NOH are the 3-pyridyl analogs (isomers) of (py)CHNOH (Section 5.2) and (py)C(Me)NOH (Section 5.4), respectively. The free ligand (3-py)CHNOH is commercially available. Its crystal structure has been determined [45]. Infinite 1D chains are assembled through a head-to-tail O–H···N hydrogen bond involving the oxime O–H and the pyridine nitrogen atom. Adjacent chains are related by a glide plane and the two chains are linked through a C–H···O hydrogen bond to form an 1D ribbon; the ribbons are arranged in a herringbone motif and are hydrogen bonded to neighboring ribbons via $C–H\cdots N_{oxime}$ interactions to produce an overall 3D hydrogen bonded structure. The free ligand (3-py)C(Me)NOH can be synthesized by the reaction of 3-acetylpyridine, (3-py)C(Me)O, with $NH_2OH\cdot HCl$ in $EtOH/H_2O$ under reflux in the presence of excess Na_2CO_3 [45]. In the crystal structure of this compound, the molecules form infinite 1D chains assembled through a head-to-tail $O–H\cdots N_{pyridine}$ hydrogen bond; additional $C–H\cdots N_{oxime}$ and C–H···O hydrogen bonds cross-link the 1D chains to produce a 3D hydrogen bonded infinite architecture [45]. In contrast to their 2-pyridyl analogs, the published coordination chemistry of (3-py)CHNOH and (3-py)C(Me)NOH is very limited.

Aakeröy and co-workers [102,103] have employed (3-py)CHNOH and (3-py)C(Me)NOH as versatile tools

Table 2
Structurally characterized metal complexes containing (py)C(ph)NOH and/or (py)C(ph)NO$^-$ligands

Complex[a]	Coordination mode of the oxime/oximate ligand	Coordination spheres; coordination geometries	Reference

for supramolecular assembly of silver(I)- and copper(I)-containing hydrogen-bonded architectures. The crystal structure of $[Ag\{(3\text{-py})CHNOH\}_2](PF_6)$ [102] contains cations (Fig. 36) comprised of two ligands coordinated through the 3-pyridyl nitrogen atoms to a Ag^I ion (coordination mode 1.010, Fig. 37). The oxime moieties are *cis* with respect to each other, and cations are linked by complementary O–H···N hydrogen bonds between oxime moieties on neighboring ligands (**I** in Fig. 4), generating infinite 1D chains. Adjacent chains are linked by C–H···O hydrogen bonds, resulting in 2D cationic sheets, Fig. 36. The PF_6^- counterions occupy the resulting "holes" within the cationic sheet, and are held in position by several C–H···F hydrogen bonds. The result is an anisotropic, lamellar structure. The crystal structure of $[Ag\{(3\text{-py})CHNOH\}_2](ClO_4)$ [102] is very similar to that of the PF_6^- salt, even though the size of the anion has changed significantly from the PF_6^- to the ClO_4^- salt (molecular volumes of 72 and 55 $Å^3$, respectively).

The crystal structure of $[Ag\{(3\text{-py})C(Me)NOH\}_2](PF_6)$ [102] contains cations comprised of two 1.010 ligands. The oxime moieties are arranged *trans* with respect to each other and neighboring cations are linked by oxime O–H···N hydrogen bonds, $R_2^2(6)$, into 1D chains. The chains are arranged within well-defined 3D regions, connected by intermolecular hydrogen bonds. The anions, positioned *between* layers, act as "bridges", via C–H···F hydrogen bonds (Fig. 38). The crystal structure of $[Ag\{(3\text{-py})C(Me)NOH\}_2](ClO_4)$ [102] is very similar to that of the PF_6^- salt.

The persistence of the intermolecular $R_2^2(6)$ motif in the presence of different counterions and ligand substituents in the crystal structures of the above described Ag(I) complexes is testimony to the utility of the oxime

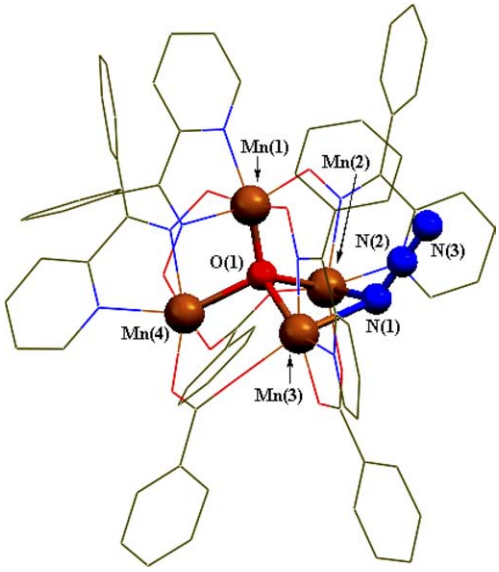

Fig. 30. The molecular structure of the complex $[Mn_3^{II}Mn^{IV}O(N_3)(O_2CPh)_3\{(py)C(ph)NO\}_4]$ emphasizing its core.

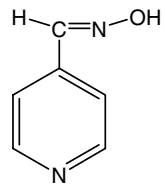
5.8. Pyridine-4-carbaldehyde oxime, (4-py)CHNOH



(4-py)CHNOH

The free ligand is commercially available. In a general project that is aimed at assembling metal complexes through hydrogen bonds to form porous molecular materials, Aakeröy and co-workers [104] synthesized the complex $[Ni\{(4\text{-py})CHNOH\}_4(H_2O)_2]Br_2 \cdot 6H_2O$2-(4-py)CHNOH. The ligand adopts the 1.010 coordination mode (see Fig. 40).

The oxime hydroxy groups link through complementary O–H···O hydrogen bonds to form sheets with large, hourglass-shaped holes. The sheets are cross-linked by hydrogen bonds between the axially coordinated H_2O molecules and the bromide counterions, forming a 3D network, where the large holes are aligned into channels. Twofold interpenetration of the 3D network blocks the center of the large hole, leaving two smaller channels at each end. A host–guest complex is formed, and the guest molecules, (4-py)CHNOH, are contained inside the channels, held in the lattice by hydrogen bonds to the bromide ion and the coordinated oxime ligands. The structure of this complex demonstrates that an octahedral system can generate a 3D network with holes large enough to hold relatively small organic molecules.

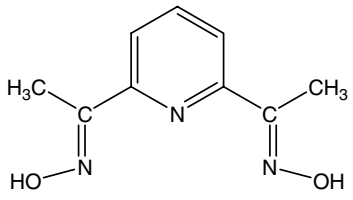
Fig. 40. The coordination mode of (4-py)CHNOH in the structurally characterized complex $[Ni\{(4\text{-py})CHNOH\}_4(H_2O)_2]Br_2 \cdot 2(4\text{-py})CHNOH$.

6. Ligands containing two oxime groups and one or two pyridyl groups, with no other donor atoms

6.1. 1-[6-(1-Hydroxyimino-ethyl)pyridin-2-yl]-ethanone oxime, (py){C(Me)NOH}$_2$



$(py)\{C(Me)NOH\}_2$

The free ligand can be synthesized [105,106] by the reaction of 2,6-diacetylpyridine, $(py)\{C(Me)O\}_2$, with 2 equiv. of $NH_2OH \cdot HCl$ and 2 equiv. of NaOH in $MeOH/H_2O$ under heating. The two oxime groups have strongly overlapping titration curves; the pK_{a1} and pK_{a2} values are ~10.1 and ~10.8, respectively [107]. The ligand was first investigated by Hartkamp [108], who reported that aqueous Ni(II) solutions of $(py)\{C(Me)NOH\}_2$ are oxidized by air. The ligand was also investigated by Irvine and co-workers [107], who studied Fe(II) complexes in solution. It was found that pK_a for the ligand dropped markedly upon coordination, an effect that was attributed to resonance stabilization of the anionic conjugate base.

Early solid-state coordination chemistry with this ligand involved nickel. Following Hartkamp's report [108], Baucom and Drago [105] isolated several complexes, including $[Ni\{(py)\{C(Me)NOH\}_2\}_2]^{2+}$, the deprotonated species $[Ni\{(py)\{C(Me)NO\}_2\}_2]^{2-}$ and the formally Ni(IV) complex $[Ni\{(py)\{C(Me)NO\}_2\}_2]$. Subsequently, Sproul and Stucky [109] reported the crystal structure of $[Ni\{(py)\{C(Me)NO\}_2\}_2]$ (Fig. 41), and showed that the ligand is planar with coordination through nitrogen (1.00111, Fig. 42) and that considerable strain is introduced into the $(py)\{C(Me)NO\}_2^{2-}$ moiety when it coordinates to Ni^{IV}. A comparison of the nickel-nitrogen bond distances with those found in analogous Ni(II) complexes suggests a shortening of 0.17 Å in the Ni^{IV}–N bond.

X-ray structures of cationic octahedral complexes of the general formula $[M\{(py)\{C(Me)NOH\}_2\}_2]X_2$, where M = Mn, X = ClO_4 [106], M = Fe, X = Cl [110] and M = Cu, X = ClO_4 (Fig. 43) [106] have been reported. X-ray diffraction studies of the 1:1 five-coordinate

Fig. 42. The crystallographically established coordination modes of $(py)\{C(Me)NOH\}_2$ and its mono- and dianionic forms.

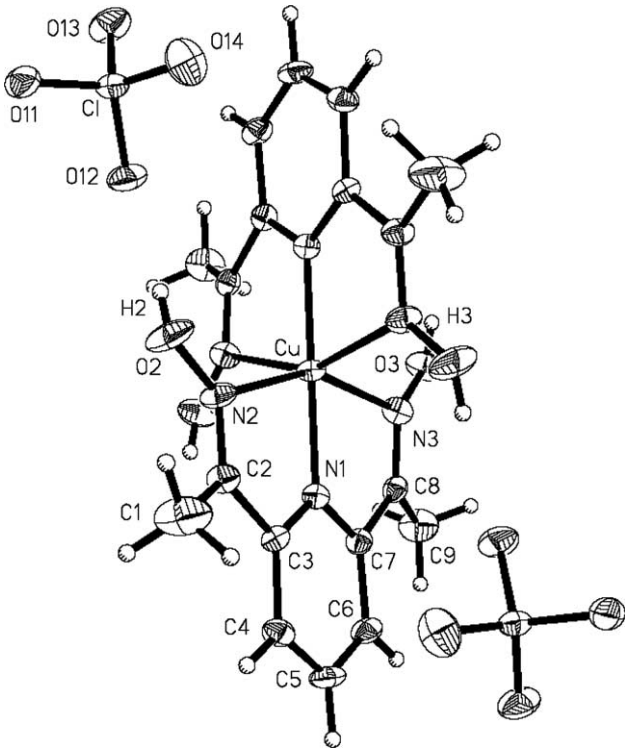

Fig. 43. X-ray structure of $[Cu\{(py)\{C(Me)NOH\}_2\}_2](ClO_4)_2$ [106].

complexes $[M\{(py)\{C(Me)NOH\}_2\}Cl_2]$, where M = Cu and Zn (Fig. 44), were also performed [111]. For the Cu(II) complex, the coordination environment about the metal center resembles a distorted square pyramid with a chloro ligand at the apex. For the Zn(II) complex, the environment about the metal ion can be viewed as a distorted trigonal bipyramid, with the equatorial positions occupied by the two chloro ligands and the pyridine nitrogen. A second form (monoclinic) of the Cu(II) complex was structurally characterized in 1994 [112]. The stoichiometrically similar Mn(II) complex [113,114], $[Mn\{(py)\{C(Me)NOH\}_2\}Cl_2]_n$, has an interesting polymeric structure. The metal ion coordinates to form pentagonal bipyramids $Mn^{II}(N_3Cl_2)Cl_2$ in which each chloro ligand occupies axial and equatorial sites on

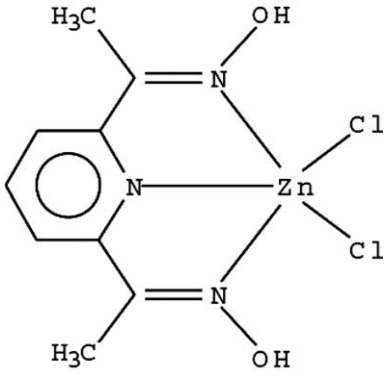

Fig. 44. A structural drawing of $[Zn\{(py)\{C(Me)NOH\}_2\}Cl_2]$.

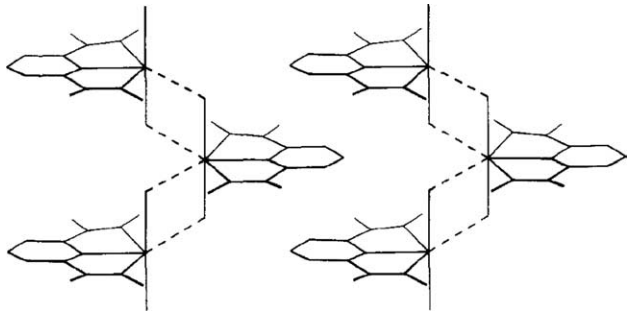

Fig. 45. View of small portions (three monomer units) of two chains in complex $[Mn\{(py)\{C(Me)NOH\}_2\}Cl_2]_n$ [113].

adjacent monomer units in the helical chains (Fig. 45). Variable-temperature magnetic susceptibility studies [112] indicate weak ferromagnetic coupling.

The (2,6-diacetylpyridine dioxime)copper(II) unit is also present in the trinuclear cluster $[Cu_3\{(py)\{C(Me)NOH\}_2\}_2Cl_6]$ [115]. The complex is a "sandwich" made of two $Cu\{(py)\{C(Me)NOH\}_2\}Cl^+$ cationic units (the "bread") and a $CuCl_4^{2-}$ anionic unit (the "filling"); the latter can be viewed as a bis(monodentate) "bridging" ligand, see Fig. 46. The three Cu^{II} centers are ferromagnetically coupled.

A series of monomeric In(III) complexes containing neutral 1.00111 $(py)\{C(Me)NOH\}_2$ ligands are also known. The ligand reacts with $InCl_3$ in MeOH to give the seven-coordinate complex $[InCl_3\{(py)\{C(Me)NOH\}_2\}(MeOH)]$ (Fig. 47) [116]. The MeOH ligand can be replaced by Cl^- or H_2O to give the complex anion $[InCl_4\{(py)\{C(Me)NOH\}_2\}]^-$ and $[InCl_3\{(py)\{C(Me)NOH\}_2\}(H_2O)]$, respectively. The pentagonal bipyramidal coordination environment of the metal is preserved during the substitution reactions [116]. The MeOH-containing complex can react with bidentate

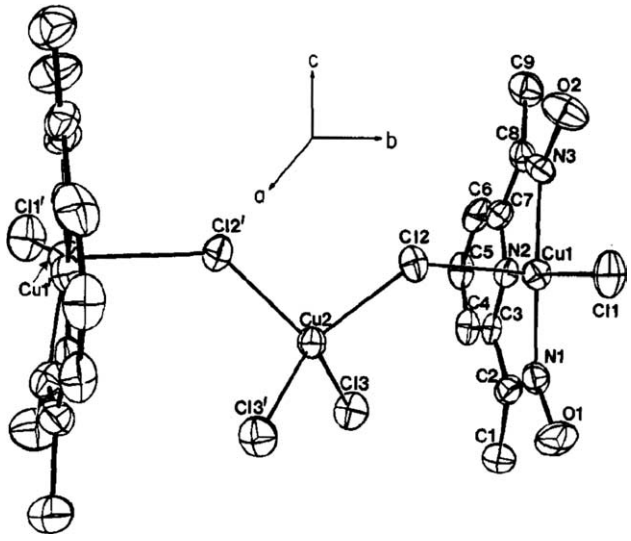

Fig. 46. The "sandwich" structure of $[Cu_3\{(py)\{C(Me)NOH\}_2\}_2Cl_6]$ [115].

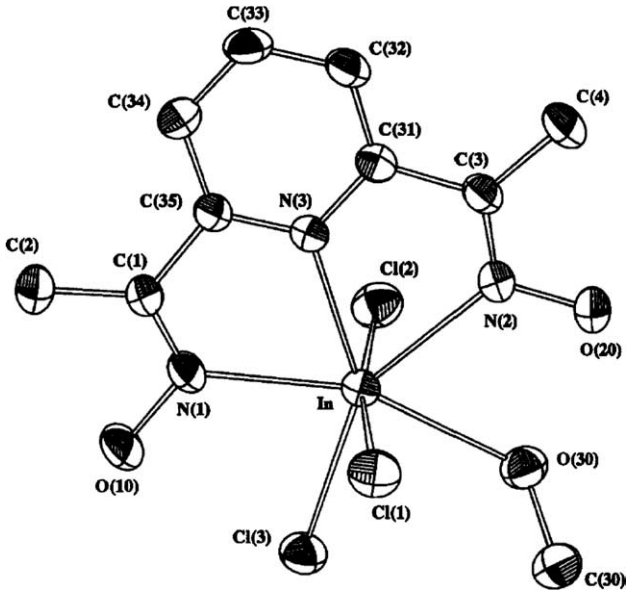

Fig. 47. X-ray structure of $[InCl_3\{(py)\{C(Me)NOH\}_2\}(MeOH)]$ [116].

ligands by ligand exchange [117]. A seven-coordinate complex of the composition $[InCl(ox)\{(py)\{C(Me)NOH\}_2\}(H_2O)]$ is formed with potassium oxalate (K_2ox); the oxalato(−2) ligand occupies the equatorial plane of a pentagonal bipyramid together with the tridentate chelating oxime. With sodium 1,2-dicyanoethene-1,2-dithiolate (Na_2mnt) the analogous reaction produces the six-coordinate, mixed-ligand complex $[InCl(mnt)\{(py)\{C(Me)NOH\}_2\}]$, which has a distorted octahedral coordination sphere (Fig. 48). Ligands which form four-membered chelate rings, like dialkyldithiocarbamates or pyridine-2-thiolate, are able to replace all ligands of $[InCl_3\{(py)\{C(Me)NOH\}_2\}(MeOH)]$ to form neutral tris chelates [117].

We have up to now discussed in this part metal complexes containing the neutral, $(py)\{C(Me)NOH\}_2$, or the dianionic, $(py)\{C(Me)NO\}_2^{2-}$, ligand. Two complexes containing the monoanionic ligand $(py)\{C(Me)NOH\}\{C(Me)NO\}^-$ have been also reported. Complex $[Cu\{(py)\{C(Me)NOH\}_2\}_2Cl_2]$ [111] is remarkably acidic [118], the value of pK_a being 2.8 at 25 °C. Deprotonation of this complex in alcoholic solution leads to the dinuclear dication $[Cu_2\{(py)\{C(Me)NOH\}\{C(Me)NO\}\}_2(H_2O)_2]^{2+}$ which has been isolated [118] as the chloride or tetrafluoroborate salt. The crystal structure of the latter has been determined [119] to establish the coordination mode of the monoanionic ligand, see Fig. 49. The structural analysis revealed that the nearly planar $(py)\{C(Me)NOH\}\{C(Me)NO\}^-$ ion behaves as a bridging tetradentate ligand adopting the 2.10111 coordination mode, see Fig. 42. The same coordination mode is adopted by the ligand in the mixed-valence trinuclear cluster $[Fe^{II}\{(py)\{C(Me)NOH\}\{C(Me)NO\}\}_2$-$Fe_2^{III}(\mu\text{-}O)Cl_4]$ [110].

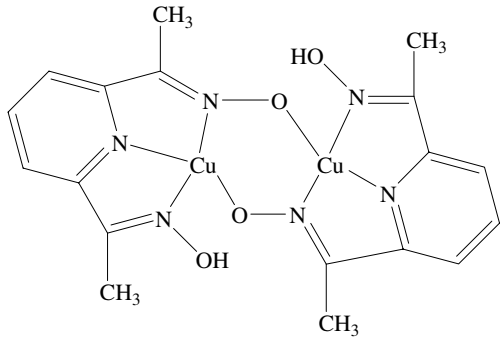

Fig. 49. A structural drawing of the dinuclear dication $[Cu_2\{(py)\{C(Me)NOH\}\{C(Me)NO\}\}_2(H_2O)_2]^{2+}$; the weakly bound aqua ligands have been omitted for clarity.

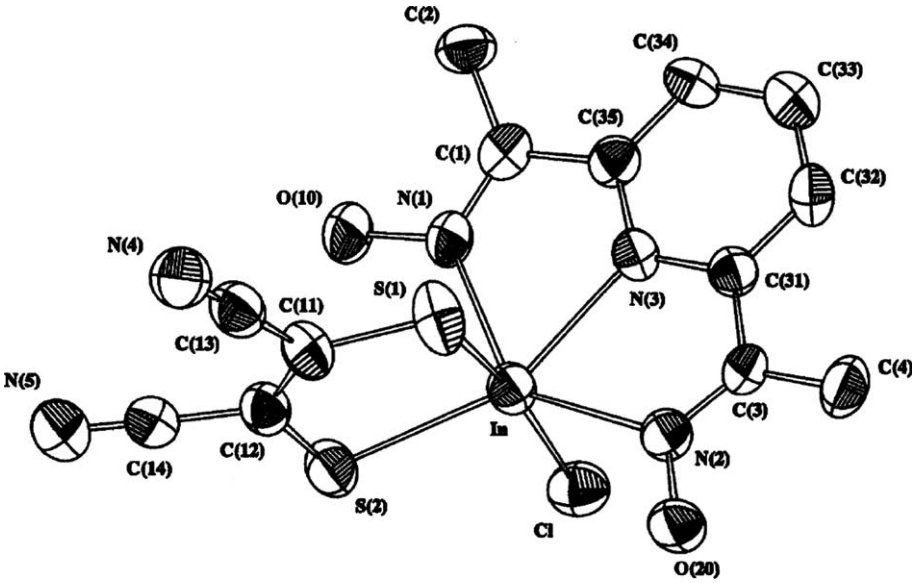

Fig. 48. X-ray structure of $[InCl(mnt)\{(py)\{C(Me)NOH\}_2\}]$ [117].

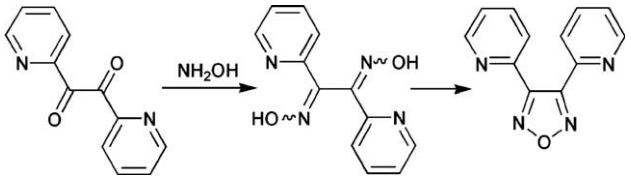


Scheme 5. Synthesis of (py)(CNOH)$_2$(py) and 3,4-di(2-pyridyl)-1,2,5-oxadiazole.

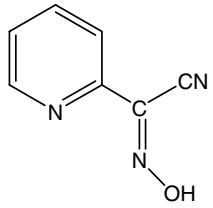
The kinetics and mechanism of ester hydrolysis by metal complexes of (py){C(Me)NOH}$_2$ and (py){C(Me)NOH} {C(Me)NO}$^-$ were studied by Yatsimirsky's group a few years ago [120,121]. The rate constants of the cleavage of 4-nitrophenyl acetate by the ligand over the pH interval 6–8 increase 10^3–10^4 times in the presence of Pb(II), Mn(II) and Cd(II), and 2–100 times in the presence of Ni(II), Hg(II), Pr(III) and Zn(II). The reactive species are monomeric complexes of the type M{(py){C(Me)NOH}{C(Me)NO}}$^+$.

6.2. Di-2-pyridylglyoxal dioxime, (py)(CNOH)$_2$(py)

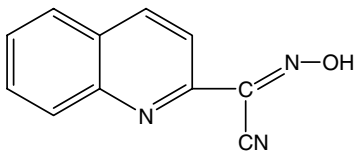
The free ligand was first reported in 2002 as an intermediate in the synthesis of 3,4-di(2-pyridyl)-1,2,5-oxadiazole [122], see Scheme 5. The dioxime was prepared, in 52% yield, by reacting the commercially available diketone di-2-pyridylglyoxal (2,2′-pyridil) with an excess of aqueous NH_2OH. The compound was characterized by melting point, ^{1}H and ^{13}C NMR spectroscopy, positive-ion EI mass spectrometry and elemental analysis. Subsequent heating of the dioxime at 185 °C for 18 h in a sealed tube effected cyclodehydration to give the substituted oxadiazole [122].

7. Ligands containing one pyridyl group, one oxime group and a third donor group

7.1. Hydroxyimino-pyridin-2-yl-acetonitrile, (py)C(CN)NOH, and the 2-quinolyl analogue



(py)C(CN)NOH

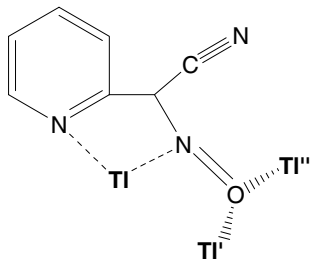


(qu)C(CN)NOH

These compounds belong to a relatively new class of ligands which have the general name cyanoximes. The coordination chemistry of cyanoximes first received detailed attention about two decades ago [123,124]. These ligands have the general formula RC(CN)NOH, where R is usually an electron withdrawing group such as an amide, ester or keto group [125]. The presence of the cyano group close to the oxime fragment makes the acidity of cyanoximes about 10^3–10^5 times greater than that of common oximes or dioximes. Thus, all currently known cyanoximes readily form yellow-colored conjugated anions in water or alcoholic solutions. The deprotonated cyanoximes form numerous complexes with different metal ions [126–131]. These anions demonstrate ambidentate properties participating in complex formation through different donor atoms in complexes with different metal ions. In addition, some cyanoximes and their metal complexes have demonstrated biological activities such as growth-regulating [132], antimicrobial [133], detoxifying agricultural pesticide [134] and antiproliferating [131] properties.

The free ligands (py)C(CN)NOH and (qu)C(CN)NOH are synthesized by the reaction of equimolar quantities of 2-pyridylacetonitrile and 2-quilonylacetonitrile, respectively, and KNO_2 in glacial CH_3COOH at −50 °C [135]. The structures of the two free ligands have been determined by single-crystal X-ray crystallography [135]. There are two planar fragments in the molecular structure of (py)C(CN)NOH, the 2-pyridyl group and the cyanoxime NCCNO group. The dihedral angle between these planes is 10.6(1)°. This compound exists in a *cis–anti* configuration with respect to the orientation of the CNO group and the nitrogen atom of the 2-pyridyl ring. The crystal structure of the monohydrate of (qu)C(CN)NOH, (qu)C(CN)NOH · H_2O, reveals that the molecule adopts a *trans–anti* configuration (see the structural formulae of the free ligands in the beginning of this part). Compound (qu)C(CN)NOH exhibits a nitroso-oxime equilibrium in polar solvents [136].

The crystal structure of [Tl{(py)C(CN)NO}]$_n$ reveals polymer formation (Fig. 50) [137]. The anionic ligand is planar, exists in its nitroso form and adopts the *cis–anti* conformation; it exhibits a simultaneously chelating and bridging behavior. Compound [Cs{(py)C(CN)NO}]$_n$ is also polymeric. The anionic ligand is planar, exists in its nitroso form and adopts the *trans–anti* configuration [138]. Complexes of the general composition

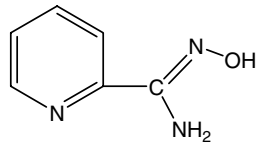


3.2110

Fig. 50. The basic unit in compound [Tl{(py)C(CN)NO}]$_n$.

$[M\{(py)C(CN)NO\}_2L_2]$, where M = Fe^{II}, Ni^{II}, Cu^{II} and L = pyridine, 3-picoline, have been prepared [139]. The authors used spectroscopic methods to propose the structures of the complexes. Based on such data the complexes appear to have monomeric, *trans*-octahedral structures in the solid state. The anionic ligand seems to adopt its nitroso form exhibiting the *N*(2-pyridyl), *N*(nitroso)-chelating mode. The anions $(py)C(CN)NO^-$ and $(qu)C(CN)NO^-$ have an important analytical application as reagents for the photometric determination of Fe^{2+}, because of the great stability and large molar absorptivities of the low-spin, 1:3 monoanionic Fe(II) complexes [135]. It has been established that the presence of other metal ions, such as Co^{2+}, Mn^{2+} and Ni^{2+}, does not affect the quantitative determination of Fe^{2+}.

7.2. *N*-Hydroxy-pyridine-2-carboxamidine, $(py)C(NH_2)NOH$



$(py)C(NH_2)NOH$

Amidoximes and their metal complexes find a wide range of applications in technology, medicinal chemistry and agriculture [140]. As a bidentate ligand, $(py)C(NH_2)NOH$ incorporates the structural features of pyridine-2-carbaldehyde oxime (Section 5.2) and 2-pyridylamine, $(py)CH_2NH_2$, in a single molecule. The experimental procedure for its synthesis [141] consists of liberating the hydroxylamine from its hydrochloride by means of sodium carbonate in water, adding an equivalent amount of 2-cyanopyridine and enough ethanol to obtain a clear solution, and finally keeping the mixture at 85 °C for 2 h; the yield of the crude product can reach 98%. The crystal structure of the free ligand [142] reveals that the molecule exists as the *syn* isomer (Fig. 51), with the N atom of the 2-pyridyl ring on the same side of the exocyclic C–C bond as the NH_2 group.

$(py)C(NH_2)NOH$ had been known to form stable complexes with various metal ions (characterized by spectroscopic methods) [143], some of which were exploited in analytical chemistry [144]. Few transition metal complexes containing the neutral ligand have been structurally characterized [142,145–147]. The X-ray structure of $[Cu\{(py)C(NH_2)NOH\}_2(H_2O)]Cl_2$ (Fig. 52) was reported independently by two groups in 1989 [142,145]. The structure of the complex shows the five-coordinate nature of the metal ion which is bound

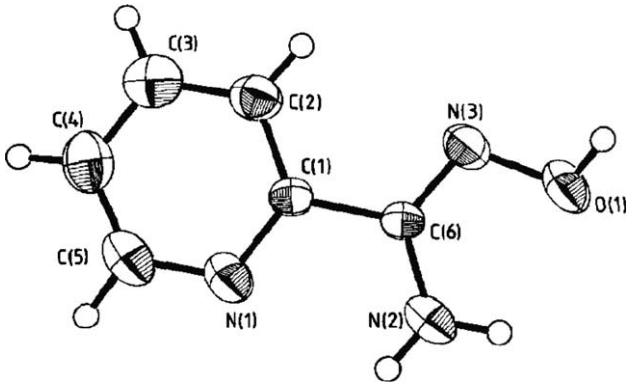


Fig. 51. Molecular structure of $(py)C(NH_2)NOH$ [142].

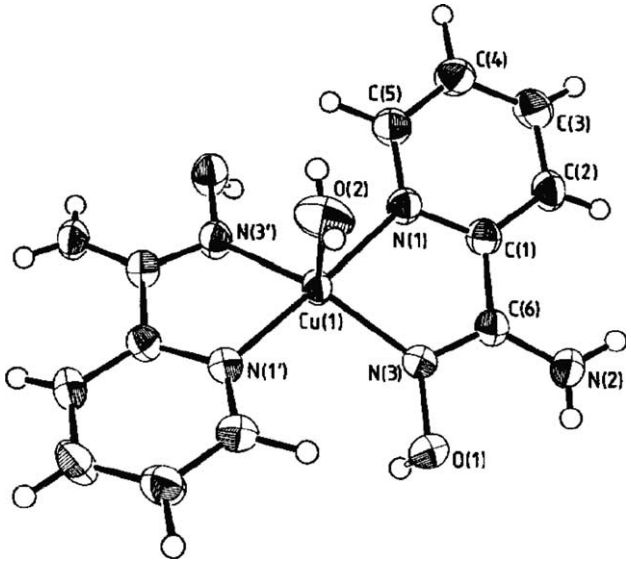

Fig. 52. Molecular structure of the cation present in complex $[Cu\{(py)C(NH_2)NOH\}_2(H_2O)]Cl_2$ [142].

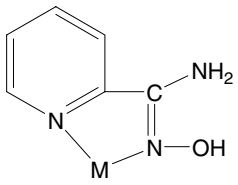
through the heterocyclic and oxime nitrogen atoms (Fig. 53) of two *trans*-oriented bidentate ligands plus a H_2O molecule to give a square-based pyramidal chelate. When an ethanolic solution of $Ni(NO_3)_2 \cdot 6H_2O$ is treated with $(py)C(NH_2)NOH$, a dark blue solution results if the ratio of ligand to metal does not exceed 2:1. From this solution the blue complex $[Ni(NO_3)_2\{(py)C(NH_2)$-



1.0110

Fig. 53. The coordination mode of $(py)C(NH_2)NOH$ in its structurally characterized transition metal complexes.

$NOH\}_2$] crystallizes [146]. If three equivalents of ligand are added to one equivalent of $Ni(NO_3)_2 \cdot 6H_2O$ in aqueous solution the initial color is blue, which changes to wine-red and the 1:3 complex $[Ni\{(py)C(NH_2)NOH\}_3](NO_3)_2$ is obtained as red-brown crystals. In both complexes the neutral ligand adopts the 1.0110 chelating mode (Fig. 53). The octahedral 1:2 complex (Fig. 54) has two coordinated nitrato groups in the equatorial plane which are *cis* to each other [146]. As $(py)C(NH_2)NOH$ is added, the two *cis* equatorial monodentate nitrato groups are replaced by the third ligand, resulting in the 1:3 cationic complex which has the structure [146] shown in Fig. 55. In the neutral 1:2 complex, the two heterocyclic nitrogens are in a *cis* arrangement. The three organic ligands in the cationic 1:3 complex have their heterocyclic nitrogens co-planar with one oxime nitrogen and the metal ion; this results in the two remaining oxime nitrogens being *trans* to each other.

In an attempt to deprotonate $(py)C(NH_2)NOH$, Jones and co-workers [147] performed the 1:2 reaction between $Ni(O_2CMe)_2 \cdot 4H_2O$ and the ligand in EtOH. The ligand is not deprotonated during complex formation, as was confirmed by the X-ray structure of the resulting mononuclear octahedral complex $[Ni(O_2CMe)_2\{(py)C(NH_2)NOH\}_2]$ (Fig. 56). It is possible [147] that the NH_2 group stabilizes the oxime group by delocalization of the lone pair at the N atom of the amino group; the ensuing reduced electron density is the probable reason for its low affinity for the metal ion, i.e., the non-participation of the NH_2 group in coordination, in all the structurally characterized complexes of this

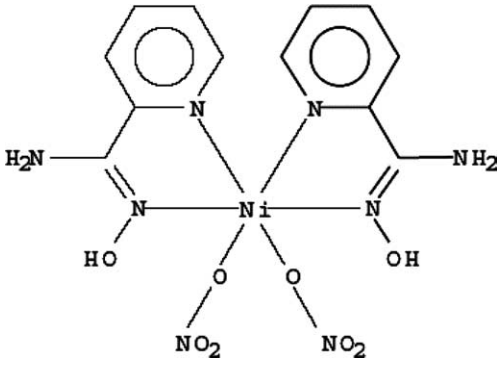


Fig. 54. Block diagram structure of $[Ni(NO_3)_2\{(py)C(NH_2)NOH\}_2]$.

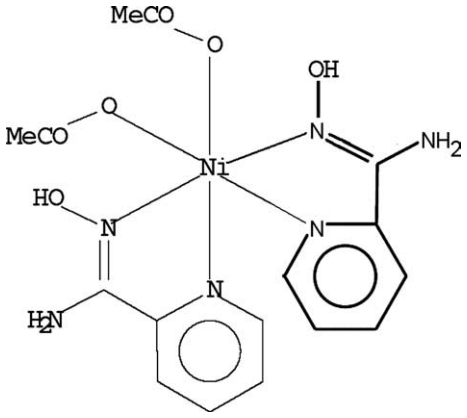

Fig. 56. Block diagram structure of $[Ni(O_2CMe)_2\{(py)C(NH_2)NOH\}_2]$.

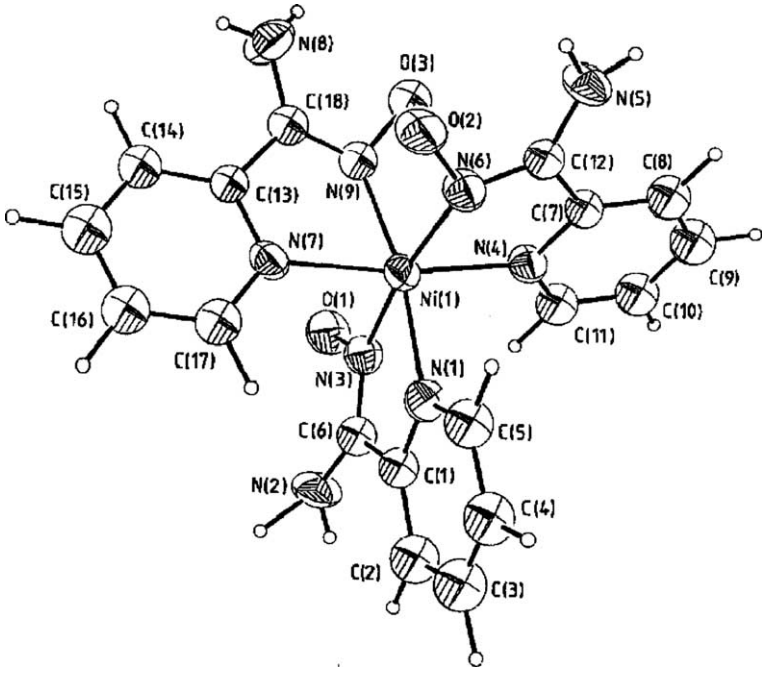

Fig. 55. X-ray structure of the octahedral cation present in complex $[Ni\{(py)C(NH_2)NOH\}_3](NO_3)_2$ [146].

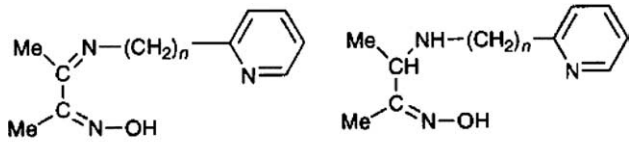
ligand. Two mutually *cis* positions in the nickel(II) distorted octahedron are occupied by the O atoms of the two monodentate acetato ligands and the two other pairs by two 1.0110 (Fig. 53) ligands. The oxime nitrogens are mutually *trans* and the 2-pyridyl nitrogens mutually *cis*.

The coordination chemistry of the anionic ligand $(py)C(NH_2)NO^-$ remains to be studied.

Although the 3- and 4-pyridyl isomers of $(py)C(NH_2)NOH$ have been synthesized [141,148], their coordination chemistry has not been investigated.

7.3. 3-(2-Pyridin-2-yl-methylimino)-butan-2-one oxime (pmiboH), 3-(2-Pyridin-2-yl-ethylimino)-butan-2-one oxime (peiboH) and their reduced amino analogs (pmaboH, peaboH)



pmiboH (n= 1) pmaboH (n= 1)

peiboH (n= 2) peaboH (n= 2)

The above shown ligands contain 2-pyridyl groups that are not directly attached to the oxime carbon atom. The abbreviations of the ligands in this part derive [149] from the non-systematic names 2-[2-(α-pyridyl)methyl] imino-3-butanone oxime (pmiboH), 2-[2-(α-pyridyl)ethyl]imino-3-butanone oxime (peiboH), 2-[2-(α-pyridyl)methyl]amino-3-butanone oxime (pmaboH) and 2-[2-(α-pyridyl)ethyl]amino-3-butanone oxime (peaboH); H denotes the oximic hydrogen.

Detailed syntheses of the four free ligands were reported by Randacci and co-workers [150]. The compounds pmiboH and peiboH were synthesized starting from diacetyl monoxime and the appropriate aminopyridine following the usual procedure for the preparation of Schiff bases; the solvent used was diisopropyl ether. The compounds pmaboH and peaboH were prepared by treating pmiboH and peiboH, respectively, with $NaBH_4$ in methanol; the reactions involves hydrogenation of the $>C{=}N{-}CH_2{-}$ imino groups to $>CHNH{-}CH_2{-}$ amino groups. The crystal structure of pmiboH has been determined [151].

The crystallographically established coordination modes of the neutral and monoanionic ligands are shown in Fig. 57.

The first structurally characterized complex of these ligands was $[Cu_2(peibo)_2(MeCN)_2](ClO_4)_2$ [152]. The cation (Fig. 58) contains a six-membered ring formed by two Cu^{II} atoms and two oximate groups; the ring is distinctly non-planar with a twisted-boat conformation. Each $peibo^-$ ligand adopts the 2.1111 coordination mode (Fig. 57). Perchlorate and nitrate salts containing the structurally similar cations $[Cu_2(peibo)_2]^{2+}$, $[Cu_2(peibo)_2(H_2O)_2]^{2+}$ and $[Cu_2(pmibo)_2]^{2+}$ have been prepared [149]. The $-2J$ values ($H = -2JS_1S_2$) are in the 510–835 cm^{-1} range, indicative of strong antiferromagnetic coupling. The dinuclear complexes showed relatively narrow ^1H NMR signals in the −0.5–30 ppm range ($\Delta\nu_{1/2} = 60$–1500 Hz), indicating that the antiferromagnetic interaction is maintained in DMSO-d_6 [149]. The $-2J$ values roughly correlate with the ^1H NMR parameters; the larger the $-2J$ values, the smaller the chemical shifts and linewidths. The cation $[Cu_2(pmibo)_2]^{2+}$ was found to undergo an autoreduction reaction in DMSO, DMF and DMA. The triply-bridged dinuclear copper(II) complexes $[Cu_2(peibo)_2(pz)](ClO_4)$ and $[Cu_2(peibo)_2(phta)](ClO_4)_2$ (Fig. 59), where pz^- is the pyrazolate anion and phta is phthalazine, have been prepared [153]; a very strong antiferromagnetic interaction ($2J = -760$ cm^{-1}) between the metal ions was observed for the latter. In the dinuclear complexes $[Cu_2(OMe)(ClO_4)(peibo)(bpy)](ClO_4)$ and $[Cu_2(O_2CMe)_2(peibo)(bpy)](ClO_4)$ the two Cu^{II} atoms are bridged by one 2.1111 $peibo^-$, one methoxo and one perchlorato ligands, and one 2.1111 $peibo^-$ and two acetato ligands, respectively [154]. Matsumoto and co-workers [155] prepared and structurally characterized the dinuclear, end-on azido-bridged complexes $[Cu_2(N_3)(peibo)(bpy)](ClO_4)_2$ and $[Cu_2(N_3)(peibo)(pmdt)](ClO_4)_2$, where pmdt is the tridentate chelating ligand *N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine. The $peibo^-$ ligand is in the 2.1111 (Fig. 57) coordination mode. For both complexes, the two Cu^{II} atoms are antiferromagnetically coupled with a singlet-triplet separation of $2J = -520$ and -296 cm^{-1} for the bpy and pmdt complexes, respectively. The complexes are EPR-silent in the solid state at room temperature. Two other $peibo^-$-containing Cu(II) complexes have been reported; these are $[Cu_3(N_3)_2(peibo)_2(NO_3)_2(H_2O)_2]$ [156] and $[Cu_2(peibo)_2(OClO_3)_2]_n$ [157], in which the ligand is in the 2.1111 mode. In the perchlorato coordination polymer, the dinuclear units are bridged by one inorganic anion which adopts an $\eta^1{:}\eta^1{:}\eta^1{:}\mu_3$ mode [157].

The Ni(II) coordination chemistry of pmiboH and peiboH is practically unknown. The crystal structure of the complex $[Ni(peiboH)_2](NO_3)_2$ has been reported [158]. In the all-*trans* mononuclear octahedral cation, the neutral ligand adopts the 1.0111 mode (Fig. 57).

Contrary to Ni chemistry, the Co coordination chemistry of pmiboH and peiboH is well developed; most of the known complexes are organometallic. The first reference to a Co complex of these ligands in the literature came in 1983 in the X-ray structure of $[Co^{III}(peibo)_2](ClO_4)$ (Fig. 60) [159]. The Co^{III} ion is coordinated to six N atoms from two tridentate chelating anionic

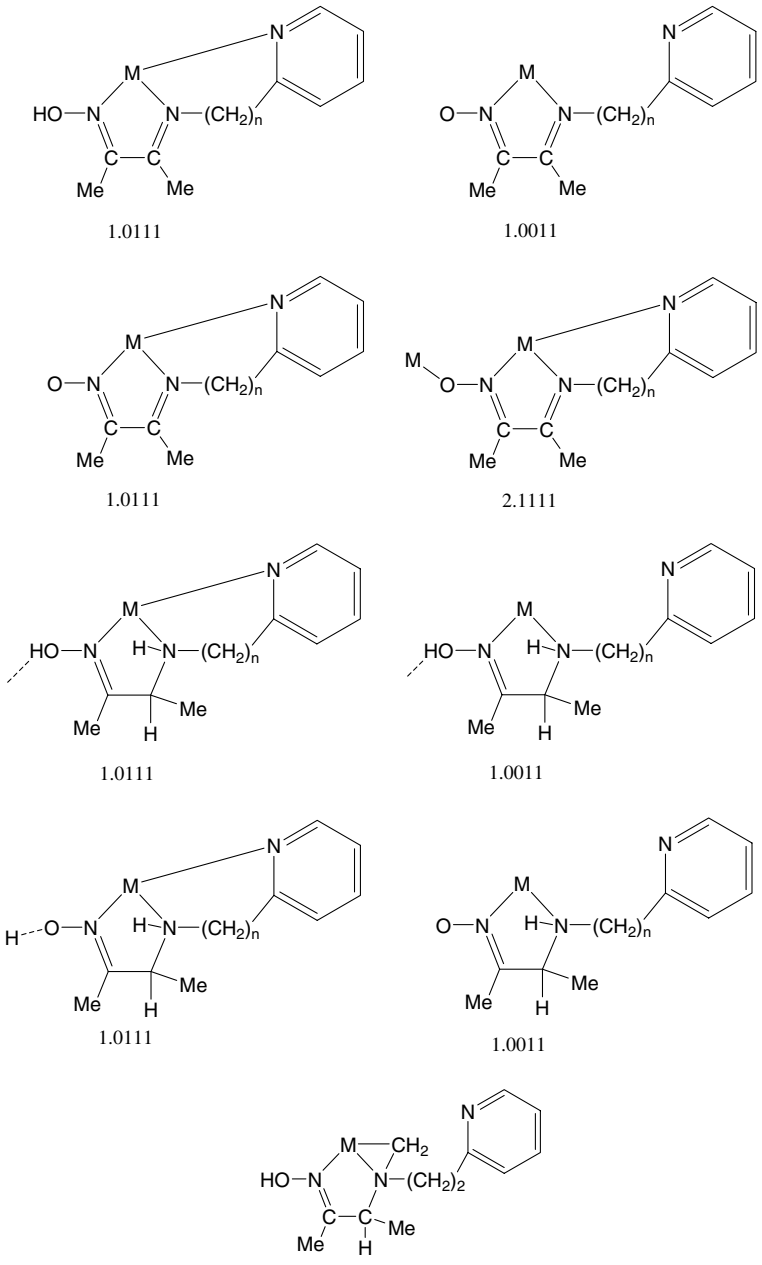


Fig. 57. The crystallographically established coordination modes of pmiboH, peiboH, pmaboH, peaboH and their monoanions, and the Harris notation [44] that describes these modes. The dashed lines indicate hydrogen bonds.

ligands (1.0111, Fig. 57) in a slightly distorted octahedral arrangement. Each peibo$^-$ ligand forms one five- and one six-membered chelating ring. The ligands are almost planar in a *mer* configuration around the metal. The molecular structure of the cation $[Co(pmibo)_2]^+$ is similar (Fig. 60) [150]. The decrease in the Co^{III}–N_{py} distances and N_{py}–Co–N_{im} angles from $[Co(peibo)_2]^+$ to $[Co(pmibo)_2]^+$ has been ascribed to the steric constraint imposed by the closure of the five-membered ring, containing the N_{py} atom in the latter [150]. The aminooximes pmaboH and peaboH react with $CoCl_2 \cdot 6H_2O$ in MeOH in the presence of ClO_4^- under atmospheric conditions to give the complexes $[Co(pmabo)(pmaboH)](ClO_4)_2$ and $[Co(peabo)(peaboH)](ClO_4)_2$ [150]. In both structures (Fig. 61), one protonated 1.0111 and one deprotonated 1.0111 ligand coordinate the Co^{III} ion through their N donors in a *fac* configuration, in such a way that the two 2-pyridyl rings are *trans* to each other. The two O atoms make a strong intramolecular hydrogen bond. The formation of the hydrogen bond serves further to stabilize the *fac* arrangement of the ligands.

The reduction of $[Co^{III}(peibo)_2](ClO_4)$ with $NaBH_4$ in alkaline media produces a nucleophilic Co(I) species

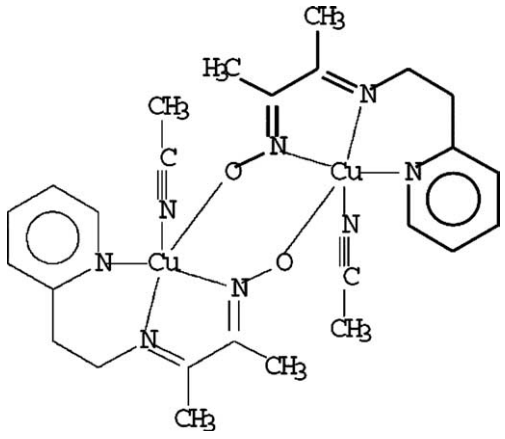

Fig. 58. Block diagram structure of the cation $[Cu_2(peibo)_2(MeCN)_2]^{2+}$.

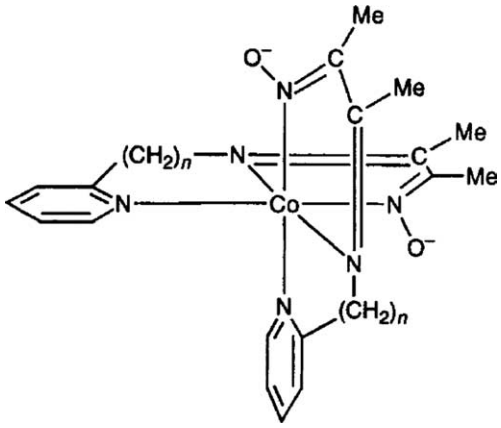

Fig. 60. Block diagram structure of the cations $[Co(pmibo)_2]^{+}$ and $[Co(peibo)_2]^{+}$.

which, upon reaction with alkyl halides, gives stable organocobalt dinuclear complexes (Scheme 6). This reactivity pattern parallels that observed for cobaloximes and other vitamin B_{12} models [160]. The molecular structure of the methyl complex [161] is shown in Fig. 62. The $R = CH_2CF_3$, Cy analogues have similar structures [162]. The peibo^{-} ligand adopts the 2.1111 mode. On the contrary, the reduction of $[Co^{III}(pmibo)_2](ClO_4)$ involves hydrogenation of the ligand from imino- to amino-oxime, with the formation of a stable Co(II) species; the latter can be oxidized to afford $[Co(pmabo)(pmaboH)](ClO_4)_2$, see Scheme 6. The different reactivity was attributed [150] to the more strained coordination in $[Co^{III}(pmibo)_2](ClO_4)$ with respect to that in $[Co^{III}(peibo)_2](ClO_4)$.

Addition of $NaBH_4$ to an alkaline solution of $[Co^{III}(peibo)_2](ClO_4)$ under a nitrogen atmosphere, followed by addition of benzyl chloride gave the mononuclear complex $[Co^{III}(C_6H_5CH_2)(peibo)L](ClO_4)$, where L is

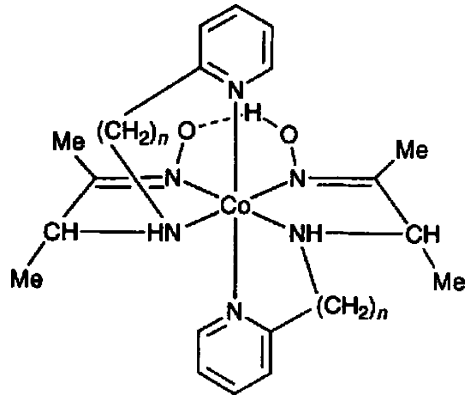

Fig. 61. Block diagram structure of the cations $[Co(pmabo)(pmaboH)]^{2+}$ $(n = 1)$ and $[Co(peabo)(peaboH)]^{2+}$ $(n = 2)$.

2-[(2-pyridylethyl)amino]-3-aminobutane [163]. The peibo^{-} tridentate ligand in a *mer* configuration coordinates Co^{III} through its *N*-donors (1.0111). The complex

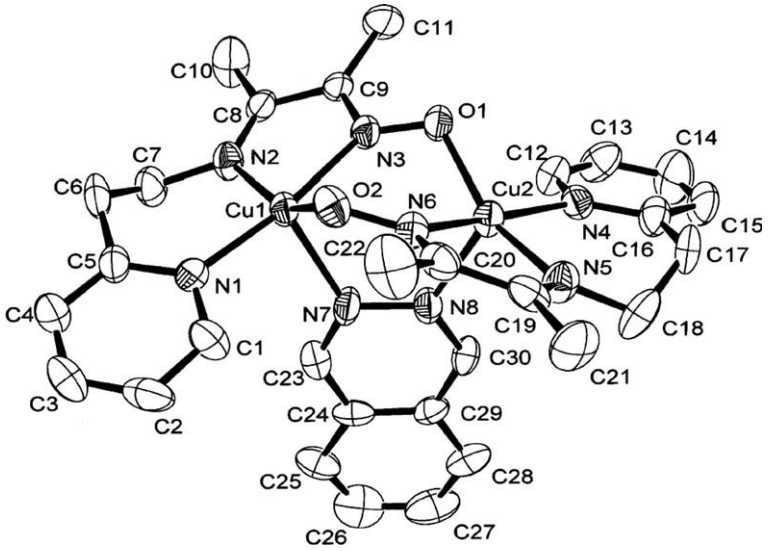

Fig. 59. X-ray structure of the cation present in complex $[Cu_2(peibo)_2(phta)](ClO_4)_2$ [153].

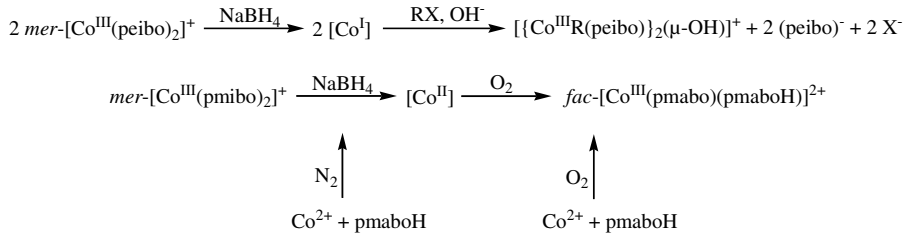

Scheme 6. Redox reactivity pattern of $[Co^{III}(peibo)_2]^+$ and $[Co^{III}(pmibo)_2]^+$.

undergoes Co–C homolytic cleavage under acidic conditions, giving dibenzyl under a nitrogen atmosphere and benzaldehyde in the presence of air [163].

The oxidative addition of alkyl halides to the Co^I species generated by the reduction of $[Co^{III}(peabo)(peaboH)](ClO_4)_2$ (Fig. 61) [150], led to the formation of a new class of organocobalt complexes of general formula $[Co^{III}R(peabo)(peaboH)](ClO_4)$ [164], where R = Me, Et, CH_2CF_3, ^{n}Bu and CH_2Cl. The X-ray structures of the R = Me, Et (Fig. 63) and CH_2CF_3 compounds provide conclusive evidence for a distorted octahedral structure, where peaboH and $peabo^-$ act as 1.0011 (Fig. 57) and 1.0111 (Fig. 57) ligands, respectively. In fact, the non-organometallic ligand system about Co^{III} can be considered as $(peabo\cdots H\cdots peabo)^-$; adopting this formulation, the hydrogen bridged anion behaves as a pentadentate chelating ligand. The axial geometry in the R = Me compound is closer to that found in methylcobalamin than that reported for other models, suggesting steric and electronic *cis* influences of the equatorial ligands close to those of the corrin nucleus [164].

Treatment of the complexes $[Co^{III}R(peabo)(peaboH)](ClO_4)$ [164], where $R = CH_2X$ (X = halogen), with diluted NaOH afforded [165] the complex $[Co^{III}(peabo)L](ClO_4)$, where L is the monoanionic ligand whose coordination mode is shown on the bottom of Fig. 57. The three-membered ring is formed by a pathway involving intramolecular nucleophilic addition of an equatorial nitrogen donor to the axial carbon.

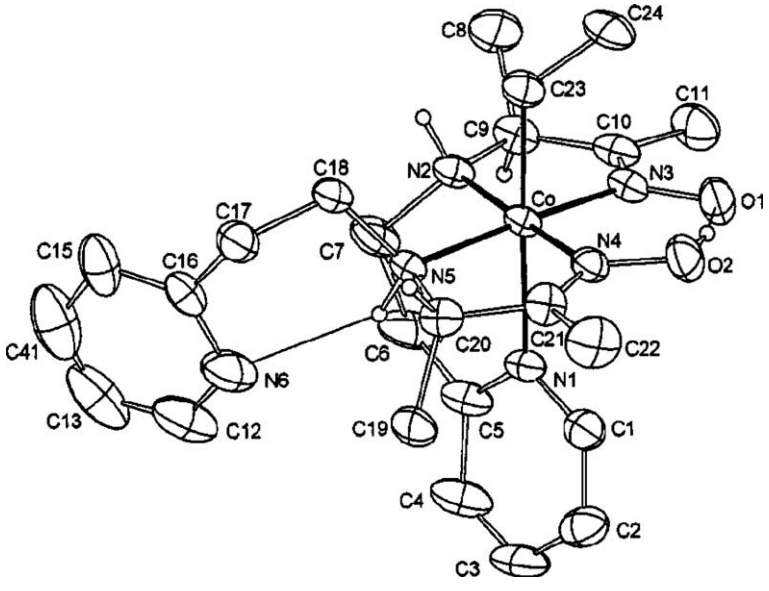

Fig. 63. X-ray structure of the cation present in the complex $[Co^{III}(Et)(peabo)(peaboH)](ClO_4)$ [164].

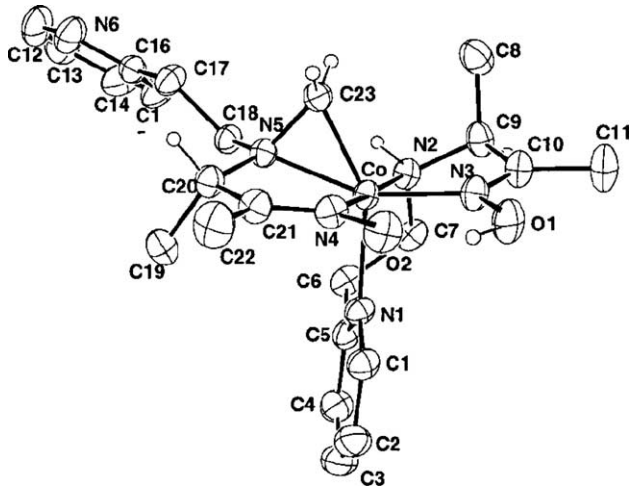

Fig. 64. X-ray structure of the cation present in complex $[Co^{III}(peabo)L](ClO_4)$ [165].

X-ray analysis reveals a highly distorted structure (Fig. 64). The C–Co–N angle is acute (42.8°). The $peabo^-$ ion behaves as 1.0111 ligand.

Complex *mer*-$[Co^{III}(pmibo)_2](ClO_4)$ (Fig. 60) [150] gives cobalt alkyl derivatives after reduction with $NaBH_4/Pd^{2+}$ to Co^I and alkylation [166]. The formation of the Co–C bond is accompanied by the reduction of the amino form of one or both imino ligands (depending on the experimental conditions) initially present in the starting material. In one series of experiments, complexes of the type *fac*-$[Co^{III}R(pmibo)(pmaboH)](ClO_4)$ (R = Me, *i*-Pr, CH_2Cl, CH_2Br, CH_2CF_3, Bz) were obtained, in which only one of the two ligands was reduced to the amino form (pmaboH). The molecular structures of two representative cations are shown in Fig. 65. The anion of the unmodified imino ligand acts as a bidentate N_{imino}, $N_{oximate}$-ligand (1.0011, Fig. 57), whereas the neutral amino-oxime molecule (pmaboH) acts as a tridentate ligand (1.0111, Fig. 57). The saturation of one azomethine group causes the product to assume a *fac*-configuration and induces the formation of one asymmetric carbon and one asymmetric nitrogen center in the chelating system. When an excess of reducing agent was used, both azomethine groups were saturated, causing the introduction of one pair of chiral carbons and one pair of chiral nitrogens. Two isomers of the methyl derivative $[Co^{III}(Me)(pmabo)(pmaboH)]^+$ were isolated (Fig. 66) [166]. The $pmabo^-$ and pmaboH ligands adopt the 1.0011 and 1.0111 modes, respectively. One isomer differs from the other in the opposite configuration of the C and N centers located on the bidentate ligand. One isomer closely resembles the $peabo^-$/peaboH analog [164]. Similarities and differences in the reactivity exhibited by $[Co^{III}(pmibo)_2]^+$ and $[Co^{III}(peibo)_2]^+$ were discussed [166].

7.4. Other ligands

Ligands featuring a 6-alkylaminomethyl-2-pyridinealdoxime moiety (alkyl = CH_3, *n*-$C_{12}H_{25}$) have been synthesized as outlined in Scheme 7 [167]. The reactivity of their Ni(II), see Fig. 67, and Zn(II) complexes in the cleavage of *p*-nitrophenylacetate and *p*-nitrophenylhexanoate has been investigated in the absence (R = CH_3) or in the presence (R = *n*-$C_{12}H_{25}$)

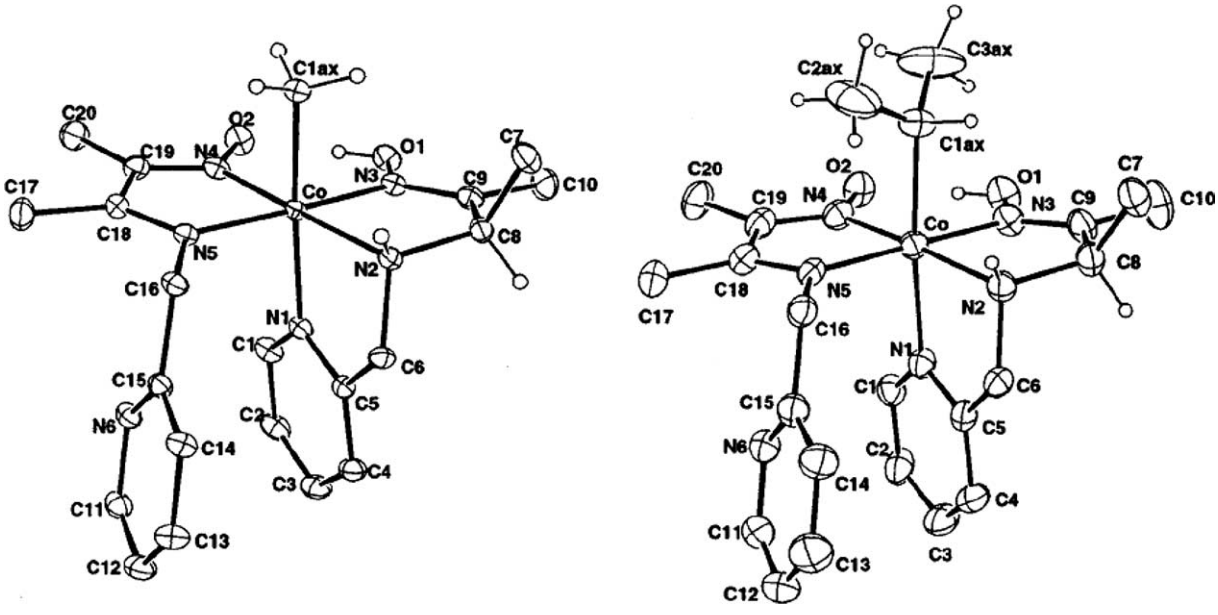

Fig. 65. Molecular structures [166] of the cations present in complexes *fac*-$[Co^{III}(Me)(pmibo)(pmaboH)](ClO_4)$ (left) and *fac*-$[Co^{III}$-(*i*-Pr)(pmibo)(pmaboH)$](ClO_4)$ (right).

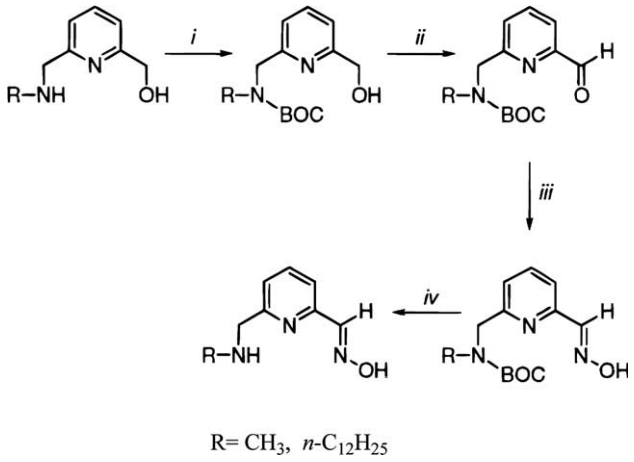

Scheme 7. Synthesis of ligands featuring a 6-alkylaminomethyl-2-pyridinealdoxime moiety. Conditions: (i) di-*tert*-butyl dicarbonate, triethylamine, dioxane, 20 °C; (ii) selenium dioxide, dioxane, reflux; (iii) hydroxylamine hydrochloride, Na_2CO_3, EtOH, 60 °C; (iv) trifluoroacetic acid, 20 °C.

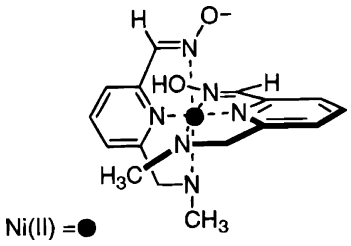

Fig. 67. Proposed structure of the 1:2 nickel(II)/6-methylaminomethyl-2-pyridinealdoximate complex.

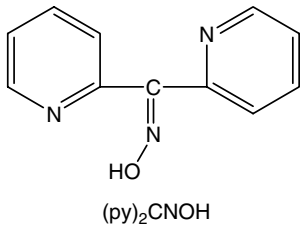
of hexadecyltrimethylammonium bromide micelles. The micellar complexes are effective in promoting the cleavage of the substrate with accelerations strongly dependent on pH, being larger in moderately acidic than in neutral solutions. The coordination chemistry of these 2-pyridyl oximes remains completely unexplored.

8. The rich coordination chemistry of di-pyridin-2-yl-methanone oxime (di-2-pyridyl ketone oxime), $(py)_2CNOH$

8.1. Introduction



Di-pyridin-2-yl-methanone oxime (di-2-pyridyl ketone oxime), $(py)_2CNOH$, occupies a special position amongst the 2-pyridyl oximes. One area to which the anionic ligand $(py)_2CNO^-$ is relevant is the chemistry of metallamacrocycles. Another attractive aspect of $(py)_2CNO^-$ is its great coordinative flexibility and versatility, characteristics that have led to polynuclear 3d-metal complexes with impressive structures and interesting magnetic properties. A third interesting feature is the activation of $(py)_2CNOH$ by 3d-metal centers, which appears to be a fruitful area of synthetic inorganic chemistry; examples of this activation will be described below.

The published coordination chemistry of $(py)_2$-CNOH is rich [168–188]. The free ligand is commercially available. Since several complexes of $(py)_2CNO^-$ can be considered as metallamacrocycles, and especially as metallacrowns, we feel obliged to give brief information about these compounds. Metallamacrocycles have gained increasing attention over the past decade due to their potentially unique properties. These molecules have already been used in applications as diverse as catalysts [189], sensors [190] or as chiral building

blocks for 2D and 3D solids [191,192]. Metallamacrocycles include complexes such as metallacrowns [67,193], metallacrowns containing carbon in the macrocycle [194,195], metallacrown ethers [196], azametallacrowns [197,198], anticrowns [199], metallahelicates [200], metallacalixarenes [201], metallacryptates [202], molecular squares and boxes [203], and the aesthetically pleasant polynuclear fluoro, alkoxo or oxo metal complexes [204–206]. Metallacrowns (MCs) [67], the inorganic structural and functional analogs of crown ethers [207], are usually formed when a transition metal ion and a nitrogen replace the methylene carbon atoms. MCs exhibit selective recognition of cations and anions, and can display intramolecular magnetic exchange interactions. The isolation of metallacrowns requires the employment of tri- and tetradentate ligands containing hydroxamate or oximate functionalities to provide a scaffolding within which the desired metal-containing core can be realized. One example of such a ligand is $(py)_2CNO^-$. This approach yields clusters with M–N–O–M networks. Metallacrown nomenclature has been given in refs. [67,181] and [193]. There are nine metals in four oxidation states (II–IV) that have been incorporated into the MC ring, while more than 20 metal ions, i.e., lanthanide, actinide, alkali, alkaline earth and transition metal ions have been captured in the central cavity of MCs. For 12-MC-4 complexes, two structural motifs have been reported: classical or regular [67,181,193,208] and inverse [66,67,172,179,184,185]. In the regular motif,

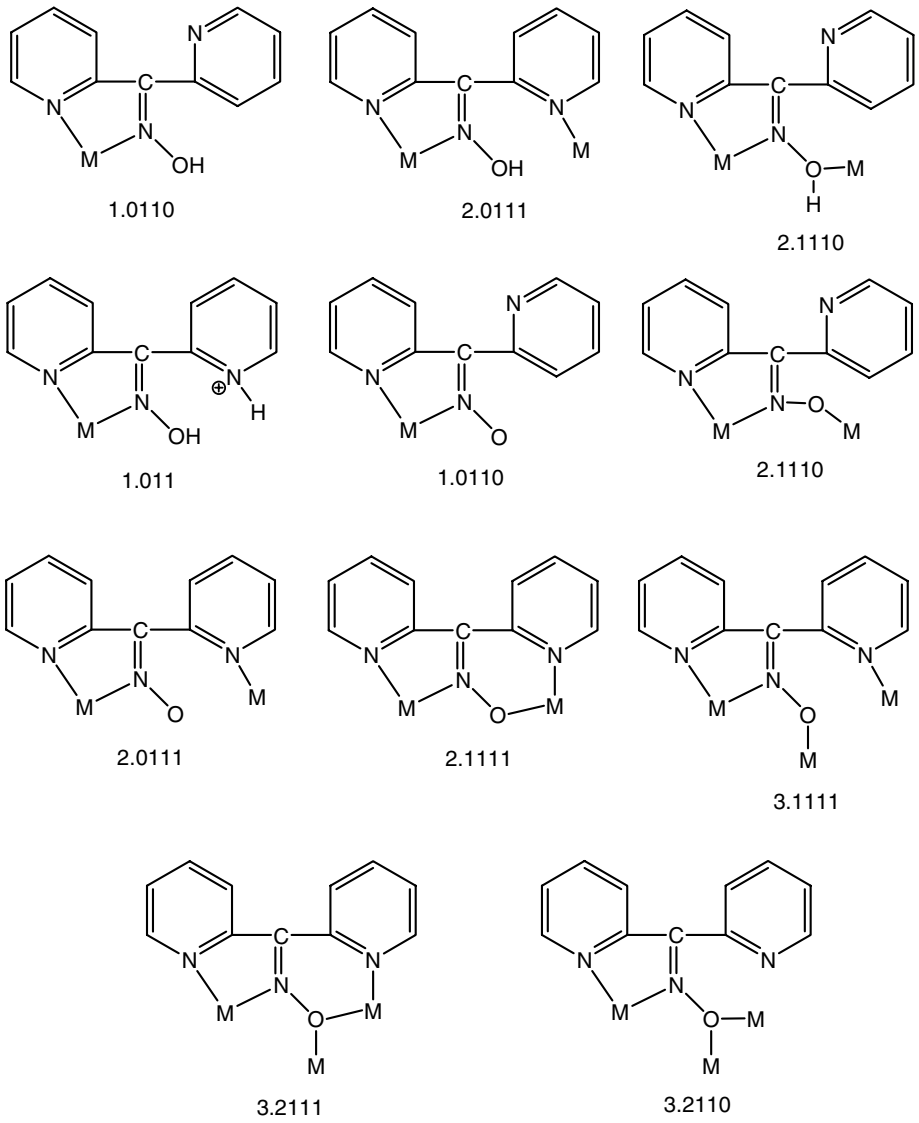


Fig. 68. The crystallographically established coordination modes of $(py)_2CNOH$ and $(py)_2CNO^-$, and the Harris notation [44] that describes these modes.

there is an N–O–M–N–O–M linkage, i.e., an [M–N–O]$_n$ repeat unit, with the oxygen atoms oriented towards the center of the cavity and capable of binding cations. In the inverse motif, which has been realized only for Zn and Co, the ring metal ions are oriented towards the center of the cavity which is now capable of encapsulating anions, whereas the connectivity is transposed to N–O–M–O–N–M. It should be mentioned at this point that some researchers prefer to consider MCs simply as one sub-area of metal wheel (ring) chemistry, avoiding the use of their specialized nomenclature.

The crystallographically established coordination modes of (py)$_2$CNOH and (py)$_2$CNO$^-$ are shown in Fig. 68.

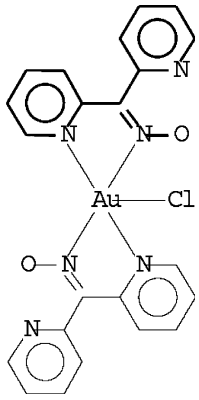

Fig. 69. Block diagram structure of the square pyramidal complex [AuCl{(py)$_2$CNO}$_2$].

8.2. Metal complexes containing terminal (py)$_2$CNOH and/or (py)$_2$CNO$^-$ ligands

These complexes are listed in Table 3. Molecular structures of representative complexes are shown in Figs. 69–71. Six out of the eight complexes listed in Table 3 are mononuclear and present no special structural interest. In the trinuclear complex [Ni$_3$(shi)$_2${(py)$_2$CNOH}$_2$(py)$_2$], the Ni^{II} ions are bridged by the shi^{3-} ligands [169]; two metal ions have a square planar geometry while the third one is in an octahedral environment. The open array of the three metal ions is angular, with an Ni···Ni···Ni dihedral angle of 46.5°. The structure of [Cu(NCS){(py)$_2$CNOH}]$_n$ features tetrahedral geometry around Cu^I atoms (Fig. 70) with a *N*,*S*-bridging thiocyanate group creating zig-zag chains along the *c*-axis of the unit cell [171].

Complex [Cu$_2^{II}$(μ-Cl)$_2$Cl$_2${(py)(pyH)CNOH}$_2$-(H$_2$O)$_2$]Cl$_2$ (Fig. 71), not listed in Table 3, is unique, because it contains the monocation of di-2-pyridyl ketone oxime as a ligand [186b]. The cation (py)(pyH)CNOH behaves as a terminal 1.011 ligand, see Fig. 68.

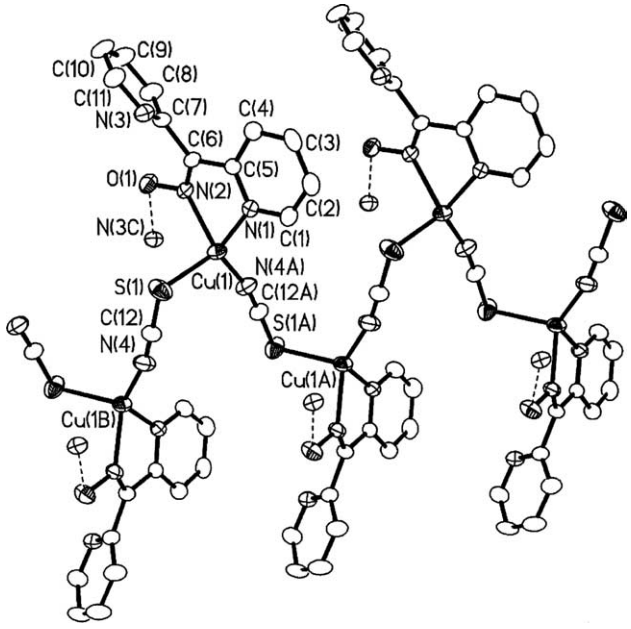

Fig. 70. A small portion of one of the zig-zag chains present in the complex [Cu(NCS){(py)$_2$CNOH}]$_n$ [171].

Table 3
Structurally characterized metal complexes containing *exclusively* terminal (py)$_2$CNOH and/or (py)$_2$CNO$^-$ ligands

Complex[a]	Coordination mode	Coordination sphere; coordination geometry	Reference
[Mn(O$_2$CPh)$_2${(py)$_2$CNOH}$_2$]	1.0110	*cis*,*cis*,*trans*-Mn^{II}O$_2$(N$_{py}$)$_2$(N$_{ox}$)$_2$; oct	[168]
[Ni$_3$(shi)$_2${(py)$_2$CNOH}$_2$(py)$_2$]	1.0110	Ni^{II}O$_3$N, NiO$_4$N$_2$; sp, oct	[169]
[Co(NO$_2$){(py)$_2$C(OH)O}{(py)$_2$CNO}][b]	1.0110	Co^{III}ON$_5$; oct	[170]
[Ni(O$_2$CPh)$_2${(py)$_2$CNOH}$_2$]	1.0110	*cis*,*cis*,*trans*-Ni^{II}O$_2$(N$_{py}$)$_2$(N$_{ox}$)$_2$; oct	[97]

[Cu(NCS){(py)$_2$CNOH}]$_n$	1.0110	Cu^{I}N$_3$S; tet	[171]
[ZnCl$_2${(py)$_2$CNOH}$_2$]	1.0110	Zn^{II}N$_2$Cl$_2$; tet	[172]
[AuCl{(py)$_2$CNO}$_2$]	1.0110	Au^{III}N$_4$Cl; spy	[173]

Abbreviations: N$_{ox}$, oxime or oximate nitrogen; N$_{py}$, 2-pyridyl nitrogen; oct, octahedral; (py)$_2$C(OH)O$^-$, the mononanion of the *gem*-diol derivative of di-2-pyridyl ketone; shi^{3-}, the fully deprotonated form of salicylhydroxamic acid; sp, square planar; spy, square pyramidal; tet, tetrahedral.

[a] Solvate molecules have been omitted.

[b] The NO$_2^-$ ligand is in its nitro form.

[c] In fact, the ligand system about Cu^{II} can be considered as {(py)$_2$CNO···H···ONC(py)$_2$}$^-$; adopting this formulation, the hydrogen-bridged anion behaves as a tetradentate chelating ligand.

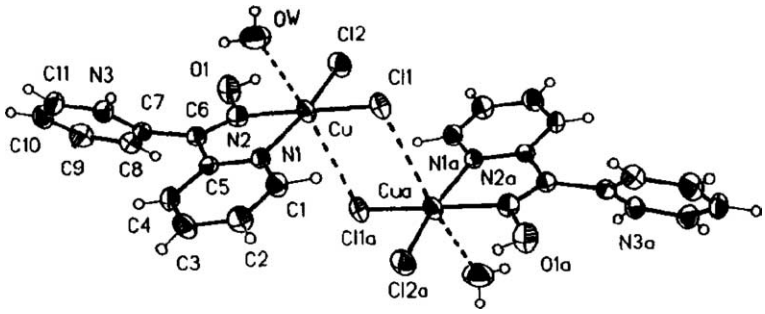

Fig. 71. X-ray structure of the dinuclear cation present in the complex $[Cu_2Cl_4\{(py)(pyH)CNOH\}_2(H_2O)_2]Cl_2$, which contains the monocation of $(py)_2CNOH$ as a ligand [186b].

8.3. Metal complexes containing bridging $(py)_2CNOH$ and/or $(py)_2CNO^-$ ligands

These complexes are listed in Table 4. Molecular structures of representative complexes are shown in Figs. 73–95. The majority of the listed complexes are dinuclear and polynuclear (clusters).

The Mn/$(py)_2CNO^-$ chemistry is interesting [168,174–178]. Using a variety of synthetic routes the complexes $[Mn_2^{II}Mn_2^{III}(O_2CR)_2\{(py)_2CO_2\}_2\{(py)_2CNO\}_2X_2]$, where R = Me, Ph and X = Cl, Br, NO_3, etc. have been isolated in good yields [168,176]. Remarkable features of the reactions are the in situ transformation of an amount of $(py)_2CNOH$ to yield the coordinated dianion, $(py)_2CO_2^{2-}$, of the *gem*-diol derivative of di-2-pyridyl ketone, $(py)_2CO$ (Fig. 72) and the coordination of nitrate ligands in the $X^- = NO_3^-$ cluster (Fig. 73) although the starting materials were nitrate-free (Scheme 8). It is noteworthy that a similar transformation of $(py)_2CNOH$ to the monoanion (and not to the dianion as observed in the $Mn_2^{II}Mn_2^{III}$ clusters) of the *gem*-diol derivative of di-2-pyridyl ketone, $(py)_2C(OH)O^-$ (Fig. 72), was also reported by Jensen and co-workers [170]. The 1:2 reaction between $[Co^{III}(CO_3)(NH_3)_4](NO_3)$ and $(py)_2CNOH$ in H_2O yielded the complex $[Co^{III}(NO_2)\{(py)_2C(OH)O\}\{(py)_2CNO\}]$, see Table 3. The authors avoided mechanistic discussions and it is not clear whether the nitro ligand present in the product resulted from oxidation of the oxime or from reduction of the NO_3^- counterion of the starting material. The tetranuclear clusters have completely analogous molecular structures [168,176]. The centrosymmetric tetranuclear molecule contains two Mn^{II} and two Mn^{III} six-coordinate ions (the Mn^{II} ions are seven-coordinate in the nitrato cluster because of the chelating behavior of the NO_3^- ions) held together by four μ-oxygen atoms from the two 3.2211 $(py)_2CO_2^{2-}$ ligands to give the $\{Mn^{II}(\mu\text{-}OR'')Mn^{III}(\mu\text{-}OR'')_2Mn^{III}(\mu\text{-}OR'')Mn^{II}\}^{6+}$ core consisting of a planar zig-zag array of the four metal ions (R″ = $(py)_2C(OH)$–). Peripheral ligation is provided by two 2.1110 $(py)_2CNO^-$, two 2.11 RCO_2^- and two terminal X^- ligands. Variable-temperature magnetic susceptibility studies in the 2–300 K range reveal weak antiferromagnetic exchange interactions, leading to non-magnetic $S = 0$ ground states.

Reaction of $Mn(hfac)_2 \cdot 3H_2O$ ($hfac^-$ = hexafluoroacetylacetonate) with one equivalent of $(py)_2CNOH$ in CH_2Cl_2 gives the dinuclear complex $[Mn_2(O_2CCF_3)_2(hfac)_2\{(py)_2CNOH\}_2]$ in 70% yield. The $CF_3CO_2^-$ ligand is one of the decomposition products of the $hfac^-$ ligand [168]. The two Mn^{II} ions are bridged by two neutral $(py)_2CNOH$ ligands which adopt the 2.0111 coordination mode.

The trinuclear complexes $[Mn_2^{II}Mn^{IV}(OMe)_2X_2\{(py)_2CNO\}_4]$ are rare examples of complexes simultaneously containing Mn^{II} and Mn^{IV} ions ($X^- = Cl^-$, NCO^-, NCS^-) [174,175]. The molecular structure of the $X^- = NCS^-$ cluster is shown in Fig. 74. X-ray crystallography and XANES spectroscopy clearly distinguish the $Mn_2^{II}Mn^{IV}$ valence isomer from the more commonly observed $Mn_2^{III}Mn^{II}$ formulation. There is a central six-coordinate Mn^{IV} ion in an MnO_6 coordination environment and two terminal six-coordinate Mn^{II} ions having an $MnO\Psi N_4$ chromophore. Fits to variable-temperature magnetic susceptibility data (Fig. 75) indicate that the Mn^{II} and Mn^{IV} ions are ferromagnetically coupled and that the compounds have an $S = 13/2$ ground state.

Complex $[Mn_3^{II}Mn^{IV}O(3,4\text{-}D)_4\{(py)_2CNO\}_4]$, where $3,4\text{-}D^-$ is the anion of 3,4-dichlorophenoxyacetic acid, has the $\{Mn_3^{II}Mn^{IV}(\mu_4\text{-}O)(\eta^1:\mu_2\text{-}O_2CR)\}^{7+}$ core [177]; its molecular structure (Fig. 76) is very similar to that (Fig. 30) of the complex $[Mn_3^{II}Mn^{IV}O(N_3)(O_2CPh)_3\{(py)C(ph)NO\}_4]$ [96], the only essential difference being the presence of one η^1:μ_2 carboxylate group instead of one η^1:μ_2 azido group. Magnetization measurements (Fig. 77) support an $S = 6$ ground state.

Reaction of $Mn(ClO_4)_2 \cdot 6H_2O$ with $(py)_2CNOH$ in MeOH in the presence of NaOH gives the mixed-valent cluster $[Mn_4^{II}Mn_6^{III}Mn_2^{IV}(\mu_3\text{-}OH)_4(\mu_3\text{-}O)_4(\mu_4\text{-}O)_2(\mu\text{-}OMe)_2\{(py)_2CNO\}_{12}](OH)(ClO_4)_3$. The cluster contains a 24-MC-8 ring which wraps a 16-membered, star-shaped ring containing four metal ions [178]. This

Table 4
Structurally characterized metal complexes containing bridging $(py)_2CNOH$ and/or $(py)_2CNO^-$ ligands

Complex[a]	Coordination mode	Coordination sphere; coordination geometry	Reference

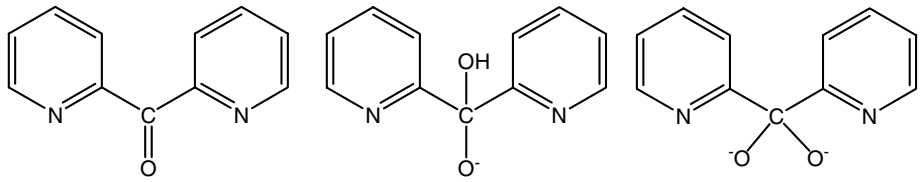
Abbreviations: $acac^-$, acetylacetonate; 3,4-D^-, 3,4-dichlorophenoxyacetate(−1); $hfac^-$, hexafluoroacetylacetonate; $Hshi^{2-}$, the dianion of salicylhydroxamic acid; M = Ru, Os; $MCPA^-$, 2-methyl-4-chlorophenoxyacetate(−1); N_{ox}, oxime or oximate nitrogen; N_{py}, 2-pyridyl nitrogen; O_{carb}, carboxylate oxygen; O_{ox}, oximate oxygen; oct, octahedral; pbp, pentagonal bipyramidal; $(py)_2CO_2^{2-}$, the dianion of the *gem*-diol derivative of di-2-pyridyl ketone; R = Me, Ph; R′ = H, Me; S, solvate molecule; shi^{3-}, the trianion of salicylhydroxamic acid; sp, square planar; sph, sphenocorona; spy, square pyramidal; tbp, trigonal bipyramidal; tet, tetrahedral; $X^- = Cl^-$, Br^-, NO_3^-, $X'^- = Cl^-$, N_3^-, OCN^-, SCN^-, $Z^- = acac^-$, $MeCO_2^-$.

[a] Solvate molecules have been omitted.

[b] Considering only the Ni^{II}; the O atom of $(py)_2CNO^-$ interacts with Na^+ ions.

[c] These complexes contain simultaneously terminal and bridging $(py)_2CNO^-$ ligands.

[d] These molecules have metal–metal bonds.



$(py)_2CO$ $(py)_2C(OH)O^-$ $(py)_2CO_2^{2-}$

Fig. 72. The formulae of the $(py)_2CO$-based ligands discussed in the text; note that $(py)_2C(OH)O^-$ and $(py)_2CO_2^{2-}$ do not exist as free species but exist only in their respective metal complexes.

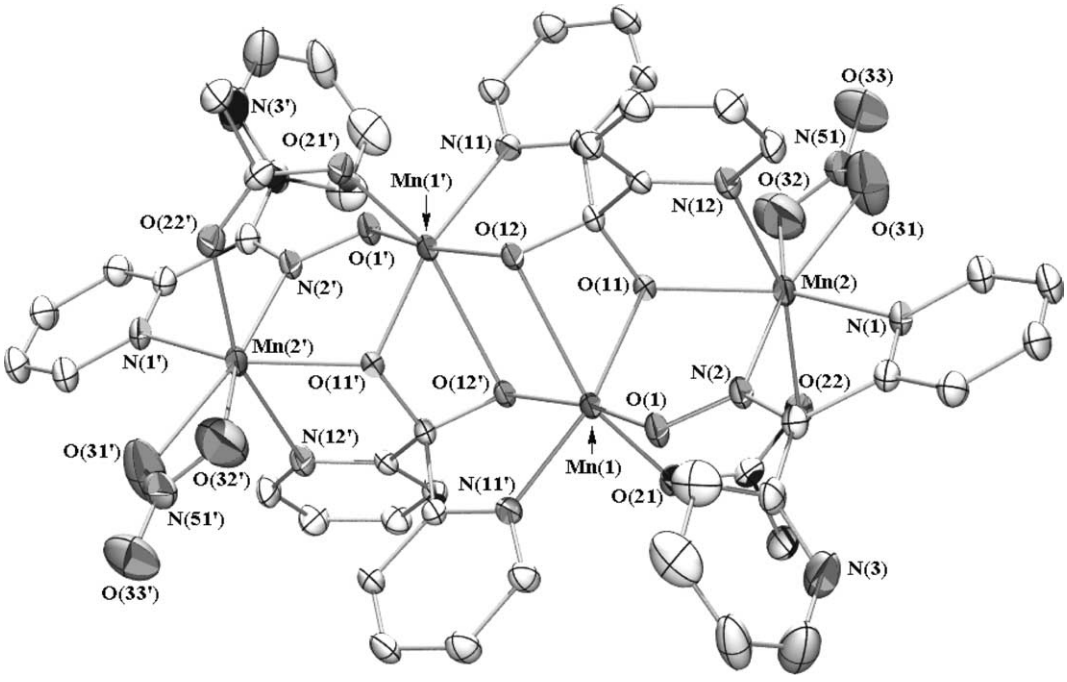


Fig. 73. X-ray structure of $[Mn_2^{II}Mn_2^{III}(O_2CMe)_2\{(py)_2CO_2\}_2\{(py)_2CNO\}_2(NO_3)_2]$. Mn(1) and Mn(1′) are assigned as the Mn^{III} ions [168].

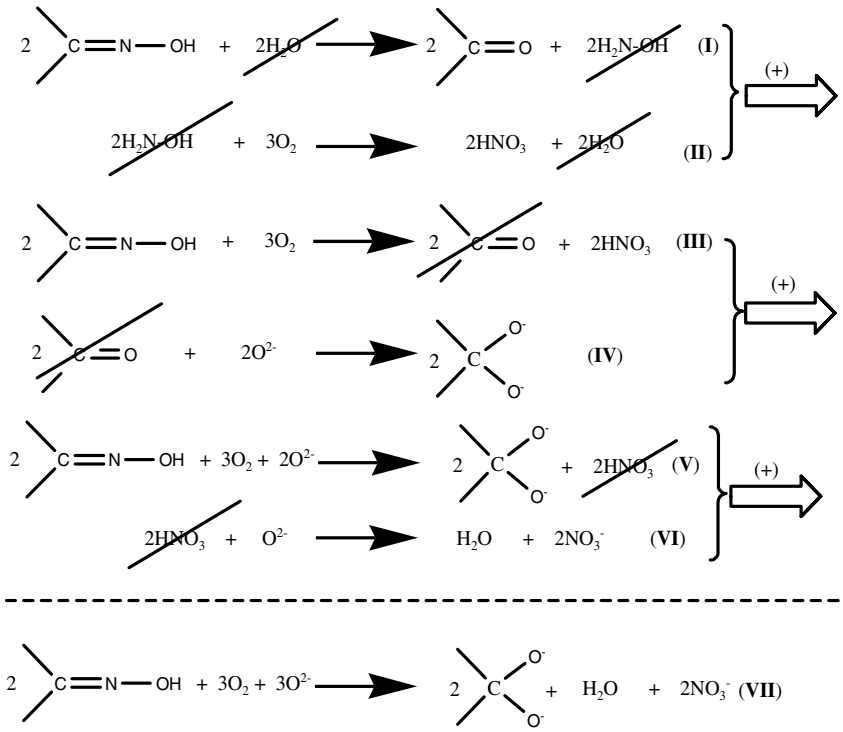
complex is the first metallacrown with ring metal ions in three different oxidation states.

Aerobic reactions of $Co(O_2CR)_2 \cdot 4H_2O$ with $(py)_2$-CNOH, in the presence of counterions (ClO_4^-, PF_6^-), give complexes [179] containing the tetranuclear, mixed-valence cobalt(II/III) cations $[Co_2^{II}Co_2^{III}(OR')_2$-$(O_2CR)_2\{(py)_2CNO\}_4S_2]^{2+}$ (R = Me, Ph; R′ = H, Me; S = MeOH, EtOH) depending on the solvent mixture [179]. These complexes are the first Co members in the family of metallacrowns adopting the extremely rare inverse 12-MC-4 motif (Fig. 78). The $(py)_2CNO^-$ ligands comprise two pairs arranged along the edges and the sides of the Co_4 rectangle. Edge $(py)_2CNO^-$ ions function as 2.1110 ligands, whereas long side $(py)_2CNO^-$ ions adopt the 2.1111 coordination mode.

All known polynuclear Ni(II)/$(py)_2CNO^-$ complexes come from Pecoraro's, Kessissoglou's and our groups. Complex $[Ni_4\{(py)_2CNO\}_6(MeOH)_2](ClO_4)(OH)$ [180], containing both 2.1110 and 2.1111 $(py)_2CNO^-$ ligands, is a rare example of an $\{Ni_4(OR)_2\}^{6+}$ core based on a chair or butterfly "out-of-face" topology (Fig. 79). The complex is characterized by the presence of both ferromagnetic and antiferromagnetic exchange interactions.

The "monomeric", vacant mixed-ligand metallacrown $[Ni_4(NCS)_2(Hshi)_2\{(py)_2CNO\}_2(DMF)(H_2O)]$ shows [181] the connectivity pattern [–O–Ni–O–N–Ni–N–]$_2$. Two Ni^{II} ions are bound only to nitrogen atoms along the metallacrown core and are in a square planar arrangement. The other two Ni^{II} ions are coordinated only to oxygen atoms along the metallacrown ring and are in an octahedral environment. This complex can be described as the acid form of metallacrown, i.e., $H_2$12MC4 [181]. The refinement of $[Ni_4Na_2(acac)_4\{(py)_2CNO\}_4](ClO_4)_2$ has not been completed yet [97]; the MC ring encapsulates two Na^+ ions.

Complex $[Ni_5(O_2CMe)_2(shi)_2\{(py)_2CNO\}_2]$ has an interesting structure [181]. The two shi^{3-} and two $(py)_2CNO^-$ (in the 3.2111 mode) ligands are arranged in a *trans* configuration to construct a 12-MC-4 core



Scheme 8. A proposed simplified reaction scheme for the metal-mediated, partial transformation of di-2-pyridyl ketone oxime, $(py)_2CNOH$, towards the dianion of the *gem*-diol form of di-2-pyridyl ketone, $(py)_2CO_2^{2-}$, involving NO_3^- generation. The O^{2-} species can be derived from H_2O and/or the oxidation of Mn^{II} by atmospheric dioxygen. The 2-pyridyl rings have been omitted for clarity.

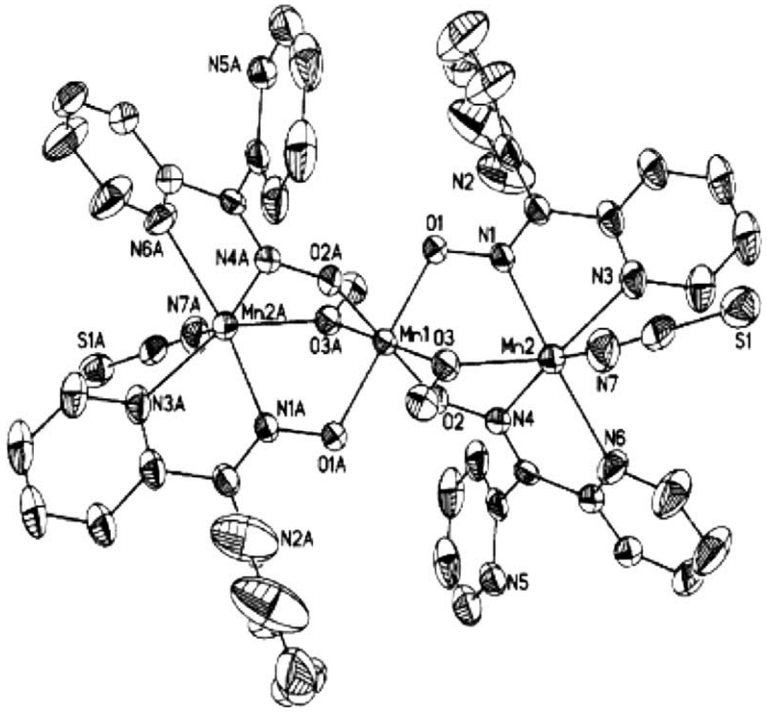


Fig. 74. X-ray structure of $[Mn_2^{II}Mn^{IV}(OMe)_2(NCS)_2\{(py)_2CNO\}_4]$ [174].

with a fifth Ni^{II} encapsulated ion (Fig. 80). The two $MeCO_2^-$ ions bridge the encapsulated metal ion to two ring metal ions giving an overall neutral charge to the molecule. The $(py)_2CNO^-$ ligand is nonplanar due to steric hindrance between the two pyridyl rings; this confers a nonplanar conformation to the metallacrown

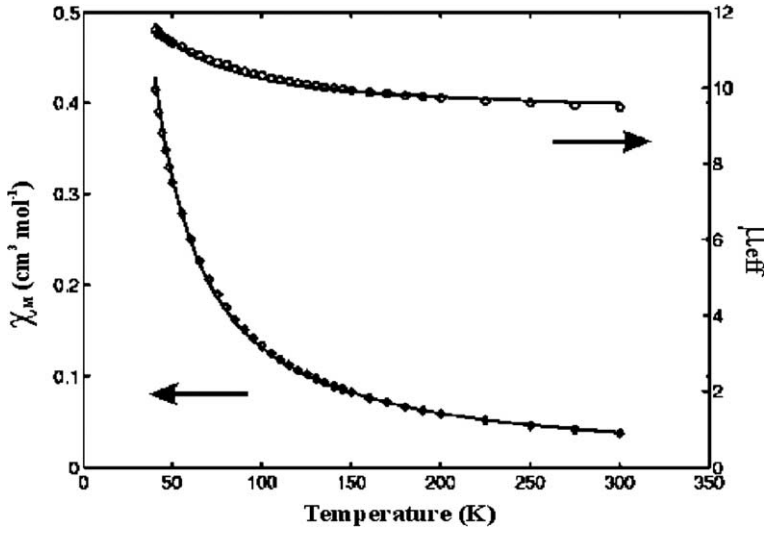

Fig. 75. Variable-temperature magnetic susceptibility for $[Mn_2^{II}Mn^{IV}(OMe)_2(NCS)_2\{(py)_2CNO\}_4]$ [174].

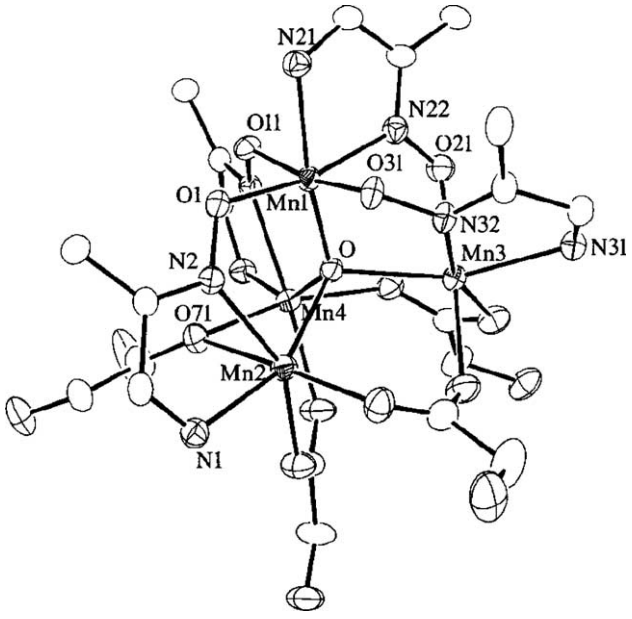

Fig. 76. X-ray structure of $[Mn_3^{II}Mn^{IV}O(3,4\text{-}D)_4\{(py)_2CNO\}_4]$ [177].

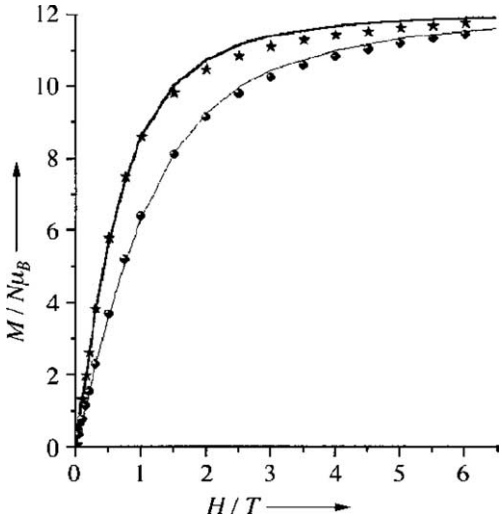

Fig. 77. Magnetization measurements for $[Mn_3^{II}Mn^{IV}O(3,4\text{-}D)_4\{(py)_2CNO\}_4]$ in the field range 0–6.5 T at 2.5 K (∗) and 4.5 K (•). The solid lines represent the simulations according to the Brillouin function of a system with an $S = 6$ ground state and $D = 0.025$ cm^{-1} [177].

ring or a "saddle" shape. Two Ni^{II} ions in the ring are octahedral and two are square planar; the encapsulated metal ion is also in an octahedral oxygen environment with four oxygens coming from the MC cavity and two from the bridging *syn*, *anti* $MeCO_2^-$ ligands. The relationship between the bridging acetates and the MC ring requires that stereoisomers are present. Magnetically the compound is characterized by weak antiferromagnetic exchange interactions. Our group have also isolated a series of pentanuclear Ni(II) clusters [97] based on $(py)_2CNO^-$, see Table 4 and Figs. 81–83. Their magnetic properties are being studied.

The molecular structure of the azido-bridged heptanuclear cluster $[Ni_7(O_2CMe)_6(N_3)_2\{(py)_2CNO\}_6(H_2O)_2]$ is based on the fusion (at a central metal ion) of two tetranuclear fragments [97].

The X-ray structure of $[Ni_{10}(MCPA)_2(shi)_5\{(py)_2CNO\}_3(MeOH)(H_2O)]$ (Fig. 84), where $MCPA^-$ is the anion of 2-methyl-4-chlorophenoxyacetic acid, consists of two 12-MC-4 units with charges of +1 and −1 [181]. Each tetranuclear unit has one additional encapsulated Ni^{II} ion. The cationic unit is bound to the anionic unit via O bridges. The ground state of this cluster is $S = 0$, with $S = 1$, 2 low-lying excited states [193]; this leads to a non-Brillouin behavior of the magnetization.

Complex $[Mn_2Ni_2(O_2CMe)_2(shi)_2\{(py)_2CNO\}_2(DMF)_5]$ consists of a mixed metal/mixed ligand "collapsed" 12-MC-4 motif (Fig. 85) [181]. The oxophilic

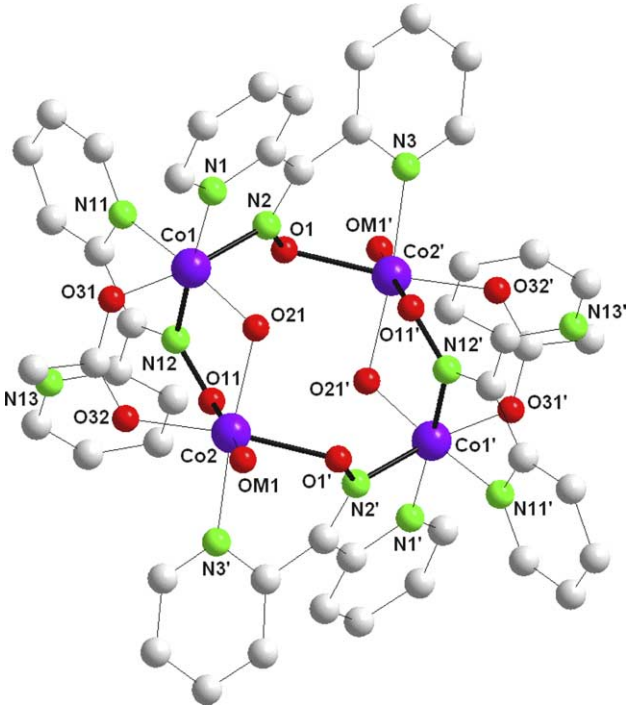

Fig. 78. X-ray structure of the cation of $[Co_2^{II}Co_2^{III}(OH)_2(O_2CMe)_2\{(py)_2CNO\}_4(MeOH)_2](ClO_4)_2$. O(21) and O(21′) are the hydroxo oxygen atoms, while OM(1) and OM(1′) are the oxygen atoms of the methanol ligands. The metallacrown ring is outlined in bold [179].

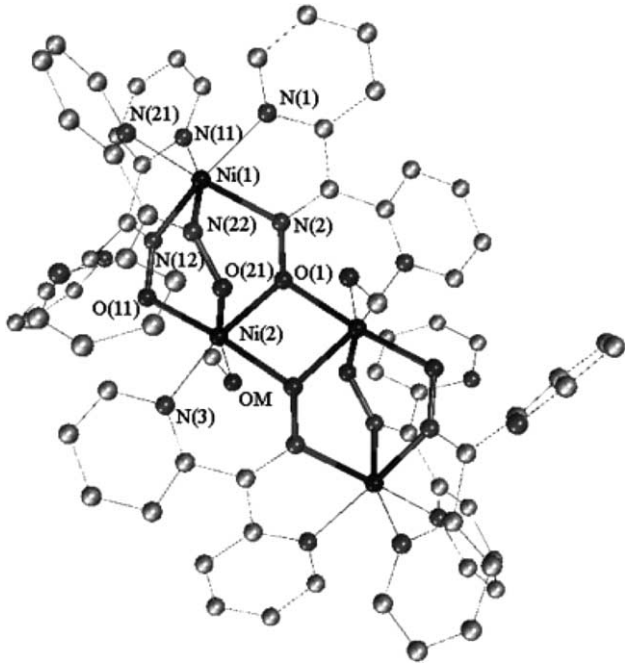

Fig. 79. X-ray structure of $[Ni_4\{(py)_2CNO\}_6(MeOH)_2]^{2+}$ [180].

Mn^{III} ions are bound to the O, N chelating part of the shi^{3-} ligand and then bind across the core to the oxime oxygens instead of the pyridyl nitrogens of the 2.1110

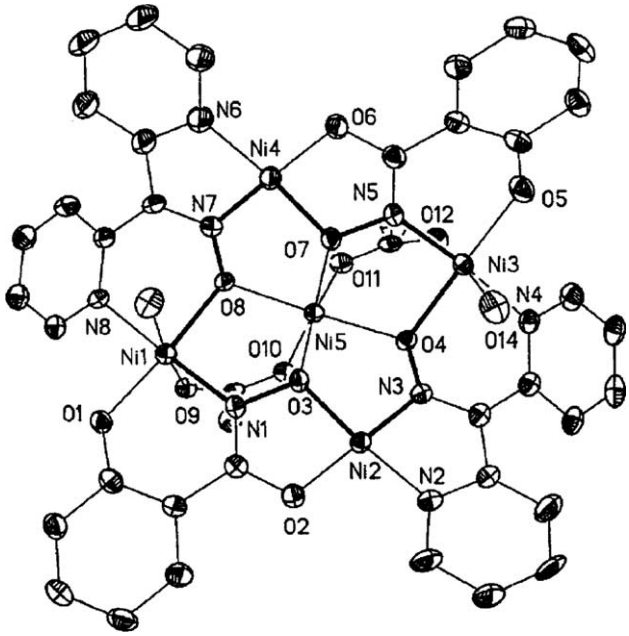

Fig. 80. X-ray structure of $[Ni_5(O_2CMe)_2(shi)_2\{(py)_2CNO\}_2]$; the molecule shown here is the Λ isomer as defined by the screw axis oriented along the C_2-axis [181].

$(py)_2CNO^-$ ligands. Paramagnetic ^1H NMR studies demonstrate that the mixed metallacrown retains its structure in solution [181].

The only copper(I) complex containing bridging $(py)_2CNOH$ or $(py)_2CNO^-$ ligands is [171] the dimer $[Cu_2Cl_2\{(py)_2CNO\}_2]$, in which each Cu^I ion is coordinated by one chloride and three nitrogen atoms in a distorted tetrahedral environment.

Copper(II) complexes possessing bridging $(py)_2CNOH$ or $(py)_2CNO^-$ ligands have not been studied extensively. The crystal structure of $[Cu_2\{(py)_2CNO\}_4]\cdot 2H_2O$ [182,183] consists of dinuclear molecules containing both 1.0110 and 2.1110 $(py)_2CNO^-$ ligands (Fig. 86); the Cu^{II} coordination geometry is slightly distorted trigonal bipyramidal. Employment of carboxylates in the reaction mixtures gives trinuclear complexes of the general formula $[Cu_3(OH)(O_2CR)_2\{(py)_2CNO\}_3]$; the molecular structure of the acetate complex is shown in Fig. 87. The trinuclear cluster, which has an inverse 9-MC-3 motif, is held together by one μ_3-OH group, one $\eta^1:\eta^1:\mu_2$-$MeCO_2^{2-}$ ligand and three 2.1110 $(py)_2CNO^-$ ions [183]; a monodentate acetate completes five coordination at one Cu^{II} center. Two trinuclear molecules are "dimerized" in the crystal lattice through weak interactions between two Cu^{II} ions and "free" 2-pyridyl nitrogen atoms creating a hexamer. The benzoate analogue consists of well-isolated trinuclear molecules [183]. In the dinuclear complex $[Cu_2(hfac)_2\{(py)_2CNO\}_2]$, the two five-coordinate Cu^{II} ions are bridged by two 2.1110 $(py)_2CNO^-$ ligands.

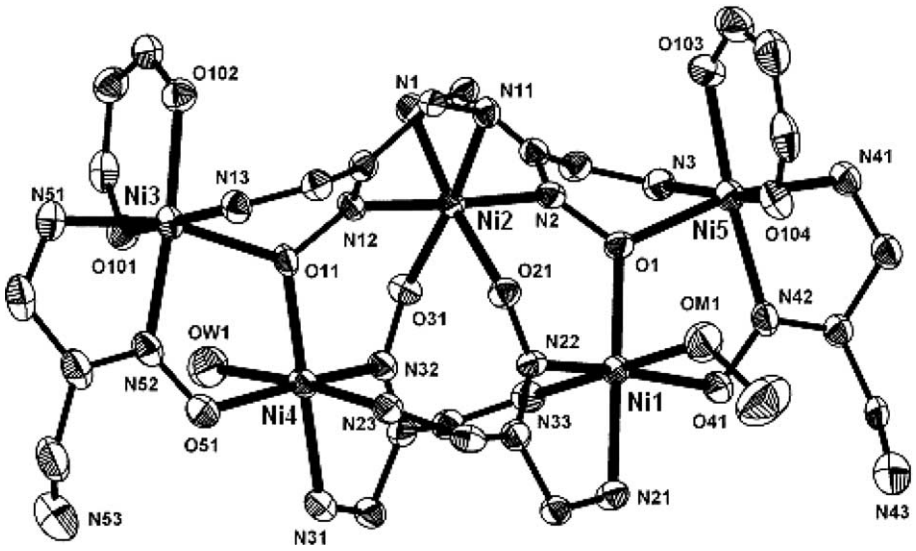

Fig. 81. X-ray structure of the cation present in the complex $[Ni_5(acac)_2\{(py)_2CNO\}_6(H_2O)(MeOH)][ClO_4)_2$; many carbon atoms have been omitted for clarity [97].

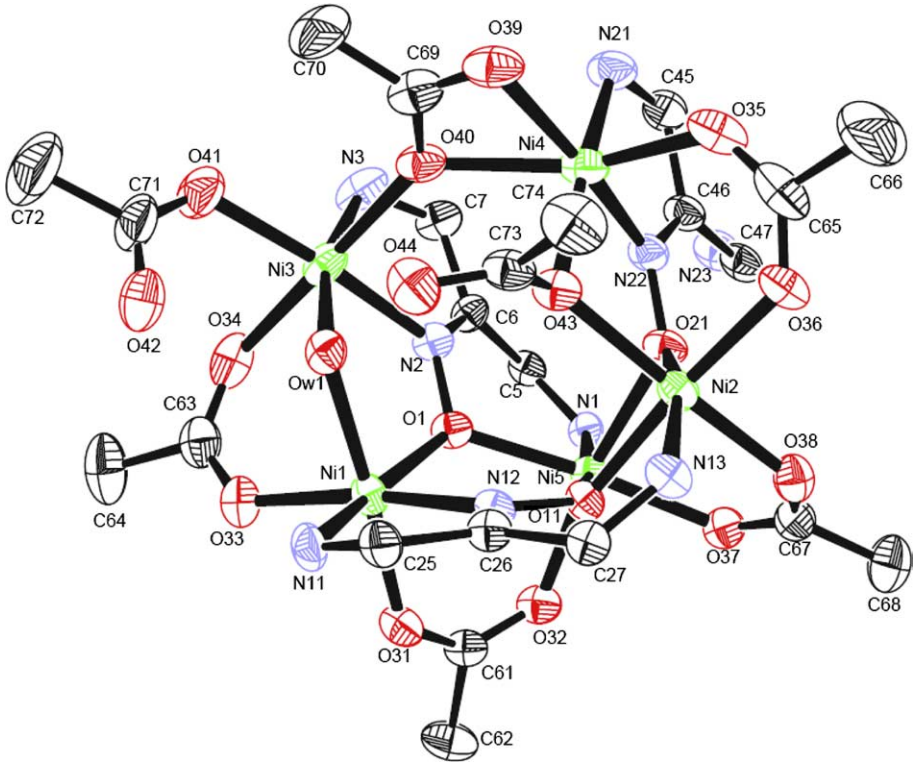

Fig. 82. X-ray structure of $[Ni_5(O_2CMe)_7\{(py)_2CNO\}_3(H_2O)]$; many carbon atoms of the $(py)_2CNO^-$ ligands have been omitted [97].

The use of $(py)_2CNO^-/X^-$ "blends" ($X^- = MeCO_2^-$, $PhCO_2^-$, Cl^-, N_3^-, NCO^-, $acac^-$, NCS^-, Cl^-/NCS^-) in Zn^{II} chemistry yields neutral tetranuclear and cationic pentanuclear clusters [172,184,185], see Scheme 9. Various synthetic procedures have led to the synthesis of compounds $[Zn_4(OH)_2X'_2\{(py)_2CNO\}_4]$ ($X'^- = Cl^-, N_3^-$, NCO^-), $[Zn_4(OH)_2Z_2\{(py)_2CNO\}_4]$ ($Z^- = MeCO_2^-, acac^-$), $[Zn_5Cl_2\{(py)_2CNO\}_6][ZnCl(NCS)_3]$ and $[Zn_5(NCS)_2\{(py)_2CNO\}_6(MeOH)][Zn(NCS)_4]$; representative structures are shown in Figs. 88 and 89. The tetranuclear molecules have an inverse 12-MC-4 topology. The triply bridging hydroxides are accommodated in the center of the metallacrown ring. The $(py)_2CNO^-$ ligands form a propeller configuration that imposes absolute stereoisomerism with Λ and Δ chirality. Two metal ions are in distorted O_2N_4 octahedral environments,

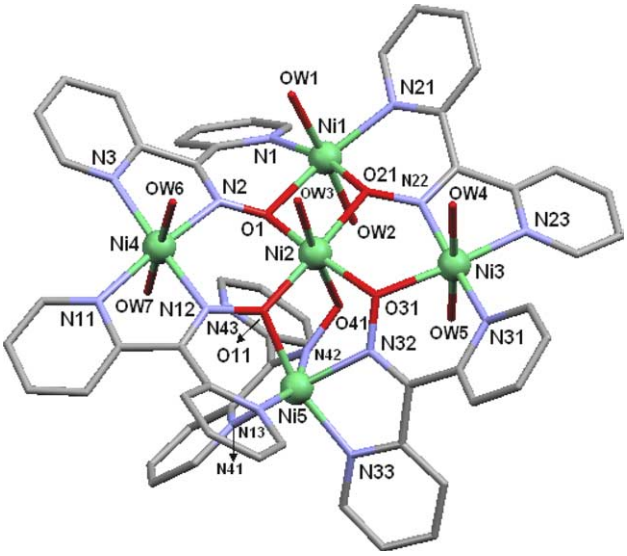

Fig. 83. X-ray structure of the cation present in complex $[Ni_5\{(py)_2CNO\}_5(H_2O)_7](NO_3)_5$ [97].

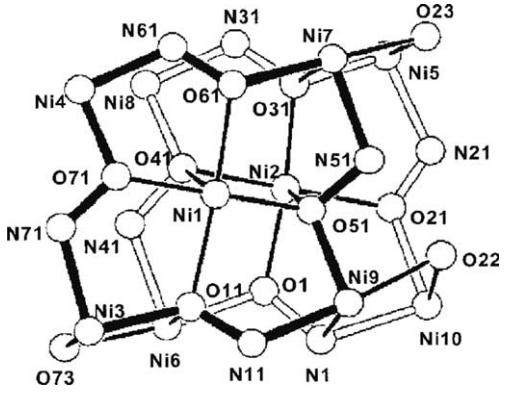

Fig. 84. A view of $[Ni_{10}(MCPA)_2(shi)_5\{(py)_2CNO\}_3(MeOH)(H_2O)]$; many atoms have been omitted for clarity [181].

whereas the rest are in severely distorted tetrahedral ($X'^{-} = Cl^-, N_3^-, NCO^-, PhCO_2^-$) or tbp ($Z^- = MeCO_2^-, acac^-$) environments. The five Zn^{II} ions of the pentanuclear cations are held together by six $(py)_2CNO^-$ ligands which adopt three different coordination modes (2.1110, 3.1111, 3.2111); the chloro and isothiocyanato ligands in these cluster cations are terminal. The five Zn^{II} ions define two nearly equilateral triangles sharing a common apex, and the novel Zn_5 topology can be described as two "collapsed" 9-MC-3 structures sharing a common metal apex.

Employment of shi^{3-} in $ZnCl_2/(py)_2CNO^-$ chemistry yields [172] the octanuclear cluster $[Zn_8(shi)_4\{(py)_2CNO\}_4(MeOH)_2]$. The molecule contains a 12-MC-4 core constructed by four metal ions, i.e., Zn(3), Zn(5), Zn(7) and Zn(8) in Fig. 90, and four shi^{3-} ligands. The MC core accommodates a dinuclear $Zn_2\{(py)_2CNO\}_4$ component (Zn(1), Zn(4)), while the ring metal ions Zn(3) and Zn(5) create dinuclear units with Zn(2) and Zn(6), respectively, through oxygen bridges.

There also exist $(py)_2CNO^-$-based complexes of 4d- and 5d-metals, including organometallic compounds. Treatment of $[Ru_3(CO)_{12}]$ with $(py)_2CNOH$ in refluxing THF leads [186a] to a separable mixture of $[Ru_3\{(py)_2CNO\}_2(CO)_8]$ (Fig. 91) and $[Ru_2\{(py)_2CNO\}_2(CO)_4]$. Compounds $[M_3(CO)_{10}(MeCN)_2]$ (M = Ru, Os) react with $(py)_2CNOH$ in THF at room temperature to give $[M_3(\mu\text{-}H)\{(py)_2CNO\}(CO)_9]$ [186a]. The thermal reaction of $[Os_3(\mu\text{-}H)\{(py)_2CNO\}(CO)_9]$ with $(py)_2CNOH$ gives [186a] $[Os_3\{(py)_2CNO\}_2(CO)_8]$, which is isostructural with the Ru analogue. These complexes display low activity as DNA cleavage agents. The crystals of $[Ag_2(NO_3)_2\{(py)_2CNOH\}_2]$ were found [186b] to contains neutral dinuclear molecules (Fig. 92). The $(py)_2CNOH$ ligands bridge the two Ag^I ions in a 2.0111 fashion, see Fig. 68. The nitrato ligands are monodentate

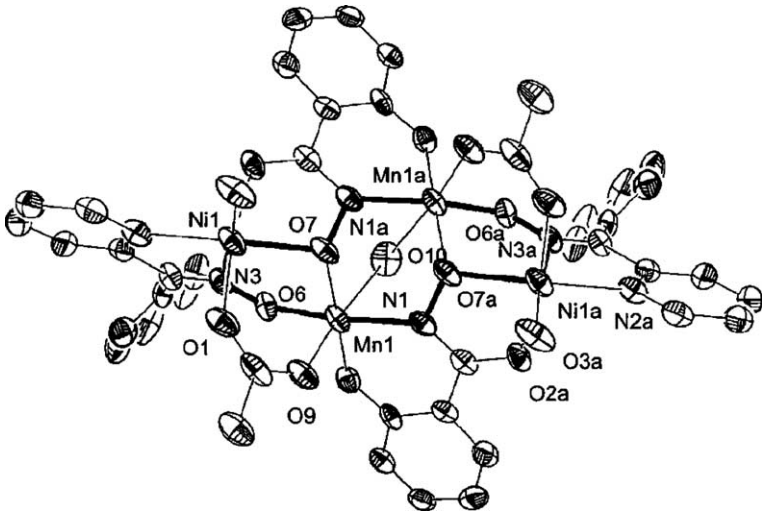

Fig. 85. X-ray of the mixed metal/mixed ligand "collapsed" 12-MC-4 complex $[Mn_2Ni_2(O_2CMe)_2(shi)_2\{(py)_2CNO\}_2(DMF)_5]$ [181].

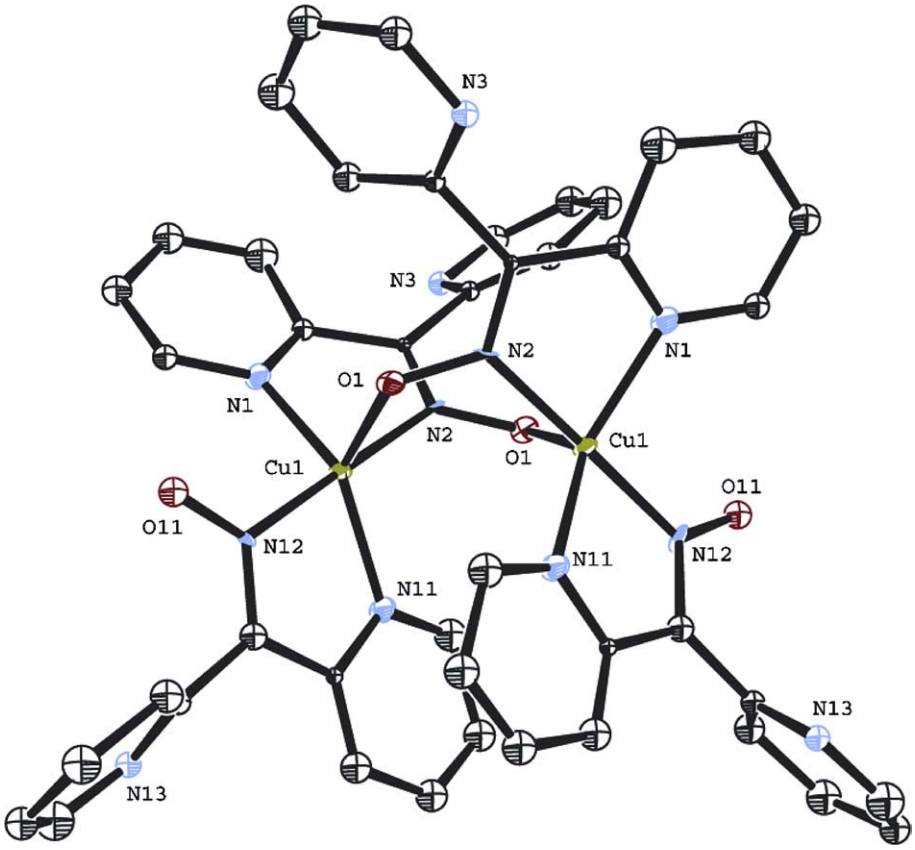

Fig. 86. X-ray structure of $[Cu_2\{(py)_2CNO\}_4]$ [183].

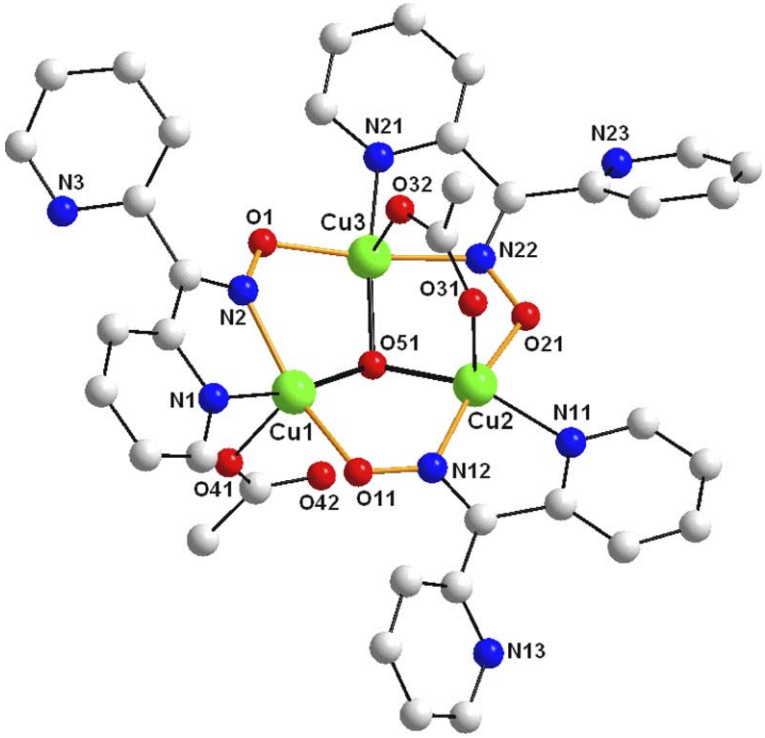

Fig. 87. X-ray structure of $[Cu_3(OH)(O_2CR)_2\{(py)_2CNO\}_3]$; the ''dimerization'' of the trinuclear molecules is not shown [183].

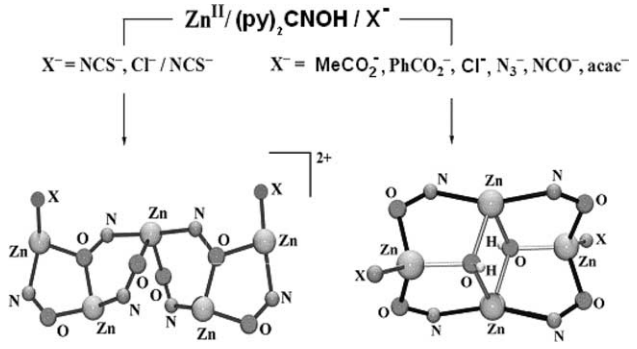

Scheme 9. The $Zn^{II}/(py)_2CNOH/X^-$ reaction scheme that leads to neutral tetranuclear and cationic pentanuclear clusters.

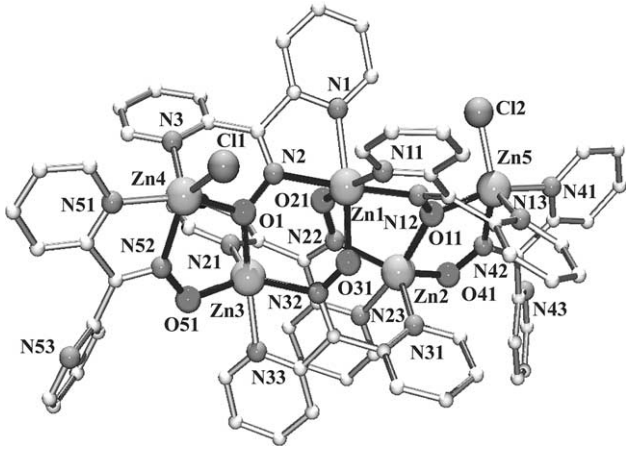

Fig. 89. X-ray structure of the pentanuclear cation present in the complex $[Zn_5Cl_2\{(py)_2CNO\}_6][ZnCl(NCS)_3]$.

and the geometry around the metal centers can be described as distorted tetrahedral. The 2.0111 ligation mode is also adopted by the neutral ligand in the dinuclear complexes $[Cd_2(O_2CR)_4\{(py)_2CNOH\}_2]$ (R = Me, Ph) and the coordination polymer $[Cd(O_2CMe)(SCN)\{(py)_2CNOH\}]_n$ [187]. The structurally characterized mercury(II) complexes are [97] $[Hg_2(O_2CMe)_4\{(py)_2CNOH\}_2]$, $[Hg_2(O_2CPh)_3\{(py)_2CNO\}\{(py)_2CNOH\}(MeOH)]$ (Fig. 93) and $[HgCl(O_2CPh)\{(py)_2CNOH\}]_n$; details are given in Table 4. The three complexes contain 2.0111 ligands.

Working with $(py)_2CNOH$, we have been able to apply the "metal complexes as ligands" strategy [73,209] to isolate mixed-metal 3d/4f complexes [187]. Complexes $[M\{(py)_2CNOH\}_2(H_2O)_2](NO_3)_2$ [187], which have yet to be structurally characterized, most probably contain 1.0110 neutral oxime ligands. Since these species contain two potentially free (the oxime oxygen, the second 2-pyridyl nitrogen) coordination sites, they can be regarded as "ligands". Reactions between equimolar quantities of $[M\{(py)_2CNOH\}_2(H_2O)_2](NO_3)_2$, where M = Mn, Ni, Cu, Zn, and $Ln(NO_3)_3 \cdot xH_2O$ (Ln = lanthanide) in various solvents lead to hexanuclear clusters of the general formula $[M_3Ln_3\{(py)_2CNO\}_6(NO_3)_9]$ (Eq. (7)).

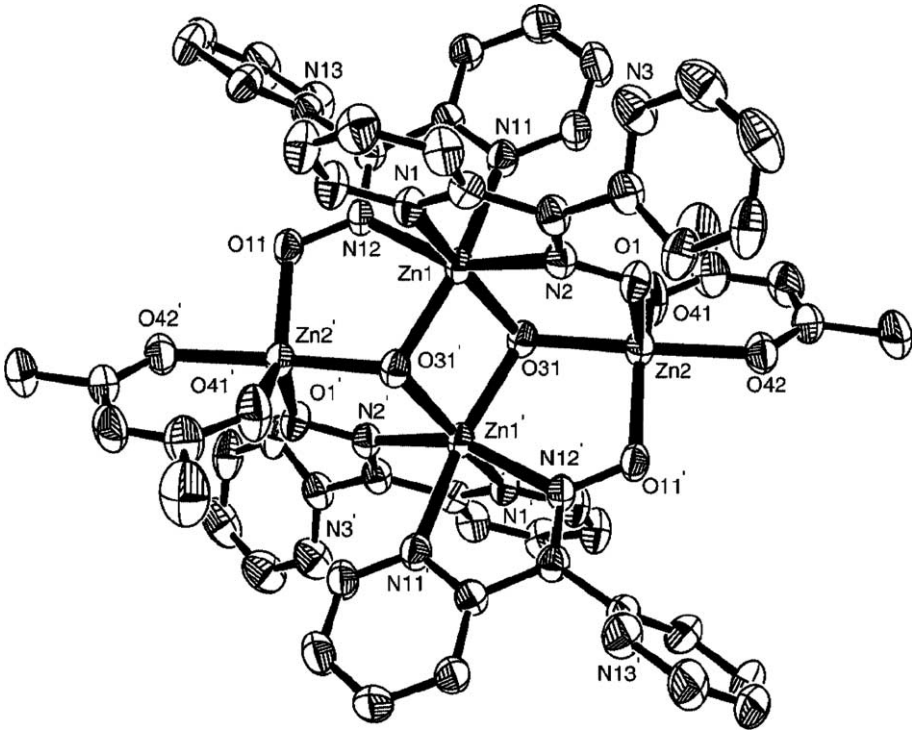

Fig. 88. X-ray structure of $[Zn_4(OH)_2(acac)_2\{(py)_2CNO\}_4]$ [184].

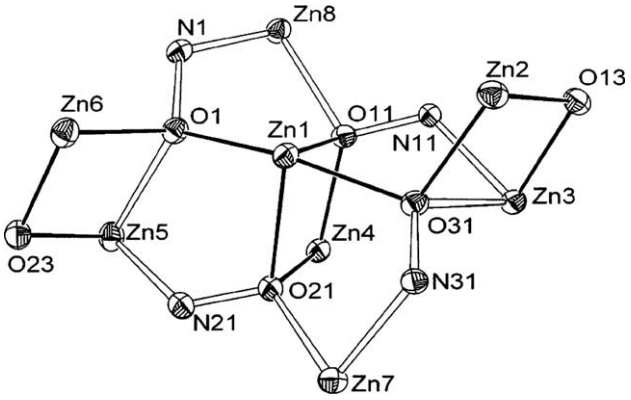

Fig. 90. The connectivity pattern of the complex $[Zn_8(shi)_4\{(py)_2CNO\}_4(MeOH)_2]$ [172].

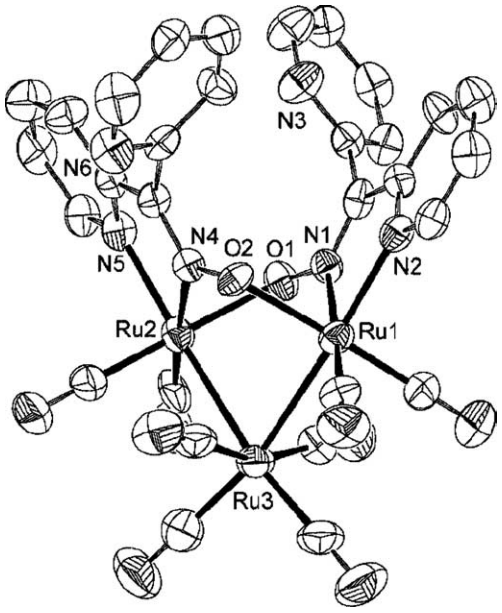

Fig. 91. X-ray structure of $[Ru_3\{(py)_2CNO\}_2(CO)_8]$ [186a].

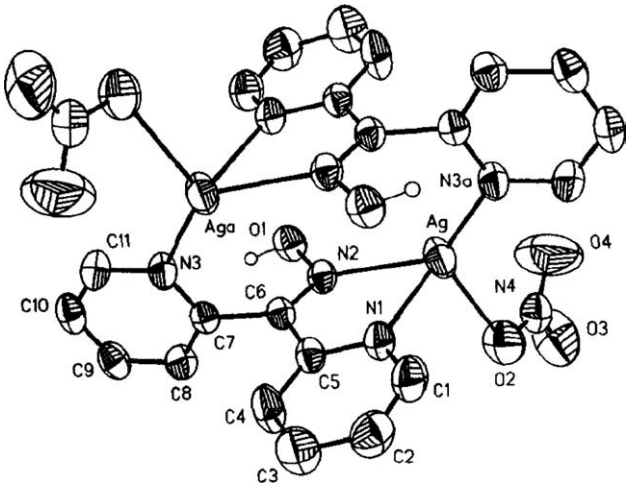

Fig. 92. X-ray structure of $[Ag_2(NO_3)_2\{(py)_2CNOH\}_2]$ [186b].

$$3[M\{(py)_2CNOH\}_2(H_2O)_2](NO_3)_2 + 3Ln(NO_3)_3 \cdot xH_2O + 6LiOH \rightarrow [M_3Ln_3\{(py)_2CNO\}_6(NO_3)_9] + 6LiNO_3 + 3(4+x)H_2O$$

The molecular structure of the M = Zn, Ln = Tb complex is shown in Fig. 94. The $(py)_2CNO^-$ ligands adopt the 3.2111 coordination mode, each bridging two Zn^{II} ions and one Tb^{III} center; three chelating nitrates are bound to each Tb^{III} ion. The two donor atoms, that were free in the mononuclear "ligand" 3d-metal complex, are indeed coordinated to terbium(III), as anticipated; however, the deprotonated oximate oxygen is bound to a second Zn^{II} ions and this does not permit a full synthetic control of the reaction. Five, out of the six, metal ions define a trigonal bipyramid (Fig. 95). The Tb^{III} ions occupy the equatorial positions, while the third Zn^{II} ion lies in the middle of the equatorial plane. Trinuclear Ni^{II}/Ln^{III} clusters based on $(py)_2CNO^-$ and containing chelating $hfac^-$ as ancillary ligand have also been communicated at a conference [188].

8.4. Metal-ion assisted transformations of $(py)_2CNOH$

We have already mentioned the in situ transformations of $(py)_2CNOH$ to give the coordination dianion and monoanion of the *gem*-diol derivative of di-2-pyridyl ketone (Fig. 72) during the preparation of $[Mn_2^{II}Mn_2^{III}(O_2CR)_2\{(py)_2CO_2\}_2\{(py)_2CNO\}_2X_2]$ (Fig. 73, Scheme 8) [168,176] and $[Co(NO_2)\{(py)_2C(OH)O\}\{(py)_2CNO\}]$ (Table 3) [170], respectively. In these complexes, an amount of the oximate ligand still remains coordinated in the product. We shall briefly discuss here the few cases in which the initially $(py)_2CNOH$ ligand employed does not appear in the products.

The synthetic utility of the metal-mediated organic transformations and the reactions of coordinated ligands is an important subject [210]. It is based on the enhancement in reactivity of organic ligands as a consequence of metal coordination. For example, the metal can act as a 'super acid' and cause enhanced nucleophilic attack on coordinated carbonyl and imine ligands. The metal ion can also enable the ligand itself to act as a nucleophile, sometimes by direct activation, sometimes by protecting other parts of the ligand and sometimes by a combination of both. The ligands which undergo reaction can be bound to the metal ion in the transition state or in relatively stable, isolable complexes.

The reaction between $[VCl_3(THF)_3]$ and $(py)_2CNOH$ is solvent dependent (Scheme 10) [211]. In THF, the product is $[VOCl_2\{(py)_2CNH\}(THF)]$, where $(py)_2CNH$ is di-2-pyridylimine. The molecular structure of this

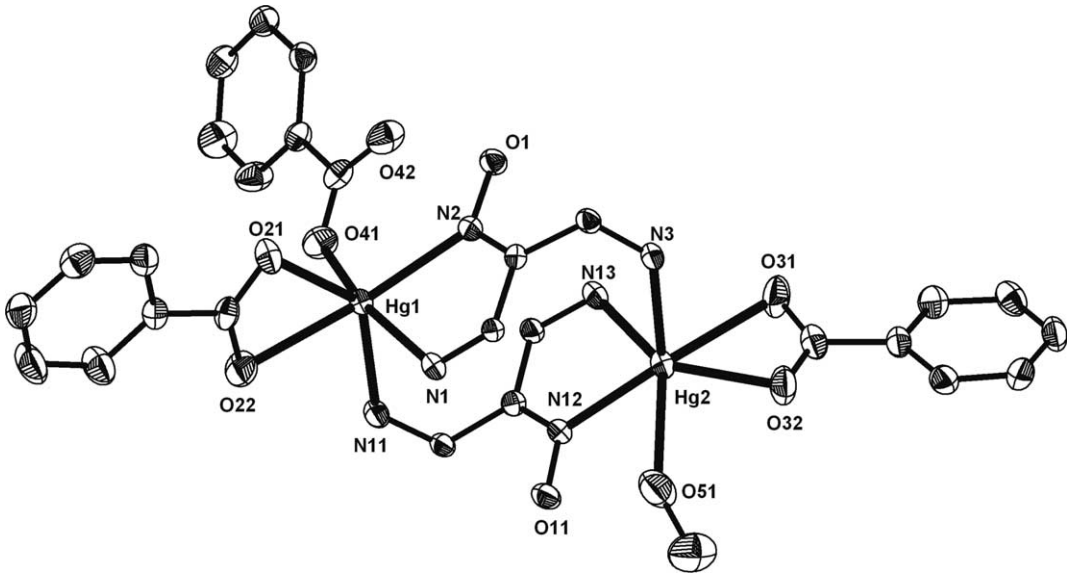

Fig. 93. X-ray structure of $[Hg_2(O_2CPh)_3\{(py)_2CNO\}\{(py)_2CNOH\}(MeOH)]$; many carbon atoms of the oxime and oximate ligands have been omitted for clarity [97].

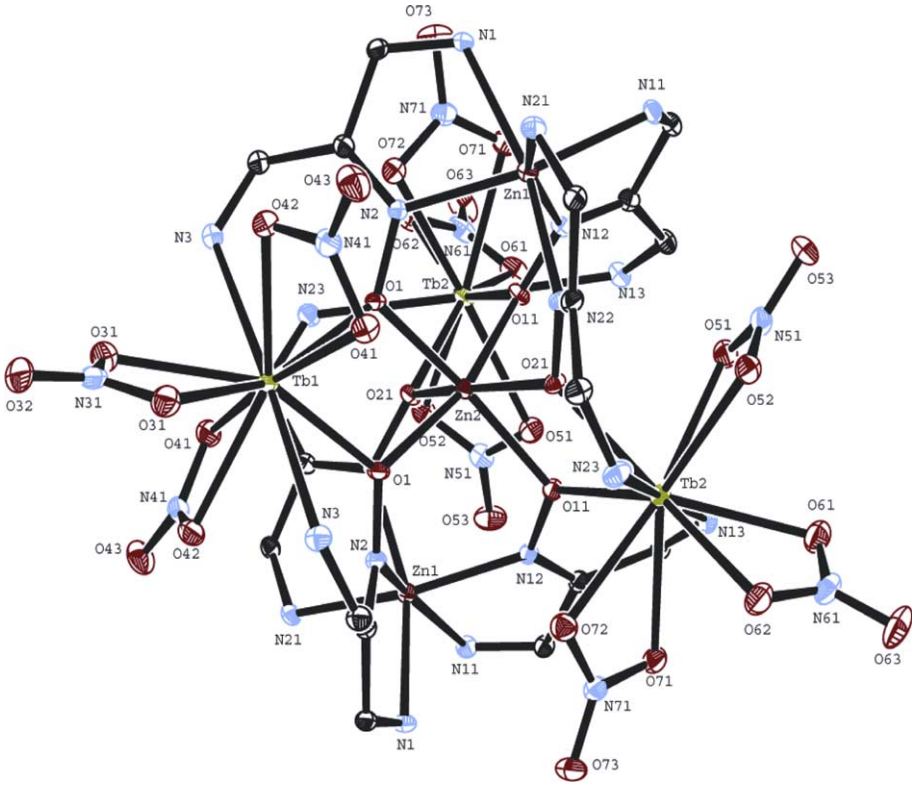

Fig. 94. X-ray structure of $[Zn_3Tb_3\{(py)_2CNO\}_6(NO_3)_9]$ [187].

compound is shown in Fig. 96. The structure reveals two important features: (a) the oxidation of the initially V^{III} ion to the oxovanadium(IV) ion, $V^{IV}O^{2+}$ and (b) the transformation of the oxime group to an imino group. In EtOH the product is $[VOCl_2\{(py)_2C(OEt)(NH_2)\}]$, where $(py)_2C(OEt)(NH_2)$ is amino-di-2-pyridyl-methyl ethyl ether. The new ligand exhibits an $(N_{py})_2(N_{amino})$ chelating behavior (Fig. 97). The reaction in MeOH gives a mixture of two-coordination isomers of $[VOCl_2\{(py)_2C(OMe)(NH_2)\}]$, where $(py)_2C(OMe)$-

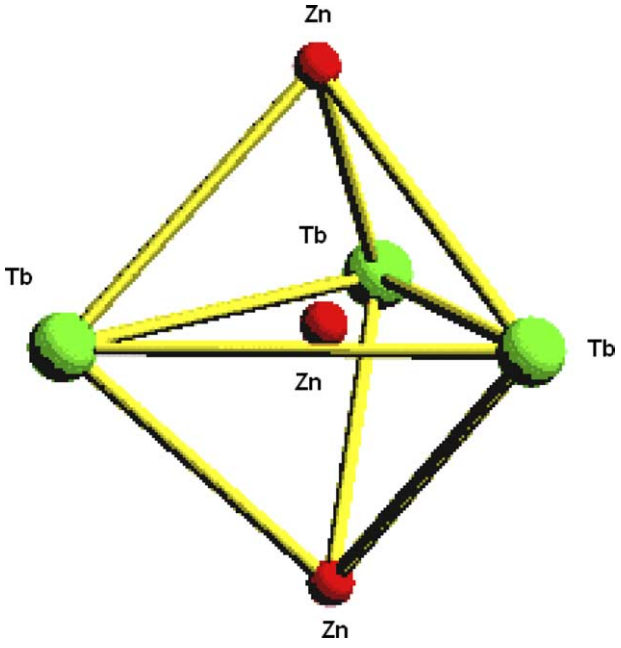

Fig. 95. The topological arrangement of the six metal ions in the 3d/4f cluster $[Zn_3Tb_3\{(py)_2CNO\}_6(NO_3)_9]$ [187].

(NH_2) is amino-di-2-pyridyl-methyl methyl ether. One isomer bears striking structural resemblance to $[VOCl_2\{(py)_2C(OEt)(NH_2)\}]$ (Fig. 97), while in the other isomer an $(N_{py})_2(O_{ether})$ chelating behavior of the ligand is realized (Fig. 98). One pyridyl nitrogen atom exhibits no interaction with V^{IV} in $[VOCl_2\{(py)_2CNH\}(THF)]$ due to the sp^2 character of the central carbon atom (C(6)), whereas the coordination of both pyridyl nitrogen atoms has been observed in the rest of the complexes as a result of flexibility of C(6) due to sp^3 hybridization [211]. It was concluded that the vanadyl oxygen comes from N–O bond cleavage.

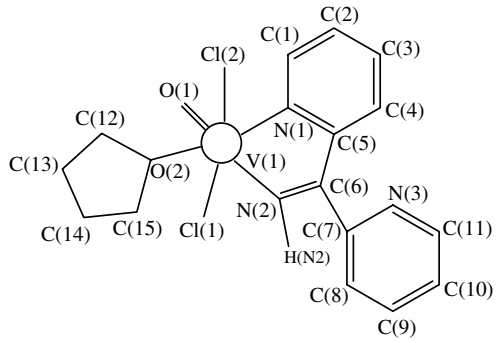

Fig. 96. X-ray structure of $[VOCl_2\{(py)_2CNH\}(THF)]$.

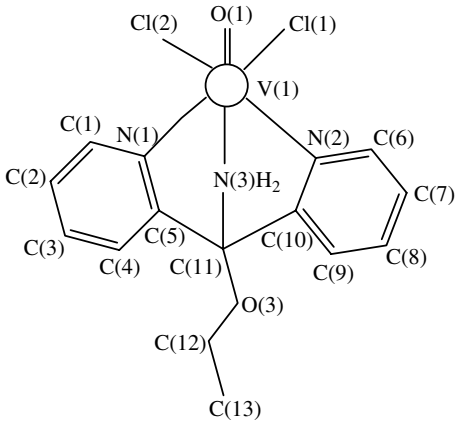

Fig. 97. X-ray structure of $[VOCl_2\{(py)_2C(OEt)(NH_2)\}]$.

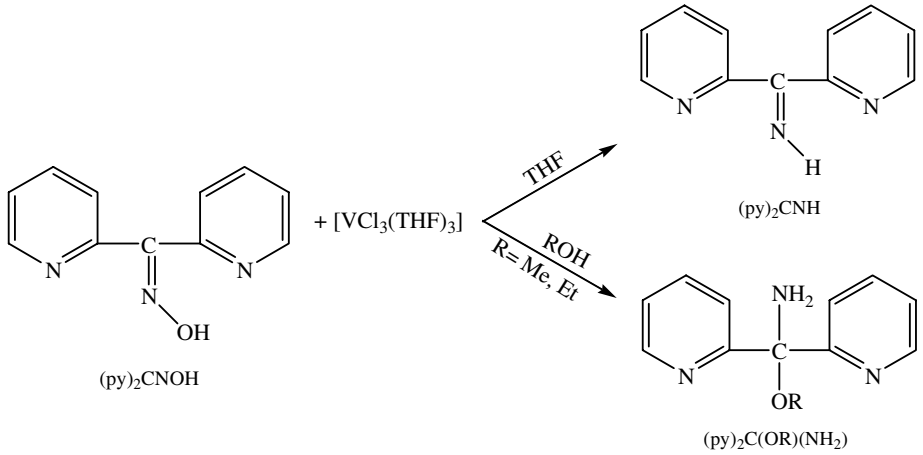
Recent results [97] reveal that the $Co(O_2CMe)_2 \cdot 4H_2O/(py)_2CNOH/NaN_3$ reaction mixture in MeCN gives the complex $[Co_4(N_3)_2(O_2CMe)_2\{(py)_2C(OH)O\}_4]$. The remarkable feature of the reaction is the in situ transformation of $(py)_2CNOH$ to yield the triply-



Scheme 10. The $[VCl_3(THF)_3]/(py)_2CNOH$ reaction system [211].

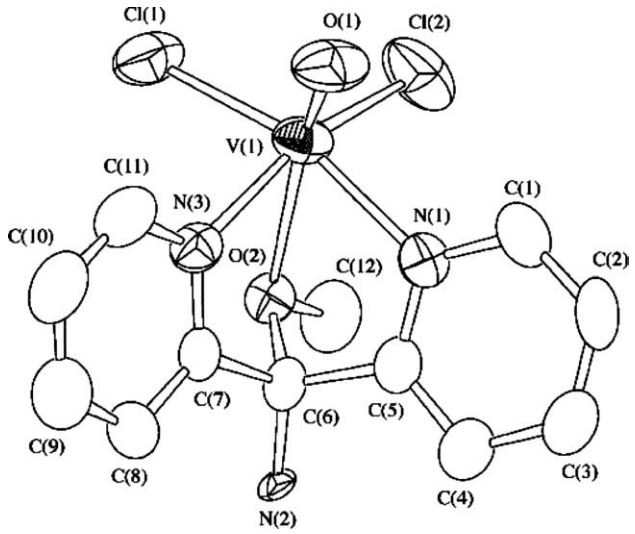


Fig. 98. X-ray structure of the second coordination isomer of $[VOCl_2\{(py)_2C(OMe)(NH_2)\}]$.

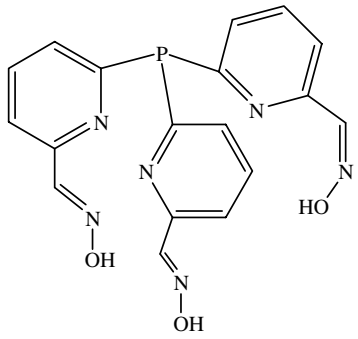
bridging monoanion, $(py)_2C(OH)O^-$, of the *gem*-diol derivative of di-2-pyridyl ketone, $(py)_2CO$, see Fig. 72. The X-ray diffraction analysis shows (Fig. 99) a defective double-cubane, tetranuclear entity in which the Co^{II} ions are linked by end-on (2.100) azido ligands and two kinds of O-bridges from two 3.3011 and two 2.2011 $(py)_2C(OH)O^-$ ligands. Magnetic susceptibility studies of this compound in the 2–300 K range indicate bulk ferromagnetic coupling. Efforts are in progress to elucidate the mechanism of this transformation.

9. The coordination chemistry of tris(2-aldoximo-6-pyridyl)phosphine, P{(py-H)CHNOH}$_3$, and of the related clathro-chelates



$P\{(py\text{-}H)CHNOH\}_3$

The ligand was synthesized by Holm's group some 35 years ago [212,213] during his successful project for the design of complexes containing encapsulated metal ions with trigonal prismatic coordination. As shown in Scheme 11, $P\{(py\text{-}H)CHNOH\}_3$ can be obtained in ~20% overall yield from 2,6-dibromopyridine in a six-step process.

Reaction of Fe^{II}, Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} salt with $P\{(py\text{-}H)CHNOH\}_3$ in MeCN yields the cations $[M(P\{(py\text{-}H)CHNOH\}_2\{(py\text{-}H)CHNO\})]^+$, which can be isolated as analytically pure perchlorate salts; the

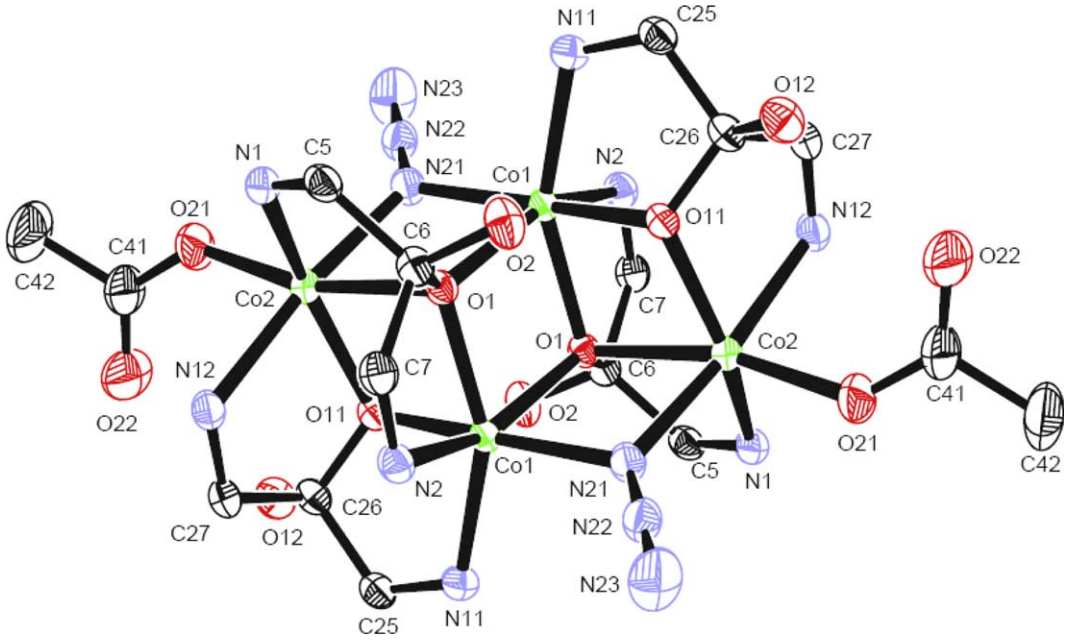


Fig. 99. X-ray structure of $[Co_4(N_3)_2(O_2CMe)_2\{(py)_2C(OH)O\}_4]$; this $(py)_2CNO^-$-free complex is prepared by the reaction of $Co(O_2CMe)_2 \cdot 4H_2O$, $(py)_2CNOH$ and NaN_3 in MeCN.

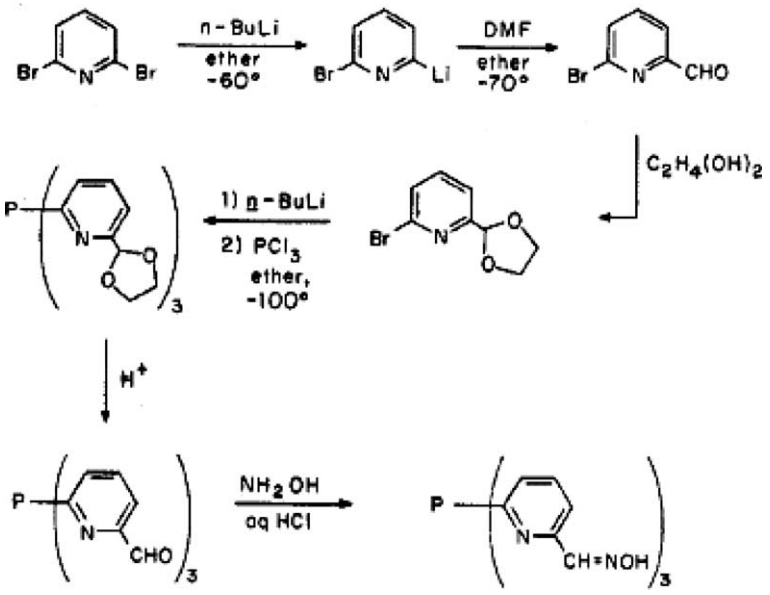
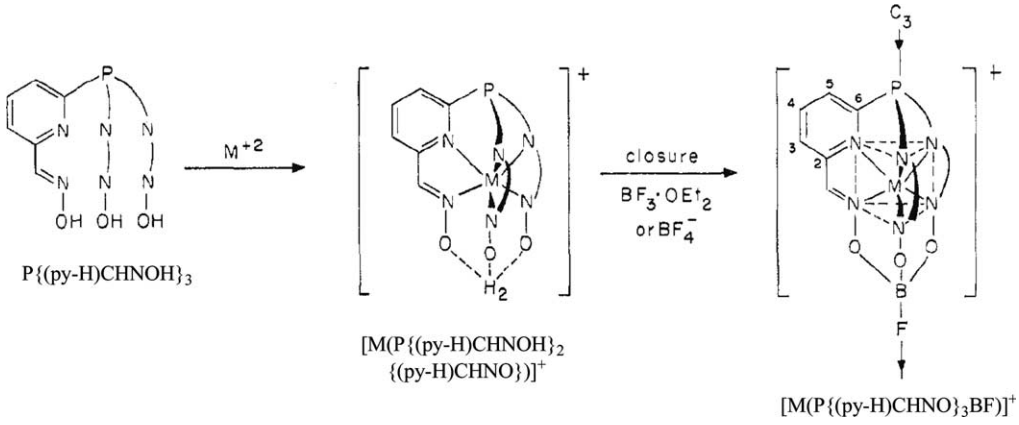


Scheme 11. Synthesis of P{(py-H)CHNOH}$_3$.

formation of these cations and their proposed structures (based on physical and spectroscopic data) [213] are shown in Scheme 12.

The chlathro-chelate fluoroborotris(2-aldoximo-6-pyridyl)phosphinemetal(II) cations, [M(P{(py-H)CHNO}$_3$BF)]$^+$, containing Fe(II), Co(II), Ni(II) and Zn(II), were prepared by closure reactions of [M(P{(py-H)CHNOH}$_2${(py-H)CHNO})]$^+$ with boron trifluoride etherate or tetrafluoroborate ion and isolated as BF_4^- salts (Scheme 12). X-ray results have shown [214] that the desired trigonal prismatic coordination has been very closely approached in [Ni(P{(py-H)CHNO}$_3$BF)](BF_4), and that the Co(II) and Zn(II) salts are isomorphous with the Ni^{II} compound. The general synthetic procedure shown in Scheme 12 failed when applied to the synthesis of the Cu^{II} clathro-chelate.

In a synthetically smart and magnetically elegant paper [68], Chaudhuri and co-workers used the metal-containing fragment $\{Cr^{III}L\}^{3+}$, instead of the B-capping unit, for encapsulation of the [Ni(P{(py-H)CHNO}$_3$)]$^-$ unit to yield the bicyclic chlathro-chelate (L = 1,4,7-trimethyl-1,4,7-triazacyclononane). The molecular structure of the resulting cation [LCr^{III}(P{(py-H)CHNO}$_3$)Ni^{II}]$^{2+}$ is shown in Fig. 100. The Cr^{III} and Ni^{II} coordination geometries are distorted octahedral and trigonal prismatic, respectively. The effective magnetic moment, μ_{eff}, for this complex exhibits an essentially temperature-independent behavior in the range 290–30 K (Fig. 101). Below 30 K the μ_{eff} decreases reaching a value of 3.82 BM at 2 K. The solid line in Fig. 4 represents the best fit with the parameters $J = 0$, $g_{Cr} = 1.98$, $g_{Ni} = 2.16$, $\theta = -1.42$ K. The isoelectronic



Scheme 12. Synthesis of [M(P{(py-H)CHNO}$_3$BF)]$^+$ complexes from P{(py-H)CHNOH}$_3$ using boron trifluoride etherate or tetrafluoroborate ion as ring-closure reagents. No specific stereochemistry of the intermediate six-coordinate complexes is implied. For purposes of clarity only one chelate ring structure is shown in each species (M = Fe, Co, Ni, Zn) [213].

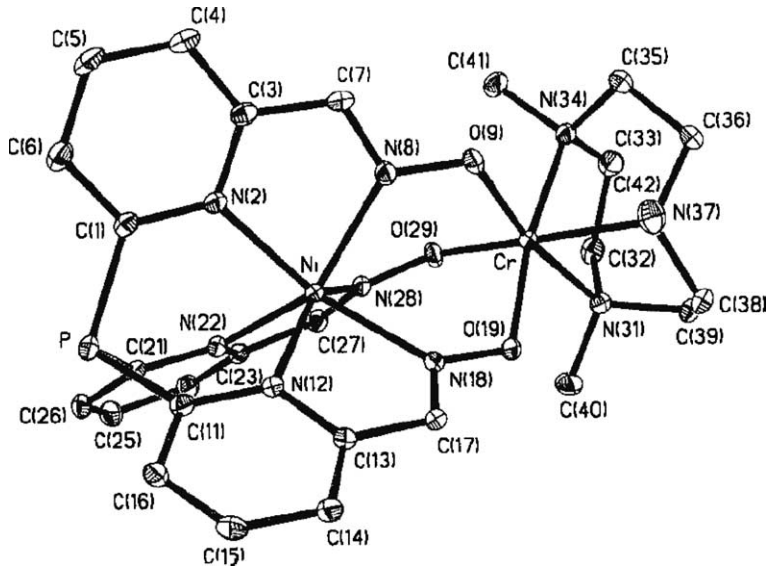


Fig. 100. X-ray structure of the cation $[LCr^{III}(P\{(py\text{-}H)CHNO\}_3)Ni^{II}]^{2+}$ in its perchlorate salt [68].

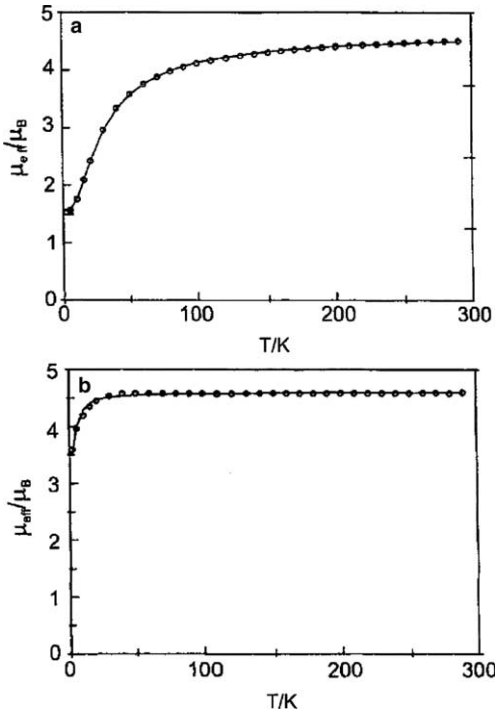

Fig. 101. Plots of μ_{eff} vs. T for solid $[LCr^{III}\{(py\text{-}H)CHNO\}_3Ni^{II}](ClO_4)_2$ (a) and $[LCr^{III}(P\{(py\text{-}H)CHNO\}_3)Ni^{II}](ClO_4)_2$ (b). The solid lines represent the best fit of the data to the Heisenberg-Dirac-van Vleck model.

analogue $[LCr^{III}\{(py\text{-}H)CHNO\}_3Ni^{II}](ClO_4)_2$ exhibits (Fig. 101) a weak antiferromagnetic exchange interaction between the Cr^{III} and Ni^{II} ions ($J = -9.2$ cm^{-1}, $g_{Cr} = 2.0$, $g_{Ni} = 2.19$) and has an $S_t = 1/2$ ground state [68]. These two complexes are rare examples of weak antiferromagnetic or no coupling at all between Cr^{III} and Ni^{II}. Interestingly, most of the known Cr^{III}–Ni^{II} interactions in the literature are in accord with the predictions made nearly 35 years ago [215], namely ferromagnetic in nature.

10. Conclusions and perspectives

It is obvious from the preceding pages that, just over a half century since the first preparations of metal complexes of pyridyl oximes, the coordination chemistry of such ligands is an expanding field of great current interest. This chemistry is an area that has something for everyone: from smart synthetic inorganic chemistry to complexes (both polynuclear and polymeric) with aesthetically pleasant structures, and from high-spin molecules to single-chain magnets. For example, in the area of homo- and heterometallic polynuclear transition metal complexes we hope that this report illustrates what is possible through very simple coordination chemistry. The monoanions of simple 2-pyridyl oximes have fulfilled their promise as a source of polynuclear 3d-metal complexes with interesting structures and properties. The immense structural diversity of the complexes described here stems from the ability of the $(py)C(R)NO^-$ ligands to exhibit many distinct coordination modes (Figs. 8 and 68). Presumably, the presence of dissimilar donor atoms within these anionic ligands leads to this coordinative flexibility; however, their versatility was unexpected. Employment of carboxylates, β-diketonates and sulfates in the $(py)C(R)NO^-$ metal chemistry gives an extraordinary structural flexibility in the resulting mixed-ligand systems (“blends” [216]). The remarkable diversity of structures has prevented any guiding structural principles from being proposed. It is clear that the

pyridyloximato clusters do not correspond in a straightforward manner to fragments of common minerals or to polyhedral archetypes, but rather, display a richness of topology and nuclearity that is unpredictable but intriguing. In the area of molecular magnetism, the oximato group of the anionic pyridyl oximes can mediate exchange interactions of varying range, from weak and moderate ferromagnetic to strong antiferromagnetic. Although almost all of the complexes discussed in this report have been structurally characterized, our current knowledge of magnetostructural correlations is still poor. As also emphasized by Chaudhuri [6], the "irregular spin-state structure" approach, resulting from a particular spin topology, is more effective in obtaining high-spin molecules than the more rational approach of obtaining ferromagnetically coupled systems through the approach of the strict orthogonality of the magnetical orbitals of the interacting metal centers. An additional important chemical lesson of this report is that the activation of the oxime group of 2-pyridyl oximes by 3d-metal ions towards further reactions seems to be an emergent area of synthetic inorganic chemistry.

This area of research will undoubtedly continue to expand, given the relatively recent nature of the majority of references in this paper, and the numerous synthetic routes now documented for the isolation of pyridyloximato metal complexes. Obvious areas for further investigation include:

1. The chemistry of other 3d-metals, and second and third row transition metals with such ligands. The reactions of V, Cr and Fe sources with pyridyl oximes should be studied in detail, considering how interesting the magnetic properties of the products could be. For example, it is surprising that iron(II) and iron(III) pyridyloximato complexes have little been investigated; high-spin Fe^{III} ($S = 5/2$) complexes are promising candidates to obtain large S values in the ground state.
2. Studies of the chemistry of pyridyl oximes with the generally oxophilic lanthanide ions. Such studies are completely lacking.
3. Further studies of the chemistry of heterometallic pyridyloximato complexes. For example, 3d/4f clusters are extremely rare, and in the context of the recent discovery that such complexes can be single-molecule magnets [217–220], could be very interesting.
4. The use of pyridyl oximes in supramolecular systems; the published studies are interesting but, simultaneously, limited in number. Several pyridyl oximes can be proven versatile tools for supramolecular assembly of metal-containing supramolecular architectures and interesting building blocks for crystal engineering.
5. Studies of the reactivity of some known pyridyloximato complexes; such studies are lacking. The paramagnetism of many known compounds makes NMR a method of limited applicability, especially in case where some ligands are weakly bound, creating additional problems of fluxionality. Therefore, solution studies have been limited. The growing use of electrospray mass spectrometry suggests more may be done. According to our experience, there are several systems in which several clusters can be crystallized from very similar reaction mixtures, and an examination of which of these clusters is present in solution would be a step toward understanding how, and when, these complexes form.
6. The use of new pyridyl oximes in metal chemistry. Synthesizing new ligands will be challenging and may lead to novel properties. A characteristic example is provided by the polydentate ligand 1,10-phenanthroline-2,9-dicarbaldehyde dioxime (L), synthesized [221] as illustrated in Scheme 13. The attachment of two oxime groups to a metal-chelating, pyridyl-based ligand is an attractive way of developing the design of small metal complexes which are potentially able to hydrolyze the phosphodiester backbone of nucleic acids (chemical nucleases). The oximate group has been chosen because it can effectively act as a nucleophile endowed with nucleolytic activity [221]. The complexes of the monoanion of L are designed to interact with the initial negatively charged phosphate, and to promote hydrolysis of the phosphodiester P–O bond through nucleophilic attack on the P atom by one oximate group, the other oxime group stabilizing the leaving oxygen atom (Fig. 102).

Scheme 13. Synthesis of 1,10-phenanthroline-2,9-dicarbaldehyde dioxime (L) [221].

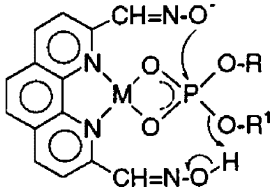

Fig. 102. Schematic representation of a model ternary metal ion/monoanion of L/phosphodiester system [221].

The results of the above proposed future investigations will be probably described in another polyhedron report.

Acknowledgments

The described work from our group is in the main based on the Ph.D. work of two of us (C.J.M., Th.C.S.) and eight talented scientists: Dr. Eugenia Katsoulakou, Dr. Eleanna Diamantopoulou, Dr. Elena Kefalloniti, Dr. Athanassios Boudalis, Constantina Papatriantafyllopoulou-Efthymiou, Gina Vlahopoulou, Konstantina Priggouri and Constantinos Stoumpos. We also acknowledge our longstanding collaboration with Dr. Aris Terzis, Dr. Catherine P. Raptopoulou and Dr. Vassilis Psycharis (NCSR "Demokritos", Athens) for X-ray crystallography, Dr. Vassilis Tangoulis and Dr. Nikolia Lalioti (University of Patras, Greece), Dr. Yiannis Sanakis (NCSR "Demokritos", Athens), Professors Albert Escuer and Ramon Vicente (University of Barcelona, Spain) for performing magnetic and EPR studies, Lecturer Panagiotis Kyritsis (University of Athens, Greece) for electrochemistry and Professor Evangelos G. Bakalbassis (University of Thessaloniki, Greece) for quantum-chemical calculations. We thank Professors George Christou (University of Florida, USA), Richard E.P. Winpenny (University of Manchester, UK), Dimitris Kessissoglou (University of Thessaloniki, Greece), and Lecturers Euan Brechin (University of Edinburgh, UK), Sarah L. Heath (University of Manchester, UK), Anastasios Tasiopoulos (University of Cyprus, Cyprus) for helpful discussions. Th.C.S. and S.P.P. are grateful to the European Social Fund (ESF), Operational Program for Educational and Vocational Training II (EPEAEK II), and particularly the Program PYTHAGORAS (Grant b.365.037), for funding our research efforts in the area of the pyridyloximato clusters. S.P.P. also thanks the Research Committee of the University of Patras (K. Caratheodory Program No. 03016) for support of our work on the coordination polymers of pyridyl oximes.

