The magnetochemical studies of the mononuclear complex **1** in the temperature range 2–290 K revealed that the magnetic susceptibility χ decreases with increasing temperature, which is indicative of the paramagnetic character of the complex. The Curie–Weiss law is followed in the whole

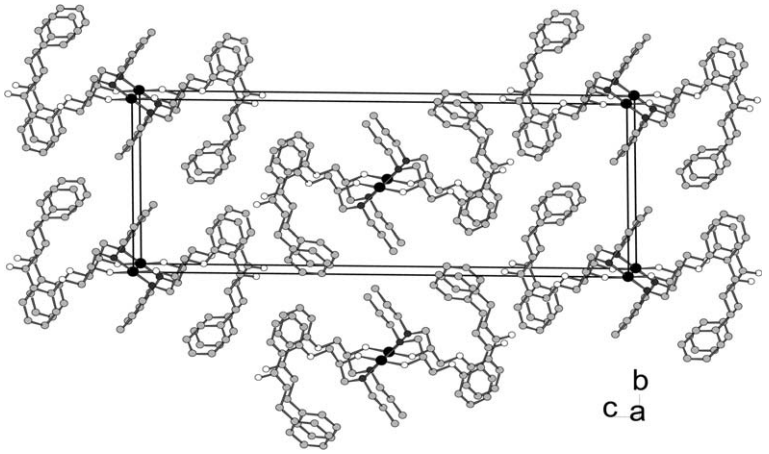

Fig. 3. Unit cell and 3D packing in complex **1**.

temperature range studied with a correlation coefficient of 0.9943. The effective magnetic moment determined with a value of the Weiss constant $\theta = -16$ was $\mu_{eff} = 1.70\mu_{eff}/\mu_B$.

The fulfillment of the Curie–Weiss law indicates that the Cu^{2+}-ions are in an octahedral crystal field, as μ_{eff} does not depend on the temperature. The experimentally found magnetic moment is lower than the theoretical one, which for a crystal field of 10 000 cm^{-1} is about $2.01\mu_{eff}/\mu_B$ [27]. The smaller value of the experimental magnetic moment is probably due to a weak intermolecular antiferromagnetic exchange interaction between the copper centers. This assumption is in accordance with the X-ray data showing a distance of 4.711 Å between the copper ions in axial positions along the *a*-axis.

3.1.5. Thermogravimetric data

The thermogravimetric (TG) study confirmed the elemental analysis, the IR and X-ray data that there is no solvent included in the isolated mononuclear species **1**.

3.2. Binuclear $Cu_2Pr_2Cl_2$ complex **2**

3.2.1. Electronic and IR spectra

The UV–Vis spectra of the complex **2** in methanol show two absorption bands: a broad band of low intensity at 710 nm ($\varepsilon \approx 40$ l mol^{-1} cm^{-1}) assigned to a d–d transition in the near square-planar copper(II) structure, and a second, more intense one at 385 nm ($\varepsilon \approx 1330$ l mol^{-1} cm^{-1}), that is typical for copper(II) polynuclear complexes with oxygen bridges of the type Cu—O—Cu. This band has been attributed to a charge-transfer transition O → Cu, which explains its higher intensity [28,29].

The IR spectra of **2** show that the *v*(NH) band is shifted 110 cm^{-1} to lower frequency, in comparison with the same band in the free ligand, while *v*(OH) is absent, indicating that the ligand is coordinated again through its NH group and deprotonated OH function. This conclusion is supported also by the appearance of new bands in the far IR-spectrum at 590, 415 and 270 cm^{-1} ascribed to the stretching vibrations *v*(Cu—N), *v*(Cu—O) and *v*(Cu–Cl), respectively [26].

3.2.2. NMR spectra

Additional information about the coordination mode of the ligand in **2** was obtained by a comparison between the NMR spectra of the free ligand and complex **2**. In the ^{13}C spectrum of **2** the signals for C_7, C_8, C_9, C_{10}, $C_{11}$and C_{12} (at 70.40, 64.79, 49.73, 48.80, 18.71 and 10.97 ppm, respectively) disappeared, due to the strong influence of the adjacent paramagnetic copper(II) centers, bonded to O^- and NH functions. At the same time the intensities of the signals for the other C-atoms remained practically unchanged. Analogous results were revealed also by the ^1H NMR spectra of the ligand and complex **2**. Here again a strong decrease in the intensities down to a complete disappearance was observed for the proton signals of the NH- and OH-groups (9.05 and 5.94 ppm) and for those bonded with the carbon atoms C_7, C_8, C_9, C_{10}, C_{11} and C_{12} (at 4.12, 4.27, 3.08, 2.72, 1.64 and 0.04 ppm, respectively), while the intensities for the protons at the other C-atoms were practically unchanged. Such effects have been already observed with another copper(II) complex with an aminoalcohol drug [1,16,30].

These results confirmed again the coordination sites of the ligand in the complexes formed with copper(II).

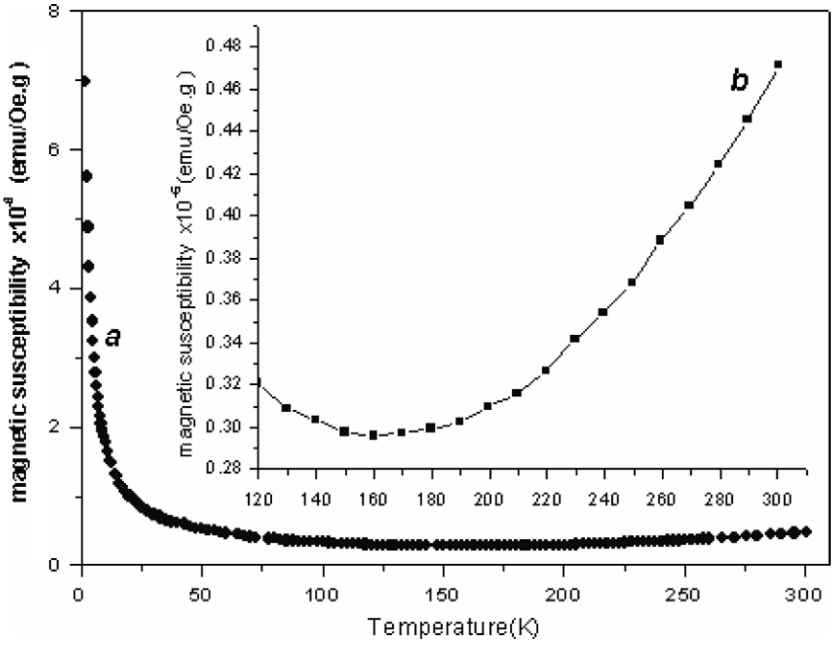

Fig. 4. Magnetic susceptibility vs. *T* for the binuclear complex **2**, measured at 1kOe applied field: (a) in the range 2–300 K; (b) in the range 120–300 K, χ_g being shown in a different scale.

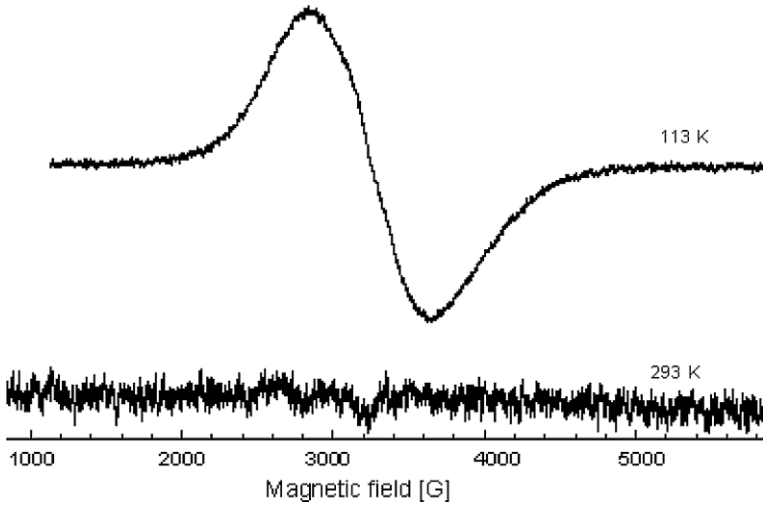

Fig. 5. The X-band EPR-spectra of the methanolic green solution of complex **2**.

3.2.3. Magnetochemical and EPR data

The temperature dependence of the specific magnetic susceptibility χ_g is given in Fig. 4a. In the range 2–150 K the complex shows a typical paramagnetic character. At temperatures above 150 K, χ_g begins to increase (Fig. 4b). The Curie–Weiss law is not followed in the whole temperature range (2–300 K). This complicated behaviour of χ_g could be considered as a result of superposition of the data for two different components. The first is a paramagnetic one, present as a monomeric impurity. The second component is an antiferromagnetic one, formed as a result of an intramolecular indirect exchange interaction between the copper(II) centers. An analogous course of the χ_g/T plot is also observed for other copper(II) complexes, described in the literature [31–35].

According to the theory [36,37] for complexes with closely located copper centers, the χ versus T plot must have a different course and is expected to pass through a maximum. In the present system such a maximum was not yet reached in the temperature range studied.

Similar effect must be also expected for the EPR spectra, measured at low and high temperatures. Fig. 5 shows the EPR spectra of the complex at 113 and 293 K in solution. Analogous spectra were obtained also with a solid state sample. At low temperatures the typical broad signal for paramagnetic Cu(II) has been observed. At higher temperatures the increased antiferromagnetic interaction leads to the complete quenching of the signal.

3.2.4. Thermogravimetric (TG) data

The TG study showed that, as in **1**, there are no solvent molecules included in the structure.

4. Conclusion

Propafenone forms two complexes with copper(II) – the mononuclear $CuPr_2$ (**1**) and the binuclear $Cu_2Pr_2Cl_2$ (**2**). In both cases the drug acts as a bidentate ligand through its NH- and deprotonated OH-functions. In **1** only two ligands are coordinated around copper(II), while in **2**, each one of the two metal centers are bound by one nitrogen, by one terminal chlorine and by two deprotonated OH-groups from two different propafenone molecules, forming oxygen bridges between the metal centers in the $Cu_2Pr_2Cl_2$ chromophore. No solvent molecules have been detected in the crystal structures of **1** and **2**. The relatively short distance between the two metal centers in **2**, linked by the oxygen bridges, leads to the appearance of a measurable antiferromagnetism.

5. Supplementary information

Full crystallographic details have been deposited in cif-format with the Cambridge Crystallographic Data Centre, CCDC 279128 for **1**. Copies of this information could be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033, email: deposit@ccdc.cam.ac.uk, web: http://www.ccdc.cam.ac.uk/conts/retrieving/html).

2. Experimental

2.1. Materials

The starting compound tetramethyldiamidophosphoric acid chloride was prepared according to [14] and isolated via double distillation on b_8 106–107 °C [15] and *p-tert*-butylcalix[4]arene was synthesized according to procedure reported [16].

All solvents used, $NaClO_4 \cdot H_2O$ and $NaAuClO_4 \cdot 2H_2O$ were purchased from Fluka AG and Aldrich. The solvents were dried before use by standard procedures.

2.2. Analytical and physicochemical measurements

Elemental analyses for C, H, N were performed by Dr. H. Eder from the Microchemical Laboratory of the University of Geneva, of P – according to the method described in [17], of Cl in the Laboratory of Elemental Analysis of the Department of Chemistry, University of Sofia, Bulgaria.

The atomic absorption analysis (AAA) for Na and Au was performed on a Perkin–Elmer 1100 B spectrometer. The IR spectra were recorded on a FT-IR spectrometer "IFS 113v Bruker" (KBr and CsI pellets), ^1H, $^{13}C\{^1H\}$-DEPT-135, $^{31}P\{^1H\}$ NMR spectra were recorded (solvent $CDCl_3$) on a "Bruker Biospin Avance 400". Chemical shifts (δ) are expressed in ppm from $(CH_3)_4Si$; J values are in Hertz. In the NMR spectra, the Ar notation defines the aromatic nuclei of the calixarene backbone, considering the phenol oxygen as the main substituent to which the *ipso*, *ortho*, *meta* and *para* position refer. A DEPT spectrum was used to distinguish resonances belonging to tertiary or quaternary carbons.

The ES-MS spectra were obtained on a Finnigan SSQ 710C spectrometer using 10^{-5}–10^{-4} M solutions in methanol, capillary temperature 200 °C and acceleration potential 4.5 kV. In the case of the ligand, the liquid phase was $CH_3OH/H_2O/HCOOH$ 50/50/1 (by volume) and in the case of the complexes – CH_3OH. The FAB-MS spectra were obtained on a Fision VG Autospect instrument employing 3-nitrobenzyl alcohol as a matrix.

2.3. Synthesis of L

A solution of tetramethyldiamidophosphoric acid chloride (3.46 g, 20.3 mmol) in toluene (20 cm^3) was added dropwise to a refluxed fine suspension of the sodium derivative of *p-tert*-butylcalix[4]arene in toluene. The latter was prepared by addition of sodium (0.47 g, 20.3 mmol) to a solution of *p-tert*-butylcalix[4]arene (2.92 g, 4.5 mmol), methanol (50 cm^3) and toluene (150 cm^3), followed by remove of methanol by distillation. The suspension thus obtained was refluxed with stirring under a nitrogen atmosphere for 60 h. After cooling the reaction system it was washed repeatedly with water until a negative reaction for chloride ions was obtained, followed by drying over Na_2SO_4 and evaporation of the solvent. The yield of the crude product was 3.83 g (72%). The latter was recrystallized from DMSO; m.p. 305–310 °C with decomposition ($R_f = 0.57$, C_6H_{12}:$CHCl_3$:CH_3COOH 7:3:1 v/v). Calc. for $C_{52}H_{78}N_4O_6P_2$ (917.16): C, 68.10; H, 8.57; N, 6.11; P, 6.75. Found: C, 67.96; H, 8.60; N, 6.00; P, 6.67. IR (KBr disc, cm^{-1}): ν(P=O) 1242 cm^{-1}, ν(P–O–Ph) 1186(s), δ(P–N–CH_3) 1306, ν(Ar–OH) 3538.

2.4. Synthesis of [NaL]$AuCl_4 \cdot 4H_2O$ (1)

An ethanolic solution of L (0.020 g, 0.0218 mmol in 1.5 ml) and $NaAuCl_4 \cdot 2H_2O$ (0.0079 g, 0.0218 mmol in 1 ml) were mixed with constant stirring at ambient temperature, resulting in the formation of a yellow precipitate. The latter was centrifugated, washed repeatedly with ethanol and dried under high vacuum over P_4O_{10} for 4 h. Yield: 0.0274 g (95.47%). Calc. for $C_{52}H_{84}N_2O_9P_2Cl_4AuNa$ (1332.9): C, 46.86; H, 6.35; Cl, 10.64; Au, 14.78; Na, 1.72. Found: C, 46.55; H, 6.51; Cl, 9.05; Au, 15.06; Na, 1.75%. IR (KBr and CsI pellet, cm^{-1}) ν(P=O) 1200 (s), ν(P–O–Ph) 1169(s), ν(P–N–CH_3) 999 (s), ν(Ar–OH) 3561(s), $AuCl_4^-$ vibrations [18]: $\nu_1 = 361$, $\nu_2 = 140$, $\nu_4 \sim 324$ (sh).

2.5. Synthesis of [Na_2L_2](ClO_4)$_2 \cdot 4CH_3OH$ (2)

Methanolic solutions of L (0.020 g, 0.0218 mmol in 1 ml) and $NaClO_4 \cdot H_2O$ (0.0031 g, 0.0218 mmol in 1 ml) were mixed and stirred for 1 week at ambient temperature, resulting in the formation of a colourless precipitate of $[Na_2L_2](ClO_4)_2 \cdot 4CH_3OH$.

2.6. X-ray crystallography for L and [Na_2L_2](ClO_4)$_2 \cdot 4CH_3OH$ (2)

Basic crystallographic data for the free ligand and the complex, data collection and structural refinement are listed in Table 1.

Single crystals of the ligand L suitable for X-ray diffraction were obtained from DMSO solution of the compound by slow evaporation of the solvent. Diffraction data were collected at 143 K on a mar345 Imaging Plate. Data reduction was performed with marHKL release 1.9.1 [19]. The structure solution was determined with ab initio direct methods [20]. The structure was refined using the full-matrix least-squares on F^2 with all non-H atoms anisotropically defined. H atoms were placed at calculated positions using the «riding model» with $U_{iso} = a \times U_{eq}(X)$ [where a is 1.5 for CH_3 and OH groups and 1.2 for others, while X is the parent atom]. Structure refinement, molecular graphics and geometrical calculation have been carried with the SHELXTL software package, release 5.1 [21].

Colourless transparent single crystals of $[Na_2L_2](ClO_4)_2 \cdot 4CH_3OH$ were obtained from a methanolic solution of the compound by slow evaporation of the solvent.

Largest differential peak and hole (e Å^{-3})	0.456 and −0.220	1.091 and −0.507

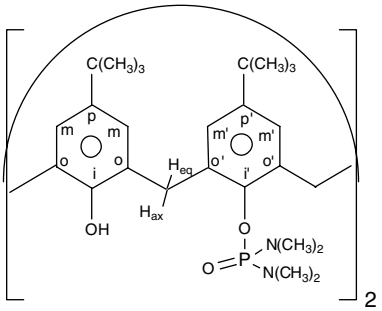
These crystals are stable only in the presence of CH_3OH. If they are dried, a sharp increase of the lattice defects appears leading to a quick collapse of the crystal lattice. This phenomenon has been observed for other compounds as well, where the solvent is fundamental for retainment of the crystal lattice [9]. For this reason the intensity data were collected from crystals sealed in a quartz capillary in the presence of the solvent.

Data collection was performed on a mar345 IPDS diffractometer system by using graphite-monochromated Mo Kα (0.71070 Å) radiation at 140(2) K. Data reduction was performed by CrysAlis RED, release 1.7.0 [22]. A semiempirical absorption correction [23] was applied to the raw data set. Structure solution, refinement and molecular graphics were performed by using the SHELXTL release 5.1 [21] software package. The structure was solved by direct methods and successive interpretation of the difference Fourier maps, followed by full-matrix least-squares refinement (against F^2). All atoms were refined anisotropically. The contribution of the hydrogen atoms, at their calculated positions, was included in the refinement using a riding model (except the hydrogen belonging to the bridging methanol). Some geometrical restraints (card DFIX) have been employed for the coordinating ClO_4^- anion. Crystallographic data are in cif format.

3. Results and discussion

3.1. Synthesis and structural characterization of L

The ligand was prepared in 72% yield by refluxing the sodium derivative of *p-tert*-butylcalix[4]arene and tetramethyldiamidophosphoric acid chloride in toluene.



L

3.1.1. Crystal structure of the ligand

The orientation of the four aromatic rings, which lie below the reference plane passing through the four CH_2 bridging groups, determine the well known flattened cone conformation of the molecule (Fig. 1).

Above the reference plane a top hydrophilic part of the molecule is formed by the hydroxyl groups and the phosphoamide groups. Compound L has an elliptic conformation testified by the following geometric parameters:

(a) The angles between the aromatic rings of the calix[4]-arene are:
[A^C = 9.92°; B^D = 80.41°; A^B = 84.23°; B^C = 88.33°; C^D = 83.46°; A^D = 88.89°], where [A(C1, C2, C3, C4, C5, C6); B(C8, C9, C10, C11, C12, C13); C(C15, C16, C17, C18, C19, C20); D(C22, C23, C24, C25, C26, C27)].
The two opposite rings (A^C = 9.92°) are almost parallel while the other two (B^D = 80.41°) are almost perpendicular.

(b) The distances between the opposite *t*-butyl groups are: [C29...C37 = 6.199(6) Å; C33...C41 = 11.967(7) Å]. The steric orientation of the four *t*Bu groups is different due to free rotation around C–*t*Bu, which is conformationally advantageous.

Parameters dealing with the two P atoms are in good agreement with the presence of double bonds between P1 and O5 [1.457(3) Å] and P2 and O6 [1.451(3) Å] whereas all the other bond lengths refer to single ones [P–O_{av} = 1.623(2) Å, P–N_{av} = 1.624(3) Å]. Both P=O groups are oriented in opposite directions.

The geometry around the two P atoms is, as expected, tetrahedral, showing some distortions [O5–P1–N1 = 116.3(2)°, N1–P1–O1 = 98.1(2)°, O6–P2–N4 = 115.9(2)°, N4–P2–O3 = 98.4(1)°]. O5 and O6 interact only weakly with –$N(Me)_2$ or –CH_2-groups [O5···H48B = 2.48 Å, O5···H7A = 2.49 Å, O5···H45B = 2.69 Å; O6···H21A = 2.46 Å, O6···H49B = 2.54 Å, O6···H51B = 2.63 Å].

The torsion angles [C2–C1–O1–P1 = 98.08°; C16–C15–O3–P2 = 99.17°] show almost one and the same orientation of the P=O groups towards the aromatic part of the molecule. This fact explains the presence of only one $\nu_{P=O}$ band in the IR spectrum.

The molecular structure is stabilized by the formation of two strong intramolecular H-bonds: O2···O1 and O4···O3 (Table 2). The 3D packing of the molecules is stabilized by intermolecular hydrogen bonds of C–H···O type and C–H···π(Ph) interactions (Table 2, Fig. 2).

In the unit cells two calixarene molecules are present (Fig. 3a), arranged head to tail.

3.1.2. Structure of L in solution

The NMR and ES-MS data obtained (Tables 3–5) show the existence of the cone structure of the ligand in solution as well. The ^{1}H NMR data (Table 3) correspond to the structure of the cone symmetrical 1,3-esterificated *p-tert*-butylcalix[4]arene and not to 1,2-esterification, as the ^{1}H NMR spectrum shows only signals for one kind of Ar–CH_2–Ar protons present. The resonances of these protons are two doublets with equal $^2J_{HH}$ of 13.8 Hz. An additional evidence of the molecule symmetry is the fact that only two kinds of Ar–*H* protons are present. The resonance signals for two kinds of $(CH_3)_3C$ were registered too: one for the non-esterificated unit and the second for the esterificated one. The first one is observed at a stronger field (δ 0.83 ppm) and the second at δ 1.34 ppm. Moreover, the

[24]. Also only singlets are observed for the aromatic carbon atoms in the $^{13}C\{^1H\}$ spectrum in $CDCl_3$ (Table 4) and the $^{13}C\{^1H\}$ NMR shows only one absorption for the bridging methylene carbon at 32.1 ppm.

The only resonance signal for the $^{31}P\{^1H\}$ NMR is a singlet, whilst that of ^{31}P NMR is septet at the same shift.

3.2. Synthesis and characterization of the complex $[NaL]^+[AuCl_4]^-\cdot 4H_2O$ (*1*)

The elemental analysis data for complex **1** indicates the formation of the complex salt $[NaL]^+[AuCl_4]^-\cdot 4H_2O$. The IR data available are also in agreement with this supposition as in the range 500–150 cm^{-1} region three bands due to $AuCl_4^-$ vibrations are observed (see Section 2).

Comparing the IR spectral data for the free ligand and the complex in the range 4000–400 cm^{-1}, a significant shift of the P=O valent vibration is observed – from 1242 to 1200 cm^{-1} thus indicating coordination of the P=O groups via the O atom. This supposition was supported by $^{31}P\{^1H\}$ NMR data – in the $^{31}P\{^1H\}$ NMR spectrum of complex **1** a shift from 16.62 to 16.84 ppm is seen (Table 3).

All the resonances of complex **1** in the ^1H , $^{13}C\{^1H\}$ and DEPT-135 NMR spectra (see Tables 3 and 4) also show the cone conformation of the ligand.

Both ES-MS and FAB spectral data confirm the formation of the complex salt (Table 5). The corresponding spectra display peaks due to $[L + Na]^+$, $[L]^+$ and $[L + H]^+$ species.

The presence of four H_2O molecules was proved by TG analysis. In the temperature range 50–200 °C a mass loss of 5.5% is observed, the calculated one being 5.4%.

3.3. Crystal structure for $[Na_2L_2](ClO_4)_2\cdot 4CH_3OH$ (*2*)

The X-ray structure of complex **2** is shown in Fig. 4. It is evident that the whole molecule lies over an inversion centre and comprises of 2 calix[4]arene ligands, $2Na^+$, $2(ClO_4)^-$ and $4CH_3OH$. Each of the calix[4]arene ligands participate in the complex, bonded to Na^+ only by one of the P=O groups. It should be noted that both Na^+ cations are placed outside of the ligand cavities. As in free L, the modified calix[4]arenes show an elliptic conformation. The asymmetric unit contains a calix[4]arene molecule coordinated to Na^+ via a P=O group. At the same time, each cation is coordinated to one ClO_4^- (Na^+ is directly bonded to one oxygen of the perchlorate), one terminal and two bridging CH_3OH molecules.

The geometric parameters of the ligand in complex **2** are as follows:

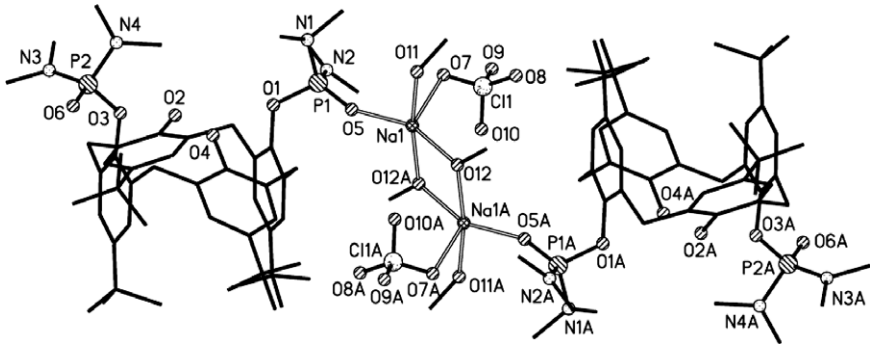

Fig. 4. Crystal structure of complex **2**.

Table 6
H-bond lengths in complex **2**

D	H	A	D–H	H···A	D···A	D–H···A	Symmetric codes
O2	H2	O3	0.84	2.16	2.987(6)	166.2	
O4	H4	O1	0.84	2.38	3.204(6)	166.3	
O11	H11	O6	0.84	1.93	2.707(7)	152.8	$-1-x, -1-y, -z$
C47	H47A	O3	0.98	2.62	3.404(4)	137.3	$-x, -1-y, -z$
C45	H45A	C9	0.98	2.78	3.67(3)	151.4	$-x, -1-y, -z$

(a) The dihedral angles are:
[A^C = 3.72°; B^D = 74.57°; A^B = 88.72°; B^C = 86.40°; C^D = 85.65°; A^D = 82.20°], where [A(C1, C2, C3, C4, C5, C6); B(C8, C9, C10, C11, C12, C13); C(C15, C16, C17, C18, C19, C20); D(C22, C23, C24, C25, C26, C27)].
(b) The torsion angles:
C2–C1–O1–P1 = 80.98° (at the coordinated P═O group)C16–C15–O3–P2 = 104.20°.

There are two complex molecules in the unit cell (Fig. 3b) arranged head to tail and exhibiting a cone conformation of the ligand.

The geometrical parameters of both P atoms are in good agreement with those found for the free ligand L. In the complex a number of inter and intramolecular hydrogen bonds are formed (Table 6).

The formation of intramolecular hydrogen bonds of the type O–H···O is realized within the ligand moiety, though, due to the coordination of Na^+ via the P═O group, the hydrogen bond distances are different. Two intramolecular H-bonds exist in the complex: in the ligand part [O2···O3 (at P-uncoordinated) = 2.987 Å and O4···O1 (at P-coordinated) = 3.204 Å]. In addition there is one intermolecular H-bond: O6–O11 = 2.708 Å (between the oxygen of the uncoordinated P═O group of the ligand and a terminal CH_3OH of the neighboring complex moiety). It was impossible to find the position of the OH hydrogen atom. In spite of that, it is evident that there is a strong hydrogen bond between the O12···O10 (ClO_4) atoms, because the O12···O10 distance is 2.740 Å. The 3D packing of the complex moiety is stabilized by C–H···π(Ph) interactions, similarly to that in the structure of L (Table 6).

*3.4. Comparison between the structure of the ligand L and complex **2***

Both compounds crystallize in the $P\bar{1}$ space group. The coordination seems to play a negligible influence on the general features of the ligand conformation and structure. In fact the lattice parameter *a*, which depends mainly on the steric interactions between calixarenes, does not change significantly in both structures; while the length of the *c* axis, which depends mainly on the size of the ions housed in the intermolecular cavity, shows a small but significant increase passing from the free ligand to the complex $[Na_2L_2](ClO_4)_2 \cdot 4CH_3OH$ (Fig. 3a and b). The bond distances and angles within the calix[4]arene moiety are comparable in both compounds. The molecular geometry characteristics of complex **2** are only slightly different, as it was mentioned above.

4. Conclusion

A new ligand, containing two functional groups, phosphine oxide and tertiary amide, on the same arm has been synthesized. The Na^+ coordination does not induce a serious conformation change in the ligand part of the complex. The complexation is realized outside the ligand cavity. The presence of phenyl rings leads to the formation of a series of C–H···π(Ph) interactions, which together with hydrogen bonds stabilize the 3D packing of both structures.

5. Supplementary Data

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC reference numbers 282678 and 282679. Copies of this information may be obtained free of charge from CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgments

The authors thank Prof. Dr. Sci. T. Spassov from the Department of Chemistry, Sofia University for running the TG analysis. This work was supported through a grant from the Swiss National Science Foundation (Project SCOPES 7BUPJ062293.00/1).

easy oxidation of copper(I) to copper(II) has retarded the progress of research on copper(I) compounds considerably.

Very few two-coordinated copper(I) complexes comprising simple unidentate nitrogen donor ligands without any steric bulk are represented in the literature. The structurally characterized ones are even rarer primarily due to the relative instability of two-coordinated copper(I) compounds [6–10]. Different strategies have been employed to overcome the challenge of stabilizing cuprous ions. Sorrell et al. observed that two-coordinate linear copper(I) complexes with sterically hindered heterocyclic ligands having increased orbital overlap between the ligating atoms and copper(I) are inert toward reaction with CO and less reactive with O_2 in aprotic solvents [6]. However, in protic solvents, these complexes react rapidly and irreversibly with dioxygen to form Cu^{2+}. Sanyal et al. also observed a similar phenomenon in a two-coordinate linear complex of copper(I) with the imidazole ligand [7]. On the other hand, Le Clainche et al. emphasized the importance of preorganization of the metal binding site provided by the calix[4]-arene platform and an increased orbital overlap between the imidazole-nitrogen atom and copper(I) as the key features for the inertness of copper(I) ions toward dioxygen in the solid state as well as in coordinating or protic solvents [8]. However, the analogous pyridine-based complex is extremely sensitive to air and undergoes auto-oxidation within seconds [8]. Recently, we have demonstrated a simple model system with a unidentate ligand that allows more geometrical freedom as well as exceptional inertness toward dioxygen [10]. The unusual stability was attributed to the electronic factors provided by the 4-aminophthalimide moiety of the ligand framework and the perchlorate counteranion moieties [10]. In this study, we now establish that the extraordinary stabilization of the copper(I) complexes is provided by the electron deficient 4-aminophthalimide moiety of the ligand framework and the perchlorate counteranion by presenting a new ligand system $\mathbf{L^2}$ and its copper(I) complex $\mathbf{Cu(L^2)_2}$. This new copper(I) complex, which has been characterized by X-ray crystallography, is also highly resistant towards oxidation in the solid state and is stable in air even in potentially coordinating or protic solvents. However, the present complex, in which the metal center is more separated from the 4-aminophthalimide moieties, exhibits lesser stability than $\mathbf{Cu(L^1)_2}$. Thus, the electronic factor provided by an electron-deficient 4-aminophthalimide moiety is indeed one of the key features for the stabilization of cuprous ions. The single crystal structure of both the ligand systems, $\mathbf{L^1}$ and $\mathbf{L^2}$, are also described in this report.

2. Experimental

2.1. Materials and methods

The solvents used in this study, dioxane, tetrahydrofuran and acetonitrile were rigorously purified following standard procedure [11]. 4-Aminophthalimide (TCI (Japan)) was recrystallized twice from ethanol for spectroscopic measurements but used as received for synthesis. All other reagents are commercially available and used as received. Column chromatography was performed using Brockman I activated neutral aluminium oxide (150 mesh). Thin-layer chromatography (TLC) analysis was performed using Merck F254 aluminium oxide-60 and viewed by UV light. IR spectra were recorded on a Jasco FT-IR/5300 spectrometer as KBr pellets. NMR spectra were recorded on a Bruker AVANCE 400 MHz spectrometer at ambient temperature and were referenced to the internal ^1H and ^{13}C solvent peaks. EPR spectra were recorded on a Jeol JES-FA200 spectrometer. Solution electrical conductivities were measured with a Digisun DI-909 conductivity meter. *Caution:* The copper complexes contain perchlorate ions, which can detonate explosively and without warning. Although we have encountered no incidents with the reported compounds, all due precautions should be taken.

2.2. Synthesis of 2-(4′-aminophthalimidomethyl)pyridine ($\boldsymbol{L^1}$)

4-Aminophthalimide (0.5 g, 3.09 mmol) and 2-aminomethylpyridine (0.38 mL, 3.7 mmol) were placed in a 25-mL pear-shaped flask fitted with a water condenser and potassium hydroxide guard tube. The reaction mixture was heated at 65 °C with constant stirring for 6 h. The sticky material thus formed was purified by column chromatography on neutral alumina using chloroform as an eluent to obtain the desired product that was further recrystallized from chloroform/hexane to yield a yellow crystalline solid. Single crystals suitable for X-ray crystallography were grown by the slow evaporation of the chloroform solution over a period of several days. Yield: 0.7 g, 90%.

CHN *Anal*. Calc. for $C_{14}H_{11}N_3O_2$: C, 66.4; H, 4.35; N, 16.6. Found: C, 65.8; H, 4.24; N, 16.4%. IR (KBr, cm^{-1}): 3422, 3312, 1769, 1696, 1618; ^1H NMR ($CDCl_3$, 25 °C): δ (ppm) = 4.45 (s, 2H), 4.96 (s, 2H), 6.79 (dd, 1H), 6.99 (d, 1H), 7.14 (m, 2H), 7.56–7.60 (m, 2H), 8.51 (d, 1H); ^{13}C NMR ($CDCl_3$, 25 °C): δ (ppm) = 168.84, 168.51, 155.72, 153.46, 148.96, 137.20, 134.68, 12 5.33, 122.57, 121.46, 119.14, 117.71, 108.38, 42.43.

2.3. Synthesis of 2-(4′-aminophthalimidoethyl)pyridine ($\boldsymbol{L^2}$)

4-Aminophthalimide (0.5 g, 3.09 mmol) and 2-aminoethylpyridine (0.44 mL, 3.7 mmol) were placed in a 25-mL pear-shaped flask fitted with a water condenser and potassium hydroxide guard tube. The reaction mixture was heated at 80 °C with constant stirring for 6 h. Initially a clear solution was formed which then solidified into a thick mass, which was triturated and washed with hexane. Recrystallization from chloroform/hexane yielded the desired product as a yellow crystalline solid. Single crystals suitable for X-ray crystallography were grown by the slow evaporation of the chloroform solution over a period of several days. Yield: 0.76 g, 92%.

CHN *Anal. Calc.* for $C_{15}H_{13}N_3O_2$: C, 67.42; H, 4.87; N, 15.73. Found: C, 67.1; H, 4.78; N, 15.55%. IR (KBr, cm^{-1}): 3401, 3350, 1755, 1696, 1615; ^1H NMR ($CDCl_3$, 25 °C): δ (ppm) = 3.15 (t, 2H), 4.04 (t, 2H), 4.33 (s, 2H), 6.79 (dd, 1H), 6.99 (d, 1H), 7.14–7.18 (m, 2H), 7.56–7.60 (m, 2H), 8.51 (d, 1H); ^{13}C NMR ($CDCl_3$, 25 °C): δ (ppm) = 168.89, 168.63, 158.0, 153.44, 148.77, 137.07, 134.51, 125.0, 123.58, 121.89, 119.0, 117.46, 108.11, 37.43, 36.48.

2.4. Synthesis of $[Cu(L^2)_2]ClO_4$ ($Cu(L^2)_2$)

To a solution of L^2 (4 mmol) in 1:1 methanol–acetonitrile (50 mL), $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) dissolved in methanol (20 mL) was added drop-wise and the resulting solution was stirred for 24 h at room temperature and filtered. The filtrate was subsequently stored for slow evaporation to afford brown colored crystals suitable for X-ray crystallography. Conductivity measurements of both the complexes reveal the 1:1 cation:anion ratio. Both the complexes are EPR silent.

$Cu(L^2)_2$: Yield: 65%; IR (KBr, cm^{-1}): 3437, 3360, 1752, 1689, 1609, 1076; ^1H NMR (CD_3CN, 25 °C): δ (ppm) = 3.12 (t, 2H), 3.92 (t, 2H), 5.12 (bs, 2H), 6.85 (dd, 1H), 6.94 (d, 1H), 7.34–7.39 (m, 2H), 7.48 (d, 1H), 7.82 (m, 1H), 8.48 (b, 1H).

2.5. Collection and reduction of X-ray data

A tiny single crystal was mounted on the tip of a glass fiber and then mounted on the goniometer. The X-ray data for L^1, L^2 and $Cu(L^2)_2$ were collected on a Bruker CCD X-ray diffraction system with graphite-monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å) controlled by a Pentium-based PC running the SMART software package [12]. The raw data frames were integrated by the SAINTPLUS program package [12]. Empirical absorption corrections were applied with the SADABS program [12] and the space group was determined by examining systematic absences and confirmed by the successful solution and refinement of the structure. The structures were solved by direct methods for L^1 and L^2; by Patterson methods for $Cu(L^2)_2$ and refined by full matrix least-squares and difference Fourier techniques with SHELXTL [12]. Multipurpose crystallographic tools, PLATON [13], ORTEP-3 [14] and MERCURY [15] were used for molecular graphics. Hydrogen atoms attached to amine nitrogen atoms were introduced as found on the Fourier difference maps and refined with the restraint N–H = 0.87 Å and a displacement parameter equal to 1.5 times that of the parent atom. All other hydrogen atoms were introduced geometrically and refined using a riding model with a displacement parameter equal to 1.2 (CH, CH_2) times that of the parent atom. All non-hydrogen atoms were refined anisotropically. The high proportion of weak reflections for $Cu(L^2)_2$ is due to the not very good quality of the crystal. In fact, during the refinement process, a disorder of position was observed for the terminal oxygen atom of the perchlorate anion that was split over two distinct sites with an occupancy factor of 0.5 each.

2.6. Steady-state absorption and emission spectroscopy

The UV–Vis absorption spectra were recorded using a Shimadzu spectrophotometer (UV-3101PC). Steady-state emission spectra were recorded with a Spex spectrofluorimeter (Fluoromax-3). All spectra were corrected for instrumental response. The fluorescence quantum yield of the samples was determined relative to that of 4-aminophthalimide ($\phi_f = 0.7$ in tetrahydrofuran) [16].

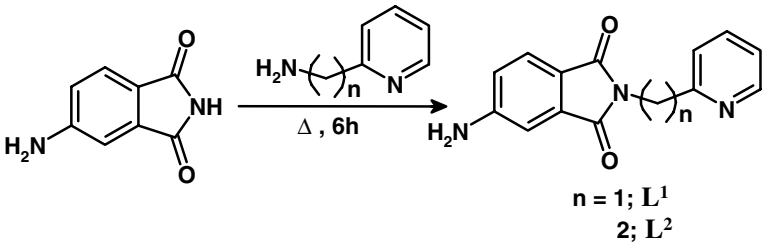
2.7. Cyclic voltammetry

A CH-Instruments model 620A electrochemical analyzer was used for cyclic voltammetric experiments with acetonitrile solutions of the systems containing $[Bu_4N]ClO_4$ as supporting electrolyte. The three-electrode measurements were carried out at room temperature under nitrogen atmosphere with a platinum disk working electrode, a platinum wire auxiliary electrode and a saturated calomel reference electrode. The potentials reported are uncorrected for junction contributions.

3. Results and discussion

3.1. Synthesis

The syntheses of the ligands L^1 and L^2 are straightforward and high yielding. The reaction of 4-aminophthalimide with neat 2-aminomethylpyridine or 2-aminoethylpyridine at 65 or 80 °C yielded L^1 or L^2 respectively (Scheme 1). The copper(I) complex, $Cu(L^2)_2$, was prepared by reacting L^2 with $Cu(ClO_4)_2 \cdot 6H_2O$ in 1:1 methanol–acetonitrile at room temperature for 24 h. One novel aspect about the synthesis of these complexes is that neither the use of any external reducing agent nor that of the relatively unstable copper(I) salt is needed. The relative stability of copper(I) and copper(II) in solution depend very strongly on the nature of the anions and the ligands present and vary considerably with solvent or nature of the neighboring atoms [10]. When the reaction was carried out with 1:2 metal–ligand molar ratio, the yield of the desired complex reduces substantially, suggesting that the ligand systems L^1 or L^2 acts as a reducing agent for Cu^{2+} [10]. It should be noted here that when the corresponding NO_3^- salt was used, neither the Cu^{2+} nor the Cu^+ complex could be isolated. Thus, the ClO_4^- anion also plays an important role in the stabilization Cu^+. In recent years, hydrothermal/solvothermal reactions under pressure have been used as a synthetic strategy to reduce various metal ions, including copper. Thus, the simultaneous reduction of copper(II) and formation of a two-coordinate copper(I) complex has significant implication with a synthetic viewpoint.



Scheme 1.

3.2. Absorption and fluorescence properties

The absorption and fluorescence spectra of $\mathbf{L^1}$, $\mathbf{L^2}$ and $\mathbf{Cu(L^2)_2}$ are characterized by broad bands, typical of the transition to the intramolecular charge-transfer state of the fluorophore moiety. A typical plot in acetonitrile (AN) is shown in Fig. 1. The 4-aminophthalimide moiety in these systems gives rise to a charge transfer transition in the UV–Vis region due to the push-pull effect of the electron-donating amino and the electron-withdrawing carbonyl groups of the fluorophore. Both the absorption and the fluorescence spectra are red-shifted (9–10 nm in absorption and 14–22 nm in the fluorescence) relative to the parent fluorophore. Apart from the spectral shift, the photophysical behavior of these systems are similar to that of the parent fluorophore, 4-aminophthalimide. These systems exhibit high fluorescence quantum yield ($\phi_f \sim 0.8$ in AN). The fluorescence quantum yield of the complexes is found to be slightly lower ($\phi_f \sim 0.6$ in AN) than that of their respective ligand systems, which could be due to the interaction of the fluorophore with the metal center. The photophysical data of the present systems in acetonitrile are listed in Table 1.

3.3. Structural studies. Crystal structure of L^1 and L^2

Slow evaporation of the chloroform solution of $\mathbf{L^1}$ and $\mathbf{L^2}$ yielded yellow crystals, suitable for X-ray diffraction studies. An ORTEP view with the atom numbering scheme is given in Fig. 2(a) and (b), respectively. Compounds $\mathbf{L^1}$ and $\mathbf{L^2}$ bearing a *fluorophore–spacer–receptor* architecture differ only in one methylene unit that separates the 4-aminophthalimide and pyridine moieties. However, a large difference exists in their crystallization space groups. While $\mathbf{L^1}$ crystallizes in the non-centrosymmetric orthorhombic space group *Fdd*2, $\mathbf{L^2}$ crystallizes in the monoclinic space group *C*2/*c* (Table 2). In both the compounds, the packing is determined by the intermolecular N–H···O and N–H···N hydrogen bonds involving the amino nitrogen atom, the carbonyl oxygen atom and the pyridine nitrogen atom. However, the network of the packed molecules in these systems is largely different (Fig. 3). Moreover, the molecules are more closely packed in $\mathbf{L^1}$ as compared to $\mathbf{L^2}$. This difference in the packing of the molecules is also reflected by the bending of the plane of the pyridine ring with respect to the phthalimide ring in these compounds. The dihedral angle between the planes defined by phthalimido and pyridyl rings in $\mathbf{L^1}$ and $\mathbf{L^2}$ is 85.79(23)° and 39.33(6)°, respectively.

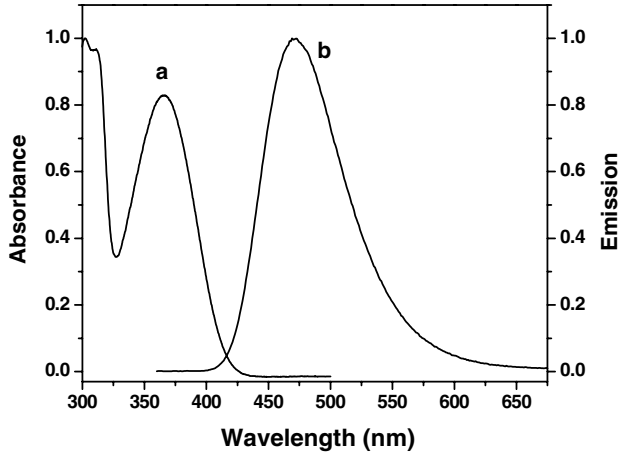

Fig. 1. Absorption (a) and fluorescence (b) spectra of $\mathbf{L^2}$ in acetonitrile.

3.4. Crystal structure of $Cu(L^2)_2$

The crystal structure of $[Cu(L^2)_2]ClO_4$ ($\mathbf{Cu(L^2)_2}$) shows a mononuclear complex in which copper is coordinated to the pyridine nitrogen atom of each ligand unit. The crystallographic parameters and data are collected in Table 2 and the molecular structure is shown in Fig. 2(c). The copper atom is situated on a two-fold axis and the geometry of the cationic portion is a linear L–Cu^I–L moiety with Cu1–N1 = Cu1–N1A = 1.89 Å. The Cu–N bond length is very similar to that previously reported for two-coordinate copper(I) complexes with nitrogen donor ligands [6–8]. A strong intermolecular N–H···O hydrogen bond between

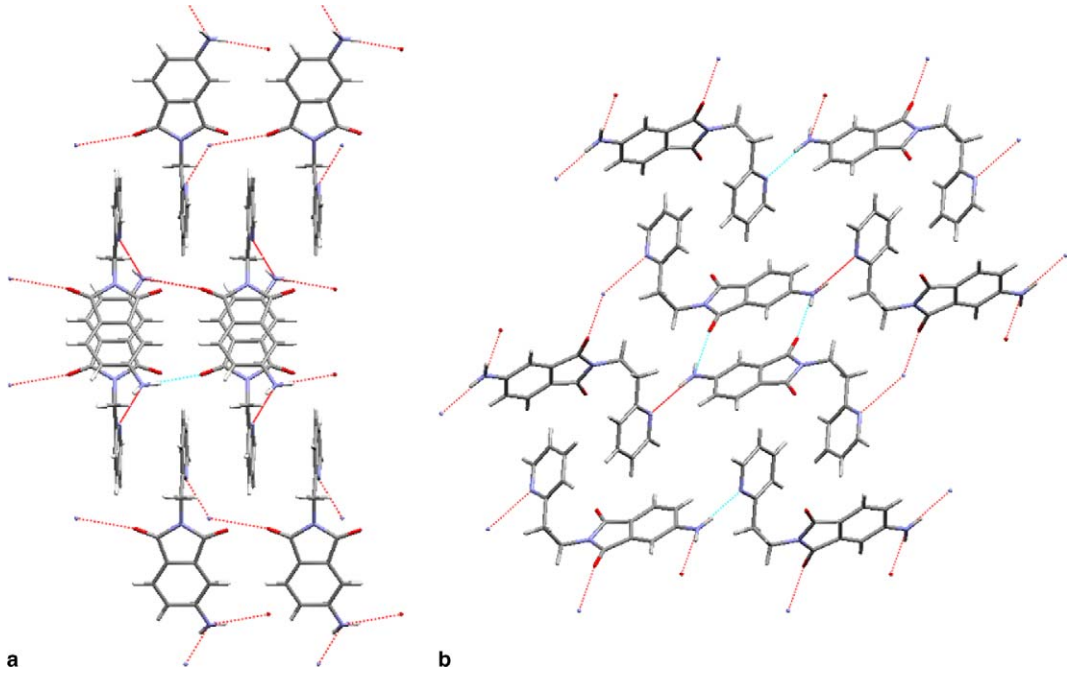

Fig. 3. Packing diagram along the y-axis illustrating the intermolecular hydrogen bonding shown as dashed lines for (a) $\mathbf{L^1}$: d(N3–H3A···N1[$-x$, $-y$, z]) = 3.034 Å, ∠N3–H3A···N1[$-x$, $-y$, z] = 158.95°; d(N3–H3B···O1[$-x$, $-y+1/2$, $z+1/2$]) = 3.026 Å, ∠N3–H3B···O1[$-x$, $-y+1/2$, $z+1/2$] = 152.45° and (b) $\mathbf{L^2}$: d(N3–H3A···N1[x, $-y+1$, $z-1/2$]) = 3.020 Å, ∠N3–H3A···N1[x, $-y+1$, $z-1/2$] = 167.89°; d(N3–H3B···O2[$-x$, $-y$, $-z$]) = 3.044 Å, ∠N3–H3B···O2[$-x$, $-y$, $-z$] = 155.71°.

the amino nitrogen atom and the imide oxygen atom of a neighboring molecule, forming a two-dimensional network, is observable in the complex (Fig. 4). The dihedral angle between the planes defined by the pyridyl and phthalimido rings is 22.49(15)°. Comparison with $\mathbf{L^2}$ indicates that the twisting of the pyridyl ring with respect to the phthalimido ring is significantly reduced upon coordination. The relatively large bending in $\mathbf{Cu(L^1)_2}$ (61.8(16)°) [10] brings O2 and O2A in close contact with the copper ion (Cu1···O2 = Cu1···O2A = 3.03 Å and ∠O2···Cu1···O2A = 180°), reflecting a weak electronic interaction between Cu^I and one of the imide oxygen atoms of the ligand unit. On the other hand, $\mathbf{Cu(L^2)_2}$ experiences a very weak interaction from the imide oxygen atom (Cu1···O2 = Cu1···O2A = 4.0 Å).

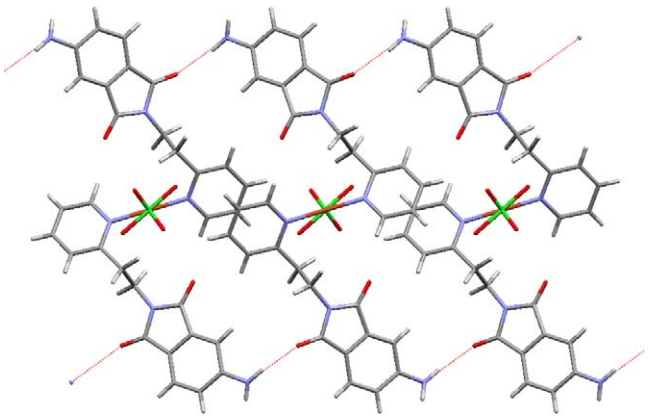

Fig. 4. View of $\mathbf{Cu(L^2)_2}$ along the y-axis illustrating the intermolecular hydrogen bonding, shown as dashed lines, leading to a 2-D network: d(N3–H3A···O1[x, $-y+1$, $z+1/2$]) = 2.965 Å and ∠N3–H3A···O1[x, $-y+1$, $z+1/2$] = 172.75°.

Upon careful inspection, a weak $Cu^I\cdots O$ interaction between Cu^+ and oxygen atoms of the ClO_4^- anion was also observed (Cu1···O4 = 2.707 Å). It should be noted that the ClO_4^- anion is disordered and that there are errors in the oxygen positions. However, the interacting oxygen atom is situated on a 2-fold axis and that leads to a T-shaped structure. The T-shaped molecular units are stacked over one another to form a linear network (Fig. 5). Weak Cu···O interactions of about 3 Å are found in copper-containing enzymes [17]. Although such additional or multiple weak interactions [18] with an oxygen atom of the ClO_4^- anion are known for linear L–M–L complexes [19], the resulting T-shaped geometry leading to a linear network illustrates the novelty of this complex.

3.5. Stability and redox properties

$\mathbf{Cu(L^2)_2}$ exhibits indefinite stability in the solid state. Oxidation of Cu^+ to Cu^{2+} in polar or coordinating solvents such as acetonitrile or even in protic solvents such as methanol was not observed even when kept in the open air for several months. Although the linear geometry is known to disfavor O_2 and CO interaction under certain conditions, two-coordinate copper(I) complexes with sterically unhindered monodentate ligands undergo rapid auto-oxidation in air, especially in protic solvents [6–8]. Thus, the stability of the complex towards oxidation is remarkable and quite interesting.

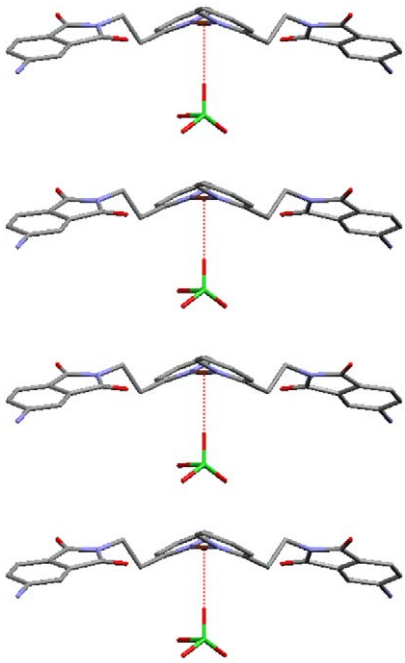

Fig. 5. View of $\mathbf{Cu(L^2)_2}$ along the z-axis showing the close contact of copper with one of the oxygen atoms of the ClO_4^- counter-anion, forming a T-shaped molecule and leading to a linear network: Cu1···O4 = 2.707(8) Å, ∠O4···Cu1···N1 = ∠O4···Cu1···N1A = 91.58(12)°.

Cyclic voltammetry studies of the ligands $\mathbf{L^1}$, $\mathbf{L^2}$ and their copper(I) complexes, $\mathbf{Cu(L^1)_2}$ and $\mathbf{Cu(L^2)_2}$ in acetonitrile reveal an irreversible oxidation with very high current associated with the oxidation property of the electron-deficient 4-aminophthalimide of the ligand framework (Fig. 6). The measured potentials range between 1.58 and 1.44 V (vs Fc/Fc^+ in CH_3CN/0.1 M $[Bu_4N]ClO_4$). The absence of an oxidation wave for the Cu(I)/Cu(II) couple [20,21] indicates significant stabilization of the monovalent oxidation state. The extraordinary stabilization of the Cu(I) state in these complexes is achieved by its weak interactions with the imide and perchlorate oxygen atoms which put the Cu^+ ion in an octahedral hole. This is further substantiated by the fact that $\mathbf{Cu(L^2)_2}$, the metal center of which is more separated from the 4-aminophthalimide moiety, exhibits a lesser stability compared to $\mathbf{Cu(L^1)_2}$. Moreover, copper(II) complexes have a tendency to form four-coordinate and in some cases five-coordinate complexes in solution, typically via coordination of a solvent molecule as the fifth ligand. Steric and/or electronic shielding provided by the 4-aminophthalimide moiety is also likely to disfavor the formation of the Cu(II) oxidation state. Therefore, this exceptional inertness is attributable to the highly favorable electronic factors provided by the 4-aminophthalimide and the perchlorate moieties.

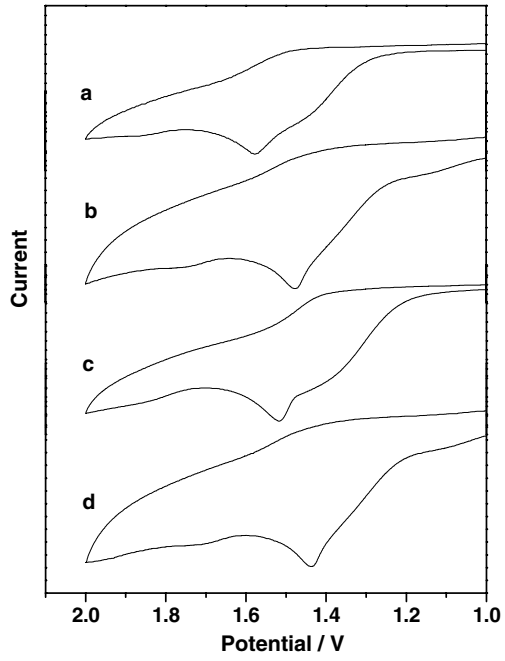

Fig. 6. Cyclovoltammogram for $\mathbf{L^1}$ (a), $\mathbf{Cu(L^1)_2}$ (b), $\mathbf{L^2}$ (c) and $\mathbf{Cu(L^2)_2}$ (d) in acetonitrile with 0.1 M $[Bu_4N]ClO_4$ as supporting electrolyte (potential plotted against the Fc/Fc^+ couple).

4. Conclusions

In conclusion, we have synthesized a new fluorescent ligand $\mathbf{L^2}$ and its two-coordinate copper(I) complex, $\mathbf{Cu(L^2)_2}$, having a linear geometry and resistance to oxidation even in a protic aerated medium. The single crystal structures of $\mathbf{L^2}$ and a previously reported ligand $\mathbf{L^1}$ are also presented. The new copper(I) complex $\mathbf{Cu(L^2)_2}$, in which the metal center is more separated from the 4-aminophthalimide moiety, exhibits lesser stability than the copper(I) complex of $\mathbf{L^1}$, $\mathbf{Cu(L^1)_2}$, suggesting the importance of the electronic environment around the metal binding site in controlling the Cu(I)-oxidation reactivity. The judicious choice of the ligand system and the counter-anion forms an essential condition in the formation of stable two-coordinate complexes of copper(I). This complex is a second example of its kind with a potential for the development of copper(I) chemistry. Furthermore, the spectroscopic properties associated with these complexes may be utilized to monitor the reactivity of copper(I) with various other molecules.

5. Supplementary data

CCDC-278525–278527 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgements

The authors thank Prof. S. Pal for his help and suggestions in solving the crystal structure of the compounds. Financial support for this work is provided by the Council

of Scientific and Industrial Research (CSIR) and the Department of Science and Technology (DST), Government of India. S.B. thanks CSIR for a Fellowship. The National Single Crystal Diffractometer Facility (funded by the DST), School of Chemistry, University of Hyderabad, India and the UPE Program of the University Grants Commission (UGC) are gratefully acknowledged.

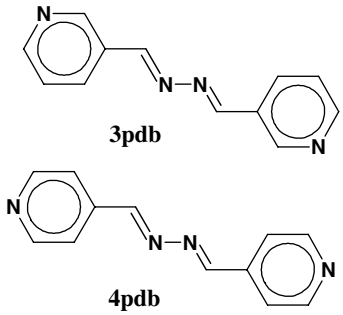
such as monodentate, bridging bidentate and as monoatomic bridge, either alone (one oxygen atom connect two metal ions) or with an additional bridging (the second oxygen atom acts as monodentate) [4]. In particular, in the coordination polymers obtained from $Zn(OAc)_2 \cdot 2H_2O$ with NN spacers the acetate ion has shown several of its structural arrays: (a) monodentate in the complex $[Zn(OAc)_2(4,4'\text{-dps})]_n$ (4,4′-dps = 4,4′-dipyridylsufide) [5] with the cation Zn(II) as node, (b) bidentate and bridging bidentate modes in the complex $[Zn(OAc)_2(4,4'\text{-bpy})]_n$ (4,4′-bpy = 4,4′-bipyridine) that it includes the neutral binuclear $\{Zn(OAc)_2\}_2$ core [6], (c) bidentate, bridging and monoatomic with additional bridging configurations in the complex $[Zn_2(OAc)_4(4,4'\text{-bpy})]_n$ [7] with $\{Zn(OAc)_2\}$ dimeric units as nodes and (d) bridging and monoatomic with additional bridging modes in the heptanuclear derivatives $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(bpe)]_n$ (bpe = 1,2-bis (4-pyridyl)ethane) and $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(dpds)]_n$ (dpds = 4,4′-dipyridyldisulfide) [8] with the oxo-acetate core $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}\}$. These results show that the species that reach the highest nuclearity are the metal-organic frameworks $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(NN)]_n$. which involves the flexible NN spacers bpe and dpds. The main characteristic of these two Zn_7 compounds is in the presence of two assembled tetrahedral oxo groups $\{Z_4(\mu_4\text{-}O)\}$ [9], which together with the ten bridging acetates interconnect the seven zinc ions. These oxoacetate products, obtained by reacting zinc acetate with the plastic NN spacers in a 7:1 ratio, form one-dimensional coordination polymeric chains. On the other hand, the results also show that by using non-flexible NN ligands in reactions with zinc acetate have lead exclusively to the synthesis of low nuclearity Zn(II) systems. In other words, the rigid linkers 4,4′-bpy and 4,4′-dps lead to coordination polymers with metal-to-ligand ratio of 1:1 ($[Zn(OAc)_2(NN)]_n$ (NN = 4,4′-bpy; 4,4′-dps)) [5,6] and 2:1 ($[Zn_2(OAc)_4(4,4'\text{-bpy})]_n$) [7]. Other carboxylate systems containing the $\{Zn_7(\mu_4\text{-}O)_2(carboxylate)_{10}\}$ core have been reported, but they are formulated as the discrete acetate-based clusters $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(L_2)]$ (L = pyridine [10], 1-methylimidazole [11], pyrazine [12]) and the 2,6-difluorobenzoate-based clusters $[Zn_7(\mu_4\text{-}O)_2(2,6\text{-difluorobenzoate})_{10}(L_2)]$ (L = THF, MeCN) [13].

Considering the above overview we decided to study how the increase of the length of the linker ligands affect to the nuclearity and the overall framework of polymeric structures. In this regard, herein we report on our finding when zinc acetate reacts with the NN spacers 1,4-bis(3-pyridyl)-2,3-diaza-1,3-butadiene (3pdb) [14] and 1,4-bis(4-pyridyl)-2,3-diaza-1,3-butadiene (4pdb) [15] (Scheme 1), which would appear at this moment as the longest employed in this type of systems. These *N*,*N*′ bidentate azine ligands have been used to generate coordination polymers with several metal centres (Co^{II}, Cd^{II}, Ni^{II}, Ag^{I}, Mn^{II}, Pb^{II}, Cu^{II}) containing diverse counterions (NO_3^-, SCN^-, I^-, saccharinate, α-thenoyltrifluoroacetonate) [14–16] where carboxylates are not included. Besides, the conjugated 3pdb and 4pdb ligands have demonstrated to be rigid connectors like



Scheme 1.

4,4′-bpy and 4,4′-dps, but longer than them due to the introduction of the spacer portion –CH=N–N=CH– between two pyridyl groups. Apparently, this could justify that the longer ligands 3pdb and 4pdb show a different behaviour from that of 4,4′-bpy and 4,4′-dps; they are able to carry out self-assembly reactions with zinc acetate to produce very easily under mild conditions the high nuclearity coordination polymers $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(3pdb)]_n$ (**1**) and $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(4pdb)]_n$ (**2**).

2. Experimental

All solvents were purchased from commercial sources and used without further purification. The compound $Zn(OAc)_2 \cdot 2H_2O$ was obtained from Merck. The 3pdb [14] and 4pdb [15] ligands were prepared following the literature procedures. The coordination polymers $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(3pdb)]_n$ and $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(4pdb)]_n$ were prepared in a similar manner from the reaction of $Zn(OAc)_2 \cdot 2H_2O$ with the appropriate bidentate Schiff-base ligand in a 7:1 metal-to-ligand ratio. A typical preparation is described below.

Synthesis of $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(3pdb)]_n$ (**1**). The ligand 3pdb (4.0 mg, 0.019 mmol) was dissolved in MeCN (1.0 cm^3). A methanolic solution (2.0 cm^3) of $Zn(OAc)_2 \cdot 2H_2O$ (29.2 mg, 0.133 mmol) was then added and the mixture stirred for 1 min. The solution was warmed with gentle heating (60 °C) for 3 h. The crystalline solid formed was washed firstly with MeOH (3×3.0 cm^3) and then with diethyl ether (2×3.0 cm^3). The well formed yellow crystals were dried on the air (9.0 mg, 36.6% yield). *Anal.* Calc. for $C_{32}H_{40}N_4O_{22}Zn_7$: C, 29.79; H, 3.12; N, 4.34. Found: C, 29.87; H, 3.25; N, 4.16%. IR (KBr disc, cm^{-1}): 3433 (br), 1595 (s), 1430 (s), 1028 (m), 674 (m). For $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(4pdb)]_n$ (**2**): (22.4% yield). *Anal.* Calc. for $C_{32}H_{40}N_4O_{22}Zn_7$: C, 29.79; H, 3.12; N, 4.34. Found: C, 29.63; H, 3.30; N, 4.22%. IR (KBr disc, cm^{-1}): 3440 (br), 1603 (s), 1429 (s), 1025 (m), 678 (m).

3. Instruments

IR spectra were recorded as KBr pellets on a Bruker Model IFS-55 FTIR instrument. The C, H and N contents of the compounds were determined on a Fisons-Carlo Erba EA 1108 microanalizer (CEPEDEQ Universidad de Chile).

4. Crystallography

The pertinent crystal and structure refinement are summarized in Table 1 and Table 2 lists the selected bond lengths and angles for compounds **1** and **2**. The yellow crystals measured approximately $0.22 \times 0.16 \times 0.10\ mm^3$ (**1**) and $0.40 \times 0.32 \times 0.18\ mm^3$ (**2**), respectively. Data were collected on a Bruker AXS SMART APEX CCD diffractometer with SMART [17] as the driving software; data integration was performed using SAINT [18] and a semi-empirical absorption correction applied. The structure was solved by direct methods and difference Fourier, and refined by least squares on F^2 with anisotropic displacement parameters for non-H atoms. All the hydrogen atoms were defined by the stereochemistry and accordingly placed at their calculated positions and allowed to ride onto their host carbons (C–H_{arom}, 0.95 Å; C–H_{methyl}, 0.95 Å) both in coordinates as well as thermal parameters (U_{iso} values were set to $1.2U_{eq}$ for aryl H and $1.5U_{eq}$ for methyl H). All calculations to solve the structures, refine the models proposed and obtain derived results were carried out with the computer programs SHELXTL [19] and local programs. Full use of the CCDC package was also made for searching in the CSD database [20].

For **2**: #1 $-x, -y, -z$; #2 $x, y, -z$.

5. Results and discussion

The coordination polymers **1** and **2** were isolated from a MeOH–MeCN solution by treatment of $Zn(O_2CMe)_2 \cdot 2H_2O$ with the bis-pyridyl Shiff-base ligands 3pdb and 4pdb in a molar ratio 7:1 (metal-to-ligand) under gentle conditions (60 °C). Both compounds are stable in air and insoluble in common organic solvents. The IR spectra for **1** and **2** are very similar in the region characteristic of the acetate anions [4] showing the bands for ν_{asym}(COO) [1595 cm^{-1} (**1**); 1603 cm^{-1} (**2**)], ν_{sym}(COO) [1430 cm^{-1} (**1**); 1429 cm^{-1} (**2**)] and δ(OCO) [674 cm^{-1} (**1**); 677 cm^{-1} (**2**)]. For acetate derivatives the difference between ν_{asym}(COO) and ν_{sym}(COO) ($\Delta\nu$) in comparison with the ionic species has been used as a criteria for establishing its bonding mode [4,21]. In particular, the bands are shifted to higher frequencies with respect to that of the sodium acetate and they present a $\Delta\nu$ value of 165 cm^{-1} for **1** and 159 cm^{-1} for **2**, which is very close to that of the NaOAc of 159 cm^{-1}. This behaviour would indicate that

the acetate ions are bonded to the zinc atoms in a bridging mode which agree with the X-ray results discussed below.

The molecular diagrams of **1** and **2** are shown in Fig. 1(a) and (b), respectively, while in Table 1 the crystal and refinement data are presented. These compounds join the few ones already reported in the literature [8,10–12] containing the very tightly bound $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}\}$ core. In both structures the unsaturated heptanuclear units act as nodes connected by the bridging 3pdb and 4pdb ligands to form chains. The Zn–N bond distances (2.070(5) and 2.069(5) Å, respectively) are slightly shorter than those observed in the related Zn(II) complexes, the non-polymeric compounds $[Zn(4pdb)_2(MeOH)_2(H_2O)_2](ClO_4)_2 \cdot 4pdb \cdot 1.72MeOH \cdot 1.28H_2O$ (2.120(2) Å) [22] and $[Zn(4pdb)_2(H_2O)_4](ClO_4)_2$ (2.131(3) Å) [23]. The N···N separation between the pyridyl nitrogen atoms in **1** (10.65(1) Å) and **2** (11.45(1) Å) are notably longer than the terminal N···N separations of 4,4′-dps (7.40(1) Å) and 4,4′-bpy (7.17(1) Å) found, e.g., in the 1:1 metal-to-ligand ratio complexes $[Zn(OAc)_2(4,4'\text{-dps})]_n$ [5] and $[Zn(OAc)_2(4,4'\text{-bpy})]_n$ [6], respectively.

Each seven nuclear core in **1** and **2** reveals a central Zn1 laying on a symmetry centre, two Zn3 atoms on a mirror plane which halves the hole group and four Zn2 atoms at general positions, thus accounting for the seven Zn sites per formula. Two oxo groups, also laying on the mirror plane are fourfold linked to four different zinc cations, acting as quadruple bridges. The remaining intercationic cohesion is implemented by six bidentate acetates (four of them generated by a single unit (A) in a general position and two by a second one (B) in a special position, halved by the mirror plane) in addition to four tridentate acetates, generated by single moiety (C) also in a general position. Completing the assemblage, there are two organic spacer molecules bonded to the Zn3 providing two nitrogens to the overall bonding scheme. The final result is Zn1 and Zn3 being

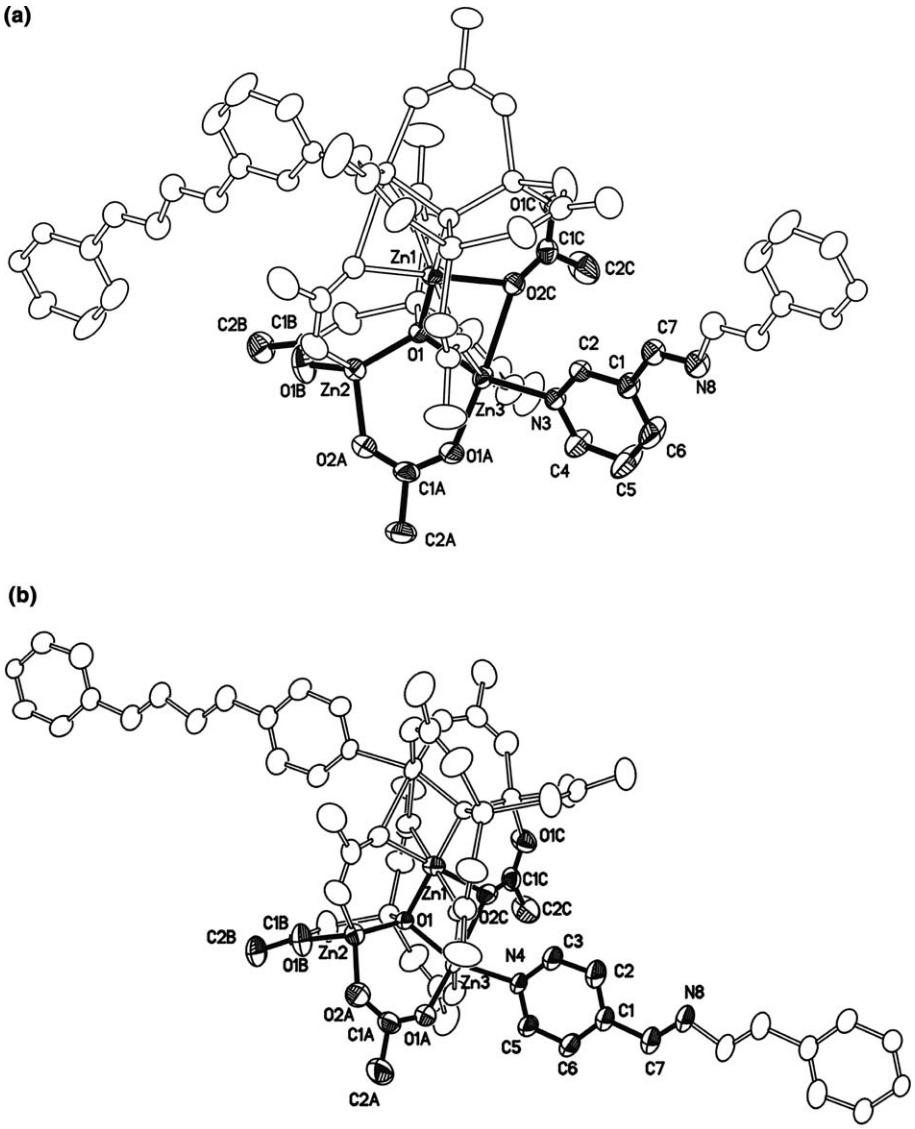

Fig. 1. (a) Molecular diagram of **1** and (b) molecular diagram of **2**. In both cases showing the independent part of the structure in full 40% thermal ellipsoids, and symmetry related atoms as open ellipsoids joined by open bonds.

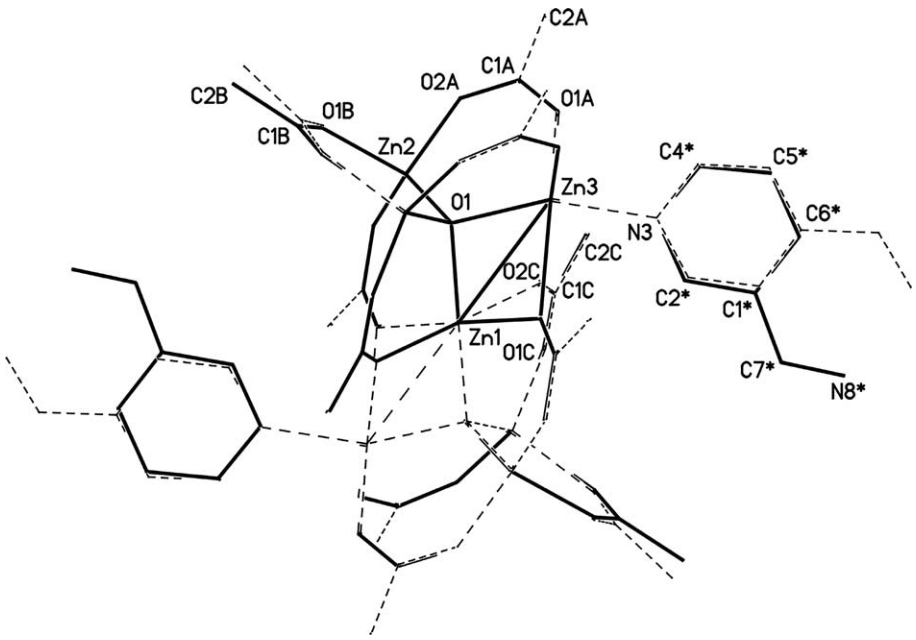

Fig. 2. Least squares fitting of the (enlarged) $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(NN)\}$ cores in **1** and **2**. Labelling corresponds to atoms in **1**. Starred atoms not included in the calculations.

octahedrally coordinated while Zn2 displays a tetrahedral environment, in due balance with the 34 bonds provided by the ligands. The Zn3 octahedron appears as highly distorted with four rather normal bonds (those to the pyridyl nitrogen, one oxo group and two oxygens from two bridging acetates, in a 1.960(4)–2.070(5) Å range) and two apical, loosely bonded, symmetry related oxygens from the tridentate acetates ($Zn\text{–}O_{apical}$: $2 \times 2.468(3)$ Å in **1**, $2 \times 2.419(3)$ Å in **2**). These latter weak Zn···O interactions are present in all the previously reported species containing the $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}\}$ core [8,10–12], and are decidedly shorter than the sum of the van der Waals radii (2.9 Å) [24].

Table 2 presents a detailed survey of distances and angles around the metal centres. Inspection of the values therein confirms that in all cases the geometry around the cations is rather irregular in consonance with the stringent restraints imposed by chelation. In spite of this, the whole unit is very robust, and little prone to further distortions. This can be assessed by comparison of the present two $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}\}$ moieties, even though that they appear surrounded by different environments and bound to dissimilar ligands, they look strikingly similar. In particular, the least squares fitting of the 41 atoms in the enlarged cores (two coordinated N atoms included) in **1** and **2** gave a r.m.s. deviation for the matched atoms as low as 0.09 Å (see Fig. 2). Being the cores identical, the main reason for the structural differences between **1** and **2** (viz., crystal system, space group, etc.) resides in the coordination mode of the bridging *N*,*N*′-bipyridyl ligands. When the coordinating nitrogens are in positions 4,4′ the coordination is "straighter", and the resulting chain less twisted than in the case of 3,3′. Fig. 3(a) and (b) show this in detail as well as the consequences of this has on the piling mode of the chains. The very twisted ones in **1** can superpose parallel to each other but with a shift along the chain direction, (parallel to the *a*-axis, Fig. 3(a)) of half a link, so as to have the very thin diazine ligands[1] superimposed to the bulky $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}\}$ nodes of the neighbouring chains. In the case of **2**, this can only be achieved through a right angle disposition of the 1D arrays, with chains at level 0 running in one direction and those at level 0.5 at right angles (Fig. 3(b)).

The interaction between chains are very weak, with just one C–H···O contact per structure (Table 3). These interactions link chains at different heights (Fig. 3(a) and (b)), in an alternating way so as to determine a very weakly bound 3D network. These two at first sight quite dissimilar types of chain disposition in **1** and **2**, are however much alike in that they seek the opposition of peaks in one layer with troughs in the next, promoting a good fit between layers. This is a very different approach to the packing modes found in the remaining two polymeric structures already reported $[Zn_7(\mu_4\text{-}O)_2(OAc)_{10}(NN)]_n$ (NN = 1,2-bis(4-pyridyl)ethane, 4,4′-dipyridyldisulfide) [8], where "planes" of adjacent chains are simply superimposed to each other by means of a unit cell translation, with the result that peaks oppose with peaks and troughs oppose with troughs. The difference in packing efficiency is apparent: both **1** and **2** surprisingly achieve the same density, D_c: 1.859 g/cm^3, significantly larger than 1.65 and 1.72 g/cm^3 for the other two, in spite of a formula weight some 3% smaller. The reasons for this compactness preference are not clear, since the spacers 1,2-bis(4-pyridyl)ethane and 4,4′-dipyridyldisulfide

[1] The 3pdb and 4pdb ligands are halved by crystallographic symmetry centres, for what they show a strictly planar structure.

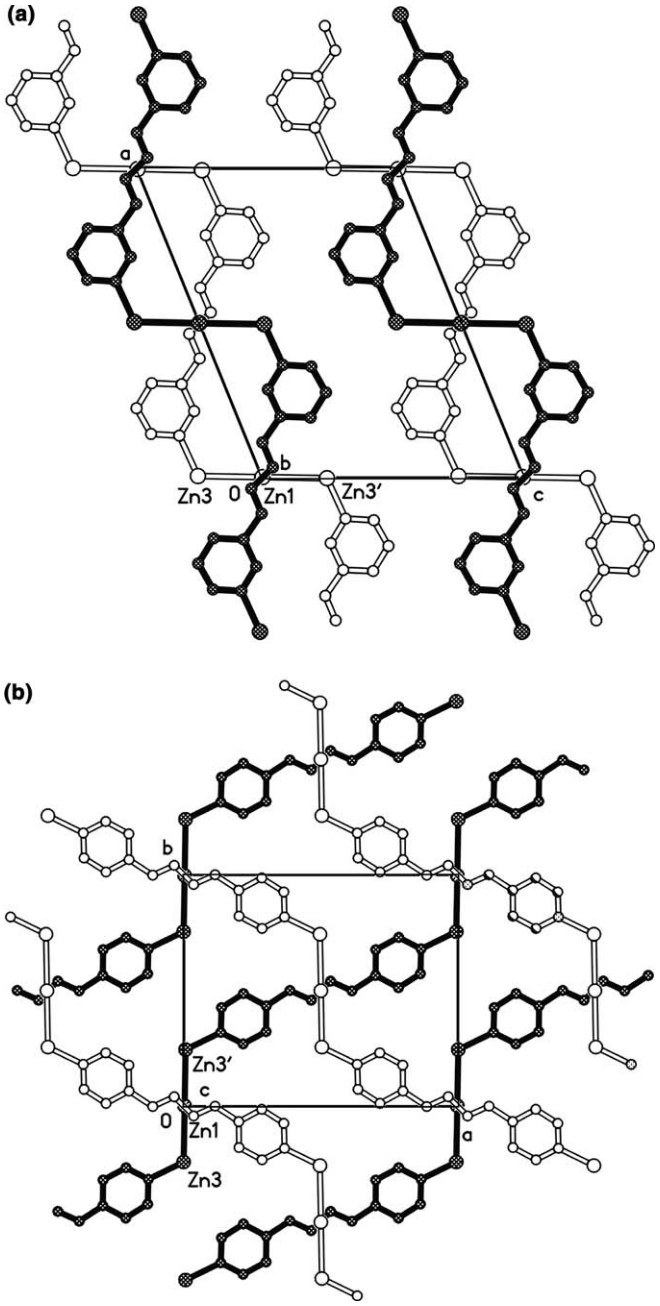

Fig. 3. (a) Packing diagram of **1**, drawn down the *b*-axis. (b) Packing diagram of **2**, drawn down the *c*-axis. The two figures show in heavy lining, chains at height $y = 0$, in light lining, those at $y = 0.50$. The bulky $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}\}$ groups have been schematized by their Zn3–Zn1–Zn3′ nuclei, for clarity.

are in principle more flexible than 3pdb and 4pdb, the ones in **1** and **2**, and accordingly potentially able to adapt a variety of conformations and prone to avoid undesirable steric collisions. Additional structural information on related polymers will be needed to clarify the subject, as well as to assess which is the leading parameter deciding the formation of the Zn_7 nuclei under very similar synthetic conditions. So far, the trend seems to be that those ligands promoting a very weak interaction between potentially adjacent Zn_7 groups (very long bridging spacers) favour the formation and stability of these nuclei. On the other hand, when shorter spacers are used, instead (4,4′-bpy, 4,4′-dps) much simpler Zn nuclei are stabilized.

Table 3
Weak interchain contacts (Å, °)

Structure	Contact	C—H	H···O	C···O	∠C–H···O
1	C2A–H2AB···O2A#3	0.96	2.53	3.470(9)	166

Symmetry codes. #3: $-1/2 - x$, $-1/2 - y$, $1 - z$; #4: $-1/2 + x$, $1/2 - y$, $-1/2 + z$.

6. Conclusion

This research gives evidence that the thin, rigid and long ligands 1,4-bis(3-pyridyl)-2,3-diaza-1,3-butadiene (3pdb) and 1,4-bis(4-pyridyl)-2,3-diaza-1,3-butadiene (4pdb) are able to join the bulky heptanuclear $\{Zn_7(\mu_4\text{-}O)_2(OAc)_{10}\}$ fragments through their terminal 3- and 4-pyridyl nitrogen donor atoms. Indeed, the results show that divergent *N*,*N*′-bipyridyl spacers could form coordination polymers with zinc carboxylates nodes of significant high nuclearities, under the requirement that they be long enough to avoid steric repulsions. On the other hand, the characteristic rigid planar structure of the ligands like 3pdb and 4pdb could be a factor to be considered that would permit an efficient piling producing a high density packing scheme, such as the observed in the compounds **1** and **2**, in contrast with the low density of the polymers with the flexible 4,4′-bpy and 4,4′-dps linkers.

Electrochemical measurement was performed (acetonitrile solution) on a CH 620A electrochemical analyzer using a platinum electrode. Tetraethylammonium perchlorate (TEAP) [9] was used as a supporting electrolyte and the potentials are referenced to the standard calomel electrode (SCE) without junction correction. Magnetic measurement was carried out on a polycrystalline sample with a Quantum Design MPMS XL SQUID susceptometer operating at a magnetic field of 0.1 T between 2 and 300 K. The diamagnetic corrections were evaluated from Pascal's constants. Elemental analysis (C, H, N) was performed on a Perkin–Elmer 2400 Series II elemental analyzer.

2.3. Synthesis of the complex

$[Ni_2(L)(HL)(\mu_{1,1}\text{-}N_3)_2]ClO_4$ (**1**). To a methanolic solution (10 mL) of nickel(II) perchlorate hexahydrate (0.183 g, 0.5 mmol) was added HL (0.168 g, 0.5 mmol) and sodium azide (0.046 g, 0.7 mmol). The resulting pale blue solution was stirred for 0.5 h at room temperature. Slow evaporation of the solution yielded the pale blue crystalline product. Yield: 0.140 g (70%). *Anal.* Calc. for $C_{42}H_{45}N_{12}ClO_6Ni_2$: C, 52.1; H, 4.7; N, 17.4. Found: C, 51.6; H, 4.7; N, 17.6%. UV–Vis (λ_{max}/nm (ε/M^{-1} cm^{-1}) CH_3CN solution): 388 (sh, 322); 590 (31); 987 (54). IR (KBr, cm^{-1}): ν(OH) 3320; $\nu(N_3^-)$ 2085, 2070; (νClO_4^-) 1120, 620. $E_{1/2}$ (Ni^{III}/Ni^{II} couple): 0.47 V (ΔE_p, 50 mV).

2.4. Crystallographic studies

Suitable crystals of complex **1** were grown by slow evaporation of the methanolic solution. The X-ray intensity data were measured at 293 K on Bruker AXS SMART APEX CCD diffractometer (Mo Kα, $\lambda = 0.71073$ Å). The detector was placed at a distance of 6.03 cm from the crystal. A total of 606 frames were collected with a scan width of 0.3° in different settings of φ. The data were reduced in SAINTPLUS [10] and empirical absorption correction was applied using the SADABS package [10]. Nickel atoms were located by direct methods and the rest of the non-hydrogen atoms emerged from successive Fourier synthesis. The structures were solved by the direct method using the program SHELXS-97 [11] and were refined by the full matrix least-square procedure on F^2. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the methyl groups (C(20), C(21), C(41) and C(42)) were included in calculated positions. All other hydrogen atoms of the complex were directly located in difference Fourier maps. Calculations were performed using the SHELXTL V5.03 [12] program package. The molecular structure plot was drawn using ORTEP [13]. Relevant crystal data are given in Table 1.

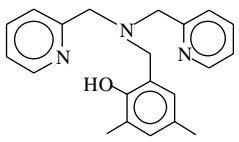
3. Results and discussion

The tetradentate tripodal ligand of the general formula HL has been used in this present work and it has been synthesised by the reported procedure [8].



HL

The stoichiometric reaction of $[Ni(H_2O)_6](ClO_4)_2$ with HL in the presence of an excess of sodium azide furnished the pale blue colored complex of the formula $[Ni_2(L)(HL)(\mu_{1,1}\text{-}N_3)_2]ClO_4$, **1**, in good yield.

The perchlorate stretches occur near 600 and 1100 cm^{-1} and the hydrogen bonded phenolic OH appears as a broad peak near 3250 cm^{-1} [14]. The azide stretches appear as a doublet at 2085 and 2070 cm^{-1}.

The solution of the complex exhibits relatively weak peaks at about 580 and 980 nm. These two broad peaks are presumably assigned as $^3A_2 \rightarrow {}^3T_2$ and $^3A_2 \rightarrow {}^3T_1$ transitions, respectively. On the other hand, a shoulder is observed near 400 nm and this absorption is due to phenolate $\rightarrow Ni^{II}$ LMCT origin [15].

The cyclic voltammogram was recorded in acetonitrile solution at a scan rate of 50 mV/s and displays a quasireversible couple near 0.5 V. This is probably due to $Ni^{II} \rightarrow Ni^{III}$ oxidation [16].

3.1. Crystal structure

The crystal structure of $[Ni_2(L)(HL)(\mu_{1,1}\text{-}N_3)_2]ClO_4$ (**1**) has been determined. The ORTEP diagram of the cationic part is shown in Fig. 1. Selected bond distances and angles are given in Table 2. In the compound, three nitrogen atoms of the tetradentate ligand assume a *fac* configuration and the phenolic oxygen is coordinated equatorially.

The nickel units are linked by a bridging azide ion forming a double end-on asymmetric bridged dimeric complex. The geometry around each nickel ion is distorted octahedron. In the NiN_5O environment, the equatorial plane is formed by three nitrogen atoms and one oxygen atom, and the nickel atom is shifted by ~0.065 Å towards the axial pyridine nitrogen atom. The remaining position is occupied by the bridging azide nitrogen atom of the other unit. The Ni–N bond distances are usual [6a] and span the range 2.075–2.171 Å. The N–N–N angle of the azide ion is ~179° and the N–N bond lengths are ~1.15 and 1.2 Å, respectively. In the dimer the Ni···Ni bond separation is 3.240(6) Å and the Ni–N–Ni angle is ~98°.

Recently, we have reported [17] an end-on double azido-bridged copper(II) complex with the same ligand in which both the phenolic oxygen atoms bind in the protonated form and are coordinated axially *trans* to each other. In the present case, the two phenolic groups are disposed equatorially in a *cis* configuration and one of them binds in the protonated form. These two *cis* phenolic groups are linked by an O–H···O hydrogen bond [O···O, 2.369(4) Å]. However the Ni–O bond distances, Ni(1)–O(1), 2.047(2) Å and Ni(2)–O(2), 2.0316(14) Å and O–H bond lengths, O(1)–H(50A), 1.171(5) Å and O(1)···H(50A), 1.230(6) Å, strongly support extensive charge delocalisation between the two phenolic oxygen atoms via the hydrogen atom. From this point of view it is assumed that besides the double end-on azido-bridge the complex is also linked by an $[O_{phenol}\text{–}H\cdots O_{phenoxide}]^-$ moiety.

3.2. Magnetic studies

The variable temperature magnetic susceptibility measurement was carried out in the temperature range of 2–300 K. The experimental $\chi_M T$ value is 2.8 $cm^3\,mol^{-1}$ K at 300 K [characteristic feature for a Ni^{II} ion with $g > 2.00$]. This value increases to 3.6 $cm^3\,mol^{-1}$K at 25 K. After passing through the maximum, the $\chi_M T$ value decreases abruptly to 2.4 $cm^3\,mol^{-1}$ K at 2 K. The shape of the curve is typical of intramolecular ferromagnetic coupling with the presence of either zero-field splitting (D parameter) and/or an intermolecular antiferromagnetic interaction (J'). Both D and J' are strongly correlated and show same results at low temperature. Thus it is not possible to separate them in any attempt to fit the experimental data [18]. So two different approaches have been used to fit the experimental data: the first one was full diagonalisation formalism introducing the single-ion D parameter employing, thus, the spin Hamiltonian $H = -JS_1S_1 + D[S_z^2 - 1/3S(S+1)] + g\beta HS_z$ and the second one using the molecular field approximation, with the intermolecular J' parameter, according to the method given by Kahn with the Hamiltonian, $H = -JS_1S_1 + g\beta HS_z - z'J'\langle S_z^2\rangle S_z$ [19]. In both the approaches, the best J values were obtained by minimizing the function $R = \sum(\chi_M^{calc} - \chi_M^{obs})^2/\sum(\chi_M^{obs})^2$. By using the molecular field approach (neglecting the D parameter), the best-fit parameters obtained were as follows: $J = 12.26\ cm^{-1}$, $J' = -0.42\ cm^{-1}$, $g = 2.31$ and $R = 2.9 \times 10^{-4}$ (Fig. 2). By using the full diagonalisation method introducing the D parameter (Fig. 3), the best-fit was obtained with the following parameters: $J = 10.65\ cm^{-1}$, $D = 6.5\ cm^{-1}$, $g = 2.30$ and $R = 2.3 \times 10^{-3}$.

The magnitude of both the J values are in good agreement. The D value is consistent with those typical for nickel(II) complexes [20]. The reduced magnetisation has been performed at 2 K and the plot of the reduced magnetisation versus H is shown in Fig. 4. The curve of

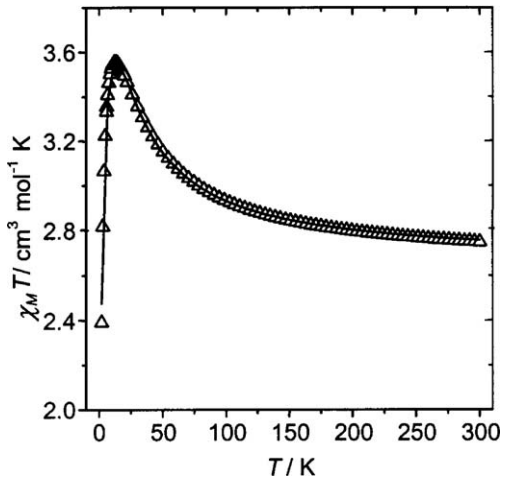

Fig. 2. Plot of $\chi_M T$ vs. T for complex **1**, solid line represents the best-fit assuming intermolecular interaction (J').

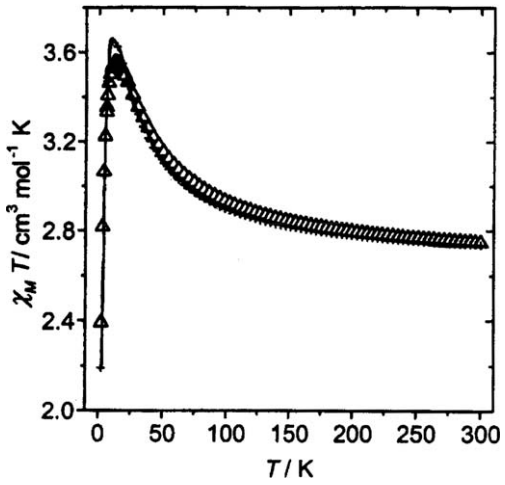

Fig. 3. Plot of $\chi_M T$ vs. T for complex **1**. Solid state indicates the fit considering the D parameter.

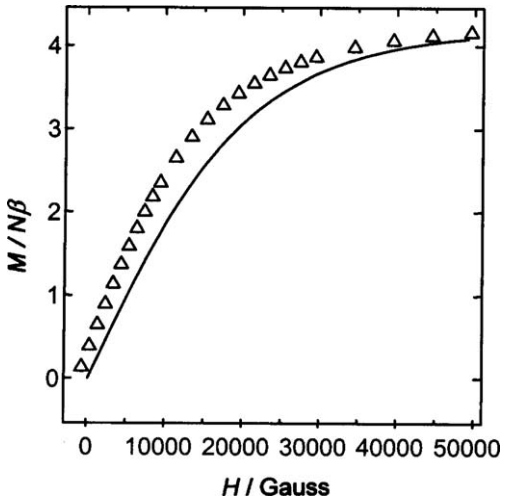

Fig. 4. Plot of the reduced magnetization (M/Nβ) vs. H at 2 K for **1**.

the reduced magnetisation is useful to know whether D or J' is predominant. The shape of the curve is Brillouin-like for $S = 2$ and $g = 2.2$, with the experimental points lying above the theoretical ones. This feature is indicative of a dominant ferromagnetic coupling.

End-on and end-to-end azido bridged nickel(II) complexes exhibit ferromagnetic and antiferromagnetic interactions, respectively [21]. It has been observed that in the case of end-on azido bridged binuclear nickel(II) complexes the J values fall in the range 20–40 cm^{-1} for a Ni–N–Ni angle close to 101–104° [22]. However in the present case the Ni–N–Ni angles are comparatively lower. These geometrical features may explain the low J value.

4. Conclusion

We have prepared and characterised a binuclear complex of the formula $[Ni_2(L)(HL)(\mu_{1,1}\text{-}N_3)_2]ClO_4$ (**1**) incorporating a N_3O-coordinating tripodal ligand. In the complex the two phenoxide oxygen atoms are linked by an O–H···O hydrogen bond. The variable temperature magnetic moment confirmed the ferromagnetic behavior. Further research aimed at the synthesis of polynuclear nickel(II) complexes involving both a bridging ligand and hydrogen bonding using different polydentate ligands along with the study of their solid and solution state is currently in progress.

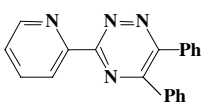
fluorescent whereas complexes with pyridyltriazine and pyrazinyltriazine ligands exhibit weak fluorescence in solution.

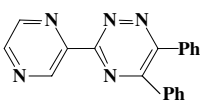
2. Results and discussion

2.1. Synthesis and characterisation

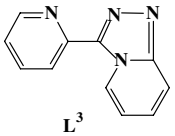
The heterocyclic ligands used in the present work are 5,6-diphenyl-3-(2-pyridyl)-1,2,4-triazine (L^1) (**1**), 5,6-diphenyl-3-(pyrazin-2-yl)-1,2,4-triazine (L^2) (**2**) and triazolopyridine (L^3) (**3**) (general abbreviation L). The ligands L^1 and L^2 were synthesized as in the reported procedure [6,7]. The reported syntheses of the triazolo ligand L^3 includes the reaction of 2-picolinic acid (or its acid chloride/ester) with 2-hydrazinopyridine [8] and the oxidative cyclization of the 2-pyridylhydrazone of pyridine-2-aldehyde [9]. We have found that L^3 is also formed in good yield (70%) via the reactions of Scheme 1 in which the cyclization step involves loss of ammonia from the intermediate amidrazone.



L^1
1



L^2
2



L^3
3

Upon reaction of $Re^I(CO)_5Cl$ with L^1 in boiling benzene in the molar ratio 1:1.1, the red colored $Re^I(CO)_3Cl(L^1)$ was obtained in good yield. The complex $Re^I(CO)_3Cl(L^2)$ was prepared similarly. In the case of L^3, the reaction was carried out in a boiling 5:1 benzene–acetonitile mixture and the complex $Re^I(CO)_3Cl(L^3)$ is bright yellow in color.

The complexes show C≡O stretches in the frequency range 1870–2030 cm^{-1}. In addition to bands in the UV region, the complexes (in dichloromethane) display a band of moderate intensity in the visible region near 440 nm (Table 1). This band is tentatively assigned to a $\pi(Re)$–$\pi^*(L)$ MLCT excitation. The solutions are also fluorescent, the peak lying near 675 nm in the case of the L^1 and L^2 complexes and near 590 nm in the case of the L^3 complex. Relevant data are collected in Table 1. Excitation spectral studies have demonstrated that the fluorescence is associated with the above noted MLCT band. A representative case is shown in Fig. 1.

The fluorescence is believed to originate from the ^{3}MLCT state. It is interesting to note that whereas $Re^I(CO)_3Cl(L^1)$ and $Re^I(CO)_3Cl(L^2)$ are weakly fluorescent with quantum yields (Φ) near 6×10^{-4} (Table 1), the $Re^I(CO)_3Cl(L^3)$ complex is much more strongly fluorescent with $\Phi = 0.036$. This can be attributed to the presence of the quinoid structure in L^3. Indeed it is nearly as fluorescent as $Ru(bpy)_3^{2+}$ ($\Phi = 0.042$) [10]. We note that the $Re^I(CO)_3Cl(bpy)$ complex is only weakly fluorescent ($\Phi = 0.0031$ (295 K)) [11]. Further studies on the photophysical properties of the present complexes are in progress and in this context we record that $Re^I(CO)_3$ complexes are of current interest in terms of their potential photophysical properties [5,12] (e.g. photosensitizers for photochemical reactions). The complexes display well-resolved ^{1}H NMR spectra in $CDCl_3$ solution. The $Re^I(CO)_3Cl(L)$ complexes are electroactive in acetonitrile solution, exhibiting an irreversible one-electron oxidative response near 1.4 V versus SCE which is assigned to the Re^{II}/Re^I couple. Representative voltammograms are shown in Fig. 2. The acidity, i.e., electron withdrawing ability order of the ligands is $L^2 > L^1 > L^3$ [13]. The observed electrochemical pattern of the $Re^I(CO)_3Cl(L)$ species is qualitatively similar with the ligand acidity and the anodic peak potentials order is $Re^I(CO)_3Cl(L^2) > Re^I(CO)_3Cl(L^1) > Re^I(CO)_3Cl(L^3)$.

2.2. Structure

The X-ray structures of $Re(CO)_3Cl(L^1)$ and $Re(CO)_3Cl(L^3)$ have been accurately determined. Molecular views are shown in Figs. 3 and 4 and selected bond parameters are listed in Table 2. In the distorted octahedral ReC_3N_2Cl coordination sphere the three carbon monoxide ligands are facially disposed to maximize Re—CO back-bonding.

In $Re^I(CO)_3Cl(L^1)$ the chelate ring is satisfactorily planar with a mean deviation of 0.03 Å. The dihedral angles

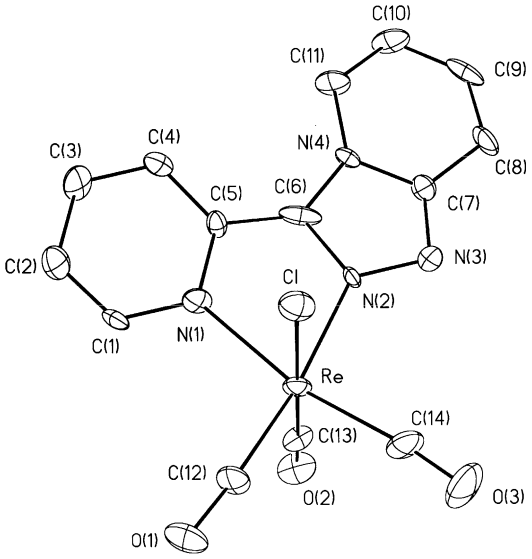

Fig. 4. Molecular view and atom labelling scheme for $[Re(CO)_3Cl(L^3)]$.

of the two pendant phenyl rings with the triazine ring are 38.3° (C9–C14) and 40.7° (C15–C20). The triazine and the pyridine rings are not quite coplanar, the dihedral angle between them being 6.3°.

[a] Average value of Re—C bonds.

In $Re^I(CO)_3Cl(L^3)$ the mean deviation of the chelate ring is again 0.03 Å. The ligand L^3 is only approximately planar (mean deviation 0.06 Å). This happens because the otherwise highly planar pyridine ring (incorporating C5) and the bicyclic triazolo fragment are not quite coplanar, there being a dihedral angle of 7.4° between them. The average Re—N, Re—C and Re—Cl lengths in the present complexes are closely like those reported [14] in $Re^I(CO)_3$ complexes having a ReC_3N_2Cl coordination sphere.

3. Experimental

3.1. Materials

The ligands L^1 and L^2 were prepared by the method [6,7]. The commercially available chemicals utilized in the present work were of analytical grade and in most cases these were used as obtained. The utilized chemicals and their sources are as follows: 2-hydrazinopyridine, pentacarbonylchlororhenium(I) from Aldrich (USA); acetic acid from Merk (India); phosphorus pentoxide (P_4O_{10}) from S.D Fine Chem. Ltd. (India). The purification and dying of dichloromethane and acetonitrile for synthesis as well as for electrochemical and spectral work were done using standard procedures [15].

3.2. Physical measurements

Electronic and IR spectra were recorded with a Shimadzu UV-1601PC spectrophotometer and a Nicolet Magna IR series II spectrometer, respectively. ^1H NMR spectra were obtained using a Bruker 300 MHz FT NMR spectrometer. The numbering scheme used for ^1H NMR is the same as in the crystallography. Spin–spin structures are abbreviated as: s, singlet; d, doublet; t, triplet; m, multiplet. Microanalyses (C, H, N) were performed using a Perkin–Elmer 240 C elemental analyzer. The electrochemical measurements were performed at a platinum electrode under nitrogen atmosphere in dichloromethane solution by using a model 620A electrochemical analyzer of CHI Instruments. The supporting electrolyte was tetraethylammonium perchlorate and potentials are referenced to the saturated calomel electrode (SCE).

3.3. Preparation of ligand (L^3)

2-Cyanopyridine (500 mg, 4.76 mmol) and 2-hydrazinopyridine (520 mg, 4.76 mmol) were mixed in a small amount of ethanol. After stirring overnight at room temperature, the crystals of 2-pyridine carboxamidrazone could be filtered off. The product was washed with diethyl ether and dried in the air. The solid obtained (~820 mg) was added to a mixture of acetic acid and acetic anhydride (1:1) at 0 °C and the solution was then brought to room temperature and stirred for 2 h. The solution was then concentrated under reduced pressure and the resulting oil was heated at 130 °C for 1 h. The solid obtained was purified by repeated crystallization from di-isopropyl ether. Yield: 660 mg (70%).

3.4. Synthesis of $Re^I(CO)_3Cl(L)$

The three complexes were prepared by the same general procedure and details are given for one.

3.4.1. $Re^I(CO)_3Cl(L^3)$

L^3 (30 mg, 0.153 mmol) was added to a hot solution of $Re(CO)_5Cl$ (50 mg, 0.138 mmol) in 40 mL benzene (better in a benzene–acetonitrile mixture 5:1). On subsequent heating to reflux for 1 h the solution color changed from light yellow to bright yellow. The solvent was then evaporated under reduced pressure and the residue was washed thoroughly with hexane for the removal of excess ligand. It was dried, and then recrystallized from a dichloromethane/hexane mixture affording a crystalline

product which was dried in vacuo over fused calcium chloride. Yield: 56 mg (81%). *Anal.* Calc. for $C_{14}H_8ClN_4O_3Re$: C, 33.50; H, 1.61; N, 11.20. Found: C, 33.42; H, 1.55; N, 11.20%. IR (cm^{-1}, KBr pellet): 1896, 2021 (C≡O). ^1H NMR ($CDCl_3$, δ, J/Hz): 9.11 (d, 1H, H(1), J 5.22), 7.81 (t, 1H, H(2), J 6.99), 8.40 (t, 1H, H(3), J 7.77), 8.81 (d, 1H, H(4)), 9.31 (d, 1H, H(8), J 6.75), 7.77 (t, 1H, H(9), J 7.47), 7.46 (t, 1H, H(10), J 6.78), 8.19 (d, 1H, H(11), $J = 8.82$). $E_{pa}(Re^{II}/Re^{I}$ couple): 1.37 V.

3.4.2. $Re(CO)_3Cl(L^1)$

$Re(CO)_5Cl$ (50 mg, 0.138 mmol) and L^1 (44 mg, 0.142 mmol) were employed. Yield: 66 mg (78%). *Anal.* Calc. for $C_{23}H_{14}ClN_4O_3Re$: C, 44.84; H, 2.29; N, 9.09. Found: C, 44.80; H, 2.25; N, 9.10%. IR (cm^{-1}, KBr pellet): 1902, 1936, 2017 (C≡O). ^1H NMR ($CDCl_3$, δ, J/Hz): 9.10 (d, 1H, H(1), J 5.62), 8.77 (t, 1H, H(2), J 7.65), 8.18 (t, 1H, H(3), J 7.77), 7.96 (d, 1H, H(4), J 7.92), 7.99–7.41 (aromatic multiplet). $E_{pa}(Re^{II}/Re^{I}$ couple): 1.43 V.

3.4.3. $Re(CO)_3Cl(L^2)$

$Re(CO)_5Cl$ (50 mg, 0.138 mmol) and L^2 (33 mg, 0.142 mmol) were used. Yield: 68 mg (80%). *Anal.* Calc. for $C_{22}H_{13}ClN_5O_3Re$: C, 42.82; H, 2.12; N, 11.35%. Found: C, 42.75; H, 2.15; N, 11.30%. IR (cm^{-1}, KBr pellet): 1881, 1906, 2021 (C≡O). ^1H NMR ($CDCl_3$, δ, J/Hz): 8.98 (d, 1H, H(1), J 5.03), 9.04 (d, 1H, H(2), J 4.99), 9.94 (s, 1H, H(3)), 7.75–7.43 (aromatic multiplet) E_{pa}-$(Re^{II}/Re^{I}$ couple): 1.48 V.

3.5. X-ray structure determination

Single crystals of $Re(CO)_3Cl(L^1)$ ($0.25 \times 0.25 \times 0.20$ mm^3) and $Re(CO)_3Cl(L^3)$ ($0.30 \times 0.25 \times 0.20$ mm^3) were grown by slow diffusion of hexane into dichloromethane solutions at room temperature. Cell parameters were determined by a least-squares fit of 30 machine-centred reflections ($2\theta = 14$–$28°$). Data were collected by the ω-scan technique on a Siemens R3m/V four-circle diffractometer with graphite-monochromated Mo Kα radiation ($\lambda =$ 0.71073 Å). Two check reflections measured after every 198 reflections showed no significant intensity reduction in any case. All data were corrected for Lorentz polarisation effects and an empirical absorption correction [16] was done on the basis of an azimuthal scan of six reflections for the crystals.

The metal atom was located from Patterson maps and the rest of the non-hydrogen atoms emerged from successive Fourier syntheses. The structures were refined by full matrix least-squares procedures. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of $Re(CO)_3Cl(L^1)$ and $Re(CO)_3Cl(L^3)$ were located and refined isotropically. Calculations were performed using the SHELXTL, Version 5.03 [17] program package. Significant crystal data are listed in Table 3.

Table 3
Crystal data for $Re(CO)_3Cl(L^1)$ and $Re(CO)_3Cl(L^3)$

Total reflections	3368	1567
Independent reflections (R_{int})	3368(0.0000)	1567(0.0000)
R_1[a], wR_2[b] [$I > 2\sigma(I)$]	0.0597, 0.1552	0.0618, 0.1549

[a] $R_1 = \sum\|F_o\| - \|F_c\| / \sum\|F_o\|$.
[b] $wR_2 = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$.

3.5.1. Determination of quantum yield (Φ)

Quantum yields were determined by comparing with a $Ru(bpy)_3^{2+}$ standard [10] ($\Phi_s = 0.042$) measured in aqueous solution. The relevant formula is given in the following equation:

$$\Phi_x = [\Phi_s(A_s XI_x)/A_x XI_s](\eta_x/\eta_s)^2 \quad (1)$$

Here x and s subscripts refer to the experimental sample and standard, respectively, A is the absorbance (set near 0.1 in a 1 cm cell) at the absorption peak (436 nm in the case of the standard), I is the area under the emission spectrum and η is the refractive index of the solvent used in the standard solution – water in this case.

4. Conclusion

Complexes of the type $Re^I(CO)_3Cl(L)$, incorporating a facial ReC_3N_2Cl coordination sphere, have been synthesized and characterized including structure determination of the L^1 and L^3 complexes.

The complexes are electroactive in acetonitrile solution (irreversible oxidation, 1.4 V) and display fluorescence in the visible region near 675 nm in the case of $Re^I(CO)_3Cl(L^1)$ and $Re^I(CO)_3Cl(L^2)$, and near 592 nm in the case of $Re^I(CO)_3Cl(L^3)$. The quantum yield of the L^3 complex, 0.036, is comparable to that of $Ru(bpy)_3^{2+}$.

Scheme 1.

as well as stereospecific interligand interactions [10,11]. Thus, in the present work we decided to explore the effect of changing the adjacent groups of the potential bonding nitrogen atom in several pyrimidine derivatives.

Differences and similarities of the pyrimidine ligands presented in this paper are drawn in Scheme 1. In the cytosine and isocytosine ligands there exist a similar moiety, H_2N–C═N–C═O, with a nitrogen sterically hindered by the two flanking amino and carbonyl groups, but its relative position inside the pyrimidine ring is able to discriminate between N(1) or N(3) binding to the metal ion. Two opposite effects should be considered: intramolecular hydrogen bond interactions [NH_2(ligand)···O(binary complex)] that facilitate the stabilisation of the complexes and the presence of stereo-electronic effects [C═O(ligand)···O(binary complex)] that disturb their formation. The resulting interaction with the ligand should be that which presents a maximum of attractive interactions between the copper(II)–N-salicylideneserinato moiety and the ligand (hydrogen bonds) and a minimum of repulsive interactions (stereo-electronic effects). On the other hand, although there are several ternary complexes with 2-aminopyridines which present an additional H-bond interaction [1,7,8], the 2-aminopyrimidine ligand has been chosen for comparison with a structure free of negative stereo-electronic effects.

The nitrogen atom N(3) has been established as the predominant metal binding site of the natural nucleobase cytosine [11–15], 1-methylcytosine [16,17] and the non-natural isomer isocytosine [18,19], a moiety of the biopterine ligand. However, monodentate exocyclic oxygen coordination have been also reported in Mn(II) [20] and Ni(II) [21,22] compounds. In addition, crystallographic studies of the related ligand 2-pyridone (2-hydroxypyridine) show three modes for metal coordination in mono-nucleating complexes: interaction via the exocyclic O-atom, interaction via the endocyclic N-atom and through a double interaction via both O and N atoms [23].

As a continuation of our work on the preparation and characterization of ternary copper(II) N-salicylideneaminoacidato Schiff base complexes, in this paper, we present five new crystal structures in order to evaluate the effects mentioned above: [Cu(sal-ser)(cytosine)] · $2H_2O$ (**1**), [Cu(sal-ser)-(1-methylcytosine)] · $1.25H_2O$ (**2**), [Cu(sal-ser)(isocytosine)]· $1.25H_2O$ (**3**), [Cu(sal-ser)(2,4-diamino-6-hydroxypyrimidine)] · $2H_2O$ (**4**) and [Cu(sal-ser)(2-aminopyrimidine) (H_2O)] · H_2O (**5**).

2. Experimental

2.1. General remarks

Elemental analyses of the complexes were carried out using a Carlo Erba Analyser Model 1106. The infrared spectra (KBr pellets) were recorded on a PE 683 with a PE 1600 infrared data station. The visible absorption spectra were recorded in DMSO solutions on a PE 552 spectrophotometer. Thermogravimetric data in the range from 30 to 700 °C were obtained (heating rate 5 °C/min) on a PE TGA-2 thermobalance. Magnetic susceptibility measurements (at 298 K) were carried out on polycrystalline samples with a Manics DSM8 pendulum-type magnetometer equipped with a helium continuous-flow cryostat and a Bruker BE15 electromagnet. The magnetic field was ca. 1.5 T. Diamagnetic corrections were estimated from Pascal's constants. The ESR spectra were recorded at X-band frequencies with a Bruker ES200 spectrometer at 298 K.

2.2. Materials

Salicylaldehyde, L-serine, cytosine, 1-methylcytosine, isocytosine, 2,4-diamino-6-hydroxipyrimidine (6-aminoisocytosine), 2-aminopyrimidine and copper(II) acetate monohydrate were obtained from Aldrich and used without further purification. The [Cu(sal-L-ser)H_2O] · H_2O starting complex was obtained as indicated in reference [8].

2.3. Syntheses

The complexes were synthesised by treatment of [Cu(sal-L-ser)H_2O] · H_2O with the pyrimidine ligand in water, EtOH/H_2O or MeOH/H_2O. In all cases, the synthetic procedure has been difficult because of the appearance of a polymeric blue precipitate of variable composition which must be carefully filtered off to obtain transparent solutions where, slowly, appear a few dark green crystals over another sticky polymeric material. Sometimes its is very difficult to isolate completely these crystals and the use of few drops of ethanol or methanol permit the isolation of them in a pure form, but the yield is reduced to a considerable extent.

2.3.1. [Cu(sal-ser)(cytosine)] · $2H_2O$ (**1**)

Cytosine (0.11 g, 1 mmol) was added to a warm solution (60 °C) of 1 mmol (0.30 g) of [Cu(sal-L-ser)H_2O] · H_2O in

25 mL of 2:1 water/ethanol mixture. The dark green solution was stirred at 60 °C for 2 h until a blue precipitate of variable composition was obtained and separated by filtration. A few dark green crystals appeared in the mother solution after several days of evaporation of the solvent in air. Yield: 10%. Due to the poor yield and reproducibility and stability of this complex, the 1-methylcytosine derivative was also synthesised. TG: The complex exhibits a mass decrease (found 8.6; calcd. 8.6%) between 115 and 150 °C corresponding to the loss of two water molecules per formula unit. *Anal*. Calc. for $C_{14}H_{18}N_4O_7Cu$ (417.9): C, 40.23; H, 4.31; N, 13.41. Found: C, 40.23; H, 4.27; N, 13.31%. IR (KBr disk, cm^{-1}): $\nu = 3395$ (s), 3190 [s, $\nu_s(NH_2)$ and $\nu_a(NH_2)$], 1643 [sh, ν(C=N)], 1605 [s, ν_a(COO)], 1525 (m), 1449 (s), 1360 [s, ν_s(COO)], 1303 (m), 744 (w), 757 (m), 438 [w, ν(Cu–N)], 332 [m, ν(Cu–O)]. UV–Vis (DMSO): nm (ε): 662 (144), 366 (1.3×10^4), 268 (3.5×10^4). Λ_M (Ω^{-1} cm^2 $mol^{-1}/10^{-3}$ M in DMSO, 24 °C) = 1.8.

2.3.2. [Cu(sal-ser)(1-methylcytosine)] · 1.25H_2O (2)

Prepared as described for **1** although [1-methylcytosine (0.12 g, 1 mmol) in H_2O (10 mL) was added to the starting complex [Cu(sal-L-ser)H_2O] · H_2O in 10 mL of 2:1 water/ethanol warm solution]. Yield: 15%. TG: The complex exhibits a mass decrease (found 5.4; calcd. 5.5%) between 130 and 160 °C corresponding to the loss of 1.25 water molecules per formula unit. *Anal*. Calc. for $C_{15}H_{18.5}N_4O_{6.25}Cu$ (418.4): C, 43.06; H, 4.42; N, 13.39. Found: C, 42.99; H, 4.38; N, 13.15%. IR (KBr disk, cm^{-1}): $\nu = 3376$ (s), 3173 (s), 3157 [s, $\nu_s(NH_2)$ and $\nu_a(NH_2)$], 1663 [sh, ν(C=N)], 1607 [sh, ν_a(COO)], 1535 (m), 1469 (m), 1448 (s), 1344 [s, ν_s(COO)], 1308 (s), 764 (m), 450 [w, ν(Cu–N)], 347 [w, ν(Cu–O)]. 2.3.3. [Cu(sal-ser)(isocytosine)] · 1.25H_2O (3)

[Cu(sal-L-ser)H_2O] · H_2O (0.30 g, 1 mmol) in 1:1 water/methanol mixture (20 mL) was added to a warm water solution (10 mL, 60 °C) of isocytosine (0.11 g, 1 mmol). The dark green solution was stirred at 60 °C for 1 h. The obtained precipitate was separated by filtration. Dark green crystals appeared after several days from a solution of the obtained solid in 1:1 water/methanol. Yield: 18%. TG: The complex exhibits a mass decrease (found 5.5; calcd. 5.5%) between 160 and 190 °C corresponding to the loss of 1.25 water molecules per formula unit. *Anal*. Calc. for $C_{14}H_{16.5}N_4O_{6.25}Cu$ (404.3): C, 41.58; H, 4.08; N, 13.86. Found: C, 41.60; H, 4.09; N, 13.81%. IR (KBr disk, cm^{-1}): $\nu = 3385$ (s), 3351 [s, $\nu_s(NH_2)$ and $\nu_a(NH_2)$], 1661 [s, ν(C=N)], 1575 [sh, ν_a(COO)], 1533 (m), 1476 (m), 1356 [s, ν_s(COO)], 1307 (s), 770 (m), 446 [w, ν(Cu–N)], 349 [w, ν(Cu–O)]. UV–Vis (DMSO): nm (ε): 657 (111), 370 (6.6×10^3), 272 (1.8×10^4). Λ_M (Ω^{-1} cm^2 $mol^{-1}/10^{-3}$ M in DMSO, 24 °C) = 1.6.

2.3.4. [Cu(sal-ser)(2,4-diamino-6-hydroxypyrimidine)] · 2H_2O (4)

Prepared as described for **1** although in this case [Cu(sal-L-ser)H_2O] · H_2O (0.30 g, 1 mmol) in 1:1 water/ethanol mixture (40 mL) was added to a warm 1:1 water/ethanol solution (10 mL, 60 °C) of 2,4-diamino-6-hydroxy pyrimidine (0.12 g, 1 mmol). Yield: 20%. TG: The complex exhibits a mass decrease (found 8.3; calcd. 8.3%) between 70 and 160 °C corresponding to the loss of two water molecules per formula unit. *Anal*. Calc. for $C_{14}H_{19}N_5O_7Cu$ (432.9): C, 38.84; H, 4.39; N, 16.18. Found: C, 38.93; H, 4.39; N, 16.33%. IR (KBr disk, cm^{-1}): $\nu = 3477$ (s), 3338 [s, $\nu_s(NH_2)$ and $\nu_a(NH_2)$], 1645 [s, ν(C=N)], 1617 [s, ν_a(COO)], 1545 (m), 1460 (m), 1452 (s), 1348 [s, ν_s(COO)], 1293 (s), 745 (w), 763 (m), 770 (m), 465 [w, ν(Cu–N)], 326 (w), 348 [w, ν(Cu–O)]. UV–Vis (DMSO): nm (ε): 660 (112), 365 (8.7×10^3), 268 (2.3×10^4). Λ_M (Ω^{-1} cm^2 $mol^{-1}/10^{-3}$ M in DMSO, 24 °C) = 2.0.

2.4. X-ray crystallography

X-ray data for single crystals of **1**–**5** were collected with an Enraf-Nonius CAD4 diffractometer using monochromatic Mo Kα radiation ($\lambda = 0.71069$ Å). The cell parameters were determined from least-squares refinement against a set of reflections randomly searched. Data were collected at room temperature using ω–2θ scans. Lorentz-polarisation, decay and ψ-scan empirical absorption [24] corrections were applied using the WinGX program [25] for **1** and **3** and the MolEN package [26] for **2**, **4** and **5**. The structures were solved by direct methods and refined by a full-matrix, least squares method using the SHELX-97 programs [27]. Non-H atoms were anisotropically refined. H atoms were positioned in calculated positions, except those in water molecules, which were located in Fourier difference maps. In **3**, **4** and **5** a global isotropic vibration parameter was refined for all hydrogens while in **1** and **2** the isotropic thermal vibrations of these atoms were fixed to 1.2–1.5 times the U_{iso} of the bonded atom. Crystal

parameters, data collection details and results of the refinements are summarized in Table 1.

3. Results and discussion

Although a number of structural studies have been performed on Cu(II)–salicylideneserinato [Cu(sal-ser)] ternary compounds with different substituted pyridines [28–33], no systematic studies are known with ligands able to stabilize the Cu(sal-ser) moiety with additional weak interactions. In order to explore the main factors working on the formation and stabilization of copper salicylideneserinato ternary complexes we have checked several pyrimidine ligands that are potentially able to form additional hydrogen bond interactions, namely cytosine, 1-methylcytosine, isocytosine, 2,4-diamino-6-hydroxypyrimidine and 2-aminopyrimidine. In the cytosine derivative compounds with two flanking groups, amino and carbonyl substituents [O=C–N(3)=C–NH_2], specific repulsive interactions with exocyclic oxygens of the ligand can also exert their influence on the relative orientation of the pyrimidine plane or even decide the specific ring donor atom to the metal cation.

Reaction between the binary [Cu(sal-L-ser)H_2O]·H_2O complex and the corresponding pyrimidine ligand, has permitted the isolation of five new ternary complexes in the form of suitable monocrystals for X-ray diffraction studies. Crystal parameters, data collection details and results of the refinements are summarised in Table 1.

3.1. Structures of complexes *1*–*5*

Complexes **1** and **2** have a slightly distorted square planar geometry, with the four coordination sites occupied by the tridentate N-salicylideneserinato group [N(9), O(16) and O(7)] and the heterocyclic nitrogen N(3) of the pyrimidine ligand (Figs. 1 and 2). As observed in other cytosine

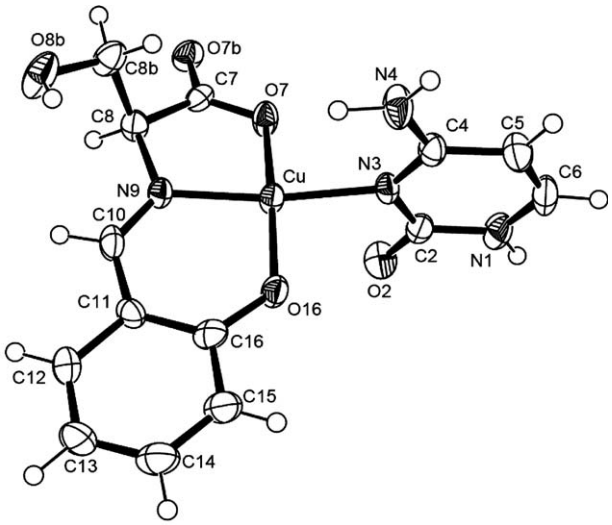

Fig. 1a. ORTEP of [Cu(sal-ser)(cytosine)]·$2H_2O$ (**1**).

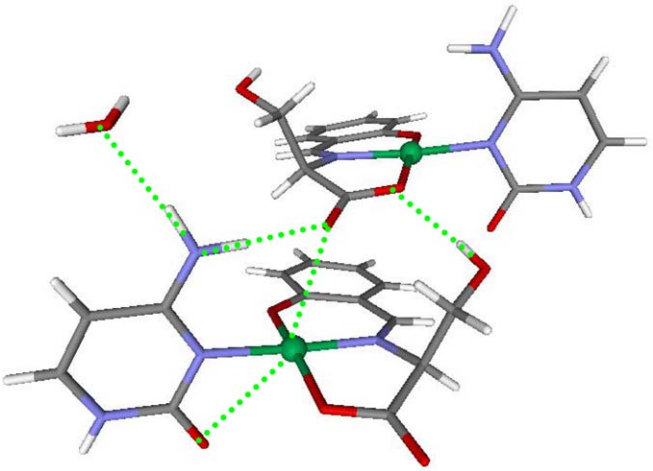

Fig. 1b. Additional interactions observed in complex **1**: [Cu···O(7b)($COO^{\#}$): 2.818 Å; O(8b)–H···O(7)($COO^{\#}$): 2.763 Å; N(4)–H···O(7b)($COO^{\#}$): 2.829 Å; N(4)–H···O(W): 2.909 Å].

compounds [34], an additional weak interaction between copper(II) and the C=O group is observed in both complexes [Cu–O(2): 2.856 Å for **1** and 2.731 Å for **2**].

Complexes **3** and **4** present a similar basal coordination with the isocytosine moiety bonded via N(1) in complex **3** while complex **4** interacts through the exocyclic oxygen O(4). Additional weaker axial interactions on Cu(II) are: Cu–N(2):2.656 Å for **3** and Cu–O(16): 2.627 Å for **4** which allows the association of dimeric complex units (Figs. 3 and 4).

Complex **5** has a square pyramidal geometry with the oxygen atom of one water molecule occupying the fifth axial position (Fig. 5). Copper(II) environment distances are shown in Table 2.

A slight distortion in the square planar environment of Cu(II) in all cases is indicated by the observed bond angles, which vary from 82.38 to 95.87 °C. The distance of N–C(CH_2OH) is shorter than the usual C–N single bond and the values of C=N are in good agreement with the values of Schiff bases Type I described by Ueki et al. [35]. Selected bond distances and angles are given in Table 3.

Additional intramolecular interactions between the ligand and the Cu(sal-ser) moiety are not observed in cytosine complexes **1** and **2** in which the pyrimidine base, coordinated through N(3) to the copper atom, is nearly perpendicular to the Schiff base plane. In the case of a coplanar disposition, a repulsive interaction between O(phenol) and O(C=O) necessarily occurs and can force

the pyrimidine plane towards the orthogonal orientation to avoid steric hinderance. Contrarily to that reported in rhodium(II)–cytosine studies [11] these are two specific cases in which the cytosine ligand is bound through the sterically hindered N(3) to the metal atom without the participation of O(C=O) and N(amino) substituents in intramolecular hydrogen bonds. In the case of complex **3**, the isocytosine ligand is coplanar and is coordinated to Cu(II) through N(1), probably due to the effective and strong additional intramolecular interaction between the amino group of the pyrimidine ligand and the O(phenol) [N(2)–H···O(16): 2.631(3) Å] which is not possible in the cytosine analogs where the ligand is bound to the metal via N(3). Several structural studies [10] on interligand interactions affecting specific metal bonding to nucleobases and quantum chemical studies [36] about rotation of N(3) metallated cytosines have been described.

Surprisingly, monodentate coordination via O(4) of the 2,4-diamino-6-hydroxypyrimidine ligand with both [H_2N–C–N(1)–C–NH_2] and [O–C–N(3)–C–NH_2] moieties, is obtained in the coplanar complex **4** which permits the

adjacent heterocyclic nitrogen to participate in an additional intramolecular hydrogen bond interaction [N(3)–H···O(7): 2.821 Å] that stabilizes the structure. As indicated previously, in order to avoid steric constraints about the metal center, cytosine can binds to the metal ion via the exocyclic O(2) atom [20,21,37–40].

In the case of complex **5**, the aminopyrimidine ligand rotates to permit the optimal and typical intramolecular interaction between the amino group and the carboxylate oxygen atom [N(2)–H···O(7): 2.920 Å] [8].

Intermolecular interactions involving crystallisation water molecules and interactions between complex units stabilize the crystal packing in all the complexes (see Figs. 1–5).

3.2. Infrared and electronic spectra

The IR spectra of the complexes were recorded down to the region around 400 cm^{-1} and compared with those of the free ligand. Tentative band assignments (cm^{-1}) for the cytosine derivatives have been published previously [14,15,18–20]. For 2,4-diamino-6-hydroxypyrimidine and 2-aminopyrimidine tentative assignments have been made by analogy with those of cytosine. In all the complexes several peaks are observed between 3500 and 3200 cm^{-1} which are related to the stretching vibrations $\nu_{as}(NH_2)$ and $\nu_s(NH_2)$. The strong band appearing between 1660 and 1630 cm^{-1} is assignable to ν(CN) [41] and the peaks located in the ranges 1620–1570 and 1390–1350 cm^{-1} are attributed to ν_{as}(COO) and ν_s(COO), respectively [42]. The separation between the two bands is consistent with a monodentate coordination of the carboxylate group. Other bands in the range 1500–1100 cm^{-1} are related to ν(Phe) ring and ν(OPhe). Finally, the peaks appearing between 460–420 and 380–320 cm^{-1} are attributed to ν(Cu–N) and ν(Cu–O).

The d–d transition spectra of the complexes in DMSO show a broad band between 655 and 662 nm that is suggestive of approximate square pyramidal geometry about Cu(II) in solution. The π–π^* bands corresponding to the pyrimidine ligand appear in the 370–268 nm range. For these compounds, the Λ_M (10^{-3} M) values in DMSO at 20 °C imply the presence of non-electrolyte type species [43].

3.3. ESR spectra and magnetic properties

The effective magnetic moments $\mu_{eff} = 1.93$ (**2**), 1.77 MB (**3**), 1.80 MB (**4**) and 1.98 MB (**5**) at room temperature are normal for magnetically diluted d^9 systems. The X-band ESR spectra of a polycrystalline powder of the complexes recorded at 298 K show axial symmetry with values of $g_\parallel = 2.21$ and $g_\perp = 2.06$ (**2**), $g_\parallel = 2.24$ and $g_\perp = 2.07$ (**3**), $g_\parallel = 2.13$ and $g_\perp = 2.05$ (**4**) and $g_\parallel = 2.20$ and $g_\perp = 2.09$ (**5**). Simulated spectra obtained by using the WINEPR program gave good agreement with the experimental g values. These spectra are consistent with square planar or square pyramidal geometry. The results are in agreement with the symmetry of Cu(II) derived from the X-ray structure determination. Unfortunately, the values for complex **1** were not obtained owing to difficulties in preparing enough pure crystalline sample and the highest instability of this complex compared to compound **2**.

4. Conclusion

In this study, we have synthesized and structurally characterized five new Schiff base ternary Cu(sal-ser) complexes with different pyrimidine (cytosine or isocytosine derivatives) ligands and explored the effect of changing the adjacent

groups of the potential binding heterocyclic atom. The presence of an intramolecular hydrogen bond and specific interligand repulsive interactions seem to be important factors, playing a crucial role on the stability of the complexes and the relative orientation of the pyrimidine plane or even deciding the particular donor atom to the copper(II) ion.

As a consequence of repulsive O(C=O)···O(Phe) interactions, the approximate orthogonal disposition is obtained allowing an additional weak attractive interaction Cu···O(C=O) in the cytosine derivatives (**1** and **2**).

For the isocytosine complex **3**, the chosen metal binding site N(1) and a coplanar disposition allow the additional hydrogen bond interaction NH(amino)···O(Phe). In complex **4**, the aminoisocytosine ligand binds to the metal ion through the oxygen atom in a monodentate way which permits the additional [N(3)H···O(COO)] interaction. Finally, in the case of complex **5**, the additional hydrogen bond [N(amino)···O(carboxylate) = 2.92Å] implies rotation of the 2-amino pyrimidine plane with respect to the Schiff base plane.

The ammine ligand in $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_3)]PF_6$ had proved to be resistant to replacement by carbonylation and to deprotonation [9].

There are very comprehensive nomenclature systems for the unique identification of isomeric transition metal compounds but they have proved very cumbersome for routine application [10,11]. We have opted for the simple approach related to that used by organic practitioners. The stereochemical descriptors used for organometallic compounds are a modification of the Cahn–Ingold–Prelog rules and treat the cyclopentadienyl group as a single atom of atomic weight 60 for prioritization [12,13]. The structural diagrams in this paper are drawn to normally show the metal chirality denoted as $\mathbf{S}_{Ru}$ for convenience ($Cp > PPh_3 > NH_2R > CN^tBu$) but unless explicitly stated the starting materials and products represented are racemic. One of the spectroscopic probes used throughout this work is that of diamagnetic anisotropy; protons held over an aromatic ring system will normally be shielded (δ decreases) in ^1H NMR spectra while protons held over a triple bond will be deshielded (δ increases). The effect is usually observable at distances up to 4 Å and drops off rapidly although measurable effects up to 14 Å have been observed in polyaromatic systems [14,15].

2. Results and discussion

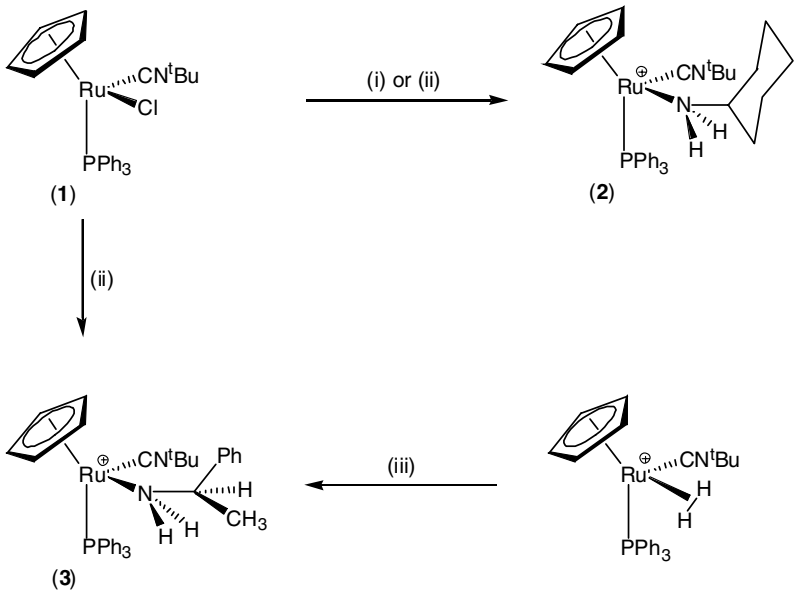
Treatment of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(Cl)]$ (**1**) with a halide abstractor in the presence of cyclohexylamine produced yellow crystalline $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2C_6H_{11})]PF_6$ (**2**). The halide abstraction system could be either thallium hexafluorophosphate in dichloromethane or the methanolic potassium hexafluorophosphate–thallium (I) carbonate mixture used previously to prepare ammine complexes [9]. The first system gave a 97% yield compared with 38% for the latter indicating some degree of competition between methanol and the amine for the solvento cationic intermediate in that synthetic route. The main features of spectroscopic interest are the differentiation of the diastereotopic NH protons by 1.21 ppm in the ^1H NMR spectrum and weak bands at 3311, 3270, and 1587 cm^{-1} in the infrared spectrum due to the amine ligand. Encouraged by the degree of chemical shift difference which suggested that one of the amine protons is oriented into the region near the phenyl rings of the triphenylphosphine ligand and hence shielded, implying strongly preferred conformations and a useful spectroscopic probe, we decided to prepare a family of cations containing *C*-chiral amines in order to investigate diastereomeric resolution. The chiral amines used were of at least 98% e.e. and the diastereomeric excesses reported below have not been recalculated; given the integration errors for routine ^1H NMR spectroscopy the diastereomeric excesses reported probably underestimate the true selectivities.

Reaction of **1** with thallium hexafluorophosphate in dichloromethane and *S*(−)-α-methylbenzylamine, *R*(−)-1-cyclohexylethylamine, or (±)-1-(1-naphthyl)ethylamine gave the salts $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2CH\{Me\}Ph)]PF_6$ (**3**), $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2CH\{Me\}Cy)]PF_6$ (**4**), and $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2CH\{Me\}Np)]PF_6$ (**5**), respectively. Initial crystallization of **3** from dichloromethane–diethyl ether (1:3) at −78 °C gave fine yellow crystals, which proved to be predominantly the $\mathbf{R}_{Ru}\mathbf{S}_C$ diasteromer (**3RS**) in 74% diastereomeric excess. Concentration of the filtrate and crystallization at −25 °C gave a second set of yellow crystals, which proved to be predominantly the $\mathbf{S}_{Ru}\mathbf{S}_C$ diastereomer (**3SS**) in 98% d.e. The infrared spectrum of **3** contains four bands due to ν(NH) at 3325, 3308, 3284, and 3265 cm^{-1} confirming the presence of two diastereomers with the bands at 3325 and 3284 cm^{-1}being due to the more soluble diastereomer **3SS**. While the definitive assignment of absolute structure for the two diastereomeric salts was made by single crystal X-ray crystallography our initial assignment was made by consideration of the ^1H NMR spectra of the enriched diastereomers. The spectrum of the least soluble compound **3RS** has a cyclopentadienyl singlet resonance at δ 4.30 and a doublet at δ 1.11 for the α-methyl group whereas the more soluble compound **3SS** has these resonances at δ 4.72 and δ 1.29, respectively. The diastereomers **3RR** and **3SR** were also prepared, from *R*(+)-α-methylbenzylamine to ensure complementarity and reciprocity and this pair were used for the X-ray single crystallographic studies (Scheme 1).

Davies has demonstrated the use of α-methyl group shielding by the aromatic ring current of triphenylphosphine to distinguish stereoisomers of the metal acyls $[(\eta^5\text{-}C_5H_5)Fe(PPh_3)(CO)(COCH(Me)R)]$; in $\mathbf{S}_{Fe}\mathbf{S}_C/\mathbf{R}_{Fe}\mathbf{R}_C$ diastereomers the group resonates between δ 0.00 and δ 0.50 whereas in the $\mathbf{S}_{Fe}\mathbf{R}_C/\mathbf{R}_{Fe}\mathbf{S}_C$ diastereomers the resonance is found between δ 0.8 and δ 1.30 [16]. Fig. 1 illustrates the relative relationships between the ruthenium and iron compounds; note that the priority rules reverse the metal centre descriptors on changing from an amine group to an acyl group.

The single crystal X-ray structures of **3SR** and **3RR** (vide infra) confirm the basic conformations shown in Fig. 2 and support the additional assumption that the phenyl ring of the amine ligand shields the cyclopentadienyl protons in **3SR** and **3RS**. Our criterion is that the diastereomer with the highest ^1H NMR chemical shifts for both the cyclopentadienyl and α-methyl groups is the **RR** or **SS** diastereomer while that with the lowest values for both chemical shifts is the **RS** or **SR** isomer in the isonitrile series. Davies has published extensively on the conformational preferences of the alkyl groups in the iron acyl complexes [17]; we have not performed similar modeling studies but the close spectroscopic similarities suggest that qualitatively the structures indicated are correct, in particular that the methine hydrogen points in towards the isonitrile or carbonyl group.

While the described preparation of **3** yields an overall racemic product in that equal amounts of **3RS** and **3SS** are produced from **2** and *S*(−)-α-methylbenzylamine



(i) KPF_6, Tl_2CO_3, MeOH, amine, 60°C (ii) $TlPF_6$, amine, CH_2Cl_2, RT (iii) amine, CH_2Cl_2

Scheme 1. Synthetic routes to **2** and **3**.

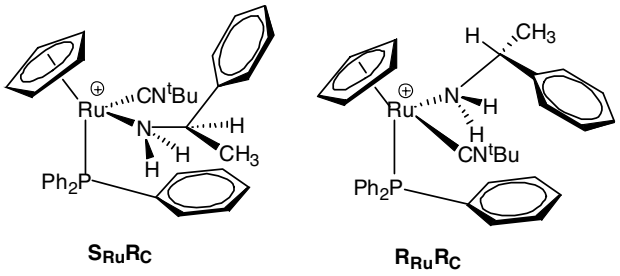

Fig. 2. Idealized solution conformation of **3SR** and **3RR**.

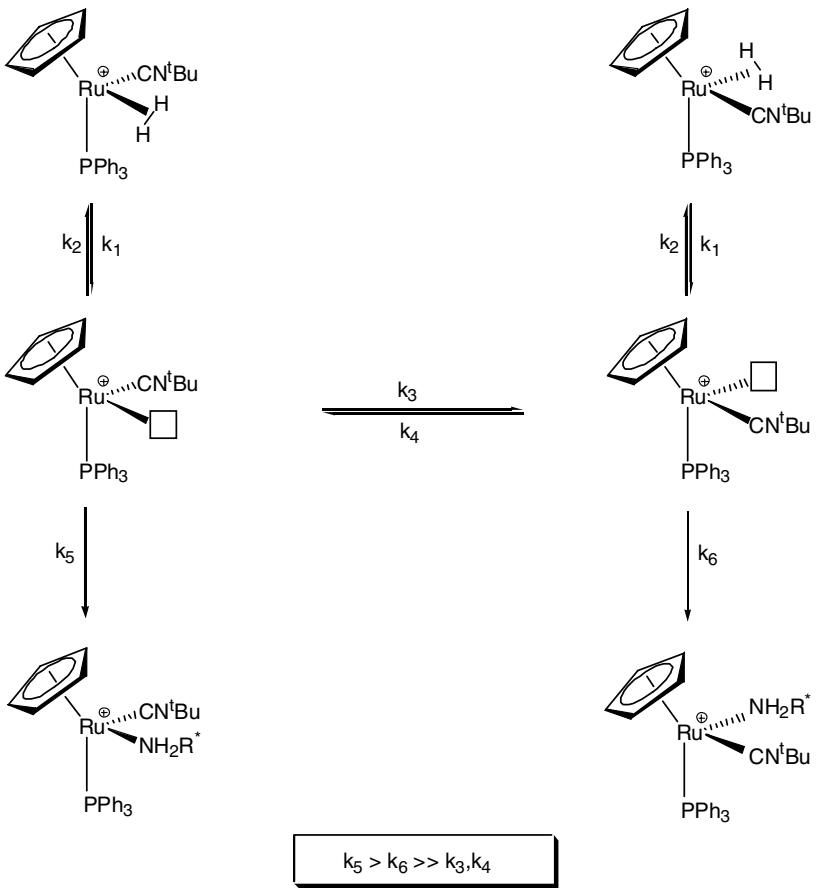
thermodynamically, this was not necessarily anticipated. A kinetic experiment was therefore carried out by monitoring the formation of **3SS** and **3RS** from the reaction of the molecular hydrogen cation $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(\eta^2\text{-}H_2)]PF_6$ [18] with *S*(−)-α-methylbenzylamine in deuterodichloromethane by ^1H NMR spectroscopy at room temperature. Addition of 0.3 equivalents of the amine immediately generated only **3SS** and the further addition of 0.7 equivalents of amine subsequently generated **3RS** within 10 min; the final ratio of diastereomers was 50:50 and remained unchanged after 1 h at room temperature. Under the ambient conditions the Lewis acid fragment $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)]^+$ formed initially does not racemise and despite a kinetic preference for **3SS** the lack of racemization prevents diastereomeric induction. Under these conditions there is no interconversion of **3SR** and **3SS** as evidenced both by this experiment and from monitoring enriched samples over a period of days. Further, the single crystals used for the X-ray structural determinations of **3RR** and **3SR**, respectively were each dissolved in CD_2Cl_2 at 22 °C and ^1H NMR spectra of the solutions were immediately obtained; in each case the appropriate single diastereomer was the only observed species and the other diastereomers, **3SR** and **3RR**, respectively, were not observed after several hours.

There has been a considerable history of investigating the ease of racemization of chiral at metal compounds [4–8] with the general conclusion that such centres are often not stereochemically rigid; we conclude that in this case the rate of racemization is much less than the rate of complexation and that none of the ligands attached to ruthenium in the final products reversibly dissociate (Scheme 2).

The salt $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2CH\{Me\}\text{-}Cy)]PF_6$ (**4**) was also enriched on initial crystallization to produce **4SR** as the least soluble diastereomeric salt in 61% d.e. and the more soluble isomer **4RR** in 79% d.e.



Scheme 2. Curtin–Hammett scheme for the interconversion of **3**.

Similarly a single crystallization of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2CH\{Me\}Np)]PF_6$ (**5**) gave the **RS/SR** product in 73% d.e. and the more soluble **RR/SS** product in 56% d.e. A further recrystallization of the **RS/SR** product increased the diastereomeric excess up to 91%; both products in this case being racemic because racemic (±)-1-(1-naphthyl)ethylamine was used. In contrast to the large difference in ^{1}H NMR chemical shift, (0.43 ppm), for the cyclopentadienyl resonances of **3RS** and **3SS** these resonances differ by 0.001 ppm for the diastereomers of **4** suggesting that the aromatic ring of the amine in **3** can shield these protons. In the case of **5** which also contains an aromatic group in the amine ligand the separation is 0.54 ppm for the diastereomers.

Further diastereomeric enrichment of **3** and **5** was carried out to establish the principle and usually a maximum of three crystallizations was sufficient to give products of ca. 98.5% d.e. for **3** and **5**. Enrichment of **4** was not explored fully because the spectroscopic parameters of **4** made accurate quantitation problematic beyond the 90% d.e. level.

The reaction of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CO)Cl]$ (**6**) with thallium hexafluorophosphate and *S*(−)-α-methylbenzylamine in dichloromethane produced a very low yield (3%) of yellow crystals of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CO)(NH_2CH\{Me\}Ph)]PF_6$ (**7**). The two diastereomeric salts were again partially separable with the $\mathbf{R_{Ru}S_C}$ product (**7RS**) being the least soluble. The assignment of $\mathbf{R_{Ru}}$ stereochemistry in this diastereomeric salt was made by comparing the cyclopentadienyl resonances in the ^{1}H NMR spectra at δ 5.13 and 4.57 with the lower chemical shift being assigned to **7RS** and the higher to **7SS**; this reflects the pattern found for the diastereomers of **3** and **5** induced by the orientation of the aromatic substituent on the amine ligand. The small quantity of **7SS** obtained after the initial crystallization which gave a sample of **7RS** in 42% d.e. combined with the low chemical yield, prevented the full assignment of the ^{1}H NMR spectrum and means that we have used a single parameter in this case.

Decomplexation of the bound amine from diastereomerically enriched samples of **3**, **4**, or **7** should produce enantiomerically enriched samples of the metal moieties. A variety of procedures was explored using $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2C_6H_{11})]PF_6$ (**2**) as a model compound. Reaction of **2** with carbon monoxide (5 atm., 294 K, 120 h.) in dichloromethane, with iodomethane or tetraethylammonium fluoride or tetraethylammonium cyanide in dichloromethane, with methanolic sodium methoxide, with sodium iodide or sodium azide in acetone, with lithium triethylborohydride in THF (all at 294 K, 1–48 h), or with 2-methyl-1-butanethiol in refluxing methanol gave in each case high recovery (>80%) of

2 and no other tractable products. Treatment of **2** with excess sodium iodide and excess trimethylamine-*N*-oxide in methanol under reflux generated [(η^5-C_5H_5)-Ru(PPh_3)(CN^tBu)(I)] (**8**) in moderate yield together with recovered **2**. Since this reaction probably proceeds by the generation of iodine and its subsequent reaction with **2** we proceeded to react **2** with iodomethane in refluxing 1,2-dichloroethane or by photolysis of a solution in dichloromethane containing iodine. Careful optimization of these reactions suggested initial conditions for the attempted decomplexation of **3**, the chiral metal centre target. Samples of **3RS** (90% d.e.) and **3SS** (96% d.e.) were converted via the iodomethane route into **8** in 98% and 82% isolated yield, respectively. A sample of **3RS** of the same purity was also converted via the photolysis route in 54% isolated yield.

The samples of **8** obtained were assayed for enantiomeric purity by two methods; reaction with *S*(−)-α-methylbenzylamine to regenerate **3RS** and **3SS** and by a ^{1}H NMR spectroscopic method. Addition of *R*(−)-2,2,2-trifluoro-1-(9-anthryl)ethanol (*R*(−)-TFAE) to racemic **8** causes doubling of the cyclopentadienyl and *tert*-butyl resonances with the optimum separation (300 MHz: 5.7 and 3.6 Hz, respectively) occurring on addition of 1.2 equivalents of TFAE. Both methods confirmed that the samples of **8** obtained on decomplexation from **3RS** and **3SS** were racemic (±2%). The high chemical stability of **3** and the nature of the forcing conditions required to produce **8** demonstrates that our resolution strategy was unsuccessful.

The reaction of a secondary amine ligand could potentially generate an additional chiral centre and [(η^5-C_5H_5)-Ru(PPh_3)(CN^tBu)(Cl)] (**1**) was reacted with diethylamine and $TlPF_6$ in dichloromethane to confirm that a secondary amine could ligate to the ruthenium centre. The orange-yellow crystals of [(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)($NHEt_2$)]PF_6 (**9**) were moderately air-sensitive and showed a single band at 3269 cm^{-1} (ν_{NH}) in the infrared spectrum in contrast to the two bands seen for a primary amine containing cation. The ^{1}H and ^{13}C{^{1}H} NMR spectra of **9** demonstrated that the ethyl groups of the diethylamine ligand were diastereotopic as expected. *S*(−)-*N*-methyl-1-phenylethylamine reacted similarly to yield yellow crystalline [(η^5-C_5H_5)-Ru(PPh_3)(CN^tBu)(NH(Me)CH{Me}Ph)]PF_6 (**10**) as a mixture of four diastereomers in the ratio 9.6%:38.5%:3.9%:48.0% while concentration of the initial mother-liquor and crystallization produced the same diastereomers in the ratio 21.7%:52.2%:8.7%:17.4%. While these precise ratios reflect the degree of crystallization achieved they also indicate the relative stability of the nitrogen chiral centres, these being freely selectable under the reaction conditions unlike the ruthenium and carbon chiralities, one of which is not racemisable under the conditions and the other of which is set. Analysis of the ^{1}H NMR spectra of these mixtures using the criteria established above for the relative disposition of the metal and carbon chiralities suggests the assignments $\mathbf{S_{Ru}S_NS_C}$:$\mathbf{S_{Ru}R_NS_C}$:$\mathbf{R_{Ru}R_NS_C}$:$\mathbf{R_{Ru}S_NS_C}$ for the diastereomers (Table 1). In particular the cyclopentadienyl group and α-methyl resonances reflect the neighbouring phenyl ring induced shieldings. The *N*-methyl group shieldings also reflect the existence of two diastereomers with these groups pointing towards the isonitrile unsaturation (deshielded) and two with these groups pointing away (shielded).

Calculation of the total quantities of each diastereomer *isolated* reveals the overall ratio is 12.3%:41.4%:4.9%:41.4%; fortuitously the quantity of **10RSS** and **10SRS** material is similar and demonstrates that the metal centre prefers to induce opposite chirality at the nitrogen centre. While the *isolated* material does not represent 100% of the theoretical yield it is clear that a preference of at least 4:1 is present. Fig. 3 below shows all four diastereomers.

The conformations shown are those that can be reasonably predicted based upon the structures of the diastereomeric salts of **3RR** and **3SR** analyzed earlier by ^{1}H NMR spectroscopy and confirmed by X-ray single crystal structure determination. It is clear that the *N*-methyl group would prefer to be external (**SRS**,**RSS**) rather than internal (**RRS**,**SSS**) on steric grounds.

Table 1
Comparison of chemical shifts for the diastereomers of **3** and **10**

Assignments	3RS	3SS	10RSS	10RRS	10SRS	10SSS

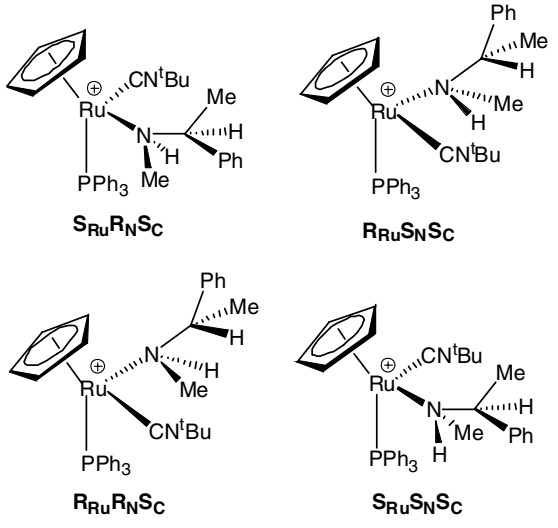

Fig. 3. The diastereomers of **10** derived from *S*(−)-*N*-methyl-1-phenylethylamine.

An alternative method to produce a ruthenium complex resolved at the metal centre which could be taken on further in asymmetric chemistry would involve the preparation of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CNZ)(Cl)]$, where Z contains a chiral element. Combining our experience of the amine chemistry and the utility of the ring shielding effect as a spectroscopic probe we decided to use *S*(−)-α-methylbenzylisonitrile (*S*(−)-Ph(Me)CHNC) as a ligand. A sample of *S*(−)-α-methylbenzylamine was determined to be >99.6% e.e by ^{1}H NMR spectroscopy using *R*(−)-TFAE as a chiral auxiliary [19]. Conversion of this amine to the isonitrile was achieved in 50% yield by a phase transfer Hofmann carbylamine procedure; polarimetry and subsequent reactions indicate that the optical purity was retained in the product.

Reaction of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2(Cl)]$ with *S*(−)-α-methylbenzylisonitrile in hot toluene gave a bright orange powder after chromatography in 45% yield. Characterization of this material showed it to be a racemic mixture of the diastereomeric salts $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CNCH(Me)Ph)(Cl)]$ (**11SS**,**11RS**). The solid and solution infrared spectra of the product contained bands at 2102 and 2104 cm^{-1} assignable to *ν*(CN), while the mass spectrum contained the parent ion and then subsequent losses of the chloro group and the isonitrile group. It proved possible with considerable effort to enrich a sample to 30% d.e. by crystallization from toluene–hexane mixtures in order to assign the individual ^{1}H NMR parameters to each diastereomer. The ^{1}H NMR spectroscopic signals of the C*H*Me (*δ* 4.87 and 4.70) and CH*Me* (*δ* 1.29 and 1.39) groups were baseline resolved in the diastereomer mixture and could be used quantitatively. The remoteness of the chiral centre in **11** in comparison to the amine complexes such as **3** did not permit complete confidence in an absolute assignment because the linear isonitrile functionality removes the α-methyl group away from the ring current of the triphenylphosphine aromatic rings, but after looking at the solid state structures of **12**, we assign the signals at *δ* 4.87 and 1.29 to **11SS**.

The mixture (**11SS**,**11RS**) was converted into the ammine salts $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CNCH(Me)Ph)(NH_3)]PF_6$ (**12SS**,**12RS**) by means of ammonium hexafluorophosphate and thallium carbonate in hot methanol with a view to improving the separation of the diastereomeric centres by crystallization. It should be noted that the ruthenium chirality descriptors reverse when the chloro ligand is replaced by the ammine ligand. Thus, assuming retention at the metal centre, **11SS** produces **12RS** and **11RS** produces **12SS**. The yellow crystalline product obtained in 47% yield proved to an equimolar mixture of the diastereomeric salts. All attempts to effect partial resolution failed and indeed single crystals of **12** proved to contain both diastereomeric centres. In particular the single crystal used for the X-ray single crystal structure determination was later dissolved in CD_2Cl_2 and confirmed this point and that the equimolar mixture was perfectly configurationally stable in solution.

3. X-ray crystal structures

The X-ray single crystal structure of **2** was determined at 223 K; many crystals of **2** were examined under a polarizing microscope and found to be twinned but a few single crystals were located and examined. The crystal used for the data collection was of an acceptable quality for the intended purpose. The crystal specimens of **3RR** and **3SR** were of very high optical quality and highly faceted; it would be possible to resolve a mixed sample by triage, picking the diastereomers apart under a microscope. Both structures were determined at 233 K (Table 2).

The crystal of **2** contained molecules with the *R*-configuration at ruthenium and the absolute structure parameter of 0.31(8) reflects the correct choice for the single chiral centre. Analysis of a second crystal revealed that it only contained molecules with an *S*-configuration at ruthenium (Rogers *η* 1.11(12)), thus the bulk sample is probably best described as a racemic conglomerate. The unit cell also contained one molecule of dichloromethane per cation. Racemic twin refinement was attempted on the data obtained for the first crystal and did not significantly improve the refinement; the nature of the sample did not suggest that further exploration was necessary or required.

The overall geometry of the cation is pseudo octahedral as expected with the cyclohexyl group in a chair conformation with the proton on C(41) pointing in towards the isonitrile ligand (Fig. 4). One of the amine protons points towards the centre of a phenyl ring while the other is oriented away as anticipated providing the origin of the chemical shift differentiation in the ^{1}H NMR spectrum. The ruthenium–nitrogen bond length of 2.172(8) Å compares with 2.190(5), 2.216(2) and 2.174(8) Å for

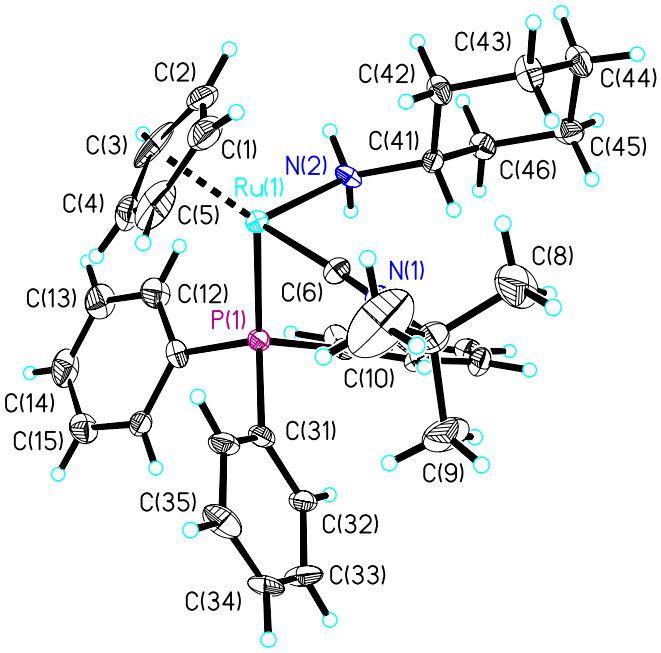

Fig. 4. The cation present in **2** showing 25% probability ellipsoids.

Table 2
Crystallographic data collection parameters for **2**, **3SR**, **3RR**, and (**12RS**,**12SS**)

$[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2(NH_2CH_2Ph)]BF_4$ [20], $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(P\{OMe\}_3)(NH_2CMe_3)]SO_3CF_3$ [21], and $[(\eta^5\text{-}C_5H_5)Ru(Cy_2PCH_2CH_2PCy_2)(NH_2C_8H_{17})]SO_3CF_3$ [22], respectively.

The structures of **3SR** (Fig. 5) and **3RR** (Fig. 6) have the same gross geometry as that found in **2**, and are both absolute structure determinations with parameter values of −0.01(3) and 0.00(3), respectively. The ruthenium–nitrogen bond lengths are 2.168(3) and 2.184(3) Å, respectively, and there are other small metric differences at the ruthenium centre (Table 3). These differences for the diastereomeric cations are likely to be due to steric factors such as the disposition of the benzyl group. The most striking structural difference between **3RR** and **3SR** is the position of the α-methyl group caused by the preference of the benzyl hydrogen atom to point inwards towards the isonitrile group in both diastereomers. The proximity of the α-methyl group in **3SR** to the aromatic rings of the triphenylphosphine ligand and of the α-phenyl group to the cyclopentadienyl ring hydrogens supports the earlier ^{1}H NMR spectroscopic analysis where both these interactions produce shielding relative to **3RR**. The differentiation of the two NH resonances in the ^{1}H NMR spectrum of each diastereomeric salt can also be seen to be a consequence of shielding from aromatic rings. It is implicit in this analysis that the solid state structures and solution structures for each diastereomeric cation are similar; given that rotation around the Ru(1)–N(1) bond and about the N(1)–C(8) bond is likely to be restricted in both diastereomers this is a reasonable outcome.

C(6)–N(2)–C(7)	169.0(4)	176.5(2)

The X-ray single crystal structure of **12** was carried out at 233 K and the crystal contained both diastereomers of the cation in the unit cell, permitting both a relative and an absolute structure determination. The outcome is that the isonitrile ligand was confirmed to be of *S*-configuration. Visual comparison of the two diastereomeric cations suggests why the **12RS** (Fig. 7) and **12SS** (Fig. 8) compounds are difficult to fractionally separate and do co-crystallize; the volumes and molecular shapes are very similar in that only the disposition of the α-methyl group perturbs the near mirror symmetry in the unit cell (see Table 4).

4. Conclusions

Diastereomers containing only two chiral centres can be designated as *p*-(RR or SS) or *n*-(RS or SR) [23,24]. The most soluble diastereomeric salts in dichloromethane are the *p*-forms of **3**, **4**, **5**, and **7**; possibly this relationship will also hold if small modifications are made to these generic molecules (e.g., change of cyclopentadienyl group, use of PR_2Ph in place of PPh_3, ring *para*-substitution at phenyl rings of phosphine or amine). The use of ring shielding effects in ^{1}H NMR spectroscopy has proved a useful tool in determining diastereomer ratio and relative assignment

for this family of compounds and extends the work of Davies on cyclopentadienyliron compounds. The crystallographic work illustrates some of the variations possible when one or more chiral centres are present. For example **2** crystallized as a racemic conglomerate where each single crystal is itself homochiral but the bulk sample is racemic, **3** can be crystallized to yield single crystals of each of the four diastereomers, while **12** generated by using a homochiral ligand produces single crystals containing both possible diastereomers.

All of the cationic compounds in this work are configurationally stable in solution at room temperature for periods in excess of one week. In particular the single crystal actually used for each structural measurement was redissolved and monitored by ^{1}H NMR spectroscopy within minutes of solution and then periodically. The solution spectra exactly mirrored the composition determined in the crystal. The nature of the ligands used in this study

and the strong metal–ligand bonding undoubtedly prevents epimerization which has been found to be a major problem elsewhere [6–8]. Indeed the bond strengths in compounds such as **2** and **3** prevented our ultimate aim of producing resolved at ruthenium materials for subsequent asymmetric synthesis.

5. Experimental

5.1. General comments

All reactions and preparations were carried out using conventional Schlenk tube techniques and all solvents were degassed prior to use. Chromatographic work-ups were performed with columns made up of Grade IV neutral alumina prepared with petroleum ether (40–60 °C). Cyclohexylamine and diethylamine were dried over barium oxide and distilled before use. *R*(+)- and *S*(−)-α-methylbenzylamine (99.6% e.e.) were supplied by Seal Sands Chemicals Ltd. The amines *R*(−)-α-cyclohexylethylamine (98% e.e.) and (±)-1-(1-naphthyl)ethylamine from Aldrich were used as supplied. *S*(−)-*N*-methyl-1-phenylethylamine (98% e.e.) was supplied by Fluka Chemika. *R*(−)-2,2,2-trifluoro-1-(9-anthryl)ethanol (99.5% e.e., Aldrich) was dried under reduced pressure at 70 °C overnight. Photolysis reactions were performed using a P.W. Allen A409 medium pressure mercury lamp (313, 366 nm). Infrared spectra were recorded on a Perkin–Elmer 1710 FT-IR instrument calibrated against polystyrene film and only significant absorption bands are reported. Optical rotation measurements were made on an Optical Activity Ltd. AA–100 polarimeter. Nuclear magnetic resonance spectra were recorded on Bruker AC300 (300.13 MHz, ^{1}H NMR; 75.47 MHz, ^{13}C; 121.49 MHz, ^{31}P) and Avance 400 (400.13 MHz, ^{1}H NMR; 100.61 MHz, ^{13}C; 161.98 MHz, ^{31}P) spectrometers. All ^{1}H and ^{13}C NMR chemical shifts are expressed in ppm relative to $SiMe_4$ (0.0 ppm) and ^{31}P shifts relative to $P(OPh)_3$ (126.5 ppm). All spectra were measured at room temperature and homonuclear decoupling and DEPT spectra were obtained when appropriate. Elemental analyses were obtained by Butterworth Laboratories, London. Mass spectral analyses were performed by Fast Atom Bombardment (FAB) on a Kratos Concept S1 Spectrometer. Crystal structure data were collected on a Siemens R3m/V Diffractometer at 233 K for $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2Cy)]PF_6$ (**2**), ($S_{Ru}R_C$)- and ($R_{Ru}R_C$)-$[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2CHMePh)]PF_6$ (**3SR**) and (**3RR**), and at 293 K for $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CNCH(Me)Ph)(NH_3)]PF_6$ (**12**). The starting compounds $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)Cl]$ (**1**) [25,26], $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CO)Cl]$ (**6**) [27], and $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CN^tBu)I]$ (**8**) [28] were prepared by the published literature procedures.

The optical purity of the *R*(+)- and *S*(−)-α-methylbenzylamines was checked by ^{1}H NMR spectroscopy using *R*(−)-2,2,2-trifluoro-1-(9-anthryl)ethanol [19]. The optical purity of the *R*(−)-α-cyclohexylethylamine and *S*(−)-*N*-methyl-1-phenylethylamine was not verified.

5.2. Preparation of *S*(−)-α-methylbenzylisonitrile {*S*(−)-CNCHMePh}

The published procedure for the synthesis of *tert*-butylisonitrile was adapted [29,30]. A two-neck round-bottomed flask (500 ml) equipped with a magnetic stirrer bar, a reflux condenser, and a pressure equalising dropping funnel was charged with sodium hydroxide (24 g, 0.6 mol). Stirring was commenced and deionized water (3 × 30 ml) was added in portions to maintain smooth stirring. The funnel was charged with a mixture of *S*(−)-α-methylbenzylamine (20 ml, 0.158 mol), chloroform (15 ml, 0.188 mol) and benzyltriethylammonium chloride (0.4 g, 1.75 mmol) in dichloromethane (30 ml). The mixture was added dropwise to the stirred, warm solution (at ca. 45 °C) over a 30-min period. The reaction mixture began to reflux slowly 10 min after initiation of the addition and subsided within 2 h; stirring was continued for an additional hour. The reaction mixture was diluted with ice and deionized water (1:1, 150 ml), and the organic layer (pale yellow) was separated and retained. The colourless aqueous layer was extracted with dichloromethane (2 × 30 ml), and the combined extracts were successively washed with deionized water (20 ml), aqueous sodium chloride solution (5% w/w, 20 ml), and dried over excess anhydrous magnesium sulphate for 1 h.

The drying agent was removed by filtration, washed with dry dichloromethane (10 ml), and the pale yellow combined filtrate and washings were distilled at ca. 65 °C using a Vigreux column (1.5 cm × 10 cm) to remove the solvent (dichloromethane).

The remaining yellow solution was placed under nitrogen, and distilled under reduced pressure to remove final traces of dichloromethane, unreacted chloroform (at 25 °C, 13 mmHg), and any excess *S*(−)-α-methylbenzylamine (34–39 °C, 3 mmHg). Finally, the fraction which distilled at 29–30 °C (0.01 mmHg) was collected as a colourless oil. Yield 11.0 ml (50%).

IR (neat): ν_{max} 2140vs cm^{-1} (CN). ^{1}H NMR ($CDCl_3$): δ 7.29–7.42 (m, 5H, Ph), 4.81 (q{1:1:1}t, 1H, ^{3}J(HH) 7 Hz and ^{2}J(NH) 2 Hz, C*H*MeN), 1.67 (d{1:1:1}t, 3H, ^{3}J(HH) 7 Hz and ^{3}J(NH) 2 Hz, CH*Me*N) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ 156.6 (t, *J*(CN) 4.5 Hz, *C*N), 138.6 (s, C_{ipso}, Ph), 128.9 (s, C_{ortho}, Ph), 128.3 (s, C_{para}, Ph), 125.4 (s, C_{meta}, Ph), 53.8 ({1:1:1}t, ^{1}J(NC) 6 Hz, N*C*HPh), 25.1 (s, CH*Me*). *5.2.1. [(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2Cy)]PF_6 (**2**)*

A Schlenk tube was charged with a solution of **1** (1.00 g, 1.83 mmol) in dichloromethane (40 ml), thallium hexafluorophosphate (1.60 g, 4.58 mmol), and a magnetic stirrer bar. The orange solution was stirred in the dark under nitrogen at room temperature for 1 h to give a tomato-orange suspension. Excess cyclohexylamine (2 ml, 17.48 mmol) was added and the solution was stirred in the dark at room temperature overnight. Filtration, evaporation of the filtrate under reduced pressure, and crystallization of the yellow residue from dichloromethane and diethylether (1:3, 40 ml) at −30 °C for 2 days afforded bright yellow crystals of **2**. Yield 1.34 g (97%). (Calc. for $C_{34}H_{42}F_6N_2P_2Ru \cdot CH_2Cl_2$: C, 50.00; H, 5.28; N, 3.33. Found: C, 49.93; H, 5.33; N, 3.30%). IR (Nujol): ν_{max} 3311w, 3270w, 1587vw (NH), 2121m (CN), and 842s cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2): δ 7.2–7.5 (m, 15H, PPh_3), 4.74 (s, 5H, C_5H_5), 3.20 (br.t, 1H, $^{2,3}J$(HH) 11 Hz, NH), 1.99 (br.d, 1H, ^2J(HH) 12 Hz, NH), 0.7–1.90 (m, 11H, Cy), 1.25 (s, 9H, C*Me*$_3$) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 134.20 (d, C_{ipso}, PPh_3), 133.77 (d, ^2J(PC) 11 Hz, C_{ortho}), 131.05 (s, C_{para}), 129.14 (d, ^3J(PC) 10 Hz, C_{meta}), 81.94 (s, C_5H_5), 59.29 (s, C_1, Cy), 58.00 (s, *C*Me$_3$), 35.82 (s, C_2, Cy), 33.13 (s, C_3, Cy), 30.73 (s, C*Me*$_3$), 25.49 (s, C_4 and C_5, Cy), 25.29 (s, C_6, Cy) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 59.91 (s, PPh_3), −145.40 (septet, ^1J(PF) 712 Hz, PF_6) ppm. MS (FAB): 611 $[M - PF_6]^+$(50%), 512(100), 429(41).

*5.2.2. ($S_{Ru}R_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMePh$)]PF_6 (**3SR**)*

A solution of **1** (0.23 g, 0.42 mmol) in dichloromethane (30 ml) was treated with thallium hexafluorophosphate (0.42 g, 1.20 mmol) and excess *R*(+)-α-methylbenzylamine (0.8 ml, 6.21 mmol). This yellow-orange solution was stirred in the dark at room temperature for 24 h. After filtration and solvent removal from the filtrate under reduced pressure, fine yellow crystals were obtained by crystallizing the residue at −30 °C from dichloromethane and diethylether (1:3, 20 ml) overnight. Yield 0.19 g (58%) 80% d.e. (Calc. for $C_{36}H_{40}F_6N_2P_2Ru.CH_2Cl_2$: C, 51.51; H, 4.91; N, 3.25. Found: C, 50.93; H, 4.82; N, 3.39%.) *5.2.3. ($R_{Ru}R_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMePh$)]PF_6 (**3RR**)*

The mother-liquor from the crystallization procedure above was reduced in volume (to ca. 10 ml) under reduced pressure, and was left to crystallize out at −80 °C for 2 days, producing yellow crystals which were isolated by filtration. Yield 0.07 g (21%) 98% d.e.

IR (Nujol): ν_{max} 3325w, 3284w, 1591w (NH), 2126s (CN), 1712w (Ph overtone) and 840s cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2): δ 7.23–7.45 (m, 15H, P*Ph*$_3$), 6.96–6.98 (m, 5H, Ph), 4.72 (s, 5H, C_5H_5), 3.49 (br.t, 1H, $^{2,3}J$(HH) 10 Hz, NH), 3.35 (m, 1H, NC*H*Me), 2.12 (br.d, 1H, ^2J(HH) 10 Hz, NH), 1.29 (d, 3H, ^3J(HH) 7 Hz, Me), 1.25 (s, 9H, C*Me*$_3$) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 134.11 (d, C_{ipso}, PPh_3), 133.63 (d, ^2J(PC) 11 Hz, C_{ortho}), 130.98 (s, C_{para}), 129.17 (d, ^3J(PC) 8 Hz, C_{meta}), 128.23 (s, C_{para}, Ph), 126.21 (s, C_{meta}, Ph), 81.81 (s, C_5H_5), 61.65 (s, N*C*HPh), 30.65 (s, C*Me*$_3$), 22.63 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 59.08 (s, PPh_3) ppm.

*5.2.4. ($R_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMePh$)]PF_6 (**3RS**)*

To a solution of **1** (0.16 g, 0.29 mmol) in dichloromethane (30 ml) was added thallium hexafluorophosphate (0.4 g, 1.15 mmol) and excess *S*(−)-α-methylbenzylamine (0.8 ml, 6.21 mmol). This yellow/orange solution was stirred overnight in the dark, at room temperature. After solvent removal under reduced pressure, fine yellow crystals were obtained by crystallising the residue at −80 °C from dichloromethane and diethylether (1:3, 20 ml) overnight. Yield 0.13 g (57%) 74% d.e.

*5.2.5. ($S_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMePh$)]PF_6 (**3SS**)*

The mother-liquor from above was concentrated to low volume (to ca. 10 ml) under reduced pressure, and was left to crystallize out in the dark at −30 °C for 7 h, from which yellow crystals were isolated. Yield 0.05 g (22%) 98% d.e.

*5.2.6. ($S_{Ru}R_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMeCy$)]PF_6 (**4SR**)*

To a solution of **1** (0.21 g, 0.384 mmol) in dichloromethane (30 ml) was added thallium (I) hexafluorophosphate (0.40 g, 1.15 mmol) and excess *R*(−)-1-cyclohexylethylamine (1.0 ml, 6.81 mmol). This orange solution was stirred at room temperature in the dark under nitrogen for 67 h. After solvent removal under reduced pressure, fine yellow crystals were obtained by crystallising the yellow residue at −30 °C from dichloromethane and diethylether (1:3, 40 ml) overnight. Yield 0.13 g (43%) 61% d.e. (Calc. for $C_{36}H_{46}F_6N_2P_2Ru \cdot CH_2Cl_2$: C, 51.16; H, 5.57; N, 3.22. Found: C, 52.98; H, 5.57; N, 3.45%.) IR (Nujol): ν_{max} 3312m, 3275w, 1584w (NH), 2116s (CN), 1721br.w (Ph overtone) and 843vs cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2): δ 7.28–7.50 (m, 15H, PPh_3), 4.744 (s, 5H, C_5H_5), 3.15 (br.dd, 1H, $^{2,3}J$(HH) 12, 6 Hz, NH), 2.09 (qd, 1H, $^{3,3}J$(HH) 6, 4 Hz, NC*H*Me), 1.24 (s, 9H, C*Me*$_3$), 0.70 (d, 3H, ^3J(HH)

7 Hz, Me), 0.7–0.98, 1.05–1.45 and 1.65–1.74 (m, 11H, $^{2,3,3}J$(HH) 12, 12, 4 Hz, Cy) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 133.77 (d, ^1J(PC) 44 Hz, C_{ipso}, P*Ph*$_3$), 133.71 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), 131.10 (s, C_{para}, PPh_3), 129.24 (d, ^3J(PC) 9 Hz, C_{meta}, PPh_3), 81.88 (s, C_5H_5), 60.99 (s, N*C*HCy), 42.59 (s, C_1, Cy), 30.66 (s, C*Me*$_3$), 26.84 (s, C_2, Cy), 26.71 (s, C_3, Cy), 26.34 (s, C_4 and C_5, Cy), 25.49 (s, C_6, Cy), 17.02 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 59.57 (s, PPh_3) ppm. MS (FAB): 639 $[M - PF_6]^+$(20%), 512(100), 429(31).

5.2.7. ($R_{Ru}R_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMeCy$)]PF_6 (**4RR**)

The mother-liquor from above was concentrated to low volume (ca. 10 ml) under reduced pressure, and was then left to crystallize out in the dark at −30 °C overnight, from which yellow crystals were isolated. Yield 0.11 g (37%) 79% d.e.

IR (Nujol): ν_{max} 3315w, 3274w, 1585w (NH), 2121m (CN), 1725br.w (Ph overtone) and 843s cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2): δ 7.28–7.51 (m, 15H, PPh_3), 4.745 (s, 5H, C_5H_5), 2.95 (br.t, 1H, $^{2,3}J$(HH) 11 Hz, NH), 2.00 (m, 1H, NC*H*Me), 1.26 (s, 9H, C*Me*$_3$), 0.99 (d, 3H, ^3J(HH) 7 Hz, Me), 0.52–0.70, 1.0–1.3 and 1.60–1.83 (m, 11H, $^{2,3,3}J$(HH) 11, 11, 4 Hz, Cy) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 134.02 (d, ^1J(PC) 44 Hz, C_{ipso}, PPh_3), 133.83 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), 131.12 (s, C_{para}, PPh_3), 129.22 (d, ^3J(PC) 10 Hz, C_{meta}, PPh_3), 81.95 (s, C_5H_5), 61.35 (s, N*C*HCy), 45.22 (s, C_1, Cy), 30.74 (s, C*Me*$_3$), 29.61 (s, C_2, Cy), 27.04 (s, C_3, Cy), 26.50 (s, C_4 and C_5, Cy), 25.91 (s, C_6, Cy), 16.24 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 59.68 (s, PPh_3) ppm.

5.2.8. ($R_{Ru}S_C$,$S_{Ru}R_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-(NH_2CHMe{1-$C_{10}H_7$}$)]PF_6$ (**5RS,5SR**)

An orange solution of **1** (0.20 g, 0.366 mmol) and thallium (I) hexafluorophosphate (0.40 g, 1.15 mmol) in dichloromethane (30 ml) was stirred for 90 min to give a tomato-orange solution. Excess (±)-1-(1-naphthyl)ethylamine (1.0 ml, 6.21 mmol) was added. The mixture was stirred at room temperature in the dark under nitrogen for 52 h to give a bright yellow solution. After solvent removal under reduced pressure, the yellow treacly solid was washed with diethylether (2 × 15 ml). Extraction with dichloromethane (2 × 15 ml), filtration, and concentration under reduced pressure (ca. 10 ml) gave a yellow solution. Addition of diethylether (30 ml) afforded fine yellow crystals on storing at −30 °C under nitrogen overnight. Yield 0.05 g (17%) 73% d.e.

IR (Nujol): ν_{max} 3303w, 3271vw, 1587vw (NH), 2108m (CN) and 843vs cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2): δ 7.93–7.97 (m, 2H, Np), 7.88 (d, 1H, ^3J(HH) 8 Hz, Np), 7.24–7.63 (m, 19H, Np and PPh_3), 4.35 (m, 1H, NC*H*Me), 4.23 (s, 5H, C_5H_5), 3.68 (br.t, 1H, $^{2,3}J$(HH) 11 Hz, NH), 2.15 (br.d, 1H, ^2J(HH) 11 Hz, NH), 1.29 (d, 3H, ^3J(HH) 7 Hz, Me), 1.23 (s, 9H, C*Me*$_3$) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 138.97 (s, C_{ipso}, Np), 134.18 and 130.82 (s, 2× $C_{bridging}$, Np), 133.66 (d, ^1J(PC) 45 Hz, C_{ipso}, PPh_3), 133.71 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), 131.19 (s, C_{para}, PPh_3), 129.67, 128.96, 126.81, 126.34, 126.09, 123.19, and 122.57 (s, 7× C_{aryl}, Np), 129.32 (d, ^3J(PC) 10 Hz, C_{meta}, PPh_3), 81.50 (s, C_5H_5), 58.34 (s, N*C*HNp), 30.68 (s, C*Me*$_3$), 25.53 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 59.46 (s, PPh_3) ppm.

5.2.9. ($R_{Ru}R_C$,$S_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-(NH_2CHMe{1-$C_{10}H_7$}$)]PF_6$ (**5RR,5SS**)

The mother-liquor from above was reduced in volume (ca. 10 ml) under reduced pressure, and was then left to crystallize out in the dark at −30 °C for 46 h, from which yellow crystals were isolated. Yield 0.07 g (23%) 56% d.e. of the least soluble (**5RS,5SR**). (Calc. for $C_{40}H_{42}F_6N_2P_2Ru \cdot 0.5CH_2Cl_2$: C, 55.90; H, 4.98; N, 3.22. Found: C, 56.29; H, 4.75; N, 3.40%.) IR (Nujol): ν_{max} 3314w, 3257w, 1587w (NH), 2108m (CN) and 841s cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2): δ 7.70 (m, 2H, Np), 7.20–7.59 (m, 19H, Np and PPh_3), 7.40 (t, 1H, ^3J(HH) 7 Hz, Np), 4.35 (m, 1H, NC*H*Me), 4.77 (s, 5H, C_5H_5), 3.84 (br.t, 1H, $^{2,3}J$(HH) 11 Hz, NH), 3.05 (br.d, 1H, ^2J(HH) 11 Hz, NH), 1.42 (d, 3H, ^3J(HH) 7 Hz, Me), 1.21 (s, 9H, C*Me*$_3$) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ ~133.58 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), ~133.37 (d, ^1J(PC) 45 Hz, C_{ipso}, PPh_3), ~129.13 (d, ^3J(PC) 10 Hz, C_{meta}, PPh_3), 128.30, 126.65, 126.25, 122.25, and 121.90 (s, C_{aryl}, Np), 81.81 (s, C_5H_5), 56.93 (s, N*C*HNp), 30.78 (s, C*Me*$_3$), 22.95 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 59.57 (s, PPh_3) ppm. 5.2.10. ($R_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CO)-($NH_2CHMePh$)]PF_6 (**7RS**)

To a yellow-brown solution of **6** (0.50 g, 1.02 mmol) in dichloromethane (30 ml) was added thallium hexafluorophosphate (0.81 g, 2.33 mmol) and *S*(−)-α-methylbenzylamine (1 ml, 7.76 mmol). The brown mixture was stirred under nitrogen at 45–50 °C for 17.5 h (overnight) to give a cream brown suspension. Filtration, washing the off-white residue with dichloromethane (3 × 5 ml) gave a brown filtrate. After solvent removal under reduced pressure, the brown residue was extracted with diethylether (5 × 10 ml) and filtered to give a yellow solution. This was placed onto an alumina column (2 × 15 cm), the excess amine was eluted with light petroleum ether (60 ml) and the pale yellow product band was eluted with dichloromethane (60 ml) to give a pale yellow solution. After solvent removal under reduced pressure, a mustard yellow powder was obtained by crystallising the residual oil from diethylether (10 ml) at −80 °C for 54 h. Yield 0.04 g (5%) 42% d.e. (Calc. for $C_{32}H_{31}F_6NOP_2Ru$: C, 53.19; H, 4.32; N, 1.94. Found: C, 53.30; H, 4.60; N, 1.75%.) IR (Nujol): ν_{max} 3306w, 3267w, 1587vw (NH), 1950sh.w, 1941m (CO) and 843s cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2/$CDCl_3$): δ 7.55–7.60 and 7.34–7.40 (m, 15H, PPh_3), 7.26 (m, 5H, Ph), 4.57 (s, 5H, C_5H_5), 4.26 (br.t, 1H, $^{2,3}J$(HH) 11 Hz, NH), 3.26 (br.sextet {br.m}, 1H,

^3J(HH) 7 Hz, NC*H*Me), 1.95 (br.d, 1H, ^2J(HH) 11 Hz, NH), 1.09 (d, 3H, ^3J(HH) 7 Hz, CH*Me*) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2/CDCl_3$): δ 203.92 (d, ^2J(PC) 19 Hz, CO), 134.34 (d, C_{ipso}, PPh_3), 133.95 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), 132.11 (s, C_{para}, P*Ph*$_3$), 129.92 (d, ^3J(PC) 10 Hz, C_{meta}, PPh_3), 129.54 (s, C_{ortho}, Ph), 129.12 (s, C_{para}, Ph), 128.12 (s, C_{meta}, Ph), 86.39 (s, C_5H_5), 64.19 (s, N*C*HPh), 25.59 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2/CDCl_3$): δ 55.58 (s, PPh_3) ppm. 5.2.11. ($S_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMePh$)]PF_6 (**7SS**)

The partial data was obtained from the spectra obtained from the sample of (**7RS**) above.

^1H NMR ($CD_2Cl_2/CDCl_3$): δ 7.40–7.52 and 7.27–7.34 (m, 15H, P*Ph*$_3$), 6.95 (m, 5H, Ph), 5.13 (s, 5H, C_5H_5), 1.39 (d, 3H, ^3J(HH) 7 Hz, CH*Me*) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2/CDCl_3$): δ 142.67 (s, C_{ipso}, PPh_3), 133.85 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), 131.56 (s, C_{para}, PPh_3), 129.38 (d, ^3J(PC) 10 Hz, C_{meta}, PPh_3), 127.03 (s, C_{meta}, Ph), 86.71 (s, C_5H_5), 64.06 (s, N*C*HPh), 23.17 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2/CDCl_3$): δ 54.25 (s, PPh_3) ppm.

5.2.12. [(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)($NHEt_2$)]PF_6 (**9**)

A Schlenk tube was charged with a solution of **1** (0.20 g, 0.37 mmol) in dichloromethane (30 ml), thallium hexafluorophosphate (0.19 g, 0.54 mmol), and a magnetic stirrer bar. The orange solution was stirred in the dark under nitrogen at room temperature for 1 h to give a tomato-orange suspension. Excess diethylamine (0.4 ml, 3.87 mmol) was added and the solution was stirred in the dark at room temperature overnight. Filtration, evaporation of the filtrate under reduced pressure, and crystallization of the yellow residue from dichloromethane and diethylether (1:3, 20 ml) at −30 °C afforded orange-yellow crystals of **9**. Yield 0.16 g (60%).

IR (Nujol): ν_{max} 3269w, 1613vw (NH), 2129m, 2062sh.w (CN), and 841s cm^{-1} (PF_6). ^1H NMR (CD_2Cl_2): δ 7.26–7.49 (m, 15H, PPh_3), 4.78 (s, 5H, C_5H_5), 2.78 (m, 2H, $^{2,3}J$(HH) 7 Hz, CH_2CH_3), 2.67 (m, 2H, $^{2,3}J$(HH) 7 Hz, CH_2CH_3), 1.68 (br.s, 1H, NH), 1.20 (s, 9H, C*Me*$_3$), 1.08 (t, 3H, $^{2,3}J$(HH) 7 Hz, CH_2CH_3), 0.44 (t, 3H, $^{2,3}J$(HH) 7 Hz, CH_2 CH_3) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 133.88 (d, C_{ipso}, PPh_3), 133.37 (d, ^2J(PC) 11 Hz, C_{ortho}), 131.32 (s, C_{para}), 129.52 (d, ^3J(PC) 10 Hz, C_{meta}), 82.08 (s, C_5H_5), 58.45 (s, *C*Me$_3$), 56.13, 51.54 (2s, CH_2), 30.45 (s, C*Me*$_3$), 14.67, 14.08 (2s, CH_3) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 58.3 (s, PPh_3), −145.40 (septet, ^1J(*P*F) 712 Hz, PF_6) ppm. MS (FAB): 585 $[M - PF_6]^+$(15%), 512(100), 454(9), 429(37).

5.2.13. [(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)(NH(*Me*)-*CHMePh*)]PF_6 (**10**)

A solution of **1** (0.20 g, 0.37 mmol) in dichloromethane (30 ml) was treated with thallium hexafluorophosphate (0.20 g, 0.57 mmol) and excess *S*(−)-*N*-methyl-1-phenylethylamine (0.25 ml, 1.72 mmol). This yellow-orange solution was stirred in the dark at room temperature for 24 h. After filtration and solvent removal from the filtrate under reduced pressure, fine yellow crystals were obtained by crystallizing the residue at −30 °C from dichloromethane and diethylether (1:3, 15 ml) overnight. Yield 0.18 g (62%). IR (Nujol): ν_{max} 3263w, 1585vw (NH), 2122s (CN), and 841br.s cm^{-1} (PF_6). MS (FAB): 647 $[M - PF_6]^+$(11%), 511(100), 454(11), 429(38).

The ^1H NMR spectrum of the crystals revealed four diastereomers were present; integration of the cyclopentadienyl ligand singlets produced a ratio of 5:20:2:25 for **SSS**:**SRS**:**RRS**:**RSS**. Concentration of the mother-liquor above to ca. 7 ml and cooling to −25 °C gave yellow crystals, yield 0.05 g. (17%), whose spectrum showed the diastereomer ratio to be 5:12:2:4.

*5.2.14. ($R_{Ru}S_C$,$R_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)-(CNCHMePh)Cl] (**11RS,11SS**)*

A suspension of **1** (0.70 g, 0.964 mmol) and excess (*S*)-α-methylbenzylisonitrile (0.5 ml, 3.58 mmol) in toluene (30 ml) was stirred and heated under reflux at 100 °C under nitrogen for 24 h. The cooled orange solution was reduced in volume (to ca. 10 ml) under reduced pressure and put onto an alumina column (1.5 × 20 cm.). PPh_3 was eluted with toluene (20 ml) and the orange product band eluted with dichloromethane (30 ml) and ultimately acetone (10 ml) to give an orange solution. Solvent removal under reduced pressure gave a frothy orange solid. Wash with petroleum ether (b.p. 40–60 °C, 2 × 10 ml) followed by drying under reduced pressure afforded a bright orange powder. Yield 0.26 g (45%) [**11SS**:**11RS** 49:51].

Recrystallization of a small sample (0.15 g) from toluene and hexane (1:3, 20 ml) at −30 °C for 16 h afforded an oily orange solid after filtration and solvent removal under reduced pressure. Yield 0.02 g [**11SS**:**11RS** 65:35].

IR (Nujol): ν_{max} 2104, 2102s cm^{-1} (CN). MS (FAB): 595 $[M]^+$(38%), 560(85), 429(93).

11SS: ^{1}H NMR ($CDCl_3$): δ 7.41–7.54 and 7.22–7.33 (m, 15H, PPh_3), 7.10–7.13 and 7.03–7.06 (m, 5H, Ph), 4.87 (q, 1H, ^3J(HH) 7 Hz, C*H*Me), 4.55 (s, 5H, C_5H_5), 1.39 (d, 3H, ^3J(HH) 7 Hz, CH*Me*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 136.65 (d, ^1J(PC) 44 Hz, C_{ipso}, P*Ph*$_3$), 133.71 (d, ^2J(PC) 11 Hz, C_{ortho}, P*Ph*$_3$), 129.41 (s, C_{para}, PPh_3), 128.65 (s, C_{para}, Ph), 127.82 (d, ^3J(PC) 11 Hz, C_{meta}, PPh_3), 125.37 (s, C_{meta}, Ph), 81.66 (s, C_5H_5), 56.20 (s, N*C*HPh), 25.01 (s, CH*Me*) ppm.

11RS: ^{1}H NMR ($CDCl_3$): δ 7.41–7.54 and 7.22–7.33 (m, 15H, P*Ph*$_3$), 7.10–7.13 and 7.03–7.06 (m, 5H, Ph), 4.70 (q, 1H, ^3J(HH) 7 Hz, C*H*Me), 4.53 (s, 5H, C_5H_5), 1.29 (d, 3H, ^3J(HH) 7 Hz, CH*Me*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 136.47 (d, ^1J(PC) 44 Hz, C_{ipso}, PPh_3), 133.71 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), 129.41 (s, C_{para}, PPh_3), 128.65 (s, C_{para}, Ph), 127.82 (d, ^3J(PC) 11 Hz, C_{meta}, PPh_3), 125.37 (s, C_{meta}, Ph), 81.66 (s, C_5H_5), 56.09 (s, N*C*HPh), 25.01 (s, CH*Me*) ppm.

*5.2.15. ($R_{Ru}S_C$,$R_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)-(CNCHMePh)(NH_3)]PF_6 (**12RS,12SS**)*

A mixture of (**11RS**,**11SS**) (0.21 g, 0.353 mmol), ammonium hexafluorophosphate (0.25 g, 1.54 mmol), and thallium (I) carbonate (0.50 g, 1.07 mmol) in methanol (40 ml) was stirred at 60 °C for 22 h. Removal of the solvent under reduced pressure and crystallization of the residue from dichloromethane–diethylether (1:3, 40 ml) at −30 °C afforded yellow crystals of (**12RS**,**12SS**). Total yield 0.12 g (47%) [racemate]. (Calc for $C_{32}H_{32}F_6N_2P_2Ru \cdot 3CH_2Cl_2$: C, 43.06; H, 3.92; N, 2.87. Found: C, 43.56; H, 3.63; N, 3.13%.) IR (Nujol): ν_{max} 3370m, 3296w, 1622w (NH), 2119br.s (CN) and 838br.vs cm^{-1} (PF_6). ^{1}H NMR ($(CD_3)_2CO$): δ 7.36–7.58 (m, 30H, P*Ph*$_3$), 7.25–7.36 and 7.11–7.14 (m, 10H, Ph), 5.21 (q, 1H, ^3J(HH) 7 Hz, C*H*Me) and 5.19 (q, 1H, ^3J(HH) 7 Hz, C*H*Me), 4.88 (s, 10H, C_5H_5), 2.60 (br, 6H, NH_3), 1.52 (d, 3H, ^3J(HH) 7 Hz, CH*Me*), 1.43 (d, 3H, ^3J(HH) 7 Hz, CH*Me*) ppm. $^{13}C\{^1H\}$ NMR ($(CD_3)_2CO$): δ 135.41 (d, ^1J(PC) 45 Hz, C_{ipso}, PPh_3), 134.29 (d, ^2J(PC) 11 Hz, C_{ortho}, PPh_3), 131.29 (s, C_{para}, PPh_3), 129.58 (d, ^3J(PC) 10 Hz, C_{meta}, PPh_3), 128.88 (s, C_{ortho}, PPh_3), 126.48 (s, C_{para}, Ph), 126.36 (s, C_{meta}, Ph), 82.52 (s, C_5H_5), 57.38 (s, N*C*HPh), 25.22 (s, CH*Me*), 25.09 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 58.47 (s, PPh_3) and 58.17 (s, PPh_3) ppm. MS (FAB): 577 $[M - PF_6]^+$(24%), 560(100), 429(53).