Abstract

The novel ligand *N*,*N*′-di(2-pyridyl)-2,4-diamino-6-phenyl-1,3,5-triazine (dpdapt) has been synthesized and the reactions of $CuCl_2 \cdot 2H_2O$ and $Cu(NO_3)_2 \cdot 8H_2O$ with the new ligand afforded two crystalline forms [Cu(dpdapt)Cl_2] (**1**) and [Cu(dpdapt)-(NO_3)(H_2O)] · NO_3 · H_2O (**2**), respectively. The molecular structures of **1** and **2** were established by single-crystal X-ray diffraction studies. The copper(II) atoms in complexes **1** and **2** are both five-coordinated in trigonal bipyramidal environments. In **1**, antiparallel dimers construct a two-dimensional supramolecular architecture by π–π stacking and hydrogen bonding, whereas **2** is connected by the same interactions to form a three-dimensional supramolecular framework. Quantum chemical calculations have been performed using Density Functional Theory (DFT) in order to gain some insight about the coordination behavior of dpdapt and complex **1**.

Keywords: Novel ligand; Copper(II) complexes; Crystal structure; Supramolecular compounds; DFT studies

1. Introduction

The crystal engineering of coordination polymers and supramolecular compounds has attracted considerable current attention, not only because of their fascinating structural diversities [1], but also for their potential applications in optical, electrical, magnetic and biological materials [2]. The design of suitable organic ligands is one of the important roles in the synthetic strategies for these polymers and supramolecular compounds [3]. The modified 1,3,5-triazine ligand 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tpt) [4] and several transition-metal complexes using the ligand tpt have been reported [5,6]. We have synthesized a novel modified 1,3,5-triazine ligand, *N*,*N*′-di(2-pyridyl)-2,4-diamino-6-phenyl-1,3,5-triazine (dpdapt). The ligand dpdapt is a versatile ligand like tpt, but with more diversity than 2,2,:6′,2″-terpyridine (tpy). Dpdapt, which functions as a tridentate or a bis-bidentate ligand, has gained our interest because of its use as a spacer for designing supramolecular complexes. Thus, dpdapt has its own coordination feature and functions primarily as a tridentate ligand (Scheme 1(a); *anti–anti–anti–anti*) forming complexes of the general type ($[Cu(dpdapt)]^{2+}$), as we described in this paper.

a. anti-anti-anti-anti b. syn-syn-anti-anti c. syn-syn-syn-syn

Scheme 1. Coordination modes of the ligand dpdapt.

The second coordination mode as a bis-bidentate ligand, including *syn–syn–anti–anti* (b) and *syn–syn–syn–syn* (c), is shown in Scheme 1. DFT studies have been applied to dpdapt. Theoretical calculations illuminate the coordination modes of the ligand.

Herein, we report the copper(II) complexes with dpdapt as a tridentate ligand. The crystal structures of the copper(II) complexes with the all-*anti* conformation of the chelating ligand are presented. Complex **1** consists of dimeric units, doubly bridged by π–π stacking and hydrogen bonding, thus forming an unusual 1-D ladder structure. Complex **2** self-assembles into a 1-D chain by hydrogen bonding and π–π stacking, and a 3-D layer structure which is sustained via hydrogen bonds. We also employed DFT studies to **1** and explained its coordination behavior.

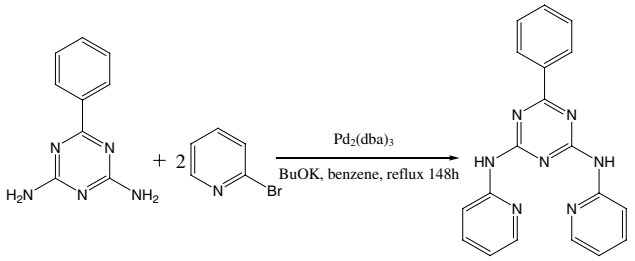
2. Experimental

2.1. Materials and physical measurements

Commercially available chemicals were reagent grade and were used without further purification. Infrared spectra on KBr pellets were recorded on a Nicolet 170SX FT-IR spectrophotometer in the range 4000–400 cm^{-1}. Elemental analyses were determined with a Perkin–Elmer model 240C instrument. Electronic spectra were recorded on a Cary 300 Bio UV–Vis spectrophotometer. FAB-MS mass spectra were obtained with a JEOL HX-110 HF double focusing spectrometer operating in the positive ion detection mode. Fluorescence experiments used a HITACHI F-4500 Fluorescence Spectrophotometer and were measured in methanol.

2.2. Synthesis of N,N′-di(2-pyridyl)-2,4-diamino-6-phenyl-1,3,5-triazine (dpdapt)

2,4-Diamino-6-phenyl-1,3,5-triazine (5.0 g, 26.7 mmol), BuOK (14.3 g, 127.7 mmol) and tris(dibenzylideneacetone)dipalladium ($Pd_2(dba)_3$) (2.0 g, 2.2 mmol) were added to a 200 ml flask under nitrogen. Then 100 ml dry benzene and 2-bromopyridine (14 g, 13.5 ml, 88.6 mmol) were injected into the former solid sequentially also under nitrogen. The resulting solution was stirred for 148 h under reflux. The product was filtered and washed three times each with methanol and water.



Dpdapt was obtained as a white powder in 64% yield (5.8 g). *Anal*. Calc. for $C_{19}H_{15}N_7$: C, 66.86; H, 4.399; N, 28.74. Found: C, 66.87; H, 4.328; N, 28.56%. IR (KBr, cm^{-1}): $v = 3025$(w), 2952(w), 1604(m), 1563(w), 1496(s), 1425(s), 1364(m), 1307(m), 1244(w), 1194(w), 1047(w), 989(m), 934(w), 770(s), 729(m), 693(w). MS (FAB) *m*/*z* (%) 342.1 (dpdapt).

2.3. Synthesis of [Cu(dpdapt)Cl_2] (1)

A green solution was obtained by adding a methanol solution (10 ml) of $CuCl_2 \cdot 2H_2O$ (34.1 mg, 0.20 mmol) to a methanol suspension (15 ml) of dpdapt (75.0 mg, 0.22 mmol) and stirring for 4 h. Diffused in Et_2O, after filtering green needle-shaped crystals of **1** were produced. Yield: 56%. *Anal*. Calc. for $[Cu(C_{19}H_{15}N_7)Cl_2]$:C, 47.92; H, 3.152; N, 20.60. Found: C, 47.86; H, 3.185; N, 20.52%.

2.4. Synthesis of [Cu(dpdapt)(NO_3)(H_2O)] · NO_3 · H_2O (2)

A suspension of $Cu(NO_3)_2 \cdot 8H_2O$ (53.9 mg, 0.2 mmol) in 10 ml water was allowed to react with dpdapt (75.0 mg, 0.22 mmol) dissolved in 20 ml methanol. The resulting mixture was stirred for 3 h and the product was removed by filtration. After a few days, dark green crystals were obtained by diffusion in Et_2O. Yield: 48%. *Anal*. Calc. for $[Cu(dpdapt)(NO_3)(H_2O)] \cdot NO_3 \cdot H_2O$: C, 40.36; H, 3.363; N, 22.30. Found: C, 40.46; H, 3.385; N, 22.52%.

2.5. Crystal structures determination

X-ray diffraction data were collected on a BRUKER SMART APEX-II diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) for complexes **1** and **2**. The structures were solved by direct methods [7]. Then the structures were refined by the least-squares method using SHELXL-97 [8] with anisotropic temperature factors for all non-H atoms. Crystal data and structure refinement details are summarized in

Table 1. Selected bond lengths and bond angles are given in Table 2.

2.6. Computational details

The calculations were carried out using the GAUSSIAN-03 program suite [9], including optimized geometries, and calculation of vibrational frequencies were carried out at the B3LYP [10,11] level of theory. Mulliken population analysis was also performed under this method. We employed the 6-31G(d) basis set for H, C, N and Cl, and the LANL2DZ effective core potential (ECP) set of Hay and Wadt [12] for Cu. All of the results (structures and energies) from the DFT calculations are available as electronic supplementary information.

3. Results and discussion

3.1. Description of structures

The crystal structure of complex **1** reveals that the coordination geometry around the copper(II) atom is a distorted trigonal bipyramid with the dpdapt ligand existing in an all-*anti* configuration. The Cu(1) atom is coordinated by three nitrogen atoms (N(3) of triazine and N(5), N(1) of different pyridyls) with two additional chloride atoms resulting in five-coordinated geometry (Fig. 1). The Cu(1)–N(3) distance is 2.024(2) Å and the distance to the pyridyl donors N(5) and N(1) are 2.079(2) and 2.066(2) Å, respectively. The distance of Cu(1)–Cl(2) is 2.288(1) Å whereas Cu(1)–Cl(1) forms a long bond with a distance of 2.424(1) Å. The average Cu–N bond length is observed to be 2.056 Å while the average Cu–Cl bond length is 2.356 Å. The bond angles N(1)–Cu(1)–N(5) (124.53(7)°), N(5)–Cu(1)–Cl(1) (113.66(5)°) and N(1)–Cu(1)–Cl(1) (120.32(5)°) sum up approximately to 360° and the angle N(3)–Cu(1)–Cl(2) (177.41(5)°) is approximately 180°, so the coordinated geometry of Cu(II) may be described as distorted trigonal bipyramidal with Cu(1), N(1), N(5) and Cl(1) forming the equatorial plane and Cl(2), N(3) occupying the axial positions. The dihedral angle between the plane (Cu(1), N(1), N(5), Cl(1)) and the triazine plane is 86.7°.

Two molecules of **1** form an antiparallel dimer structure as a result of two N–H···Cl hydrogen bonds (Cl(1A)···N(4B) 3.258 Å, N(4A)···Cl(1B) 3.258 Å) which are symmetry related, then each dimer is linked

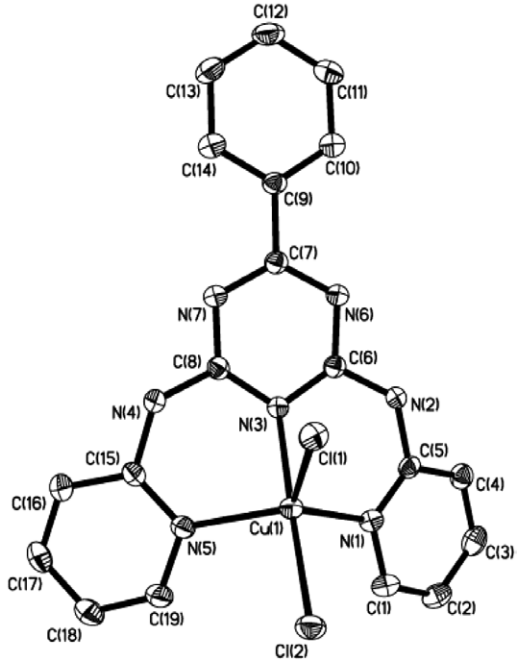

Fig. 1. The ORTEP drawing of Cu(dpdapt)Cl_2 (**2**). Thermal ellipsoids are drawn at the 50% probability level. Hydrogen atoms are omitted for clarity.

by face to face π–π stacking (3.461 Å) (between the triazine rings of two neighboring dimers) and two weak hydrogen bonds interactions (Cl···H–C 3.405 Å) forming a 1-D supramolecular ladder structure along the *c*-axis (Fig. 2). The structural characterization of such hydrogen-bonded dimeric structures linked by self-complementary donor/accepter groups is scarce for metal organic framework [13]. On the other hand, the 1-D supramolecular stacking in the *ab*-plane using N(2)–H···Cl(2) hydrogen bonds, thereby gives rise to a 2-D layer structure (Fig. 3).

Complex **2** has the same coordination configuration as **1**. The Cu(1) atom sits in a five-coordinated environment composed of three nitrogen donors (N(3) of triazine and N(5), N(1) of different pyridyls) with two different oxygen atoms, one (O(7)) from a water molecule, the other (O(5)) from a nitrate anion (Fig. 4). The bond distance to the terminal triazine N(3), (Cu(1)–N(3)) is 2.018(2) Å and the distance to the pyridyl donors N(5) (Cu(1)–N(5)) and N(1) (Cu(1)–N(1)) are 1.980(2) and 1.974(2) Å, respectively. The average Cu–N bond length is observed to be 1.990 Å, which is shorter than that of **1**. Both Cu–N bond lengths are typical of those found for the five–coordinate Cu(II)-μ-

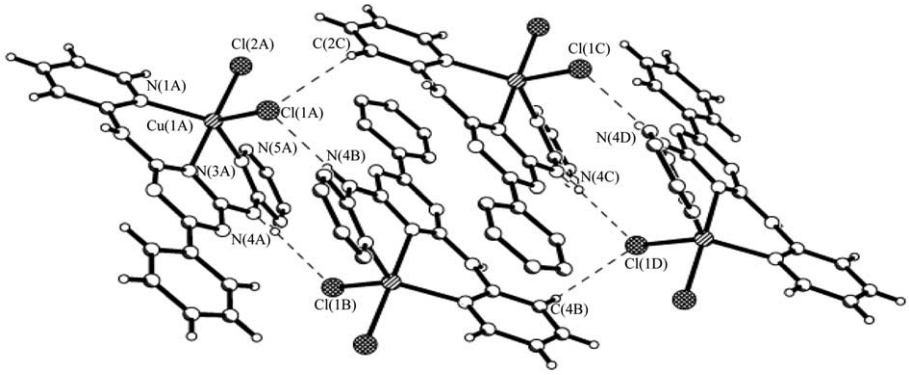

Fig. 2. The one-dimensional ladder structure of $[Cu(dpdapt)Cl_2]$ (**1**) formed by hydrogen-bonding interactions (dashed lines) and π–π stacking along the *c*-axis. Some hydrogen atoms are omitted for clarity.

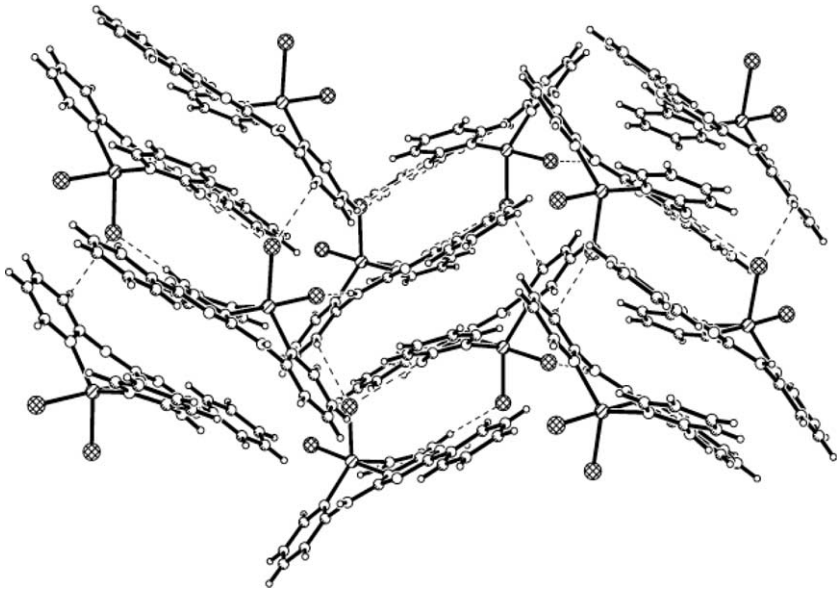

Fig. 3. The layer structure of $[Cu(dpdapt)Cl_2]$ (**1**).

pmea analogues [14]. The Cu(1)–O(7) distance is 2.225(2) Å and Cu(1)–O(5) is 2.114(3) Å. The coordination geometry of Cu(1) is also distorted trigonal bipyramidal with O(7), N(3), Cu(1) and O(5) in the equatorial plane and the apical sites are occupied by the N(1) and N(5) atoms of the pyridyl rings. The dihedral angle between the plane (Cu(1), O(5), O(7), N(3)) and the triazine ring plane is 85.8°.

The crystal framework testifies a one-dimensional chain along the *b*-axis with hydrogen bonds and π–π stacking interactions. As depicted in Fig. 5, the one-dimensional chains along the *b*-axis are formed by three different types of hydrogen bonds involving the coordinated molecular water, the coordinated nitrate anion and the non-coordinated nitrate anion (N(2A)–H···O(4B), 3.051 Å; O(7A)–H···O(1A), 2.815 Å; C(12B)–H···O(2A), 3.201 Å) as well as π–π stacking (3.345 Å) between the phenyl and pyridyl rings of two neighboring molecules. Moreover, the crystal structure consists of alternate layers with an antiparallel alignment of the molecules, and each layer is built up via solvent molecular interactions and hydrogen bonds in the *ac*-plane as shown in Fig. 6. The adjacent layers are interconnected by solvent molecules, resulting in a 3-D structure.

Although the structures of **1** and **2** exhibit the coordination character of dpdapt in part, the framework structures of **1** and **2** are scarce for inorganic triazine compounds. To the best of our knowledge, only one dimeric unit of a transition-metal complex based on tpt has been reported [6a], but no π–π interactions were discussed. Additionally, the ladder and layer frameworks of **1** and **2** are exclusive and structures of this type containing tpt have not been reported to date. The coordination of one metal ion, especially Cu(II), to tpt induces the hydrolysis of tpt [5,6]. Dinuclear metal complexes of tpt have also been described [6]. Although tpt has a more versatile coordination ability [6b] than

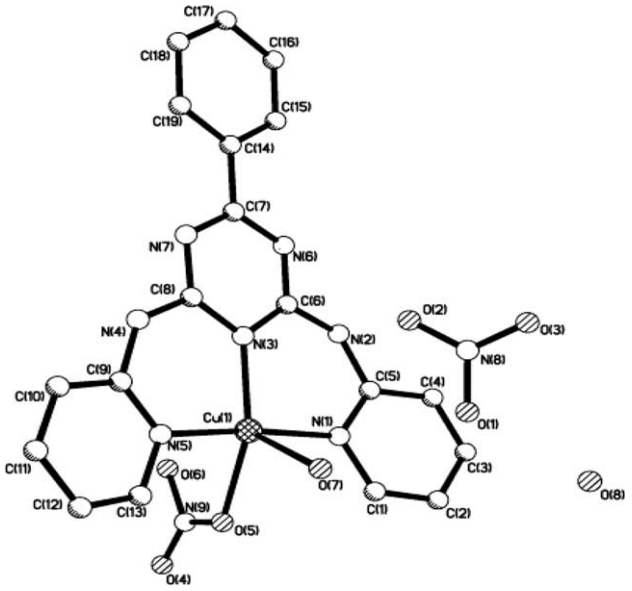

Fig. 4. Molecular structure of $[Cu(dpdapt)(NO_3)(H_2O)] \cdot NO_3 \cdot H_2O$ (**2**) Thermal ellipsoids represent the 50% probability surfaces. Hydrogen atoms are omitted for clarity.

dpdapt, in theory, the dpdapt ligand has its intriguing character revealed in this article.

3.2. Spectroscopic properties

The IR spectra of the complexes exhibit several characteristic strong bands. In complex **1**, the bands around 1425 and 1496 cm^{-1} in the ligand dpdapt, attributed to the C=N groups, are shifted to 1464 and 1570 cm^{-1}, respectively, confirming the involvement of dpdapt in the copper complexation. In complex **2**, the corresponding bands are shifted to 1580 and 1640 cm^{-1}. The bands corresponding to NO_3^- are at 1421, 1382, 1022 and 775 cm^{-1} and the broad band at 3290–3421 cm^{-1} represents the existence of $\nu(H_2O)$ in complex **2**.

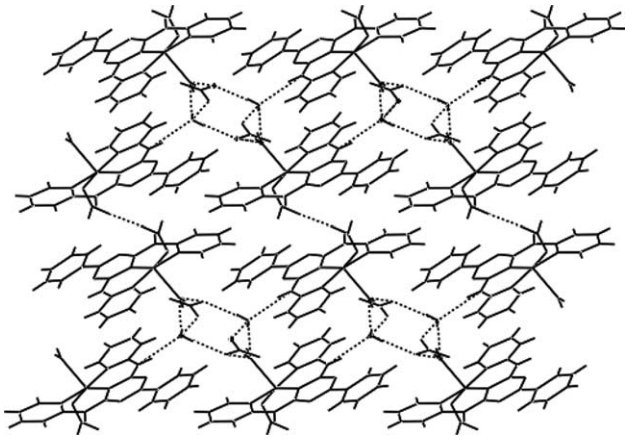

Fig. 6. Layer framework of $[Cu(dpdapt)(NO_3)(H_2O)] \cdot NO_3 \cdot H_2O$ (**2**) in the *ac*-plane.

The UV–Vis spectra of the complexes are recorded in methanol and are characterised by several spectral regions. The absorption bands in the region of 260 and 285 nm for the ligand dpdapt are ligand-centered (LC) due to π–π* transitions [15,16]. The shoulder at 300 nm for complexes **1** and **2** is due to a d–d transition and the low-energy bands at 341, 384 and 389 nm are assigned to metal-to-ligand charge transfer (MLCT) transitions [17,18].

The luminescence data were recorded in methanol at room temperature. The excitation–emission spectrum of dpdapt shows the strongest emission peak at 375.4 nm with the excitation peak at 330.0 nm. The emission band of dpdapt is attributed to the π*–n transitions. The strongest excitation peak for complex **1** is at 310.0 nm and for complex **2** at 300.0 nm, and their emission spectra show a main strong peak at 413.6 and 438.0 nm, respectively. These shoulder peaks of the emission spectra are probably due to the ligand-to-metal charge-transfer (LMCT) bands [19]. The strong fluorescent emissions of the dpdapt supramolecular complexes **1**

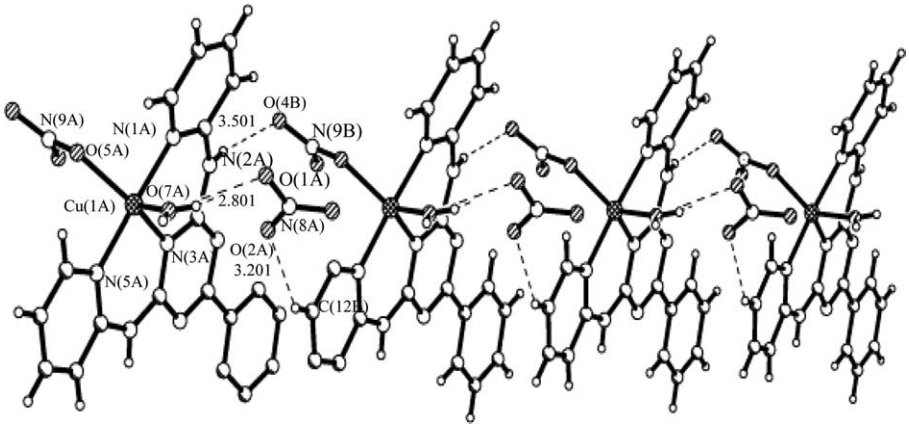

Fig. 5. The one-dimensional chain structure of $[Cu(dpdapt)(NO_3)(H_2O)] \cdot NO_3 \cdot H_2O$ (**2**) formed by hydrogen-bonding interactions (dashed lines) and π–π stacking along the *b*-axis. Some hydrogen atoms are omitted for clarity.

and **2** make them potentially useful photoactive materials.

3.3. Computational results and discussion

DFT calculations (B3LYP/6-31G(d)) have been carried out for the coordination conformations of dpdapt, and the optimized structures (verified by calculating the vibrational frequencies that result in the absence of imaginary eigenvalues) are shown in Fig. 7. The relative energies of each conformation given in this article include zero-point corrections (ZPE). $E_{anti\text{–}anti\text{–}anti\text{–}anti}$, $E_{syn\text{–}syn\text{–}anti\text{–}anti}$ and $E_{syn\text{–}syn\text{–}syn\text{–}syn}$ equal −1115.698749, −1115.700689 and −1115.699802 hartree, respectively. It is found that the energies of the conformers are similar, while the *syn–syn–anti–anti* conformer is the most stable by 5.09–2.33 kJ mol^{-1}. Complexes **1** and **2** exist with the ligand in the all-*anti* conformation. Clearly the free ligand, with its preferred *syn–syn–anti–anti* conformation, does not effect the conformation change in **1** and **2** because of its minimal energy difference.

Optimized geometries for **1** were verified by performing a frequency calculation. The optimized bond lengths and angles are presented in Table 2. In general, the calculated bond lengths and angles are in agreement with experimental crystal data and the large differences (∼0.2 Å, ∼3°) may be noticed for deviations around the central copper atoms. The deviations come mainly from two factors: one is that the theoretical calculations do not consider the effects of chemical environment (the complex is treated as a free molecule), and basis sets are still approximate to a certain extent. However, the coordination geometry of Cu(II) is also a distorted trigonal bipyramid. The bond angles N(1)–Cu(1)–N(5) (121.56°), N(5)–Cu(1)–Cl(1) (111.44°) and N(1)–Cu(1)–Cl(1) (124.77°) sum up approximately to 360° and the angle N(3)–Cu(1)–Cl(2) is 180°. So the results should be significant in computations of this large system.

The overlap populations (Table 3) between Cu(1) and Cl(1) (0.2663) is stronger than that of Cu(1)–Cl(2) (0.2275), which is consistent with the experimental result that the bond length of Cu(1)–Cl(2) is clearly longer than that of Cu(1)–Cl(1). The bond intensity order is Cu(1)–N(3) > Cu(1)–N(1) > Cu(1)–N(5) in accord with that in the experimental results (Cu(1)–N(5) > Cu(1)–N(1) > Cu(1)–N(3)). Because N(3) is coordinated to the center Cu atom, the populations of N(3)–C(6) and N(3)–C(8) are less than that of N(6)–C(7) and N(7)–C(8).

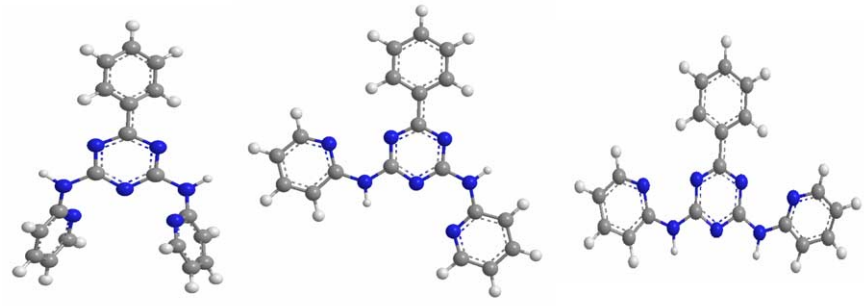
Table 3
Population analysis of **1**

Bond	
Cu(1)–Cl(1)	0.2663
Cu(1)–Cl(2)	0.2275
Cu(1)–N(3)	0.1236
Cu(1)–N(1)	0.1123
Cu(1)–N(5)	0.1065
N(3)–C(6)	0.2716
N(3)–C(8)	0.2790
N(6)–C(7)	0.3589
N(7)–C(8)	0.4484

The Mulliken charge of the central Cu metal (Table 4) changes from +2 to 0.275. Obviously, Cu has been coordinated by the ligand and its charge transfers to the ligand. The net atomic charge of the coordinated Cl(1), Cl(2), N(1), N(3) and N(5) atoms are negative. Compared to the dpdapt ligand (N(1), −0.259; N(3) and N(5), −0.438; N(6) and N(7), −0.353), the change in the charge distribution value of the donor nitrogen atoms (N(1), N(3), N(5)) are more than that of the non-coordinated nitrogen atoms (N(6), N(7)) in triazine.

Table 4
Mulliken atomic charges (e) for **1**

Atom	Charge
Cu(1)	0.275
Cl(1)	−0.397
Cl(2)	−0.383
N(3)	−0.498
N(5)	−0.518
N(1)	−0.545
N(6)	−0.432
N(7)	−0.437



a. anti-anti-anti-anti b. syn-syn-anti-anti c. syn-syn-syn-syn

Fig. 7. Optimized structures of dpdapt's coordination conformations.

Table 5
The energy (eV) and character of the selected molecular orbitals with α spins for **1**

Orbital	Energy	Character
HOMO − 3	−6.126	π(Cu–Cl), π(Cl)
HOMO − 2	−5.711	d_{xz}(Cu), π(Cl)
HOMO − 1	−5.472	d_{yz}(Cu), π(Cl)
HOMO	−5.364	d_{xy}(Cu), π(Cl)
LUMO	−3.096	π*(dpdapt), d_{xy}(Cu)
LUMO + 1	−1.989	π*(dpdapt)
LUMO + 2	−1.686	π*(dpdapt), d_{xy}(Cu)
LUMO + 3	−1.600	d_{z^2}(Cu)–σ(Cl)

All this data show strong complexation between Cu and its coordinated atoms.

The energies and characters of the selected MOs for **1** are presented in Table 5. According to molecular orbital theory, the frontier orbital and nearby molecular orbitals are the most important factors to the activity. The highest occupied molecular orbital (HOMO) and the nearby occupied molecular orbitals are prone to donate electrons, but the lowest unoccupied molecular orbital (LUMO) and the nearby unoccupied orbitals are prone to accept electrons. The more different the frontier orbitals are, the more stable the molecular structure is [20]. The copper d_π atomic orbitals (d_{xz},d_{yz} and d_{xy}) and π orbitals of the chlorine atoms make the main contributions into the HOMO − 2 , HOMO − 1 and HOMO. The LUMO orbital has predominantly π*(dpdapt) character. The results approved its coordination behavior and the value of ΔE ($\Delta E = E_{LUMO} - E_{HOMO}$) is 2.268 eV, which shows that the complex **1** can exist stably.

Appendix A. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 260645 for compound **1** and 260646 for compound **2.** Copies of this information may be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk). Supplementary data associated with this article can be found, in the online version at doi:10.1016/j.poly.2005.06.061.

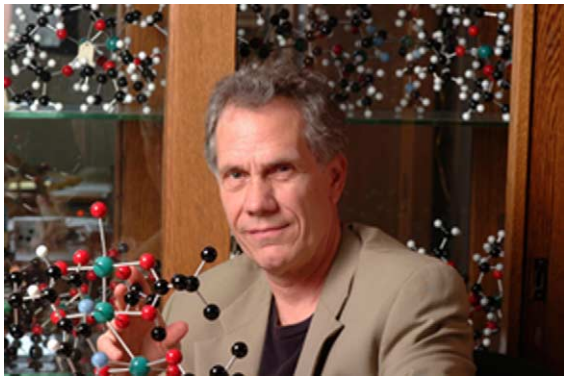
Preface



Professor Malcolm H. Chisholm

It gives me great personal pleasure to edit this special issue of *Polyhedron* dedicated to Professor Malcolm H. Chisholm on the occasion of his 60th birthday. Malcolm and I were inorganic chemistry colleagues at Indiana University for 17 years from 1983 to 2000, when he moved to Ohio State University. Those years in Indiana were extremely enjoyable for me and for everyone else associated with what by the late 1990s had become a top 10 inorganic division in the USA. A major reason for this was the presence there of Malcolm Chisholm and his research program. My memories of those years will always be of a very exciting, stimulating and intellectual environment with which it was a pleasure to be associated, and it had a great impact on the scientific education and training of a whole host of graduate students and postdoctoral associates from around the world.

Malcolm Chisholm has worked in transition metal chemistry his whole research career, which has been characterized by outstanding levels of creativity, innovation, and sheer quality over some four decades. But then what else could one expect from a scientist whose first paper as a young student, 'Iron Enneacarbonyl' was in *Nature* [1], and who has since been the author of 600 or so first-class publications. His Ph.D. advisor at Queen Mary College, London, was Professor Don Bradley, who recalls those early days:

"Malcolm joined my research group at Queen Mary as a Ph.D. student in the late 1960s when we were studying the dialkylamido compounds of the early transition metals, and he quickly provided a tremendous impetus to the programme. He obtained the tungsten hexadimethylamide and gave a sample to a (nameless!) crystallographer friend who accidentally dropped the flask spilling the precious contents on the bench. Seeing that the compound had not disappeared in a puff of smoke, Malcolm quickly scooped it up, fished out the fragments of glass, redissolved and recrystallized it, and grew a single crystal for the X-ray structure! Interestingly, a few years later when he was a faculty member at Princeton where he brilliantly developed the triple metal–metal bonded compounds, he showed that our hexadimethylamide was in fact a solid solution containing both tungsten hexadimethylamide and the ditungsten hexadimethylamide, which were remarkably close in structure due to the short W≡W triple bond. Malcolm had the ability to inspire everyone else in the lab to greater efforts and it became perceptibly quiet when he left to do postdoctoral research with Howard Clark in Canada. In addition to being a brilliant chemist, Malcolm is also a most friendly and generous spirited person with whom it was a privilege to be associated closely for a few exciting years".

Malcolm Chisholm has made great contributions to numerous areas of transition metal chemistry, and will always be particularly associated with the properties and reactivity of the Mo≡Mo and W≡W triple bonded compounds with dialkylamide or alkoxide ligands, truly seminal work that he began in the mid-1970s and which has greatly influenced the research of subsequent generations

doi:10.1016/j.poly.2005.11.003

of workers. However, his impact on the scientific community goes far beyond just his publication list. He has also given so much of himself to the selfless service of chemistry and to the cause of higher education through his numerous organizational and other activities for the American Chemical Society and the Royal Society of Chemistry, as well as for many other societies and individual universities around the world. His well-deserved awards are too numerous to list here, but include the prestigious Royal Society of Chemistry Ludwig-Mond Lectureship for the year 2000, and election as both Fellow of the Royal Society of the UK, and member of the National Academy of Sciences of the USA.

One issue of a journal is a sadly limited forum, but nevertheless I have attempted as far as possible to have this special issue of *Polyhedron* reflect the great respect that Malcolm commands throughout the world. This issue certainly contains contributions from some of his many ex-students, and from ex-colleagues such as myself, but there are also many others who gladly and indeed eagerly accepted my invitation to participate as a means to show their great admiration for the man and his chemistry. There is no unifying scientific theme to the issue, other than that the papers are all dedicated to Malcolm Chisholm, who was also Executive Editor for the Americas/Symposia-in-Print Editor of Polyhedron from 1983 to 1997. On behalf of all of these authors, and indeed the scientific community as a whole, I wish him a Happy 60th Birthday, and many more years of success in his future scientific endeavors.

Abstract

Reaction of $CeCl_3$ with an excess of LiTMP (TMP-H = 2,2,6,6-tetramethylpiperidine) gave $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$. The alkoxide ligand originated from THF, which was used as the solvent in the reaction. $CeCl_3$ reacted with 3 equiv. of LiTMP in THF to produce, after crystallization, a 3:2 crystalline mixture of $Ce(TMP)_3$ and $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$. $Ce(TMP)_3$ could not be isolated cleanly or separated from the mixture except by handpicking the crystals under a microscope. The homoleptic amide complex $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ was obtained by reacting $CeCl_3(THF)_2$ with 3 equivalents of $LiN\text{-}t\text{-}Bu(SiMe_3)$. In the solid state, $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ is a dimer with a $Ce(\mu\text{-}OR)_2Ce$ four-member ring, while $Ce(TMP)_3$ and $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ are trigonal planar monomers. There is structural evidence to suggest the presence of a Ce–vinyl group interaction in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$.

Keywords: Cerium; Amide; Alkoxide

1. Introduction

The dialkyl amide complexes $Si(NMe_2)_4$, $Sn(NMe_2)_4$, $Zr(NEt_2)_4$, $Ta(NMe_2)_5$, and $Zn(TMP)_2$ (TMP-H = 2,2,-6,6-tetramethylpiperidine) have been used as precursors to silicon, tin, zirconium, tantalum, and zinc oxide thin films, respectively [1–4]. We were interested in synthesizing cerium alkyl amide complexes for possible use as precursors to cerium oxide films. In this paper, we describe the syntheses and X-ray crystal structures of two homoleptic cerium alkylamide complexes and $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$, a complex derived from the decomposition of THF solvent.

A limited number of neutral lanthanide tris(alkylamide) derivatives have been reported previously. The first report appears to be from 1976 when Bradley and co-workers [5] described the synthesis of $Yb(N\text{-}i\text{-}Pr_2)_3$ and $Nd(N\text{-}i\text{-}Pr_2)_3(THF)$. Almost 20 years later, $Nd(N\text{-}i\text{-}Pr_2)_3(THF)$ was prepared as part of mixture with the related lithium "ate" complex, and the neutral complex was partially structurally characterized [6]. Aspinall and Tillotson [7] reported the preparation of the analogous Yb complex, $Yb(N\text{-}i\text{-}Pr_2)_3(THF)$, and Gambarotta and co-workers [8] synthesized and structurally characterized $Sm(NCy_2)_3(THF)$. Finally, Lappert and co-workers [9] described the preparation of $Ce(TMP)_3(THF)$. In the same paper, they also reported the preparation of $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ from the apparent decomposition of diethyl ether solvent, which is an observation relevant to this study.

2. Results and discussion

2.1. Synthetic studies

The reaction of $CeCl_3$ with 5 equiv. of LiTMP (TMP-H = 2,2,6,6-tetramethylpiperidine) in THF produced $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ in high yield.

Proposed mechanisms for the formation of $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ involving fragmentation of the solvent THF are presented in Scheme 1. Evans et al. [10] prepared similar lanthanide complexes $[Ln(\mu\text{-}OCH{=}CH_2)(C_5H_4R)_2]_2$ (R = H, CH_3; Ln = Lu, Yb) by reacting $LiOCH{=}CH_2$ with $[(C_5H_4R)_2LnCl]_2$. They also prepared $[Yb(\mu\text{-}OCH{=}CH_2)(C_5H_5)_2]_2$ by thermolysis of $[(C_5H_5)_2YbCH_3]_2$ in the presence of LiCl and THF. In the latter case, they proposed a mechanism for formation of the alkoxide complexes involving metallation of THF. More recently, Lappert et al. [9] prepared $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ by stirring $Ce(TMP)_3(THF)$ with diethyl ether. In this case, the ethoxide ligand was proposed to result from cleavage of diethyl ether with formation of TMP-Et. Alternative plausible mechanistic routes for the cleavage of diethyl ether could involve deprotonation of coordinated ether (at the γ position, $EtOCH_2CH_3$) with formation of TMP-H, ethylene, and an ethoxide ligand (i.e., mechanistic routes analogous to those in Scheme 1).

The reaction of $CeCl_3$ with 3 equiv. of LiTMP (rather than 5 equiv.) in THF produced a mixture of $Ce(TMP)_3$ and $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ in an approximate ratio of 3:2, as determined by examination of the crystalline mixture under a microscope. The use of $CeCl_3(THF)_2$ in place of $CeCl_3$ in this reaction failed to produce $Ce(TMP)_3$, $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$, or any other crystalline products. Attempts to prepare $Ce(TMP)_3$ cleanly by using less than 3 equiv. LiTMP per Ce ion in the reaction, decreasing the reaction temperature, or letting the reactants stir for one week failed. The closely related complex $Ce(TMP)_3(THF)$ was obtained by Lappert et al. [9] by reacting $Ce(OTf)_3$ (TfO-H = triflic acid) with KTMP and crystallizing from hexane/THF.

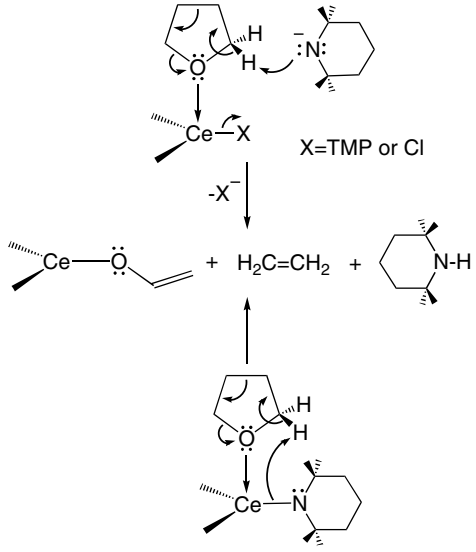
Yellow crystalline needles of $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ were obtained by reacting $CeCl_3(THF)_2$ with 3 equiv. of $LiN\text{-}t\text{-}Bu(SiMe_3)$ in THF (Eq. (1)). The analogous samarium complex $Sm[N\text{-}t\text{-}Bu(SiMe_3)]_3$ was prepared previously by following a similar procedure [11]. A problem with the cerium preparation was the presence of an unidentified amorphous brown solid that always accompanied the yellow crystals of the product. Despite repeated purification attempts, $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ could not be isolated free of these contaminants and, consequently, a satisfactory carbon elemental analysis was not obtained for $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$. Attempts to prepare $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ in better yield or more cleanly by varying the reaction temperature or using fewer or more equivalents of $LiN\text{-}t\text{-}Bu(SiMe_3)$ per Ce ion in the reaction were also not successful. An attempt to carry out the reaction in diethyl ether at 70 °C in a pressure flask resulted in the isolation of an unidentified waxy red solid and yellow crystalline needles of $[Ce(\mu\text{-}OEt)\{N\text{-}t\text{-}Bu(SiMe_3)\}_2]_2$ (as identified by X-ray crystallography).

$$CeCl_3(THF)_2 + 3LiN\text{-}t\text{-}Bu(SiMe_3) \rightarrow Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3 + 3LiCl + 2THF \quad (1)$$

The complexes $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$, $Ce(TMP)_3$, and $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ are soluble in hexanes and toluene. They decomposed rapidly with formation of brown solids during attempted sublimations.

2.2. X-ray crystallographic studies

The X-ray structures of $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ and $Ce(TMP)_3$ were determined (Figs. 1 and 2, respec-



Scheme 1. Possible mechanisms to explain the formation of the alkoxide ligand in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ from THF.

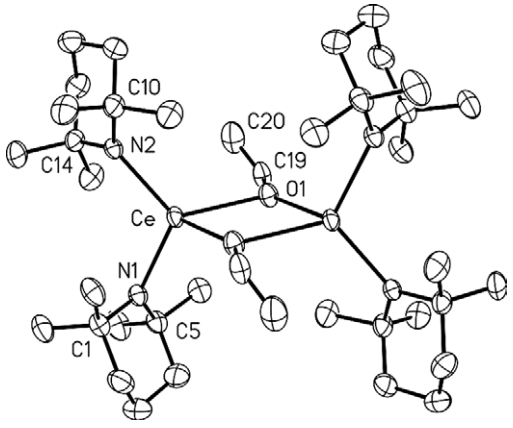


Fig. 1. View of the $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ molecule showing the atom-numbering scheme. Thermal ellipsoids are 40% equiprobability envelopes, with hydrogen atoms omitted.

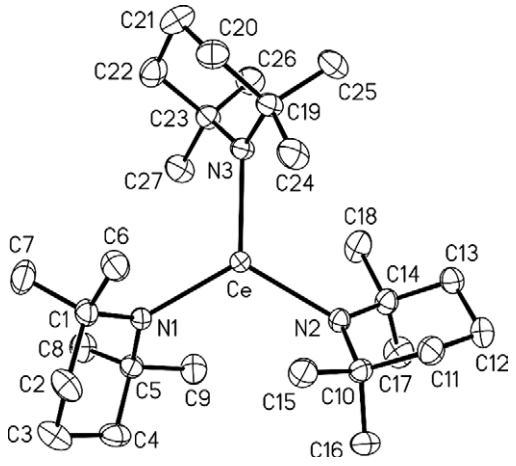

Fig. 2. View of the $Ce(TMP)_3$ molecule showing the atom-numbering scheme. Thermal ellipsoids are 40% equiprobability envelopes, with hydrogen atoms omitted. One position of the disordered Ce atom is shown.

tively). Selected bond distances and angles are presented in Table 1. The $Ce(TMP)_3$ complex is isostructural with $La(TMP)_3$ [12]. Preliminary data indicated that $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ was isostructural with $Sm[N\text{-}t\text{-}Bu(SiMe_3)]_3$ [13]; therefore, a full data collection and refinement were not performed for $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$.

The asymmetric unit of $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ consists of one-half of a dimer situated about an inversion center. The coordination geometry around Ce can be described as trigonal pyramidal with O1′ in the apical position and N1, N2, and O1 defining the trigonal plane (Ce is displaced 0.28 Å from the plane; see Drawing I). The $Ce–O_{bridge}–C$ angles are significantly different (Ce′–O1–C19 = 147.9(2)° versus Ce–O1–C19 = 100.7(2)°). The wide Ce′–O1–C19 angle allows the vinyl group (C19 and C20) to approach Ce trans to the O1′ position, resulting in Ce–C19 and Ce–C20 distances of 3.03 and 3.27 Å, respectively. These distances, along with the distorted Ce coordination geometry, suggest the possibility of a weak vinyl group to cerium donor–acceptor interaction. The Ce–C19 and Ce–C20 distances are long, however, compared to Ce–C bonds such as those in cerium cyclopentadienyl complexes ($Ce–C_{Cp} = 2.74–2.84$ Å) [14,15], and the C19–C20 distance (1.309(6) Å) in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ is not lengthened compared to a normal C–C double bond as might be expected if there were an interaction with cerium. Conversely, the Ce–C19 and Ce–C20 distances may be as short as the geometric constraints of the bridging ligand will allow, and the vinyl C–C distance may appear shortened because a libration correction was not applied [16].

Relevant to the question of whether there is an interaction between the Ce and vinyl group are the structures of $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ [9], a molecule that differs only slightly in composition from $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$, and $[Ce(\mu\text{-}OSiPh_3)(OSiPh_3)_2]_2$ (Drawing II) [17]. The complex $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ shows none of the distortions discussed for $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ (i.e., $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ has a normal edge-shared tetrahedral geometry and the ethyl substituent on oxygen does not approach Ce). By contrast, in $[Ce(\mu\text{-}OSiPh_3)(OSiPh_3)_2]_2$ one of the phenyl substituents on Si bends towards Ce to allow for the interaction of three phenyl carbon atoms with Ce ($Ce–C_{phenyl} = 2.97–3.26$ Å and O1–Si1–C13 = 102°). The apparent interaction between the Ce and the phenyl group results in structural distortions analogous to those discussed for $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ (e.g., in $[Ce(\mu\text{-}OSiPh_3)(OSiPh_3)_2]_2$ the atoms Ce, O1, O2, and O3 lie in a plane and the Ce–O1–Si angles are significantly different, 110° versus 144°, to accommodate the cerium–phenyl group interaction). In both $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ and $[Ce(\mu\text{-}OSiPh_3)(OSiPh_3)_2]_2$ there are two short and two long (shown as open rods in I and II) Ce–O bonds, whereas in $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ the ethoxide ligands are symmetrically bonded between the Ce atoms. The asymmetry in Ce–O bond distances in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ and $[Ce(\mu\text{-}OSiPh_3)(OSiPh_3)_2]_2$ allow the vinyl and phenyl substituents, respectively, to approach the Ce atom at a more favorable angle. The undistorted structure of $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ and the similar pattern of distortions observed for both $[Ce(\mu\text{-}OSiPh_3)(OSiPh_3)_2]_2$ and $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ support the notion of a cerium–vinyl interaction in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$.

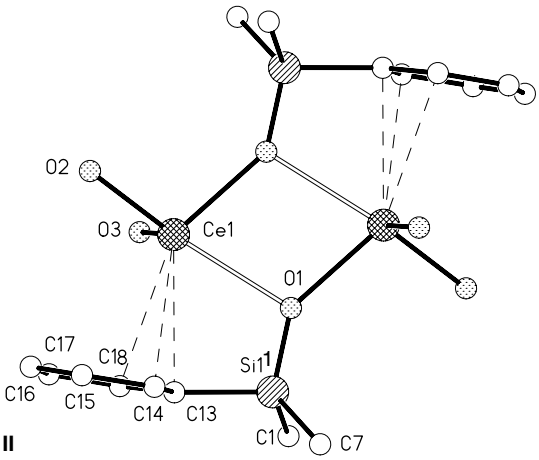
I



II

The three-coordinate amide complexes $Ce(TMP)_3$, and $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ are trigonal planar, resembling closely the structures of $Ln[N(SiMe_3)_2]_3$ (Ln = Ce, Nd, Eu, Dy, Er, and Yb) [18–22]. The Ce–N distances in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ and $Ce(TMP)_3$ range from 2.298(3) to 2.346(7) Å, with the longest distance found in the sterically congested monomer $Ce(TMP)_3$. These Ce–N distances are similar to those found in $[Ce(\mu\text{-}OEt)(TMP)_2]_2$ (average 2.333(2) Å) and $Ce(TMP)_3(THF)$ (average 2.361(2) Å) [9].

3. Summary

The cerium amide complexes $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$, $Ce(TMP)_3$, and $Ce(N\text{-}t\text{-}BuSiMe_3)_3$ were synthesized. The alkoxide ligand in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ was derived from the THF solvent used in the synthesis. $Ce(TMP)_3$ could not be separated from $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$. The motivation for this study was the possible use of cerium amide complexes as chemical vapor deposition precursors to cerium oxide films. None of the new compounds were found to be suitable precursors: $Ce(TMP)_3$ was not isolated cleanly, and upon heating, all of the compounds decompose before they are vaporized.

4. Experimental

4.1. Synthesis

4.1.1. General considerations

All manipulations were carried out in a glove box or by using Schlenk techniques. The solvents were purified according to standard methods and stored until needed in the glove box over molecular sieves. The amines were purchased from Aldrich and distilled over CaH_2 before use. $CeCl_3$ was purchased from Strem and used as received. The preparation of $CeCl_3(THF)_2$ was based on the literature method [23]. Midwest Microlab, LLC, Indianapolis, IN USA performed the chemical analyses.

4.1.2. Synthesis of complexes

4.1.2.1. $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$. To a milky white slurry of $CeCl_3$ (0.20 g, 0.76 mmol) in THF (15 mL), LiTMP (0.57 g, 3.9 mmol) was added slowly. The mixture turned yellow immediately after the addition began. After 12 h of stirring, the mixture was dark red. The THF was removed under vacuum to yield a yellow solid. The solid was extracted with hexanes (3×15 mL) and the extracts were filtered over Celite. The yellow filtrates were combined and the solution was concentrated under vacuum to 4 mL. The flask was placed in the freezer (−35 °C). After 16 h, yellow crystalline plates had formed, which were isolated and dried under vacuum (Yield: 0.28 g, 0.30 mmol, 79%). *Anal.* Calc. for $C_{40}H_{78}N_4O_2Ce_2$: C, 51.77; H, 8.48; N, 6.04. Found: C, 51.42; H, 8.34; N, 5.94%. IR (Nujol, NaCl, cm^{-1}): 1591 s, 1396 w, 1356 m, 1336 m, 1307 s, 1284 s, 1228 m, 1191 w, 1170 m, 1120 m, 1070 w, 1043 s, 1002 s, 973 m, 956 w, 935 w, 875 m, 850 s, 825 s.

4.1.2.2. $Ce(TMP)_3$. To a milky white slurry of $CeCl_3$ (0.20 g, 0.8 mmol) in THF (15 mL), LiTMP (0.36 g, 2.4 mmol) was added slowly. The mixture turned yellow immediately after the addition began. After 12 h of stirring, the mixture was dark red. The THF was removed under vacuum to yield an orange-red solid. The solid was extracted with hexanes (3×15 mL), and the extracts were filtered over Celite. The orange filtrates were combined and concentrated under vacuum to 4 mL, and the flask was placed in the freezer (−35 °C). After 16 h, a mixture of crystalline orange-red columns and yellow plates had formed, which were isolated and dried under vacuum (Yield 0.36 g). The orange-red columns and yellow plates were determined to be $Ce(TMP)_3$ and

$[Ce(TMP)_2(\mu\text{-}OCH{=}CH_2)]_2$, respectively, by X-ray crystallographic analysis. A ratio of approximately 3:2, $Ce(TMP)_3$ to $[Ce(TMP)_2(\mu\text{-}OCH{=}CH_2)]_2$, was determined from an examination of the crystalline mixture under a microscope. IR (Nujol, NaCl, cm^{-1}): 1591 s, 1556 w, 1396 m, 1350 s, 1305 s, 1284 s, 1232 s, 1184 s, 1170 s, 1128 s, 1070 m, 1054 s, 1010 s, 974 s, 954 m, 937 m, 908 m, 883 s, 848 s, 825 s.

4.1.2.3. Ce[N-t-Bu(SiMe$_3$)]$_3$. To a solution of $CeCl_3(THF)_2$ (0.30 g, 0.77 mmol) in THF (20 mL), LiN-*t*-Bu($SiMe_3$) (0.36 g, 2.4 mmol) was added slowly. The mixture was stirred for 14 h after the addition was completed. The THF was removed under vacuum from the reaction mixture to yield a yellow solid. The solid was extracted with hexanes (2 × 15 mL), and the extracts were filtered over Celite. The filtrates were combined and concentrated under vacuum to 4 mL, and the flask was placed in the freezer (−35 °C). After 14 h yellow crystalline needles had formed, which were isolated and dried under vacuum (Yield: 0.34 g, 0.59 mmol, 77%). A satisfactory carbon analysis was not obtained despite repeated attempts to do so. The best analysis is reported here. *Anal.* Calc. for $C_{21}H_{54}N_3Si_3Ce$: C, 44.01; H, 9.50; N, 7.33. Found: C, 44.98; H, 9.30; N, 7.29%. IR (Nujol, NaCl, cm^{-1}): 1356 s, 1240 s, 1190 s, 1037 s, 1012 s, 916 m, 890 m, 856 m, 820 m, 759 s, 692 s, 661 m, 646 m, 613 s.

$R_1 = \sum ||F_o| - |F_c|| / \sum |F_o|; wR_2 = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$.

4.2. X-ray crystallography studies

X-ray crystallographic data were collected for yellow plates of $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ and orange-red columns of $Ce(TMP)_3$ that were hand picked from a crystalline mixture grown from a cold (−35 °C) hexanes solution. All measurements were made with a Siemens SMART platform diffractometer equipped with a 1 K CCD area detector. Crystal data are presented in Table 2. In $Ce(TMP)_3$, the Ce atom is disordered 50:50 over two positions separated by 0.23 Å along a virtual C_3 axis.

5. Supplementary material

Crystallographic data for $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ and $Ce(TMP)_3$ have been deposited with the Cambridge Crystallographic Data Center as CCDC-242597 and 242598, respectively. These data can be obtained free of charge by contacting The Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [fax: + 44 1223 336033, e-mail: deposit@ccdc.cam.ac.uk, or www at http://www.ccdc.cam.ac.uk].

Synthesis and molecular structure of mixed alkyne-cyclopentadienyl clusters via the ionic coupling of $[Os_3(CO)_9(R_2C_2)]^{2-}$ with $[Ru(\eta^5\text{-}C_5H_5)(MeCN)_3]^+$ and the reaction $[Os_3RuH(\eta^5\text{-}C_5H_5)(CO)_{10}(MeCN)]$ with alkynes (R_2C_2) (R = Me, Ph)

Dedicated to Professor Malcolm Chisholm in recognition of this outstanding contribution to inorganic chemistry.

Abstract

The ionic coupling reaction of the dianion $[Os_3(CO)_9(R_2C_2)]^{2-}$ (R = Me, Ph) with two equivalents of the monocation $[Ru(\eta^5\text{-}C_5H_5)(CH_3CN)_3]^+$ affords the neutral clusters $[Os_3Ru_2(CO)_9(R_2C_2)(\eta^5\text{-}C_5H_5)_2]$ [R = Me, **1** and R = Ph, **2**] in ca. 80% yield. An X-ray crystallographic study of **1** confirms that these clusters exhibit a capped pseudo-octahedral $Os_3Ru_2C_2$ core, with the alkyne bonded parallel to the hinge bond of the capped butterfly metal geometry in a μ_4–η^2 manner, the Ru atoms adopting the wing-tip and capping positions. Reaction of the activated cluster $[Os_3RuH(\eta^5\text{-}C_5H_5)(CO)_{10}(MeCN)]$ (**3**) with RCCR (R = Me, Ph) affords the related clusters $[Os_3RuH(CO)_9(\eta^5\text{-}C_5H_5)(R_2C_2)]$ (R = Me, **4** and R = Ph, **5**) in ca. 35% yield. The reaction with PhCCPh also produces $[Os_3Ru(CO)_8(\eta^5\text{-}C_5H_5)(PhCCPh)(PhCC(H)Ph)]$ (**6**) in ca. 15% yield. An X-ray crystallographic study shows that this cluster has a pseudo-octahedral Os_3RuC_2 core, with the $Ru(\eta^5\text{-}C_5H_5)$ unit adopting the wing-tip position, the alkyne bonded in a μ_4–η^2 arrangement and the ethenyl ligand bridging an Os–Os edge in a μ_2–η^1:η^2 configuration.

Keywords: Osmium; Ruthenium; Cluster carbonyl; Alkyne; X-ray crystal structure

1. Introduction

The chemistry of alkyne-substituted metal clusters has developed extensively over the last four decades and remains a central theme of cluster chemistry [1,2]. The earliest studies were concentrated in the area of late transition metal cluster carbonyls, but Chisholm, in an elegant series of studies, has been responsible for extending the chemistry to include earlier transition elements to form polynuclear complexes stabilised by π-donor ligands [3]. Now, for both early and late alkyne-substituted polynuclear metal complexes there is an interest in generating mixed-metal species, and this paper provides an example of the synthesis and characterisation of mixed-osmium and ruthenium alkyne-substituted clusters.

Studies have shown that osmium and mixed osmium/ruthenium clusters with both arene and alkyne ligands may be synthesised via two principal routes, either ionic coupling of an Os-alkyne cluster dianion with a mononuclear Ru or Os arene cation [4,5] or reaction of an acetonitrile-activated Os arene cluster with an alkyne [5]. The ionic coupling method provides a high-yield route to the sythesis of the butterfly clusters $[Os_3M(C_6H_6)(RCCR')(CO)_9]$ from the dianions $[Os_3(CO)_9(RCCR')]^{2-}$ with $[M(\eta^6\text{-}C_6H_6)(CH_3CN)_3]^{2+}$, where M = Ru or Os, R, R′ = Me or Ph [4,5]. In these clusters, the Os_3MC_2 unit adopts a quasi-octahedral arrangment with a formal valence electron count of 66, and the arene ligand is η^6-coordinated in the wing-tip position. The Os clusters $[Os_4(C_6H_6)(RCCR')(CO)_9]$ (R = R′ = Me; R = Me, R′ = Ph) may also be prepared in lower yield via the reaction of $[Os_4H_2(CO)_9(\eta^6\text{-}C_6H_6)(CH_3CN)]$ with the respective alkyne RCCR′ [5]. However, with Ph_2C_2, the arene ligand is displaced and the major product is the alkyne cluster $[Os_4H_2(CO)_9(PhCCPh)_2]$ [5,6].

Similarly, heating the cyclopentadiene complexes $[PPh_4][MRu_3(CO)_{12}(\eta^5\text{-}C_5H_5)]$ (where M = W or Mo) with the alkynes, MeCCMe or PhCCH, under reflux in THF gave products of the type $[PPh_4][MRu_3(CO)_{10}(\eta^5\text{-}C_5H_5)(RCCR')]$ (where M = W or Mo) in which the MRu_3C_2 unit forms the same quasi-octahedral arrangement [7]. However, in these structures the $M(\eta^5\text{-}C_5H_5)$ unit was found in the hinge position of the butterfly regardless of the alkyne employed. More recently, it has been shown that the mixed-metal cluster $[Os_3Rh(\mu_3\text{-}H)_3(CO)_9(COD)]$ (COD = cycloocta-1,5-diene) reacts with Ph_2C_2 at 60 °C with the loss of the COD ligand and insertion of a diphenylacetylene ligand into an Os–Rh bond to generate the cluster $[Os_3Rh(CO)_{10}(\mu_4\text{–}\eta^2\text{-}Ph_2C_2)(\mu_2\text{–}\eta^1\text{:}\eta^2\text{-}PhCC(H)Ph)]$ [8] with a pseudo-octahedral Os_3RhC_2 core and the Rh atom in the wing-tip position.

We have shown recently that either one or two $Ru(\eta^5\text{-}C_5H_5)$ units may be added to Os cluster anions via ionic coupling with $[Ru(\eta^5\text{-}C_5H_5)(CH_3CN)_3]^+$ [9–13]. In this paper, we extend these studies to include a discussion of the ionic coupling reaction of $[Os_3(CO)_9(RCCR')]^{2-}$ with the monocation $[Ru(\eta^5\text{-}C_5H_5)(CH_3CN)_3]^+$. The reactivity of $[HOs_3Ru(\eta^5\text{-}C_5H_5)(CO)_{10}(MeCN)]$ with alkynes, as an alternative route to mixed alkyne/cyclopentadienyl clusters, is also investigated.

2. Results and discussion

2.1. Reaction of alkyne-substituted triosmium cluster anions with $[Ru(\eta^5\text{-}C_5H_5)(CH_3CN)_3][PF_6]$

The ionic coupling reaction between the dianion $[Os_3(CO)_9(R_2C_2)]^{2-}$ (where R = Me or Ph) and two equivalents of the monocation $[Ru(\eta^5\text{-}C_5H_5)(CH_3CN)_3]^+$ (as its PF_6^- salt) affords the neutral clusters $[Os_3Ru_2(CO)_9(R_2C_2)(\eta^5\text{-}C_5H_5)_2]$ [R = Me, **1** and R = Ph, **2**] in high yield (ca. 80%) upon separation by TLC using dichloromethane/hexane (1:1) as eluent (Scheme 1). Compounds **1** and **2** were characterised initially by spectroscopic methods (Table 1). The IR spectra of **1** and **2** are very similar, indicating that the structures are closely related. The singlets observed in the ^1H NMR spectrum

of complex **1** at δ 4.87 and 4.44 and of **2** at 4.92 and 4.41 may be assigned to two inequivalent η^5-coordinated cyclopentadienyl ligands. Similar chemical shifts have been observed for the cyclopentadienyl protons in other mixed Ru/Os clusters [9–13]. The singlet peak at δ 3.61 corresponds to the two methyl groups of the acetylene in cluster **1**, similarly the multiplet at δ 7.12 for **2** results from the resonance of the 10 phenyl protons. The molecular ion peak is observed in the mass spectra for both **1** and **2**, and the sequential loss of nine carbonyls is evident.

Slow evaporation from a dichloromethane/hexane solution of **1** gave single crystals suitable for a crystal structure determination (Table 2). The molecular structure is shown in Fig. 1, and relevant bond parameters are listed in Table 3. The metal framework in cluster **1** may be described as being based on a quasi-octahedral $RuOs_3C_2$ unit, the alkyne being σ-bonded to the hinge atoms Os(1) and Os(3) and π-bonded to Ru(1) and Os(2), with the Os_2Ru face capped by a second ruthenium atom Ru(2). A similar capped butterfly arrangement is exhibited by the alkyne cluster $[Ru_5(CO)_{11}(\mu_2\text{-}PPh_2)_2$-(cyclohex-1-yne-4-ene)] [14]. The dihedral angle of the metal butterfly (113°) is comparable to that in $[Os_3Ru$-$(C_6H_6)(MeCCMe)(CO)_9]$ (111°) [4], and the hinge Os(1)–Os(3) edge is longer than the hinge-tip Os(1)–Os(2) and Os(2)–Os(3) edges, as in the benzene cluster.

One of the cyclopentadiene ligands is symmetrically η^5-bound to the ruthenium atom in the ''wing-tip'' position, Ru(1), while the second is η^5-coordinated to the other ruthenium atom which is in the ''capping'' position, Ru(2). There are eight terminal carbonyls, three of which are coordinated to the Os(2) and Os(3) atoms, while two are associated with Os(1). A bridging carbonyl spans the Os(1)–Ru(2) edge, which is significantly shorter [2.634(3) Å] than the corresponding Os(3)–Ru(2) edge [2.877(4) Å]. It is thought that this bridging carbonyl assists the redistribution of electron density to the formally electron-deficient Ru(2) centre.

The structure is related formally to that of the trigonal bi-pyramidal cluster $[Os_3Ru_2(\eta^5\text{-}C_5H_5)(CO)_9(\mu_3$-$CO)_2]$ [10] by the loss of two carbonyl ligands and insertion of the alkyne into a Ru–Os bond. In both $[Os_3$-$Ru_2(\eta^5\text{-}C_5H_5)(CO)_9(\mu_3\text{-}CO)_2]$ [10] and $[Os_6Ru_2$-$(\eta^5\text{-}C_5H_5)(CO)_{15}(\mu_3\text{-}CO)_2(Au_2dppm)_2]$ [11], the μ_3-CO ligands can be rationalised on the basis of both Ru atoms being formally electron-deficient. In cluster **1**, Ru(2) is electron-precise and thus a different arrangement of carbonyl ligands is observed.

In terms of electron counting, an appropriate way to consider alkyne-substituted clusters is to include both the metals and the acetylenic carbons as the ''cluster core''. Using this approach polyhedral skeletal electron pair theory (PSEPT) [15] can be used to rationalise the cluster geometries. The initial cluster dianion $[Os_3(CO)_9$-$(RCCR)]^{2-}$ (R = Me, Ph) has 54 valence electrons and

[b] Goodness-of-fit $= [\sum [w(F_o^2 - F_c^2)^2]/(n-p)]^{1/2}$, where n is the number of reflections and p the number of parameters.

7 skeletal electron pairs for Os_3C_2 core bonding that is consistent with the *nido*-octahedral (square-based pyramidal) geometry. Similarly, clusters **1** and **2** have 78 valence electrons and 7 skeletal electron pairs for bonding in the $Os_3Ru_2C_2$ core. Thus, the seven core atoms are held by seven electron pairs consistent with the observed capped octahedral framework geometry.

2.2. Reaction of $Os_3RuH(CO)_{11}(\eta^5\text{-}C_5H_5)$ with alkynes

To activate $[Os_3RuH(CO)_{11}(\eta^5\text{-}C_5H_5)]$ [10] towards nucleophilic substitution, the acetonitrile derivative $[Os_3RuH(CO)_{10}(\eta^5\text{-}C_5H_5)(CH_3CN)]$ (**3**) was prepared by adding one equivalent of Me_3NO to an acetonitrile solution of $[Os_3RuH(CO)_{11}(\eta^5\text{-}C_5H_5)]$ [10]. After stirring for 0.5 h the solution was filtered and taken to dryness. The orange-red product was unstable in oxygen, and was therefore not isolated, but was formulated as the acetonitrile derivative **3** on the basis of IR spectroscopy (Table 1). An excess of the alkynes Me_2C_2 and Ph_2C_2, respectively, were added to a dichloromethane solution of the activated complex and the resultant mixture was stirred at room temperature for 24 h, after which an IR spectrum indicated total consumption of the starting material. Separation by TLC, using a dichloromethane/hexane (1:1) mixture as eluent, gave an orange-brown compound [R = Me, **4**; R = Ph, **5**] in approximately 35% yield for both reactions (Scheme 1). A second orange compound **6** was isolated, in 15% yield, in the Ph_2C_2 reaction. Other trace products in both reactions, could not be characterised because of their low abundance. The three new clusters **4**, **5** and **6** were fully characterised by IR and NMR spectroscopy (Table 1), and the complex **6** was also characterised by X-ray diffraction.

The molecular ion peaks in the mass spectra of **4** and **5** are consistent with the formulation $[Os_3RuH(CO)_9(\eta^5\text{-}C_5H_5)(R_2C_2)]$ (R = Me, **4** or R = Ph, **5**). The ^{1}H NMR spectra of **4** and **5** are similar, with a singlet peak in the region typical for η^5-coordinated cyclopentadiene

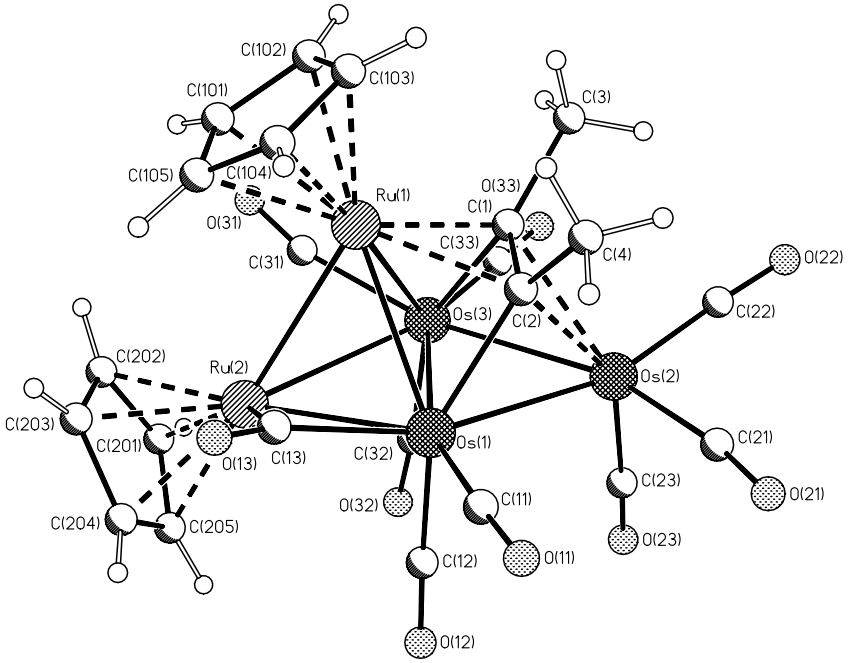

Fig. 1. The molecular structure of $[Os_3Ru_2(Me_2C_2)(CO)_9(\eta^5\text{-}C_5H_5)_2]$ (**1**).

ligands (δ 4.55 and 4.49, respectively) and a high-field hydride resonance (δ −22.69 and −20.33, respectively). In addition, the ^{1}H NMR spectrum of **4** shows a singlet at δ 3.39 for the methyl protons, while that of **5** displays a phenyl multiplet centred at δ 7.5. Although attempts to obtain single crystals of **4** and **5** were unsuccessful this indicates that the alkyne substituents are in chemically equivalent environments, suggesting that the Ru(η^5-C_5H_5) unit occupies the wing-tip position of a quasi-octahedral Os_3RuC_2 structure, as is observed in the solid-state structure of **6** (vide infra). Thus, in the synthesis of **4** and **5**, the CH_3CN and one carbonyl ligand are substituted by the alkyne which inserts into a Ru–Os edge of the tetrahedral metal core of the starting cluster $[Os_3RuH(CO)_{10}(\eta^5\text{-}C_5H_5)(MeCN)]$ (**3**).

This interpretation of the structures of **4** and **5** is consistent with an analysis using PSEPT [15]. From the formulation both clusters have 66 valence electrons, and the observed, closed-octahedral Os_3RuC_2 core is consistent with the presence of seven electron pairs for framework bonding.

The molecular ion peak (1325) in the mass spectrum of compound **6** corresponds to a formulation of $[Os_3RuH(CO)_8(Ph_2C_2)_2(C_5H_5)]$. In the ^{1}H NMR spectrum of **6**, the peak at δ 5.05 gives evidence for the η^5-coordination of the cyclopentadiene group and the phenyl resonances occur in two distinct regions, δ 7.5 and 6.9, which suggests that the two diphenylacetylene ligands are coordinated in different environments. To confirm the molecular structure of **6**, single crystals were grown by slow evaporation from dichloromethane/hexane solution. The molecular structure is presented in Fig. 2 and relevant bond parameters are listed in Table 4. As in the structure of **1**, the Ru and three Os atoms adopt a butterfly framework geometry with the Ru atom occupying the wing-tip position. One diphenylacetylene ligand spans the Os(2)–Os(3) hinge, forming two σ-bonds with the hinge osmium atoms and two π-bonds with the wing-tip atoms to make up a quasi-octahedral Os_3RuC_2 unit. The metal–carbon bond distances within the Os_3RuC_2 core are closely similar to those in **1**. The cluster is formally derived from the tetrahedral structure of $[Os_3RuH(CO)_{11}(\eta^5\text{-}C_5H_5)]$ [10] by insertion of the alkyne into an Ru–Os edge, the cyclopentadiene ligand remaining symmetrically η^5-coordinated to the Ru atom. The second diphenylacetylene has transformed into a 1,2 diphenylethenyl ligand by hydride transfer from the cluster core, and is μ_2–η^1:η^2-coordinated across the Os(1)–Os(3) edge, with the σ bond to Os(3), thus acting as a 3-electron donor. This type of transformation of a diphenylacetylene ligand on osmium and ruthenium hydrido clusters is well established, with similar bond distances in the resulting 1,2-diphenylethenyl unit to those in $[Os_3Ru(\mu\text{-}CO)(CO)_7(\eta^5\text{-}C_5H_5)(PhCCPh)(PhC(H)CPh)]$ (**6**) being found in previous studies [16].

There are seven terminal carbonyl ligands which are pseudo-linearly coordinated, two each to Os(1) and Os(3) and three to Os(2). Os(3) also has a bridging carbonyl ligand associated with it which spans the Os(3)–Ru edge, which is ca. 0.2 Å longer than the unbridged Os(2)–Ru edge. As in cluster **1**, this arrangement allows redistribution of electron density to the otherwise formally electron-deficient Ru(η^5-C_5H_5) unit. The structure

is closely related to that of $[Os_3Rh(\mu\text{-}CO)(CO)_9(PhCCPh)(PhC(H)CPh)]$ [8], in which $Rh(CO)_2$ occupies an equivalent site to the $Ru(\eta^5\text{-}C_5H_5)$ unit in **6** and the remaining ligands adopt essentially the same arrangement. As in the Rh complex, the hinge Os(2)–Os(3) bond is substantially longer than the other Os–Os bonds in **6**, and the alkenyl-bridged Os(1)–Os(3) bond is shorter than the unbridged Os(1)–Os(2) edge.

As with clusters **4** and **5**, cluster **6** has 66 valence electrons and 7 skeletal electron pairs for bonding in the Os_3RuC_2 cluster core. This is consistent with the observed distorted octahedral geometry for the Os_3RuC_2 core.

The minor product $[Os_3Ru(CO)_8(\eta^5\text{-}C_5H_5)(PhCCPh)(PhC(H)CPh)]$ (**6**) is related to the major insertion product $[Os_3RuH(CO)_9(\eta^5\text{-}C_5H_5)(PhCCPh)]$ (**5**) by the substitution of a further CO ligand with diphenylacetylene and hydride transfer to this alkyne. Conversely, it would seem that the dimethylacetylene analogue **4** is not susceptible to further reaction with dimethylacetylene at room temperature.

3. Experimental

All manipulations were performed under an atmosphere of dry, oxygen-free nitrogen using standard Schlenk and vacuum-line techniques, at room temperature, unless otherwise stated. Solvents were distilled over appropriate drying agents, under an inert nitrogen atmosphere, prior to use. Routine separation of products was performed by thin layer chromatography (TLC), using commercially prepared glass plates, precoated to 0.25 mm thickness with Merck Kieselgel 60 F_{254}, as supplied by Merck; or using laboratory prepared glass plates, coated to 1 mm thickness with Merck Kieselgel 60 F_{254}. IR spectra were recorded as solution spectra on a Perkin–Elmer 1710 Fourier Transform infra-red spectrophotometer using 0.5 mm NaCl or CaF_2 cells. NMR spectra were recorded on a Bruker WM250 or WM400 FT-NMR spectrometer. FAB mass spectra were recorded on a Kratos AEI MS 902 instrument.

The reagents $[Ru(C_5H_5)(MeCN)_3][PF_6]$ [16], $[Os_3(CO)_9(R_2C_2)]^{2-}$ (where R = Ph or Me) [4] and $[Os_3RuH(CO)_{11}(\eta^5\text{-}C_5H_5)]$ [10] were prepared and purified according to literature methods. Other chemicals were used as purchased without further purification.

3.1. Preparation of $[Os_3Ru_2(R_2C_2)(CO)_9(\eta^5\text{-}C_5H_5)_2]$ where R = Me 1 or Ph 2

A solution of $[Os_3(CO)_9(R_2C_2)]^{2-}$ [R = Me or Ph] (prepared from 11.5×10^{-5} mol of $[Os_3(CO)_9(R_2C_2)]$ as described previously [4]) in dichloromethane was cooled to −78 °C and 2 molar equivalents of $[Ru(C_5H_5)(CH_3CN)_3][PF_6]_2$ (100 mg, 23.1×10^{-5} mol) were added. The brown solution darkened immediately and was allowed to warm to room temperature, with stirring, over a period of 30 min. After removal of solvent, the solid residue was chromatographed by TLC using 1:1 CH_2Cl_2/hexane as eluent. $[Os_3Ru_2(CO)_9(\eta^5\text{-}C_5H_5)_2(R_2C_2)]$ [R = Me **1** or Ph **2**] was isolated as an orange-brown solid in 82% yield for **1** (109 mg, 9.0×10^{-5} mol) and 80% yield for **2** (117 mg, 8.8×10^{-5} mol). Calc. for $C_{23}H_{16}O_9Os_3Ru_2$ (**1**): C, 26.85; H, 1.32. Found: C, 26.07; H, 1.27%.

3.2. Preparation of $[Os_3RuH(CO)_{10}(\eta^5\text{-}C_5H_5)(CH_3CN)]$ (3)

To an acetonitrile solution (20 ml) of $[Os_3RuH(CO)_{11}(\eta^5\text{-}C_5H_5)]$ (100 mg, 9.6×10^{-5} mol) one equivalent of Me_3NO (8 mg, 10.5×10^{-5} mol) in CH_3CN (5 ml) was added dropwise at room temperature and the mixture stirred for 45 min. The IR spectrum showed complete consumption the starting material and the newly formed species was tentatively formulated as $[Os_3RuH(CO)_{10}(\eta^5\text{-}C_5H_5)(CH_3CN)]$ (**3**). The solvent was

removed in vacuo and the resulting orange-red solid was used for reactions without further purification.

3.3. Reaction of $[Os_3RuH(CO)_{10}(\eta^5\text{-}C_5H_5)(CH_3CN)]$ (**3**) with Ph_2C_2 and Me_2C_2

Freshly prepared $[Os_3RuH(CO)_{10}(\eta^5\text{-}C_5H_5)(CH_3CN)]$ (**3**) (from 100 mg, 9.6×10^{-5} mol $[Os_3RuH(CO)_{11}(\eta^5\text{-}C_5H_5)]$) was dissolved in CH_2Cl_2 and an excess of R_2C_2 (where R = Me or Ph) was added to the solution and the reaction followed by IR spectroscopy. The reaction mixture was stirred for 24 h at room temperature, the solvent subsequently evaporated and the residue separated by TLC using 1:1 CH_2Cl_2/hexane as eluent. With Me_2C_2, the complex $[Os_3RuH(Me_2C_2)(CO)_9(\eta^5\text{-}C_5H_5)]$ (**4**) was isolated as the major product in 35% yield (35 mg, 3.4×10^{-5} mol). With Ph_2C_2, two complexes $[Os_3RuH(Ph_2C_2)(CO)_9(\eta^5\text{-}C_5H_5)]$ (**5**) (35% yield, 40 mg, 3.4×10^{-5} mol) and $[Os_3Ru(CO)_8(Ph_2C_2)(PhCC(H)Ph)(\eta^5\text{-}C_5H_5)]$ (**6**) (15% yield, 19 mg, 1.4×10^{-5} mol). Calc. for $C_{28}H_{16}O_9Os_3Ru$ (**5**): C, 28.79; H, 1.37. Found: C, 29.32; H, 1.46%. Calc. for $C_{41}H_{26}O_8Os_3Ru$ (**6**): C, 37.36; H, 1.97. Found: C, 36.68; H, 2.45%.

3.4. Crystallography

Poor quality crystals of clusters **1** and **6** were obtained by recrystallisation from dichloromethane/hexane. These crystals were irregular blocks (**1**) and plates (**6**) that precluded face indexing and, therefore, the application of numerical absorption corrections. The materials were

also relatively weakly diffracting. Details of crystal data, data collection and structure refinement are summarised in Table 2. Structures were solved via direct methods [17] and refined by full-matrix least squares on F^2 [18]. Because of the poor quality of the crystals and low resolution of the data only the heavier atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in geometrically idealised positions.

4. Conclusions

In this paper, we have shown that the coupling reaction between cluster anions and mononuclear metal cations such as the labile, cyclopentadiene-substituted complex $[Ru(\eta^5\text{-}C_5H_5)(CH_3CN)_3]^+$, leading to controlled cluster build up, can be extended to include the alkyne-substituted cluster anion $[Os_3(CO)_9(R_2C_2)]^{2-}$ (R = Me, Ph). The resultant, neutral cluster $[Os_3Ru_2(CO)_9(R_2C_2)(\eta^5\text{-}C_5H_5)_2]$ [R = Me, **1** and R = Ph, **2**] is obtained in high yield as the single product. An alternative approach to the synthesis of mixed alkyne, cyclopentadienyl-substituted clusters has also been exploited in which the alkyne is added directly to a labilised cyclopentidenyl-cluster, such as $[Os_3RuH(\eta^5\text{-}C_5H_5)(CO)_{10}(MeCN)]$, but here the reaction is less controllable, and more than one cluster product is obtained.

5. Supplementary data

Crystallographic data for **1** and **6** have been deposited in CIF format at the Cambridge Crystallographic Data Centre. CCDC 208283–208284 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; or deposit@ccdc.cam.ac.uk).

Dedicated to Prof. Malcolm H. Chisholm for his contributions to the chemistry of metal–metal bonded compounds.

Abstract

A new molecular pair composed of two quadruply bonded $Mo_2(DAniF)_3^+$ units (DAniF = (*p*-$MeOC_6H_4$)NC(H)N-(*p*-$MeOC_6H_4$)) linked by a trishomobarrelene-1,5-dicarboxylate dianion has been prepared. This compound, $[Mo_2(DAniF)_3]_2(O_2CC_{11}H_{12}CO_2)$ (**1**), has been characterized by X-ray crystallography and by ^1H NMR and UV–Vis spectroscopy. There is only weak electronic coupling between the two Mo_2 units according to electrochemical measurements. A comparison with other dicarboxylate-linked molecular pairs is presented.

Keywords: Quadruple bond; Dimolybdenum compounds; Trishomobarrelene-1,5-dicarboxylate; Electronic coupling

1. Introduction

It has been known that metal–metal bonded Mo_2^{n+} and Rh_2^{4+} units may be linked into pairs, loops, triangles, squares and a few other types of assembly by employing the dianions of dicarboxylic acids [1–3]. Although products containing more than 25 such dianions have already been reported, the work described here was prompted by several questions that were still not fully answered by the earlier work. With regard to compounds of the type $(DAniF)_3Mo_2O_2CXCO_2Mo_2(DAniF)_3$, the use of the bridge with trishomobarrelene as X, namely, the title dianion (Scheme 1) provides a compound in which the bridge has very little flexibility and consists entirely of C–C single bonds. This means that the distance between the Mo_2 units as determined in the crystal structure may be assumed with confidence to pertain to the molecule in solution. Given the "insulating" character of the trishomobarrelene unit and the rather large separation between the two Mo_2 units electronic coupling between these Mo_2 units should be negligible. Therefore, the difference between the potentials for the first and second oxidations should be of essentially electrostatic origin and should be small.

We report here the preparation of $(DAniF)_3Mo_2(O_2CC_{11}H_{12}CO_2)Mo_2(DAniF)_3$ (**1**) where $C_{11}H_{12}$ is the trishomobarrelene diradical. Also reported are the structure of **1** and some of its spectroscopic properties.

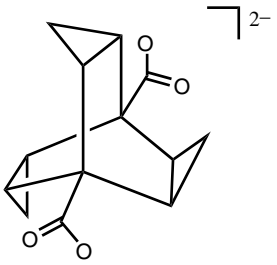

Scheme 1. Trishomobarrelenedicarboxylate dianion.

2. Experimental

2.1. Materials and methods

All manipulations and procedures were conducted under N_2 using either an N_2 drybox or standard Schlenk line techniques. Solvents were distilled and degassed prior to use: MeCN was twice distilled under N_2, first from activated molecular sieves and then from CaH_2. Dichloromethane was dried and distilled from P_2O_5, and ethyl ether was dried and distilled from Na/K-benzophenone. The compound $Mo_2(DAniF)_3Cl_2$ was prepared by the literature method [4]. The salt $(Bu_4N)_2(O_2CC_{11}H_{12}CO_2)$ was prepared and isolated as a colorless solid by neutralizing the corresponding diacid with 2 equiv. of Bu_4NOH. It was then carefully dried in vacuum. All other reagents were purchased from commercial sources and used as received.

Elemental analysis was performed by Canadian Microanalytical Service, Delta, British Columbia. The ^1H NMR spectrum was recorded on a Mercury 300 System NMR spectrometer, with chemical shifts (δ) referenced to CD_2Cl_2. The differential pulse voltammogram and cyclic voltammogram were recorded on a CH Instruments electrochemical analyzer in 0.1 M Bu_4NPF_6 solution (CH_2Cl_2) with Pt working and auxiliary electrodes, an Ag/AgCl reference electrode. The scan rate for the CV was 100 mV/s. The oxidation potentials are referenced to the Ag/AgCl electrode, and under the present experimental conditions, the $E_{1/2}(Fc^+/Fc)$ was measured at 440 mV.

2.2. Preparation of trishomobarrelene-1,5-dicarboxylic acid

This linker was prepared from 1,5-dichlorotrishomobarrelene according to a modified protocol from a previously published one [5]: to a solution of 1,5-dichlorotrishomobarrelene (214 mg, 1 mmol) in anhydrous dichloromethane (2 ml) cooled to −78 °C (dry ice/acetone) was added under an inert atmosphere (N_2) within 10 min a 1 M solution of antimony pentachloride in anhydrous dichloromethane (Aldrich, 4 ml, 4 mmol). After stirring for an additional 1 h at the same temperature, dry carbon monoxide was bubbled through the suspension at −78 °C. The suspension was then transferred under N_2 via a cannula to a cold solution (−78 °C) of sodium methoxide (5 g, 217 mmol) in methanol (65 ml). The mixture was warmed up to ambient temperature, water (20 ml) was added, and the resulting mixture stirred for 6 h at 70 °C. The precipitate was filtered off, the filtrate was extracted with pentane (4 × 40 ml). The aqueous phase was evaporated to dryness, and the residue dissolved in a minimum of water so that the resulting solution was completely clear. Under cooling in an ice-water bath, conc. hydrochloric acid was added to pH 1–2. After extraction with ether (6 × 50 ml) and evaporation to dryness, the residue weighed 164 mg and was crude trishomobarrelenedicarboxylic acid containing a little sodium chloride. Pure diacid was obtained by dissolving the crude material in saturated aqueous sodium hydrogencarbonate (5 ml), extracting the solution with ether (5 ml) and acidifying the aqueous phase with conc. hydrochloric acid under cooling in an ice-water bath to pH 1–2. The resulting colorless precipitate was filtered off and dissolved in ether (150 ml). The ether solution was filtered through a 2 cm pad of Celite, and the Celite was washed with an additional 100 ml of ether. The solvent was evaporated and the crystalline residue dried in vacuum to yield 106 mg (45%) of pure trishomobarrelene-1,5-dicarboxylic acid (m.p. 230 °C, dec). ^1H NMR (600 MHz, [d_6]-DMSO): $\delta = 0.15$ (dt, $^3J = 7.5$ Hz, $^2J = 5.5$ Hz, 3H), 0.78 (dd, $^3J = 7.5$ Hz, $^3J = 4.0$ Hz, 6H), 0.87 (dt, $^2J = 5.5$ Hz, $^3J = 4.0$ Hz, 3H), 12.33 ppm (s, 2H, COOH). ^{13}C NMR (62.9 MHz, [d_6]-DMSO, additional DEPT): $\delta = 0.6$ (−, 3C, CH_2), 12.7 (+, 6C, CH), 38.4 (quat, 2C), 177.8 ppm (quat, 2C, COOH). MS (EI, 70 eV), m/z (5): 234.1 (52) [M^+], 189.1 (46) [$M^+ - COOH$], 171.1 (47), 143.1 (99), 128.1 (100), 115.1 (77), 111.1 (56), 105.1 (29), 91.1 (87), 77.0 (76), 65.0 (38), 51.0 (30), 41.0 (35).

2.3. Preparation of $[Mo_2(DAniF)_3]_2(O_2CC_{11}H_{12}CO_2)$ (1)

A solution of $Mo_2(DAniF)_3Cl_2$ (0.450 g, 0.441 mmol) in 50 ml of MeCN was treated with Zn dust (4.5 g). The resulting suspension was stirred vigorously for 1.5 h. The yellow filtrate was transferred to a flask containing $(Bu_4N)_2(O_2CC_{11}H_{12}CO_2)$ (0.142 g, 0.200 mmol). Within a few minutes of stirring, a yellow precipitate appeared. Stirring was continued for 2 h. The mixture was concentrated to about 5 ml, and 30 ml of methanol was added. The precipitate was isolated by filtration, washed with methanol (2 × 20 ml) and ether (1 × 30 ml), dried in vacuum, and then extracted with 20 ml of dichloromethane. The extract was layered with 40 ml of ether, and allowed to stand undisturbed for two days. A yellow crystalline product was isolated and dried for 24 h in vacuum.

Yield, 210 mg (49%). *Anal.* Calc. for (**1**), $C_{103}H_{102}Mo_4N_{12}O_{16}\cdot 0.5CH_2Cl_2$: C, 56.55; H, 4.73; N, 7.65. Found: C, 56.34; H, 4.85; N, 7.47%. ^{1}H NMR δ (ppm in CD_2Cl_2): 8.509 (s, 2H, –NCHN–), 8.385 (s, 4H, –NCHN–), 6.617 (m, 32H, aromatic), 6.471 (d, 8H, aromatic), 6.254 (d, 8H, aromatic), 3.692 (s, 24H, $-OCH_3$), 3.650(s, 12H, $-OCH_3$), 1.261 (s, 9H,), 0.395 (q, 3H).

2.4. X-ray structure determination

Single crystals suitable for X-ray diffraction analysis were grown by diffusion of ether into a CH_2Cl_2 solution of the compound. The data were collected on a Bruker SMART 100 CCD area detector system. Cell parameters were determined using the program SMART [6]. Data reduction and integration were performed with the software package SAINT [7], while absorption corrections were applied by using the program SADABS [8]. The positions of the Mo atoms were found by direct methods using the program package SHELXTL [9]. Subsequent cycles of least-squares refinement followed by difference Fourier syntheses revealed the positions of the remaining non-hydrogen atoms. Hydrogen atoms were added in idealized positions. Non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were included in the calculation of the structure factors.

The bridging dicarboxylate ligand has two rotational orientations in a ratio of 0.6–0.4 in the crystallographic structure. Some methoxyl groups of DAniF ligands are disordered in two positions. Disorder in the interstitial solvent molecules was also found. Cell parameters and refinement results are summarized in Table 1. Selected bond distances and angles are listed in Table 2.

3. Results

3.1. Structure

The structure of $[Mo_2(DAniF)_3]_2(O_2CC_{11}H_{12}CO_2)$ is presented in Fig. 1, where the formamidinate ligands are shown as N–C–N chains and hydrogen atoms are omitted for clarity. In this compound, two $[Mo_2(DAniF)_3]^+$ units are linked by the trishomobarrelene-1,5-dicarboxylate dianion. The twist angle between Mo_2 axes is 22.8°. The dimensions of the $[Mo_2]$ units retain the characteristics of quadruply bonded dimolybdenum

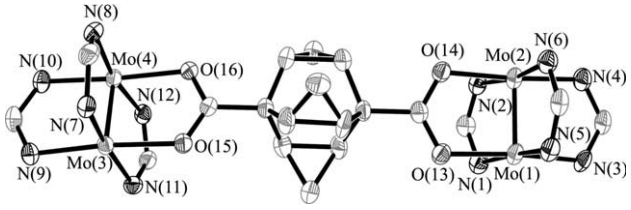

Fig. 1. Core structure of **1** in $\mathbf{1}\cdot 2CH_2Cl_2$ drawn with 50% probability ellipsoids. All *p*-anisyl groups and hydrogen atoms have been omitted for clarity.

compounds. The Mo–Mo distances are 2.0916(7) Å for Mo(1)–Mo(2) and 2.0920(6) Å for Mo(3)–Mo(4). The Mo–O and Mo–N distances fall in narrow ranges, 2.142(3)–2.153(4) Å for Mo–O and 2.109(4)–2.172(4) Å for Mo–N, respectively. The distance between the centers of the two Mo_2 units is 11.06 Å. The structure of the dicarboxylate ligand is first studied here even though the trishomobarrelene core has been known for decades [10]. Within the error limits all structural parameters of this dicarboxylate ligand are in agreement with the ones for the parent hydrocarbon [11]. The single C–C bond distances are close to 1.52 Å. The distances in the cyclopropyl rings do not significantly differ from others. However, the C–C–C angles vary considerably. The bicyclo[2.2.2]octane moiety in the trishomobarrelene-1,5-dicarboxylate ligand is similar to that of the bicyclo[2.2.2]octane-1,4-dicarboxylic acid with bond angles close to 109.5° [12]. In contrast, the angles inside the cyclopropyl groups are very close to 60°. The dihedral angles between the planes of the cyclopropyl groups and the plane defined by the axis of the propeller and two atoms from the cyclopropyl group are in the range of 62.0–66.6°. A more detailed listing of bond angles and distances is available as supplementary material.

3.2. Electrochemistry

The CV and DPV of $[Mo_2(DAniF)_3]_2(O_2CC_{11}H_{12}CO_2)$ in CH_2Cl_2 have the shape and current of a single step charge transfer of 2 electrons. This is not surprising because the coupling capability between the two Mo_2 dimers is weak due to the large distances between them and the properties of the linker. The $\Delta E_{1/2}$ between the two successive one-electron oxidations was calculated to be 66 mV from the differential pulse voltammogram by the method of Richardson and Taube [13].

3.3. Electronic spectrum

The only absorption band observed between 380 and 600 nm was a shoulder on the absorption rising into the shorter wave length region. This had a maximum at 430 ± 10 nm and a molar extinction of about 800 $mol^{-1}\,cm^{-1}$. It is very similar to a band found in $(DAniF)_3Mo_2O_2CCH_3$ [14] at 430 nm and $\varepsilon = 1000$, and assignment to the $\delta \rightarrow \delta^*$ transition is indicated.

4. Discussion

The mere existence of compound **1** is not particularly interesting, but several features of interest arise when it is compared with other compounds of the type $(DAniF)_3Mo_2O_2CXCO_2Mo_2(DAniF)_3$ [15,16]. These features are evident in the data plot of $\Delta E_{1/2}$ versus d (the distance between centers of Mo_2 units) shown in Fig. 2. Points 1–4 shown by circles are for compounds with "insulating" bridges in which the connector X is a rigid unit that does not provide a π-orbital pathway, except point 1 which is for oxalate where there is no X. The lack of a π-orbital pathway is obvious for 3 and 4, but it is also true of 2, which has π electrons but the adjacent double bonds are orthogonal to each other.

We first note that compound **1**, as represented by point 4, provides a significant extension to the line through points 1, 2 and 3. However, Fig. 2 also shows that there is a dearth of data for compounds with "insulating" bridges. There are none for distances between 7 and 9 Å, and none beyond about 11 Å. While there is little likelihood of filling the 7–9 Å gap, one or more compounds in the region beyond 11 Å should be affordable. For example, if the dicarboxylic acid with two trishomobarrelenes instead of only one could be made, a point at about 15 Å would be possible.

Also shown in Fig. 2 are points for compounds in which X is one of five $(CH{=}CH)_n$ ($n = 1$–4) groups as well as C≡C. For details see the figure caption. Apart from some scatter among points 5, 6 and 7, there is a smooth (though not linear) downward trend in $\Delta E_{1/2}$ values. This presumably means that the presence of a π bond, or an extended sequence of conjugated π bonds, allows electronic coupling in addition to electrostatic coupling.

In connection with Fig. 2, it must be noted that regardless of the nature of the coupling mechanism, as $d \rightarrow \infty$, the value of $\Delta E_{1/2}$ should drop to 35.6 mV,

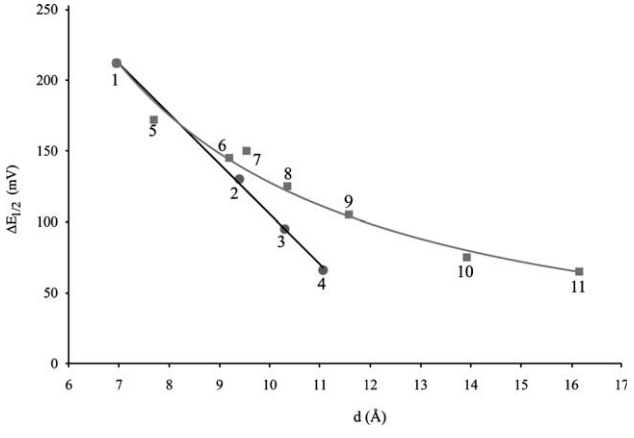

Fig. 2. The $\Delta E_{1/2}$ values for two classes of $(DAniF)_3Mo_2O_2CXCO_2Mo_2(DAniF)_3$ compounds, plotted against the distance between the two Mo_2 units. Points 2–4 are for those in which there is little or no electronic coupling between them. Points 5–11 are for those in which π electrons are present. The X for point 1 is simply the C–C bond. For the others the X groups are as follows: 2 – C=C=C; 3 – C(μ–CH_2)$_3$C; 4 – trishomobarrelene; 5 – *cis*-CH=CH; 6 – *trans*-CH=CH; 7 – C≡C; 8 – *cis*,*cis*-CH=CH–CH=CH; 9 – *trans*,*trans*-CH=CH–CH=CH; 10 – all *trans*-$(CH{=}CH)_3$; 11 – all *trans*-$(CH{=}CH)_4$.

which corresponds to the purely statistical value for K_C (the comproportionation constant) of 4. On this basis, the linear trend in the points for compounds with "insulating" connection cannot continue; instead, the $\Delta E_{1/2}$ values for longer distances (d) must asymptotically approach 35.6 mV. Thus, data for one or two more compounds in the range above $d = 11$ Å would be very desirable.

It is also interesting that the points for the compounds with conjugated polyene connectors appear to approach an asymptote of about 60 mV instead of 35.6 mV. This observation makes it even more interesting to extend the range of d for compounds with "insulating" connectors, and we shall seek to do so. It is known that $\Delta E_{1/2}$ values may have a "significant – and sometimes unpredictable – dependence" on the solvents and counter ions [17].

5. Supplementary material

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Center as supplementary publication No. CCDC 259665. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033, e-mail: deposit@ccdc.cam.ac.ukvia, www.ccdc.cam.ac.uk/data_request/cif.

Abstract

Treatment of $[(2,6\text{-}i\mathrm{Pr}_2\mathrm{C}_6\mathrm{H}_3)\mathrm{NC}(t\mathrm{Bu})\mathrm{CH}_2\mathrm{C}(t\mathrm{Bu})\mathrm{N}(2,6\text{-}i\mathrm{Pr}_2\mathrm{C}_6\mathrm{H}_3)](\mathrm{L}^{\mathrm{Ar}'}\mathrm{H})$ with potassium hydride in tetrahydrofuran afforded $\mathrm{K}(\eta^1\text{-}\mathrm{L}^{\mathrm{Ar}'})(\mathrm{THF})_3$ (89%) as a yellow crystalline solid after workup. The crystal structure of $\mathrm{K}(\eta^1\text{-}\mathrm{L}^{\mathrm{Ar}'})(\mathrm{THF})_3$ revealed an open monomeric molecule in which the potassium ion is bonded to three tetrahydrofuran ligands and one η^1-β-diketiminato ligand through one of the nitrogen atoms. Treatment of $\mathrm{K}(\eta^1\text{-}\mathrm{L}^{\mathrm{Ar}'})(\mathrm{THF})_3$ with equimolar amounts of MI_2 (M = Ca, Ba) afforded $[\mathrm{Ca}(\eta^5\text{-}\mathrm{L}^{\mathrm{Ar}'})(\mu\text{-I})(\mathrm{THF})]_2$ (62%) and $[\mathrm{Ba}(\eta^2\text{-}\mathrm{L}^{\mathrm{Ar}'})(\mu\text{-I})]_2$ (27%) as yellow crystalline solids. Treatment of $\mathrm{M}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})_2$ (M = Ca, Sr, Ba, $\mathrm{L}^{t\mathrm{Bu}} = t\mathrm{BuNC}(\mathrm{CH}_3)\mathrm{CHC}(\mathrm{CH}_3)\mathrm{N}t\mathrm{Bu}^-$) with the corresponding metal iodide in tetrahydrofuran afforded $[\mathrm{Ca}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})(\mu\text{-I})(\mathrm{THF})]_2$ (68%), $[\mathrm{Sr}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})(\mu\text{-I})(\mathrm{THF})]_2$ (53%), and $[(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})\mathrm{Ba}(\mu\text{-I})(\mu\text{-}\eta^2\text{:}\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})\mathrm{Ba}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})]_2$(24%). Structural assignments for these complexes were based on spectral and analytical data as well as X-ray crystallography. $[\mathrm{Ca}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})(\mu\text{-I})(\mathrm{THF})]_2$ and $[\mathrm{Sr}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})(\mu\text{-I})(\mathrm{THF})]_2$ are dimers that are held together by bridging iodide ligands, while $[\mathrm{Ba}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})(\mu\text{-I})(\mu\text{-}\eta^2\text{:}\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})\mathrm{Ba}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})]_2$ is a tetramer containing two symmetrical dimeric units that are linked by two bridging iodide ligands. In benzene-d_6 solution, $[\mathrm{Ca}(\eta^5\text{-}\mathrm{L}^{\mathrm{Ar}'})(\mu\text{-I})(\mathrm{THF})]_2$ and $[\mathrm{Ba}(\eta^2\text{-}\mathrm{L}^{\mathrm{Ar}'})(\mu\text{-I})]_2$ are stable toward ligand redistribution. $[\mathrm{Ca}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})(\mu\text{-I})(\mathrm{THF})]_2$ exists as mixtures of three species in toluene-d_8, but the mixed ligand complex is strongly favored under the conditions studied. At 31.3 °C, the equilibrium constant for ligand redistribution of $[\mathrm{Sr}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})(\mu\text{-I})(\mathrm{THF})]_2$ to $\mathrm{Sr}(\eta^5\text{-}\mathrm{L}^{t\mathrm{Bu}})_2$ and $\mathrm{SrI}_2(\mathrm{THF})_2$ in toluene-d_8 was 5.3×10^{-5} M.

Keywords: N-ligands; Group 2 elements; Calcium; Strontium; Barium

1. Introduction

Recent efforts in the coordination chemistry of calcium, strontium, and barium have been driven by applications in film growth by chemical vapor deposition (CVD) and related techniques [1], as well as organic synthesis and polymerization catalysis [2–4]. In polymerization reactions, unsymmetrical LMX complexes are the desired precatalysts, since X^- possesses the needed nucleophilic properties to initiate catalysis and the steric properties of L can be designed to promote stereoselectivity in the growing polymer [2–4]. As part of the development of group 2-based polymerization catalysis, there is a growing need to understand the redistribution equilibria of LMX, since ML_2 is unlikely to initiate catalysis efficiently and MX_2 may not promote stereoselective polymerization. Most calcium, strontium, and barium complexes containing mixed ligand sets are of the formula $[\mathrm{M}(\mathrm{C}_5\mathrm{R}_5)(\mathrm{X})(\mathrm{L})_n]_y$, where $\mathrm{C}_5\mathrm{R}_5$ is a bulky substituted cyclopentadienyl ligand, X is a halide ligand, and L is a neutral oxygen donor ligand [5–10]. Bulky cyclopentadienyl ligands appear to stabilize these mixed ligand complexes toward ligand redistribution through steric inhibition of dimerization

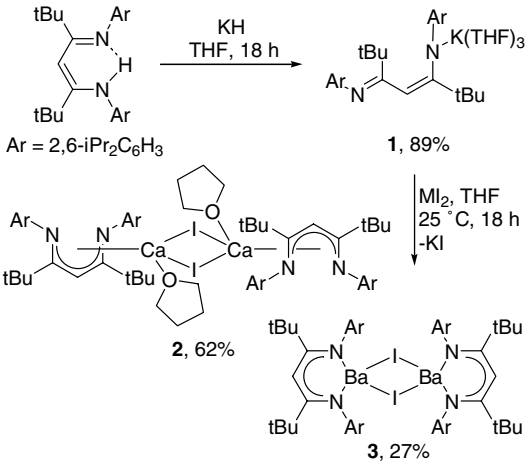
[11]. Strongly coordinating oxygen ligands such as tetrahydrofuran also contribute to the stability of the mixed ligand complexes toward ligand redistribution [11a]. However, complexes of the formula $[M(C_5R_5)(X)(L)_n]_y$ are difficult to handle in aromatic solvents in the absence of coordinating ligands, due to the appearance of facile redistribution equilibria (e.g., $2M(C_5R_5)(X) \leftrightarrow M(C_5R_5)_2 + MX_2$) [10,11a]. Furthermore, replacement of the halide ligand in $[M(C_5R_5)(X)(L)_n]_y$ by salt metathesis routes can be problematic. For example, treatment of $MN(SiMe_3)_2$ (M = Li, Na, K) with $(C_5H_2(SiMe_3)_3)$-CaI(THF) resulted in the formation of $M(C_5H_2$-$(SiMe_3)_3)$ and $Ca(N(SiMe_3)_2)(I)(THF)_n$ [6].

Recently we [12] and others [3,4] have been exploring the use of β-diketiminato ligands as ancillary ligands for the stabilization of the heavier group 2 metal complexes. The β-diketiminato ligand is isoelectronic with cyclopentadienyl and β-diketonato ligands, and its steric profile is easily adjusted at both the core nitrogen and carbon atoms [13]. Such steric manipulations can have a profound effect on the bonding modes of the β-diketiminato ligands, especially with barium [12b,14,15]. For example, the complex $Ba_2(L^{Cy})_3(N(SiMe_3)_2)$ ($L^{Cy} = C_6H_{11}NC(CH_3)CHC(CH_3)N(C_6H_{11})^-$) contains η^5-, μ-η^2:η^5-, and μ-η^2:η^3-β-diketiminato ligands [14], $Ba_2(L^{iPr})_4$ ($L^{iPr} = i$PrNC(CH$_3$)CHC(CH$_3$)NiPr$^-$) features η^5-, μ-η^5:η^5-, and μ-η^1:η^1-β-diketiminato ligands [12b], and $Ba(L^{Ar})_2$ ($L^{Ar} = (2,6\text{-}i\text{Pr}_2C_6H_3)NC(CH_3)$-$CHC(CH_3)N(2,6\text{-}i\text{Pr}_2C_6H_3)^-$) possesses η^2-β-diketiminato ligands [15]. We have recently reported that homoleptic calcium, strontium, and barium complexes containing η^5-β-diketiminato ligands have many similarities to the analogous metallocenes [12b]. In view of the increasing importance of mixed ligand group 2 complexes in polymerization reactions [3,4], we set out to explore the synthesis and ligand redistribution reactions of calcium, strontium, and barium complexes that contain both halide and β-diketiminato ligands. Herein, we describe the synthesis, structure, and properties of a series of calcium, strontium, and barium complexes that contain $L^{Ar'}$ ($L^{Ar'} = (2,6\text{-}i\text{Pr}_2C_6H_3)$-$NC(C(CH_3)_3)CHC(C(CH_3)_3)N(2,6\text{-}i\text{Pr}_2C_6H_3)^-$) or L^{tBu} ($L^{tBu} = t$BuNC(CH$_3$)CH-C(CH$_3$)NtBu$^-$) and iodide ligand sets. Depending on the nature of the β-diketiminato ligand nitrogen atom substituents and the group 2 ion, iodide-bridged tetrahydrofuran-coordinated dimers, iodide-bridged solvent-free dimers, and a unique tetramer are obtained. In addition, the tendency of these complexes to undergo redistribution reactions in solution is described. $[Ca(\eta^5\text{-}L^{Ar'})(\mu\text{-}I)(THF)]_2$ and $[Ba(\eta^2\text{-}L^{Ar'})(\mu\text{-}I)]_2$ show no evidence for redistribution equilibria in benzene, while $[Ca(\eta^5\text{-}L^{tBu})(\mu\text{-}I)(THF)]_2$ and $[Sr(\eta^5\text{-}L^{tBu})(\mu\text{-}I)(THF)]_2$ exist as equilibrium mixtures of two or more species. Estimated equilibrium constants, however, suggest that the mixed ligand species are strongly favored at ambient temperature.

2. Results

2.1. Synthetic aspects

Treatment of $L^{Ar'}H$ with KH (1 equiv.) in tetrahydrofuran afforded $K(\eta^1\text{-}L^{Ar'})(THF)_3$ (**1**, 89%) as a yellow crystalline solid after workup (Eq. (1)). Complex **1** is soluble in toluene, easily crystallized, can be stored for several months under argon without decomposition, and is thus a very useful reagent. Treatment of **1** with MI_2 (M = Ca, Ba) (1 equiv.) in anhydrous tetrahydrofuran afforded $[Ca(\eta^5\text{-}L^{Ar'})(\mu\text{-}I)(THF)]_2$ (**2**, 62%), and $[Ba(\eta^2\text{-}L^{Ar'})(\mu\text{-}I)]_2$ (**3**, 27%) as yellow crystalline solids after workup (Eq. (1)). The structural assignments for **1**–**3** were based upon spectral and analytical data as well as X-ray structure determinations. In the solid state, **1** exists as a monomeric molecule in which the β-diketiminato ligand is bonded to the potassium center through one nitrogen atom with an η^1-coordination mode. The potassium ion is also coordinated to three tetrahydrofuran ligands. The structural determination for **1** was of low precision, and is not discussed further herein. The solid state structures of **2** and **3** revealed dimeric molecules that are held together by bridging iodide ligands. Further details of the ligand bonding modes are described below. Several attempts were made to prepare the analogous strontium complex, however, this complex did not crystallize well and was very difficult to isolate in a pure state in good yields. In one case, a few crystals of the strontium complex were obtained, and analysis of the diffraction data revealed a molecular structure similar to that of **3**.



(1)

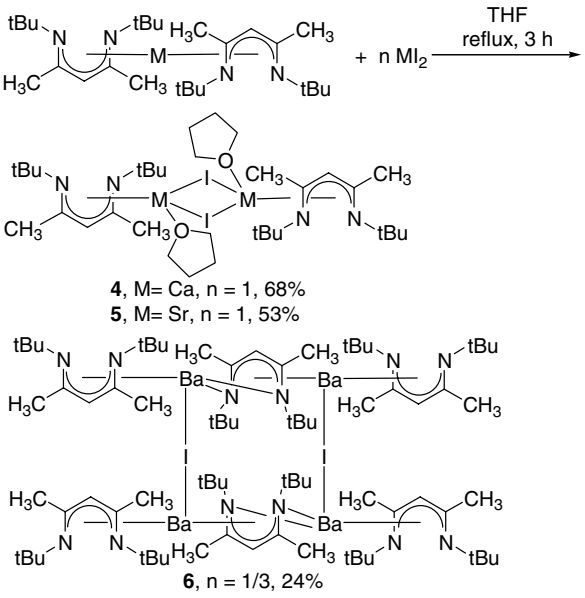
The ^{1}H NMR spectrum of **1** in toluene-d_8 at 25 °C showed one type of 2,6-diisopropylphenyl group, one type of *tert*-butyl group, and one type of tetrahydrofuran ligand. The β-C*H* resonance of the β-diketiminato ligand appeared as a singlet at δ 4.89. These resonances are inconsistent with the solid state structure, where the potassium ion is coordinated to only one of the

nitrogen atoms. It is very likely that the potassium ion exchanges with the two nitrogen atoms very rapidly on the NMR timescale, and thus an averaged spectrum is obtained. Alternatively, both nitrogen atoms could be coordinated to the potassium ion in solution, thus affording a species with a plane of symmetry. There were two doublets for the isopropyl methyl groups (δ 0.96, 1.33), and one septet for the isopropyl methine groups at δ 3.27. The observation of only one methine septet demonstrates that the isopropyl methyl groups are diastereotopic. There were no major changes in the ^{1}H NMR spectra of **1** between −60 and +80 °C. The lability of the tetrahydrofuran ligands in **1** was probed by drying a sample for 18 h at 0.1 Torr in a drying tube heated with refluxing acetone (56 °C). A ^{1}H NMR spectrum of the dried material showed free $L^{Ar'}H$ and unidentified resonances, demonstrating facile loss of tetrahydrofuran and concomitant decomposition.

The ^{1}H NMR spectrum of **2** in benzene-d_6 at 25 °C showed a single species, with the β-diketiminato ligand β-C*H* resonance at δ 5.52, isopropyl methyl resonances at δ 1.34 and 1.17, and a *tert*-butyl resonance at δ 1.24. The isopropyl methine resonance ($\sim\delta$ 3.2) overlapped with the α-CH_2 resonance of the tetrahydrofuran ligand. The ^{1}H NMR spectrum of **2** at 75 °C was very similar, except for small chemical shift changes.

The ^{1}H NMR spectrum of **3** in benzene-d_6 at 25 °C shows a single species. The β-diketiminato ligand β-C*H* proton resonance appeared at δ 5.24, which is δ 0.28 upfield of the same resonance in **2**. The difference in the positions of this resonance for **2** and **3** may be related to the η^5-β-diketiminato coordination mode in **2** and the η^2-β-diketiminato coordination mode in **3**. The isopropyl methyl group resonances appeared at δ 1.24 and 1.21, while the isopropyl methine resonance was observed at δ 2.99. The latter resonance is upfield compared to that of **2** (δ 3.27). The *tert*-butyl protons resonated at δ 1.19.

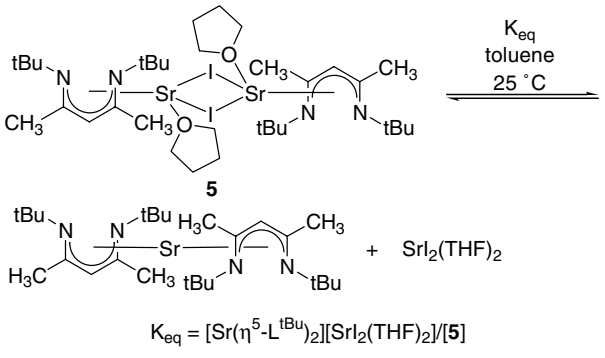
The synthesis of mixed ligand complexes containing L^{tBu} proceeded by a different route than was used for **2** and **3**. Treatment of M(η^5-L^{tBu})$_2$ (M = Ca, Sr, Ba) [12b] and MI_2 in refluxing tetrahydrofuran as indicated in Eq. (2) afforded [Ca(η^5-L^{tBu})(μ-I)(THF)]$_2$ (**4**, 68%), [Sr(η^5-L^{tBu})(μ-I)(THF)]$_2$ (**5**, 53%), and [Ba(η^5-L^{tBu})-(μ-I)(μ-η^2:η^5-L^{tBu})Ba(η^5-L^{tBu})]$_2$ (**6**, 24%) as colorless (**4**, **5**) or yellow crystals (**6**) after workup. The structural assignments for **4**–**6** were based upon spectral and analytical data, as well as X-ray structure determinations as described below. In the solid state, **4** and **5** exist as iodide-bridged dimers with molecular structures analogous to that of **2**. In contrast to **2**–**5**, the molecule of **6** is a tetramer which consists of two dimeric units that are bridged by two iodide ligands. Further details of the ligand bonding modes are described below.



(2)

The ^{1}H NMR spectrum of **4** in toluene-d_8 at 25 °C showed three β-diketiminato ligand β-C*H* resonances at δ 4.45, 4.30, and 4.21 in a 26:61:13 ratio. The resonance at δ 4.21 corresponds exactly to the resonance for Ca(η^5-L^{tBu})$_2$ [12b]. Presumably, one of the other two resonances corresponds to **4**. However, the presence of three β-diketiminato ligand β-C*H* resonances suggests that **4** is engaged in multiple equilibria in solution. Unlike **4**, the ^{1}H NMR spectrum of **5** in toluene-d_8 at 25 °C showed two β-diketiminato ligand β-C*H* resonances at δ 4.34 and 4.21 in a 94:6 ratio. The resonance at δ 4.21 corresponds exactly to the resonance for Sr(η^5-L^{tBu})$_2$ [12b]. The observation of a major species with resonances consistent with **5**, along with Sr(η^5-L^{tBu})$_2$, suggests the equilibrium process that is outlined in Eq. (3). The ^{1}H NMR spectra of **5** were recorded between 30 and 85 °C in toluene-d_8 to assess how the equilibrium was affected by temperature. Above 60 °C, the resonances for Sr(η^5-L^{tBu})$_2$ disappeared, and only one species was observed. Cooling the sample of **5** to −50 °C did not change the ratio of the major species to Sr(η^5-L^{tBu})$_2$, within experimental error. Due to the small amount of Sr(η^5-L^{tBu})$_2$ and the inherent errors associated with measuring the concentrations by integration, we did not carry out a van't Hoff analysis to obtain the equilibrium thermodynamic parameters. However, at 31.4 °C, K_{eq} was calculated to be 5.3×10^{-5} M for a 0.0134 M solution of **5** in toluene-d_8. Thus, the equilibrium strongly favors the mixed ligand species **5** at all of the temperatures that we examined. We note that the assignment of $SrI_2(THF)_2$ is uncertain, and is offered for convenience to allow correct stoichiometry. $SrI_2(THF)_5$ has been crystallographically characterized,

but rapidly loses tetrahydrofuran in the solid state [16]. The number of coordinated tetrahydrofuran ligands in solution is thus unclear.



(3)

The ^{1}H NMR spectrum of **6** in toluene-d_8 at 25 °C consisted of very broad singlets centered at δ 4.26, 2.07, and 1.39 for the β-diketiminato ligand β-C*H*, backbone methyl, and *tert*-butyl resonances, respectively. Further studies were hampered by the low solubility of **6** in toluene. The broad resonances suggest that the β-diketiminato ligands undergo site exchange in solution.

2.2. Structural aspects

The X-ray crystal structures of **2**–**6** were determined to establish the geometries about the metal centers and the bonding modes of the β-diketiminato ligands. Experimental crystallographic data are summarized in Table 1, selected bond lengths and angles are given in Tables 2–6, and perspective views are presented in Figs. 1–5.

A perspective view of **2** is shown in Fig. 1. The overall molecular structure consists of a dimer connected by two bridging iodide ligands, with one tetrahydrofuran and one η^5-$L^{Ar'}$ ligand bonded to each calcium ion. The calcium–iodine bond lengths are 3.210(1) and 3.273(1) Å. The calcium–iodine–calcium angle is 104.62(1)°. The calcium–oxygen bond distance is 2.407(2) Å. The calcium–nitrogen bond lengths are 2.386(2) and 2.416(2) Å, while the calcium–carbon distances are 2.748(3) and 2.723(3) Å for C(14) and C(15) and 2.955(3) Å for C(13). The longer Ca–C(13) bond length appears to arise from steric interactions associated with accommodation of the tetrahydrofuran ligand on the same side of the calcium ion as C(13). For comparison, the calcium–nitrogen and calcium–carbon bond lengths in $Ca(\eta^5\text{-}L^{tBu})_2$ range from 2.34 to 2.36 and 2.84 to 2.90 Å, respectively [12b]. The calcium–carbon distance in $Ca(C_5(CH_3)_5)_2$ is 2.64(2) Å [17]. The nitrogen–calcium–nitrogen bite angle is 79.16(7)°.

[a] Primes indicate symmetry equivalent positions.

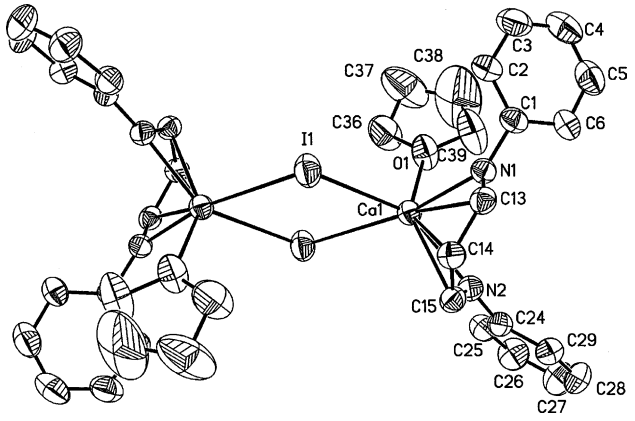

Fig. 1. Perspective view of **2** with probability ellipsoids at the 50% level. The isopropyl and *tert*-butyl groups have been removed for clarity.

A perspective view of **3** is shown in Fig. 2. The overall structure of **3** consists of two barium ions that are bridged by two iodide ligands. Each barium ion is also coordinated to one $L^{Ar'}$ ligand. Unlike the η^5-$L^{Ar'}$ ligands in **2**, the $L^{Ar'}$ ligand core in **3** is bonded to the barium atoms with the η^2-coordination mode. The barium–iodine distances are 3.362(2) and 3.523(2) Å, which indicate some asymmetry in the Ba_2I_2 core. The barium–nitrogen bond distances are 2.680(7) and 2.695(7) Å.

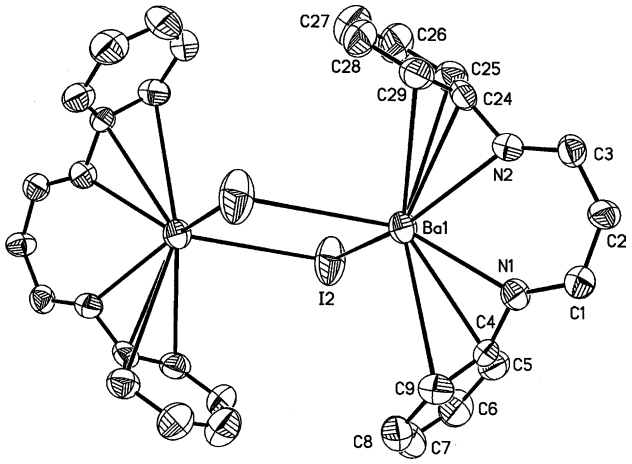

Fig. 2. Perspective view of **3** with probability ellipsoids at the 50% level. The isopropyl and *tert*-butyl groups have been removed for clarity.

The Ba–C(1,2,3) distances range from 3.79–4.14 Å, and are consistent with the η^2-β-diketiminato ligand coordination mode. Several of the aryl group carbon atoms have short contacts to the barium ion. In particular, the Ba–C(4) and Ba–C(24) distances are 3.029(8) and 2.940(8) Å, respectively. Distances from barium to the *ortho*-carbon atoms of the aryl rings range from 3.31 to 3.66 Å. For comparison, the barium– carbon distances in Ba(η^5-L$^{t\mathrm{Bu}}$)$_2$ range from 3.06 to 3.16 Å [12b], while the barium–carbon distances in Ba($C_5(CH_3)_5$)$_2$ are 2.98–2.99 Å [16]. Thus the barium–carbon distances to the *ipso*-carbon atoms of the aryl groups are comparable to those of metallocenes, and must constitute strong interactions. The fact that **3** is isolated as a solvent free complex is probably related to the saturation of the coordination sphere about the barium atoms by bonding to the bulky aryl groups.

A perspective view of **4** is shown in Fig. 3. The molecular structure of **4** is similar overall to that of **2**. The calcium–iodine bond lengths are 3.131(1) and 3.157(1) Å, and the angles associated with the Ca_2I_2 core are very close to 90°. The calcium–oxygen bond length is 2.390(2) Å, which is identical to that of **2** within experimental error. The calcium–nitrogen bond distances are 2.332(2) and 2.333(3) Å, while the calcium–carbon distances range from 2.695(3) to 2.779(3) Å. The calcium–nitrogen bond distances in **4** are shorter than those of **2**, possibly due to accommodation of the very bulky aryl groups in **2**. The calcium–carbon distances are similar in **2** and **4**, except that there is no asymmetry in the bond distances to L$^{t\mathrm{Bu}}$ in **4**. The lack of asymmetry in the calcium–carbon distances is probably due to the lower steric profile of L$^{t\mathrm{Bu}}$ compared to L$^{\mathrm{Ar'}}$. The nitrogen–calcium–nitrogen bite angle is 76.75(9)°.

A perspective view of **5** is shown in Fig. 4. The molecular structure of **5** consists of a dimer that is held together by two bridging iodide ligands. Each strontium ion is additionally coordinated to one η^5-L$^{t\mathrm{Bu}}$ and one tetrahydrofuran ligand. The overall molecular structure is similar to those of **2** and **4**. The strontium–iodine bond distances are 3.275(2) and 3.289(2) Å. The angles associated with the Sr_2I_2 core are close to 90°, and the equivalent strontium–iodine bond lengths make this core nearly a perfect square. The strontium–nitrogen bond distances are 2.466(3) and 2.473(3) Å, while the strontium–carbon distances range from 2.845(4) to 2.921(4) Å. For comparison, the strontium–nitrogen and strontium–carbon bond lengths in Sr(η^5-L$^{t\mathrm{Bu}}$)$_2$ range from 2.49 to 2.52 and 2.96 to 3.02 Å, respectively [12b]. Thus, the strontium–nitrogen and strontium–carbon bond lengths in **5** are slightly shorter than those of Sr(η^5-L$^{t\mathrm{Bu}}$)$_2$, and support the assignment of η^5-L$^{t\mathrm{Bu}}$ ligands in **5**. Unlike in **2**, there is only a small bond length asymmetry on the side of the L$^{t\mathrm{Bu}}$ ligand that is closest to the tetrahydrofuran ligand. The larger size of the

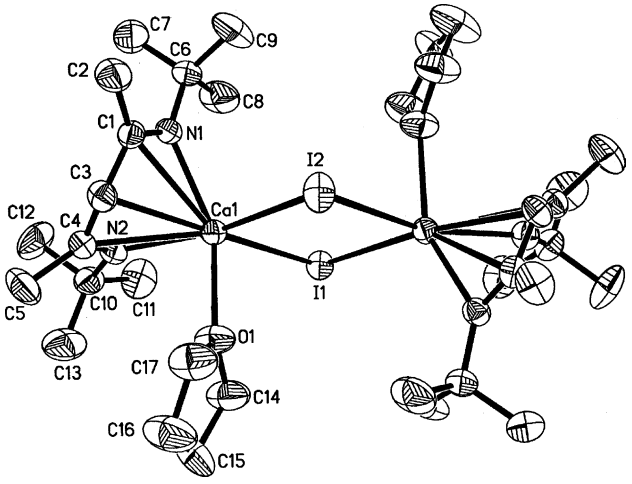

Fig. 3. Perspective view of **4** with probability ellipsoids at the 50% level.

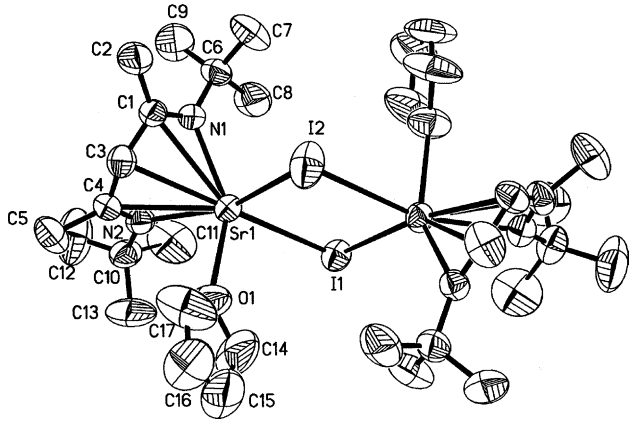

Fig. 4. Perspective view of **5** with probability ellipsoids at the 50% level.

strontium ion, compared to the calcium ion, lessens the steric interactions between the β-diketiminato and tetrahydrofuran ligands. The nitrogen–strontium–nitrogen bite angle is 72.79(11)°.

Perspective views of **6** are shown in Fig. 5. Fig. 5(a) shows one half of the tetrameric structure, while Fig. 5(b) presents the complete tetrameric molecule. Complex **6** is located on an inversion center, which makes the two halves of the molecule identical by symmetry. The overall structure consists of two $Ba_2(L^{tBu})_3I$ units that are connected through two essentially linear bridging iodide ligands. Each barium ion within the $Ba_2(L^{tBu})_3I$ unit bonds to one iodide and one terminal η^5-L^{tBu} ligand, and is connected to an adjacent barium ion through a μ-η^2:η^5-β-diketiminato ligand. The barium–iodine bond lengths are 3.362(1) and 3.454(1) Å, and are thus slightly asymmetric. These bond lengths and degree of asymmetry are very similar to those of **3**. The barium–nitrogen and barium–carbon distances associated with the terminal η^5-L^{tBu} ligands range from 2.638(8) to 2.680(8) and 2.989(10) to 3.114(10) Å, respectively. These barium–nitrogen distances are very similar to those of **3**. These values for **6** can also be compared to those of Ba(η^5-L^{tBu})$_2$, for which the barium nitrogen and barium–carbon distances were 2.62–2.68 and 3.08–3.16 Å, respectively [12b]. These bond lengths for Ba(η^5-L^{tBu})$_2$ are essentially identical to the values for the terminal η^5-L^{tBu} ligands in **6**. The barium–nitrogen distances associated with the μ-η^2:η^5-L^{tBu} ligands are 3.032(7) and 3.070(8) Å for the η^5-interaction with Ba(1) and 2.837(7) and 2.860(8) Å for the η^2-interaction with Ba(2). These values are longer than those of the terminal η^5-L^{tBu} ligands, the related values in **3**, and those of Ba(η^5-L^{tBu})$_2$ [12b], as expected for a bridging β-diketiminato ligand. The barium–carbon distances for the bridging η^5-interaction with Ba(1) range from 3.14 to 3.18 Å, which are slightly longer than those of the terminal η^5-L^{tBu} ligands in **6** and **3** and are comparable to the related distances in Ba(η^5-L^{tBu})$_2$ [12b]. The barium–carbon distances to Ba(2) ranged from 3.54 to 3.76 Å, supporting the assignment of an η^2-interaction to the nitrogen atoms. The bite angles of the terminal η^5-L^{tBu} ligands were 67.7(2)° and 68.5(3)°, while the values for the μ-η^2:η^5-L^{tBu} ligand were 66.4(2)° and 61.5(2)°.

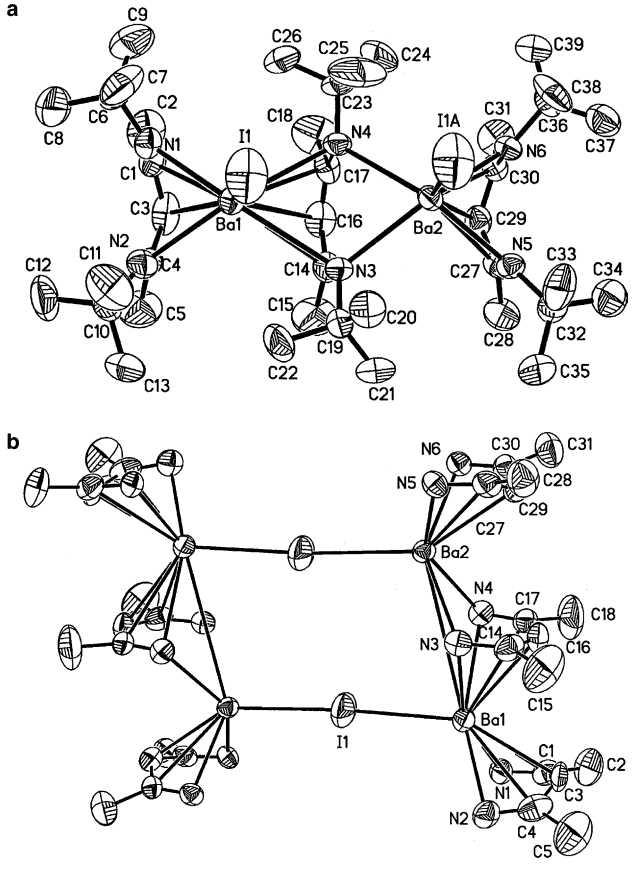

Fig. 5. Perspective views of **6** with probability ellipsoids at the 50% level: (a) one-half molecule with atom labels, (b) overall tetrameric molecule, with *tert*-butyl groups removed for clarity.

3. Discussion

3.1. Characterization of the η^5-bonding

The η^5-coordination of the β-diketiminato ligands is a prominent structural feature of **2** and **4**–**6**. We have recently reported that group 2 complexes adopt sandwich-like structures with η^5-L^{tBu} ligands [12]. In our paper on M(η^5-L^{tBu})$_2$ (M = Ca, Sr, Ba) [12b], the η^5-L^{tBu} bonding was analyzed in terms of the planes incorporating the atoms MN_2 (a), $N_2(C_\alpha)_2$ (b), and $(C_\alpha)_2C_\beta$ (c). For these complexes, the *a*/*b* angles were between 70° and 72°, the *b*/*c* angles were between 25° and 26°, and these metrical parameters were used to support the η^5-coordination mode and differentiate it from the more common η^2-form (which has much smaller *a*/*b* and *b*/*c* values [12b,13]). The corresponding metrical parameters for **2**–**5** are as follows: **2**, $a/b = 74.0(1)°$ and $b/c = 30.0(2)°$; **3**, $a/b = 172.0(4)°$ and $b/c = 4.6(1.4)°$; **4**, $a/b = 77.7(1)°$ and $b/c = 28.4(2)°$; **5**, $a/b = 75.5(1)°$ and 28.3(3)°. For **2**, **4** and **5**, these values are close to those of M(η^5-L^{tBu})$_2$, and are consistent with similar η^5-bonding of the L^{tBu} ligands. For **6**, the terminal η^5-L^{tBu} ligands have *a*/*b* values of 73.3(3)° and 75.3(4)° and *b*/*c* values of 31(2)° and 31.5(8)°, which are similar to those of M(η^5-L^{tBu})$_2$, **2**, **4**, and **5**. For the μ-η^2:η^5-β-diketiminato ligand, the side with the η^5-interaction has $a/b = 89.4(4)°$ and $b/c = 5(2)°$, while the side with the η^2-interaction has $a/b = 54.2(5)°$ and $b/c = 5(2)°$. The a/b angle associated with η^5-interaction in **6** is larger than the related angles in M(η^5-L^{tBu})$_2$, **2**, **4**, **5**, and the η^5-L^{tBu} terminal ligands in **6**, possibly to maximize bonding to C(16) (which is essentially coplanar with the other μ-η^2:η^5-β-diketiminato ligand core atoms). In **3**, the assignment of the

η^2-coordination mode is clearly warranted by the large *a*/*b* and small *b*/*c* angles.

3.2. Comparison with previously reported group 2 β-diketiminato complexes

All of the other heavier group 2 β-diketiminato complexes described to date feature 2,6-diisopropylphenyl [3,4b,4c,4d,15], 2-methoxyphenyl [4a], or cyclohexyl [14] moieties as the nitrogen atom substituents and methyl groups on the α-carbon atoms of the ligand core. Calcium, strontium, and barium complexes containing L^{Ar} exhibit the η^2-coordination mode, through the nitrogen atoms of L^{Ar}. Adoption of the η^2-coordination mode in complexes containing L^{Ar} is presumably a steric effect that is driven by the bulky aromatic isopropyl substituents. Use of the *N*-cyclohexyl-substituted diketiminato ligand L^{Cy} afforded the dimeric barium complex $Ba_2(L^{Cy})_3(N(SiMe_3)_2)$, which contains η^5-, μ-η^2:η^5-, and μ-η^2:η^3−β-diketiminato ligands [14]. The various coordination modes of β-diketiminato ligands have been recently reviewed [13]. The terminal η^5-β-diketiminato ligand has been structurally documented in a few main group, lanthanide, and early transition metal complexes, but still remains rare [12b,13,18]. In the present work, **2** and **4**–**6** possess the terminal η^5-β-diketiminato ligand coordination mode. In particular, **2** is the first group 2 complex that contains an η^5-$L^{Ar'}$ ligand. In **3**, the η^2-coordination mode appears to be stabilized through several close Ba–C_{aryl} contacts. With the smaller calcium ion in **2**, such contacts may be too long to afford much stabilization, and instead tetrahydrofuran and η^5-$L^{Ar'}$ coordination ensue. The present results, our previous report on $M(\eta^5\text{-}L^{tBu})_2$ [12b], and $Ba_2(L^{Cy})_3(N(SiMe_3)_2)$ [14] suggest that the η^5-β-diketiminato coordination mode should be common in the heavier group 2 complexes when alkyl groups or less bulky aromatic rings are present on the nitrogen atoms. Adoption of the η^5-β-diketiminato coordination mode with $L^{Ar'}$ and related ligands containing bulky aryl groups will depend upon the size of the group 2 metal ion, the degree of coordinative unsaturation at the metal center, and the possibility of aryl group interactions with the metal center.

3.3. Redistribution equilibria in solution

The redistribution equilibria of **2**–**6** are of relevance to recent reports of lactide polymerization catalysis by unsymmetrical group 2 complexes (LMX) containing β-diketiminato ligands (L) [3,4]. A recent report by Hill has explored the stability of β-diketiminato complexes of the formula $L^{Ar}M(N(SiMe_3)_2)(THF)$ toward ligand redistribution in solution [3c]. Interestingly, $L^{Ar}Ca(N(SiMe_3)_2)(THF)$ was found to be inert toward ligand redistribution in toluene-d_8 solution at ambient temperature, while $L^{Ar}Ba(N(SiMe_3)_2)(THF)$ was in equilibrium with $Ba(L^{Ar})_2$ and $Ba(N(SiMe_3)_2)(THF)_x$ under the same conditions. It was proposed that the larger size and lower Lewis acidity of the barium ion makes it more susceptible toward ligand redistribution, compared to $L^{Ar}Ca(N(SiMe_3)_2)(THF)$ [3c]. In the present work, **2** and **3** did not show any evidence for ligand redistribution in solution. The lack of ligand redistribution in **3** is probably related to the coordination of both aryl ligands to the barium ion, which creates a more rigid, very large ligand. Harder has reported the synthesis and structure of $Ba(L^{Ar})_2$, which contains no Ba–C_{aryl} interactions and only η^2-L^{Ar} ligands [15]. The $L^{Ar'}$ ligand employed in the present work is bulkier than L^{Ar}, due to the presence of the *tert*-butyl groups on the α-carbon atoms of the ligand core. These *tert*-butyl groups may provide enough steric bulk to destabilize $Ba(L^{Ar'})_2$, and thus remove low energy ligand redistribution paths for **3**. The lack of redistribution equilibria for **2** may also be related to destabilization of $Ca(L^{Ar'})_2$. In solution, **4** showed multiple equilibria, and as a result, it was not possible to carry out equilibrium constant determinations. However, the amount of products other than the unsymmetrical starting materials was small and the equilibrium constants are thus small. For **5**, NMR spectra suggested the equilibrium process depicted in Eq. (3), and an equilibrium constant of 5.3×10^{-5} M was determined at 31.3 °C. Thus, the equilibrium lies far toward the unsymmetrical starting material **5**. These experiments demonstrate that the unsymmetrical complexes **2**–**5** are strongly favored thermodynamically in solution. There are few other equilibrium constant data with which the behavior of **2**–**5** can be compared. $Cp^*CaI(THF)_2$ is reported to dissociate in tetrahydrofuran-d_8 to afford $Cp^*_2Ca(THF)_2$ and $CaI_2(THF)_2$ with $K_{eq} = 4$ [5]. $(C_5HiPr_4)CaI(OEt_2)_n$ dissociates in diethyl ether to $Ca(C_5HiPr_4)_2$ and $CaI_2(OEt_2)_n$ with $K_{eq} = 2$ [6]. Mixtures of $Ba(CH_2C_6H_5)_2(THF)_2$ and $Ba(C_5Me_4SiMe_2C_6H_5)_2$ favor the heteroleptic complex $Ba(C_5Me_4SiMe_2C_6H_5)(CH_2C_6\ H_5)(THF)$ with K_{eq} values that are much greater than one [19]. The complex $[Ba(C_5HiPr_4)(I)(THF)_2]_2$ resists ligand redistribution in tetrahydrofuran, but does scramble ligands in less coordinating solvents such as benzene [8]. We have recently reported that $[Sr(\mu\text{-}\eta^5\text{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ exists in equilibrium with $Sr(\eta^5\text{-}L^{tBu})_2$ and $Sr_4(tBu_2pz)_8$ (tBu_2pz = 3,5-di-*tert*-butylpyrazolato) [12c]. A van't Hoff analysis of this equilibrium between 46 and 104 °C afforded $\Delta H^0 = 22.2 \pm 0.7$ kcal/mol, $\Delta S^0 = 43.7 \pm 1.9$ cal/mol · K, and $\Delta G^0(298K) = 9.2 \pm 0.9$ kcal/mol. The equilibrium constant at 46.0 °C was 2.17×10^{-6} M. Thus, the mixed ligand complex $[Sr(\mu\text{-}\eta^5\text{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ is strongly favored thermodynamically. Redistribution equilibria are also important for the heavier group 2 Grignard analogs [20].

3.4. Conclusions

We have prepared and characterized a series of mixed ligand complexes containing β-diketiminato and iodide ligands. Observation of tetrahydrofuran coordination depended on the nature of the β-diketiminato ligand and the metal ion. $[Ca(\eta^5\text{-}L^{Ar'})(\mu\text{-}I)(THF)]_2$, $[M(\eta^5\text{-}L^{tBu})(\mu\text{-}I)(THF)]_2$ (M = Ca, Sr), and $Ba_4(L^{tBu})_6(I)_2$ contain terminal η^5-β-diketiminato ligands, which is a novel coordination mode for this class of ligands. In addition, $Ba_4(L^{tBu})_6(I)_2$ contains novel $\mu\text{-}\eta^2\text{:}\eta^5$-β-diketiminato ligands. The complex $[Ba(\eta^2\text{-}L^{Ar'})(\mu\text{-}I)]_2$ contains η^2-β-diketiminato ligands, and this coordination mode appears to be stabilized by close Ba–C_{aryl} contacts to the *ipso*- and *ortho*-carbon atoms of the aryl rings. $[M(\eta^5\text{-}L^{tBu})(\mu\text{-}I)(THF)]_2$ (M = Ca, Sr) undergo ligand redistribution in solution, although the position of the equilibrium strongly favors the mixed ligand complexes under the conditions studied. $[Ca(\eta^5\text{-}L^{Ar'})(\mu\text{-}I)(THF)]_2$ and $[Ba(\eta^2\text{-}L^{Ar'})(\mu\text{-}I)]_2$ show no evidence for ligand redistribution equilbria in solution. The combined results suggest that $L^{Ar'}$ and L^{tBu} are strongly coordinating ligands for group 2 metal ions, and are effective at stabilizing mixed ligand complexes toward redistribution equilibria.

4. Experimental

4.1. General considerations

All reactions were performed under an inert atmosphere of argon using either glove box or Schlenk line techniques. Tetrahydrofuran and toluene were distilled from sodium. $M(\eta^5\text{-}L^{tBu})_2$ [12b], $L^{tBu}H$ [21], and $L^{Ar'}H$ [22] were prepared according to literature methods. Anhydrous metal iodides were purchased from Aldrich Chemical and were used as received. ^1H and $^{13}C\{^1H\}$ NMR were obtained at 300 and 75 MHz in the indicated solvents. Infrared spectra were obtained using Nujol as the medium. Elemental analyses were performed by Midwest Microlab, Indianapolis, IN. Melting points were obtained on a Haake-Buchler HBI digital melting point apparatus and are uncorrected.

4.2. Preparation of $K(L^{Ar'})(THF)_3$ (**1**)

A 100-mL Schlenk flask was charged with $L^{Ar'}H$ (5.00 g, 9.96 mmol) and tetrahydrofuran (60 mL). To this solution was added potassium hydride (0.80 g, 19.9 mmol), and the resultant solution was stirred at ambient temperature for 24 h. During this time a deep-yellow solution was observed. The resulting solution was filtered through a 2-cm pad of Celite on a coarse glass frit to afford a clear yellow solution. The volume of the filtrate was reduced to 20 mL, and then this solution was layered with hexane (40 mL). Equilibration at ambient temperature for 48 h gave yellow crystals. Removal of the solvent with a cannula, followed by vacuum drying, afforded **1** as a yellow crystalline solid (6.70 g, 89%): m.p. 332–334 °C (dec); IR (Nujol, cm^{-1}) 1547 (w), 1311 (s), 1254 (s), 1165 (s), 1082 (s), 1018 (s), 921 (w), 798 (s); ^1H NMR (toluene-d_8, 23 °C, δ) 6.77–6.99 (m, 6H, aryl-*H*), 4.89 (s, 1 H, β-C*H*), 3.54 (m, 12H, OCH_2CH_2), 3.27 (septet, $J = 6.3$ Hz, 4H, $CH(CH_3)_2$), 1.46 (m, 12H, OCH_2CH_2), 1.34 (s, 18H, $C(CH_3)_3$), 1.33 (d, $J = 6.3$ Hz, 12H, $CH(CH_3)_2$), 0.96 (d, $J = 6.3$ Hz, 12H, $CH(CH_3)_2$); $^{13}C\{^1H\}$ NMR (toluene-d_8, 23 °C, ppm) 166.13 (s, $CC(CH_3)_3$), 151.69 (s, C_{ipso}), 135.96 (s, C_{ortho}), 123.5 (s, C_{para}), 118.43 (s, C_{meta}), 89.83 (s, β-*C*H), 67.57 (s, OCH_2CH_2), 44.22 (s, $C(CH_3)_3$), 32.74 (s, $C(CH_3)_3$), 27.21 (s, $CH(CH_3)_2$), 25.67 (s, OCH_2CH_2), 25.00 (s, $CH(CH_3)_2$), 23.47 (s, $CH(CH_3)_2$).

Anal. Calc. for $C_{47}H_{77}KN_2O_3$: C, 74.55; H, 10.25; N, 3.70. Found: C, 75.46; H, 10.32; N, 4.06%.

4.3. Preparation of $[Ca(L^{Ar'})(THF)(\mu\text{-}I)]_2$ (**2**)

A 100-mL Schlenk flask was charged with **1** (0.553 g, 0.731 mmol), CaI_2(0.215 g, 0.731 mmol), and tetrahydrofuran (40 mL). The resultant solution was stirred for 18 h at ambient temperature to afford a yellow solution. The volatile components were removed under reduced pressure and the residue was extracted with toluene (40 mL). This mixture was filtered through a 2-cm pad of Celite on a medium glass frit to afford a clear yellow solution. The filtrate was concentrated to a volume of 15 mL, hexane (10 mL) was mixed with the toluene solution, and this solution was stored at −25 °C for 7 days to afford **2** as yellow crystals (0.35 g, 62%): m.p. 340–347 °C (dec); IR (Nujol, cm^{-1}) 1546 (s), 1399 (s), 1259 (s), 1211 (w), 1185 (w), 1097 (w), 1024 (s), 930 (w), 871 (s), 798 (s), 687 (w); ^1H NMR (benzene-d_6, 23 °C, δ) 7.00–7.06 (m, 12H, aryl-*H*), 5.52 (s, 2H, β-C*H*), 3.24 (septet, $J = 7.2$ Hz, 8H, $CH(CH_3)_2$), 3.12 (m, 8H, OCH_2CH_2), 1.34 (d, $J = 7.2$ Hz, 24H, $CH(CH_3)_2$), 1.24 (s, 36H, $C(CH_3)_3$), 1.17 (d, $J = 7.2$ Hz, 24H, $CH(CH_3)_2$), 0.89 (m, 8H, OCH_2CH_2); $^{13}C\{^1H\}$ NMR (benzene-d_6, 23 °C, ppm) 174.63 (s, $CC(CH_3)_3$), 145.69 (s, C_{ipso}), 139.25 (s, C_{ortho}), 123.64 (s, C_{meta}), 123.33 (s, C_{para}), 90.25 (s, β-*C*H), 69.65 (s, OCH_2CH_2), 44.77 (s, $C(CH_3)_3$), 32.46 (s, $CH(CH_3)_3$), 28.63 (s, $CH(CH_3)_2$), 26.44 (s, $CH(CH_3)_2$), 24.52 (s, OCH_2CH_2), 23.46 (s, $CH(CH_3)_2$).

Anal. Calc. for $C_{78}H_{122}Ca_2I_2N_4O_4$: C, 63.22; H, 8.30; N, 3.78. Found: C, 62.98; H, 8.15; N; 3.31%. The X-ray crystal structure was solved as $\mathbf{2}\cdot(C_6H_{14})_{1.0}$, but the crystals lose hexane rapidly at ambient temperature and the bulk material was isolated as hexane-free crystals (*Anal.* Calc. for $C_{78}H_{122}Ca_2I_2N_4O_4\cdot C_6H_{14}$: C, 64.35; H, 8.74; N, 3.57%).

4.4. Preparation of $[(L^{Ar'})Ba(\mu\text{-}I)]_2$ (3)

In a fashion similar to the preparation of **2**, treatment of **1** (0.553 g, 0.731 mmol) with BaI_2 (0.288 g, 0.731 mmol) afforded **3** as yellow crystals (0.150 g, 27%): m.p. 310–314 °C (dec); IR (Nujol, cm^{-1}) 1614 (w), 1544 (s), 1404 (s), 1260 (s), 1214 (w), 1139 (w), 1092 (s), 1020 (m), 872 (w), 798 (s); ^1H NMR (benzene-d_6, 23 °C, δ) 7.03–7.17 (m, 12H, aryl-*H*), 5.24 (s, 2H, β-C*H*), 2.99 (septet, $J = 6.9$ Hz, 8H, C*H*$(CH_3)_2$), 1.24 (d, $J = 6.9$ Hz, 24H, CH(C*H*$_3)_2$), 1.21 (d, $J = 6.9$ Hz, 24H, CH(C*H*$_3)_2$), 1.19 (s, 36 H, C(C*H*$_3)_3$); ^{13}C $\{^1H\}$ NMR (benzene-d_6, 23 °C, ppm) 169.77 (s, *C*C$(CH_3)_3$), 146.68 (s, C_{ipso}), 137.67 (s, C_{ortho}), 126.43 (s, C_{meta}), 123.76 (s, C_{para}), 94.55 (s, β-*C*H), 43.83 (s, *C*$(CH_3)_3$), 32.41 (s, C(*C*$H_3)_3$), 28.19 (s, *C*H$(CH_3)_2$), 24.47 (s, CH(*C*$H_3)_2$), 23.37 (s, CH(*C*$H_3)_2$).

Anal. Calc. for $C_{70}H_{106}Ba_2I_2N_4$: C, 54.88; H, 6.97; N, 3.66. Found: C, 53.86; H, 6.83; N, 3.54%.

4.5. Preparation of $[Ca(L^{tBu})(\mu\text{-}I)(THF)]_2$ (4)

A 100-mL Schlenk flask was charged with $Ca(\eta^5\text{-}L^{tBu})_2$ (0.40 g, 0.87 mmol), CaI_2 (0.255 g, 0.87 mmol), a stir bar, and tetrahydrofuran (30 mL). The resultant solution was refluxed for 3 h, and then the volatile components were removed under reduced pressure. The residue was dissolved in hot toluene (40 mL) and the resultant solution was filtered through a 2-cm pad of Celite on a medium glass frit. The clear, colorless solution was then concentrated to a volume of 30 mL and was stored at −25 °C for 7 days to afford **4** as a colorless solid (0.53 g, 68%): m.p. 202–204 °C (dec); IR (Nujol, cm^{-1}) 1631 (w), 1548 (s), 1519 (m), 1496 (s), 1359 (s), 1256 (s), 1210 (s), 1093 (w), 1032 (s), 1002 (m), 975 (w), 917 (w), 879 (m), 799 (m), 725 (m); ^1H NMR (toluene-d_8, 23 °C, δ) 4.30 (s, 2H, β-C*H*), 3.85 (m, 8H, OCH_2CH_2), 2.05 (s, 12H, C-CH_3), 1.47 (s, 8H + 36H, overlapped OCH_2CH_2 and C(C$H_3)_3$); ^{13}C $\{^1H\}$ NMR (toluene-d_8, 23 °C, ppm) 161.18 (s, *C*-CH_3), 90.07 (s, β-*C*H), 69.66 (O*C*H_2CH$_2$), 54.38 (s, *C*$(CH_3)_3$), 32.89 (s, C(*C*$H_3)_3$), 25.39 (OCH$_2$*C*H$_2$), 24.81 (s, C-*C*H_3). NMR data are reported only for the major isomer (61% of total integration). In addition, $Ca(\eta^5\text{-}L^{tBu})_2$ (13% of total integration) and an unidentified species (26% of total integration) were observed.

Anal. Calc. for $C_{34}H_{66}Ca_2I_2N_4O_2$: C, 45.53; H, 7.42; N, 6.25. Found: C, 46.18; H, 7.45; N, 5.88%.

4.6. Preparation of $[Sr(L^{tBu})(\mu\text{-}I)(THF)]_2$ (5)

In a fashion similar to the preparation of **4**, treatment of $Sr(\eta^5\text{-}L^{tBu})_2$ (0.80 g, 1.58 mmol) with SrI_2 (0.60 g, 1.58 mmol) in tetrahydrofuran afforded **5** as colorless crystals (0.83 g, 53%): m.p. 250–255 °C (dec); IR (Nujol, cm^{-1}) 1630 (w), 1548 (m), 1459 (s), 1379 (s), 1358 (s), 1260 (s), 1210 (m), 1093 (m), 1025 (m), 878 (w), 800 (s); ^1H NMR (toluene-d_8, 23 °C, δ) 4.32 (s, 2H, β-C*H*), 3.69 (m, 8H, OCH_2CH_2), 2.05 (s, 12H, C-CH_3), 1.46 (s, 8H + 36H, overlapped OCH_2CH_2 and C(C$H_3)_3$); ^{13}C $\{^1H\}$ NMR (toluene-d_8, 23 °C, ppm) 160.55 (s, *C*-CH_3), 89.73 (s, β-*C*H), 68.74 (O*C*H_2CH$_2$), 54.49 (s, *C*$(CH_3)_3$), 32.98 (s, C(*C*$H_3)_3$), 25.60 (OCH$_2$*C*H$_2$), 24.79 (s, C-*C*H_3).

Anal. Calc. for $C_{34}H_{66}Sr_2I_2N_4O_2$: C, 41.17; H, 6.71; N, 5.65. Found: C, 39.79; H, 6.63; N, 5.63%.

4.7. Preparation of $Ba_4(L^{tBu})_6(I)_2$ (6)

In a fashion similar to the preparation of **4**, treatment of $Ba(\eta^5\text{-}L^{tBu})_2$ (0.20 g, 0.359 mmol) with BaI_2 (0.047 g, 0.112 mmol) in tetrahydrofuran afforded **6** as yellow crystals (0.06 g, 24%): m.p. 244–248 °C (dec); IR (Nujol, cm^{-1}) 1529 (s), 1406 (s), 1248 (s), 1092 (w), 1023 (s), 996 (w), 963 (m), 799 (m), 773 (w), 751 (w), 693 (w); ^1H NMR (toluene-d_8, 23 °C, δ) 4.31 (broad s, 6H, β-C*H*), 1.99 (broad s, 36H, C-CH_3), 1.39 (broad s, 108H, C(C$H_3)_3$); the low solubility in toluene-d_8 precluded collection of the ^{13}C $\{^1H\}$ NMR spectrum.

Anal. Calc. for $C_{78}H_{150}Ba_4I_2N_{12}$: C, 45.49; H, 7.34; N, 8.16. Found: C, 46.84; H, 7.36; N, 7.45%.

4.8. X-ray crystallographic structure determinations for 2–6

Diffraction data for **2**–**6** were collected on a Bruker *P4/CCD* diffractometer equipped with Mo radiation and a graphite monochromator. Complexes **2**, **3**, **5**, and **6** were mounted in thin walled glass capillaries. Data collections were conducted at ambient temperature. The data collection for **4** was carried out at −61 °C. In all cases, a sphere of data was measured at 10–20 s/frames and 0.2° between frames. The frame data were indexed and integrated with the manufacturer's SMART, SAINT, and SADABS software [23]. The models were refined and reported using Sheldrick's SHELX-97 software [24].

Complex **2** crystallized as yellow flat fragments. The hydrogen atoms were placed in calculated positions. One equivalent of hexane solvate was disordered near an inversion center and was modeled with partial atoms and refined isotropically. All other non-hydrogen atoms were refined anisotropically. There is a tetrahydrofuran ligand on the calcium atom that exhibits unreliable bond lengths and angles due to disorder. The overall molecule occupies a crystallographic inversion center.

Complex **3** crystallized as yellow rods. Hydrogen atoms were placed in calculated positions. All non-hydrogen atoms were refined anisotropically. The molecule occupies a crystallographic inversion center with no solvent present.

Complex **4** crystallized as colorless flat rods. The dimer occupies a crystallographic 2-fold rotation axis with

both bridging iodine atoms on the 2-fold axis. Hydrogen atoms were placed in observed or calculated positions. Partial occupancy positions were used to describe the disorder in the *tert*-butyl group on C(10) and the disordered tetrahydrofuran carbon atoms. All non-hydrogen atoms were nevertheless refined anisotropically. Complex **5** crystallized as colorless cubes, is isostructural with **4**, and shows similar disorder.

Complex **6** crystallized as yellow rhomboids. The molecule is a tetramer occupying a crystallographic inversion center. Hydrogen atoms were placed in calculated positions, and all non-hydrogen atoms were refined anisotropically.

5. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, quoting No. 267402 for **2**, No. 267403 for **3**, No. 267404 for **4**, No. 267405 for **5**, and No. 267406 for **6**. An iron(II) complex of 2,6-di(pyrazol-1-yl)pyrazine that crystallises in three forms, two of which exhibit an unusual angular Jahn–Teller distortion

Colin A. Kilner, Malcolm A. Halcrow *

School of Chemistry, University of Leeds, Woodhouse Lane, Leeds LS2 9JT, UK

Received 30 March 2005; accepted 24 June 2005
Available online 10 August 2005

Dedicated to Malcolm Chisholm on the occasion of his 60th birthday.

Abstract

Treatment of hydrated $FeCl_2$ with 2 equiv. of 2,6-di(pyrazol-1-yl)pyrazine (L^1H) and $AgSbF_6$ in refluxing $MeNO_2$ yields $[Fe(L^1H)_2][SbF_6]_2$ (**1**[**SbF$_6$**]$_2$). This compound is fully high-spin as a powder between 5 and 300 K, and exhibits a small zero-field splitting consistent with it adopting an unusual angularly distorted six-coordinate coordination geometry. Slow diffusion of Et_2O into a $MeNO_2$ solution of the compound gives varying proportions of three different crystal forms. Solvent-free **1**[**SbF$_6$**]$_2$ and solvated **1**[**SbF$_6$**]$_2 \cdot 2CH_3NO_2$ are both high-spin at 150 K, and have undergone the proposed angular Jahn–Teller distortion to differing extents. This is the first time that this structural distortion has been observed in an iron(II) complex of a 2,6-di(pyrazol-1-yl)pyrazine derivative. In contrast **1**[**SbF$_6$**]$_2 \cdot 3CH_3NO_2$ is low-spin at room temperature and has a regular six-coordinate geometry.

1. Introduction

We have been studying the spin-crossover [1] properties of iron(II) complexes of ligands from the 2,6-di(pyrazol-1-yl)pyrazine (L^1R) [2–6] and 2,6-di(pyrazol-1-yl)pyridine (L^2R) series [2,6–13]. A wide range of L^1R and L^2R derivatives with different 'R' groups are synthetically accessible, yielding homoleptic iron(II) complexes whose spin states depend on the steric and inductive properties of 'R' in a qualitatively predictable way [2,10]. A complication of this chemistry, however, is the existence of an unusual angular Jahn–Teller distorted structure in some of our high-spin $[Fe(L^2R)_2]^{2+}$ compounds, which traps them in a high-spin state [8,12,13]. Similar structures have also been observed in some iron(II) complexes of 6,6″-disubstituted 2,2′:6′,2″-terpyridines [14]. As a part of this work, we have described two iron(II) complex salts of the unsubstituted 2,6-di(pyrazol-1-yl)pyrazine ligand, $[Fe(L^1H)_2][BF_4]_2$ (**1**[**BF$_4$**]$_2$) and $[Fe(L^1H)_2][ClO_4]_2$ (**1**[**ClO$_4$**]$_2$) [3,4,6]. Both these solids undergo abrupt high → low spin transitions upon cooling, at 223 and 206 K, respectively. Although neither compound is crystalline, powder diffraction studies showed that they are not isostructural, that both spin transitions were accompanied by a crystallographic phase change [3,4], and that the high-spin phase of **1**[**ClO$_4$**]$_2$ (but *not* **1**[**BF$_4$**]$_2$) was isostructural with the chemically very similar compound $[Fe(L^2H)_2][BF_4]_2$ (**2**[**BF$_4$**]$_2$) [4]. Interestingly, a solvated crystal phase **1**[**BF$_4$**]$_2 \cdot 3CH_3NO_2$ was also characterised which undergoes abrupt spin-crossover at 198 K, a very similar temperature to the unsolvated material [3]. We

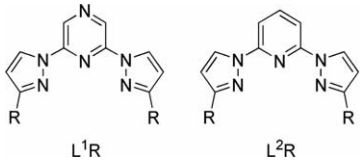
report here a new compound, [Fe-(L^1H)$_2$][**SbF$_6$**]$_2$ (**1**[**SbF$_6$**]$_2$), whose crystallographic and magnetochemical behaviour is very different from the other two salts of the same complex dication.



2. Experimental

All manipulations were carried out in air, using distilled water or reagent-grade solvents. Ligand L^1H was prepared by the literature procedure [15], while all other organic and inorganic reagents were used as supplied.

2.1. Synthesis of [Fe(L^1H)$_2$][SbF$_6$]$_2$(1[SbF$_6$]$_2$)

A mixture of L^1H (0.25 g, 1.2 mmol), $FeCl_2 \cdot 4H_2O$ (0.12 g, 0.59 mmol) and $AgSbF_6$ (0.45 g, 1.2 mmol) in CH_3NO_2 (50 cm^3) was heated at 80 °C for 1 h, yielding a brown solution with a white suspension. The solution was filtered and concentrated in vacuo to ca. 5 cm^3 volume. Addition of excess Et_2O to this solution yielded a yellow precipitate which was stored overnight at −30 °C, then collected, washed with Et_2O and dried in vacuo. Yield: 0.39 g, 68%. Calc. for $C_{20}H_{16}F_{12}FeN_{12}Sb_2$: C, 25.2; H, 1.7; N, 17.7. Found C, 25.3; H, 1.8; N, 17.8%.

2.2. Single crystal X-ray structure determinations

Slow diffusion of Et_2O vapour into a CH_3NO_2 solution of the compound at room temperature yielded a mixture of three different forms: yellow cubic prisms of solvent-free **1**[**SbF$_6$**]$_2$; yellow plates of formula **1**[**SbF$_6$**]$_2 \cdot 2CH_3NO_2$; and brown needles of **1**[**SbF$_6$**]$_2 \cdot 3CH_3NO_2$. Experimental details for all the structure determinations are given in Table 1. X-ray data for **1**[**SbF$_6$**]$_2$ and **1**[**SbF$_6$**]$_2 \cdot 2CH_3NO_2$ were collected on a Nonius KappaCCD area-detector diffractometer, using graphite-monochromated Mo Kα radiation. Data for **1**[**SbF$_6$**]$_2 \cdot 3CH_3NO_2$ were obtained using a Bruker X8

Apex diffractometer, with graphite-monochromated Mo Kα radiation generated by a rotating anode. All the structures were solved by direct methods (SHELXS 97 [16]) and refined by full matrix least-squares on F^2 (SHELXL 97 [17]).

2.2.1. Single crystal X-ray structure of ***1[SbF$_6$]$_2$***

The asymmetric unit contains half a formula unit, with Fe(1) lying on the crystallographic C_2 axis $-x$, y, $1/2 - z$. No disorder was detected during refinement, and no restraints were applied. All non-H atoms were refined anisotropically, while all H atoms were placed in calculated positions and refined using a riding model. The deepest residual Fourier hole of -1.7 e Å^{-3} is 0.9 Å from Sb(18).

2.2.2. Single crystal X-ray structure of ***1[SbF$_6$]$_2$ · 2CH$_3$-NO$_2$***

Both SbF_6^- anions in the asymmetric unit are disordered: one over two equally-occupied orientations, and the other over three sites with a 0.4:0.4:0.2 occupancy ratio. All Sb–F bonds were restrained to 1.86(2) Å, and *trans*-F···F distances within each SbF_6 octahedron to 3.72(2) Å. All non-H atoms except for F atoms with occupancy <0.5 were refined anisotropically. All H atoms were placed in calculated positions and refined using a riding model. The deepest Fourier hole of -1.4 e Å^{-3} lies within one of the disordered anions.

2.2.3. Single crystal X-ray structure of ***1[SbF$_6$]$_2$ · CH$_3$-NO$_2$ (3/2.7)***

Two of the three CH_3NO_2 sites in the asymmetric unit are wholly occupied, while the third was modelled with an occupancy of 0.7. This makes a total solvent content of 2.7 mole equivalents of CH_3NO_2 in the crystal examined. One of the two SbF_6^- anions is disordered over two equally occupied sites, and was modelled with the restraints Sb–F = 1.87(2) Å, and *trans*-F···F = 3.74(2) Å. All non-H atoms were refined anisotropically. All H atoms were placed in calculated positions and refined using a riding model. The highest residual Fourier peak of 1.1 e Å^{-3} lies 0.8 Å from the wholly occupied Sb atom.

2.3. Other measurements

CHN microanalyses were performed by the University of Leeds, Department of Chemistry microanalytical service. Variable temperature magnetic susceptibility measurements were obtained in the solid state using a Quantum Design SQUID magnetometer in an applied field of 1000 G. Diamagnetic corrections for the sample (from Pascal's constants [18]) and the sample holder were applied to the data. Theoretical fits of the susceptibility data to the equation for the zero-field splitting of a high-spin d^6 transition ion [18] were carried out using SIGMAPLOT [19].

3. Results and discussion

The title compound was prepared by reaction of hydrated $FeCl_2$, L^1H and $AgSbF_6$ in a 1:2:2 molar ratio in refluxing CH_3NO_2. The resultant brown solution was filtered to remove an off-white AgCl precipitate and concentrated in vacuo. Addition of a excess Et_2O to the solution yielded a yellow microcrystalline product which analysed cleanly as solvent-free $[Fe(L^1H)_2][SbF_6]_2$ (**1[SbF$_6$]$_2$**). Variable temperature susceptibility data from a powder sample produced by grinding these microcrystals showed that, in contrast to **1[BF$_4$]$_2$** and **1[ClO$_4$]$_2$**, **1[SbF$_6$]$_2$** is fully high-spin over this temperature range (Fig. 1). The small decrease in $\chi_M T$ below 30 K arises from zero-field splitting of the high-spin d^6 ^5E ground term (in the D_{2d} symmetry shown by undistorted compounds of this type). These data were modelled to derive the zero-field splitting parameter [18], yielding $g = 2.18 \pm 0.01$ and $|D| = 5.6 \pm 0.1$ cm^{-1}. This value of $|D|$ is at the low end of the range exhibited by high-spin $[Fe(L^2R)_2]^{2+}$ derivatives ($3 \leqslant |D| \leqslant 13$ cm^{-1} [8,10,13]), which we have suggested might be characteristic of an unusual angular Jahn–Teller distortion in these compounds [13]. The crystallographic study of **1[SbF$_6$]$_2$** described below confirms that this complex does adopt such a distorted structure in the crystal.

Slow diffusion of Et_2O vapour into solutions of **1[SbF$_6$]$_2$** in acetone or CH_3CN afforded homogeneous solvate crystals that suffered from twinning. However, similar crystallisations of **1[SbF$_6$]$_2$** from CH_3NO_2 yielded three different single crystalline phases which were all crystallographically characterised. Two of these were the same yellow colour at room temperature, but had distinct prismatic and plate morphologies. They were, respectively, formulated as solvent-free **1[SbF$_6$]$_2$** and as solvated **1[SbF$_6$]$_2$** · $2CH_3NO_2$. The third crystal form

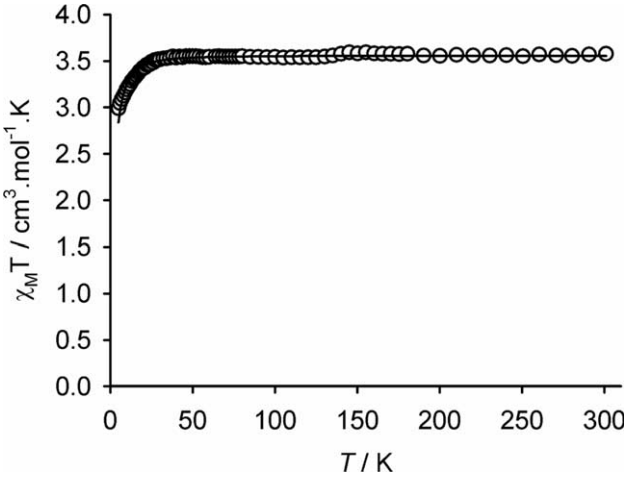

Fig. 1. Variable temperature magnetic susceptibility data for powdered **1[SbF$_6$]$_2$** (○). The line shows the theoretical fit of these data to the equation deriving the zero-field splitting parameter $|D|$. See text for more details.

existed as layered brown needles, from which single crystalline fragments could be separated. These had the formulation **1**[SbF_6]$_2$ · $3CH_3NO_2$ (although one of the three CH_3NO_2 sites was only ca. 70% occupied in the crystal examined). Both solvates rapidly decompose to a yellow powder upon exposure to air. The yellow and brown colours of these crystals are characteristic of high- and low-spin iron centres, respectively, in this series of complexes [3,7–13]. The distribution of the three crystal types in different crystallisation vials appeared to be essentially random. So, different batches of crystals each contained at least two of the three crystal types, with a different one predominating in each case.

The complex dication in unsolvated **1**[SbF_6]$_2$ is six-coordinate, with Fe–N bond lengths that are typical of a high-spin iron centre in this ligand environment [3–5, 7–13] (Table 2, Fig. 2). The coordination geometry about the iron centre is strongly distorted away from octahedral, however. This unusual structure is also exhibited by several $[Fe(L^2R)_2]^{2+}$ complex salts [8,12, 13], including $[Fe(L^2H)_2][SbF_6]_2$ (**2**[SbF_6]$_2$) which is isostructural with **1**[SbF_6]$_2$ [13]. This is the first time it has been observed in a complex from the $[Fe(L^1R)_2]^{2+}$ series, however. The distortion results from a Jahn–Teller splitting of the high-spin iron(II) centre and has two components, which can occur independently of each other [13]. These are a twisting of the plane of one ligand relative to the other about the N{pyridine}–Fe–N{pyridine} vector (so that $\theta < 90°$, Scheme 1); and, a rotation of one ligand about the Fe ion ($\phi < 180°$, Scheme 1). Examples of $[Fe(L^2R)_2]^{2+}$ complexes showing $61.2 \leqslant \theta \leqslant 90°$ and $154.4 \leqslant \phi \leqslant 180°$ have been previously characterised. In **1**[SbF_6]$_2$, θ (the dihedral angle between the least squares planes of the two symmetry-related ligands in the molecule) is 59.84(3)° and ϕ (the angle N(2)–Fe(1)–N(2^i), related by $-x$, y, $1/2 - z$) is 154.52(14)°. So, the structural distortion in **1**[SbF_6]$_2$ is the most pronounced yet observed. In order to accommodate this geometry, Fe(1) also protrudes out of the least-squares planes of the symmetry-related L^1H ligands by 0.4814 (15) Å (Fig. 3).

Table 2
Selected bond lengths (Å) and angles (°) in the crystal structure of **1**[SbF_6]$_2$

Fe(1)–N(2)	2.158(3)
Fe(1)–N(9)	2.191(3)
Fe(1)–N(14)	2.228(3)
N(2)–Fe(1)–N(2^i) (ϕ)	154.52(14)
N(2)–Fe(1)–N(9)	72.05(10)
N(2)–Fe(1)–N(9^i)	129.38(11)
N(2)–Fe(1)–N(14)	71.65(10)
N(2)–Fe(1)–N(14^i)	89.24(10)
N(9)–Fe(1)–N(9′)	84.59(15)
N(9)–Fe(1)–N(14)	141.27(10)
N(9)–Fe(1)–N(14^i)	108.70(11)
N(14)–Fe(1)–N(14^i)	83.85(14)
θ	59.84(3)

The parameters ϕ and θ are those defined in Scheme 1. Symmetry code (i): $-x$, y, $1/2 - z$.