5.3. Decomplexation of amine ligands

*5.3.1. [(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)(NH_2Cy)]PF_6 (**2**)*

Method A. Complex **2** (0.10 g, 0.13 mmol), trimethylamine *N*-oxide dehydrate (0.05 g, 0.45 mmol), and sodium iodide (0.08 g, 0.53 mmol) were placed in a Fischer–Porter bottle and suspended in methanol (30 ml). After heating and stirring at 85 °C for 48 h the solvent was removed under reduced pressure. Extraction with dichloromethane (30 ml) gave an orange-red solution which was washed with water (3 × 10 ml). The dichloromethane layer was dried with anhydrous magnesium sulphate, filtered and the solvent removed. The orange foam (0.09 g) was identified as a mixture (70:30) of **8** and unreacted **2** by ^{1}H NMR and infrared spectroscopies.

Method B. A Fischer–Porter bottle was charged with **2** (0.20 g, 0.27 mmol), iodomethane (2 ml, 32 mmol), and 1,2-dichloroethane (30 ml). Heating and stirring for 22 h at 120 °C gave a dark red solution. Cooling, removal of solvent, and washing the residue with petroleum ether (2 × 5 ml) then water (3 × 5 ml) gave a red solid which was dried under reduced pressure and identified as **8** (0.16 g, 95%) by ^{1}H NMR and infrared spectroscopies.

Method C. A stirred solution of **2** (0.10 g, 0.13 mmol) and iodine (0.10 g, 0.39 mmol) in dichloromethane was photolyzed for 24 h at room temperature. The product solution was washed with sodium thiosulfate solution (10%, 3 × 20 ml), the separated organic layer was washed with water (3 × 20 ml), then dried with granular calcium chloride. Removal of the solvent under reduced pressure gave **8** (0.08 g, 95%).

*5.3.2. ($S_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMePh$)]PF_6 (**3SS**)*

A sample of **3RS** (96% d.e.) was treated under Method B above. The isolated **8** was recrystallized from dichloromethane and petroleum ether. Analysis of the ^{1}H NMR spectra obtained in the absence and presence of *R*(−)-TFAE (1.05 equiv) showed the product to be a racemic mixture of **8R** and **8S**.

*5.3.3. ($R_{Ru}S_C$)-[(η^5-C_5H_5)Ru(PPh_3)(CN^tBu)-($NH_2CHMePh$)]PF_6 (**3RS**)*

A sample of **3RS** (90% d.e.) was treated under Method B above. The isolated **8** was treated with thallium hexafluorophosphate and excess *S*(−)-*N*-methyl-1-phenylethylamine using the procedures described earlier. The crude product

before crystallization was shown by ^{1}H NMR spectroscopy to be a racemic mixture of **3RS** and **3SS**.

A sample of **3RS** (90% d.e.) was treated under Method C above. The product **8** was analyzed by the ^{1}H NMR–TFAE method and by conversion back to **3**. Both methods revealed the original sample of **8** to be racemic.

5.4. X-ray crystallography

The crystals of **2**, **3SR**, **3RR**, and **12** were grown by slow layer diffusion of diethyl ether into dichloromethane solutions. Suitable crystal specimens were mounted on a glass fibre with epoxy resin and cooled on the goniometer head by means of nitrogen gas. Precession photographs and intensity data were collected on a Siemens R3m/V diffractometer using graphite monochromatized Mo Kα X-rays. Cell dimensions were obtained from 25 to 50 centred reflections with 2θ values from 20° to 32°. Intensity data were collected using a 2θ–θ scan technique. The intensities of three reflections measured periodically showed a decrease of less than 1% over the data collection for all four datasets. An empirical absorption correction was applied using azimuthal scan data for twelve selected reflections. The structures were solved by standard heavy atom routines and refined by full-matrix least-squares methods. All non-hydrogen atoms were given anisotropic temperature factors. Hydrogen atoms were placed in the models at calculated positions and allowed to ride on their respective carbon atoms. The hexafluorophosphate anions were rotationally disordered in both **3SR** and **3RR** and were modeled by simple partial occupancy methods. Table 2 contains the collection and solution parameters for all four determinations.

Acknowledgements

We thank the E.P.S.R.C. for a studentship (D.M.W.) and Johnson-Matthey Chemicals Ltd. for a generous loan of ruthenium trichloride. Dr. N.M. Boag (Salford) is thanked for stimulating discussions and we acknowledge the use of the E.P.S.R.C. Chemical Database Service at Daresbury [35].

Appendix A. Supplementary data

The supplementary crystallographic data for this paper are contained in the deposition files CCDC-277650 (**2**), CCDC-277651 (**3SR**), CCDC-277652 (**3RR**), and CCDC-277653 (**12**). These data can be obtained free of charge via ccdc.cam.ac.uk/data_request/cif, by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK: fax +44 1223 336033. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.01.016.

an infinite 1D coordination polymer. The anion-encapsulated 3D cages, induced by the anion-templating assembly, are $[[[Cu_4(\mu\text{-}OMe)_4(\mu\text{-}btp)_4(BF_4)_2(MeCN)_2] \supset (BF_4)](BF_4)]$-$[[[Cu_4(\mu\text{-}OMe)_4(\mu\text{-}btp)_4(BF_4)(MeOH)(MeCN)_2] \supset (BF_4)]$-$(BF_4)_2]$ (**2**) and $[[Cu_4(\mu\text{-}OMe)_4(\mu\text{-}btp)_4(ClO_4)_2(MeCN)_2] \supset (ClO_4)](ClO_4) \cdot 2H_2O$ (**3**). A 1D infinite coordination polymer of $[[Cu_2(\mu\text{-}OMe)_2(\mu\text{-}OTf)_2(btp)_2](H_2O)]_n$ (**4**) was also isolated.

2. Experimental

2.1. Material and instrumentation

Infrared spectra were recorded on Nicolet AVATAR 360 FT-IR instrument as KBr plates. Elemental analysis (C, H, N) were performed with Element Analysis system EA 1112 CE Instruments by the Korea Basic Science Institute. 2,6-Bis(*N*1-1,2,4-triazolyl)pyridine (btp) was prepared according to the literature [9]. All other materials were used as received without further purification.

2.2. Synthesis

2.2.1. $[Cu_2(OAc)_4(btp)_2] \cdot 2MeOH$ (**1**)

To a methanol solution (100 mL) containing $Cu(OAc)_2 \cdot H_2O$ (1.917 g, 9.6 mmol) was added a solution of btp (1.023 g, 4.8 mmol) in a mixture of MeOH (100 mL) and CH_2Cl_2 (20 mL). After stirring for 24 h, the solution was concentrated to ca. half of its original volume. The green microcrystalline product was collected by filtration and dried in air (1.92 g, 96%). *Anal*. Calc. for $C_{28}H_{32}Cu_2N_{14}O_{10}$ (851.76): C, 39.48; H, 3.79; N, 23.02. Found: C, 39.35; H, 3.70; N, 23.39%. IR (KBr, *v*): 1632(s), 1607(s), 1515(m), 1478(s), 1426(s), 1277(m), 1211(m), 1138(m), 1064(w), 980(m), 810(m), 778(w), 681(m), 644(w) cm^{-1}.

2.2.2. $[[[Cu_4(\mu\text{-}OMe)_4(\mu\text{-}btp)_4(BF_4)_2(MeCN)_2] \supset (BF_4)](BF_4)][[[Cu_4(\mu\text{-}OMe)_4(\mu\text{-}btp)_4(BF_4)(MeOH)(MeCN)_2] \supset (BF_4)](BF_4)_2]$ (**2**)

A mixture of **1** (0.248 g, 0.3 mmol) in acetonitrile (50 mL) and CH_3OH (50 mL) was added dropwise to a methanol solution (100 mL) of $Cu(BF_4)_2 \cdot 6H_2O$ (0.140 g, 0.6 mmol) over 24 h. This solution was concentrated to ca. a quarter of its original volume. Carefully covered with *n*-pentane, X-ray suitable single crystals **2** were obtained at low temperature (0.142 g, 28%). *Anal*. Calc. for $C_{89}H_{105}B_8Cu_8F_{32}N_{60}O_9$ (3362.13): C, 31.79; H, 3.15; N, 25.00. Found: C, 32.01; H, 2.86; N, 24.74%. IR (KBr, *v*): 1614(s), 1533(s), 1487(s), 1373(m), 1286(s), 1224(s), 1147(s), 1072(s), 983(s), 891(m), 808(s), 781(m), 671(m), 521(w) cm^{-1}.

2.2.3. $[[Cu_4(\mu\text{-}OMe)_4(\mu\text{-}btp)_4(ClO_4)_2(MeCN)_2] \supset (ClO_4)](ClO_4) \cdot 2H_2O$ (**3**)

The procedure is similar with that of **2** using $Cu(ClO_4)_2 \cdot 6H_2O$ (0.222 g, 0.6 mmol) instead of $Cu(BF_4)_2 \cdot 6H_2O$ (0.133 g, 25%). *Anal*. 2.3. Crystal structure and determination

X-ray diffraction measurements were performed on a Bruker SMART diffractometer equipped with a CCD area detector with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 233(2) K for **1** and **4**. The reflections were successfully indexed by an automated indexing routine built in the SMART program [10]. The structures of complexes **1** and **4** were solved by direct methods and refined by full-matrix least-squares calculations on F^2 with SHELX-97 [11]. All non-hydrogen atoms were refined anisotropically and hydrogen atoms were located in the calculated positions using the riding model. The diffraction data for complex **2** and **3** were collected on a Nonius Kappa-CCD diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) at 150(1) K. The CCD data were integrated and scaled using the DENZO-SMN software package [12]. The structures were solved by SIR-92 and refined by using SHELXTL/PC V6.12 [13]. All hydrogen atoms were located in calculated positions using the riding model. Crystallographical data and refinement details for **1**–**4** are listed in Table 1.

3. Results and discussion

3.1. Synthesis of complexes

The btp ligand reacted with two equivalents of $Cu(OAc)_2 \cdot H_2O$ to afford the SBU precursor **1**. In the IR spectrum of **1** the characteristic bands of the acetate groups appear at 1632 and 1426 cm^{-1}, which means that the acetate ligands bridge two copper ions to lead to a paddle wheel type copper acetate ($Cu_2(OAc)_4$). In accordance with elemental analysis, **1** possesses two btp ligands and two methanol molecules per $Cu_2(OAc)_4$ unit. Btp acts as a unidentate ligand in **1**, though it has a strong tendency [9,14] to bridge metal ions for polymeric architectures. Even when 1:1 and 1:2 ligand to metal ion ratios were employed only **1** was isolated. In the reaction of **1** with CuX_2 salts ($X = [BF_4]^-$, $[ClO_4]^-$ and $[OTf]^-$), a novel $[Cu_2(OMe)_2]^{2+}$ SBU appears where each copper center is bridged by two methoxide ligand in the μ-mode. As the solvothermal reaction

[15] of copper acetate in methanol afforded copper methoxide, the acetate ligands of **1** play an important role in fabricating methoxide-bridged dicopper SBUs on the grounds that the admixture of CuX_2 salts ($X = [BF_4]^-$ and $[ClO_4]^-$) with just btp ligands instead of **1** does not afford $[Cu_2(OMe)_2]^{2+}$ modules but gives 1D coordination polymers of $[Cu(btp)_2X_2]_n$ in which the copper ions are doubly bridged by btp ligands and the anions occupy the axial sites of the metal centers [16]. The cage **2** was prepared by the reaction of **1** with $Cu(BF_4)_2 \cdot 6H_2O$ in a mixture of MeOH and MeCN at room temperature. Similarly **1** also reacted with $Cu(ClO_4)_2 \cdot 6H_2O$ to afford 3D cage (**3**). Slow evaporation of the reaction mixture afforded blue-green crystals of **2** and **3**, which lost their crystallinity out of the mother liquor. The infrared spectra of **2** show a very strong vibration absorption band of the $[BF_4]^-$ anion (1072 cm^{-1}). The absorption bands of the $[ClO_4]^-$ anion appear at 1077 cm^{-1} in **3**. Meanwhile, the reaction of **1** with $Cu(OTf)_2$ led to the 1D coordination polymer of **4**. The presence of the triflate anion is indicated by infrared absorptions around 1030, 1250 and 1291 cm^{-1}. In all cases of **2**, **3** and **4**, the absorption bands corresponding to acetate ligands vanish.

3.2. Structural properties

A single crystal X-ray analysis of **1** revealed that four acetate ligands bridge copper centers in a μ-mode leading to a paddle wheel type copper acetate. Two btp ligands acting as a unidentate ligands bind the axial sites of the copper centers through the 4-positioned nitrogen atoms in its triazole unit, with a Cu1–N1 distance of 2.167(3) Å (see Fig. 1).

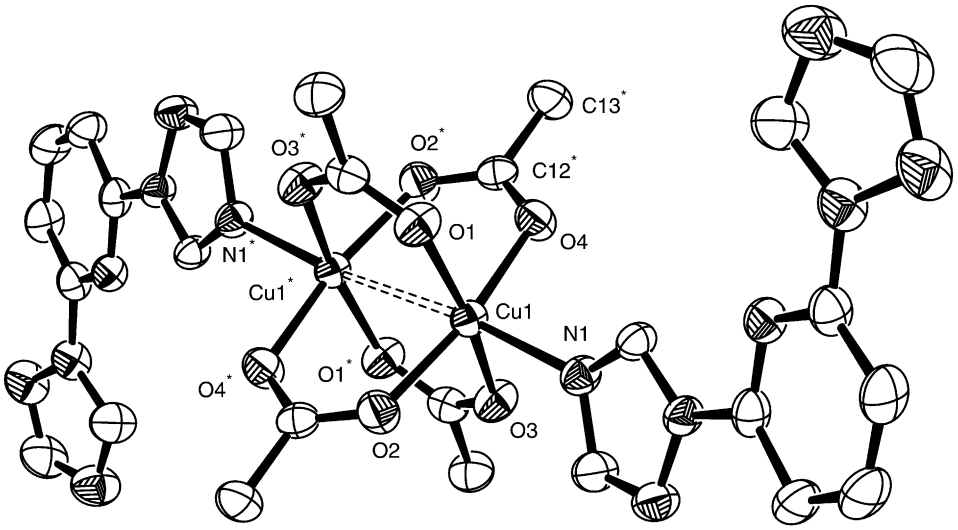

Fig. 1. Ortep drawing of **1** with 50% ellipsoid level. H atoms and MeOH molecules are omitted for clarity. Symmetry code: (*) $-x+1, -y+1, -z+2$.

An inversion center lies on the midpoint of the copper centers (Cu1 and Cu1*). Thus, **1** is centrosymmetric. The distance of Cu1–Cu1* is 2.6452(8) Å and the angle of N1–Cu1–Cu1a is 173.84(7)° and is nearly linear. Selected bond lengths and bond angles of **1** are listed in Table 2.

In the cage **2** there exist four crystallographically independent cages which are classified into two types. Each cage is represented by **2A** and **2B** which are intrinsically induced by anion-templating self-assembly with $[Cu_2(OMe)_2(btp)_2]$ units (see Fig. 2). Counter ions are often

Symmetry code: (*) $= -x+1; -y+1; -z+2$.

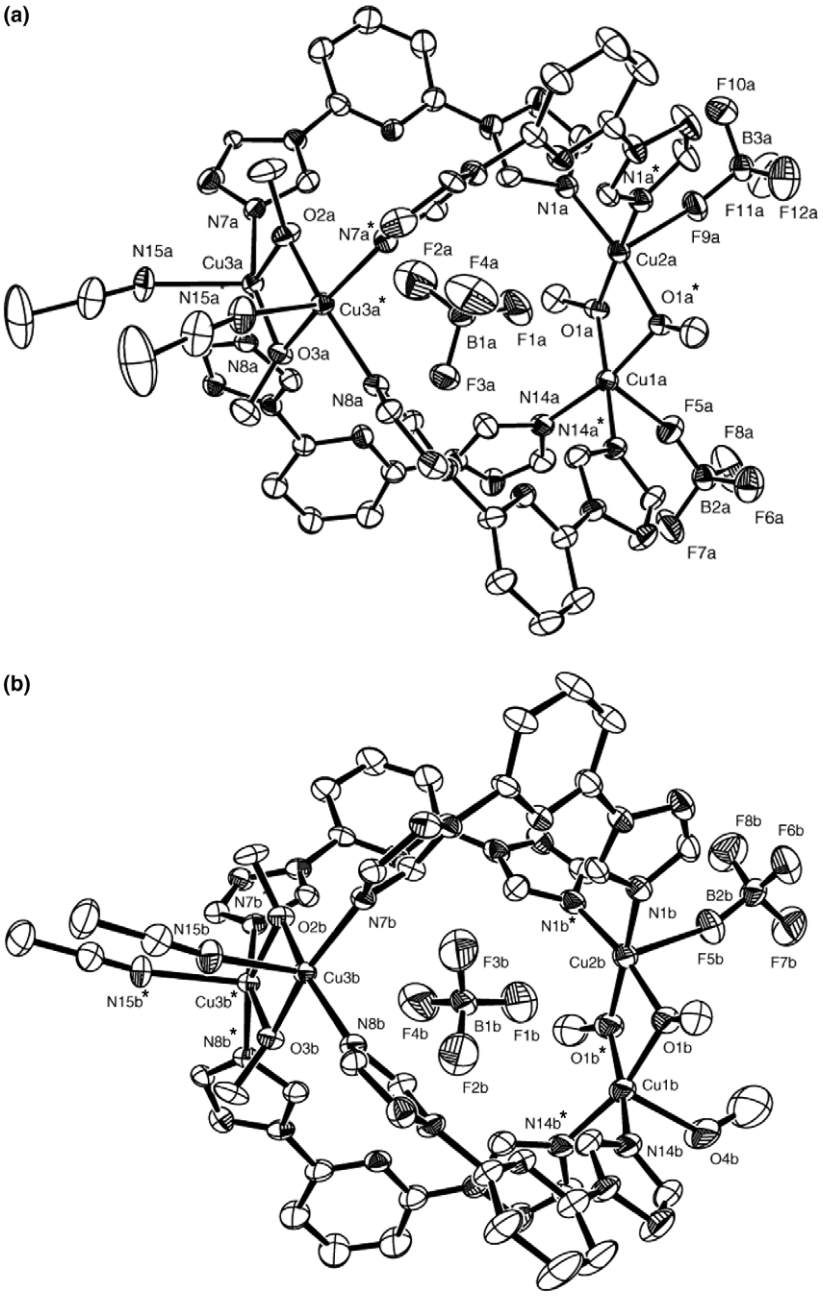

Fig. 2. The 3D cage structure of **2A** (top) and **2B** (bottom) showing that the $[BF_4]^-$ anion is encapsulated in each cavity. Displacement ellipsoids are drawn at the 30% probability level. H atoms and uncoordinated $[BF_4]^-$ anions are omitted for clarity. Symmetry code: (*) $-x+1, -y+1, -z+2$.

able to exert a templating effect in forming 3D cages in which the central void encapsulates the anions [6]. In addition to the orthogonal arrangement of Cu···Cu axes, the bending of Cu_2O planes along the O···O hinge causes btp arms to get close enough to interconnect two $[Cu_2(OMe)_2]^{2+}$ SBUs, which affords tetracupric 3D cages. Each copper center has square pyramidal geometry in common. The equatorial planes comprise two oxygen atoms of methoxide ligands and two nitrogen atoms of btp ligands. Solvent molecules and counter anions occupy the apical sites to complete the environment of the copper centers. Four btp ligands interconnect the dicopper modules through 4-positioned nitrogen atoms of the triazole rings. Since each edge-shared plane is bent down towards the void, the Cu···Cu separation (2.8848(2)–2.9640(2) Å) is much shorter than that of the average value of 3.0(1) Å found in methoxide bridged copper complexes [15]. While methoxide groups bridging the copper centers (Cu1a and Cu2a in **2A**, Cu1b and Cu2b in **2B**) incline in the direction of the cavity, the other methoxide groups pin towards the apical direction of the copper centers (Cu3a and Cu3a* in **2A** and Cu3b and Cu3b* in **2B**). The different behaviors of the methoxide ligands discriminate the copper centers to exert an influence on selective coordination of apical ligands. The apical sites of Cu1a, Cu2a, Cu1b and Cu2b are less hindered than those of Cu3a and Cu3b on account of small dihedral angles of the CuO_2 planes (for **2A**, $\Delta Cu1aO_2$ and $\Delta Cu2aO_2$ (148.7°); for **2B**, $\Delta Cu1bO_2$ and $\Delta Cu2bO_2$ (158.6°)). Thus, two large $[BF_4]^-$ anions prefer the less hindered copper centers of Cu1a and Cu2a in **2A**. In another crystallographically independent cage of **2B** one MeOH molecule and one $[BF_4]^-$ anion locate in the axial sites of Cu1b and Cu2b, respectively. The MeOH molecule binds Cu1b with a Cu–O–C angle of 129.5(1)°, which means that MeOH has an effective volume comparable to the $[BF_4]^-$ anion (Fig. 2, bottom). On the other hand, owing to the crowded environment around Cu3a and Cu3b the only linear MeCN molecules can protrude towards the copper centers to complete the square pyramidal geometry. In **2A** the angle of Cu3a–N–C is 164.9(9)°. In **2B** the Cu3b–N–C angle is 166.7(7)°. Each cage captures one $[BF_4]^-$ anion in its cavity. Similar to the $[BF_4]^-$ anion, the $[ClO_4]^-$ anion can also play a role in forming another 3D cage (**3**) which is structurally similar to **2A**. The apical sites of the Cu centers are occupied with two $[ClO_4]^-$ anions and two MeCN molecules. A $[ClO_4]^-$ anion locates in the cavity of **3** instead of the $[BF_4]^-$ anion. Two $[ClO_4]^-$ anions lie on the less hindered axial sites of Cu1 rather than those of Cu2, owing to the small dihedral angles (149.5°) of the $Cu1O_2$ planes. The selected bond lengths and angles of **2** and **3** are listed in Table 3.

As depicted in Fig. 3, **4** turns to be a sinusoidal 1D infinite coordination polymer, since the large $[OTf]^-$ anion is not able to template a 3D cage structure. The components of **4** are much like **2** and **3** in that btp ligands connect $[Cu_2(OMe)_2]^{2+}$ SBUs with a 1:1 molar ratio of metal to ligand. The $[Cu_2(OMe)_2]^{2+}$ SBUs are doubly bridged by btp ligands in a zigzag pattern. The dihedral angle of CuO_2 planes along the O···O hinge is 179.2°. The Cu···Cu distance of 2.9517(1) Å is comparable with 2.9385(2) Å of the linear 1D coordination polymer of $[Cu(OMe)_2]_n$ [15]. Since the methoxide groups lie coplanar with the Cu_2O_2 plane, the axial sites of the copper centers are bared to better coordinate $[OTf]^-$ than $[BF_4]^-$ and $[ClO_4]^-$ anions [17]. Above and below the Cu_2O_2 plane two $[OTf]^-$ anions are located to bridge copper centers in a μ-mode. The distances of Cu centers and oxygen atoms (O1, O2, O4, and O5) of $[OTf]^-$ anions are much shorter that the sum of the van der Waals radii [18]. All equatorial Cu–X (X = N or O) distances remain in the range 1.90–2.00 Å while axial Cu–O distances fall in the range 2.49–2.67 Å, as expected for Jahn-Teller distorted copper(II) systems. This means the local coordination environment around the copper centers

and $[Zn(bpp)(SO_4)\cdot CH_3OH]_n$, form the subject of this report.

2. Experimental

2.1. General procedures

The IR spectra were recorded on a Jasco FT/IR-460 plus spectrometer. Elemental analyses were obtained from a PE 2400 series II CHNS/O analyzer, Perkin–Elmer CHN-2400 analyzer and Heraeus VaruoEL analyzer. Thermogravimetric analyses (TGA) were obtained on a DuPon TGA 2050. Differential scanning calorimetry (DSC) measurements were carried on a Dupon DSC Q-10.

2.2. Starting materials

The reagents $Zn(O_2CCH_3)_2\cdot 6H_2O$, $ZnSiF_6\cdot 6H_2O$, $ZnSO_4\cdot 6H_2O$, and bpp (bpp = 1,3-bis(4-pyridyl)propane) were purchased from Aldrich Chemical Co. and used as received.

2.3. Preparation of $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(bpp)\cdot 4H_2O]_n$ (1)

Bpp (0.20 g, 1.0 mmol) in 10 mL CH_3OH was layered onto a solution of $Zn(O_2CCH_3)_2\cdot 6H_2O$ (1.3 g, 7.0 mmol) in 5 mL H_2O. The resultant solution was allowed to slowly diffuse for several weeks to give colorless crystals. The crystals were collected, washed by methanol and dried in vacuum. Yield: 0.91 g (68%). *Anal.* Calc. for $C_{33}H_{52}N_2O_{26}Zn_7$: C, 29.35; H, 3.88; N, 2.07. Found: C, 29.43; H, 3.70; N, 1.92%. IR (KBr disk): 3418(br), 2951(s), 1618(m), 1586(m), 1433(m), 1393(m), 1336(m), 1223(s), 1071(m), 1030(m), 932(m), 856(m), 821(m), 809(s), 675(m), 619(m), 517(m).

2.4. Preparation of $[Zn(SiF_6)(bpp)_2\cdot 4H_2O\cdot 2CH_3OH]_n$ (2)

Prepared as described as for **1**. Yield: 0.66 g (78%). *Anal.* Calc. for $C_{28}H_{44}F_6N_4O_6SiZn$: C, 45.44; H, 5.99; N, 7.57. Found: C, 45.41; H, 5.88; N, 7.72%. IR (KBr disk): 3418(br), 3037(m), 2859(m), 2493(m), 1949(m), 1621(m), 1558(m), 1505(m), 1456(m), 1416(m), 1357(m), 1221(m), 1071(m), 1031(m), 991(m), 857(m), 619(s), 603(m), 575(s), 506(s).

2.5. Preparation of $[Zn(bpp)(SO_4)\cdot CH_3OH]_n$ (3)

Prepared as described as for **1**. Yield: 0.32 g (83%). *Anal.* Calc. for $C_{14}H_{18}N_2O_5SZn$, C, 42.92; H, 4.63; N, 7.15%. Found: C,42.84; H, 4.42; N, 7.06%. FT-IR (cm^{-1}) (KBr disk): 3386(br), 3050(m), 2950(m), 1978(m), 1619(m), 1558(m), 1508(m), 1434(m), 1226(m), 1118(m), 1006(m), 948(m), 860(m), 802(m), 651(s), 620(m), 520(s), 489(s).

3. X-ray crystallography

The diffraction data of **1**–**3** were collected on a Siemens CCD diffractometer which was equipped with graphite-monochromated Mo Kα ($\lambda_\alpha = 0.71073$ Å) radiation [12]. Data reduction was carried by standard methods with the use of well-established computational procedures [13].

A crystal of **1** suitable for X-ray crystallography was mounted on the top of a glass fiber with epoxy cement. The hemisphere data collection method was used to scan the data points at $4.62 \leqslant 2\theta \leqslant 50.00°$. The structure factors were obtained after Lorentz and polarization corrections. The positions of the heavier atoms, including the Zn atom, were located by the direct method. The remaining atoms were found in a series of alternating difference Fourier maps and least-square refinements. The final residuals of the refinement were $R_1 = 0.0541$ and $wR_2 = 0.1512$ for **1**. The X-ray crystallographic procedures for **2** and **3** were similar to those for **1**. Basic information pertaining to crystal parameters and structure refinement is summarized in Table 1.

4. Results and discussion

4.1. Syntheses and spectroscopic studies

The complexes, $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(bpp)\cdot 4H_2O]_n$ (**1**), $[Zn(SiF_6)(bpp)_2\cdot 4H_2O\cdot 2CH_3OH]_n$ (**2**), and $[Zn(bpp)(SO_4)\cdot CH_3OH]_n$ (**3**), were prepared by layering solutions of bpp (bpp = 1, 3-bis(4-pyridyl)propane) in CH_3OH with solutions of $Zn(O_2CCH_3)_2\cdot 6H_2O$, $ZnSiF_6\cdot 6H_2O$ and $ZnSO_4\cdot 6H_2O$, respectively, in H_2O. The IR spectra of complexes **1**–**3** show characteristic C–N and C–C vibrational frequencies for the bpp ligands.

4.2. Structure of $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(bpp)\cdot 4H_2O]_n$ (1)

The structure of complex **1** was solved in the space group *Pccn*. Selected bond distances and angles are listed in Table 2. Fig. 1(a) shows a perspective view of the heptanuclear building block. Complex **1** forms 1-D chains which consists of bent bpp ligands bridging two $\{Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O_2)\}$ clusters (Zn(2)–N = 2.040(7) Å). The overall Zn_7 framework involves two $\{Zn_4O\}$ tetrahedrons joined at Zn(1), Fig. 1(b). The Zn(1) atom occupies an inversion center and adopts a slightly distorted octahedral coordination geometry with the O–Zn–O bond angles only deviating slightly from 90° or 180°. The heptanuclear cluster of **1** closely resembles the related polymeric structures of $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(bpe)]$ (bpe = 1,2-bis (4-pyridyl)ethane) [14a], $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(dpds)]$ (dpds = 4,4′-dipyridyldisulfide) [14a] and the discrete cluster $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(Pz)_2]$ (Pz = pyrazine) [14b]. In all these complexes, the coordination geometry of the Zn atoms coordinated by the nitrogen atoms of the ligands may be described as a [4+2] geometry with two long Zn–O bonds, and in the absence of these two weak Zn–O

Symmetry transformations used to generate equivalent atoms: A: $-x + 1$, $-y + 1$, $-z$.

interactions, the coordination geometry at these Zn atoms can be described as a highly distorted tetrahedral geometry [14a]. It is noted that the distances of the two longer bonds in $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(bpe)]$ are 2.341(4) and 2.539(4) Å, and those in $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(dpds)]$ are from 2.420(11) to 2.584 Å [14a], which are significantly different from the two long Zn–O distances, Zn(2)–O(8A) = 2.488(7) and Zn(2)–O(10A) = 2.512(6) Å, in **1**, most probably due to the different nature of the spacer ligands. These distances are also significantly different from those in the discrete cluster $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(Pz)_2]$, which are 2.508 and 2.735 Å [14b]. These distances are all far less than the sum of the van der Waals radii of the Zn and O atoms, which is 2.9 Å. Both Zn(3) and Zn(4) atoms are bonded to four oxygen atoms to form the distorted-tetrahedral coordination geometry.

The heptanuclear building blocks are linked by the bpp ligands to form a zig-zag polymeric structure, Fig. 1(c). For comparison, it is noted that by changing the backbone of the dipyridyl ligand from –CH_2–CH_2– [14] to –CH_2–CH_2–CH_2–, the structure of the 1-D polymeric complex varies from quasi-linear to zig-zag chain, which is similar to that of the complex $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(dpds)]$ (dpds = 4,4′-dipyridyldisulfide) containing the dpds ligand with the –S–S– backbone [14a]. While the ligand identity plays an important role in determining the structural type, no significant difference in the Zn–N bond distances is found for these complexes.

4.3. Structure of $[Zn(SiF_6)(bpp)_2 \cdot 4H_2O \cdot 2CH_3OH]_n$ (**2**)

Colorless crystals of complex **2** conform to the space group *Imm2*. Selected bond distances and angles are listed

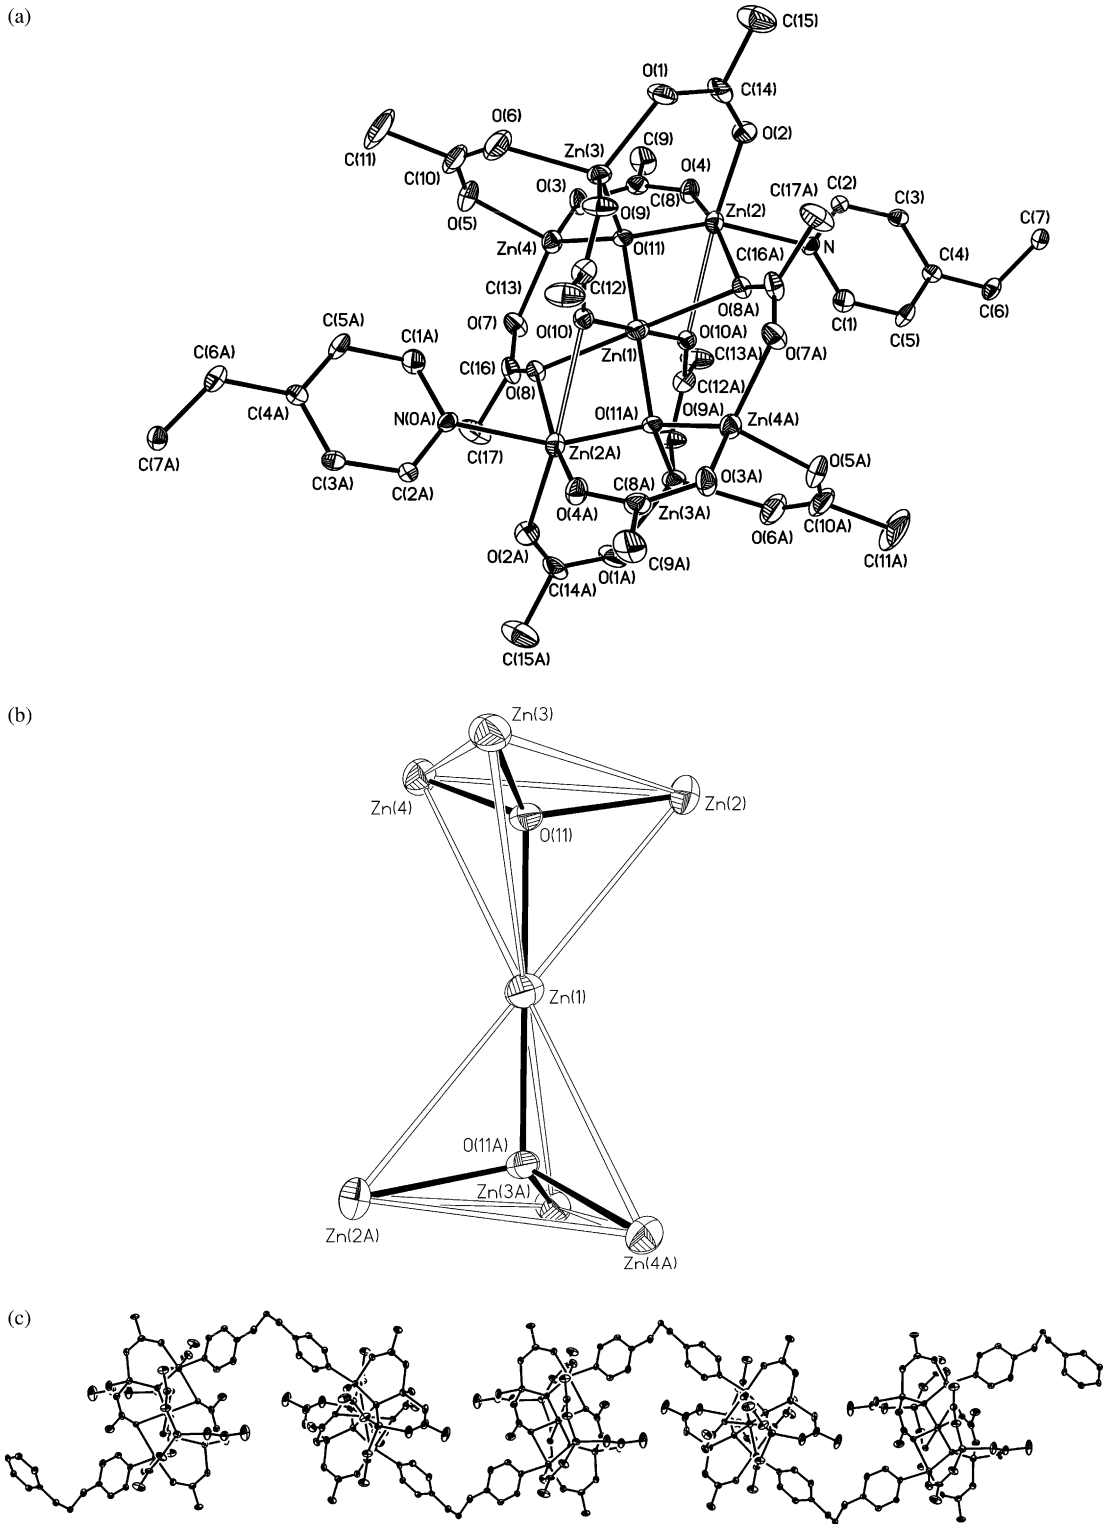

Fig. 1. (a) ORTEP drawing of the local coordination of Zn in **1**. Ellipsoids are scaled to enclose 20% of the electron density. (b) ORTEP drawing shows the tetrahedron of $\{Zn_4O\}$ in $\{Zn_7(O_2CCH_3)_{10}O_2\}$. (c) The polymeric zig-zag chain of **1**.

in Table 3. Fig. 2 shows an ORTEP diagram about the Zn metal center. It is seen that the Zn atom is bonded to four pyridyl nitrogen atoms (Zn–N = 2.145(2)–2.170(2) Å) in the equatorial plane. The dihedral angle of the two *trans* pyridyl rings that are coordinated to the Zn atom is 0.1°. Each bpp ligand acts as a bidentate ligand and exhibits a typical twisted conformation, with dihedral angles between the planes of two pyridyl rings

Table 3
Selected bond distances (Å) and angles (°) for **2** and **3**

Symmetry transformations used to generate equivalent atoms: A: $-x+1$, $-y+1$, z for **2**; A: $x+1/2$, $-y+3/2$, $-z+1$; B: $-x+1/2$, $-y+1$, $z-1/2$ for **3**.

of 78.5° and 78.7°. The Zn atom is also bonded to two hexafluorosilicate ligands through the fluorine atoms (Zn–F = 2.1352(14) Å, F–Zn–F = 178.2(4)° in the axial position to complete the distorted octahedral coordination geometry. The octahedron contains a crystallographic C_4 axis passing through the two bonded F atoms and the Zn center. Along the *b* axis, adjacent Zn atoms are linked to each other through the pyridyl nitrogen atoms to form double-stranded chains involving 24-membered rings (Fig. 3, top), while along the *a* axis, adjacent Zn atoms are linked to each other through the fluoride atoms from hexafluorosilicate to form linear chains (Fig. 3, middle). A view looking down the *c* axis shows that the molecules of **2** form a 2-D grid involving double-stranded chains linked by the SiF_6^{2-} anions (Fig. 3, bottom). The rectangular cavities, each with an area of 7.780×12.431 Å^2, are occupied by the solvent molecule. The water and methanol molecules are interlinked through OH–F (O–F = 2.828 Å) and OH–O (O–O = 1.910, 2.465 and 2.550 Å) interactions in the cavities. For comparison, it is noted that complex **2** is similar to the 3-D rectangular network $[Cu(SiF_6)(4,4'\text{-bipyridine})_2]_n$ that was based on the square grid of $[Cu(4,4'\text{-bipyridine})_2]_n$ and pillars of SiF_6^{2-} anions [15].

4.4. Structure of $[Zn(bpp)(SO_4)\cdot CH_3OH]_n$ (3)

The structure of complex **3** was solved in the space group *Pbca* and each asymmetric unit of **3** contains one Zn atom, one bpp group, a sulfate molecule and one included methanol. Selected bond distances and angles are listed in Table 3. Fig. 4(a) shows an ORTEP diagram about the Zn metal center. The Zn atom is bonded to two pyridyl rings through the nitrogen atoms (Zn–N = 2.015(3) Å, N–Zn–N = 118.52(11)°, with a dihedral angle of 145.8° between the two pyridyl rings. The Zn atom is also bonded to two oxygen atoms from two sulfate ligands (Zn–O = 1.956(3)–1.965(2) Å, O–Zn–O = 96.93(11)° to complete the distorted tetrahedral geometry.

Along the *b* axis, adjacent Zn atoms are linked to each other through the bpp ligands to form helical chains, Fig. 4(b), which are interlinked by the μ_2-SO_4^{2-} anions to form a 3-D porous structure, where the open channels are occupied by the methanol molecules, Fig. 4(c). The longer Zn–Zn distance, separated by bridging bpp ligands, is 12.184 Å, while the shorter Zn–Zn distance, separated by the SO_4^{2-} anions, is 5.184 Å. Each bpp ligand acts as a bidentate ligand and exhibits a typical twisted conformation, with a dihedral angle of 141.3° between the pyridyl rings. In the helical chain, each pitch contains two zinc metals and two bpp ligands and the Zn–Zn separation distance is 22.396 Å. The methanol molecules are interlinked through CH–O (O–H = 2.318 Å, ∠C–H–O = 173.2°) interactions, while the sulfate groups are also interlinked through CH–O (O–H = 2.492–2.503 Å, ∠C–H–O = 150.9–152.1°) hydrogen bondings.

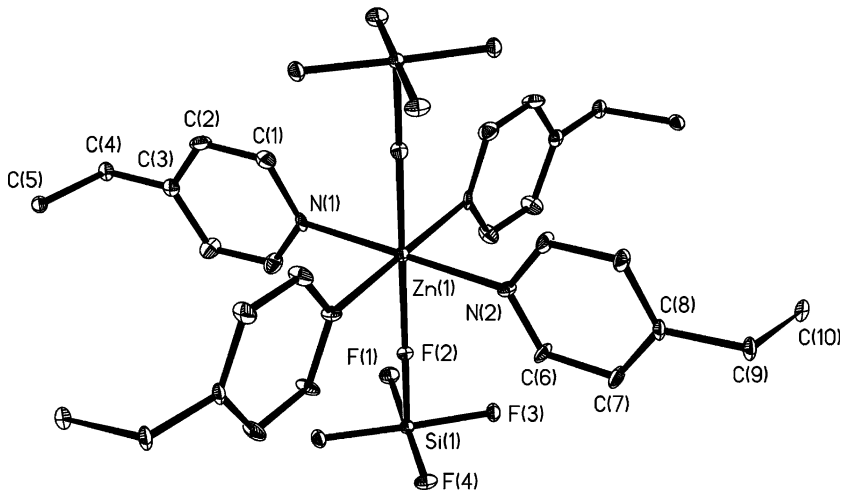

Fig. 2. An ORTEP drawing of the local coordination of Zn(II) in **2**. Ellipsoids are scaled to enclose 20% of the electron density.

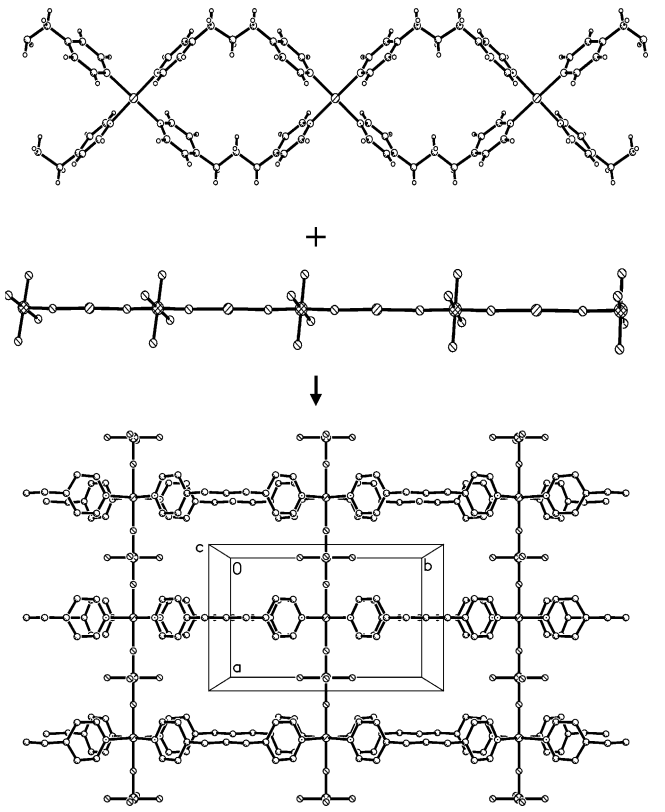

Fig. 3. ORTEP drawings for **2**, showing the double-stranded chain involving bpp ligands, top, linear chain involving anions, middle, and the two dimensional structure, bottom.

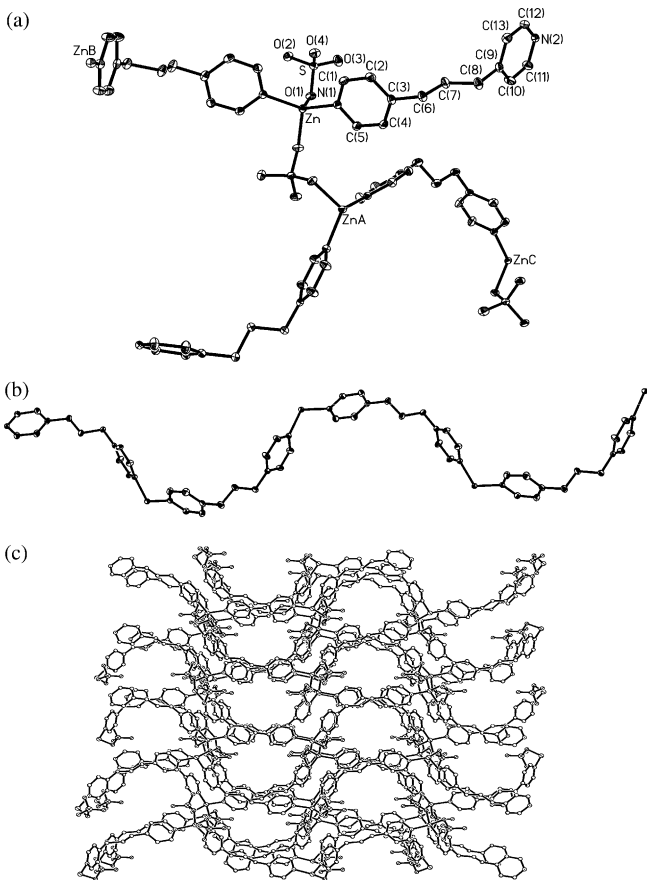

Fig. 4. (a) ORTEP drawing showing the coordination geometry of zinc metal center for **3**. Ellipsoids are scaled to enclose 20% of the electron density. (b) Along the *b* axis, adjacent Zn atoms are linked by bpp to form a helical chain, viewing down the *b* axis. (c) The 3-D porous structure of **3**, viewing down the *c* axis.

4.5. Conformation of the bpp ligand

All the bpp ligands in complexes **2** and **3** adopt the *gauche, gauche*-conformation. While the C–C–C–C dihedral angles of the bpp ligands in **2** are all 180°, those in **3** are 171.2° and 173.9°. Noticeably, the bpp ligand in complex **1** adopts the *anti*, *anti*-conformation with a dihedral angle of 65.0 °.

4.6. Thermogravimetric analyses

Complexes **1**–**3** are very stable in air at ambient temperature and almost insoluble in common solvents such as water, alcohol, acetonitrile, chloroform, methanol and acetone. Thermal gravimetric analyses (TGA) were carried out to examine their thermal stability. The samples of **1**–**3** were heated from 50 to 800 °C in air at 1 atm pressure with a heating rate of 10 °C min^{-1}. The TGA curve shows that **1** is stable up to 56 °C. A total weight loss of 5.1% occurred in the temperature range 56–156 °C, presumably due to the removal of the guest water molecules per formula unit (calculated 5.3%), and a sharp weight loss occurred in the temperature range 210–297 °C, consistent with the removal of bpp ligands and decomposition of the polymeric chain. On further heating, another weight loss between 380 and 430 °C was observed, corresponding to the decomposition of the $\{Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2\}$ cluster. The results of **2** showed that **2** is stable up to 116 °C with the first weight loss of 15.3% in the range 116–200 °C, corresponding to the loss of the two methanol and four water guest molecules per formula (calculated 15.6%). In the temperature range of 200–443 °C, complex **2** underwent complicated multiple weight loss steps, with the total weight loss corresponding to loss of the two bpp ligands (observed 45.1%, calculated 44.9%). The thermal decomposition behavior of **3** is quite different from that of compound **2**, showing that the first weight loss (8.1%) occurs from 80 to 180 °C which corresponds to the loss of the methanol guest molecules (calculated 8.2%). On further heating, another weight loss between 180 and 320 °C was observed, corresponding to the loss of the bpp ligand (observed 50.9%, calculated 50.7%). Their T_m values have been measured by using differential scanning calorimetry (DSC), and they are 187, 239 and 226 °C for complexes **1**–**3**, respectively. The 2-D and 3-D Zn(II) polymeric complexes show higher T_m values than the 1-D complex.

5. Conclusions

The synthesis and structures of three complexes $[Zn_7(O_2CCH_3)_{10}(\mu_4\text{-}O)_2(bpp)\cdot 4H_2O]_n$ (**1**), $[Zn(SiF_6)$-

$(bpp)_2 \cdot 4H_2O \cdot 2CH_3OH]_n$ (**2**) and $[Zn(bpp)(SO_4) \cdot H_3OH]_n$ (**3**) have been successfully accomplished. In complex **1**, the CH_3COO^- anions coordinate to the Zn(II) metal centers to form heptanuclear clusters which are bridged by the bpp ligands to form 1-D zig-zag chains. In complex **2**, the double-strained chains of octahedral Zn(II) cations containing bpp ligands are bridged by the octahedral SiF_6^{2-} anions through two *trans* F atoms to form 2-D grids, while in complex **3**, the single-strained helical chain of tetrahedral Zn(II) cations containing bpp ligands are bridged by the tetrahedral μ_2-SO_4^{2-} anion to form a 3-D porous structure. The structures of these complexes are in marked contrast to that found in $Zn(NO_3)_2(bpp)$ [9a], where the monodentate NO_3^- anions coordinate to the Zn(II) metal center in a zig-zag chain to complete the tetrahedral coordination geometry. The role of anions in controlling network formation has been noted in several cases [16,17]. The anions thus show significant influence on the supramolecular structures of Zn(II) complexes containing bpp ligands, presumably due to the various types of coordination abilities and geometries of the anions.

2. Experimental

2.1. Materials and measurements

α-Naphthylamine and β-naphthylamine were purchased from Thomas Baker & Co. Pyridine-2-carboxaldehyde was purchased from Lancaster Ltd., England. Alkyl halides (MeI, EtI) were Merck reagents. The organic solvents were purified and dried by standard methods [24]. α/β-Naphthyl-(2-pyridylmethylene)amine were synthesized by equimolar condensation of pyridine 2-carboxaldehyde and naphthylamine in ethanol following the reported procedure [13]. 1-Alkyl-2-(naphthylazo)imidazoles were prepared by the published procedure [22]. All other chemicals used were of A.R. quality and were used as received.

UV–Vis spectra were recorded using JASCO UV–VIS–NIR V-570 spectrophotometer and infrared spectra were obtained from a JASCO FTIR-420 instrument. Microanalyses were collected from a Perkin–Elmer 2400 CHN elemental analyser. ^{1}H NMR spectra were recorded on a Brucker 300 MHz FT-NMR. Solution electrical conductivity was measured in a Systronics 305 digital conductivity meter. Luminescence property was measured using a Perkin–Elmer LS 55 fluorescence spectrophotometer at room temperature (298 K) and low temperature (77 K) in MeCN solution using a 1 cm path length quartz cell.

The fluorescence quantum yield of the Schiff bases (NaiPy) and their zinc-azido complexes was determined using Coumarin-120 laser dye as a reference with a known ϕ_R of 0.63 in MeCN. The complex and the reference dye were excited at 340 nm, maintaining nearly equal absorbance (~0.1), and the emission spectra were recorded from 350 to 600 nm. The area of the emission spectrum was integrated using the software available in the instrument and the quantum yield is calculated according to the following equation:

$$\phi_S/\phi_R = [A_S/A_R] \times [(\mathrm{Abs})_R/(\mathrm{Abs})_S] \times [\eta_S^2/\eta_R^2]$$

Here, ϕ_S and ϕ_R are the fluorescence quantum yields of the sample and reference, respectively. A_S and A_R are the areas under the fluorescence spectra of the sample and the reference respectively, $(\mathrm{Abs})_S$ and $(\mathrm{Abs})_R$ are the respective optical densities of the sample and the reference solution at the wavelength of excitation, and η_S and η_R are the values of refractive index for the respective solvents used for the sample and reference.

2.1.1. Synthesis of bis-azido-(α-naphthyl-(2-pyridylmethylene)amine)zinc(II)Zn(α-NaiPy)(N_3)$_2$] (5)

α-Naphthyl-(2-pyridylmethylene)amine (0.25 g, 1.08 mmol) in MeOH (10 cc) was added dropwise to a methanolic solution (10 cc) of $Zn(OAc)_2 \cdot 2H_2O$ (0.1 g, 0.46 mmol) at room temperature and stirred for 30 min. To the yellow solution NaN_3 (0.065 g, 1.00 mmol) was added and stirred for an additional 2 h. The deep brown solution was filtered and allowed to evaporate slowly in air. Orange-yellow crystals were deposited on the wall of the beaker. These were then filtered and washed with water followed by cold methanol–water (1:1, V/V). The crystals were then dried in a $CaCl_2$ desiccator. The yield was 0.12 g (68%).

Microanalytical and different spectral data are given as follows. *Anal.* Calc. for $C_{16}H_{12}N_8Zn$ (**5**): C, 50.35; H, 3.15; N, 29.37. Found: C, 50.27; H, 3.08; N, 29.50%. UV–Vis spectral data in MeCN λ_{max}(nm) (10^{-3} ε ($dm^3\,mol^{-1}\,cm^{-1}$)), for [Zn(α-NaiPy)(N_3)$_2$]$_2$ 344 (8850), 296 (8350), 269 (11,370). ^{1}H NMR ($CDCl_3$), δ, ppm (*J*, Hz): 8.16 (3H, d, 7.0 Hz), 8.19 (4, 5H, t, 8.0 Hz), 8.45 (6H, d, 8.0 Hz), 8.90 (7H, s), 8.10 (9H, d, 7.0 Hz), 8.00 (10, 11H, m), 7.75 (12H, m), 7.55 (13, 14H, m), 7.95 (15H, d, 7.0). [Zn(β-NaiPy)(N_3)$_2$]$_2$ was prepared similarly in 68% yield. *Anal.* Calc. for $C_{16}H_{12}N_8Zn$ (**6**): C, 50.35; H, 3.15; N, 29.37. Found: C, 50.25; H, 3.18; N, 29.47%. UV–Vis spectral data in MeCN λ_{max}(nm) (10^{-3} ε ($dm^3\,mol^{-1}\,cm^{-1}$)), 334 (7780), 300 (6850), 270 (10.980). ^{1}H NMR ($CDCl_3$), δ, ppm (*J*, Hz): 8.15 (3H, d, 7.0 Hz), 8.18 (4, 5H, t, 8.0 Hz), 8.43 (6H, d, 8.0 Hz), 8.92 (7H, s), 7.91 (8H, s), 8.04 (10H, d, 7.0), 8.00 (11H, m), 7.74 (12H, m), 7.56 (13, 14H, m), 7.63 (15H, d, 7.0).

2.1.2. Synthesis of [Zn(1-ethyl-2-(naphthyl-β-azo)-imidazole)$_2$(N_3)$_2$], [Zn(β-NaiEt)$_2$(N_3)$_2$] (8b)

1-Ethyl-2-(naphthyl-β-azo)imidazole (0.25 g, 1.00 mmol) in MeOH (10 cc) was added dropwise to a methanolic solution (10 cc) of $Zn(OAc)_2 \cdot 2H_2O$ (0.11 g, 0.50 mmol) at room temperature and stirred for 1/2 h. To the orange-red solution NaN_3 (0.065 g, 1.00 mmol) was added and stirred for a further 2 h. The volume of solution was reduced to half of its original volume by slow evaporation in air. It was then filtered and allowed to evaporate slowly. Red crystalline compounds were deposited on the beaker and filtered. The bright crystalline product was then recrystallized by diffusion of a CH_2Cl_2 solution into hexane. The yield was 0.18 g, 55%.

Other compounds were prepared following identical procedures and isolated in yields of 54–65%. Microanalytical data are as follows: *Anal.* Calc. for Zn(α-NaiMe)$_2$(N_3)$_2$ (**7a**) $C_{28}H_{24}N_{14}Zn$: C, 54.08; H, 3.86; N, 31.55. Found: C, 54.00; H, 3.90; N, 31.48%. UV–Vis spectral data in MeCN λ_{max}(nm) (10^{-3} ε ($dm^3\,mol^{-1}\,cm^{-1}$)), for [Zn(α-NaiMe)$_2$-(N_3)$_2$] 420 (450), 345 (7900), 290 (12000), 245 (7860). ^{1}H NMR ($CDCl_3$), δ, ppm (*J*, Hz): 7.40 (4H, b), 7.33 (5H, b), 8.40 (9H, d, 7.0 Hz), 7.75 (10H, t, 7.0 Hz), 7.44 (11H, m), 7.08 (12H, m), 7.08 (13H, m), 7.11 (14H, m), 7.00 (15H, d, 7.0 Hz), 4.10 (1Me, s). *Anal.* Calc. Zn-(α-NaiEt)$_2$(N_3)$_2$ (**7b**) $C_{30}H_{28}N_{14}Zn$: C, 55.44; H, 4.31; N, 30.19. Found: C, 55.53; H, 4.27; N, 30.14%. UV–Vis spectral data in MeCN λ_{max}(nm) (10^{-3} ε ($dm^3\,mol^{-1}\,cm^{-1}$)), for [Zn(α-NaiEt)$_2$(N_3)$_2$] 414 (600), 348 (7590), 295 (12480), 245 (8600). ^{1}H NMR ($CDCl_3$), δ, ppm (*J*, Hz): 7.44 (4H, b), 7.38 (5H, b), 8.41 (9H, d, 7.0 Hz), 7.73 (10H, t, 7.0 Hz), 7.44 (11H, m), 7.11 (12H, m), 7.11 (13H, m), 7.14 (14H, m), 7.05 (15H, d, 7.0 Hz), 4.40 (1–CH_2–, q, 12.0 Hz), 1.48 (CH_3, t, 7.0 Hz). *Anal.* Calc. Zn(β-NaiMe)$_2$(N_3)$_2$ (**8a**) $C_{28}H_{24}N_{14}Zn$: C, 54.08; H, 3.86;

N, 31.55. Found: C, 54.03; H, 3.81; N, 31.50%. UV–Vis spectral data in MeCN λ_{max}(nm) (10^{-3} ε ($dm^3\,mol^{-1}\,cm^{-1}$)), for $[Zn(\beta\text{-NaiMe})_2(N_3)_2]_2$ 422 (760), 358 (8890), 300 (12,680), 250 (8880). ^1H NMR ($CDCl_3$), δ, ppm (J, Hz): 7.40 (4H, b), 7.30 (5H, b), 8.05 (8H, sb), 7.70 (10H, t, 7.0 Hz), 7.45 (11H, m), 7.26 (12H, m), 7.26 (13H, m), 7.33 (14H, m), 7.15 (15H, d, 7.0 Hz), 3.98 (1Me, s). *Anal.* Calc. $Zn(\beta\text{-NaiEt})_2(N_3)_2$ (**8b**) $C_{30}H_{28}N_{14}Zn$: C, 55.44; H, 4.31; N, 30.19. Found: C, 55.50; H, 4.37; N, 30.26%. UV–Vis spectral data in MeCN λ_{max}(nm) (10^{-3} ε ($dm^3\,mol^{-1}\,cm^{-1}$)), for $[Zn(\beta\text{-NaiEt})_2(N_3)_2]$ 420 (850), 345 (9500), 295 (11,600), 245 (9450). ^1H NMR ($CDCl_3$), δ, ppm (J, Hz): 7.44 (4H, b), 7.38 (5H, b), 8.01 (8H, sb), 7.73 (10H, t, 7.0 Hz), 7.48 (11H, m), 7.28 (12H, m), 7.28 (13H, m), 7.34 (14H, m), 7.20 (15H, d, 7.0 Hz), 4.40 (1–CH_2–, q, 12.0 Hz), 1.48 (CH_3, t, 7.0 Hz) (where s, singlet; sb, singlet broad; t, triplet; m, multiplet; d, doublet).

2.2. Crystallographic data collection and refinement

The data of $[Zn(\beta\text{-NaiPy})(N_3)_2]_2$ (**6**) (crystal size: $0.30 \times 0.20 \times 0.20$ mm) were collected on an Enraf-Nonius CAD-4 diffractometer (Mo Kα radiation, $\lambda = 0.70930$ Å). A crystal suitable for X-ray analysis of $[Zn(\beta\text{-NaiEt})_2(N_3)_2]$ (**8b**) (crystal size: $0.40 \times 0.30 \times 0.25$ mm) was mounted in a fine focus sealed tube in a CCD Area detector with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Data were collected at 293 (2) K for both the crystals. Unit cell parameters were determined from least-squares refinement of setting angles within the 2θ range 3.8–56.14° for **6** and 4.58–49.86° for **8b**. A summary of the crystallographic data and structure refinement parameters are given in Table 1. Unique data of **6** are 2655 ($R_{int} = 0.000$) and out of 9111 collected data 3443 are unique ($R_{int} = 0.068$) for **8b** ($I > 2\sigma(I)$) recorded using the ω-scan technique. Data were corrected for Lorentz polarization effects and for linear decay. A semi-empirical absorption correction based on ψ-scans was applied. The structure **6** was solved by direct methods using a Nonius MACH3 data collection, refinement and reduction process. The structure of **8b** was solved by direct methods using the Bruker SMART data collection and refinement technique following the Bruker SHELXTL and XPREP reduction process [26]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed geometrically and refined using the riding model. In the final difference Fourier map the residual maxima and minima were 0.226 and −0.269 e $Å^{-3}$ for **6** and 0.493 and −0.180 e $Å^{-3}$ for **8b**. All calculations were carried out using SHELXL-97 [27], ORTEP-32 [28] and PLATON-99 [29] programs.

[a] $R = \sum|F_o - F_c|/\sum F_o$.

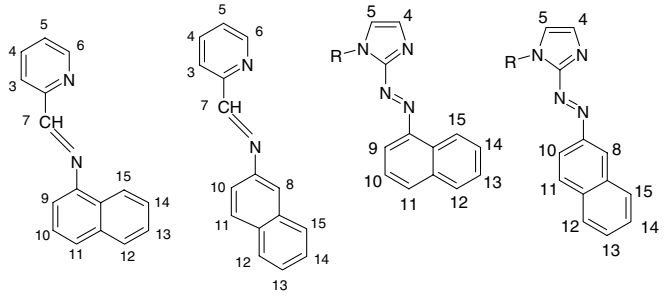
[b] $wR = [\sum w(F_o^2 - F_c^2)/\sum wF_o^4]^{1/2}$, $w = 1/[\sigma^2(F_o^2) + (0.0352P)^2 + 0.3755P]$ where $P = (F_o^2 + 2F_c^2)/3$ for **6**, $w = 1/[\sigma^2(F_o^2) + (0.0465P)^2 + 0.0000P]$ where $P = (F_o^2 + 2F_c^2)/3$ for **8b**.

[c] Goodness-of-fit is defined as $[w(F_o - F_c)/(n_o - n_v)]^{1/2}$ where n_o and n_v denote the number of data and variables, respectively.

3. Results and discussion

3.1. The synthesis and formulation

α/β-Naphthyl-(2-pyridylmethylene)amine, (α-NaiPy (**1**), β-NaiPy (**2**)) and 1-alkyl-2-(naphthyl-α/β-azo)imidazoles (α-NaiMe (**3a**), α-NaiEt (**3b**); β-NaiMe (**4a**), β-NaiEt (**4b**)) are used in this work



The complexes were synthesized by reacting methanolic solutions of the ligands and $Zn(OAc)_2$ in equimolar quantities followed by the addition of two equivalents of NaN_3 to the same reaction mixture. The solution was then filtered and evaporated slowly in air. Orange-red crystals of $[Zn(\mathbf{3}\text{ or }\mathbf{4})_2(N_3)_2]$ (**7** or **8**) were filtered in good yield while $[Zn(\mathbf{1}\text{ or }\mathbf{2})(N_3)_2]_2$ (**5** or **6**) are orange-yellow. Microanalytical data support the composition of the complexes. Interestingly, an increase in the Schiff base (NaiPy, **1** or **2**): Zn(II) molar ratio > 3:1 proportion could prepare complexes of the

same composition as have been obtained from the 1:1 molar ratio of ligand:Zn(II) in the presence of 2 equiv. of NaN_3. Molar conductance measurements suggest that the compounds are non-conducting in acetonitrile.

3.2. Molecular structures

3.2.1. [Zn(β-NaiPy)(N$_3$)$_2$]$_2$ (6)

The crystal structure is shown in Fig. 1 and metric parameters are listed in Table 2. The structure shows an azido bridged ZnN_5 coordination sphere, which includes the coordination from a chelated ligand, two end-on bridged azido-N and one terminal azido-N. The ligand serves as a diimine (—N=C—C=N—) chelator in which one N is pyridine-N and second one is an exocyclic imine, —C=N—, group. The chelate plane constituting from Zn, N(1), C(5), C(6), N(2) is planar (deviation < 0.02 Å). The pendant β-naphthyl makes a dihedral angle of 18.59(8)° with the chelate plane. The chelate angle, N(1)–Zn–N(2), is 77.68(7)° and is deviated from a regular pentagonal angle. The end-on bridge angle N(3)–Zn–N(3)* is 78.71(8)° (*symmetry: $-x, 1-y, 1-z$). The angles around Zn do not fit exactly indicate a regular square pyramidal geometry; rather the terminal N_3 is inclined to one of the bridged end-on N_3 groups. The imine —C=N— distance is 1.270(3) Å; the Zn–N(pyrdine) [Zn–N(1), 2.0870(18) Å] and Zn–N(naphthylimine) [Zn–N(2), 2.2027(17) Å] bond distances are not equivalent and show better interaction with the pyridine nitrogen than the imine-N. An intermolecular hydrogen bond is observed between the bridged azide-N and pyridine C–H: C(2)–H(2)–N(5), distances are C(2)–H(2), 0.95; H(2)–N(5), 2.72(3), C(2)–N(5), 3.564(4) Å and angle ∠C–H–N, 172.0(2)° (symmetry: $1-x, 1-y, 1-z$). This implies a hydrogen bonded dimer of azido bridged motif. A packing view shows hydrogen bonding and π–π interactions between proximately disposed naphthyl groups (Fig. 2). A significant C–H–π interaction, C(11)–H(11)–Cg(3): H–Cg(3), 3.351 Å and ∠C–H–Cg(3), 80.79° forms a π-polymer. Besides, the π–π interaction [Cg(2)–Cg(5), 3.934 Å; Cg(3)–Cg(5), 3.667 Å; Cg(3)–Cg(4), 3.580 Å, where Cg(2): Zn(1), N(1), N(2), C(5), C(6); Cg(3): N(1), C(1), C(2), C(3), C(4), C(5); Cg(4): C(7), C(8), C(9), C(10), C(15), C(16); Cg(5): C(10), C(11), C(12), C(13), C(14), C(15). Symmetry: $1/2+x, 3/2-y, -1/2+z$] enhances the strength of the non-covalent interaction.

Table 2
Selected bond distances (Å) and angles (°) for [Zn(β-NaiPy)(N$_3$)(1,1-N$_3$)]$_2$ (**6**)

Bond distance (Å)		Bond angle (°)	
Zn(1)–N(1)	2.0870(18)	N(6)–Zn(1)–N(3)[a]	117.77(9)

		N(3)–N(4)–N(5)	178.1(3)
		N(6)–N(7)–N(8)	175.8(3)

[a] Symmetry: $-x, 1-y, 1-z$.

3.2.2. [Zn(β-NaiEt)$_2$(N$_3$)$_2$] (8b)

The molecular structure of Zn(β-NaiEt)$_2$(N$_3$)$_2$ (**8b**) is shown in Fig. 3 and bond parameters are given in

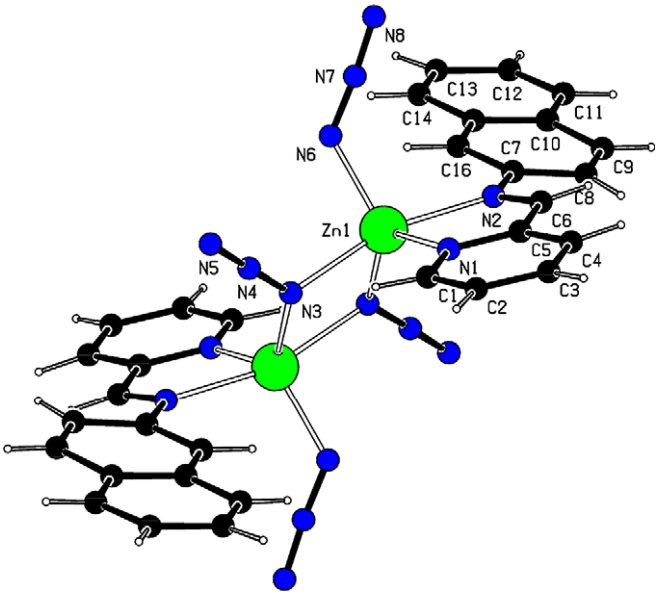

Fig. 1. Molecular structure of [Zn(β-NaiPy)(N$_3$)$_2$]$_2$ (**6**).

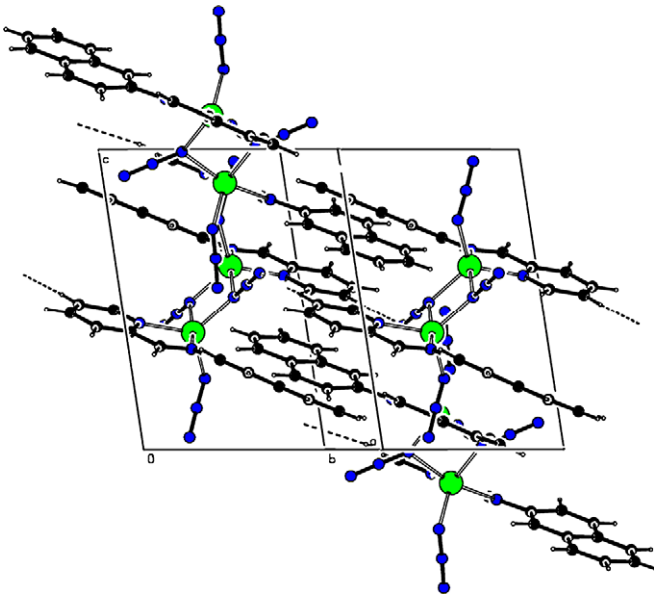

Fig. 2. Packing view along the *b*-axis of **6** showing intermolecular hydrogen bonding.

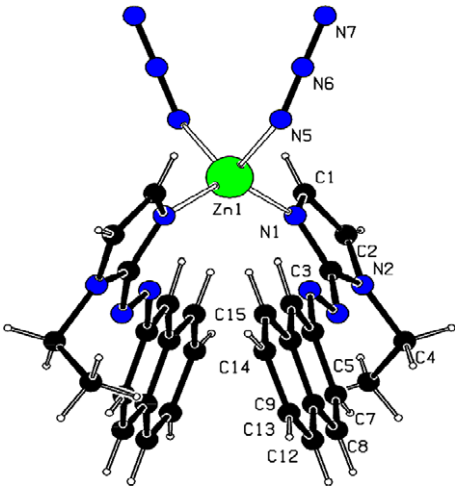

Fig. 3. X-ray structure of $[Zn(\beta\text{-NaiEt})_2(N_3)_2]$ (**8b**).

Table 3
Selected bond distances (Å) and angles (°) for $[Zn(\beta\text{-NaiEt})(N_3)_2]$ (**8b**)

Bond distance (Å)		Bond angle (°)	
Zn(1)–N(1)	2.016(2)	N(1)–Zn–N(5)	113.50(11)
Zn(1)–N(5)	1.993(3)	N(1)–Zn(1)–N(5)[a]	95.11(11)
Zn(1)–N(1)[a]	2.016(2)	N(5)–Zn(1)–N(5)[a]	104.71(19)
Zn(1)–N(5)[a]	1.993(3)	N(1)–Zn(1)–N(1)[a]	132.93(15)
N(5)–N(6)	1.176(3)	N(1)[a]–Zn(1)–N(5)[a]	113.50(11)
N(6)–N(7)	1.161(4)	C(3)–N(1)–Zn(1)	128.14(19)
N(3)–N(4)	1.267(3)	C(1)–N(1)–Zn(1)	126.0(2)
C(3)–N(3)	1.393(4)	N(6)–N(5)–Zn(1)	131.5(2)
C(6)–N(4)	1.420(3)	N(1)[a]–Zn(1)–N(5)	95.11(11)

[a] Symmetry: $1-x, y, 3/2-z$.

Table 3. The structure shows a distorted tetrahedral structure with ZnN_4 coordination. In the coordination zone two azide groups act as monodenate donors and the two β-NaiEt also act as monodentate imidazole-N donor ligands. Azoimidazoles act as both bidentate chelators, N(azo) and N(imidazole), [20,21] as well as monodentate imidazole-N donor ligands [15,16,30,31]. The distortion from a regular tetrahedral geometry is reflected from the metric parameters: Zn–N(imidazole) (Zn(1)–N(1)), 2.016(2) Å is longer than Zn–N(azide) (Zn(1)–N(5)), 1.993(3) Å. The N=N distance is 1.267(3) Å which is closer to the free ligand data [23]. The bond angles, which are extended by N(imidazole) and N(azide) with Zn(II) and are equal to 95.11(11)° (N(5)–Zn(1)–N(1)*, *symmetry: $1-x, y, 3/2-z$) and 113.50(11)° (N(5)–Zn(1)–N(1)), are away from the tetrahedral angle. The maximum deviation is observed for ∠N(1)–Zn(1)–N(1)*, 132.93 (15)° (*symmetry: $1-x, y, 3/2-z$). This may be due to large steric crowding provided by two pendant azonaphthyl groups. Additionally, the imidazole and β-naphthyl are inclined at an angle of 13.57(18)°.

The packing view of this structure (Fig. 4) shows two intermolecular hydrogen bondings: C(2)–H(2)–N(7) (C–H, 0.93 Å; H(2)–N(7), 2.566(8) Å, C(2)–N(7), 3.407(4) Å; ∠C–H–N, 150.61°) and C(4)–H(4a)–N(3) (C(4)–H(4a), 0.97 Å; H(4a)–N(3), 2.523(1) Å, C(4)–N(3), 2.940(4) Å; ∠C–H–N, 105.83° (symmetry: $1-x, 1-y, 1-z$)) which make a hydrogen bonded dimer with a 16 membered ring. Two C–H–π interactions (C(5)–H(5b)–Cg(2), 3.349(6) Å; C(11)–H(11)–Cg(1), 2.863(2) Å; symmetry: $1-x, y, 3/2-z$, where Cg(1) and Cg(2) refer to imidazole and β-naphthyl rings) and a π–π interaction between imidazole and β-naphthyl rings (distance 4.022 Å; symmetry: $3/2-x, 3/2-y, 2-z$) enhance the rigidity of the structure.

3.3. Spectral characterization

The vibration bands are assigned by comparing to the free ligand data [13,32]. The $\nu_{asym}(N_3)$ appears as a sharp strong single band at 2070–2080 cm^{-1} for **5** and **6** [33] while doublets are found at 2095–2098 and 2063–2075 cm^{-1} for **7** and **8** [34]. In **5** and **6** N_3^- serves as only a terminal donor while in **7** and **8** both end-on bridging and terminal bonds are present. The N=N and C=N vibrations are observed at 1420–1430 and 1590–1600 cm^{-1}, respectively, for **7** and **8**. The complexes **5** and **6** exhibit a very strong vibration at 1590–1605 cm^{-1} and support the presence of ν(C=N) which is red shifted by 15 cm^{-1} compared to the free ligand value (1620 cm^{-1}).

The electronic spectra in MeCN solution of $[Zn(NaiPy)(N_3)(\mu\text{-}1,1\text{-}N_3)]$ (**5**, **6**) show intense absorptions in the UV region at ca. 350 nm and ca. 300 nm ($\varepsilon \sim 10^4$ M^{-1} cm^{-1}). These transitions may be assigned to intraligand charge transfer (n–π^* and π–π^*) transitions. Naphthylazo complexes are intense orange by virtue of the —N=N— function while Schiff bases are yellow. $[Zn(NaiR)_2(N_3)_2]$ (**7** and **8**) exhibits intense transitions in the UV region which correspond to intraligand charge transfer transitions along with a weak absorption ($\varepsilon \sim 400$–900 M^{-1} cm^{-1}) at the longer wavelength (414–422 nm) region. The longer wavelength weak transition may be assigned to the $d^{10}(Zn) \rightarrow \pi^*$(azoimine) transition. The spectra of the complexes were taken in three different solvents: MeCN, $CHCl_3$ and DMF. However, the complexes do not exhibit any significant solvatochromism.

The ^1H NMR spectra are recorded in $CDCl_3$ solution. Data are given in Section 2. The assignment has been made on the basis of spin–spin interactions, and on comparing with free ligand values [13a]. In the complexes **5** and **6**, the proton signals of the coordinated ligand α/β-naphthyl-(2-pyridylmethylene)amine are shifted to downfield by 0.1–0.2 ppm compared to the free ligand value. The most downfield singlet is assigned to —HC=N— (7H) (8.90–8.92 ppm). Pyridyl protons (3H–6H) appear at 8.2–8.5 ppm and naphthyl protons (8H–15H) exhibit resonances at the upperfield side, 8.1–7.6 ppm. In $Zn(NaiR)_2(N_3)_2$ (**7** and **8**) the imidazole protons (4-, 5H) show signals at 7.3–7.4 ppm, which are 0.3–0.4 ppm downfield shifted, while the naphthyl protons are insignificantly shifted compared to the free ligand data [24]. This, in fact, supports the structural aspect of these complexes as depicted in Fig. 3.

The photoluminescence properties of pyridyl-2-(naphthylmethylene)amines and their Zn(II)-complexes (**5**

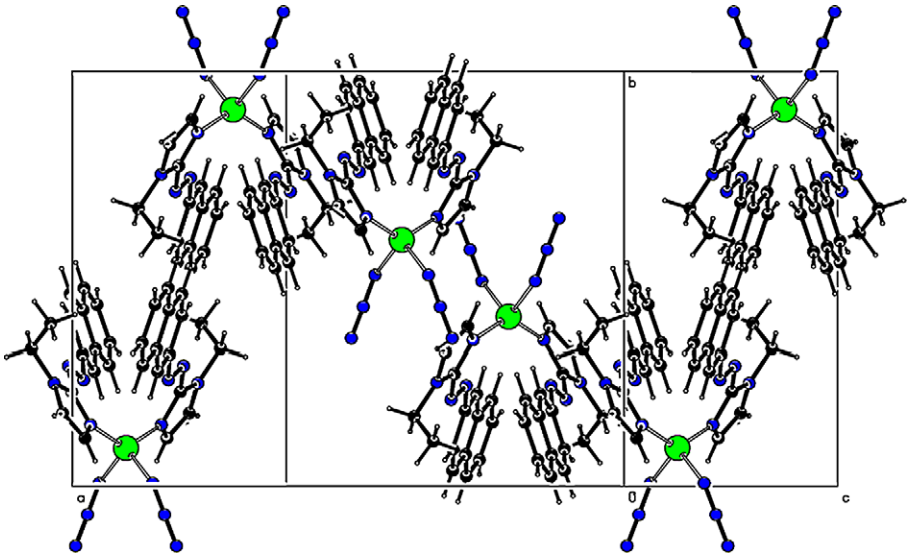

Fig. 4. Packing view in the unit cell of **8b** showing hydrogen bonding and π–π interactions.

and **6**) were studied at room temperature (298 K) and 77 K (Fig. 5). Naphthylazoimidazoles (NaiR) and their Zn(II)-compounds do not exhibit emission phenomena. The Schiff bases exhibit photoluminescence with emissions at 431 and 406 nm for α-NaiPy and β-NaiPy, respectively, at 298 K upon excitation at 340 nm. Under low temperature conditions (77 K) these compounds show emissions at 455 nm for α-NaiPy and 448 nm for β-NaiPy.

No emission originating from metal-centred or MLCT/LMCT excited states are expected for the Zn(II) complexes, since the Zn(II) ion is difficult to oxidize or reduce due to its d^{10} configuration. Thus, the emission observed in the complexes is tentatively assigned to the (π–π^*) intraligand fluorescence. It is interesting that the Zn(II) complexes show higher intensity than that of the free ligand values. This is supported from their calculated quantum yield (Table 4) with reference to coumarin-120. It has been reported that the metal ions can enhance or quench the fluorescence emission of pyridine containing compounds [35–37]. In the absence of metal ions the fluorescence of the ligand is probably quenched by the occurrence of a photoinduced electron transfer (PET) process due to the presence of a lone pair of nitrogen atoms. Such a PET process is prevented by the complexation of L with metal ions; thus the fluorescence intensity may be greatly enhanced by the coordination of Zn(II). The chelation of the ligands to Zn(II) increases the rigidity of the ligands and thus reduces the loss of energy by thermal vibrational decay. At low

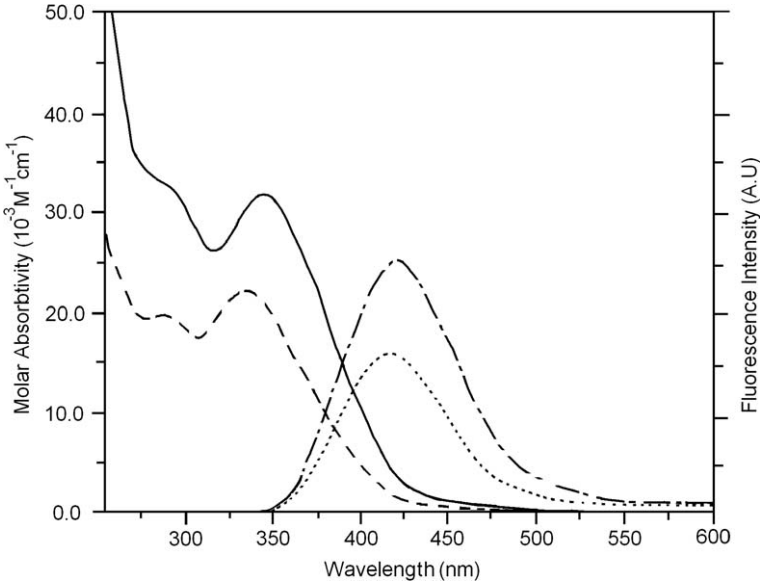

Fig. 5. Electronic spectra of **5** (——), α-NaiPy (-----) and emission spectrum of **5** (— · — · —) and α-NaiPy (– – –) in MeCN at 298 K.

Table 4
Absorption (main band), emission spectral data and quantum yield[a]

Compound	Abs (λ_{max})	Emission (λ_{max})	Quantum yield (ϕ)
α-NaiPy	342	431	0.0018
β-NaiPy	340	406	0.0008
$[Zn(\alpha\text{-NaiPy})(N_3)(1,1\text{-}N_3)]_2$ (**5**)	344	426	0.0165
$[Zn(\beta\text{-NaiPy})(N_3)(1,1\text{-}N_3)]_2$ (**6**)	324	398	0.0044

[a] Solvent: MeCN, excitation at 340 nm, reference compound is coumarine-120, $\phi_R = 0.63$ in MeCN.

temperature (77 K) the complexes show a bright greenish-blue emission and have been red shifted by 40–50 nm from the emission in solution at 298 K. This is probably caused by intermolecular interactions in the frozen conditions that effectively decreases the energy gap.

4. Conclusion

Diimine (—N=C—C=N—) and azoimine (—N=N—C=N—) are isoelectronic functions. α/β-Naphthyl-(2-pyridylmethylene)amine (α/β-NaiPy) belongs to the diimine family and 1-alkyl-2-(naphthyl-α/β-azo)imidazoles (α/β-NaiR) belongs to the azoimine family. Zinc(II)-azide complexes of these two molecules are described. α/β-NaiPy forms an azido bridged complex while α/β-NaiR gives monodenate Zn-N_3 bonding. Additionally a structural study reveals that α/β-NaiPy acts as a chelating ligand and α/β-NaiR serve as a monodentate imidazole-N donor system. Photoluminescence studies prove that $Zn(\alpha/\beta\text{-NaiR})_2(N_3)_2$ complexes are photo-inactive while $[Zn(\alpha/\beta\text{-NaiPy})(N_3)\text{-}(\mu\text{-}1,1\text{-}N_3)]_2$ complexes are photo-active.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic data centre, CCDC No. 290239 for $[Zn(\beta\text{-NaiPy})(N_3)_2]_2$ (**6**) and 288382 for $[Zn(\beta\text{-NaiEt})_2(N_3)_2]$ (**8b**). Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1233 336 033; email: deposit@ccdc.cam.ac.uk; or the web: http://www.ccdc.cam.ac.uk.

arrays [2,3]. A wide variety of donor groups can be readily attached to the cyclotriphosphazene platform via nucleophilic substitution reactions at the phosphorus with primary and secondary amine, alcohol and phenol groups that incorporate appropriate donor atoms such as nitrogen or phosphorus. Previously, it has been shown that pyrazolyl substituted cyclotriphosphazenes are particularly versatile multimodal ligands which bind to metals via both the ring nitrogen atoms of the cyclophosphazene and the pyridinic nitrogen atom of the pyrazolyl rings [4]. More recently we have reported [5] that the reaction of hexakis(2-pyridyloxy)cyclotriphosphazene (L) and the related hexakis(4-methyl-2-pyridyloxy)cyclotriphosphazene (MeL) both form a diverse range of complexes with copper(II) halides which exhibit both κ^3N and κ^5N coordination modes, including $[(CuCl_2)_2(MeL)]$, which contains two copper(II) ions bound to the cyclotriphosphazene ring nitrogen atoms. The ligand L also forms a cationic dimeric copper(II) complex $[(CuLCl)_2(CuCl_2)]^{2+}$, which contains two octahedral κ^5N-CuCl centres linked by a $CuCl_2$ moiety [6]. A key feature of the design of L is the incorporation of the flexible pyridyloxy pendant arms which facilitate binding of the metal ion to the less basic phosphazene ring nitrogen atoms. In this paper, we extend our work with copper(II) halides to examine the structures of the products formed when the divalent halides of cobalt, nickel and zinc react with L and MeL and report that some new structural types are found. As for the copper(II) halides, cobalt and nickel form five-coordinate κ^3N complexes, e.g., $[CoLCl_2]$, but in the case of nickel a six-coordinate κ^4N complex $[NiLCl_2]$ is also obtained. The dimetallic cobalt complexes of the empirical formula $[(CoX_2)_2L]$ (X = Cl or Br) are in fact zwitterions with the formulation $[(CoLX)CoX_3]$. Only one of the cobalt(II) ions bound to a phosphazene ring nitrogen in a six-coordinate κ^5N environment with the other bound to a single pyridyloxy nitrogen. In contrast, the dimetallic zinc complex contains one metal ion in a five-coordinate κ^3N environment and the other in a tetrahedral κ^2N site.

2. Experimental

2.1. Materials and instrumentation

All manipulations were carried out under nitrogen using standard Schlenk techniques. Analytical grade solvents were purchased from standard chemical suppliers and with the exception of tetrahydrofuran (THF), which was distilled from sodium/benzophenone, were used without further purification. Hydrated metal halides were dehydrated at 110 °C prior to use except for $ZnCl_2$ which was used from a freshly opened container. The ligands (L and MeL) and $[Ag(CH_3CN)_4]PF_6$ were prepared by the literature methods [5,7,8]. Mass spectra were obtained using a Varian VG70-250S double-focussing magnetic sector spectrometer by the method of liquid secondary ion mass spectroscopy (LSIMS) using *m*-nitrobenzyl alcohol as the matrix or by the electrospray technique (ESMS) from MeCN solutions using a micromass ZMD spectrometer. Listed peaks correspond to the most abundant isotopomer; assignments were made by a comparison of observed and simulated spectra. Microanalyses were performed by the Campbell Microanalytical Laboratory, University of Otago.

2.2. Preparation of the complexes

2.2.1. *[CoLCl$_2$] (**1**)*

To a stirred suspension of anhydrous $CoCl_2$ (9.3 mg, 0.071 mmol) in CH_2Cl_2 (20 mL), L (50 mg, 0.071 mmol) was added and the mixture was stirred overnight at room temperature. The solvent was removed under vacuum affording a pale blue residue which was filtered, dissolved in hot CH_3CN which on cooling yielded purple/blue crystals of **1** (49 mg, 83%). *Anal.* Calc. for $C_{30}H_{24}Cl_2CoN_9O_6P_3$: C, 43.48; H, 2.92; N, 15.22. Found: C, 43.45; H, 2.80; N, 15.69%. *m*/*z* (LSIMS): 793 $[CoLCl]^+$.

2.2.2. *[CoLBr$_2$] (**2**)*

Using the same procedure as for **1** but with $CoBr_2$ (15.6 mg, 0.071 mmo1), purple/blue crystals of **2** (40 mg, 61%) were obtained. *Anal.* Calc. for $C_{30}H_{24}Br_2CoN_9O_6P_3$: C, 39.24; H, 2.63; N, 13.73. Found: C, 39.50; H, 2.40; N, 13.54%. *m*/*z* (LSIMS): 839 $[CoLBr]^+$.

2.2.3. *[Co(MeL)Cl$_2$] · 1.5CH$_2$Cl$_2$ (**3** · 1.5CH$_2$Cl$_2$)*

A mixture of $CoCl_2$ (8.3 mg, 0.064 mmol) and MeL (50 mg, 0.064 mmol) in CH_2Cl_2 (20 mL) was stirred at room temperature overnight. The resulting solution was filtered and reduced in volume to ca. 5 mL. *t*-Butylmethyl ether was added and slow evaporation of the solution yielded small, violet blue crystals of $\mathbf{3} \cdot 1.5CH_2Cl_2$ (38 mg, 57%). *Anal.* Calc. for $C_{36}H_{36}Cl_2CoN_9O_6P_3 \cdot 1.5CH_2Cl_2$: C, 43.27; H, 3.78; N, 12.11. Found: C, 43.34; H, 3.80; N, 12.33%. *m*/*z* (LSIMS): 877 $[Co(MeL)Cl]^+$.

2.2.4. *[Co(MeL)Br$_2$] · 1.5CH$_2$Cl$_2$ (**4** · 1.5CH$_2$Cl$_2$)*

Following the same procedure as described for compound **3** but using $CoBr_2$ (14 mg, 0.064) yielded **4**.l.5CH_2Cl_2 (40 mg, 55%). *Anal.* Calc. for $C_{36}H_{36}Br_2CoN_9O_6P_3 \cdot 1.5CH_2Cl_2$: C, 39.87; H, 3.48; N, 11.16. Found: C, 39.69; H, 3.19; N, 11.16%. *m*/*z* (LSIMS): 923 $[Co(MeL)Br]^+$. Crystals suitable for X-ray diffraction were grown from *t*-butylmethylether/CH_2Cl_2.

2.2.5. *[(CoLCl)CoCl$_3$] · 0.5CH$_2$Cl$_2$ (**5** · 0.5CH$_2$Cl$_2$)*

To a stirred suspension of $CoCl_2$ (30 mg, 0.231 mmol) in THF (20 mL), L (50 mg, 0.071 mmol) was added and the reaction heated at reflux for 24 h. The reaction mixture was filtered and the solvent removed under vacuum. The residue was dissolved in CH_3CN, taken to dryness and extracted with CH_2Cl_2 (this intermediary CH_3CN dissolution improved the CH_2Cl_2 extraction). The CH_2Cl_2 solution was filtered and after *t*-butylmethylether was added

slow evaporation yielded blue crystals of $\mathbf{5}\cdot 0.5CH_2Cl_2$ (25 mg, 37%). *Anal.* Calc. for $C_{30}H_{24}Cl_4Co_2N_9O_6P_3\cdot 0.5CH_2Cl_2$: C, 36.57; H, 2.52; N, 12.59. Found: C, 36.60; H, 2.35; N, 12.62%. *m/z* (LSIMS): 959 $[Co_2LCl_3]^+$, 793 $[CoLCl]^+$. Crystals of $\mathbf{5}\cdot 2CH_3CN$ suitable for X-ray diffraction were grown from a CH_3CN/diethylether solution at −20 °C.

2.2.6. *[(CoLBr)CoBr$_3$] (**6**)*

A mixture of $CoBr_2$ (125 mg, 0.571 mmol) and L (100 mg, 0.143 mmol) in $CHCl_3$ (25 mL) was stirred at reflux temperature for ca. 18 h. and the reaction worked-up as described for **5**. Evaporation of the CH_2Cl_2 solution yielded blue crystals of **6** (110 mg, 68%). *Anal.* Calc. for $C_{30}H_{24}Br_4Co_2N_9O_6P_3$: C, 31.69; H, 2.13; N, 11.09. Found: C, 31.67; H, 1.71; N, 11.00%. *m/z* (LSIMS): 1058 $[Co_2LBr_3]^+$, 839 $[CoLBr]^+$. Evaporation from CH_2Cl_2 yielded crystals of $\mathbf{6}\cdot 3CH_2Cl_2$ suitable for X-ray diffraction which readily lost solvent.

2.2.7. *[{Co(MeL)Cl}CoCl$_3$]·0.5CH$_2$Cl$_2$ (**7**·0.5CH$_2$Cl$_2$)*

A mixture of $CoCl_2$ (16.6 mg, 0.128 mmol) and MeL (50 mg, 0.064 mmol) in CH_2Cl_2 (20 mL) was stirred at room temperature overnight. The solution was filtered, concentrated, *t*-butylmethylether added and cooled to −20 °C to afford blue crystals of $\mathbf{7}\cdot 0.5CH_2Cl_2$ (55 mg, 79%). *Anal.* Calc. for $C_{36}H_{36}Cl_4Co_2N_9O_6P_3\cdot 0.5CH_2Cl_2$: C, 40.38; H, 3.43; N, 11.61. Found: C, 40.41; H, 3.41; N, 11.65%. *m/z* (LSIMS): 877 $[Co(MeL)Cl]^+$. Slow evaporation of the *t*-butylmethylether/CH_2Cl_2 solution yielded crystals suitable for X-ray diffraction.

2.2.8. *[{Co(MeL)Br}CoBr$_3$]·CH$_2$Cl$_2$ (**8**·CH$_2$Cl$_2$)*

The same procedure as described for **7** was used but using $CoBr_2$ (28 mg, 0.128 mmol). Slow evaporation of the *t*-butylmethylether/CH_2Cl_2 solution yielded blue crystals of $\mathbf{8}\cdot CH_2Cl_2$ (37 mg, 44%). *Anal.* Calc. for $C_{36}H_{36}Br_4Co_2N_9O_6P_3\cdot CH_2Cl_2$: C, 34.03; H, 2.93; N, 9.65. Found: C, 34.21; H, 2.64; N, 9.67%.

2.2.9. *[CoLCl]PF$_6$·CH$_2$Cl$_2$ (**9**·CH$_2$Cl$_2$)*

Following the same procedure as for **1** but after stirring overnight $[Ag(CH_3CN)_4]PF_6$ (15 mg, 0.071 mmol) was added and the reaction stirred in the absence of light for an additional 1 h. The reaction mixture was filtered, the filtrate volume reduced to ca. 5 mL and hexane (2–3 mL) was added. Slow evaporation of this solution yielded pale-purple crystals of $\mathbf{9}\cdot CH_2Cl_2$ (47 mg, 64%). *Anal.* Calc. for $C_{30}H_{24}ClCoF_6N_9O_6P_4\cdot CH_2Cl_2$: C, 36.37; H, 2.56; N, 12.31. Found: C, 36.41; H, 2.48; N, 12.11%.

2.2.10. *[CoLBr]PF$_6$·CH$_2$Cl$_2$ (**10**·CH$_2$Cl$_2$)*

Following the same method described for **9** but using $CoBr_2$ (15.6 mg, 0.071 mmol) yielded pale-purple crystals of $\mathbf{10}\cdot CH_2Cl_2$ (61 mg, 80%). *Anal.* Calc. for $C_{30}H_{24}BrCoF_6N_9O_6P_4\cdot CH_2Cl_2$: C, 34.86; H, 2.45; N, 11.80. Found: C, 34.83; H, 2.23; N, 11.66%. *m/z* (LSIMS): 839 $[CoLBr]^+$.

2.2.11. *[NiLCl$_2$] (**11**)*

A mixture of L (100 mg, 0.143 mmol) and $NiCl_2$ (18.5 mg, 0.143 mmol) in CH_2Cl_2 (25 mL) was stirred for 5 days at room temperature. The reaction mixture was filtered and the volume of the filtrate reduced to ca. 8 mL. After a small volume of hexane was added to the solution, slow evaporation afforded light-green crystals of **11** (92 mg, 78%). *Anal.* Calc. for $C_{30}H_{24}Cl_2N_9NiO_6P_3$: C, 43.46; H, 2.92; N, 15.20 Found: C, 42.97; H, 2.82; N, 14.92%. *m/z* (LSIMS): 792 $[NiLCl]^+$. Diffusion of pentane into CH_2Cl_2 or $CHCl_3$ solutions of **11** resulted in the crystallisation of the red isomer, **12**.

2.2.12. *[NiLCl]PF$_6$ (**13**)*

A mixture of L (100 mg, 0.143 mmol) and $NiCl_2$ (18.5 mg, 0.143 mmol) in CH_2Cl_2 (25 mL) was allowed to stir over 5 days. $[Ag(CH_3CN)_4]PF_6$ (30 mg, 0.143 mmol) was added and the mixture stirred in the absence of light for a further 1 h. The reaction mixture was filtered, the filtrate reduced to ca. 5 mL and hexane (2–3 mL) was added, to yield pale green crystals of **13**. *Anal.* Calc. for $C_{30}H_{24}ClF_6N_9NiO_6P_4$: C, 38.39; H, 2.58; N, 13.43. Found: 38.00, 2.94, 13.19%. *m/z* (LSIMS): 792 $[NiLCl]^+$.

2.2.13. *[(ZnCl$_2$)$_2$L] (**14**)*

A mixture $ZnCl_2$ (39 mg, 0.286 mmol) and L (100 mg, 0.143 mmol) in CH_2Cl_2 (25 mL) was stirred overnight. The reaction mixture was filtered and the volume of the filtrate reduced (ca. 8 mL). After a small volume of hexane was added to the solution slow evaporation yielded colourless crystals of **14** (123 mg, 88%). *Anal.* Calc. for $C_{30}H_{24}Cl_4N_9O_6P_3Zn_2$: C, 37.07; H, 2.49; N, 12.97. Found: C, 37.20; H, 2.49; N, 12.77. ^{31}P NMR (CD_2Cl_2): δ 5.5 ppm. *m/z* (LSIMS): 798 $[ZnLCI]^+$. Slow diffusion of hexane into a 1,2-dichloroethane solution of **14** yielded crystals suitable for X-ray diffraction.

2.3. Crystallography

The X-ray data was collected on a Siemens P4 four circle diffractometer, using a Siemens SMART 1K CCD area detector. The crystals were mounted in an inert oil, transferred into the cold gas stream of the detector and irradiated with graphite monochromated Mo Kα ($\lambda =$ 0.71073 Å) X-rays. The data were collected by the SMART program and processed with SAINT to apply Lorentz and polarisation corrections to the diffraction spots (integrated 3 dimensionally). Crystal data are given in Table 1. The structures were solved by direct methods and refined using the SHELXTL program [9]. Hydrogen atoms were calculated at ideal positions. Complexes **4**, **7**, and **14** contained disordered solvent which could not be modelled satisfactorily. The contributions in each case were removed using PLATON/SQUEEZE [10]. Complex **4**: 29 electrons per cell corresponding to approximately 0.33 CH_2Cl_2 (disordered around the position 1, 0.5, 0.5) was removed and 266 Å^3

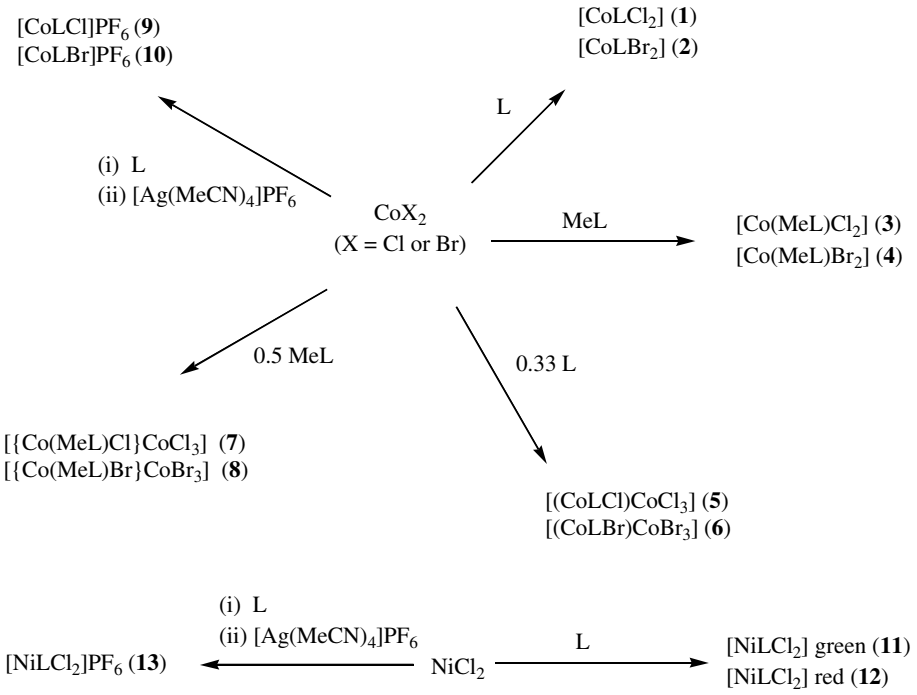
was left by the void. The reported formula is **1** · $0.17CH_2Cl_2$. Complex **7**: 339 electrons per cell corresponding to 2 · CH_2Cl_2 molecules (disordered over several positions and orientations) were removed and 937 Å^3 was left by the void. The reported formula is **7** · $2CH_2Cl_2$. Complex **14**: 163 electrons per cell corresponding to 3.2 $C_2H_4Cl_2$ molecules were removed and 1789 Å^3 was left by the void. Another molecule of $C_2H_4Cl_2$ per formula unit is present and was refined in the model. The reported formula is **14** · $1.4C_2H_4Cl_2$.

3. Results and discussion

3.1. Syntheses of compounds

The reactions between L or MeL and CoX_2 (X = Cl or Br) are shown in Scheme 1. Allowing CoX_2 suspended in a solution of L or MeL in CH_2Cl_2 in equimolar amounts to stir at room temperature affords the 1:1 complexes **1**–**4**. From the reactions between an excess of CoX_2 and L or MeL, the dimetallic compounds **5**–**8** were



Scheme 1. The reactions of L and MeL with cobalt(II) and nickel(II) halides.

obtained which contain both four- and six-coordinate cobalt(II) centres. Following the treatment of the 1:1 adducts in situ with $[Ag(MeCN)_4]PF_6$, the monocationic CoX adducts were isolated as hexafluorophosphate salts (**9** and **10**).

The reaction between 3 equiv. of $NiCl_2$ and **L** also produces a 1:1 adduct. Green and red crystalline forms of $[NiLCl_2]$ (**11** and **12**) were obtained under different crystallisation conditions, in which the nickel(II) centres are six- and five-coordinate, respectively. Treatment of the monoadduct in situ with $[Ag(MeCN)_4]PF_6$ produces the six-coordinate $[NiLCl]PF_6$ (**13**). We were only able to isolate 1:1 adducts of L using $NiCl_2$. From the reaction between $ZnCl_2$ and L we isolated the dimetallic adduct, $[(ZnCl_2)_2L]$ (**14**), which contains both four- and five-coordinate zinc(II) centres. In all cases the positive ion mass spectra (LSIMS) of the complexes exhibit significant peaks assignable to $[MLX]^+$ ions although the dimetallic cobalt complexes of L also show weak peaks corresponding to $[Co_2LX_3]^+$ (X = Cl or Br) ions.

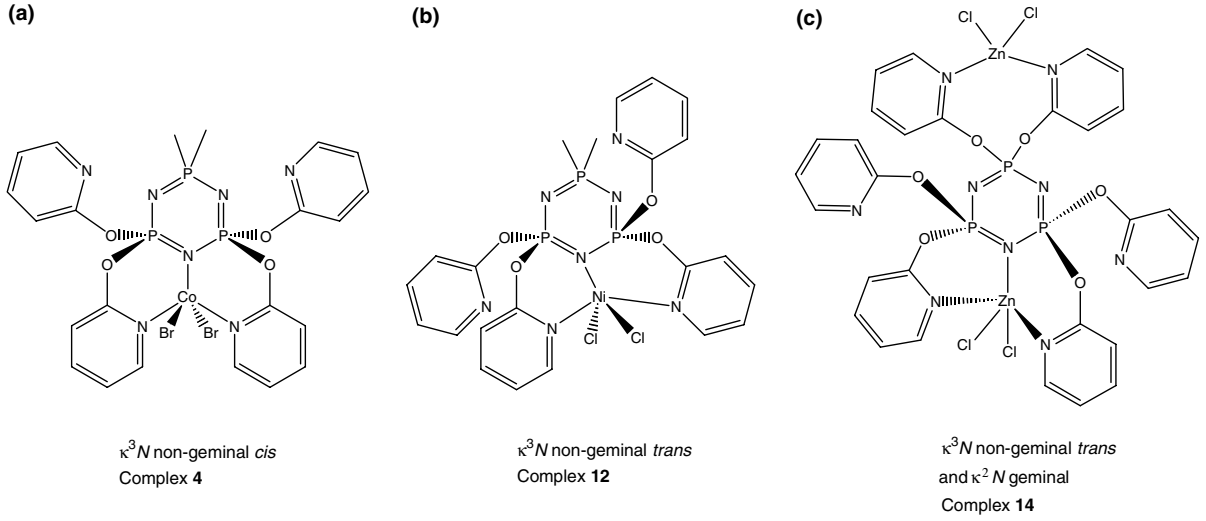
3.2. Description of structures

3.2.1. The five-coordinate complexes $[Co(MeL)Br_2]$ (**4**) and $[NiLCl_2]$ (**12**)

The $[Co(MeL)Br_2]$ (**4**) complex (Fig. 1) is a neutral species containing a five-coordinate 'CoN_3Br_2' centre. The ligand MeL coordinates in a κ^3N non-geminal *cisoid* manner (Scheme 2a) through phosphazene ring nitrogen N(1) and the nitrogen atoms N(16) and N(36) from two pyridyloxy arms. The geometry around the cobalt is distorted trigonal bipyramidal ($\tau = 0.83$[1]) with the axial bonds being defined as Co–N(16) and Co–N(36). Selected bond lengths and bond angles are given in Table 2. The overall structure is similar to that observed for $[CuLCl_2]$ although **4** is considerably less distorted from trigonal bipyramidal geometry

[1] The structural index, τ, is used to define the geometry of five coordinate systems and equals 1 for a perfect trigonal bipyramid and 0 for a perfect square pyramid Ref. [11].



Scheme 2. Structural types: complexes **4**, **12** and **14**. Some parts have been omitted for clarity.

($\tau = 0.47$ in [CuLCl$_2$]) [5]. The contact between the metal and the phosphazene ring, Co–N(1), is much closer in **4** [2.0897(19) cf. 2.264(2) Å] and this bond is significantly shorter than the axial Co–N bonds [both 2.243(2) Å], whereas in [CuLCl$_2$] the converse is true. The angles within the cobalt(II) coordination sphere are unremarkable. The phosphazene ring in **4** is more distorted from planarity than in [CuLCl$_2$]: the distances of N(1) and N(2) above and below the plane described by the remaining atoms in the ring are approximately 0.164 and 0.189 Å (cf. 0.068 and 0.096). P–N–P and N–P–N angles in the ring are typical for cyclophosphazenes but the P(1)–N(1) and P(2)–N(1) bonds [1.6261(18) and 1.6277(17) Å] which flank the coordinated ring nitrogen are longer than the remaining P–N bonds [1.5724(18)–1.5944(18) Å]. This feature has been observed on other cyclic phosphazene complexes that contain a coordinated ring nitrogen [4,5].

Complex **12**, the red NiCl$_2$ adduct of L (Fig. 2 and Table 2), has a similar five-coordinate structure to **4** but

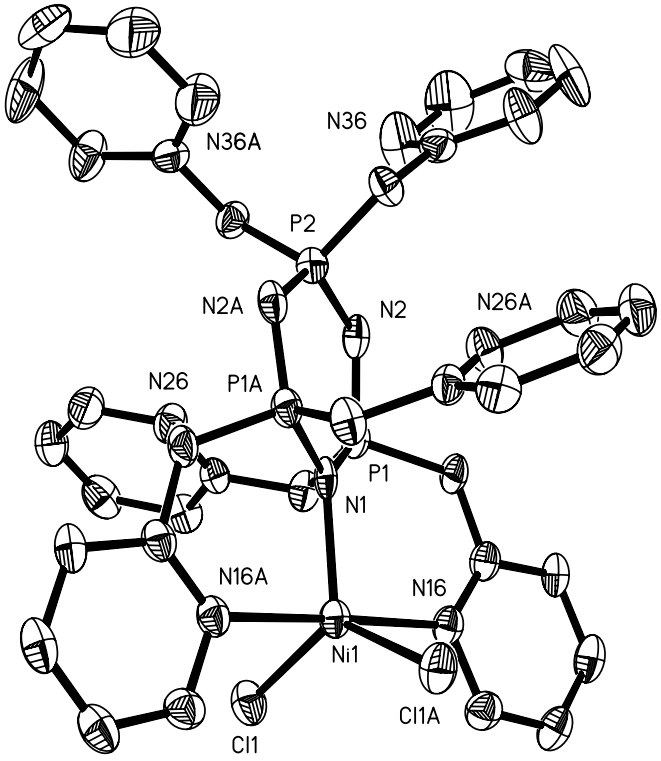

Fig. 2. View of the complex [NiLCl$_2$] (**12**). Ellipsoids are drawn at the 50% probability level.

in this case the ligand coordinates in a κ^3N non-geminal *transoid* manner (Scheme 2b). The geometry about the nickel(II) ion in $[NiLCl_2]$ is also approximately trigonal bipyramidal although it is more distorted than **4** ($\tau = 0.78$). The nickel(II) ion makes a short contact of 2.023(6) Å with N(1) in the phosphazene ring and longer contacts of 2.160(4) Å with the symmetry related axial pyridyl nitrogen atoms. The nickel centre lies directly in the plane described by N(1), P(1), P(1A) and P(2). N(2) and its symmetry equivalent lie approximately 0.137 Å above and below this plane. Other distortions in the phosphazene ring are apparent in the P–N bond lengths and as with **4**, the flanking P–N(1) bond lengths are the longest [1.608(3) Å]. The P(1)–N(2) and P(1A)–N(2A) distances are considerably shorter [1.549(5) Å] and the final pair, P(2)–N(2) and P(2)–N(2A), have an intermediate value of 1.581(4) Å.

3.2.2. The dimetallic complexes *[(CoLCl)$CoCl_3$] (**5**), [(CoLBr)$CoBr_3$] (**6**), [{Co(MeL)Cl}$CoCl_3$] · (**7**) and [($ZnCl_2$)$_2$L] (**14**)*

The dimetallic cobalt(II) complexes **5**, **6** and **7**, have the same basic structure in which the ligands (L or MeL) bridge two Co(II) ions (Fig. 3). The ligands coordinate in both the tetrapodal κ^5N binding mode, using four pendant pyridyloxy arms and a phosphazene ring nitrogen, and in a monodentate κ^1N binding mode, using one pyridyloxy arm. The complexes contain both six-coordinate 'CoN_5X' and four-coordinate '$CoNX_3$' centres making them neutral and zwitterionic (Scheme 3a). Selected bond lengths and angles are given in Table 3. The geometry at the six-coordinate centres is elongated rhombic octahedral, similar to that previously observed in the $[CuLCl]^+$ monocation [5]. The complexes contain a pair of long axial bonds, Co–N(16) and Co–N(46) which range between 2.327(4) and

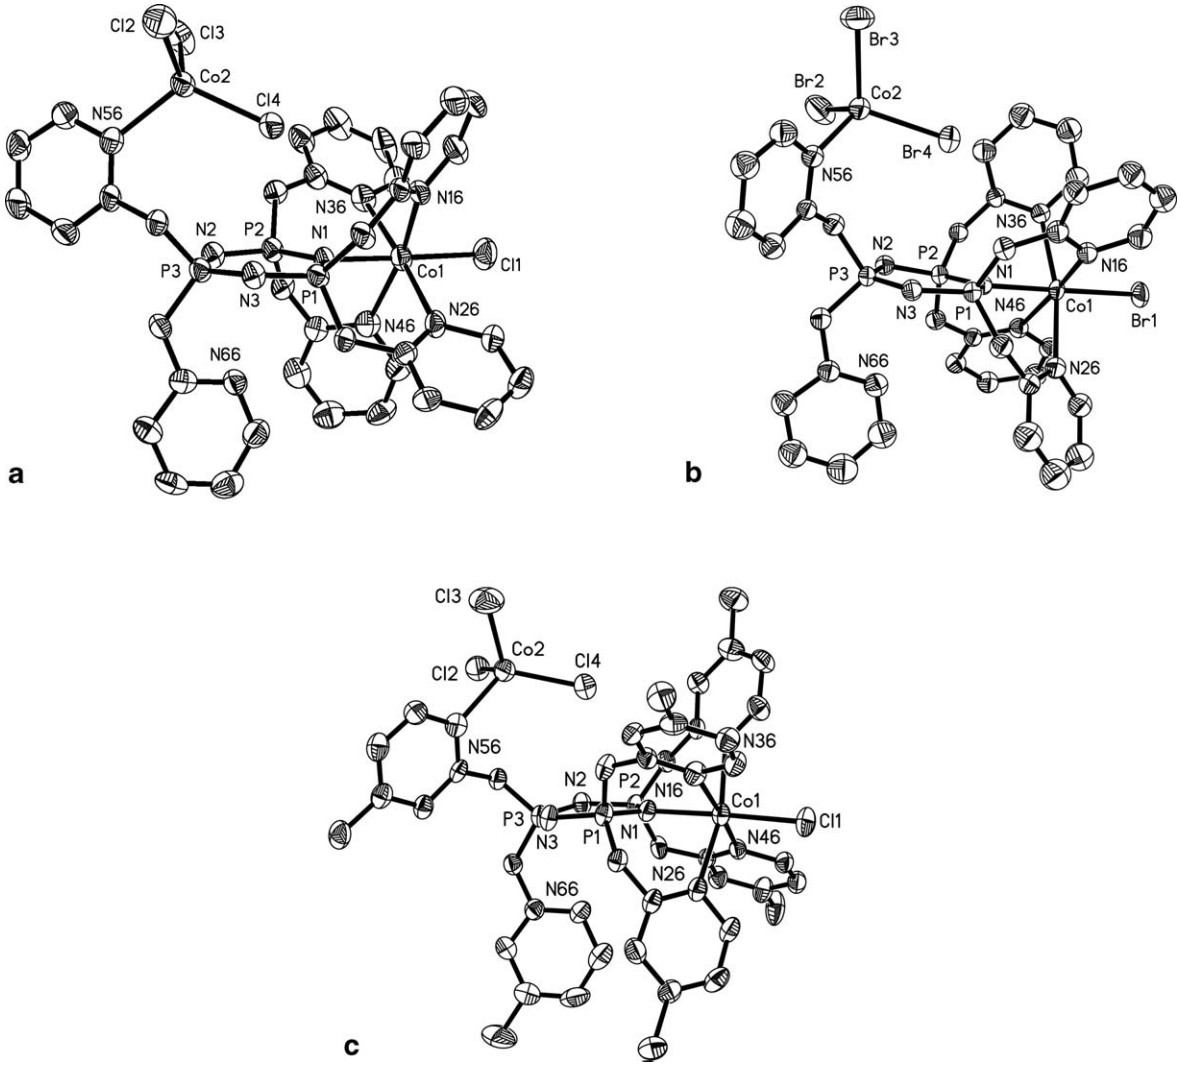

Fig. 3. View of the complexes: (a) [(CoLCl)$CoCl_3$] (**5**); (b) [(CoLBr)$CoBr_3$] (**6**); (c) [{Co(MeL)Cl}$CoCl_3$] (**7**). Ellipsoids are drawn at the 50% probability level.

N(56)–Co(1)–X(4)	117.12(17)	111.77(16)	115.57(13)

2.402(5) Å and a pair of shorter equatorial Co–N(py) bonds, Co–N(26) and Co–N(36) that range between 2.189(6) and 2.198(4) Å. The pyridyl rings that give rise to the axial bonds are approximately coplanar (the mean planes are twisted by approximately between 2.2° (**8**), 6.4° (**5**) and 11.2° (**6**) to one another) whereas the mean planes of the equatorial pyridyl rings are twisted to one another by approximately 73°, 69° and 70°. In each case the shortest metal to ligand contact at ~2.035(4) Å in the six-coordinate centre is between the cobalt and the phosphazene ring nitrogen N(1).

A close examination of the '$CoNX_3$' centres points to an interaction of the halogen atoms with the π-electron density on pyridyl rings 1 or 3 (Scheme 4). These compressed tetrahedral centres in **5**, **6** and **7** are more distorted than similar '$CoNCl_3$' and '$CoNBr_3$' centres reported in the literature [12–15]. The Co–N(56) distances are approximately 0.2–0.5 Å longer than the corresponding bonds in the related structures and the tetrahedral angles are more varied. Particularly affected is the angle N(56)–Co(1)–X(4) which varies between 111.77(16)° and 117.12(17)°. The persistent orientation of the '$CoNX_3$' fragment in this manner is significant since it is independent of the ligand, the nature

	α (°)	d (Å)
[(CoLCl)$CoCl_3$] (**5**)	32	3.774
[(CoLBr)$CoBr_3$] (**6**)	20	3.744

Scheme 4. Interaction of halogen atoms with pyridyloxy rings for complexes **5**, **6** and **7**.

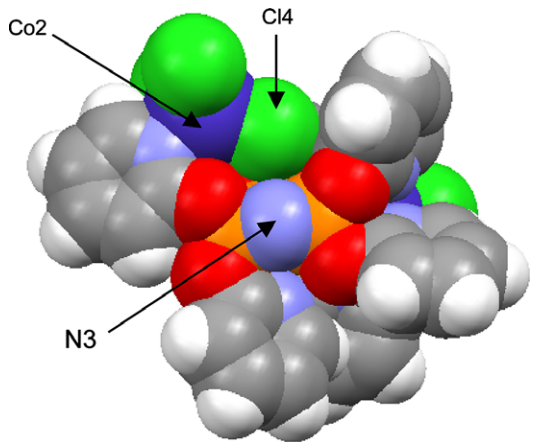

Fig. 4. Space filling diagram of $[(CoLCl)CoCl_3]$ (**5**) showing the interaction of a Cl with a pendant pyridyloxy ring.

of the anion and the different unit cell types. The zwitterions have an overall compact shape (Fig. 4) because of this interaction with the pyridyl rings 1 or 3. The influence of halogen–π interactions on crystal packing has been recognised before (e.g., Refs. [16–18]) and the geometrical parameters for complexes **5**–**7** relevant to the recent treatment by Swierczynski et al. [19] are given in Scheme 4. In each case the distance (*d*) of X(4) from the closest pyridyl ring centroid is below 4 Å (being in the range 3.744–3.928 Å) and the angle (α) between the vector along the aryl ring centroid-halogen centre and the perpendicular vector originating in the aryl centre is between 20° and 38°.

In contrast, the dimetallic zinc complex $[(ZnCl_2)_2L]$ (**14**) (Fig. 5 and Table 2), contains two $ZnCl_2$ units in both five- and four-coordinate geometry, bridged by L. Here L acts in κ^2N geminal bidentate and κ^3N non-geminal *transoid* coordination modes (Scheme 2c). The five-coordinate centre is comparable to that in the five-coordinate nickel complex $[NiLCl_2]$ (**12**). The geometry is distorted trigonal bipyramidal ($\tau = 0.82$) with the axial bonds being to the pyridyloxy nitrogen atoms N(16) and N(46). As in **12**, the equatorial bond length, Zn(1)–N(1) at 2.089(3) Å, is considerably shorter than the axial Zn–N bonds [2.328(3) and 2.349(3) Å]. The four coordinate '$ZnCl_2$' centre is approximately tetrahedral and similar to that observed for $[Zn(py)_2Cl_2]$ (py = pyridine) [20] although the Zn–N distances in this complex are shorter [2.046(5) and 2.052(6) Å]. The phosphazene ring plane in **14** is essentially undistorted. The atoms N(1) and N(3) lie 0.0813 and 0.0675 Å, respectively, above and below the plane described by the other atoms in the ring and are the biggest deviations. Within the ring, as in the other five-coordinate complexes, $[Co(MeL)Br_2]$ (**4**) and $[NiLCl_2]$ (**12**), the P–N(1) bonds flanking the metal binding site are the longest [1.612(3) and 1.603(3) Å] with the remaining P–N bonds ranging between 1.563(3) and 1.571(3) Å.

3.2.3. The six-coordinate complexes $[CoLBr]PF_6$ (**10**), $[NiLCl_2]$ (**11**) and $[NiLCl]PF_6$ (**13**)

The cationic cobalt complex $[CoLBr]PF_6$ (**10**) (Fig. 6 and Table 4) contains a distorted rhombic 'CoN_5Br' coordination sphere derived from the tetrapodal κ^5N binding mode of L (Scheme 3b) which is essentially the same as that found in the dimetallic complex **6** although the bond to the phosphazene ring nitrogen atom, Co–N(1), is longer than the corresponding bond in **6** [2.064(2) cf. 2.025(8) Å]. The two longest Co–N bonds involve the nitrogen atoms from two of the bound pyridyloxy rings. The structure of $[NiLCl]PF_6$ (**13**) (Fig. 7 and Table 4) is essentially the same as that of (**10**) and, in fact, crystals of **10** · $2CH_2Cl_2$, **13** · $2CH_2Cl_2$ and $[CuLCl]PF_6 \cdot 2CH_2Cl_2$ [5] are all isomorphous belonging to the space group $Pna2_1$.

The green complex $[NiLCl_2]$ (**11**) (Fig. 8 and Table 4) contains a six-coordinate 'NiN_4Cl_2' coordination sphere which is best described as distorted octahedral. The ligand acts as a tripodal κ^4N donor forming two short bonds to

the nickel through N(1) and N(36) which are *cis* [2.1705(18) and 2.180(2) Å, respectively] and two longer bonds through N(16) and N(46) which are *trans* [2.221(2) and 2.3652(16) Å, respectively]. As a result of L acting as a pentadentate in **13** there is a closer contact between the nickel (II) ion [2.027(3) Å] and the phosphazene ring nitrogen N(1) than in **11**. Also the nickel(II) ion lies closer to the mean plane of the phosphazene ring (approximately 0.0678 from the plane, cf. 0.4576 Å in **11**).

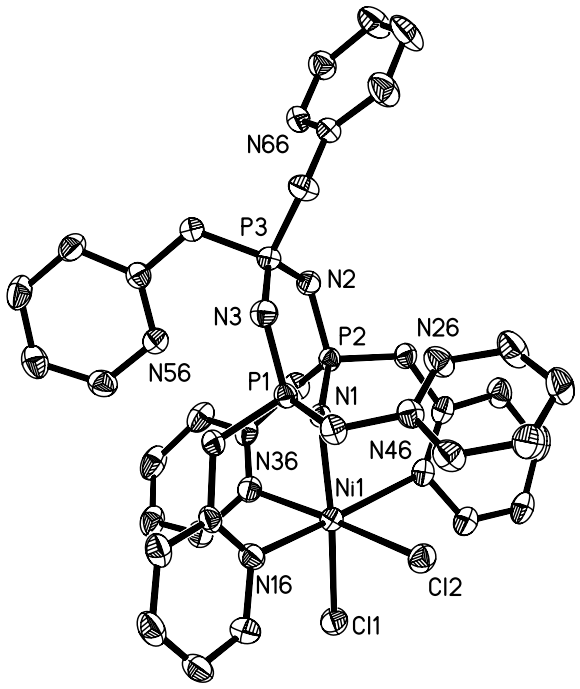

Fig. 8. View of the complex $[NiLCl_2]$ (**11**). Ellipsoids are drawn at the 50% probability level.

4. Conclusions

This report, along with our earlier work [3,5,6], clearly demonstrates that the design of the ligands L and MeL makes them particularly effective multimodal ligands capable of binding one or two metal atoms in a variety of coordination modes, ranging from κ^1N to κ^5N, depend-

[b] From Ref. [6].

ing on the number of pyridyloxy pendant arms are involved. Monodentate κ^1N binding using a pyridyloxy nitrogen atom, as exhibited in the tetrahedral sites in the dimetallic complexes $[(CoLX)CoX_3]$ (X = Cl or Br) (**5** and **6**) and $[\{Co(MeL)Cl\}CoCl_3]$ (**7**), do not involve the phosphazene ring nitrogen atom as a donor. However, this binding mode does allow the linking of two cyclophosphazene platforms into a dimer, viz., $[(CuLCl)_2(CuCl_2)]^{2+}$ [6]. Bidentate κ^2N binding is seen in the tetrahedral site in the dimetallic complex, $[(ZnCl_2)_2L]$ (**14**), and again the phosphazene nitrogen atoms do not bind to the metal. In contrast, in the silver(I) complexes, $\{[AgL]^+\}_\infty$ and $\{[Ag(MeL)]^+\}_\infty$, a different κ^2N binding mode is observed with one nitrogen donor coming from the phosphazene ring and the other from a pendant pyridyloxy nitrogen hence affording supramolecular cationic columns [3]. Complexes with five-coordinate sites all have the ligand binding in a κ^3N fashion via the nitrogen atoms from two non-geminal pyridyloxy pendant arms and a nitrogen atom in the phosphazene ring, e.g., in $[Co(MeL)Br_2]$ (**4**), the red isomer of $[NiLCl_2]$ (**12**), the five-coordinate site in $[(ZnCl_2)_2L]$ (**14**), $[CuLCl_2]$ and both copper sites in $[\{CuCl_2\}_2MeL]$ [5]. In the majority of the six-coordinate sites, the ligand binds via the κ^5N mode using nitrogen atoms from four pendant pyridyloxy arms and a phosphazene ring nitrogen, e.g., in $[CoLBr]PF_6$ (**10**), $[NiLCl]PF_6$ (**13**) the six-coordinate sites in the dimetallic complexes **5**, **6** and **7** and in $[CuLCl]PF_6$ [5]. The exception to this in found in the green isomer of $[NiLCl_2]$ (**11**) which has the nickel bound to L via a κ^4N mode using only three of the pendant pyridyloxy nitrogen donors.

In the compounds of L and MeL reported in this study and in our earlier papers [3,5,6], the cyclophosphazene platform does not deviate significantly from planarity which is in marked contrast to what is observed for complexes of hexakis(3,5-dimethylpyrazolyl)cyclotriphosphazene, $N_3P_3(3,5\text{-}Me_2Pz)_6$, and related ligands [4,21]. Another major difference is that for each of the κ^3N, κ^4N and κ^5N complexes of L and MeL with the divalent metal ions with the exception of κ^3N copper complexes (which are significantly distorted from trigonal bipyramidal), the phosphazene nitrogen metal bond is shorter than the pendant pyridyloxy nitrogen metal bonds (Table 5) whereas a reversal of these bond lengths is seen when the pyrazolyl is the pendant arm [4,21] For example, L and $N_3P_3(3,5\text{-}Me_2Pz)_6$ form dimetallic complexes with zinc(II) with the same stoichiometry, i.e., $[(ZnCl_2)_2L]$ (**14**) and $[(ZnCl_2)_2\{N_3P_3(3,5\text{-}Me_2Pz)_6\}]$ [21], which contain the metal in both κ^2N four-and κ^3N five-coordinate sites. However, to accommodate the steric demands of $N_3P_3(3,5\text{-}Me_2Pz)_6$ the cyclophosphazene ring puckers markedly towards the zinc atom in the five-coordinate site, the displacement of the phosphazene nitrogen bound to the zinc being 0.490 Å from the plane defined the other ring atoms. As mentioned in Section 3.2.2, the phosphazene ring is essentially undistorted in **14**. The phosphazene nitrogen bond distance in **14** is 2.089(3) Å [cf. 2.328(3) and 2.349(3) Å for the other Zn–N bonds] whereas in the analogous $N_3P_3(3,5\text{-}Me_2Pz)_6$ complex it is longer at 2.332(6) Å [cf. 2.200(6) and 2.141(6) Å]. The marked differences observed between the L and MeL complexes and the pyrazolyl complexes can be ascribed to the presence of the phenoxy hinge linking the pyridyloxy pendant arms to the phosphazene ring, hence allowing the formation of six-membered chelate rings rather than the more strained five-membered rings in the latter systems.

Acknowledgements

We acknowledge financial support, including postdoctoral fellowships (to C.V.D. and C.A.O.), from the Massey University Research Fund and the RSNZ Marsden Fund (MAU208). We thank Dr. A.K. Burrell, Dr. A. Derwahl and Professor G.B. Jameson for valued crystallographic advice and the Otsuka Chemical Co. Ltd. for a gift of cyclotriphosphazene.

Appendix A. Supplementary material

Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. CCDC 293045–293053. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk). Scheme 1. The most usual coordination modes of 3-hydroxypicolinic acid in 12th group metal complexes.

bridging ligand as found in the structure of $[Cu(pic)_2]\cdot 2H_2O$ [4] and $[Mn(pic)(N_3)(H_2O)]_n$ [10]. In the structure of $[Mn(pic)(picH)Cl]_2$ was established the co-existence of both neutral and *N*,*O*-bidentate forms, as in Hg(pic)(picH). Another example of a *N*,*O*,*O*-tridentate chelating bridge ligand is found in $[Mn(pic)(N_3)(H_2O)]_n$, but interestingly even a *N*,*O*,*O*,*O*′-tetradentate coordination mode of binding of picH is observed in $[Cu(pic)Cl]_n$ [9]. The cadmium ion is well known for making coordination polymers by catenation, in contrast, for instance, to zinc of the group 12 elements. Catenation is achieved by cadmium's ability to form polymers with extended coordination numbers (usually six in the form of a distorted octahedron or seven in the form of a pentagonal bipyramid) and simultaneously pyridinecarboxylic acids, by suitable positions of the donor atoms, uphold two or more cadmium ions. Various solvent molecules can be accommodated in the coordination sphere as well.

Table 1 lists the major structural features of Cd complexes with mono pyridinecarboxylic acids and with benzoic acid for comparison.

The benzoic acid, acting as ligand, appears in Cd complexes as an anionic *O*,*O*′-bidentate ligand forming a four-membered chelate ring (bite distance angle around 55°) [11]. Three such mononuclear complexes are known (Table 1) indicating Cd coordination between trigonal prismatic and octahedral, such as in the case of diaquabis(*p*-chlorobenzoato)cadmium(II) [11] and diaquabis(*p*-nitrobenzoato)cadmium(II) [11], while in the structure of aquabis(*p*-chlorobenzoato)bis(pyridine)cadmium(II) [11] the cadmium coordination number is seven in the form of a pentagonal bipyramid. The additional ligand molecules, such as water or pyridine, occupy the remaining cadmium coordination sites. The Cd–O (carboxylato) bond distances are rather different in these complexes, varying from 2.255(2) Å to 2.502(2) Å [both in the structure of diaquabis(*p*-nitrobenzoato)cadmium(II)]. It is obvious that one carboxylato oxygen atom participates in bond formation with cadmium poorly. The water oxygen atom is bonded to cadmium in the range 2.213(2)–2.254(3) Å.

The structural survey reveals that in Cd complexes the most usual ligation of picolinic acid is the *N*,*O*-chelate mode for picolinic acid [12] (in compound NELNIB one picolinic acid is bonded as a neutral ligand and another as a picolinato anionic ligand, but in the same *N*,*O*-chelate coordination mode) [12], or *N*,*O*,*O*′-bridging between two (REXJAF) [13] or three cadmium ions (REXHUX) [14]. In the structure of $Cd(pic)_2$ [15] *N*,*O*,*O*′-bridging between two Cd(II) ions is achieved, too.

In the structures of Cd complexes with nicotinic acid the *O*,*O*′-chelate mode is observed (ZOZKII) [16], (HIBSBUG) [17], while simultaneously polymerization occurs through pyridine N-atoms [17] and/or Br^- bridge anions [16]. The complex of the formula $[Cd(SCN)_2(HL^1)_2]\cdot HL^1$ (HL^1 = nicotinic acid) is an example with an uncoordinated carboxylic group which forms head-to-head double intermolecular hydrogen bonds [17]. In the structures with isonicotinic acid [17,18] three complexes are found (QIFMIB, KEJBOQ and KEJHIQ) in the form of three-dimensional wave-like networks (QIFMIB) [17] or polymeric diamondoid structures (KEJBOQ and KEJHIQ) [19].

As a part of our wider interest in coordination chemistry of the metals of 12th group of elements with molecules of biological interest, we synthesized the titled cadmium(II) complexes with 3-hydroxypicolinic acid, identified them by chemical analysis, characterized the species that exist in solution as well as in the solid state to get some more information on how to control Zn, Cd, Hg homeostasis.

2. Experimental

2.1. Materials and physical measurements

3-hydroxypicolinic acid, cadmium(II) chloride and cadmium(II) bromide tetrahydrate were used as received from Aldrich without further purification. CHN analyses were performed in the Analytical Services Laboratories of the Institute Ruđer Bošković. The IR spectra were obtained from KBr pellets in the range 4000–450 cm^{-1} with a Bruker Equinox 55 spectrometer.

The one- and two-dimensional homo- and heteronuclear ^1H and ^{13}C NMR spectra were recorded with a Bruker AV 600 spectrometer, operating at 600.133 MHz for the ^1H nucleus and 150.917 MHz for the ^{13}C nucleus. Samples were measured from DMF-d7 solutions at 22 °C (295 K) in 5 mm NMR tubes. Chemical shifts, in ppm, are referred to TMS as internal standard. FID resolution in ^1H NMR and ^{13}C NMR spectra was 0.29 Hz and 0.54 Hz per point, respectively. The following measurement techniques were used: standard ^1H, ^{13}C gated proton decoupling, APT, COSY, HMQC and HMBC. The 2D NMR spectra, were measured in pulsed field gradient mode (*z*-gradient).

The thermal measurements were performed using a simultaneous TGA-DTA analyser (*TA Instruments*, SDT Model 2960). The samples were placed in small aluminium oxide sample pans. The TGA and DTA curves were obtained by placing samples of about 10 mg in mass, in

open sample pans, with a heating rate of 5 °C/min and argon (purity above 99.996%) pouring at a flow rate of 50 ml/min. The SDT was calibrated with indium.

2.2. [CdCl(OH-pic)(OH-picH)(H_2O)]$_2$ (**1**)

A solution of 3-hydroxypicolinic acid (0.25 g, 1.8 mmol) in 20 mL of water was added dropwise to a solution of cadmium(II) chloride (0.165 g, 0.9 mmol) in 15 mL water. Yellowish needles started to crystallize upon mixing but the reaction mixture was left to stand for a few days to complete the crystallization. The crystals were filtered off, washed with cold water and dried. Yield: 0.31 g (77.8%). *Anal*. Calc. for $C_{12}H_{11}CdClN_2O_7$ (443.097): C, 32.53; H, 2.50; N, 6.32. Found: C, 32.74; H, 2.64; N, 6.50%.

2.3. [CdBr(OH-pic)(OH-picH)(H_2O)]$_2$ (**2**)

A solution of 3-hydroxypicolinic acid (0.25 g, 1.8 mmol) in 20 mL of water was added dropwise to a solution of cadmium(II) bromide tetrahydrate (0.31 g, 0.9 mmol) in 25 mL water. Yellowish needles started to crystallize upon mixing but the reaction mixture left to stand for a few days to complete the crystallization. The crystals were filtered off, washed with cold water and dried. Yield: 0.35 g (79.5%). *Anal*. Calc. for $C_{12}H_{11}CdBrN_2O_7$ (487.548): C, 29.56; H, 2.27; N, 5.74. Found: C, 29.57; H, 2.35; N, 5.88%.

2.4. X-ray crystallographic structure determination of **1** and **2**

The general and crystal data and summary of intensity data collection and structure refinement for compounds **1** and **2** are given in Table 2.

The data collection for both structures was carried out on Xcalibur four-circle κ geometry single-crystal diffractometer with Xcalibur Sapphire 3 CCD detector by applying the CrysAlis Software system, Version 171.23 [20]. Seven sets containing 1047 data collection frames were collected (four sets with 0.75° scan width and three sets with 1.00° scan width) at a crystal-detector distance of 60 mm with an exposure time of 20 s and ω scan type for both structures.

The Lorentz-polarization effect was corrected and intensity data reduced by the CrysAlis RED application of the CrysAlis Software system, Version 171.23 [20]. The diffraction data were corrected for absorption by the optimization of a built 3-D shape model against the diffraction data.

The coordinates of the heavy atoms were determined by direct methods with the SHELXS program [21]. The coordinates and anisotropic thermal displacement parameters for all non-hydrogen atoms were refined by the least-squares methods based on F^2 using the SHELXL97 program [22]. The coordinates of the hydrogen atoms belonging to the oxygen or nitrogen atoms were found by the examination of electron-density Fourier maps at the final stages of refinement and refined freely [the bond distance range is from 0.75(3) Å for O1–H1O to 0.89(4) Å for O4–H4O].

The other hydrogen atoms, which belong to pyridine carbon atoms were generated at ideal geometrical positions [Csp^2–H 0.93 Å, $U_{iso}(H) = 1.2\ U_{eq}(C)$] and refined applying the riding model. The molecular graphics were obtained using the PLATON98 program [23].

3. Results and discussion

3.1. Preparation

The interaction between cadmium(II) halides and 3-hydroxypicolinic acid in aqueous solution afforded yellowish needle crystals of complexes **1** and **2**. Both complexes have the same general formula [CdX(OH-pic)(OH-picH)-(H_2O)]$_2$, X = Cl$^-$, Br$^-$. They are air-stable substances and very soluble in methanol, *N*,*N*-dimethylformamide (DMF) and dimethylsulfoxide (DMSO). The NMR measurements in a DMSO solution of the prepared complexes

[e] $S = \sum[w(F_o^2 - F_c^2)^2/(N_{obs} - N_{param})]^{1/2}$.

showed that they are not stable in DMSO. This conclusion was drawn from the fact that there are no significant changes in the ^1H and ^{13}C NMR chemical shifts of the dissolved compounds in comparison with those of the free ligand. By contrast in DMF solution $Cd(OH\text{-}pic)_2$ is identified as the only existing compound (vide infra).

3.2. Infrared and NMR spectra

The room temperature IR spectral data of the crystalline OH-picH and its cadmium(II) complexes **1** and **2** were analyzed and their tentative assignments were based on those found in the literature [19,24–28]. From the analysis of the IR spectral data the isostructural nature of **1** and **2** was recognized and this has been approved by the results of the X-ray structure determinations. From the observed absorption bands, which were assigned as asymmetric and symmetric modes of vibration of the carboxylic group i.e., from the shifting of these absorption bands relatively to IR data of free OH-picH, one can conclude that OH-picH acts as a chelate *N*,*O*-ligand. There are two bands at 1390 cm^{-1} and 1300 cm^{-1} for **1** and 1370 cm^{-1} and 1300 cm^{-1} for **2** suggesting two different modes of binding of the COO-group. Shifting of ν_s(COO) to lower wavenumbers compared to the free ligand (1322 cm^{-1}) is indicative of a unidentate mode of binding of the carboxylic group. Moreover, the presence of two bands which correspond to a ν(C–N) stretching vibration is also indicative of two modes of binding OH-picH to the cadmium(II) ion. In the spectrum of the free acid (OH-picH) in the high frequency region where hydrogen bonding is found of the type O–H···O involving the carboxylic acid group, a very broad band centred around 3440 cm^{-1} is observed, whilst hydrogen bonding of the type O–H···N is supported by the presence of broad medium strong bands near 2600 cm^{-1} and 2000 cm^{-1}. In the IR spectra of the complexes **1** and **2** the very broad absorption band of medium intensity centered at 3246 cm^{-1} for **1** and 3244 cm^{-1} for **2**, as well as

bands around 2600 cm^{-1} and 2000 cm^{-1}, are indicative of hydrogen bonding in the structures of **1** and **2**, respectively.

The assignment of NMR spectra of the free ligand (OH-picH) and its cadmium(II) complexes **1** and **2** are shown in Table 3. The enumeration of the atoms is consistent with IUPAC nomenclature and it is shown in Scheme 2.

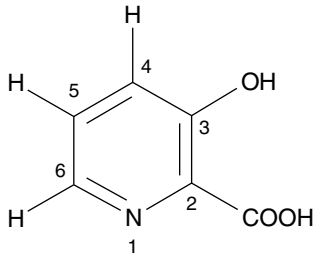
[a] Recorded in DMF-d_7 solutions. Referred to TMS. Number of protons in brackets.

[b] Cadmium induced chemical shifts ($\Delta\delta$/ppm) are obtained by substracting the chemical shifts of the parent compound (OH-picH) from the chemical shifts of the Cd-complex. Sign (+) denotes deshielding effect, while (−) denotes shielding effect of cadmium.

[c] *n* denotes the number of bonds between nuclei in spin–spin coupling; (s) singlet, (d) doublet.



Scheme 2. Enumeration of the atoms in 3-hydroxypicolinic acid.

Since **1** and **2** dissociate in DMSO, NMR measurements were performed in DMF solution. The ^{1}H and ^{13}C NMR spectra are very simple suggesting that $Cd(OH\text{-}pic)_2$ exists in DMF solution.

NMR spectra of DMF solutions of **1** and **2** are very similar. Cadmium induced ^{1}H and ^{13}C NMR shifts are defined as the difference of proton or carbon chemical shifts in the complexes and the free ligand molecule.

The ^{1}H NMR spectra revealed the largest complexation shift ($\Delta\delta$) for the H-4 proton in both complexes. This proton is far off from the cadmium atom that has a shielding effect on this proton. Complexation with cadmium induces shielding effects for all H-atoms (−0.107 to −0.192 ppm) of the ligand molecule. The signal of the hydroxyl group, due to large broadening, was not observed.

In the ^{13}C NMR spectra the greatest change upon complexation with cadmium was observed for the chemical shift of C-6. Deshielding effects were observed for C-2, C-6 and the carboxylic carbon (1.75–2.06 ppm) and shielding effects for C-3, C-4 and C-5 (−0.23 to −1.60 ppm). It has to be mentioned that all signals were broadened.

From both ^{1}H and ^{13}C NMR experiments it seems that cadmium complexes of OH-picH in DMF solution exist only in the symmetrical form. The cadmium ion has an influence on all proton and carbon atoms of the ligand molecule.

NMR data demonstrate that both hydrogen and carbon atoms are sensitive to cadmium binding even if they are not near and thus long-range shifts may be useful for the complexation monitoring. Long-range complexation shifts are the consequence of conformational changes and an extensive network of both intramolecular and intermolecular hydrogen bonds, which in turn induces a subtle electron redistribution throughout the molecule.

*3.2.1. Structural description of **1** and **2***

ORTEP views of the molecular structures of compounds **1** and **2** are depicted in Fig. 1, and their crystal structures in Fig. 2. The selected molecular geometry is listed in Table 4 along with the hydrogen bond geometry in Table 5.

Complexes **1** and **2** are isostructural. The molecular structures of the complexes comprise centrosymmetrical dimers containing the two Cd(II) ions with distorted octahedral coordination geometries. The coordination environment contains two Cl atoms, one water molecule

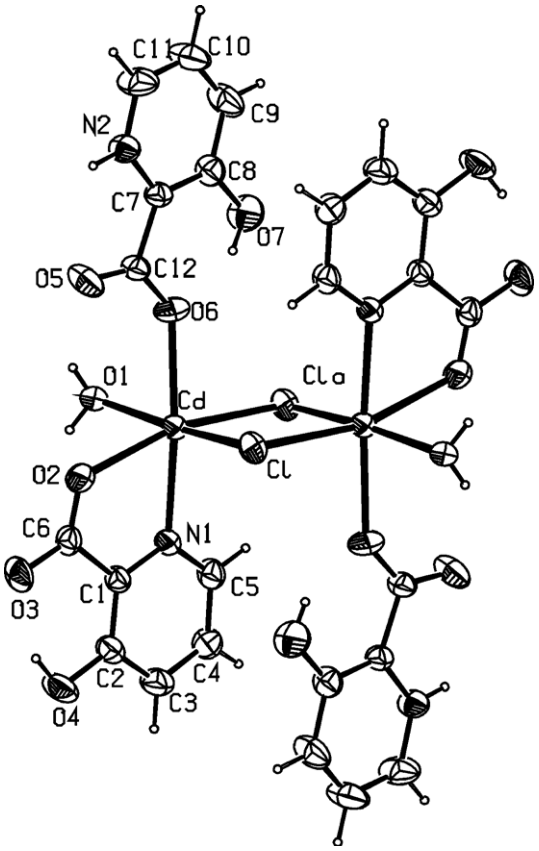


Fig. 1. ORTEP drawing of di-μ-chloro-[aqua-(3-hydroxypyridine-2-carboxylato-*N*,*O*)(3-hydroxypyridinium-2-carboxylato-*O*)cadmium(II)] (**1**) with the atomic numbering scheme of the asymmetric unit. The thermal ellipsoids are drawn at the 50% probability level at 293 K. The bromo derivative (**2**) is isostructural.

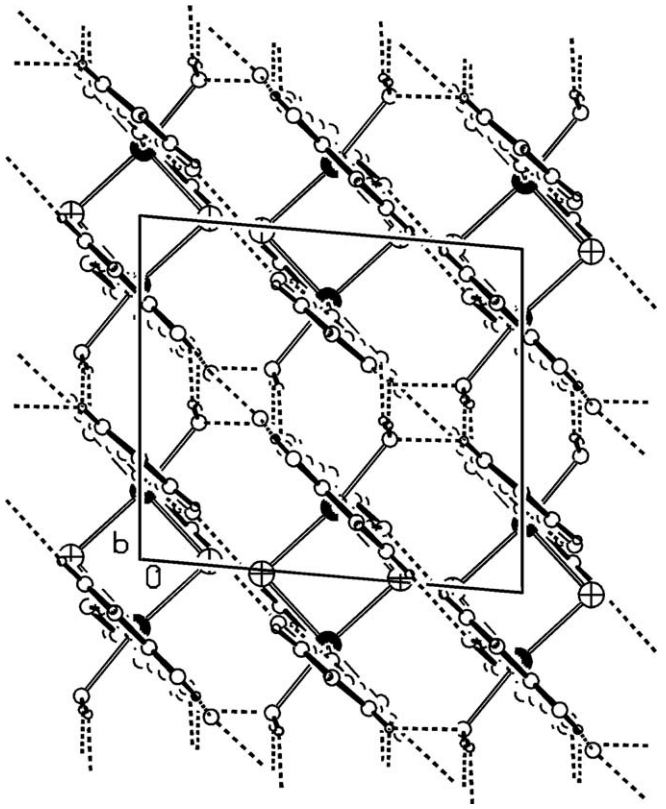

Fig. 2. Crystal structure of di-μ-chloro-[aqua-(3-hydroxypyridine-2-carboxylato-*N*,*O*)(3-hydroxypyridinium-2-carboxylato-*O*)cadmium(II)] (**1**) in *ac* projection. Hydrogen bonds are indicated by dashed lines.

and two OH-pic ligands, one bonded to the Cd(II) ion in a monodentate mode through the carboxylate O atom and the other in the bidentate *N*,*O*-chelated mode forming a five-membered chelate ring. The hydroxyl group does not take part in the coordination. There has been no example of OH-participation in the metal coordination sphere in complexes with OH-picolinic acid up until now. The charge balance of the molecular formulas of the complexes requires one OH-pic ligand to be in a neutral form (that is the ligand acting monodentately) and the other acting as a *N*,*O*-chelate is an anion formed by the deprotonation of the carboxylic group. The proton transfer from the carboxylic group to the pyridine N-atom, revealing its zwitterionic form, realizes the neutral form of one of the ligands. The example of a Cd complex with the two same ligands, but coordinated as picH acid and the pic$^-$ anion is di-μ-chloro-bis[(2-pyridinecarboxylato-*N*,*O*)(2-pyridinecarboxylic acid-*N*,*O*)cadmium(II)] ethanol solvate (NELNIB) [12], but tautomerization from the carboxylic oxygen to the pyridine nitrogen atom is not observed due to the participation of the N-atom in coordination. There are two examples of 3-OH-pic coordination in the zwitterionic form in the vanadium complex aqua-bis(3-hydroxypyridine-2-carboxylato)-oxo-vanadium hydrate [29] and in the structure of *catena*-(μ_2-3-hydroxypicolinato)-aqua-bis(3-hydroxypicolinato)europium(III) hydrate [30].

The coordination environment contains two halogen atoms [Cd–Cl 2.6056(7) Å; Cd–Cl^{i} 2.6231(7) Å; $i = -x, -y, 1-z$; Cd–Br 2.7418(6) Å; Cd–Br^{i} 2.7488(5) Å in **1** and **2**, respectively], one water molecule [Cd–O1 2.305(2) and 2.307(4) Å in **1** and **2**, respectively] and two OH-pic ligands, one bonded to the Cd(II) ion in a monodentate mode through the carboxylate O atom [Cd–O2 2.344(2) and 2.340(3) Å in **1** and **2**, respectively] and the other in the bidentate *N*,*O*-chelated mode forming a five-membered chelate ring [Cd–N1 2.328(2) and 2.334(4) Å; Cd–O6 2.314(2) and 2.324(3) Å in **1** and **2**, respectively]. The participation of Cl atoms in the Cd coordination sphere is found in dimeric di-μ-chloro-bis[(2-pyridinecarboxylato-*N*,*O*)(2-pyridinecarboxylic acid-*N*,*O*)cadmium(II)]ethanol solvate (NELNIB) [12], with similar bond distance values (2.588(1) and 2.608(1) Å) as in our complex. In the structure of poly-[μ-(nicotinato-*O*,*O*′:*N*)-μ-bromo-monoaquacadmium] [13] the Cd–Br distances are 2.6678(9) and 2.7804(8) Å, comparable with our Cd–Br bond distance values.

The bond distances Cd–O_w are in agreement with those found in the structures of other Cd complexes with pyridinecarboxylic acids (see Table 1). The bond distances Cd–O_w in the structures of Cd complexes with pyridinecarboxylic acids vary in the range 2.288(3) Å in $Cd(SCN)_2(HL^1)_2]\cdot HL^1$, ($HL^1$ = nicotinic acid) [17] to 2.378(2) Å in poly-[aquacadmium-bis(μ-nicotinato-κ*N*:κ*O*, κ*O*′] [17], being longer than in the Cd-benzoato complexes, in general. The bond distances Cd–O(solvate) are usually shorter than those with oxygen atoms from acids since the later oxygen atoms usually act as bridging atoms. The bond range for Cd–N(pyridine) distances is 2.272(3) Å in poly[μ-(nicotinato-*O*,*O*′:*N*)-μ-bromo-monoaquacadmium] (octahedral coordination) [18] to 2.396(3) Å in catena[aqua-bis(μ_2-isonicotinato-*N*,*O*,*O*′) cadmium(II)] pyrazine solvate (pentagonal bipyramid coordination) [18]. The Cd–O (from protonated or non-protonated acids) bond distances vary to a greater extent than Cd-(pyridine) distances, being in the range 2.247(5) Å in *catena*-(μ_2-azido)(μ_3-picolinato)-cadmium(II) (distorted octahedral coordination) [14] to 2.879(2) Å in poly[aquacadmium-bis(μ-nicotinato-κ*N*:κ*O*, κ*O*′] (distorted pentagonal bipyramidal coordination) [17]. The later complex is of particular interest since the nicotinato ligand acts as a bridging ligand only through the N-atom, while the carboxylato groups are coordinated only to one Cd(II) ion with one Cd–O bond considerably longer than the other. A similar trend is observed in the monomeric diaquabis(*p*-nitrobenzoato)cadmium(II) [11] (2.255(2) vs. 2.502(2) Å).

Angles indicating the largest distortion from the ideal octahedral geometry, O2–Cd–N1 amounting to 71.4(1) and 71.1(1)° in **1** and **2**, respectively, are the bite angles of the five-membered chelate rings with the donor atoms O2 and N1.

The dihedral angles between the least squares calculated planes through the atoms of the two pyridine rings are 4.5(1)° and 4.6(2)° in **1** and **2**, respectively. The measures of carboxylic (and carboxylato) group distortion from coplanarity with the pyridine rings to which they are attached, are the dihedral angles of 5.4(1)° and 4.6(2)° in **1** and 5.2(3)° and 5.1(3)° in **2**, calculated for the chelating bonded ligand and for the zwitterionic ligand, respectively. This coplanarity is preserved by intramolecular hydrogen bond formation of the type O–H···O between carboxylic (carboxylato) and hydroxyl groups (see Table 5) and it is an indicator of the stereochemical rigidity of the ligands themselves and their ability to accommodate to the cadmium coordination sphere.

There are three intramolecular hydrogen bonds, two of the type O–H···O (formed by the hydroxyl groups and one of the carboxylato oxygens) and one of the type N–H···O (in the zwitterionic picH ligand). The intramolecular O–H···O bond in the anionic pic^- ligand is shorter [O4···O3 2.562(3) and 2.567(6) Å, in **1** and **2**, respectively] than the O–H···O bond in the zwitterionic picH ligand [O7···O6 2.581(3) and 2.588(7) Å, in **1** and **2**, respectively] since in the later the proton acceptor is the O6 atom which

is also a donor atom. The N···O distance in the zwitterionic ligand is 2.673(3) Å in **1** and 2.677(7) Å in **2**, both being longer than O–H···O bonds.

Intermolecular hydrogen bonds of the type O–H···O are formed between water molecules and the carboxylato oxygen atoms (O···O distances are 2.738(2) and 2.734(6) Å in **1** and **2**, respectively) (Table 5).

3.3. Thermal analysis (TGA-DTA)

Samples of the complexes **1** and **2** were heated from room temperature up to 500 °C. Thermal decomposition of the complexes is shown in Figs. 3 and 4. A similar shape of both DTA and TGA curves can be seen in Figs. 3 and 4. This thermal behaviour is in good correlation with their isostructurality established by X-ray structure analysis. In addition, the determined bond distances in the complexes can be incorporated into the explanation of their thermal behaviour. Compounds **1** and **2** are thermally stable up to 150 °C. Above this temperature, a water molecule is eliminated in one stage in the temperature range 150–200 °C. The minimum of the endothermic peak is at a lower temperature (214.0 °C) for **2** and at a higher temperature for **1** (228.0 °C) and in good agreement with a stronger Cd–O1 bond in **1** (2.304 Å) and a weaker bond in **2** (2.307 Å). A further step of the thermal decomposition, which takes place in the temperature range 200–270 °C, is characterized by the release of two OH-pic ligands. The products are thermally stable up to 300 °C. The thermal degradation continues through an

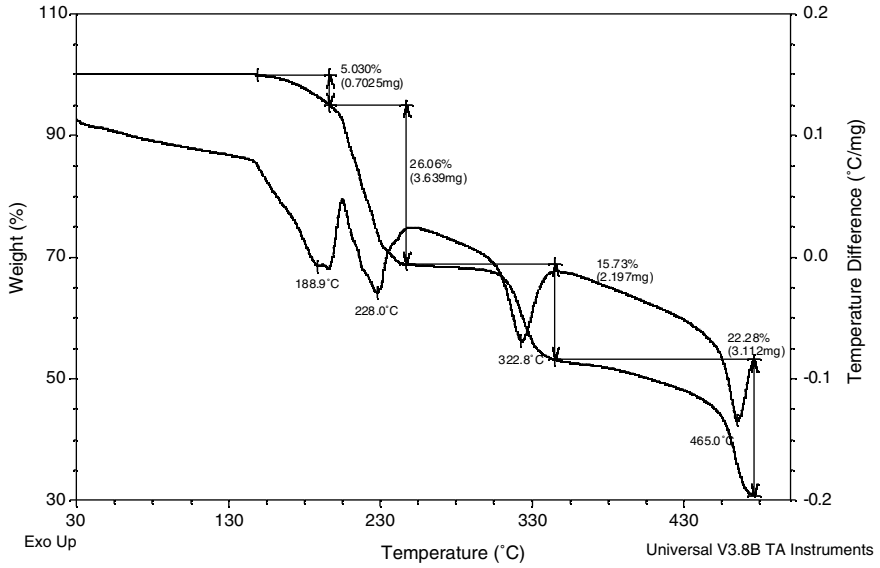

Fig. 3. DTA/TGA curves of **1**.

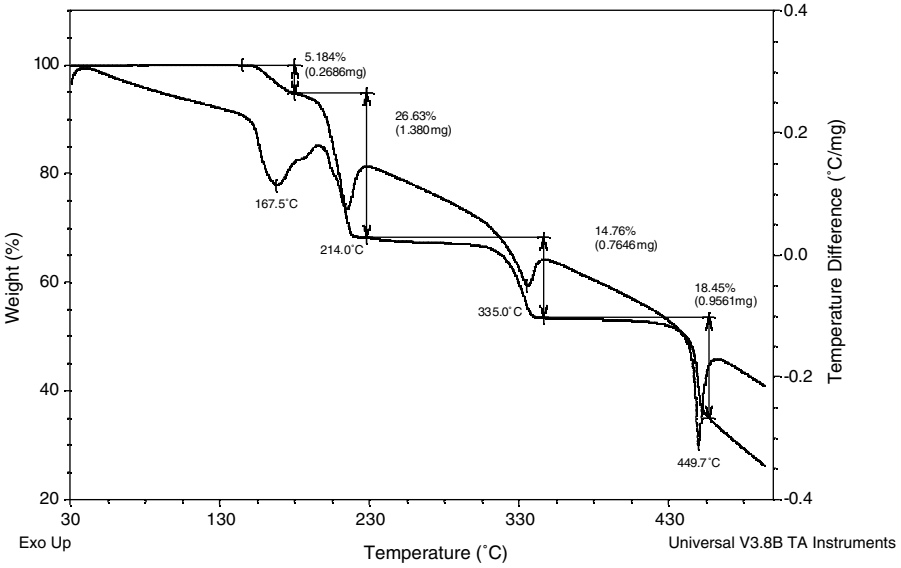

Fig. 4. DTA/TGA curves of **2**.

additional two steps. The first one happens in the temperature range 300–420 °C and the second one in the range 420–470 °C. Based on the mass loss results, we suppose that in the first step the elimination of one OH-pic ligand per complex takes place (endothermic effect on the DTA curves) at 322.8 and 335.0 °C, for **1** and **2**, respectively. The rest of the complexes partially degrade in the final stage in which the remainder of the ligand decomposes through an endothermic processes at 465.0 and 449.7 °C. The higher value of the temperature of the endothermic peak in **2** (in the second-to-last step) indicates the important role of the stronger Cd–N1 bond. During the last step, a lower temperature of the endothermic peak in **2** is observed, which refers to a weaker bond in **2** complex than in **1** complex.

4. Conclusions

Cadmium(II) chloride and bromide react almost instantaneously with 3-hydroxypicolinic acid in water solution giving isostructural dinuclear complexes of the general formula $[CdX(OH\text{-}pic)(OH\text{-}picH)(H_2O)]_2$; $X = Cl^-$, Br^-, which has been established by X-ray structural analysis and also supported by thermal analysis. These compounds are not stable in solutions and NMR spectral analysis revealed the presence of cadmium(II) 3-hydroxypicolinate as the only cadmium(II) compound in solution. Although the synthesis conditions permit the formation of $Cd(OHpic)_2$, apparently the packing forces in the solid state yield the title complexes.

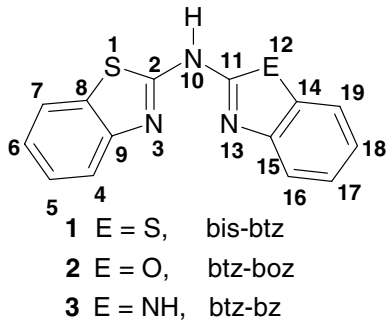


Scheme 1. Benzothiazole derived ligands.

posses versatile chemical, structural and tautomeric behavior, that upon coordination to metal ions, may give rise to different structures. Our aim was to study the effect of the heteroatoms (nitrogen, oxygen or sulfur) in their coordination mode; as to investigate the participation of the metal ions, in the formation of six-membered rings with alternating sp^2 carbon and nitrogen atoms in an aromatic pentacyclic system [30]. Therefore, herein we report the synthesis and characterization of coordination compounds **4**–**16** of these benzothiazole ligands **1**–**3** with Co^{2+}, Ni^{2+}, Zn^{2+} and Hg^{2+} ions (Scheme 2), which may form supramolecular arrangements by interaction of the heteroatoms, hydrogen bonds or π stacking. Compounds **4** and **5** have been described in a patent [34] but their structural study was not reported.

2. Experimental

2.1. Materials

All chemicals were reagent grade: methanol (J.T. Baker), 2-aminobenzothiazole (Aldrich); $Co(OAc)_2 \cdot 4H_2O$, $Ni(OAc)_2 \cdot 4H_2O$, $Zn(OAc)_2 \cdot H_2O$ and $Hg(OAc)_2$ (J.T. Baker), were used without further purification. Compounds **1**–**3** were synthesized according to the reported methods by Merchán et al. [35,36].

2.2. Physical measurements

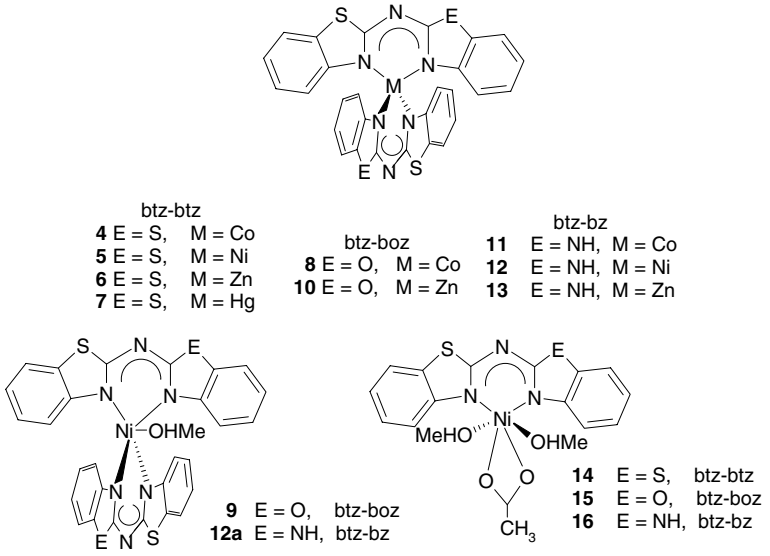
A FT IR spectrometer (Perkin–Elmer 1600) was used for obtaining IR spectra of solid samples in KBr pellets (4000–400 cm^{-1}). UV–Vis–NIR spectra (diffuse reflectance, 40 000–4000 cm^{-1}) were recorded on a Cary-5E (Varian) spectrometer. Elemental analyses were carried out with a Fisons EA 1180 analyzer. The MS spectra were obtained by DIP (Direct Insertion Probe) at 20 eV in an HP 5989 spectrometer.

2.3. Crystallography

Crystal data and information about the data collection and structure refinement details are given in Table 1. X-ray diffraction studies were performed with KAPPA-CCD area detector and CAD4-Enraf-Nonius. The crystal structures were determined and refined with the SHELXTL [*x*, *y*] system. Hydrogen atoms of compounds **6**, **7**, **9** and **12** were systematically placed on idealized positions and refined with a riding model. For compounds **14** and **15** all aromatic hydrogen atoms were found on the difference-Fourier maps and refined with free coordinates and fixed isotropic thermal parameters [37].

2.4. Syntheses of complexes: general procedure

All compounds were synthesized following the same procedure as described for compound **4**. Compounds **5**–**13** from a 2:1 molar ratio (ligand:metal) and **14**–**16** employing an equimolar ratio.



Scheme 2. Obtained coordination compounds from ligands **1**–**3**.

2.4.1. *[Co(bis-btz)$_2$] · DMSO (**4**)*

Bis-btz (284 mg, 1 mmol) was dissolved in hot methanol (30 mL), and a solution of $Co(OAc)_2\cdot4H_2O$ (125 mg, 0.5 mmol) in hot methanol (5 mL) was added. An orange precipitate was obtained by evaporation of the solvent, which was filtered and recrystallized in DMSO, the orange crystals were suitable for X-ray diffraction studies. Yield: 203 mg (65%). Dec. at 380 °C. *Anal.* Calc. for $C_{28}H_{16}N_6S_4Co$: C, 53.92; H, 2.58; N; 13.48. Found: C, 53.86; H, 2.61; N, 13.42%. $\mu_{eff}=4.79$ BM. MS: m/z 623(72) $[M]^+$.

2.4.2. *[Ni(bis-btz)$_2$] (**5**)*

The previous procedure was repeated using $Ni(OAc)_2\cdot4H_2O$ (125 mg, 0.5 mmol) and bis-btz (284 mg, 1 mmol), yielding a dark red microcrystalline powder. Yield: 153 mg (49%). Dec. at 320 °C. . *Anal.* Calc. for $C_{28}H_{16}N_6S_4Ni$: C, 53.94; H, 2.58; N, 13.48. Found: C, 54.02; H, 2.59; N, 13.49%. $\mu_{eff}=2.99$ BM. MS: m/z 623(56) $[M]^+$.

2.4.3. *[Zn(bis-btz)$_2$] · 0.5DMSO (**6**)*

$Zn(OAc)_2\cdot H_2O$ (100 mg, 0.5 mmol) was reacted with bis-btz (284 mg, 1 mmol). A pale yellow powder was isolated which was recrystallized from hot DMSO. The crystals were suitable for X-ray diffraction. Yield: 194 mg (62%). Dec. at 310 °C. *Anal.* Calc. for $C_{29}H_{19}N_6O_{0.5}S_{4.5}Zn$: C, 52.05; H, 2.86; N, 12.56. Found: C, 51.45; H, 2.76; N, 12.23%. MS: m/z 628(98) $[M]^+$.

2.4.4. *[Hg(bis-btz)$_2$] · DMSO (**7**)*

The previous procedure was repeated using $Hg(OAc)_2$ (160 mg, 0.5 mmol) and bis-btz (284 mg, 1 mmol). A pale yellow powder was filtered off and recrystallized from hot DMSO. Yield: 238 mg (63%). Dec. at 260 °C. *Anal.* Calc. for $C_{30}H_{22}N_6O_1S_5Hg$: C, 42.72; H, 2.63; N, 9.96. Found: C, 42.68; H, 2.42; N, 10.16%. MS: m/z 283(100) $[C_{14}H_9N_3S_2]^+$.

2.4.5. *[Co(btz-boz)$_2$] (**8**)*

The same procedure was repeated using $Co(OAc)_2\cdot4H_2O$ (125 mg, 0.5 mmol) and btz-boz (267 mg, 1 mmol), yielding a microcrystalline orange powder. Yield: 156 mg (52%). Dec. at 375 °C. *Anal.* Calc. for $C_{28}H_{16}N_6S_2O_2Co$: C, 56.85; H, 2.72; N, 14.20. Found: C, 56.77; H, 2.66; N, 14.02%. $\mu_{eff}=5.11$ BM. MS: m/z 591(100) $[M]^+$.

2.4.6. *[Ni(btz-boz)$_2$(MeOH)] (**9**)*

$Ni(OAc)_2\cdot4H_2O$ (125 mg, 0.5 mmol) was reacted with btz-boz (267 mg, 1 mmol). A dark red powder was isolated and recrystallized from hot DMSO. An X-ray diffraction study was carried out for the obtained crystals. Yield: 144 mg (48%); m.p. 322–326 °C. *Anal.* Calc. for $C_{29}H_{20}N_6S_2O_3Ni$: C, 55.88; H, 3.23; N, 13.48. Found: C, 55.92; H, 2.61; N, 13.67%. $\mu_{eff}=2.99$ BM. MS: m/z 591(100) $[M]^+$.

2.4.7. *[Zn(btz-boz)$_2$] · 0.5DMSO (**10**)*

$Zn(OAc)_2\cdot H_2O$ (100 mg, 0.5 mmol) was reacted with btz-boz (267 mg, 1 mmol), it was recrystallized from hot DMSO, yielding a microcrystalline pale yellow powder. Yield: 203 mg (68%). Dec. at 300 °C. *Anal.* Calc. for $C_{29}H_{19}N_6S_{2.5}O_{2.5}Zn$: C, 54.67; H, 3.01; N, 13.20. Found: C, 54.33; H, 2.98; N, 12.90%. MS: m/z 593(100) $[M]^+$.

2.4.8. *[Co(btz-bz)$_2$] · MeOH (**11**)*

The previous procedure was repeated using $Co(OAc)_2\cdot4H_2O$ (125 mg, 0.5 mmol) and btz-bz (267 mg, 1 mmol).

An orange powder was filtered off and washed in methanol. Yield: 153 mg (49%). Dec. at 350 °C. *Anal*. Calc. for $C_{29}H_{22}N_8O_1S_2Co$: C, 55.86; H, 3.17; N, 18.74. Found: C, 56.03; H, 3.57; N, 18.03%. $\mu_{eff} = 4.49$ BM. MS: *m*/*z* 589(100) $[M]^+$.

*2.4.9. [Ni(btz-bz)$_2$(MeOH)] (**12a**)*

$Ni(OAc)_2 \cdot 4H_2O$ (125 mg, 0.5 mmol) was reacted with btz-bz (267 mg, 1 mmol). A dark red powder was obtained. Yield: 97 mg (31%). Dec. at 390°. IR(KBr), *v* (cm^{-1}): 3435.5 (OH). *Anal*. Calc. for $C_{29}H_{20}N_8O_1S_2Ni$: C, 56.06; H, 3.57; N, 18.03. Found: C, 56.25; H, 3.15; N, 18.46%. $\mu_{eff} = 3.05$ BM. MS: *m*/*z* 589(100) $[M]^+$. The red crystalline powder was recrystallized from methanol, by standing at r.t. for 2 months, it gave crystals suitable for single X-ray diffraction. During crystallization the MeOH molecule was lost giving compound [Ni(btz-bz)$_2$] (**12**), which was characterized by X-ray diffraction analysis.

*2.4.10. [Zn(btz-bz)$_2$] (**13**)*

A solution of $Zn(OAc)_2 \cdot H_2O$ (100 mg, 0.5 mmol) was added to btz-bz (267 mg, 1 mmol). The product of the reaction was isolated and filtered. A pale yellow powder was obtained. Yield: 150 mg (50%). Dec. at 310 °C. *Anal*. Calc. for $C_{28}H_{18}N_8S_2Zn$: C, 56.43; H, 3.04; N, 18.80%. Found: C, 56.29; H, 3.30; N, 18.80%. MS: *m*/*z* 594(10) $[M]^+$.

The coordination compounds **14**–**16** were synthesized following the same procedure, as described for compound **14** using an equimolar ratio ligand to metal.

*2.4.11. [Ni(bis-btz)(OAc)(MeOH)$_2$] (**14**)*

Bis-btz (284 mg, 1 mmol) was dissolved in hot methanol (30 mL) and a solution of $Ni(OAc)_2 \cdot 4H_2O$ (249 mg, 1 mmol) in hot methanol (5 mL) was added. Green crystals were obtained by partial evaporation of the solvent and isolated by filtration. Yield: 195 mg (42%). Dec. at 370 °C. *Anal*. Calc. for: $C_{18}H_{19}N_3O_4S_2Ni$: C, 46.57; H, 4.12; N, 9.05. Found: C, 46.53; H, 4.11; N, 8.97%. MS: *m*/*z* 464(90) $[M]^+$.

*2.4.12. [Ni(btz-boz)(OAc)(MeOH)$_2$] (**15**)*

The previous procedure was repeated using $Ni(OAc)_2 \cdot 4H_2O$ (249 mg, 1 mmol) and btz-boz (267 mg, 1 mmol). After two weeks, green crystals suitable for X-ray diffraction were obtained by slow evaporation at r.t. Yield: 204 mg (46%). *Anal*. Calc. for $C_{18}H_{19}N_3O_5SNi$: C, 48.25; H, 4.27; N, 9.38. Found: C, 48.26; H, 4.20; N, 9.48%. The obtained compound was not suitable for mass spectrometry, it decomposed without melting.

*2.4.13. [Ni(btz-bz)(OAc)(MeOH)$_2$] (**16**)*

Complex **16** was synthesized with an analogous procedure to **14**. A solution of $Ni(OAc)_2 \cdot 4H_2O$ (249 mg, 1 mmol) in methanol was added to a solution of btz-bz (267 mg, 1 mmol). A green powder was obtained by slow evaporation of the solvent. Yield: 145 g (32%). *Anal*. Calc. for $C_{18}H_{19}N_4O_4S_1Ni$: C 48.46; H, 4.29; N, 12.56. Found: C, 47.95; H, 4.47; N, 12.47%. The obtained compound was not suitable for mass spectrometry, it decomposed without melting.

3. Results and discussion

Ligands **1**–**3** were reacted with cobalt(II), nickel(II) and zinc(II) acetates; ligand **1** was also reacted with mercury(II) acetate; in all coordination compounds the N–H group was deprotonated, as was deduced from the neutral character of the compounds. Cobalt(II) compounds **4**, **8**, **11** presented an orange color, while zinc(II) **6**, **10**, **13** and mercury(II) **7** complexes were characterized as pale yellow microcrystalline powders, regardless of the ligand used in the reaction synthesis. While for nickel(II), red compounds were isolated when two ligands are coordinated to the metal center **5**, **9**, **12**, **12a**; when only one ligand is present, green complexes **14**–**16** were obtained.

3.1. Mass spectrometry

The analyses by mass spectrometry at 20 eV for compounds **4**–**6**, **8** and **10**–**13**, showed the molecular ion peaks. This behavior confirms that both ligands are strongly attached to the metal(II) ion, surrounding the metal atom and preventing further reactions that could lead to fragmentation. Whereas for mercury(II) **7**, the molecular ion peak was not observed indicating weaker coordination bonds, only the main peak at *m*/*z* 283 due to the ligand $[C_{14}H_8N_3S_2]^+$ was identified. In compound **9**, the methanol molecule was lost and the peak at 590 corresponds to the nickel(II) bonded to two ligands. The molecular ion for compound [Ni(bis-btz)(OAc)(MeOH)$_2$] (**14**) is observed together with another at *m*/*z* 622 which corresponds to two ligand molecules attached to the metal ion due to intermolecular rearrangements. Compounds [Ni(btz-boz)-(OAc)(MeOH)$_2$] (**15**) and [Ni(btz-bz)(OAc)(MeOH)$_2$] (**16**) decomposed without melting and their mass spectra were not recorded.

3.2. Infrared spectroscopy

The symmetric ligand bis-btz **1**, exhibits two IR bands assigned to the *v*(C=N) at 1560 and 1542 cm^{-1}, which are shifted ($\Delta \cong 100$ cm^{-1}) upon coordination to the metal ions **4**–**7** to 1479–1462 and 1451–1444 cm^{-1}, respectively. Whereas for the non-symmetric ligands, btz-boz and btz-bz and their corresponding coordination compounds **8**–**13**, different *v*(C=N) bands corresponding to the thiazole, oxazole or benzimidazole rings were observed (Table 2), which shifted upon coordination. In all cases a strong bonding of the nitrogen atoms to the metal ions is shown. The *v*(C=N) bands in complexes **14**–**16** are in the expected regions.

3.3. Electronic spectra

*3.3.1. Cobalt(II) compounds **4**, **8** and **11***

The orange [Co(bis-btz)$_2$] (**4**), [Co(btz-boz)$_2$] (**8**) and [Co(btz-bz)$_2$] (**11**) compounds, have a magnetic moment

characteristic of a cobalt(II) ion, $\mu_{eff} = 4.79$, 5.11 and 4.49 BM, respectively.

The diffuse reflectance spectra of these tetrahedral compounds are unusual with two CT broad absorption bands in the 28 000–22 500 cm^{-1} region which are extended up to the visible region. The $\nu_3\ {}^4T_1(P) \leftarrow {}^4A_2(F)$ transition is observed as a well defined a shoulder at 20 250, 20 768 and 21 818 cm^{-1}, for **4**, **8** and **11** respectively; while a multicomponent band in the NIR assigned to $\nu_2\ {}^4T_1(P) \leftarrow {}^4A_2(F)$, at 9456, 9775 and 9534 cm^{-1} respectively, Table 3. Their electronic spectra show the influence of the high electronic density from the planar conjugated ligands, when coordinated to the cobalt(II) ion, forming a six-membered chelate ring. The electronic delocalization in the system, which is extended to the metal ion, would also explain the shifting of the transitions ν_2 and ν_3 to higher energy giving rise to the orange color of the complexes. It is observed that when changing the heteroatom in the 12 position, S in **1** (bis-btz), O in **2** (btz-boz) and N in **3** (btz-bz), the electronic transitions are shifted respectively, indicating stronger ligand fields. This is consistent with their mass spectra and IR, which are in agreement with a strong bonding from the ligands towards the metal ions.

3.3.2. Nickel(II) compounds 5, 9 and 12a

The electronic spectrum of the crystalline complex $[Ni(bis\text{-}btz)_2]$ (**5**) is rather similar to the already discussed tetrahedral cobalt(II) compounds, with two CT broad absorption bands extended up to the visible region (32 500–20 000 cm^{-1}) and transitions at 18 900 and 8009 cm^{-1} assigned to $\nu_3\ {}^3T_1(P) \leftarrow {}^3T_1(F)$ and $\nu_2\ {}^3A_2(F) \leftarrow {}^3T_1(F)$ for a nickel(II) ion in a distorted tetrahedral geometry [38,39].

Compounds $[Ni(btz\text{-}boz)_2(MeOH)]$ (**9**) and $[Ni(btz\text{-}bz)_2(MeOH)]$ (**12a**) showed the corresponding bands for a pentacoordinated nickel(II) in a square pyramidal geometry with absorption bands centered at 20 000, 16 500, 10 826, 9730 and 8190 cm^{-1} for compound **9**, whereas for **12a** are at 20 720, 16 413, 10 600, 9325 and 7250 cm^{-1}. They also present two charge transfer bands in the 30 400–24 000 cm^{-1} region (Table 3).

3.3.3. Nickel(II) compounds 14–16

The reflectance spectra of the green nickel(II) complexes, $[Ni(bis\text{-}btz)(OAc)(MeOH)_2]$ (**14**), $[Ni(btz\text{-}boz)(OAc)(MeOH)_2]$ (**15**) and $[Ni(btz\text{-}bz)(OAc)(MeOH)_2]$ (**16**) showed three absorption bands (Table 3), which may be assigned to a distorted octahedral geometry, as observed in previously reported thiabendazol nickel(II) bis- and tris-chelates [28]; with transitions $\nu_1\ {}^3T_{2g}(F) \leftarrow {}^3A_{2g}(F)$, $\nu_2\ {}^3T_{1g}(F) \leftarrow {}^3A_{2g}(F)$ and $\nu_3\ {}^3T_{1g}(P) \leftarrow {}^3A_{2g}(F)$ in the regions 9300–9800, 14 828–14 964 and 23 252–25 000 cm^{-1}, respectively. Additionally,

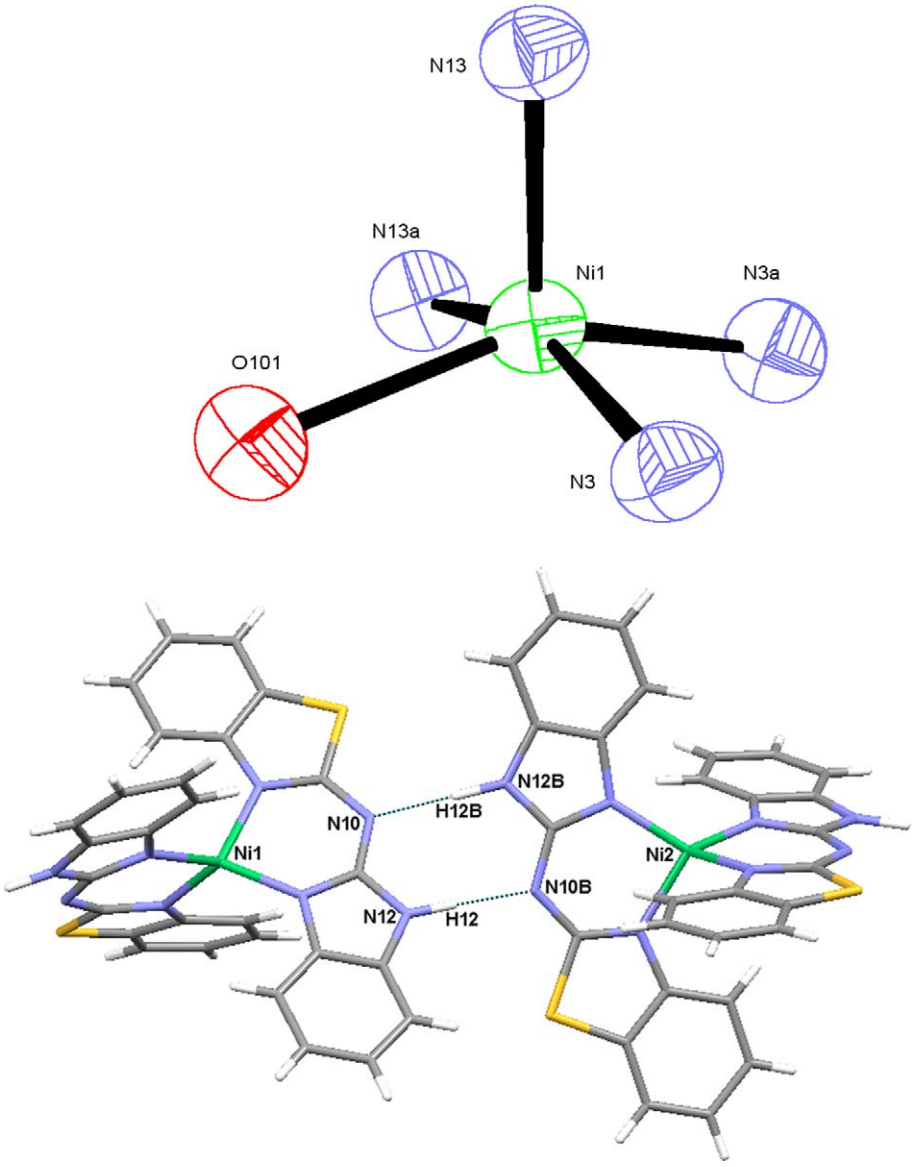

Fig. 5. Hydrogen bonds in compound **12**.

angles of the ligands are ca. 92° in compounds **4** and **12**, ca. 93° in **6** and while for **7** is 85°, due to its larger ionic radii. Coordination to the metal atoms gives rise to a quasi-planar pentacyclic arrangement for the aromatic rings, some distortion of the ligand is observed, in the cobalt(II) compound **4** the torsion angle M1–N3–C9–C4 is 12°, while in zinc(II) **6** is 14°, in the mercury(II) **7** is 5° and for **12** there is no distortion.

In compound **6** two molecules are associated through two N···H hydrogen bonds and one sulfur atom has an intermolecular π allylic interaction with three atoms [C2–N3–C9] as is shown in Fig. 2.

The crystal packing for compound **7** is shown in Fig. 3. In compound **12**, hydrogen bonding between N10 and N13, 2.926 Å (176.64°) gives rise to a dimeric arrangement, Fig. 5.

3.4.2. Square-based pyramidal geometry, compound *9*

The nickel(II) compound **9** is pentacoordinated in a square pyramidal geometry, which is consistent with its observed electronic spectrum, with two btz-boz ligands and a methanol molecule, Fig. 6. This complex has a structural angular parameter τ value of 0.14, where $\tau = (\beta - \alpha)/60$; $\alpha = 151.94$ and $\beta = 160.15$, indicating a square pyramidal geometry with a small trigonal component [40]. The bond lengths between the nickel(II) ion and the nitrogen atoms are in the range of 2 Å, Table 5. The apical position is occupied by N13 of the boz ring, Fig. 6. The Ni–O1 bond length [2.107(3) Å] is in the range expected for oxygen–nickel(II) bonds. Similar values of the bond lengths in the central ring between N3–C2 1.324(5), N10–C2 1.345(5), C11–N10 1.320(5) indicate the delocalization of the π system. A supramolecular arrangement is formed by hydrogen bonding of the imino nitrogen N10 with the oxygen atom of the coordinated methanol N10···H1–O1 1.951 Å, Fig. 6.

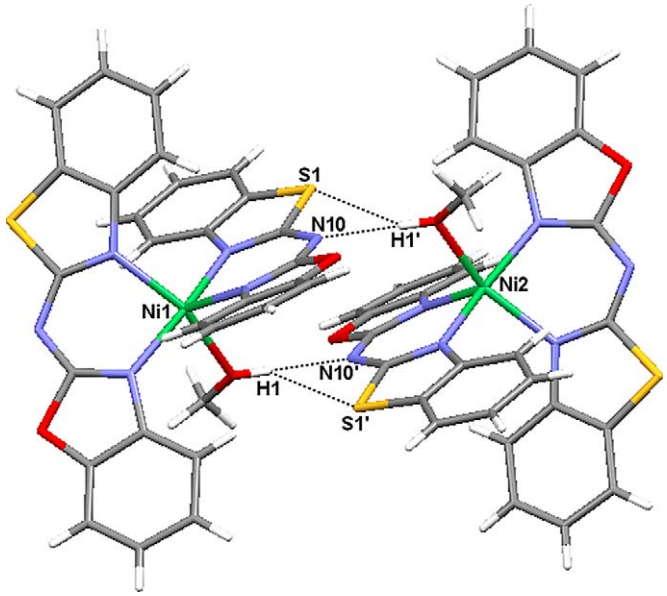

Fig. 6. Dimeric association by short hydrogen bonding between N10···H1′ 2.726, N10′···H1 1.951 and S1′···H1 2.944 Å, in compound **9**. The upper inset represents the square-based pyramidal geometry of nickel atom **9**.

3.4.3. Octahedral compounds *14* and *15*

The nickel(II) compounds **14** and **15** have a similar distorted octahedral geometry, with one ligand molecule bonded to the metal ion forming a pentacyclic frame, a bidentate acetate group, and two *trans*-methanol molecules completing the hexacoordination (Figs. 7–10).

The compounds have two slightly different nickel(II)-nitrogen bond lengths, Ni–N3 2.032(2) and Ni–N13 2.019(2) for **14** and 2.043(4) and 2.011(3) Å for **15**, which are longer that those observed in the bis-chelate tetrahedral compound **12** [Ni–N3 1.989(3) Å and Ni–N13 1.950(3) Å]. In both compounds, the *trans* methanol molecules are perpendicular to the main plane and in the range of 2.10 Å, as those of the bidentate chelating carboxylates, Table 5.

The main difference between both compounds is that the conformation of the bis-btz ligand in **14** is folded in a butterfly shape, the torsional angle between the two halves of the pentacyclic system is 127°, whereas in **15** the btz-boz ligand is planar, Fig. 8. The explanation for this difference is that in **15** there is a double intermolecular π-interaction between C2 and C11 of two molecules (3.318 Å), this dimer is reinforced by two cooperative intermolecular hydrogen bonding of the coordinated methanol and the imine nitrogen, O1–H1···N10′ (2.101 Å), Fig. 9. In addition, the dimers form a mono dimensional polymer by two O2–H2···O3′ hydrogen bonds (2.018 Å). Whereas in **14** there is a 2D arrangement formed by intermolecular interactions: a π-interaction of O–CH proton with C15 (2.892 Å) and two hydrogen bonds, O1–H1···N10′ (1.920 Å) and O2–H2···O4″ (1.990 Å), Fig. 10.

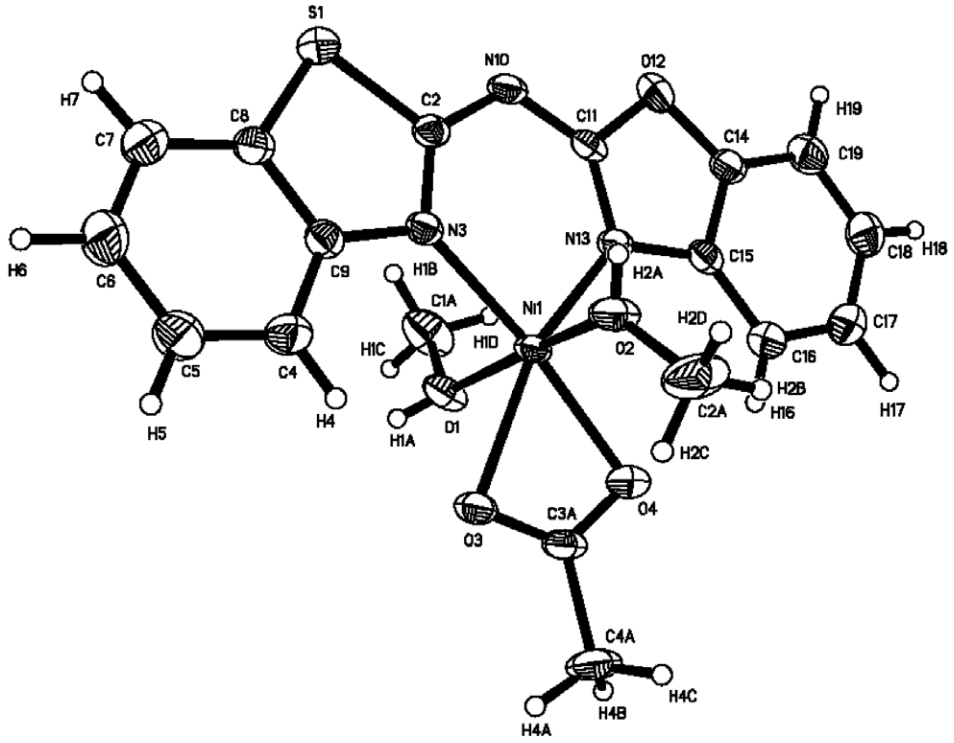

Fig. 7. ORTEP drawing of the molecular structure of **15**. Thermal ellipsoids are drawn on the 30% probability level.

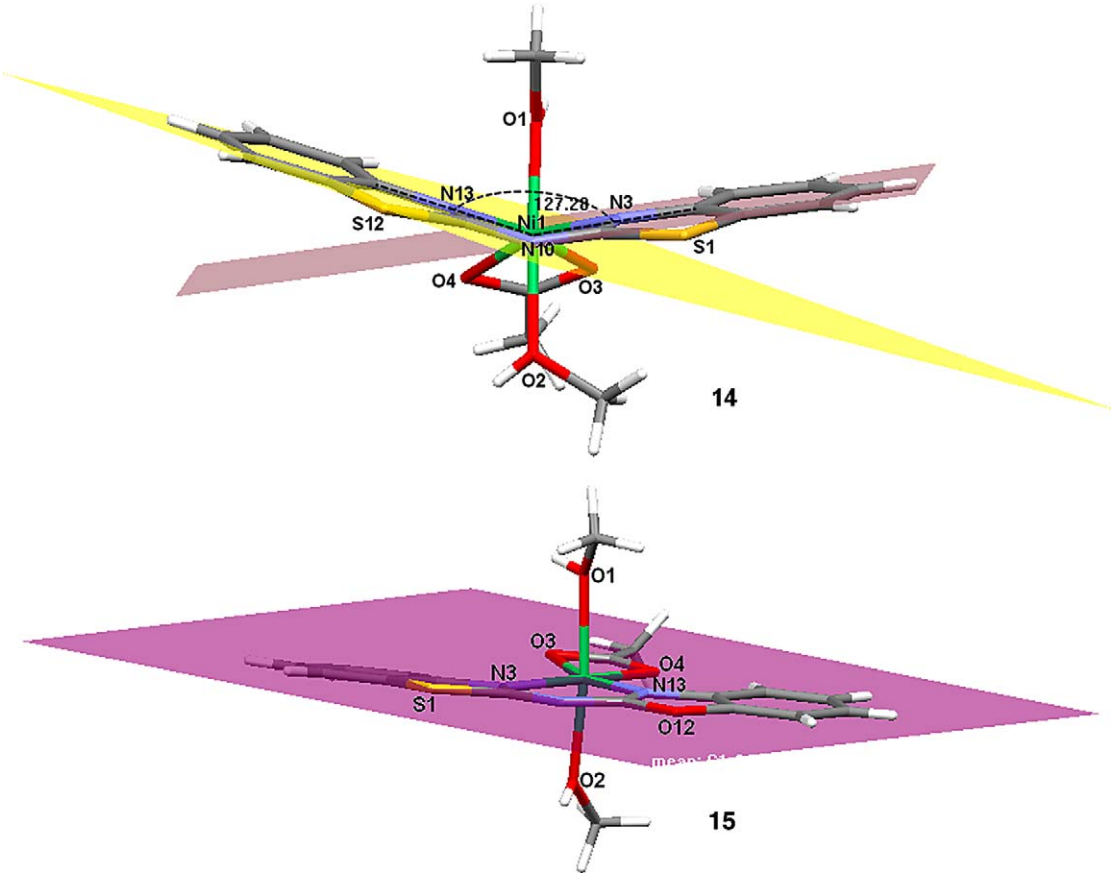

Fig. 8. Butterfly shape of the bis-btz ligand in **14** hydrogen atoms are omitted for clarity and a view of compound **15** showing the plane depicted by the pentacyclic framework.

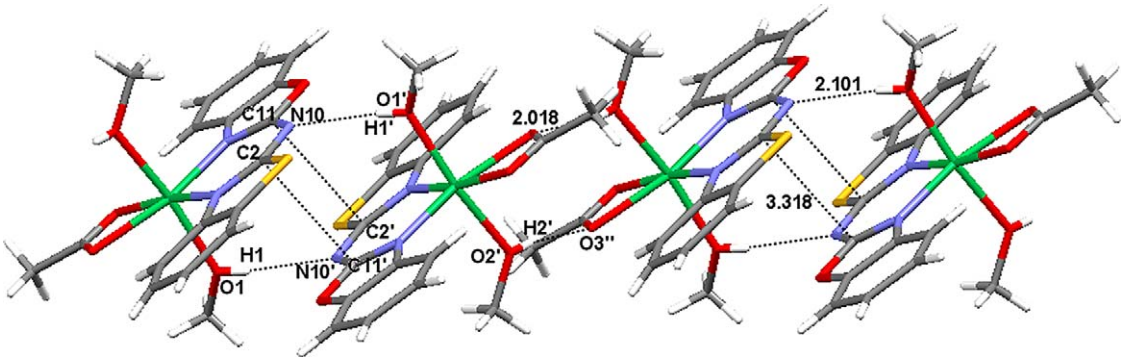

Fig. 9. Mono dimensional arrangement in compound **15** due to intermolecular hydrogen bonds between O1–H1···N10′ and O2′–H2′···O3″ and π-interactions between C2···C11″ and C11···C2′.

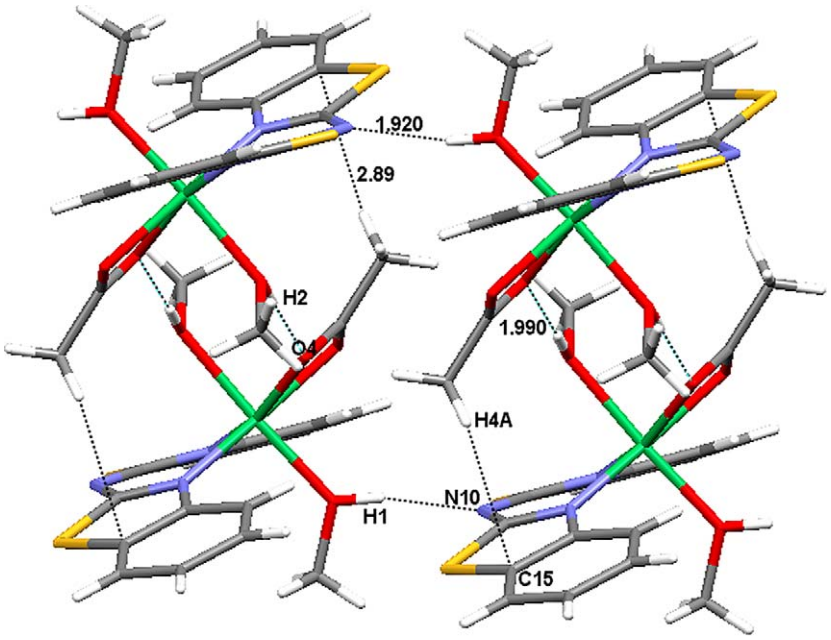

Fig. 10. Two dimensional polymer in compound **14** is formed by π and hydrogen bonds cooperative interactions.

4. Summary

We have obtained a series of interesting compounds that have in common a six-membered ring, by inclusion of a metal(II) ion in a planar delocalized system, formed by alternating sp^2 carbon and nitrogen atoms, integrated in a pentacyclic aromatic framework. Nitrogens N3 and N13 atoms were the binding sites with the metal ions, the nature of the heteroatom (S, O, N) in 12 position, did not affected the coordination behavior of the ligand. The orange cobalt(II) compounds, showed the participation of the metal ions in the electronic delocalization.

In the tetrahedral compounds, with exception of the mercury compound **7**, the two large polycyclic systems surround the metal ion, protecting it and allowing to observe the molecular ions in their mass spectra.

In the studied compounds, supramolecular arrangements were formed by intermolecular hydrogen bonds with the iminic nitrogen N10 and by π-interactions. In the octahedral nickel(II) compounds, with coordinated acetate and methanol molecules, the oxygen atoms participated into stabilizing 1D and 2D network systems, via intermolecular hydrogen bonds.

chemical and oxotransfer properties of oxomolybdenum complexes [13,17]. One of our previous studies [13a] on the Mo^{VI} complexes provided the first instance of using thiosemicarbazone-type ONS donor ligands in the modeling of molybdenum-binding site of the molybdenum cofactor (contains a mononuclear molybdenum atom coordinated to the sulfur atoms of a pterin derivative named molybdopterin) and showed for the first time that the steric factor is not absolutely essential to prevent the (μ-oxo)Mo^{V} dimer formation.

In this contribution we report the synthesis and structural characterization of some diamine/diimine-bridged dinuclear oxomolybdenum(VI) complexes of the type $[(MoO_2L)_2(\mu\text{-N–N})]$ (**2**–**5**) as well as their precursor complex $[MoO_2L(C_2H_5OH)]$ (**1**) where L^{2-} is the dianion of a tridentate ONO donor ligand and N–N is a neutral *exo*-bidentate ligand. Again, oxo abstraction from the dimolybdenum(VI,VI)-dioxo complex (**2**) using PPh_3 has been successfully used to obtain the corresponding dimolybdenum(IV,IV)-oxo species (**2a**) which is quite stable in the solid state and is hitherto unreported. An account of the chemistry of all the oxomolybdenum complexes, synthesized in this study, is presented here with special references to their formation, structure, and spectral and electrochemical properties.

2. Results and discussion

2.1. Synthesis

The complex **1**, $[MoO_2L(C_2H_5OH)]$ was prepared by refluxing an ethanol solution of the ligand H_2L and $MoO_2(acac)_2$ in equimolar quantities for 3 h. The Schiff base ligand H_2L was prepared by condensing 2-hydroxybenzoylhydrazine and 2-hydroxybenzaldehyde in 1:1 molar proportion at room temperature by stirring in alcohol for 2–3 h. Compounds **2**–**5** are synthesized by refluxing an ethanol solution of **1**, $[MoO_2L(C_2H_5OH)]$ and the appropriate spacer in 2:1 molar ratios for 4 h. All the compounds are sparingly soluble in alcohol, CH_3CN, $CHCl_3$, and CH_2Cl_2 but fairly soluble in DMF and DMSO. The compounds are air and heat stable, non-conducting in DMF solution and are diamagnetic as expected for a species with d^0 Mo(VI) center.

2.2. Spectral characteristics

The spectral data of all the complexes are summarized in Table 1. IR spectrum of the ligand exhibits prominent bands at 3075 and 1660 cm^{-1} assigned to ν(NH) and ν(C=O) modes [13c,13d,18–21], respectively. Characteristic strong bands in the spectra of both the complexes and the ligands are located at 3390 and 3195 cm^{-1} due to O–H stretching modes of the ligand, [13c,13d,18–21]. Conspicuous high intensity bands located in the 1600–1610 cm^{-1} region in the spectra of both the ligand and these are due to ν(C=N) bands [13b,13c,13d,20,21]. All the complexes exhibit two new bands in the 920–893 cm^{-1} region which are assigned to the symmetric and the antisymmetric ν(Mo=O) vibrations of the *cis*-dioxo molybdenum(VI) moiety [13].

[a] In KBr pellet.
[b] In DMF.

Electronic spectra (Table 1) of all the complexes **1**–**5** in DMF exhibit two intense absorption bands in the 410–400, and the 320–310 nm region, which are assignable to L → Mo LMCT and intraligand transitions, respectively [13].

The ^1H NMR (DMSO d_6) data of the free ligand and its monomeric and dimeric oxomolybdem(VI) complexes are given in the experimental section. The spectrum of the free ligand exhibits two different OH (phenolic) resonances at two different positions (12.02 and 11.76 ppm), one CH proton signal at 8.68 ppm, one NH proton response at 11.18 ppm and aromatic proton bands at 7.90–6.90 ppm, respectively [13c,13d,21]. The signals for one OH proton and the NH proton are found to disappear in the spectra of the monomeric **1** and all the dimeric MoO_2L **2**–**5** complexes and only one OH proton signal is located at 11.38 ppm. These changes imply that the ligand coordinates to the MoO_2^{2+}-core in the enolate form.

2.3. Cyclic voltammetry

Results of cyclic voltammetric studies of all the complexes are given in Table 2. The CV trace of the complex **1** displays two irreversible reductive responses [13] within the potential window −0.9 to −1.4 V. These are assigned to the Mo(VI)/Mo(V) and the Mo(V)/Mo(IV) processes [13,22,23], respectively. The ligand is found to be redox inactive within this potential window. The dinuclear complexes **2**–**5** exhibit three successive irreversible one-electron reductions within the potential window −0.60 to −2.0 V versus SCE in acetonitrile which are assigned to

Mo^{VI}–Mo^{VI}/Mo^{V}–Mo^{VI} and Mo^{V}–Mo^{VI}/Mo^{V}–Mo^{V} processes [24] and the ligand (bridging)-centered reduction, respectively. The presence of strong and hard (N,O) donor points in the Schiff base ligand tend to stabilize the molybdenum center in the higher oxidation state.

2.4. Description of crystal structure

2.4.1. $[MoO_2L(C_2H_5OH)]$ (1)

The molecular structure and the atom-numbering scheme for the complex **1** are shown in Fig. 1 and the bond parameters are given in Table 3. The mononuclear complex **1** has a distorted octahedral geometry with one nitrogen atom and five oxygen atoms. Three atoms, O(1), N(1) and O(2) (from the tridentate ligand), and one terminal oxo atom, O(3), occupy the meridional plane. The Mo(1) atom lies 0.253 Å out from this plane in the direction of the other terminal oxygen atom O(4). Both O(4) and O(6), the latter from the coordinated ethanol molecule, occupy the axial positions forming an O(4)–Mo–O(6) angle of 170.15(14)° which indicate the distorted octahedral nature of the donor environment around the Mo(VI) center. The MoO_2 moiety has a *cis* configuration with conventional [13c,13d,25] average values for the Mo–O(3)/O(4) distance (1.698(3) Å), and O(3)–Mo–O(4) bond angle (106.03(16)°), which is close to the energy minimum value estimated from MO theory [26]. The Mo–O(6) bond *trans* to the terminal oxygen atom O(4) is significantly longer [2.356(4) Å] compared to the length of other molybdenum oxygen bonds (enolate) Mo–O(2) distance (1.917(3) Å) and (phenolate) Mo–O(1) distance [2.021(3) Å], indicating that the ethanol molecule is weakly coordinated to the metal center and can behave as a substrate-binding site. This expectation is realized in the formation of the binuclear complexes **2**–**5** which are formed by the replacement of the weakly coordinated C_2H_5OH molecule by the nitrogen atom of one-half of the N–N bridging ligands.

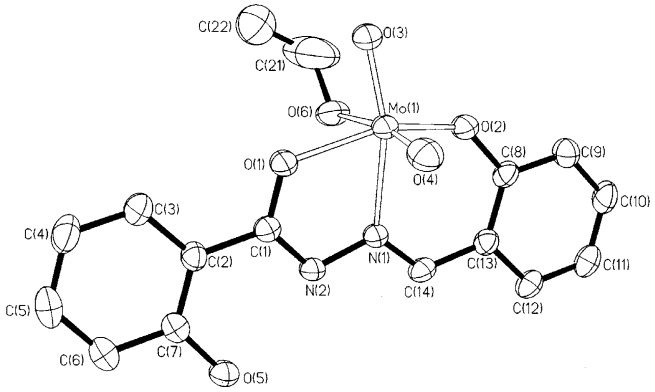

Fig. 1. An ORTEP plot and atom-numbering scheme of $[MoO_2L(C_2H_5OH)]$ (**1**) hydrogen atoms are omitted for clarity.

O(2)–Mo(1)–O(6)	80.99(15)	O(1)–Mo(1)–O(6)	78.42(15)

The estimated standard deviations are shown in parentheses.

2.4.2. $[(MoO_2L)_2(\mu\text{-}4,4'\text{-bpy})]$ (2)

The orange dimeric complex $[(MoO_2L)_2(\mu\text{-}4,4'\text{-bpy})]$ (**2**) crystallized in the triclinic space group $P\bar{1}$ and two halves of the dimeric complex **2** are not crystallographically equivalent but they posses closely matching structural dimensions. Therefore, structure of one of the halves will be representing the structure of the other half of the dimeric molecule quite closely. Molecular structure and the atom labelling scheme of complex **2** is illustrated in Fig. 2 and all metric data are collected in Table 4. Structure of one-half of the complex involving the Mo(1) acceptor center is described in details.

The two oxo-oxygen atoms of one $Mo(1)O_2^{2+}$ moiety, ONO donor atoms of the ligand H_2L and one nitrogen atom of the bridging 4,4′-bipy molecule complete the distorted octahedral coordination around the metal center Mo(1) in a $MoO_2L \cdot 0.5$ 4,4′-bipy unit. The ligand binds the metal in it's enolate form and behaves in a dianionic tridentate manner, the three donor points O(2), N(1), O(1) occupying a meridonial plane [27,28] and forming one five-membered and another six-membered chelate ring around one $Mo(1)O_2^{2+}$ center with bite angles of 71.36(14)° and 81.06(15)° in case of Mo(1). Similar bite angle of 71.90(15)° and 81.34(15)° are also generated at Mo(2). Least-square calculations shows the molybdenum

N(3)–Mo(2)–N(6)	81.20(16)		

The estimated standard deviations are shown in parentheses.

atom Mo(1) to be 0.311 Å above the basal plane defined by [O(2) N(1) O(1) O(4)], the other oxo-oxygen O(3) occupying an apical position in the coordination sphere of Mo(1) and this deviation of the Mo(1) atom from the basal plane towards the apical oxo-oxygen atom O(3) is also apparent from the angles subtended at the Mo center. The other apical position in the coordination octahedron of Mo(1) is occupied by the nitrogen atom N(5) of one-half of the 4,4′-bipy group. The Mo(1)–N(5) bond [2.477(5)] Å is much longer than the other Mo(1)–N(1) bond [2.247(4)] Å and indicates that the bipyridine nitrogen is weakly bonded to the MoO_2^{2+}-core pointing to the possibility of further ligand exchange reaction at this point.

2.4.3. $[(MoO_2L)_2(\mu\text{-bpe})]\cdot 0.5C_2H_5OH$ (**3**)

The molecular structure and atom-labeling scheme for complex **3** are shown in Fig. 3. Selected bond distances and angles are collected in Table 5. The dinuclear complex crystallizes in the triclinic space group $P\bar{1}$ with the molecule sitting across a crystallographic center of inversion. Accordingly, the two equivalent halves of the molecule have a *trans* disposition with respect to the double bond [C(20)═C(20A)] at the center. An ethanol moiety was found to be disordered about another center of symmetry and was modeled with partial occupancy, giving an overall stoichiometry of $[(MoO_2L)_2(\mu\text{-bpe})]\cdot 0.5C_2H_5OH$.

The coordination environment around the Mo(VI) center is octahedral and highly distorted. As is the case in compounds **2** and **5**, the ligand H_2L is dianionic and tridentate, with its meridionally situated donor sites O(2), N(1), and O(1) lying in the equatorial plane along with the oxo oxygen O(4). The bond distances about Mo(1) reveal the

Bond angles		
O(3)–Mo(1)–O(4)	105.2(2)	106.5(2)
O(3)–Mo(1)–O(2)	99.6(2)	100.9(2)
O(4)–Mo(1)–O(2)	103.79(18)	102.7(2)
O(3)–Mo(1)–O(1)	95.7(2)	96.5(2)
O(4)–Mo(1)–O(1)	97.04(17)	98.24(19)
O(2)–Mo(1)–O(1)	149.79(18)	147.60(18)
O(3)–Mo(1)–N(1)	94.3(2)	93.4(2)
O(4)–Mo(1)–N(1)	158.45(19)	158.7(2)
O(2)–Mo(1)–N(1)	81.48(17)	80.33(19)
O(1)–Mo(1)–N(1)	71.49(17)	71.47(18)
O(3)–Mo(1)–N(3)	172.11(18)	170.4(2)
O(4)–Mo(1)–N(3)	82.18(18)	82.85(19)
O(2)–Mo(1)–N(3)	81.05(17)	78.63(18)
O(1)–Mo(1)–N(3)	80.37(16)	79.76(18)
N(1)–Mo(1)–N(3)	77.99(16)	77.08(18)

Estimated standard deviations are shown in parentheses.

magnitude of the distortions, as can be seen in Table 5. The Mo–O distances range from 1.681(5) Å for the oxo ligand O(3), located in an axial position, to 2.001(4) Å for the enolate oxygen O(1). The Mo(1)–O(2) (phenolate) distance is slightly shorter at 1.922(4) Å. The second axial position is occupied by a nitrogen atom of the bridging bpe ligand, which is significantly farther from the Mo center than are the other five ligated atoms. Mo(1)–N(3), at 2.461(5) Å, is undoubtedly the weakest of the six Mo–L bonds and consequently the most susceptible to ligand exchange. The *trans* angles in the equatorial plane

[O(1)–Mo(1)–O(2), 149.79(18)°; O(4)–Mo(1)–N(1), 158.45(19)°] indicate that the central Mo is not in the equatorial plane; it lies 0.312(2) Å out of the plane, toward the distal oxo ligand O(3). The chelate bite angles for the five- and six-membered rings have values within the expected ranges [O(1)–Mo(1)–N(1), 71.49(17)°; O(2)–Mo(1)–N(1), 81.48(17)°].

The extended structure of **3** can be viewed as having a basic bilayer motif in which layers formed by the tridentate ligand L are separated by bpe spacers. Fig. 3 shows the pattern formed by four complete molecules. The distance between the planes of the phenyl groups of two adjacent molecules (related to each other by a center of symmetry) is 3.67(4) Å. Fig. 3 displays a detail of the intermolecular interactions. Three half-molecules are shown in the figure. The phenyl ring labeled C2A...C7A is related to the basic unit (no letters appended to the atom names) by the center of symmetry at (0.5, 0.0, 0.5); this is the 3.67(4) Å interaction.

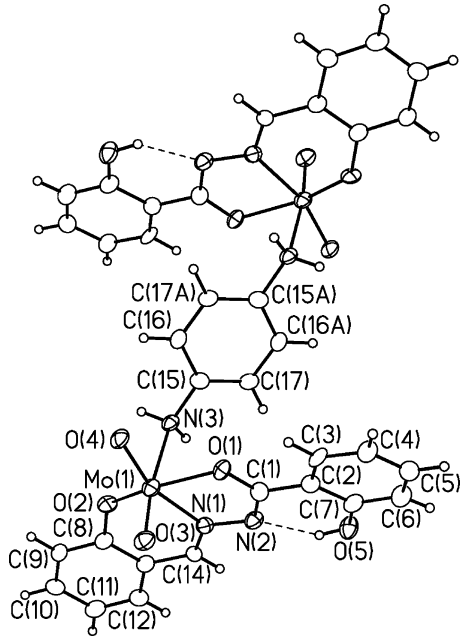

Fig. 4. Thermal ellipsoid plot of one molecule of $[(MoO_2L)_2(\mu\text{-ppda})]$ (**5**) showing the atom labeling scheme. Non-hydrogen atoms are represented by their 50% probability ellipsoids.

2.4.4. $[(MoO_2L)_2(\mu\text{-ppda})]$ (**5**)

The dinuclear molecule $[(MoO_2L)_2(\mu\text{-ppda})]$ (**5**) (where ppda = *p*-phenylenediamine) sits astride a crystallographic inversion center in space group *Pbca*, with the symmetry element lying in the middle of the ppda ligand. Fig. 4 shows one complete molecule, and selected bond distances and angles are collected in Table 5. The ligand, as found in complex **5**, is the result of enolisation followed by deprotonation to give a planar, dianionic, tridentate moiety with a meridional disposition. The donor points O(1) (enolate), N(1) (azomethine), and O(2) (phenolate) occupy the equatorial plane [27,28] along with oxo oxygen atom O(4). The highly distorted octahedral coordination environment about Mo is completed at the axial positions by oxo ligand O(3) and the amine nitrogen atom N(3) of ppda. As with compound **3**, the Mo–L bond distances are bounded at the short end by the Mo=O bonds of ca. 1.7 Å (Table 6) and at the long end by a weak interaction to the amine nitrogen atom of the organic spacer [Mo(1)–N(3) = 2.470(5) Å]. The latter suggests that the Mo(1)–N(3) bond is a possible target for ligand exchange. The *trans* angles in the equatorial plane, O(2)–Mo(1)–O(1) [147.60(18)°] and O(4)–Mo(1)–N(1) [158.7(2)°], deviate significantly from linearity, as the Mo(VI) center is shifted out of the basal plane towards the apical oxo-oxygen atom O(3). The distance of Mo(1) from the plane of O(1), N(1), O(2), and O(4) is 0.338(2) Å.

Due to enolisation of the ligand, the C(1)–O(1) bond assumes single bond character, but the bond length of 1.307(8) Å lies between the lengths of C–O single and C=O double bonds and reflects a certain degree of electron delocalisation in the coordinated ligand [22,23]. The adjacent C(1)–N(2) bond length of 1.313(8) Å is closer to the usual C=N distance than to the normal C–N distance. The N(1)–N(2) bond distance of 1.375(7) Å reveals its predominantly single bond character. All of the above facts are consistent with enolisation of the hydrazone ligand and subsequent coordination to the MoO_2^{2+} core in the enolate form, with concomitant delocalisation along the ligand backbone [22,23]. The bite angles of the ligand in complex **5** are 71.47(18)° for O(1)–Mo(1)–N(1) and 80.33(19)° for O(2)–Mo(1)–N(1), typical values for five- and six-membered chelate rings, respectively.

3. Reactivity of the complex 2 [$(MoO_2L)_2(\mu$-4,4′-bpy)]

3.1. Oxo transfer to substrate: Isolation of dimolybdenum(IV,IV)-oxo complex (2a)

The dimolybdenum(IV,IV)-oxo complex (**2a**) was synthesized by a common method reported previously [13,17]. Formation of this complex illustrates the oxo transfer ability of the precursor dioxodimolybdenum(VI) complex, **2** [5,6,12–14]. This Mo(IV)–Mo(IV) dimer is quite rare. To the best of our knowledge, no diimine- and diamine-bridged dinuclear oxomolybdenum(IV) complex has been reported previously.

This Mo^{IV} dimer is air stable in the solid state and is found to be much stable in solution than the previously reported [13c,13d] Mo^{IV} monomers in similar type ligand environment. However, the compound is not sufficiently stable to get them recrystallized from acetonitrile or any other solvent and are slowly transformed to the parent yellow Mo(VI)–Mo(VI) dimer after 3–4 days. We failed to isolate good single crystals of Mo(IV)–Mo(IV) dimer by this process or from the actual reaction medium. Like the corresponding Mo(VI)–Mo(VI) dimers this Mo(IV)–Mo(IV) dimer is also sparingly soluble in solvents like CH_2Cl_2, $CHCl_3$ and CH_3CN, but are highly soluble in DMF and DMSO. This complex is a non-electrolyte and diamagnetic at room temperature [13].

Some spectral (IR and UV–Vis) characteristics of the compound **2a** are listed in Table 1. As in the case of the dinuclear MoO_2^{2+} complexes, IR spectral features of this MoO(IV) complex clearly reveals coordination from the deprotonated phenolic and enolic oxygens and the azomethine nitrogen. This complex exhibits a single strong, sharp band in the 960–940 cm^{-1} region, representing the $\nu(Mo{=}O)_t$ [13] mode.

Electronic spectra of the dimeric Mo(IV)-oxo compound is recorded in dry DMF solution, and the complex is found to display (Table 1) several absorption maxima in the 310–620 nm region and a new band of moderate intensity in the low energy 600–620 nm region. Absorption in this region is a characteristic feature of the $[MoO]^{2+}$ core [13,29,30].

4. Experimental

4.1. Materials

$[MoO_2(acac)_2]$ was prepared as described in the literature [31]. Reagent grade solvents were dried and distilled prior to use. All other chemicals were reagent grade, available commercially and used as received. Tetraethylammonium perchlorate (TEAP) used for electrochemical work was prepared as reported in the literature [32].

4.2. Physical measurements

Elemental analyses were performed on a Perkin–Elmer 240 C, H, N analyser. IR spectra were recorded on a Perkin–Elmer 783 spectrometer. ^1H NMR spectra were recorded with a Bruker AVANCE DPX 300 MHz spectrometer using $SiMe_4$ as internal standard. Electronic spectra were recorded on a Shimadzu UV/Vis recording spectrophotometer. Magnetic susceptibility was measured with a PAR model 155 vibrating sample magnetometer with Hg $[Co(SCN)_4]$ as calibrant. Electrochemical data were collected using an EG&G PARC electrochemical analysis system (model 250/5/0) and using a PC-controlled EG&G/PARC-VERSASTAT2 potentiostat at 298 K under a dry nitrogen. Cyclic voltammetry experiments were carried out with platinum working electrode, platinum auxiliary electrode and SCE as reference electrode and TEAP as supporting electrolyte.

4.3. Synthesis of ligand (H_2L)

The ligand, 2-hydroxybenzoylhydrazone of 2-hydroxybenzoylhydrazine (H_2L) was prepared [21] by reacting 2-hydroxybenzoylhydrazine (7.5 g, 49.34 mmol) and 2-hydroxybenzaldehyde (6.1 g, 50.00 mmol) in stirring ethanol (25 ml) for 2 h. The resulting yellowish-white compound was filtered, washed thrice with ethanol and dried over fused $CaCl_2$; m.p. 170 °C. Yield 70%. *Anal.* Calc. for $C_{14}H_{12}N_2O_3$: C, 65.62; H, 4.72; N, 10.94. Found: C, 65.36; H, 4.59; N, 11.06%. ^1H NMR (DMSO d_6, δ): 7.91–6.91 (m, 8H, C_6H_4), 8.68 (s, 1H, CH), 11.18 (s, 1H, NH), 11.76 (s, 1H, OH), 12.02 (s, 1H, OH),

4.4. Synthesis of [$MoO_2L(C_2H_5OH)$] (1)

0.28 g (1.09 mmol) of H_2L was dissolved in 30 mL ethanol by refluxing on a water bath and 0.33 g (1.01 mmol) of solid $MoO_2(acac)_2$ was added to the ligand solution and the mixture was refluxed for 3 h and filtered. Slow evaporation of the orange filtrate over 5 days produced orange-red crystals. Yield 75%. *Anal.* Calc. for $C_{16}H_{16}N_2O_6Mo$: C, 44.83; H, 3.76; N, 6.53. Found: C, 44.45; H, 3.51; N,

6.51%. ^{1}H NMR (DMSO d_6, δ): 7.82–6.97 (m, 8H, C_6H_4), 9.12 (s, 1H, CH), 11.39 (s, 1H, OH).

4.5. Synthesis of $[(MoO_2L)_2(\mu\text{-}4,4'\text{-bpy})]$ (2)

To a clear orange solution (obtained by refluxing) **1** (0.22 g, 0.51 mmol) in ethanol (50 mL) alcoholic solution of 4,4′-bpy (0.08 g, 0.51 mmol) was added and the mixture was allowed to reflux for 2 h. The yellowish turbid solution was filtered through qualitative filter paper. On standing for 12–14 h at room temperature, the yellow filtrate deposited orange crystals. The crystals were thoroughly washed with alcohol and dried over fused $CaCl_2$ and a suitable single crystal was selected for X-ray crystal structure analysis. Yield 79%. *Anal*. Calc. for $C_{38}H_{28}N_6O_{10}Mo_2$: C, 49.54; H, 3.06; N, 9.12. Found: C, 49.57; H, 2.94; N, 9.27%. ^{1}H NMR (DMSO d_6, δ): 8.73–6.96 (m, 16H, C_6H_4, $C_{10}H_8N_2$), 9.12 (s, 1H, CH), 11.39 (s, 1H, OH).

4.6. Synthesis of $[(MoO_2L)_2(\mu\text{-}4,4'\text{-bpe})]\cdot 0.5C_2H_5OH$ (3)

This compound was prepared using same procedure as in the case of compound **2** using *trans*-1,2-bis(4-pyridyl) ethene (bpe) in place of 4,4′-bipy as the bridging ligand. Yield 80%. *Anal*. Calc. for $C_{41}H_{33}N_6O_{10.5}Mo_2$: C, 50.74; H, 3.43; N, 8.66. Found C, 50.51; H, 3.52; N, 8.67%. ^{1}H NMR (DMSO d_6, δ): 8.60–6.96 (m, 16H, C_6H_4, $C_{12}H_{10}N_2$), 9.12 (s, 1H, CH), 11.39 (s, 1H, OH).

4.7. Synthesis of $[(MoO_2L)_2(\mu\text{-}4,4'\text{-bpa})]$ (4)

This compound was prepared using same procedure used in the case of compound **2** taking *trans*-1,2-bis(4-pyridyl) (bpa) ethane as the bridging ligand. Yield 80%. *Anal*. Calc. for $C_{42}H_{36}N_6O_{11}Mo_2$: C, 50.77; H, 3.65; N, 8.46. Found: C, 50.61; H, 3.75; N, 8.59%. ^{1}H NMR (DMSO d_6, δ): 8.55–6.95 (m, 16H, C_6H_4, $C_{12}H_{12}N_2$), 9.10 (s, 1H, CH), 11.24 (s, 1H, OH).

4.8. Synthesis of $[(MoO_2L)_2(\mu\text{-}4,4'\text{-ppda})]$ (5)

This compound was prepared using same procedure used in the case of compound **2** using *p*-phenylenediamine (ppda) as the bridging ligand. Yield 78%. *Anal*. Calc. for $C_{34}H_{28}N_6O_{10}Mo_2$: C, 46.76; H, 3.23; N, 9.62. Found: C, 47.20; H, 3.25; N, 9.65%. ^{1}H NMR (DMSO d_6, δ): 7.81–6.35 {m, 12H, C_6H_4, $C_6H_4(NH_2)_2$}, 9.12 (s, 1H, CH), 11.39 (s, 1H, OH), 4.28 (s, 2H, NH_2).

4.9. Synthesis of $[(MoOL)_2(\mu\text{-}4,4'\text{-bpy})]$ (2a)

This compound was prepared using same procedure as our previous works [13]. To a refluxing solution of 0.22 g (0.24 mmol) of $[(MoO_2L)_2(\mu\text{-}4,4'\text{-bpy})]$ (**2**) in 25 mL of degassed acetonitrile 0.197 g (0.75 mmol) of PPh_3 in 5 mL of acetonitrile is added. The orange solution turned reddish brown and a reddish brown compound separated within 1 h was collected by rapid filtration of the hot mixture, washed well with hot acetonitrile and dried in vacuo; yield 65%. *Anal*. Calc. for $C_{38}H_{28}N_6O_9Mo_2$: C, 50.41; H, 3.12; N, 9.29. Found: C, 50.77; H, 3.04; N, 9.13%.

4.10. Crystal structure determination

Suitable single crystals of **1** ($0.34\times0.32\times0.24$ mm), **2** ($0.23\times0.28\times0.19$ mm), **3**, ($0.18\times0.17\times0.08$ mm^3) and **5** ($0.10\times0.10\times0.15$ mm) were chosen for X-ray diffraction studies. Crystal data and other parameters for Complexes **1**, **2**, **3**, and **5** are given in Table 6. Intensity data for **1**, **2** and **3** were collected at room temperature and for **5** at 100 K, on Bruker Smart CCD diffractometers using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The intensities were corrected for absorption effects using SADABS [33]. The structures were solved by direct methods. All non-hydrogen atoms were refined anisotropically by full-matrix least squares, with a riding model for the hydrogen atoms, using the SHELXTL package [34].

5. Concluding remarks

A few diamine/diimine-bridged dimolybdenum(VI) complexes of the type $[(MoO_2L)_2(\mu\text{-N–N})]$ (**2–5**) are obtained from their mononuclear precursor $[MoO_2L(C_2H_5OH)]$ (**1**) involving a dianionic tridentate ONO donor ligand. Three such dinuclear Mo(VI)–Mo(VI) complexes are structurally characterized by X-ray crystallography. One corresponding Mo(IV)–Mo(IV) complex **2a** is prepared by utilizing the oxo-transfer (to substrate) capacity of the corresponding Mo(VI)–Mo(VI) dinuclear species to the substrate triphenylphosphine.

6. Supplementary data

The view of the extended crystal structure and the details of the packing for the complex $[(MoO_2L)_2(\mu\text{-bpe})]$ (**3**) are reported as Supporting Information (Fig. 3a and b). Crystallographic data have been deposited with the CCDC. Copies of this information may be obtained free of charge from the director, CCDC, 12, Union Road, Cambridge, CB2 1EZ, UK [fax(internet.): +44 1223/336 033; e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk quoting the deposition number CCDC 244288 (complex **1**), 244289 (complex **2**), 244290 (complex **3**) and 244291 (complex **5**).

Acknowledgments

Financial support from the Spanish Ministry of Science and Technology (Grant BQU2002-00554) and the European Regional Development Fund is gratefully acknowledged by L.R.F. and M.T. Valuable assistance from Drs. Rosa Llusar and Tatiana Soler is also appreciated.

R.D. thanks Dr. S.K. Chattopadhyay, Bengal Engineering College (Deemed University) for fruitful discussion.

2. Experimental

2.1. Materials and methods

Cadmium acetate, mercury acetate, tmeda (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine), tri-*n*-octylphosphineoxide (TOPO) and hexadecylamine (HDA) were obtained from commercial sources and were used without further purification. $HgCl_2 \cdot$ tmeda was prepared by refluxing $HgCl_2$ and excess tmeda in dichloromethane under an inert atmosphere for 2 h. Bis(2-dimethylaminoethyl)diselenide was prepared according to the literature method [25]. Solvents were dried and distilled before use under a nitrogen atmosphere. HPLC grade toluene was used in all experiments involved with a capping agent and pyridine was used in pyrolysis experiments for optical studies. Melting points were determined in capillary tubes and are uncorrected. Elemental analyses were carried out by the Analytical Chemistry Division of B.A.R.C. ^{1}H and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker DPX-300 NMR spectrometer operating at 300 and 75.47 MHz, respectively. Chemical shifts are relative to the internal chloroform peak at δ 7.26 for ^{1}H and δ 77.0 for $^{13}C\{^1H\}$. UV–Vis absorption spectra were recorded on a Chemito Spectrascan UV 2600 double beam UV–Vis spectrophotometer. Fluorescence spectra were recorded using a Hitachi F-4010 spectrofluorometer. Time-resolved fluorescence measurements were carried out using a diode laser based time-correlated-single-photon-counting (TCSPC) spectrometer. In the present investigation, a 408 nm diode laser (1 MHz) was used as the excitation source and a TBX4 detection module coupled with a special Hamamatsu PMT was used for fluorescence detection. The instrument response function was ~230 ps at the FWHM. IR spectra were recorded on a Bomem MB-102 FT-IR spectrometer. Thermogravimetric analyses (TGA) were carried out on a Mettler TA–3000 instrument, which was calibrated with $CaC_2O_4 \cdot H_2O$. TG curve was recorded at a heating rate of 10 °C min^{-1} under a flow of nitrogen. X-ray powder diffraction data were collected on a Philips X-ray diffractometer (Model PW 1729) using Cu Kα radiation. A JEOL-2000FX transmission electron microscope operating at accelerating voltages up to 200 kV was used for TEM studies. The samples for TEM and SAED were prepared by placing a drop of a dilute solution of nanoparticles in acetone or pyridine on a carbon coated copper grid. EDAX was performed using a JEOL JSM-T330A instrument.

2.2. Synthesis of complexes

2.2.1. $[Cd(SeCH_2CH_2NMe_2)_2]$

A dichloromethane suspension (20 cm^3) of $Cd(OAc)_2 \cdot 2H_2O$ (664 mg, 2.49 mmol) was added to a freshly prepared methanolic solution of $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (757 mg, 2.51 mmol) and $NaBH_4$ (193 mg, 5.10 mmol)] with continuous stirring at room temperature. After 3 h the colorless solution was dried in vacuo and the oily residue was washed with hexane and dried again in vacuo. The residue was extracted with CH_2Cl_2 (3×10 cm^3), filtered to remove NaOAc and the filtrate was evaporated under reduced pressure to give a white solid, which was recrystallized from dichloromethane-ethylacetate mixture. Yield: 702 mg (68%). mp 93–95 °C. *Anal.* Calc. for $C_8H_{20}N_2CdSe_2$: C, 23.2; H, 4.8; N, 6.8. Found: C, 23.0; H, 4.9; N, 6.6%. ^{1}H NMR (in $CDCl_3$) δ: 2.28 (s, NMe_2); 2.56 (br, $SeCH_2$); 2.74 (br, NCH_2). $^{13}C\{^1H\}$ NMR (in $CDCl_3$) δ: 15.5 (s, $SeCH_2$); 45.8 (s, NMe_2); 62.9 (s, NCH_2). The NMR spectra (^{1}H) in some samples showed additional peaks of low intensity (<5%) which may be attributed to $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$. The microanalysis of the latter (Calc. for $C_{20}H_{46}Cd_3N_4O_4Se_4$: C, 22.6; H, 4.3; N, 5.3%) is not significantly different from the bis derivative.

2.2.2. $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$

To a dichloromethane solution (5 cm^3) of $[Cd(SeCH_2CH_2NMe_2)_2]$ (187 mg, 0.45 mmol), a methanolic solution (5 cm^3) of $Cd(OAc)_2 \cdot 2H_2O$ (59 mg, 0.22 mmol) was added and the whole was heated at 40 °C with stirring for 2 h. The solvents were evaporated under vacuum and the residue was extracted with dichloromethane (5 cm$^3 \times 4$) and filtered through a fine filter. The filtrate was concentrated under vacuum to give a colorless powder (230 mg, 96%), mp 170 °C (dec. turns red). ν_{max}/cm^{-1} 1560 (C=O). ^{1}H NMR (in $CDCl_3$) δ: 2.05 (s, O_2CMe); 2.33 (s, NMe_2); 2.63 (br, $SeCH_2$); 2.82 (br, NCH_2). $^{13}C\{^1H\}$ NMR (in $CDCl_3$) δ: 16.4 (s, $SeCH_2$, ^1J(Se–C) = 57 Hz); 21.6 (s, O_2CMe); 45.5 (s, NMe_2); 62.0 (s, NCH_2); 179.4 (s, C=O).

2.2.3. Attempted preparation of $[Hg(SeCH_2CH_2NMe_2)_2]$

A dichloromethane solution (20 cm^3) of $HgCl_2 \cdot$ tmeda (201 mg, 0.51 mmol) was added to a freshly prepared methanolic solution of $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (159 mg, 0.53 mmol) and $NaBH_4$ (44 mg, 1.16 mmol)] with continuous stirring at room temperature. After 3 h, a black precipitate settled down. The supernatant was decanted and the black precipitate was washed with hexane, acetone in sequence and then with water, acetone and dried in vacuo. Found: C, 1.8; H, 0.2; N, <0.2%. XRD pattern of this black powder was well in agreement with the pattern for cubic HgSe (JCPDS File No.73-1668). Similar results were obtained when $Hg(OAc)_2$ was used in place of $[HgCl_2 \cdot$ tmeda].

2.3. Synthesis of CdSe nanoparticles

2.3.1. Pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ in HDA–TOPO mixture

In a three necked flask fitted with a thermometer, a continuously stirred mixture of HDA (2.39 g) and TOPO (185 mg) was degassed at 120 °C under argon atmosphere for 1 h. The temperature was slowly raised to 187 °C and stabilised at this temperature. To this, a solution of $[Cd(SeCH_2CH_2NMe_2)_2]$ (140 mg, 0.34 mmol) in a mixture

of dichloromethane (2 cm^3), toluene (2 cm^3) and TOPO (200 mg) was injected rapidly. The temperature dropped to 160 °C and was slowly raised to and maintained at 185 °C. Fractions were collected at 4 min (***fraction 1***) and 6 min (***fraction 2***) in vials containing methanol (5 cm^3). The hot solution at the end of 30 min (***fraction 3***) was cooled down to 70 °C and methanol was added to precipitate red nanoparticles. The red floculate was given a thorough washing with methanol followed by centrifuging and drying under vacuum.

Under similar conditions, a larger quantity of $[Cd(SeCH_2CH_2NMe_2)_2]$ (414 mg, 1.00 mmol) was pyrolysed in a mixture of HDA (7.09 g) and TOPO (1.00 g) and the reaction was quenched after 20 min (***fraction 4***) by adding methanol.

2.3.2. Pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ in a furnace

Pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ was carried out in a furnace under different conditions. In each experiment a weighed quantity (~80 mg) of the complex was dispersed in a small quartz boat by using dichloromethane and was subjected to pyrolysis. In one experiment the boat containing the complex was rapidly introduced into a preheated (180 °C) furnace and was kept at this temperature for 1 h under flowing nitrogen whereupon a yellowish-orange coat of CdSe (***fraction 5***: Found: C, 6.3; H, 1.8; N, 2.8%) was formed. In other experiments the furnace temperature was raised from room temperature to 200 °C in 5 min and the samples were heated at this temperature for 1 h either under flowing N_2 (***fraction 6***: Found: C, 6.9; H, 1.2; N, 1.6%) or under vacuum (***fraction 7***: Found: C, 5.6; H, 1.0; N, 1.6%), leading to the formation of a dark red CdSe coat. For optical measurements, small quantities of ***fractions 5–6*** were immediately dissolved in pyridine.

Table 1
Crystallographic and refinement data for $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$

Chemical formula	$C_{20}H_{46}Cd_3N_4O_4Se_4$
Formula weight	1059.65
Crystal size (mm^3)	$0.2 \times 0.2 \times 0.1$
Wavelength (Å)	0.71069
Crystal system	monoclinic
Space group	C_2/c
Unit cell dimensions	
a (Å)	24.700 (5)
b (Å)	13.309 (3)
c (Å)	11.575 (3)
β (°)	115.38 (4)

2.4. Crystallography

X-ray data of a colorless crystal of $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$ were collected at room temperature on an Enraf-Nonius CAD-4 diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71069$ Å) and employing the ω–2θ scan technique. The unit cell parameters (Table 1) were determined from 25 reflections measured by a random search routine. The intensity data were corrected for Lorentz, polarization and absorption effects (ψ scans). The structure was solved by direct methods using the SIR-92 program. The structure was completed by successive Fourier synthesis and refined using the SHELXL-97 program. The non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms could not be located reliably through difference Fourier maps due to disorder of the carbon atoms and hence were ignored.

3. Results and discussion

3.1. Synthesis and spectroscopy

Reaction of $Cd(OAc)_2 \cdot 2H_2O$ with $NaSeCH_2CH_2NMe_2$, prepared by the reduction of $(Me_2NCH_2CH_2Se)_2$ with $NaBH_4$ in methanol, gave a colorless homoleptic selenolate complex $[Cd(SeCH_2CH_2NMe_2)_2]$ (Eq. (1)). The freshly prepared complex is soluble in CH_2Cl_2, $CHCl_3$, benzene, toluene and methanol, but solubility decreases with aging, finally leading to a poorly soluble product. The NCH_2 and $SeCH_2$ proton resonances in the ^1H NMR spectrum appeared as broadened triplets which were shielded from the corresponding resonances for $(Me_2NCH_2CH_2Se)_2$. Several attempts to recrystallize the product from a mixture of solvents (CH_2Cl_2–hexane, CH_2Cl_2–MeCOOEt) gave either a colorless powder or flakes from which in some cases a few cubic crystals were separated which were identified by X-ray crystallography as a trinuclear cadmium complex, $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$. The latter complex, however, can readily be prepared by a redistribution reaction between $Cd(OAc)_2 \cdot 2H_2O$ and the bis complex, $[Cd(SeCH_2CH_2NMe_2)_2]$. Attempts to prepare the mercury complex, $[Hg(SeCH_2CH_2NMe_2)_2]$ using reaction route 1 led to excessive decomposition with the formation of cubic HgSe at room temperature.

3.2. Crystal structure of $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$

The molecular structure of $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$, established unambiguously by X-ray diffraction analysis, is shown in Fig. 1 and selected interatomic parameters are listed in Table 2. The molecule has a twofold rotation axis passing through the central cadmium atom and hence half the molecule forms the crystallographic asymmetric unit. The $Me_2NCH_2CH_2Se$ fragments in the molecule are disordered and act in a chelating bridging fashion. The two terminal cadmium atoms adopt a skew trapezoidal planar geometry in which the basal plane is defined by two O and two Se atoms. The two remaining positions are occupied by the N atoms which are almost linear (∠N(1)–Cd(1)–N(2) 178.2 (3)°). The acetate ligand is asymmetrically chelated with two slightly different Cd–O distances, whereas the two C–O distances are essentially similar. The two Cd–Se distances differ marginally.

The coordination around the central cadmium is defined by four selenium bridges and adopts a pyrimidalized configuration with various angles varying between the ideal values of tetrahedral (109°) and square plane (90°). The two Cd–Se bonds are shorter than the other two. All the Cd–Se [28,29], Cd–N [28,30] and Cd–O [31] distances are well in agreement with values reported in other complexes.

3.3. Thermal studies

The TG curve (Fig. 2) of $[Cd(SeCH_2CH_2NMe_2)_2]$ showed that the complex decomposed in a single step at 155 °C to CdSe as inferred from the weight loss (Found: weight loss 52.6%; calcd. weight loss 53.8%).

Pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ was carried out under different conditions, either in HDA/TOPO mixture or in a furnace. Pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ in a furnace gave either cubic (***fractions 5*** and ***6***) or hexagonal (***fraction 7***) CdSe nanoparticles (from XRD, see later) which were formed under a flowing inert gas or vacuum, respectively. The microanalyses data of ***fractions 5–7*** suggest that the CdSe may be capped by the amine residues evolved on pyrolysis of the complex.

Pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ in a HDA/TOPO mixture gave HDA capped CdSe nanoparticles. The IR

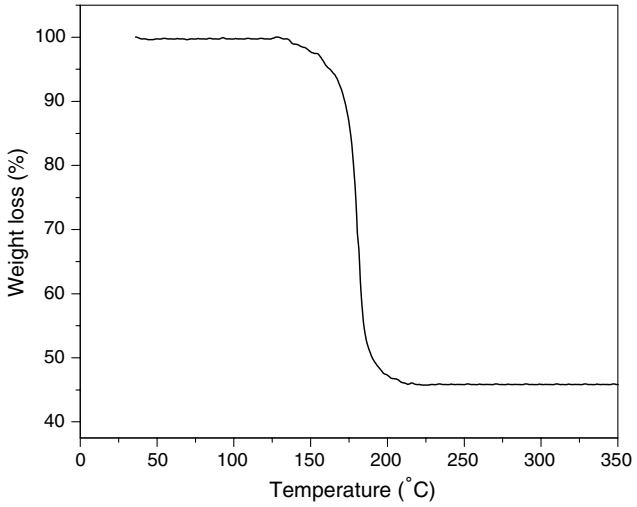

Fig. 2. TG curve of $[Cd(SeCH_2CH_2NMe_2)_2]$.

spectra of ***fractions 1–4*** (Fig. 3) displayed a shift of ν(N–H) to lower wavenumbers compared to that of free HDA (for free HDA ν(N–H) = 3333 cm^{-1}), indicating coordination of HDA. The $^{31}P\{^1H\}$ NMR chemical shifts for

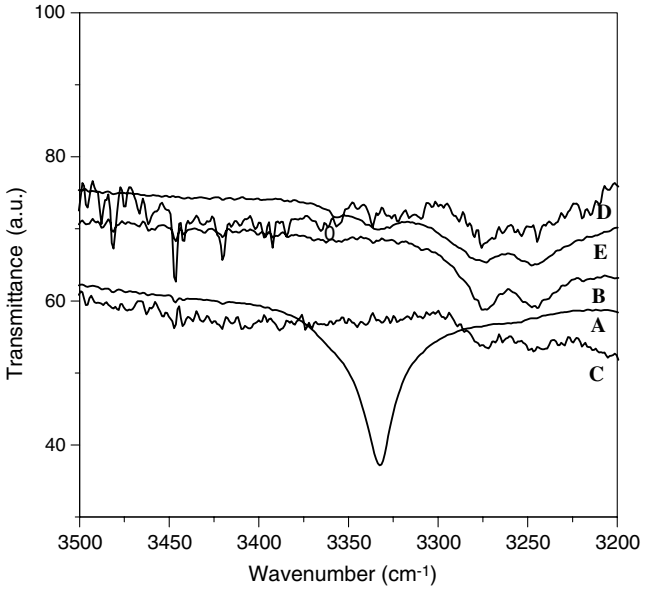

Fig. 3. IR spectra of **A**: free HAD, **B**: ***fraction 1***, **C**: ***fraction 2***, **D**: ***fraction 3*** and **E**: ***fraction 4***.

fraction 4 (δ 44.0 ppm) and free TOPO (δ 43.5 ppm) are comparable suggesting the absence of TOPO capping of CdSe nanoparticles.

3.4. Powder X-ray diffraction

XRD patterns (Fig. 4) of CdSe prepared by pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ under different conditions showed broad peaks which are typical for particles in the nano regime. The particle sizes estimated from Scherrer's formula come out to be 12, 6, 4, 9 and 8.3 nm for ***fractions 3***, ***4***, ***5***, ***6*** and *7*, respectively. The pattern can be assigned to the cubic phase of CdSe in the case of ***fractions 5*** and ***6*** and the hexagonal phase of CdSe in the case of ***fraction 7*** (Table 3). In the case of ***fraction 7***, we have used X-ray peak fitting software to confirm whether the first peak is a single peak or the overlap of three peaks and it is fitted into three peaks, which coincides with the hexagonal phase of CdSe. Assignment of the hexagonal phase of CdSe to ***fraction 7*** is further confirmed by its SAED pattern.

[b] JCPDS File No. 08-0459 (International Centre for Diffraction data – 1998).
[c] TEM of the sample was recorded after one month and therefore ripening might have taken place and hence a larger size compared to the one estimated from the XRD pattern.

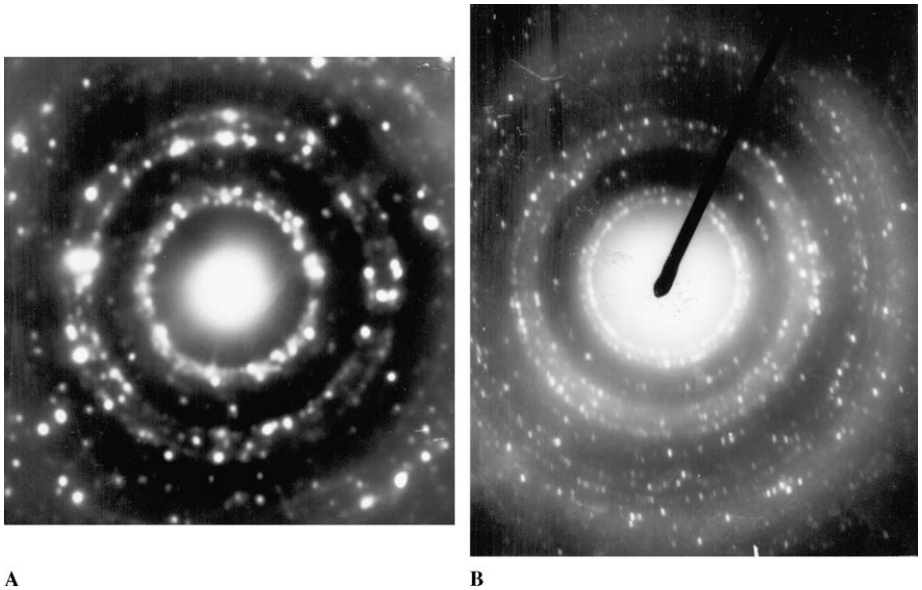
3.5. Electron microscopy

The selected area electron diffraction (SAED) patterns of ***fractions 4*** and *7* (Fig. 5) revealed the formation of crystalline CdSe. Clear diffraction rings corresponding to the lattice planes (111), (220) and (311) in the SAED pattern of the ***fraction 4*** were attributed to cubic CdSe. The SAED pattern of ***fraction*** *7* has been interpreted in terms of the hexagonal phase of CdSe with diffraction rings corresponding to the lattice planes (100), (101), (102), (110), (103), (112), (202) and (203). The phases determined from the SAED and XRD patterns were in agreement with each other. The TEM images of ***fraction 4*** (Fig. 6) and ***fraction*** *7* (Fig. 7) shows the particles are spherical in shape. The average diameters of particles of ***fraction 4*** and ***fraction*** *7*, estimated from TEM images, are $7.5 \pm 4\%$ and $21 \pm 8\%$ nm, respectively. In the case of ***fraction 4***, the particle size obtained from the TEM image is closer to that of the particle size calculated from the XRD pattern using Scherrer's formula. EDX spectra of ***fractions 3***, ***4***, ***6*** and *7* exhibited peaks for Cd and Se, which were in 1:1 ratios.

3.6. Optical properties

CdSe nanoparticles, prepared by pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ in a furnace, displayed absorption maxima at 423 (***fraction 5***), 538, 580 (***fraction 6***) and 455 nm (***fraction*** *7*) (Fig. 8). The excitation spectrum of ***fraction*** *7* at room temperature showed a broad exciton peak at 400 nm, whereas a broad maximum at 499 nm was observed in the emission spectrum (Fig. 8).

Absorption, excitation and emission spectra of HDA capped CdSe nanoparticles, prepared by pyrolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ in HDA/TOPO mixture are given in Figs. 9–11. Absorption spectra (Fig. 9) of HDA capped CdSe nanoparticles displayed a typical band edge absorption with an exciton band and the spectra are well in agreement with those reported earlier [17,19,32]. ***Fractions 1–4*** showed exciton maxima at 490, 549, 625 and 582 nm,



A B

Fig. 5. SAED pattern CdSe nanoparticles of **A**: ***fraction 4*** and **B**: ***fraction*** *7*.

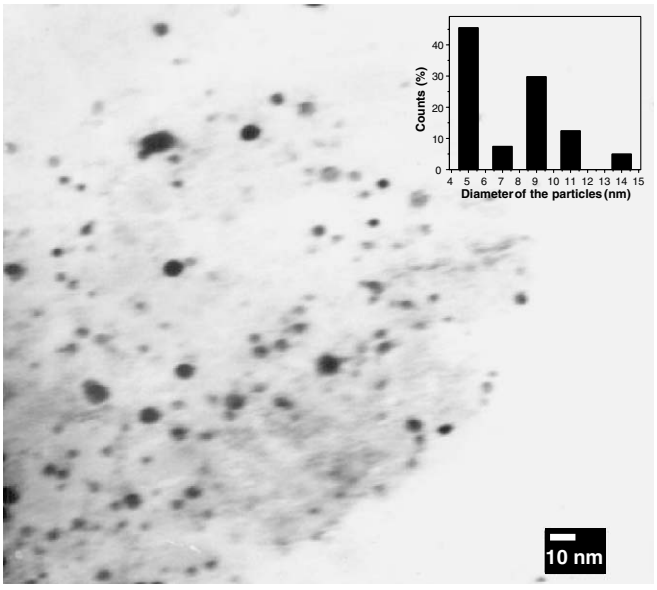


Fig. 6. TEM picture of capped CdSe nanoparticles of ***fraction 4***. Inset shows particle size distribution.

respectively, which are blue shifted with respect to bulk CdSe ($\lambda_{onset} = 713$ nm), confirming the quantum confinement effect of the particles. The absorption maximum of the fractions collected at different time intervals showed a red shift with increasing time, which is in accordance with earlier reports [33]. The excitation spectra (Fig. 10) for each fraction are found to have maxima at 494, 549 and 625 nm, respectively, at room temperature. These excitation maxima coincide well with the absorption band edges of the three ***fractions 1–3*** at 490, 547 and 625 nm, respectively. The emission spectra (Fig. 11) displayed two peaks each in ***fractions 1*** (518, 640 nm) and ***2*** (573 and 719 nm) corresponding to band edge and trap state emissions [34–36].

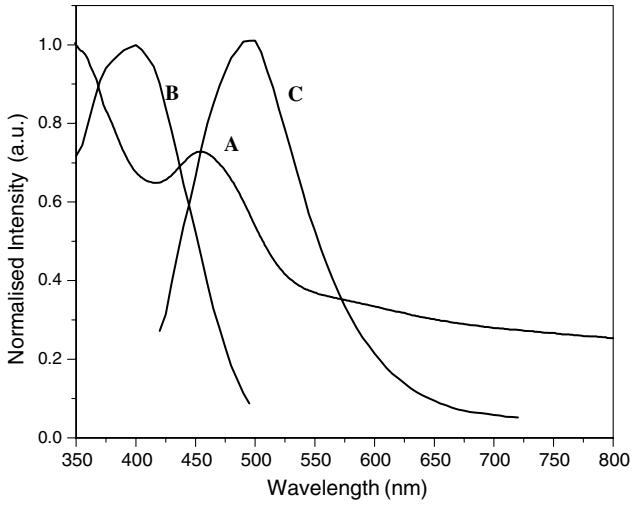

Fig. 8. **A**: Absorption spectrum, **B**: excitation spectrum and **C**: emission spectrum of CdSe nanoparticles of ***fraction 7***.

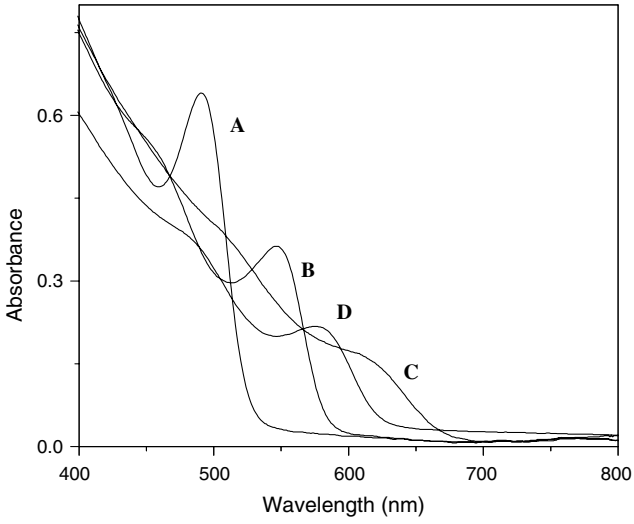

Fig. 9. Absorption spectra of HDA capped CdSe nanoparticles **A**: ***fraction 1***, **B**: ***fraction 2***, **C**: ***fraction 3*** and **D**: ***fraction 4***.

The spectra showed narrow band edge emission peaks in these fractions, implying that the particle size distribution is narrow as the width of the emission peaks depend on the size distribution of the particles [19]. The ***fractions 3*** and ***4***, however, showed only a broad and a narrow peak corresponding to band edge emissions at 637 and 605 nm, respectively, implying a slightly broad and narrow distribution of the particles in these fractions. The particle sizes estimated using Brus's expression [37] for the ***fractions 1–4*** are 5, 6.4, 12.2 and 7.9 nm, respectively, and compare well with the size estimated employing Scherrer's formula (Table 3).

To understand the charge carrier dynamics, we have carried out time-resolved luminescence measurements (Fig. 12) of ***fractions 1*** and ***3***. For all the samples, excitation was carried out at 408 nm. For ***fraction 1***, lifetimes for both the band edge and trap state components were taken while

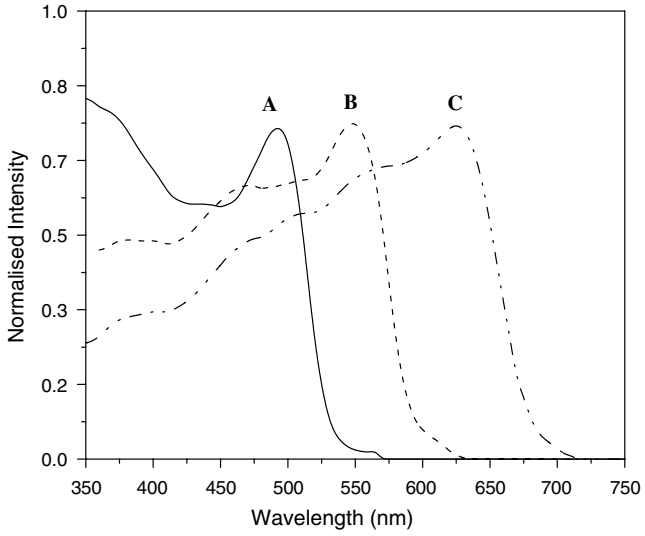

Fig. 10. Excitation spectra of HDA capped CdSe nanoparticles **A**: ***fraction 1***, **B**: ***fraction 2*** and **C**: ***fraction 3***.

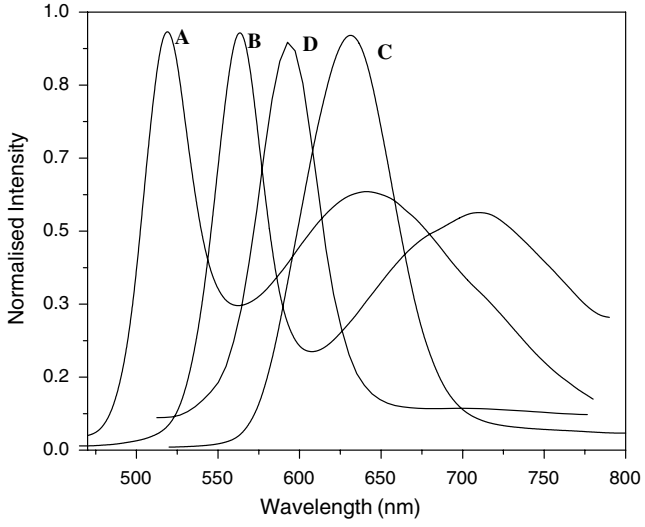

Fig. 11. Emission spectra of HDA capped CdSe nanoparticles **A**: ***fraction 1***, **B**: ***fraction 2***, **C**: ***fraction 3*** and **D**: ***fraction 4***.

for ***fraction 3***, the band edge component was studied. A multi-exponential function has been used to fit the data for a reasonable fit in all the cases. Three different decay times for each band edge [0.5 (68%), 8.3 (24%), 61.5 (8%) ns] and trap state components [1.8 (29%), 12.3 (36%), 73.7 (35%) ns] for ***fraction 1*** were observed. Similarly three decay times [2.9 (45%), 12.5 (46%) and 49.1 (9%) ns] for the band edge emission for ***fraction 3*** were identified. The multi-exponential character of the decay, even when photoluminescence shows well resolved lines, can be attributed to the overlap of various contributions arising from different particles [38]. The decay times of band edge and trap state emission of ***fraction 1*** shows that the former component is faster than the latter. The decay times of the band edge component of ***fraction 1*** is also faster than that of ***fraction 3***, showing size dependence of life times and is in agreement with the reported data [32].

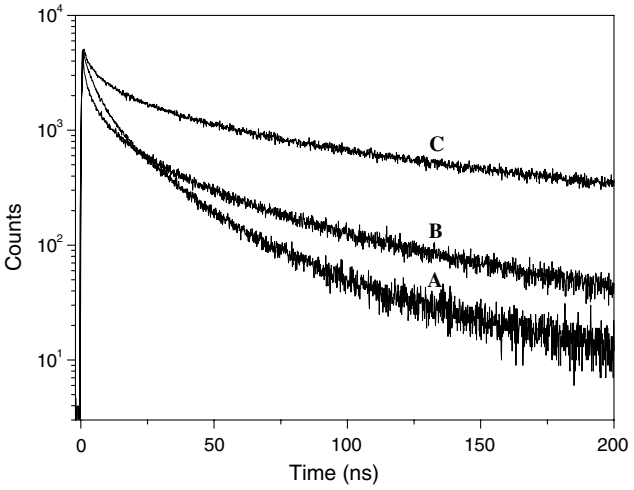

Fig. 12. Lifetime measurements of **A**: band edge component of ***fraction 3***, **B**: band edge component of ***fraction 1*** and **C**: trap state component of ***fraction 1***.

4. Conclusion

The single source precursor $[Cd(SeCH_2CH_2NMe_2)_2]$, prepared conveniently, has been employed for the synthesis of CdSe nanoparticles. The size and phase (cubic and hexagonal) of these particles is conveniently controlled by varying the pyrolysis conditions. Both absorption and emission bands of these nanoparticles showed size dependence and were blue shifted with decreasing particle size. The band edge and trap state showed three different decay times.

5. Supplementary materials

CCDC-277552 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (internat.) +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk].

Acknowledgements

We thank Drs. T. Mukherjee and S.K. Kulshreshtha for encouragement of this work. We are also grateful to Dr. M. Sudarsanan, Head, Analytical Chemistry Division for providing microanalyses of the complexes and Dr. G. Ramakrishna for helpful discussions.

2.2. Preparation of $RuOs_3(\mu\text{-}H)_2(CO)_{11}(PMe_3)_2$

The previously reported procedure was employed, except that an excess of PMe_3 was used, which upon chromatographic separation afforded two isomers initially as separate bands.

$RuOs_3(\mu\text{-}H)_2(CO)_{11}(PMe_3)_2$, Ru,Os-**3h**, yield = 38%; ν_{CO}/cm^{-1} (hexane) 2076m, 2050mw, 2042vs, 2012s, 2001s, 1992mw, 1970mw, 1755mw, br. MS: 1133.5 (M^+). *Anal.* Calc. for $C_{17}H_{20}O_{11}Os_3P_2Ru \cdot CH_2Cl_2$: C, 17.73; H, 1.82. Found: C, 17.61; H, 1.93%.

$RuOs_3(\mu\text{-}H)_2(CO)_{11}(PMe_3)_2$, Ru,Ru-**3h**, yield = 35%; ν_{CO}/cm^{-1} (hexane) 2082m, 2050s, 2025vs, 2005s, 1984m, 1978m, 1943mw. MS: 1133.5 (M^+).

2.3. Crystal structure determinations

Crystals were mounted on quartz fibres. X-ray data were collected on a Bruker AXS APEX system, using Mo Kα radiation, with the SMART suite of programs [3]. Data were processed and corrected for Lorentz and polarisation effects with SAINT [4], and for absorption effects with SADABS [5]. Structural solution and refinement were carried out with the SHELXTL suite of programs [6]. Atomic coordinates are given in the Supporting Information; crystal and refinement data are listed in Table 1.

The structures were solved by direct or Patterson methods to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. Organic hydrogen atoms were placed in calculated positions and refined with a riding model. The metal hydrides were either located by low angle difference maps (Ru,Os-**3a**,**3h**) or placed by potential energy calculations with the program XHYDEX [7]. The hydrides were given fixed isotropic thermal parameters and the M–H distance fixed at 1.84 Å. With the exception of those mentioned below involving disordered parts, all non-hydrogen atoms were given anisotropic thermal parameters in the final model. Refinements were on $\sum[w(F_o^2 - F_c^2)^2]$.

With the exception of Ru,Ru-**3h**, all the clusters exhibited disorder of the metal core. Each disordered site was modelled with a partial osmium and ruthenium, given identical anisotropic thermal parameters and positions, with sum of the occupancies of ruthenium over all sites restrained to 1.0. The Ru/Os disorder was modelled over two sites and (except for Os,Os-**3a**) these were the vertices attached to the group 15 atoms. There was also disorder of phenyl over cyclohexyl rings over two sites in **3f**, and of one of the phenyl rings in **3c** over two orientations, which were modelled with fixed occupancies and the same isotropic thermal parameters for atoms at the same corresponding site. Appropriate restraints were also applied. Solvent molecules were found in Ru,Os-**3a**, **3c** and **3f**, and they were also disordered and modelled accordingly with restraints as appropriate.

3. Results and discussion

3.1. Solid state structures

The single crystal X-ray structures of seven disubstituted derivatives have been determined, which are those for the ligands EPh_3 (E = P, As, Sb), PCy_2Ph, and PMe_3. As may be expected, the number of structural types is more diverse than for the monosubstituted derivatives; the six clusters may be classified into four structural types A–D. The ORTEP plots for Os,Os-**3a**, **3b**, Ru,Os-**3h** and Ru,Ru-**3h**, illustrating the four structural types, are shown in Figs. 1–4, respectively. For PPh_3,

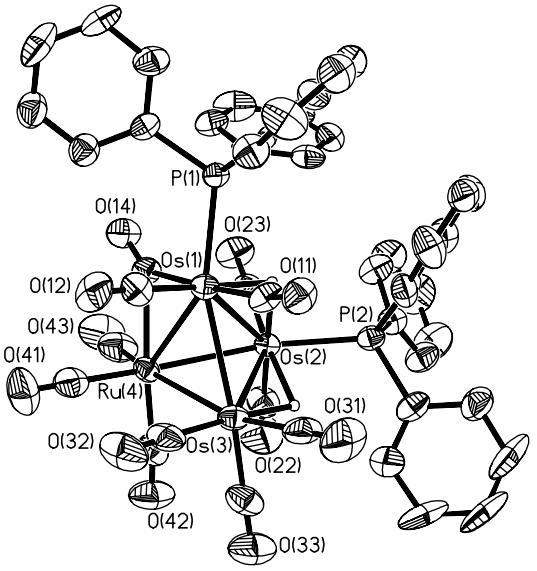

Fig. 1. ORTEP diagram of Os,Os-**3a** (50% thermal ellipsoids) with organic hydrogens omitted.

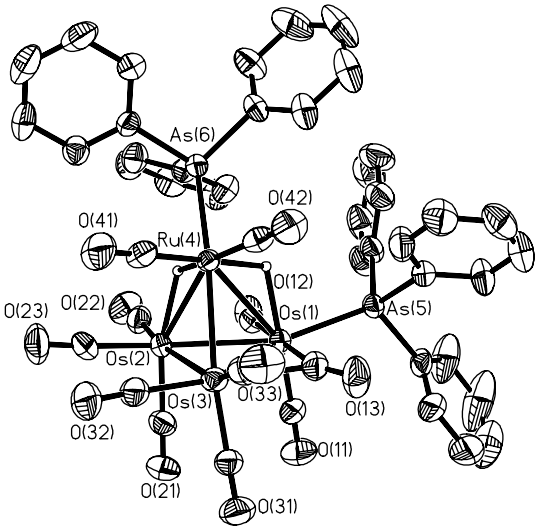

Fig. 2. ORTEP diagram of **3b** (50% thermal ellipsoids) with organic hydrogens omitted.

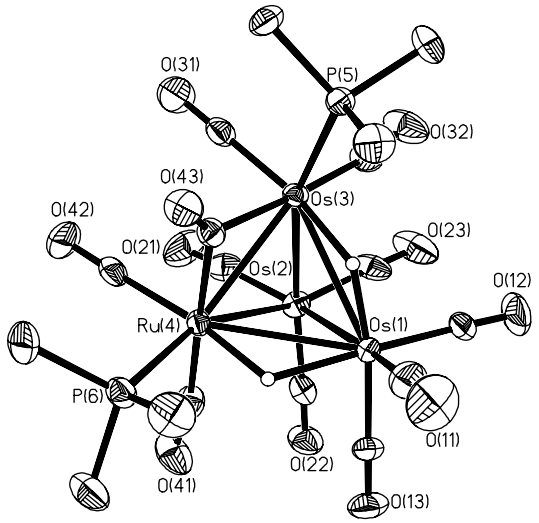

Fig. 3. ORTEP diagrams of Ru,Os-**3h**. Thermal ellipsoids are drawn at the 50% probability level; organic hydrogens are omitted.

the disorder in the structure of Os,Os-**3a** has been modelled such that in 2/3 (refined value) of the molecules both the phosphine ligands are on different Os vertices, while the other 1/3 has one of the phosphine ligands on the Ru vertex; they correspond to structural types A and B, respectively. For PMe_3, two isomeric forms were available as crystals, one of which had both the phosphine ligands substituted at the same Ru vertex (Ru,Ru-**3h**). With the exception of Ru,Ru-**3h**, the solid-state structures of the others exhibit disorder of the Ru/Os vertices. There appears to be some trend to the disorder for, with the exception of Os,Os-**3a**, the Ru/Os disorder is over the

two vertices carrying the group 15 ligands. Furthermore, for those with the EPh_3 (E = P, As, Sb) ligands, viz., **3a**–**c**, the degree of disorder is similar (an approximate 1:3 ratio).

Table 2 shows the selected bond parameters for the six structurally characterised disubstituted derivatives. Besides the two bridging hydrides, which share a common vertex, there are at least two bridging or semi-bridging carbonyls as well. Five of the clusters have a group 15 ligand on a Ru and an Os vertex. As already pointed out for the monosubstituted derivatives, there is an electronic preference for substitution at a Ru vertex; the reason for generally only one substitution at a vertex is probably steric since disubstitution at the same vertex is observed only for the ligand with the smallest cone angle

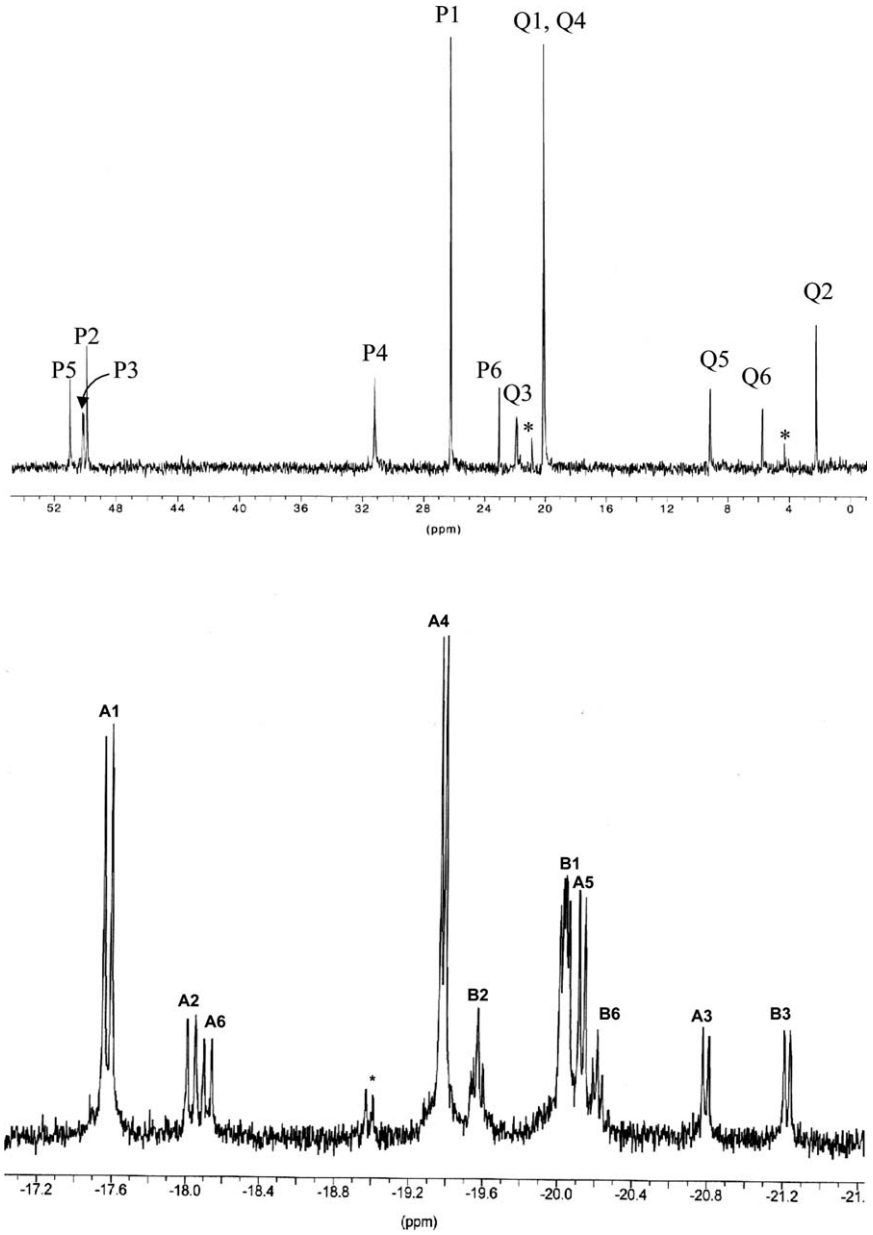

Fig. 6. $^{31}P\{^1H\}$ (top) and ^1H (bottom) NMR spectra ($CDCl_3$, 300 K) of **3a**. Resonances marked (*) have not been assigned.

(PMe_3). Similarly, without exception, both hydrides share a common vertex.

All the structures also exhibit at least two bridging or semi-bridging carbonyls. This probably is a consequence of the greater electron density imparted to the cluster core by the strong σ donating group 15 ligands; bridging carbonyls are better π-acceptors than terminal CO ligands [8]. Furthermore, most of the structures contain a $RuOs_2$ face that is bridged by two hydrides and one carbonyl ligand.

There are four pairs of compounds for which the crystal structures of both mono- and disubstituted derivatives have been obtained. These are for the ligands PPh_3 (Os-**2a**, Os-**2a**, Os,Os-**3a** and Ru,Os-**3a**), $AsPh_3$ (**2b** and **3b**), $SbPh_3$ (**2c** and **3c**) and PCy_2Ph (**2f** and **3f**). The disubstituted derivatives may be regarded as being derived from the corresponding monosubstituted derivatives by substitution of a carbonyl ligand by the second ER_3 ligand. Surprisingly, it seems that the positions substituted are those that are in closer proximity to the first ER_3 ligand (positions 'a' in Fig. 5), rather than those for which the ligand would have pointed away from it (positions 'b'). Thus the site of the substitution of the second ER_3 ligand is dictated by electronic rather than steric factors. This point is further reinforced by substitution at position 'c' for the sterically small PMe_3 ligand, (i.e., double ligand substitution at the Ru vertex). This is unlike the case for $M_3(CO)_{10}L_2$ clusters where the two L ligands occupy equatorial sites on adjacent metal centres and are oriented away from each other [9].

As in the case of the monosubstituted derivatives, the similarity of the Ru and Os atomic radii predisposes the $RuOs_3$ clusters to positional disorder. For five of the disubstituted structures, the disorder merely interchanges the ER_3-substituted vertices in the cluster and thus does not

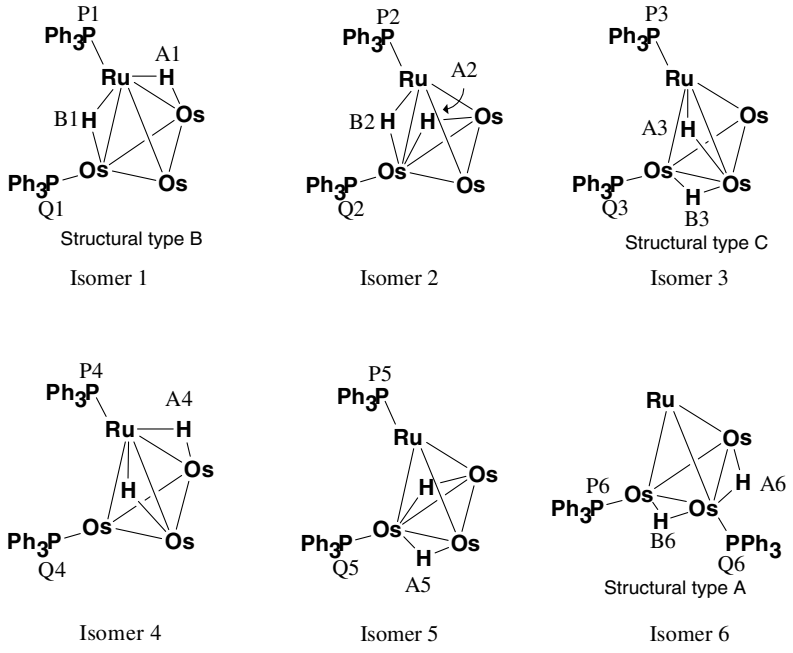

Fig. 7. Proposed structures and tentative NMR assignments for the six isomers of **3a**. Structural types corresponding approximately to the solid-state structures are also indicated.

Relative amounts are obtained by integration of NMR resonances with respect to isomer 1 (major isomer); for those with two resonances the value given is the mean and for those with one resonance it is halved.

[a] From integration of $^{31}P\{^1H\}$ resonances.

[b] From a sample that has been allowed to stand for ~2 months.

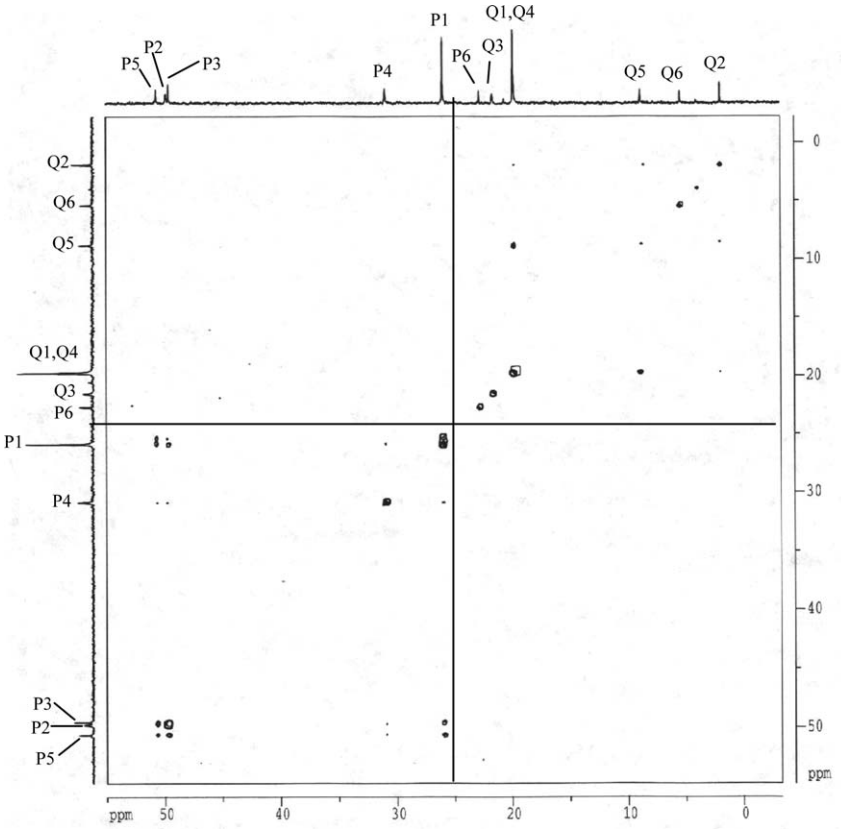

Fig. 8. ^{31}P EXSY spectrum ($CDCl_3$, 300 K) of **3a**.

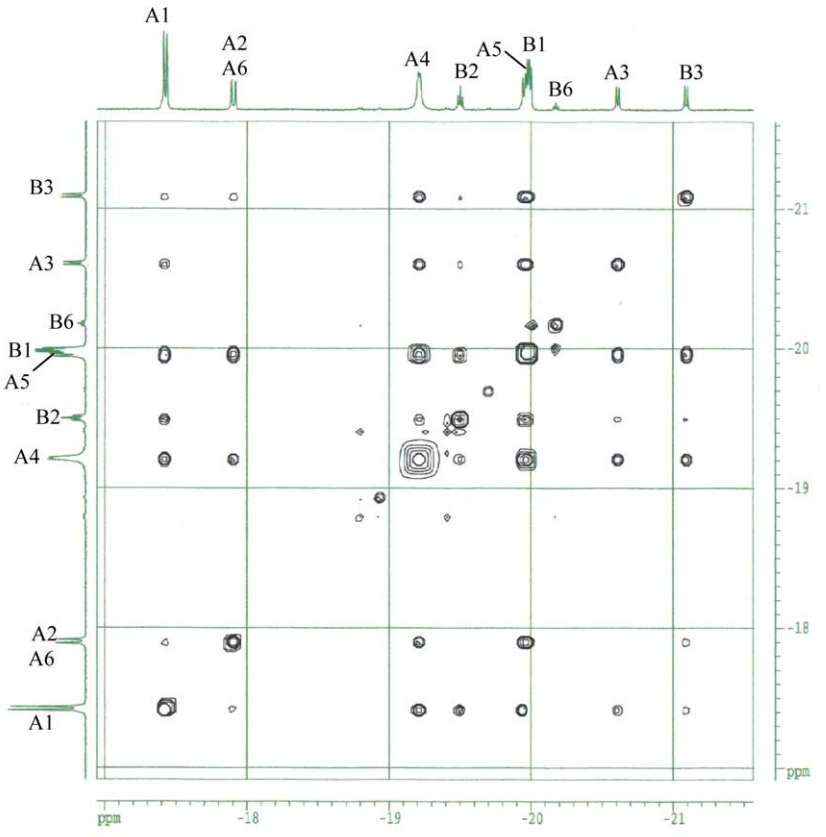

Fig. 9. ^{1}H EXSY spectrum ($CDCl_3$, 300 K, $\tau_m = 0.5$ s) of **3a**.

necessarily suggest different isomers. For Os,Os-**3a**, however, the modelled disorder implies a minor isomer of structural type B, i.e., Os,Os-**3a**. Evidence for the existence of many of these minor isomers in solution comes from the ^{1}H and ^{31}P NMR spectra, and is discussed presently.

3.2. Solution structures

The solution spectra suggest that there is more than one isomer in solution. For instance, the $^{31}P\{^{1}H\}$ NMR spectrum of **3a** taken at 300 K consists of at least 11 resonances; the ^{1}H NMR spectrum (Fig. 6) also clearly shows that there are many isomers present in solution. The hydride resonances are observed to lie between δ −17.1 and −22.3 ppm. The IR spectrum of **3a** recorded in a number of solvents: hexane, toluene, tetrachloromethane, dichloromethane, tetrahydrofuran and acetonitrile, shows no variation with solvent that may suggest a change in isomer distribution with solvent polarity. This is also corroborated by the ^{1}H NMR spectrum of **3a** in d_8-toluene, which does not show significant variations in relative peak intensities from that in $CDCl_3$.

A total of seven isomeric structures have been assigned with reasonable certainty based on the NMR data of the six disubstituted derivatives studied (see Supplementary Information). In our tentative assignments of the solution structures, we have assumed that the various isomers could be attributed to different relative arrangements of the phosphorus and hydride ligands only, and that the CO ligands are in rapid exchange. The latter is corroborated by the ambient temperature $^{13}C\{^{1}H\}$ NMR spectra of **3a**, **3f** and **3h**, which show no distinct CO resonances; this is indicative of rapid fluxionality of the carbonyls in solution. The IR spectra also show broad, and most often no, bridging carbonyl signals although these groups are present in the solid-state structures. The proposed structures for the six isomers of **3a** are given in Fig. 7, and the tentative structural and NMR assignments for all the derivatives studied are given in Table 3.

The arsine and stibine analogues of **3a** exhibit similar isomerism to **3a**, while the other derivatives generally exhibit an appreciably smaller number of isomers. For Ru,Ru-**3h**, which represents the seventh isomeric form for the disubstituted derivatives, it was observed to isomerise over days to Ru,Os-**3h**; the NMR spectra taken a month later showed that Ru,Ru-**3h** was completely absent. The results suggest that Ru,Ru-**3h** is the kinetic product, and that there is preferential substitution at the Ru vertex; this is also in accord with observations on the $RuOs_2(CO)_{12}$ system [10]. In addition, it appears that substitution of a second ligand at the substituted vertex is electronically favoured, and that substitution at a different second site is primarily a consequence of steric reasons. Subsequent isomerisation to the thermodynamically more stable isomers of Ru,Os-**3h** presumably proceeded via phosphine migration. A similar site selectivity was also observed with **3d** (cone angle for P(*n*-Bu)$_3$ = 132°).

As may be expected, the isomers are rapidly interconverting; the ^{31}P and ^{1}H EXSY spectra of **3a** are given in Figs. 8 and 9, respectively. Unlike in the monosubstituted analogue, there is no reversible PPh_3 migration between Ru and Os vertices, and no intra-isomer hydride exchanges are observed; the ^{31}P exchange crosspeaks are ascribable to "virtual" exchanges due to hydride migrations. These observations appear to be general for all the disubstituted compounds studied. Like its monosubstituted analogue, a variable temperature ^{1}H NMR experiment on **3f** indicated broadening of the main resonances below 273 K which is ascribable to the slowing down of restricted rotation about the metal–phosphorus bond.

3.3. Comparisons with the $FeRu_3$ system

An outstanding feature of the analogous $FeRu_3$ system is that the positions of the two bridging hydrides and the two bridging carbonyls in the parent cluster remain unchanged even after mono- and disubstitution. At most two types of isomers (labelled C_S and C_1 in the original paper) have been noted for the monosubstituted derivatives and only one for the disubstituted derivatives [1]. The isomers in the $RuOs_3$ system arise not only from differences in the position of the PR_3 ligand, but also from the locations of the bridging hydrides.

No derivatives disubstituted at the same vertex were observed in the $FeRu_3$ system, even with the relatively small PMe_3 ligand. In both systems, there is an interesting tendency towards substitution at a ruthenium vertex. For the monosubstituted $FeRu_3$ derivatives, it has been found that the C_S/C_1 isomer ratio is dependent on ligand size and basicity, as well as the solvent employed. In contrast, we have not observed any solvent effect on the isomeric distribution in the $RuOs_3$ system.

4. Concluding remarks

In this study, we have shown that the substitution of carbonyl ligands in the heteronuclear cluster $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ by group 15 ligands can give rise to a very large number of isomers which depend on the nature of the group 15 ligand. These isomers are largely a consequence of the different arrangements, and relative orientations, of the group 15 ligands and metal hydrides, and are probably a reflection of the well-established similarity in chemistry (electronic properties and size) of the two metals, viz., ruthenium and osmium. There is a clear preference for structures in which one group 15 ligand is substituted at a ruthenium and another at an osmium vertex; the five such isomeric forms include all possible combinations of hydride positions in which the two hydrides share a common vertex and bridge M–M edges where at least one group 15 ligand is at the vertices of those edges. This disposition of ligands has also been observed for similar derivatives of the other group 8 clusters [1,11]. The three derivatives of the triphenyl group 15 ligands,

viz., **3a**–**c**, present the largest number of isomers – six each. Clusters **3d** and **3h** are the only ones in which isomers with both trialkyl phosphine ligands on the same vertex are observed, and has probably to do with the relatively small cone angles ($\theta = 118°$ and 132° for PMe_3 and $P(n\text{-}Bu)_3$, respectively) and similar electronic parameters ($\chi = 8.0$ and 4.2, respectively) [12]. Evidence has been presented that the initial substitution appears to be predominantly at the ruthenium vertex and subsequently isomerisation proceeds via migration of the group 15 ligand(s).

The present study reports the improved conditions of the synthesis and also the structural characterization of the crystalline phases formed in the $Ba(OH)_2$–MeOH system.

2. Experimental

Anhydrous $Ba(OH)_2$ was prepared by dehydration of $Ba(OH)_2 \cdot 8H_2O$, and BaO by decomposition of BaO_2, at 400 and 800 °C, respectively. Methanol was dehydrated by refluxing over $Mg(OMe)_2$, and was subsequently applied in preparation of solutions with exact concentrations of water. All operations were carried out in dry argon or nitrogen atmosphere. The barium concentration was determined by acidimetric titration with Methyl Orange as indicator (using distilled water, purified from carbon dioxide by prolonged refluxing under an inert atmosphere). FTIR spectra have been recorded with the dry powders of the samples between KBr pellets on a Perkin–Elmer FTIR 1600 Instrument.

2.1. Crystallography

The crystals were placed in glass capillaries, and sealed under nitrogen gas. The data were collected for compounds **1** and **2** using a SMART CCD 1k instrument at room temperature (295 K) using graphite monochromated Mo Kα radiation, $\lambda = 0.71073$ Å. The experimental details are summarized in Table 1. The structures were solved by direct methods. Barium atoms were located from the initial solutions, and the other non-hydrogen atoms were isolated in subsequent difference Fourier syntheses. All non-hydrogen atoms were refined by least squares techniques on F^2, first in isotropic and then in anisotropic approximations. The coordinates of hydrogen atoms were added geometrically and applied in isotropic approximations riding on the corresponding carbon atoms. Hydrogen atoms of the OH-groups and solvating water molecules within the metal–oxygen cores could not be objectively located in the Fourier syntheses and the assignment of the nature of oxygen atoms was made on the basis of bond distances in comparison with the literature data (see below). Doubtless location of hydrogen atoms in the structures of barium hydroxide solvates or halide solvates can be achieved only in low temperature neutron diffraction experiments. The residual electron density 2.364 e/Å^3 for **1** and 5.426 e/Å^3 for **2** was located in the proximity of the barium atoms.

Table 1
Crystallographic data for complexes **1** and **2**

Compound	**1**, Plates	**2**, Needles
Formula	$C_2H_{14}O_6Ba$	$C_3H_{14}O_5Ba$
Formula weight	271.48	253.46

Independent reflections [R_{int}]	557 [0.2154]	2126 [0.1317]
Data/restraints/parameters	557/0/23	2126/0/153
Goodness-of-fit on F^2	1.194	0.855
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0656$, $wR_2 = 0.1628$	$R_1 = 0.0634$, $wR_2 = 0.1725$
R indices (all data)	$R_1 = 0.0659$, $wR_2 = 0.1644$	$R_1 = 0.0789$, $wR_2 = 0.1874$
Absolute structure parameter	0.1(3)	

2.2. Synthesis and isolation of *1* and *2*

Preparation of the crystals was carried out using solutions of BaO or $Ba(OH)_2$ in anhydrous MeOH and also in MeOH containing up to 10% water (for comparison). After long-term stirring at 0 °C with the Ba-containing reactant, taken in large excess, the concentration of solutions achieved 20–23 mass% in relation to $Ba(OH)_2$. The solutions were removed from the residual solids by decantation and concentrated in vacuum or in a dessicator with P_2O_5 until crystallization commenced. The obtained crystalline samples were washed with anhydrous MeOH and dried in vacuum at room temperature. Crystallo-optical investigation of the samples revealed normally the presence of several types of crystals. In addition to the compounds **1** and **2** described below, there have been also observed "rectangular rods" (described in [5]), which could not be isolated in the form of single crystals suitable for X-ray studies. Phases of the same type could only be isolated under controlled conditions as described below.

2.2.1. *[Ba(OH)$_2$(H$_2$O)$_2$](MeOH)$_2$ (1)*

Crystallized as rectangular plates from solutions of BaO in 90–95% methanol at 20 °C (this phase was isolated from solutions of BaO in 90%-methanol according to [5]). *Anal.* Calc. for $BaC_2H_{14}O_6$: Ba, 50.6. Found: Ba, 50.3%. IR, cm^{-1}: 3575 s, 3483 s, 3360 vs br, 2914 vs, 2860 vs, 2783 s sh, 1645 w, 1473 s, 1154 s, 1060 m, 836 vs, 720 m.

2.2.2. *[Ba(OH)$_2$(MeOH)$_2$](MeOH) (2)*

Crystallized as thin needles from 98% to 100% methanol solutions of BaO or $Ba(OH)_2$ subjected to reflux for 2–3 h with subsequent cooling to 0–20 °C. *Anal.* Calc. for $BaC_3H_{14}O_5$: Ba, 51.3. Found: Ba 51.0%. IR, cm^{-1}: 3580 vw, 3386 vs br, 2915 s, 2851 s, 2780 m, 1655 sh, 1439 sh, 1176 vw, 1141 w, 1062 vs, 824 vs, 720 w. (The needle-shaped form described in [5] as $Ba(OH)_2 \cdot 2MeOH \cdot H_2O$, crystallized from solutions not subjected to reflux at 20 °C).

The total concentration of $Ba(OH)_2$ in the mother liquors over **1** and **2** was about 20%, but the isolated crystalline products are almost insoluble in MeOH or $MeOC_2H_4OH$.

3. Results and discussion

The obtained synthetic results permitted the conclusion that the composition of the products crystallizing from the $Ba(OH)_2$–MeOH system is, in contradiction to the data reported in [5], not dependent on the nature of the starting reagent – BaO or $Ba(OH)_2$. Preliminary refluxing of the solution can supposedly influence the equilibrium of replacement of the inner-sphere water molecules with those of methanol, enhancing the transformation of $[Ba(OH)_2(H_2O)_2](MeOH)_2$ (**1**) into $[Ba(OH)_2(MeOH)_2](MeOH)$ (**2**). Anhydrous barium oxide, BaO, is evidently only a metastable solid phase in this system. The total concentration of the mother liquor with respect to barium hydroxide over it at 0 °C is rather high, up to ~20%, which permits the use of these solutions in sol–gel processes, but decreases with the increase in temperature, supposedly due to the following equilibria:

$$BaO + 2MeOH \rightleftharpoons Ba(OMe)_2 + H_2O$$

$$Ba(OMe)_2 + 2H_2O \rightleftharpoons Ba(OH)_2 + 2MeOH$$

and subsequent formation of the stable barium hydroxide phase, almost insoluble in the alcohol. It should be noted that the hydrated barium hydroxide, $Ba(OH)_2 \cdot 8H_2O$, displays rather high solubility at 20 °C even in anhydrous methanol (~25% $Ba(OH)_2$).

The structure of $[Ba(OH)_2(H_2O)_2](MeOH)_2$ (**1**) (see Fig. 1, Table 2) consists of planar layers of tetragonally distorted $[Ba(OH)_{4/2}(H_2O)_{4/2}]$ cubes, sharing edges situated along the *c*-axis (Fig. 1). Barium atoms form in this way a regular square net. Methanol molecules are placed only between the layers, perpendicularly to them and parallel to the *c*-axis. This "distancing" of the layers from each other results in a much longer axial *c*-parameter (22.404 Å) compared to the basal ones, $a = b = 4.6297$ Å in the observed tetragonal cell. The extinctions in the collected data permitted a comparably broad choice of possible space groups from $I\bar{4}$ to $I4/mmm$, with a combined figure of merit strongly favoring the choice of $I\bar{4}$. The structure could be solved using a higher symmetry group (in particular $I4/mmm$), but the refinement could not converge as the high symmetry imposed equivalence between hydroxide groups and water molecules, which resulted in an anomalous distribution of the electron density (maximum corresponding to the potential unique oxygen atom was localized at an abnormally low distance of 2.45 Å from the barium atom). We consider therefore that the lower symmetry, permitting these groups to be distinguished clearly and localized at reasonable distances from the barium atoms at 2.763(9) and 2.918(15) Å, does really represent the true structure of this compound. The bridges are asymmetric and the bonding roles within the core are equivalent. The hydrogen bonding to the interlayer alcohol molecules, however, permits them to be distinguished as the O(1)–O(2) distance is considerably shorter, 2.546(9) Å, in comparison with O(1)–O(3) distance, 2.666(9) Å, which gives a hint that O(2) stays for an OH-group and O(3) for the water molecule. Thus each alcohol molecule is hydrogen bonding to an OH-group and a water molecule in the nearest hydroxide layer.

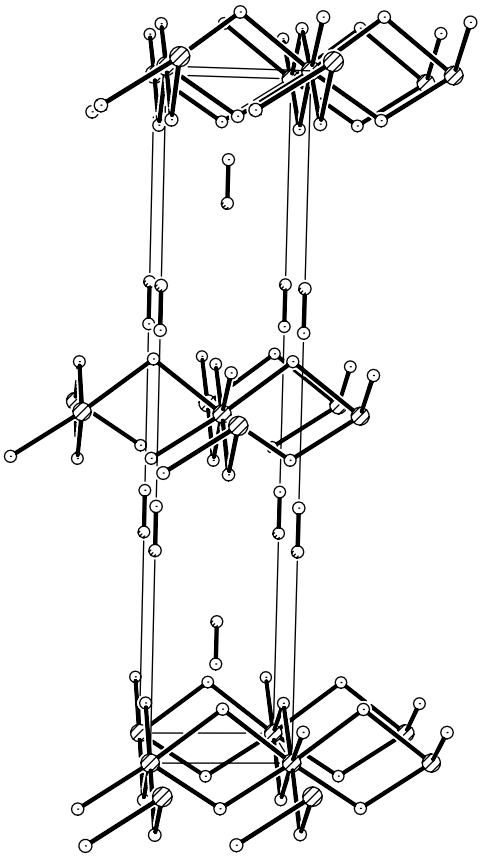

Fig. 1. Fragment in the crystal structure of $[Ba(OH)_2(H_2O)_2](MeOH)_2$ (**1**).

Table 2
Selected bond distances (Å) and angles (°) in the structure of $[Ba(OH)_2(H_2O)_2](MeOH)_2$ (**1**)

Ba(1)–O(3)#1	2.763(9)	Ba(1)–O(2)	2.918(15)
O(3)#1–Ba(1)–O(3)#2	107.3(3)	O(2)#4–Ba(1)–O(2)#3	111.8(4)
O(3)#1–Ba(1)–O(3)#3	113.8(6)	O(2)#4–Ba(1)–O(2)	105.0(8)
O(3)#1–Ba(1)–O(2)#4	175.6(5)	O(3)#2–Ba(1)–O(2)#4	70.6(2)

Symmetry transformations used to generate equivalent atoms: #1 $y, -x-1, -z$; #2 $x+1, y, z$; #3 $y, -x, -z$; #4 $x, y+1, z$; #5 $y+1, -x, -z$; #6 $x, y-1, z$; #7 $x-1, y, z$.

The task of distinguishing between the hydroxide and water ligands in general is very much dependent on the nature of the considered compounds and the structural functions of the groups. In the structures of barium halide hydrates, such as $BaCl_2 \cdot H_2O$ [7], $BaCl_2 \cdot 2H_2O$ [8], $BaBr_2 \cdot H_2O$ [7], $BaBr_2 \cdot 2H_2O$ [9], $BaI_2 \cdot H_2O$ [7] and $BaI_2 \cdot 2H_2O$ [10], the water molecules occupy a terminal positions in relation to the barium atoms, which results in rather uniform Ba–O distances in the range 2.84–2.87 Å, which are intermediate values for the distances in the structure of **1**. The structures of hydroxide halides, such as Ba(OH)Cl [11], $Ba(OH)Cl \cdot 2H_2O$ [12] or $Ba(OH)I \cdot 4H_2O$ [13], contain hydroxide groups together with halide

ones in the bridging positions, while the water molecules occupy the sites in the layer not attached directly to barium atoms and connected to the hydroxide groups through hydrogen bonding. The bond length variations for these compounds are in the range 2.69–2.79 Å and cover one of the two distances (for each oxygen atom) in **1**. Incorporation of two hydroxide ligands per barium atom leads normally to formation of highly asymmetric bridges, which already in the structure of the water-free $Ba(OH)_2$ [14] vary in length between 2.72 and 2.92 Å and thus cover the observed variation in **1**. In the structure of $Ba(OH)_2 \cdot 8H_2O$ [15], where the water molecules are connected exclusively to the barium atoms, while the hydroxide anions in contrast are attached to the solvated cations via hydrogen bonding, the Ba–$O(H)_2$ bond lengths vary in the interval 2.73–2.81 Å in both the solid state and in the water solution of this compound. In the structures of mono- and tri-hydrates of barium hydroxide, i.e. $Ba(OH)_2 \cdot H_2O$ [16] and $Ba(OH)_2 \cdot 3H_2O$ [17], the hydroxide ligands form shorter contacts to barium atoms, of about 2.70 Å, while the water molecules coordinated by the metal atoms and involved also in the hydrogen bonding with OH-groups and each other are situated in the range 2.78–2.93 Å from the barium atoms, covering thus the variation observed in **1**. In view of this comparison, the strategy of identification of the nature of groups via additional hydrogen bonding appears reliable.

The structure of $[Ba(OH)_2(MeOH)_2](MeOH)$ (**2**) (see Figs. 2–4, Table 3) is formed by planar layers of distorted antiprisms connected to each other via four opposite edges. The antiprisms around two different symmetrically independent barium atoms have equally long diagonals, but their centers are replaced in such way that the basis of one antiprism is formed by two shorter, and the basis of the other – two longer Ba–OH bonds. The structure of the layer is displayed in the Figs. 2 and 3. Both antiprisms have coplanar upper and lower planes, for Ba(1) with a ±0.122 Å margin for the upper plane (O2A, O3A, O5, O6) and with a ±0.030 Å margin for the lower one (O1, O2, O3, O4), for Ba(2) with a ±0.001 Å margin for the upper plane (O1, O8, O1A, O8A) and with a ±0.039 Å margin for the lower one (O5, O7, O5A, O7A). The angles between the planes are 8.7° and 0.7° for Ba(1) and Ba(2), respectively. Both Ba-atoms are displaced towards the "lower" planes from the geometric centers of the prisms. The distance from the planes are 1.734 and 1.101 Å, respectively, for Ba(1) and 1.830 and 0.956 Å, respectively, for Ba(2) (see Fig. 4). The structure of **2** contains also interlayer alcohol molecules but they are relatively strongly hydrogen-bonded to the layers (2.65 and 2.82 Å) and not placed along the axis perpendicular to the layer (*a*-axis for this structure).

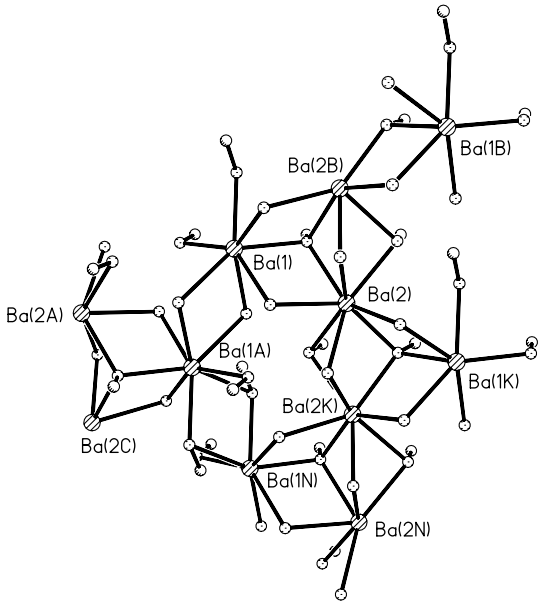

Fig. 2. Fragment of the metal–oxygen core in the layered structure of $[Ba(OH)_2(MeOH)_2](MeOH)$ (**2**).

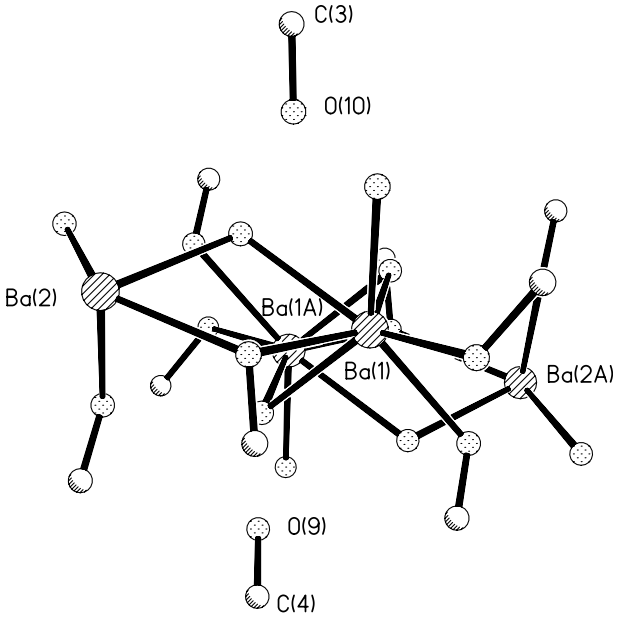

Fig. 3. View of $[Ba(OH)_2(MeOH)_2](MeOH)$ (**2**) along the *c*-axis.

The major difference between the two structures is that the alcohol molecules in the structure of **1** are situated between the $Ba(OH)_2$ layers, while in **2** they are incorporated in the coordination sphere of the Ba atoms within the layer. The four coordinated MeOH molecules have different functions in the coordination spheres of the two symmetrically independent atoms: one tridentate, two bidentate and one terminal for Ba(1), i.e. $[Ba(\mu_3\text{-}ROH)(\mu\text{-}OH)_4(\mu\text{-}ROH)_2(ROH)]$, and two tridentate and two bidentate for Ba(2), i.e. $[Ba(\mu_3\text{-}ROH)_2(\mu\text{-}ROH)_2(\mu\text{-}OH)_4]$.

The difference between compounds **1** and **2** can be traced in the positions of the *ν*-O–H bands in the IR spectra of these two complexes. The structure of **1** involves MeOH molecules situated only in the interlayer space, which is reflected by the presence of three intensive bands in its spectrum at 3575, 3483 and 3360 cm^{-1}. The first two of them are narrow and have their origin in the hydrogen bonds formed by more loosely connected alcohol mol-

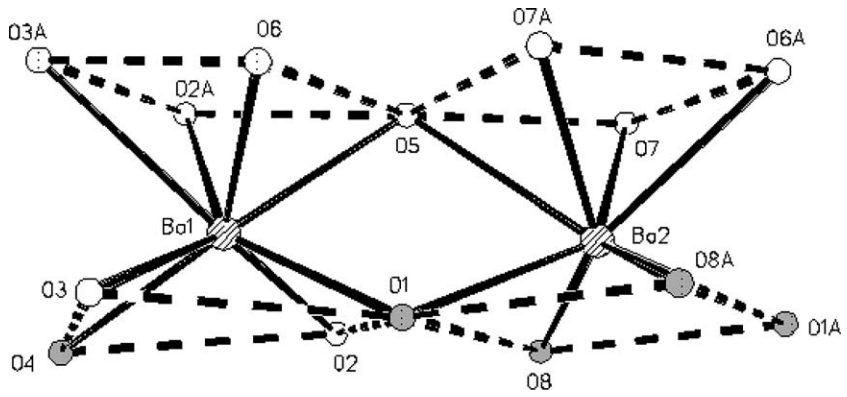

Fig. 4. Atom numbering scheme for the two symmetrically independent prismatic fragments in the structure of $[Ba(OH)_2(MeOH)_2](MeOH)$ (**2**). Oxygen atoms of the alcohol molecules are identified by the grey color.

Symmetry transformations used to generate equivalent atoms: #1 $-x, -y, -z$; #2 $-x, -y, -z+1$; #3 $x, -y+1/2, z-1/2$; #4 $x, -y+1/2, z+1/2$; #5 $x, y, z+1$; #6 $x, y, z-1$.

ecules, while the third broad one corresponds to vibrations associated with the OH or H_2O fragments involved in the coordination sphere of the barium atoms. At the same time, in the spectrum of **2** the lower frequency bands are rather weak, while the band with the maximum at 3360 cm^{-1}, corresponding to the vibration of the O–H fragments of coordinated polydentate molecules, is the most intensive one.

It is interesting to compare the structures of **1** and **2** with those of known hydrates of barium hydroxide, i.e. $Ba(OH)_2\cdot 3H_2O$ and $Ba(OH)_2\cdot H_2O$. The first of them contains chains of distorted antiprisms, *cis*-$[Ba(OH)_2(H_2O)_{6/2}]$, and the second – a network of nine-vertex polyhedra, $[Ba(OH)_{6/.3}(H_2O)_{3/3}]$, where seven bonds within the polyhedron are much shorter than those to the interlayer molecules of water (2.69–2.91 and 3.14 Å). The Ba–OH distance in **1** and **2** fall in the same range as those in the hydrate structures and all have the same structural function – doubly bridging. It is noteworthy that the alcohol molecules coordinated by the barium atoms in **2** all have different types of functions – μ_3-O(1) with the distances 2.655–2.757 Å, μ_2-O(8) 2.849–2.870 Å and terminal O(4) 2.718 Å. It can be concluded that this family of compounds has a well pronounced electrostatic character of bonding with the bond length determined to a greater extent by the packing effects rather than by the bonding mode of the coordinated ligands.

4. Supplementary materials

Supplementary data are available from the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk. on request, quoting the deposition numbers CCDC 286852 and 286853 for **1** and **2**, respectively.

(napy) in place of ppy to form the $(napy)_2Ir(acac)$ complex and shifted the emission to 595 nm which is 71 nm longer than that of $(ppy)_2Ir(acac)$ [17].

In the present work, the (napy) ligand was modified by incorporating a trifluoromethyl group onto the pyridine ring to produce a new ligand, 2-naphthalen-1-yl-*n*-trifluoromethyl-pyridine (*n*-fnapy). It is expected that the introduction of the trifluoromethyl group would generate a larger bathochromic effect on the emission wavelength of the corresponding Ir-complexes. The effects of the trifluoromethyl substituent and the importance of its position are described.

2. Experimental

2.1. Equipment

^1H NMR and ^{13}C NMR in $CDCl_3$ or d_6-acetone were recorded using a Bruker (Avance 300) spectrometer at 400 MHz and 100 MHz, respectively. High-resolution mass spectra were recorded using a Finnigan MAT-95XL in EI mode. Elemental analyses were carried out on an Elementar vario EL III analyzer. Absorption spectra (in CH_2Cl_2) were recorded on a Agilent 8453 spectrophotometer, and concentrations were 1×10^{-5} M to obtain the extinction coefficient. Emission spectra (1×10^{-3} M in CH_2Cl_2) were recorded on a HITACHI model F-2500 FL Spectrophotometer. Cyclic votlammetry (CV) was performed in 1.0 mM CH_2Cl_2 solution with a Valtammetric Analyzer CV-50 W. All oxidation CV measurements were carried out in CH_2Cl_2 containing 0.1 M tetrabutylammonium perchlorate (n-Bu_4NClO_4) as a supporting electrolyte. A Pt disk electrode was used as a working electrode, a Pt wire as a counter electrode, and $Ag/AgNO_3$ as a reference electrode. The ferrocenium/ferrocene redox couple in CH_2Cl_2/$n$$Bu_4NClO_4$ occurred at $E^{0'} = +0.35$ V vs. $Ag/AgNO_3$. The oxidation potential of the Ir complexes were determined against the ferrocenium/ferrocene redox couple.

2.2. Reagents

All chemicals were of reagent grade and used as purchased. $IrCl_3 \cdot nH_2O$ was purchased from Alfa Aesar, USA, 1-naphthylboronic acid and 2-chloro-trifluoromethyl-pyridine from Lancaster Chemicals, USA, and the remaining compounds from Aldrich Chemicals, USA.

2.3. Syntheses

2.3.1. 2-Naphthalen-1-yl-3-trifluoromethyl-pyridine (3-fnapy)

Add 1-naphthylboronic acid 0.75 g (4.4 mmol), 2-chloro-3-trifluoromethyl-pyridine 0.53 g (2.9 mmol), PPh_3 79 mg (0.30 mmol), and Cs_2CO_3 2.33 g into 15 mL 1,4-dioxane. Stir the mixture under nitrogen. Heat the mixture to 60 °C and add $Pd(OAC)_2$ 17 mg (0.075 mmol), and keep on refluxing for 4 h. After removing the solvent, extract the mixture twice with H_2O and ethyl acetate. Remove the ethyl acetate, and purify with a chromatographic column using ethyl acetate–hexane (1:5) as the eluant to obtain 0.66 g (83%) of a yellow liquid. EI-HRMS: *m*/*z* calcd 272.0765, found 272.0699 $[M]^+$, ^1H NMR (d-acetone, 300 MHz) δ 8.95 (d, $J = 4.7$ Hz, 1H), 8.34 (d, $J = 7.8$ Hz), 8.00 (m, 2H), 7.72 (m, 1H), 7.58 (t, $J = 7.8$ Hz, 1H), 7.52 (t, $J = 7.2$ Hz, 1H), 7.39 (m, 2H), 7.28 (d, $J = 8.4$ Hz, 1H).

2.3.2. 2-Naphthalen-1-yl-4-trifluoromethyl-pyridine (4-fnapy)

Yield 92%, yellow liquid. EI-HRMS: *m*/*z* calcd 272.0765, found 272.0701 $[M]^+$, ^1H NMR (d-acetone, 300 MHz) δ 9.04 (d, $J = 5.1$ Hz, 1H), 8.11 (d, $J = 7.8$ Hz, 1H), 8.04 (d, $J = 8.7$ Hz, 1H), 7.78 (m, 2H), 7.70 (d, $J = 6.2$ Hz, 1H), 7.62 (t, $J = 7.78$ Hz, 2H), 7.56 (m, 2H).

2.3.3. 2-Naphthalen-1-yl-5-trifluoromethyl-pyridine (5-fnapy)

Yield 87%, yellow solid. M.p.: 58 °C. EI-HRMS: *m*/*z* calcd 272.0765, found 272.0707 $[M]^+$, ^1H NMR ($CDCl_3$, 400 MHz) δ 9.07 (s, 1H), 8.07 (t, $J = 8.2$ Hz, 2H), 7.96 (m, 2H), 7.74 (d, $J = 8.2$ Hz, 1H), 7.62 (m, 2H), 7.54 (m, 2H).

2.3.4. 2-Naphthalen-1-yl-6-trifluoromethyl-pyridine (6-fnapy)

Yield 83%, yellow liquid. EI-HRMS: *m*/*z* calcd 272.0765, found 272.0696 $[M]^+$, ^1H NMR ($CDCl_3$, 500 MHz) δ 8.12 (d, $J = 2.4$ Hz, 1H), 7.95 (m, 3H), 7.75 (d, $J = 7.8$ Hz, 1H), 7.72 (d, $J = 7.8$ Hz, 1H), 7.66 (d, $J = 7.2$ Hz, 1H), 7.59 (d, $J = 7.8$ Hz, 1H), 7.54 (m, 2H).

2.3.5. bis[2-Naphthalen-1-yl-4-trifluoromethyl-pyridine-N,$C^{2'}$]-iridium(acetylacetonate)(4-fnapy)$_2$ Ir(acac)

The synthesis process can be found in [16]. Yield 63%, orange solid, EI-HRMS: *m*/*z* calcd 836.1449, found 836.1452 $[M]^+$, ^1H NMR (CD_2Cl_2, 300 MHz) δ 8.74 (s, 2H), 8.70 (t, $J = 7.3$ Hz, 2H), 8.47 (d, $J = 8.0$ Hz, 2H), 7.65 (d, $J = 8.0$ Hz, 2H), 7.53 (t, $J = 7.3$ Hz, 2H), 7.29 (m, 4H), 7.09 (d, $J = 8.0$ Hz, 2H), 6.28 (d, $J = 8.0$ Hz, 2H), 5.28 (s, 1H), 1.81(s, 6H). ^{13}C NMR (CD_2Cl_2, 75 MHz) δ 185.4, 170.5, 157.0, 149.3, 139.2, 138.7, 136.7, 131.9, 131.6, 131.2, 130.0, 127.2, 122.9, 120.7, 117.9, 116.0, 100.7, 28.625. *Anal.* Calc. for $C_{37}H_{25}F_6IrN_2O_2$: C, 53.17; H, 3.01; N, 3.35. Found: C, 53.35; H, 3.42; N, 3.35%.

2.3.6. bis[2-Naphthalen-1-yl-5-trifluoromethyl-pyridine-N,$C^{2'}$]-iridium(acetylacetonate)(5-fnapy)$_2$ Ir(acac)

Yield 78%, orange solid, EI-HRMS: *m*/*z* calcd 836.1449, found 836.1458 $[M]^+$, ^1H NMR (CD_2Cl_2, 300 MHz) δ 8.79 (s, 2H), 8.62 (d, $J = 8.7$ Hz, 2H), 8.47 (d, $J = 8.7$ Hz, 2H), 7.99 (d, $J = 8.7$ Hz, 2H), 7.64 (d, $J = 8.0$ Hz, 2H), 7.48 (t, $J = 8.0$ Hz, 2H), 7.26 (m, 2H), 7.09 (d, $J = 8.0$ Hz, 2H), 6.30 (d, $J = 8.7$ Hz, 2H), 5.31 (s, 1H), 1.82 (s, 6H). ^{13}C NMR (CD_2Cl_2, 75 MHz) δ 185.6, 172.6, 158.6, 145.6,

136.5, 134.2, 132.3, 131.9, 131.2, 130.3, 130.0, 127.1, 124.7, 122.9, 122.5, 122.0, 121.7, 121.1, 120.9, 100.9, 28.5. *Anal.* Calc. for $C_{37}H_{25}F_6IrN_2O_2$: C, 53.17; H, 3.01; N, 3.35. Found: C, 53.31; H, 3.30; N, 3.22%.

2.4. OLED fabrication and testing

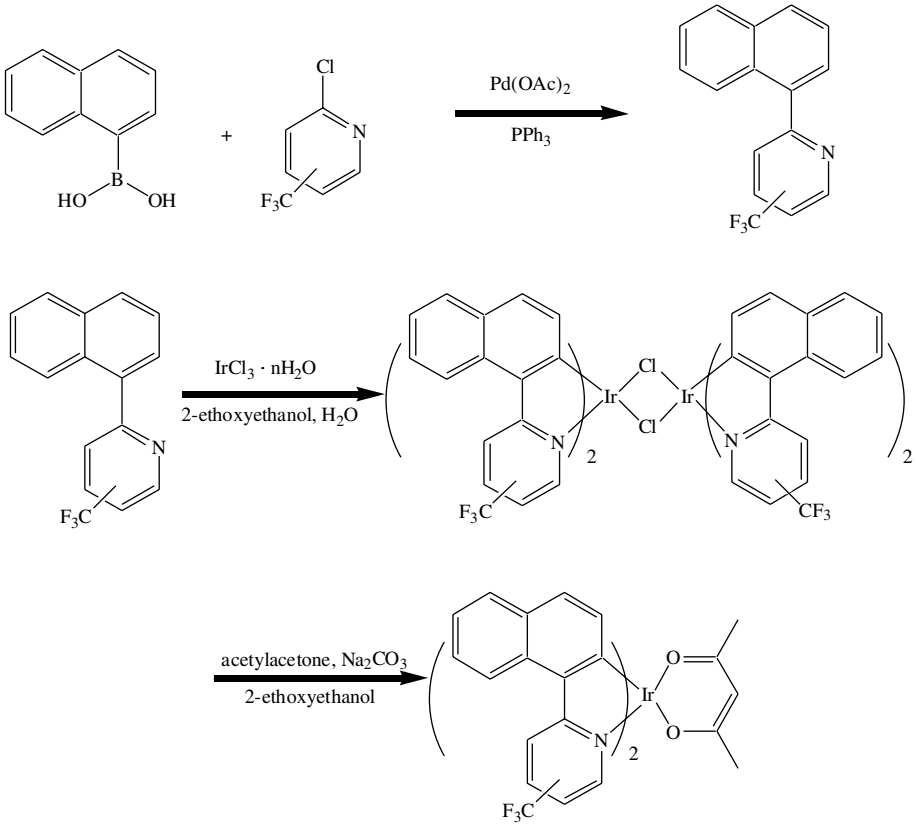
EL devices were fabricated with a similar structure to [Ir(ppy)$_3$] as reported by Thompson et al. [18] by vacuum-deposition techniques. The device structure used in this work was a typical multi-layer, employing indium tin oxide (ITO) as the anode, 4,4′-bis[*N*-(1-naphthyl)-*N*-phenyl-amino]biphenyl (NPB)(50 nm) as the hole-transport material, and 4,4′-di(carbazole-9-yl)biphenyl (CBP) as the host material (30 nm). Bathocuproine (BCP) (10 nm) was applied as the hole-blocking material, tris(8-quinolinolato)aluminum (Alq_3) (30 nm) as the electron-injection layer, and Al as the cathode.

2.5. X-ray crystallographic analyses

Crystals of (napy)$_2$Ir(acac) and (4-fnapy)$_2$Ir(acac) were obtained from solutions of CH_2Cl_2-Ether. The crystal data were selected for indexing and intensity data collection on a Siemens SMART CCD diffractometer equipped with a normal focus, 3-kW sealed tube X-ray source at 21–23 °C. No significant decay was observed for all samples during the data collection. Data were process on a PC using the Bruker AXS SHELXTL NT software package. Neutral atom scattering factors were taken from Cromer and Waber. The crystals of (napy)$_2$Ir(acac) and (4-fnapy)$_2$Ir(acac) belong to the monoclinic space group $P2(1)/n$ and triclinic space group $P\bar{1}$, respectively. All structure were solved by direct methods. All non-hydrogen atoms were refined anisotropically. The positions for all hydrogen atoms were either calculated or located directly from different Fourier maps and their contributions in structural factor calculation were included. The crystallographic data of (napy)$_2$Ir(acac) and (4-fnapy)$_2$Ir(acac) are given in Table 3, and selected bond lengths and angles are summarized in Table 4.

3. Results and discussion

The trifluoromethyl-substituted napy ligands were synthesized by the reaction of 1-naphthylboronic acid with the corresponding 2-chloro-*n*-trifluoromethyl-pyridine in the presence of Cs_2CO_3, $Pd(OAc)_2$, and PPh_3 (Scheme 1). The synthesized ligands including 2-naphthalen-1-yl-3-trifluoromethyl-pyridine (*3*-fnapy), *4*-fnapy, *5*-fnapy, and *6*-fnapy were reacted with $IrCl_3$ and acetylacetone in the presence of 2-ethoxyethanol and Na_2CO_3 in order to prepare the corresponding (*n*-fnapy)$_2$Ir(acac) complexes (Scheme 1). All the ligands and the Ir-complexes were characterized by HRMS, ^{1}H and ^{13}C NMR. Due to the steric hindrance effect of the bulky trifluoromethyl group, stable



Scheme 1. Synthesis route of iridium complexes.

(*3*-fnapy)$_2$Ir(acac) and (*6*-fnapy)$_2$Ir(acac) complexes could not be obtained. Stable ((3-fnapy)$_2$IrCl)$_2$ could be prepared but the naphthalene and pyridine ring had to be in the same plane in order to form the (*3*-fnapy)$_2$Ir(acac) complex. The trifluoromethyl group on the 3-position, however, suppresses this possibility. In the case of 6-fnapy ligand, the trifluoromethyl group directly faces to the bridging chloride of the $IrCl_3$, preventing the active site of the ligand from approaching the active site of $IrCl_3$, and as a result no desired product can be obtained. Thus, this discussion will focus on (*4*-fnapy)$_2$Ir(acac) and (*5*-fnapy)$_2$Ir(acac).

Fig. 1 shows the UV–Vis absorption spectrum of 1×10^{-5} M of (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) complexes in dichloromethane. The absorption spectra of the ligands and (napy)$_2$Ir(acac) complex are also included for comparison. The data taken from these spectra are collected in Table 1. As can be seen, the spectra of the two iridium complexes are fairly similar in terms of peak position. Weak absorption bands between 330 nm to 560 nm that are observed for both (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) complexes are not observed for the pure ligands. These weak bands can be assigned to singlet and triplet metal to ligand charge transfer (MLCT) transitions. The intense absorption bands at wavelengths shorter than 350 nm are due to the π–π^* transition of the fnapy ligands. Note that the differences observed between the spectra of the pure fnapy ligands and their corresponding iridium complexes indicates that coordination between ligands and iridium ions had indeed taken place. Compared to the corresponding absorption spectra of the ligands, the peaks of π–π^* transition from (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) complexes have blue-shifted approximately 20 nm.

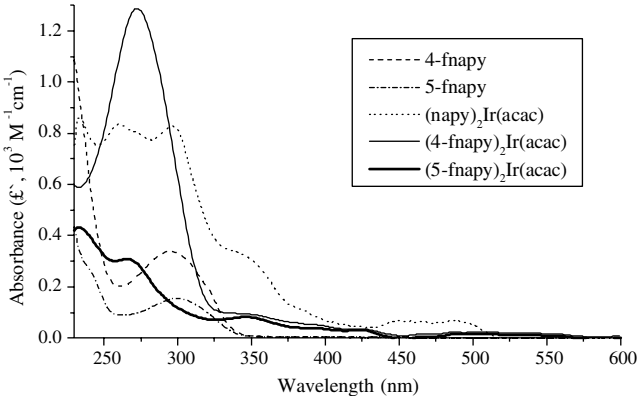


Fig. 1. UV–Vis spectra of ligands and iridium complexes which were collected in CH_2Cl_2 solution (1×10^{-5} M).

Table 1
UV–Vis (1×10^{-5} M) and photoluminescence (1×10^{-3} M) data of compound in CH_2Cl_2 solution

	UV–Vis absorption	Photoluminescence
Compound	λ (nm) {ε, 10^3 M^{-1} cm^{-1}}	emission λ_{max}(nm)
4-fnapy	230(108.0), 294(33.7)	
5-fnapy	229(44.8), 298(14.8)	
(napy)$_2$Ir(acac)	296(84.04), 448(7.7), 486(8.20)	590
(4-fnapy)$_2$Ir(acac)	273(128.32), 347(8.18), 395(3.45), 424(2.43), 502(1.50)	617
(5-fnapy)$_2$Ir(acac)	233(82.82), 266(59.22), 394(3.37), 423(2.78), 502(1.52)	613

Fig. 2 shows the photoluminescence spectra of 1×10^{-3} M of (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) complexes in dichloromethane. For comparison, the spectra of (napy)$_2$Ir(acac) is also included in this figure. The data taken from these spectra are summarized in Table 1. It can be seen that (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) emit red light at 617 and 613 nm, respectively. With regard to (napy)$_2$Ir(acac), which emits orange light at 595 nm, it is clear that the incorporation of the trifluoromethyl group leads to a 20 nm bathochromic shift. The trifluoromethyl group changes the π–π conjugation of the cyclometalated ligand and lowers the triplet energy level, thus lowering the lowest unoccupied molecular orbital (LUMO) level. Under the same excitation condition, the intensity of the emission of (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) are the same and the full width at half maximum (FWHM) is 40 nm for both complexes, which is about the same as the FWHM for the (napy)$_2$Ir(acac) which contains no trifluoromethyl group.

Cyclic voltammetry experiments were carried out for the (napy)$_2$Ir(acac), (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) iridium complexes in dichloromethane and the data taken from the cyclic voltammograms are summarized in Table 2. Due to the limited electrochemical window of the solvent, only the oxidation process for the complexes was obtained. For the electrochemical behavior of Ir(ppy)$_3$ analogues it is generally accepted that the oxidation process involves the iridium moiety of the complexes, and the highest occupied molecular orbital (HOMO) levels are mostly due to the d orbital of iridium with some π-orbital contributions from the ligand. Fig. 3 shows that both (4-fnapy)$_2$Ir(acac) and (5-fnapy)$_2$Ir(acac) exhibit reversible oxidation waves at potential more

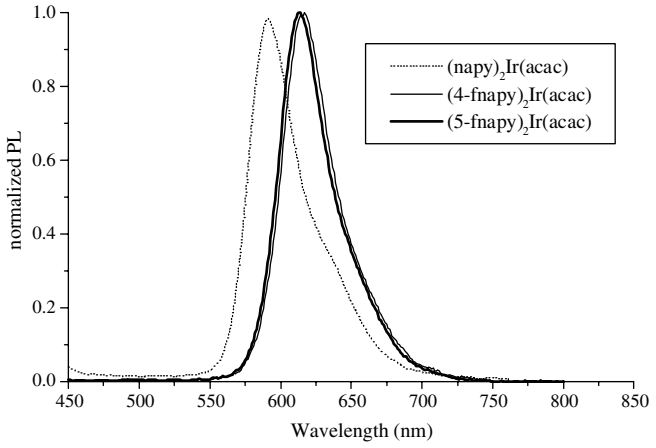

Fig. 2. Normalized photoluminescence spectra of iridium which were collect in CH_2Cl_2 solution (1×10^{-3} M).

Table 2
Electrochemical data, absorption edge, HOMO, LUMO, and energy gap of $(napy)_2Ir(acac)$, $(4\text{-}fnapy)_2Ir(acac)$, and $(5\text{-}fnapy)_2Ir(acac)$

Complex	$E_{1/2}$ (mV)[a]	ΔE_p (mV)	Adsorption edge (nm)[b]	HOMO (eV)	LUMO (eV)	Energy gap (eV)

[b] Data were collected in CH_2Cl_2 solution by UV–Vis spectrophotometer.

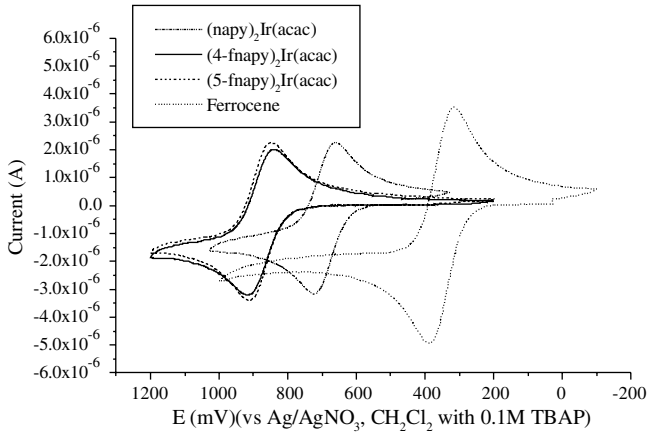

Fig. 3. The cyclic voltammograms of $(napy)_2Ir(acac)$, $(4\text{-}fnapy)_2Ir(acac)$, $(5\text{-}fnapy)_2Ir(acac)$ at the concentration 1×10^{-3} M in CH_2Cl_2. The scan rate is 50 mV/s.

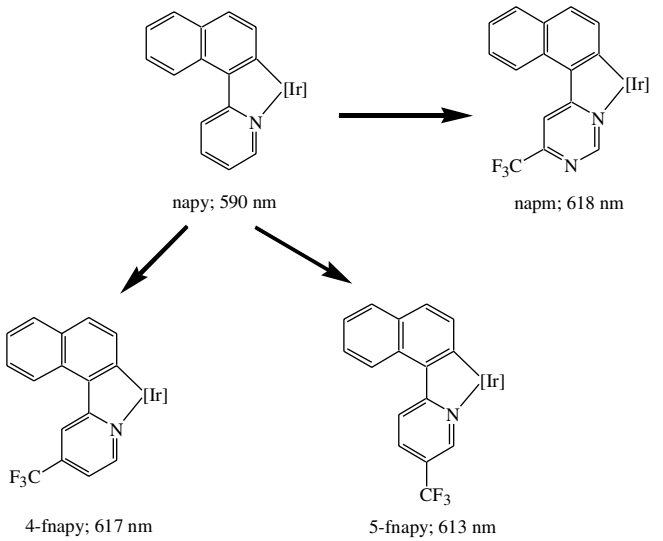
positive than (napy), indicating the relative difficulty of oxidation. This can be ascribed to the electron-withdrawing ability of the trifluoromethyl group. Based on method in the literature [19], the HOMO values for the iridium complexes were calculated by using the oxidation potentials collected from cyclic voltammograms. The calculated HOMO values are presented in Table 2. This table shows that $(4\text{-}fnapy)_2Ir(acac)$ and $(5\text{-}fnapy)_2Ir(acac)$ have the same HOMO value, −5.3 eV, while the HOMO level of $(napy)_2Ir(acac)$ is −5.1 eV. From the spectroscopy absorption edge it is found that $(4\text{-}fnapy)_2Ir(acac)$ and $(5\text{-}fnapy)_2Ir(acac)$ have the same energy gap, 2.2 eV. According to the theory presented by Burrows et al. [20] the LUMO energy level for the iridium complexes are determined from the energy gap and the HOMO energy level. As shown in Table 2, $(4\text{-}fnapy)_2Ir(acac)$ and $(5\text{-}fnapy)_2Ir(acac)$ have the same LUMO energy, −3.1 eV, while the LUMO level of $(napy)_2Ir(acac)$ is −2.7 eV. These results indicate that the trifluoromethyl group has a stronger influence on lowering the LUMO levels than on the HOMO levels.

Some studies regarding the substituent effect of the trifluoromethyl group on the cyclometalated Ir(III) complexes have been discussed in the literature [21,22]. It has been concluded that when the substitution is on the electron-deficient ring, like pyridine or pyrimidine, red shift in the emission wavelength often occurs due to the lowering of the LUMO energy level. Recently, Chi et al. [23] demonstrated that when the pyridine ring of the $(napy)_2[Ir]$ complex was replaced by a CF_3 substituted pyrimidine to form the $(fnapm)_2[Ir]$ complex (Scheme 2) a significant decrease in the LUMO energy level occurred and the emission wavelength shifted from 590 nm of $(napy)_2[Ir]$ to 618 nm of $(fnapm)_2[Ir]$. They attributed this to the effect of the electronegative nitrogen of the pyrimidine fragment. However, they may have overlooked the effect of the CF_3 group, because our data indicate that simply introducing a CF_3 group to the pyridine ring shifts the emission wavelengths to 617 $(4\text{-}fnapy)_2Ir(acac)$ and 613 nm $(5\text{-}fnapy)_2Ir(acac)$ which are very close to that of $(fnapm)_2Ir(acac)$. Since there is such a small difference between the emission wavelength of the $(n\text{-}fnapy)_2Ir(acac)$ and that of the $(fnapm)_2Ir(acac)$, the bathochromic effect of the nitrogen on the pyrimidine should be much weaker than Chi et al. expected.

ORTEP diagrams of $(napy)_2Ir(acac)$ and $(4\text{-}fnapy)_2Ir(acac) \cdot CH_2Cl_2$ are shown in Fig. 4, and the X-ray diffraction data are listed in Table 3. The iridium complexes were dissolved in CH_2Cl_2 by slowly adding ethylether, and letting the mixture stand for crystallization for 2 days. In the case of $(4\text{-}fnapy)_2Ir(acac) \cdot CH_2Cl_2$, each unit cell contains two $(4\text{-}fnapy)_2Ir(acac)$ and two CH_2Cl_2 molecules. In the $(napy)_2Ir(acac)$ crystals, each unit cell contains four $(napy)_2Ir(acac)$ molecules and no solvent molecule. Apparent stacking phenomenon was observed in the



Scheme 2.

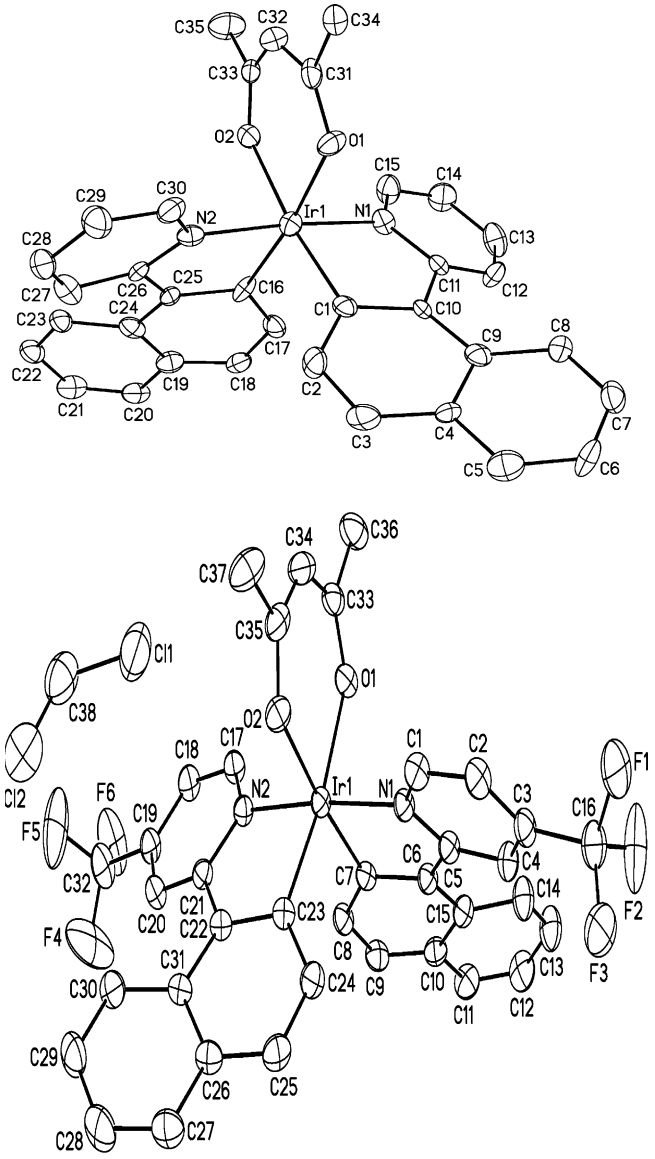


Fig. 4. ORTEP diagram with 50% probability thermal ellipsoids of $(napy)_2Ir(acac)$ (up) and $(4\text{-}fnapy)_2Ir(acac) \cdot CH_2Cl_2$ (down).

$(napy)_2Ir(acac)$ crystal; the complex molecules are so close to each other that there is not enough space for the incorporation of other solvent molecules. On the other hand, the $(4\text{-}fnapy)_2Ir(acac)$ molecules spread in a dimension structure and the CH_2Cl_2 molecules are distributed between the one dimension chains. The trifluoromethyl group seems to keep the $(4\text{-}fnapy)_2Ir(acac)$ molecules from gathering together, and this fact would help to lower the concentration quenching effect in the OLED device. The distorted octahedral geometry around the iridium is a consequence of the ligand structure, two mutually *trans* pyridyl and two *cis* naphthalenyl rings connected to the iridium atom. The average Ir–C (1.98) and Ir–N (2.02) distances are normal when compared to other Ir(III) bis-ppy derivatives [24]. The bond lengths and angles around the iridium atom are listed in Table 4.

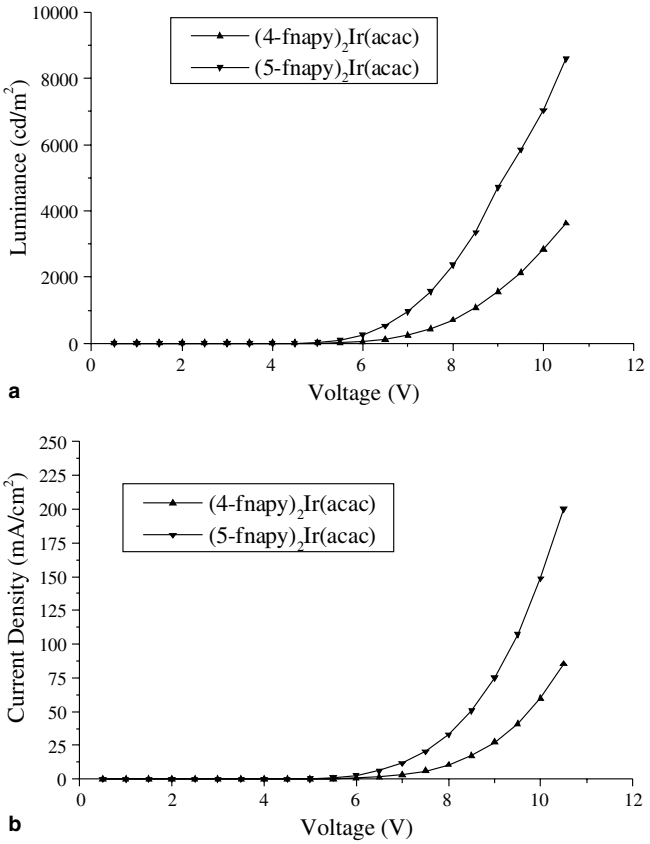

Fig. 5. (a) The luminance-voltage characteristics of OLED devices. (b) The current density-voltage characteristics of OLED devices.

emission peaks from CBP or Alq_3, indicating that the emission originates mostly from the dopant. Electrophosphorescence data for the iridium complexes are summarized in Table 5. The EL performances of the device are presented in Fig. 5. The turn-on voltage of the two OLED devices for emission were both about 5.0 V. The maximum efficiency and brightness of $(5\text{-fnapy})_2\text{Ir(acac)}$ are almost twice that of $(4\text{-fnapy})_2\text{Ir(acac)}$. The luminance of 3600 cd m^{-2} at 10.5 V and efficiency of 4.2 cd A^{-1} at 85 mA cm^{-2} was achieved by using $(4\text{-fnapy})_2\text{Ir(acac)}$ at 6 wt% doping level. The higher luminance of 8600 cd m^{-2} at 10.5 V and efficiency of 4.3 cd A^{-1} at 200 mA cm^{-2} was achieved by using $(5\text{-fnapy})_2\text{Ir(acac)}$. Due to the weaker Forster energy transfer [12,25] efficiency from CBP to the iridium complex, there is a downward tendency in quantum efficiencies with a red-shift of the emission peak. At the same applied volatge, the luminance of $(5\text{-fnapy})_2\text{Ir(acac)}$ is apparently higher than $(4\text{-fnapy})_2\text{Ir(acac)}$. High luminous efficiency of this series of iridium complexes has been confirmed. Due to the decrease of triplet–triplet annihilation, a gradual increase in the external quantum efficiency along with a decrease in the current density was observed for each device. At a current density of 10 mA cm^{-2}, the luminous efficiencies were reached at 6.82 and 8.43 cd A^{-1}. The emission of Commission Internationale de L'Eclairage (CIE) coordinates are (0.66, 0.34) and (0.65, 0.35). The colors emitted are both belong to red in the OLED devices.

4. Conclusions

A series of trifluoromethyl-substituted 2-naphthalen-1-yl-pyridine ligands and the corresponding iridium complexes have been synthesized and characterized by spectroscopic methods as well as by X-ray crystallography. The photoluminescent and electrochemical properties of these red-emitting Ir(III) complexes were measured. Significant bathochromic shift was observed with the incorporation of trifluoromethyl group. We have demonstrated that the emission wavelength of $(napy)_2\text{(acac)}$ can be tuned to more than 20 nm so that the color is close to pure red. Using $(5\text{-fnapy})_2\text{Ir(acac)}$ as the red dopant in CBP, the device has a maximum efficiency of 8.43 cd A^{-1} and a brightness of 830 cd m^{-2} at 10 mA cm^{-2}.

Appendix A. Supplementary data

Crystallographic data (excluding structure factors) for $(napy)_2\text{Ir(acac)}$ and $(4\text{-fnapy})_2\text{Ir(acac)} \cdot CH_2Cl_2$ have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC 260872 and 260873, respectively. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.02.003.

example $[MoO(N_3)(CN)_4]^{3-}$ [5], $[WO(F)(CN)_4]^{3-}$ [6] and $[ReO(NCS)(CN)_4]^{2-}$ [7].

An excellent relationship exists between the pK_{a1}-values obtained from the different $[MO(OH_2)(CN)_4]^{n-}$ complexes, the M–OH_2 bond distances and the formal metal ion charge. Thus the pK_{a1} decreased from 10.0 for the molybdenum(IV) complex [8] (Mo–OH_2 bond distance 2.271(4) Å) to 1.4 for the rhenium(V) complex [9] (Re–OH_2 bond distance 2.142(7) Å). The profound effect of the central metal ion on the chemistry of these complexes was also demonstrated by the rate of substitution of the aqua ligand. A decrease of a factor 10^4 was observed for the substitution of the aqua ligand by NCS^- in $[ReO(OH_2)(CN)_4]^-$ [10] compared to the same reaction for $[WO(OH_2)(CN)_4]^{2-}$ [11].

One of the major differences between the chemistry of the $[MO(H_2O)(CN)_4]^{n-}$ complexes (M = Mo and W) and the iso-electronic $[ReO(OH_2)(CN)_4]^-$ complex was the ability of the former to react with bidentate ligands, substituting the aqua as well as one of the cyanide ligands to form the corresponding $[MO(LL)(CN)_3]^{n-}$ complexes, e.g., $[MoO(phen)(CN)_3]^-$ [12] and $[WO(pic)(CN)_3]^{2-}$ [13]. The absence of bidentate substitution reactions for the $[ReO(OH_2)(CN)_4]^-$ complex (pK_{a1} 1.4) is attributed to the protonation of the bidentate ligand at low pH-values.

The same protonation behaviour (Eq. (2)) was observed for $[MN(H_2O)(CN)_4]^{n-}$, (M = Re(V) and Os(VI)) [14,15] with the exception that the $[MN(O)(CN)_4]^{n-}$ type complex was never observed.

$$[MN(HO)(CN)_4]^{(n+1)-} \underset{+H^+}{\overset{-H^+;K_{a1}}{\rightleftharpoons}} [MN(H_2O)(CN)_4]^{n-} \qquad (2)$$

These studies highlighted the influence of the nitrido ligand compared to that of oxygen as terminal ligand. The nitrido ligand had a large influence on the pK_{a1} value. The pK_{a1} increased from 1.4 for $[ReO(OH_2)(CN)_4]^-$ to 11.6(2) for $[ReN(OH_2)(CN)_4]^{2-}$. The same large increase in pK_{a1} value was observed for the osmium (VI) complexes [15]. These studies also indicated a large labilising effect by the N^{3-} ligand [16]. This substantial increase in the pK_{a1}-values prompted the research for the isolation and the kinetic study of possible reactions using bidentate ligands with the nitrido complexes. The first step in this search was the investigation of the photolytic reaction between $[ReN(H_2O)(CN)_4]^{2-}$ and ethylenediamine [17]. Contrary to the expected di-hapto behaviour, a novel ethanediamine bridged rhenium complex, $[\{ReN(CN)_4\}_2(\mu\text{-en})]^{2-}$, was isolated.

With the above in mind and the still elusive bidentate ligand behaviour for the rhenium-nitrido complex as our aim, we continued investigating the possible reactions between $[ReN(H_2O)(CN)_4]^{2-}$ and different bidentate ligands. In this paper we report the successful preparation and identification of the first $[ReN(LL')(CN)_3]^{n-}$ complex as $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ (pic = pyridine-2-carboxylato ion) as well as the kinetic study of the reactions involved in the formation of the final complex.

2. Experimental

All the preparations were performed in an efficient fume cupboard. The UV–Vis spectra were recorded on a Varian Carey (model 50 Conc) or a Hitachi (model 150–20) spectrophotometer at room temperature. IR spectra were recorded as powder or crystals on a Digilab Merlin FTIR spectrophotometer.

2.1. Syntheses of the complexes

2.1.1. $K_2[ReN(CN)_4]\cdot H_2O$

$K_2[ReN(CN)_4]\cdot H_2O$ was synthesised according to the literature method [18]. Spectral data: ν(R≡N), 993, 966 cm^{-1}; ν(CN), 2117 cm^{-1}; % yield = 58.

2.1.2. $(Ph_4As)_2[ReN(\eta^2\text{-pic})(CN)_3]\cdot 4H_2O$

$K_2[ReN(CN)_4]\cdot H_2O$ (0.5 g, 0.12 mmol) was dissolved in H_2O (2 ml). Picolinic acid (0.75 g, 6.1 mmol) and Na_2CO_3 (0.33 g, 3.1 mmol) were dissolved in H_2O (10 ml), and added to the first solution after the effervescence has ceased. The reaction mixture was heated at 80 °C for 6 h. The volume of the solution was kept constant at 12 ml by adding distilled water from time to time. $AsPh_4Cl\cdot H_2O$ (0.82 g, 0.19 mmol) was dissolved in H_2O (2 ml) and added to the cooled reaction mixture. The yellow-orange crystals were obtained after about 10 h. These crystals were suitable for X-ray analysis.

Spectral data. ν(Re≡N), 1061 cm^{-1}; ν(C≡N), 2106 cm^{-1}; $\lambda_{max} = 400$ nm; $\varepsilon_{(400)} = 2.3\times10^3$ mol^{-1} dm^3 cm^{-1}; $\lambda_{max} = 355$ nm; $\varepsilon_{(355)} = 2.0\times10^3$ mol^{-1} dm^3 cm^{-1} (see Table 1).

2.2. Kinetics

All reagents and chemicals were of analytical grade and distilled H_2O was used in all the experiments. Picolinic acid was recrystallised from hot ethanol. All pH measurements were performed on a Hannah model 8519 pH meter with a combined glass/calomel electrode using standard buffer solutions for calibration and an ionic strength 5.0 M KCl. Kinetic measurements were made on a Hitachi model 150–20 and Varian Carey (model 50 Conc) spectrophotometer. Temperature control of the reaction solutions was maintained by means of a Labcon CPE 50 circulating water bath system and APPA-51 Digital thermometer (accurate within 0.1–1.0°). The kinetic reactions were measured aerobically under pseudo first-order conditions with at least 100-fold excess of the ligand concentration. All the reactions were monitored at 400 nm with 1.00 ± 0.001 cm tandem quartz cells. The absorbance versus time spectra showed two distinctive reactions, a fast reaction with a half-life of a few seconds followed by a second slow reaction with a half-life of 10–20 min. Each kinetic run and pH titration for the slow reaction was performed at least two times and an average of both values

was taken. Kinetic runs and pH titrations for the fast reaction were monitored on a stopped-flow (model 05–109 Photophysics) spectrophotometer coupled with a personal computer (SX 18 MV) capable of performing least-square analyses on absorbance versus time data. Data of 150 points per trace were collected and at least 120 points for each trace were analyzed by least-square fit to give the rate constant. The reported rate constants are an average of 4–12 runs The Scientist program was used to fit the data to selected functions. Linear plots of $\ln(A_\infty - A_t)$ versus time were obtained for at least two half-lives under all conditions. The solid line in the figures present computer least-square fits of the data while the experimentally determined values are presented by the dots.

2.3. X-ray crystallography

Intensity data were collected on a Bruker SMART 1K CCD area detector diffractometer (Jan Boeyens Structural Chemistry Laboratory, School of Chemistry, University of the Witwatersrand) with graphite monochromated Mo Kα radiation (50 kV, 30 mA). The collection method involved ω-scans of width 0.3°. Data reduction was carried out using the program SAINT+ [19] and absorption corrections were made using the program SADABS [20].

The crystal structure was solved by direct methods using SHELXTL [21]. Non-hydrogen atoms were first refined isotropically followed by anisotropic refinement by full matrix least-squares calculations based on F^2 using SHELXTL. With exception of the H-atoms attached to the water molecules all H-atoms were first located in the difference map then positioned geometrically and allowed to ride on their respective parent atoms. In addition to the Re molecule and two $AsPh_4^-$ counter ions the structure also contains four water molecules. Two of these (O1W and O2W) were successfully refined anisotropically while the other two (O3W and O4W) were refined isotropically. Where possible H-atom positions were calculated for water molecules involved in hydrogen bonding. However, it was not possible to unambiguously calculate a position for one H-atom on O2W, O3W and O4W, respectively. The contribution of these has however been added to the sum formula, moiety formula, crystal density and $F(000)$. Diagrams and publication material were generated using SHELXTL and PLATON [22].

3. Results and discussion

3.1. Synthesis

The IR stretching frequencies of the product corresponds very well with the other rhenium-nitrido complexes that were prepared and identified previously. The ν(Re≡N) stretching frequency of 1061 cm^{-1} of the title complex is almost identical to the value of 1060 cm^{-1} that was obtained for $[ReN(H_2O)(CN)_4]^{2-}$ but significantly different from 1040 cm^{-1} that was obtained for $[ReN(CN)_5]^{3-}$. The difference in stretching frequency is indicative of the relative *trans* influence of the group *trans* to the nitrido ligand [16]. These results clearly indicate that the *trans* influence of the H_2O in $[ReN(H_2O)(CN)_4]^{2-}$ and the oxo group of the picolinate anion in $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ are compatible. The ν(CN) of 2106 cm^{-1} is also in good agreement with the cyano stretching frequencies of the other rhenium-nitrido complexes.

3.2. Crystal structure

The most important bond lengths and angles of both the cation and anion are listed in Table 2. The numbering scheme of the $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ anion is shown in the perspective drawing, Fig. 1. The structure consists of discrete $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ anions and $AsPh_4^+$ cations. The As atoms are tetrahedrally surrounded by four phenyl rings. The average As–P bond distance is 1.915(4) Å while the C–As–C bond angles range between 107.3(2)° and 111.0(2)°. These results are in good agreement with those found in other structures containing $AsPh_4^+$ cations (1.911(8) Å, 107.6–111.5° [23], 1.912(11) Å, 107.3(4)–111.6(4)° [24], 1.889 Å, 109.5° [25] and 1.906 Å, 109.5° [12]).

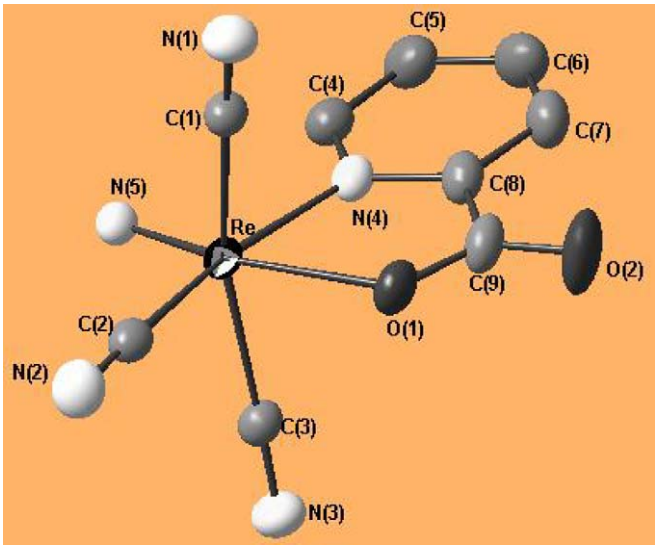

Fig. 1. Perspective view of the $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ ion with atomic labeling scheme.

The rhenium atom has a distorted octahedral geometry and is surrounded by the nitrido ligand, three cyano groups an a picolinate anion that is bonded bidentally via the oxygen and nitrogen atoms. The distortion has two main features namely a displacement of 0.2979(2) Å of the rhenium from the equatorial C(1), C(2), C(3) and N(4) plane towards the nitrido ligand and a 13.3° distortion of the Re–O(1) bond from the expected linear N(5)–Re–O(1) axis. The latter is mainly the result of bite angle restrictions due to the five-membered chelate ring. The former displacement is typical for $[MO(L)(CN)_4]^{m-}$ or $[MN(L)(CN)_4]^{n-}$ complexes where different bond strengths along the *trans* O=M–L or N≡M–L moieties prevail [26]. The Re≡N(5) bond distance is 1.655(3) Å and may be compared with the corresponding bond length in $[ReN(N_3)(CN)_4]^{3-}$ [27] (1.65(2) Å), $[ReN(H_2O)(CN)_4]^{2-}$ [24] (1.639(8) Å) and $[ReN(CN)_5]^{3-}$ [28] (1.68(1) Å). The Re–O(1) bond length of 2.289(3) Å is significantly shorter than the 2.496(7) Å of the Re–O bond length in $[ReN(H_2O)(CN)_4]^-$ [24], but longer than the same bond in the $[WO(\eta^2\text{-pic})(CN)_3]^{2-}$ and the $[MoO(\eta^2\text{-pic})(CN)_3]^{2-}$ anions [13,29] (2.171(8) and 2.191(2) Å, respectively). The latter result fits in well with the general tendency where the bond distances in the rhenium-nitrido complexes are longer than the corresponding bonds in the molybdenum(IV), tungsten(IV) and rhenium(V) oxo complexes [30–32]. The carboxylate oxygen of the picolinate ligand is bonded *trans* to the nitrido ligand with a N(5)≡Re–O(1) bond angle of 166.5(1)°. This value corresponds well with the bond angles of 164.7(5)° and 162.0(1)° which was obtained for the same bonds in $[WO(\eta^2\text{-pic})(CN)_3]^{2-}$ and the $[MoO(\eta^2\text{-pic})(CN)_3]^{2-}$, respectively. The pyridine nitrogen of the picolinate ligand with a N(5)–Re–N(4) bond angle of 94.2(2)° and a Re–N(4) bond distance of 2.169(3) Å compares favourably with the data of $[WO(\eta^2\text{-pic})(CN)_3]^{2-}$ (92.2(5)° and 2.188(13) Å). The rest of the bond distances and angles in the picolinate ligand are normal and agrees well with those found in other complexes containing the same bidentate ligand [13,29].

The Re–C–N chains are nearly linear (ranging between 174.8(4)° and 178.0(4)°). Another interesting aspect of this structure is that the rhenium cyano bond length *trans* to the pyridine nitrogen of the picolinate anion is shorter than the other two metal cyano bond lengths (*trans* with respect of one another). The Re–C(2) is 2.067(5) Å compared to the 2.105(4) and 2.111(4) Å of the other two metal cyano bond lengths. The same tendency was observed for the corresponding tungsten complex. The phenomenon is attributed to weak or no π-bonding capability of the pyridine nitrogen of the picolinate anion. This leads to extensive π-shortening of the Re–C bond due to back-bonding from the metal to the π^*-orbital of the cyanide ligand. This shortening of the metal cyanide bond can also be explained in terms of the thermodynamic *trans*-influence of the different ligands. The cyanide ligand has a greater thermodynamic *trans* influence than the nitrogen of the picolinate anion. This will also lead to a shortening of the Re–C bond *trans* to the nitrogen compared to the two *trans*-orientated cyanide ligands.

This structure determination is the first rhenium-nitrido cyano complex in which a bidentate ligand is bonded to the metal center.

3.3. Kinetics

The UV/Vis spectra taken at 80 °C of the reaction between $[ReN(H_2O)(CN)_4]^{2-}$ and pic^- (Fig. 2) showed the formation of two distinctive peaks, one at 355 nm (B) and the other at 400 nm (C). It was decided to follow the substitution reaction at 400 nm. The formation of these peaks correspond to formation of the final complex, $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$. Two different reactions were observed at close inspection of absorbance versus time spectra at this temperature. The first reaction was relatively fast and resulted in a decrease in absorption at 400 nm (A in Fig. 2). The second reaction was much slower (B and C in Fig. 2) and yielded the UV/Vis spectrum which was identical to that of the final product. A reaction mechanism is proposed in Scheme 1 for all the reactions which are possible under the experimental conditions that prevailed during the study.

The low solubility of the picolinic acid at pH values lower than 5 ($pK_{a(picH)} = 5.52$ [33]) restricted the concentration range in which the reactions could be performed and no reactions were observed between the rhenium complex and the picolinic acid at or below a pH of 4. This completely eliminates the k_4 and k_{-4} pathway from the final rate law.

The crystal structure determination clearly indicates that both the aqua and a cyano ligand are replaced during the substitution reaction. Previous studies [27,28] have indicated that the substitution of the aqua ligand from $[ReN(H_2O)(CN)_4]^{2-}$ by ligands such as $CN^-$and N_3^- are relatively fast, while the ring-closure step was found to be rate-determining [13] for the reaction between $[WO(H_2O)(CN)_4]^{2-}$ and pic^-. The fast reaction that was observed in this study is thus also regarded as the substitution of the aqua ligand to form the mono substituted $[ReN(\eta^1\text{-pic})(CN)_4]^{2-}$ complex.

Figs. 3 and 4 illustrate the pH dependence on rate of the reaction for both the fast and slow reactions, respectively, while Fig. 5 illustrates the effect of pH on the absorbance of the reaction mixture. Figs. 6 and 7 illustrate the temperature and $[pic]_T$ dependence of the fast and slow reactions at low pH (pH ~8), respectively, while Fig. 8 illustrates the temperature and $[pic]_T$ dependence of the slow reaction at high pH (pH ~12.5). The influence of pH on the reactivity of the incoming ligand was investigated at low pH (between 4 and 8) and these results are given in Fig. 9.

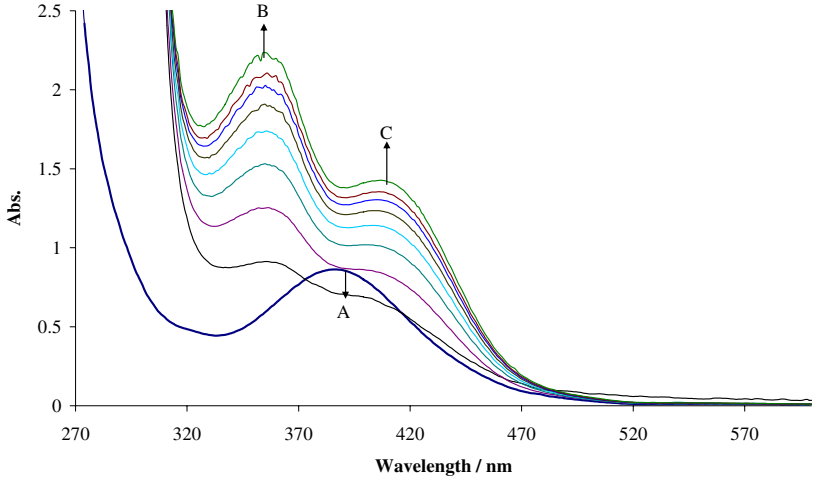

Fig. 2. UV–Vis spectral changes during the reaction between $[ReN(H_2O)(CN)_4]^{2-}$ and picolinic acid ($[pic]_T$), $T = 80.3$ °C, pH 8.04, $[ReN(H_2O)(CN)_4{}^{2-}] = 1.0 \times 10^{-3}$ M, $[pic]_T = 1.0$ M: A = initial fast reaction, B and C = subsequent slow reaction. Time intervals 1.0 min.

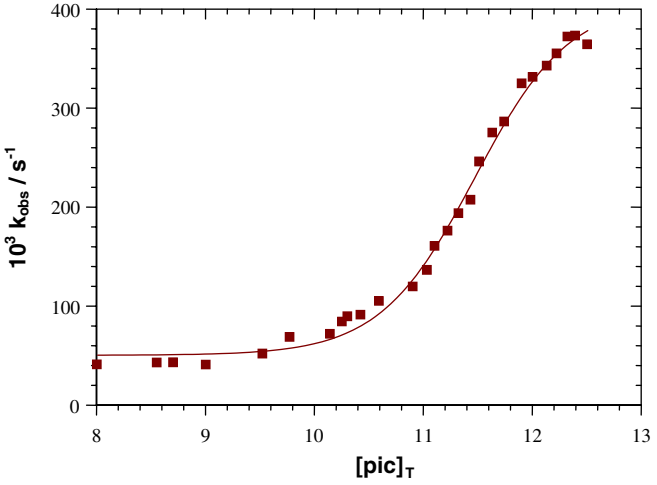

Fig. 3. Plot of k_{obs} vs. pH, $T = 40.3$ °C, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-2}$ M, $[pic]_T = 0.1$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

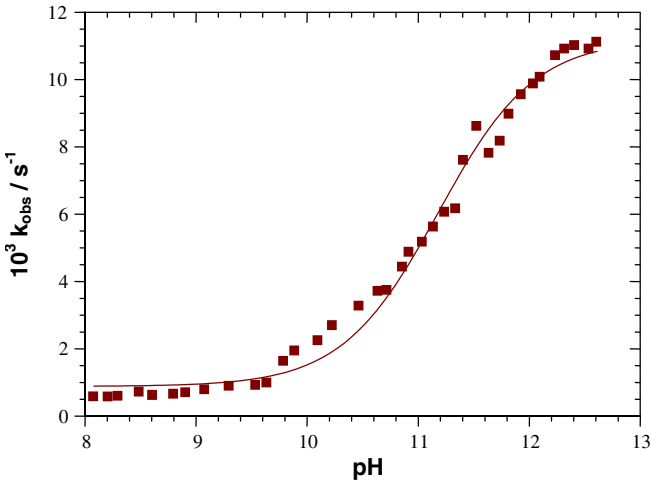

Fig. 4. Plot of k_{obs} vs. pH, $T = 80.2$ °C, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-3}$ M, $[pic]_T = 0.1$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

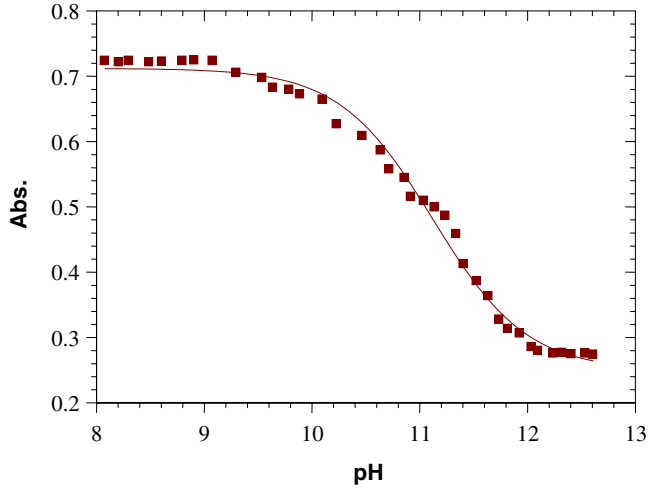

Fig. 5. Plot of absorbance vs. pH, $T = 80.2$ °C, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-3}$ M, $[pic]_T = 0.1$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

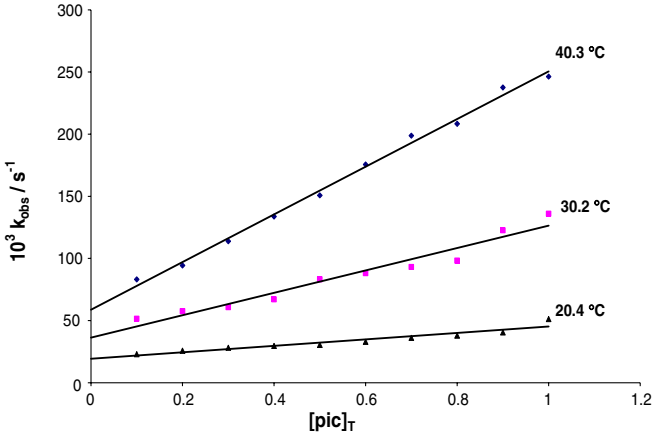

Fig. 6. Plot of k_{obs} vs. $[pic]_T$ at different temperatures, pH 8.05, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-2}$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

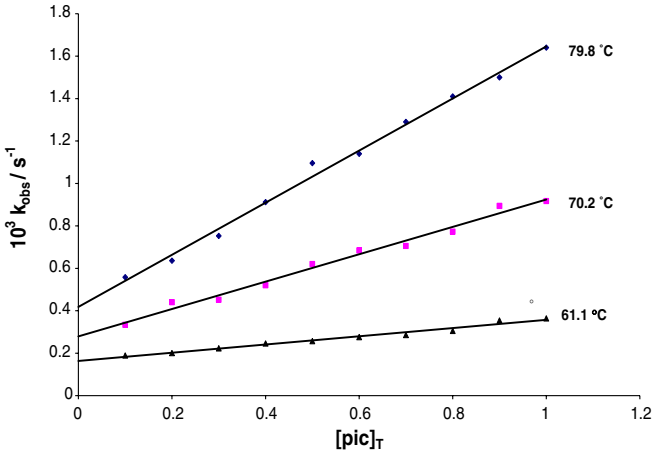

Fig. 7. Plot of k_{obs} vs. $[pic]_T$ at different temperatures, pH 8.06, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-3}$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

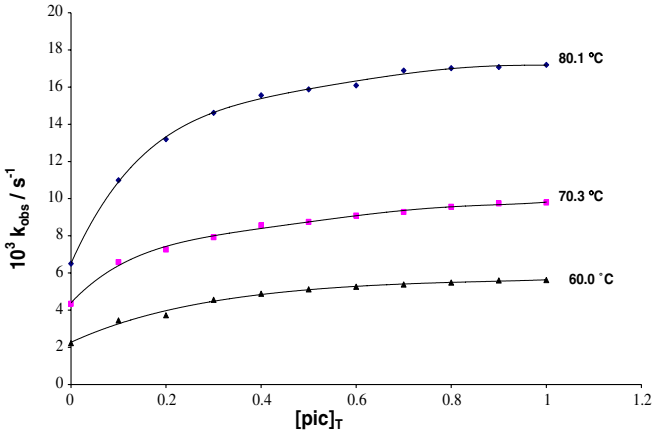

Fig. 8. Plot of k_{obs} vs. $[pic]_T$ at different temperatures, pH 12.6, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-3}$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

The stability constant (K_{eq}, Table 4) for the overall reaction was spectrophotometrically determined by a least-square fit of absorbance versus $[pic]_T$ to Eq. (3) and

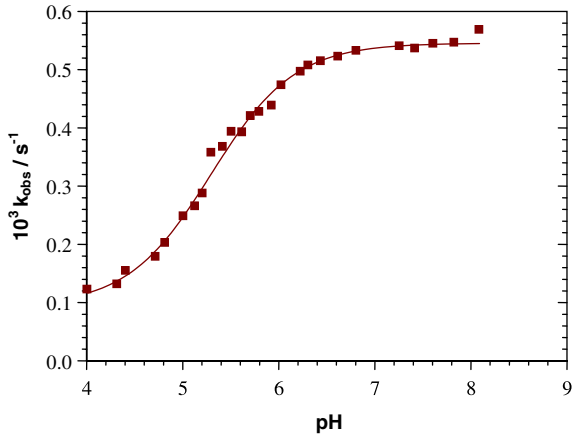

Fig. 9. Plot of k_{obs} vs. pH, $T = 80.3$ °C, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-3}$ M, $[pic]_T = 0.1$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

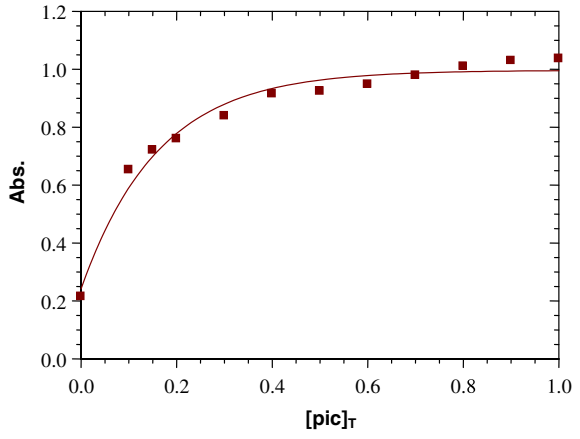

Fig. 10. Plot of absorbance vs. $[pic]_T$, $T = 79.8$ °C, pH ≈8.06, $[ReN(H_2O)(CN)_4^{2-}] = 1.0 \times 10^{-3}$ M, $\lambda = 400$ nm, $\mu = 1.0$ M $NaClO_4$.

illustrated in Fig. 10. This equation is derived using Beer's law, mass balance as well as the definition of K'' for the overall reaction.

$$A = \frac{A_{ReH_2O} + A_{Repic}K''[pic]_T}{1 + K''[pic]_T}, \quad (3)$$

where A_{ReH_2O} = absorbance of $[ReN(H_2O)(CN)_4]^{2-}$, A_{Repic} = absorbance of $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ and $[pic]_T$ = analytical concentration of picolinic acid.

The acid dissociation constant for the $[ReN(H_2O)(CN)_4]^{2-}$ complex, $K_{a(ReH_2O)}$, were calculated from the experimental data in Fig. 5 which were fitted to Eq. (4) and the value for $K_{a(ReH_2O)}$ is reported in Table 4

$$A = \frac{A_{ReH_2O}K_{a(ReH_2O)} + A_{ReOH}[H^+]}{K_{a(ReH_2O)} + [H^+]}, \quad (4)$$

where A_{ReH_2O} = absorbance of $[ReN(H_2O)(CN)_4]^{2-}$ and A_{ReOH} = absorbance for $[ReN(OH)(CN)_4]^{3-}$.

3.4. Fast reaction

The rate law corresponding to the fast reaction in the biphasic time–concentration data, taking into account that the formation of the final product ($[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$) is much slower (more so at the lower temperatures at which these reactions were followed) and does not influence the rate of the $[ReN(\eta^1\text{-pic})(CN)_4]^{3-}$ formation, is given in Eq. (5)

$$\begin{aligned}\text{Rate} = {} & k_1[ReN(H_2O)(CN)_4^{2-}][pic^-] \\ & + k_2[ReN(OH)(CN)_4^{3-}][pic^-] \\ & + k_4[ReN(H_2O)(CN)_4^{2-}][picH] \\ & - k_{-1}[ReN(\eta^1\text{-pic})(CN)_4^{3-}] \\ & - k_{-2}[ReN(\eta^1\text{-pic})(CN)_4^{3-}][OH^-] \\ & - k_{-4}[ReN(\eta^1\text{-picH})(CN)_4^{2-}]. \end{aligned} \quad (5)$$

At a pH between 4 and 6 ($[H^+] \gg K_{a(ReH_2O)}$, and k_2, $k_{-2} \sim 0$), the pseudo first-order rate constant is given by

$$\begin{aligned} k_{obs} = {} & (k_1 + k_4[H^+]/K_{a(picH)})(1 + [H^+]/K_{a(picH)})[pic]_T \\ & + (k_{-1} + k_{-4}[H^+]/K_{a(picH)})/(1 + [H^+]/K_{a(picH)}), \end{aligned} \quad (6)$$

where $[pic]_T$ represents the total picolinate/picolinic acid concentration.

The pseudo first-order rate constant ($[pic]_T > [Re]_t$) at higher pH (pH between 8 and 13) is given by

$$\begin{aligned} k_{obs} = {} & (k_1 + k_2K_{a(ReH_2O)}/[H^+])/(1 + K_{a(ReH_2O)}/[H^+]) \\ & \times [pic]_T + k_{-1} + k_{-2}[OH^-]. \end{aligned} \quad (7)$$

Eq. (7) simplifies to Eq. (8) at a pH < 9 ($pK_{a(ReH_2O)} \sim 11.6$)

$$k_{obs} = k_1[pic]_T + k_{-1}. \quad (8)$$

Eq. (8) predicts a straight line with slope k_1 and an intercept of k_{-1} ($[OH^-]$ very small). The experimental k_{obs} versus $[pic]_T$ data obtained at the three different temperatures (Fig. 6) were used to calculate the values for k_1 and k_{-1} using a least-squares fit to Eq. (8) and these values are reported in Table 3. The values of k_2, $K_{a(ReH_2O)}$ and k_{-2} were calculated from Eq. (7), using the k_1 and k_{-1} values from the pH variation (Fig. 3) and are also reported in Table 3.

3.5. Slow reaction

From Scheme 1 the overall rate law for the slow reaction is given by

$$\begin{aligned}\text{Rate} = {} & k_3[ReN(\eta^1\text{-pic})(CN)_4^{3-}] - k_{-3}[CN^-] \\ & \times [ReN(\eta^2\text{-pic})(CN)_4^{2-}] \\ = {} & k_{obs}([ReN(\eta^1\text{-pic})(CN)_4^{3-}] \\ & + [ReN(H_2O)(CN)_4^{2-}] \\ & + [ReN(OH)(CN)_4^{3-}]) - k_{-3}[CN^-]. \end{aligned} \quad (9)$$

The pseudo first-order rate constant ($[pic]_T > [Re]_T$) is given by

Table 3

Temperature (°C)	Constant	Value
40.3	k_1 (M^{-1} s^{-1})[a]	$1.92(5) \times 10^{-1}$
	k_1 (M^{-1} s^{-1})[b]	$5.3(3) \times 10^{-1}$
	k_{-1} (s^{-1})[a]	$5.9(3) \times 10^{-2}$
	k_{-1} (s^{-1})[b]	$5.9(3) \times 10^{-2}$
	K_1 (M^{-1})[c]	3.3(1)
	k_2 (M^{-1} s^{-1})[b]	4.1(2)
	k_{-2} (s^{-1})[b]	$1.0(1) \times 10^{-3}$
30.2	k_1 (M^{-1} s^{-1})[a]	$8.98(7) \times 10^{-2}$
	k_{-1} (s^{-1})[a]	$3.65(5) \times 10^{-2}$
	K_1 (M^{-1})[c]	2.46(1)
20.4	k_1 (M^{-1} s^{-1})[a]	$2.1(1) \times 10^{-2}$
	k_{-1} (s^{-1})[a]	$2.11(5) \times 10^{-2}$
	K_1 (M^{-1})[c]	1.0(2)
	$pK_{a(ReH_2O)}$[b]	11.43(2)
	$\Delta H^{\neq}$ (k_1) kJ mol^{-1}	82.5(2)
	$\Delta S^{\neq}$ (k_1) J K^{-1} mol^{-1}	5.01(6)
	$\Delta H^{\neq}$ (k_{-1}) kJ mol^{-1}	36.8(1)
	$\Delta S^{\neq}$ (k_{-1}) J K^{-1} mol^{-1}	−151.4(1)

[a] Slope and intercept, Fig. 6, Eq. (8).
[b] Data in Fig. 3, Eq. (7).
[c] $K_1 = k_1/k_{-1}$.

$$k_{obs} = (k_3K_1 + k_3K_2K_{a(ReH_2O)}/[H^+])[pic]_T/(K_1[pic]_T + K_2[pic]_TK_{a(ReH_2O)}/[H^+] + K_{a(ReH_2O)}/[H^+] + 1) + k_{-3}. \quad (10)$$

Eq. (10) predicts a non-linear relationship between k_{obs} and $[pic]_T$. The experimental results obtained from the plot of k_{obs} versus $[pic]_T$ in Fig. 7 (at pH ~8) clearly show a linear relationship between these two variables indicating that the term $K_1[pic]_T \ll 1$, Eq. (10) simplifies to Eq. (11)

$$k_{obs} = (k_3K_1 + k_3K_2K_{a(ReH_2O)}/[H^+]) \times [pic]_T/(K_2[pic]_TK_{a(ReH_2O)}/[H^+] + K_{a(ReH_2O)}/[H^+] + 1) + k_{-3}. \quad (11)$$

At a pH well below the $pK_{a(ReH_2O)}$, Eq. (11) simplifies further to

$$k_{obs} = k_3K_1[pic]_T + k_{-3}. \quad (12)$$

This equation predicts a straight line with slope k_3K_1 and intercept k_{-3}. The experimental results in Fig. 7 were fitted to Eq. (12) to yield the slopes and intercepts. The values for the different rate constants are reported in Table 4.

The reaction was also followed at a pH (between 4 and 8) where the incoming ligand changed from the protonated picolinic acid (picH) to the free picolinate anion (pic^-). These results are shown in Fig. 9 and the values for k_3K_1 and $pK_{a(picH)}$ were fitted to Eq. (13), where $K_{a(picH)}$ represents the acid dissociation constant of picolinic acid and are reported in Table 4

$$k_{obs} = k_3K_1[pic]_T/(1 + [H^+]/K_{a(picH)}) + k_{-3}, \quad (13)$$

where $[pic]_T = [pic^-] + [picH]$.

The non-linear experimental data reported in Fig. 8 was fitted to Eq. (11) (pH between 8 and 12) and the final rate and equilibrium constants calculated are reported in Table 4. As was the case for the fast reaction, it appeared that the complex is also reactive at the pH where $[ReN(OH)(CN)_4]^{3-}$ is the predominant species in solution.

The reactivity of the final product $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ towards CN^- ions was confirmed with the addition of free CN^- to a solution containing the final product (Fig. 11), but these results not only point to the reverse reaction, k_{-3}, but also to successive further cyanide substitution of the picolinate anion from the coordination sphere [14].

The $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values for the k_1, k_{-1} and k_3 paths were obtained from a least-squares fit of the k_3 versus temperature data to the Eyring–Polanyi equation and are reported in Tables 3 and 4.

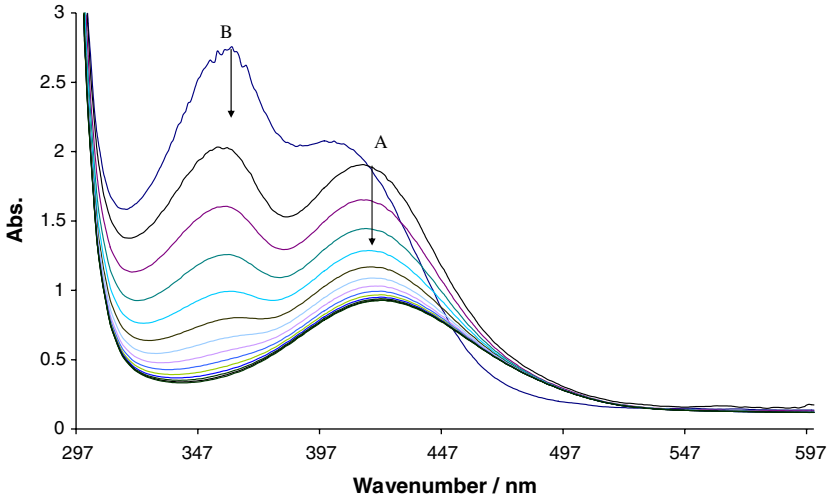

Fig. 11. UV/Vis spectral changes during the reaction between $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ (1.0×10^{-3} M), with [NaCN] = 1.0 M, $T = 70.3$ °C, pH ≈8.01. Time intervals of 0.1 min.

4. Discussion

The reaction between $[ReN(H_2O)(CN)_4]^{2-}$ and picolinate, as presented in Scheme 12, is largely based on the results obtained from previous kinetic and structural studies. Monodentate substitution reactions between $[ReN(H_2O)(CN)_4]^{2-}$ and CN^- or N_3^- [27,28] clearly indicate that only the aqua ligand is substituted in a relatively fast reaction and that the rest of the coordination sphere is left unchanged (except for an increase in octahedral distortion [14,27]). A comparison between the aqua substitution rate for the $[ReX(H_2O)(CN)_4]^{n-}$ complexes ($k_1 = 3.48(4) \times 10^{-3}\ M^{-1}\ s^{-1}$ at 25 °C for NCS^- for $X = O^{2-}$ and $k_1 = 7.2(4) \times 10^3\ M^{-1}\ s^{-1}$ for CN^- at 25 °C for $X = N^{3-}$) clearly indicated that the Re–OH_2 bond lengths (2.142(7) and 2.496(7) Å for $[ReO(H_2O)(CN)_4]^-$ and $[ReN(H_2O)(CN)_4]^{2-}$, respectively) is a very good indicator of the lability of the complex towards substitution reactions. The relatively large *trans* influence of the terminal ligand, resulting in the labilisation of the *trans* ligand, is clearly illustrated by the *cis* and *trans* cyano bond lengths in the $[ReN(CN)_5]^{3-}$ complex. The average equatorial Re–CN bond length is equal to 2.12(1) Å while the apical Re–CN bond length is equal to 2.39(1) Å.

The final products for these reactions, as well as a number of other iso-electronic complexes all revealed that the incoming group is situated *trans* with respect to the strongly bonded terminal ligand. It is well known [34] and in accordance with the present structure determination that the carboxylate group in the picolinate ion will coordinate before the pyridine nitrogen atom. It is therefore concluded that the first step in the reaction between the starting complex and the picolinate ion in this study is the substitution of the aqua ligand by the carboxylate oxygen and the subsequent ring-closure step (slow) with the displacement of a cyano group with bonding of the pyridine nitrogen to the metal center.

The rate of aqua substitution in the $[ReN(H_2O)(CN)_4]^{2-}$ complex by the picolinate anion was determined as $2.1(1) \times 10^{-2}\ M^{-1}\ s^{-1}$ at 20.4 °C which is substantially slower (factor 10^5) than the corresponding reaction when CN^- was the incoming group. This is due to the difference in the coordination capability of the two ligands which is also manifested in the stability constant for the two different complexes which were determined as $471(1)\ M^{-1}$ for $[ReN(CN)_5]^{3-}$ and $1.0(2)\ M^{-1}$ (k_1/k_{-1}) for the $[ReN(\eta^1\text{-pic})(CN)_4]^{3-}$, respectively, indicating the weak σ-donating ability of the COO^- group compared to that of the cyano group. The same tendency was observed for the corresponding reaction between $[WO(H_2O)(CN)_4]^{2-}$ and picolinate where a decrease in substitution rate with a factor of 2.5 was observed when compared to the rate with CN^- as incoming group [23] . A decrease of a factor of 10^3 was also observed for the stability constant of $[WO(H_2O)(CN)_4]^{2-}$ and picolinate when compared to that of the reaction between $[WO(H_2O)(CN)_4]^{2-}$ and CN^- [23] .

A very interesting result from this study is the reactivity of the $[ReN(OH)(CN)_4]^{3-}$ complex towards the picolinate anion. Results obtained in the pH variation as indicated in Fig. 3 clearly indicate acceleration in the substitution rate with an increase in pH. The calculated k_2 value at 40.3 °C of $4.1(2)\ M^{-1}\ s^{-1}$ is a factor 20 faster than the corresponding aqua reaction. These results are quite novel in the sense that in all the previous studies, except maybe for the substitution between $[ReN(H_2O)(CN)_4]^{2-}$ and CN^-, indications are that the hydroxo complexes are normally inert with respect to substitution. In the case of the reaction between $[ReN(H_2O)(CN)_4]^{2-}$ and CN^- [14] a hydroxo substitution rate of $1.5(4) \times 10^1\ M^{-1}\ s^{-1}$ was obtained, but due to the large error was interpreted as zero and therefore non-reactive towards the incoming ligand.

The acid dissociation constant, $pK_{a(ReH_2O)}$ for the $[ReN(H_2O)(CN)_4]^{2-}$ complex was kinetically determined as 11.43(2) (Fig. 3) and spectrophotometrically as

11.09(3) (Fig. 5). These values correspond very favourably with the 11.6(2) that was previously determined [14].

The relatively small activation enthalpy and entropy (Table 3) for the forward reaction is compatible with the $\Delta H^{\neq} = 70(9)$ kJ mol^{-1} and $\Delta S^{\neq} = -12(31)$ J K^{-1} mol^{-1} values that was obtained for the corresponding reaction between $[WO(H_2O)(CN)_4]^{2-}$ and picolinate.

The substitution of the CN^- group by the pyridine nitrogen atom of the picolinate anion (slow reaction) was substantially slower than the aqua substitution and these reactions were studied at much higher temperatures. It is anticipated that the stronger bonded cyano ligand would be much more difficult to substitute than the more labile aqua ligand, hence the slower ring-closure step. The value for the ring-closure step for the $[ReN(\eta^1\text{-pic})(CN)_4]^{3-}$ to form the final $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ complex at 80 °C was determined as $1.84(2) \times 10^{-2}$ s^{-1}. The pH variation as indicated in Fig. 4 also clearly illustrates the increase in substitution rate with an increase in pH. The stability constants calculated from these kinetic results clearly show that the k_2 pathway ($K_2 = 14.8$ M^{-1} compared to $K_1 = 6.6(1) \times 10^{-2}$ M^{-1}) is favoured above the k_1 pathway for the fast reaction, while the K_3 value of 731(1) M (slow reaction) is substantially larger than the previous two (K_1 and K_2) stability constants. These results clearly indicate an increase towards thermodynamic stability which is normally associated with chelation reactions. The $pK_{a(ReH_2O)}$ value for the $[ReN(H_2O)(CN)_4]^{2-}$ complex of 11.54(6) is also in good agreement with the values obtained for the fast reaction.

The reaction between the $[ReN(H_2O)(CN)_4]^{2-}$ and picolinate/picolinic acid, see Fig. 9, at low pH values (k_4, $k_{-4} \sim 0$) yielded a $pK_{a(picH)}$ value of 5.29(2) for the picolinic acid which agrees also very well with the literature value of 5.52.

The activation entropy, $\Delta S^{\neq}$, for the slow reaction (Table 4) is clearly negative (−133.4(3) J K^{-1} mol^{-1}), indicating associative activation during the last step of the reaction. It is anticipated that the strongly bonded cyano group will not dissociate easily and that substantial bond formation between the picolinate anion and the metal complex takes place before the dissociation of the cyanide group. An increase in coordination number for these transition metal complexes is well known, for example the isolation of the $[Re(CN)_7]^{4-}$ complex [35]. The free energy of activation, $\Delta G^{\neq}$, for the fast reaction (81.1 kJ mol^{-1}) has a very large contribution from the activation enthalpy (82.5 kJ mol^{-1}) indicating that this particular reaction is mainly enthalpy driven whilst the reverse process is more entropy driven. The $\Delta G^{\neq}$ for the slow reaction of 98.8 kJ mol^{-1} (80 °C) on the other hand has a large activation entropy component (47.1 kJ mol^{-1}), pointing to a substantial entropy contribution resulting from stereochemical changes in the final reaction.

Additional free cyanide ions was added to a solution containing $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ complex in an effort to investigate the reverse reaction of the slow chelating step (k_{-3} in Scheme 12). A relatively fast reaction was observed (see Fig. 11) and a $[CN^-]_T$ variation clearly showed a linear dependence [36] in cyanide concentration. The slope in the plot of k_{obs} versus $[CN^-]_T$ (suppose to be k_{-3}) is however orders of magnitude smaller than the values obtained in this study while the intercept (suppose to be k_3) is orders of magnitude larger than the present values obtained for the k_3 pathway. The final spectrum (Fig. 11) with absorption maximums at 273 and 420 nm corresponds very well with the values of 272.2 (not shown in Fig. 11 due to large extinction coefficient) and 422 nm obtained for the $[ReN(CN)_5]^{3-}$ complex in a previous study [14]. These results suggested that the reaction sequence between $[ReN(\eta^2\text{-pic})(CN)_3]^{2-}$ and CN^- ions is as follows:

$$[ReN(\eta^2\text{-pic})(CN)_3]^{2-} + CN^- \rightarrow [ReN(\eta^1\text{-pic})(CN)_4]^{3-} \rightarrow [ReN(CN)_5]^{3-} + pic^- \quad (14)$$

and that the picolinato anion is completely substituted from the coordination sphere.

2. Experimental

2.1. Materials

Kpiv was synthesized in water by treatment of Hpiv with KOH in 1:1 molar ratio. Admtrz and adetrz were prepared according to the literature methods [13]. All other chemicals were commercial products and used as received.

2.2. Synthesis

2.2.1. $[Ni_2(\mu\text{-}H_2O)(\mu\text{-admtrz})_2(piv)_4(H_2O)_2]\cdot 13H_2O$ ($\mathbf{1}\cdot 13H_2O$)

To a 10 mL ethanol solution of $NiCl_2\cdot 6H_2O$ (0.2 g, 0.84 mmol) was added Kpiv (0.353 g, 2.52 mmol) and admtrz (0.094 g, 0.84 mmol) while stirring. The solution was stirred at room temperature for 17 h and then filtered. Green crystals of $\mathbf{1}\cdot 13H_2O$ were obtained by slow evaporation of the resulting solution, which readily lost lattice water molecules to give product **1** when they left their mother liquor at room temperature. The dried powder sample of product **1** was used for its characterization and magnetic study. Yield 0.050 g (15%). *Anal.* Calc. for **1** $C_{28}H_{58}N_8Ni_2O_{11}$: C, 42.03; H, 7.31; N, 14.00. Found: C, 41.74; H, 7.54; N, 13.72%. IR (KBr pellet, cm^{-1}): 3459 (m), 3300 (m), 3184 (m), 2962 (s), 2929 (m), 2871 (w), 1648 (w), 1528 (vs), 1485 (s), 1458 (w), 1415 (m), 1362 (m), 1268 (w), 1226 (m), 1098 (w), 1049 (w), 1029 (w), 905 (w), 879 (w), 792 (w), 608 (w), 554 (w).

2.2.2. $[Ni_2(\mu\text{-}H_2O)(\mu\text{-adetrz})_2(piv)_4]\cdot 3H_2O$ ($\mathbf{2}\cdot 3H_2O$)

To a 10 mL ethanol solution of $NiCl_2\cdot 6H_2O$ (0.2 g, 0.84 mmol) was added Kpiv (0.236 g, 1.68 mmol) and adetrz (0.236 g, 1.68 mmol) while stirring. The solution was stirred at room temperature for 17 h and then filtered. Green crystals of $\mathbf{2}\cdot 3H_2O$ were obtained by slow evaporation of the resulting solution, which readily lost lattice water molecules to give product **2** when they left their mother liquor at room temperature. The dried powder sample of product **2** was used for its characterization and magnetic study. Yield 0.034 g (10%). *Anal.* Calc. for **2** $C_{32}H_{62}N_8Ni_2O_9$: C, 46.86; H, 7.62; N, 13.66. Found: C, 46.89; H, 7.84; N, 13.37%. IR (KBr pellet, cm^{-1}): 3295 (m), 3216 (m), 3191 (m), 2977 (s), 2929 (m), 2873 (w), 1655 (m), 1525 (vs), 1486 (s), 1459 (m), 1434 (s), 1412 (m), 1372 (w), 1360 (m), 1285 (w), 1227 (m), 1142 (w), 1095 (w), 1054 (w), 904 (w), 878 (w), 791 (w), 609 (w).

2.3. Crystal structure determination

Data for $\mathbf{1}\cdot 13H_2O$ and $\mathbf{2}\cdot 3H_2O$ were collected on a Bruker SMART-CCD diffractometer with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) and corrected for absorption using SADABS program [14]. These two structures were solved by direct methods and refined on F^2 against all reflections by full-matrix least-squares methods with SHELXTL program [15]. The hydrogen atoms in two compounds were positioned geometrically and refined in the riding-model approximation. All non-hydrogen atoms were refined anisotropically. Some disorders were detected for the carbon atoms of the *t*-butyl groups in $\mathbf{1}\cdot 13H_2O$, which were refined over two sites, yielding occupation factors of 0.647(7), 0.647(7) and 0.647(7) for C8, C9 and C10, respectively. Crystal data and structure refinement details for $\mathbf{1}\cdot 13H_2O$ and $\mathbf{2}\cdot 3H_2O$ are summarized in Table 1. The selected bond distances and bond angles for $\mathbf{1}\cdot 13H_2O$ and $\mathbf{2}\cdot 3H_2O$ are given in Tables 2 and 3, respectively. The selected hydrogen bond distances and angles for $\mathbf{1}\cdot 13H_2O$ and $\mathbf{2}\cdot 3H_2O$ are given in Table 4.

2.4. Measurements

Elemental analyses (C, H and N) were carried out on a Perkin–Elmer 240C analytical instrument. IR spectra were recorded on a VECTOR 22 Bruker spectrophotometer with KBr pellets in the 4000–400 cm^{-1} region. Magnetic susceptibilities on powder samples of **1** and **2** were carried out with a Quantum Design MPMS-XL SQUID magnetometer in the 1.8–300 K range. The applied magnetic field was 0.2 T and diamagnetic corrections were made with Pascal's constants as -586×10^{-6} emu mol^{-1} for **1** and -595×10^{-6} emu mol^{-1} for **2**.