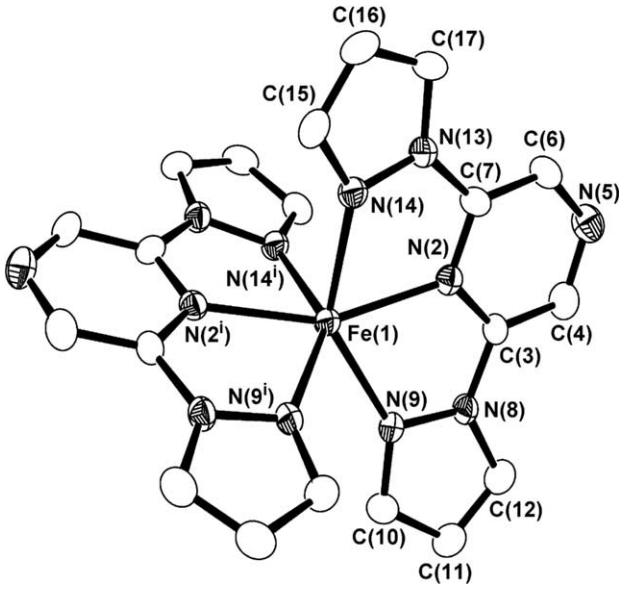

Fig. 2. View of the $[Fe(L^1H)_2]^{2+}$ dication in the crystal structure of **1**[SbF_6]$_2$, showing the atom numbering scheme employed. All H atoms have been omitted for clarity, and thermal ellipsoids are at the 50% probability level. Symmetry code (i): $-x$, y, $1/2 - z$.

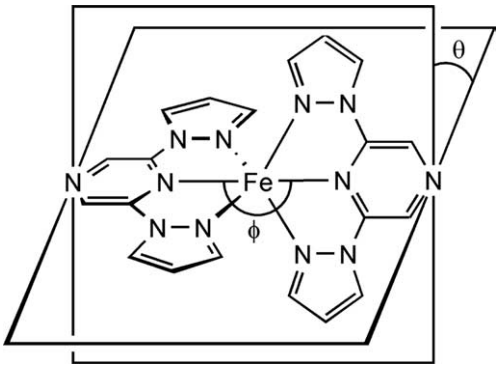

Scheme 1. The angles referred to in the discussion of the angular Jahn–Teller distortion in high-spin $[Fe(L^1H)_2]^{2+}$.

There is an intermolecular π–π interaction between pyrazole rings N(13)–C(17) and N(8)–C(12^{ii}) (related by $1/2 + x$, $-1/2 + y$, z), which are 3.356(5) Å apart at closest approach with a dihedral angle of 14.6(2)° between them. This gives rise to a four-way 'terpyridine embrace' packing motif [20], forming 2-D layers of π-stacked complex centres running parallel to the (110) crystal plane. While the X-ray analysis of **1**[SbF_6]$_2$ was performed at 150 K, further cooling of the crystal to 90 K did not cause it to darken in colour. That implies that the crystalline compound does not undergo a high → low spin-transition within this temperature range. The magnetic properties of **1**[SbF_6]$_2$ as a powder are consistent with that observation, and are what would be expected for a compound with this distorted coordina-

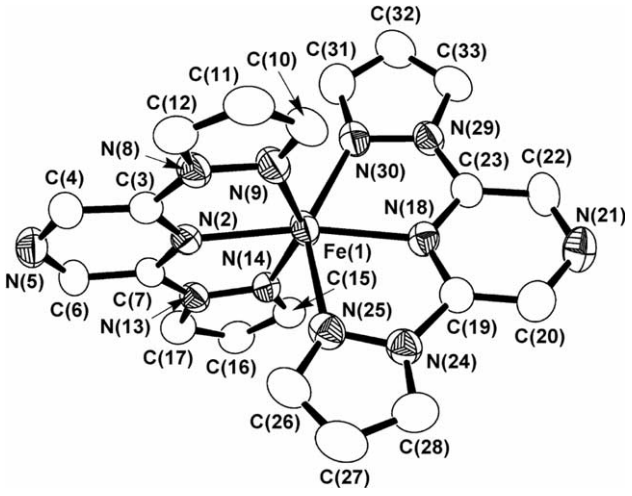

Fig. 3. View of the $[Fe(L^1H)_2]^{2+}$ dication in the crystal structure of $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 2CH_3NO_2$, showing the atom numbering scheme employed. All H atoms have been omitted for clarity, and thermal ellipsoids are at the 50% probability level. The complex dication in $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 3CH_3NO_2$ is visually similar to the one here, and uses the same atom numbering scheme.

tion geometry (see above). Hence, rapidly precipitated bulk samples of $\mathbf{1}[\mathbf{SbF_6}]_2$ also probably have this structure.

The iron centre in $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 2CH_3NO_2$ is also six-coordinate, and high-spin from its Fe–N bond distances (Table 3, Fig. 3). However, the coordination geometry about Fe(1) in this crystal is more regular (Fig. 4). The two ligands in the molecule are nearly perpendicular [$\theta = 84.66(4)°$], ϕ is closer to its ideal value at

Table 3
Selected bond lengths (Å) and angles (°) in the crystal structures of the two solvates of $\mathbf{1}[\mathbf{SbF_6}]_2$

N(18)–Fe(1)–N(30)	73.09(14)	79.95(15)
N(25)–Fe(1)–N(30)	144.91(14)	160.17(15)
θ	84.66(4)	88.59(4)

The parameters ϕ and θ are those defined in Scheme 1.

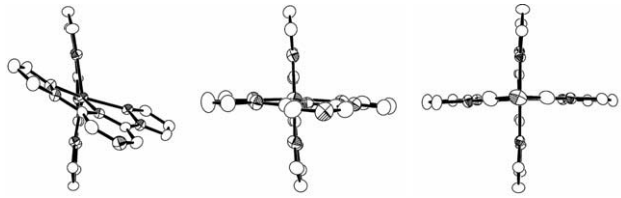

Fig. 4. Comparative views of the $[Fe(L^1H)_2]^{2+}$ dications in the crystal structures of $\mathbf{1}[\mathbf{SbF_6}]_2$ (left), $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 2CH_3NO_2$ (centre) and $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 3CH_3NO_2$ (right), emphasising the structural differences between them. The view in each case is parallel to the Fe(1)–N(2) bond with the ligand N(2)–C(17) vertical. All H atoms have been omitted for clarity, and thermal ellipsoids are at the 50% probability level.

163.23(13)°, and the Fe(1) site protrudes from the planes of each L^1H ligand by <0.1 Å. The complex dications in the structure again pack in the crystal through a four-way terpyridine embrace [20] with two unique intermolecular π–π interactions. These are between pyrazole rings N(8)–C(12) and $N(13^{iii})$–$C(17^{iii})$ (related by $1 + x$, y, z), which are 3.301(8) Å apart at closest approach with a dihedral angle of 4.4(3)° between them; and, between N(24)–C(28) and $N(29^{iv})$–$C(33^{iv})$ (related by x, $1 + y$, z), which are separated by 3.530(7) Å with a dihedral angle of 6.1(2)°. The resultant sheets of π-stacked complex molecules are aligned parallel to the (0 0 1) crystal plane and are separated by layers of CH_3NO_2 solvent molecules. While the full X-ray dataset was collected at 150 K, the crystal did not darken in colour upon further cooling to 90 K (the lowest temperature accessible with our N_2 cryostat). This strongly implies that $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 2CH_3NO_2$ also remains fully high-spin at this temperature and above.

In contrast to the other two crystal forms, the Fe–N bond lengths in $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 3CH_3NO_2$ are characteristic of a fully low-spin iron(II) centre [3–5,7–11] (Table 3). That is consistent with the dark brown colouration of this phase. As expected, the six-coordinate geometry about this low-spin iron(II) centre is more regular than for the two high-spin phases, with distortion angles θ [88.59(4)°] and ϕ [178.59(15)°] that are very close to their ideal values (Fig. 4). In contrast to the other two structures, there are no π–π interactions between neighbouring complex molecules in $\mathbf{1}[\mathbf{SbF_6}]_2 \cdot 3CH_3NO_2$, which does not exhibit the 'terpyridine embrace' packing motif. Rather, adjacent molecules in the crystal are linked through weak C–H···F and C–H···O hydrogen bonding interactions and van der Waals contacts only.

4. Conclusion

The polymorphism shown by $\mathbf{1}[\mathbf{SbF_6}]_2$ is consistent with several other $[Fe(L^1R)_2]^{2+}$ and $[Fe(L^2R)_2]^{2+}$ compounds we have studied, which also crystallise as mixtures of phases [3,8,12,13]. Interestingly unsolvated

1[SbF_6]$_2$ and **2**[SbF_6]$_2$ are the first pair of otherwise identical complex salts we have found from the [Fe(L^1R)$_2$]$^{2+}$ and [Fe(L^2R)$_2$]$^{2+}$ series that are isostructural. Importantly, **1**[SbF_6]$_2$ is the first known compound from the [Fe(L^1R)$_2$]$^{2+}$ series to undergo the angular Jahn–Teller distortion, which is quite common in [Fe(L^2R)$_2$]$^{2+}$ compounds [8,12,13]. Rapidly precipitated **1**[SbF_6]$_2$ also probably adopts this coordination geometry according to its susceptibility data. The now-proven existence of the angular distortion in [Fe(L^1R)$_2$]$^{2+}$ complexes emphasises that the magnetic properties of future compounds from this series will have to be interpreted with care if crystallographic data are not available. Structurally, **1**[SbF_6]$_2$ also represents the most severe example of this angular distortion yet discovered.

It is also notable that **1**[SbF_6]$_2 \cdot 2CH_3NO_2$ also remains high-spin at 90 K and above, despite showing a greatly reduced structural distortion. In comparison, **1**[BF_4]$_2 \cdot 3CH_3NO_2$ (which is not isostructural with **1**[SbF_6]$_2 \cdot 3CH_3NO_2$) does undergo an abrupt high $\rightarrow$ low spin-transition at 198 K and shows $\phi =$ 173.18(11)° in its high-spin form (Scheme 1) [3]. Clearly, the contraction of ϕ by an extra 9.95(17)° in **1**[SbF_6]$_2 \cdot 2CH_3NO_2$ compared to **1**[BF_4]$_2 \cdot 3CH_3NO_2$ is sufficient to prohibit a thermal spin-transition at accessible temperatures.

5. Supplementary data

Full crystallographic data for the compounds in this study are available on request from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk. The CCDC deposition numbers are 266335 (**1**[SbF_6]$_2$), 266336 (**1**[SbF_6]$_2 \cdot 2CH_3NO_2$) and 266337 (**1**[SbF_6]$_2 \cdot 3CH_3NO_2$).

Acknowledgements

The authors thank Dr. M. J. Hardie (University of Leeds) for the X-ray data collection of **1**[SbF_6]$_2 \cdot 3CH_3NO_2$ and Dr. H.J. Blythe (University of Sheffield) for the solid state susceptibility measurements. This work was funded by the EPSRC and the University of Leeds.

Abstract

Zn_4OL_6 (L = S_2CNEt_2, S_2PEt_2 and $OCNEt_2$) complexes are readily formed by hydrolysis of the mixed alkylzinc-carbamato, thiophophinato or thiocabamato (RZnL) compounds. These oxyzinc complexes all adapt a basic beryllium-acetate-like tetrahedral (μ_4-O)Zn_4 core. The coordination of each zinc atom is completed by bridging carbamato, thiocarbamato or thiophosphinato groups. Disorder is observed in the zinc positions for the two sulfur-containing compounds, with zinc atoms disordered over the eight corners of a cube. The geometry of the core (μ_4-O)Zn_4 moiety is compared with ZnO and a number of related complexes.

1. Introduction

Dithiocarbamates are used in rubber chemistry and technology, inorganic analysis and in agriculture as fungicides. Bis(diethyldithiocarbamato)zinc(II) and alkyl-(dialkyldithiocarbamato)zinc(II) have successfully been used to grow thin films and nanoparticles of ZnS using MOCVD and colloidal methods, respectively [1–4]. The structures of bis(diethyldithiocarbamato)zinc(II) [5] bis(dimethyldithiocarbamato)zinc(II) [6] asymmetric bis(dialkyldithiocarbamato)zinc(II) [7] and alkyl(dialkyldithiocarbamato)zinc(II) [8] have been reported.

Dialkylcarbamato complexes have been prepared by various methods including the reaction of metal chlorides with carbon dioxide and a secondary amine [9], the elemental metal with carbon dioxide and a secondary amine [10] and the insertion of carbon dioxide into a M-NR_2 (R = alkyl, M = metal) bond [11]. We have reported the synthesis of a series of diseleno- and dithiocarbamato complexes ($[RME_2CNR'_2]_2$, E = S, Se) [8,12–17] via insertion reaction with CS_2 or CSe_2. The structural chemistry of these compounds is dominated by the formation of dimeric species. The reaction of CO_2 with alkylzincdiethylamides ($RZnNEt_2$) gave unusual tetrameric species such as $[(CH_3)_2Zn_4(O_2CN(C_2H_5)_2)_6]$ [18] and $[(CH_3)_4Zn_4(O_2CN(C_2H_5)_2)_4]$ [19] which on further reaction with tetramethylethylenediamine or pyridine gave monomeric $[(Me_2NCH_2)_2Zn(O_2CN(C_2H_5)_2)_2]$ and dimeric $[C_5H_5NZn_2Me(O_2CN–(C_2H_5)_2)_3]$ species, respectively [20,21]. $Zn_4O(O_2CN\text{-}(C_2H_5)_2)_6]$ [10] was obtained when elemental zinc was reacted with CO_2/$HNEt_2$. This structure was found to exhibit the beryllium acetate structural motif [22], with a (μ_4-O)Zn_4 tetrahedron at the core of the molecule.

Dithiophosphinates have many important industrial and agricultural applications, including solvent extraction reagents for metals [23], insecticides and pesticides, flotation agents for mineral ores, and additives to lubricant oils [24]. Metal complexes of such ligands have the

doi:10.1016/j.poly.2005.06.033

potential to be new precursors for use in LP-MOCVD. The deposition of II/VI semiconductors had been previously achieved with zinc and cadmium dimethyldithiophosphinates by Takahashi et al. [25]. They grew good quality ZnS and CdS films on silver-plated glass substrates between 400 and 500 °C.

In continuation of our studies on carbamato, thiophophinatio and thiocarbamato complexes, here we report the synthesis and the X-ray single crystal structures of the zinc complexes: $[Zn_4(\mu_4\text{-}O)(O_2CNEt_2)_6]$ (**1**), $[Zn_4(\mu_4\text{-}O)(S_2PEt_2)_6]$ (**2**) and $[Zn_4(\mu_4\text{-}O)(S_2CNEt_2)_6]$ (**3**) which all exhibit the beryllium acetate structural motif.

2. Experimental

2.1. Chemicals

All operations were carried out under air sensitive conditions using a standard Schlenck line. Diethylzinc, carbon dioxide and diethylamine were supplied by Aldrich Chemical Co. Ltd, dimethylzinc from Epichem Ltd. Sulfur, zinc sulfate (99%) and solvents were obtained from BDH.

2.2. Synthesis

2.2.1. $[Zn_4(\mu_4\text{-}O)(O_2CNEt_2)_6]$ (1)

This compound was first prepared serendipitously by the reaction of carbon dioxide with Et_2NZnMe in toluene containing traces of water. The expected product $MeZnO_2CNEt_2$was later prepared using dry toluene [19]. $[Zn_4(\mu_4\text{-}O)(O_2CNEt_2)_6]$ (**1**) was subsequently reproducibly prepared by the reaction of dimethylzinc (4.64 g, 48.6 mmol) with diethylamine (3.55 g, 48.6 mmol) in toluene at 70 °C for 2 h and then bubbling carbon dioxide through this product solution after addition of 2 ml of wet toluene (prepared by adding a drop of water in 50 ml of dry toluene) at 0 °C. The solvent was evaporated completely and the solid crystallised from hot toluene. The product was identified as $Zn_4O(O_2CNEt_2)_6$ (**1**) (2.9 g, yield: 60%). Elemental *Anal*. Calc.: C, 36.97; H, 6.16; N, 8.63. Found: C, 37.12; H, 6.20; N, 8.69%. I.R. spectrum Nujol (cm^{-1}): 2975–2580 s, 1566 vs, 1425 s, 1220 s, 518 s. ^1H NMR (ppm): 1.01 (t, CH_3), 3.53 (q, CH_2).

2.2.2. $[Zn_4(\mu_4\text{-}O)(S_2PEt_2)_6]$ (2)

Compound (**2**) was isolated by first preparing sodium diethyldithiophosphinate using the method of Kuchen et al. [26]. An aqueous solution of sodium diethyldithiophosphinate (3.5 g, 20 mmol) was then reacted with zinc sulfate (1.6 g, 10 mmol) to produce diethyldithiophophinatozinc(II) [9]. The product was recrystallised from acetone at room temperature. Diethyldithiophophinatozinc(II) (2.6 g, 7 mmol) was then reacted with diethylzinc (0.4 g, 3 mmol) in wet toluene to give $Zn_4O(S_2PEt_2)_6$. X-ray quality crystals were obtained from the toluene solution (yield: 2.4 g, 87%). Elemental *Anal*. Calc.: C, 24.07; H, 5.05; S, 32.13. Found: C, 24.21; H, 5.11; S, 32.34%. I.R spectrum major bands (nujol (cm^{-1})): 2980–2840 s, 1555, 1510 vs, 987 s, 560 s. ^1H NMR (ppm): 1.03 (t, CH_3), 3.67 (q, CH_2).

2.2.3. $[Zn_4(\mu_4\text{-}O)(S_2CNEt_2)_6]$ (3)

The preparation of compound (**3**) was carried out by first preparing diethyldithiocarbamatozinc(II) using a slight modification of the method of Bernard and Woodbrige [27]. The ammonium salt of thiocarbamic acid was prepared by the reaction of carbon disulfide and diethylamine in 1:2 mole ratio at room temperature in methanol. A solution of zinc dichloride in water was then added to this mixture dropwise at 10 °C to give diethyldithiocarbamatozinc(II). A white precipitate was separated by filtration and dried under vacuum. Diethyl zinc (0.9 g, 7.3 mmol) was added to the solution of diethyldithiocarbamatozinc(II) (8.0 g, 22.0 mmol) in toluene in the presence of 2 ml of wet toluene (Eq. (10)) to give $Zn_4O(S_2CNEt_2)_6$ as a white crystalline solid (3.7 g, yield: 44%). Elemental *Anal*. Calc.: C, 30.88; H, 5.18; N, 7.20; S, 32.98. Found: C, 31.07; H, 5.21; N, 7.28; S, 33.36%. I.R. spectrum Nujol (cm^{-1}): 2977–2834 s, 1558 vs, 1433 s, 1211 s, 975 vs. ^1H NMR (ppm) 1.01 (t, CH_3), 3.41 (q, CH_2).

2.3. Physical measurements

^1H NMR spectra were recorded using a Bruker AM250 pulsed Fourier transform spectrometer. Infrared spectra were measured on a Matteson Polaris FT-IR spectrometer as nujol mulls.

2.4. X-ray crystallography

X-ray diffraction data were collected on selected crystals of compounds (**1**), (**2**) and (**3**). The intensity data for (**1**) were collected using a FAST area detector at 120(2) K. Data collection, reduction and cell refinement procedures are described elsewhere [28]. Intensity data for (**2**) and (**3**) were collected on an Enraf Nonius CAD-4 diffractometer using Mo Kα radiation ($\lambda = 0.71069$ Å) with ω–2θ scans at 293(2) K. Data for were corrected for absorption using the program SORTAV [29] for (**1**) and DIFABS [30] for (**2**) and (**3**). All structures were solved by direct methods using SHELXS-97 [31–33] and refined on F^2 using SHELXL-97 [31–33]. Anisotropic parameters were refined for all non-hydrogen atoms. The H atoms were calculated geometrically and refined using a riding model. Molecular graphics were obtained using ORTEP3 for Windows [34]. Data collection and structure refinement details are summarised in Table 1. CCDC reference numbers 264145–264147.

3. Results and discussion

$[Zn_4(\mu_4\text{-}O)(O_2CNEt_2)_6]$ (**1**) was first prepared serendipitously instead of an expected product $MeZnO_2CNEt_2$ during the insertion reaction of carbon dioxide into the Zn–N bond of Et_2NZnMe. The insertion of the oxide into the expected product was believed to have derived from poorly dried toluene which was used as a solvent in the reaction. The expected product $MeZnO_2CNEt_2$ was then successfully prepared by using dry toluene [19] and the serendipitous product was reproducibly prepared using wet toluene (Eq. (1)) and then bubbling carbon dioxide through this product solution after addition of 2 ml of wet toluene (prepared by adding a drop of water in 50 ml of dry toluene) at 0 °C (Eq. (2)).

$$Me_2Zn + Et_2NH \xrightarrow[70^\circ C]{\text{toluene}} Et_2NZnMe + CH_4 \quad (1)$$

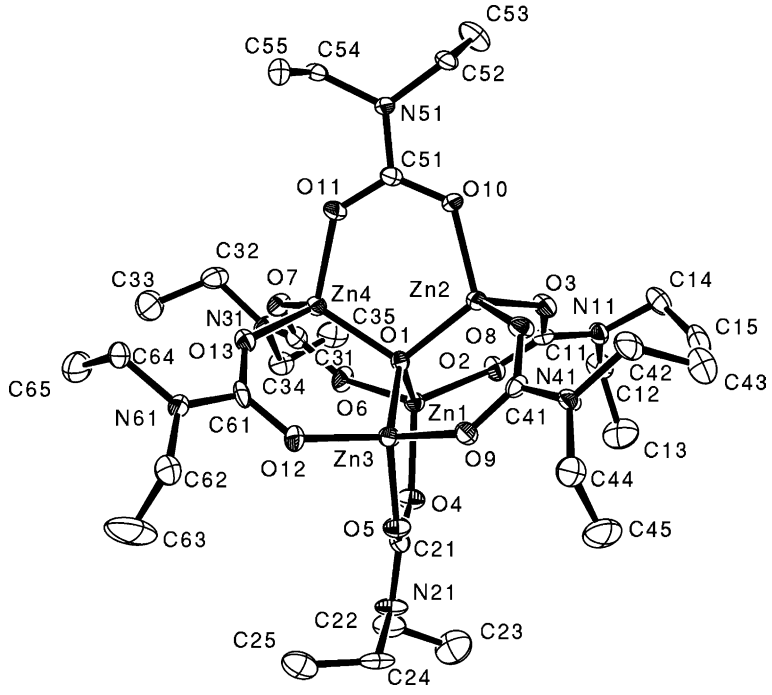

Fig. 1. Thermal ellipsoid plot (50% probability) showing structure of $[Zn_4(\mu_4\text{-}O)(O_2CNEt_2)_6]$ (**1**). Molecule a is only shown.

$$6Et_2NZnMe + 6CO_2 + 3H_2O \xrightarrow[0^\circ C]{\text{toluene}} Zn_4O(O_2CNEt_2)_6 + 2ZnO + 6CH_4 \quad (2)$$

Compound (**2**) was isolated by first preparing sodium diethyldithiophosphinate using the method of Kuchen et al. [26] (Eqs. (3)–(5)).

$$4EtMgBr + 2PSCl_3 \rightarrow Et_2PSSPEt_2 + 4MgBrCl + Cl_2 \quad (3)$$

$$Et_2PSSPEt_2 + Na_2S + S \rightarrow 2NaS_2PEt_2 \quad (4)$$

$$2NaS_2PEt_2(aq) + ZnSO_4(aq) \rightarrow Zn(S_2PEt)_2 + Na_2SO_4(aq) \quad (5)$$

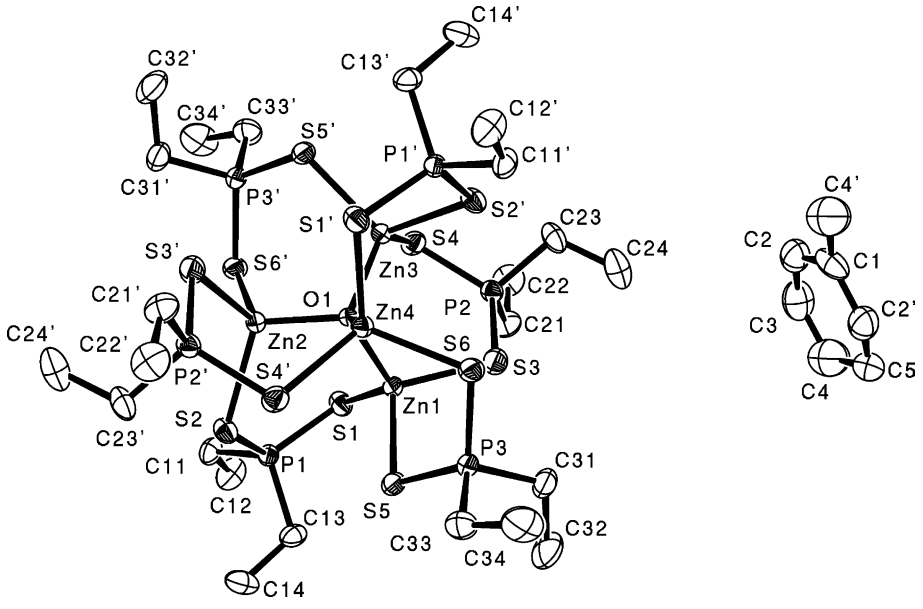

Fig. 2. Thermal ellipsoid plot (50% probability) showing structure of $[Zn_4(\mu_4\text{-}O)(S_2PEt_2)_6]\cdot C_7H_8$ (**2**). Disorder in Zn positions and solvent molecule not shown for clarity.

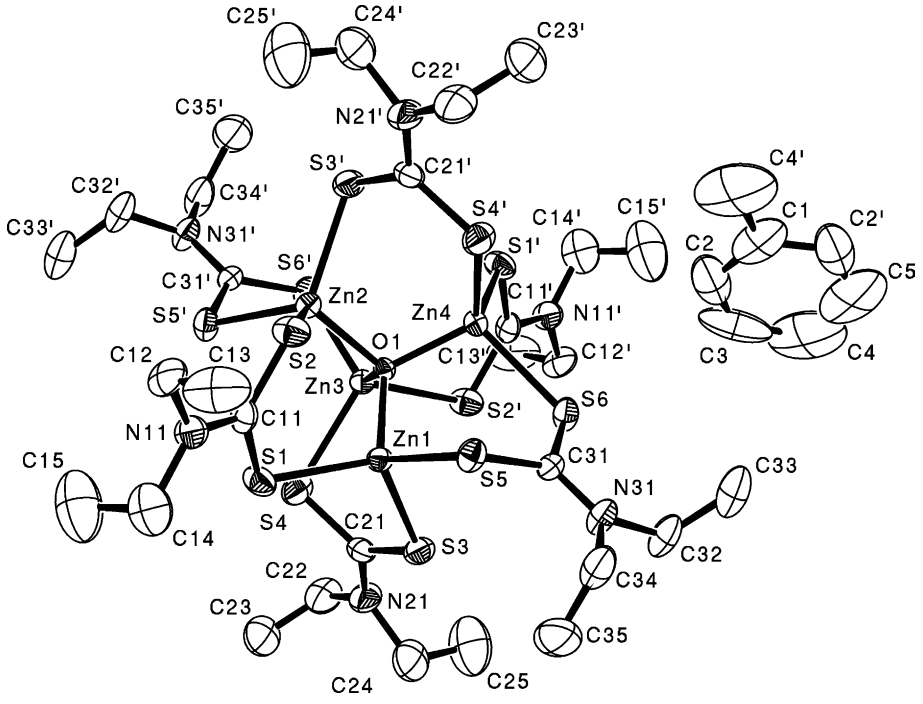

Fig. 3. Thermal ellipsoid plot (50% probability) showing structure of $[Zn_4(\mu_4\text{-}O)(S_2CNEt_2)_6]\cdot C_7H_8$ (**3**). Disorder in Zn positions and solvent molecule not shown for clarity.

Individual molecules in the asymmetric unit are designated **a**–**d**. Estimated standard deviations are given in parentheses.

The reaction of diethyldithiophophinatozinc(II) with diethylzinc in wet toluene (Eqs. (6) and (7)) gave $Zn_4O(S_2PEt_2)_6$.

$$Zn(S_2PEt_2)_2 + Et_2Zn \rightarrow 2EtZnS_2PEt_2 \quad (6)$$

$$6EtZnS_2PEt_2 + 3H_2O \rightarrow Zn_4O(S_2PEt_2)_6 + 6C_2H_6 + 2ZnO \quad (7)$$

Compound (**3**) was similarly prepared from diethyldithiocarbamatozinc(II) using a slight modification of the method of Bernard and Woodbrige (Eq. (8)) [27].

$$CS_2 + 2Et_2NH \rightarrow (S_2CNEt_2)^-(Et_2NH_2)^+ \quad (8)$$

A solution of zinc dichloride in water was then added to this mixture dropwise at 10 °C (Eq. (9)) to give diethyldithiocarbamatozinc(II)

$$2(S_2CNEt_2)^-(Et_2NH_2)^+ + ZnCl_2 \rightarrow Zn(S_2CNEt_2)_2 + 2Et_2NH_2^+Cl^- \quad (9)$$

A white precipitate was separated by filtration and dried under vacuum. Diethyl zinc was added to the solution of diethyldithiocarbamatozinc(II) in toluene in the presence of 2 ml of wet toluene (Eqs. (10) and (11)) to give $Zn_4O(S_2CNEt_2)_6$ as a white crystalline solid.

$$Zn(S_2CNEt_2)_2 + Et_2Zn \rightarrow 2EtZnS_2CNEt_2 \quad (10)$$

$$6EtZnS_2CNEt_2 + 3H_2O \rightarrow Zn_4O(S_2CNEt_2)_6 + 6C_2H_6 + 2ZnO \quad (11)$$

All three compounds are soluble in most organic solvents and can readily be crystallised from toluene to give good quality transparent cubic crystals. These complexes are stable at room temperature under nitrogen

for a period of several months but on exposure to air, they slowly decompose to give ZnO powder.

The structures of (**1**), (**2**) and (**3**) were determined by X-ray single crystal methods. All three structures are closely related to each other (Figs. 1–3). The structures of (**2**) and (**3**) show a degree of disorder and in order to describe them it is helpful to start with a description of the ordered structure of (**1**). Significant contact distances and angles in the structure of (**1**) are given in Table 2. The crystal structure of (**1**) has four unique molecules in the asymmetric unit that are closely related. Small differences are observed in the bond lengths and angles between the four unique molecules, particularly in the alkyl moieties. Each molecule consists of a beryllium acetate like (μ_4-O)Zn_4 core, with zinc atoms located at four corners of a cube of average edge length 2.25 Å, resulting in a tetrahedral coordination of the central oxygen atom, with an average Zn–O bond length of 1.946 Å. The zinc atoms are also tetrahedrally coordinated (Fig. 4(a)), with oxygen atoms of the bridging carbamato ligands making up the Zn coordination sphere. Each carbamato group bridges two zinc atoms on the central unit, i.e., one edge of the (μ_4-O)Zn_4 tetrahedron, giving an overall molecular formula of $[Zn_4(\mu_4O)(O_2CNEt_2)_6]$.

Significant distances and angles in the crystal structure of (**2**) are given in Table 3. The structure of (**2**) is very similar to that of (**1**), however, the zinc atoms of

the central (μ_4-O)Zn_4 unit are disordered over the eight corners of a cube of approximate edge length 2.29 Å (Fig. 4(b)), with an average Zn–O bond length of 1.980 Å. Each Zn site is half occupied and therefore it is likely that in any one particular molecule a tetrahedral coordination exists around the central oxygen atom as in Fig. 4(a). Bridging sulfur atoms from the thiocarbamato groups complete the tetrahedral coordination geometry around each of the Zn atoms. There is no disorder observed in the atomic positions of the thiocarbamato ligands. As in the structure of (**1**), each ligand effectively bridges two zinc atoms, which are distributed over four sites (i.e., four half occupied Zn sites in the disordered central unit). This again results in all edges of the central tetrahedral (μ_4-O)Zn_4 unit being shared with a ligand.

The structure of (**3**) also shows disorder of the zinc atoms of the central (μ_4-O)Zn_4 core (Fig. 4(c)), with ordered positions for the thiophosphinato ligands. Significant distances and angles in the crystal structure of (**3**) are presented in Table 4. The Zn atoms are disordered over the eight corners of a cube of average edge length 2.240 Å, with an average Zn–O bond length of 1.941 Å. As in the structure of (**2**), bridging ligands occupy the edges of the μ_4O-Zn_4 central tetrahedral unit, with each thiophosphinato ligand bridging two Zn atoms disordered over four sites.

[a] $D_b = \frac{\sum |l_i - \bar{l}|}{4\bar{l}}$; $D_e = \frac{\sum |s_i - \bar{s}|}{6\bar{s}}$; $D_a = \frac{\sum |\theta_i - \bar{\theta}|}{6\bar{\theta}}$; where l_i is the central atom to vertex distance for vertex i and $\bar{l}$ is the mean value; s_i is the ith vertex to vertex distance and $\bar{s}$ is the mean value and θ_i is the ith angle and $\bar{\theta}$ is the mean value.

The crystal structure of (**1**) was determined previously by Belforte et al. [10] and refined in the tetragonal space group $I4_1/a$, with cell dimensions $a = 21.928$ Å and $c = 37.86$ Å. These cell dimensions are similar to the monoclinic dimensions presented here and the structures are in reasonable agreement. These authors, reported problems with low intensity data and consequently a low reflection/parameter ratio that prevented an anisotropic refinement or location of H atoms. It is therefore doubtful that the structure reported here and that by Belforte et al. represent different polymorphs.

Table 5 shows a comparison of geometrical parameters for structures containing the $(\mu_4\text{-O})(ZnX_3)_4$ moiety (X = O, S). These are compared with those for ZnO. Tetrahedral volumes have been calculated using the determinant method and vary from 3.72 Å^3 in $[Zn_4(\mu_4\text{-O})(O_2CMe)_6]$ to 4.13 Å^3 in $[Zn_9(\mu_4\text{-O})(Et)_6(thf)_2(O_3PBu^t)_4(O_2PBu^t_2)_4]$ and compare with a value of 3.97 Å^3 in ZnO. The secondary coordination sphere of the Zn atoms appears to have little affect on the volume of the $(\mu_4\text{-O})Zn_4$ core, despite the increase in average Zn–X bond length in the sulfur containing compounds. The distortion away from regular tetrahedral geometry has been characterised by Bauer in terms of three characteristic distortion indices reflecting distortions in bond length, edge length and angle (defined here as D_b, D_e and D_a, respectively) [35]. The structure of (**1**) shows average distortion indices ($D_b = 0.002$, $D_e = 0.007$, D_a 0.010) close to those of pure ZnO ($D_b = 0.003$, $D_e =$ 0.006, D_a 0.013), but with a significantly smaller average Zn–O distance. Structure **2** has a significantly larger bond distortion index ($D_b = 0.010$), which reflects the large Zn–O bond length range seen in this structure (Table 2), while D_e and D_a values (0.004 and 0.015, respectively) are close to those seen in ZnO. Interestingly, structure (**2**) show an average Zn–O bond length (1.980 Å) and a tetrahedral volume (3.978 Å^3) close to that in the pure oxide. Structure (**3**) has significantly larger values for D_b and D_a (0.012 and 0.018, respectively). The tetrahedral volume (3.75 Å^3) and average Zn–O bond length (1.941 Å) are similar to the values seen in structure (**1**).

4. Conclusions

The complexes (**1**), (**2**) and (**3**) are readily formed through the reaction of the appropriate alkyl zinc carbamate, thiocarbamates or thiophosphinates with water. The crystal structures of these complexes all exhibit a beryllium acetate like $(\mu_4\text{-O})Zn_4$ core. This structural motif appears to be relatively common in oxyzinc complexes, with the central $(\mu_4\text{-O})Zn_4$ tetrahedron showing geometrical parameters close to that of pure ZnO. These parameters are relatively unaffected by the secondary coordination sphere of the Zn atoms.

Synthesis and reactivity of $(silox)_2R_2WO$ (R = Cl, Me, Et, ^{n}Pr and ^{n}Bu; silox = OSi^tBu_3) and $(silox)_2MO_2$ (M = Mo and W)

Devon C. Rosenfeld, David S. Kuiper, Emil B. Lobkovsky, Peter T. Wolczanski *

Dedicated to Prof. Malcolm H. Chisholm, whose mastery of group 6 helped inspire this and related research.

Abstract

Addition of Na(silox) (silox = OSi^tBu_3) to Cl_4WO afforded $(silox)_2Cl_2WO$ (**3**), and subsequent alkylation with appropriate Grignard reagents yielded $(silox)_2R_2WO$ (**4**-R; R = Me, Et, ^{n}Pr, ^{n}Bu). **4**-R adopt distorted trigonal bipyramidal structures with axial silox groups, as implied by the X-ray crystal structure of **4**-^{n}Bu. New metathetical procedures were utilized in the preparation of $(silox)_2M(O)_2$ (M = Mo, **6**; W, **7**); the addition of Na(silox) to $(DME)Cl_2M(O)_2$ (M = Mo, W) in THF afforded the dioxo species. None of the oxo complexes exhibited oxygen atom transfer (OAT) to PMe_3. The thermolysis of **4**-Et and **4**-^{n}Bu afforded olefin derivatives $(silox)_2$(ole)WO (**5**-ole; ole = C_2H_4, C_4H_8) as the primary products. Thermal degradation of $(silox)_2(CD_3CH_2)_2WO$ (**4**-CH_2CD_3) revealed H/D-scrambling among α- and β-positions indicative of reversible β-H-elimination prior to alkane loss. A brief discussion of the lack of OAT is presented.

Keywords: Tungsten; Oxo; Atom transfer; Alkyl

1. Introduction

Recent investigations of oxygen atom transfer (OAT) [1] to $(silox)_3M$ (**1**-M, M = V, Nb, Ta; silox = OSi^tBu_3) from EO (EO = OPR_3, R = Me, Ph, ^{t}Bu; $(silox)_3WNO$ (**2**)) revealed that a linear reaction coordinate was symmetry (orbitally) forbidden, as shown in Fig. 1 [2]. Where EO = OPR_3 and R = Me and Ph, OAT to **1**-M (M = Nb, Ta) was facile because a bent transition state (or intermediate) was sterically feasible. When R = ^{t}Bu, no atom transfer was observed, and the X-ray crystal structure of (silox)V-O-P^{t}Bu$_3$ ($\angle$V–O–P = 180°) suggested that a similar bent transition state was sterically implausible. In corroboration, deoxygenations of $(silox)_3W$-NO (**2**) by $(silox)_3M$ (**1**-M, M = NbL (L = py, PMe_3), Ta) were extremely slow, although the free energy of reaction for each deoxygenation was calculated to be roughly −100 kcal/mol. A bent L_nM-O-E geometry allowed mixing of σ- and π-type orbitals in the lower symmetry environment, thereby rendering each step orbitally allowed. As a consequence, intersystem crossing events necessary for OAT occurred at lower energies. While the orbital symmetry arguments are compelling for the examples at hand, whether the bent versus linear transition state differences are general is still in question.

In search of additional examples of OAT, group 6 was an attractive target, especially tungsten and molybdenum [1]. For these metals, a published thermodynamic scale [3] of OAT suggested that the transfer might occur from the metal to a substrate such as a

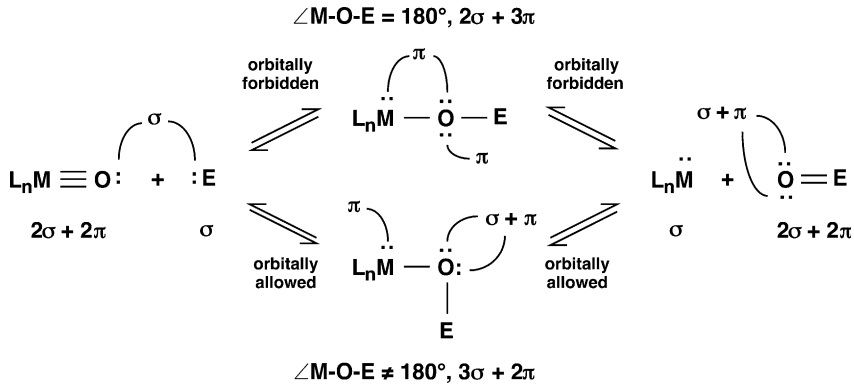

Fig. 1. Consequences of orbital symmetry upon oxygen atom transfer (OAT).

phosphine, since the bond dissociation energies of Cl_4WO and Ph_3PO were purported to be roughly 127 and 133 kcal/mol, respectively. Drew et al. [4] provided literature corroboration of the crude thermodynamics for OAT because exposure of Cl_4WO to PPh_3 yielded $Cl_4W(PPh_3)_2$, $Cl_4WO(OPPh_3)(PPh_3)$ and $OPPh_3$. It was postulated that OAT from $(silox)_2Cl_2WO$ would lead to $(silox)_2WCl_2$, a much sought after d^2 square planar compound whose reactivity could be compared with that of the trigonal group 5 d^2 species [2]. Cummins et al. have recently investigated the electronic differences between Mo and W [5], and have concluded that for tungsten, the torus of $5d_{z^2}$ is severely attenuated due to mixing with the 6s. A similar electronic origin to second versus third row reactivity differences has been proposed for Nb versus Ta [2]. As a consequence, a focus on the second and third row of group 6 seemed particularly appealing.

2. Results and discussion

2.1. Oxo-dichloride $(silox)_2Cl_2WO$ (3)

2.1.1. Synthesis

Exploratory NMR tube experiments prompted a simple metathesis approach, wherein treatment of Cl_4WO with 2 equiv of $NaOSi^tBu_3$ in

$$Cl_4WO + 2Na(silox) \xrightarrow[4\,h,\,25\,^\circ C]{Et_2O} (silox)_2Cl_2WO + 2NaCl \quad (1)$$

diethyl ether afforded yellow $(silox)_2Cl_2WO$ (**3**) in 73% yield according to Eq. (1). ^1H and $^{13}C\{^1H\}$ NMR spectral data for all compounds are listed in Table 1.

2.1.2. Oxygen atom abstraction attempts

Given precedent [4], initial OAT experiments were conducted with $(silox)_2Cl_2WO$ (**3**) and Ph_3P (cone angle = 145°) [6] in benzene-d_6. Even under thermolysis conditions (100 °C, 45 h), there was no evidence of a reaction. The combined sterics of the two chlorides and two siloxides might have been a greater factor than anticipated, hence the smaller PMe_3 (cone angle = 118°) [6] was employed. Varying amounts of phosphine (1, 3 and 5 equiv) were utilized, but while a reaction occurred, there was no evidence of $OPMe_3$ formation (δ 0.88, d, $J_{PH} = 13$) amidst the eventual degradation of **3**. Attempts to induce OAT using $P(OMe)_3$ (cone angle = 107°) [6] also failed under increasingly harsh conditions (5 d, 25 °C; 38 h, 60 °C; 47 h, 100 °C).

2.2. Oxo-dialkyls $(silox)_2R_2WO$ (R = Me, Et, ^{n}Pr, ^{n}Bu)

2.2.1. Synthesis

It seemed plausible that the substitution of silox for chloride rendered the OAT from $(silox)_2Cl_2WO$ (**3**) endoergic relative to Cl_4WO. Substitution of the remaining chlorides by less electronegative groups such as alkyls was considered to enable OAT, hence the alkylation of **3** was attempted. The addition of a slight excess (typically 2.05 equiv) of the appropriate Grignard reagent to **3** in diethyl ether provided the yellow to yellow/orange dialkyl compounds $(silox)_2R_2WO$ (**4**-R; R = Me, Et, ^{n}Pr, ^{n}Bu) in decent yield ($\geqslant$64%), as indicated by Eq. (2). The ^1H NMR spectrum of **4**-Me revealed a singlet at δ 1.65, accompanied by ^{183}W (14.40%) satellites ($J_{WH} = 12$ Hz), that was assigned to the tungsten-methyl groups. In $^{13}C\{^1H\}$ NMR spectra of **4**-R, tungsten satellites enabled ready identification of the Me resonance of **4**-Me (δ 47.01, $J_{WC} = 90$ Hz) and the α-CH_2

$$(silox)_2Cl_2WO + \underset{\substack{R = Me, Et; X = Br\\ R = {}^n Pr, {}^n Bu; X = Cl}}{2RMgX} \xrightarrow[4\,h,\,25\,^\circ C]{Et_2O} \underset{\substack{\mathbf{4}\text{-R, R = Me(64\%), Et(85\%),}\\ {}^n\text{Pr(68\%), }{}^n\text{Bu(67\%)}}}{(silox)_2R_2WO} \quad (2)$$

resonances (**4**-Et, δ 56.21, $J_{WC} = 88$ Hz; **4**-^{n}Pr, δ 66.93, $J_{WC} = 86$ Hz; **4**-^{n}Bu, δ 64.10, $J_{WC} = 87$ Hz) of the remaining dialkyls. Use of alkyllithiums typically generated mixtures that hinted at problems related to reduction.

[c] Assignments tentative.

Attempts to synthesize secondary and tertiary dialkyl derivatives (i.e., R = ^{i}Pr, ^{t}Bu) led to intractable mixtures.

The stability of the diethyl, di-*n*-propyl and di-*n*-butyl complexes with respect to β-H-elimination is unusual, but not without precedent. Boncella et al. reported the synthesis and isolation of stable [C_6H_4-1,2-($NSiMe_3$)$_2$]R_2W=NPh (R = Et, ^{n}Pr, ^{i}Bu, C_2H_3Ph) compounds, and showed that β-H-abstraction chemistry was induced by the addition of 2 equiv of PMe_3 to afford alkane and [C_6H_4-1,2-($NSiMe_3$)$_2$](PMe_3)$_2$(olefin)W=NPh [7]. It must be noted that (silox)$_2$R$_2$WO (**4**-R) and [C_6H_4-1,2-($NSiMe_3$)$_2$]R_2W=NPh can be considered 18e$^-$ species, which undoubtedly contributes to their stability. Nonetheless, the vacant site in these complexes and the limited donor capacity of the siloxide entities suggests that β-H-elimination or -abstraction should be facile.

2.2.2. Structure of (silox)$_2$(^{n}Bu)$_2$WO (**4**-^{n}Bu)

The most plausible limiting structures for (silox)$_2$R$_2$-WO (**4**-R; R = Me, Et, ^{n}Pr, ^{n}Bu) are a trigonal bipyramid (tbp) with diaxial siloxides and a square pyramid with *trans*-basal siloxides and an apical oxo group. The structure of (silox)$_2$(^{n}Bu)$_2$WO (**4**-^{n}Bu) was determined by X-ray crystallography; structural details are given in Table 2 and selected bond distances and angles are listed in Table 3. As Fig. 2 illustrates, its geometry is best described as distorted tbp [8]. Aside from a modest disorder in one *n*-butyl group, structure solution in $P2_1/n$ proved to be routine. The axial siloxides possess 1.880(2) and 1.878(2) Å tungsten–oxygen distances and are bent away from the oxo (∠O1–W1–O3 = 98.74(11)°, ∠O2–W1–O3 = 98.83(11)°, ∠O1–W1–O2 =

162.31(10)°), and toward the *n*-butyls (∠O1–W1–C1 = 86.46(13)°, ∠O2–W1–C5 = 85.89(13)°). The oxo has a normal *d*(WO) of 1.705(2) Å [2,8,9], and the tungsten–carbon distances are also standard (2.102(4), 2.151(3) Å). In the equatorial plane, the C1–W1–C5 angle is splayed slightly (128.35(14)°), and is compensated by the O3–W1–C1 and O3–W1–C5 angles of 114.96(13)° and 116.68(14)°, respectively. While the siloxides might be expected to occupy the sterically less demanding equatorial sites in a tbp, their high ionic character relative to the alkyls renders them axial, while the greater covalent bonding inherent in the equatorial plane better suits the *n*-butyl ligands [8,10].

2.2.3. Reactivity of $(silox)_2R_2WO$

Attempts at oxygen atom transfer to PMe_3 from $(silox)_2R_2WO$ (**4**-R; R = Me, Et) met with failure. No reaction was noted when **4**-Me was heated with 3 equiv PMe_3 in THF-d_8 for 33 h at 60 °C, and **4**-Et was stable to prolonged exposure of 2 equiv PMe_3 at 25 °C in benzene-d_6.

In the absence of any evidence of OAT, some thermolysis studies were undertaken. When **4**-Et was heated in benzene-d_6 for 27 h at 60 °C, the predominant product was the ethylene complex, $(silox)_2(C_2H_4)WO$ (**5**-C_2H_4) along with ethane and some ethylene according to Eq. (3). While the reaction

$$\underset{\textbf{4}\text{-Et}}{(silox)_2Et_2WO} \xrightarrow[3\text{ d, }60\text{ °C}]{\text{benzene-}d_6} \underset{\textbf{5}\text{-}C_2H_4}{(silox)_2(C_2H_4)WO} + EtH + C_2H_4 + \cdots \quad (3)$$

was not completely clean, it was scaled up to yield **5**-C_2H_4 in 89% yield upon precipitation from hexanes. The ethylene complex was not analyzed due to persistent 5–10% impurities, but its spectral characteristics in comparison to $(silox)_2(C_2H_4)W{=}N^tBu$ [11] leave little doubt as to its composition. Telltale broad singlets corresponding to two different ethylene resonances (δ 2.04, 2.95) in the ^{1}H NMR spectrum are accompanied by a singlet at δ 54.46 (J_{WC} = 33 Hz) in the $^{13}C\{^1H\}$ NMR spectrum, indicating that the ethylene in **5**-C_2H_4 is roughly perpendicular to the W=O linkage. Variable temperature ^{1}H NMR experiments placed the barrier for ethylene rotation at $\Delta G^{\ddagger}$(62 °C) = 15.1(1) kcal/mol in comparison to 15.3(5) kcal/mol at 69 °C for $(silox)_2(C_2H_4)W{=}N^tBu$ [11]. Thermolysis of the products at 90 °C for 24 h effected total degradation, with a roughly 1:1 ratio of ethane and ethylene

$$\underset{\textbf{4}\text{-}^n\text{Bu}}{(silox)_2{}^nBu_2WO} \xrightarrow[3\text{ d, }60\text{ °C}]{\text{benzene-}d_6} \underset{\textbf{5}\text{-}C_4H_8\text{(1-butene)}}{(silox)_2(C_4H_8)WO} + {}^nBuH + \text{1-butene} + \cdots \quad (4)$$

Thermolysis of $(silox)_2{}^nBu_2WO$ (**4**-^{n}Bu) for 4 h at 90 °C in benzene-d_6 afforded an appreciable amount (>50%) of the 1-butene adduct $(silox)_2(C_4H_8)WO$ (**5**-C_4H_8), but extended thermolysis effected decomposition, and no attempt was made to scale up this reaction. The 1-butene complex was tentatively identified via ^{1}H NMR spectral comparisons with $(silox)_3M(C_4H_8)$ (M = Nb, **1**-Nb(C_4H_8); Ta, **1**-Ta(C_4H_8)) [12] in addition to the observation of inequivalent silox groups, consistent with its lack of any symmetry element.

The thermolysis of **4**-Et was also conducted under excess dihydrogen (~400 Torr) for 15 h at 90 °C, but a side-by-side comparison with a reaction without added hydrogen revealed no difference. Similarly, when $(silox)_2Me_2WO$ (**4**-Me) was treated with 510 Torr dihydrogen, a minute amount of methane was seen after 6 h at 25 °C, and full degradation, accompanied by release of methane, was seen after 7 d at 90 °C.

β-Abstraction chemistry similar to that of $[C_6H_4$-1,2-$(NSiMe_3)_2]R_2W{=}NPh$ [7] was not observed for $(silox)_2R_2WO$ (**4**-R; R = Me, Et) in the presence of PMe_3, so labeling experiments were conducted to obtain further information about their thermal degradation. The synthesis of $(silox)_2(D_3CCH_2)_2WO$ (**4**-CH_2CD_3) was effected according to Eq. (2) via use of D_3CCH_2MgBr, and a thermolysis was conducted at 90 °C and crudely analyzed. H/D-Scrambling was revealed in the major product, $(silox)_2(H_{2-x}D_xC{=}CH_{2-y}D_y)WO$ (**5**-$H_{2-x}D_xC{=}CH_{2-y}D_y$) and in the trace of ethylene released as noted by NMR isotope-shifted resonances in the ^{1}H NMR spectrum. Scrambling is unlikely to occur concomitant with β-H-abstraction – assuming it is not induced by any of the minor products – hence the results point toward the standard mechanism of reversible β-H-elimination followed by EtH reductive elimination. The crude relative degradation rates of **4**-Et and **4**-CH_2CD_3 were similar, hence no large KIE for the process was evident, consistent with scrambling. If the β-H-abstraction mechanism were operational, there would be a large kinetic isotope effect: $k_H/k_D = 6.1(5)$ for $[C_6H_4$-1,2-$(NSiMe_3)_2]R_2W{=}NPh$ [7] and 5.2(2) for $Cp_2Zr(SCH_2Ph)(Me)$ [13]. No further investigation was undertaken.

2.3. $(silox)_2M(O)_2$ (M = Mo (**6**), W (**7**))

2.3.1. Synthesis

In a last effort to observe OAT, $(silox)_2M(O)_2$ (M = Mo, **6**; W, **7**) were considered attractive targets due to their lower coordination number, which would presumably allow access by an abstracting agent. A previously reported synthesis consisted of the thermolysis of MoO_3 and 2 equiv of $HOSi^tBu_3$ at 160 °C for 48 h, followed by pentane extraction of **6** [14], but this procedure failed in these laboratories. Given the unknown providence of the extended solid "MoO_3" in either instance, an alternative synthesis was sought. Treatment of $(DME)_2Cl_2M(O)_2$ (M = Mo, W) [15,16] with 2 equiv of Na(silox) in THF afforded the off-white dioxo derivatives, $(silox)_2M(O)_2$ (M = Mo, **6** (60%); W, **7** (52%)) in reasonable yield according to the following equation:

$$(DME)_2Cl_2M(O)_2 + 2Na(silox) \xrightarrow[12\ h,\ 25\ ^\circ C]{THF} \underset{M=Mo,\mathbf{6};W,\mathbf{7}}{(silox)_2M(O)_2} + 2NaCl \quad (5)$$

2.3.2. Attempted OAT

The first deoxygenation attempt was conducted by exposing $(silox)_2MoO_2$ (**6**) to 1 equiv of PPh_3. After 7 d at 25 °C there was no reaction, and thermolysis of the mixture at 60 °C for 4 d, followed by 49 h at 100 °C, resulted in no reaction. When **6** was treated to 2 or 4 equiv of PMe_3 in d_6-benzene or d_8-THF there was also no reaction even after extended thermolysis, and exposure of $(silox)_2WO_2$ (**7**) to 2 equiv of PMe_3 in d_6-benzene also resulted in no reaction, even after extended heating.

3. Conclusions

3.1. General

The syntheses of $(silox)_2Cl_2WO$ (**3**) and $(silox)_2R_2WO$ (**4**-R, R = Me, Et, ^{n}Pr, ^{n}Bu) were readily accomplished by metathetical procedures, and the structure of **4**-R implicated a distorted trigonal bipyramidal geometry for these five coordinate complexes. The dialkyls that contain β-hydrogens (e.g., **4**-Et, **4**-^{n}Bu) proved to be remarkably stable, and appeared to ultimately decompose via standard β-H-elimination and reductive elimination paths to afford $(silox)_2$(olefin)WO (**5**-ole; ole = ethylene, 1-butene).

3.2. Oxygen atom transfer attempts

The original premise for this study was to investigate OAT in group 6 compounds. The general lack of OAT by these compounds is difficult to interpret, simply because the absence of reactivity – in most cases thermal degradation was eventually noted – provides few hints about the transformation of interest! One obvious possibility is that OAT from the M(VI) derivatives to the various phosphines is endoergic. One could make the argument that the estimated thermochemistry is off [3], or that substitution of chloride, etc. by the silox anion renders these metal centers more oxophilic and more stable in their higher oxidation states. This might be convincing except that $(silox)_2Mo(O)_2$, the second row derivative, does not lose its oxygen either, and here it is doubtful that the thermodynamics are unfavorable.

It is plausible that a combination of kinetics and thermodynamics is responsible for the lack of OAT chemistry. Previously, it has been noted that OAT to $(silox)_3M$ (**1**-M, M = Nb, Ta) is extremely slow, even in instances where ΔG° is roughly −100 kcal/mol according to calculations [2]. It can be concluded that symmetry forbidden OAT reactions may be observed if the driving force is large. If the kinetic barrier is not partially offset by a large favorable free energy change, the barrier may be exceedingly difficult to overcome, even when the symmetry of the transition state can be lowered. An apparent exception to this statement is the ability of d^0 group 6 *cis*-dioxo derivatives to transfer oxygen under relatively mild conditions [1,17–19]. In these cases, the *cis*-dioxo disposition is unique in that of the four pπ-pairs of electrons, only three have the symmetry to interact with the metal; the fourth pair is asymmetric and delocalized on the two oxygens as non-bonding. It is this orbital – through extensive mixing as E: attacks at $\theta \neq 180°$ (see Fig. 1) – that helps facilitate the transfer of electron density from the σ-orbital on E to the ultimate π-receptor orbital on the metal [20].

In the mono-oxo and tetrahedral dioxo derivatives above, all pπ-pairs of electrons are involved in π-bonding, yet one pair must be transferred to the metal in the OAT process. Without a non-bonding π-orbital to facilitate the transfer via additional mixing at lower symmetry, this is quite difficult. Reduction of L_nM is also likely to place two electrons in d_{z^2} in both $(silox)_2X_2W$ and $(silox)_2M{=}O$, therefore the second orbitally forbidden process (i.e., L_nM: + OE is $3\sigma + 2\pi$ in Fig. 1), which does not really exist for the *cis*-dioxo cases because the pair of electrons resides in an orbital of π-symmetry (i.e., L_nM: +OE is $2\sigma + 3\pi$), can present a major kinetic barrier [20].

4. Experimental

4.1. General considerations

All manipulations were performed using either glovebox or high vacuum techniques. Hydrocarbon or ethereal solvents were refluxed over sodium, then vacuum transferred from sodium benzophenone ketyl (with 3–6 mL tetraglyme/L added to hydrocarbons). Benzene-d_6 was sequentially dried over sodium, then 4 Å molecular sieves and vacuum transferred from 4 Å molecular sieves. All glassware was oven dried for a minimum of 4 h and NMR tubes were flame dried under dynamic vacuum prior to use. Tungsten (VI) tetrachloride oxide was used as received from Aldrich and molybdenum (VI) dichloride dioxide was used as received from Strem chemicals. $(DME)Cl_2MO_2$ (M = Mo, W) were prepared according to the published procedures [15,16].

NMR spectra were obtained on Varian XL-200, XL-400, VXR-400S and Unity 500 spectrometers, and chemical shifts are reported relative to C_6D_6 (^1H, δ 7.15; $^{13}C\{^1H\}$, δ 128.00) and d_8-THF (^1H, δ 1.75). Infrared spectra were recorded using a Nicolet Impact 410 spectrophotometer interfaced to an IBM PC. Combustion analyses were performed by Robertson Microlit Laboratories, Madison, NJ.

4.2. Procedures

4.2.1. $(silox)_2Cl_2WO$ (**3**)

Into a round bottom flask containing $OWCl_4$ (0.200 g, 0.585 mmol) and Na(silox) (0.279 g, 1.17 mmol) was distilled 25 mL diethyl ether. The solution was allowed to warm to 25 °C and stirred for 4 h. The resulting yellow/green solution was filtered with 20 mL diethyl ether until there was no yellow color left in the filter cake. The filtrate volume was reduced to 8 mL and cooled to −78 °C for 1 h. Filtration yielded 0.302 g **3** as a yellow solid (74%). IR (Nujol Mull, cm^{-1}): 1477 (s), 1360 (s), 1188 (w), 1009 (s), 940 (s), 850 (br, s), 684 (w), 623 (s), 590 (s). *Anal.* Calc. for $H_{54}C_{24}O_3Si_2W$: C, 41.09; H, 7.76. Found: C, 41.06; H, 7.66%.

4.2.2. $(silox)_2Me_2WO$ (**4**-Me)

To slurry of **3** (0.344 g, 0.491 mmol) in 10 mL diethyl ether was syringed 0.36 mL (2.15 equiv, 1.056 mmol) MeMgBr (3.0 M in diethyl ether) at −78 °C under an argon counterflow. The mixture was allowed to warm to 25 °C and stirred for 4 h. The volatiles were removed in vacuo and the yellow residue was triturated with hexanes (3 × 10 mL). A 10-mL slurry in hexanes was filtered and washed until the filter cake was no longer yellow. The filtrate was reduced to 3 mL and cooled to −78 °C for 30 min to afford **4**-Me, which was collected as a dark yellow solid by filtration (0.208 g, 64%). IR (Nujol Mull, cm^{-1}): 1387 (m), 1003 (w), 944 (m), 857 (s), 818 (s), 731 (w), 625 (m). *Anal.* Calc. for $H_{60}C_{26}O_3Si_2W$: C, 47.30; H, 9.19. Found: C, 45.79; H; 8.88%.

4.2.3. $(silox)_2Et_2WO$ (**4**-Et)

To slurry of **3** (0.604 g, 0.861 mmol) in 18 mL diethyl ether was syringed 0.59 mL (2.05 equiv, 1.756 mmol) EtMgBr (3.0 M in diethyl ether) at −78 °C under an argon counterflow. The mixture was allowed to warm to 25 °C and stirred for 6 h. The volatiles were removed in vacuo and the yellow residue was triturated with hexanes (2 × 154 mL). A 15-mL slurry in hexanes was filtered and washed until the filter cake was no longer yellow. The filtrate was reduced to 5 mL and cooled to −78 °C for 30 min to yield **4**-Et as a yellow microcrystalline solid (0.504 g, 85%). IR (Nujol Mull, cm^{-1}): 1414 (w), 1367 (s), 1176 (w), 967 (s), 917 (m), 900 (br,s), 811 (s), 625 (s).

4.2.4. (silox)$_2$(^{n}Pr)$_2$WO (4-^{n}Pr)

To slurry of **3** (0.249 g, 0.355 mmol) in 12 mL diethyl ether was syringed 0.36 mL (2.05 equiv, 0.728 mmol) ^{n}PrMgCl (2.0 M in diethyl ether) at −78 °C under an argon counterflow. The mixture was allowed to warm to 25 °C and stirred for 3 h. The volatiles were removed in vacuo and the yellow residue triturated with hexanes (2 × 8 mL). A 10-mL slurry in hexanes was filtered and washed until the filter cake was no longer yellow. The filtrate was reduced to 2 mL and cooled to −78 °C for 20 min to afford **4**-^{n}Pr as a yellow-orange solid (0.172 g, 68%). IR (Nujol Mull, cm^{-1}): 1381 (m), 983 (m), 930 (m), 900 (m), 838 (s), 811 (s), 784 (s), 625 (s).

4.2.5. (silox)$_2$(^{n}Bu)$_2$WO (4-^{n}Bu)

To slurry of **3** (0.501 g, 0.714 mmol) in 18 mL diethyl ether was syringed 0.75 mL (2.05 equiv, 1.464 mmol) ^{n}BuMgCl (2.0 M in diethyl ether) at −78 °C under an argon counterflow. The mixture was allowed to warm to 25 °C and stirred for 4 h. The volatiles were removed in vacuo and the yellow residue was triturated with pentane (3 × 10 mL). A 10-mL slurry in hexanes was filtered and washed until the filter cake was no longer yellow. The filtrate was reduced to 5 mL and cooled to −78 °C for 2 h to yield **4**-^{n}Bu as a yellow-orange solid (0.355 g, 67.1%). IR (Nujol Mull, cm^{-1}): 1388 (s), 1368 (s), 1017 (w), 976 (s), 910 (m), 860 (br,s), 811 (s), 672 (w), 625 (s). *Anal.* Calc. for $H_{72}C_{32}O_3Si_2W$: C, 51.60; H, 9.74. Found: C, 51.60; H; 9.81%.

4.2.6. (silox)$_2$(C_2H_4)WO (5-C_2H_4)

To a 150-mL bomb reactor was added 0.330 g (0.479 mmol) of **4**-Et and 8 mL benzene. The reactor was freeze–pump–thaw degassed, sealed and heated to 90 °C for 24 h. All volatiles were removed and the residue was triturated with hexanes (3 × 5 mL) and filtered. Removal of solvent afforded 0.281 g of red-brown **5**-C_2H_4 (89%; 5–10% impurity resonances, as assayed by silox groups, were typically present).

4.2.7. (silox)$_2$$MoO_2$ (6)

Into a flask containing (DME)Cl_2MoO_2 (0.418 g, 1.446 mmol) and Na(silox) (0.688 g, 2.89 mmol) was distilled 15 mL tetrahydrofuran. The solution was warmed to 25 °C with stirring. After 12 h of stirring, the volatiles were removed in vacuo and the resulting off-white residue was triturated with pentane (3 × 10 mL). Filtration using pentane (10 mL), reduction of the solvent to 3 mL, cooling to −78 °C for 45 min and filtration yielded 0.482 g **6** as an off-white microcrystalline solid (60%). *Anal.* Calc. for $H_{54}C_{24}O_4Si_2Mo$: C, 51.60; H, 9.74. Found: C, 51.33; H; 10.03%.

4.2.8. (silox)$_2$$WO_2$ (7)

Into a flask containing (DME)Cl_2WO_2 (0.287 g, 0.762 mmol) and Na(silox) (0.362 g, 1.52 mmol) was distilled 13 mL tetrahydrofuran. The solution was allowed to warm to 25 °C with stirring. After 12 h of stirring, the volatiles were removed in vacuo, the resulting off-white residue was triturated with hexanes (3 × 10 mL) and filtered (8 mL). Reduction of the solvent to 3 mL, cooling to −78 °C for 1 h and filtration yielded 0.257 g **7** as an off-white microcrystalline solid (52%).

4.3. NMR tube reactions

Flame dried NMR tubes, sealed with 14/20 ground glass joints, were charged with the metal reagent (e.g., 0.012–0.025 g) in the dry box, and removed to the vacuum line on needle valve adapters. The NMR tubes were degassed, and after transfer of deuterated solvent, a calibrated gas bulb was used to introduce volatile reagents (e.g., PMe_3) at 77 K. The tubes were sealed with a torch. Solid substrates (e.g., PPh_3) were loaded along with the metal complex followed by solvent transfer on the vacuum line and flame sealing. Freshly distilled deuterated solvent was added to NMR tubes containing substrate and metal complex while in the dry box. The mixture was then degassed on the vacuum line and the tube flame sealed.

4.4. Single crystal X-ray structure determination of (silox)$_2$(^{n}Bu)$_2$WO (4-^{n}Bu)

Slow evaporation at 25 °C of a saturated benzene solution of (silox)$_2$(^{n}Bu)$_2$WO (**4**-^{n}Bu) yielded dark yellow block crystals suitable for X-ray analysis. A few crystals were immersed in polyisobutylene, and one with dimensions 0.30 × 0.20 × 0.10 mm was extracted with a glass fiber, and placed under a 173 K nitrogen stream on the gonimeter head of a Siemens SMART CCD area detector system equipped with a fine-focus molybdenum X-ray tube ($\lambda = 0.71073$ Å). Preliminary diffraction revealed a monoclinic crystal system. A hemisphere routine was used to determine the space group as $P2_1/n$, obtain precise lattice constants and for data collection (θ limits were 1.79–28.28°, the limiting indices were $-16 \leqslant h \leqslant 16$, $-17 \leqslant k \leqslant 17$, $-32 \leqslant l \leqslant 32$). The data was processed with the Bruker SAINT program to yield 39 390 reflections with 9497 of the reflections being symmetry independent ($R_{int} = 0.0478$). The data were corrected for absorption by SADABS. The structure was solved by direct methods (SHELXS), completed by subsequent difference Fourier syntheses, and refined by full-matrix least squares procedures (SHELXL, on F^2). A disordered *n*-butyl group was modeled with partial occupancies. All non-hydrogen atoms were refined using anisotropic displacement parameters and hydrogen atoms were included at calculated positions.[1]

Dedicated to Professor Malcolm H. Chisholm on the occasion of his 60th birthday.

Abstract

The complex $[Ti_2Cl_4(NNMe_2)_2(py)_3]$ (**1**) has been prepared via the reaction of $TiCl_4$ with $LiN(H)NMe_2$, followed by treatment with pyridine. Preparation of the complex $[TiCl(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]$ (**2**) was carried out by treatment of $TiCl_4$ with $Li[PhC\{N(SiMe_3)_2\}]$tmeda, followed by reaction with $LiN(Me)NMe_2$. The structures of **1** and **2** were determined by single crystal X-ray diffraction. The single crystal X-ray structure of $Li[PhC\{N(SiMe_3)_2\}]$tmeda (**3**) has also been determined.

1. Introduction

Several single-source precursors to titanium nitride have been reported over the past 15 years, including homoleptic titanium amides and mixed titanium amide/alkyl compounds [1], amides such as $[CpTiCl_2\{N(SiMe_3)_2\}]$ [2] and $[TiCl_2(NH\text{-}t\text{-}Bu)_2(NH_2\text{-}t\text{-}Bu)_2]_n$ [3], several imides [4], adducts of the type $[TiCl_4(NH_3)_2]$ [5] and azides such as $[Cp_2Ti(N_3)_2]$ [6] and $[Ti(NMe_2)_2(N_3)_2(py)_2]$ [7]. Ideally, the TiN single source precursor should possess reasonable volatility in order to facilitate vapor transport. In turn, this implies the avoidance of oligomerization. A second desirable precursor feature is an all-nitrogen coordination environment around the titanium atom since the presence of, e.g., titanium–chlorine or titanium–carbon bonds can result in the presence of chlorine or carbon impurities in the TiN films or particles.

In the present work, two strategies were employed in an effort to prepare monomeric titanium nitride precursors with all-nitrogen coordination spheres. The first approach featured the use of alkylhydrazido ligands; the second involved the use of alkylhydrazido ligands in conjunction with amidinate ligands. A major potential advantage of hydrazido ligands stems from the expectation that N–N bond cleavage will be more facile than N–C bond cleavage owing to the order of bond enthalpies N–C > N–N. In principle, this should result in lower deposition temperatures and less carbon incorporation for titanium hydrazides than for precursors with Ti–N–C linkages. Such a view is supported by the observation [8] that the decomposition of methylhydrazine on a titanium surface is initiated by N–N bond cleavage at modest temperatures (~200 °C). Moreover, Winter et al. [9,10] have demonstrated that alkylhydrazide ligands can be employed for the deposition of high quality TiN films; however, the inclusion of chloride ligands in these precursors led to chloride incorporation in the films that were grown at lower temperatures. A second potential advantage of the use of hydrazido ligands is

doi:10.1016/j.poly.2005.06.035

that they are capable of binding to titanium in an η^2-fashion, thus facilitating the achievement of an all-nitrogen coordination environment. A similar comment applies to the use of amidinate ligands which also are capable of exhibiting an η^2-binding mode.

In the present contribution, we describe the reaction of $TiCl_4$ with $LiN(H)NMe_2$, followed by treatment with pyridine and the reaction of $TiCl_4$ with Li[PhC{N-$(SiMe_3)_2$}]tmeda, followed by treatment with LiN-$(Me)NMe_2$. Both products were characterized by single-crystal X-ray diffraction. We also report the X-ray crystal structure of Li[PhC{$N(SiMe_3)_2$}]tmeda. Although the latter is a known compound [11], it has not been structurally characterized previously.

2. Experimental

2.1. General procedures

All manipulations and reactions were performed under catalyst-scrubbed Ar, using a combination of glove box and standard Schlenk techniques. Dichloromethane was purified by distillation under N_2 from calcium hydride, and all other solvents were distilled under N_2 from sodium/benzophenone ketyl. Additional degassing of solvents was performed using either vigorous Ar bubbling, or freeze/pump/thaw cycling.

A 1.6 M hexane solution of *n*-BuLi was purchased from a commercial source, and used without further purification. Titanium(IV) chloride was purchased from a commercial source, and purified as necessary by vacuum distillation. 1,1,-Dimethylhydrazine was purchased from a commercial source, and purified by distillation. Trimethylhydrazine [12] and Li[PhC{$N(SiMe_3)_2$}]tmeda [11] were prepared and purified using literature methods.

2.2. Spectroscopic measurements

All CI mass spectra were recorded on a Finnigan MAT TSQ-700 instrument; the samples were sealed in glass capillaries under Ar in a glove box. NMR spectra were recorded at 295 K on a GE QE-300 spectrometer. The CD_2Cl_2 used in these measurements was purchased in sealed vials, either pure or with 1% (v/v) tetramethylsilane. The THF-d_8 was purchased from a commercial source and vacuum distilled under Ar prior to use. The ^1H NMR chemical shifts are reported relative to tetramethylsilane and are referenced either directly or to solvent.

2.3. Single crystal X-ray structure determinations

Crystals of $[Ti_2Cl_4(NNMe_2)_2(py)_3]$ (**1**), [TiCl(PhC{N-$(SiMe_3)_2$}$_2)_2(MeNNMe_2)$] (**2**) and Li[PhC{$N(SiMe_3)_2$}]-tmeda (**3**) of suitable quality were collected directly from Schlenk-type flasks under Ar pressure, and covered immediately with degassed perfluorinated polyether oil. The data for **1** were collected at 293(2) K on a Siemens P 4 diffractometer and the data for **2** and **3** were collected at 153(2) K on a Nonius Kappa CCD diffractometer. Each data set was corrected for Lorentz and polarization effects. All three structures were solved by direct methods, and refined by full-matrix least-squares on F^2 using the SHELXTL PLUS software package [13]. All non-hydrogen atoms were allowed anisotropic thermal motion and hydrogen atoms, which were included at calculated positions, were refined using a riding model and a general isotropic thermal parameter. The total number of reflections, collection ranges, and final *R* values are listed in Table 1.

2.4. Synthesis of $[Ti_2Cl_4(NNMe_2)_2(py)_3]$ (**1**)

A solution of NH_2NMe_2 (3.8 g, 63 mmol) in 40 mL of tetrahydrofuran was chilled to −78 °C and 25 mL of an *n*-BuLi solution (1.6 M in hexane) was added over a period of 10 min. The reaction mixture was allowed to warm to room temperature over several hours, then stirred overnight. Titanium tetrachloride (5.2 mL, 16 mmol) was added via syringe to 80 mL of tetrahydrofuran at −10 °C, to which was added the solution of $LiN(H)NMe_2$ over a period of 10 min. The reaction mixture was allowed to warm to room temperature overnight, following which the solvent was removed under reduced pressure and the resulting solids extracted with CH_2Cl_2 (3×75 mL). Filtration through a glass frit covered with diatomaceous earth resulted in a red colored filtrate. The volume of the latter solution was reduced to 100 mL, and pyridine (0.5 mL, 6 mmol) was added to a 30 mL aliquot. Cooling of this mixture to −20 °C for a period of days produced large red crystals of **1** in 40% yield.

^1H NMR (300 MHz, 298 K, CD_2Cl_2): δ 8.83 (m, 6H, *m*-py), 7.79 (t, 3H, *p*-py), 7.35 (t, 6H, *o*-py), 3.47 (s, 12H, Me_2N). MS (CI^+, CH_4): *m/e* 556 $[Ti_2Cl_3(NNMe_2)_2(py)_3]^+$ (5%), 475 $[Ti_2Cl_3(NNMe_2)_2(py)_2]^+$ (24%), 434 $[Ti_2Cl_3N_3C_2H_7(py)_2]^+$ (27%), 396 $[Ti_2Cl_3(NNMe_2)_2(py)]^+$ (49%), 355 $[Ti_2Cl_3N_3C_2H_7(py)]^+$ (100%), 317 $[Ti_2Cl_3(NNMe_2)_2]^+$ (23%).

2.5. Synthesis of $[TiCl(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]$ (**2**)

Titanium tetrachloride (2.0 mL, 18 mmol) was added via syringe to a solution of Li[PhC{$N(TMS)\}_2$]tmeda (13.9 g, 36 mmol) in 100 mL of tetrahydrofuran. The reaction mixture was stirred overnight, after which the volatiles were removed under reduced pressure and the resulting orange-red solid was extracted with diethyl ether (2×70 mL). After filtration through a glass frit covered with diatomaceous earth, the red filtrate was concentrated and maintained at −20 °C overnight. The intermediate, $TiCl_2(PhC\{N(SiMe_3)_2\}_2)_2$, was isolated as

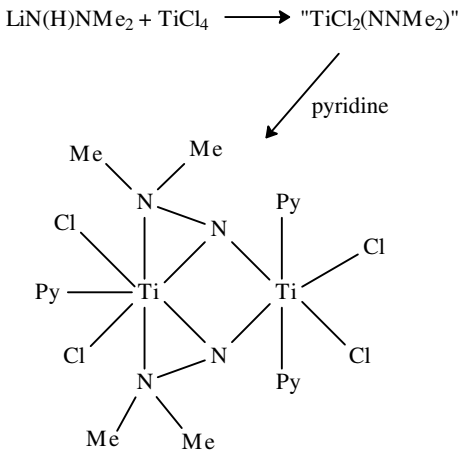
red crystals in 45% yield. This is a slight variation of the literature methods [11,14,15]. [^{1}H NMR (300 MHz, 298 K, CD_2Cl_2): δ 7.41 (m, 3H, *o*,*p*-Ph), 7.28 (m, 2H, *m*-Ph), 0.05 (s, 18H, Me_3Si)]. Trimethylhydrazine (0.23 g, 3 mmol) in 30 mL of diethyl ether was lithiated by treatment with 1.9 mL of a solution of *n*-BuLi (1.6 M in hexane) at −78 °C. The reaction mixture was allowed to assume room temperature and stirring was continued overnight. A solution of $TiCl_2(PhC\{N(SiMe_3)_2\}_2)_2$ (1.0 g, 1.5 mmol) in 50 mL of diethyl ether was then added, and the reaction mixture was stirred overnight. Following filtration through a glass frit covered with diatomaceous earth, the resulting orange filtrate was concentrated and chilled to −78 °C, affording an orange oil. A crop of orange-red crystals of **2** (0.22 g (0.33 mmol, 22% yield)) formed upon storage of the oil at ambient temperature. ^{1}H NMR (300 MHz, 298 K, THF-d_8): δ 7.44 (m, 6H, Ph), 7.31 (m, 4H, Ph), 2.74 (s, 3H, MeN), 2.36 (s, 6H, Me_2N), 0.07 (s, 18H, Me_3Si); MS (CI^+, CH_4) m/e 683 [M + 1, 14%], 647 [M-Cl^-, 15%], 609 [$TiCl_2(PhC\{N(SiMe_3)_2\}_2)_2$, 100%].

3. Results and discussion

3.1. Synthesis and preliminary identification of $[Ti_2Cl_4(NNMe_2)_2(py)_3]$ (**1**)

The initial phase of the synthesis was monolithiation of H_2NNMe_2 to form $LiN(H)NMe_2$. This lithium reagent was allowed to react with $TiCl_4$ in a 4:1 mole ratio in THF solution. The synthesis of **1** was completed by the addition of pyridine in an effort to prevent oligomerization (Scheme 1). ^{1}H NMR spectroscopic assay provided two clues to the structure of **1**, namely (i) no N–H signal was evident thus suggesting that the hydrazido ligand is attached to titanium in an η^1 or η^2 fashion, and (ii) the hydrazido and pyridine ligands are present in a 2:3 mole ratio. However, it was necessary to appeal to X-ray crystallography to provide more definitive structural information.



1

Scheme 1.

3.2. Single crystal X-ray structure of $[Ti_2Cl_4(NNMe_2)_2(py)_3]$ (1)

The X-ray analysis reveals a dititanium structure in which the two coordination environments are quite distinct (Fig. 1 and Table 2). One titanium atom [Ti(1)] is seven coordinate and features a pyridine molecule, two chlorides, and two η^2-attached $[Me_2NN]^{2-}$ ligands.

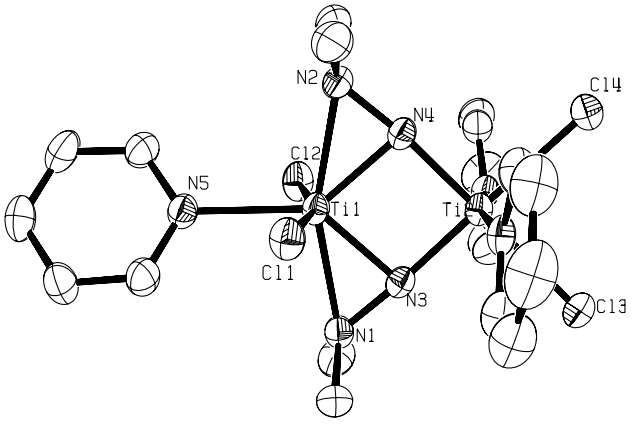


Fig. 1. Molecular structure of $[Ti_2Cl_4(NNMe_2)_2(py)_3]$ (**1**) showing the atom numbering scheme. Thermal ellipsoids are set to 30% probability. All hydrogen atoms and two molecules of CH_2Cl_2 of crystallization have been omitted for clarity.

The overall geometry at Ti(1) can be described as pentagonal bipyramidal. Thus, the sum of bond angles in the pentagonal plane described by the five nitrogen atoms is 360.0(1)°. Note, however, that the angles in this plane are very distorted and range from 38.1(1)° to 101.0(1)°. The departures from the ideal bond angle of 72° are caused by the very small bite angles of the η^2-hydrazide ligands. If, however, a pseudo-trigonal bipyramidal geometry is considered by defining the midpoints of the N–N moieties as "ligands" the "bond angles" in the equatorial plane would be 120.3°, 118.1°, and 121.6°. The axial ligands at N(1) are distorted from linearity as reflected by the Cl–Ti–Cl bond angle of 160.99(6)°. Note that both of these chloride ligands are inclined away from the more "crowded" side of the molecule.

The geometry at Ti(2) is octahedral. Two pyridine molecules are arranged in a *trans* fashion while the two chlorides and the two imido nitrogens [N(3) and N(4)] each possess a mutually *cis* arrangement. The departures from the ideal angle of 90° are modest and of the order of 5–6° (see Table 2). The view down the Ti(1)–Ti(2) vector shows that the C(13)–C(14)–N(3)–N(4)–N(1)–N(2) and N(6)–N(7)–C(11)–C(12) planes are close to orthogonal (Fig. 2).

The two hydrazides feature an imido nitrogen [N(3) and N(4)], each of which is formally σ-bonded to Ti(1)

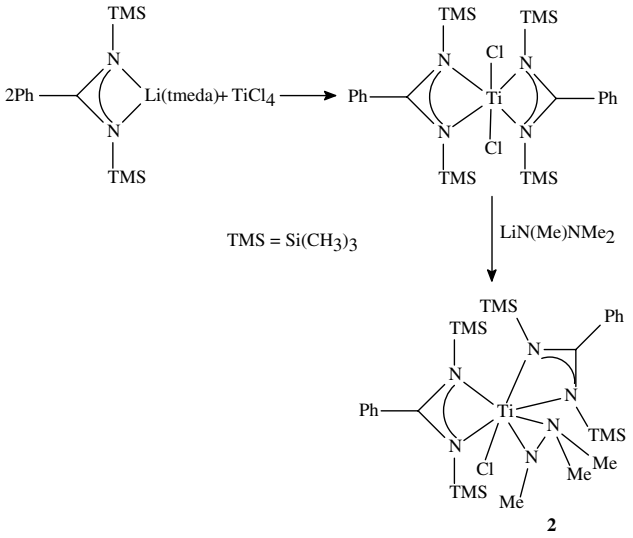

Scheme 2.

and coordinated to Ti(2). The geometries at N(3) and N(4) are close to trigonal planar as reflected by the sums of bond angles, 352.9(3)° and 348.3(3)°, respectively. The remaining nitrogens [N(1) and N(2)] are of the amido type and form donor–acceptor bonds to Ti(1). As expected, the average Ti–N bond distance for the imido nitrogens (1.948(4) Å) is considerably shorter than that for the amido nitrogens (2.216(4) Å). The Ti(1)–N(3)–Ti(2)–N(4) core is close to planar (sum of bond angles = 346.8(2)°); however, the average Ti–N bond distance to Ti(1) (1.948(4) Å) is longer than that to Ti(2) (1.856(4) Å). As anticipated on the basis of the higher coordination number of Ti(1), the N(3)–Ti(1)–N(4) bond angle (83.3(1)°) is more acute than the N(3)–Ti(2)–N(4) bond angle (88.5(2)°). Overall, the close-to-planar Ti_2N_2 core is similar to those reported for other dinuclear imido-bridged titanium complexes [16].

3.3. Synthesis and preliminary identification of $[TiCl(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]$ (2)

The initial phase of the synthesis involved the lithiation of trimethylhydrazine to form $LiN(Me)NMe_2$. The latter was allowed to react in Et_2O solution with 0.5 equiv. of $TiCl_2(PhC\{N(SiMe_3)_2\}_2)_2$ which was prepared by a slight variation of the literature methods [11,16]. The overall process is summarized in Scheme 2. The reason for selecting the trimethylhydrazide ligand was to minimize the chance of dimerization by imido bridge formation (as happens in the case of **1**). ^1H NMR spectroscopic examination of the product revealed the presence of amidinate and hydrazide resonances in a 2:1 mole ratio. The CI^+ mass spectrum of **2** evidenced low intensity peaks attributable to $[Ti(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]^+$ and $[TiCl(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]^+$ suggesting that the identity of the product is $[TiCl(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]$. This suggestion was confirmed by X-ray crystallography.

3.4. Single crystal X-ray structure of $[TiCl(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]$ (2)

The X-ray crystal structure confirms the presence of one chloride ligand in the product. Thus, even though there is sufficient space around the titanium atom (Fig. 3 and Table 2), the second equivalent of $LiN(Me)NMe_2$ fails to react. The coordination sphere comprises two η^2-bonded amidinate ligands, one chloride, and one η^2-bonded trimethylhydrazide. The titanium(IV) center is therefore heptacoordinate. The

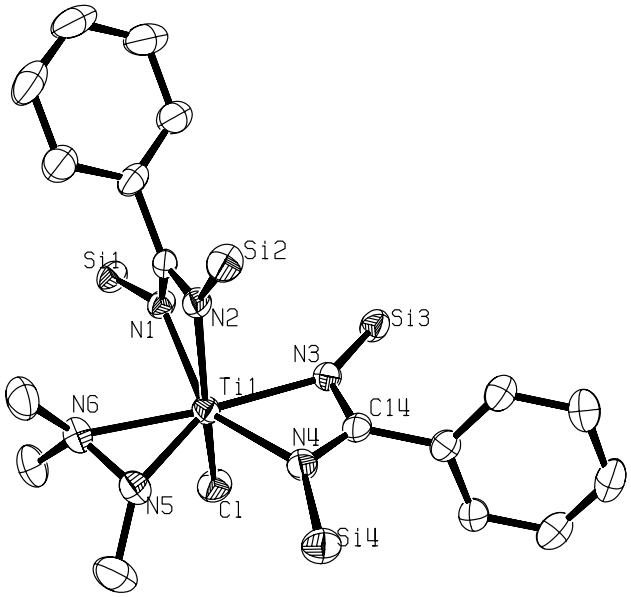

Fig. 3. Molecular structure of $[TiCl(PhC\{N(SiMe_3)_2\}_2)_2(MeNNMe_2)]$ (**2**) showing the atom numbering scheme. Thermal ellipsoids are set to 30% probability. All hydrogen atoms and the methyl groups on the silicon atoms have been omitted for clarity.

geometry of **2** does not fall in an easily described category. Nitrogen N(2) and the chloride ligand possess a mutually *trans* relationship with a Cl–Ti–N(2) bond angle of 158.08(8)° and, together with N(1) these atoms roughly describe a trigonal plane. Likewise, nitrogen atoms N(3) and N(6) are almost directly opposite each other (∠N(6)–Ti–N(3) = 171.6(1)°) and, in turn, nitrogen atoms N(3), N(4), N(5) and N(6) are close to planar. The maximum deviation from said plane is 0.185 Å for N(5). The N(1)–N(2)–Cl and N(3)–N(4)–N(5)–N(6) planes are roughly orthogonal, e.g., N(2) forms angles of 88.9(1)° and 91.4(1)° with N(3) and N(6), respectively.

As in the case of **1**, the N–Ti bond distance for the σ-bonded nitrogen of the hydrazide ligand, N(5) (1.897(3) Å) is shorter than that for the donor nitrogen, N(6) (2.196(3) Å). Although the two amidinate ligands are, as expected, bonded in an η^2-fashion, the two Ti–N bond distances are unequal. For example, the N(3)–Ti bond distance is 0.085(3) Å longer than that for the N(4)–Ti bond and the N(2)–Ti bond distance exceeds the N(1)–Ti bond distance by 0.097(3) Å. The average bite angle of the amidinate ligands in **2** is 62.6(1)° and thus considerably larger than that of the trimethylhydrazide ligand (39.4(1)°).

3.5. Single crystal X-ray structure of Li[PhC{N(SiMe$_3$)$_2$}]tmeda (3)

The structure of **3** (Fig. 4 and Table 2) is similar to those of other lithium amidinates [17]. In contrast to the structure of the titanium compound **2**, the C–N bond distances in the lithio derivative **3** are equal within experimental error and shorter than the average C–N bond distance in **2**.

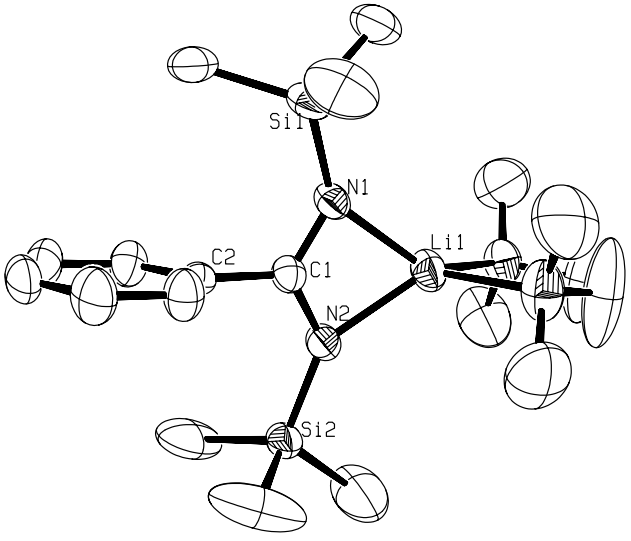

Fig. 4. Molecular structure of Li[PhC{N(SiMe$_3$)$_2$}]tmeda (**3**) showing the atom numbering scheme. Thermal ellipsoids are set to 30% probability.

4. Concluding remarks

Although LiN(H)NMe$_2$ is sufficiently reactive toward TiCl$_4$ to cause both LiCl and HCl elimination reactions, only two of the four chloride ligands are displaced. Repetition of this reaction with higher lithium hydrazide/TiCl$_4$ mole ratios did not change the outcome and **1** was the sole isolated product. Furthermore, the pronounced tendency of the hydrazide (2-) ligand to adopt a bridging position resulted in a dinuclear structure. The use of pyridine ligands to saturate the titanium centers, and thus preclude dimerization, was unsuccessful. In the case of **2**, despite the increase of size in going from hydrazide to amidinate ligands, again it was not possible to eliminate all the chloride ligands of TiCl$_4$.

Self-assembly of organometallic polymers through hydrogen bonding: A diplatinum(IV) complex with a single bridging halide ligand

Christopher S.A. Fraser, Dana J. Eisler, Richard J. Puddephatt *

Department of Chemistry, University of Western Ontario, Richmond Street, London, Canada N6A 5B7

Received 8 April 2005; accepted 15 August 2005
Available online 7 October 2005

Dedicated to Professor Malcolm Chisholm, master of molecular architecture, in recognition of his outstanding contributions to inorganic chemistry.

Abstract

The reaction of $[PtMe_2(bu_2bipy)]$, $bu_2bipy = 4,4'$-di-*t*-butyl-2,2′-bipyridine (**1**) with RCH_2Br occurs by *trans* oxidative addition to give the platinum(IV) complexes $[PtBrMe_2(CH_2R)(bu_2bipy)]$, $R = C_6H_4CO_2H$ (**2**); $R = C_6H_4CH_2CO_2H$ (**3**) and these reacted with half an equivalent of $Ag[PF_6]$ to give the unusual diplatinum(IV) complexes $[\{PtMe_2(CH_2R)(bu_2bipy)\}_2(\mu\text{-}Br)][PF_6]$, $R = C_6H_4CO_2H$ (**4**); $R = C_6H_4CH_2CO_2H$ (**5**). These diplatinum(IV) complexes, each of which contains a hydrogen bonding carboxylic acid group, are connected only by an unsupported bridging bromide ligand. In the solid state, complex **4** forms a self-assembled zig-zag polymer through intermolecular hydrogen bonding between pairs of carboxylic acid groups.

Keywords: Platinum; Self-assembly; Polymer; Hydrogen bond

1. Introduction

Hydrogen bonding is widely used in supramolecular chemistry, such as in crystal engineering and in the design of molecular materials [1–3]. However, this approach has natural limitations in organometallic chemistry, since many alkyl-metal bonds react with the functional groups (e.g. OH or NH bonds) typically used as hydrogen bond donors [4]. Although methylplatinum(II) bonds can be cleaved by carboxylic acids [5], the reactions of $[PtMe_2(bu_2bipy)]$, $bu_2bipy = 4,4'$-di-*t*-butyl-2,2′-bipyridine (**1**) with $BrCH_2C_6H_4CO_2H$ and $BrCH_2C_6H_4CH_2CO_2H$ occur selectively by *trans* oxidative addition of the C–Br bond to give the platinum(IV) complexes **2** and **3**, rather than by protonolysis of a methylplatinum bond, as shown in Scheme 1 [6–8]. Since methyl-platinum(IV) bonds are typically inert towards protonolysis [4,5], with the notable exception of tetramethylplatinum(IV) compounds [9], the organoplatinum(IV) products, **2** and **3** of Scheme 1, that contain a carboxylic acid functional group are stable compounds. In the solid state, they form dimers by self-assembly as illustrated for complex **2** in Scheme 1 [6].

In order to form polymers by self-assembly, it is necessary to have at least two hydrogen-bonding donor/acceptor pairs per molecule. One way to prepare such "building block" molecules is to abstract the bromide ligand from **2** or **3** in the presence of an assembling ligand such as 4,4′-bipyridine, and the diplatinum(IV) complexes formed in this way have been shown to self-assemble to give unusual supramolecular polymers [6–8]. This paper reports a simpler way to prepare diplatinum(IV) complexes by formation of a bridging halide linking group, and shows that self-assembly can then give a supramolecular polymer.

2. Experimental

All reactions were performed under a nitrogen atmosphere by using standard Schlenk techniques. NMR and

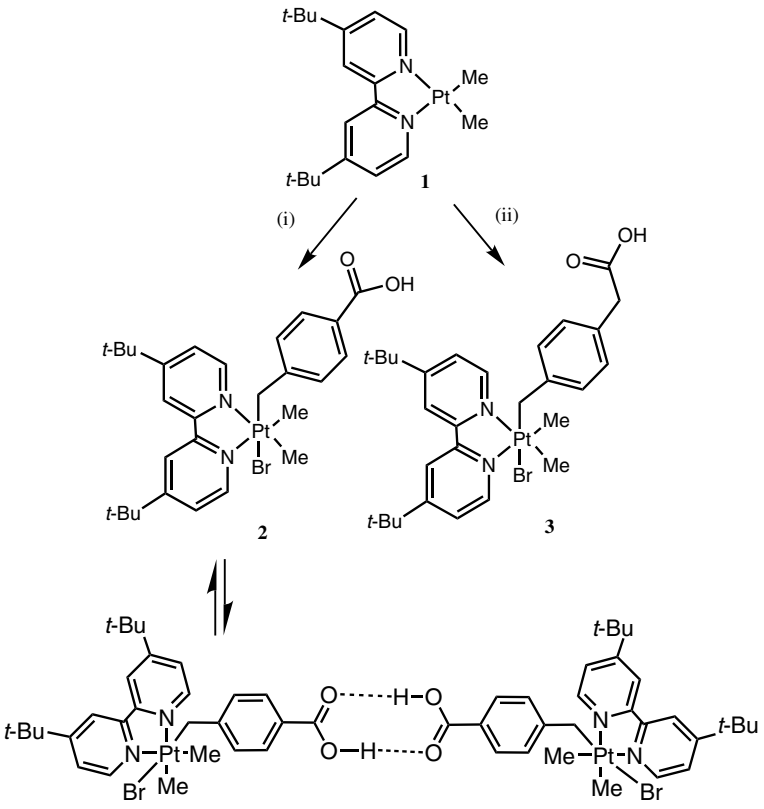

Scheme 1. Reagents are: (i) $BrCH_2C_6H_4CO_2H$ and (ii) $BrCH_2C_6H_4CH_2CO_2H$.

IR spectra were recorded by using a Varian Gemini 400 NMR and a Perkin-Elmer FT-IR 2000 spectrometer, respectively. Compound **1** was prepared using a method reported in the literature [10].

2.1. [{$PtMe_2(bu_2bipy)(CH_2C_6H_4CO_2H)$}$_2(\mu$-Br)][$PF_6$] (**4**[$PF_6$])

To a solution of [$PtMe_2(bu_2bipy)$] (100 mg) in acetone (30 mL) was added bromotoluic acid (44 mg), and the solution was stirred for 30 min., after which time a solution of $AgPF_6$ (26 mg) in acetone (5 mL) was added. After stirring for further 30 min, the mixture was filtered through Celite and evaporated under vacuum to give a white solid. Yield: 86%. *Anal.* Calc. for $C_{56}H_{74}BrF_6N_4O_4PPt_2$: C, 45.38; H, 5.03; N, 3.78. Found: C, 45.07; H, 5.21; N, 3.55%. NMR in acetone-d_6: $\delta(^1H) = 1.04$ [s, 12H, $^2J(PtH) = 70$ Hz, PtMe]; 1.44 [s, 36H, bu]; 2.82 [s, 4H, $^2J(PtH) = 90$ Hz, $PtCH_2$]; 6.35 [m, 4H, C_6H_4 H^2]; 7.25 [m, 4H, C_6H_4 H^3]; 7.70 [m, 4H, bipy H^5]; 8.45 [m, 4H, bipy H^3]; 8.60 [m, 4H, bipy H^6]. IR (Nujol mull): $\nu(CO) = 1697$ cm^{-1}, $\nu(OH) = 2624$, 2548 cm^{-1}.

2.2. [{$PtMe_2(bu_2bipy)(CH_2C_6H_4CH_2CO_2H)$}$_2(\mu$-Br)][$PF_6$] (**5**[$PF_6$])

This was prepared similarly from [$PtMe_2(bu_2bipy)$] (100 mg), bromomethylphenylacetic acid (46 mg) and $AgPF_6$ (26 mg). Yield: 87%. *Anal.* Calc. for $C_{58}H_{78}BrF_6N_4O_4PPt_2$: C, 46.13; H, 5.20; N, 3.71. Found: C, 45.71; H, 5.21; N, 3.58%. NMR in acetone-d_6: $\delta(^1H) = 1.02$ [s, 12H, $^2J(PtH) = 70$ Hz, PtMe]; 1.48 [s, 36H, bu]; 2.75 [s, 4H, $^2J(PtH) = 90$ Hz, $PtCH_2$]; 6.15 [m, 4H, C_6H_4 H^2]; 7.45 [m, 4H, C_6H_4 H^3]; 7.70 [m, 4H, bipy H^5]; 8.3–8.6 [m, br, 8H, bipy H^3 + bipy H^6]. IR (Nujol mull): $\nu(CO) = 1696$ cm^{-1}, $\nu(OH) = 2652$, 2516 cm^{-1}.

2.3. X-ray structure determination

Crystals of **4**[PF_6]$\cdot 4C_6H_6$ were grown by slow diffusion of benzene into an acetonitrile solution. A colorless plate was mounted on a glass fiber. Data were collected at 200 K using a Nonius Kappa CCD diffractometer with COLLECT (Nonius, B.V., 1998) software. The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using the Nonius DENZO package. After data reduction, the data were scaled based on equivalent reflections using SCALEPACK (Nonius, B.V. 1998). The crystal data and refinement parameters are listed in Table 1. The SHELX-TL 5.1 (Sheldrick, G.M., Madison, WI) program package was used to solve the structure by direct methods. There was some disorder in the hexafluorophosphate anion, which was modeled as a mixture of two 50:50 occupancy groups, with the phosphorus fluorine bond lengths restrained to be equal and allowed to refine. Several of the solvent molecules were disordered and were modeled as isotropic 50:50 mixtures.

All other non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were calculated geometrically and were riding on their respective carbon atoms.

3. Results and discussion

The synthesis of the building blocks for self-assembly was achieved according to Scheme 2. The organoplatinum(IV) complexes **2** and **3**, each of which contains a single carboxylic acid substituent, were prepared in situ by reaction of $[PtMe_2(bu_2bipy)]$ with the corresponding benzyl bromide derivative according to Scheme 1. Reaction of these complexes with silver hexafluorophosphate in a 2:1 molar ratio occurred by bromide abstraction, to give insoluble AgBr, and then by formation of a bridging bromide group to give the cationic diplatinum(IV) complexes **4** and **5**, which were isolated as the hexafluorophosphate salts. In these reactions, it can be considered that the bromo ligand of one platinum(IV) center acts as a ligand at the

5, R = $CH_2C_6H_4CH_2CO_2H$

Scheme 2. In the self-assembled polymer only the core atoms of the bu_2bipy ligands are shown.

second platinum(IV) center by occupying the coordination site which is opened up by the bromide abstraction step.

The complexes **4** and **5** are air-stable complexes which are soluble in organic solvents such as acetone and dichloromethane. In acetone-d_6 solution, the ^{1}H NMR spectrum of complex **4** contained a single methylplatinum resonance at $\delta(^1H) = 1.04$, with coupling constant $^2J(PtH) = 70$ Hz, showing that all methylplatinum(IV) groups are equivalent. The benzylic protons also occurred as a singlet resonance at $\delta = 2.82$, with coupling constant $^2J(PtH) = 90$ Hz. The infrared spectrum of complex **4** as a Nujol mull contained a band due to ν(C=O) at 1697 cm^{-1} and bands due to ν(OH) at 2624 and 2548 cm^{-1}. The NMR data are fully consistent with the proposed structure of **4** in solution (Scheme 2), while the IR data indicate the presence of hydrogen-bonded carboxylic acid groups in the solid state [8,9]. Complex **5** was characterized spectroscopically in a similar way.

The molecular structure of complex **4** is shown in Fig. 1. It confirms the overall stereochemistry deduced from the spectroscopic data, with the methylplatinum groups *trans* to the bipyridine ligand and the substituted benzyl group *trans* to bromide. The bromide ligand bridges the two platinum atoms with roughly equal distances Pt(1)–Br(1) = 2.560(2) Å and Pt(2)–Br(1) = 2.565(2) Å. The large angle Pt(1)–Br(1)–Pt(2) = 127.88(8)° and correspondingly long distance Pt···Pt = 4.60 Å are clear indications that there is no platinum-platinum bonding interaction [10]. Thus, the natural bond angle M–X–M is close to 90° for complexes containing a bridging halide and no other bridging halides [10]. An M–X–M angle much less than 90° then indicates the presence of a metal–metal bonding interaction, while an M–X–M angle much greater than 90° indicates both the lack of an attractive force between the metals and the presence of steric interactions around the bridging halide [10–15].

The molecules of complex **4** associate through complementary hydrogen bonding between carboxylic acid

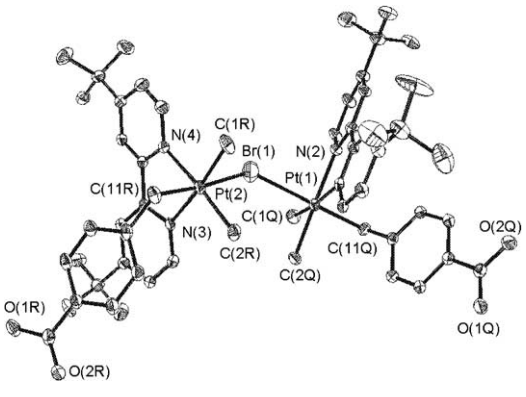

Fig. 1. A view of the structure of the cationic diplatinum(IV) complex **4**. Selected bond parameters: Pt(1)–C(2Q) 2.044(9) Å, Pt(1)–C(11Q) 2.074(9) Å, Pt(1)–C(1Q) 2.075(10) Å, Pt(1)–N(2) 2.145(7) Å, Pt(1)–N(1) 2.161(7) Å, Pt(1)–Br(1) 2.560(2) Å, Pt(2)–C(2R) 2.058(10) Å, Pt(2)–C(11R) 2.077(10) Å, Pt(2)–C(1R) 2.107(11) Å, Pt(2)–N(4) 2.136(8) Å, Pt(2)–N(3) 2.159(7) Å, Pt(2)–Br(1) 2.565(2) Å, C(11Q)–Pt(1)–Br(1) 175.0(3)°, C(11R)–Pt(2)–Br(1) 174.3(3)°, Pt(1)–Br(1)–Pt(2) 127.88(8)°.

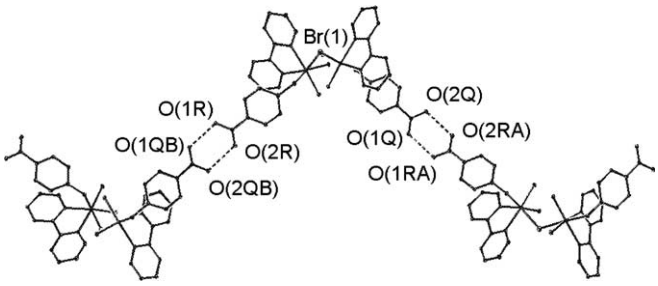

Fig. 2. Part of the zig-zag polymeric chain structure formed by self-assembly through hydrogen bonding between units of complex **4**.

substituents, as shown in Fig. 2. The intermolecular hydrogen bonding between the V-shaped building blocks **4** naturally leads to formation of a zig-zag polymeric structure. The O···O distances O(1Q)···O(1R) = 2.62(2) Å and O(2Q)···O(2R) = 2.71(2) Å are in the expected range for hydrogen bonds in carboxylic acids [5–7,9].

There are very few diplatinum complexes that have been characterized to contain a single unsupported halide bridge, and particularly few organoplatinum(IV) examples [11–14], so the characterization of the molecular structure of complex **4** is significant. More noteworthy is the observation that this is the first time that a complex of this type has been used in the self-assembly of supramolecular polymeric structures. Since the oxidative addition of alkyl halides to platinum(II) is a versatile method for the synthesis of alkyl(halogeno)platinum(IV) complexes containing functionally substituted alkyl groups [5–7], the finding that these monoplatinum(IV) complexes can easily be converted to the diplatinum(IV) complexes with bridging halide provides a valuable new method for the synthesis of bifunctional organodiplatinum(IV) complexes for use in the self-assembly of molecular materials.

Dedicated with admiration to Professor Malcolm H. Chisholm on the occasion of his 60th birthday.

Abstract

Visible and near infrared (NIR) luminescence are observed in heterobimetallic 3d–4f Schiff base complexes $[ZnLEu(OAc)(NO_3)_2]\cdot EtOH\cdot H_2O$ (**2**) and $[ZnLNd(OAc)(NO_3)_2(H_2O)]\cdot EtOH$ (**3**), respectively (H_2L = *N*,*N*′-bis(5-bromo-3-methoxysalicylidene)phenylene-1,2-diamine, OAc = acetate).

1. Introduction

Luminescent lanthanide (Ln) complexes have attracted a great deal of attention for many years due to their potential use in numerous analytical applications, ranging from proton relaxation agents for NMR imaging to luminescent probes in time-resolved fluoroimmunoassays [1]. Most trivalent lanthanide ions exhibit long-lived and linelike emission bands at characteristic wavelengths ranging from green (Tb^{3+}) to near-infrared (NIR) light (Nd^{3+}, Er^{3+}). However, for lanthanide ions, because the f–f transitions are parity forbidden, the absorption coefficients are normally very low and the emissive rates are slow. In order to overcome this, well-designed organic chromophores have been used to excite lanthanide ions as sensitizers (antenna effect) [2]. Over the past two decades, many studies have focused on complexes of Eu^{3+} and Tb^{3+}, which emit in the visible region of the spectrum. Currently, much interest is also devoted to lanthanide ions emitting in the NIR region because of potential applications in bioassays and laser systems [3]. Several recent investigations, by Bünzli and others, of sensitizers for NIR luminescence have focused on organic dyes and d-block metal complexes (i.e., $M = Pt^{II}$, Ru^{II} and Cr^{III}) [4], which display absorption bands in the near-UV or visible ranges.

There are several reports which describe the use of modified "salen" type of Schiff-base ligands for the

H_2L

Scheme 1.

stabilization of heteronuclear 3d–4f complexes. Many of these studies have focused on magnetic behaviour while relatively few have described the photophysical properties of the compounds [5]. Recently, Wong and co-workers [6] described the room temperature NIR luminescence of a series of heteronuclear Zn–Ln Schiff-base complexes formed with ligands that are based on 1,2-diaminoethane (Scheme 1; H_2L^1, H_2L^2). Conjugated organic ligands, with absorption bands generally at longer wavelengths compared to non-conjugated systems, should function as improved sensitizers for the NIR luminescence of lanthanide ions compared to their non-conjugated counterparts. As part of our interest in luminescent lanthanide complexes [7–9], we describe here the synthesis, structures and photophysical properties of two heterobimetallic Zn–Ln complexes based on the Schiff base ligand $\mathbf{H_2L}$, which features an aromatic (phenylene) backbone. In addition the X-ray crystal structure of the ligand $\mathbf{H_2L}$ and the related dinuclear zinc complex [Zn_2LCl_2MeOH] (**1**) are also described.

2. Results and discussion

2.1. Free Schiff base ligand H_2L

The bright-red Schiff base ligand $\mathbf{H_2L}$ was prepared according to well established procedures [10]. The solid state structure of this compound was determined by an X-ray crystallographic study (Table 1) and two views

[a] $R_1 = \sum|F_o| - |F_c|/\sum|F_o|$.
[b] $wR_2 = [\sum w[(F_o^2 - F_c^2)^2]/\sum|[w(F_o^2)^2]]^{1/2}$. $w = 1/[\sigma^2(F_o^2) + (0.075P)^2]$, where $P = [\max(F_o^2, 0) + 2F_c^2]/3$.

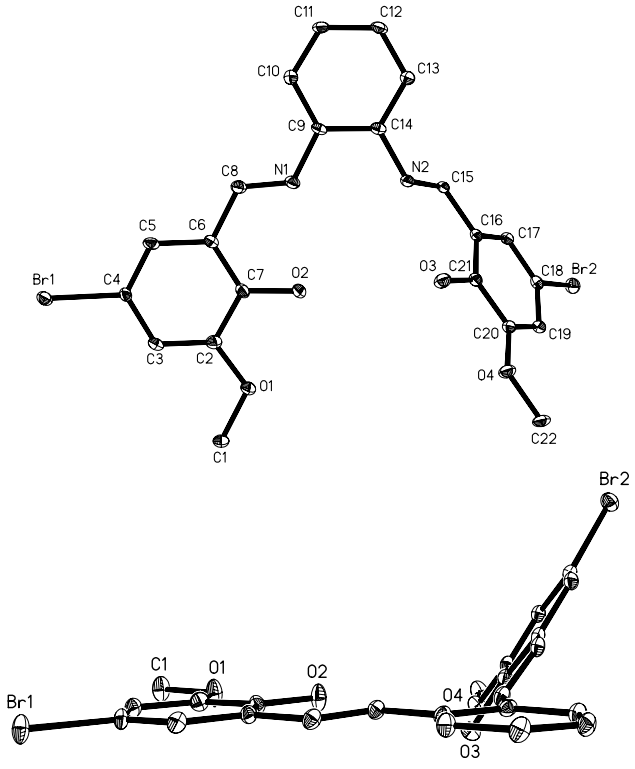

Fig. 1. Views of the crystal structure of the free ligand $\mathbf{H_2L}$. Thermal ellipsoids are drawn at the 25% probability level. Hydrogen atoms are omitted for clarity.

of the molecule are shown in Fig. 1. The compound crystallizes in the $P\bar{1}$ space group with two molecules per unit cell. There are no short intermolecular contacts and the metrical parameters fall within normal limits (Table 2). A noteworthy feature of the structure is the non-planarity of the molecule. This is caused by a twist of one of the "sal" rings which creates an angle of 56.2° with the rest of the molecule. It seems reasonable to assume that this occurs in order to minimize steric interactions between the two phenolic OH protons which would otherwise be directed at each other.

2.2. Metal complexes

Reaction of $\mathbf{H_2L}$ with $ZnCl_2$ (1:2) in MeOH/EtOH produces a yellow solution from which the dinuclear complex $[Zn_2LCl_2MeOH]$ (**1**) may be isolated in 30% yield as a yellow crystalline solid. A view of the molecule is shown in Fig. 2. In **1**, the deprotonated Schiff base ligand now adopts the expected planar configuration. One zinc atom (Zn(1)) is located slightly above the central N_2O_2 plane by 0.669 Å and has a square based pyramidal geometry via the coordination of a chlorine atom in the axial position. The other zinc atom (Zn(2)) has a pseudotetrahedral geometry formed by coordination to the two phenolic oxygen atoms, a chlorine atom and a molecule of MeOH. The Zn–Zn separation is 3.113 Å. It is interesting to note that neither of the two OMe

groups participate in bonding to Zn(2) with an average O–Zn separation of 2.702 Å.

Compound **1** may be regarded as a combination of a mononuclear Zn Schiff base complex "ZnL" and one mole of $ZnCl_2$. Since the presence of the second Zn moiety might hinder the subsequent formation of heterodinuclear Zn–Ln complexes, we chose $Zn(OAc)_2 \cdot 2H_2O$ as an alternative starting material. Reaction of $\mathbf{H_2L}$ with $Zn(OAc)_2 \cdot 2H_2O$ (1:1) in EtOH produces yellow solutions but we have been unable to isolate a pure compound from these reaction mixtures. We assume that a zinc Schiff base complex is formed under these conditions since further addition of $Ln(NO_3)_3 \cdot 6H_2O$ (Ln = Eu, Nd) in EtOH produces the heterodinuclear complexes $[ZnLEu(OAc)(NO_3)_2]$ (**2**) and $[ZnLNd(OAc)(NO_3)_2(H_2O)]$ (**3**). The X-ray structures of **2** and **3** are shown in Figs. 3 and 4, respectively. The compounds have similar structures with the Zn^{2+} and Ln^{3+} ions located in the N_2O_2 and O_2O_2 ligand binding sites, respectively. In both compounds the metal centers are bridged by a single bidentate acetate (OAc) ligand in addition to the phenolic oxygen atoms of the Schiff base ligand. The Zn–Eu and Zn–Nd separations are 3.369 and 3.400 Å in **2** and **3**, respectively. The oxygen atom of the μ-OAc group coordinated to Zn gives the metal center a distorted square pyramidal geometry. In both compounds the zinc atoms lie slightly above the N_2O_2 plane (0.586 Å (**2**), 0.558 Å (**3**)). In **2**, the Eu^{3+} ion is nine coordinate with an inner coordination environment provided by nine oxygen atoms, four from the Schiff base ligand, four from two bidentate nitrates and one from the μ-OAc group. In **3** the larger Nd^{3+} ion is 10 coordinate and has an additional bound H_2O molecule. In both **2** and **3**, the average distances for Zn–O(phenolic) (2.009 Å (**2**), 2.007 Å (**3**)), Zn–N (2.020 Å (**2**), 2.038 Å (**3**)), Ln–O(phenolic) (2.330 Å (**2**), 2.429 Å (**3**)) and Ln–O(methoxy) (2.600 Å (**2**), 2.735 Å (**3**)) are comparable to those found in the literature [6].

The UV–Vis absorption spectra of $\mathbf{H_2L}$, **2** and **3** in MeCN solution are shown in Fig. 5. The free ligand $\mathbf{H_2L}$ exhibits absorption bands at 235, 280 and 335 nm, which become red-shifted upon coordination to the metals in **2** and **3**. Complexes **2** and **3** exhibit similar solution absorption spectra and are stable in MeCN at room temperature as shown by the lack of changes over one week. Molar conductivity studies for **2** and **3** have also confirmed the presence of neutral, undissociated species in MeCN solutions. The visible emission spectra of the free ligand $\mathbf{H_2L}$, **2** and **3** in CH_3CN are shown in Fig. 6, and the NIR luminescence of **3** in Fig. 7. Excitation of the absorption band at 279 nm of $\mathbf{H_2L}$ produces a broad emission band at $\lambda_{max} = 468$ nm. Excitation of the ligand-centered absorption bands of **2** and **3** produces typical visible emission bands of the Eu^{3+} ion ($^5D_0 \rightarrow {}^7F_J$ transitions, $J = 1, 2, 3$ and 4) and NIR luminescence of Nd^{3+} ion ($^4F_{3/2} \rightarrow {}^4I_J$ transitions, $J = 9/2$, 11/2 and 13/2), respectively. It is noticeable that, the

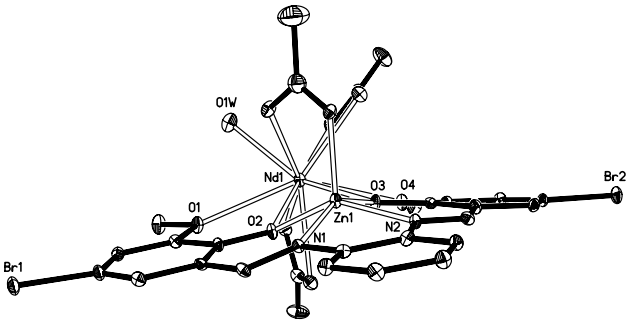

Fig. 4. X-ray structure of **3**. Thermal ellipsoids are drawn at the 25% probability level. Hydrogen atoms are omitted for clarity.

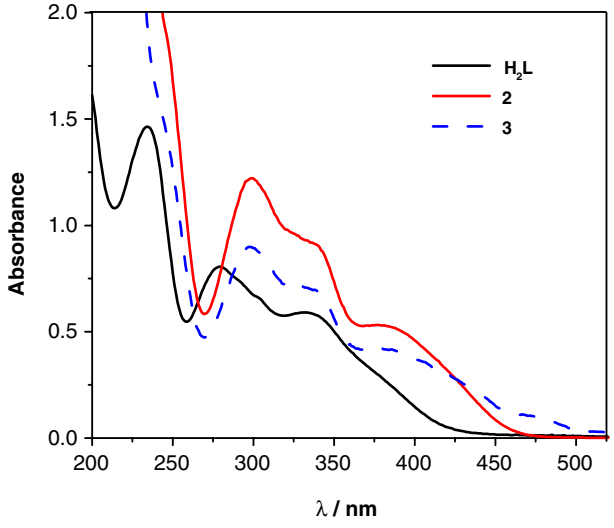

Fig. 5. Absorption spectra of the free ligand $\mathbf{H_2L}$, complexes **1** and **2** in CH_3CN at 298 K.

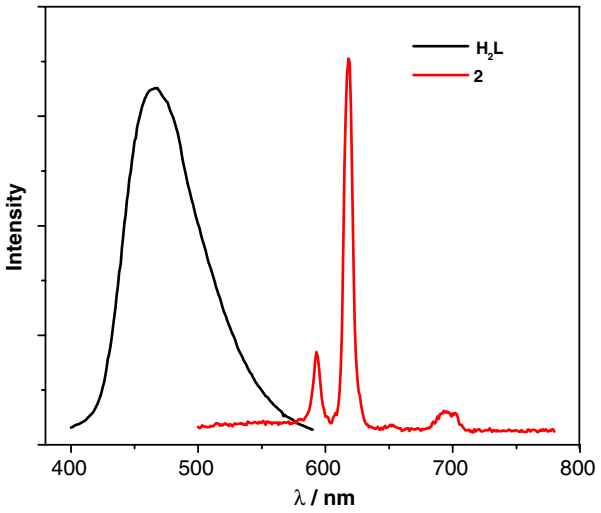

Fig. 6. Visible emission spectra of the free ligand $\mathbf{H_2L}$, complexes **2**, **3** and Zn–GdL in CH_3CN (10^{-4}–10^{-5} M). $\lambda_{ex} = 275$ nm.

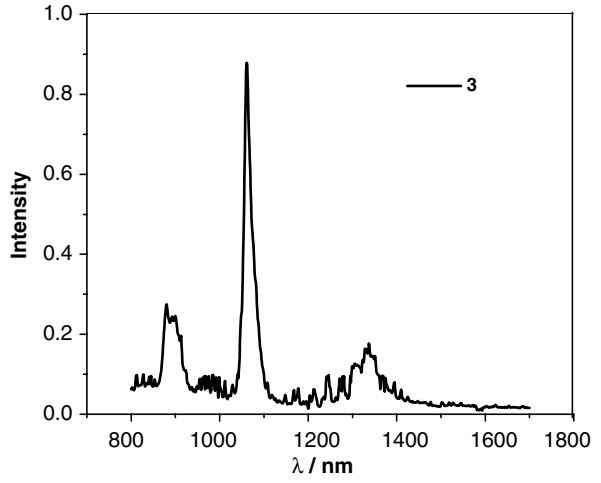

Fig. 7. Sensitized NIR emission spectrum of **3** in MeCN (6.31×10^{-4} M). The excitation was provided by an argon ion laser using either the UV multiline optics (333.6–363.8 nm range) or the 275.4 nm laser line.

fluorescence of ligand-centered (antenna) in visible region is almost quenched in both **2** and **3**, which suggests that the energy transfer from the antenna to lanthanide ion takes place efficiently [11]. The fluorescence quantum yields (Φ_{em}) of **2** in CH_3CN is 0.067 [12], while the NIR luminescence quantum yield of **3** could not be measured directly due to limitations with our instrumentation. However, its maximum possible quantum yield was estimated to be 0.082 using comparative methods as described by van Veggel et al. [4c].

In conclusion, we have shown that the aromatic salen-type ligand $\mathbf{H_2L}$ may be used for the preparation of 3d–4f bi-metallic Schiff base complexes, and it can act as an antenna for Eu^{3+} and Nd^{3+} luminescence while its emission in the visible region is effectively suppressed.

3. Experimental

3.1. Synthesis

3.1.1. Preparation of ligand H_2L

A solution of *o*-phenylenediamine (1.08 g, 0.01 mol) in ethanol (20 ml) was added to a solution of 5-bromo-2-hydroxy-3-methoxybenzaldehyde (4.62 g, 0.02 mol) in ethanol (60 ml). The mixture was stirred at room temperature (12 h) and the product filtered and washed with ethanol (20 ml). The material was recrystallized from ethanol. Yield: 3.373 g, 70%. m.p. = 170 °C. ESI-MS (CH_3CN) *m*/*z*: 535 $[M + H]^+$. ^1H NMR (400 MHz, DMSO-d_6): δ (ppm) 3.848 (s, 6H), 7.263 (s, 2H), 7.446 (m, 4H), 7.487 (s, 2H), 8.907 (s, 2H). IR (CH_3CN, cm^{-1}): 3385, 2971, 1644, 1636, 1558, 1487, 1458, 1245, 1060, 746, 618. Single crystals for X-ray crystallographic analysis were obtained by vapor diffusion of diethyl ether into solutions of $\mathbf{H_2L}$ in MeCN.

3.1.2. Preparation of $[Zn_2LCl_2MeOH] \cdot EtOH \cdot MeOH$ (**1**)

A solution of $ZnCl_2$ (0.068 g, 0.5 mmol) in 10 ml MeOH was added to a solution of $\mathbf{H_2L}$ (0.134 g, 0.25 mmol) in 5 ml EtOH. The mixture was stirred and refluxed for 10 min, cooled to room temperature, and filtered. Diethylether was allowed to diffuse slowly into the filtrate at room temperature and yellow single crystals were obtained in one month. Yield: 0.063 g, 30%. ESI-MS (CH_3CN) *m*/*z*: 730 $[M - Cl^- - EtOH - MeOH]^+$. m.p. >270 °C (dec). IR (CH_3CN, cm^{-1}): 3456.05, 1658.25, 1551.56, 1448.54, 1411.34, 1341.88, 1234.95, 1188.33, 1048.54, 1029.13, 681.25, 679.61.

3.1.3. Preparation of $[ZnLEu(OAc)(NO_3)_2] \cdot EtOH \cdot H_2O$ (**2**)

A mixture of $\mathbf{H_2L}$ (0.054 g, 0.10 mmol) and $Zn(OAc)_2 \cdot 2H_2O$ (0.022 g, 0.10 mmol) in EtOH (20 ml) was stirred and heated under reflux for 20 min. A solution of $Eu(NO_3)_3 \cdot 6H_2O$ (0.045 g, 0.10 mmol) in EtOH (10 ml) was added and the mixture was stirred and refluxed for 30 min. The mixture was allowed to cool to room temperature and filtered. The filtrate was allowed to evaporate in the air. Yellow single crystals of **2** were formed (3 weeks). Yield: 0.055 g, 56%, m.p. >310 °C (dec). ESI-MS (CH_3CN) *m*/*z*: 871 $[M - NO_3^- - EtOH - H_2O]^+$. IR ($CH_3CN$, cm^{-1}): 3382.52, 1611.65, 1541.75, 1440.78, 1355.34, 1231.07, 1188.35, 1048.54, 1013.59, 947.57, 831.07, 788.35, 741.75, 664.08.

3.1.4. Preparation of $[ZnLNd(OAc)(NO_3)_2(H_2O)] \cdot EtOH$ (**3**)

The method was similar to that used for **2** (above). $\mathbf{H_2L}$ (0.054 g, 0.10 mmol), $Zn(OAc)_2 \cdot 2H_2O$ (0.022 g, 0.10 mmol) and $Nd(NO_3)_3 \cdot 6H_2O$ (0.044 g, 0.10 mmol) were employed. Yield: 0.069 g, 70%, yellow crystals,

m.p. >308 °C (dec). ESI-MS (CH_3CN) *m/z*: 881 $[M - NO_3^- - EtOH]^+$. IR (CH_3CN, cm^{-1}): 3375.50, 1613.89, 1550.91, 1443.01, 1352.55, 1230.23, 1040.32, 1020.41, 948.08, 835.62, 789.57, 744.80, 660.11.

3.2. Photophysical measurements

Solvents for the photophysical investigations were dried over molecular sieves and freshly distilled under dry nitrogen before use. Absorption spectra were obtained on a BECKMAN DU 640 spectrophotometer, excitation and visible emission spectra on a QuantaMaster PTI fluorimeter. Near-infrared (NIR) emission spectra were measured with a one-meter SPEX 1704 spectrometer and a liquid-nitrogen cooled Ge detector, using an argon ion laser as excitation source. The fluorescence quantum yield of **2** was determined by using $[Ru(bipy)_3]Cl_2$ (bipy = 2,2′-bipyridine; $\Phi = 0.028$ in water) as a standard [12,13].

3.3. X-ray crystallographic studies

Details of crystallographic parameters, data collection and refinements are listed in Table 1. Selected bond lengths (Å) and angles (°) for H_2L, **1**, **2** and **3** are listed in Tables 2–5, respectively. Intensities were collected on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 153 K. Absorption corrections were applied using GAUSSIAN. The structures were solved by direct methods and refined anisotropically using full-matrix least-squares methods with the SHELX-97 program package [14]. The coordinates of the non-hydrogen atoms were

Abstract

The synthesis and characterization of complexes with a tridentate amido-diamine ligand $-N(CH_2CH_2NMe_2)_2$, $[ClZnN(CH_2CH_2NMe_2)_2]_2$ (**1**), $[EtZnN(CH_2CH_2NMe_2)_2]_2$ (**2**), $\{Zn[N(CH_2CH_2NMe_2)_2]_2\}_2$ (**3**) and $[^tBu_2NZnN(CH_2CH_2NMe_2)_2]_2$ (**4**), are described. Compounds **1** (57% yield) and **2** (49% yield) were obtained from the reactions of $ZnCl_2$ with 1 equiv. of $LiN(CH_2CH_2NMe_2)_2$ and $ZnEt_2$ with excess $HN(CH_2CH_2NMe_2)_2$, respectively. Compounds **3** (52% yield) and **4** (75% yield) were isolated from the reactions of $[Zn(N^tBu_2)_2]_2$ with $HN(CH_2CH_2NMe_2)_2$ in 1:4 and 1:2 molar ratios, respectively. Mass spectral data and NMR analyses suggested that all four compounds were dimeric. The solid-state structures of compounds **2** and **3** were determined via X-ray crystallography. Both compounds were centrosymmetric containing a four-membered Zn_2N_2 ring with bridging amido ligands. In both structures, one NMe_2 group in each bridging ligand bonded to a Zn center forming a five-membered ring. The ethyl groups in **2** and the second $-N(CH_2CH_2NMe_2)_2$ ligand in **3** occupied the terminal positions.

1. Introduction

Zinc coordination chemistry, involving a variety of nitrogen ligands, is of fundamental importance in chemistry, biology and materials science [1]. Structurally characterized diamido zinc compounds, $Zn(NR_2)_2$, where R is a bulky alkyl, silyl or aryl group, are typically monomeric with dicoordinate zinc [2–7] or dimeric with tricoordinate zinc atoms [4,6,8–10] (Scheme 1, **i** and **ii**).

Compounds with less sterically demanding ligands, such as bis(dimethylamido)zinc [11] and bis(diethylamido)-zinc [12], are polymeric. The coordinative saturation of zinc amido complexes can also be achieved with addition of Lewis base ligands. Examples include monomeric $Zn(NPh_2)_2(THF)_2$ [8] and dimeric $[MeN(SiMe_2NEt)_2$-$Zn(pyridine)]_2$ [13]. For less bulky bidentate amido-amine ligands, only hydrido and alkyl zinc derivatives are known. Examples are $[HZnNMe(CH_2)_2NMe_2]_2$ [14] and $[RZnNMe(CH_2)_nNMe_2]_2$ ($n = 2$ or 3 and R = Me or Et) [15] (Scheme 1, **iii**).

We are interested in preparing the volatile zinc complexes for the chemical vapor deposition of zinc-containing films. This led us to investigate the chemistry of a tridentate amido-diamine ligand, $-N(CH_2CH_2NMe_2)_2$. The lithium salt of $[N(CH_2CH_2NMe_2)_2]^-$ has been reported [16,17], and a volatile five-coordinate gallium dihydride has been characterized [18]. In this paper, we report the synthesis and characterization of several zinc complexes bearing a $-N(CH_2CH_2NMe_2)_2$ ligand.

2. Experimental

2.1. Materials and general procedures

Zinc chloride (Aldrich) was heated under vacuum prior to use to remove trace moistures. $ZnEt_2$ (Aldrich) was used as received. Toluene was dried with alumina using an MBraun solvent purification system. Diethyl ether and pentane were dried over calcium hydride under nitrogen. All solvents were vigorously degassed. Diisobutylamine and benzene-d_6 were distilled over CaH_2 under nitrogen. $[Zn(N^iBu_2)_2]_2$ [4], $LiN(CH_2CH_2NMe_2)_2$ [19] and $HN(CH_2CH_2NMe_2)_2$ [19] were prepared according to the literature procedures. All experiments were conducted under an oxygen-free, dry-nitrogen atmosphere using standard Schlenk and glovebox techniques.

NMR spectra were obtained in benzene-d_6 solutions at room temperature on a Varian INOVA 300 spectrometer. The residual proton at 7.15 ppm and the carbon resonance at 128.39 ppm in benzene-d_6 were used as the internal standards for ^1H and ^{13}C NMR, respectively. Chemical-ionization mass spectra were acquired on a Finnigan Mat 95 spectrometer using a direct insertion probe. The samples were evaporated at 150 °C and the ionization gas mixture was methane with 4% ammonia. Melting points were measured in sealed glass capillaries and were uncorrected. The elemental analyses were performed by Desert Analytics, Tucson, AZ.

2.2. Synthesis of $[ClZnN(CH_2CH_2NMe_2)_2]_2$ (1)

To a stirred slurry of $ZnCl_2$ (3.00 g, 22.0 mmol) in 50 mL of toluene was added a solution of $LiN(CH_2CH_2NMe_2)_2$ (3.64 g, 22.0 mmol) in 50 mL of toluene. The mixture was refluxed for 28 h and then filtered to separate a white precipitate (LiCl) and a clear solution. After the solution was concentrated to ca. 20 mL and stored at −10 °C for a few days, colorless crystalline compound **1** precipitated and was isolated (3.22 g, 57% yield). Mp: 178 °C, decomp. ^1H NMR: δ 2.04 (24H, s, NMe_2), 2.30 (8H, t, $CH_2CH_2NMe_2$), 2.92 (8H, t, $CH_2CH_2NMe_2$). ^{13}C NMR: δ 46.5 (NMe_2), 52.7 ($CH_2CH_2NMe_2$), 62.2 ($CH_2CH_2NMe_2$). CI MS (assignment, % relative intensity): 519 ($\{[ClZnN(CH_2CH_2NMe_2)_2]_2 + H\}^+$, 5.6), 258 ($[ClZnN(CH_2CH_2NMe_2)_2 + H]^+$, 64), 160 ($[H_2N(CH_2CH_2NMe_2)_2]^+$, 100). *Anal.* calc. for $C_{16}H_{40}N_6Cl_2Zn_2$: C, 37.08; H, 7.78; N, 16.22. Found: C, 36.84; H, 7.45; N, 16.10%.

2.3. Reaction of $ZnCl_2$ with 2 equiv. of $LiN(CH_2CH_2NMe_2)_2$

To a stirred slurry of $ZnCl_2$ (0.400 g, 2.94 mmol) in 30 mL of toluene was added a solution of $LiN(CH_2CH_2NMe_2)_2$ (0.970 g, 5.87 mmol) in 50 mL of toluene. The mixture was refluxed for 5 h and then filtered to separate a white precipitate and a clear solution. After the solution was concentrated to ca. 40 mL and stored at −10 °C for several days, colorless small blocks precipitated. When isolated from the solution, the crystals lost solvent toluene molecules that had been co-crystallized in the lattice, and a white powder was obtained after drying under vacuum (0.72 g). Mp: 173 °C, decomp. ^1H NMR: δ 2.37 (s, NMe_2), 2.94 (br s, $CH_2CH_2N\ Me_2$), 3.23 (br s, $CH_2CH_2NMe_2$). ^{13}C NMR: δ 46.5 (NMe_2), 53.4 ($CH_2CH_2NMe_2$), 63.0 ($CH_2CH_2NMe_2$). This compound did not sublime under vacuum below its decomposition temperature.

The above reaction was also carried out in refluxing toluene for 16 h, and a partial decomposition leading to a gray solid (presumably zinc metal) was observed. After filtration and recrystallization, the same compound as described above was isolated.

2.4. Synthesis of $[EtZnN(CH_2CH_2NMe_2)_2]_2$ (2)

A mixture of neat $ZnEt_2$ (0.400 g, 3.24 mmol) and $HN(CH_2CH_2NMe_2)_2$ (1.03 g, 6.48 mmol) was heated at 100 °C for 2 h. During this period, gas evolution (C_2H_6) was observed. Unreacted $HN(CH_2CH_2NMe_2)_2$ was removed under vacuum leaving a wet, white solid, which was dissolved in pentane (4 mL). The resulting solution was cooled at −60 °C to precipitate a white solid. Vacuum sublimation of the solid at 90 °C afforded colorless, crystalline compound **2** (0.40 g, 49% yield). Mp: 83.0–84.0 °C. ^1H NMR: δ 0.42 (4H, q, CH_2CH_3), 1.71 (6H, t, CH_2CH_3), 2.08 (24H, s, NMe_2), 2.37 (8H, t, $CH_2CH_2NMe_2$), 3.00 (8H, t, $CH_2CH_2NMe_2$). ^{13}C NMR: δ −2.61 (CH_2CH_3), 15.4 (CH_2CH_3), 46.5 (NMe_2), 54.4 ($CH_2CH_2NMe_2$), 62.8 ($CH_2CH_2NMe_2$). CI MS (assignment, % relative intensity): 506 ($\{[EtZnN(CH_2CH_2NMe_2)_2]_2 + H\}^+$, 0.8), 475 ($\{[EtZnN(CH_2CH_2NMe_2)_2]_2 - Et\}^+$, 1.0), 346 ($\{[EtZnN(CH_2CH_2NMe_2)_2]_2 - N(CH_2CH_2NMe_2)_2\}^+$, 4.8), 256 ($[EtZnN(CH_2CH_2NMe_2)_2 + H]^+$, 100), 239 ($[EtZnN\ (CH_2CH_2NMe_2)_2 - Et + NH_3]^+$, 5.3), 222 ($[EtZnN(CH_2CH_2NMe_2)_2 - Et]^+$, 1.8), 193 ([EtZnN(CH$_2$-

$CH_2NMe_2)_2 - CH_2NMe_2]^+$, 6.3), 160 ($[H_2N(CH_2CH_2NMe_2)_2]^+$, 52). *Anal.* calc. for $C_{20}H_{50}N_6Zn_2$: C, 47.52; H, 9.97; N, 16.63. Found: C, 47.03; H, 10.16; N, 16.44%.

2.5. Synthesis of $\{Zn[N(CH_2CH_2NMe_2)_2]_2\}_2$ (3)

To a stirred solution of $[Zn(N^iBu_2)_2]_2$ (8.00 g, 12.5 mmol) in 40 mL of Et_2O was added a solution of $HN(CH_2CH_2NMe_2)_2$ (8.20 g, 51.5 mmol) in 30 mL of Et_2O. The mixture was refluxed for 20 h resulting in a clear solution. Volatiles were removed under vacuum affording a white solid. Colorless, crystalline compound **3** (4.90 g, 52% yield) was isolated after repeated recrystallization from toluene. Mp: 102.0–104.0 °C. ^{1}H NMR: δ 2.14 (24H, s, NMe_2), 2.17 (12H, s, NMe_2), 2.32 (12H, s, NMe_2), 2.47 partially overlapped with 2.45 (total 12H, t, $CH_2CH_2NMe_2$), 2.55 (4H, t, $CH_2CH_2NMe_2$), 3.01 (4H, t, $CH_2CH_2NMe_2$), 3.32 partially overlapped with 3.34 (12H, t, $CH_2CH_2NMe_2$). ^{13}C NMR: δ 46.0, 46.5 and 47.1 (NMe_2), 54.4, 54.8 and 55.3 ($CH_2CH_2NMe_2$), 62.7, 63.2 and 65.0 ($CH_2CH_2NMe_2$). CI MS (assignment, % relative intensity): 606 ($[\{Zn[N(CH_2CH_2NMe_2)_2]_2\}_2 - N(CH_2CH_2NMe_2)_2]^+$, 1.7), 381 ($[Zn[N(CH_2CH_2NMe_2)_2]_2 + H]^+$, 100), 322 ($[Zn[N(CH_2CH_2NMe_2)_2]_2 - CH_2NMe_2]^+$, 18), 160 ($[H_2N(CH_2CH_2NMe_2)_2]^+$, 34). *Anal.* calc. for $C_{32}H_{80}N_{12}Zn_2$: C, 50.31; H, 10.56; N, 22.00. Found: C, 50.06; H, 10.13; N, 21.74%.

2.6. Synthesis of $[^iBu_2NZnN(CH_2CH_2NMe_2)_2]_2$ (4)

To a stirred solution of $[Zn(N^iBu_2)_2]_2$ (3.00 g, 4.66 mmol) in 40 mL of Et_2O at room temperature was added a solution of $HN(CH_2CH_2NMe_2)_2$ (1.49 g, 9.32 mmol) in 20 mL of Et_2O. The mixture was stirred for 1 h and a clear solution was obtained. After the solution was cooled at −10 °C overnight, colorless blocks of compound **4** precipitated and were isolated (2.45 g, 75% yield). Mp: 134.5–136.0 °C. ^{1}H NMR: δ 1.15 (24H, d, $CHMe_2$), 2.03 (4H, m, CH), 2.15 (24H, s, NMe_2), 2.75 (8H, br s, $CH_2CH_2NMe_2$), 2.96 (8H, br s, CH_2CHMe_2), 3.20 (8H, br s, $CH_2CH_2NMe_2$). ^{13}C NMR: δ 21.9 ($CHMe_2$), 29.3 ($CHMe_2$), 46.5 (NMe_2), 55.2 ($CH_2CH_2NMe_2$), 62.8 ($CH_2CH_2NMe_2$), 65.0 (CH_2CHMe_2). CI MS (assignment, % relative intensity): 576 ($\{[^iBu_2NZnN(CH_2CH_2NMe_2)_2]_2 - N^iBu_2\}^+$, 2.8), 546 ($\{[^iBu_2NZnN(CH_2CH_2NMe_2)_2]_2 - N(CH_2CH_2NMe_2)_2\}^+$, 2.7), 351 ($[^iBu_2NZnN(CH_2CH_2NMe_2)_2 + H]^+$, 100), 160 ($[H_2N(CH_2CH_2NMe_2)_2]^+$, 18). *Anal.* calc. for $C_{32}H_{76}N_8Zn_2$: C, 54.61; H, 10.88; N, 15.92. Found: C, 54.30; H, 11.16; N, 15.74%.

2.7. X-ray data collection, structure solution and refinement

The detailed experimental procedure and structure solution method were previously described [20]. A Bruker SMART system and a Siemens SMART system were used for compounds **2** and **3**, respectively. The final cell constants were calculated from 2748 strong reflections for **2** and 3665 strong reflections for **3**. For both structures, all non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in ideal positions and refined as riding atoms with relative isotropic displacement parameters. The experimental conditions and unit cell information are summarized in Table 1.

3. Results and discussion

3.1. Syntheses and characterizations of compounds 1–4

Several diamido zinc complexes have been synthesized from the metathesis reactions of $ZnCl_2$ with Li or Na amide compounds [2–9,12,13,21]. In this study, however, the mono-substituted complex, $[ClZnN(CH_2CH_2NMe_2)_2]_2$ (**1**), was obtained in 57% yield from the reaction of $ZnCl_2$ with 1 equiv. of $LiN(CH_2CH_2NMe_2)_2$ in refluxing toluene (Eq. (1))

$$ZnCl_2 + LiN(CH_2CH_2NMe_2)_2 \rightarrow 1/2[ClZnN(CH_2CH_2NMe_2)_2]_2 + LiCl \quad (1)$$

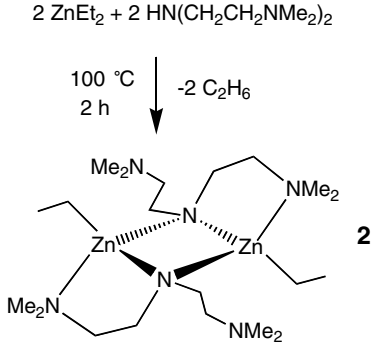
The reaction of $ZnCl_2$ with 2 equiv. of $LiN(CH_2CH_2NMe_2)_2$ in refluxing toluene for 5 h led to a white solid, in which the presence of the $-N(CH_2CH_2NMe_2)$ ligand was indicated by ^{1}H and ^{13}C NMR spectroscopy. Full

characterization, however, was not achieved due to its involatility and our inability in obtaining a single crystal. It is possible that it was a lithium zincate compound resulted from an incomplete elimination of LiCl. Zincate complexes including $LiZn[N(SiMe_3)_2]_3(THF)_4$ are known [22]. Increasing the reaction time to 16 h did not facilitate further LiCl elimination, rather this led to a partial decomposition.

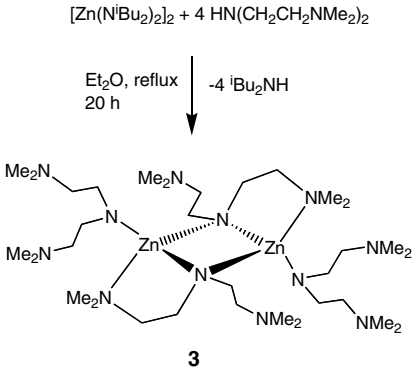
After a mixture of $ZnEt_2$ and $HN(CH_2CH_2NMe_2)_2$ in 1:2 molar ratio was heated at 100 °C for 2 h, the mono-substituted compound, $[EtZnN(CH_2CH_2NMe_2)_2]_2$ (**2**), was isolated in 49% yield (based on Zn) according to the reaction shown in Scheme 2. This result was not particularly surprising. In the literature, incomplete Et elimination was observed from the reaction of $ZnEt_2$ with excess amines [12], and even with more acidic alcohols, the reactions of dialkyl zinc usually led to mono-substituted $(RZnOR')_n$ compounds [11,23–25].

An alternative route was sought for preparing the diamido zinc compound. It was reported that reactions of $Zn[N(SiMe_3)_2]_2$ with alcohols led to a variety of zinc dialkoxides [25,26]. This process avoided the use of $ZnCl_2$ and alkaline metal alkoxides. Recently, Armstrong et al. [10] adopted this strategy to prepare $[ZnN(CH_2Ph)_2]_2$ in the reaction of $Zn[N(SiMe_3)_2]_2$ with $HN(CH_2Ph)_2$. Recognizing that $HN(CH_2Ph)_2$ is a weaker acid than $HN(SiMe_3)_2$, they rationalized that the driving force of this transamination was obtained from the increased coordination number of Zn, e.g. three in $[ZnN(CH_2Ph)_2]_2$ and two in $Zn[N(SiMe_3)_2]_2$. As an extension of these synthetic methods, we started with a different diamido zinc, $[Zn(N^iBu_2)_2]_2$, and isolated bis-[bis(2-dimethylaminoethyl)amido] zinc dimer $\{Zn[N(CH_2CH_2N\text{-}Me_2)_2]_2\}_2$ (**3**), in 52% yield (Scheme 3).

The reaction proceeded via two transaminations as depicted in Eqs. (2) and (3). In contrast to earlier work, where the proposed intermediate $(Me_3Si)_2NZnN(CH_2Ph)_2$ was not isolable, the intermediate, $[^iBu_2NZnN(CH_2CH_2NMe_2)_2]_2$ (**4**), was readily isolated in 75% yield from a separate reaction according to the stoichiometry in Eq. (2)



Scheme 2.



Scheme 3.

$$[Zn(N^iBu_2)_2]_2 + 2HN(CH_2CH_2NMe_2)_2 \rightarrow [^iBu_2NZnN(CH_2CH_2NMe_2)_2]_2 + 2HN^iBu_2 \quad (2)$$

$$[^iBu_2NZnN(CH_2CH_2NMe_2)_2]_2 + 2HN(CH_2CH_2NMe_2)_2 \rightarrow \{Zn[N(CH_2CH_2NMe_2)_2]_2\}_2 + 2HN^iBu_2 \quad (3)$$

Compounds **1**–**4** were colorless, crystalline solids. Except for **1** that decomposed when melted at 178 °C, all compounds exhibited sharp melting points. Compounds **1**, **3** and **4** were soluble in Et_2O, THF and aromatic solvents, and compound **2** was soluble in all common organic solvents. Compounds **2** and **3** sublimed at 90 °C under vacuum.

All compounds were characterized analytically and spectroscopically, and the dimeric structures of compounds **2** and **3** were determined using single crystal X-ray crystallography. In chemical ionization mass spectra, the highest observed masses were for the dimer ions (plus 1) for compounds **1** and **2** or for the ions closely related to the dimer ions, e.g. $[\{Zn[N(CH_2CH_2NMe_2)_2]_2\}_2 - N(CH_2CH_2NMe_2)_2]^+$ for **3** and $[(^iBu_2NZnN(CH_2CH_2NMe_2)_2)_2 - N^iBu_2]^+$ for **4**, suggesting that compounds **1** and **4** were also dimeric.

The ^1H NMR spectrum of compound **3** exhibited resonances attributable to three different dimethylaminoethyl groups, and the ^{13}C NMR showed clearly nine carbon resonances, also consistent with the dimeric structure in Scheme 3. Compound **2** would be expected to display spectroscopic differences between the two arms of the amido ligand, however, only one set of resonances were observed in the ^1H and ^{13}C NMR spectra. The ^1H NMR peaks were somewhat broad. We suggest that a fast exchange of the coordination to Zn between the two $-NMe_2$ groups in each bridging $-N(CH_2CH_2NMe_2)_2$ ligand was present in solution.

The ^1H and ^{13}C NMR spectra of compound **1** gave a set of sharp resonances for the $N(CH_2CH_2NMe_2)_2$ ligand. Based on the mass spectral data, a monomeric structure, which would give this NMR result, is ruled

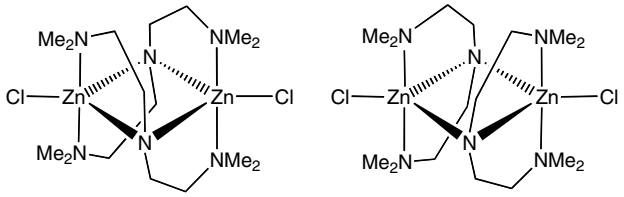


Fig. 1. Proposed structures for compound **1**.

out. A dimeric structure similar to those for compounds **2** and **3** combined with a fast exchange as suggested for compound **2** could explain the NMR results. Alternatively, the smaller size and higher electronegativity of the chloro ligand in compound **1** might favor a five-coordinate zinc as seen in some of the other chloro-containing zinc complexes [27,28]. Two structures are proposed in Fig. 1. However, despite of the equivalence of the $CH_2CH_2NMe_2$ moieties in each structure due to the D_2 symmetry for **a** and the C_{2h} symmetry for **b**, in each $CH_2CH_2NMe_2$ group the two methyls are not magnetically equivalent and neither are the two protons on each carbon atom. Thus, to account for the NMR results, a fast coordination exchange of each CH_2-CH_2NMe_2 between the two zinc centers would also be proposed for either structure.

The ^1H and ^{13}C NMR spectra of compound **4** each showed one set of sharp resonances for the $-N^iBu_2$ groups and one set of broad resonances for the $-N(CH_2CH_2NMe_2)_2$ groups. A dimeric structure similar to compounds **2** and **3** coupled with ligand exchange as suggested above is consistent with the NMR results. It should be noted that a dimer–monomer equilibrium in solution is less likely present for either compound **4** or **2**, otherwise, at least two sets of resonances for the N^iBu_2 or Et groups should be observed, as in the case for $[Zn(N^iBu_2)_2]_2$ where this type of equilibrium was present in solution [12].

3.2. Structures of compounds 2 and 3

Both **2** and **3** crystallized in space group $P\bar{1}$. For **2**, two chemically identical, but slightly structurally different molecules were determined. For **3**, half of a molecule acts as the asymmetric unit and each unit cell consists of one molecule. Selected bond lengths and angles for compounds **2** and **3** are given in Tables 2 and 3, respectively. One molecular structure of **2** and the molecular structure of **3** are shown in Figs. 2 and 3, respectively.

Both compounds **2** and **3** are dimeric containing a crystallographically imposed inversion symmetry and a four-membered Zn_2N_2 ring with bridging $-N(CH_2$-$CH_2NMe_2)_2$ ligands. In both structures, one NMe_2 group in each bridging ligand is bonded to a zinc center forming a five-membered ring. The Et group in compound **2** and one $-N(CH_2CH_2NMe_2)_2$ ligand in **3** occupy terminal positions. Reflective of the strains produced by the four- and five-membered rings, the zinc centers in both structures are distorted from ideal tetrahedral geometry. As a result, substantially larger bond angles are obtained between the other ligands and the terminal $-N(CH_2CH_2NMe_2)_2$ or ethyl ligand. For example, in **2**,

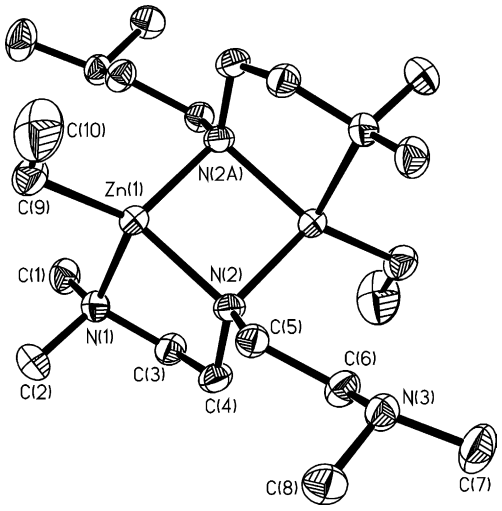

Fig. 2. Structure of **2** showing 50% thermal ellipsoids. The hydrogen atoms are omitted for clarity.

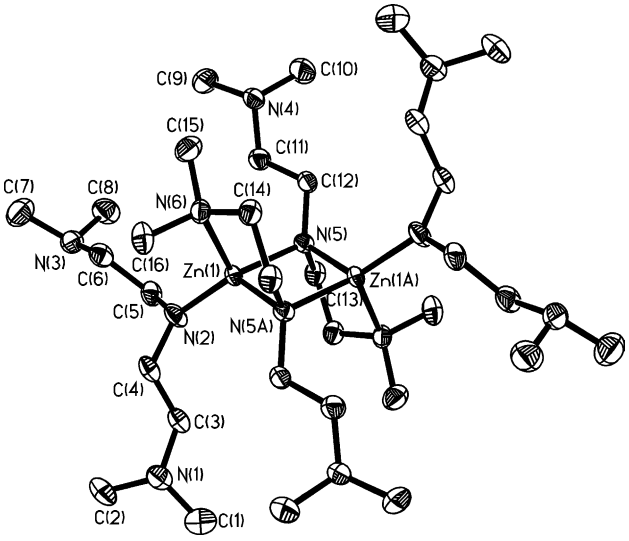

Fig. 3. Structure of **3** showing 50% thermal ellipsoids. The hydrogen atoms are omitted for clarity.

the N(2)–Zn(1)–C(9) bond angle is 135.70(11)° and in **3** the N(2)–Zn(1)–N(5) and N(2)–Zn(1)–N(5A) bond angles are 122.02(9)° and 124.56(8)°, respectively. This type of distortion on tetrahedral Zn was previously observed in compounds containing similar ring structures such as $[RZnMeN(CH_2)_nNMe_2]_2$ ($n = 2$ or 3 and R = Me or Et) [15].

The four Zn–N bonds in **3** are representative of three types of bondings. The terminal Zn(1)–N(2) bond length (1.895(2) Å) is slightly shorter than those in the four-coordinate zinc complexes, $Zn(NPh_2)_2(THF)_2$ (1.919(4)–1.927(5) Å) and $[MeN(SiMe_2NEt)_2Zn(pyridine)]_2$ (1.940(4) Å). The three-coordinate zinc compounds exhibit Zn–N bond lengths in the range of 1.844(2)–1.902(2) Å [4,6,8–10,26] while those in two-coordinate amido zinc complexes are still shorter (1.813(2)–1.850(3) Å) [2–7]. In **3**, the terminal N(2) adopts a trigonal planar geometry with the sum of the angles around it being 359.8(5)°. This is also seen in $[Zn(N^iBu_2)_2]_2$ [4], $Zn(N^tBu_2)_2$ [4] and $Zn[N(CMe_2(CH_2)_3CMe_2)]_2$ [5]. The dative Zn(1)–N(6) bond length (2.176(2) Å) in compound **3** is shorter than those in **2** (2.210(2) and 2.224(2) Å). This is because the Zn atoms in compound **3** are bonded to more electronegative N atoms on the terminal positions. The dative Zn–N bond lengths in **2** are comparable to those in compounds $[RZnMeN(CH_2)_nNMe_2]_2$ ($n = 2$ or 3 and R = Me or Et) (2.192(3)–2.226(5) Å) [15]. The geometries of the Zn_2N_2 rings in both structures are typical for dimeric zinc amido complexes [4,6,8–10].

Dedicated to Malcolm Chisholm, a colleague and friend, on the occasion of his 60th birthday.

Abstract

With the exception of triallylboron compounds, allyl derivatives of the group 13 elements are uncommon and none have been structurally authenticated. A substituted allyl complex of gallium, tris(1,3-bis(trimethylsilyl)allyl)gallium, $[1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga$, has been synthesized from the reaction of $K[1,3\text{-}(SiMe_3)_2C_3H_3]$ and $GaCl_3$ in THF and characterized with X-ray crystallography and NMR spectroscopy. In the solid state, the complex displays σ-bound ligands in a trigonal planar arrangement around the metal, with an average Ga–C distance of 1.980(5) Å. In solution at room temperature, the molecule is fluxional and the ligands appear as if symmetrically bound in a π-type fashion. The fluxionality is observed even at −75 °C. Density functional theory calculations indicate that the structure found in the solid state, with one allyl ligand antiparallel to the other two, is the lowest in energy, but an alternate arrangement with all three ligands parallel (C_3 symmetry) is less than 3 kcal mol^{-1} higher in energy.

1. Introduction

In the years since Wilke synthesized the first homoleptic allyl complex, $(C_3H_5)_2Ni$ [1], allyl complexes of the transition metals have become well-known fixtures of organometallic chemistry, widely studied for their use in organic synthesis [2–5] and catalysis [6–8]. In contrast, interest in allyl complexes of the main-group elements varies considerably. Compounds of lithium and magnesium (e.g., $Li(C_3H_5)$, $(C_3H_5)MgX$) are commonly used to prepare transition metal derivatives, and among homoleptic allyl complexes of the p-block elements, attention has been focused on those of silicon [9–16], germanium [17–21], boron [22–29], and tin [30–41], the latter two being used predominantly as allylation reagents in organic reactions. Allyl complexes with other posttransition metals have received far less attention. For example, only a single report describes the use of triallylgallium and -indium reagents (of the form $(allyl')_3M$ and $(allyl')_3M_2X_3$; X = Br, I) as regioselective allylation reagents with α,β-unsaturated nitrile and carbonyl compounds [42]. The gallium and indium allyl complexes were prepared from the metal halides and Grignard reagents, and were used without isolation or further characterization. Gallium nitride film formation has been described from triallylgallium and ammonia under CVD conditions [43,44].

Just as sterically bulky cyclopentadienyl rings (e.g., C_5Me_5) and indenyl ligands have been used for several decades to alter the properties of their associated organometallic complexes, the same modifications could be

doi:10.1016/j.poly.2005.06.044

made to other organic anions that are used as ligands. Only in the last few years has this approach been applied to the allyl anion, $C_3H_5^-$. Not only have new classes of metal complexes been prepared with the use of this methodology (e.g., $[1,3\text{-}(SiMe_3)_2C_3H_3]_2M$ (M = Cr, 12-e$^-$ [45]; Fe, 14-e$^-$ [46]; Co, 15-e$^-$ [47])), but allyl compounds with ligands substituted by trimethylsilyl and dimethyl(*tert*-butyl)silyl [48] groups have also provided versions of known compounds that are more robust and easily studied than the unsubstituted species. The nickel compound $[\eta^3\text{-}1,3\text{-}(SiMe_3)_2C_3H_3]_2Ni$, for example, is stable in water for several hours and in air for several days, unlike $(C_3H_5)_2Ni$, which inflames on contact with air [49]. Similarly, in contrast to $(C_3H_5)_4Th$, which decomposes at 0 °C, the trimethylsilylated derivatives $[(SiMe_3)_nC_3H_{5-n}]_4Th$ ($n = 1$, 2) are stable up to 90 °C [50]. Despite the kinetic stabilization provided by the bulky ligands, the geometries of the compounds are often similar to their parent counterparts (e.g., the Ni–C bond lengths in $[1,3\text{-}(SiMe_3)_2C_3H_3]_2Ni$ and $(C_3H_5)_2Ni$ differ by an average of only 0.02 Å).

It seemed reasonable that p-block allyl compounds could be stabilized by trimethylsilylated ligands, and we describe here the synthesis and characterization of the first gallium complex to benefit from such substitution. Density functional theory (DFT) calculations have been used to probe the preferences for particular metal–ligand bonding conformations in $(allyl')_3Ga$ compounds.

2. Results and discussion

2.1. Synthesis and solution behavior of $[1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga$

The synthesis of a trimethylsilyl-substituted triallylgallium complex was achieved by a halide metathesis reaction performed under an inert atmosphere at −78 °C,

$$3K[1,3\text{-}(SiMe_3)_2C_3H_3] + GaCl_3 \xrightarrow[-78^\circ C]{THF} [1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga + 3KCl \quad (1)$$

The triallylgallium compound was recovered in good yield as air- and moisture-sensitive pale yellow crystals, soluble in ethers and both aromatic and aliphatic hydrocarbons. It is stable indefinitely under an inert atmosphere at room temperature and can survive brief (minutes) exposure to air before substantial decomposition occurs.

The complex is diamagnetic and ^1H NMR spectra at room temperature have the appearance of a structure with symmetrically bound (“π-type”) allyl ligands; e.g., the resonance for the $SiMe_3$ groups appears as a sharp singlet, and the central hydrogen atom on the allyl ligands appears as a triplet. Such a structure differs from that found in the solid state, and is unlikely from theoretical considerations (see below); a variable temperature ^1H NMR study (Fig. 1) confirmed the fluxionality of the molecule in solution. The central doublet resonance at δ 3.91 broadens and coalesces to a single peak at −40 °C, and nearly disappears into the baseline by −75 °C. The triplet resonance at δ 6.35 and the trimethylsilyl peak at δ 0.16, however, only shift slightly downfield and broaden on cooling to −75 °C. Most notably, the $SiMe_3$ signal shows no sign of splitting into a more complex set of resonances. Obviously, a limiting spectrum is not reached, which is in contrast to the behavior of the related Group 13 allyl compound triallylboron, $(C_3H_5)_3B$. The latter exhibits a symmetric AX_4 NMR pattern at room temperature, but displays a static A_2BX_2 spectrum at −40 °C [51]; the activation barrier for the 1,3-sigmatropic shifts involved is estimated at 10 ± 1 kcal mol^{-1}. Evidently, the rearrangements represented in the spectra of $[1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga$ must have a lower activation barrier.

2.2. X-ray crystal structure of $[1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga$

The complex crystallizes from hexanes as a well-separated monomer with the gallium atom σ-bound to

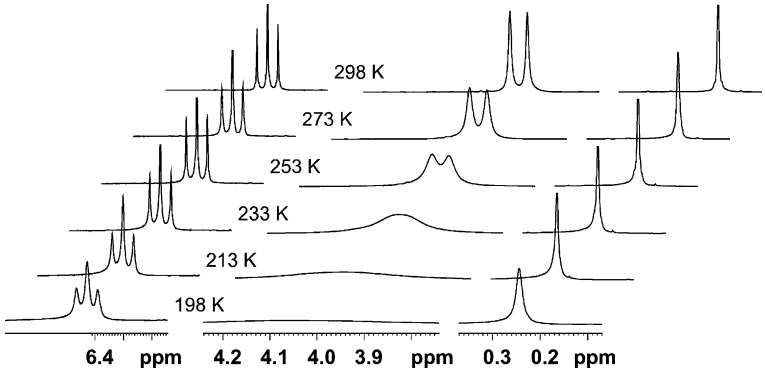

Fig. 1. Variable temperature ^1H-NMR spectra of $[1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga$ (tol-d_8). Resonances (left to right) represent protons on the central carbon ($C_{(2)}$), the outer carbons ($C_{(1,3)}$), and the trimethylsilyl carbons. The peak heights of the three resonances are not to scale.

the bis(trimethylsilyl)allyl ligands in a trigonal planar manner. All three ligands are roughly perpendicular to the GaC_3 plane, with one antiparallel to the other two. The terminal trimethylsilyl groups are *syn* to the central hydrogen atoms of the allyl ligands. A summary of bond distances and angles for $[1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga$ is given in Table 1 and an ORTEP view of the complex is displayed in Fig. 2.

The average Ga–C distance of 1.980(5) Å is typical for gallium–carbon single bonds; cf. those of trimethylgallium (1.957(3) Å) [52], trimesitylgallium (1.968(4) Å) [53], and triethylgallium (1.966(3)–1.996(3) Å) [52]. The Ga–C bonds in $(\sigma\text{-Cp})_3Ga$ are slightly longer (2.05(3) Å) [54]. The near perfect planarity of the central GaC_3 unit in $[1,3\text{-}(SiMe_3)_2C_3H_3]_3Ga$ is indicated by the sum of the C–Ga–C′ angles of 359.7°; the gallium atom lies only 0.058 Å from the C_3 plane. The fully localized C–C bonding in the allyl ligands is indicated by the average C=C bond distance of 1.329(7) Å and the average C–C bond length of 1.497(6) Å. The Ga–C–C angles average 106.6°, far less than the values observed in $GaEt_3$ (113.2–118.8°); in the latter compound, hyperconjugative effects between the gallium p-orbital and C–H bond orbitals may be operative [52] (see Table 2).

2.3. Computational modeling of $(R_2C_3H_3)_3Ga$ ($R = H$, SiH_3, $SiMe_3$)

The occurrence in the solid state of the antiparallel "2 up, 1 down" arrangement of the allyl ligands, and the evidently low energy required for rearrangements in solution, prompted a computational study on the relative energies of possible configurations of the complex. Structures of triallylgallium complexes using $C_3H_5^-$, $1,3\text{-}(SiH_3)_2C_3H_3^-$, and $1,3\text{-}(SiMe_3)_2C_3H_3^-$ ligands were calculated at the B3PW91/cc-pVDZ level (Fig. 3). Two all σ-bound geometries were examined, one of which had one ligand initially antiparallel to the other two ("2 up, 1 down"), similar to the asymmetric conformation

Table 1
Crystallographic summary of $[C_3(SiMe_3)_2H_3]_3Ga$

Empirical formula	$C_{27}H_{63}GaSi_6$
Formula weight	626.03
Temperature (K)	173(2)
Wavelength (Å)	0.71073
Crystal system	triclinic
Space group	$P\bar{1}$

C(11)–C(10)–Ga(1)	104.40(17)
C(20)–C(19)–Ga(1)	108.43(17)

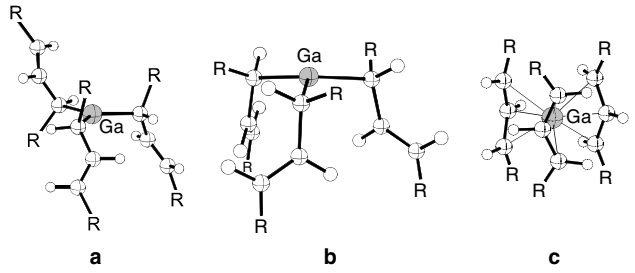

Fig. 3. Schematics of the three structural types examined for (1,3-$R_2C_3H_3)_3$ Ga (R = H, SiH_3, $SiMe_3$): all σ-bound (“2 up, 1 down”, C_1 symmetry); all σ-bound (“3 up”, C_3 symmetry); all π-bound (C_{3h} symmetry).

(C_1 symmetry) found in the crystal structure. In the second all σ conformation, the ligands were grouped together (“3 up”), with C_3 symmetry. Although it was not found to be an energetically realistic alternative, a π-bound geometry with C_{3h} symmetry was also computed for all three ligand types; such a structure would match the symmetry observed in the room temperature NMR spectra.

Key features of the geometry calculated for [1,3-($SiMe_3)_2C_3H_3]_3$Ga (Fig. 4) agree well with those observed in the crystal structure. These include the Ga–C bond distances (2.012 Å (av)), the C_α–C_β single bond distance (1.495 Å (av)), and the C_β=C_γ double bond distance (1.351 Å (av)). The calculated distances change relatively little as the $SiMe_3$ groups are replaced with SiH_3 and then H substituents. In $(C_3H_5)_3$Ga, for example, the Ga–C bond length is 2.007 Å, and the average C–C and C=C distances are 1.490 and 1.341 Å, respectively, all of which differ by less than 0.01 Å from the $SiMe_3$ version. The major change on substitution of SiH_3 and then H for $SiMe_3$ is a rotation of one of the allyl ligands so that the C_β atom is closer to the plane defined by the gallium and three C_α atoms. In the experimental and calculated structures of [1,3-($SiMe_3)_2C_3H_3]_3$Ga, the C_β atoms are >1.1 Å from the GaC_3 plane; in the SiH_3-substituted model, C(2) is 0.51 Å from the plane; in $(C_3H_5)_3$Ga, C(2) is 0.38 Å from the plane. Apparently the bulk of the substituents serve to keep the allyl ligands roughly perpendicular to the central GaC_3 plane.

Regardless of the identity of the allyl substituents, ΔG° of the C_1 form is the lowest, although that of the “3 up” C_3 form is at most only 2.6 kcal mol^{-1} higher in energy (Table 3). This difference is on the edge of being computationally significant, so that the two forms are nearly equienergetic. The “2 up, 1 down” form found for [1,3-($SiMe_3)_2C_3H_3]_3$Ga in the solid state is possibly reinforced by packing forces.

That the two σ-bound forms are close in energy is significant in the context of the solution fluxionality of the complex, as they are reasonable limiting structures in the rearrangement process. The energy of transition structures that involve delocalized allyl ligands depends critically on the identity of all the ligands in a complex. Correlated ab initio calculations have been used to find that the energy of (π-$C_3H_5)BH_2$ (C_s) is only 1.8 kcal mol^{-1} above that of (σ-$C_3H_5)BH_2$ (C_1), for example, but that (π-$C_3H_5)BMe_2$ is 9.2 kcal mol^{-1} above (σ-$C_3H_5)BMe_2$ (C_1) [55]. Considering that the vacant p orbital on the metal is involved in stabilizing a “π-bound” ligand, it is not surprising that threefold π-bound geometries (C_{3h} symmetry) can play no role in the fluxional process. They represent high-order transition structures ($N_{imag} = 4$) that are more than

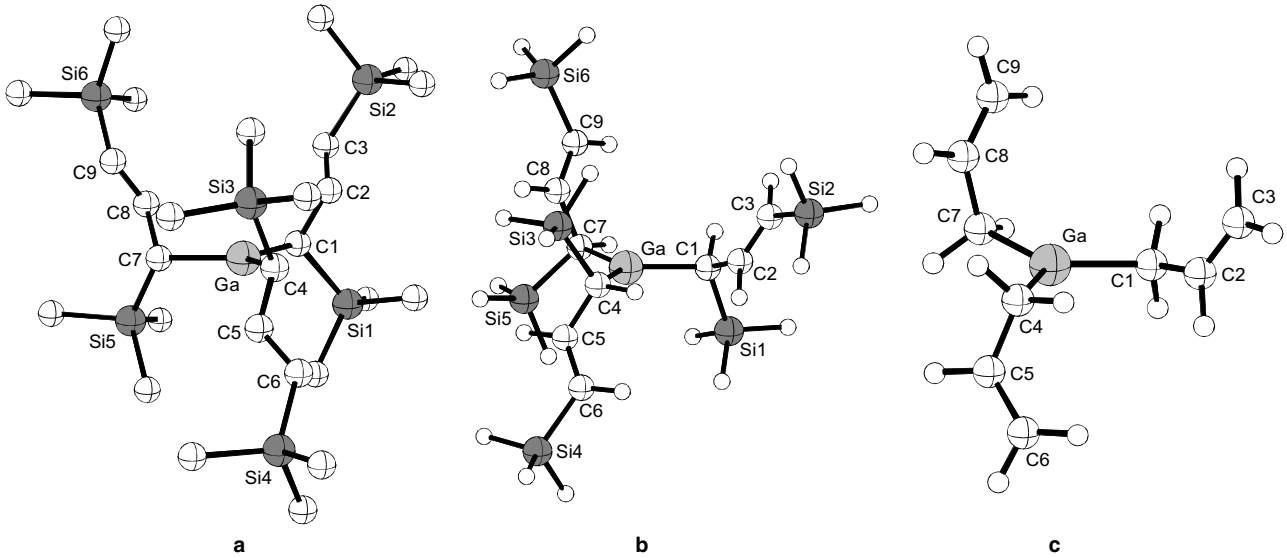

Fig. 4. Optimized lowest energy structures of [1,3-($SiMe_3)_2C_3H_3]_3$Ga (a), [1,3-($SiH_3)_2C_3H_3]_3$Ga (b), and $(C_3H_5)_3$Ga (c). For clarity, the hydrogen atoms (open circles in b and c) have been omitted from the drawing of [1,3-($SiMe_3)_2C_3H_3]_3$Ga.