3. Results and discussion

3.1. Synthesis

Compounds $\mathbf{1}\cdot 13H_2O$ and $\mathbf{2}\cdot 3H_2O$ were obtained from the reaction of $NiCl_2\cdot 6H_2O$, Kpiv and the corresponding triazoles in ethanol at room temperature with 10–15%. A reaction mixture of $NiCl_2\cdot 6H_2O$, Kpiv and admtrz in a molar ratio of 1:3:1 gave pure $\mathbf{1}\cdot 13H_2O$ while $\mathbf{2}\cdot 3H_2O$ was synthesized from a reaction mixture of $NiCl_2\cdot 6H_2O$, Kpiv and adetrz in a molar ratio of 1:2:2. Some green uncharacterized powder samples were formed after the isolation of $\mathbf{1}\cdot 13H_2O$ and $\mathbf{2}\cdot 3H_2O$, which might be responsible for the low yields (10–15%). It was further found that the reaction mixture of the correct stoichiometric molar ratio (Ni:piv:triaz = 1:2:1) did not yield $\mathbf{1}\cdot 13H_2O$ and $\mathbf{2}\cdot 3H_2O$.

[a] Symmetry transformations used to generate equivalent atoms: #1, $-x+3/2$, y, $-z+3/2$; #2, $x+1/2$, $1-y$, $z+1/2$; #3, x, $y+1$, z; #4, $x-1/2$, $1-y$, $z-1/2$ for $\mathbf{1}\cdot 13H_2O$; #1, $1+x-y$, $2-y$, $-z+4/3$; #3, y, $1+x$, $2-z$; #4, x, $y-1$, z; #5, $1+x-y$, $2-y$, $-z+1/3$ for $\mathbf{2}\cdot 3H_2O$.

3.2. IR spectroscopy

The IR spectra show an absorption peak at 1648 cm^{-1} for **1** and 1655 cm^{-1} for **2**, which can be assigned to the C=O stretching vibration of the pivalate ligand. And the *t*-butyl groups appear at frequencies at 1362 and 1226 cm^{-1} for **1**, and at 1372, 1360, and 1227 cm^{-1} for **2**. The IR spectra also exhibit a series of signals at 1528, 1485 and 1458 cm^{-1} for **1**, and at 1525, 1486 and 1459 cm^{-1} for **2**, which can be attributed to the triazole ring.

3.3. Crystal structures

3.3.1. $[Ni_2(\mu\text{-}H_2O)(\mu\text{-admtrz})_2(piv)_4(H_2O)_2]\cdot 13H_2O$ ($\mathbf{1}\cdot 13H_2O$)

The crystal structure of $\mathbf{1}\cdot 13H_2O$ consists of a dinuclear nickel compound **1** and thirteen lattice water molecules. The structure determination reveals that **1** has two six-coordinated Ni(II) centers, both with a distorted octahedral geometry, which are held together by two bridged admtrz ligands and one bridging water molecule (see Fig. 1). There is a twofold rotation axis going through O1 atom and the middle center of Ni1–Ni1$^{\#1}$ [symmetry

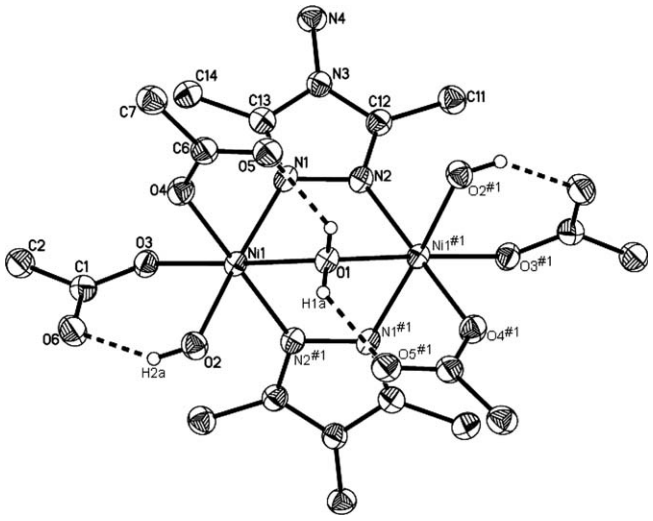

Fig. 1. ORTEP drawing (30% probability level) of $\mathbf{1} \cdot 13H_2O$, showing the atom-labeling scheme; all hydrogen atoms (except the hydrogen atoms involving the intramolecular hydrogen bonds), lattice water, and methyl groups in pivalates have been omitted for clarity [symmetry code: #1, $-x + 3/2$, y, $-z + 3/2$]. Dashed lines indicate the intramolecular hydrogen bonds.

code: #1, $-x + 3/2$, y, $-z + 3/2$]. Ni1 atom is coordinated by one oxygen atom (O1) from the bridging water molecule (Ni1–O1 = 2.095(2) Å), one oxygen atom (O2) from a terminally coordinated water molecule (Ni1–O2 = 2.078(3) Å), two oxygen atoms (O3 and O4) from two terminally coordinated pivalate ligands (Ni1–O3 = 2.066(3), Ni1–O4 = 2.053(3) Å) and two nitrogen atoms (N1 and $N2^{\#1}$) from the bridged admtrz groups (Ni1–N1 = 2.084(3), Ni1–$N2^{\#1}$ = 2.112(3) Å). The Ni1–N1 and Ni1–$N2^{\#1}$ bonds are somewhat longer than those in the reported dinuclear Ni(II) complexes with double and triple triazole bridges (2.013–2.074 Å) [9,10]. The bond angles N2–N1–Ni1 and N1–N2–$Ni1^{\#1}$ are 119.0(2)° and 117.0(2)°, respectively, smaller than those in the reported dinuclear Ni(II) compounds with double and triple triazole bridges (124.3–138.8°) [9,10]. The Ni1···$Ni1^{\#1}$ distance in $\mathbf{1} \cdot 13H_2O$ is 3.444(2) Å, much shorter than those observed in the previously reported dinickel(II) complexes with only double triazole bridge (4.10–4.14 Å) [9]. These differences can be attributed to the additional water molecule bridge between the two Ni(II) centers in $\mathbf{1} \cdot 13H_2O$. There are two types of intramolecular O–H···O hydrogen bonds: one hydrogen bond with the O···O distance of 2.595(3) Å

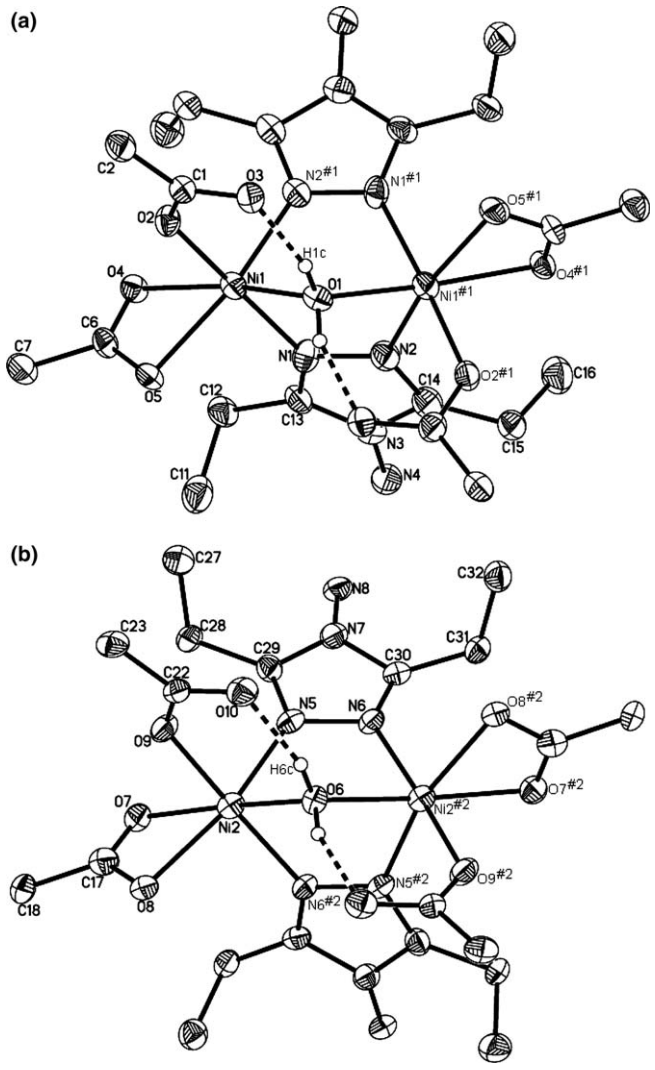

Fig. 3. ORTEP drawing (30% probability level) of **A** (a) and **B** (b), showing the atom-labeling scheme; all hydrogen atoms (except the hydrogen atoms involving the intramolecular hydrogen bonds), lattice water, and methyl groups in pivalates have been omitted for clarity [symmetry codes: #1, $x - y + 1$, $-y + 2$, $-z + 4/3$; #2, $x - y + 1$, $-y + 2$, $-z + 7/3$]. Dashed lines indicate the intramolecular hydrogen bonds.

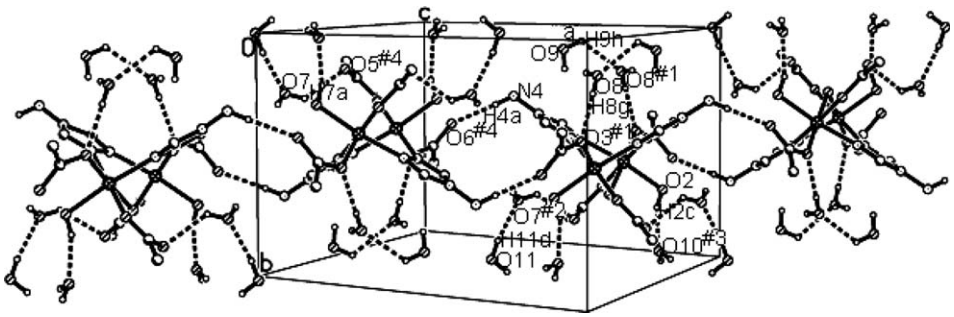

Fig. 2. The one-dimensional chain structure of $\mathbf{1} \cdot 13H_2O$ in the crystal lattice. The isolated water molecules and methyl groups in pivalates and admtrz have been omitted for clarity [symmetry codes: #1, $-x + 3/2$, y, $-z + 3/2$; #2, $x + 1/2$, $1 - y$, $z + 1/2$; #3, x, $y + 1$, z; #4, $x - 1/2$, $1 - y$, $z - 1/2$]. Dashed lines indicate the intermolecular hydrogen bonds.

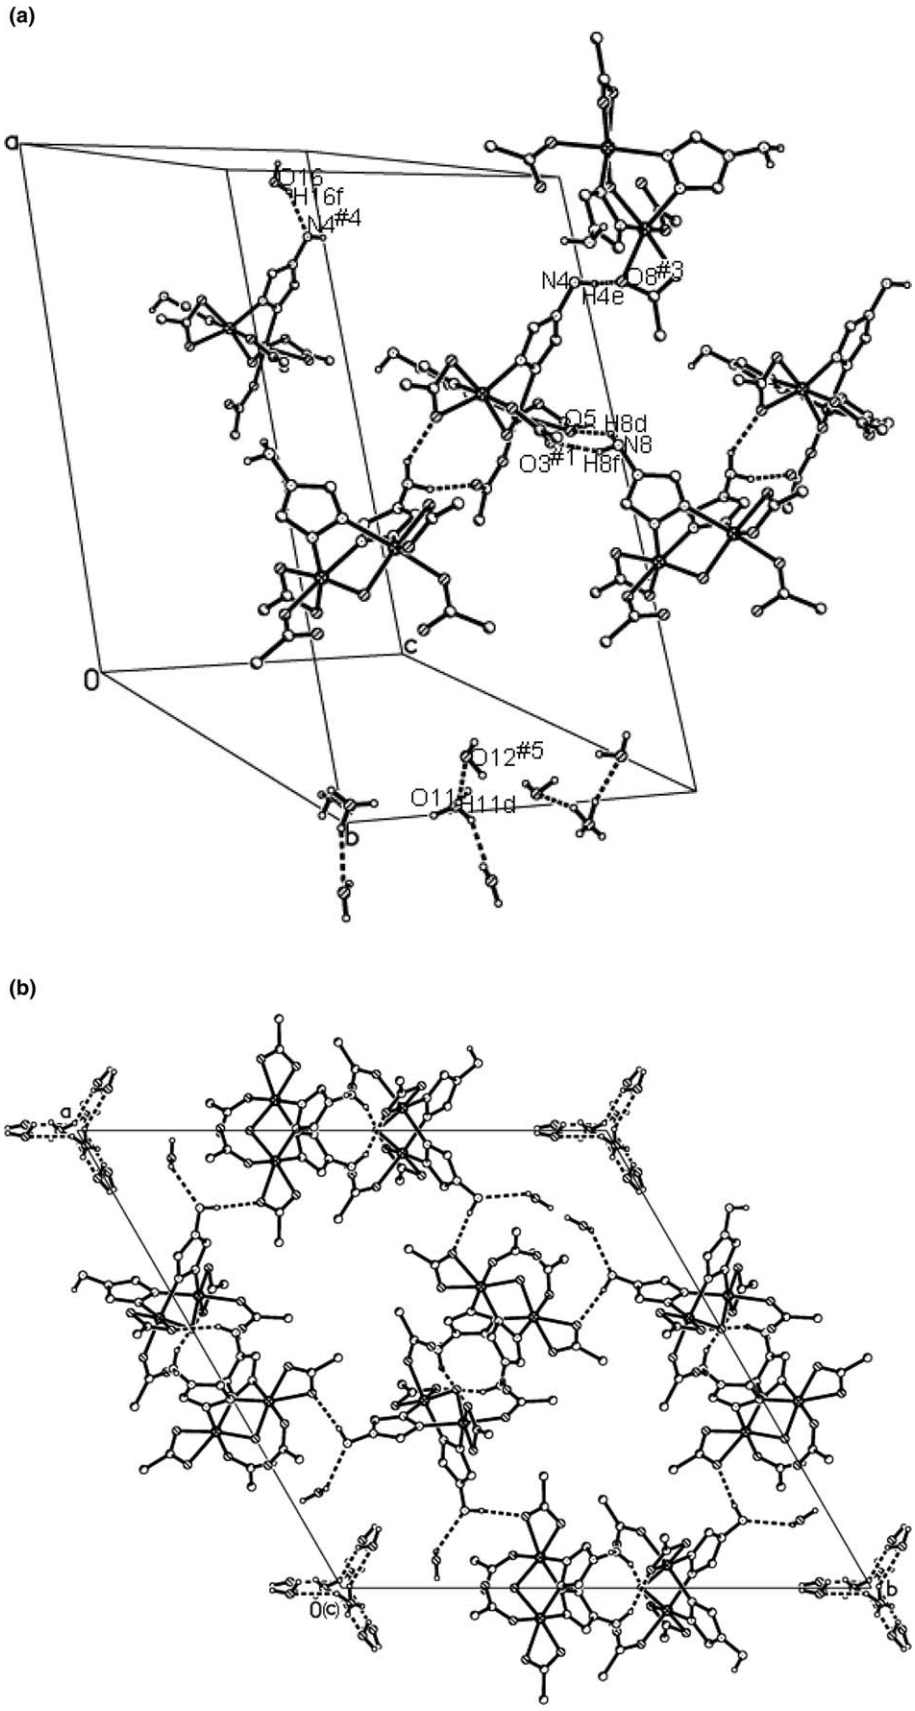

Fig. 4. (a) The intermolecular hydrogen bonds of $\mathbf{2}\cdot 3H_2O$ [symmetry codes: #1, $1+x-y$, $2-y$, $-z+4/3$; #3, y, $1+x$, $2-z$; #4, x, $y-1$, z; #5, $1+x-y$, $2-y$, $-z+1/3$]. (b) Projection showing the three-dimensional network for $\mathbf{2}\cdot 3H_2O$ viewed down the c axis. The ethyl groups in adetrz and methyl groups in pivalates have been omitted for clarity. Dashed lines indicate intermolecular hydrogen bonds.

between the bridging water molecule O1 and O5$^{\#1}$ atom from the terminally coordinated pivalate ligand and the other hydrogen bond with the O···O distance of 2.565(4) Å between the terminally coordinated water molecule O2 and O6 atom from the terminally coordinated pivalate ligand (see Table 4). The molecular packing of **1** · 13H_2O in the crystal lattice is shown in Fig. 2. The adjacent dinuclear molecules are linked through the intermolecular N4–H4a···O6$^{\#4}$ hydrogen bond along the [1 0 1] direction, leading to one-dimensional chains of molecules. The one-dimensional chain is surrounded by three lattice water molecules (O7, O8 and O10$^{\#3}$) via three types of intermolecular hydrogen bonds, i.e., O7–H7a···O5$^{\#4}$, O8–H8g···O3$^{\#1}$ and O2–H2c···O10$^{\#3}$. O8$^{\#1}$ and O7$^{\#2}$ are further connected with another two water molecules (O9 and O11) via intermolecular hydrogen bonds O9–H9h···O8$^{\#1}$ and O11–H11d···O7$^{\#2}$ [symmetry codes: #1, $-x+3/2$, y, $-z+3/2$; #2, $x+1/2$, $1-y$, $z+1/2$; #3, x, $y+1$, z; #4, $x-1/2$, $1-y$, $z-1/2$] (see Table 4). The other lattice water molecules are isolated in the crystal structure.

3.3.2. [$Ni_2(\mu$-$H_2O)(\mu$-adetrz$)_2$(piv$)_4$] · 3H_2O (**2** · 3H_2O)

In the crystal structure of **2** · 3H_2O, there are two types of crystallographically independent molecules (**A** and **B**) in addition to the lattice water molecules, which have the same structure except the different orientation of ethyl groups of the bridged adetrz (see Fig. 3). Both **A** and **B** have a twofold rotation axis passing the oxygen atom of bridging water molecule and the middle center of Ni–Ni [Ni1–Ni1$^{\#1}$ for **A** and Ni2–Ni2$^{\#2}$ for **B**, symmetry codes: #1, $x-y+1$, $-y+2$, $-z+4/3$; #2, $x-y+1$, $-y+2$, $-z+7/3$]. The bond length parameters in **A** and **B** are not significantly different. Therefore only the structural detail of **A** is discussed here. Similar to the structure of **1**, **A** has a dinuclear Ni(II) unit bridged with one water molecule and two adetrz ligands. Besides the occurrence of one terminally coordinated pivalate ligand, the other two remaining donor atoms around Ni(II) ion are different in **1** and **A**. As discussed above, the two coordination sites of Ni(II) ion in **1** are completed by one oxygen atom from the pivalate ligand and one oxygen atom from the terminal water molecule. In **A**, the two coordination sites are occupied by two oxygen atoms (O4 and O5) from one pivalate ligand with the O4–Ni1–O5 angle of 61.0(1)°, which leads to more seriously distorted octahedral geometry of Ni(II) center than that in **1**. The bond angles N2–N1–Ni1 and N1–N2–Ni1$^{\#1}$ (117.6(2)° and 112.8(3)°) are comparable to those in **1**. The Ni1···Ni1$^{\#1}$ distance is 3.312(1) Å. There are two symmetrically related intramolecular O–H···O hydrogen bonds with the O···O distance of 2.441 Å between the bridging water molecule (O1) and O3 or O3$^{\#1}$ atom from the terminally coordinated pivalate ligand (see Table 4). The molecular packing of **2** · 3H_2O in the crystal lattice is shown in Fig. 4. **A** and adjacent **B** are linked through the intermolecular N8–H8d···O5 and N8–H8f···O3$^{\#1}$ hydrogen bonds, leading the assembly of

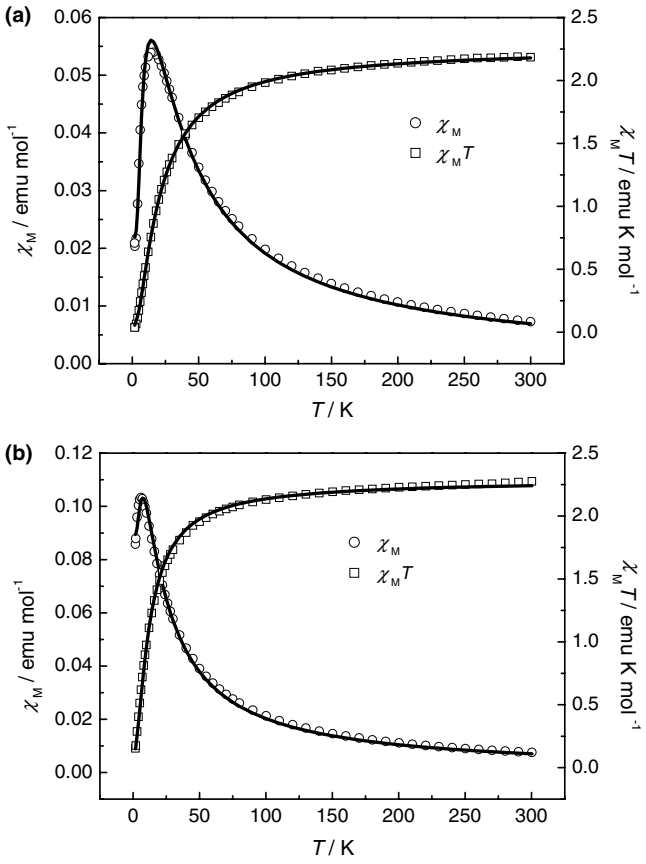

Fig. 5. Plots of χ_m (○) and $\chi_m T$ (□) vs. temperature for **1** (a) and **2** (b), where the solid line represents the theoretical curve.

one-dimensional zigzag chains of molecules along the c axis (see Fig. 4(a)). Neighboring chains of molecules are connected through the intermolecular N4–H4e···O8$^{\#3}$ hydrogen bond, resulting in a three-dimensional network (see Fig. 4(b)). One water molecule (O16) interacts with the amino group via the intermolecular O16–H16f···N4$^{\#4}$ hydrogen bond. Besides, there are two water molecules O11 and O12$^{\#5}$ clustered together via the intermolecular O11–H11d···O12$^{\#5}$ hydrogen bond in the crystal lattice [symmetry codes: #1, $1+x-y$, $2-y$, $-z+4/3$; #3, y, $1+x$, $2-z$; #4, x, $y-1$, z; #5, $1+x-y$, $2-y$, $-z+1/3$] (see Table 4). The other lattice water molecules are isolated in the crystal structure.

3.4. Magnetic properties

The powder samples of **1** and **2**, in which the lattice water molecules are completely removed, but the bridging water molecule remains in its place and in the case of **1** also two terminal water molecules, were used for magnetic study. The temperature dependence of the magnetic susceptibility of **1**, in the form of χ_m and $\chi_m T$, is shown in Fig. 5(a), χ_m being the magnetic susceptibility per dinuclear Ni(II) compound and T the temperature. The room-temperature $\chi_m T$ product is 2.18 cm^3 K mol^{-1} for **1**, which is slightly larger than that expected for two magnetically

isolated Ni(II) ions ($2.0\ cm^3\ K\ mol^{-1}$). The $\chi_m T$ value decreases slowly upon cooling till about 100 K, then decreases rapidly and reaches $0.04\ cm^3\ K\ mol^{-1}$ at 2 K. The magnetic behavior reveals the antiferromagnetic interactions between two Ni(II) centers in **1** and the ground state is $S = 0$. The magnetic data was analysed on the basis of the model including the zero-field splitting developed by Ginberg et al. [16]. The best fit leads to $g = 2.198$, $D = -10.03\ cm^{-1}$, and $J = -6.88\ cm^{-1}$ with the agreement factor $R = 1.1 \times 10^{-6}$ ($R = \sum |(\chi_m T)_{exp} - (\chi_m T)_{calc}|^2 / \sum (\chi_m T)^2_{exp}$). The χ_m and $\chi_m T$ versus T plot of **2** is very similar to that of **1** (see Fig. 5(b)). The room temperature $\chi_m T$ value of $2.28\ cm^3\ K\ mol^{-1}$ is close to that of **1** ($2.23\ cm^3\ K\ mol^{-1}$). The $\chi_m T$ value decreases rapidly below 75 K, which indicates weak antiferromagnetic interactions between two Ni(II) centers. The best fitting result is $g = 2.143$, $D = -12.31\ cm^{-1}$, and $J = -5.63\ cm^{-1}$ with $R = 6.0 \times 10^{-4}$. Since **1** and **2** are the first group dinuclear Ni(II) compounds with one water and two triazole bridges, it is difficult to rationalize their magnetic properties due to limited data available. More closely related compounds will be needed together with their magnetic studies.

4. Conclusions

In this paper the syntheses, structures and magnetic properties of two new water bridged dinuclear nickel(II) complexes containing derivatives of 1,2,4-triazole and pivalate ligands, namely, $[Ni_2(\mu\text{-}H_2O)(\mu\text{-admtrz})_2(piv)_4(H_2O)_2] \cdot 13H_2O$ (**1** · $13H_2O$) (admtrz = 4-amino-3,5-dimethyl-1,2,4-triazole, piv = pivalate anion) and $[Ni_2(\mu\text{-}H_2O)(\mu\text{-adetrz})_2(piv)_4] \cdot 3H_2O$ (**2** · $3H_2O$) (adetrz = 4-amino-3,5-diethyl-1,2,4-triazole), have been reported. They have similar structural features with unprecedented dinuclear Ni(II) units bridged by one water molecule and two triazole ligands. Variable temperature magnetic susceptibility measurements for the solid samples of **1** and **2** in the range of 1.8–300 K show that weak antiferromagnetic interactions occur in **1** and **2**.

5. Supplementary data

Crystallographic data of **1** · $13H_2O$ and **2** · $3H_2O$ in the CIF format have been deposited with the Cambridge Crystallographic Data Center as supplementary publication Nos. CCDC 279103 for **1** · $13H_2O$ and CCDC 279104 for **2** · $3H_2O$. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 003, e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk.

novel transition metal complexes, hydroquinone complexes and Ni(dmit)$_2$ salts of verdazyl radicals have also been studied [17–21].

Although the spin distribution in verdazyl radicals has been mainly studied by ESR [6,7,22–24], other techniques such as electron–nuclear double resonance, ENDOR [25], electron–electron double resonance, ELDOR [26], and nuclear magnetic resonance (NMR) [27] have also been used.

The synthesis and spectroscopic characterization of 6-(4-acetamidophenyl)-1,4,5,6-tetrahydro-2,4-dimethyl-1,2,4,5-tetrazin-3(2*H*)-one (**1**) has been reported previously [28]. This free radical, as a monohydrate, forms stable red crystals that were accidentally left for five years in a sample vial before a crystal structure and magnetic measurements were undertaken. This is some eighteen years less than the length of time that Koelsch's free radical was left prior to characterization but nevertheless illustrates the exceptional stability of this free radical [29,30].

Here we present the crystal structure of the radical **1**, solved by synchrotron radiation due to the small size of the single crystals, as well as its complete magnetic characterization (thermal variation of the magnetic susceptibility and the solid-state and solution Q-band ESR spectra). These magnetic studies show the presence of weak antiferromagnetic coupling between the radicals in the solid state and the spin distribution in the radical.

2. Crystal structure

The radical crystallizes as a monohydrate. The radical itself is essentially planar except for hydrogen atoms, with an r.m.s. deviation of 0.041 Å, and has unremarkable internal geometry; its structure is shown in Fig. 1, which also includes the water molecule of the asymmetric unit. Molecules are stacked parallel to each other along the crystallographic *b*-axis (Figs. 2 and 3). Within the stack, pairs of molecules form dimers with a high degree of overlap (Fig. 2), and successive dimers display a significant lateral offset (Fig. 3). The spacing in the stacks is uniform, the difference between perpendicular distances within (3.349 Å) and between (3.345 Å) dimers being insignificant.

The molecules within a stack do not lie perpendicular to the stacking direction, but are inclined to it. Successive adjacent stacks in the crystallographic *c* direction have alternating directions of inclination, to give an overall criss-cross pattern when viewed in this direction (Fig. 4). Lateral interactions between stacks are further supported by hydrogen bonds mediated by the water molecules, with O···O and N···O distances between 2.841 and 2.922 Å, and near-linearity at the H atoms (161–178°). Both oxygen atoms of the radical act as acceptors for water O–H bonds, and the N–H group serves as a donor to water; there are no hydrogen bonds directly between radicals. Fig. 4 shows the overall packing arrangement including these interactions.

3. Magnetic properties

The thermal variation of the product of the molar magnetic susceptibility times the temperature ($\chi_m T$) of the title compound shows at room temperature a value of ca. 0.38 emu K mol^{-1}, which is the expected value for a radical with one unpaired electron ($S = 1/2$) with a *g* value close to 2. On lowering the temperature, $\chi_m T$ remains constant down to ca. 50 K and then smoothly decreases to reach a value of ca. 0.16 emu K mol^{-1} at 2 K (Fig. 5). This behavior indicates that the title compound behaves essentially as an $S = 1/2$ paramagnet with weak antiferromagnetic interactions. Since the structure of this compound shows the presence of short distances between the two molecules forming the eclipsed dimer in the solid state and also between the molecules of different dimers, we can envisage three possible exchange schemes: (i) that this antiferromagnetic coupling takes place between the two molecules forming the almost eclipsed dimer, neglecting the interdimer interactions; that the coupling also takes place between dimers, leading either to (ii) a regular antiferromagnetic $S = 1/2$ chain (if the intra- and interdimer exchange are equal); or to (iii) a dimerised chain (a chain of dimers or alternating chain, if the intra- and interdimer exchange are different). A close inspection of the intermolecular distances also reveals short distances between molecules of different "chains of dimers" and therefore (iv) an isotropic exchange scheme can also be envisaged. According to these possible exchange schemes, we have fitted the magnetic data to the four aforementioned schemes with the following models: (i) an $S = 1/2$ dimer [31], (ii) a regular antiferromagnetic chain [32], (iii) an alternating antiferromagnetic $S = 1/2$ chain

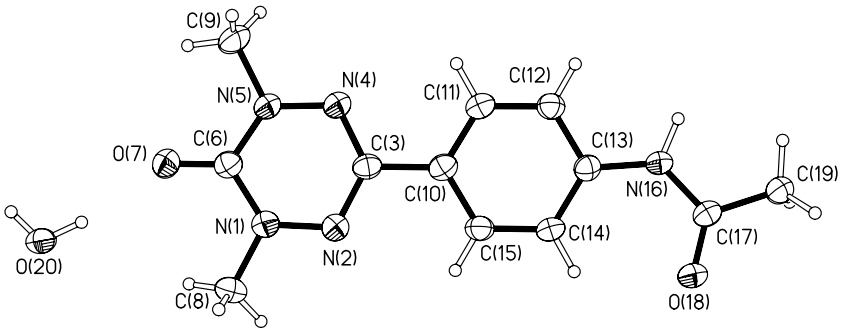

Fig. 1. The asymmetric unit of the crystal structure, with 50% probability displacement ellipsoids for non-hydrogen atoms.

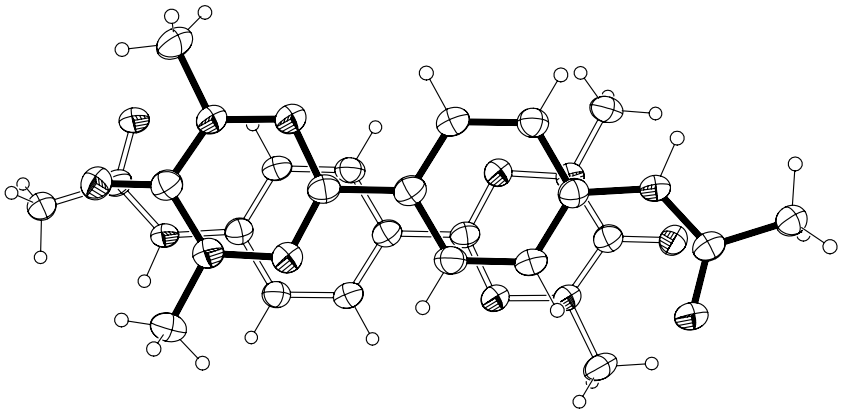

Fig. 2. The overlap of pairs of radicals to form dimers within a stack. The view direction, as for Fig. 1, is perpendicular to the mean plane of each individual radical. The further radical is shown with open bonds for greater clarity.

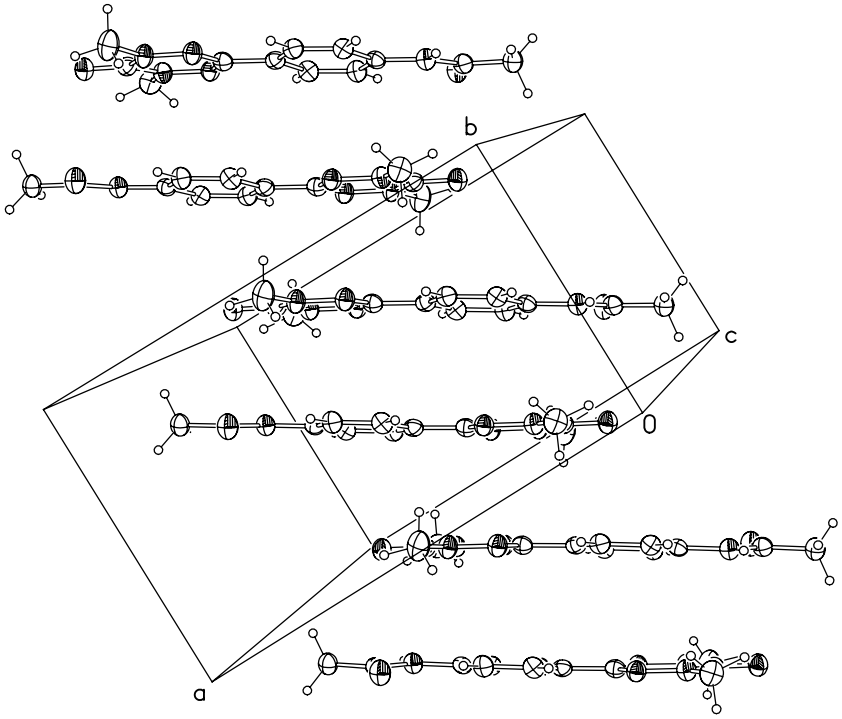

Fig. 3. Part of a stack of radicals, showing three successive dimers and the unit cell outline.

[33], and (iv) a simple Curie–Weiss law: $\chi = C/T - \theta$. Although the general behavior of the magnetic data can be well reproduced with any of these four models with g values very close to 2, and with θ, J (intradimer or intrachain) and J' (interdimer) values in the -1.5 to -2.5 K range, the best fit is obtained for the antiferromagnetic regular chain (solid line in Fig. 5). This model reproduces very satisfactorily the magnetic moment over the whole temperature range with the following parameters: $g = 2.012(1)$ and $J = -1.54(1)$ K $= -1.07(1)$ cm^{-1} (the Hamiltonian is written as $H = -2J\Sigma J_i J_{i+1}$). This result agrees with the perpendicular distances between mean planes of the stacked molecules in the title compound, which are essentially identical (3.349 Å for the intra- and 3.345 Å for the interdimer distance). A further confirmation of the spin ground state and the presence of antiferromagnetic interactions is provided by the isothermal magnetization of the title compound at 2 K, which shows an almost linear behavior that can be well reproduced with a Brillouin function for an $S = 1/2$ spin ground state with a reduced g value that accounts for the antiferromagnetic interactions (Fig. 6).

The ESR spectrum of the title compound shows a single narrow feature at $g = 2.0049$ with a line-width (ΔH) of ca. 14.1 G at room temperature (Fig. 7). Both the position and the line-width are typical of this kind of radical. The intensity of the ESR signal increases when lowering the temperature, whereas both the ΔH and g values remain almost

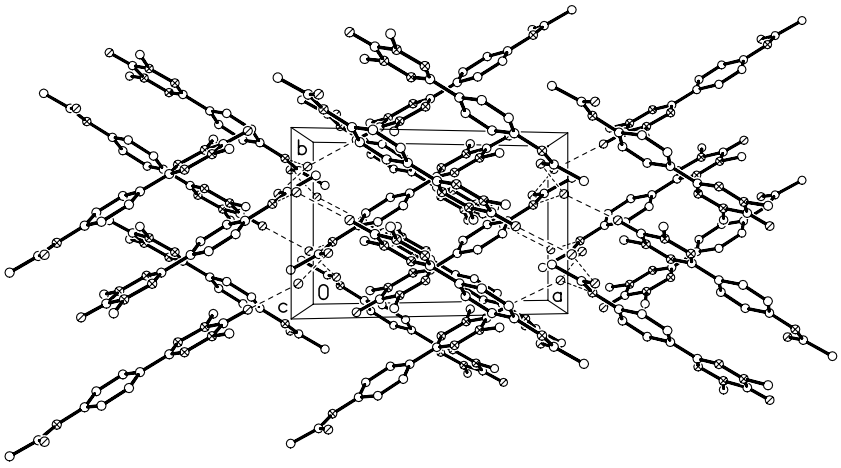

Fig. 4. The crystal structure, viewed along the *c*-axis, showing hydrogen bonds as dashed lines.

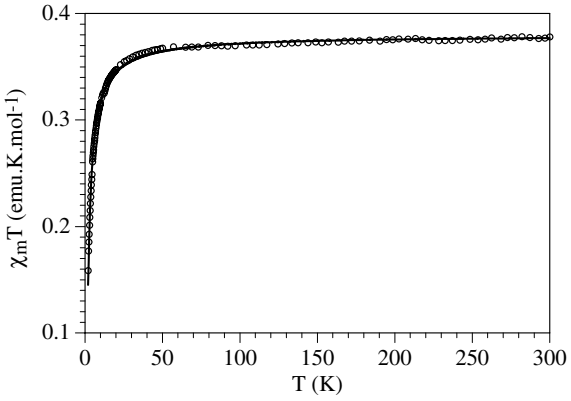

Fig. 5. Thermal variation of the $\chi_m T$ product for the title compound. The solid line is the best fit to the regular antiferromagnetic $S = 1/2$ chain (see text).

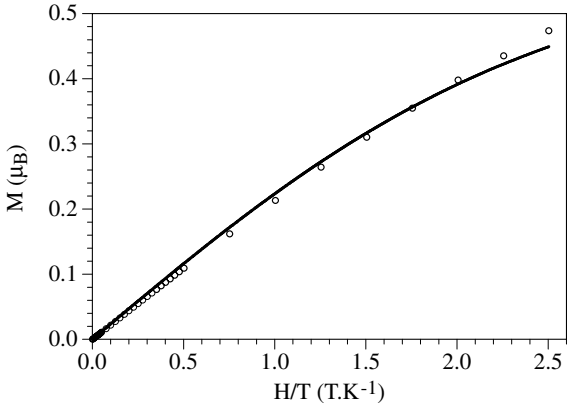

Fig. 6. Isothermal magnetization at 2 K of the title compound. Solid line shows the best fit to a Brillouin function with $S = 1/2$ (see text).

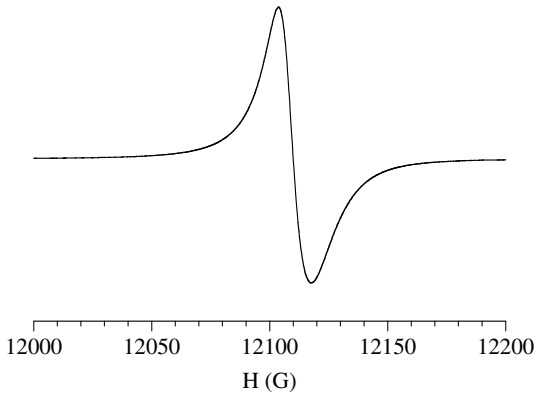

Fig. 7. Q-band solid state ESR spectrum at room-temperature of the title compound.

constant (ΔH and g smoothly increase up to ca. 16.7 G and ca. 2.0082, respectively, at low temperatures). The area of the ESR signal (proportional to the spin susceptibility) follows a "Curie–Weiss like" law with a negative Weiss temperature, as observed in the static susceptibility magnetic measurements. Note that the precision in the determination of the ESR area precludes the discrimination among any of the four aforementioned magnetic models. This behavior confirms the presence of an unpaired electron in the title compound as well as the paramagnetic behavior with weak antiferromagnetic interactions.

Besides the solid-state ESR spectra, we have also obtained ESR spectra of the title compound in CH_3CN and toluene solutions. The spectrum in CH_3CN solution shows a single feature with the same g value as in the solid and a lower line width (7.2 G). When the temperature is decreased, the g and ΔH values follow similar variations to those observed in the solid. The lower line width indicates that the radical in solution has fewer spin relaxation pathways (or less effective) than in the solid state and suggests the formation of small aggregates in solution. More interesting is the ESR spectrum of the toluene solution, since this radical is much less soluble in toluene, precluding the formation of aggregates. Thus, the ESR spectra of a dilute toluene solution show a hyperfine structure centred at $g = 2.00505$ (value obtained from the simulation), very close to the value obtained in the ESR spectrum of the solid at room temperature (2.0049, see above). This hyperfine structure shows up to 13 main signals above the freezing point of the solvent (180 K). Furthermore, most

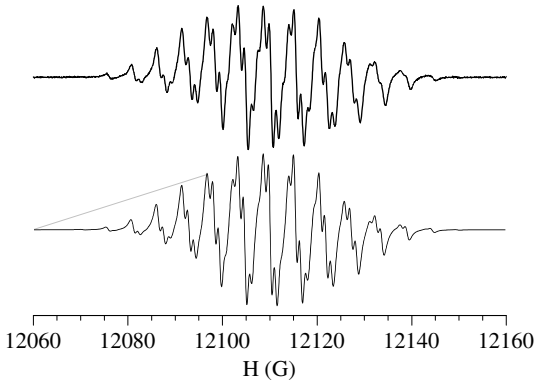

Fig. 8. Top: Q-band ESR spectrum at room temperature of a toluene solution of the title compound. Bottom: the simulated spectrum with $g = 2.0050$, $a(N_{2,4}) = 6.5$ G, $a(N_{1,5}) = 5.4$ G and $a(H_{1,5}) = 5.3$ G.

of these 13 signals are split into four or more, rendering a very complex spectrum, as can be seen in Fig. 8(top). A very satisfactory simulation of the shape, intensity and position of all the lines in this spectrum (Fig. 8, bottom) can be obtained by taking into account a hyperfine coupling with the two groups of two equivalent nitrogen atoms (N1–N5 and N2–N4) (^{14}N, $I = 1$, natural abundance = 99.635%) plus an additional coupling with the six hydrogen atoms of the two methyl groups bonded to the N1 and N5 atoms in the verdazyl ring (^{1}H, $I = 1/2$, natural abundance = 99.9844%). The hyperfine coupling constants obtained are: $a(N_{2,4}) = 6.5\ \text{G} = 6.08 \times 10^{-4}\ \text{cm}^{-1}$, $a(N_{1,5}) = 5.4\ \text{G} = 5.05 \times 10^{-4}\ \text{cm}^{-1}$ and $a(H_{1,5}) = 5.3\ \text{G} = 4.96 \times 10^{-4}\ \text{cm}^{-1}$ for the six equivalent hydrogen atoms. These values are very similar to those obtained by Neugebauer et al. [22b]. According to Neugebauer et al. [22], the larger hyperfine coupling is assigned to the two 2-coordinated nitrogen atoms (N2 and N4), indicating that the unpaired electron is mainly delocalized over the N=C–N group of the verdazyl ring, rather than over the Me–N–CO–N–Me group. It is important to indicate that a change from six to four hydrogen atoms does not change significatively the simulated spectrum and, therefore, it is not possible to unambiguously determine if the superhyperfine structure observed in the ESR spectrum is due to the four hydrogens on the phenyl ring or to the six hydrogen atoms of the two methyl groups of the verdazyl ring. Albeit, previous NMR measurements have shown that the coupling constants with the hydrogen atoms of the phenyl ring are well below 1 G and, therefore, the observed coupling can be assigned to the six hydrogen atoms of the two methyl groups of the verdazyl ring [27].

4. Conclusion

The structural and magnetic characterization of the title compound five years after its synthesis indicate that it is a very stable radical. The magnetic susceptibility measurements confirm the presence of one unpaired electron per molecule with weak antiferromagnetic exchange interactions that can be well reproduced with a regular antiferromagnetic chain model, in agreement with the structural data. ESR spectra in solid state and in solution confirm that the title compound is a radical whose unpaired electron is delocalized over the verdazyl ring, showing hyperfine coupling with the four nitrogen atoms of the verdazyl ring and the six hydrogen atoms of the two methyl groups bonded to the verdazyl ring.

5. Experimental

5.1. Magnetic properties

Variable-temperature susceptibility measurements were carried out in the temperature range 2–300 K at an applied magnetic field of 0.1 T on a polycrystalline sample with a Quantum Design MPMS-XL-5 SQUID magnetometer. The susceptibility data were corrected for the sample holder previously measured using the same conditions and for the diamagnetic contributions of the salt as deduced by using Pascal's constant tables. Isothermal magnetization measurements were performed at 2 K with magnetic fields up to 5 T. ESR spectra were recorded in Q band (33.98 GHz) with a Bruker E-500 ELEXSYS spectrometer in the temperature range 4–300 K on a polycrystalline sample and on toluene and acetonitrile solutions. The simulation of the toluene solution spectrum at room temperature was performed with the Win-EPR SimFonia software from Bruker.

5.2. X-ray crystal structure determination

Crystallographic data for $C_{12}H_{14}N_5O_2 \cdot H_2O$: $a = 12.616(3)$ Å, $b = 7.904(2)$ Å, $c = 14.122(4)$ Å, $\beta = 111.682(3)°$ at 120 K, with $Z = 4$ in the monoclinic space group $P2_1/c$. $R = 0.051$ for F values of 1539 reflections with $F^2 > 2\sigma(F^2)$, $R_w = 0.139$ for all 2290 unique F^2 values (7543 data measured, $2\theta < 48.6°$, $R_{int} = 0.044$) and 197 refined parameters, GOF = 1.039 on F^2. Data were collected with synchrotron radiation ($\lambda = 0.6902$ Å) and a Bruker APEX2 diffractometer at station 9.8 of the SRS, Daresbury Laboratory, from a crystal of size $0.08 \times 0.06 \times 0.01$ mm. Structure solution was by direct methods. A final difference synthesis contained no features outside ± 0.25 e Å^{-3}. Programs were standard Bruker APEX2, SAINT and SHELXTL.

6. Supplementary material

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition number 297266. Crystallographic data are in CIF format. This material is also available free of charge via the Internet at http://pubs.acs.org.

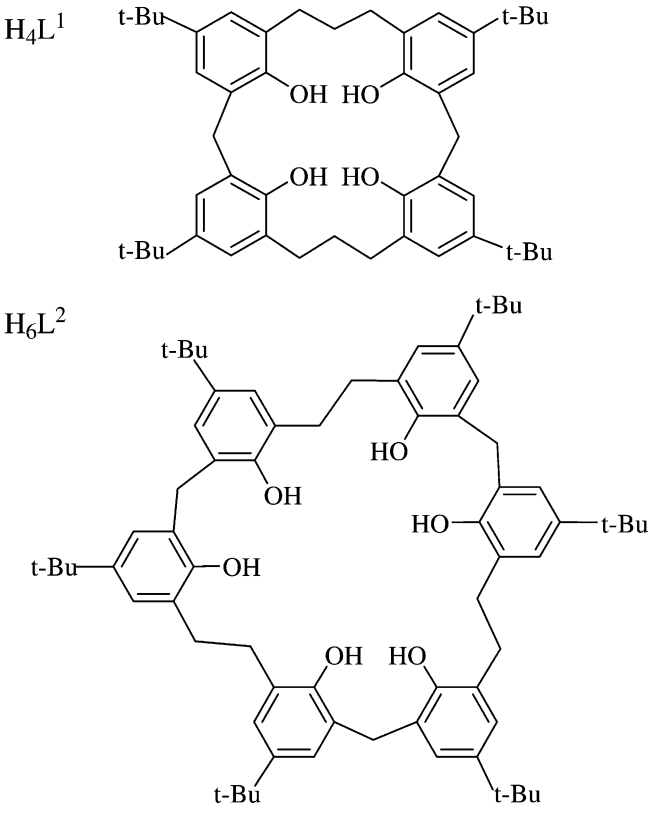
$n = 4$, 6 and 8, respectively [10]. We have also investigated the reaction of UCl_4 or $U(OSO_2CF_3)_4$ with homooxacalix[*n*]arenes ($n = 4$, 6, 8) in pyridine, with the unexpected finding of homooxacalixarene cleavage to give di- or triphenoxide species, likely as a result of nucleophilic attack by pyridine on the benzylic ether carbon atom of the macrocycle, assisted by initial uranium coordination to the ether groups [11]. New uranium(IV) [11a] and uranyl [11b] complexes with acyclic polyphenoxide ligands were thus obtained. In order to avoid this cleavage reaction, we turned to macrocycles in the related homocalixarene family, in which the ether links present in homooxacalixarenes are replaced by aliphatic linkages [12]. We report herein the crystal structure of the complexes obtained by reaction of UCl_4 with *p-tert*-butylhomocalix[*n*]arenes ($n = 4$ and 6), or, more precisely, *p-tert*-butyltetrahydroxy[3.1.3.1]- and *p-tert*-butylhexahydroxy[2.1.2.1.2.1]metacyclophanes, denoted H_4L^1 and H_6L^2, respectively (Scheme 1), as well as that of the uncoordinated form of the latter. These macrocycles differ from the calix[*n*]arenes by both the length of the aliphatic linkage and the presence of the *p-tert*-butyl groups. The uranyl complex of the tetraanionic L^1 ligand has been reported previously; its crystal structure was the first to be determined for a complex of a homocalix[4]arene [13].



Scheme 1. The *p-tert*-butylhomocalixarenes H_4L^1 and H_6L^2.

2. Experimental

2.1. Syntheses

All reactions were carried out under argon (<5 ppm oxygen or water) using standard Schlenk-vessel and vacuum-line techniques or in a glove box. Solvents were dried by standard methods and distilled immediately before use. The uranium salts UCl_4 and $U(acac)_4$ were synthesized as reported in the literature [14]. The ^1H NMR spectra were recorded on a Bruker DPX 200 instrument and referenced internally using the residual protio solvent resonances relative to tetramethylsilane.

The homocalixarenes H_4L^1 (6,13,22,29-tetra-*tert*-butyl-9,16,25,32-tetrahydroxy[3.1.3.1]metacyclophane) and H_6L^2 (5,12,20,27,35,42-hexa-*tert*-butyl-8,15,23,30,38,45-hexahydroxy[2.1.2.1.2.1]metacyclophane) were synthesized as previously described [15,16]; ^1H NMR (C_5D_5N, 200 MHz, $T = 23$ °C): $\delta = 1.27$ (36H, *t*Bu), 1.73 (4H, $-CH_2-$), 2.84 (8H, $-CH_2-$), 4.20 (4H, $-CH_2-$), 7.08 and 7.53 (2×4H, aromatic H), 10.71 (4H, OH) and ^1H NMR (thf, 200 MHz, $T = 23$ °C): $\delta = 1.60$ (54H, *t*Bu), 3.10 (12H, $-CH_2-$), 4.20 (6H, $-CH_2-$), 7.29 and 7.56 (2×6H, aromatic H), 8.48 (6H, OH) for H_4L^1 and H_6L^2, respectively. Single crystals of $H_6L^2 \cdot 5py$ (**1**) were obtained by slow evaporation of a pyridine solution of H_6L^2.

[Hpy][UCl$_2$(L^1)] · 2.5py (**2**). An NMR tube was charged with H_4L^1 (5 mg, 0.0071 mmol) and UCl_4 (2.7 mg, 0.0071 mmol) in C_5D_5N (0.4 ml). Immediately, the ^1H NMR spectrum of the resulting brown solution indicated the complexation of the ligand: δ (200 MHz, $T = 23$ °C) = 1.5 (br, 52H, $-CH_2-$ and *t*Bu), 11.9 (br, 2H, aromatic H), 12.8 (br, 4H, aromatic H), 26.9 (br, 2H, aromatic H). δ (200 MHz, $T = -20$ °C) = −9.71 and −3.48 (2×2H, $-CH_2-$), −0.63 (18H, *t*Bu), 0.93, 1.21 and 1.85 (3×2H, $-CH_2-$), 2.15 (4H, $-CH_2-$), 3.36 (18H, *t*Bu), 5.07 (2H, $-CH_2-$), 11.67, 13.35, 14.41 and 15.35 (4×1H, aromatic H), 18.33 (2H, aromatic H), 25.03 and 26.12 (2×1H, aromatic H). Prolonged heating at 110 °C led to the formation of a mixture of dark brown crystals of compound **2** and colourless crystals of HpyCl which were deposited at the bottom of the tube. When the reaction was performed with $U(acac)_4$ (acac = acetylacetonato) instead of UCl_4, or in thf, no reaction occurred and the NMR spectra showed only the signals of the uncomplexed ligand H_4L^1, even at high temperature.

[U$_4$Cl$_2$O$_2$(L^2)$_2$(H$_2$O)(thf)] · 3thf (**3**). An NMR tube was charged with H_6L^2 (7 mg, 0.0069 mmol) and UCl_4 (5.2 mg, 0.0138 mmol) in tdf (0.4 ml). Adventitious traces of water probably entered the reaction flask during prolonged heating at 80 °C, which resulted in the formation of dark brown needles of compound **3** from the brown solution. Attempts to prepare this complex in a controlled way, by introducing measured quantities of water into the reaction mixture, were unsuccessful. The crystals could not be characterized by ^1H NMR because of their insolubility in organic solvents.

2.2. Crystallography

The data were collected on a Nonius Kappa-CCD area detector diffractometer [17] using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The crystals were introduced in glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from ten frames, then refined on all data. A 180° φ-range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed to 28 or 30 mm. The data were processed with HKL2000 [18]. The structures were solved by direct methods with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix (**1** and **2**) or blocked matrix (**3**) least-squares on F^2 with SHELXL-97 [19]. Absorption effects in **2** and **3** were corrected empirically with the program DELABS in PLATON [20]. All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms bound to oxygen atoms in **1** and to nitrogen atoms in **2** were found on Fourier-difference maps, whereas those of the water molecule in **3** were not found, nor introduced. The other hydrogen atoms were introduced at calculated positions and all were treated as riding atoms with a displacement parameter equal to 1.2 (OH, NH, CH, CH_2) or 1.5 (CH_3) times that of the parent atom. For compound **2**, some restraints on displacement parameters were applied for the terminal carbon atoms of one *tert*-butyl group and some atoms of the pyridine solvent molecules; the highest residual electron density is located near the uranium atom. The very low quality of the crystals of compound **3**, and the resulting low quality of the diffraction data only enabled a rough structure determination to be obtained. In particular, some short H···H contacts indicate that some parts of the complex, particularly the *tert*-butyl groups, are not perfectly described. However, the main features of the structure are unambiguously determined. Restraints on bond lengths and/or displacement parameters had to be applied, particularly for the *tert*-butyl groups and the tetrahydrofuran molecules. Some large voids in the lattice indicate the presence of other, unresolved solvent molecules. Crystal data and structure refinement parameters are given in Table 1. The molecular plots were drawn with SHELXTL [21].

3. Results and discussion

The ligand H_6L^2 crystallizes in pyridine to give the compound $H_6L^2 \cdot 5py$ (**1**) in which three pyridine molecules are associated with the macrocycle by hydrogen bonding (Fig. 1). The H_6L^2 molecule, which has no crystallographic symmetry but only a pseudo-trigonal geometry, assumes a rather flat shape, with the three methylene-linked diphenolic subunits in "butterfly" conformation and with their concave side oriented in the same direction, giving to the macrocycle the shape of a very shallow cone. The dihedral angles between the aromatic rings in these diphenolic units are 63.1(2)°, 72.1(2)° and 67.3(2)°, whereas the dihedral angles between adjacent aromatic rings linked by an ethylene bridge are much smaller, 1.28(12)°, 11.7(2)° and 26.7(2)°. The C(arom)–C–C–C(arom) torsion angles defined by the ethylene bridges are all *anti*, with values of 176.3(4)°, 173.8(5)° and 175.8(5)°, whereas all the

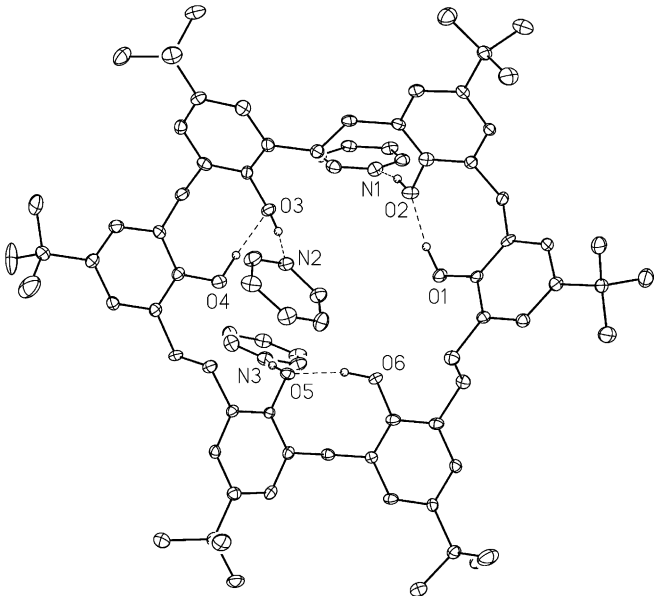

Fig. 1. View of the structure of $H_6L^2 \cdot 5py$ (**1**). The hydrogen atoms and solvent molecules not involved in hydrogen bonding are omitted for clarity. Hydrogen bonds are shown as dashed lines. Displacement ellipsoids are drawn at the 30% probability level.

C(arom)–C(arom)–C–C torsion angles are in the range 81.9(6)–103.0(6)°. The ethylene-bridged rings are thus nearly parallel to one another, albeit not coplanar. Each methylene-bridged diphenolic unit is associated with an intramolecular O–H···O hydrogen bond (Table 2), the second phenolic proton being diverted to form a hydrogen bond with a pyridine solvent molecule. Two of these three pyridine molecules (N1 and N3) are located on the convex side of the macrocycle and the third one (N2) in the concave cavity. The crystal packing further unites the molecules in slightly offset pairs related by a symmetry centre, with their concave sides facing each other and encompassing the two pyridine molecules, which are likely involved in C–H···π interactions (shortest H···centroid distance 2.73 Å) [22].

The reaction between UCl_4 and H_4L^1 in pyridine gives the mononuclear uranium(V) complex $[Hpy][UCl_2(L^1)] \cdot 2.5py$ (**2**); this result contrasts with the synthesis in thf, at room temperature, of the $[UCl_2(calix[4]arene\text{-}2H)(thf)_2]$ uranium(IV) complex recently reported [10]. The uranium(V) centre is bound to the four phenoxide groups and retains also two chlorine atoms (Fig. 2). The asymmetric unit contains two independent but nearly identical complex molecules. By contrast with the uranyl complex of the same ligand [13], in which the macrocycle is in the cone conformation and the four phenoxide oxygen atoms are in a plane so as to match the tetra-coordinated equatorial environment suitable for this ion, the macrocycle in **2** is distorted so as to provide, together with the chlorine atoms in adjacent positions, a slightly distorted octahedral environment for the uranium centre (Table 3). The U–O bond lengths are in the range 2.072(4)–2.113(4) Å [mean value 2.093(14) Å], i.e., lower than those in the other uranium(V) complex with a calixarene [7a] [mean value 2.15(3) Å], whereas the U–Cl bond lengths are in the range 2.6342(15)–2.6472(16) Å [mean value 2.639(5) Å], which corresponds to the largest values for U(V)–Cl bond lengths reported in the Cambridge Structural Database [23] [range 2.467–2.640, mean value 2.52(5) Å]. The macrocycle adopts a distorted cone conformation. The two 1,3-propylene bridges assume different geometries; in both molecules A and B, one of the bridges corresponds to C(arom)–C(arom)–C–C and C(arom)–C–C–C torsion angles which are roughly *gauche*, in the range 48.5–95.3°, whereas the other bridge contains two C(arom)–C–C–C torsion angles nearer to *syn* or *anti* geometries (larger and smaller values 36.5° and 169.4°, respectively). The complex unit $[UCl_2(L^1)]$ is monoanionic and its charge is compensated by the presence of one pyridinium ion, involved in a hydrogen bond with a pyridine molecule (Table 2). As shown in Fig. 2, the two [Hpy]py ensembles thus formed in the asymmetric unit are located in the cavity formed by the two macrocycles facing each other, in which they are held by various weak interactions. The two hydrogen bonded [Hpy]py assemblies are reversed with respect to one another and are thus possibly held together by dipole-dipole interactions. They may also be involved in two weak π–π interactions, each of them associating a pyridinium and a pyridine rings, with centroid···centroid distances of

[a] Hydrogen atoms not found.

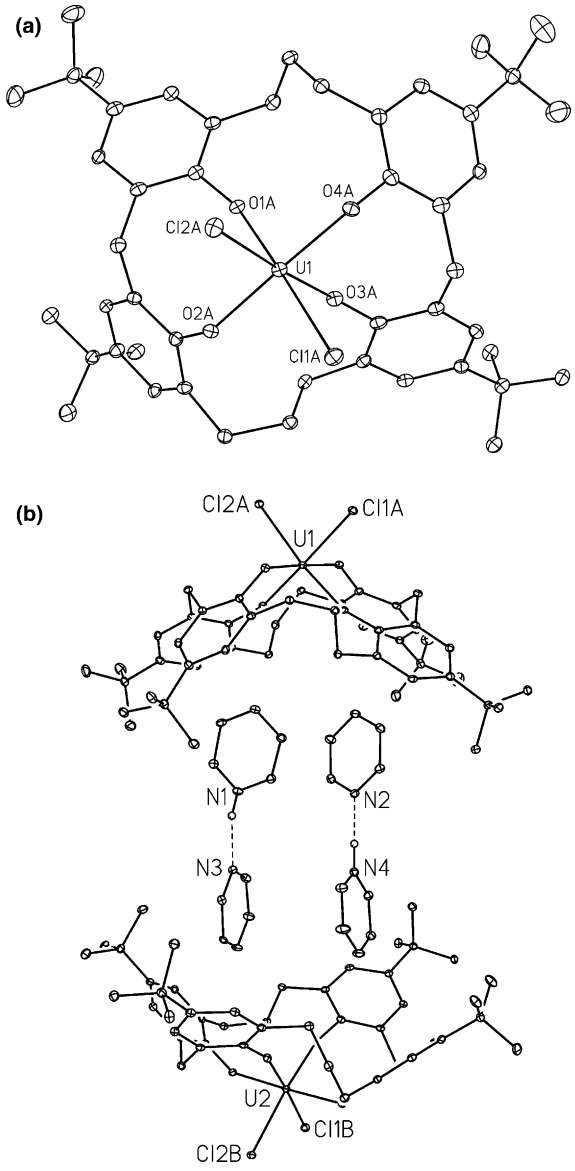

Fig. 2. (a) View of one of the two independent molecules of the monoanionic complex $[UCl_2(L^1)]$ in **2**. Hydrogen atoms are omitted for clarity. Displacement ellipsoids are drawn at the 20% probability level. (b) View showing the dimerization in **2**. The hydrogen atoms and solvent molecules not involved in hydrogen bonding are omitted for clarity. Displacement ellipsoids are drawn at the 10% probability level.

4.087(4) and 4.025(4) Å, dihedral angles of 18° and 11° and centroid offsets of 1.7 and 1.5 Å, for the ring pairs containing N1, N2 and N3, N4, respectively. The cohesion of the whole assembly seems to involve numerous CH–π interactions [22], in addition to cation-anion interactions. Seven such interactions can be found, which associate the protons of the pyridinium/pyridine moieties and the aromatic rings of the homocalixarenes, with H···centroid distances shorter than 2.9 Å and as low as 2.45 Å and C–H···centroid angles in the range 126–160°. Similar situations have been found in uranyl complexes of homooxacalixarenes with an included protonated [2.2.2]cryptand [24]. However, by contrast with these other cases, cation–π interactions [25] do not seem to be present in **2**, since no short contact is found between the protonated nitrogen atoms or their α-carbon atoms and the centroids of the aromatic rings. As a matter of fact, an evaluation of the relative importance of these weak interactions in such complex systems is unattainable on the basis of limited structural data alone [26].

When reacted with UCl_4 in tetrahydrofuran, H_6L^2 gives the neutral tetranuclear complex $[U_4Cl_2O_2(L^2)_2(H_2O)(thf)]\cdot 3thf$ (**3**), the structure of which is represented in Fig. 3. No crystallographic symmetry is present and the complex only possesses a pseudo-inversion centre at the intersection of the U1–U3 and U2–U4 lines. Complete deprotonation of the two macrocycles implies that **3** is a mixed valence compound comprising two U^{IV} and two U^{V} centres. The four metal atoms are at the apexes of an elongated rhombus which contains two μ_3-oxo ions and further bridging is ensured by two chlorine and two phenoxide groups. The average side length of the rhombus is 3.85(9) Å and the two diagonals are 6.6004(14) Å (U1···U3) and 3.9597(14) Å (U2···U4). This U_4O_2 assemblage can also be viewed as two coplanar U_3O triangles sharing a common edge, U2 and U4 being bound to both μ_3-oxo ions. These six atoms define a plane with an rms deviation of 0.08 Å, which also contains the chlorine and phenoxide bridges. Such tetranuclear planar arrangements around two μ_3-oxo centres are somewhat frequent in uranyl chemistry [27], and some examples are also found among uranium(IV) complexes [28]; in one case, two uranyl and two uranium(V) centres are involved [29]. In complex **3**, the μ_3-oxo ions are not perfectly trigonal, which is due to the differences in U–O bond lengths (see below) and to the enlargement by ca. 14° of the U–O–U angles associated with the chlorine bridges. Two uranium atoms are located within the ring defined by the six oxygen atoms of each macrocycle (U1 and U2 in the ligand denoted A, U3 and U4 in B). In addition to the μ_3-oxo ion and the bridging chlorine atoms, each metal atom is bound to three adjacent phenoxide oxygen atoms from the same calixarene, and U1 and U3 are also bound to one bridging phenoxide (O5A and O5B) from the other calixarene. The resulting coordination number is six for U1 and U3, with a distorted octahedral environment, whereas U2 and U4 are bound to an extra ligand, water for U2 and tetrahydrofuran for U4, which results in seven-coordinate environments with a distorted pentagonal bipyramidal geometry (O4A, O6A and O4B, O6B in axial positions for U2 and U4, respectively). The two pairs of atoms (U1 and U3) and (U2 and U4) show further differences when the average bond lengths are considered. ⟨U–O(oxo)⟩, ⟨U–O(terminal phenoxide)⟩, ⟨U–O(bridging phenoxide)⟩ and ⟨U–Cl⟩ are respectively equal to 2.04(2), 2.09(2), 2.28(4), 2.734(6) Å for (U1 and U3) and 2.36(3), 2.116(17), 2.46(2), 2.947(12) Å for (U2 and U4). Apart from the values for ⟨U–O(terminal phenoxide)⟩ which are not significantly different for the two sets of atoms and close to the values in the uranium(V) complex **2** and in the uranium(IV) complexes with *p-tert*-butylcalix[*n*]arene [2.125(12)–2.15(4) Å]

[10] (but slightly smaller than those in the uranium(IV) complexes with acyclic polyphenoxides [2.138(4)–2.208(6) Å]), all the bond lengths are larger, by ca. 0.2–0.3 Å, for the (U2 and U4) pair. The differences in U–Cl and U–O bond lengths between uranium(IV) and uranium(V) are 0.10 and 0.17 Å, respectively, for the structures reported in the Cambridge Structural Database (terminal chlorine ligands only since there is no example of a bridging chlorine bound to U^V). Besides, the ionic radii reported for uranium(IV) with a coordination number of seven and uranium(V) with a coordination number of six are 0.95 and 0.76 Å, respectively [30]. It can also be noticed that the U^V–O(μ_3-oxo) bond length in the other example reported is 2.08(2) Å [29], close to the value relative to U1 and U3 in the present case and that the average U^{IV}–O(μ_3-oxo) bond length is 2.23(8) Å [8], smaller than the value for U2 and U4, but closer to it than to the previous one. All this allows to consider that complex **3** is a mixed-valence species with uranium(IV) and uranium(V) centres localized at the (U2 and U4) and (U1 and U3) sites, respectively. This is the third example of a uranium mixed-valence complex involving a calixarene-like ligand, the other ones being the localized U^{III}/U^{IV} species obtained with the calix[4]tetrapyrrole tetraanion [9], and the delocalized U^V/U^{VI} complex with *p-tert*-butylcalix[4]arene [7a].

As stated above, each macrocycle encompasses two uranium ions (one U^{IV} and one U^V) within the ring defined by its six phenoxide groups. This is in agreement with previous observations relative to the number of uranyl ions included versus the size of macrocycles in the calixarene and homooxacalixarene families [31]. The ligand $[L^2]^{6-}$ provides an hexa-phenoxide coordination site surrounded by a 27-membered bond array and it is thus roughly equivalent in this respect to *p-R*-calix[7]arene and *p-R*-tetrahomodioxacalix[6]arene, which present a 28-membered array. Mononuclear uranyl complexes have been obtained with these two latter ligands, but *p*-benzylcalix[7]arene has also been shown to behave as a ditopic ligand for uranyl ions [27]. However, it must be noted that the geometrical requirements of uranyl and $U^{IV,V}$ ions are very different, as well as the finer geometry of the ligands. In compound **3**, the six oxygen atoms of each macrocycle define mean planes with rms deviations of 0.34 and 0.36 Å, the atoms O5A,B and O6A,B being the most displaced out of the plane; both planes are nearly parallel to one another, with a dihedral angle of 1.1(3)°, and perpendicular to the U_4O_2 central core, with dihedral angles of 88.5(3)° and 89.5(3)°. The conformation of the macrocycle can be seen as a shallow cone, as in the uncomplexed form **1**, but of course the pseudo-trigonal geometry observed in the latter is replaced

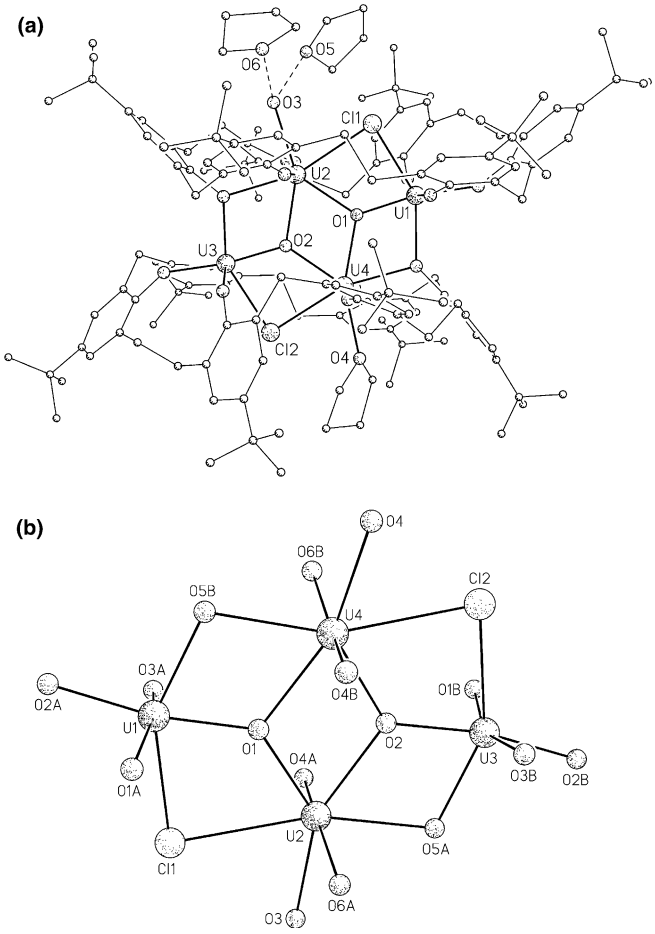

Fig. 3. (a) View of the complex $[U_4Cl_2O_2(L^2)_2(H_2O)(thf)]\cdot 3thf$ (**3**). The hydrogen atoms and the isolated thf molecule are omitted. For the sake of clarity, the atoms are represented as spheres, the carbon ones being arbitrarily reduced. Hydrogen bonds are shown as dashed lines. (b) View of the uranium atoms environment.

by a more elongated, roughly elliptical one, due to the inclusion of the two metal atoms. As in **1**, the dihedral angles between adjacent aromatic rings are larger for the rings separated by a methylene bridge [57.4(7)–86.1(7)°] than for those separated by an ethylene bridge [8.2(10)–30.2(9)°]. As in **1** also, the C(arom)–C–C–C(arom) torsion angles defined by the ethylene bridges are close to *anti* conformations, with values in the range 142(2)–165(2)°, while the C(arom)–C(arom)–C–C torsion angles are in the range 72(3)–112(3)°. The chlorine atoms and the coordinated water and tetrahydrofuran molecules are located in the calixarene cavities and the water molecule (O3) is further hydrogen bonded to two tetrahydrofuran molecules.

4. Conclusion

Compounds **2** and **3** provide rare examples of structural characterization of complexes involving homocalixarenes and they also extend the limited family of uranium (uranyl excepted) complexes of calixarene-like molecules. Unfortunately, they cannot be compared with the complexes obtained by reaction of UCl_4 with the closely related homooxacalixarenes, due to the macrocycle cleavage observed with the latter. Both compounds **2** and **3** confirm the ready metal oxidation previously encountered in attempts to complex uranium(IV) with calixarenes [7], since only in **3** half the metal centres remain in this oxidation state. As frequently observed in calixarene complexes, large assemblies are obtained, either through weak interactions involving the counter-ions and the solvent molecules (**2**) or as a result of metal aggregation due to the polytopic nature of the macrocycle and the presence of additional bridging species (**3**). Eventually, compound **2** is the first U(V) mononuclear complex with a calixarene ligand and it could be used as a starting material for the synthesis of derived complexes by substitution of the two chlorine atoms.

Appendix A. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 296822–296824. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk). Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.02.006.

absorption and Raman spectroscopy and emission spectroscopy. The crystal structures of the ADA and AZA complexes were also determined.

2. Experimental

2.1. Syntheses

Uranyl benzoylacetonate (ba) was prepared by reacting 1-3-diphenyl-1,3-propanedione (dibenzoylmethane, Aldrich) in ethanolic solution, in slight excess, with uranyl carbonate in aqueous suspension, under stirring. Typical preparations involved ca. 100 mg of uranyl carbonate in suspension in ca. 5 mL of distilled water and a slight stoichiometric excess of dibenzoylmethane dissolved in ca. 10 mL of absolute ethanol. Precipitation was immediate. The suspension was filtered after 1 h, to ensure complete precipitation, washed with water and dried in vacuo in a desiccator with anhydrous calcium chloride. Yields obtained were typically 97%. This compound was characterized by IR spectroscopy.

The complexes were prepared as follows: uranyl ba dissolved in acetone (50 mg in ca. 5 mL) was added to methanolic solutions of the corresponding neutral ligands in a slight stoichiometric excess (typically 50 mg in 5 mL of analytical grade methanol). Precipitation was observed after some minutes, but the suspensions were left for one day before filtering. The precipitates were filtered, washed with methanol and dried in vacuo over anhydrous calcium chloride. Recrystallization from methanol, by slow solvent evaporation, yielded crystals suitable for structure determinations. Typical yields were 80%. Characterization procedures involved elemental analyses, IR, Raman and emission spectroscopy. They are described below in Section 3.

2.2. Instrumentation

Elemental analyses were carried out in a Perkin–Elmer 240 microanalyzer. Infrared absorption spectra were recorded in a Nicolet FT-IR-510 spectrometer using KBr pellets. Visible emission spectra were recorded in a modified Hitachi–Perkin–Elmer MPF4 spectrofluorimeter at 298 and 77 K. Raman spectra were recorded in a FT-Raman Bruker FRS-100 S spectrometer, using a Nd/YAG laser (Coherent Compass 1064-500 N) for excitation at $\lambda = 1064$ nm and 40 mW power, using an InGaAs detector.

2.3. X-ray crystallography

Suitable crystals were mounted on glass fibers and aligned on an Enraf-Nonius CAD-4 diffractometer. Data were obtained with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) and 2ω–2θ scan mode, at room temperature, in the ranges 1.59–25.01° (ADA complex) and 2.02–27.50° (AZA complex).

Final R/wR [$I > 2\sigma(I)$]	0.0522/0.1145	0.0452/0.0914
R/wR (all data)	0.1412/0.1539	0.0642/0.1014
Largest difference in peak and hole (e/Å^3)	0.966/−1.722	0.257/−0.247

During data collection, the intensities of three selected reflections (for both crystals) were monitored each 1800 s of X-ray exposure, showing no significative decay. Data were corrected for Lorentz-polarization and absorption.

Structures were solved by the standard heavy-atom Patterson method, using SHELX-86 program [19], followed by normal difference Fourier techniques that yielded the positions of the remaining non-H atoms. These latter were located on stereochemical grounds and refined with fixed geometry, each riding on a carrier atom with an isotropic displacement parameter amounting to 1.2 times the value of the equivalent isotropic displacement parameter of the atom to which they are attached. Structures were refined anisotropically by full-matrix least-squares methods on F^2, using SHELXL-97 program [20]. Molecular displays were carried out by ZORTEP program [21]. Table 1 reports crystal data and refinement parameters for the two complexes.

3. Results and discussion

Microanalytical results were the following: for the ADA complex, calculated (experimental) percent values were: C, 55.6 (56.3); H, 4.2 (4.7); N, 1.5 (1.1); for the AZA complex, C, 53.3 (53.6); H, 4.2 (4.5); N, 1.6 (1.4); for the TPPO

Selected IR and Raman bands of $UO_2(ba)_2L$ complexes (cm^{-1})

Compound	$UO_2(\nu_1)$	$UO_2(\nu_2)$	$UO_2(\nu_3)/\nu CC + \nu CO$	$\nu CC + \nu CO$	$\nu CC + \nu CO$
(a) Infrared					
$UO_2(ba)_2$ TPPO	829w		938w	1540s	1349m
$UO_2(ba)_2$ ADA	815w		941w	1541s	1359m
$UO_2(ba)_2$ AZA	811w		941w	1539s	1351m
Compound	$UO_2(\nu_1)$	$UO_2(\nu_2)$	$UO_2(\nu_3)/\nu CC + \nu CO$	$\delta CH + \nu CC$	C_6H_6 ring stretching
(b) Raman					
$UO_2(ba)_2$ TPPO	830s	211w	942m	1185m	1597s
$UO_2(ba)_2$ ADA	816m	212w	943m	1191s	1597s
$UO_2(ba)_2$ AZA	814s		943m	1185m	1598s

complex, C, 57.6 (58.0); H, 5.2 (4.9). These results indicate the general composition $UO_2(ba)_2L$ (L = ADA, AZA, TPPO). The small difference in the CHN percents observed for the ADA complex was explained when its crystal structure was determined. This complex has one crystallization solvent molecule (methanol) per unit cell.

Table 2 shows some selected frequencies obtained from infrared absorption and Raman spectra. Benzoylacetonate bands were assigned according to the literature [22–25]. The $\nu CC + \nu CO$ acetonate bands are in the same region of the UO_2 ν_3 mode. These acetonate bands point out to O-bonded complexes. On the other hand, if the complexes were C-bonded, the C=O frequency would be around 1650–1620 cm^{-1} [26–28].

The uranyl ion frequencies observed (for the same complex) in IR and Raman spectra are identical within 4 cm^{-1}; this difference can be due to calibrations of the respective spectrometers. The appearance of $\nu_2(UO_2^{2+})$ in the Raman spectra can be explained by the asymmetric field created by the ligands; the same explanation holds for the appearance of $\nu_1(UO_2^{2+})$ in the infrared spectra [29]. Since UO_2^{2+} is a symmetric linear ion, ν_3 should also be absent in the Raman spectra. In this case, since the $\nu CC + \nu CO$ (acetonate combination bands) fall in the same region, no such verification could be made. Since the bands observed in the Raman spectra at 942–943 cm^{-1} are of medium intensity, it is reasonable to assign them to the $\nu CC + \nu CO$ combination band.

In all Raman spectra the most intense bands appear at ca. 1597 cm^{-1}. This band has been assigned to benzene ring stretching [30].

Table 3 shows some bands related to the neutral ligands, which appear in the infrared spectra. A comparison is also made with the corresponding free ligands. In all cases it can be verified that the CO or PO stretching frequencies are shifted to lower frequencies. These shifts point out to bondings through the respective CO and PO oxygen atoms.

All complexes are luminescent and their emission spectra present several vibronic bands. This is a common feature in uranyl compounds. It is believed that the emitting state is one in which an electron has been transferred from an UO_2^{2+} molecular orbital to a 5f U atomic orbital (in other words, a charge transfer) [31]. A strong argument in favor of this excited state is the pronounced radical-like activity of these excited molecules [6].

Table 3
Selected IR bands related to the neutral ligands (cm^{-1})

Compound	νCO	νPO
$UO_2(ba)_2$ ADA	1626	
ADA	1649	
$UO_2(ba)_2$ AZA	1630	
AZA	1643	
$UO_2(ba)_2$ TPPO		1119
TPPO		1127

All emission spectra were obtained with excitation at $\lambda = 370$ nm. Excitation spectra show only a broad band with maxima near that wavelength.

For the three complexes, even at 77 K the emission bands are broad, with poorly resolved vibronic structures. For the TPPO complex, five bands appear, with maxima at 482, 503, 535, 560 and 586 nm; for the ADA complex, only one broad band appears, with maxima at 542, 566, a shoulder at 589 and a smaller maximum at 606 nm; for the AZA complex, three bands appear at 417, 440 and 467 nm, and a more intense, broader band with maximum intensity at 541 nm and a smaller peak at 567 nm. The mean energy separations are: for TPPO, 818; for ADA, 810 and for AZA, 784 cm^{-1}.

The different values for these energy separations point out to differences in the uranyl ions immediate environments in the different complexes. It is important to emphasize that the uranyl nitrate complexes previously studied in this laboratory [16,18] emit more strongly than the ba complexes described in this paper. It is known that the most intense uranyl emission bands are zero-phonon transitions, which are magnetic dipole allowed when the U atom is situated in a centrosymmetrical environment [32]. Such is indeed the case for the complexes described in Refs. [16,18]. In the complexes here described (heptacoordinated) no center of symmetry exists.

Comparing the values of energy separations of the emission bands with the corresponding IR and Raman spectra (Table 2), it is apparent that more than one vibrational

mode of the UO_2^{2+} ion may be involved in the observed progressions, for the three complexes.

The crystal structures of the ADA and AZA complexes were determined. In the ADA complex (compound **1**) there is a disordered molecule of solvent (methanol) per unit cell which could not be modeled, and that is the reason for the high residual electron density. In the AZA complex (compound **2**) there are two independent molecules in the asymmetric unit. The structures are shown in Figs. 1 (compound **1**), 2 (compound $\mathbf{2_1}$) and 3 (compound $\mathbf{2_2}$). Selected bond distances and angles are listed in Table 4. The structure shows that, in all cases, the U atom is surrounded by seven O atoms, four of ba, one of the other ligand and the two uranyl O atoms. The U–O_{uranyl} distances are in the range of other seven coordinated similar compounds; in fact, a search in Cambridge Structural Database [33] showed that for 118 distances, the mean value is 1.76 Å. The U–O_{ba} distances are in good agreement, to within experimental accuracy, with the ones found in the literature ([9] and references therein). The overall bond lengths and angles show that the U atom is in a distorted pentagonal bipyramidal geometry coordination, with O (uranyl) occupying the apices. Regarding the basal plane, the maximum deviation of the oxygens from the best least-square plane through them are 0.138(3), 0.172(3) and 0.055(3) Å, for (**1**), ($\mathbf{2_1}$) and ($\mathbf{2_2}$), respectively. In the ba ligands the benzene rings are not coplanar, forming different dihedral angles: 40.4(5)° and 42.3(5)° in (**1**) and 9.8(2)° and 64.2(2)° in ($\mathbf{2_1}$) and 24.7(3)° and 17.3(2)° in ($\mathbf{2_2}$). The molecular packing is stabilized by intermolecular C–H···O interactions involving the aromatic rings (Table 5).

Acknowledgements

The authors wish to thank Prof. Marcia L.A. Temperini (Laboratório de Espectroscopia Molecular, Instituto de Química, Universidade de São Paulo) for the recording of Raman spectra. Prof. M. Martinez-Ripoll is gratefully acknowledged for making possible the use of the CSD. This work was partially supported by CNPq and FAPESP.

Appendix A. Supplementary data

The structures reported in this paper and all pertinent Supplementary data have been deposited at the Cambridge Crystallographic Date Centre under Register Nos. 294835 and 294836. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.02.009.

number of extensive studies that have been reported in the literature dealing with the formation of micelles in aqueous surfactant solutions. Increasing attention is being devoted to the study of the incorporation or solubilization of neutral molecules into micelle in aqueous solution. The nature of a cosolvent determines the direction of changes in the CMC of surfactants. The effect of different cosolvents having an –OH group, such as PEG, sucrose, ethylene glycol and alcohols, on the micellization process has been studied [11,12]. Some of the most studied solubilizates are alcohols, because of the important role they have in the preparation of microemulsions. An excellent review of earlier work on the effect of *n*-alcohols on micellar solutions was given by Leung and Shah [13] and Zana [14]. Addition of alcohol can strongly influence the behaviour of the micelles and increase or decrease the micellar size depending upon the hydrophilic/hydrophobic character of alcohol [15,16]. Whereas the hydrophilic alcohols (methanol to propanol) mainly solubilize in aqueous solution and affect the micellization process by modifying the solvent, the more hydrophobic alcohol molecules (butanol, pentanol and higher alcohols) take part in the micellization process and become unique components of the micelle aggregate. To differentiate them from "inverted micelles which are formed in non-polar organic solvents, the term "solvophobic" has been applied by various researchers [17–20] to organic solvents, in analogy with the "hydrophobic interactions" causing micellization in aqueous media. The micelle formed due to a "solvophobic interaction" in polar non-aqueous solvents are similar in many respects to the micelles that are formed in aqueous media, although in general, micelle formation is not as favoured in non-aqueous solvents (with a low dielectric constant) as in water for a given surfactant [17–20].

In the present work, efforts have been made to study the effect of temperature variations on the CMC of metallosurfactants in non-aqueous solvents using a conductivity technique. Various aspects of the interaction of these surfactants in formamide during micelle formation in the presence of alcohols with various chain lengths are also discussed. In addition, the thermodynamic parameters, Gibbs free energy changes (ΔG^0_{mic}), enthalpies (ΔH^0_{mic}) and entropies (ΔS^0_{mic}), have also been estimated and analyzed for Cr^{III} metallosurfactants in non-aqueous solvents.

2. Experimental methods

2.1. Materials

Surface active Cr^{III} complexes, *cis*-$[Cr(en)_2(C_{12}H_{25}NH_2)F](ClO_4)_2$, *cis*-$[Cr(en)_2(C_{12}H_{25}NH_2)Cl](ClO_4)_2$ and *cis*-$[Cr(en)_2(C_{12}H_{25}NH_2)Br](ClO_4)_2$ used in the present work were prepared similar to those complexes reported earlier [3]. Their purity was tested by UV–Vis spectroscopy and CHN analysis. All other chemicals were obtained from Fluka and were used without purification.

Safety note: caution. Perchlorate salts of Cr^{III} complexes containing organic ligands are potentially explosive! Although we have experienced no problems with the compounds reported in this work, they should only be handled in small quantities and never scraped from sintered glass frits nor heated in the solid state.

2.2. Determination of CMC

CMC values of the complexes were calculated using electrical conductance data measured using a digital conductivity meter (Metrohm 712). The conductivity cell (dip-type with a cell constant of 1.0) was calibrated with KCl solutions in the appropriate concentration range. The cell constant was calculated using molar conductivity data for KCl published by Barthel et al. [21]. Various concentrations of Cr^{III}–surfactant complexes were prepared in the range 10^{-6}–10^{-2} mol dm^{-3}. All the measurements were done in a jacketed vessel, which was maintained at the desired temperature (±0.1 °C) with a circulating water thermostat bath. The conductivity of these solutions was measured at 293–313 K. The conductance was measured after thorough mixing and temperature equilibrium at each dilution. The measurement was started with a dilute solution and the subsequent concentrated solutions were prepared by adding a previously prepared stock solution. Establishment of equilibrium was checked by taking a series of readings after 15 min intervals until no significant change occurred.

3. Results and discussion

3.1. Temperature dependence of CMC

The CMC values of metallosurfactants in *n*-alcohol–formamide mixtures of different compositions and at various temperatures were determined from conductance measurements. Fig. 1. shows representative plots of specific conductivity corrected by that of the solvent $k–k_o$, as a function of the surfactant concentration at a fixed solvent composition and at different temperatures. Similar plots (not shown) were obtained in all the cases studied. The specific conductance of the solution in *n*-alcohol increases with increasing surfactant concentration. The increase seems to be due to the tendency of the metallosurfactants to form aggregates at higher surfactant concentration. It may be also attributed to the combined effect of ionic atmosphere, solvation of ions and decrease of mobility and ionization with the formation of micelles. When the conductivity of solutions with increasing concentration of surfactant is measured, the specific conductivity–surfactant concentration plots show two straight lines with different slopes. The first one corresponds to the concentration range below the CMC, when only monomers of surfactant exist in solution. Micelles start to form and a change of slope appears because the conductivity increases in a different manner. The intersection of these two straight lines was taken as the CMC value of the surfactant. The CMC values were computed from the slope of [Cr(III)] versus specific

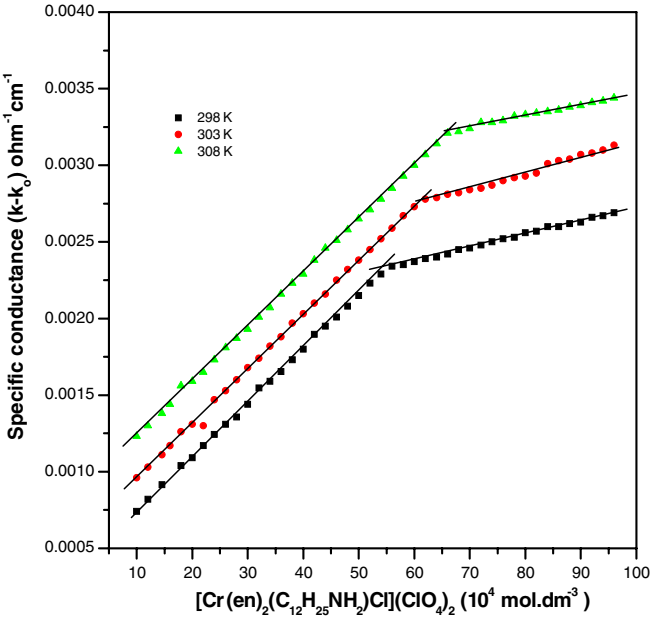

Fig. 1. Electrical conductivity vs. [Cr(III)] in methanol solution.

conductance data. At all temperatures a break in the conductance versus concentration plots, characteristic of micelle formation, was observed. The CMC values were determined by fitting the data points above and below the break to two equations of the form $y = mx + c$ and solving the two equations simultaneously to obtain the point of intersection. Least-squares analysis was employed and correlation coefficients were greater than 0.98 in all the cases. The conductivity measurements at different temperatures have been repeated three times and the accuracy of the CMC values are found to be within ±3% error. Tables 1 and 2 show the values of the CMCs of Cr^{III} ethylenediamine surfactant as a function of temperature. It is found that the CMC values increase on increasing the temperature for a given system. It is observed that by changing the ion from F^- to Br^-, the CMC decreases. It may be due to the increase in the size of the ion in the coordination sphere, which makes it more weakly hydrated. Weakly hydrated ions can be adsorbed more readily in the micellar surface which decreases the charge repulsion between the polar groups and thus facilitates the micellization.

3.2. Effect of the solvent on the CMC

It is well known that micellar properties of surfactants are significantly influenced by solvents. The physicochemical properties of solvents, dielectric constant, hydrogen bonding ability and cohesiveness parameters all play vital roles [22–24]. An increase in CMC is seen (Table 1, Figs. 1 and 2) for methanol and ethanol and a decrease in CMC is observed for higher alcohols when compared with the CMC obtained for aqueous solution [3]. Decrease in CMC on addition of *n*-propanol, *n*-butanol, *n*-pentanol and *n*-hexanol may result from the penetration of alcohol molecules into the micelle. The decrease in CMC can be explained as follows: it is known that the major factor that determines the inter-micellar solubility of long chain alcohols is the change in hydrophilic balance of the micelle during the inclusion of alcohol in it [25,26]. Moreover, the solvophobic effect associated with the solvophobic moiety of alcohol molecules favours micellization and increases as the length of the hydrocarbon chain of the alcohol increases. This explains the increased lowering of the CMC as the number of carbon atom increases in the alcohol series. Herein we report the micellization of metallosurfactants in binary combinations of the *n*-alcohol–formamide mixture. The changes in CMC with increasing concentration of methanol, ethanol, *n*-propanol, *n*-butanol and *n*-pentanol in formamide are reported in Table 2. Fig. 3 shows the critical aggregation concentration as a function of molar concentrations of alcoholic hydroxyl group in methanol, ethanol, *n*-propanol, *n*-butanol, *n*-pentanol in formamide (as representative for C1–C5 containing one hydroxyl group, respectively). The increase in CMC on addition of methanol and ethanol is due to the solvent power of the formamide–alcohol mixture. All the other surfactants gave similar behaviour for methanol and ethanol CMC increases on increasing its concentration in formamide which can be explained on the basis of increased solubility of the non-polar part of the surfactants in a non-aqueous medium. This is because the addition of methanol and ethanol disrupts the formamide structure or solvates the solute molecules preferentially. Similar behaviour was found for simple surfactants in formamide in the presence of alcohols for various chain lengths [26,27].

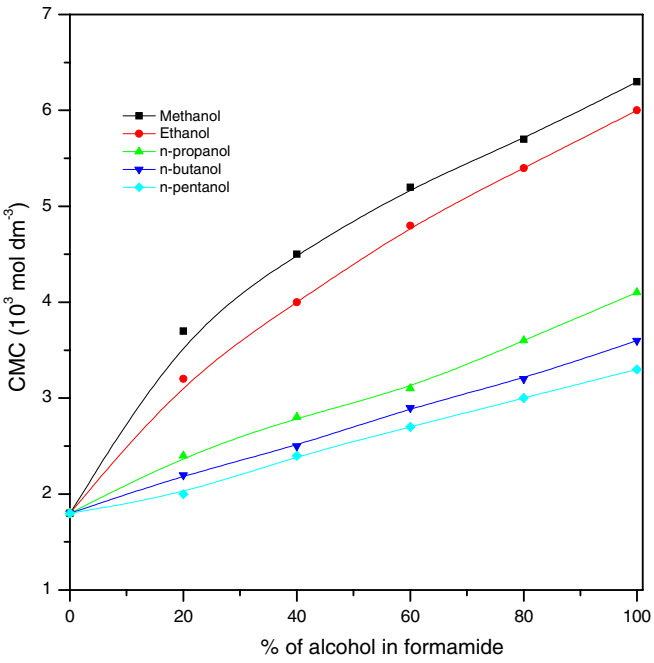

Fig. 3. Effect of different alcohols in formamide on the CMC values for *cis*-$[Cr(en)_2C_{12}H_{25}NH_2F]^{2+}$ at 303 K.

3.3. Effect of dielectric constant on the CMC

Furthermore, the CMC value of the metallosurfactant is a function of the dielectric constant of the medium. In alcohols the CMC values were in the order methanol > ethanol > *n*-propanol > *n*-butanol > *n*-pentanol > *n*-hexanol, whereas the dielectric constant decreases from methanol to *n*-hexanol [28]. The decrease in CMC with the

change in dielectric constant is due to a less favourable interaction between the polar groups of the surfactant molecules and the solvent causing micellization to occur at relatively lower concentrations. The effect of van der Waals interactions, which will of course be different in each case, is difficult to predict but it is obvious that it is the interaction between polar groups and solvent (affected by the dielectric constant) which mainly controls the variations of the CMC [13].

In alcohol–formamide mixtures, a similar variation in CMC is also observed. The CMC for these surfactants in formamide was much lower than water. Since, the dielectric constant of water is lower than the dielectric constant of formamide; it seems that the dielectric constant plays a more dominant role in micelle formation than the dipole moment [29,30]. The ionization of the surfactant in formamide is higher than in water, therefore there is a tendency of forming micelles at a lower concentration. Further the observation that the CMC decreases with the decrease in dielectric constant (methanol to *n*-pentanol) also shows that the degree of ionization of micellar units changes with solvent and in solvents of low dielectric constant, smaller micelles would form. This is because if the degree of ionization of micellar units is constant with a change in dielectric constant, then a decrease of the dielectric constant would surely imply an increase in CMC since the repulsion between charged groups of micelle would increase [31,32].

3.4. Thermodynamics of micelle formation

The study of CMC versus temperature is often undertaken to obtain information on hydrophobic and head group interactions. This involves driving various thermodynamic parameters of micelle formation. Two models are generally used, the mass-action or equilibrium model and the phase separation or pseudo-phase model [33–35]. The mass-action model assumes that an equilibrium exists between the monomeric surfactant and the micelles. The phase separation model assumes that the aggregates with their counterions in the surrounding atmosphere are in a separate phase. According to these models, the standard Gibbs free energy of micelle formation per mole of monomer, ΔG^0_m, is given by

$$\Delta G^0_m = RT \ln \mathrm{CMC} \quad (1)$$

where R and T are the gas constant and absolute temperature, respectively, even though the size of the micelle is not known at present.

The standard enthalpy of micelle formation, ΔH^0_m, can be obtained from the temperature variation of CMC by applying the Gibbs–Helmholtz equation to Eq. (1):

$$\Delta H^0_m = -RT^2 \mathrm{d}\ln\ \mathrm{CMC}/\mathrm{d}T \quad (2)$$

Once the Gibbs free energy and the enthalpy of micelle formation are obtained, obviously the entropy of micelle formation can be determined by

$$\Delta S^0_m = (\Delta H^0_m - \Delta G^0_m)/T \quad (3)$$

Also the low CMC values in *n*-alcohols may invalidate the use of the above mentioned equations, because the monomer activity would be quite different from the monomer concentration. Moreover, since the changes of CMC with temperature are small, the values of ΔG^0_m, ΔH^0_m and ΔS^0_m must be rather inaccurate. Therefore, the thermodynamic parameters in Table 3 must be viewed only as approximate. Nevertheless, from the present data some generalization can be extracted. The observed more negative Gibbs free energy of micellization for the surfactants with increasing head polarity indicates more favoured micellization. It also suggests that a strong solvophobic interaction takes place for long alkyl chains in formamide. Our data show that the free energy of micellization is negative in all cases and becomes less negative with increasing concentration of co-solvents. As can be seen from Table 3, the standard Gibbs free energy of micelle formation decreases as the number of carbon atoms in the alkyl chains of various alcohols increases, as shown in Fig. 4. It suggests that a strong solvophobic interaction take place for long alkyl chains in formamide. It is also observed that the enthalpy of micellization (ΔH^0_m) is negative and becomes smaller as the co-solvent increases. Negative values of enthalpy of micellization indicate an exothermic nature of the micellization process. Nusselder and Engberts [36] have suggested that for negative ΔH^0_m, the London-dispersion forces play a major role in the micellar process. The entropic contribution of micelle formation, ΔS^0_m, presents positive values and are larger than ΔH^0_m, showing the importance of solvophobic interactions in the micelle formation process. Therefore, the fact that ΔS^0_m values decrease as the formamide content increases indicates that the presence of formamide in the system produces a weakening of the solvent cohesiveness, thereby increasing the solubility of the hydrocarbon tails and decreasing the solvophobic effect. It is evident from Table 3 that in all cases micellization is exothermic. This may be interpreted as a consequence of the decrease in energy required to break up the iceberg structure surrounding the hydrocarbon chains of the monomeric surfactants. It is also observed that in the presence of higher alcohols (*n*-butanol, *n*-pentanol and *n*-hexanol) the enthalpy was more negative and entropy was less positive. Therefore, the contribution of the enthalpy to the micellization becomes increasingly important with the lengthening of the carbon chain length of the alcohol in contrast to the predominance of the entropy in the aqueous solution. Similar behaviour of a more negative enthalpy in the presence of organic additives has been observed [26,37].

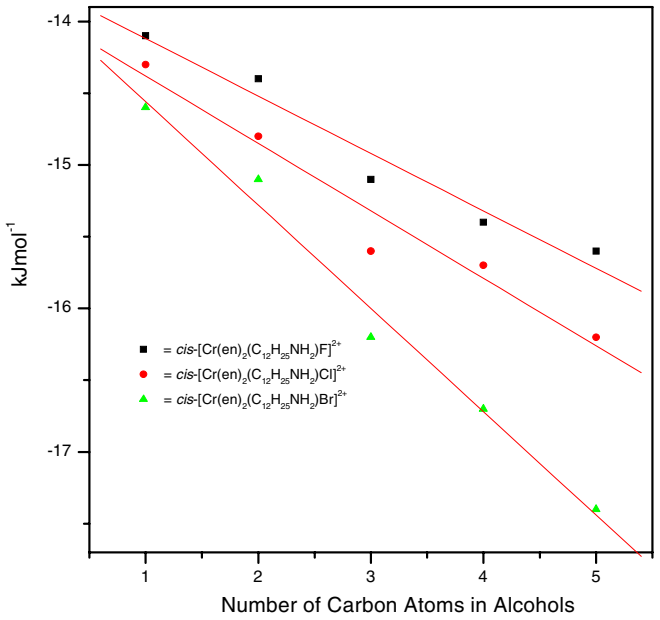

Fig. 4. Gibbs energy change of Cr(III) metallosurfactants in formaide in presence of 20% of various *n*-alcohols.

polydentate salicylidenimines [12–15]. It was reported on the synthesis and structure of μ-oxo-dioxotetrakis(*N*-methylsalicylidenimine) dimolybdenum(V) binuclear complex with the bridging oxygen [16]. However, there are no reports on di-μ-oxo-molybdenum(V) complexes with alkylsalicylidenimine ligands.

2. Experimental

2.1. Synthesis

Chemicals were purchased from commercial sources and used without further purification. The starting complex $[Mo_2O_3(OCOCH_3)_3Cl]_2 \cdot (CH_3CO)_2O$ was synthesised as previously reported in [17].

2.1.1. General procedure for synthesis of $RNH_3[Mo_2O_4(N\text{-}R\text{-}salim)_2OCOCH_3] \cdot C_6H_6 \cdot CH_3COOH$

The same procedure was followed for the preparations of all complexes (Scheme 1). The products were obtained from $[Mo_2O_3(OCOCH_3)_3Cl]_2 \cdot (CH_3CO)_2O$ and freshly prepared *N*-R-salicylidenimines in molar ratio 1:16. Since the starting compound is a tetranuclear complex that includes eight potentially exchangeable ligand sites, the molar ratio should be 1:8. To facilitate the ligand exchange higher molar ratio was used. Imines were prepared by the simple condensation reaction of salicylaldehyde and appropriate alkylamine in equimolar ratio at room temperature. The mixture of these compounds (16 mmol of each) was left for 2 h, afterwards was added in small portions the well powdered Mo-starting complex. After stirring of 2–3 h at 35 °C, the dark red "sticky mass" was formed and left overnight at room temperature. A small volume of benzene was added and the crystalline products were filtered off, washed with ether and dried in vacuo. For preparation of imines with R = Me and Et, the gaseous amines, produced from amine water solutions by sodium hydroxide, were brought into aldehyde. Water present in the imines was not removed. Yields were between 60% and 70%.

2.1.2. Synthesis of $BuNH_3[Mo_2O_4(N\text{-}Bu\text{-}salim)_2OCOCH_3] \cdot C_6H_6 \cdot CH_3COOH$

Representative procedure for synthesis of butyl derivate: a mixture of 1 g (1 mmol) $[Mo_2O_3(OCOCH_3)_3Cl]_2 \cdot (CH_3CO)_2O$ and freshly prepared *N*-Bu-salimH ($C_6H_4(OH)CHNC_4H_9$) (ca. 16 mmol) was stirred for 2 h. A very viscous dark mixture was left overnight, 3 mL of C_6H_6 were added, and after stirring a crystalline product was isolated. Yield (based on the initial Mo complex): 1.15 g (68%). IR data (KBr, cm^{-1}) 3424 w-m br [ν(OH)], 3200–2330 w br, [$\nu(NH_3^+)$], 2959 w-m, 2931 w-m and 2871 w [$\nu(CH_3)$, $\nu(CH_2)$], 1700 w [ν(C=O)], 1628 vs [ν(C=N), $\nu_{as}(OCO_b)_{acetate}$], 1600 m [$\nu$(C=C), $\delta(NH_3^+)$], 1549 s [ν(C=C), $\nu(C\text{–}O)_{phenolate}$], 1302 s br [$\nu_s(OCO_b)_{acetate}$], 954 s and 935 sh [$\nu(Mo{=}O)_t$], 756 m and 740 m [$\nu_{as}(Mo\text{–}O\text{–}Mo)_b$], 612 w-m [$\nu$(Mo–N)], 471 w-m and 456 sh [$\nu(Mo\text{–}O)_{acetate}$]. UV/Vis [DMF, λ_{max}/nm ($\varepsilon/M^{-1}\,cm^{-1}$)] 312 (15170), 377 (4656).

2.2. Physical measurements

The infrared spectra in the region 4000–400 cm^{-1} were recorded as KBr pellets on a Perkin–Elmer spectrum BX FTIR System. UV/Vis spectra were measured on a Perkin–Elmer lambda 35 spectrophotometer. Magnetic susceptibilities in the solid state were measured at room temperature by the standard Gouy method using a Cahn-Ventron RM-balance and $CuSO_4 \cdot 5H_2O$ as the susceptibility standard. Elemental analyses were performed on a Carlo Erba instrument.

2.3. X-ray crystallography and data collection

The crystal used for data collection was an orange prism, dimensions $0.3 \times 0.15 \times 0.1$ mm. Three intensity control reflections measured every 120 min did not show any significant loss of intensity during the data collection, which was performed on an Enraf Nonius CAD4 diffractometer with a graphite monochromated Cu Kα (1.54179 Å) radiation at temperature of 150 (2) K (cooled by a stream of dry nitrogen gas using Oxford Cryostream 700 series). The crystal data are shown in Table 1. The WinGX standard procedure was applied for data reduction [18]. Cell parameters were calculated from 25 reflections (θ range 8.15–17.1°). An absorption correction based on eight Ψ-scan reflections was performed [19]. The structure was solved using the Patterson method implemented in SHELXS97 [20] and refined with SHELXL97 [21]. Molecular geometry calculations were performed with PLATON [22], and molecular graphics were prepared using ORTEP-3 [23],

and CCDC-Mercury [24]. The model was refined using the full-matrix least-squares refinement on $|F|^2$ with hydrogen atoms refined as the riding entities, their initial positions calculated according to stereochemistry. All non-hydrogen atoms except C24 were refined anisotropically. Disorder of C23 and C24 can explain the residual electron density (Table 1). The atomic scattering factors were those included in SHELXL97 [21].

3. Results and discussion

3.1. Synthesis and spectroscopic studies

The reaction of $[Mo_2O_3(OCOCH_3)_3Cl]_2 \cdot (CH_3CO)_2O$ with Schiff base ligands, derived from salicylaldehyde and alkyl amines, gave complexes generally formulated as $RNH_3[Mo_2O_4(N\text{-R-salim})_2OCOCH_3] \cdot C_6H_6 \cdot CH_3COOH$.

Syntheses of some complexes, either Mo(VI) or Mo(V) with Schiff bases, reported in the literature [12–15] were carried out in the presence of suitable solvents or solvent mixtures. The syntheses of the title complexes were performed without solvents but in high excess of the imine ligands. Water present in imines has not biased reactions; even more, water destabilised starting complex and assisted replacement of acetate by imines.

The complexes are diamagnetic compounds moderately stable in the air, except the very hygroscopic complex with *N*-Me-salim ligand. Solubility of complexes decreases as R of imines increases; solubility in solvents decreases as follows:

$$CH_2Cl_2 > CHCl_3 > (CH_3)_2CO > C_6H_6 > n\text{-}C_6H_{14}$$

The structural characterisation of the title complexes: coordinated di-μ-oxo-dimolybdate(V) and small alkyl ammonium cation, is based on analytical data, infrared and visible spectra and X-ray structure analysis of $BuNH_3[Mo_2O_4(N\text{-Bu-salim})_2OCOCH_3] \cdot C_6H_6 \cdot CH_3COOH$. The efforts to prepare crystals of all complexes suitable for X-ray structure determinations failed. Nevertheless, the analytical and spectral data indicated analogy among their structures.

The IR spectra of the complexes are very complicated with extensive vibrational coupling and overlapping of absorption bands. In spite of this, the results obtained clearly point to modes of the metal–ligand coordination in these compounds, and agree well with the X-ray analysis of complex derived from butyl derivative. The great similarity in spectra of the complexes suggests that their structure is also similar (see Table 2). The bonding of the Schiff base in the anionic form through the azomethine nitrogen and the deprotonated phenolic oxygen is supported by the presence of very strong absorption at ca. 1630 cm^{-1} and strong band at 1550 cm^{-1} assigned to ν(C=N) and phenolic ν(C–O) vibration, respectively [25,26]. In the former region appears also the acetate ν_{as}(OCO) absorption while in the later frequency region are displayed also the aromatic ν(C=C) vibrations. A weak to medium band at around 612 cm^{-1} may be attributed to the Mo–N stretching of the coordinating azomethine nitrogen [27]. Besides the phenolic oxygen, there are three other groups with the oxygen donor atoms in the complexes. A strong absorption in the 960–930 cm^{-1} region confirms the presence of the terminal oxo ligands [16]. A strong band at 954 cm^{-1} with a shoulder on the lower frequency side about 940 cm^{-1} in the butyl complex or a closely spaced doublet in the same region in all other complexes assignable to terminal ν(Mo=O) vibration is consistent with

Table 2

syn arrangement of two oxo ligands relative to the central Mo_2O_2 core. The splitted band of medium intensity with two or three maxima between 762 and 739 cm^{-1} of the stretching vibrations of the bridging Mo–O–Mo group, are characteristic for the doubly bridged Mo_2O_2 moiety. The reduced symmetry of the complexes may cause complexity and splitting of metal–ligand bands. A weak to medium band at around 470 cm^{-1} with shoulder on the lower frequency side may be ascribed to the acetate bridging Mo–O stretching vibrations. A marked lengthening of the bridged Mo–$O_{acetate}$ bonds in the complexes gives rise that differences between the C–O asymmetric and symmetric frequencies is increased with respect to values expected for the acetato bridging complexes [28]. Thus the ν_{as}(OCO) absorption superimposed upon that of the ν(C=N) absorption gives a very strong band at around 1630 cm^{-1} while a strong and broad band at 1303 cm^{-1} may be assigned to the corresponding ν_s(OCO) vibration. A broad ν(OH) absorption around 3425 cm^{-1} and ν(C=O) band at 1700 cm^{-1} indicate the presence of the undissociated acetic acid in the complexes that is hydrogen bonded both to the alkylammonium cation and the anionic complex. The ammonium asymmetric and symmetric stretching vibrations in the spectra of complexes give a very broad complex progression of the combination of absorptions covering the whole 3200–2350 cm^{-1} frequency region, overlapping the weak aromatic C–H stretching absorption normally expected below 3080 cm^{-1} as well as the alkane C–H stretching region with three weak to medium sharp bands between 2960 and 2870 cm^{-1}. The complexity of this absorption arises from hydrogen bond interactions with the solvate acetic acid and oxygen atoms of the anionic complex.

The electronic absorption spectra of complexes in DMF are characterised by a strong absorption at 312 nm along with less intense band at around 377 nm, which may be assigned to metal–ligand charge transfers, possible superposed by ligand internal π–π^* and n–π^* transitions [25]. A decrease in the intensity of both these absorptions takes place very slowly on time; therefore it may be presumed that complexes are stable towards solvolysis in DMF solution.

3.2. Crystal structure of butylammonium di-μ-oxo-μ-acetato-bis[(N-butylsalicylideniminato-N,O) oxomolybdenum(V)] benzene acetic acid solvate

The anionic complex (Fig. 1) is dinuclear, with both molybdenum atoms having a slightly distorted octahedral coordination (Table 3). Each Mo atom is coordinated by a terminal oxo ligand and chelated by a *N*-butylsalicylideniminate ion. Further, Mo atoms are bridged by two μ_2-oxygen atoms and a μ_2-acetato group. Mo–Mo distance is 2.5675 (5) Å, corresponding to a single Mo–Mo bond. Mean bond lengths of Mo–O and Mo–N (O and N of the *N*-butylsalicylideniminate ligands) are 2.050(3) and 2.192(3) Å, respectively. They agree to the values of

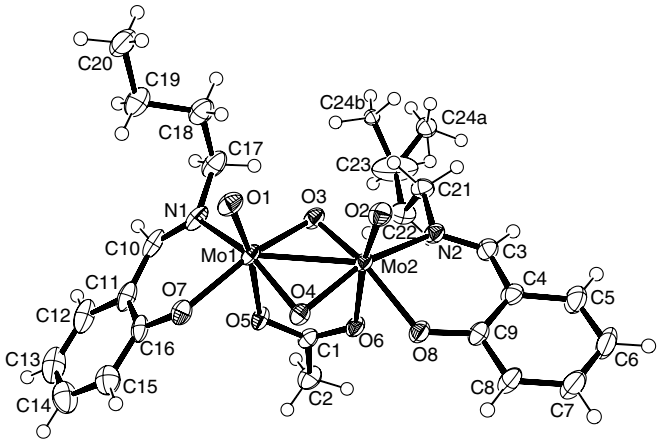

Fig. 1. Di-μ-oxo-μ-acetato-bis[(*N*-butylsalicylideniminato-*N*,*O*)oxomolybdenum(V)] anion. Thermal ellipsoids are drawn at 50% probability. Hydrogen atoms are depicted as spheres of arbitrary radii.

Mo–O and Mo–N distances found in μ-glycine-O:O′-di-μ-oxo-bis[(glycinato-*N*,*O*)oxomolybdenum(V)] [29], whereas Mo-μ-O and Mo=O distances agree with the values observed in similar binuclear Mo(V) species such as $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ [30,31]. However, $Mo–O_{acetato}$ bonds, *trans* to the terminal O atoms, are significantly longer than other Mo–O single bonds, indicating a *trans* influence of the terminal O atoms (Table 3). The coordination polyhedra are slightly distorted octahedra; their equatorial L–Mo–L angles are 85(1)°. The octahedra of the title complex are more regular than others observed in binuclear Mo(V) complexes [30,31].

A static disorder is present in one of the pendant *N*-butyl moieties. Therefore, the atom C24 is split between two positions (C24a and C24b) with occupancies about 0.75 and 0.25, respectively. Their temperature parameters were refined isotropically. The atom C23 is also disordered over two positions, however, they are very close to each other, producing a rather elongated ellipsoid.

An asymmetric unit consists of a di-μ-oxo-μ-acetato-bis[(*N*-butylsalicylideniminato-*N*,*O*)oxomolybdenum(V)] anion, a butylammonium cation, a molecule of benzene and a molecule of undissociated acetic acid (Fig. 2). Hydrogen bonds (Table 4, Fig. 2) connect the anionic complex, butylammonium cation and a molecule of acetic acid. The $[BuNH_3]^+$ is hydrogen bonded to the acetic acid via N40–H401···O51 and through N40–H402···O4 (bridging oxygen) to the complex. The acetic acid molecule is hydrogen bonded to the complex through O50–H50···O6. Two such groups link to each other via N40–H400···O7 hydrogen bond and form a centrosymmetric "supra-dimer". The hydrogen bond O50–H50···O6 of 2.595 (4) Å is a relatively short one [32]. The significant elongation of O50–H50 covalent bond can be deduced from a location of H50 in a difference Fourier map.

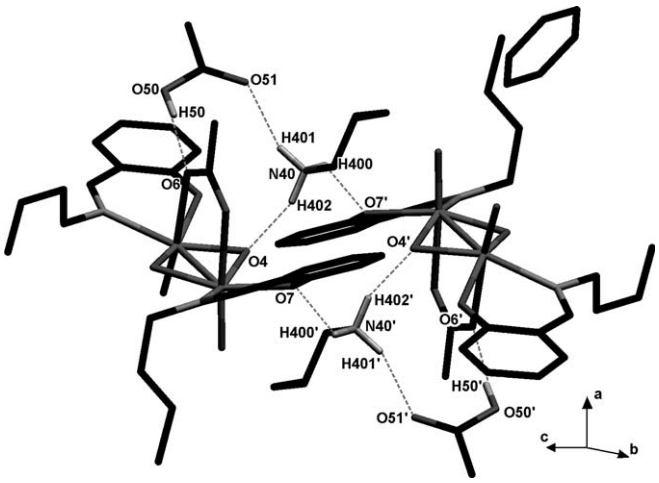

Fig. 2. Crystal structure with hydrogen bonding pattern of butylammonium di-μ-oxo-μ-acetato-bis[(*N*-butylsalicylideniminato-*N*,*O*)oxomolybdenum(V)]benzene, acetic acid solvate. Hydrogen bonds are drawn as dashed lines. Hydrogen atoms which do not participate in hydrogen bonding are omitted for clarity. Separation distance between the aromatic rings is larger than 7 Å and too far for π···π stacking interaction.

Table 4

4. Conclusion

The Mo(V) Schiff base complexes derived from alkylamines and salycilaldehyde, $RNH_3[Mo_2O_4(N–C_4H_9\text{-salim})_2OCOCH_3]\cdot xC_6H_6\cdot xCH_3COOH$ (R = Me, Et, Pr, Bu) were prepared and characterised by elemental analysis, magnetic measurements, and spectroscopic methods. The structure of butylammonium cation complex was determined by X-ray structure analysis: it is composed of a di-μ-oxo-μ-acetato-bis[(*N*-butylsalicylideniminato-*N*,*O*)-oxomolybdenum(V)] anion, cation and two solvent molecules, benzene and acetic acid. The Mo atoms of this dinuclear complex [with Mo–Mo bond of 2.5675(5) Å] exhibit the octahedral geometry.

2. Computational details

All structures have been fully optimized at the B3LYP/LANL2DZ(d,p) level of theory [9,10] and verified to be minima on the potential energy surface. The LANL2DZ(d,p) basis set is identical to that used in previous research [3] and was constructed from the standard LANL2DZ basis [11] by adding the following polarization functions: p-function for H (1.0), and d-functions for C (0.75), N (0.8), Al (0.4), Ga (0.16), Cl (0.56), and I (0.15). The GAUSSIAN 98 program package [12] has been employed throughout. Standard enthalpies were obtained taking into account zero point energies and thermal corrections. Zero point energies, thermal corrections and standard entropies have been computed by standard statistical thermodynamic methods using the ideal gas rigid rotor – harmonic oscillator approximations using optimized geometries and computed vibrational frequencies (unscaled).

It was earlier shown that the B3LYP/LANL2DZ(d,p) level of theory satisfactory predicts the dissociation enthalpies of complexes between group 13 metal halides and ammonia [3]. However, in recent work [13] Gilbert has reported that the B3LYP/6-311++G(d,p) level of theory significantly underestimates the B–N bond energies in molecular complexes of BX_3 with ammonia and methylamines. Therefore, a more detailed assessment of the performance of the theoretical method for the DA complexes of the heavier analogs of boron is desirable.

A comparison between available experimental and theoretical data for model compounds and reactions is presented in Tables 1 and 2. Computed standard entropies of compounds are in good agreement with the experimental data, with mean absolute deviation 2 J mol^{-1} K^{-1} (Table 1). Agreement between predicted and experimental standard enthalpies is less satisfactory. Hydrogen elimination from piperidine (reaction 1) is underestimated by 15–20 kJ mol^{-1}. Large differences (30–55 kJ mol^{-1}) are found for the standard enthalpies of reactions of gaseous Al and Ga with HCl and HI (reactions 2–5), which are both overestimated and underestimated at the B3LYP/LANL2DZ(d,p) level of theory. This may be attributed to the known deficiency of DTF methods for the description of isolated atoms [15]. When a halogen exchange reaction (6) is considered, the B3LYP/LANL2DZ(d,p) endothermicity is underestimated by 15 kJ mol^{-1}. Table 2 summarizes theoretical and experimental dissociation enthalpies and entropies of donor–acceptor complexes with ammonia (reactions 7–9), pyridine (10–13) and piperidine (process 14). With the exception of the $AlCl_3 \cdot NH_3$ complex, the B3LYP/LANL2DZ(d,p) level of theory underestimates the dissociation enthalpies. Surprisingly good agreement is found for the case of $GaCl_3$, where the differences between theoretical and experimental values for the complexes with ammonia, pyridine and piperidine are all less then 4 kJ mol^{-1}. However, this may be due to a fortuitous cancellation of errors for this particular acceptor. Note that use of more extensive all-electron 6-311G++G** basis set with diffuse functions leads to worse agreement with experiment. Thus, at the B3LYP/6-311++G** level of theory the dissociation enthalpy of the $AlCl_3 \cdot NH_3$ complex [14] is 120 kJ mol^{-1} and is underestimated by 17 kJ mol^{-1}. The dissociation enthalpy of the $GaCl_3 \cdot NH_3$ complex is predicted to be 96 kJ mol^{-1} and it is underestimated by 38 kJ mol^{-1} [14]. A joint experimental and theoretical study of the $GaCl_3 \cdot$ pyrazine adduct showed that at the B3LYP/pVDZ level of theory the dissociation enthalpy is underestimated by 8 kJ mol^{-1} [7,8]. For the AlI_3 and GaI_3 complexes with pyridine, the dissociation energies predicted at the B3LYP/LANL2DZ(d,p) level of theory are underestimated by 15–20 kJ mol^{-1}.

Thus, from comparison with available experimental results we conclude that underestimation of the dative bond energy at the B3LYP/6-311++G(d,p) level of theory, reported recently by Gilbert for the B–N complexes [13],

B3LYP/LANL2DZ(d,p) level of theory.
[a] Estimated value.

holds for the Al–N and Ga–N complexes as well. However, the role of the basis set is also of great importance: while the dissociation enthalpies are strongly overestimated with the LANL2DZ basis set without polarization functions [3], they are strongly underestimated with the 6-311++G** basis set that includes both diffuse and polarization functions [13,14]. Results obtained with LANL2DZ(d,p) and pVDZ basis sets fall between the two, and the B3LYP/LANL2DZ(d,p) level of theory is able to predict the reaction enthalpies of donor–acceptor complexes with an error of about 4–15 kJ mol^{-1}.

3. Results and discussion

3.1. Thermodynamics of the decomposition reactions of $MX_3 \cdot$ pip adducts

Three major reaction pathways have been considered (Scheme 1):

(**A**) dissociation of the complex:

$$MX_3 \cdot \text{pip (g)} = MX_3 \text{ (g)} + \text{pip (g)}$$

(**B**) elimination of HX with formation of amidodimers:

$$MX_3 \cdot \text{pip (g)} = \tfrac{1}{2}[MX_2C_5H_{10}N]_2 \text{ (g)} + HX \text{ (g)}$$

(**C**) elimination of H_2 with formation of pyridine (py, C_5H_5N) complexes:

$$MX_3 \cdot \text{pip (g)} = MX_3 \cdot \text{py (g)} + 3H_2 \text{ (g)}$$

The thermodynamic characteristics of the processes considered are given in Table 3. The dissociation enthalpies of piperidine complexes are about 20 kJ mol^{-1} higher compared to the analogous complexes with pyridine (Table 2). Thus, the complexes with piperidine are more stable with respect to dissociation of the donor–acceptor bond, in agreement with the early experimental findings of Greenwood and Perkins [26].

Elimination of HX from the DA complexes with formation of monomeric $MX_2C_5H_{10}N$ amido compounds is strongly endothermic. Note that subsequent dimerization of amido monomers is highly exothermic (by −150 to 230 kJ per mole of dimer), but does not fully compensate the unfavorability of the HX elimination. The dimerization enthalpies are decreasing in order Al > Ga and Cl > I.

Analysis of the thermodynamic characteristics of the three processes (**A**–**C**) shows that all reactions are strongly endothermic but favored by entropy. At the standard temperature 298 K all the processes are thermodynamically unfavorable. As the entropies of the decomposition reactions are positive, temperature elevation results in lowering the ΔG^0_T values for all reactions. Process (**C**) (molecular hydrogen elimination) is the most favorable from entropic considerations, and it becomes thermodynamically favorable above 500 K. Both the HCl and HI elimination reactions are highly endothermic and remain unfavorable even at high temperatures. On the basis of our thermodynamic analysis, the formation of $MX_3 \cdot$ py complexes is expected as a result of the thermolysis of source $MX_3 \cdot$ pip compounds above 500 K. Alternative pathways (dissociation into components or hydrogen halide elimination) require much higher temperatures.

To test the validity of these theoretical predictions, we have carried out an experimental study of the thermal

decomposition of the $GaCl_3 \cdot pip$ adduct. This complex has been previously reported by Greenwood and Wade [25], but its thermal decomposition was not studied.

3.2. Experimental studies of the thermal decomposition of the $GaCl_3 \cdot pip$ adduct

Due to the high air and moisture sensitivity of gallium trichloride and its complexes, all experiments have been performed in a glass apparatus under a vacuum ($\sim 10^{-5}$ Torr). $GaCl_3$ has been synthesized from its elements and purified by multiple (no less than four times) resublimations in a vacuum. Piperidine was dried above KOH, distilled, degassed in vacuum, stored above the mixture of zeolites (NaA, CaX), and distilled in vacuum before use. Purity control of the samples was performed by means of mass spectrometry and vapor pressure measurements. The adduct was synthesized by direct reaction of the components in the vacuum and purified by multiple sublimations in vacuum at 120–140 °C. The chemical composition of the complex was verified to be $GaCl_3 \cdot pip$ from the chemical analysis. Measured by the thermography method, the melting point is 140 °C (literature value 134 °C) [25]. Mass spectrometry (MS) studies have been carried out using a standard MX1321 mass spectrometer with direct probe introduction. The temperature of the ionization chamber was 200 °C, electron energy 70 and 19 eV, and the temperature of the vaporization chamber 120 °C. Major ions in MS (relative intensity, %) were: $GaCl_2C_5H_{11}N^+$ (44); $GaCl_2C_5H_{10}N^+$ (11); $GaCl_2CH_3N^+$ (8); $GaCl_2^+$ (23); $GaCl^+$ (5); $C_5H_{11}N^+$ (59); $C_5H_{10}N^+$ (100); Ga^+ (8); HCl^+ (31); Cl^+ (8).

Tensimetry studies were performed by a static method with a glass membrane as null-manometer. The $GaCl_3 \cdot pip$ complex (55.55 mg) was introduced into the measurement chamber (volume 42.28 ml), and the system was heated in a furnace with a speed of about 0.5–1 °C per minute. The temperature was controlled by means of two chromel–alumel thermocouples, and the vapor pressure was measured with a mercury manometer. The vapor pressure–temperature dependence for the first two heating/cooling runs over $GaCl_3 \cdot pip$ complex is given in Fig. 1. For the

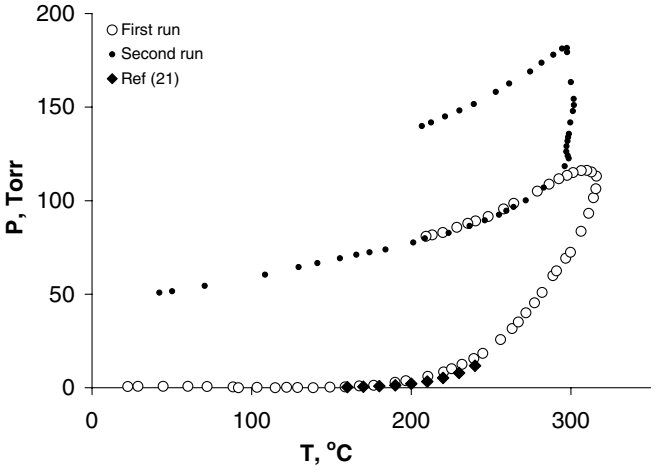

Fig. 1. Vapor pressure–temperature dependence for the $GaCl_3 \cdot pip$ complex. For the first run the lower circles refer to heating up to 316 °C. The upper curve circles for the first run refer to cooling for temperatures below 316 °C. For the second run the lower set of small solid dots refer to heating up to 298 °C. The upper set of small solid dots refers to cooling for temperatures below 298 °C.

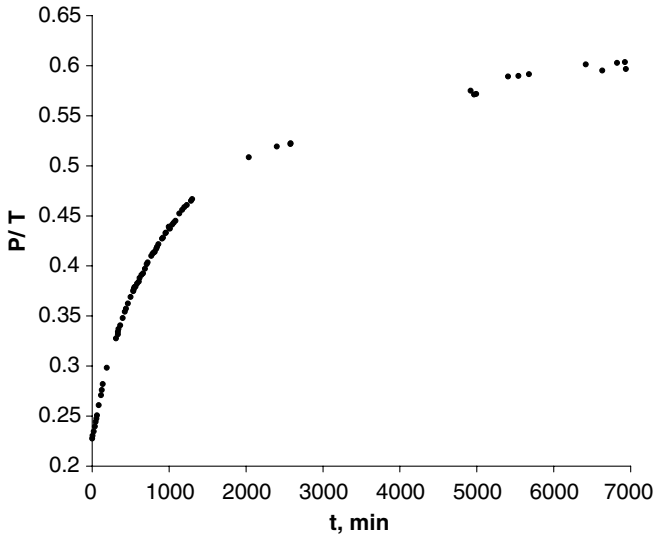

Fig. 2. Dependence of the P/T value on the decomposition time.

first run the measured vapor pressure is in agreement with the reported literature data [25]. In the temperature range 190–275 °C the vapor pressure is approximated by the equation $\lg P(\text{Torr}) = 8.003 \pm 0.022 - (3491 \pm 11)/T$. The vaporization enthalpy $\Delta H^{0\,\text{vap}}_{505} = 66.8 \pm 0.2$ kJ mol^{-1} lies below the literature value of $\Delta H^{0\,\text{vap}}_{473} = 85.9$ kJ mol^{-1} [25]; vaporization entropy $\Delta S^{0\,\text{vap}}_{505} = 98.1 \pm 0.4$ J mol^{-1} K^{-1}. As may be seen from Fig. 1, heating above 275 °C results in an irreversible pressure increase. The decomposition process proceeds slowly, as can be seen from Fig. 2, which displays the P/T – time dependence at 299 ± 4 °C. The P/T value is proportional to gas concentration ($P/T = nR/V$). The P/T – time dependence falls close to the logarithmic law. MS analysis of the volatile products after the thermal decomposition reveals the disappearance of the ions $GaCl_2C_5H_{11}N^+$, $GaCl_2C_5H_{10}N^+$, $C_5H_{11}N^+$ and $C_5H_{10}N^+$, indicating complete thermal destruction of the $GaCl_3 \cdot$ pip complex. Major species detected by MS after pyrolysis are: $GaCl_2NH_3^+$ (100); $GaCl_2C_5H_5N^+$ (53) and its homologues $GaCl_2C_5H_5(CH_2)_xN^+$ (with relative intensities 50; 17; 4; 2; 3; 2; 0.6 for $x = 1, 2, 3, 4, 5, 6, 7$, respectively) and the products of dissociative ionization $GaCl_2^+$ (54); $GaCl^+$ (21); Ga^+ (70); C_5H_5N (35); and $C_5H_5(CH_2)_xN^+$ (with relative intensities 78; 40; 6; 3; 5 for $x = 1, 2, 3, 4, 5$, respectively). Thus, formation of the DA complex $GaCl_3 \cdot$ py is observed experimentally, and it is accompanied by formation of DA complexes with methyl pyridines, which are probably originate from the Friedel–Crafts reactions in the condensed phase, catalyzed by $GaCl_3$.

4. Conclusions

Dissociation enthalpies of donor–acceptor complexes obtained at the B3LYP/LANL2DZ(d,p) level of theory are usually underestimated by 4–15 kJ mol^{-1}. Thus, the underestimation of the dative bond energy at B3LYP level of theory, reported recently by Gilbert for the B–N complexes [13], holds for the Al–N and Ga–N complexes as well. The present theoretical study of three possible thermal decomposition pathways of $MX_3 \cdot$ pip adducts suggests that hydrogen elimination with formation of $MX_3 \cdot$ py complexes is expected at temperatures near 500 K. Dissociation into components and hydrogen halide elimination requires much higher temperatures. In agreement with these expectations, experimental study of thermal decomposition of $GaCl_3 \cdot$ pip revealed the evolution of hydrogen gas and formation of the $GaCl_3 \cdot$ py complex and its homologues due to Friedel–Crafts reactions in the condensed phase.

through both *N*,*O*- and *O*,*O*-chelating fashions, as shown by the crystal structure of $[Eu(picOH)_2(\mu\text{-}HpicO)(H_2O)]\cdot 3H_2O$ [6]. The 2-hydroxynicotinate ion coordinates through *O*,*O*-chelation to lanthanides as registered for the complexes $[Ln(HnicO)_2(\mu\text{-}HnicO)(H_2O)]\cdot nH_2O$ (Ln = Eu, Tb) [7]. Lanthanide complexes with pyridine-carboxylic acids usually form polymeric structures, with the carboxylate group establishing a bridge between lanthanide ions [5–7,13–15,17]. In this work, the coordination modes of the pyridine-carboxylic ligands, as *N*,*O*- or *O*,*O*-chelators, together with the photoluminescence of the Sm^{3+} in these complexes have been investigated.

2. Results and discussion

2.1. Crystal structure of $K_2[Sm_2(pic)_6(\mu\text{-}pic)_2]\cdot 7.5H_2O$ (1)

The crystal structure of $K_2[Sm_2(pic)_6(\mu\text{-}pic)_2]\cdot 7.5H_2O$ (**1**) shares striking similarities with the compounds recently reported by Sendor et al. [17] belonging to the $X[Ln(pic)_4]\cdot nH_2O$ family (where $X = Na^+$ or NH_4^+, and $Ln^{3+} = Eu^{3+}$, Gd^{3+}, Tb^{3+} and Ho^{3+}), in the sense that the one-dimensional anionic $[Sm_2(pic)_6(\mu\text{-}pic)_2]_n^{2n-}$ coordination polymer present in **1** is structurally similar to those found in the above mentioned compounds. More recently, the same material containing Tb^{3+} cations could also be isolated and was described elsewhere [18]. However, crystal solution and refinement of **1** proved to be a challenge (see Section 3 dedicated to crystallography), not because of poor data quality (crystal data were collected several times from crystals isolated from different batches), but most probably due to the presence of the larger, and sterically bulkier, K^+ cations in **1**. While all compounds reported by Sendor et al. [17] were solved and refined in either the $P6_122$ or $P6_522$ space groups, which ultimately led to only one crystallographically unique Ln^{3+} cation in their crystal structures, compound **1** could only produce a reasonable structural model when the overall symmetry was reduced to that of the $P6_5$ space group (even though structural tests for missed symmetry elements, with the ADDSYMM routines provided with PLATON [19,20], still indicate an overall pseudo-symmetry identical to that of $P6_522$ space group).

The crystal structure contains two crystallographically independent Sm^{3+} sites, Sm(1) and Sm(2), both coordinated to four *N* and five *O*-donor atoms from five distinct picolinate (pic^-) ligands (Fig. 1a), leading to a nine-coordination fashion, $\{SmN_4O_5\}$, resembling a highly distorted tricapped trigonal prism, in close agreement with the geometries described by Sendor et al. [17] for the $X[Ln(pic)_4]\cdot nH_2O$ family. For Sm(1), the basal planes of the trigonal prism are formed by O(1)···O(3)···O(7) and O(5)···O(15)···N(2) (dihedral angle between planes of ca. 23.8°), with N(1), N(3) and N(8) capping the lateral faces [N–Sm–N angles found within the 100.3(4)–136.6(4)° range; see Fig. 1a and Table 1]. For Sm(2), the basal planes are instead formed by O(13)···O(16)···N(5) and N(4)···N(6)···O(11) (dihedral angle between planes of ca. 14.1°) with, in this case, O(8), O(9) and N(7) capping the lateral faces [(O,N)–Sm–(O,N) angles found within the 108.6(4)–130.0(4)° range; see Fig. 1a and Table 1]. The Sm–N and Sm–O bond distances are found within the 2.640(10)–2.752(9) Å and 2.355(13)–2.437(11) Å [for Sm(1)], and 2.634(1)–2.760(9) Å and 2.358(13)–2.452(10) Å [for Sm(2)] ranges, respectively. These values are in good agreement with those typically found in related compounds, as revealed by a search in the Cambridge Structural Database (CSD) (Version 5.25, November 2003) [21,22]: while the typical Sm–N bond distances are in the 2.12–2.98 Å range (from 294 entries with a median of 2.54 Å), the $Sm–O_{carboxylate}$ bond distances are instead in the 2.19–3.08 Å bond range (from 61 entries with a median of 2.41 Å).

As usually found in related compounds [5,13,16], particularly those belonging to the above mentioned $X[Ln(pic)_4]\cdot nH_2O$ family [17], all picolinate ligands in **1** are coordinated to the Sm^{3+} metal centres through the typical *N*,*O*-chelation mode, with average bite angles of ca. 63.6° and 63.4° for Sm(1) and Sm(2), respectively (Table 1, Fig. 1 and Scheme 1a). However, one picolinate residue further establishes a *skew*-bridge [via O(7); see Fig. 1 and Scheme 1b] with the neighbouring Sm^{3+}, thus completing the nine-coordination sphere of the metal centre and leading to the formation of a one-dimensional (1D) anionic coordination polymer, $[Sm_2(pic)_6(\mu\text{-}pic)_2]_n^{2n-}$, running along the [0 1 0] direction (Fig. 1b and c). The *skew*-bridge is also responsible for the zigzag distribution of the Sm^{3+} metal centres along the aforementioned crystallographic direction, imposing an intermetallic Sm(1)···Sm(2) separation of 6.462(2) Å.

2.2. Crystal structure of $[Sm(picOH)_2(\mu\text{-}HpicO)(H_2O)]\cdot 3H_2O$ (2)

While investigating the luminescent properties of lanthanide complexes containing 3-hydroxypicolinic acid (HpicOH) residues, we have also described in a previous study the structural properties of the series of materials with empirical formula $[Ln(picOH)_2(\mu\text{-}HpicO)(H_2O)]\cdot 3H_2O$ (where $Ln^{3+} = Eu^{3+}$, Tb^{3+} and Er^{3+}) [6]. In this manuscript we report the synthesis of the analogous compound containing Sm^{3+}, providing details on the coordination environment of Sm^{3+} and the coordination modes of the organic ligand.

Compound **2** contains a single Sm^{3+} centre, which appears coordinated to four HpicOH residues (of which only three are crystallographically independent) and one water molecule, $\{SmN_2O_6\}$, with an eight-coordination geometry closely resembling a distorted dodecahedron (Fig. 2a), in which the Sm–N [2.583(5)–2.597(5) Å] and Sm–O [2.313(3)–2.423(3) Å] bonds (Table 2) are well within the expected ranges found by the in-depth survey of the CSD (see above). Two $picOH^-$ residues (*trans*-positioned in the coordination sphere – see Fig. 2a) are coordinated to the metallic centre forming a typical *N*,*O*-chelate with an aver-

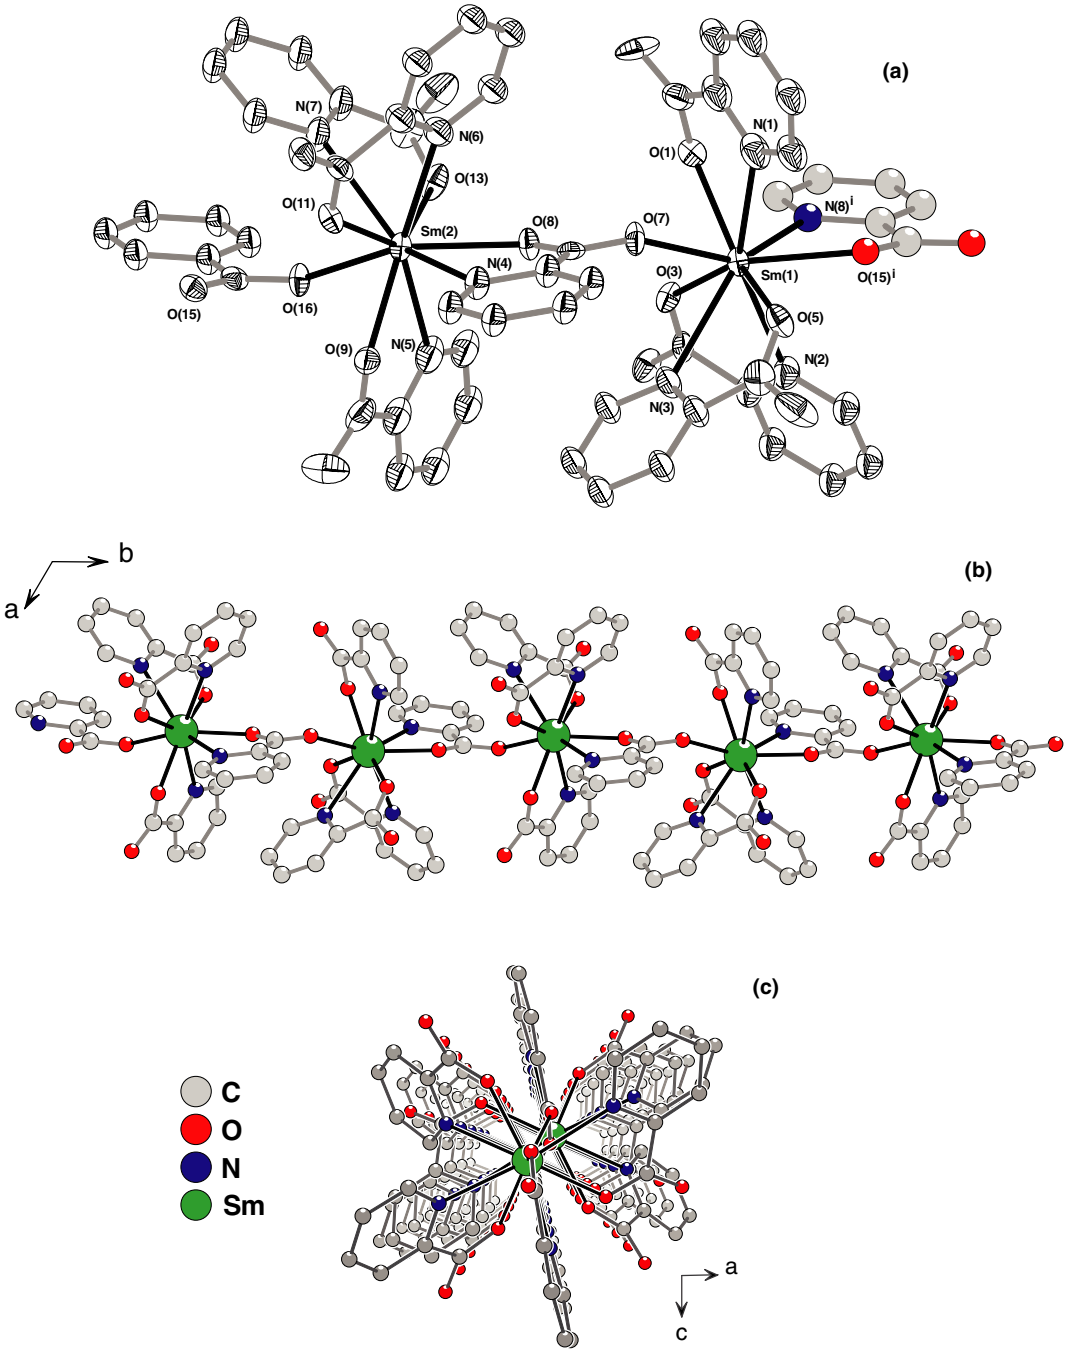

Fig. 1. (a) Tricapped trigonal prismatic coordination environments of Sm(1) and Sm(2) in $K_2[Sm_2(pic)_6(\mu\text{-pic})_2]\cdot 7.5H_2O$ (**1**), showing the labelling scheme for the atoms belonging to the first coordination sphere. Thermal ellipsoids are drawn at the 30% probability level. (b and c) Perspective views of the one-dimensional anionic $[Sm_2(pic)_6(\mu\text{-pic})_2]_n^{2n-}$ coordination polymer viewed along the [0 1 0] and [0 0 1] directions of the unit cell. Hydrogen atoms have been omitted for clarity purposes. For selected bond lengths and angles see Table 1. Symmetry code used to generate equivalent atoms: (i) x, $1+y$, z.

age bite angle of ca. 64.6° (Scheme 1c). The remaining crystallographically independent organic ligand (μ-HpicO$^-$) is, on the one hand, forming a six-membered chelate ring but, in this case, via the deprotonated phenolic and carboxylic acid groups (*O*,*O*-chelate) with a bite angle of 71.85(11)° (Fig. 2a); on the other hand, the deprotonated carboxylate group if further establishing a physical bridge (of the *syn*,*anti*-μ_2 type – Scheme 1d) with a neighbouring Sm^{3+}, imposing an intermetallic Sm(1)···Sm(1)^i separation of 6.963(1) Å [symmetry code: (i) x, $1.5-y$, $1/2+z$]. Once again, this latter bridging coordination fashion is responsible for the formation of the one-dimensional neutral $[Sm(picOH)_2(\mu\text{-HpicO})(H_2O)]$ coordination polymer (Fig. 2b), running parallel to the *c*-axis of the unit cell (Fig. 2c). As expected, this hybrid polymer is very much similar to those found for the $[Ln(picOH)_2(\mu\text{-HpicO})(H_2O)]\cdot 3H_2O$ (where $Ln^{3+} = Eu^{3+}$, Tb^{3+} and Er^{3+}) materials [6].

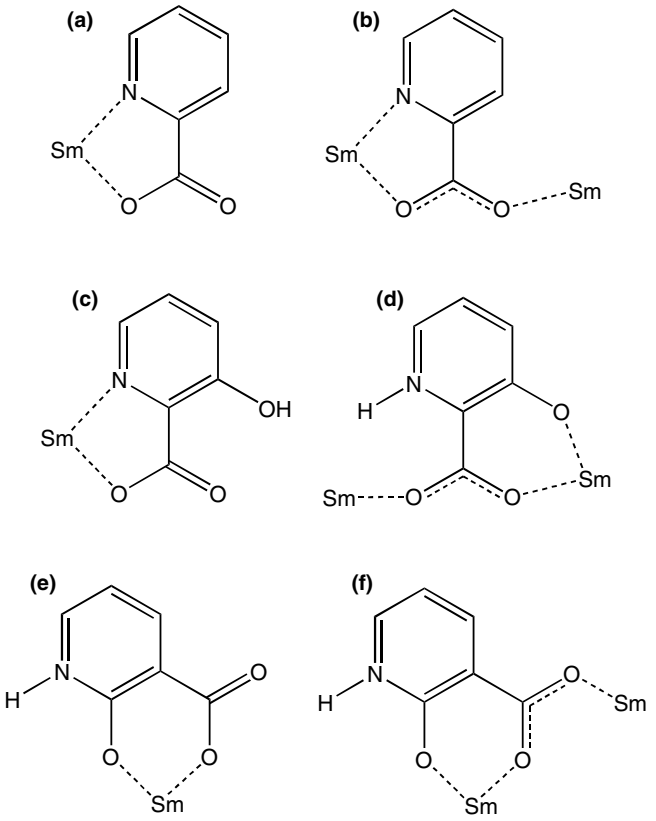
2.3. Crystal structure of $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)] \cdot 5H_2O$ (3)

In another recent study, we have described the crystal structures of $[Tb(HnicO)_2(\mu\text{-}HnicO)(H_2O)] \cdot 1.75H_2O$ and $[Eu(HnicO)_2(\mu\text{-}HnicO)(H_2O)] \cdot 1.25H_2O$ [7]. When Sm^{3+} cations were added to the reactive system, the systematic poor quality of the isolated crystals (usually very thin and long needles) avoided the collection of good-quality X-ray data, both of powder and single-crystal. Only recently its structure could be fully elucidated by collecting crystal data at the low temperature of 180(2) K in a diffractometer with a much higher CCD sensitivity (see section dedicated to single-crystal X-ray diffraction). Indeed, and as expected, $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)] \cdot 5H_2O$ (**3**) proved to be structurally identical to the above mentioned materials with Eu^{3+} and Tb^{3+}, with the major difference between the three compounds being the amount of water molecules of crystallisation accounted in their crystal structures.



Scheme 1. Coordination modes of the ligands present in compounds **1**–**3**: (a and b) picolinic acid, (c and d) 3-hydroxypicolinic acid, and (e and f) 2-hydroxynicotinic acid.

As observed for the analogous materials with Eu^{3+} and Tb^{3+}, compound **3** contains only one crystallographically unique Sm^{3+} metallic centre, coordinated to four 2-hydroxynicotinic acid (H_2nicO) residues and one water molecule, $\{SmO_8\}$, in an eight-coordination geometry which, as for **2**, is best described as a distorted dodecahedron (Fig. 3a). The Sm–O bonds are found within 2.362(5)–2.490(7) Å, well within the expected bond range (see above).

The various functional groups present in the H_2nicO residues confer richness to the coordination flexibility of this organic molecule. On the one hand, the three crystallographically unique $HnicO^-$ ligands appear in the crystal structure with both phenolic and carboxylic acid groups deprotonated and coordinated to the Sm^{3+} centres, in a typical *O*,*O*-chelating coordination fashion (Scheme 1e) with an average bite angle of ca. 70.7° (Table 3). Even though the latter value is slightly smaller than that registered for the previous compound, it is also well within the range of values typically found in related materials as

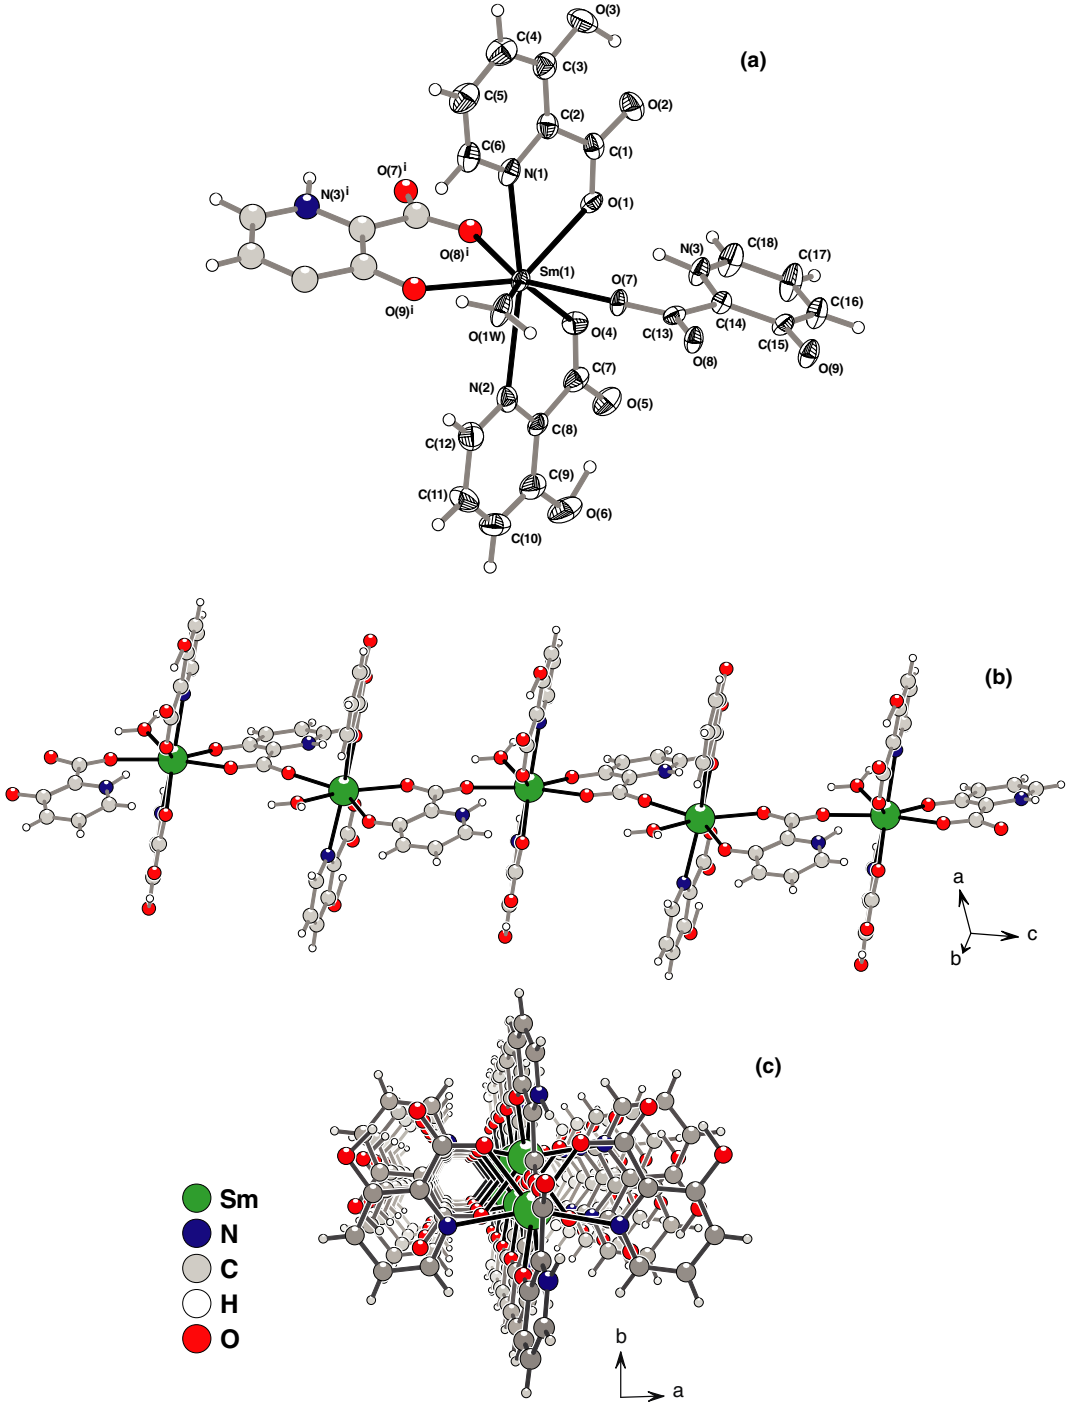


Fig. 2. (a) Distorted dodecahedral coordination environment of Sm(1) in $[Sm(picOH)_2(\mu\text{-}HpicO)(H_2O)]\cdot 3H_2O$ (**2**), showing the labelling scheme for all non-hydrogen atoms belonging to asymmetric unit. Thermal ellipsoids are drawn at the 50% probability level. (b and c) Perspective views of the one-dimensional $[Sm(picOH)_2(\mu\text{-}HpicO)(H_2O)]$ coordination polymer. For selected bond lengths and angles see Table 2. Symmetry code used to generate equivalent atoms: (i) x, $1.5 - y$, $1/2 + z$.

revealed by a search in the CSD (from 8 database entries, with values found in the ca. 61.0–74.1° range; median of ca. 69.2°) [21,22]. On the other hand, and as observed in the two previously described structures, a carboxylate group from one of these *O*,*O*-chelating $HnicO^-$ residues establishes a physical *syn, anti*-bridge with a neighbouring Sm^{3+} cation (μ-$HnicO^-$ – see Scheme 1f), thus forming a one-dimension neutral $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)]$ coordination polymer which runs parallel to the [1 0 0] direction of the unit cell (Fig. 3b and c). Such coordination fashion for the μ-$HnicO^-$ moiety imposes significant steric constrain in the carboxylate group, leading to a dihedral angle (with respect to the aromatic ring) of ca. 26.4° (see Fig. 3b). The minimum $Sm(1)\cdots Sm(1)^i$ intermetallic separation

[a] Symmetry transformations used to generate equivalent atoms: (i) x, $1.5 - y$, $1/2 + z$.

imposed by this organic ligand is of 6.521(1) Å [symmetry code: (i) $-1 + x$, y, z], a distance very much equivalent to those registered for the analogous Eu^{3+} and Tb^{3+} materials [7].

In compound **3** the *N*-donor atoms from the aromatic rings are not engaged in any type of coordination to the metal centres. Indeed, even though both *N*,*O*-chelation [23] and *N*-unidentate [24] coordination fashions are commonly observed for transition metal centres, in the case of lanthanides, coordination involving the nitrogen atom is even yet to be observed [7].

2.4. Vibrational spectra

Selected vibrational data and the molecular formulae for all complexes studied in this paper are supplied in Table 4, and are in accordance with the crystallographic studies summarised in the previous subsections. Infrared and Raman vibrational bands have been tentatively assigned, for Hpic, HpicOH, H_2nicO and their lanthanide complexes [5–7]. In Table 4 only the bands sensitive to metal coordination are reported. In the spectra of the picolinate and 3-hydroxypicolinate complexes, the asymmetric mode $\nu_{as}(CO_2)$ shifts (up to 106 cm^{-1}) to lower wavenumber, whereas the symmetric mode $\nu_s(CO_2)$ shifts to higher wavenumber (up to 40 cm^{-1}) when compared to the respective free ligands. Opposite shifts are observed for the 2-hydroxynicotinate complex. In the IR and Raman spectra of the complexes **1** and **2** the pyridine ν(CN) and ν(CC) stretches of the pyridinic ring show shifts to lower wavenumber (up to 23 cm^{-1}) when compared to Hpic and HpicOH. These shifts are in accordance with the *N*,*O*-chelation, as seen in the crystal structures of the complexes **1** and **2**. As expected, no shifts were observed for pyridine stretches in complex **3** because the coordination to the Sm^{3+} does not involve the nitrogen atom. Shifts of 21 cm^{-1} observed in the spectra of **2** for the band assigned to the $\nu(C–O)_h$ stretch are a result of the *O*,*O*-chelation of one ligand ($HpicO^-$). Similar shifts in the vibrational bands have been reported in the literature for other lanthanide complexes with aromatic ambidentate ligands [5–7].

2.5. Photoluminescence spectra

Fig. 4 shows the room-temperature emission spectra for the solid samarium complexes **1**–**3** under excitation at 325 nm. The emission spectra of the complexes are composed of a series of straight lines assigned to the Sm^{3+} intra-$4f^5$ transitions, $^4G_{5/2} \rightarrow {}^6H_{5/2,7/2,9/2,11/2}$ and of a large broad band in the range 380–550 nm for complexes **1** and **2**, and 380–680 nm for complex **3**, which may arise from the ligands excited states. The large broad bands observed in the emission spectra of the complexes **2** and **3** are blue-shifted comparatively with the previous reported for the Gd^{3+}-based complexes [7]. For all the complexes the more intense straight line characteristic of the Sm^{3+} is the magnetic dipole transition $^4G_{5/2} \rightarrow {}^6H_{7/2}$. Changes are detected in the energy, number of Stark components and in the full-width at half-maximum of the intra-$4f^5$ lines, reflecting the different Sm^{3+}-local coordination sites in each complex. For the three complexes a series of intra-$4f^5$ self-absorptions superimposed on the large broad band are also detected. The relative intensity between the broad band and the Sm^{3+} emission lines suggests that the efficiency of the energy transfer ligand-to-metal process is not efficient for the three complexes. Only compound **1** showed room-temperature emission under a Xe lamp (not shown) allowing the measurement of the correspondent excitation spectrum of the solid compound, monitored around the cation's more intense line at 595 nm, Fig. 5. The spectrum displays a large broad band between 250 and 325 nm associated with Hpic ligand [6], and a series of sharp lines assigned to transitions between the ground multiplet ($^6H_{5/2}$) and several excited states of the Sm^{3+}. The lower relative intensity of the ligand band indicates that the Sm^{3+} ions are essentially excited via direct metal excitation, rather than by an efficient sensitised process.

3. Experimental

3.1. Preparation of samarium (III) complexes

All chemicals were supplied by Aldrich and used as received.

The syntheses of samarium (III) complexes were performed as earlier described for the other lanthanide complexes with picolinic [5], 3-hydroxypicolinic [6] and 2-hydroxynicotinic [7] acids.

Compound **1** was prepared by adding an aqueous solution (5 ml) of the samarium salt ($SmCl_3 \cdot 6H_2O$, 1 mmol,

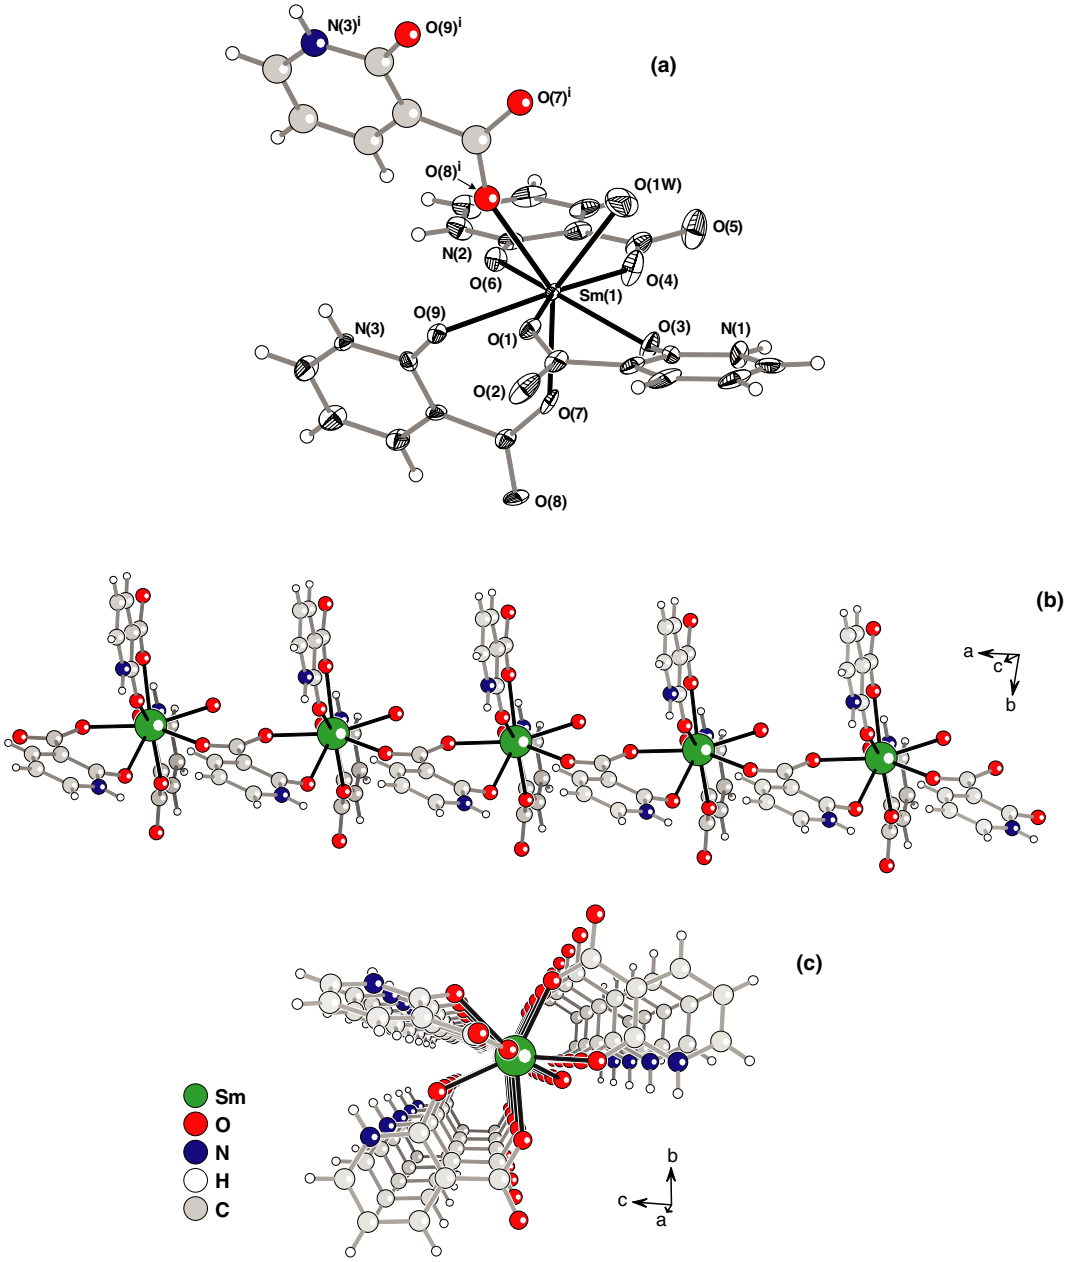

Fig. 3. (a) Slightly distorted dodecahedral coordination environment of Sm(1) in $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)] \cdot 5H_2O$ (**3**), showing the labelling scheme for selected non-hydrogen atoms belonging to asymmetric unit. Thermal ellipsoids are drawn at the 50% probability level. (b and c) Perspective views of the one-dimensional $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)]$ coordination polymer. For selected bond lengths and angles see Table 3. Symmetry code used to generate equivalent atoms: (i) $-1 + x, y, z$.

364 mg) to an aqueous solution (20 ml, pH ~ 6.7) of picolinic acid (Hpic, 4 mmol, 492 mg) and KOH (4 mmol, 224 mg). After stirring the mixture during approximately 1 h, an aqueous solution (5 ml) of tetrabutylammonium chloride hydrate ($^n Bu_4NCl \cdot nH_2O$, 4 mmol, 1.12 g) was added dropwise. The resulting solution was then heated (~100 °C), leading to the isolation of a white precipitate which was collected by filtering, followed by washing with distilled water. The materials were dried over silica gel. Colourless crystals with hexagonal habit of $K_2[Sm_2(pic)_6(\mu\text{-}pic)_2] \cdot 7.5H_2O$ were obtained from the mother solution by slow evaporation of the solvent during 3 days.

Compound **2** was synthesised by adding an aqueous solution (8 ml) of KOH (4.5 mmol, 252 mg) to an equal volume of a second aqueous solution containing the samarium salt ($SmCl_3 \cdot 6H_2O$, 1.5 mmol, 546 mg). The resulting mixture was stirred during approximately 90 min, after which time it was filtered, washed thoroughly with distilled water and added to an aqueous solution (25 ml) containing 3-hydroxypicolinic acid (4 mmol, 556 mg). This mixture was stirred during 1 h, heated for 30 min at 80 °C, and further stirred

over 8 h at room temperature. The isolated solid material was filtered, washed thoroughly with distilled water and dried over silica gel. Single-crystals of $[Sm(picOH)_2(\mu\text{-}HpicO)(H_2O)]\cdot 3H_2O$ were obtained from the filtrate after slow evaporation over a period of 3 days.

Compound **3** was prepared by adding an aqueous solution (5 ml) of the samarium salt ($SmCl_3\cdot 6H_2O$, 0.5 mmol, 182 mg), to an aqueous solution (15 ml, pH 6.0) of 2-hydroxynicotinic acid (2 mmol, 278 mg) and KOH (2 mmol, 112 mg). After stirring the mixture at ambient temperature for 1 h, the solid which was formed was collected by filtering, and then washed thoroughly with distilled water. The material was dried over silica gel. Single-crystals of $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)]\cdot 3H_2O$, were obtained by recrystallisation from aqueous solution.

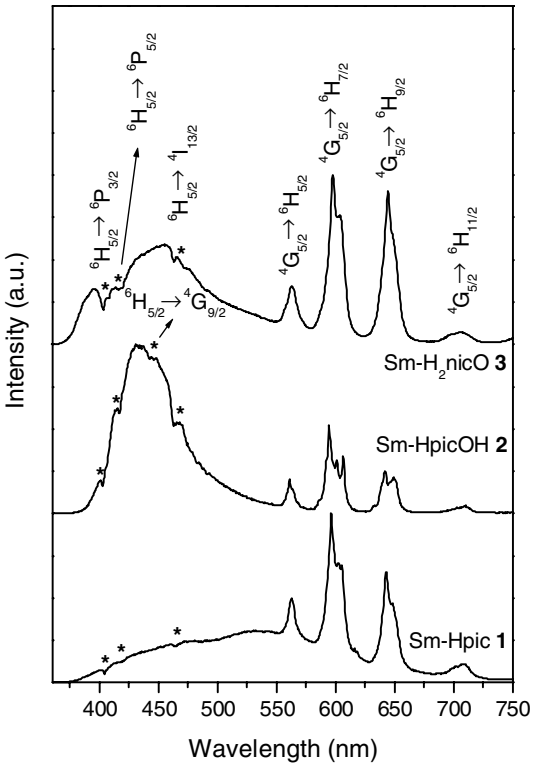

Fig. 4. Room-temperature emission spectra of compounds **1**–**3** excited at 325 nm. The asterisks denote intra-$4f^5$ self-absorptions.

3.2. Crystallography

Suitable single-crystals of $K_2[Sm_2(pic)_6(\mu\text{-}pic)_2]\cdot 7.5H_2O$ (**1**), $[Sm(picOH)_2(\mu\text{-}HpicO)(H_2O)]\cdot 3H_2O$ (**2**) and $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)]\cdot 5H_2O$ (**3**) were mounted on glass fibres using perfluoropolyether oil [25]. Data for **1** and **2** were collected at 180(2) K on a Nonius Kappa charge coupled device (CCD) area-detector diffractrometer (Mo Kα graphite-monochromated radiation, $\lambda = 0.7107$ Å), equipped with an Oxford Cryosystems cryostream

and controlled by the Collect software package [26]. Images were processed using the software packages Denzo and Scalepack [27], and data were corrected for absorption by the empirical method employed in Sortav [28,29]. Data for **3** were collected at 100(2) K (at the Unidade de Raios-X, RIAIDT, University of Santiago de Compostela, Spain) on a Bruker SMART 1000 charge coupled device (CCD) area-detector diffractometer (Mo Kα graphite-monochromated radiation, $\lambda = 0.7107$ Å), controlled by the SMART software package [30]. Images for **3** were processed using the SAINTPlus software package [31], and data were corrected for absorption by using the semi-empirical method of SADABS [32]. All structures were solved using SHELXS-97 [33], and refined by full-matrix least-squares on F^2 using SHELXL-97 [34].

Information concerning crystallographic data collection and structure refinement details are summarised in Table 5. Selected bond lengths and angles are given in Tables 1–3 for structures **1**–**3**, respectively.

3.2.1. Structure solution and refinement details for $K_2[Sm_2(pic)_6(\mu\text{-}pic)_2]\cdot 7.5H_2O$ (1)

Systematic absences, inspected using the interface *XPREP*, suggested four possible non-centrosymmetric and chiral space groups for **1**: $P6_1$, $P6_5$, $P6_122$ and $P6_522$. The structure was solved in $P6_5$ (all other space groups led to unrealistic solutions) using Patterson synthesis which allowed the initial location of the Sm^{3+} and K^+ cations. The remaining non-hydrogen atoms were located from difference Fourier maps calculated in successive least-squares refinements. All non-hydrogen atoms were successfully refined using anisotropic displacement parameters.

The eight crystallographically unique aromatic rings were refined with geometry heavily restrained to ensure a chemically reasonable structural model for these moieties: on the one hand, the *intra*-ring distances were restrained to common values, one for direct connections [ca. 1.37(1) Å], and another two for those which are one [ca. 2.37(1) Å] and two [ca. 2.73(1) Å] bonds apart; on the other hand, the six atoms of each aromatic ring were restrained to lie in a common plane using the *FLAT* instruction, and to share common anisotropic displacement parameters (*EADP* instruction). Hydrogen atoms attached to carbon were located at their idealised positions using the *HFIX 43* instruction in SHELXL, and included in the refinement in riding-motion approximation with an isotropic thermal displacement parameter fixed at 1.2 times U_{eq} of the carbon atom to which they are attached.

The seven and a half crystallographically unique water molecules of crystallisation were directly located from difference Fourier maps and refined with a common thermal isotropic displacement parameter. Even though no attempt was made to either locate the hydrogen atoms associated with these molecules, or to place them in calculated positions, the hydrogen atoms were included in the empirical formula of the compound (see Table 5).

The last difference Fourier map synthesis showed the highest peak (1.541 e $Å^{-3}$) located at 0.08 Å from O(1W), and the deepest hole (−0.960 e $Å^{-3}$) at 0.99 Å from Sm(2).

3.2.2. Structure solution and refinement details for $[Sm(picOH)_2(\mu\text{-}HpicO)(H_2O)] \cdot 3H_2O$ (**2**)

The structure was solved using direct methods, which allowed the location of the majority of non-hydrogen atoms. The remaining atoms were located from difference Fourier maps calculated in successive least-squares refinement cycles. All non-hydrogen atoms were successfully refined using anisotropic displacement parameters.

The four crystallographically unique water molecules were directly located from difference Fourier maps and refined successfully using anisotropic displacement parameters. Hydrogen atoms associated with the coordinated O(1W) and the lattice O(3W) water molecules were successfully located from difference Fourier maps, and refined with the O–H and H···H distances restrained to 0.84(1) Å and 1.37 Å, respectively (in order to ensure a chemically reasonable geometry for these molecules), and using a riding model with an isotropic displacement parameter fixed at 1.5 times U_{eq} of the atom to which they are attached. Hydrogen atoms from O(2W) and O(4W) could not be located and, even though no attempt was made to place these in calculated positions, they have been included in the empirical formula (Table 5).

Despite the hydrogen atoms associated with the hydroxyl groups were markedly visible in difference Fourier maps, their position in the structure was constrained using the *HFIX 147* instruction with isotropic thermal displacement parameters fixed at 1.5 times U_{eq} of the parent oxygen atom. Hydrogen atoms attached to carbon (from the three single 3-hydroxypicolinate aromatic residues) were located at their idealised positions using the *HFIX 43* instruction, and included in the refinement in riding-motion approximation with an isotropic thermal displacement parameter fixed at 1.2 times U_{eq} of the carbon atom to which they are attached.

One 3-hydroxypicolinate aromatic residue needs to be protonated so to balance the crystal charge. A close inspection of the crystal structure reveals that only the bridging 3-hydroxypicolinate ligand has the nitrogen atom not directly bound to a metal centre. Moreover, one *Q* peak neighbouring the mentioned nitrogen was markedly visible in difference Fourier maps. This hydrogen atom was subsequently refined with the N–H distance restrained to 0.95(1) Å and U_{iso} fixed at $1.5 \times U_{eq}$(N).

The last difference Fourier map synthesis showed the highest peak (1.137 e $Å^{-3}$) located at 1.19 Å from H(4), and the deepest hole (−0.955 e $Å^{-3}$) at 0.82 Å from Sm(1).

3.2.3. Structure solution and refinement details for $[Sm(HnicO)_2(\mu\text{-}HnicO)(H_2O)] \cdot 5H_2O$ (**3**)

The position of the crystallographically unique Sm^{3+} centre was located using Patterson synthesis, and the remaining non-hydrogen atoms were located from difference Fourier maps calculated in successive least-squares refinement cycles. Non-hydrogen atoms belonging to the neutral [Sm(HnicO)$_2$(μ-HnicO)(H$_2$O)] coordination polymer were successfully refined using anisotropic displacement parameters.

Hydrogen atoms bound to carbon were located at their idealised position using the *HFIX 43* instruction in SHELXL, and were included in subsequent refinement cycles in riding-motion approximation with U_{iso} fixed at $1.2 \times U_{eq}$ of the carbon atom to which they are attached. So to balance the crystal charge, three positive charges per Sm^{3+} cation were required. As the *N*-donor atoms from the three crystallographically independent 2-hydroxynicotinic acid residues are not bound to the Sm^{3+} metallic centres, and following the structural assumptions previously reported for the Tb^{3+} and Eu^{3+} analogue materials [7], the required hydrogen atoms were attached to the nitrogen atoms using the *HFIX 43* instruction in SHELXL. As for the aromatic hydrogen atoms, these were refined in riding-motion approximation with U_{iso} fixed at $1.2 \times U_{eq}$(N). The last difference Fourier map synthesis showed the highest peak (2.443 e $Å^{-3}$) located at 0.85 Å from Sm(1), and the deepest hole (−2.079 e $Å^{-3}$) at 0.11 Å from O(10W).

Eleven independent crystallographic sites, ascribed to highly disordered water molecules of crystallisation, could be directly located from difference Fourier maps. In good agreement with the values calculated in unrestrained refinement cycles (so to produce chemically reasonable temperature factors for the oxygen atoms), these water molecules were refined with fixed rates of occupancy of 50% [from O(2W) to O(10W)] and 25% [O(11W) and O(12W)]. Moreover, these moieties were refined using a common isotropic thermal displacement parameter.

Hydrogen atoms associated with the coordinated water molecule and those belonging to the crystal lattice were not visible in difference Fourier maps, mainly due to the smeared-out electron density associated with the latter moieties. However, the hydrogen atoms were included in the empirical formula (see Table 5).

In order to further validate the refined structural model, and since the collected crystal data showed strong evidence for the existence of extensive thermal disorder associated with all water molecules of crystallisation, the contribution of these moieties to the total electron density was removed by using the SQUEEZE [35] subroutine included with the crystallographic software package PLATON [19]. The calculated solvent-free reflection data were used in subsequent least-squares refinement cycles, converging to a structural model which does not differ significantly from that already obtained using the original reflection data set. As expected, using the solvent-free reflection data the global reliability factors improved, with R_1 $[I > 2\sigma(I)] = 0.0444$ and wR_2 (all data) = 0.1074. PLATON estimated that the unit cell contains ca. 304 Å^3 of total accessible solvent area (ca. 25% of the total volume), located in only one large cavity centred at (−0.010 0.500 0.000), totally containing ca. 83 electrons. These values are in good agreement with the total amount of just about 5 water molecules of crystallisation which were included in the final structural model of **3**.

3.3. Instrumentation

Infrared spectra were measured as KBr disks using a Mattson 7000 FT instrument. Raman spectra were recorded using a Bruker RFS100/S FT-Raman spectrometer (Nd:YAG laser, 1064 nm excitation). Elemental analysis (C, H and N) were measured in the Department of Chemistry, University of Aveiro. Solid-state room-temperature luminescence spectra were recorded on a Jobin Yvon-Spex spectrometer (HR 460) coupled to a R928 Hamamatsu photomultiplier. A He–Cd laser beam (325 nm and P = 30 mW) and a Xe-arc lamp (150 W) were used as excitation sources. All the emission spectra were corrected for the response of the detector.

4. Conclusions

New Sm^{3+} complexes of three pyridine-carboxylic acid derivatives (picolinic, 3-hydroxypicolinic and 2-hydroxynicotinic acids) were obtained and structurally characterised. The X-ray crystal structures show one-dimensional polymeric chains for all complexes presenting *N*,*O*- or *O*,*O*-chelation for the ligands. Four picolinate ligands coordinate to Sm^{3+} through *N*,*O*-chelation in complex **1**, with an one-dimensional chain being formed by a carboxylate bridge from one of the pic^- ligands. In the 3-hydroxypicolinate complex **2** *N*,*O*-chelation is observed for two $picOH^-$ ligands and the third ligand $HpicO^-$ coordinates through *O*,*O*-chelation and forms the carboxylate bridge of the chain. The coordination sphere of complex **2** is completed by one water molecule as also happens for complex **3**. In the 2-hydroxynicotinate complex **3** *O*,*O*-chelation is observed for the three ligands bonded to lanthanide centre, one of which forms the carboxylate bridge of the chain. In complexes **2** and **3** Sm^{3+} is eight-coordinated, while in complex **1** a coordination number of nine was obtained through four chelating ligands and a carboxylate bridge, thus avoiding water coordination. All complexes show room-temperature photoluminescence.

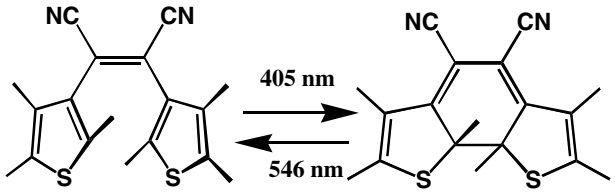

Scheme 1. Photochromic reaction of *cis*-dbe.

properties of Rh(II), dirhodium pivalate was selected as the metal salt in this work and three novel Rh(II) complexes were prepared, which are different from the previously dirhodium trifluoroacetate complexes [28] both in coordination modes and in conformation. Furthermore it was found that the dirhodium complex with the closed-dbe, where the metal atom has a direct coordination with the thienyl ring, is transferred to the open-form upon excitation with 529 nm light during the cycloreversion reaction.

2. Experimental

2.1. General methods

Unless otherwise indicated, all starting materials were used as received from commercial suppliers (Aldrich and Wako Chemicals). All reactions and manipulations were carried out under an argon atmosphere prior to use. Solvents were dried using standard procedures and distilled under an argon atmosphere. $[Rh_2(O_2CC(CH_3)_3)_4]$ was prepared according to the known literature procedure [29]. Closed-dbe was obtained by separating a *cis*-dbe hexane solution irradiated with 405 nm light.

Infrared spectra were recorded using KBr disks on a JASCO FT/IR-430 spectrometer. Absorption spectra in the crystalline state were measured by diffuse reflection using the Kubelka–Munk method on a SHIMADZU UV-2450 spectrometer, and barium sulfate was used as a reference. Photoirradiation was carried out using a 150 W Xe lamp and monochromatic light was obtained by passing the light through a monochromator.

2.2. Syntheses

2.2.1. $[Rh_2(O_2CC(CH_3)_3)_4(cis\text{-}dbe)_2]$ (1)

$[Rh_2(O_2CC(CH_3)_3)_4]$ (15.3 mg, 0.03 mmol) and *cis*-dbe (8.2 mg, 0.03 mmol) were dissolved in 5 mL benzene, and the resultant solution was carefully introduced into a 7 mm glass tube, which afforded complex **1** as green brick crystals after standing in the dark at an ambient temperature for 1 week. IR (KBr pellet, range 4000–400 cm^{-1}): 2965 (m), 2920 (m), 2864 (m), 2214 (m), 1578 (s), 1547 (w), 1484 (w), 1457 (w), 1439 (w), 1416 (m), 1376 (w), 1363 (w).

2.2.2. $[Rh_2(O_2CC(CH_3)_3)_4]$ (trans-dbe)$](CH_2Cl_2)_4$ (2)

Red-brown brick crystals were obtained similarly to those of complex **1** using dichloromethane instead of benzene. Yield: 63.8%. $Rh_2S_2O_8N_2C_{39.5}H_{57}Cl_3$: C, 44.58; H, 5.40; N, 2.63. Found: C, 44.42; H, 5.33; N, 2.61%. IR (KBr pellet, range 4000–400 cm^{-1}): 2987 (m), 2958 (m), 2923 (m), 2867 (m), 2237 (w), 1585 (s), 1484 (m), 1454 (w), 1415 (s), 1376 (m), 1363 (w).

2.2.3. $[Rh_2(O_2CC(CH_3)_3)_4]$ (closed-dbe) (3)

Red brick crystals were obtained similarly to those of complex **1** using closed-dbe in place of *cis*-dbe. Yield: 70.0%. *Anal.* Calc. for $Rh_2S_2O_8N_2C_{38}H_{54}$: C, 48.72; H, 5.81; N, 2.99. Found: C, 47.78; H, 5.51; N, 2.90%. IR (KBr pellet, range 4000–400 cm^{-1}): 3446 (m), 2959 (m), 2928 (m), 2904 (m), 2871 (m), 1584 (s), 1540 (w), 1505 (m), 1483 (s), 1457 (w), 1444 (w), 1414 (s), 1375 (m), 1363 (m).

2.3. X-ray data collection and structure solution and refinement

Diffraction data for complexes **1**–**3** were collected on a Rigaku MSC Mercury CCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71069$ Å). Intensity data were collected at 150 K using the ω scanning technique and a total of 6623, 6235 and 12071 reflections were collected for complexes **1**–**3**, respectively. No decay correction was applied. The linear absorption coefficients μ for the Mo Kα radiation were 7.28, 10.62 and 7.38 cm^{-1}, respectively.

The structures were solved by direct methods followed by subsequent Fourier calculations [30]. The non-hydrogen atoms were refined anisotropically for all complexes. For complex **1** the hydrogen atoms were located from difference density maps and their coordinates were refined. The C—H and O—H bonds lengths are 0.69(3)–1.14(3) Å. For complexes **2** and **3** the hydrogen atoms were introduced as fixed contributors. The final cycle of the full-matrix least squares refinement was based on 6059, 5809 and 9635 observed reflections and 442, 307 and 470 variable parameters for **1**–**3**, respectively, converged with the unweighted and weighted agreement factors of $R = \sum ||F_o| - |F_c|| / \sum |F_o|$ and $R_w = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$. The atomic scattering factors and anomalous dispersion terms were taken from the International Tables for X-ray Crystallography, vol. IV [31]. All calculations were performed using the TEXSAN crystallographic software package [32]. Details of the X-ray experiments and crystal data are summarized in Table 1. Selected bond lengths and bond angles are given in Table 2.

3. Results and discussion

3.1. Structural characterizations

The structures of the three Rh(II) coordination compounds were determined by X-ray crystallographic analyses and are showed in Figs. 1–3. The crystallographic data and lengths and angles of selected bonds of complexes **1**–**3** are listed in Tables 1 and 2.

In complex **1** it was found that two Rh(II) ions are coordinated with two S atoms of thienyl groups from two different ligands to give a 2:1 mononuclear complex with a dirhodium unit and the two thienyl groups of the ligand are arranged in a parallel conformation (Fig. 1). As in Rh(II) trifluoroacetate complexes the metal ions have no interaction with the thieophene rings of the bisthienylethenes, this implies the coordination mode and conformation of the crystals are influenced by the carboxylates. Complex **1** is also quite distinguished from the structures of Ag(I) complexes with *cis*-dbe [27] where the metal center is coordinated with one cyano group as well as one thienyl S atom of different bisthienylethene molecules.

The crystals of complex **2** were synthesized similarly to complex **1** using dichloromethane instead of benzene. The X-ray crystallographic analyses show *cis*-dbe is changed to *trans*-dbe to coordinate with Rh(II). Each Rh(II) atom is coordinated to one cyano group of the *trans*-dbe with a bond length of 2.173(3) Å, which lead to an almost straight 1-D chain (Fig. 2). The coordination environment around the rhodium ions of complex **2** is notably different from that of complex **1**. In comparison with a Cu(I) complex with *trans*-dbe [26], both metal atoms are coordinated with two cyano groups from two different *trans*-dbe. The Rh—Rh bond length has a slightly change from 2.394(1) Å in complex **1** to 2.3802(4) Å in complex **2**.

Complex **3** was synthesized in the same manner as complex **1** using rigid closed-dbe, of which two thienyl groups are almost in the same plane, in the place of the flexible *cis*-dbe. The X-ray crystallographic analyses found the metal atoms are coordinated with one cyano group and one thienyl S atom from two different closed-dbe molecules to give a 1-D chain structure (Fig. 3). The Rh—S bond distance in both complexes coordinated to at least one thienyl group, namely complexes **1** and **3** is 2.544(1) Å and 2.588(2) Å, respectively. The short Rh—S bond distance in complex **3** is considered less favorable in photogenerated reactions based on the free rotation of the two thienyl groups. The Rh—Rh distance is 2.394(1) Å in complex **1** and 2.3987(8) Å in complex **3**, which are slightly longer values than that of the parent compound $[Rh_2(O_2CC(CH_3)_3)_4]$ (2.371(1) Å).

In conclusion, three Rh(II) complexes with *cis*, *trans* and closed-dbe were synthesized in which the coordination modes are different. In addition there are some differences in structures and conformations of three complexes: complexes **2** and **3** are coordination polymers whereas complex **1** is a mononuclear complex. In fact only complex **1** in this

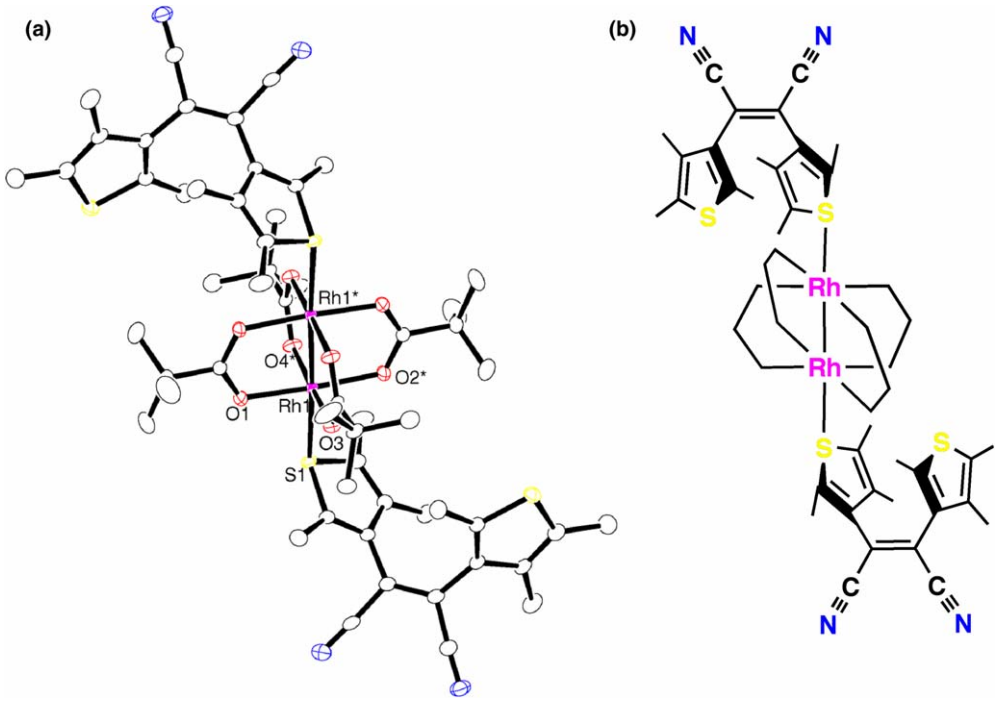

Fig. 1. Crystal structure of complex **1** ([$Rh_2(O_2CCMe_3)_4$(*cis*-dbe)$_2$]). (a) ORTEP view with the atomic labelling scheme, showing 50% thermal ellipsoids. Hydrogen atoms have been omitted for clarity. (b) Schematic figure.

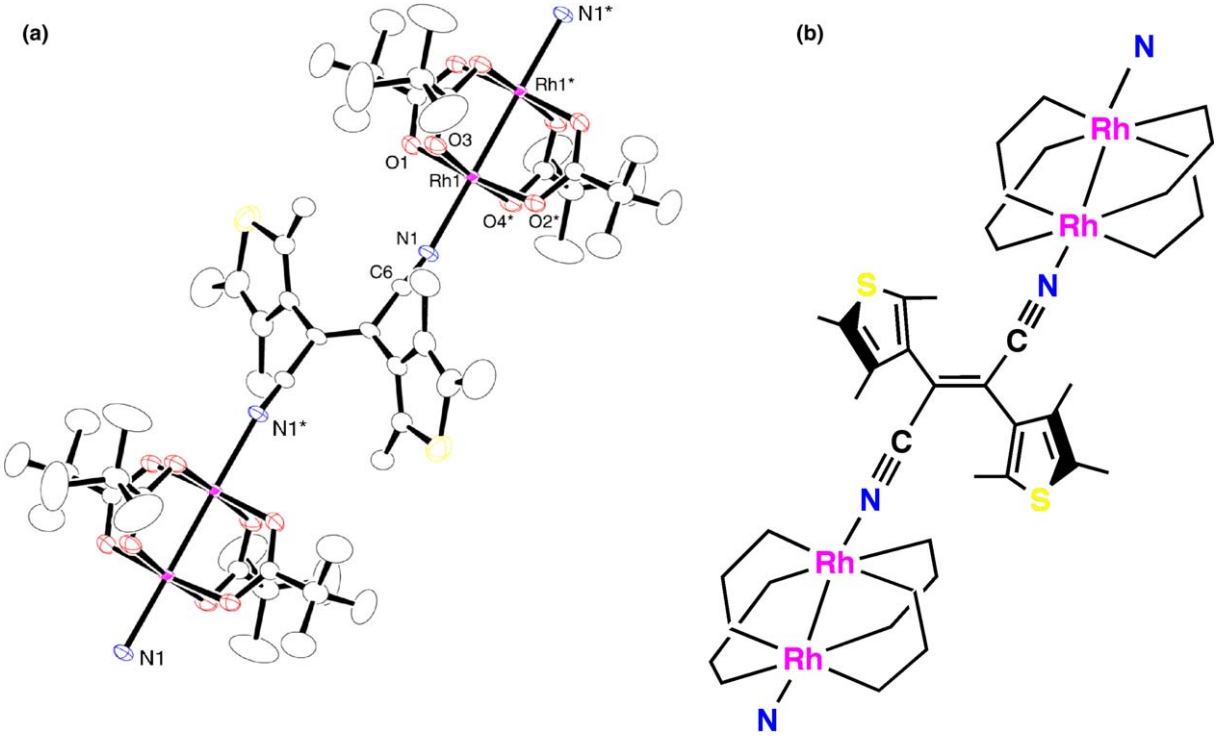

Fig. 2. Crystal structure of complex **2** ([$Rh_2(O_2CCMe_3)_4$(*trans*-dbe)](CH_2Cl_2)$_4$). (a) ORTEP view with the atomic labelling scheme, showing 50% thermal ellipsoids. Hydrogen atoms have been omitted for clarity. (b) Schematic figure.

work is not a chain structure, unlike the five dirhodium(II) trifluoroacetate and other pivalate complexes. A detailed comparison of Rh(II) complexes with *cis*-dbe or closed-dbe is summarized in Table 3.

3.2. Photochromism in the crystalline phase

The green complex [$Rh_2(O_2CC(CH_3)_3)_4$] (*cis*-dbe) **1** was synthesized in benzene. The most remarkable feature of **1** is

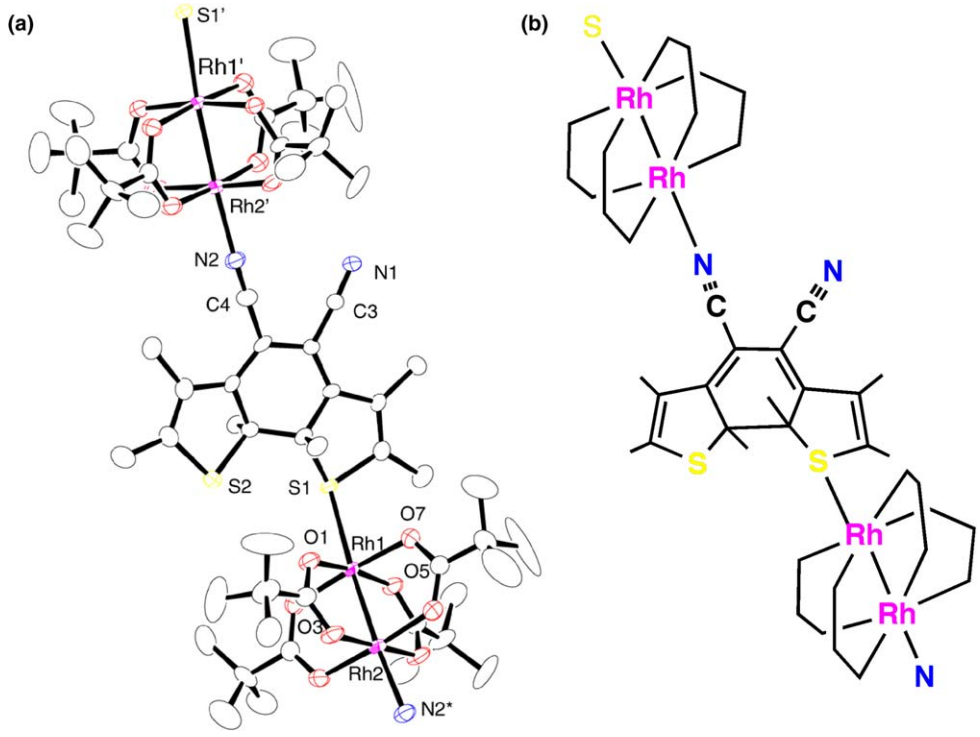

Fig. 3. Crystal structure of complex **3** ([$Rh_2(O_2CCMe_3)_4$(closed-dbe)]). (a) ORTEP view with the atomic labelling scheme, showing 50% thermal ellipsoids. Hydrogen atoms have been omitted for clarity. (b) Schematic figure.

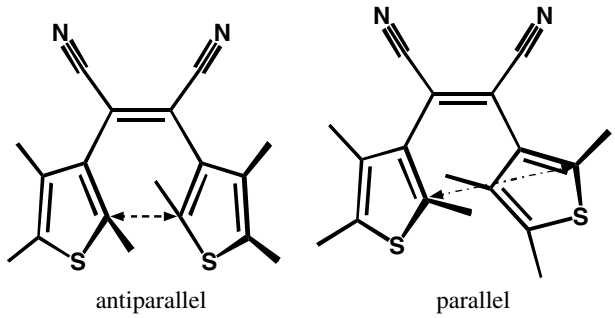
Table 3
Rh(II) complexes with dbe

Complex	Anion	Ligand	Bridging	Conformation	Reference
[$Rh_2(O_2CCF_3)_4$(*cis*-dbe)](benzene)	$O_2CCF_3^{2-}$	*cis*-dbe	two cyano groups	three kinds	[28]
[$Rh_2(O_2CCF_3)_4$(closed-dbe)](*p*-xylene)	$O_2CCF_3^{2-}$	closed-dbe	two cyano groups	antiparallel	[28]
[$Rh_2(O_2CC(CH_3)_3)_4$(*cis*-dbe)]	$O_2CC(CH_3)_3^{2-}$	*cis*-dbe	two thienyl groups	parallel	this work
[$Rh_2(O_2CC(CH_3)_3)_4$ (*trans*-dbe)](CH_2Cl_2)$_4$	$O_2CC(CH_3)_3^{2-}$	*cis*-dbe	two cyano groups	*trans*	this work
[$Rh_2(O_2CC(CH_3)_3)_4$ (closed-dbe)]	$O_2CC(CH_3)_3^{2-}$	closed-dbe	one thienyl group and one cyano group	antiparallel	this work

one thienyl group of *cis*-dbe is coordinated to Rh to give two thienyl groups in a parallel conformation, which suppress the photocyclization reaction proceeding (Scheme 2). A bisthienylethene molecule could exist in two conformations: (i) parallel, in which the two thiophene rings are in mirror symmetry; (ii) antiparallel, in which the rings are in C_2 symmetry. According to the Woodward–Hoffmann rules, photochromic performance of diarylethene derivatives in crystals strongly depends on the



Scheme 2. Antiparallel and parallel conformations.

conformation of the molecules and the photocyclization reaction can only occur from the antiparallel conformation [1]. Further the distance between the reactive carbon atoms C(5) and C(9) in parallel complex **1** is 4.174 Å, which is too long for a covalent C—C single bond formation [1]. Thus in complex **1** a photocyclization reaction could not happen without the necessary antiparallel conformation and short distances between the reactive carbons. In contrast to Rh(II) trifluoroacetates complexes [28], of which each metal ion of the dimetal trifluoroacetates is coordinated with a cyano group of *cis*-dbe and three kinds of conformations coexist in the compound, each Rh(II) ion is coordinated with one thienyl group from each ligand and only a parallel conformation is packed in complex **1**. This phenomenon shows that the carboxylates influence not only the coordination mode but also the conformation of the ligand, and subsequently the photoinduced behavior.

Complex **2** was synthesized in dichloromethane using the same ligand. *cis*-dbe is changed to *trans*-dbe accompanying the coordination of two cyano groups to different Rh(II) atoms and the formation of molecular packing

including dichloromethane molecules. This shows the solvent has a close correlation with the coordination mode and conformation of dbe in the complex. Further investigation on NMR spectra of the free *cis*-dbe ligand in deuterated benzene and deuterated dichloromethane shows the signals of the methyl protons in different solvents are quite different (see Supplementary Information). This result suggests the existence of both *cis* and *trans* conformations in solution, which is agreeable with the previous examination of *cis*-dbe in deuterated CCl_4 solution [9], but there is different equilibrium between the two conformers in both solvents. The interesting solvent effect responsible for the different conformation in complexes **1** and **2** may be decided by which conformer, *cis* or *trans*, is superior in benzene or dichloromethane, and in which the metal complex is predominantly crystallized. Similarly to the previously reported Cu(I) complex with *trans*-dbe [26], complex **2** shows no visible color change upon any reasonable period of irradiation. The λ_{max} of complex **2** is 539 nm and is shifted to 570 nm after irradiation with 405 nm light for 30 min, indicating that the structure of complex **2** is changed with the irradiation.

The reddish purple complex **3** was prepared by using closed-dbe to avoid the rotation of *cis-trans* isomerization and the parallel conformation of two thienyl groups of *cis*-dbe. The most interesting feature of this complex is that one thienyl group, as well as one cyano group of *cis*-dbe, is coordinated to the rhodium atoms. Fig. 4 shows the absorption spectra changes of complex **3** in the crystalline phase. Before irradiation complex **3** has strong absorptions in the UV region and at 529 nm. Upon irradiation, the reddish purple complex **3** of closed-ring form is transformed to the green open-ring form and the 529 nm peak gradually flattens. The spectrum changed showing two constant isosbestic points (456 and 632 nm), and subsequently indicates that the transformation is occurring without the decomposition of the original and resulting complexes. The shoulder band around 529 nm did not disappear by further irradiation, indicating completeness of the conversion. The open-form of complex **3** shows a new absorption band with a λ_{max} value of 593 nm due to a $\pi^* \rightarrow \sigma^*$ transition band, which is at 683 nm in $[Rh_2(O_2CC(CH_3)_3)_4]$, as shown in Fig. 5.

It is noted that in this work the closed-dbe of antiparallel conformation in complex **3** is transferred to the ring-open isomer in spite of the special coordination environment of Rh(II). It is known that the photocycloreversion reaction of bisthienylethene in the crystalline phase varies depending on the molecular structure [2], but the details have not been clarified at present. The conversion of the closed-form to the open-form in complex **3** clearly suggests that the photocycloreversion reaction of bisthienylethene complexes could proceed with metal atoms being coordinated with a thienyl group. It is expected that this finding is useful to further understand the photochromic behavior of bisthienylethene coordination compounds in the crystalline phase.

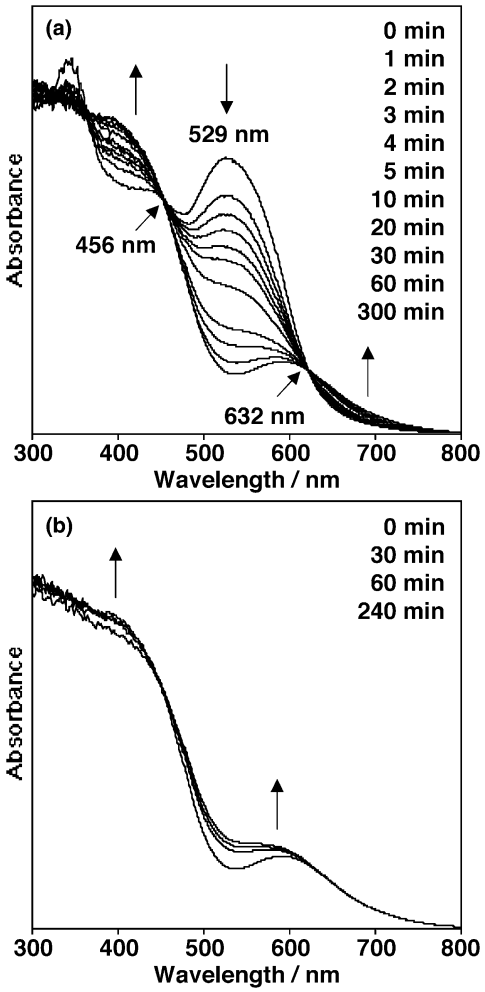


Fig. 4. Absorption spectral changes of complex **3** ($[Rh_2(O_2CC(CH_3)_3)_4$ (closed-dbe)]) by photoirradiation in the crystalline phase: (a) the closed-form was transformed to the open-form with 529 nm light and irradiation times are 0, 1, 2, 3, 4, 5, 10, 20, 30, 60 and 300 min; (b) the open-form was not transformed to the closed-form with 405 nm light and irradiation times are 0, 30, 60 and 240 min.

However, the resultant open-form of complex **3** is not converted to the initial closed-form on exposure to 405 nm light. The precise mechanism of the cyclization reaction remains unknown, while some consideration is necessary. Generally, a rotational motion encounters steric hindrance in the crystal. Therefore, the cyclization reaction in crystalline phases is dependent on the conformation and crystal packing [33]. In the previous report [27] we found that Ag(I) complexes with *cis*-dbe were transferred to the closed form where two thienyl S atoms were coordinated with metal atoms. No transformation of the open-form to the closed-form in complex **3** may be attributable to the steric hindrance of pivalate to the rotation of the thiophene rings.

It is well established that UV–Vis spectroscopy is the most common and effective detection method used in the solid state by far, where the photochromic states are identified by measuring the absorption bands characteristic of the open and closed isomers [4,14,26–28]. The photoreaction of the closed-dbe of complex **3** with irradiation of light

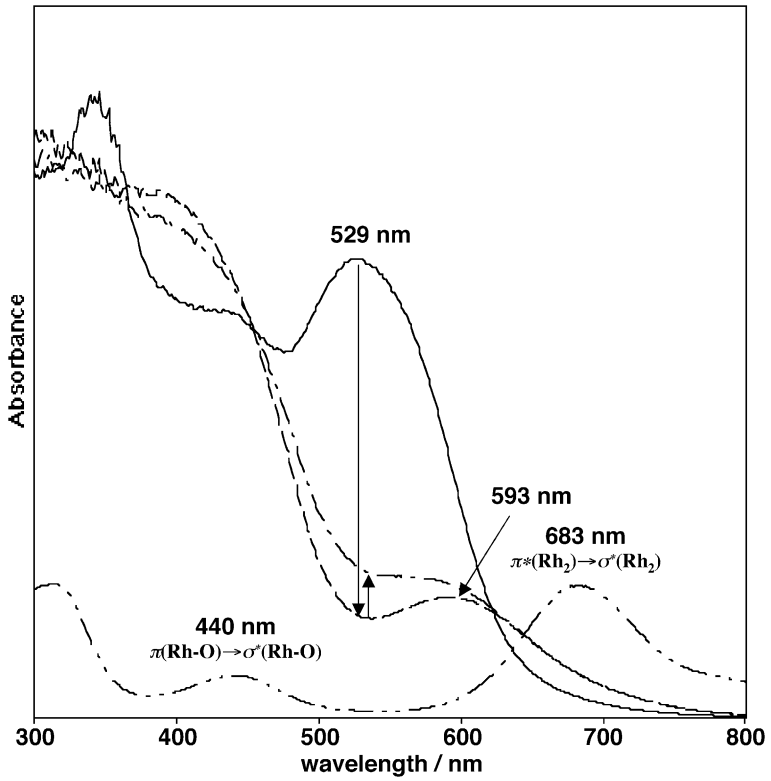

Fig. 5. Absorption spectral changes of complex **3** by photoirradiation in the crystalline phase: before irradiation (—), irradiation with 529 nm light for 300 min (---) and in the photostationary state under irradiation with 405 nm light for 240 min (-··-). Absorption spectrum of $[Rh_2(O_2CC(CH_3)_4)$ (-···-), $\lambda_{max} = 311$, 440, 683 nm.

occurs only on the surface of the crystals and subsequently the small amount of product (open-ring form) may not be detected by MAS NMR spectroscopy. Despite the limited monitoring method the green open form of complex **3** is considered not identical to complex **1**. The crystals of complex **3** are packed in a fixed orientation in the crystalline phase and a marked transformation from antiparallel to parallel is unacceptable. Also the open form of complex **3** seems not to decompose on exposure to 405 nm light which shows two constant isosbestic points judging from the UV spectra (Fig. 4(b)).

In contrast, λ_{max} of the metal-free closed-dbe (484 nm) < complex **3** (529 nm) < $[Rh_2(O_2CCF_3)_4$ (closed-dbe)] (574 nm). The absorption maximum is shifted much with coordination of both cyano groups compared to coordination with one cyano group and one thienyl group.

4. Conclusions

Three novel Rh(II) pivalate complexes were prepared where the dirhodium moieties are linked via 1,2-dicyano-1,2-bis(2,4,5-trimethyl-3-thienyl)ethene of *cis*, *trans* and closed forms. X-ray crystallographic analyses demonstrated that dirhodium pivalate leads to three kinds of coordination mode, that is the metal ions can be coordinated with two thienyl groups (complex **1**), two cyano groups (complex **2**) and one cyano group as well as one thienyl group (complex **3**). The three coordination modes are of interest in connection with the syntheses of photochromic complexes with bisthienylethene. *cis*-dbe is coordinated to Rh(II) accompanied by parallel conformation and *trans* isomerization to generate complex **1** and **2**, respectively. On the other hand, the closed-dbe of complex **3** shows typical spectral changes to the open-form on irradiation at 529 nm in spite of the Rh(II) being coordinated to both thienyl and cyano groups.

pane) [10] contain the corresponding fragments bonded to cyclic $(V_4O_{12})^{4-}$ units. In $[\{Co(phen)_2\}_2(V_6O_{17})]_n$ [11], the $Co(phen)_2$ fragments are covalently bonded to $\{V_6O_{17}\}_n^{n-}$ chains which are composed of alternate $V_4O_{12}^{4-}$ and $V_4O_7^{4-}$ building units.

Specifically, the $CuSO_4$–*phen*–V_2O_5–H_2O system yielded under hydrothermal conditions the compound $[\{Cu(phen)_2\}_4V_{10}O_{29}]\cdot 6H_2O$. The structure of this compound consists of discrete tetradeca-nuclear clusters built up from $V_{10}O_{29}^{8-}$ moieties and four $[Cu(phen)_2]^{2+}$ fragments [11]. The compound $[Cu(phen)(H_2O)(V_2O_6)]$ [12] was isolated after the hydrothermal reaction in the similar $Cu(NO_3)_2$–*phen*–Na_3VO_4 system. The structure of this compound consists of ribbon-like chains composed of $V_4O_{12}^{4-}$ clusters connected by $Cu(phen)(H_2O)$ fragments.

Nearly all these complexes were prepared by hydrothermal methods. In addition to the evident advantages of hydrothermal methods of syntheses of inorganic–organic hybrid compounds (increased solubility of the reactants, enhanced crystallization of metastable phases) they also have some drawbacks. Hydrothermal methods often lead to the formation of mixtures of several compounds that are hard to separate, and study of their properties, with the exception of X-ray diffraction analysis of mechanically separated monocrystals, is then questionable. There is also a limited ability to follow the course of reactions, and the relationship between the conditions of syntheses, composition and structure of the products is not very clear.

This paper is a part of our study dealing with the influence of some reaction conditions on the composition and structure of inorganic–organic hybrid compounds. We have chosen a simple Cu(II)–1,10-phenanthroline–oxovanadate system to avoid possible ambiguities in the ligand–metal bonding. 1,10-Phenanthroline represents a relatively rigid compound, which is usually bound as a bidentate chelate ligand in the *cis*-positions of a coordination polyhedron.

2. Experimental

2.1. Materials, instruments and analytical methods

KVO_3 was prepared according to Ref. [13]. All other chemicals were used as supplied (Lachema, Aldrich). The IR spectra were measured on a Nicolet Magna 750 spectrophotometer as nujol mulls or KBr pellets.

C, H, N were estimated on a CHN analyser (Carlo Erba). Vanadium(V) was determined by titration with $FeSO_4$.

2.2. Syntheses

2.2.1. $[Cu_2(H_2O)_2(OH)_2(phen)_2][Cu_2(OH)_2(phen)_2(V_4O_{12})]\cdot 6H_2O$ (**3**)

Hot solutions of $CuSO_4\cdot 5H_2O$ (1.25 g, 5 mmol in 100 ml H_2O) and 1,10-phenathroline (0.90 g, 5 mmol in 100 ml H_2O) were mixed. The obtained solution was added to a hot solution of KVO_3 (1.38 g, 10 mmol in 600 ml H_2O), the pH of which was adjusted to 12 using KOH (10%). A dark blue solution and brown-yellow precipitate were formed. On standing at room temperature, the precipitate gradually dissolved and the solution decolorized. The pH of the solution after 1 month decreased to 9.6. Blue crystals were isolated after 1 month. *Anal.* Calc. for $C_{48}H_{52}N_8O_{24}Cu_4V_4$ (1582.92): C, 36.4; H, 3.3; N, 7.1; V, 12.9. Found: C, 36.4; H, 2.9; N, 7.4; V, 13.2%.

2.2.2. $[Cu_2(phen)_4(V_4O_{12})]\cdot 4H_2O$ (**4**)

About 20 g KCl was dissolved in water (170 ml) and solid $CuSO_4\cdot 5H_2O$ (0.25 g, 1 mmol) was added. The yellow-green solution obtained was mixed with a hot solution of KVO_3 (1.65 g, 12 mmol in 30 ml H_2O). Finally, solid 1,10-phenanthroline (0.360 g, 2 mmol) was added. After a short reflux (30 min), the solution was left to crystallize at room temperature, the initial pH was 8.1. Blue crystals were isolated after 3 months and the final pH value was 6.9. *Anal.* Calc. for $C_{48}H_{40}N_8O_{16}Cu_2V_4$ (1315.73): C, 43.8; H, 3.1; N, 8.5; V, 15.5. Found: C, 44.2; H, 2.9; N, 8.6; V, 15.1%.

2.2.3. $[Cu_2(phen)_4(V_4O_{12})]\cdot 6H_2O$ (**5**)

Solutions of $CuSO_4\cdot 5H_2O$ (0.125 g, 0.5 mmol in 250 ml H_2O) and KVO_3 (0.138 g, 1 mmol in 250 ml H_2O) were mixed and a hot solution of 1,10-phenanthroline (0.180 g, 1 mmol in 50 ml H_2O) was added. The solution was refluxed (20 h) and the small amount of precipitate formed was filtered off. The filtrate was heated at 80 °C and blue green crystals were isolated after 30 h of heating. The final pH value at 25 °C was 7.1. *Anal.* Calc. for $C_{48}H_{44}N_8O_{18}Cu_2V_4$ (351.77): C, 42.6; H, 3.3; N, 8.3; V, 15.1. Found: C, 42.0; H, 3.0; N, 8.2; V, 14.8%.

2.2.4. $[Cu_2(phen)_4(VO_3)_4]\cdot 10H_2O$ (**6**)

Solution A: $CuSO_4\cdot 5H_2O$ (0.5 g, 2 mmol) was dissolved in water (200 ml). The solution was warmed and 1,10-phenanthroline (0.72 g, 4 mmol) was added and dissolved. The pH was adjusted to 8 using KOH (10%). Solution B: KVO_3 (1.6 g, 11.6 mmol) was dissolved in water (300 ml). Hot solutions A and B were mixed, the pH was adjusted to 11 with KOH (10%) and, after cooling to room temperature, ethanol (200 ml) was added. Large blue crystals were isolated after 3 months. *Anal.* Calc. for $C_{48}H_{52}N_8O_{22}Cu_2V_4$ (1423.837): C, 40.5; H, 3.7; N, 7.9; V, 14.3. Found: C, 40.4; H, 3.2; N, 7.6; V, 13.8%.

2.2.5. $[Cu(phen)_3]_2V_4O_{12}\cdot phen\cdot 22H_2O$ (**7**)

A mixture of $CuSO_4\cdot 5H_2O$ (0.25 g, 1 mmol), KVO_3 (0.276 g, 2 mmol), 1,10-phenanthroline (0.72 g, 4 mmol) and H_2O (400 ml) was refluxed for 10 h. Blue crystals of compound **12** were filtered off from the hot solution. After cooling the solution, grey crystals with a metallic shine crystallized out from the solution (pH 7.4). *Anal.* Calc. for $C_{84}H_{100}N_{14}O_{34}Cu_2V_4$ (2180.62): C, 46.3; H, 4.6; N, 9.0; V, 9.3. Found: C, 46.7; H, 4.1; N, 8.8; V, 8.8%.

*2.2.6. [Cu(phen)(VO$_3$)$_2$] (**9**)*

$CuSO_4 \cdot 5H_2O$ (0.25 g, 1 mmol), KVO_3 (0.276 g, 2 mmol), 1,10-phenanthroline (0.18 g, 1 mmol) and H_2O (70 ml) were refluxed for 25 h. After several minutes of refluxing, green needle-like crystals formed, which were then isolated after 25 h. The final pH (25 °C) was 6.4. For a given ratio $n(phen)/n(Cu) = 1$, the variation of the $n(V)/n(Cu)$ ratio in the interval 2–12 had no effect on the composition of the final product. The crystals were too small for X-ray structure determination. *Anal.* Calc. for $C_{12}H_8N_2O_6CuV_2$ (441.63): C, 32.6; H, 1.8; N, 6.3; V, 23.1. Found: C, 32.7; H, 1.8; N, 6.4; V, 22.8%.

*2.2.7. [Cu$_2$(phen)$_4$(V$_4$O$_{12}$)] · 4H$_2$O (**12**)*

A mixture of $CuSO_4 \cdot 5H_2O$ (0.25 g, 1 mmol), KVO_3 (0.414 g, 3 mmol), 1,10-phenanthroline (0.36 g, 2 mmol) and H_2O (300 ml) was refluxed for 10 h. The blue crystals of **12** were then isolated from the solution (pH 7.2, 25 °C). If the ratio $n(phen)/n(Cu) = 2$ was maintained, a change in the $n(V)/n(Cu)$ ratio in the interval 2–24 had no influence on the composition of the final product. *Anal.* Calc. for $C_{48}H_{40}N_8O_{16}Cu_2V_4$ (1315.73): C, 43.8; H, 3.1; N, 8.5; V, 15.5. Found: C, 44.3; H, 2.8; N, 8.5; V, 15.1%.

2.3. Crystal structure determination

X-ray measurements on the selected crystals of compounds **3**, **5**, **6**, **7** and **12** were performed on a Enraf–Nonius KappaCCD diffractometer equipped with a Oxford Cryostream Cooler using Mo Kα radiation ($\lambda = 0.71073$ Å) and a graphite monochromator. The data sets were corrected for Lorentz and polarization effects. All the data collection, cell refinement, data reduction and correction procedures were carried out using purchased software.

The X-ray measurement of compound **4** was performed on a Kuma KM-4 four-circle κ-axis diffractometer equipped with a Oxford Cryostream Cooler. Mo Kα radiation ($\lambda = 0.71073$ Å), a graphite monochromator and a CCD detector under a nitrogen atmosphere were used. The data set was corrected for Lorentz and polarization effects. All data collection, cell refinement, data reduction and correction procedures were performed using the CRYSALIS CCD and CRYSALIS RED software.

The phase problem was solved by direct methods using SIR-97 [14] (compounds **3**, **5**, **6**, **7** and **12**) and SHELXS-97 [15] (compound **4**) software. SHELXL-97 [16] was used to refine all the structures by full-matrix least-squares on F^2. All atoms other than the hydrogens were refined as independent atoms using anisotropic thermal parameters. Details of refinement are commented in supplemental CIF files.

3. Results and discussion

3.1. Syntheses

The formation of compounds **1**–**12** (Table 2) is a result of the interaction of oxovanadate ions with $[Cu(phen)_x(H_2O)_y]^{2+}$ complexes. There are at least five factors which influence the composition and structure of the reaction products: the $n(phen)/n(Cu)$ molar ratio, pH, concentration, temperature and reaction time.

Although we were not able to clarify fully the effect of these factors, some distinct tendencies were observed. The key factor determining the composition of the products is the $n(phen)/n(Cu)$ ratio (denoted here as R). If we suppose a coordination number of 5 or 6 for Cu(II) in these compounds, then in the case that R is smaller than 3, all the *phen* ligands are evidently coordinated to the central atom, leaving one or two positions (for $R = 2$, compounds **1**, **4**, **5**, **6**, **12**) and three or four positions (for $R = 1$, compounds **2**, **3**, **9** and **10)** vacant in the coordination sphere of the copper atom. These free positions (eventually occupied by weakly bonded molecules of water) are available for bonding of oxovanadate entities. For some R values we changed the $n(V)/n(Cu)$ ratio, but we did not observe any dependence of composition of the solid products on this ratio.

A variety of species may be present in these solutions, the least soluble of which will crystallize out. Obviously, both the relative stability of the solution species and their relative solubilities will decide the composition of the solid products. The ionic form of the vanadate ions is mainly dependent on the pH value. In the pH range 4–12 used in this study, monomeric HVO_4^- and $H_2VO_4^{2-}$ ions are predominant at lower vanadium concentrations and $HV_2O_7^{3-}$, $V_4O_{12}^{4-}$ and $H_xV_{10}O_{28}^{(6-x)-}$ (the latter anions for pH < 6.3) species at higher vanadium concentrations. We obtained most of the products from approximately neutral and slightly alkaline solutions where the $V_4O_{12}^{4-}$ ion prevails. We did not observe formation of any divanadates for pH > 9.5, although the HVO_4^{2-}, $V_2O_7^{4-}$ and $HV_2O_7^{3-}$ ions dominate in this pH range [17]. On the other hand, a relatively high pH can lead to the formation of hydroxo complexes of copper, as was observed in the case of compound **3**. At pH < 6 we obtained the solid product ($[Cu(phen)_2Cl]_3H_3V_{10}O_{28} \cdot 7H_2O$ [18]) only when HCl was used for acidification. From ten Cu–*phen*–V compounds prepared in our laboratory, six contain the $V_4O_{12}^{4-}$ group, three include an endless anionic chain $(VO_3)_n^{n-}$ and one compound is a decavanadate [18]. A preferential formation of compounds containing the $V_4O_{12}^{4-}$ unit is surprising as all metavanadates with simple inorganic cations are constructed from $(VO_3)_n^{n-}$ chains.

So far we have not been able to reveal how the composition of the products depends on reaction time and temperature.

3.2. Infrared spectra

The characteristic bands in the IR spectra enable the polymeric $(VO_3)_n^{n-}$ chain and $V_4O_{12}^{4-}$ group to be unequivocally distinguished (Table 3). In addition to the bands at 958, 939, 910 and 894 cm^{-1}, corresponding to

stretching vibrations of the terminal V=O groups, the infrared spectrum of compound **6** exhibits bands at 643 (vs, broad) and 507 (w) cm^{-1} (Fig. 1) which can be assigned to the υ_{as}(VOV) and υ_s(VOV) vibrations and which are characteristic for the polymeric chain structure $(VO_3)_n^{n-}$ consisting of VO_4 tetrahedra [20]. The strong band at 785 cm^{-1}, which is absent in the IR spectra of vanadates with isolated $(VO_3)_n^{n-}$ chains (KVO_3, NH_4VO_3) [20], was assigned to the stretching vibrations of the V–O–Cu groups. A similar spectral pattern is exhibited by other compounds containing a pyroxene-like chain (**9** – see Fig. 1, **11**).

In addition to the characteristic υ(V=O) bands, the infrared spectrum of compound **12** (Fig. 2) and similarly the spectra of compounds **3**, **4**, **5**, **7** (Fig. 2) and **10** [19] exhibit bands in the 820–730 cm^{-1} interval and at about 650 cm^{-1}, which we assigned to υ_{as}(VOV) and υ_s(VOV), respectively. These bands seem to be characteristic for the presence of the V_4O_{12} group in the structure (Table 3), irrespective of whether this cluster is isolated or coordinated to a central atom. The relatively high wavenumbers of these bands are probably due to the shorter V–O–V bonds and the larger V–O–V angles in the V_4O_{12} fragment [21, this work] in comparison with the bonds and angles in the endless pyroxene-type chain that was found, e.g. in KVO_3 [23].

3.3. Crystal structures

3.3.1. $[Cu_2(H_2O)_2(OH)_2(phen)_2][Cu_2(OH)_2(phen)_2(V_4O_{12})]\cdot 6H_2O$ (3)

The structure of compound **3** consists of binuclear $[Cu_2(H_2O)_2(OH)_2(phen)_2]^{2+}$ cations and $[Cu_2(OH)_2(phen)_2(V_4O_{12})]^{2-}$ units forming the anionic chain. In both structural parts, Cu(II) has the coordination number 5, and the coordination polyhedra are trigonal bipyramidal distorted square based pyramids (TBDSBP) according to τ-factors 0.34 (Cu1) and 0.11 (Cu2). The cations are formed by two $[Cu(H_2O)(phen)]^{2+}$ units connected through two OH^- bridging ligands in a binuclear complex (Fig. 3a). The $[Cu_2(OH)_2(phen)_2(V_4O_{12})]^{2-}$ units form an anionic chain in the direction of the *x* axis (Fig. 3b). They consist of binuclear $[Cu_2(OH)_2(phen)_2]$ fragments, in which OH^- acts again as a bridging ligand. The Cu(II) atoms attain the coordination number 5 via the formation of Cu–O–V bonds, in which the oxygen atom is the terminal atom of the $(V_4O_{12})^{4-}$ ring, formed by four VO_4 tetrahedra joined at the apices. Two binuclear $[Cu_2(OH)_2(phen)_2]$ units are mutually bonded through the tetravanadate ligand $(V_4O_{12})^{4-}$, which forms a μ_2^1-bridge.

Each binuclear unit is bonded through Cu(II) atoms to two different tetravanadate $(V_4O_{12})^{4-}$ bridging ligands,

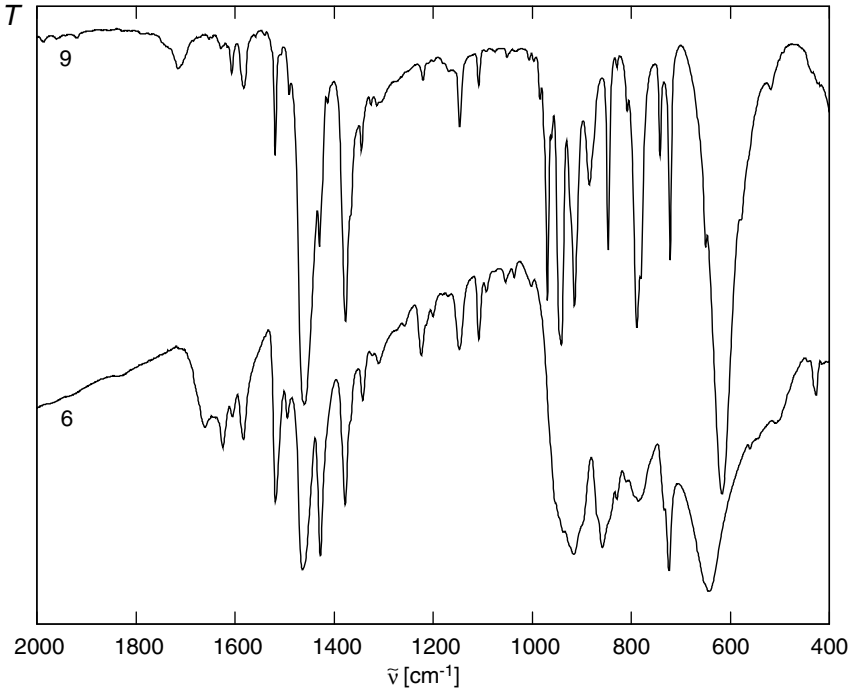

Fig. 1. IR spectra of $[Cu_2(phen)_4(VO_3)_4]\cdot 10H_2O$ (**6**) and $[Cu(phen)(VO_3)_2]$ (**9**).

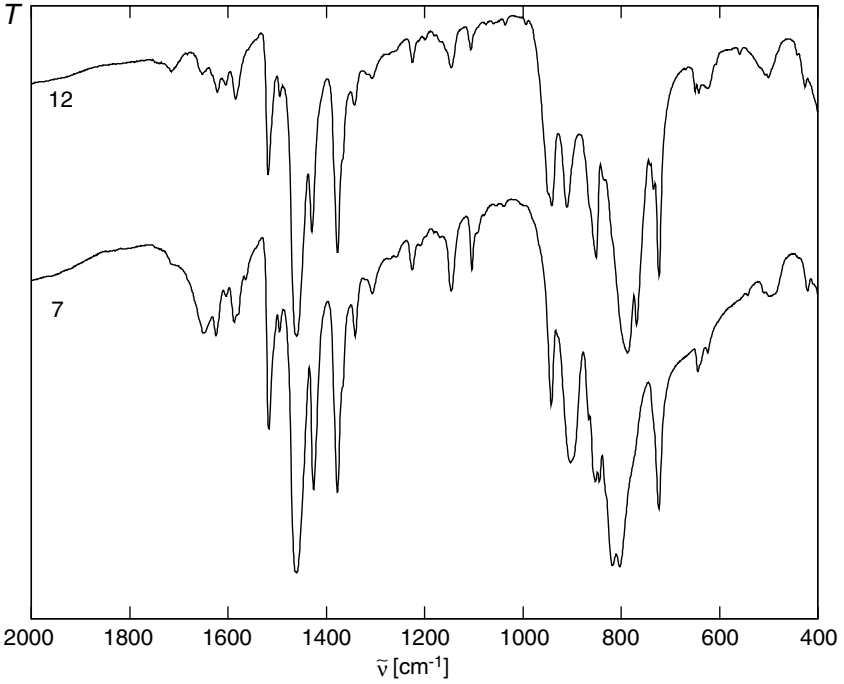

Fig. 2. IR spectra of $[Cu(phen)_3]_2V_4O_{12}\cdot phen\cdot 22\ H_2O$ (**7**) and $[Cu_2(phen)_4(V_4O_{12})]\cdot 4H_2O$ (**12**).

forming an endless anionic chain. Discrete $[Cu_2(H_2O)_2(OH)_2(phen)2]^{2+}$ binuclear complex cations are located between the anionic chains. Molecules of water of crystallization occupy the cavities in the structure (Fig. 3c); radii of these intersectioning voids were calculated by the PLATON suite and lie in the interval 1.45–1.83 Å.

3.3.2. $[Cu_2(phen)_4(V_4O_{12})]\cdot 4H_2O$ (*4*)

The basic structural units in the structure of compound **4** are neutral binuclear $[Cu_2(phen)_4V_4O_{12}]$ complexes. They are formed of two $[Cu(phen)_2]^{2+}$ units bonded through a cyclic μ^1_2-$V_4O_{12}{}^{4-}$ bridge. The CuN_4O coordination polyhedron has the TBDSBP shape with $\tau = 0.35$. An

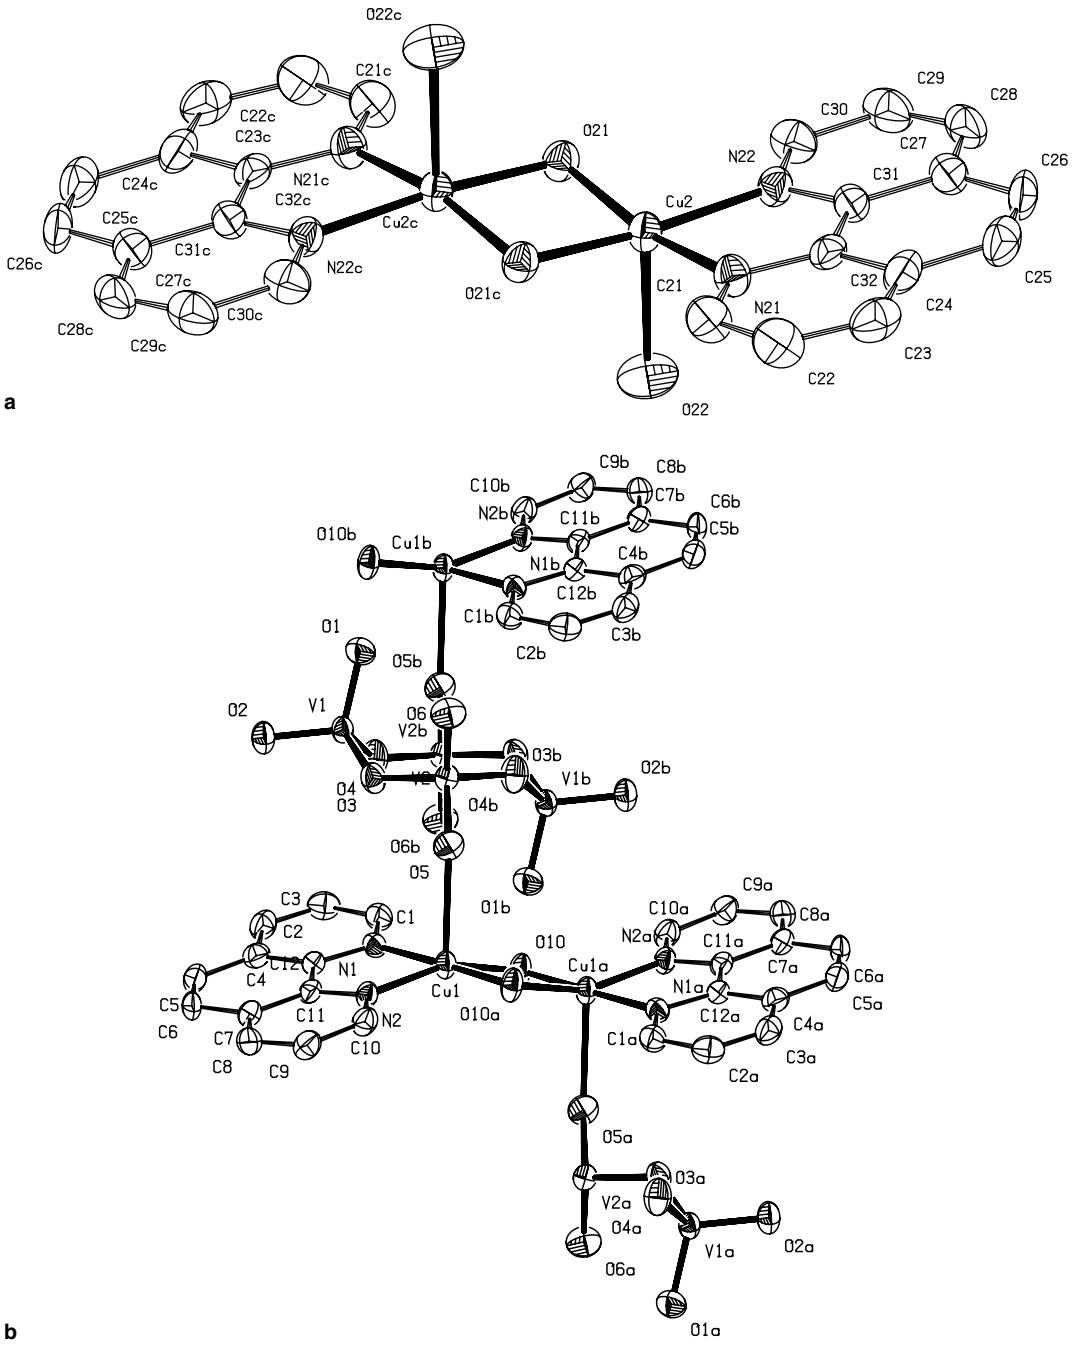

Fig. 3. ORTEP drawings of the cationic dimers (a) and anionic chains (b) of compound **3** with the numbering system and PLUTON packing diagram (c, view in the direction of the *x* axis). (All the H atoms are excluded for clarity, non-H atoms in ORTEP drawings are drawn as 50% probability ellipsoids).

interesting feature of the structure is the formation of chains between the $V_4O_{12}^{4-}$ tetravanadate rings in the direction along the *z* axis through strong hydrogen bonds (donor–acceptor distances between 2.78 and 2.99 Å), with participation of molecules of water of crystallization (Fig. 4).

3.3.3. $[Cu_2(phen)_4(V_4O_{12})]\cdot 6H_2O$ (**5**)

The structural units in the structure of compound **5**, similar to those in compound **4**, are neutral binuclear $[Cu_2(phen)_4V_4O_{12}]$ complexes. However, in compound **5**, the $V_4O_{12}^{4-}$ ligand is a μ_2^2-bridge. This means that every Cu(II) atom is bonded to two terminal atoms of the neighbouring VO_4 tetrahedra of the $V_4O_{12}^{4-}$ ring. Thus, the Cu(II) atoms have a coordination number of 6 and the CuN_4O_2 coordination polyhedron has the shape of a deformed octahedron (Fig. 5). Molecules of water of crystallization are located in the cavities.

3.3.4. $[Cu_2(phen)_4(VO_3)_4]\cdot 10H_2O$ (**6**)

The metavanadate anion $(VO_3)_n^{n-}$ forms a pyroxene type chain along the *x* axis. The structural units of the

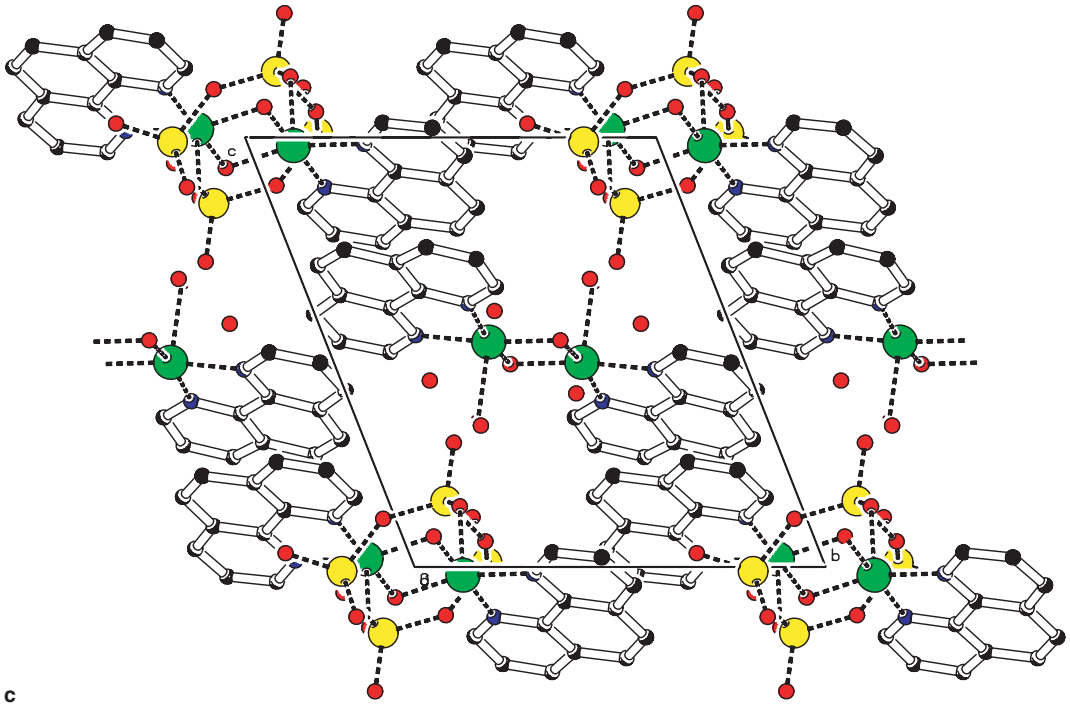

Fig. 3 (*continued*)

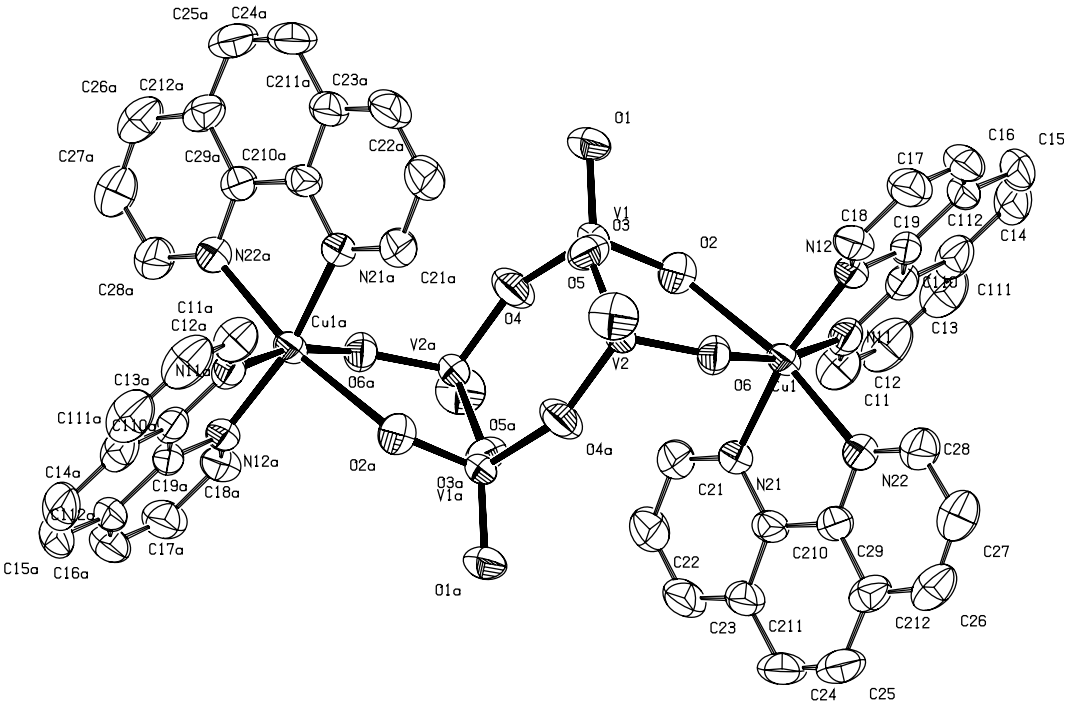

Fig. 5. ORTEP drawing of the $[Cu_2(phen)_4(V_4O_{12})]$ complex in compound **5**, showing the chair conformation of μ_2^2-$V_4O_{12}{}^{4-}$ bridge with the numbering system. (All the H atoms are excluded for clarity, non-H atoms are drawn as 50% probability ellipsoids.)

chain are VO_4 tetrahedra connected through two apices. The charge on the chain is compensated by formation of Cu–O–V bonds with the $[Cu(phen)_2]^{2+}$ units. These units are bonded to the terminal oxygen atoms of two neighbouring VO_4 tetrahedra on both sides of the chain, where two VO_4 tetrahedra, without bonded cations, are located between them (Fig. 6). This bonding mode of the complex units to the anionic $(VO_3)_n{}^{n-}$ chain has not been observed previously. The CuN_4O coordination polyhedron has the TBDSBP arrangement with τ-factors practically identical for both Cu1 and Cu2 atoms ($\tau = 0.38$). The water molecules are located between the chains.

3.3.5. *[Cu(phen)$_3$]$_2$V$_4$O$_{12}$ · phen · 22H$_2$O (7)*

The structure of this substance contains two layers parallel to the [0 0 1] plane: cationic and anionic. The cationic

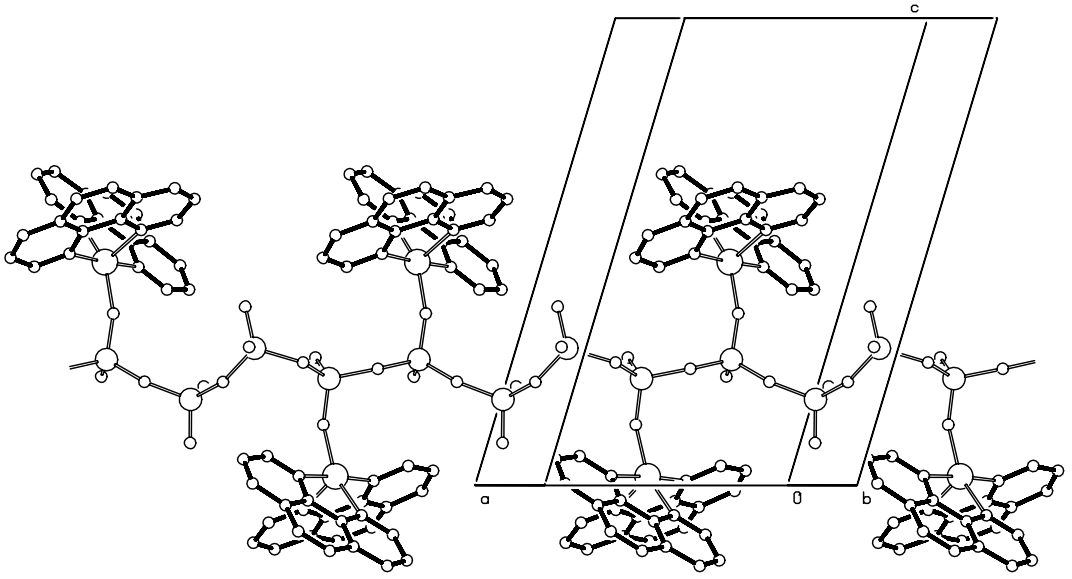

Fig. 6. PLUTON drawing of the pyroxene-like chain $(VO_3)_n{}^{n-}$ in compound **6**, illustrating the binding mode of complex $[Cu(phen)_2]^{2+}$ to the oxygen atoms of the vanadium–oxygen chain (view in the direction of the *y* axis; all the H atoms are excluded for clarity).

layer is formed by $[Cu(phen)_3]^{2+}$ cations and molecules of uncoordinated phenanthroline occupying the cavities in the layer. The anionic layer consists of cyclic $V_4O_{12}^{4-}$ anions, with water molecules located between them in the same layer (Fig. 7). This type of structure was also determined for two other compounds $[M(II)(phen)_3]_2V_4O_{12} \cdot phen \cdot 22H_2O$, where M(II)=Co or Ni [24]. The number of molecules of water of crystallization was determined in all three substances by studying their thermal decomposition [25].

3.3.6. $[Cu_2(phen)_4(V_4O_{12})] \cdot 4H_2O$ (12)

The structure of compound **12** contains neutral $[Cu_2(phen)_4(V_4O_{12})]$ complexes formed by connection of two $[Cu_2(phen)_4]^{2+}$ units through a μ_2^1-$V_4O_{12}^{4-}$ bridge. Cu(II) forms two types of CuN_4O chromophores with TBDSBP geometry and τ-factors 0.24 (Cu1) and 0.39 (Cu2). The cavities in the structure are occupied by water molecules (Fig. 8).

The basic structural motifs of substances **12** and **4** are similar. In substance **12**, the positions of the oxygen atoms in the tetravanadate ligand $V_4O_{12}^{4-}$ are somewhat disordered and they could not be described on the basis of two different positions of the VO_4 tetrahedra. A measurement at a lower temperature led to destruction of the crystal. The main difference between the structures lies in the following fact: while in the structure of **4** the hydrogen bonds between the $V_4O_{12}^{4-}$ rings and water molecules lead to the formation of chains, in substance **12** the hydrogen bonding network is more complicated due to disorder and formation of a 3D framework by water molecules.

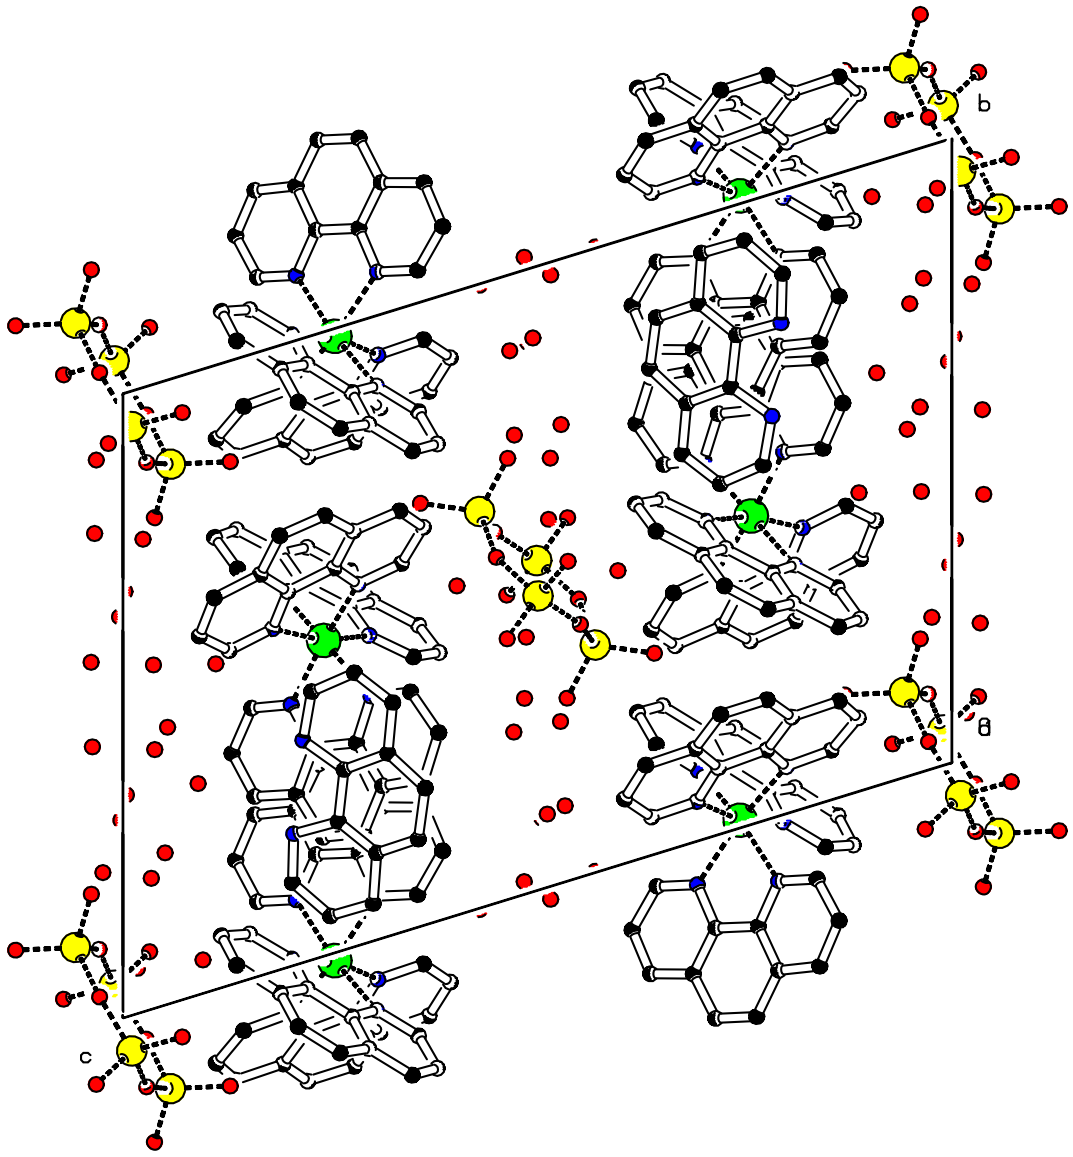

Fig. 7. PLUTON packing diagram for compound **7** showing alternate anionic and cationic layers (view in *x* axis direction; all H atoms are excluded for clarity).

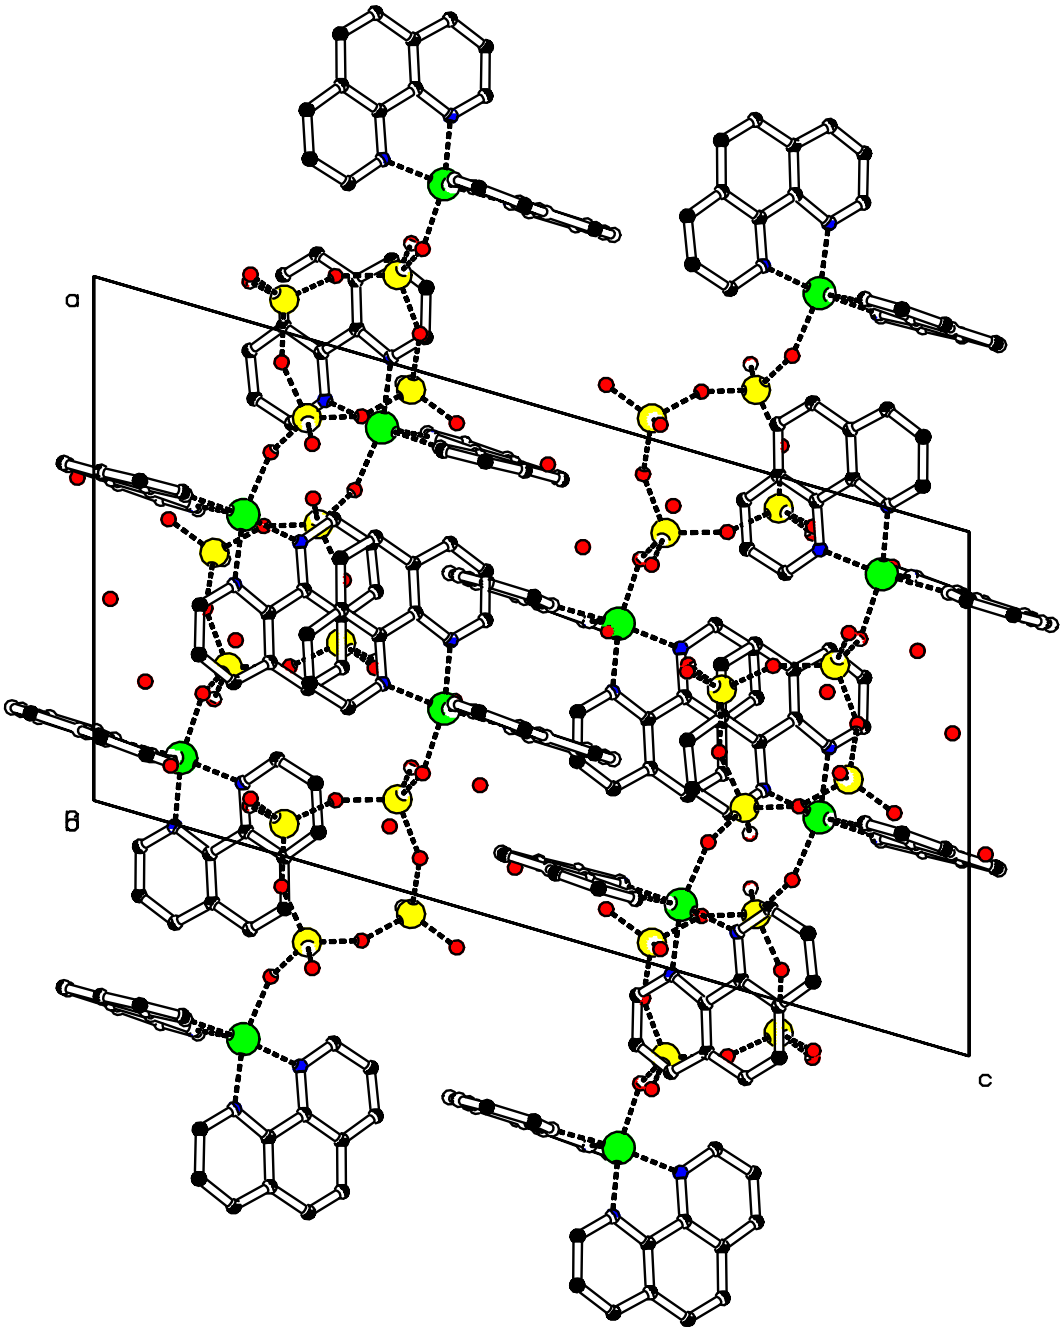

Fig. 8. PLUTON packing diagram for compound **12** (view in the direction of the *x* axis; all the H atoms are excluded for clarity).

All copper(II)–phenanthroline compounds described in this work could be classified as metavanadates, as the ratio n(V):n(O) = 1:3 indicates the presence of the metavanadate anion $(V_nO_{3n})^{n-}$. One of them, the substance **6**, contains the metavanadate anion as a chain of the pyroxene type. An anionic chain of the pyroxene type formed by mutually connected VO_4 tetrahedra is also present in other metavanadates containing Cu(II) complexes with organic ligands, e.g. [Cu(*en*)(V_2O_6)], [Cu(*bpy*)(V_2O_6)] and [Cu(*bpy*)$_2$(V_2O_6)] [8]. In the latter compound, the organocopper fragments form covalent Cu–O–V bonds at the terminal oxygens of every second VO_4 tetrahedron of the chain, while in compound **6**, described here, the $[Cu(phen)_2]^{2+}$ fragments are bonded to two neighbouring VO_4 tetrahedra and the next two do not bind any fragment.

The other compounds characterized in this work contain in their structure a cyclic $V_4O_{12}^{4-}$ anion, forming an 8-membered V_4O_4 ring. In the structure of substance **7**, this anion is present as an isolated structural unit. In the structures of the other prepared compounds, $V_4O_{12}^{4-}$ is a bridging ligand, which bonds two copper fragments. In substance **5**, the μ_2^2-bridge has a chair conformation, so that every Cu(II) atom is also bonded through two terminal oxygen atoms to two neighbouring VO_4 tetrahedra.

The boat conformation of the μ_2^2-$V_4O_{12}^{4-}$ bridge is also known, e.g. in the structure of $[\{Co(phen)_2\}_2(V_4O_{12})]\cdot H_2O$ [26]. In this compound, the tetravanadate anion is bonded to the cobalt atom through two terminal oxygen atoms which do not belong to the neighbouring but opposing VO_4 tetrahedra. The boat conformation of the bridge has not yet been found in phenanthroline–copper vanadates. The $V_4O_{12}^{4-}$ anion is a μ_2^1-bridge in all other compounds (**3**, **4** and **12**). Devi et al. found in the structure of $[Cu(phen)(H_2O)(V_2O_6)]$ [12] another type of bridge, namely the μ_4^1-$V_4O_{12}^{4-}$ anion. Here, the tetravanadate anion is bonded through the terminal oxygen atoms of all tetrahedra on four Cu(II) atoms.

Amongst the formerly prepared inorganic–organic hybrid phenanthroline-copper compounds, there are two which contain a decavanadate anionic unit. The first, $[\{Cu(phen)_2\}_4V_{10}O_{29}]\cdot 6H_2O$, was described by Zhang et al. [11]. The $V_{10}O_{29}^{8-}$ unit is formed of two V_4O_{12} rings connected by a V_2O_7 bridge. The structure of $[Cu(phen)_2Cl]$-$H_3V_{10}O_{28}\cdot 7H_2O$, prepared in our laboratory, contains $H_3V_{10}O_{28}^{3-}$ as an isolated structural unit consisting of 10 VO_6 octahedra [18].

The coordination polyhedra of Cu(II), CuN_4O, in all the compounds prepared (except **5** and **7**), are variously deformed tetragonal pyramids, characteristic for copper(II); in compound **5** this is a deformed CuN_4O_2 octahedron, while in compound **7** it is a CuN_6 octahedron. From a chemical point of view, compound **3** is interesting, as it contains two kinds of bridging ligands, hydroxide and $V_4O_{12}^{4-}$ anions. The hydroxide anions form two kinds of binuclear copper complexes, while the $V_4O_{12}^{4-}$ anions bond only one kind of these binuclear complexes in endless anionic chains.

From the standpoint of the supramolecular architecture, hydrogen bonds play a very important role in structures of the prepared compounds; in some compounds (e.g. in compound **4**), interesting structural motifs, chains of $V_4O_{12}^{4-}$ rings, are formed. Various types of π–π interactions between the phenanthroline rings, which were found in the structures of all these compounds, are also of great importance in the stabilization of the structure.

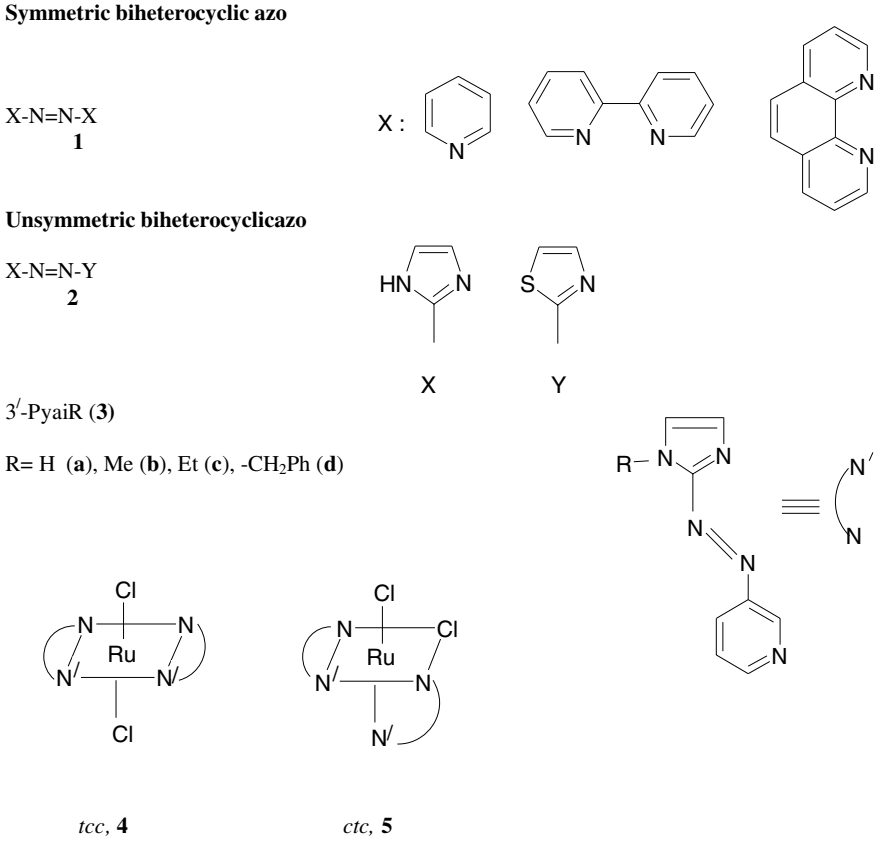

Scheme 1.

ruthenium trichloride and ruthenium phosphine carbonyl compounds, $Ru(CO)_3(PPh_3)_2$. The structure in one case has been confirmed by X-ray diffraction study.

2. Result and discussion

2.1. Ruthenium(II) coordination complexes and their isomer characterisation

2-(3′-Pyridylazo)imidazole (3′-PyaiH, **3a**) and 1-alkyl-2-(3′-pyridylazo)imidazoles (3′-PyaiR: R = Me (**3b**), Et (**3c**), CH_2Ph (**3d**)) have been used in the synthesis of coordination complexes of ruthenium(II). An ethanolic solution of 3′-PyaiR reacts with $RuCl_3$ under dinitrogen and affords the complexes, $Ru(3'\text{-PyaiR})_2Cl_2$ (**4**,**5**) via spontaneous reductive chelation (Eq. (1)). Dark colored crystalline compounds are collected from the cold solution. Two isomers, green and blue-violet have been separated from the mixture by chromatographic separation. The pseudo-octahedral complexes of the formula, $Ru(N,N')_2Cl_2$ with unsymmetric chelating ligands may exist in five geometrically isomeric forms [14]. The isomers are assigned in terms of sequences of coordination of pairs of Cl; N(imidazole) and N(azo): two isomers *trans–trans–trans* and *trans–cis–cis* belong to *trans*-$RuCl_2$ and three isomers *cis–trans–cis*, *cis–cis–trans* and *cis–cis–cis* belong to *cis*-$RuCl_2$ configurations. In this case the green (**4**) and blue-violet (**5**) complexes are assigned to *trans–cis–cis* (tcc) and *cis–trans–cis* (ctc) $Ru(3'\text{-PyaiR})_2Cl_2$. The complexes are diamagnetic (t_{2g}^6) and non-conducting. The microanalytical data support their composition. The spectroscopic data determine the structure of these complexes. The reaction between 3′-PyaiH and $RuCl_3$ in refluxing ethanol under a N_2 environment has separated dark coloured insoluble compounds. Because of the insolubility of the complexes we would not proceed further to identify the compounds.

$$RuCl_3 + 2\,3'\text{-PyaiR} \xrightarrow{\text{EtOH/boil}} Ru(3'\text{-PyaiR})_2Cl_2 + Cl^- \qquad (1)$$

Infrared spectra of the free ligands and complexes were compared to assign the major frequencies. The complexes exhibit stretching frequencies ν(N=N) and ν(C=N) at 1370–1380 and 1550–1580 cm^{-1}, respectively, and ν(N=N) has been shifted to shorter wavelength by 10–15 cm^{-1} compared to the free ligand value. The green isomers (**4**) display a single ν(Ru–Cl) stretch at 320–325 cm^{-1}; blue-violet isomers (**5**) exhibit two stretches at 310–315 and 320–325 cm^{-1}. These values support the *trans*-$RuCl_2$ and *cis*-$RuCl_2$ configuration of **4** and **5**, respectively. We have not been attempted to assign all other stretches; however they are shifted to higher frequency compared to free ligand spectra.

The electronic spectral data were collected in MeCN (Table 1, Fig. 1). The transitions <400 nm are of the intra-ligand charge transfer type and are not considered

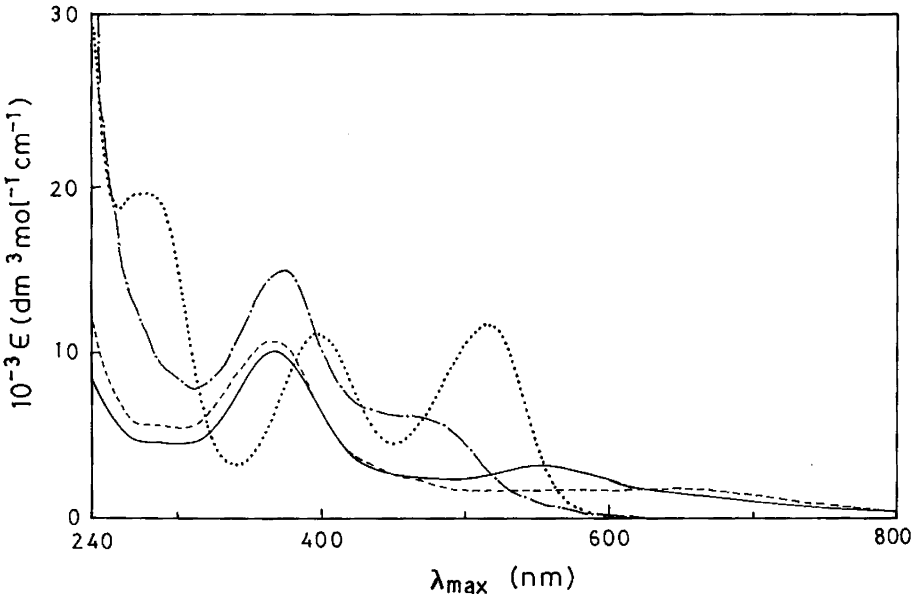

Fig. 1. UV–Vis spectra of ctc-Ru(3′-PyaiMe)$_2$Cl$_2$ (**5b**) (—); tcc-Ru(3′-PyaiMe)$_2$Cl$_2$ (**4b**) (---); Ru(3′-PyaiMe)(CO)(PPh$_3$)$_2$ (**6b**) (—·—·—); [Ru(3′-PyaiMe)(CO)(Cl)(PPh$_3$)$_2$](ClO$_4$) (**7b**) (···).

further. *tcc*-Ru(3′-PyaiR)$_2$Cl$_2$ (**4**) show high intense transitions ($\varepsilon \sim 10^4$ dm^3 mol^{-1} cm^{-1}) in the region 640–660 nm while the blue-violet isomers, ctc-Ru(3′-PyaiR)$_2$Cl$_2$ (**5**) give transitions at higher energies 550–560 nm (Fig. 2). These are assigned to the MLCT transitions.

The stereochemistry of the complexes is supported by ^{1}H NMR spectral data (Table 2) collected in $CDCl_3$. The signals were assigned on the basis of the spin–spin interaction and on comparing with free ligand values. The N(1)–R signals are as follows. The N–Me signal appears at 4.2 and 4.1 ppm in the green (**4a**) and blue-violet (**5a**) complexes, respectively. The methylene, –N–CH_2–(CH_3) appears as a quartet at 4.4 ppm (^2J, 10.0 Hz) and the methyl, (–N–CH_2)–CH_3 shows a triplet signal at 1.6 ppm ($^2J = 8.0$ Hz) for the green complexes (**4b**). The methylene of –N–CH_2–(Ph) of green **4c** appears as a singlet at 5.5 ppm. The difference in the stereochemical description of the two chelating azoimine groups in the blue-violet isomer, **5**, has been ascribed from the inequivalent AB type splitting of –CH_2– in –N–CH_2–(CH_3) (**5b**) and –N–CH_2–(Ph) (**5c**). There are, however, neither neighbouring chiral centers nor any appreciable bond rotational barrier but a distorted coordination around the metal centre does exist. This overall distortion may lead to molecular dissymmetry [14,20].

[a] In $CDCl_3$.
[b] Doublet.
[c] Singlet.
[d] Triplet.
[e] Multiplet.
[f] 1-CH_3.
[g] Quartet for –CH_2–.
[h] 1-CH_2(Ph), and δ(Ph): 7.4–7.5 ppm.
[i] N(1)–H, broad.

Imidazole 4-H and 5-H appear as doublet signals at 7.1–7.2 and 7.0–7.1 ppm, respectively. A singlet signal appearing at the most downfield position, 8.6 ppm, is unambiguously assigned to 7-H. The second highest chemical shift is observed at 8.3 ppm which is a doublet signal ($^2J = 9.0$ Hz) and is assigned to 11-H. Two other protons 9-H and 10-H appear as a doublet and triplet at ca. 7.8 and 7.5 ppm, respectively.

Redox activities of the complexes have been examined by cyclic voltammetry. Fig. 2 shows four redox responses in the potential range 1.2 to −1.4 V versus SCE (Table 1) in MeCN. A couple positive to SCE at 0.7–0.8 V is oxidative in nature. This is quasireversible in nature as evident from ΔE_p values (>90 mV). This is referred to the Ru(III)/Ru(II) couple. Three reduction responses appear negative to SCE and are quasireversible in nature. The chelated azoimine (–N=N–C=N–) groups are well known π-acidic agents which have low lying azo-centered π^*-molecular orbitals. Thus, the reductions are referred to electron accommodation at LUMOs characterized by the azo function.

The potential data (Table 1) related to the blue-violet isomers (**5**) exhibit higher redox potentials by 0.1–0.2 V than those of the green isomers (**4**). An increase in stability of the Ru(II) state in the blue-violet isomer (**5**) may be due to a cisoid orientation of the azoimine function. In *ctc*-$Ru(3'\text{-PyaiR})_2Cl_2$ (**5**) the back bonding interaction may in turn occur with two different dπ-orbitals, while in the *trans*-orientation two groups will compete for the same dπ-orbitals. This may be associated with the increase in effective charge on the ruthenium in **5** and may shift the Ru(III)/Ru(II) couple to more positive values than in **4**. The present set of Ru(III)/Ru(II) redox potential data are higher than $Ru(RaaiR')_2Cl_2$ (RaaiR′ = 1-alkyl-2-(arylazo)imidazole) [14] but lower than $Ru(aapm)_2Cl_2$ (aapm = 2-(arylazo)pyrimidine) [19]. This suggests that the π-acidity order of the ligands is as follows: arylazoimidazole < pyridylazoimidazole < arylazopyrimidine.

2.2. Ruthenium carbonyl complexes of 3′-PyaiR

2.2.1. Synthesis and formulation

$Ru(CO)_3(PPh_3)_2$ has been used as a starting material in the synthesis of mixed ligand Ru(0)-carbonyl compounds. In extremely moisture free conditions under a dinitrogen atmosphere, $Ru(CO)_3(PPh_3)_2$ has been reacted with 3′-PyaiR in MeCN under reflux for 2–2.5 h.

$$Ru(CO)_3(PPh_3)_2 + 3'\text{-PyaiR} \rightarrow \underset{\mathbf{6}}{Ru(CO)_3(3'\text{-PyaiR})(PPh_3)_2} + 2CO \quad (2)$$

3′-PyaiR is an efficient π-acidic chelating agent and acts as an effective CO supplement in the stabilization of low metal oxidation states. The product isolated after filtration has been purified by a chromatography process. The complexes are extremely stable and remain unchanged upon exposure to air even in solution for a month. The composition of the complexes, $Ru(CO)(3'\text{-PyaiR})(PPh_3)_2$ (**6**) has been supported by microanalytical data. The complexes are non-electrolytes and are diamagnetic.

2.2.2. X-ray structure determination

The X-ray structure of $Ru(CO)(3'\text{-PyaiH})(PPh_3)_2$ (**6a**) has been determined and is shown in Fig. 3. Selected bond parameters are listed in Table 3. The molecule consists of a central Ru atom surrounded by five coordination centers and the arrangement is quite a regular square pyramid. The atomic arrangement involves two *trans*-phosphines, cheated pyridylazo-imidazole and a CO within the RuP_2N_2C coordination sphere. The atomic group Ru, N(1), C(1), N(4), N(3) constitute a chelate plane (rms deviation ⩽0.031 Å). The 3′-pyridyl ring is inclined at an angle of 37.38(15)° with the chelate ring. The *trans*-phosphine angle, P(1)–Ru–P(2) is 167.62 (2)° and lies in the lower

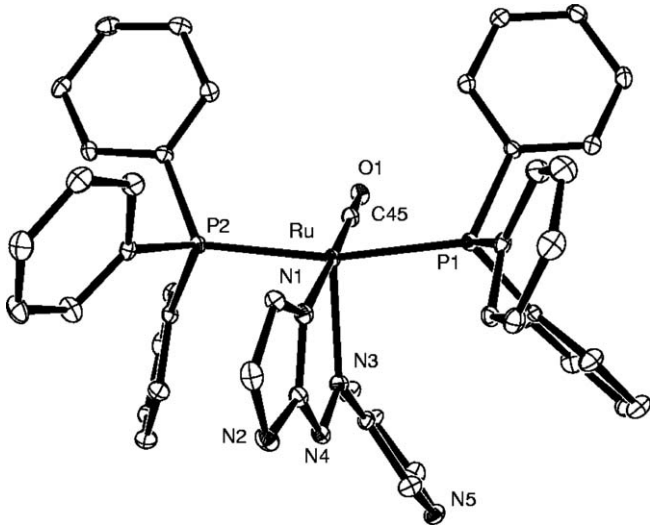

Fig. 3. X-ray structure of $Ru(3'\text{-PyaiH})(CO)(PPh_3)_2$ (**6a**).

Table 3
Selected bond distances (Å) and angles (°) for $[Ru(CO)(3'\text{-PyaiH})(PPh_3)_2]$ (**6a**) along with their esd in parentheses

Distances (Å)		Angles (°)	
Ru–C(45)	1.8545(13)	N(1)–Ru–N(3)	73.79(8)
Ru–N(1)	2.111(2)	N(1)–Ru–C(45)	176.04(7)
Ru–N(3)	2.1938(19)	N(3)–Ru–C(45)	103.79(7)
Ru–P(1)	2.3605(7)	N(1)–Ru–N(3)	73.79(8)
Ru–P(2)	2.3478(7)	Ru–N(1)–C(1)	112.97(16)
N(3)–N(4)	1.284(3)	Ru–N(3)–N(4)	117.93(15)
N(1)–C(1)	1.347(3)	P(1)–Ru–P(2)	167.62(2)
		P(1)–Ru–C(45)	88.54(4)
		P(2)–Ru–C(45)	89.10(4)
		P(1)–Ru–N(1)	94.79(6)
		P(1)–Ru–N(3)	95.40(5)
		P(2)–Ru–N(1)	88.10(6)
		P(2)–Ru–N(3)	96.96(5)

range of reported data [27–34]. This large deviation from *trans*-angle values may be due to steric crowding. The chelate bite angle N(1)–Ru–N(3) is 73.79(8)°. Other angles around Ru define a distorted quite regular pyramidal geometry.

The Ru–N(3) (N(3) is the azo–N) bond length of 2.194(2) Å is slightly longer than Ru–N(1) (N(1) is imidazole) (2.112(3) Å). This is unusual to the structural chemistry of Ru–azoheterocycles [14–18]. The N=N distance is 1.284(3) Å and is longer than the free ligand value (1.268(2) Å) [32]. It is elongated due to $d\pi(Ru) \rightarrow \pi^*(azo)$ charge transfer. The observed Ru–P distances are very short (2.3478(7), 2.3605(7) Å) in the series of $Ru(PPh_3)$ chemistry [30–33]. Ru(0) may be associated with PPh_3 by strong π-back bonding which causes shortening of the Ru–P distances. Ru(0) is a better donor than Ru(II) and this may support the shortening of the Ru–P distances.

The Ru–C bond length (1.8545(13) Å) is comparable with the data reported for the Ru(II)-carbonyl system [27,33,34]. This shows that the Ru(0) oxidation state has little influence on the Ru–CO distance. The C–O bond length is 1.141(4) Å and is also insignificantly influenced by the zero oxidation state of ruthenium. The EHMO results also support this data (Fig. 4).

2.2.3. Spectra and bonding

The complexes $[Ru(CO)(3'\text{-PyaiR})(PPh_3)_2]$ (**6**) show a sharp stretch at ca. 1925 cm^{-1} that corresponds to ν(CO). Presence of a single ν(CO) band is in support of a 'Ru(CO)' type carbonyl derivative [33,34]. Other significant stretchings are ν(N=N) and ν(C=N) at 1410–1415 and 1580–1600 cm^{-1}, respectively. Comparisons of the infrared data for monocarbonyl ruthenium/osmium complexes of other heterocyclic–N chelators [27,33,34] also helped us to identify the present series of complexes.

The complexes are sparingly soluble in non-polar solvents but reasonably soluble in polar solvents. The electronic spectra of the complexes in MeCN show a high intense transition at 360–380 nm (inter-ligand charge transfer) with a reasonably intense shoulder at 460–470 nm (Table 1, Fig. 1). The absorption at 460–470 nm may be assigned to a transition involving metal orbitals, e.g., d–d, MLCT/LMCT type. Upon excitation at 365 nm the complexes give an observable emission at the longer wavelength of 418–426 nm in MeCN, which originates from the (π–π^*) type.

To explain the electronic properties of the complexes, extended Huckel calculation were performed using crystallographic parameters of $[Ru(CO)(3'\text{-PyaiH})(PPh_3)_2]$. Some

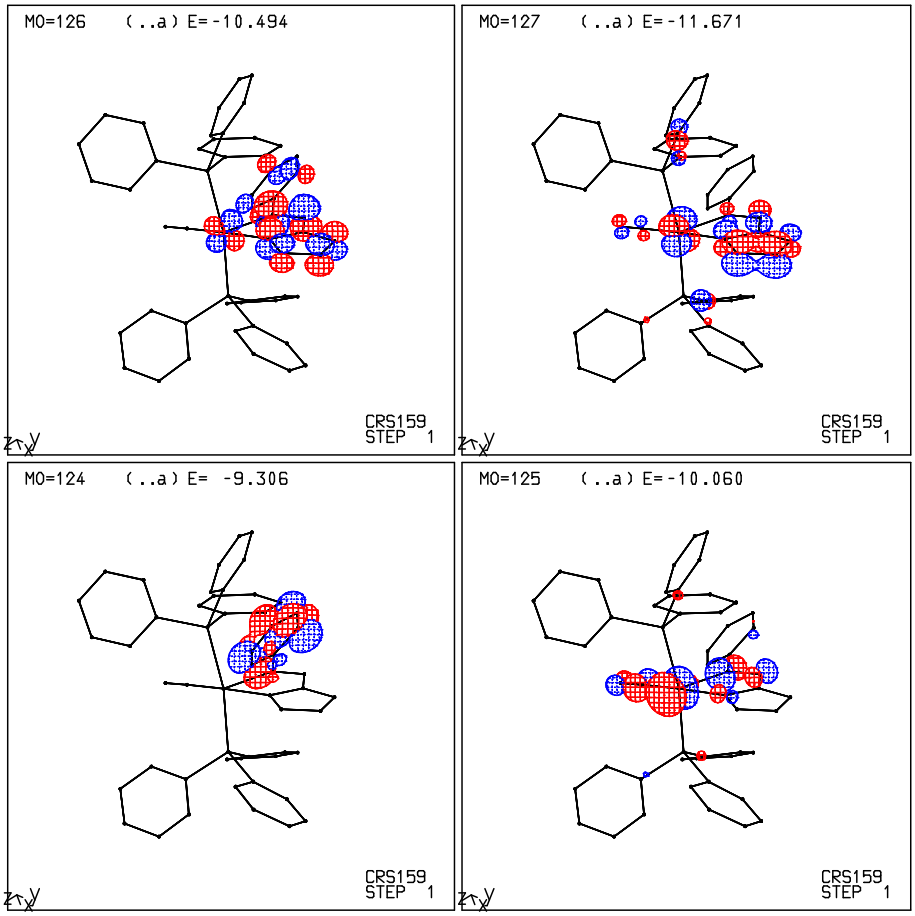

Fig. 4. EHMO plots of HOMO − 1, HOMO, LUMO, LUMO + 1 MO = 127 (HOMO − 1) Ru 46%, 3′-PyaiH = 33%, azo = 10%; MO = 126 (HOMO) Ru = 16%, 3′-PyaiH = 78%, azo = 48%; MO = 125 (LUMO) Ru = 63%, 3′-PyaiH = 19%, azo = 17%, CO = 10%; MO = 124 (LUMO + 1) Ru = 0%, 3′-PyaiH = 99%.

of the MOs are shown in Fig. 4. The transition HOMO → LUMO may be assigned to a LMCT transition; since the HOMO is composed of 78% ligand function and the LUMO brings 63% metal function. Thus the electronic transition at 460–470 nm may be assigned to a LMCT and the intense band at 370–380 comprises intra-ligand transitions. Emission spectra observed upon excitation at 365 nm thus originate from a ligand centered π–π* state.

The ^{1}H NMR spectra of the complexes (**6**) were carried out in $CDCl_3$. Data are set out in Table 2. Imidazole protons, 4- and 5-H, appear as a pair of doublets at 7.2–7.4 and 7.0–7.1 ppm, respectively. A singlet appears at 8.5 ppm and is assigned to 7-H. Other signals are also assigned on comparing with the free ligand data [26]. The 1-R signals appear in their usual positions. 1-Me appears as a singlet at 4.2 ppm; 1-CH_2-CH_3 gives a quartet (4.5 ppm, ($J = 12.0$ Hz)) and a triplet (1.5 ppm ($J = 8.0$ Hz)); 1-CH_2-(Ph) gives a singlet at 6.00 ppm. PPh_3 shows multiplets at 7.3–7.5 ppm. Because of the low solubility in $CDCl_3$ we could not perform ^{13}C NMR spectral measurements.

2.2.4. Electrochemistry

The redox data are summarised in Table 1 and a representative voltammogram is shown in Fig. 2. An initial scan (+ve to SCE) from 0.0 to 1.8 V shows three responses at 0.6–0.7, 0.9–1.0 and 1.2–1.3 V. Scan reversal does not give cathodic peak potentials and suggests irreversibility of the electrochemical reaction. The nature of the redox program does not change with scan rate (50–250 mV S^{-1}). Ru(0) in the complexes **6** can sequentially exhibit Ru(I)/Ru(0), Ru(II)/Ru(I) and Ru(III)/Ru(II) redox processes. We do not have any definite proof to the existence of these redox couples. Because of small difference in E_{pa} (peak potential) values we could not perform coulometric oxidation at a definite potential, and oxidation at the highest potential (>1.4 V) does not complete the coulomb count. This may be due to participation of the solvent in oxidation. The solution colour changes to bright brown red. We did not proceed further.

On scanning to the negative direction (0 to −1.8 V) three redox responses are observed. First two responses are quasireversible ($\Delta E_p \geqslant 100$ mV) and the third one appears at <−1.2 V which is irreversible in nature. The chelated ligand belongs to a π-acidic family and can accommodate two electrons centered at the azo group (–N=N–). On comparing with literature information [14–20], we may assign the first two reductive responses (−0.7 and −0.9 V) as azo reductions [–N=N–]/[–NN---N]$^-$ and [–NN---N]$^-$/[–N–N–]$^{2-}$.

2.2.5. Reaction with Cl_2

$$\mathrm{Ru(CO)(3'\text{-}PyaiR)(PPh_3)_2} + \mathrm{Cl_2} \xrightarrow[\mathrm{NaClO_4(aq)}]{\mathrm{MeCN}} \underset{\mathbf{7}}{[\mathrm{Ru(CO)Cl(3'\text{-}PyaiR)(PPh_3)_2}](\mathrm{ClO_4})} \quad (3)$$

A MeCN solution of the complex was stirred with a Cl_2 saturated solution in the same solvent for 15 min. The solution colour changed from brown to red-brown within a few minutes. The solution was evaporated to dryness, washed with cold water and extracted with chloroform. The solution was chromatographed and eluted by MeCN–MeOH (3:2, v/v). To a methanolic solution of the brown mass $NaClO_4$(aq) was added and a dark coloured precipitate was filtered and then washed with cold water.

The dry mass was chromatographed over silica gel, prepared in benzene. An orange brown band was eluted by MeCN and evaporated slowly in air. Crystalline compound **7** (40–50%) was then separated. A black mass was adhered on the column head and rejected. The molar conductance data in MeCN solutions ($\Lambda_M = 70$–$90\ \Omega^{-1}\ M^{-1}\ cm^{-1}$) suggested a 1:1 electrolyte. The complex may exist in two different isomeric forms. However, we could not separate them by the chromatographic process. So the spectral property may be referred to the mixture of isomeric data. Infrared spectra of the complexes show a strong sharp stretch at 1085–1090 cm^{-1} along with a weak transmission at 625–630 cm^{-1}. This corresponds to $\nu(ClO_4)$. A sharp strong stretch at 1953–1965 cm^{-1} is assigned to ν(CO), which is blue shifted by 30–35 cm^{-1} compared to ν(CO) of the precursor, [Ru(CO)$(PPh_3)_2$(3′-PyaiR)]. This is obviously due to weakening of the π-back donation ability of Ru(II) in the product compared to Ru(0). Additionally, a weak stretch is observed at 310–320 cm^{-1} which is absent in precursor. This is assigned to a ν(Ru–Cl) stretch. Other significant stretchings are ν(N=N) at 1410–1400 and ν(C=N) at 1590–1600 cm^{-1}. We could not crystallize this complex to get a good single crystal for X-ray analysis.

The solution electronic spectra of these complexes exhibit absorptions at 500–510, 400–390 and 350–280 nm (Table 1, Fig. 1). The longer wavelength band, which is absent in the precursor, is assigned to a $d\pi(Ru) \rightarrow \pi^*$ (3′-PyaiR), MLCT transition. Other transitions may be ligand centered (LC) transitions. The cyclic voltammogram of [Ru(CO)Cl(3′-PyaiR)$(PPh_3)_2$](ClO_4) (**5**) shows a quasireversible oxidative response at >0.7 V. This refers to the Ru(III)/Ru(II) redox process (Fig. 2). Ligand centered reductions are observed at <−0.6 V and correspond to electron addition to the –N=N– bond.

3. Conclusion

Pyridylazoimidazole (3′-PyaiR) stabilizes the Ru(0) state in collaboration with CO and PPh_3. The structure shows quite a regular square pyramid of the formula Ru(CO)-$(PPh_3)_2$(3′-PyaiR) (**6**). Cl_2 oxidation has isolated the Ru(II) complex [Ru(CO)Cl(3′-PyaiR)$(PPh_3)_2$](ClO_4) (**7**). Upon oxidation ν(CO) is blue shifted by 30–35 cm^{-1}. The electronic and ^{1}H NMR spectra are also reported. Cyclic voltammograms shows irreversible oxidations corresponding to Ru(0) → Ru(I), Ru(I) → Ru(II) and Ru(II) → Ru(III) while **6** shows a quasireversible Ru(II) → Ru(III) oxidation. Ligand reductions are usually observed at the azo centre. Ru(II) complexes of the formula Ru(3′-PyaiR)$_2$$Cl_2$ are isolated from the reaction between $RuCl_3$ and 3′-PyaiR.

Two isomers, green tcc-Ru(3′-PyaiR)$_2$Cl$_2$ and blue-violet ctc-Ru(3′-PyaiR)$_2$Cl$_2$ are also characterised.

4. Experimental

4.1. Materials and methods

3-Aminopyridine was purchased from Lancaster, UK. Imidazole and all other organic chemicals and inorganic salts were available from the Sisco Research Lab, Mumbai, India. Ru(CO)$_3$(PPh$_3$)$_2$ was synthesized as in the reported procedure [33]. For the solution spectral studies, spectroscopic grade solvents were used from Lancaster, UK. Microanalyses (C, H, N) were performed using a Perkin–Elmer 2400 CHNO elemental analyzer. Spectroscopic measurements were carried out using the following instruments: UV–Vis spectra, JASCO UV–Vis/NIR model V-570; IR spectra (KBr disk, 4000–200 cm^{-1}), JASCO FT-IR model 420; ^{1}H NMR spectra in CDCl$_3$ and CD$_3$CN Bruker 300 MHz FT-NMR spectrometers in the presence of TMS as internal standard. Molar conductances (Λ_M) were measured in a Systronics conductivity meter 304 model using ca. 10^{-3} M solutions in DMSO. Silver is measured gravimetrically. Emission was examined by a F-4500 Hitachi spectrofluorimeter at room temperature (298 K) in MeCN under non-degassed conditions.

4.1.1. Synthesis of the ligands 3′-(pyridyazo)imidazole

Pyridylazoimidazole is a new class of unsymmetric biheterocycle and has been synthesized by coupling the diazonium salt of 3-aminopyridine with imidazole in Na$_2$CO$_3$ solution. N(1)-alkylation has been performed by the reported method using RX in dry THF in the presence of NaH. The chromatographic process has been used to purify the N(1)-alkylated product. Detailed procedures have been reported earlier [26].

4.1.2. Preparation and separation of tcc- and ctc-[Ru(3′-PyaiMe)$_2$Cl$_2$] (**4** and **5**)

A degassed dry ethanol (10 ml) solution of 3-PyaiMe (0.25 g, 1.34 mmol) was added slowly using a pressure equalising funnel to a green Ru(II) solution (prepared by reduction of RuCl$_3 \cdot 3$H$_2$O (0.17 g, 65 mmol) in 10 ml dry ethanol and refluxed for 3 h under nitrogen environment). The volume of the solution was reduced to half of its original volume by nitrogen bubbling and was kept in refrigerator overnight. The precipitate so obtained was filtered and washed with water, cold ethanol and finally with ether. It was then dried over CaCl$_2$. A CH$_2$Cl$_2$ solution of the dry mass was chromatographed over silica gel prepared in petroleum ether (60–80 °C). A green band was eluted by toluene–acetonitrile (9:1 v/v) and a blue violet band was collected using toluene–acetonitrile (3:2 v/v). The solutions were evaporated in air and crystalline products were isolated in 35% and 20% yields.

The microanalytical data of the complexes are as follows: *Anal.* Calc. for C$_{18}$H$_{18}$N$_{10}$Cl$_2$Ru (**4b**): C, 39.47; H, 3.39; N, 25.71. Found: C, 39.56; H, 3.30; N, 25.64%. *Anal.* Calc. for C$_{22}$H$_{22}$N$_{10}$Cl$_2$Ru (**4c**): C, 41.74; H, 3.88; N, 24.30. 4.1.3. Preparation of [Ru(CO)(PPh$_3$)$_2$(3′-PyaiH)] (**6a**)

To a solution of [Ru(CO)$_3$(PPh$_3$)$_2$] (0.200 g, 0.282 mmol) in MeCN (20 ml) was added 3′–PyaiH (0.05 g, 0.289 mmol) in acetonitrile. The solution was stirred for 8 h. The yellow solution turned red. The solution was filtered and evaporated slowly. Red coloured crystals developed after four days. The crystals were collected by filtration, washed with cold water–acetonitrile (1:1, v/v) and dried over CaCl$_2$ in vacuo. The yield was 0.16 g (78%). The microanalytical data of the complexes are as follows: *Anal.* Calc. for C$_{45}$H$_{37}$N$_5$OP$_2$Ru (**6a**): C, 65.37; H, 4.48; N, 8.47. Found: C, 65.29; H, 4.43; N, 8.39%. *Anal.* Calc. for C$_{46}$H$_{39}$ C$_{46}$H$_{39}$N$_5$OP$_2$Ru (**6b**): C, 65.71; H, 4.64; N, 8.33. Found: C, 65.66; H, 4.60; N, 8.27%. *Anal.* Calc. for C$_{47}$H$_{41}$N$_5$OP$_2$Ru (**6c**): C, 66.04; H, 4.80; N, 8.20. Found: C, 65.96; H, 4.76; N, 8.15%. *Anal.* Calc. for C$_{52}$H$_{43}$ N$_5$OP$_2$Ru (**6d**): C, 68.12; H, 4.69; N,7.64. Found: C, 68.06; H, 4.65; N, 7.58%.

4.1.4. Oxidation of [Ru(CO)(PPh$_3$)$_2$(3′-PyaiMe)] by Cl$_2$ (**6b**)

To a MeCN solution (15 ml) of [Ru(CO)(PPh$_3$)$_2$(3′-PyaiMe)] (0.2 g, 0.24 mmol) 3 ml of Cl$_2$ saturated MeCN solution was added, dropwise, and stirred. The solution colour changed immediately from brown red to orange red. The solution was stirred for 30 min and then evaporated in air to reduce its volume to half of its original value. Upon addition of a 2 ml saturated solution of NaClO$_4$ to this solution, a dark coloured compound precipitated. This was then filtered, washed with water and dried over CaCl$_2$. The CH$_2$Cl$_2$ solution of the dry mass was chromatographed over silica gel prepared in petroleum ether (60–80 °C). A deep orange red band was eluted by MeCN–toluene (1:3, v/v) and a black mass was attached on the column head. The solution was evaporated via rotary evaporation and the solid product was recrystallised by diffusion of a CH$_2$Cl$_2$ solution to hexane. Yield, 0.14 g, 60%.

The other compounds were prepared by an identical procedure and the yield varied from 60% to 65%.

The microanalytical data of the complexes are as follows: *Anal.* Calc. for C$_{45}$H$_{37}$N$_5$O$_5$P$_2$Cl$_2$Ru (**7a**): C, 56.26; H, 3.80; N, 7.17. Found: C, 56.19; H, 3.85; N, 7.28%. *Anal.*

4.2. X-ray diffraction study

Crystals of [Ru(CO)(3′-PyaiH)(PPh_3)$_2$] (**6a**) were grown by slow diffusion of a CH_2Cl_2 solution of the complex into hexane. Crystal parameters and refinement results are summarized in Table 4. Data were collected on a Bruker SMART CCD diffractometer using graphite monochromatised Mo Kα radiation ($\lambda = 0.71073$ Å) at 295(2) K. Data collections were performed in the 2θ range 4–56°. Empirical absorption corrections were carried out based on ψ and ω-scans. The structure was solved by direct methods and refined by full-matrix least-squares refinement based on F_o^2 and including all reflections. All non-hydrogen atoms were refined anisotropically. Data reduction, structure solution and refinement were performed with SHELX-97.

5. Supporting information available

Crystallographic data for structural analysis are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033 (e-mail: deposit@ccdc.cam.ac.uk or www:http://www.ccdc.cam.ac.uk) on request, quoting the CCDC No. 256887.

Acknowledgements

The financial support has been received from the University Grants Commission and Department of Science and Technology, New Delhi, India. Miss. Chun Yu Chen of the National Science Council in Taiwan is acknowledged for her data collection of X-ray diffraction.

2. Experimental

2.1. Materials

Platinum chloride was purchased from Arrora Mathey, Calcutta, India. Dipotassium tetrachloroplatinate(II) was prepared by a reported method [7]. Dipotassium tetraiodoplatinate (K_2PtI_4) was obtained from SRL. 2-Ethyl sulfanyl aniline was synthesized by reacting ethyl bromide with 2-aminothiophenol [5]. All other chemical and solvents were reagent grade and used as received from E-Marck, Calcutta, India. Silica gel (60–120 mesh) was used for the column chromatography.

2.2. Syntheses of ligands

The ligand L^1H, L^2H and L^3H were prepared by a similar procedure. The detailed method is given below for L^1H.

2.2.1. L^1H

0.5 g (3.26 mmol) of 2-(ethylsulfanyl) aniline was dissolved in (15 cm^3) glacial acetic acid and 0.35 g (3.26 mmol) of nitrosobenzene was added pinchwise within 10 min. Stirring was continued for 3 h, maintaining the temperature at 70 °C, the dark mass thus obtained was dissolved in benzene and subjected to column chromatography over silica gel (60–120 mesh). The first fraction eluted by pet. ether (60–80 °C) afforded the solid L^1H ligand upon evaporation of the solvent. Yield: 70%. *Anal.* Calc. for $C_{14}H_{14}N_2S$: C, 69.42; H, 5.78; N, 11.57. Found: C, 69.45; H, 5.73; N, 11.55%. UV–Vis (CH_2Cl_2) $\lambda_{max}/\varepsilon$ nm (/M^{-1} cm^{-1}): 397(4951), 321(17660), 278(13030), 268(14218), 233(16339). IR (KBr): $\nu_{N=N}$ 1450 cm^{-1}.

2.2.2. L^2H and L^3H

The other ligands (L^2H and L^3H) were prepared similarly using *p*-methyl nitrosobenzene and *p*-chloro nitrosobenzene in place of nitrosobenzene. Yield for L^2H: 70% and L^3H: 65%. *Anal.* Calc. for $C_{15}H_{16}N_2S$: C, 70.31; H, 6.25; N, 10.93. Found: C, 70.25; H, 6.30; N, 11.00%. UV–Vis (CH_2Cl_2) $\lambda_{max}/\varepsilon$ nm (/M^{-1} cm^{-1}): 407(4096), 328(19267), 268(10240), 238(14920). IR (KBr): $\nu_{N=N}$ 1454. *Anal.* Calc. for $C_{14}H_{13}N_2SCl$: C, 60.75; H, 4.70; N, 10.12. Found: C, 60.71; H, 4.73; N, 10.55%. UV–Vis (CH_2Cl_2) $\lambda_{max}/\varepsilon$ nm (/M^{-1} cm^{-1}): 405(5327), 327(18267), 266(12442), 235(16460). IR (KBr): $\nu_{N=N}$ 1454 cm^{-1}.

2.3. Syntheses of complexes

2.3.1. $Pt(L^1)Cl$

To an aqueous solution (5 cm^3) of K_2PtCl_4 (0.05 g, 0.121 mmol), a methanolic solution of L^1H (0.03 g, 0.121 mmol) was added. The mixture was stirred for 12 h. The dark solid precipitate was separated by filtration and purified by column chromatography using silica gel (60–120 mesh). The eluent was toluene–acetonitrile mixed solvent (80/20 v/v) and upon evaporation of the solvent, the dark red solid $Pt(L^1)Cl$ was obtained. Yield: 80%. *Anal.* Calc. for $C_{14}H_{13}N_2SPtCl$: C, 35.63; H, 2.75; N, 5.93. Found: C, 35.60; H, 2.80; N, 5.90%. UV–Vis (CH_2Cl_2) $\lambda_{max}/\varepsilon$ nm (/M^{-1} cm^{-1}): 234(7903), 260(5540), 360(3878), 381(4332), 410(3878), 472(1800). IR (KBr): $\nu_{N=N}$ 1361, ν_{Pt-Cl} 335 cm^{-1}.

2.3.2. $Pt(L^2)Cl$ and $Pt(L^3)Cl$

The other complexes $Pt(L^2)Cl$ and $Pt(L^3)Cl$ were prepared by a similar method using L^2H and L^3H in place of L^1H. Yield for $Pt(L^2)Cl$: 70% and $Pt(L^3)Cl$: 65%. *Anal.* Calc. for $C_{15}H_{15}N_2SPtCl$: C, 36.92; H, 3.07; N, 5.74. Found: C, 36.95; H, 3.10; N, 5.75%. UV–Vis (CH_2Cl_2) $\lambda_{max}/\varepsilon$ nm (/M^{-1} cm^{-1}): 581(330), 490(705), 417(2220), 381(2070), 362(1744), 342(1410), 264(2682), 228(3865). IR (KBr): $\nu_{N=N}$ 1365, ν_{Pt-Cl} 340 cm^{-1}. *Anal.* Calc. for $C_{14}H_{12}N_2SPtCl_2$: C, 33.20; H, 2.37; N, 5.53. Found: C, 33.24; H, 2.41; N, 5.50%. UV–Vis (CH_2Cl_2) $\lambda_{max}/\varepsilon$ nm (/M^{-1} cm^{-1}): 573(2207), 496(2348), 415(12702), 381(13035), 362(11878), 261(15075), 231(13207). IR (KBr): $\nu_{N=N}$ 1357 ν_{Pt-Cl} 345 cm^{-1}.

2.3.3. $Pt(L^1)I_3$

To an aqueous solution (5 cm^3) of K_2PtI_4 (0.05 g, 0.064 mmol) a methanolic solution of L^1H (0.015 g, 0.064 mmol) was added. The mixture was stirred for 12 h. The dark solid precipitate was separated by filtration and purified by column chromatography using silica gel (60–120 mesh). The eluent was pet. ether–toluene mixed solvent (80/20 v/v) and upon evaporation of the solvent, the dark red solid $Pt(L^1)I_3$ was obtained. Yield: 80%. *Anal.* Calc. for $C_{14}H_{13}N_2SPtI_3$: C, 20.63; H, 1.59; N, 3.43. Found: C, 20.65; H, 1.63; N, 3.48%. UV–Vis (CH_2Cl_2) $\lambda_{max}/\varepsilon$ nm (/M^{-1} cm^{-1}): 425(9881), 390(9920), 332(7800), 268(26610), 230(21900). IR (KBr): $\nu_{N=N}$ 1387 cm^{-1}.

2.3.4. $Pt(L^2)I_3$ and $Pt(L^3)I_3$

The other complexes, $Pt(L^2)I_3$ and $Pt(L^3)I_3$, were prepared by a similar method using L^2H and L^3H in place of L^1H. Yield for $Pt(L^2)I_3$: 70% and $Pt(L^3)I_3$: 65%. *Anal.* Calc. for $C_{15}H_{15}N_2SPtI_3$: C, 21.73; H, 1.81; N, 3.38. Found: C, 21.76; H, 1.85; N, 3.35%. 2.4. Physical measurements

Microanalysis (C, H, N) was performed using a Perkin–Elmer 240C elemental analyzer. Fourier transforms IR spectra were obtained on a Nicolet spectrophotometer with samples prepared as KBr pellets. Electronic spectra were recorded using a Hitachi U-2001 spectrophotometer. ^1H NMR spectra were obtained on Brucker AC-200 and Brucker Avance DPX 300 spectrometers in $CDCl_3$, using TMS as the internal standard.

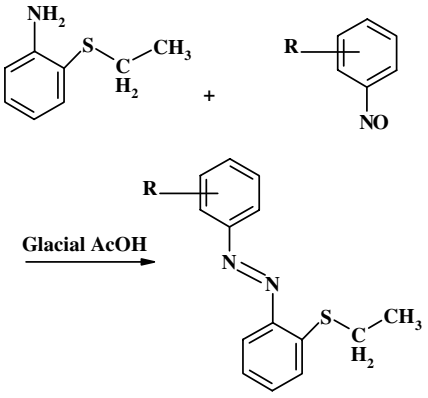
2.5. Crystallography

Crystals of $Pt(L^3)I_3$ were grown by slow diffusion of hexane into dichloromethane solutions at 25 °C. Data were collected by the ω-scan technique on an Enraf-Nonius CAMX-3 diffractometer with Mo Kα radiation, monochromated by a graphite crystal. The structure solution was done by a direct method with the SHELXS-97 program. Full-matrix least-square refinements were performed using the SHELX-97 program (PC version). All non-hydrogen atoms were refined anisotropically using reflections $I > 2\sigma(I)$. Hydrogen atoms were included in calculated positions. The crystal data and data collection parameters are listed in Table 1.

3. Results and discussion

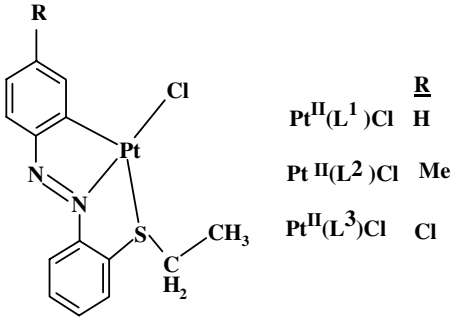
3.1. Synthesis

The ligands LH were synthesized by treating 2-ethyl sulfanyl aniline (prepared by reacting 2-amino thiophenol with ethyl bromide in sodium ethoxide) with the appropriate nitrosoarenes in glacial acetic acid in the following equation [8]:



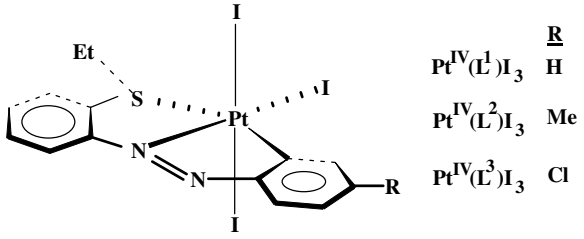
(1)

Reactions of K_2PtCl_4 with the LH ligands afforded the orthometallated complexes of bivalent platinum as shown in **3**.



3

On the contrary, the reaction of LH with K_2PtI_4 (in warm methanol) afforded the Pt(IV) orthometallated species as shown in **4**. It is believed that in the case of K_2PtI_4, the reactions proceeded either via oxidative addition of LH or addition of I_2 that was generated in situ due to aerial oxidation of I^- which was released from K_2PtI_4 upon the initial formation of Pt(L)I. We tried our best to obtain Pt(L)I, performing the reaction in a nitrogen atmosphere, but always ended up with $Pt(L)I_3$. However, these $Pt(L)I_3$ compounds are examples of new Pt(IV) orthometallated azobenzene complexes [5,6].



4

All the complexes, Pt(L)Cl and Pt(L)I_3, are non-electrolytic, diamagnetic and soluble in common organic solvents.

3.2. Characterization

The ligands and complexes display characteristic UV–Vis spectra. Representative spectra of L^3H, Pt(L^3)Cl and Pt(L^3)I_3 are shown in Fig. 1. Data are collected in Section 2.

The LH ligands exhibit $\nu_{N=N}$ near 1454 cm^{-1} in the IR spectra, which shifts to the lower energy range 1357–1365 cm^{-1} for Pt(L)Cl and 1385–1387 for Pt(L)I_3 upon complex formation, indicating coordination of the azo nitrogen [5]. The ν_{Pt-Cl} of Pt(L)Cl were observed at ~350 cm^{-1}. The significant IR data are collected in Section 2.

In the ^1H NMR spectra of LH, 13-H and 14-H (atom numbering scheme is shown in Fig. 2) resonances of the ethyl group of the thioether fragment appeared near δ 3.0 and δ 1.7 as a quartet and triplet, respectively. The total proton counts matched well with the composition. The *p*-Me protons of L^2H were observed at δ 2.44. The chemical shift values and integrations of the aromatic protons are collected in Table 2. The downfield shifting of 13-H (~δ 0.4) upon complexation [5] indicated S coordination. The resonance at δ 7.9 for two equivalent protons in the case of L^1H has been assigned for 2-H and 6-H. This signal shifts a little in the downfield region (δ 8.1) for Pt(L^1)Cl and the proton count is matched with one equivalent

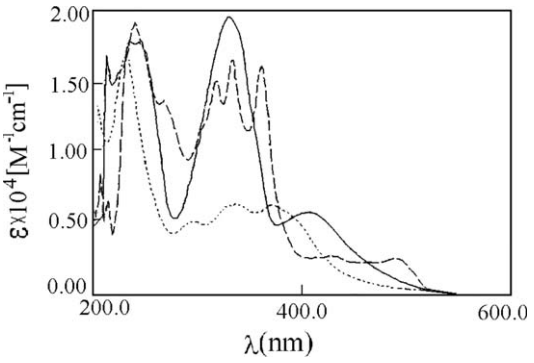


Fig. 1. UV–Vis spectra of (L^3H) (——), Pt(L^3)Cl (-----) and Pt(L^3)I_3 (···).

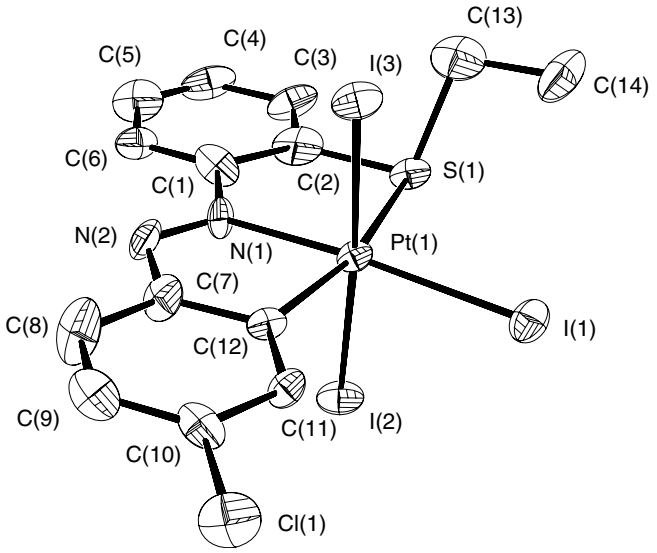

Fig. 2. Perspective view of Pt(L^3)I_3 with the atom numbering scheme. Hydrogen atoms are omitted for clarity.

Table 2
^1H NMR spectra of all the ligands (LH), complexes Pt(L)Cl and Pt(L)I_3 in $CDCl_3$

Compound	δ^b (X, *n*H)[a]		
	Aromatic protons	Non-aromatic protons	R (CH_3)

[a] X = multiplicity (m, multiplet; s, singlet; d, doublet; t, triplet; b, broad; q, quartet), *n*, proton count.
[b] In ppm.

proton, unlike L^1H (two equivalent protons), indicating dissociation of a C–H proton due to M–C bond formation. An important feature of $Pt(L)I_3$ complexes in the ^1H NMR spectra is the non-equivalent nature of the methylene (13-H) protons of the ethyl group on sulfur. Two resonances at $\sim\delta$ 3.65 and $\sim\delta$ 4.15 appeared for these two protons with a separation of $\sim\delta$ 0.5. This is characteristic for all the $Pt(L)I_3$ complexes and may be attributed to the non-equivalent magnetic environment about the two methylene protons due to three bulkier I^- ligands within the coordination sphere.

3.3. X-ray structure of $Pt(L^3)I_3$

Crystals suitable for X-ray studies were grown by slow diffusion of dichloromethane into hexane. The platinum is hexacoordinated in a distorted octahedral geometry indicating the tetravalent platinum. The deprotonated ligand, $[L^3]^-$, binds the metal in a tridentate (C, N, S) fashion and it is meridionally oriented. Three I^- ligands satisfy the hexacoordination about platinum (IV). The asymmetric unit contains two molecules. During the anisotropic refinement, N(4) and C(25) showed non-positive thermal parameters. Thus those two atoms were not refined anisotropically. However, the bond parameters, within the coordination sphere of Pt, of the two molecules were similar. Only the azo N(3)–N(4) distance (1.26(3) Å) of one molecule did not match with the azo N(1)–N(2) distance (1.21(3) Å) of the other. Thus we considered only the N(1)–N(2) distance for the discussion as more reliable than N(3)–N(4) since N(4) could not be refined anisotropically. A perspective view of the molecular structure is shown in Fig. 2. Selected bond distances and bond angles are collected in Table 3.

The Pt–N(azo), Pt–C and Pt–I lengths are within the normal values for Pt(IV) species [5]. The N=N(azo) length (1.20 (3) Å) is also within the normal value. However, the Pt–S (thioether) distance (2.430(7) Å) is larger than the expected Pt–S length (2.25 Å) due to the strong *trans* influence of the aryl carbon atom [5].

Table 3
Selected bond distances (Å) and bond angles (°) for $Pt(L^3)I_3$

Distances			
Pt(1)–I(1)	2.636(3)	S(1)–C(2)	1.80(3)
Pt(1)–I(2)	2.667(2)	C(1)–C(2)	1.38(4)
Pt(1)–I(3)	2.655(2)	N(1)–C(1)	1.49(3)
Pt(1)–S(1)	2.430(7)	N(1)–N(2)	1.20(3)

4. Conclusions

The reaction of 1-arylazo-2-ethyl sulfanyl benzene (LH) with K_2PtCl_4 and K_2PtI_4 has been studied. In both the cases orthoplatinated compounds were isolated and characterized. K_2PtCl_4 afforded Pt(II) complexes, Pt(L)Cl, while K_2PtI_4 produced the Pt(IV) compounds, $Pt(L)I_3$. The oxidation of Pt in the case of $Pt(L)I_3$ is believed to occur as a result of oxidative addition of LH.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC reference number CCDC280164. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK. E-mail: deposite@ccdc.cam.ac.uk.

Acknowledgments

We are thankful to the Council of Scientific and Industrial Research, (CSIR), New Delhi, for funding and fellowship to BS. We are also thankful to DST (New Delhi) for funding and fellowship to J.P. (No. SR/S1/IC-09/2003). We acknowledge the help of Dr. S. Pal of the University of Hyderabad for X-ray studies.

2.1.1. $[(C_6H_6)RuCl_2(\alpha\text{-pic})_2]$

Yield: 78%. Colour: red. IR (KBr): 3056 $\nu_{CH\text{-phen}}$; 2933 $\nu_{CH\text{-phenyl}}$; 1605 ν_{CN}; 1481 $\delta_{(C–CH\text{ in the plane})}$; 1436 $\nu_{C=C}$; 1303 ν_{ring}; 1117 δ_{CH}; 1064 δ_{CH}; 832 $\nu_{Ru–N}$; 719 δ_{pic}. ^{1}H NMR (δ, $CDCl_3$): 8.59 (dd H6 pic); 7.20 (t H5 pic); 7.67 (td H4 pic); 7.16 (d H3 pic); 5.69 (s C_6H_6); 3.16 (s CH_3). UV–Vis (CH_2Cl_2, λ, nm): 434.6 (2.88), 346.2 (3.05), 263.0 (3.56), 227.0 (3.69) *Anal.* Calc. for $C_{12}H_{13}Cl_2NRu$: C, 51.31; H, 4.55; Cl, 16.83; N, 3.32; Ru, 23.99. Found: C, 51.41; H, 4.35; N, 3.33%.

2.1.2. $[(C_6H_6)RuCl_2(\beta\text{-pic})_2]$

Yield: 81%. Colour: orange. IR (KBr): 3060 $\nu_{CH\text{-phen}}$; 2949 ν_{CH3}; 1605 ν_{CN}; 1478 $\delta_{(C–CH\text{ in the plane})}$; 1433 $\nu_{C=C}$; 1112 δ_{CH}; 1049 δ_{CH}; 841 $\nu_{Ru–N}$; 700 δ_{pic}. ^{1}H NMR (δ, $CDCl_3$): 8.85 (H2 pic); 7.33 (d H4 pic); 7.31 (dd H5 pic); 8.80 (d H6 pic); 5.89 (s C_6H_6); 2.19 (s CH_3). UV–Vis (CH_2Cl_2, λ, nm): 409.8 (2.93), 256.8 (3.90), 224.4 (3.96), 213.4 (4.02). *Anal.* Calc. for $C_{12}H_{13}Cl_2NRu$: C, 51.31; H, 4.55; Cl, 16.83; N, 3.32; Ru, 23.99. Found: C, 51.42; H, 4.37; N, 3.32%.

2.1.3. $[(C_6H_6)RuCl_2(\gamma\text{-pic})_2]$

Colour: yellow-orange. Yield: 82%. Colour: orange. IR (KBr): 3032 $\nu_{CH\text{-phen}}$; 2947 $\nu_{CH\text{-phenyl}}$; 1613 ν_{CN}; 1494 $\delta_{(C–CH\text{ in the plane})}$; 1423 $\nu_{C=C}$; 1107 δ_{CH}; 1041 δ_{CH}; 815 $\nu_{Ru–N}$; 721 δ_{pic}.^{1}H NMR (δ, $CDCl_3$): 8.50 (d H2, H6 pic); 7.25 (d H3, H5 pic); 5.98 (s C_6H_6); 2.61 (s CH_3). UV–Vis (CH_2Cl_2, λ, nm): 402.4 (2.66), 249.8 (3.98), 220.4 (3.99), 218.0 (4.06). *Anal.* Calc. for $C_{12}H_{13}Cl_2NRu$: C, 51.31; H, 4.55; Cl, 16.83; N, 3.32; Ru, 23.99. Found: C, 51.40; H, 4.32; N, 3.31%.

2.2. Physical measurements

Infrared spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the sample in the form of a KBr pellet. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 800–200 nm in deoxygenated dichloromethane solution. Elemental analyses (C, H, N) were performed on a Perkin–Elmer CHN-2400 analyzer. The ^{1}H NMR spectra were recorded on a INOVA 300 spectrometer in $CDCl_3$ solutions.

2.3. Crystal structure determination and refinement

A red needle crystal was mounted on a KM-4-CCD automatic diffractometer equipped with CCD detector, and was used for data collection. X-ray intensity data were collected with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at the temperature 293(2) K, with the ω scan mode. A 16.00 seconds exposure time was used and all reflections of the Ewald sphere were collected up to $2\theta = 63.12°$. The unit cell parameters were determined from least-squares refinement of the setting angles of 7033 strongest reflections. Details concerning crystal data and refinement are given in Table 1. Examination of 52 reflections on two reference frames monitored after each 20 frames measured showed 2.31% loss of the intensity. During the data reduction the above decay correction coefficient was taken into account. Lorentz, polarization and numerical absorption [5] corrections were applied. The structure was solved by direct methods and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix, least-squares technique on F^2. All the hydrogen atoms were found from the difference Fourier synthesis after four cycles of anisotropic refinement, and refined as ''riding'' on the adjacent carbon atom with an individual isotropic temperature factor equal to 1.2 times the value of the equivalent temperature factor of the aromatic parent carbon atom and equal to 1.5 times the value of equivalent temperature factor of the methyl parent carbon atom. The methyl group was allowed to rotate during refinement about its local threefold axis. SHELXS 97 [6], SHELXL 97 [7] and SHELXTL [8] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.4. Computational details

The GAUSSIAN 03 program [9] was used in the calculations. The geometry optimisation was carried out with

the DFT method with the use of the B3LYP functional [10,11]. The electronic spectrum was calculated with the TDDFT method [12]. The calculations were performed using the DZVP basis set [13] with f functions with exponents 1.94722036 and 0.748930908 on the ruthenium atom and polarization functions to all other atoms: 6-31g(2d,p) – chlorine, 6-31g** – carbon, nitrogen and 6-31g(d,p) on hydrogen atoms.

3. Results and discussion

Refluxing the ruthenium(II) benzene complex $[(C_6H_6)RuCl_2]_2$ with an excess of 2, 3 and 4-methylpyridine in methanol leads to the half-sandwich complexes $[(C_6H_6)RuCl_2(pic)]$, where pic = α-, β-, γ-picoline. The elemental analyses of the complexes are in good agreement with their formulation. Infrared spectra of the complexes exhibit characteristic bands due to picoline ring vibrations. The $\nu_{C=N}$ band in the complexes appear around 1605 (complex with α- and β-picoline) and 1613 cm^{-1} ($[(C_6H_6)RuCl_2(\gamma\text{-pic})]$). The $\nu_{C=C}$ absorption bands are visible at 1436, 1433, and 1423 cm^{-1}, respectively. The absorption bands at 832 cm^{-1} (complex with α-picolne), 841 cm^{-1} (β-picoline) and 915 (γ-picoline) are due to ν_{Ru-N}. The ^1H NMR spectra of the complexes confirm the presence of picoline molecules in the coordination spheres. The positions of the ^1H NMR signals and their assignment are given in the experimental part of the paper.

The obtained complexes were crystallized from methanolic solution but only the complex with α-picoline gave well-shaped crystals suitable for X-ray analysis.

The complex $[(C_6H_6)RuCl_2(\alpha\text{-pic})]$ crystallizes in the monoclinic space group $P2_{1/n}$ and the crystal structure is built up of two independent molecules in the asymmetric unit. The relative orientation of the molecules is depicted in Fig. 1, which also shows the displacement ellipsoids of the non-hydrogen atoms. The picoline substituent of the molecule indicated by Ru(2) atom is statically disordered over two sites with participation of domains in the ratio 3:1. Both domain atoms are coplanar, and are rotated along the axis going through the Ru(2) atom and perpendicular to the picoline atoms weighted least squares plane. The second molecule picoline substituent also shows signs of disorder, but it is rather dynamical in character. Selected bond lengths and angles are given in Table 2. The distances and the angles between the appropriate atoms in the two molecules are similar. The most different distance is Ru(1)–Cl(2) 2.438(8) Å and Ru(2)–Cl(52) 2.423(9) Å, and most different angles are N(1)–Ru(1)–Cl(2) 89.98(8)° and N(51)–Ru(2)–Cl(52) 96.0(6)°; N(1)–Ru(1)–C(10) 161.62(13)° and N(51)–Ru(2)–C(60) 167.0(6)°; C(8)–Ru(1)–N(1) 110.77(15)° and C(58)–Ru(2)–N(51) 105.5(6)°. The coordination about ruthenium is formally six and the structure adopts a distorted piano-stool type of geometry with angles (average value) around the ruthenium of 85.54(17)° (Cl(1)–Ru–Cl(2)), 89.52(8)° (N(1)–Ru–Cl(1)), 92.99(3)° (N(1)–Ru–Cl(2)).

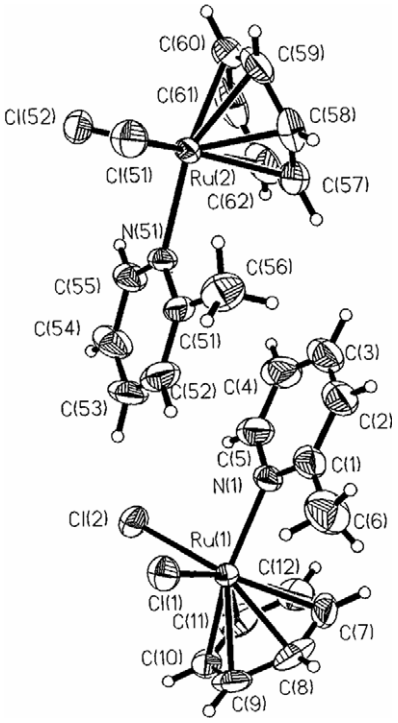

Fig. 1. ORTEP drawing of $[(C_6H_6)RuCl_2(\alpha\text{-pic})]$ with 50% probability displacement ellipsoids. The disordered part of picoline substituent is omitted for clarity.

The Ru–Cl bonds length are of the same order as in related compounds [14]. The picoline ligand displays a Ru–N distance of 2.188(3) Å for Ru(1)–N(1) and 2.184(7) Å for Ru(2)–N(51), which are similar and in the range of Ru–N distances. The ruthenium atom is π-bonded to the benzene ring with an average Ru–C distance of 2.176(4) Å (2.173(4) Å for Ru(1)–C to 2.178(4) Å for Ru(2)–C), whereas the distance between the ruthenium atom and the centroid of the ring varies from 1.665(9) Å (Ru(1)) to 1.671(2) Å (Ru(2)) and is consistent with those reported for other Ru(II) η^6-arene complexes [15,16].

The bond valences were computed as $v_{ij} = \exp[(R_{ij} - d_{ij})/b]$ [17–19], where R_{ij} is the bond-valence parameter (in the formal sense the R_{ij} parameter value can be considered as an idealised single-bond length between i and j atoms). The R_{Ru-N}, $R_{Ru-\pi}$, R_{Ru-Cl} values were taken as 1.656, 1.731 and 1.932 [20], respectively, and b was taken as 0.37 [17]. The computed bond valences of ruthenium are $v_{Ru-N} = 0.237$, 0.240; $v_{Ru-\pi} =$ 1.195, 1.176; $v_{Ru-Cl} = 0.267$, 0.268 and 0.255, 0.265 v.u. (valence units) which means that the Ru–π bond is almost four times stronger than the other bonds, and the Ru–N bond is the weakest one. The valence sum rule states that the sum of the valences of the bonds formed by an atom is equal to the valence of the atom. The computed total valence of the Ru(1) atom is 1.954 and of Ru(2) – 1.949 v.u., which agree with the formal oxidation state and confirm the correctness of the coordination sphere solution.

The two intermolecular hydrogen bonds [21–23] linking the chlorine ligand and picoline C(3)–H(3)...Cl(52)(1# x, $y+1$, z) (D···A distance 3.611(5) Å, D–H···A angle

146.3°), C(8)–H(8)...Cl(1)(2# $-x+1/2, y+1/2, -z+1/2$) (D···A distance 3.660(4) Å, D–H···A angle 174.3°) atoms are observed. Four other intramolecular weak hydrogen bonds are presented in the structure of the complex between picoline C(5)–H(5) and Cl(2) (D···A distance 3.210(4) Å, D–H···A angle 122.9°), C(6)–H(6A)···Cl(1) (D···A distance 3.423(5) Å, D–H···A angle 146.6°), and C(55)–H(55)...Cl(52) (D···A distance 3.178(8) Å, D–H···A angle 116.7°), C(56)–H(56C)...Cl(51) (D···A distance 3.341(7) Å, D–H···A angle 143.5°). In this way an infinite three-dimensional hydrogen-bonded net has been created (see Table 3). In the molecule two C–H···π interactions can also be found, which, according to Desiraju and Steiner [21] can be classified as weak hydrogen bonds: C(2)–H(2)···Cg(picoline$_{(N51)}$# $-x+1, -y+1, -z$) and C(59)–H(59)··· Cg(benzene$_{(C7)}$# $-x+1/2, y+1/2, -z+1/2$) with D···A distances 3.417(8), 3.241(5) Å, and D–H···A angles 89.55°, 74.21°, respectively. The structure is stabilised by intermolecular stacking interactions between almost coplanar benzene rings: indicated by C(7) and C(57# $-x+3/2, y+1/2, -z+1/2$) atoms with a Cg···Cg# distance 3.542(5) Å, angle between Cg···Cg# vector and normal to plane Cg# equal to 24.2(3)° and perpendicular distance of Cg on ring Cg# 3.231(5) Å.

C(8)–H(8)...Cl(1)#2	0.93	2.73	3.660(4)	174.3
C(55)–H(55)...Cl(52)	0.93	2.65	3.178(8)	116.7
C(56)–H(56C)...Cl(51)	0.96	2.52	3.341(7)	143.5

Symmetry transformations used to generate equivalent atoms: #1 $x, y+1, z$; #2 $-x+1/2, y+1/2, -z+1/2$.

3.1. Geometry and electronic structure

The optimised geometry parameters for the complex with α-picoline are given in Table 2. The optimized bond distances and angles of $[(C_6H_6)RuCl_2(\alpha\text{-pic})_2]$ agree with the experimental values. The largest differences were found for the ruthenium–benzene carbons distances. The calculated Ru–benzene distance is 1.7219 Å. Although the X-ray structures of the complexes with β- and γ-picoline were not determined, their geometries, electronic transitions and IR frequencies were calculated. A good agreement of the calculated spectroscopic properties of $[(C_6H_6)RuCl_2(\beta\text{-pic})_2]$ and $[(C_6H_6)RuCl_2(\gamma\text{-pic})_2]$ with the experimental ones indicates the calculated geometries correspond to the real structures. The maximum error between the calculated and experimental IR frequencies is about 4.8% for the complex with β-picoline and 3.5% for $[(C_6H_6)RuCl_2(\gamma\text{-pic})]$.

The formal charge of ruthenium is +2 in these complexes. The calculated charges on the ruthenium atoms, obtained from natural population analysis, are equal to 0.735 for the complex with α-picoline, 0.745 for β- and γ-picoline The charges on the chloride ligands are higher

than −1 (−0.516, −0.525 for α-picoline; −0.528 for β-picoline; −0.527, −0.529 for γ-picoline); the charge on the picoline nitrogen atom is negative and amounts to −0.453, −0.431 and −0.442 for complexes with α-, β- and γ-picoline, respectively. The HOMO–LUMO gap is 4.06 eV for $[(C_6H_6)RuCl_2(\alpha\text{-pic})]$, 4.03 eV for $[(C_6H_6)RuCl_2(\beta\text{-pic})]$ and 4.04 eV for $[(C_6H_6)RuCl_2(\gamma\text{-pic})]$.

The bonding between benzene and ruthenium, formed by the two π orbitals of e_{1g} symmetry (π_2 and π_3) and the empty d_{xz} and d_{yz} orbitals of the metal atom (donation from benzene to ruthenium), is visible in the HOMO − 12 and HOMO − 13 molecular orbitals and the antibonding are LUMO and LUMO + 1. In the back-donation (metal to ligand), the occupied $d_{x^2-y^2}$ and d_{xy} metal orbitals and empty π_4^*, π_5^* benzene orbitals participate (HOMO − 1, HOMO and LUMO + 3, LUMO + 5). The HOMO − 2 is a combination of d ruthenium and π chlorine orbitals. HOMO − 3 is a π chlorine orbital. The chlorine orbitals have a contribution, with the d metal orbitals, in the HOMO − 4, HOMO − 7 and HOMO − 8 molecular orbitals. The picoline ligand has a significant contribution in the HOMO − 5 (with the π chlorine), HOMO − 10 and HOMO − 11 molecular orbitals. The LUMO + 2 and LUMO + 4 molecular orbitals are composed of picoline rings.

3.2. Electronic spectrum

The experimental spectra of the investigated complexes show bands at 434.6, 346.2, 263.0, 227.0 nm for $[(C_6H_6)RuCl_2(\alpha\text{-pic})]$, 409.8, 256.8, 224.4, 213.4 nm for $[(C_6H_6)RuCl_2(\beta\text{-pic})]$ and 402.4, 249.8, 220.4, 218.0 nm for $[(C_6H_6)RuCl_2(\gamma\text{-pic})]$. The measured (solid line) and calculated (dashed line) electronic spectrum of $[(C_6H_6)RuCl_2(\alpha\text{-pic})]$ is shown in Fig. 2. Each calculated transition in Fig. 2 was represented by a Gaussian function with the height equal to the oscillator strength and width equal to 0.05. With the use of the TDDFT method 90 electronic transitions were calculated for these complexes using the DZVP with f functions basis set on the ruthenium atom and the polarization functions on the other atoms. The calculated spectra are in good agreement with the experimental ones.

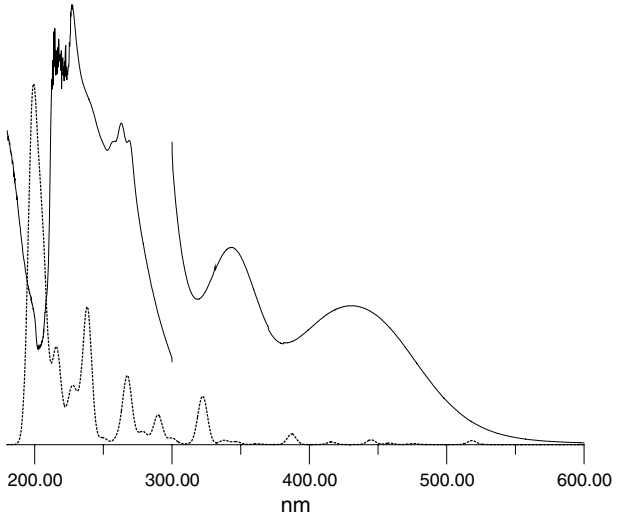

Fig. 2. The UV–Vis spectrum of the $[(C_6H_6)RuCl_2(\alpha\text{-pic})]$ complex.

In the calculated electronic spectra of $[(C_6H_6)RuCl_2(picoline)]$ the lowest energy transitions (above 400 nm) are of d → d origin and they are characterised with small oscillator strengths. The experimental bands at 346.2 nm for the complex with α-picoline, 256.8 nm for β-picoline and 249.8 nm for γ-picoline correspond to the MLCT ($d \rightarrow \pi^*_{pic}$) and LMCT ($Cl \rightarrow d$) transitions. The higher energy bands at 263.0, 224.4, 220.4 nm and 227.0, 213.4, 218 nm for complexes with α-, β- and γ-picoline complexes, respectively, are of LLCT type (inter and intraligand) and consist of $\pi_{Cl} \rightarrow \pi^*_{Cl}$, $\pi_{pic} \rightarrow \pi^*_{pic}$, $\pi_{Cl} \rightarrow \pi^*_{pic}$, $\pi_{pic} \rightarrow \pi^*_{Cl}$ transitions. The $\pi_{benz} \rightarrow d$ (LMCT) excitation is visible in the highest energy bands.

4. Supplementary material

More details of the crystal structure determination have been deposited with the Cambridge Crystallographic Data Centre with the deposition number: CCDC 264833. followed by water (40 ml). The dichloromethane layer was separated and dried over anhydrous sodium sulfate. Distillation of dichloromethane extract gave *N*-benzoylimidazole (yield 90%) a colorless pasty liquid. IR (neat, cm^{-1}) 3150(s), 2843(s), 1711(s), 1603(s), 1552(s), 1383(s), 1327(m), 1327(m), 1276(s), 1178(m), 1071(s), 835(s), 717(s); ^1H NMR ($CDCl_3$) 7.84(s, 1H) 7.76–7.69(m, 1H), 7.56–7.53(m,2H), 7.46–7.42(m, 1H) 7.33–7.29(m, 2H), 6.918(s, 1H); ^{13}C NMR ($CDCl_3$) 137.48, 132.86, 131.12, 130.95, 129.06, 128.26, 127.65, 126.92; GC mass (*m/e*) 344 (for dimer), 277, 176, 116, 106, 78, 49, 38.

2.2. Synthesis of N-benzoyl 3,5-dimethylpyrazole (*II*)

To a solution of benzoylchloride (700 mg, 5 mmol) in dichloromethane (5 ml), triethylamine (606 mg, 6 mmol) was added. To this solution another solution of 3,5-dimethylpyrazole (480 mg, 5 mmol) in dichloromethane (6 ml) was added dropwise at room temperature. The solution was stirred for 3.5 h and to the reaction mixture dichloromethane (20 ml) was added, followed by addition of water (40 ml). The dichloromethane layer was separated by a separating funnel and dried over anhydrous sodium sulfate. Distillation of the dichloromethane extract gave the crude product. The crude product was washed with hexane (10 ml) to remove any hexane soluble impurity. The residue was filtered and the residue was found to be *N*-benzoyl 3,5-dimethylpyrazole (yield 92%). IR (neat, cm^{-1}) 3068(w), 2981(m), 2935(m), 1700(s), 1598(s), 1459(s), 1413(s), 1342(s), 1280(s), 1193(m), 1127(m), 1039(m), 978(s), 922(s), 804(m), 712(s). ^1H NMR ($CDCl_3$) 7.96–7.94(m, 2H), 7.58–7.40(m, 1H), 7.39–7.37(m, 2H), 6.0(s, 1H), 2.59(s, 3H), 2.20(s, 3H); ^{13}C NMR ($CDCl_3$): 167.82, 151.59, 144.59, 132.96, 131.96, 130.95, 127.40, 110.72, 14.17, 13.69. GC mass (*m/e*) 202, 172, 115, 105, 77, 59, 39.

2.3. Synthesis of imidazolium benzoate (*III*)

N-benzoylimidazole (176 mg 1 mmol) was dissolved in ethyleneglycol (1 ml). To this solution water (0.2 ml) was added. Standing for two days gave white crystals of imidazoliumbenzoate (60 mg). IR(KBr, cm^{-1}): 3401(bs), 3139(s), 2842(s), 1710(s), 1598(s), 1547(s), 1465(s), 1383(s), 1306(s), 1255(s), 1183(s), 1070(s), 1024(s), 896(s), 717(s). Elemental *Anal*. Calc. for $C_{10}H_{10}N_2O_2$: C, 63.13; H, 5.30; N, 14.73. Found: C, 63.58; H, 5.28; N, 14.26%. ^1H NMR ($CDCl_3$): 13.5(s,1H), 8.00–7.96(m, 1H), 7.67–7.65(m, 2H), 7.45–7.34(m,1H), 7.30–7.28(m, 2H), 7.06–7.01(m, 2H).

2.4. Synthesis of cis-$(pz)_2Cu(OBz)_2 \cdot$ trans-$(pz)_2Cu(OBz)_2H_2O$ (*B*)

To a solution of copper(II) nitrate trihydrate (242 mg, 1 mmol) in acetonitrile (3 ml) *N*-benzoyl 3,5-dimethylpyrazole (404 mg, 2 mmol) was added. The mixture was stirred to obtain a homogeneous solution. To this solution water (1 ml) was added. A blue crystalline precipitate appeared after 7 days (30 mg) on standing. The crystals were picked out and the structure was determined by X-ray diffraction. Elemental *Anal*. Calc. for $C_{48}H_{54}N_8O_9Cu_2$: C, 56.83; H, 5.37; N, 11.05. Found: C, 57.05; H, 5.56; N, 10.95; IR(KBr, cm^{-1}): 3206(m), 3145(m), 3047(w), 1628(s), 1582(m), 1531(s), 1403(s), 1296(m), 1183(w), 1070(w), 860(w), 804(w), 717(s). Crystal parameters of **B:** Monoclinic, space group *C2/c*, $a = 39.461(5)$, $b = 16.2272(17)$, $c = 11.6867(12)$ Å, $\alpha = 90.00°$, $\beta = 94.998(7)°$, $\gamma = 90.00°$, $V = 7455.1(15)$ Å^3, $Z = 4$, $T = 296$ K.

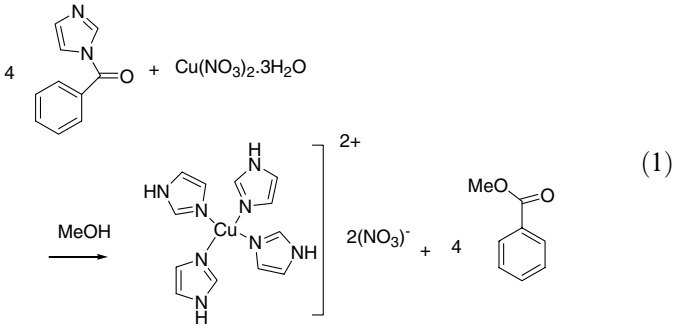
2.5. Copper(II) catalyzed benzoylation of alcohols by N-benzoylimidazole

In a typical experiment *N*-benzolylimidazole (115 mg, 1 mmol), copper(II) nitrate trihydrate (12 mg, 0.05 mmol) and nitric acid (0.01 M, 0.1 ml) were mixed together in methanol (2 ml) and stirred at room temperature. After 2 h of stirring, water (20 ml) was added to the reaction mixture and the organic products were extracted with dichloromethane (40 ml). The dichloromethane layer was separated using a separating funnel and dried over anhydrous sodium sulfate. Removal of dichloromethane from this extract under reduced pressure gave methylbenzoate as the only product. The compound was characterized by recording its ^1H NMR and IR spectra and comparing them with an authentic sample. Products from similar reactions with other alcohols were also confirmed by recording ^1H NMR and GC–MS spectra. For benzoylation of solid alcohols dry acetonitrile was used as the solvent. From a similar reaction of ethyleneglycol with *N*-benzoylimidazole under catalytic conditions only the mono-benzoylated ester was obtained. Spectral details of $C_6H_5COOCH_2CH_2OH$: IR (neat, cm^{-1}) 3416(bs), 1716(s), 1603(m), 1347(s), 1265(s), 1117(s), 707(s). ^1H NMR ($CDCl_3$): 8(m, 2H), 7.55(m, 1H), 7.4(m, 2H), 4.4(m, 2H), 3.9(m, 2H), 2.4(bs, exchangeable, 1H). GC–MS: (*m/e*), 167, 148, 135, 105, 77, 51.

3. Results and discussions

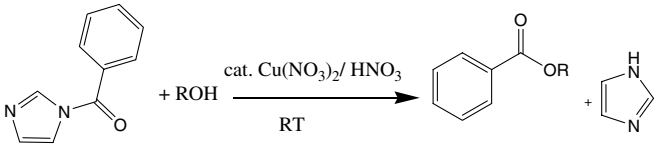
N-benzoylimidazole reacts with copper(II) nitrate trihydrate in methanol to form methylbenzoate and tetra-(imidazole)copper(II) nitrate (**A**) (Eq. (1)) under ambient conditions. Complex **A** has been characterized by determining its crystal structure by single crystal X-ray diffraction. The structure of this complex tallies with the one reported in the literature [28]. This reaction is a stoichiometric reaction. From this reaction, we could prepare the corresponding ester of methanol by using 1/4 molar ratio of copper(II) nitrate with respect to the *N*-benzoylimidazole. However, we had an important observation at this stage, if a drop of dilute nitric acid is added to the reaction mixture the esterification reaction worked catalytically. Inspired by this observation, we carried out a series of

benzoylation reactions by *N*-benzoylimidazole with different alcohols (Eq. (2)). The results showing the reaction time and yield obtained from these esterification reactions catalyzed by copper(II) under ambient conditions are listed in Table 1. In order to ascertain that the copper(II) nitrate, along with nitric acid, acts as a catalyst, we have carried out reactions under identical conditions without the catalyst and observed no significant reaction in this case. It is worth mentioning that the reaction of *N*-benzoylimidazole with nitric acid without copper(II) nitrate led to the formation of benzoic acid (1 ml, 0.1 M HNO_3, approximately 2 h for conversion of 1 mmol of *N*-benzoylimidazole). However, we used a lesser amount of the acid in our reactions; namely 0.1 ml of 0.01 M nitric acid for conversion of 1 mmol of *N*-benzoylimidazole to ester. These results clearly indicate that the catalytic ability of the copper(II) nitrate trihydrate is enhanced by the presence of the nitric acid. This probably happens because of protonation of the imidazole that is formed in the reaction by C–N bond cleavage. Imidazole in the absence of an acid can otherwise coordinate strongly to the copper(II) ion. This is further confirmed by adding nitric acid to tetra(imidazole)copper(II) nitrate in an independent experiment, which led to decomposition of this complex.



(1)

In addition to the primary alcohols, secondary alcohols such as isopropyl alcohol reacted very well to give the corresponding esters. The reaction does not work with tertiary alcohols such as *tert*-butanol. We also examined the reaction of *N*-benzoylimidazole with methanol in the presence of *tert*-butanol under catalytic conditions to ascertain if *tert*-butanol has a retarding effect on the rate. In this reaction only methylbenzoate was formed. It showed that *tert*-butanol does not hinder the benzolyation and also it does not itself give the corresponding ester under ambient conditions. Different allylic esters from allylic alcohols were also prepared by this copper(II) catalyzed reaction. However, in the case of decanol the reaction had to be carried out by suspending copper(II) nitrate trihydrate under heterogeneous conditions, as the later is not soluble in decanol. This solubility problem could be overcome by using complex **A** with very dilute nitric acid as a catalyst in acetonitrile as the solvent. Thus, the use of tetra(imidazole)copper(II) nitrate (**A**) as a catalyst instead of copper(II) nitrate trihydrate has an advantage as it minimizes the solubility problem in the case of long chain alcohols. Complex **A** is soluble in common solvents such as methanol, ethanol, acetonitrile; so the benzoylation reactions using complex **A** as a catalyst could be carried out in solvents other than the alcohols. The copper complex **A** does not have any water of crystallization, so the water content in the reaction is minimized and also the side reaction to give benzoic acid. Two illustrative examples using complex **A** as a catalyst are given in Table 1 (last two rows). Since our interest is on an alternative reagent for benzoylchloride, it is essential to know the stability of *N*-benzoylimidazole. *N*-benzoylimidazole itself gets hydrolytically cleaved in methanol/water mixture (1:1) in 24 h to give methylbenzoate and benzoic acid. However, it undergoes slow hydrolysis in ethyleneglycol. When *N*-benzoylimidazole was dissolved in ethyleneglycol containing traces of water; the water present in the ethyleneglycol reacted with it. After two days of reaction, we obtained white crystals of imidazoliumbenzoate from the reaction mixture. The role of ethyleneglycol in this salt formation reaction is presumably to provide a medium for the reaction to control the crystallization process. This fact is supported by the observation that an aqueous methanolic solution of *N*-benzoylimidazole on standing under ambient conditions gave benzoic acid as a crystalline product after five days. The reaction of ethyleneglycol with *N*-benzoylimidazole in the presence of a catalytic amount of copper(II) nitrate trihydrate and nitric acid gave the mono-benzolylated derivative of ethyleneglycol. It was earlier reported [18] that 1-(benzoyl)benzotriazole can be used for benzoylation of different diols in methylenechloride to give mono-benzoylated derivatives. These reactions were carried out in basic



R = Methyl, Ethyl, *iso*-propyl, benzyl, allyl, crotyl, propargyl etc.

[a] With a catalytic amount of tetra(imidazole)copper(II) nitrate.

medium in the presence of triethylamine. Our copper catalyzed benzoylation reactions of *N*-benzoylimidazole with diols also gave only the mono-benzoylated product, but the difference is that the copper(II) catalyzed reactions were carried out under acidic conditions.

N-benzoyl 3,5-dimethylpyrazole on reaction with copper(II) nitrate trihydrate (2:1 molar ratio) in aqueous methanol at 25 °C for three days gave an interesting mixed copper(II) benzoate complex having the composition *cis*-$(pz)_2Cu(OBz)_2 \cdot$ *trans*-$(pz)_2Cu(OBz)_2H_2O$ (**B**) (where pz = 3,5-dimethylpyrazole and OBz = benzoate anion). The compound is structurally important (Fig. 1) as it has the distinction of having a unique lattice in which both *cis* and *trans* coordination of 3,5-dimethylpyrazole are present around two independent copper(II) centers. From this structure, the process can be understood to be co-crystallization of two inorganic neutral molecules in the form of an adduct. It is interesting to note that each of the two independent units, namely *cis*-$(pz)_2Cu(OBz)_2$ and *trans*-$(pz)_2Cu(OBz)_2H_2O$, is not held by any common weak interactions such as hydrogen-bonding, π-interactions or C–H···O interactions in the lattice but probably they are held by dipolar interactions due to a difference in the dipole moment of two the units. Such a difference in dipole moments is obvious from the orientation of the ligand as well as the coordination number of the two counterparts. The adduct (**B**) can also easily be prepared by the reaction of copper(II) acetate with benzoic acid in the presence of 3,5-dimethylpyrazole in methanol. However, reactions of copper(II) acetate with *o*-chlorobenzoic acid or *o*-nitrobenzoic acid and 3,5-dimethylpyrazole gives monomeric bis-3,5-dimethylpyrazole copper(II) *o*-chlorobenzoate or bis-3,5-dimethylpyrazole copper(II) *o*-nitrobenzoate respectively. Complex **B** has an interesting packing pattern, as shown in Fig. 2. It forms a parallel layered structure and the layers are formed by H-bonding interactions among the *cis*-$(pz)_2Cu(OBz)_2$ and *trans*-$(pz)_2Cu(OBz)_2H_2O$, independently. The layers are held by H-bonding interactions between the NH groups of the 3,5-dimethylpyrazole and the carboxylate oxygen atoms of each independent *cis*-$(pz)_2Cu(OBz)_2$ unit. In the *trans* counterpart, the H-bonding interactions occurs through the carboxyl oxygens with coordinated water and also through N–H···O interactions among carboxyl groups and N–H protons of the 2,3-dimethylpyrazole ligands.

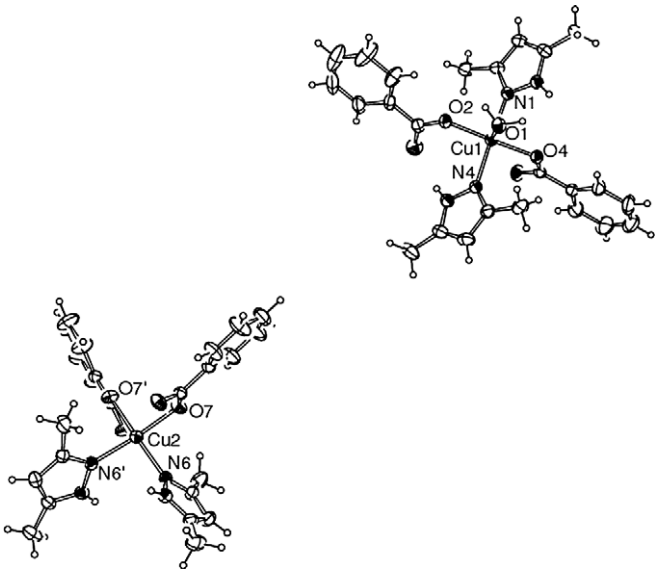

Fig. 1. Crystal structure of the adduct *cis*-$(pz)_2Cu(OBz)_2 \cdot$ *trans*-$(pz)_2Cu(OBz)_2H_2O$ (**B**).

All these results show that the formation of complex **A** is one of the driving forces for catalysis of *N*-benzoylimidazole, but in the case of *N*-benzoyl 3,5-dimethylpyrazole, such reactions gave a catalytically inactive complex **B**.

In conclusion we have shown that C–N bond cleavage by copper(II) complexes are not only useful for catalytic

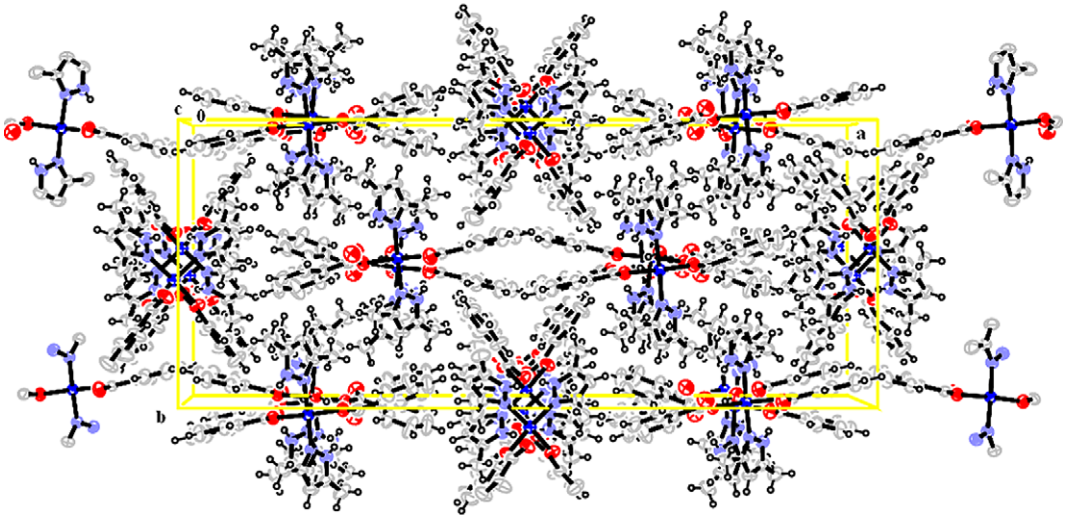

Fig. 2. The crystal packing in the adduct **B** viewed along crystallographic *c*-axis.

benzoylation reactions but also provide a method for the preparation of metal complexes.

Acknowledgments

The authors thank DST (New Delhi, India) for funding and the X-ray diffractometer facility. We thank Mr. R.J. Sarma for help with the crystallography.

Appendix A. Supplementary material

Crystallographic data for the structure have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 281721. Copies of this information can be obtained from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, e-mail: deposit@ccdc.cam.ac.uk.

The GC mass of the *N*-benzoylimidazole and *N*-benzoyl 3,5-dimethylpyrazole are also available. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.02.019

starting from aminomethylferrocene and substituted benzaldehydes [8a]. As a part of our current research related to the cyclo-metallation of ferrocenylamines[8b], in this communication, we wish to report the synthesis of ferrocenylamines [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH_2N(CH_3)CH_2$-C_6H_4R-4)] (R = CH_3(**b**), Cl(**d**)), starting from ferrocenylcarboxaldehyde and *p*-substituted benzylamines, and the cycloplatination reactions of these five ferrocenylamines as mentioned above (Scheme 1) and to try to elucidate the relationship between the structures of the substrates and their selectivities.

2. Results and discussion

2.1. Synthesis of *6a–e*

Condensations of ferrocenylcarboxaldehyde and *p*-methyl (**2b**) or *p*-chloroaniline (**2d**) in methanol at room temperature produced the corresponding aldimines **3b**, **d**, which followed by reduction with lithium aluminum hydride in THF afforded quantitatively **4b**, **d**, respectively. Methylation of **4b**, **d** with sodium cyanoborohydride, aqueous formaldehyde and acetic acid [9] at room temperature gave the aliphatic tertiary ferrocenylamines **5b**, **d** [8] in good yield. Like their analogues, compounds **5b**, **d** are very stable in air, and they are normally liquid or solid with low melting points.

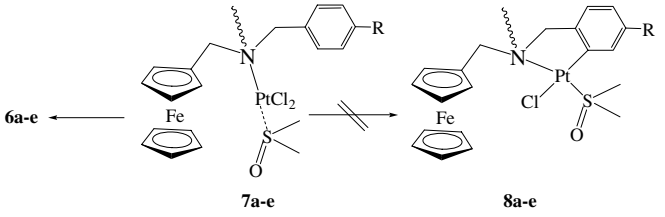
The reactions of **5a–e** and *cis*-[Pt(DMSO)$_2$Cl$_2$] were carried out in methanol under nitrogen. The mixtures were refluxed and stirred for 30 min and cooled down to room temperature. The solvent was evaporated in vacuo and water was then added. Extraction of the water phase with dichloromethane three times (3×30 cm^3) and removal of solvent afforded residues which were further purified by column chromatography (silica gel, ethyl acetate/hexane = 1:5 (v/v)) to give **6a–e** as orange-yellow solids. The yields of **6a–e** are relevant to the character of the substituents on the phenyl ring. For instance, when the substituents are methoxy (**5a**) or methyl (**5b**), the yields of **6a**, **b** are moderate (65%, 60%, respectively), whereas when the substituents are chloro (**5d**) or nitro (**5e**), lower yields of **6d**, **e** (55%, 40%, respectively) are normally obtained. Complexes **6a–e** are very stable in air and are easily soluble in most organic solvents, but are poorly soluble in hexane.

2.2. Spectral characterization of *6a–e*

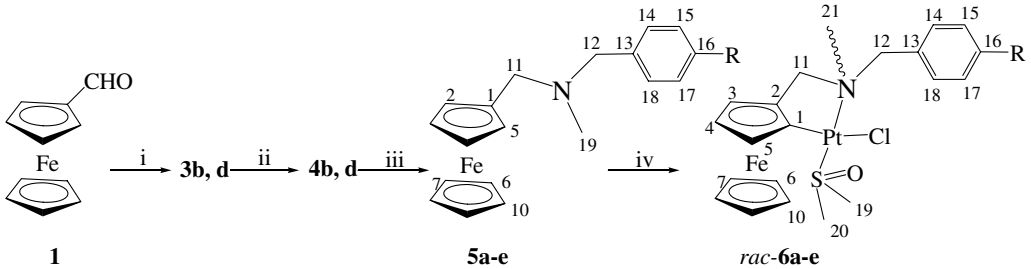
Compounds **3b–5b**, **3d–5d** and **6a–e** were characterized by elemental analyses, IR and ^{1}H NMR. Elemental analyses for these compounds are in good agreement with the proposed formula. The IR and ^{1}H NMR spectra of compounds **3b–5b**, **3d–5d** are very similar to their analogues, e.g., **3a–5a** [8]. The IR spectra of **6a–6e** all display two medium absorption bands around ν 1100 and 1000 cm^{-1}, indicating that the cycloplatination of **5a–e** occurs at the substituted cyclopentadienyl (Cp) rings [10]. In the ^{1}H NMR spectra, the δ values of N—CH_3 range from 3.02 (**6a**) to 2.81 (**6b**), suggesting that N—Pt coordination exists in these molecules. Also in the ^{1}H NMR spectra of **6**, a doublet and multiplet around δ4.10 ppm are assigned to H5 and H4, respectively, and a singlet around δ4.20 ppm is attributed to H3. In addition, H11 exhibit a typical AB spin–spin coupling system (δ3.62 ppm) due to the formation of a five membered platinocycle (in **6a**, the chemical shifts of H11 are overlapped with those of H19 and H20). It seems that H12 have a similar coupling system (around δ4.00 ppm) to that for H11. The protons in *p*-substituted phenyl rings all give their corresponding AA′XX′ splitting patterns.

2.3. Chemoselectivity and stereoselectivity

In all cases, a preferred cycloplatination occurred at the Cp ring over the phenyl ring in **5** (Scheme 2). According to the rule of cyclometallation, the reactions of **5** and *cis*-[Pt(DMSO)$_2$Cl$_2$] form initially the coordinated complexes **7** (Scheme 2) which then direct the platinum to activate its adjacent C—H bonds and hence give the cycloplatinated



Scheme 2. The preferred activation of C—H bond in Cp ring over that in phenyl ring.



Scheme 1. (i) Amines **2**: 4-R$C_6H_4CH_2NH_2$, R = CH_3O(**a**); CH_3(**b**); H(**c**) Cl(**d**), NO_2(**e**), methanol, room temperature. (ii) $LiAlH_4$, THF, reflux. (iii) $NaCNBH_3$, HCHO(aq), AcOH, room temperature. (iv) *cis*-[Pt(DMSO)$_2$Cl$_2$], methanol, reflux 30 min.

compounds. It should be noted that two kinds of C—H bonds are present in **5**, i.e., the $C_{ferrocenyl}$—H bond and the C_{phenyl}—H bond, and activation of both C—H bonds could afford the corresponding stable five membered platinocycles **6a**–**e** and **8a**–**e**, respectively. In fact, only **6a**–**e** were isolated in our experiment. The compounds **8a**–**e** resulting from activation of C_{phenyl}—H bonds in **7a**–**e** were not observed. The preferred activation of the $C_{ferrocenyl}$—H bond over the C_{phenyl}—H bond is consistent with Lopez's observations [7], and this phenomenon is easily explained by the fact that electrophilic substitution of platinum is more facile on a ring with a high electron density (Cp ring) than on one with a low electron density (phenyl ring) [11].

Surprisingly, of the cycloplatinated complexes **6a**–**e** only **6a** crystallizes in two forms, i.e., prismatic crystal and plate, which are difficult to separate from each other in the mixture. A prismatic crystal suitable for X-ray diffraction was carefully picked out of the mixture and its configuration was determined to be R_NR_P [12] (Fig. 1). The optical rotations of **6a**–**e** have been determined to be zero at a given wavenumber ($\lambda = 5893$ Å) and conditions (CH_2Cl_2, $T = 298$ K), implying that complexes **6** are probably composed of racemers. It is possible that each form of **6a** corresponds to one isomer of the racemers. This result may be echoed by the possible mechanism for the formations of **6** as shown in Scheme 3.

Theoretically, an orbital reversion at nitrogen is present between the two isomers **5α** and **5β** (Scheme 3) and each isomer will possess the same stable conformation as that of [(*N*-methyl-*N*-4-methylbenzyl)amino]methyl-ferrocene [13]. Thus, coordination of platinum and **5α**,**β** will afford

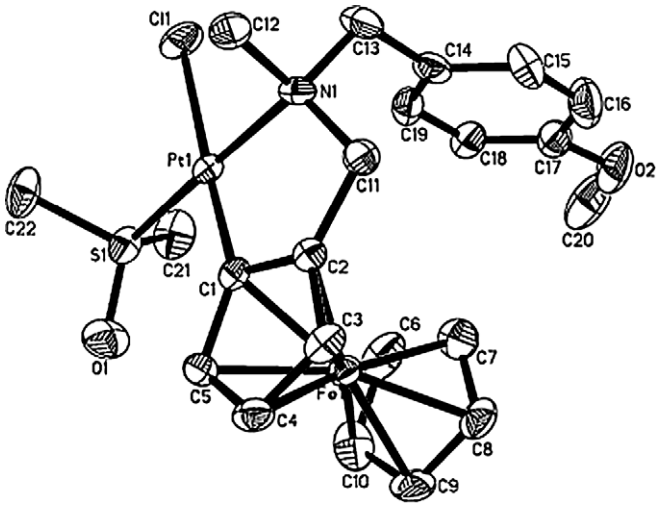


Fig. 1. Crystal structure of **6a** with the numbering scheme (H atoms are omitted for clarity).

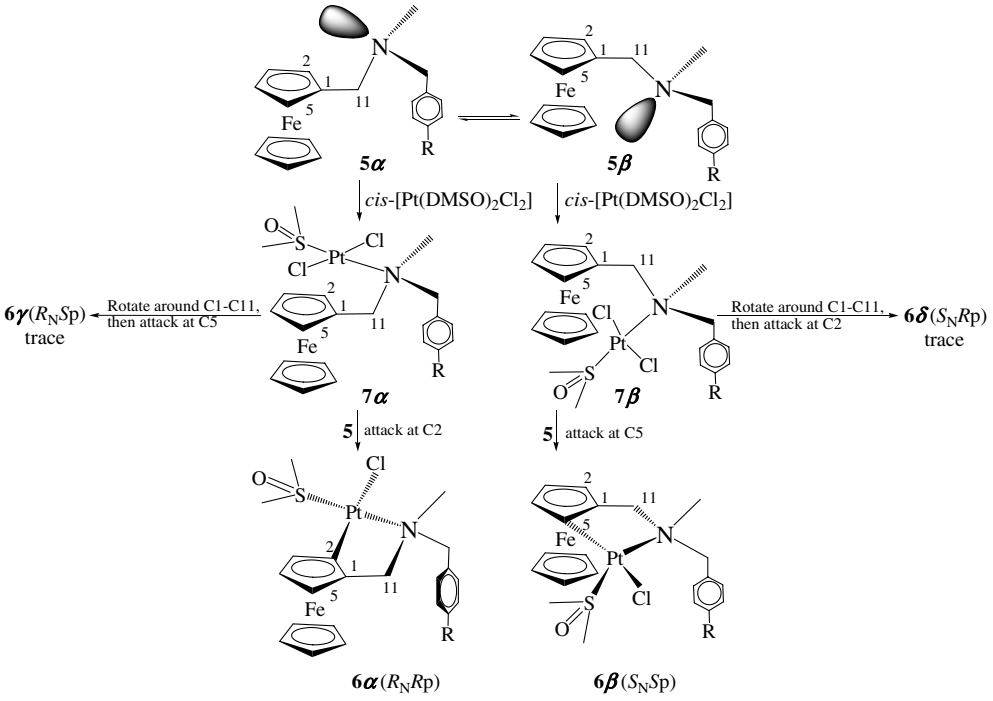
the corresponding intermediates **7α**,**β** with a similar conformation to that of the coordinated Pt—FcN complex [5]. When platinum in **7α**,**β** activates the C2(5)—H bonds, a pair of racemers **6α**,**β** will be generated. Alternatively, the N—Pt moiety in **7α**,**β** could rotate freely around the axis of the C1—C11 bond and subsequently activate the C5(2)—H bonds to give another pair of racemers **6γ**,**δ**. Obviously, cycloplatination of **5** will produce two pairs of enantiomers, and moreover, the pair **6α**,**β** are the diastereomers of the other pair **6γ**,**δ**.

On the other hand, the orientation of platinum in **7α**,**β** approaches the C2—H, C5—H bonds, respectively [5], the



Scheme 3. The possible mechanism for the formation of **6**.

activation of these two C—H bonds to produce **6α,β** by platinum will be favored. However, this orientation may disfavor the activation of C5(2)—H bonds to generate **6γ,δ** probably because the free rotation of the N—Pt moiety around the axis of the C1—C11 bond is retarded by the steric hindrance between the phenyl group and the H atom in the Cp ring. Diastereomers are easily separated by column chromatography, and we indeed obtained a trace product (probably **6γ,δ**) of insufficient quantity to identify. Based upon the discussion as mentioned above and the configuration of **6a** (Fig. 1), it is suggested that **6** consists probably of **6α,β**.

2.4. Crystal structure of *6a*

The structure of **6a** was also confirmed by X-ray single crystal diffraction (Fig. 1). Crystallographic data for **6a** are presented in Table 1, selected bond lengths and angles are listed in Table 2. X-ray diffraction studies for **6a** (Fig. 1) demonstrate that the structure of **6a** consists of discrete molecules σ-Pt[(η^5-C_5H_5)Fe(η^5-$C_5H_3CH_2N(CH_3)CH_2C_6H_4OCH_3$-4)]-Cl(DMSO) separated by van der Waals distances in which platinum is in a slight distorted square-planar environment, bonded to Cl1, S1, N1 and C1. The deviations of the atoms from the mean plane defined by the former five atoms in **6a** are Pt1 0.0218, Cl1 −0.0317, S1 0.0225, N1 0.0272 and C1 −0.0398 Å. In **6a**, the DMSO moiety adopts a *trans* configuration to the N1 atom with a bond angle N1–Pt1–S1 178.20(9)° and this array is very common in platinum complexes [5,6a]. **6a** contains two fused five-membered rings, i.e., the substituted pentagonal ring of the ferrocenyl fragment and a five-membered platinocycle with an envelope-like conformation. The bond length of N1—Pt1 (2.128(3) Å) is shorter than that in cycloplatinated FcN (2.141(6) Å) [5]. The metallated Cp and phenyl rings are nearly perpendicular with an angle of 89.7°. The bond length of Pt1—C1 (1.985(3) Å) is nearly the same as that in cycloplatinated FcN (1.988(7) Å) [5]. The average C—C bond length in the pentagonal rings (1.410 Å) is similar to the values reported for other ferrocene derivatives [10]. The Fe—C (Cp ring) bond lengths range from 1.381(6) to 1.424(5) Å. The two pentagonal rings of the ferrocenyl moiety are planar and nearly parallel (interplanar angle 2.2°). In addition, the Cp rings are also nearly eclipsed and they are skewed from the eclipsed conformation with an angle of 2.56°.

3. Conclusion

Stereoselective cycloplatination of ferrocenylamines of the formula $FcCH_2NMeCH_2Ar$ produced the corresponding two pairs of racemers in which the pair R_NR_P, S_NS_P was the major product. No products resulting from the activation of C_{phenyl}—H bonds were observed. It is anticipated that cyclometallation of ferrocenylamines such as $FcCHRN(CH_3)CH_2Ar$ or $FcCH_2N(CH_3)CHRAr$ will afford four diastereomers which can be easily separated by column chromatography.

4. Experimental

4.1. Materials and instruments

Ferrocenylamines **5a**, **c**, **e** [8] and *cis*-[Pt(DMSO)$_2$Cl$_2$] [14] were prepared according to the literature procedure. Ferrocenylcarboxaldehyde, *p*-methylbenzylamine, *p*-chlorobenzylamine, lithium aluminum hydride, aqueous formaldehyde, sodium cyanoborohydride, acetic acid were obtained commercially and used without further purification. All of the solvents were purified by the standard methods prior to use. Melting points were obtained from a Yanaco micro melting point apparatus and were uncorrected. Elemental analyses were obtained from a Carlo Erba 1106 Elemental analyzer. IR spectra were taken on BIO-RAD 3000 and Digilab FTIR spectrometers. ^{1}H NMR spectra were measured with a Bruker AV-400 spectrometer

by using $CDCl_3$ as a solvent and TMS as the internal standard.

4.2. Synthesis of [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH_2N$-(CH_3)$CH_2C_6H_4R$-4)] (**5b, d**)

4.2.1. [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH{=}NCH_2C_6H_4CH_3$-4)] (**3b**)

3b was prepared by condensation of ferrocenyl-carboxaldehyde and 4-methylaniline in methanol at room temperature under nitrogen. Red brown solid. Yield 54%. M.p. 70–72 °C. *Anal*. Calc. for $C_{19}H_{19}FeN$: C, 71.94; H, 6.04; N, 4.42. Found: C, 71.84; H, 6.01; N, 4.42%. FT-IR(KBr): *v* 3092(w), 2935(w), 2888(w), 1636(vs), 1516(s), 1340(m), 1246(w), 1167(s), 1106(m), 1000(m), 809(s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.10(s, 3H, Ar—CH_3), 3.84(d, 2H, H2, H5), 4.14(m, 2H, H3, H4), 4.17(s, 5H, η^5-C_5H_5), 4.50(s, 2H, H12), 7.70–7.89 (AA′XX′, 4H, H15, H17, H14, H18), 8.10(s, 1H, H11) ppm.

4.2.2. [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH{=}NCH_2C_6H_4Cl$-4)] (**3d**)

3d was prepared with the same procedure as that for **3b**. Red brown solid. Yield 88%. M.p. 57–59 °C. *Anal*. Calc. for $C_{18}H_{16}ClFeN$: C, 64.03; H, 4.78; N, 4.15. Found: C, 63.98; H, 4.76; N, 4.13%. FT-IR(KBr): *v* 3085(w), 2917(w), 2823(w), 1638(vs), 1449(s), 1240(w), 1105(m), 1001(m), 817(s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.86(d, 2H, H2, H5), 4.15(m, 2H, H3, H4), 4.18(s, 5H, η^5-C_5H_5), 4.51(s, 2H, H12), 7.81–7.93 (AA′XX′, 4H, H14, H18, H15, H17), 8.15(s, 1H, H11) ppm.

4.2.3. [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH_2NHCH_2C_6H_4CH_3$-4)] (**4b**)

4b was prepared by reduction of imine **3b** with lithium aluminum hydride in THF under nitrogen. Yellow solid, Yield 80%. M.p. 28–30 °C. *Anal*. Calc. for $C_{19}H_{21}FeN$: C, 71.49; H, 6.63; N, 4.39. Found: C, 71.45; H, 6.60; N, 4.38%. FT-IR (KBr): *v* 3329(s), 3093(s), 2920(s), 2814(m), 1514(vs), 1449(s), 1354(w), 1105(vs), 1001(s), 809(vs) cm^{-1}. ^1H NMR($CDCl_3$): δ 1.88(s, 1H, NH), 2.11(s, 3H, Ar—CH_3), 3.47(s, 2H, H11), 3.71(s, 2H, H12), 3.80(d, 2H, H2, H5), 4.09(s, 5H, η^5-C_5H_5), 4.13(t, 2H, H3, H4), 6.85–7.23 (AA′XX′, 4H, H15, H17, H14, H18) ppm.

4.2.4. [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH_2NHCH_2C_6H_4Cl$-4)] (**4d**)

4d was prepared with the same procedure as that for **4b**. Yellow liquid. Yield 80%. *Anal*. Calc. for $C_{18}H_{18}ClFeN$: C, 63.65; H, 5.34; N, 4.12. Found: C, 63.41; H, 5.24; N, 4.11%. FT-IR (KBr): *v* 3298(w), 3086(s), 2911(s), 2828(m), 1487(m), 1452(s), 1104(vs), 1000(vs), 818(vs) cm^{-1}. ^1H NMR($CDCl_3$): δ 1.90(s, 1H, NH), 3.49(s, 2H, H11), 3.72(s, 2H, H12), 3.81(d, 2H, H2, H5), 4.11(s, 5H, η^5-C_5H_5), 4.15(t, 2H, H3, H4), 6.93–7.45 (AA′XX′, 4H, H14, H18, H15, H17) ppm.

4.2.5. [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH_2N(CH_3)$-$CH_2C_6H_4CH_3$-4)] (**5b**)

5b was prepared according to the literature method [9]. Yellow solid. Yield 80%. M.p. 32–34 °C. *Anal*. Calc. for $C_{20}H_{23}FeN$: C, 72.08; H, 6.96; N, 4.20. Found, C, 71.99; H, 6.94; N, 4.21%. FT-IR (KBr): *v* 3091(w), 2928(w), 1513(s), 1453(s), 1361(w), 1105(s), 1020(vs), 805(vs) cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.12(s, 3H, Ar—CH_3), 2.34(s, 3H, N—CH_3), 3.40(s, 2H, H11), 3.43(s, 2H, H12), 4.09(s, 5H, η^5-C_5H_5), 4.12(m, 2H, H2, H5), 4.18(d, 2H, H3, H4), 7.20–7.28 (AA′XX′, 4H, H15, H17, H14, H18) ppm.

4.2.6. [(η^5-C_5H_5)Fe(η^5-$C_5H_4CH_2N(CH_3)$-$CH_2C_6H_4Cl$-4)] (**5d**)

5d was prepared with the same procedure as that for **5b**. Yellow solid. Yield 72%. M.p. 38–40 °C. *Anal*. Calc. for $C_{19}H_{20}ClFeN$: C, 64.52; H, 5.70; N, 3.96: Found, C, 64.33; H, 5.68; N, 3.95%. FT-IR (KBr): *v* 3085(m), 2929(s), 2834(s), 1492(s), 1452(s), 1361(w), 1105(s), 1022(vs), 1000(vs), 818(vs) cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.12(s, 3H, N—CH_3), 3.42(s, 4H, H11, H12), 4.06(s, 5H, η^5-C_5H_5), 4.10(m, 2H, H2, H5), 4.16(d, 2H, H3, H4), 7.12–7.19 (AA′XX′, 4H, H14, H18, H15, H17) ppm.

4.3. Synthesis of σ-Pt[(η^5-C_5H_5)Fe(η^5-$C_5H_3CH_2N(CH_3)$-$CH_2C_6H_4$-R-4)]Cl(DMSO) (**6a–e**)

General procedure: To a stirred solution of amine (0.5 mmol) in methanol (20 cm^3) was added *cis*-[Pt($DMSO)_2Cl_2$] (105 mg, 0.25 mmol). The mixture was stirred and refluxed for 30 min under nitrogen and cooled down to room temperature. The solvent was removed in vacuo and water was then added. The mixture was extracted with dichloromethane (3×30 cm^3) and separated. The organic layer was dried over anhydrous sodium sulfate and filtered. Removal of solvent gave the crude product which was further purified by column chromatography (silica gel, ethyl acetate/hexane = 1:5 (v/v)) to afford **6**.

4.3.1. σ-Pt[(η^5-C_5H_5)Fe(η^5-$C_5H_3CH_2N(CH_3)$-$CH_2C_6H_4OCH_3$-4)]Cl(DMSO) (**6a**)

Yellow powder. Yield 65%. M.p. 218–220 °C. *Anal*. Calc. for $C_{22}H_{28}ClFeNO_2PtS$: C, 40.22; H, 4.30; N, 2.13. Found: C, 40.18; H, 4.29; N, 2.13%. FT-IR (KBr): *v* 3091(w), 1610(s), 1511(vs), 1455(m), 1253(s), 1132(s, S═O), 1101(m), 1000(m), 819(s) cm^{-1}. Far IR (Nujol): *v* 272(Pt—Cl), 352(Pt—S) cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.02(s, 3H, H21), 3.18(s, 3H, OCH_3), 3.55(m, 8H, H19, H20, H11), 3.72(AB, 2H, $J = 14.8$ Hz, H12), 3.82(d, 1H, $J_{Pt-H} = 33.2$ Hz, H5), 4.00(s, 5H, η^5-C_5H_5), 4.11(m, 1H, H4), 4.22(s, 1H, H3), 6.86–6.94 (AA′XX′, 4H, H15, H17, H14, H18) ppm.

4.3.2. σ-Pt[(η^5-C_5H_5)Fe(η^5-$C_5H_3CH_2N(CH_3)$-$CH_2C_6H_4CH_3$-4)]Cl(DMSO) (**6b**)

Yellow powder. Yield 60%. M.p. 184–186 °C. *Anal.* Calc. for $C_{22}H_{28}ClFeNOPtS$: C, 41.23; H, 4.40; N, 2.19. Found: C, 41.18; H, 4.38; N, 2.18%. FT-IR (KBr): *v* 3094(w), 2917(w), 1457(m), 1411(s), 1132(vs, S=O), 1103(m), 1000(m), 807(s) cm^{-1}. Far IR (Nujol): *v* 273(Pt—Cl), 353(Pt—S) cm^{-1}. ^{1}H NMR ($CDCl_3$): *δ* 2.32(s, 3H, Ar—CH_3), 2.81(s, 3H, H21), 3.53(s, 3H, H19), 3.57(s, 3H, H20), 3.62(AB, 2H, $J = 12.8$ Hz, H11), 4.04(AB, 2H, $J = 14.8$ Hz, H12), 4.12(s, 5H, η^5-C_5H_5), 4.16(d, 1H, $J_{Pt-H} = 33.2$ Hz, H5), 4.25(m, 1H, H4), 4.31(s, 1H, H3), 6.89–7.77 (AA′XX′, 4H, H15, H17, H14, H18) ppm.

4.3.3. σ-Pt[(η^5-C_5H_5)Fe(η^5-$C_5H_3CH_2N(CH_3)$-CH_2-C_6H_5)]Cl(DMSO) (**6c**)

Yellow powder. Yield 56%. M.p. 210–212 °C. *Anal.* Calc. for $C_{21}H_{26}ClFeNOPtS$: C, 40.24; H, 4.18; N, 2.23. Found: C, 40.19; H, 4.16; N, 2.20%. FT-IR (KBr): *v* 3092(w), 1559(w), 1457(m), 1130(vs, S=O), 1102(m), 1000(m) cm^{-1}. Far IR (Nujol): *v* 274(Pt—Cl), 353(Pt—S) cm^{-1}. ^{1}H NMR ($CDCl_3$): *δ* 1.55(s, 3H, H21), 2.83(s, 3H, H21), 3.54(s, 3H, H19), 3.57(s, 3H, H20), 3.62(AB, 2H, $J = 12.8$ Hz, H11), 4.10(AB, 2H, $J = 14.8$ Hz, H12), 4.13(s, 5H, η^5-C_5H_5), 4.21(d, 1H, $J_{Pt-H} = 33.2$ Hz, H5), 4.29(m, 1H, H4), 4.34(s, 1H, H3), 7.04–7.94 (m, 5H, H14, H15, H16, H17, H18) ppm.

4.3.4. σ-Pt[(η^5-C_5H_5)Fe(η^5-$C_5H_3CH_2N(CH_3)$-$CH_2C_6H_4Cl$-4)]Cl(DMSO) (**6d**)

Yellow powder. Yield 55%. M.p. 181–183 °C. *Anal.* Calc. for $C_{21}H_{25}Cl_2FeNOPtS$: C, 38.14; H, 3.81; N, 2.12. Found: C, 38.00; H, 3.78; N, 2.11%. FT-IR (KBr): *v* 3081(w), 2915(w), 1455(m), 1407(w), 1130(vs, S=O), 1103(m), 1002(m), 806(m) cm^{-1}. Far IR (Nujol): *v* 272(Pt—Cl), 352(Pt—S) cm^{-1}. ^{1}H NMR ($CDCl_3$): *δ* 2.91(s, 3H, H21), 3.49(s, 3H, H19), 3.55(s, 3H, H20), 3.60(AB, 2H, $J = 12.8$ Hz, H11), 4.02(AB, 2H, $J = 14.8$ Hz, H12), 4.12(s, 5H, η^5-C_5H_5), 4.15(d, 1H, $J_{Pt-H} = 33.2$ Hz, H5), 4.24(m, 1H, H4), 4.30(s, 1H, H3), 7.94–8.27 (AA′XX′, 4H, H14, H18, H15, H17) ppm.

4.3.5. σ-Pt[(η^5-C_5H_5)Fe(η^5-$C_5H_3CH_2N(CH_3)$-$CH_2C_6H_4NO_2$-4)]Cl(DMSO) (**6e**)

Yellow powder. Yield 40%. M.p. 176–179 °C. *Anal.* Calc. for $C_{21}H_{25}ClFeN_2O_3PtS$: C, 37.54; H, 3.75; N, 4.17. Found: C, 37.44; H, 3.73; N, 4.16%. FT-IR (KBr): *v* 3092(w), 2914(w), 1522(vs), 1458(m), 1344(s), 1137(m, S=O), 1103(m), 1000(m), 810(m) cm^{-1}. Far IR (Nujol): *v* 271(Pt—Cl), 352(Pt—S) cm^{-1}. ^{1}H NMR ($CDCl_3$): *δ* 2.84(s, 3H, H21), 3.51(s, 3H, H19), 3.58(s, 3H, H20), 3.64(AB, 2H, $J = 12.8$ Hz, H11), 4.06(AB, 2H, $J = 14.8$ Hz, H12), 4.14(s, 5H, η^5-C_5H_5), 4.18(d, 1H, $J_{Pt-H} = 33.2$ Hz, H5), 4.27(m, 1H, H4), 4.33(s, 1H, H3), 8.22–8.38 (AA′XX′, 4H, H14, H18, H15, H17) ppm.

4.4. X-ray determination of **6a**

The prismatic single crystal of **6a** suitable for X-ray analysis was obtained by slow evaporation of a mixture of ethyl acetate and hexane at room temperature over a period of one week. This single crystal was mounted on a Bruker SMART CCD diffractometer equipped with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation at ambient temperature ($T = 293$ K) using the *ω*-2*θ* multi-scans technique for data collection. Semi-empirical absorption corrections were applied using the SABABS program [15]. The structure was solved by direct methods and refined by full-matrix least-squares procedure on F^2 using the SHELX suite of programs [16].

5. Supplementary materials

Crystallographic data (excluding structure factors) for the structure of **6a** in this paper has been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 286580. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +144 1223 336033 or e-mail: deposit@ccdc.cam.ac.uk).

$(PPh_3)_2](ReO_4)\cdot\frac{1}{2}H_2O$ ($\mathbf{2}\cdot\frac{1}{2}H_2O$). The reaction of $ReOCl_3(AsPh_3)(OAsPh_3)$] with 1,10-phenanthroline in acetone leads to the [$ReOCl_3$(phen)] complex. Similarly, the diimine ligands pyox and pyth react with [$ReOCl_3(PPh_3)_2$] in benzene to give oxo species of the [$ReOCl_3$(N–N)] type [11]. However, the refluxing of [$ReOCl_3(PPh_3)_2$] with phen in ethanol affords [$ReCl_2$(phen)$(PPh_3)_2$](ReO_4) (**2**). Likewise, the complexes with biimidazole and 2(2-pyridyl)benzimidiazole, $[ReX_2(PPh_3)_2(biimH_2)]^+$ and $[ReX_2(PPh_3)_2$-(pbimz)]$^+$, are obtained from [$ReOX_2$(OEt)$(PPh_3)_2$] or [$ReOX_3(PPh_3)_2$] and the ligand [12,13]. It can be supposed that an endeavour in this area would lead to a new families of variable-valence rhenium compounds.

The electronic structures of **1** and **2** have been determined on the basis of results of density functional theory (DFT) calculations. The spin-allowed electronic transitions of the $[ReCl_2(phen)(PPh_3)_2]^+$ cation, ReO_4^- anion and [$ReOCl_3$(phen)] complex have been calculated with the the time-dependent DFT method (TDDFT), and the UV–Vis spectra of the title compounds have been discussed on this basis.

The recent calculations with the TD-DFT method for open- and closed-shell 5d-metal complexes (including rhenium complexes) have supported the TD-DFT method to be applicable for such systems giving good assignment of experimental spectra [14–16].

2. Experimental

2.1. General procedure

All the reagents used in the synthesis were commercially available and were used without further purification. The $ReOCl_3(AsPh_3)(OAsPh_3)$] and [$ReOCl_3(PPh_3)_2$] complexes were prepared according to the literature methods [17,18].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV-VIS 8500 in the range 900–200 nm in deoxygenated dichloromethane solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of [$ReOCl_3$(phen)] (1)

A mixture of $ReOCl_3(AsPh_3)(OAsPh_3)$] (0.5 g, 0.53 mmol), phen (0.20, 1.0 mmol) and acetone (50 ml) was stirred for 12 h. 30 ml of acetone was distilled off and 100 ml of diethyl ether was added. [$ReOCl_3$(phen)] was filtered off, washed with ethanol, diethyl ether and dried. Yield 70%. The green crystals of **1** for X-ray investigation were obtained by recrystallization from acetonitrile.

IR (KBr): 1628 (w), 1605(m), 1575 (w), 1520 (m) ν_{CN} and $\nu_{C=C}$; 985 (s) $\nu_{Re=O}$.

Anal. Calc. for $C_{12}H_8Cl_3N_2ORe$: C, 29.49; H, 1.65; N, 5.73. Found: C, 29.45; H, 1.55; N, 5.80%.

2.3. Preparation of [$ReCl_2$(phen)$(PPh_3)_2$](ReO_4) (2)

[$ReOCl_3(PPh_3)_2$] (0.83 g, 1 mmol) was added to phenanthroline (0.40 g, 2.0 mmol) in ethanol (100 ml) and the reaction mixture was refluxed overnight. 60 ml of ethanol was distilled off and 100 ml of diethyl ether was added and the precipitate of **2** was collected by filtration. Yield 50%.

Red crystals of water solvate $\mathbf{2}\cdot\frac{1}{2}H_2O$ were obtained by slow evaporation of a chloroform–ethanol solution of **2** in air.

IR (KBr): 1633 (m, br), 1570 (w) ν_{CN} and $\nu_{C=C}$; 1480 (m) δ(C–CH in the plane); 1438 $\nu_{Ph(P-Ph)}$; 912(vs) $\nu_{Re=O(ReO4)}$. *Anal.* Calc. for $C_{48}H_{38}Cl_2N_2O_4P_2Re_2$: C, 47.56; H, 3.16; N, 2.31. Found: C, 47.8; H, 3.25; N, 2.41%.

2.4. Crystal structure determination and refinement

The X-ray intensity data of **1** and $\mathbf{2}\cdot\frac{1}{2}H_2O$ were collected on a KM-4-CCD automatic diffractometer equipped with a CCD detector. 32 and 38 s exposure time was used, respectively, and reflections were collected up to $\theta = 25°$. The unit cell parameters were determined from least-squares refinement of the setting angles of 4065 and 4325 strongest reflections, respectively, for **1** and $\mathbf{2}\cdot\frac{1}{2}H_2O$. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and numerical absorption corrections [19] were applied. The structure was solved by the Patterson method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix, least-squares technique. The hydrogen atoms were treated as ''riding'' on their parent carbon atoms and assigned isotropic temperature factors equal to 1.2 times the value of equivalent temperature factor of the parent atom. SHELXS97 [20], SHELXL97 [21] and SHELXTL [22] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

3. Computational details

The GAUSSIAN03 program [23] was used in the calculations. The geometry optimisations of the $[ReCl_2(phen)(PPh_3)_2]^+$ cation, ReO_4^- anion and [$ReOCl_3$-(phen)] complex were carried out with the DFT method with the use of the B3LYP functional [24,25]. The electronic spectra of the $[ReCl_2(phen)(PPh_3)_2]^+$ cation, ReO_4^- anion and [$ReOCl_3$(phen)] complex were calculated with the TDDFT method [26]. The LANL2DZ basis set [27] with additional d (with exponent $\alpha = 0.3811$) and f (with exponent $\alpha = 2.033$) functions was used on the rhenium, 6-31g* on the chlorine, phosphorous, nitrogen and carbon atoms and 6-31g basis on the hydrogen atoms in the calculations.

Natural bond orbital (NBO) calculations were performed with the NBO code [28] included in Gaussian03.

Table 1
Crystal data and structure refinement for the complexes **1** and **2** · $\frac{1}{2}H_2O$

	1	**2** · $\frac{1}{2}H_2O$

3.1. Magnetic measurement

The magnetic measurements of the powdered samples were measured over the temperature range 1.8–300 K using a Quantum Design SQUID – based MPMSXL-5-type magnetometer. The superconducting magnet was generally operated at a field strength ranging from 0 to 5 T. Measurements of samples of the compounds were made at a magnetic field of 0.5 T.

The SQUID magnetometer was calibrated with a palladium rod sample. Corrections are based on subtracting the sample-holder signal and contribution χ_D estimated from the Pascal constants [29], equal to 610×10^{-6} cm^3 mol^{-1} for the complex $[ReCl_2(phen)(PPh_3)_2](ReO_4)$ (**2**). The effective magnetic moment was calculated from the equation $\mu_{eff} = 2.83(\chi_M T)^{1/2}$ (BM).

4. Results and discussion

4.1. Preparation

Treatment of the *mer*,*cis*-$[ReOCl_3(AsPh_3)(OAsPh_3)]$ oxo compound with an excess of 1,10-phenanthroline in acetone at ambient temperature leads to the $[ReOCl_3(phen)]$ complex (**1**), whereas the refluxing of *mer*,*trans*-$[ReOCl_3(PPh_3)_2]$ with phen in ethanol affords $[ReCl_2(phen)(PPh_3)_2](ReO_4)$ (**2**). The formation of **2** is accompanied by disproportionation of Re(V) into Re(III) and Re(VII), similar to that taking place in the synthesis of $[Re(bipy)_3](ReO_4)_2$ from K_2ReF_6 and bipy [30].

4.2. Infrared data

The IR spectrum of **1** exhibits a strong band at 985 cm^{-1} assignable to the ν(Re=O) mode. This value compares well with those reported for rhenium(V) complexes containing a chelating ligand in the coordination sphere: $[ReOBr_3(dppen)]$ [dppen = *cis*-$Ph_2PCH{=}CHPPh_2$] – 984 cm^{-1}, $[ReOBr_3(dppm)]$ [dppm = $Ph_2PCH_2PPh_2$] – 980 cm^{-1} and $[ReOBr_3(dppe)]$ [dppe = $Ph_2PCH_2CH_2PPh_2$] – 982 cm^{-1} [31]. A strong absorption band at 912 cm^{-1} in the IR spectrum of **2** corresponds to the ν(Re=O) mode of the perrhenate anion and its location is in agreement with the literature value of ν_3(Re–O) 918 cm^{-1} for ReO_4^- [32].

The characteristic bands corresponding to the ν(CN), ν(C=C) modes of the phen ligand appear in the range 1640–1570 cm^{-1} in the IR spectra of complexes **1** and **2**.

4.3. Crystal structures

The complex **2** crystallises as the solvate **2** · $\frac{1}{2}H_2O$, with a water molecule multipositionally disordered around the special position b of the $P\bar{1}$ space group at 0, 0, $\frac{1}{2}$ (one water molecule per unit cell). The crystal data for **1** and **2** · $\frac{1}{2}H_2O$ are given in Table 1. The molecular structures of **1** and **2** are presented in Figs. 1 and 2, respectively. For complex **2** · $\frac{1}{2}H_2O$, there are no significant contacts involving either the cation or anion, with the possible exception of some rather weak hydrogen bonds from the perrhenate anion to the phenyl rings. The weak intra- and intermolecular hydrogen bonds [33,34] of **1** and **2** · $\frac{1}{2}H_2O$ are presented in Table 2. The most important angles and bond lengths for **1** and **2** are reported in Tables 3 and 4, respectively.

The rhenium atom in **1** is in a distorted octahedral environment with the three chloride ligands arranged in a *meridional* fashion. The pseudooctahedral environment of the Re center in **1** shows clear distortions, induced by the multiple bonding ligand (oxo) and narrow bite angle of the chelating 1,10-phenanthroline. The high concentration

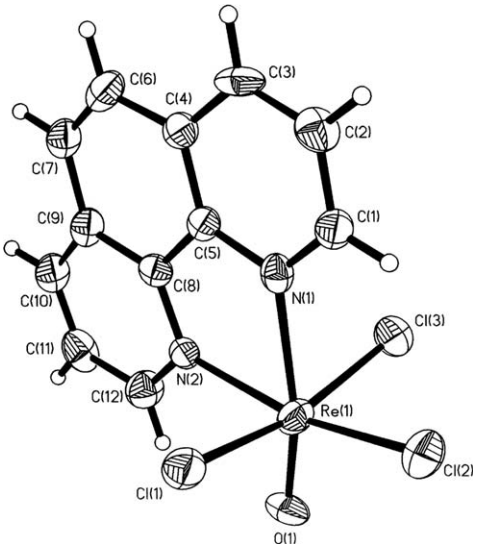

Fig. 1. The molecular structure of $[ReOCl_3(phen)]$.