Table 3
Energies of (allyl′)$_3$Ga conformations[a]

Ligand type		$\pi(C_{3h}$ symmetry)	σ (C_3 symmetry)	σ (C_1 symmetry)
C_3H_5	ΔH°	−2276.288137 (+81.4)	−2276.416999 (+0.5)	−2276.417834 (0.0)
	ΔG°	−2276.335697 (+90.4)	−2276.476641 (+2.0)	−2276.479762 (0.0)
1,3-$(SiH_3)_2C_3H_3$	ΔH°	−4020.156916 (+75.3)	−4020.276907 (0.0)	−4020.276101 (+0.5)
	ΔG°	−4020.237254 (+85.4)	−4020.372047 (+0.8)	−4020.373333 (0.0)
1,3-$(SiMe_3)_2C_3H_3$	ΔH°	−4727.225657 (+97.7)	−4727.37849 (0.0)	−4727.381309 (+1.8)
	ΔG°	−4727.374070 (+108.2)	−4727.54244 (+2.6)	−4727.546544 (0.0)

[a] The energies in parenthesis are calculated relative to the most stable form of each molecule (listed as "0.0"). All the π-bound forms had 4 imaginary frequencies; the σ-bound forms had none.

85 kcal mol^{-1} above the lowest energy σ-bonded configurations (Table 3). Structures with only one π-bound ligand are more reasonable and a preliminary search of the potential energy surface using the parent allyl ligand has identified a (π-C_3H_5)(σ-C_3H_5)$_2$Ga configuration (C_s symmetry) that is 7.3 kcal mol^{-1} above the lowest energy σ-bound form. It is a second order saddle point ($N_{imag} = 2$), but may be close to a transition structure of slightly lower symmetry. Similar structures may exist for the SiH_3 and $SiMe_3$ complexes, although these have not yet been investigated.

3. Conclusion

The use of trimethylsilyl substituents has afforded the first isolated example of a thermally stable, heavy Group 13 allyl complex. The allyl ligands are σ-bound in an asymmetric fashion, but DFT calculations indicate that a more symmetrical C_3 form is only a few kcal mol^{-1} higher in energy. This result is consistent with variable temperature NMR measurements, which suggest that the molecule has a low energy of activation for rearrangement.

The successful use of trimethylsilylated allyl ligands with gallium suggests that other substituents could be equally successful in stabilizing additional gallium species. Heavier members of the Group 13 metals could also be incorporated into new allyl complexes and we are examining this possibility.

4. Experimental

4.1. General considerations

All manipulations were performed with the rigorous exclusion of air and moisture using high vacuum, Schlenk, or glovebox techniques. Proton (^{1}H) and carbon (^{13}C) NMR experiments were obtained on a Bruker DPX-300 spectrometer at 300 and 75.5 MHz, respectively, or on a Bruker DPX-400 at 400 MHz (^{1}H), and were referenced to residual proton and ^{13}C resonances of toluene-d_8 (δ 2.09 and 20.4) and C_6D_6 (δ 7.15 and 128.1). Elemental analysis was performed at the Micro-Mass Facility, University of California, Berkeley (Berkeley, CA). Hexanes and diethyl ether were distilled under nitrogen from potassium benzophenone ketyl. Anhydrous tetrahydrofuran (THF) was purchased from Aldrich and used as received. Anhydrous gallium trichloride was purchased from Strem Chemicals and used as received. C_6D_6 and toluene-d_8 were vacuum-distilled from Na/K (22/78) alloy and stored over Type 4 molecular sieves prior to use. K[1,3-$(SiMe_3)_2C_3H_3$] was prepared following the literature procedure [8].

4.2. Preparation of [1,3-$(SiMe_3)_2C_3H_3$]$_3$Ga

A 125-mL Schlenk flask was charged with $GaCl_3$ (0.500 g; 2.84 mmol) in 20 mL THF. K[1,3-$(SiMe_3)_2C_3H_3$] (1.90 g; 8.52 mmol) in 20 mL THF was added to the dropping funnel. The apparatus was cooled to −78 °C. The THF solution of K[1,3-$(SiMe_3)_2C_3H_3$] was added dropwise with stirring over the course of 15 min. The solution was allowed to warm to room temperature overnight. Removal of solvent under vacuum, followed by extraction of the residue with hexanes, filtration of the extract over a medium-porosity glass frit, and removal of hexanes under vacuum, afforded air- and moisture-sensitive colorless to pale-yellow crystals (1.67 g, 94%), m.p. 44–46 °C. *Anal.* Calc. for $C_{27}H_{63}GaSi_6$: C, 51.80; H, 10.14. Found: C, 51.49; H, 10.55%. ^{1}H NMR (C_6D_6, 298 K): δ 6.38 (t, $J = 14.8$ Hz, 3H), 3.94 (d, $J = 14.8$ Hz, 6H), 0.18 (s, 54H, $SiMe_3$); (tol-d_8, 298 K, 300 MHz): δ 6.35 (t, $J = 14.8$ Hz, 3H), 3.91 (d $J = 14.8$ Hz, 6 H), 0.16 (s, 54H, $SiMe_3$). ^{13}C NMR (C_6D_6, 298 K): δ 145.31 ($C_{(2)}$, central), 83.72 ($C_{(1,3)}$, outer), 0.15 ($SiMe_3$). Variable temperature ^{1}H (tol-d_8, 400 MHz, δ): (198 K) 6.43 (t, $J = 14.8$, 3H), 3.7-4.3 (v br s, 2H), 0.24 (s, 54 H, $SiMe_3$); (213 K) 6.41 (t, $J = 14.8$ Hz, 3H), 4.01 (broad singlet, 6H), 0.23 (s, 54H, $SiMe_3$); (233 K) 6.40 (t, $J = 14.8$ Hz, 3H), 3.96 (broad singlet, 6H), 0.21 (s, 54H, $SiMe_3$); (253 K) 6.38 (t, $J = 14.8$ Hz, 3H), 3.94 (br d, $J = 14.2$ Hz, 6H), 0.20 (s, 54H, $SiMe_3$); (273 K) 6.37 (t, $J = 14.8$ Hz, 3H), 3.93 (d, $J = 14.8$ Hz, 6H), 0.18 (s, 54H, $SiMe_3$).

4.3. X-ray crystallography of [1,3-(SiMe$_3$)$_2$C$_3$H$_3$]$_3$Ga

Crystals of [1,3-(SiMe$_3$)$_2$C$_3$H$_3$]$_3$Ga were obtained as pale yellow plates upon removal of hexanes. A suitable crystal was located, placed onto the tip of a 0.1-mm diameter glass capillary and mounted on a Bruker SMART Platform CCD diffractometer for a data collection at 173(2) K. The intensity data were corrected for absorption (SADABS) [56], and the structure was solved using SIR97 and refined using SHELXL-97. The triclinic space group $P\bar{1}$ was indicated from intensity statistics and the lack of systematic absences. A direct-methods solution was calculated that provided most non-hydrogen atoms from the E-map. Full-matrix least squares/difference Fourier cycles were performed that located the remaining non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters. All methyl hydrogen atoms were placed in ideal positions and refined as riding atoms with relative isotropic displacement parameters. The allylic hydrogen atoms were found from the difference map and refined with individual isotropic displacement parameters. Additional crystal and data collection parameters are given in Table 1.

4.4. Computational details

Calculations were performed using the GAUSSIAN 03W suite of programs [57]. The B3PW91 functional, which incorporates Becke's three-parameter exchange functional [58] with the 1991 gradient-corrected correlation functional of Perdew and Wang [59], was used. This hybrid functional has previously been shown to provide realistic geometries for organometallic species [60]. The correlation consistent double zeta basis set cc-pVDZ was used for geometry optimization and final energy calculations [61]. Zero-point corrections were applied to the energies of the final geometries.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC 268307. Copies of this information may be obtained free of charge from The Director CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or at www.ccdc.cam.ac.uk/index.html).

Abstract

Alcohol exchange reactions applied to $HfAl_2(OPr^i)_{10}$ (**1**) afforded heterometallic Hf–Al aminoalkoxides namely $HfAl_2(OPr^i)_8(dmae)_2$ (dmae = *N*,*N*-dimethylaminoethoxide) (**2**) and $HfAl_2(OPr^i)_8(dmap)_2$ (dmap = dimethylaminopropoxide) (**3**). They were characterized by elemental analysis, FT-IR, ^1H NMR, mass spectrometry and TGA. The molecular structure of **2**, as established by single-crystal X-ray diffraction, $HfAl_2(\mu\text{-}OPr^i)_2(\mu,\eta^2\text{-}OC_2H_4NMe_2)_2(OPr^i)_6$, is based on an open-shell trinuclear unit with a central 6-coordinate Hf atom and 5-coordinate Al centres. Compound **2** was tested as a single-source precursor for the deposition of hafnium aluminate films by liquid-injection MOCVD. The films growth rate, composition and morphology were studied in relation with the deposition temperature. The as-deposited at 500–800 °C films (both on sapphire and silicon) were amorphous; partial crystallization occurred after 1 h annealing at 900 °C. The bulk of the films was Al-rich (Al/Hf = 1.2–1.6) and contained small amounts of carbon (2–4%) and nitrogen (4–5%).

1. Introduction

Amorphous silicon oxide has been used for many years as dielectric layer in the microelectronic industry due to its dielectric properties and high stability interface with silicon. However, the increase in the circuit density and scaling down in the dimensions of field effect transistors in CMOS (complementary metal oxide semiconductor) technologies forces the thinning of the oxide layer down to a thickness where leakage current is an obstacle for device reliability [1,2]. A solution is to use as gate dielectric oxide materials with higher dielectric constants (κ) than SiO_2 ($\kappa = 3.9$). Various oxides were considered among which HfO_2 was the most investigated due to the high quality dielectric properties of its polycrystalline films [2]. However, in order to stabilize the interface between metal oxide and silicon it is desirable that the gate dielectric remains amorphous during CMOS processing [1]. Unfortunately, HfO_2 films crystallize during MOCVD deposition at ~500 °C

(monoclinic phase) independently of the precursor used [3–5]. Grain boundaries in polycrystalline films can result in high leakage current. Hafnium silicate [1] or other binary alloys remaining amorphous up to 800–900 °C on silicon were considered as alternatives. Hafnium aluminate, actually an alloy $(HfO_2)_x(Al_2O_3)_{1-x}$, is especially attractive, it remains amorphous at 900 °C ($x = 0.75$) and even at 1050 °C ($x = 0.25$) [6] and has a higher dielectric constant ($\kappa \sim 15$) than hafnium silicate ($\kappa \sim 7$) [1].

$(HfO_2)_x(Al_2O_3)_{1-x}$ films have been deposited on Si(1 0 0) by physical (sputtering [7], pulsed laser deposition [8,9]) and chemical methods such as atomic layer deposition (ALD) and metal-organic chemical vapor deposition (MOCVD). Among chemical techniques ALD mainly has been applied for deposition of hafnium aluminate films [6,10] using combinations of various Hf and Al precursors. Major advantages of ALD are good control of the growth at a monolayer level and excellent step coverage [11]. MOCVD also has many advantages since it allows the growth of uniform layers on large, even non-planar substrates, good step coverage and composition control, but much higher growth rates than ALD. This technique is thus highly desirable for bulk production. Only few studies have been reported on the growth of hafnium aluminate films by MOCVD [12–14]. Two separate sources namely $Hf(mmp)_4$ ($mmp = OCMe_2CH_2OMe$) and $[Al(OiPr)_3]_4$ have been used for vapor generation [13,14]. Another alternative for the MOCVD growth of $(HfO_2)_x(Al_2O_3)_{1-x}$ films is the use of an heterometallic precursor containing both metals in a single molecule. Such an approach offers a good control of the composition of multimetallic oxides films and thus high homogeneity [15]. Recently, Joo et al. [12] reported about the use of the single cocktail liquid source $HfAl(mmp)_2(OiPr)_5$ for MOCVD of $(HfO_2)_x(Al_2O_3)_{1-x}$ films. However, no information on the origin, properties and structure of this precursor was given, it remains thus unclear if this source was an heterometalic precursor or a mixture of two alkoxides.

We report herein the synthesis and characterization of the first mixed-metal Hf–Al aminoalkoxides namely $HfAl_2(OPr^i)_8(dmae)_2$ (**2**) and $HfAl_2(OPr^i)_8(dmap)_2$ (**3**) (dmae = *N*,*N*-dimethylaminoethoxide, dmap = $OCHMeCH_2NMe_2$ = dimethylaminopropoxide). Compound **2** was tested as single-source heterometallic precursor for the deposition of $(HfO_2)_x(Al_2O_3)_{1-x}$ films by pulsed liquid-injection MOCVD.

2. Experimental

2.1. Synthesis

All reactions were performed under argon using Schlenk tubes and vacuum line techniques. Solvents were purified by standard methods. dmaeH (2-dimethylaminoethanol) and dmapH (1-dimethylamino-2-propanol) were distilled and stored over molecular sieves. FT-IR spectra were recorded with a Perkin–Elmer Paragon 500 Spectrometer as Nujol mulls. NMR spectra were recorded on an AM250 Bruker spectrometer, the peak of the solvent was used as reference. Mass spectra were obtained with a Thermofinnigan Mat95XL spectrometer under standard electron ionization conditions ($E_1 = 70$ eV). Elemental analyses were done at the Centre de microanalyses du CNRS.

$Al_2Hf(OPr^i)_{10}$ (**1**) was prepared by a slightly modified procedure [16]. $Hf_2(OPr^i)_8(Pr^iOH)_2$ (2.46 g, 5.01 mmol) and $[Al(OPr^i)_3]_4$ (2.05 g, 1.28 mmol) were mixed in 25 ml of toluene and refluxed for 6 h. Evaporation to dryness gave a white powder (4.00 g, 95%). IR (cm^{-1}): 594 m, 553 s, 540 s, 475 m, 450 m (νM-OR). ^1H NMR ($CDCl_3$, 20 °C): 4.8 sept ($J = 6$ Hz, 4H, CH), 4.64 sept ($J = 6$ Hz, 2H, CH), 4.58 sept ($J = 6$ Hz, 4H, CH), 1.57 d ($J = 6$ Hz, 12H, Me), 1.52 d ($J = 6$ Hz, 24H, Me), 1.48 d ($J = 6$ Hz, 24H, Me).

Synthesis of $Al_2Hf(OPr^i)_8(OR)_2$. R = $C_2H_4NMe_2$ (**2**), $CHMeCH_2NMe_2$ (**3**) dimethylaminoethanol (0.25 g, 2.82 mmol) was added to a solution of $Al_2Hf(OPr^i)_{10}$ (1.164 g, 1.41 mmol) in 20 ml of toluene. After refluxing for 3 h and filtration, the filtrate was evaporated to dryness. The crude powder was recrystallized in pentane. Crystals of **2** (0.96 g, 77%) were obtained at −20 °C. *Anal.* Calc. for $C_{32}H_{76}N_2O_{10}Al_2Hf$: C, 43.61; H, 8.69; N, 3.18. Found: C, 43.82; H, 8.75; N, 3.40%. IR (cm^{-1}): 632 m, 581 m, 545 s, 467 s (νM-OR). ^1H NMR ($CDCl_3$, 20 °C): 4.48 sept ($J = 6$ Hz, 4H, CH), 4.20 sept ($J = 6$ Hz, 2H, CH), 4.08 sept ($J = 6$ Hz, 2H, CH); 3.7 m (4H, CH_2), 2.7–2.22 m (4H, NCH_2); 2.35 s (12 H, NMe_2), 1.47–1.08 (overlapping of d, $J = 6$ Hz, 48H, Me). MS (m/z^+, I): M − $OC_2H_4NMe_2$ (3), M − OPr^i − Pr^iOH (3), M − $Al(OPr^i)_3$ − CH_4 (8), M − $Al(OPr^i)_3$ − Pr^iOH (18), M − $Al(OPr^i)_3$ − OH- $C_2H_4NMe_2$ (58), M − $Al(OPr^i)_3$ − OHC_2H_4-NMe_2 − C_2H_4 (25), M − $Al_2(OPr^i)_4(OC_2H_4NMe_2)$-$(OCH_2)$ 488 (10), $Al_2(OPr^i)_3(OC_2H_4N)$ (8), M − Hf $(OPr^i)_2$- $(OC_2H_4NMe_2)_2$ (1 0 0), $Hf(OPr^i)_4$ − C_2H_4 − 1/2 O_2 (20), $Al_2(OPr^i)_3$ − 3/2 H_2 (35), $Al(OPr^i)_3$ − C_3H_4 (50), $AlO(OPr^i)_2$ − 1/2 H_2 (30), $CH_2{=}NMe_2$ (64).

The same procedure applied to 1.14 g (1.38 mmol) of $Al_2Hf(OPr^i)_{10}$, 0.28 g (2.76 mmol) of $OCHMeCH_2NMe_2$ gave **3** after extraction of the crude product with petroleum ether and evaporation to dryness (1.14 g, 80%). *Anal.* Calc. for $C_{34}H_{80}N_2O_{10}Al_2Hf$: C, 44.90; H, 8.87; N, 3.08. Found: C, 44.60; H, 8.75; N, 3.10%. IR (cm^{-1}): 596 w, 546 s, 530 sh, 498 w, 444 m (νM-OR); ^1H NMR ($CDCl_3$, 20 °C): 4.45 sept, 4.47 sept ($J = 6$ Hz, 4H, 1:1, CH), 4.1 m (2H, CH), 4.0 m (2H, CH), 3.80–3.75 m (OCH, 2H), 2.15–2.6 (m, 4H, NCH_2), 2.2 (s, 12H, NMe_2), 1.1–1.35 overlapping of d ($J = 6$ Hz, 54H, Me(Pr^i) and CHMe).

The compounds were poorly soluble in aliphatic hydrocarbons and more soluble in toluene, THF, DME.

2.2. Crystallography of $HfAl_2(OPr^i)_8(dmae)_2$

Crystal data for **2**: $C_{32}H_{76}Al_2N_2O_{10}Hf$, FW 881.40, triclinic, $P\bar{1}$, $a = 9.5552(2)$, $b = 12.2673(2)$, $c = 19.9092(5)$ Å, $\alpha = 79.540(1)°$, $\beta = 82.661(1)°$, $\gamma = 82.661(1)°$, $V = 2262.99(8)$ Å^3, $Z = 2$, $T = 160(2)$ K, μ(Mo Kα) = 2.390 mm^{-1}.

Suitable crystals of **2** were grown by recrystallization in petroleum ether as colorless plates. 42 348 Reflections of which 10 057 were unique were measured with a Nonius CCD diffractometer. The data were collected using the COLLECT software they were processed through the DENZO reduction software [17]. The structure was solved and refined on F^2 using the SHELXTL software [18]. All non-hydrogen atoms were refined with anisotropic thermal parameters. Final data R_1 (all data) = 0.0743, $wR_2 = 0.1315$ for 424 parameters, GOF = 1.060. The hydrogen atoms were included in the final refinement in calculated positions with isotropic thermal parameters.

2.3. CVD experiments and films characterization

Pulsed liquid-injection MOCVD (PI-MOCVD) [19,20] was used for testing **2** as precursor for aluminate film deposition. This technique is based on repetitive injections of microdoses of solution of a metal-organic precursor, flash evaporation, vapor transport by a carrier gas ($Ar + O_2$) and decomposition on a hot substrate. Its advantages over classical MOCVD are better reproducibility of precursor feeding rate and easy control of film thickness and growth rate by changing injection parameters (injection frequency and injected drop size, concentration of solution). The deposition conditions are presented in Table 1. The substrates, Si(1 0 0) and R-plane sapphire, were cleaned in boiling toluene before use (sapphire was cleaned in an ultrasound bath in toluene for 15 min before; silicon was dipped in ~8% HF for 10 s to remove oxide). After deposition, films were cooled down to rt in an O_2 atmosphere (~760 Torr).

Table 1
Deposition conditions of $(HfO_2)_x(Al_2O_3)_{1-x}$ films

Evaporator temperature (°C)	280
Substrate temperature (°C)	500–800
Ar flow (l/h)	54
O_2 flow (l/h)	36
Total pressure (Torr)	5
Solvent	toluene
Precursor concentration (M)	0.01
Injection duration (ms)	2.5
Injection frequency (Hz)	2
Microdose mass (mg)	~3.5

Films were studied by X-ray diffraction (XRD) with a Bruker D8 diffractometer (Cu Kα radiation). X-ray photoelectron spectroscopy (XPS; RIBER LAS-3000, Mg Kα radiation) was used for composition analysis (precision of about ±10%) on film surface and in the depth (after the removal of surface layer by sputtering for 30 min with 1.5 keV Ar^+). The data were referenced to the peak of carbon (284.6 eV) for charge effects correction. The morphology of the film surface was examined by atomic force microscopy (AFM) (Digital Instruments Multimode Scanning Probe Microscope, tapping mode). Thickness of the films on Si(1 0 0) was determined by profilometry (Taylor–Hobson) on the steps formed by lithography and wet etching. The determined thickness was used for the calculation of the film growth rate.

3. Results and discussion

3.1. Synthesis, characterization and molecular structure

The reactions between $HfAl_2(OPr^i)_{10}$ (**1**) and aminoalcohols, namely dimethylaminoethanol (dmaeH) and dimethylaminopropanol (dmapH) in 1:2 stoichiometry in toluene at reflux give access to heteroleptic mixed-metal species, $HfAl_2(OPr^i)_8(OR)_2$ (R = dmae) (**2**), dmap (**3**), respectively. The compounds were characterized by elemental analysis, FT-IR, ^{1}H NMR and mass spectrometry. FT-IR spectra confirmed the absence of vOH absorption bands and thus formation of non-solvated species. The compounds were also characterized by vM-OR absorption bands in the 600–450 cm^{-1} range different from those of $HfAl_2(OPr^i)_{10}$. ^{1}H NMR data confirm the integration ratio between the isopropoxide and the aminoalkoxide ligands. As for the homoleptic $HfAl_2$ alkoxide, the various isopropoxide groups appear magnetically inequivalent even at rt in $CDCl_3$ solutions. Indeed, the spectra of **2** for instance show three type of methine CH groups at 4.48, 4.20, 4.08 ppm in a 4:2:2 integration ratio. According to the mass spectrometry data, compound **2** is also present in the vapor phase. However, the fragmentation pattern indicates quite an easy loss of aluminium fragments. Although moisture sensitive, **2** and **3** were more stable than the homoleptic derivative **1**.

Single crystal X-ray diffraction of **2** confirmed it to be a heterometallic species of formula $HfAl_2(\mu\text{-}OPr^i)_2(\mu,\eta^2\text{-}OC_2H_4NMe_2)_2(OPr^i)_6$. The structure (Fig. 1) is derived from that of $HfAl_2(\mu\text{-}OPr^i)_2(OPr^i)_8$ the bridging-chelating aminoalkoxide leading to fivefold coordination of the aluminium centres and a less symmetrical structure [16].The central hafnium is six-coordinate with a quite distorted surrounding due to the acute O–Hf–O angles of the bridge [65.4(1)° and 70.6(1)°] (Table 2). The Al

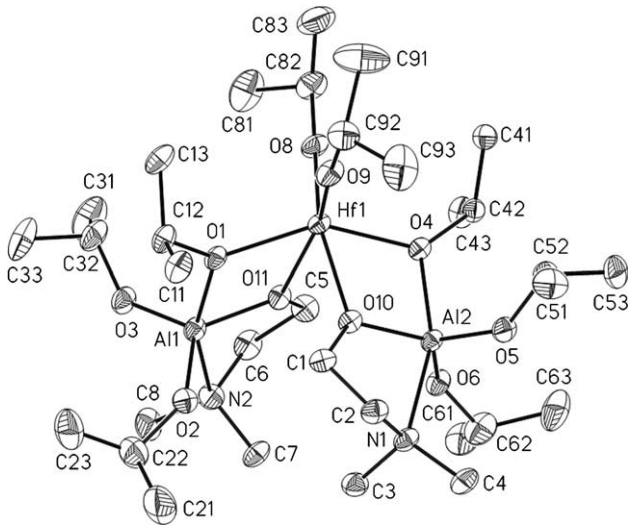

Fig. 1. Molecular structure of $HfAl_2(OPr^i)_8(dmae)_2$ showing the atom numbering scheme (thermal ellipsoids at 30% probability).

coordination geometry can be described as a trigonal bipyramid with the bridging μ-O(Pr^i) and μ-N(dmae) at the axial positions thus leading to significant distortions. The bite angles of the aminoethoxide ligand are quite small (77.5° av.) but comparable to the literature body [21]. The ranking of bond distances is Al–OR < Al–μOR < Hf–OR < Hf–μOR < Al–N. The bridges are thus asymmetrical. The terminal Hf–OR bond lengths are quite different (1.829(4) and 2.016(4) Å) although they have similar large Hf–O–C angles (175.5° av.) accounting for π-bonding. The increase of the coordination number of aluminium, by comparison to **1**, reflects in the Al–OPr^i bond distances [1.682(4)–1.932(4) Å versus 1.667(6)–1.803(5) Å], the Al–O–C angle being similar (136.7° av.) [22]. The Al–N coordination bonds are quite different for the two Al centres 2.143(5) and 2.380(5) Å, the longest one being *trans* to the longest Al-μOPr^i, 2.011(4) Å this suggesting the aminoethoxide ligand exerts a quite strong *trans* effect. The Al–N bond distances are quite long is comparison with the literature body [23]. The Hf–Al distances of 3.246(2) Å are longer than those of $HfAl_2(OPr^i)_{10}$ [3.125(2) Å] [16]. The modification of **1** by functional aminoalkoxide ligands giving **2** and **3** proceeds with retention of the initial Hf:Al stoichiometry since the increase in coordination of the Al centres allows to use the additional coordination site of the aminoalkoxide ligands with respect to the OPr^i one.

3.2. MOCVD deposition and properties of the films

Amorphous $(HfO_2)_x(Al_2O_3)_{1-x}$ films (50–120 nm thick) were deposited with **2** on Si(100) and R-plane sapphire substrates at 500–800 °C. In order to study the stability of the films toward crystallization, those

deposited at 700 °C were annealed for 1 h at 900 °C (under vacuum for the films on silicon; in air for those on sapphire). The signs of crystallization can be seen in Fig. 2, indicating partial separation of a monoclinic HfO_2 phase in films during the long time annealing. This demonstrates that despite the significantly higher resistance to crystallization compared to HfO_2 films, MOCVD grown hafnium aluminate films do not remain completely amorphous during annealing for 1 h. Nevertheless, this result can be considered as promising since it suggests that films might still remain amorphous during a rapid high-temperature annealing step (~20 s) in the CMOS process. For comparison, hafnium aluminate films grown by MOCVD from $HfAl(mmp)_2(O^iPr)_5$ became already crystalline after 30 s annealing at 900 °C [12].

The Arrhenius type plot of growth rate versus deposition temperature is presented in Fig. 3. The growth enters a diffusion controlled range at ~650 °C. The activation energy of the reaction was ~38 kJ/mol, thus, less than for completely kinetically limited growth ($E_a > 70$ kJ/mol). The growth rates of $(HfO_2)_x(Al_2O_3)_{1-x}$ films in the range of 500–800 °C (1.6–3.8 nm/min or 330–780 nm/mmol of injected precursor) were sufficiently high for the growth of thin dielectric films. Our growth rates were similar to those achieved with the $HfAl(mmp)_2(OPr^i)_5$ source [12]. It is worth noting that although this liquid precursor was injected continuously in a vaporizer chamber, we obtained similar growth rates through a pulsed injection of very diluted (0.01 M) solutions. This can be considered as an advantage of our new precursor and our deposition technique.

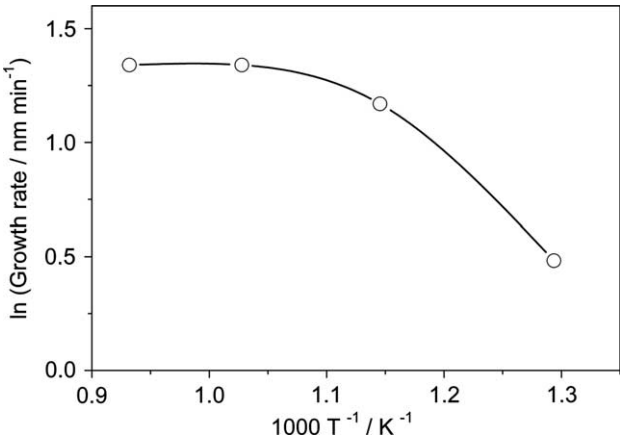

Fig. 3. Growth rate of $(HfO_2)_x(Al_2O_3)_{1-x}$ films vs. deposition temperature.

The films deposited at different temperatures were studied by AFM (Fig. 4). The relative roughness (ratio R_a/thickness, where R_a is an average roughness) was small (~2%) at low temperatures (500–600 °C) and significantly higher (~5%) at 800 °C where film growth vas diffusion controlled. This result is in agreement with previous observations that the grain size and roughness of HfO_2 [4,5] and Al_2O_3 [24] films increased with the deposition temperature.

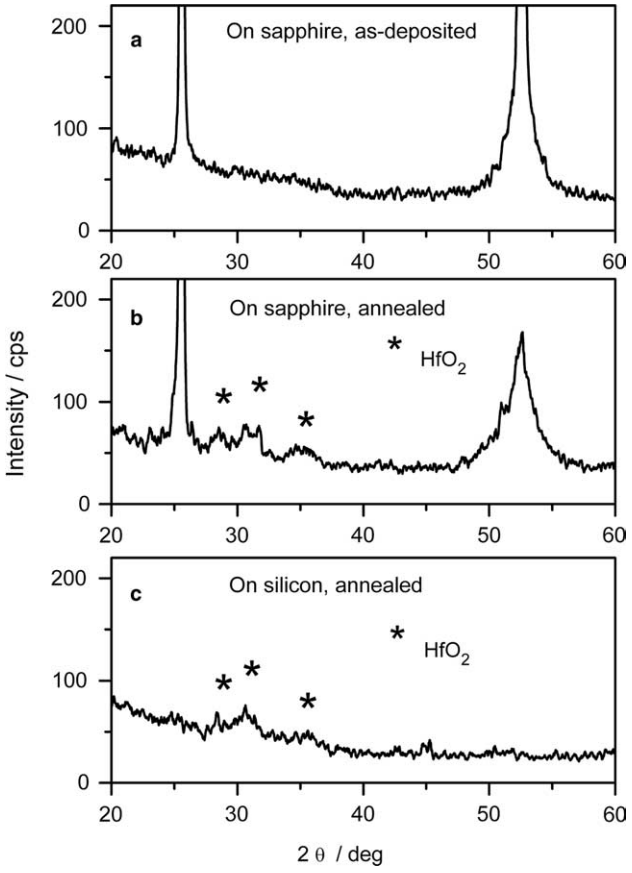

Fig. 2. XRD patterns of as-deposited and annealed at 900 °C $(HfO_2)_x(Al_2O_3)_{1-x}$ films, grown on sapphire (a, b) and (c) silicon at 700 °C. The thickness of as-deposited films is 105 nm.

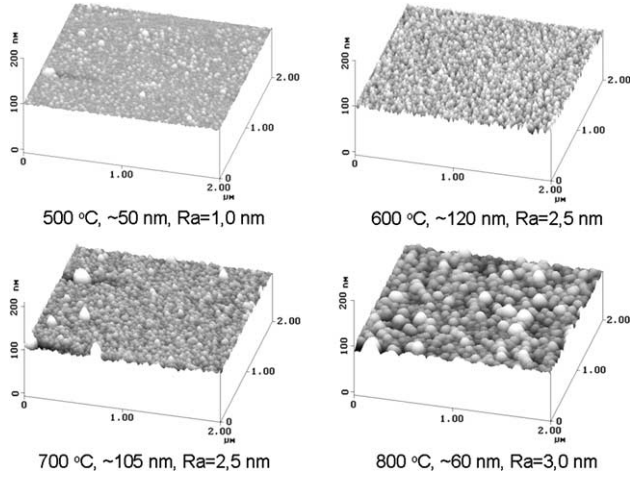

Fig. 4. AFM images of $(HfO_2)_x(Al_2O_3)_{1-x}$ films deposited on silicon at 500–800 °C. Deposition temperature, film thickness and roughness average (R_a) are indicated.

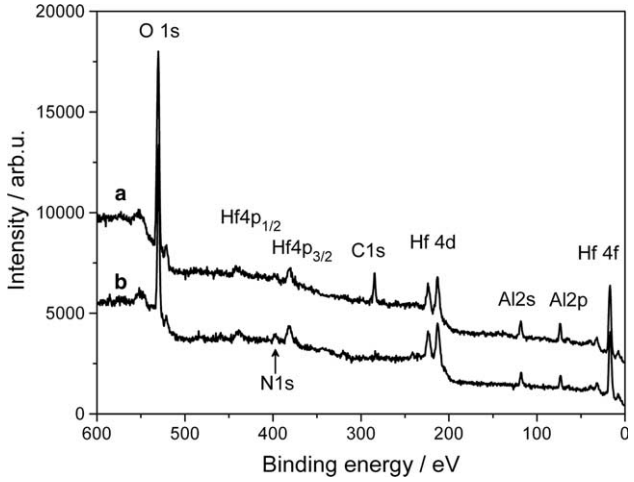

Fig. 5. XPS spectra of an $(HfO_2)_x(Al_2O_3)_{1-x}$ film deposited at 700 °C: (a) surface, (b) after 30 min of sputtering with Ar^+ at 1.5 keV.

The composition of the films on silicon was studied by XPS (Fig. 5). The XPS study revealed films that the Al/Hf ratios were 1.65–1.8 on the surface and 1.2–1.6 in the bulk of the films depending on deposition temperatures (Fig. 6(a)). Higher Al/Hf ratios compared to the bulk were also found with $HfAl(mmp)_2(OPr^i)_5$ [12]. The carbon content decreased after removal of the surface layer (by sputtering with 1.5 keV Ar^+ for 30 min) from ~10–14 to 2–4 at.% (Fig. 6(b)), while the nitrogen amount remained in the range ~4–5% (Fig. 6(c)). The presence of nitrogen (as nitride) in the films may be seen as an advantage since N dopants were reported to improve carrier mobility at the interface [1]. The Al/Hf ratio in films is lower than in the heterometallic precursor (Al/Hf = 2). The difference between the Al/Hf ratio on the surface and in the film depth suggests that the depth profile is not very homogeneous. TGA data of **2** (N_2, 1 atm) indicate loss of an $Al(OiPr)_3$ moiety as the first step of decomposition (~200 °C). Mass spectrometry data of **2** are also in agreement with an easy loss of Al-fragments. It is thus possible, that partial precursor segregation occurs in the gas phase near the substrate causing the deviation of the Al/Hf ratio between the films and the precursor. Partial desorption of Al-containing fragments of the precursor from the surface can also play a role. However, it is worth to note that the film growth from our heterometallic precursor is much less influenced by such secondary processes than the growth from $HfAl(mmp)_2(OPr^i)_5$ [12]. Indeed, the later led to films in which the Al/Hf ratio varied in a large range namely from 0.4 to 2.4 and the film composition was only poorly related with that of the source used (Hf/Al = 1). These results on the Hf/Al ratio are similar to those obtained by using a mixture of two homometallic precursors with variable ratio [13]. The deposition temperature appeared as the main factor of variation with $HfAl(mmp)_2(OPr^i)_5$, higher deposition temperatures reducing the incorporation of Al_2O_3 into HfO_2.

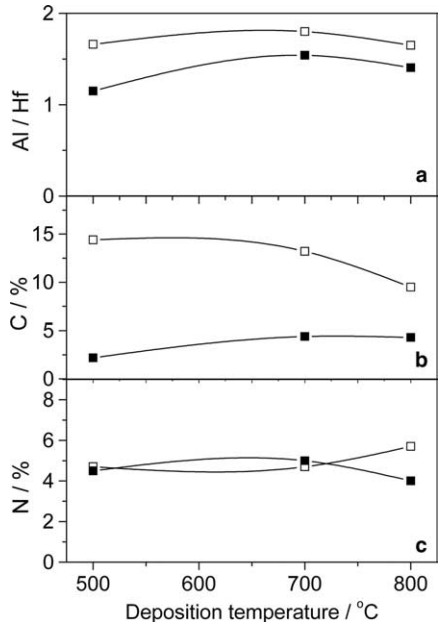

Fig. 6. The dependence of film composition on deposition temperature: (a) Al/Hf ratio, (b) carbon contamination, (c) nitrogen contamination. Composition determined by XPS on film surface (□) and after sputtering with 1.5 keV Ar^+ for 30 min (■).

Our preliminary results show that the use of an Hf/Al heterometallic precursor does not ensure exactly the same Hf/Al ratio in the hafnium aluminate alloy film than in the precursor. However, the new heterometallic precursor **2** is suitable for the deposition of amorphous $(HfO_2)_x(Al_2O_3)_{1-x}$ films with a controllable Al/Hf ratio in a quite narrow range namely 1.2–1.6.

4. Conclusions

The first Hf–Al heterometallic aminoalkoxides $HfAl_2(OPr^i)_8(dmae)_2$ (**2**) and $HfAl_2(OPr^i)_8(dmap)_2$ (**3**) were synthesized and characterized by elemental analysis, FT-IR, ^1H NMR, mass spectrometry and by single crystal X-ray diffraction for **2**. To the best of our knowledge**, 2** represents the first example of a well-defined, structurally characterized Hf–Al heterometallic species used for MOCVD of hafnium aluminate films. It gives amorphous hafnium aluminate $(HfO_2)_x(Al_2O_3)_{1-x}$ films in the 500–800 °C temperature range. Long time (1 h) annealing at 900 °C led to crystallization of some monoclinic HfO_2. Films contamination by carbon was rather low (2–4% by XPS). The films were rich in Al compared to Hf, however, the Al/Hf ratio (1.2–1.6) was lower than in the initial precursor **2** and was function of the deposition temperature. This shows that the use of an heterometallic precursor is less able to control the metal stoichiometry in alloys than in multimetallic oxides

having a definite formula. However, the composition of the $(HfO_2)_x(Al_2O_3)_{1-x}$ films is mainly defined by that of the heterometallic precursor used, 2, and can be controlled in a rather narrow range. The presence of N-donor ligands results in the presence of nitrogen as nitride in the films and might improve the properties of the films, further studies are in progress.

5. Supplementary material

Crystallographic data (tables of coordinates, of thermal parameters, of bond lengths and angles) have been deposited at the Cambridge Crystallographic Data Base Centre. CCDC reference number for **2** is 227405. Abstract

Details are reported of the preparation and X-ray structural characterisation of the new compounds (PhCb^o)$_2$X, where PhCb^o = 2-Ph-1,2-$C_2B_{10}H_{10}$ and X = S (**1**) or SO (**3**), prepared from PhCb^{o}Li and SCl_2 or $SOCl_2$ respectively, as well as the known compound with X = S_2 (**2**). Hydrogen in the presence of palladium/carbon reduced (**3**) to (**1**). Features of their structures (*exo* C–S and cage C–C distances and substituent orientations) are consistent with significant *exo* S=C dative π-bonding from their sulfur atoms to the cage hypercarbon atoms and weak *exo* π-bonding from the phenyl groups. Attempts to prepare systems (Cb^{o}Y)$_2$, in which two *ortho*-carboran-di-yl residues Cb^o are linked through two bridging units Y (S, SO) are also reported, as are their calculated structures.

1. Introduction

Researches into carboranes with cage C–sulfur substituents were originally developed in the 1960s [1–4] and after a quiet period have acquired renewed momentum recently. Reactions between alkali metal (normally lithium) carborane derivatives and elemental sulfur or sulfur halides were used primarily to prepare derivatives of formula types $HCB_{10}H_{10}CSR$, $RCB_{10}H_{10}CSR'$ or $RSCB_{10}H_{10}CSR'$, where R and R′ = H, alkyl or aryl [1–8]. Derivatives Cb^o(SR)$_2$ of *ortho* carborane have attracted particular interest, in part in connection with their ligand potential, whether as bidentate chelating ligands, or as components of macrocycles when the substituents R are linked through successive ether or thioether units [9,10]. Where SR is SH they can be used as precursors to form [*closo*-$RC_2B_{10}H_{10}S]^-$ or [*closo*-$C_2B_{10}H_{10}S_2]^{2-}$ anionic residues [11–18]. They have also

doi:10.1016/j.poly.2005.06.046

been used as precursors from which [*nido*-$C_2B_9H_9(SR)_2]^{2-}$ anionic residues, offering yet further ligand potential, can be prepared [19–22].

Although many C–sulfur *ortho*-carboranes are now listed in the Cambridge Structural Database [23], it is perhaps surprising to find that there is only one reported compound, [$Cb^oSCb^oSiMe_2$] [24], in which two *ortho*-carboran-di-yl residues are linked through their carbon atoms by a single sulfur atom. This compound also contains a dimethylsilyl bridge between the two carboran-di-yl residues [24]. One other compound, $(MeCb^o)_2S$, with a sulfur bridge between *ortho*-carboranyl residues has been reported [4] but it was not structurally characterised.

In previous studies of the derivative chemistry of icosahedral carboranes, we have explored the effect on the 2-phenyl-*ortho*-carborane cage of the attachment of more strongly π-donor substituents to the cage hypercarbon atom C1 and found that the cage opens up from a *closo* to a near *nido* geometry as the *exo* bond order increases [25–27]. Our own published work so far has concentrated on one-cage systems and here we extend our investigation to the effect of one π-donating atom connected to *two ortho*-carborane cages. We prepared systems $(PhCb^o)_2X$ (X = S (**1**), S_2 (**2**) or SO (**3**)) in which the second cage carbon atom bore a phenyl substituent [26,28], choosing 2-phenyl-*ortho*-carborane derivatives because they generally form suitable crystals for X-ray crystallographic studies (over fifty such compounds have been structurally characterised) [29–34]. We also explored the synthesis of heterocyclic systems $(Cb^oY)_2$ (Y = S (**4**) or SO (**5**)) in which two C–S–C or C–S(O)–C bridges link pairs of *ortho* carborane icosahedra, and report calculated structures of (**4**) and (**5**). (See Fig. 1 for representative structures of (**1**)–(**5**).)

A very recent paper [35] by Viñas, Teixidor et al. on synthesis and structural characterisation of carborane mono- and di-sulfides appeared during submission of this work. While our synthetic route to the monosulfide differed from theirs, their structural findings and interpretations broadly agree with ours.

2. Results and discussion

2.1. Preparative aspects

The new compounds (**1**) and (**3**) prepared in the present work were made from the lithio-carborane $PhCb^oLi$ with SCl_2 and $SOCl_2$, respectively, and characterised by NMR spectroscopic, elemental analytical and X-ray crystallographic study. To our knowledge, thionyl chloride has not been used to make carboranyl sulfur compounds previously. Compound **3** represents the first example containing an SO link between two *ortho*-carboranyl residues. It is easily reduced to compound **1** with hydrogen in the presence of palladium-carbon. It is, however, quite susceptible to deboronation. While compound **1** is stable in wet DMSO, compound **3** in wet DMSO gave a mixture of derivatives with *nido*-$C_2B_9H_{12}^-$ residues detected by NMR spectroscopy, and C–S cleavage was also evident. Some carboranyl derivatives are known to be susceptible to deboronation with mild solvents such as DMSO and alcohols [36–38]. Here, carboranes with C–S(O)R substituents were found to be much more susceptible to C–S bond cleavage and deboronation than those with C–SR substituents, as expected because the S(O)R residue is more electron-withdrawing than SR, facilitating nucleophilic attack on the most positive boron atom at B3 (or B6). The known compound **2** was made from $PhCb^oLi$ with sulfur and then oxidised with iodine [4].

Attempts to prepare and characterise (**4**) and (**5**), from reactions between dilithio-*ortho*-carborane and sulfur dichloride and thionyl chloride, respectively, were less successful in that, although the reactions appeared to proceed to formation of lithium chloride and the intended products (**4**) and (**5**) (obtained as colourless microcrystalline materials analysing correctly for the expected products), attempts to grow crystals suitable for X-ray characterisation were unsuccessful. Unlike **4**, compound **5** could not be purified further due to its facile deboronation and C–S bond cleavage with certain solvents.

2.2. Structural aspects

2.2.1. Systems $(PhCb^o)_2S$, $(PhCb^oS_2$, $(PhCb^oS)_2S$ and $(PhCb^o)_2SO$

Compounds **1**–**3**, like the related trisulfide $(PhCb^oS)_2S$ we have described elsewhere [27], all adopt orientations of their *exo*-SR units, and have cage C–C and *exo* C–S distances, consistent with significant dative S⇌C π-bonding from their *exo*-sulfur atoms to their cage hypercarbon atoms (see Figs. 2–4 and Table 1, which lists selected bond distances and angles for compounds **1**–**3** and the trisulfide $(PhCb^oS)_2S$). For compound **1** the *exo* bonds C–S–C lie in a plane roughly perpendicular to the C(2)–C(1)–S plane whereas for **2**,

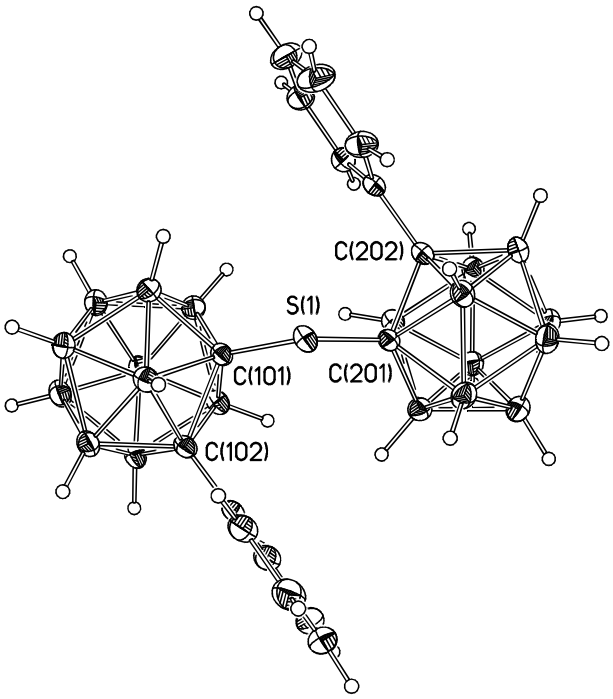

Fig. 2. Molecular structure of **1**, showing thermal ellipsoids at 50% probability level.

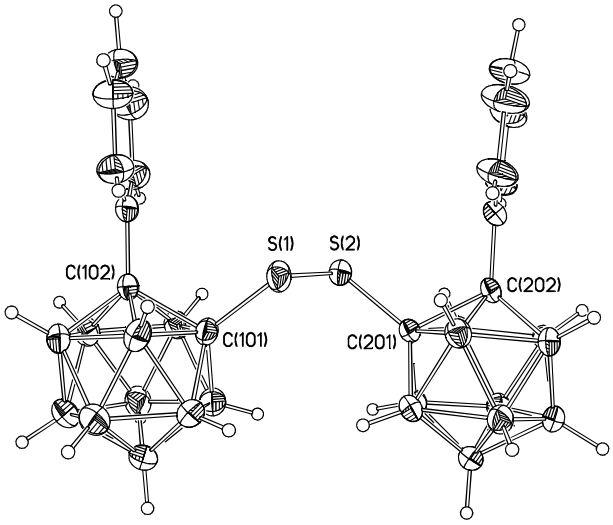

Fig. 3. Molecular structure of **2**.

3 and the trisulfide these bond orientations depart more from perpendicular (see torsion angle C–S–C/S in Table 1). We recently showed, in our discussion of a series of systems PhCb^{o}Z showing *exo* C⇐Z π-bonding (including the trisulfide (PhCb^{o}S)$_2$S), that such a perpendicular orientation optimised *exo* π-bonding [27].

The phenyl substituent on C(2) in compounds **2** and **3** also lies in a plane roughly perpendicular to the plane C(2)–C(1)–S, whereas in **1** and the trisulfide the orientations depart more from perpendicular. A perpendicular orientation minimises non-bonding repulsions with the

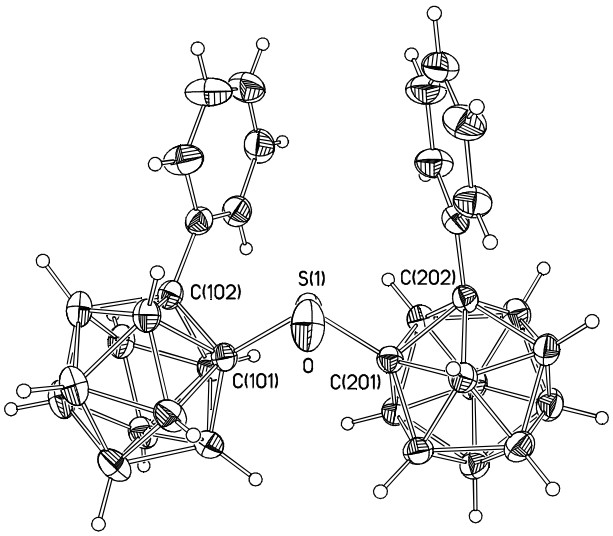

Fig. 4. Molecular structure of **3**.

other substituent on C(1), and maximises the opportunity for dative π-bonding from the π-system of the phenyl group to the carborane cage [39,40].

The cage carbon–carbon distance, C(1)–C(2), of *ortho* carborane is the cage edge link known to be most sensitive to the presence of π-bonding substituents on the cage hypercarbon atoms [27,41–43]. Its length increases as *exo* π-bonding increases. Steric effects have previously been invoked to explain the lengthening of the cage C–C bond in various disubstituted-*ortho*-carboranes [29–34]. In *ortho* carborane itself, HCb^{o}H, the C(1)–C(2) distance has been shown to be 1.62 Å by both X-ray studies of crystalline hydrogen-bonded adducts [44–47] and by gas-phase electron diffraction and calculational studies [48]. Attachment of a phenyl substituent to one carbon atom, oriented (as here) so that its ring plane is roughly perpendicular to the C(1)–C(2)–C(phenyl) plane, increases the cage C(1)–C(2) distance by some 0.04 Å to 1.66 Å [49]. In compound **2** (Table 1), where the orientations of the sulfur and phenyl substituents offer greater *exo* π-bonding effects compared to the trisulfide, the C(1)–C(2) distance is 1.755(4) Å. The sulfur atom lengthens the C(1)–C(2) bond distance by some 0.1 Å. The trisulfide has a shorter C(1)–C(2) bond distance of 1.735(3) Å, as expected for orientations of the substituents which lead to less effective *exo* π-bonding.

Surprisingly, compounds **1** and **2** have similar C(1)–C(2) and C(1)–S distances, suggesting a similar degree of S⇌C π-bonding in these two compounds. We had expected there to be weaker S⇌C π-bonding in **1**, where both carborane cages are attached to the same sulfur atom, and so competing for π-electron density from the same source. The C–S–C angle in **1** (112.8(1)°) is significantly greater than the C–S–S angle in **2** (105.5(2)°) which is due to steric repulsion between the two cages. Intramolecular B–H···H–B distances between the two

[f] E = C (**1**, **3**), S (**2**).
[g] Shows statistically significant variations, individual e.s.d.'s 0.003–0.004 Å, which relate to the orientation of the group at sulfur.
[h] Calculated as the angle between the Ph (Py) ring and the C1–C2–C(Ph/Py) moiety.

cages are 2.27, 2.40 and 2.49 Å. Interestingly, the C(1)–C(2) bond in **2** is some 0.03 Å longer than in $PyCb^oSH$ (X-ray [50]) and $PhCb^oSH$ (calc [27]) which suggests that the disulfur bridge (S–S) is a more effective π-bond donor to the *ortho*-carborane cage than is a thiol (S–H) group.

The C(1)–C(2) and C(1)–S distances in compound **3**, $(PhCb^o)_2SO$ (Table 1), differ from those in **1** and **2**, though less than expected. The electron-withdrawing oxygen atom on the bridging sulfur atom in **3** was expected to reduce its capacity for S⇌C *exo* π-bonding relative to the lower oxidation state bridging sulfur atoms in **1** and **2**. Compound **3** appears to be affected (though to a lesser extent than **1**) by repulsive interactions between the cages; shortest intramolecular B–H···H–B contacts in **3** are 2.25 and 2.37 Å, and the C–S–C angle is 106.2(1). The *exo*-C–S bond distance in **3** is some 0.07 Å longer (less π-bonding) than that in **1**. Interestingly, **1** and **3** differ in their conformations, **1** is *trans* and **3** is *cis*. Besides our derivatives and those in the very recent report [35], only two neutral RCb^oSR' systems have been structurally characterised: HCb^oSpy [51] (Py = 2′-pyridyl) and $MeCb^oSPh$ [52] with C–S distances of 1.78 Å and cage C(1)–C(2) distances of 1.64 and 1.71 Å, respectively.

2.2.2. Systems $(Cb^oS)_2$ and $(Cb^oSO)_2$

Although our attempts to prepare crystalline samples of these species suitable for X-ray characterisation were unsuccessful, we carried out calculations to determine their likely structures, encouraged by our previous experience of the reliability of such calculations for calculating the structures of derivatives of *ortho*-carborane containing dative π-bonding substituents for which structures had separately been determined by X-ray studies [27]. Selected bond distances and angles are listed in Table 2, which also gives comparable bond distances and angles determined crystallographically for the compound $(Cb^oSCb^oSiMe_2)$ [24].

The C–C bond length of 1.62 Å in the calculated structure of **4** (see Fig. 5) is identical to that of parent *ortho*-carborane [48]. This may reflect both ring strain in the C_4S_2 heterocycle and inappropriate orientations of the bonds at sulfur for *exo* dative π-bonding to the cage C–C bond. The reported crystal structure of a related heterocycle, $Cb^oS_2C{=}S$, has a cage C–C bond length of 1.632(3) Å [53]. These lengths contrast with long cage C(1)–C(2) distances of 1.80 Å reported for neutral $Cb^o(SR)_2$ systems (R = Me or Ph) [43,54]. In **5**, the two SO moieties may exist in *trans* or the more stable *cis* configuration. The *cis*-configuration is lower by only 0.1 kcal mol^{-1}. As expected, the C–S distance in the sulfoxy compound is longer than that in the sulfide.

Table 2
Selected bond distances (Å) and angles for the compounds $(Cb^oSCb^oSiMe_2)$, $(Cb^oS)_2$ and $(Cb^oSO)_2$

Compound	$(Cb^oSCb^oSiMe_2)$[a]	$(Cb^oS)_2$ (**4**)[b]	$(Cb^oSO)_2$ (**5**)[b]	HCb^oH[c]
C(1)–C(2)	1.652(4)	1.621	1.637	1.62
C(1)–S	1.794(3)	1.800	1.873	
C(1)–B(3)/(6)	1.721(6)	1.734	1.716	1.71
C–S–C	111.2(2)	106.9	101.5	
C–C–S	126.2(3)	126.6	129.2

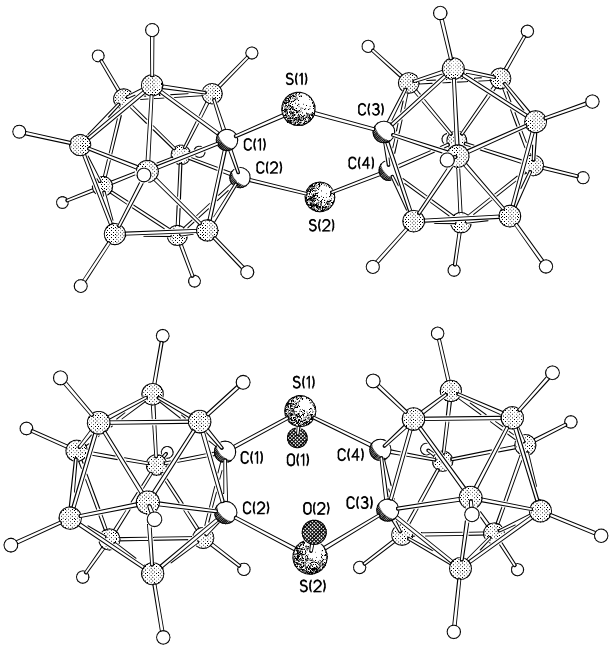

Fig. 5. MP2-optimised geometries for **4** and **5**.

3. Conclusions

The monosulfide $(PhCb^{o})_2S$ and sulfoxide $(PhCb^{o})_2SO$ in which two phenyl-*ortho*-carborane residues are linked at the cage carbon through a sulfur atom were synthesised simply by reactions of the lithio-*ortho*-carborane $PhCb^{o}Li$ with sulfur dichloride or thionyl chloride, respectively. Their structures show significant cage C(1)–C(2) bond lengthening relative to the parent carborane, an effect attributable mainly to π-bonding from the sulfur atom and to a lesser extent to π-bonding from the phenyl substituent. By contrast, the C(1)–C(2) bond lengths in the heterocyclic system $(Cb^{o}S)_2$, in which two C–S–C bridges link pairs of *ortho* carborane icosahedra, are calculated to be similar to the parent *ortho* carborane.

4. Experimental

4.1. General

All manipulations were carried out under dry, oxygen-free N_2. Commercial grade acetic acid, 10% palladium on carbon, SCl_2, $SOCl_2$ and *n*-butyllithium in hexanes were used without further purification. Dry Et_2O was obtained by reflux and distillation over Na wire. Demineralised water was used in the aqueous stages of syntheses. Compound **2** was prepared by the literature method [4].

Elemental analyses were performed using Exeter Analytical CE-440 apparatus. ^{1}H, ^{11}B, ^{13}C NMR spectra were recorded from room-temperature solutions on a Varian Unity 300 MHz spectrometer equipped with the appropriate decoupling accessories. Chemical shift values for ^{11}B NMR spectra were referenced to external $BF_3 \cdot OEt_2$, those for ^{1}H- and $^{13}C\{^{1}H\}$ NMR spectra were referenced to $SiMe_4$. ^{1}H NMR spectra were referenced to residual protio impurity in the solvent ($CDCl_3$, 7.26 ppm). ^{13}C NMR spectra were referenced to the solvent resonance ($CDCl_3$, 77.0 ppm). Chemical shifts are reported in units of parts per million downfield from reference. Mass spectra (MS) were recorded on a VG Micromass 7070E instrument under E.I conditions (EI) at 70 eV.

4.2. Preparation of *1*

Phenyl-*ortho*-carborane (0.71 g, 3.2 mmol) was dissolved in diethyl ether (20 ml) and BuLi (2.4 ml of 1.6 M solution in hexane, 3.8 mmol) was added under a nitrogen atmosphere at 0 °C. Sulfur dichloride (0.1 ml, 1.6 mmol) in diethyl ether (5 ml) was added. The solution was stirred at ambient temperature for 2 h. The solution was diluted with ether (60 ml). A white precipitate (0.22 g) was filtered off. The solution was washed with water (3×50 ml) and dried over $MgSO_4$. The solvent was removed under reduced pressure to yield white crystals. The crystals were washed with 60–80° petroleum ether to remove unreacted carborane, then recrystallised from a 50:50 benzene–hexane mixture (0.36 g, 49%). M.p. 237 °C. *Anal*. Calc. for $C_{16}H_{30}B_{20}S$: C, 40.8; H, 6.4. Found: C, 41.0; H, 6.5%. EI-MS 452–476 (with characteristic carborane isotope pattern). δ_H 7.6–7.2 (phenyl), 3.8–0.8 (BH). δ_B −1.3 (1B), −3.2 (1B), −9.8 (6B), −12.0 (2B).

4.3. Preparation of *3*

To a solution of 1-phenyl-*ortho*-carborane (925 mg, 4.2 mmol) in dry ether (40 ml) at 0 °C was added *n*BuLi in hexanes (1.6 ml, 2.7 M, 4.2 mmol), and this was stirred under N_2 for 1 h. $SOCl_2$ (0.19 ml, 2.1 mmol) was added, forming a white precipitate (LiCl). After warming to room temperature, the solid was removed by filtration, and the ether evaporated, leaving a white solid. Pure **3** was obtained by recrystallisation from a mixture of ethyl acetate and cyclohexane (1:9), affording colourless crystals. (0.35 g, 34%). M.p. 262 °C. *Anal*. Calc. for $C_{16}H_{30}B_{20}SO$: C, 39.5; H, 6.2. Found: C, 39.7; H, 6.3%. EI-MS 484-489 (with characteristic carborane isotope pattern). δ_H 7.4–7.2 (phenyl), 3.8–0.8 (BH). δ_B 1.5 (1B), −3.1 (1B), −8.6 (6B), −11.7 (2B). δ_C 131.9, 131.3, 128.8, 128.5, 92.3, 87.3.

4.4. Reduction of *3*

Hydrogen gas was slowly bubbled through a stirred suspension of **3** (84 mg, 0.17 mmol) and 10% palladium

on carbon (15 mg) in acetic acid (10 ml) for 15 h. Removal of the solvent from the filtered solution gave crystalline **1** (54 mg, 66%).

4.5. Preparation of **4**

ortho-Carborane (1.11 g, 7.72 mol) was dissolved at 0 °C in dry ether (30 ml) under N_2 and *n*BuLi in hexanes (6.4 ml, 2.42 M, 15.4 mmol) was added, precipitating white 1,2-dilithio-*ortho*-carborane. After 15 min stirring, SCl_2 (0.50 ml, 811 mg, 7.9 mmol) was added and the reaction was left to warm to room temperature over 1 h. Water (30 ml) was added and the ether layer was further washed before being isolated and dried over $MgSO_4$. Filtration and removal of the solvent gave a white solid which was sublimed in vacuo at 40 °C to remove unreacted *ortho*-carborane, then at 100 °C to give a white powder identified as pure **4**. 73.6 mg (5%). M.p. 122 °C. *Anal*. Calc. for $C_4H_{20}B_{20}S_2$: C, 13.8; H, 5.8. Found: C, 14.0; H, 5.9%. EI-MS, 346–352 (typical carborane isotope pattern).

4.6. Attempted synthesis of **5**

Ortho-carborane (0.723 g, 5.02 mmol), was dissolved at 0 °C under N_2 in dry ether (30 ml) and *n*BuLi in hexanes (4.3 ml, 2.42 M, 10.4 mmol) was added, precipitating white 1,2-dilithio-*ortho*-carborane. After 15 min stirring, $SOCl_2$ (0.37 ml, 5.07 mmol) was added and the reaction was left to warm to room temperature overnight. Water (30 ml) was added, dissolving the nascent LiCl, and the ether layer was washed with further water (2×30 ml) before being isolated and dried over $MgSO_4$. Removal of the solvent in vacuo gave a white solid. This was sublimed in vacuo at 50 °C to remove unreacted *ortho*-carborane. The unsublimed material contained **5**, based on mass spectroscopy with a carborane peak pattern observed at 375–381 (EI-MS). Purification attempts of the white powder (458 mg) were unsuccessful – several solvents were shown by boron NMR spectroscopy to degrade the carborane cages.

4.7. Crystallography

Single-crystal diffraction experiments (Table 3) for **1** and **3** were carried out on a Rigaku AFC6S 4-circle diffractometer, for **2** on a Stoe STADI4 4-circle diffractometer using graphite-monochromated Mo Kα (**1**) and Cu Kα (**2**, **3**) radiation. The structures were solved by direct methods and refined by full-matrix least-squares methods with F^2 of all unique data, using SHELXTL software. Hydrogen atoms positions were freely refined (except for the phenyl groups in **3**, in which they were constrained with a riding model). Structure **2** has been reported elsewhere [35]. The non-standard unit cell setting used in that report can be transformed by the operation $(001, \bar{1}00, 0\bar{1}0)$ to give the reduced cell $a = 10.511(5)$ Å, $b = 11.579(3)$ Å, $c = 12.917(4)$ Å, $\alpha = 85.09(3)°$, $\beta = 69.05(3)°$, $\gamma = 77.72(3)°$. The volume of this cell (1434.5(9) Å^3) is ca. 0.8% larger than found by us, although both experiments were carried out at room temperature. Our data gave rather lower residual electron density peaks near the sulfur atoms, but these can be successfully refined also as part of a very minor disorder component, with an occupancy of 0.059(3), similar to that recently reported. This disorder has no significant effect on the geometry of the molecule. Overall our results are of greater precision. Full crystallographic data, excluding structure factors, have been deposited at the Cambridge Crystallographic Data Centre, CCDC Nos. 269295, 269296 and 269297.

4.8. Computational section

The ab initio computations were carried out with the GAUSSIAN 03 package [55]. The geometries of **4** and **5** (*cis* and *trans*) were optimised at the HF/6-31G* level with no symmetry constraints. Frequency calculations were computed on these optimised geometries at the HF/6-31G* level and revealed no imaginary frequencies. Optimisation of these geometries were then carried out at the MP2/6-31G* level. Total energies at MP2/6-31G* are −1454.57589 a.u. for **4** and −1604.55461 (*trans*) and −1604.55479 (*cis*) for **5**. The C_4S_2 rings in these geometries are planar.

Dedicated to Malcolm Chisholm on the occasion of his sixtieth birthday.

Abstract

The synthesis of 3,4-dialkoxy and 3,4,5-trialkoxy derivatives of 2- and 3-stilbazole are reported along with their related complexes with silver dodecylsulphate and silver triflate. The single crystal structures of one ligand and two complexes are reported. While none of the complexes of the 2-stilbazoles is liquid-crystalline, several complexes of the 3-stilbazoles show columnar mesophases as characterised by polarised optical microscopy and X-ray diffraction. The liquid crystal phase behaviour is compared with that of the parent 4-stilbazole derivatives.

1. Introduction

The study of metallomesogens [1,2] represents a major subject within liquid crystals that has developed strongly within the last twenty years or so. Large swathes of the periodic table have been investigated and a very large number of different elements have been incorporated into mesomorphic systems in one way or another. In a developing area such as this, there is a simultaneous need constantly to discover new systems, perhaps targeted because of particular properties, and to undertake systematic structure/function studies in order to determine how the properties of the new systems may be compared with and understood in relation to the existing literature. Both approaches have been adopted in the study of metallomesogens, and one feature of the latter has been the extra structural flexibility offered on account of the coordination around the metal under study.

Our own work has contributed to both approaches to the subject, but in particular regard to the latter, systematic approach, we have engaged extensively with the liquid crystal behaviour of stilbazoles in areas such as hydrogen- [3] and halogen- [4] bonding as well in combination with metals [5]. In particular, we have looked at both calamitic and polycatenar *bis*(ligand) metal complexes of Pd, Pt [6] and Ag [7] and have looked at how

control may be exercised over the nature of the phase formed, particularly in relation to the formation of the cubic phase [8], and the lamellar-to-columnar transition in polycatenar systems [9].

Within these studies, silver(I) complexes have offered the greatest opportunity for systematic evaluation due both to the availability of a range of stilbazoles and to the fact that the complexes are formally ionic making different anions available. In our initial work with 4-alkoxy-4′-stilbazoles (**1**, Fig. 1) we examined a range of counter-anions, but as the work progressed to complexes of di- and tri-alkoxy stilbazoles (**2**, **3** and **4**, Fig. 1), we settled on studies using triflate and alkyl sulphates (mainly dodecylsulphate).

Having investigated the effect of ligand chain substitution on these systems, more recently we turned our attention to varying the structure of the core by synthesising silver(I) complexes of a range of 4-alkoxy-2′- and 3′-stilbazoles (**5** and **6**, Fig. 2) [10]. Whereas with complexes of the 4-stilbazoles we had found polymorphism that included nematic and cubic phases, these isomeric systems showed a much more limited mesomorphism and only the SmA phase was seen.

In order to complete this study, we then turned our attention to polycatenar [11,12] systems. Our previous investigations had shown that the 3,4-tetracatenar complexes with DOS anions (**2a**) showed a progression from cubic to columnar (Col_h) phase as *n* increased, as did the related triflate complexes (**2b**) but at longer chain lengths. These results are consistent with arguments that invoke surface curvature as a driving force for this transition by analogy with the behaviour of lyotropic materials [9,13]. The mesomorphism of the 3,5-tetracatenar complexes (**3a**,**b**) and the hexacatenar complexes (**4a,b**) was dominated by the formation of columnar phases [14]. We have, therefore, undertaken the synthesis of 3,4-dialkoxy and 3,4,5-trialkoxy derivatives of 3′- and 2′-stilbazole, and have synthesised their complexes with silver(I). This work, along with the characterisation of the mesomorphism by optical microscopy and X-ray diffraction, is now described.

2. Synthesis

In previous studies where stilbazoles had been used, we had employed either Heck coupling methodologies [15] or condensation reactions [3b], but in the present case, neither was particularly effective. Thus, here we employed a Siegrist methodology [16,17] in which a benzylidene group (derived from an imine) is transferred to an aromatic aldehyde function leading to a 1,2-diarylethene with high stereoselectivity. The approach, which we have used recently in the construction of prototypical dendrimers [18], and has been used in the synthesis of related stilbazole systems [19], is very effective and allowed access to the desired materials in good yield as indicated in Scheme 1.

Thus, 3,4-dialkoxybenzaldehyde (from 3,4-dihydroxybenzaldehyde and the appropriate 1-bromoalkane) [13] was reacted with aniline in ethanol to give *N*-phenyl-3,4-dialkoxybenzaldimine in isolated yields of 89–97%. The imine, which was used without further purification, was then treated with either 3- or 2-picoline in dimethylformamide in the presence of an excess of potassium *tert*-butoxide to yield 3,4-dialkoxy-3′-stilbazole (**7**) or 3,4-dialkoxy-2′-stilbazole (**8**), respectively, as colourless solids

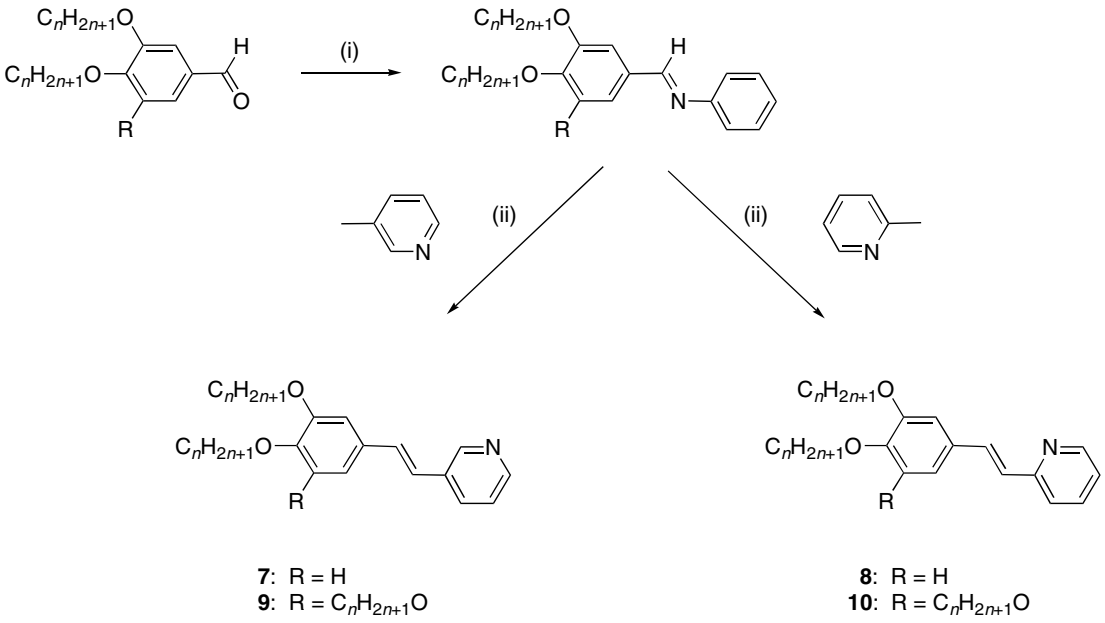

Scheme 1. Synthesis of the new stilbazole ligands: (i) Ph–NH_2/EtOH/TsOH (cat); (ii) KO^{t}Bu/DMF (ligands are identified in the text as, e.g., **8**-*n*, where *n* refers to the number of carbons in the alkoxy chain).

in moderate-to-good yields (over 53–88%) after purification by column chromatography on silica gel and crystallisation from hot hexane. The *trans* nature of the two isomeric compounds was confirmed by the ^{1}H NMR spectra with coupling constants of the AB systems of around 16 Hz. 3,4,5-Trialkoxystilbazoles (**9** and **10**) were prepared similarly from 3,4,5-trialkoxybenzaldehyde [14].

The silver(I) dodecylsulfate complexes of all four ligands were prepared by stirring the appropriate stilbazole with silver(I) dodecylsulfate in dichloromethane at room temperature in the dark for 4 h, yielding complexes **11a**, **12a**, **13a** and **14a**, respectively (Fig. 3). The silver(I) triflate complexes were similarly accessed using acetone as solvent to give complexes **11b**, **12b**, **13b** and **14b** (Fig. 3) in good yield.

2.1. Crystal and molecular structure of 3,4-dimethoxy-3′-stilbazole and of complexes *11b-1* and *11b-4*

In order to obtain more detailed information about the conformation of these new polycatenar stilbazoles and some of their complexes, 3,4-dimethoxy-3′-stilbazole was prepared and single crystals grown successfully by crystallisation from hexane. Single crystals of the silver triflate complex of this ligand (**11b-1**) and of the related 3,4-butyloxy-3′-stilbazole (**11b-4**) were also obtained from dichloromethane/methanol and from hot hexane, respectively. Crystallographic data are collected in Table 1.

2.1.1. 3,4-Dimethoxy-3′-stilbazole (7-1)

Two views of the structure are shown in Fig. 4. The molecular structure consists of two essentially planar moieties, namely, the pyridine ring (N1, C1 to C5) bonded *trans* across a C=C double bond to a 3,4-dimethoxystyryl group (C8 to C13, O1, C14, O2, C15). The planar fragments are related by a dihedral angle of 20.9(3)°. Although there are four possible 'planar' conformations about the trans double bond (180° rotations of the pyridyl and dimethoxyphenyl rings), only one is observed in the crystal structure.

2.1.2. Bis(3,4-dimethoxy-3′-stilbazole)silver(I) triflate (*11b-1*)

Two views of the structure are shown in Fig. 5. The molecular structure is quite complex, with two conformationally differing silver complexes in the asymmetric unit. Here three of the 3,4-dimethoxy-3′-stilbazole ligands (labelled **A**, **B** and **C**) adopt the same basic conformation as observed for **7-1**, but with slightly varying degrees of twist (16.1(4)°, 13.2(4)°, 14.7(5)°). The fourth (labelled **D**) has the pyridyl group rotated by 180° about the C64–C66 bond with respect to the other ligands. It still has adopts a similar twist (15.5(4)°). Although there are no Ag–Ag close contacts, there are Ag–$O_{triflate}$ contacts ranging from 2.84(1)–3.13(1) Å. These are similar, if a touch longer, than those found in known silver triflate complexes. In fact the triflate anions act as bridges between the two differing silver complexes with the third oxygen of each triflate co-ordinating towards the disordered water molecule. This results in an infinite slipped stack (Fig. 6).

2.1.3. Bis(3,4-dibutyloxy-3′-stilbazole)silver(I) triflate (*11b-4*)

Two views of the structure are shown in Fig. 7 and structural refinement parameters and crystal data are

summarised in Table 1. The molecular structure is dimeric and as such is broadly the same as that found for the silver(I) octylsulfate and silver(I) perchlorate complexes described by, for example, Adams et al. [20] and Gallardo et al. [21], respectively. It consists of two essentially planar bis(3,4-dibutoxy-3′-stilbazole)silver(I)

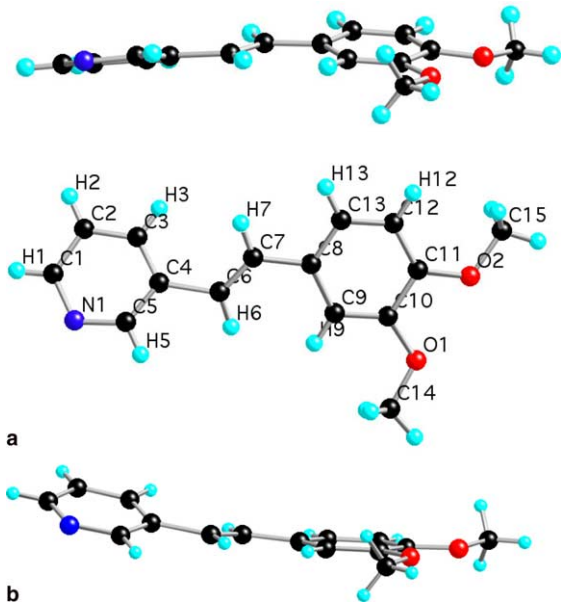

Fig. 4. Molecular structure of the 3,4-dimethoxy-3′-stilbazole.

cations that are arranged parallel to one another, supported by the two triflate anions. The Ag–Ag distance is 3.136(1) Å which is very similar to the equivalent distance in the octylsulfate (ca. 3.2 Å) and perchlorate (ca. 3.35 Å) salts. The triflate anions effectively bridge the dimeric structure and there are three, ionic Ag–O contacts at about 2.8 Å with a fourth Ag–O distance of 3.4 Å. This is slightly different from the octylsulfate and perchlorate structures where all four Ag–O distances are in the range 2.7–2.9 Å. Here, there are no strong interactions beyond the dimer and its pair of triflate anions. Also, and as can be seen clearly in Fig. 7, the stilbazoles exist in two differing conformations. Thus, two of the stilbazoles adopt the same conformation as **7-1**, while the other two adopt its 'inverse' (i.e. both rings rotated by 180° with respect to the *trans* double bond). Interestingly the stilbazoles that adopt the same conformation as **7-1** exhibit a greater twist (19.4(1)° and 33.6(1)°) compared to the two that adopt the inverse (13.9(1)° and 10.7(1)°).

Of course, one thing that is not known in relation to both silver complexes is the nature of the species present in the mesophase. Previously, structural arguments have suggested [13] that the dimeric structure is maintained in the columnar phase of mesomorphic, polycatenar DOS salts and this may be the case here, too, but in the absence of hard information, the discussion of the mesomorphism found below will make no assumptions about the state of aggregation.

2.2. Mesomorphism of the new silver(I) complexes

The mesomorphic behaviour of the new complexes was studied by polarised optical microscopy, differential scanning calorimetry (DSC), X-ray diffraction and miscibility studies. The thermal behaviour of the new complexes is collected in Table 2 and we found that the compounds behaved reproducibly over the lifetime of the DSC and microscopy experiments carried out.

Neither of the new 3,4-dialkoxy-2′-stilbazole ligands (**8**) was mesomorphic, rather melting to an isotropic liquid at 55.2 °C for $n = 8$ and at 68.7 °C for $n = 12$, and complexation of these two ligands to AgDOS (**12a**) or AgOTf (**12b**) did not lead to mesomorphic materials.

However, complexation of the non-mesomorphic 3,4-dialkoxy-3′-stilbazoles (**7**) with the two silver complexes did lead to mesomorphic, materials providing the alkoxy chain was long enough. Whilst the un-complexed ligand was not mesomorphic, melting straight to the isotropic phase between 54.2 °C for $n = 4$ and 68.0 °C for $n = 12$, complex **11a** was mesomorphic for $6 \leqslant n \leqslant 12$, with all homologues displaying a columnar hexagonal phase, characterised by its optical texture (Fig. 8).

[a] Complex was in the mesophase at room temperature.

Two of the complexes **11b** were mesomorphic showing a columnar hexagonal phase over a narrow temperature range, monotropic for $n = 10$ and enantiotropic for $n = 12$.

None of the new 3,4,5-trialkoxystilbazole ligands (**9** or **10**) was mesomorphic and all melted directly into the isotropic phase. However, complexation of 3,4,5-trialkoxy-3′-stilbazoles to silver(I) dodecylsulfate or silver(I) triflate resulted in complexes (**13a** and **13b**) that were mesomorphic. The octyloxy homologue of complex **13a** was already in a columnar hexagonal mesophase at room temperature and cleared to the isotropic phase on heating to 86.8 °C. The dodecyloxy homologue also showed a columnar hexagonal phase from 37.1 to 81.2 °C, a smaller temperature range than for $n = 8$. These mesophases were characterised by optical microscopy.

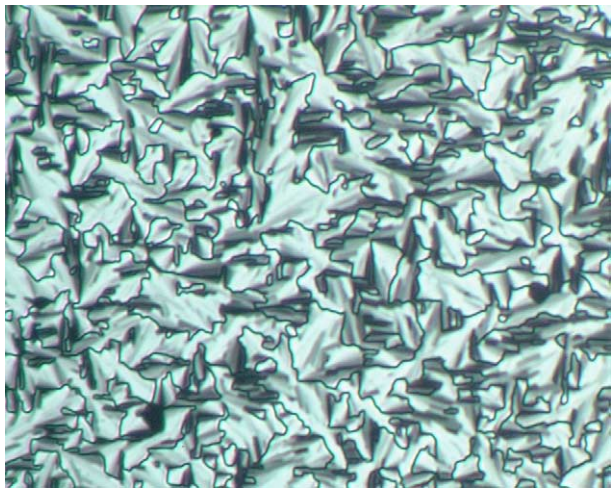

Fig. 8. The optical texture of the columnar hexagonal phase of **11a**-12 on cooling from the isotropic phase at 93.4 °C.

Bis(3,4,5-trioctyloxy-3′-stilbazole)silver(I) triflate was a pasty solid that melted at 39.8 °C to a columnar hexagonal phase which cleared to the isotropic at 105.3 °C. The mesophase was characterised by polarised optical microscopy from its optical texture. The dodecyloxy homologue of complex **13b** showed two crystal phases before melting to a columnar hexagonal phase at 50.0 °C and clearing at 119.8 °C. On cooling, the mesophase reappeared at 117 °C and remained until crystallisation at 21.8 °C. On second heating, the complex melted straight into the mesophase at 30.4 °C but cleared at the same temperature as the first heating. Subsequent cooling and heating repeated the behaviour of the second cycle so crystallisation from a solvent must result in a crystalline form that needs to rearrange on heating before it can melt into the mesophase. The columnar hexagonal phase was characterised from its optical texture (Fig. 9).

2.3. X-ray diffraction

X-ray diffractions studies were carried out on complexes **11a**, **11b**, **13a** and **13b**, and the results for complex **11a**, **13a** and **13b** are collected in Table 3, which contains both experimental and, in parentheses for cases with >1 observed reflection, calculated lattice parameters; the lattice parameter, a, and columnar cross-sectional area,

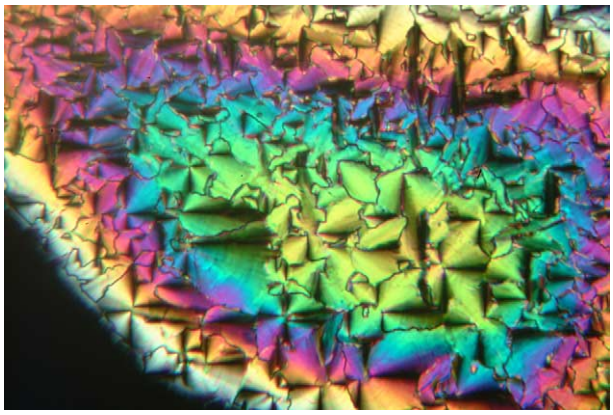

Fig. 9. The optical texture of the columnar hexagonal phase of **13b**-12 on cooling from the isotropic phase at 41.9 °C.

S, are derived from calculated data where these are available. Due to the small temperature range of the mesophases of **11b**, no conclusive results were obtained by X-ray diffraction studies so the mesophase remains assigned from its optical texture alone.

For **11a**-12 the X-ray diffraction studies confirmed the assignment of the mesophase as columnar hexagonal since two, sharp, small-angle reflections were observed in the patterns corresponding to the squared spacing ratios 1:3, and to the indexation $(h\,k) = (1\,0)$ and $(1\,1)$, as shown in Fig. 10. Diffuse reflections were also recorded for all complexes at around 4.5 Å, which corresponds to the liquid-like order of the molten alkoxy chains, and at around 10 Å, which may be due to loose interactions between dimeric species formed by these silver complexes [10].

The lattice parameter *a*, for the dodecyloxy homologue was found to be ca. 42 Å, which is around 12 Å smaller than the estimated length of the complex in its most extended form (53.8 Å). It is possible that this is due to the way the molecules may pack together in the repeat unit with the chains curled round in order to fill space efficiently (Fig. 11). However, another possibility is that in common with the generalised model for the packing of polycatenar mesogens that some of us advanced recently [22], the complexes can tilt at some angle within the column or otherwise organise to give a circular cross-section normal to the column direction that then allows formation of a columnar phase of hexagonal symmetry. The model in Fig. 11 would be one possible expression of this general approach.

The calculated value of the reflections is deduced from the mathematical expression: $\langle d_{10}\rangle = \frac{1}{N_{hk}}(\sum_{hk} d_{hk}.\sqrt{h^2+k^2+hk})$, where N_{hk} is the number of $h\,k$ reflections for the Col_h phase; *a* is the lattice parameter of the Col_h phase $(a = \frac{2}{\sqrt{3}}\langle d_{10}\rangle)$, *S* is the lattice area $(S = a\langle d_{10}\rangle)$.

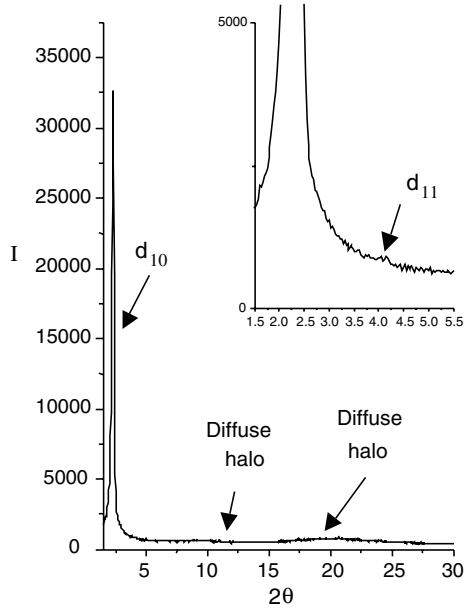

Fig. 10. X-ray diffraction pattern of **11a**-12 at 90 °C.

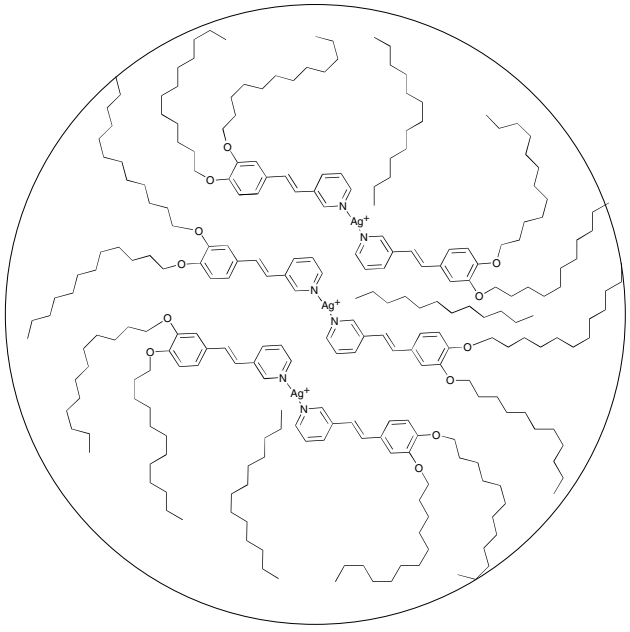

Fig. 11. Schematic of the possible packing of molecules in a columnar repeat unit.

For complexes **11a** with $n = 6$, 8 and 10, only one reflection was observed and so it was impossible to make an unequivocal assignment of the mesophase symmetry on this basis. Thus, to try to confirm the identity of the phase they form, contact preparations were carried out. Contact preparations between compound **11a**-12 and either compound **11a**-8 or **11a**-10 failed to show any miscibility as shown for **11a**-10 and **11a**-8 in Fig. 12; the same experiment for **11a**-6 was impossible due to incompatible temperature ranges. Such immiscibility does not preclude assignment of the phase of the shorter chain homologues of **11a** as Col_h and indeed, given the comparison of the d(10) data within the homologous series (Table 3), this is our assignment, which we believe to be sound.

X-ray diffraction studies of **13a**-12 confirmed the columnar hexagonal nature of the mesophase displayed (Table 3) since four, sharp, small-angle reflections were observed (Fig. 13), corresponding to the squared spacing ratios 1, 3, 4 and 7 with indexation $(h\,k) = (1\,0)$, (1 1), (2 0) and (2 1). In the case of **13b**-12, two, sharp, small-angle reflections were observed in the diffraction pattern corresponding to the squared spacing ratios 1 and 3 with indexation $(h\,k) = (1\,0)$ and (1 1). For **13a**-12 and **13b**-12, the lattice parameter, a, was around 14 and 11 Å shorter, respectively, than the estimated length of the complexes in their most extended form (53.8 Å). This behaviour was discussed above. Shorter-chain homologues of both triflate and DOS salts were characterised by optical microscopy alone since no satisfactory X-ray results were obtained.

3. Discussion

Fig. 14 summarises the thermal behaviour of complexes **11a** and **12a** and compares it with the behaviour of the 'parent' complexes bis(3,4-dialkoxy-4′-stilbazole)silver(I) dodecylsulfate (**2a**) (see Fig. 15).

The most noticeable difference in the mesomorphism of these three complexes is in the number of mesophases displayed. Thus, the parent complex (**2a**) is polymorphic and shows a cubic phase for $4 \leqslant n \leqslant 10$ and a Col_h phase for $6 \leqslant n \leqslant 12$. Complex **11a**, however, shows only one mesophase, namely a columnar hexagonal phase for $n \geqslant 6$. Thus, the melting point drops steeply from $n = 4$ (99.8 °C) to $n = 6$ (36.5 °C) and at the latter chain length a Col_h phase is introduced. The temperature range of the mesophase stays roughly constant with chain length (between 23 and 20 °C), but the temperature at which the phase is seen does increase with chain length ($T_{Col\text{-}I} = 60.0$, 80.9, 94.9 and 95.7 °C for $n = 6$, 8, 10 and 12, respectively). Combined with the very limited mesomorphism of the triflate analogues (**11b**) and the absence of mesomorphism in all the tetracatenar complexes of the 2-stilbazoles, the observations once more suggest a profound effect consequent on the reduction in anisotropy associated with the isomeric ligands.

In these complexes, the dodecylsulfate anion acts as a flexible lateral substituent and, therefore, prevents efficient packing of the molecules so the transition temperatures are lowered. Since the core length of these silver(I) complexes of the 3-stilbazole ligand is shorter than that of the complexes of the 4-stilbazole ligand, the dodecylsulfate alkyl chain is expected to extend beyond the length of the silver(I) core as it does in the case of the 'parent' [7].

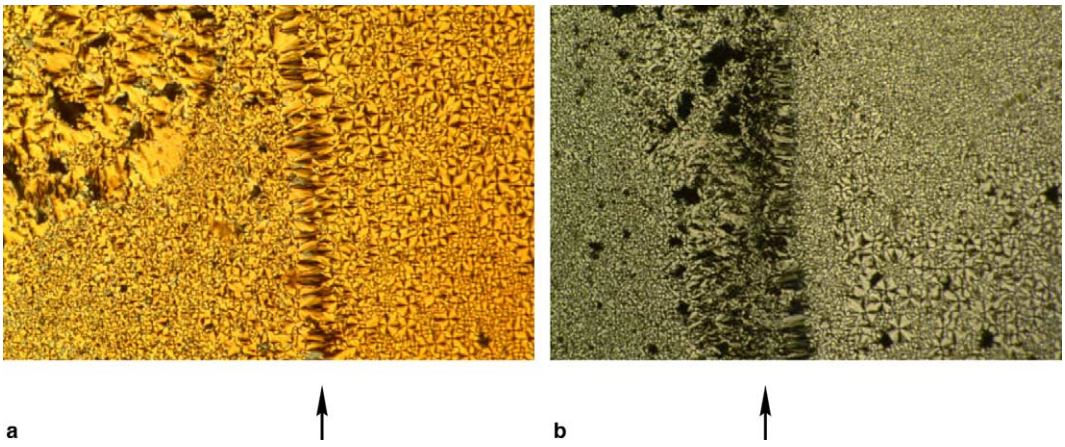

Fig. 12. Contact preparation (a) at 88.7 °C between the Col_h phase of complex **11a**-12 (left) and the unidentified mesophase of complex **11a**-10 (right), and (b) at 79.9 °C between **11a**-12 (left) and **11a**-8 (right). Lines of immiscibility are indicated by arrows.

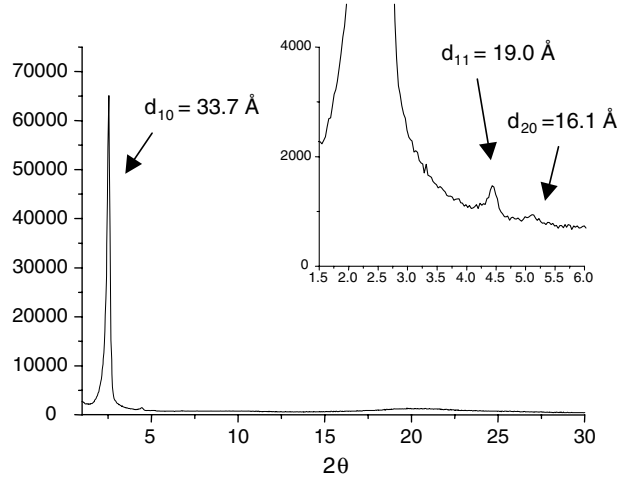

Fig. 13. X-ray diffraction pattern for **13a**-12 at 70 °C.

This affects the balance between the relative volumes of the core and the chain, a factor known to be important in determining the mesomorphism of polycatenar systems [7,9]. On this basis, the absence of a cubic phase in these isomeric materials may be rationalised. Further, it appears true that cubic phase formation requires the presence of discrete molecular aggregates [8,9,23], and the increased steric congestion caused by the reduction in ligand and complex anisotropy, as evidenced in the figures above from the crystal structures, may be the cause.

Because, in general, the mesomorphism of 3,4,5-hexacatenar complexes is restricted to a columnar phase, few examples were synthesised. In common with the preceding materials, none of the 2-stilbazole derivatives was mesomorphic and they melted between 55 and 67 °C with little apparent dependence on the anion.

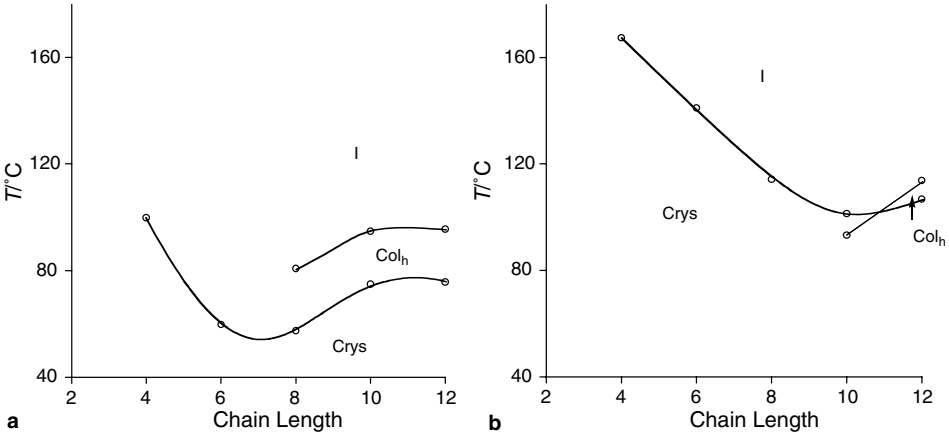

Fig. 15. Phase diagrams of complexes **11a** (a) and **11b** (b) plotted on the same scale.

4. Experimental

All solvents and chemicals were used as received, apart from THF which was dried by distillation over sodium and benzophenone immediately prior to use under an atmosphere of oxygen-free nitrogen. NMR spectra were recorded on a Bruker DRX-400, ACF 300 or ACF-200, operating at 400, 300 or 200 MHz, respectively, for protons and 100.6, 75.4 or 50.3 MHz, respectively, for carbon. Analysis by hot stage microscopy was carried out using an Olympus BX50 microscope equipped with a Link-Am HFS91 hot stage, and TMS92 controller and LNP2 cooling unit. Analysis by DSC was carried out on a Perkin–Elmer DSC7 instrument using heating and cooling rates of 10 and 5 K min^{-1}. All analytical data are collected in Table 4.

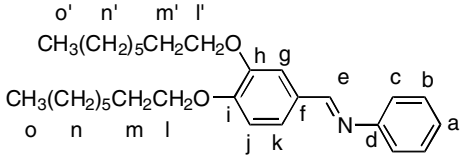
The XRD patterns were obtained with two different experimental set-ups. In the first, a linear monochromatic Cu Kα_1 beam ($\lambda = 1.5405$ Å) was obtained using a Guinier camera with a sealed-tube generator (900 W). In the second, a Debye–Scherrer camera equipped with a bent quartz monochromator and an electric oven was used. In both cases, the crude powder was filled in Lindemann capillaries of 1 mm diameter. An initial set of diffraction patterns was recorded with a curved Inel CPS 120 counter gas-filled detector linked to a data acquisition computer; periodicities up to 60 Å can be measured, and the sample temperature controlled to within ±0.05 °C. The second set of diffraction patterns was recorded on an image plate; cell parameters were calculated from the position of the sharp reflections at the smallest Bragg angle, which were in all cases the most intense. Periodicities up to 90 Å can be measured, and the sample temperature controlled to within ±0.3 °C. In each case, exposure times were varied from 1 to 24 h depending on the mesophase being observed and upon the specific reflections being sought (weaker reflections obviously taking longer exposure times).

Suitable single crystals were selected and data collected on a Bruker Nonius KappaCCD Area Detector at the window of a Bruker Nonius FR591 rotating anode ($\lambda_{Mo K\alpha} = 0.71073$ Å) driven by COLLECT [24] and DENZO [25] software at 120 K. The structure was determined in SHELXS-97 [26] and refined using SHELXL-97 [27].

4.1. Preparation of 3,4-dialkoxybenzylideneaniline

All homologues were made in the same way as 3,4-dioctyloxybenzylidene aniline described.

3,4-Dioctyloxybenzaldehyde (1.09 g, 3.0 mmol) was dissolved in ethanol (60 cm^3) and aniline (0.39 g, 4.2 mmol) was added. A few crystals of *para*-toluene sulfonic acid were added and the solution became yellow. It was stirred at room temperature for 2 h after which time there was no precipitate, so the mixture was placed in the freezer for 15 h. A white fluffy solid precipitated and was filtered off and used without further purification (1.27 g, 97%). For the longer-chain homologues, heating was required to dissolve the starting benzaldehyde and the product precipitated upon cooling the solution to room temperature.



^{1}H NMR (400 MHz, CD_2Cl_2): $\delta = 8.39$ (1H, s, H**e**), 7.60 (1H, d, H**g**, $^4J_{HH} = 1.4$ Hz), 7.42 (2H, m, H**b**), 7.35 (1H, dd, H**k**, $^3J_{HH} = 8.2$ Hz, $^4J_{HH} = 1.4$ Hz), 7.24 (1H, m, H**a**), 7.23 (2H, m, H**c**), 6.97 (1H, d, H**j**, $^3J_{HH} = 8.2$ Hz) 4.11 (2H, t, H**l′**, $^3J_{HH} = 6.6$ Hz), 4.09 (2H, t, H**1**, $^3J_{HH} = 6.6$ Hz), 1.87 (2H, m, H**m′**), 1.84 (2H, m, H**m**), 1.44 (20H, m, H**n**, H**n′**), 0.92 (6H, 2 × t, H**o**, H**o′**, $^3J_{HH} = 6.7$ Hz).

^{13}C NMR (100.61 MHz, CD_2Cl_2): $\delta = 160.1$ (**e**), 152.8, 152.7 (**i**,**d**), 149.9 (**h**), 129.9 (**f**), 129.5 (**b**), 125.8

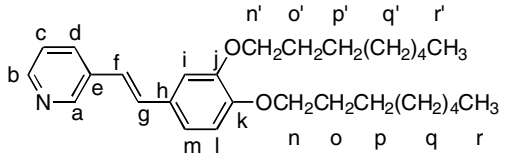
*4.2. Preparation of 3,4-dialkoxy-3′-stilbazole (**7**) and 3,4-dialkoxy-2′-stilbazole (**8**)*

The preparation of 3,4-dodecyloxy-3′-stilbazole will be described; the same method was used for the other homologues. The series of 3,4-didecyloxy-2′-stilbazoles were made in the same way except that 3-picoline was replaced by 2-picoline. The reaction was carried out in an atmosphere of argon.

3,4-Didodecyloxybenzylidene aniline (5.00 g, 10.1 mmol) was dissolved with heating in DMF (50 cm^3). 3-Picoline (0.82 g, 8.8 mmol) was added with stirring, followed by potassium *tert*-butoxide (4.40 g, 36.0 mmol) in fractions. The solution immediately turned dark red. The system was heated to 80 °C and was stirred for 2.5 h. After cooling, HCl solution (10%) was added dropwise until the pH of the mixture was neutral. Water (100 cm^3) was added and the solution became yellow. The product was extracted into DCM (2×75 cm^3) and was washed with $NaHCO_3$ solution (200 cm^3 saturated) and water (200 cm^3). The organic phase was dried over magnesium sulfate and the DCM was removed. The

residue was then taken into toluene (100 cm^3) and washed repeatedly with water (4×100 cm^3) to remove the DMF. The toluene was then removed in vacuo to leave a light brown solid. This was purified by column chromatography on silica gel using DCM:methanol, 100:1 as eluant. A few drops of triethylamine were added to prevent the stilbazole sticking to the column. The product was then crystallised from hot hexane to give a colourless powder (3.17 g, 73%).



(7)

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.70$ (1H, d, H**a**, $^4J_{HH} = 1.8$ Hz), 8.46 (1H, dd, H**b**, $^3J_{HH} = 4.7$ Hz, $^4J_{HH} = 1.8$ Hz), 7.81 (1H, dt, H**d**, $^3J_{HH} = 7.9$ Hz, $2 \times {}^4J_{HH} = 1.8$ Hz), 7.28 (1H, dd, H**c**, $^3J_{HH} = 7.9$ Hz, $^3J_{HH} = 4.7$ Hz), 7.10 (1H, AB, H**g**, $J_{AB} = 16.4$ Hz), 7.09 (1H, d, H**i**, $^4J_{HH} = 1.9$ Hz), 7.06 (1H, dd, H**m**, $^3J_{rm\ HH}$ 8.3 Hz, $^4J_{HH} = 1.9$ Hz), 6.92 (1H, AB, H**f**, $J_{AB} = 16.4$ Hz), 6.87 (1H, d, H**l**, $^3J_{HH} = 8.3$ Hz), 4.06 (2H, t, H**n**′, $^3J_{HH} = 6.7$ Hz), 4.02 (2H, t, H**n**, $^3J_{HH} = 6.8$ Hz), 1.84 (4H, m, H**o**, H**o**′), 1.50 (4H, m, H**p**, H**p**′), 1.33 (16H, m, H**q**, H**q**′), 0.90 (6H, $2 \times$ t, H**r**, H**r**′, $^3J_{HH} = 6.9$ Hz).

(8)

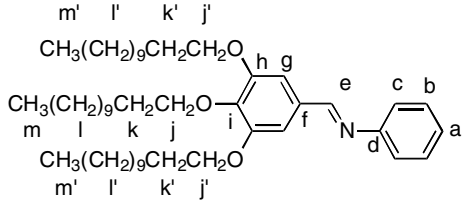
^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.59$ (1H, dd, H**a**, $^3J_{HH} = 4.8$ Hz, $^4J_{HH} = 1.8$ Hz), 7.65 (1H, dt, H**c**, $2 \times {}^3J_{HH} = 7.7$ Hz, $^4J_{HH} = 1.8$ Hz), 7.55 (1H, AB, H**g**, $J_{AB} = 16.1$ Hz), 7.38 (1H, d, H**d**, $^3J_{HH} = 7.9$ Hz), 7.16 (1H, d, H**i**, $^4J_m = 1.8$ Hz), 7.11 (2H, m, H**b**, H**m**), 7.04 (1H, AB, H**f**, $J_{AB} = 16.1$ Hz), 6.87 (1H, d, H**l**, $^3J_{HH} = 8.3$ Hz), 4.05 (2H, t, H**n**′, $^3J_{HH} = 6.7$ Hz), 4.02 (2H, t, H**n**, $^3J_{HH} = 6.6$ Hz), 1.85 (2H, m, H**o**′), 1.83 (2H, m, H**o**), 1.49 (4H, m, H**p**, H**p**′), 1.32 (16H, m, H**q**, H**q**′), 0.89 (6H, $2 \times$ t, H**r**, H**r**′, $^3J_{HH} = 6.9$ Hz).

^{13}C NMR (100.61 MHz, $CDCl_3$): $\delta = 155.9$ (**e**), 149.8 (**j**), 149.5 (**a**), 149.2 (**k**), 136.5 (**g**), 132.8 (**g**), 129.6 (**h**), 125.8 (**f**), 121.7 (**b**), 121.6 (**d**), 120.9 (**m**), 113.4 (**l**), 111.7 (**i**), 69.3 (**n**), 69.2 (**n**′), 31.8, 29.4, 29.3, 29.2, 26.0, 22.7 (**o**, **o**′, **p**, **p**′, **q**, **q**′), 14.1 (**r**, **r**′).

4.3. Preparation of 3,4,5-trialkoxybenzylideneaniline

3,4,5-Trioctyloxybenzylidene aniline was prepared in the same way as 3,4,5-tridodecyloxybenzylidene aniline, which is described.

3,4,5-Tridodecyloxybenzaldehyde (7.90 g, 12.0 mmol) was heated with stirring in ethanol (150 cm^3) until it dissolved. Aniline (1.58 g, 17.0 mmol) was then added followed by a few crystals of toluene sulphonic acid. The mixture was stirred and was allowed to cool to room temperature, as it did so a thick, white precipitate formed. The mixture was stirred for a further 2 h and the colourless precipitate was then filtered off and dried in a dessicator (7.67 g, 10.5 mmol, 88% yield). It was used without further purification.



^{1}H NMR (400 MHz, CD_2Cl_2): $\delta = 8.36$ (1H, s, H**e**), 7.43 (2H, m, H**b**), 7.26 (1H, m, H**a**), 7.22 (2H, m, H**c**), 7.17 (2H, s, H**g**) 4.08 (4H, t, H**j**′, $^3J_{HH} = 6.5$ Hz), 4.04 (2H, t, H**j**, $^3J_{HH} = 6.5$ Hz), 1.86 (4H, m, H**k**′), 1.77 (2H, m, H**k**), 1.44 (52H, m, H**l**, H**l**′), 0.91 (9H, $2 \times$ t, H**m**, H**m**′, $^3J_{HH} = 7.0$ Hz).

^{13}C NMR (100.61 MHz, CD_2Cl_2): $\delta = 160.3$ (**e**), 153.8 (**h**), 152.6 (**d**), 141.5 (**i**), 131.79 (**f**), 129.5 (**b**), 126.0 (**a**), 121.1 (**c**), 107.2 (**g**), 73.8 (**j**), 69.5 (**j**′), 32.3, 30.8, 30.2, 30.1, 30.1, 30.0, 29.8, 29.7, 26.5, 23.1 (**k**, **k**′, **l**, **l**′), 14.3 (**m**, **m**).

4.4. Preparation of 3,4,5-trialkoxy-3′-stilbazole (*9*) and 3,4,5-trialkoxy-2′-stilbazole (*10*)

The preparation of 3,4,5-tridodecyloxy-3′-stilbazole will be described; 3,4,5-trioctyloxy-3′-stilbazole was made in the same way. The isomeric 3,4,5-trialkoxy-2′-stilbazoles were made in the same way except that the 3-picoline was replaced with 2-picoline.

3,4,5-Tridodecyloxybenzylidene aniline (3.50 g, 4.8 mmol) was dissolved with heating in DMF (30 cm^3). 3-Picoline (0.82 g, 8.8 mmol) was added with stirring, followed by potassium *tert*-butoxide (4.40 g, 36.0 mmol) in fractions. The solution immediately

turned dark red. The system was heated to 80 °C and was stirred for 2.5 h. After cooling HCl solution (10%) was added dropwise until the pH of the mixture was neutral. Water (100 cm^3) was added and the solution became yellow. The product was extracted into DCM (2×75 cm^3) and was washed with $NaHCO_3$ solution (200 cm^3 saturated) and H_2O (200 cm^3). The organic phase was dried over magnesium sulfate and the DCM was removed. The residue was then taken into toluene (100 cm^3) and was repeatedly with water (4×100 cm^3) to remove the DMF. The toluene was then removed in vacuo to leave a light brown solid. This was purified by column chromatography on silica gel. The solvent system was ethyl acetate:hexane, 1:4. A few drops of triethylamine were added to prevent the stilbazole sticking to the column. The product was then crystallised from hot hexane to give a colourless powder (2.59 g, 88%).

(10)

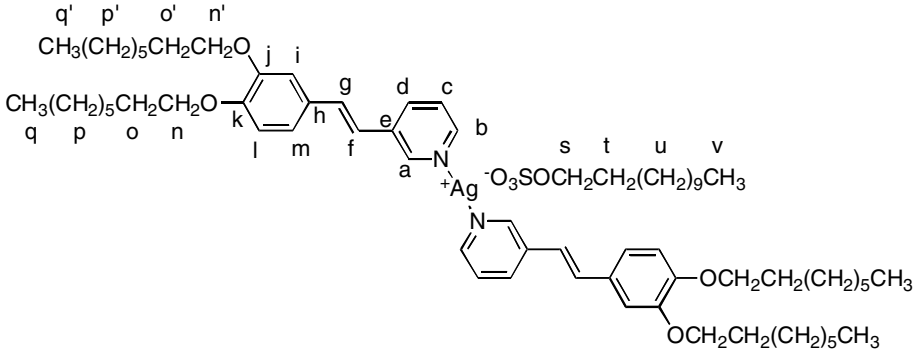
^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.59$ (1H, dd, H**a**, $^3J_{HH} = 5.0$ Hz, $^4J_{HH} = 1.5$ Hz), 7.67 (1H, dt, H**c**, $^3J_{HH} = 7.6$ Hz, $^4J_{HH} = 1.5$ Hz), 7.52 (1H, AB, H**g**, $J_{AB} = 16.0$ Hz), 7.41 (1H, d, H**d**, $^3J_{HH} = 7.6$ Hz), 7.15 (1H, dd, H**b**, $^3J_{HH} = 7.6$ Hz, $^3J_{HH} = 5.0$ Hz), 7.06 (1H, AB, H**f**, $J_{AB} = 16.0$ Hz), 6.80 (2H, s, H**i**), 4.02 (4H, t, H**l**′, $^3J_{HH} = 6.7$ Hz), 3.98 (2H, t, H**l**, $^3J_{HH} = 6.8$), 1.83 (4H, m, H**m**′), 1.76 (2H, m, H**m**), 1.48 (6H, m, H**n**, H**n**′), 1.27 (40H, m, H**o**, H**o**′), 0.89 (9H, t, H**p**, H**p**′, $^3J_{HH} = 6.8$ Hz).

^{13}C NMR (100.61 MHz, $CDCl_3$): $\delta = 155.6$ (**e**), 153.3 (**j**), 149.4 (**a**), 138.9 (**k**), 136.7 (**c**), 133.2 (**g**), 131.6 (**h**), 126.6 (**f**), 121.9 (**b**), 121.7 (**d**), 105.7 (**i**), 73.6 (**l**), 69.1 (**l**′), 31.9, 30.3, 29.8, 29.7, 29.6, 29.4, 26.1, 22.7 (**m**, **m**′, **n**, **n**′, **o**, **o**′), 14.1 (**p**, **p**′).

*4.5. Preparation of bis(3,4-dialkoxy-3′-stilbazole)-silver(I) dodecylsulfate (**11a**) and bis(3,4-dialkoxy-2′-stilbazole)silver(I) dodecylsulfate (**12a**)*

All homologues were made by the same method as for bis(3,4-dioctyloxy-2′-stilbazole)silver(I) dodecylsulfate which is described. Bis(3,4-dialkoxy-3′-stilbazole) silver(I) dodecylsulfates were made in the same way.

In a vessel protected from light, silver(I) dodecylsulfate (97 mg, 0.26 mmol) was stirred as a suspension in DCM (10 cm^3). 3,4-Dioctyloxy-2′-stilbazole (250 mg, 0.27 mmol) dissolved in DCM (10 cm^3) was added slowly. The mixture was stirred at room temperature for 4 h. It was then filtered through celite, to remove any unreacted silver(I) dodecylsulfate, and the solvent was removed in vacuo to leave a yellow residue, which was crystallised from hot acetone and recrystallised from hot methanol to give a colourless, crystalline solid (199 mg, 62%).



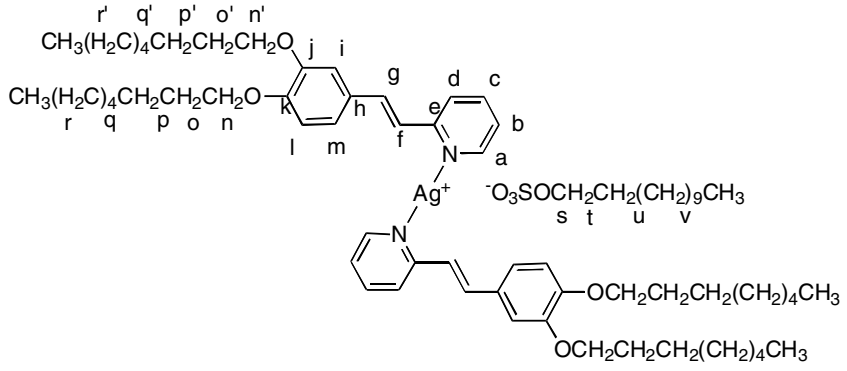
(11a)

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.92$ (2H, d, H**a**, $^4J_{HH} = 1.8$ Hz), 8.60 (2H, dd, H**b** $^3J_{HH} = 5.5$ Hz, $^4J_{HH} = 1.8$ Hz), 7.78 (2H, dt, H**d**, $^3J_{HH} = 8.0$ Hz, $^4J_{HH} = 1.8$ Hz), 7.29 (2H, dd, H**c**, $^3J_{HH} = 5.5$ Hz, $^3J_{HH} = 8.0$ Hz), 7.17 (2H, AB, H**g**, $J_{AB} = 16.3$ Hz), 7.07 (2H, d, H**i**, $^4J_{HH} = 1.8$ Hz), 7.03 (2H, dd, H**m**, $^3J_{HH} = 8.4$ Hz, $^4J_{HH} = 1.8$ Hz), 6.81 (2H, d, H**l**, $^3J_{HH} = 8.4$ Hz), 6.81 (2H, AB, H**f**, $J_{AB} = 16.3$ Hz), 4.14 (2H, t, Hs, $^3J_{HH} = 6.9$ Hz), 4.04 (4H, t, H**n**′, $^3J_{HH} = 6.6$ Hz), 4.02 (4H, t, H**n**, $^3J_{HH} = 6.3$ Hz), 1.83 (8H, m, H**o**, H**o**′), 1.65 (2H, m, H**t**), 1.54 (58H, m, H**p**, H**p**′, H**u**), 0.89 (15H, m, H**q**, H**q**′, H**v**).

4.6. Preparation of bis(3,4-dialkoxy-3′-stilbazole)silver(I) triflate (**11b**) and bis(3,4-dialkoxy-2′-stilbazole)silver(I) triflate (**12b**)

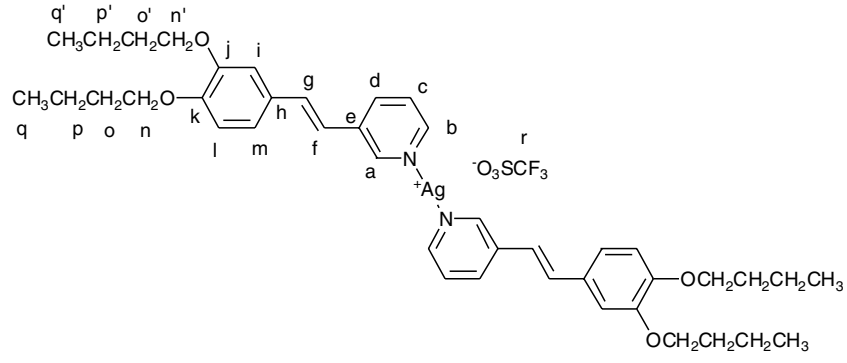
All homologues were made by the same method as for bis(3,4-dibutyloxy-3′-stilbazole) silver(I) triflate which is described. Bis(3,4-alkoxy-2′-stilbazole) silver(I) triflate was made in the same way.

4-Dibutyloxy-3′-stilbazole (0.300 g, 0.92 mmol) and silver(I) triflate (0.113 g, 0.044 mmol) were placed in a flask protected from light. Acetone (5 cm^3) was added and the mixture was stirred at room temperature for 4 h. After cooling in ice the colourless precipitate was filtered off and was washed with cold acetone giving a colourless solid of analytical purity (0.350 g, 86%).



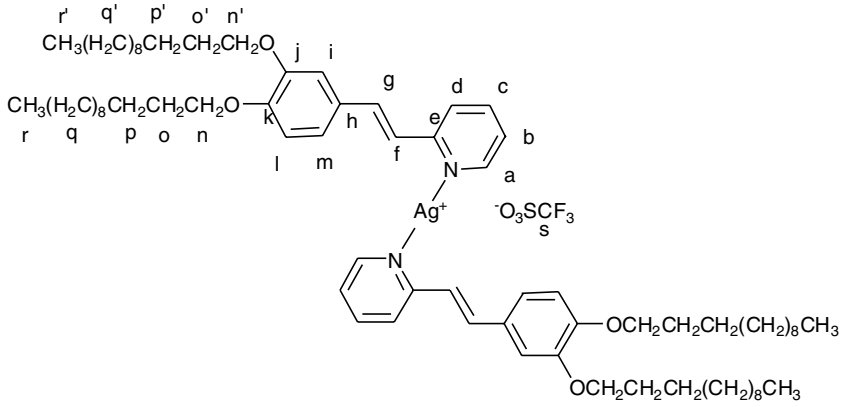
(12a)

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.95$ (2H, dd, H**a**, $^3J_{HH} = 4.5$ Hz, $^4J_{HH} = 1.5$ Hz), 7.80 (2H, dt, H**c**, $^3J_{HH} = 7.8$ Hz, $^4J_{HH} = 1.5$ Hz), 7.66 (2H, d, H**d**, $^3J_{HH} = 8.2$ Hz), (2H, dd, H**b**, $^3J_{HH} = 7.8$ Hz, $^3J_{HH} = 4.5$ Hz), 7.21 (2H, AB, H**g**, $J_{AB} = 16.2$ Hz), 7.06 (1H, AB, H**f**, $J_{AB} = 16.2$ Hz), 7.88 (2H, d, H**i**, $^4J_m = 1.8$ Hz), 6.84 (2H, d, H**m**, $^3J_{HH} = 8.2$ Hz, $^4J_{HH} = 1.8$ Hz), 6.68 (2H, d, H**l**, $^3J_{HH} = 8.2$ Hz), 4.09 (2H, t, H**s**, $^3J_{HH} = 6.7$ Hz), 3.96 (4H, t, H**n**′, $^3J_{HH} = 6.7$ Hz), 3.79 (4H, t, H**n**, $^3J_{HH} = 6.6$ Hz), 1.80 (4H, m, H**o**′), 1.73 (4H, m, H**o**), 1.63 (2H, m, H**t**), 1.52 (8H, m, H**p**, H**p**′), 1.34 (50H, m, H**q**, H**q**′, H**u**), 089 (15H, 2 × t, H**r**, H**r**′, $^3J_{HH} = 6.6$ Hz).



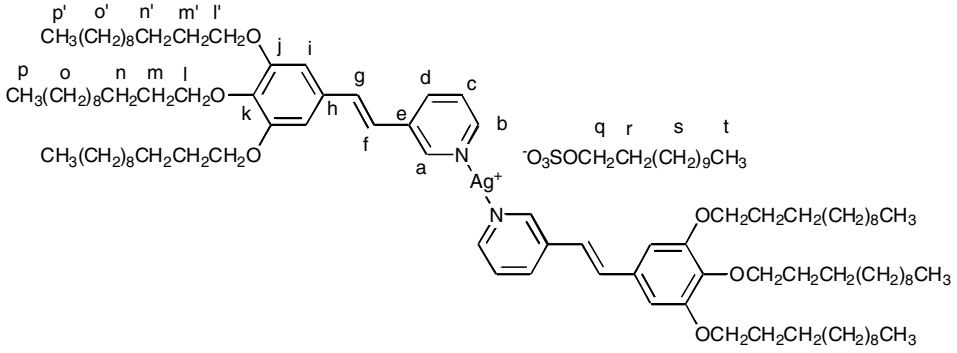
(11b)

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.84$ (2H, d, H**a**, $^4J_{HH} = 1.8$ Hz), 8.51 (2H, dd, H**b** $^3J_{HH} = 5.2$ Hz, $^4J_{HH} = 1.8$ Hz), 7.72 (2H, dt, H**d**, $^3J_{HH} = 8.1$ Hz, $^4J_{HH} = 1.8$ Hz), 7.24 (2H, dd, H**c**, $^3J_{HH} = 5.2$ Hz, $^3J_{HH} = 8.1$ Hz), 7.13 (2H, AB, H**g**, $J_{AB} = 16.4$ Hz), 7.05 (2H, d, H**i**, $^4J_{HH} = 1.8$ Hz), 6.99 (2H, d, H**m**, $^3J_{HH} = 8.3$ Hz, $^4J_{HH} = 1.8$ Hz), 6.80 (2H, d, H**l**, $J = 8.3$ Hz), 6.74 (2H, AB, H**f**, $J_{AB} = 16.4$ Hz), 4.03 (4H, t, H**n**′, $^3J_{HH} = 6.6$ Hz), 4.02 (4H, t, H**n**, $^3J_{HH} = 6.6$ Hz), 1.83 (8H, m, H**o**, H**o**′), 1.53 (8H, m, H**p**, H**p**′), 1.00 (12H, m, H**q**, H**q**′).



(12b)

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.95$ (2H, dd, H**a**, $^3J_{HH} = 4.5$ Hz, $^4J_{HH} = 1.5$ Hz), 7.80 (2H, dt, H**c**, $^3J_{HH} = 7.8$ Hz, $^4J_{HH} = 1.5$ Hz), 7.66 (2H, d, H**d**, $^3J_{HH} = 8.2$ Hz), (2H, dd, H**b**, $^3J_{HH} = 7.8$ Hz, $^3J_{HH} = 4.5$ Hz), 7.21 (2H, AB, H**g**, $J_{AB} = 16.2$ Hz), 7.06 (1H, AB, H**f**, $J_{AB} = 16.2$ Hz), 7.88 (2H, d, H**i**, $^4J_m = 1.8$ Hz), 6.84 (2H, d, H**m**, $^3J_{HH} = 8.2$ Hz, $^4J_{HH} = 1.8$ Hz), 6.68 (2H, d, H**l**, $^3J_{HH} = 8.2$ Hz), 3.96 (4H, t, H**n**′, $^3J_{HH} = 6.7$ Hz), 3.79 (4H, t, H**n**, $^3J_{HH} = 6.6$), 1.80 (4H, m, H**o**′), 1.73 (4H, m, H**o**), 1 (8H, m, H**p**, H**p**′), 1.34 (64H, m, H**q**, H**q**′), 089 (12H, 2 × t, H**r**, H**r**′, $^3J_{HH} = 6.6$ Hz).



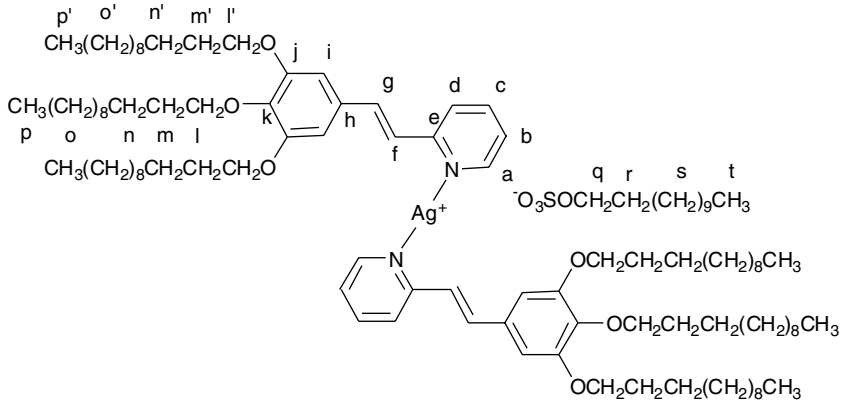
(13a)

*4.7. Preparation of bis(3,4,5-trialkoxy-3′-stilbazole)-silver(I) dodecylsulfate (**13a**) and bis(3,4,5-trialkoxy-2′-stilbazole)silver(I) dodecylsulfate (**14a**)*

The preparation of bis(3,4,5-dodecyloxy-2′-stilbazole)silver(I) dodecylsulfate is described and the octyloxy homologue was made in the same way. Bis(3,4,5-alkoxy-3′-stilbazole)silver(I) dodecylsulfates were prepared in the same way as is described for bis(3,4,5-alkoxy-2′-stilbazole)silver(I) dodecylsulfates except that the 2′-stilbazole was replaced by 3′-stilbazole.

In a vessel protected from light, silver(I) dodecylsulfate (56 mg, 0.15 mmol) was stirred as a suspension in DCM (10 cm^3). 3,4,5-Tridodecyloxy-2′-stilbazole (250 mg, 0.14 mmol) dissolved in DCM (10 cm^3) was added slowly. The mixture was stirred at room temperature for 4 h. It was then filtered over celite, to remove any unreacted silver(I) dodecylsulfate, and the solvent was removed in vacuo to leave a yellow residue. This was crystallised from hot acetone and recrystallised from hot methanol to give a colourless crystalline solid (189 mg, 67%).

^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 8.90$ (2H, d, H**a**, $^4J_{HH} = 1.6$ Hz), 8.59 (2H, dd, H**b** $^3J_{HH} = 5.1$ Hz, $^4J_{HH} = 2.0$ Hz), 7.82 (2H, dt, H**d**, $^3J_{HH} = 8.07$ Hz, $^4J_{HH} = 2.0$ Hz), 7.29 (2H, dd, H**c**, $^3J_{HH} = 5.1$ Hz, $^3J_{HH} = 8.0$ Hz), 7.16 (2H, AB, H**g**, $J_{AB} = 16.3$ Hz), 6.90 (2H, AB, H**f**, $J_{AB} = 16.3$ Hz), 6.74 (4H, s, H**i**), 4.09 (2H, t, H**q**, $^3J_{HH} = 6.77$ Hz), 4.06 (8H, t, H**l**′, $^3J_{HH} = 6.8$ Hz), 3.99 (4H, t, H**l**, $^3J_{HH} = 6.8$ Hz), 1.80 (14H, m, H**m**, H**m**′, H**r**), 1.36



(14a)

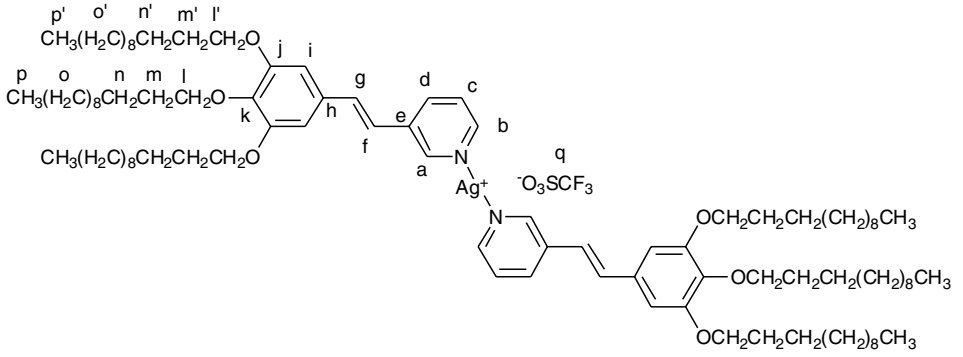
(126H, m, H**n**, H**n**′, H**o**, H**o**′, H**s**), 0.88 (21H, m, H**p**, H**p**′, H**t**).

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.97$ (2H, dd, H**a**, $^3J_{HH} = 4.8$ Hz, $^4J_{HH} = 1.5$ Hz), 7.82 (2H, dt, H**c**, $^3J_{HH} = 7.7$ Hz, $^4J_{HH} = 1.5$ Hz), 7.65 (2H, d, H**d**, $^3J_{HH} = 7.7$ Hz), 7.33 (2H, dd, H**b**, $^3J_{HH} = 4.8$ Hz, $^3J_{HH} = 7.7$ Hz), 7.16 (2H, AB, H**g**, $J_{AB} = 15.8$ Hz), 7.06 (2H, AB, H**f**, $J_{AB} = 15.8$ Hz), 6.44 (4H, s, H**i**), 4.11 (2H, t, H**q**, $^3J_{HH} = 6.7$ Hz), 3.92 (4H, t, H**l**, $^3J_{HH} = 6.6$ Hz), 3.76 (8H, t, H**l**′ $^3J_{HH} = 6.0$), 1.69 (12H, m, H**m**′, H**m**), 1.34 (128H, m, H**n**, H**n**′, H**o**, H**o**′, H**r**, H**s**), 0.89 (21H, 2 × t, H**r**, H**r**′, H**t**, $^3J_{HH} = 6.4$ Hz).

*4.8. Preparation of bis(3,4,5-trialkoxy-3′-stilbazole) silver-(I) triflate (**13b**) and bis(3,4,5-trialkoxy-2′-stilbazole)-silver(I) triflate (**14b**)*

Bis(3,4,5-tridodecyloxy-3′-stilbazole)silver(I) triflate is described and the other homologues were prepared in the same way. Bis(3,4,5-dodecyloxy-2′-stilbazole)silver(I) triflate was also prepared in the same way except that the 3′-stilbazole was replaced by 2′-stilbazole.

3,4,5-Tridodecyloxy-3′-stilbazole (200 mg, 0.27 mmol) and silver(I) triflate (20 mg, 0.19 mmol) were placed in a flask protected from light. Acetone (5 cm^3) was added and the mixture was stirred at room temperature for 4 h. The mixture was then cooled in ice before being

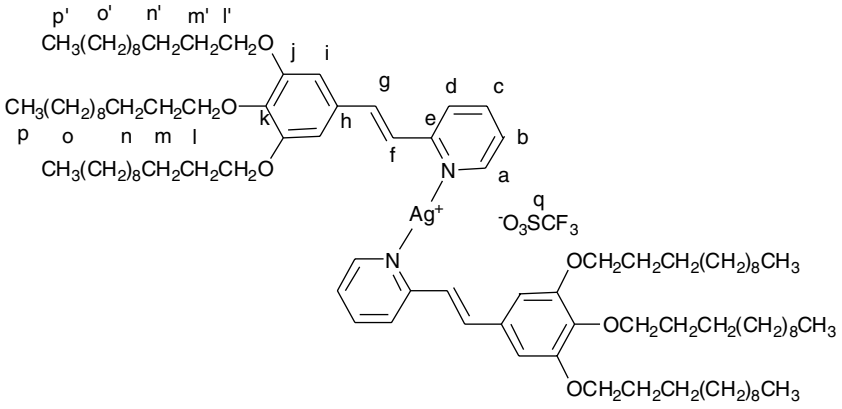


(13b)

filtered and washed with cold acetone giving a colourless solid (190 mg, 84%).

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.87$ (2H, d, H**a**, $^4J_{HH} = 1.6$ Hz), 8.50 (2H, dd, H**b** $^3J_{HH} = 5.2$ Hz, $^4J_{HH} = 1.8$ Hz), 7.82 (2H, dt, H**d**, $^3J_{HH} = 8.1$ Hz, $^4J_{HH} = 1.6$ Hz), 7.29 (2H, dd, H**c**, $^3J_{HH} = 5.2$ Hz, $^3J_{HH} = 8.1$ Hz), 7.14 (2H, AB, H**g**, $J_{AB} = 16.4$ Hz), 6.81 (2H, AB, H**f**, $J_{AB} = 16.4$ Hz), 6.73 (4H, s, H**i**), 4.01 (8H, t, H**l**′, $^3J_{HH} = 6.3$ Hz), 3.98 (4H, t, H**l**, $^3J_{HH} = 6.7$ Hz), 1.79 (12H, m, H**m**, H**m**′), 1.36 (108H, m, H**n**, H**n**′, H**o**, H**o**′), 0.88 (18H, m, H**p**, H**p**′).

^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.91$ (2H, dd, H**a**, $^3J_{HH} = 5.1$ Hz, $^4J_{HH} = 1.5$ Hz), 7.85 (2H, dt, H**c**,



(14b)

$^3J_{HH} = 7.7$ Hz, $^4J_{HH} = 1.46$ Hz), 7.66 (2H, d, H**d**, $^3J_{HH} = 7.7$ Hz), 7.36 (2H, dd, H**b**, $^3J_{HH} = 5.1$ Hz, $^3J_{HH} = 7.7$ Hz), 7.15 (2H, AB, H**g**, $J_{AB} = 16.2$ Hz), 7.08 (2H, AB, H**f**, $J_{AB} = 16.2$ Hz), 6.41 (4H, s, H**i**), 3.91 (4H, t, H**l**, $^3J_{HH} = 6.5$ Hz), 3.73 (8H, t, H**l**′, $^3J_{HH} = 6.4$), 1.86 (12H, m, H**m**′, H**m**), 1.30 (108H, m, H**n**, H**n**′, H**o**, H**o**′), 0.81 (18H, 2 × t, H**r**, H**r**′, H**t**, $^3J_{HH} = 6.4$ Hz).

5. Supplementary material

Crystallographic data (excluding structure factors) for the structures in this paper, has been deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC 267944, 267945 and 267946. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44(0) 1223 336033 or e-mail: deposit@ccdc.cam.ac.uk).

Abstract

Reaction of the tripodal ligand 1,1,1-tris(hydroxymethyl)ethane (H_3thme) with a variety of Fe(III) precursors under both ambient and solvothermal conditions has led to the isolation of a number of new complexes ranging in nuclearity from 4 to 16. These include the rhomb or diamond-like clusters $[Fe_4(thme)_2Cl_4(O_2CR)_2(R'OH)_2]$ (**1**, R = Me, R′ = Et; **2**, R = Ph, R′ = Me; **3**, R = CMe_3, R′ = Me); the related nonanuclear and undecanuclear clusters $[Fe_9O_4(O_2CCMe_3)_{13}(thme)_2]$ (**4**) and $[NEt_4][Fe_{11}O_4(O_2CPh)_{10}(thme)_4(dmhp)_2Cl_4]$ (**5**) (dmhp = 4,6-dimethyl-2-hydroxypyrimidine) and the octametallic and hexadecametallic wheels $[Fe_8(O_2CR)_{12}(thme)_4]$ (**6**, R = Ph; **7**, R = CMe_3) and $[Fe_{16}(EtO)_4(O_2CPh)_{16}(Hthme)_{12}](NO_3)_4$ (**8**). Magnetic studies reveal the presence of dominant antiferromagnetic interactions between the Fe centres in all eight complexes which results in the presence of small spin ground states for complexes **1**–**4** and **6**–**8**. For **5** however, these stabilise an $S = 11/2$ spin ground state with an axial zero-field splitting parameter of $D = -0.46\ cm^{-1}$. Single crystal hysteresis loops in magnetisation versus external magnetic field measurements show the temperature and sweep rate dependence indicative of single-molecule magnetism behaviour.

1. Introduction

Polymetallic cluster complexes of paramagnetic transition metal ions have attracted intense study since the discovery that such molecules can display the phenomenon of single-molecule magnetism (SMM) [1]. There is a barrier to relaxation of magnetisation in SMMs due to the combination of a large ground state spin multiplicity and a significant negative zero-field splitting of that ground state and this imparts a molecular magnetic memory effect that can be observed as hysteresis loops in M versus H studies. All SMMs made to date only exhibit this memory effect at very low temperatures and there is therefore an intense effort in synthesizing larger clusters in an attempt to generate larger spin ground states and higher energy barriers to loss of magnetization [2]. Here, we describe the synthesis of some new Fe^{III} clusters with the tripodal ligand 1,1,1-tris(hydroxymethl)ethane (H_3thme). Tripodal ligands such as H_3thme have previously been used in the solvothermal synthesis of oxo-vanadium and oxo-molybdenum clusters but until recently, very rarely in the synthesis of paramagnetic 3d transition metal clusters [3]. To date most cluster

synthesis has involved "conventional" coordination chemistry techniques, i.e., solution chemistry under atmospheric pressure and at temperatures limited to the boiling points of common solvents. Solvothermal techniques allow the application of high temperatures to reactions in low boiling solvents and are also an excellent method for the preparation of pure, crystalline products [4]. In this work, we have explored reactions of Fe^{III} precursors with H_3thme under both ambient and solvothermal conditions and we observe a very wide range of cluster topologies and nuclearities depending on subtle changes in the reaction conditions.

2. Experimental

2.1. Synthesis

The complexes $[Fe_3O(O_2CR)_6(H_2O)_3]X$ (R = Me, CMe_3, Ph; X = Cl, NO_3, O_2CMe_3) and $[NEt_4]_2[Fe_2OCl_6]$ were made as previously described [5].

2.1.1. $[Fe_4(thme)_2Cl_4(O_2CMe)_2(EtOH)_2]$ (**1**)

$FeCl_3 \cdot 6H_2O$ (2.0 g, 7.39 mmol), H_3thme (0.30 g, 2.46 mmol) and NaO_2CMe (0.61 g, 7.39 mmol) were dissolved in acetonitrile (30 ml) with stirring. The resultant yellow solution was stirred for 8 h, filtered and taken to dryness under reduced pressure. The resulting residue was then re-dissolved in MeOH (15 ml) and filtered. Yellow crystals grew upon diffusion of ethanol during three weeks. Yield: ~17%. Elemental *Anal*. Calc. for **1**: C, 45.86; H, 7.60; Fe, 15.99. Found: C, 45.91; H, 7.68; Fe, 16.02%. IR (KBr; ν/cm^{-1}): 2997 (w), 2953 (m), 2912 (w), 2862 (w), 1527 (s), 1461 (w), 1433 (s), 1399 (w), 1321 (m), 1208 (w), 1119 (m), 1016 (s), 979 (s), 917 (w), 866 (m), 722 (w), 663 (m), 608 (m), 551 (w), 502 (s), 413 (w).

2.1.2. $[Fe_4(thme)_2Cl_4(O_2CPh)_2(MeOH)_2]$ (**2**)

$FeCl_3 \cdot 6H_2O$ (2.0 g, 7.39 mmol), H_3thme (0.30 g, 2.46 mmol) and NaO_2CPh (1.06 g, 7.39 mmol) were dissolved in methanol (30 ml) with stirring. The yellow solution was stirred for 8 h, filtered and taken to dryness under reduced pressure. The resulting residue was re-dissolved in methanol (15 ml) and filtered. Yellow-brown crystals grew upon diffusion of diethyl ether during three weeks. Yield: ~20 %. Elemental *Anal*. Calc. for **2**: C, 37.00; H, 4.14; Cl, 14.56; Fe, 22.94. Found: C, 37.69; H, 3.61; Cl, 14.59; Fe, 22.25%. IR (KBr; ν/cm^{-1}): 2976 (w), 2934 (w), 2867 (w), 1600 (m), 1562 (m), 1519 (m), 1493 (w), 1406 (s), 1178 (m), 1121 (m), 1070 (m), 1017 (s), 918 (w), 834 (w), 790 (w), 721 (m), 676 (w), 607 (w), 488 (s), 406 (w).

2.1.3. $[Fe_4(thme)_2Cl_4(O_2CCMe_3)_2(MeOH)_2]$ (**3**)

$FeCl_3 \cdot 6H_2O$ (2.0 g, 7.39 mmol), H_3thme (0.30 g, 2.46 mmol) and NaO_2CCMe_3 (0.92 g, 7.39 mmol) were dissolved in methanol (30 ml) with stirring. The yellow solution was stirred for 8 h, filtered and taken to dryness under reduced pressure. The resulting residue was re-dissolved in methanol (15 ml) and filtered. Yellow-brown crystals grew upon diffusion of diethyl ether after 2–3 weeks. Yield: ~17 %. Elemental *Anal*. Calc. for **3**: C, 32.47; H, 4.77; Cl, 15.97; Fe, 25.16. Found: C, 31.89; H, 4.46; Cl, 16.50; Fe, 24.39%. IR (KBr) ν/cm^{-1}): 2932 (w), 2863 (w), 1587 (m), 1561 (w), 1514 (s), 1445 (w), 1401 (s), 1177 (w), 1119 (m), 1037 (m), 1017 (s), 985 (w), 913 (w), 723 (s), 677 (m), 607 (m), 487 (s).

2.1.4. $[Fe_9O_4(O_2CCMe_3)_{13}(thme)_2]$ (**4**)

$[Fe_3O(O_2CCMe_3)_6(H_2O)_3](O_2CCMe_3)$ (0.30 g, 0.32 mmol) and H_3thme (0.038 g, 0.32 mmol) were dissolved in acetonitrile (6 ml) and placed in a 23 ml Teflon-lined autoclave. This was then heated at a rate of 1.0 °C min^{-1} to 150 °C and maintained at this temperature for 12 h. Cooling to room temperature at a rate of 0.05 °C min^{-1} resulted in the formation of large orange/brown crystals. These were washed with several portions of fresh acetonitrile and air dried. Yield: ~50 %. Elemental *Anal*. Calc. for **4**: C, 44.75; H, 6.63; Fe, 20.80. Found: C, 45.13; H, 7.26; Fe, 20.93%. IR (KBr ν/cm^{-1}): 29.62 (s), 2931 (m), 2903 (m), 2873 (m), 1567 (s), 1538 (s), 1484 (s),1459 (m) 1428 (s), 1393 (w), 1379 (s), 1362 (m), 1230 (s), 1153 (m), 1073 (s), 1015 (s), 966 (w), 939 (w), 919 (w), 896 (w), 788 (m), 608 (s), 441 (s).

2.1.5. $[NEt_4][Fe_{11}O_4(O_2CPh)_{10}(thme)_4(dmhp)_2Cl_4]$ (**5**)

$[NEt_4][Fe_2OCl_6]$ (0.5 g, 0.83 mmol), NaO_2CPh (0.24 g, 1.66 mmol) dmhp (0.103 g, 0.83 mmol) and H_3thme (0.1 g, 0.83 mmol) were added to MeCN (30 ml) and stirred for 12 h and then filtered. The resulting orange solution was allowed to evaporate yielding complex **5** in approximately 20% yield after one week. Elemental *Anal*. Calc. for **5**: C, 45.86; H, 4.24; N, 2.43. Found: C, 45.15; H, 4.23; N, 2.57%. IR (KBr ν/cm^{-1}): 1590 (w), 1533 (s), 1480 (m), 1447 (w), 1394 (s), 1171 (w), 1123 (w) , 1047 (m), 1021 (m), 996 (m), 778 (w), 721 (m), 677 (w), 608 (w), 477 (m).

2.1.6. $[Fe_8(O_2CPh)_{12}(thme)_4]$ (**6**)

(a) $[Fe_3O(O_2CPh)_6(H_2O)_3]Cl$ (0.30 g, 0.30 mmol) and H_3thme (0.036 g, 0.30 mmol) were dissolved in acetonitrile and placed in a 23 ml Teflon-lined autoclave. This was then heated at a rate of 1.0 °C min^{-1} to 150 °C and maintained at this temperature for 12 h. Cooling to room temperature at a rate of 0.05 °C min^{-1} resulted in the formation of large orange/brown crystals. These were washed with several portions of fresh acetonitrile and air dried. Yield: ~50%. (b) $[Fe_3O(O_2CPh)_6(H_2O)_3](NO_3)$ (0.5 g 0.49 mmol) and H_3thme (0.06 g, 0.49 mmol) were stirred in MeCN (30 ml) for 12 h. The resulting precipitate was filtered, air-dried and re-dissolved in CH_2Cl_2. Crystals formed in two days after diffusion of diethyl ether into the solution in approximately 30% yield.

Elemental *Anal*. Calc. for **6**: C, 52.74; H, 4.09; Fe, 18.75. Found: C, 52.73; H, 4.10; Fe, 18.86%. IR (KBr ν/cm^{-1}): 3055 (w), 1598 (m), 1555 (m), 1530 (m), 1521 (m), 1429

2.1.7. $[Fe_8(O_2CCMe_3)_{12}(thme)_4]$ (7)

$[Fe_3O(O_2CCMe_3)_6(H_2O)_3]Cl$ (0.30 g, 0.34 mmol) and H_3thme (0.041 g, 0.34 mmol) were dissolved in acetonitrile and placed in a 23 ml Teflon-lined autoclave. This was then heated at a rate of 1.0 °C min^{-1} to 150 °C and maintained at this temperature for 12 h. Cooling to room temperature at a rate of 0.05 °C min^{-1} resulted in the formation of large orange/brown crystals. These were washed with several portions of fresh acetonitrile and air dried. Yield: ~50 %. Elemental *Anal*. Calc. C, 45.15; H, 6.82; Fe, 20.95. Found: C, 45.13; H, 7.07; Fe, 20.99%. IR (KBr) ν/cm^{-1}: 2962 (m), 2931 (w), 1567 (s), 1536 (s), 1484 (s), 1427 (s), 1379 (m), 1362 (m), 1231 (s), 1153 (w), 1071 (s), 1015 (m), 897 (w), 789 (w), 606 (m), 442 (s).

2.1.8. $[Fe_{16}(EtO)_4(O_2CPh)_{16}(Hthme)_{12}](NO_3)_4$ (8)

$[Fe_3O(O_2CPh)_6(H_2O)_3](NO_3)$ (0.5 g, 0.49 mmol) and H_3thme (0.06 g, 0.49 mmol) were stirred in MeCN (30 ml) for 12 h. The resulting precipitate was filtered, air-dried and re-dissolved in a 1:1 mixture of CH_2Cl_2 and EtOH. Crystals formed after two days in approximately 15% yield. Elemental *Anal*. Calc. C, 46.22; H, 4.74; N, 1.20. Found: C, 46.08; H, 4.41; N, 1.14%. Selected IR data (KBr pellet, cm^{-1}): 1554 (s), 1528 (s) 1493 (m), 1409 (s), 1307 (w), 1176 (m), 1158 (w), 1069 (w), 1045 (m), 1025 (m), 877 (w), 717 (s).

2.2. X-ray crystallography and structure solution

All structures were solved by direct methods. The data are summarised in Table 1.

For complexes **1**, **2**, and **6** all the non-hydrogen atoms were refined anisotropically and the H atoms were included in calculated positions. **3**: the asymmetric unit contains half a molecule and two disordered MeOH molecules. The CMe_3 group of the pivalates was disordered. All non-H atoms were refined anisotropically except those of the disordered atoms of the solvent at lower occupancy. H atoms were included in calculated positions except those bonded to C1T and C2T which were omitted. **4**: a number of the CMe_3 groups were disordered over two sites whose occupancies were constrained to sum to 1.0 with restraints on the geometric parameters. All non-H atoms were refined anisotropically except the disordered atoms. H atoms were included in calculated positions. **5**: the asymmetric unit contains half the molecule together with a number of solvent fragments; there are two CH_2Cl_2 molecules and three highly disordered fragments which were not recognisable so the atoms were all defined as C with some at occupancy 0.5. The non-H atoms were refined anisotropically. H atoms were included in calculated positions except those of the disordered solvent. **7**: the atoms C23–C25 and C42, C43, C45 were disordered over two sites each whose

occupancies were constrained to sum to 1.0. There were two partially occupied MeCN solvent molecules one of which was incomplete. All non-H atoms were refined anisotropically except the disordered atoms and those of the solvent. H atoms were included in calculated positions except those of the solvent. **8**: initially, the *R* value was very high and twinning was suspected. A twin matrix which exchanges the *h* and *k* axes was applied (01010000−1), and the twin fraction was found to be 0.44788. Accounting for the twinning reduced the *R* value from over 30% to under 10%. The asymmetric unit contains one quarter of the molecule together with a nitrate and a disordered solvent fragment, assumed to be CH_2Cl_2, and some water molecules. The phenyl rings were constrained to ideal geometry. Most of the non-H atoms were refined anisotropically except those of the solvent fragments, using restraints. H atoms were included in calculated positions except for the solvent H atoms.

3. Crystal structure description

3.1. Structure of $[Fe_4(thme)_2Cl_4(O_2CR)_2(R'OH)_2]$ (**1**, R = Me, R′ = Et; **2**, R = Ph, R′ = Me; **3**, R = CMe_3, R′ = Me)

The core structures of complexes **1**–**3** (Fig. 1) are isostructural and consist of a central $[Fe_4O_6]^{6+}$ planar rhomb or diamond in which each of the oxygen atoms is derived from bridging $[thme]^{3-}$ ligands. These sit one-above and one-below the $[Fe_4]$ plane and each provide one μ_3-oxygen arm that bridges between the two central Fe^{III} ions and one outer Fe^{III} ion, and two μ_2-oxygen arms that each bridge between an outer and central Fe^{III} ion. These ions are also bridged by the two carboxylates which adopt their common *syn*, *syn* μ-mode. Each of the four Fe^{III} ions contains a terminal chloride ion, while the coordination spheres of each of the two terminal Fe ions is completed by one R′OH molecule. The Fe centres are in distorted octahedral geometries and all are in the +3 oxidation state as confirmed by a combination of charge balance and bond length considerations and BVS calculations.

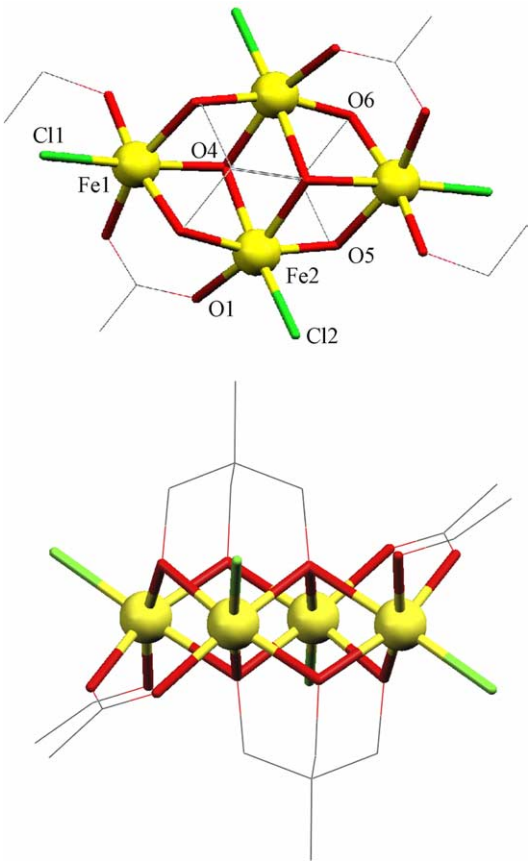

Fig. 1. The structure of complex **1** viewed perpendicular (top) and parallel (bottom) to the $[Fe_4]$ plane.

3.2. Structure of $[Fe_9O_4(O_2CCMe_3)_{13}(thme)_2]$ (**4**)

Complex **4** (Fig. 2) has a near planar rhomb-like array of nine Fe^{III} ions linked via a combination of oxide and alkoxide ions to give a $[Fe_9(O^{2-})_4(RO^{1-})_6]^{13+}$ core. Closer inspection reveals that the complex contains the identical $[Fe_4O_6]^{6+}$ rhomb (Fe6–Fe9, O25–O30) seen in complexes **1**–**3**. To this rhomb are now attached four $[Fe_3O]^{7+}$ triangular units which each share one Fe ion (Fe8, Fe9 or Fe6) with the $[Fe_4O_6]^{6+}$ rhomb. The two central $[Fe_3O]^{7+}$ triangular units (containing Fe2, Fe3, Fe9 and O6 and Fe3, Fe4, Fe9 and O11) edge share to form a $[Fe_4O_2]^{8+}$ rhomb. The two peripheral $[Fe_3O]^{7+}$ triangles (containing Fe4, Fe5, Fe6 and O16, and Fe1, Fe2, Fe8 and O1) each share one vertex with the $[Fe_4O_2]^{8+}$ rhomb and one vertex with the $[Fe_4O_6]^{6+}$ rhomb. The $[Fe_4O_6]^{6+}$ unit and the $[Fe_3O]^{7+}$ triangles are linked to each other through the thirteen carboxylate ligands that bind in three different modes: the usual μ, η_1, η_1, mode, the less common μ, η_2, η_1 mode

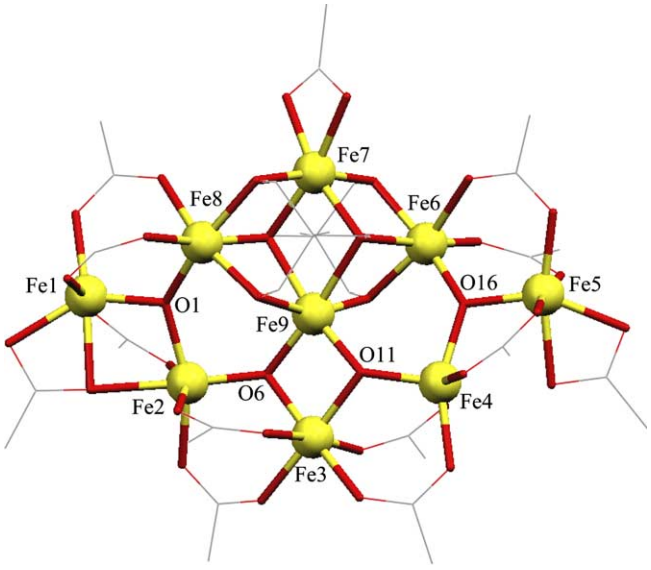

Fig. 2. The structure of complex **4** viewed perpendicular to the $[Fe_9]$ 'plane'.

(e.g., between Fe1 and Fe2), and as simple chelates (completing the coordination geometries of Fe(5) and Fe(7)).

All the Fe ions are in the +3 oxidation state and exhibit distorted octahedral geometries, with the exception of Fe(4), which is five-coordinate and in a distorted square based pyramidal geometry.

3.3. Structure of $[NEt_4][Fe_{11}O_4(O_2CPh)_{10}(thme)_4(dmhp)_2Cl_4]$ (5)

The structure of complex **5** (Fig. 3) closely resembles that observed in **1**–**3** and **4**. This time the structure contains two identical $[Fe_4O_6]^{6+}$ rhombs (containing Fe2, Fe4, Fe5 and Fe6 and symmetry equivalents), one at each 'end' of the molecule, linked to a central linear $[Fe_3O_4]^{1+}$ unit (containing Fe1, Fe3 and Fe1A). Alternatively the core can be thought of as four vertex sharing $[Fe_4]^{n+}$ units in which the two peripheral $[Fe_4O_6]^{6+}$ rhombs are connected to two central $[Fe_4O_2]^{8+}$ rhombs (comprising Fe1, Fe2 and symmetry equivalents) which themselves share one vertex (Fe3) forming a $[M_7O_4]^{13+}$ sub-unit. The 10 $PhCO_2^-$ ligands bridge in their familiar *syn*, *syn* μ-mode both within and between the various $[Fe_4]$ units. The coordination geometries of Fe2 and Fe4 are completed by a combination of terminal Cl^- ions and neutral dmhp ligands. These latter ligands are protonated with the nitrogen atom hydrogen bonding to a μ_2-oxygen of a $thme^{3-}$ ligand. The $[M_4]$ units seen in all of the above complexes are common building blocks in the structures of Fe^{III} and Mn^{III} clusters and the $[M_7O_4]^{13+}$ sub-unit is also a common feature in larger clusters, including $[Fe_{17}]$/$[Fe_{19}]$ [6], $[Mn_8]$ [7], and $[Fe_{11}]$ clusters [8]. In fact the $[Fe_{11}]$ core is similar to a $[Mn_{11}]$ cluster reported by Christou and co-workers [9], but in this case the peripheral units are $[Mn_4]$ cubes not rhombs.

While there are many examples of tetranuclear Fe aggregates, complex **4** is only the fifth nonanuclear Fe cluster reported [10] and complex **5** is only the second undecanuclear Fe complex reported. The original $[Fe_{11}]$ has no structural resemblance to **5** being based on a penta-capped trigonal prism [5].

3.4. Structure of $[Fe_8(O_2CR)_{12}(thme)_4]$ (6, R = Ph; 7, R = CMe_3)

The structure of both complex **6** and complex **7** (Fig. 4) can be described as a wheel of eight Fe^{III} ions bridged by a combination of RCO_2^- and $thme^{3-}$ ligands. The RCO_2^- ligands bridge neighbouring Fe^{III} ions in the usual *syn*, *syn* μ-manner while the triply-deprotonated $thme^{3-}$ ligands show much greater flexibility in each bridging four iron centres – each arm providing a μ_2-oxygen for adjacent metals. The iron ions all lie in distorted octahedral geometries and are of four types: Fe1, Fe3, Fe5 and Fe7 are bridged to three RCO_2^- and two $thme^{3-}$ ligands; Fe2 and Fe6 are bound to four RCO_2^- and two $thme^{3-}$ ligands; and Fe4 and Fe8 bond to two RCO_2^- and two $thme^{3-}$ ligands. The "Fe_8" wheel is non-planar and perhaps best described as ladle-shaped with a diameter of approximately 8 Å.

3.5. Structure of $[Fe_{16}(EtO)_4(O_2CPh)_{16}(Hthme)_{12}](NO_3)_4$ (8)

The size of the wheel seen in complex **7** is doubled by the addition of a coordinating alcohol in the crystallisation step – use of EtOH produces the hexadecametallic wheel $[Fe_{16}(EtO)_4(O_2CPh)_{16}(Hthme)_{12}](NO_3)_4$. Complex **8** (Fig. 5) can be described as a wheel of sixteen Fe^{III} ions bridged by $PhCO_2^-$, $Hthme^{2-}$ and EtO^- ligands. The

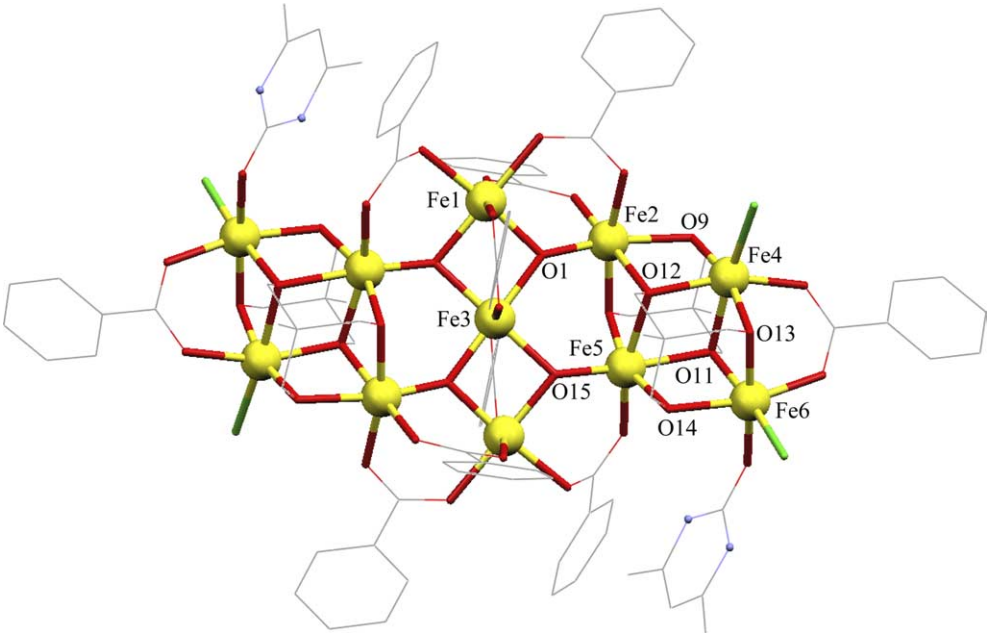

Fig. 3. The structure of complex **5** viewed perpendicular to the $[Fe_{11}]$ 'plane'.

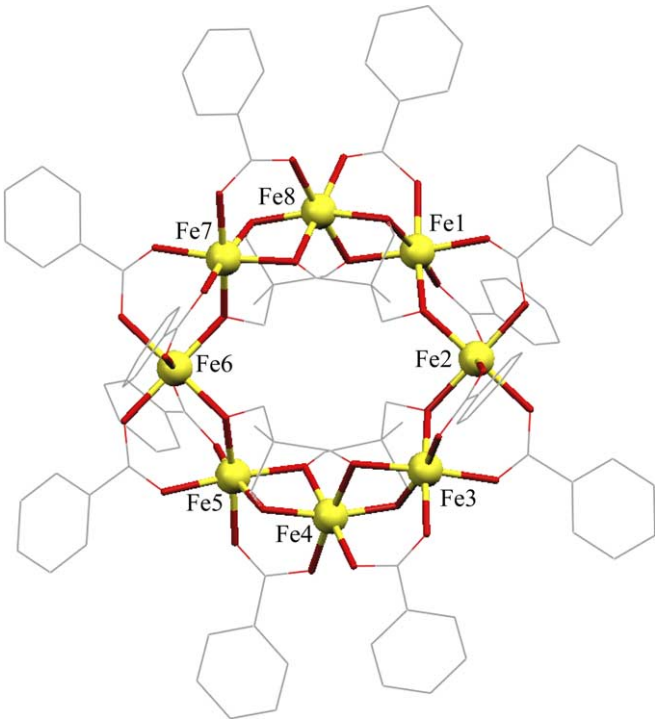

Fig. 4. The structure of complex **6** viewed parallel to the [Fe8] 'plane'.

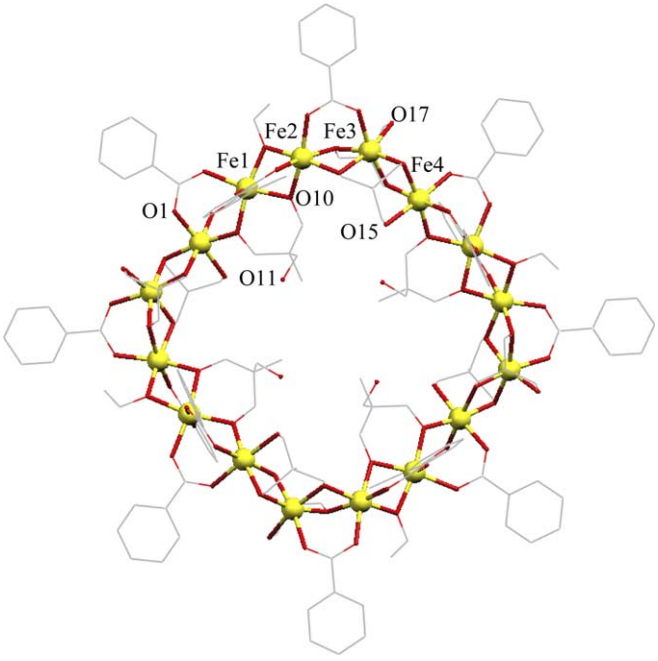

Fig. 5. The structure of complex **8** viewed perpendicular to the [Fe_{16}] 'plane'.

$PhCO_2^-$ ligands again bridge in their familiar μ-mode: above, below and in the 'plane' of the [Fe_{16}] wheel. The $Hthme^{2-}$ ligands are of two types. Eight ligands use their two deprotonated arms as μ_2-bridges forming a nearly linear chain of three metals, with the third protonated arm bonded only to the central iron center. Four $Hthme^{2-}$ ligands occupy the central cavity of the wheel: the deprotonated arms again acting as μ_2-bridges, with the protonated arm hydrogen bonding to the monodentate arm of an adjacent $Hthme^{2-}$ ligand (for example, O11–O15B 2.591(6) Å) and to a water molecule above the central cavity of the wheel (O11–O1S, 2.804(6)) Å. The four EtO^- ligands each bridge two iron centres on the outside edge of the wheel. The iron ions are all in distorted octahedral geometries and bound to six oxygen atoms. For Fe(1) these are derived from three $PhCO_2^-$, two $Hthme^{2-}$ ligands and one EtO^-. For Fe(2) from two $PhCO_2^-$, three $Hthme^{2-}$ ligands and one EtO^-. For Fe(3) from one $PhCO_2^-$ and five $Hthme^{2-}$ ligands, and for Fe(4) from two $PhCO_2^-$ and four $Hthme^{2-}$ ligands. Again the wheel is non-planar and best described as bowl-shaped with an approximate diameter of 16 Å.

4. Magnetic measurements

4.1. Magnetism of $[Fe_4(thme)_2Cl_4(O_2CR)_2(R'OH)_2]$ (1–3)

Solid state DC susceptibility measurements of complexes **1**–**3** were taken in the range of 2–300 K in a field of 3 kG. The data for all three complexes is essentially identical and here we limit our discussion to complex **1**. The $\chi_m T$ value of 10.61 $cm^3\,mol^{-1}$ K at 300 K gradually decreases with decreasing temperature to a minimum of 1.24 $cm^3\,mol^{-1}$ K at 6 K before increasing slightly to 1.52 $cm^3\,mol^{-1}$ K at 2 K. The spin only ($g = 2$) value expected for four non-interacting Fe^{III} centres is approximately 17.5 $cm^3\,mol^{-1}$ K. This behaviour is indicative of antiferromagnetic exchange between the Fe^{III} centres with the $\chi_m T$ value at low temperature consistent with a ground state spin of $S = 0$ or $S = 1$. Magnetisation data were collected in the range of 0–5.0 T at 2 K. The magnetisation increases beyond the expected saturation value for $S = 1$, most likely because higher multiplicity states become more stable as the magnetic field is increased due to the close proximity of these states to the ground state. Because of this no fit of the data was attempted.

4.2. Magnetism of $[Fe_9O_4(O_2CCMe_3)_{13}(thme)_2]$ (4)

Solid state DC susceptibility measurements of complex **4** were taken in the range 2–300 K in a field of 5 kG. The $\chi_m T$ value of 28.3 $cm^3\,mol^{-1}$ K at 300 K gradually decreases with decreasing temperature approaching a value of approximately 0.40 $cm^3\,mol^{-1}$ K at 2 K. The room temperature $\chi_m T$ value is smaller than the spin only value for nine non-interacting high spin Fe^{III} centres (39.38 $cm^3\,mol^{-1}$ K) indicating the presence of antiferromagnetic interactions. The low temperature value is close to that expected for a complex exhibiting a $S = 1/2$ spin ground state. Magnetisation data collected in the range of 0–5.0 T at 2 K are consistent with a small spin ground state with the presence of low-lying excited states of larger multiplicity that become

populated with increasing field – as indicated by an inflexion point (at ca. 2.2 T) and the continual rise in magnetization with applied field.

4.3. Magnetism of $[NEt_4][Fe_{11}O_4(O_2CPh)_{10}(thme)_4(dmhp)_2Cl_4]$ (5)

Solid state dc magnetization measurements were performed on **5** in the range 2–300 K in a field of 0.2 T between 300 and 50 K and 0.05 T between 50 and 2.0 K. (Fig. 6). The room temperature $\chi_m T$ value of approximately 18.7 $cm^3\,mol^{-1}\,K$ decreases to a minimum of 12.4 $cm^3\,mol^{-1}\,K$ at 70 K and then rises to a maximum of 15.4 $cm^3\,mol^{-1}\,K$ at 12 K. This indicates that **5** has a non-zero spin ground state and that the ground spin state is higher than $S = 9/2$. In order to obtain the ground state spin value magnetization data were collected in the ranges of 2.0–6.0 K and 0.01–5.5 T (Fig. 6). The fits were made simultaneously on the four different temperatures (2, 3, 4 and 6 K), assuming only the ground state is populated, giving a best fit of $S = 11/2$, $g = 2.03$ and $D = -0.46\ cm^{-1}$. The maximum value of $\chi_m T$ at low temperature (15.4 $cm^3\,mol^{-1}\,K$) and the fact that the magnetization data at 2 and 6 K can be fit with one set of parameters is a strong indication that the ground state is indeed $S = 11/2$ and that the first excited state is rather high in energy. The previously reported $[Fe_{11}]$ complex has an $S = 1/2$ spin ground state [5]. Given the nature of S and sign of D, measurements were taken to see if **5** acts as a SMM. Low-temperature (1.2–0.04 K) single crystal magnetic measurements were performed on **5** using a micro-SQUID instrument equipped with three orthogonal field that allow the magnetic field to be scanned in all directions [11]. Below 1.2 K hysteresis loops are seen in magnetization versus field studies whose coercivities increase with decreasing temperature (Fig. 7). A detailed study of the field sweep rate dependence of the hysteresis loops showed that the hysteresis at non-zero fields is not due to a phonon bottleneck but due to slow relaxation because of the anisotropy barrier. Slow relaxation is seen at $H = 0$ but the presence of strong tunnelling does not allow for a reliable Arrhenius plot. For all SMMs the barrier is reduced at $H = 0$ because of the presence of tunnelling. Even for half-integer spin systems which in theory should not tunnel do so because of coupling with the environment – dipolar coupling between molecules, hyperfine coupling, spin–spin cross relaxation, and other multibody quantum processes. For a system with $S = 11/2$ and $D = -0.46\ cm^{-1}$ for example, and assuming an internal transverse field of approximately 10 mT, one can estimate a tunnel splitting of ca. 2.8×10^{-6} K and thus a tunnel probability of $P = 0.68$ for a sweep rate of 0.1 $T\,s^{-1}$ in good agreement with our

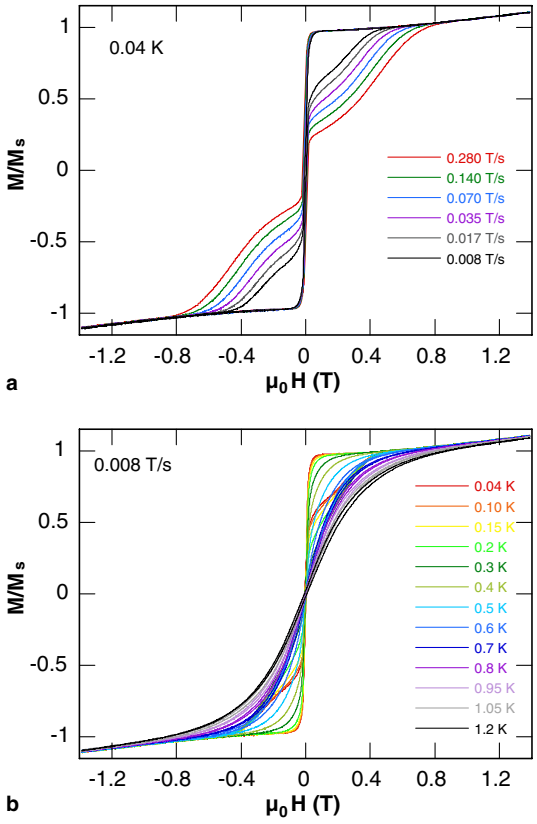

Fig. 7. Magnetisation (M) of **5** plotted as a fraction of maximum M_s vs. applied magnetic field ($\mu_0 H$). The loops are shown at different field sweep rates (top) and different temperatures (bottom).