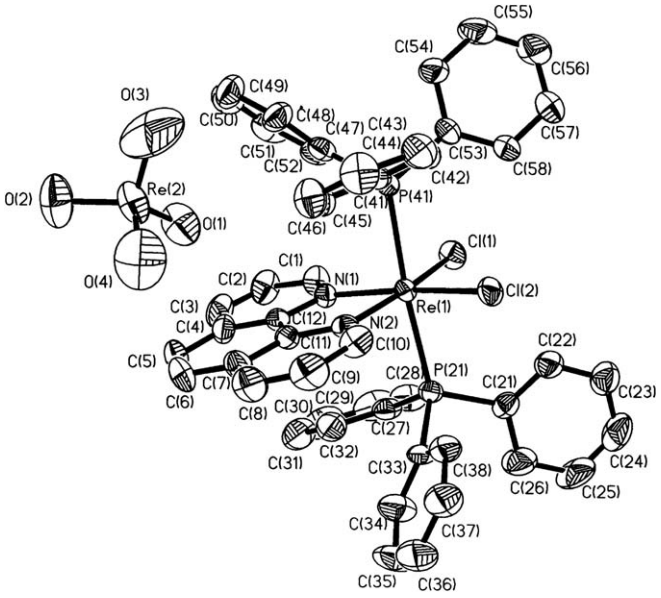

Fig. 2. The molecular structure of $[ReCl_2(phen)(PPh_3)_2](ReO_4)$.

of electronic density along the Re–O axis strongly influences the positions of the adjacent chlorine atoms, which are pushed away – the mean of the O–Re–Cl angles is 99.5°. This also can explain the local electron density distortion inside the rhenium radii [35] (the highest peak and deepest hole on the difference Fourier synthesis are located respectively at 0.87 and 0.76 Å from rhenium atom centre). The Re–O bond in **1** is a typical example of reported terminal multiple $Re–O_{oxo}$ distances in mononuclear $[ReO]^{3+}$ compounds and indicates the presence of a triple Re≡O bond [36]. The Re(1)–N(1) distance is affected by the *trans* influence of the oxo ligand and therefore it is significantly longer than the Re–N(2) bond length located in a *trans* position to the chloride ligand. The large structural *trans* effect of the oxo ligand has been documented for many transition metal complexes [37]. The shortest Re···Re distance is 5.916 Å (second Re atom obtained by x, $-y+1/2$, $z+1/2$ symmetry transformation).

The chloride ions and phen molecule of the $[ReCl_2(phen)(PPh_3)_2]^+$ cation in the structure $\mathbf{2}\cdot\frac{1}{2}H_2O$ hold

the equatorial positions. The axial positions of the distorted octahedron of the cation are occupied by triphenylphosphine molecules. Likewise in **1**, the narrow phen bite angle causes a strong departure from an ideal octahedron. The Re–N bond lengths (2.119(5) and 2.120(5) Å) of the title complex are similar to those found for the rhenium(III) polypyridyl compounds: in $[ReCl_2(bipy)_2]PF_6$ – 2.094(5) and 2.096(5) Å [38] and in the $[ReL(terpy)_2]^{2+}$ (L = Cl, OH, NCS) complexes – about 2.10 Å [39]. These values are significantly shorter than comparable distances for saturated amine complexes, where metal-to-ligand π-back bonding is not possible, for instance, the Re–NH_2 distance in the compound $[Re(N_2)(ampy)(tbpy)(PPh_3)]PF_6$ is 2.197(7) [40]. A lengthening of the Re–N_{phen} distances in the Re(V) complex (2.143(9) and 2.260(10) Å) in comparison with **2** is consistent with the notion of the greatest M–L back bonding occurring when the metal is most electron-rich. The shortest Re···Re distance is 5.914 Å (first Re(2) atom and second Re(2) atom obtained by $-x$, $-y$, $-z$ symmetry transformation).

4.4. Geometry optimisation

The geometries of **1** and **2** were optimised by the DFT method with the B3LYP functional. For the $[ReCl_2(phen)(PPh_3)_2]^+$ cation, the geometry optimisation was carried out in triplet and singlet states. The energy of the singlet state is 13.8 kcal higher. The geometries of $[ReOCl_3(phen)]$ and ReO_4^- were optimised in a singlet state. The optimised geometric parameters of **1** and **2** are gathered in Tables 3 and 4, respectively. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

4.5. Charge distribution and NBO analysis

Table 5 presents the atomic charges from the natural population analysis (NPA) for complexes **1** and **2**. The calculated charges on the rhenium atoms in $[ReOCl_3(phen)]$, $[ReCl_2(phen)(PPh_3)_2]^+$ and ReO_4^- are considerable lower than the formal charges +5, +3 and +7. This is a result of significant charge donation from the ligands. There are large positive charges on the P atoms, and the negative charges on the chloride and oxo ligands are significantly smaller than −1 and −2, respectively.

Three natural bond orbitals were detected for the Re–O bond in complex **1**. Each natural bond orbital (NBO) σ_{AB}

Table 5

Table 6
The occupancies and hybridization of the calculated natural bond orbitals (NBOs) between the rhenium and the oxo ligands for **1**

BD	Occupancy	Hybridization of NBO	BD*	Occupancy
Re–O_t	1.968	$0.496(sd^{4.22})_{Re} + 0.868(sp^{2.21})_O$	$0.868(sd^{4.22})_{Re} - 0.496(sp^{2.21})_O$	0.264
Re–O_t	1.884	$0.519(d)_{Re} + 0.855(p)_O$	$0.855(d)_{Re} - 0.519(p)_O$	0.243
Re–O_t	1.968	$0.563(d)_{Re} + 0.826(p)_O$	$0.826(d)_{Re} - 0.563(p)_O$	0.251

BD denotes 2-center bond. * denotes antibond NBO.

can be written in terms of two directed valence hybrids (HHOs) h_A and h_B on atoms A and B:

$$\sigma_{AB} = c_A h_A + c_B h_B$$

where c_A and c_B are polarization coefficients. Each valence bonding NBO must in turn be paired with a corresponding valence *anti*-bonding NBO:

$$\sigma^*_{AB} = c_B h_A - c_A h_B$$

to complete the span of the valence space [41]. In the case of the $[ReOCl_3(phen)]$ complex, three Re–O_t natural bond orbitals were detected. The occupancies and hybridization of the calculated Re–O_t natural bond orbitals (NBOs) are given in Table 6. The σ and π Re–O bonds are clearly polarized towards the oxygen end. The s and p oxygen orbitals and s and d rhenium orbitals take part in the σ_{Re-Ot} bond formation, whereas the π_{Re-Ot} bond orbitals result from overlapping of the empty d_{xy} and d_{yz} rhenium orbitals with the occupied p_x and p_z orbitals of the terminal oxygen ligands.

The Re–N natural bonds were not detected in **1** and $[ReCl_2(phen)(PPh_3)_2]^+$, indicating predominant Coulomb-type interactions between the central ion and the phen ligand [42].

4.6. Electronic structure

The energies, characters and contours of several lowest unoccupied molecular orbitals (LUMO or L) and highest occupied molecular orbitals (HOMO or H) of **1** are presented in Figs. 3a and 3b, respectively. The HOMO–LUMO gap is 2.84 eV. The highest occupied MO of **1** is of d_{xz} type with antibonding contributions from p_π chlorine orbitals. The remaining four d-type orbitals of rhenium are found among unoccuppied MOs. It confirms the d^2 configuration of the rhenium atom. The rhenium–oxygen interac-

(For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

tion in **1** is described as a triple bond. The $\pi_{Re\equiv O}$ bonds arise from overlap of the two occupied oxygen p_π orbitals with the empty d_{xy} and d_{xz} metal orbitals. The contribution of the π^*_{Re-O} orbitals are visible in the LUMO, LUMO + 1 and LUMO + 3 orbitals. The LUMO and LUMO + 3 orbitals, however, also have an admixture of π-antibonding phenanthroline orbitals. The percent participations of the atomic orbitals in the HOMO and LUMO orbitals are given in round brackets. The LUMO + 5 and LUMO + 7 orbitals are predominantly of d_{z^2} and $d_{x^2-y^2}$ rhenium orbital character, respectively.

The energies and characters of several highest occupied and lowest unoccupied α(spin-up) and β(spin-down) molecular orbitals of $[ReCl_2(phen)(PPh_3)_2]^+$ are presented in Table 7. The percent participations of the atomic orbitals in the molecular orbitals are given in round brackets. The selected α molecular orbitals of $[ReCl_2(phen)(PPh_3)_2]^+$ are depicted in Fig. 4. The d_{xz}, d_{yz} and d_{xy} metal orbitals make main contributions into the HOMO − 3, HOMO − 1 and HOMO with α spin and HOMO, LUMO and LUMO + 1 with β spin. In all these molecular orbitals, the d_{xz}, d_{yz} and d_{xy} rhenium orbitals bear antibonding character towards the p_π orbitals of the chloride ligands. The remaining two d-type orbitals of rhenium are found among unoccuppied MOs of high energy. It confirms the $(d_{xz})^2(d_{yz})^1(d_{xy})^1$ configuration of the rhenium atom in the $[ReCl_2(phen)(PPh_3)_2]^+$ cation. The HOMO − 3, and HOMO with α spin and LUMO with β spin also display some contribution of π-antibonding phenyl orbitals, whereas the HOMO with β spin has admixture of π_{phen} orbitals. The LUMO orbital with α-spin has predominantly π^*phen character. In some of the lowest unoccupied molecular orbitals of $[ReCl_2(phen)(PPh_3)_2]^+$, the contribution of the phosphorous orbitals is visible. In classical

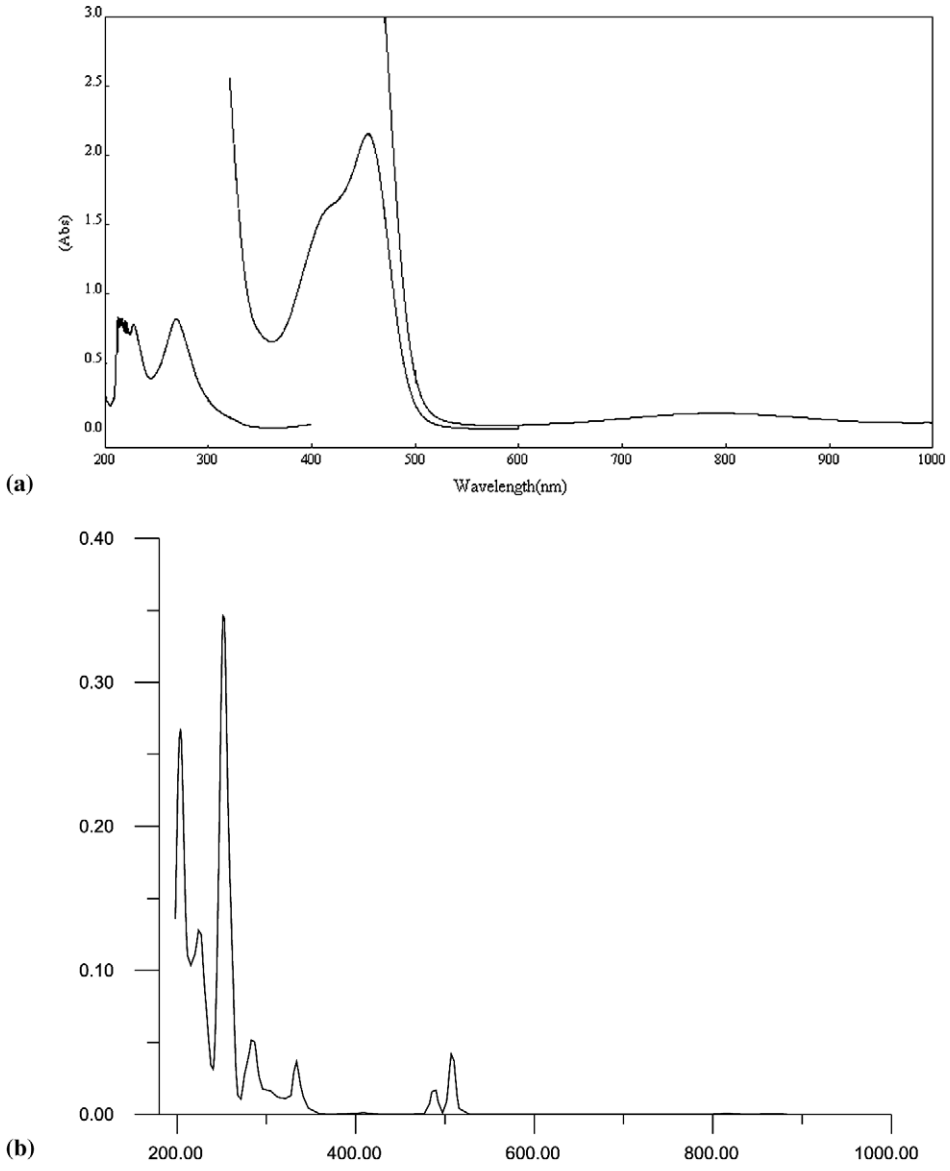

Fig. 5. The experimental (a) and calculated (b) electronic absorption spectra of **1**.

concepts, empty phosphorous 3d orbitals are used in π-back bonding between the metal center and the phosphine ligand. Now it is generally recognised that the d orbitals are very high in energy and play only a minor role in π_{M-PR3} bond formation [43]. In the π-back bonding between the metal center and the phosphine ligand are involved the σ^*(P–C) orbitals.

4.7. Electronic spectra

The experimental electronic spectra of **1** and **2** are presented in Figs. 5a and 6a, respectively. Figs. 5b and 6b present the calculated electronic spectra of $[ReOCl_3(phen)]$ and $[ReCl_2(phen)(PPh_3)_2]^+$. Each calculated transition in Figs. 5b and 6b was represented by a gaussian function $y = ce^{-bx^2}$ with height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}.

For the perrhenate anion, electronic transitions of π(O) → d character were calculated at ~225 and 197 nm.

Tables 8 and 9 present the position of the experimental absorption bands of **1** and **2** and the spin-allowed electronic transitions calculated with the TDDFT method for $[ReOCl_3(phen)]$ and $[ReCl_2(phen)(PPh_3)_2]^+$, respectively. The calculations result in many transitions with very small oscillator strengths. Except for the low energy part of the spectrum, only transitions with oscillator strengths larger than 0.010 for **1** and 0.005 for **2** are listed in Tables 8 and 9.

The assignment for complex **2** is not complete. The $[ReCl_2(phen)(PPh_3)_2]^+$ cation is of large size (882 basis

ε – molar absorption coefficient ($dm^3\ mol^{-1}\ cm^{-1}$).
f – oscillator strength.
H – highest occupied molecular orbital.
L – lowest unoccupied molecular orbital.

functions), and 90 calculated electron transitions do not comprise all the experimental absorption bands. As solution spectra of PPh_3 and 1,10-phenanthroline exhibit intense absorption bands in 260–200 nm region, some additional intraligand and interligand transitions are expected to be found at higher energies in the calculations for $[ReCl_2(phen)(PPh_3)_2]^+$.

The assignment of the calculated transitions to the experimental bands is based on the criterion of the energy and oscillator strength of the calculated transitions. In the description of the electronic transitions the main components of the molecular orbital are used.

The UV–Vis spectrum of **1** exhibits a few intense absorption bands in the range 500–200 nm and a weak absorption in the low energy range, at 807.4 nm.

The longest wavelength experimental band of **1** is attributed to the transitions of d → d character with small oscillator strengths, calculated at 869.0 and 817.3 nm.

The absorption bands at 459.6 and 416.6 nm are assigned to the electronic transitions calculated at 508.0 and 487.7 nm, respectively. They have MLCT (metal–ligand charge transfer) character and originate from the d_{Re} orbitals to the π^*_{phen} orbitals.

The experimental bands below 300 nm result from ligand–metal charge transfer: (π(Br)/π(O)/π(phen) → d) and ligand–ligand charge transfer: (π(Br)/π(O)/π(phen) → π*(phen) transitions. Nevertheless, the main contribution can be assigned to the LLCT excitations. The oscillator strengths of the LLCT transitions are considerable larger than those of LMCT transitions.

ε – molar absorption coefficient ($dm^3\ mol^{-1}\ cm^{-1}$).
f – oscillator strength.
H – highest occupied molecular orbital.
L – lowest unoccupied molecular orbital.

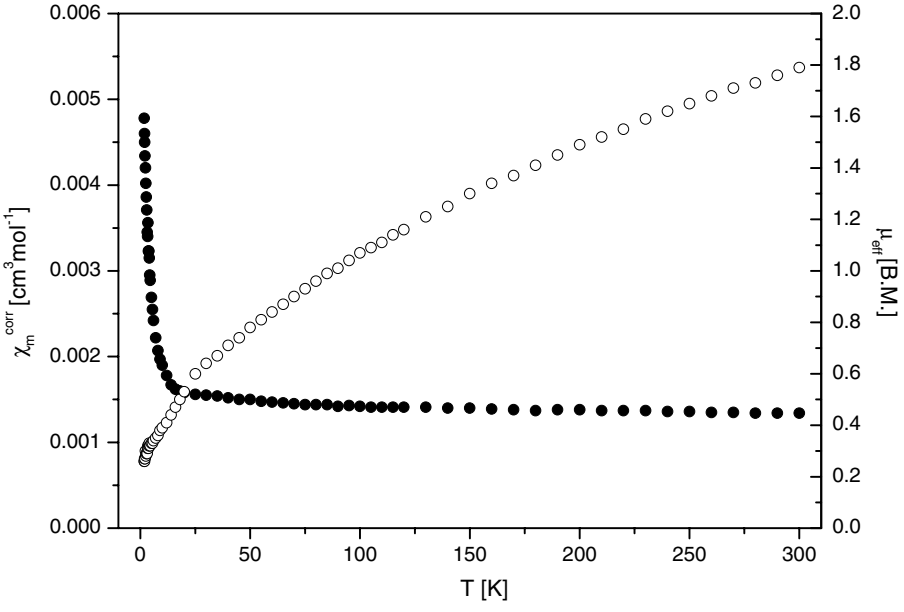

Fig. 7. Plots of the experimental magnetic data χ_M (•) and μ_{eff} (○) vs. T for the complex $[ReCl_2(phen)(PPh_3)_2](ReO_4)$ (**2**).

The broad intense asymmetric experimental band of **2** with a maximum at 540.8 nm is attributed to the three electronic transitions calculated at 638.2, 629.9 and 565.8 nm. The first one has LMCT and originates from triphenylphosphine orbitals to the d_{yz} rhenium orbital. The next two calculated excitations are of $d \rightarrow \pi^*_{phen}$ (MLCT) character.

The MLCT transitions from the d rhenium orbitals to the π^*_{phen} orbitals and LMCT excitations from triphenylphosphine orbitals to the d_{Re} orbitals are also responsible for the experimental bands at 411.0 and 331.0 nm. The LF (ligand field) electronic transitions calculated in the range 395–330 nm have small oscillator strengths and they do not contribute significantly to the overall shape of the absorption band at 331 nm.

4.8. Magnetic properties

The magnetic properties of the $[ReCl_2(phen)(PPh_3)_2](ReO_4)$ (**2**) complex under the form χ_M versus T and μ_{eff} versus T (χ_M being the molar magnetic susceptibilities and μ_{eff} the effective magnetic moment) are shown in Fig. 7. The rhenium(III) complex shows a room temperature magnetic moment of 1.79 BM (0.401 $cm^3\,mol^{-1}\,K$). The magnetic moment of the solid complex is temperature independent between 300 and 90 K. This value is characteristic of a mononuclear complex with low-spin rhenium(III) (d^4) ions in an O_h field ($^3T_{1g}$ ground state) [44–52] and arises because of the large spin–orbit coupling ($\zeta = 2500\ cm^{-1}$ [53]), which gives a diamagnetic ground state.

5. Supplementary data

Supplementary data for $C_{12}H_8Cl_3N_2ORe$ and $C_{48}H_{39}Cl_2N_2O_{4.50}P_2Re_2$ are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition numbers 297650 and 297651.

Acknowledgements

The Gaussian03 calculations were carried out in the Wrocław Centre for Networking and Supercomputing, WCSS, Wrocław, Poland.

The crystallographic part was financed by funds allocated by the Ministry of Scientific Research and Information Technology to the Institute of General and Ecological Chemistry, Technical University of Łódź.

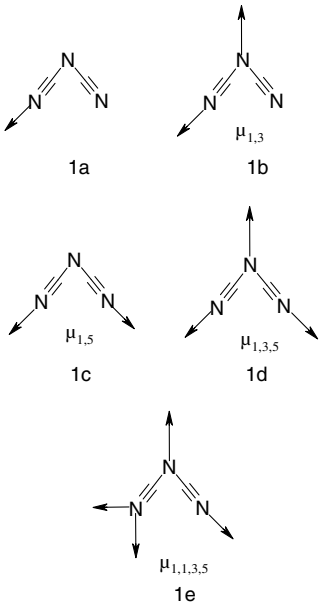

Scheme 1.

nitrogen, bidentate mode through two nitrile nitrogen atoms with end-to-end bridging, tris–monodentate bridging of three metal atoms, as well as an unusual μ-4 coordination where one nitrile nitrogen binds to two metal atoms. The coordination properties thus allow for the preparation of compounds with a large variety of architectures: mononuclear, dinuclear, as well as one-, two- and three-dimensional (nD, $n = 1$–3) networks [5] and therefore both its homo- and heteroleptic complexes have rich topologies and excellent magnetic properties [6]. A series of binary compounds of the general formula $[M^{II}(dca)_2]$, with a 3D rutile type structure, have gained much interest as several of these have been shown to be ferromagnetic (Co, $T_c = 9$ K; Ni, $T_c = 20$ K; Fe, $T_c = 19$ K), antiferromagnetic (Cr, $T_N = 47$ K; Mn, $T_N = 16$ K; Fe, $T_N = 19$ K) and paramagnetic [3]. Introduction of auxiliary ligands into the M^{II}–dca system has allowed the syntheses of several ternary systems, $[M^{II}L_x(dca)_y]$ (L = organic ligand, $x = 1$ or 2, $y = 1$ or 2), with a wide variety of topologies [7]. Coordination compounds with extended networks have been widely reported exhibiting different combinations of metallic cations, dipyridyl-type organic ligands and dca ligands [8]. A literature survey reveals the fact that dca-complexes in combination with 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tptz) are rare. We have chosen tptz for its flexible coordination sites [9]. We have recently reported some novel observations utilising dca in the synthesis of chain structures with single, symmetrical, $\mu_{1,5}$-dca bridged Cu(II) and Ni(II) polymers [10]. In the present work, we describe the syntheses and crystal structures of three new supramolecular frameworks with dca and the auxiliary ligand, 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tptz): $[Mn(ac)(tptz)(dca)(H_2O)] \cdot (H_2O)_2$ (**1**) (where ac = acetate anion), $[Zn(tptz)(dca)_2] \cdot (H_2O)_2$ (**2**) and $[Cd_2(tptz)_2(dca)_2(H_2O)_2] \cdot (ClO_4)_2$ (**3**). To date, a number of higher-dimensional architectures of different transition metals have been reported using dca as a bridging ligand, but the number of dinuclear compounds with bridging dca, are scarce [11]. To the best of our knowledge, this is the first dinuclear complex of Cd(II) using dca as a bridging ligand.

2. Experimental

2.1. Physical techniques

The infrared spectra of the complexes were recorded on a Perkin–Elmer RX 1 FT-IR spectrometer with a KBr disc. The electronic spectrum of **1** was recorded on a Perkin–Elmer Lambda 40 (UV–Vis) spectrophotometer in methanol. Elemental analyses were carried out using a Perkin–Elmer 2400 II elemental analyser. The electrochemical study was performed on a CH 600A cyclic voltammeter instrument for complex **1** in dimethylformamide solvent and using tetrabutylammonium perchlorate as the supporting electrolyte. The magnetic susceptibility was measured on a powder sample in a vibrating sample magnetometer for **1** using mercury(tetrathiocyanato)cobaltate as the standard.

2.2. Materials

All the chemicals and solvents used for the syntheses were of reagent grade. Manganese acetate tetrahydrate, zinc nitrate hexahydrate, cadmium perchlorate hydrate (Merck), 2,4,6-tris(2-pyridyl)-1,3,5-triazine (Aldrich) and sodium dicyanamide ($NaN(CN)_2$) (Fluka) were used as received. *Caution*! Although no problems were encountered in this work, perchlorate salts are potentially explosive. They should be prepared in small quantities and handled with care.

2.3. Synthesis

2.3.1. Synthesis of $[Mn(ac)(tptz)(dca)(H_2O)] \cdot (H_2O)_2$ (**1**)

Complex **1** was synthesised by adding 1 mmol (0.312 g) of tptz to a solution of 1 mmol (0.246 g) of manganese acetate tetrahydrate in 10 ml of methanol, followed by the dropwise addition of 1 mmol (0.089 g) of sodium dicyanamide dissolved in the minimum quantity of water. The resulting clear yellow solution was filtered off and left to stand in air. After 3 days, yellow needles of **1** were obtained that were suitable for X-ray determination. Yield: 0.41 g (74.6%). *Anal.* Calc. for $C_{22}H_{21}MnN_9O_5$: C, 48.31; H, 3.84; N, 23.06. Found: C, 48.25; H, 3.79; N, 22.97%.

2.3.2. Synthesis of $[Zn(tptz)(dca)_2] \cdot (H_2O)_2$ (**2**)

Crystals of complex **2** were separated as a pale yellow crystalline solid by adding 1 mmol (0.089 g) aqueous solution of sodium dicyanamide to a methanolic solution containing a mixture of zinc nitrate hexahydrate (1 mmol, 0.297 g) and tptz (0.312 g, 1 mmol). Yield: 0.39 g (72%).

Anal. Calc. for $C_{22}H_{16}N_{12}ZnO_2$: C, 48.36; H, 2.93; N, 30.77. Found: C, 48.32; H, 2.87; N, 30.71%.

2.3.3. Synthesis of $[Cd_2(tptz)_2(dca)_2(H_2O)_2]\cdot(ClO_4)_2$ (**3**)

Complex **3** was obtained as pale yellow hexagonal crystals by the reaction of 20 ml methanolic solution containing cadmium perchlorate hydrate (0.311 g, 1 mmol) and tptz (0.312 g, 1 mmol) with 10 ml aqueous of sodium dicyanamide (0.089 g, 1 mmol). Yield: 0.46 g (75%). *Anal.* Calc. for $C_{20}H_{14}CdClN_9O_5$: C, 39.32; H, 2.30; N, 20.64. Found: C, 39.23; H, 2.26; N, 20.51%.

2.4. X-ray crystallography

Experimental details for **1** and **3** are given in Table 1. The data processing was performed by the Kappa CCD analysis software [12] and the lattice constants were refined by least-square refinement. No absorption correction was applied to the data sets. The unit-cell parameters, crystal system, space group and refinement details are summarised in Table 1. The structures were solved by direct methods (SIR97 program [13]) combined with Fourier difference syntheses and refined against F using reflections with $[I/\sigma(I) > 3]$ (CRYSTALS program [14]). All non-hydrogen atoms were successfully refined anisotropically.

Intensity data for **2** were collected on a Bruker SMART APEX diffractometer, equipped with a CCD area detector and graphite monochromated Mo-Kα radiation ($\lambda =$ 0.71073 Å), controlled by a Pentium-based PC running the SMART software package [15]. Single crystals were mounted and measured at room temperature. All data were corrected for Lorentz and polarization effects. Semi-empirical absorption corrections were applied using the SADABS program [16]. Both data processing programs were integrated with the Bruker SAINTPLUS program [17]. The structure was solved by the Patterson method, completed by difference Fourier techniques and refined by full-matrix least-squares on F^2 (SHELXL/97) [18] with initial isotropic, but subsequently anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined riding on carbon atoms with free isotropic displacement parameters. The hydrogen atoms of the two water molecules were located from the difference Fourier map, and their positions were refined with a restrained O–H = 0.9 Å distance [18]. Further details are given in Table 1.

3. Results and discussion

3.1. Description of the crystal structures

3.1.1. $[Mn(ac)(tptz)(dca)(H_2O)]\cdot(H_2O)_2$ (**1**)

The molecular structure of **1** is shown in Fig. 1. Selected bond distances and bond angles are presented in Table 2. Each manganese atom is hepta-coordinated, with a coordination polyhedron close to a pentagonal bipyramid. Hepta-coordination is achieved by means of three N atoms belonging to the tptz ligand (N10, N21 and N33) and two

oxygen atoms from the bidentate acetato ligand (O8 and O9), which determine the equatorial plane and finally the nitrogen N1 atom from the terminal dicyanamido ligand and a water molecule (O34) are in a *trans* disposition (yielding N1–Mn1–O34 as the *trans-axial* angle 177.48(13)°).

The shorter bond lengths, 2.184(5) and 2.137(3) Å, correspond to the axial positions occupied by the terminal monodentate dca ligand, Mn1–N1 and water molecule Mn1–O34, respectively, whereas the equatorial sites show similar bond lengths in the 2.291(3)–2.415(4) Å range which are more or less comparable to similar systems [9,19]. The deviation from ideal pentagonal-bipyramidal geometry is indicated by the difference in the basal angles which vary from 85.95(10)° to 55.76(9)°. The source of distortion primarily comes from the bites taken by the ligand, smaller than the ideal value of 72°, because of the constraint imposed in the five-membered chelate rings. Three kinds of bond angles may be found in the equatorial plane: the lower of 55.76(9)° corresponds to the bidentate acetate ligand O8–Mn1–O9 bond angle, two intermediate ones of 68.50(10)° and 68.26(11)° corresponding to the N(tptz)–Mn1–N(tptz) bond angles and two greater O(acetate)–Mn1–N(tptz) bond angles of 85.95(10)° and 82.58(9)°. These values are consistent with those found for related complexes [20]. The bond distance of Mn(II) to the middle nitrogen N21 is significantly shorter than the Mn1–N10 and Mn1–N33 distances, which is usually observed in tptz-type ligands [19]. The tptz ligand is almost planar; the angles between the central triazine ring and the attached pyridyl rings are 2.5(1)°, 2.1(1)° and 3.5(1)° which are in accordance with the values reported in the literature in related systems [9,21] and the tptz plane is inclined by an angle of 15.7(1)° to the bidentate acetate plane. In tptz, the $C(sp^2)$–$C(sp^2)$ distances within the ring are normal (1.45 Å) and the exterior bonds (C16–C15, 1.48(5) Å; C20–C28, 1.47(5) Å; C18–C22, 1.49(6) Å) are also normal. The manganese atom is 0.071(1) Å out of the basal pentagonal plane. The deviations of the atoms N10, N21, N33, O8 and O9 from the mean basal plane are 0.097(3), −0.003(3), −0.092(3), 0.195(3) and 0.194(3) Å, respectively. The dihedral angles between the equatorial plane and the plane of the tptz and dca groups are 3.11(5)° and 86.6(2)°, respectively.

The structure also contains uncoordinated water molecules in the lattice. Both hydrogen atoms of the coordinated water molecule (O34) are involved in making hydrogen bonds with (i) the oxygen atom of an uncoordinated water molecule (O35) and with (ii) the oxygen atom (O8) of the counter anion ($CH_3CO_2^-$) which belongs to a

neighbouring manganese-complex. Thus, infinite chains are formed. The second oxygen atom (O9) of the $CH_3CO_2^-$ anion makes a hydrogen bond with one of the hydrogen atoms of the other lattice water molecule (O36). O36 is also connected to N5 (the terminal nitrogen atom of the $N(CN)_2^-$ ligand) and is further involved in hydrogen bonding interactions to the other neighbouring terminal nitrogen atom and thus connects the 1D chains together to form 2D sheets which lie in the [1 0 0] plane. O35 is connected via hydrogen bonds to O36 and to N27 (nitrogen atoms belonging to the external ring of the tptz ligand connected to another manganese-complex), connecting the sheets together to form a 3D supramolecular network. Due to the presence and the number of uncoordinated water molecules inside this structure, many hydrogen bonds are formed connecting isolated complexes together and thus the structure can be assumed to be a pseudo 3D network (Table 3, Fig. 2). This hydrogen bonding network is reinforced by two types of weak C–H···O interactions (Table 3). This weak hydrogen bonding is possibly a contributing factor in the supramolecular assembly and stabilisation of the lattice, however, the strong O–H···O interactions are obviously the dominant intermolecular interactions. The significant π–π stacking distance between the two parallel planar rings of the tptz ligand is 3.76(1) Å. This distance is very similar to other π–π stacked systems [22].

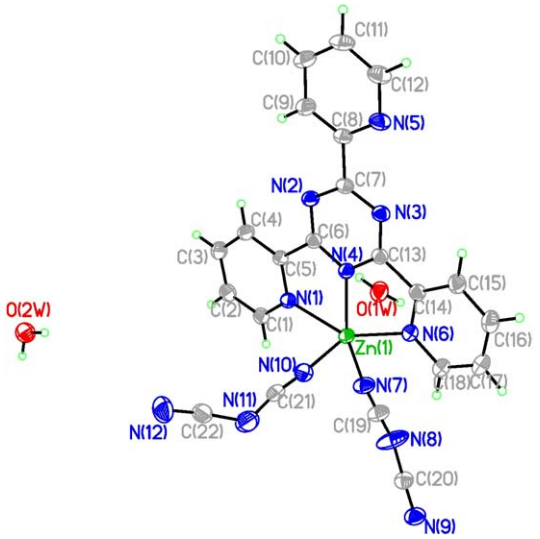

Fig. 3. Local coordination environment of the metal in complex **2** with the atom numbering scheme.

3.1.2. $[Zn(tptz)(dca)_2]\cdot(H_2O)_2$ (**2**)

The structure of **2** consists of the neutral mononuclear unit, $[Zn(tptz)(dca)_2]\cdot(H_2O)_2$ (Fig. 3), in which the three tptz nitrogen atoms and a terminal dca nitrogen bind to zinc in equatorial positions (Zn1–N1, 2.216(2) Å; Zn1–N4, 2.077(2) Å; Zn1–N6, 2.225(2) Å and Zn1–N7, 1.974(3) Å), and another terminal dca nitrogen resides in an apical position (Zn–N10, 2.064(2) Å). Considering these bonds, the zinc coordination geometry may be described as distorted square pyramidal, the trigonality parameter τ being 0.21 [23].

Selected bond distances and bond angles are summarised in Table 4. The Zn–pyridyl bond distances are comparable and the values are similar to those found in similar systems [24]. The deviation from the ideal square pyramid is indicated by the difference in *cisoid* (63.53(8)–110.29(10)°) and *transoid* angles (147.62(7)–160.22(11)°). The source of distortion primarily comes from the bites taken by the ligand; the bite angles N1–Cd1–N4 and N4–Cd1–N6 are 74.21(7)° and 73.53(8)°, respectively, significantly smaller than the ideal value of 90°. The deviations of the atoms N1, N4, N6 and N7 from the mean basal plane are −0.0850, +0.1121, −0.0910 and 0.0638 Å, respectively, and the zinc atom is displaced by 1.1202 Å from the plane towards the apical dca. The dihedral angles between the equatorial plane and the plane of the tptz and two dca groups are 8.5°, 62.7° (apical) and 58.4°, respectively. The

N4–Zn1–N6	73.53(8)	N7–Zn1–N10	98.14(11)

pyridyl rings of tptz are planar and the angles between the central triazine ring and the attached pyridyl rings are 1.8° (Py–N1), 2.7° (Py–N5) and 2.4° (Py–N6). The tptz group acts as a tridentate ligand through its three nitrogen atoms, the zinc to triazine-nitrogen (N4) bond being significantly shorter than the two zinc to pyridyl-nitrogen ones (Zn1–N1 and Zn1–N6 distances), a pattern usually observed in this type of three point attachment of tptz-type ligands [25]. The average $C(sp^2)$–$C(sp^2)$ bond lengths in the tptz ligand within the ring are normal and the exterior bonds (C5–C6, 1.483(3) Å; C7–C8, 1.482(4) Å; C13–C14, 1.480(3) Å) are also in agreement with those reported previously [26] and with complexes **1** and **3** also.

There are extensive arrays of hydrogen bonding interactions involving the dicyanamide, tptz moieties and lattice water molecules yielding a 1D supramolecular chains-like architecture (Fig. 4, Table 5). The two lattice water molecules with their centrosymmetric homologous are linked by strong hydrogen bonds, giving rise to quadrilateral frameworks (O1W–H2W···O2W = 2.864(3) Å and O2W–H4W···O1W = 2.854(3) Å). The four remaining hydrogen atoms bind, respectively, to two terminal nitrogen atoms of $N(CN)_2^-$ ligands and two pyridyl nitrogen atoms (belonging to the external ring of the tptz ligand) of the neighbouring zinc complex (Fig. 4 and Table 5). The resulting supramolecular network thus can be described as layers of complexes with the aromatic ligands lying parallel to (1 0 1) planes linked by hydrogen bonds provided by the water molecules. There are also weak π–π interactions between tptz ligands (closest non-hydrogen contact is 3.644 (2) Å).

3.1.3. $[Cd_2(tptz)_2(dca)_2(H_2O)_2]\cdot(ClO_4)_2$ (**3**)

A perspective view of complex **3** with the atom numbering scheme is shown in Fig. 5. Selected bond distances and bond angles are summarised in Table 6. Two dca groups bridge the metal atoms in a symmetric end-to-end fashion.

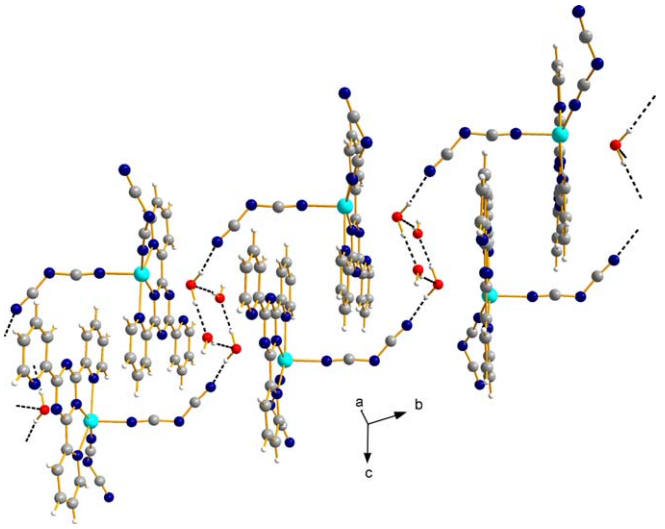

Fig. 4. Perspective view of **2** showing 1D-layers formed by the hydrogen bond interaction in the [0 1 0] plane. Hydrogen atoms are omitted for clarity.

Symmetry transformations used to generate equivalent atoms: (i) x, $1+y$, z; (ii) $-x$, $1-y$, $2-z$; (iii) $1-x$, $1-y$, $2-z$; (iv) x, $-1+y$, z; (v) x, y, $1+z$.

Complex **3** is an unusual dinuclear entity bridged by dca. One nitrogen from triazine and two from pyridyl moieties along with the two dca anions and one water molecule form the distorted octahedral geometry around each Cd(II). Three nitrogen atoms (N18, N1 and N12) from the tptz ligand and one bridging dca (N25) form the mean equatorial base, while O35 from water and N29 from another bridging dicyanamide occupy the axial positions.

The bond lengths are in accordance with those observed in the literature [27]. The deviation from ideal octahedral geometry is indicated by the difference in *cisoid* (67.97(15)–122.9(2)°) and *transoid* angles (136.84(14)–172.75(19)°). The deviations of the atoms N1, N12, N18 and N25 from the mean basal plane are 0.073(4), −0.070(5), −0.057(4) and 0.076(6) Å. The source of distortion primarily comes from the bites taken by the ligand; the bite angles N18–Cd1–N1 and N1–Cd1–N12 are 67.97(15)° and 68.87(15)°, respectively, significantly smaller than the ideal value of 90°. The bond distance of Cd(II) to the middle nitrogen N1 (2.330(4) Å) is significantly shorter than the Cd1–N18 (2.426(4) Å) and Cd1–N12 (2.378(6) Å) distances, a pattern observed for complexes **1**–**3**, and the values are comparable for these types of bonds [28]. The

Symmetry transformations used to generate equivalent atoms: (i) $2-x$, $-y$, $2-z$; (ii) $1-x$, $1-y$, $2-z$; (iii) $1-x$, $1-y$, $1-z$; (iv) $-x$, $1-y$, $2-z$; (v) $1-x$, $-y$, $2-z$; (vi) x, y, $-1+z$.

Cd1–N(dca) distances vary from 2.199(7) to 2.287(6) Å and Cd1–O(water) is 2.365(5) Å. In the ligand tptz, the C(sp^2)–C(sp^2) distances within the ring are normal (in the range 1.272(10)–1.486(7) Å) and the exterior bond distances (C6–C7, 1.486(7) Å; C2–C13, 1.483(7) Å; C4–C19, 1.495(7) Å) are also normal. The tptz ligands do not deviate much from planarity [24,29]; the three pyridyl rings are twisted with respect to the central triazine ring by angles of 0.8(1)°, 4.5(1)° and 4.6(1)°, with the non-coordinating ring displaying the highest degree of twisting. The cadmium···cadmium separation within the dinuclear unit is 7.537(5) Å, and the shortest inter-dimer cadmium···cadmium distance is 7.713(1) Å. Each dimer is connected to each other via hydrogen bonding interactions, building infinite neutral chains running along the following vector: [0.08; −0.47; 0.87]. The structural cohesion between these chains is then assumed by coulombic interactions. Both the hydrogen atoms of O35 are involved in hydrogen bonding interactions: (i) with the oxygen atom of the ClO_4^- counter anion; (ii) with one nitrogen atom (N20) of the external pyridyl ring of the tptz ligand belonging to the neighbouring cadmium. The later hydrogen bond allows the connection between dimers to form infinite chains. These 1D chains are further connected into supramolecular 2D sheets along the *bc*-plane (Table 7, Fig. 6). There exist weak π–π interactions between the tptz ligands (closest non-hydrogen contact is equal to 3.77(2) Å). The directed H-bond, which gives this complex an overall 2D structure, may be responsible for the stabilisation of the coordinated dinuclear form.

3.2. Infrared spectra

Complexes **1**–**3** exhibit strong absorptions in the region 2325–2155 cm^{-1} that correspond to $\nu_{C\equiv N}$ modes for dca groups, attributed to $\nu_{as} + \nu_s(C\equiv N)$ combination modes, $\nu_{as}(C\equiv N)$ and $\nu_s(C\equiv N)$. The shift towards higher wave numbers for the peaks of dca in **1**–**3** when compared to those of free dicyanamide is consistent with the coordination of dca in the complexes. These three bands appear at 2293, 2239, 2177 cm^{-1} for complex **1**, at 2299, 2237, 2178 cm^{-1} for complex **2**, and at 2312, 2245, 2183 cm^{-1}

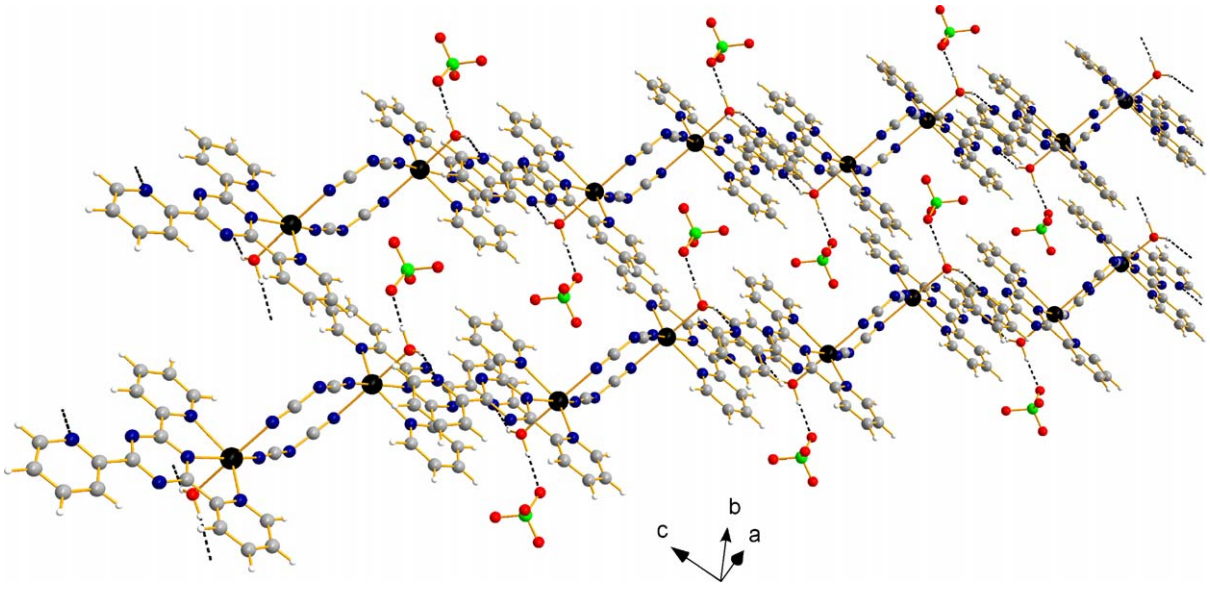

Fig. 6. 3D-supramolecular architecture formed by the hydrogen bonding interactions in **3**.

for complex **3** [1,5,11,30]. Bands dealing with the ν_{as}(C–N) stretching frequencies (1400–1300 cm^{-1} region) and the ν_s(C–N) stretch (950–900 cm^{-1} region) occur in all the spectra. Additionally, pyridyl ring breathing signals have been detected around 1050 cm^{-1} for these compounds. Complex **1** shows a broad signal at about 3400 cm^{-1} which corresponds to coordinated water and indicates the presence of hydrogen bonding [1a]. A strong and broad absorption at 3340 cm^{-1} (O–H stretching of water) in the infrared spectrum of **3** is due to the presence of coordinated water with hydrogen bonds [30b]. Strong bands at 1560 and 1520 cm^{-1} for **1**, 1564 and 1519 cm^{-1} for **2** and 1572 and 1524 cm^{-1} for **3** correspond to the coordinated tptz ligand. Peaks at 1625, 1593, 1530, 1479, 1461, 1443, 1369 and 973 cm^{-1} present in **1**–**3** can be assigned to the C=C and C=N ring stretching vibrations [19]. Peaks are also observed at 766 cm^{-1} (C–H stretching) and 586 cm^{-1} (pyridyl out-of-ring deformation) for all the three complexes [31]. The characteristic strong bands of carboxylate groups appeared at 1560 (for asymmetric stretching) and 1416 cm^{-1} (for symmetric stretching) [19,31]. The difference ($\Delta\nu = 144\ cm^{-1}$) between $\nu_{asym}(COO^-)$ and $\nu_{sym}(COO^-)$ bands suggests the presence of a chelating acetate group linked with the metal center for complex **1**. Broad intense bands at ca. 1100 cm^{-1} due to ClO_4^- show no splitting, indicating the absence of coordinated ClO_4^- in **1** [32].

3.3. Electronic spectrum

The electronic spectrum of **1** was recorded in dimethylformamide and showed two strong bands at about 240 and 265 nm which are clearly charge transfer in origin and an absorption band observed at 295 nm can be assigned to charge transfer from the coordinated ligand to Mn(II). The complex does not show any d–d transitions [33].

3.4. Electrochemical study

An electrochemical study of complex **1** was performed using dimethylformamide as solvent and tetrabutylammonium perchlorate as the supporting electrolyte at a scan rate of 50 mV s^{-1}. One irreversible reductive response at −1.05 V versus SCE was observed, which is attributed to a ligand-centered reduction. No oxidation response was found on the positive side of SCE.

3.5. Magnetic study

The effective magnetic moment at 20 °C for complex **1** is 5.98 BM, which is near to the spin-only value of the manganese(II) ion relative to mercury(tetrathiocyanato)cobaltate as the standard.

4. Conclusion

We have synthesised three dicyanamido complexes obtained from room temperature reactions. Complexes **1** and **2** are mononuclear and complex **3** is a dicyanamide-bridged dinuclear complex. To the best of our knowledge, complex **3** is the first example of a dicyanamide-bridged dinuclear cadmium(II) system. In fact, dca has a strong tendency to form polymeric complexes and that is why dinuclear dicyanamido-bridged complexes are rare in the literature. The difference in preferred coordination number between manganese (5–7), zinc (4–6) and cadmium (2–8) inspires significant differences in their respective structures. Here, the numerous hydrogen bonding interactions

involving the constituent materials enhance the stability of all the complexes and lead to the supramolecular architectures.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 284526–284528 for **1**–**3**, respectively. Copies of this information may be obtained free of charge from The Director, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Acknowledgements

The research was supported by grant from DST, New Delhi, India. We thank Dr. Andrés Ibañez for the structural data analysis and the diagrams.

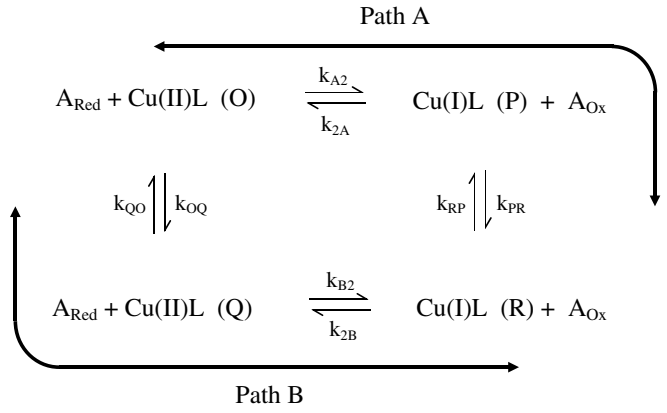

Fig. 1. The dual-pathway square scheme [1].

15,18-dithia-9,24-diaza-cyclohexadeca-9,23-diene, possible model systems of blue copper proteins. $[Cu^{I}(bite)](BF_4)$ (Fig. 2) reveals a distorted tetrahedral N_2S_2 coordination about copper, with highly unequal Cu–S distances (2.194(2) and 2.323(2) Å). The distortions from perfect C_2 symmetry may be related to the unusually high redox potential of the $[Cu^{I/II}(bite)]^{+/2+}$ couple. $[Cu^{II}(bite)](BF_4)_2$ reveals an approximately square-planar CuN_2S_2 structure of C_2 symmetry (Fig. 3) with two distant axial BF_4^- anions (Cu–F distance of 2.546(4) Å) in the solid state. However, the spectral data indicate the existence of only four-coordinate $[Cu^{I/II}(bite)]^{+/2+}$ complexes in acetone and dichloromethane solutions [3].

Cyclic voltammetry experiments [3] of the $[Cu^{I/II}(bite)](BF_4)_{1,2}$ redox couple in acetonitrile show only quasi-reversible behavior with wide peak-to-peak separation. Copper(I/II) electron self-exchange kinetics measured by ^1H NMR line broadening of $[Cu^{I}(bite)]^+$ in the presence

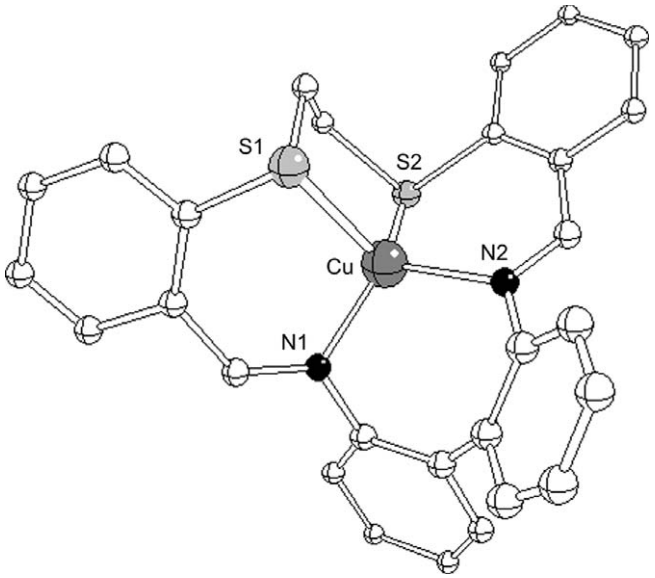

Fig. 2. The structure of quasi-tetrahedral $Cu(bite)^+$ (H atoms omitted) [3].

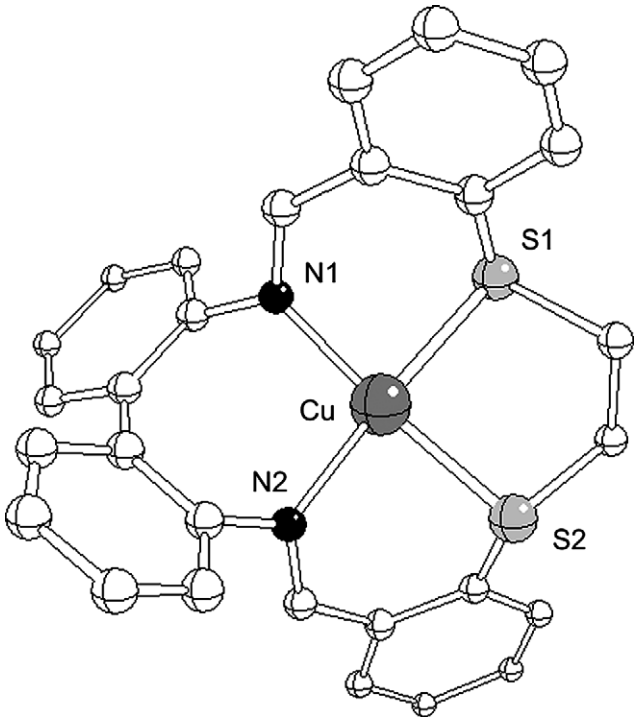

Fig. 3. The structure of quasi-square planar $Cu(bite)^{2+}$ (H atoms omitted) [3].

of $[Cu^{II}(bite)]^{2+}$ reveal an overall first-order process with a rate constant of $21.7 \pm 1.9\ s^{-1}$ at 295 K in acetone-d_6, which corresponds to fully gated electron transfer [3].

Electron-transfer kinetics of the $[Cu(bite)]^{+/2+}$ redox couple with Co(II), Ru(II) and Fe(III) complexes in acetonitrile has been studied by UV–Vis stopped-flow methods and explained in terms of a dual-pathway square mechanism (Fig. 1). All of the cross-reactions proceed through the same intermediate, and the outer-sphere self-exchange reaction should fulfill a second-order rate law with a rate constant of $0.01\ M^{-1}\ s^{-1}$ [4].

The preferable electron transfer to the pseudo-tetrahedral $[Cu^{I}(bite)]^+$ as an initial step in the anodic oxidation of $[Cu^{I}(bite)]^+$ has been observed by in situ ESR/UV–Vis–NIR cyclovoltammetry at different temperatures in various solutions [5]. Domination of the more stable square-planar $[Cu^{II}(bite)]^{2+}$ structure, observed during the oxidation of $[Cu^{I}(bite)]^+$ even at 230 K, indicates very fast transformation of metastable tetrahedral $[Cu^{II}(bite)]^{2+}$ to square-planar $[Cu^{II}(bite)]^{2+}$. In dichloromethane, where no adsorption phenomena arise, the rate constant for heterogeneous electron transfer, $k = 2 \times 10^{-4}$ cm s^{-1}, has been estimated.

In the first part of this study [6] the geometry and corresponding electronic structure parameters of DFT optimized tetrahedral and square-planar $Cu(bite)^q$ complexes, $q = +1$ and $+2$, have been investigated and compared with experimental data. A simple change of the cation charge does not cause a qualitative change of Cu coordination, which indicates an energy barrier for the

tetrahedral ↔ square-planar coordination transition during oxidation. Substantial differences in Cu–S bond lengths, observed in the tetrahedral reduced complex, are of intrinsic origin (mechanical strain of the bite ligand). Due to the plasticity of the central Cu atom, the energy effects implied by mechanical strain are low but the geometry deformations of the Cu coordination polyhedron may substantially change the composition as well as the relative energy of the frontier molecular orbitals and thus decrease the Franck–Condon barrier. The first order rate constant ($21.7 \pm 1.9\ s^{-1}$ at 295 K in acetone-d_6) obtained by ^{1}H NMR line broadening kinetic studies [3] corresponds to oxidation in the tetrahedral geometry (path B of Fig. 1).

Many experts (such as most referees of biochemical and biophysical journals) denote the macrocyclic compounds as very poor model systems of blue copper proteins (blue copper proteins cannot be modelled by strained complexes, their electronic structure is quite different, their electron transfer rate is very low, etc.). One of their arguments is the large mechanical strain in comparison with real blue copper proteins. The aim of this study is to evaluate the strain and reorganization energy in the $[Cu(bite)]^{+/2+}$ system and to compare them with analogous data for tetracoordinate copper complexes with monodentate imidazole and thiolate ligands that are used as model systems for blue copper proteins [2].

2. Calculations

As in the first part of this study [6], the standard DFT method of quantum chemistry (Amsterdam Density Functional – ADF program package) [7] with Vosko–Wilk–Nussair parameterization for the local density approximation (LDA), and Becke exchange and Perdew correlation gradient corrections has been used in order to find the optimal geometries of tetrahedral and square-planar $Cu(bite)^q$, $q = +1$ or $+2$ (denoted as R/Q and P/O structures, respectively – see Table 1 and Figs. 1–3) as well as of the bite ligand alone (tetrahedral T and square-planar S structures). No symmetry restrictions were applied. Cu(II) systems were treated within the unrestricted formalism. The geometries of the individual model systems starting from experimental structures were optimized until the maximum and the root-mean-squared gradients were below 0.01 and 0.007 Hartree/Å and the maximum and root-mean-squared changes in geometry were below 0.01 and 0.007 Å, respectively. For H, C, N and S atoms, standard basis sets III (of DZP type) from the ADF library have been used (with the 1s orbitals of C, N and S and

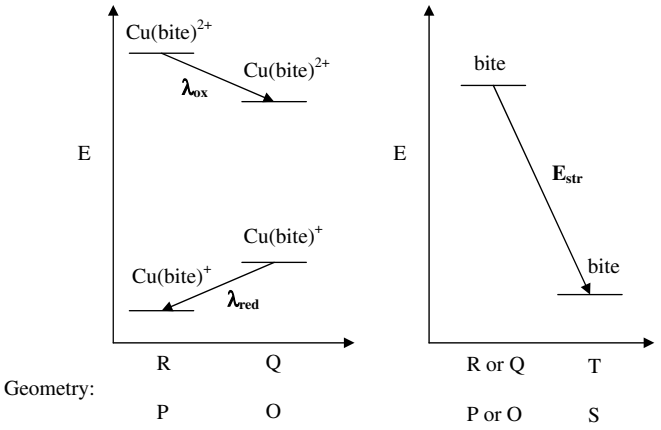

Fig. 4. Schematic illustration of reorganization (λ_{ox}, λ_{red}) and strain (E_{str}) energies.

the 2p orbitals of the S atoms frozen). For copper, a similar (IV) type basis set (containing only 4p polarization functions) has been enhanced with 4d and 4f functions (with frozen 2p orbitals) with exponent values of 1.70 (4d) and 1.05 (4f) , respectively [8].

For the sake of simplicity, the values of the total energy of the molecule, E_{tot}, are related to the total energy of the most stable tetrahedral *R* conformation of $Cu(bite)^+$ complex cation , $\Delta E_{tot} = E_{tot} - E_{tot}(R)$. Using the E_{tot} values of the individual systems under study, some energy characteristics of the $Cu(bite)^{+/2+}$ redox system are estimated [2].

The inner-sphere reorganization energy for the oxidized complex, λ_{ox}, is calculated as the difference in energy of the Cu(II) system at its optimal geometry and at the optimal geometry of the reduced complex. Likewise, the reorganization energy for the reduced complex, λ_{red}, is calculated as the energy of the Cu(I) system at its optimal geometry minus the energy of the Cu(I) complex calculated at the geometry optimal for the Cu(II) complex (see Fig. 4). The total inner-sphere reorganization energy for a self-exchange reaction, λ_i, is the sum of λ_{ox} and λ_{red}.

The strain energy, E_{str}, is the energy of the ligand molecule (i.e., without the Cu ion) in the optimal geometry of the complex related to the optimal geometry of the ligand alone (see Fig. 4) [2].

3. Results and discussion

As mentioned in [6], the results of the geometry optimization of $Cu(bite)^+$ (R and P structures), $Cu(bite)^{2+}$ (Q and O structures) and $bite^0$ (T and S structures) starting from experimental quasi-tetrahedral and quasi-planar geometries (Table 1) exhibit no qualitative changes in the starting S_2N_2 polyhedron. This indicates an energy barrier for the tetrahedral ↔ square-planar coordination transition. The geometry and electronic structure of the tetrahedral and square-planar $Cu(bite)^q$ complexes has been discussed in the first part of this study [6]. Substantial differences in Cu–S bond lengths may be observed in the tetrahedral reduced (R) complex only. As proposed by Flanaghan and and co-workers [3], higher non-equivalence of Cu-phenyl non-planarity (such as higher differences in Cu distances from the phenyl plane) in Cu(I) systems than in Cu(II) ones implies that the origin of this ligand geometry perturbation is in mechanical strain caused by the larger Cu(I) ion in the same macrocyclic bite ligand. Thus, we described the Cu volume by the surrounding S_2N_2 tetrahedron dimensions (Table 1) and compared them with these dimensions in the optimized geometry of the free bite molecule. The resulting bite geometry is different for starting tetrahedral and square-planar S_2N_2 arrangements. It may be expected that the edges of the S_2N_2 tetrahedron in the free bite molecule (i.e., without the central copper atom) are shorter than in the corresponding $Cu(bite)^q$ complexes but this relation has many exceptions (see the S1–S2, N1–N2 and S1–N2 distances in Table 1) . Analogously, these edges need not be longer for Cu(I) than for Cu(II) in quasi-tetrahedral systems. Such a behavior is reflected by bond angles, too. The extent of non-planarity of the phenyl rings bonded to S atoms (Cu, S and N atoms distances from phenyl planes) in the free bite ligands may substantially differ from the corresponding Cu complexes (up to 0.11 Å in the T model versus over 0. 18 Å in R and Q models).

As mentioned in the first part of this study [6], the most stable reduced structure is tetrahedral (R) whereas the most stable oxidized one is square-planar (O) in agreement with the dual-pathway square scheme [1]. The total energy of the quasi-tetrahedral *R* conformation of $Cu(bite)^+$ is taken as the reference energy value in Table 2.

Calculated values of reorganization and strain energies are presented in Table 3. The total inner-sphere reorganization energy is higher within quasi-tetrahedral conformations (28.3 kJ/mol) in comparison with the square-planar ones (23.5 kJ/mol). If the tetrahedral ↔ planar structural change is accounted for, the reorganization energy increases ca. 3–4 times (93.7 kJ/mol). A similar increase of the strain energy is not observed, its highest value corresponds to the tetrahedral Cu(I) system (36.5 kJ/mol). It

means that Cu(I) in this system causes the largest deformation of the bite ligand (evaluated in energy units) that should increase the reactivity of this system as a whole.

Table 4 presents similar data for some copper protein model systems with monodentate imidazole (Im) and thiolate (SCH_3^- and $S(CH_3)_2$) ligands in vacuo [2d] or in which a substantially larger environment has been included by QM/MM treatment at the B3LYP level of theory [2e]. It may be seen that $Cu(bite)^{+,2+}$ reorganization energies within the same coordination type (24–28 kJ/mol) in vacuo are comparable with those for $Cu(Im)_2(SCH_3)(S(CH_3)_2)^{0/+}$ in various environments (27–57 kJ/mol) and are significantly lower than these ones in vacuo (62–78 kJ/mol). Only the $Cu(bite)^{+,2+}$ reorganization energy for the tetrahedral ↔ planar transition is higher (94 kJ/mol). The strain energy data calculated for $Cu(bite)^{+,2+}$ (14–37 kJ/mol) are comparable or lower than for $Cu(Im)_2(SCH_3)(S(CH_3)_2)^{0/+}$ in various environments (34–66 kJ/mol). It may be expected that the environment effect inclusion should decrease the above quantities also for $Cu(bite)^{+,2+}$ model systems.

The inner-sphere reorganization energy λ_i in the real proteins azurin and plastocyanin has been estimated to 19 kJ/mol [9] and 18 kJ/mol [10], respectively. It is evident that our λ_i results for the case of the preserved coordination polyhedra type (28.3 kJ/mol for tetrahedral ↔ tetrahedral and 23.5 kJ/mol for square-planar ↔ square-planar coordination transitions in vacuo, see Table 3, should be lowered in the above mentioned environments, too) agree very well with these experimental data as well. It might be an indirect proof that the Cu coordination polyhedron type is preserved during the oxidation/reduction of blue copper proteins. Nevertheless, it must be kept in mind that the self-exchange reactions of Cu(II)/Cu(I) model complexes, in general, tend to have large inner-sphere reorganization barriers in comparison with copper proteins just owing to the different geometric preferences of the two oxidation states [11].

4. Conclusions

Our results indicate that the reorganization and strain energy of the macrocyclic bite ligand are comparable with simple monodentate ligands of blue copper proteins model systems. This may be explained by the plasticity of the central copper atom. On the contrary to monodentate imidazole and thiolate ligands where the ligand positions are determined by the central atom properties and to a lower extent by the mutual ligands repulsion, the mechanical strain in the bite ligand forces the N and S atoms to adopt such positions that are determined prevailingly by the ligand sterical demands and are only influenced to a lower extent by the central Cu atom. It may result in unusual Cu–S bond lengths, bond angles deformations as well as significant changes of molecular orbitals. The deformations of the electronic structure of the active center may be crucial for the electron transfer. Consequently, thermal vibrations with minimal energy demands may lead to the active center geometry possessing molecular orbitals with energies and symmetry properties suitable for oxidation/reduction and thus reducing the Franck–Condon energy barrier.

As mentioned above, many experts denote the macrocyclic compounds as very poor model systems of blue copper proteins due to many reasons. The aim of this study cannot be the polemics with them. Nevertheless, our results indicate that large mechanical strain cannot be the argument against these model systems.

Acknowledgments

We thank Prof. P. Coppens (SUNY at Buffalo, USA) for helpful discussions and valuable suggestions. This work has been supported by National Science Foundation, USA (Project No. NSF-CHE9981864) and by Slovak Grant Agency, Slovakia (Project Nos. 1/2449/05 and 1/3566/

06). Computational support has been provided by the Center for Computational Research of SUNY-Buffalo, USA, which is supported by grant DBI9871132 from the US National Science Foundation.

under nitrogen over Na\benzophenone and distilled before use. Methylene chloride, *n*-hexane and petroleum ether were refluxed under nitrogen over calcium hydride and distilled before use. Methylaluminoxane (MAO, 10 wt.% solution in toluene, $M = 800\ g\ mol^{-1}$, Al = 5.3 wt.%) was purchased from Wtico, *n*-butyl lithium, methyl lithium, phenyl lithium trimethylchlorosilane and titanium tetrachloride were purchased from Aldrich. ^1H and ^{13}C NMR spectra were recorded on a Varian Mercury-300 NMR spectrometer with $CDCl_3$ as solvent and TMS as an internal standard. IR spectra were recorded on a Nicolet Impact 410 FTIR spectrometer using KBr pellets. Elemental analyses were performed on a Perkin–Elmer 240c element analyzer. The crystal structure was determined with a CCD diffraction apparatus. Viscosity-average molecular weights of the polystyrenes were determined in *o*-dichlorobenzene at 135 °C using a Schott Gerate Mod. AVS/T2 Ubbelohde viscosimeter. Melting transition temperatures (T_m) of the polystyrenes were determined by DSC (Du Pont 910 differential scanning calorimeter) at a heating rate of 10 °C min^{-1}.

2.2. Synthesis of ligands

1,2-Diphenyl-4-methylcyclopentadiene (**1**) and 1,2,4-triphenylcyclopentadiene (**3**) were synthesized according to the literature procedures [19,20]. Compound **1** was obtained as a white crystalline material after purification by column chromatography through silica (methylene chloride/petroleum ether, 1:4 in v/v). Yield: 68%. ESI-MS, *m*/*z*: 232.4 $[M]^+$, 178.1 $[M-CH_3-C_3H_3]^+$. ^{13}C NMR ($CDCl_3$, 75 MHz): δ 16.4 (CH_3), 49.1, 132.3, 137.6, 141.6, 144.3 (C_5H_3), 126.2, 127.1, 127.9, 128.4, 128.6, 137.6, 137.8 (C_6H_5).

Compound **3** was purified by column chromatography through silica (methylene chloride/petroleum ether, 1:5 in v/v) as a white solid. Yield: 61%. ESI-MS, *m*/*z*: 294.3 $[M]^+$, 178.2 $[M-C_6H_5-C_3H_3]^+$. ^{13}C NMR ($CDCl_3$, 75 MHz): δ 45.2, 132.1, 137.1, 142.3, 145.3 (C_5H_3), 125.2, 126.8, 127.2, 127.4, 128.0, 128.5, 128.7, 128.8, 129.0, 136.0, 137.4, 139.6 (C_6H_5).

1,2-Diphenyl-4-*n*-butylcyclopentadiene (**2**) was synthesized by a similar procedure as follows: To a solution of butyl lithium (27.7 mmol) in THF (20 mL) was slowly added a solution of 3,4-diphenyl-2-cyclopentenone (7.03 g, 30 mmol) in THF (40 mL) under nitrogen with stirring at 0 °C. The resulting solution was allowed to warm to room temperature slowly and stirred overnight. The reaction mixture was quenched with ice-water (60 mL), treated with concentrated hydrochloric acid (9 mL) and the organic layer was separated. The aqueous layer was extracted with diethyl ether (3 × 20 mL). The combined organic layers were washed with 80 mL of saturated aqueous solution of sodium chloride, dried over anhydrous $MgSO_4$, filtered and evaporated under reduced pressure. The pure product (5.15 g, 62.5%) was obtained by column chromatography through silica (methylene chloride/petroleum ether, 1:4 in v/v) as a yellowish oil. ESI-MS, *m*/*z*: 274.4 $[M]^+$, 232.3 $[M-C_3H_6]^+$, 178.2 $[M-CH_3-C_3H_3]^+$. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.96 (s, 3H, CH_3), 1.41 (q, 2H, CH_2), 1.52 (q, 2H, CH_2), 2.47 (t, 2H, CH_2), 3.46 (s, 2H, C_5H_3), 6.34 (s, 1H, C_5H_3), 7.10–7.41 (m, 10H, C_6H_5). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 14.2, 22.8, 30.7, 31.9 (*n*-Bu), 47.5, 131.2, 137.6, 141.4, 149.4 (C_5H_3), 126.2, 127.1, 127.9, 128.4, 128.6, 128.6, 137.6, 137.8 (C_6H_5).

2.3. Synthesis of 1,2-diphenyl-4-methylcyclopentadienyltitanium trichloride (*4*)

To a solution of 1,2-diphenyl-4-methyl-cyclopentadiene (1.16 g, 5.0 mmol) in diethyl ether (40 mL) was slowly added a solution of *n*-BuLi (5.1 mmol) in *n*-hexane (20 mL) at −78 °C with stirring. After 1 h, the reaction mixture was allowed to warm to room temperature and stirred overnight. The solvent was removed under vacuum and the residue was washed with dry *n*-hexane (3 × 20 mL). The obtained white powder was dissolved in THF (30 mL), and Me_3SiCl (5.1 mmol) was slowly added at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred for 2 h. The solvent and excess Me_3SiCl were removed under reduced pressure. The residue was extracted with toluene (20 mL) and slowly added to a solution of $TiCl_4$ (4.75 mmol) in 30 mL of toluene at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred for 24 h. The precipitate was filtered off and the solvent was removed to leave a red solid. Recrystallization from methylene chloride/*n*-hexane (1:3 in v/v) gave pure **4** (1.30 g, 68.2%). *Anal.* Calc. for $C_{18}H_{16}Cl_3Ti$ (385.54): C, 56.08; H, 3.92. Found: C, 56.00; H, 3.98%. IR (KBr, cm^{-1}): 3100w, 2957w, 2925m, 2850w, 1491m, 1453w, 1424m, 1163w, 1079w, 1050w, 1022w, 889m, 769vs, 706vs, 676m, 663m. ^1H NMR ($CDCl_3$, 300 MHz): δ 2.59 (s, 3H, CH_3), 7.12 (s, 2H, C_5H_2), 7.56–7.35 (m, 10H, C_6H_5). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 18.4 (CH_3), 129.4, 132.8, 140.5 (C_5H_2), 124.3, 128.4, 129.4, 138.4 (C_6H_5).

2.4. Synthesis of 1,2-diphenyl-4-n-butylcyclopentadienyltitanium trichloride (*5*)

Complex **5** was synthesized in almost the same manner as complex **4** except that 1,2-diphenyl-4-butyl-cyclopentadiene (1.37 g, 5.0 mmol) was used as the starting material and its deprotonation reaction was carried out in *n*-hexane. Pure **5** (1.32 g, 61.5%) was obtained as red crystals by recrystallization from methylene chloride/*n*-hexane (1:4 in v/v). *Anal.* Calc. for $C_{21}H_{21}Cl_3Ti$ (427.62): C, 58.98; H, 4.95. Found: C, 59.05; H, 4.89. IR (KBr, cm^{-1}): 3086w, 2960m, 2932m, 2875w, 1494m, 1452w, 1427m, 1156w, 1079w, 1030w, 923w, 885m, 853m, 796s, 772vs, 757vs, 729m, 698s, 670m, 606m. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.98 (t, $^3J_{HH} = 7.5$ Hz, 3H, CH_3), 1.47 (m, $^3J_{HH} = 7.4$ Hz, 2H, CH_2), 1.73 (m, $^3J_{HH} = 7.3$ Hz, 2H, CH_2), 2.93 (t, $^3J_{HH} = 7.5$ Hz, 2H, CH_2), 7.13 (s, 2H, C_5H_2), 7.36–7.57

(m, 10H, C_6H_5). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 13.8, 22.5, 32.2, 32.5 (C_4H_9), 129.4, 132.9, 145.9 (C_5H_2), 123.4, 128.4, 129.5, 138.3 (C_6H_5).

2.5. Synthesis of 1,2,4-triphenyl-cyclopentadienyltitanium trichloride (6)

Complex **6** was synthesized in the same manner as complex **4** with 1,2,4-triphenylcyclopentadiene (1.47 g, 5.0 mmol) as the starting material. Pure **6** (1.36 g, 60.6%) was obtained as red crystals by recrystallization from methylene chloride/*n*-hexane (1:3 in v/v). *Anal.* Calc. for $C_{23}H_{17}Cl_3Ti$ (447.61): C, 61.72; H, 3.83. Found: C, 61.55; H, 3.78%. IR (KBr, cm^{-1}): 3079w, 2959w, 2931m, 2867w, 1487m, 1452w, 1425m, 1157w, 1072w, 1018w, 924w, 882w, 875m, 854m, 792s, 773vs, 759vs, 726m, 699s, 669m, 661m, 609m. ^1H NMR (300 MHz, $CDCl_3$): δ 7.08 (C_5H_2), 7.24–7.55 (C_6H_5). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 123.2, 132.4 (C_5H_2), 123.8, 128.5, 129.6, 138.3 (C_6H_5).

2.6. X-ray structural determination of complex 4

Single crystals of complex **4** suitable for X-ray diffraction were grown from a saturated solution in methylene chloride/*n*-hexane (1:4, v/v) at room temperature. A red crystal of dimensions $0.37 \times 0.31 \times 0.26$ mm sealed in a glass capillary was used. Data collection was performed using a standard Siemens SMART CCD diffractometer with graphite monochromated Mo Kα radiation. The data were integrated using the siemens SAINT program with intensities corrections for lorentz factor, polarization and air absorption [21]. The structure was solved by the direct method and was refined by full-matrix least squares techniques [22]. All non-hydrogen atoms were refined with anisotropic thermal parameters, while all hydrogen atoms were placed by geometrical considerations and refined isotropically. Crystallographic data, details of the data collection and refinement parameters are summarized in Table 1.

2.7. Polymerization of styrene

Styrene polymerization experiments were carried out in a 250 mL Schlenk flask with magnetic stirring. Fifty milliliters of toluene, 5 mL of freshly distilled styrene and an appropriate amount of MAO were added to the flask that was placed in an oil bath at the desired temperature and the mixture was stirred for 10 min. The titanium catalyst (2.5 μmol in toluene) was injected into the flask and the polymerization was performed at 25, 50 or 75 °C for 30 or 60 min periods. The polymerization was terminated by addition of 10% HCl in methanol. The precipitated polymer was washed three times with methanol and dried at 100 °C in vacuo to a constant weight. The polymer was extracted with refluxing 2-butanone for 24 h in a Soxhlet extractor to remove atactic polymer and dried again at 100 °C for 24 h.

3. Results and discussion

3.1. Synthesis of ligands

1,2-Diphenyl-4-methyl-1,3-cyclopentadiene (**1**) and 1,2,4-diphenyl-1,3-cyclopentadiene (**3**) were synthesized according to the literature procedures [19,20] and characterized by ^1H and ^{13}C NMR as well as mass spectroscopy. The ^1H NMR data are identical to that reported. The ^{13}C NMR and mass spectroscopy data are in agreement with the structures of compounds **1** and **3**. 1,2-Diphenyl-4-butyl-1,3-cyclopentadiene (**2**) was synthesized in similar way via the 1,2-addition reaction of 3,4-diphenyl-2-cyclopentenone with butyllithium, followed by dehydration of the 1-hydroxy-1-butyl-3,4-diphenyl-2-cyclopentene with concentrated HCl. Compound **2** was also characterized by ^1H and ^{13}C NMR as well as mass spectroscopy. These spectroscopy data are consistent with the structure of compound **2**.

3.2. Synthesis of titanium complexes

Complexes **4**, **5** and **6** were synthesized in similar way to the published procedure [23,24]. Treatment of compounds **1**, **2** and **3** with *n*-butyl lithium, followed by reaction with trimethylchlorosilane, produced the trimethylsilyl substituted derivatives of **1**, **2** and **3**, respectively. The

deprotonation reaction of compounds **1** and **3** was carried out in diethyl ether, while the same reaction of compound **2** was conducted in *n*-hexane since **2** has pretty good solubility in *n*-hexane and the produced lithium salt readily precipitated from *n*-hexane, which resulted in the easy separation of the lithium salt. Reactions of the trimethylsilyl substituted derivatives with $TiCl_4$ in toluene (Scheme 1) gave the corresponding complexes **4**, **5** and **6**, respectively. These titanium complexes are quite soluble in benzene, toluene and methylene chloride, whilst being slightly soluble in *n*-pentane and *n*-hexane. Therefore, they can be recrystallized from a mixture of methylene chloride and *n*-hexane. These complexes were found to be relatively stable to air and moisture in the solid state, and could be exposed to air for several hours without obvious decomposition, but they decomposed readily in solution when exposed to air.

3.3. The crystal structure of complex *4*

The crystal structure of the complex **4** is shown in Fig. 1, and selected bond distances and angles are summarized in Table 2. The coordination geometry about the Ti atom can be described as a distorted tetrahedron, formed by the substituted Cp ring and three Cl atoms, which is similar to that of known titanium complexes (η^5-C_9H_7)$TiCl_3$ and (η^5-C_9Me_7)$TiCl_3$ [8j,25]. The distances of Ti–C1 (2.388(2) Å) and Ti–C2 (2.405(3) Å) are longer than those of known Ti–Cp-ring carbon distances [8j,8k], which could be obviously attributed to the steric effect of the two phenyl groups on the Cp-ring. The C–C distances in the substituted Cp ring range from 1.396(4) to 1.430(3) Å, and the C1–C2 bond length (1.430(3) Å) is the longest among these values, which could also be explained by the steric and conjugate effects of the two phenyl groups on the Cp-ring. The average Ti–Cl distance of 2.2347(9) Å is close to that of 2.2308(1) Å in (η^5-C_9H_7)$TiCl_3$ [8j]. The Cl–Ti–Cl angles in complex **4** are in the range of 101.19(4)°–103.66(3)°. The two phenyl groups on the Cp-ring construct a partially crowded environment around the metal center, which might have a greater or lesser effect on the polymerization of styrene (see Table 2).

3.4. Styrene polymerization

Upon activation with MAO, complexes **4**, **5** and **6** can all catalyze the polymerization of styrene to form syndiotactic polystyrene. The results of styrene polymerization catalyzed by these complexes under different conditions are summarized in Table 3. For comparison, polymerization experiments catalyzed by $CpTiCl_3$/MAO were also carried out under identical conditions. As can be seen from Table 3, the **4**–**6**/MAO systems show better catalytic performance than the $CpTiCl_3$/MAO system for styrene polymerization in terms of catalytic activity, syndiotacticity, melting temperature and molecular weight of the produced polystyrene. It has been known that the phenyl substituent

on the cyclopentadienyl group of similar titanium catalysts can improve the catalytic property due to the increased resonance stabilization [8l,26].

For all complexes **4**, **5** and **6**, the catalytic activity increases with the increase in polymerization temperature, and reaches the highest value at about 50 °C. Further increase in the polymerization temperature results in a decrease in the catalytic activity. All catalytic systems exhibit higher catalytic activities for 30 min polymerization experiments than 60 min ones, which indicates that the active catalysts deactivate during the polymerization. The results in Table 3 also demonstrate the substituent effect of the R group on the cyclopentadienyl ligand of complexes **4**, **5** and **6** on their catalytic properties. The catalytic activity of these complexes is in the order of **6** < **5** < **4**, which implies that both the electronic and steric factors of the R group play roles in determining the catalytic activity of these complexes. In addition, in comparison with the $CpTiCl_3$ catalyst system, the syndiotacticity of polystyrenes produced with the **4**, **5** or **6** catalyst system is higher, which might be attributed to the relatively crowded environment around the metal center of **4**, **5** and **6**.

4. Conclusions

We have synthesized and characterized 1,2-diphenyl-4-R-cyclopentadienyl titanium trichloride (R = Me (**4**), *n*-Bu (**5**), Ph (**6**)). The molecular structure of complex **4** has been confirmed by X-ray crystallography. When activated with MAO, these titanium complexes are efficient catalysts for the syndioselective polymerization of styrene.

The magnetic properties of the compound have been investigated as well.

2. Experimental

2.1. Synthesis and characterization

The reactants V_2O_5 (0.182 g, 1 mmol), H_3PO_3 (0.410 g, 5 mmol) and *N*,*N*′-dimethylpiperazine, (0.3 ml, 4.48 mmol) were added to 2 ml (166 mmol) distilled water. The initial pH was 4.2. The mixture was placed in a 23 ml capacity teflon-lined stainless steel hydrothermal bomb, under autogenous pressure, heated at 160 °C for 120 h, followed by slow cooling to room temperature. The pH of the mixture was 5.6. The product was washed with deionized water and dried at room temperature.

The synthesis was carried out in a 23 mL teflon-lined stainless steel vessel under autogenous pressure with a filling capacity of ~10%. The elemental analysis was performed on a Perkin–Elmer 2400 element analyzer and the inductively coupled plasma (ICP) analysis was performed on a Perkin–Elmer Optima 3300 DV ICP spectrometer. Magnetic susceptibility data were collected over the temperature range 2.4–300 K at a magnetic field of 5 kG on a Quantum Design MPMS-7 SQUID magnetometer.

2.2. Determination of crystal structure

A suitable single crystal with dimensions $0.20 \times 0.20 \times 0.14$ mm was selected for X-ray diffraction analysis. The intensity data collected on a Siemens SMART CCD diffractometer with graphite-monochromatic Mo Kα ($\lambda = 0.71073$ Å) radiation at a temperature of 293 ± 2 K. A hemisphere of data was collected using a narrow-frame method with scan widths of 0.30° in ω and an exposure time of 30 s/frame. Data processing was accomplished with the SAINT processing program [25]. The structure was solved by direct methods using the SHELXTL crystallographic software package [26]. The zinc and phosphorus atoms were first located, whereas the carbon, nitrogen and oxygen atoms were found in the difference Fourier maps. The hydrogen atoms residing on the amine molecules and the phosphorus were placed geometrically. A total of 2692 reflection intensities, of which 1594 were independent ($R_{int} = 0.0338$), were collected within the range $2.40° < \theta < 23.23°$ ($-8 \leqslant h \leqslant 8$, $-8 \leqslant k \leqslant 9$, $-10 \leqslant l \leqslant 8$) for the compound. The final cycle of refinement performed on F_o^2 afforded residuals $R = 0.0372$ and $R_w = 0.0981$. A summary of the crystallographic data is presented in Table 1.

3. Results and discussion

3.1. Characterization

The elemental analysis found (wt%): V, 23.01; P, 18.41; C, 10.52; N, 4.23; H, 3.51%. These are consistent with the calculated values from the formula of $(C_6H_{16}N_2)[V^{III}(OH)_2(V^{IV}O)_2(HPO_3)_4]\cdot H_3O$: V, 22.66; P, 18.40; C, 10.68; N, 4.15; H, 3.71%.

The powder X-ray diffraction pattern for $(C_6H_{16}N_2)[V^{III}(OH)_2(V^{IV}O)_2(HPO_3)_4]\cdot H_3O$ was consistent with the simulated one on the basis of the single-crystal structure, as shown in Fig. 1. The diffraction peaks on both patterns correspond well in position, indicating the phase purity of the synthesized sample. The difference in reaction intensities between the simulated and experimental patterns was due to the variation in crystal orientation for the power sample.

The IR spectrum of the product exhibited medium bands at 2995, 2923 and 1629 cm^{-1} due to the terminal NH_3^+ stretch, and the stretching vibrations of —CH_2— groups were at 2854 cm^{-1}. The bands at 2389 and 1074 cm^{-1} were attributed to the terminal P—H stretch

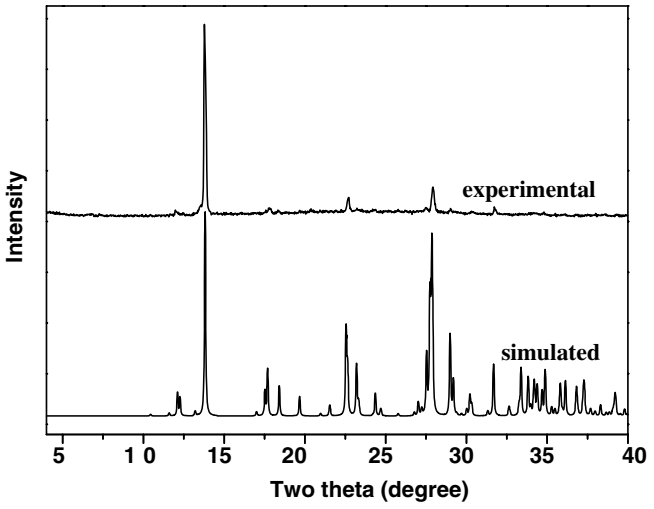

Fig. 1. Simulated and experimental powder X-ray diffraction patterns of the compound **1**.

and deformation. Absorptions at 1154, 626, 567 cm^{-1} can be attributed to P—O vibrations. The IR results showed clearly the vibrations from the [HPO_3^{2-}] phosphite group and the template molecule.

3.2. Description of the structure

The structure of the compound consists of V—O—P layers, the interlamellar space of which is occupied by protonated water molecules and double protonated *N*,*N*′-dimethylpiperazine cations. Final atomic positional and thermal parameters for $(C_6H_{16}N_2)[V^{III}(OH)_2(V^{IV}O)_2(HPO_3)_4]\cdot H_3O$ are given in Table 2, and selected bond distance and bond angle data are summarized in Table 3. The asymmetric unit of **1** is presented in Fig. 2.

There are 17 non-hydrogen atoms in compound **1**, 12 of which belong to the ''framework'' (two V, two P and eight O atoms) and five to the guest (three C, one N and O). In this structure two independent vanadium atoms present two different coordination geometries. V(1) is square pyramidal coordinated by five oxygen atoms, two connections to the P(1) atom and two connections to P(2) via oxygen and one classical short-bond V=O(5) bond (1.581 Å). V(2) is octahedral coordinated by six oxygen atoms, two occur as terminal V—O(8)H, two make V—O—P(1) linkages and the remaining two form V—O—P(2) linkages. As expected, the two distinct P atoms form the centre of pseudo pyramid hydrogen phosphite groups. P(1) has two connections to the V(1) atom via oxygen atoms (O1 and O3) and one connection to the V(2) atom via oxygen atom O6. The atom P(2) has its three oxygen atoms bonded to two V(1) and one V(2) atom. The infinite V/P/O layer is constructed from VO_6 octahedral, VO_5 square pyramids and $[HPO_3]^{2-}$ pseudo pyramids by sharing vertices. The framework structure of $(C_6H_{16}N_2)[V^{III}(OH)_2(V^{IV}O)_2(HPO_3)_4]\cdot H_3O$ consists of alternate inorganic and organic layers. Fig. 3 shows the inorganic layer viewed down the [1 0 0] direction. The inorganic layer, with the composition $[V(OH)_2(VO)(HPO_3)_2]^-$, is constructed by connecting $[(VO)(HPO_3)_2]^{2-}$ chains through bridging $V(OH)_2$ frag-

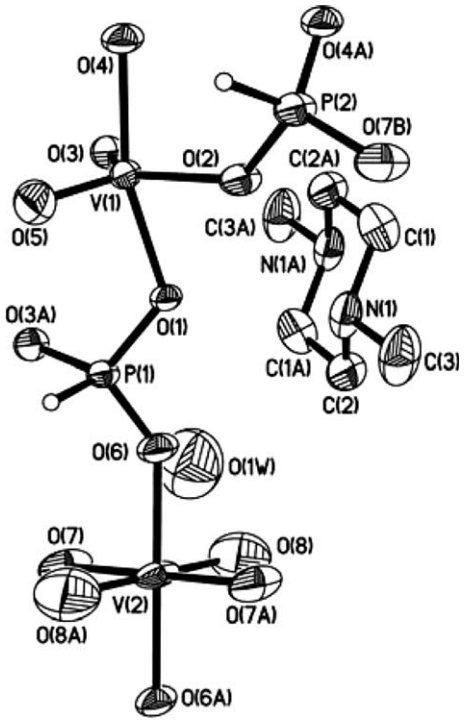

Fig. 2. Asymmetric unit of $(C_6H_{16}N_2)[V^{III}(OH)_2(V^{IV}O)_2(HPO_3)_4]\cdot H_3O$ with thermal ellipsoids shown at 50% probability.

ments. The chains are composed of vertex-sharing $[VO_5]$ square pyramids and $[HPO_3]^{2-}$ pseudo-pyramids, fused together via V—O—P bonds. Each $[VO_5]$ group forms four V—O—P links, resulting in polyhedral "four-rings" with strict alternation of the V and P species. The polyhedral chain-linkage pattern of vertex-linked $[VO_5]$/$[HPO_3]$ four-rings is similar to that found in $[CN_3H_6][VO(H_2O)(HPO_4)(H_2PO_4)]\cdot H_2O$ [27], $Ba_2VO(PO_4)_2\cdot H_2O$ [28] and $VO(H_2PO_4)_2\cdot H_2O$ [29] with a one-dimensional chain structure.

Fig. 4 shows the stacking of the inorganic layer with the intercalated organic cations viewed along the [1 1 0] direction. The inorganic layers are stacked exactly one over the other in an AAAA fashion. The double protonated *N*,*N*′-dimethylpiperazine is intercalated between the layers with hydrogen bonding. As in many inorganic framework compounds, $(C_6H_{16}N_2)[V^{III}(OH)_2(V^{IV}O)_2(HPO_3)_4]\cdot H_3O$ exhibits significant hydrogen bond interactions between *N*,*N*′-dimethylpiperazine cations and framework oxygens. The *N*,*N*′-dimethylpiperazine cation is situated between two vanadium phosphite layers and interacts with the layers though N—H···O hydrogen bonds (Fig. 5). The water molecule connects with the inorganic layer via hydrogen bonds as evidenced by the short O(8)···O(1W) distances of 2.698 Å.

3.3. Physical data

The magnetic susceptibility of **1** was measured between 4 and 300 K in a 5000 G field and the temperature-dependence of χ_M and reciprocal molar magnetic susceptibility χ^{-1} are shown in Fig. 6. The molar magnetic susceptibility, χ_M, increases with decreasing temperature, which shows paramagnetic behavior in compound **1**. The thermal evolution of χ_M follows the Curie–Weiss law $[\chi_M = C_m/(T-\theta)]$ above 50 K, with $C_m = 0.391$ emu K^{-1} mol^{-1} and $\theta = -38.99$ K. At 300 K the magnetic moment (μ_{eff}) per vanadium, determined from the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$, is 1.73 μB which is slightly lower than that expected for a trivalent/tetravalent system with $\mu_{eff} = 1.75$ μB. The magnetic susceptibility confirmed the valances of the vanadium atoms to be mixed valence of +3/+4 for compound **1**.

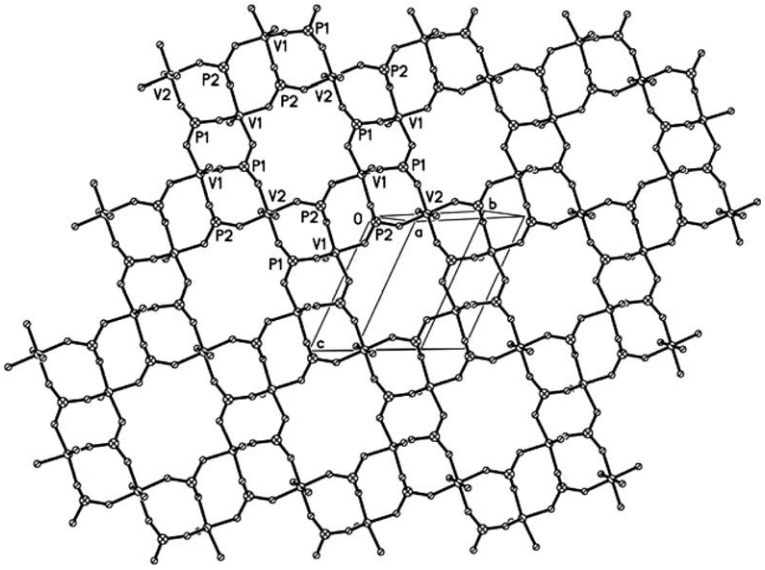

Fig. 3. The inorganic layer structure of compound **1** viewed along the [0 1 0] direction.

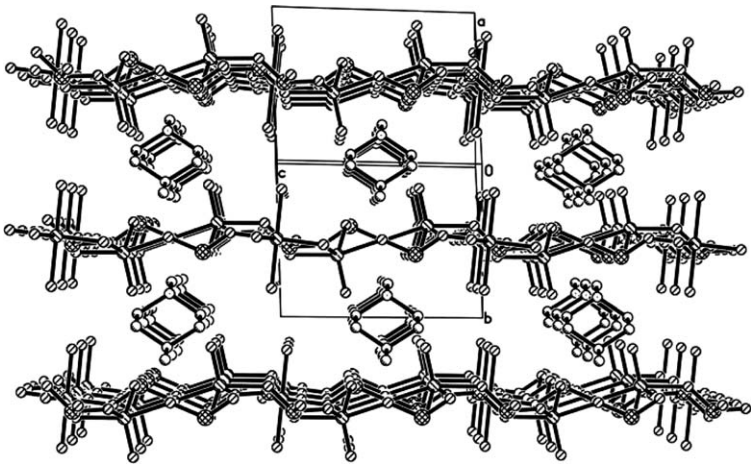

Fig. 4. The stacking of the layers with the intercalated organic cations viewed along the [1 1 0] direction.

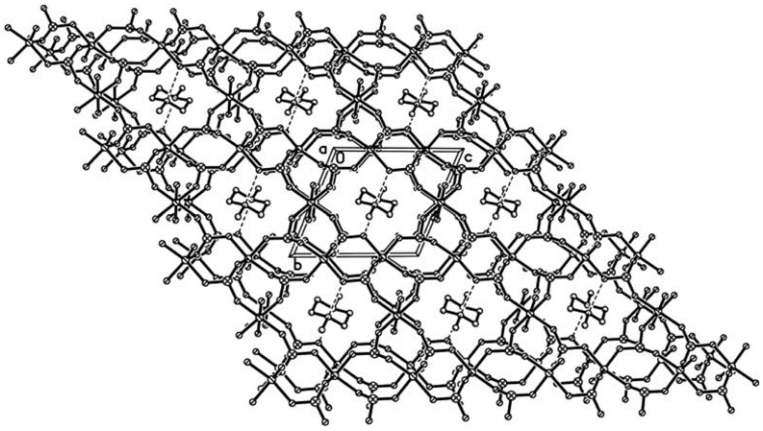

Fig. 5. View the structure of compound **1** along [1 0 0]. Dotted lines represent the various hydrogen bond interactions.

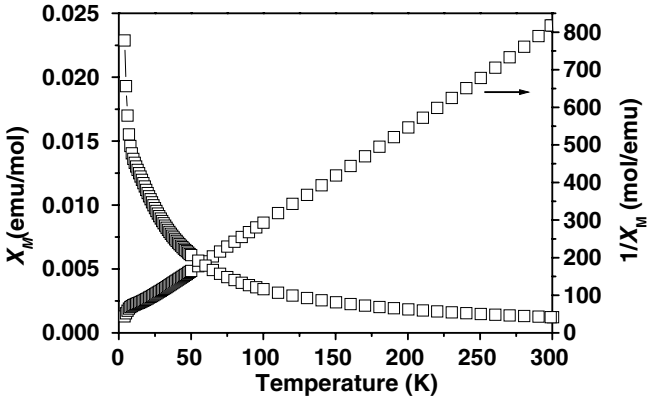

Fig. 6. Thermal dependence of χ_M (open block) and $\chi_M T$ (solid block) for compound **1**.

4. Conclusions

In summary, a novel open-framework vanadium phosphite $(C_6H_{16}N_2)[V^{III}(OH)_2(V^{IV}O)_2(HPO_3)_4]\cdot H_3O$ was obtained as good quality single crystals by the hydrothermal method. The structure of compound **1** is built up from alternate V(III)O_6 octahedra, V(IV)O_5 square pyramids and [HPO_3^{2-}] pseudo pyramids by sharing vertices. This organically templated vanadium phosphite possesses alternate inorganic and organic layers, formed by four- and eight-membered rings. The *N*,*N*′-dimethylpiperazine cation acts as a template for directing occupies between two vanadium phosphite layers and interacts with the layers though N—H···O hydrogen bonds.

5. Supplementary material

The supplementary material in the form of a CIF file has been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 IEZ, UK, as supplementary material No. CCDC-266817 and can be obtained by contacting the CCDC (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk) quoting the article details and the corresponding SUP number.

spectra in the X band were recorded with a Bruker System ESP 300 equipped with a Bruker ER035M gaussmeter and a HP 5350B microwave counter. Cyclic voltammetry was carried out at a 100 mV/s scan rate in dichloromethane/0.1 M Bu_4NPF_6 using a three-electrode configuration (glassy carbon electrode, Pt counter electrode, Ag/AgCl reference) and a PAR 273 potentiostat and function generator. A two-electrode capillary was used in radical complex generation for X band EPR studies [9].

2.2. Syntheses

The ligand bik was synthesized according to the literature [3], single crystals were grown in DMF at −30 °C. The ligands bis(1-methyl-2-imidazolyl)methoxymethane (bimm) and bis(1-methyl-2-imidazolyl)hydroxymethane (bihm) were obtained as described previously [4,10].

2.2.1. *[$AuCl_2$(bik)]Cl, (**1**)Cl*

A solution of $KAuCl_4$ (262 mg: 0.69 mmol) in 15 mL methanol was added to a 15 mL methanol solution of bik (131 mg: 0.69 mmol) in the dark and stirred for 18 h at ambient temperature. The yellow solid formed was filtered and washed with methanol to obtain the product in 69% yield (236 mg). Single crystals suitable for X ray diffraction could be grown as methanol solvates by slow evaporation from an acetonitrile solution. *Anal.* Calc. for $C_{10}H_{14}AuCl_3N_4O_2$ (525.57): C, 22.85; H, 2.69; N, 10.66. Found: C, 22.83; H, 2.48; N, 10.58%. ^{1}H NMR (DMSO-d_6): 4.08 (s, 6H, NCH_3), 7.6 (s, 2H, CH), 7.9 (s, 2H, CH). ^{13}C NMR (DMSO-d_6): 36.9 (NCH_3), 125.8 (C im), 129.8 (C im), 138.65 (C im), 165.6 (CO). IR (KBr): 1684 cm^{-1} (CO).

2.2.2. *[$AuCl_2$(bimm)]($AuCl_2$), (**2**)($AuCl_2$)*

A solution of $KAuCl_4$ (126 mg: 0.33 mmol) in 15 mL methanol was added to a methanol solution of bimm (72 mg: 0.34 mmol) in the dark and stirred for 18 h. The precipitated product (59 mg, 48%), insoluble in methanol, was isolated and gave suitable crystals for X ray analysis after slow evaporation from a dichloromethane solution. *Anal.* Calc. for $C_{10}H_{14}Au_2Cl_4N_4O$ (741.99): C, 16.19; H, 1.90; N, 7.55. Found: C, 16.23; H, 1.89; N, 7.51%. ^{1}H NMR (DMSO-d_6): 3.41 (s, 3H, OCH_3), 4.00 (s, 6H, NCH_3), 6.29 (CH), 7.59 (s, 2H, im), 7.77 (s, 2H, im). ^{13}C NMR (DMSO-d_6): $\delta = 35.44$ (NCH_3), 56.85 (CHOMe), 63.04 (OCH_3), 123.96 (C im), 125.22 (C im), 138.9 (C im).

2.2.3. *[$AuCl_2$(bihm)]Cl, (**3**)Cl*

A solution of $KAuCl_4$ (307 mg: 0.81 mmol) in 20 mL of THF was added to a THF solution (80 mL) of bihm (155 mg: 0.806 mmol) in the dark and stirred for 25 h. The resulting yellow suspension was cooled to −30 °C to cause the yellow solid product to settle down which was then filtered to yield 301 mg (75%) of a THF hemi-solvate. *Anal.* Calc. for $C_{11}H_{16}AuCl_3N_4O_{1.5}$ (531.54): C, 24.86; H, 3.03; N, 10.54. Found: C, 24.88; H, 3.07; N, 9.14%. ^{1}H NMR (DMSO-d_6): 1.73 (m, 4H, CH_2 from THF), 3.59 (m, 4H, CH_2 from THF), (3.99 s, 6H, NCH_3), 6.22 (d, CH), 6.35 (d, COH), 7.68 (s, 2H, im), 7.73 (s, 2H, im). ^{13}C NMR (CD_3OD): 38.59 (NCH_3), 60.67 (COH), 127.8 (C im), 128.8 (C im), 145 (C im). IR (KBr): 3430 cm^{-1} (OH). The analogous reaction was carried out in methanol from which suitable solvent-containing crystals for X ray analysis could be grown by slow evaporation.

2.3. Crystallography

Single crystals of bik were obtained from a DMF solution kept at −30 °C. A colorless crystal of 0.6 × 0.3 × 0.1 mm size was used to collect data at 293 K with a Siemens P3 diffractometer. Single crystals of (**1**)Cl, (**2**)($AuCl_2$) and (**3**)Cl were obtained, partially as methanol solvates, by slow evaporation from solutions as described above. Data were collected of selected specimens (yellow platelets

in each case, $0.1 \times 0.1 \times 0.04$ mm (**1**)Cl · CH_3OH, $0.15 \times 0.1 \times 0.04$ (**2**)($AuCl_2$), and $0.2 \times 0.2 \times 0.06$ mm (**3**)Cl · 1/2CH_3OH) with a NONIUS Kappa CCD diffractometer at 100 K ((**1**)Cl · CH_3OH, (**3**)Cl · 1/2CH_3OH), and 293 K ((**2**)($AuCl_2$)), respectively. Additional crystallographic information is given in Table 1. The structures were solved using direct methods with refinement by full-matrix least-squares of F^2, employing the program system SHELXL-97 in connection with absorption correction [11]. Except for C10 from the methanol molecule in (**1**)Cl · 1/2CH_3OH all non-hydrogen atoms were refined anisotropically, hydrogen atoms were introduced at appropriate positions.

2.4. DFT calculations

Density functional (DFT) calculations were carried out using the program package GAUSSIAN [12], the hybrid functional B3LYP with 6-31G* or LANL2DZ basis sets was employed. The latter was used for the calculations involving metal complexes although this basis systematically yielded slightly longer bonds. Energy and bond parameter differences between conformers were calculated with very similar results for both basis sets.

3. Results and discussion

3.1. Crystal structure of bik

Although bik has been used several times as a ligand in biomimetic coordination chemistry [3] no crystal structure had been reported so far. Crystallographic data for bik as obtained from crystallization from DMF at −30 °C are summarized in Table 1, selected data and their reproduction by DFT calculations are listed in Table 2. Fig. 1 shows the molecular structure in the crystal, the N1–C1–C5–O1 and N3–C6–C5–O1 torsional angles are 31.0° and 27.5°, respectively (calculated: 27.9°). The C1–N1–C3–C2–N2 plane has an angle of 49.4° with respect to the plane of the other methylimidazole ring (C6–N3–C8–C7–N4). The conformation adopted reflects an approximate *s-trans*/*s-trans* arrangement of the π accepting (N=C)–(C=O)–(C=N) bonds.

On reduction to bik$^{\bullet-}$ the major bond length change calculated is a lengthening of the C–O bond as befits a ketyl-type radical (Table 2).

Table 2
Selected experimental and calculated bond lengths (Å) and angles (°) for bik and bik$^{\bullet-}$ (see Scheme 3 for numbering)

	bik		bik$^{\bullet-}$
	Experimental	DFT	DFT
Bond lengths (Å)

3.2. Synthesis, structure, spectroscopy and electrochemistry of complexes $[AuCl_2(L)](X)$

The gold(III) complex cations **1**–**3** were obtained from reacting $KAuCl_4$ with bik, bimm or bihm, respectively. Two of the cationic complexes have Cl^- as the counter ion while the complex with bimm contains the reductively generated dichlorogold(I) anion, the result from elemental analyses being supported by X ray crystallography. The equivalence of the downfield shifted imidazole protons in the ^1H NMR spectra suggests Au^{III} coordination to both N atoms in each case. At 1684 cm^{-1} the IR carbonyl stretching frequency for complex **1** is 50 cm^{-1} higher than that of free bik. Similar effects were found for a previously reported dimethylgold(III) complex of bik [3a]. The presence of a broad O–H stretching band at 3430 cm^{-1} is indicative of a non-coordinating OH group in **3**.

The results from the X ray diffraction analyses (Table 1) for the gold(III) complexes are summarized in Table 3. Fig. 2 shows the molecular structures.

In all three cases **1**–**3** the N,N′ coordination of nearly square planar Au^{III} with the formation of six-membered chelated rings was observed. While there are slight differences of the bond distances between Au^{III} and the nitrogen atoms, the Au–Cl bond lengths are almost invariant. The six-membered chelate rings adopt a distorted boat conformation as specified for **1**–**3** and as calculated for **1** (Table 3).

The Au–N–C–C torsional angles within the six-membered rings are smaller than 11°. The dihedral (''boat'') angles Au–N1–C1–C5/C5–C6–N3–Au reflect considerable structural flexibility as evident from the experimental variation between **1** or **3** (ca. 17°) and **2** (ca. 45°) and from the difference between the experimental and the calculated value (0°) for system **1**. The experimentally observed boat conformation for **1** is calculated to lie 0.167 eV (3.85 kcal/mol) higher than the planar energy minimum conformation, supporting the notion of a flat energy surface. Otherwise, the structure of **1** is reasonably reproduced by DFT calculations, however, the calculated bond distances involving the metal are typically too long relative to the experiment. The N,O coordination alternative with a five-membered Au–N–C–C–O chelate ring is calculated

to lie 25.0 kcal/mol higher than the six-membered chelate ring configuration with N,N′ coordination.

3.3. Cyclic voltammetry and EPR spectroscopy

The cyclic voltammetry of complexes (**1**)Cl and (**3**)Cl at 20 °C in CH_2Cl_2/0.1 M Bu_4NPF_6 gave only irreversible waves for the cathodic reduction. Reversibility corresponding to $i_c/i_a \approx 1.0$ and $\Delta E_{pp} \approx 120$ mV was achieved only by cooling to 195 K; a very negative potential of −3.03 V versus ferrocene/ferrocenium was measured for (**3**)Cl while complex (**1**)Cl reacted with the reference. There was no detectable EPR signal for complex **1**$^{\cdot}$ after in situ reduction at 195 K and measurement at 4 K. This result signifies chemical lability of the neutral species [(bik)$AuCl_2$]$^{\cdot}$ and/or rapid EPR relaxation because of strong contributions from the heavy atom; DFT calculation results for the [(bik)$AuCl_2$]$^{+}$/[(bik)$AuCl_2$]$^{\cdot}$ pair (Table 3, Fig. 3) serve to rationalize these observations.

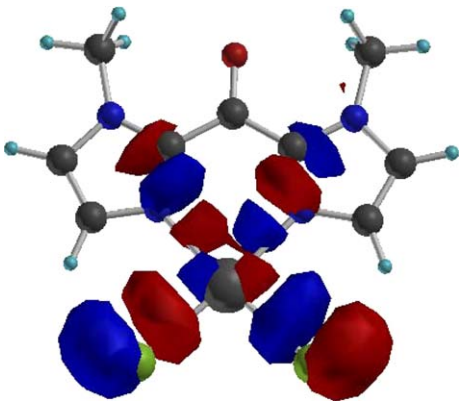

Fig. 3. DFT calculated SOMO of [(bik)$AuCl_2$]$^{\cdot}$.

The lowest unoccupied MO of **1** which is related to the singly occupied MO, SOMO, of [(bik)$AuCl_2$]$^{\cdot}$ shows almost no contributions from the organic ligand (Fig. 3), the bonds affected in terms of considerable elongation are those involving the metal. Metal–ligand dissociation is thus expected to occur on reduction at higher temperatures, consistent with the DFT results.

4. Supplementary data

CCDC 271455–271457, 604458 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

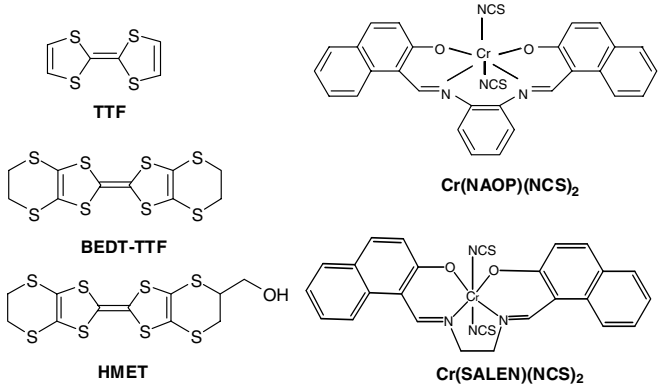
few are simple paramagnets [9,10]. That alternating cation–anion arrangement and π–π cation–anion stacking are necessary for observing bulk magnetic order in this class of compound has been demonstrated by some negative examples [9–12] which, although S···S cation–anion contacts are present, are simple paramagnets down to 2 K. Continuing our efforts in this line, we chose another anion based on a much bigger conjugated system containing a tetradentate Schiff base containing five aromatic rings, hoping to increase the π–π interactions and enhance the π–d magnetic exchange. Compared to the anions reported before, $[Cr(NAOP)(NCS)_2]^{2-}$ ($NAOP^{2-} = N,N'$-(1,2-phenylenebis(nitrilomethylidyne))bis-2-naphtholate) is sterically more demanding, more delocalized and has only two isothiocyanates *trans* to each other. Herein, we report the preparation of the precursor complexes, $(Bu_4N)[Cr(NAOP)(NCS)_2]$ (**1**) and $(Bu_4N)[Cr(SALEN)(NCS)_2]\cdot CH_3OH$ (**2**), the crystal structures and magnetic properties of [TTF][Cr(NAOP)(NCS)$_2$] (**3**), [BEDT-TTF][Cr(NAOP)-(NCS)$_2$]$\cdot$ 1.5CH_2Cl_2 (**4**), [HMET][Cr(NAOP)(NCS)$_2$]$\cdot$ 2.5CH_2Cl_2 (**5**) and $[TTF]_3[Cr(SALEN)(NCS)_2]_3\cdot 4CH_2Cl_2\cdot H_2O$ (**6**) (where $NAOP^{2-} = N,N'$-(1,2-phenylenebis (nitrilomethylidyne))bis(2-naphtholate), $SALEN^{2-} = N,N'$-ethylenebis(salicylideneiminate), TTF = tetrathiafulvalene, BEDT-TTF = ethylenedithio(tetrathiafulvalene) and HMET = hydroxymethyl-ethylenedithio(tetrathiafulvalene)). The following scheme shows the structural formulae of the donors and the metal-complex anions.



2. Experimental

2.1. Syntheses

All the chemicals were analytical grade and purchased from Aldrich. The Schiff base NAOP-H_2 (*N*,*N*′-bis(2-hydroxy-1-naphthylmethylene)-1,2-phenylenediamine) was prepared by refluxing 2-hydroxy-1-naphthaldehyde and 1,2-phenylenediamine in 2:1 in absolute ethanol. $[Cr(SALEN)(H_2O)_2]Cl$ [13], $(TTF)_3(BF_4)_2$ [14] and HMET [15] were prepared by the published methods.

2.2. Physical measurements

Variable temperature DC magnetization experiments were made with a Quantum Design MPSM1 SQUID magnetometer using randomly orientated polycrystalline material in a gelatine capsule. Magnetization was recorded from 2 to 300 K with an applied field of 100–500 G. Two-probe DC transport measurements were made with an Oxford instruments Mag Lab 2000 equipped with an EP probe. Gold wire electrodes (0.0025 mm diameter) were attached to the crystals using Au paste. Reflective Raman spectra were recorded at room temperature with a Renishaw InVia Raman microscope equipped with a diode laser (785 nm) and a 1200 l/mm grating using a laser power of ca 1 mW. The reported spectra are the result of 20 accumulations of 5 s each. The X-ray diffraction measurements were performed with a Nonius KappaCCD area detector at 120 K using ϕ scans and ω scans to fill asymmetric unit sphere for compounds **3**–**6**. All structures were solved by direct methods using the program SHELXS-97 and refined on F^2 by full-matrix least-squares procedures using SHELXL-97.

2.2.1. $[Cr(NAOP)(H_2O)_2]Cl$

A modification of the procedure described in the Ref. [13] was adapted. To a solution of $CrCl_3\cdot 6H_2O$ (0.01 mol) in ethylene glycol–water–methanol (1:1:3, 100 ml) were added NAOP-H_2 (0.01 mol). After the mixture was heated at 110 °C for about 30 min, sodium carbonate (0.007 mol) was added in small portions to the solution, followed by refluxing the solution for 4 h. On concentrating the solution, a brown precipitate was obtained. The precipitate was recrystallized from methanol to give dark brown crystal of the desirable complex used directly for the next reaction. Yield: 86%. *Anal*. Calc. for $C_{28}H_{22}N_2O_4ClCr$: C, 62.51; H, 4.13; N, 5.21. Found: C, 63.39; H, 4.40; N, 4.77%.

2.2.2. $(Bu_4N)[Cr(NAOP)(NCS)_2]$ (**1**)

The method described for $[Cr(SALEN)(NCS)_2K\cdot H_2O]$ [16] ($SALEN^{2-} = N,N'$-ethylenebis(salicyldeneiminate)) was adapted here. To a methanol solution (100 ml) was added $[Cr(NAOP)(H_2O)_2]Cl$ (0.005 mol) and tetrabutylammonium thiocyanate (0.02 mol). The resulting mixture was refluxed for 4 h with stirring. Some red brown solid was obtained when cooled to room temperature, which was filtered and washed with cold methanol. Dark red brown crystals were obtained after recrystallizing the solid from acetonitrile. Yield: 73%. *Anal*. Calc. for $C_{46}H_{54}N_5O_2S_2Cr$: C, 66.95; H, 6.61; N, 8.49. Found: C, 67.02; H, 6.58; N, 8.49%. IR (KBr, cm^{-1}): 2061s ($\nu_{C\equiv N}$) and 2089m ($\nu_{C\equiv N}$).

2.2.3. $(Bu_4N)[Cr(SALEN)(NCS)_2]\cdot CH_3OH$ (**2**)

The method described for $[Cr(SALEN)(NCS)_2K\cdot H_2O]$ [16] ($SALEN^{2-} = N,N'$-ethylenebis(salicyldeneiminate)) was adapted. To a methanol solution (15 ml) was added $[Cr(SALEN)(H_2O)_2]Cl$ (0.001 mol) and tetrabutylammonium thiocyanate (0.004 mol). The resulting mixture was

refluxed for 4 h with stirring. Red orange crystals were obtained when cooled to room temperature, which was filtered and washed with cold ether. Yield: 83%. *Anal*. Calc. for $C_{35}H_{54}N_5O_3S_2Cr$: C, 59.32; H, 7.63; N, 9.89. Found: C, 59.47; H, 7.48; N, 10.06%. IR (KBr, cm^{-1}): 2078s ($\nu_{C=N}$) and 2102m ($\nu_{C=N}$).

2.2.4. *[TTF][Cr(NAOP)(NCS)$_2$] (3)*

A dilute solution of $(TTF)_3(BF_4)_2$ (12 mg) in hot acetonitrile (40 ml) was filtered and to it was added an acetonitrile solution (10 ml) of $(Bu_4N)[Cr(NAOP)(NCS)_2]$ (25 mg). Storage at room temperature overnight afforded black needle-like crystals of the desired salt. Yield: 64% based on [Cr]. *Anal*. Calc. for $C_{36}H_{22}N_4O_2S_6Cr$: C, 54.93; H, 2.82; N, 7.12. Found: C, 54.55; H, 2.88; N, 7.33%. IR (KBr, cm^{-1}): 2071s ($\nu_{C=N}$).

2.2.5. *[BEDT-TTF][Cr(NAOP)(NCS)$_2$] · 1.5CH$_2$Cl$_2$ (4)*

The charge transfer salt was prepared by in situ oxidation of BEDT-TTF (5 mg), placed in the anode of an H-shaped electrochemical cell. The remainder of the cell was filled with a filtered solution of $(Bu_4N)[Cr(NAOP)(NCS)_2]$ (15 mg) in freshly distilled CH_2Cl_2 (30 ml). 0.5 μA was applied across the cell for a week giving about 1 mg of dark brown needle-like crystals which grew on the anode. *Anal*. Calc. for $C_{40}H_{26}N_4O_2S_{10}Cr$ (corresponding to complete loss of volatile solvent dichloromethane): C, 49.66; H, 2.71; N, 5.79. Found: C, 49.30; H, 2.77; N, 5.53%. IR (KBr, cm^{-1}): 2074s ($\nu_{C=N}$).

2.2.6. *[HMET][Cr(NAOP)(NCS)$_2$] · 2.5CH$_2$Cl$_2$ (5)*

The HMET charge transfer salt was prepared using an identical method to that which gave the BEDT-TTF salt. About 0.5 mg of black needle-like crystals was grown on the anode after twelve days. *Anal*. Calc. for $C_{41.5}H_{28}N_4O_3S_{10}CrCl$ (corresponding to loss of two volatile solvent dichloromethane): C, 48.00; H, 2.70; N, 5.40. Found: C, 48.14; H, 2.84; N, 5.35%. IR (KBr, cm^{-1}): 2077s ($\nu_{C=N}$).

2.2.7. *[TTF]$_3$[Cr(SALEN)(NCS)$_2$]$_3$ · 4CH$_2$Cl$_2$ · H$_2$O (6)*

TTF (10 mg) was placed in the anode of an H-shaped electrochemical cell. The remainder of the cell was filled with a filtered solution of $(Bu_4N)[Cr(SALEN)(NCS)_2]\cdot CH_3OH$ (30 mg) in freshly distilled CH_2Cl_2 (30 ml). 1.5 μA was applied across the cell for three days giving about 0.5 mg of black needle-like crystals which grew on the anode. *Anal*. Calc. for $C_{72}H_{56}N_{12}O_7S_{18}Cr_3$ (corresponding to complete loss of volatile solvent dichloromethane): C, 44.72; H, 2.90; N, 8.70. Found: C, 44.57; H, 2.81; N, 8.53%. IR (KBr, cm^{-1}): 2071s ($\nu_{C=N}$).

3. Results and discussion

3.1. Crystal structures

Single crystals of salts **3**–**6** were found to be suitable for single crystal X-ray diffraction. Standard ORTEP drawings of compound **3** and **4** are shown in Figs. 1, 2 with the atom numbering scheme and 50% thermal ellipsoids. A molecular structure of compound **6** is shown in Fig. 3. The crystal and refinement data are given in Table 1. Selected bond lengths of the donors are listed in Table 2.

The asymmetric unit of **3** contains one $TTF^{+\cdot}$ and one $[Cr(NAOP)(NCS)_2]^-$ (Fig. 1). The Cr atom is six-coordinate with the tetradentate ligand $NAOP^{2-}$ in the equatorial plane and two NCS in the axial positions coordinated via the N atoms. The Cr–N and Cr–O ($NAOP^{2-}$) distances are in good agreement with those observed in other Cr^{III} Schiff base complexes [16] and slightly shorter than those to N of NCS (i.e., Cr1–N1, Cr1–N2, Cr1–O1 and Cr1–O2 are 1.998(3), 2.004(3), 1.936(2) and 1.918(2) Å, respectively, as compared to 2.030(3) and 2.018(3) Å for Cr1–N31 and Cr1–N32, respectively). The bond angles of O1–Cr1–N2 and O2–Cr1–N1 are 173.45(10)° and 173.59(10)°, respectively, showing the Cr atom is slightly displaced from the equatorial plane. The NCS bond angles (175.6(3)–178.8(3)°) are nearly linear, whereas Cr1–N32–C32 (163.2(3)°) is much smaller than Cr1–N31–C31 (176.5(3)°). In $TTF^{+\cdot}$, both the C–S bond lengths (1.712(3)–1.727(3) Å) and C=C bond lengths (C43=C44, C41=C42, C45=C46 are 1.387(4), 1.338(5) and 1.332(5) Å, respectively) are in good agreement with those observed in other $TTF^{+\cdot}$ charge transfer salts [3,4,17].

A crystal packing diagram for compound **3**, showing the *ab*-plane and viewed in the *c*-direction, is given in Fig. 4. The $TTF^{+\cdot}$ and the $[Cr(NAOP)(NCS)_2]^-$ are segregated into layers and linked by hydrogen bonds and van der Waals forces. There is π–π stacking between TTF^+ and the $NAOP^{2-}$ ligand in the *c*-direction. Their planes are nearly parallel, e.g., the one bounded by S41, S43 and S44 makes an angle of 13.32° to the plane C6–C15–C23.

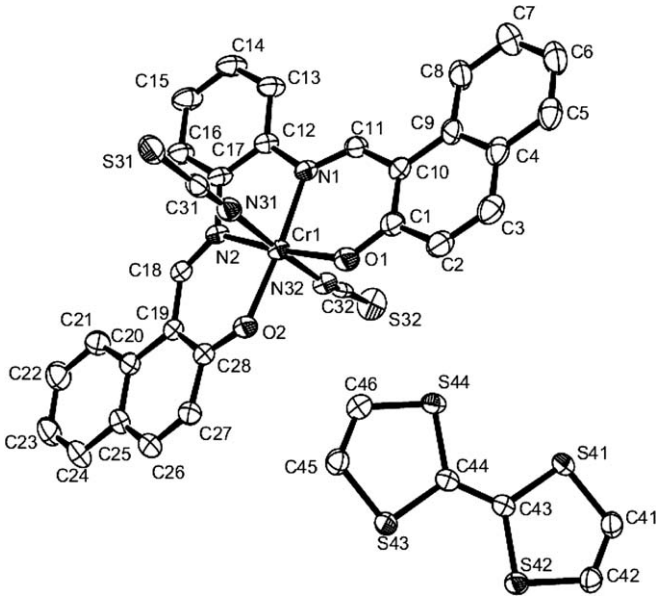


Fig. 1. ORTEP diagram with 50% probability for compound **3**.

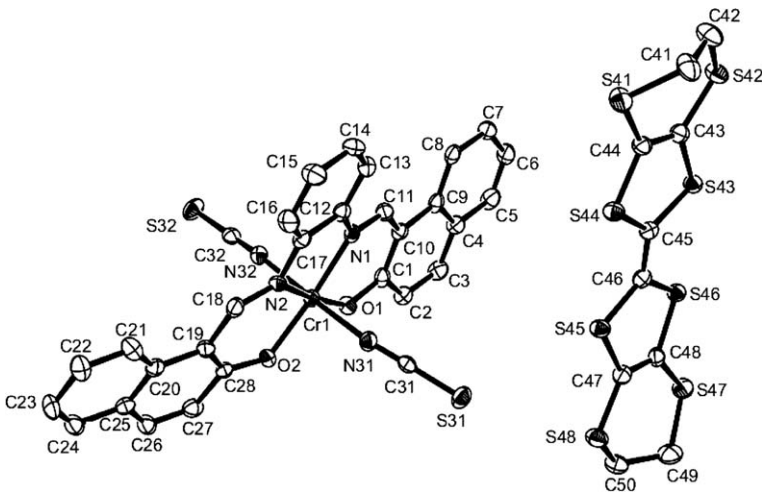

Fig. 2. ORTEP diagram with 50% probability for compound **4**, the solvate dichloromethane molecules and hydrogen atoms have been omitted for clarity.

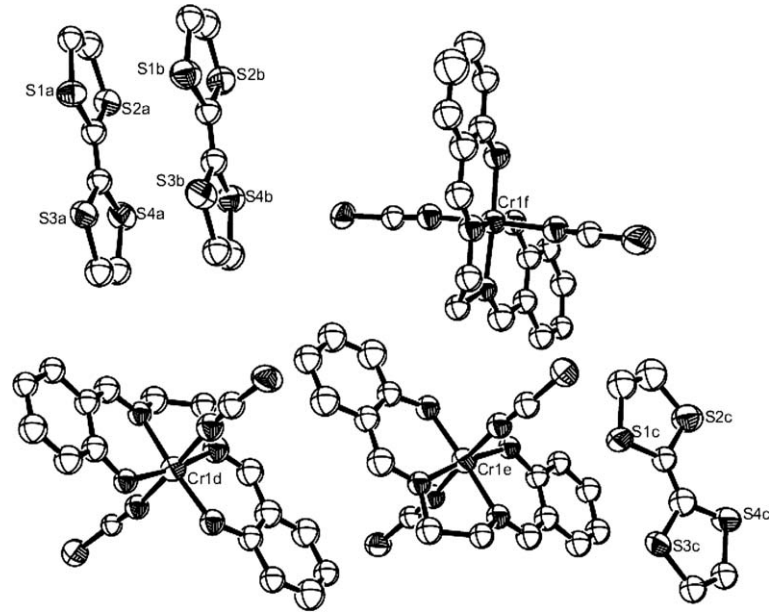

Fig. 3. Molecular structure for compound **6**; only the heavier atoms (Cr, Cl and S) were refined anisotropically. The solvate dichloromethane, water molecules and hydrogen atoms are omitted for clarity.

There are two kinds of S···S close contacts between $TTF^{+\cdot}$ and the anion, one (3.431 Å) between S31 and S41 involving π stacking and another (3.356 Å) between S32 and S42 not involving π stacking, both shorter than the S···S van der Waals distance of 3.6 Å. The $TTF^{+\cdot}$ occur as dimers with inter-cation distances of 3.282 Å (S41···S43) and 3.368 Å (S42···S44) but the shortest S···S distance between the dimers is very long (6.386 Å), much longer than in other TTF salts (4.33 Å) [17]. In addition there are also close S···S contacts between anions (e.g., S31···S31, 3.521 Å) and many other kinds of short contacts, such as weak C14–H14···C31 interactions between the non parallel anions and C–H···S (C16–H16···S32) with H16···S32 of 2.960 Å. The shortest distance between the parallel anions is 3.517 Å but there is no obvious π stacking among them.

Like compound **3**, compound **4** also shows many close contacts between the donor BEDT-TTF and the anion (S31···S43, 3.346 Å; S31···S42, 3.527 Å and S32···S47, 3.425 Å) (Fig. 5). The plane bounded by S44, S45 and S46 makes an angle of 28.78° to the plane C6–C15–C23. Unfortunately, the BEDT-TTF in compound **4** also form dimers with the shortest intermolecular distances of 3.439 Å (S43···S45) and 3.422 Å (S44···S46). From the well-known correlation between C–S and C=C bond lengths and donor charges for BEDT-TTF salts [18], the

charge on the BEDT-TTF in **4** can be estimated as 0.9 ± 0.1, which is in agreement with the stoichiometry and Raman data [19]. Furthermore, there are weak C–H···S interactions between the dimerized donors with a C50–H50B···S42 angle of 138.42° and H50B···S42 of 2.991 Å. If we define a plane bounded by C6, C15 and C23 then the anions are parallel to each other with the shortest inter-anion distance being 3.249 Å, similar to compound **3**, but the anions are arranged side by side and there is no π stacking between them. Thus, the 'dimerized' anions and the dimerized donors form a two-dimensional lattice via many kinds of weak interactions (hydrogen bonds and van der Waals forces). Solvent CH_2Cl_2 molecules are situated between the layers.

The crystal structure of compound **5** shows that it is a 1:1 salt, with CH_2Cl_2 molecules included in the lattice. The HMET and anions form a layer structure parallel to the *ab*-plane (Fig. 6). The structure was resolved in the *Pbca* space group, and its overall cell dimensions and structural arrangement closely resemble compound **4**, which could also be solved in the same space group to $R = 7.7\%$. However, in compound **5** the total structure is not as well defined ($R = 16\%$) since there is disorder in the point of attachment of the hydroxymethyl-sidechain. This necessarily affects the positions of the adjacent CH_2Cl_2 molecules, which are also disordered. Nevertheless, it is clear that the HMET donor molecules occur in pairs, face to face, but isolated from other donor molecules. This is the first structure containing the hydroxymethyl-ET molecule.

The unit-cell contents and relative dispositions of the molecules in the crystal of compound **6** were obtained

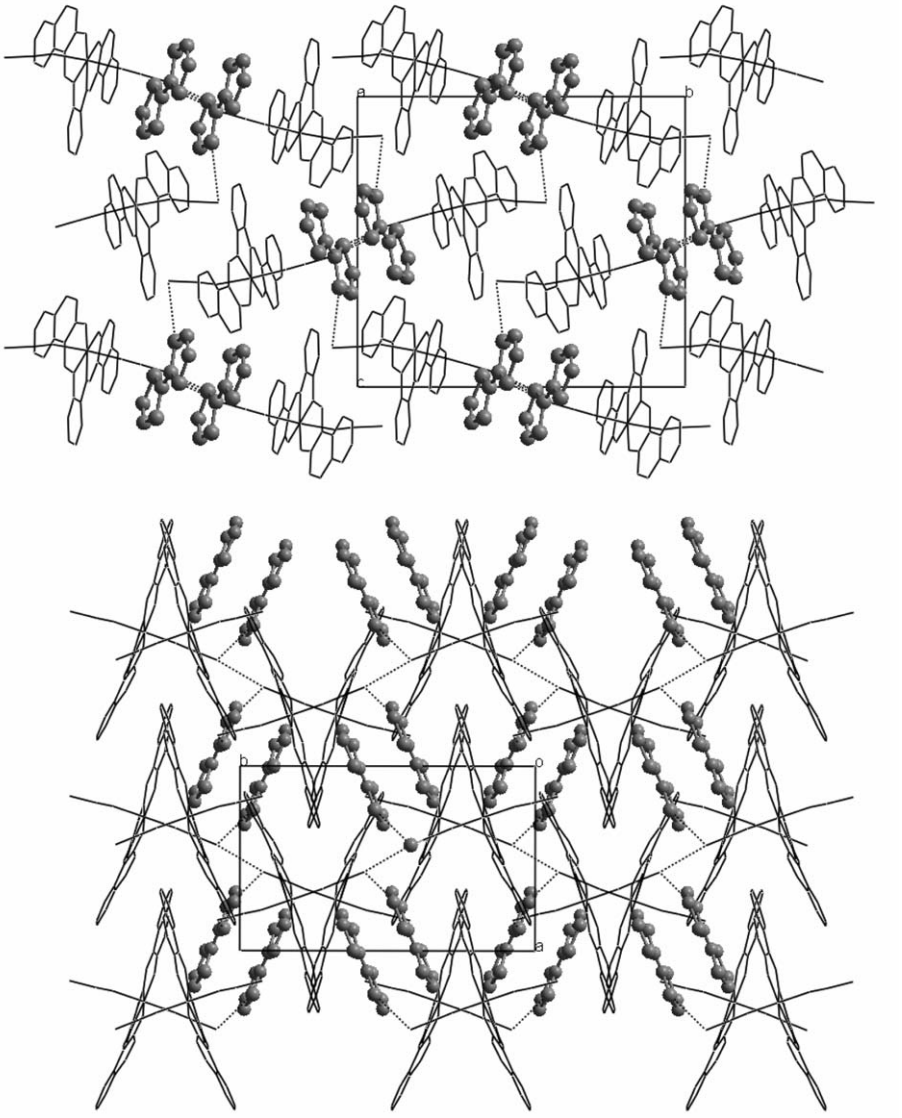

Fig. 4. Crystal packing diagrams for compound **3** viewed in the *a* (top) and *c* (bottom) directions, showing the S···S cation–anion and anion–anion close contacts and the cation dimers.

by single crystal X-ray diffraction. However the quality of the data ($R_{int} = 0.313$) meant that no full refinement was possible and only the heavier atoms (Cr, Cl and S) were refined anisotropically in a model with final *R*-value of 0.1946. It should be noted that the monoclinic *b*-axis is particularly long (57.434 Å). Nevertheless, it is clear that the asymmetric unit contains three $TTF^{+\cdot}$, three $[Cr(SALEN)(NCS)_2]^-$, four CH_2Cl_2 molecules and one disordered H_2O (Fig. 3). In $[Cr(SALEN)(NCS)_2]^-$, the Cr atom is coordinated with the tetradentate ligand $SALEN^{2-}$ in the equatorial plane and two NCS in the axial positions via the N atoms. The Cr–N and Cr–O (of $SALEN^{2-}$) distances are in good agreement with those observed in $[Cr(SALEN)(NCS)_2K \cdot H_2O]$ [16] and $[Cr(NAOP)(NCS)_2]^-$. A crystal packing diagram viewed along the *a*-direction is given in Fig. 7. As is common in this type of compound, the anions and the cations are linked together by many kinds of short contacts and H bonds which include the cation–anion S···S and $S \cdots O_{SALEN^{2-}}$ contacts. All the TTF cations are present as dimers with the shortest S···S distances in the range 3.227–3.394 Å. Compared to $[Cr(NAOP)(NCS)_2]^-$, $[Cr(SALEN)(NCS)_2]^-$ is much smaller in size with less extensive conjugation, which may diminish the possibilities of π–π stacking between the anions. Indeed, in compound **6**, there are no π–π stacking interactions between the anions and the nearest two anions are situated in the opposite positions. Finally, as shown in Fig. 7, the dimerized $TTF^{+\cdot}$ and the two nearest anions are arranged alternately and propagate approximately along the *b*-direction.

3.2. Magnetic properties

As was expected from the structures, no long-range magnetic ordering was observed down to 2 K among

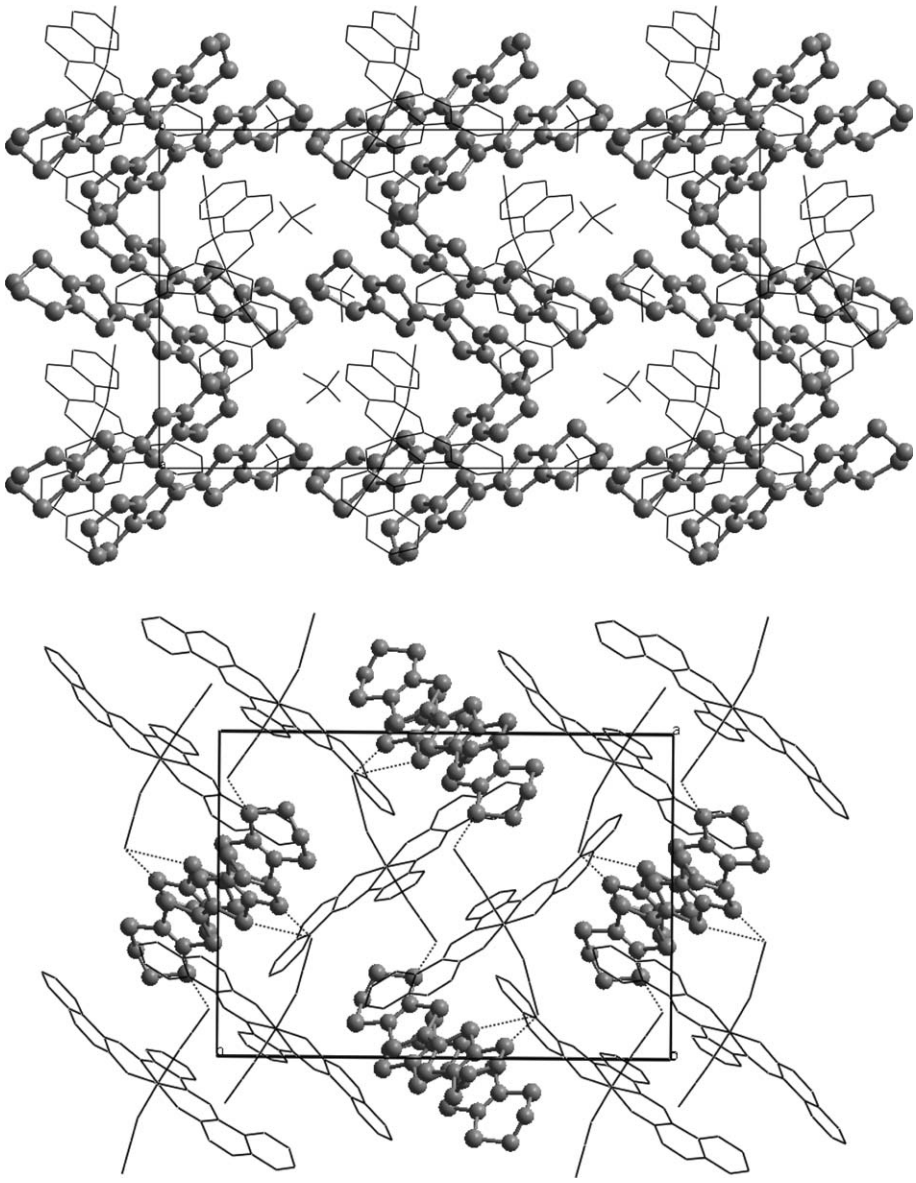

Fig. 5. Crystal packing diagram for compound **4** viewed in the *a*-direction, showing the cation–anion layered structure and dichloromethane molecules are situated between the layers (top); one layer viewed in the *c*-direction showing the S···S contacts between the donor and the anion (bottom).

all these charge transfer salts due to the lack of alternating cation–anion π–π contacts. Table 3 gives details of the Curie and Weiss constants of these compounds, determined from fits to the Curie–Weiss law $\chi_m = C/(T-\theta)$ from 2 to 300 K. The magnetic susceptibility of compound **3** is typical of a simple paramagnet (Fig. 8). The temperature variation of χ_m^{-1} follows the Curie–Weiss law over the whole temperature range with a Curie constant of 1.79 emu mol^{-1} K and a very small Weiss constant of +0.11 K. The C value is slightly lower than the spin-only value of 1.875 emu mol^{-1} K expected for one magnetically isolated Cr^{III} ($S = 3/2$) and the low temperature magnetization is dominated by the individual metal centers of the anions. For compounds **4**–**6**, the Weiss constants (−1.2 to −1.4 K) indicate the presence of weak antiferromagnetic interactions between the anions.

Two-probe DC transport measurements were made on compounds **3**–**6**. As expected, none of the compounds is a conductor; they are insulators with room temperature resistance higher than the largest that could be measured with the instrumentation (10^9 Ω).

3.3. Raman spectroscopy

Reflective Raman spectroscopy is used as a rapid means for determining or confirming the charge on the donor molecule by comparing the ν_3 and ν_4 of the symmetrical

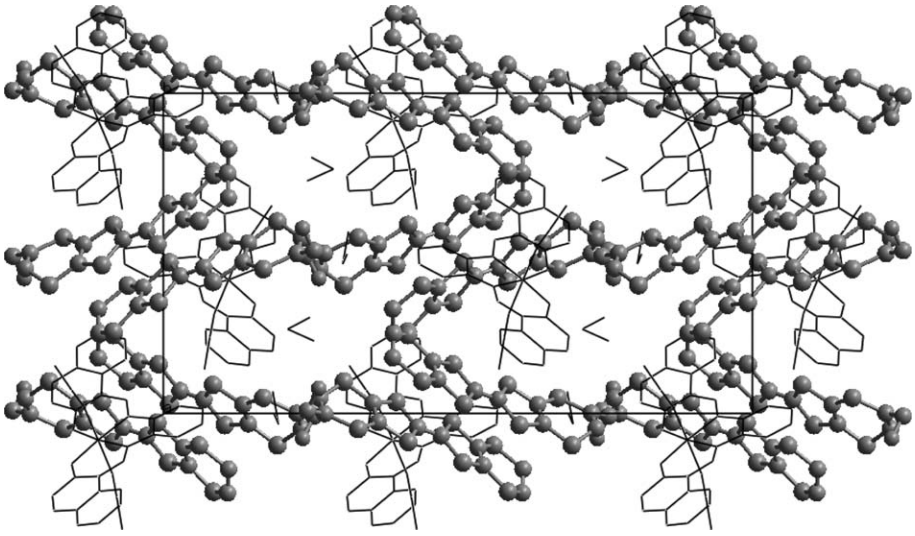

Fig. 6. Crystal packing diagram for compound **5** viewed in the *b*-direction, showing the layer stacking and dichloromethane molecules are situated between the layers. Only one orientation is shown for the donor and each solvent molecule.

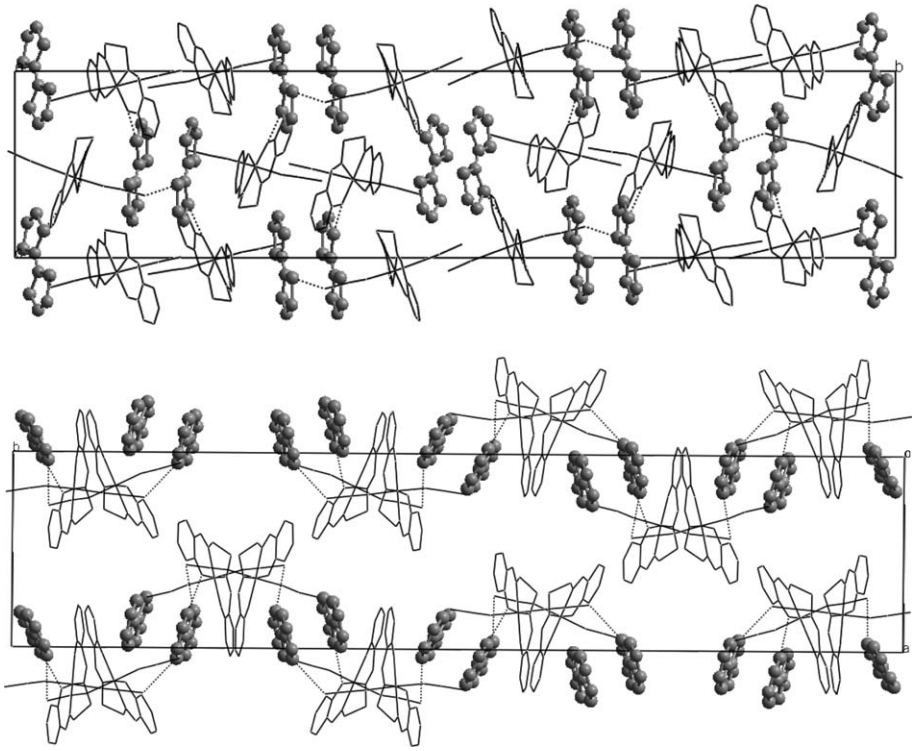

Fig. 7. Crystal packing diagram for compound **6** viewed in the *a* (top) and *c* (bottom) directions, showing the S···S and S···O ($SALEN^{2-}$) close contacts between the donor and the anion.

central C=C bond in the range of 1400–1480 cm^{-1} [19]. Compound **4** shows two peaks at 1420.9 and 1450.9 cm^{-1} and two weak and broad peaks are at 1535.7 and 1574.5 cm^{-1}. The two prominent peaks correspond to a charge of +0.9, which agrees well with that calculated from bond lengths for the donor ET^{+} in **4**. For compound **5**, there are two very prominent peaks at 1414 (ν_4) and 1456.1 (ν_3) cm^{-1} and three very weak peaks at 1533.0, 1575.2 and 1601.8 cm^{-1}. Using the formula in [19], the calculated charge of the TTF is +1.0, in agreement with the value 1.0 ± 0.1 from the bond length–charge correlation [18] and the stoichiometry.

Table 3
Curie and Weiss constants for compounds **3**–**6**

	3	**4**	**5**	**6**
Curie constant, C (emu mol^{-1} K)	1.79	1.79	1.80	1.85
Weiss constant, θ (K)	0.11	−1.4	−1.2	−1.3

4. Conclusions

We have described the synthesis of two precursors, $(Bu_4N)[Cr(NAOP)(NCS)_2]$ and $(Bu_4N)[Cr(SALEN)(NCS)_2]\cdot CH_3OH$, and the synthesis and crystal structures of four new charge transfer salts with stoichiometry [donor][Cr(SA)(NCS)$_2$] where SA = $NAOP^{2-}$ for donor = TTF, ET and HMET and SA = $SALEN^{2-}$ for donor = TTF. Anions $[Cr(NAOP)(NCS)_2]^-$ and $[Cr(SALEN)(NCS)_2]^-$ which have a tetradentate Schiff base in the equatorial plane and two isothiocyanates *trans* to each other are different from $[M(phen)(NCS)_4]^-$ and [M(isoquinoline)$(NCS)_4]^-$ (M = Cr or Fe) both in shape and size. Some charge transfer salts which contain the latter anions and various donors have been proved to show long-range π–d ferrimagnetic ordering at low temperature because of the alternating cation–anion arrangement in at least two directions. As for $[Cr(NAOP)(NCS)_2]^-$, increasing the size of the donor from TTF to ET and HMET was not sufficient to inhibit dimerization of the cations, with loss of the cation moment, and formation of alternating cation–anion stacks. It could mean that the shape of this anion plays an important role in directing the final crystal structures or it might be worth trying some bigger donors with more rings and more sulphur atoms.

It is not easy to find common features among the structures of this family of Schiff-base charge transfer salts; nevertheless with TTF as the donor, the structures do all contain alternate stacks consisting of segregated cations and anions with the $TTF^{+\cdot}$ separated clearly from the anions because of its smaller size. With ET and HMET, however, cations and anions are interleaved. To explore the crystal chemistry of the charge transfer salts containing this class of anion further, and in an effort to match the donor cation size with that of the anions, we chose $[Cr(SALEN)(NCS)_2]^-$ which is smaller and contains three fewer aromatic rings than $[Cr(NAOP)(NCS)_2]^-$. However the TTFs in $[TTF]_3[Cr(SALEN)(NCS)_2]_3\cdot 4CH_2Cl_2\cdot H_2O$ are also present as dimers. The arrangement of the donors and anions is quite similar to that in [TTF][Cr(NAOP)(NCS)$_2$]. It seems probable that it is primarily the overall shape of the anion that determines the arrangement of the anions and cations in the final structures. Summarizing, the challenge in designing new charge transfer salts with long-range π–d ferrimagnetic order remains open. From the crystal engineering point of view, the compounds described here should provide useful information for further design and investigation on this elusive class of π–d magnets.

1

A large number of fluorescent PET sensors that follow the basic design principle of a chromophore-spacer-receptor architecture have been reported to date [4]. The signaling process of these sensors depends on a molecular recognition event to inhibit, or initiate PET between a covalently linked chromophore and a receptor, leading to the generation (off–on), or quenching (on–off) of fluorescence. The role of the saturated spacer unit in these assemblies is to preserve the independence of the chromophore and the receptor in the electronic ground state.

The modular nature of this design has led to the development of a large number of molecules that are capable of functioning as sensors for a variety of cations. We have previously reported a fluorescent PET sensor based on the bis-(2-picolyl)amine receptor, that is capable of generating a fluorescence signal upon binding zinc ions [5]. In this paper we report a new sensor that is based on a coumarin chromohore and the same receptor, and also extend our cation binding studies to several transition and post transition metal ions [6].

The PET process responsible for the signaling in **1**, occurs from the receptor (tertiary amine) to the excited chromophore (coumarin), quenching the fluorescence of the coumarin. The driving force for this process (ΔG_{et}) can be expressed by modified Weller equation as follows:

$$\Delta G_{et} = -E_s - E_{red.chrom} + E_{ox.receptor},$$

where E_s, $E_{red.chrom}$ and $E_{ox.receptor}$ are the singlet energy, reduction potential of the chromophore and the oxidation potential of the receptor, respectively [4]. An increase in the oxidation potential of the receptor, caused by the binding of a cation, will increase the ΔG_{et}, which will decrease and eventually quench the PET process. This in turn will allow the excited chromophore to relax by fluorescence, and will result in the generation of a fluorescent signal in **1** due to cation binding.

2. Experimental

Nuclear magnetic resonance spectra were recorded on a Bruker Avance 300/300MHz FT-NMR Spectrometer. All NMR spectra were obtained in $CDCl_3$ at room temperature and the chemical shifts are reported in δ values (ppm) relative to TMS. High Resolution mass spectra were obtained at the Mass Spectrometry Service Laboratory at the Department of Chemistry, University of Minnesota. Elemental analysis was carried out at Robertson-Microlit Laboratories, Madison, New Jersey. Ultraviolet and visible spectra were recorded on Cary 300 Bio UV–Vis Spectrophotometer and Agilent 8453 Spectrophotometers. Excitation and emission spectra were recorded on a Cary Eclipse Fluorescence Spectrophotometer. Cation binding studies were carried out in anhydrous acetonitrile using metal perchlorate salts. Ionic strength of all solutions was maintained at 0.1 M using sodium perchlorate. (*Warning! Metal perchlorate salts are potentially explosive; the isolated salts should never be dried and should not be subjected to shock!*).

2.1. 4-[(Bis(pyridin-2-ylmethyl)amino)methyl]-7-methoxychromen-2-one (1)

A mixture of 4-(bromomethyl)-7-methoxycoumarin (1.102 g, 4.095 mmol), 2,2′dipicolylamine (0.808 g, 4.095 mmol), triethylamine (0.816 g, 8.08 mmol) in ethanol (77 mL) was refluxed for two days. After cooling to room temperature, dichloromethane (30 mL) was added and the mixture was washed with 3 M hydrochloric acid (4×30 mL). The aqueous layer was neutralized with sodium carbonate and extracted into dichloromethane (50 mL). The organic layer was dried over magnesium sulfate, filtered, and evaporated to give an oily residue. Purification by column chromatography (silica: methanol/ethyl acetate 5:95) gave **1** as a viscous residue (1.01 g, 53%). ^{1}H NMR ($CDCl_3$): δ 8.35–8.30 (m, 2H), 7.50–7.25 (m, 5H), 7.00–6.90 (m, 2H), 6.60–6.50 (m, 2H), 6.42 (s, 1H), 3.71 (s, 4H), 3.69 (s, 2H), 3.61 (s, 3H). ^{13}C NMR ($CDCl_3$): δ 161.96, 160.77, 157.89, 154.94, 152.62, 148.63, 136.09, 125.18, 122.63, 121.84, 111.71, 111.44, 110.92, 100.27, 60.01, 55.17, 54.16. HRMS (ESI) for $C_{23}H_{21}N_3O_3$ (M + Na) calculated 410.1475, found 410.1475. *Anal.* Calc. for $C_{23}H_{21}N_3O_3$: C, 71.29; H, 5.47; N, 10.85. Found: C, 71.02; H, 6.16; N, 10.87%.

3. Results and discussion

The fluorescence of **1** is quenched due to the thermodynamically favored PET between the tertiary amine and the excited chromophore. Increasing the oxidation potential of the tertiary amine due to cation binding prevents this PET and regenerates the fluorescence of the chromophore [5]. Three metal ions, Zn^{2+}, Cd^{2+} and Pb^{2+} show a significant fluorescence enhancement of **1**. No fluorescence enhancement was observed with Hg^{2+}, Ag^{+} and Cu^{2+}. The Job's plot data indicated that the ligand:metal binding ratio is 1:1 (see Figs. 1 and 2).

Sensor **1**, when dissolved in acetonitrile showed two peaks at 262 and 321 nm on the UV–Vis spectrum. On binding of Zn^{2+}, Cd^{2+} and Pb^{2+}, the peak at 262 nm remained the same while a small bathochromic shift was observed for the peak at 321 nm. For Cd^{2+} and Zn^{2+}, the new peak was observed at 328 nm while for lead it was 331 nm. This indicates the possibility of an interaction

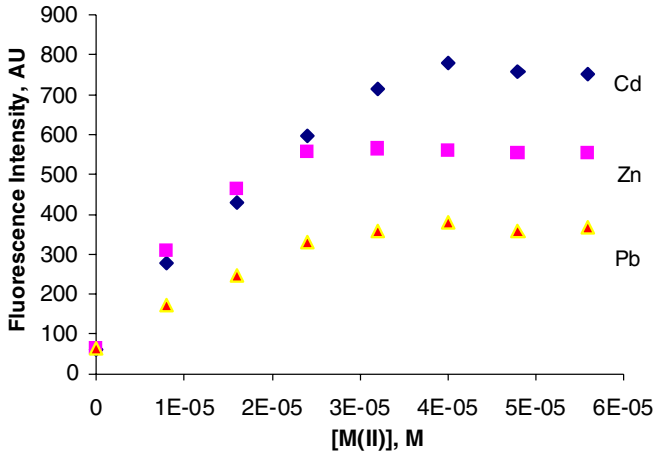

Fig. 1. Fluorescence intensity (I_f) of **1** (4.0×10^{-5} M) vs. metal ion concentration (0–5.6×10^{-5} M) in acetonitrile ($\lambda_{ex} = 330$, $\lambda_{em} = 410$ nm).

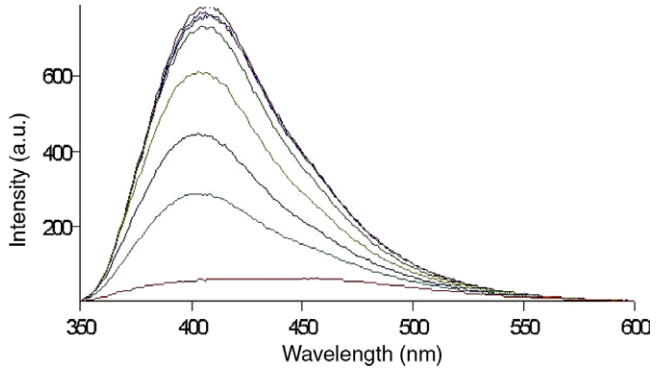

Fig. 2. Fluorescence emission spectra of **1** (4.0×10^{-5} M) with 0, 0.8, 1.6, 2.4, 3.2, 4.0, 4.8, 5.6 ($\times 10^{-5}$ M) of [Cd^{2+}] (in order of increasing intensity) in acetonitrile ($\lambda_{ex} = 330$ nm, $\lambda_{em} = 350$–600 nm).

between the metal bound ligand and the coumarin. The extinction coefficients (ε) of Zn^{2+}, Cd^{2+} and Pb^{2+} complexes were found to be 9434, 9832, 11 977 cm^{-1} M^{-1}, respectively.

Similar shifts attributed to the formation of charge transfer complexes between the cation bound receptor and the chromophore are documented [4a]. The binding constants ($\log \beta$) for these metal ions with **1** were measured, and found to be 6.10 ± 0.4, 6.37 ± 0.3, and 5.67 ± 0.3, respectively [7]. These values calculated from fluorescence measurements are in agreement with binding constants reported in the literature [5,6,11]. These results also indicate that **1** preferentially binds cadmium over zinc or lead.

Cadmium and lead are toxic heavy metal pollutants in the environment. It is believed that much of the physiological action of cadmium arises from its chemical similarity to zinc [8]. Specifically, cadmium may replace zinc in some zinc enzymes, thereby altering the stereostructure of the enzyme and impairing its catalytic activity [8]. Lead poisoning is one of the most common pediatric health problems in the US [9], and in particular in New York City. These factors make the detection and quantification of cadmium and lead in the environment a significant area of research.

Zinc is an integral part of many biologically important enzymes [10]. Interestingly, the adverse effects of both cadmium and lead are known to arise due to their ability to replace zinc from zinc-binding enzymes. Therefore, we were interested in comparing the binding properties of **1** with all three cations in order to compare its binding and sensing preference. We have observed that **1** preferentially binds cadmium over zinc or lead and we plan to carry out further studies to investigate this observation. Although there are many elegant examples of zinc [6a,6b,11] and lead [12] sensors reported to date, there are only a very few cadmium sensors reported [4d,13].

In summary, we have presented a fluorescent PET sensor that can function as a fluorescent off–on switch for Zn^{2+}, Cd^{2+}, and Pb^{2+}. Importantly, this cation sensor shows preferential binding and sensing for Cd^{2+}. The coumarin chromophore is expected to make this sensor more cell permeable than our previous sensor based on an anthracene chromophore. We are currently working on fluorescent PET sensors that would be more selective towards these cations, and more water soluble. We also hope to evaluate the signaling capabilities of these sensors in vivo.

peptide O atom to a third copper(II) ion. Only in the Cu(II) complexes with glycyl-amino acid dipeptides, 1:1 and 1:2 metal:ligand stoichiometries have been found, showing monomeric and dimeric compounds [16,17]. When the dipeptides contain side chains with additional donor atoms, such as histidine, those groups also participate in the coordination [18,19]. However, there is still lack of systematic studies.

On the other hand, the structure of copper complexes in solution is an issue that has not received proper attention, especially in the case of labile metal complexes such as those of copper(II). Relevant to the rationalization of the molecular structure–biological activity relationship in solution, is the atomic-resolution information provided by solid state structural determinations. In spite of the fact that there are several studies that present stability constant data and stoichiometry of the species in solution [2,3], it is necessary to have additional structural data before inferring the structures in solution from their crystal counterpart. In fact, there are some antecedents where combined potentiometric and EPR studies were instrumental in disclosing the molecular structure of species in solution.

As a continuation to our studies of copper(II) complexes with amino acids [20–22] and oligopeptides [10,11,23], the synthesis, analytical, structural and spectroscopic characterization of four new Cu(II) dipeptide complexes with gly-val, val-gly, val-phe and phe-phe as ligands are described in this work. The crystallographic analyses of the four Cu(II) complexes are presented. A preliminary characterization of their structures in solution, based on EPR and electronic spectroscopic techniques is also reported.

2. Experimental

2.1. Synthesis of the complexes and analytical characterization

The copper (II) complexes of stoichiometry [Cu(L-dipeptide)] · nH$_2$O were obtained by adding 0.15 mmol of CuCO$_3$ to 5 mL of an aqueous solution containing 0.1 mmol of dipeptide (dipeptide: L-gly-L-val, L-val-L-gly, L-val-L-phe, L-phe-L-phe, SIGMA). After stirring, the remaining excess of carbonate was filtered off and the obtained blue solution was concentrated by slow evaporation until the formation of crystals. They were separated by filtration and washed with small portions of a 1:2 water:acetone mixture. In all the studied complexes, the yield of the reactions was about 70%.

The composition of the complexes was confirmed by elemental analysis. *Anal.* Calc. for [Cu(gly-val)] · $\frac{1}{2}$H$_2$O (C$_7$H$_{13}$N$_2$O$_{3.5}$Cu): C, 34.35; H; 5.35; N, 11.45. Found: C, 34.52; H, 5.53; N, 11.51%. *Anal.* Calc. for [Cu(val-gly)] (C$_7$H$_{12}$N$_2$O$_3$Cu): C, 35.67; H, 5.13; N, 11.88. Found: C, 35.92; H, 5.58; N, 11.96%. *Anal.* Calc. for [Cu(val-phe)] (C$_{14}$H$_{18}$N$_2$O$_3$Cu): C, 51.60; H, 5.57; N, 8.60. Found: C, 51.96; H, 6.01; N, 8.60%. *Anal.* Calc. for [Cu(phe-phe)] (C$_{18}$H$_{18}$N$_2$O$_3$Cu): C, 57.82; H, 4.85; N, 7.49. Found: C, 57.42; H, 4.76; N, 7.57%.

2.2. Spectroscopic measurements

Electronic absorption spectra were recorded on aqueous solutions of the complexes with a Milton Roy Spectronic 3000 spectrophotometer, employing 1 cm quartz cells.

FTIR spectra, in the range between 4000 and 200 cm^{-1}, were measured as KBr pellets on a BOMEN MB 102 instrument.

2.3. Crystal structure determination

The X-ray diffraction data were collected on an Enraf-Nonius Kappa-CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Bragg reflections were collected up to 50° in 2θ, with a redundancy of 4 in all cases. The final unit cell parameters were determined by least-squares refinement of the angular settings for all collected reflections. The measurements were performed at low temperature, which was controlled with an Oxford Cryosystem device. Data collections were made using the COLLECT program [24]; integration and scaling of the reflections were performed with the HKL DENZO-SCALEPACK system of programs [25]. Absorption corrections were carried out using the multi-scan method [26]. The structures were solved using direct methods with SHELXS-97 [27]. The models were refined by full-matrix least-squares procedures on F^2 using SHELXL-97 [28]. The H atoms of the phenyl and methyl groups were positioned stereo chemically and refined with fixed individual displacement parameters [U_{iso}(H) = 1.2U_{eq}(C) or 1.5U_{eq}(C$_{methoxy}$)] using the SHELXL riding model with C–H length ranging from 0.93 to 0.98 Å. The WINGX program was used to analyze and prepare the data for publication [29]. The ORTEP3 for Windows [30] was used to prepare the molecular graphics. Crystal data, data collection procedures, structure determination methods and refinement results are summarized in Table 1.

2.4. EPR measurements

X-band (9.5 GHz) EPR measurements were carried out on aqueous solutions both at room temperature and at 77 K (as frozen solutions), and on solid samples at 77 K, using a Varian E109 spectrometer and cavities with 100 kHz field modulation. The g-values were obtained from spectral simulations using the QPOW [31,32] and the SimFonia [33] programs.

3. Results and discussion

3.1. Crystal structure of the complexes

The copper–dipeptide complexes crystallized in different spatial groups ($C2$, $P2_12_12_1$ and $P2_1$) as shown in Table 1. Figs. 1–4 show ORTEP plots from part of the unit cell of

the Cu(II) complexes with gly-val, val-gly, val-phe and phe-phe, respectively.

In the four studied complexes the Cu(II) has a pyramidal square-based coordination geometry. The copper occupies the centre of the square base, being equatorially coordinated to a dipeptide molecule acting as a tridentate ligand through the N-atom of the terminal NH_2 group, the deprotonated N-atom from the amide group, and one of the oxygen atoms of the carboxylate group. The fourth equatorial ligand is a carboxylate oxygen of a second

dipeptide molecule, giving rise to carboxylate bridged polymeric chains. The pyramid apex is occupied by an oxygen atom of the amide bond belonging to a third dipeptide molecule which, in turn, links adjacent chains through amidate bridges. The configuration around the copper ion, even in the case of copper complexes with glycyl dipeptides, is similar to those previously reported for related Cu-dipeptide complexes with non-coordinating side-chains [10]. The bond distances and angles around the copper centre are summarized in Tables 2–5.

The bond lengths are similar to those found in previously reported complexes [10–14]. The distances between

O(11)^{i}CuN(2)	102.3(1)	N(2)CuO(21)^{ii}	82.3(1)

Symmetry transformations used to generate equivalent atoms: (i) $-x+2$, $y+1/2$, $-z+2$; (ii) $x+1$, y, z.

two adjacent Cu(II) ions of the same chain linked by carboxylate bridges are 5.248, 5.087, 5.192 and 5.275 Å for [Cu(gly-val)] · $\frac{1}{2}H_2O$, [Cu(val-gly)], [Cu(val-phe)] and [Cu(phe-phe)], respectively, while the distances between neighbouring copper ions on different chains linked by amidate bridges are longer: 5.430, 5.770, 5.463 and 5.535 Å, respectively.

In spite of the common features exhibited by the four structures, there are some significant structural differences. The distances of the copper ion to the mean plane determined by the four equatorial ligands and the dihedral angles between adjacent planes are shown in Table 6. While the Cu(II) ion departs from the equatorial plane in distances that vary from 0.1444 Å (for the phe-phe complex) to 0.1950 Å (in the val-gly complex), the dihedral angle

Table 6
(1) Distances of the copper atom to the equatorial plane of ligands, and (2) dihedral angles between consecutive least-square planes

Compound	(1) Distance (Å)	(2) Angle (°)
[Cu(gly-val)] · $\frac{1}{2}H_2O$	0.1913	31.9
[Cu(val-gly)]	0.1950	77.4
[Cu(val-phe)]	0.1857	0.0
[Cu(phe-phe)]	0.1444	56.8

between adjacent planes varies from 0° (val-phe complex) to 77° (val-gly complex).

Consideration of the crystal packing shows that the aromatic rings in [Cu(phe-phe)] and [Cu(val-phe)] are planar to within experimental error and are parallel to the corresponding equivalent in the other molecule. It is interesting to note that the arrangement of the ligands in the lattice gives rise to hydrophobic layers of aromatic rings alternated with hydrophilic layers defined by the copper and the hetero-atoms of the ligands. In the case of [Cu(gly-val)] · $\frac{1}{2}H_2O$ a similar layered structure was found although this is now interrupted by water molecules near the glycine residues sites. In contrast, the crystal packing of [Cu(val-gly)] does not show these differentiated regions.

3.2. Infrared spectra

A tentative assignment of the most characteristic bands out of the band-rich infrared spectra of the complexes was carried out. In order to find such distinctive pattern of bands, the spectra of the copper complexes were studied and compared to those of the free dipeptides, and also to those found in our previous work on amino acids and dipeptide copper complexes [10,11,20,22,34]. The positions of the IR bands of the new copper-dipeptide complexes are presented in Table 7.

The free dipeptides exist as zwitterions in the solid state, as evidenced by the presence of a medium intensity band near the 2100 cm^{-1} region, which has been assigned to the combination of $\delta(NH_3^+)$ and $\rho(NH_3^+)$ [35]. This band disappears upon reaction with copper and the N–H stretching vibration of the NH_2 group is displaced to higher energies in relation to the free dipeptides. These spectroscopic facts signal the copper binding to the NH_2 group.

The N–H stretching band of the amido group disappears after coordination, in agreement with the deprotonation process that this group undergoes.

The two carboxylate stretching modes suffer only small changes upon coordination compared to the free dipeptide, in agreement with the usual behaviour exhibited by bridging carboxylate groups. The differences between $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ also support this coordination mode [36].

3.3. EPR spectra of solid samples

The powder EPR spectra of [Cu(gly-val)] · $\frac{1}{2}H_2O$, [Cu(val-gly)] and [Cu(phe-phe)] complexes are very similar. Fig. 5 shows the spectrum of [Cu(phe-phe)]. The EPR spectra do not show any hyperfine structure. This is probably due to exchange interactions between the paramagnetic ions mediated by the carboxylate bridges, which are known to provide relatively strong exchange couplings [37,38]. In such cases, exchange interaction may average out other interactions such as hyperfine [39]. This is in agreement with the polymeric structure found in the complexes.

Remarkably, in the case of [Cu(val-phe)], the EPR spectrum shows three lines that can not be explained in terms of a $S = 1/2$ spin (Fig. 6).

3.4. EPR spectra of solutions

The EPR spectra of frozen 1 mM solutions of all the studied compounds are very similar. Fig. 7 shows the spectra of

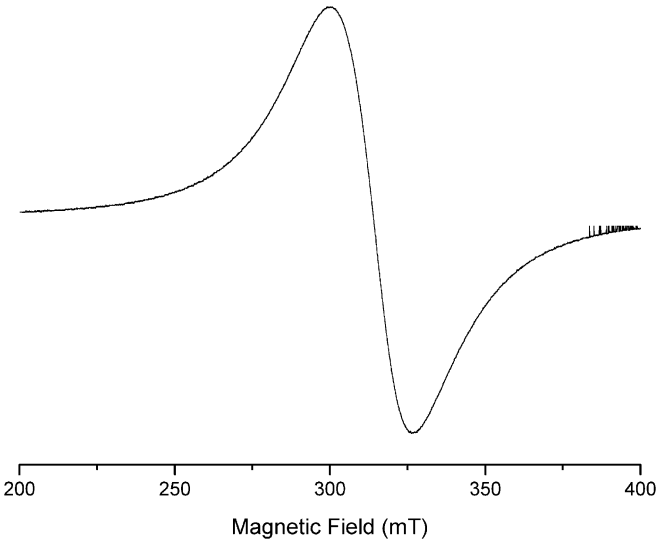

Fig. 5. EPR spectrum of [Cu(phe-phe)].

Table 7
Characteristic IR bands (cm^{-1}) of complex spectra

[Cu(gly-val)] · $\frac{1}{2}H_2O$	[Cu(val-gly)]	[Cu(val-phe)]	[Cu(phe-phe)]	Assignment
3392s/3260sh	3365s/3296m	3351m/3281m	3357m/3281w	$\nu(NH_2)$
1580s	1585s	1576s	1574s	ν(C=O)amide I
1600m	1626s/1613s	1611sh	1616m	$\delta(NH_2)$
1538s	1551s	1543s	1547s	$\nu_{as}(COO^-)$
1464m	1461m	1431m	1453m	$\nu_s(COO^-)$

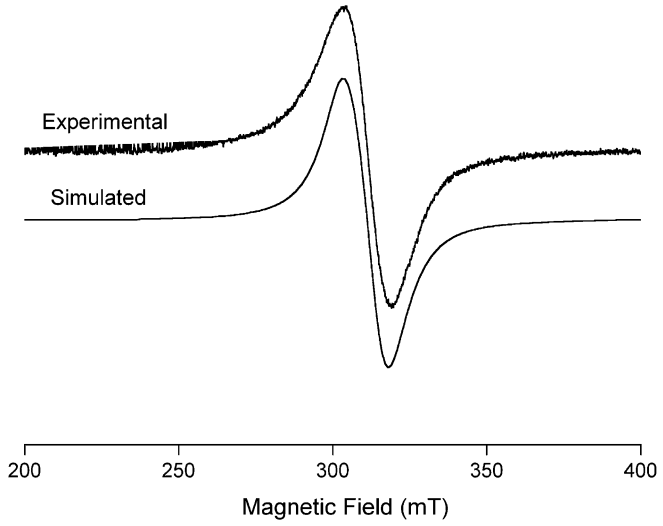

Fig. 7. EPR spectrum of a frozen 1 mM solution of the [Cu(phe-phe)] complex.

[Cu(phe-phe)], along with a simulation obtained with the QPOW program. Table 8 shows the parameters which fitted best the experimental spectra.

These results are typically found in the spectra of exchange coupled copper complexes [39].

In order to observe some hyperfine structure, it is necessary to reduce the concentration to about 0.5 mM. These results suggest that in the frozen solutions the complexes exist mostly as polymeric species, with exchange operating

Table 8
g-Parameters which gave the best simulations

Compound	$g_{\parallel}$	$g_{\perp}$
[Cu(gly-val)] · $\frac{1}{2}H_2O$	2.165	2.076
[Cu(val-gly)]	2.155	2.070
[Cu(val-phe)]	2.160	2.065
[Cu(phe-phe)]	2.150	2.075

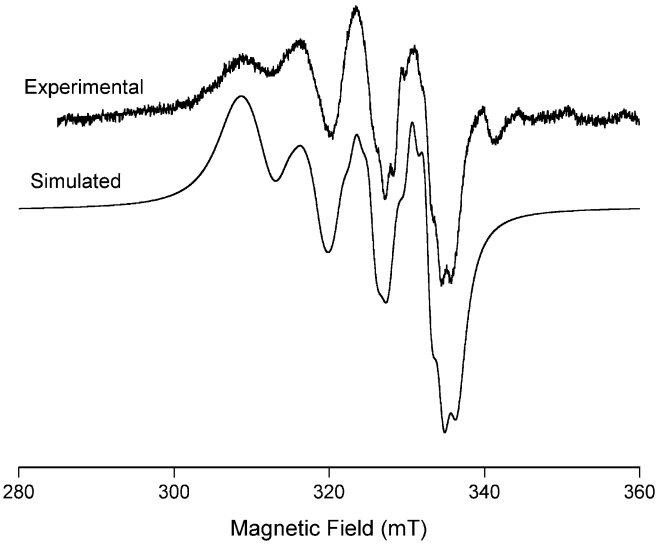

Fig. 8. EPR spectrum of a 0.5 mM solution of [Cu(val-phe)].

between their copper centres, while at lower concentrations the EPR spectrum is mainly due to uncoupled monomeric species.

In an attempt to determine whether these results reflect the composition of the solution at room temperature, additional spectra were recorded at 25 °C.

Fig. 8 shows the spectrum, at room temperature, of 0.5 mM solution of [Cu(val-phe)] and its simulated spectrum using the SIMFONIA program. The spectra of the other complexes are similar to the spectrum of [Cu(val-phe)].

In the spectrum shown in Fig. 8, the hyperfine structure due to the copper nuclear spin and the super-hyperfine structure due to the nitrogen nuclear spin can be clearly observed. This indicates that there is no exchange coupling between the copper atoms. Therefore, at room temperature the solution contains mostly uncoupled monomeric species. In addition, the extra peaks in the high-field line indicate the coordination through two equivalent nitrogens.

Summing up, it can be concluded that solutions of 0.5 mM, at room temperature, mostly contain monomeric species. On the other hand, at lower temperatures, the equilibrium is displaced towards the formation of the polymeric complexes, perhaps as a result of the concentration of solutes in small pockets. This idea has been previously suggested by Sigel et al. [2].

3.5. Electronic spectra

The electronic spectra of 5 mM aqueous solution of all the complexes at room temperature are very similar to one another. Table 9 shows the λ_{max} and the ε_M values of the complexes.

The complexes containing glycine residues present an absorption band near 635 nm while those containing bigger N-terminal residues show absorption band maxima at slightly minor wavelengths. These spectra are characteristic of Cu(II) in an octahedral environment and the main

Table 9
λ_{max} (nm) and ε_M (M^{-1} cm^{-1}) of the complexes

Compound	λ_{max} (nm)	ε_M (M^{-1} cm^{-1})
[Cu(gly-val)]	635	80
[Cu(val-gly)]	636	70
[Cu(val-phe)]	627	90
[Cu(phe-phe)]	626	100

absorption can be assigned to the $d_{xy} \rightarrow d_{x^2-y^2}$ transition [40].

The λ_{max} of these compounds lie close to those of the previously studied [Cu(ala-val)] and other Cu-dipeptide complexes [10,11].

The EPR spectroscopic results show that the monomeric moiety is the dominant species in diluted solutions of the copper complexes. Assuming that each copper ion is coordinated only to one dipeptide through the carboxylate oxygen atom, the amide nitrogen and the amine nitrogen atoms, and that the rest of the coordination positions are occupied by water, then, according to the empirical equation proposed by Prenesti et al. [41], the calculated λ_{max} would be 627 nm. This wavelength is similar to that found for [Cu(val-phe)] and [Cu(phe-phe)] complexes. In the case of complexes containing the glycine residue, where the experimental λ_{max} is slightly higher, it is possible that the molecules undergo further hydrolysis processes.

Acknowledgements

The authors are especially grateful to Prof. Dr. Otaciro Nascimento for the very helpful advice and discussion of the EPR spectra. $[Zn(4,4'\text{-bipy})_2(H_2O)_4](ClO_4)_2 \cdot 2(4,4'\text{-bipy})$ (**1**), $[Zn_3(4,4'\text{-bipy})_4(OAc)_4](ClO_4)_2 \cdot 2(H_2O)$ (**2**), $[Zn_3(4,4'\text{-bipy})_3(OAc)_4(H_2O)_2](ClO_4)_2 \cdot (H_2O)$ (**3**), $[Zn(4,4'\text{-bipy})(ClO_4)(H_2O)(OH)]$ (**4**), $[Zn(4,4'\text{-bipy})(DMSO)_4](ClO_4)_2$ (**5**), and $[Zn(4,4'\text{-bipy})_3(DMSO)_2](ClO_4)_2 \cdot 2(4,4'\text{-bipy}) \cdot (H_2O)$ (**6**). The series of compounds provides a clear illustration of the versatility of bipy as a spacer ligand when assembling transition metal ions into coordination polymers, providing examples of monomeric, linear chain, zig-zag chain, ladder, and two-dimensional network structures (Scheme 1). Varied structural topologies often appear from the same synthesis, differing in the weak hydrogen bonding and π-stacking interactions that are also present. A review of Zn(II) coordination polymers, including those containing bipy, has recently been published by Erxleben [17].

2. Experimental

2.1. Materials

The starting materials zinc(II) perchlorate hexahydrate (98%) and 4,4′-bipyridine (98%) were purchased from Aldrich Chemical Co. Dimethyl sulfoxide (99.9%) was purchased from Fisher Scientific. Absolute ethanol was purchased from Aaper Chemical Co. All reagents were used without further purification.

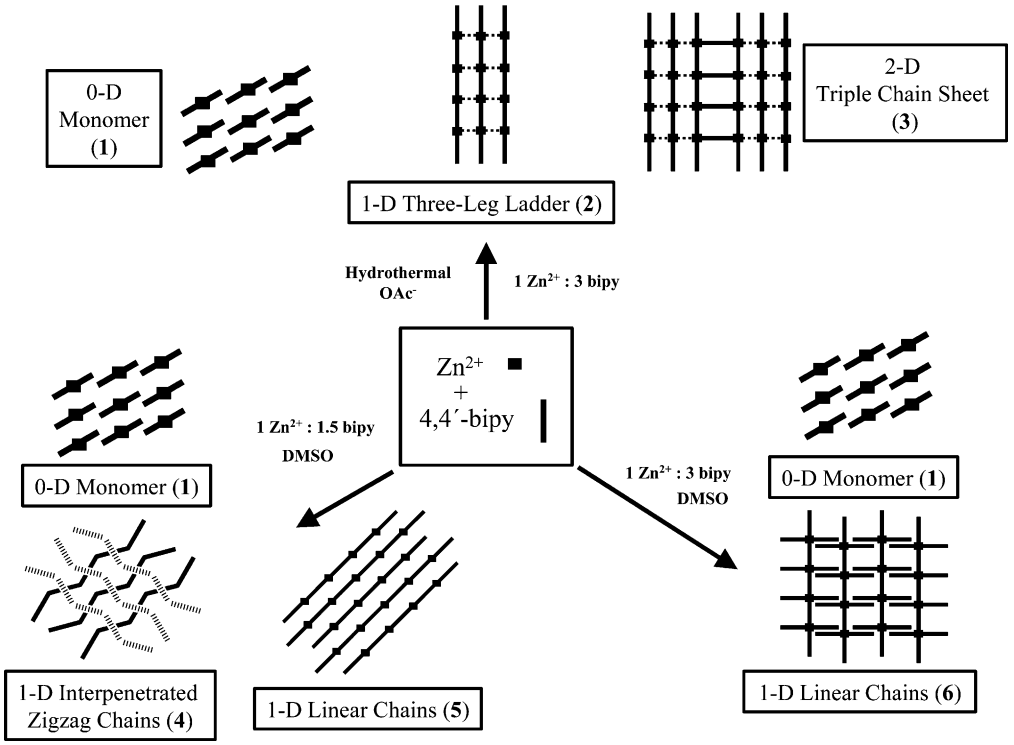
Caution! Perchlorate salts of metal complexes with organic ligands are potentially explosive. Although no explosive decomposition of compounds **1**–**6** has been observed in experiments performed up to 150 °C, caution should still be exercised when handling perchlorate salts.

2.2. Synthesis of $[Zn(4,4'\text{-bipy})_2(H_2O)_4](ClO_4)_2 \cdot 2(4,4'\text{-bipy})$ (**1**), $[Zn_3(4,4'\text{-bipy})_4(OAc)_4](ClO_4)_2 \cdot 2(H_2O)$ (**2**), and $[Zn_3(4,4'\text{-bipy})_3(OAc)_4(H_2O)_2](ClO_4)_2 \cdot (H_2O)$ (**3**)

A solution was prepared by dissolving 741 mg of $Zn(ClO_4)_2 \cdot 6H_2O$ (2.0×10^{-3} mol) in 10 mL of water contained within a Teflon canister. Addition of 934 mg of 4,4′-bipyridine (6.0×10^{-3} mol) and 2 mL of absolute ethanol produced in a white suspension. The Teflon canister was sealed within a homemade, stainless steel, hydrothermal autoclave, purged with argon gas, and heated to 150 °C for 5 days. The container was subsequently cooled to room temperature over a period of 24 h without any specific control over the rate of cooling. From this reaction mixture, colorless plates of **1** were obtained as the majority product and colorless needles of **2** and **3** crystallized as the minority products. The crystals were washed with water before further characterization. The composition of the products was determined by X-ray structure analysis.

2.3. Synthesis of $[Zn(4,4'\text{-bipy})(ClO_4)(H_2O)(OH)]$ (**4**) and $[Zn(4,4'\text{-bipy})(DMSO)_4](ClO_4)_2$ (**5**)

A solution containing 741 mg of $Zn(ClO_4)_2 \cdot 6H_2O$ (2.0×10^{-3} mol) dissolved in 10 mL of DMSO was combined with a solution containing 467 mg of 4,4′-bipyridine (3.0×10^{-3} mol) dissolved in 10 mL of DMSO. The resulting colorless solution, contained within an evaporating dish, produced colorless plates of **1** as the majority product and colorless crystals of **4** and **5** as the minority products within 2–4 weeks of solvent evaporation. The crystals were



Scheme 1.

washed with DMSO before further characterization. The composition of the products was determined by X-ray structure analysis.

2.4. Synthesis of [Zn(4,4′-bipy)$_3$(DMSO)$_2$](ClO$_4$)$_2$ · 2(4,4′-bipy) · (H$_2$O) (6)

A solution containing 741 mg of $Zn(ClO_4)_2 \cdot 6H_2O$ (2.0×10^{-3} mol) dissolved in 10 mL of DMSO was combined with a solution containing 934 mg of 4,4′-bipyridine (6.0×10^{-3} mol) dissolved in 10 mL of DMSO. The resulting colorless solution, contained within an evaporating dish, produced colorless plates of **1** as the majority product and colorless blocks of **6** as the minority product within 2 weeks of solvent evaporation. The crystals were washed with DMSO before further characterization. The composition of the products was determined by X-ray structure analysis.

2.5. X-ray structure determination

A colorless plate of compound **1** ($0.17 \times 0.21 \times 0.30$ mm^3), a needle of **2** ($0.04 \times 0.33 \times 0.51$ mm^3), a needle of **3** ($0.11 \times 0.15 \times 0.18$ mm^3), a plate of **4** ($0.07 \times 0.10 \times 0.12$ mm^3), a plate of **5** ($0.04 \times 0.20 \times 0.23$ mm^3), and block of **6** ($0.08 \times 0.19 \times 0.20$ mm^3) were selected for X-ray analysis. Each crystal was mounted on a glass fiber under nitrogen gas. The same data collection procedures were used for each sample. Data were collected at 173 K on a Siemens SMART PLATFORM equipped with a CCD area detector and a graphite monochromator utilizing Mo Kα radiation ($\lambda = 0.71073$ Å). Cell parameters were refined using 8192 reflections. A hemisphere of data (1381 frames) was collected using the ω-scan method (0.3° frame width). The first 50 frames were re-measured at the end of data collection to monitor instrument and crystal stability (maximum correction of I was <1%). Absorption corrections by integration were applied based on measured indexed crystal faces.

All structures were solved by the direct methods in SHELLXTL6 [18] and refined using full-matrix least squares. The non-H atoms were treated anisotropically, whereas the hydrogen atoms were calculated in ideal positions and were refined by riding on their respective carbon atoms. For compound **1**, the asymmetric unit consists of a Zn(II) ion, three 4,4′-bipy molecules, two water molecules, and one perchlorate anion. A total of 411 parameters were refined with F^2 in the final cycle using 6416 reflections with $I > 2\sigma(I)$ to yield $R_1 = 3.85\%$ and $wR_2 = 9.79\%$. For compound **2**, the asymmetric unit consists of two Zn(II) ions, two 4,4′-bipy molecules, two acetate molecules, a water molecule, and a perchlorate anion. Both acetate ligands are disordered and refined in two parts. Their site occupation factors were dependently refined to 0.49(7) and 0.50(3) for the first and second parts, respectively. A total of 362 parameters were refined with F^2 in the final cycle using 5939 reflections with $I > 2\sigma(I)$ to yield $R_1 = 4.59\%$ and $wR_2 = 11.12\%$. For compound **3**, the asymmetric unit consists of two Zn(II) ions, 1.5 4,4′-bipy molecules, two acetate molecules, a water molecule, and a perchlorate anion. A total of 329 parameters were refined with F^2 in the final cycle using 5088 reflections with $I > 2\sigma(I)$ to yield $R_1 = 3.63\%$ and $wR_2 = 9.08\%$. For compound **4**, the asymmetric unit consists of a Zn(II) ion, one 4,4′-bipy molecule, one water molecule, one hydroxide ion, and one coordinated perchlorate anion. The hydroxide proton is disordered and was refined in two positions, obtained from a difference Fourier map, with their site occupation factors fixed at 50% and their thermal parameters set at 1.5 that of their parent O atom. A total of 190 parameters were refined with F^2 in the final cycle using 2827 reflections with $I > 2\sigma(I)$ to yield $R_1 = 3.13\%$ and $wR_2 = 7.73\%$. For compound **5**, the asymmetric unit consists of two Zn(II) ions, one 4,4′-bipy molecule, four DMSO molecules, and two perchlorate anions. A total of 363 parameters were refined with F^2 in the final cycle using 6951 reflections with $I > 2\sigma(I)$ to yield $R_1 = 2.74\%$ and $wR_2 = 6.71\%$. For compound **6**, the asymmetric unit consists of a Zn(II) ion, five 4,4′-bipy molecules, two DMSO molecules, one water molecule, and two perchlorate anions. One of the 4,4′-bipyridine molecules is disordered and refined in two parts. Their site occupation factors were dependently refined to 0.54(1) for the major part, and consequently 0.46(1) for the minor part; C53 was found to be common to both parts. Both perchlorate counter ions were found to be disordered and each was refined in two parts with each pair's site occupation factors dependently refined to 0.62(1)/0.38(1) for the first and 0.53(1)/0.47(1) for the second, respectively. A 0.4 occupancy water molecule was found midway between the perchlorate ions. A total of 717 parameters were refined with F^2 in the final cycle using 11994 reflections with $I > 2\sigma(I)$ to yield $R_1 = 4.72\%$ and $wR_2 = 11.38\%$.

3. Results and discussion

3.1. Compound synthesis

Compounds **1**, **2**, and **3** resulted from the direct combination of one equivalent of $Zn(ClO_4)_2 \cdot 6H_2O$ with three equivalents of 4,4′-bipyridine under hydrothermal conditions (Scheme 1). Since 4,4′-bipy is relatively insoluble in water, elevated temperatures (150 °C) and pressures are necessary for the dissolution of the Zn–bipy suspension. Compound **1** is the majority product and crystallizes as colorless plates. Only relatively small quantities of **2** and **3** were obtained, both as colorless needles of similar morphology. To prevent the formation of unwanted side-products, such as high oxidation state metal oxides, the reaction mixtures were purged with argon gas and treated with a small quantity of ethanol (acting as a mild reducing agent) before heating. However, the ethanol itself was apparently oxidized, accounting for the presence of acetate ligands in **2** and **3**. Note that while compounds **1** and **3**

Symmetry transformations used to generate equivalent atoms: (a) $x, y-1, z$.

incorporate three equivalents of bipy per Zn(II) ion within their structures, **2** has four equivalents of bipy instead.

Compounds **4** and **5** were crystallized from DMSO by the combination of one equivalent of $Zn(ClO_4)_2 \cdot 6H_2O$ with 1.5 equivalents of bipy under ambient laboratory conditions while **6** was obtained using three equivalents of bipy (Scheme 1). From these reactions, compound **1** also co-crystallized as the major product while **4**, **5** (both present as colorless plates of similar morphology), and **6** (colorless blocks) were the minor products. Note that the initial Zn:bipy stoichiometries do not reflect those contained within the products. Additionally, reducing the relative quantity of bipy has no apparent effect on the quantity of **1** produced but favors the formation of compounds **4** and **5** compared to **6**. None of the compounds **1**–**6** are sensitive to loss of solvent or inclusions.

3.2. Description of the structures

Crystallographic and structural refinement data for the title compounds are given in Table 1. Selected bond distances and angles for **1**, **2**, **3**, **4**, **5** and **6** are shown in Tables 2–7, respectively.

3.3. $[Zn(4,4'\text{-bipy})_2(H_2O)_4](ClO_4)_2 \cdot 2(4,4'\text{-bipy})$ (1)

Compound **1** consists of sheet-like arrays of monomeric $[Zn(4,4'\text{-bipy})_2(H_2O)_4]^{2+}$ cations connected by intermediary, uncoordinated bipy molecules arranged to form hydrophobic, triangular channels. The ZnN_2O_4 unit (Fig. 1a) adopts a slightly distorted octahedral geometry, being coordinated axially by two *trans*-related 4,4′-bipyridine ligands with the equatorial sites occupied by four aqua ligands. The pyridyl rings of the bipy ligands are not coplanar but twisted along the central C–C bonds at angles of 27.9° with respect to one another. The monomeric $[Zn(4,4'\text{-bipy})_2(H_2O)_4]^{2+}$ cations form stacks along the *a*-axis. The uncoordinated pyridyl rings of the bipy ligands interdigitate with those in adjacent stacks giving

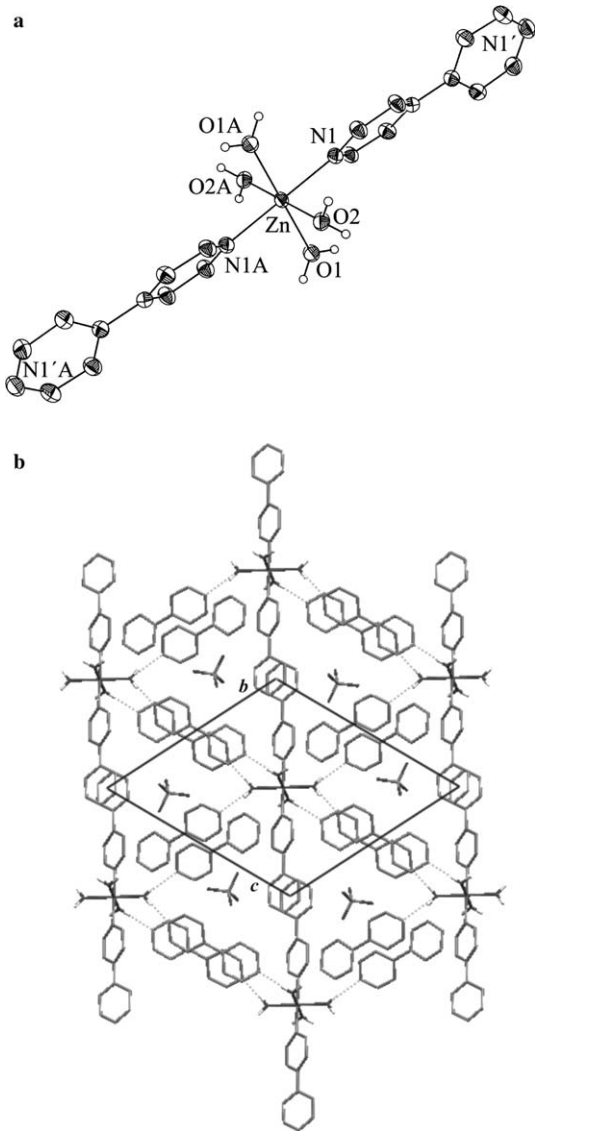

Fig. 1. Crystal structure of $[Zn(4,4'\text{-bipy})_2(H_2O)_4](ClO_4)_2 \cdot 2(4,4'\text{-bipy})$ (**1**): (a) ORTEP plot (drawn to encompass 50% of electron density) of a $[Zn(4,4'\text{-bipy})_2(H_2O)_4]^{2+}$ monomer with atomic numbering scheme and (b) perspective view parallel to the *a*-axis depicting the layered structure and triangular channels. All aromatic hydrogen atoms have been omitted for clarity.

rise to pseudo two-dimensional sheets. The offset face-to-face distances range from ≈3.1 to 3.5 Å indicative of relatively strong π-stacking interactions sustaining the sheets.

The sheets of monomers are well separated by uncoordinated bipy molecules and perchlorate counterions (Fig. 1b). The uncoordinated bipy's crosslink the sheets through an extensive array of N···H–O hydrogen bonds (1.98–2.08 Å) between the uncoordinated pyridyl nitrogen atoms and nearby aqua ligands, ultimately giving rise to a three-dimensional hydrogen-bonded network. The stacks of bipy guests define triangular, hydrophobic channels along the *a*-axis that clathrate perchlorate counterions. Two- and three-dimensional hydrogen-bonded networks

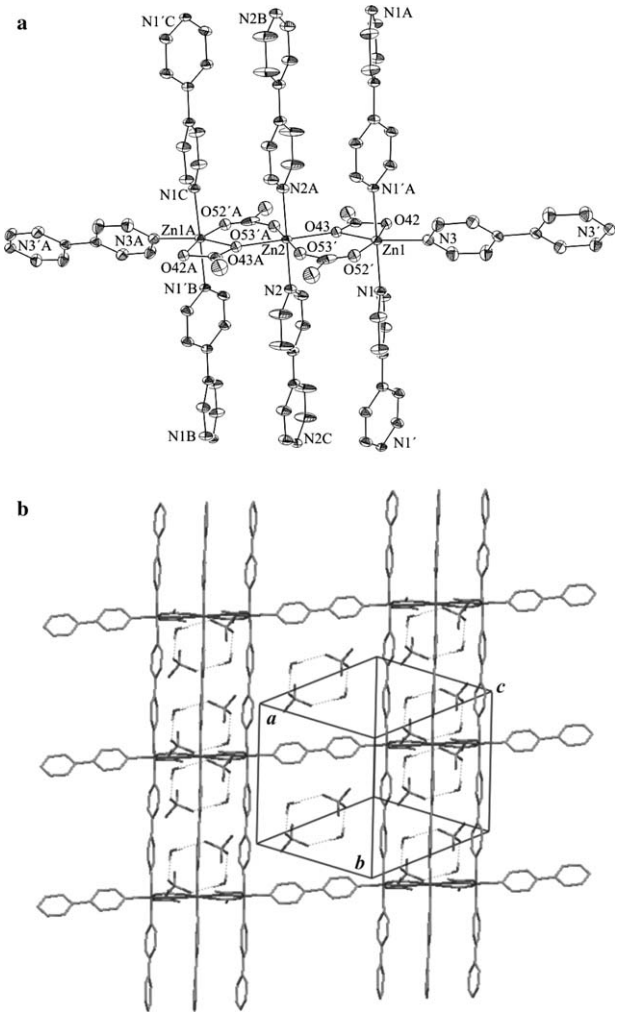

Fig. 2. Crystal structure of $[Zn_3(4,4'\text{-bipy})_4(OAc)_4](ClO_4)_2 \cdot 2(H_2O)$ (**2**): (a) ORTEP plot (drawn to encompass 50% of electron density) of a $[Zn_3(4,4'\text{-bipy})_8(OAc)_4]^{2+}$ moiety with atomic numbering scheme and showing only one orientation of the disordered acetate ligands and (b) perspective view of a sheet within the *ac*-plane depicting the prismatic and rectangular cavities as well as the cyclic, hydrogen-bonded perchlorate-water moieties. All aromatic and aliphatic hydrogen atoms have been omitted for clarity.

sustained through intermediary, uncoordinated bipy molecules have also been reported for $[Zn(4,4'\text{-bipy})(H_2O)_4](NO_3)_2 \cdot (4,4'\text{-bipy})$, $[Zn(4,4'\text{-bipy})(H_2O)_4](NO_3)_2 \cdot 2(4,4'\text{-bipy}) \cdot 3(H_2O)$ [2], and $[Zn(4,4'\text{-bipy})(H_2O)_3(ClO_4)](ClO_4) \cdot (4,4'\text{-bipy}) \cdot 1.5(H_2O)$ [19,20].