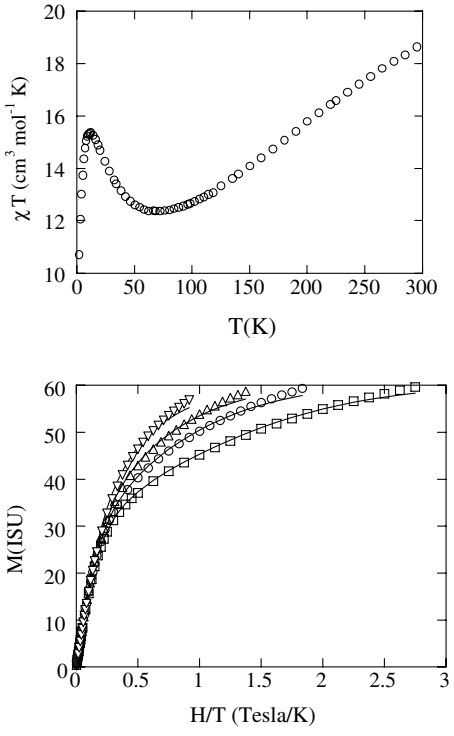

Fig. 6. Thermal variation of $\chi_m T$ in ranges 300–50 K at 0.2 T and 50–2 K at 0.05 T (top) and magnetization vs. H/T plot at 2 (□), 3 (○), 4 (△) and 6 (▽) K (bottom) for complex **5**.

measurements. This has also been observed in a $[Mn_4]$ cluster with $S = 9/2$ [7].

4.4. Magnetism of $[Fe_8(O_2CR)_{12}(thme)_4]$ (**6**, R = Ph; **7**, R = CMe_3) and $[Fe_{16}(EtO)_4(O_2CPh)_{16}(Hthme)_{12}](NO_3)_4$ (**8**)

The magnetic behaviour of compounds **6** and **7** are essentially identical and thus here we limit the discussion to complex **6**. Magnetic studies of both **6** and **8** indicate antiferromagnetic exchange between the metal centres. For both **6** and **8** the value of $\chi_m T$ declines rapidly from room temperature (~19, ~28 cm^3 K mol^{-1}, respectively) to a value approaching 0 cm^3 K mol^{-1} at 1.8 K indicative of $S = 0$ ground states for both complexes. The room temperature $\chi_m T$ value is approximately half the expected value for 8 (~35 cm^3 K mol^{-1}) and 16 (~70 cm^3 K mol^{-1}) non-interacting iron centres, indicating the existence of strong antiferromagnetic interactions even at room temperature. This is commonly found for iron-oxo clusters with Fe–O–Fe angles between 100° and 120° [12]. Both **6** and **8** can be broken down into simple units of two metal ions and the bridging ligands that connect them (Scheme 1). In this scheme, J_1, J_2 and J_3 are the magnetic coupling constants between two Fe^{III} ions for each of the three different bonding interactions found. These are: one alkoxo and two carboxylate bridging ligands (J_1); two alkoxo and one carboxylate bridging ligands (J_2); and two alkoxo bridging ligands (J_3). In order to analyse the magnetic behaviour of **6** and **8** we have found exact analytical equations for the χT product as a function of the temperature using the interaction topologies shown in Scheme 1. These equations have been developed following the classical spin approach and the methodology previously described by Fischer for one-dimensional systems [13]. This methodology can be applied since the spin correlation paths generated by the interaction schemes shown in Scheme 1 are large enough to neglect spin auto-correlation contributions through an entire loop [14]. The obtained analytical law is:

$$\chi T = \chi T_{\text{freeion}} \sum_{i,j,k} c_{i,j,k} u^i v^j w^k, \quad (1)$$

where u,v and w are the Langevin functions for J_1, J_2 and J_3, respectively, and $c_{i,j,k}$ are the coefficients of each term.

The best fits of the χ versus T curves (Fig. 8) in the 300–10 K temperature range are obtained with the following parameters: $g = 2.0$, $J_1 = -22.2$ cm^{-1} and $J_2 = -8.5$ cm^{-1} for **6**; and $g = 2.0$, $J_1 = -16.0$ cm^{-1}, $J_2 = -9.1$ cm^{-1} and $J_3 = -74.4$ cm^{-1} for **8**.

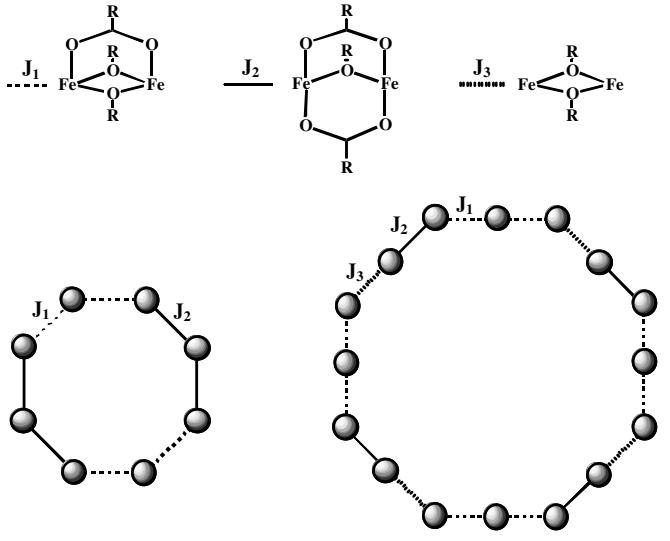
5. Conclusions

The tripodal ligand H_3thme has led to the isolation of a series of new Fe^{III} clusters. A simple combination of $FeCl_3$, NaO_2CR and H_3thme in a mixture of MeCN and MeOH under ambient temperature and pressure gives rise to a series of rhomb- or diamond-like $[Fe_4]$ clusters. The identical $[Fe_4]$ units are seen as building blocks in the formation of related $[Fe_9]$ and $[Fe_{11}]$ clusters, appearing once in the $[Fe_9]$ cluster and twice in the $[Fe_{11}]$ cluster. The $[Fe_9]$ cluster was made via the solvothermal reaction of $[Fe_3O(O_2CR)(H_2O)_3]O_2CR$ with H_3thme in MeCN – the same reaction at room temperature produces no isolable products. Repeating this reaction but simply replacing the RCO_2^- counter ion with NO_3^- or Cl^- under the same conditions produces dramatically different compounds with the formation of octametallic wheel-like clusters. The benzoate (R = Ph) form of this cluster can also be made under ambient conditions, albeit in much lower yields and in lower purity due to a tendency to co-crystallise with unreacted starting material $[Fe_3O(O_2CPh)_6(H_2O)_3]NO_3$. The solvothermal reaction gives much higher yield and pure crystalline product directly. The pivalate analogue (R = CMe_3) could only be isolated by a solvothermal route. The size of the wheel formed can be doubled via the introduction of alcohol to the reaction mixture to give a $[Fe_{16}]$ wheel.



Scheme 1. The different bonding interactions (J_1, J_2, J_3) present in complexes **6**–**8**.

Previously reported cyclic [Fe_8] compounds have contained alkali metal ions within the central cavity of the wheel and the [Fe_{16}] complex is unprecedented. The above reactions highlight the very wide range of product cluster nuclearities and topologies that can result from subtle changes in reaction conditions – for example, changes in counter-ion, or solvothermal versus lower temperature routes.

All of the Fe species display dominant antiferromagnetic exchange interactions, but in the case of [Fe_{11}] this stabilises a rather large $S = 11/2$ spin ground state. Negative zero-field splitting within this ground state gives rise to single-molecule magnetism behaviour that is manifested in the presence of temperature and sweep rate dependent hysteresis loops.

Abstract

Atmospheric chemical vapour deposition (APCVD) was used to deposit composite TiO_2–VO_2 films on glass. The films were characterised by X-ray photoelectron spectroscopy, X-ray diffraction, Raman, energy dispersive X-ray analysis and scanning electron microscopy. These composite films exhibited photo-induced hydrophilicity, photocatalysis and a thermochromic switching temperature of 54 °C.

1. Introduction

Thermochromic coatings change their reflectance – transmission properties with temperature. Thermochromic materials are usually characterised by a semiconductor to metal transition occurring from a reversible change in their crystalline structure as a function of temperature [1]. They could find application in commercial and domestic windows in climates where there are significant fluctuations in temperature during the day and year (Northern Europe, Asia, North America, Near East). At temperatures below the thermochromic transition temperature (T_c) the material is largely transparent to sunlight and enables solar gain through a window. Above T_c the material increases its reflectivity and a reduction in solar gain occurs. The thermochromic material could thus make an 'intelligent glazing' as it responds to the external environment.

The thermochromic change has been observed in transition metal oxides such as Ti_2O_3, Fe_3O_4, Mo_9O_{26} [1,2] and in several forms of vanadium oxide, V_nO_{2n-1}. Among them, VO_2 has received the most attention because of the large reversible change of electric, magnetic and optical properties at temperatures around 70 °C [3]. Indeed of all of the transition metal oxides studied this material has its switching temperature closest to room temperature.

The thermochromic phase transition in vanadium dioxide was first demonstrated in 1959 [4]. This transition is due to a structural transformation from monoclinic to tetragonal. The optical properties of vanadium oxide through the transition temperature are characterised by a sharp decrease in transmission in the infrared spectrum. This is coupled with a concomitant increase in its IR reflectivity and electrical conductivity. Essentially in the monoclinic phase electrons are localised in V^{4+}–V^{4+} homopolar bonds and the material is a semiconductor. Above the transition temperature, the tetragonal phase is metallic and the V^{4+}–V^{4+} homopolar bonds are broken and the electrons free to enter the conduction band. Because of this unusual behaviour, VO_2 thin films have attractive applications as window coatings, electrical or optical switches, optical storage, laser protection and energy control for space satellites.

We have shown that substitutional doping of tungsten into the VO_2 lattice leads to a significant reduction in the thermochromic switching temperature – with a linear

doi:10.1016/j.poly.2005.08.018

decrease in T_c with tungsten content (a reduction in T_c of 20 °C is seen per atom% W) [5,6]. Such a reduction in switching temperature offers a potentially useful commercial application because the T_c is now down below that desired for window applications (25–30 °C).

This paper details the reaction of $Ti(OiPr)_4$, $VOCl_3$ and water. The initial aim was to produce Ti-doped VO_2 thin films. However, we found that the reaction produced a TiO_2–VO_2 composite thin films – notably these films showed a reduction in switching temperature, photocatalytic activity and photoinduced superhydrophilicity. They also showed a sharp thermochromic transition with minimal hysteresis.

2. Experimental

All APCVD experiments were performed on a custom built apparatus consisting of a horizontal-bed cold-wall reactor connected to an arrangement of stainless-steel heated pipes, valves and bubblers [5,6]. A syringe driver was attached to the plain-line gas-flow for the introduction of water. A schematic of the APCVD rig has been published previously [5,6]. All heaters were regulated by Eurotherm controllers and RS type k thermocouples.

2.1. APCVD procedure

$VOCl_3$ (Aldrich UK, 99%) was transferred to bubbler 2 and titanium isopropoxide to bubbler 1 [5,6]. Distilled water was injected into the plain-line gas-flow using a fixed rate syringe driver (0.473 cm min^{-1}). The amount of water introduced was controlled via the size of the syringe. The substrate was SiO_2-precoated standard float glass (Pilkington, UK) 15 cm × 4.5 cm × 0.3 cm. The glass substrate was cleaned before use by being wiped with a tissue soaked in water, then with a tissue soaked in propan-2-ol and finally rinsed with propan-2-ol. The glass was allowed to dry in air prior to it being mounted in the CVD chamber.

A flow of nitrogen (BOC, 99.9%) was passed through the apparatus during all operations of the APCVD rig. The amount of $VOCl_3$ introduced into the system was calculated from

$$a = (\mathrm{VP} \times F)/((760 - \mathrm{VP}) \times 24.4),$$

where a is the amount of material introduced (mol min^{-1}), VP is the vapour pressure of the material at the temperature of the bubbler (mmHg), and F is the carrier-gas flow-rate through the bubbler (L min^{-1}).

The plain line and $VOCl_3$ bubbler-line flow-rates were set to 0.5 L min^{-1}. Once all the temperatures had been stabilised, the syringe driver valve was opened and distilled water was introduced into the plain-line gas-flow. Nitrogen was passed through the bubbler and the bypass valve was closed. $VOCl_3$ chloride was seen to pass through the exhaust. After allowing the flow to stabilise for approximately 10–20 s the three-way valve was switched to allow the precursor to pass into the mixing chamber and on to the reactor. Once the allotted reaction time was complete (60 s), the three-way valve was switched to the exhaust, the bypass valve opened and the nitrogen flow through the bubbler closed. The reactor heater was turned off and the substrate was allowed to cool under an atmosphere of nitrogen. The substrate was removed from the reactor below 200 °C. All samples were handled and stored in air.

The conditions for introducing titanium isopropoxide as a reactant involved setting the inert N_2 gas flow rate at 0.2 L min^{-1} for the bubbler containing the titanium isopropoxide, and the $VOCl_3$ flow rate was constant at 0.5 L min^{-1}. The substrate temperatures were 550, 600 and 650 °C – these temperatures were measured by an external thermocouple directly on the surface of the glass substrate. To achieve these temperatures on the substrate the control thermocouple within the graphite susceptor was set at between 8 and 10 °C higher (i.e., 560 °C rather than 550 °C).

2.2. Film analysis

Analysis of the resulting films consisted of UV/Vis absorption spectroscopy, contact angle measurements, scratch tests, solubility tests, photocatalysis measurements, Vis/IR reflectance–transmittance, Raman spectroscopy, SEM/EDAX and glancing angle X-ray diffraction. X-ray analysis of the films was determined using glancing angle incidence (1.5°) on a Siemens D5000 machine using primary monochromated Cu $K_{\alpha 1}$ radiation (1.5406 Å). SEM/EDAX was determined on a JEOL 35-CF instrument using ISIS software (Oxford Instruments). Electronic absorption measurements were obtained using a Thermospectronic Helios-α spectrometer from 300 to 1100 nm. Reflectance/transmittance measurements were made on a Zeiss miniature monolithic spectrometer (range 380–1150 nm) connected to a PC. Sheet resistance measurements were determined on a four-probe instrument. Raman measurements were carried out using a Renishaw System 1000 Raman spectrometer with a HeNe (632.8 nm) laser excitation source. Contact angles of selected glass samples were determined by measuring the spread of a 1.0 μL droplet of water. Scratch tests were determined with a paper towel, brass stylus and stainless steel scalpel. Solubility tests were achieved by immersion of small pieces of the coated glass in a range of solvents (toluene, acetone, methanol, hexane, water, 2 M NaOH, 2 M HCl and 2 M HNO_3). The adhesion of the films to the substrate was determined by the Scotch tape test (removal of an X shaped piece of sticking tape).

2.3. Photocatalytic analysis

Photocatalytic activity of the samples was assessed by the destruction of an overlayer of a test organic – stearic acid, on a 3 cm × 3 cm portion of coated glass. This coated glass had been irradiated at 254 nm for 1 h prior to measurement. The stearic acid was applied by dropping

7.5 μL of a 0.4 mmol methanol solution onto the glass surface, which was spun at 1500 revolutions a minute during the dropping procedure. The infrared spectra of the stearic acid overlayer was measured over the range 2950–2800 cm^{-1}. The glass coated with stearic acid was irradiated with 254 nm radiation provided by BDH germicidal lamps (2×8 W). The IR spectra of the stearic acid were measured after 30 min intervals for up to 2 h and the areas of the bands attributed to the C–H stretches quantified.

2.4. Thermochromic analysis

The thermochromic switching temperature was determined by measuring the absorption of the film at 4000 cm^{-1} at different temperatures using a Nicholet FT-IR spectrometer.

3. Results and discussion

The APCVD reaction of titanium isopropoxide, $VOCl_3$ and water at substrate temperatures of 650, 600 and 550 °C deposited composite TiO_2–VO_2 films. It was found with all samples that the films had a uniform composition across the substrate. The films were light brown, passed the scotch tape test, were not removed by a tissue or felt but were scratched with both brass and steel. All films were insoluble in water and common organic solvents (methanol, ethanol, acetone), but they did dissolve in both acid (HCl, 2 M) and alkali (NaOH, 2 M). The films showed no change in optical properties on storage in air for one year.

Glancing angle X-ray diffraction confirmed the presence of both crystalline anatase TiO_2 and VO_2 in the composite films as shown in Fig. 1. A strong signal at approximately 27.8° 2θ can be seen in the XRD data, this strong signal corresponds to the (0 1 1) reflection of monoclinic VO_2, and indicates the films are preferentially orientated on the substrate. The additional weaker reflections at 38°, 54° and 56° 2θ are as expected for the anatase phase of titania [7]. The X-ray data confirms that a composite film is formed and furthermore no shift in the main (0 1 1) diffraction peak of VO_2 is seen indicating that very little if any titanium is actually present within the VO_2 lattice as in a solid solution.

Raman spectroscopy of the films showed a pattern consistent with that for a composite film and showed the expected bands for both anatase TiO_2 and monoclinic VO_2, Fig. 2. The Raman pattern showed monoclinic VO_2 with bands at 144, 190, 315, 389, 498 and 611 cm^{-1}. These are comparable to reference values identified by Parker [8] and Aronov [9,10]. No bands due to VO_2(B), the metastable form of VO_2 were observed [11]. There are also peaks present that indicate the presence of anatase TiO_2 at 143, 396 and 612 cm^{-1}. There are no shifts in the Raman peaks that would indicate the incorporation of Ti into the VO_2 network as in a solid solution.

SEM imaging confirmed that the films are composed of two distinct types of particle – the majority where 'rectangle like' particles of size ca. 3 μm by 200 nm at a deposition temperature of 650 °C and 2 μm by 200 nm at both 600 and 500 °C. The second particle type were approximately spherical aggregates of varying diameter across the film surface at all substrate temperatures and flow rates, averaging ca. (1 μm, Fig. 3). Side on SEM analysis indicated a growth rate of ca. 400 nm min^{-1}.

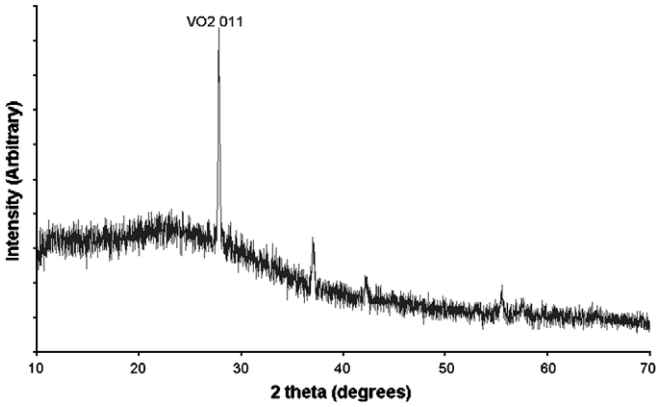

Fig. 1. X-ray diffraction pattern of the film formed by the APCVD reaction of $VOCl_3$, $Ti(O^iPr)_4$ and water at 650 °C.

Spot EDAX (wavelength dispersive detector) analysis showed that the 'rectangle-like' particles contained only vanadium and oxygen in a 1:2 ratio and the non-uniform 'blob' like particles contained only titanium and oxygen in a 1:2 ratio. The wide area EDAX analysis showed that the films were composed of 1 part TiO_2 to 10 parts VO_2. Notably carbon was not detected by EDAX (less than 1 atom%). The elemental analysis gave results that were comparable to the gas-phase concentration of the precursors used – a constant ratio was used in the reactions. Therefore, there was a good transferability from the solution to the deposited films. Spot analysis on all the rectangle particles and aggregated particles from all films yielded similar results which suggests a homogeneous distribution of the TiO_2 on the surface of the film at a ratio of ca. 1 part TiO_2 to 10 parts VO_2.

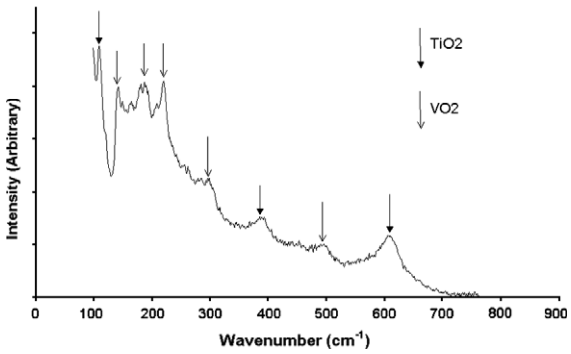

Fig. 2. Raman pattern obtained from the film formed by the APCVD reaction of $VOCl_3$, $Ti(O^iPr)_4$ and water at 650 °C.

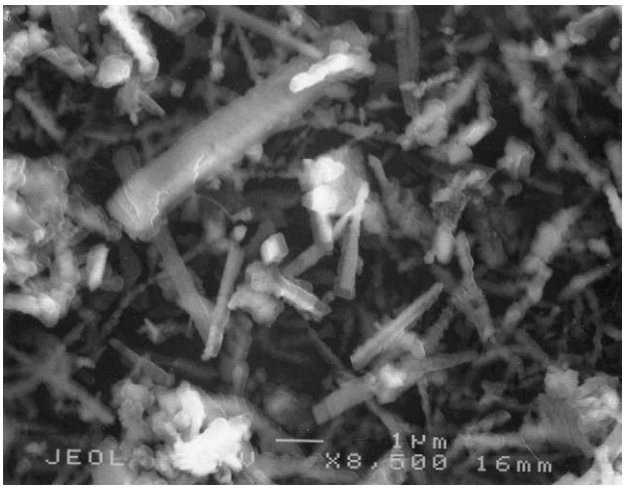

Fig. 3. SEM image obtained from the film formed by the APCVD reaction of $VOCl_3$, $Ti(O^iPr)_4$ and water at 650 °C.

All of the composite films exhibited a band gap of 0.7 eV by the Tauc method. This value is directly comparable to reference values for VO_2 [12]. All of this data ties in well with the formation of a composite film that is in effect a matrix of interlocked TiO_2 and VO_2 particles with no evidence for the formation of a solid solution of $Ti_xV_yO_2$.

3.1. Functional properties

The thermochromic transition temperature was measured for the TiO_2–VO_2 films at 54 °C. This was determined by measuring the transmission through the film at a fixed wavelength of 2.5 μm, Fig. 4.

The thermochromic switching temperatures did not alter with reaction conditions such as flow rate or substrate temperature. There is a clear decrease in switching temperature from that of pure VO_2 films and is most probably related to the morphology of the VO_2 films which all have one axis that is ca. 200 nm in dimension and this is likely to have induced some strain [13]. Physical vapour deposited VO_2 films that have one dimension less than 300 nm have been reported as causing a reduction in up to 20 °C in the thermochromic switch. Notably as all of the VO_2 films were made up of the same morphology of crystallite, with the same restricted length axis, it is probably not too surprising that they all had similar reductions in T_c. Beteille et al. [14], prepared $Ti_xV_yO_2$ solid solutions via the sol gel process and found that the T_c increases and the hysteresis width lowers with increasing Ti dopant. This lends further evidence to the formation of a composite film in this APCVD study as a reduction in T_c was observed – the opposite to what would be expected for solid solution formation.

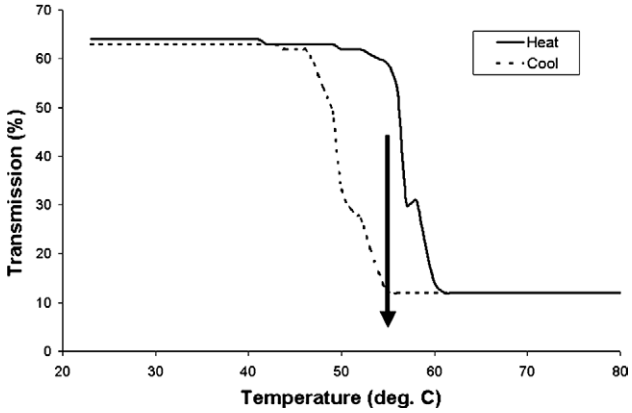

Fig. 4. Variable temperature transmission plot at 2.5 μm for the film formed by the APCVD reaction of $VOCl_3$, $Ti(O^iPr)_4$ and water at 650 °C.

The composite TiO_2–VO_2 films displayed photocatalytic activity and exhibited photo-induced hydrophilicity. The initial contact angles for water droplets were in the range 85–105° prior to irradiation, this reduced to 31–48° on exposure to 254 nm radiation for 1 h and decreased further to values of 16–20° after 12 h exposure to sunlight. Leaving the films in the dark for 24 h lead to an increase in contact angles to ca. 60–69°. The system could be multiply light–dark cycled and the same variation in contact angle was noted. The variations in contact angle are readily explained by the TiO_2 component of the films. Anatase is an excellent photocatalyst that also exhibits photo-induced superhydrophilicity [15] and water contact angles of less than 5° are often observed for pure anatase films. The composite films formed contain ca. 10% TiO_2 that is sufficient to allow part of the surface to show low contact angles. The photocatalytic results are also indicative of small amounts of titania incorporated into the film.

We have investigated the formation of VO_2–TiO_2 films previously from a different precursor set – $TiCl_4$ and $VOCl_3$ and water [5,6]. The morphology of the films formed is quite different – the VO_2 component was made from 'worm-like' particles as opposed to the straight edged crystalline materials seen here from the APCVD of $VOCl_3$, titanium tetraisopropoxide and water. The proportion of titanium to vanadium in both sets of films was quite surprising at 1:10. Furthermore, both sets of films showed a similar reduction in T_c values 54 °C measured in this study and 51 °C previously. The films formed in this work were more robust and importantly the hysteresis width of the transition was narrower – ca. 6–8 °C here compared to ca. 10–15 °C previously. This is significant because for a commercial application the minimum possible hysteresis is required to maximise solar reflection at a specific temperature.

3.2. Solid solution versus composite film

The films produced in this study were composite mixtures of TiO_2 and VO_2 rather than a solid solution $Ti_xV_yO_2$. Solid solutions are readily formed from a sol–gel approach so the fact that it is not formed here is not related to atomic incompatibility [14]. Furthermore, the heat treatments used in making sol–gel $Ti_xV_yO_2$ are

comparable to the temperatures used in this CVD reaction (albeit for a longer duration). The most likely determining factor in the formation of composite films is reaction kinetics. The titanium tetraisopropoxide used as a titanium precursor reacts much faster under CVD conditions with water than $VOCl_3$. Hence, the titanium dioxide particles found in the films have a rounded morphology that strongly suggest that they have arisen from gas phase nucleation – reaction between titanium isopropoxide and water and become trapped within a vanadium dioxide matrix. The fact that the vanadium dioxide has a well-defined crystalline morphology indicates that it is predominantly formed from surface reactions – that is conventional CVD growth. This hypothesis would readily explain why a solid solution is not formed because the titanium tetraisopropoxide has effectively already reacted before it hits the surface and hence few if any titanium species are available for incorporation into the vanadium dioxide lattice.

3.3. Multifunctional coatings

The composite films formed in this study show photocatalysis, hydrophilicity and a thermochromic switch. The photocatalysis is less than a pure CVD prepared anatase TiO_2 thin film – about 10% of the activity. This level of activity scales exactly with the titania content of the film. Although this photoactivity is relatively low it still sufficient for self-cleaning action. The reduction in water contact angle of the TiO_2/VO_2 thin film when exposed to sunlight again is less than what would be expected for a CVD prepared anatase film – however, it does render the surface hydrophilic. The reduction in thermochromic switching temperature observed for the films is a result of induced strain. The reduction of 16 °C from pure VO_2 is noteworthy and somewhat larger than that seen for pure VO_2 formed by CVD (where a reduction of ca. 10 °C is common). Furthermore, the hysteresis width of the transition is significantly lowered in the films formed in this study. It is possible that the co-location of titania particles within the VO_2 matrix improves marginally the thermochromic performance.

4. Conclusion

Composite TiO_2–VO_2 films were deposited via the APCVD reaction of $VOCl_3$, titanium isopropoxide and water. The composite films formed show three useful functional properties – photocatalysis, low contact angles and some significant reduction in thermochromic switching temperature, 54 °C. It also shows that composite films of this kind do not interfere with the functionality of each individual component and that solid solutions are not formed.

DFT calculations of NMR J_{C-H} coupling constants: An additional tool to characterize the α-agostic interaction in high oxidation state M-alkylidene complexes (M = Re, Mo and Ta)

Xavier Solans-Monfort, Odile Eisenstein *

Laboratoire de Structure et Dynamique des Systèmes Moléculaires et Solides (UMR 5636, CNRS), cc14, Institut Gerhardt, Université Montpellier II, F-34095 Montpellier Cedex 05, France

Received 27 April 2005; accepted 11 August 2005
Available online 23 September 2005

Abstract

NMR spin–spin J_{C-H} coupling constants have been calculated for the α-alkylidene C–H bond in several high oxidation state d^0 transition metal-alkylidene complexes (M = Re, Mo, Ta). The DFT(B3PW91) calculations have been carried out using the GIAO method for the isolated molecules, with no solvent effect or thermal corrections. The experimental systems have been modeled either by replacing all large size ligands by ligands of smaller size with similar electronic properties or by calculating the full chemical entities. It is shown that the calculations are able to reproduce well the trends in the J_{C-H} values over a range of 75–150 Hz when the IGLO basis sets are used. In addition, the calculated J_{C-H} values differ from the experimental ones by about 10% in the case of weak α-C–H agostic interactions (pseudotetrahedral Re and Mo complexes) and by 15% in the case of strong α-C–H agostic interactions (pseudooctahedral Ta complexes). This shows that the electronic environment of the alkylidene C–H bonds, associated with the α-agostic interaction, is properly evaluated at this level of calculations for transition metal complexes of rather large size.

1. Introduction

High oxidation state (d^0) transition metal-alkylidene complexes were discovered 30 years ago, and since this time, a large variety of them have been synthesized, in part because they are potential olefin metathesis catalysts [1–7]. In several of these complexes, the J_{C-H} NMR spin–spin coupling constant of the α-alkylidene C–H bond is low. This has been attributed to a weakening of the C–H bond due to the presence of an α-C–H agostic interaction, i.e., an intramolecular interaction between the C–H bond, acting as a Lewis base, and the electron deficient metal center acting as a Lewis acid [8–11].

The NMR spin–spin coupling constant is a key tool to characterize the C–H···M agostic interactions because the J_{C-H} varies over a rather large range of values whereas the C–H bond length varies little. The J_{C-H} value of a non-agostic $C(sp^2)$–H bond is around 160 Hz [12] whereas values as low as about 75 Hz have been observed in some complexes (see later). In contrast, the C–H bond is lengthened by 0.05 Å at most [13]. Furthermore, the C–H bond length cannot be determined experimentally with high accuracy by other techniques than the expensive and difficult neutron diffraction method. Vibrational stretching frequencies of the agostic C–H bond may be hard to identify because the band can be weak and broad [13]; computational studies are therefore very useful. The geometrical optimizations give C–H values, which usually compare very well with

doi:10.1016/j.poly.2005.08.015

experiment in the few complexes whose structure has been studied by neutron diffraction [10]. Associated with the lengthening of the C–H bond, the stretching frequency is lower than that of a non-agostic C–H bond. However, direct comparison between the calculations and the experiment requires the calculations of J_{C-H}.

In general, calculations of NMR chemical shifts and spin–spin coupling constants require considerable computational effort [14–18]. However computations of NMR parameters for transition metal complexes have been made possible because of the successful development of the DFT methods as described in the recent review by Autschbach [17]. The key point is that calculations using the GIAO [19,20] or IGLO [21,22] methods, along with extended basis sets, give NMR chemical shifts and spin–spin coupling constants that can be reasonably compared with experiment. In the case of the spin–spin coupling constant, the calculated values differ from the experimental ones by 10–20% [17,23]. Because of the computational effort involved, spin–spin C–H coupling constants have so far only been calculated for various relatively small organic molecules [23–26] and few metal complexes [27–29]. In the case of transition metal complexes, NMR spin–spin coupling constant calculations have been focused on ligand–ligand, metal–ligand and metal–metal coupling constants [30–37].

It has been shown that the spin–spin coupling constant is influenced both by the solvent and by vibrational effects [23,38,39] and that the solvent effect is especially important in the case of electron deficient complexes [33,34,40]. In the case of transition metal complexes, the solvent effect has been shown to be due in large part to the coordination of molecule of solvent, which changes the coordination number of the metal center. Anharmonicity and vibrational effects have been shown to be most important in the case of two atoms with distance that are far from usual distance. For instance these effects will be more important in the case of compressed dihydride and stretched dihydride complexes than in the case of regular dihydrogen or dihydride complexes [30,37]. In such cases, a temperature effect is expected [41].

These limitations being known, it should be possible to calculate J_{C-H} for agostic C–H bonds. An agostic interaction requires an electron deficient metal but is usually observed in weakly or non-coordinating solvent. The C–H bond is only very slightly elongated by the agostic interaction so that the vibrational effect should be negligible since temperature effects have never been reported. We can thus study if the calculations reproduce, with reasonable computational effort (DFT with electronic core potential on heavy atoms and limited basis sets), the changes in the J_{C-H} values in systems where it should be acceptable to neglect the temperature and solvent effects. To better test the validity of the computational method, we have studied two sets of complexes. One set is the pseudotetrahedral series, Re(≡C*t*Bu)(=CH*t*Bu)(X)(Y) (X = Y = CH_2*t*Bu; X = Y = O*t*Bu; X = CH_2*t*Bu, Y = $OSiPh_3$) [42–46] and Mo(=NR)(=CH*t*Bu)(X)(Y) (R = 2,6-*i*Pr_2-(C_6H_3) or CPh_3; X = Y = CH_2*t*Bu; X = Y = O*t*Bu) [47–51] where the agostic interaction is weak and has been observed only in one of the two isomers. The second set is the pseudooctahedral cyclopentadienyl tantalum alkylidene series, Ta(C_5R_5)(=CH*t*Bu)(X)(Y) (R = H (Cp) or CH_3(Cp*), X = Y = Cl; X = Y = CH_2*t*Bu) where the alkylidene C–H α-agostic interaction is strong [52]. The alkylidene group has a relatively high barrier for rotation in all these complexes [1,27,44,48,53,54], which avoids averaging problems. The following pattern emerges from the experimental results. Changing the metal and the coordination number changes J_{C-H} significantly but changes of only a few hertz result from a substitution of ligands in a given complex. Experimentalists consider, nevertheless, these small changes as meaningful and it is therefore of interest to establish if the computations are able to reproduce the detailed changes in J_{C-H} as well as the absolute values in a quantitative way.

The GIAO method with basis sets including functions with large exponents for accurate representation of the core electrons such as the IGLO-II and IGLO-III basis sets, elaborated by Kutzelnigg et al. [55] give very good results for NMR properties including spin–spin coupling constants. Good results have been also obtained with aug-cc-pXVZ basis sets after addition of supplementary core functions [14,23]. However, the vast number of calculations of transition metal complexes have been carried out with 6-31G(d,p) Pople type basis set on the organic ligand [56]. We will thus compare the results obtained with the Pople basis set and the IGLO basis set in the case the rhenium complexes. Only the IGLO basis sets will be used for the other systems.

2. Computational details

In one set of calculations, the experimental rhenium Re(≡C*t*Bu)(=CH*t*Bu)(X)(Y) (X = Y = CH_2*t*Bu, Re-1; X = CH_2*t*Bu, Y = $OSiPh_3$, Re-2; X = Y = O*t*Bu, Re-3) complexes, the molybdenum Mo(=NR)(=CH*t*Bu)(X)(Y) (R = 2,6-*i*Pr_2-(C_6H_3), X = Y = CH_2*t*Bu, Mo-1; R = CPh_3, X = Y = CH_2*t*Bu, Mo-2; R = 2,6-*i*Pr_2-(C_6H_3),X = Y = O*t*Bu, Mo-3) complexes and the tantalum Ta(C_5R_5)(=CH*t*Bu)(X)(Y) (R = CH_3, X = Y = CH_2*t*Bu, Ta-1; R = CH_3, X = Y = Cl, Ta-2 and R = H, X = Y = CH_2*t*Bu, Ta-3; R = H, X = Y = Cl, Ta-4) complexes have been represented by small models, constructed by substitution of *t*Bu by Me, *i*Pr groups by H and Ph by H. The calculated small systems are labeled with a subscript q (i.e., Re-1_q, Re-2_q, Re-3_q, etc.) by analogy with our previous contribution [27]. In another

set of calculations, the full experimental systems have been calculated only for the rhenium and selected tantalum complexes in order to evaluate the influence of the bulk of the substituents in the pseudotetrahedral and pseudooctahedral coordination spheres. All systems are shown in Scheme 1.

Geometry optimizations are performed, without any geometrical constraint, with the hybrid B3PW91 density functional [57,58], as implemented in the GAUSSIAN03 package [59] for the small systems and with the ONIOM (B3PW91:UFF) approach [60,61] for the full systems. In the ONIOM scheme the inner layer is equal to the small model. The Re, Mo, Ta and Si atoms are represented with the quasi relativistic effective core pseudopotentials (RECP) of the Stuttgart group and the associated basis set augmented with a polarization function [62,63]. The remaining atoms (C, H, and O) are represented with 6-31G(d,p) basis sets [64].

NMR J_{C-H} coupling constants are computed using the GIAO method [19,20] with a full DFT (B3PW91) calculation at the previous optimized (B3PW91 or ONIOM) geometries. To test the dependence of J_{C-H} on the basis set level, the J_{C-H} coupling constants have been calculated using six different basis sets for the rhenium complexes within the small model approximation. In all systems, Si and the metal atoms are represented with the previously described basis sets and only the representation of C, O and H has been varied. The Pople's double-ζ 6-31G(d,p) (BS1) and 6-31+G(d,p) [64] (BS2) and triple-ζ 6-311+G(d,p) (BS3) and 6-311++G(2df, 2pd) [65] (BS4) basis sets have been chosen to test the effect of valence electron representation on computing J_{C-H}. These basis sets have been previously used for computation of J_{C-H} coupling constants involving agostic interactions [27,29]. The Kutzelnigg's IGLO-II (BS5) and IGLO-III [55] (BS6) basis sets have been used. These basis sets are derived from Huzinaga's basis sets [66] and adapted to reproduce NMR properties [22,67]. They have been shown to give good results for NMR chemical shifts and coupling constants especially for organic molecules [14,15,23,28]. Finally the J_{C-H} coupling constants have been calculated at the optimized B3PW91/IGLO-II geometry.

The J_{C-H} values for Mo and Ta complexes are only calculated with IGLO-II basis set, which is found to give the best results at a competing level.

As mentioned in the introduction, the solvent effect was not included because agostic interaction is only observed in weakly or non-coordinating solvent. The anharmonicity, vibrational and thermal effects have been neglected because the C–H bond is relatively close to its usual length.

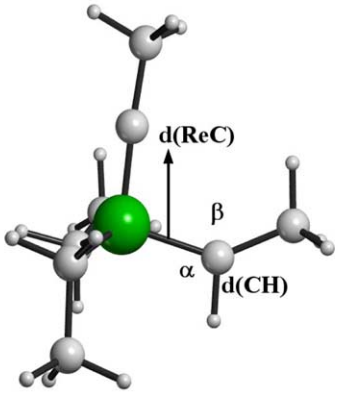
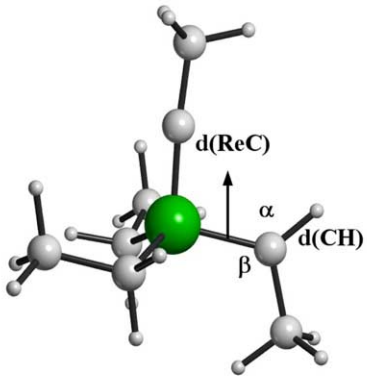
3. Results and discussion

3.1. The Re(≡CtBu)(=CHtBu)(X)(Y) complexes: methodology and calibration

The geometries of Re complexes, presented in Fig. 1, have been discussed at length in our previous contribution [27]. Thus, only key points will be mentioned here when needed. The overall geometries of the complexes for the small models are in good agreement with the available experimental data. The presence of the full ligands introduced only minor changes in the structures, the main difference residing in a slight change in the difference in the energy between the *syn* and *anti* isomers, the two isomers being always close in energy. The *syn* isomer is more stable than the *anti* isomer for the small and full models for Re-1 and Re-2. The situation is different for complex Re-3: the *syn* isomer is more stable





Re-1s$_q$ d(ReC) = 1.861, d(CH) = 1.112, α = 104.2, β = 140.3
Re-2s$_q$ d(ReC) = 1.873, d(CH) = 1.110, α = 107.2, β = 138.8
Re-3s$_q$ d(ReC) = 1.876, d(CH) = 1.108, α = 108.3, β = 137.8
Re-1s d(ReC) = 1.860, d(CH) = 1.119, α = 97.5, β = 148.1
Re-2s d(ReC) = 1.867, d(CH) = 1.117, α = 99.3, β = 147.3
Re-3s d(ReC) = 1.874, d(CH) = 1.114, α = 101.6, β = 145.6

Re-1a$_q$ d(ReC) = 1.872, d(CH) = 1.090, α = 128.5, β = 115.7
Re-2a$_q$ d(ReC) = 1.882, d(CH) = 1.091, α = 127.9, β = 117.4
Re-3a$_q$ d(ReC) = 1.884, d(CH) = 1.090, α = 127.8, β = 117.1
Re-1a d(ReC) = 1.897, d(CH) = 1.094, α = 118.0, β = 130.3
Re-2a d(ReC) = 1.890, d(CH) = 1.093, α = 122.6, β = 123.0
Re-3a d(ReC) = 1.891, d(CH) = 1.092, α = 123.7, β = 122.6

Fig. 1. Optimized geometries of *syn* and *anti* Re(≡CCH$_3$)(=CHCH$_3$)(CH$_2$CH$_3$)$_2$ isomers and a selected list of geometrical parameters for all Re(≡CR)(=CHR)(X)(Y) complexes [12]. Distances in Å and angles in degrees.

for the small model and the *anti* isomer is more stable for the full model. The changes in the geometries of the Re–alkylidene–alkylidyne moiety from Re-1 to Re-3 are small. Focusing on the C–H alkylidene bond, the geometrical parameters suggest that the C–H bond is weaker in the *syn* isomer than in the *anti* isomer and support the presence of an α-agostic interaction in the *syn* isomer. However, the small magnitude of the geometrical changes, which furthermore are spread over several bond distances and bond angles, makes the structural analysis difficult. The analysis of the wave function shows that, among the five empty metal d orbitals, three of them are used for Re–C multiple bonds with the alkylidene and alkylidyne groups provided that the two groups are coplanar (best conformation). Another empty metal orbital, at relatively low energy, is well adapted to overlap with the σ_{C-H} of the alkylidene group, hence giving rise to the stabilizing agostic interaction only in the *syn* isomer [27].

The J_{C-H} coupling constants calculated with 6-31G(d,p) basis set for the small (Re-1$_q$ to Re-3$_q$) and large systems (Re-1 and Re-3) are shown in Table 1. As shown in our previous article, DFT calculations with 6-31G(d,p) basis sets on C and H overestimate J_{C-H} by about 20 Hz [27]. However, the J_{C-H} for the *syn* isomer is smaller than for the *anti* isomer by 30–40 Hz in good agreement with experiment [42,44,46]. This suggests that the different environment for the alkylidene C–H bond in the *syn* and *anti* isomer is well reproduced, consistent with the presence of an α-agostic bond in the *syn* isomer only. Enlarging the system by inclusion of the real substituents decreases J_{C-H} by only 3–8 Hz. This is rationalized by the fact that the geometries of the small and full complexes are similar with the exception of the C–H bond which is slightly elongated in the full system. This

[e] Ref. [44].

suggests that the small structural changes, associated with the bulky ligands, do not much affect the local electronic environment of the alkylidene C–H bond. It also shows that there are no long range electronic effects of the *t*Bu groups on the alkylidene J_{C-H}. Therefore, even if the chemical identity of the whole complexes are taken into account, the calculated J_{C-H} values are still significantly larger than the observed values. The influence of X and Y on J_{C-H} is small although a slight increase in J_{C-H} from Re-1s to Re-3s suggests a weakening of the agostic interaction. A similar trend is seen in the experimental data [42,44,46]. The same conclusion was reached from the analysis of the wave functions [27]. We conclude that the calculations also reproduce the small variations in J_{C-H} between isomers and the effect of the ancillary ligands (X and Y). However, further calculations with the aim of better reproducing the absolute values of J_{C-H} should be done. Thus, we tested the influence of the basis set on the small systems.

Calculations of J_{C-H} coupling constants in organic molecules have shown an important influence of the basis set [23,24]. We decided to stay within the DFT methodology, which has been recognized as appropriate for a wide variety of systems and which allows the calculations of large species and in particular of transition metal complexes. Therefore, we have studied the variation of J_{C-H} with the basis set level, within the DFT-(B3PW91) method (Table 2).

In a first set of calculations we have improved mostly the representation of the valence electrons, without significantly changing the representation of the inner shells. The values for J_{C-H} vary little between BS1 and BS2 showing little influence of the diffuse orbital. The coupling constants become closer to the experimental values with BS3 and BS4 and the biggest change is obtained when going from BS2 to BS3. The change from a double-ζ type basis set to a triple-ζ improves the results although the calculated J_{C-H} values are lower than the experimental values. Furthermore, the lack of convergence in the results shows that these basis sets are inappropriate. It is should be mentioned that a continuous decrease of the J_{C-H} value with the basis set up to convergence is not necessarily expected [14,17]. The changes in J_{C-H} should not be attributed entirely to the improvement in the representation of the valence shell because the inner shell is different for (BS3- BS4) and for (BS1-BS2).

The single point calculations with the IGLO-II and IGLO-III basis sets at the BS1 optimized geometries give very good results. The results are similar for the two basis sets, showing, as already known, that the good performance of the IGLO basis sets comes most probably from a better representation of the orbitals near the nucleus. The influence of X and Y is fairly reproduced

[h] Ref. [44].

for the *syn* isomers. Thus, J_{C-H} is higher for Re-3s$_q$ than for Re-1s$_q$ and Re-2s$_q$, which have almost equal J_{C-H}. The accuracy of the calculations for the *anti* isomers can only come from the comparison between Re-2a and Re-3a because no *anti* isomer has been observed for X = Y = alkyl. The calculations do not reproduce the lower value for Re-2a$_q$ compared to Re-3a$_q$ with the exception of the non satisfying BS1 basis set. A difference of 2 Hz is probably challenging to reproduce in the absence of the steric effect of the bulky groups. No further studies can be carried because no other anti isomers have been identified experimentally.

The geometry of the complexes was re-optimized with the IGLO-II basis sets. The geometries are essentially unchanged and accordingly the values for the coupling constants are equal to those obtained with the 6-31G(d,p) basis set geometry optimization (Table 3). In total, the calculated values for the small model differ from the experimental ones by less than 4 Hz.

Additional calculations for the full system have been carried out for Re-1 and Re-3 (Re-2 J_{C-H} calculation is not feasible). As already noted for the calculations with 6-31G(d,p) basis set, the J_{C-H} is always lower by around 10 Hz for the full systems compared with the small systems, which is consistent with a slightly increase of the α-agostic interaction in the presence of the bulky groups. The calculated J_{C-H} values for the best level of calculation (large model and IGLO-II basis sets) are always lower than the experimental values by about 10 Hz, giving a relative error of about 10%.

3.2. The Mo(=NR)(=CHtBu)(X)(Y) complexes

The molybdenum complexes, isolobal to the rhenium complexes, have been studied. They have been represented only with the small models at the B3PW91 level and the NMR J_{C-H} values have been computed with the IGLO-II basis sets (Table 4 and Fig. 2). The geometries of the Mo complexes are similar to those of the small rhenium complexes and close to the X-ray structures of similar complexes [68–70]. In particular, the C–H bond length is almost equal in the Re and Mo complexes, which should lead to a similar J_{C-H} value. However, the calculated J_{C-H} values are lower for the molybdenum complexes than that for rhenium complexes by about 4-6 Hz in agreement with experiment [47–49,51]. The J_{C-H} values of around 105 Hz found for the *syn* Mo complexes have been considered as indicative of an α-agostic interaction [53] whereas no such suggestion have been done for the Re complexes where the J_{C-H} values are 10 Hz higher. However, the calculations show that the difference between the J_{C-H} of the *syn* isomer and that of the *anti* isomer is similar for all Re and Mo complexes suggesting an α-agostic interaction of the same strength. Further studies are needed to clarify this point. It is worth pointing out that the calculated and experimental J_{C-H} values differ by less than 2–3 Hz. Although such agreement may be somewhat fortuitous because it is obtained for the small model, these results show that the present methodology is appropriate to reproduce trends (metal and ligand effects) for weak α-C–H agostic interactions.

3.3. The Ta(C$_5$R$_5$)(=CHtBu)(X)(Y) complexes

These 16 electron Ta(C$_5$R$_5$)(=CH*t*Bu)(X)(Y) (C$_5$H$_5$ = Cp; C$_5$Me$_5$ = Cp*) complexes, shown in Fig. 3, are pseudooctahedral and display a strong α-agostic interaction with coupling constants less than 84 Hz [52]. Molecular orbital (MO) analysis have rationalized the strength of the α-agostic interaction in electron deficient tantalum complexes [71]. Another MO study has provided an interpretation for the stronger α-agostic interaction in the octahedral field relative to the tetrahedral coordination [72]. Thus, the present calculations are only concerned with the ability of the present computational methodology to reproduce quantitatively the J_{C-H} values for strong α-agostic interactions.

Fig. 2. Optimized geometry of *syn* and *anti* Mo(=NPh)(=CHCH$_3$)(CH$_2$CH$_3$)$_2$ isomers and selected list of geometrical parameters for all Mo(=NR′)(=CHR)(X)(Y) complexes. Distances in Å and angles in degrees.

The optimized geometries of *syn* isomer agree well with the experimental parameters of available similar complexes (Fig. 3) [73,74]. In particular the optimized Ta=C bond length is around 1.91 Å for all complexes, which is within the range of the experimental values (1.883–1.925 Å). The Ta=C–C angle is remarkably open and reaches values up to 155–175°, which is also close to the experimental values of 165°. The hydrogen atom cannot be located by X-ray diffraction spectroscopy and its position can only come from the calculations. The C–H bond length is found to be between 1.125 and 1.150 Å, which corresponds to a strong elongation. The Ta=C–H angle is always less than 90°, which leads to a short nonbonding Ta···H distance (ranging between 1.972 and 2.207 Å). These geometrical features, quite different from those of the Re and Mo complexes, are indicative of a significantly weakened C–H bond and maybe even of a direct, albeit very weak, Ta···H interaction. These geometries support the proposal of a strong α-agostic interaction.

The geometrical parameters are consistent with a weaker α-agostic interaction for X = Y = Cl than X = Y = alkyl. A similar trend was found for the Re complexes where the α-agostic interaction is weaker for X = Y = OR than for X = Y = alkyl. The interpretation given in our previous work [27] applies also for the tantalum complexes: π-donor groups disfavor the agostic interaction by raising the energy of the empty metal d orbital responsible of the agostic interaction.

Calculations for the full systems with the ONIOM method, give similar geometries. As in the case of Re, the structural parameters associated with the C–H alkylidene bond suggest that the α-agostic interaction becomes stronger in the full system due to the steric repulsion between the *t*Bu of the alkylidene and the cyclopentadienyl ring; in particular, the α-agostic interaction is stronger for Cp* than for Cp. The strengthening of an α-agostic interaction caused by steric factors has been observed before and has been rationalized by QM/MM calculations [75,76].

The *anti* isomer, which has never been observed experimentally for these complexes, has geometrical features notably different from the *syn* isomer. In particular, the Ta=C bond is considerably longer (around 1.95 Å) than in the *syn* isomer, the Ta=C–C angle 105–115° is close to what is expected for a sp^2 carbon and no C–H elongation is observed (the C–H bond length is around 1.09 Å). Inclusion of the real substituents leads to similar geometries. Therefore, no α-agostic interaction is present in the *anti* isomer. The *anti* isomer is always less stable than the corresponding *syn* complexes in line with the sole observation of the latter.

The calculated NMR J_{C-H} coupling constants for tantalum complexes are shown in Table 4. The J_{C-H} values for the *syn* isomer within the small model are higher than the experimental data [52], in contrast to what was obtained for Re and Mo complexes. Although the difference between experimental and calculated values is larger than for Re and Mo (the largest difference being

Fig. 3. Optimized geometry of *syn* and *anti* $Ta(C_5Me_5)(=CHCH_3)(CH_2CH_3)_2$ isomers and selected list of geometrical parameters for all $Ta(C_5R'_5)(=CHR)(X)(Y)$ complexes. Distances in Å and angles in degrees.

7 Hz), the present methodology leads to reasonable agreement with experiment. In addition, the influence of X and Y on the J_{C-H} coupling constant is reasonably represented with the small model. However, these results must be considered with caution because the agreement between calculations and experiment is slightly worse for the full system than for the small systems (see next).

The calculations for the full systems are carried out only for the *syn* isomer and for Ta-2s, Ta-3s and Ta-4s due to computational limitations. The J_{C-H} values are significantly lower than those computed with the small models when X = Y = Cl, the difference between the two models ranging from 10 to 15 Hz (15–20%). In contrast, for Ta-3s (X = Y = alkyl), very little variation is obtained in J_{C-H} value between small and full models (3 Hz). Overall, the present level of theory gives fair results for the J_{C-H} in the case where the C–H bond is engaged in a strong agostic interaction and the largest difference between computed and experimental values is 11 Hz for a coupling constant of around 80 Hz, i.e., 14% error. Furthermore, the influence of X and Y on J_{C-H} being rather small (<10 Hz), is thus rather difficult to reproduce. With the full models, the changes in J_{C-H} observed by replacing Cp by Cp* are well reproduced but not that for replacing X = Y = alkyl by X = Y = Cl. This poorer agreement between calculated and experimental values for the Ta complexes compared to the Re and Mo cases, is most probably associated with the approximations done in the calculations of the coupling constant: the neglect of the thermal effect and of the anharmonicity is probably less valid in the case of a flat potential energy surface associated with a strongly weakened C–H bond and a possible weak direct Ta···H interaction (distance around 2 Å).

The J_{C-H} values calculated for the *anti* isomer are lower than those for Mo and Re. Although comparison with experiment is not possible because the *anti* isomer has not been characterised for this set of substituents in the Ta complexes, the overall quality of the agreement between the calculations and experiments suggests that the values found for Ta are reasonable. Since the C–H bond length for all *anti* isomers in the Re, Mo and Ta complexes is around 1.09 Å, the differences in J_{C-H} is not due to differences in the C–H distances but in the change of the metal center. Thus, the nature of the metal influence the absolute NMR J_{C-H} value and these results

open the question of the J_{C-H} value to take as reference to define the α-agostic interaction strength; an unique reference independent of the metal center may not be entirely justified.

4. Conclusion and perspective

This study shows that NMR J_{C-H} coupling constants can be calculated accurately without excessive computational effort. B3PW91 NMR calculations with IGLO-II basis sets for main group atoms on geometries optimized with the same functional and 6-31G(d,p) basis sets is accurate enough to reproduce the experimental J_{C-H} values associated with either weak or strong α-C–H agostic interactions in d^0 metal–alkylidene complexes (Re, Mo and Ta). It appears that the computed values with the full systems are always lower than experimental J_{C-H}, the average error being 10–15%. In addition, the influence of the isomer (*syn* versus *anti*), of the metal and of the ligands are overall well reproduced by the calculations, the agreement for the later being better for Re and Mo. However, for a given metal, J_{C-H} is only slightly influenced by the nature of X and Y. The values computed for the pseudooctahedral Ta complexes, where the α-agostic C–H interaction is strong, are overall in less good agreement with experiment than for the pseudotetrahedral Re and Mo complexes where the α-agostic interaction is weak. This may be attributed to the neglect of the vibrational and anharmonic effects in the calculations in the case of a significantly weakened C–H bond. It should be pointed out that the complexes selected for this study are good benchmark species because of the absence of interconversion between the *syn* and *anti* isomers, which could have averaged the J_{C-H} values.

The ability to compute with fair to good accuracy a magnetic J_{C-H} spin–spin coupling constant opens interesting perspectives in the computational analysis of organometallic complexes and in particular in that of the agostic interactions. Similar calculations of J_{C-H} can therefore be carried out for a wide variety of transition metal complexes, which will allow a more direct comparison between calculations and experiments.

Acknowledgements

It is my great pleasure to thank Malcolm Chisholm, an old friend, who initially attracted me to Indiana University as visiting professor. He has always been an enthusiastic supporter of the dialogue between experimental and computational chemists. The present work is far removed from the simple MO pictures that we used to draw over a cup of tea in his office while looking out at the autumn foliage turning red during an Indian summer.

X.S.M. thanks the CNRS for a post-doctoral fellowship. We are indebted to IDRIS for a generous donation of computing time through Grant 041744.

Benzene and ethylene binding to copper(I)–ziconium(IV) chloride materials: The crystal structure and solid-state reactivity of $((bz)_2Cu)_2Zr_2Cl_{10} \cdot bz$

Andrew M. Dattelbaum, James D. Martin *

Department of Chemistry, North Carolina State University, Box 8204, Raleigh, NC 27695-8204, United States

Received 29 April 2005; accepted 9 August 2005
Available online 5 October 2005

In dedication to Malcolm H. Chisholm on the occasion of his 60th birthday. Professor Chisholm's work describing metal alkoxides as models of metal oxides planted the seed for JDM's work designing metal halide analogs of metal oxides and the exploration of their reactivity.

Abstract

The solvothermal reaction of Cu_2ZrCl_6 and $ZrCl_4$ in benzene is shown to yield the molecular species $((bz)_2Cu)_2Zr_2Cl_{10} \cdot bz$ (**1**), which is characterized by single crystal X-ray diffraction. The structure consists of edge-shared dimers of zirconium chloride octahedra whose axial chlorides are bridged by bis-benzene chlorocuprate fragments. The Cu_2Zr_2 tetramers are linked in the crystal lattice by edge-to-face π-stacking of the coordinated and lattice benzene molecules, as well as benzene-to-chloride hydrogen bonding. Benzene is lost from this material in a stepwise fashion resulting in what are described to be chain, $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) and layered clay-type materials, $Cu_2Zr_2Cl_{10}$ (**3**). The desolvated materials, **2** and **3**, reversibly sorb ethylene, as characterized by sorption isotherms, in situ pressure-resolved synchrotron X-ray diffraction and UV/Vis diffuse reflectance spectroscopy.

Keywords: Metal halides; Olefin; Aromatic; Pressure resolved XRD; Copper(I); Zirconium(IV); Chemisorption; Sorptive reconstruction

1. Introduction

The reactivity of small molecules with crystalline materials is of significant importance for separations and heterogeneous catalysis applications [1,2]. In spite of this, structural and mechanistic aspects of such heterogeneous reactions are not well understood on the molecular scale. We recently articulated the mechanism of sorptive reconstruction of the $CuAlCl_4$ framework upon ethylene sorption [3]. In that system, the reactivity of Cu(I) toward ethylene was dramatically enhanced by the strong Lewis acid, Al(III), which is a co-building block of the framework. The binding of neutral ligands, L = benzene, ethylene, CO, to the copper(I) center in these metal–halide frameworks suggested to us a potential structural analogy between phosphonates, RPO_3^{2-}, and chlorocuprates, $LCuCl_3^{2-}$ [4]. In the latter, the neutral ligand L bound to copper(I) is more labile than the R group that is bound to P in a phosphonate. Nevertheless, the ligands L may provide a similar pillaring-type function that open galleries of molecular dimension in the inorganic framework. The pillaring structural motif and the lability of the Cu–L bond, specifically when L is an olefin, aromatic, or carbonyl, makes such structures of considerable interest for separations and catalysis applications. In an effort to create clay-type architectures (i.e., patterned after aluminosilicate clays with octahedral Al(III) and tetrahedral Si(IV)) we have

doi:10.1016/j.poly.2005.08.011

prepared several materials which employ the octahedral Lewis acidic metal zirconium(IV) as a co-building block with copper(I). The parent network compound Cu_2ZrCl_6 [5] was previously shown to react with benzene under solvothermal conditions to form the linear chain compound $((bz)CuCl_3)_2Zr$ [4]. In the present work we demonstrate that under more zirconium rich conditions, solvothermal reaction in benzene yields the molecular species $((bz)_2Cu)_2Zr_2Cl_{10}\cdot bz$ (**1**). Strong aromatic π-stacking and hydrogen bonding orients the crystal lattice of these molecules such that framework condensation is proposed to occur during the step-wise loss of benzene to yield the chain $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) and a layered clay-type material, $Cu_2Zr_2Cl_{10}$ (**3**). The lattice of **2** is sufficiently rigid to support a long-lived excited state such that it is a brilliant yellow phosphor under UV illumination. Both **2** and **3** are further shown to reversibly sorb ethylene under modest pressures.

2. Experimental

2.1. General information

All reactions were performed under an inert atmosphere of dry N_2 in a glove box or using Schlenk techniques. $ZrCl_4$ (99.99%) was used as received from Aldrich. CuCl was prepared from Cu metal and $CuCl_2$ (Aldrich) according to literature methods and further purified by sublimation [6]. The syntheses of Cu_2ZrCl_6 is reported elsewhere [5]. Benzene (99.9%, Fisher) was distilled from Na/benzophenone, and stored under nitrogen over 4 Å molecular sieves. Elemental analyses were performed by Atlantic Microlab, Inc. Routine powder X-ray diffraction characterization was obtained using an Enraf-Nonius Guinier camera and an Inel diffractometer with a CPS-120 detector, using monocromated Cu Kα radiation.

2.2. Preparation of $((bz)_2Cu)_2Zr_2Cl_{10}\cdot bz$ (*1*)

Cu_2ZrCl_6 (0.100 g, 0.232 mmol) and $ZrCl_4$ (0.0540 g, 0.232 mmol) were ground together in a mortar and pestle and transferred to a thick walled fused silica tube (10 mm o.d. × 6 mm i.d.). On a Schlenk line, 1.0 mL of benzene was added to the reaction vessel. The reaction mixture was frozen with liquid N_2 and sealed using a torch such that the fused silica vessel was filled to 25% volume. The reaction mixture was heated to 125 °C for one week then slow cooled to ambient temperature at a rate of 0.05 °C/min. (*Note of caution*. Significant pressures are generated upon heating the sealed reaction vessel, which can lead to vessel rupture. Appropriate shielding should be utilized such as placing the reaction vessels in a capped iron pipe during heating.) Upon standing at room temperature for two days, colorless crystals of **1** grew from which a single crystal was isolated for an X-ray structure determination. The crystalline material rapidly looses solvent when removed from the benzene yielding a pale yellow powder, $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) precluding reliable elemental analysis.

2.3. Desolvation of *1* to prepare $((bz)Cu)_2Zr_2Cl_{10}$ (*2*) and $Cu_2Zr_2Cl_{10}$ (*3*)

To prepare bulk quantities of $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) Cu_2ZrCl_6 (1.00 g, 2.32 mmol), and $ZrCl_4$ (0.541 g, 2.32 mmol) were placed in a 100 mL Schlenk flask to which 30 mL of benzene was added. The reaction mixture was heated to reflux with stirring under a passive flow of N_2 for 15 h., during which time about half the solids dissolved. The solid residue, a combination of an as yet unidentified phase and unreacted starting material, was separated from the supernatant using a medium porosity glass frit. Shock exposure to liquid N_2 or a dry ice/acetone bath stimulated the crystallization of **1**. The benzene was removed from **1** in vacuo to yield **2** with approximately a 50% yield based on the initial starting material concentration. Elemental analysis for $((C_6H_6)Cu)_2Zr_2Cl_{10}$ Calc.: C, 17.56; H, 1.48. Found: C, 16.96; H, 1.70%. The remaining benzene is slowly lost over a period of weeks when stored in a glove box under a nitrogen atmosphere, or, it can be removed over the course of several hours under dynamic vacuum to yield a yellow solid, $Cu_2Zr_2Cl_{10}$ (**3**). However, **2** can be stored in a capped vial, which significantly reduces the amount of benzene loss.

2.4. $((et)Cu)_2Zr_2Cl_{10}$ (*4*)

A sample of **2** (300 mg) was distributed across the base of a 25 mL Pyrex vessel so as to maximize reactant surface area. The reaction vessel was then affixed to a gas line (<10 mTorr) and evacuated for 6 h. as appropriate for the in situ synthesis of **3**. The sample was then exposed to ethylene at a pressure of 1500 Torr for 3 h. The resulting product was also pale yellow in color, though qualitative observation suggested that a reaction had occurred. Elemental analysis of the product is consistent with the displacement of the benzene by ethylene to yield $((et)Cu)_2Zr_2Cl_{10}$ (**4**). Elemental analysis for $((C_2H_4)Cu)_2Zr_2Cl_{10}$ Calc.: C, 6.66; H, 1.11. Found: C, 6.04; H, 1.51%. As was the case for the benzene adduct, **2**, ethylene is slowly lost from **4** over a period of weeks. However, desorption can be significantly reduced by storing the sample in a sealed container.

2.5. X-ray structure determination of $((C_6H_6)_2Cu)_2Zr_2Cl_{10}\cdot C_6H_6$ (*1*)

Under a flow of argon a single crystal (0.3 × 0.2 × 0.14 mm) covered in silicone grease was mounted on

the end of a glass fiber, and immediately transferred to the diffractometer where it was cooled to −116 °C under a stream of dry nitrogen. Data were then collected on an Enraf-Nonius CAD4-Mach diffractometer with monochromated Mo(Kα), $\lambda = 0.71073$ Å, radiation. Lattice constants were determined by a symmetry-constrained fit of 24 well centered reflections between $32° < 2\theta < 36°$ and their Friedel pairs to yield $a = 21.144(2)$ Å, $b = 7.4987(5)$ Å, $c = 24.170(2)$ Å, and $\beta = 90.365(6)°$. A unique quadrant, h, $\pm k$, l, was collected with 4144 independent reflections by ω-scans with $0° < 2\theta < 54°$. The data were scaled to three intensity check reflections using a five point smoothing routine. An empirical absorption correction was applied using psi scan data. Systematic absences were found to be consistent with the space group $I2/a$ (No. 15), which was confirmed in the subsequent refinement. The structure of $((C_6H_6)_2Cu)_2Zr_2Cl_{10} \cdot C_6H_6$, $Z = 4$, was refined using the NRCVAX suite of programs [7]. All non-hydrogen atoms were located by direct methods using the SIR92 program [8] and refined anisotropically in the final refinement. Hydrogen atoms bound to the benzene rings were then added in calculated positions (idealized to C–H = 0.96 Å) and assigned fixed temperature factors. A full matrix least squares calculation using the 2989 unique reflections ($I > 1.0\sigma(I)$) gave a final refinement with R factors of $R_f = 0.058$ and $R_w = 0.060$.

A room temperature data set was also collected, $a = 21.616(3)$ Å, $b = 7.658(1)$ Å, $c = 24.308(5)$ Å, and $\beta = 90.95(2)°$. However, structural disorder, due in part to solvent loss, prevented a quality structural refinement.

2.6. Adsorption isotherm measurements

A stainless steel volumetric gas line, described previously [3], was utilized for the measurement of sorption isotherms. Powdered samples were dispersed across the 7 cm^2 base of a 16 mL fused silica sample holder. The dead-volume of the sample holder was measured by an N_2 isotherm prior to each experiment. In a typical sorption experiment $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) (0.026 g, 0.032 mmol) was weighed out in the sample holder, which was just enough to cover the sample holder base. The calibrated volume of the gas line was filled to the dosing pressure of 100 Torr, then the valve to the sample holder was opened and the gas was allowed to expand into the sample volume. The amount of ethylene sorbed by the sample was determined using the ideal gas law and the difference between the pressure expected from Boyle's law, based on expansion to the line + sample volume, and the equilibrated pressure. In subsequent steps, 100 Torr of ethylene above the equilibrated pressure was added to the line and then opened to the sample volume until an equilibrated pressure of 1500 Torr was achieved. Equilibration times of one hour were used before final pressure readings were recorded. Greater than 99.9% of the gas was sorbed within the first 5 min after exposure. Therefore, subsequent experiments, including the spectroscopic and diffraction investigations described below, were performed with 10-min equilibration times.

2.7. Spectroscopy

In situ Diffuse Reflectance Spectra were taken using a Cary 3e UV–Vis spectrometer equipped with an integrating sphere. Spectra were measured with respect to a pressed polytetrafluoroethylene (Teflon) powder standard. Reflectance spectra were collected as $R_\infty = R_{sample}/R_{reference}$, then plotted as the remission function, $F(R_\infty) = (1 - R_\infty)^2/2\,R_\infty$, based on the Kubelka–Munk theory of diffuse reflectance [9]. A quartz diffuse reflectance cell ($1.0 \times 10 \times 40$ mm) was affixed to a gas line to measure spectra as a function of ethylene pressure. The gas pressure was monitored from 1×10^{-3} to 760 Torr using a Varian Ba2C SenTorr Gauge Controller and a ConvecTorr vacuum tube gauge transducer. Pressures greater than 760 Torr were controlled using the regulator attached directly to the gas tank.

In a typical experiment $((C_6H_6)Cu)_2Zr_2Cl_{10}$ (**2**) (0.200 g, 0.243 mmol) was diluted into 2.0 g of fused silica (ground and passed through 60 mesh (0.1 mm) sieve and dried at 160 °C for at least 24 h.) and ground together in a mortar and pestle. A portion of that mixture was used to completely fill the quartz sample holder. The sample was evacuated, then dosed with ethylene. Diffuse reflectance spectra were recorded at 100 Torr intervals up to 1500 Torr. Spectra were recorded after approximately 10 min of equilibration at each pressure. The sample was then exposed to vacuum and the ethylene was removed under reduced pressure. Sorption and desorption experiments were also performed with $Cu_2Zr_2Cl_{10}$ (**3**) diluted in ground fused silica. In this case the sample was directly exposed to 1500–1800 Torr of ethylene and the sorption monitored periodically by diffuse reflectance spectroscopy.

Steady-state fluorescence spectra were measured with an ISS PC-1 fluorometer equipped with a Xenon arc lamp and using a front-face detection geometry to orient the sample face at an angle of 22.5° with respect to the incident beam. A low band-pass UG-11 filter was placed after the excitation monochromator. Excitation spectra were corrected with respect to a standard quinine sulfate solution and the NIST spectrum. Emission spectra were plotted using the relative emitted energy per constant interval ($\Phi_E = \Phi_\lambda \lambda^2/hc$) [10].

2.8. Time/pressure resolved powder X-ray diffraction

Time and pressure resolved powder X-ray diffraction experiments were performed at the X7B beamline of the National Synchrotron Light Source at Brookhaven National Laboratories with a wavelength of approximately

0.93 Å, in a Debye–Scherrer collection geometry using either a translating image plate (TIP) detector mounted on a four circle Huber diffractometer [11], or a MAR345 image plate detector system. The wavelength, sample to detector distance, tilting angle of the IP and zero shift position of the IP for the data collection were determined using full Debye–Scherrer rings of LaB_6. Data reduction of the full rings was done using Fit2d [12,13]. Powdered samples placed in 0.7 mm fused silica capillaries, were affixed to a gas line with Swagelok fittings and aligned on a goniometer head [14]. Samples were exposed to ethylene pressures of 100–1500 Torr, or vacuum.

3. Results

3.1. Structure of $((bz)_2Cu)_2Zr_2Cl_{10} \cdot (bz)$ (1)

A summary of crystallographic data for $((bz)_2Cu)_2Zr_2Cl_{10} \cdot (bz)$ (**1**) is available in cif format as supplementary information. An ORTEP drawing of the $((bz)_2Cu)_2Zr_2Cl_{10}$ molecule is shown in Fig. 1. Selected bond distances and angles are reported in Table 1. This molecule sits on a C_2 axis of symmetry. The core of the molecule consists of an edged-shared zirconium bioctahedron with two slightly asymmetric chloride bridges Zr–Cl(1) = 2.607(2) Å and Zr–Cl(2) = 2.582(2) Å. As expected, the four terminal Zr–Cl bonds in the equatorial plane are about 0.2 Å shorter than the corresponding equatorial bridges, Zr–Cl(5) = 2.371(2) Å × 2 and Zr–Cl(6) = 2.358(2) Å × 2. The axial chlorides, Cl(3) and Cl(4), bound to zirconium at an intermediate distance (Zr–Cl(3) = 2.463(2) Å and Zr–Cl(4) 2.475(2) Å), form bridges to Cu(I) cations (Cu–Cl(3) 2.372(2) Å and Cu–Cl(4) = 2.417(2) Å) such that a boat-like geometry is observed for the $Cu_2Zr_2Cl_4$ tetrameric ring with the two copper bridges both bent to the same side of the axial plane of the bioctahedron. The Cl(3)–Cu–Cl(4) plane is bent about 31° out of the Cl(3)–Zr′–Cl(4)′–Cl(3)′–Zr–Cl(4) molecular plane. The pseudo-tetrahedral coordination sphere of the copper cations is completed with

two equivalents of benzene; one bound in an η^2-fashion, Cu–C(7) = 2.237(7) Å and Cu–C(8) = 2.235(8) Å, and the other is weakly coordinated in an η^1-fashion with a Cu–C(1) = 2.385(8) Å. The coordination to Cu(I) does not dramatically distort the C–C bond distances in the benzene ligands. The quality of the crystal structure demands that care must be taken to not over interpret C–C distances, nevertheless, it is worth noting that the longest C–C contact is observed for the C(7)–C(8) bond, 1.41(1) Å, which also corresponds to the site of the η^2-coordination. Greater variation between C–C bond distances is observed for both types of coordinated benzene ligands, 1.35(1) to 1.41(1) Å ($\Delta = 0.06$ Å), compared to the lattice solvated molecule, 1.38(1) to 1.40(1) Å ($\Delta = 0.02$ Å), presumably a result of charge transfer upon coordination to the Cu(I). The thermal parameters are notably larger for the carbon atoms of the η^1-bound benzene ligand consistent with its weaker coordination as opposed to the η^2-coordinated ligand and the strong hydrogen bonding of the solvated benzene molecules.

3.2. Excitation and emission spectroscopy

The partially desolvated material $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) exhibits brilliant yellow photoluminescence at room temperature under UV excitation. The excitation and

emission maxima for **2**, shown in Fig. 2, were observed at 26 110 cm^{-1} (383 nm) and 17 390 cm^{-1} (575 nm), respectively. The emission intensity is approximately 25% the intensity of anthracene [15]. Desorption of the benzene from **2** to form **3** results in a loss of the observed room temperature luminescence.

3.3. Ethylene sorption isotherms

Room temperature ethylene sorption isotherms were measured to demonstrate both ligand exchange and olefin sorption capacity of these materials. The luminescent, partially desolvated material **2**, was used as the starting sorbate for the sorption, desorption and resorption measurements for which the data are presented in Fig. 3. Monitoring the luminescence of the sample using a hand held mercury lamp (350 nm), confirmed that the initial evacuation of the sample prior to the sorption isotherm did not significantly convert compound **2** to compound **3**. To interpret this sorption data, we further recognize that the vapor pressure of benzene is low at room temperature with respect to ethylene. Thus, as the benzene is displaced by ethylene, it does not significantly contribute to the measured gas pressure in the line. Significant sorption is observed immediately upon exposure of **2** to ethylene at a pressure of 100 Torr. An inflection in the initial sorption isotherm is observed at approximately 0.5 equivalents of ethylene per mole of copper. Additional sorption is observed as the equilibrated pressure of ethylene exceeds about 400 Torr. At an equilibrated pressure of 1500 Torr approximately 1.5 equivalents of ethylene are sorbed per equivalent of copper. Upon desorption, there is a plateau in the isotherm at a 1:1 stoichiometric ratio of ethylene to copper, consistent with the formation of **4**. Ethylene is not lost from the one equivalent adduct until pressures well below 50 Torr are achieved. To achieve full desorption, the sample was exposed to dynamic vacuum overnight resulting in the formation of **3** prior to resorption. While the one-equivalent ethylene adduct is not luminescent, compound **3** is a significantly deeper shade of yellow than are the adduct phases providing a visual indication of its formation. Upon resorption starting with the darker yellow material **3**, ethylene up-take is not initially as facile as low-pressure sorption into **2**. However, at equilibrium pressures above about 400 Torr the sorption isotherms for the initial sorption into **2** and resorption into **3** are nearly equivalent. The sorption and desorption of ethylene is reversible without any appreciable loss of activity, having been repeated for five cycles in our laboratory.

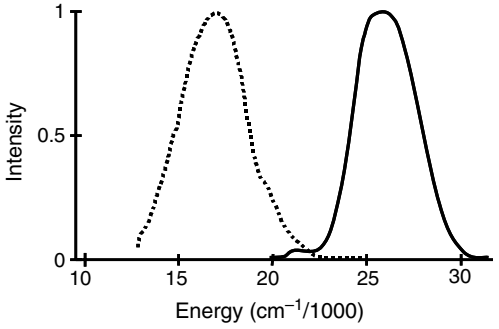

Fig. 2. Excitation (dotted line) ($\lambda_{em} = 575$ nm) and emission (solid line) ($\lambda_{ex} = 383$ nm) spectra for $((bz)Cu)_2Zr_2Cl_{10}$ (**2**).

3.4. Diffuse reflectance spectroscopy

Diffuse reflectance data collected during the sorption and desorption of ethylene into $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) are shown in Fig. 4. The initial spectrum of **2** exhibits a

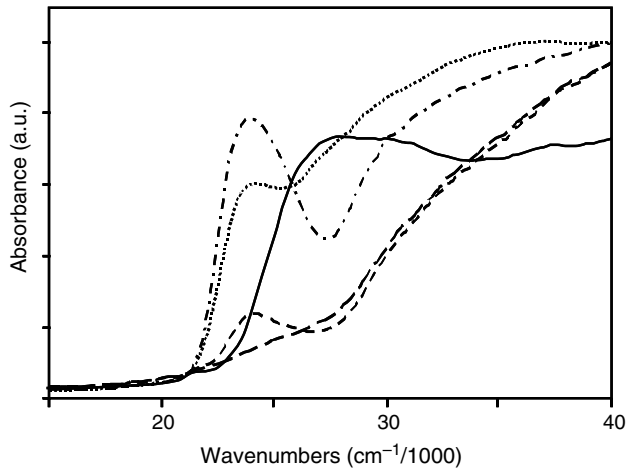

Fig. 4. Diffuse reflectance UV/Vis spectra of $((bz)Cu)_2Zr_2Cl_{10}$ (**2**) (—); **2** exposed to ethylene in 100 Torr steps, shown at 300 Torr (– – –), $(et)Cu_2Zr_2Cl_6$ (**5**) and at 1000 Torr (- - - -), $((et)Cu)_2Zr_2Cl_{10}$ (**4**); $Cu_2Zr_2Cl_{10}$ (**3**) from desorbtion of ethylene adducts (· · ·); and high pressure ethylene adduct at ~1500 Torr (–·–·–).

broad band-edge at ca. 24 900 cm^{-1} (416 nm, 3.09 eV). As a point of reference, this band edge is red shifted from that of CuCl (3.2 eV) and that of $ZrCl_4$, which is in the vacuum ultraviolet, but is very similar to the diffuse reflectance spectrum of Cu_2ZrCl_6 [5]. Exposure to 100 and 200 Torr of ethylene appeared to have little effect on the position of the band edge, although a slight increase in absorption intensity is observed at higher energy. At 300 Torr of ethylene, the band edge shifts abruptly to ca. 30 000 cm^{-1} (333 nm, 3.72 eV) with a much less intense broad shoulder at ~25 000 cm^{-1}. A well-defined peak with a maximum at 24 038 cm^{-1} (416 nm, 2.98 eV) is observed to gradually grow upon increasing ethylene pressure from 300 to 1000 Torr, with a clear isosbestic point at 26 200 cm^{-1}. The spectrum at 1000 Torr of ethylene corresponds to the formation of the one equivalent adduct, **4**. Evacuation of the sample results in the appearance of the spectrum of **3** with a significantly red-shifted band edge, 24 400 cm^{-1}, consistent with the deeper yellow color observed for **3**. Allowing the sample to stand overnight under a pressure of 1500 Torr of ethylene results primarily in the increasing intensity of a well-resolved peak at 24 000 cm^{-1}.

3.5. Variable pressure X-ray diffraction

In situ synchrotron powder X-ray diffraction experiments as a function of ethylene pressure were preformed to monitor the structural changes taking place during the sorption of ethylene by $((bz)Cu)_2Zr_2Cl_{10}$ (**2**). For the experiment shown in Fig. 5, the sample was evacuated then the ethylene pressure was increased in 100 or 200 Torr increments to 1500 Torr. Diffractograms shown are those taken after 10 min equilibration at each given ethylene pressure. Under these conditions, the incremental addition of ethylene to **2** results in the gradual formation of the ethylene adduct phase, **4**. Subtraction of diffractogram Fig. 5(b) from Fig. 5(c) shows only trace formation of **4** and loss of **2**. Principal component analysis of this pressure resolved diffraction data finds that 99.898% of the total variance is explained by the first two principal components. After rotating these two components by −37° the diffraction patterns of **2** and **4** are reproduced. Existence curves, determined by normalization of the first two eigenvectors (rotated by 37°) of the principle component analysis, shown in Fig. 6, provide no evidence for a crystalline 0.5 equivalent intermediate. The curves for the loss of crystalline **2** and appearance of crystalline **4** cross at 50% transformation confirming that no amorphous intermediate exists either. However, a similar analysis looking only at the intensity of the major reflections shows that beyond 500 Torr the diffraction intensity of the major peaks gradually increases to a maximum at about 1100 Torr, and then slightly decreases with increased pressure. Diffraction data of the desorption of ethylene from **4** was not obtained because the seal of the sample capillary to the goniometer gas line was insufficient to obtain adequate vacuum to remove the ethylene without decomposing the sample due to exposure to atmospheric moisture.

Lattice constants for the one equivalent benzene and ethylene adduct phases, **2** and **4**, were refined from the diffractograms of Fig. 5(b) and (k), respectively (Table 2). Monoclinic symmetry is apparently retained upon loss of benzene from **1**, and upon ethylene for benzene substitution. The most dramatic effect of the solvent loss is a significant collapse by 5.5 and 7.0 Å along the *a* and *c* lattice directions, respectively. Only modest collapse by 0.3 Å is observed along the *b* direction. Exchange of ethylene for benzene results in further collapse of the *a* and

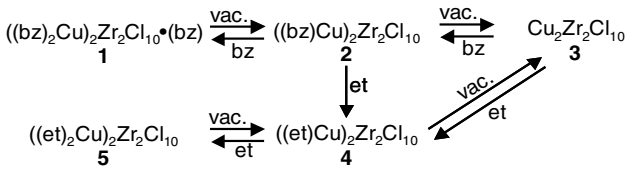
c lattice constants by 1.4 and 2.0 Å, respectively, and b by about 0.7 Å.

4. Discussion

A complex pattern of reactivity of crystalline copper zirconium chloride materials with benzene and ethylene is indicated by the diffraction, absorption isotherm and diffuse reflectance data presented here. The reaction pathways are summarized in Scheme 1. The reactivity of this gas/solid system, similar to that previously reported for the ethylene/$CuAlCl_4$ system [3], is significantly correlated to the structure of these materials. To understand these structure/reactivity correlations, we begin with a discussion of the crystal structure of the solvothermally synthesized molecular adduct **1**. Spectroscopic and diffraction data provide insight into the structural transformation upon loss of benzene and mechanistic insight regarding the sorption of ethylene by this system.

4.1. Molecular versus extended structure of *1*

The binding of aromatic molecules to Cu(I) centers has significant precedent in the literature [16], although a search of the Cambridge Structural Database finds only three other examples of benzene coordinated to chlorocuprates [4,17,18]. Furthermore, there are no previously reported crystal structures with more than one aromatic ligand coordinated to Cu(I). The filled π- and empty π*-orbitals of benzene can participate in bonding to transition metals, however, the benzene π*-orbitals do not effectively compete with the Lewis acidity of the Zr(IV) chloride also coordinated to copper. Therefore, the benzene–Cu bonding is almost exclusively of a non-classical type (i.e., donation into the empty s/p-hybrid orbitals of Cu(I) with no back-bonding into the benzene π*-orbitals) [19]. The strong Lewis acidity of Zr(IV) coordinated to Cu(I) through the chloride bridges enhances the σ-acceptor nature of Cu(I) making the coordination of multiple benzene ligands possible. Nevertheless, the d^{10}-copper center is not significantly electron deficient, and thus exhibits modest bonding to one benzene ligand in an η^2-fashion, but only very weak binding to the second benzene ligand in an η^1-fashion.



Scheme 1.

The local geometry of the pseudo-tetrahedral Cu(I) and octahedral Zr(IV) is consistent with that expected for these ions. The local geometry of these cations, however, gives no hint as to the reason for the unusual distortion of both copper tetrahedra to the same side of the zirconium chloride bioctahedron, seen in the molecular structure, Fig. 1. Rather, this unusual boat-type configuration is a result of a complex pattern of inter- and intra-molecular π-stacking and benzene–chloride hydrogen bonding. Numerous short contacts between the edge ($\delta+$) of one benzene molecule and the face ($\delta-$) of a neighboring molecule, and between chloride atoms and the edges of benzene molecules are observed, as shown in Fig. 7, with distances tabulated in Table 3. As a point

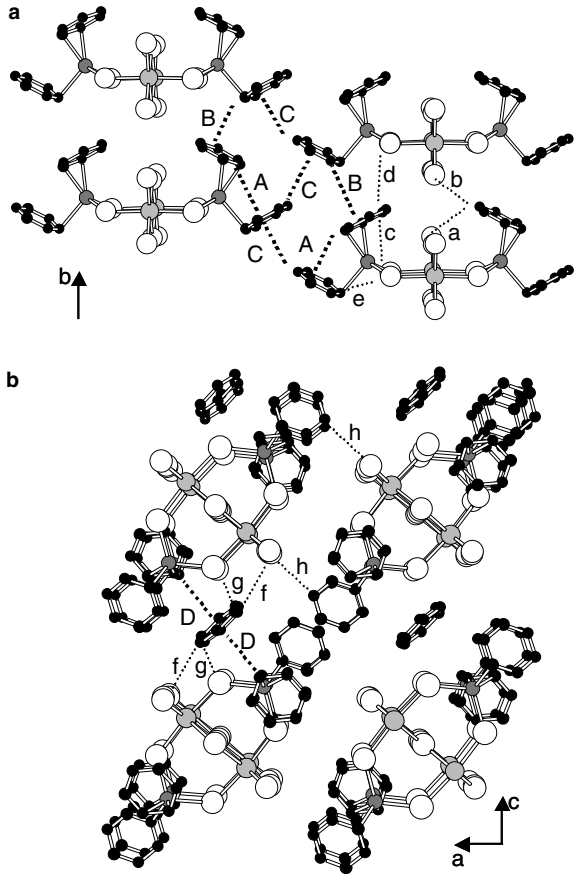


Fig. 7. Ball and stick drawings of **1** describing the intra- and intermolecular π-stacking and hydrogen bonding interactions. (Capital letters represent benzene–benzene π-stacking contacts and lower case letters represent benzene–Cl hydrogen bonding.) The view in (a) is a slice parallel to the (1,0,1) plane and (b) is a projection looking down the [0 1 0] direction.

The center of the lattice solvate, η^1- and η^2-benzene molecules is represented by B_s, B_1, and B_2, respectively. Distances are reported in Å.

of reference, the edge-to-face contact in crystalline benzene is 3.6 Å [20,21]. The shortest of these contacts are the intra-molecular contacts between the edge of the η^2-benzene ligand and the face of the η^1-benzene ligand, 3.36 Å (A), and between the edge of the η^2-benzene and the equatorial chlorides of the Zr_2Cl_{10} bioctahedron, 3.43 and 3.67 Å (a). The contacts between the edge of the η^1-benzene ligand and the axial-chloride ligands, 3.52–3.66 Å (e), are only slightly longer. While a majority of these inter-ligand contacts are best described as the edge-to-face motif, the contacts c and d (Cl–η^2-benzene–Cl) are similar to a classical π-stack where the center of the benzene molecules are slipped off the axis of the stack. These π-to-π and hydrogen bond contacts cause the unusual boat-shape distortion, and stabilize the crystalline lattice of **1**. However, these interactions are not sufficient to stabilize this material in the absence of excess benzene. When removed from its mother liquor, three equivalents of benzene are readily lost from this crystalline lattice.

4.2. Solvent loss/framework construction

Three equivalents of benzene per formula unit are readily lost from the crystalline structure of **1**, as confirmed by elemental analysis. Diffraction and spectroscopic measurements confirm that the material formed, **2**, retains the remaining one equivalent of benzene/copper even under modest vacuum. It is likely that the lattice solvated- and weakly bound η^1-benzene ligands are those that are most readily lost. A model for the structure of the desolvated material can be constructed by removal of all but the η^2-benzene ligands, and consideration of the nearest intermolecular Cu···Cl contacts; an inverse of the sorptive reconstruction described for ethylene sorption by $CuAlCl_4$ [3]. The shortest intermolecular Cu···Cl contact is only 5.55 Å, along the direction of the η^1-edge to Cl(6) hydrogen bonded contact of the parent structure (described as contact h in Fig. 7). Several other intermolecular contacts between 6.4 and 7 Å exist, each of which link molecules within the *ab* plane. By collapsing the unit cell of **1**, with the lattice solvated and η^1-benzene ligands removed but otherwise maintaining the $((\eta^2\text{-bz})Cu)_2Zr_2Cl_{10}$ molecular geometry, to the lattice dimensions indexed from the X-ray powder pattern of **2** (Table 2), the model structure shown in Fig. 8 is achieved. These metrical parameters bring the

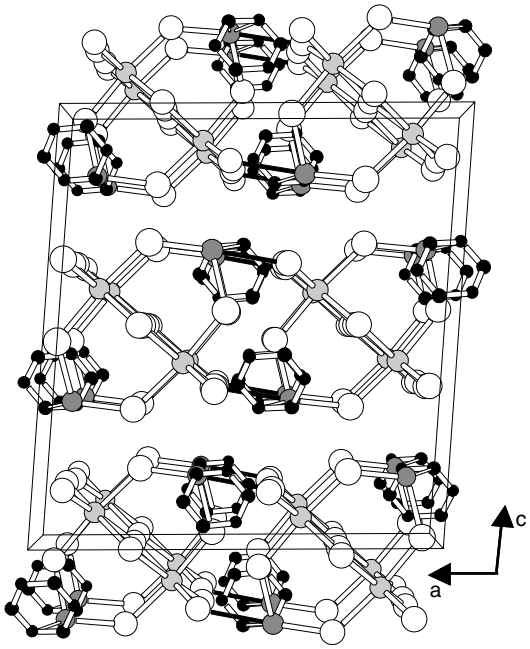

Fig. 8. Model for the structure of **2** based on the collapse of **1** to the observed unit cell dimensions after loss of the lattice solvated and η^1-benzene ligands. The bold, black lines represent the likely bonds formed between Cu and Cl(6) upon framework construction.

copper and Cl(6) atoms into bonding distance, well below the sum of their van der Waals radii (3.2 Å). This model structure is not the correct structure, since the peak intensities of the calculated powder pattern do not match the observed intensities. This is not surprising given that with the loss of the π-stacking interactions, the boat-geometry of the Cu_2Zr_2 core is likely to be lost, and the molecular orientations would need to be rotated to optimize crystal packing. Nevertheless, this model is a helpful starting point for consideration of the chemistry. Here, the large collapse along the *a* direction is consistent with the formation of covalent chains. The $(\eta^2\text{-bz})CuCl_3$ unit is reminiscent of bridging phosphonate-type ligands, as previously demonstrated for another copper zirconium halide chain [4]. The *b* lattice direction decreases the least upon solvent loss, consistent with this being the lattice direction in which the coordinated benzene remains. Solvent loss from the clay-like gallery between layers of these chains accounts for the 7 Å collapse along *c*.

The UV/Vis spectrum of **2**, exhibits a characteristic band structure similar to that observed for $[H_2NMe_2]$-$CuZrCl_6$ and Cu_2ZrCl_6 [5], which supports the proposal of a condensed framework rather than isolated molecules. However, it is challenging to fully decipher this absorption spectrum. While the d^{10}-copper M–Lσ* orbitals are the HOMO in this system, unoccupied benzene-π*, Zr-d and Cu-s/p states all provide relatively low energy acceptor states. Comparison of the excitation spectrum, Fig. 2, with the absorption spectrum, Fig. 4, clearly demonstrates that absorption at the band edge is responsible for the luminescence. Previously we showed that the higher energy blue luminescence of $CuAlCl_4$ was due to a copper centered d ← s/p transition [22]. Because of its higher energy this copper centered mechanism can likely be ruled out in the present case. Cu_2ZrCl_6, for which the LUMO was shown to be Zr-4d states [5], does not exhibit luminescence at room temperature. Furthermore, when the benzene is replaced with ethylene, which we propose to be isostructural (see below), the luminescence is also lost. Therefore we propose that a metal to ligand charge transfer between Cu and benzene is responsible for the luminescence of **2**. This assignment is consistent with that recently reported for the $Cu_2(CF_3SO_3)_2(bz)$ complex [23]. The benzene ligands in **2** must be held in a fairly rigid orientation so as not to quench the room temperature luminescence. If the Cl–bz–Cl π-to-anion stacking along the *b* lattice direction (represented as c and d in Fig. 7) persists as proposed in the model structure of **2**, this could in part account for such lattice rigidity.

The final equivalents of benzene are only lost when the sample is evacuated for several hours under dynamic vacuum forming $Cu_2Zr_2Cl_{10}$ (**3**). As the benzene is removed from the lattice, a significant structural rearrangement occurs such that the copper to zirconium charge transfer in **3** is at a lower energy than either the copper–benzene or copper–ethylene charge transfer in **2** or **4**, respectively, Fig. 4. This lower energy Cu → Zr charge transfer is responsible for the darker shade of yellow of this desolvated material. We have not yet been able to index a powder pattern for **3**, however, we speculate that loss of the η^2-benzene ligands results in further collapse along the *b* axis to yield a layered structure that may be related to a smectite-clay. We further suggest that retention of a layered structure is the most consistent model to accommodate the reversible sorption of ethylene, described below.

4.3. Ethylene sorption

Compounds **2** and **3** readily react with ethylene at room temperature, and at a pressure well below one atmosphere of ethylene. The general feature of the enhanced reactivity of copper(I) chlorides toward olefins and aromatics when associated with a strong Lewis acid shows considerable parallel between this copper(I) zirconium(IV) system and that previously reported for the copper(I) aluminum(III) system [3]; although higher ethylene pressure is required for the present system to achieve the comparable sorption capacity. Copper chloride itself does not sorb ethylene until pressure of >60 atm of ethylene is achieved [24]. Comparison of the powder diffraction patterns of **2** and **4** (Fig. 5) suggests that these two materials have a similar structural topology. Their diffraction patterns exhibit a similar peak profile, albeit at higher values of reciprocal space for the ethylene adduct because of the lattice contraction upon replacement of the benzene molecules with the smaller ethylene. Compound **4** is formed either by the replacement of benzene in **2** by ethylene, or by the addition of ethylene to the completely desolvated **3**.

Interestingly, a parallel comparison of the sorption isotherm and pressure resolved X-ray diffraction and diffuse reflectance spectroscopy data suggest a significant variation in the mechanisms of sorptive reconstruction between this copper zirconium system and the $CuAlCl_4$ system. The sorption isotherm, Fig. 3, clearly demonstrates that ethylene is immediately sorbed into the framework of **2**, with nearly 0.5 equivalents sorbed by an equilibrium pressure of 100 Torr. By contrast, the diffuse reflectance spectrum at 100 Torr of ethylene pressure shows little change from that of the parent material **2**. No significant change is observed in the diffuse reflectance spectra until the ethylene pressure is increased to 300 Torr (Fig. 4); an equilibrium pressure that corresponds to a plateau in the sorption isotherm. Similarly, only a trace of the diffraction signature for the ethylene adduct, **4**, is observed at ethylene pressures below 300 Torr. This seemingly contradictory behavior is highlighted by comparison of the existence curve determined by diffraction for the formation of **4** from

2, Fig. 6, with the corresponding sorption isotherm measured with the calibrated gas line, Fig. 3. By contrast, for the sorption of ethylene into the condensed framework of $CuAlCl_4$, the analogous sorption isotherm, diffuse reflectance and X-ray diffraction data are nearly superimposable. We suggest that the model with a rigid clay-like structure of the copper zirconium chloride inorganic framework, in which a significant range of benzene or ethylene solid solubility is possible, provides the most consistent explanation to the observed data. Whereas sorption of ethylene into $CuAlCl_4$ required a drastic framework transformation, sorption into the pseudo lamellar structure of **2** need not drastically restructure the framework because "galleries" for ligand exchange are held open by pillars of the remaining benzene ligands. Thus, no major structural change is required until all the benzene is displaced, apparently at approximately 0.5 equivalents of ethylene/copper site that occurs at an equilibrium ethylene pressure of around 300 Torr. Above 300 Torr, the sorption isotherm, diffraction and diffuse reflectance data provide parallel evidence of continued ethylene sorption. The diffraction data suggest that complete structural transformation occurs over the narrow pressure range between 300 and 500 Torr of ethylene. By contrast, the diffuse reflectance and sorption isotherm data imply a continued increase in the sorption of ethylene with increasing pressure. These data suggest that **4** in fact exists over a range of ethylene stoichiometry, $((et)_{1-x}Cu)_2Zr_2Cl_{10}$, where $x = 0$–0.5. This interpretation is further consistent with the slightly different profile of the sorption isotherm for sorption into 3. If 3 has the collapsed clay-type structure, as proposed, then initial sorption must open the "galleries" within the framework, rather than simply exchanging ethylene for benzene ligands. Once the "galleries" are opened with 0.5 equivalents of ethylene (>400 Torr), there is no discernable difference in the ethylene sorption starting from 2 or 3. The sorption isotherm, spectroscopic and diffraction data imply that the full stoichiometric loading of one equivalent of ethylene/copper site is achieved at around 1000 Torr of ethylene pressure.

Increasing the ethylene pressure beyond 1000 Torr demonstrates further sorption capacity of this material. Diffraction data at these higher pressures begin to show a slight decrease in the diffraction intensity although no evidence of a new crystalline phase is observed. However, the diffuse reflectance spectra show a dramatic growth of the copper → ethylene charge transfer band at 24 000 cm^{-1} (Fig. 4). This sharp MLCT band is most consistent with a further deconstruction of an extended framework, and the formation of a molecular species; likely $((et)_2Cu)_2Zr_2Cl_{10}$ (**5**) the bis-ethylene analog to the molecular structure of **1**.

The ethylene desorption isotherm (Fig. 3) demonstrates no significant hysteresis for the higher ethylene adduct, **5**, consistent with the facile loss of benzene from **1**. However, like the mono-benzene adduct **2**, the mono-ethylene adduct **4** only begins to exhibits ethylene loss at pressures less than 20 Torr.

5. Conclusion

The reactivity of a family of copper zirconium chloride materials toward benzene and ethylene has been characterized by single crystal and powder X-ray diffraction, diffuse reflectance spectroscopy and by volumetric adsorption analysis. Adduct phases with one and two equivalents of benzene or ethylene per equivalent of copper have been identified, as well as the ligand free inorganic host. The single crystal structure of **1** provides the first crystallographically characterized example of multiple aromatic ligands coordinated to a copper(I) center. Significant π-stacking of the benzene ligands and benzene–chloride hydrogen bonding cause a unique molecular distortion to **1** as well as providing the basis for organization of the crystalline lattice. The benzene ligands of **1** can be lost under relatively mild conditions resulting in the construction of a clay-type inorganic framework, or be exchanged for ethylene under modest pressures.

Like the previously reported reactivity of $CuAlCl_4$ toward ethylene, the Lewis acidic zirconium(IV) chloride dramatically enhances the reactivity of copper chloride toward olefins and aromatics by lowering the energy of copper(I)'s empty s/p orbitals to make it a more effective electron acceptor. Both $CuAlCl_4$ and $Cu_2Zr_2Cl_{10}$ undergo solid state, sorptive reconstruction reactions by a classic mechanism of nucleophilic substitution/addition. However, the framework of $CuAlCl_4$ is more flexible exhibiting a mechanism for the reaction with ethylene that was described as a 'rat-snake' model in which there is a continuous structural transition at the reacting phase boundary. The more rigid framework of $Cu_2Zr_2Cl_{10}$ appears to undergo an abrupt transformation where structural plates are separated by a given concentration of ethylene. The remaining coordination sites, opened by the pillaring of the initially sorbed ligands, can then sorb additional small molecules up to a stoichiometric loading.

This paper is dedicated to Professor Malcolm Chisholm on the occasion of his 60th birthday.

Abstract

The 1-methylbenzotriazole ligand (1-Mebta) has been successfully incorporated into four new 1-D coordination polymers of general formula $[M^{II}(dca)_2(1\text{-Mebta})_2]$ (M = Mn (**1**), Fe (**2**) and Cu (**3**)) and $[Cu^{II}(tcm)_2(1\text{-Mebta})_2]$ (**4**) containing the dicyanamide $(N(CN)_2^-, dca^-)$ or tricyanamide $(C(CN)_3^-, tcm^-)$ $\mu_{1,5}$-bridging ligands. Magnetic susceptibility measurements reveal weak antiferromagnetic interactions between the M^{II} centres without any long-range order. Spin-Hamiltonian parameters ($g = \pm 0.01$, $J = \pm 0.01$) were obtained using a chain model; $[M^{II}(dca)_2(1\text{-Mebta})_2]$ (Mn (**1**): $g = 1.94$, $J = -0.15\ cm^{-1}$, Fe (**2**): $g = 2.17$, $J = -0.38\ cm^{-1}$, and $g = 2.18$, $J = -0.01\ cm^{-1}$) in $[Cu^{II}(tcm)_2(1\text{-Mebta})_2]$ (**4**). To increase the dimensionality of these benzotriazole-based networks, two benzotriazole molecules were linked together via alkyl chains in the form of the 1,3-di(benzotriazol-1-yl)propane (dbtp) and 1,4-di(benzotriazol-1-yl)butane (dbtb) ligands and these have produced 1-D, 2-D and 3-D networks. The dbtp ligand yields a 1-D 'step-like' chain coordination polymer in $[Cu^{II}(dca)_2(dbtp)]$(**5**), where the dbtp ligands propagate the 1-D chains; a role normally carried out by bridging dca^- ions. Reaction of the dbtp ligand with Co^{II} increases the dimensionality by producing the α-Po related 3-D $[Co^{II}(dca)_2(dbtp)]$ (**7**) network. Compound **7** consists of 2-D (4,4) connecting sheets, linked together by the bridging dbtp ligand. The Ni^{II} analogue $[Ni^{II}(dca)_2(dbtp)]$ (**8**) has also been synthesized in polycrystalline form and characterized by powder X-ray diffraction. Magnetic measurements on **7** indicate extremely weak antiferromagnetic exchange interactions between the Co^{II} ions while $[Ni^{II}(dca)_2(dbtp)]$ (**8**) exhibits short range ferromagnetic coupling with best-fit parameters $g = 2.13$ and $J = +0.24\ cm^{-1}$. The synthesis of a 2-D (4,4) connected sheet $[Cu^{II}(dca)_2(dbtb)]$ (**9**) (where dbtb is 1,4-di(benzotriazol-1-yl)butane) illustrates how increasing the alkyl chain by one carbon length has dramatically changed the topology and dimensionality of the network. Magnetic susceptibility measurements reveal weak antiferromagnetic exchange coupling.

1. Introduction

The design and synthesis of 1-, 2- and 3-D coordinated networks containing the dicyanamide $(N(CN)_2^-, dca)$ and tricyanamide $(C(CN)_3^-, tcm)$ bridging ligands has grown significantly over the past decade. Interest in these networks intensified with the discovery of interesting magnetic properties such as long-range magnetic ordering in the rutile-like 3-D α-$M(dca)_2$ compounds (M = Cr, Mn, Fe, Co, Ni and Cu) [1–4]. The introduction of N-based bridging and terminal co-ligands into M/dca/tcm systems has led to many interesting architectures in all three dimensions. 1-D topologies include the zigzag chains in *cis*-$[M^{II}(dca)_2(2,2'\text{-bipy})]$, M = Mn [5] or Cd

[6] and the 1-D infinite tubes of $[M^{II}(dca)_2(2\text{-aminopyrimidine})]$ ($M = Co^{II}$, Ni^{II}) [7] while examples of 2-D systems include the (4,4) sheets in $[Mn^{II}(dca)_2(H_2O)] \cdot phz$ (where phz is the phenazine ligand) [8]. The structures in $[M^{II}(dca)_2(pyrimidine)] \cdot EtOH$ ($M = Fe^{II}$, Co^{II}, Ni^{II} and Cu^{II}) are isostructural, consisting of M^{II}/dca (4,4) sheets bridged by the pyrimidine co-ligands, resulting in the 3-D networks of α-Po geometry with magnetic ordering at very low temperatures [9]. More recently, the incorporation of countercations while increasing the dca/M^{II} ratios has resulted in numerous novel cation templated 2-D and 3-D networks exhibiting interesting topological features. Examples include the 2-D sheets: $[M(2,2'\text{-bipy})_3][M'(dca)_3]_2$ ($M = Fe^{III}$, $M' = Mn^{II}$ or Fe^{II}; $M = Ni^{II}$, $M' = Mn^{II}$) [10] and $(Ph_4X)[Mn^{II}(dca)_3]$ ($X = P$ [11] or As [12]). Previously reported 3-D cation templated systems include the α-polonium type network $[Cp^*_2M][M'(dca)_3]$ (where $M = Fe^{III}$, Co^{III}; $M' = Mn^{II}$, Fe^{II}, Co^{II}, Ni^{II} and Cd^{II}) [13] and the spin-canted $(SPh_3)[Mn(dca)_3]$ system [14]. It has also been noted that slight variations in the size and shape of the countercations significantly changes the topologies of the anionic metal dicyanamide networks [15]. One such example is the move from 2-D topology in $(Ph_4P)[Mn^{II}(dca)_3]$ to 3-D in $(MePh_3P)[Mn^{II}(dca)_3]$; simply by substitution of one phenyl group in PPh_4^+ with a methyl substituent [15].

The series of 1-D, 2-D and 3-D networks described in this work contains derivatives of the benzotriazole pro-ligand (btaH). The coordination chemistry of benzotriazole (btaH) and its analogues has been an area of intense research over recent years due to their ability to inhibit corrosion of copper and its alloys [16]. Valuable insights into the bonding modes observed between benzotriazole and the oxygen rich $Cu^{I/II}$ surfaces in corrosion inhibition processes resulted in numerous pentametallic Cu^{II} clusters of general formula $[Cu_5^{II}(bta)_6(L)_4]$ (L includes the tropolonate [17], acetylacetonate [18] and tert-butyl isocyanate ligands [19]). In the case of these pentametallic Cu^{II} complexes, the bta^- anion bonds via all three nitrogen atoms (μ_3). However, bidentate bonding via adjacent [20] and non-adjacent [21] nitrogen atoms has been observed, along with terminal unidentate μ_1-bonding [22]. Furthermore, the important area of single-molecule magnetism (SMM) has benefited from the btaH pro-ligand through the synthesis of numerous high nuclearity $M^{III/IV}$ clusters, including the high-spin $S \geqslant 23$ Fe_{14} [23] and the $S = 4$ hexaicosametallic Mn_{26} SMM [24]. The flexibility in bonding, their neutral charge and their reactivity with first row transition metals made benzotriazole derivatives ideal ligands for the synthesis of 1-D, 2-D and 3-D networks.

2. Experimental

Sodium dicyanamide (Na(dca)) was supplied by Fluka chemicals and the 1-methylbenzotriazole (1-Mebta) ligand was supplied by Lancaster chemicals. The K(dca) [25] and K(tcm) salts [26], 1,3-di(benzotiazol-1-yl)propane (dbtp) and 1,4-di(benzotriazol-1-yl)butane (dbtb) were prepared using methods previously described in the literature [27].

2.1. Synthesis

2.1.1. $[Mn^{II}(dca)_2(1\text{-Mebta})_2]$ (1)

An aqueous solution (7.0 ml) of $Mn^{II}(ClO_4)_2 \cdot 6H_2O$ (25.0 mg, 0.07 mmol) and Na(dca) (12.4 mg, 0.14 mmol) was stirred at room temperature for 5 min and then filtered. A methanolic solution (10.0 ml) of 2 equivalents 1-methylbenzotriaozle (18.0 mg, 0.14 mmol) was carefully layered on top of the aqueous Mn^{II}/dca solution. Clear needle-like crystals of **1** crystallised in the $P\bar{1}$ triclinic space group in moderate yield (⩽30%) after 4 weeks. *Anal.* Calc. for $C_{18}H_{14}N_{12}Mn \cdot H_2O$: C, 45.85; H, 3.39; N, 35.67. Found: C, 45.59; H, 3.05; N, 35.39%. Selected IR data (KBr): 3578(m), 3450(b), 2297(s), 2241(s), 2177(vs), 1454(m), 1346(s), 1216 (m), 779(m), 739(vs).

2.1.2. $[Fe^{II}(dca)_2(1\text{-Mebta})_2]$ (2)

An aqueous solution (7.0 ml) of $Fe^{II}(ClO_4)_2 \cdot xH_2O$ (25.0 mg, 0.1 mmol) and Na(dca) (18.0 mg, 0.2 mmol) was stirred at room temperature for 5 min and then filtered. A methanolic solution (10.0 ml) of 2 equivalents 1-methylbenzotriaozle (26.0 mg, 0.2 mmol) was carefully layered on top of the aqueous Fe/dca solution. Yellow plate-like crystals of **2** formed in the $P\bar{1}$ triclinic space group in good yield (⩽45%) after 2 weeks. Elemental analysis: Calc.for $C_{18}H_{14}N_{12}Fe \cdot 2H_2O$: C, 45.76; H, 3.38; N, 35.55. Found: C, 45.56; H, 3.06; N, 35.05%. Selected IR data (KBr): 3449(b), 2294(m), 2244(m), 2181(vs), 1341(m), 1218(m), 779(m), 740(s).

2.1.3. $[Cu^{II}(dca)_2(1\text{-Mebta})_2]$ (3)

An aqueous solution (7.0 ml) of $Cu^{II}(ClO_4)_2 \cdot 6H_2O$ (25.0 mg, 0.07 mmol) and Na(dca) (12.4 mg, 0.14 mmol) was stirred at room temperature for 5 min and then filtered. A methanolic solution (10.0 ml) of 2 equivalents of 1-methylbenzotriaozle (18.0 mg, 0.14 mmol) was carefully layered on top of the aqueous Cu/dca solution. Blue thin plate-like crystals of **3** formed in the $P\bar{1}$ triclinic space group in good yield (⩽40%) after 1 week. *Anal.* Calc. for $C_{18}H_{16}N_{12}Cu.2H_2O$: C, 43.42; H, 3.62; N, 33.77. Found: C, 43.13; H, 3.35; N, 34.05%. Selected IR data (KBr): 3425(b), 2297(s), 2248(s), 2182(vs), 1351(m), 780(m), 744(s).

Pure microcrystalline bulk quantities of **1**–**3** were synthesised using the following method.

A 1:2 stoichiometric ratio of $M^{II}(ClO_4)_2 \cdot xH_2O$ and K(dca) was dissolved in a minimum quantity of methanol (5.0 ml). A methanolic solution of 1-methylbenzotriazole (2 equivalents in 5.0 ml) was then added dropwise into the methanolic M^{II}/dca solution yielding

microcrystalline powders of **1**–**3** after 10 min. IR spectral and Elemental analysis confirmed these powders to be compounds **1**–**3**.

*2.1.4. [$Cu^{II}(tcm)_2(1\text{-}Mebta)_2$] (**4**)*

An aqueous solution (10 ml) of $Cu^{II}(ClO_4)_2 \cdot 6H_2O$ (25.0 mg, 0.07 mmol) and K(tcm) (17.55 mg, 0.14 mmol) was stirred for 5 min and then filtered. A methanolic solution (10 ml) containing two equivalents of 1-methylbenzotriazole (17.92 mg, 0.14 mmol) was then carefully layered on top of the aqueous Cu/tcm solution. Thin brown irregular block crystals of **4** crystallised in the $P\bar{1}$ triclinic space group after four weeks in moderate yield (⩽30%). Elemental *Anal*. Calc. for $C_{22}H_{14}N_{12}Cu$: C, 51.81; H, 2.75; N, 32.97. Found: C, 51.80; H, 2.77; N, 33.17%. Selected IR data (KBr): 3423(b), 2239(m), 2188(vs), 1226(m), 780(m), 748(s).

*2.1.5. [$Cu^{II}(dca)_2(dbtp)$] (**5**)*

An aqueous solution (7.0 ml) of $Cu^{II}(ClO_4)_2 \cdot 6H_2O$ (25.0 mg, 0.07 mmol) and Na(dca) (12.0 mg, 0.14 mmol) was stirred for 5 min and then filtered. A 50:50 MeOH/H_2O solution (5.0 ml) was then layered on top of the Cu/dca solution. This was then layered with a methanolic solution (10.0 ml) containing 1 equivalent of 1, 1-dbtp (18.0 mg, 0.07 mmol). Thin blue plates of **5** were obtained overnight in adequate yield (⩽20%), crystallising in the monoclinic *C*2/*c* space group. *Anal*. Calc. for $C_{19}H_{14}N_{12}Cu$: C, 47.59; H, 2.91; N, 35.26. Found: C, 48.15; H, 2.96; N, 35.46%. Selected IR data (KBr): 3449(b), 2960(w), 2297(s), 2236(s), 2169(vs), 1363(m), 780(w), 756(m).

*2.1.6. [$Cu_2^{II}(tcm)_2(dbtp)_4](ClO_4)_2$ (**6**)*

An aqueous solution (7.0 ml) of $Cu^{II}(ClO_4)_2 \cdot 6H_2O$ (25.0 mg, 0.07 mmol) and K(tcm) (17.55 mg, 0.14 mmol) was stirred for 5 min and then filtered. Two equivalents of 1,1-dbtp (36.0 mg, 0.14 mmol) in methanolic solution (10.0 ml) was then carefully layered on top of the aqueous Cu/tcm solution. Dark green plate-like crystals of **6** were obtained overnight in moderate yield (⩽30%), crystallising in the *I*4/*m* tetragonal space group. *Anal*. Calc. for $C_{68}H_{56}N_{30}O_8Cl_2Cu_2$: C, 50.43; H, 3.46; N, 25.95; Cl, 4.38. Found: C, 50.89; H, 3.46; N, 26.66; Cl, 4.68%. Selected IR data (KBr); 3422(b), 2371(m), 2344(m), 2169 (vs), 1092(m), 780(s), 756(s).

*2.1.7. [$Co^{II}(dca)_2(dbtp)$] (**7**)*

$Co^{II}(NO_3)_2 \cdot 6H_2O$ (25.0 mg, 0.086 mmol) and Nadca (15.3 mg, 0.172 mmol) were dissolved in 5 ml distilled water. This aqueous solution was then carefully layered with a methanolic (10 ml) solution of the dbtp ligand (23.0 mg, 0.086 mmol). Thin lilac needles of **7** were obtained in 20% yield after 24 h. Compound **7** crystallized in the triclinic $P\bar{1}$ space group. Calc.for $C_{19}H_{14}N_{12}Co \cdot H_2O$: C, 46.84; H, 3.41; N, 34.49. Found: C, 46.88; H, 3.12; N, 33.10%. Selected IR data (KBr); 3487(b), 2318(m), 2245(m), 2172(s), 1720(m), 1638(m), 1544(m), 1525(m), 1385(m), 781(m), 746(s).

*2.1.8. [$Ni^{II}(dca)_2(dbtp)$] (**8**)*

$Ni^{II}(NO_3)_2 \cdot 6H_2O$ (30.0 mg, 0.103 mmol) and Nadca (18.6 mg, 0.206 mmol) were dissolved in 5 ml distilled water. This aqueous solution was then carefully layered with a methanolic (10 ml) solution of the dbtp ligand (28.6 mg, 0.103 mmol). Blue plates of **8** were obtained in 20% yield after 24 h. Compound **8** crystallized in the triclinic $P\bar{1}$ space group. Calc.for $C_{19}H_{14}N_{12}Ni$: C, 48.65; H, 2.99; N, 35.85. Found: C, 48.85; H, 3.07; N, 35.61%. Selected IR data (KBr); 3449(b), 2291(m), 2269(m), 2178(s), 1775(w), 1720(w), 1655(m), 1544(m), 1452(m), 1424(m), 1383(m), 1321(m), 1298(m), 1223(m), 1173(m), 782(m), 746(s).

*2.1.9. [$Cu^{II}(dca)_2(dbtb)$] (**9**)*

An aqueous solution (7.0 ml) of $Cu^{II}(ClO_4)_2 \cdot 6H_2O$ (25.0 mg, 0.07 mmol) and Na(dca) (12.0 mg, 0.14 mmol) was stirred for 5 min and then filtered. One equivalent of 1,1-dbtb (20.0 mg, 0.07 mmol) was dissolved with warming in *iso*-propanol (10.0 ml) and carefully layered on top of the aqueous Cu^{II}/dca solution. Light green needle-like crystals of **9** were obtained after 2 days in 30% yield. Compound **9** crystallised in the monoclinic $P2_1/c$ space group. Calc.for $C_{20}H_{16}N_{12}Cu$: C, 49.23; H, 3.28; N, 34.46. Found: C, 49.09; H, 3.38; N, 34.20%. Selected IR data (KBr); 3419(b), 2933(w), 2367(w), 2296(s), 2181(s), 1637(m), 1494(w), 1458(m), 1359(m), 1234(m), 1168(w), 780(m), 742(s), 668(w), 516(m).

2.2. Physical measurements

Elemental analyses (CHN) were carried out by Campbell Microanalytical laboratory, University of Otago, Dunedin, New Zealand. IR spectra were recorded on a Perkin–Elmer 1600 Series Spectrometer with the samples prepared as KBr discs.

2.3. Magnetic susceptibilities

DC magnetic susceptibility measurements were carried out on a Quantum Design MPMS 5 SQUID magnetometer calibrated by use of a standard palladium sample (Quantum Design) of accurately known magentisation or by use of magnetic calibrants such as $CuSO_4 \cdot 5H_2O$. A powder sample of ~30 mg was contained in a calibrated gelatine capsule held at the centre of a drinking straw at the end of the sample rod. Samples of Co^{II} and Fe^{II} were dispersed in Vaseline to avoid torquing of the crystallites at low temperatures and high fields. A 1 T field was generally used, but in a number of cases fields of 0.01 and 0.1 T (2–100 K) were used to check for evidence of long-range

order. Magnetisation isotherm measurements were made in fields of between 0 and 5 T.

2.4. X-ray crystallographic studies

Data were collected using a Nonius KappaCCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Integration was carried out by the program DENZO-SMN [28] and data were corrected for Lorentz polarization effects and for absorption using the program SCALEPACK [28]. Solutions were obtained by direct methods (SHELXS-97) [29] followed by successive fourier difference methods, and refined by full-matrix least-squares on F^2obs (SHELXL-97) [29].

All structures were solved using direct methods and their corresponding data summarized in Table 1.

The crystal structure of $[Cu_2^{II}(dbtp)_4(tcm)_2](ClO_4)_2$ (**6**) crystallized in space group $I4/m$ and was found to be merohedrally twinned with two domain orientations related by twofold rotation about the 110 direction. The twin component refined to 0.44, which was consistent with the disparity between the R_{int}'s for the $4/m$ (0.042) and $4/mmm$ (0.071) Laue groups. The structure also exhibited disorder within the tcm^- ligands and perchlorate counter ions. The tcm^- ligands are disordered over four positions, related by a fourfold rotation. Steric effects dictate that the tcm^- ligands on adjacent dimers within the structure must be related by inversion and are relatively close together (C10···C10* ~ 3.38 Å) resulting in moderate π–π overlap, however, the structure solution shows that the four tcm positions on each Cu(II) relate to their neighbours by mirror plane symmetry. Suitable geometry for the tcm^- anions was obtained using distance restraints (SADI) with rigid bond restraints (DELU) applied to the anisotropic displacement parameters (ADP's). The perchlorate counter ions in **6** were also disordered over four close positions related by inversion and mirror plane symmetry. Restraints were applied to the Cl–O and O···O distances and oxygen atoms were constrained to have the same ADP's.

The crystal structure of $[Cu^{II}(dca)_2(dbtb)]$ (**9**) contained a 90:10 disorder of the Cu^{II} atom and dbtb ligand positions. These positions are related by non-crystallographic mirror plane symmetry perpendicular to the *b*-axis. The two Cu^{II} positions are 0.64 Å apart. The minor component of the dbtb ligand was restrained to be the same as the major component using SAME. Additionally, the dca ligands are disordered due to disorder of the Jahn–Teller distorted Cu^{II} ions which involve elongation of two of the four bonds to dca ligands. The dca ligands for the major component were refined with 50:50 disorder (i.e., 0.45 occupancy each), while only single dca positions were modeled for the minor component. The refinement required numerous

2.5. Powder X-ray diffraction studies

A Scintag high-resolution automated powder diffractometer was employed using Cu Kα radiation ($\lambda = 1.54059$ Å).

3. Results and discussion

3.1. Structures of $[M^{II}(dca)_2(1\text{-}Mebta)_2]$ (M = Mn (**1**), Fe (**2**), Cu (**3**)) and $[Cu^{II}(tcm)_2(1\text{-}Mebta)_2]$ (**4**)

We report here the synthesis, structures and magnetic properties of a family of dca (**1**, **2** and **3**) or tcm (**4**) based 1-D coordination polymers where the 1-methylbenzotrioazole (1-Mebta) ligand acts as the co-ligand. The structures of **1**–**4** are closely related and so are described together. Structures **1**–**3** ($[M^{II}(dca)_2(1\text{-}Mebta)_2]$ (M = Mn (**1**), Fe (**2**), Cu (**3**))) consist of 1-D linear chains, in which each M^{II} centre is bridged by two $\mu_{1,5}$-dca^- ligands via the nitrile nitrogen atoms (N1). The coordination sphere at each M^{II} centre is completed by two 1-methylbenzotriazole ligands occupying the axial sites. In each case the coordination geometry around the M^{II} ion is distorted octahedral, with M1–N1(dca) bond lengths of 2.1973(12) (**1**), 2.1364(13) (**2**) and 2.157(10) (**3**) Å and M–N4(1-Mebta) distances of 2.289(11) (**1**), 2.2086(13) (**2**) and 2.042(5) Å (**3**) respectively (Table 2). Each M^{II} lies on a centre of inversion resulting in N4–M1–N4′ angles of 180° in all cases (Fig. 1). The d^9 electronic configuration at the Cu^{II} centres in **3** gives rise to a Jahn–Teller contraction about the N(1-Mebta)–Cu–N(1-Mebta) *z*-axis. Each chain propagates parallel along the *a*-axis, with the M···M distance corresponding to their unit cell lengths *a* of 7.4682(2) (**1**), 7.3932(2) (**2**) and 7.3355(3) (**3**) Å respectively. These angles and distances are comparable to other related coordinated polymers of general formula $[M^{II}(dca)_2(L)_2]$ (M = Mn, Fe, Co, Ni, Cu and L includes H_2O [30], pyridazine [31], 2,2′-bipy [32] and solvents such as DMF, pyridine and MeOH [33]). The structures of **1**–**3** consist of interdigitated linear chains, where each 1-Mebta ligand lies between two 1-Mebta ligands of an adjacent chain. The 1-Mebta ligands are crystallographically related via a centre of inversion and have centroid-centroid distances at the higher limit of π–π stacking classification (3.766 (**1**), 4.034 (**2**) and 3.797 (**3**) Å respectively) (see Fig. 1) [34].

Attempts in increasing the dimensionality of these linear chains led to the use of the tricyanomethanide (tcm) tridentate bridging ligand in complex $[Cu^{II}(tcm)_2(1\text{-}Mebta)_2]$ (**4**) (Fig. 2). However, just as observed in the 1-D chains **1**–**3**, the tcm^- ligands bridge via only two of its three available nitrile nitrogen atoms (N1), resulting in a 1-D linear chain, analogous to those observed in complexes **1**–**3**. The tcm^- ligands bridge the Cu^{II} metal centres in the $\mu_{1,5}$-tcm^- coordination mode, each disordered over two sites (half occupancy) at the equatorial positions (Fig 2). Each Cu^{II} lies on an inversion centre (N5–Cu–N5#3 = 180°) and exhibits distorted octahedral geometry. The coordination sphere at each Cu^{II} centre is completed by two axial 1-methylbenzotriazole terminal ligands. Like complexes **1**–**3**, the 1-D linear chains in **4** propagate parallel to the *a*-axis, giving rise to an M···M distance equal to that of the unit cell length *a* (7.2605(7) Å). The linear chains pack in the customary interdigitated fashion and the 1-methylbenzotriazole ligands are 3.719 Å apart. All Cu^{II}–N(1-Mebta) and Cu^{II}–N(tcm) bond lengths are comparable to those observed in **1**–**3** except for the long in-chain Cu(1)–N(1) of 2.454(4) (Table 2).

3.2. Magnetism on networks 1–4

Solid-state dc magnetic susceptibility studies were carried out on samples **1** to **4** in a field of 1 T over a temperature field range of 300–2 K. Plots of $\chi_m T$ versus *T* for samples **1**, **2** and **4** are shown in Fig. 3, and these are indicative of very weak antiferromagnetic interactions occuring between the M^{II} centres. The data were fitted using the Fisher chain model [35] giving the following Spin Hamiltonian parameters: $[M^{II}(dca)_2(1\text{-}Mebta)_2]$ ($M = Mn^{II}$(**1**): $S = 5/2$, $g = 1.94$, $J = -0.15\ cm^{-1}$, $M = Fe^{II}$(**2**): $S = 2$, $g = 2.17$, $J = -0.38\ cm^{-1}$, $M = Cu^{II}$(**4**) $S = 1/2$, $g = 2.18$, $J = -0.01\ cm^{-1}$ in $[Cu^{II}(tcm)_2(1\text{-}Mebta)_2]$ (**4**). Such *J* values are typical of $\mu_{1,5}$-dca^- and $\mu_{1,5}$-tcm^- bridging modes [15]. The tiny value for **4** implies essentially zero-coupling and this is because the unpaired spin on each Cu^{II} centre is in the $d_{x^2-y^2}$ orbital, at 90° to the chain direction. The small decrease in χT below 5 K could also be due to Zeeman level depopulation effects in the 1 T field. Complex **3** showed a somewhat unusual (almost linear) decrease of $\chi_m T$, from 0.38 $cm^3\ mol^{-1}\ K$ (1.74 μ_B) to 0.29 $cm^3\ mol^{-1}\ K$ (1.52 μ_B) at 4.2 K. This could not be simulated well using a chain model and we have no obvious explanation for this behaviour. In the case of **2**, the spin–orbit effects are included in the high value of *g*. The shape of the χT curve shows that the orbital degeneracy of the $^5T_{2g}$ single-ion state is largely removed and thus use of the Fisher model is a reasonable approximation.

3.3. Structures of networks 5–7

The results in **1**–**4** strongly suggest that the 1-Mebta ligand inevitably leads to linear chains due to its preference for terminal bonding via N4. It was anticipated that one way to increase the directionality of these systems would be to extent the methyl group in the

Table 2

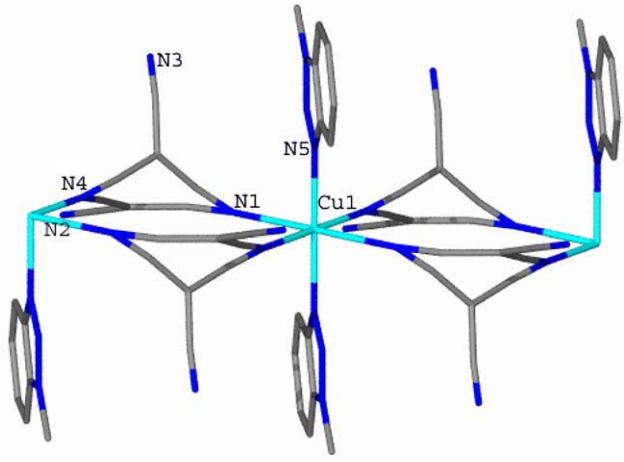

Fig. 2. The structure of $[Cu^{II}(tcm)_2(1\text{-Mebta})_2]$ (**4**), showing the disordered positioning of the tcm^- ligands over two sites. H atoms are omitted for clarity. Selected inter-atomic bond distances of **4** (Å): Cu1–N1 = 2.454(4), Cu1–N4 = 1.998(3), Cu1–N5 = 2.023(3), Cu1–Cu1′ of ~7.261.

1-Mebta ligand by linking two benzotriazole groups together via alkyl chains of various lengths, the premise being that these dibenzotriazole type ligands would link M^{II} centres in one direction while the anionic dca/tcm bridging ligands (Fig. 4) would propagate the system in the 2-D or 3-D modes. Extensive research by Katritzky et al. in 1996 produced a large family of these dibenzotriazol(alkane) molecules, the synthetic strategies for which were employed here. The first such ligand synthesised was 1,3-dibenzotriazol-1-yl)propane ($n = 3$ in Fig. 4) (abbreviated as dbtp) which, upon reaction with a Cu^{II}/dca solution, afforded a rather novel 1-D linear chain complex **5**. Unexpectedly, the dbtp ligands propagate the chains in **5**, while the dca^- ligands bond terminally (Fig. 5).

Each distorted square planar Cu^{II} centre in **5** is bridged by one dbtp ligand (Cu1–N4 = 2.014(5) Å) and is terminally bonded in the *trans* positions by two nitrile bonded dca^- ligands (Cu1–N1 = 1.966(6) Å). The twisting of the alkyl links of the dbtp ligands allow the propagation of the chains, resulting in 'step-like' 1-D polymer chains (Fig. 5). The terminal dca^- ligands are situated away from the linear dbtp-Cu-dbtp plane (N1–Cu1–N4 = 180.00°) at an angle of ~36.1°. Each square-planar $\{Cu(dca)_2(dbtp)\}$ moiety along an individual chain is related to its neighbour by a twist of approximately 90°, resulting in alternating criss-crossing

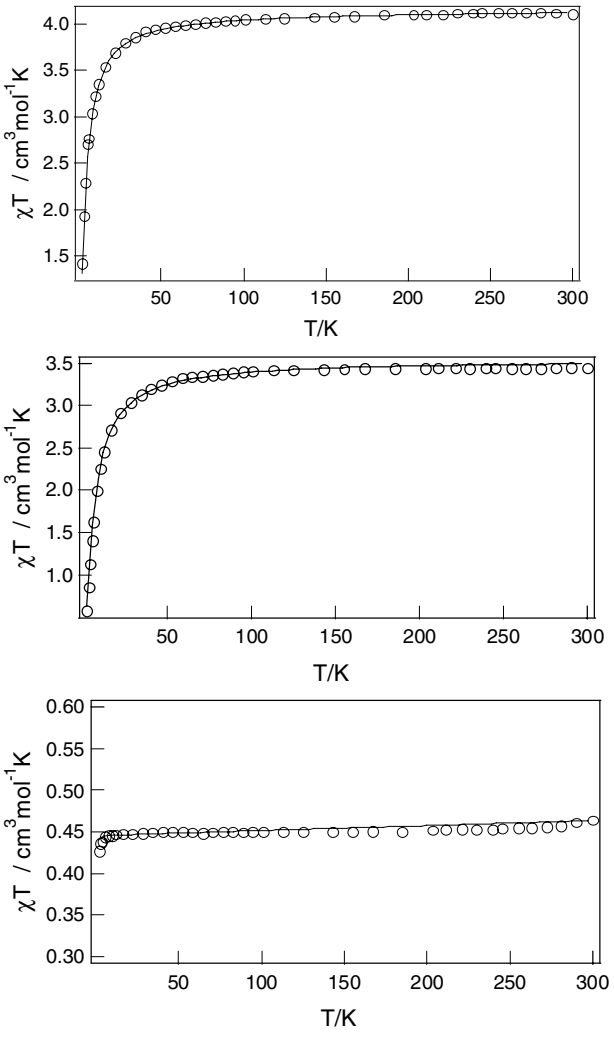

Fig. 3. Magnetic susceptibility ($\chi_m T$) vs. temperature, T, for complexes **1** (top), **2** and **4** (bottom). The solid lines are the best fits described in the text. Fitting of these data using the Fisher model ($g \pm 0.01$, $J \pm 0.01$) results in the following parameters: (**1**) $g = 1.94$, $N\alpha$ (temperature independent paramagnetic susceptibility) $= 50 \times 10^{-6}$ cm^3 mol^{-1}, $J = -0.15$ cm^{-1} (**2**) $g = 2.17$, $J = -0.38$ cm^{-1} and (**4**) $g = 2.18$, $N\alpha = 60 \times 10^{-6}$ cm^3 mol^{-1}, $J = -0.01$ cm^{-1}.

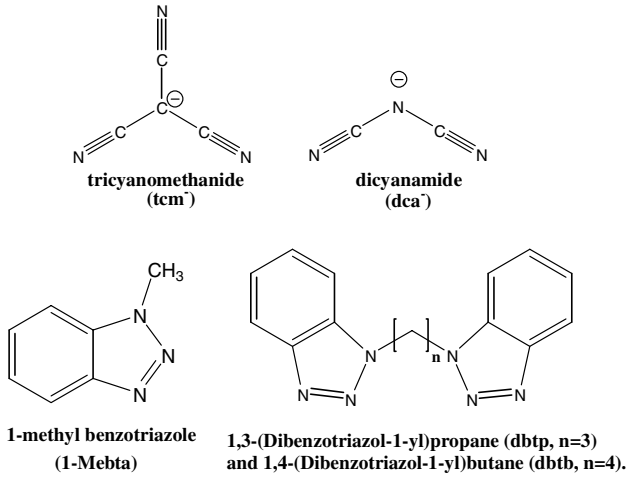

Fig. 4. Molecular structures of tricyanomethanide (tcm), dicyanamide (dca), 1-methylbenzotriazole (1-Mebta) and the 1,ω-(dibenzotriazol-1-yl)alkane (dbtp ($\omega = 3$), dbtb; ($\omega = 4$)) ligands.

when viewed along the plane of each 1-D chain. The chains in **5** pack in an efficient 'brickwork' formation.

Substitution of dca$^-$ with the potentially tridentate tcm$^-$ bridging ligand in the above reaction does not afford the analogous 1-D 'step-like' polymer in **5**, or even a 2-D or 3-D network, instead choosing to form a porous dimeric complex $[Cu_2^{II}(tcm)_2(dbtp)_4](ClO_4)_2$ (**6**) (Fig. 6). Compound **6** crystallises in the tetragonal I4/m space group, exhibiting a fourfold rotation axis along the Cu–Cu plane (along *c*-axis). The five-coordinate Cu^{II} centres in **6** exhibit distorted square based pyramidal geometry and are linked by four dbtp bridging ligands resulting in a Cu···Cu distance of 8.397 Å. The coordination sphere at each metal centre is completed by one tcm$^-$ ligand which is disordered over four sites (Fig. 7(left)). Each tcm$^-$ ligand is relatively close in proximity to an adjacent tcm$^-$ ligand, resulting in moderate π–π overlap (~3.38 Å). These relatively weak interactions form chains of dimers along the *c*-axis (Fig. 7(right)). The Cu^{II}–N(tcm) and Cu^{II}–N(dbtp) bond lengths are comparable to previously reported structures and are documented in Table 3. The perchlorate counter ions are disordered over four close positions (Section 2.1.3) and occupy the edges of the *ab* face and centres of the *ac* and *bc* faces.

This unexpected result can perhaps be attributed to the added steric effects the introduction of a tridentate tcm$^-$ ligand brings when competing with the already rather bulky dbtp ligand. This competition leads to the tcm$^-$ ligands bonding terminally at the apices of each $Cu^{(II)}$ centre, with the four bridging dbtp ligands occupying the basal plane positions. This view is supported by the general observation that tcm-based networks incorporating co-ligands are rare and the co-ligands are relatively small in size in relation to the dbtp ligand used here. Examples include the 2-D sheet structures $[Ag^{(II)}(tcm)_2(phenazine)_{1/2}]$, and $[Ag^{(II)}(tcm)_2(pyrazine)]$ [36] and the 3-D network $[M^{(II)}(tcm)_2(Me_4pyrazine)]$ (M = Co, Ni) [37].

The coordination geometries around the Cu^{II} centres in **5** and **6** are distorted square planar and distorted square based pyramidal respectively, and can be attributed to partial (square-based pyramidal) and extreme (square-planar) Jahn–Teller elongations along the *z*-direction. The question which arose from these findings was whether the extra coordinating node(s) of a six-coordinate metal centre would encourage 2-D and 3-D networks to form. This proved to be the case when the reaction of $Co^{II}(NO_3)_2 \cdot 6H_2O$ and Na(dca) in H_2O, followed by careful layering of a methanolic solution of the dbtp ligand resulted in the formation of the novel α-Po related 3-D network in $[Co^{II}(dca)_2(dbtp)]$ (**7**). Each

						N(7′)–Cu(1′)–N(10′)	171.4(6)

of the octahedral Co^{II} centres in **7** is bonded to four others by four equatorial $\mu_{1,5}$-dca^- bridging ions, resulting in distorted square grid-like (4,4) sheets of $\{Co^{II}(dca)_2\}$ (Fig. 8). The axial positions are occupied by two different dbtp ligands, each twisting away and bridging to opposite and adjacent (4,4) sheets to produce the 3-D array in **7** (Fig. 9). Selected bond angles and distances observed in **7** are given in Table 3. The analogous $[Ni^{II}(dca)_2(dbtp)]$ (**8**) 3-D network was synthesised using the same general method (Section 2.1), giving crystals of poor quality and so powder X-ray diffraction studies were employed to confirm its identity. Thus, the powder XRD pattern of **8** obtained at ambient temperature compares well to the generated powder XRD pattern using the crystal data from **7** (see Supplementary information).

3.4. Magnetic susceptibility measurements on 7 and 8

Magnetic susceptibility measurements were carried out on $[Co^{II}(dca)_2(dbtp)]$ (**7**) and $[Ni^{II}(dca)_2(dbtp)]$ (**8**) in a field of 1 T, giving room temperature μ_{eff} ($=2.83\sqrt{\chi_m T}$) values (per M^{II}) of 4.62 and 3.02 μ_B respectively, which are typical of such octahedrally coordinated ions having $^4T_{1g}$ and $^3A_{2g}$ single-ion ligand field states, respectively. The μ_{eff} values obtained from **7** then decreases gradually before becoming steeper at temperature of 150 K ($\mu_{eff} = 4.6\ \mu_B$), reaching a value at 4 K of 3.16 μ_B (Fig. 10(top)). This is the plot expected for a very weakly antiferromagnetically exchange coupled Co^{II} system. Similar curves have been observed in other Co^{II}–dca or tcm^- network systems [15]. The μ_{eff} values are independent of field when varied between 0.01 and 1 T in the 4–100 K region, thus ruling out any long-range magnetic ordering.

The plot in $[Ni^{II}(dca)_2(dbtp)]$ (**8**) differs greatly to that observed in $[Co^{II}(dca)_2(dbtp)]$ (**7**). The μ_{eff} value at 300 K of 3.02 μ_B remains almost constant with decreasing temperature, before increasing sharply below 40 K. A maximum is then reached at 4 K, giving a μ_{eff} value of 3.28 μ_B, before decreasing sharply (Fig. 10(bottom)). The shape of this curve strongly indicates the presence

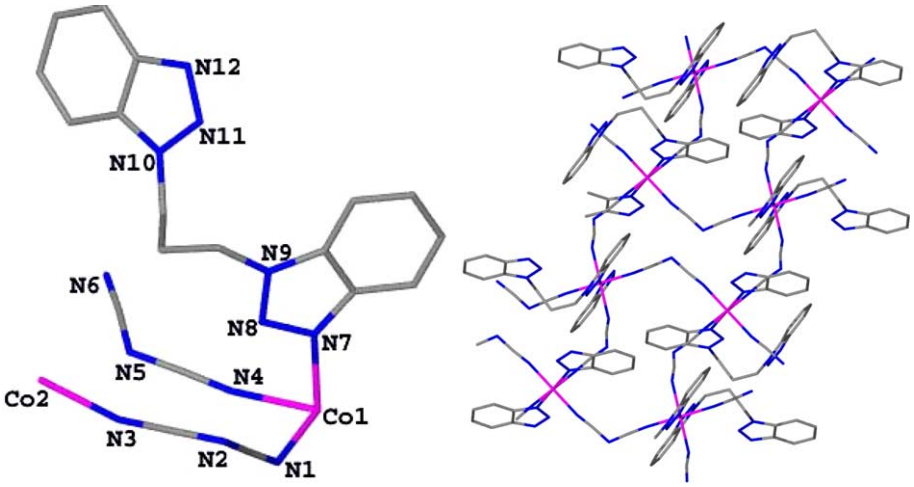

Fig. 8. (Left) The asymmetric unit in **7**. Selected inter-atomic bond distances (Å): Co1–N1 = 2.153(7), Co1–N4 = 2.087(7), Co2–N3 = 2.109(7), Co1–N7 = 2.136(7) Å. (Right) The 2-D (4,4) connecting distorted square-like $Co^{II}(dca)_2$ grids observed in **7**. H atoms omitted for clarity. Co···Co intrasheet distances = 7.918(2) Å.

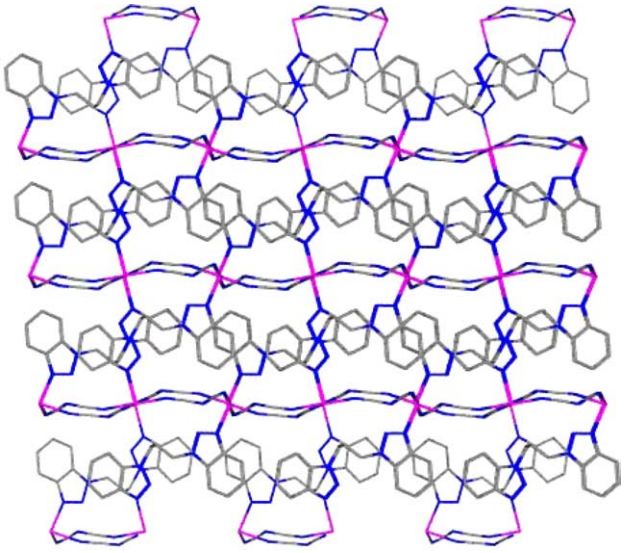

Fig. 9. The 3-D structure in **7**, illustrating the linking of adjacent 2-D (4,4) $Co^{II}(dca)_2$ sheets via the dbtp ligands. H atoms omitted for clarity. Intersheet $Co^{II}\cdots Co^{II}$ distance of ~8.22 Å.

of weak ferromagnetic coupling between the neighbouring Ni^{II} ions. As in the Co^{II} analogue, the μ_{eff} data in fields of 0.01 and 0.1 T (4–100 K) showed the same values as those observed in the 1 T field, thus indicating a lack of long-range magnetic ordering. The common observation [15] of traces of ferromagnetic α-$[Ni^{II}(dca)_2]$ showing a rapid increase in μ_{eff}, in the lower fields, at 21 K, did not occur here. The magnetic susceptibility data obtained from **8** were fitted using an $S = 1$ Fisher chain model. The best fit resulted in Spin-Hamiltonian parameters of $g = 2.13$ and $J = +0.24\ cm^{-1}$ (Fig. 11). Magnetizations isotherms were measured on the same sample of **8** at temperatures of 2, 3, 4, 5.5, 10 and 20 K. The plots in Fig. 12 show that magnetization saturation is not achieved even at $H = 5$ T and $T = 2$ K.

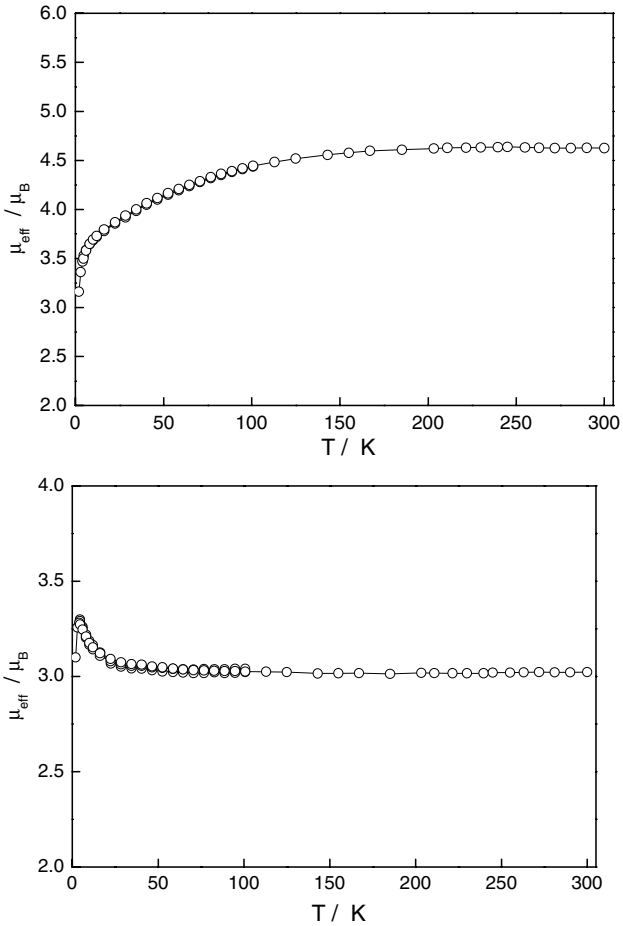

Fig. 10. Plot of μ_{eff} (per M^{II} ion) vs. temperature for **7** (top) and **8** (bottom) in a field of 1 T. (The solid lines just join the experimental points.)

The M value at this point (2.14 $N\beta$) and the shapes of the isotherms support very weak ferromagnetic coupling within $[Ni^{II}(dca)_2(dbtp)]$ (**8**) (Fig. 12).

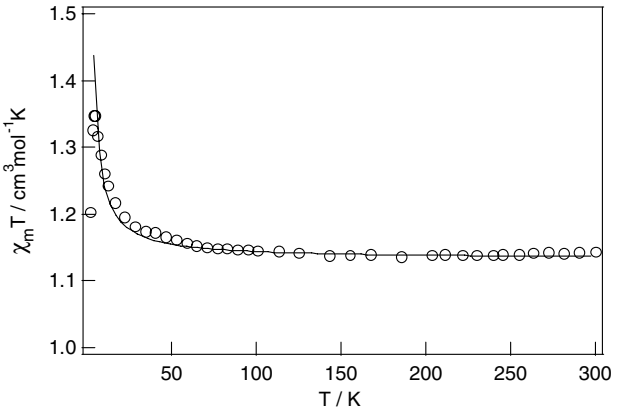

Fig. 11. $\chi_m T$ (○) vs. temperature plot for **8**. The solid line is best fit using a Fisher chain model, resulting in parameters of $S = 1$, $g = 2.13$ and $J = +0.24\ cm^{-1}$. The model cannot account for the decrease in $\chi_m T$ at very low temperatures due to zero-field splitting or inter-chain coupling.

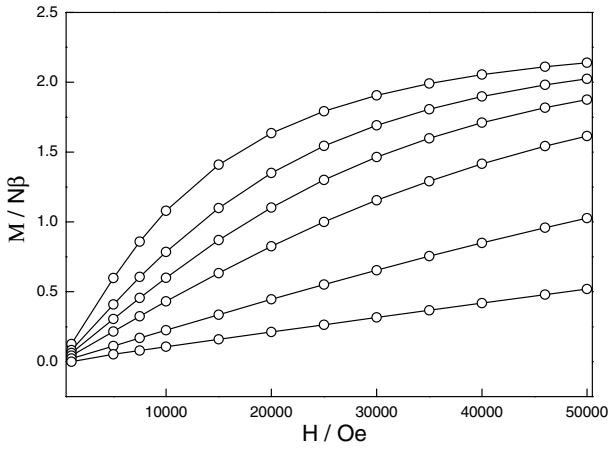

Fig. 12. Plots of magnetization ($M/N\beta$) vs. field (H) for [Ni^{II}(dca)$_2$-(dbtp)] (**8**) at temperatures: 2 (top), 3, 4, 5.5, 10 and 20 K (bottom). (The solid lines just join the experimental points.)

The reason for weak ferromagnetic coupling being observed in **8** while weak antiferromagnetic coupling occurs in **7** is not immediately obvious. There is precedence for such differences in other weakly coupled Co^{II} and Ni^{II}-dca networks [15]. Even in 3-D systems of the present kind, a fine balance in the sign of the M(dca)M coupling, around zero-coupling, is apparent.

3.5. Structure and magnetism of [Cu^{II}(dca)$_2$(dbtb)] (**9**)

The type of 3-D connectivity in **7** and **8** has been observed previously in 3-D networks including those of the pyrazine based family α-[M^{II}(dca)$_2$(pyz)] (M = Mn, Fe, Co, Ni and Zn) [38], in which two such 3-D networks interpenetrate, [Mn(dca)$_2$(C_2H_5OH)$_2$]·(CH_3)$_2$CO [33] and the [M(dca)$_2$(pyrimidine)] · EtOH (M = Fe^{II}, Co^{II}), [Ni(dca)$_2$(pyrimidine)] · H_2O and [Cu(dca)$_2$(pyrimidine)] · MeCN families [9]. In order to investigate the effect of increasing the alkyl chain length between the benzotriazole molecules, the butyl bridged ligand 1,4-di(benzotriazol-1-yl)butane (dbtb) was synthesized. Careful layering of a propan-2-ol solution of dbtb on top of an aqueous Cu^{II}/dca solution resulted in the formation of the 2-D [4,4] connected sheet system [Cu^{II}(dca)$_2$(dbtb)] (**9**). The Cu^{II} centres in **9** are distorted octahedral in geometry and are linked together by two dca$^-$ bridging ligands in the equatorial positions, each exhibiting the familiar $\mu_{1,5}$-dca$^-$ bonding modes. Two individual dbtb ligands occupy the axial sites at each Cu^{II} centre, which then twist away through the alkyl chain, thus linking the neighbouring Cu^{II}/dca rows together, forming the 2-D [4,4] sheet (Fig. 13(bottom)). Another way of rationalising the topology in **9** is by considering that the {Cu^{II}(dca)$_2$} chains are not only interdigitating (as observed in structures **1**–**4**) but are also covalently bound through the interdigitating moieties (Fig. 13(bottom)). The 2-D sheets in **9** then pack in parallel rows in a spatially efficient staggered arrangement (Fig. 14).

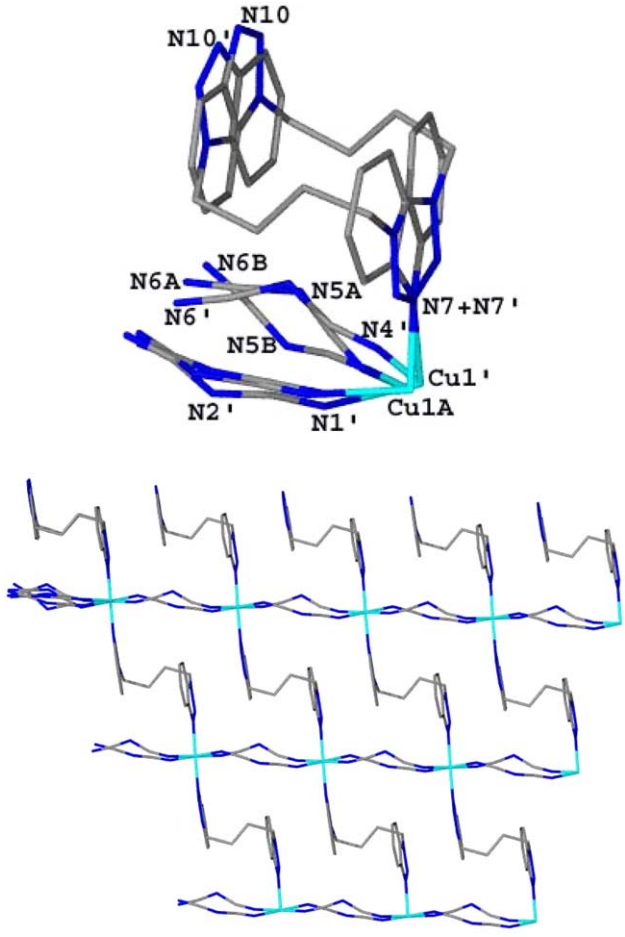

Fig. 13. (Top) The asymmetric unit in **9** showing high disorder of both the dbtb and dca$^-$ ligands. H atoms omitted for clarity. (Bottom) Observed linking of the interdigitating (Cu^{II}(dca)$_2$) chain rows in **9**, propagating along the *c*-axis. H atoms have been omitted for clarity.

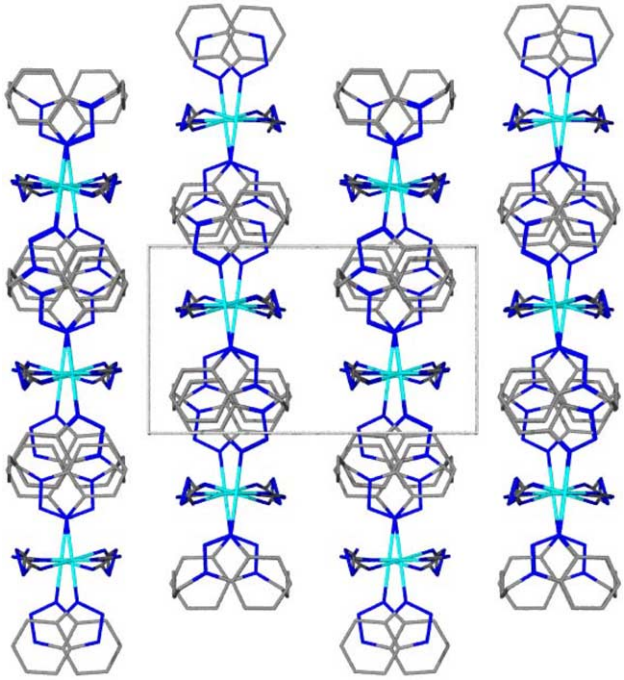

Fig. 14. Observed crystal packing in **9**. Viewed along the *c*-axis, H atoms have been omitted for clarity.

$[Cu^{II}(dca)_2(dbtb)]$ (**9**) contains a 90:10 disorder of the Cu^{II} atom and dbtb ligand position which are related by non-crystallographic mirror plane symmetry. The dca^- ligands are highly disordered due to disorder of the Jahn–Teller distorted Cu^{II} ions which involve elongation of two of the four bonds to dca ligands. As a result of this disorder, equivalent Cu–N(dca) bonds were restrained to be the same length, however, due to the nature of the disorder these lengths are not particularly reliable (Table 3).

The magnetic moment for **9** of 1.87 μ_B at 300 K (Fig. 15) is typical of that displayed by an isolated or very weakly coupled Cu^{II} ion. The susceptibilities are Curie-like, with μ_{eff} values largely independent of temperature, a small decrease below 10 K being due to very weak antiferromagnetic coupling or to Zeeman depopulation effects. These findings can be rationalized by looking at the structure in **9**. It is made up of individual $\{Cu^{II}(dca)_2\}$ chains linked in the second dimension by the dbtb ligands. The dbtb ligands separate these chains considerably and so it can be assumed that the Cu^{II} ions separated by the dbtb ligands are too far apart to exhibit magnetic exchange (interchain Cu1A···Cu1A distance ~8.8 Å) and any exchange will be between the Cu^{II} ions within the $\{Cu^{II}(dca)_2\}$ chains. Indeed, the data obtained from **9** are similar to those of the chain systems $[Cu^{II}(dca)_2(1\text{-Mebta})_2]$ (**3**) and $[Cu^{II}(tcm)_2(1\text{-Mebta})_2]$ (**4**) and those in previously reported $[Cu^{II}(dca)_2(L)_2]$ systems [39,40]. The spin coupling is extremely weak and there is, consequently, no evidence of long range magnetic ordering.

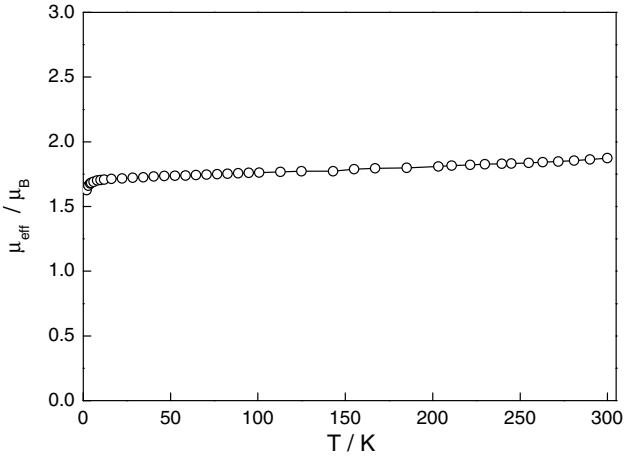

Fig. 15. Plot of μ_{eff} (per Cu^{II}) vs. *T* observed in **9** in a field of 1 T. (The solid lines just join the experimental points.)

4. Conclusions

In this work, we have expanded the coordination chemistry of benzotriazole and its derivatives into the area of metal coordination design and synthesis. The 1-D, 2-D and 3-D networks presented in this paper further illustrate the bonding affinity and flexibility that benzotriazole and its derivatives have with first row transition metal ions. The 1-methylbenzotriazole (1-Mebta) ligand has been shown to be a good terminal ligand in the synthesis of 1-D coordination polymers of general formula $[M^{II}(dca)_2(1\text{-Mebta})_2]$ (**1**–**3**) and $[M^{II}(tcm)_2(1\text{-Mebta})_2]$ (**4**). In an attempt to produce benzotriazole based bridging ligands, the 1,3-dibenzotriazol-1-yl(propane) (dbtp) and 1,4-dibenzotriazol-1-yl(butane) (dbtb) ligands have been synthesized and utilized in conjunction with the dicyanamide (dca^-) and tricyanomethanide (tcm^-) bridging ligands to good effect. The dbtp ligand has produced both the 1-D polymer $[Cu^{II}(dca)_2(dbtp)]$ (**5**) and the α-Po related $[Co^{II}(dca)_2(dbtp)]$ (**7**) and $[Ni^{II}(dca)_2(dbtp)]$ (**8**) 3-D networks. Magnetic susceptibility measurements on the 3-D networks **7** and **8** reveal weak to zero antiferromagnetic coupling in the former and weak ferromagnetic coupling in the latter.

In rationalizing the change in structural dimensionality, the transition from the 1-D chains in $[Cu^{II}(dca)_2(dbtp)]$ (**5**) to the 3-D networks in $[M^{II}(dca)_2(dbtp)]$ ($M = Co^{II}$ (**7**) and $M = Ni^{II}$ (**8**)) is largely due to the preference of cobalt and Nickel for octahedral geometries, whereas Cu^{II} can adopt other topologies because of Jahn–Teller distortion. Pseudo-octahedral geometries at the Cu^{II} centres are observed in the 2-D sheet in $[Cu^{II}(dca)_2(dbtb)]$ (**9**). Here, the slightly longer and more flexible butyl bridged dbtb ligand links the $Cu^{II}(dca)_2$ chains via the axial positions to form the 2-D (4,4) connecting sheets. Magnetic susceptibility measurements on

9 nevertheless, show that very weak coupling is occurring, a feature of all the present Cu^{II} network species.

Dedicated to Professor Malcolm H. Chisholm, a Chemist who appreciates all kinds of Chemistry, on the happy occasion of his 60th birthday.

Abstract

Reaction of 2,2′-diphthalimidodiethylamine with 2-vinylpyridine in H_2O/MeOH and deprotection with HCl(aq) does not give the anticipated tripodal ligand *N*-2-(2-pyridylethyl)-*N*,*N*-bis(2-aminoethyl)amine. Instead, the new linear tetradentate tetraamine ligand *N*-{2-[(2-pyridin-2-ylethyl)amino]ethyl}ethane-1,2-diamine (peda) is formed. The synthesis and characterisation of the Co(III) complexes $[Co(peda)O_2CO]X \cdot H_2O$ (X = ClO_4, I), *trans*-$[Co(peda)Cl_2]ClO_4$ and *trans*-$[Co(peda)Br_2]Br$ is reported, and an X-ray crystal structure of $[Co(peda)O_2CO]I \cdot H_2O$ shows the presence of the *fm*$_s$ isomer only. Rate data for the acid hydrolysis of $[Co(peda)O_2CO]ClO_4 \cdot H_2O$ over the $[H_3O^+]$ range 0.2–1.0 M (I = 1.0, $NaClO_4$) are reported. Strict first-order kinetics are observed and the data are consistent with the currently accepted mechanism for the hydrolysis of bidentate carbonate complexes.

1. Introduction

Multidentate amine ligands have played an important role in the development of synthetic, structural and stereochemical aspects of coordination chemistry. An enormous number of such ligands are now known, ranging from simple bidentate ethylenediamine to complex multidentate tripodal [1] polypyridine [2], macrocyclic [3] and azacryptand [4] ligands. Of the many methods available for the synthesis of multidentate amine ligands, one of the most widely used is the functionalisation of a preexisting amine ligand by alkylation with an amine-containing fragment. 2-Vinylpyridine has proven particularly useful in this respect as a reagent for the introduction of a 2-pyridylethyl group at either a primary or secondary amine centre [5–8]. However, 2-vinylpyridine tends to react with all available primary and secondary amine centres in a molecule and this means that protecting groups are usually necessary in cases where specific alkylation of a multidentate amine ligand is required. The phthaloyl group is often used in order to specifically protect primary amine centres, and it may be easily introduced by reaction of the polyamine with phthalic anhydride. Phthaloyl-protected diethylenetriamine and dipropylenetriamine have been used in the synthesis of the tripodal amine ligands baep (baep = 3-aminopropylbis(2-aminoethyl)amine) [9] and abap (abap = 2-aminoethylbis(3-aminopropyl)amine) [10], where alkylation at the secondary nitrogen atom using the appropriate bromoalkylphthalimide is followed by deprotection with HCl to give the ligand hydrochloride.

As part of our studies into the synthesis of new tripodal tetraamine ligands [1], we were interested in investigating the reaction of phthaloyl-protected triamines with 2-vinylpyridine in an attempt to prepare tripodal ligands containing mixed amine and pyridine donor atoms through pyridylethylation at the secondary N atom. However, the reaction of phthaloyl-protected diethylenetriamine with 2-vinylpyridine did not proceed as expected and in this paper we describe the serendipitous synthesis of the new *linear* tetradentate ligand *N*-{2-[(2-pyridin-2-ylethyl)amino]ethyl}ethane-1,2-diamine (peda, **1**) from a reaction designed to prepare the new tripodal ligand *N*-2-(2-pyridylethyl)-*N*,*N*-bis(2-aminoethyl)amine (**2**). We detail the synthesis of several Co(III) complexes of this ligand, as well as the X-ray structure of $[Co(peda)(O_2CO)]I \cdot H_2O$ and the acid-hydrolysis kinetics of $[Co(peda)(O_2CO)]ClO_4 \cdot H_2O$.

2. Experimental

All syntheses were carried out under aerobic conditions. ^{13}C and ^{1}H NMR spectra were recorded using either a Gemini 200 MHz or a UNITYInova 300 MHz spectrometer operating at (25 ± 1) °C. UV/Vis spectra and kinetic data were recorded using a Cary 219 Spectrophotometer thermostated at (25.0 ± 0.1) °C. Elemental analyses were carried out by the Campbell Microanalytical Laboratory at the University of Otago. 2,2′-Diphthalimidodiethylamine was synthesised according to the literature methods [11,12].

2.1. N-{2-[(2-Pyridin-2-ylethyl)amino]ethyl}ethane-1,2-diamine tetrahydrochloride dihydrate ($peda \cdot 4HCl \cdot 2H_2O$)

2,2′-Diphthalimidodiethylamine (22.1 g, 0.0608 mol) and 2-vinylpyridine (13.2 ml, 0.122 mol) were refluxed for 6 days in an H_2O/methanol mixture (550:220 ml). The solution was then cooled and evaporated under reduced pressure (rotavap) and the resulting residue was dissolved in chloroform (100 ml) and added dropwise to ether (600 ml). The white precipitate which formed was removed by filtration and refluxed overnight in HCl (8 M, 100 ml). The solution was cooled on ice for 3 h and a small amount of phthalic acid was filtered off. The filtrate was evaporated under reduced pressure to give a yellow residue which was dissolved in water and loaded onto a Dowex 50W × 2 cation exchange column. The column was washed with 1 M HCl and the product was eluted using 4 M HCl. Removal of solvent (rotavap) gave the product as a yellow oil (17.3 g, 73 %). Although ^{1}H NMR showed this to contain impurities, it was sufficiently pure for use in the synthesis of metal complexes. Analytically pure material can be obtained by repeated trituration with ethanol to give a solid which can then be crystallised from hot methanol to give the product as a white powder, although this decreases the yield significantly. *Anal*. Calc. for $C_{11}H_{24}N_4Cl_4 \cdot 2H_2O$: C, 33.86; H, 7.23; N, 14.36. Found: C, 33.94; H, 7.61; N, 14.43%. ^{1}H NMR (D_2O, 25 °C): δ 8.76–8.73 (d, 1H); 8.59–8.53 (t, 1H); 8.04–7.96 (m, 2H); 3.59–3.42 (m, 12H). ^{13}C NMR (D_2O, 25 °C): δ 151.9, 148.4, 143.4, 128.9, 127.3, 50.1, 45.9 45.8, 44.7, 44.6, 36.6 ppm.

2.2. $[Co(peda)(O_2CO)]ClO_4 \cdot H_2O$

Solid $Na_3[Co(O_2CO)_3] \cdot 3H_2O$ (6.63 g, 0.0183 mol) was added to a solution of $peda \cdot 4HCl \cdot 2H_2O$ (6.82 g, 0.0175 mol) in water (50 ml). The solution was stirred for 5 days then evaporated to low volume to give a maroon solid which was filtered off. Crystallisation as the ClO_4^- salt was effected by dissolution in the minimum volume of hot water, addition of $NaClO_4$(s) and cooling on ice. Yield: 3.01 g (38%). *Anal*. Calc. for $CoC_{12}H_{22}N_4O_8Cl$: C, 32.41; H, 4.99; N, 12.60; Cl, 7.97. Found: C, 32.31; H, 5.12; N, 12.56; Cl, 7.92%. ^{1}H NMR (D_2O, 25 °C): δ = 8.72–8.71 (d, 1H, 5.7); 8.04–7.99 (t, 1H, 6); 7.59–7.54 (m, 2H); 3.5–2.62 (m, 12H). ^{13}C NMR (D_2O, 25 °C): δ = 167.6, 162.8, 152.8, 141.5, 127.5, 125.4, 54.7, 53.9, 48.3, 47.6, 42.3, 35.4 ppm. UV/Vis (λ_{max}/nm (ε/mol^{-1} L cm^{-1})): 518 (187); 364 (157).

X-ray quality crystals of $[Co(peda)(O_2CO)]I \cdot H_2O$ were obtained by slow cooling of a hot concentrated solution of the Cl^- salt of the complex (above) to which NaI had been added.

2.3. trans-$[Co(peda)Cl_2]ClO_4$

$[Co(peda)O_2CO]ClO_4 \cdot H_2O$ (0.132 g, 3×10^{-4} mol) was added to aqueous HCl (5 M, 2 ml). Green crystals of the product formed on standing overnight, and these were filtered off and air dried. Yield: 0.10 g (72%). *Anal*. Calc. for $CoC_{11}H_{20}N_4O_4Cl_3$: C, 30.19; H, 4.61; N, 12.81; Cl, 24.31. Found: C, 30.30; H, 4.59; N, 12.72; Cl, 24.34%. ^{1}H NMR (DMSO, 25 °C): δ 8.94–8.92 (d, 1H, 5.1); 8.11–8.05 (t, 1H, 8); 7.68–7.59 (m, 2H); 7.23 (br s, 1H); 6.86 (br s, 1H); 6.61 (br s, 1H); 6.46–6.43 (br d, 1H); 3.75–2.99 (m, 12H). ^{13}C NMR (DMSO, 25 °C): δ 164.4, 157.9, 142.9, 131.4, 127.4, 60.1, 55.2, 53.0, 49.7, 48.7, 39.9 ppm.

2.4. trans-[Co(peda)Br$_2$]Br

[Co(peda)O_2CO]$ClO_4 \cdot H_2O$ (0.120 g, 2.70×10^{-4} mol) was added to aqueous HBr (5 M, 2 ml). Olive-green crystals of the product formed on standing overnight, and these were filtered off, washed with acetone, and air-dried. Yield: 0.105 g (77%). *Anal.* Calc. for $CoC_{11}H_{20}N_4Br_3$: C, 26.06; H, 3.98; N, 11.05; Br, 47.28. Found: C, 25.98; H, 4.06; N, 10.95; Br, 47.23%. The complex decomposed rapidly on dissolution in either d^6-Me_2SO or 5 M DBr to give a brown solution, the ^{1}H NMR spectrum of which showed the presence of more than one species.

2.5. X-ray data collection and refinement

X-ray structural data for *fm*$_s$-[Co(peda)O_2CO]I $\cdot H_2O$ were collected at −120 °C on a Siemens Smart system using graphite-monochromated Mo Kα radiation with exposures over 0.3°. Data were corrected for Lorentz and polarisation effects using SAINT [13]. The structure was solved using SHELXS-97 [14] with the resulting Fourier map revealing the locations of all non-hydrogen atoms. Weighted full matrix refinements on F^2 were carried out using SHELXL-97 [15] with all non-hydrogen atoms being refined anisotropically. All hydrogen atoms except those on the water of crystallisation (H41 and H42) were included in calculated positions and were refined as riding atoms with individual (or group, if appropriate) isotropic displacement parameters. H41 and H42 were located in a search of the Fourier map and were included in the final refinement cycles. Crystal data and collection parameters are given in Table 1.