3.4. $[Zn_3(4,4'\text{-bipy})_4(OAc)_4](ClO_4)_2 \cdot 2(H_2O)$ (**2**)

The structure of compound **2** consists of cationic, two-dimensional $[Zn_3(4,4'\text{-bipy})_4(OAc)_4]^{2+}$ sheets that feature hydrophobic rectangular and prismatic cavities. The basic repeating units within the sheets are centrosymmetric, planar, $[Zn_3(OAc)_4]$ trimers that contain Zn(II) metal centers connected by *syn–syn* bridging acetate ligands (Fig. 2a). The peripheral Zn(II) ions are connected to the central metals each through unsymmetrical bridging (η-1,1) and bridging/chelating (η-1,3) acetate anions. The acetates are disordered in two parts about the central carbon atoms: one orientation consists of the η-1,1-mode and the other part is the η-1,3-chelate/bridge.

There are two distinct types of Zn(II) ions within the $[Zn_3(OAc)_4]$ trimers and the local coordination environments of the metal centers are depicted in Fig. 2a. For the peripheral Zn(II) ions, the $Zn1N_3O_3$ unit adopts a highly distorted octahedral geometry. The equatorial *cis*- and *trans*-N–Zn1–O and O–Zn1–O angles deviate significantly from the expected 90° and 180°, respectively, due to the chelating acetate ligands. The bite angles of the four-member chelating acetate rings (O42–Zn1–O43 and O52–Zn1–O53) are 58.8° and 58.5°, respectively. The central $Zn2N_2O_4$ site is also distorted, being coordinated axially by two *trans*-related 4,4′-bipyridine ligands and equatorially by oxygen atoms from four disordered acetate ligands. The Zn1–O43 (43A)–Zn2 and Zn1–O53 (O53A)–Zn2 bridging angles are 119.1° and 120.3°, respectively.

The axial bipy ligands link adjacent $[Zn_3(OAc)_4]$ trimers to form Zn–bipy triple chains which extend along the *b*-axis. The Zn–bipy–Zn distances along the three chains are all equal (11.464 Å). While the pyridyl rings of the outer chain bipy's are twisted 30.1° along the central C–C bonds, those of the central bipy ligands are coplanar. Adjacent aromatic rings participate in weak, offset π-stacking interactions with face-to-face contacts of ≈3.8 Å, reflecting the Zn1–Zn2 and Zn1A–Zn2 separation distances of 3.784 Å. The close approach of the aromatic rings causes slight distortions along both the peripheral and central bipy chains.

The equatorial bipy ligands further link the peripheral Zn(II) ions of the trimers perpendicular to the chains to form two-dimensional, cationic sheets (Fig. 2b). The sheets possess two distinct types of cavities. Narrow, prismatic cavities (3.78×11.64 Å^2) within the triple chains and larger, rectangular hydrophobic cavities (11.46×11.59 Å^2) are found between the triple chains. Sheet topologies exhibiting a related connectivity as well as possessing both prismatic and rectangular cavities similar to **2** are observed in $[M_8(ip)_8(4,4'\text{-bipy})_8]$ (M = Ni, Cd; ip = isophthalate) [21] and [M(tp)(4,4′-bipy)] (M = Co, Cd, Zn; tp = terephthalate) [22], all of which incorporate carboxylate-bridged, metal–bipy double chains rather than the triple chains observed for **2**.

Adjacent sheets are offset, super-positioning the prismatic cavities within the triple chains toward the faces of the rectangular, hydrophobic cavities on adjacent sheets. The space between the sheets is occupied by anionic, cyclic, dimeric units (Fig. 2b) comprised of two perchlorate counterions and two lattice water molecules that are sustained by two short (1.99 Å) and two long (2.22 Å) O···H–O hydrogen bonds. Similar clusters have been observed in $[Cd(4,4'\text{-bipy})_2(H_2O)_2] \cdot (NO_3)_2 \cdot 4(H_2O)$ [23].

3.5. $[Zn_3(4,4'\text{-bipy})_3(OAc)_4(H_2O)_2](ClO_4)_2 \cdot (H_2O)$ (3)

The structure of compound **3** consists cationic $[Zn_3(4,4'\text{-bipy})_3(OAc)_4(H_2O)_2]^{2+}$ three-leg ladders containing hydrophobic, prismatic cavities. The basic repeating units within the ladders are centrosymmetric, planar, $[Zn_3(OAc)_4]$ trimers, similar to those in **2**, that contain Zn(II) metal centers connected by *syn–syn* bridging acetate ligands (Fig. 3a). In contrast to **2**, the peripheral $Zn2N_2O_4$ moiety contains an equatorial aqua ligand (O5) in place of the bridging bipy.

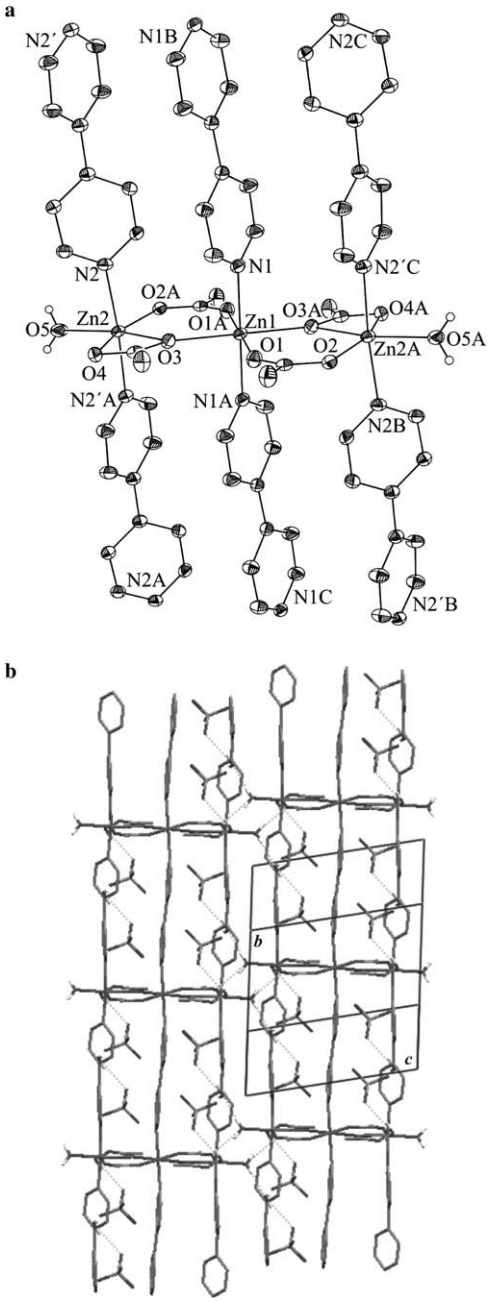

Fig. 3. Crystal structure of $[Zn_3(4,4'\text{-bipy})_3(OAc)_4(H_2O)_2](ClO_4)_2 \cdot (H_2O)$ (**3**): (a) ORTEP plot (drawn to encompass 50% of electron density) of a $[Zn_3(4,4'\text{-bipy})_6(OAc)_4(H_2O)_2]^{2+}$ moiety with atomic numbering scheme and (b) perspective view of a sheet of three-leg ladders within the *bc*-plane depicting prismatic cavities. All aromatic and aliphatic hydrogen atoms have been omitted for clarity.

The bipy ligands coordinated above and below the plane containing the $[Zn_3(OAc)_4]$ moieties link adjacent trimers together to form three-leg ladders which extend along the crystallographic *b*-axis (Fig. 3b). The Zn–bipy triple chains act as the legs and the $[Zn_3(OAc)_4]$ moieties act as the rungs. The replacement of the equatorial bridging bipy ligands in **2** by aqua ligands prevents **3** from extending along the *c*-axis to form two-dimensional sheets. The Zn–bipy–Zn distances along the three chains are all equal (11.325 Å). While the pyridyl rings of the outer leg bipy's are twisted 36.7° along the central C–C bonds, those of the central bipy ligands are coplanar. Adjacent aromatic rings participate in weak, offset π-stacking interactions with face-to-face contacts ranging from ≈3.8 to 4.0 Å. The close approach of the twisted aromatic rings causes a significant distortion along the central bipy chains. In contrast, the peripheral chains experience only a slight distortion. Narrow, prismatic cavities (3.89×11.33 Å^2) are present within the three-leg ladders. Adjacent three-leg ladders are juxtaposed on a side-by-side fashion to form pseudo two-dimensional sheets sustained by double, inter-ladder hydrogen bonds (O···H–O, 1.98 Å) between the aqua and acetate ligands on adjacent ladders. The sheets adopt a layered topology, similar to that in **2**. The interlayer space is occupied by lattice waters and perchlorate counterions. Acetate-bridged, three-leg ladder coordination polymers similar to **3** have been reported for $[Zn_3(OAc)_4(4,4'\text{-bipy})_3\{N(CN)_2\}_2]$ [24] and $[Co_3(OAc)_4(bpe)_3(dca)_2]$ (bpe = 1,2-bis-(4-pyridyl)ethane, dca = dicyanamide) [25] while $[Cu(4,4'\text{-bipy})(OAc)_2]_2 \cdot 2.5(H_2O)$ and $[Zn(4,4'\text{-bipy})(OAc)_2]_2$ [26] are analogous two-leg ladders.

3.6. Structure of $[Zn(4,4'\text{-bipy})(ClO_4)(H_2O)(OH)]$ (4)

Compound **4** is a network of neutral, interpenetrating, zig-zag chains. The ZnN_2O_3 unit (Fig. 4a) adopts a distorted trigonal bipyramidal geometry, being coordinated axially by aqua (O1) and hydroxide (O2) ligands while the equatorial sites are occupied by two 4,4′-bipyridine ligands and a monodentate perchlorate anion (O3). The Zn–O bond distances exhibit considerable variation. The Zn–O3 bond (1.96 Å) is short compared to the distances reported for other Zn(II)–monodentate ClO_4^- complexes (2.32–2.38 Å) however, the equatorial coordination of perchlorate in **4** would account for this discrepancy [20]. Similarly, the long Zn–O1 (2.24 Å) and intermediate Zn–O2 (2.09 Å) bonds are longer than those distances reported for aqua-Zn(II) (2.12–2.19Å) [2] and hydroxo-Zn(II) (1.94–1.97 Å) [27] complexes due to their axial coordination. The intermediate Zn–O2 bond is reasonable for a coordinated hydroxide ion rather than an aqua ligand based on bond distance and charge balance considerations.

Compound **4** exhibits a form of inclined interpenetration with the zig-zag chains weaving a three-dimensional network in the *bc* plane, intersecting at an angle of ≈80° (Fig. 4b). The sheets then stack along the *a* axis, held together by hydrogen bonds (O···H–O, 1.92 Å) between

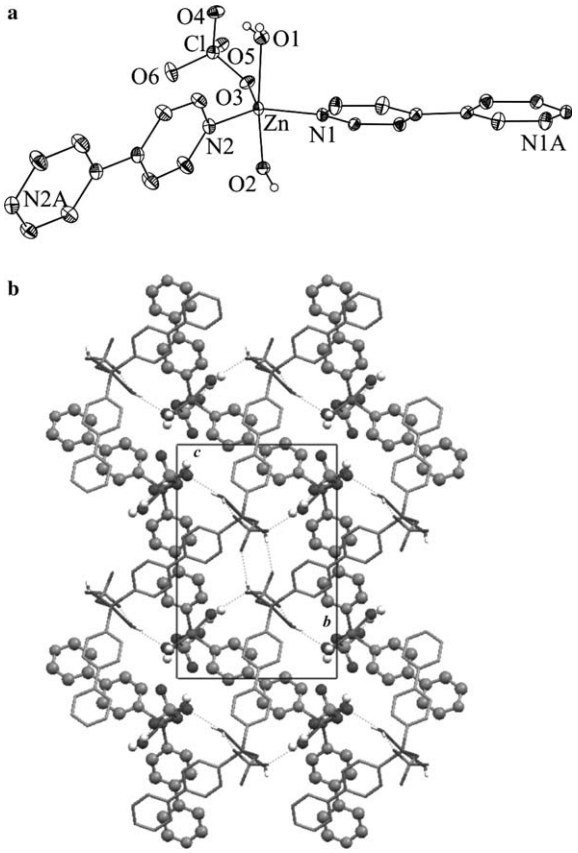

Fig. 4. Crystal structure of $[Zn(4,4'\text{-bipy})(ClO_4)(H_2O)(OH)]$ (**4**): (a) ORTEP plot (drawn to encompass 50% of electron density) of a $[Zn(4,4'\text{-bipy})_2(ClO_4)(H_2O)(OH)]$ fragment with atomic numbering scheme and (b) perspective view parallel to the *a*-axis depicting the network of mutually interpenetrated chains; adjacent parallel chains are shown in tube form and adjacent inclined chains are shown as ball-and-stick representation. All aromatic hydrogen atoms have been omitted for clarity.

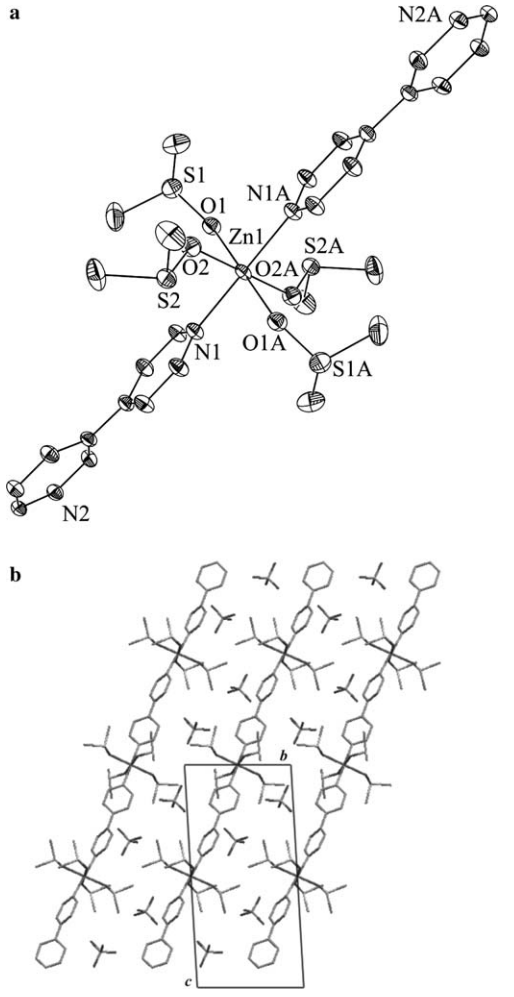

Fig. 5. Crystal structure of $[Zn(4,4'\text{-bipy})(DMSO)_4](ClO_4)_2$ (**5**): (a) ORTEP plot (drawn to encompass 50% of electron density) of a $[Zn(4,4'\text{-bipy})_2(DMSO)_4]^{2+}$ fragment with atomic numbering scheme and (b) perspective view parallel to the *a*-axis depicting the linear chains. All aromatic and aliphatic hydrogen atoms have been omitted for clarity.

the hydroxide and perchlorate oxygen atoms on adjacent chains. This self-inclusion reduces the volume of void space so that no lattice guests or counterions are present. Interpenetration to fill void space within a lattice is now a common feature of coordination polymers [28]. Some related examples include $[Cu(bpe)_2][Cu(bpe)(H_2O)_2(SO_4)_2]\cdot 2H_2O$ (bpe = *trans*-1,2-bis(4-pyridyl)ethylene), which is a three-dimensional interpenetrated network resulting from one-dimensional $[Cu(bpe)_2]$ chains threading through and filling void space within the rhombic channels of adjacent two-dimensional $[Cu(4,4'\text{-bpe})(H_2O)_2(SO_4)_2]$ grids [29]. Additionally, $[Cu(bpe)(H_2O)(SO_4)]$ is a mutually interpenetrated, three-dimensional network resulting from the inclusion of undulating, two-dimensional grids into the rhombic channels of adjacent sheets [29].

3.7. Structure of $[Zn(4,4'\text{-bipy})(DMSO)_4](ClO_4)_2$ (5)

Compound **5** consists of cationic, one-dimensional $[Zn(4,4'\text{-bipy})(DMSO)_4]^{2+}$ chains. The ZnN_2O_4 unit (Fig. 5a) adopts a slightly distorted octahedral geometry, being coordinated axially by two *trans*-related bipy ligands while the equatorial sites are occupied by four DMSO ligands. As shown in Fig. 5b, the *trans*-coordination of the bridging bipy ligands produces linear chains that extend along the [0 −1 1] direction. The pyridyl rings and the bipy ligands are not coplanar but twisted at an angle of 38.0°. Adjacent chains are arranged in a staggered fashion (Fig. 5b) with perchlorate anions tying them together via weak O···H–C contacts (2.43–2.67 Å) with nearby methyl and aromatic hydrogen atoms.

3.8. $[Zn(4,4'\text{-bipy})_3(DMSO)_2](ClO_4)_2\cdot 2(4,4'\text{-bipy})(H_2O)$ (6)

The structure of compound **6** consists of cationic, one-dimensional $[Zn(4,4'\text{-bipy})_3(DMSO)_2]^{2+}$ chains. The ZnN_4O_2 unit (Fig. 6a) is a slightly distorted octahedron with axial DMSO ligands and four equatorial bipy ligands. Two *trans* bipy ligands bridge the Zn(II) ions to form infinite linear chains (Fig. 6b) whereas the other *trans* pair are

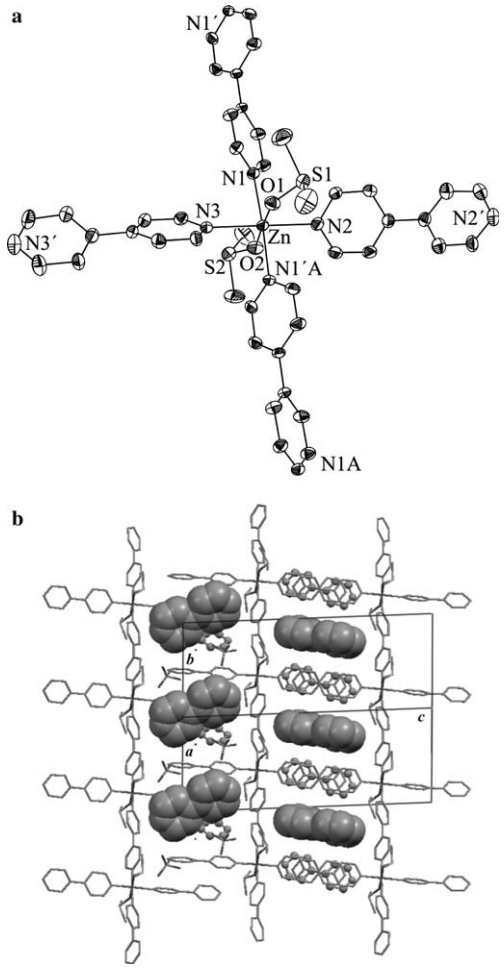

Fig. 6. Crystal structure of $[Zn(4,4'\text{-bipy})_3(DMSO)_2](ClO_4)_2 \cdot 2(4,4'\text{-bipy}) \cdot (H_2O)$ (**6**): (a) ORTEP plot (drawn to encompass 50% of electron density) of a $[Zn(4,4'\text{-bipy})_4(DMSO)_2]^{2+}$ moiety with atomic numbering scheme and (b) perspective view depicting the hydrophobic channels that extend along the [1 1 0] and [−1 1 0] directions as well as the intercalating, non-disordered guest molecules (in ball-and-stick representation) and disordered guest molecules (in space filling representation). All aromatic and aliphatic hydrogen atoms have been omitted for clarity. Only one orientation of the disordered bipy molecules is shown.

monocoordinate, accounting for the 1:3 metal:bipy stoichiometry within the host.

Adjacent Zn–bipy chains are linked by overlapping the monocoordinate bipy ligands to form two-dimensional sheets (Fig. 6b). The closest face-to-face distance between the aromatic rings is ≈3.6 Å indicating strong π-stacking interactions sustaining the sheets. One set of the uncoordinated bipy molecules intercalates between pairs of the monocoordinate bipy ligands to link adjacent sheets in the *a* direction with similarly strong π-stacking interactions (3.6–3.9 Å). Compound **6** is nearly isostructural with the previously reported copper analog, $[Cu(4,4'\text{-bipy})_3(DMSO)_2](ClO_4)_2 \cdot 2(4,4'\text{-bipy})$ [30].

The characteristic alignment of the Zn–bipy chains produces hydrophobic, rectangular cavities of dimensions of 11.45×12.89 Å^2 within the sheets. The offset superpositioning of the sheets aligns the hydrophobic cavities to form oblique channels that extend along the [1 1 0] and [−1 1 0] directions. The void space within the channels is occupied by a set of disordered uncoordinated bipy molecules, lattice waters, and perchlorate counterions. The disordered bipy's are partially stabilized by edge-to-face C–H···π facial interactions (close contacts ≈2.8–2.9 Å) with the edges of nearby non-disordered bipy molecules and pairs of monodentate bipy ligands. Compound **6** is related to a number of porous metal–bipy coordination polymers possessing hydrophobic cavities that clathrate guests. The compounds $[Ni(4,4'\text{-bipy})_3(H_2O)_2](ClO_4)_2 \cdot 1.4(4,4'\text{-bipy}) \cdot 3(H_2O)$, $[Co(4,4'\text{-bipy})_3(H_2O)_2](ClO_4)_2 \cdot 1.4(4,4'\text{-bipy}) \cdot 3(H_2O)$ [30], $[Zn(4,4'\text{-bipy})(H_2O)_4](NO_3)_2 \cdot 2(4,4'\text{-bipy}) \cdot 3H_2O$ [2], and $[Cu(4,4'\text{-bipy})(H_2O)_2(BF_4)_2] \cdot (4,4'\text{-bipy})$ [31] consist of one-dimensional chains that form porous, layered, sheet-like topologies, similar to that in **6**, sustained by various hydrogen bonding and hydrophobic interactions. In contrast, in $[Cd(4,4'\text{-bipy})_2(H_2O)_2] \cdot (NO_3)_2 \cdot 4(H_2O)$ [8,23], $[Zn(4,4'\text{-bipy})_2(H_2O)_2](ClO_4)_2 \cdot 2(2,4'\text{-bipy}) \cdot (H_2O)$, and $[Cu(4,4'\text{-bipy})_2(H_2O)_2](ClO_4)_4 \cdot (4,4'\text{-}H_2\text{bipy})$ [19], the monodentate bipy's are replaced by bridging bipy's to form two-dimensional grids, but the rectangular, hydrophobic cavities similar to those in **6** that clathrate bipy guests are retained.

4. Conclusions

This paper reports the crystal structures of six novel zinc(II)–4,4′-bipyridine coordination polymers that exhibit a diverse array of structural topologies common in supramolecular chemistry. The compounds $[Zn(4,4'\text{-bipy})_2(H_2O)_4](ClO_4)_2 \cdot 2(4,4'\text{-bipy})$ (**1**), $[Zn_3(4,4'\text{-bipy})_4(OAc)_4](ClO_4)_2 \cdot 2(H_2O)$ (**2**), and $[Zn_3(4,4'\text{- bipy})_3(OAc)_4(H_2O)_2](ClO_4)_2 \cdot (H_2O)$ (**3**) were crystallized under hydrothermal conditions. Compound **1** contains hydrogen-bonded, sheet-like arrays of discreet monomers connected by uncoordinated bipy molecules arranged into stacks of hydrophobic, triangular channels. Compounds **2** and **3** consist of acetate-bridged, Zn–bipy triple chains arranged in layered, two-dimensional sheets and three-leg ladders, respectively, with hydrophobic, prismatic channels. In contrast, $[Zn(4,4'\text{-bipy})(ClO_4)(H_2O)(OH)]$ (**4**), $[Zn(4,4'\text{-bipy})(DMSO)_4](ClO_4)_2$ (**5**), and $[Zn(4,4'\text{-bipy})_3(DMSO)_2](ClO_4)_2 \cdot 2(4,4'\text{-bipy}) \cdot (H_2O)$ (**6**) were crystallized from DMSO under ambient laboratory conditions. Compound **4** is a mutually interpenetrated network of hydrogen-bonded, one-dimensional Zn–bipy zig-zag chains while compound **5** exists as isolated, linear chains. Compound **6** is a porous, three-dimensional network of Zn–bipy chains, sustained by π-stacking interactions between bipy ligands and guests, which possess clathrated, hydrophobic channels. The title compounds not only demonstrate the ability of bipy to create novel and diverse coordination solids, but also show that weak hydrogen-bonding and π-stacking interactions in addition to covalent bonds can be employed to assemble supramolecular networks and porous solids.

that for a given ligand coordination environment, the more highly organized structure will have lower spin-state crossover temperatures and more abrupt crossovers than those with less highly or more "loosely" organized structures. In contrast, we have shown that differences in the molecular, rather than supramolecular, structure of the two crystallographically independent molecules in $Fe[(p\text{-}HC{\equiv}CC_6H_4)B(3\text{-}Mepz)_3]_2$ can have an impact on the temperature and abruptness of the observed spin-state crossover.

Herein we report the synthesis, solid-state structure, and magnetic and Mössbauer spectral properties of $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$, the parent complex of the $Fe[(p\text{-}R\text{-}C_6H_4)B(3\text{-}Mepz)_3]_2$ complexes referred to above. Analyses of these results provide interesting new insight into the factors that control the spin-crossover behavior of this class of compounds.

2. Experimental

2.1. General considerations

Unless otherwise specified, all operations were carried out under a nitrogen atmosphere by using either standard Schlenk techniques or a Vacuum Atmospheres HE-493 inert atmosphere dry box. Solvents for synthetic procedures and spectroscopic studies were dried by conventional methods and distilled under a N_2 atmosphere immediately prior to use. All chemicals were purchased from Aldrich Chemicals. 3-Methylpyrazole was distilled under vacuum before use. Robertson Microlit Laboratories performed all elemental analyses. Melting point determinations were made on samples contained in glass capillaries using an Electrothermal 9100 apparatus and are uncorrected. Mass spectrometric measurements recorded in ESI(±) mode were obtained on a Micromass Q-Tof spectrometer. NMR spectra were recorded by using a Varian Gemini 300. Chemical shifts were referenced to solvent resonances at δ_H 7.26 for $CDCl_3$, and δ_H 3.31 for CD_3OD.

Magnetic susceptibilities were measured between 4 and 300 K in an applied field of 0.5 T using a Quantum Design MPMS XL SQUID magnetometer. The sample was measured in a gelatin capsule whose very small diamagnetic susceptibility made a negligible contribution to the overall observed susceptibility. The molar magnetic susceptibility of $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ was calculated with a molecular mass of 718.26 g/mol and was corrected by -364.5×10^{-6} emu/mol for the diamagnetism of the complex, a value which was obtained from tables of Pascal's constants.

The Mössbauer spectral absorber contained 42 mg/cm^2 of crushed but unground crystals of $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ mixed with boron nitride. The spectra were measured at 4.2, 78, and 295 K on a constant-acceleration spectrometer which utilized a room temperature rhodium matrix cobalt-57 source and was calibrated at room temperature with α-iron foil. The spectra have been fit with a single symmetric quadrupole doublet and the estimated relative errors of the fitting parameters are ±0.005 mm/s for the isomer shifts and ±0.01 mm/s for the quadrupole splittings and line widths. The absolute errors are approximately twice as large.

2.2. $Na[(C_6H_5)B(3\text{-}Mepz)_3]$ (1)

In the drybox, neat BBr_3 (3.76 g, 15.0 mmol. *Caution*. The vapors of neat boron tribromide are very corrosive toward stopcock grease and plastics) was added by pipette to neat phenyltrimethylsilane (2.04 g, 13.6 mmol) contained in a PTFE-stopcock Schlenk flask and was capped with a PTFE-taped glass stopper. The stopper of the Schlenk flask was reinforced with rubber bands, taken out of the dry box, and placed in a 60 °C oil bath, with the stopcock closed, for 4.5 h (*Caution*. Adequate shielding must be used at this point because a closed system is being heated; the rubber bands, in conjunction with the glass stopper, act as a check valve for pressure build-up). After the reaction was complete, the volatile components were removed by vacuum distillation at room temperature to yield 3.16 g (94%) of crude $C_6H_5BBr_2$ as an off-white solid. The glass stopper was replaced with a rubber septum, and the $C_6H_5BBr_2$ (3.16 g, 12.8 mmol) was dissolved, in situ, in 50 mL toluene. The $C_6H_5BBr_2$ solution was added via cannula to a solution of 3-methylpyrazole (3.14 g, 38.3 mmol) and NEt_3 (3.55 mL, 25.6 mmol) in toluene (150 mL). After the resulting cloudy suspension was stirred at room temperature overnight, the toluene solution [presumably containing $(C_6H_5)B(3\text{-}Mepz)_2(3\text{-}MepzH)$] was transferred to a 500 mL Schlenk flask by cannula filtration thereby removing the colorless precipitate of $(HNEt_3)Br$ (4.38 g, 94%). A solution of NaO^tBu (1.23 g, 12.8 mmol) in 1:1 toluene/THF (50 mL) was added by cannula to the solution of "$(C_6H_5)B(3\text{-}Mepz)_2(3\text{-}MepzH)$" and the resulting suspension was stirred for 12 h. The colorless solid was separated by filtration, washed with hexanes (2 × 100 mL) and was dried under vacuum to leave 4.00 g (85%, from phenyltrimethylsilane) of $Na[(C_6H_5)B(3\text{-}Mepz)_3]$ as a white solid. Mp, 282 °C sinters; 300 °C dec. black liquid. ^{1}H NMR (300 MHz, CD_3OD, 25 °C): $\delta = 7.25$ (m, 2H, *meta*-H), 7.11 (m, 3H, *ortho*-H and *para*-H), 7.05 (d, $J = 1.5$ Hz, 3H, H_5-pz), 5.86 (d, $J = 1.5$ Hz, 3H, H_4-pz), 2.23 (s, 9H, CH_3); ^{13}C NMR (125.79 MHz, CD_3OD, 25 °C): $\delta = 149.23$, 136.78, 135.14, 134.14, 127.28, 125.74 (C_3- and C_5-pz, aryl) 103.67 (C_4-pz), 13.44 (–CH_3) High Res. ESI(−)MS, Calc. (Obs.) for anion: 331.1843 (331.1844).

2.3. $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ (2)

Under inert atmosphere, the addition of an aqueous solution (50 mL) of $FeCl_2\cdot4H_2O$ (0.153 g, 0.77 mmol) to a methanol solution (20 mL) of **1** (0.546 g, 1.54 mmol) yielded a copious amount of colorless solid that was isolated by filtration. The solid was then taken up in CH_2Cl_2, the solution was dried over $MgSO_4$, filtered, and the

$MgSO_4$ was extracted with boiling benzene (2×100 mL, caution) and filtered hot. After cooling, the solvent was removed from the combined organic fractions by rotary evaporation to yield 0.360 g (65%) of pure $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ as a colorless solid. Recrystallization of this solid by layering a CH_2Cl_2 solution of the complex with methanol and allowing the solvents to diffuse slowly over two days yielded 0.280 g (78% from 0.360 g) of X-ray quality, colorless block crystals. Mp, 289 °C slowly darkens; 293–294 °C dec. charred, black solid. *Anal.* Calc. for $C_{36}H_{40}B_2FeN_{12}$: C, 60.20; H, 5.61; N, 23.40. Found: C, 60.42; H, 5.78; N, 23.25. ^1H NMR (300 MHz, $CDCl_3$, 25 °C) 45.6, 43.4, 23.8, 4.4, 2.9, −5.9. High Res. ESI(+)MS, Calc. (Obs.): 718.3047 (718.3052).

2.4. X-ray structure determination of $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ at 90 and 294 K

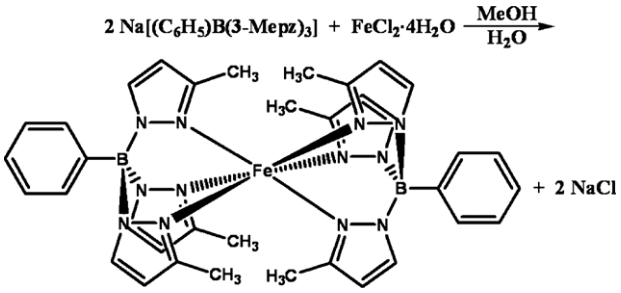
Two X-ray intensity data sets were measured at 90(1) and 294(1) K on a Bruker SMART APEX CCD-based diffractometer [4] with Mo Kα radiation at $\lambda = 0.71073$ Å. The same prismatic crystal was used for both measurements. At higher temperatures, the crystal is light green, whereas, upon cooling, a gradual, barely noticeable, transition occurs to a light pink color. There is no change in crystal system or space group (see below) between 90 and 294 K. Raw data frame integration and Lp corrections were performed with SAINT+ [4]. Final unit cell parameters were determined by least-squares refinement of all reflections with $I > 5\sigma(I)$ from each data set. Analysis of the data showed negligible crystal decay during data collection. The data were not corrected for absorption. Direct methods structure solution, difference Fourier calculations and full-matrix least-squares refinement against F^2 were performed with SHELXTL [5].

$Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ (**2**) crystallizes in the triclinic system, and the $P\bar{1}$ space group was confirmed by the successful solution and refinement of both data sets. Half of one $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ complex, situated on an inversion center, is present in the asymmetric unit at both temperatures. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were placed in geometrically idealized positions and included as riding atoms.

3. Results

3.1. Tris(pyrazolyl)borate chemistry

The new ligand, sodium tris(3-methylpyrazolyl)phenylborate (**1**), was prepared according to a previous synthetic scheme for an analogous ligand [3a] by using commercially obtained phenyltrimethylsilane as the starting material. $Na[(C_6H_5)B(3\text{-}Mepz)_3]$ was then used to prepare $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ (**2**) in acceptable yield by the salt metathesis reaction between two equivalents of the ligand and iron(II) chloride (Eq. 1), resulting in a slightly off-white powder. The crystals of **2**, grown as discussed below, were colorless which corresponds to a high-spin iron(II) complex. Low spin, octahedral iron(II) complexes of this type are usually purple. Prior to X-ray structural analysis, a few of the crystals of **2** were placed in liquid nitrogen in order to determine whether a spin-state crossover occurred; no color change to purple was observed (vide infra), indicating that no crossover occurred upon cooling to 78 K.



(1)

3.2. Structural analysis

The $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ (**2**) complex was obtained as exquisite crystals by layering a methylene chloride solution with methanol and allowing the two solvents to slowly diffuse. The crystallization process is best performed in the absence of light, thus reducing the formation of iron(III) impurities [3a]. Crystallographic information and selected bond distances and angles are given in Tables 1 and 2. The molecular structure of **2** was determined at 90 and 294 K; as is indicated in Table 2, the two structures are nearly identical. An ORTEP diagram of **2** from the structure obtained at 294 K is shown in Fig. 1.

The complex consists of two negatively charged *tris*-(3-methylpyrazolyl)phenylborate ligands κ^3-bonded to the iron(II) center in the required facial arrangement. The average Fe–N bond distances in both structures of approximately 2.18 Å clearly indicate that the complex is high spin in the solid state at both temperatures (Table 2). Low-spin complexes tend to have shorter Fe–N bond distances of ca. 1.98 Å, whereas high-spin complexes have distances of 2.17–2.19 Å as a result of the antibonding character of the partially filled e_g^* orbitals in the high-spin complexes. The FeN_6 octahedral core is only slightly distorted by the restrictions in the intraligand bond angles caused by the chelate rings.

Although the crystal structure shows that the FeN_6 core has only small distortions from pseudooctahedral geometry, because the bite angles of tris(pyrazolyl)borate ligands are generally fixed by the tetrahedral central boron atom, there are other subtle distortions of the ligand framework that occur on binding to large metal ions. In order to bond to larger metals, tris(pyrazolyl)-borate and tris(pyrazolyl)methane ligands that have a fourth group bonded to the boron other than hydrogen

undergo a twisting of the pyrazolyl rings from the ideal C_{3v} symmetry. The MN(n1)–N(n2)B torsion angles, where n is the pyrazolyl ring number, describes the degree of twisting [6]. When these ligands bind to smaller metals, e.g., to low-spin iron(II), the MN–NB torsion angles approach their ideal values of 0°. In contrast, when they bind to larger metals, e.g., to high-spin iron(II), the MN–NB angles increase in magnitude [3]. This twisting is best visualized in Fig. 2, which shows the molecule oriented down the pseudo threefold axis. As indicated in Table 3, the pyrazolyl rings are highly distorted in this high-spin complex, with the 3-ring (shown vertically in Fig. 2) severely twisted by 22.3° away from the ideal torsion angle of 0°. It is important to note that this extreme twisting of the 3-ring also correlates with the long Fe–N31 bond distance.

In contrast to the $Fe[(p\text{-}R\text{-}C_6H_4)B(3\text{-}Mepz)_3]_2$ derivatives studied previously [3], an analysis of the intermolecular structure of **2** revealed no supramolecular organization within the crystal. The molecules are held together within the crystal only by van der Waals forces.

3.3. Magnetic studies

The temperature dependence of the magnetic susceptibility of **2** has been measured between 4 and 300 K, and the results, in terms of the inverse magnetic susceptibility and the magnetic moment, are shown in Fig. 3. The inset to this figure indicates that **2** is a dilute high-spin paramagnetic iron(II) complex that exhibits Curie law behavior with a Curie constant of 3.21 (Kemu)/mol, a corresponding magnetic moment of 5.06 μ_B, and a zero susceptibility intercept of 0.86 K, a value which is very close to the expected zero Kelvin value. No change or hysteresis was observed in the magnetic susceptibility upon repeated cooling and reheating.

At room temperature, the observed magnetic moment of 5.06 μ_B for **2** is slightly higher than the spin-only moment of 4.9 μ_B expected for a high-spin iron(II) complex and indicates the expected [7] presence of a small orbital contribution to the moment. This moment is also in good agreement with the room temperature moments observed in related high-spin iron(II) complexes such as $Fe[HB(3,5\text{-}Me_2pz)_3]_2$, which exhibits a moment of 5.0 μ_B at 298 K [8].

Upon cooling, the magnetic moment of **2** increases linearly from 5.06 μ_B at 300 K to 5.12 μ_B at 30 K, and then decreases more substantially below ca. 20 K. However, as may be seen in the inset of Fig. 3, $1/\chi$ versus T is linear even at the lowest temperatures. The decrease in the moment below ca. 20 K is exactly that expected [7,9] from zero field splitting in a magnetically dilute high-spin iron(II) complex in a distorted octahedral coordination environment. Thus the decrease in moment of **2** at the lowest temperatures is not associated with any change in the spin state of the iron(II) ion, i.e., **2** is a magnetically dilute high-spin paramagnetic iron(II) complex at all temperatures above 4 K.

3.4. Mössbauer spectral studies

The same sample used for the magnetic studies was subsequently used for Mössbauer spectral studies and the resulting spectra are shown in Fig. 4. The spectra have been fit with a single symmetric quadrupole doublet and the resulting hyperfine parameters are given in Table 4.

The 4.2, 78, and 295 K spectra of fine unground, but crushed, crystals of **2** indicate that this complex is high-spin at these temperatures. The observed hyperfine parameters are very similar to those observed for the high-spin iron(II) component in $Fe[HB(3,5\text{-}Me_2pz)_3]_2$ at the same temperatures [10]. There is a slight decrease in the isomer shift and increase in the quadrupole splitting of **2** as compared with $Fe[HB(3,5\text{-}Me_2pz)_3]_2$, changes that may be related to small differences in the coordination geometry in the complexes.

4. Discussion

We have carefully studied [3] the spin-state crossover properties of several $Fe[(p\text{-}R\text{-}C_6H_4)B(3\text{-}Mepz)_3]_2$ derivatives because they all have very similar FeN_6 coordination environments; changes in the distal *para* position of the phenyl ring attached to boron should have a minimal direct

electron and steric impact on the iron(II) coordination environments and, hence, its electronic spin state. In contrast, by systematically introducing R-groups in these "third generation" tris(pyrazolyl)borate ligands that can enter into supramolecular interactions, we anticipated delineating the relationship between the inter- and intramolecular structure and the spin-crossover phenomenon. Mössbauer spectral data, in conjunction with magnetic susceptibility and X-ray crystallographic data, clearly demonstrate that **2**, the parent molecule of this family of complexes, remains at least 98% high spin down to 4 K (the crystals color slightly at 90 K, but no low-spin signals are detected in the Mössbauer spectra). In contrast, all but one of the Fe[(*p*-R-C_6H_4)B(3-Mepz)$_3$]$_2$ derivatives, where R is I, —C≡C—H, —C≡C—$SiMe_3$, or —C≡C—C_6H_5 undergo a spin-state crossover at low temperatures.

In our previous work, two factors have been shown to influence the temperature at which the various molecules undergo a spin crossover: the type of supramolecular structure observed and the degree of pyrazolyl ring twisting in the molecular structure. As most clearly indicated by the behavior of the two polymorphs of Fe[(*p*-IC_6H_4)-B(3-Mepz)$_3$]$_2$, one of which does and one of which does not undergo a spin-state crossover at low temperatures, we proposed that highly organized three-dimensional supramolecular structures can energetically "lock in" the high-spin state, even at very low temperatures. The lack of an R-functional group in **2** that can undergo π–π, C–H···π, and other weak hydrogen bonding interactions has produced a structure in which no supramolecular forces are observed, making this issue moot.

In contrast, it appears that the degree of twisting of the pyrazolyl rings in the high temperature structure explains the lack of a spin-state crossover for **2**. Our best previous evidence that greater twisting in the high-spin form leads to spin-state crossover at lower temperatures was with the two independent molecules in the structure of Fe-[(*p*-HC≡CC_6H_4)B(3-Mepz)$_3$]$_2$. Table 5 gives the torsion angles along with the Fe–N bond distances for the known Fe[(*p*-R-C_6H_4)B(3-Mepz)$_3$]$_2$ complexes. In the case of Fe[(*p*-HC≡CC_6H_4)B(3-Mepz)$_3$]$_2$, the molecule containing Fe2, the one showing the lesser ring twisting undergoes a spin-state crossover at a higher temperature than those containing Fe1, the one showing the greater ring twisting. In this case, the two-dimensional supramolecular structures of each of the crystallographically distinct iron(II) sites were very similar leading to the conclusion that the ring twisting issue dominated the spin-crossover behavior.

In the case of **2** reported herein, it is clear that the supramolecular structure is not an issue in the spin-state crossover behavior. As indicated in Table 5, this complex has the

highest degree of ring twisting of any of the known Fe[(*p*-R-C_6H_4)B(3-Mepz)$_3$]$_2$ complexes. Especially notable is the large distortion of the 3-ring at 22.3°, a twisting which is accompanied by the longest Fe–N bond distance. We propose that this *pyrazolyl ring twisting is the reason for the lack of a spin-state crossover in this complex*; the ligand rearrangement needed to lower this ring twisting as the bonds would shorten to the normal low-spin values is a barrier to the spin crossover. This result strengthens our earlier proposals that indicated the degree of pyrazolyl ligand ring twisting in the high-spin structure is an important factor controlling the spin-state crossover behavior of poly(pyrazolyl)borate [3] and poly(pyrazolyl)methane complexes [11b]. Significant twisting of the rings energetically favors the larger high-spin complexes because it favors the longer Fe–N bond distances such that **2** does not undergo the crossover even at 4 K because of the extreme degree of twisting. These results are parallel to those observed with {Fe[HC(3,5-Me_2pz)$_3$]$_2$}-(BF_4)$_2$, in which a phase transition at low temperature converts the equivalent iron(II) sites in the high temperature structure to two non-equivalent sites [11]. One of the sites has highly twisted pyrazolyl rings, and this site remains high spin; it does not undergo spin crossover down to 4 K. In contrast, for the other site, the rings are not twisted and the iron(II) exhibits a spin-state crossover to the low-spin state at the temperature of the phase transition.

It is interesting to note that the molecule in Table 5 with the second most twisted rings, Fe[(*p*-$C_6H_5C{\equiv}C{-}C_6H_4$)B(3-Mepz)$_3$]$_2$, also has an organized three-dimensional supramolecular structure, but undergoes spin crossover at low temperatures [3b]. In this case, as with {Fe[HC-(3,5-Me_2pz)$_3$]$_2$}(BF_4)$_2$ [11] and Fe[(*p*-$Me_3SiC{\equiv}C{-}C_6H_4$)-B(3-Mepz)$_3$]$_2$ [3b], a phase change is observed at the same temperature that spin crossover occurs. Clearly, phase changes will dominate the more subtle influences of ring twisting and the relatively weak supramolecular interactions that are present in these complexes. The detailed analysis of the importance of the more subtle effects of ring twisting reported herein was possible because **2** does not undergo a structural phase change upon cooling from 294 to 90 K and, most likely, not below 90 K.

5. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited at the Cambridge Crystallographic Data Center, CCDC 290338 (294 K) and 290339 (90 K). Copies of the information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 336 033, email: data_request@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk.

witnessed as model complexes. Hence, the synthesized heterobinuclear complexes are used for modeling the properties of the active site of the metallobiosites. In our earlier works [16,17] we have reported the spectral, electrochemical and kinetic properties of homobinuclear copper(II) complexes and in this work we rationalize how the heterobinuclear complexes behave differently from homobinuclear complexes.

2. Experimental

Elemental analysis was carried out on a Carlo Erba Model 1106 elemental analyzer. ^{1}H NMR spectra were recorded using FX-80-Q Fourier transition NMR spectrometer. Electronic spectral studies were carried out on a Hitachi 320 spectrophotometer in the range 200–800 nm. IR spectra were recorded on a Hitachi 270-50 spectrophotometer on KBr disks in the range 4000–250 cm^{-1}. The mass spectra were obtained on JEOL DX-303 mass spectrometer. Cyclic Voltammograms were obtained on CHI600A (CHI Instruments Co., USA) electrochemical analyzer using DMF. The measurements were carried out under oxygen free condition by purging nitrogen gas, using a three electrode cell in which glassy carbon electrode was working electrode, saturated Ag/AgCl electrode was reference electrode and platinum wire was used as auxiliary electrode. Glassy carbon electrode surface was pretreated by metallographic polishing with alumina on a velvet cloth (abraded with fine grade of emery paper), followed by ultrasonic cleaning in double distilled water and washing with small amount of highly diluted acid and DMF. Ferrocene/ferrocenium (1+) couple was used as standard and $E_{1/2}$ of the Ferrocene/ferrocenium (Fc/Fc^+) couple under the experimental condition is 470 mV in DMF and ΔE_p for Fc/Fc^+ is 70 mV. Tetra (*n*-butyl)ammonium perchlorate (TBAP) was used as supporting electrolyte. The kinetic investigation of catechol oxidation and hydrolysis of 4-nitrophenyl phosphate was carried out spectrophotometrically by choosing the strongest absorbance at appropriate wavelength and monitoring the increase in the absorbance at this wavelength as a function of time. A plot of log $(A_\infty/A_\infty - A_t)$ versus time was made for each complexes and the rate constant was calculated. All the kinetic studies were carried out in DMF solvent at room temperature (25 °C).

2.1. Materials

5-Methylsalicylaldehyde [18], 3-chloromethyl-5-methylsalicylaldehyde [19] and 3,4:9,10-dibenzo-1,12-diaza-5,8-dioxocyclotetradecane [20,21] were prepared from the literature methods. TBAP used as supporting electrolyte in electrochemical measurement was purchased from Fluka and recrystallised from hot methanol. (Caution! TBAP is potentially explosive; hence care should be taken in handling the compound). DMF and CH_3CN were obtained from E. MERCK. All other chemicals and solvents were of analytical grade and were used as received without any further purification.

2.2. Synthesis of precursor compound

2.2.1. 3,4:9,10-Dibenzo-1,12[N,N′-bis{(3-formyl-2-hydroxy-5-methyl)benzyl}diaza]-5,8-dioxocyclotetradecane [16] (precursor compound)

A mixture of 3,4:9,10-dibenzo-1,12-diaza-5,8-dioxocyclotetradecane (0.95 g, 3.2 mmol) and triethylamine (1.32 g, 6.4 mmol) in 30 ml of THF was added slowly to a stirred solution of 3-chloromethyl-5-methylsalicylaldehyde (1.16 g, 6.4 mmol) in 30 ml of THF. After the addition was over the stirring was continued further for one more hour. The whole solution was then refluxed under water bath for 3 h and was allowed to cool on standing at room temperature. Copious water was added to this solution to dissolve any salt obtained. Then the required compound was extracted in organic medium using chloroform. The extraction was repeated for two to three times. A pale yellow compound was obtained on evaporation of solvent at room temperature (25 °C). Light yellow microcrystals were obtained on recrystallization from chloroform. Yield: 1.82 g (80%), m.p.: 100 °C. *Anal.* Calc. for $C_{36}H_{38}O_6N_2$: C, 60.50; H, 5.32; N, 3.92. Found: C, 60.72; H, 5.36; N, 3.98%. IR data (ν cm^{-1}): 1678 (νC=O, s), 3448 (νOH, br). ^{1}H NMR (δ ppm in $CDCl_3$): 10.0 (s, 2H, CHO protons), 7.0 (m, 12H, aromatic protons), 4.7 (m, 4H, methylene protons attached to oxygen atom), 3.8 (m, 8H, benzylic protons), 3.5 (s, 4H, methylene protons attached to nitrogen atom), 2.3 (s, 6H, CH_3 protons attached to aromatic ring). Mass (EI) *m*/*z*: 594 (m^+).

2.3. Synthesis of macrobicyclic heterobinuclear complexes

2.3.1. $[CuZnL^1](ClO_4)_2$

A methanolic solution (20 ml) of zinc(II)perchlorate hexahydrate (0.707 g, 1.9 mmol) [Caution! zinc(II) perchlorate salt is potentially explosive; hence care should be taken in handling the compound] was added to the hot solution of mononuclear copper(II) complex [16] $[CuL^1](ClO_4)$ (1.562 g, 1.9 mmol) in 25 ml of methanol followed by the addition triethylamine (0.192 g, 1.9 mmol) in 5 ml of methanol. The solution was refluxed on water bath for 24 h. After the reaction was over, the solution was filtered at hot condition and allowed to stand at room temperature. After slow evaporation of the solvent at 25 °C, the dark green compound obtained was washed with methanol and dried in vacuum. Yield: 1.48 g (80%). *Anal.* Calc. $C_{42}H_{46}O_{12}N_6Cl_2CuZn$: C, 49.17; H, 4.48; N, 8.19. Found: C, 49.28; H, 4.62; N, 8.20%. Selected IR (KBr): 1628 (s), 1100 (s), 622 (s) cm^{-1}. λ_{max} (nm) (ε/M^{-1} cm^{-1}) in CH_3CN: 565 (121), 372 (16870), 272 (37200).

2.3.2. $[CuZnL^2](ClO_4)_2$

$[CuZnL^2](ClO_4)_2$ was synthesized by following the previously described procedure for $[CuZnL^1](ClO_4)_2$, using the

mononuclear complex $[CuL^2](ClO_4)$ instead $[CuL^1](ClO_4)$. The compound obtained was dark green. Yield: 1.44 g (77%). *Anal*. Calc. for $C_{43}H_{48}O_{12}N_6Cl_2CuZn$: C, 49.66; H, 4.61; N, 8.08. Found: C, 49.79; H, 4.73; N, 8.20%. Selected IR (KBr): 1620 (s), 1100 (s), 626 (s) cm^{-1}. λ_{max} (nm) ($\varepsilon/M^{-1}\,cm^{-1}$) in CH_3CN: 595 (131), 352 (14 590), 271 (37 160).

2.3.3. $[CuZnL^3](ClO_4)_2$

$[CuZnL^3](ClO_4)_2$ was synthesized by following the previously described procedure for $[CuZnL^1](ClO_4)_2$, using the mononuclear complex $[CuL^3](ClO_4)$ instead $[CuL^1](ClO_4)$. The compound obtained was dark green. Yield: 1.49 g (79%). *Anal*. Calc. for $C_{44}H_{50}O_{12}N_6Cl_2CuZn$: C, 50.14; H, 4.74; N, 7.97. Found: C, 50.22; H, 4.84; N, 8.11%. Selected IR (KBr): 1622 (s), 1101 (s), 627 (s) cm^{-1}. λ_{max} (nm) ($\varepsilon/M^{-1}\,cm^{-1}$) in CH_3CN: 625 (125), 355 (15 440), 273 (32 400).

2.3.4. $[CuZnL^4](ClO_4)_2$

$[CuZnL^4](ClO_4)_2$ was synthesized by following the previously described procedure for $[CuZnL^1](ClO_4)_2$, using the mononuclear complex $[CuL^4](ClO_4)$ instead $[CuL^1](ClO_4)$. The compound obtained was blackish green. Yield: 1.51 g (78%). *Anal*. Calc. for $C_{46}H_{46}O_{12}N_6Cl_2CuZn$: C, 51.44; H, 4.28; N, 7.82. Found: C, 51.62; H, 4.41; N, 7.93%. Selected IR (KBr): 1628 (s), 1100 (s), 625 (s) cm^{-1}. λ_{max} (nm) ($\varepsilon/M^{-1}\,cm^{-1}$) in CH_3CN: 605 (110), 412 (13 400), 375 (12 300), 275 (33 500).

2.3.5. $[CuZnL^5](ClO_4)_2$

$[CuZnL^5](ClO_4)_2$ was synthesized by following the previously described procedure for $[CuZnL^1](ClO_4)_2$, using the mononuclear complex $[CuL^5](ClO_4)$ instead $[CuL^1](ClO_4)$. The compound obtained was blackish green. Yield: 1.62 g (80%). *Anal*. Calc. for $C_{50}H_{48}O_{12}N_6Cl_2CuZn$: C, 53.52; H, 4.28; N, 7.49, Found: C, 53.59; H, 4.37; N, 7.59%. Selected IR (KBr): 1624 (s), 1101 (s), 625 (s) cm^{-1}. λ_{max} (nm) ($\varepsilon/M^{-1}\,cm^{-1}$) in CH_3CN: 635 (140), 401 (15 300), 368 (18 300), 268 (34 000).

In all cases we could obtain only microcrystals and attempts to obtain the crystals suitable for X-ray analysis were unsuccessful.

3. Results and discussion

Schiff's base condensation of the precursor compounds with diamines in the presence of metal ion by template method results into various macrobicyclic hetero binuclear Cu(II)—Zn(II) complexes. Scheme 1 represents the synthetic pathway of hetero binuclear Cu(II)—Zn(II) complexes. In our previous study [16] the crystal structures of mono and binuclear copper(II) complexes have been rationalized. Hence, in accordance with this, it is proposed that the geometry around copper(II) and zinc(II) ion is distorted square planar. Extensive spectral, electrochemical and kinetic studies of the heterobinuclear complexes were carried out and discussed.

Scheme 1. Synthesis of macrobicyclic heterobinuclear Cu(II)—Zn(II) complexes.

3.1. Spectral studies

The IR spectra of the complexes show ν(C=N) peak [22] at 1620–1630 cm^{-1}. The peaks appeared near 1100 and 620 cm^{-1} are characteristics of the uncoordinated perchlorate ion. The electronic spectra of the complexes show three main transitions. A weak band observed in the range 565–635 nm is due to *d–d* transition of the Cu(II) ion presents in the heterobinuclear complexes. On moving from the complexes of ligand L^1 to L^3 and L^4 to L^5, an increase in λ_{max} (red shift) [23] of the *d–d* transition of Cu(II) ion in the complexes was observed. A moderate intensive band observed in the range 352–375 nm is due to ligand-to-metal charge transfer transition and the strong band observed in the range 268–275 nm is due to intraligand charge transfer transition [24]. Apart from these, additional peaks are observed for the complexes of ligands L^4 to L^5 due to the presence of aromatic ring in the imine nitrogen compartment.

The solid state ESR spectra of the heterobinuclear Cu(II)—Zn(II) complexes show four line hyperfine splittings due to Cu(II) ion with a nuclear hyperfine spin of 3/2. Fig. 1 represents the ESR spectrum of the complex $[CuZnL^1](ClO_4)_2$ with $g_{\|}$ value 2.14 and $g_{\perp}$ value 2.02.

3.2. Electrochemistry

The electrochemical properties of the complexes reported in the present work were studied by cyclic voltammetry in the potential range 0 to −1.4 V in dimethylformamide containing 10^{-1} M tetra(*n*-butyl)ammonium perchlorate and the data are represented in Table 1. All the heterobinuclear Cu(II)—Zn(II) complexes undergo one quasi reversible reduction at negative potential. Fig. 2 depicts the cyclic voltammograms of the heterobinuclear Cu(II)—Zn(II) complexes and the redox processes are assigned as follows:

$$Cu^{II}Zn^{II} \rightleftharpoons Cu^{I}Zn^{II}$$

The interesting feature connoted for heterobinuclear complexes is shifting of reduction potential towards anodic from −0.98 to −0.78 as we move from complexes of ligand L^1 to L^3. This is because of the reason that the increase in chain length in imine nitrogen compartment increases the macrocyclic ring size and hence causes more flexibility [25–27] which, in turn makes the reduction of the complexes easier. In our earlier work [16] we have reported the reduction potentials of the corresponding mono and

Table 1

binuclear copper(II) complexes and in the case of heterobinuclear Cu(II)—Zn(II) complexes the observed reduction potentials fall in the vicinity of the potentials of the corresponding mononuclear copper(II) complexes. Hence, it is worthwhile to assign this potential to the corresponding Cu(II) ion presents in the imine nitrogen compartment. The Zn(II) ion presents in the tertiary nitrogen compartment does not undergo reduction in this potential range. Thus, cyclic voltammetric technique is a useful tool to assign the site specificity of metal ion in the heterobinuclear complexes.

An inspection on the reduction potential of the heterobinuclear Cu(II)—Zn(II) complexes reveals that the observed reduction potentials are comparatively lesser than the corresponding homobinuclear [16] Cu(II) complexes. This clearly indicates that the interaction between two metal ions in homobinuclear Cu(II) complexes is effective when compared to the heterobinuclear Cu(II)—Zn(II) complexes. Because of this, heterobinuclear complexes have more or less the same reduction potential as mononuclear Cu(II) complexes.

3.3. Kinetic studies

All the heterobinucler Cu(II)—Zn(II) complexes were subjected for both catecholase activity and phosphate hydrolysis. The investigation of the kinetic studies of the heterobinuclear Cu(II)—Zn(II) complexes implies that the complexes act as model for catecholase and phosphate hydrolase. The kinetics of the catecholase activity was carried out using 10^{-3} M of complex and 10^{-1} M of 3,5-di-*tert*-butylcatechol in DMF. The product *o*-quinone is fairly stable and has a strong absorbance at 390 nm. The kinetics of the hydrolysis of 4-nitrophenyl phosphate was carried out using an equal concentration of the complex catalyst and tetramethylammonium hydroxide (10^{-3} M) and 4-nitrophenyl phosphate (10^{-1} M) in DMF. The chromophore leaving group 4-nitrophenolate, which is the hydrolysis product of the substrate was monitored at 420 nm. The course of the reaction in both cases was followed nearly 45 min at regular time interval. The slope was determined by monitoring the growth of the band of the corresponding product.

Plots of $\log(A_\infty/A_\infty - A_t)$ versus time for both catecholase activity and phosphate hydrolysis are obtained and shown in Figs. 3 and 4, respectively. The rate constant values are also reported in Table 2. The first apparent result was that the reactivities of the complexes differ significantly, as the size of macrocycle increases. In both kinetics, the catalytic activities of heterobinuclear Cu(II)—Zn(II) complexes are found to increase as the macrocyclic ring size increases due to the intrinsic flexibility. The catalytic activity of the complexes containing aromatic diimines is found to be less than that of the complexes containing aliphatic diimines. This can be explained that the planarity, which is associated with aromatic ring, imparts less catalytic efficiency due to the rigidity of the systems as observed in the

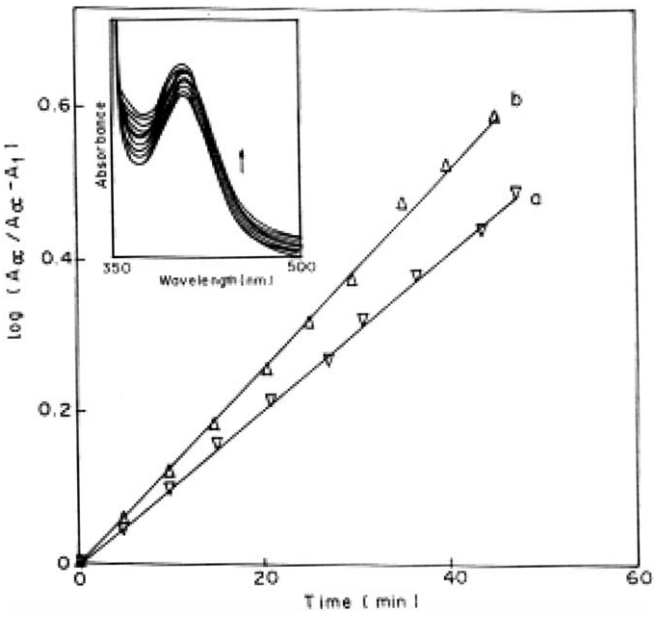

Fig. 3. Catecholase activity of heterobinuclear complexes (a) $[CuZnL^1](ClO_4)_2$ (b) $[CuZnL^2](ClO_4)_2$.

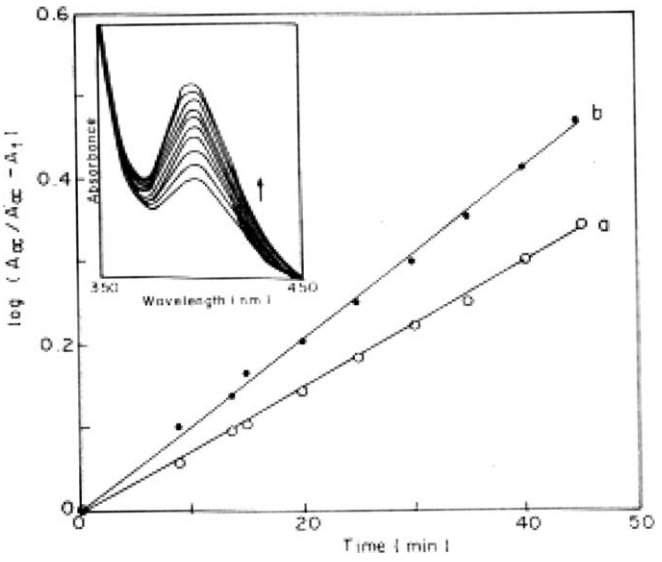

Fig. 4. Catalytic activity of heterobinuclear complexes for hydrolysis of 4-nitrophenylphosphate (a) $[CuZnL^1](ClO_4)_2$ (b) $[CuZnL^2](ClO_4)_2$.

Table 2
Catalytic activity[a] of heterobinuclear Cu(II)—Zn(II) complexes for catecholase activity and hydrolysis of 4-nitrophenyl phosphate

Complexes	Rate constant (min^{-1})	
	Catecholase activity	Hydrolysis activity
$[CuZnL^1](ClO_4)_2$	2.91×10^{-3}	1.75×10^{-2}
$[CuZnL^2](ClO_4)_2$	3.05×10^{-3}	2.27×10^{-2}
$[CuZnL^3](ClO_4)_2$	3.39×10^{-3}	3.43×10^{-2}
$[CuZnL^4](ClO_4)_2$	2.81×10^{-3}	1.68×10^{-2}
$[CuZnL^5](ClO_4)_2$	2.89×10^{-3}	2.12×10^{-2}

[a] Measured spectrophotometrically in DMF medium.

case of electrochemical reduction of the complexes. It seems interesting to observe that the rate constant values of heterobinuclear Cu(II)—Zn(II) for catecholase activities are less when compared to the rate constant values of corresponding mono and homobinuclear [16] Cu(II) complexes.

4. Conclusion

This work involves the synthesis of lateral macrobicyclic compartmental heterobinuclear Cu(II)—Zn(II) complexes with phenolate bridging atoms. Their extensive spectral, electrochemical and catalytic studies were carried out with slight modification in the ligand framework and compared with their corresponding mono and homobinuclear Cu(II) complexes. The increase in macrocyclic ring size in the ligand framework influences the spectral, electrochemical and catalytic properties of the complexes. Electronic spectral studies indicate that the *d–d* transition of Cu(II) ion is responsible for the appearance of band in the visible region. Electrochemical studies imply that the Zn(II) ion does not undergo reduction in the given potential range.

2.2. Spectroscopic measurements

The solid state IR spectra of the ligands and their mercury(II) complexes were recorded on a Perkin–Elmer FTIR 180 spectrophotometer using KBr pellets over the range 4000–400 cm^{-1}.

All NMR measurements were carried out on a Jeol JNM-LA 500 NMR spectrophotometer at 297 K. The ^{1}H NMR spectra were recorded at a frequency of 500.00 MHz. The ^{13}C NMR spectra were obtained at a frequency of 125.65 MHz with ^{1}H broadband decoupling and relative to TMS. The spectral conditions were: 32 k data points, 0.967 s acquisition time, 1.00 s pulse delay and 45° pulse angle.

The ^{15}N NMR spectrum was recorded at 50.55 MHz using $^{15}NH_4NO_3$ as external reference, which lies at −358.63 ppm relative to pure $MeNO_2$. The spectral conditions for ^{15}N were: 32 K data points, 0.721 s acquisition time, 2.50 s delay time, 60° pulse angle and approximately 5000 scans. ^{77}Se NMR spectra were recorded at 95.35 MHz, using 0.160 s acquisition time and a 2.00 s pulse delay. Chemical shifts were measured relative to external SeO_2 at 1301 ppm [20].

Natural abundance ^{13}C solid state NMR spectra were obtained on a JEOL LAMBDA 500 spectrometer operating at 125.65 MHz (11.74 T), at ambient temperature of 25 °C. Samples were packed into 6 mm zirconium oxide rotors. Cross-polarization and high power decoupling were employed. Pulse delay of 7.0 s and a contact time of 5.0 ms were used in the CPMAS experiments. The magic angle spinning rates were from 2 kHz to 5 kHz. Carbon chemical shifts were referenced to TMS by setting the high frequency isotropic peak of solid adamantane to 38.56 ppm. Solid state cross-polarization magic-angle spinning (CP MAS) $^{199}Hg\{^{1}H\}$ NMR spectra were obtained at ambient temperature on the same spectrometer operating at a frequency of 89.30 MHz. Contact time of 20 ms was used with a proton pulse width of 6 μs, with a recycle delay of 10 s. Approximately 5000 FID's were collected and transformed with a line broadening of 100 Hz. Chemical shifts were referenced using an external sample of solid $[Hg(DMSO)_6](O_3SCF_3)_2$ ($\delta Hg = -2313$ ppm from Me_2Hg) [21]. CP MAS ^{77}Se spectra were obtained on the same instrument operating at a frequency of 95.35 MHz. The contact time of 5 ms with proton pulse width of 6.0 μs, with a recycle delay of 12 s were used. Sample was spun at 3 and 5 kHz at the magic angle to determine the isotropic peaks. Approximately 5000 scans were employed. ^{77}Se chemical shifts are referenced using an external solid ammonium selenate ($\delta_{Se} = 1040.2$ ppm relative to liquid Me_2Se at 23 °C) [22]. Center band signals were located by varying the spinning speed. The CP MAS spectra (^{199}Hg and ^{77}Se) containing spinning side-band manifolds were analyzed using a program based on Maricq and Waugh and developed by Durham University, UK, using an iterative method, to yield shielding tensor values [23]. Calculated tensor values and the isotropic chemical shifts are shown in Table 3. Errors in the shielding tensor parameters for ^{77}Se are considered high (±30 ppm) because of the high noise level and base line correction. Errors in ^{199}Hg tensors are estimated to be around 20 ppm. For some complexes only the isotropic chemical shifts are reported as the quality of spectra did not allow the calculation of individual shielding tensors.

2.3. Synthesis of the complexes

The complexes were prepared by adding selones in acetonitrile to mercuric chloride solution in acetone in the molar ratios of 2:1 or 4:1 and stirring for 15–20 min [12]. The resulting white precipitates were filtered and washed with acetone.

The elemental analysis of these complexes is given in Table 1.

2.4. X-ray data collection and structure determination

A crystal of the complex (N-*i*-PrImSe)$_2HgCl_2$ was mounted on a glass fiber. Diffraction data were recorded on a Bruker-Axs Smart Apex system equipped with a graphite monochromatized Mo Kα radiation (λ = 0.71073 Å). The data were collected using SMART [24]. The data integration was performed using SAINT [25]. An empirical absorption correction was carried out using SADABS [26]. The structure was solved with the direct methods and refined by full-matrix least-square methods based on F^2, using the structure determination and graphics package SHELXTL [27] based on SHELX 97 [28]. Hydrogen atoms were included at calculated positions using a riding

model and an sp^2 hybridization was assumed for the nitrogen atoms of the NH groups. The crystallographic data are given in Table 4. Selected bond lengths and angles are given in Table 5. Complete bond lengths and bond angles, anisotropic thermal parameters and calculated hydrogen coordinates are deposited as supplementary materials. The ORTEP atomic labeling scheme is given in Fig. 1.

3. Results and discussion

The complexes were synthesized by reacting $HgCl_2$ with selones in 1:2 or 1:4. However, the elemental analyses of the complexes showed that except for selenourea a tetrakis complex (M:L = 1:4) could not be obtained and for other selones; maximum three ligands could coordinate to Hg(II) resulting in tris complexes, $[(\rangle C{=}Se)_3HgCl]Cl$ [12]. For DmSeU only a bis complex, $[Hg(DmSeU)_2Cl_2]$ was isolated. The NMR results also showed that for the complex prepared with M:L = 1:4, the resonances appeared at the same positions as observed for $[Hg(DmSeU)_2Cl_2]$. The steric hindrance offered by methyl groups seems to be a major factor due to which a tris or tetrakis complex could not be obtained.

3.1. IR spectroscopic studies

In the IR spectra of the complexes, the ν(C═Se) vibration, which occurs around 600 cm^{-1} for the free ligands shifts towards lower frequency upon complexation, in accordance with the data observed for selone complexes of other metal ions [15,16,29]. There are also strong absorptions around 3200 cm^{-1} corresponding to ν(NH) mode. The presence of a band around 3200 cm^{-1} in free ligands as well as in the complexes indicates the existence of the selone form of the ligands in the solid state. The IR frequencies of the complexes are given in Table 1.

3.2. ^1H and ^{13}C NMR solution studies

The ^1H and ^{13}C NMR chemical shifts of the complexes in DMSO-d_6 are summarized in Table 2. In ^1H NMR spectra of the complexes, the N—H signal of thiones became

less intense upon coordination and shifted downfield by 0.5–1.1 ppm from their positions in free ligands. Deshielding of the N—H proton is related to an increase of the π electron density in the C—N bond upon complexation [8,15,16]. The appearance of N—H signal in ^{1}H NMR shows that the ligands are coordinating in the selone form in solution [15,16].

In all complexes, the C-2 resonance of selones appears upfield by 6–12 ppm compared to free ligands as observed for other complexes of Ag(I) and Au(I) with selones [15,16]. The upfield shift is attributed to a lowering of the >C=S bond order upon coordination and a shift of N → C electron density producing partial double bond character in the C—N bond [8,13,15]. The upfield shift decreases as the number of ligands attached to mercury(II) increases from two in $[L_2HgCl_2]$ to three in $[L_3HgCl]Cl$ or four in $[L_4Hg]Cl_2$ (Table 2). This is because of the increase in number of electronegative groups attached to metal ion. This observation is demonstrated for number of complexes e.g. $Hg(ImSe)_2Cl_2$, $Hg(ImSe)_3Cl_2$; $Hg(MeImSe)_2Cl_2$, $Hg(MeImSe)_3Cl_2$; $Hg(Diaz)_2Cl_2$, $Hg(Diaz)_3Cl_2$; in all these complexes the bis complex show more ^{13}C shift compare to tris complex. A small shift of about 1 ppm is observed in other carbon atoms, which shows that nitrogen atoms are not involved in coordination. In the complexes of ImSe and MeImSe, a deshielding effect is observed at C-4/5 while in the DiazSe complexes, a deshielding effect is observed at C-4 and C-6 (C-4 and C-7 in DiapSe), but C-5 bears a shielding effect. The deshielding at C-4/6 is due to an increase in π character of the C–N bond [13]. Similar observation was made for ^{13}C chemical shift of the >C=Se resonance of SeU in $Ag(SeU)NO_3$ which was shifted by 12 ppm upfield compared to free SeU ligand, while in $Ag(SeU)_2NO_3$, the upfield shift was only by 7 ppm. The upfield shift is attributed to a lowering of >C=Se bond order upon coordination and a shift of N → C electron density producing a partial double bond character in the C—N bond, as observed in metal complexes of thiourea [29].

The ^{13}C NMR shift difference for the C-2 resonance of selones upon complexation is related to the strength of the metal-selenium bond [8]. The C-2 shift of 12 ppm is the highest in $[(DiapSe)_2HgCl_2]$ showing that the Hg—Se bond in $[(DiapSe)_2HgCl_2]$ should be the strongest among these complexes. It can be seen from Table 2 that as the ring size of the ligand is increased the shift difference at C-2 also increases. Thus DiapSe forms more stable complexes with mercury(II) compared to ImSe and DiazSe which shifted by approximately 8.90 ppm for both complexes.

[a] From Ref. [34].

3.3. ^{15}N NMR solution studies

^{15}N NMR could be recorded for SeU complexes only because the ligand contains ~5% enriched ^{13}C and ^{15}N. The ^{15}N signal for NH_2 resonance of SeU appears downfield by 4–5 ppm in the complexes compared to free ligand (Table 2). The downfield shift is consistent with an increase in double bond character of the C—N bond [8,13,21]. A smaller downfield, instead of a large upfield shift in ^{15}N NMR rules out the binding of selones to mercury(II) via nitrogen [13,22]. There is no significant difference between ^{15}N resonances of $(SeU)_2HgCl_2$ and $(SeU)_4HgCl_2$ probably because N is far from the Hg(II) and it also suggest that —NH_2 of the ligand is not involved in the binding to Hg(II).

3.4. ^{77}Se NMR solution studies

^{77}Se NMR seems to be the most effective technique for characterizing these complexes because in ^{77}Se NMR a large upfield shift is observed for all the ligands upon complexation. On coordination selenium resonances are shielded by about 22–71 ppm. This very large shielding provides a clear evidence for selenium binding to mercury(II). A decrease in the upfield shift is observed as the number of coordinating ligands increases. The less upfield shift in the tris or tetrakis complexes is because each ligand is sharing approx. 1/3 or 1/4 metal ion, compared to that in $[L_2HgCl_2]$ where each L is sharing 1/2 ion. As observed in ^{13}C NMR, the shift difference in ^{77}Se NMR is highest for DiapSe complexes suggesting that the Hg—Se bond is the strongest in these complexes. It is also observed that the shift difference increases with the ring size of the ligand. This again suggests that DiapSe forms more stable complexes with mercury(II) compared to ImSe and DiazSe. This observation is consistent with ^{13}C NMR data as indicated earlier, both ^{77}Se and ^{13}C NMR data show $[(DiapSe)_2HgCl_2]$ is the most stable complex.

We measured ^{199}Hg NMR spectra for the few complexes as reported in Table 2 because of the solubility of these complexes. However, there is no trend observed, therefore, some solid ^{199}Hg NMR spectra were measured and discussed below.

3.5. ^{199}Hg and ^{77}Se CP MAS NMR studies

The ^{199}Hg and ^{77}Se CPMAS spectra of the complex $(N\text{-}i\text{-}PrImSe)_2HgCl_2$ are shown in Figs. 2 and 3 respectively with the calculated spectra shown as stick plots. The ^{199}Hg, ^{77}Se and ^{13}C chemical shifts and some shielding anisotropies for the complexes are shown in Table 3, along with the corresponding data for the free ligand. While solid-state ^{199}Hg NMR spectroscopy reports of thiolate complexes are somewhat common [30], those of selone complexes are scarce in the literature [12]. The chemical shift of Hg nucleus is determined by the arrangement of atoms directly bonded to the Hg atom while the arrangement of the other atoms in the ligand plays a minor role

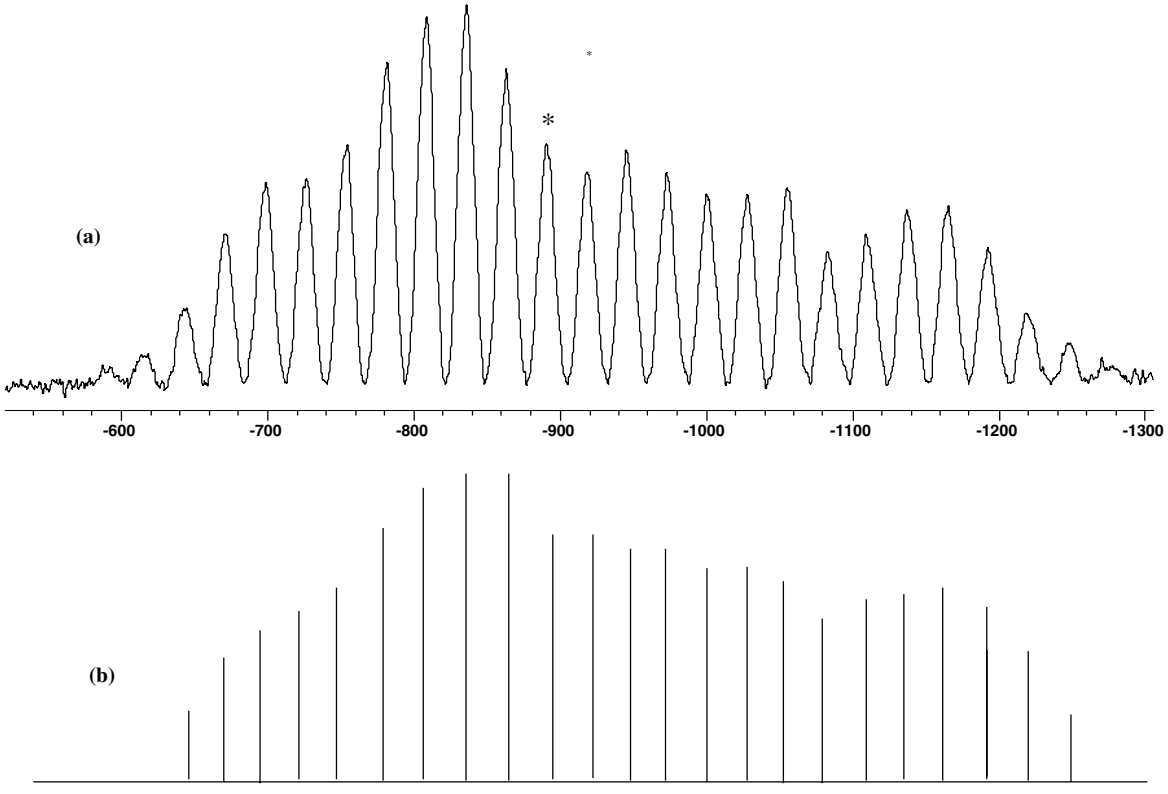

Fig. 2. ^{199}Hg CPMAS spectrum of $(N\text{-}i\text{-}PrImSe)_2HgCl_2$. (a) Observed and (b) calculated. The * denotes the isotropic peak.

[31]. The Hg nucleus in the tris complexes are more shielded by about 100 ppm compared to the bis complexes. The linear Hg(SeCN)$_2$ complex shows a large shielding anisotropy ($\Delta\sigma$) of 2520 ppm [31]. It has been found that the magnitude of the shielding anisotropy of mercury decreases from linear through trigonal planar to a perfect tetrahedral geometry, where it approaches a value of zero. A larger anisotropy is shown by the *bis* complex (N-*i*-PrImSe)$_2$HgCl$_2$, compared to the *tris* complexes. The asymmetry parameters for the complexes indicate that the point symmetry of site occupied by mercury atom is away from the axial symmetry (see Table 3).

An analysis of the orientation of the three orthogonal principal axes of the chemical shift tensor with respect to the molecular framework can be attempted. This is based on the criteria that the shielding effect of a given M—L bond is maximal in the direction perpendicular to the M—L vector and that the Se is the most deshielding atom [32]. On the basis of above, the most deshielded component σ_{11} should be disposed nearly collinear with the Hg—Cl axis in the *tris* complexes, whereas in the (N-*i*-PrImSe)$_3$HgCl$_2$ complex the component σ_{11} should be disposed perpendicular to the planes containing the two selenium atoms and the mercury atom.

The three different selenium environments are shown by the *tris* complexes and two different environments are shown by the *bis* complexes. However, in (N-*i*-PrImSe)$_2$HgCl$_2$ complex, we were able to see only one selenium environment in the NMR (Fig. 3). This may be due to an accidental degeneracy of the chemical shifts for the two selenium sites. The selenium chemical shift tensors calculated for (N-*i*-PrImSe)$_2$HgCl$_2$ are then an average for the two sites. Better overlap of the filled Hg orbitals with lowest unoccupied orbitals of Se should lead to shielding of the Se nucleus. Hence we can assign Se shifts based on their bond length to the mercury atom. With the shortest bond length leading to largest shielding. In the case of the ImSe complexes we observe a deshielding of the selenium upon

complexation. For the complexes we observe positive ^{77}Se anisotropy, while the ligands show a negative anisotropy. This arises because of apparent swapping of the components σ_{11} and σ_{33}.

The ^{13}C NMR spectra also showed the three distinct environments for the selone carbons in the tris complexes and two distinct environments in the bis complexes. On complexation, the selenocarbonyl carbon atoms are more shielded, and this shielding is largest in the case of $(DiazSe)_2HgCl_2$ complex.

3.6. Crystal structure of $(N\text{-}i\text{-}PrImSe)_2HgCl_2$

The complex $(N\text{-}i\text{-}PrImSe)_2HgCl_2$ adopts a distorted tetrahedral geometry. The Se—Hg—Cl bond angles range from 108.22(5)° to 111.73(4)° while the remaining bond angles are Cl1—Hg1—Cl2 105.89(7)° and Se1—Hg1—Se2 111.87(3)°. The average Hg—Se and Hg—Cl bond lengths are 2.585(1) Å and 2.527(2) Å, respectively. To the best of our knowledge, this structure represents the first X-ray structure reported so far for a mononuclear selone mercury (II) complex with $[Se_2Cl_2]$ coordination sphere. The Hg—Se

and Hg—Cl bond distances are in the same range as those reported for the complexes $[HgCl(py)(SeEt)]_4$ [33] and $[Hg(MeImSe)_3Cl]^+$ [12]. Short N···Cl contacts take place (N2···Cl2: 3.168 Å and N3···Cl1: 3.187 Å), suggesting intramolecular NH···Cl hydrogen bonding between the NH groups of the two imidazoline rings and the two chlorine atoms.

The distortion from the ideal tetrahedral geometry is stabilized by hydrogen bonding interactions. As a matter of fact, the existing hydrogen bonding scheme gives rise to two six-membered rings namely $Hg_1Se_2C_7N_3H_3Cl_1$ and $Hg_1Se_1C_1N_2H_2Cl_2$. Both rings adopt a pseudo half-boat conformation in which the five atom Se—C—N—H—Cl fragment, excluding the metal ion, is essentially planar. The metal ion displacement from this mean plane is 0.699(3) Å and 0.311(4) Å for the former and later ring respectively. The half boat conformation is thus less pronounced in the $Hg_1Se_1C_1N_2H_2Cl_2$ ring resulting in more strain and a higher Se1—Hg1—Cl2 bond angle (111.73(4)°) compared to Se2—Hg1—Cl1 bond angle (108.24(5)°).

4. Conclusion

In this study, we have shown that a series of selones react with $HgCl_2$ to form complexes of the type HgL_2Cl_2, HgL_3Cl_2 and HgL_4Cl_2 in which the ligands exist in selone form both in solution as well as in the solid state. The X-ray structures of $(N\text{-}i\text{-}PrImSe)_2HgCl_2$ complex revealed a distorted tetrahedral geometry. The ^{13}C and ^{77}Se solution NMR data clearly indicate that as the ring size of the ligand is increased, the chemical shift difference for the free and bound resonance also increases. Thus DiapSe forms more stable complexes with mercury(II) compared to ImSe and DiazSe. The chemical shifts for different complexes presented here are useful, especially if the ^{77}Se NMR is used to study the metal–ligand interactions in biological systems.

5. Supplementary materials

The supplementary X-ray data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk) on request, quoting the deposition No. 268447.

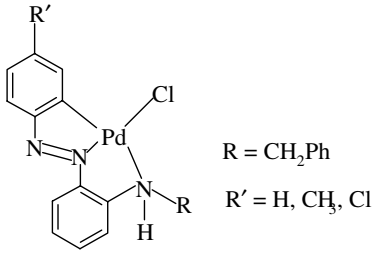
2 (HL[a])

2. Results and discussion

2.1. Syntheses

The 1*N*-(2-pyridyl-2-methyl)-2-arylazo aniline, HL (**1**), ligands were prepared by refluxing 2-(arylazo) aniline with 2-chloromethyl pyridine in acetonitrile in the presence of potassium carbonate and a catalytic amount of potassium iodide (Scheme 1). The ligands were isolated as orange solids.

The reactions of the new HL ligands with Na_2PdCl_4 in methanol afforded pink complexes of palladium (II) of the composition (L)PdCl (**3**) incorporating a new tridentate (*N*,*N*,*N*) ligand (Scheme 1). The deprotonated secondary amino and the azo nitrogens bind the metal, forming a six membered diazoketiminato chelate, while the other 1*N*-alkyl-2-arylazo aniline, HL[a] (**2**) [7] produced the orthopalladated species (L[a])PdCl (**4**) upon treatment with Na_2PdCl_4. Formation of a six membered azoimine chelate in the case of HL has been attributed to the delocalisation of the negative charge within the ligand backbone.



4

The general mechanism of the formation of orthopalladated azobenzene was described to proceed via initial coordination of azo nitrogen followed by electrophilic substitution at the pendant aryl ring [11]. This mechanism was plausible in the cases of HL[a] since these ligands also underwent facile orthopalladation upon treatment with Na_2PdCl_4 (Scheme 2). Whereas reaction of HL with Na_2PdCl_4 did not afford the orthopalladated product and the reaction pathway has been proposed as shown in Scheme 3. Coordination of the amino nitrogen upon concomitant dissociation of its proton was assumed to occur as a result of prior binding of the pyridyl nitrogen to Pd(II). These preceding coordinations of pyridyl and amido nitrogens enabled the ligand to form the diazoketiminato chelate upon subsequent binding through the azo nitrogen and delocalisation of negative charge, which grows upon amino proton dissociation.

2.2. Characterisation

All the ligands displayed characteristic UV–Vis spectra with an absorption near 325 nm for the n–π^* transition of azo compounds [6]. The (L)PdCl complexes exhibited a characteristic low energy absorption near 560 nm, which was assigned to a MLCT transition. Representative UV–Vis spectra of the ligand HL[3]and (L[3])PdCl are shown in Fig. 1. Relevant data are collected in Section 3.

The IR spectra of HL display a sharp singlet near 3189 cm^{-1} for ν_{N-H} which was absent in spectra of (L)PdCl, indicating dissociation of the amino proton on complexation. The $\nu_{N=N}$ band of the ligands ($\sim$1510 cm^{-1}) shifts to lower frequency after formation of the Pd(II) chelates (1350–1400 cm^{-1}), consistent with coordination of the azo nitrogen [6]. The ν_{Pd-Cl} of the palladium complexes appear in the range 290–333 cm^{-1} [7]. Relevant data are included in Section 3.

The ^1H NMR spectra of the ligands and the corresponding palladium complexes are consistent with the formulae and structures. Although the amino proton of HL appears as a broad signal, due to the vicinal coupling of the methylene protons its splitting into a broadened triplet can be observed. On the other hand, the methylene proton resonance also splits as a doublet due to vicinal coupling of the N–H proton. In contrast, the ^1H NMR spectra of (L)PdCl do not display the N–H resonance and the methylene protons appear as a singlet (the vicinal coupling of N–H is absent), signifying the dissociation of the amino proton upon complexation. The methylene proton reso-

nance of (L)PdCl (~δ 5.24) is shifted downfield compared to that of the HL ligands (~δ 4.68). The ^{1}H NMR data are given in Section 3.

2.3. X-ray structure

Suitable crystals of $(L^1)PdCl$ were grown by slow diffusion of hexane into a dichloromethane solution. The X-ray structure of the complex was determined and the perspective view of the $(L^1)PdCl$ molecule, along with the atom numbering scheme, is shown in Fig. 2. Selected bond distances and angles are collected in Table 1. The geometry about palladium is distorted square planar, where the mono anionic deprotonated ligand $(L^1)^-$ binds in a tridentate (*N*,*N*,*N*) fashion. A chloride ligand satisfies the tetracoordination. Three chelating nitrogens are: azo (*N*(azo)), pyridyl (*N*(py)) and amino (*N*(am)). The Pd–*N*(azo), Pd–*N*(py) and Pd–Cl lengths (1.988(4) Å, 2.037(5) Å and

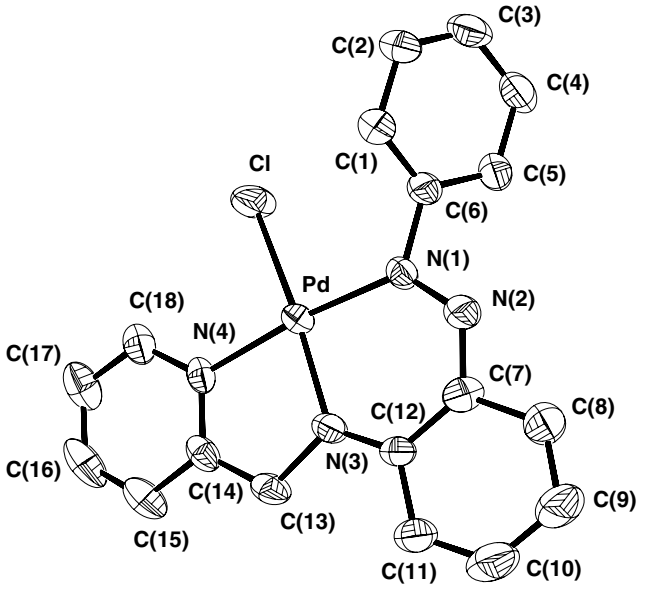

Fig. 2. Perspective view of (L^1)PdCl with the atom numbering scheme. Hydrogen atoms are omitted for clarity.

Table 1
Selected bond distances (Å) and angles (°) for (L^1)PdCl

Pd–N(4)	2.037(5)	N(3)–C(12)	1.330(9)
Pd–N(1)	1.988(4)	C(7)–C(8)	1.429(9)
Pd–N(3)	1.968(5)	C(8)–C(9)	1.349(10)
Pd–Cl	2.330(2)	C(9)–C(10)	1.385(13)
N(1)–C(6)	1.454(8)	C(10)–C(11)	1.368(12)
N(1)–N(2)	1.284(7)	C(11)–C(12)	1.419(10)
N(2)–C(7)	1.346(8)	N(3)–C(13)	1.466(8)
C(7)–C(12)	1.421(1)	C(13)–C(14)	1.454(10)
C(7)–C(8)	1.344(2)	C(14)–N(4)	1.350(9)
N(4)–Pd–N(3)	82.3(2)	N(1)–N(2)–C(7)	124.6(5)
N(1)–Pd–N(4)	173.7(2)	C(13)–C(14)–N(4)	118.0(6)
N(1)–Pd–Cl	94.8(2)	C(14)–N(4)–Pd	113.4(4)
N(3)–Pd–Cl	172.2(3)	Pd–N(1)–N(2)	126.7(4)
C(6)–N(1)–Pd	123.9(4)	C(7)–C(12)–N(3)	121.5(6)
C(13)–N(3)–Pd	114.6(4)	C(12)–N(3)–Pd	126.6(5)

2.330(2) Å, respectively) are within the normal range [9a]. The geometry about palladium is planar (mean deviation 0.042 Å) justifying the oxidation state of Pd(II) and the uninegative ligand since the complex is a non-electrolyte.

The delocalisation of the negative charge within the ligand backbone causes the bond lengths to be suitably altered [6]. The C(12)–N(3) length (1.330(9) Å) is shorter compared to the C–N single bond (N(1)–C(6), 1.454(8) Å) in the same molecule and is similar to the imine (C=N) distance [6]. Also the effect of imine formation due to delocalisation has been reflected in the adjacent phenyl ring (C(7), C(8), C(9), C(10), C(11) and C(12)) which is distorted with two short (~1.35 Å) and four long (~1.4 Å) bonds. Thus the formation of an azoimine chelate could be inferred from the X-ray studies [6] and the structural formula of (L^1)PdCl has been drawn accordingly in **3** of Scheme 1 (vide supra). All the non-hydrogen atoms of (L^1)PdCl, excluding the pendant phenyl ring (C(1)–C(6)), make a good plane (mean deviation 0.114 Å).

3. Experimental

3.1. Materials

The solvents used in the reactions were of reagent grade, obtained from E. Merck, Kolkata, India and purified and dried by reported procedures [6]. 2-(Arylazo) anilines were prepared according to the reported procedure [6]. Palladium chloride and potassium carbonate were purchased from E. Merck, Kolkata, India. 2-(Chloromethyl) pyridine hydrochloride was purchased from Lancaster, England. Disodium tetrachloropalladate was prepared by a reported procedure [6a].

3.2. Syntheses of the ligands

All the ligands, HL^1, HL^2 and HL^3, were prepared following similar procedures. A representative procedure for HL^1 is given below.

3.2.1. HL^1

A mixture of 2-(phenylazo) aniline (0.3 g, 1.52 mmol), 2-chloromethyl pyridine hydrochloride (0.25 g, 1.52 mmol), 1 g of K_2CO_3 and a catalytic amount of KI (0.01 g, 0.06 mmol) in 30 cm^3 dry acetonitrile was refluxed for 3 h. The orange solid mass that was obtained after evaporation of the solvent, afforded the ligand, HL^1, which was isolated by column chromatography on silica gel (60–120 mesh) using the eluent petroleum ether–benzene (3/1 v/v). Upon evaporation of the solvent after chromatography, the orange-red solid of pure HL^1 was obtained. Yield: 0.262 g, 60%. *Anal.* Calc. for $C_{18}H_{16}N_4$, HL^1: C, 75.00; H, 5.20; N, 19.44. Found: C, 74.42; H, 5.35; N, 19.35%. UV–Vis (λ_{max}/nm (ϵ/M^{-1} cm^{-1}) in dichloromethane): 465 (1620), 420 (9430), 325 (10 570). IR (KBr pellets, cm^{-1}): ν_{N-H} 3189, $\nu_{N=N}$ 1512. ^1H NMR ($CDCl_3$): $\delta = 9.50$ (b, NH); 8.66 (d, 1H, $J = 6.0$); 7.90 (d, 3H, $J = 9.0$); 7.66 (t, 1H, $J = 8.5$); 7.49 (t, 2H, $J = 7.5$); 7.41 (d, 1H, $J = 7.2$); 7.36 (t, 1H, $J = 6.0$); 7.28 –7.20 (m, 2H); 6.81 (t, 1H, $J = 7.2$); 6.73 (d, 1H, $J = 8.4$); 4.69 (d, 2H, $J = 4.5$).

3.2.2. HL^2 and HL^3

Ligands HL^2 and HL^3 were prepared using 2-(*p*-tolylazo) aniline and 2-(*p*-chlorophenylazo) aniline in place of 2-(phenylazo) aniline, respectively. Yield: HL^2, 62% and HL^3, 65%.

Anal. Calc. for $C_{19}H_{18}N_4$, HL^2: C, 75.50; H, 5.96; N, 18.54. Found: C, 75.42; H, 6.00; N 18.60%. UV–Vis (λ_{max}/nm (ϵ/M^{-1} cm^{-1}) in dichloromethane): 451 (37 287), 419 (32 681), 321 (61 303). IR (KBr pellets, cm^{-1}): ν_{N-H} 3196, $\nu_{N=N}$ 1512. ^1H NMR ($CDCl_3$): $\delta = 9.37$ (b, NH); 8.65 (d, 1H, $J = 5.0$); 7.86 (d, 1H, $J = 8.0$); 7.79 (d, 1H, $J = 8.5$); 7.64 (t, 1H, $J = 7.5$); 7.35 (d, 1H, $J = 10.0$); 7.29 (d, 2H, $J = 8.0$); 7.24–7.19 (m, 3H); 6.79 (t, 1H, $J = 7.5$); 6.73 (d, 1H, $J = 8.5$); 4.68 (d, 2H, $J = 5.5$); 2.42 (s, 3H).

Anal. Calc. for $C_{18}H_{15}N_4Cl$, HL^3: C, 66.97; H, 4.65; N, 17.37. Found: C, 66.50; H, 4.70; N, 17.25%. UV–Vis (λ_{max}/nm (ϵ/M^{-1} cm^{-1}) in dichloromethane): 461 (10854), 426 (8483), 324 (17123), 253 (19435). IR (KBr pellets, cm^{-1}): ν_{N-H} 3196, $\nu_{N=N}$ 1511. ^1H NMR ($CDCl_3$): $\delta = 9.55$ (b, NH); 8.66 (d, 1H, $J = 4.0$); 7.88 (d, 1H, $J = 8.0$); 7.84 (d, 2H, $J = 7.0$); 7.66 (t, 1H, $J = 7.5$); 7.46 (d, 2H, $J = 9.0$); 7.33 (d, 1H, $J = 7.5$); 7.25 (m, 1H); 7.22 (t, 1H, $J = 6.5$); 6.83 (t, 1H, $J = 8.0$); 6.75 (d, 1H, $J = 8.5$); 4.68 (d, 2H, $J = 5.0$).

3.3. Syntheses of the complexes

All the complexes, $(L^1)PdCl$, $(L^2)PdCl$ and $(L^3)PdCl$ were prepared following similar procedures. A representative procedure for $(L^1)PdCl$, is given below.

3.3.1. $(L^1)PdCl$

A solution of HL^1 (0.150 g, 0.52 mmol) in 10 cm^3 methanol was added to a solution of Na_2PdCl_4 (0.153 g, 0.52 mmol) in 5 cm^3 methanol. The mixture was stirred for 5 h. The dark solid precipitate was separated by filtration and purified by column chromatography using silica gel (60–120 mesh). The eluent was benzene–acetonitrile (19/1 v/v) mixed solvent. Upon evaporation of the solvent, a violet solid of pure $(L^1)PdCl$ was obtained. Yield: 0.122 g, 55%. *Anal.* Calc. for $C_{18}H_{15}N_4PdCl$, $(L^1)PdCl$: C, 50.32; H, 3.49; N, 13.04. Found: C, 50.35; H, 3.50; N, 13.00%. UV–Vis (λ_{max}/nm (ϵ/M^{-1} cm^{-1}) in dichloromethane): 565 (14660), 525 (3230), 325 (31870). IR (KBr pellets, cm^{-1}): $\nu_{N=N}$ 1357, ν_{Pd-Cl} 333. ^1H NMR ($CDCl_3$): $\delta = 9.39$ (d, 1H, $J = 6.0$); 7.86 (t, 2H, $J = 7.2$); 7.52 (d, 1H, $J = 7.8$); 7.45–7.30 (m, 7H); 7.02 (d, 1H, $J = 9.0$); 6.68 (t, 1H, $J = 7.8$); 5.24 (s, 2H).

3.3.2. $(L^2)PdCl$ and $(L^3)PdCl$

Complexes $(L^2)PdCl$ and $(L^3)PdCl$ were prepared using the ligands HL^2 and HL^3 in place of HL^1, respectively. Yield: $(L^2)PdCl$, 55% and $(L^3)PdCl$, 55%.

Anal. Calc. for $C_{19}H_{17}N_4PdCl$, $(L^2)PdCl$: C, 51.46; H, 3.83; N, 12.64. Found: C, 51.40; H, 3.90; N, 12.70%. UV–Vis (λ_{max}/nm (ϵ/M^{-1} cm^{-1}) in dichloromethane): 563 (25711), 529 (22733), 460 (19844), 327 (37666). IR (KBr pellets, cm^{-1}): $\nu_{N=N}$ 1354, ν_{Pd-Cl} 332. ^1H NMR ($CDCl_3$): $\delta = 9.40$ (d, 1H, $J = 5.5$); 7.86 (m, 2H); 7.53 (d, 1H, $J = 8.0$); 7.43 (t, 1H, $J = 7.0$); 7.35–7.31 (m, 3H); 7.18 (d, 2H, $J = 8.0$); 7.01 (d, 1H, $J = 8.5$); 6.67 (t, 1H, $J = 7.5$); 5.22 (s, 2H); 2.39 (s, 3H).

Anal. Calc. for $C_{18}H_{14}N_4PdCl_2$, $(L^3)PdCl$: C, 46.60; H, 3.02; N, 12.08. Found: C, 46.55; H, 3.00; N, 12.10%. UV–Vis (λ_{max}/nm (ϵ/M^{-1} cm^{-1}) in dichloromethane): 566 (21488), 534 (18813), 334 (40348), 247 (159395). IR (KBr pellets, cm^{-1}): $\nu_{N=N}$ 1357, ν_{Pd-Cl} 333. ^1H NMR ($CDCl_3$): $\delta = 9.35$ (d, 1H, $J = 5.5$); 7.86 (t, 1H, $J = 7.5$); 7.79 (d, 1H, $J = 8.5$); 7.53 (d, 1H, $J = 7.5$); 7.44–7.32 (m, 6H); 7.02 (d, 1H, $J = 9.0$); 6.68 (t, 1H, $J = 7.5$), 5.23 (s, 2H).

Table 2

Goodness-of-fit	1.04

3.4. Physical measurements

Microanalyses (C,H,N) were performed using a Perkin–Elmer 240C elemental analyser. Infrared spectra were recorded on a Perkin–Elmer L120-00A FT-IR spectrometer with the samples prepared as KBr pellets. Electronic spectra were recorded on a Shimadzu UV-2401 PC spectrophotometer. ^1H NMR spectra were obtained on Brucker Avance DPX 300 and Brucker RPX 500 NMR spectrometers in $CDCl_3$, using TMS as the internal standard.

3.5. Crystallography

A crystal of $C_{18}H_{15}N_4PdCl$ was grown by slow diffusion of hexane into a dichloromethane solution at 298 K. Data were collected by the ω-scan technique on a Enraf–Nonius CAD4 diffractometer with Mo Kα radiation monochromated by a graphite crystal. The structure solution was done by the direct method with the SHELXS-97 program. Full matrix least square refinements were performed using the SHELX-97 program (PC version). All non-hydrogen atoms were refined anisotropically using reflections $I > 2\sigma(I)$. Hydrogen atoms were included in calculated positions. The crystal data and data collection parameters are listed in Table 2.

4. Conclusion

Reactions of transition metal substrates with preformed ligands describe the actual metal–ligand interaction which is important to rationalise several biological and catalytic processes. The work presented here is a unique example in this regard. In this report we have described that the M–C interaction in polyfunctional organic molecules may be influenced not only electronically but also by suitable arrangements of the hetero donor atoms. The *N*-alkylated arylazo anilines, HL^a, were demonstrated to be appropriate for C–H bond activation via orthometallation [7] while

reactions of the newly synthesised ligands, HL with Na_2PdCl_4 afforded the remarkable azoimine chelates. A plausible rationale has been given considering the logical progress of the reactions.

Acknowledgments

We are thankful to the DST (New Delhi) for funding and fellowship to J.P. under the DST-SERC project. The necessary laboratory and infrastructural facility are provided by the Department of Chemistry, University of Kalyani. We are thankful to Prof. G.K. Lahiri (IIT, Mumbay) for his continuous help. The support of the DST under the FIST program to the Department of Chemistry, University of Kalyani is acknowledged.

Appendix A. Supplementary data

Figs. S1–S6, UV–Vis spectra; Figs. S7–S12, IR spectra and Figs. S13–S18, ^{1}H NMR spectra are supplied as supplementary material. Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC reference number 250543. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, e-mail: deposite@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.03.019.

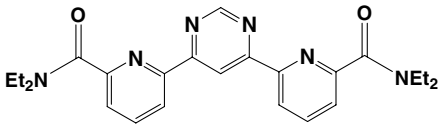

Fig. 1. Structure of ligand **L**.

appropriate metal ions, we observed that complexes of different architectures were obtained depending mainly on the kind of metal ions used for coordination, as a consequence of preferred coordination geometry.

Herein we report new investigations into the coordination chemistry of ligand **L** with transition metal ions and show that it is able to form novel polynuclear complexes.

2. Experimental

2.1. Measurements

NMR spectroscopic data were run on a Varian Gemini 300 MHz spectrometer, were calibrated against the residual protonated solvent signal ([D_6]DMSO: $\delta = 2.50$) and are given in ppm. Mass spectra were determined by a Waters Micromass ZQ spectrometer in acetonitrile. The samples were run in the positive-ion mode. The concentrations of the compounds were about 10^{-4} mol dm^{-3}. Sample solutions were introduced into the mass spectrometer source with a syringe pump with a flow rate of 40 μL min^{-1} with a capillary voltage of +3 kV and a desolvation temperature of 300 °C. Source temperature was 120 °C. Cone voltage (V_c) was set to 30 V to allow transmission of ions without fragmentation processes. Scanning was performed from $m/z = 200$ to 1000 for 6 s, and 10 scans were summed to obtain the final spectrum. Microanalyses were obtained using a Perkin–Elmer 2400 CHN microanalyzer. IR spectra were obtained with a Perkin–Elmer 580 spectrophotometer and are reported in cm^{-1}.

2.2. Preparation of Mn(II) complex (*1*)

An equimolar mixture of $Mn(ClO_4)_2 \cdot 6H_2O$ (8.4 mg, 23 μmol) and ligand **L** (10.0 mg, 23 μmol) in MeCN (5 cm^3) was stirred at RT for 24 h. The solvent was evaporated under reduced pressure to give a quantitative yield a yellowish powder. Slow diffusion of toluene into solution of **1** in acetonitrile over period of 2 months in air gave the single crystals of **1**. ^{1}H NMR (300 MHz, DMSO): $\delta = 9.46$, 9.25, 8.56, 8.18, 7.77, 5.31, 4.22, 3.51, 3.34, 2.91, 1.98, 1.77, 1.23, 1.18, 0.85, 0.19 ppm. ESI-MS *m/z* (%) = 586 (30 [Mn**L**(ClO$_4$)]$^+$), 460 (40 [Mn$\mathbf{L}_2$]$^{2+}$), 433 (2 [**L**]$^+$), 358 (30 [Mn$_2\mathbf{L}_2$(ClO$_4$)]$^{3+}$), 244 (100 [Mn**L**]$^{2+}$). IR (KBr [cm^{-1}]): $\bar{\nu} = 3364$, 3094, 2980, 1598, 1570, 1493, 1438, 1388, 1362, 1290, 1262, 1239, 1142, 1122, 1089, 1021, 993, 951, 834, 757, 636, 626, 574, 521, 464, 409. *Anal.* Calc. for $Mn_n(\mathbf{L})_n(ClO_4)_n \cdot (C_7H_8)$ (778.50): C, 47.83; H, 4.66; N, 10.80. Found: C, 47.91; H, 4.67; N, 10.81%.

2.3. Preparation of Cu(I) complex (*2a*)

An equimolar mixture of [Cu(CH$_3$CN)$_4$]PF$_6$ (9.7 mg, 26 μmol) and ligand **L** (11.3 mg, 26 μmol) in MeCN (5 cm^3) was stirred at room temperature for 24 h. The solvent was evaporated under reduced pressure to give a quantitative yield of **2a** as purple-violet powder. Slow diffusion of methanol into solution of **2a** in acetonitrile over period of 2 months in air gave the single crystals of **2a**. ^{1}H NMR (300 MHz, DMSO): $\delta = 9.85$ (s), 9.35 (s), 9.18 (d, $J = 8.1$ Hz), 8.53 (t, $J = 8.1$ Hz), 8.03 (d, $J = 8.1$ Hz), 3.35 (q, $J = 6.6$ Hz), 1.23 (t, $J = 6.6$ Hz), 0.87 (t, $J = 6.6$ Hz) ppm. ESI-MS: $m/z = 928$ (5 [Cu$\mathbf{L}_2$]$^+$), 496 (100 [Cu$_4\mathbf{L}_4$]$^{4+}$), 433 (7 [**L**]$^+$). IR (KBr [cm^{-1}]): $\bar{\nu} = 3429$, 3105, 2978, 1636, 1597, 1567, 1492, 1435, 1385, 1366, 1303, 1266, 1249, 1213, 1125, 1090, 1011, 950, 841, 751, 715, 655, 557, 492, 403. *Anal.* Calc. for $Cu_4(\mathbf{L})_4(PF_6)_4 \cdot (CH_3OH)_{0.5} \cdot H_2O$ (2598.15): C, 44.61; H, 4.50; N, 12.94. Found: C, 44.51; H, 4.53; N, 12.98%.

2.4. Preparation of Cu(I) complex (*2b*)

A solution of ligand **L** (10.2 mg, 24 μmol) and $(CuCF_3SO_3)_2 \cdot C_6H_6$ (5.9 mg, 12 μmol) in MeCN (3 cm^3) was stirred at room temperature for 24 h. The violet complex **2b** was isolated in quantitative yield upon evaporation of the solvent. ^{1}H NMR (300 MHz, DMSO): $\delta = 9.49$ (s), 9.27 (s), 8.58 (d, $J = 8.4$ Hz), 8.19 (t, $J = 8.4$ Hz), 7.80 (d, $J = 8.4$ Hz), 3.36 (q, $J = 7.2$ Hz), 3.04 (q, $J = 7.2$ Hz), 1.24 (t, $J = 7.2$ Hz) ppm. ESI-MS: $m/z = 928$ (5 [Cu$\mathbf{L}_2$]$^+$), 495 (100 [Cu$_4\mathbf{L}_4$]$^{4+}$), 433 (2 [**L**]$^+$). IR (KBr [cm^{-1}]): $\bar{\nu} = 3081$, 2978, 1636, 1567, 1488, 1438, 1382, 1368, 1278, 1257, 1224, 1159, 1127, 1031, 947, 824, 756, 638, 572, 516, 475, 408. *Anal.* Calc. for $Cu_4(\mathbf{L})_4(CF_3SO_3)_4$ (2580.53): C, 46.54; H, 4.37; N, 13.03; S, 4.97. Found: C, 46.51; H, 4.36; N, 13.11; S, 4.99%.

2.5. Preparation of Ag(I) complex (*3a*)

A solution of ligand **L** (12.0 mg, 28 μmol) and $AgBF_4$ (5.4 mg, 28 μmol) in MeCN (5 cm^3) was stirred at room temperature for 24 h. The pale yellow complex **3a** was isolated in quantitative yield by evaporation of the solvent. ^{1}H NMR (300 MHz, DMSO): $\delta = 9.48$ (s), 9.26 (s), 8.57 (d, $J = 8.1$ Hz), 8.19 (t, $J = 7.8$ Hz), 7.79 (d, $J = 7.8$ Hz), 3.34 (q, $J = 7.2$ Hz), 1.22 (t, $J = 4.5$ Hz) ppm. ESI-MS: $m/z = 974$ (3 [Ag$\mathbf{L}_2$]$^+$), 539 (100 [Ag$_4\mathbf{L}_4$]$^{4+}$), 433 (2 [**L**]$^+$). IR (KBr, [cm^{-1}]): $\bar{\nu} = 3439$, 3081, 2978, 1636, 1572, 1534, 1486, 1438, 1382, 1365, 1268, 1220, 1081, 1033, 827, 756, 656, 522. *Anal.* Calc. for $Ag_4(\mathbf{L})_4(BF_4)_4$ (2508.76): C, 45.96; H, 4.50; N, 13.40. Found: C, 45.39; H, 4.43; N, 13.25%.

2.6. Preparation of Ag(I) complex (*3b*)

A solution of ligand **L** (17.0 mg, 39 μmol) and $AgCF_3SO_3$ (10.1 mg, 39 μmol) in MeCN (5 cm^3) was stirred

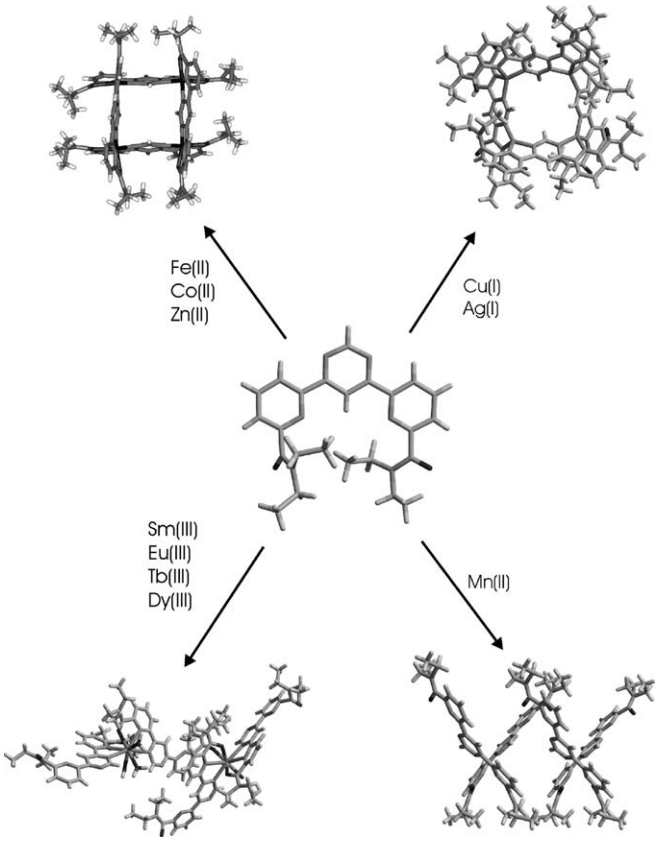
2.7. Crystal structure determination of complexes *1* and *2a*

The crystals of both compounds were of poor quality. We decided to lower the temperature of data collection, and the diffraction data for **1** and **2a** were therefore collected at 100(1) K by the ω-scan technique up to $2\theta = 50°$, on a KUMA-KM4CCD diffractometer [44] with graphite-monochromatized Mo Kα radiation ($\lambda =$ 0.71073 Å). Temperature was controlled by an Oxford Cryosystems cooling device. The data were corrected for Lorentz-polarization effects [45]. Unit-cell parameters were determined by the least-squares fit of 1356 (**1**) and 2300 (**2a**) reflections of highest intensity, chosen from the whole experiment. The structures were solved with SHELXS97 [46] (in both structures additional solvent molecules were found: in **1** toluene, in **2a** water and disordered methanol), and refined with the full-matrix least-squares procedure on F^2 by SHELXL97 [47,48]. Scattering factors incorporated in SHELXL97 were used. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were placed geometrically in idealized positions and refined as rigid groups; U_{iso} of hydrogen atoms were set as 1.2 (1.3 for CH_2 and CH_3 groups) times U_{eq} of the appropriate carrier atom. A number of constraints had to be applied during refinement. However, these constraints were not applied to the geometry of main structural elements (complexes and counterions); therefore, despite the relatively high *R*-factors the discussion of the composition and structure of the complexes formed seems to be reasonable. Relevant crystal data are listed in Table 1, together with refinement details.

3. Results and discussion

In view of the successful synthesis of Fe(II), Co(II), Zn(II) [43], Sm(III), Eu(III), Tb(III) and Dy(III) [49] complexes with **L** (Scheme 1), we investigated the preparation of complexes with Mn(II) (**1**), Cu(I) (**2a**, **2b**) and Ag(I) (**3a**, **3b**). Scheme 1 shows that ligand **L** forms a variety of polynuclear coordination architectures and coordination modes.

In previous papers we carried out studies of self-assembly of ligand **L** in the presence of metal ions with preferred octahedral coordination geometry, such as Fe(II), Co(II) and Zn(II), and found out that the ligand is correctly preorganized for the assembly of tetranuclear grid-type complexes [43]. Initial investigations into the lanthanide complexation behaviour of **L** focussed upon the reaction between 1:1 stoichiometric combinations of M^{3+}:L ($M^{3+} = Sm^{3+}$, Eu^{3+}, Tb^{3+}, Dy^{3+}) in the hope of obtaining $[M_4L_4]^{12+}$ grid-type products. Evidence for the existence of



Scheme 1.

$[M_4L_4]^{12+}$ species which may be of a grid-type structure was obtained for the $M^{3+} = Eu^{3+}$ system using ESI-MS. The result of ESI-MS indicated that many kinds of multinuclear structures co-existed in solution, in the form of grids or helicates. Since we could not obtain crystals suitable for X-ray analysis, and thereby confirm the structural identity of the components in the mixture, we decided to change the molar ratio of M^{III}:**L** to 3:2 and we obtained intricate dinuclear complexes of Sm(III), Eu(III), Tb(III) and Dy(III): $[M_2L_4(CF_3SO_3)_6]$ [49]. As a continuation of this work, herein we report the use of ligand **L** in the complexation with manganese(II) ion whose tendency to form polymeric complexes is well-known, and we observed the formation of a new linear coordination polymer complex: $[MnL]_n$ (**1**). In reaction with tetrahedrally coordinated metal ions such as Cu(I) (**2a**, **2b**) and Ag(I) (**3a**, **3b**) ligand **L** acts in a bidentate fashion and generates of $[2 \times 2]$ grids. The new compounds have been characterized on the basis of spectroscopic data in solution (IR, ^{1}H NMR, ESI-MS), and confirmed in the solid state in the case of complexes **1** and **2a** by X-ray crystallography.

3.1. Synthesis and characterization of the polymeric complex of Mn(II)

An equimolar reaction of manganese(II) perchlorate with amide ligand **L** provided a new polymeric zigzag complex **1**. Each ion in this chain is situated in a distorted octahedral coordination environment comprising two N,N,O ligand donor sets.

The ^{1}H NMR spectrum of paramagnetic complex of manganese(II) shows strongly shifted signals. In addition to NMR and elemental analysis, the complex was also characterized with electrospray ionization mass spectrometry. The ESI-MS spectrum of complex **1** showed the signals at $m/z = 586$ $[MnL(ClO_4)]^+$, 460 $[MnL_2]^{2+}$, 433 $[L]^+$, 358 $[Mn_2L_2(ClO_4)]^{3+}$, 244 $[MnL]^{2+}$. While this may indicate the presence of some smaller linear oligomers in solutions, the peaks may be fragments of a high mass polymeric species [50].

3.2. Crystal data for complex *1*

Crystals of the manganese complex **1** were obtained by diffusion of toluene into a solution of the complex in acetonitrile and its structure was determined by X-ray crystallography (Fig. 2). Complex **1** in the solid state turned out to be a polymeric structure. The Mn(II) ions are six-coordinated (by ring nitrogen atoms, but also by carbonyl oxygen atoms), and the coordination is close to octahedral (Table 2). The Mn–N and Mn–O bond lengths are typical, but lie among smaller values found in similar complexes.

In the free ligand [43] the disposition of three rings was *trans–trans* (with respect to nitrogen atoms), and the amide oxygen atoms were *trans* with respect to nitrogen atoms of the neighbouring ring. The formation of the complex molecule changes this conformation basically: Three rings are in *cis–cis* orientation, as can be seen from the values of dihedral angles N–C–C–N of 0.2° and −3.2°, and the oxygen atoms are also close to *cis* positions: the N(ring)–C–C–O torsion angles are 15.6° and 21.9°. This conformation makes three-dentate "bay area" N,N,O; two such fragments from two consecutive, almost perpendicular, ligand

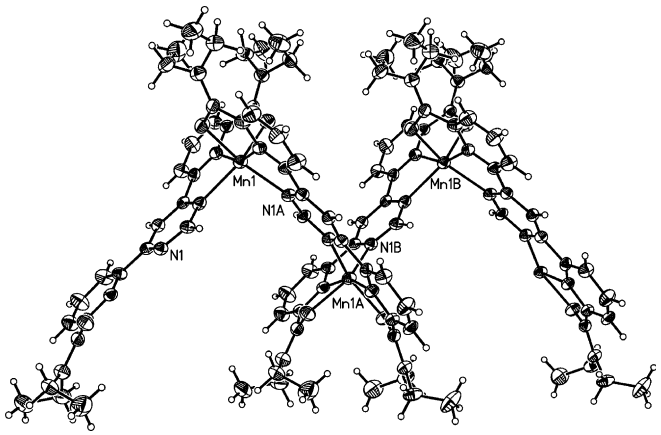


Fig. 2. Anisotropic-ellipsoid representation of a fragment of polymer **1**. The ellipsoids are drawn at the 33% probability level, hydrogen atoms are represented by spheres of arbitrary radii. The counterions are omitted for clarity.

Symmetry code: $^{i}3/2 - x, 1/2 + y, 1/2 - z$.

molecules fulfill the coordination of one Mn ion. Further, the approximate C_2 symmetry of the ligand allows for the polymer formation (Fig. 2). The rings are planar within the experimental error, and the dihedral angles between them are small, comparable with the free ligand molecule (3.1–9.6°). In the crystal structure there are also perchlorate counterions, and solvent–toluene molecules. These molecules fill the voids between the ligand molecules and are kept by weak π-stacking interactions; the distance between the ring planes is ca. 3.3 Å.

The subsequent units in the polymer are organized in a zigzag fashion (Fig. 2), and the neighbouring zigzag ribbons are connected through perchlorate ions by weak hydrogen bonds C–H···O.

3.3. Synthesis and characterization of the grid-type complexes of Cu(I) and Ag(I)

A multitopic ligand with N,N,O type donor sets has only infrequently been employed in the metal ion directed assembly of coordination architectures. Ligand **L** was found to form complexes with Cu(I) and Ag(I) ions, giving $[2 \times 2]$ grid-type structures with each metal ion tetrahedrally coordinated by two N,N donor atoms.

The self-assembly of $[2 \times 2]$ grid-type compounds was achieved by reaction at room temperature in acetonitrile, using ligand **L** and tertakis(acetonitrile)copper(I) hexafluorophospate (**2a**), copper(I) triflate (**2b**), silver(I) tetrafluroborate (**3a**) and silver(I) triflate (**3b**), respectively. The complexation reactions were followed by ESI-MS, IR and NMR spectroscopy.

For the complex of **3a**, three charge-states were observed in the ESI mass spectrum at $m/z = 974$ $[AgL_2]^{+}$, 539 $[Ag_4L_4]^{4+}$, 433 $[L]^{+}$. These data confirm the presence of grid **3a** in solution. The spectra of all the grid-type complexes include the following signals: $[ML_2]^{+}$, $[M_4L_4]^{4+}$, $[L]^{+}$, which means that in solution significant dissociation of the grid complexes to mononuclear species and ligand molecules occurs [31,51].

3.4. Crystallographic characterization of grid complex **2a**

Crystals of complex **2a** were obtained by diffusion of methanol into a solution of the complex in acetonitrile and its structure was determined by X-ray crystallography at 100 K (Figs. 3 and 4). It shows that it is a $[2 \times 2]$ grid-type (Fig. 3), stable from 100 K, at least to room temperature. The unit cell contains, besides the grid molecules, counterions PF_6^{-}, water molecule and disordered solvent (methanol) molecules.

The shape of the grid is close to a square, the lengths of diagonals are 0.83 and 0.86 nm. The Cu(I) are four-coordinated (by ring nitrogen atoms only), and the coordination polyhedra are distorted tetrahedra (Table 3). On complexation, the conformation of the ligand had to change from *transoid*, observed in free ligand **L** [43], to *cisoid*, as was also observed in the formation of Zn(II) and Co(II) complexes [43].

In the free ligand the three rings do not deviate seriously from coplanarity; the maximum value of the dihedral angle between the ring planes being ca. 12° [43]; in the grid the dihedral angles between the ring planes are larger (up to 23.5°), in order to allow grid formation. The amide planes are almost perpendicular to the ring planes, the dihedral angles between these planes are in the range of 54–88°.

In the crystal structure the grids are connected – by means of relatively short C–H···F hydrogen bonds – via hexafluorophosphate counterions. Two such counterions lie below and above the grid plane (Fig. 4), and all four counterions act as 'glue' for the 3D structure.

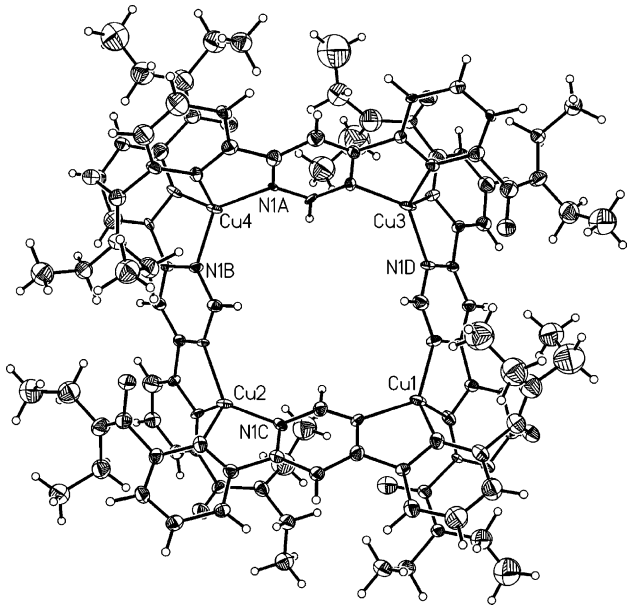

Fig. 3. Anisotropic-ellipsoid representation of grid **2a**. The ellipsoids are drawn at the 33% probability level, hydrogen atoms are represented by spheres of arbitrary radii. The counterions and solvent molecules are omitted for clarity.

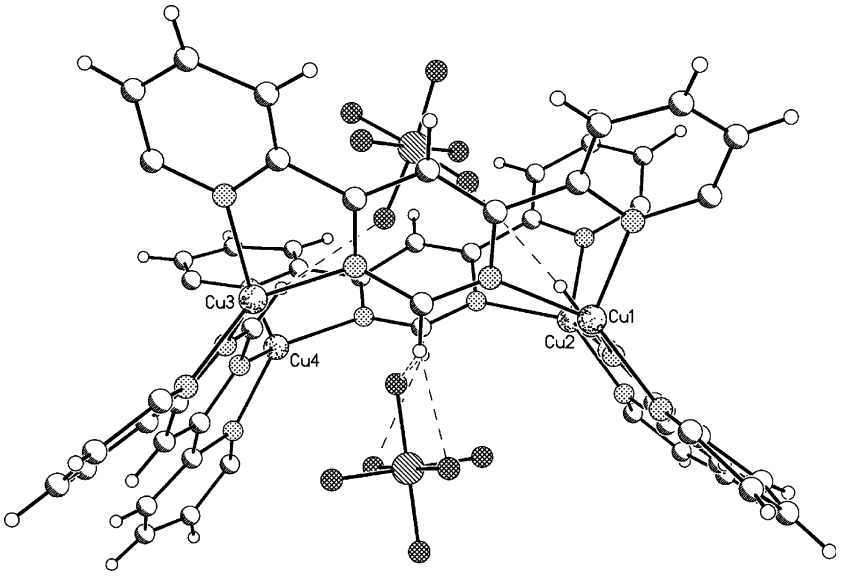

Fig. 4. Fragment of the 3D structure of complex **2a** with PF_6^- counterions below and above the Cu-plane. Weak hydrogen bonds are drawn as dashed lines.

4. Conclusion

We report the synthesis of new grid-type complexes of Cu(I), Ag(I) and a polymeric complex of Mn(II) with ligand **L**, comprising two tridentate N,N,O(carbonyl) binding subunits. The Mn(II) ions present octahedral, and Cu(I) and Ag(I) ions distorted tetrahedral geometry.

The present results demonstrate that ligand **L** is flexible, versatile and capable of stabilizing complexes with metals in different coordination environments. These assemblies are potentially useful for example as functional components in molecular electronics [52,53] and they could find various applications in nanotechnology [54] and catalysis [55].

5. Supplementary material

Crystallographic data (excluding structure factors) for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, Nos. CCDC-290966 (**1**), and CCDC-290965 (**2a**). Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 336 033, e-mail: deposit@ccdc.cam.ac.uk, or www: www.ccdc.cam.ac.uk.

Acknowledgments

This research was carried out as part of the Polish Ministry of Education and Science project (Grant No. 4 T09A 049 24).

2.2. Synthesis of $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$ (**1**)

Complex **1** was synthesized by the reaction of a 20 ml $CHCl_3$ solution of $Cu(n\text{-}Pr_2dtc)_2$ (0.0416 g, 0.1 mmol) and a 20 ml acetone solution of $CuCl_2 \cdot 2H_2O$ (0.0170 g, 0.1 mmol). The black single crystals, suitable for X-ray diffraction, were obtained from the mixture by recrystallization with hexane in a glass tube over a period of more than 1 week. *Anal.* Calc. for $C_{42}H_{84}Cl_8Cu_8N_6S_{12}$: C, 27.27; H, 4.58; N, 4.54. Found: C, 27.30; H, 4.50; N, 4.54%.

2.3. X-ray structure determination

Single crystal X-ray data collection was performed on a RIGAKU R-AXIS RAPID imaging plate area detector with graphite monochromated Mo Kα (0.71069 Å) radiation. The intensity data were collected at angles up to 55° at room temperature. The crystal data and experimental parameters are listed in Table 1. The structure was solved by a direct method (SHELX97) [24] and expanded using Fourier techniques (DIRDIF99) [25]. Non-hydrogen atoms were refined anisotropically, whereas hydrogen atoms were introduced as fixed contributors. All calculations were performed using the CRYSTALSTRUCTURE crystallographic software package [26].

2.4. Magnetic measurement

The magnetic susceptibilities of the polycrystalline sample of **1** were studied in a field of 10000 Oe using a Quantum Design MPMS SQUID Magnetometer. Diamagnetic corrections were estimated from Pascal's constants.

3. Results and discussion

The X-ray structural analysis reveals an octanuclear cluster structure of **1**, which is shown in Fig. 1. Complex **1** consists of two chloride-bridged dinuclear units, $Cu_2(n\text{-}Pr_2dtc)_2Cl_2$, and one tetranuclear unit, $[Cu_2(n\text{-}Pr_2dtc)Cl_2]_2$. In the dinuclear units, the $n\text{-}Pr_2dtc^-$ ligand coordinates to each copper ion with a four-membered chelate ring, and the two copper ions are bridged by the two chloride ions. The copper ions Cu(1) and Cu(2) have distorted square-pyramidal coordination geometries. The apical positions of the Cu(1) and Cu(2) ions are respectively occupied by a chloride ion and a sulfur atom from the nearest neighbor chloride bridged dinuclear unit in the crystallographically equivalent octanuclear cluster, with weak Cu(1)···Cl(2**) (2.9178(8) Å) and Cu(2)···S(1**) (3.0116(9) Å) coordination bonds, which are significantly longer than the Cu–S and Cu–Cl distances in the basal plane. Based on the weak coordination bonds, the octanuclear cluster creates an infinite one-dimensional assembly as shown in Fig. 2(a). In this one-dimensional assembly, a dimer of $[Cu_2(n\text{-}Pr_2dtc)_2Cl_2]_2$ which is formed by the two chloride-bridged dinuclear units, and the tetranuclear unit of $[Cu_2(n\text{-}Pr_2dtc)Cl_2]_2$ are alternately aligned. Fig. 2(a) shows the two adjacent one-dimensional assemblies. There are no open spaces between the assemblies because the spaces created by the one-dimensional assemblies are actually filled by the alkyl groups of the $n\text{-}Pr_2dtc^-$ ligand. The tetranuclear unit of $[Cu_2(n\text{-}Pr_2dtc)Cl_2]_2$ includes two crystallographically equivalent dinuclear copper units, in which the Cu(3) and Cu(4) ions have distorted tetrahedral and square-pyramidal coordination geometries, respectively. The Cu(3) and Cu(4) ions are bridged by two chloride ions. The Cu(4) ion is coordinated by a Pr_2dtc^- ligand with a four-membered chelate ring, and the Cu(3) ion is coordinated by a sulfur atom of the chloride-bridged dinuclear unit, $Cu_2(n\text{-}Pr_2dtc)_2Cl_2$. The apical position of the Cu(4) ion is occupied by one of the bridging chloride ions in the centrosymmetric tetranuclear unit with a weak Cu(4)···Cl(3*) coordination bond (2.8389(11) Å).

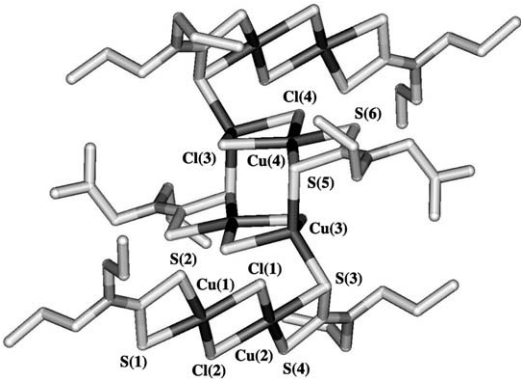

Fig. 1. The structure of $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$.

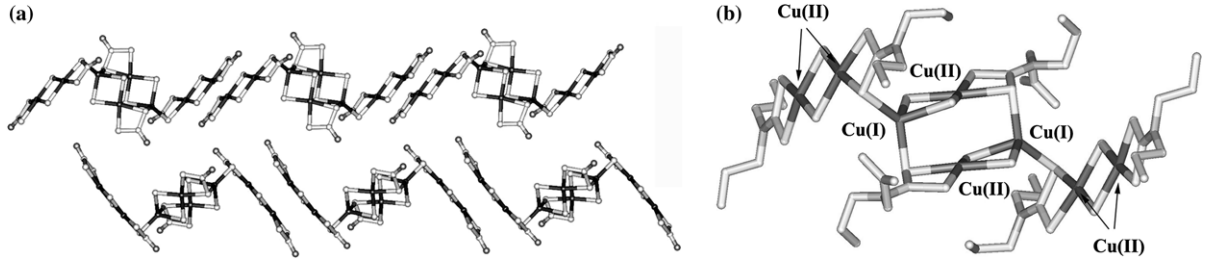

Fig. 2. A view of the one-dimensional assembly (a) and the valence states of the copper ions (b) for $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$.

For the dinuclear unit, $Cu_2(n\text{-}Pr_2dtc)_2Cl_2$, the dihedral angles between the planes of S(1)–Cu(1)–S(2) and Cl(1)–Cu(1)–Cl(2) in the Cu(1) coordination sphere and between the planes of Cl(1)–Cu(2)–Cl(2) and S(3)–Cu(2)–S(4) in the Cu(2) coordination sphere are 13.295° and 5.216°, respectively. While for the tetranuclear unit, $Cu_4(n\text{-}Pr_2dtc)_2Cl_4$, the dihedral angles between the planes of S(3)–Cu(3)–S(5) and Cl(3*)–Cu(3)–Cl(4*) in the Cu(3) coordination sphere and between the planes of S(5)–Cu(4)–S(6) and Cl(3)–Cu(4)–Cl(4) in the Cu(4) coordination sphere are 85.712° and 14.963°, respectively, indicating that the Cu(3) ion, having a large distortion, could be ascribed as a Cu(I) ion. Although the other copper ions of Cu(1), Cu(2) and Cu(4) also have apparent distortions, this is common for Cu(II)-dithiocarbamate complexes with square-pyramidal coordination geometry; for example, $Cu(Et_2dtc)_2$ [27], $Cu(n\text{-}Pr_2dtc)_2$ [23], $Cu(n\text{-}Bu_2dtc)_2$ [23], $Cu(Bz_2dtc)_2$ [23] and $Cu(EtOH_2dtc)_2$ [28], which have square-pyramidal coordination geometry by the dimerization of the mononuclear Cu(II) complexes, have largely distorted basal planes in which the dihedral angles are 18.89°, 19.00°, 17.71°, 10.84° and 20.86°, respectively. Meanwhile, the distortion of Cu(II) complexes with square-planar coordination geometry, such as $Cu(i\text{-}Pr_2dtc)_2$ [23], Cu(BuEt-dtc)$_2$ [23] and Cu(Piperidine-dtc)$_2$ [29], is almost zero, that is they have flat basal planes.

The Cu–S bond lengths in the basal planes are 2.2604(14)–2.2912(10) Å for Cu(1), 2.2518(12)–2.3195(8) Å for Cu(2), 2.2709(8)–2.2896(11) Å for Cu(3) and 2.2722(12)–2.3362(9) Å for Cu(4), in which no remarkable differences between the tetrahedral Cu(3) ion and the other distorted square-pyramidal Cu(1), Cu(2) and Cu(4) ions could be found. The distances are similar to those of other Cu(II)-dithiocarbamate mononuclear complexes, such as $Cu(Et_2dtc)_2$ (2.312 Å (av.)) [27], Cu(EtPr-dtc)$_2$ (2.284 Å (av.)) [23], $Cu(Bu_2dtc)_2$ (2.308 Å (av.)) [23] and $Cu(Bz_2dtc)_2$ (2.293 Å (av.)) [23]. However there are apparent differences in the Cu–Cl bond distances, that is the Cu–Cl bond distances in the copper spheres are 2.3153(10)–2.3252(12) Å for Cu(1), 2.2755(13)–2.3486(12) Å for Cu(2), 2.3805(10)–2.4431(8) Å for Cu(3) and 2.3063(8)–2.3186(9) Å for Cu(4), in which the Cu–Cl bond distances in the Cu(3) basal plane are significantly larger than the other Cu–Cl bond distances. Assuming that the distorted tetrahedral Cu(3) ion having long Cu–Cl distances is monovalent and the distorted square-pyramidal Cu(1), Cu(2) and Cu(4) ions are divalent, the total charge would be zero, consistent with the results of the X-ray study and magnetic measurements mentioned below. Namely, this complex is a mixed-valence Cu(I)–Cu(II) octanuclear cluster consisting of a mixed-valence Cu(I)–Cu(II) tetranuclear unit and two chloride-bridged Cu(II) dinuclear units, and it would formally be represented as $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$ (see Table 2, Fig. 2(b)).

Magnetic susceptibilities were measured from 300 to 2.0 K and plotted in Fig. 3 as the molar magnetic susceptibility χ_M and the effective magnetic moment μ_{eff} vs. temperature. The χ_M value increases with decreasing temperature without any peaks concerned with an antiferromagnetic phase transition, while the μ_{eff} value decreases with decreasing temperature because of the existence of the strong antiferromagnetic interaction between the

Table 2

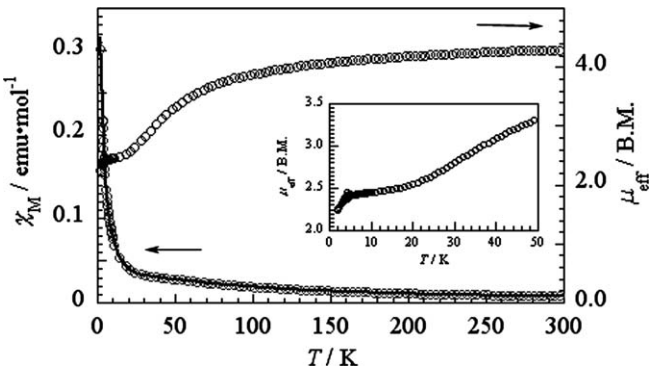

Fig. 3. Temperature dependence of the molar magnetic susceptibility χ_M and the effective magnetic moment μ_{eff} of $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2$-$[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$.

Cu(II) ions in the one-dimensional assembly. The effective magnetic moment at 300 K is 4.28 B.M., in accordance with the expected value (4.24 B.M.) for the six Cu(II) ions in the mixed-valence Cu(I)–Cu(II) octanuclear $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$, as characterized by the X-ray study. It is expected that the exchange interaction between the Cu(1) and Cu(2) ions of the dinuclear units, $Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2$, is the largest, because the magnetic orbitals, $d_{x^2-y^2}$, of the two copper ions would effectively overlap through the chloride ions since they lie in the same plane of the dinuclear unit. Meanwhile, the other interactions between Cu(1)···Cu(1**), Cu(1)···Cu(2**) and Cu(4)···Cu(4*) must be much smaller since the magnetic orbitals are not in the same planes and the weak Cu···S or Cu···Cl bonds to the apical sites are included between the Cu(II) ions as described in the structural part. The Cu(2)···Cu(4) interaction via the d^{10} Cu(3) ion would also provide a small antiferro- or ferro-magnetic interaction. The effective magnetic moment in the low temperature region gradually approaches the value (2.45 B.M.) of the two remaining paramagnetic Cu(II) ions, Cu(4) and Cu(4*), with decreasing temperature as shown in the inset of the Fig. 3, and decreases again with decreasing temperature below 5 K because of the weak antiferromagnetic interactions. The exchange interactions of complex **1** were estimated with the following equation:

$$\chi_M = 2 \times \frac{N_A g^2 \mu_B^2}{3k_B(T-\theta)} \frac{2}{1+1/3\exp(-2J/k_BT)} + 2 \times \frac{N_A g^2 \mu_B^2}{4k_B(T-\theta)} + N\alpha,$$

where N_A, g, μ_B and k_B have the usual meaning, and $N\alpha$ is the temperature independent paramagnetism. In this equation, the magnetic interaction between the Cu(1) and Cu(2) ions in the chloride-bridged dinuclear units $[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$ and the paramagnetic species of the magnetically isolated Cu(II) ions in the tetranuclear unit $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2$ were treated with the Bleany–Bowers equation [30] in the first term and the equation in the second term, respectively, both of which included the Weiss constant θ in order to treat the other weak magnetic interactions between Cu(1)···Cu(1**), Cu(1)···Cu(2**), Cu(2)···Cu(4) and Cu(4)···Cu(4*). Least-squares analysis of the data for complex **1** led to $J = -35.6\ cm^{-1}$, $\theta = -0.53$ K and $g = 2.07$. The agreement factor R[1] was equal to 0.99993. The estimated J value is a little smaller than those of the chloride-bridged dinuclear Cu(II) complexes, $Cu^{II}_2(Bz_2dtc)_2Cl_2$, $Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2$, $Cu^{II}_2(n\text{-}Bu_2dtc)_2Cl_2$, $Cu^{II}_2(n\text{-}Pen_2dtc)_2Cl_2$, $Cu^{II}_2(Hex_2dtc)_2Cl_2$ and $Cu^{II}_2(Bz\text{-}n\text{-}Pr\text{-}dtc)_2Cl_2$ in which the estimated exchange interactions were −49, −55, −65, −70, −68 and −50 cm^{-1}, respectively [31].

[1] $R = \sum_i (x_i - \bar{x})(y_i - \bar{y}) / \left(\sqrt{\sum_i (x_i - \bar{x})^2} \sqrt{\sum_i (y_i - \bar{y})^2} \right)$.

4. Conclusions

We found a simple synthetic method to create a new Cu(I)–Cu(II) mixed-valence octanuclear cluster, $[Cu^{I}Cu^{II}(n\text{-}Pr_2dtc)Cl_2]_2[Cu^{II}_2(n\text{-}Pr_2dtc)_2Cl_2]_2$, from a mononuclear Cu(II) complex, $Cu(n\text{-}Pr_2dtc)_2$, and copper(II) chloride. This mixed-valence Cu(I)–Cu(II) cluster has been structurally and magnetically characterized. The exploitation of such mixed-valence metal-assembled complexes could be important for new functional materials based on inter-valence charge transfer, therefore this simple synthetic method for the mixed-valence Cu(I)–Cu(II) cluster might be useful for generating a variety of functional mixed-valence metal-assembled complexes.

bimetallic assemblies, $Ln(DMF)_4(H_2O)_3Co(CN)_6 \cdot H_2O$ (DMF = *N*,*N*′-dimethylformamide, Ln = Tb, Dy, Ho and Er), and X-ray photoelectron spectroscopy (XPS) studies of several analogous 3d–4f complexes, $Ln(DMF)_4(H_2O)_3Co(CN)_6 \cdot H_2O$ (Ln = Ce, Nd, Sm, Gd, Tb, Dy, Ho and Er; M = Co and Fe). We also discuss both structural and electronic factors changed by substitution of metal elements for a series of cyano-bridged 3d–4f systems in order to elucidate the reasons for photo-induced magnetization.

2. Experimental

2.1. Materials and physical measurements

Chemicals of the highest commercial grade available (Aldrich and Wako) were used as received without further purification. Elemental analyses (C, H, N) were carried out on an Elementar Vario EL analyser at Keio University. Infrared spectra were recorded as KBr pellets on a JASCO FT-IR 660 plus spectrophotometer in the range of 4000–400 cm^{-1} at 298 K. Diffuse reflectance electronic spectra were measured on a JASCO V-560 spectrophotometer equipped with an integrating sphere in the range of 850–220 nm at 298 K. Emission spectra were measured with a JASCO FP-6500 spectrofluorometer in the solid state at 298 K. The mass concentration of Ln^{III} and Fe^{III} or Co^{III} ions was measured with a HORIBA X-ray analytical microscope XGT-2700 using X-ray fluorescence analyses. XPS spectra were recorded with a JEOL JPS-9000MX at 298 K. Powder samples were pressed as pellets and put under UHV to reach the 10^{-8} Pa range. The non-monochromatized Mg Kα source was used at 10 kV and 10 mA, as a flood gun to compensate for the non-conductive samples. The binding energy of the spectra was calibrated in relation to the C1s binding energy (284.0 eV), which was applied as an internal standard.

2.2. Preparations

The complexes were prepared according to the literature procedure [18,22]. Characterization was carried out by elemental analyses, IR spectroscopy (Table S1) and X-ray fluorescence analyses (Table S2) for the 16 complexes investigated.

2.3. X-ray crystallography

The previously unknown crystal structures of **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co** have been determined, and their crystallographic data are summarized in Table 2. The single crystals of prismatic morphology suitable for X-ray crystallography were mounted on a glass fiber coated with epoxy glue. The intensity data were collected on a Rigaku AFC-7R diffractometer with graphite monochromated Mo Kα ($\lambda = 0.7073$ Å) radiation using ω–2θ scan techniques at 297 K. The calculations were performed on an SGI O2 workstation with the TEXSAN [35] software package. Empirical absorption corrections were applied based on ψ scans. No significant decay in the intensity of three standard reflections was observed throughout the data collection. The structures were solved by direct methods using SIR-92 [36] and refined on F^2 anisotropically for non-hydrogen atoms by full-matrix least-squares methods with SHELXL-97 [37]. The hydrogen atoms, except for hydrogen atoms connected with O5, O6, O7 and O8 as water molecules, were added at geometrically expected positions with bond distances of 0.96 Å, and they were refined isotropically as riding models. Residual electron density could not found in the difference Fourier maps completely. The refinement with the models containing additional water molecules resulted in an increase of *R* values. Therefore, only one oxygen atom was assigned as water molecules of crystallization for the refinement carried out.

Table 2
Crystallographic data for **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co**

Compound	Tb–Co	Dy–Co	Ho–Co	Er–Co

[b] $R_w = (\sum w(|F_o| - |F_c|)^2 / \sum w|F_o|^2)^{1/2}$, $w = 1/(\sigma^2(F_o) + (0.1P)^2)$ where $P = (F_o^2 + 2|F_c^2|)/3$.

3. Results and discussion

3.1. Crystal structures

The molecular structures of **Tb–Co** are depicted in Fig. 1. Selected bond lengths and angles for **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co** are given in Table 3. The isostructural four heterometallate complexes crystallize in the monoclinic space group $P2_1/a$ with $Z = 4$, showing slight differences of cell parameters and geometrical parameters. The Ln^{III} ions are eight-coordinated with a distorted dodecahedral geometry, which consists of seven oxygen atoms (four DMF ligands and three coordinated water molecules) and one nitrogen atom of the bridging cyanide ligand. The former Ln–O bond distances are shorter than the latter Ln–N6 ones. The order of the Ln–O bond distances are **Tb–Co** > **Dy–Co** > **Ho–Co** > **Er–Co**, which is attributed to the typical lanthanoid contraction [38]. The features are also similar to the related **Ln–Fe** complexes

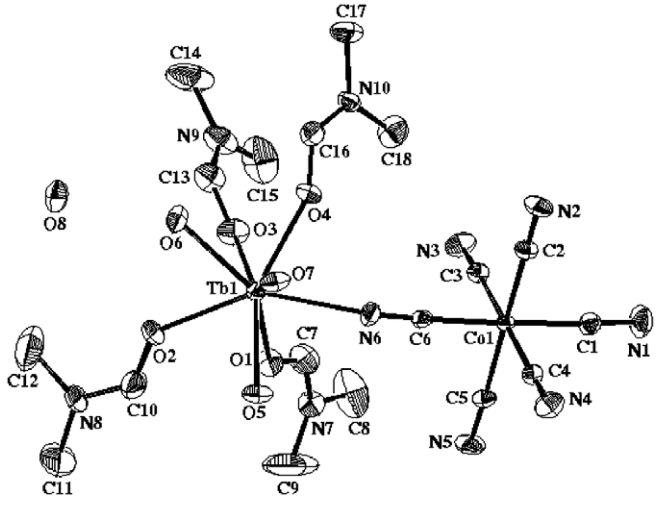

Fig. 1. The molecular structure of **Tb–Co** showing the atomic labelling scheme. Displacement ellipsoids are drawn at the 30% probability level. H atoms are omitted for clarity.

Table 3
Selected geometric parameters (Å, °) for **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co**

Co1–C6–N6	177.0(5)	176.8(4)	177.1(4)	176.8(4)
Co–C≡N (mean)	178.0	178.0	178.9	177.8
Ln1–N6–C6	162.6(4)	162.9(4)	163.2(4)	163.7(3)

[16–20]. The magnitude of the Ln1–C6–N6 bond angles of the bridging cyanide ligands is similar, as follows: 162.6(4)°, 162.9(4)°, 163.2(4)° and 163.7(3)° for **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co**, respectively. However, it should be noted that the Ln1–C6–N6 bond angles in the **Nd–Co** and **Nd–Fe** complexes showed exceptional values, that is **Ce–Co** (163.0(2)°) < **Nd–Co** (165.1(4)°) > **Sm–Co** (163.5(5)°), while **Ce–Fe** (165.3(9)°) > **Nd–Fe** (162.3(6)°) < **Sm–Fe** (165.0(4)°). These characteristic bent-bond features are similar to the proposed photo-excited structures of **Nd–M** complexes by powder XRD patterns [7]. The $[Co(CN)_6]^{3-}$ moieties adopt a slightly distorted octahedral coordination environment and no obvious differences are observed among the four complexes. Because hydrogen atoms could not be introduced completely, we cannot discuss intramolecular or intermolecular hydrogen bonding interactions at present. Intramolecular hydrogen bonds are formed around the DMF ligands (O1–O4) and coordination water (O5–O7) atoms. Intermolecular hydrogen bonds are formed along the crystallographic *a* axis via solvent water (O8) to create the two-dimensional networks. Possible intermolecular hydrogen bonding distances between the cyanide nitrogen and solvent water $O8\cdots N4^{i}$ are 2.824(7), 2.848(7), 2.851(5) and 2.831(6) Å for **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co**, respectively [symmetry code: (i) $x-3/2, -y+1/2, z$]. On the other hand, possible intermolecular hydrogen bonds between the cyanide nitrogen and coordinated water of the adjacent molecules $N5\cdots O5^{ii}$ are 2.712(5), 2.717(5), 2.719(4) and 2.715(5) Å for **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co**, respectively [symmetry code: (ii) $-x+5/2, y+1/2, -z+2$].

3.2. X-ray photoelectron spectroscopy (XPS)

The intensity is plotted by arbitrary scales for XPS in this paper. The C 1s, N 1s and O 1s peaks for 16 **Ln–M** complexes are summarized in Table 4, and the corresponding spectra for eight **Ln–Fe** and **Ln–Co** complexes are shown in Figs. S1 and S2, respectively. For example, distinct and sharp peaks of the XP spectra for **Tb–Co** can be assigned as follows: Tb $4d_{3/2}$ around 154 eV, C 1s at 284 eV, N 1s at 397 eV, O 1s at 531 eV, Co $2p_{3/2}$ at 781 eV, Co $2p_{3/2}$ at 796 eV [39–41]. No significant differences could be observed for the C 1s, N 1s and O 1s peaks of the ligand moieties.

Table 4
The XPS C 1s, N 1s and O 1s peaks (eV) for **Ln–M** complexes

Compound	C 1s	N 1s	O 1s
Ce–Co	284	396	529
Nd–Co	284	396	530
Sm–Co	284	395	530
Gd–Co	284	395	530
Tb–Co	284	397	531
Dy–Co	284	397	531
Ho–Co	284	397	531
Er–Co	284	397	530
Ce–Fe	284	397	531
Nd–Fe	284	397	530
Sm–Fe	284	397	530
Gd–Fe	284	396	530
Tb–Fe	284	396	530
Dy–Fe	284	396	530
Ho–Fe	284	396	530
Er–Fe	284	396	530

The narrow survey XPS of Co $2p_{3/2}$ for **Ln–Co** and Fe $2p_{3/2}$ for **Ln–Fe** complexes are shown in Figs. S3–S6, respectively. The Co $2p_{3/2}$ peak binding energies are at 785.1, 784,7, 785.0, 784.8, 785.4, 785.3, 785.4 and 785.1 eV for **Ce–Co**, **Nd–Co**, **Sm–Co**, **Gd–Co**, **Tb–Co**, **Dy–Co**, **Ho–Co** and **Er–Co**, respectively. While the Fe $2p_{3/2}$ peak binding energies are at 712.7, 712.3, 712.0, 711.7, 712.6, 712.1, 711.9, 712.5 eV and the Fe $2p_{1/2}$ peaks are at 726.4, 724.8, 725.3, 724.7, 725.9, 726.9, 726.3, 726.6 eV for **Ce–Fe**, **Nd–Fe**, **Sm–Fe**, **Gd–Fe**, **Tb–Fe**, **Dy–Fe**, **Ho–Fe** and **Er–Fe**, respectively. These peaks are ascribed to Co^{III} (or Fe^{III}) oxidation states. Thus, no remarkable shift of peaks could be observed for Fe^{III} or Co^{III} ions regardless of the Ln^{III} ions. Furthermore, we could not clearly observe shake-up satellites, typical features of anti-bonding π molecular orbitals (π–π* transitions).

Figs. 2–5 show the narrow survey Ce and Nd (Fig. 2), Sm and Gd (Fig. 3), Tb and Dy (Fig. 4), and Ho and Er (Fig. 5) $4d_{3/2}$ XPS for 16 **Ln–M** complexes. The Ce $4d_{3/2}$ peak binding energies are at 114.0 and 114.7 eV for **Ce–Co** and **Ce–Fe**, Nd $4d_{3/2}$ are at 124.7 and 125.4 eV for **Nd–Co** and **Nd–Fe**, Sm $4d_{3/2}$ are at 134.6 and 135.8 eV for **Sm–Co** and **Sm–Fe**, Gd $4d_{3/2}$ are at 144.3 and 145.4 eV for **Nd–Co** and **Nd–Fe**, Tb $4d_{3/2}$ are at 153.7 and 153.1 eV for **Tb–Co** and **Tb–Fe**, Dy $4d_{3/2}$ are at 159.7 and 159.2 eV for **Dy–Co** and **Dy–Fe**, Ho $4d_{3/2}$ are at 165.6 and 165.3 eV for **Ho–Co** and **Ho–Fe**, Er $4d_{3/2}$ are at 172.2 and 171.8 eV for **Er–Co** and **Er–Fe**, respectively. These peaks are ascribed to Ln^{III} oxidation states, and the binding energies of **Ln–Co** complexes are lower than that of **Ln–Fe** complexes for Ln = Ce, Nd, Sm and Gd (the number of 4f electrons are less than 7). In contrast, the binding energies of **Ln–Co** complexes are similar or higher than that of **Ln–Fe** complexes for Ln = Tb, Dy, Ho and Er (the number of 4f electrons are more than 7).

Commonly, XPS was used to investigate valence states of metal ions and coordination bonding natures in the field of coordination chemistry [42,43]. For example, it has been reported that XPS binding energies indicate good correlations between substituted groups in Au complexes [44], mixed valence in Au complexes [45], electron transfer in tungsten complexes [46], magnetic properties in copper complexes [47,48] and Moessbauer isomer shift in iron complexes [49]. Recently, inorganic solids containing Ln^{III} ions were also measured by using synchrotron radiation [50]. According to them, the bonds with more electronegative atoms would result in greater positive XPS chemical shifts. The peaks of higher oxidized ions would appear with

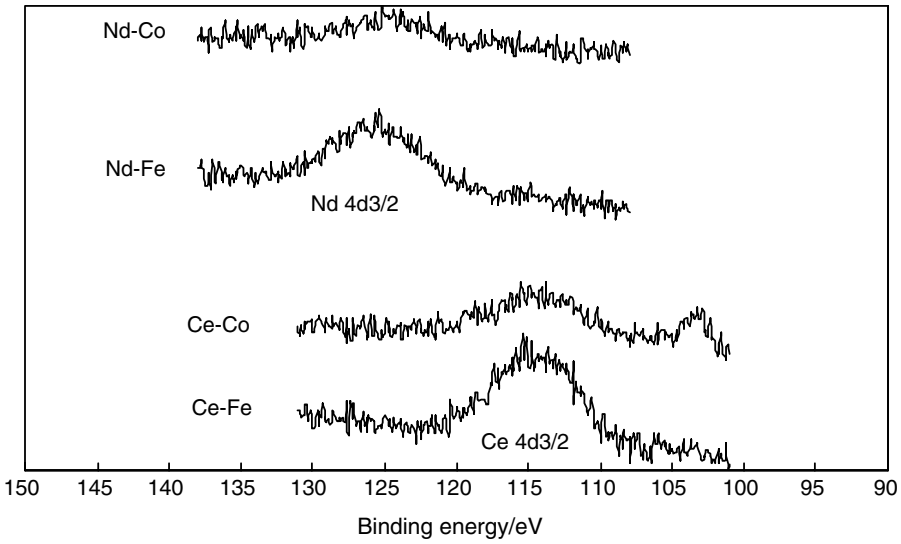

Fig. 2. Narrow survey Ce or Nd $4d_{3/2}$ XPS for **Ce–M** or **Nd–M** (M = Co and Fe).

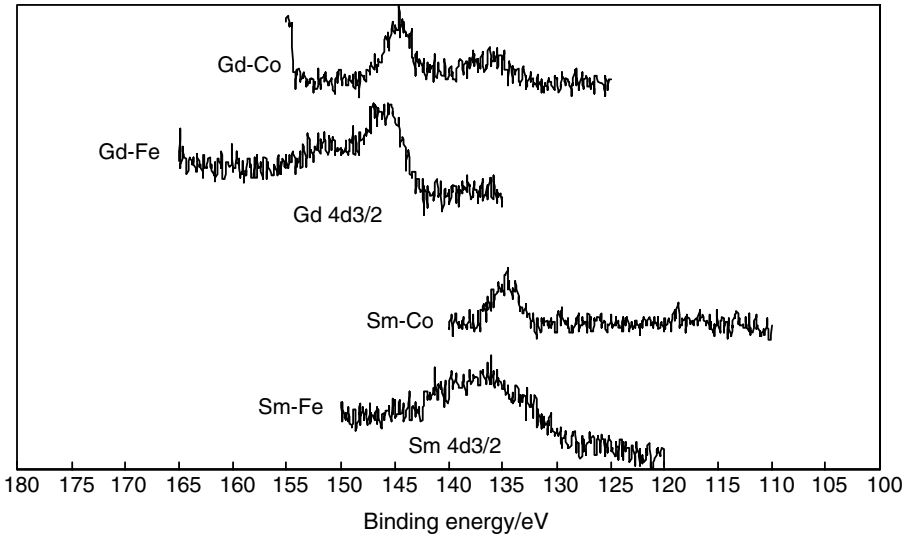

Fig. 3. Narrow survey Sm or Gd $4d_{3/2}$ XPS for **Sm–M** or **Gd–M** (M = Co and Fe).

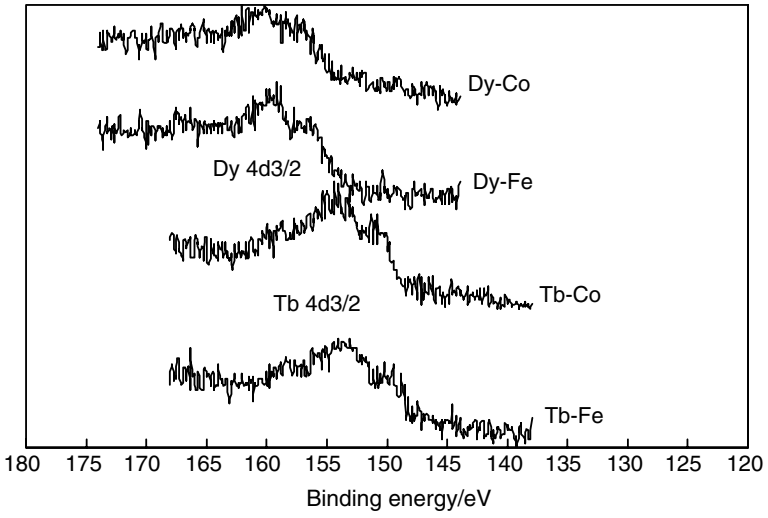

Fig. 4. Narrow survey Tb or Dy $4d_{3/2}$ XPS for **Tb–M** or **Dy–M** (M = Co and Fe).

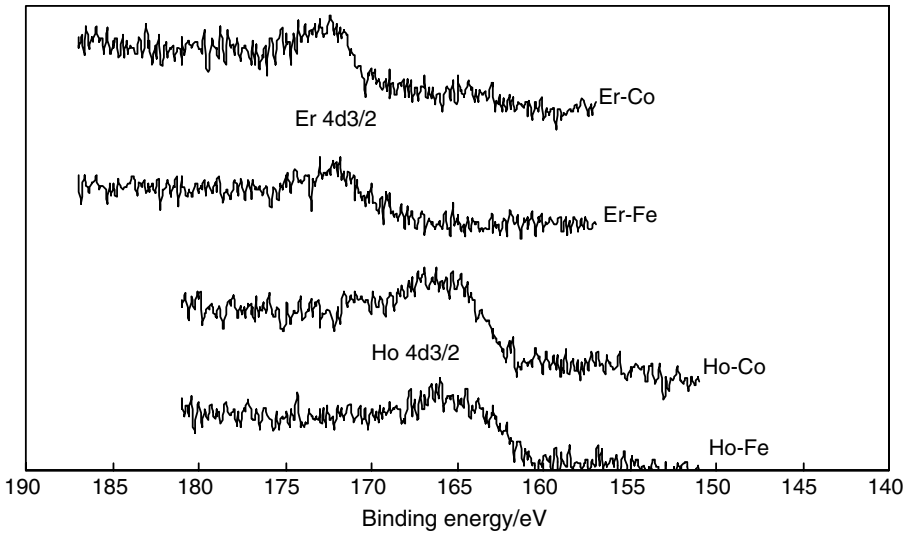

Fig. 5. Narrow survey Ho or Er $4d_{3/2}$ XPS for **Ho–M** or **Er–M** (M = Co and Fe).

higher binding energies. Accordingly, two kinds of Ln $4d_{3/2}$ XPS peak shifts suggest that the cyano-bridged Ln ions of **Ln–Fe** complexes for Ln = Ce, Nd, Sm and Gd easily release electrons even under these conditions. In other words, these selected Ln ions are easy to take mixed-valence states.

3.3. IR and electronic spectra

As listed in Table 1, cyanide stretching bands of the IR spectra of **Ln–Co** and **Ln–Fe** complexes are in the range of 2127–2137 cm^{-1} and 2123–2128 cm^{-1}, respectively. As for the simple $K_3[Fe(CN)_6]$ complex in O_h point group, normal vibration modes were assigned as follows: 2315 cm^{-1} (A_{1g}), 2130 cm^{-1} (E_g) and 2118 cm^{-1} (F_{1u}) [51]. Despite being sensitive to valence or spin states, the present values are comparable to analogous 3d–4f bimetallic assemblies. By comparing with the related 3d–3d or 3d–4f complexes [52], spectral shift features, that is substitution of Co^{III} and Fe^{III} ions, is more effective than substitution of Ln^{III} ions. The spectral features of the IR spectra should also correspond to shifts in the charge transfer absorption bands between the 3d orbitals of M^{III} ions and the unoccupied π^* orbitals of bridging cyanide ligands. The splitting by bridged and uncoordinated cyanide ligands was unclear for the present cases.

On the other hand, electronic spectra (Figs. S7–S10) exhibit strong and broad bands in the UV region due to π–π^* transitions from ligands of both DMF and low-spin $[Co(CN)_6]^{3-}$ or low-spin $[Fe(CN)_6]^{3-}$ moieties. The electronic spectra for the **Ln–Fe** complexes show two peaks around 23 000–32 000 cm^{-1} and 30 000–34 000 cm^{-1}, while **Ln–Co** complexes show a peak around 28 000–32 000 cm^{-1}. The spectral shapes of the UV region depend on the electronic states of the $[M(CN)_6]^{3-}$ moieties. In addition, several sharp peaks could be observed in the visible region for **Nd–M** (Nd^{3+}: $^4I_{9/2}$ ground state), **Dy–M** (Dy^{3+}: $^6H_{15/2}$ ground state), **Ho–M** (Ho^{3+}: $^5I_8$ ground state) and **Er–M** (Er^{3+}: $^4I_{15/2}$ ground state) (M = Co and Fe). In this way, visible light-sensitivity depends on Ln ions for these complexes. Although we have also tried to measure emission spectra (λ_{ex} = 250, 300 and 350 nm) in the solid states at 298 K, we could not detect emission from these complexes under these experimental conditions.

3.4. Electronic properties of 3d–4f cyanide-bridged systems

The effect of interaction between Ln^{III} and M^{III} ions through cyano-bridges can lead to a different charge distribution, overshadowing the decreasing extent of π-back-donation. As elucidated in the present results, this effect is mixed by both structural factors and electronic factors and appeared for specific Ln^{III} elements remarkable for the ground states of these complexes.

As for 3d–3d Prussian blue analogues, the electron configurations corresponding to the strongest ferromagnetic interaction are t_{2g}^3–$t_{2g}^6e_g^2$, while weak antiferromagnetic interaction are t_{2g}^m–$t_{2g}^ne_g^1$ or t_{2g}^m–$t_{2g}^ne_g^2$. Unpaired electrons in the t_{2g} orbitals can be used for superexchange interactions through unoccupied π^* orbitals of cyanide bridging ligands. So oxidation states as well as the kind of 3d elements are important for the mechanism of these magnetic interactions. Indeed, it has been elucidated that in cyano-bridged Mo–M systems, containing $[Mo(CN)_8]^{n-}$ moieties, Mo^{III} ions show larger exchange coupling constants than the equivalent compounds with first transition series elements due to the more diffuse character of the 4d orbitals in comparison with the 3d orbitals [15].

The nature of the coordination bonds of the $[Fe(CN)_6]^{3-}$ moiety is π-backdonation, in which five 3d electrons occupying t_{2g} orbitals are provided to unoccupied π^* orbitals of the cyanide ligands. Recently, detailed electronic states have been confirmed by means of X-ray absorption spectra [53–56]. In O_h symmetry, the electron

configuration of the Fe^{III} ion is $t_{2g}^5 e_g^0$ and irreducible representations of 2π orbitals of the cyanide ligands are t_{1g}, t_{1u}, t_{2g} and t_{2u}. Qualitatively speaking, the formation of a $[Fe(CN)_6]^{3-}$ complex results in molecular orbitals which are split into occupied t_{2g}, degenerated t_{1g}, t_{1u} and t_{2u}, and t_{2g} orbitals and unoccupied degenerated t_{1g}, t_{1u} and t_{2u}, e_g and t_{2g} orbitals. When the electrons of cyanides are excited to π^* orbitals (formed from unoccupied t_{1g}, t_{1u} and t_{2u} orbitals) associated with metal to ligand charge transfer from the t_{2g}^5 orbital in the Fe^{III} ion to unoccupied π^* orbitals in cyanide ligands [56], π-backdonation may be weaken because of electronic repulsion of electrons in the unoccupied π^* orbitals.

4. Conclusion

Consequently, we can point out characteristic structural and electronic features for photo-induced magnetization of **Nd–M** complexes. Systematic crystal structures revealed that gradually changes of isostructural crystals due to lanthanoid contraction lead to remarkable Ln–O coordination bond distances or a decrease of the cell volume. However, only **Nd–Fe** and **Nd–Co** complexes show exceptional bent Ln–N–C bond angles, which may be proposed photo-excited structures of bent-bonds. The patterns of Ln $4d_{3/2}$ XPS peak shifts for Ln = Ce, Nd, Sm and Gd differ from that of Ln = Tb, Dy, Ho and Er, which suggests that the cyano-bridged Ln^{III} ions of **Ln–Fe** complexes for Ln = Ce, Nd, Sm and Gd easily become mixed-valence states. In addition, absorption spectra exhibit that π-backdonation of cyano-bridging ligands uses unoccupied π^* orbitals and unoccupied t_{2g} orbitals in $[Fe(CN)_6]^{3-}$ moieties. Further studies on the structural and electronic natures of other cyano-bridging heterometallic assemblies are in progress in order to rationalize the design of multi-functional materials which consist of (transition) metal complexes.

complexes) have supported the TD-DFT method to be applicable for such systems giving good assignment of experimental spectra [10–16].

2. Experimental

2.1. General procedure

All synthetic manipulations were carried out open to the atmosphere. The solvents were of reagent grade and were used as received. Ammonium perrhenate, Ph_3P and PPh_2py were purchased from Aldrich and used as received. $[ReOX_3(PPh_3)_2]$ (X = Cl, Br) were prepared according to the literature methods [17].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a Lab Alliance UV–VIS 8500 spectrophotometer in the range 900–200 nm in deoxygenated dichloromethane solution. Elemental analyses (C, H, N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of *[$ReCl_3(PPh_3)(OPPh_2py$-O,N)]* (*1*)

$[ReOCl_3(PPh_3)_2]$ (0.83 g, 1 mmol) and PPh_2py (0.26 g, 1 mmol) were suspended in acetone (100 cm^3) and stirred for 5 h. The volume was condensed to 10 cm^3 and a dark red precipitate was filtered off. The product was washed with diethyl ether and dried in vacuo. Yield 90%. Slow evaporation of the acetonitrile solution of **1** gave red crystals of the acetonitrile solvate (**1** · **CH_3CN**).

IR (KBr, cm^{-1}) 3055(m), 1986(w), 1915(w), 1836(w), 1776(w), 1647(w), 1618(w), 1585(m), 1570(sh), 1481(m), 1435(s), 1367(w), 1313(w), 1284(w), 1230(w), 1190(w), 1120(s), 1092(m), 1042(s), 1021(m), 996(m), 918(w), 738(s), 693(s), 566(s), 531(s), 510(sh), 493(m), 459(w), 428(w).

Anal. Calc. for $C_{35}H_{29}NP_2Cl_3ORe$: C, 50.40; H, 3.50; N, 1.68. Found: C, 50.55; H, 3.60; N, 1.75%.

2.3. Preparation of *[$ReBr_3(PPh_3)(OPPh_2py$-O,N)]* (*2*)

A procedure similar to that for **1** was used with $[ReOBr_3(PPh_3)_2]$ (0.97 g, 1 mmol) and PPh_2py (0.26 g, 1 mmol). A dark red crystalline precipitate of **2** was collected in 80% yield. Crystals of **2** suitable for X-ray investigation were obtained by recrystallization from a mixture of chloroform–ethanol.

IR (KBr, cm^{-1}) 3049(m), 1963(w), 1896(w), 1817(w), 1768(w), 1668(w), 1586(m), 1481(m), 1433(s) 1333(w), 1313(w), 1284(w), 1234(w), 1186(w), 1118(s), 1091(m), 1043(s), 1023(m), 997(w), 924(w), 845(w), 738(s), 691(s), 563(s), 531(s), 518(sh), 492(m), 454(w), 427(m), 502(s), 465(m), 450(sh).

Anal. Calc. for $C_{35}H_{29}NP_2Br_3ORe$: C, 43.45; H, 3.02; N, 1.45. Found: C, 43.35; H, 3.08; N, 1.36%.

2.4. Crystal structure determination and refinement

The X-ray intensity data of **1** · **CH_3CN** and **2** were collected on a KM-4-CCD automatic diffractometer equipped with a CCD detector, with 20 and 60 s exposure time being used receptively. The unit cell parameters were determined from least-squares refinement of the setting angles of 12909 and 4387 strongest reflections respectively for **1** · **CH_3CN** and **2**. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and numerical absorption corrections [18] were applied. The structures were solved by the Patterson method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix, least-squares technique. The aromatic ring hydrogen atoms were found by difference Fourier synthesis and they were refined as "riding" on their parent carbon atoms [d(C–H) = 0.93 Å] and assigned isotropic temperature factors equal to 1.2 times the value of the equivalent temperature factor of the parent carbon atom. The methyl group hydrogen atoms were also found by difference

Fourier synthesis and refined as "riding" on their parent carbon atoms [d(C–H) = 0.96 Å] and they were assigned isotropic temperature factors equal to 1.5 times the value of equivalent temperature factor of the parent carbon atom. The methyl group was allowed to rotate about its local threefold axis. SHELXS97 [19] and SHELXL97 [20] programs were used for the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.5. Computational details

The Gaussian03 program [21] was used in the calculations. The geometry optimization was carried out with the DFT method with the use of the B3LYP functional [22,23]. The electronic spectrum of **1** was calculated with the TDDFT method [24]. The calculations were performed using the ECP basis set on the rhenium atom, the standard 6-31+g(2d) basis for chlorine, 6-31+g** for oxygen and nitrogen, 6-31+g* for carbon and 6-31G basis for hydrogen atoms. The Xe core electrons of Re were replaced by an effective core potential and DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [25] was used for the valence electrons. An additional d function with exponent $\alpha = 0.3811$ and f function with exponent $\alpha = 2.033$ were added on the rhenium atom.

2.6. Magnetic measurements

The magnetic measurements of the powdered samples were measured over the temperature range 1.8–300 K using a Quantum Design SQUID – based MPMSXL–5-type magnetometer. The superconducting magnet was generally operated at a field strength ranging from 0 to 5 T. Measurements of samples of the compounds were made at magnetic field of 0.5 T.

The SQUID magnetometer was calibrated with a palladium rod sample. Corrections are based on subtracting the sample – holder signal and contribution χ_D estimated from Pascal constants [26] and equal -467×10^{-6} cm^3 mol^{-1} for complex [$ReCl_3(PPh_3)(OPPh_2py$-O,N)] (**1**) and -497×10^{-6} cm^3 mol^{-1} for complex [$ReBr_3(PPh_3)(OPPh_2py$-O,N)] (**2**). The effective magnetic moments were calculated from the equation, $\mu_{eff} = 2.83(\chi_M T)^{1/2}$(B.M.).

3. Results and discussion

The [$ReCl_3(PPh_3)(OPPh_2py$-O,N)] (**1**) and [$ReBr_3(PPh_3)$-($OPPh_2py$-O,N)] (**2**) complexes have been obtained in high yield in the reactions of [$ReOX_3(PPh_3)_2$] (X = Cl, Br) with diphenyl(2-pyridyl)phosphine in acetone at room temperature (Eq. (1)):

$$[ReOX_3(PPh_3)_2] + PPh_2py \rightarrow [ReX_3(PPh_3)(OPPh_2py - O, N)] + PPh_3 \quad (1)$$

The well-known capacity of phosphines to interact with the Re≡O bond in rhenium(V) oxo-complexes explains the course of the reactions between [$ReOX_3(PPh_3)_2$] and PPh_2py.

The elemental analyses of complexes **1** and **2** are in good agreement with their formulations. The IR spectra of **1** and

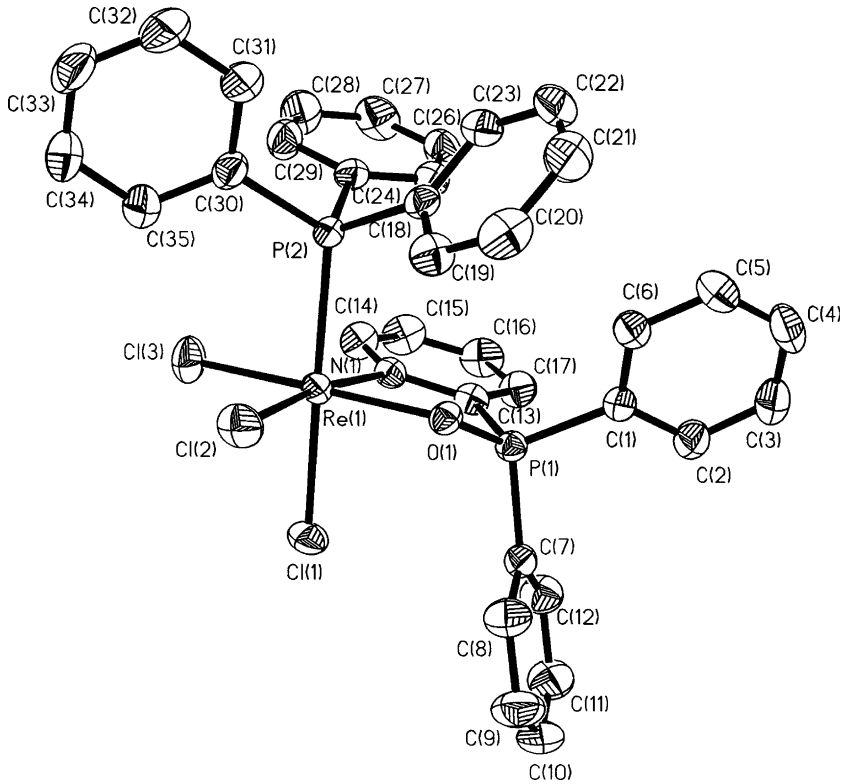

Fig. 1. The molecular structure of **1**. The hydrogen atoms of the phenyl rings are omitted for clarity.

2 are governed by the vibrations of the phosphine ligands. The absence of the characteristic strong ν(Re=O) band at $\sim$980 cm^{-1} is a clear indication that there is no oxo-Re(V) starting material left in the samples of **1** and **2**. A strong band corresponding to the stretching vibration of the P=O group appears in **1** and **2** at 1120 and 1118 cm^{-1}, respectively. The absorption bands at $\sim$1580 cm^{-1} are typical of C=N stretching modes [27].

3.1. X-ray structures

The chloride complex crystallises as the solvate **1** · MeCN. The acetonitrile molecule from crystallization is not bonded to any other atom, with the exception of some rather weak hydrogen bonds [28,29].

A perspective drawing of **1** is given in Fig. 1. The rhenium atoms of both complexes are in a distorted octahedral environment with two halogen ions and the bidentate ligand – diphenyl(2-pyridyl)phosphine oxide – in the equatorial plane. Deviations from an ideal octahedron can be ascribed to the bite angle of the five membered chelate ring.

The X-ray structures of a few [$ReCl_3(PPh_3)L$] and [$ReCl_3(PPh_3)L_2$] complexes are known. The $ReCl_3$ fragments have *fac* and *mer* geometries. The geometrical preferences of the $ReCl_3$ unit can be rationalized in terms of the electronic nature of the L ligands. Triphenylphosphine is a π-accepting ligand, σ^*(P–C) phosphine orbitals are involved in π-back bonding between the metal center and the phosphine ligand. Trivalent rhenium is prone to back-bonding. When the L ligand is a π-acid, the facial geometry is expected to be favored. Assuming an idealized octahedral geometry, the back bonding has $t_{2g}(Re) \rightarrow \sigma^*(P–C)$ and $t_{2g}(Re) \rightarrow \pi^*(L–L)$ components. This bonding is maximized when the acceptor ligands are *facially* disposed so that competition between ligands for identical metal orbitals is minimal [30–37]. Back bonding is believed

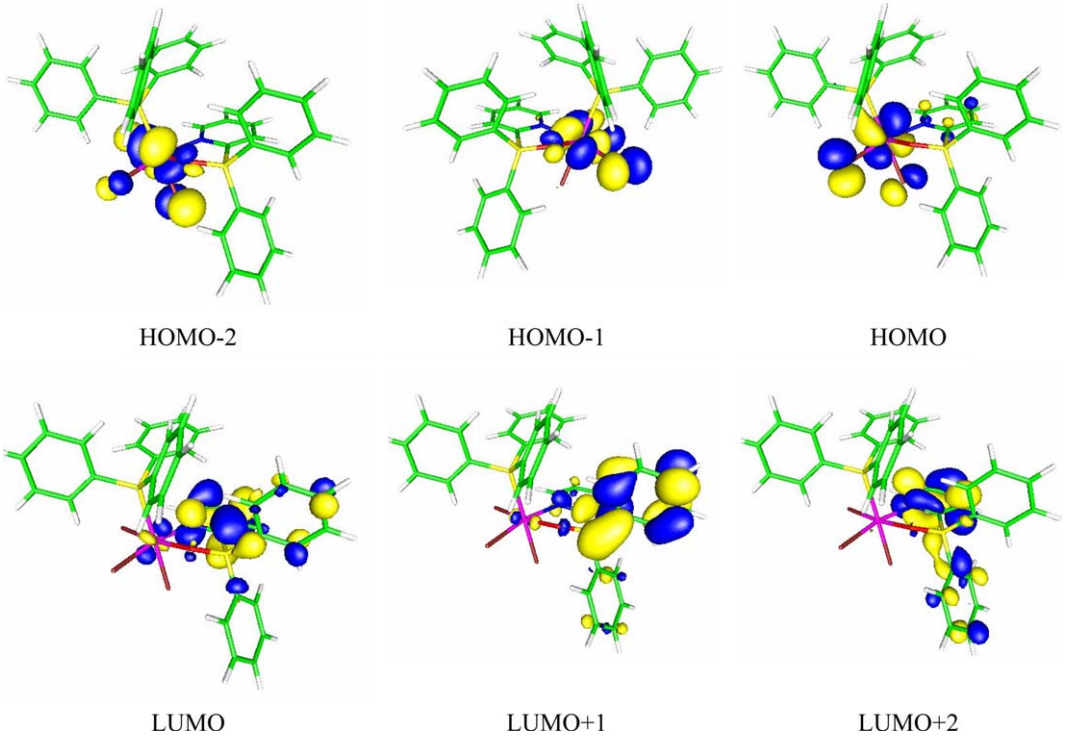

Fig. 2. Selected HOMO and LUMO orbitals with α-spin for **1**.

to sustain the *fac* geometry in **1** and **2** by more than offsetting the steric and electrostatic advantages of the *mer* geometry, as has been observed in related species.

The most important experimental bond lengths and angles for **1** and **2** are reported in Table 2. In both complexes, a notable *trans* influence of triphenylphosphine ligand is observed; the Re–X(1) bond lengths are longer in comparison to the corresponding Re–X(2) and Re–X(3) distances. Furthermore, the Re–X(2) bond lengths in the *trans* position to the N atom of the bidentate ligand are considerable longer in comparison with the Re–X(3) bonds opposite the O atom of the PPh_2py molecule. The shortest Re···Re distances are 8.601(1) and 9.394(1) Å respectively for **1** · MeCN and **2**.

The bond valences were computed as $v_{ij} = \exp[(R_{ij} - d_{ij})/b]$ [38–40], where R_{ij} is the bond-valence parameter (in the formal sense the R_{ij} parameter value can be considered as the idealised single-bond length between i and j atoms). R_{Re-N}, R_{Re-P}, R_{Re-O}, R_{Re-Cl} and R_{Re-Br} were taken as 2.06, 2.46, 1.97, 2.23 and 2.45 [41] respectively, and b was taken as 0.37 [40]. The computed bond valences of the rhenium are $v_{Re-N} = 0.82$; $v_{Re-P} = 1.08$, $v_{Re-O} = 0.65$; $v_{Re-Cl} = 0.58$, 0.66 and 0.74 v.u. (valence units) for **1** and $v_{Re-N} = 0.80$; $v_{Re-P} = 1.06$, $v_{Re-O} = 0.68$; $v_{Re-Br} =$ 0.66,

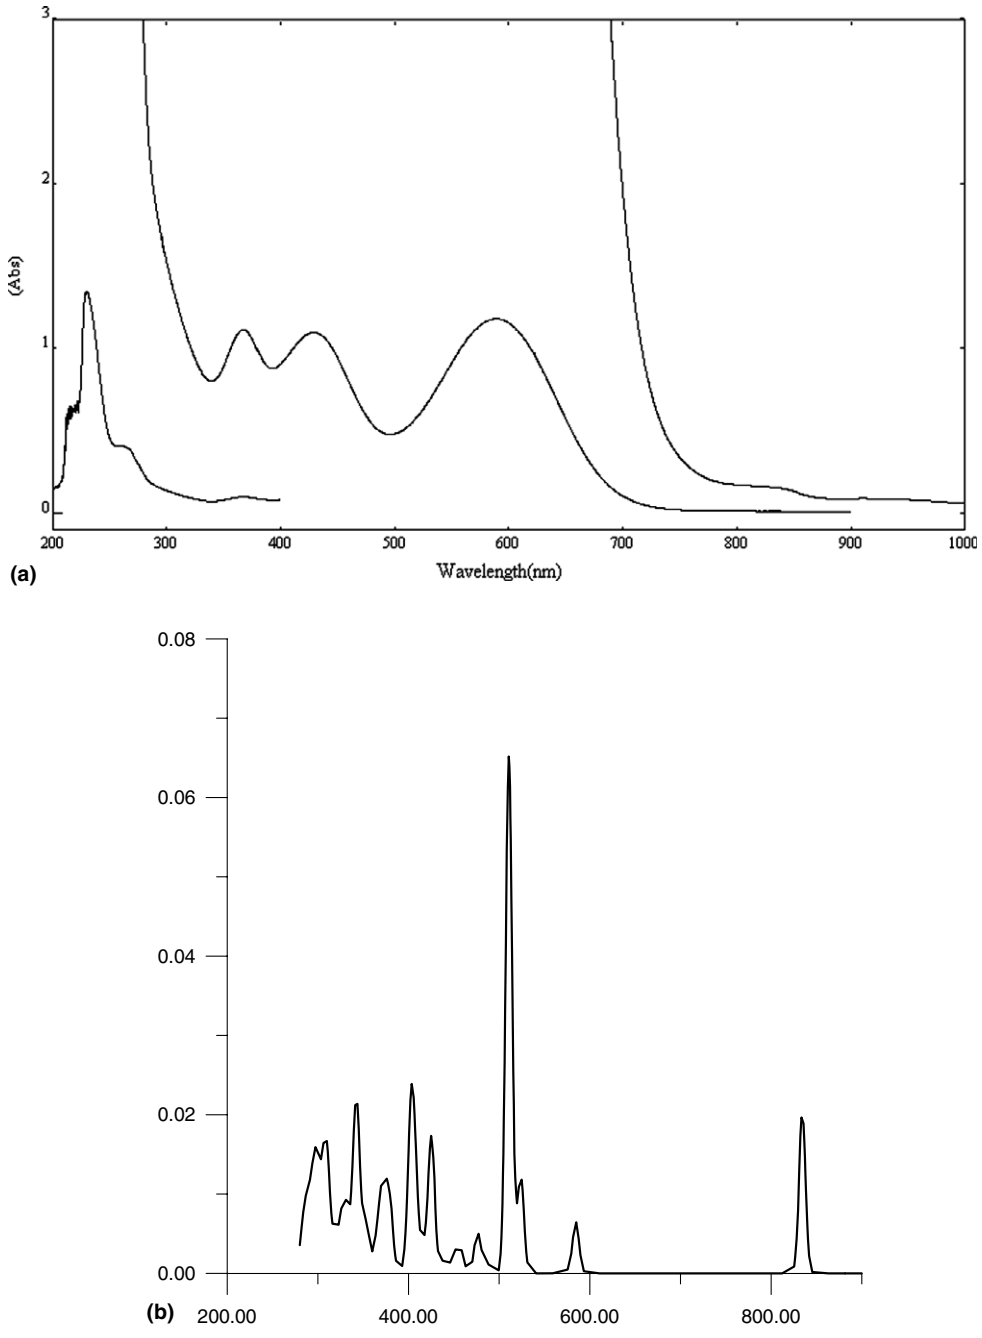

Fig. 3. The experimental (a) and calculated (b) electronic absorption spectra of **1**.

0.76 and 0.90 v.u for **2,** which means the Re–P bonds are the strongest ones and Re–O Re–X(1) bonds are the weakest ones (X(1) notation as above).

3.2. Optimized geometry

The geometry of **1** was optimized in triplet and singlet states using the DFT method with the B3LYP functional. The energy of the singlet state is 14.5 kcal/mol higher. The optimized geometric parameters of the triplet state of **1** are gathered in Table 2. In general, the predicted bond lengths and angles are in good agreement with the values based upon the X-ray crystal structural data, and the general trends observed in the experimental data are well reproduced in the calculations.

3.3. Charge distribution

Table 3 presents the atomic charges from the Natural Population Analysis (NPA) for **1**. The calculated charge on the rhenium atom is considerable lower than the formal charge +3. It results from charge donation from the chloride ions and triphenylphosphine ligand. There is large positive charge on the P atom, and the charges on the chloride ions are significantly smaller than –1. Some differences in the values of the charges can be noticed for the halogen

ligands – the least negative is the chloride ion in the *trans* position to the oxygen atom of the PPh_2py ligand, whereas the most negative is Cl(1) in the *trans* position to the PPh_3 molecule. It corresponds to differences in the Re–Cl bonds lengths.

3.4. Molecular orbitals

The energies and characters of selected MOs of **1** are presented in Table 4, and the selected contours of the HOMO and LUMO orbitals with α spin are depicted in Fig. 2. The rhenium atom possesses a $(d_{xy})^2(d_{xz})^1(d_{yz})^1$ configuration. The metal d_{xz}, d_{yz} and d_{xy} orbitals make the main contributions into HOMO − 2, HOMO − 1 and HOMO with α spin and HOMO, LUMO, LUMO + 1 and LUMO + 2 with β spin. In all these molecular orbitals the rhenium d_{xz}, d_{yz} and d_{xy} orbitals bear antibonding character towards the p_π orbitals of the chloride ligands. The HOMO − 2 and HOMO − 1 orbitals with α spin and LUMO and LUMO + 2 with β spin also have an admixture of π oxygen orbitals, and some contribution of the π-antibonding pyridine ring orbitals is visible in the LUMO, LUMO + 1 and LUMO + 2 with β spin. The LUMO with α spin is composed of π-antibonding of the pyridine and phenyl rings of the $OPPh_2py$ ligand.

3.5. Electronic spectrum from the TDDFT calculations

The experimental and calculated electronic spectra of the chloro complex are represented graphically in Fig. 3. Each calculated transition in Fig. 3b is represented by a gaussian function with the height equal to the oxidator strength and width equal to 0.04. The solution spectrum of **1** exhibits a very weak absorption band at 819.8 nm and some more absorptions in the low energy range at 591.4, 432.4, 380.2, 261.4 and 231.2 nm. The shape of the UV–Vis spectrum of **2** is the same as for the chloro analogue; the absorption bands of the bromo complex were recorded at 820.0, 589.4, 431.0, 341.0, 260.0 and 231.2 nm.

Table 5 shows the energy and molar absorption coefficients of the experimental absorption bands of **1** and the spin-allowed triplet–triplet electronic transitions calculated with the TDDFT method. The assignment of the calculated transitions to the experimental absorption bands was based on the criterion of the energy and oscillator strength of the calculated transitions.

The investigated complex is of a large size; the number of basis functions is equal to 743. A hundred electron transitions calculated by the TDDFT method do not comprise all the experimental absorption bands. The UV–Vis spectrum of **1** was calculated to ~285 nm, so the shortest wavelength experimental band is not assigned to the calculated transitions, and the assignment to the band at 261.4 nm is probably not complete. As the solution spectra of PPh_3 and PPh_2py exhibit intense absorption bands in 280–200 nm region, some additional intraligand and interligand transitions are expected to be found at higher energies in the calculations for **1**.

The longest wavelength weak experimental band at 819.8 nm is assigned to the transitions from HOMO(β) to LUMO + 1(β) and LUMO + 2(β) orbitals. As the LUMO + 1 and LUMO + 2 orbitals have a substantial admixture of π^* orbitals of the pyridine ring, these transitions are classified as $d \rightarrow d/\pi^*(py)$. It explains the relatively high value of the oscillator strength of the calculated excitation at 834.5 nm.

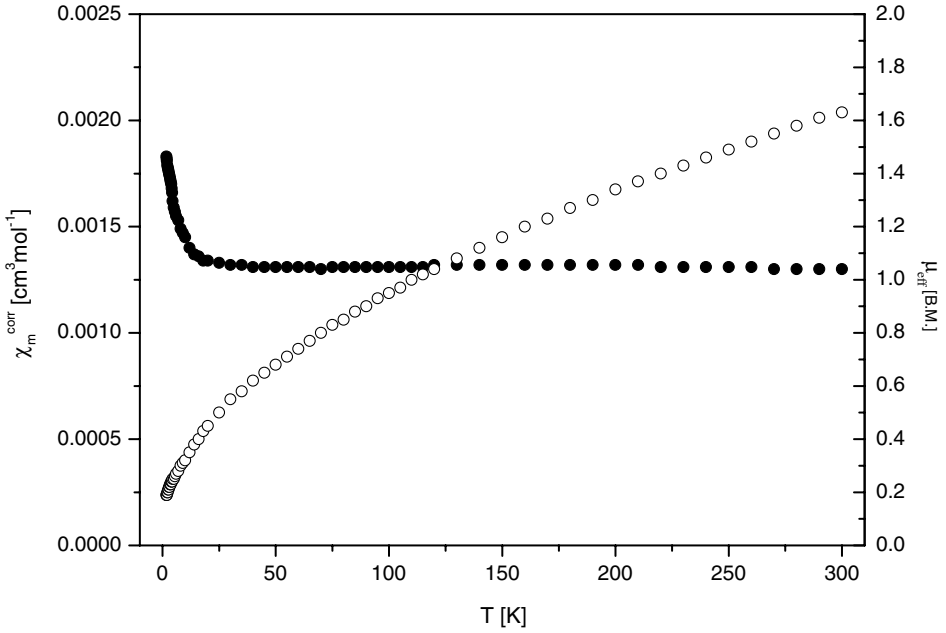

Fig. 4. Plots of the experimental magnetic data χ_M(●) and μ_{eff} (○) vs. *T* for the complex $[ReCl_3(PPh_3)(OPPh_2py\text{-}O,N)]$ (**1**).