Table 1
Crystal data and structure refinement for [Co(peda)(O_2CO)]I $\cdot H_2O$

Empirical formula	$C_{12}H_{22}CoIN_4O_4$
Formula weight	472.17
T (K)	153(2)
λ (Å)	0.71073
Crystal system	monoclinic
Space group	$P2_1/n$
Unit cell dimensions	
a (Å)	7.70720(10)
b (Å)	13.7724(3)
c (Å)	16.0599(3)
α (°)	90
β (°)	97.3930(10)
γ (°)	90
V (Å^3)	1690.53(5)
Z	4
D_{calc} (Mg/m^3)	1.855
Absorption coefficient (mm^{-1})	2.863
F(000)	936
Crystal size (mm^3)	$0.5 \times 0.33 \times 0.18$
θ Range for data collection (°)	1.95–30.57
Index ranges	$-6 \leqslant h \leqslant 10$, $-19 \leqslant k \leqslant 8$, $-22 \leqslant l \leqslant 20$
Reflections collected	10869
Independent reflections (R_{int})	4685 (0.0236)
Completeness to $\theta = 25.00°$ (%)	99.4
Absorption correction	semi-empirical from equivalents
Maximum and minimum transmission	1 and 0.752629
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	4685/0/201
Goodness-of-fit on F^2	1.052
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0202$, $wR_2 = 0.0492$
R indices (all data)	$R_1 = 0.0239$, $wR_2 = 0.0501$
Largest difference in peak and hole (e Å^{-3})	0.742 and −0.910

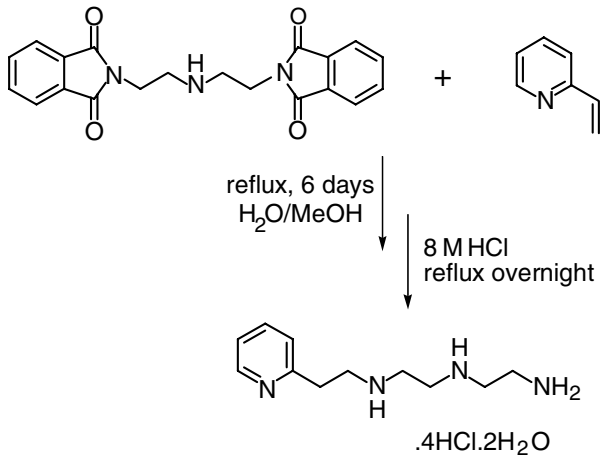
2.6. Acid hydrolysis of [Co(peda)O_2CO]$ClO_4 \cdot H_2O$

Rate data for acid hydrolysis of [Co(peda)O_2CO]-$ClO_4 \cdot H_2O$ in acidic aqueous solution were collected over the [H_3O^+] range 0.2–1.0 M at 25.0 ± 0.1 °C (I = 1.0 M, $NaClO_4$). Reactions were carried out under pseudo first-order conditions with $[H_3O^+] \gg [Co]_T$ ($[Co]_T$ typically 2.5×10^{-3} mol L^{-1}), and were monitored over at least six half lives by following the decrease in absorbance at 360 nm. The absorbance infinity values (A_∞) were evaluated at the end of each run and k_{obs} values were obtained from plots of $\ln(A_t - A_\infty)$ versus t.

3. Results and discussion

3.1. Synthesis of peda · 4HCl · 2H_2O

The reaction of 2,2′-diphthalimidodiethylamine with excess 2-vinylpyridine followed by deprotection in 8 M HCl was expected to give the tripodal ligand *N*-2-(2-pyridylethyl)-*N*,*N*-bis(2-aminoethyl)amine (**2**) as the hydrochloride salt. However, observation of 11 signals in the ^{13}C NMR spectrum of the product showed it to be of lower symmetry than expected and all analytical data were consistent with the formation of the asymmetric linear tetradentate tetraamine ligand peda · 4HCl · 2H_2O (**1**, Scheme 1). Pyridylethylation at a secondary N atom using 2-vinylpyridine has substantial precedent in the literature [16] and the secondary N atom of 2,2′-diphthalimidodiethylamine has significant nucleophilic character, as evidenced by its relatively facile alkylation in reactions to form tripodal tetraamine ligands [9,10]. Thus, it was expected that pyridylethylation of the secondary amine N atom would occur in this case. However, it appears that partial deprotection of 2,2′-diphthalimidodiethylamine occurs during the reaction with 2-vinylpyridine, and this then allows pyridylethylation at a primary N atom to give the monophthaloylated linear tetraamine ligand. Alkaline media (40% aqueous methylamine solution) have been used previously to effect deprotection of phthaloyl-protected amines [17] and similar reactivity is proposed to occur in this case, through either base- or 2-vinylpyridine-catalysed hydrolysis of a single phthaloyl group.



Scheme 1. Synthesis of peda.

Although peda has been mentioned previously in the patent literature as a possible corrosion inhibitor, a detailed synthesis was not given [18] and peda now joins the known asymmetric linear polyamine ligands containing terminal 2-pyridyl and aliphatic amine substituents outlined in Fig. 1.

3.2. Synthesis and X-ray structure of $[Co(peda)(O_2CO)]X \cdot H_2O$ ($X = ClO_4$, 1)

The maroon complex $[Co(peda)(O_2CO)]^+$ was prepared by reaction of peda $\cdot$ 4HCl $\cdot$ $2H_2O$ with $Na_3[Co(O_2CO)_3] \cdot 3H_2O$ in aqueous solution over 5 days. The product was initially isolated as the Cl^- salt following evaporation of the reaction mixture to low volume, and was crystallised as the ClO_4^- and I^- salts, with the latter giving X-ray quality crystals. There are numerous possible isomers of the complex which arise from the different possible foldings of the ligand, but both ^{13}C NMR and X-ray crystallographic data are consistent with the presence of only one isomer in both the solid state and solution. The X-ray structure of $[Co(peda)(O_2CO)]I \cdot H_2O$ (Fig. 2) shows the Co(III) ion coordinated to all four N atoms of the peda ligand, with the remaining two *cis* coordination sites occupied by a chelating carbonate ligand. The angle subtended by the chelated carbonate ligand (68.87°) is typical of those found in other structurally characterised Co(III) carbonate complexes.[1] The complex crystallises as the fm_s isomer [19] in which the two five membered chelate rings adopt δ conformations while the six-membered chelate ring exists in a distorted boat conformation. The *exo* oxygen atom of the chelated carbonate ligand is hydrogen-bonded to the water of crystallisation ($d_{O-O} = 2.739$ Å, O–H–O = 160.34°), while it also displays a close contact with N12 of a neighbouring cation ($d_{O-N} = 2.896$ Å).

Fig. 1. Previously prepared asymmetric ligands containing terminal 2-pyridyl and aliphatic amine substituents (see [22–27]).

3.3. Acid hydrolysis of $[Co(peda)(O_2CO)]ClO_4 \cdot H_2O$

The $[Co(peda)(O_2CO)]^+$ cation undergoes acid-catalysed hydrolysis to give dechelation of the carbonate ligand with the final product dependent on the nature of the acid used. Reaction in 5 M aqueous HCl or HBr gives *trans*-$[Co(peda)Cl_2]ClO_4$ and *trans*-$[Co(peda)Br_2]Br$, respectively, as green crystalline solids. These complexes are assigned the *trans* configuration on the basis of their colour[2] and, in the case of the dibromo complex, a poor quality crystal structure. Reaction of $[Co(peda)(O_2CO)]^+$ in $HClO_4$ medium gives absorbance decreases at λ_{max} (518 and 364 nm) and results in formation of the diaqua complex $[Co(peda)(OH_2)_2]^{3+}$.[3] Rate data for this reaction were collected by monitoring the absorbance decrease at 360 nm and resulting values of k_{obs} versus $[H_3O^+]$ are given in Table 2. Strict first-order kinetics were observed under all conditions of $[H_3O^+]$ studied with no evidence of biphasic kinetics that obtain for more reactive $[(L)Co(O_2CO)]^+$ complexes. The data are consistent with the mechanism that has been proposed previously for the acid-catalysed hydrolysis of a number of Co(III) chelated carbonate complexes outlined in Scheme 2, with chelate ring-opening (k_1) being rate-determining [20]. Fitting of the observed data to the rate law derived for this mechanism

$$k_{obs} = \frac{Kk_1[H_3O^+]}{1 + K[H_3O^+]}$$

gives $K = 0.36 \pm 0.14$ M^{-1} and $k_1 = 0.043 \pm 0.013$ s^{-1} (Fig. 3). This corresponds to a half life of approximately 1 min in 1 M $HClO_4$, meaning that $[Co(peda)(O_2CO)]^+$

[1] The mean value for the O–Co–O bond angle in 49 structures from the Cambridge Structural Database is 68.80 (standard deviation = 0.61).

[2] Both *trans*-$[Co(en)_2Cl_2]^+$ and *trans*-$[Co(en)_2Br_2]^+$ are green, while the respective *cis* isomers are violet.

[3] We have thus far been unable to assign this as either the *cis* or *trans* isomer.

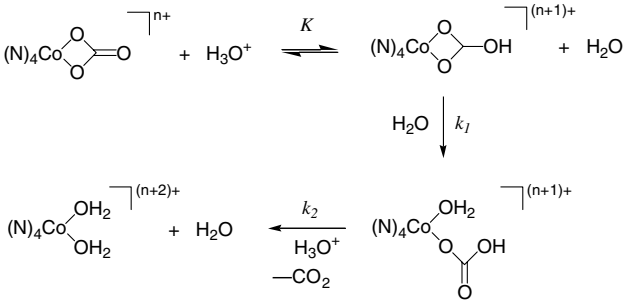
Table 2
Rate data for the acid-catalysed hydrolysis of $[Co(peda)(O_2CO)]^+$

$[H_3O]^+$ (M)	$10^3 k_{obs}$ (s^{-1})
0.2	3.20
0.4	5.43
0.6	7.79
0.8	9.16
1.0	11.8



Scheme 2. Mechanism for the acid-catalysed hydrolysis of chelated carbonate complexes.

undergoes chelate ring opening significantly more slowly than complexes such as $[Co(NH_3)_4(O_2CO)]^+$ and $[Co(en)_2(O_2CO)]^+$ (k_1 values of 1.68 and 0.85 s^{-1}, respectively). Inspection of a space-filling model of $[Co(peda)(O_2CO)]I \cdot H_2O$ shows that methylene protons H6B and H8B of the peda ligand create significant steric hindrance at O2, one of the coordinated *endo* oxygen atoms of the chelated carbonate ligand (Fig. 4). Given that protonation at an *endo* O atom has been proposed to be the mechanistically important process which leads to chelate ring opening [20], this provides a possible

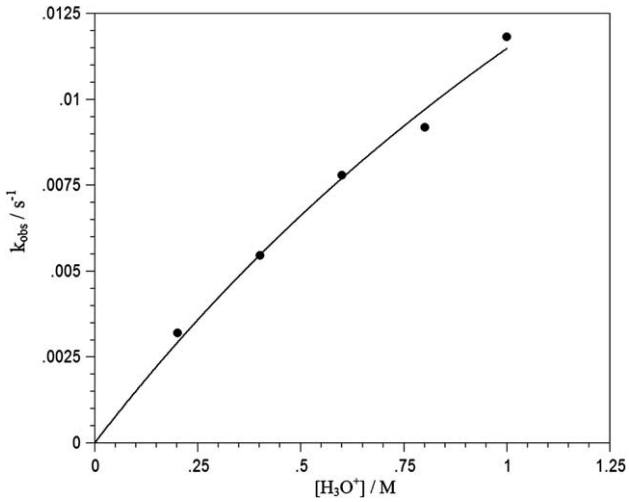


Fig. 3. Plot of k_{obs} vs. $[H_3O]^+$ for the acid-catalysed hydrolysis of $[Co(peda)(O_2CO)]^+$. Points depict observed data while the solid line is drawn using the equation $k_{obs} = \frac{Kk_1[H_3O^+]}{1+K[H_3O^+]}$ with $K = 0.36$ M^{-1} and $k_1 = 0.043$ s^{-1}.

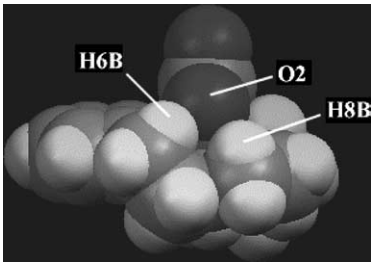

Fig. 4. Space filling diagram of the $[Co(peda)(O_2CO)]^+$ cation showing the steric hindrance of the *endo* oxygen atom O2.

rationalisation of the relatively low reactivity of this complex. Similar arguments have been advanced previously to explain the range of reactivities of a number of $[(L)Co(O_2CO)]^{n+}$ complexes [21].

4. Conclusions

We have shown that the phthaloyl protecting group is susceptible to hydrolysis in predominantly aqueous solutions containing 2-vinylpyridine and that the reaction of 2-vinylpyridine with phthaloyl-protected triamines is thus not a viable method by which to prepare tripodal tetraamine ligands. We are currently investigating alternative routes to the synthesis of the still-unknown ligand **2**.

Dedicated to Professor Malcolm Chisholm F.R.S. on the occasion of his 60th birthday.

Abstract

Four structural classes have been established for rare earth anthranilates, which have been prepared from the lanthanoid chloride or triflate and anthranilic acid (anthH) followed by pH adjustment to 4. $[La(anth)_3]_n$ is a polymeric complex with nine coordinate lanthanum and bridging tridentate (O,O,O′) anthranilate ligands, whereas $[Nd(anth)_3(H_2O)_3] \cdot 3H_2O$ is monomeric with nine coordinate neodymium and solely chelating (O,O) anthranilate groups. Both chelating (O,O) and bridging bidentate (O,O′) ligands are observed in dimeric $[Er_2(anth)_6(H_2O)_4] \cdot 2H_2O$, in which erbium is eight coordinate and the water ligands are in a *trans* arrangement. A polymer is observed for $[Yb(anth)_3(H_2O)]_n$ with solely bridging bidentate (O,O′) ligands and seven coordination for ytterbium. The NH_2 groups of the anthranilate ligands are not coordinated to the metal but is unusually involved in hydrogen-bond networks with water molecules for Ln = Er, Yb.

Keywords: Rare earths; Anthranilates; X-ray crystal structures; Amino acids

1. Introduction

Although there have been widespread studies of complexes of rare earth ions with amino acids [1], there are only two structurally characterised complexes with anthranilate ions (anth) (Fig. 1), viz. $[Y(anth)_3(H_2O)]_n$ [2] and $[Eu_2(anth)_6(bpy)_2]$ (bpy = 2,2′-bipyridine) [3]. This contrasts the extensive structural chemistry of anthranilate ions with alkali metals [4,5], alkaline earth metals [6,7], and transition metals [8–12].

Structural proposals have been made for rare earth anthranilates $Ln(anth)_3 \cdot nH_2O$ ($n = 0$, Ln = La, Ce, Pr, Nd, Sm; $n = 2$, Ln = Y, Tb–Lu; and $n = 1$, Ln = Eu, Gd) on the basis of analytical, IR, and X-ray powder data [13,14]. It was suggested that the lighter rare earth anthranilates form two isostructural groups, (i) La–Sm, and (ii) Y, Eu, Gd [13]. A subsequent study found Tb–Lu to be isostructural [14]. IR data suggested coordination of both carboxylate and amino groups.

The insoluble nature of lanthanoid anthranilates makes growing crystals suitable for X-ray diffraction difficult. However because of our interest in lanthanoid anthranilates as possible "green" corrosion inhibitors [15], we have undertaken a study of the structures of representative lanthanoid anthranilates to assist in understanding the structural basis of corrosion inhibitors.

2. Experimental

2.1. Materials and instrumentation

Lanthanoid oxides (Nd_2O_3 and Yb_2O_3) were obtained from Honeywell. Er_2O_3 was supplied by Aldrich. Lanthanoid chlorides (other than $LaCl_3$) were prepared by dissolving lanthanoid oxides in hydrochloric acid. $Er(OTf)_3$ was prepared by dissolving Er_2O_3 in trifluoromethanesulfonic acid (HOTf). The resulting solutions were diluted, and the concentrations of the prepared solutions were accurately determined by complexometric titration with standardised 0.01 M Na_2H_2–EDTA. $LaCl_3 \cdot 7H_2O$ was obtained from Chempur. Reagent grade anthranilic acid was obtained from Merck, and used without further purification. All other starting materials were used as received. Microanalyses were performed in duplicate by the Campbell Microanalytical Laboratory of the University of Otago, Dunedin, New Zealand. Rare earth analyses were carried out by digesting accurately weighed samples in concentrated nitric and sulphuric acid and boiling the solutions to dryness. The resulting residues were diluted with water, and aliquots were buffered with hexamethylenetetramine and titrated against standardised 0.01 M Na_2H_2–EDTA with Xylenol Orange as the indicator. Infrared spectra were recorded as Nujol mulls sandwiched between NaCl plates using a Perkin Elmer 1600 FTIR instrument in the range 4000–500 cm^{-1}. ^{19}F NMR spectra were recorded on a Bruker DPX 300 spectrometer, using $CFCl_3$ in d_6-acetone as an external reference. Thermogravimetric analysis (TGA) was performed using a Perkin Elmer Pyris 1 instrument at a heating rate of 10 °C min^{-1}, using a platinum sample pan.

2.2. Synthesis

2.2.1. $[La(anth)_3]_n$ (**1**)

Anthranilic acid (0.35 g, 2.6 mmol) was dissolved in 2 mL of MeOH, and the solution added to a stirred aqueous solution of $LaCl_3$ (5.0 mL, 5.0 mmol) heated to 70 °C. The pH of the reaction mixture was raised by the dropwise addition of 0.5 M NaOH. At a pH of approximately 4, a faint permanent precipitate formed. The reaction mixture was then cooled, and the precipitate filtered off. Crystals appeared following the slow evaporation of the reaction mixture at room temperature.

Yield: 0.21 g (45%). *Anal.* Calc. for $C_{21}H_{18}N_3O_6La$: C, 46.09; H, 3.32; N, 7.68; La, 25.38. Found: C, 46.23; H, 3.40; N, 7.83; La, 25.40%. Infrared (cm^{-1}): 3467 m, 3421 m, 3356 m, 3324 m, 1615 s, 1574 m, 1505 s, 1456 s, 1385 s, 1338 m, 1309 m, 1258 m, 1156 m, 1133 m, 1027 w, 978 w, 946 w, 875 m, 853 w, 811 m, 753 m, 707 m, 669 m.

2.2.2. $[Nd(anth)_3(H_2O)_3] \cdot 3H_2O$ (**2**)

The compound was synthesised using the above procedure except that $NdCl_3$ (4.0 mL, 3.3 mmol) and anthranilic acid (0.21 g, 1.5 mmol) were used.

Yield: 0.12 g (36%). *Anal.* Calc. for $C_{21}H_{30}N_3O_{12}Nd$: C, 38.18; H, 4.58; N, 6.36; Nd, 21.83. Found: C, 38.17; H, 4.43; N, 6.16; Nd, 22.65%. 2.2.3. $[Er_2(anth)_6(H_2O)_4] \cdot 2H_2O$ (**3**)

The compound was synthesised using the above procedure except that $Er(OTf)_3$ (4.0 mL, 3.5 mmol) and anthranilic acid (0.21 g, 1.5 mmol) were used. Single crystals of **3** were separated by hand picking. The bulk product analysed as $[Er_2(anth)_6(H_2O)_4] \cdot HO_3SCF_3 \cdot 2H_2O$, ($\mathbf{3} \cdot HO_3SCF_3$).

Yield: 0.18 g. *Anal.* Calc. for $C_{43}H_{49}F_3N_6O_{21}SEr_2$ ($\mathbf{3} \cdot HO_3SCF_3$): C, 36.64; H, 3.50; N, 5.96; Er, 23.73. Found: C, 36.23; H, 3.54; N, 5.25; Er, 24.30%. Infrared (cm^{-1}): 3627 m, 3478 s, 3361 m, 3343 s, 3312 m, 1614 m, 1574 m, 1538 m, 1514 m, 1506 m, 1485 s, 1421 s, 1340 m, 1302 m, 1262 m, 1260 m, 1159 m, 1156 m, 1032 m, 960 w, 879 m, 820 m, 770 m, 750 m, 704 m, 673 m, 641 m. ^{19}F NMR (d_6-acetone) $\delta = -37.66$ ppm.

2.2.4. $[Yb(anth)_3(H_2O)]_n$ (**4**)

The compound was synthesised using the above procedure except that $YbCl_3$ (9.5 mL, 7.6 mmol) and anthranilic acid (0.52 g, 3.8 mmol) were used. Single crystals of **4** were separated but the bulk crystalline product analysed as $\mathbf{4} \cdot 2H_2O$ after prolonged desiccation at room temperature.

Yield: 0.22 g. *Anal.* Calc. for $C_{21}H_{24}N_3O_9Yb$ ($\mathbf{4} \cdot 2H_2O$): C, 39.69; H, 3.81; N, 6.61; Yb, 27.23. Found: C, 39.91; H, 4.10; N, 6.49; Yb, 27.26%. Infrared (cm^{-1}): 3479 m, 3394 m, 3343 m, 3278 m, 3178 m, 1682 m, 1613 m, 1572 m, 1542 m, 1521 m, 1506 m, 1483 m, 1416 s, 1339 w, 1303 m, 1272 w, 1260 m, 1155 m, 1024 w, 880 m, 820 w, 767 w, 750 m, 704 w, 674 w. TGA: % mass loss 50–200 °C: 8.2%. Calculated mass loss of three H_2O molecules: 8.5%.

2.3. X-ray crystallography

Intensity data for complexes **1**–**4** were collected using an Enraf–Nonius KAPPA CCD at 123 °K with Mo Kα

radiation ($\lambda = 0.7170$ Å). Suitable crystals were immersed in viscous hydrocarbon oil, mounted on a glass fibre which was mounted on the diffractometer. Using psi and omega scans N_t (total) reflections were measured, which were reduced to N_o unique reflections, with $F_o > 2\sigma(F_o)$ being considered observed. Data were corrected for absorption with a SORTAV multi-scan absorption correction [16]. The structures were solved using direct methods, and observed reflections were used in least squares refinement on F^2, with anisotropic thermal parameters refined for non-hydrogen atoms. Aromatic hydrogen atoms were constrained in calculated positions and refined with a riding model. All other hydrogen atoms were found directly from the difference Fourier map and refined isotropically. Structure solutions and refinements were performed using the programs SHELXS-97 [17] and SHELXL-97 [18] through the graphical interface X-Seed [19]. Crystal data and structural refinement data for complexes **1**–**4** are given in Table 1. Selected bond lengths for complexes **1**–**4** are listed in Table 2, and hydrogen bond lengths and angles for complexes **2**–**4** are given in Table 3.

Bond angles and other crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary Publication No. CCDC-270607 for compound **1**, CCDC-270608 for compound **2**, CCDC-270609 for compound **3** and CCDC-270610 for compound **4**. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: (+44) 1223 336 033; deposit@ccdc.cam.ac.uk).

3. Results and discussion

3.1. Synthesis of the complexes

Lanthanoid carboxylate complexes are typically synthesised by adding the carboxylate salt to a solution of the lanthanoid salt. An alternative procedure is to add the carboxylic acid to precipitated lanthanoid hydroxides, a method utilised by Brzyska and Rzaczynska [13,14] during their study of lanthanoid anthranilates. The insolubility of lanthanoid anthranilates limits the usefulness of these two methods to grow crystals suitable for single crystal X-ray analysis. The use of a diffusion apparatus yielded crystals of the complex $[Y(anth)_3(H_2O)]_n$ [2]. We have found that the use of a simpler method can yield suitable crystals. The addition of anthranilic acid to lanthanoid chloride solutions followed by the addition of NaOH dropwise to the reaction mixture to form the Na anthranilate salt led to the isolation of La, Nd, Er and Yb anthranilates after slow evaporation of the reaction mixture (pH ca. 4) at room temperature. This approach has been previously employed using higher pH conditions in the synthesis of lanthanoid hydroxo clusters [20].

Both the La and Nd anthranilates crystallise as large (diameter greater than 2 mm) single crystals, and the micro and metal analysis results of the La and Nd anthranilates confirm the stoichiometry obtained from the X-ray crystallography results. The Er and Yb anthranilates crystallise as clusters of thin needles, the clusters partially decomposing into watery solution as they are broken apart with a needle. Consequently, suitable crystals

of Er and Yb anthranilates for X-ray analysis were handpicked from the bulk product. The unit cells of several crystals obtained from the Yb anthranilate reaction mixture were in agreement with that of the crystal of the solved structure. The discrepancy between the X-ray determined composition and the observed micro and metal analysis values is likely to be due to the presence of additional water molecules trapped within the clusters of crystals. Microanalyses of bulk products from two preparations and a metal analysis were all consistent with $[Yb(anth)_3(H_2O)] \cdot 2H_2O$, i.e., $\mathbf{4} \cdot 2H_2O$, as was the TGA weight loss over 60–200 °C. Prior to analysis, the samples were dried in a desiccator to constant weight and they remained at constant weight for 2 days after removal from the desiccator. No disordered water was evident in the crystal structure but it is possible that highly disordered waters could be present in holes in the lattice. The issue of hydration in lanthanoid anthranilates is also observed in comparing the anhydrous $Nd(anth)_3$ composition proposed by Brzyska and Rzaczynska [13] from a synthesis in water with the composition of **2**, which contains six water molecules. Possibly small differences in reaction conditions and drying techniques have a major effect on hydration and structure.

An even more marked difference between single crystal structure and bulk composition is observed with **3**, where the bulk composition corresponds more closely to $\mathbf{3} \cdot HO_3SCF_3$, and the ^{19}F NMR spectrum shows clear evidence of a CF_3 resonance, somewhat paramagnetically shifted (by Er^{3+}) from the free acid value ($\delta = -77.9$ ppm). Plausibly, isolation at pH 4 leads to protonation of one amino group of **3** giving $\mathbf{3}H^+(OTf^-)$.

3.2. Crystal structure descriptions

Complexes **1**–**3** represent new structural classes of lanthanoid anthranilates, while complex **4** is isostructural with the previously reported Y anthranilate [2]. In all four structures, the anthranilate ligand is bound to the lanthanoid solely through the carboxylate group, in contrast to carboxylate and NH_2 coordination found in transition metal anthranilates and proposed for rare earth anthranilates [13,14]. Although the amino group is not bound to the lanthanoid cation, the amino group participates in hydrogen bonding in complexes **3** and **4**, stabilising the crystal structures. The results of this study demonstrate that lanthanoid anthranilates exhibit a range of structural classes, even more diverse than the closely related lanthanoid *p*-aminobenzoates [21].

Complex **1** crystallises as an anhydrous species in the monoclinic space group $P2_1/c$. Selected bond lengths are given in Table 2. The structure consists of two crystallographically distinct polymer chains. The bonding in the two chains is almost identical with only negligible differences in bond lengths (Table 2). Only bridging tridentate (O,O,O′) ligands are present. The asymmetric unit consists of two independent La mononuclear units, each bound to three anthranilate ligands. Each polymer strand (Fig. 2) is built up from the monomeric units by links to two adjacent La cations, through bridging tridentate anthranilate ligands. Overall, each lanthanum is surrounded by six bridging tridentate ligands, three of which chelate (O,O) to a given lanthanum, and three are unidentate (O). Consequently, each La ion displays a coordination number of nine. In chain 1 the average La(1)–O (carboxylate) bond distance is 2.556 Å, and the distances between adjacent La ions is 3.901 Å. In chain 2, the average La(2)–O carboxylate distance is 2.560 Å and the distance between adjacent La ions is 3.893 Å. The coordination environment around La(1) is best described as a doubled trigonal prism [22], while for La(2) the coordination environment most closely resembles a capped cube [22]. The presence of two independent polymer chains with the same composition but slightly different structures in the same crystal is uncommon, but it has been previously reported in a praseodymium β-alanine complex [23].

Complex **2** crystallises in the hexagonal space group *R3c* and is monomeric. Selected bond lengths are listed in Table 2. As displayed in Fig. 3, the Nd cation is surrounded by three chelating anthranilate ligands, and three water O atoms giving a coordination number of nine. The coordination environment around the Nd most closely resembles a doubled trigonal prism [22]. The Nd–O (carboxylate) distances are markedly different, being 2.464 (2) Å (Nd–O(1)) and 2.549 (2) Å (Nd–O(2)), indicating asymmetric chelation of the anthranilate ligands. The carboxylate angles (O(1)–C(1)–O(2)) are 119.1 (3)°. The angle between the Nd cation and centroids generated between the carboxylate oxygens of the anthranilate ligands is 99.36°, indicating that the anthranilate ligands adopt a *cisoid* geometry around the Nd cation. The Nd–O (water) distances are 2.492 (2) Å, comparable with the Nd–O carboxylate distances. The angle between the O atoms of coordinated water molecules and the Nd is 74.25 (10)°, indicating the coordinated water molecules are also arranged in a *cisoid* geometry. Three water molecules (two are symmetry generated) reside in the lattice and hydrogen bonding links coordinated water and lattice water molecules. Hydrogen bonding also occurs between the coordinated water and the carboxylate oxygen of the anthranilate ligand. Hydrogen bond lengths and angles are given in Table 3. Surprisingly, the structure is isostructural with the closely related lanthanoid *m*-aminobenzoate hydrate structures, despite the different positions of the NH_2 substituent. Lanthanoid complexes of *m*-aminobenzoates have been shown to be isostructural from La to Lu including Y [24], unlike the anthranilates.

Complex **3** crystallises in the orthorhombic space group *Pbca* and is a dimer. Selected bond lengths are listed in Table 2. In addition to two bound water molecules, each Er cation is encircled by four anthranilate ligands which exhibit two different binding modes (Fig. 4). Two chelating anthranilate ligands and two bridging bidentate anthranilate ligands give an overall

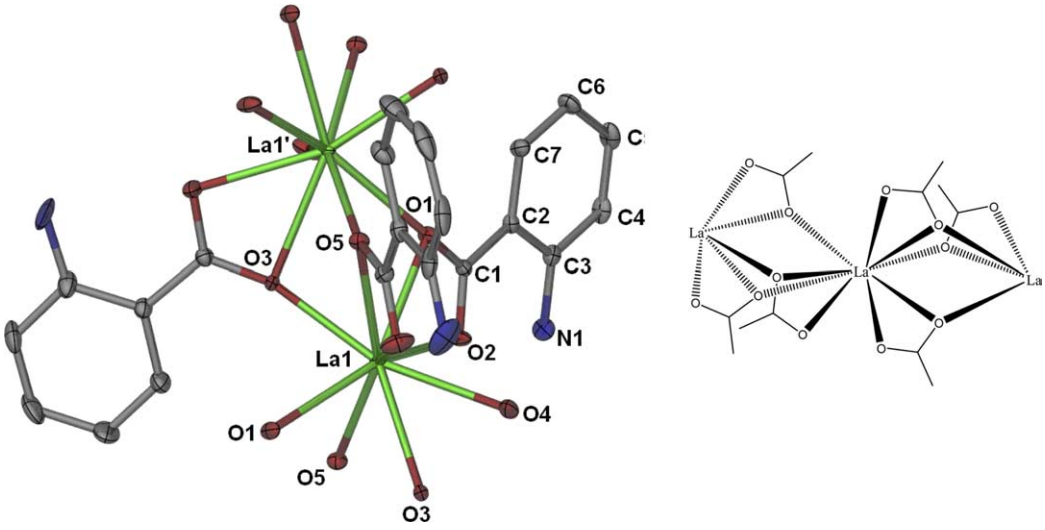

Fig. 2. An ORTEP representation of one of the unique polymer strands of **1**, displaying the bridging tridentate anthranilate ligands present in polymer strands. The second polymer strand is very similar to the pictured polymer strand. Hydrogen atoms have been omitted for clarity (ellipsoids at 50% probability). Inset – stylised diagram showing the ligand connectivity in both polymer strands (aromatic groups omitted for clarity).

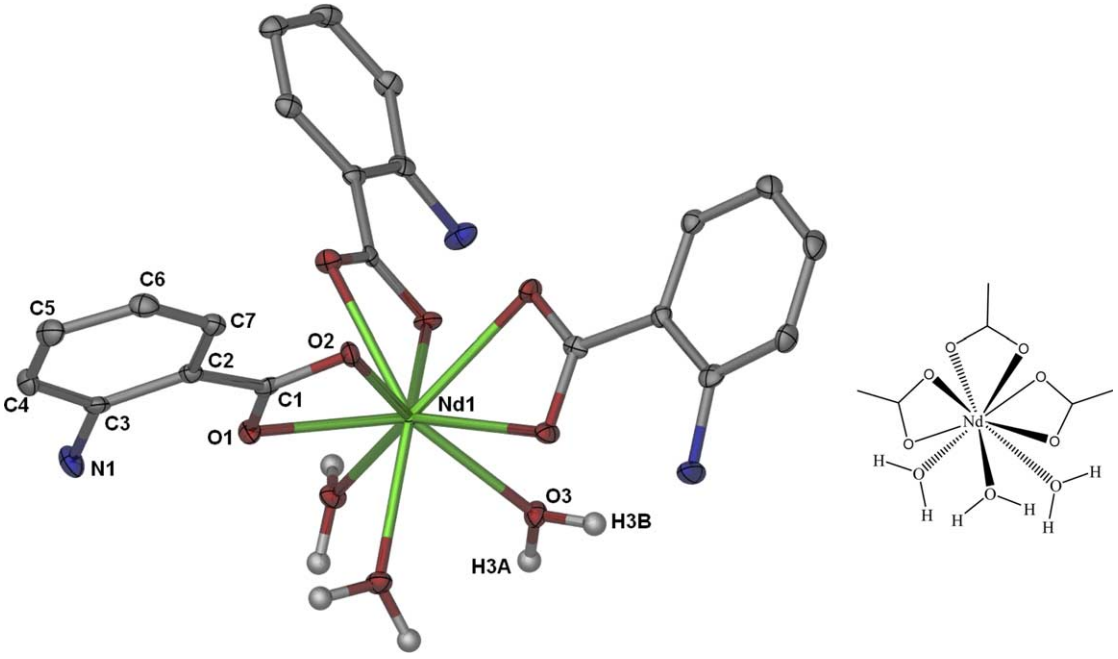

Fig. 3. An ORTEP representation of **2**, exhibiting the chelating anthranilate ligands. Lattice water molecules and hydrogen atoms on anthranilate ligands have been omitted for clarity (ellipsoids at 50% probability). Inset – stylised diagram displaying the ligand connectivity (aromatic groups omitted for clarity).

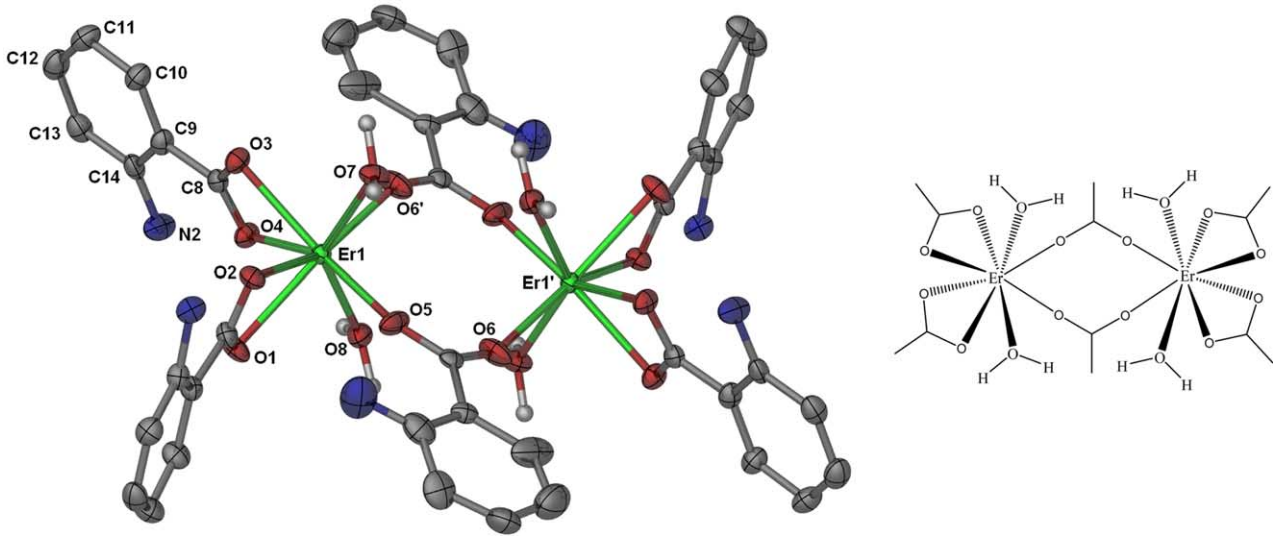

Fig. 4. An ORTEP representation of **3**, displaying the dimeric structure. Lattice water molecules and hydrogen atoms on anthranilate ligands have been omitted for clarity (ellipsoids at 50% probability). Inset – stylised diagram showing the ligand connectivity (aromatic groups omitted for clarity).

coordination number of eight for each Er cation. The coordination geometry around each Er centre most closely resembles a square antiprism [22]. The average carboxylate bite angle for the chelating anthranilate ligands is 118.95°, while for the bridging anthranilate ligands it is 122.82°. The chelating anthranilate ligands adopt a *cisoid* geometry around the Er cation, while the coordinated water molecules are arranged in a *transoid* geometry. The average Er–O distance for chelating anthranilate ligands is 2.381 Å, and for bridging anthranilate ligands is 2.257 Å. The average Er–O (water) distance is 2.357 Å. Two water molecules reside in the lattice. Hydrogen bonding links the lattice water molecule to the carboxylate group of the anthranilate ligand. The coordinated water molecules also participate in hydrogen bonding, and are linked to lattice water molecules and additionally to the amino groups of anthranilate ligands bound to neighbouring Er cations, therefore generating a polymeric supramolecular structure. Hydrogen bond lengths and angles are given in

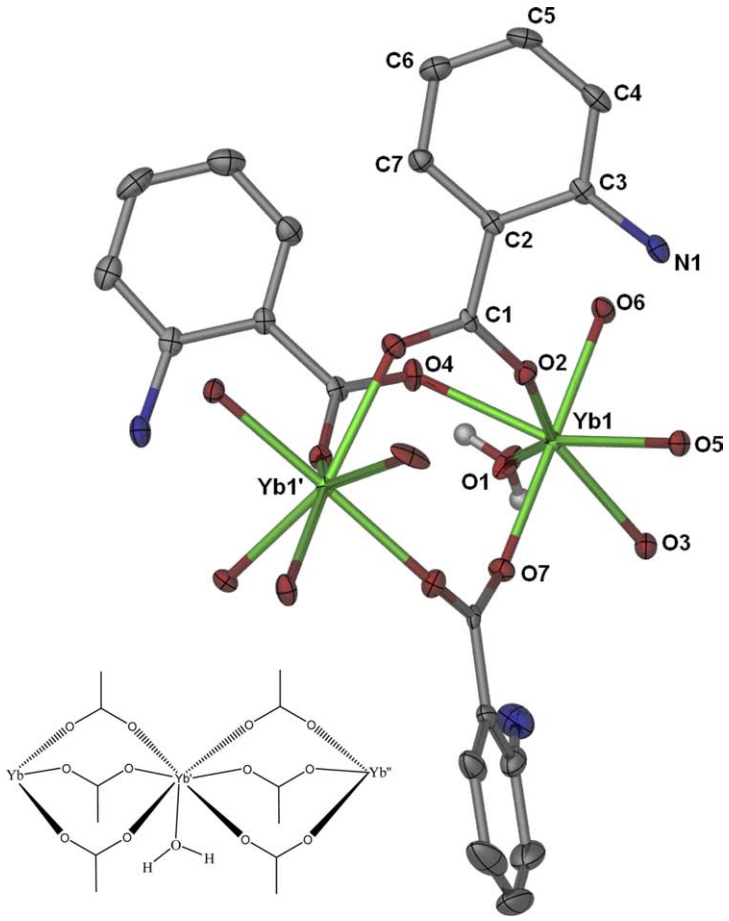

Fig. 5. An ORTEP representation of **4**, illustrating the bridging bidentate anthranilate ligands present in the polymeric structure. Hydrogen atoms on anthranilate ligands have been omitted for clarity (ellipsoids at 50% probability). Inset – stylised diagram displaying the ligand connectivity (aromatic groups omitted for clarity).

Table 3. The structure of complex **3** is similar to that of the related Er salicylate [25].

Complex **4** crystallises in the monoclinic space group *C2/c*. Selected bond lengths are listed in Table 2. The polymeric structure consists of Yb cations linked by six bridging bidentate anthranilate ligands, resulting in the formation of linear polymer chains (Fig. 5). In addition to one O atom from each of six anthranilate ligands, each Yb cation is also bound to one water molecule giving a coordination number of seven. The coordination environment around the Yb cation is best described as a pentagonal bipyramid [22]. The average Yb–O carboxylate distance is 2.263 Å, while the Yb–O (water) distance corresponds closely (2.285 Å). The Yb···Yb distance is 4.714 Å. Hydrogen bonding links the coordinated water molecule to the amino groups of two anthranilate ligands in an adjacent polymer chain. Hydrogen bond lengths and angles are given in Table 3. The complex is isostructural with the reported Y anthranilate [2]. Significant differences in the C–O distances of the carboxylate groups were reported for the Y anthranilate, but in the Yb anthranilate structure the C–O carboxylate distances are comparable. The Y–O (water) distance (2.301 Å) and the Y···Y distance (4.742 Å), are comparable with analogous values for complex **4** allowing for ionic radius differences.

Selected rare earth anthranilate complexes have been tested as potential "green" corrosion inhibitors. The results of these tests indicate that rare earth anthranilates do act as corrosion inhibitors; however they are less effective inhibitors than the closely related rare earth salicylates [15].

4. Conclusions

By employing an alternative synthetic route we have synthesised and crystallised a range of lanthanoid anthranilates, and probed the solid state structures using X-ray crystallography. The results reveal a diverse range of structural classes exhibited by lanthanoid anthranilates. In all cases, the amino group of the anthranilate ligand is not coordinated to the lanthanoid cation. The carboxylate groups of the anthranilate ligand exhibited three different binding modes, chelating, bridging bidentate and bridging tridentate. The variations in structural

class can be related to the lanthanoid contraction, with a decline from nine coordination (La) to seven (Yb). However other factors such as slight variations in reaction conditions including pH may influence the structural class isolated. Further investigation is required to unravel completely the origin of the structural diversity.

Dedicated to Professor Malcolm Chisholm on the occasion of his 60th birthday

Abstract

N-ferrocenyl salicylaldimine (FcPI)H, readily accessible from aminoferrocene and salicylaldehyde, reacts with dibutylmagnesium in THF to afford a red crystalline $(FcPI)_2Mg(THF)_2$ (**2**). The reactions of the Li(FcPI) with $CpTiCl_3$ gave $CpTiCl_2(FcPI) \cdot CH_2Cl_2$ (**4**), whereas with $CpZrCl_3 \cdot DME$ a mixture of three products is formed: $CpZrCl(FcPI)_2$ (**5**), $CpZrCl_2(FcPI)$ (**6**), and $(FcPI)_2ZrCl_2 \cdot CH_2Cl_2$ (**3** $\cdot CH_2Cl_2$). The crystal structures of compounds **2**–**6** are reported. Typically, the N–O chelates are oriented such that O donors are mutually *trans*, while N donors prefer to be *trans* to Cl ligands. The redox potentials of these complexes are very similar to ferrocene. On activation with methylaluminoxane, the Ti complex **4** shows moderate activity for ethylene polymerisation, while $(FcPI)_2ZrCl_2$ is highly active for the oligomerisation of ethylene, to give products with average degrees of polymerisation of 12–16.

Keywords: Titanium; Zirconium; Magnesium; Chelate ligands; Ferrocene; Polymerisation catalysis

1. Introduction

Complexes based on ferrocenyl-substituted Schiff-base ligands have been widely explored, mainly based on the facile condensation reactions of amines with acyl- or formylferrocenes [1–3]. Alternatively, ligands derived from amino- and 1,1′-diaminoferrocene [4] can be employed. For example, Arnold et al. [5,6] reported a number of amido and tetradentate salen-type ligands in which the 1,1′ferrocenediyl unit is incorporated into the ligand backbone. A similar family of ligands were reported by Gibson et al. [7,8], including iminopyridines with pendant ferrocenyl substituents. Applied to group 4 complexes suitable for polymerisation catalysis, such ligands offer the possibility, at least in principle, of activating metal alkyl catalyst precursors electrochemically, taking advantage of redox active ferrocenyl substituent in the immediate vicinity of the active metal centre. In the course of a programme investigating the potential of new heteroatom chelates in olefin polymerisation catalysis [9], especially based on N–O ligands of the salicylaldiminato type [10], we became interested in ferrocenyl-substituted derivatives and report here the syntheses and structures of magnesium, titanium and zirconium complexes.

2. Results and discussion

2.1. Syntheses

The ferrocenyl salicylaldimine (FcPI)H (**1**-H) was prepared by reaction of 3-*tert*-butyl salicylaldehyde with

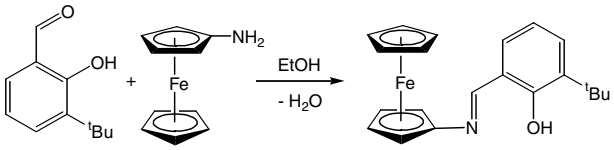
doi:10.1016/j.poly.2005.07.012

aminoferrocene in ethanol over molecular sieves (Eq. (1)). On concentrating the solution, **1**-H was obtained as a pale-red, microcrystalline powder in 65% yield.

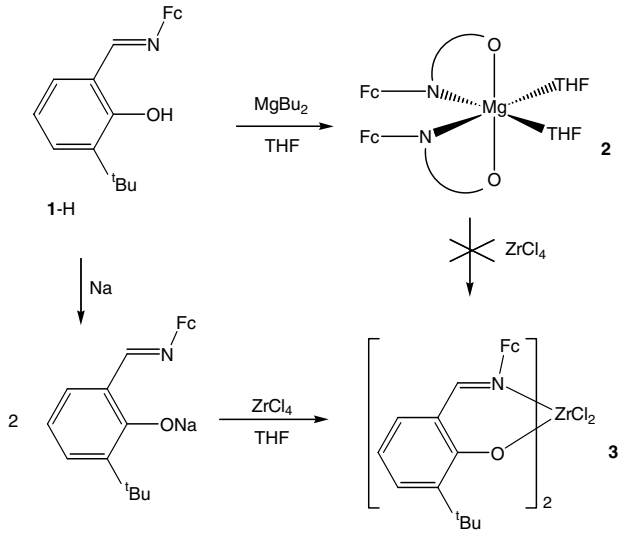


(1)

The reaction of **1**-H with dibutylmagnesium in tetrahydrofuran afforded a red crystalline compound, which was identified as $(FcPI)_2Mg(THF)_2$ (**2**). It had been the intention to use this magnesium reagent in reactions with $TiCl_4$ and $ZrCl_4$; however, no clean products could be isolated from these reactions under a variety of conditions. The treatment of group 4 metal halides with the lithium salt of **1** proved similarly unsatisfactory, whereas mixtures of the sodium salt **1**-Na with $ZrCl_4$ in tetrahydrofuran afforded the bis(*N*-ferrocenylsalicyliminato)-zirconium dichloride **3** (Scheme 1).

By contrast, the reaction of **1**-Li with $CpTiCl_3$ in THF proceeded as expected. Extraction of the crude product with dichloromethane and layering the concentrated dichloromethane solution with light petroleum afforded dark red-brown cubic crystals of $CpTiCl_2(FcPI) \cdot CH_2Cl_2$ (**4**).

In a similar manner, **1**-Li was reacted with $CpZrCl_3 \cdot DME$. However, this reaction led to several products which co-crystallised from dichloromethane solution: red-brown cubic crystals of $CpZrCl_2(FcPI)$ (**5**), clusters of dark red-brown needles of $CpZrCl(FcPI)_2$ (**6**), and dark red-brown cubic crystals of $(FcPI)_2ZrCl_2$

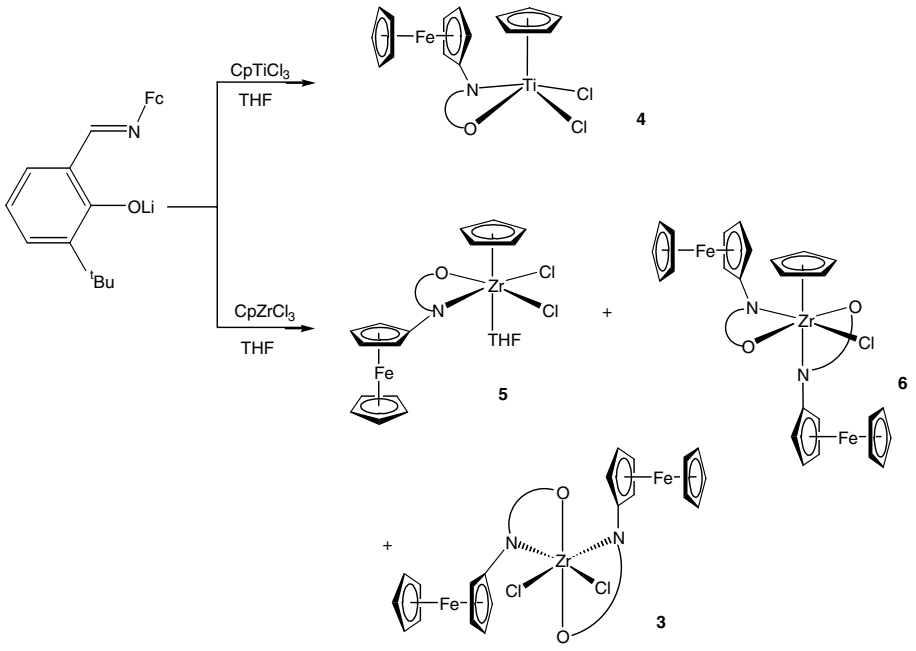


Scheme 1.

$(3 \cdot CH_2Cl_2)$ (Scheme 2). The latter is identical to the product from **1**-Na and $ZrCl_4$ but was obtained in this case as the dichloromethane solvate. The formation of **3** evidently results from Cp ligand exchange. The three products were separated manually and identified by single-crystal X-ray diffraction.

2.2. Structural studies

The magnesium complex **2** has octahedral geometry, with the salicylato-O atoms in *trans* and two THF ligands in *cis*-positions (Fig. 1). Selected bond lengths and angles are collected in Table 1. This contrasts with



Scheme 2.

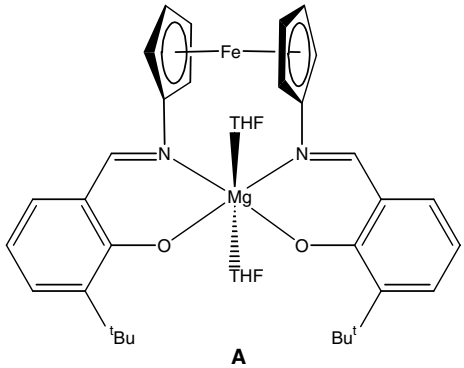
a related complex of a tetradentate ferrocenediyl ligand reported by Arnold et al. [6] (compound **A**) where the salicylic O and N atoms are *cis* to one another in equatorial positions, while the THF ligands are *trans* [∠O(3)–Mg–O(4) = 169.3(2)°]. The bond distances from the THF–O atom to magnesium are similar in both complexes, 2.161(5) and 2.141(4) Å in **A** and 2.136(5) Å in **2**, as are the Mg–O(anionic) distances (1.974(5) and 1.984(5) Å, compared to 1.982(4) Å). The Mg–N bonds in **2** are 2.175(6) Å, significantly shorter than in **A**.



A

The titanium complex $CpTiCl_2(FcPI)$ (**4**), crystallises with one molecule of dichloromethane (Fig. 2). Selected bond lengths (Å) and angles (°) are collected in Table 2. The five-coordinate titanium resides in a distorted square-based pyramidal environment, with the cyclopentadienyl ring at the apex and the chlorides *cis* to each other. The N–O chelating ligand forms a plane which includes the phenoxide ring and the –C=N group. This pattern is similar to that seen in the previously published

Table 1
Selected bond lengths (Å) and angles (°) for $(FcPI)_2Mg(THF)_2$ (**2**)

Mg–O1	1.982(4)
Mg–N	2.174(6)
Fe–Cp1	1.632
Mg–O3	2.136(5)
Fe–Cp2	1.638
O(1)–Mg–O(1′)	175.5(3)
O1–Mg–N′	85.8(2)
O1–Mg–N	97.3(2)
O(1)–Mg–O(3)	90.6(2)
O1′–Mg–N′	97.3(2)
N–Mg–O1′	85.8(2)
O(3)–Mg–O(3′)	87.7(3)
N–Mg–N′	93.3(3)
O(3)–Mg–N	171.64(19)
Cp1–Fe–Cp2	177.9

The prime signifies a symmetry operation about a twofold symmetry axis. Here, and in all the complexes, the centroid of the substituted Cp ring of the Fc group is labelled as Cp1, and that of the outer Cp ring as Cp2.

structure of (trimethylphenyl)phenoxyimine titanium monocyclopentadienyl dichloride [10b]. The Ti–Cl bond length of the chlorine ligand *trans* to N is significantly longer than that *trans* to O. The Ti–Cp (centroid) distance is 2.053 Å, typical for Ti(IV) Cp complexes.

Complex **5** is the zirconium analogue of **4**. However, the larger zirconium also coordinates to one tetrahydrofuran molecule, to give a complex with a distorted octahedral geometry (Fig. 3). Selected bond lengths and angles are given in Table 3. Crystals of **5** were of limited quality ($R_1 = 0.127$). The chlorides are in *cis* positions [Cl(1)–Zr–Cl(2) angle 88.5(2)°] and in the same plane as the ferrocenyl phenoxyimine, with the cyclopentadienyl ring *trans* to the tetrahydrofuran [Cp(centroid)–Zr–O(2) angle 174.2°]. As was the case with the Ti complex **4**, the Zr–Cl(1) bond *trans* to N is slightly longer than Zr–Cl(2), although this difference is less pronounced than in the titanium example.

The mono-chloro complex **6** is also octahedral (Fig. 4), analogous to but slightly more distorted than the previously reported bis(*N*-ethylsalicyliminato) complex $CpZrCl(EtPI)_2$ [10d]. Selected bond lengths and angles are shown in Table 4. One N–O chelate is equatorially bound, while the Cp ring and the N atom of the second N–O ligands occupy axial positions. The oxygen atoms are approximately *trans* to one another [∠O(1)–Zr–O(2) = 156.1(2)°]. Steric pressures force the *cis*-nitrogen donors closer together, viz. ∠N(1)–Zr–N(2) = 74.2(3)°. This is similar to structures previously reported and is the expected structural trend for the favoured geometry of zirconium complexes containing two phenoxy-imine ligands [10,11]. As was the case in $CpZrCl(EtPI)_2$, the plane of one of the phenoxy-imine ligands, C(31)–O(2)–Zr–N(2), in complex **6** is almost parallel to the Cp plane, while the plane of the second phenoxy-imine, C(17)–N(1)–Zr–O(1), is nearly perpen-

dicular to the Cp plane. The zirconium–chloride bond distances in **6**, 2.509(3) Å, is slightly longer than in **5**. Other geometric parameters resemble previous examples [5–12].

The last product isolated from the reaction of **1**-Li with $CpZrCl_3$ was the bis(ferrocenyl phenoxyimine) zirconium dichloride complex **3**, crystallised as CH_2Cl_2 solvate. The structure is shown in Fig. 5, with selected bond lengths and angles collected in Table 5. The complex possesses distorted octahedral goemetry. The phenoxy-oxygen atoms occupy *trans* positions [∠O(1)–Zr–O(2) 166.5(2)°], similar to Fujita's bis(*N*-phenyl phenoxyimine) zirconium complex, $ZrCl_2(Ph–PI)_2$ [13]. This leaves the nitrogen atoms in *cis* positions [∠N(1)–Zr–N(2) 75.3(2)°] and *trans* to the chlorine ligands. The bond lengths in **3** are very similar to Fujita's complex. The

Zr–Cl distances in **3**, 2.4394(14) and 2.420(2) Å, are significantly shorter than those found in **6** [2.509(3) Å].

2.3. Electrochemistry

Cyclic voltammetry (CV) of the ligand **1** and zirconium complex **3** show that in each case quasi-reversible (electron transfer is slow relative to scan rate) one-electron transfers for the Fe^{II}–Fe^{III} redox couple of the ferrocenyl species are observed (Table 6). The dominant species recorded in the CV for **1** has a ΔE_p of 77 mV (Fig. 6), a good correspondence to that for a reversible reaction where $n = 1$ (for a fully reversible "Nernstian"

Table 6
Cyclic voltammetry of **1** and **3**

Compound	E_p^c (mV)	E_p^a (mV)	$E_{1/2}$ (mV)	ΔE_p
Ferrocene (Fc)	446	560	503	104
(FcPI)H (**1**)	505	582	543	77
$(FcPI)_2ZrCl_2$ (**3**)	455	568	511	113

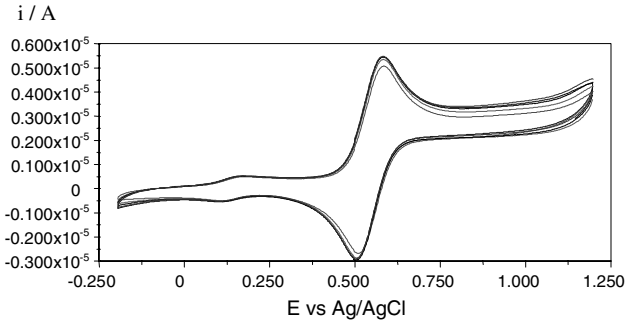

Fig. 6. Cyclic voltammogram of **1** in dry dichloromethane with 0.1 M in $[^nBu_4N]^+[PF_6]^-$ as supporting electrolyte.

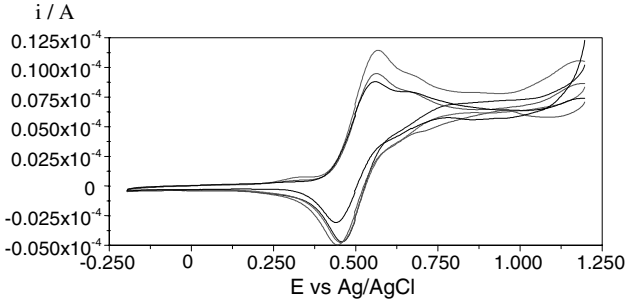

Fig. 7. Cyclic voltammogram of **3** (CH_2Cl_2, 0.1 M $[^nBu_4N]^+[PF_6]^-$).

type redox couple, $\Delta E_p = 60$ mV for $n = 1$). For **3**, the major species couple has $\Delta E_p = 113$ mV (Fig. 7); although a lot larger than 60 mV, it is in line with the ΔE_p of ferrocene (104 mV, $n = 1$). The difference is probably due to different electron transfer kinetics. The CV for **1** also shows a minor signal, $E_{1/2} = 134$–503 mV $= -369$ mV, similar to one reported by Gibson et al. [8]. These authors assigned this signal to an irreversible electrochemical reduction of C=N to an amine group, although in the case of **1** this process appears to be reversible. $\Delta E_p = 44$ mV for this signal ($E_{1/2} = 116$ mV) suggests $n = 2$, or the compound is adsorbed onto the electrode ($\Delta E_p = 0$ mV).

On coordination of the ligand to the zirconium metal centre, the Fe^{II}/Fe^{III} oxidation shifts to a lower potential, which is unexpected [8]. The two ferrocene moieties show independent behaviour, resulting in identical potentials. A shoulder appearing on the flank of the major signal for **3**, $E_{1/2} = 644$ mV, may be due to a redox active oxidation product or an impurity. In a similar cyclic voltammetry study over a wider potential range, this shoulder became more prominent after irreversible electrochemical oxidation took place, while the peaks of the major species assigned to **3** were unchanged by this process.

2.4. Polymerisation studies

The ethylene polymerisation of two representative examples of ferrocenyl-substituted phenoxyimine complexes, **3** and **4**, was investigated using MAO as the activator.

Complex **4**/MAO (Al:Ti = 4000) readily polymerises ethene (1 bar) at room temperature with a productivity of 1×10^4 g PE $(mol^{-1}$ Ti$) \cdot h^{-1} \cdot bar^{-1}$ (Table 7) (PE = polyethylene). This activity is quite similar to that exhibited by the mesityl-substituted analogue, $CpTiCl_2$(MesPI) (1.3×10^4 g PE $(mol^{-1}$ Ti$) \cdot h^{-1} \cdot bar^{-1}$) [10b].

By contrast, the bis(ferrocene phenoxyimine)zirconium dichloride, **3**, when activated with MAO, shows very high activity at 23 °C, 2×10^6 g PE $(mol^{-1}$ Zr$) \cdot h^{-1} \cdot bar^{-1}$, which increased further on cooling to 0 °C and on reducing the catalyst concentration. This activity is less than that reported by Fujita for $(PhPI)_2ZrCl_2$/MAO, although those results were obtained with a substantially higher Al/Zr ratio of 62 500:1. The catalyst based on **3** is thermally unstable, however, and conducting the polymerisation at 60 °C afforded only traces of polymer; again this is in line with the known behaviour of phenoxyimine catalysts which are prone to deactivation by C=N double bond reduction [10d,13–15]. Interestingly, complex **3** differs from the titanium complex **4** as well as comparable alkyl and aryl-substituted zirconium catalysts in producing ethene oligomers with excellent productivities, with average degrees of polymerisation of 12–16.

Table 7

3. Experimental

Unless otherwise stated, syntheses were performed with exclusion of oxygen and moisture under nitrogen using standard Schlenk techniques in flame-dried glassware. Solvents were distilled over sodium benzophenone (diethyl ether, tetrahydrofuran), sodium (toluene), sodium–potassium alloy (petroleum ether, bp 40–60 °C), or CaH_2 (dichloromethane). NMR solvents were dried over activated 4 Å molecular sieves and degassed by several freeze–thaw cycles. NMR spectra were recorded using a Bruker DPX300 spectrometer. Chemical shifts are reported in ppm and referenced to residual solvent resonances (^{1}H, ^{13}C), ^{19}F is relative to $CFCl_3$. Nitrogen, argon and ethene (BOC, 99.5%) were purified by passing through columns of supported P_2O_5 with moisture indicator, and activated 4 Å molecular sieves. Aminoferrocene was prepared according to the literature procedures [16].

3.1. Preparation of 2-tert-butyl-6-(N-ferrocenylaldimino)phenol, (FcPI)H (1-H)

3-*tert*-Butylsalicylaldehyde (2.1 g, 12 mmol) was added dropwise to a stirred mixture of aminoferrocene (2.3 g, 11.4 mmol) with molecular sieves 4 Å (2 g) in ethanol (50 mL), at room temperature. The mixture was stirred for 18 h, filtered and the molecular sieves washed with diethyl ether (20 mL). Crystallisation from the concentrated solution gave **1**-H as a red microcrystalline powder (2.7 g, 7.5 mmol, 65%). ^{1}H NMR (300 MHz, 298 K, $CDCl_3$): δ 8.61 (s, 1H, C*H*=N), 7.34 (d, 1H, $J = 7.8$ Hz, ar-*H*), 7.14 (d, 1H, $J = 7.8$ Hz, ar-*H*), 6.82 (t, 1H, $J = 7.8$ Hz, ar-*H*), 4.57 (m, 2H, C_5H_4N), 4.25 (m, 2H, C_5H_4N), 4.17 (s, 5H, C_5H_5), 1.45 (s, 9H, ^{t}Bu). ^{13}C NMR (75.5 MHz, 298 K, $CDCl_3$): δ 161.1 (*C*H=N), 137.5 (ar-*C*), 129.5 (ar-*C*H), 129.3 (ar-*C*H), 119.5 (ar-*C*), 118.2 (ar-*C*H), 102.4 (ar-*C*), 69.8 (C_5H_5), 67.4 (C_5H_4N), 62.4 (C_5H_4N), 34.9 ($C(CH_3)_3$), 29.4 ($C(CH_3)_3$). *Anal.* Calc. for $C_{21}H_{23}NOFe$: C, 69.82; H, 6.42; N, 3.88. Found: C, 69.72; H, 6.56; N, 3.85%.

3.2. Preparation of (FcPI)$_2$Mg(THF)$_2$ (2)

Dibutylmagnesium (1.0 M in hexanes, 1 mL, 1 mmol) was added dropwise to a stirred solution of **1**-H (0.72 g, 2 mmol) in THF at −78 °C. The mixture was allowed to reach room temperature and stirred for 15 h. The solution was then concentrated, carefully layered with light petroleum and cooled to 5 °C to afford the title compound as red crystals in 51% yield (0.45 g, 0.5 mmol). ^{1}H NMR (C_6D_6): δ 8.63 (s, 1H, C*H*=N), 7.54 (dd, 1H, $J = 7.4$, 1.7 Hz, ar-*H*), 7.09 (dd, 1H, $J = 7.8$, 1.5 Hz, ar-*H*), 6.70 (t, 1H, $J = 7.6$ Hz, ar-*H*), 4.30 (m, 2H, N–Cp), 3.89 (s, 5H, Cp), 3.73 (m, 2H, N–Cp), 3.56 (m, 8H, THF), 1.70 (s, 9H, ^{t}Bu), 1.40 (m, 8H, THF). ^{13}C NMR (C_6D_6) δ 169.8 (*C*=N), 142.1 (ar-C), 134.6 (ar-C), 132.5 (ar-C), 122.0 (ar-C), 114.5 (ar-C), 105.8 (ar-C), 70.0 (Cp), 67.8 (N–Cp), 66.9 (THF), 62.9 (N–Cp), 35.6 (N–Cp), 35.6 ($C(CH_3)_3$), 29.9 ($C(CH_3)_3$), 25.7 (THF). *Anal.* Calc. for $C_{42}H_{44}N_2O_2Fe_2Mg.OC_4H_8$: C, 61.98; H, 6.24; N, 2.89. Found: C, 61.62; H, 7.29; N, 2.90%.

3.3. Preparation of (FcPI)$_2$ZrCl$_2$ (3)

Sodium hydride (0.07 g, 3.0 mmol) was added to a solution of **1**-H (1.00 g, 2.8 mmol) in tetrahydrofuran (50 mL). The dark red solution was stirred for 3 h at room temperature, cooled to −78 °C. Zirconium tetrachloride was added (0.32 g, 1.4 mmol), the mixture was allowed to reach room temperature and stirred for 18 h. The volatiles were removed in vacuo, and the resulting dark red solid was extracted with dichloromethane (50 mL), concentrated and layered with light petroleum. The title compound was obtained as dark red micro-crystals (0.51 g, 0.6 mmol, 42%) at −20 °C. This sample recovered did not contain dichloromethane of crystallisation. ^{1}H NMR (CCl_2D_2): δ 9.10 (s, 1H, CH=N), 7.50 (d, 1H, $J = 6.2$ Hz, ar-H), 7.19 (d, 1H, $J = 6.3$ Hz, ar-H), 6.87 (d, 1H, $J = 7.1$ Hz, ar-H), 4.49 (br, 1H, Cp–H), 4.17 (br, 5H, Cp–H), 3.84 (br, 1H, Cp–H), 3.68 (br, 1H, Cp–H), 1.46 (s, 9H, ^{t}Bu). ^{13}C NMR (CCl_2D_2): δ 172.9 (CH=N), 159.7 (ar-C), 134.4 (ar-C), 133.3 (ar-C), 123.9 (ar-C), 120.0 (ar-C), 69.7 (FcCH, C_5H_5), 66.9 (FcCH, C_5H_4), 64.9 (FcCH, C_5H_4), 35.2 ($C(CH_3)_3$), 29.9 ($C(CH_3)_3$). *Anal.* Calc. for $C_{42}H_{44}N_2O_2Cl_2Fe_2Zr$: C, 57.15;H, 5.02; N, 3.17; Cl, 8.03. Found: C, 56.82; H,5.28; N, 3.05; Cl, 9.42.

3.4. Preparation of CpTiCl$_2$(FcPI) · CH$_2$Cl$_2$ (4)

The lithium salt **1**-Li, prepared from **1**-H (0.5 g, 1.38 mmol) and ^{n}BuLi (0.9 mL, 1.6 M in hexanes, 1.38 mmol), was treated with $CpTiCl_3$ (0.30 g, 1.38 mmol) in THF (50 mL), stirred at −78 °C for 20 min, allowed to reach room temperature and stirred overnight. The volatiles were removed under vacuum and the product extracted with CH_2Cl_2 (20 mL). The solution was concentrated, layered with light petroleum and cooled to −20 °C to give **4** as dark red/brown, cubic crystals (0.28 g, 0.4 mmol, 32%). ^{1}H NMR (C_6D_6): δ 9.54 (s, 1H, C*H*=N), 8.35 (d, 1H, $J = 7.4$ Hz, ar-*H*), 7.43 (d, 1H, $J = 7.5$ Hz, ar-*H*), 6.80 (t, 1H, $J = 7.6$ Hz, ar-*H*), 6.31 (s, 5H, Cp), 4.28 (m, 4H, NC_5H_4), 3.95 (m, 5H, Cp), 1.56 (s, 9H, ^{t}Bu). ^{13}C NMR (C_6D_6) δ 129.8 (ar-*C*), 128.3 (ar-*C*), 124.3 (ar-*C*), 124.0 (ar-*C*), 122.1 (ar-*C*), 121.9 (Cp), 70.1 (FeC_5H_4), 69.9 (FeC_5H_4), 53.3 (FeC_5H_5), 35.2 ($C(CH_3)_3$), 29.7 ($C(CH_3)_3$). *Anal.* Calc. for $C_{26}H_{27}NOCl_2TiFe \cdot CH_2Cl_2$: C, 51.55; H, 4.65; N, 2.23; Cl, 22.54. Found: C, 51.70; H, 4.63; N, 2.07; Cl, 21.78%.

3.5. Isolation of $(FcPI)_2ZrCl_2 \cdot CH_2Cl_2$ (3), $CpZrCl_2(FcPI)$ (5) and $CpZrCl(FcPI)_2$ (6)

Following the procedure given for **4**, to a solution of **1**-Li (1.38 mmol) in THF (50 mL) was added $CpZrCl_3 \cdot DME$ (0.49 g, 1.38 mmol). The volatiles were removed and the products extracted with CH_2Cl_2. The solution was concentrated and layered with light petroleum. Dark red-brown cubic crystals of $(FcPI)_2ZrCl_2 \cdot CH_2Cl_2$ (**3** · CH_2Cl_2) dark red-brown needle clusters of $CpZrCl(FcPI)_2$ (**6**) and red-brown cubic crystals of $CpZrCl_2(FcPI)(THF)$ (**5**), which were isolated from the same Schlenk flask and picked out manually. The compounds were identified by X-ray crystallography. Unlike the preparation of **3** from **1**-Na, this crystallisation produced the dichloromethane solvate, **3** · CH_2Cl_2. No further characterisation has been undertaken.

3.6. Ethylene polymerisations

Ethylene polymerisation was carried out under 1 bar ethene in toluene. Toluene (total volume 50 mL including MAO) and co-catalyst (MAO) were introduced into the ethylene-purged reactor and stirred. After ethylene saturation and temperature equilibration, polymerisation was initiated by addition of a toluene solution of pre-catalyst into the reactor under vigorous stirring (1000 rpm). After the required amount of time, methanol (5 mL) was added to terminate the polymerisation, and the ethene gas flow halted. The polymer was precipitated, washed with a mixture of methanol (~300 mL) and 15% HCl (~5 mL), filtered, washed with methanol and dried in an oven at 80 °C to constant mass.

3.7. Electrochemistry

Electrochemical data were obtained at 298 K using a glassy-carbon working electrode, a platinum-wire auxiliary electrode and a silver wire (coated with AgCl by anodising in KCl solution) pseudo-reference electrode. Voltammetry was run at 20 mV s^{-1} on ca. 10^{-4}–10^{-3} M solutions in deoxygenated, dry dichloromethane with 0.1 M in $[^nBu_4N]PF_6$ as supporting electrolyte. The error in the reported potentials is estimated from comparison of successive scans to be ca. ±10 mV [17].

3.8. X-ray crystallography

Crystals coated with dry nujol or perfluoropolyether were mounted on a glass fibre and fixed in the cold nitrogen steam ($T = 140(1)$ K). Intensity data were collected on a Rigaku R-Axis IIc image plate diffractometer equipped with a rotating anode X-ray source (Mo Kα radiation) and graphite monochromator (Mo Kα, $\lambda = 0.71073$ Å). Data were processed using the DENZO/SCALEPACK programs [18] and absorption corrections applied in SORTAV [19]. The structures were determined by direct methods in the SHELXS programs and refined by full-matrix least-squares methods, on F^2 values, in SHELXL [20]. Crystal and refinement data are given in Table 8. Hydrogen atoms were included in idealized positions, and their U_{iso} values set to ride on the U_{eq} values of the parent carbon atoms. Scattering factors for neutral atoms were taken from the literature [21]. Computer programs were run on a DEC-AlphaStation 200 4/100 in the Biological Chemistry Department, John Innes Centre.

4. Supplementary material

Full tables of bond lengths and angles, tables of non-hydrogen and hydrogen atomic coordinates and anisotropic thermal parameters for non-hydrogen atoms are available from the Cambridge Crystallographic Data Centre, quoting CCDC deposition numbers 269489 (compound **2**), 269490 (**4**), 269491 (**3**), 269492 (**6**) and 269493 (**5**). Studies on 1,2-phenylenedioxoborylcyclopentadienes and some of their metal (Ti, Zr, Fe) complexes

Michael J. Davies, Michael F. Lappert *

Department of Chemistry, University of Sussex, Falmer, Brighton BN1 9QJ, UK

Received 4 May 2005; accepted 29 June 2005
Available online 18 August 2005

Dedicated to Professor M.H. Chisholm, F.R.S., as a mark of friendship and esteem.

Abstract

Various properties of 1,2-phenylenedioxoborylcyclopentadienes $C_5H_4BO_2C_6H_4$-1,2 (≡C_5H_5BCAT), its 4-^{t}Bu (≡$C_5H_5BCAT^t$) and 3,5-^{t}Bu$_2$ (≡$C_5H_5BCAT^{tt}$) analogues are reported. Under ambient conditions [Zr(η^5-$C_5H_4BCAT)_2Cl_2$] (**3a**) in PhMe was unreactive towards ethene, but in the presence of a large excess of methylaluminoxane (MAO) it catalysed the conversion of propene into a low average molecular weight atactic polypropylene. Whereas various Ti(IV) complexes [Ti(η^5-$C_5H_4BX)Cl_3$] [BX = BCAT (**2a**), BCAT^t (**2b**), BCAT^{tt} (**2c**)] did not react under these conditions with C_2H_4, a number of corresponding Zr and Hf analogues, as well as the related metallocene dichlorides, afforded polyethylene of moderate polydispersity and average molecular weight, but were less active than [$ZrCp_2Cl_2$]. From ^{11}B NMR spectral data, it is concluded that the product of treating **3a** with MAO is possibly [Zr(η^5-$C_5H_4BMe_2)_2Cl_2$]. ^{11}B NMR chemical shifts on the three series of compounds Cl-BX (**10a**–**10c**), $Me_3SiC_5H_4$–BX (**1a**–**1c**) and **2a**–**2c** fall within the narrow range 27.2 (**2a**) to 29.5 (**1a**) with **10a** at 29.0. Cyclic voltammetry on a number of the metal complexes, including **2a**–**2c**, [Zr(η^5-$C_5H_4BCAT^t)_2Cl_2$] (**3c**) and [Fe(η^5-$C_5H_4BCAT^t)_2$] (**9**), showed three reduction waves, but only the first of these was reversible for **3c**. For **2a**–**2c** there was evidence for formation of successively [**2**]$^-$ and solvated $TiCl_3$ (together with oxidation of the anion [C_5H_4BCAT]$^-$); support for these Ti(III) species came from the EPR spectra of the in situ generated species obtained by the controlled potential electrolysis of **2a** and comparison with similar data derived from [Ti{η^5-$C_5H_3(SiMe_3)_2$-1,3}$_2Cl_2$]; while from **3c**, the formation of [**3c**]$^-$ is inferred.

1. Introduction

Recently, we described the synthesis and characterisation of a series of 1,2-phenylenedioxoborylcyclopentadienes of formulae **1a**–**1e** [1] and of some of their metal complexes **2**–**9** [2].

As previously noted [2], these studies were planned as a prelude to examining the potential of some of the organometallic compounds **2**–**9** as pro-catalysts for α-olefin polymerisation. The conceptual basis for undertaking this challenge lay in the knowledge that several mono-or bis-cyclopentadienylmetal complexes or of related ligands, particularly of Ti or Zr, were established as being effective in such catalysis when used with an excess of methylaluminoxane (MAO), or a similar Lewis acid metal alkyl, as cocatalyst [3].

We considered that a BX_2 substituent in the spectator ligand, such as the conjugate base of **1a**–**1e**, might serve a dual role by virtue of its readily available vacant p-orbital on the boron atom: in increasing the electrophilicity of the transition metal (M) active site compared

with its BX_2-free analogue and also in enhancing the prospect of an intramolecular M → B shift of Cl^-. Various X(X′)B-*ansa*-bridged-bis(cyclopentadienyl)-or -bis (indenyl)zirconium(IV) complexes have been reported, including salts containing the anion $[X(X')B(\eta^5\text{-}C_5H_4)_2ZrY_2]^-$ (X = Ph, X′ = Me, Y = Cl [4]; X = Ph, X′ = C_6F_5 = Y, or X = C_6F_5 = X′ = Y [5]), and the zwitterionic complexes $[Ph(Ph_3P^+CH_2)B^-(\eta^5\text{-}C_5H_4)_2\text{-}ZrCl_2]$ or two bis(η^5-indenyl) analogues [6]. Some of these with MAO were active catalysts for the polymerisation of ethene [5,6], as was $[Zr(\eta^5\text{-}C_5H_4BPh_2)_2Cl_2]$ with $AlEt_3$ [7]; while the above bis(η^5-indenyl) compounds with MAO were effective for propene polymerisation [6].

The objectives of the present work were to examine the effect of the BX_2 substituent in a selection of the compounds **1**–**9** by comparing their catalytic activity, as well as appropriate NMR, CV and E_{red} data, with those for BX_2-free analogues.

2. Results and discussion

An initial aim of these studies was to test the notion that 1,2-phenylenedioxoborylcyclopentadienylmetal complexes, particularly those of the group 4 metals, might be single site homogenous α-olefin polymerisation catalysts without recourse to a cocatalyst such as MAO. This objective was abandoned when it became clear that, at any rate in toluene under ambient conditions, $[Zr(\eta^5\text{-}C_5H_4BCAT)_2Cl_2]$ (**3a**) did not react with C_2H_4.

Accordingly, we then chose to focus on the following themes: (i) the polymerisation of ethene or propene, using some of the new [2] Ti(IV), Zr(IV) and Hf(IV) compounds as procatalysts with MAO, and the nature of the reaction between such a group 4 metal compound and MAO (Section 2.1); probing the electronic effect of the boryl substituent on some of the compounds **1**–**9** by means of (a) ^{11}B NMR spectroscopy (Section 2.2), (b) cyclic voltammetry (Section 2.3) and (c) EPR spectroscopy on controlled potential electrolysis products of some of the Ti or Zr complexes (**2**–**6**) (Section 2.4), and comparing for (b) and (c) the data with similar values for boryl-free analogous metal complexes.

2.1. Polymerisation of ethene and propene

The general conditions used to test the activity of various potential catalysts for the polymerisation of ethene or propene were as follows. A solution of toluene (ca. 50 ml), containing the appropriate catecholborylcyclopentadienylmetal complex (ca. 16 μmol) and MAO (ca. 3.2 mol) was placed under an atmosphere of ethene or propene (1.4 bar) at ambient temperature; after ca. 1 h, the mixture was quenched with a solution of HCl in methanol.

Under these conditions $[Zr(\eta^5\text{-}C_5H_4BCAT)_2Cl_2]$ (**3a**) and propene afforded a viscous oil. The ^1H NMR spectrum in $CDCl_3$ (Fig. 1) showed it to be low molecular weight atactic polypropylene (PP). In the light of the low activity of this catalytic system, producing ca. 50 kg PP mol^{-1} Zr^{-1} bar^{-1}, as well as the low average molecular weight (M_w) of the PP (M_w: 3360, GPC), no further catalytic experiments with C_3H_6 were carried out.

Several of the metal complexes **2**–**7** were next examined as procatalysts for the polymerisation of ethene in the presence of an excess of MAO in toluene, using the mild conditions indicated above. Surprisingly, the titanium complexes $[Ti(\eta^5\text{-}C_5H_4BX)Cl_3]$ [BX = BCAT

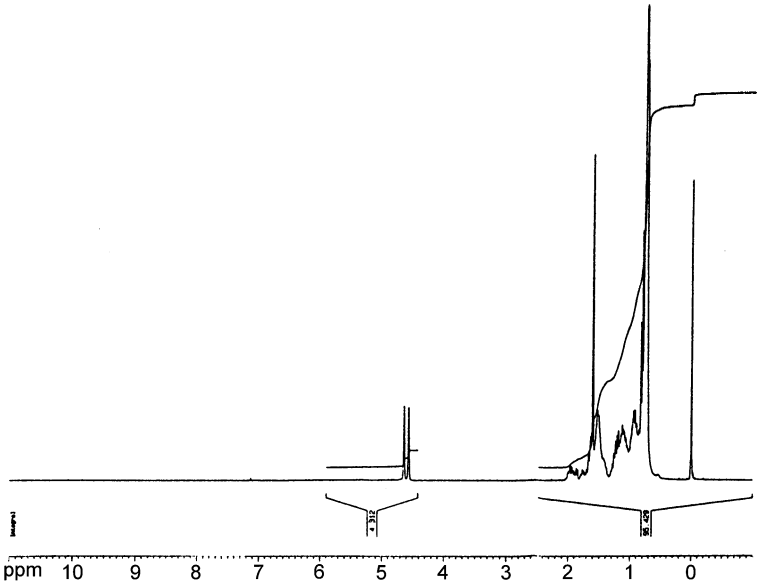

Fig. 1. The ^1H NMR spectrum of the produced polypropylene from $[Zr(C_5H_4BCAT)_2Cl_2]$ (**3a**) with MAO in $CDCl_3$ at 298 K and 300 MHz.

[a] ETA is the viscosity index.
[b] M_w is the weight-average molecular weight.
[c] M_n is the number average molecular weight.
[d] Q is the polydispersity, M_w/M_n.

(**2a**), BCAT^t (**2b**), BCAT^{tt} (**2c**)], as well as the 4f element analogues **7a**–**7c**, proved to be inactive. However, the majority of the zirconium and hafnium complexes **3**–**6** afforded polyethylene of moderate average molecular weight (M_w) and fairly high polydispersity (Q), somewhat typical of Ziegler Natta systems. The results are summarised in Table 1; comparison with zirconocene chloride under the same conditions reveals that the new complexes are slightly less active than $[ZrCp_2Cl_2]$.

The data of Table 1 raised the possibility that the catecholboryl moiety in each of the metal complexes there cited had been cleaved by treatment with MAO. In further support for this hypothesis were the following observations from the literature: (i) treatment of $C_5H_5BEt_2$ with Li^{n}Bu in hexane or Na[HBEt] in Et_2O under mild conditions caused the fission of the B–Cp bond, yielding LiCp or NaCp, respectively [8]; (ii) the B–O bond of borates $B(OR)_3$ is readily ruptured by organometallic reagents, as in the formation of BMe_3 from $B(OMe)_3$ and $AlMe_3$ [9]. Hence, a large excess of MAO was added to a solution of $[Zr(\eta^5\text{-}C_5H_4\text{-}BCAT^t)_2Cl_2]$ (**3c**) in toluene and the ^{11}B NMR spectrum recorded. Whereas the spectrum of **3c** in toluene showed the ^{11}B chemical shift at $\delta = 29.9$, the above experiment revealed a single ^{11}B resonance at $\delta = 84$. We conclude that the reaction of **3c** with MAO may have yielded $[Zr(\eta^5\text{-}C_5H_4BMe_2)_2Cl_2]$. Furthermore, it was shown, by using the same technique, that B(CAT)Cl reacted with MAO in toluene.

2.2. Trends in ^{11}B NMR spectral chemical shifts

^{11}B NMR spectroscopy of organic boron compounds provides a method of studying the environment at the boron atom. There is no direct link between the ^{11}B NMR spectral chemical shift $\delta[^{11}B]$ and the electron density at the corresponding boron atom. Nevertheless, in related series of compounds there is at least a qualitative correlation. For example, the trend in $\delta[^{11}B]$ (shown in parenthesis [10]) for $B(Me)_{3-n}(OMe)_n$ [BMe_3(86.3) > $BMe_2(OMe)$(53.1) > $BMe(OMe)_2$ (31.1) > $B(OMe)_3$(18.1)] corresponds to the progressive decrease of Lewis acidity of the four compounds.

The ^{11}B NMR spectral chemical shifts for the compounds **2**–**7a**, **8** and **9** in $CDCl_3$ at 298 K were in the range δ 26–30 [1,2]. Although these signals were broad, typically $\omega_{1/2} = 400$ Hz, they were reproducible to $\delta \pm 0.25$. Table 2 shows such data for the three related series: 1,2-phenylenedioxoboryl chlorides (Cl-BX) (**10a**–**10c**), trimethylsilylcyclopentadienes ($Me_3SiC_5H_4$–BX) (**1a**–**1c**), and trichlorotitanium η^5-cyclopentadienyls $[Cl_3Ti(\eta^5\text{-}C_5H_4\text{–}BX)]$ (**2a**–**2c**) [BX = BCAT (**a**), BCAT^t (**b**), BCAT^{tt} (**c**)].

The chemical shifts shown in Table 2 fall within a narrow range. Nevertheless, some minor trends are discernible, Fig. 2. (i) The *tert*-butyl substituents in the aromatic ring cause a shift in $\delta[^{11}B]$ to lower frequency (**a** > **b** > **c**) for the metal-free compounds **1** and **10**, consistent with the electron-releasing property of the ^{t}Bu groups being transmitted to the boron atom. (ii) A small frequency increase is noted by replacing the Cl atom of **10** by $Me_3SiC_5H_4$ in **1**. (iii) The π-electron acceptance by the Cl_3Ti moiety of **2** is reflected not only in a small low frequency shift ($\delta[^{11}B]$ for **2** < **1** or **10**), but also in neutralising the effect of the ^{t}Bu groups ($\delta[^{11}B]$ for **2a**–**2c** = 27.6 ± 0.4).

Table 2
^{11}B NMR spectral chemical shifts (δ, relative to $BF_3 \cdot OEt_2$) for compounds **1a**–**1c**, **2a**–**2c** and **10a**–**10c** in $CDCl_3$ at 298 K and 80.3 MHz

Compound	BX		
	BCAT	BCAT^t	BCAT^{tt}
Cl-BX (**10**)	29.0 (**10a**)	28.2 (**10b**)	26.4 (**10c**)
$Me_3SiC_5H_4$–BX (**1**)	29.5 (**1a**)	29.3 (**1b**)	28.1 (**1c**)
$Cl_3Ti(\eta^5\text{-}C_5H_4\text{–}BX)$ (**2**)	27.2 (**2a**)	27.9 (**2b**)	27.6 (**2c**)

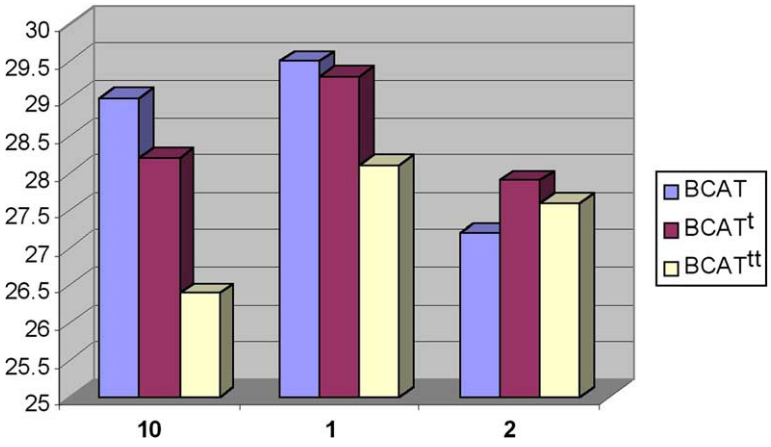

Fig. 2. Variation of $\delta[^{11}B]$ as a function of complex type (**10**, **1**, or **2**) and 1,2-phenylenedioxoboryl [BCAT (**a**), BCAT^{t} (**b**), or BCAT^{tt} (**c**)].

It is noted that the $\delta[^{11}B]$ value for the boron product of the reaction of **3c** with MAO, $\delta = 84$, is consistent with our assignment (Section 2.1) as due to $[Zr(\eta^5\text{-}C_5H_4BMe_2)_2Cl_2]$ (cf. the close correspondence to $\delta[^{11}B] = 86.3$ for BMe_3 [10]).

2.3. Cyclic voltammetry for a selection of 1,2-phenylenedioxoboryl compounds

Measurements were recorded in THF with $[N^nBu_4][PF_6]$ as supporting electrolyte at a platinum working electrode. Potentials were internally referenced to the ferrocene–ferrocenium redox couple. Results are summarised in Table 3.

Bis(4-*tert*-butylbenzene-1,2-dioxoborylcyclopentadienyl)zirconium(IV) chloride (**3c**) exhibited three, one-electron reductions in the range 0 to −2 V, Fig. 3. Both of the first two reductions showed peak-reverse to peak-forward current, i_p^f/i_p^r, equal to unity; and ΔE_{pp}, the difference between the potentials at peak-cathodic and peak-anodic potentials, for each of the first two was close to the 59 mV expected for thermodynamic reversibility. The final reduction waveform was, however, quasi-reversible, indicated by i_p^f/i_p^r being greater than unity and $\Delta E_{pp} = 180$ mV.

Likewise, bis(4-*tert*-butylbenzene-1,2-dioxoborylcyclopentadienyl)hafnium(IV) chloride (**3d**) exhibited three one-electron reductions in the range 0 to −2.5 V. In this case, the first reduction was quasi-reversible, with i_p^f/i_p^r being less than unity and $\Delta E_{pp} = 130$ mV. The latter reductions were irreversible with little reverse current being observed.

The ferrocene derivative **9** exhibited a partially reversible waveform in the oxidation sweep due to the Fe^{2+}/Fe^{3+} couple. Although the peak-reverse to peak-forward current i_p^f/i_p^r, was equal to unity, ΔE_{pp} was much greater than the required 59 mV for reversibility. Two quasi-reversible one-electron reductions were also

[a] A 2×10^{-3} solution in THF, containing 0.2 mol dm^{-3} $[N^nBu_4][PF_6]$ as supporting electrolyte, at a platinum working electrode. Potentials were internally referenced to the ferrocene–ferrocenium redox couple (+0.535 V with respect to s.c.e.). Values quoted were obtained at 200 mV s^{-1}.

[b] E_o is the potential measured halfway between the potentials of peak-cathodic and -anodic currents where the signal is reversible, or the potential of the peak-anodic current in the case of the irreversible signals.

[c] ΔE_{pp} is the difference between the potentials at peak-anodic and peak-cathodic potentials.

[d] The ratio of peak-forward to peak-reverse currents.

[e] Not measured, as signal was irreversible.

[f] Waveform due to oxidation of free anionic cyclopentadienyl ligand.

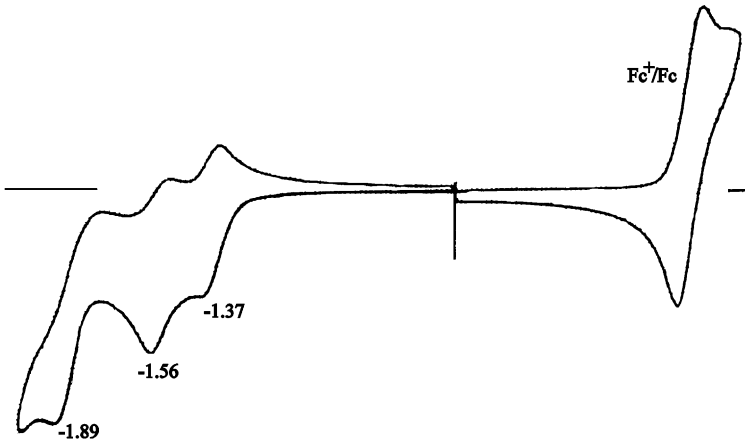

Fig. 3. The cyclic voltammogram of $[Zr\{\eta^5\text{-}C_5H_4(BCAT^t)\}_2Cl_2]$ (**3c**) in THF, at a vitreous carbon electrode, 200 mV/s sweep rate.

observed in the reverse sweep in the range 0 to −1.6 V. In both cases, i_p^f/i_p^r was not equal to unity and ΔE_{pp} was greater than 59 mV.

The only obvious difference between these complexes and other previously reported related species, such as $[Zr(\eta^5\text{-}C_5H_4SiMe_3)_2Cl_2]$ (E° −1.60 V, ΔE_{pp} 0.22 V, i_p^f/i_p^r 1.0 [11]) is the substituent. It is proposed, therefore, that the further unexpected reductions were due to the 1,2-phenylenedioxoboryl substituent. In that context, it is noteworthy not only that triarylboranes BAr_3 are well known to form one- or two-electron reduction products by treatment with sodium: $[BAr_3]^-$, $[Ar_3B\text{–}BAr_3]^{2-}$ or $[BAr_3]^{2-}$ [12], but also that ferrocenyldi(chloro)borane displayed partially reversible reduction waves at −0.16 and −0.33 V (as well as the reversible one-electron oxidation at $E_{1/2}$ 0.45 V, a similar value to that found for ferrocene) [13].

In an effort to discover whether these further reductions were boron-centred, the precursors to the borylcyclopentadienyl ligands were examined. Thus, 4-*tert*-butylbenzene-1,2-dioxo(chloro)borane (**10a**) was therefore studied; it did not show a reduction product in the range 0 to −3 V, but displayed a single waveform in the oxidation sweep due to Cl^- oxidation. The inertness to reduction is attributed to the lack of a stabilising aryl substituent.

The parent borylcyclopentadiene $C_5H_4(BCAT)(SiMe_3)$ (**1a**) displayed a single, irreversible reduction in the range 0 to −2.5 V. To study further whether the presence of an aromatic substituent favoured reduction under cyclic voltammetric conditions, 1,2-phenylenedioxo(phenyl)borane (**11**) was examined; it underwent two one-electron reductions. Although both were irreversible, it appeared that at higher scan rates the waveforms became more reversible.

If it is assumed that reduction at boron is possible due to the availability of a formally vacant p-orbital, it may prove possible to hinder this by coordination of a Lewis base to the Lewis acidic boron. Thus, the pyridine adduct $[Zr\{\eta^5\text{-}C_5H_4(BCAT^t)\}_2Cl_2(py)_2]$ (**12**) was studied. The reduction sweep in the range 0 to −2.5 V showed that a single, irreversible reduction was observed, which occurred at the same potential as the first (reversible) reduction of $[Zr\{\eta^5\text{-}C_5H_4(BCAT^t)\}_2Cl_2]$ (**3c**). Thus, the coordinated pyridine did not prevent the reduction at boron occurring; the second and third (boron-centred) reductions were observed, but were poorly defined.

The collected data from these experiments leads to several conclusions. The presence of two extra reduction waves in the cyclic voltammograms of the metal complexes studied is attributed to two sequential one-electron reductions at boron. The first of these appears to be more reversible than the second, which is consistent with previous experimental results on a borylferrocene [13]. The reduction potentials for **3c** and **3d** are significantly lower than in the appropriate $[M(\eta^5\text{-}C_5H_4SiMe_3)_2Cl_2]$ (M = Zr or Hf) [11], which is consistent with the view that the borylcyclopentadienyl ligands are removing electron density from the metal centre. A slightly greater oxidation potential for the iron complex **9** compared with ferrocene is in agreement with this conclusion.

The trichlorotitanium complex **2a** exhibited complex electrochemistry at ambient temperature, displaying several irreversible reduction waveforms in the range 0 to −2.2 V, Fig. 4. Three irreversible reduction products were observed, the first at −1.07 V. In the reverse sweep, an irreversible oxidation process was seen at −0.27 V, consistent with the oxidation of a free anionic cyclopentadienyl ligand [11]. The forward sweep exhibited a strong irreversible oxidation process, due to chloride oxidation. This oxidation [14] process hindered internal referencing to the Fc^+/Fc redox couple. Cooling the sample to 0 °C greatly simplified the electrochemistry, Fig. 5. A single irreversible reduction was now apparent

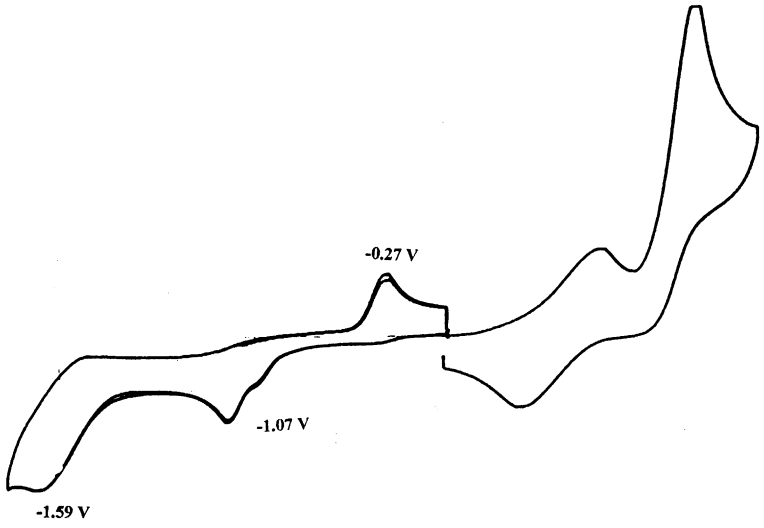

Fig. 4. The cyclic voltammogram of $[Ti\{\eta^5\text{-}C_5H_4(BCAT)\}Cl_3]$ (**2a**) at 20 °C in THF, at a vitreous carbon electrode, 200 mV/s sweep rate.

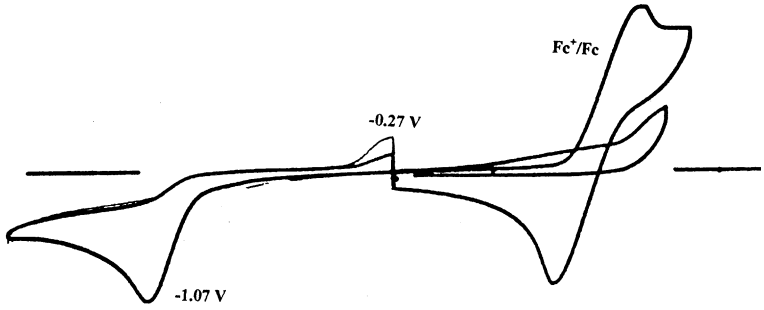

Fig. 5. The cyclic voltammogram of $[Ti\{\eta^5\text{-}C_5H_4(BCAT)\}Cl_3]$ (**2a**) at 0 °C in THF, at a vitreous carbon electrode, 200 mV/s sweep rate.

in the reverse sweep at −1.07 V. An irreversible oxidation process at −0.27 V, due to cyclopentadienyl oxidation, was still observed. The forward sweep was also simplified at lower temperature. Chloride oxidation became less prevalent, allowing internal referencing to the Fc^+/Fc redox couple. Broadening of the reference waveform was observed due to partial precipitation of the $[N^nBu_4][PF_6]$ electrolyte. The analogous complexes **2b** and **2c** behaved similarly.

2.4. EPR spectral studies on electrochemically generated radicals

We had earlier collected EPR spectroscopic data on Ti(III) [15a] and Zr(III) [15b] complexes, electrochemically generated from corresponding metallocene precursors $[MCp^x_2Cl_2]$ $[Cp^x = C_5H_5,\ C_5H_4SiMe_3,$ or $C_5H_3(SiMe_3)_2$-1,3, abbreviated as Cp, Cp′, or Cp″, respectively]. We now present for comparison similar data on the Ti(IV) compound **2a** and the Zr(IV) metallocene **3c**, as summarised in Table 4. The spectra were obtained by controlled potential electrolysis of the appropriate sample in THF with $[N^nBu_4][PF_6]$ as supporting electrolyte at −40 °C; the potential employed was only slightly greater than that at which the first reduction was observed for **2a**, **3c** and $[TiCp''_2Cl_2]$ [15a]; for $[ZrCp''_2Cl_2]$ only a single reversible reduction had been found [15b].

Electrolysis of $[Zr\{\eta^5\text{-}C_5H_4(BCAT^t)\}_2Cl_2]$ (**3c**) under these conditions gave rise to the EPR spectrum

Table 4
EPR spectroscopic data for M(III) (Ti or Zr) complexes, generated by in situ electrolysis

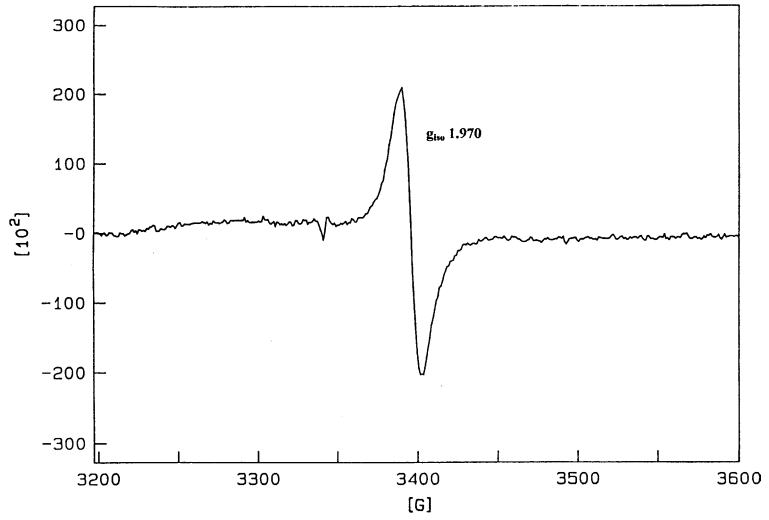

Fig. 7. The EPR spectrum of the electrochemically reduced $[Ti\{\eta^5\text{-}C_5H_4(BCAT^t)\}Cl_3]$ (**2a**) in THF at 223 K.

shown in Fig. 6, attributed to the d^1 reduction product $[Zr\{\eta^5\text{-}C_5H_4(BCAT^t)\}_2Cl_2]^-$. Increasing the applied potential to a greater negative voltage did not give rise to a further signal. A similar study of $[Ti\{\eta^5\text{-}C_5H_4(BCAT^t)\}Cl_3]$ (**2a**) gave a broad signal (Fig. 7), which by recording the second harmonic spectrum (Fig. 8) was shown to be derived from overlapping signals assigned to $[Ti\{\eta^5\text{-}C_5H_4(BCAT^t)\}Cl_3]^-$ and $[Ti\{\eta^5\text{-}C_5H_4(BCAT^t)\}Cl_2]$, respectively. The evidence is based on analogy with the $[TiCp''_2Cl_2]$ system, a detailed study of which concluded that the electrolysis products were $[TiCp''_2Cl_2]^-$ and $[TiCp''Cl_2]$, the latter formed by the decay of the former (Section 2.3).

3. Experimental

The 1,2-phenylenedioxoborylcyclopentadienes [1] and their metal complexes [2] were prepared and characterised as described in our two earlier papers.

3.1. Polymerisation experiments

In a typical experiment, $[Zr\{\eta^5\text{-}C_5H_4(BCAT)\}_2Cl_2]$ (**3a**) (8.5 mg, 16.1 mol) in toluene (50 cm^3) at room temperature was activated with MAO (approximately 200 molar excess, 10% by weight solution in toluene). The catalytic mixture was placed under an ethene atmosphere of 1.4 bar pressure for 1 h at room temperature. The mixture was then quenched with MeOH/HCl, filtered and the collected PE dried at 50 °C.

For the homogeneous polymerisation of propene with **3a**, the reaction conditions were identical to those described above. The PP produced was isolated by standard organic procedures, producing a viscous oil which was analysed by ^1H NMR spectroscopy.

3.2. Electrochemistry

Cyclic voltammetry measurements were initially carried out using a vitreous carbon electrode, and then

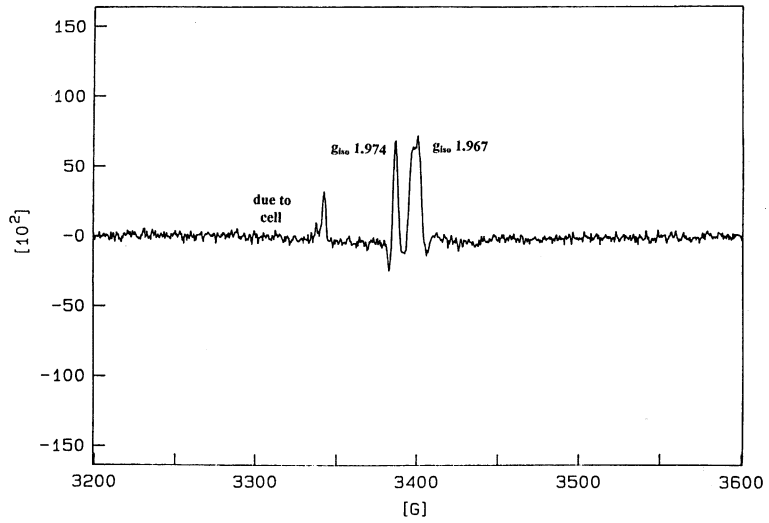

Fig. 8. The second harmonic EPR spectrum of the electrochemically reduced [Ti{η^5-C_5H_4(BCAT^t)}Cl_3] (**2a**) in THF at 223 K.

repeated at a platinum electrode, using a three electrode system. A Hi-Tek Instruments DT2101 potentiostat and waveform generator, connected to a Philips PM8042 X-Y recorder were utilised. All potentials were internally referenced to the potential for the one-electron oxidation of ferrocene (+0.535 V with respect to the standard calomel electrode = 0 V). The supporting electrolyte in all cases was tetra-*n*-butylammonium hexafluorophosphate; electrolysed solutions were 0.2 mol dm^{-3} in supporting electrolyte and approximately 2 mmol dm^{-3} in metal complex. The general experimental procedure was based upon that described in the literature [16].

3.3. EPR spectra

X-band EPR spectra were recorded with a Bruker ESP-300 spectrometer. The electrochemically produced species were generated in situ at a platinum electrode by a controlled potential electrolysis using a three electrode configuration at potentials slightly greater than the measured reduction potential of the complex. The apparatus used was a modification of that previously described [17]. Electrolyses were carried out at −40 °C using the Varian variable-temperature attachment.

Acknowledgements

We are grateful to BASF (and Dr. Marc Kristen) for the award of a studentship to M.J.D. and for facilitating the characterisation of the PE samples.

Abstract

W(IV) and Nb(IV) derivatives: [W(L1)MeI] (**1**), [W(L1)MeH] (**2**) and [W(L1)O] (**3**), [W(L2)Cl_2] (**4**), [W(L2)H_2] (**5**), [W(L2)H_3][BF_4] (**6**), [Nb(L2)Cl_2] (**7**) and [Nb(L2)(η^2-BH_4)] (**8**), where L1 = [(η-C_5H_4)$_2$$SiMe_2$]$^{2-}$ and L2 = [(η-C_5H_3TMS)$_2$$SiMe_2$]$^{2-}$, have been prepared and characterised. The crystal structures of compounds **5** and **8** have been determined. Thermodynamic parameters for the elimination of methane from compound **2** have been evaluated based on ^{1}H NMR studies in C_6D_6. Trimethylsilyl substituents on the cyclopentadienyl rings appear to moderate the structural and dynamic properties of the silicon-bridged *ansa*-tungstenocenes.

Keywords: *Ansa*-metallocenes; Methane elimination; Organometallics

1. Introduction

Early transition metals complexes incorporating *ansa*-metallocenes are of widespread interest as catalytic precursors in organic synthesis [1–4]. We and others have shown that the presence of an *ansa*-bridge induces a significant modification of the electronic properties and hence reactivity of metallocene compounds, compared to the analogous non-bridged compounds [5–25,15,26–50]. These developments have led to considerable growth in the study of bridged- or '*ansa*'-metallocenes. We have undertaken to study the relationship between structure and reactivity in *ansa*-metallocenes. Earlier work on silicon-bridged metallocenes of Groups 5–7 [19,25,30] has highlighted the changes in reactivity that the *ansa*-bridge brings to the chemistry of the dihydride compound [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}H_2] with respect to that of [W(η-C_5H_5)$_2$$H_2$] and [W{($\eta$-$C_5H_4$)$CMe_2$($\eta$-$C_5H_4$)}$H_2$]. This work includes ^{1}H NMR studies of the corresponding trihydride cations and the reactivity of the dihydride compounds towards photolysis in benzene [19,25,51,52].

Here, we report new synthetic and spectroscopic studies of silicon-bridged W(IV) and Nb(IV) *ansa*-metallocenes with both unsubstituted and substituted cyclopentadienyl rings. Also, the thermodynamic parameters for the elimination of methane from a silicon-bridged *ansa*-tungstenocene are discussed.

2. Results and discussion

2.1. Syntheses

The preparation of [Li_2{(C_5H_4)$SiMe_2$(C_5H_4)}] (**Li_2L1**) has been reported elsewhere [25]. $WCl_4 \cdot DME$ and **Li_2L1** were stirred together in the absence of solvent. Diethyl ether was then added at −78 °C and after stirring for 3 days the compound [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Cl_2] was isolated as a brown solid [25]. The compound [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me_2] was subsequently prepared via a procedure analogous to that described earlier [25]. Reaction of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me_2] with NH_4I (in THF at 65 °C) gave [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}MeI]

(**1**) as a green powder in 19% yield. The treatment of [W(η-$C_5H_5)_2$MeI] with sodium *bis*(2-methoxyethoxy)aluminium hydride, [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}], gave the corresponding metal hydride has been reported [53] and has been successfully applied to give *ansa*-tungstenocenes such as [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}(I)] ($n = 2$, 1, 0) [14,53].

In an analogous procedure, compound **1** was treated with [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}] in toluene at −78 °C to give, after cautious hydrolysis of excess [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}], the compound [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me(H)] (**2**) as a yellow crystalline solid in 63% yield.

The action of NaOH on the dichloride [W(η-$C_5H_5)_2Cl_2$] yields the oxo complex [W(η-$C_5H_5)_2$O] [54,55]. We have prepared [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}O] (**3**) by applying a similar method (Scheme 1). The compound [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Cl_2] was treated with excess KOH in a 1:1 mixture of H_2O and ethanol. A colour change from brown/green to blue was observed, and subsequent removal of volatiles gave **3** as a red/blue crystalline solid in 46% yield.

For the preparation of [Li_2{(C_5H_3TMS)$SiMe_2$(C_5H_3TMS)}] (**Li_2L2**), [Na(C_5H_5)] was reacted with Me_3SiCl in THF, to give C_5H_5TMS, which was further purified by distillation under reduced pressure. Addition of ^{n}BuLi to C_5H_5TMS in petroleum ether (b.p. 40–60 °C) at −78 °C resulted in the formation of [Li(C_5H_4TMS)]. Me_2SiCl_2 was added to a suspension of this air- and moisture-sensitive solid in THF and the resulting ligand [(C_5H_4TMS)$SiMe_2$(C_5H_4TMS)] (**H_2L2**) was isolated. Addition of ^{n}BuLi at −78 °C resulted in the formation of **Li_2L2** as an air- and moisture-sensitive solid in 64% yield (Scheme 1). (*N.B.* Synthesis of [K_2{(C_5H_3TMS)$SiMe_2$(C_5H_3TMS)}] (**K_2L2**) has been reported previously in the preparation of *ansa*-zirconocenes [56]).

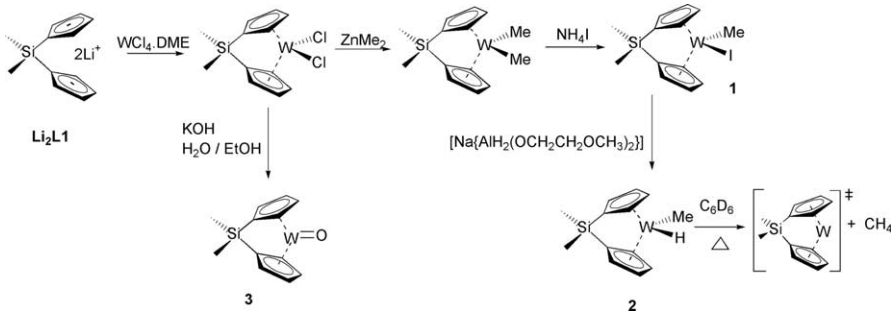
The compound [W{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}-Cl_2] (**4**) was prepared by an analogous method with [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Cl_2] [25]. For the synthesis of [W{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}H_2] (**5**), addition of an excess of $LiAlH_4$ as a suspension in diethyl ether to a suspension of **4** in diethyl ether at −78 °C resulted in a gradual colour change from dark brown to orange as the reaction mixture warmed to room temperature. The orange suspension was stirred overnight before the excess $LiAlH_4$ was hydrolysed with distilled water. Compound **5** was isolated as yellow crystals in 22% yield. Protonation of *ansa*-tungstenocene dihydrides to form the corresponding trihydride species [14,25] was carried out by the addition of a solution of HBF_4 in diethyl ether to a suspension of compound **5** in diethyl ether. As a result, the cationic trihydride species [W{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}H_3][BF_4] (**6**) [14,25] was obtained as a flocculent, air-sensitive white solid in 59% crude yield and was used in ^{1}H VT NMR experiments without further purification.

The TMS-substituted compound [Nb{(η-C_5H_3TMS)-$SiMe_2$(η-C_5H_3TMS)}Cl_2] (**7**) was prepared via a method similar to that used to synthesise [Nb{(η-C_5H_4)$SiMe_2$-(η-C_5H_4)}Cl_2] [30]. A suspension of [Li_2{(C_5H_3TMS)-$SiMe_2$(C_5H_3TMS)}] in THF was added slowly to a suspension of $NbCl_4 \cdot 2THF$ in THF at room temperature. After work-up, complex **7** was obtained as a dark brown solid, in 50% yield (Scheme 2). Reaction between [Nb{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}Cl_2] and $LiBH_4$ was performed [30] to yield the corresponding tetrahydroborate derivative [Nb{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}(η^2-BH_4)] (**8**). Treatment of **7** with excess $LiBH_4$ in DME at room temperature gave green, extremely air-sensitive, crystals of **8** in 58% yield (Scheme 2).

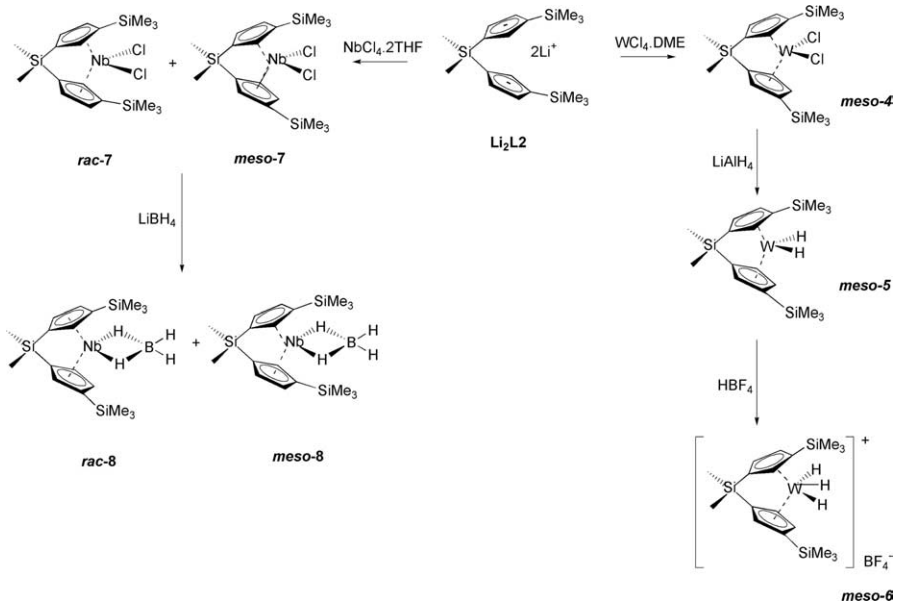
The complexes **1**–**8** have been characterised by elemental analysis, mass spectrometry (FAB^+), infrared, ^{1}H and $^{13}C\{^1H\}$ NMR spectroscopy and selected data are given in Table 1. Structure–relationship correlations in the series of metal-hydrides **5**, **6**, and **8** have been investigated by ^{1}H NMR and IR spectroscopies and are discussed below. In case of compounds **5** and **8**, the structures were confirmed by single crystal X-ray diffraction.

2.2. ^{1}H NMR studies

The ^{1}H NMR spectrum of **5** (in C_6D_6, Fig. 1) contains partial triplets at δ 4.99, 4.32 and 4.24 corresponding to the cyclopentadienyl protons. A singlet at δ 0.34 arising from the 18 protons of the two TMS groups on the cyclopentadienyl rings is also observed, as well as two singlets at δ 0.25 and −0.16 corresponding to the protons on the inequivalent methyl groups on the $SiMe_2$ bridge. Two further doublets at δ −10.31 and −10.68



Scheme 1. Syntheses of silicon-bridged W(IV) *ansa*-metallocenes with unsubstituted cyclopentadienyl rings.



Scheme 2. Syntheses of silicon-bridged W(IV) and Nb(IV) *ansa*-metallocenes with TMS-substituted cyclopentadienyl rings.

were assigned to the two inequivalent hydride protons. Associated with these doublets were the characteristic ^{183}W satellites with $^{1}J_{WH} = 83.8$ and 80.0 Hz respectively. $^{1}J_{WH}$ of **5** is similar to that for the unsubstituted silicon- and ethylene-bridged analogues (Table 2) and this value is also mid-way between that of the unbridged and Me_2C-bridged compounds. It appears that a silicon-bridge does not constrain the rings as much as a Me_2C-bridge.

The $[W(\eta\text{-}C_5H_5)_2H_3]^+$ cation shows a H_A–H_B coupling constant, J_{AB}, of 8.5 Hz at all temperatures [52]. However when an *ansa*-bridge is introduced between the cyclopentadienyl rings the J_{AB} varies with temperature by several orders of magnitude [14,25]. For $[W\{(\eta\text{-}C_5H_4)SiMe_2(\eta\text{-}C_5H_4)\}H_3][BF_4]$, J_{AB} varies from 8 Hz at 133 K to 75 Hz at 273 K, while for $[W\{(\eta\text{-}C_5H_4)C_2Me_4(\eta\text{-}C_5H_4)\}H_3][Cl]$, J_{AB} is found to vary from 8 Hz at 193 K to 35 Hz at 293 K [25]. The compound $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}H_3][PF_6]$ shows more extreme behaviour with J_{AB} varying from 2900 Hz at 133 K to 16 000 Hz at 203 K [14]. The main change in this series is that the inter-ring angle α increases (i.e. the bending angle β decreases, see Table 3 for details) as the bridge becomes more sterically constraining. This has been explained in terms of the ability of the hydride ligands to undergo quantum mechanical exchange coupling [57]. J_{AB} has two distinct contributors: $J_{AB} = -2J_{ex} + J_m$, where J_m is the *classical component* (i.e. the result of conventional Fermi contact interaction, temperature-independent and typically between 2 and 28 Hz) and J_{ex} is the *quantum mechanical exchange coupling*. The coupling J_{ex} arises from the quantum mechanical exchange of a pair of identical hydrogens, H_1 and H_2 between two chemically inequivalent sites, **A** and **B**. There are two possible configurations, which can be associated with two potential energy wells separated by an energy barrier (a ''double-well'' model). Tunnelling through this energy barrier gives rise to the quantum mechanical exchange coupling, as rationalised by Sabo-Etienne and Chaudret [58]:

(1) A soft bending vibration allows close approach of the two exchanging hydrogens.
(2) This vibration initiates a chemical pathway which brings the exchanging hydrogens closer together than the sum of their van der Waals radii.
(3) The barrier to chemical (classical) exchange must be between 35 and 75 kJ mol^{-1} to allow quantum mechanical exchange coupling to be observed by ^{1}H NMR spectroscopy.
(4) There is vibrational and rotational tunnelling through the energy barrier.
(5) The observed temperature dependence of J_{ex} is a consequence of thermal population of excited vibrational states.

The variable temperature ^{1}H NMR experiment on compound **6** showed temperature-independent behaviour. At room temperature the high field region was found to have a pair of triplets at δ −6.19 and −6.32 ppm (corresponding to a single proton) and a pair of doublets at δ −6.55 and −6.69 ppm (corresponding to two protons). The J_{AB} coupling constant was found to be 8.20 Hz at all temperatures, hence no evidence of quantum mechanical exchange coupling can be assumed in case of **6**. This behaviour is similar to that of the non-bridged trihydride $[W(\eta\text{-}C_5H_5)_2H_3]^+$ which exhibits a temperature-independent ^{1}H NMR spectrum with J_{AB} of 8.5 Hz [59]. This experiment suggests that the presence of bulky

NMR data are given as chemical shift (δ) [multiplicity, relative intensity, assignment, coupling] at 298 K unless otherwise stated.
All IR data are expressed in wavenumbers (cm^{-1}). For the FAB mass spectrometry data, the characteristic isotope patterns were observed.
[a] Low solubility in common solvents prevented reliable NMR measurements.

TMS groups in *ansa*-metallocenes could induce changes in the structural properties such that these species' behaviour resembles more closely that of their non-bridged analogues.

The room temperature ^{1}H NMR spectra of compound **8** showed the presence of both *rac*- and *meso*-isomers, in the ratio of 1:2. In order to investigate the exchange between bridging and terminal hydrogens in the BH_4 ligand in compound **8**, a variable temperature ^{1}H NMR study was undertaken. Partial variable temperature ^{1}H NMR ($C_6D_5CD_3$) spectra between 193 and 363 K are shown in Fig. 2. At high temperature, exchange is fast on the NMR timescale and a single broad resonance is observed at δ −5.1 ppm. As temperature is decreased this resonance

broadens until coalescence occurs at $T_c = 291 \pm 3$ K. Below the coalescence temperature T_c a broad resonance is observed centred at δ 5.65 ppm, corresponding to the bridging M–H–B protons. There are also three singlets, at δ −14.79, −14.91 and −15.31 ppm, corresponding to the terminal B–H protons of the *rac*- and *meso*-isomers. The free energy barrier $\Delta G^{\ddagger}$ at the coalescence temperature to bridge-terminal hydrogen exchange (calculated according to equation: $\Delta G^{\ddagger}$ (kJ mol^{-1}) $= 10^{-3}[RT_c(22.96 + \ln(T_c/\Delta v))]$) was evaluated from a variable temperature ^{1}H NMR study to be $\Delta G^{\ddagger} = 48.1 \pm 1$ kJ mol^{-1}. This is within the same range with the values found for related niobium metallocene tetrahydroborate complexes (Table 4). Here we assumed that $\Delta S^{\ddagger}$ for the exchange process is essentially the same for all species, and exchange proceeds via the same mechanism in all cases. The presence of an *ansa*-bridge reduces $\Delta G^{\ddagger}$ for the exchange process for the niobium complexes. The effect is most pronounced when the bending angle β is reduced the most, as in the case of the methylene-bridged compound. A silicon- or ethylene-bridge has a less marked effect both in the reduction of $\Delta G^{\ddagger}$ and the reduction of β (Tables 3 and 4). The barrier to exchange of the TMS substituted compound is similar to that for the unsubstituted silicon-bridged compound, and is consistent with the similarity in structural properties between compound **8** and the unsubstituted silicon-bridged compound. Density functional theoretical calculations (DFT) rationalised the changes in structure and reactivity of metallocenes upon introduction of an *ansa*-bridge and provided an explanation for the dynamic properties of related tetrahydroborate complexes [28,32,60,61]. A mechanism proposed for bridge-terminal hydrogen exchange is shown in Fig. 3. Based on the analogy between **8** and our earlier systems (described by NMR experiments and DFT modelling [28,32,60,61]), we assumed that at the mid-point of the exchange reaction the interchanging hydrogens are in equivalent positions. In the mechanism proposed, this equivalence is ensured by the presence of a mirror plane over *xz*. As a result H_a stays in the same position throughout the exchange process. The energy difference between the ground and transition states for the compounds studied was found to be in good agreement with the experimental values of $\Delta G^{\ddagger}$, making the proposed mechanism a good candidate for the exchange process. The introduction of an *ansa*-bridge increases the angle between the rings, α, and decreases the bending angle, β. This is manifested most

in the case of the methyl-bridged compound. This structural change reduces the covalent M–BH_4 interaction in the groundstate, while increasing the binding in the proposed transition state. This as a result facilitates the interchanging of the terminal and bridging hydrogens in the η^2-BH_4 unit [32]. In the case of the compound **8**, these factors are shown to reflect those found in the unsubstituted silicon- and ethyl-bridged compounds.

2.3. IR spectra

Compound [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}O] (**3**) was characterised by elemental analysis, FAB mass spectrometry and infrared spectrometry (Table 1). The infrared stretching frequency was observed at 869 cm^{-1}. This is comparable to the values observed for *v*(W=O) in the related *oxo*-tungsten complexes [W{(η-C_5H_5)$_2$}O] of 799–879 cm^{-1}, and [W{(η-C_5H_4Me)$_2$}O], of 850 cm^{-1} [54,55].

The infrared spectrum of **5** (Nujol) showed two strong bands at 1895 and 1871 cm^{-1}, attributed to W–H stretching modes. Table 4 gives a comparison of *v*(W–H) stretching frequencies within the series. The values of *v*(W–H) show that the presence of an *ansa*-bridge reduces the stretching frequency, suggestive of a weakened W–H bond. This is most striking in the case of the methylene-bridged dihydride [W{(η-C_5H_4)CMe_2(η-C_5H_4)}H_2]. Compound **5** shows *v*(W–H) values between those of the unsubstituted silicon-bridged and the non-bridged analogue; this indicates that the trimethylsilyl groups have the effect of reducing the strain on the bridged system. DFT calculations have shown that, as the angle between the rings α is increased and thus the corresponding bending angle β is decreased, additional ligands at the metal centre of a metallocene become more weakly bound [32]. Compound **5** has a bending angle β of 135.13°, compared to 129.6° for [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}H_2] [25]. It can be seen that the TMS groups have the effect of increasing the bending angle β relative to the unsubstituted silicon-bridged *ansa*-tungstenocene. As a result the stretching frequency of W–H is increased, suggesting a relatively stronger bond.

The IR spectrum of the compound **8** shows four bands in the terminal B–H region at 2462, 2422, 2362, and 2336 cm^{-1} and four bands in the bridging H–B region at 1728, 1715, 1642, and 1631 cm^{-1}. This is consistent with the existence of both *rac*- and *meso*-isomers. The bands were assigned by analogy to [Nb(η-C_5H_5)$_2$(η^2-BH_4)] and are consistent with a bidentate η^2-BH_4 binding mode [62]. Covalent interaction between the metal and the BH_4 unit is shown by the difference in energy between the terminal B–H and bridging B–H stretches, with the terminal B–H bond stretches being higher in energy. These stretching frequencies are compared to other selected Group 5 metallocene tetrahydroborate complexes (Table 5). The relationship between the average symmetric and asymmetric

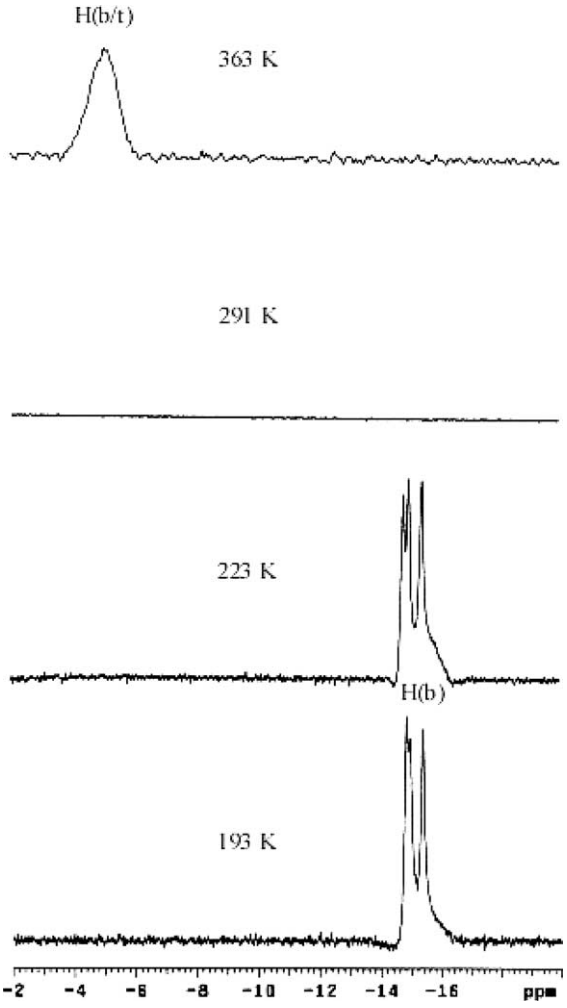

Fig. 2. Partial variable temperature ^{1}H NMR spectra of the compound [Nb{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}(η^2-BH_4)] (**8**).

stretching frequencies for the B–H_t and B–H_b bonds has been used as a gauge of the M–BH_4 covalent interaction [63]. The data suggest there is a strengthening of the B–H_b bonds and weakening of the B–H_t bonds in the methylene-bridged species ***B*** relative to the non-bridged analogue, suggesting a reduced M–BH_4 covalent interaction. The average stretching frequencies for the silicon- and ethylene-bridged complexes, ***C*** and ***D***, are similar to the non-bridged analogue ***A***. Earlier DFT studies have shown that as the bending angle β is reduced, two of the metal d-orbitals become more involved in metal-ring bonding and are less available for binding other ligands [32]. Complex **8** shows an average B–H_b stretching frequency expected for a silicon-bridged compound. The B–H_t stretching frequency is however lower than expected, indicating an increased B–H_t bond strength compared to the non-substituted silicon-bridged compound ***D***.

2.4. X-ray diffraction studies

A search of the Cambridge Structural Database revealed that a total of 239 *ansa*-metallocenes containing $SiMe_2$ as the bridging unit have been reported so far. However, only 7 of these are niobocenes [9–13,20,30] and 6 are tungstenocenes [17,25]. Tungsten- and niobium-hydrides of this family are still rare examples, probably on the account of their extremely high reactivity and particularly their air- and moisture-sensitivity. Crystals suitable for single crystal X-ray structural determination were obtained for the hydrides [W(L2)H_2] (**5**) and [Nb(L2)(η^2-BH_4)] (**8**), where L2 = [(η-C_5H_3TMS)$_2SiMe_2$]$^{2-}$. ORTEP diagrams for these compounds are presented in Figs. 4(a) and (b) and Fig. 5, and relevant molecular parameters are listed in Table 6. In all cases, molecular structural determinations are consis-

tent with the observations made by elemental analysis and NMR spectroscopy. The slow cooling of a concentrated solution of compound **5** in pentane to −80 °C gave single crystals suitable for X-ray molecular structure determination, which proved to be those of the *meso*-isomer. The asymmetric unit contains two (crystallographically unique) identical molecules. The structural parameters of **5** are similar to those of the silicon- and ethyl-bridged compounds but the rings are far more constrained in the case of the methyl-bridged compounds. The increased bending of the rings in the single-carbon bridged compounds corresponds to a significant decrease in the C_{ipso}–C_{ipso} distance. It is also noted that the angles ϕ are large in the case of single atom bridges; for compound **5**, ϕ were found to be 24.8° and 25.1°, i.e. somewhat larger than the ϕ values observed for the unsubstituted silicon-bridged analogue (of 21.9° and 20.7°) [25]. Note that the ϕ values found for the ethylene-bridged analogous compound were 3.8° and 3.3° [25].

Slow cooling of a concentrated solution of compound **8** in toluene to −80 °C afforded single crystals of the *meso*-isomer suitable for X-ray molecular structure determination, however the quality of these deteriorated rapidly during the data collection despite being handled under inert atmosphere and at low temperature. This accounts for the low data quality and the structure assignment is supported by evidence from other spectroscopic investigations. Selected interatomic distances and angles and other structural information are shown in Table 6. The molecular structure is shown in Fig. 5 and details of the structure determination are given in Table 7. Selected structural parameters for compound **8** are compared to other bridged and non-bridged niobocene tetrahydroborate compounds in Table 3b. The greatest influence on the structure is exerted by a single carbon-bridge. The bending angle β is reduced ca. 16° in the compound with the CMe_2 bridging unit. This compares to a reduction of ca. 2–3° in the case of the silicon- and ethylene-bridged compounds and compound **8**. There is a large deviation from planarity at the *ipso*-carbon atoms, with an average value of ϕ of ca. 17–20° for the single atom-bridged compounds, whereas for the ethylene-bridged compound $\phi = -2.5°$. Compound **8** shows similar structural properties to the unsubstituted silicon- and ethylene-bridged, and the non-bridged analogue.

(η-C_5H_4)}MeH] [19,14,60], the presence of the CMe_2 *ansa*-bridge was shown to induce a substantially increased thermal stability.

For [W(η-C_5Me_5)$_2$MeH] and [W{(η-C_5Me_4)$SiMe_2$(η-C_5Me_4)}MeH] [65] the *ansa*-bridge also *inhibits* the reductive elimination of CH_4, however, the same bridge was found to significantly *promote* reductive elimination in the related tantalum systems [21]. The investigation of the thermal stability of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}MeH] discussed here provides further information regarding the changes imparted on the reactivity of tungstenocene compounds upon the introduction of an *ansa*-bridge.

When the reductive elimination of methane from [W(η-C_5H_5)$_2$Me(H)] is performed at sufficiently low concentrations to avoid bimolecular reaction pathways, the elimination proceeds via an intramolecular mechanism supported by the first-order kinetics of the reaction [64,65]. The methyl-bridged *ansa*-tungstenocene was observed to have increased thermal stability relative to the non-bridged compound. This is of particular significance since both complexes display intramolecular hydrogen exchange between alkyl ligand and hydride sites [64,65]. The increased thermal stability in the CMe_2 *ansa*-compound is supported by a DFT study into hydrogen exchange and methane elimination from [W(η-C_5H_5)$_2$MeH] and [W{(η-C_5H_5)-CH_2(η-C_5H_5)}-MeH]. This showed that the tungstenocene [W(η-C_5H_5)$_2$] has a lowest energy structure in the triplet state; geometry optimisation predicts the non-bridged tungstenocene to have a ring angle of 172.1° due to a Jahn–Teller distortion [60]. This compares to a ring angle (β) of 127° in [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Me_2] [14] and 136° in [W{(η-C_5H_4)-$SiMe_2$(η-C_5H_4)}Me_2] [25]. This explains the differences in reaction enthalpies, both calculated and experimental, that enable the thermal elimination of methane to occur at much lower temperature for [W{(η-C_5H_5)$_2$}Me(H)] than for the CMe_2-bridged analogue.

First-order plots for the elimination of methane from **2** over the temperature range 55–80 °C are shown in Fig. 6. Reactions were followed by monitoring the decrease in intensity of a selected resonance (i.e. the hydride resonance, at δ −10.26) of the starting complex in C_6D_6. Reaction temperatures were maintained by using constant temperature baths (±1 °C). The high-field ^{1}H NMR spectra recorded at different times at 65 °C are shown in Fig. 7. The NMR tubes were sealed and total submersion in the

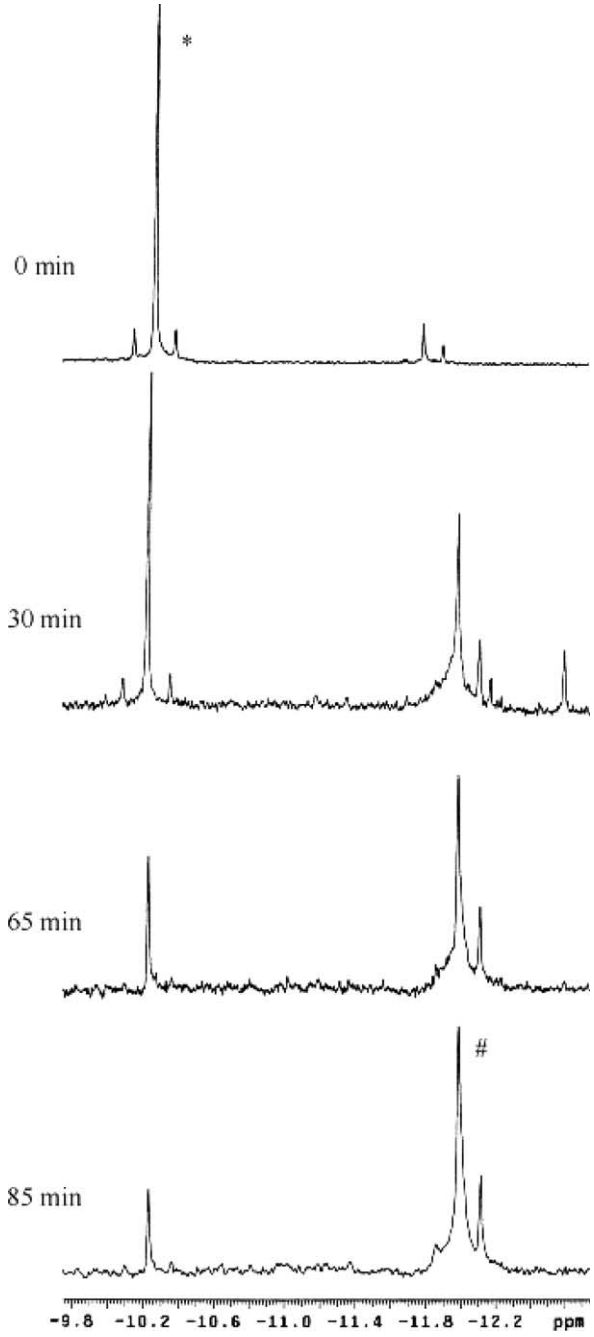

Fig. 7. Selected high field ^{1}H NMR spectra of elimination of methane from [W{(η-C_5H_5)$SiMe_2$(η-C_5H_5)}MeH] **(2)** at 65 °C (* denotes hydride peak in compound **2**, # denotes hydride peaks appearing in the high field region).

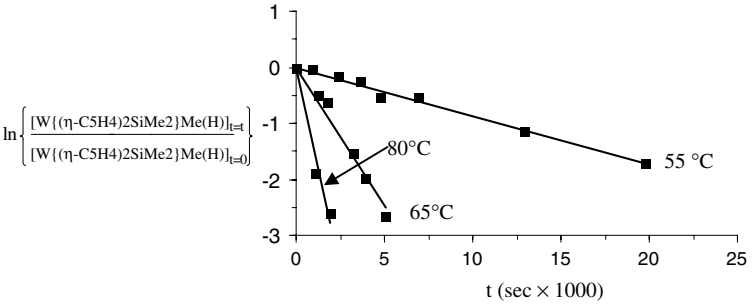

Fig. 6. First-order plots for the elimination of methane from [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me(H)] (**2**) at 55, 65 and 80 °C.

baths prevented the deuterated benzene from refluxing at elevated temperatures. The rate of elimination can be calculated at each temperature, and are shown in Table 8, and activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ have been calculated from an Eyring plot (Fig. 8). Table 9 shows a comparison of the activation parameters in related bridged- and non-bridged tungstenocene systems. It is believed that the alkane elimination from this type of alkyl hydride proceeds via a σ-complex intermediate [66,67]. The symmetry of the exchange pathway implies at some stage a η^2-H, H structure **I**, where both hydrogens are equidistant from the metal, as shown in Fig. 9. Elimination can occur through the η^2-H, C structure **II** or η^1-H structure **III**. Alkane elimination from an alkyl-hydride complex generates a highly reactive intermediate, which can undergo oxidative addition to other C–H bonds. Species capable of reacting with aromatic and aliphatic C–H bonds can occur upon thermolysis [53,68] or photolysis [69] of [W(η-C_5H_5)$_2$MeH]. In the absence of any suitably reactive C–H substrates, dinuclear compounds can be formed. The proposed mechanism involves the 16 electron tungstenocene intermediate [W(η-C_5H_5)$_2$] reacting with the C-H bonds in the cyclopentadienyl rings of [W{(η-C_5H_5)$_2$}MeH]. A similar reaction appears to have happened in the case of **2** even though the solution is dilute, since new peaks appear in the ^{1}H NMR spectrum, two singlets appear at δ −11.99 and −12.73 suggesting two new hydride sites (Fig. 7). The possible dinuclear compounds formed are shown in Fig. 10.

It appears that, under the conditions studied, the activation parameters at the methane elimination from [W{(η-C_5H_4)SiMe$_2$(η-C_5H_4)}Me$_2$] are similar to those found for

Table 8
Rates of methane elimination from [W{(η-C_5H_4)SiMe$_2$(η-C_5H_4)}Me(H)] (**2**)

Temperature (°C)	k, rate of elimination (10^{-4} s^{-1})
55	0.87
65	4.98
80	14.46

Ansa-[W{(η-C_5Me_4)SiMe$_2$(η-C_5Me_4)}MeH]	27.3(2.6)	10(6)	k(100 °C) = 3.74(2) × 10^{-6}	100–159	C_6D_6	[17]

N.B. [(a)]For [W{(η-C_5H_4)$_2$}MeH], DFT calculated activation energy E_a = 19.12 kcal mol^{-1} (80 kJ mol^{-1}) and overall reaction energy = 19.6 kJ mol^{-1}; for *ansa*-[W{(η-C_5H_4)CH_2(η-C_5H_4)}MeH], DFT calculated E_a = 20.31 kcal mol^{-1} (85 kJ mol^{-1}) and overall reaction energy = 78.3 kJ mol^{-1} [60]. In C_6D_6 solutions, *ansa*-[W{(η-C_5H_4)CMe_2(η-C_5H_4)}MeH] and *ansa*-[W{(η-C_5H_4)CMe_2(η-C_5H_4)}EtH] are stable with respect to reductive elimination of alkane up to 120 °C; [14].
[(b)]Slow decomposition above 48 °C [64].

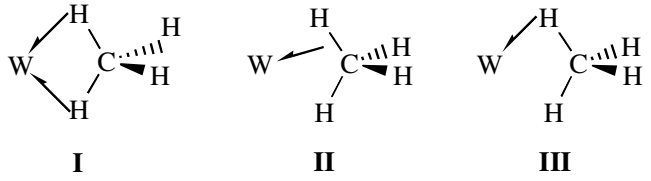

Fig. 9. Intermediates formed at the elimination of methane from alkyl-hydride tungstenocenes.

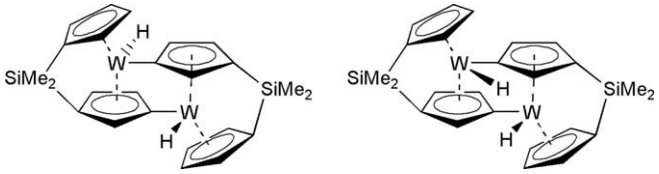

Fig. 10. Proposed species formed at the thermolysis of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}MeH] (**2**).

[W{(η-C_5H_5)$_2$}RH] (where R = Me, C_6H_5) [64,65]. The effect on the thermal stability is most pronounced in the case of a methylene-bridge [60], and it decreases as the *ansa*-bridge becomes less constraining (i.e. as the bending angle β is increased).

4. Conclusion

Studies of the synthesis of neutral W(IV) and Nb(V) complexes have led to the isolation and characterisation of [W(L1)MeI] (**1**), [W(L1)MeH] (**2**) and [W(L1)O] (**3**), [W(L2)Cl_2] (**4**), [W(L2)H_2] (**5**), [W(L2)H_3][BF_4] (**6**), [Nb(L2)Cl_2] (**7**) and [Nb(L2)(η^2-BH_4)] (**8**), where L1 = [(η-C_5H_4)$_2SiMe_2$]$^{2-}$ and L2 = [(η-C_5H_3TMS)$_2SiMe_2$]$^{2-}$. These have been characterised spectroscopically and for **5** and **8** structures were confirmed by X-ray diffraction.

We have shown that the silicon-bridged trimethylsilylsubstituted compounds have properties that are intermediate between the unsubstituted silicon-bridged *ansa*-compounds and the corresponding non-bridged compounds.

5. Experimental

5.1. General

All preparations and manipulations of air- and/or moisture-sensitive materials were carried out under an inert atmosphere of dinitrogen, using standard Schlenk line techniques, or in an inert atmosphere dry box containing dinitrogen. For the dry box dinitrogen was purified by passage through columns filled with molecular sieves (4 Å) and BASF catalyst. Solvents and solutions were transferred through stainless steel cannulae, using a positive pressure of inert gas. Filtrations were similarly performed using modified stainless steel cannulae fitted with glass fibre filter discs. All glassware and cannulae were thoroughly cleaned and then dried at 150 °C before use. All solvents were deoxygenated before use, either by repeated evacuation followed by admission of dinitrogen, or by bubbling dinitrogen through the solvent for approximately 15 min. Solvents were pre-dried over activated 4 Å molecular sieves and distilled over sodium (toluene, petroleum ether b.p. 100–120 °C), sodium/potassium alloy (diethyl ether, *n*-pentane, light petroleum ether b.p. 40–60 °C), potassium (THF, benzene), calcium hydride (acetonitrile, CH_2Cl_2) under a slow continuous stream of dinitrogen. Deionised H_2O was deoxygenated before use by bubbling dinitrogen through the solvent for approximately 15 min. Deuterated solvents for NMR spectroscopy were deoxygenated and dried over calcium hydride (d_2-dichloromethane) or potassium (d_6-benzene and d_8-toluene) and then distilled before use. NMR spectra were recorded on either a Varian Unit Plus 500: (^{1}H and ^{13}C NMR spectra were recorded at 499.868 and 125.704 MHz, respectively), or Bruker AM300 (^{1}H and ^{11}B NMR spectra were recorded at 300.1 and 96.3 MHz). The spectra were referenced internally using the residual protio solvent (^{1}H) and carbon solvent (^{13}C) resonances and measured relative to TMS (^{1}H and ^{13}C; $\delta = 0$ ppm) and $BF_3 \cdot Et_2O$ (^{11}B; $\delta = 0$ ppm).

Mass spectra (FAB) were obtained by the EPSRC Mass Spectrometry Service, Swansea. The characteristic isotope pattern was observed for all spectra. IR spectra were recorded on a Perkin–Elmer 1710 FTIR spectrometer. Samples were prepared as a Nujol mull between NaCl plates. Elemental analyses were performed by the Microanalytical Department of the Inorganic Chemistry Laboratory, Oxford.

WCl_6 (99%), $LiAlH_4$ (95%), $ZnMe_2$ (2.0 M solution in toluene), NH_4I, $NaBH_4$, $NbCl_5$, ^{n}BuLi (2.5 M solution in light petroleum ether (b.p. 40–60 °C)), HBF_4 (54 + wt% solution in diethyl ether), [Na{AlH_2($OCH_2CH_2OCH_3$)$_2$}] (3.3 M solution in toluene) and dichlorodimethylsilane (99%) were purchased from Aldrich and used as received. The following compounds were prepared by standard literature methods: [WCl_4(DME)] [70], TMSCp [71], [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Cl_2] [25] and $NbCl_4 \cdot 2THF$ [72]. Li_2[{(C_5H_4)$SiMe_2$(C_5H_4)}] (**Li_2L1**) was prepared by the literature method via the reaction between Na(C_5H_5) and Me_2SiCl_2, followed by deprotonation by ^{n}BuLi [25].

5.2. Preparation of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me_2]

A variation of the previously reported synthesis was used [25].

To a suspension of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Cl_2] (1.04 g, 2.27 mmol) in toluene (150 cm^3) at −78 °C, a solution of $ZnMe_2$ (2.0 M solution in toluene, 12 cm^3, 6 mmol) was added dropwise. The resulting mixture was allowed to slowly warm to room temperature and then stirred overnight. The orange/brown solution was pumped to dryness under reduced pressure to remove any excess of $ZnMe_2$. The residual solid was then extracted with pentane (3×20 cm^3). The extracts were combined, concentrated

and cooled to −80 °C to yield orange crystals of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me_2]. Yield: 0.16 g, 17%.

5.3. Preparation of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}MeI] (1)

A solution of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me_2] (0.16 g, 0.38 mmol) in THF (50 cm^3) was added to NH_4I (0.20 g, 1.38 mmol) in a small ampoule. The orange solution was refluxed for 18 h in a constant temperature oil bath at 66 °C. The resulting green solution was pumped to dryness under reduced pressure to leave a green solid. The solid was extracted with toluene (3 × 10 cm^3). The extracts were combined and concentrated to 10 cm^3, 10 cm^3 of pentane was then added and the solution cooled to −80 °C to yield a green powder of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me(I)] (**1**). Yield: 0.038 g, 19%.

5.4. Preparation of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}MeH] (2)

To a green solution of compound 1 (0.038 g, 0.07 mmol) in toluene (30 cm^3) at −78 °C, a solution of [Na{AlH_2($OCH_2CH_2OCH_3$)$_2$}] in toluene (3.3 M, 0.75 cm^3, 2.5 mmol) was added. The solution was allowed to slowly warm to room temperature and stir overnight. The resulting yellow solution was cooled to 0 °C and unreacted [Na{AlH_2($OCH_2CH_2OCH_3$)$_2$}] was hydrolysed by the cautious addition of a few drops of distilled H_2O. After stirring for 30 min the reaction mixture was pumped to dryness under reduced pressure. The resulting yellow solid was extracted into pentane (3 × 10 cm^3). The extracts were combined, concentrated and cooled to −80 °C, to yield a yellow crystalline solid of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Me(H)] (**2**). Yield: 0.017 g, 63%.

5.5. Preparation of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}O] (3)

To a solution of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}Cl_2] (0.075 g, 0.17 mmol) in 1/1H_2O/EtOH (40 cm^3), a few drops of saturated KOH solution in 1/1H_2O/EtOH was added with vigorous stirring. The solution changed colour from brown/green to blue. After stirring for 2 h the product was extracted into CH_2Cl_2 (3 × 25 cm^3). The CH_2Cl_2 extracts were combined and pumped to dryness under reduced pressure. The solid was extracted with toluene (3 × 5 cm^3) to give a red solution. The extracts were combined and concentrated to 5 cm^3, 5 cm^3 of pentane was then added and the solution cooled to −20 °C and then to −80 °C to yield a red/blue crystalline solid of [W{(η-C_5H_4)$SiMe_2$(η-C_5H_4)}O] (**3**). Yield: 0.030 g, 46%.

5.6. Preparation of [Li_2{(C_5H_3TMS)$SiMe_2$(C_5H_3TMS)}] (**Li_2L2**)

To a solution of LiCpTMS (3.5 g, 24.3 mmol) in THF (60 cm^3) at −78 °C, dichlorodimethylsilane (1.463 cm^3, $d = 1.07$ g cm^{-3}, 12.13 mmol) was added with vigorous stirring. The reaction mixture was allowed to slowly warm to room temperature and stirred overnight to yield a deep red solution. The solvent was removed under reduced pressure to yield a deep red oil. The oil was taken up in light petroleum ether b.p. 40–60 °C (60 cm^3). The solution was cooled to −78 °C and ^{n}BuLi (1.6 M solution in hexane, 15.5 cm^3, 24 mmol) was slowly added. A flocculent white solid was immediately formed. The mixture was allowed to warm to room temperature and stirred overnight. The air- and moisture-sensitive solid of [Li_2{(C_5H_3TMS)$SiMe_2$-(C_5H_3TMS)}] (**Li_2L2**) was washed with light petroleum ether b.p. 40–60 °C and dried under reduced pressure. Yield: 2.61 g, 63%.

5.7. Preparation of [W{(η-C_5H_3TMS)$SiMe_2$-(η-C_5H_3TMS)}Cl_2] (4)

A mixture of the two solids [WCl_4(DME)] (2.678 g, 6.44 mmol) and [Li_2{(C_5H_3TMS)$SiMe_2$(C_5H_3TMS)}] (2.678 g, 6.4 mmol) was stirred in the absence of solvent until a homogeneous mixture was formed. Diethyl ether (100 cm^3) was added at −78 °C, the resulting brown solution was allowed to warm to room temperature and stirred for 4 days. The mixture was pumped to dryness under reduced pressure. The resulting solid was extracted into pentane (3 × 20 cm^3). The pentane extracts were combined, concentrated and cooled to −80 °C to yield dark green crystals of [W{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}Cl_2] (**4**). Yield: 0.61 g, 16%.

5.8. Preparation of [W{(η-C_5H_3TMS)$SiMe_2$-(η-C_5H_3TMS)}H_2] (5)

A suspension of $LiAlH_4$ (0.30 g, 7.9 mmol) in diethyl ether (20 cm^3) at −78 °C was added dropwise to a suspension of compound 4 (0.42 g, 0.72 mmol) in diethyl ether (30 cm^3) at −78 °C. The resulting yellow suspension was allowed to slowly warm to room temperature and stirred overnight. The suspension was filtered and the residual solid extracted into diethyl ether (3 × 40 cm^3). The diethyl ether extracts were combined and unreacted $LiAlH_4$ was hydrolysed by cautious addition of diethyl ether saturated with deionised H_2O (20 cm^3) and then deionised H_2O (10 cm^3) at 0 °C. After stirring for 30 min the organic phase was decanted off and the aqueous phase extracted with diethyl ether (3 × 20 cm^3). The yellow diethyl ether extracts were combined, washed with distilled water (10 cm^3) and pumped to dryness under reduced pressure to leave a yellow/orange oily solid. The solid was extracted into pentane (3 × 15 cm^3). The pentane extracts were combined, concentrated and cooled to −80 °C to yield yellow crystals of [W{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}H_2] (**5**). Yield: 0.080 g, 22%.

5.9. Preparation of [W{(η-C_5H_3TMS)$SiMe_2$-(η-C_5H_3TMS)}H_3][BF_4] (6)

A dark yellow solution of compound **5** (0.025 g, 0.05 mmol) in diethyl ether (10 cm^3) was treated with a solution of HBF_4 in diethyl ether (0.066 mol dm^{-3}, 1.0 cm^3, 0.66 mmol). The resulting pale grey suspension was stirred for 30 min. The complex [W{(η-C_5H_3TMS)Si-Me_2(η-C_5H_3TMS)}H_3][BF_4] (**6**) was isolated as a white powder by filtration and washing with diethyl ether (2×10 cm^3) and then dried under reduced pressure. Yield: 0.018 g, 59%.

5.10. Preparation of [Nb{(η-C_5H_3TMS)$SiMe_2$-(η-C_5H_3TMS)}Cl_2] (7)

A mixture of the two solids $NbCl_4 \cdot 2THF$ (1.0 g, 2.64 mmol) and [Li_2\{(C_5H_3TMS)$SiMe_2$(C_5H_3TMS)\}] (0.908 g, 2.64 mmol) was stirred in the absence of solvent until a homogeneous mixture was formed. Diethyl ether (50 cm^3) was added at −78 °C, the resulting brown solution was allowed to warm to room temperature and stirred for 4 days. The mixture was pumped to dryness under reduced pressure. The resulting solid was extracted into CH_2Cl_2 (3×20 cm^3). The CH_2Cl_2 extracts were combined and pumped to dryness to yield an oily solid. The solid was washed with pentane (2×20 cm^3) at −78 °C and dried under reduced pressure to give a brown powder of [Nb{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}Cl_2] (**7**). Yield: 0.67 g, 50%.

5.11. Preparation of [Nb{(η-C_5H_3TMS)$SiMe_2$-(η-C_5H_3TMS)}(η^2-BH_4)] (8)

A mixture of the compound **7** (0.35 g, 0.708 mmol) and $LiBH_4$ (0.17 g, 7.9 mmol) was suspended in DME (40 cm^3) at room temperature. Effervescence was observed on addition of the solvent. The brown reaction mixture was stirred overnight and then the volatiles were removed under reduced pressure. The resulting solid was extracted into petroleum ether b.p. 100–120 °C (2×30 cm^3). The petroleum ether b.p. 100–120 °C extracts were combined, concentrated and cooled to −80 °C, yielding the compound [Nb{(η-C_5H_3TMS)$SiMe_2$(η-C_5H_3TMS)}(η^2-BH_4)] (**8**) as dark green crystals. Yield: 0.18 g, 58%.

5.12. X-ray crystallography

In each case, a single crystal was selected under an inert atmosphere, encased in perfluoro-polyether oil, and mounted on the end of a glass fibre. The fibre, secured in a goniometer head was then placed under a stream of cold nitrogen maintained at 150 K and data collected on an Enraf-Nonius DIP2000 image plate diffractometer with graphite monochromated Mo Kα radiation ($\lambda =$ 0.71069 Å) The images were processed with the DENZO and SCALEPACK programs [73] and corrections for Lorentz and polarisation effects were performed. All solution, refinement, and graphical calculations were performed using the CRYSTALS and CAMERON [74,75] software packages.

The structures of were solved by direct methods using the SIR92 [76] program and refined by full-matrix least-squares procedure on F. The crystallographic data are summarised in Table 8. In each case, all non-hydrogen atoms were refined with anisotropic displacement parameters and hydrogen atoms were generated and allowed to ride on their corresponding carbon atoms with fixed thermal parameters. Empirical absorption corrections were applied [77], as well as the 3-term Chebychev polynomial weighting scheme.

The crystal structures have been deposited at the Cambridge Crystallographic Data Centre, CCDC Nos. 271121 and 271122.

Appendix A. Supplementary data

This paper is dedicated to our friend and colleague Malcolm Chisholm on the occasion of his 60th birthday, and recognizes his scientific achievements and his long association with Polyhedron.

Abstract

A series of compounds containing polyalkyne frameworks decorated with dicobalt carbonyl clusters and containing up to 10 Co atoms has been prepared and characterized; spectroscopic data for new compounds are analyzed to provide correlations to assist in the characterization of cobaltadendrimers.

Keywords: Alkyne; Polyalkyne; Dendrimer; Cobalt carbonyl

1. Introduction

Among the potential applications of metallostars and metallodendrimers [1] are those in electrochemistry and photochemistry [2–4], liquid crystals [5], artificial photosynthetic systems [6–9], catalysis [10,11], molecular electronics [12,13] and in the development of new materials. In contrast to stars and dendrimers with flexible arms, those with rigid frameworks possess well-defined structures. We have previously reported the synthesis of high nuclearity stars and dendrimers containing alkyne functionalities that react with $Co_2(CO)_8$ to give cluster-containing species [14–16]. While we have been able to structurally characterize representative alkyne frameworks [16], characterization of the cobaltadendrimers has relied on MALDI-TOF mass spectrometry and ^{1}H and ^{13}C NMR spectroscopies. In a system such as that shown in Scheme 1, the reaction of each C≡C group with $Co_2(CO)_8$ can easily be monitored by a shift in the ^{1}H NMR spectrum from δ 3.06 to 6.37 ppm for the signal assigned to the terminal CH group [14,16]. This diagnostic spectroscopic signature is a powerful tool for the characterization, not only in the first generation star shown in Scheme 1, but also for the outer generations of related stars and dendrimers [14–16]. However, characterization of the inner generations and the concomitant confirmation of the extent to which all C≡C functionalities in polyalkynes such as $C\{(C_6H_4C{\equiv}C)_nH\}_4$ [14–16] have reacted with $Co_2(CO)_8$, is not straightforward. Furthermore, in the case of non-terminal alkynes, there is no convenient ^{1}H NMR spectroscopic spectator group for monitoring the cluster-formation reaction. Before extending our studies of this type of dendrimer, we have therefore carried out a systematic study of the reactions of a series of smaller alkynes with $Co_2(CO)_8$, in order to correlate

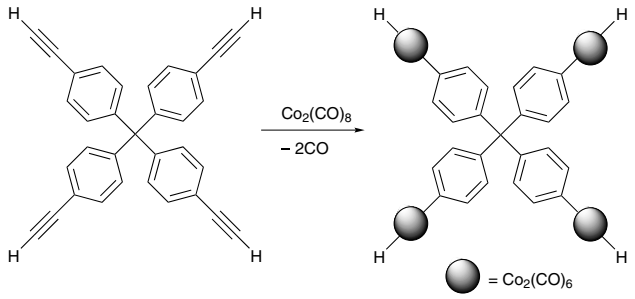


Scheme 1.

^{13}C NMR shift changes as the alkyne units (which will form the central cores of more extended systems) react with $Co_2(CO)_8$. These relatively small alkynes represent the cores from which we aim to synthesize cobaltadendrimers by a divergent strategy.

2. Experimental

2.1. General procedures

Commercially available chemicals were reagent grade and were used without further purification. ^1H and ^{13}C NMR spectra were recorded on a Bruker 400 MHz spectrometer; chemical shifts are defined with TMS δ 0 ppm for ^1H and ^{13}C spectra and are measured relative to residual $CHCl_3$. Infrared spectra were recorded on a Shimadzu FTIR-8400S spectrophotometer with neat samples on a Golden Gate diamond ATR accessory. FAB mass spectra were recorded on a Finnigan MAT95Q mass spectrometer; MALDI-TOF mass spectra were recorded on a Voyager-DE PRO spectrometer, in positive mode with α-cyano-4-hydroxycinnamic acid matrix. The microanalyses were performed with a LECO CHN-900 apparatus. Compounds **1** [17], **3** [18,19] and **14** [20] were prepared according to the literature, but using CuCl as catalyst in place of CuI. All solvents were freshly distilled and degassed; all reactions were carried out under argon. *Abbreviations*. TMS, trimethylsilyl; TIPS, triisopropylsilyl.

2.2. Compound 2

Compound **1** (100 mg, 0.37 mmol) was dissolved in CH_2Cl_2 (50 cm^3). $Co_2(CO)_8$ (557 mg, 1.63 mmol) was added and the mixture stirred at room temperature for 6 h. The solvent was removed and the residue purified by chromatography (silica, hexane:CH_2Cl_2/10:1) to give **2** as a dark red solid (290 mg, 93.0%). ^1H NMR (400 MHz, $CDCl_3$, δ/ppm): 7.44 (s, 4H, H^{Ar}) 0.42 (s, 18H, Me); ^{13}C NMR (100 MHz, $CDCl_3$, δ/ppm): 200.4 (CO), 138.5 (C^{Ar}), 130.8 (HC^{Ar}), 104.9 (C≡C), 79.9 (C≡C), 1.3 (Me). IR (cm^{-1}): 2075 m, 2023 s, 2005 vs (CO). FAB-MS, *m/z* 815 $[M + H - CO]^+$ with sequential loss of 12 CO and 4 Co to *m/z* 271 $[M + H - 12CO - 4Co]^+$.

2.3. Compound 4

Compound **3** (335 mg, 0.915 mmol) was dissolved in CH_2Cl_2 (50 cm^3). $Co_2(CO)_8$ (2.06 g, 6.02 mmol) was added and the mixture stirred at room temperature for 2 h. The solvent was removed and the residue purified by chromatography (silica, hexane) to give **4** as a dark red solid (815 mg, 72.8%). ^1H NMR (400 MHz, $CDCl_3$, δ/ppm): 7.52 (s, 3H, H^{Ar}) 0.40 (s, 27H, Me); ^{13}C NMR (100 MHz, $CDCl_3$, δ/ppm): 200.2 (CO), 140.5 (C^{Ar}), 130.8 (HC^{Ar}), 104.5 ($C_{cluster}$), 81.2 ($C_{cluster}$), 1.3 (Me). IR (cm^{-1}): 2083 m, 2044 s, 1983 vs (CO). FAB-MS *m/z* 1140 $[M + H - 3CO]^+$.

2.4. Compound 5

The method described by Stang was used [21]. ^{13}C NMR spectroscopic data in $CDCl_3$ were as reported [22]. ^1H NMR (400 MHz, $CDCl_3$): δ/ppm 7.64 (s, 2H, CH), 0.25 (s, 36H, Me). FAB-MS: *m/z* 462 M^+, 447 $[M - Me]^+$, 390 $[M - SiMe_3]^+$.

2.5. Compound 6

Compound **5** (200 mg, 0.433 mmol) was dissolved in CH_2Cl_2 (50 cm^3). $Co_2(CO)_8$ (1.30 g, 3.80 mmol) was added and the mixture stirred at room temperature for 4 h. The solvent was removed and the residue purified with chromatography (silica, hexane) to give **6** as a black solid (484.0 mg, 69.6%). ^1H NMR (400 MHz, $CDCl_3$, δ/ppm): 7.56 (s, 2H, H^{Ar}), 0.24 (s, 27 H, Me); ^{13}C NMR (100 MHz, $CDCl_3$, δ/ppm): 200.5 (CO), 136.4 (C^{Ar}), 125.7 (C^{Ar}), 102.4 ($CC_{cluster}$), 101.3 ($CC_{cluster}$), 0.3 (Me). IR (cm^{-1}): 2083 m, 2044 s, 1998 vs (CO). FAB-MS *m/z* 1630 $[M + Na]^+$ with sequential loss of 28 CO ligands.

2.6. Compound 7

1,2-Di(4-bromophenyl)ethyne (500 mg, 1.49 mmol) was dissolved in Et_3N (50 cm^3) and CuCl (21.8 mg, 0.22 mmol) and $[Pd(PPh_3)_2Cl_2]$ (154.4 mg, 0.22 mmol) were added. After the addition of HC≡CTMS (0.64 ml, 4.46 mmol), the reaction mixture was stirred for 6 h at 70° C. The solvent was removed and the residue extracted with hexane (150 cm^3). The solvent was evaporated and the crude product purified by chromatography (alumina, hexane/CH_2Cl_2, initially 1:0, gradually changing to 3:1) to give **7** as a white solid (546 mg, 99.0%). The ^1H and ^{13}C NMR spectroscopic data in $CDCl_3$ were as reported [23].

2.7. Compound 8

Compound **7** (500 mg, 1.35 mmol) was dissolved in THF (25 cm^3) and aqueous NaOH (25 cm^3 1 M) was added to the solution. The reaction mixture was stirred at room temperature for 20 h, after which time water (25 cm^3) was added until a precipitate began to form. The mixture was extracted with chloroform (100 cm^3), the solvent evaporated and the residue was purified by chromatography (alumina, hexane/CH_2Cl_2, initially 1:0, gradually changing to 2:1) to give **8** (282 mg, 92.4%). Characterization data were consistent with those reported [23].

2.8. Compound 9

Compound **8** (100 mg, 0.44 mmol) was dissolved in CH_2Cl_2 (50 cm^3). $Co_2(CO)_8$ (1.36 g, 3.98 mmol) was added and the mixture stirred at room temperature for 4 h. The solvent was removed and the residue purified by chromatography (silica, hexane) to give **9** as a black solid (305 mg, 63.9%). ^1H NMR (400 MHz, $CDCl_3$, δ/ppm): 7.62 (s, 8H, H^{Ar}), 6.72 (s, 2H, $C_{cluster}H$); ^{13}C NMR (100 MHz, $CDCl_3$, δ/ppm): 199.7 (CO), 138.7 (C^{Ar}), 137.9 (C^{Ar}), 131.1 (HC^{Ar}), 130.0 (HC^{Ar}), 91.7 ($CC_{cluster}$), 89.5 ($CCH_{cluster}$), 73.3 ($CCH_{cluster}$). IR (cm^{-1}): 2083 m, 2041 s, 1985 vs FAB-MS, *m/z* 1084 M^+, 1056 $[M - CO]^+$, 1028 $[M - 2CO]^+$, sequential loss of CO to 719 $[M - 13CO]^+$, 663 $[M - 15CO]^+$, 226 $[M - 6Co - 18CO]^+$.

2.9. Compound 10

Compound **10** was prepared by a route adapted from that reported by Bunz and coworkers [24]. 1,3-Dibromo-5-iodobenzene (1.00 g, 2.76 mmol) was dissolved in Et_3N (75 cm^3), and then CuCl (41 mg, 0.42 mmol) and $[Pd(PPh_3)_2Cl_2]$ (291 mg, 0.42 mmol) were added. After the addition of 1,3-dibromo-5-ethynylbenzene (718 mg, 2.76 mmol), the reaction mixture was stirred for 6 h at 60 °C. The solvent was then removed, and the residue extracted with hexane (150 cm^3). The mixture was filtered, the solvent removed and the crude product purified by chromatography (alumina, hexane:CH_2Cl_2, 3:1) to yield **10** as a yellow solid (1.10 g, 80.8%). The spectroscopic properties of **10** were consistent with those published [23].

2.10. Compound 11

Compound **10** (550 mg, 1.11 mmol) was dissolved in Et_3N (50 cm^3) and CuCl (11.0 mg, 0.11 mmol) and $[Pd(PPh_3)_2Cl_2]$ (77.9 mg, 0.11 mmol) were added. After the addition of HC≡CTMS (0.65 ml, 4.55 mmol), the mixture was stirred for 6 h at 60 °C. Then solvent was removed and the residue extracted with hexane (100 cm^3). The mixture was filtered, the solvent removed, and the product was purified by chromatography (alumina, hexane) to yield **11** as a light brown solid (490 mg, 78%). ^1H NMR (400 MHz, $CDCl_3$, δ/ppm): 7.52 (s, 6H, H^{Ar}), 0.24 (s, 32H, Me); ^{13}C NMR (100 MHz, $CDCl_3$, δ/ppm): 135.1 (HC^{Ar}), 134.6, (HC^{Ar}), 123.9 (C^{Ar}), 123.3 (C^{Ar}), 103.0 (C≡CTMS), 95.3 (C≡CTMS), 88.7 (central C≡C), –0.2 (Me).

2.11. Compound 12

Compound **11** (440 mg, 0.78 mmol) was dissolved in THF (35 cm^3) and after the addition of aqueous NaOH (30 cm^3 1 M), the mixture was stirred at room temperature for 4 h. Then water (100 cm^3) was added until a precipitate began to form. The mixture was extracted with CH_2Cl_2, the solvent evaporated and the residue purified by chromatography (silica, hexane) to give **12** as a light yellow solid (205 mg, 95.9%). ^1H NMR (400 MHz, $CDCl_3$, δ/ppm): 7.597 AB (d, $J = 1.5$ Hz, 4H, H^{Ar}), 7.573 AB (t, $J = 1.5$ Hz, 2H, H^{Ar}), 3.12 (s, 4H, C≡CH); ^{13}C NMR (100 MHz, $CDCl_3$, δ/ppm): 135.4 (HC^{Ar}), 135.1 (HC^{Ar}), 123.4 (C^{Ar}), 123.3 (C^{Ar}), 88.6 (central C≡C), 81.6 (*C*≡CH), 78.7 (C≡*C*H). FAB-MS *m/z* 274 M^+.

2.12. Compound 13

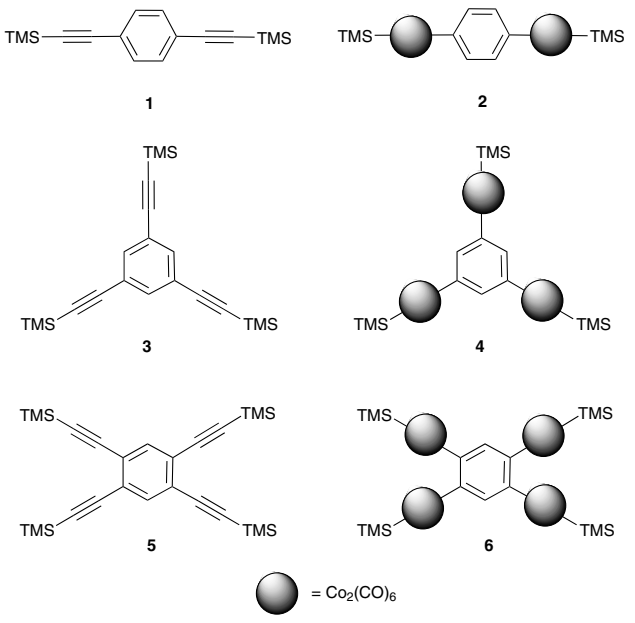
Compound **12** (25 mg, 0.091 mmol) was dissolved in CH_2Cl_2 (25 cm^3). $Co_2(CO)_8$ (343 mg, 1.00 mmol) was added and the reaction mixture was stirred at room temperature for 4 h. The solvent was removed and the product purified by chromatography (silica, hexane) to give **13** as a black solid (110 mg, 70.8%). ^1H NMR (400 MHz, $CDCl_3$, δ/ppm): 7.58 (overlapping multiplets, 6H, H^{Ar}), 6.36 (s, 4H, $C_{cluster}$ H); ^{13}C NMR (100 MHz, $CDCl_3$, δ/ppm): 199.0 (CO), 139.7 (C^{Ar}), 139.4 (C^{Ar}), 130.8 (C^{Ar}), 129.4 (C^{Ar}), 91.4 ($CC_{cluster}$), 88.4 ($CCH_{cluster}$), 72.8 ($CCH_{cluster}$). IR (cm^{-1}): 2091 m, 2044 s, 2006 vs MALDI-TOF MS *m/z* 1745 $[M + K]^+$ with 30 CO losses followed by 10 Co losses.

2.13. Crystal structure determination

Data were collected on an Enraf Nonius Kappa CCD instrument; data reduction, solution and refinement used the programmes COLLECT [25], SIR-92 [26] and CRYSTALS [27]. Crystal data: $C_{14}H_6Br_4$, $M = 493.82$, monoclinic, space group $P2_1/n$, $a = 13.336(2)$ Å, $b = 3.9189(7)$ Å, $c = 14.222(2)$ Å, $\beta = 110.74(1)°$; $U = 695.1(2)$ $Å^3$, $Z = 2$, $D_c = 2.359$ Mg m^{-3}, μ(Mo Kα) = 11.557 mm^{-1}, $T = 173$ K, 1560 reflections collected. Refinement of 1048 reflections (95 parameters) with $I > 3.0\sigma(I)$ converged at final $R_1 = 0.0376$, $wR_2 = 0.0454$, Gof = 1.11.

3. Results and discussion

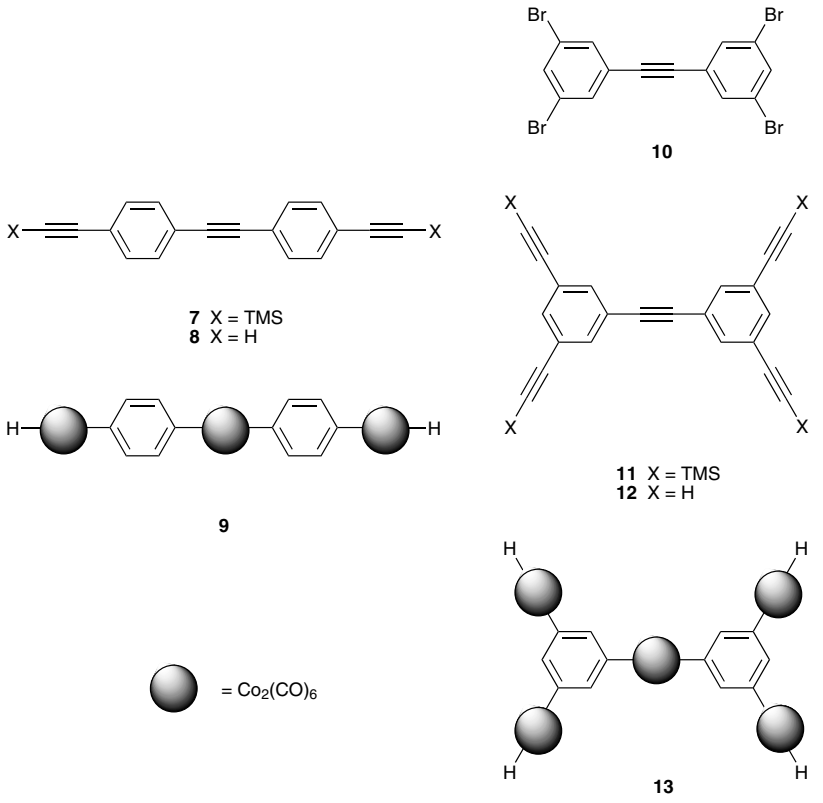
As part of a wider investigation of star and dendrimer molecules in which alkyne frameworks are decorated with cobalt carbonyl clusters, we have undertaken a systematic study of the basic building blocks in order to provide a database of NMR spectroscopic chemical shifts which will aid characterization of larger systems. Two series of compounds were chosen for the study and these are shown in Schemes 2 and 3. The alkynes in Scheme 2 are of type $C_6H_{6-n}(C{\equiv}CTMS)_n$ ($n = 2$, 3 or 4) with the substituents providing representative *para*, *meta* and *ortho*-substitution patterns. Compounds **1**, **3** and **5** have previously been reported [17–19,21,22]. Each reacts with an excess of $Co_2(CO)_8$ to give compounds **2**, **4** and **6**, respectively, in high yield. The IR spectrum of each cobalt carbonyl derivative shows a diagnostic pattern of absorptions around 2000 cm^{-1}. The simplicity of the ^1H NMR spectrum of each of compounds **2**, **4** and **6** provides evidence that all alkyne functionalities have reacted with $Co_2(CO)_8$, and that mixtures of less symmetrical products containing clusters and unreacted C≡C units have not been obtained. For compounds **2** and **4**, FAB mass spectra showed sequential loss of CO and loss of Co, and relatively intense fragment peaks corresponding to the alkynes **1** and **3**, respectively. For the higher molecular mass cobalt carbonyl derivative **6**, we were not able to obtain satisfactory mass spectrometric data using the FAB technique. However, using MALDI-TOF MS with α-cyano-4-hydroxycinnamic acid as matrix, excellent mass spectra were obtained which provided unambiguous evidence for the formulation of **6** shown in Scheme 2. A peak at *m/z* 1630 was assigned to $[M + Na]^+$. A series of intense fragment peaks from *m/z* 1630 to 1048 were consistent with sequential loss of 12 CO and 4 Co. Less intense peaks are observed for fragments arising from the loss of the remaining cluster fragments.



Scheme 2.

We mentioned earlier that on going from a HC≡C to $HC_2Co_2(CO)_6$ unit, a diagnostic shift in the ^1H NMR spectrum for the signal assigned to the alkyne proton from $\approx\delta$ 3.1 to 6.4 ppm is a clear indication that the alkyne has reacted to give the cobalt carbonyl derivative. However, in TMS or TIPS protected derivatives (which are favored for reasons of stability), no such ^1H NMR spectroscopic spectator is available. A similar situation occurs when we are investigating the reactions of inner generation alkynes with $Co_2(CO)_8$ in multigeneration stars and dendrimers. In these cases, ^{13}C NMR spectroscopy is diagnostic. Table 1 shows the changes in ^{13}C NMR shifts for the alkyne carbon atoms on going from compounds **1** to **2**, **3** to **4** and **5** to **6**. When the TMS-protected alkyne or cluster groups are mutually *meta* or *para*, the ^{13}C NMR spectroscopic signatures are similar, with a pair of signals at δ 96 and 104 ppm shifting to δ 80 and 105 upon reaction of the alkyne unit with $Co_2(CO)_8$. The same trend is observed on going from $C(C_6H_4\text{-}4\text{-}C{\equiv}CTMS)_4$ (**14**, Scheme 4) with δ 94.8 and 104.7 ppm for C_{alkyne} [20] to the cluster derivative **15** (δ 80.4 and 105.2 ppm for $C_{cluster}$) [28]. When two of the TMS-protected alkyne or cluster groups are *ortho* to each other, steric crowding leads to a deshielding effect; the pair of signals at δ 100.8 and 102.0 ppm in **5** shift only slightly to δ 101.3 and 102.4 ppm in the cobalt derivative **6**. Attempts to prepare the hexacluster derivative $C_6\{C_2Co_2(CO)_6TMS\}_6$ to complete this series of derivatives have not yet been successful.

The second set of model compounds, **7**–**9** and **11**–**13**, was designed so that we could investigate the effects of the alkyne to cobalt carbonyl cluster conversion on an internal alkyne group as well as peripheral deprotected alkyne functionalities. In compounds **7**–**9**, the alkyne or cluster groups are mutually *para* to one another, while in compounds **11**–**13**, they are *meta*. Compound **7** was prepared by a standard procedure, and deprotection with base leads to compound **8**. The ^1H and ^{13}C NMR spectroscopic properties of **7** and **8** were in accord with literature data [23]. Alkyne **8** reacted with $Co_2(CO)_8$ under ambient conditions to give **9** in 64% yield. The IR spectrum of **9** exhibited absorptions close to 2000 cm^{-1} indicative of the $C_2Co_2(CO)_6$ cluster unit, although these data alone do not provide evidence that all three alkynes have undergone reaction. On going from **8** to **9**, the retention of a simple spectrum indicated that **9** possessed the expected symmetry, and a shift in the ^1H NMR spectroscopic signal assigned to the terminal proton from δ 3.17 to 6.72 ppm confirmed that the both terminal C≡C groups had been converted to



Scheme 3.

Table 1
Summary of ^{13}C NMR spectroscopic data for alkyne and cluster carbon atoms; all data were recorded in $CDCl_3$ (see Section 2 or text for references)

Compound (identity of terminal group X)	δ/ppm C≡C–X	δ/ppm $C_{cluster}$–$C_{cluster}$–X	δ/ppm C≡C (central alkyne)	δ/ppm $C_{cluster}$–$C_{cluster}$ (central unit)
1 (X = TMS)	96.6, 104.8			
2 (X = TMS)		79.9, 104.9

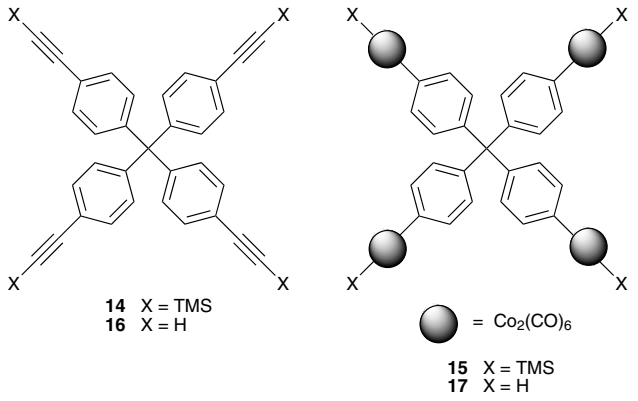
23 (X = H)		73.6, 89.7		91.5, 92.2

$C_2Co_2(CO)_6$ clusters. The FAB mass spectrum of **9** showed a parent ion at *m*/*z* 1084 with fragment peaks arising from sequential loss of CO followed by Co, leading to a peak at *m*/*z* 226 assigned to $[M - 6Co - 18CO]^+$, i.e., to the free alkyne **8**. We return to the ^{13}C NMR characterization of **8** and **9** later.



Scheme 4.

The precursor for compounds **11–13** was the tetrabromo derivative **10** which was prepared by a route adapted from that reported by Bunz and coworkers [24]. X-ray quality crystals of **10** were grown from a $CDCl_3$ solution and the molecular structure is shown in Fig. 1(a). The molecule is planar, and selected bond parameters are given in the figure caption. The molecules stack along the crystallographic *b*-axis (central stack in Fig. 1(b)) with distance between the molecular planes of 3.578 Å. The angle at which the plane containing a molecule is tilted with respect to the *b*-axis is 24°, and the centroid-to-centroid distance between adjacent molecules is 3.191 Å. It follows that both the shortest Br···Br and C···C contacts are both 3.191 Å, i.e., twice the van der Waals radius of Br (1.95 Å), but shorter than the optimum distance for π–π stacking between aromatic rings. A search of the Cambridge Structural Database [29] revealed the Br···Br interaction was common and present in 1274 bromobenzene derivatives in the data base. More interestingly, only 94 hits were obtained in which the aromatic rings were oriented approximately coplanar in a face-to-face manner. The interplanar distance depends upon the mutual rotation of the two rings, and is best described by the pseudotorsion angle Br–C···C–Br. At 0°, the two C–Br bonds lie above each other in an eclipsed conformation with the interplanar distance dictated by the van der Waals radius of the Br atom. The greater the pseudorotation angle, the closer the planes can come together, until the staggered conformation is reached at 60°. In compound **10**, the pseudorotation angle is 0°.

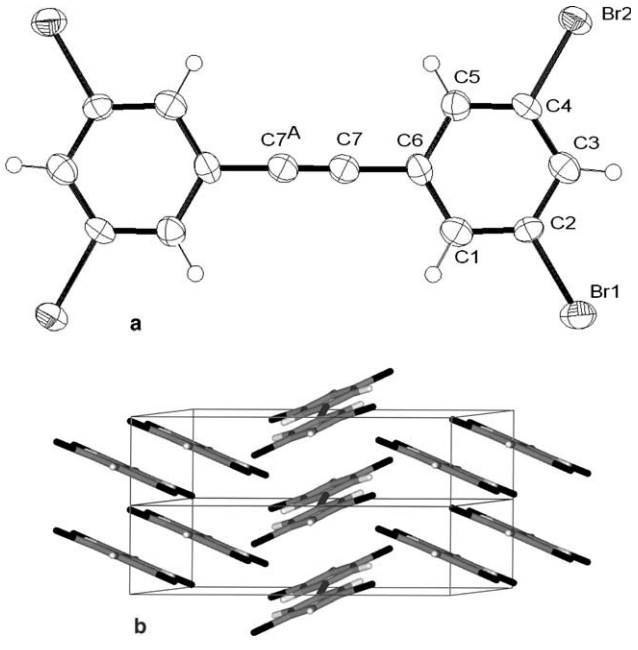


Fig. 1. (a) Molecular structure of compound **10**. Selected bond lengths and angles: C(7)–C(7A) = 1.17(1), C(6)–C(7) = 1.444(8), C(2)–Br(1) = 1.890(5), C(4)–Br(2) = 1.899(5) Å; C(5)–C(6)–C(7) = 119.3(5), C(1)–C(6)–C(7) = 121.0(5), C(6)–C(7)–C(7A) = 179.3(8)°. (b) Packing diagram of **10** showing two unit cells stacked along the crystallographic *b*-axis.

The reaction of **10** with four equivalents of HC≡CTMS under standard coupling conditions led to the formation of **11** in 78% yield. Subsequent deprotection with base gave the tetraalkyne **12** in almost quantitative yield. The FAB mass spectrum of **12** gave a parent ion at *m/z* 274, and ^1H and ^{13}C NMR spectra were fully consistent with the structure shown in Scheme 3. Compound **12** reacted with an excess of $Co_2(CO)_8$ at room temperature, and the black solid product **13** was isolated in 71% yield. In the ^1H NMR spectrum, a shift from δ 3.12 ppm for the C≡CH protons to δ 6.36 ppm is consistent with the conversion of all four peripheral alkyne groups to $C_2Co_2(CO)_6$ clusters. However, this gives no insight into the fate of the inner alkyne functionality. The highest mass region of the MALDI-TOF mass spectrum of **13** is shown in Fig. 2 and provides evidence for the fact that compound **13** contains five $C_2Co_2(CO)_6$ cluster units. The highest mass peak at *m/z* 1745 can be assigned to $[M + K]^+$, and the loss of 30 CO (28 of which are shown in the figure) followed by loss of 10 Co are observed.

We now look at correlations in ^{13}C NMR spectroscopic data on going across the series of compounds **7–9** and **11–13**. Data for the alkyne carbon atoms are summarized in Table 1. Deprotection on the terminal alkyne on going from **7** to **8**, and from **11** to **12**, shifts the ^{13}C NMR signals for the C≡C carbon atoms to lower frequencies as expected. On reaction of the terminal C≡CH units with $Co_2(CO)_8$, the two ^{13}C NMR signals for the alkyne C atoms move apart: $\Delta\delta$ = 4.2 ppm in **8** and 16.2 ppm in **9**, and $\Delta\delta = 2.9$ ppm in **12** and 15.6 ppm in **13**. We have also observed this trend on going from compound **16** ($\Delta\delta = 5.6$ ppm [20]) to **17** ($\Delta\delta = 16.5$ ppm [16]) (Scheme 4), from **18** ($\Delta\delta = 4.4$ ppm) to **19** ($\Delta\delta = 16.3$ ppm), from **20** ($\Delta\delta = 4.3$ ppm) to **21** ($\Delta\delta = 16.2$ ppm), and from **22** ($\Delta\delta = 4.2$ ppm) to **23** ($\Delta\delta = 16.1$ ppm) (Scheme 5) [16]. While changes in ^{13}C NMR shifts are diagnostic for the characterization

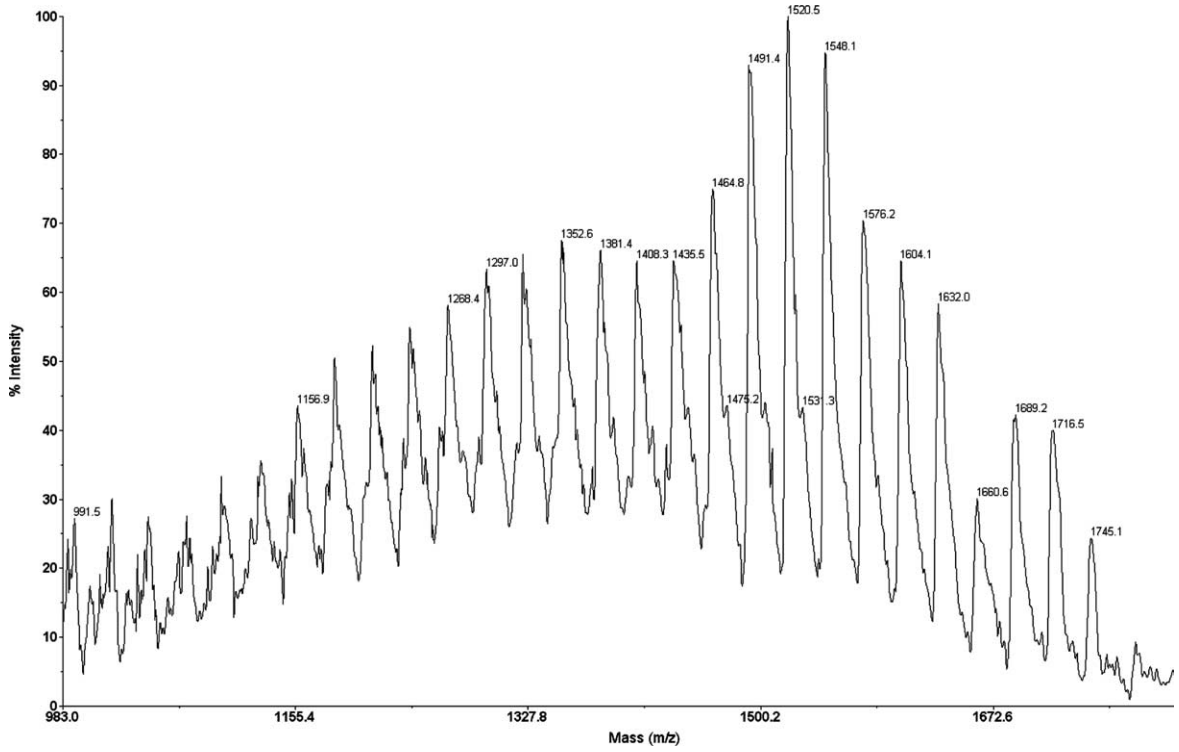

Fig. 2. The highest mass region of the MALDI-TOF mass spectrum of compound **13**. The highest mass peak is *m/z* 1745 assigned to $[M + K]^+$.

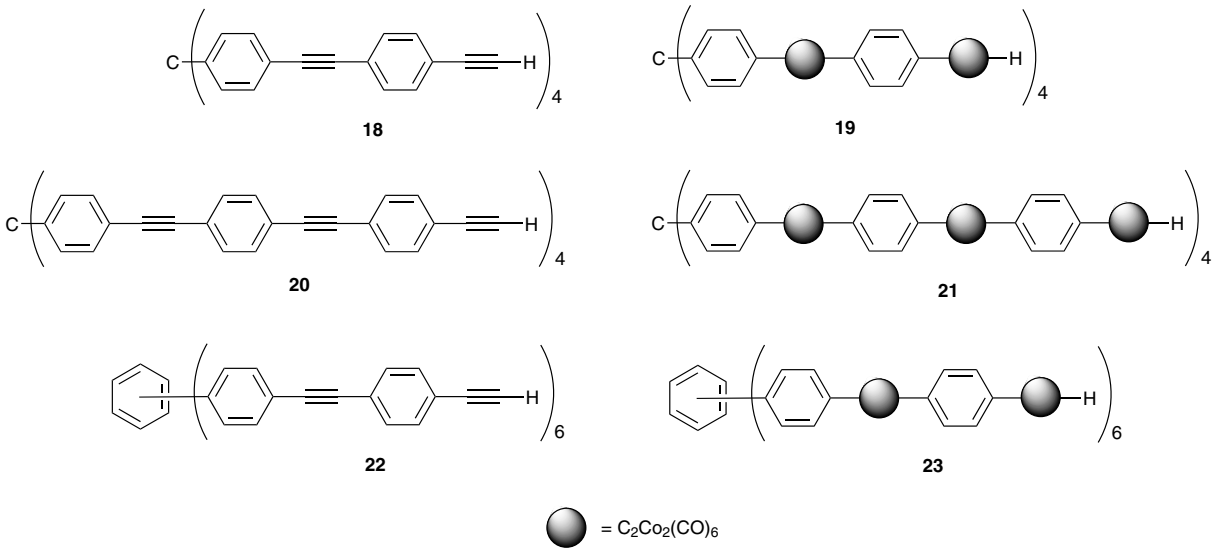

Scheme 5.

of the outer generation of alkynes/clusters, the results in Table 1 for the inner alkyne units are less clear cut. On going from compound **8** to **9**, or from **12** to **13**, only a small shift to higher frequency accompanies the transformation from C_{alkyne} to $C_{cluster}$. However, while the shift in δ values are indeed small, the trends are reproducible for the reactions of the inner alkynes with $Co_2(CO)_8$, for example on going from **8** to **9**, **12** to **13** (Scheme 3), **18** to **19**, **20** to **21** and **22** to **23** (Scheme 5).

4. Conclusions

Previous investigations of cobaltadendrimers have illustrated some of the problems associated with the characterization of such species. Our present studies of reactions between $Co_2(CO)_8$ and model alkynes (chosen so as to represent the core units for the divergent growth of stars and dendrimers) taken along with our past results [14–16] have allowed us to construct a database

of NMR chemical shift data which will invaluable for future work in this area. In addition, we have noted the limitations of FAB mass spectrometry in characterizing multicluster-containing species of the types shown in Schemes 2 and 3, and the power of the MALDI-TOF technique for analysing the cluster content of high molecular weight compounds.

5. Supplementary data

Crystallographic data including atomic coordinates, bond distances and angles for **10** have been deposited with the CCDC (Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) and may be obtained free of charge on quoting the deposition number CCDC 270614.

Abstract

The synthesis, characterization and reactivity of novel carbometalla[2]ferrocenophanes (η-C_5Me_4)Fe(η-C_5H_4)CH_2ER_2 (**14**) and (**15**) (E = Pb, R = Ph or E = Zr, R = (η-C_5H_5)) are reported. Compounds **14** and **15** were prepared by the reaction of the dilithiated species (η-C_5Me_4)Fe(η-C_5H_4Li)$CH_2Li \cdot x$TMEDA with the appropriate dichlorodiorganoplumbane or dichlorozirconocene in low yields (ca. 20%). The Pb species **14** was characterized by ^1H and ^{13}C NMR, and MS, however it could not be cleanly separated from pentamethylferrocene. Moreover, it was found that the C–Pb bonds of **14** underwent facile cleavage, and under ambient light or at room temperature, **14** decomposed to Pb_2Ph_6 and pentamethylferrocene. Compound **15**, on the other hand, was stable and readily purified; this species was characterized by ^1H and ^{13}C NMR, UV–Vis, MS, and elemental analysis. Single crystal X-ray diffraction studies of this compound revealed the presence of a moderate degree of ring-tilt with a value of $\alpha = -5.5(2)°$ (a negative value is used to denote tilting away from the bridging elements), and a potentially moderate degree of strain due to a large β(Zr) of 31.6(1)° (angle between Cp′(Fe) plane and *ipso*-Cp′–Zr bond). Attempted thermal ring-opening polymerization (ROP) of **15** resulted only in decomposition and attempted transition metal-catalyzed and photolytic ROP were also unsuccessful. The reaction of **15** with $HCl \cdot Et_2O$ resulted in cleavage of the C–Zr bonds, and led to the formation of pentamethylferrocene.

1. Introduction

[1]Ferrocenophanes have been the focus of much recent research due to the ring-strain imposed upon these organometallic species by the bridging of the cyclopentadienyl (Cp) rings by one atom [1–7]. This ring-strain leads to interesting reactivity for these compounds, and has led to their use in surface derivatization methods [8] and ring-opening polymerization (ROP) reactions [3,4]. Since the initial report of the thermal ROP of silicon-bridged [1]ferrocenophanes such as **1** ($(ER_x)_y$ = $SiMe_2$) to yield high molecular weight polymer **2** [3], the polymerization methods have been successfully expanded to include transition metal-catalyzed ROP [9,10], living anionic ROP [11], and photolytic ROP [12]. In addition, the ROP protocol has been extended to include other atoms in the bridge (E = B, P, Ge, Sn, S) [5–7], different metals (e.g., Ru, Cr and Ti) and also alternative π hydrocarbon ligands [6,7]. The resulting ring-opened polymers are attracting considerable attention due to their interesting physical and preceramic properties [13–20], and copolymers incorporating a ferrocene-containing block have intriguing applications in supramolecular chemistry [21,22]. In addition,

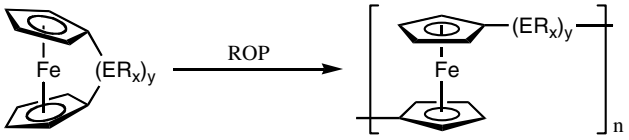
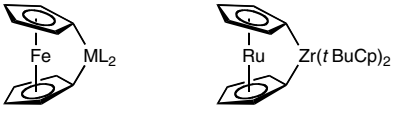
polyferrocenylsilanes have recently been used in the area of redox-responsive photonic crystals [23], as etch resists for the nanopatterning of substrates [24] and as precursors to patterned metal catalysts for the growth of carbon nanotubes [25].



1 2

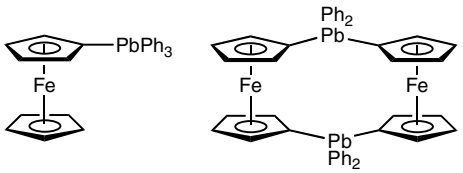
Examples of [1]ferrocenophanes with transition metals in the bridge have also been explored. Broussier et al. [26] reported the synthesis and reactivity of [1]ferrocenophanes (**3**) containing group 4 bridges. Analogues containing titanium, zirconium and hafnium bridges were prepared and single crystal X-ray diffraction of **3b** (L = *t*-BuCp) determined the tilting of the cyclopentadienyl rings to be moderate ($\alpha = 6.0°$). These [1]ferrocenophanes were shown to be reactive towards water and oxygen, in addition to heavier chalcogens leading to insertion of the chalcogen into the *ipso*-Cp–Zr bond [26]. In addition, we recently reported the synthesis of a zirconium-bridged [1]ruthenocenophane (**4**) with a larger tilt angle of the metallocene fragment ($\alpha = 10.4°$) [27].



3a: M = Ti, L =Cp, *t*-BuCp
3b: M = Zr, L = Cp, *t*-BuCp
3c: M = Hf, L = Cp, *t*-BuCp

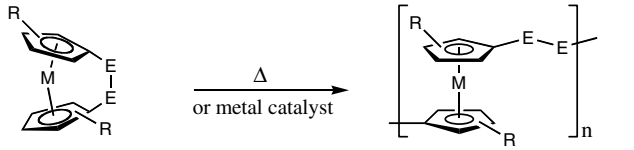
4

Attempts have also been made to introduce heavy atoms into ferrocenophane structures. Ferrocene was reacted with *n*-BuLi in hexanes to yield a mixture of $(\eta\text{-}C_5H_5)Fe(\eta\text{-}C_5H_4Li)$ and $(\eta\text{-}C_5H_4Li)_2Fe$ to which Ph_3PbCl and Ph_2PbCl_2 were added in situ [28]. The products isolated were a mixture of the plumbylferrocene (**5**), and the [1,1′]diplumbylferrocenophane (**6**). These products were characterized by NMR, MS and elemental analysis; however single crystals were not obtained, and no evidence for the formation of a [1]plumbaferrocenophane was reported [28].



5 **6**

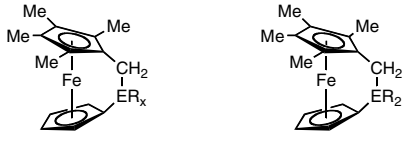
The preparation and reactivity of [1]ferrocenophanes have been well explored over the past few decades, however until recently the area of [2]ferrocenophanes has received comparatively less attention. Previous work has shown that highly strained hydrocarbon-bridged monomers **7** (M = Fe, R = H, Me, $E_2 = CH_2CH_2$) and the analogous [2]ruthenocenophane (**7**) (M = Ru, R = H, $E_2 = CH_2CH_2$), undergo thermal ROP [29,30], whereas ring-opening metathesis polymerization of [2]ferrocenophane (**7**) (M = Fe, R = H, $E_2 = CH{=}CH$) has also been described [31]. In contrast, [2]metallocenophanes with Si–Si bridges such as **7** (M = Fe or Ru, $E_2 = SiMe_2SiMe_2$), are relatively unstrained and resist ROP [32], whereas an analogue with a Ge–Ge bridge (**7**: M = Fe, $E_2 = GeMe_2GeMe_2$) has been successfully polymerized [33].



7: M = Fe or Ru,
R = H or Me,
$E_2 = CH_2CH_2$ or CH=CH
$E_2 = SiMe_2SiMe_2$ or $GeMe_2GeMe_2$

8: M = Fe or Ru,
R = H or Me,
$E_2 = CH_2CH_2$ or CH=CH
$E_2 = GeMe_2GeMe_2$

Recently, our group has studied the synthesis and ROP behaviour of [2]ferrocenophanes with unsymmetrical C–E bridges **9**–**13** [34,35]. It was shown for compounds **9**–**11** (E = Si, P, S) as the covalent radius of E was varied, the ring-strain was varied accordingly [34]. The least strained of these species (**9**, $\alpha = 11.8(1)°$) was found to be completely resistant to polymerization under all conditions studied, whereas the more strained species **10** ($\alpha_{avg} = 16.5°$) and **11** ($\alpha = 18.5(1)°$) were found to undergo successful ROP. This work recently prompted us to explore the synthesis and ROP behaviour of the [2]ferrocenophanes **12** and **13**. The presence of weak C–Ge and C–Sn bonds were expected to increase reactivity of group 14 carbo[2]ferrocenophanes, despite the decrease in tilt angle between the cyclopentadienyl rings. It was found however that the C–E bonds of **12** and **13** were insufficiently weak to permit ring-opening polymerization [35].



9 : $ER_x = SiMe_2$
10 : E = P, R = Ph, Mes
11 : $ER_x = S$

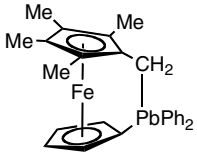
12 : E = Ge, R = Me, Ph
13 : E = Sn, R = Me, *t*-Bu, Mes

In this paper, we report on our attempts to further explore the area of carbon-heteroatom bridged [2]ferrocenophanes via the introduction of heavy main group elements and transition metals into the bridge. We report the synthesis and reactivity of the novel carboplumba[2]ferrocenophane (**14**) and carbozircona[2]ferrocenophane (**15**).

2. Results and discussion

2.1. Attempted synthesis of lead-bridged [2]ferrocenophanes

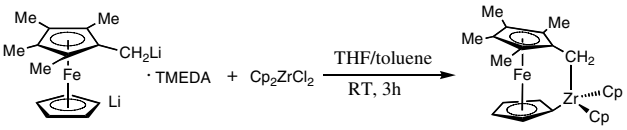
We attempted to prepare the C–Pb bridged [2]ferrocenophane (**14**) from the reaction of (η-C_5Me_4)Fe(η-C_5H_4Li)$CH_2Li \cdot x$TMEDA with Ph_2PbCl_2. This regenerated the precursor pentamethylferrocene as the major isolated product in addition to the desired C–Pb bridged [2]ferrocenophane (**14**). The mixture was isolated as an orange gummy material in 17% total yield. ^{1}H NMR characterization demonstrated the fraction of **14** in the reaction solution to be approximately 25%. One feature of the ^{1}H NMR spectrum of **14** is the methylene resonance observed at 3.23 ppm which is significantly more downfield than in compounds **9**–**13**, and the ^{1}H–^{207}Pb coupling observed for these protons ($J(^{207}Pb/^1H) = 54$ Hz). The structure of **14** was also confirmed by ^{13}C NMR analysis and mass spectrometry. The impetus for preparing compound **14** was to further weaken the C–E bond of group 14-containing carbo[2]ferrocenophanes (E = Si, Ge, Sn) which do not undergo ring-opening polymerization under thermal, transition metal-catalyzed, anionic or photolytic conditions [34,35]. Indeed, compound **14** possesses weak C–Pb bonds such that this species is both sensitive to light and temperature; attempts to recrystallize **14** from a concentrated hexanes solution under an inert atmosphere at room temperature led to the deposition of a black precipitate, the formation of $Ph_3PbPbPh_3$ and an increase in the amount of (η-C_5Me_5)Fe(η-C_5H_5) as detected by ^{1}H NMR and X-ray diffraction. At low temperature (−30 °C), decomposition did not occur as readily, however **14** could still not be successfully isolated in pure form from mixtures containing (η-C_5Me_5)Fe(η-C_5H_5).



14

2.2. Synthesis and characterization of C–Zr bridged [2]ferrocenophane (*15*)

We attempted to prepare the C–Zr bridged [2]ferrocenophane (**15**) by the reaction of (η-C_5Me_4)Fe(η-C_5H_4Li)$CH_2Li \cdot x$TMEDA with (η-C_5H_5)$_2ZrCl_2$. A yellow product precipitated from THF/toluene, and ^{1}H and ^{13}C NMR analysis confirmed the structure of the product was **15**, which was isolated in 19% yield. In the ^{13}C NMR spectrum (in C_6D_6), however, it was difficult to assign the *ipso*-Cp′ and *ipso*-Cp* (Cp* = C_5Me_4) resonances due to low solubility of **16** in C_6D_6 and apparent overlapping with the Cp′ and Cp* resonances. In the solid state CP-MAS ^{13}C NMR, a peak was observed for the *ipso*-Cp′ at 156 ppm which is consistent with the *ipso*-Cp′ resonances of **3b** observed at 159 ppm [26]. The *ipso*-Cp* resonance was observed as a shoulder at 80 ppm of the broad peak at 86 ppm corresponding to Cp* carbon resonances. In moderately strained [1]ferrocenophanes [5–7] and C–E bridged [2]ferrocenophanes [34,35], the resonances for the *ipso*-Cp′ and/or *ipso*-Cp* carbons are shifted upfield which is consistent with a deviation from planar sp^2 hybridization imposed by the bridging of the rings. By comparison with NMR characterization of **3b** [26], **9** [34], **12** [35], it appears that **15** is relatively unstrained.



15

2.3. X-ray structural analysis of [2]ferrocenophane (*15*)

Suitable single crystals of **15** were obtained through low temperature (−30 °C) recrystallization from a concentrated toluene solution. Only one type of species was found in the unit cell. The molecular structure of **15** is shown in Fig. 1, and selected bond angles are given in Table 1. Of note in the molecular structure of **15** is the "bowtie" configuration of the Cp′Cp*Fe and Cp_2Zr rings and the relatively small α angle (−5.5(2)°) found between the planes of the Cp′ and Cp* rings. (*Note*. The negative α angle denotes tilting of the cyclopentadienyl rings away from the C–Zr bridge.) The tilt angle is expected to be moderate due to the large size of the zirconium atom ($r_{cov} = 1.55$ Å) [36] in comparison with other heteroatom-bridged [2]ferrocenophanes (cf. **12b**, $\alpha = 7.1(1)°$, Sn: $r_{cov} = 1.40$ Å) [35]. Due to the presence of two bridging atoms, it was expected that **15** would exhibit a smaller α angle relative to the corresponding [1]ferrocenophane (**3b**) ($\alpha = 6.0°$) [26], however the tilting of the cyclopentadienyl rings away from the bridge was unanticipated. This structure represents a rare case of [*n*]ferrocenophanes that contain "negative" tilt angles [37], and the first example for a [2]ferrocenophane that we are aware of. Since the tilt angle of the pentamethylferrocene fragment is small, other structural parameters may be of importance when discussing the strain of this compound. For example, the zirconium atom is found in an approximate tetrahedral environment (i.e., C(6)–Zr–C(15) = 109.0(1)°, Cp-centroid–Zr–Cp-centroid = 126.6(2)°) which may indicate moderate strain at the bridging atom, the staggering angle is relatively small (σ = 1.3(5)°) (σ = angle with which the Cp(Fe) rings deviate from an eclipsed conformation) and the torsional

[e] In THF.

angle (τ) is 1.5(2)° (τ = angle between the CH_2–$ZrCp_2$ bond and the plane containing the Cp*/Cp′(Fe) centroids and iron atom) which would suggest that **15** may possess a small degree of strain. In addition, the structure revealed a β(CH_2) of 1.9(3)° (angle between Cp* plane and *ipso*-Cp*–CH_2 bond) and a β(Zr) of 31.6(1)° (angle between Cp′(Fe) plane and the *ipso*-Cp′–Zr bond). These results suggest that **15** possesses some degree of strain, since in non-bridged ferrocenes these angles would be expected to approach zero [38]. In addition, in comparison with other carbon-heteroatom bridged [2]ferrocenophanes **9**–**13** [34,35], compound **15**

contains the largest β(E) (where E = Si, P, S, Ge, Sn, Zr).

2.4. Attempted ROP of [2]ferrocenophane (15)

The thermal polymerization behaviour of **15** was initially investigated by heating a sample in an evacuated tube at temperatures up to 300 °C for up to 48 h. Alternatively, a sample was heated in solution (C_6D_6) in an NMR tube at 50 °C for up to 96 h. In each case, ^{1}H NMR analysis displayed peaks corresponding to unreacted **15** as well as amounts of (η-C_5Me_5)Fe(η-C_5H_5).

Transition metal-catalyzed ROP, which is a very useful method for preparing high molecular weight polyferrocenylsilanes and for achieving molecular weight control of these polymers [39], was also explored as a means to polymerize **15**. Karstedt's catalyst was added to a sample of **15** in solution in an NMR tube at 25 °C. However, after 48 h ^{1}H NMR characterization of this solution revealed the presence only of unreacted **15**. This sample was then heated to 40 °C for 96 h. The conversion of **15** to (η-C_5Me_5)Fe(η-C_5H_5) in 40% yield after 96 h, was most probably a result of the heating of the sample.

Photolytic ROP is a novel polymerization method for ferrocenophanes, and is expected to become an important technique for the preparation of polyferrocenylsilanes [12]. Photolytic treatment in the presence of phosphines has also been recently shown to induce ring-opening reactions of [2]ferrocenophanes **7** (M = Fe or Ru, $E_2 = CH_2CH_2$) [12d]. In order to probe the reactivity of **15**, photolytic ring-opening reactions were attempted. Samples of **15** in the presence of catalytic and equimolar amounts of Na[η-C_5H_5], equimolar amounts of the stronger donor Li[C_5H_4Me], and equimolar amounts of bis(diphenylphosphino)ethane were irradiated for several hours. In each case, only unreacted **15** was detected by ^{1}H NMR characterization.

2.5. Reaction of 15 in the presence of a strong protic acid

A sample of **15** was treated with an equimolar amount of HCl (2.0 M in Et_2O) at room temperature. The solution immediately changed colour to a deep red. After solvent was removed, ^{1}H NMR showed the presence of two products. One of the products was identified as pentamethylferrocene, however the fate of the {$ZrCp_2$} fragment could not be conclusively identified. Reaction with HCl seems to successfully ring-open **15**, however the reaction is not limited to breaking only one C–Zr bond.

3. Summary

The synthesis of carboplumba[2]ferrocenophane (**14**) and carbozircona[2]ferrocenophane (**15**) was achieved through the reaction of (η-C_5Me_4)Fe(η-C_5H_4Li)-CH_2Li · *x*TMEDA and dichlorodiphenylplumbane or dichlorozirconocene. Species **14** could not be isolated in pure form from pentamethylferrocene (η-C_5Me_5)-Fe(η-C_5H_5), however it was found that this compound possessed weaker C–E bonds (E = Si, Ge, Sn, Pb) than the analogous group 14-containing carbo[2]ferrocenophanes **9**, **12** and **13** since it decomposed under ambient light and room temperature conditions. By contrast, compound **15** which is the first example of a carbo[2]-ferrocenophane containing a transition metal as the bridging heteroatom, was isolated as yellow crystals with a moderate ring-tilt ($\alpha = -5.5(2)°$). Attempts to induce ring-opening polymerization under thermal, transition metal-catalyzed or photolytic conditions were unsuccessful; however the C–M bonds underwent cleavage in the presence of a strong protic acid.

4. Experimental

4.1. Materials

All reagents, unless otherwise specified, were purchased from Aldrich Chemical Co. and were used as received. Solvents were dried by standard procedures and distilled immediately prior to use. Cp_2ZrCl_2 was recrystallized from a concentrated $CHCl_3$ solution prior to use. Karstedt's catalyst (2.1–2.4% Pt in xylenes) was purchased from Gelest and used as received. Ph_2PbCl_2 was purchased from Strem Chemical Co. and was used as received. (η-C_5Me_4)Fe(η-C_5H_4Li)CH_2Li · *x*TMEDA was prepared according to the literature procedures [35].

4.2. Equipment

All reactions and manipulations were performed under an inert atmosphere (prepurified N_2) using either standard Schlenk techniques or an inert atmosphere glovebox (Mbraun). ^{1}H NMR (400 or 300 MHz) and ^{13}C NMR (100.5 MHz) spectra were recorded on Varian Unity 400 or Varian Mercury 300 spectrometers. All solution ^{1}H and ^{13}C NMR spectra were referenced internally to residual protonated solvent shifts. Solid state CP-MAS ^{13}C spectra were obtained on a Bruker DSX200 instrument with a spin rate of 8 KHz. UV–Vis spectra were obtained using a Perkin–Elmer Lambda 900 UV–Vis–near-IR spectrophotometer in THF at concentrations of 3.6 mmol L^{-1}. Mass spectra were obtained with the use of a VG 70-250S mass spectrometer operating in electron impact (EI) mode. The calculated isotopic distribution for each ion was in agreement with experimental values. The photoirradiation experiments were performed by placing the reaction flask next to a 125-W high

pressure Hg arc lamp (Philips). The emission was filtered by Pyrex glass ($\lambda >$ ca. 300 nm). Elemental analyses were obtained using a Perkin–Elmer Series II 2400 CHNS analyzer maintained by the Analest facility at the University of Toronto.

4.3. Synthesis of (η-C_5Me_4)Fe(η-C_5H_4)CH_2PbPh_2 (**14**)

To a suspension of (η-C_5Me_4)Fe(η-C_5H_4Li)-$CH_2Li \cdot x$TMEDA ($x = 0.66$) (2.0 g, 5.8 mmol) in Et_2O (150 mL) kept at −78 °C was added slowly with stirring a solution of Cl_2PbPh_2 (3.0 g, 6.9 mmol) in 150 mL Et_2O also kept at −78 °C. The resulting solution was allowed to stir for 2.5 h at −78 °C in the absence of light. The orange solution was then allowed to warm to room temperature and was filtered cold to remove LiCl. Solvent was removed under vacuum for approximately 5 h after which time the product was extracted from hexanes, filtered cold once more and solvent was removed completely to yield a light orange gummy material. The product contained quantities of (η-C_5Me_5)Fe(η-C_5H_5) and attempts to isolate **14** were unsuccessful. The product is light and temperature sensitive as attempts to recrystallize at room temperature under inert atmosphere led to a black precipitate on the side of the vial, formation of crystals of $Ph_3PbPbPh_3$ confirmed by single crystal X-ray diffraction; (see [40]) and an increase in the amount of (η-C_5Me_5)Fe(η-C_5H_5) as observed by ^{1}H NMR analysis. Purification of **14** from a concentrated hexanes solution at −30 °C proved unsuccessful. Crude yield: 0.61 g (17%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 7.77$–7.75 (m/m, $J(^{207}Pb/H) = 72$ Hz, 4H, *o*-C_6H_5), 7.31–7.27 (m/m, $J(^{207}Pb/H) = 38.4$ Hz, 4H, *m*-C_6H_5), 7.15 (m, 2H, *p*-C_6H_5), 4.46 (ps t/m, $J(^{207}Pb/H) = 12.4$ Hz, 2H, C_5H_4), 3.80 (ps t/m, $J(^{207}Pb/H) = 12.4$ Hz, 2H, C_5H_4), 3.23 (s/d, $J(^{207}Pb/H) = 54$ Hz, 2H, CH_2-Pb), 2.24 (s, 6H, C_5Me_4), 1.77 (s, 6H, C_5Me_4) ppm. ^{13}C NMR (100 MHz, C_6D_6, 25 °C): $\delta = 155.5$ ($J(^{207}Pb/^{13}C) = 30$ Hz, *ipso*-C_6H_5), 137.1 ($J(^{207}Pb/^{13}C) = 15$ Hz, *o*-C_6H_5), 131.1 (*p*-C_6H_5), 128.2 ($J(^{207}Pb/^{13}C) = 11$ Hz, *m*-C_6H_5), 107.2 ($J(^{207}Pb/^{13}C) = 35$ Hz, *ipso*-C_5Me_4), 92.4 ($J(^{207}Pb/^{13}C) = 10$ Hz, C_5Me_4), 82.6 ($J(^{207}Pb/^{13}C) = 9$ Hz, C_5Me_4), 80.1 (C_5H_4), 79.5 (C_5H_4), 71.8 ($J(^{207}Pb/^{13}C) = 16$ Hz, *ipso*-C_5H_4), 29.3 ($J(^{207}Pb/^{13}C) = 430$ Hz, CH_2-Pb), 11.9 (C_5Me_4), 11.7 (C_5Me_4) ppm. MS (70 eV, EI): *m*/*z* (%) 616 (27) [M^+], 439 (43) [M^+] − Fe − C_5Me_4, 254 (100) [M^+] − $PbPh_2$.

4.4. Synthesis of (η-C_5Me_4)Fe(η-C_5H_4)CH_2ZrCp_2 (**15**)

To a solution of (η-C_5Me_4)Fe(η-C_5H_4Li)$CH_2Li \cdot x$TMEDA ($x = 0.66$) (5.0 g, 14.5 mmol) in a THF/toluene mixture (50/50 v/v, 15 mL/15 mL) was added very slowly with stirring a solution of Cp_2ZrCl_2 (4.23 g, 14.5 mmol) in a THF/toluene mixture (50/50 v/v, 15 mL/15 mL) at room temperature. After the addition was complete, the deep purple solution was allowed to stir at room temperature for 2 additional hours. The resulting solution was filtered under N_2 resulting in the collection of a light yellow precipitate. This powder was washed with cold toluene (5–10 mL) and residual solvent was removed under vacuum overnight. The product is stable in air for several hours in the solid state. Recrystallization of this material at −30 °C from a concentrated solution in hot toluene afforded **15** as yellow crystals. Yield: 1.31 g (19%). ^{1}H NMR (C_6D_6, 400 MHz, 25 °C): $\delta = 5.61$ (s, 10H, Zr(η-C_5H_5)$_2$), 3.81 (ps t, 2H, C_5H_4), 3.21 (ps t, 2H, C_5H_4), 1.82 (s, 6H, C_5Me_4), 1.08 (s, 2H, CH_2-Zr), 1.01 (s, 6H, C_5Me_4) ppm. ^{13}C NMR (C_6D_6, 100 MHz, 25 °C): $\delta = 105.6$ (Zr(η-C_5H_5)$_2$), 85.6 (C_5Me_4), 84.6 (C_5Me_4), 76.9 (C_5H_4), 76.5 (C_5H_4), 12.7 (C_5Me_4), 12.3 (C_5Me_4), -2.7 (CH_2-Zr) ppm. Cp-MAS ^{13}C NMR (100.6 MHz, $k = 8$ KHz, 25 °C) $\delta = 156$ (*ipso*-Cp′), 106 (Zr(η-C_5H_5)$_2$), 86 (C_5Me_4), 80 (*ipso*-Cp*), 77 (C_5H_4), 76 (C_5H_4), 15 (C_5Me_4), 14 (C_5Me_4), −3 (CH_2-Zr) ppm. UV–Vis (THF): $\lambda_{max} = 366$ nm ($\varepsilon = 299$ M^{-1} cm^{-1}). MS (70 eV, EI): *m*/*z* (%) 474 (100) [M^+], 338 (49) [M^+] − $C_5Me_4CH_2$, 254 (35) [M^+] − $ZrCp_2$. *Anal*. Calc. for $C_{25}H_{28}ZrFe$ (475): C, 63.16; H, 5.93. Found: C, 63.32; H, 6.25%.

4.5. Attempted thermal polymerization of **15**

A sample of **15** (0.5 g) was sealed in an evacuated Pyrex tube and heated up to 300 °C for 48 h, however there was no observable increase in viscosity. The resulting material was characterized by ^{1}H NMR and contained unreacted **15** as well as (η-C_5Me_5)Fe(η-C_5H_5).

Alternatively, a solution of **15** (25 mg) in C_6D_6 (1.5 mL) was heated in an NMR tube under inert atmosphere at 50 °C for a period up to 96 h. After approximately 12 h, ^{1}H NMR characterization revealed 15% conversion to (η-C_5Me_5)Fe(η-C_5H_5). After 96 h, ^{1}H NMR characterization displayed very broad peaks and 70% conversion to (η-C_5Me_5)Fe(η-C_5H_5). No other products could be isolated.

4.6. Attempted platinum-catalyzed ring-opening reactions of **15**

To a solution of **15** (25 mg) in C_6D_6 (1.5 mL) was added Karstedt's catalyst (0.5% wt, 6.46 μL) in an NMR tube. The mixture was allowed to react under inert atmosphere for 48 h, after which time ^{1}H NMR characterization displayed only the presence of **15**. This solution was then heated to 40 °C for a period up to 96 h. After approximately 48 h, no change was observed in the ^{1}H NMR spectrum. At 96 h, ^{1}H NMR characterization revealed approximately 40% conversion to (η-C_5Me_5)Fe(η-C_5H_5).

4.7. Attempted photolytic ring-opening reactions of **15**

A solution of **15** (50 mg, 105 μmol) in THF (1 mL) in a Schlenk flask was treated with: (i) 10% $Na(C_5H_5)$ (2.0 M in THF, 5.25 μL), (ii) 1 equivalent of $Na(C_5H_5)$ (2.0 M in THF), 52.5 μL), (iii) 1 equivalent of $Li(C_5H_4CH_3)$ (9.0 mg), and (iv) 1 equivalent of bis(diphenylphosphino)ethane (41.9 mg). Solutions were placed in a 5 °C bath and irradiated for approximately 3–5 h. In each case, only unreacted **15** could be detected by ^{1}H NMR.

4.8. Reaction of **15** in the presence of a strong protic acid

One equivalent of $HCl \cdot Et_2O$ (2 M in Et_2O, 31.5 μL) was added dropwise to a yellow solution of **15** (30 mg, 63.1 μmol) in Et_2O (2 mL) at room temperature. Upon addition of $HCl \cdot Et_2O$, the solution immediately changed colour to deep red. The mixture was allowed to stir for an additional hour and remained a deep red colour, after which time solvent was removed under vacuum. Initial ^{1}H NMR characterization revealed a mixture of products, however after the product was kept under an inert atmosphere for 12 h, orange crystals were obtained which were identified as $(\eta\text{-}C_5Me_5)Fe(\eta\text{-}C_5H_5)$ by ^{1}H NMR.

4.9. X-ray crystallography

Selected crystal, data collection, and refinement parameters for **15** are given below. Selected angles are given in Table 1. Single-crystal X-ray diffraction data of air-sensitive yellow needles of **15** (approximate size: $0.15 \times 0.14 \times 0.07\ mm^3$) were collected at 150 K using a Nonius Kappa-CCD diffractometer and monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The chemical formula of the compound is $C_{25}H_{28}FeZr$ and **15** crystallized in the monoclinic crystal system and $P2_1/c$ space group containing four chemical units per cell. The unit cell parameters were determined to be: $a = 14.1433(5)$ Å, $b = 8.2367(2)$ Å, $c = 16.4805(6)$ Å, $\alpha = 90°$, $\beta = 90.467(2)°$, $\gamma = 90°$. The number of reflections collected were 15612, the number of independent reflections were 4385 [$R_{int} = 0.047$] and completeness to $\theta = 27.50°$ was 99.3%. The data were integrated and scaled using the DENZO-SMN package [41]. The SHELXTL/PC package was used to solve and refine the structures [42]. Refinement was by full-matrix least-squares on F^2 using all data (negative intensities included). The $R_1[I > 2(I)] = 0.0438$ and wR_2(all data) $= 0.1003$, where $R_1 = \sum||F| - |F_o|/\sum|F_o|$. $wR_2 = \{\sum[\omega(F_o^2 - F_c^2)^2]/\sum[\omega(F_o^2)^2]\}^{1/2}$. Hydrogen atoms were placed in calculated positions and included in the refinement in riding motion.

5. Supplementary material

CCDC 270933 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgements

We thank the Natural Science and Engineering Research Council of Canada (NSERC) for funding this research. In addition, A. Bartole-Scott would like to thank the Ontario Government for an O.G.S. scholarship (2004–2005) and I. Manners is grateful to the Government of Canada for a CRC award (2001–2008). We also thank Dr. Andrew Baer from the Solid State NMR facility at the University of Toronto for help performing CP-MAS experiments.

This paper is dedicated to our friend and colleague Malcolm Chisholm on the occasion of his 60th birthday, and in recognition of his contributions to chemistry in general and to this journal in particular.

Abstract

Strategies for the preparation of multinuclear complexes containing homoditopic and heteroditopic ligands based upon 2,2′-bipyridine (bpy) and 2,2′:6′,2″-terpyridine metal binding domains are presented. Both conventional approaches based upon preparation of a free ligand and subsequent coordination and metal-directed reactions of coordinated ligands are utilized in the various strategies. A representative series of complexes of these ligands has been prepared.

1. Introduction

Multinuclear metal complexes are of interest in areas as disparate as bioinorganic chemistry, materials science, photophysics and artificial photosynthetic systems, redox and photoactive polymers, dendrimer chemistry and nanoscience, catalysis and sensors [1,2]. A useful concept for the design of such systems is that of a "metal-binding domain" – in other words a part of a polyfunctional molecule that is recognized as a ligand in its own right and which will bind metal centres in a predictable way, based upon knowledge of the coordination chemistry of the parent systems. We and others have developed synthetic approaches to metallodendrimers, metallostars, metallopolymers and metallooligomers based upon 2,2′-bipyridine (bpy) and 2,2′:6′,2″-terpyridine (tpy) metal-binding domains [3–14]. A variety of synthetic strategies have been adopted, most of which rely upon the initial synthesis of the desired free ligands with the metal-binding domains of choice. An increasingly commonly adopted synthetic strategy relies upon the generation of the new polytopic ligands within the coordination sphere of one or more metals by the reaction of electrophilic and nucleophilic components, either or both of which might be a mono- or multinuclear oligopyridine-metal complex [15–30]. Strategies involving preformed ligands or in situ ligand syntheses may be divergent, starting from a single metal centre and building outwards, or convergent, in which the final reaction

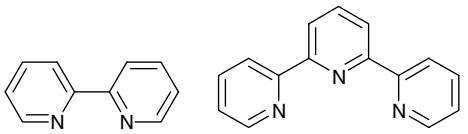
step involves the combination of metal-containing units with the total desired number of metal centres.



bpy tpy

An attractive metal-binding domain for incorporation into such systems is bpy which has an exceptionally well-understood coordination chemistry and which forms complexes with most elements in the periodic table [31,32]. Much of the interest in bpy-based systems relates to the useful photochemical and photophysical properties of $\{Ru(bpy)_3\}^{2+}$ and related coordination units which can readily be incorporated into polynuclear compounds [33–35]. Our original motivation for studying tpy-containing systems developed from the major disadvantage of compounds containing multiple $\{M(bpy)_3\}$ units – each $\{M(bpy)_3\}$ motif is chiral and may possess a Δ or Λ configuration, and whilst this presents no significant difficulties if a single such moiety is present, compounds containing multiple $\{M(bpy)_3\}$ motifs will exist as diastereoisomers with different spatial relationships between metal centres and hence, at least in principle, different energy and electron-transfer characteristics [36,37]. In contrast, the $\{M(tpy)_2\}$ motif is achiral provided that the substitution of the tpy ligand is symmetrical and multinuclear complexes will exist as single stereoisomers. Unfortunately, the photophysical properties of $\{Ru(tpy)_2\}$ units are seriously inferior to those of $\{Ru(bpy)_3\}^{2+}$ (short-lived ^{3}MLCT state, non-emittive in fluid solution) and we have extended our studies to heteropolytopic ligands containing both bpy and tpy metal binding domains. In this paper, we describe approaches to a series of homo- and heteroditopic ligands incorporating bpy and tpy metal-binding domains and describe a series of homo- and heteronuclear complexes.

2. Experimental

2.1. General experimental

Commercially available chemicals were reagent grade and were used without further purification; the compounds 2,2′-bipyridine *N*-oxide [38–51], 4-nitro-2,2′-bipyridine *N*-oxide [40,45,47,50,51], 4-bromo-2,2′-bipyridine (Brbpy) [40,51–53], 4-chloro-2,2′-bipyridine (Clbpy) [44,49,52,54,55], 2,2′-bipyridin-4(1H)-one (HObpy) [56], 4-amino-2,2′-bipyridine [47,56,57], 4′-chloro-2,2′:6′,2″-terpyridine (Cltpy) [58] and 4′-hydroxy-2,2′:6′,2″-terpyridine (HOtpy) [58] were prepared by minor modifications of the literature methods. ^{1}H and ^{13}C NMR spectra were recorded on Bruker 250, 400, 500 or 600 MHz; chemical shifts are defined with TMS $\delta = 0$ ppm and are measured relative to residual $CHCl_3$ or CHD_2CN. Infrared spectra were recorded on Shimadzu FTIR-8400S or Mattson Genesis FTIR spectrophotometers with neat samples on a Golden Gate diamond ATR accessory or in compressed KBr pellets. UV/VIS measurements were performed using a Varian Cary 5000 UV–Vis–NIR spectrophotometer; spectra were recorded for $\approx 10^{-5}$ M solutions in $CHCl_3$ (ligands) or MeCN (coordination compounds). FAB mass spectra were recorded on Jeol SX102, VG70-250 or a Finnigan MAT312 instruments. EI mass spectra were recorded on VG 70 SE or Kratos MS-50 mass spectrometers and electrospray (ES) mass spectra on a Finnigan MAT LCQ mass spectrometer. Maldi TOF mass spectra were recorded using a PerSeptive Biosystems Voyager-RP or a PerSeptive Biosystems Voyager-DE TM PRO Biospectrometry workstation. All electrochemical data were measured with a EG&G potentiostat/galvanostat model 263 or a BAS 100 B/W electrochemical workstation and a three electrode cell consisting of $Ag/AgNO_3$ reference, a glassy carbon disk as the working and a platinum wire as counter electrode was used. Tetra-*n*-butylammonium hexafluorophosphate acted as the electrolyte. All solutions were degassed thoroughly for at least 15 min with argon and during the measurement an inert gas blanket was maintained over the solution. After obtaining a full set of voltammograms, ferrocene was added in order to determine the exact position of the signals within the potential window.

2.2. Synthesis

2.2.1. 1,4-bis(2,2′:6′,2″-terpyridin-4′-yloxy)benzene (9)

A mixture of HOtpy (416 mg, 1.67 mmol) and K_2CO_3 (690 mg, 4.94 mmol, dried overnight at 180 °C) was added to DMF (25 mL, dried over molecular sieves) and stirred at 60 °C for 20 min, after which period 1,4-$BrCH_2C_6H_4CH_2Br$ (200 mg, 0.758 mmol) was added and the reaction mixture kept at 60 °C for 3 h. The mixture was then cooled to room temperature and water (50 mL) added to give a white precipitate that was collected by filtration. The filtrate was washed with water and recrystallized from ethanol/DMF to give **9** as a white solid (410 mg, 82%). ^{1}H NMR (300 MHz, $CDCl_3$): δ/ppm 8.71 (H_{A6}, m, 4H), 8.63 (H_{A3}, d, 4H, J 7.8 Hz), 8.14 (H_{B3}, s, 4H), 7.86 (H_{A4}, t, 4H, J 7.8 Hz), 7.55 (H_C, s, 4H), 7.34 (H_{A5}, m, 4H), 5.36 ($H_{methylene}$, s, 4H); ^{13}C NMR (100 MHz, $CDCl_3$): δ 164.4 (B4), 156.9 (A2/B2), 156.8 (A2/B2), 148.8 (A6), 137.8 (C1,4), 135.6 (A4), 127.8 (C2,3), 123.9 (A5), 121.5 (A3), 107.9 (B3), 69.8 (CH_2) *m*/*z*: (EI MS): 601 (M), 352 (M-Otpy). *Anal*. 2.2.2. 1,4-bis(2,2′bipyridin-4-yloxy)benzene (7)

A mixture of HObpy (882 mg, 5.12 mmol) and K_2CO_3 (2.134 g, 15.26 mol, dried overnight at 170 °C) was added to DMF (20 mL, dried over molecular sieves) and heated to 60 °C. After 30 min 1,4-$BrCH_2C_6H_4CH_2Br$ (615 mg, 2.33 mmol) was added and the mixture was kept at 60 °C for 5 h after which time it was cooled to room temperature and water (50 mL) added to give an off-white precipitate. This was collected by filtration and washed with water to give **7** as a white solid (943 mg, 90.6%). ^{1}H NMR (300 MHz, $CDCl_3$): δ/ppm 8.69 (H_{A6}, m, 2H), 8.51 (H_{B6}, d, 2H, J 6.0 Hz), 8.41 (H_{A3}, d, 2H, J 7.8 Hz), 8.10 (H_{B3}, s, 2H), 7.83 (H_{A4}, t, 2H, J 7.8 Hz), 7.52 (H_C, s, 4H), 7.33 (H_{A5}, m, 2H), 6.93 (H_{B5}, m, 2H), 5.26 ($H_{methylene}$, s, 4H); ^{13}C NMR (100 MHz, $CDCl_3$): δ/ppm 165.8 (B4), 158.2 (A2/B2), 156.0 (A2/B2), 150.4 (B6), 149.1 (A6), 136.9 (C1,4), 136.0 (A4), 127.9 (C2,3), 123.8 (A3), 121.3 (A5), 111.4 (B3), 106.9 (B5), 69.5 (CH_2); m/z: (FAB MS) 447 (M). *Anal*. Calc. for $C_{25}H_{17}N_4O_2$: C, 77.5; H, 4.4; N, 18.1. Found: C, 77.6; H, 4.7; N, 17.7%. IR $\bar{\nu}$/cm^{-1} (KBr): 3340w, 2980m, 1736s, 1704s, 1624w, 1576m, 1448m, 1416m, 1368m, 1255s, 1160s, 1096w, 1032w, 984m, 904w, 840m, 760m, 664m, 584w; mp: 175–178 °C.

2.2.3. [Ru(bpy)$_2$(Brbpy)][PF$_6$]$_2$

Brbpy (30 mg, 0.13 mmol) and [Ru(bpy)$_2$Cl$_2$] (62 mg, 0.13 mmol) were added to $HOCH_2CH_2OH$ (4 mL) and the mixture was refluxed in a microwave oven for two 5 min periods. The red-brown solution was allowed to cool to room temperature and the complex precipitated with aqueous ammonium hexafluorophosphate. The crude red solid was purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) to give [Ru(bpy)$_2$(Brbpy)][PF$_6$]$_2$ as a red solid (90 mg, 75%). ^{1}H NMR (250 MHz, CD_3CN): δ/ppm 8.70 (H_{B3}, d, 1H, J 2.4 Hz), 8.46 ($H_{A3,C3,D3,E3,F3}$, d, 5H, J 7.5 Hz), 8.04 ($H_{A4,C4,D4,E4,F4}$, m, 5H), 7.74–7.68 ($H_{A6,C6,D6,E6,F6}$, m, 5H), 7.54 (H_{B6}, d, 1H), 7.37 ($H_{A5,B5,C5,D5,E5,F5}$, m, 6H); m/z: (ES–MS): 792/794 ([M−PF$_6$]$^+$); IR $\bar{\nu}$/cm^{-1} (KBr): 3600–3300w, 3100m, 3080m, 1590m, 1470m, 1450m, 1430m, 1380w, 850w, 760m, 700m; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}): 235 (22 600), 287 (65 400), 454 (11 100); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm): 620 (451). *Anal*. Calc. for $C_{30}H_{23}N_6BrRuP_2F_{12}\cdot 1.5H_2O$: C, 37.3; H, 2.7; N 8.7. Found: C, 37.3; H, 2.9; N, 8.8%. E^0/V vs. Fc: +0.92, −1.68, −1.90, −2.12.

2.2.4. [Ru(bpy)$_2$(Clbpy)][PF$_6$]$_2$

Clbpy (100.0 mg, 0.522 mmol) and [Ru(bpy)$_2$Cl$_2$] (253 mg, 0.522 mmol) were added to a 25 ml round bottom flask containing $HOCH_2CH_2OH$ (3 mL) and the mixture refluxed for two 5 min periods in a microwave oven. Aqueous ammonium hexafluorophosphate was then added and the red precipitate was collected and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) to give [Ru(bpy)$_2$(Clbpy)][PF$_6$]$_2$ as a red solid (404 mg, 87%). ^{1}H NMR (300 MHz, $CDCl_3$): δ/ppm 8.55 (H_{B3}, d, 1H, J 2.4 Hz), 8.47 ($H_{A3,C3,D3,E3,F3}$, br d, 5H), 8.10–8.00 ($H_{A4,C4,D4,E4,F4}$, m, 5H), 7.77–7.67 ($H_{A6,C6,D6,E6,F6}$, m, 5H), 7.63 (H_{B6}, d, 1H, J 6.3 Hz), 7.37 ($H_{A5,B5,C5,D5,E5,F5}$, m, 6H); m/z: (ES–MS): 749/751 ([M−PF$_6$]$^+$), 302/303 ([M−2PF$_6$]$^{2+}$); IR $\bar{\nu}$/cm^{-1} (KBr): 3117w, 1605m, 1558m, 1463m, 1443m, 1430m, 1311m, 1242m, 1165m, 1128m, 1041m, 964w, 818s, 764m, 725m, 648m; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 241 (35 000), 284 (57 000), 448 (10 200); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm) 628 (445); E^0/V vs. Fc: +0.90, −1.78, −1.97, −2.19.

2.2.5. [Ru(bpy)$_2$(**16**)][PF$_6$]$_2$

16 (70 mg, 0.41 mmol) and [Ru(bpy)$_2$Cl$_2$] (197 mg, 0.410 mmol) were added to methanol–water (20 mL, 3:1) and the solution refluxed for 5 h, after which period the reaction mixture was allowed to cool to room temperature and the methanol was removed in vacuo to give a red precipitate which was purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) to give [Ru(bpy)$_2$(**16**)][PF$_6$]$_2$ as a red solid (100 mg, 42.0%). ^{1}H NMR (250 MHz, CD_3CN): δ/ppm 8.48 ($H_{C3,D3,E3}$, m, 4H), 8.25 (H_{A3}, d, 1H, J 7.8 Hz), 8.06–7.94 ($H_{A4,C4,D4,E4,F4}$, m, 5H), 7.89 (H_{A6}, m, 1H) 7.78–7.65 ($H_{BC6,D6,E6,F6}$, m, 4H) 7.62 (H_{B3}, d, 1H, J 2.4 Hz), 7.43–7.32 ($H_{A5,C5,D5,E5,F5}$, m, 5H), 7.02 (H_{B6}, d, 1H, J 6.0 Hz), 6.56 (H_{B5}, dd, 1H, J 6.0, 2.4 Hz); m/z: (ES–MS): 584.1 (584.6[M−2PF$_6$]$^+$), 292.5 (292.3 [M−2PF$_6$]$^{2+}$); IR $\bar{\nu}$/cm^{-1} (KBr): 3409w, 3240w, 3116w, 1635m, 1334m, 1164w, 1103w, 1049w, 964w, 818s, 784s, 656m, 625m;UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 241 (41 000), 288 (68 500), 458 (12 500); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm) 645 (455); E^0/V vs. Fc: +0.70, −1.78, −1.97.

2.2.6. [Ru(bpy)$_2$(HObpy)][PF$_6$]$_2$

[Ru(bpy)$_2$(Clbpy)][PF$_6$]$_2$ (100 mg, 1.00 mmol) was added to 2 M aqueous sodium hydroxide solution (20 mL) and the mixture refluxed overnight. The reaction mixture was cooled to give an orange precipitate of [Ru(bpy)$_2$(Obpy)][PF$_6$] (60 mg). This was dissolved in hot water and re-precipitated by the addition of HPF_6 to give red crystals of [Ru(bpy)$_2$(HObpy)][PF$_6$]$_2$. ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.51–8.40 ($H_{C3,D3,E3,F3}$, m, 4H), 8.18 (H_{A3}, d, 1H, J 8.1 Hz), 8.05 (H_{A6}, m, 1H), 8.01–7.92 ($H_{A4–D4}$, m, 4H), 7.86 (H_{E4}, H_{D6}, m, 2H), 7.75 (H_{B6}, d, 1H, $J = 4.8$ Hz), 7.69 (H_{C6}, d, 1H, $J = 6.0$ Hz), 7.57 (H_{E6}, d, 1H, $J = 6.0$ Hz), 7.47 (H_{A5}, m, 1H), 7.40 (H_{D5}, m, 1H), 7.29 ($H_{B5,C5}$, m,

2H), 7.17 (H_{A5}, m, 1H), 7.12 (H_{B3}, d, 1H, *J* 2.7 Hz), 6.51 (H_{B6}, d, 1H, *J* 6.9 Hz), 6.01 (H_{B5}, dd, 1H, *J* 6.9, 2.7 Hz); *m/z*: (ES–MS): 585.1($[M-PF_6]^+$). *Anal*. Calc. for $C_{30}H_{24}N_6ORuP_2F_{12}$: C, 41.2; H, 2.8; N, 9.6. Found: C, 41.0; H 2.6; N 9.6%. IR $\bar{\nu}/cm^{-1}$ (KBr): 3641m, 3572m, 3116w, 2970w, 1630m, 1604m, 1463m, 1442m, 1423m, 1358m, 1242m, 1165m, 1126w, 1026m, 818s, 764s, 656m; UV/VIS (CH_3CN): λ_{max}/nm (ε/$dm^3\,mol^{-1}\,cm^{-1}$) 242 (22 700), 287 (36 900), 446 (6500); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm) 627 (443); E^0/V vs. Fc: +0.84, −1.82, −2.05, −2.15.

2.2.7. *[Ru(HOtpy)Cl$_3$]*

Commercial ruthenium trichloride trihydrate (250 mg, 0.946 mmol) and HOtpy (233 mg, 0.946 mmol) were added to ethanol (10 mL) and the mixture refluxed for 2 h. The mixture was then cooled to room temperature and the brown precipitate was filtered off and washed with cold ethanol, water and diethyl ether to give [Ru(HOtpy)Cl_3] (360 mg, 75%). The compound was used without any further purification.

2.2.8. *[Ru(tpy)(Cltpy)][PF$_6$]$_2$*

[Ru(tpy)Cl_3] (327 mg, 0.750 mmol) and Cltpy (200 mg, 0.75 mmol) were dissolved in methanol (50 mL), a few drops of *N*-ethylmorpholine were added and the mixture heated to reflux. After 4 h the mixture was cooled to room temperature, most of the solvent removed and aqueous ammonium hexafluorophosphate added to give a red precipitate. Purification by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) gave a major red fraction from which [Ru(tpy)(Cltpy)][PF_6]$_2$ was obtained as a red solid (301 mg, 45%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.84 (H_{B3}, s, 2H), 8.74 (H_{D3}, d, 2H, *J* 8.1 Hz), 8.48 ($H_{A3,C3}$, d, 2H, *J* 8.1 Hz), 8.42 (H_{D4}, t, 1H, *J* 8.1 Hz), 7.91 ($H_{A4,C4}$, m, 4H), 7.36 ($H_{C6,A5}$, m, 4H), 7.16 ($H_{C5,A6}$, m, 4H); *m/z*: (ES–MS): 747/749 ($[M-PF_6]^+$), 301/302 ($[M-2PF_6]^{2+}$); IR $\bar{\nu}/cm^{-1}$ (KBr): 3124m, 3100w, 1597m, 1550m, 1477m, 1427m, 1388m, 1288m, 1424m, 1157m, 1118m, 903m, 818s, 793s, 764s, 648m; UV/VIS (CH_3CN): λ_{max}/nm (ε/$dm^3\,mol^{-1}\,cm^{-1}$) 237 (19 900), 271 (26 300), 307 (43 100), 478 (10 700); E^0/V vs. Fc: +0.91, −1.58, −1.87, −2.19.

2.2.9. *[Ru(tpy)(HOtpy)][PF$_6$]$_2$*

[Ru(HOtpy)Cl_3] (100 mg, 0.195 mmol) and tpy (45.0 mg, 0.195 mmol) were added to methanol (10 mL) containing a few drops of *N*-ethylmorpholine and the mixture refluxed for 2 h, after which it was cooled, filtered and the solvent removed in vacuo. The red/brown solid was dissolved in acetonitrile and an aqueous ammonium hexafluorophosphate was added to give a red/brown precipitate that was purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) yielding [Ru(tpy)(Cltpy)][PF_6]$_2$ (72 mg, 39.8%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.70 (H_{D3}, d, 2H, *J* 8.1 Hz), 8.47 (H_{C3}, d, 2H, *J* 8.1 Hz), 8.38 (H_{A3}, d, 2H, *J* 8.1 Hz), 8.35 (H_{C4}, t, 1H, *J* 8.1 Hz), 8.22 (H_{B3}, s, 2H), 7.89 ($H_{A4,C4}$, m, 4H), 7.45 (H_{A6}, d, 2H, *J* 5.1 Hz), 7.27 (H_{C6}, d, 2H, *J* 5.7 Hz), 7.18 (H_{A5}, m, 2H), 7.10 (H_{C5}, m, 2H); *m/z*: (ES–MS): 729 ($[M-PF_6]^+$), 292 ($[M-2PF_6]^{2+}$); IR $\bar{\nu}/cm^{-1}$ (KBr): 3487m, 3109m, 1620m, 1590m, 1552m, 1450m, 1423m, 1399m, 1342m, 1288m, 1211m, 1165m, 1111w, 1049w, 941m, 810s, 764s, 655m; UV/VIS (CH_3CN): λ_{max}/nm (ε/$dm^3\,mol^{-1}\,cm^{-1}$) 237 (45 000), 269 (43 400), 304 (57 500), 481 (15 100); E^0/V vs. Fc: +0.78, −1.77 (quasi reversible).

2.2.10. *[Ru(tpy)(N,N′-HOtpy)Cl][PF$_6$]*

[Ru(tpy)Cl_3] (35 mg, 8.0×10^{-2} mmol) and HOtpy (20 mg, 8.0×10^{-2} mmol) were dissolved in methanol (10 mL) containing a few drops of *N*-ethylmorpholine. The mixture was refluxed for 3 h. After cooling to room temperature, the solvent was removed and the residue was redissolved in a small amount of acetonitrile to give a purple solution. Aqueous ammonium hexafluorophosphate was added and a purple precipitate was collected. Purification by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) gave red [Ru(tpy)(HOtpy)][PF_6]$_2$ (50%) and purple [Ru(tpy)(*N*,*N*′-HOtpy)Cl][PF_6] (15 mg, 21%). ^{1}H NMR (300 MHz, acetone-d_6): δ/ppm 10.31 (H_{A6}, d, 1H, *J* 4.8 Hz), 9.17 (H_{B3}, bs, 1H), 9.00 (H_{A3}, d, 1H, *J* 7.8 Hz), 8.69 (H_{D3}, d, 2H, *J* 8.1 Hz), 8.63 ($H_{C3,E6}$, m, 3H), 8.40 (H_{A4}, dt, 1H, *J* 1.2, 7.2 Hz), 8.32 (H_{E3}, d, 1H, *J* 8.1 Hz), 8.22 (H_{A5}, dt, 1H, *J* 1.5, 7.0 Hz), 8.08 (H_{D4}, t, 1H, *J* 8.1 Hz), 8.03–7.97 ($H_{C4,C6,E4}$, m, 5H), 7.57 (H_{E5}, ddd, 1H, *J* 1.2, 4.8, 7.8 Hz), 7.49 (H_{C5}, dt, 2H, *J* 0.9, 5.4 Hz), 7.18 (H_{B5}, bs, 1H); IR $\bar{\nu}/cm^{-1}$ (KBr): 3734w, 3633w, 3418w, 3294w, 3070w, 2924w, 2854w, 2360m, 1705w, 1597w, 1543m, 1443m, 1442m, 1350m, 1288m, 1249m, 1157w, 1095w, 1010w, 833s, 764s, 648m, 548s; UV/VIS (CH_3CN): λ_{max}/nm (ε/$dm^3\,mol^{-1}\,cm^{-1}$) 324 (37 500), 352 (32 000), 389 (28 000), 596 (17 000).

2.2.11. *[Ru(tpy)(**20**)][PF$_6$]$_2$*

1,4-$BrCH_2C_6H_4CH_2Br$ (415 mg, 1.57 mmol) was added to a suspension of [Ru(tpy)(HOtpy)][PF_6]$_2$ (275 mg, 0.315 mmol) and potassium carbonate (175 mg, 1.26 mmol) in acetonitrile (35 mL) and the reaction mixture heated at 80 °C for 3 h. After this time, the resulting red solution was cooled to room temperature and aqueous ammonium hexafluorophosphate was added to give a red precipitate which was collected on celite by filtration, redissolved in the minimum volume of acetonitrile and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5). The main red fraction was collected and aqueous ammonium hexafluorophosphate was added. The mixture was reduced in volume in vacuo to precipitate the complex, which was

then collected by filtration and washed with ether. Recrystallization from 1:1 acetonitrile–water afforded [Ru(tpy)(**20**)][PF_6]$_2$ as a red solid (246 mg, 74%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.70 (H_{E3}, d, 2H, J 8.1 Hz), 8.48 (H_{A3}, d, 2H, J 8.1 Hz), 8.46 (H_{D3}, d, 2H, J 8.1 Hz), 8.39 (H_{B3}, s, 2H), 8.34 (H_{E4}, t, 1H, J 8.1 Hz), 7.93 (H_{D4}, td, 2H), 7.89 (H_{A4}, td, 2H), 7.65 (H_{C2}, d, 2H, J 8.1 Hz), 7.58 (H_{C3}, d, 2H, J 8.1 Hz), 7.39 (H_{A6}, d, 2H, J 5.4 Hz), 7.27 (H_{D6}, d, 2H, J 5.4 Hz), 7.19 (H_{D5}, m, 2H), 7.13 (H_{A5}, m, 2H), 5.60 (CH_2O, s, 2H), 4.66 (CH_2Br, s, 2H); m/z: (ES–MS): 912/914 ([M−PF_6]$^+$), 383/384 ([M−2PF_6]$^{2+}$); IR $\bar{\nu}$/cm^{-1} (KBr): 3090w, 1705m, 1666s, 1562m, 1466s, 1443s, 1423w, 1354m, 1323m, 1303w, 1219m, 1165s, 1092m, 1065m, 1026m, 995w, 960w, 826w, 760m, 683w, 656w, 617w; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 242 (69 300), 304 (31 000), 481 (7600); E^0/V vs. Fc: +0.80, −1.71 (quasi reversible).

2.2.12. [Ru(bpy)$_2$(**22**)][PF_6]$_2$

A suspension of [Ru(bpy)$_2$(Obpy)][PF_6] (55 mg, 0.0063 mol) and K_2CO_3 (34.2 mg, 0.245 mmol, dried at 170 °C) in acetonitrile (10 mL) was heated to reflux for 30 min after which the reaction mixture was cooled and 1,4-Br$CH_2C_6H_4CH_2$Br (81.2 mg, 0.310 mmol) was added and the mixture brought back to reflux. After 3 h the reaction mixture was cooled to room temperature. The solvent was removed in vacuo and the red compound was redissolved in acetonitrile, aqueous ammonium hexafluorophosphate added and a red precipitate was collected and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5). The major red fraction was collected to give [Ru(bpy)$_2$(**22**)][PF_6]$_2$ (17.5 mg, 26.4%). ^{1}H NMR (300 MHz, $CDCl_3$): δ/ppm 8.50 ($H_{F3,E3,D3,A3,G3}$, d, 5H, J 7.9 Hz), 8.11 (H_{B3}, s, 1H), 8.03 ($H_{G4,F4,E4,D4,A4}$, m, 5H), 7.75 ($H_{G6,F6,E6,D6,A6}$, m, 5H), 7.49 (H_{B6}, d, 1H, J 4.1 Hz), 7.45 (H_{C2}, dd, 2H, J 6.0, 2.4 Hz), 7.42–7.34 ($H_{G5,F5,E5,D5,A5,C3}$, m, 7H), 7.00 (H_{B5}, dd, 1H, J 7.5, 2.5 Hz), 5.28 (OCH_2, s, 2H), 4.58 (CH_2Br, s, 2H); m/z: (ES–MS): 916/918 ([M−PF_6]$^+$). *Anal*. Calc. for $C_{38}H_{31}N_6OBrRuP_2F_{12}$: C, 43.2; H, 2.9; N, 8.0. Found: C, 43.1; H, 2.9; N, 7.9%. IR $\bar{\nu}$/cm^{-1} (KBr): 3649w, 3325w, 3085w, 1621m, 1429m, 1417m, 1390m, 1366m, 1222m, 1190m, 1081m, 987m, 835sm, 792m, 745s, 656m; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 286 (60 400), 456 (11 300); E^0/V vs. Fc: +0.86, −1.73, −1.89, −2.01, −2.14, −2.40.

2.2.13. [Ru(tpy)(**21**)][PF_6]$_2$

[Ru(tpy)(**20**)][PF_6]$_2$ (85 mg, 0.080 mmol) was added to a suspension of HOtpy (60 mg, 0.24 mmol) and potassium carbonate (100 mg, 0.72 mmol) in acetonitrile (15 mL), and the reaction mixture heated at 80 °C for 3 h. The resulting red solution was allowed to cool, and water (30 mL) along with excess methanolic [NH_4][PF_6] were added to precipitate the complex mixture. This was collected by filtration, washed well with water and then redissolved in the minimum volume of acetonitrile and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) to give a major orange band. Recrystallization from 1:1 acetonitrile–water yielded [Ru(tpy)(**21**)][PF_6]$_2$ as a fine orange solid (61 mg, 74%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.72 (H_{E3}, d, 2H, J 8.1 Hz), 8.48 (H_{A3}, d, 2H, J 8.1 Hz), 8.46 (H_{D3}, d, 2H, J 8.1 Hz), 8.41 (H_{B3}, s, 2H), 8.36 (H_{E4}, t, 1H, J 8.1 Hz), 7.93 (H_{D4}, td, 2H), 7.89 (H_{A4}, td, 2H), 7.69 (H_{C2}, d, 2H, J 8.1 Hz), 7.54 (H_{C3}, d, 2H, J 8.1 Hz), 7.42 (H_{A6}, d, 2H, J 5.4 Hz), 7.30 (H_{D6}, d, 2H, J 5.4 Hz), 7.19 (H_{D5}, m, 2H), 7.13 (H_{A5}, m, 2H), 5.62 (CH_2Otpy, s, 2H), 5.18 (CH_2OAc, s, 2H), 2.09 (CH_3CO, s, 3H). *Anal*. Calc. for $RuC_{40}H_{32}N_6O_3P_2F_{12}$: C, 46.4; H, 3.1; N, 8.1. Found: C, 44.9; H, 3.1; N, 8.1%. IR $\bar{\nu}$/cm^{-1} (KBr): 1736m, 1617m, 1449m, 1419m, 1387m, 1222m, 838s; m/z(MALDI-TOF) 746 ({M−2PF_6}$^+$), 687 ({M−OAc−2PF_6}$^+$). E^0/V vs. Fc: +0.80.

2.2.14. [(tpy)Ru(**9**)][PF_6]$_2$

A suspension of [Ru(tpy)Cl_3] (88 mg, 0.20 mmol) and $AgBF_4$ (117 mg, 0.600 mmol) were heated to reflux in acetone (25 mL) for 2 h. After this time the resulting blue suspension was filtered through celite to remove silver chloride, reduced to dryness and then redissolved in DMF (20 mL). This solution was added dropwise over 40 min to a solution of **9** in DMF (20 mL) at 110 °C, and the mixture then heated to reflux for a further 2 h. The resulting red suspension was then allowed to cool, before water (80 mL) and excess methanolic [NH_4][PF_6] were added to precipitate the complex mixture. This was collected on celite by filtration, and then redissolved in the minimum volume of acetonitrile and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5). Recrystallization from 1:1 acetonitrile–water afforded [(tpy)Ru(**9**)][PF_6]$_2$ as an orange powder (104 mg, 42%) and [(tpy)Ru(**9**)Ru(tpy)][PF_6]$_4$ as a brown solid (26 mg, 14%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.94 (H_{F6}, m, 2H), 8.72 (H_{E3}, d, 2H, J 8.1 Hz), 8.61 (H_{F3}, d, 2H, J 8.7 Hz), 8.47 ($H_{D3,A3}$, m, 4H), 8.42 (H_{B3}, s, 2H), 8.37 (H_{E4}, t, 2H, J 8.1 Hz), 8.17 (H_{G3}, s, 2H), 7.92 ($H_{D4,A4}$, m, 4H), 7.81–7.72 ($H_{F4,C}$, m, 6H), 7.43 (H_{A6}, d, 2H, J 5.4 Hz), 7.30 (H_{D6}, d, 2H, J 6.3 Hz), 7.21–7.09 ($H_{D5,A5,F5}$, m, 6H), 5.65 (CH_2, s, 2H), 5.60 (CH_2, s, 2H); IR $\bar{\nu}$/cm^{-1} (KBr): 3649w, 3078w, 1604m, 1576m, 1558m, 1450m, 1411m, 1350m, 1203m, 1018m, 825s, 787m, 655w, 625w; m/z (MALDI-TOF): 1080 ({M−PF_6}$^+$), 935 ({M−2PF_6}$^+$), 687 ({M−Otpy−2PF_6}$^+$); UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 237 (37 700), 273 (11 500), 305 (38 000), 479 (10 000); E^0/V vs. Fc: +0.79, −1.69, −1.81, −2.15.

2.2.15. [(bpy)$_2$Ru(7)][PF$_6$]$_2$

[Ru(bpy)$_2$Cl$_2$] (32.5 mg, 6.73×10^{-5} mol) and silver tetrafluoroborate (58.2 mg, 2.99 mmol) were added to acetone (25 mL) and the mixture refluxed for 2 h. Silver chloride was then filtered off and the solvent removed in vacuo. The compound was redissolved in DMF (20 mL) and the solution added dropwise to a solution of **7** (30 mg, 6.7×10^{-2} mmol) in DMF (20 mL) maintained at 110 °C over 40 min. After stirring the mixture for 3 h at 110 °C the mixture was cooled to room temperature and the solvent removed in vacuo. The red compound was redissolved in acetonitrile and aqueous ammonium hexafluorophosphate added to give a red precipitate that was collected by filtration and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) to give [Ru(bpy)$_2$(**7**)][PF$_6$]$_2$ (21.3 mg, 37%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.55–8.45($H_{A3,D3,E3,F3,G3,H3,H6,I6}$, m, 8H), 8.09 ($H_{B3}$, d, 1H, *J* 2.8 Hz), 8.08–7.93 ($H_{A4,D4,E4,F4,G4,H4}$, m, 6H), 7.80–7.72 ($H_{A6,D6,E6,F6,G6}$, m, 5H) 7.55 (H_{I3}, s, 1H) 7.53 (H_C, s, 4H) 7.48 (H_{B6}, dd, 1H, *J* 6.6, 2.6 Hz) 7.44–7.36 ($H_{A5,D5,E5,F5,G5,H5,I5}$, m, 7H), 7.01 (H_{B5}, dd, 1H, *J* 6.6, 2.6 Hz) 5.37 (CH_2OB_{ring}, s, 2H) 5.31 (CH_2OI_{ring}, s, 2H); *m*/*z* (ES–MS): 1005.3 ([M−PF$_6$]$^+$), 430.2 ([M−2PF$_6$]$^{2+}$). *Anal*. Calc. for $C_{48}H_{38}N_8O_2RuP_2F_{12}K$: C, 48.5; H, 3.2; N, 9.4. Found: C, 48.3; H, 2.7; N, 9.2%. IR $\bar{\nu}$/cm^{-1} (KBr): 3657w, 3587w, 3085w, 1604m, 1463m, 1442m, 1421m, 1327m, 1226m, 1164m, 1010m, 826s, 764m, 656m; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 285 (90 600), 453 (14 600); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm) 623 (450); E^0/V vs. Fc: +0.83, −1.77, −1.94, −2.18, −2.58.

*2.2.16. [Ru(bpy)$_2$(**5**)][PF$_6$]$_2$*

HOtpy (20.8 mg, 0.0840 mmol) and K_2CO_3 (34.7 mg, 0.250 mmol, dried overnight at 180 °C) were added to acetonitrile (20 mL) and stirred at room temperature, after 20 min [Ru(bpy)$_2$(4Clbpy)][PF$_6$]$_2$ (50 mg, 0.056 mmol) or [Ru(bpy)$_2$(Brbpy)][PF$_6$]$_2$ (52.5 mg, 0.0560 mmol) was added and the red mixture taken to reflux. After 3 h the reaction mixture was cooled to room temperature and filtered, and most of the solvent removed. Aqueous ammonium hexafluorophosphate was added and a red precipitate was collected and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) to give [Ru(bpy)$_2$(**5**)][PF$_6$]$_2$ as a red solid (25.0 mg, 41%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm 8.77 (H_{D6}, dm, 2H, *J* 5.1 Hz), 8.68 (H_{D3}, d, 2H, *J* 8.1 Hz), 8.49 ($H_{E3,B3,G3,H3}$, m, 4H), 8.41 (H_{A3}, d, 1H, *J* 7.8 Hz), 8.31 (H_{D4}, t, 2H, *J* 8.0 Hz), 8.26 (H_{C3}, s, 2H), 8.23 (H_{B3}, s, 1H), 8.11–7.95 ($H_{A4,E4,F4,G4,H4}$, m, 5H), 7.87 (H_{E6}, d, 1H, *J* 5.4 Hz), 7.78–7.65 ($H_{D5,F6,H6,G6,A6,B6}$, m, 7H), 7.49–7.30 ($H_{A5,E5,F5,G5,H5}$, m, 5H), 7.16 (H_{B5}, dd, 1H, *J* 6.6, 2.4 Hz); *m*/*z*: (ES–MS): 961.8 ([M−PF$_6$]$^+$), 408.4 ([M−2PF$_6$]$^{2+}$). *Anal*. Calc. for $C_{45}H_{33}N_{10}O_4RuP_2F_{12} \cdot 0.5HPF_6$: C, 43.5; H, 2.7; N, 11.3. Found: C, 43.5; H, 2.7; N, 11.8%, IR $\bar{\nu}$/cm^{-1} (KBr): 3090, 1705, 1666, 1562, 1466, 1443, 1423, 1354, 1323, 1303, 1219, 1165, 1092, 1065, 1026, 995, 960, 826, 760, 683, 656, 617; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 245 (36 500), 292 (69 600), 460 (9400); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm) 620 (457); E^0/V vs. Fc: 0.88, −1.69, −1.89, −2.13, −2.49, −2.64.

*2.2.17. [Ru(bpy)$_2$(**2**)][PF$_6$]$_2 \cdot 3H_2O$*

[Ru(bpy)$_2$Cl$_2$] (95 mg, 0.29 mmol) and **2** (70 mg, 0.18 mmol) together with 4 drops of *N*-ethylmorpholine were added to ethanol (80 mL) and the mixture refluxed for 13 h. After cooling to room temperature the solvent was removed in vacuo and an orange solid was collected and purified by chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5) to give [Ru(bpy)$_2$(**2**)][PF$_6$]$_2$ as an orange solid (74 mg, 55%). ^{1}H NMR (250 MHz, CD_3CN): δ/ppm 8.92 (H_{B3}, s, 1H), 8.85 (H_{C3}, s, 2H), 8.72 ($H_{A3,D3,D6}$, d overlapping, 5H), 8.51 ($H_{E3,F3,G3,H3}$, dd, 4H), 8.15–7.98 ($H_{A4,D4E4,F4,G4,H4}$, m, 7H), 7.88 (H_{B5}, d, 1H, *J* 5.9 Hz), 7.85–7.72 ($H_{A6,B6,E6,F6,G6,H6}$, m, 6H), 7.61 (H_{HD}, dd, 2H, *J* 7.3, 5.8 Hz), 7.48–7.38 ($H_{A5,E5,F5,G5,H5}$, m, 5H); *m*/*z*: (ES–MS): 946.1 ([M−PF$_6$]$^+$) 400.6 ([M−2PF$_6$]$^{2+}$). *Anal*. Calc. for $C_{45}H_{33}N_9RuP_2F_{12} \cdot 3H_2O$: C, 47.2; H, 3.4; N, 11.0. Found: C, 47.2; H, 3.5; N, 11.2%. IR $\bar{\nu}$/cm^{-1} (KBr): 3430m, 1617m, 1475w, 1446w, 1423w, 842s, 793w, 765m, 558s; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 243 (59 400), 287 (82 500), 461 (14 500). 2.2.27. *[(bpy)2Ru(5)Mn(5)Ru(bpy)2][PF6]6*

[Ru(bpy)$_2$(**5**)][PF_6]$_2$ (22.1 mg, 0.0200 mmol) was dissolved in methanol (3 mL) and a few drops of acetonitrile. A methanol (2 mL) solution of $Mn(OAc)_2\cdot 4H_2O$ (1.73 mg, 0.0100 mmol) was added and the mixture heated to reflux with a heat gun. The dark red solution was filtered through a cotton plug and methanolic ammonium hexafluorophosphate was added dropwise. A dark red precipitate was collected and dried to

give $[(bpy)_2Ru(\mathbf{5})Mn(\mathbf{5})Ru(bpy)_2][PF_6]_6$ as a red solid (31.8 mg, 61.9%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm all peaks broadened due to paramagnetism; *m/z*: (ES–MS): 1134.5 ($[M-2PF_6]^{2+}$); IR $\bar{\nu}/cm^{-1}$ (KBr): 3660w, 3326m, 3085w, 1594m, 1460m, 1420m, 1359m, 1301w, 1223m, 1163w, 1053w, 1018w, 964w, 815s, 763s, 656m, 640m; UV/VIS (CH_3CN): λ_{max}/nm (ε/$dm^3\,mol^{-1}\,cm^{-1}$) 240 (83800), 287 (140800), 455 (22900); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm) 622 (453); E^0/V vs. Fc: +0.87, −1.69, −1.89, −2.13.

2.2.28. *[(bpy)$_2$Ru(**2**)Ru(**2**)Ru(bpy)$_2$][PF$_6$]$_6$ · 6H$_2$O*

A solution of $[(bpy)_2Ru(\mathbf{2})][PF_6]_2$ (10 mg, 0.009 mmol) and commercial $RuCl_3 \cdot 3H_2O$ (1 mg, 0.004 mmol) in $HOCH_2CH_2OH$ (4 mL) together with two drops of *N*-ethylmorpholine was heated to reflux in a microwave oven (800 W) for 6 min. A solution of saturated aqueous ammonium hexafluorophosphate (25 mL) was then added to the orange solution, the precipitate was collected by filtration over celite and dissolved in acetonitrile. The solvent was evaporated in vacuo and the residue was purified by column chromatography (SiO_2, MeCN-saturated aqueous KNO_3–H_2O 7:1:0.5). To the major red fraction, an excess of ammonium hexafluorophosphate was added and the solution reduced in volume. The precipitate was collected by filtration over celite, washed with acetonitrile and evaporated to dryness to give $[(bpy)_2Ru(\mathbf{2})Ru(\mathbf{2})Ru(bpy)_2][PF_6]_6$ as a red-orange powder (6.0 mg, 51%). ^{1}H NMR (250 MHz, CD_3CN): δ/ppm 9.25 (H_{F3}, d, 2H, *J* 2.4 Hz), 9.17 (H_{G3}, s, 4H), 8.98 (H_{E3}, d, 2H, *J* 7.9 Hz), 8.73 (H_{H3}, d, 4H, *J* 7.9 Hz), 8.59–8.54 (H_{A3-D3}, m, 8H), 8.23–8.08 ($H_{F5,F6,A4-E4}$, m, 14H), 8.01–7.92 ($H_{E6,H4}$, m, 6H), 7.86–7.78 (H_{A6-D6}, m, 8H), 7.53–7.40 ($H_{A5-E5,\ H6}$, m, 14H), 7.25–7.18 (H_{H5}, m, 4H); ES–MS: *m/z* 1141.6 ($[M-2PF_6]^{2+}$), 713.0 ($[M-3PF_6]^{3+}$), 498.3 ($[M-4PF_6]^{4+}$), 369.9 ($[M-5PF_6]^{5+}$), 283.9 ($[M-6PF_6]^{6+}$). *Anal*. 2.2.31. *[(bpy)$_2$Ru(**2**)Mn(**2**)Ru(bpy)$_2$][PF$_6$]$_6$*

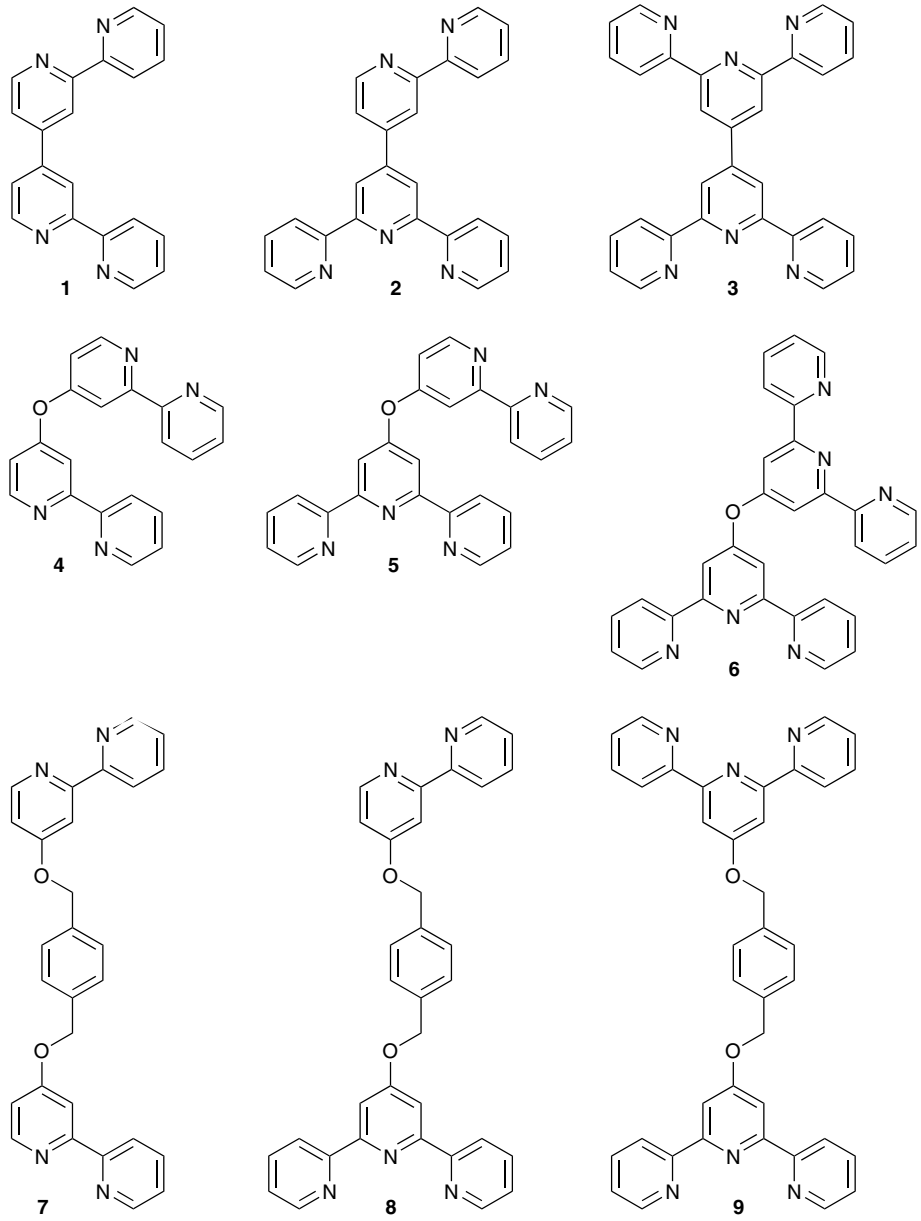
$[Ru(bpy)_2(\mathbf{2})][PF_6]_2$ (21.8 mg, 0.0200 mmol) was dissolved in methanol (3 mL) and a few drops of acetonitrile. A methanol (2 mL) solution of $Mn(OAc)_2 \cdot 4H_2O$ (1.73 mg, 0.0100 mmol) was added and the mixture heated to reflux with a heat gun. The dark red solution

was filtered through a cotton plug and methanolic ammonium hexafluorophosphate was added dropwise. A dark red precipitate was collected and dried to give $[(bpy)_2Ru(\mathbf{2})Mn(\mathbf{2})Ru(bpy)_2][PF_6]_6$ as a red solid (20.0 mg, 39.6%). ^{1}H NMR (300 MHz, CD_3CN): δ/ppm all peaks broadened due to paramagnetism; m/z: (ES–MS): 1118.4 ($[M-2PF_6]^{2+}$); IR $\bar{\nu}$/cm^{-1} (KBr): 3649w, 3325w, 3085w, 1604m, 1535w, 1463m, 1427m, 1311w, 1242m, 1165m, 1018m, 818s, 764s, 663m; UV/VIS (CH_3CN): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) 244 (80 300), 293 (153 100), 460 (20 700); Fluorescence (CH_3CN): λ_{em}/nm (λ_{ex}/nm) 636 (457); E^0/V vs. Fc: +0.95, −1.28, −1.51, −1.70, −1.87, −2.20.

3. Results and discussion

3.1. Strategy and ligand design

A large number of ligands incorporating two (or more) bpy or tpy metal-binding domains have been described. In this paper, we concentrate upon three classes of ditopic ligands (Scheme 1). In the first class, metal-binding domains are directly linked through a C–C single bond which, in principle, allows free rotation and leads to potentially maximum conjugation of the two components; the bpy–bpy compound **1** is well known [55,59–64] and our initial report of the tpy–tpy analogue



Scheme 1. Homo- and heteroditopic bpy and tpy ligands discussed in this paper.

3 [58] has been followed up by studies of coordination oligomers and polymers incorporating this species [22,65–83]. We have made brief reports concerning the bpy-tpy compound **2** [84,85] and will discuss further aspects of its coordination behaviour in this manuscript. In general, complexes containing ligands **1**–**3** will be prepared by conventional methods involving initial synthesis of the free ligand. The second class is typified by the linkage of the two metal-binding domains by a single ether oxygen atom, giving a greater degree of conformational freedom at the expense of conjugation of the subunits; of this ligand series, we have described the tpy–tpy compound **6** [30,86,87] and the bpy–bpy analogue **4** has been reported [20,88,89] but the heteroditopic species **5** has not hitherto been described. Synthetic strategies for ligands of this type are of four main types: (i) synthesis and subsequent coordination of the appropriate free ligand, (ii) reactions of coordinated electrophilic Xbpy or Xtpy ligands (Xbpy = 4-chloro-2,2′-bipyridine or 4-bromo-2,2′-bipyridine, Xtpy = 4′-chloro-2,2′:6′,2″-terpyridine or 4′-bromo-2,2′:6′,2″-terpyridine) with nucleophilic HObpy or HOtpy (HObpy = 2,2′-bipyridin-4(1*H*)-one, HOtpy = 4′-hydroxy-2,2′:6′,2″-terpyridine), (iii) reactions of coordinated HObpy or HOtpy with Xbpy or Xtpy or (iv) reactions of coordinated HObpy or HOtpy with Xbpy or Xtpy complexes. The final ligand type that we discuss incorporates a 1,4-$OCH_2C_6H_4CH_2O$ spacer between the metal-binding domains; we have reported a few complexes containing the tpy–tpy compound **9** [87] but compounds **7** and **8** have not yet been described. Synthetic approaches resemble those for ligands **4**–**6**, although the commonest strategies involve reaction of 1,4-bis(bromomethyl)benzene with HObpy or HOtpy or their complexes.

3.2. Ligand synthesis

This section briefly presents the synthesis of the key electrophilic and nucleophilic tpy derivatives that are used for the preparation of the multitopic ligands. The overview represents many years investigating synthetic routes to these compounds and presents the strategies which we consider to be the best.

3.2.1. Simple 2,2′-bipyridine derivatives

The synthesis of 4-heteroatom-substituted bpy ligands almost always commences with bpy itself which is activated by conversion to the *N*-oxide **10** by reaction with 3-chloroperbenzoic acid in chlorinated solvent or H_2O_2 in acetic acid [38–51]. In our hands, the latter procedure is more reliable and gives higher yields (>70%). The *N*-oxide **10** is readily nitrated in classical conditions to give 4-nitro-2,2′-bipyridine *N*-oxide **11** in yields ≈65% [40,45,47,50,51]. In our hands, the reaction of **11** with acetyl bromide in acetic acid gives a mixture of 4-bromo-2,2′-bipyridine *N*-oxide **12** and 4-bromo-2,2′-bipyridine, Brbpy, **13**. Subsequent reduction of **12** with PBr_3 in $CHCl_3$ gives **13** in quantitative yield and the overall conversion of **11**–**13** is usually greater than 90% [40,51–53]. We find the most convenient route to 4-chloro-2,2′-bipyridine, Clbpy, **14** is directly from **10** rather than the more classical route from **11** [44,49,51,54,55]. We have investigated routes to HObpy **15** starting from the halo-compounds Brbpy or Clbpy, but have found no reliable hydrolysis method for the preparation of the free ligands, and the method of choice for the preparation is reduction of **11** to 4-amino-2,2′-bipyridine **16** [47,54,57] followed by diazotization and hydrolysis [56]. These transformations are summarized in Scheme 2.

3.2.2. Simple 2,2′:6′,2″-teripyridine derivatives

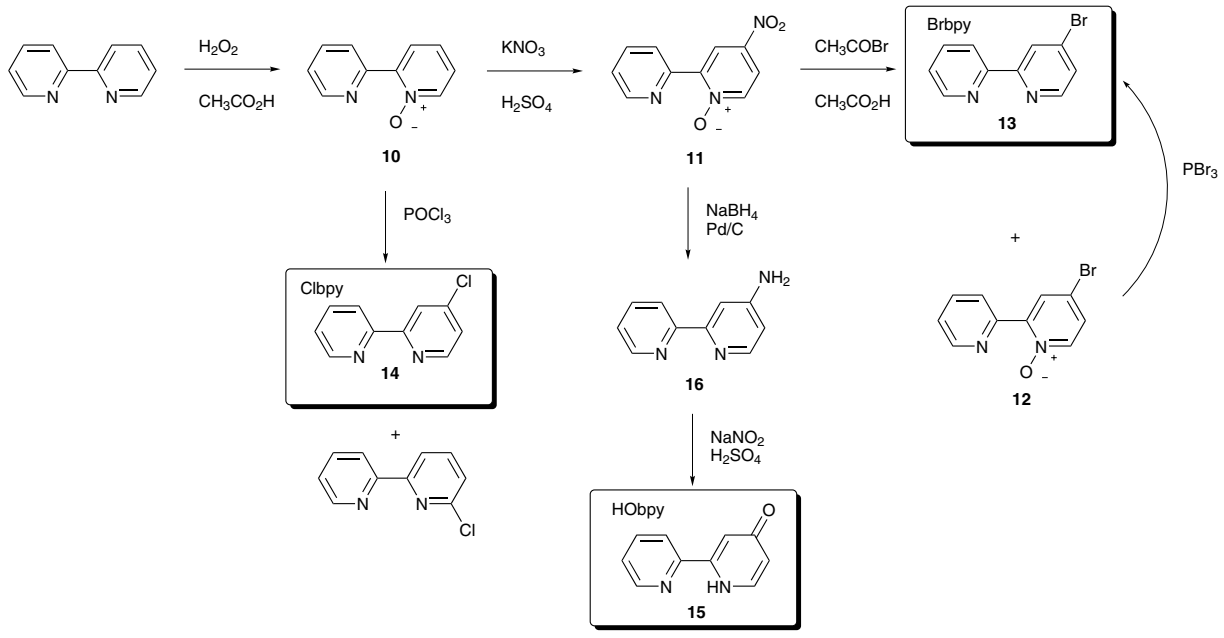
The key intermediates in the tpy series are Cltpy and HOtpy; HOtpy **17** is readily prepared in good yield in a two step process from ethyl picolinate. The reaction of ethyl picolinate with the enolate of acetone gives the triketone **18** [58], which is cyclized by reaction with ammonium acetate to give HOtpy. The conversion of HOtpy to Cltpy **19** by reaction with PCl_5 in $POCl_3$ is quantitative [58]. These transformations are presented in Scheme 3.

3.2.3. Synthesis of free ditopic ligands

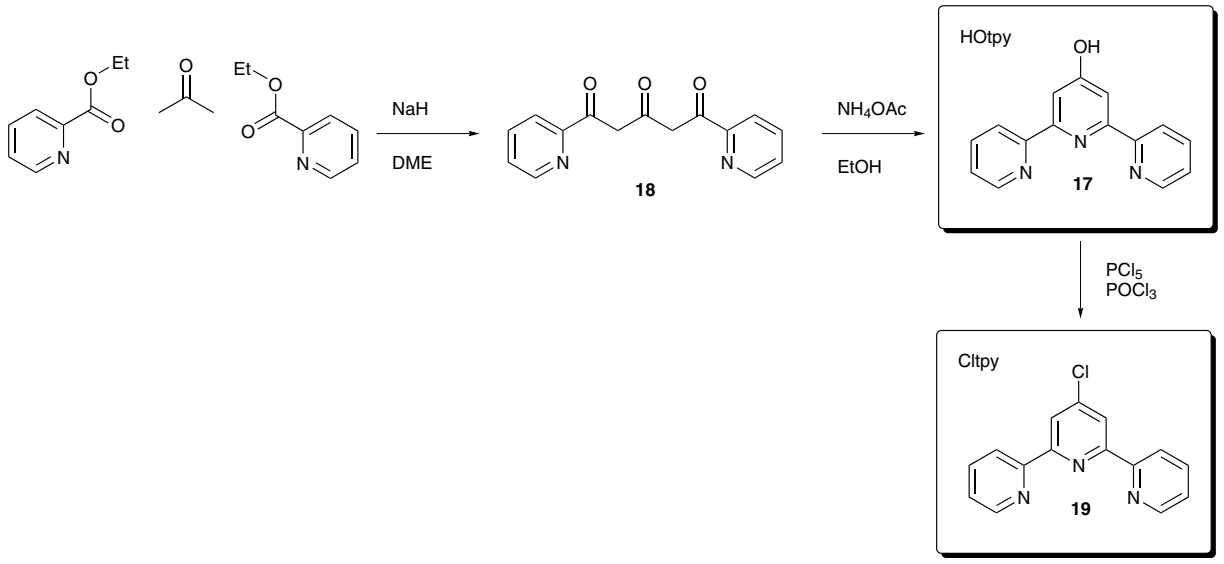
Of the directly-linked ditopic ligands, **1**–**3**, we only present new results for ligand **2** in this paper. The heteroditopic ligand **2** was prepared as a white crystalline solid in 23% yield by the literature method [84,85].

The free ligand **6** is prepared by the reaction of HOtpy with Cltpy in the presence of base for prolonged periods [86]. Although it would be possible to prepare the ditopic ligands **4** and **5** by analogous reactions (HObpy with Clbpy for **4**, HObpy with Cltpy or Clbpy with HOtpy for **5**) it is more convenient to make use of reactions of coordinated Clbpy or Cltpy to give complexes of unambiguous constitution in a single step.

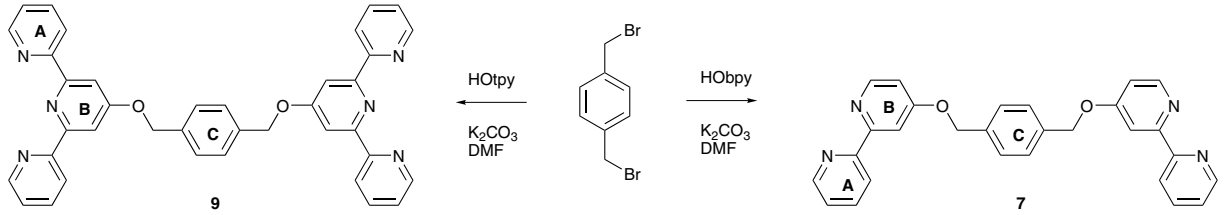
The homoditopic tpy–tpy free ligand **9** was prepared in 82% yield by the reaction of HOtpy with 1,4-$BrCH_2C_6H_4CH_2Br$ in DMF in the presence of K_2CO_3 as a white crystalline solid. The bpy–bpy analogue **7** was prepared in a similar manner from HObpy as a white solid in 91% yield Scheme 4. The two new ligands were fully characterized by conventional methods. The EI mass spectrum of **9** exhibited a parent ion at *m*/*z* 601 whilst the FAB MS of **7** showed a parent ion at *m*/*z* 447. The high symmetry of the new ligands is seen in both the ^{13}C and ^{1}H NMR spectra; in the ^{1}H NMR spectra in $CDCl_3$ the phenylene and methylene protons appear as equal intensity singlets at δ 7.54 and 5.35 ppm in **7** and at δ 7.56 and 5.36 ppm in **9**. We have not attempted to prepare the heteroditopic free ligand **8** for two reasons. Firstly, selective reaction of one side of the 1,4-$BrCH_2C_6H_4CH_2Br$ with HOtpy or HObpy



Scheme 2. Key transformations within the 2,2′-bipyridine ligand series.



Scheme 3. Key transformations within the 2,2′:6′,2″-terpyridine ligand series.



Scheme 4. Synthesis of heterotopic bridging ligands **7** and **9** showing the nomenclature system adopted to distinguish the aromatic rings.

followed by subsequent reaction with HObpy or Hotpy, respectively, seemed likely to give mixtures of mono- and bis-functionalized compounds. Secondly, even if we did obtain **8**, it would be necessary to selectively address the bpy or tpy metal-binding domains. Accordingly, for all compounds containing **8**, we adopted alternative approaches based upon reactions of coordinated ligands.

3.3. Synthesis of mononuclear ruthenium(II) complexes and simple ligand reactions

In the majority of the chemistry reported in this paper we utilize kinetically inert ruthenium(II) complexes, both as reaction scaffolds for reactions at coordinated ligands and as synthetic targets in their own right. We are primarily interested in tuning the redox and photophysical properties of multinuclear species containing metal-centred chromophores and lumophores, and $\{Ru(bpy)_3\}$ and $\{Ru(tpy)_2\}$ motifs are at the core of these studies.

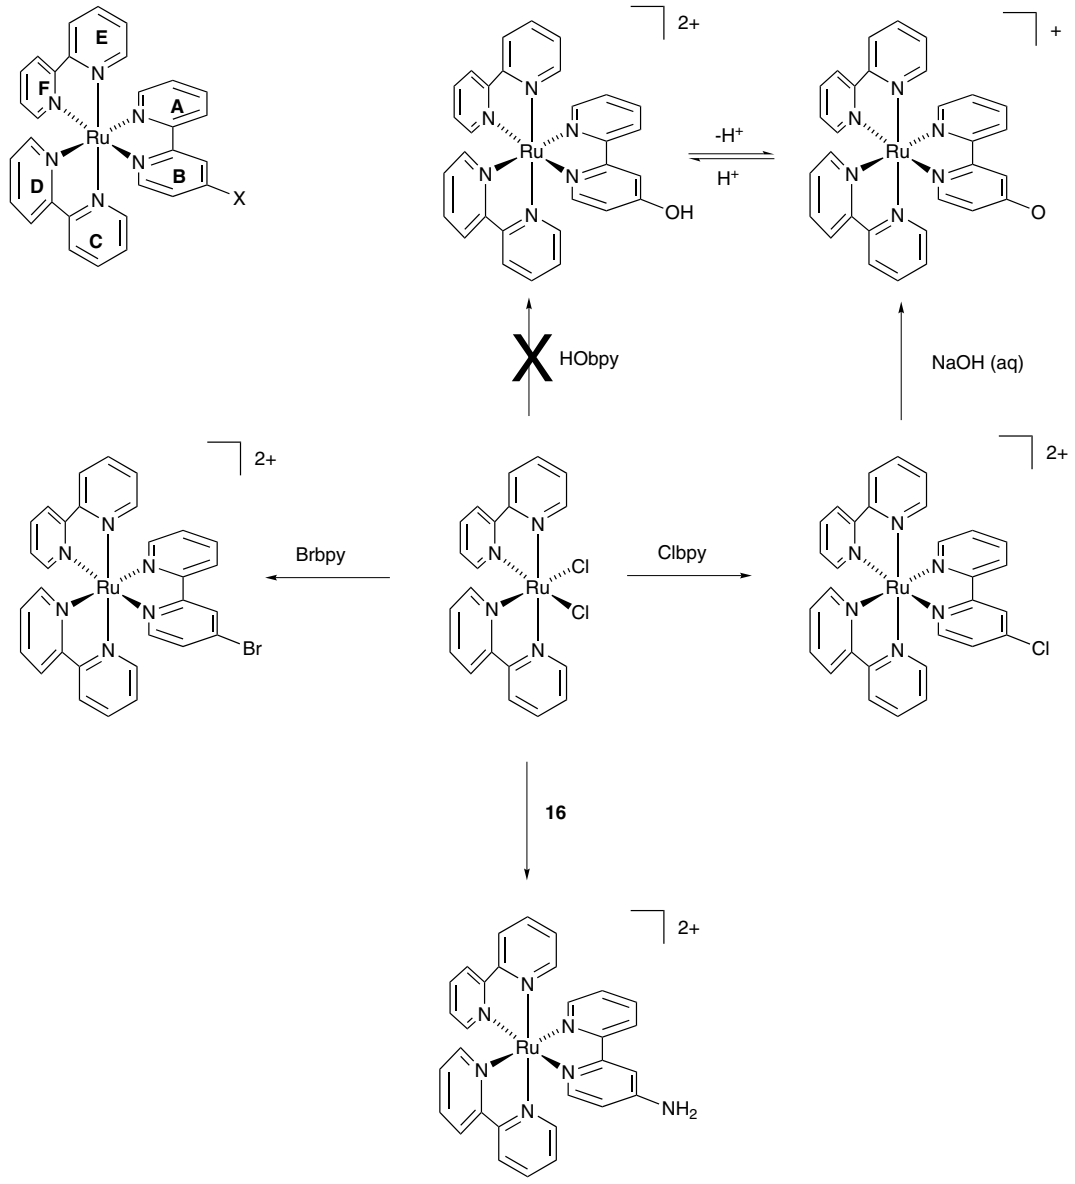
The complexes $[Ru(bpy)_2(Clbpy)][PF_6]_2$ [90–92] and $[Ru(bpy)_2(Brbpy)][PF_6]_2$ [20,64,89] were prepared by the reaction of *cis*-$[Ru(bpy)_2Cl_2]$ with Clbpy or Brbpy, respectively, in refluxing $HOCH_2CH_2OH$ in a modified domestic microwave oven. This technique allows for very fast reaction times of the order of minutes in contrast to conventional thermal reactions which require many hours at reflux. The crude products were precipitated as hexafluorophosphate salts and purified by chromatography over silica using a highly polar mobile phase (acetonitrile, water, aqueous KNO_3). The complexes $[Ru(bpy)_2(Clbpy)][PF_6]_2$ and $[Ru(bpy)_2(Brbpy)][PF_6]_2$ were obtained as bright red solids in yields of 75% and 87% respectively. These two compounds will be used as electrophilic bpy complexes for the unambiguous introduction of $\{Ru(bpy)_3\}$ motifs. The two complexes are luminescent with absorption and emission spectra essentially identical to $[Ru(bpy)_3]^{2+}$. The ligands are slightly more electron withdrawing than bpy, and the ruthenium(II)–(III) redox process is shifted to slightly more positive potentials (+0.92 and +0.90 V for the Brbpy and Clbpy complexes, respectively, all potentials quoted vs. internal Fc/Fc^+, MeCN solution) than $[Ru(bpy)_3]^{2+}$ (+0.85 V). We note at this point that all $\{Ru(bpy)_2(Xbpy)\}$ centres described in this paper are racemates comprising equal amounts of the Δ and Λ enantiomers, as is the starting *cis*-$[Ru(bpy)_2Cl_2]$.

An analogous reaction of *cis*-$[Ru(bpy)_2Cl_2]$ with the amino compound **16** under microwave conditions gave an uncharacterized mixture of compounds possessing various colours, but prolonged (5 h) reaction in aqueous methanol under normal thermal conditions, followed by chromatographic purification gave $[Ru(bpy)_2(\mathbf{16})][PF_6]_2$ [90–92] as a red solid in 42% yield. All attempts to use $[Ru(bpy)_2(\mathbf{16})][PF_6]_2$ as a nitrogen nucleophile in reactions with electrophiles were unsuccessful. The amino group is highly conjugated with the bpy and this is observed in the properties of the complex; the MLCT absorption is red shifted to 458 nm and the ruthenium(II)–(III) redox process is now observed at +0.70 V, shifted 150 mV to less positive potential than $[Ru(bpy)_3]^{2+}$. The luminescence is also significantly red-shifted to 645 nm with respect to $[Ru(bpy)_3]^{2+}$ (620 nm).

The phenolic hydroxy group in complexes of HObpy and HOtpy is readily deprotonated to give complexes of enhanced (but still very low) nucleophilicity. Regardless of the tautomeric state of the free ligands (pyridone or hydroxypyridine), the complexes are forced to adopt the hydroxypyridine structure. Attempts to prepare salts of either $[Ru(bpy)_2(HObpy)]^{2+}$ or $[Ru(bpy)_2(Obpy)]^{+}$ from HObpy and $[Ru(bpy)_2Cl_2]$ under microwave or thermal conditions only resulted in mixtures of numerous products in our hands. However, although we could not obtain good yields of HObpy by alkaline hydrolysis of Clbpy or Brbpy, we considered that the enhanced electrophilicity of coordinated Clbpy might allow us to perform the hydrolysis in the coordination sphere and prepare $[Ru(bpy)_2(HObpy)]^{2+}$ or $[Ru(bpy)_2(Obpy)]^{+}$ directly from $[Ru(bpy)_2(Clbpy)][PF_6]_2$. Upon heating $[Ru(bpy)_2(Clbpy)][PF_6]_2$ to reflux overnight with 2 M aqueous sodium hydroxide solution, a red solution was obtained from which the orange complex $[Ru(bpy)_2(Obpy)][PF_6]$ was isolated. Protonation yielded the parent complex $[Ru(bpy)_2(HObpy)][PF_6]_2$ as a red solid. In contrast to the complex with the amino compound **16**, the HOtpy complex shows no great difference in its electrochemical or spectroscopic behaviour from $[Ru(bpy)_3]^{2+}$. These compounds will act as nucleophilic complexes for the introduction of $\{Ru(bpy)_3\}$ moieties upon reaction with electrophiles. These reactions are summarized in Scheme 5.

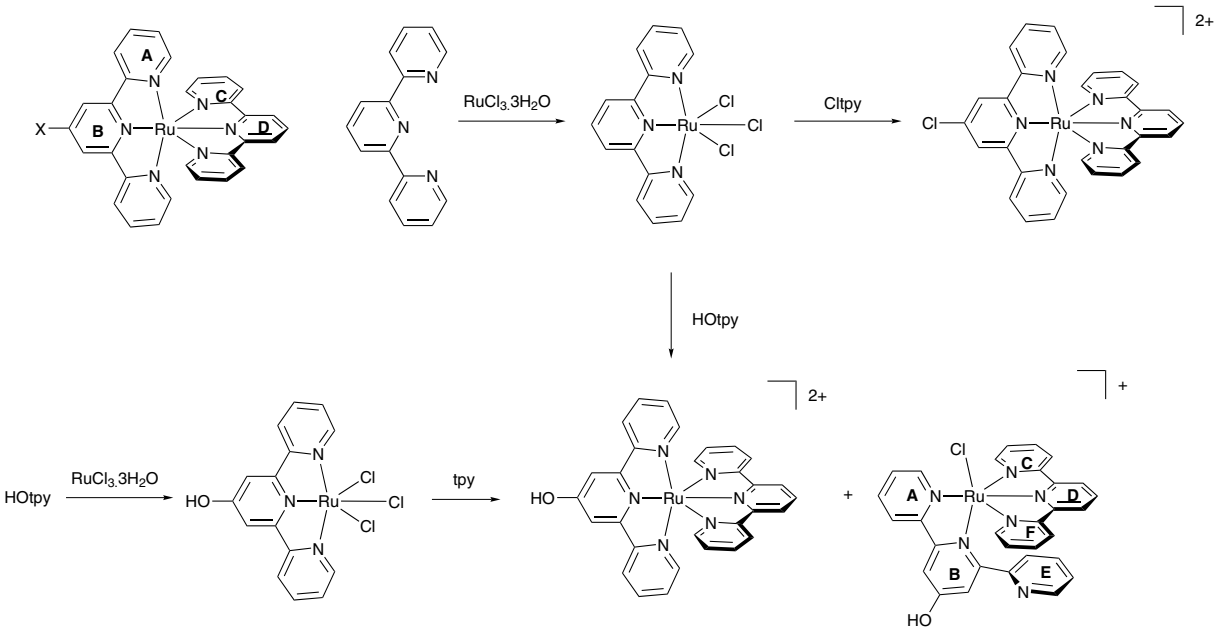
In the series of complexes based upon $\{Ru(tpy)_2\}$ motifs, the complexes $[Ru(tpy)(Cltpy)][PF_6]_2$ and $[Ru(tpy)(HOtpy)][PF_6]_2$ act as electrophilic and nucleophilic species, respectively. The standard method for the preparation of $[Ru(tpy)(Xtpy)][PF_6]_2$ complexes involves the reaction of $[Ru(tpy)Cl_3]$ with Xtpy or $[Ru(Xtpy)Cl_3]$ with tpy under reducing conditions (Scheme 6) [24]. It is most convenient to use an alcohol solvent containing an amine such as *N*-ethylmorpholine as the reductant. The desired ruthenium(III) complexes $[Ru(Xtpy)Cl_3]$ are prepared by the reaction of Xtpy with ethanolic solutions of commercial hydrated ruthenium trichloride and obtained as very dark brown or black insoluble solids. The electrophilic complex $[Ru(tpy)(Cltpy)][PF_6]_2$ is prepared in 45% yield as a red solid from the reaction of $[Ru(tpy)Cl_3]$ with Cltpy.

We were somewhat surprised to find that the two complementary routes for the preparation of $[Ru(tpy)(HOtpy)][PF_6]_2$, $[Ru(tpy)Cl_3]$ with HOtpy or $[Ru(HOtpy)Cl_3]$ with tpy, proceeded in significantly different



Scheme 5. The preparation and reactivity of mononuclear $[Ru(bpy)_2(Xbpy)]^{n+}$ complexes. The numbering scheme used to describe the various aromatic rings is also given.

manners. The compound $[Ru(HOtpy)Cl_3]$ is obtained as a brown solid in 75% yield from the reaction of HOtpy with "$RuCl_3 \cdot 3H_2O$" and subsequent reaction with tpy in ethanol containing *N*-ethylmorpholine gave $[Ru(tpy)(HOtpy)][PF_6]_2$ [24] as a red solid in 40% yield after chromatographic purification. In contrast, the reaction of $[Ru(tpy)Cl_3]$ with HOtpy in methanol containing *N*-ethylmorpholine gave a dark coloured solution. Chromatographic workup gave $[Ru(tpy)(HOtpy)][PF_6]_2$ as a red solid in 50% yield and a purple compound $\{Ru(tpy)(HOtpy)Cl(PF_6)\}$ in 21% yield. This latter complex has a number of characteristic features in its ^1H NMR spectrum; the tpy ligand remains symmetrical with the two terminal rings magnetically equivalent, but in the HOtpy ligand the two terminal rings are non-equivalent. Furthermore, the H_6 resonance of one of the terminal rings of the HOtpy ligand has a very characteristic chemical shift of δ 10.31 ppm which is typical of an oligopyridine *cis* to chlorine in which the C–Cl bond is approximately parallel to the Ru–Cl bond. In the other terminal ring of the HOtpy, H_6 (δ 8.63 ppm) is to higher frequency (down-field) than H_3 (δ 8.32 ppm) with the assignments being made by COSY methods, and H_6 and H_3 being distinguished on the basis of the coupling constants ($J_{5,6} < 6$ Hz, $J_{3,4} > 7$ Hz) [93]; this pattern is typical of a non-coordinated pyridine. The purple compound is the hypodentate [94–104] complex $[Ru(tpy)(HOtpy)Cl][PF_6]$ which contains a bidentate tpy ligand. On the NMR time-scale, rings C and F appear equivalent. It is unclear why the



Scheme 6. Preparation of electrophilic and nucleophilic {Ru(tpy)$_2$} complexes and the hypodentate complex [Ru(tpy)(HOtpy)Cl][PF$_6$]. The labelling scheme for the normal and the hypodentate complexes is indicated.

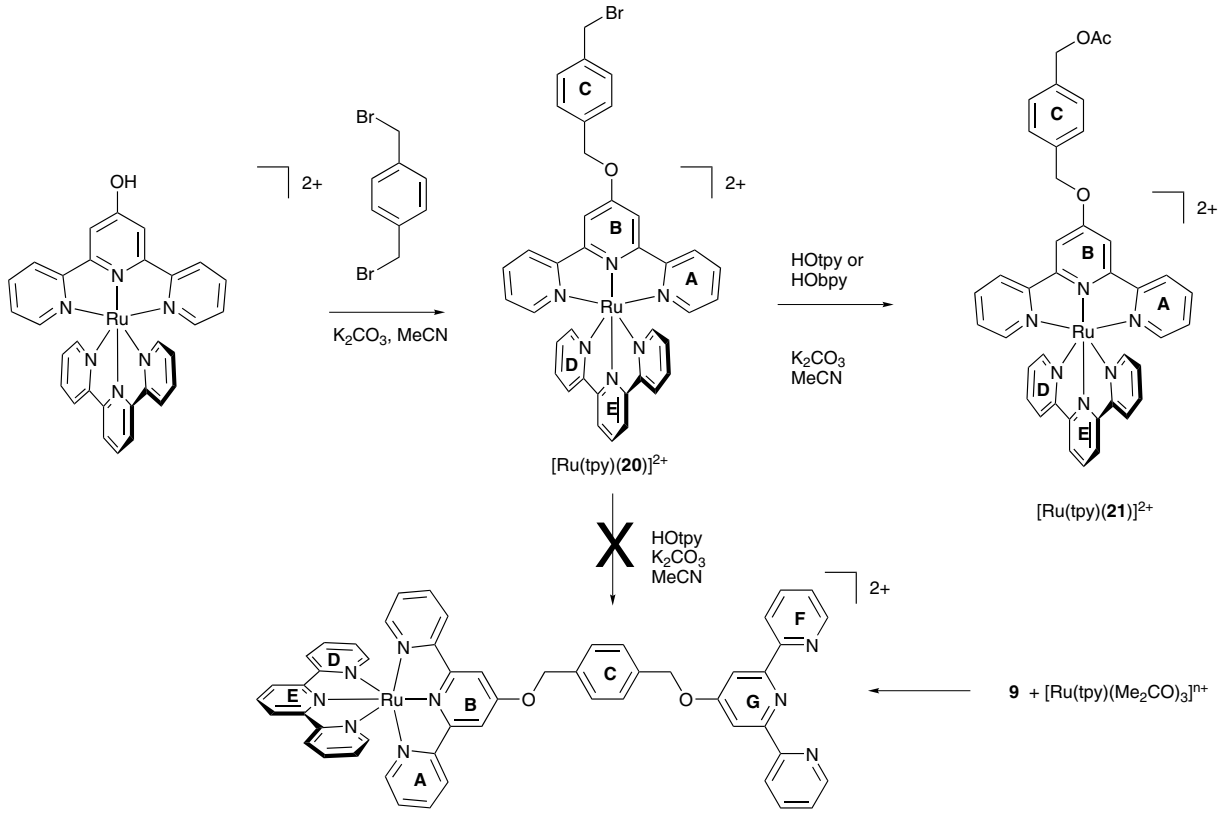
hypodentate complex should be particularly favoured in this reaction.

3.4. Structural development of mononuclear ruthenium(II) complexes and complexes with pendant metal-binding domains

For the specific preparation of heterodinuclear and higher nuclearity complexes it is necessary to have metal-containing building blocks with pendant metal-binding domains. These species are often conveniently prepared from reactions of functionalized metal complexes with appropriate ligand species. We attempted to extend this methodology to the new spaced ligands **7**–**10**.

The reaction of the nucleophilic metal complex [Ru(tpy)(HOtpy)][PF$_6$]$_2$ with one equivalent of 1,4-BrCH$_2$C$_6$H$_4$CH$_2$Br in MeCN containing K$_2$CO$_3$ gave a red solution from which a new complex, [Ru(tpy)(**20**)]-[PF$_6$]$_2$ may be isolated in good yield (Scheme 7). This complex contains the new ligand (4′-bromomethylphenylmethyloxy)-2,2′:6′,2″-terpyridine which has been generated in situ by nucleophilic attack of the oxygen of the HOtpy ligand on the electrophilic 1,4-BrCH$_2$C$_6$H$_4$CH$_2$Br; indeed, the free ligand **20** has never been prepared. The new complex has been fully characterized and pertinent spectroscopic features include the observations of peak envelopes in the mass spectrum possessing the calculated isotopomer distributions for RuBr$_2$ species, together with the observation of two methylene singlets in the ^{1}H NMR spectrum typical of BrCH$_2$ (δ 4.66 ppm) and ArOCH$_2$ (δ 5.60 ppm) species. This complex with a pendant bromomethyl group is not particularly activated by coordination and may be recrystallized from aqueous acetonitrile without hydrolysis. Accordingly, we planned to use [Ru-(tpy)(**20**)][PF$_6$]$_2$ for the preparation of the homoditopic and heteroditopic pendant ligand complexes [Ru-(tpy)(**9**)][PF$_6$]$_2$ and [Ru(tpy)(**8**)][PF$_6$]$_2$ by reaction with HOtpy and HObpy, respectively. However, although the complex [Ru(tpy)(**20**)][PF$_6$]$_2$ is reasonably water stable, all attempts to react it with HOtpy or HObpy in MeCN containing potassium carbonate resulted in the formation of the [Ru(tpy)(**21**)][PF$_6$]$_2$ in which the bromine has been displaced by an acetoxy group in a mechanistically obscure reaction, but which presumably involves hydrolysis of the acetonitrile. Confirmation of this comes from the observation of a C=O stretch in the IR spectrum (1736 cm^{-1}), the observation of the parent ion in the mass spectrum and an acetate methyl resonance at δ 2.09 ppm in the ^{1}H NMR spectrum.

Attempts to prepare [Ru(bpy)$_2$(**7**)][PF$_6$]$_2$ by a similar route were also unsuccessful. The reaction of [Ru-(bpy)$_2$(Obpy)][PF$_6$] with 1,4-BrCH$_2$C$_6$H$_4$CH$_2$Br proceeded smoothly and the complex [Ru(bpy)$_2$(**22**)][PF$_6$]$_2$ was obtained as an orange solid in 25% yield after chromatographic purification. Once again, two methylene singlets are observed in the ^{1}H NMR spectrum typical of BrCH$_2$ (δ 4.58 ppm) and ArOCH$_2$ (δ 5.28 ppm) species and comparing well with [Ru(tpy)(**20**)][PF$_6$]$_2$. Attempts to prepare [Ru(bpy)$_2$(**7**)][PF$_6$]$_2$ or [Ru(bpy)$_2$(**8**)][PF$_6$]$_2$ by the reaction of [Ru(bpy)$_2$(**22**)][PF$_6$]$_2$ with HObpy or HOtpy in acetonitrile only gave the acetoxy derivative [Ru(bpy)$_2$(**23**)][PF$_6$]$_2$.

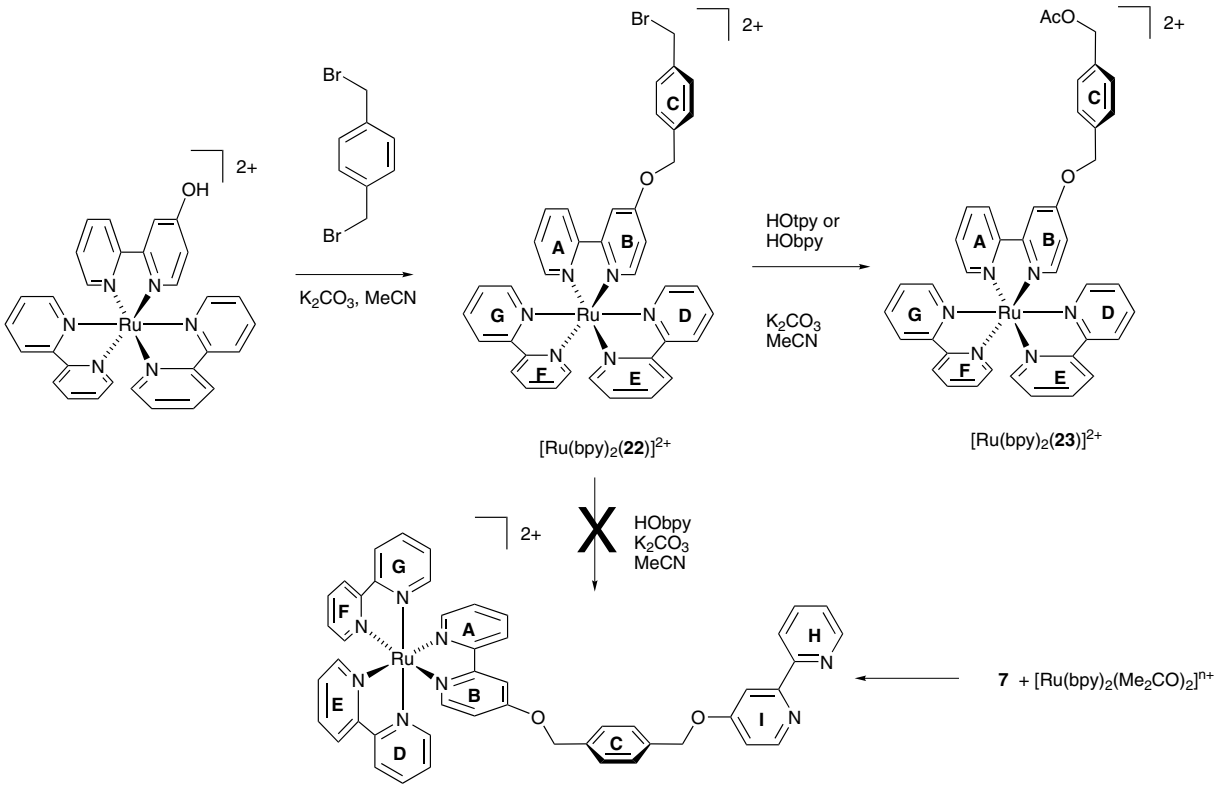


Scheme 7. Synthesis of mononuclear complex [Ru(tpy)(**9**)][PF_6]$_2$ with a pendant tpy metal-binding domain.

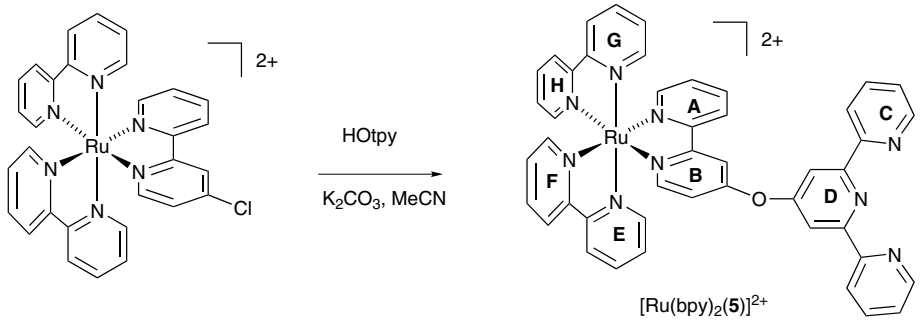
The complex [Ru(tpy)(**9**)][PF_6]$_2$, which has a free tpy metal-binding domain can, however, be prepared by the reaction of **9** with the solvento complex [Ru(tpy)(Me_2CO)$_3$]$^{n+}$. The new complex has the expected ^{1}H NMR spectroscopic characteristics for a species which has an uncoordinated tpy residue, with H_6 appearing at the typical free ligand position of δ 8.94 ppm. The bpy analogue [Ru(bpy)$_2$(**7**)][PF_6]$_2$, which has a free bpy metal-binding domain is prepared in a similar manner by the reaction of **7** with the solvento complex [Ru(bpy)$_2$(Me_2CO)$_2$]$^{n+}$ (prepared in situ by the reaction of silver tetrafluoroborate with [Ru(bpy)$_2$Cl$_2$] in acetone). The new complex has the expected ^{1}H NMR spectroscopic characteristics for a species which has an uncoordinated bpy residue. The {Ru(bpy)$_3$} luminophore is unperturbed and the complex shows an emission from the ^{3}MLCT level at 623 nm. The introduction of the ether-functionality at the 4-position of the bpy results in slightly greater ligand field and the ruthenium(II)–(III) process is shifted to slightly lower potential (+0.83 V) (see Scheme 8).

Metal-directed approaches to complexes containing the heteroditopic ligand **5** would involve the reaction of [Ru(tpy)(Cltpy)][PF_6]$_2$ with HObpy or [Ru(bpy)$_2$(Clbpy)][PF_6]$_2$ with HOtpy under the conditions used for the preparation of complexes of **1** or **3**. We elected to utilize the latter approach on the basis that the future use of enantiomerically pure [Ru(bpy)$_2$(Clbpy)][PF_6]$_2$ would allow the preparation of homochiral metallopolymers and metallodendrimers. The complex [Ru(bpy)$_2$(**5**)][PF_6]$_2$ was obtained in 41% yield from the reaction of either [Ru(bpy)$_2$(Clbpy)][PF_6]$_2$ or [Ru(bpy)$_2$(Brbpy)][PF_6]$_2$ with HOtpy in acetonitrile containing K_2CO_3 (Scheme 9). Again, the complex has characteristic properties associated with the non-coordinated tpy metal-binding domain (H_6 of the tpy domain at δ 8.77 ppm), behaves as a typical {Ru(bpy)$_3$} luminophore with an emission at 620 nm and exhibits a ruthenium(II)–(III) redox process at +0.88 V.

The principle of selectively addressing bpy or tpy domains in heteroditopic ligands is illustrated by the preparation of [Ru(bpy)$_2$(**2**)][PF_6]$_2$ from [Ru(bpy)$_2$Cl$_2$] and **2**. The complex [Ru(bpy)$_2$Cl$_2$] has two labile monodentate ligands and will react with bidentate oligopyridine metal-binding domains. In the case of ligand **2**, bidentate bpy and tpy domains are available, but the steric effects associated with the non-coordinated terminal pyridine ring of the didentate tpy destabilize this complex with respect to that with a coordinated bipyridine. The reaction of [Ru(bpy)$_2$Cl$_2$] with **2** in ethanol containing *N*-ethylmorpholine gives the complex [Ru(bpy)$_2$(**2**)][PF_6]$_2$ in 55% yield as an orange solid. The ^{1}H NMR spectrum clearly indicates that it is the tpy domain that is not-coordinated. The complex behaves as



Scheme 8. Synthesis of mononuclear complex [Ru(tpy)(**7**)][PF_6]$_2$ with a pendant bpy metal-binding domain.



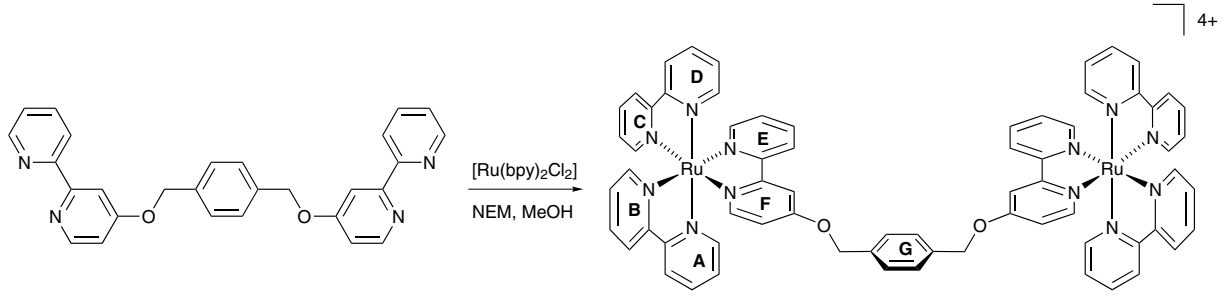
Scheme 9. Reaction of coordinated Cltpy with HObpy to form the new heteroditopic ligand **5**, coordinated to Ru(II).

a typical {Ru(bpy)$_3$} derivative, with essentially no perturbation of the ruthenium(II)–(III) redox process (+0.93 V) or the MLCT absorption (461 nm) and also retains the typical luminescent properties of this luminophore and shows an emission at 628 nm.

3.5. Preparation of diruthenium complexes of homoditopic and heteroditopic ligands

In this section, the various ways of preparing diruthenium complexes will be exemplified. The simplest method is the reaction of a ditopic ligand with two equivalents of a commensurate ruthenium complex. For every tpy metal-binding domain, use of complex [Ru(tpy)Cl$_3$] will give a new {Ru(tpy)$_2$} motif whilst for every bpy metal-binding domain reaction with [Ru(bpy)$_2$Cl$_2$] will give a new {Ru(bpy)$_3$} motif. In the case of the homoditopic ligands this procedure is trivial, although the complexes containing two {Ru(bpy)$_3$} groups will exist as a mixture of ΔΔ, ΔΛ and ΛΛ diastereoisomers. It is unlikely that the heteroditopic ligands can be selectively addressed.

A typical example is the preparation of [(bpy)$_2$-Ru(**7**)Ru(bpy)$_2$][PF_6]$_4$ from **7** and [Ru(bpy)$_2$Cl$_2$] (Scheme 10). The complex is obtained (as an uncharacterized mixture of diastereoisomers) as a red solid. We cannot state anything about the presence or ratio of diastereoisomers on the basis of the ^{1}H NMR spectra. There is no strong electronic interaction between the ruthenium centres and a single ruthenium(II)–(III)



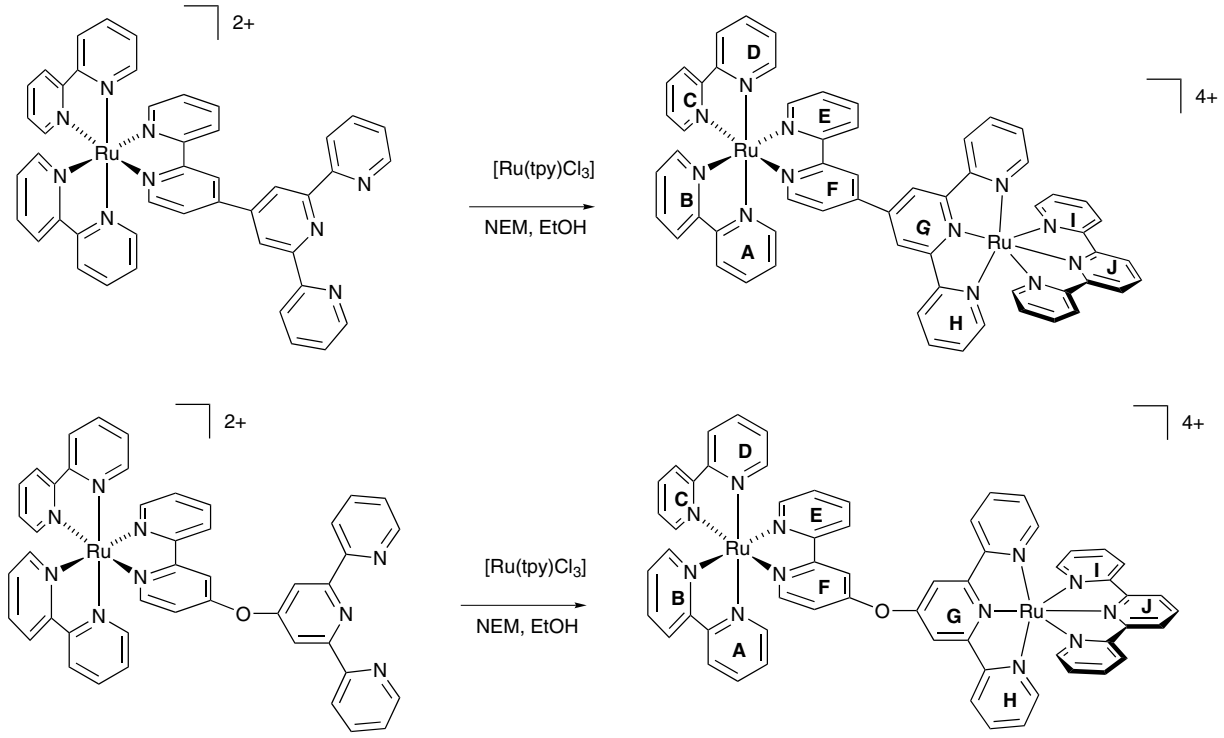
Scheme 10. Preparation of $[(bpy)_2Ru(\mathbf{7})Ru(bpy)_2][PF_6]_4$ from **7** and $[Ru(bpy)_2Cl_2]$ (only the ΛΔ diastereoisomer is shown).

redox process is observed at +0.81 V. The molar absorption coefficients are roughly twice that of model mononuclear complexes (or rather, the molar absorptivity per ruthenium centre is roughly constant) (see Schemes 11 and 12).

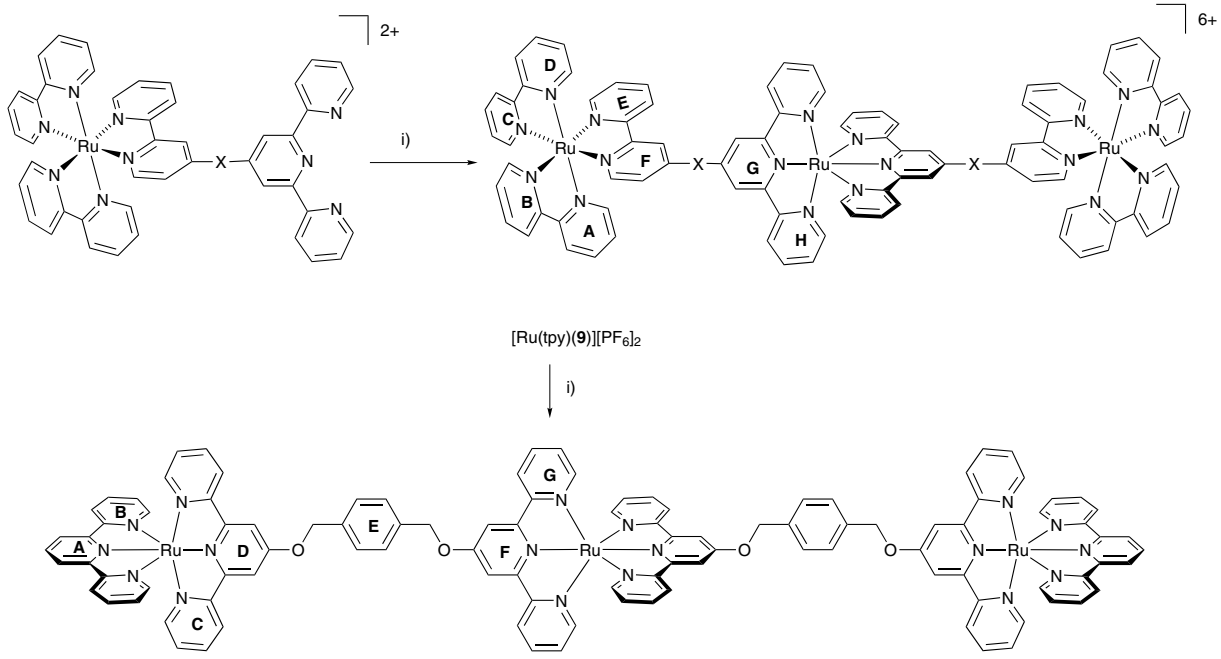
For heteroditopic ligands, the best strategy is to prepare a complex with a pendant metal-binding domain and to cap with a commensurate complex. The reaction of ruthenium complexes with pendant tpy metal-binding domains is exemplified by the use of the complexes $[Ru(bpy)_2(\mathbf{2})][PF_6]_2$ and $[Ru(bpy)_2(\mathbf{5})][PF_6]_2$ with $[Ru(tpy)Cl_3]$ to give the dinuclear complexes $[(bpy)_2Ru(\mathbf{2})Ru(tpy)][PF_6]_4$ and $[(bpy)_2Ru(\mathbf{5})Ru(tpy)][PF_6]_4$. These complexes, which contain only a single $\{Ru(bpy)_3\}$ motif are obtained as a racemate of the Δ and Λ enantiomers. The complexes exhibit a single observable ruthenium(II)–(III) process in their cyclic voltammogram or differential pulse voltammogram, although these are very broad and can be deconvoluted to two Gaussians for the $\{Ru(bpy)_3\}$ and $\{Ru(tpy)_2\}$ motifs. Both complexes are red-brown, but the absorption for $[(bpy)_2Ru(\mathbf{2})Ru(tpy)][PF_6]_4$ is red shifted to 500 nm with respect to $[(bpy)_2Ru(\mathbf{5})Ru(tpy)][PF_6]_4$ (467 nm). Both complexes are luminescent with $[(bpy)_2Ru(\mathbf{5})Ru(tpy)][PF_6]_4$ showing a typical $\{Ru(bpy)_3\}$ emission at 626 nm, but the emission from $[(bpy)_2Ru(\mathbf{2})Ru(tpy)][PF_6]_4$ is observed at 689 nm.

3.6. Preparation of trinuclear complexes of homoditopic and heteroditopic ligands

In the final section, we demonstrate the utility of complexes containing pendant tpy metal-binding domains as building blocks and illustrate their use for



Scheme 11. The preparation of $[(bpy)_2Ru(\mathbf{2})Ru(tpy)][PF_6]_4$ and $[(bpy)_2Ru(\mathbf{5})Ru(tpy)][PF_6]_4$ by selectively capping the pendant tpy metal-binding domain with a (tpy)Ru unit.



Scheme 12. Preparation of homo- and heterotrinuclear complexes with $\{Ru(bpy)_3\}$ and $\{M(tpy)_2\}$ domains: X = nothing or O, M = Ru (only for X = nothing) (i) $RuCl_3 \cdot 3H_2O$, $HOCH_2CH_2OH$, microwave; M = Co (i) $Co(OAc)_2 \cdot 4H_2O$; M = Fe (i) $Fe(BF_4)_2 \cdot 4H_2O$, MeOH; M = Mn (i) $Mn(OAc)_2 \cdot 4H_2O$.

the formation of a range of homo and heterotrinuclear complexes. The complex $[Ru(bpy)_2(\mathbf{2})][PF_6]_2$ contains a non-coordinated metal binding domain and is expected to react rapidly with labile first row divalent transition metal salts to give heterotrinuclear $[(bpy)_2Ru(\mathbf{2})M(\mathbf{2})Ru(bpy)_2]^{6+}$ species and under forcing conditions with less-labile ruthenium sources to give the homotrinuclear compound $[(bpy)_2Ru(\mathbf{2})Ru(\mathbf{2})Ru(bpy)_2]^{6+}$ with two $\{Ru(bpy)_3\}$ and one $\{Ru(tpy)_2\}$ motif.

The reaction of $[Ru(bpy)_2(\mathbf{2})][PF_6]_2$ with commercial $RuCl_3 \cdot 3H_2O$ under microwave conditions in $HOCH_2CH_2OH$ gave an orange solution from which the trinuclear compound $[(bpy)_2Ru(\mathbf{2})Ru(\mathbf{2})Ru(bpy)_2][PF_6]_6$ was isolated in 51% yield. The ^1H NMR spectrum reveals the high symmetry and the presence of the $\{Ru(bpy)_3\}$ and $\{Ru(tpy)_2\}$ motifs. The complex is presumably a statistical mixture of ΔΔ, ΔΛ and ΛΛ diastereoisomers. The nuclearity of these trinuclear complexes is very conveniently determined by the high resolution mass spectrometry, where the envelope of isotopomer peaks arising from the various ruthenium isotopes is very characteristic. This is illustrated in Fig. 1, where calculated isotopomer distributions are compared with the experimental electrospray mass spectrum for the dipositive ion $\{[(bpy)_2Ru(\mathbf{2})Ru(\mathbf{2})Ru(bpy)_2][PF_6]_4\}^{2+}$.

The presence of the $\{Ru(bpy)_3\}$ and $\{Ru(tpy)_2\}$ motifs domains is also seen in the spectroscopic and electrochemical properties of the complex. The differential pulse voltammogram of $[(bpy)_2Ru(\mathbf{2})Ru(\mathbf{2})Ru(bpy)_2][PF_6]_6$ (MeCN vs. Fc/Fc^+, $[^nBu_4N][PF_6]$ supporting electrolyte) is presented in Fig. 2, showing the asymmetric process associated with the two different ruthenium centres. The peak fitting to two Gaussians in a ratio of 2:1 is shown and allows us to extract E^0 values of +0.91 and +0.98 V for the $\{Ru(bpy)_3\}$ and $\{Ru(tpy)_2\}$ domains, respectively. The complex also shows two overlapping but distinct MLCT absorptions at 460 and 512 nm, assigned to the $\{Ru(bpy)_3\}$ and $\{Ru(tpy)_2\}$ domains, respectively. As expected, the complex is luminescent and shows a red-shifted $\{Ru(bpy)_3\}$-type emission at 670 nm.

The complexes $[(bpy)_2Ru(\mathbf{2})M(\mathbf{2})Ru(bpy)_2][PF_6]_6$ (M = Co, Fe, Mn) are even simpler to prepare and are isolated by the addition of NH_4PF_6 to methanol solutions containing $[Ru(bpy)_2(\mathbf{2})][PF_6]_2$ and appropriate salts in a 2:1 ratio. All of the complexes are luminescent with MLCT absorption maxima 460–470 nm and a typical $\{Ru(bpy)_3\}$-type emission at 628–636 nm. In the case of the purple iron(II) complex $[(bpy)_2Ru(\mathbf{2})Fe(\mathbf{2})Ru(bpy)_2][PF_6]_6$, there is a second MLCT absorption due to the $\{Fe(tpy)_2\}$ chromophore at 591 nm. The complexes all show a ruthenium(II)–(III) process in their cyclic voltammograms at +0.92–0.95 V. In the cases of the iron(II) and cobalt(II) complexes, an additional metal-centred process due to the central first row metal is observed at +0.79 and −0.07 V, respectively. Taken collectively, these data argue strongly for uncoupled metal centres in the heterotrinuclear species. The ^1H NMR spectra of the complexes are of varying degrees of utility, the diamagnetic iron complex is assigned by usual

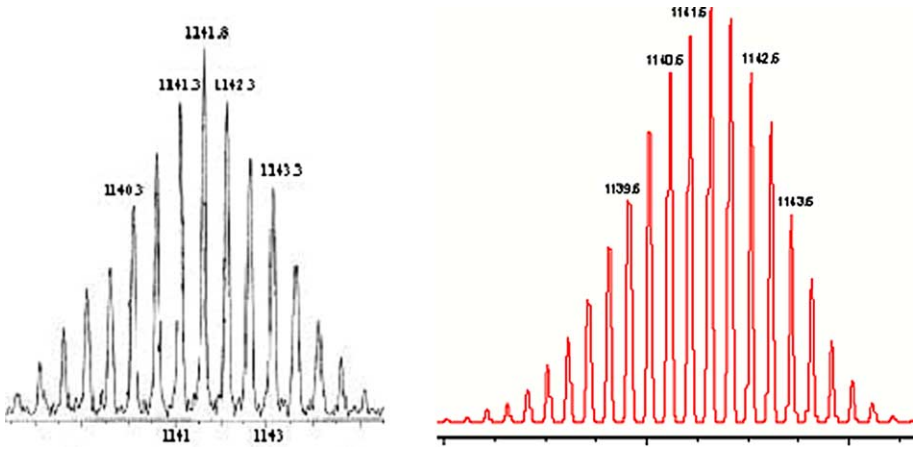


Fig. 1. Experimental (left) and calculated (right) isotopomer distribution for the species $\{[(bpy)_2Ru(\mathbf{2})Ru(\mathbf{2})Ru(bpy)_2][PF_6]_4\}^{2+}$.

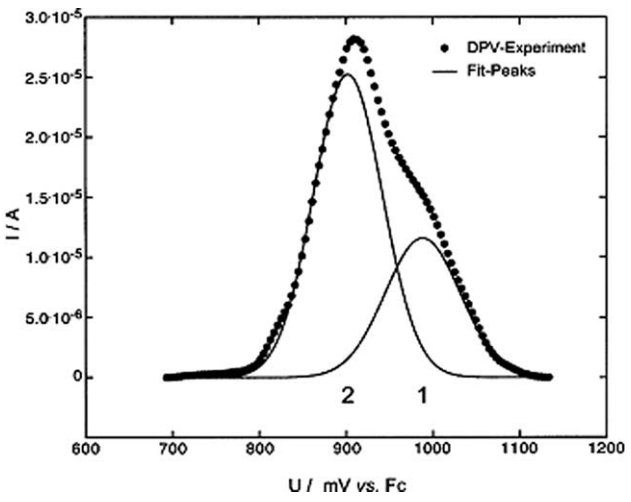

Fig. 2. Differential pulse voltammogram of $[(bpy)_2Ru(\mathbf{2})Ru(\mathbf{2})Ru(bpy)_2][PF_6]_6$ (MeCN vs. Fc/Fc^+, $[^nBu_4N][PF_6]$ supporting electrolyte) and fitting of two Gaussian curves for the $\{Ru(bpy)_3\}$ and $\{Ru(tpy)_2\}$ processes at +0.91 and +0.98 V, respectively.

methods. Both the cobalt(II) and manganese(II) complexes are paramagnetic; in the case of $[(bpy)_2Ru(\mathbf{2})Mn(\mathbf{2})Ru(bpy)_2][PF_6]_6$ all signals are exceptionally broad and no assignments can be made, but for $[(bpy)_2Ru(\mathbf{2})Co(\mathbf{2})Ru(bpy)_2][PF_6]_6$ the peaks of the $\{Co(tpy)_2\}$ domain are shifted but not excessively broadened, allowing a full assignment [93].

The analogous heterotrinuclear compounds $[(bpy)_2Ru(\mathbf{5})M(\mathbf{5})Ru(bpy)_2][PF_6]_6$ and $[(bpy)_2Ru(\mathbf{9})M(\mathbf{9})Ru(bpy)_2][PF_6]_6$ (M = Co, Fe, Mn) were prepared using $[Ru(bpy)_2(\mathbf{5})][PF_6]_2$ or $[Ru(bpy)_2(\mathbf{9})][PF_6]_2$, respectively. No significant differences from the compounds discussed above were observed: all compounds with **5** exhibited $\{Ru(bpy)_3\}$ MLCT absorption maxima at 450–458 nm and a typical $\{Ru(bpy)_3\}$-type emission at 620–625 nm, whilst those with **9** were non-luminescent in fluid solution having only a $\{Ru(tpy)_2\}$ luminophore, and show typical $\{Ru(tpy)_3\}$ MLCT absorption maxima at 478–482 nm. The iron(II) complexes with both **5** and **9** show an additional iron-centred MLCT absorption at 550–560 nm. The complexes are redox active showing essentially unperturbed $\{Ru(bpy)_3\}$ ruthenium(II)–(III) processes at +0.86 to +0.90 V, $\{Ru(tpy)_2\}$ ruthenium(II)–(III) processes at +0.80 to +0.90 V, {Co(tpy)} cobalt(II)–(III) processes at +0 V, and $\{Fe(tpy)_2\}$ iron(II)–(III) processes at ≈+0.70 V.

4. Conclusions

We have demonstrated that combinations of conventional ligand and complex synthesis with metal-directed reactions of coordinated ligands may be used to prepare a suite of building blocks containing hetero- and homoditopic ligands. Representative homo- and heterotrinuclear complexes with these building blocks have been prepared.

Abstract

Both MH(Ph)(CO)L_2 (L = P^tBu_2Me; M = Ru and Os) react with vinyl fluoride to form M–F bonds; however, Ru eliminates benzene, while Os eliminates ethylene. In contrast, Ru(H)$_2$(CO)L_2 and Os(H)$_2$(CO)(1-butene)L_2 both react with vinyl fluoride to give ethylene and MHF(CO)L_2. Ethylene production from *both* dihydrides is attributed to β-F migration to M from an MCH_2CH_2F transient, while the unique behavior of RuH(Ph)(CO)L_2 (giving the C–F oxidative addition product Ru(η^1-vinyl)F(CO)L_2) is attributed to the difficulty of achieving Ru^{IV}, and the ability of the strongly π-acidic vinyl fluoride to rapidly trigger reductive elimination of benzene. The products of reaction of RuH(Ar)(CO)L_2 with vinyl fluoride are redirected more towards ethylene formation when Ar carries fluorine substituents. The reaction products of OsH(R)(CO)L_2 with vinyl fluoride revert to R-H elimination when R is methyl. Finally, the more π-acidic $H_2C{=}CF_2$ triggers very rapid CH_4 elimination from OsH(CH_3)(CO)L_2; cleavage of the second C–F bond yields the vinylidene $OsF_2(CCH_2)(CO)L_2$. All selectivity is rationalized via the fate of the adduct MH(R)($C_2H_{4-n}F_n$)(CO)L_2.

1. Introduction

C–F bond cleavage is a goal for accomplishing catalytic transformation of perfluoroalkanes (and arenes) and Freons to valuable or environmentally benign materials [1–5]. This is also a topic of interest in organic synthesis [6–19]. The early transition elements have a strong tendency to cleave F–C(sp^2) bonds [20–25]. A fundamental problem in C–F activation by soluble transition metal complexes is selective cleavage of the C–F in preference to the C–H bond in partially fluorinated alkanes and arenes since the C–F bond is normally stronger than the C–H bond [26]. That is, kinetic selectivity is required [27–32]. In at least one case, C–F bond cleavage is thermodynamically favored, but kinetically disfavored [33]. However, rarely has there been a report of different selectivity for reaction of a metal complex with vinyl fluoride versus aryl fluoride. Such an example is documented here.

2. Results

2.1. MH(Ph) Reactivity with $H_2C{=}CHF$

(a) M = Os. The molecule OsH(Ph)(CO)L_2 (L = P^tBu_2Me) (**1**), is reported to be "triggered" by reaction with fluoroarenes ($C_6H_{6-n}F_n$, with $n = 1, 2, 5$) at 25 °C to eliminate C_6H_6 and oxidatively add an arene C–H

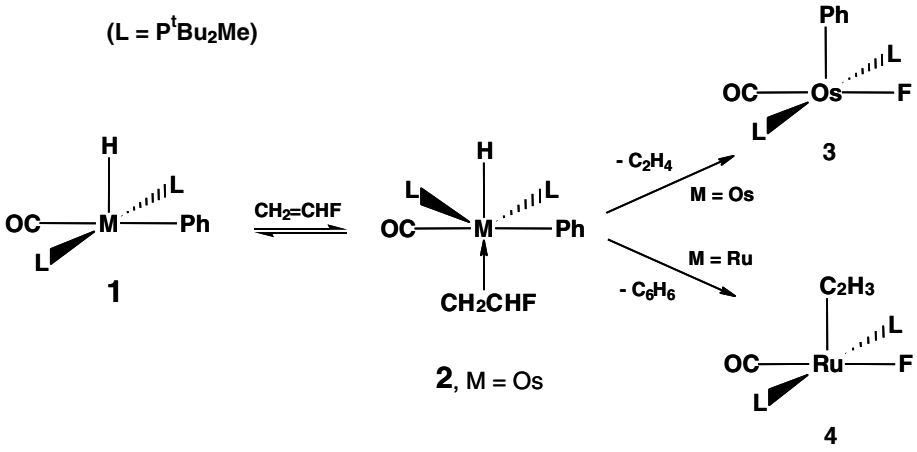


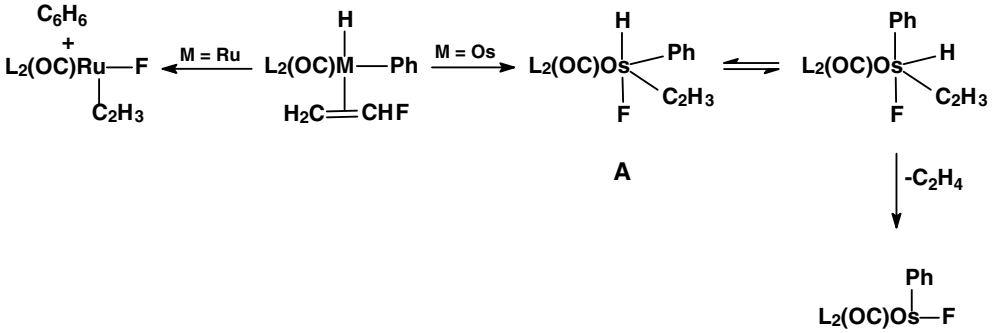
Scheme 1.

bond, to yield $OsH(Ar^F)(CO)L_2$ [34]. The reactions are thus selective *against* C–F bond scission; indeed, C_6F_6 does not react. In contrast, **1** is now reported to react with vinyl fluoride to ultimately produce a C–F bond-cleaved product. Reaction of $OsH(Ph)(CO)L_2$ with excess vinyl fluoride at −90 °C in toluene (Scheme 1) gives a π-adduct (**2**), $OsH(Ph)(CO)L_2(C_2H_3F)$. The ^1H NMR spectrum of **2** shows a hydride peak at −3.7 ppm as an apparent triplet. The coordinated vinyl protons appear at 2.7, 2.9 and 7.6 ppm and the ^{19}F NMR signal of the bound vinyl fluoride (−171 ppm) is shifted significantly upfield, compared to that of free vinyl fluoride (−113 ppm) [35]. The $^{31}P\{^1H\}$ NMR spectrum of this adduct at −50 °C is an AB quartet and the relatively small $J'_{PP} = 162$ Hz is indicative of two phosphines bent significantly away from a ~180° P–Os–P angle, consistent with strong back donation to this olefin [35]. At 25 °C, **2** reacts further (complete in 4 h) to release ethylene and form **3**, $OsPh(F)(CO)L_2$. The ^{19}F NMR spectrum shows a triplet ($^2J_{PF} = 28$ Hz) at a chemical shift (−202.1 ppm) consistent with F bonded to osmium (not carbon), and $^{31}P\{^1H\}$ NMR shows a doublet with the same splitting. The ^{t}Bu groups are diastereotopically inequivalent and they, as well as the PCH_3 groups, are virtual triplets consistent with structure **3**. The ν_{CO} value (1874 cm^{-1}) is low enough to be consistent with a push/pull F → COπ* donation when these ligands are mutually *trans*. There are four (one of intensity 2) distinct phenyl proton NMR signals, suggesting slow rotation of the Ph around the Os–C(*ipso*) bond [36].

(b) M = Ru. $RuH(Ph)(CO)L_2$ also cleaves the C–F bond of vinyl fluoride but it gives a different product. Combination of $RuH(Ph)(CO)L_2$ with 1 atm $CH_2=CHF$ in benzene[1] gives quantitative formation of $Ru(CH{=}CH_2)F(CO)L_2$ (**4**), after 12 h at room temperature (Scheme 1). The ^{19}F NMR spectrum of **4** shows a broad triplet ($^3J_{PF} = 22$ Hz) and the $^{31}P\{^1H\}$ NMR spectrum shows a doublet with the same J_{PF} value. The ^1H NMR spectrum of **4** features an α-vinyl proton at 8.3 ppm (ddd, $J_{HH} = 14.7$ Hz, $J_{HH} = 7.5$, $J_{FH} = 6.9$ Hz) with the β-protons at higher field (5.4 and 5.1 ppm). The low ν(CO) value (1894 cm^{-1}) is consistent with CO *trans* to F. For comparison, **4** can also be synthesized from $RuHF(CO)L_2$ and C_2H_2. Combination of $RuHF(CO)L_2$ and 1 atm C_2H_2 in benzene gives $Ru(C_2H_3)F(CO)L_2$ quantitatively in 30 min at room temperature.

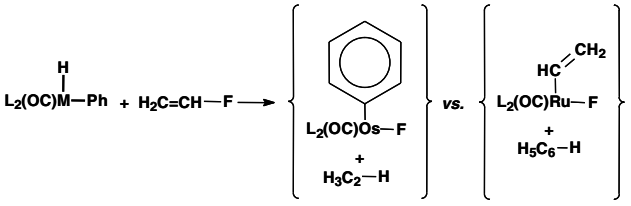
(c) Mechanism. We interpret these results without invoking a wholly different mechanism for the reaction of the Ru and Os species $MH(Ph)(CO)L_2$ with vinyl fluoride. The idea that an oxidant, including even an electron deficient olefin like $(NC)_2C{=}C(CN)_2$, can trigger reductive elimination is termed oxidatively induced reductive elimination [37–41]. We suggest that the absence of *detectable* vinyl fluoride adduct for M = Ru is of quantitative (i.e., a few kcal/mol) rather than qualitative significance. Indeed, it serves as a reminder that Os is a more potent π base than Ru, since back-bonding is an important component of binding of the fluorinated olefin. This difference in π-basicity can also be used to interpret the distinct selectivities shown by Ru and Os. In brief (Scheme 2), osmium is more tolerant to high oxidation states, so the C–F oxidation product, containing Os^{IV}, can be achieved. This seven-coordinate species will be sufficiently persistent and nonrigid, to permit isomerization of H to a site *cis* to the vinyl group; reductive elimination of ethylene follows. For M = Ru, η^2 binding of π-acidic $H_2C{=}CHF$ triggers rapid reductive elimination of H with C_6H_5 as the lowest energy process, in order to avoid the high (versus Os) energy of Ru^{IV}; the prompt character of these two events prohibits establishing any inherent (i.e., thermodynamic) preference for phenyl versus vinyl remaining on ruthenium. That is, selectivity is truly kinetically controlled for Ru

[1] No detectable amount of adduct is formed from $RuH(Ph)(CO)L_2$ under 1 atm vinyl fluoride in d_{14}-methylcyclohexane at −70° by ^1H and ^{31}P NMR spectroscopy.



Scheme 2.

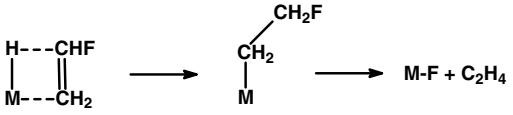
but probably not so for Os. Based on our earlier evidence that M–F bond formation is thermodynamically favored for the reactions of the various five-coordinate species studied here [33], the metal dependent products in Scheme 1 probably involve very small differences in reaction enthalpy (i.e., they differ by vinyl versus phenyl on the metal (Eq. (1)) but share the production of a M–F bond). The different products are thus best explained by being under kinetic control via the distinct accessibility of redox changes at a 4d versus a 5d metal.



(1)

In order to test for possible phosphine dissociation at or prior to the rate determining step in the reaction of $MH(Ph)(CO)L_2$ with vinyl fluoride, a rate comparison was made in the absence and presence of 2–5 equivalents of free phosphine (P^tBu_2Me). For either M = Ru or Os, the half-lives for product appearance were observed to be comparable with and without added L, eliminating phosphine dissociation as a mechanistic component.

Based on the mechanism previously deduced for reaction of $OsHCl(CO)(P^iPr_3)_2$ with RCCH [42], a direct attack of the M–H bond on the olefin must also be considered here (Eq. (2)). Here, no prior η^2-olefin adduct is on the reaction path and the first M/C interaction is concurrent with C/H bond formation.



(2)

Since this is a path to M–F and ethylene, it might explain the results when M = Os, but not for Ru. Because it is not clear *why* this mechanism would have higher $\Delta G^{\ddagger}$ for Ru, we discount it. In contrast, the known redox differences of Ru and Os naturally account for the observed selectivity difference via Scheme 2.

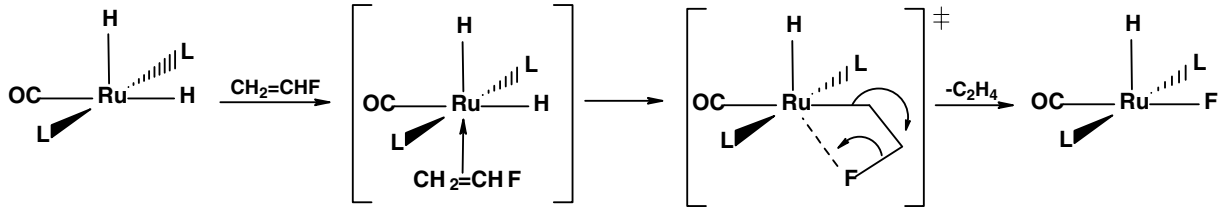
$M(H)_2$ reactivity with H_2C=CHF. A mechanism which incorporates the adduct $MHR(H_2C{=}CHF)(CO)L_2$ also naturally explains the high rate and *similar* products, for M = Ru and Os, when R = H, as will now be described. The feature common to the reactions in Scheme 1 is that the hydride ligand cannot react immediately with a vinyl fluoride ligand *trans* to itself, and thus metal-dependent selectivity develops from within the adduct. To create the contrasting situation of hydride *cis* to the olefin, excess vinyl fluoride was reacted with $Ru(H)_2(CO)L_2$ [36]: immediately at −80 °C ethylene and $RuHF(CO)L_2$ are formed. We propose the reaction proceeds by insertion of vinyl fluoride into the *cis* Ru–H bond, followed by β-F migration (Scheme 3).

To compare this dihydride reactivity of Ru to that for Os, $Os(H)_2$(1-butene)$(CO)L_2$ [43,44] (as a source of the currently unknown $Os(H)_2(CO)L_2$) was prepared from $Os(H)_2(H_2)(CO)L_2$ and 1-butene. This molecule reacts with excess (19 equivalents) vinyl fluoride within 30 min at 25 °C in C_6D_6 to give ethylene and $OsHF(CO)L_2$; since this product molecule shows dynamic NMR effects from binding olefin, identification is simplified by first removing all volatiles, then redissolving in benzene.

Thus, and in contrast to $MH(Ph)(CO)L_2$, unsaturated Ru and Os show analogous reactivity when a hydride is *adjacent* to the empty coordination site.

2.2. Influence of R group identity in $MH(R)(CO)L_2$

The essential feature of species **A** is that C_2H_3 and H are *not* mutually *cis* because H, Ph, C_2H_3, and F are coplanar. Therefore, the different results seen for Ru and Os were argued to occur because the unstable Ru(IV) intermediate analogous to **A** would not allow time for rearrangement, followed by elimination of the most thermodynamically favorable products, $MF(Ar)(CO)L_2$ and olefin. The furthest extension of this mechanism, where a Ru(IV) intermediate never exists, is represented in Scheme 4.



Scheme 3.

In order to understand what role M–R bond strength plays in these reactions, we synthesized $RuH(2\text{-}C_6H_4F)(CO)L_2$ and $RuH(C_6F_5)(CO)L_2$ by reacting $RuH(Ph)(CO)L_2$ with monofluorobenzene and pentafluorobenzene, respectively. We expect that these species will have greater thermal stability against arene elimination with increasing number of fluorines on the aryl ring since $OsH(2,6\text{-}C_6F_2H_3)(CO)L_2$ persists unchanged after 30 h at 70 °C in d_{12}-cyclohexane, but $OsH(C_6H_5)(CO)L_2$ decomposes to free benzene, phosphine and unidentified osmium products under the same conditions. Previous DFT-calculations on $OsH(C_6H_5)(CO)(PH_3)_2$ showed that π donation was partially responsible for restricted rotation about the M–C(*ipso*) bond. The calculated and observed thermodynamic preference for metal–aryl complexes with fluorine *ortho* to the metal suggest that fluorines on the aryl ring increase the amount of π donation from a fluoroaryl ring to a metal.

(a) Ru–Ar^F. When $RuH(2\text{-}C_6H_4F)(CO)L_2$ was reacted with one equivalent of vinyl fluoride for 20 h at 50 °C, the products, $Ru(C_2H_3)F(CO)L_2$ and C_6H_5F, are analogous to those in Eq. (2), i.e., aryl/H reductive elimination. Reaction of the less oxidizable $RuH(C_6F_5)(CO)L_2$ with less than one equivalent C_2H_3F for 7 days at 85 °C yields $Ru(C_2H_3)F(CO)L_2$, C_6F_5H, $Ru(C_6F_5)F(CO)L_2$, and C_2H_4. These last two products therefore indeed indicate that reactions of *both* types in Scheme 2 compete for this more stable ruthenium hydrido-fluoroaryl reagent, consistent with Ru–C bond strength influencing the decay mode of the intermediate.

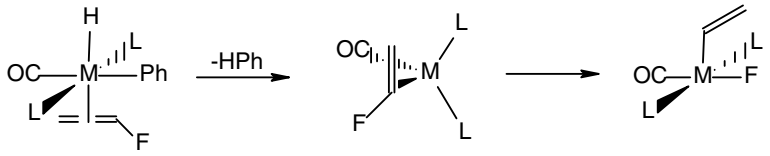
(b) Os–CH$_3$. Continuing this hypothesis, an osmium species with a *weaker* Os–C bond than Os–C_6H_5 should change reaction selectivity. To that end, $OsH(CH_3)(CO)L_2$ (**5**), was synthesized by reaction of $OsHCl(CO)L_2$ with one equivalent of MeLi. Centrifugation of the solution most efficiently removed the LiCl co-product. The NMR signatures of **5** are consistent with other five-coordinate osmium complexes where hydride is in the apical position. The hydride chemical shift is far upfield (−33.2 ppm). The methyl ^{1}H NMR signal (integrated to intensity 3) is a triplet at 0.46 ppm. The *t*-butyl signals are diastereotopic virtual triplets and the ^{31}P NMR spectrum shows one sharp singlet. In benzene at 22 °C, **5** undergoes slow conversion to $OsH(Ph)(CO)L_2$. Species **5** thus has a weaker Os–C bond than $OsH(Ph)(CO)L_2$.

Compound **5** is completely consumed by excess vinyl fluoride at −75 °C in d_8-toluene; *two* new species were observed by ^{19}F NMR. The ^{31}P NMR spectrum of *one* of these showed an AB pattern ($J_{PP} = 161$ Hz). ^{1}H NMR gave two defining signals, a hydride signal at −6.3 ppm (d of d) and signal intensity 3 at −1.1 ppm (assigned to Os–CH_3). These spectroscopic features are consistent with assignment of (Eq. (3)) the most abundant primary product as the simple adduct $OsH(CH_3)(CO)L_2(C_2H_3F)$.

$$\begin{aligned} &OsH(CH_3)(CO)L_2 + H_2C{=}CHF \\ &\quad \rightleftharpoons OsH(CH_3)(CO)L_2(C_2H_3F) \\ &\quad \xrightarrow{RT} OsF(CH_3)(CO)L_2 + H_2C{=}CH_2 \end{aligned} \tag{3}$$

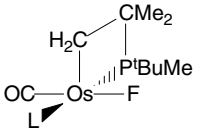
Warming the mixture to −15 °C increased the rate of olefin exchange sufficiently to cause the ^{19}F NMR signals at −169 ppm for bound olefin to broaden nearly into the baseline. Significant conversion of this olefin adduct to the final product did not occur until room temperature, but this is faster than the corresponding reaction of $OsH(Ph)(CO)L_2$. A ^{19}F NMR triplet (−198 ppm, $J_{FP} = 27$ Hz), a $^{31}P\{^1H\}$ NMR doublet (26.0 ppm, $J_{PF} = 27$ Hz), the loss of the hydride signal, and the production of ethylene are all consistent with assignment of the new compound as $OsF(CH_3)(CO)L_2$. This represents reactivity analogous to that of $OsH(Ph)(CO)L_2$ with vinyl fluoride.

The amount and spectral features of the *second* low temperature product change very little upon warming the sample from −45 to 20 °C. Over those temperatures,



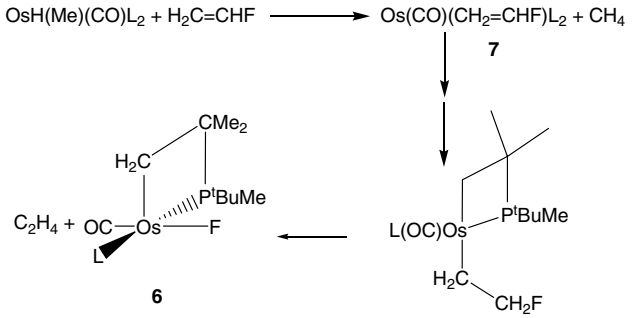
Scheme 4.

the $^{31}P\{^{1}H\}$ NMR spectrum showed an AM pattern ($\Delta\delta = 32$ ppm) with a J_{PP} of 148 Hz. One of the phosphorus nuclei showed coupling to fluorine ($J_{PF} = 15$ Hz) whose magnitude is consistent with F on Os. This fluorine is detected at −195 ppm as a doublet of multiplets. AM patterns with large $\Delta\delta$ are typical for metallated alkyl ligands on phosphines; we propose structure **6**. The presence of this second product where the osmium complex has lost methane, HR, shows the competitive occurrence of a second mechanism, that used by Ru in Scheme 2, prior to activation of a C–F bond. This species declines in intensity as the temperature is raised and ultimately disappears from both ^{31}P and ^{19}F NMR spectra.



6

Detection of this species is especially important because it has the stoichiometry of $Os(CO)L_2$ *minus* one H and *plus* one F. It is thus a plausible product of a second fate for $OsH(Me)(CO)L_2$, following olefin-induced reductive elimination of methane. The primary product would then be zerovalent, unsaturated **7** (Scheme 5), in which oxidative addition of a *t*-Bu C–H bond would permit hydrogen migration to vinyl fluoride, then fluorine migration to Os, with liberation of ethylene.

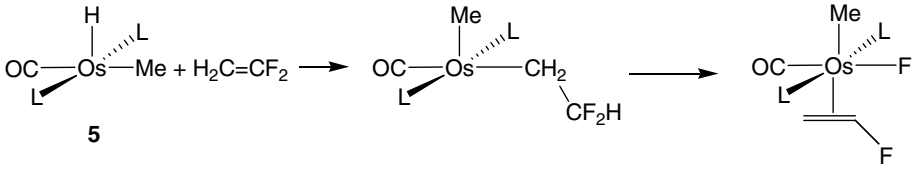


Scheme 5.

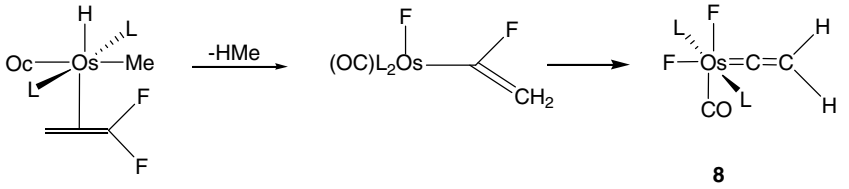
The detection of a second competitive reaction channel for $OsHMe(CO)L_2$ in reacting with vinyl fluoride thus links the ruthenium chemistry ($RuH(Ph)(CO)L_2$) to that of osmium; the more facile elimination of H with an sp^3 carbon (versus sp^2 in $OsH(Ph)(CO)L_2$) makes this oxidatively induced reductive elimination now detectable (but not dominant) for $OsHMe(CO)L_2$.

2.3. A more oxidizing olefin

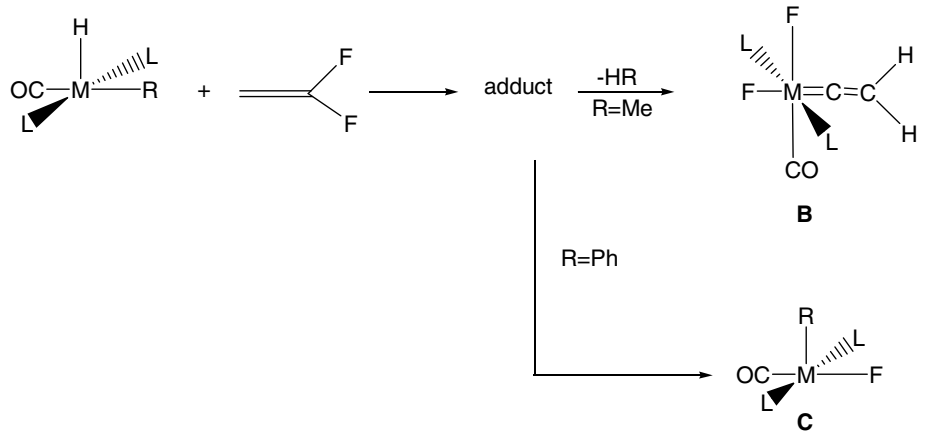
(a) Os–CH₃. The *gem*-difluoro olefin $H_2C{=}CF_2$ provides an additional test of mechanism. An insertion mechanism for reaction of $H_2C{=}CF_2$ with **5** would yield vinyl fluoride (Scheme 6). If, on the other hand, this more π-acidic difluoro olefin promptly triggers methane elimination, then the first C–F oxidative addition to Os(0) could be followed by a second F migration (Scheme 7). Reaction of $OsH(CH_3)(CO)L_2$ with gem-difluoroethylene at 0 °C with subsequent slow warming to room temperature, then removal of excess olefin, gave 75% yield of product **8** with 100% conversion of **5**. The $^{31}P\{^{1}H\}$ NMR spectrum of **8** is a doublet of doublets ($J_{PF} = 41$, 25 Hz). ^{19}F NMR revealed an AB pattern due to inequivalent F on Os. The lower field doublet ($J_{FF} = 143$ Hz) also showed triplet coupling to phosphorus ($J_{FP} = 25$ Hz), while the lines of the higher field doublet were each triplets of triplets, due to two phosphorus ($J_{PF} = 41$ Hz) and two protons ($J_{FH} = 7$ Hz). ^{1}H NMR showed the absence of a hydride chemical shift as well as the appearance of a new signal at 2.0 ppm (vinylidene CH_2), which was a doublet of triplets ($J_{HF} = 7$ Hz,



Scheme 6.



Scheme 7.



Scheme 8.

$J_{HP} = 3$ Hz). $^{13}C\{^1H\}$ NMR showed the β-carbon signal at 94 ppm as a doublet ($J_{CF} = 16$ Hz).

An osmium difluoride product is consistent with an intermediate with fluorine located α to the metal because such species exhibit α-fluoro migration. The "prompt" elimination of H–CH_3 in Scheme 7 contrasts to the reaction of $OsH(Ph)(CO)L_2$ with vinyl fluoride, and may be attributed to the more oxidizing (cf. π-acid) character of $H_2C{=}CF_2$ (versus $H_2C{=}CHF$).

(b) Os–Ph. To test the influence of Os–C(sp^3) versus C(sp^2) on reactivity, the reaction of $OsH(Ph)(CO)L_2$ with excess $H_2C{=}CF_2$ was studied. This yielded primarily $Os(Ph)F(CO)L_2$ on the same time scale as vinyl fluoride; only a trace amount of $OsF_2(CO)(CCH_2)L_2$ forms. This result further illustrates how the energetics of HR elimination from the proposed M(IV) intermediate affects the outcome of the reaction (Scheme 8). When HR elimination is the fastest process from the adduct, then metal difluoride **B** would result. However, if rearrangement (to hydride *cis* to olefin) and elimination of the vinyl species are faster, five-coordinate $OsRF(CO)L_2$ (**C**), forms. Clearly, the latter is favored for osmium: the Os–Ph bond persists through reaction with both $H_2C{=}CHF$ and $H_2C{=}CF_2$.

3. Conclusion

We have demonstrated here several C–F bond cleavage reactions of vinyl fluoride by five-coordinate hydrides $MHR(CO)L_2$ (R = Ph, CH_3, H; M = Os, Ru). The reaction products are highly dependent on the identity of the metal when R = Ph. For Os, Os–H/C–F "exchange" is the dominant pathway, while for Ru and R = Ph, the reaction features reductive elimination of C_6H_6, followed by C–F bond cleavage of vinyl fluoride. The facility for H-Ph formation and the relative stability of (II versus IV) oxidation states are the two factors influencing the metal-dependence. It is also remarkable that benzene loss from $RuH(Ph)(CO)L_2$ is followed by oxidative addition of the C–H bond of partially fluorinated arene [33], but of the C–F bond of vinyl fluoride. It is noteworthy that both metals show kinetic selectivity (C–H cleavage) when reacting with fluorinated arenes to give $MH(Ar^F)(CO)L_2$ but thermodynamic selectivity (M–F bond formation) when reacting with fluorinated olefins.

In a sense, this reaction of $RuH(Ph)(CO)L_2$ as a "$Ru^0(CO)L_2$ equivalent" is analogous to that of elemental magnesium, to generate a Grignard reagent by C–F oxidative addition [45]. In contrast, in *both* dihydride cases reported here, the net reaction is M–H/ C–F exchange, but apparently by a β-F migration mechanism.

This work began by raising the question of the curious selectivity for C–H over C–F scission in reaction of $OsH(Ph)(CO)L_2$ with partially fluorinated arenes. However, vinyl fluoride substrate shows quite the opposite selectivity, and what was discovered here is contrasting *metal* selectivity: Ru versus Os. The question of reversion to "normal" selectivity for C–F scission with fluoro olefins (cf. fluoroarenes) probably relates to the greater ease of binding olefins (versus arenes) to metals, together with the very different ability of metal to attack F–C(H)CH_2 versus F–$C(CH)_2$ (i.e., arene) moieties.

4. Experimental

4.1. General procedures

All manipulations were performed using standard Schlenk techniques or in an argon filled glovebox unless otherwise noted. Solvents were distilled from Na, Na/benzophenone, CaH_2, or 4 Å molecular sieves, degassed

prior to use, and stored in air-tight vessels. OsHCl(CO)(P^tBu_2Me)$_2$ [46], OsH(Ph)(CO)(P^tBu_2Me)$_2$ [34], RuHF(CO)(P^tBu_2Me)$_2$ [47], Ru(H)$_2$(CO)(P^tBu_2Me)$_2$ [36] and RuH(Ph)(CO)(P^tBu_2Me)$_2$ [36] were prepared according to published procedures. All other reagents were purchased from commercial vendors and used as received after drying/degassing when necessary. ^{1}H NMR chemical shifts are reported in ppm relative to protio impurities in the deuterated solvents; ^{31}P (always proton-decoupled) and ^{19}F spectra are referenced to external standards of 85% H_3PO_4 and $CFCl_3$, respectively (both at 0 ppm). NMR spectra were recorded with a Varian Gemini 2000 (300 MHz ^{1}H; 121 MHz ^{31}P; 75 MHz ^{13}C, 282 MHz ^{19}F), a Varian Unity Inova instrument (400 MHz ^{1}H; 162 MHz ^{31}P; 101 MHz ^{13}C, 376 MHz ^{19}F), or a Varian Unity Inova instrument (500 MHz ^{1}H, 126 MHz ^{13}C). Infrared spectra were recorded on a Nicolet 510P FT-IR spectrometer.

4.2. *Os(Ph)F(CO)(P^tBu_2Me)$_2$*

An NMR tube containing OsH(Ph)(CO)(P^tBu_2Me)$_2$ (16.5 mg, 2.68×10^{-5} mol) in 500 μL d_8-toluene had 200 Torr (7.7×10^{-4} mol) of vinyl fluoride condensed into it. At low temperature the η^2-adduct formed: diagnostic ^{1}H NMR (C_7D_8, −90 °C) −3.7, (t, 1H, Os*H*, $J_{PH}=29$ Hz); 2.7, (d, 1H, CCH, $J_{HF}=20.4$ Hz); 2.9 (d, 1H, CCH, $J_{HF}=22$ Hz); 7.54, (d, 1H, CCH, $J_{FH}=72.0$ Hz). ^{31}P NMR (C_7D_8, −90 °C) −2.5, (AB, $J_{PP}=162$ Hz). ^{19}F(C_7D_8, −90 °C) −171.3 (dt, 1F, CCF, $J_{FH}=73$ Hz, $J_{FH}=20$ Hz). Conversion to the final product did not occur until 10 °C and was complete within 4 h at room temperature. The ^{1}H NMR detection of ethylene confirmed product identity. ^{1}H NMR (C_7D_8, 20 °C) 1.00, (vt, 18H, OsPCC*H*$_3$, $J_{PH}=5.8$ Hz); 1.04, (vt, 18H, PCC*H*$_3$, $J_{PH}=5.8$ Hz); 1.29, (broad s, 6H, PC*H*$_3$); 6.39, (t, 1H, Ar-*H*, $J_{PH}=6.0$ Hz); 6.5, (t, 2H, Ar-*H*, $J_{HH}=6$ Hz); 7.32, (d, Ar-*H*, $J_{HH}=6$ Hz); 7.64, (d, Ar-*H*, $J_{HH}=6.0$ Hz). ^{31}P NMR (C_7D_8, 20 °C) 26.5, (d, 2P, $J_{PF}=28$ Hz). ^{19}F(C_7D_8, 20 °C) −202.1 (t, 1F, CCF, $J_{FP}=28$ Hz) ν(CO) = 1874 cm^{-1}.

4.3. *Reaction of OsH(Ph)(CO)(P^tBu_2Me)$_2$ + C_2H_3F in the presence of P^tBu_2Me*

When OsH(Ph)(CO)(P^tBu_2Me)$_2$ (10.5 mg, 1.70×10^{-5} mol) was dissolved in 500 μL C_6D_6 and reacted with two equivalents P^tBu_2Me and C_2H_3F (600 Torr, 5.2 equivalents) the reaction reached completion in 4 h. A similar time scale was observed in the absence of free phosphine.

4.4. *Ru(C_2H_3)F(CO)(P^tBu_2Me)$_2$*

RuHF(CO)L$_2$ (150 mg, 0.32 mmol) was dissolved in diethyl ether (3 mL). The solution was degassed and the headspace was charged with acetylene gas (1 atm). The mixture was stirred at room temperature for 30 min before the volatiles were removed under vacuum. The residue was dissolved in pentane, filtered through a Celite pad and concentrated to ca. 2 mL. After cooling the solution at −40 °C for one day, dark orange crystals were obtained. Yield: 120 mg (76%). ^{1}H NMR (C_6D_6, 20 °C, 300 MHz): 1.20 (vt, N = 12.5, 18H, PC(CH$_3$)$_3$), 1.25 (vt, 18H, N = 12 Hz, PC(CH$_3$)$_3$), 1.21 (vt, 6H, N = 5.9, PCH$_3$), 5.10 (dt, $J_{HH}=14.5$, $J_{PH}=2.0$ Hz, 1H β-H(vinyl)), 5.45 (dt, $J_{HH}=6.4$ Hz, $J_{PH}=2.4$ Hz, 1H, β-vinyl), 8.30 (doublet of apparent triplets, 1H, $J_{HH}=14.5$ Hz, $J_{HH}=7.5$ Hz, $J_{HF}=6.9$ Hz, α-H of vinyl). ^{13}C{^{1}H} NMR (toluene-d_8, 75 MHz, 20 °C): 3.16 (vt, N = 15 Hz, PCH$_3$), 29.7, 29.8 (s, PC(*C*H$_3$)$_3$), 35.4, 35.5 (s, P*C*(CH$_3$)$_3$), 117.5 (s, =CH$_2$), 156.3 (t, J = 20.3 Hz, Ru–CH). ^{31}P{^{1}H} NMR: 41.2 (d, $J_{PF}=22$ Hz). ^{19}F NMR: −214 (t, $J_{PF}=22$ Hz). IR (C_6D_6): 1894 (ν(CO)).

4.5. *Reaction of RuH(Ph)(CO)L$_2$ with vinyl fluoride*

RuH(Ph)(CO)(P^tBu_2Me)$_2$ (10 mg, 0.019 mmol) was dissolved in C_6D_6 (0.5 mL) and degassed by three freeze–pump–thaw cycles. To the tube, C_2H_3F (1 atm) was charged. The mixture was agitated for 12 h. NMR spectroscopies reveal clean formation of Ru(C_2H_3)(F)(CO)L$_2$ by comparison to data in the preceding experiment.

4.6. *Reaction of RuH(Ph)(CO)(P^tBu_2Me)$_2$ with vinyl fluoride in the presence of added phosphine ligand*

In an NMR tube, RuH(Ph)(CO)L$_2$ (10 mg, 0.019 mmol) and P^tBu_2Me (15 mg, 5 eq.) were dissolved in cyclohexane-d_{12}. The solution was degassed and the headspace of the tube was charged with 1 atm vinyl fluoride. After 12 h at room temperature, RuH(Ph)(CO)L$_2$ was completely consumed and Ru(C_2H_3)F(CO)L$_2$ was formed as revealed by its ^{31}P{^{1}H} NMR spectrum.

4.7. *Os(H)$_2$(η^2-1-butene)(CO)(P^tBu_2Me)$_2$*

Reaction of OsH$_2$(H$_2$)(CO)(P^tBu_2Me)$_2$ (5.6 mg, 1.04×10^{-5} mol) with 1-butene (100 Torr, 6.95×10^{-5} mol) in C_6D_6 at room temperature gives the title compound within 5 min. The room temperature NMR signals are broadened by dynamic equilibrium. ^{1}H NMR (C_6D_6, 293 K) −11.2 (t, OsH, 1H, $J_{PH}=23$ Hz); −8.66 (t, OsH, 1H, $J_{PH}=33.5$ Hz); 0.86 (t, CH$_2$C*H*$_3$, 3H, $J_{HH}=4$ Hz); 1.26 (vt, PCCH$_3$, 18H, $J_{PH}=6.3$ Hz); 1.28 (vt, PCCH$_3$, 18H, $J_{PH}=6.3$ Hz); 1.62 (m, C*H*$_2$CH$_3$); 2.2 (br s, vinyl CH, 1H); 2.6 (br s, vinyl CH, 1H); 3.2 (br s, vinyl CH, 1H). ^{31}P NMR (C_6D_6, 293 K) 29.6, 29.9 (AB, $J_{PP}=148$ Hz).

4.8. Reaction of $OsH_2(\eta^2\text{-1-butene})(CO)(P^tBu_2Me)_2$ with C_2H_3F

To $OsH_2(\eta^2$-1-butene)(CO)$(P^tBu_2Me)_2$ (1.83×10^{-5} mol) was added C_2H_3F (150 Torr, 19 equivalents); $OsHF(\eta^2\text{-}C_2H_3F)(CO)(P^tBu_2Me)_2$ was formed within 30 min. The signals for this species were broad due to exchange of olefin. The species was identified by ^{1}H NMR (C_6D_6, 293 K); 2.8, (br s, C_2H_3F); −3.1 (br s, Os*H*) and ^{31}P NMR (C_6D_6, 293 K): 24.5 (br s). Evacuation of the excess olefin left $OsHF(CO)(P^tBu_2Me)_2$. ^{1}H NMR (C_6D_6, 293 K) −32.2 (td, OsH, 1H, $J_{PH}=13$ Hz, $J_{HF}=8.7$ Hz); 1.20 (vt, $PCCH_3$, 18H, $J_{PH}=6.9$ Hz); 1.22 (vt, $PCCH_3$, 18H, $J_{PH}=6.9$ Hz). ^{31}P NMR (C_6D_6, 293 K) 44.78 (d, $J_{PF}=26$ Hz). ^{19}F NMR (C_6D_6, 293 K): −184.6 (t, $J_{FP}=26$ Hz).

4.9. Reaction of $Ru(H)_2(CO)(P^tBu_2Me)_2$ with vinyl fluoride

$Ru(H)_2(CO)(P^tBu_2Me)_2$ (10 mg) in toluene-d_8 (0.5 mL) in an NMR tube was freeze–pump–thaw degassed, and the headspace of the NMR tube was charged with vinyl fluoride (1 atm) at −80 °C. The tube was transferred to a precooled NMR probe for observation. At −80 °C, no $Ru(H)_2(CO)L_2$ but only $RuHF(CO)L_2$ was detected by its $^{31}P\{^1H\}$ NMR spectrum (52.5 ppm, doublet $J_{PF}=20$ Hz). The volatiles of the reaction mixture were vacuum transferred to another NMR tube where the ^{1}H NMR spectrum revealed ethylene (5.34, singlet).

4.10. Reaction of $RuH(2\text{-}C_6FH_4)(CO)(P^tBu_2Me)_2$

$RuH(Ph)(CO)(P^tBu_2Me)_2$ (200 mg, 0.38 mmol), cyclohexane (10 mL), and fluorobenzene (1 mL) were stirred together for 18 h. After removal of the volatiles, the residue was extracted with pentane. The pentane solution was filtered through a Celite pad, concentrated to ca. 3 mL, and cooled to −78 °C for 2 h to give yellow crystals after 12 h. The crystals were filtered, washed with pentane and dried in vacuo to yield 125 mg (70%) of the title compound. Newly prepared product contains two rotamers about the Ru–Aryl bond, with 10:6 ratio based on NMR integration of the PCH_3 peaks. Spectroscopic data for the major isomer: ^{1}H NMR (C_6D_6, 20 °C) −28.7 (td, $J_{PH}=19.2$, $J_{FH}=7.6$ Hz, 1H, RuH); 0.70 (vt, 5.5 Hz, 6H, PCH_3); 1.13 (vt, 13 Hz, 18H, $PCCH_3$); 1.20 (vt, 12.7 Hz, 18H, $PCCH_3$); 6.9, 7.1, 7.6 (m, 4H, ArH). ^{31}P NMR (C_6D_6, 20 °C) 57.0 (s). ^{19}F (C_6D_6, 20 °C) −96.7(s). Minor isomer: ^{1}H NMR: −27.2 (td, $J_{PH}=20$ Hz, $J_{HF}=5.2$ Hz, 1H, Ru–H), 0.66 (vt, 5.5 Hz, PCH_3), 1.09 (vt, 12 Hz, 18H, $PC(CH_3)_3$), 1.19 (vt, 13 Hz, 18H, $PC(CH_3)_3$), 6.87, 7.03, 7.55 (4H, Ar). $^{31}P\{^1H\}$ NMR: 57.1 (s). ^{19}F NMR: −84.5 (s).

4.11. Reaction of $RuH(2\text{-}C_6FH_4)(CO)(P^tBu_2Me)_2$ with vinyl fluoride

$RuH(2\text{-}C_6FH_4)(CO)(P^tBu_2Me)_2$ (10 mg, 1.8×10^{-5} mol) was dissolved in C_6D_6 (0.5 mL) and degassed by three freeze–pump–thaw cycles. To the NMR tube, 400 Torr vinyl fluoride was charged. The resulting mixture was heated at 50 °C for 20 h to give $Ru(C_2H_3)F(CO)(P^tBu_2Me)_2$ and fluorobenzene.

4.12. Reaction of $RuH(C_6F_5)(CO)(P^tBu_2Me)_2$

The same procedure as $RuH(2\text{-}C_6FH_4)(CO)(P^tBu_2Me)_2$ was followed except C_6F_5H was used instead of C_6H_5F. Alternatively, it can be prepared from reaction of $RuHF(CO)(P^tBu_2Me)_2$ with $Me_3SiC_6F_5$ in the presence of a catalytic amount of CsF.

4.13. Reaction of $RuH(C_6F_5)(CO)(P^tBu_2Me)_2$ with vinyl fluoride

In an NMR tube, $RuH(C_6F_5)(CO)(P^tBu_2Me)_2$ (10 mg, 0.016 mmol) was dissolved in C_6D_6 (0.5 mL) and degassed by three freeze–pump–thaw cycles. To the tube, vinyl fluoride (400 mm Hg) was added. The mixture was heated at 85 °C for three days to give (based on $^{31}P\{^1H\}$ NMR integration) conversion to $RuF(C_6F_5)(CO)(P^tBu_2Me)_2$ (85%) and $Ru(C_2H_3)(F)(CO)(P^tBu_2Me)_2$ (15%). Addition of CsF to the NMR tube was necessary to resolve all couplings. Spectroscopic data for $RuF(C_6F_5)(CO)(P^tBu_2Me)_2$: ^{1}H NMR (400 MHz, C_6D_6, 20 °C) 0.92 (vt, 13 Hz, 18H, PCH_3,); 0.99 (vt, 6.5 Hz,18H, $PCCH_3$,); 1.22 (broad, 6H, $PCCH_3$). $^{31}P\{^1H\}$ NMR (C_6D_6, 20 °C): 42.7 (d, 2P, $J_{PF}=24.6$Hz). ^{19}F NMR (376.3 MHz): −111.5 (dd, $J_{FRuF}=53.3$ Hz, $J_{FF}=28.8$ Hz, 1F, *o*-ArF); −113.7 (d, $J_{FF}=26.5$ Hz, 1F, *o*-ArF,); −162.3 (dt, $J_{FF}=53$ Hz, $J_{PF}=25$ Hz, Ru–F), −164.4 (dd, $J_{FF}=J_{FF}=21$ Hz, *para*-F), −164.9 (dddd, $J_{FF}=26.2$, 21, 5, 5 Hz, *meta*-F); −167.4 (dddd, $J_{FF}=28$, 23, 5, 5 Hz, *meta*-F). The volatiles of the reaction mixture were vacuum transferred to another NMR tube and ^{1}H and ^{19}F NMR spectra showed C_2H_4 and C_6F_5H.

4.14. Reaction of $OsH(CH_3)(CO)(P^tBu_2Me)_2$

A solution containing 40.5 mg (7.04×10^{-5} mol) $OsHCl(CO)(P^tBu_2Me)_2$ in 3 mL of pentane was prepared in a centrifuge tube. Dropwise addition of 49.0 μL (7.11×10^{-5} mol) MeLi solution caused a gradual darkening of the solution concurrent with the appearance of a white suspension. The solution was centrifuged and the supernate was pipetted to a Schlenk flask. The solvent was then removed to leave an orange-red solid. ^{1}H NMR (C_6D_{12}, 20 °C) −33.3, (t, 1H, Os*H*, $J_{PH}=15.1$ Hz); 0.46 (t, 3H, $OsCH_3$, $J_{PH}=7.2$ Hz); 1.18 (vt, 18H, $PCCH_3$,

$J_{PH} = 6.0$ Hz); 1.21 (vt, 18H, PCCH_3, $J_{PH} = 6.0$ Hz); 1.49 (t, 6H, PCH_3, $J_{PH} = 2.8$ Hz). ^{31}P NMR (C_6D_{12}, 20 °C) 36.5, IR(C_6D_6): 1864(ν_{CO}).

4.15. $Os(CH_3)F(CO)(P^tBu_2Me)_2$

The reaction was run in a sealed NMR tube containing 9.2 mg $OsH(CH_3)(CO)(P^tBu_2Me)_2$ (1.658×10^{-5} mol) with 100 Torr vinyl fluoride (6.786×10^{-5} mol) in d_8-toluene. At −75 °C, the adduct $OsH(Me)(\eta^2\text{-}C_2H_3F)(CO)(P^tBu_2Me)_2$ was formed. Its diagnostic spectral features were: ^{1}H NMR (C_7D_8, −75 °C) −6.3 (1H, OsH); −1.1 (3H, OsCH_3); 2.9 (d, 1H, C=CH, $J_{PH} = 22.0$ Hz); 3.2 (m, 1H, C=CH); 6.3 (1H, C=CH). ^{31}P NMR (C_7D_8, −75 °C): 15.2, 12.7 (AB, 2P, $J_{PP} = 161$Hz). ^{19}F(C_7D_8, −75 °C) −170.0 (dt, 1F, CCF, $J_{FH} = 73$Hz, $J_{FH} =$ 20 Hz). Conversion to the final product (the title compound) occurred at 20 °C; its spectroscopic features were: ^{1}H NMR (C_7D_8, 20 °C) −1.1 (3H, OsCH_3); 1.28 (vt, 18H, OsPCCH_3, $J_{PH} = 6$Hz); 1.30 (vt, 18H, PCCH_3, $J_{PH} = 6$Hz); 1.86 (6H, PCH_3). ^{31}P NMR (C_7D_8, 20 °C) 26.0, (d, 2P, $J_{PF} = 27$ Hz). ^{19}F (C_7D_8, 20 °C) −198.0 (t, 1F, OsF, $J_{FP} = 27$Hz).

4.16. $OsF_2(CCH_2)(CO)(P^tBu_2Me)_2$

When 8.5 mg (1.53×10^{-5} mol) of $OsHMe(CO)(P^tBu_2Me)_2$ was warmed slowly with 25 equivalents (3.83×10^{-4}) of *gem*-difluoroethylene, $OsF_2(CCH_2)(CO)(P^tBu_2Me)_2$ formed in 60% yield. Following vacuum removal of excess $C_2H_2F_2$, and other volatiles, the diagnostic spectroscopic signals of the major product were: ^{1}H NMR (C_6D_6, 20 °C) 1.31 (vt, 36H, PCCH_3, $J_{PH} = 7.0$ Hz); 1.44 (vt, 6H, OsPCH_3, $J_{PH} = 4.1$ Hz); 2.01 (dt, 2H, CCH_2, $J_{FH} = 7$ Hz, $J_{PH} = 3$ Hz). ^{13}C NMR (C_6D_6, 20 °C) 3.6 (t, 2C, PCH_3, $J_{CP} = 5$ Hz); 29.7 (s, 6C, PCCH$_3$): 29.5 (s, 6C, PCCH$_3$); 36.2 (t, 2C, PCCH$_3$, $J_{PC} = 10.4$); 36.4 (t, 2C, PCCH$_3$, $J_{PC} = 10.4$); 94.8 (d, 1C, OsCC, $J_{CF} = 16$). ^{31}P NMR (C_6D_6, 20 °C) 34.65 (dd, 2P, $J_{PF} = 41.9$ Hz, $J_{PF'} = 25.1$ Hz). ^{19}F (C_6D_6, 20 °C) −277.45 (dt, 1F, OsF, $J_{FF} = 143$, $J_{FP} = 25$ Hz); −278.6 (dtt, 1F, OsF, $J_{FF} = 143$, $J_{FP} = 41$, $J_{HF} = 7$ Hz).

This paper is dedicated to Malcolm H. Chisholm on the occasion of his 60th birthday.

Abstract

The diamine *rac*-H_2[HIPTN$_2$] (HIPTN$_2$ = (*N-hexa-iso*-propyl-3,5-terphenyl)diaminobinaphthalene) has been prepared through palladium-catalyzed *N*-aryl coupling of diaminobinaphthalene and 3,5-bis(2,4,6-triisopropylphenyl)bromobenzene. The reaction between H_2[HIPTN$_2$] and M(NMe$_2$)$_4$ (M = Ti, Zr, and Hf) yields [HIPTN$_2$] M(NMe$_2$)$_2$ complexes. Other complexes of [HIPTN$_2$]$^{2-}$ that have been prepared include [HIPTN$_2$]ZrCl$_2$, [HIPTN$_2$]ZrMe$_2$, [HIPTN$_2$]Zr(CH$_2$CMe$_3$)$_2$, [HIPTN$_2$]HfCl$_2$, [HIPTN$_2$]HfMe$_2$, and [HIPTN$_2$]Hf(CH$_2$CHMe$_2$)$_2$. Activation of [HIPTN$_2$]ZrMe$_2$ with a variety of Lewis acids gives rise to different species depending on the nature of the activator employed. For example, [HIPTN$_2$]ZrMe$_2$ reacts with [Ph$_3$C][B(C$_6$F$_5$)$_4$] to give a cationic complex that is active toward oligomerization of 1-hexene, while activation with B(C$_6$F$_5$)$_3$ leads to formation of [HIPTN$_2$]Zr(C$_6$F$_5$)$_2$. No polymerization of 1-hexene by activated complexes was observed.

Keywords: Olefin; Polymerization; Zirconium; Hafnium

1. Introduction

The number of non-metallocene-based catalysts for the polymerization of ordinary olefins has increased markedly in the last decade [1]. Some of these catalysts offer activity that is comparable to metallocene catalysts, and also in some cases display characteristics of a living polymerization [2]. Many of the most successful catalysts contain nitrogen-based ligands, and examples of both early and late metal catalysts are abundant. Amido ligands have been found to be especially useful for preparing early transition metal polymerization catalysts [3].

We have been interested in the synthesis of complexes that contain new amido-based supporting ligands, particularly those that when activated display characteristics of a living olefin polymerization [4–12]. However, we have yet to prepare catalysts that effect both living and stereospecific olefin polymerizations [13]. A binaphthyl-based ligand system in which pyridine donors are incorporated has demonstrated that six-coordinate dialkyl complexes of zirconium and hafnium could be prepared and activated cleanly [14]. However, activated versions of these compounds do not polymerize 1-hexene, presumably because the pyridine donors prevent coordination of the olefin to the cationic metal center. We felt that a potential remedy for this situation might involve C_2-symmetric amido complexes that lacked a pendant donor moiety. Cationic complexes that contain diamido ligands were among the first that were found to exhibit living characteristics, as long as large aryl groups (e.g., mesityl or 2,4,6-triisopropylphenyl) were present on nitrogen [15,16].

In this paper, we report the preparation and Group IV chemistry of complexes that contain a diamido ligand derived from diaminobinaphthalene, one that is N-substituted with the bulky *hexa-iso*-propyl-3,5-terphenyl, or HIPT, group. The HIPT group recently has been useful

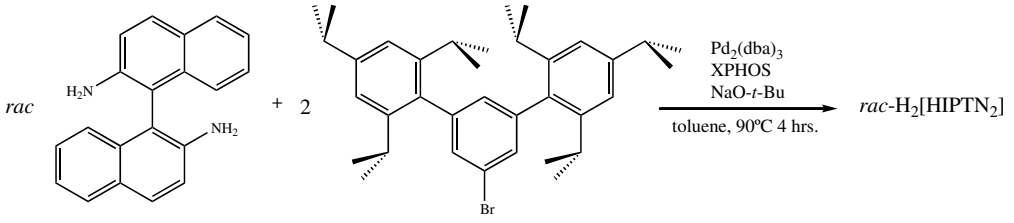
as a substituent in triamidoamine ligands bound to molybdenum. Such species are catalysts for the catalytic reduction of dinitrogen to ammonia with protons and electrons at a single Mo center [17–21]. The HIPT group is believed to provide a significant degree of steric hindrance "at a distance" that leads to the success of catalytic dinitrogen reduction.

2. Results and discussion

2.1. Synthesis of the ligand and Group IV complexes that contain it

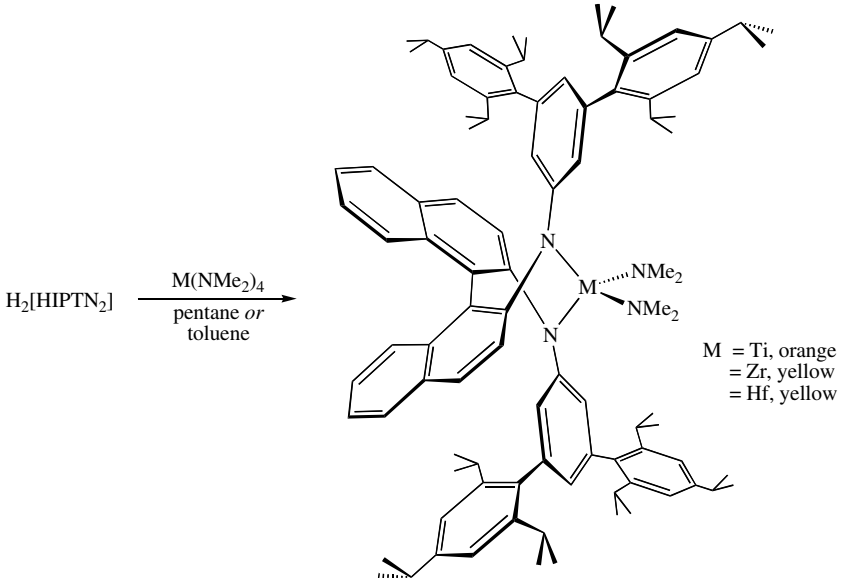
The parent diamine, *rac*-H_2[HIPTN$_2$], was prepared through a palladium-catalyzed *N*-aryl coupling between *rac*-diaminobinaphthalene and 3,5-bis(2,4,6-triisopropylphenyl)bromobenzene (HIPTBr). Using the XPHOS [22] ligand, the reaction is complete in less than 4 h, and can be scaled up to 15 g with yields of >80% after purification by flash chromatography (Eq. (1)).



(1)

White, crystalline H_2[HIPTN$_2$] is readily soluble in all organic solvents including pentane and diethyl ether. The NMR spectrum contains three septets of area 4 for each of the methine protons of the triisopropylphenyl ring, indicating that rotation about the aryl–aryl bond of the terphenyl groups is not possible, but rotation about the *N*-aryl bond is facile. Other features of the ^{1}H NMR spectrum are consistent with C_2-symmetry and no rotation about the aryl–aryl bond.

The ligand can be attached to Ti, Zr, or Hf readily upon addition of it to M(NMe$_2$)$_4$ (Scheme 1). In the case of hafnium and zirconium, the parent diamine reacts with M(NMe$_2$)$_4$ in pentane at room temperature to yield [HIPTN$_2$]M(NMe$_2$)$_2$ as yellow microcrystals after 24 h. The titanium complex is somewhat more difficult to prepare, requiring elevated temperatures and significantly longer reaction time to go to completion. Heating H_2[HIPTN$_2$] and Ti(NMe$_2$)$_4$ in toluene at 110 °C for 6 days affords [HIPTN$_2$]Ti(NMe$_2$)$_2$ as an orange solid. The ^{1}H NMR spectra of the dimethylamido complexes are similar, and all show the expected C_2-symmetry. A large singlet of area 12 near 2.7 ppm is assigned to the NMe$_2$ protons. The sharp resonances suggest that rotation about the metal–nitrogen bond is fast on the NMR time scale at room temperature, as is typically observed for early transition metal dimethylamido complexes.



Scheme 1.

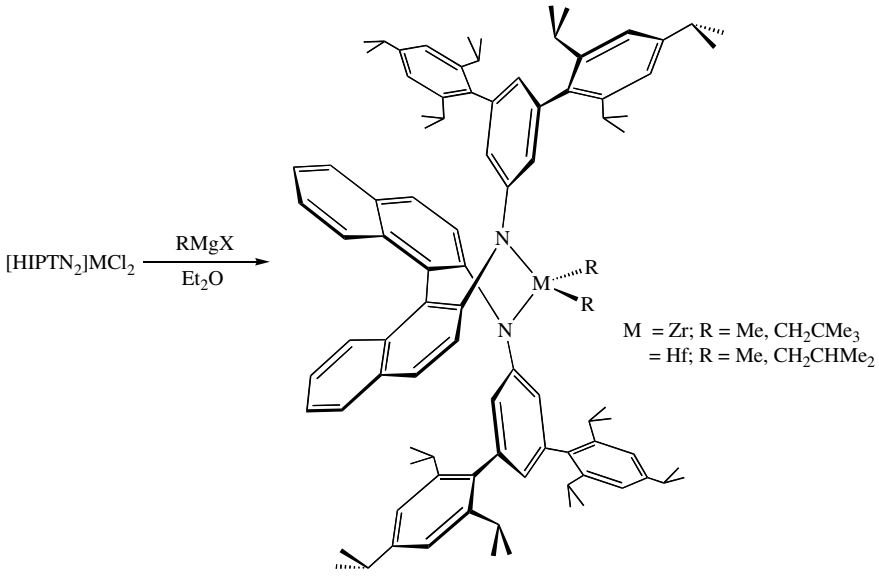
Treatment of $[HIPTN_2]M(NMe_2)_2$ (M = Zr, Hf) with two equivalents of Me_3SiCl in benzene at 60 °C affords $[HIPTN_2]MCl_2$. Proton NMR spectra of the yellow hafnium species show the expected sharp features of the ligand in a C_2-symmetric environment. However, proton spectra of the zirconium species reveal relatively broad resonances. The zirconium dichloride complex is deep red, but its solutions in diethyl ether are orange-yellow. Proton NMR spectra of samples recrystallized from diethyl ether show a broad peak for two equivalents of diethyl ether near 3.70 ppm. Combustion analyses of the Zr compound were also consistent with the presence of two molecules of diethyl ether. We suggest that a dynamic mixture of monomer and dimer exists in the zirconium case at room temperature, which gives rise to a broadened spectrum. Dimers of this type have been structurally characterized in the zirconium chemistry of diamidodonor ligands [9].

Attempts to prepare $[HIPTN_2]TiCl_2$ were unsuccessful. Heating solutions of $[HIPTN_2]Ti(NMe_2)_2$ with excess Me_3SiCl for several days resulted only in formation of $[HIPTN_2]Ti(NMe_2)Cl$, according to ^1H NMR spectra. A reaction between $[HIPTN_2]Ti(NMe_2)_2$ and $TMSOSO_2CF_3$ also resulted in formation of only $[HIPTN_2]Ti(NMe_2)(OTf)$, according to NMR spectra. These results are similar to those found in the titanium chemistry of a related diamidodonor ligand [23].

Alkylation of "$[HIPTN_2]MCl_2$" (M = Zr, Hf) yielded $[HIPTN_2]MR_2$ complexes (R = Me, CH_2CMe_3, CH_2CHMe_2; Scheme 2). The dialkyl species are all yellow solids which are readily soluble in common organic solvents, including pentane. Proton NMR spectra are consistent with monomeric C_2-symmetric species with resonances for the alkyl ligands appearing in a range typically encountered for d^0 alkyl complexes of hafnium and zirconium (Table 1). Attempts to grow X-ray quality crystals of dialkyl complexes were unsuccessful, leading in each case to small needle-like crystals or amorphous solids.

2.2. Activation of dialkyl species

Activation of $[HIPTN_2]ZrMe_2$ was attempted with $B(C_6F_5)_3$, $[Ph_3C][B(C_6F_5)_4]$, and $[HNMe_2Ph][B(C_6F_5)_4]$ with the aim of preparing a cationic monomethyl species. Reaction of $[HIPTN_2]ZrMe_2$ with $B(C_6F_5)_3$ in C_6D_6 yielded a deep red solution, a proton NMR spectrum of which showed it to contain a C_2-symmetric species,



Scheme 2.

Table 1
Selected NMR data for the alkyl ligands of complexes of $[HIPTN_2]^{2-}$

Compound	^1H NMR	^{13}C NMR
$[HIPTN_2]ZrMe_2$	0.60[a]	53.17[c]
$\{[HIPTN_2]Zr(Me)(NMe_2Ph)\}^+$	0.73[b]	51.95[b]
$\{[HIPTN_2]Zr(Me)\}^+$	0.42[b] (major); 0.64 (minor)	47.51[b] (major); 49.76 (minor)
$[HIPTN_2]Zr(C_6F_5)_2$	N/A	148.52[c] (*o*); 146.11 (*ipso*); 142.71 (*p*); 136.48 (*m*)
$[HIPTN_2]Zr(CH_2CMe_3)_2$	1.60[a], 1.11 (CH_2); 0.91 (*Me*)	99.91[c] (CH_2); 37.24 (CMe_3); 34.76 (*Me*)
$[HIPTN_2]HfMe_2$	0.46[a]	63.16[c]
$\{[HIPTN_2]Hf(Me)(NMe_2Ph)\}^+$	0.49[b]	
$\{[HIPTN_2]Hf(Me)\}^+$	0.66[b]	
$[HIPTN_2]Hf(CH_2CHMe_2)_2$	2.25[a] (*CH*); 0.97, 0.85 (CH_2); 0.81, 0.63 (*Me*)	98.11[c] (CH_2)

Measured in [a]C_6D_6, [b]C_6D_5Br, [c]CD_2Cl_2.

although no resonance could be found that could be assigned to a methyl group. Examination of the ^{19}F NMR spectrum of the product showed that the expected $[MeB(C_6F_5)_3]^-$ anion was not present, although one major species appeared to be present. Activation of the ^{13}C labeled derivative gave identical ^1H and ^{19}F NMR spectra to those obtained upon activation of the unlabeled compound. The ^{13}C NMR spectrum was more enlightening, showing only a very broad resonance at 17 ppm in bromobenzene-d_5 assignable to the $^{13}CH_3$ groups. The appearance and chemical shift of these methyl resonances points to a species with both methyl groups bound to boron. Decomposition of the $[MeB(C_6F_5)_3]^-$ anion by C_6F_5 transfer to the metal is a documented reaction pathway for Group IV methyl cations [24–26]. Such a decomposition would explain the presence of a C_2-symmetric species, which we believe to be $[HIPTN_2]Zr(C_6F_5)_2$, and one equivalent of $Me_2B(C_6F_5)$ (Eq. (2)). A double exchange of methyl for pentafluorophenyl is more rare than a single exchange and may be due to the highly electron deficient nature of the metal center and its relatively open

$$[HIPTN_2]ZrMe_2 + B(C_6F_5)_3 \longrightarrow [HIPTN_2]Zr(C_6F_5)_2 + Me_2B(C_6F_5) \quad (2)$$

architecture. This reaction can be used on larger scales to prepare $[HIPTN_2]Zr(C_6F_5)_2$ in good yield. Proton, carbon, and fluorine NMR spectra, as well as combustion analysis of the recrystallized material are all consistent with the product being $[HIPTN_2]Zr(C_6F_5)_2$; NMR spectra are also all identical to those obtained in NMR scale activation experiments. Attempts to polymerize 1-hexene by a cationic species that may be formed transiently upon activation of $[HIPTN_2]$ $ZrMe_2$ with $B(C_6F_5)_3$ were unsuccessful, even when the reaction was conducted in neat 1-hexene at −30 °C. This result contrasts with that obtained by McConville for a titanium diamido catalyst where decomposition of the $[MeB(C_6F_5)_3]^-$ anion could be avoided by conducting polymerization experiments in neat 1-hexene [25].

The reaction between $[HIPTN_2]ZrMe_2$ and $[HNMe_2Ph][B(C_6F_5)_4]$ in bromobenzene-d_5 proceeded as anticipated with elimination of methane and formation of a dimethylaniline adduct of the monomethyl cation, as shown in Eq. (3). The activation required several hours at

$$[HIPTN_2]ZrMe_2 + [HNMe_2Ph][B(C_6F_5)_4] \xrightarrow{-CH_4} \{[HIPTN_2]Zr(Me)(NMe_2Ph)\}\{B(C_6F_5)_4\} \quad (3)$$

room temperature to go to completion, perhaps as a consequence of the limited solubility of $[HNMe_2Ph][B(C_6F_5)_4]$ in bromobenzene. Proton and carbon NMR spectra are both consistent with the product being asymmetric and containing one methyl group. Two singlet resonances are found for the Me groups of dimethylaniline in the ^1H NMR spectrum, consistent with it being tightly bound. The low coordination number of (formally) a three-coordinate and sterically accessible metal in the cation apparently allows tight binding of dimethylaniline. Only one diastereomer is observed. Not surprisingly, addition of 1-hexene to $\{[HIPTN_2]Zr(Me)(NMe_2Ph)\}[B(C_6F_5)_4]$ yielded no polymer, even at 60 °C, presumably as a consequence of tight binding of dimethylaniline.

Reaction of $[HIPTN_2]ZrMe_2$ with $[Ph_3C][B(C_6F_5)_4]$ in bromobenzene-d_5 at −10 °C over a period of 20–30 min yielded a dark red solution whose ^1H and ^{13}C NMR spectra were consistent with formation of an asymmetric monomethyl cation. When a full equivalent of trityl was employed, two similar species were formed in a roughly 1:1 ratio. The two compounds have nearly identical NMR spectra, which suggests that they may be diastereomers (Table 1). The two species do not grow in at the same rate; one is formed before all $[HIPTN_2]ZrMe_2$ is consumed, while the other grows in as $[HIPTN_2]ZrMe_2$ reacts with the remaining trityl. The dimethyl species therefore may play a role in conversion of one diastereomer to the other.

Activation of dimethyl species with trityl has been shown to produce monocationic dimers through capture of the monomethyl cation by unreacted dimethyl species [27,28]. In order to test the likelihood of dimer formation upon activation of $[HIPTN_2]ZrMe_2$, activation was carried out with 0.5 equivalents of trityl. Proton NMR spectra from this reaction show a 1:1 ratio of starting material to one of the diastereomers observed above, indicating that monocationic dimeric species probably are not present. The $^1J_{C-H}$ coupling constants of 120 Hz for the methyl groups in each diastereomer also argue in favor of monomeric species. At this stage, we can only suggest that relatively strong ion pairing is the origin of two different species being observable in NMR spectra.

Solutions of $[HIPTN_2]ZrMe_2$ activated with trityl react instantly and exothermically with several equivalents of 1-hexene at −30 °C. Examination of these reactions by ^{13}C and ^1H NMR revealed that the 1-hexene had been oligomerized, not polymerized. The NMR spectrum, which is similar to that found with the $[(MesN\text{-}o\text{-}C_6H_4)_2O]^{2-}$ ligand system, suggests that chain termination by β-H elimination (from either the 1,2 or especially a 2,1 insertion product) is facile [29–31]. The relatively open environment at the metal may not allow effective discrimination between 1,2 and 2,1 olefin insertion, thereby leading to an enhanced proclivity towards β-H elimination [29–31].

Activation of the $[HIPTN_2]HfMe_2$ species with the three activators discussed above yielded results that are essentially identical to those observed with zirconium (see Section 4). Interestingly, the $[HIPTN_2]Hf(C_6F_5)_2$ formed by reaction with $B(C_6F_5)_3$ we believe to be the first such compound of hafnium to be formed by aryl transfer from boron. The $[HIPTN_2]Hf(CH_2CHMe_2)_2$ species showed similar behavior to the dimethyl species when activated with $[Ph_3C][B(C_6F_5)_4]$ and $[HNMe_2Ph][B(C_6F_5)_4]$. Unlike the methyl species, however, the isobutyl complex did not undergo exchange with $B(C_6F_5)_3$, but rather reacted slowly to give an asymmetric Hf species and isobutene as judged by ^1H NMR. This asymmetric species could not be identified positively as the isobutyl cation, but the fact that it did

not react with 1-hexene at room temperature to yield polymer or oligomer argues against it being the isobutyl cation.

The dineopentyl zirconium species was also examined as an initiator. The complex did not react readily with $B(C_6F_5)_3$, and it reacted only very slowly with the other two activators to give products which could not be identified by NMR spectroscopy.

3. Conclusions

Complexes that contain the $[HIPTN_2]^{2-}$ ligand appear to be similar in some ways to other early transition metal polymerization catalysts that contain diamido supporting ligands. Unfortunately, the "steric hindrance at a distance" that is provided by the HIPT substituents is not sufficient to stabilize pseudo three-coordinate cations against various decomposition reactions, and only oligomerization of 1-hexene was observed as a consequence of insufficient steric protection close to the metal. We conclude that although three HIPT substituents on amido nitrogens provides a significant amount of steric protection in five-coordinate complexes that contain a triamidoamine ligand [17–21], only two HIPT substituents cannot counteract the consequences of an inherently open architecture in a diamido alkyl metal cation.

4. Experimental

General comments. All manipulations of air- and moisture-sensitive materials were performed in oven-dried (200 °C) glassware under an atmosphere of nitrogen on a dual-manifold Schlenk line or in a Vacuum Atmospheres glovebox. NMR experiments were carried out in Teflon-valve sealed J. Young-type NMR tubes. HPLC grade organic solvents were sparged with nitrogen and dried by passage through activated alumina (for diethyl ether, toluene, pentane, THF, and methylene chloride) followed by passage through Q-5 supported copper catalyst (for benzene) prior to use then stored over 4 Å Linde-type molecular sieves. Benzene-d_6, toluene-d_8, and THF-d_8 were dried over sodium/benzophenone ketyl and vacuum-distilled. Methylene chloride-d_2 and bromobenzene-d_5 were dried over CaH_2, vacuum distilled and stored over 4 Å Linde-type molecular sieves. NMR spectra were recorded on a Varian 500 or Varian 300 spectrometer. Chemical shifts for ^1H and ^{13}C spectra were referenced to the residual $^1H/^{13}C$ resonances of the deuterated solvent (^1H: C_6D_6, δ 7.16; $C_6D_5CD_3$, δ 2.15; CD_2Cl_2, δ 5.32; C_6D_5Br, δ 7.29. ^{13}C: C_6D_6, δ 128.32; C_6D_5Br, δ 121.19) and are reported as parts per million relative to tetramethylsilane. ^{19}F NMR spectra were referenced externally to fluorobenzene (δ −113.15 ppm relative to $CFCl_3$). In the following discussion of NMR shifts, BINAP refers to protons on the binaphthyl rings, whereas *o*, *m*, and *p* refer to the aryl positions of the terphenyl substituent. High-resolution mass spectrometry measurements were performed at the MIT Department of Chemistry Instrument Facility, and elemental analyses were performed by H. Kolbe Microanalytics Laboratory, Mülheim de Ruhr, Germany.

2,2′-Diamino-1,1′-binaphthalene, 3,5-bis(2,4,6-triisopropylphenyl)bromobenzene, $Ti(NMe_2)_4$, $Zr(NMe_2)_4$, and $Hf(NMe_2)_4$ [32] were prepared according to published procedures, or slightly modified versions thereof. Me_3SiCl, *iso*-BuMgBr, and MeMgBr were purchased from Aldrich Chemical Co. and used as received. Tris(pentafluorophenyl)borane, trimethylsilyl trifluoromethanesulfonate (TMSOTf), $Pd_2(dba)_3$, and XPHOS were purchased from Strem Chemical Co. and used as received. Trityl tetrakis(pentafluorophenyl)borate, $\{Ph_3C\}[\{B(C_6F_5)_4\}]$, was obtained as a gift from the Exxon Mobile Corp. and used as received.

$H_2[HIPTN_2]$. A 500 mL Schlenk flask was charged with 3.97 g (14.0 mmol) of 2,2′-diamino-1,1′-binaphthalene, 17.15 g (30.5 mmol) of 3,5-bis(2,4,6-triisopropylphenyl)bromobenzene, 4.30 g (44.7 mmol) of NaO-*t*-Bu, and 300 mL of toluene. To the mixture was added a solution of 0.130 g (1 mol%) of $Pd_2(dba)_3$ and 0.138 g (2 mol%) of XPHOS dissolved in 5 mL of toluene. The resulting mixture was stirred at 90 °C for 5 h during which time the mixture became brown and a large amount of precipitate had formed. The mixture was filtered through celite and the volatiles were removed from the filtrate in vacuo. The brown residue was dissolved in a minimal amount of pentane and left to stand overnight. The compound precipitated as a white crystalline solid over a period of 18 h. The remaining mother liquor was purified by flash chromatography on silica gel eluting with 20% toluene in pentane. The pooled column fractions were evaporated to dryness in vacuo leaving a white solid; total yield 13.04 g (75%): ^1H NMR (CD_2Cl_2) δ 7.87 (d, 2 BINAP*H*), 7.82 (d, 2 BINAP*H*), 7.77 (d, 2 BINAP*H*), 7.26 (t, 2 BINAP*H*), 7.15 (t, 2 BINAP*H*), 7.09 (d, 2 BINAP*H*), 7.00 (app d, 8 *m*-*H*), 6.80 (s, 4 *o*-*H*), 6.56 (s, 2 *p*-*H*), 5.73 (s, 2 N*H*), 2.89 (sep, 4 *p*-C*H*Me$_2$), 2.73 (m, 8 *o*-C*H*Me$_2$), 1.26 (d, 24 *p*-CH*Me*$_2$), 1.09 (d, 12 *o*-CH*Me*$_2$), 1.03 (app q, 36 *o*-CH*Me*$_2$); $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ 148.59, 147.06, 142.45, 142.25, 141.54, 137.26, 134.41, 130.18, 129.98, 128.78, 127.47, 126.31, 124.63, 123.99, 120.98, 120.43, 118.45, 116.85, 34.93, 30.96, 24.84, 24.50, 24.48, 24.41; HRMS Calc. $[M+H]^+$ 1245.8898. Activation experiments. Activation of [HIPTN$_2$]ZrMe$_2$ and [HIPTN$_2$]Zr(^{13}CH$_3$)$_2$ were conducted as follows. Equimolar amounts of the complex and activator were dissolved in ~0.4 mL of bromobenzene-*d*$_5$. The solutions were cooled to −30 °C, at which point they were mixed and quickly transferred to the J-Young tube. The NMR data of the activated zirconium species are listed below.

{[HIPTN$_2$]Zr(Me)(NMe$_2$Ph)}{B(C$_6$F$_5$)$_4$}. ^{1}H NMR (C$_6$D$_5$Br) δ 8.17 (d, 1 Ar*H*), 7.87 (d, 1 Ar*H*), 7.80 (d, 1 Ar*H*), 7.77 (d, 2 Ar*H*), 7.75 (t, 1 Ar*H*), 7.69 (d, 1 Ar*H*), 7.34 (t, 1 Ar*H*), 7.23 (s, 2 Ar*H*), 7.21 (s, 2 Ar*H*), 7.19 (s, 2 Ar*H*), 7.15 (s, 2 Ar*H*), 7.05–6.85 (m, 7 Ar*H*), 6.77 (s, 2 Ar*H*), 6.68 (t, 1 Ar*H*), 6.62 (m, 4 Ar*H*), 6.43 (t, 1 Ar*H*), 3.01–2.79 (m, 12 C*H*Me$_2$), 2.21 (br s, 3 *Me*$_2$NPh), 1.47 (br s, 3 *Me*$_2$NPh), 1.35–1.12 (m, 72 CH*Me*$_2$), 0.53 (s, 3 *Me*).

Dedicated to Professor Malcolm Chisholm on the occasion of his 60th birthday.

Abstract

The reaction of the sterically hindered terphenol Ar*OH (Ar* = C_6H_3-2,6(C_6H_2-2,4,6-Pr^i_3)$_2$) with trimethylaluminum or trimethylgallium in ether led to the isolation of the corresponding ether-coordinated monophenoxide species Ar*OM(CH_3)$_2$(Et_2O) (M = Al (**1**) or Ga (**2**)). The reaction of the lithium salt of the related bulky terphenol Ar′OH (Ar′ = C_6H_3-2,6(C_6H_3-2,6-Pr^i_3)$_2$) with the divalent species MCl_2 (M = Ge, Sn) afforded the novel germanium (II) and tin (II) mono- and bisphenoxides [{Ar′OGeCl}(dioxane)] · toluene (3 · toluene), Ge(OAr′)$_2$ (**4**) and Sn(OAr′)$_2$ (**5**). The compounds were characterized by ^{1}H, ^{13}C and ^{119}Sn NMR (**5**) spectroscopy, and by IR spectroscopy and X-ray crystallography.

Keywords: Terphenyl; Aryloxide; Steric effects

1. Introduction

Previous work by us has shown that the very bulky phenols Ar*OH (Ar* = C_6H_3-2,6(C_6H_2-2,4,6-Pr^i_3)$_2$) and Ar′OH (Ar′ = C_6H_3-2,6(C_6H_3-2,6-Pr^i_2)$_2$) and some of their alkali metal salts could be synthesized and characterized by simple routes [1]. Although their oxygen atoms carry only one substituent, aryloxide ligands can be good protecting groups if the aryl substituent is very large. Thus, bulky aryloxides have been used as substituents on a wide variety of metallic centers [2,3], for the stabilization of low coordinate compounds [4], persistent odd-electron species [5] or heavier main group compounds with multiple bonds [6]. Very bulky aryloxide complexes of aluminum or gallium are an attractive target for synthesis in view of their potential applications in catalysis [7] or for isolation of new low valent, low coordinate species. In addition, despite the fact that aryloxide derivatives are well known for the majority of main group and transition metals [2], for germanium (II) and tin (II) they are rather uncommon. The first examples (M(OAr)$_2$, Ar = 2,6-Bu^t_2-4-MeC_6H_2, M = Ge or Sn) were reported by Lappert et al. [4] and some recent germanium derivatives have been reported by Rothwell et al. [8,9]; for example (*R*,*R*)-[Ge{$OC_{20}H_{10}$($OSiMe_3$)-2′-($SiMe_3$)$_2$-3,3′}$_2$], (*R*)-[Ge{$O_2C_{20}H_{10}$($SiMe_2Ph$)$_2$-3,3′}{NH_3}], or [Ge(OAr)$_2$]$_n$, where (n = 2, ArO = $OC_6H_2Me_3$-2,4,6; $OC_6H_3Pr^i_2$-2,6; n = 1, ArO = $OC_6H_3Ph_2$-2,6; OC_6HPh_4-2,3,5,6), and by Barrau et al. [10,11] (M(OAr)$_2$, Ar = 2,4,6-[$(CH_3)_2NCH_2$]$_3C_6H_2$, M = Ge, Sn and M($OCH_2CH_2NMe_2$)$_2$). However, structural data remain scarce and no ^{119}Sn spectroscopic data for a tin (II) aryloxide or alkoxide complex, in which the tin is unambiguously two coordinate, have been reported. We now describe the synthesis and characterization of some new group 13 and 14 mono and

doi:10.1016/j.poly.2005.07.025

bisterphenoxides as potentially important species for further low valent chemistry involving both homo and hetero main group or transition metal derivatives.

2. Results and discussion

2.1. Synthesis and spectroscopy

The aluminum and gallium derivatives **1** and **2** were synthesized by direct reaction of the bulky phenol Ar*OH [1] with 1.0 M ethereal solutions of trimethylaluminum and trimethylgallium, at room temperature, according to the reaction

$$Ar^*OH + M(CH_3)_3 \xrightarrow[RT]{Et_2O} Ar^*OM(CH_3)_2(Et_2O) + CH_4$$

$$M = Al(\mathbf{1}) \text{ and } Ga(\mathbf{2})$$

This method was chosen because of the commercial availability of the metal alkyls, the high solubility of the terphenylphenol in ether solvents and because X-ray quality crystals of **1** and **2** could be grown from ether solvents. Numerous attempts were made to grow crystals of unsolvated complexes from reaction mixtures in non-coordinating solvents, such as hexane, benzene or toluene. Changing the solvent or the temperature at which crystal growth was attempted (−78, −30, 5 °C, and RT) did not produce the desired result. In the absence of a coordinating solvent (i.e., Et_2O) only microcrystalline material was formed.

The reaction route employed the for synthesis of group 14 derivatives consisted of the treatment of lithium terphenoxide Ar′OLi and the divalent tin or germanium chlorides, as described below

$$2Ar'OLi + MCl_2 \xrightarrow[RT]{Et_2O} M(OAr')_2 + 2LiCl$$

$$M = Ge(\mathbf{4}) \text{ and } Sn(\mathbf{5})$$

In the case of germanium, the monoterphenoxide could also be isolated, in the form of the 1,4-dioxane solvate **3**, if a 1:1 ratio of reagents was used. Despite numerous efforts to prepare an analogous tin monoterphenoxide, we were unable to isolate a pure sample of such a compound. Likewise, efforts to synthesize the mono and bisphenoxide derivatives of lead (II) were unsuccessful. The synthesis of the latter species was attempted in many ways: by reaction of lithium phenoxide with lead (II) chloride, bromide or iodide, or by direct reaction of lead (II) bis(*N*,*N*-diisopropyl)amide with phenols. One possible explanation for the failure of these reactions could be the pronounced difference in hard/soft character between the phenoxide moiety and lead (II). In all cases the starting material used (i.e., Ar*OH or Ar′OLi) was recovered unchanged, which suggested a difference in chemical behavior of the reacting species rather than occurrence of side-reactions.

Table 1
^{1}H and ^{13}C NMR chemical shifts for the $M(CH_3)_2$ group in compounds **1** and **2**

–$M(CH_3)_2$	^{1}H NMR (ppm)	^{13}C NMR (ppm)
1, M = Al	−1.07	−9.28
2, M = Ga	−0.61	−4.65

Crystals of **3**–**5** were obtained readily from toluene solutions. The products **1**–**5** were investigated by ^{1}H and ^{13}C NMR spectroscopy, as well as by ^{119}Sn NMR spectroscopy in the case of **5**. The ^{1}H and ^{13}C NMR chemical shifts followed the expected patterns in terphenyl derivatives. For **1** and **2**, the shift values for the $M(CH_3)_2$ moiety (M = Al, Ga) are listed in Table 1.

These shifts are in agreement with the different electronegativities of the two metals, Al (EN = 1.613) being less electronegative than Ga (EN = 1.756) [12].

For **5**, the ^{119}Sn NMR spectroscopy afforded a signal that had a chemical shift of −289.7 ppm (in C_6D_6). The only other comparative literature value was reported by Barrau and coworkers [10,11] for the tin bisphenoxide $Sn[OC_6H_2\text{-}2,4,6(CH_2NMe_2)_3]_2$ which displayed a ^{119}Sn NMR signal well upfield at −529.8 ppm. The shift value for **5** is much further upfield than those found in other two coordinate tin (II) compounds. For example: 2272 ppm in $Sn[CH(SiMe_3)_2]_2$ [13], 2208 ppm in $Sn(C_6H_2\text{-}2,4,6\text{-}Pr^i_3)\{C_6H_2\text{-}2,4,6\text{-}[CH(SiMe_3)_2]_3\}$ [14], 1197 ppm in $Sn(Ar^*)[N(SiMe_3)_2]$ [15], 980 ppm in $SnMes^*_2$ [16], 776 ppm in $Sn[N(SiMe_3)_2]_2$ [17] or 723 ppm in $Sn[C_6H_2\text{-}2,4,6\text{-}(CF_3)_3]_2$ [18]. In fact, the trend found in these divalent species is opposite to that expected on the basis of σ-inductive effects. The unexpected trend in these shifts have been explained on the basis of the mixing of a low lying paramagnetic excited state which causes deshielding of the ^{119}Sn nucleus [19]. This mixing occurs to the greatest extent when electron releasing substituents are used which afford a small singlet–triplet gap and strongly deshield the tin environment. With electronegative amide or aryloxide substituents this gap becomes much larger and upfield shifts are observed as a result. The particularly large upfield shift of Barrau's compound may be a result of an increase in the effective coordination number at tin due to complexation of the tin by pendant CH_2NMe_2 groups. The upfield shift of **5** in which tin is two coordinate is surprising since the value is in the range of a tetracoordinated [20,21] rather than a dicoordinated tin compound.

3. Structures

The main feature of compounds **1**–**5** is that they all are monomers in solid state. Selected structural data for **1**–**5** are provided in Table 2 (see Fig. 1).

The structures of **1** and **2** display distorted tetrahedral metal coordination in which the metal is bound to two

oxygens and two carbons. There are significant differences between the aluminum and gallium environments and between the alkoxide ligand parameters in each complex. For example: the C(1)–O(1)–Al(1) and C(1)–O(1)–Ga(1) angles are 134.46(15)° and 122.12(17)°, respectively, and the Al–O(1) bond (1.755(2) Å) involving terphenoxide is ca 0.1 Å shorter than the Ga–O(1) bond (1.861(2) Å). This is due to the greater electropositive character of aluminum in comparison to gallium, which causes a larger ionic component in the Al–O bond which shortens it and increases steric congestion [22]. Consequently, the C(1)–O(1)–Al(1) angle widens to decrease steric strain. The M–OAr distances in **1** and **2** are ca. 0.05 Å longer than those in the compounds $Me_2MOC_6H_2$-2, 6-Bu^t_2-4-Me owing to the higher coordination number of the metals as a result of ether coordination. Also, the Ga–O(2) bond involving diethyl ether is ca. 0.16 Å longer than the corresponding Al–O(2) bond, which is consistent with the higher electronegativity and lower Lewis acidity of Ga in comparison to Al. The differences between the M–C bond lengths are much less (Al–C = 1.955(4) Å, Ga–C = 1.971(3) Å), probably because the ionic character of these bonds is lower.

Molecule **3** is, to the best of our knowledge, the first example of a fully characterized aryloxygermanium (II) chloride species. The structure involves the complexation

of two Ar′OGeCl units to each oxygen of a 1,4-dioxane molecule (see Fig. 2).

The Ge(1)–O(1) distance is 1.830(2) Å, which is shorter than the sum of the covalent radii, but it is in the range for other germanium (II) phenoxides reported in the literature [4,23]. The Ge(1)–Cl(1) distance of 2.2752(10) Å is also consistent with distances found in other Ge(II)–Cl structures and are in the normal range and approximately equal to the sum of their respective covalent radii [24–26], with correction for ionic effects [27,28]. Other distances in molecule fall within the expected range for the terphenyl derivatives. The germanium has a pyramidal geometry, with bond angles of O(1)–Ge(1)–O(2), O(1)–Ge(1)–Cl(1) and O(2)–Ge(1)–Cl(1) of 84.75(9)°, 93.80(8)°, and 88.34(7)°, respectively. Attempts to synthesize a tin analogue of **3** were unsuccessful.

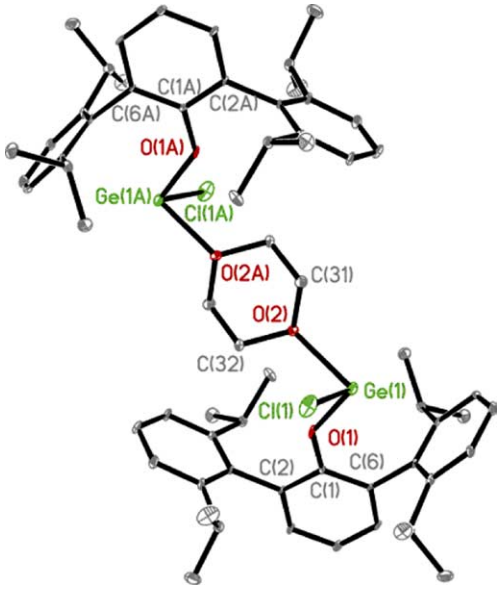

Fig. 2. Thermal ellipsoid (30%) diagram of Ar′OGeCl complex with 1,4-dioxane, **3**. H atoms and toluene solvate are not shown.

The homoleptic bis aryloxide carbene-like species **4** and **5** were readily obtained by reaction of two equivalents of terphenylphenoxide Ar′OLi and MCl_2 (M = Ge, Sn) in ether (see Fig. 3).

After extraction in toluene (in later experiments hexane also proved to be a good solvent) and storage in a ca. 5 °C refrigerator for 2 days, large, colorless blocks of **4** or **5** were obtained. The crystallographic studies revealed that the two molecules are isostructural, and that they display a V-shaped geometry with angles of O(2)–Ge(1)–O(1) and O(1)–Sn(1)–O(2) of 92.54(6)° and 92.18(6)°, respectively. This feature is somewhat different from similar examples reported in the literature [4], where O–Ge–O angle was larger than the O–Sn–O angle (i.e., 92.0(4)° and 88.8(2)° in $M(OC_6H_2Me\text{-}4\text{-}Bu^t_2\text{-}2,6)_2$ for M = Ge or M = Sn, respectively). However, this difference can be attributable to a larger steric bulk of the ligands employed in our case, which can result in an increase of the angle at tin, making it very similar to the germanium analog. The Ge–O (1.8296(14) Å) and Sn–O (2.0450(16) Å) distances are slightly shorter than expected from the sum of the radii of Ge or Sn and O because of the ionic character of the Ge–O and Sn–O bonds, but fall in the range of other similar carbene-like species reported previously [4] i.e., 1.802(8) and 1.812(7) Å for M = Ge and 1.995(4) and 2.022(4) Å for M = Sn in $M(OC_6H_2Me\text{-}4\text{-}Bu^t_2\text{-}2,6)_2$. The colorless nature of **4** and **5** is noteworthy and shows that the n → p chromophore has been shifted into the UV region of the spectrum in comparison to more highly colored alkyl, aryl, and amide analogues. In other

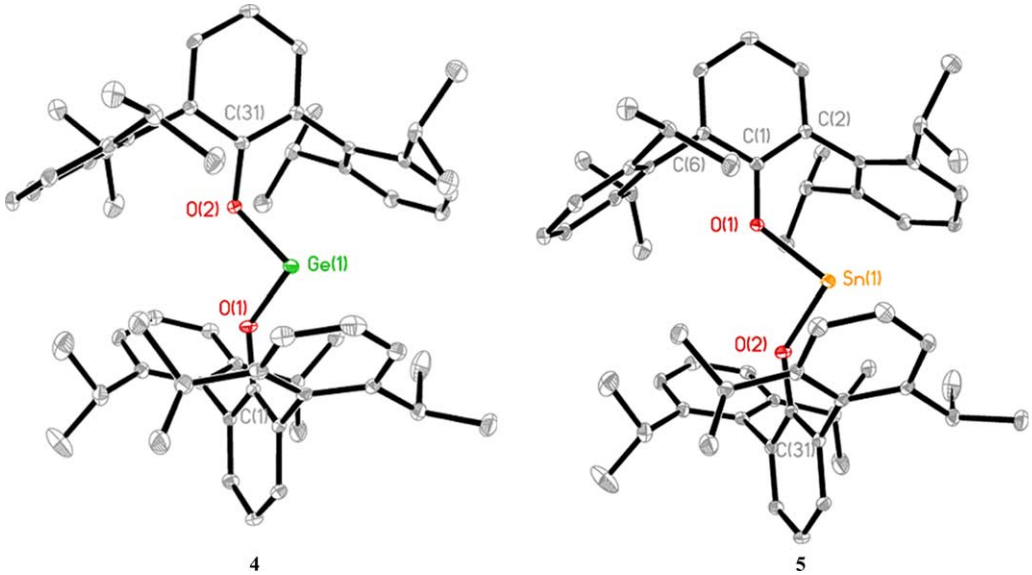

Fig. 3. Thermal ellipsoid (30%) drawings of molecules **4** and **5**. H atoms are not shown.

words the energy difference between n and p levels has been increased by the more electronegative oxygen substituents which lowers the energy of the metal lone pair. The increase in the n → p energy difference is consistent with the arguments made earlier for the ^{119}Sn NMR shifts.

4. Conclusion

The present study resulted in the synthesis and full structural characterization of new aluminum and gallium bulky monophenoxides as well as new bis-terphenylphenoxides of Sn(II) and Ge(II). A new aryloxygermanium (II) chloride was synthesized and its structure determined to be an unusual 2:1 complex with 1,4-dioxane. The yields were good in all cases, ranging from 78% to 93%, making these syntheses a very efficient and useful synthetic pathway for the title compounds.

5. Experimental

5.1. General procedures

All manipulations were carried out by using modified Schlenk techniques under an atmosphere of N_2 or Ar or in Vacuum Atmospheres HE-43 or NEXUS dryboxes. All solvents were distilled from molten Na/K alloy and degassed twice prior to use. $AlMe_3$ and $GaMe_3$ were used as 1.0 M solutions in diethyl ether, accurately prepared from pure $AlMe_3$ and $GaMe_3$. Ar*OH and Ar′OLi were prepared as described previously [1]. The ^{1}H and ^{13}C NMR spectra were recorded on a Varian 300 or 400 MHz spectrometer and referenced to known standards. Melting points were recorded in glass capillaries under N_2 and are uncorrected. Infrared spectra were recorded as Nujol mulls between CsI plates on a Perkin–Elmer 1430 spectrometer.

5.2. Ar*OAl(CH$_3$)$_2$(Et$_2$O) (1)

Ar*OH (0.5 g, 1 mmol) was dissolved in diethyl ether (30 mL) and 1 mL of a 1.0 M ethereal solution of $AlMe_3$ was added dropwise, at room temperature, via syringe, with rapid stirring. Immediate gas evolution was observed. The resulting mixture was stirred for an additional hour whereupon the solvent was pumped off and toluene (ca. 10 mL) was added to the remaining pale yellow residue. The clear solution obtained was concentrated to about 5 mL and placed in a −20 °C freezer. No crystals were formed after 3 days so about 0.1 mL ether was added to the solution and the flask was left in the freezer overnight, to afford **1** as large colorless crystals. These proved suitable for X-ray crystallographic studies. Yield: 0.585 g, 93%, m.p. 133–134 °C. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): $\delta = -1.07$ [s, 6H, $AlMe_2$], 0.54 [t, $^3J_{H-H} = 6.9$ Hz, 6H, ether CH_3], 1.17 [d, $^3J_{H-H} = 6.6$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 1.27 [d, $^3J_{H-H} = 6.9$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 1.38 [d, $^3J_{H-H} = 6.3$ Hz, 12H, *p*-CH(CH$_3$)$_2$], 2.84 [sept, $^3J_{H-H} = 6.9$ Hz, 2H, *p*-C*H*(CH$_3$)$_2$], 2.94 [q, $^3J_{H-H} = 7.2$ Hz, 4H, ether CH_2], 3.15 [sept, $^3J_{H-H} = 6.8$ Hz, 4H, *o*-C*H*(CH$_3$)$_2$], 6.88 [t, $^3J_{H-H} = 7.4$ Hz, 1H, *p*-C_6H_3], 7.16 [s, 4H, *m*-Trip], 7.18 [d, $^3J_{H-H} = 7.4$ Hz, 2H, *m*-C_6H_3] ppm. ^{13}C NMR (300 MHz, C_6D_6, 25 °C): $\delta = -9.28$ [$AlMe_2$], 13.25 [ether CH_3], 23.68 [*o*-$CHMe_2$], 24.39 [*o*′-$CHMe_2$], 25.85 [*p*-$CHMe_2$], 30.72 [*o*-*C*HMe_2], 34.74 [*p*-$CHMe_2$], 64.96 [ether CH_2], 117.30 [*o*-C_6H_3], 120.70 [*m*-C_6H_3], 130.82 [*p*-C_6H_3], 131.52 [*p*-Trip], 136.83 [*i*-Trip], 147.59 [*o*-Trip], 147.76 [*m*-Trip], 155.60 [*i*-C_6H_3] ppm. IR (Nujol): $\nu = 680$–720 cm^{-1} (Al–O, broad).

5.3. Ar*OGa(CH$_3$)$_2$(Et$_2$O) (2)

The same procedure as that described for **1** was employed in the reaction of Ar*OH (0.5 g, 1 mmol) with 1 mL of a 1.0 M ethereal solution of $GaMe_3$ at room temperature. Gas evolution was also observed during the reaction. After a similar work up procedure as that described for **1**, the resulting ethereal reaction mixture was left in the freezer for 3 days to afford large colorless crystals of **2** that were suitable for crystallographic studies. Yield: 0.613 g, 91%, m.p. 92–94 °C. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): $\delta = -0.61$ [s, 6H, $GaMe_2$], 0.66 [t, $^3J_{H-H} = 6.9$ Hz, 6H, ether CH_3], 1.17 [d, $^3J_{H-H} = 7.2$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 1.25 [d, $^3J_{H-H} = 6.3$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 1.37 [d, $^3J_{H-H} = 6.9$ Hz, 12H, *p*-CH(CH$_3$)$_2$], 2.82 [sept, $^3J_{H-H} = 6.9$ Hz, 2H, *p*-C*H*(CH$_3$)$_2$], 2.93 [q, $^3J_{H-H} = 6.7$ Hz, 4H, ether CH_2], 3.19 [sept, $^3J_{H-H} = 6.7$ Hz, 4H, *o*-C*H*(CH$_3$)$_2$], 6.87 [t, $^3J_{H-H} = 7.2$ Hz, 1H, *p*-C_6H_3], 7.16 [s, 4H, *m*-Trip], 7.21 [d, $^3J_{H-H} = 7.5$ Hz, 2H, *m*-C_6H_3] ppm. ^{13}C NMR (300 MHz, C_6D_6, 25 °C): $\delta = -4.65$ [$GaMe_2$], 14.53 [ether CH_3], 24.12 [*o*-$CHMe_2$], 24.75 [*o*′-$CHMe_2$], 26.49 [*p*-$CHMe_2$], 31.14 [*o*-*C*HMe_2], 35.12 [*p*-$CHMe_2$], 64.54 [ether CH_2], 117.08 [*o*-C_6H_3], 121.09 [*m*-C_6H_3], 131.31 [*p*-C_6H_3], 131.55 [*p*-Trip], 136.70 [*i*-Trip], 147.92 [*o*-Trip], 148.31 [*m*-Trip], 159.21 [*i*-C_6H_3] ppm. IR (Nujol): $\nu = 530$–580 cm^{-1} (Ga–O, broad).

5.4. Ar′OGeCl(0.5dioxane) (3)

A solution of 0.21 g (0.5 mmol) LiOAr′ in 20 mL diethyl ether was added via cannula, with rapid stirring, to a suspension of 0.115 g (0.5 mmol) $GeCl_2 \cdot$ dioxane in ca. 20 mL diethyl ether. The reaction mixture was stirred at room temperature overnight. The solvent was pumped off and the pale yellow solid residue was extracted in ca. 30 mL toluene. The solution was filtered through a Celite pad and concentrated to about 5 mL. After being stored in a −20 °C freezer overnight, large,

colorless crystals of **3** were formed, which were analyzed by X-ray crystallographic methods. Yield: 0.235 g, 83%, m.p. 175–180 °C. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): $\delta = 1.03$ [d, $^3J_{H-H} = 6$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 1.08 [d, $^3J_{H-H} = 6$ Hz, 12H, *o′*-CH(CH$_3$)$_2$], 2.82 [sept, $^3J_{H-H} = 6.7$ Hz, 4H, *o*-C*H*(CH$_3$)$_2$], 4.31 [s, 8H, dioxane CH$_2$], 6.78 [t, $^3J_{H-H} = 7.3$ Hz, 1H, *p*-C$_6$H$_3$], 6.91 [d, $^3J_{H-H} = 7.5$ Hz, 2H, *m*-C$_6$H$_3$], 7.06 [d, $^3J_{H-H} = 6.8$ Hz, 4H, *m*-Dipp], 7.18 [t, $^3J_{H-H} = 6.8$ Hz, 2H, *p*-Dipp] ppm. ^{13}C NMR (300 MHz, C_6D_6, 25 °C): $\delta = 23.89$ [*o*-CHMe$_2$], 24.03 [*o*-CHMe$_2$], 30.72 [*o*-*C*HMe$_2$], 66.70 (dioxane), 120.07 [*p*-C$_6$H$_3$], 123.04 [*m*-Dipp], 126.73 [*p*-Dipp], 128.81 [*m*-C$_6$H$_3$], 129.99 [*i*-Dipp], 133.64 [*o*-Dipp], 147.84 [*o*-C$_6$H$_3$], 150.91 [*i*-C$_6$H$_3$] ppm.

5.5. Ge(OAr′)$_2$ (4)

LiOAr′ 0.84 g (2 mmol) was dissolved in ca. 50 mL diethyl ether and this solution was added via cannula, with rapid stirring at room temperature, to a suspension of 0.23 g (1 mmol) of $GeCl_2 \cdot$ dioxane in 30 mL ether. The resulting reaction mixture was stirred overnight. The solvent was pumped off and toluene (ca. 30 mL) was added to the pale yellow solid residue. After filtration through a Celite pad, the volume of the solution was reduced by half and the flask was stored in a −5 °C fridge for 2 days. Large, colorless crystals of **4** were obtained which were suitable for X-ray analysis. Yield: 0.7 g, 78%, m.p. 190–195 °C (becomes red). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 0.95$ [d, $^3J_{H-H} = 6.8$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 0.99 [d, $^3J_{H-H} = 6.8$ Hz, 12H, *o′*-CH(CH$_3$)$_2$], 2.73 [sept, $^3J_{H-H} = 6.8$ Hz, 4H, *o*-C*H*(CH$_3$)$_2$], 6.73 [t, $^3J_{H-H} = 6.9$ Hz, 1H, *p*-C$_6$H$_3$], 6.90 [d, $^3J_{H-H} = 7.6$ Hz, 2H, *m*-C$_6$H$_3$], 7.04 [d, $^3J_{H-H} = 7.6$ Hz, 4H, *m*-Dipp], 7.19 [t, $^3J_{H-H} = 7.2$ Hz, 2H, *p*-Dipp] ppm. ^{13}C NMR (400 MHz, C_6D_6, 25 °C): $\delta = 24.70$ [*o*-CHMe$_2$], 24.79 [*o*-CHMe$_2$], 30.99 [*o*-*C*HMe$_2$], 119.99 [*p*-C$_6$H$_3$], 123.77 [*m*-Dipp], 128.65 [*i*-Dipp], 128.76 [*p*-Dipp], 131.10 [*m*-C$_6$H$_3$], 140.92 [*o*-C$_6$H$_3$], 146.70 [*o*-Dipp], 153.89 [*i*-C$_6$H$_3$] ppm.

5.6. Sn(OAr′)$_2$ (5)

In a similar manner to that described for **4**, an ethereal solution of 0.84 g (2 mmol) LiOAr′ was added to a suspension of 0.19 g (1 mmol) $SnCl_2$ via cannula, at room temperature. The reaction mixture was stirred overnight and the solvent was then removed under reduced pressure. The remaining dark yellow viscous residue was extracted with 30 mL toluene, filtered through Celite, concentrated to about 5 mL and stored in freezer for 3d to yield colorless crystals suitable for X-ray analysis. Yield: 0.8 g, 85%, m.p. 234–236 °C. ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 0.99$ [d, $^3J_{H-H} = 7.2$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 1.01 [d, $^3J_{H-H} = 6.8$ Hz, 12H, *o*-CH(CH$_3$)$_2$], 2.82 [sept, $^3J_{H-H} = 6.8$ Hz, 4H, *o*-C*H*(CH$_3$)$_2$], 6.71 [t, $^3J_{H-H} = 7.6$ Hz, 1H, *p*-C$_6$H$_3$], 6.81 [t, $^3J_{H-H} = 7.6$ Hz, 2H, *p*-Dipp], 6.96 [d, $^3J_{H-H} = 7.2$ Hz, 4H, *m*-Dipp], 7.08 [d, $^3J_{H-H} = 7.6$ Hz, 2H, *m*-C$_6$H$_3$] ppm. ^{13}C NMR (400 MHz, C_6D_6, 25 °C): $\delta = 23.79$ [*o*-CHMe$_2$], 24.95 [*o*-CHMe$_2$], 30.92 [*o*-*C*HMe$_2$], 122.89 [*p*-C$_6$H$_3$], 124.39 [*m*-Dipp], 128.98 [*p*-Dipp], 130.31 [*m*-C$_6$H$_3$], 130.83 [*i*-Dipp], 139.02 [*o*-C$_6$H$_3$], 146.89 [*o*-Dipp], 158.57 [*i*-C$_6$H$_3$] ppm. ^{119}Sn NMR: −289.68 ppm.

6. X-ray crystallographic studies

Crystals of **1**–**5**, after removal from the Schlenk tube, were covered with a hydrocarbon oil under a rapid flow of argon, mounted on a glass fiber attached to a copper pin and placed in the cold stream of N_2 of the diffractometer. X-ray data were collected on a Bruker SMART 1000 diffractometer at 90(2) K with use of Mo Kα ($\lambda = 0.71073$ Å) radiation. Absorption corrections were applied using SADABS [29]. The structures were solved with use of direct methods or the Patterson option in SHELXS and refined by the full-matrix least-squares procedure in SHELXL [30]. All non-hydrogen atoms were refined anisotropically, while hydrogen atoms were placed at calculated positions and included in refinement using a riding model. Some details of the data collection and refinement are given in Table 3. Further details can be found in the supporting information.

7. Supplementary material

Crystallographic data have been deposited with the Cambridge Crystallographic Data Centre, CCDC 273256-273260. Copies of this information may be obtained free of charge from the Director, CCDC, 12, Union Road, Cambridge CD2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Dedicated to Professor Malcolm Chisholm whose accomplishments in inorganic chemistry and enthusiasm for advancing the field have inspired us all.

Abstract

$K_2C_8H_8$ reacts with $(C_5Me_5)_2UCl_2$ not by substitution of both chlorides, but by Cl^{1-} and $(C_5Me_5)^{1-}$ ligand displacement to form an asymmetric, sterically unsaturated, mixed ligand metallocene chloride complex, $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (**1**). Complex **1** is a tetravalent uranium analogue of the asymmetric trivalent yttrium bimetallic complex, $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ (**2**), that has been used to evaluate coordination of bases with electropositive trivalent metallocenes. Tetravalent **1** similarly coordinates Lewis bases as demonstrated by its reaction with ε-caprolactam that generates a complex with four different ligands, $(C_5Me_5)(C_8H_8)UCl[OCNH(CH_2)_5]$ (**3**). Complex **1** also participates in ionic salt metathesis reactions with $KN(SiMe_3)_2$ to form $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (**4**).

Keywords: Cyclopentadienyl; Cyclooctatetraenyl; Uranium; Heteroleptic; Chiral metal complex; Bimetallic

1. Introduction

The synthesis of sterically unsaturated f element complexes is challenging because the presence of an open coordination site on an electropositive metal with a +3 or +4 formal charge generally results in high reactivity. Sterically unsaturated f element species tend to either react to form more stable sterically saturated products or to increase their electrostatic stabilization by interacting with any nearby available electron density [1–3]. The common occurrence of agostic interactions in f element complexes is indicative of the latter tendency [4–6]. As a consequence, sterically unsaturated complexes are difficult to isolate and crystallographically characterize.

Previously, using the lanthanide mimic, yttrium, a trivalent complex of formula $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ was isolated that had one sterically unsaturated seven-coordinate metal center as well as one metal site with the more common eight-coordinate environment [7]. The isolation of this unsaturated species was attributed to the steric bulk of the four pentamethylcyclopentadienyl ligands that prevented formation of a symmetric dimer involving two eight coordinate metal centers. This compound subsequently proved to be

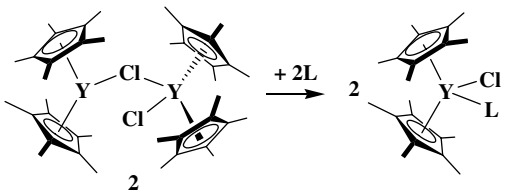
useful in evaluating the relative binding ability of Lewis bases to a metallocene complex of an electropositive trivalent metal since it was soluble in arenes and formed base adducts cleanly according to Eq. (1) [8]:



(1)

We report here the synthesis, structural characterization, and coordination chemistry of a tetravalent uranium analog of the yttrium complex, namely $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (**1**). Due to the higher valence of U(IV) compared to Y(III), a cyclooctatetraenyl dianion is used in place of a pentamethylcyclopentadienyl monoanion to make the metallocene component in this complex. As a result, it is a mixed ligand metallocene. A Th(IV) complex analogous in composition to **1** was synthesized years ago from $(C_8H_8)ThCl_2(THF)_2$ and $(C_5Me_5)MgCl(THF)$ followed by desolvation at 100 °C, but no structural information was reported on this species [9]. In contrast to the thorium synthesis, the mixed ligand uranium metallocene chloride **1** was obtained from the common precursor $(C_5Me_5)_2UCl_2$ [10] in a room temperature reaction that uses both normal substitution of a chloride ligand as well as an unusual $(C_5Me_5)^{1-}$ substitution.

Complex **1** appears to be suitable to evaluate U(IV) Lewis acid/base reactions like those examined with trivalent $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ (**2**), in Eq. (1). Structural data on a $(C_5Me_5)(C_8H_8)UCl(L)$ reaction product of this type is presented for L = ε-caprolactam, a substrate that gave unusual results with $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ [8]. In addition, we report that **1** undergoes subsequent chloride substitution to generate a uranium analog of the thorium complex, $(C_5Me_5)(C_8H_8)Th[N(SiMe_3)_2]$, reported earlier [9] that contains U(IV) ligated by three of the most common ancillary ligands in f element chemistry.

2. Experimental section

2.1. General experimental

The syntheses and manipulations of the extremely air and moisture sensitive compounds described below were conducted under nitrogen or argon with rigorous exclusion of air and water by Schlenk, vacuum line, and glovebox techniques. Unless specified otherwise, all glovebox manipulations were carried out in an argon filled glovebox that was free of coordinating solvents. THF, toluene, benzene, diethyl ether and *n*-hexane were saturated with Ar and passed through a GlassContour® column.[1] Benzene-d_6 and toluene-d_8 were distilled over NaK alloy and benzophenone and degassed by three freeze–pump–thaw cycles. $KN(SiMe_3)_2$ (Aldrich) was recrystallized from toluene before use. C_8H_8 (Aldrich) was distilled onto Type 4 activated molecular sieves, and degassed by three freeze–pump–thaw cycles. ε-Caprolactam (Aldrich) was sublimed before use. $K_2C_8H_8$ [11] and $(C_5Me_5)_2UCl_2$ [10] were prepared as previously described. NMR experiments were conducted with Bruker 400 and 500 MHz spectrometers. IR samples were analyzed as thin films using an ASI ReactIR1000 [12]. GC–MS data were obtained on a Waters (Micromass) Autospec with fused silica 30 m × 0.32 mm i.d. DB-5 GC columns. Elemental analyses were provided by Analytische Laboratorien, Lindlar Germany.

2.2. $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (1)

A dark red solution of $(C_5Me_5)_2UCl_2$ (480 mg, 0.825 mmol) in toluene (10 mL) was slowly added to a stirred suspension of $K_2C_8H_8$ (150 mg, 0.828 mmol) in toluene (5 mL). The mixture was stirred for 3 h and a white insoluble powder was removed from the red solution by centrifugation. The solvent was removed by rotary evaporation and $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ was isolated as a red solid (400 mg, 95%). ^1H NMR (C_6D_6, 21 °C) $\delta = 7.6$ (s, C_5Me_5, 30 H) −29.3 (s, C_8H_8, 16H) ppm. The ^1H NMR spectrum of **1** showed no sign of monomer/ dimer equilibrium between −75 and 75 °C. ^{13}C NMR (C_6D_6, 21 °C) $\delta = 274$ (s, C_8H_8), 273 (s, C_8H_8), 10.3 (s, C_5Me_5), −23.4 (s, C_5Me_5) ppm. IR 2964s, 2907s, 2856s, 2725w, 1640w, 1602m, 1482m, 1436s, 1378s, 1262s, 1092s, 1061s, 1019s, 903m, 861w, 803s, 722s, 676s cm^{-1}. **1** readily crystallizes from saturated solutions of hot toluene cooled to −35 °C with one molecule of toluene per formula unit. *Anal.* Calc. for $C_{36}H_{46}Cl_2U_2 \cdot C_7H_8$: C, 46.22; H, 4.83; Cl, 6.35; U, 42.61. Found: C, 46.27; H, 4.88; Cl, 6.21; U, 43.40%.

2.3. $(C_5Me_5)(C_8H_8)UCl[OCNH(CH_2)_5]$ (3)

A red solution of **1** (58 mg, 0.568 mmol) in C_6D_6 was added to an a flask charged with ε-caprolactam (13 mg, 0.112 mmol). After 2 h, the solvent was removed by rotary evaporation leaving a red oil. The oil was washed with hexane (3×), the washings were discarded, and the remaining insoluble red solids were dried under vacuum. ^1H NMR spectroscopy (C_6D_6) indicated 8.0 (s, 15H) and −32.7 (s, 8H) ppm as the major resonances, but small peaks at 0.18 (s, 3.6H) and −32.8 (s, 2H) as well

[1] THF and diethyl ether were dried over activated alumina and sieves. Toluene and *n*-hexanes were dried over Q-5 and molecular sieves. For more information on the drying system see www.glasscontour.com.

as resonances for C_5Me_5H were also present. The resonances of the ε-caprolactam were not located. **3** crystallized from toluene at −35 °C overnight.

2.4. $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (4)

A solution of **1** (280 mg, 0.272 mmol) in toluene (10 mL) was added to a solution of $KN(SiMe_3)_2$ (110 mg, 0.547 mmol) in toluene (5 mL) and the red solution was stirred for 12 h. White solids were removed by centrifugation and the solvent was removed by rotary evaporation leaving $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (310 mg, 92%) as a red solid. ^{1}H NMR (C_6D_6, 298 K) $\delta = 2.8$ (s, 15H, C_5Me_5), −11 [s br, $\Delta\upsilon_{1/2} = 3000$ Hz, $N(SiMe_3)_2$], −35.5 (s, 8H, C_8H_8) ppm. ^{1}H NMR (Toluene-d_8, 298 K) $\delta = 2.8$ (s, 15H, C_5Me_5), −12 [s br, $\Delta\upsilon_{1/2} =$ 3000 Hz, $N(SiMe_3)_2$], −35.0 (s, 8H, C_8H_8) ppm. ^{1}H NMR (Toluene-d_8, 208 K) $\delta = 29.1$ [s, 6H, $N(SiMe_3)_2$], 12.5 [s, 6H, $N(SiMe_3)_2$], 0.9 (s, 15H, C_5Me_5), −56.2 (s, 8H, C_8H_8), −93.2 [s, 6H, $N(SiMe_3)_2$] ppm. ^{1}H NMR (Toluene-d_8, 336 K) $\delta = 3.2$ (s, 15H, C_5Me_5), −9.8, [s, 18H, $N(SiMe_3)_2$], −27.7, (s, 8H, C_8H_8). IR: 2957s, 2907s, 2856s, 2725w, 1640m, 1598w, 1567w, 1482w, 1436m, 1378m, 1258s, 1092m, 1065m, 1019s, 930s, 903m, 857s, 803s, 779s, 722s, 676s cm^{-1}.

2.5. X-ray data collection, structure solution and refinement for $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)\cdot C_6H_5Me$

A red crystal of approximate dimensions $0.07 \times 0.26 \times 0.28$ mm was mounted on a glass fiber and transferred to a Bruker CCD platform diffractometer. The SMART [13] program package was used to determine the unit-cell parameters and for data collection (25 s/frame scan time for a sphere of diffraction data). The raw frame data was processed using SAINT [14] and SADABS [15] to yield the reflection data file. Subsequent calculations were carried out using the SHELXTL [16] program. The diffraction symmetry was 2/*m* and the systematic absences were consistent with the centrosymmetric monoclinic space group $P2_1/n$ which was later determined to be correct. Details are in Table 1.

The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors [17] for neutral atoms were used throughout the analysis. There was one molecule of toluene solvent present per formula unit. Hydrogen atoms were included using a riding model. Carbon atoms C(25) and C(37) were refined using isotropic temperature parameters. At convergence, $wR_2 = 0.1427$ and GOF = 1.151 for 414 variables refined against 7879 data (0.80 Å). As a comparison for refinement on *F*, $R_1 = 0.0599$ for those 6591 data with $I > 2.0\sigma(I)$.

2.6. $(C_5Me_5)(C_8H_8)UCl[OCNH(CH_2)_5]$ (3)

A red plate of approximate dimensions $0.02 \times 0.16 \times 0.17$ mm was handled as described above, with the exception that a 30 s/frame scan time for a sphere of diffraction data was used. There were no systematic absences nor any diffraction symmetry other than the Friedel condition. The centrosymmetric triclinic space group $P\bar{1}$ was assigned and later determined to be correct. The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors [17] for neutral atoms were used throughout the analysis. Hydrogen atoms were included using

[a] $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$.
[b] $wR_2 = \sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]^{1/2}$.

a riding model. There was a solvent molecule present that was presumed to be hexane. It was included as a half-molecule of hexane (located about an inversion center). The poor quality of the crystal prevented anisotropic refinement. All atoms were assigned isotropic temperature parameters. The final least-squares analysis yielded $wR_2 = 0.3030$ and GOF = 1.241 for 128 variables refined against 3926 data (0.85 Å resolution). As a comparison for refinement on F, $R_1 = 0.1186$ for those 3144 data with $I > 2.0\sigma(I)$. The structure has been established but the metric data are not reliable.

2.7. $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (4)

A red crystal of approximate dimensions $0.07 \times 0.12 \times 0.13$ mm was handled as described above. The diffraction symmetry was $2/m$ and the systematic absences were consistent with the centrosymmetric monoclinic space group $P2_1/c$ which was later determined to be correct. The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors [17] for neutral atoms were used throughout the analysis. Hydrogen atoms were included using a riding model. At convergence, $wR_2 = 0.0840$ and GOF = 1.084 for 253 variables refined against 5120 data (0.80 Å). As a comparison for refinement on F, $R_1 = 0.0296$ for those 4398 data with $I > 2.0\sigma(I)$.

3. Results

3.1. Synthesis of $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (1)

The reaction of $(C_5Me_5)_2UCl_2$ with $K_2C_8H_8$ does not result in the formation of two equivalents of KCl as is typical of reactions of $(C_5Me_5)_2UCl_2$ with potassium reagents [4–6,10,18–21]. ^{1}H NMR spectroscopy of the benzene-soluble, uranium-containing, product suggested that one $(C_5Me_5)^{1-}$ ligand had been lost since the spectrum contained resonances attributable to $(C_5Me_5)^{1-}$ and $(C_8H_8)^{2-}$ ligands with peak area ratios of 15 to 8. This observation was surprising since $(C_5Me_5)^{1-}$ is typically an unreactive ancillary ligand. Indeed, one of the important features of $(C_5Me_5)_2UCl_2$ as a reagent in organouranium chemistry is that the $[(C_5Me_5)_2U]^{2+}$ unit remains intact during reaction sequences [4–6].

Confirmation that $(C_5Me_5)^{1-}$ was lost as KC_5Me_5 via an ionic salt metathesis reaction was obtained by both hydrolysis and deuterolysis of the insoluble white solids that precipitate during the reaction. GC–MS analysis showed these to be C_5Me_5H and C_5Me_5D, respectively.

Since the NMR data on the paramagnetic uranium product were not definitive, an X-ray crystallographic study was conducted. This confirmed that substitution

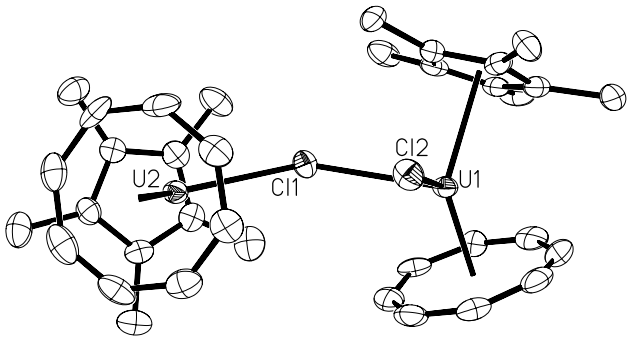

Fig. 1. Thermal ellipsoid plot of $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (**1**), drawn at the 50% probability level. The molecule of toluene that co-crystallized with **1** has been omitted.

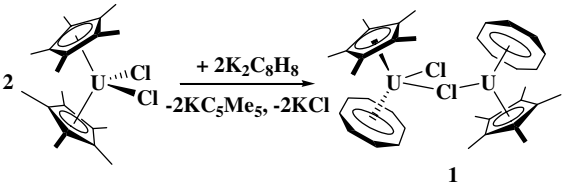
of both Cl^{1-} and $(C_5Me_5)^{1-}$ had occurred: $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (**1**), Fig. 1, was identified as the product, Eq. (2). Unlike the symmetrical trimeric trivalent



(2)

uranium metallocene chloride, $[(C_5Me_5)_2U(\mu\text{-}Cl)]_3$, which is insoluble in alkanes and arene solvents, complex **1** readily dissolves in arenes.

An analogous reaction of $(C_5Me_5)_2ThCl_2$ with $K_2C_8H_8$ forms a product with NMR spectra consistent with those reported for $[(C_5Me_5)(C_8H_8)ThCl]_2$ [9]. Crystallographic characterization of this product has been elusive.

3.2. Structure of $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (1)

Complex **1** is structurally similar to $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ (**2**), in that both compounds contain two metal centers that differ in coordination number by one, both have a single bridging chloride and a single terminal chloride, and both have the four ring centroids arranged in a roughly tetrahedral geometry. The "end on" view in Fig. 2 clearly shows the tetrahedral nature of the four ring centroids in **1**. The 138.0° and 140.7° (C_5Me_5 ring centroid)–U–(C_8H_8 ring centroid) angles are typical of $(C_5Me_5)/(C_8H_8)$ mixed metallocene complexes and are also similar to bis(pentamethylcyclopentadienyl) metallocenes of the f elements. For example, analogous angles in $(C_5Me_5)(C_8H_8)U(bipy)$ [22] and $(C_5Me_5)_2UCl_2$ [23] are 131° and 138.2°, respectively. U(1) is a chiral center and the complex crystallizes as a racemic mixture of enantiomers.

The U(1)–C(C_5Me_5) distances, which range from 2.67(1) to 2.80(1) Å and average 2.74(4) Å, are similar

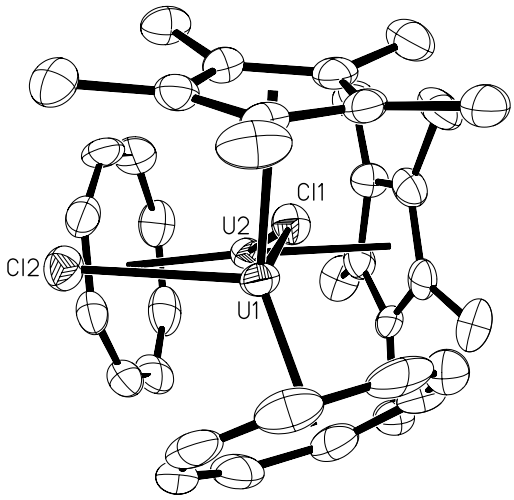


Fig. 2. Thermal ellipsoid plot $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (**1**), drawn at the 50% probability level.

to the 2.73(1)–2.75(2) Å distances in the mixed ligand metallocene $[(C_5Me_5)(C_8H_8)U(THF)_2](BPh_4)$ [24] and overlap with the 2.78(2)–2.81(2) Å distances in the bimetallic $[(C_5Me_5)(C_8H_8)U]_2(C_8H_8)$ complex [25]. The 2.74(4) Å mean U–(C_5Me_5) distance in **1** is also similar to the analogous distances in eight coordinate bis(pentamethylcyclopentadienyl) complexes, e.g. $(C_5Me_5)_2UMe_2$, 2.732(7) and 2.739(6) Å [26,27]. This shows that the U–$C(C_5Me_5)$ unit in the mixed metallocene **1** does not deviate substantially from those in metallocenes containing two $(C_5Me_5)^{1-}$ ligands.

In **1**, the $(C_8H_8)^{2-}$ ligands bind with η^8-hapticity and have U(1)–$C(C_8H_8)$ bond distances in the range 2.61(1)–2.71(1) Å that average 2.66(3) Å. These lengths are similar to analogous distances in $(C_8H_8)_2U$, 2.635(10)–2.675(11) Å [28,29], $(C_8H_8)(PC_4Me_4)U(BH_4)THF$, 2.688(9)–2.740(9) Å [30], $[(C_5Me_5)(C_8H_8)U(THF)_2](BPh_4)$, 2.62(2)–2.68(2) Å [24], and $\{[(^tBu)(C_6H_4Me_2)C{=}N]_3U(C_8H_8)\}[Na(OEt_2)]$, 2.717(7)–2.757(7) Å [31]. In complex **1**, the 2.42 and 2.49 Å U–(C_5Me_5 ring centroid) distances are substantially longer than the 1.89 and 1.98 Å U–(C_8H_8 ring centroid) distances which is typical for dianionic $(C_8H_8)^{2-}$ vs. monoanionic $(C_5Me_5)^{1-}$ ligands in uranium complexes.

The U(1) ion in **1** attaches to the terminal chloride ligand, Cl(2), with a 2.673(3) Å U(1)–Cl(2) bond distance that is longer than analogous bonds in monometallic U(IV) metallocene bis-chloride complexes such as $(C_5Me_5)_2UCl_2$ [23], $[1,3\text{-}(Me_3Si)_2C_5H_3]_2UCl_2$ [32,33], $[1,3\text{-}(^tBu)_2C_5H_3]_2UCl_2$ [33], and $[1,2\text{-}(^tBu)_2C_5H_3]_2UCl_2$ [34] which have U(IV)–Cl lengths of 2.583(6) Å [23], 2.579(2) Å [32,33], 2.577(4) Å [33], and 2.591(4) and 2.576(4) Å [34], respectively. Since these latter complexes are formally eight coordinate and U(1) is formally ten coordinate [counting the three electron pairs of $(C_5Me_5)^{1-}$ and five electron pairs of $(C_8H_8)^{2-}$], the longer distance in **1** is consistent with the higher coordination number [35]. The U(1)–Cl(2) bond distance is more similar to the 2.638(1) Å terminal U–Cl distance in $\{[Me_3SiN(CH_2CH_2NSiMe_3)_2]ClU(\mu\text{-}Cl)\}_2$ [36] which contains a sterically demanding ligand.

Both U–(μ-Cl) distances in **1** are longer than the terminal U(1)–Cl(2) length as is typical of bridging ligands. The U–(μ-Cl)–U bridge is asymmetric since the 2.738(3) Å U(2)–Cl(1) distance to the nine coordinate U(2) ion is shorter than the 2.921(3) Å U(1)–Cl(1) distance to the ten coordinate U(1) ion. Since the radii of uranium ions typically increase by only 0.05 Å with an increase of one in coordination number, the large difference between U(1)–Cl(1) and U(2)–Cl(1) cannot be explained by ionic radius alone. The long U(1)–Cl(1) distance in **1** is substantially longer than the 2.79(2) and 2.82(2) Å distances in the more symmetrically bridged trivalent complex $[(THF)_2(18\text{-crown-}6)Na]\{[(C_5H_5)_3U]_2(\mu\text{-}Cl)\}$ [37] and more similar in length to the 2.901(5) distance in the trivalent uranium complex $[(C_5Me_5)_2U(\mu\text{-}Cl)]_3$ [38]. Since the short U–Cl distance in **1** is associated with U(2), the complex appears to be more of a combination of two $(C_5Me_5)(C_8H_8)UCl$ units rather than a $[(C_5Me_5)(C_8H_8)UCl_2]^{1-}[(C_5Me_5)(C_8H_8)U]^{1+}$ cation/anion pair.

The 148.11(11)° U(1)–Cl(1)–U(2) angle, Fig. 2, is considerably more bent than the 162.8(2)° Y–Cl–Y angle in $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ [7]. The U–Cl–U angle in **1** is also more bent than the analogous 180° angle in mixed valent $\{N[CH_2N(Si^tBuMe_2)]_3U\}_2(\mu\text{-}Cl)$ [39] and the 157.5(7)° angle in trivalent $[(THF)_2(18\text{-crown-}6)Na]\{[(C_5H_5)_3U]_2(\mu\text{-}Cl)\}$ [37]. The U–Cl–U angle in trivalent $[(C_5Me_5)_2U(\mu\text{-}Cl)]_3$ is 84.5(3)°, however [38].

Recent structural studies of $(C_5Me_5)_2MeLu(\mu\text{-}Me)Lu(C_5Me_5)_2$ [40] and $(C_5Me_5)_2MeSm(\mu\text{-}Me)Sm(C_5\text{-}Me_5)_2(\mu\text{-}Me)Sm(C_5Me_5)_2$ [40], which have asymmetric bridged oligomeric structures like those of **1** and $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)$ (**2**), have revealed that in the solid state the molecules are located with the terminal Me ligand of one unit, i.e. $(C_5Me_5)_2LnMe$, oriented at long distances toward the sterically unsaturated metal center of another unit. In light of these structures, intermolecular geometries in **1** and **2** were examined.

Fig. 3 shows a portion of the extended structure of **2** that is similar to the $(C_5Me_5)_2MeLu(\mu\text{-}Me)Lu(C_5Me_5)_2$ complex and exists as a one-dimensional chain of repeating $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ units with intermolecular Y···Cl distances, such as Y(2A)···Cl(2B), of approximately 5.1 Å. The intermolecular Y(1B)–Cl(2B)–Y(1A) angle of 168° is similar to the 162.8(2)° intramolecular Y(1A)–Cl(1A)–Y(2A) angle.

The solid state structure of **1** also has the terminal ligand oriented toward the metal center of another molecule. However, as shown in Fig. 4, the terminal Cl(2)

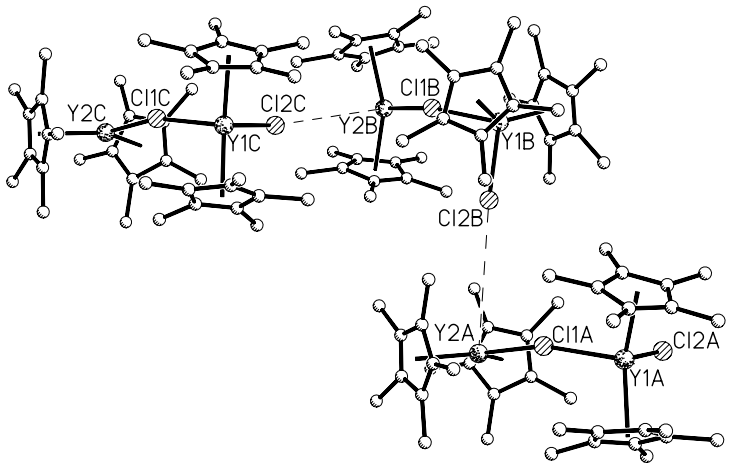

Fig. 3. A ball and stick representation of $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ (**2**), showing the 1-dimensional extended network. The dashed lines show the orientation of the chloride ligands toward the yttrium ions in adjacent molecules.

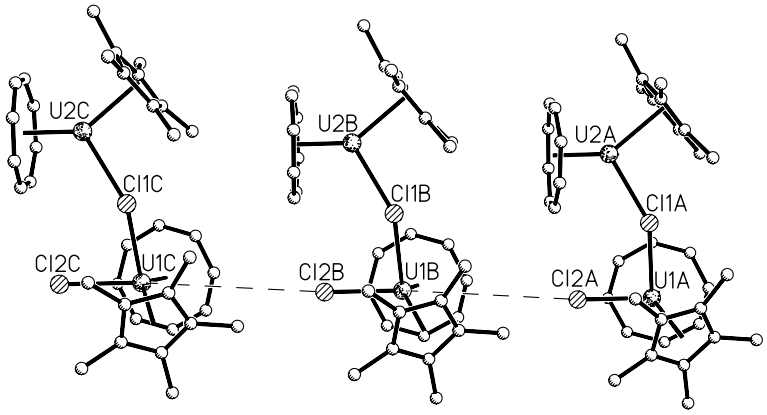

Fig. 4. Ball and stick diagram of $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (**1**), showing the 1-dimensional extended network. The dashed lines show the orientation of the chloride ligands toward the uranium ions in adjacent molecules.

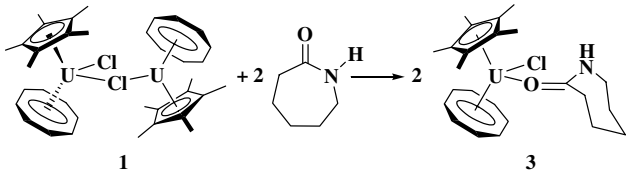
ligands in **1** are oriented to the higher coordinate U(1) positions instead of sterically less saturated U(2). The intermolecular Cl···U–Cl angles are 175° and the intermolecular distances, such as Cl(2A)···U(1C), are approximately 6.1 Å.

3.3. Coordination chemistry of *1*

To determine if **1** might be useful as a U(IV) metallocene platform for evaluating Lewis acid/base interactions analogous to $(C_5Me_5)_2ClY(\mu\text{-}Cl)Y(C_5Me_5)_2$ (**2**), in Eq. (1), complex **1** was treated with ε-caprolactam. This base generated one of the more unusual results with **2**: a bis-adduct formed that had hydrogen bonding between the amide protons and the chloride ligand [8]. Complex **1** reacts with two equiv of ε-caprolactam to form a mixture of products from which the simple mono-base adduct $(C_5Me_5)(C_8H_8)UCl[OCNH(CH_2)_5]$ (**3**), crystallizes, Eq. (3):



(3)

Complex **3** was identified by X-ray crystallography, Fig. 5. Analysis of the reaction by ^1H NMR spectroscopy in C_6D_6 reveals that other products are formed as well. Broad resonances at 0.18 and −32.8 ppm increased in size with addition of more ε-caprolactam, but these could not be definitively identified. C_5Me_5H was also observed, suggesting that the lactam can cleave a $(C_5Me_5)^{1-}$ ring from **1** by protonation. Deprotonation of ε-caprolactam would form caprolactamate, a ligand that is known to complex Ti, Y, Yb, and Er [41,42].

The crystallographic data on **3** were sufficient only to determine connectivity. Complex **3** contains four

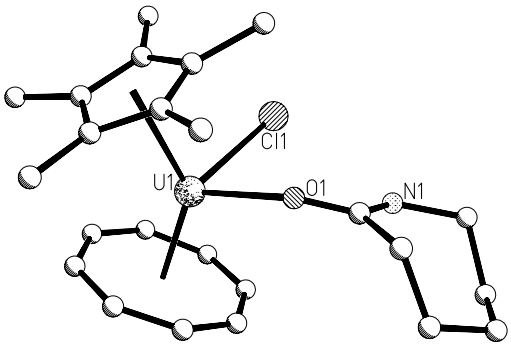


Fig. 5. A ball and stick representation of one enantiomer of $(C_5Me_5)(C_8H_8)U(Cl)[OCNH(CH_2)_5]$ (**3**). The molecules of hexane that co-crystallize with **3** have been omitted.

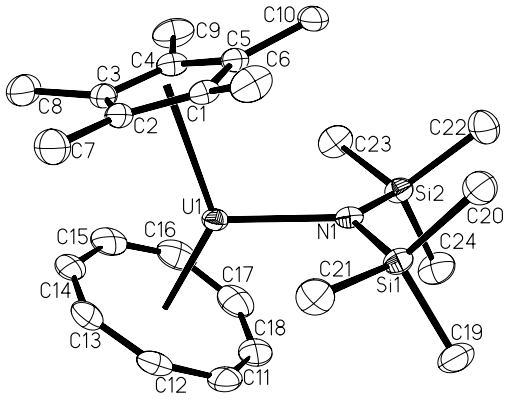

Fig. 6. Thermal ellipsoid plot of $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (**4**), drawn at the 50% probability level.

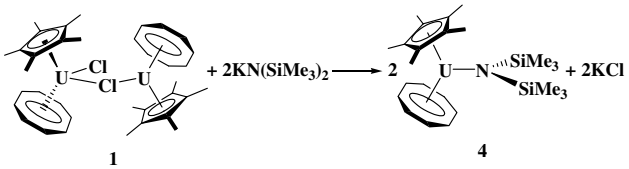
different ligands with the $(C_5Me_5)^{1-}$ and $(C_8H_8)^{2-}$ ring centroids occupying two corners of a distorted tetrahedron. The chloride and ε-caprolactam ligands occupy the other two sites and the caprolactam ring is oriented to allow the amide proton to hydrogen bond to the chloride. Enantiomers of **3** co-crystallize as a racemic mixture in the solid state, Fig. 5.

3.4. Substitution chemistry of *1*

Although addition of $K_2C_8H_8$ did not result in substitution of both chloride ligands in $(C_5Me_5)_2UCl_2$, the second chloride can eventually be removed when **1** is treated with $KN(SiMe_3)_2$. The reaction of **1** with $KN(SiMe_3)_2$ to form $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (**4**), Eq. (4), is analogous to a $[(C_5Me_5)(C_8H_8)ThCl]_2$/$KN(SiMe_3)_2$ reaction reported earlier [9]:



(4)

Complex **4** was characterized by ^1H NMR spectroscopy and its structure was confirmed by X-ray crystallographic analysis, Fig. 6. The resonances attributable to the $(C_5Me_5)^{1-}$ and $(C_8H_8)^{2-}$ ligands in the ^1H NMR spectra of **4** in benzene-d_6 and toluene-d_8 at 298 K are well resolved while the resonance for the $[N(SiMe_3)_2]^{1-}$ ligand is broadened almost completely into the baseline. At 336 K, the $[N(SiMe_3)_2]^{1-}$ resonance sharpens and the peak areas for the three ligands are as expected, 15:8:18, respectively. At 208 K, three resonances are observed for the $[N(SiMe_3)_2]^{1-}$ ligand with equal peak areas of 6. This suggests that the rotation of the trimethylsilyl substituents of the amide ligand is frozen at lower temperatures rendering each pair of methyl groups inequivalent as found in the solid state structure, Fig. 6. Complex **4** undergoes hydrolysis to form C_5Me_5H, $HN(SiMe_3)_2$, and C_8H_8 as the major products. Deuterolysis of **4** similarly gives C_5Me_5D, $DN(SiMe_3)_2$, and C_8H_8. Only small amounts of the reduced 1,3,5-cyclooctatriene and 1,5,7-cyclooctatriene were observed by GC–MS (<10% of the C_8H_8 peak).

3.5. Structure of $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (*4*)

The U–C(C_5Me_5) bond distances in **4**, which range from 2.763(5) to 2.823 Å and average 2.79(3) Å, are similar to those observed in **1**. As in other uranium mixed $(C_5Me_5)^{1-}/(C_8H_8)^{2-}$ metallocenes [43], the U–C(C_5Me_5) distances in **4** are longer than the U–C(C_8H_8) distances which range from 2.659(6) to 2.737(5) Å and average 2.70(3) Å. The 2.515 Å U–(C_5Me_5 ring centroid) and 1.990 Å U–(C_8H_8 ring centroid) distances are shorter than analogous distances in $(C_5Me_5)(C_8H_8)Th[CH(SiMe_3)_2]$, 2.54 and 2.03 Å [9], respectively, which is consistent with difference in ionic radii [35]. The 134.7° (C_5Me_5 ring centroid)–U–(C_8H_8 ring centroid) angle is similar to the analogous angles in **1**, Table 2, and the 138.1° angle in $(C_5Me_5)(C_8H_8)Th[CH(SiMe_3)_2]$ [9].

As was observed for the trivalent analogue of **4**, namely $(C_5Me_5)_2U[N(SiMe_3)_2]$ [21], the amide is bound symmetrically to the uranium ion as evidenced by the U(1)–N(1)–Si angles of 119.5(2)° and 117.7(2)° and the similar U(1)–Si distances. The 2.284(4) Å U(1)–N(1) distance is similar to those in other U(IV) amides [44] such as $[(Me_3Si)_2N]_2UCl_2$, 2.231(8) and 2.238(7) Å [45], $[(Me_3Si)_2N]_3U[O(C_6H_3{}^tBu_2)]$, 2.29(1), 2.29(1) and 2.28(1) Å [46], and $[Me_2Si(C_5Me_4)(^tBuN)]U(NMe_2)$, 2.278(4) and 2.207(4) Å [47]. The U(1)–N(1) distance in **1** is shorter than the 2.352(2) Å U–N distance in trivalent $(C_5Me_5)_2U[N(SiMe_3)_2]$ which is consistent with the differences in ionic radii and coordination number [35]. The U(1)–N(1) distance is substantially shorter than the 2.54(1) Å Th–C[$CH(SiMe_3)_2$] distance in $(C_5Me_5)(C_8H_8)Th[CH(SiMe_3)_2]$ [9].

Table 2
Selected bond distances (Å) and angles (deg) for $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)(C_5Me_5)$ (**1**) and $(C_5Me_5)(C_8H_8)U[N(SiMe_3)_2]$ (**4**)

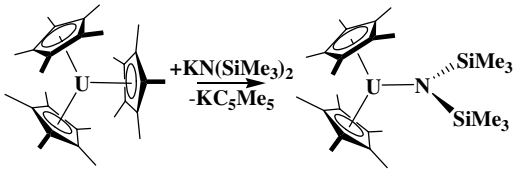
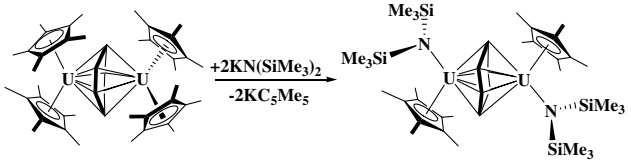
4. Discussion

The formation of **1** from $(C_5Me_5)_2UCl_2$ and $K_2C_8H_8$ represents a rare example of $(C_5Me_5)^{1-}$ ligand displacement for $(C_5Me_5)_2UCl_2$, a complex which has been such an important source of the $[(C_5Me_5)_2U]^{2+}$ unit in tetravalent uranium metallocene chemistry. $(C_5Me_5)^{1-}$ displacement via ionic salt metathesis has been recently observed with the sterically crowded complexes $(C_5Me_5)_3U$ and $[(C_5Me_5)_2U]_2(C_6H_6)$, Eqs. (5) and (6) [48],



(5)



(6)

but this is more reasonable since it relieves steric strain. Steric factors could also explain the unexpected loss of $(C_5Me_5)^{1-}$ in the synthesis of **1** if the reaction proceeded through some highly crowded intermediates, such as "$(C_5Me_5)_2UCl(C_8H_8)K$." In addition, the product that would form if two chlorides were displaced, "$(C_5Me_5)_2U(C_8H_8)$", has never been isolated, but is expected to be sterically crowded [25].

In any case, the $(C_5Me_5)_2UCl_2/K_2C_8H_8$ reaction provides a convenient route using mild conditions to an unsolvated U(IV) metallocene that contains an open coordination site. As demonstrated by the ε-caprolactam reaction, Eq. (3), complex **1** is an arene soluble option for the evaluation of the coordination chemistry of U(IV) in a metallocene environment when a mixed ligand metallocene coordination geometry is acceptable. An advantage of the mixed ligand nature of **1** is that addition of any ligand immediately generates a chiral metal center ligated with four different groups.

Replacement of the chloride in **1** with another anion generates heteroleptic complexes like **4** that have three different ligands. Such completely heteroleptic complexes are generally difficult to synthesize because ligand redistribution reactions lead to the more common and favored bis(pentamethylcyclopentadienyl) complexes or tris(cyclopentadienyl) complexes in the case of the smaller $(C_5H_5)^{1-}$ ligands.

5. Conclusion

The synthesis of $(C_5Me_5)(C_8H_8)ClU(\mu\text{-}Cl)U(C_8H_8)$-$(C_5Me_5)$ (**1**), provides a soluble, sterically unsaturated U(IV) complex that can be conveniently prepared and used to evaluate U(IV) coordination chemistry in a

neutral metallocene environment. The fact that this complex can be prepared by $(C_5Me_5)^{1-}$ displacement demonstrates that the pentamethylcyclopentadienyl ligands of $(C_5Me_5)_2UCl_2$ can be separately cleaved using the appropriate reagents. Complex **1** should be a good precursor to completely heteroleptic tri- and tetrasubstituted U(IV) metallocenes [4–6].

6. Supporting material

Details on data collection and refinement, fractional atomic coordinates, anisotropic displacement parameters and full list of bond lengths and angles in CIF format has been deposited at the Cambridge Crystallographic Data Centre, CCDC No. 269609–269611 for compounds **1–3**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Abstract

The conversion of *N*,*N*′-dilithiobis(alkylamido)phenylboranes [RN–B^{Ph}–NR]Li_2 (R = ^{t}Bu (**1**), ^{i}Pr (**2**)) to the equivalent dithallium(I) bisamides proceeds readily through the reaction with two molar equivalents of thallous chloride. The thallium amides [RN–B^{Ph}–NR]Tl_2 (R = ^{t}Bu (**3**), ^{i}Pr (**4**)) have been prepared and characterized by ^{1}H and ^{11}B{^{1}H} NMR. Single crystal X-ray structures of **2**–**4** reveal the formation of aggregates in the solid state.

1. Introduction

Many metal amides form aggregates in the solid state [1,2]. Aggregate formation is governed by steric constraints of the solid state structure, the presence of bridging ligands, and electrostatic interactions between the metal ion and amide [3]. Most extended amide structures involve lithium as the metal ion with a paucity of structurally characterized amide aggregates of other non-alkali metal cations such as thallium(I). The latter cation is of interest because extended structures may involve metallophillic interactions between the two $6s^2$ filled shell thallium(I) atoms due to dispersion forces [4]. Recent work by Gade [5] has begun to shed light on the aggregation properties of such systems. In these instances, closed-shell metal–metal interaction, as well as metal–arene interactions and the relatively low coordination numbers common to thallium(I) play a significant role in supporting extended structures of unusual patterns of aggregation.

We have recently developed a transition metal chemistry for bis(alkylamido)phenylboranes, [RN–B^{Ph}–NR]$^{2-}$, by reacting dilithio salts of bisamides with metal dihalides [6–8]. Since the dilithiobis(amido) species are so important to our synthetic schemes, they warranted characterization. Similarly, we wished to develop analogous dithallium(I) diamides as a metathetical alternative owing to the less reducing properties of thallium transmetallation agents. We now report the synthesis, spectroscopic characterization, and solid state structures of lithium and thallium aggregates of bis(alkylamido)phenylborane ligands. We find that the thallium amido complexes produce brightly colored species possessing interesting extended solid state structures.

2. Experimental

2.1. General procedures

All manipulations were carried out using modified Schlenk techniques under an atmosphere of N_2 or in a Vacuum Atmosphere HE-553-2 glove box. Solvents for synthesis were of reagent grade or better and were dried according to standard methods [9]. *N*,*N*′-dilithiobis(isopropylamido)phenylborane and *N*,*N*′-dilithiobis(*tert*-butylamido)phenylborane were prepared by literature methods [10]. All other materials were used as received.

2.2. Preparation of [RN–B^{Ph}–NR]Tl_2, R = ^{t}Bu (3) and R = ^{i}Pr (4)

Pentane solutions (7 ml) containing 400 mg of [RN–B^{Ph}–NR]Li_2 (R = ^{t}Bu (**1**) (1.64 mmol); R = ^{i}Pr (**2**) (1.85 mmol)) were frozen. Upon partial thawing, solid thallous chloride was added in three parts (800 mg (3.34 mmol) to **1**; 900 mg (3.75 mmol) to **2**) to the dilithiodiamide solutions. Some black precipitate formed immediately (thallium metal). The solution slowly turned yellow over the course of 3 h, with significant black precipitate forming. The mixture was allowed to stir for 24 h. Solvent was removed in vacuo, and 15 ml of toluene was added. The solution was then filtered through Celite to remove thallium metal and LiCl. Solvent was removed in vacuo from the resulting clear red-orange solution, yielding 539 mg (51.4% yield) of red crystalline solid **3** and 620 mg (54.5% yield) of orange powder **4**. Yields are based upon dilithium starting material. The resulting complexes readily decompose at room temperature in solution or in the solid state, but are stable for months when stored at −35 °C. *Anal.* data for **3**. ^{1}H NMR (300 MHz, C_6D_6, 25 °C) δ 1.330 (s, 18H), 7.0-7.4 (m, 5H) $^{11}B\{^1H\}$ NMR (160.490 MHz, C_6D_6, 25 °C) δ 25.454. *Anal.* data for **4**. ^{1}H NMR (300 MHz, C_6D_6, 25 °C) δ 1.280 (d, 12H, $J = 6.000$ Hz), 5.578 (br s, 2H), 7.2–7.5 (m, 5H) $^{11}B\{^1H\}$ NMR (160.490 MHz, C_6D_6, 25 °C) δ 26.843.

2.3. Physical methods

^{1}H NMR spectra were recorded on solutions at 25 °C within the magnetic fields of a Varian Mercury 300 spectrometer, which was located in the Department of Chemistry Instrumentation Facility (DCIF). Chemical shifts are reported using the standard δ notation in ppm. ^{1}H NMR spectra were referenced to residual solvent peak. $^{11}B\{^1H\}$ NMR spectra were collected at the DCIF on a Varian Inova 501 spectrometer and referenced to an external $BF_3 \cdot OEt_2$ standard at 0 ppm.

X-ray diffraction experiments were performed on single crystals grown from concentrated pentane (**2**), toluene (**3**) or pentane/ether (**4**) solutions at −35 °C. Crystals were removed from the supernatant liquid and transferred onto a microscope slide coated with Paratone N oil. Selected crystals were affixed to a glass fiber in Paratone N oil and cooled to −90 (**3**) or −173 (**2**, **4**) °C. Data collection was performed by shining Mo Kα ($\lambda = 0.71073$ Å) radiation onto crystals mounted onto a Bruker CCD diffractometer. The data were processed and refined by using the program SAINT supplied by Siemens Industrial Automation, Inc. The structures were solved by direct methods (SHELXTL v6.10,

3. Results and discussion

The dilithio salts of bis(alkylamido)phenylboranes are readily prepared from the reaction of the parent amine with 2 equiv. of *n*-BuLi. The *tert*-butyl analogue [^{t}BuN–B^{Ph}–N^{t}Bu]Li$_2$ (**1**) has previously been prepared [11] and structurally characterized [12]. The structure exhibits a heterocubane Li and N core that is familiar to other difunctional lithium amides [13–15]. The isopropyl derivative has also been reported previously, but is presented structurally here for the first time. The structure of [^{i}PrN–B^{Ph}–N^{i}Pr]Li$_2$ possesses a trimeric configuration, demonstrating a distorted Li_6N_6 hexagonal prismatic core (Fig. 1). Such configurations have been observed in iminolithium hexamers [16]. Table 2 lists selected bond lengths and angles for **2**. The monomeric Li_2N_2 core possesses metric parameters similar to that observed for the *tert*-butyl analogue, with N–B distances ranging from 1.437(2) to 1.439(2) Å and Li–N distances of 2.012(7) to 2.117(7) Å. The N–B–N angle (112.03(15)–112.9(2)°) and bite angle (N–Li–N = 70.9(2)–76.5(3)°) are also consistent with the monomeric core of [^{t}BuN–B^{Ph}–N^{t}Bu]Li$_2$. One methyl unit on each isopropyl group appears to have an agostic C(–H)···Li contact (d(C–Li) = 2.419(8) Å). This is consistent with the ^{1}H NMR, which exhibits two methyl resonances [8], indicating that the trimeric structure is maintained in solution. It is interesting to note the change in aggregation from a dimeric to a trimeric unit, with this

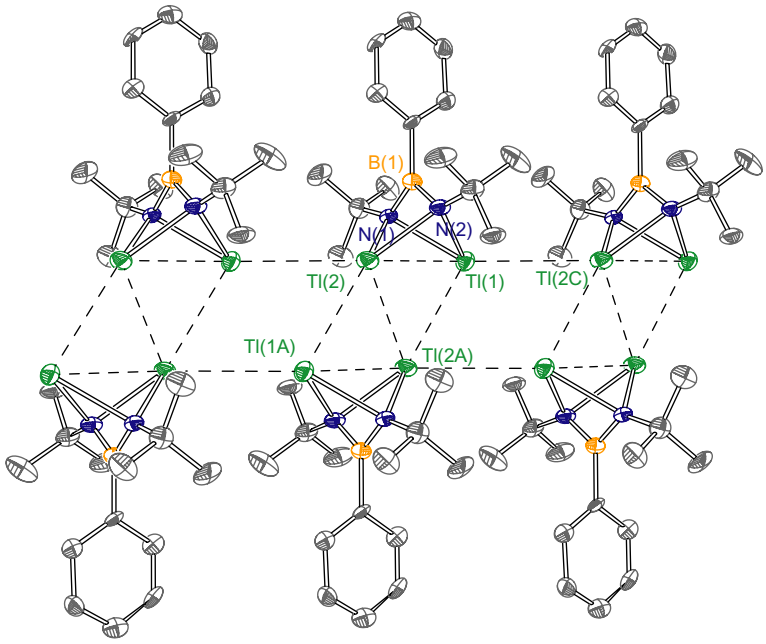

Fig. 2. Solid state structure of [^{t}BuN–B^{Ph}–N^{t}Bu]Tl$_2$ (**3**) showcasing three dimeric units and weak intermolecular thallium–thallium contacts. Thermal ellipsoids are shown at the 50% probability level.

small variance in steric bulk. This has also been observed by Brask et al. [17] for [^{t}BuN–B$^{n\text{Bu}}$–N^{t}Bu]Li$_2$ and [^{t}BuN–B$^{\text{Et}}$–N^{t}Bu]Li$_2$ with analogous dimeric and trimeric structures, respectively. In this instance, however, the difference in the steric bulk originates from the substituents on the boron bridgehead, rather than on the amido nitrogens.

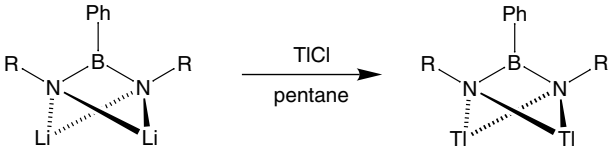
Taking these dilithio salts and stirring them in a pentane solution with thallous chloride for 24 h led to the formation of the thallium(I) amides **3** and **4**.



(1)

R = ^{t}Bu (**1**), ^{i}Pr (**2**) R = ^{t}Bu (**3**), ^{i}Pr (**4**)

Both complexes are soluble in aromatic and ethereal solvents, and are stable in solution or the solid state in a nitrogen atmosphere at −35 °C for months. Warming to room temperature or exposure to air results in the facile decomposition of these thallium(I) diamides to generate thallium metal. ^{1}H NMR exhibits only a single *tert*-butyl resonance for **3** and a single set of isopropyl resonances for **4**. A single peak is observed in the ^{11}B{^{1}H} NMR spectra of both species. Single crystal X-ray analysis of these thallium(I) bisamides demonstrate an interesting pattern of molecular packing in the solid state.

Recrystallization of **3** from a concentrated toluene solution afforded deep red single crystals. The asymmetric unit of the complex possesses a single dithallium unit that has a molecular structure in which two nitrogen and two thallium(I) atoms form a puckered spirocycle. This structure is

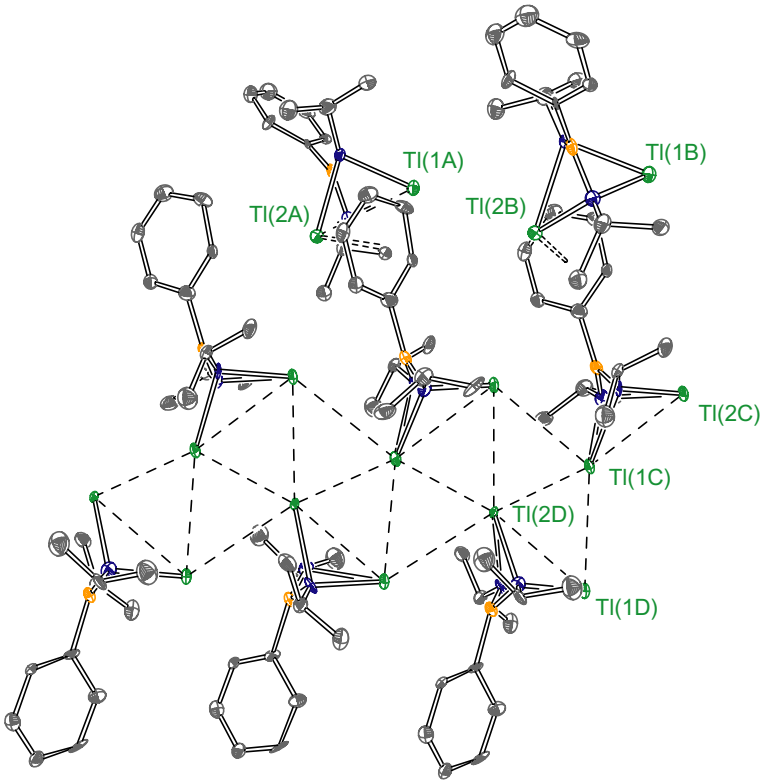


Fig. 3. Solid state structure of [^{i}PrN–B$^{\text{Ph}}$–N^{i}Pr]Tl$_2$ (**4**) demonstrating both thallium–thallium and thallium–arene interactions. Thermal ellipsoids are shown at the 50% probability level.

consistent with the observed motif in the monomeric units of the dilithium structures, with ligand metrics almost identical to those observed in **1** and **2**. This monomeric unit has been observed previously by Hellmann et al. [18] for other difunctional thallium(I) amides. Table 3 lists selected bond lengths and bond angles for **3**. The fairly short Tl···Tl distance in **3** is likely due to the nature of the bridging ligand, though it is of an appropriate length for a Tl···Tl metallophilic interaction (d(Tl···Tl) = 3.3877(18) Å). In the solid, molecular units of **3** aggregate into dimeric sets, where each thallium ion has a close contact with two intermolecular thallium atoms. The result is a pair of edge sharing triangles, with Tl···Tl distances of 3.228(3) along the shared edge and 3.5394(19) Å along the outer edge (Fig. 2). Hellmann et al. [19] have observed this type of edge sharing triangular dimerization previously in a trithallium system. Unlike the trithallium system, however, this system has additional intermolecular Tl···Tl contacts of 3.772(2) Å, resulting in a rare example [18,20,21] of an infinite chain thallium(I) amide compound.

Recrystallization of **4** from a pentane/ether solution at −35 °C, yields dark orange single crystals that demonstrate a truly unique solid state structure. Selected bond lengths and angles for **4** are listed in Table 4. The asymmetric unit possesses four dithallium units, all of which possess similar Tl_2N_2 cores and ligand metrics as **3** with slightly shorter Tl···Tl contacts (d(Tl···Tl) = 3.2653(16)–3.2667(14) Å). Two of these monomeric units aggregate to form an infinite chain of edge sharing triangles (Fig. 3). Each dithallium set of a monomeric unit forms a triangle with one thallium of another dithallium set through very close contacts of 2.950(2) and 3.004(2) Å. The remaining Tl···Tl contacts are significantly longer, ranging from 3.3727(8) to 3.5330(18) Å. The other two monomeric units are not involved in aggregation, but instead demonstrate a metal–arene interaction. One thallium from each of these units has a contact of 3.496(18) Å from the plane of the phenyl rings of the ligands in the aggregation polymer. This distance is consistent with other arene interactions in thallium(I) amide species (d(Tl···C) = 3.34–3.74 Å) [22]. The effects of thallium–arene interactions in the aggregation of thallium(I) amides has been examined by Gade and co-workers [22,23], who have shown the Tl–arene interaction to be close to the Tl···Tl interaction in influence on aggregate formation.

The marked change in the mode of aggregation between **3** and **4** results from the modest size difference between *tert*-butyl to isopropyl amido substituents, respectively. The *tert*-butyl derivative has two symmetrically inequivalent thallium atoms that possess three and four Tl···Tl close contacts, respectively. The reduced steric encumbrance of isopropyl groups permits greater access to thallium atoms. The result is an increased number of Tl···Tl contacts to a maximum of five for thallium atoms in the infinite chain of **4**. The *tert*-butyl derivative possesses thallium triangles that share a single edge, while the isopropyl derivative possesses thallium triangles sharing two edges, as well as exhibiting closer Tl···Tl contacts. Interestingly, though **4**

possesses an increase in number and a shortening of Tl···Tl contacts in the infinite chain, half of the thallium units are instead occupied with aryl interactions.

We began our foray into the synthesis and structural investigation of the dilithium and dithallium complexes **1**–**4** to develop viable transmetallation agents for the delivery of bis(alkylamido)phenylborane ligands. The dilithio species have proven to be effective in this transmetallation. We have found, in the case of the dithallium species, that the thermal instability of the complexes appears to limit the effectiveness of **3** and **4** as metathesis reagents. Regardless of the effectiveness of these complexes for transmetallation reactions, the investigation into their solid state structures showed interesting new aggregation patterns. The effects of the metallophilic Tl···Tl interactions play a significant role in the formation of an unprecedented structure-type.

Dedicated with respect to Professor Malcolm H. Chisholm on the occasion of his 60th birthday. Happy birthday Malcolm!

Abstract

$[Me_2Si(C_5Me_4)_2]MoH_2$ reacts with furan and benzofuran to yield products resulting from C–H bond cleavage, namely $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_4H_3O)H$ and $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_8H_5O)H$, whereas the corresponding reactions of selenophene and benzoselenophene yield products resulting from C–Se bond cleavage, namely $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ and $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_8H_6)$. On this basis, the reactivity of the selenophene derivatives is analogous to that of previously reported thiophene derivatives, while the reactivity of the furan derivatives is unique. DFT calculations indicate that C–E (E = O, S, Se) bond cleavage is thermodynamically more favored than C–H bond cleavage for each of the chalcogen derivatives. As such, the calculations provide evidence that C–O bond cleavage of the furan derivatives is not observed because of kinetic factors. DFT calculations also demonstrate that the observation of C–S bond cleavage of thiophene by the *ansa* metallocene $[Me_2Si(C_5Me_4)_2]MoH_2$ and C–H bond cleavage by Cp_2MoH_2 is dictated by thermodynamic factors. Specifically, the Me_2Si *ansa* bridge thermodynamically favors $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ over $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$ because the bridge promotes a shift in the coordination of the cyclopentadienyl rings from η^5-coordination towards η^3-coordination and this thermodynamically unfavorable modification is stabilized by sulfur-to-metal π-donation within $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$.

Keywords: Molybdenum; Hydrodesulfurization; Hydrodenitrogenation; Ansa metallocene; Furan; Thiophene; Seleneophen

1. Introduction

Hydrodesulfurization (HDS) is the largest volume and most important industrial catalytic application of transition metals and is the process by which sulfur containing impurities are removed from crude petroleum feedstocks and fuels [1,2]. Thiophenes, in particular, are a class of molecules that are most resistant towards hydrodesulfurization and have consequently featured prominently as substrates for model studies [2,3]. However, despite the fact that molybdenum is the most essential transition metal component of a typical HDS catalyst [4], the majority of model studies pertaining to HDS of thiophene has focused on metals other than molybdenum [5–9]. For this reason, we have initiated a series of studies directed towards activating thiophene by molybdenum compounds and have reported the first examples of thiophene C–S bond cleavage by molybdenum. Specifically, we have demonstrated that: (i) the *ansa* molybdenocene dihydride complex $[Me_2Si(C_5Me_4)_2]MoH_2$ photochemically achieves cleavage of the C–S bond of thiophene to give $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ (Scheme 1) [10]; (ii) $Mo(PMe_3)_6$ reacts with thiophene to yield the η^5-thiophene adduct $(\eta^5\text{-}C_4H_4S)Mo(PMe_3)_3$ and the butadiene–thiolate complex $(\eta^5\text{-}C_4H_5S)Mo(PMe_3)_2(\eta^2\text{-}CH_2PMe_2)$ (Scheme 2) [11–13]. In this paper, we describe the reactivity of $[Me_2Si(C_5Me_4)_2]MoH_2$ towards the oxygen and selenium counterparts of thiophene, namely furan and selenophene. These studies demonstrate that the course of the reaction between

$[Me_2Si(C_5Me_4)_2]MoH_2$ and EC_4H_4 is strongly influenced by the nature of the chalcogen (E = O, S, Se).

2. Results and discussion

2.1. Computational analysis of the thermodynamics of thiophene C–H versus C–S bond cleavage

The ability of $[Me_2Si(C_5Me_4)_2]MoH_2$ to cleave the C–S bond of thiophene and give the metallacycle $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ is not only significant because it represents the first example of thiophene C–S bond cleavage by a molybdenum compound, but it is also noteworthy because related molybdenocene complexes such as $Cp^*_2MoH_2$ and Cp_2MoH_2 do not exhibit analogous reactivity [10]. For example, the non-*ansa* counterpart $Cp^*_2MoH_2$ is inert to thiophene under comparable conditions and yields only a product of *intramolecular* C–H bond activation, namely $Cp^*(\eta^5,\eta^1\text{-}C_5Me_4CH_2)MoH$ (Scheme 1), thereby providing an interesting example of an *ansa* effect [14]. In contrast to the inertness of $Cp^*_2MoH_2$ towards thiophene, Cp_2MoH_2 is reactive. However, the reaction of Cp_2MoH_2 with thiophene gives a thienyl–hydride complex $Cp_2Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$ via cleavage of the α C–H bond (Scheme 1) [5a,15], rather than a metallathiacycle $Cp_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ via cleavage of the C–S bond; the corresponding tungsten complex, Cp_2WH_2, however, reacts with thiophene to give products derived from both C–H and C–S bond cleavage [5a,16].

While the difference in reactivity between $[Me_2Si(C_5Me_4)_2]MoH_2$ and $Cp^*_2MoH_2$ may be readily interpreted in terms of $Cp^*(\eta^5,\eta^1\text{-}C_5Me_4CH_2)MoH$ being exceptionally stable with respect to $[Cp^*_2Mo]$ compared to that of the *ansa* counterpart [17,18], the C–S versus C–H bond cleavage reactivity of $[Me_2Si(C_5Me_4)_2]MoH_2$ and Cp_2MoH_2, respectively, is not so easily rationalized. Therefore, to help explain this difference in reactivity, we have performed DFT calculations to establish the relative energies of the various C–H and C–S bond cleavage products. Furthermore, since the reaction of $[Me_2Si(C_5Me_4)_2]MoH_2$ with dibenzothiophene resulted in the formation of an η^1-*S*-dibenzothiophene adduct [10,19], we have also calculated the energies of the corresponding η^1-*S*-thiophene isomers that result from coordination of thiophene to the molybdenum center without either C–H or C–S bond cleavage.

With respect to the $\{[Me_2Si(C_5Me_4)_2]Mo\}$ system, the geometry optimized structures of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$, *endo*-$[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$, *exo*-$[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$, and $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}SC_4H_4)$ are illustrated in Fig. 1. The thiophene-derived fragment in each of these complexes lies in the equatorial metallocene plane, with the exception of the thiophene adduct $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}SC_4H_4)$, for which the angle between the molybdenum and the thiophene plane is 170°. The displacement of the metal out of the thiophene plane in η^1-thiophene complexes has been attributed to minimizing filled–filled repulsions between the sulfur π-lone pair and the metal center [20].

The relative energies of the geometry optimized structures are listed in Table 1. Significantly, the calculations indicate that the experimentally observed metallathiacycle $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ obtained by C–S bond cleavage is more stable than both (i) the thienyl–hydride resulting from C–H bond cleavage $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$ and (ii) the η^1-thiophene adduct $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}SC_4H_4)$ resulting from coordination without bond cleavage, as illustrated in Fig. 2. However, while the calculations indicate that the C–S bond cleavage product is the most stable, the calculations do not provide any indication as to whether the formation of $[Me_2Si(C_5\text{-}$

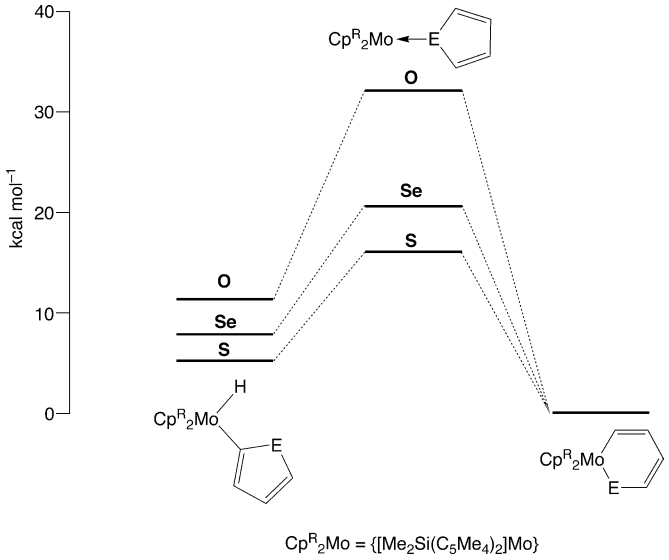

Fig. 2. Relative energies of geometry optimized structures of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,E\text{-}EC_4H_4)$, $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}EC_4H_3)H$, and $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}EC_4H_4)$ (E = O, S, Se).

$Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ is actually dictated by kinetic factors, i.e., is $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ obtained because the molybdenum center is kinetically incapable of cleaving the C–H bond of thiophene? Evidence against the latter is provided by the fact that $\{[Me_2Si(C_5Me_4)_2]Mo\}$ reacts with the C–H bond of benzene to give $[Me_2Si(C_5Me_4)_2]Mo(Ph)H$ [14,17], thereby indicating that there should not be an inherent kinetic problem with the ability of the $\{[Me_2Si(C_5Me_4)_2]Mo\}$ molybdenocene fragment to react with the C–H bond of thiophene. Thus, assuming that both molybdenocene fragments $\{[Me_2Si(C_5Me_4)_2]Mo\}$ and $[Cp_2Mo]$ have the ability to react with C–H and C–S bonds, the different reactivities towards thiophene may be attributed to thermodynamic factors. In this

regard, products of thiophene C–S bond cleavage are often considered to be more thermally stable than those of C–H bond activation [21], but examples are known in which the order is reversed [22]. For example, Jones has reported that the thienyl–hydride $Cp^*Rh(PMe_3)(\eta^1\text{-}C\text{-}C_4H_3S)H$ converts to the more stable metallathiacycle $Cp^*Rh(PMe_3)(\eta^2\text{-}C,S\text{-}SC_4H_4)$ at 25 °C [21b,23], whereas Carmona has reported that the closely related metallathiacycle $[Tp^{Me_2}]Rh(PMe_3)(\eta^2\text{-}C,S\text{-}C_4H_4)$ converts to the thienyl–hydride $[Tp^{Me_2}]Rh(PMe_3)(\eta^1\text{-}C\text{-}SC_4H_3)H$ upon heating at 90 °C [22].

To ascertain the influence of the molybdenocene fragment on the relative stabilities of the three isomers, i.e., thienyl–hydride, metallathiacycle, and thiophene adduct, analogous DFT calculations were performed on the $[Cp_2Mo]$ and $[Cp^*_2Mo]$ systems (Table 1). Most interestingly, whereas the C–S bond cleavage product $(Cp^R)_2Mo(\eta^2\text{-}C,S\text{-}C_4H_4)$ is 5.1 kcal mol^{-1} more stable than the C–H bond cleavage product $(Cp^R)_2Mo(\eta^1\text{-}C\text{-}C_4H_3S)H$ for the *ansa*-molybdenocene $\{[Me_2Si(C_5Me_4)_2]Mo\}$ system, the calculations indicate that the isomers are of comparable energy for the $[Cp_2Mo]$ ($\Delta E =$ 0.1 kcal mol^{-1}) and $[Cp^*_2Mo]$ ($\Delta E = 1.0$ kcal mol^{-1}) systems, as illustrated in Fig. 3 [24]. The calculations, therefore, demonstrate that the *ansa* bridge confers stability to the metallathiacycle relative to the thienyl–hydride and thereby provide a thermodynamic explanation for the different reactivities of Cp_2MoH_2 and $[Me_2Si(C_5Me_4)_2]MoH_2$ towards thiophene.

The origin of the stabilizing effect for the metallathiacycle isomer in the *ansa* metallocene system is the geometrical perturbation that results from the presence of a Me_2Si bridge. In general, upon incorporating a Me_2Si bridge, the cyclopentadienyl groups are displaced from their natural positions such that (i) the Cp_{cent}–M–Cp_{cent} (γ) angle decreases and (ii) the angle between the M–Cp_{cent} vector and the ring normal (τ) increases, thereby resulting in a

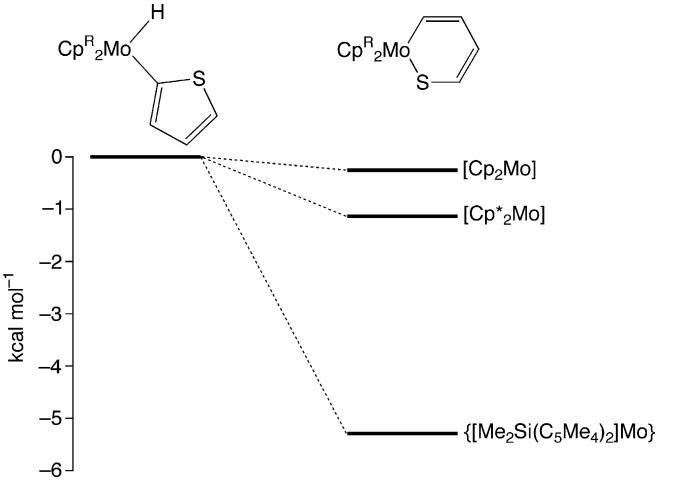

Fig. 3. Relative energies of geometry optimized structures of $(Cp^R)_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ and $(Cp^R)_2Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$. The Me_2Si *ansa* bridge thermodynamically favors the $(Cp^R)_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ derivative.

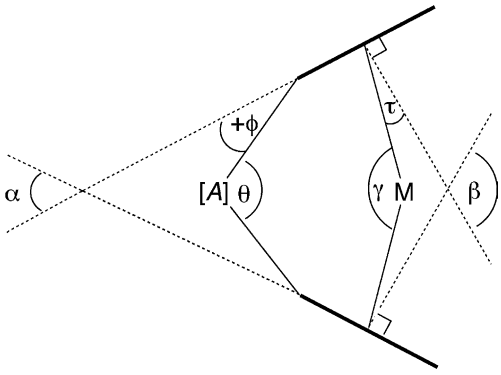

$\alpha = 180 - \beta$; $\alpha = 2\tau - \gamma + 180$; $\tau = 0.5(\gamma - \beta)$

Fig. 4. Parameters that define metallocene geometries and their relationships.

shift in coordination of the cyclopentadienyl rings from η^5-coordination towards η^3-coordination (Fig. 4) [25,26]. While this shift in coordination mode results in destabilization of a molybdenocene complex, the extent of the destabilization would be less for the metallathiacycle than for the thienyl–hydride derivative because sulfur-to-metal lone pair donation in the former isomer provides an ameliorating effect, as conceptually illustrated in Fig. 5. Thus, relative to the thienyl–hydride compound, the metallathiacycle derivative becomes more stable for the *ansa* molybdenocene system (Fig. 5). The effect is synergistic, with sulfur-to-metal lone pair donation providing a mechanism to facilitate displacement of the cyclopentadienyl rings. An indication of the displacement of the cyclopentadienyl ligands in the metallathiacycle is provided by consideration of the geometry optimized structures of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$, $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$ and $[Me_2Si(C_5Me_4)_2]Mo(SC_4H_4)$. For example, the calculated Mo–C bond lengths for the cyclopentadienyl groups in $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ (2.32–2.53 Å), *endo*-$[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$ (2.28–2.48 Å) and $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}SC_4H_4)$ (2.28–2.39 Å) clearly indicate that the cyclopentadienyl ligands in the metallathiacycle are displaced from the molybdenum center to a greater degree than for the other two derivatives.