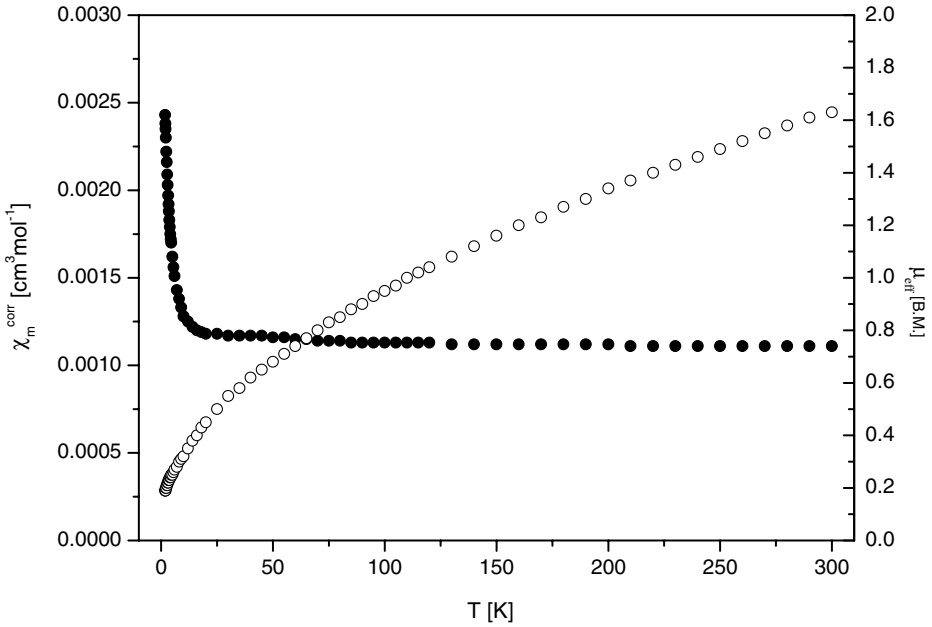

Fig. 5. Plots of the experimental magnetic data χ_M(●) and μ_{eff}(○) vs. T for the complex [$ReBr_3(PPh_3)(OPPh_2py$-O,N)] (**2**).

The experimental absorption band at 591.4 nm is attributed to the transitions calculated between 590 and 510 nm. These are excitations from central metal d orbitals to the π^* orbitals of the chelate ligand.

The absorption bands at 432.4 and 380.2 nm are ascribed to the metal–ligand charge transfer transitions ($d \rightarrow \pi^*_{OPPh_2py}$ and $d \rightarrow \pi^*_{PPh_3}$) and transitions of $\pi(Cl)/n(P)/\pi_{Ph}(PPh_3) \rightarrow d/\pi^*(py)$ character. The last ones occur mainly from chloride and phosphine ligand orbitals to the d rhenium orbitals. However, due to significant participation of π^* pyridine orbitals in the unoccupied molecular orbitals, the character of these excitations is formally ascribed as $\pi(Cl)/n(P)/\pi_{Ph}(PPh_3) \rightarrow d/\pi^*(py)$.

The experimental absorption band at 261.4 nm is mainly attributed to the transitions of LLCT type, although some MLCT and LMCT excitations are also calculated below 310 nm.

3.6. Magnetic properties

The magnetic properties of the [$ReCl_3(PPh_3)(OPPh_2py$-O,N)] (**1**) and [$ReBr_3(PPh_3)(OPPh_2py$-O,N)] (**2**) complexes under the form χ_M vs. T and μ_{eff} vs. T (χ_M being the molar magnetic susceptibility and μ_{eff} the effective magnetic moment) are shown in Figs. 4 and 5, respectively. The chloro and bromo Re(III) complexes show room temperature magnetic moments of 1.77 BM (0.389 cm^3 mol^{-1} K) and 1.63 BM (0.333 cm^3 mol^{-1} K), respectively. The magnetic moments of the solids are temperature independent between 300 and 50 K. These values are characteristic of mononuclear d^4 low-spin octahedral Re(III) complexes ($^3T_{1g}$ ground state) [42–50] and arise because of the large spin–orbit coupling ($\zeta = 2500$ cm^{-1} [51]), which gives a diamagnetic ground state.

4. Conclusions

Two novel Re(III) compounds – [$ReCl_3(PPh_3)(OPPh_2$-py-O,N)]$\cdot CH_3CN$ (**1**) and [$ReBr_3(PPh_3)(OPPh_2py$-O,N)] (**2**) – have been prepared and structurally as well as spectroscopically characterized. The well-known capacity of phosphines to interact with the Re≡O bond in the rhenium(V) oxo-complexes explains the formation of the title complexes in the reactions of [$ReOX_3(PPh_3)_2$] with PPh_2py. The DFT studies confirm the $(d_{xy})^2(d_{xz})^1(d_{yz})^1$ configuration of the central metal, and these results are in good agreement with the magnetic measurements.

5. Supplementary data

Supplementary data for $C_{37}H_{32}Cl_3N_2OP_2Re$ and $C_{35}H_{29}Br_3NP_2Re$ are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition numbers: 297775 for **1** and 297776 for **2**.

Acknowledgements

The Gaussian03 calculations were carried out in the Wrocław Centre for Networking and Supercomputing, WCSS, Wrocław, Poland.

The crystallographic part was financed by funds allocated by the Ministry of Education and Science to the Institute of General and Ecological Chemistry, Technical University of Łódź.

Scheme 3.

coligand, 2,2′-bipyridine or 1,10-phenanthroline. The presence in the electrolytic cell of the two species allows the synthesis of mixed compounds in one step.

2. Experimental

Acetonitrile, dichloromethane, 2-amino-3-picoline, 2-amino-6-picoline, *p*-toluenesulfonyl chloride, 2-mesitylenesulfonyl chloride, 2,2′-bipyridine, 1,10-phenanthroline monohydrate and all other reagents were commercial products and were used as supplied. Cobalt (Aldrich) was used as 2×2 cm plates.

2.1. Preparation of ligands

Ligands were prepared by reaction of the corresponding amine and the sulfonyl chloride in 1:1 ratio following a previously described method [14]. Analytical and spectroscopic data for the ligands are given below.

2.1.1. HMs6mepy

Anal. Calc. for $C_{15}N_2H_{18}O_2S$: C, 62.1; H, 6.2; N, 9.6; S, 11.0. 2.2. Preparation of complexes: general procedure

The complexes were obtained by an electrochemical procedure [18]. A solution of a mixture of the sulfonamide and the coligand, with a small amount of tetraethylammonium perchlorate (ca. 10 mg) as a current carrier, was electrolyzed using a platinum wire as the cathode and a cobalt plate (suspended from another platinum wire) as the sacrificial anode. The cell was a 100 mL tall-form beaker fitted with a rubber bung through which the electrochemical leads entered. Direct current was obtained from a purpose-built d.c. power supply. Applied voltages of 5–15 V allowed sufficient current flow for smooth dissolution of the cobalt metal. The current was maintained at 10 mA during one hour. In all cases, hydrogen was evolved at the cathode. These cells can be summarized as $Co_{(+)}/CH_3CN + HL + L'/Pt_{(-)}$, where L and L′ represent the corresponding sulfonamide and coligand, respectively. On completion of the electrolysis the colored solutions were filtered to remove any possible metal particle and then left to concentrate. This procedure yielded crystalline products. The solids were washed with acetonitrile and diethyl ether and dried at room temperature. The solution compositions and experimental conditions are given in Table 1.

2.3. Physical measurements

The C, N, H and S contents of the compounds (Table 2) were determined on a Carlo-Erba EA 1108 microanalyser. IR spectra (Table 2) were recorded as KBr mulls on a Bruker Vector-22 spectrophotometer. The ^1H NMR spectra of the ligands were recorded on a Bruker ARX-400 MHz spectrometer using $CDCl_3$ as solvent. Solid state electronic spectra were recorded on a Shimadzu UV 3101 PC. EI mass spectra were recorded on a Micromass instrument (70 eV, 250 °C). LSI mass spectra were recorded on a VG Autospec-M Micromass instrument using 2-nitrobenzyl alcohol (2-NBA) as the matrix material.

2.4. Crystal structure determination

The data collections were taken on a SIEMENS Smart CCD area-detector diffractometer with graphite-monochromated Mo Kα radiation. Absorption corrections were carried out using SADABS [19]. All of the structures were solved by direct methods and refined by full-matrix least-squares based on F^2 [20]. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in idealised positions and refined with isotropic displacement parameters. Atomic scattering

factors and anomalous dispersion corrections for all atoms were taken from International Tables for X-ray Crystallography [21]. Details of crystal data and structural refinement are given in Table 3.

3. Results and discussion

The analytical results (Table 2) show that the electrochemical procedure described above is an effective method for the synthesis of cobalt complexes with these sulfonamide ligands and the method represents a simple alternative to other standard chemical procedures. The compounds are of the general formula $[CoL_2L']$. The electrochemical efficiency value (Table 1) is defined as the amount of metal dissolved per Faraday of charge and was close to 0.5 mol F^{-1} in all cases. This fact, along with the evolution of hydrogen gas at the cathode, is compatible with a reaction mechanism involving the anodic oxidation to cobalt(II) and the deprotonation of the ligand at the cathode.

Anode: $Co \rightarrow Co^{2+} + 2e^-$
Cathode: $2HL + 2e^- \rightarrow 2L^- + H_2$
Overall: $Co + 2HL + L' \rightarrow [CoL_2L'] + H_2$
where L′ is 2,2′-bipyridine or 1,10-phenanthroline.

The sulfonamide compounds were obtained by air concentration of the resulting acetonitrile solution. These compounds are air stable compounds that are soluble in common organic solvents.

3.1. Description of the structures

3.1.1. Crystal structure of [Co(Ts3mepy)$_2$bipy] and [Co(Ts3mepy)$_2$phen]

The molecular structures of [Co(Ts3mepy)$_2$bipy] and [Co(Ts3mepy)$_2$phen] are shown in Fig. 1 together with the atomic numbering scheme. Selected bond lengths and angles are given in Table 4.

[Co(Ts3mepy)$_2$phen] crystallized with two molecules of acetonitrile, which are not shown in the figure since they do not interact with the complex molecule to any significant degree.

Both complexes consist of discrete molecules with the six-coordinate cobalt atoms coordinated by a 2,2′-bipyridine or 1,10-phenanthroline, which act as N,N′-bidentate ligands, and two anionic sulfonamide ligands acting as

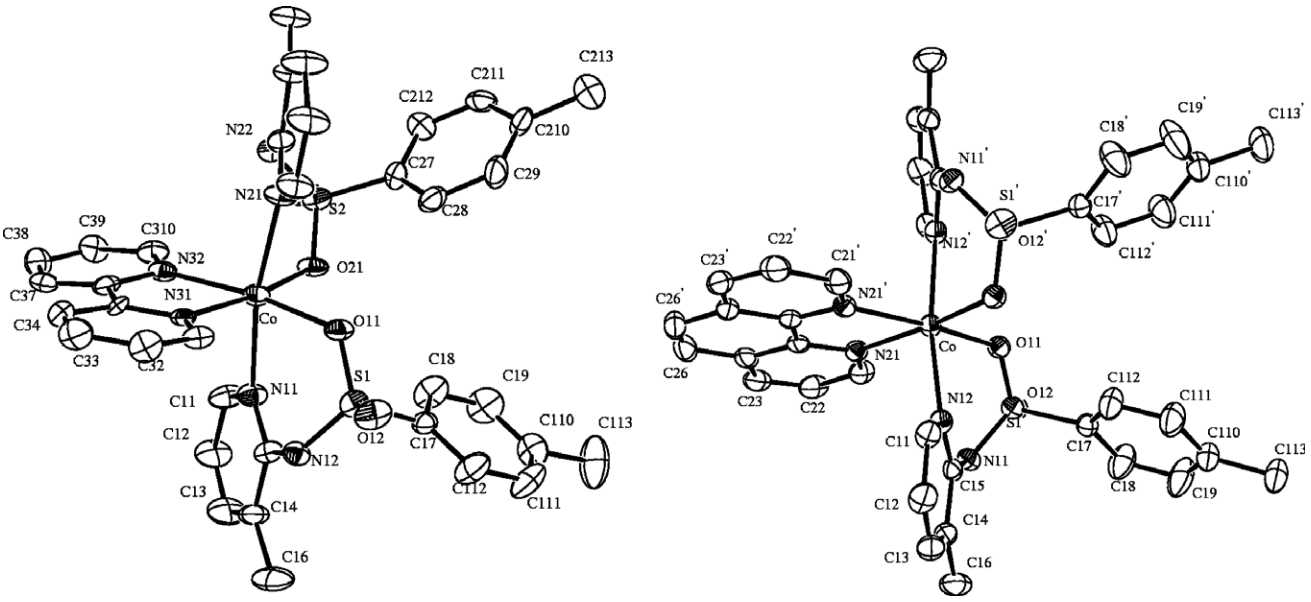

Fig. 1. The molecular structures of [Co(Ts3mepy)$_2$bipy] and [Co(Ts3mepy)$_2$phen].

N_{py},O-bidentate systems. The coordination polyhedron around the metal is best described as an octahedron, with the oxygen atoms in *cis* positions and the pyridine nitrogen atoms in *trans* positions. Such an arrangement implies a two-fold axis, which is crystallographic in [Co(Ts3mepy)$_2$-phen]. In the case of [Co(Ts3mepy)$_2$bipy] the arrangement is more distorted and, for example, the dihedral angle between the two pyridine rings in the bipyridine moiety is 9.7(4)°. In the case of [Co(Ts3mepy)$_2$phen], the phenanthroline moiety forms a dihedral angle of only 0.94(5)° with the equatorial plane, whereas in [Co(Ts3mepy)$_2$bipy] this angle is 7.6(2)°. For symmetry reasons, the best equatorial plane contains the cobalt atom in [Co(Ts3mepy)$_2$phen] and the defining atoms are only 0.005(1) Å out of this plane (RMS, 0.005). However, in [Co(Ts3mepy)$_2$bipy] the best plane (RMS, 0.0563) is at 0.008(3) Å from the cobalt(II) atom and the defining atoms are up to 0.061(2) Å out of the plane. The distortion of an octahedron can also be measured using the values of the dihedral angles α between bidentate coordination planes (related by a three-fold axis in a regular octahedron). The average values for the angle α are 84.9(2)° and 86.92(7)° in [Co(Ts3mepy)$_2$bipy] and [Co(Ts3mepy)$_2$phen], respectively, and these are not very far from 90° [22].

The pyridine ring plane and the benzene ring plane of the sulfonamide ligand form dihedral angles of 75.6(1)° for [Co(Ts3mepy)$_2$phen] and 51.4(3)° and 75.9(2)° for [Co(Ts3mepy)$_2$bipy]. These angles again highlight the differences found in the latter complex but are not significantly different from those found in the free ligand [10].

The Co–N bond distances, which range from 2.136(6) to 2.189(5) Å, and the Co–O distances, 2.040(5)–2.113(4) Å, also show the greater level of distortion in [Co(Ts3mepy)$_2$-bipy] than [Co(Ts3mepy)$_2$phen]. These values are, however, all in the range expected for hexacoordinated cobalt(II) complexes. The Co–N bond lengths are very similar to those found in the octahedrally coordinated complexes with four pyridine nitrogen donor atoms and two oxygen atoms in *cis* positions [23,24]. The average Co–O bond length is 2.076 Å for [Co(Ts3mepy)$_2$(bipy)], which is virtually the same as the symmetry imposed value of 2.075(2) Å for [Co(Ts3mepy)$_2$(phen)]. These values are very close to the Co–O bond length found for the cationic aquo complex $[Co(H_2O)_2(phen)_2]^{2+}$, 2.077(3) Å (average) [23], but are slightly shorter than that found in the neutral DMF complex [Co(Tspy)$_2$(DMF)$_2$], 2.1635(14) Å [11], or in the triflate complex [Co(triflate)$_2$(phen)$_2$], 2.215(4) Å [25].

3.1.2. Description of the structure of [Co(Ms3mepy)$_2$phen]

The molecular structure of [Co(Ms3mepy)$_2$phen] is shown in Fig. 2 together with the atomic numbering scheme. Selected bond lengths and angles are given in Table 5.

[Co(Ms3mepy)$_2$phen] crystallized with an acetonitrile solvent molecule, which is not shown in the figure since it does not interact significantly with the complex molecule.

The structure of [Co(Ms3mepy)$_2$phen] is similar to those described above, with the sulfonamide ligands acting as N_{py},O-bidentate donors and the neutral ligand as an N,N bidentate system. However, the dispositions of the ligands are different, as in this case the oxygen atoms are in an axial disposition and the pyridine nitrogen atoms of the sulfonamide ligands are in a *cis* disposition. This arrangement allows a π,π-stacking interaction between one of the mesitylene rings and the phenanthroline moiety, with a dihedral angle of 1.4(1)° and distances between rings of about 3.6 Å.

The pyridine ring plane and the benzene ring plane of this sulfonamide ligand form dihedral angles of 89.3(1)°

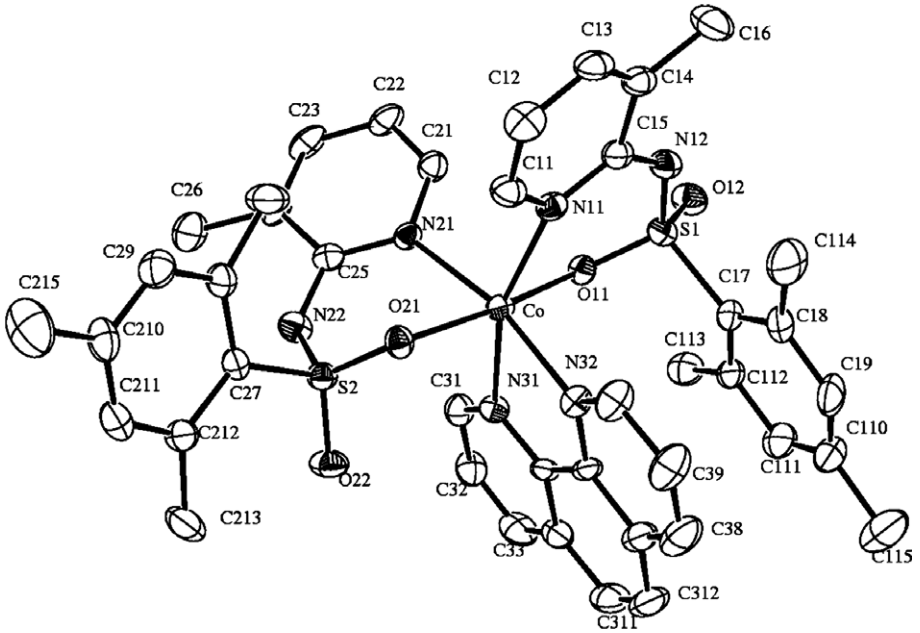

Fig. 2. The molecular structure of [Co(Ms3mepy)$_2$phen].

N(31)–Co–N(32)	77.00(14)		
Some staking interactions			
N(32)–C(17)	3.456(5)	C(19)–C(38)	3.579(8)
C(18)–C(310)	3.491(7)	C(110)–C(37)	3.562(7)
C(111)–C(37)	3.640(7)	C(112)–C(36)	3.574(6)

and these are larger than those found in the free ligand [14] or in the other ligand [74.8(1)° in the complex]. A π,π-stacking interaction has already been found in similar complexes of copper, zinc and cadmium, but only when the ligand contains a mesitylene ring. This is probably due to the electron-donating effect of the three methyl groups in the ring as well as the increase in the overall size of the group.

The average value for the angle α (vide supra) is 81.61(12)°, which deviates significantly from regularity towards a trigonal prism. In addition, the best equatorial plane defined by the four nitrogen donor atoms has an RMS deviation of 0.231, with the N32 atom up to 0.255(2) Å out of the plane. The cobalt atom is, however, only 0.047(2) Å out of this plane.

The Co–N bond distances, which are in the range 2.133(4)–2.157(4) Å, are very similar to those found in the previously described complexes. The Co–O distances, 2.084(3) and 2.114(3) Å, are slightly longer than those found in the previously described complexes, but are still shorter than those described in the literature [25].

3.1.3. Description of the structures of [Co(Ts6mepy)$_2$bipy], [Co(Ts6mepy)$_2$phen] and [Co(Ms6mepy)$_2$phen]

The molecular structures of these compounds are shown in Figs. 3–5, respectively, together with the atomic numbering schemes. Selected bond lengths and angles for the molecules are given in Tables 6 and 7. Once more, [Co(Ts6mepy)$_2$phen] crystallized with an acetonitrile solvent molecule, which is not shown in the figure since it does not interact with the complex molecule to any significant degree.

The coordination behavior of the anionic ligands in these complexes is quite different from the previous examples described in this paper. In these cases, the sulfonamide anionic ligands are N_{py},N_{amide}-bidentate ligands. A neutral 2,2′-bipyridine or 1,10-phenanthroline, both of which act as N,N-donors, completes the coordination sphere of the metal. Consequently, the coordination polyhedron around the cobalt(II) is best described as a highly distorted octahedron [CoN_6]. However, some differences can be found between the structures in terms of the disposition of the ligands around the metal. In all cases, the pyridine nitrogen atoms are in *cis* positions and in the same equatorial plane as the bipyridine moiety. The small chelate angles of the sulfonamide ligands are the main source of distortion, with angles ranging from 62.04(7)° to 62.9(3)°. The axial angles (theoretical value of 180°) range from 156.72(14)° to 165.62(14)°.

In [Co(Ts6mepy)$_2$bipy] the average value for the angle α (vide supra) is 85.5(1)° and this is close to the theoretical 90°. Another measurement of the distortion of the octahedron is

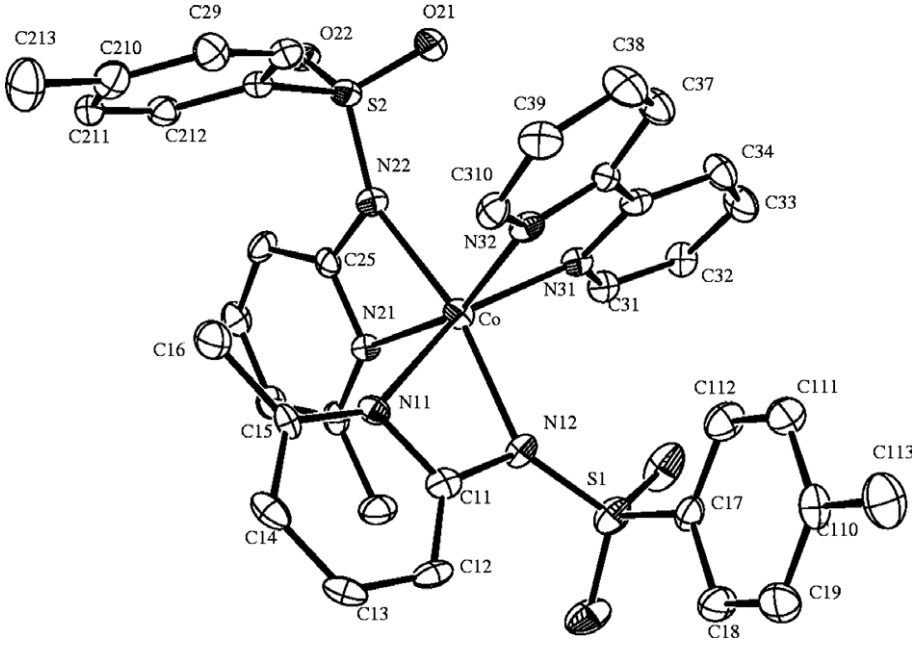

Fig. 3. Molecular structure of [Co(Ts6mepy)$_2$bipy].

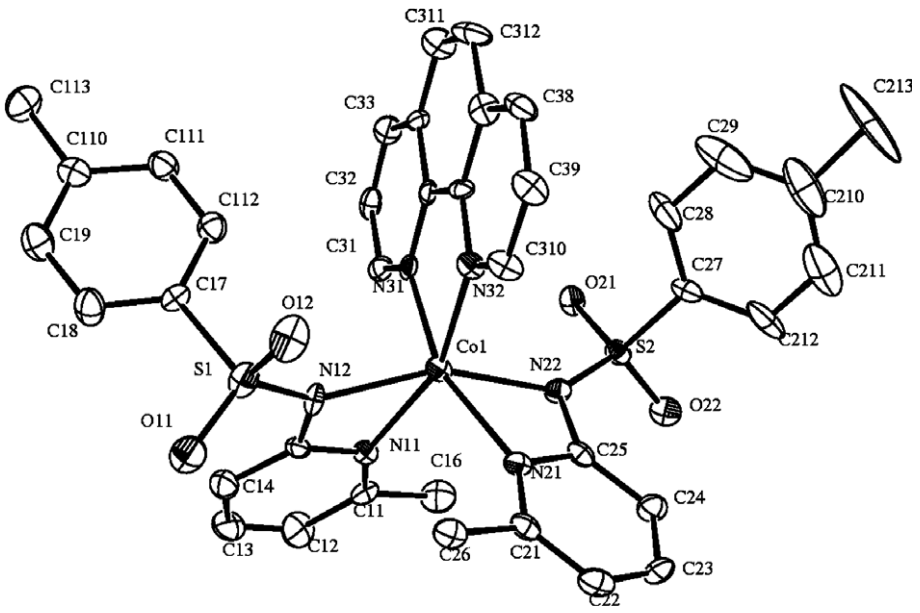

Fig. 4. Molecular structure of [Co(Ts6mepy)$_2$phen].

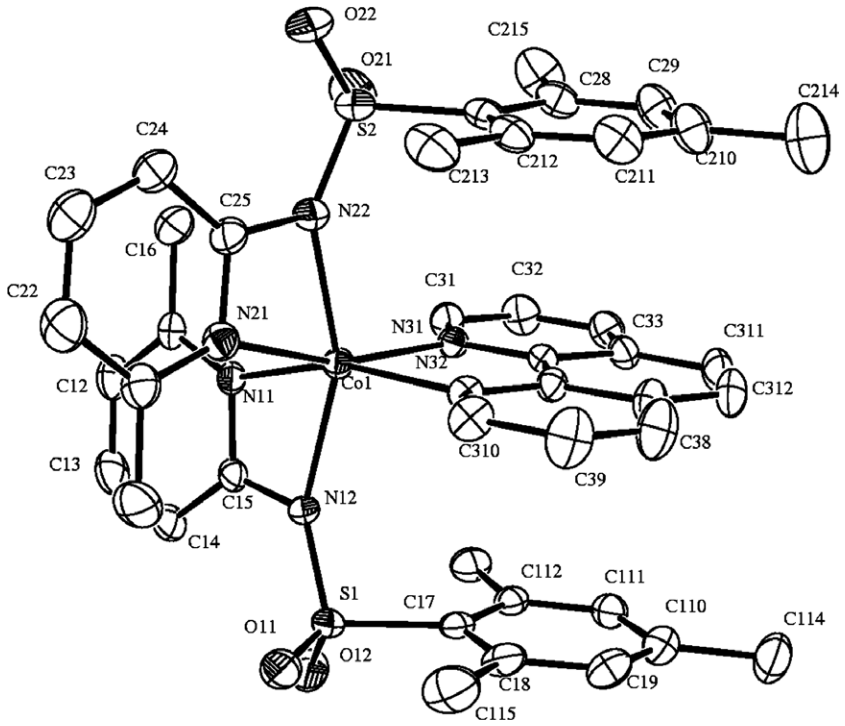

Fig. 5. Molecular structure of [Co(Ms6mepy)$_2$phen].

the angle ϕ, defined as the twist angle between the two triangles of nitrogen atoms perpendicular to a trigonal axis (Scheme 4). Unfortunately, in this compound these triangular planes are not parallel and they form dihedral angles of 20.2(2)°, 18.1(2)° and 15.5(2)°. If we consider the latter two triangles, we have N31, N21 and N12 and N32, N22 and N11 – i.e., one sulfonamide nitrogen atom, one pyridine nitrogen atom from a different ligand and a bipyridine nitrogen atom – and the values for the angle ϕ are −39.3(2)°, −39.5(2)° and −45.2(2)°.

The planarity of the equatorial plane can also be a criterion to assess the distortion of the octahedron. The best calculated plane formed by the pyridine nitrogen atoms and the nitrogen atoms of the bypiridine moiety shows an RMS deviation of 0.3898, and the atom N32 is up to 0.431(2) Å out of the plane. The cobalt(II) atom is 0.014(2) Å out of the plane.

In the case of [Co(Ts6mepy)$_2$phen], the arrangement of the ligands around the metal gives rise to an α angle with an average value of 82.4(3)°, which shows greater distortion

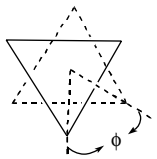

Scheme 4.

than the former complex, and values for the ϕ angle of −35.4(3)°, −38.2(3)° and −36.2(3)°. The increase in the distortion is probably due to packing reasons and also to a twist in the N22–S2 bond. However, when the planarity of the equatorial plane is considered, the RMS deviation is 0.3324 and the N31 atom is 0.372(4) Å out of the plane. The cobalt(II) atom is 0.045(4) Å out of the plane.

The coordination polyhedron around the cobalt(II) in [Co(Ms6mepy)$_2$phen] is, once again, best described as an octahedron, with dihedral α angles between bidentate coordination planes (related by three-fold axis in a regular octahedron) of 88.90(8)°, 84.49(6)° and 85.52(7)°, average 86.30(8)°, which is close to the theoretical 90° [22]. The angles ϕ, defined as above, have values of 38.94(8)°, 41.45(8)° and 39.07(9)°. The planarity of the equatorial plane is better than in the last two complexes, with an RMS deviation of 0.2981, and the N31 atom is 0.327(1) Å out of the plane. The cobalt(II) atom is only 0.004(1) Å out of the plane.

Once again, significant intermolecular "π–π stacking" stabilization is produced between the 1,10-phenanthroline unit and the benzene rings of both sulfonamide ligands. This interaction does not appear to occur in an intermolecular manner. The dihedral angles between the rings involved in these interactions are 0.74(12)° and 3.77(13)° and several short distances are shown in Table 7. It is worth noting the difference found between this compound and the complex [Cu(Ms6mepy)$_2$phen]; in the copper compound the distances in the axis N12–Cu–N22 are longer than those in the equatorial plane and the angle is nearer to 180° [average 171.2(2)°]. In the cobalt compound, the distances in the axis N12–Co–N22 are similar to those in the equatorial plane and the angle shows more distortion, 157.61(8)°.

Dihedral angles between the pyridine ring and the mesytilene ring for each ligand are 77.48(8)° and 81.69(8)°, values similar to those found in the free ligand.

The average Co–N$_{py}$ [2.169(7) Å], Co–N$_{amide}$ [2.146(7) Å] and Co–N$_{phen}$ or Co–N$_{bipy}$ [2.111(7) Å] bond lengths are similar in all of the complexes and are very close to those found in other octahedral cobalt(II) complexes with pyridine and amide nitrogen donor ligands; for example, 2.150 (9) Å is the average value for CoL_2 (HL = 1-[(4-methylphenyl)-sulfonamido]-2-[(2-pyridylmethyleneamino)benzene]) [26].

3.2. Spectroscopic studies

The IR spectra of these complexes (Table 2) do not contain the band observed in the ligand at 3248–3222 cm^{-1}, which is attributed to ν(N–H) stretching. This observation indicates that the ligand is in the anionic amidate form in the complex. The spectra also show bands in the aromatic region due to ν(C=N) (1615–1590 cm^{-1}) and ν(C=C) (1459–1413 cm^{-1}). These bands appear in similar positions to those for the free ligand in the complexes with Ts3Mepy$^-$ and Ms3Mepy$^-$ but are shifted to lower frequencies in the Ts6Mepy$^-$ and Ms6mepy$^-$ complexes as result of coordination through the sulfonamide nitrogen atom. The spectra also show bands in the region 1342–1319 cm^{-1}, which are attributed to ν_{as}(S=O), and bands in the range 1178–1081 cm^{-1}, which are attributed to the ν_{sym}(S=O) vibrations. A band is also observed at 2938–2918 cm^{-1} and this corresponds to ν(CH$_3$). In addition, the IR spectra show absorptions typical of coordinated

2,2′-bipyridine (769–766 and 736–734 cm^{-1}) [27] and 1,10-phenanthroline (1519–1517, 853–844 and 728–726 cm^{-1}) [27,28].

The solid state electronic spectra between 20 000 and 5000 cm^{-1} of all the heteroleptic complexes $[Co(Me3mepy)_2L']$ contain three bands in the regions 8700–9500 and 18 900-21 000 cm^{-1}, assigned to $^4T_{1g}(F) \rightarrow {}^4T_{2g}(\nu_1)$ and $^3T_{1g}(F) \rightarrow {}^4T_{2g}(\nu_3)$ transitions, respectively, in a distorted octahedral field. A band assignable to $^4T_{1g}(F) \rightarrow {}^4A_{2g}(\nu_2)$ [except for the $[Co(Me3mepy)_2bipy]$ (14 500 cm^{-1})] was not observed, probably because such a band must be very weak and obscured by the ν_3 transition [29].

Fig. 1. Bis(pyrazol-1-yl)methane derivatives.

prepared by Pettinari et al. [5]. It was noted that in the case of the complexes of CdI_2 and $HgCl_2$ displacement of the L^4 ligand is observed under analogous conditions. Nevertheless, L^4 reacts with mercury(II) acetate in the presence of saccharine (*o*-sulfobenzoic acid imide, SacH) in aqueous solution with the formation of a mixed-ligand complex $Hg(L^4)(Sac^-)_2$ [5].

The same authors [5] also report that ligand L^4 is displaced from the complexes $Zn(L^4)X_2$ ($X = Cl^-$, Br^-) and $Cd(L^4)Br_2$ upon their reaction with various monodentate ligands (pyrazole, *N*-methylimidazole, 4-phenylimidazole) and 2,2′-bipyridyl. Similarly, when $Hg(L^5)Cl_2$ was reacted with triphenylphosphine (PPh_3) and 2,2′-bipyridyl (bipy), only $Hg(PPh_3)_2Cl_2$ and $Hg(bipy)Cl_2$ compounds were isolated [6].

A considerable quantity of 3*d*-transition-metal mixed-ligand complexes with bis(pyrazol-1-yl)methane derivatives involves copper(I) ions. Thus, $[Cu(NO_3)(PPh_3)_2]$ reacts with L^1 [7] or L^5 [8] to form mixed-ligand adducts $[Cu(L)(PPh_3)_2](NO_3)$ ($L = L^1$, L^5). It is interesting to note that the same reaction was observed even in the case of strongly electron-deficient bis(4-nitropyrazol-1-yl)methane [7]. Similarly, complexes containing other counter-ions, namely $[Cu(L)(PPh_3)X]$ ($L = L^1$, L^2; $X = Cl^-$, Br^-) [8], $[Cu(L)(PPh_3)_2](ClO_4)$ ($L = L^1$, L^2, L^5) [9], $[Cu(L^2)(PPh_3)](ClO_4)$ [10] and $[Cu(L^1)(MeCN)_n](ClO_4)$ ($n = 1$, 2) [11] have been reported.

A binuclear mixed-ligand copper(I) complex with a bridging bidentate heterocyclic ligand, $[Cu_2(L^2)_2(MeCN)_2(\mu\text{-Prz})](ClO_4)_2$, was prepared by the reaction of $[Cu(L^2)(MeCN)](ClO_4)$ with pyrazine (Prz) in dichloromethane solution [10].

As it is seen from the literature, no copper(II) mixed-ligand complexes containing bis(pyrazol-1-yl)methane derivatives together with any other organic ligands are known.

In this contribution we report the preparation of complexes of L^1, L^2 ligands and novel bis(4-iodopyrazol-1-yl)methane (L^6) and bis(3,5-dimethyl-4-iodopyrazol-1-yl)methane (L^7) ligands with copper(II) nitrate and chloride. The reactivity of the complexes obtained with various mono- and bidentate ligands is investigated.

2. Experimental

2.1. Syntheses

Commercial reagents and solvents were used as received.

Bis(pyrazol-1-yl)methane (L^1) was prepared as previously described [12]. Briefly, 5.00 g (73.5 mmol) of 1*H*-pyrazole were dissolved in 30 ml of DMSO, and 16.46 g (294.0 mmol) of finely powdered KOH were added. The suspension was vigorously stirred for 1 h at 60 °C, and 6.40 g (2.6 ml, 36.8 mmol) of dibromomethane in 20 ml of DMSO were added dropwise over 30 min. Stirring at 60 °C was continued for an additional 4 h, and the reaction mixture was poured into 300 ml of water and extracted with chloroform (6 × 30 ml). The extract was washed with water (2 × 20 ml) and dried over anhydrous calcium chloride. Removal of the solvent produced 4.45 g (yield 82%) of solid product. M.p. 107–107.5 °C (benzene–hexane, 1:1, lit. m.p. 108 °C [13]). *Anal.* Calc. for $C_7H_8N_4$: C, 56.74; H, 5.44; N, 37.81. Found: C, 56.36; H, 5.67; N, 38.05%. ^{1}H NMR spectrum corresponds to literature data [14]. IR bands, cm^{-1}: 1610, 1510, 1450 (ν_{ring} – pyrazole ring stretching vibrations); 1355 (βCH – in-plane C–H bending vibrations); 1045 (pyrazole ring breathing); 940, 740 (δ_{C-H}). UV–Vis bands (EtOH), λ_{max}, nm (ε, $dm^3\ cm^{-1}\ mol^{-1}$): 222 (8860), 203 (sh).

Bis(3,5-dimethylpyrazol-1-yl)methane (L^2) was prepared similarly. Yield 92%, m.p. 105–105.5 °C (benzene–hexane, 1:1, lit. m.p. 105 °C [13]). *Anal.* Calc. for $C_{11}H_{16}N_4$: C, 64.68; H, 7.89; N, 27.43. Found: C, 63.88; H, 8.03; N, 26.82%. ^{1}H NMR spectrum corresponds to literature data [14]. IR bands, cm^{-1}: 1550, 1450 (ν_{ring}); 1345 (βCH); 1125; 1020 (pyrazole ring breathing); 955, 765, 700. UV–Vis bands (EtOH), λ_{max}, nm (ε, $dm^3\ cm^{-1}\ mol^{-1}$): 222 (6790), 206 (5900).

Bis(4-iodopyrazol-1-yl)methane (L^6) was prepared as previously described [15]. Briefly, a suspension of 3.50 g (23.6 mmol) of L^1, 4.80 g (18.9 mmol) of powdered iodine, 1.65 g (9.4 mmol) of HIO_3 in 30 ml of glacial acetic acid and 3 ml 30% aqueous H_2SO_4 was vigorously stirred for 15 min at 70 °C until the reaction mixture became colorless. The mixture was then poured into 250 ml of water, the precipitate formed was filtered, washed with H_2O, and dried to yield 9.25 g (98%) of compound L^6. M.p. 165–165.5 °C (benzene–hexane, 4:1), *Anal.* Calc. for $C_7H_6N_4I_2$: C, 21.02; H, 1.51; N, 14.01. Found: C, 21.47; H, 1.93; N, 13.99%. ^{1}H NMR ($CDCl_3$): δ, ppm: 6.15 (s, 2H, CH_2), 7.49 (s, 2H, H^3), 7.62 (s, 2H, H^5). IR bands, cm^{-1}: 1520 (ν_{ring}); 1395 (βCH); 1310; 1000 (pyrazole ring breathing). UV–Vis bands (EtOH), λ_{max}, nm (ε, $dm^3\ cm^{-1}\ mol^{-1}$): 238 (8410), 202 (8410).

Bis(3,5-dimethyl-4-iodopyrazol-1-yl)methane (L^7) was prepared similarly. Yield 94%, m.p. 183–184 °C (EtOH). *Anal.* Calc. for $C_{11}H_{14}N_4I_2$: C, 29.27; H, 3.09; N, 12.28. Found: C, 29.34; H, 3.04; N, 12.08%. ^{1}H NMR ($CDCl_3$):

δ, ppm: 2.12 (s, 6H, 3-CH_3), 2.40 (s, 6H, 5-CH_3), 6.08 (s, 2H, CH_2). IR bands, cm^{-1}: 1525, 1460 (ν_{ring}); 1370; 1335 (βCH); 1050 (pyrazole ring breathing). UV–Vis bands (EtOH), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 238 (6790), 204 (6560).

2.1.1. Bis(pyrazol-1-yl)methanedinitratocopper(II) monohydrate (*1*)

A solution of 0.752 g (4.0 mmol) of L^1 in 6 ml of acetone was added to a solution of 0.592 g (4.0 mmol) of $Cu(NO_3)_2 \cdot 3H_2O$ in 3 ml of the same solvent. The immediately formed light-blue precipitate was filtered after 30 min, thoroughly washed with acetone and dried in vacuo at 40 °C. The yield of compound **1** was 0.800 g (57%).

Complexes **2**–**5**, **7**, **9**, **10** were obtained similarly, whilst a 2:1 ligand to metal ratio was used in case of compounds **6** and **8**.

2.1.2. Bis(pyrazol-1-yl)methane-2,2′-bipyridyl-nitratocopper(II) nitrate (*11*)

A solution of 0.078 g (0.5 mmol) 2,2′-bipyridyl in 1 ml of acetone was added to a warmed-up (40 °C) solution of 0.168 g (0.5 mmol) of the complex $[Cu(L^1)(O_2NO)_2] \cdot H_2O$ (**1**) in 15 ml of acetone. The precipitated light-blue crystals of compound **11** (yield 0.170 g, 69%) were filtered, washed with acetone and dried in vacuo.

Compounds **12**–**14** were prepared similarly from copper complexes **2** or **3** and bidentate ligands (2,2′-bipyridyl or acetylacetone) in a 1:1 ratio. Mixed-ligand complexes **15**–**18** were obtained upon mixing one equivalent of complex **2** with two equivalents of the corresponding monodentate ligand in ethanol (compound **15**), acetone (complexes **16**, **17**) or isopropyl alcohol (compound **18**).

2.2. Analytical data

2.2.1. Bis(pyrazol-1-yl)methanedinitratocopper(II) monohydrate (*1*)

$Cu(L^1)(NO_3)_2 \cdot H_2O$. Yield 57%; m.p. 207 °C; molar conductivity $\lambda = 27.5\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_7H_{10}CuN_6O_7$: C, 23.77; H, 2.85; N, 23.76. Found: C, 24.04; H, 2.86; N, 24.10%. IR bands, cm^{-1}: 3400br (ν_{O-H}, H_2O); 2354, 2167 ($\nu_1 + \nu_3$ of NO_3^-); 1788, 1757 ($\nu_1 + \nu_4$ of NO_3^-); 1618 (δ_{O-H}, H_2O); 1514 (ν_{ring}); 1464 (ν_3 mode of NO_3^-); 1398 (ν_{ring}); 1321 (βCH); 1285 (ν_3 mode of NO_3^-); 1045 (pyrazole ring breathing); 1017 (ν_1 mode of NO_3^-); 809 (ν_2 mode of NO_3^-); 760, 729 (ν_4 mode of NO_3^-). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 935 (sh), 685 (120), 338 (sh), 256 (sh), 219 (16 580). Cyclic voltammetry, $E_{1/2} = -214$ mV, $\Delta E = 182$ mV.

2.2.2. Bis(3,5-dimethylpyrazol-1-yl)methanedinitratocopper(II) (*2*)

$Cu(L^2)(NO_3)_2$. Yield 93%; m.p. 230–231 °C; $\lambda = 19.1\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{11}H_{16}CuN_6O_6$: C, 33.72; H, 4.12; N, 21.45. Found: C, 34.20; H, 4.45; N, 20.98%. IR bands, cm^{-1}: 1540 (ν_{ring}); 1500 (ν_3 mode of NO_3^-); 1455 (ν_{ring}); 1370 (βCH); 1280 (ν_3 mode of NO_3^-); 1040 (pyrazole ring breathing); 995 (ν_1 mode of NO_3^-); 820 (ν_2 mode of NO_3^-); 730, 690 (ν_4 mode of NO_3^-). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 935 (sh); 685 (120); 338 (sh); 256 (sh); 219 (16 580). $E_{1/2} = -137$ mV, $\Delta E = 112$ mV.

2.2.3. Bis(4-iodopyrazol-1-yl)methanedinitratocopper(II) (*3*)

$Cu(L^6)(NO_3)_2$. Yield 77%; m.p. 229–230 °C. *Anal.* Calc. for $C_7H_6CuI_2N_6O_6$: C, 14.31; H, 1.03; N, 14.30. Found: C, 14.77; H, 1.30; N, 14.00%. IR bands, cm^{-1}: 1742, 1703 ($\nu_1 + \nu_4$ of NO_3^-); 1521 (ν_{ring}); 1454 (ν_3 mode of NO_3^-); 1433 (ν_{ring}); 1329 (βCH); 1293 (ν_3 mode of NO_3^-); 1032 (pyrazole ring breathing); 1003 (ν_1 mode of NO_3^-); 827 (ν_2 mode of NO_3^-); 782, 735 (ν_4 mode of NO_3^-).

2.2.4. Bis(3,5-dimethyl-4-iodopyrazol-1-yl)methanedinitratocopper(II) dihydrate (*4*)

$Cu(L^7)(NO_3)_2 \cdot 2H_2O$. Yield 94%; m.p. 222–223 °C; $\lambda = 14.5\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{11}H_{18}CuI_2N_6O_8$: C, 19.44; H, 2.67; N, 12.37. Found: C, 19.82; H, 2.95; N, 12.09%. IR bands, cm^{-1}: 3400br (ν_{O-H}, H_2O); 1620 (δ_{O-H}, H_2O); 1520 (ν_3 mode of NO_3^-); 1470 (ν_{ring}); 1370 (βCH); 1265 (ν_3 mode of NO_3^-); 1070 (pyrazole ring breathing); 1000 (ν_1 mode of NO_3^-); 835 (ν_2 mode of NO_3^-); 725, 700 (ν_4 mode of NO_3^-). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 1030 (sh); 722 (50.0); 342 (sh); 234 (13 860); 204 (27 650). $E_{1/2} = -176$ mV, $\Delta E = 183$ mV.

2.2.5. Bis(pyrazol-1-yl)methanedichlorocopper(II) (*5*)

$Cu(L^1)Cl_2$. Yield 93%; m.p. 266–267 °C (lit. m.p. 264–265 [3]); $\lambda = 15.0\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_7H_8Cl_2CuN_4$: C, 29.75; H, 2.85; N, 19.82. Found: C, 29.55; H, 2.60; N, 20.10%. IR bands, cm^{-1}: 1500 (ν_{ring}); 1260 (βCH); 1050 (pyrazole ring breathing). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 940 (sh); 765 (73); 334 (sh); 260 (sh); 215 (11630). $E_{1/2} = -169$ mV, $\Delta E = 128$ mV.

2.2.6. Bis{bis(pyrazol-1-yl)methane}copper(II) dichloride dihydrate (*6*)

$Cu(L^1)_2Cl_2 \cdot 2H_2O$. Yield 90%; m.p. 180–182 °C; $\lambda = 11.7\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{14}H_{20}Cl_2CuN_8O_2$: C, 36.02; H, 4.32; N, 24.00. Found: C, 36.03; H, 4.16; N, 23.60%. IR bands, cm^{-1}: 3400br (ν_{O-H}, H_2O); 1630 (δ_{O-H}, H_2O); 1500, 1450 (ν_{ring}); 1390 (βCH); 1045 (pyrazole ring breathing). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 1040 (sh); 765 (82); 337 (sh); 319 (163); 268 (2175); 220 (12120). $E_{1/2} = -111$ mV, $\Delta E = 45$ mV.

2.2.7. Bis(3,5-dimethylpyrazol-1-yl)methanedichlorocopper(II) (*7*)

$Cu(L^2)Cl_2$. Yield 78%; m.p. 200–202 °C; $\lambda = 52.3\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{11}H_{16}Cl_2CuN_4$: C, 39.00; H, 4.76; N, 16.54. Found: C, 38.60; H, 4.78; N,

16.90%. IR bands, cm^{-1}: 1540 (ν_{ring}); 1260 (βCH); 1015 (pyrazole ring breathing). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 950 (sh); 740 (102); 335 (sh); 268 (2433); 222 (10260). $E_{1/2} = -179$ mV, $\Delta E = 140$ mV.

2.2.8. Bis{bis(3,5-dimethylpyrazol-1-yl)methane}-copper(II) dichloride dihydrate (**8**)

$Cu(L^2)_2Cl_2 \cdot 2H_2O$. Yield 73%; m.p. 174–175 °C; $\lambda = 52.1\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{22}H_{36}Cl_2CuN_8O_2$: C, 45.63; H, 6.27; N, 19.35. Found: C, 45.62; H, 5.86; N, 19.20%. IR bands, cm^{-1}: 3430br (ν_{O-H}, H_2O); 1610 (δ_{O-H}, H_2O); 1550, 1460 (ν_{ring}); 1370 (βCH); 1020 (pyrazole ring breathing). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 945 (sh); 715 (168); 351 (sh); 265 (sh); 225 (30950). $E_{1/2} = -202$ mV, $\Delta E = 140$ mV.

2.2.9. Bis(4-iodopyrazol-1-yl)methanedichlorocopper(II) (**9**)

$Cu(L^6)Cl_2$. Yield 93%; m.p. 267–269 °C; $\lambda = 18.6\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_7H_8Cl_2CuI_2N_4$: C, 15.73; H, 1.13; N, 10.48. Found: C, 15.80; H, 1.19; N, 10.90%. IR bands, cm^{-1}: 1500, 1430 (ν_{ring}); 1360 (βCH); 1005 (pyrazole ring breathing). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 870 (38.7); 228 (15800).

2.2.10. Bis(3,5-dimethyl-4-iodopyrazol-1-yl)methane-dichlorocopper(II) dihydrate (**10**)

$Cu(L^7)Cl_2 \cdot 2H_2O$. Yield 88%; m.p. 229 °C; $\lambda = 22.7\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{11}H_{18}Cl_2CuI_2N_4O_2$: C, 21.09; H, 2.90; N, 8.94. Found: C, 21.33; H, 3.10; N, 8.49%. IR bands, cm^{-1}: 3300br (ν_{O-H}, H_2O); 1690 (δ_{O-H}, H_2O); 1585, 1520, 1470 (ν_{ring}); 1345 (βCH); 1070 (pyrazole ring breathing). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 820 (67); 341 (sh); 238 (14460). $E_{1/2} = -180$ mV, $\Delta E = 164$ mV.

2.2.11. Bis(pyrazol-1-yl)methane-2,2′-bipyridyl-nitratocopper(II) nitrate (**11**)

$Cu(L^1)(bipy)(NO_3)_2$. Yield 69%; m.p. 194–196 °C; $\lambda = 52.6\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{17}H_{16}CuN_8O_6$: C, 41.51; H, 3.28; N, 22.78. Found: C, 41.90; H, 2.90; N, 22.30%. IR bands, cm^{-1}: 2371, 2278 ($\nu_1 + \nu_3$ of NO_3^-); 1743, 1712 ($\nu_1 + \nu_3$ of NO_3^-); 1610, 1601 (ν_{ring} of pyridine); 1567 (ν_{ring}); 1475 (ν_3 mode of NO_3^-); 1343 (βCH); 1279 (ν_3 mode of NO_3^-); 1160 (βCH of pyridine ring); 1032 (pyrazole ring breathing); 1016 (ν_1 mode of NO_3^-); 902 (γCH – out-of-plane C–H bending vibrations of pyridine ring); 831, 812 (ν_2 mode of NO_3^-); 731, 705 (ν_4 mode of NO_3^-). UV–Vis bands (ethanol), λ_{max}, nm (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 880 (sh); 695 (65.3); 336 (sh); 312 (16270); 300 (17370); 242 (sh); 213 (32850). $E_{1/2} = -153$ mV, $\Delta E = 121$ mV.

2.2.12. Bis(3,5-dimethylpyrazol-1-yl)methane-2,2′-bipyridylnitratocopper(II) nitrate (**12**)

$Cu(L^2)(bipy)(NO_3)_2$. Yield 81%; m.p. 229–231 °C; $\lambda = 81.6\ \Omega^{-1}\,cm^2\,mol^{-1}$ (acetone). *Anal.* Calc. for $C_{21}H_{24}CuN_8O_6$: C, 46.03; H, 4.41; N, 20.45. 2.3. Physical measurements

Conductivities of solutions ($c = 1.0 \times 10^{-3}$ mol/dm^3 in acetone or ethanol) were measured in a temperature-controlled cell with stainless steel electrodes, cell constant $\varphi = 0.251\ cm^{-1}$.

Elemental analyses were carried out on a Carlo Erba analyzer.

IR spectra of solid samples as KBr pellets were recorded on Specord 71 IR (in the range of 4600–650 cm^{-1}) and Nicolet 5700 (4000–400 cm^{-1}) spectrophotometers.

Electronic absorption spectra were registered on Perkin–Elmer 124 (in the range of 200–800 nm) and SF-26 (800–1200 nm) spectrophotometers.

NMR spectra were recorded on a Bruker AV300 instrument.

Cyclic voltammograms were obtained on a TA-4 voltammetric analyzer (Tomanalyt, Tomsk, Russia). The three-electrode electrochemical cell consisted of a mercury-film working electrode and saturated Ag/AgCl reference and auxiliary electrodes. The concentration of the sample in the cell was 1.0×10^{-4} mol/dm^3, and 0.1 mol/dm^3 KCl was used as a supporting electrolyte. The potential was varied in the range 0 to −1.3 V at 50 mV s^{-1} scan rate. Oxygen was removed from the solutions by bubbling nitrogen through immediately before any measurements. Formal potentials were calculated as $E_{1/2} = (E_{p.c.} + E_{p.a.})/2$.

3. Results and discussion

3.1. Synthesis of the ligands

Bis(pyrazol-1-yl)methanes L^1 and L^2 were first prepared by Trofimenko [14]. We have developed a new procedure for double alkylation of azoles via the reaction of 1*H*-pyrazole or 3,5-dimethyl-1*H*-pyrazole with dibromomethane in a superbasic medium (DMSO-KOH). Iodo-derivatives L^6 and L^7 were obtained by oxidative iodination of L^1 and L^2 by an I_2–HIO_3–H_2SO_4 mixture in acetic acid.

3.2. Synthesis and characterization of bis(pyrazol-1-yl)-methane complexes

The complexes were prepared by the reaction of the ligands with copper(II) nitrate or chloride in acetone solution. In the case of $Cu(NO_3)_2$, independent of the metal to ligand ratio used (1:1 or 1:2), complexes **1**–**4** of 1:1 composition were formed. The same feature was observed for the reaction of copper(II) chloride with the ligands L^6 and L^7 (complexes **9** and **10** were obtained). When $CuCl_2$ reacted with the ligands L^1 and L^2, 1:1 complexes **5** and **7**, as well as 1:2 complexes **6** and **8** were isolated depending on the reagent ratio.

All of the coordination compounds obtained gave satisfactory elemental analysis and were characterized by molar conductivity, infra-red and electronic spectroscopy.

The complexes of copper(II) nitrate, **1**, **2** and **4**, are weak electrolytes in acetone, therefore both of the NO_3^- ions are bound to the central ion. The solubility of complex **3** was insufficient for conductivity measurements.

Bis(pyrazol-1-yl)alkanes are bidentate in most of their complexes, so the same coordination mode is to be expected for the investigated compounds with L^1, L^2, L^6 and L^7. Bidentate coordination of bis(pyrazol-1-yl)methane derivatives in the prepared complexes can be assumed from the absence of the splitting of pyrazole ring vibrational bands in the IR spectra. This splitting should have occurred if only one of pyrazole rings in bis(pyrazol-1-yl)methane ligand was coordinated to the copper(II) ion. The possibility of formation of polymeric complexes, in which metal ions are connected by bridging ligands, can

be ruled out by sharp melting points of the compounds obtained. In the copper(II) nitrate complexes, the NO_3^- ions may be coordinated in a mono- or bidentate fashion. The coordination modes of nitrate ions can be established by means of IR spectroscopy [16–19].

Bands corresponding to all of the vibrational modes of the nitrate ion were detected in the IR spectra of complexes **1**–**4** (Table 1). Two intense bands in the 1455–1500 and 1265–1295 cm^{-1} regions were assigned to stretching vibrations of N–O bonds in a NO_3^- ion (ν_3) belonging to the C_{2v} symmetry group [17]. The bands of in-plane bending vibrations (ν_4) appear at 690–735 and 725–780 cm^{-1}. Large splitting of these bands ($\Delta(\nu_3) > 160$ and $\Delta(\nu_4) > 25$ cm^{-1}) confirms the presence of bidentate nitrate ions in all of the four complexes. For monodentate coordination of NO_3^- the splitting of the ν_3 band is not higher than 120 cm^{-1} and that of ν_4 is less than 20 cm^{-1} [17].

Single bands around 820 cm^{-1} (out-of-plane bending vibrations ν_2) as well as bands of medium intensity at about 1000 cm^{-1} (symmetric stretching vibrations ν_1) were observed in IR spectra of complexes **1**–**4** [17]. The occurrence of the latter band gives further evidence for the nitrate ions coordination, since the vibrational transition ν_1 in the free NO_3^- is symmetry-forbidden, so this band does not appear in IR spectra or has a very minute intensity [16].

Furthermore, weak combination bands ($\nu_1 + \nu_4$) and ($\nu_1 + \nu_3$) with the splitting values $\Delta(\nu_1 + \nu_4)$ and $\Delta(\nu_1 + \nu_3)$ in accord with those expected for bidentate nitrate ion coordination [18] were detected in the spectra of the complexes **1** and **3**.

Therefore, in nitrate complexes **1**–**4** the bidentate organic ligands occupy two coordination places, also each of the nitrate ions occupies two places. Consequently, the copper(II) ions in these complexes are hexacoordinated. Locations of absorption bands in the region of d–d* transitions in the electronic spectra of the complexes (a shoulder in the 930–1030 nm area and a band around 685–720 nm) correspond very well to the literature values for octahedrally surrounded Cu^{2+} [20]. For example, the already mentioned $[Cu(L^2)_2(O_2NO)](NO_3)$ exhibits an absorption at 694 nm with a shoulder at 1042 nm [2].

3.3. Preparation of mixed-ligand complexes

We have also studied the reactivity of the synthesized complexes towards various mono- and bidentate ligands,

namely 2,2′-bipyridyl (bipy), acetylacetone (Hacac), triphenylphosphine (PPh_3), benzimidazole (BImH), benzotriazole (BtaH) and 3,5-dimethylpyrazole (Me_2PyrH). These compounds represent four different types of ligands – phosphorus-containing, *O*,*O*-bidentate, *N*,*N*-bidentate and monodentate nitrogen-containing heterocycles, which are widely spread among important biologically active substances. Mixed-ligand complexes with such compounds may serve as models for metalloenzymes [21] and as building blocks for supramolecular systems [22].

We have found that the complexes of copper(II) nitrate **1**–**3** react with 2,2′-bipyridyl with the formation of mixed-ligand complexes **11**–**13**, comprising of coordinated molecules of bis(pyrazol-1-yl)methane derivatives as well as those of 2,2′-bipyridyl. Moreover, complex **2** reacts with other above-mentioned compounds also forming mixed-ligand complexes **14**–**18**. At the same time, copper(II) chloride complexes **5**–**10**, as well as the nitrate complex **4** undergo a displacement of bis(pyrazol-1-yl)methanes from the coordination sphere yielding homoligand complexes. These complexes are identical by melting points and spectral characteristics to the compounds prepared under the same conditions using copper(II) chloride or nitrate instead of bis(pyrazol-1-yl)methane-copper(II) complexes.

Bands due to bis(pyrazol-1-yl)methane ligand vibrations as well as due to additional ligands were observed in the IR-spectra of the mixed-ligand complexes **11**–**18**. Strong bands in the area of 1550–1560 cm^{-1} account for pyrazole ring stretching vibrations and bands at 1030–1050 cm^{-1} correspond to ring breathing vibrations in bis(pyrazol-1-yl)methane derivatives [23]. Absorption in the 1600 and 1610 cm^{-1} regions of 2,2′-bipyridyl mixed-ligand complexes **11**–**13** spectra correspond to pyridine ring stretching vibrations [24,25]. Triphenylphosphine characteristic bands at 503 and 694 cm^{-1} [26] were detected in the spectra of the PPh_3 derivative **15**. Broad bands in the area of 3300–3500 cm^{-1} corresponding to N–H stretching vibrations were detected in the spectra of the complexes **16**–**18**, comprising of nitrogen-unsubstituted heterocycles. Strong broadening of these bands may be explained by intramolecular hydrogen-bonding with coordinated nitrate ions. The presence of these bands indicates that the heterocycles are coordinated in their neutral, not anionic forms.

Acetylacetonate and 2,2′-bipyridyl, as well as bis(pyrazol-1-yl)methane derivatives are certainly bidentate ligands. It can be assumed that the coordination sphere of the complexes **11**–**14** consists of two organic bidentate ligands and one nitrate ion is also coordinated in a bidentate fashion as follows from the IR data (see example in Fig. 2). The central copper(II) ion in these complexes is therefore hexacoordinated, and the second nitrate ion remains uncoordinated. This is consistent with the detection of two bands in the out-of-plane bending vibrations area (800–830 cm^{-1}, Table 1). Presumably, one of them is related to bound NO_3^- ions and the other is due to the free nitrate ions. Apparently, the remaining bands of the free nitrate ions overlap with the bands of organic ligands and were not registered.

The same conclusions about hexacoordination of the copper(II) ion can be made for the complexes **15**–**18** containing two monodentate molecules of triphenylphosphine or nitrogen-containing heterocycle, one bidentate molecule of L^2 ligand and one bidentate nitrate-ion, while the second NO_3^- ion remains in the outer sphere (Fig. 3).

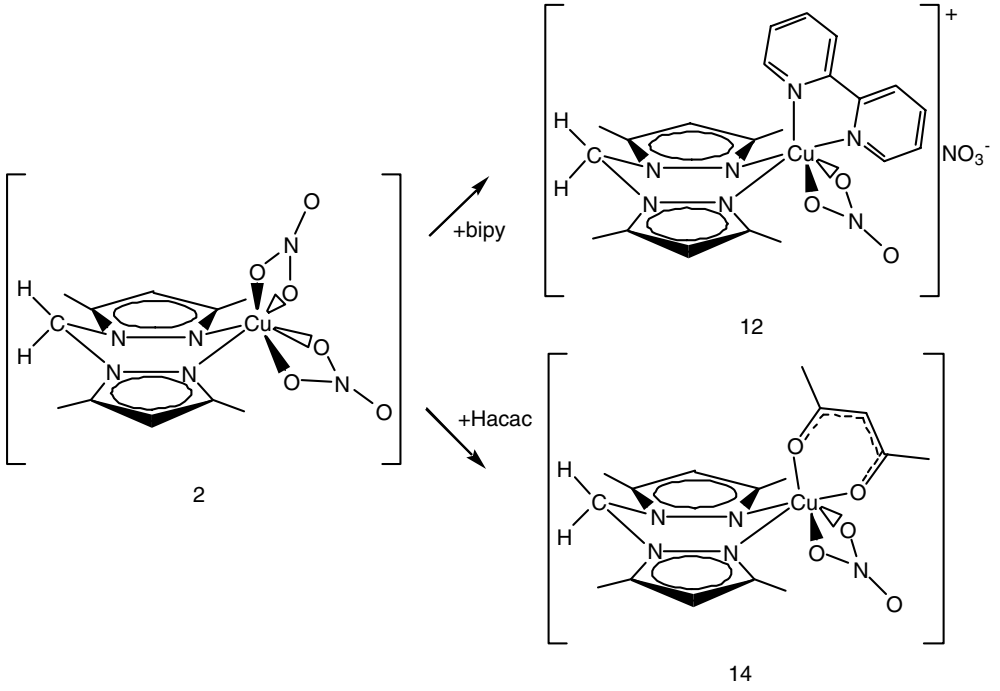

Fig. 2. Synthesis of bis(pyrazol-1-yl)methane-copper(II) mixed-ligand complexes with bidentate ligands.

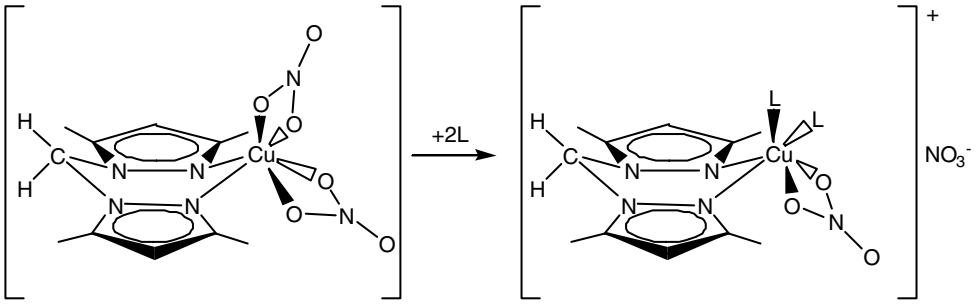

Fig. 3. Synthesis of bis(pyrazol-1-yl)methane-copper(II) mixed-ligand complexes with monodentate ligands.

3.4. Cyclic voltammetry

We have also carried out a cyclic voltammetric study of the synthesized homo- and mixed-ligand coordination compounds. Complexes of copper(II) nitrate and chloride **1**–**10** as well as mixed-ligand complexes **11**–**18** undergo a quasi-reversible (or reversible in case of the complex **6**) reduction on a mercury-film electrode in the range of potentials from −111 to −214 mV. Furthermore, cyclic voltammograms of several mixed-ligand complexes demonstrate additional peaks which are probably associated with the electrochemical activity of the organic ligands. Thus, the complex $[Cu(L^2)(PPh_3)_2(O_2NO)](NO_3)$ (**15**) undergoes a quasi-reversible reduction at a formal potential of −829 mV (relative to the saturated Ag/AgCl electrode) and the complex $[Cu(L^2)(BImH)_2(O_2NO)](NO_3)$ (**16**) is reduced at −509 mV. In the case of $[Cu(L^2)(Me_2PyrH)_2(O_2NO)](NO_3)$ (**18**) an irreversible reduction wave at −559 mV and a reversible one at a formal potential of −722 mV were observed.

Many copper complexes can mimic metalloenzymes, superoxide dismutase (SOD) being one of them. Li et al. pointed out that in order to act as a SOD mimic, the copper complex should have a redox potential in the range −0.36 ... +0.69 V (vs. the saturated Ag/AgCl electrode) [27]. Furthermore, the higher the redox potential $E_{1/2}$ and the greater the reversibility of the electrode process (characterized by the $\Delta E = E_{p.a.} - E_{p.c.}$ value), the higher the antioxidant activity of a given complex. As is seen from our cyclic voltammetry data, all of the complexes meet the specified requirements, and the highest SOD-like activity should be expected for complexes **6, 2**, **13**, **11** (in descending order of activity). A detailed study of the antioxidant properties of bis(pyrazol-1-yl)methane–copper(II) complexes will be reported elsewhere.

4. Conclusions

In summary, novel coordination compounds of copper(II) with bis(pyrazol-1-yl)methane derivatives are reported in this paper. The complexes synthesized reacted with a number of mono- and bidentate ligands yielding mixed-ligand complexes. No examples of bis(pyrazol-1-yl)methane mixed-ligand complexes with these ligands have been reported previously.

dried over NaK and vacuum transferred prior to use. ^{1}H, ^{13}C, ^{19}F, ^{207}Pb NMR spectra were recorded with Bruker DRX 400 MHz and Omega 500 MHz spectrometers. ^{19}F NMR spectra were referenced to $FCCl_3$ in C_6D_6 ($\delta = 0$). ^{207}Pb NMR spectra were referenced to $Pb(NO_3)_2$ 1 M in H_2O ($\delta = -2961.2$) [14]. Infrared spectra were recorded as thin films from benzene using a Perkin–Elmer 2000 FTIR spectrometer. Elemental analyses were performed by Desert Analytics (Tucson, AZ). MS (ES) analyses were recorded on a Micromass LCT spectrometer.

2.2. Synthesis of Pb(hfac)$_2$(diglyme) (1)

Hexafluoroacetylacetone (493 mg, 2.37 mmol) in ca 15 mL of toluene was added dropwise to a stirred suspension of PbO (210 mg, 0.94 mmol) in diglyme (148 mg, 1.10 mmol). The solution rapidly became clear and light yellow within 30 min. Solvent was removed in vacuo to give a yellow powder. Crystals of **1** (458 mg, 0.60 mmol, 64%) suitable for X-ray diffraction were obtained from diethyl ether at room temperature; m.p.: 69 °C. Complex **1** sublimes at 35 °C at 2×10^{-5} Torr. *Anal.* Calc. for $C_{16}H_{16}F_{12}O_7Pb$: C, 25.43; H; 2.12; F, 30.16; Pb, 27.43. MS (ES) 415 $[Pb(hfac)]^+$, 549 $[Pb(hfac)(diglyme)]^+$.

2.3. Synthesis of [(18-crown-6)K(hfac)]$_n$ (2)

K (4 mg, 0.10 mmol) was added to ca 5 mL of toluene containing 18-crown-6 (28 g, 0.11 mmol) and stirred for 2 h. The resulting mixture was added dropwise to $Pb(hfac)_2$(diglyme) (84 g, 0.11 mmol) in 5 mL of toluene. The solution immediately formed a gray-black precipitate which turned drab green within an hour and was allowed to stir overnight. The resulting orange solution was separated from gray-black insolubles by centrifugation. Removal of solvent in vacuo left an orange powder. Crystals of $[(18\text{-crown-6})K(hfac)]_n$ were obtained from a toluene solution of the orange powder at −35 °C.

2.4. X-ray data collection, structure solution and refinement

A colorless crystal of **1** of approximate dimensions $0.28 \times 0.30 \times 0.32$ mm and a yellow crystal of **2** of approximate dimensions $0.15 \times 0.28 \times 0.29$ mm were each mounted on a glass fiber and transferred to a Bruker CCD platform diffractometer. The SMART [15] program package was used to determine the unit-cell parameters and for data collection (25 sec/frame scan time for a sphere of diffraction data). The raw frame data were processed using SAINT [16] and SADABS [17] to yield the reflection data file. Subsequent calculations were carried out using the SHELXTL [18] program. There were no systematic absences nor any diffraction symmetry other than the Friedel condition. The centrosymmetric triclinic space group $P\bar{1}$ was assigned for both **1** and **2** and was later determined to be correct (see Table 1).

Table 1
X-ray data collection parameters for $[Pb(hfac)_2(\mu\text{-}\eta^3{:}\eta^1\text{-diglyme})]_2$ (**1**) and $[(18\text{-crown-6})K(hfac)]_n$ (**2**)

The structures were solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors [19] for neutral atoms were used throughout the analysis. Hydrogen atoms were included using a riding model. In **2**, the fluorine atoms F(4), F(5) and F(6) were disordered and included using multiple components with partial site-occupancy-factors.

3. Results and discussion

3.1. Synthesis of Pb(hfac)$_2$(diglyme) (1)

A hexafluoroacetylacetonate complex of lead can be readily synthesized in air by reacting hexafluoroacetylacetone [H(hfac)] with lead(II) oxide and diglyme in toluene, Eq. (2). This synthesis is analogous to the preparation of Ln(hfac)$_3$(diglyme) [1–3], Eq. (1). The solution turns yellow almost immediately as the suspension of PbO is rapidly consumed leaving a clear solution. The reaction reaches completion typically within an hour at room temperature. In contrast, the Ln(hfac)$_3$(diglyme) syntheses require several hours at reflux [1–3], which is typical of syntheses of other metal hfac complexes [1–4,20,21]. Crystallization from diethyl ether of the yellow powder obtained from the reaction mixture gives crystals of $[Pb(hfac)_2(\mu\text{-}\eta^3{:}\eta^1\text{-diglyme})]_2$ (**1**) suitable for X-ray analysis, Fig. 1

$$PbO + \text{diglyme} + 2Hhfac \rightarrow Pb(hfac)_2(\text{diglyme}) + H_2O \quad (2)$$

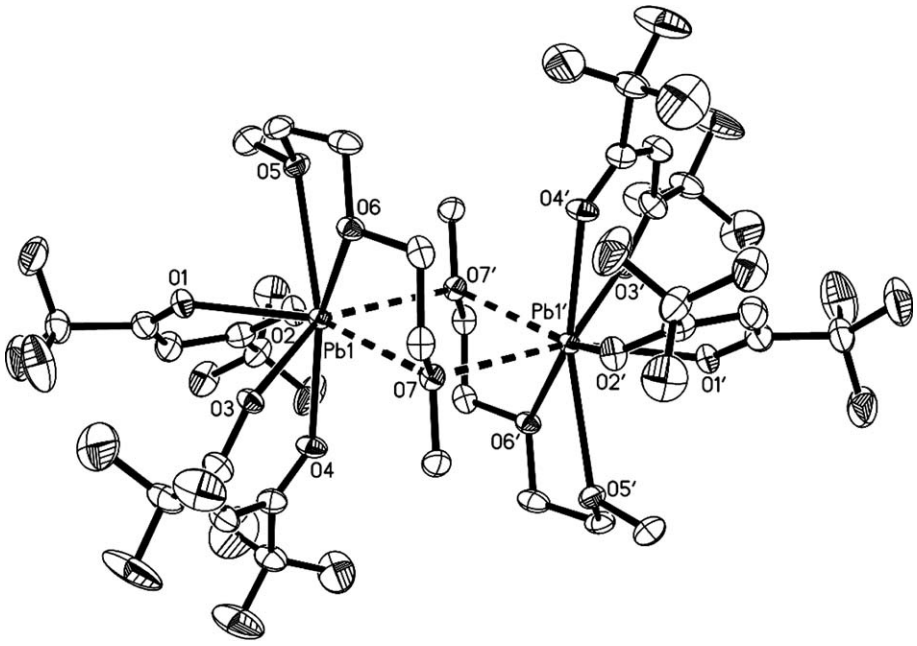

Fig. 1. Thermal ellipsoid plot of the $[Pb(hfac)_2(\mu\text{-}\eta^3{:}\eta^1\text{-diglyme})]_2$ dimer (**1**) with hydrogen atoms omitted for clarity and ellipsoids drawn at the 50% probability level.

Elemental analysis as well as NMR spectroscopy were consistent with the composition $Pb(hfac)_2(diglyme)$. The ^1H and ^{13}C NMR spectra of **1** in C_6D_6 contained a single set of signals for the diglyme protons (methylene hydrogens at δ 2.91 ppm and the methyl hydrogens at δ 3.06 ppm) and carbons (methyl carbon at δ 58.76 ppm and methylene carbons at δ 70.15 and 71.15 ppm). In an HMQC-NMR experiment, both of the methylene carbons in the ^{13}C NMR spectrum correlated with the single peak in the ^1H NMR. The ^{19}F and ^{207}Pb NMR spectra each contained single signals at δ −79.52 and −2098 ppm, respectively. Complex **1** has a ^{207}Pb resonance consistent with an oxygen coordinated ligand system [14]. The closest divalent lead complex with a fluorinated oxygen bound ligand [14] is $Pb(O_2CC_6F_5)_2$, which has a ^{207}Pb resonance at δ −1044 ppm [22]. The more negative value for **1** suggests that $Pb(hfac)_2(diglyme)$ has a coordination number greater than four [14], thus indicating at least some coordination of the diglyme to the lead in solution.

3.2. Structure of $[Pb(hfac)_2(\mu\text{-}\eta^3{:}\eta^1\text{-diglyme})]_2$ (**1**)

In the solid state, **1** exists as a racemic pair of enantiomers in which one diglyme oxygen of one monomeric unit is oriented toward the lead of the other, Figs. 1 and 2. Selected bond distances and angles are given in Table 2.

Each lead in **1** is coordinated by two hfac ligands with Pb–O distances in the range 2.417(3)–2.497(3) Å. Comparison of these distances with two other lead(II) β-diketonates shows a wide range of Pb–O lengths in these compounds. The Pb–O distances in **1** are up to 0.2 Å longer than those in bis(2,2,6,6,-tetramethylheptane-3,5-dionato)lead, $Pb(Me_3CCOCH_2COCMe_3)_2$, which has Pb–O distances of 2.287(9)–2.303(8) Å [20]. Bis(2,2-dimethyl-6,6,7,7,8,8,8-heptafluorooctane-3,5-dionato)lead, $Pb(CF_3CF_2CF_2COCH_2COCMe_3)_2$, has a range of Pb–O distances, 2.272(6)–2.410(5) Å [20], that overlaps those in both complexes. The Pb–O distances are shorter than the Ln–O distances of $Ln(hfac)_3(diglyme)$ (Ln = La, Sm, Eu, Gd, Tb) complexes [1–3] after correcting for variations in atomic radii [11]. For example, $Sm(hfac)_3(diglyme)$ has Sm–O distances of 2.386(1)–2.437(1) Å. Since the 1.079 Å eight coordinate radius of Sm is 0.21 Å shorter than that of Pb^{2+} [11], the comparable lead length in **1** would be 2.596–2.647 Å.

All of the Pb–O(diglyme) distances are longer than the Pb–O(hfac) distances. The Pb–O distances of 2.706(3) and 2.759(3) Å for the diglyme oxygen atoms, O(5) and O(6), respectively, are distinctly shorter than that of the third diglyme oxygen, O(7), which is found 2.851(3) Å from Pb(1). However, each O(7) is also oriented towards the other lead center, Pb(1′), at a distance of 3.021(3) Å.

If the long bridging Pb–O linkages are included in the coordination sphere of each metal, the formal coordination number is eight. These eight donor atoms do not describe one of the typical eight coordinate geometries [23], a result that may be due to the effect of a stereoactive lone pair. Lead complexes with this effect are described as "hemidirected" as opposed to "holo-directed" [4] when no void or perturbation is found in the sphere around the metal. The most open area in the coordination sphere of **1** is shown in the view in Fig. 3. It can be seen from this orientation that part of the coordination sphere contains no donor atoms.

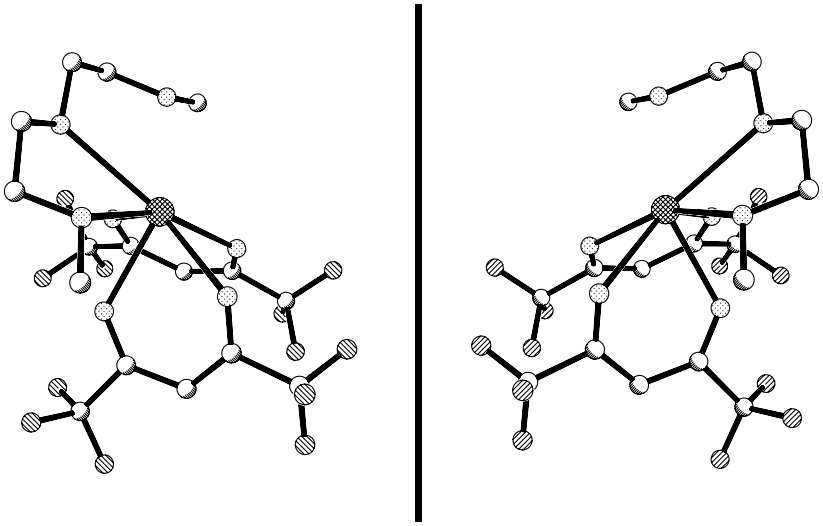

Fig. 2. The two enantiomeric units of $Pb(hfac)_2(diglyme)$ (**1**) shown as mirror images.

Pb(1)–O(7′)	3.021(3)
O(6)–Pb(1)–O(7′)	101.68(9)
O(1)–Pb(1)–O(2)	72.54(11)
O(4)–Pb(1)–O(3)	72.56(11)
O(5)–Pb(1)–O(6)	61.32(11)
O(6)–Pb(1)–O(7)	60.83(10)
O(7)–Pb(1)–O(7′)	83.94(9)
Pb(1)–O(7)–Pb(1′)	96.07

The unsymmetrical nature of the coordination sphere of **1** can best be evaluated by comparing it to the structure of the closely related $[Ba(thd)_2(diglyme)]_2$ (**3**) [24] Fig. 3 (thd = ^{t}BuC(O)CHC(O)^{t}Bu). The barium complex not only has the same composition, but the diglyme ligand bridges in a similar $\eta^3{:}\eta^1$ manner. Fig. 3 presents a view of **3** analogous to that of **1**, which shows how the full coordination sphere of a metal can be filled by this ligand set.

The differences in the orientation of diglyme in **1** versus that in **3** can be seen in several structural features. The O(6)–Pb(1)–O(7′) in **1** is 101.68(9)° compared to the analogous angle of 89.4(2)° in **3**. Similarly, the 83.94(9)° O(7)–Pb(1)–O(7′) angle in **1** is wider than the corresponding 64.4(2)° angle between the bridging oxygens and the metal in **3**. These angles show that even though lead is the smaller metal, the diglyme oxygens in **1** bend away from this part of the coordination sphere. In addition, the 2.851(3) Å Pb(1)–O(7) distance of the bridging diglyme oxygen in **1**

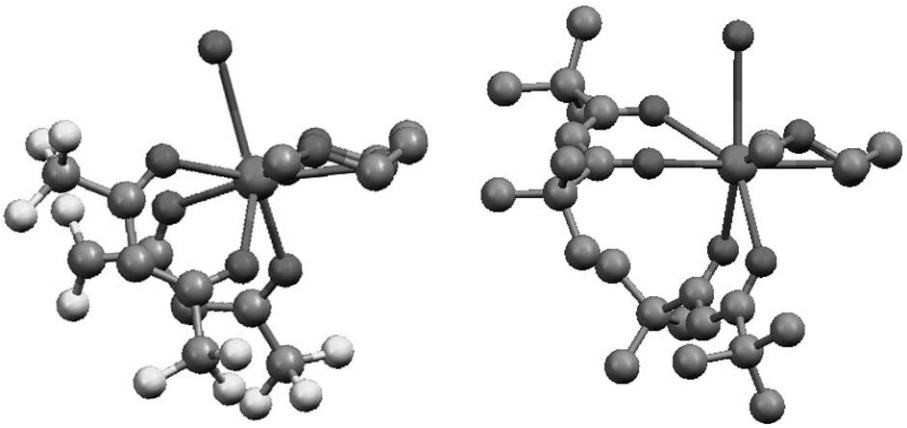

Fig. 3. Comparison of monomer units of $[Pb(hfac)_2(\mu\text{-}\eta^3{:}\eta^1\text{-diglyme})]_2$ (**1**, left) and $[Ba(thd)_2(diglyme)]_2$ (**3**, right). Both views show the coordinated diglyme oxygen in the top center. The barium complex had its ligands oriented more globally around the metal than the lead complex, which has open space in the upper right quadrant.

is much longer than either Pb(1)–O(6) or Pb(1)–O(5) at 2.759(3) and 2.706(3) Å, respectively. In contrast, the Ba–O(diglyme) distances in **3** are in the narrow range of 2.857(6)–2.888(6) Å.

3.3. Stability and volatility of Pb(hfac)$_2$(diglyme) (*1*)

The addition of diglyme to the coordination sphere of Pb(hfac)$_2$ appears to make **1** both more thermally stable and more resistant to coordination of water. Only a simple recrystallization is necessary to obtain a water-free diglyme complex, whereas Pb(hfac)$_2$ will coordinate water, even in the solid state [20]. In addition, crystals of **1** are stable at ambient temperatures for months compared to Pb(hfac)$_2$ which has a more limited lifetime [20].

Complex **1** shows a melting point of 69 °C, which is significantly lower than the 156 °C value of Pb(hfac)$_2$ [9,20]. Consistent with this, the volatility of complex **1** is high: it sublimes at 35 °C (ca 2×10^{-5} Torr). This combination of stability and volatility is not always found with metal hfac complexes [5,6,20,21], although it is consistent with the stabilizing presence of diglyme as a ligand [1–3,25], as in the Ln(hfac)$_3$(diglyme) series.

3.4. Reactivity of *1* with potassium

The addition of potassium to Ln(hfac)$_3$(diglyme) complexes containing both redox active (Eu, Sm, Nd) and traditionally redox inactive (Gd) metals has previously been found to lead to C–F bond activation and cleavage [1] with the formation of fluoride "ate" salts, Eq. (3).

$$2\mathrm{Ln(hfac)_3(diglyme)} + 2\mathrm{K} \rightarrow [\mathrm{LnF(hfac)_3K(diglyme)}]_2 \quad (3)$$

In order to compare this reactivity with that of the lead complex, **1** was treated with K and 18-crown-6 in toluene. The reaction generates a series of color changes

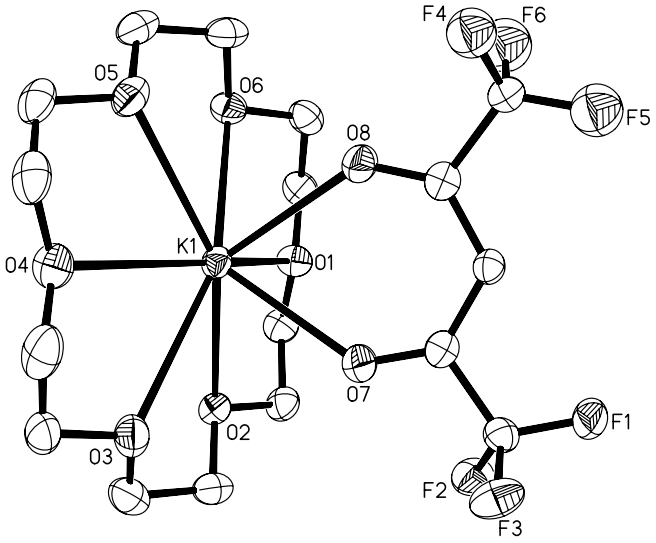

Fig. 4. Thermal ellipsoid plot of the monomer of [(18-crown-6)K(hfac)]$_n$ (**2**) with hydrogen atoms omitted for clarity and ellipsoids drawn at the 50% probability level.

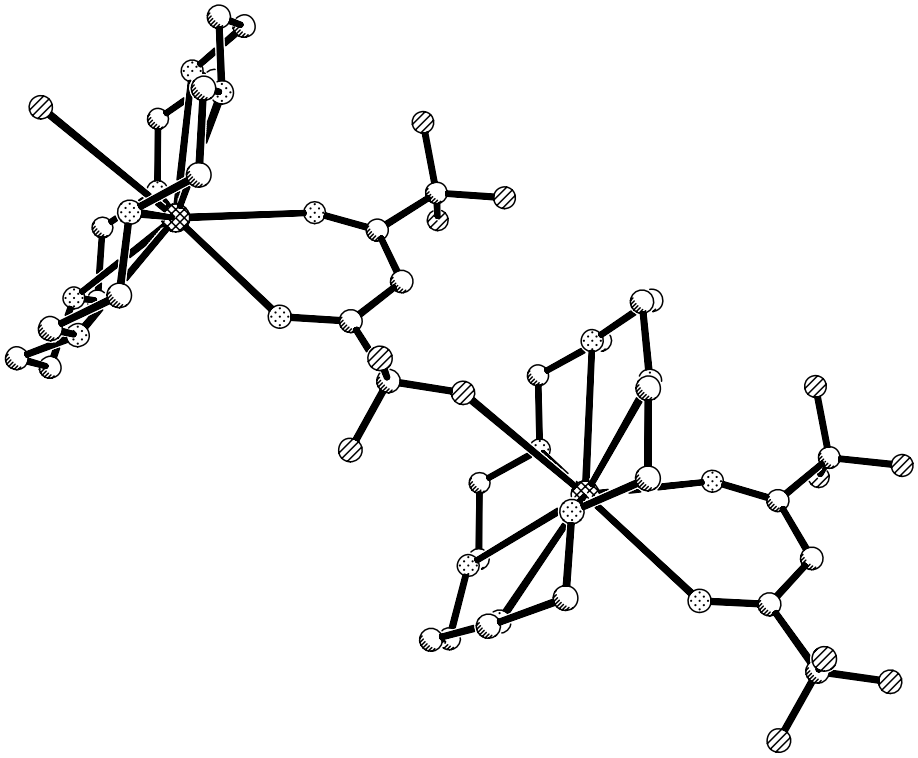

Fig. 5. Ball and stick representation of the polymer chain of [(18-crown-6)K(hfac)]$_n$ (**2**).

Table 3
Selected bond distances (Å) and angles (°) for $[(18\text{-crown-6})K(hfac)]_n$ (**2**)

Compound **2**	
K(1)–O(1)	2.802(3)
K(1)–O(2)	2.898(3)
K(1)–O(3)	2.953(3)
K(1)–O(4)	2.876(3)
K(1)–O(5)	2.864(3)
K(1)–O(6)	2.941(3)
K(1)–O(7)	2.690(3)
K(1)–O(8)	2.770(3)
K(1)–F(5B′)[a]	2.934(7)
K(1)–F(5′)	3.081(6)
O(7)–K(1)–O(8)	65.10(8)
C(17)–F(5)–K(1′)	147.0(4)
C(17)–F(5B)–K(1′)[a]	155.4(5)

[a] F5B is one of the disordered positions of F5.

as well as a complex ^1H NMR spectrum that suggest that this is a complicated reaction system. The only product definitively identified from the mixture was $[(18\text{-crown-6})K(hfac)]_n$ (**2**) which was characterized by X-ray crystallography, Fig. 4. Since K(hfac) is not readily soluble in toluene, the crown ether evidently brought this ligand into solution.

Only one other solid state structure of an 18-crown-6 adduct of a potassium β-diketonate is in the literature: (18-crown-6)K[$Me_3C(O)CHCO_2Et$] [26] (**4**). The K–O (crown ether) distances in **2** and **4** are similar, as are the K–O(acetylacetonate) lengths: 2.690(3) and 2.770(3) Å for K(1)–O(7) and K(1)–O(8), respectively, in **2**, and 2.650 and 2.732 Å in **4**. Complex **2** is different from **4** in that it contains a short F(5B)–K(1′) distance, 2.934(7) Å, that is comparable to the K(1)–O(3) and K(1)–O(6) crown ether distances of 2.953(3) and 2.941(3) Å, respectively. This produces the chain structure shown in Fig. 5. No short intermolecular contacts were found in **4** (see Table 3).

4. Conclusion

An hfac diglyme complex of lead can be prepared from PbO and Hhfac more easily than the analogous syntheses of Ln(hfac)$_3$(diglyme) complexes. The $[Pb(hfac)_2(\mu\text{-}\eta^3{:}\eta^1\text{-diglyme})]_2$ complex exists in the solid state as a dimer of chiral enantiomers connected with the third diglyme oxygen of one unit oriented toward the Pb of the other. Despite the dimeric structure, the complex is quite volatile. Treatment of $[Pb(hfac)_2(\mu\text{-}\eta^3{:}\eta^1\text{-diglyme})]_2$ with K/18-crown-6 forms $[(18\text{-crown-6})K(hfac)]_n$ that exists in the solid state as a linear polymeric chain via CF_3–K interactions.

formed to one in which it is greatly weakened. In this case, even if the lability of the amines is still linearly related to their basicity, the constant *b* for unhindered pyridines, that is their lability, is smaller than the one of other sp^3 aliphatic N-donors bases and evidences have been presented for a significant contribution of a π interaction between the filled d orbitals of the metal and the empty antibonding orbitals of the pyridine ring, that contributes to the stabilization of the ground state of the substrates. This suggestion seems to be in agreement with further deviations observed for pyridines having a *para*-substituent able to contribute to the π system [1,3]. In order to improve these experimental observations and the range of applicability of the proposed interpretation, we have now extended our study to five-membered nitrogen donors (thiazoles and isostructural species such as oxazole, isoxazole, imidazole and pyrazoles) by measuring the kinetics of the forward and reverse steps of the process (1).

$$[Pt(terpy)Cl]^+ + nu \rightleftharpoons [Pt(terpy)(nu)]^{2+} + Cl^- \quad (1)$$

(nu = thiazole, 4-methylthiazole, 4,5-dimethylthiazole, 5-methylthiazole, oxazole, isoxazole, imidazole, 3,5-dimethylpyrazole, pyrazole and only for the reverse reaction 2-aminothiazole and benzothiazole). The kinetics were carried out in methanol at 25 °C in order to directly compare the results with those obtained with other nitrogen donors under the same experimental conditions [3] and to widen and complete our precedent study regarding only two unhindered five-membered N-donors [5]. The great importance of ligand substitution reactions on $[Pt(terpy)L]^{n+}$ substrates is underlined by the recent publication of a number of papers regarding kinetics and mechanism of the reactions between biologically relevant ligands and the $[PtCl(terpy)]^+$ or $[Pt(H_2O)(terpy)]^{2+}$ cations [6–8].

2. Experimental

2.1. Materials

2,2′,6,2″-Terpyridine was purchased from Aldrich. Pure reagent-grade LiCl, CH_3SO_3Na, CH_3SO_3H, $AgClO_4$ (Aldrich) were used without further purification. The thiazoles, oxazole, isoxazole, imidazole and pyrazoles were recrystallized or distilled before use when necessary. Anhydrous MeOH was obtained by distillation over Mg wires, but traces of water did not appear to have any appreciable effect upon the reactions.

2.2. Instruments

Electronic spectra and kinetic measurements were obtained on a Perkin–Elmer Lambda 15 spectrophotometer. ^{1}H NMR spectra were taken on Bruker Avance 300 or Bruker AC 200 spectrometers. Elemental analyses were performed by the Microanalytical Laboratory of the University of Padua.

2.3. Preparation of complexes

$[Pt(terpy)Cl]ClO_4$ was prepared starting from *cis*/*trans*-$[PtCl_2(SMe_2)_2]$ as reported in the literature [9].

All other complexes of the type $[Pt(terpy)(nu)](ClO_4)_2$ (nu = thiazole, 4-methylthiazole, 3,5-dimethylthiazole, 5-methylthiazole, $2NH_2$-thiazole, benzothiazole, oxazole, isoxazole, imidazole, pyrazole and 3,5-dimethypyrazole) were prepared as follows. $AgClO_4$ (0.103 g, 0.5 mmol) was added, under stirring in the dark, to a warm mixture (10 ml, 50 °C) of $[Pt(terpy)Cl]ClO_4$ (0.281 g, 0.5 mmol) in nitromethane. After 10 min, the AgCl formed was filtered off and the solution was treated with 0.5 mmol of the nitrogen ligand, stirred for 15 min and finally diethylether (50 ml) was added. The powdery product precipitated was filtered off, washed twice with diethylether and dried in vacuo. Yields >80% in all cases. Analytical and ^{1}H NMR data for the complexes are collected in Tables 1 and 2, respectively.

^{1}H NMR for coordinated five-membered N-donors are given according to Scheme 1.

2.4. Kinetics

The reactions were initiated by adding a 0.05 mol dm^{-3} dimethylformamide solution (2–20 μl) of the substrate complex, $[Pt(terpy)Cl]^+$ or $[Pt(terpy)(nu)]^{2+}$ to a methanolic solution (3 cm^{-3}) of the appropriate reagent, the nitrogen donor or chloride ion respectively, previously brought to the reaction temperature (25 °C) in a thermostatted cell in

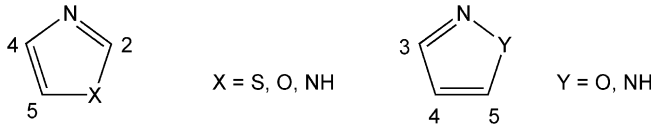
[Pt(terpy)(imidazole)](ClO$_4$)$_2$	^{1}H NMR: 8.57 (t, 1H, $^4J_{H-H} = 1.8$, imidazole-H$_2$); 8.71–7.76 (m, 11H, terpy); 7.72 (dd, 1H, $^3J_{H-H} = 2.4$, $^4J_{H-H} = 1.8$, imidazole-H$_4$); 7.65 (dd, 1H, $^3J_{H-H} = 2.4$, $^4J_{H-H} = 1.8$, imidazole-H$_5$). NH observed in d^6-DMSO, 3.33 ppm, br.
[Pt(terpy)(pyrazole)](ClO$_4$)$_2$	8.70–7.75 (m, 11H, terpy); 8.37 (d, 1H, $^3J_{H-H} = 2.4$, pyrazole-H$_3$); 8.33 (d, 1H, $^3J_{H-H} = 2.4$, pyrazole-H$_5$); 7.46 (s, br, 1H, NH); 7.00 (t, 1H, $^3J_{H-H} = 2.4$, pyrazole-H$_4$)
[Pt(terpy)(3,5-dimethylpyrazole)](ClO$_4$)$_2$	8.72–7.75 (m, 12H, terpy + NH); 6.53 (s, 1H, pyrazole-H$_4$); 2.62 (s, 3H, $^4J_{Pt-H} = 6$, pyrazole-Me$_3$); 2.56 (s, 3H, pyrazole-Me$_5$)

[a] Chemical shifts for ^{1}H NMR are reported by reference to TMS.



Scheme 1. Numeration of the considered five-membered N-donor heterocycles.

the spectrophotometer. The concentration of the entering group was always large enough to provide pseudo-first-order conditions. After preliminary repetitive scan experiments in the range 240–360 nm to search for isosbestic points and spectral changes, the kinetics were studied by measuring the changing absorbance at suitable wavelengths as a function of time. Pseudo first-order-rate constants (k_{obs}/s^{-1}) were obtained either from the gradients of plots of $\log(D_t - D_\infty)$ vs. time or from a non-linear least-squares fit of experimental data to $D_t = D_\infty + (D_0 - D_\infty)\exp(-k_{obs}t)$ with D_0, D_∞ and k_{obs} as the parameters to be optimized (D_0 = absorbance after mixing the reactants, D_∞ = absorbance at completion of the reaction). Rate constants were accurate to within 5%.

All the prepared complexes follow the Lambert–Beer equation in the considered concentration range and experimental conditions, so the presence of π-stacking effects [10] can be reasonably excluded.

3. Results and discussion

Thiazoles, oxazole, isoxazole, imidazole and pyrazoles are potentially ambidentate ligands and it is necessary to ascertain the site of binding to Pt(II) in its complexes, but there is considerable evidence to indicate bonding through nitrogen of which the following are probably the most important: (i) thiazoles and oxazoles bind to the analogous soft d^8 Au(III) through nitrogen [11]; (ii) thiazole ligands were found to be bonded to platinum through the nitrogen atom from data in the literature [12,13]; (iii) further proof of the Pt–N bond comes from the crystal structure of solid *trans*-[Pt(dmso)(thiazole)Cl$_2$] determined by X-ray diffraction [14]; (iv) there is a general similarity of the behaviour of these complexes with the corresponding R-py (N-containing six-membered heterocycles), that depends only upon the basicity of the nitrogen.

3.1. Kinetics of displacement of chloride by nitrogen donors from [Pt(terpy)Cl]$^+$

The spectrophotometric changes observed in repetitive scanning of the spectrum of the reaction mixture are characteristic of a single chemical stage, with well maintained isosbestic points. Careful examination of the spectral changes (subsequent changes have never been observed) which occur after the reagents are mixed and the close similarity of the spectra at the end of the reaction with those of authentic samples of the expected reaction products demonstrate that all the reactions that have been studied kinetically involve the displacement of coordinated chloride by the nitrogen base. The rate constants were determined in the usual way from the change

in absorbance as a function of time at a convenient wavelength within the region 300–340 nm. All the reactions were studied in the presence of a sufficient excess of nucleophile over the substrate to provide pseudo-first-order conditions and the observed rate constants, k_{obs}, collected in Table 3, obey to the general relationship $k_{obs} = k_1^f + k_2^f[nu]$, which is usual for nucleophilic substitution at planar four coordinate d^8 metal complexes [15].

Table 3
First-order rate constants, k_{obs}[a] for the reaction $[Pt(terpy)Cl]^+ + nu \rightarrow [Pt(terpy)(nu)]^{2+} + Cl^-$ in methanol at 25 °C

3.2. Kinetics of displacement of nitrogen donors by chloride from $[Pt(terpy)(nu)]^{2+}$

In all the reactions with an excess of chloride ion the spectrophotometric changes are characteristic of a single chemical stage, with the same isosbestic points observed for the forward reactions. The spectra at the end of the reactions coincide with those of authentic samples of the expected products at the same concentration, so that the displacement of the coordinated nitrogen donor by chloride is assured. The reactions were studied in the presence of 0.05 mol dm^{-3} CH_3SO_3H at constant ionic strength ($I = 0.1$ mol dm^{-3}, CH_3SO_3Na). Preliminary experiments showed that, at constant chloride concentration, the rate of reaction was independent of the concentration of the acid over the range 0.02–0.2 mol dm^{-3}. The acid simply serves to protonate the released nu and to prevent the reverse reaction. For the weakest bases, oxazole and isoxazole, the acid concentration is not sufficient to ensure complete protonation of the released ligand. However, because of their low basicity these species are poor ligands towards Pt(II) complexes and also in these cases a careful comparison of the spectra at the end of the reactions with the spectra of an authentic sample of $[Pt(terpy)Cl]^+$ and nu at the same concentration and acidity confirms the completion of the reactions. The observed rate constants, k_{obs}, collected in Table 4, obey the general relationship $k_{obs} = k_1^r + k_2^r[Cl^-]$, where k_1^r and k_2^r have the usual meaning, and k_2^r values at $I = 0.1$ mol dm^{-3} are reported in Table 5 together with the corresponding values k_2^{0r} extrapolated to zero ionic strength. The extrapolation to zero ionic strength uses the Debye–Hückel relationship, $\log k_2^{0r} = \log k_2^r - 2\alpha ZaZbI^{1/2}/(1 + \beta I^{1/2})$ with $Za = +2$, $Zb = -1$, $\alpha = 1.90$ and $\beta = 1.55$ (estimated from the relative permittivity of methanol at 25 °C). [16] Preliminary experiments showed that the rate of the processes between the monocationic $[Pt(terpy)Cl]^+$ complex and the neutral nitrogen donor is not influenced by primary salt effects over the range 0.0–0.5 mol dm^{-3} ionic strength, whereas that of the reverse reactions between the bis-cationic species $[Pt(terpy)\ (nu)]^{2+}$ and chloride ion depends upon the ionic strength. As a consequence the equilibrium constants, K, also depend upon the ionic strength and in Table 5 the values $K = k_2^f/k_2^r$ and $K^0 = k_2^f/k_2^{0r}$, determined from the ratios of the second-order rate constants for the forward and reverse reactions, are reported.

The data obtained from the reaction $[Pt(terpy)Cl]^+ + nu \rightarrow [Pt(terpy)(nu)]^{2+} + Cl^-$ are compared to the entry of pyridines and other nitrogen donors, under the same experimental conditions [3], and are reported in Fig. 1, where the values of $\log k_2^f$ are plotted against the pK_a of the entering nucleophiles. As far as the unhindered thiazole, 5-methylthiazole, oxazole, isoxazole, imidazole and pyrazole are concerned, it is evident that the data fit quite nicely the linear free-energy relationships $\log k_2^f = 0.23\,pK_a + \text{constant}$ already observed for the entry of unhin-

[a] Errors on individual k_{obs} determinations are in the ±5% range.

dered pyridines on $[Pt(terpy)Cl]^+$ [3], whereas the nucleophilicity is higher ($\Delta \log k_2^f \cong 0.60$, corresponding to a difference of about 3.4 kJ mol^{-1}) and this fact can be reasonably ascribed to the smaller C–N–X (X = C, O, N) angle (≅108°) of the five-membered N-donors with respect to that of the pyridine (C–N–C ≅ 120°), which implies a decrease of congestion in the trigonal bipyramidal transition state. Another difference between the five-membered nucleophiles (unhindered thiazoles, oxazole, isoxazole, imidazole and pyrazoles) and pyridines in the entry reaction is the amount of steric retardation, as measured from the parameter Δ[1] attributable to the presence of a methyl group in the α-position with respect to the N-donor atom. In the case of α-methylpyridines the parameter Δ_{f1} is about 1.5, corresponding to a difference of about 8.6 kJ mol^{-1}, and it reduces to $\Delta_{f2} \cong 0.25$ (1.4 kJ mol^{-1}) for the entry of 4-methylthiazole, 4,5-dimethylthiazole and 3,5-dimethylpyrazole on the same complex.

The amount of steric retardation is related to the free rotation of the ligand molecule around the Pt–N bond, which leads to steric interference with the pyridine rings of the terpy ligand placed in the axial position in the trigonal bipyramidal transition state. For this reason, the differences in reactivity can be explained by considering the different structures of the pyridines compared to that of the five-membered N-donors (Scheme 2), which leads to a decrease in steric congestion in the latter compounds if compared to the former.

As far as the reverse reaction is concerned, the replacement of the N-ligands by Cl^-, the differences between the five-membered heterocycles and the pyridines groups are quite evident. In the replacement reactions of the N-ligand from the bis-cationic Pt-terpy substrate by chloride, the six five-membered N-donors are significantly less labile than the unhindered pyridines (Fig. 2).

The dependence of the lability of the two kinds of ligands upon basicity is almost the same and the data fit nicely the free-energy relationship $\log k_2^r = -0.51\ pK_a$ + constant already reported [3] for the displacement of unhindered pyridines, and the decrease in lability corresponds to a difference of about 3 kJ mol^{-1} between the free energy of activation of the two reacting systems. The lability of the five-membered N-donor heterocycles is considerably lower than that of pyridines, strongly suggesting that, in addition to possible but unlikely solvatation effects, the Pt–N bond in the case of five-membered N-donors may be reinforced by π bonding. It seems reasonable to conclude that the π system of five-membered N-donors can interact in the ground state with the filled d orbitals of Pt(II) better than pyridines. The fact that the thiazoles are weaker σ donors but fairly better π acceptors than pyridines once coordinated to Pt(II) has been pointed out in a work concerning hydrogen isotope exchange in Pt(II)-thiazole systems [18]. Also in the present study, for the pyridines system, the relatively large dependence of the

[1] Δ can be regarded as the steric effect due to the introduction of a methyl group *ortho* to the nitrogen in the entering nucleophiles without any interference from the basicity change that might arise from the presence of the substituent.

Table 5
Second-order rate constants[a] and equilibrium constants for the reaction $[Pt(terpy)Cl]^+ + nu \underset{k_1^r+k_2^r[Cl^-]}{\overset{k_1^f+k_2^f[nu]}{\rightleftharpoons}} [Pt(terpy)nu]^{2+} + Cl^-$

pK_a values were taken from Ref. [17].
[a] Determined by weighted linear regression of k_{obs} values vs. nucleophile concentration.

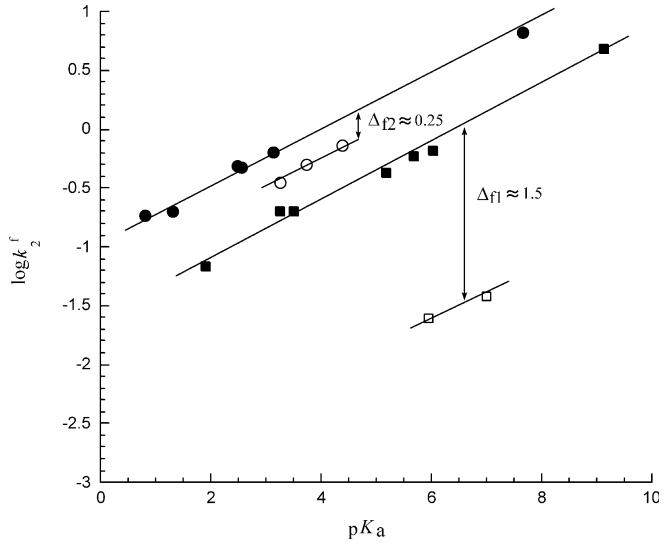

Fig. 1. $\log k_2^f$ for the reaction $[Pt(terpy)Cl]^+ + nu \rightarrow [Pt(terpy)(nu)]^{2+} + Cl^-$ plotted against pK_a of nuH$^+$: ●, oxazole, isoxazole, pyrazole, thiazole, 5-methylthiazole, imidazole; ○, 4-methylthiazole, 4,5-dimethythiazole, 3,5-dimethylpyrazole; ■, 4-cyanopyridine, 4-acetylpyridine, methylisonicotinate, pyridine, 4-methylpyridine, 3-methylpyridine, 4-aminopyridine; □, 2-methylpyridine, 2,4-dimethylpyridine; data for all the pyridines were taken from Ref. [3].

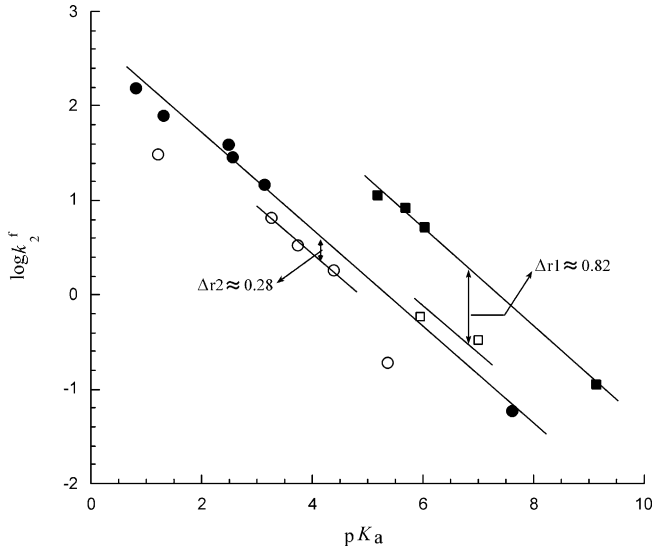

Fig. 2. $\log k_2^r$ for the reaction $[Pt(terpy)(nu)]^{2+} + Cl^- \rightarrow [Pt(terpy)Cl]^+ + nu$ plotted against pK_a of nuH$^+$: ●, oxazole, isoxazole, pyrazole, thiazole, 5-methylthiazole, imidazole; ○, 4-methylthiazole, 4,5-dimethythiazole, 3,5-dimethylpyrazole; ■, pyridine, 4-methylpyridine, 3-methylpyridine, 4-aminopyridine; □, 2-methylpyridine, 2,4-dimethylpyridine; data for all the pyridines were taken from Ref. [3].

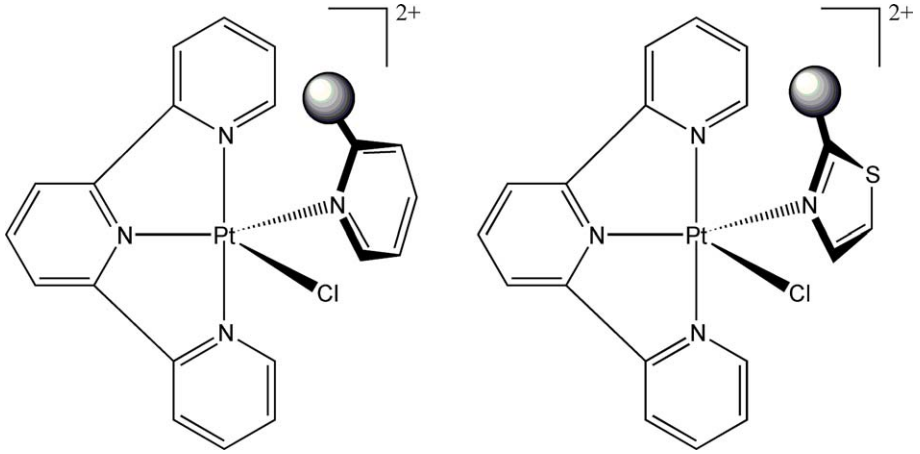

Scheme 2. Steric congestion in the trigonal bipyramidal transition state for substituted pyridines and thiazoles.

substitution lability upon ligand basicity suggests that the formation of the transition state requires a considerable change in the Pt–N bond, confirming therefore the observation already reported [1,4] that the transition state can be described as a structure containing a well formed Pt–Cl bond and a weak Pt–N bond. As far as the lability of hindered five-membered N-donors (4-methylthiazole, 4,5-dimethylthiazole and 3,5-dimethypyrazole) in the reverse reactions of process (1) is concerned, a lower (as expected, see above) steric effect for five-membered N-donors ($\Delta \cong 0.28$, 1.4 kJ mol^{-1}) than for pyridines ($\Delta \cong 0.82$, 4.6 kJ mol^{-1}) has been observed (Fig. 2). Not only α-methyl-substituted five-membered heterocycles, but also other ligands such as 2-aminothiazole and benzothiazole were considered. For these substrates the Δ value is higher (0.70, 3.9 kJ mol^{-1}) than that measured for 4-methylthiazole, 4,5-dimethylthiazole and 3,5-dimethylpyrazole. This difference is due to the greater congestion on the metal centre caused by the NH_2- and benzo-substituents, which disfavours the platinum–chloride bond formation. The ratio between the second-order rate constants for the forward and reverse reactions gives the corresponding equilibrium constants for the systems:

$$[Pt(terpy)Cl]^+ + nu \rightleftharpoons [Pt(terpy)(nu)]^{2+} + Cl^-$$

and the actual values of K at $I = 0.1$ mol dm^{-3} and K^0 at zero ionic strength are reported in Table 5. The plot of $\log K^0$ versus pK_a (Fig. 3) is linear for the group of five-membered N-donors formed by thiazole, 5-methylthiazole, oxazole, isoxazole, imidazole and pyrazole, and the free energy relationship $\log K^0 = (0.74)pK_a + \text{constant}$ can be derived.

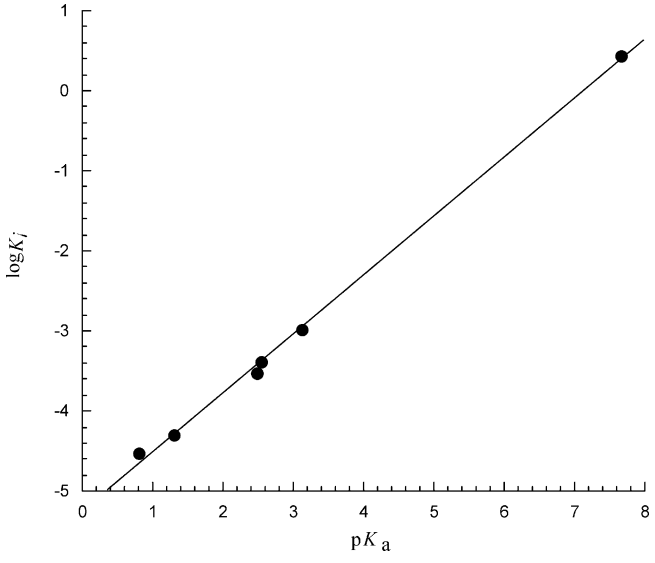

Fig. 3. $\log K^0$ for the reaction $[Pt(terpy)Cl]^+ + nu \rightleftharpoons [Pt(terpy)(nu)]^{2+} + Cl^-$ plotted against pK_a of nuH^+: ●, oxazole, isoxazole, pyrazole, thiazole, 5-methylthiazole, imidazole.

The dependence of the stability of the complexes upon the basicity of the ligands is the same as that measured for pyridines under the same experimental conditions [3]. However, the values of the equilibrium constants are higher than those found in the previous case. Such a difference may reflect a greater tendency of five-membered N-donors, in comparison with pyridines, to give π back-donation from the filled orbitals of the metal to the antibonding orbitals of the ligand, leading to a relative stabilization of the ground state of the products.

produce clusters of Mo(III) magnetically coupled to Ni(II) ions [10]. These clusters show higher magnetic anisotropy and better orbital overlap compared with the analogous compounds containing Cr(III) substituted for Mo(III). Other examples such as 2D $K_2Mn(II)_3(H_2O)_6[Mo(III)(CN)_7]_2 \cdot 6H_2O$ have used $Mo(III)(CN)_7^{4-}$ as a building block [11].

Examples of low-dimensional ruthenium(III) based polymers are rare however, having been limited until very recently [12] to M(II)Ru(III)oxalato complexes (M is a 3d ion) which typically adopt a 2D network [13,14]. Initially the sign of the exchange coupling in the M(II)Ru(III)oxalato complex (M = Cu(II)) was thought not to obey simple symmetry considerations [13], but an alternative interpretation showed that the interaction does indeed conform to symmetry-based expectations [14]. We report here the first example of a structurally characterized 1D cyano-bridged coordination polymer containing Ru(III). The magnetic coupling in this compound conforms to symmetry-based expectations, showing ferromagnetic coupling between Ru(III) and Ni(II). No long-range ordering or slow relaxation of the magnetization was observed above 3 K.

2. Experimental

2.1. General

[Ni(cyclam)]$(ClO_4)_2$ was prepared according to the literature procedure [15]. Mass spectra were obtained by infusing a methanolic solution of the compound into a Varian 1200 L single quadrupole mass spectrometer. Infrared spectra were recorded of KBr pellets using a Biorad FTS-60 FTIR spectrometer. Elemental analyses were performed by Desert Analytics (Tucson, AZ). Variable temperature magnetic susceptibility measurements were taken of powder samples on a Quantum Design MPMS SQUID magnetometer in the temperature range of 2–300 K. Susceptibilities were corrected for the sample holder and the diamagnetism of the sample calculated from Pascal's constants. Heat capacity measurements were performed in zero applied field on a Quantum Design PPMS.

2.2. Synthesis

Na[Ru(salen)$(CN)_2$], (**2**) was prepared according to Leung and Che [16]. IR (KBr pellet) $\nu_{CN} = 2099\ cm^{-1}$. MS (ESI) m/z $(M-Na)^-$ 420.1. *Anal.* Calc. for $C_{18}H_{14}N_4NaO_2Ru \cdot 1.5H_2O$ C, 46.06; H, 3.65; N, 11.94. Found: C, 46.04; H, 3.64; N, 11.67%. Blue crystalline plates of **2** were grown from slow evaporation of a methanolic solution.

[Ru(III)(salen)$(CN)_2$][Ni(II)(cyclam)](ClO_4), (**1**): [Ni(cyclam)]$(ClO_4)_2$ (104 mg; 0.226 mmol) in 5 mL of acetonitrile were added dropwise to a solution of 100 mg (0.226 mmol) **2** in 5 mL of water. The resulting blue precipitate was isolated by centrifugation, washed with water and acetronitrile and dried in vacuo yielding 126 mg **1** (72%). IR (KBr pellet) $\nu_{CN} = 2126\ cm^{-1}$. *Anal.* Calc. for $C_{28}H_{38}ClN_8NiO_6Ru$: C, 43.23; H, 4.92; N, 14.41. Found: C, 43.39; H, 5.11; N, 14.09%. Blue needle-like crystals of **1** suitable for X-ray diffraction resulted from slow diffusion of Ni(II)(cyclam)$(ClO_4)_2$ in acetonitrile into an aqueous solution of **2**.

2.3. X-ray crystallography

Crystallographic data were collected on a Bruker SMART 1000 X-ray diffractometer with CCD detector using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Data sets for **1** and **2** were obtained at 153(2) K. For **2** the data were collected with a θ range of 1.91–29.12°. Data were obtained in 0.3° oscillations with 10 s exposures. For **1**, the θ range for data collection was 1.46–28.65° and data were collected in 0.3° oscillations with 25 s exposures. The crystal-to-detector distance was 50.00 mm with the detector at the 28° swing position for both **1** and **2**. Data were processed using SAINT-NT from Bruker and were corrected for Lorentz and polarization effects. The structures were solved by direct methods [17], expanded using Fourier techniques and refined by full-matrix least-squares on F^2 [18]. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in idealized positions but not refined with the exception of the hydroxyl hydrogen in the methanol solvate of **2** and the hydrogen atoms of the water solvent molecule in **1**. These H-atoms could not be located in reasonable positions. Crystallographic data for **1** and **2** are tabulated in Table 1 with selected bond lengths and angles given in Tables 2 and 3 for **2** and **1**, respectively.

3. Results and discussion

3.1. Synthesis and structural characterization

Crystals of Na[Ru(salen)$(CN)_2$] (**2**) [16] suitable for X-ray diffraction were grown from slow evaporation of a methanolic solution (Tables 1 and 2 and Fig. 1). The sodium counterion interacts with cyanide atom N3#1 from one adjacent Ru(III) complex (at $1-x$, $-1/2+y$, $1/2-z$) and cyanide N4#2 from another nearby Ru(III) complex (at $1+x$, y, z) giving rise to a 2D layered structure (Fig. 2). As a result, the C17–Ru1–C18 angle is 172.88(7)°, while Ru1–C17–N3 and Ru1–C18–N4 display angles of 170.45(16)° and 172.18(16)°, respectively. The coordination sphere of sodium is completed by salen oxygens O1 and O2 and a methanol solvent molecule. Comparison with *trans*-NBu_4[Ru(III)(salen)$(CN)_2$] shows the significant distortion arising from the sodium counterion. As a tetrabutylammonium salt, there is no interaction between Ru(III) centers resulting in nearly linear angles for C17–Ru1–C18 (178.3(7)°), Ru1–C17–N3 (178(1)°), and Ru1–C18–N4 (176(1)°) [12]. The Ru–C and C≡N bond lengths for **2** fall within the range observed by Yeung et al.

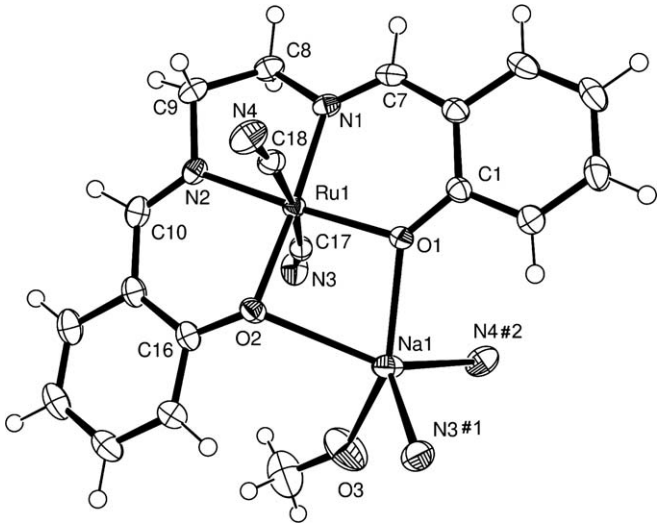

Fig. 1. Thermal ellipsoid (50%) plot of **2** · MeOH.

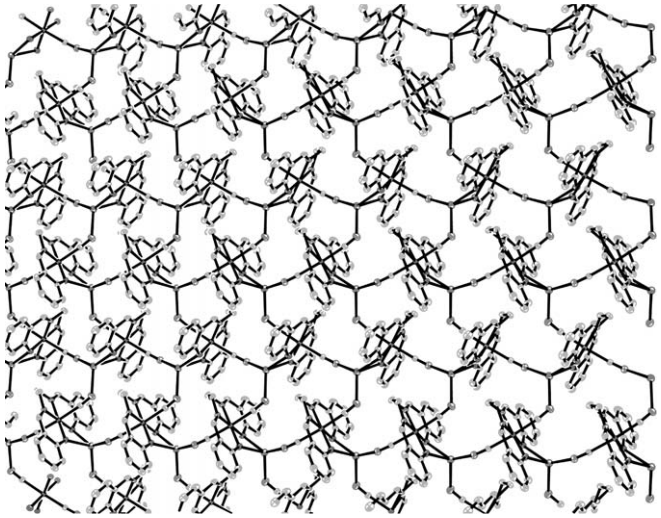

Fig. 2. View of 2D plane of **2** · MeOH with MeOH solvates removed for clarity. The 2D network lies in the plane defined by the crystallographic *a* and *b* axes.

Reaction of equimolar Ni(II)(cyclam) perchlorate [15] in solvents such as water, acetone and acetonitrile with **2** in water resulted in immediate precipitation of a fine steel blue particulate of formulation [Ru(III)(salen)(CN)$_2$][Ni(II)-(cyclam)](ClO$_4$) (**1**). X-ray quality needles of **1** resulted from slow diffusion of Ni(II)(cyclam)(ClO$_4$)$_2$ in acetonitrile into an aqueous solution of **2** (Tables 1 and 3, Fig. 3). The C≡N stretching frequency shifts to higher energy from 2099 cm^{-1} in **2** to 2126 cm^{-1} in **1**, with concomitant bond shortening of the cyano moiety from 1.153(2) Å for N3–C17 and 1.150(2) Å for N4–C18 in **2** to 1.135(6) and 1.144(5) Å, respectively, in compound **1**. These results are comparable to that seen by Yeung et al. upon addition of $NiCl_2$ and cyclam to $Ru(acac)_2(CN)_2^-$ and are consistent with N coordination to the Ni(cyclam) subunit. The Ru1–C17 distance in **1** is 2.058(4) Å while Ru1–C18 is similar to that in **2** at 2.072(4) Å. Around Ni, the Ni1–N3 distance is 2.080(4) Å while Ni2–N4 is 2.134(4) Å. With the exception of Ni2–N4, these distances are identical to those reported for the trimeric Ni(cyclam)[Ru(acac)$_2$(CN)$_2$]$_2$ [12].

The presence of the perchlorate anion results in a deviation from linearity of the –(Ru–CN–Ni–NC)– fragment giving rise to two different Ni(II) sites. The two Ni atoms lie on independent inversion centers. Along the metal cyanide axis, the Ni1 site is nearly linear with an angle of 175.6(4)° between Ni1–N3–C17 and an angle of 179.6(4)° between N3–C17–Ru1. The analogous measurements around Ni2 display a more bent shape with 159.9(4)° for Ni2–N4–C18 and 173.5(4)° between N4–C18–Ru1.

3.2. Magnetic properties

The results of variable temperature magnetic susceptibility measurements performed on powder samples of compounds **1** and **2** in a field of 1 kOe are shown in Fig. 4. At room temperature $\chi_M T$ for **2** is 0.51 cm^3 mol^{-1} K, considerably higher than the calculated spin-only value of 0.38 cm^3 mol^{-1} K for $S = 1/2$, but comparable to other monomeric Ru(III) complexes such as *trans*-Ph$_4$P[Ru(III)(acac)$_2$(CN)$_2$] [19] and Ru(III)(acac)$_3$ [20]. The shape of the curve closely resembles that observed for *trans*-Ph$_4$P[Ru(III)(acac)$_2$(CN)$_2$] and polymeric [CoCp$_2$*][ZnRu(ox)$_3$] [13], all of which display a gradual decrease in $\chi_M T$ from 300 K to approximately 15 K with a subsequent steep drop below 15 K. Correction for a temperature independent paramagnetism (TIP) contribution of 5×10^{-4} cm^3 mol^{-1} renders $\chi_M T$ independent of temperature from 300 to 100 K with a value of 0.36 cm^3 mol^{-1} K in agreement with the spin only value. As noted by Coronado et al. [13], the low temperature behavior below 15 K arises from spin–orbit coupling and incomplete quenching of the orbital contribution to the magnetic moment and can cause difficulties in the interpretation of susceptibility data containing Ru(III) ions as seen below.

For chain **1**, $\chi_M T$ is 1.57 cm^3 mol^{-1} K at 300 K, higher than the calculated spin only value of 1.38 cm^3 mol^{-1} K for uncorrelated $S = 1$ Ni(II) and $S = 1/2$ Ru(III) ions, but in good agreement with the calculated result of 1.51 cm^3 mol^{-1} K using the data obtained for **2**. Applying the same TIP correction used in the analysis of **2** gives a $\chi_M T$ of 1.42 cm^3 mol^{-1} K at 300 K but does not remove the minimum at 55 K. The presence of the minimum would seem to indicate an antiferromagnetic interaction between Ru(III) and Ni(II). This conclusion was drawn from simi-

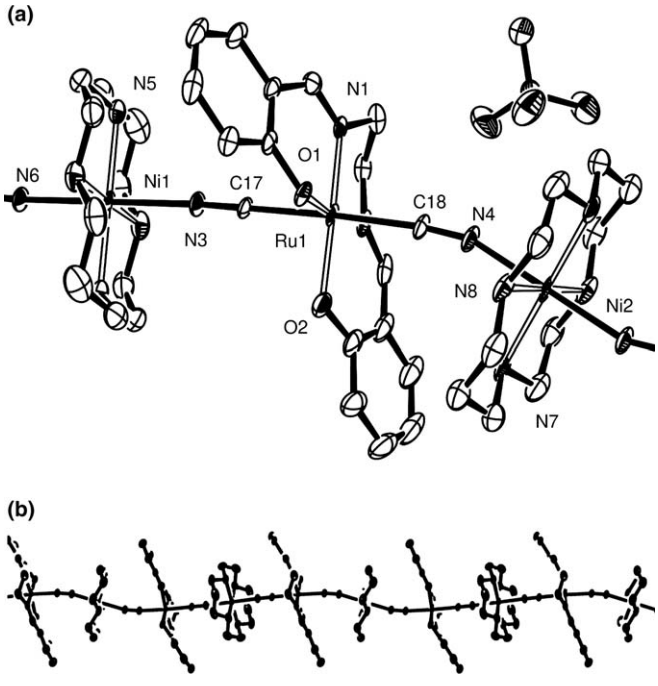

Fig. 3. (a) Thermal ellipsoid plot (50%) of [Ru(III)(salen)(CN)$_2$][Ni(II)-(cyclam)](ClO$_4$) · H$_2$O · MeCN (**1** · H$_2$O · MeCN). Water and MeCN solvates and hydrogen atoms have been removed for clarity. (b) View of cationic portion of **1** · H$_2$O · MeCN perpendicular to crystallographic *a* axis showing several repeat units. The chain axis runs along the vector difference of the crystallographic *b* and *c* axes.

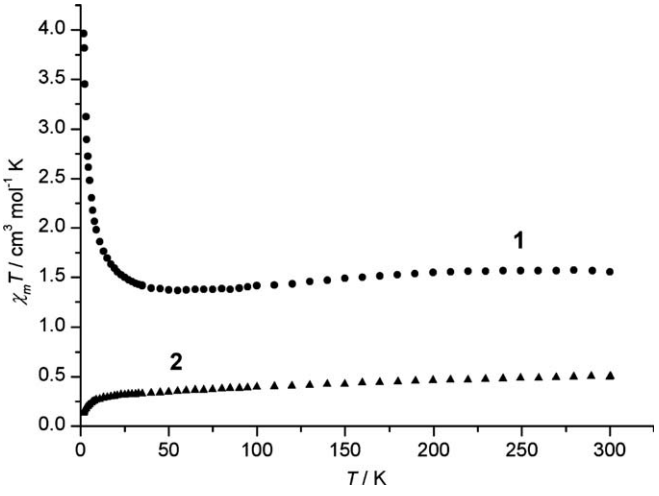

Fig. 4. The product of temperature and magnetic susceptibility as a function of temperature for compounds **1** and **2** in the range of 2–300 K at an applied field of 1 kOe. TIP correction is not included.

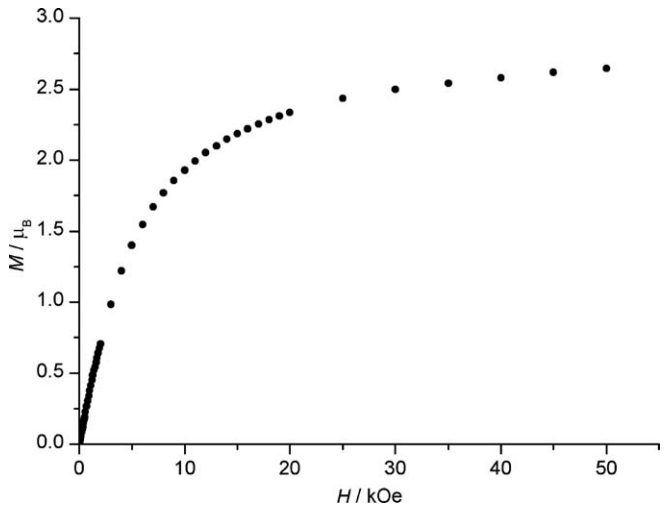

Fig. 5. Magnetization of **1** as a function of applied field at 2.0 K.

lar data by Kahn and co-workers for the 2D (NBu_4)-[Cu(II)Ru(III)$(ox)_3$] framework [14]. An alternative interpretation that appears to be more applicable in this case attributes the minimum to the anisotropic Ru(III) ion and indicates that the type of coupling must be determined through examination of the low temperature field-dependent magnetization data [13].

The magnetization of **1** as a function of applied field at 2 K is depicted in Fig. 5. At 50 kOe, the magnetization is nearly saturated with a value of 2.46 μ_B. The calculated saturation magnetization (M_s) for a spin-only system consisting of ferromagnetically coupled Ni(II) ($S = 1$) and Ru(III) ($S = 1/2$) is 3 μ_B. Antiferromagnetic coupling of the two ions results in a calculated M_s of 1 μ_B. The experimentally observed value clearly indicates ferromagnetic coupling, a conclusion that agrees with the results of Coronado et al. and with the expected orthogonality of magnetic orbitals between Ni(II) and Ru(III) [12,13]. The lower than expected saturation value can be attributed to the Ru(III) ion [13,20].

Zero-field cooled (zfc) and field-cooled (fc) magnetization experiments performed on **1** in applied fields of 3 and 50 Oe show no inflection point and little difference down to 3 K. These measurements indicate a lack of any type of long-range magnetic order above 3 K. Further evidence for the absence of 3D ordering above 2 K is given by the lack of a λ-peak in the heat capacity measurements of **1** indicating that there is no magnetic phase transition. Compound **1** displays negligible hysteresis at 2 K.

Although **1** does not display slow relaxation of the magnetization above 3 K, the salen ligand is readily amenable to synthetic modification which could be used to affect the magnetism of the compound through changes in the electronics at the Ru(III) center. It is interesting to note that a similar species, Ni(cyclam)[$Ru(acac)_2(CN)_2]_2$, is trimeric [12], reflecting the marked effect small structural changes can have on the dimensionality of the resulting mixed metal system. The current results demonstrate that Ru(III) can be incorporated into a 1D coordination polymer and provide further evidence that simple symmetry considerations can be used to predict whether the ion will display a ferro- or antiferromagnetic exchange interaction.

Acknowledgement

We acknowledge Dr. Oleksandr Chernyashevskyy for assistance with the magnetic measurements. This research was supported by NIH R01-A147003.

Appendix A. Supplementary material

Crystallographic data for structural analysis (cif files for the two structures) have been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033 or e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk. the effect of different transition metal ions (Co^{3+} and Ni^{2+}), *trans*-ligands (NO_2^- and Cl^-) and length of the alkylene bridge ($n = 2$ and $n = 4$) were studied. Therefore four complexes were synthesized and characterized by crystal structure, ^{1}HNMR and FTIR spectra.

2. Experimental

2.1. Materials and instruments

All chemicals are commercially available (CarloErba Co., Fluka, Sigma, BDH chemical Co., EKA Nobel. AB Co., May&Baker LTD., Merck Co. and Mallinck vodt Co.) and were used without further purification. All X-ray data were collected on a Siemens-Smart CCD Diffractometer. Magnetic susceptibility measurements were carried out at room temperature on a magnetic susceptibility balance model Magway MSB Mk1. The infrared spectra were measured as KBr disks on a Perkin–Elmer Model system 2000 spectrophotometer. Proton NMR were recorded on a JEOL Model INM-A500 FTNMR 500 MHz spectrometer with deuterated-chloroform (d^1-$CHCl_3$) as solvent for complexes **1** and **2**, deuterated DMSO (d^6-DMSO) for EnH_2 and complex **3**, deuterated acetone (d^6-acetone) for BnH_2 and complex **4**, and TMS was used as an internal standard.

2.2. Syntheses

2.2.1. 3,3′-(1,4-Butanediyldinitrilo)bis(2-butanone)-dioxime(BnH_2)

Ligand BnH_2 was prepared using the method described in the literature [24,25], with a slight modification. 2,3-Butanedione (20.23 g, 0.20 mole) in 50 ml of methanol was added to 1,4-diaminobutane (10.00 ml, 0.10 mole). The resulting solution was stirring at room temperature. After 15 min, a white solid precipitated. It was then isolated by vacuum filtration and washed with cool methanol, then diethyl ether and dried in a desiccator. The yield was 76%. BnH_2 has a melting point of 148–150 °C (the literature value is 149–151 °C). This ligand was identified by infrared and NMR spectra which gave a good agreement with the literature data [24]. The proton NMR spectral data are listed in Table 5.

2.2.2. 3,3′-(1,2-Ethanediyldinitrilo)bis(2-butanone)-dioxime(EnH_2)

This ligand was prepared by a similar procedure as BnH_2 using 1,2-diaminoethane instead of 1,4-diaminobutane. Its melting point is 160–161 °C. The proton NMR spectral data are listed in Table 5.

2.2.3. Complex **1**: trans-dinitro(3,3′-(1,4-butanediyldinitrilo)bis(2-butanonedioximato)cobalt(III), [Co(BnH)(NO_2)$_2$]

Solid BnH_2 (1.26 g, 5.0 mmole) was added to an aqueous solution of hydrated cobalt(II) chloride (1.19 g, 5.0 mmole in 10 ml. water). Sodium nitrite solution (0.77 g, 11.0 mmoles in 5 ml of 1 mmole sodium hydroxide) was added to the Co–BnH_2 solution. After bubbling air through the mixture for 3 h with stirring, a yellow-orange precipitate was obtained. The precipitate was collected, washed with cool water, then with diethylether and dried in a desiccator. The yield was 43%. The yellow-orange single crystal was crystallized from a mixture of water:acetone (1:3). *Anal*. Calc. C, 35.62; H, 5.24; N, 20.79. Found: C, 36.32; H, 5.14; N, 21.55%.

2.2.4. Complex **2**: trans-dichloro(3,3′-(1,4-butanediyldinitrilo)bis(2-butanonedioximato)cobalt(III), [Co(BnH)Cl_2]

Solid BnH_2 (1.26 g, 5.0 mmole) was added to cobalt(II) chloride hexahydrate (1.19 g, 5.0 mmole) in 15 ml of methanol. The mixture was stirred at room temperature with air bubbling, giving a dark green precipitate. The green solid was collected, washed with cool methanol, then with diethyl ether and dried in a desiccator. The yield was 43%. The dark green single crystals were crystallized from a mixture of water:acetone (1:3). *Anal*. Calc. C, 37.62; H, 5.52; N, 14.62. Found: C, 38.14; H, 5.45; N, 14.99%.

2.2.5. Complex **3**: trans-dichloro(3,3′-(1,2-ethanediyldinitrilo)bis(2-butanonedioximato)cobalt(III), [Co(EnH)Cl_2)]

Cobalt(II) chloride hexahydrate in 10 ml of methanol was added to a hot methanol solution of EnH_2 (1:1 molar ratio). The mixture was stirred at room temperature with air bubbling, giving a dark green precipitate. The precipitate was collected by filtration, washed with ethanol, then diethyl ether and dried in a desiccator. The dark green crystals were crystallized from a mixture of water:acetone (1:3). *Anal*. Calc. C, 33.82; H, 4.83; N, 15.77. Found: C, 33.93; H, 4.51; N, 15.99%.

2.2.6. Complex **4**: 3,3′-(1,4-butanediyldinitrilo)-bis(2-butanonedioximato)nickel(II)perchlorate, [Ni(BnH)]ClO_4

The ligand BnH_2 was added to a water:acetone mixture (1:3) containing nickel(II) chloride ($NiCl_2$) (1:1 molar ratio). This mixture was stirred until the solution was homogeneous. An aqueous solution of sodium perchlorate was added to the reaction mixture and stirred well. After the reaction mixture was allowed to stand at room temperature for 2 days, orange-red crystals formed. The crystals were collected and dried in a desiccator. *Anal*. Calc. C, 35.03; H, 5.14; N, 13.62. Found: C, 34.97; H, 5.12; N, 13.23%.

2.3. X-ray crystallographic analyses

The diffraction data for all complexes with appropriately sized crystal were collected at 298(2) K on a 1K BRUKER SMART CCD area detector diffractometer using ω rotation scans with a scan width of 0.3° and graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). For data

collections and data integration, the SMART and SAINT programs were used [26] and empirical absorption correction was done by using the program SADABS [27]. The structures were solved by direct methods using the SHELXTL program system [28] and were refined by full-matrix least-squares first with isotropic and then with anisotropic thermal parameters for all non hydrogen atoms. For all complexes the hydrogen atoms were located from a Fourier difference map and refined. Two oxygen atoms in the perchlorate ions were disordered, as can be recognized from the large values of the temperature factor. They were not refined anisotropically. Crystal data and refinement results of all the complexes are listed in Table 1. Selected bond lengths and bond angles for complexes **1**–**4** are summarized in Table 2.

3. Results and discussion

3.1. Crystal structures of the complexes

Complex **1**, $[Co(BnH)(NO_2)_2]$, and complex **2**, $[Co(BnH)Cl_2]$, are isomorphous, crystallizing in the orthorhombic system whereas complex **3**, $[Co(EnH)Cl_2]$, crystallizes in the monoclinic system. Complex **1** is a neutral mononuclear cobalt(III) complex. The distorted octahedron about the cobalt is completed by two *cis* oxime nitrogens, two *cis*-imine nitrogens and two nitro ligands in *trans* positions (Fig. 1). All atoms on the square planes are almost coplanar. The molecule consists of two five-membered imineoxime chelate rings and one seven-membered butylene chelate ring. Two nitro groups are in a staggered configuration. The bond length of Co—N(5) is shorter than that of Co—N(6) and the N(5)—Co—N(6) angle is 177.05(17)°. In one nitro group the N(5)—O(3) and N(5)—O(4) bond lengths are quite different (1.228(6) and 1.179 (6) Å) while in the other nitro group the N—O bond lengths are similar (1.217(5) and 1.226(5) Å). The shorter Co—N(5) bond distance brings one nitro oxygen atom close to the diiminedioxime square plane so that weak hydrogen bonding between the nitro oxygen and oxime hydrogen occurs. Consequently the intramolecular hydrogen bonding between *cis* oxime groups becomes weakened. A short intramolecular hydrogen bond with an O—O distance of 2.434(5) Å for this complex was observed.

The crystal structure of complex **2** consists of a neutral distorted octahedrally coordinated cobalt(III) complex (Fig. 2). There are two molecules per asymmetric unit. These two molecules are not related by any symmetry. The cobalt atom is coordinated to four nitrogen atoms of the diiminedioxime ligands and two *trans* chloro ligands, resulting in a distorted octahedral geometry. The square plane about the cobalt is slightly distorted as evident by the result of the least square plane analysis. One set of *trans*-nitrogens are below the best plane through the cobalt and four diiminedioxime nitrogens while the other set are above this plane, within 0.0240. The Co—Cl bond lengths are slightly different. No weak interaction between the chloro ligand and oxime hydrogen was observed. This complex exhibits an intramolecular hydrogen bond with an O—O distance of 2.423(4) Å in molecule 1 and 2.414(3) Å in molecule 2. This is similar to that observed for $[Co(BnH)Cl_2]$ reported by Choo [29].

In $[Co(EnH)Cl_2]$ the octahedron about the cobalt is completed by four nitrogens of the tetradentate ligand and two *trans*-chloro ligands (Fig. 3). The four Co—N bond lengths are shorter than those in $[Co(BnH)Cl_2]$, but the Co—Cl bond lengths are longer. The average

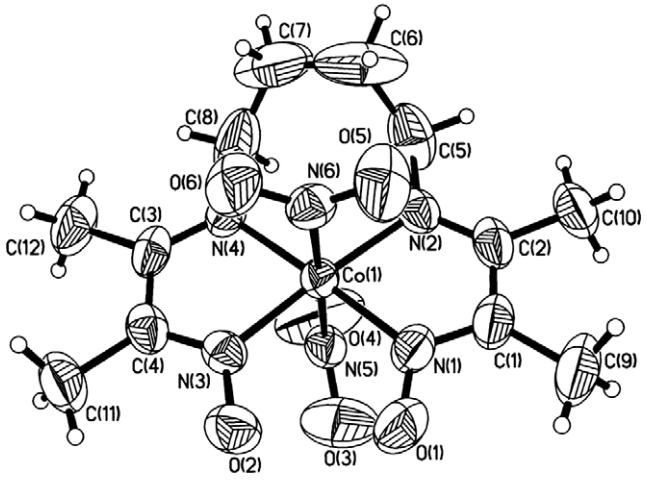

Fig. 1. Perspective view of $[Co(BnH)(NO_2)_2]$ (**1**), showing thermal ellipsoids (50% probability) and atom labelling.

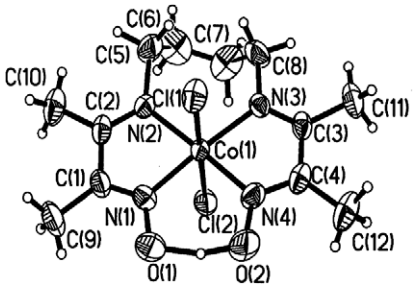

Fig. 2. Perspective view of $[Co(BnH)Cl_2]$ (**2**) showing thermal ellipsoids (50% probability) and atom labelling.

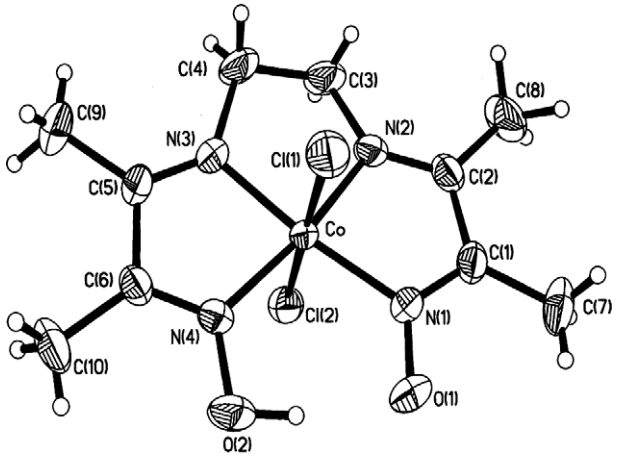

Fig. 3. Perspective view of $[Co(EnH)Cl_2]$ (**3**) showing thermal ellipsoids (50% probability) and atom labelling.

Co—$N_{(imine)}$ and Co—$N_{(oxime)}$ bond distances of $[Co(BnH)(NO_2)_2]$ and $[Co(BnH)Cl_2]$ in this study are the longest among diiminedioxime cobalt(III) complexes. A similar result was found in the diaminedioxime complexes. This is probably indicative of a weaker metal—ligand interaction in the BnH_2 complex compared with the EnH_2 and $PreH_2$ complexes. The shortest metal—nitrogen bond distances exhibited by EnH_2 suggested that this ligand forms the strongest complex with Co(III). This might be expected on the basis of chelate effects exerted by the three five-membered chelate rings in the EnH_2 complex as compared to a combination of one six-membered and five-membered chelate rings in the $PreH_2$ complex, and one seven-membered and two five-membered chelate rings in the BnH_2 complex. On the basis of cobalt—nitrogen bond distances, the relative ligand field strength of diiminedioximes for complex formation would be $EnH_2 > PreH_2 > BnH_2$ (similar to EnAO > PnAO > BnAO). In the sequence of the EnH_2, $PreH_2$ and BnH_2 complexes, the O—O distances and $N_{(oxime)}$—Co—$N_{(oxime)}$ bond angles decrease, but the $N_{(imine)}$—Co—$N_{(imine)}$ bond angles, and Co—$N_{(imine)}$ and Co—$N_{(oxime)}$ bond distances increase. Similar results were observed in EnAO, PnAO and BnAO complexes [16–21]. The $N_{(imine)}$—Co—$N_{(imine)}$, $N_{(oxime)}$—Co—$N_{(oxime)}$ and $N_{(oxime)}$—Co—$N_{(imine)}$ bond angles in this study are very close to the corresponding angles in $[Co(BnH)Cl_2]$ [29]. The longest O—O distance of 2.708(2) Å is found in $[Co(EnH)Cl_2]$ indicating no weak intramolecular hydrogen bonding. The elongation of the O—O distances in the diiminedioxime complexes of Co(III) agrees with the degree of constraint of the alkylene bridge between the two imine nitrogens. The degree of constraint follows the order: $BnH_2 < PreH_2 < EnH_2$. In $[Co(BnH)Cl_2]$ the butylene bridge between the two imine-nitrogens imposes less constraint on the ligand resulting in a larger $N_{(imine)}$—Co—$N_{(imine)}$ angle when compared to $PreH_2$ and EnH_2 complexes which impose more constraints on the complex geometry. Consequently the $N_{(imine)}$—Co—$N_{(imine)}$ angle for the $[Co(EnH)Cl_2]$ complex is smaller than that of $[Co(BnH)Cl_2]$. Hence, the longest O—O distance of 2.708 (2) Å is found in $[Co(EnH)Cl_2]$.

The crystal structure of $[Ni(BnH)]ClO_4$ consists of a distorted square planar $[Ni(BnH)]^+$ cation and a perchlorate

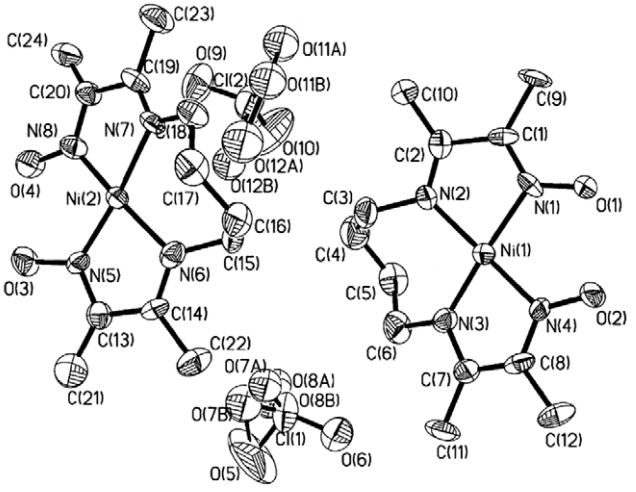

Fig. 4. Perspective view of $[Ni(BnH)]ClO_4$ (**4**) showing thermal ellipsoids (50% probability) and atom labelling for nonhydrogen atom.

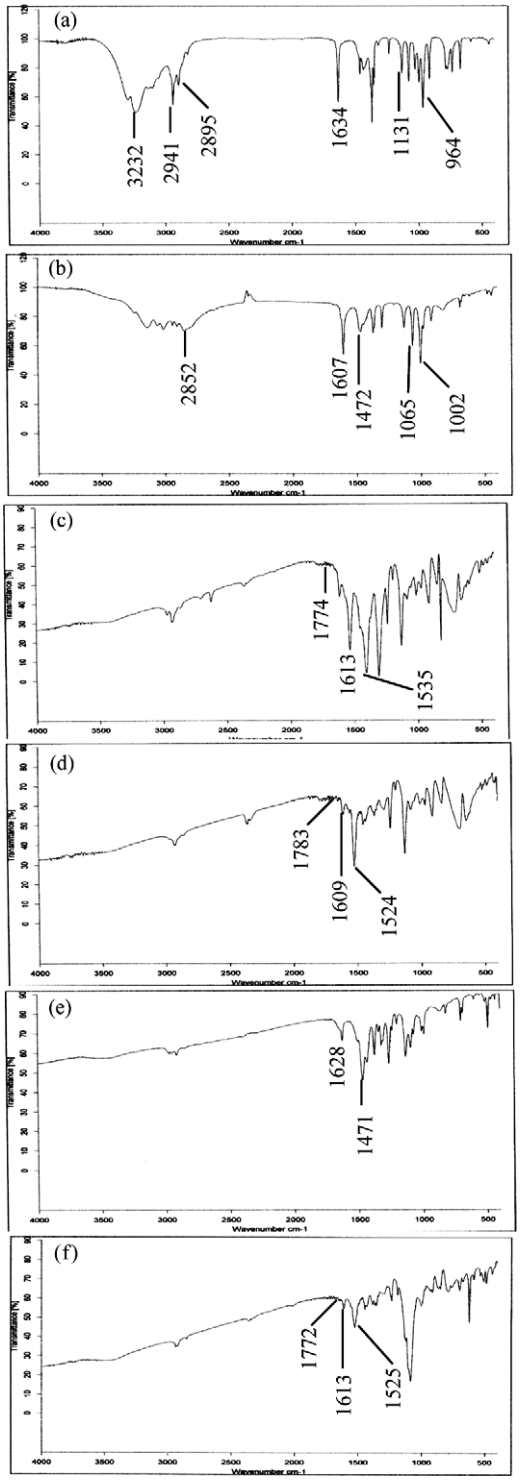

Fig. 5. FTIR spectra of (a) BnH_2 (b) EnH_2 (c) $[Co(BnH)(NO_2)_2]$ (d) $[Co(BnH)Cl_2]$ (e) $[Co(EnH)Cl_2]$ and (f) $[Ni(BnH)]ClO_4$.

counter ion (Fig. 4). There are two molecules per asymmetric unit. A least squares plane through the nickel and the four coordinate nitrogens show that two *trans*-nitrogens are above the plane, within 0.150 Å, and the other two *trans*-nitrogen are below the plane, within −0.170 Å. The O—O distances for complex **4** are 2.390(9) in molecule 1 and 2.473(8) Å in molecule 2. The average O—O distance 2.432 Å is about the same as those of $[Co(BnH)(NO_2)_2]$ and $[Co(BnH)Cl_2]$. Therefore changing Co^{3+} to the Ni^{2+} ion does not play a pronounced effect on the O—O distance. It is due to the comparable size of Co^{3+} (69 pm) and Ni^{2+} (63 pm) ions [30].

$[Co(EnAO)(NO_2)_2]$[b]	2.554 (6)	7.35	1720	[20]
$[Co(EnH)Cl_2]$	2.708 (2)			this work

[a] Crystallizes as two molecules per asymmetric unit.
[b] EnAO, PnAO and BnAO are the abbreviation of the corresponding diaminedioxime.

3.2. Magnetic susceptibility

The square planar geometry around Ni^{2+} in $[Ni(BnH)ClO_4]$ is also evident by the magnetic measurement. According to the valence bond theory, the Ni^{2+} hybridization is dsp^2 meaning that there is no unpaired electron. The measured χ_g, χ_m and μ_{eff} values for this complex are 9.29×10^{-7} c.g.s, 3.82×10^{-4} and 0.9939 BM, respectively. The calculated number of unpaired electron is zero.

3.3. Infrared spectra

The vibrational frequencies for particular bonds in the free ligand and the complexes are summarized in Fig. 5. When the complex is formed, two C=N bonds are distinguishable. Two $\nu_{C=N}$ are observed at lower frequencies than that in the free ligand, supporting the coordination at oxime and imine nitrogens (Table 3). The vibrational frequencies for weak intramolecular hydrogen bonding ν_{OHO} in the complexes occur at 1772–1783 cm^{-1}, as observed in other diiminedioxime complexes (Table 4). For $[Co(EnH)Cl_2]$, no peak was observed in this region indicating that no intramolecular hydrogen bond was formed. It was found that the O—O distances vary inversely with the ν_{OHO} value.

3.4. Nuclear magnetic resonance spectra

The proton NMR peaks for $[Co(BnH)Cl_2]$ exhibits downfield shifts when compared to the corresponding peaks for $[Co(BnH)(NO_2)_2]$ (Table 5). This may be due to the inductive effect of the chloride compared to the nitro group [31]. The intramolecular hydrogen bridge proton between two oxime groups is expected to resonate at a very low field as reported for other diaminedioxime and diiminedioxime complexes [1–22]. The signals at 19.03, 19.58 and 18 ppm are assigned to the hydrogen bridge protons in complexes **1**, **2** and **4**, respectively. No oxime hydrogen bridge proton signal is observed in the $[Co(EnH)Cl_2]$ spectrum. This is probably indicative of an exchange phenomena taking place in the complex. The oxime hydrogen easily exchanges with the water hydrogen (solvent impurity) and exchange is so rapid that no hydrogen proton resonance is detected.

Table 5
^1H NMR spectral data for the free ligands and complexes **1**–**4** δ (ppm)

		Solvent	a	b	c	d	e
	BnH_2	d^6-acetone	1.79	3.46	2.00	2.01	10.43
	EnH_2	d^6-acetone		3.69	1.88	2.01	11.43
	$[Co(BnH)(NO_2)_2]$	d^1-$CHCl_3$	1.91	4.12	2.49	2.54	19.03
	$[Co(BnH)Cl_2]$	d^1-$CHCl_3$	2.33	4.24	2.57	2.60	19.58
	$[Ni(BnH)]ClO_4$	d^6-acetone	2.0	3.6	2.1	2.2	18.0

Consequently, the signal collapses with the water hydrogen signal. There is no correlation between O—O distance and oxime hydrogen signal (Table 4).

4. Conclusions

Comparison of crystal structures for diiminedioxime (BnH_2 and EnH_2) complexes of Co(III) and Ni(II) indicates that introduction of a propylene bridge opposite the hydrogen bond imposes no significant constraint but the ethylene bridge impose significant constraint. Hence the O—O distance of $[Co(EnH)Cl_2]$ is much longer than those for $[Co(BnH)(NO_3)_2]$ and $[Co(BnH)Cl_2]$. Due to the comparable size of Co^{3+} and Ni^{2+} there is no pronounced effect on the O—O distance. The observed O—O distances for $[Co(BnH)(NO_3)_2]$ are longer than that for $[Co(BnH)Cl_2]$ due to the presence of a weak interaction between the nitro oxygen and oxime hydrogen. The ν_{OHO} frequencies of all the complexes were observed at 1772–1783 cm^{-1}. A decrease in the O—O distance tends to shift the ν_{OHO} band to high energy. The proton NMR spectra of all the complexes shows all methyl and methylene protons resonances with the expected chemical shifts and integrated intensities. The intramolecular hydrogen bond proton resonance appears at 19.03 ppm in $[Co(BnH)(NO_3)_2]$, 19.58 ppm in $[Co(BnH)Cl_2]$ and 18 ppm in $[Ni(BnH)ClO_4]$. It was found that there is an inverse relationship between the O—O distances and ν_{OHO} but no relationship between the O—O distance and oxime proton resonance.

5. Supplementary data

CCDC Nos. 294384 – 294387 contain the supplementary crystallographic data for this paper. The data can be obtained free of charge from the CCDC, 12 Union Road, Cambridge CB2, 1EZ, UK, fax: +44 1223 336 033; or e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk on request.

used as received without further purification. Infrared spectra were recorded on a Nicolet AVATAR 360 FT-IR instrument as KBr plates. Elemental analysis (C, H, N) was performed with Element Analysis system EA 1112 CE Instruments by the Korea Basic Science Institute.

2.2. Synthesis of $[Fe(btp)Cl_3]_n$ (1)

A solution of $FeCl_3 \cdot 6H_2O$ (0.015 g, 0.052 mmol) in acetone (20 ml) was allowed to diffuse into a solution of btp (0.0106 g, 0.05 mmol) in CH_2Cl_2(20 ml) slowly. After a few weeks, green crystals were separated and air-dried. Yield: 0.014 g (74.6%, based on btp). $C_9H_7Cl_3N_7Fe$ (375.42): Calc. C 50.70, H 3.31, N 45.99%; Found: C 50.35, H 3.40, N 45.96%. Selected IR data (cm^{-1}): 3137 (m), 3106 (m), 1604 (s), 1585 (s), 1522 (s), 1469 (s), 1444 (m), 1366 (m), 1283 (m), 1212 (s), 1137 (s), 1064 (m), 810 (m), 775 (m), 670 (m), 639 (m).

2.3. Crystal structure and determination

X-ray diffraction measurements were performed on a Bruker SMART diffractometer equipped with CCD area detector with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 233(2) K for **1**. The reflections were successfully indexed by an automated indexing routine built in the SMART program [10]. The solution was solved by direct methods and refined by full-matrix least-squares calculations on F^2 with SHELX-97 [11]. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were located in the calculated positions using the riding model. Crystallographical data and refinement details for **1** are listed in Table 1.

3. Results and discussion

2,6-Bis(*N*1-1,2,4-triazolyl)pyridine (btp) is a versatile ligand which has the potential to show various coordination modes: bridging two metal centres, chelating a metal ion as a terdentate ligand or functioning with the two cases simultaneously [9].

The reaction of btp with an equivalent of $FeCl_3 \cdot 6H_2O$ afforded 1D infinite chains. The btp ligands connect the ferric centres as shown in Fig. 1. Even when 1:2 or 1:3 ligand-to-metal ions ratios were employed, only the 1:1 mol ratio complex **1** was obtained. X-ray single crystal structure analysis [12] of complex **1** reveals that the geometry of the iron centre has a trigonal bipyramidal environment comprising two nitrogen atoms located on the apical sites and three chloride ligands occupying three vertices of a trigonal plane. To the best of our knowledge, there are only two examples of which the structures are fully characterized with the TBP geometry on the ferric centre; $[Fe(N_3)_5]^{2-}$ [12] and $FeCl_3(4\text{-cpy})_2$(4-cpy = 4-cyanopyridine) [13]. Until now no more TBP ferric complexes have been observed.

The average Fe–Cl bond length of 2.214(2) Å is similar to those found in $FeCl_3(4\text{-cpy})_2$[2.215(1) Å]. The deviation of Cl–Fe–Cl and N–Fe–N angles from ideal D_{3h} point symmetry is commonly observed in the case of the TBP MX_3L_2 system. The Fe–N bond lengths of 2.162(2) and 2.189(6) Å are shorter than those in $FeCl_3(4\text{-cyb})_2$ [2.214(3) and 2.231(3) Å] [13]. This is partly because the nitrogen atoms of triazole experience less steric repulsion against Cl ligands in approaching the iron centre due to a

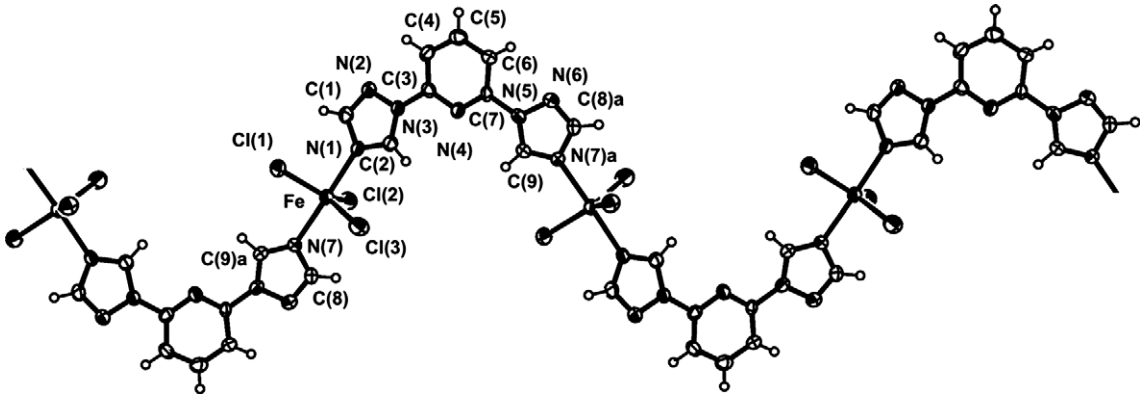

Fig. 1. 1-D zigzag chain of complex **1**. Symmetry code (a): $-x$, $0.5 + y$, $0.5 - z$.

Table 2
Selected bond lengths (Å) and bond angles (°) for **1**

Fe–N(1)	2.162(6)	Fe–N(7)	2.189(6)
Fe–Cl(1)	2.210(2)	Fe–Cl(2)	2.219(2)
Fe–Cl(3)	2.213(2)	Cu1–O4	1.979(2)
N(1)–Fe–N(7)	177.3(2)	Cl(1)–Fe–Cl(2)	127.85(9)

small inner angle of the triazole ring compared with pyridine. The selected bond lengths and angles are listed in Table 2.

As shown in Fig. 2, the stacking pattern of the 1D chains implies that there are non-classical C–H···Cl hydrogen bonds, which get 1D chains to form a 2D architecture. The chloride ligand (Cl(2)) bound to the ferric ion pro-

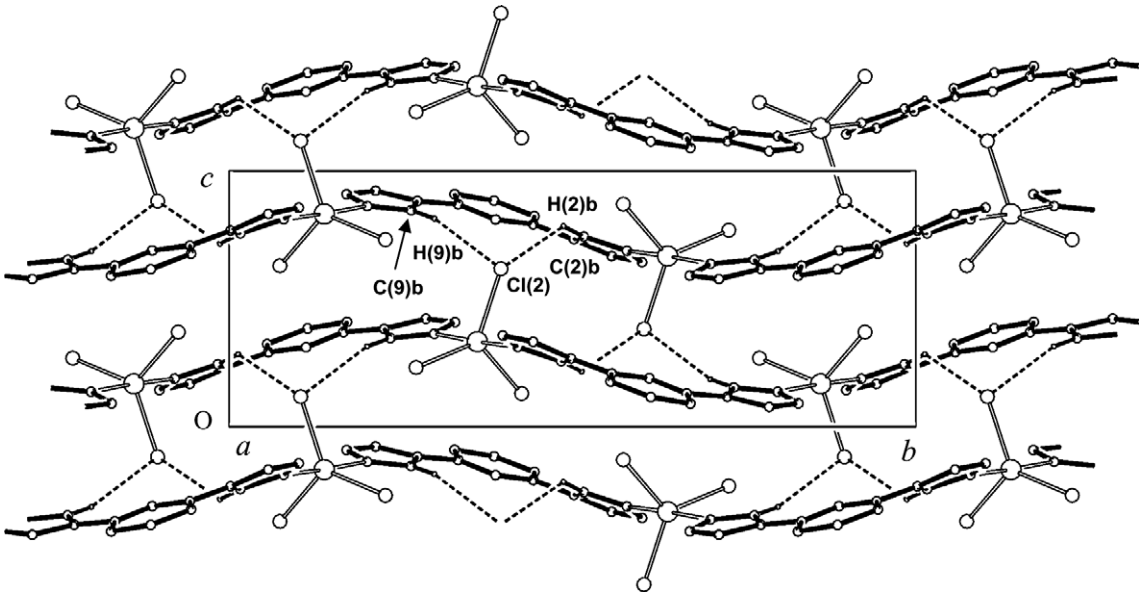

Fig. 2. Stacking diagram of **1** parallel to *x*-axis. C–H···Cl hydrogen bonds are represented as dashed lines. All hydrogen atoms except H(2) and H(9) and C–H···N hydrogen bonds are omitted for clarity. Symmetry code (b): $-x$, $1-y$, $1-z$.

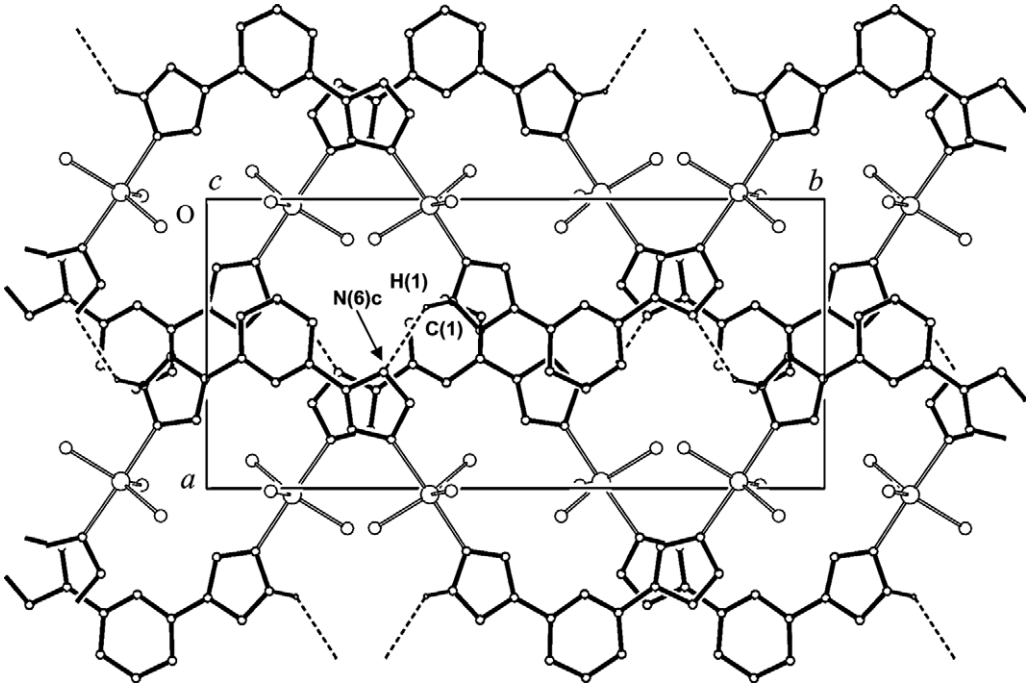

Fig. 3. Stacking diagram of **1** parallel to *z*-axis. C–H···N hydrogen bonds are represented as dashed lines. All hydrogen atoms except H(1) and C–H···Cl hydrogen bonds are omitted for clarity. Symmetry code (c): $1-x$, $-0.5+y$, $0.5-z$.

trudes into the inter-space of 1D chains along the *c*-axis so as to participate in bifurcated hydrogen bonding with two C–H groups *ortho* to the nitrogen atoms, leading to the 2D brick wall architecture. The C–H···Cl interaction is reasonably regarded as hydrogen bonding nature [4,8]. As far as we are aware, C–H units *ortho* to nitrogen frequently function as hydrogen donors and form weak hydrogen bonds with halogen atoms. In these cases, the H···Cl distances fall below the sum of van der Waals radii (2.95 Å) and the C–H···Cl angles are larger than 130°. The H···Cl distances of 2.74 and 2.80 Å and the C–H···Cl angles of 134.7° and 163.6° are in the compatible range of those reported previously [5,6,8].

On the other hand, 1D zigzag chains propagate along with the crystallographic *c*-axis as shown in Fig. 3. These sinusoidal chains are linked to one another via the C–H···N hydrogen bonds. C–H units make the hydrogen bonds with two nitrogens (N(6)) of triazole rings belonging to neighbouring chains, showing a distance of 2.48 Å and C–H···N angle of 132.0°. These values lie in the range considered as C–H···N hydrogen bonds [14]. At last, the 2D sheet parallel with the [0 0 1] plane results as depicted in Fig. 3.

Consequently, 1D sinusoidal chains formed by coordination bonds are connected with one another by two kinds of non-classical hydrogen bonds, resulting in the 3D architecture.

it was found that paramagnetic centers interact through extended bridging ligands, other applications are optic, electronic materials [17–20], ion exchange, catalysis and separation [21,22].

In the present work, we have used the *p*-aminobenzoate ligand (PAB) to prepare a 1D nickel polymer. The ligand contains a carboxylate group that can act as terminal or bridging, monodentate or bidendate, and also a monodentate amino group in the para position. The crystal structures of some *p*-aminobenzoate metals complexes have been previously determined. The studies demonstrate different ligating behavior of the *p*-aminobenzoate ion, indicating rich coordination chemistry for the complexes from monomeric to polymeric structures. In the complex bis(*p*-aminobenzoato)zinc hydrate $[Zn(4\text{-}NH_2C_6H_4COO)_2]_n \cdot 1.5nH_2O$, the zinc atoms are in a distorted tetrahedral coordination with two N atoms and two O atoms from four aminobenzoate groups, which link the complex into a polymeric structure [23]. The coordination number of lead is 6 in $[Pb(4\text{-}NH_2C_6H_4CO_2)_2]_n$. The carboxylate groups form chelate rings to the lead atom, other groups bridge two metal atoms. The nitrogen atoms of amine groups are not coordinated to the lead atom [24]. While in $[Pb(4\text{-}NH_2C_6H_4CO_2)NO_3]_n$, additional coordination by three oxygen atoms from two nitrate groups and a nitrogen atom from the amino group of PAB brings the coordination number of the lead atom to 8 [25]. The molecular structure of silver(I) *p*-aminobenzoate $[4\text{-}NH_2\text{-}C_6H_4CO_2Ag]$ consists of two types of polymeric chains: the silver atoms are linked by CO_2 groups in the first type, while in the second type the silver atoms are linked by both CO_2 and NH_2 groups of PAB [26]. Both cobalt atoms of $[Co(4\text{-}NH_2C_6H_4CO_2)_2(H_2O)_4]$ and manganese atoms of $[Mn(4\text{-}NH_2C_6H_4CO_2)_2(H_2O)_4]$ are in distorted octahedral coordination with four oxygen atoms from four H_2O molecules, and two oxygen atoms from PAB are *trans* to each other [27,28]. The nickel atoms of the diaquabis(*p*-aminobenzoato)nickel(II) complex occupy centers of symmetry and are coordinated to two oxygen atoms and two nitrogen atoms of both *p*-aminobenzoate molecules in addition to two water molecules, H-bonding makes the structure polymeric [29]. The dimer $[Cu(4\text{-}NH_2C_6H_4CO_2)(phen)(H_2O)]_2\text{-}(NO_3)_2 \cdot 2(4\text{-}NH_2C_6H_4CO_2H) \cdot 2H_2O$ has been synthesized and its X-ray structure studied (phen = phenanthroline). The dimer results through bridging of two symmetrically related *p*-aminobenzoate molecules by bidentate carboxylic groups giving a Cu–Cu distance of 3.060 Å [30].

Although the molecular structures of the above compounds have been well determined, their magnetic properties remain unexplored. Only the dimer $[Cu(p\text{-}NH_2\text{-}C_6H_4CO_2)(phen)(H_2O)]_2(NO_3)_2 \cdot 2(4\text{-}NH_2C_6H_4CO_2H) \cdot 2\,H_2O$ was characterized by EPR spectra and by magnetic measurement [30]. Excellent luminescence properties were obtained for rare-earth Eu^{3+} and Tb^{3+} complexes with *p*-aminobenzoic acid and phenanthroline incorporated into a silica gel matrix [31]. The formation constants of *p*-aminobenzoic acid with the metals Be^{2+}, Zn^{2+}, Fe^{3+}, Th^{4+} and Zr^{4+} have also been determined using potentiometric techniques [32].

As part of our investigations into the synthesis of new polymeric complexes containing the *p*-aminobenzoate ligand, a crystal of the title compound **1** was obtained and its structure, magnetic and thermal properties were studied. The formation constant and thermodynamic parameters of Ni(II) with *p*-aminobenzoic acid were also evaluated.

2. Experimental

2.1. Synthesis of $[Ni(4\text{-}NH_2C_6H_4CO_2)_2\text{-}(CH_3OH)_2] \cdot CH_3OH$ (1)

$NiCl_2 \cdot 6H_2O$ (0.56 g, 2.36 mmol) in methanol (25.0 ml) was added to sodium 4-amino benzoate (0.75 g, 4.70 mmol) in methanol (50.0 ml). The mixture was refluxed for 2 h. Light green crystals of **1** were formed within one week. The typical yield was 95% based on $NiCl_2 \cdot 6H_2O$. *Anal.* Calc. for $C_{17}H_{24}N_2NiO_7$: C, 47.81; H, 5.67, N, 6.56. Found: C, 46.60; H, 5.54; N, 6.72%.

IR (KBr): 3493.2 (m), 3368.9 (m), 3297.3 (m), 3265.9 (m), 3186.4 (m), 2956.7 (w), 2831.3 (w), 1604.7 (s), 1525.6 (s), 1430.2 (m), 1386.7 (s), 1303.8 (w), 1240.1 (m), 1180.4 (m), 1143.7 (w), 1095.5 (w), 1040.5 (m), 1016.4 (m), 970.1 (m), 851.4 (m), 785.0 (m), 698.2 (w), 632.6 (w), 588.2 (w), 559.3 (w), 515.0 (w), 430.1 (w).

2.2. Potentiometry

The potentiometric measurements were carried out using Denver instrument Model 225 pH – ion selective electrode meter fitted with a combined glass electrode (reading to ±0.01 pH unit). The cell compartment was kept constant by using a thermostatic Model Heto HMT 200 in the temperature range 20–40 °C (±0.01 °C). The K_a values of *p*-aminobenzoic acid (PABH) and the stability constants with nickel were computed using an acid–base titration technique in 50% ethanol with ionic strength 0.30 M KCl [33]. The dissociation constant was determined by titrating 50.00 ml of the acid (1.00×10^{-3} M) versus standard NaOH (1.00×10^{-2} M). The stability constant at each temperature was computed from the obtained K_a values and pH readings of the titration of a 50.00 ml solution of nickel(II) ion (5.00×10^{-4} M) with PABH ligand (1.00×10^{-3} M) versus 1.00×10^{-2} M NaOH solution.

2.3. Physical measurements

Elemental analysis of C, H, N was performed at the Elemental Analysis Lab – University of Surrey. Infrared data were collected on a Schimadzu 8300 FTIR spectrophotometer using the KBr pellet method. The magnetic susceptibility of crystalline samples was measured on an Oxford Maglab 2000 magnetic measurement system. Diamagnetic corrections were applied using Pascal's constants. Thermal

analysis was performed on a Setaram-Labsys instrument using the TG-DTA module. The heating rate was 7 °C/min. Dry nitrogen was passed over 15 mg of the sample placed in a platinum crucible.

2.4. Crystallography

2.4.1. X-ray experiment

A pale blue-green prismatic crystal of the complex having approximate dimensions of $0.20 \times 0.12 \times 0.08$ mm was mounted on a glass fiber. All measurements were made with graphite monochromated Mo Kα radiation. Cell parameters were obtained from 2359 reflections with θ ranging from 2.67° to 28.31°. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the angle $\theta_{max} = 28.31°$. The structure was solved using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atom positions were calculated using a riding mode and were refined isotropically. A summary of data collection and structure refinement is given in Table 1, and selected bond lengths and bond angles are given in Table 2.

2.4.2. Data collection

3. Results and discussion

3.1. Description of the structure

3.1.1. One-dimensional linear chain structure

The title compound $[Ni(4\text{-}NH_2C_6H_4CO_2)_2(CH_3OH)_2] \cdot CH_3OH$ (**1**) consists of Ni(II) atoms linked by PAB ligands into one-dimensional chains. The repeating unit of **1** with the atom numbering scheme is shown in Fig. 1. Each unit of **1** contains one Ni(II) center with a N_2O_4 binding set in which the Ni(1) atom coordinates to two oxygen atoms O(4) and O(4A) of carboxylate groups of two PAB anions in a monodentate fashion, two nitrogen atoms N(1) and

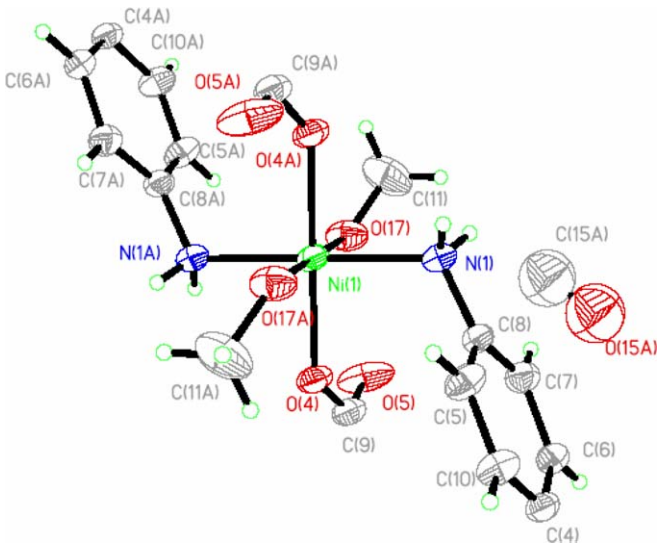

Fig. 1. Thermal ellipsoids of the repeat unit structure of compound **1**.

N1(A) of amino groups from two different PAB ligands, and two methanol oxygen atoms O(17) and O(17A). Ni(1) is thus in an elongated octahedral environment in a *trans* configuration with two long Ni–N(amino) bonds 2.1557(17) Å, two short Ni–O(methanol) bonds 2.0686(15) Å, and two short Ni–O(carboxylate) bonds 2.0432(13) Å.

Each of the *trans* bonds N(1)–Ni(1)–N(1A), O(4)–Ni(1)–O(4A), O(17)–Ni(1)–O(17A) in compounds **1** are linear with coordination angles 180.00(7)°, while the *cis* bonds in **1** form coordination angles ranging from 85.69(7)° to 94.31(7)°. The aromatic rings of two facing bridging PAB ligands are planar to one another with an angle of 180.00° (see Fig. 2). The nitrogen atom of the NH_2 group and carbon atom of the CO_2 group of PAB are not coplanar with the aromatic ring, instead the N and C atoms are bent out of the aromatic plane by 6.27° and 5.70°, respectively, towards the side of the nickel atoms. The rotation angle of the phenyl group relative to the CO_2 moiety in PAB is $\phi_{rot} = 3.12°$, Fig. 2.

The bidentate PAB ligands doubly bridge the metal ions forming infinite ribbons along the crystallographic *a*-axis. Within these ribbons the Ni–Ni distance is 9.090 Å, Fig. 2. Each of the nickel atoms in a central chain has eight neighboring nickel atoms, two from each of the four adjacent chains. The separating distances between interchain nickel atoms are 7.90 and 9.40 Å. Fig. 3 shows the chains in a cross-sectional view down the *a*-axis on the *bc* plane. The chains are packed in an –ABAB– stacking sequence along the *b*-axis on the *ab* plane, Fig. 4. The lattice includes methanol molecules occupy space between the parallel chains, Figs. 1 and 3. The guest methanol molecules are disordered and the two orientations are well resolved hinting at statistical disorder.

A linear 1D chain structure closely related to compound **1** is $[Ni(imbz)_2(H_2O)_2]_n$, where $imbz^- =$ the 4′-(imidazol-1-ylmethyl)benzoate anion. The two nickel(II) atoms, with a distance of 10.91 Å, are connected by two imbz ligands resulting in a dinuclear macrocyclic framework [34]. Another 1D chain structure is $[(\mu_{N,S}\text{-}SCN)_2\{Ni(ampy)\}]_n$ in which each nickel(II) ion is linked to two of its neighbors by two end-to-end μ-thiocyanato ligands. The neighbor Ni···Ni intrachain distance is 5.684(2) Å and the shortest Ni···Ni interchain separation is 6.833(4) Å [35]. The 1D polymeric structure of the nickel azido pyrazolate complex contains alternating dinickel(II) building units in which both pyrazolate and μ-1,3 azido bridge two metal ions in one dinuclear unit and a double μ-1,3 azido linkage bridge the next dinuclear unit resulting in two intrachain nickel···nickel distances of 4.469 and 5.183 Å [36].

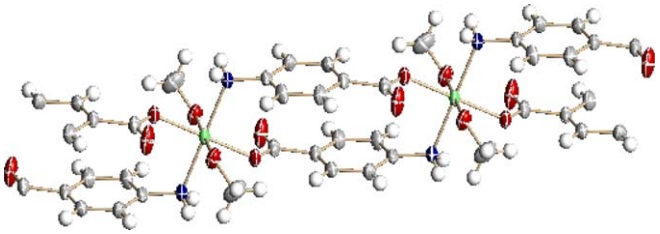

Fig. 2. View of the chain in **1** propagating along the *a*-axis.

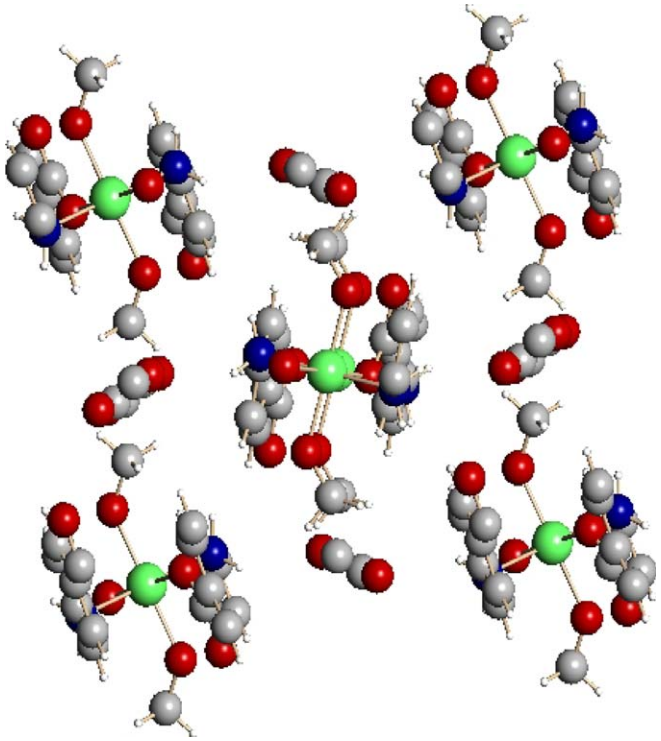

Fig. 3. Cross-sectional view of **1** down the *a*-axis on the *bc* plane. Each chain is surrounded by four other chains.

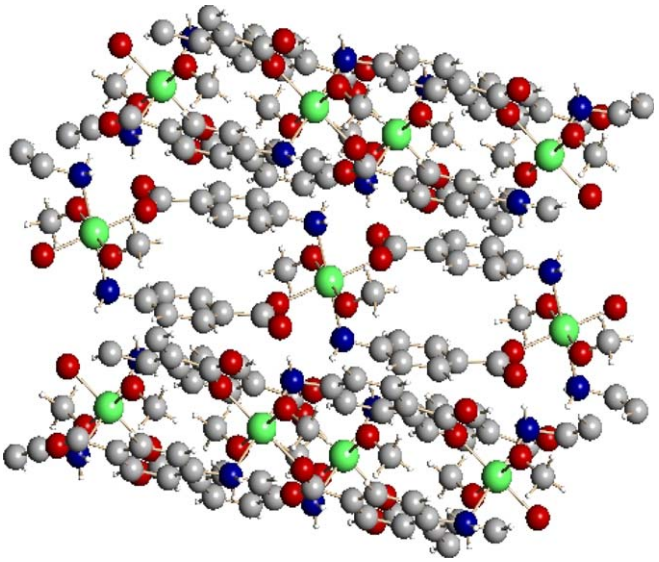

Fig. 4. View down the *c*-axis on the *ab* plane. The chains are packed in **1** in an ABAB fashion along the *b*-axis.

3.1.2. H-bonds

There is a short distance between O(17) of a coordinated methanol and O(5) of the carboxylate group of a PAB ligand: (O5···O17 = 2.563 Å), which suggests the presence of an intrachain H-bond. Each Ni octahedral unit is

involved in four interchain H-bonds. Thus each chain of type I interacts by H-bonds with four chains of type II forming a 3D network structure. Atom N(1) of an amino group of one Ni octahedral unit acts as a H-bond donor via H(1A) to O(5) of the carboxylate group of a second Ni octahedral unit. The bonds distances and angles involved in H-bonds are: N(1)···O(5), 2.979 Å; H(1A)···O(5), 2.250 Å; N(1)–H(1A)···O(5), 137.76°, Fig. 5.

3.1.3. π–π Interactions

Intrachain π–π interactions are observed between the aromatic rings of two *p*-aminobenzoate ligands bridging two adjacent nickel atoms. The aromatic rings are parallel displaced in an offset or slipped arrangement and have a centroid separation of 3.920 Å. The interplanar spacing is 3.607 Å. The interplanar angle between the arene rings is 180.00°, Fig. 6. The obtained distance between the arene rings is in agreement with the experimental value of 3.66 Å, measured for π–π stacking in a copper *p*-chlorobenzoate complex. The interaction energy for the parallel *p*-chlorobenzoic acid dimer complex is calculated to be 5.1 kcal mol^{-1} [37]. π–π Stacking interactions govern the self-assembly of a variety of complexes and interlocked molecular compounds. It occurs between π-donors rings (electron-rich) and π-accepting ring (electron-deficient) [38,39]. It is also observed between similar aromatic rings [37,40–44].

The aromatic rings in the chain are slipped so that the carboxylate group of one ring overlaps the facing ring at the edge carrying the NH_2 group. Carboxylate and amine substituents perturb the uniform charge distribution in benzene. Partial atomic charges and permanent dipoles result which introduce electrostatic dipole–dipole and dipole-induced dipole π–π interactions. Also π–σ attractions can dominate between the positively charged hydrogen atoms and the π-electrons of the rings. These van der Waals interactions are attractive and their potentials fall off rapidly with distance, $1/r^6$. The attractive forces overcome the π–π Pauli repulsions in an offset π-stacked geometry (Hunter–Sanders rule). Pauli repulsion is caused by the filled electron clouds of interacting molecules that overlap at short distances [38,43]. The separation of 3.607 Å of the rings in complex **1** falls in the usual range (3.3–3.8 Å), and it is the result of medium π–π interactions. The order of stability in the interaction of two π systems is π-deficient–π-deficient > π-deficient–π-rich > π-rich–π-rich [43]. The presence of the two substituents, carboxylate (electron-acceptor) and amine (electron-donor) in PAB of compound **1** causes an intermediate π-electron density ring and therefore intermediate π–π interactions.

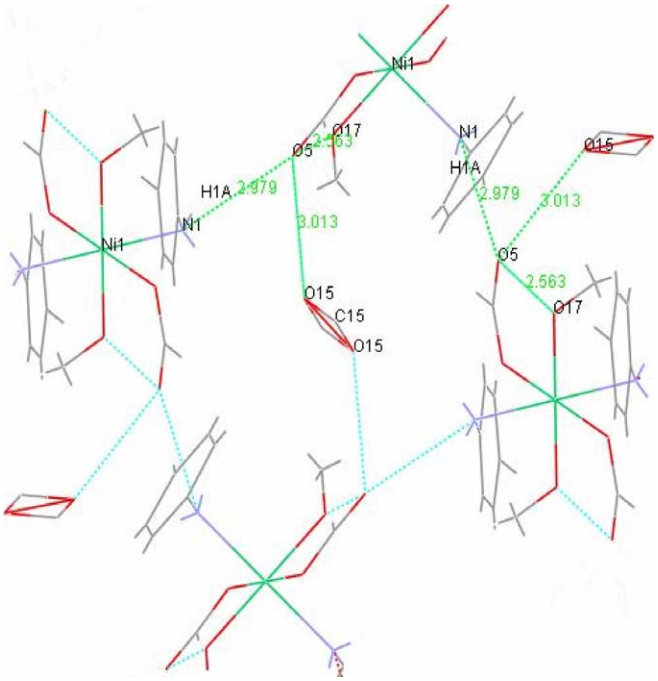

Fig. 5. H-bonding in **1**.

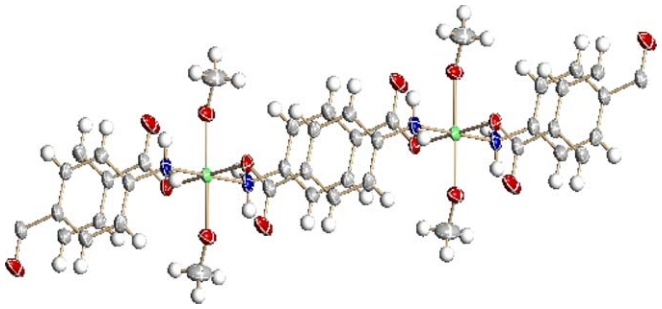

Fig. 6. Intrachain π–π interactions in **1** between aryl rings of bridging *p*-aminobenzoate ligands, centroids separation = 3.920 Å.

3.2. Discussion on IR spectra

Two carbon–oxygen stretching frequencies of the carboxylate group have been observed in compound **1**: $\nu_{asym}(CO_2) = 1525.6\ cm^{-1}$ and $\nu_{sym}(CO_2) = 1386.7\ cm^{-1}$, with $\Delta = 138.9\ cm^{-1}$. Unidentate coordination removes the equivalence of the two oxygen atoms. The carbon–oxygen bond orders are affected. This should increase $\nu_{asym}(CO_2)$ and decrease $\nu_{sym}(CO_2)$ and thus increase the separation Δ between the νCO_2 frequencies. Δ Values $>200\ cm^{-1}$ for acetate complexes appear generally associated with unidentate coordination [45]. However, exceptions to this rule have been found in two nickel complexes $Ni(O_2CMe_2)(H_2O)_2$ ($\nu_{asym}(CO_2) = 1550\ cm^{-1}$, $\nu_{sym}(CO_2) = 1425\ cm^{-1}$, $\Delta = 125\ cm^{-1}$) [46] and $Ni(O_2CMe)_2(H_2O)_2(py)_2$, ($\nu_{asym}(CO_2) = 1550\ cm^{-1}$, $\nu_{sym}(CO_2) = 1412\ cm^{-1}$, $\Delta = 138\ cm^{-1}$) [45]. The low values of Δ have been attributed to the involvement of CO_2's uncoordinated oxygen in hydrogen bonding with a water ligand. A similar situation has been found in compound **1** where also the CO_2's uncoordinated oxygen is hydrogen bonded to the amino group. Little difference has been found in bond distances of the carboxylate group of **1**;

C(9)–O(4) = 1.258 (2) Å for the uncoordinated oxygen and C(9)–O(5) = 1.254 (3) Å for the coordinated oxygen, which can explain the small value of Δ.

3.3. Magnetic study

The temperature dependence of the magnetic susceptibility ($\chi_M T$ versus T) for compound **1** in the range 3–300 K is shown in Fig. 7. The $\chi_M T$ value is approximately constant (1.38 $cm^3\,K\,mol^{-1}$) in the temperature range 100–300 K, but below 100 K it increases slightly to reach a maximum of 1.53 $cm^3\,K\,mol^{-1}$ at 9 K. This behavior is indicative of ferromagnetic intramolecular coupled nickel ions. The value of $\chi_M T$ at room temperature is greater than that expected for the spin only formula, which indicates that an orbital contribution and/or ferromagnetic coupling are involved. In the low temperature region 3–10 K, a decrease in the $\chi_M T$ value is the signature of single-ion zero field splitting D. The experimental data of the magnetic susceptibility (χT) were fitted to the analytical expression given by de Neef [47,48,35] for $S = 1$, based on a spin-Hamiltonian taking into account both the intramolecular exchange coupling (J) and the single-ion zero field splitting (D):

$$H = -2J\sum_{i=1}^{n-1} S_i S_{i+1} - D\sum_{i=1}^{n}\left(S_{iz}^2 - \frac{2}{3}\right) \quad (1)$$

and

$$\chi(J,D) = g^2\mu_B^2 \sum_{i\geqslant 1} \frac{d_i J^{i-1}}{(k_B T)^{-i}(3^i i!)} + \frac{2g^2\mu_B^2}{k_B T(2+e^{-D/k_B T})} + \frac{g^2\mu_B^2}{3k_B T}\sum_{i,j} b_{i,j}\frac{J^i D^j}{(3k_B T)^{i+j}(i+j)!} - \frac{2g^2\mu_B^2}{3k_B T} \quad (2)$$

where μ_B is the bohr magneton, k_B is the Boltzman constant, g is the Landé factor and d_i, $b_{i,j}$ are the coefficients of the susceptibility expansion given by de Neef [49]. The best least square fitting of the experimental data to Eq. (2) leads to the values of $J/k_B = 1.07$ K ($\sim 0.74\ cm^{-1}$), $D/k_B = -3.58$ K ($\sim -2.48\ cm^{-1}$) and $g = 2.35$ with an agreement factor $R = (\chi_{cal} - \chi_{exp})^2/\chi_{exp}^2 = 2.4 \times 10^{-4}$. The magnetic data for representative ferromagnetic 1D Ni polymers are listed for comparison in Table 3. It is worth noting that antiferromagnetic data has been also obtained in 1D polymeric nickel(II) complexes that contain end-to-end azido bridges as in [Ni(4-ethylpyridine)$_4$(N$_3$)][(PF$_6$) [51] and in a nickel azido pyrazolate complex [36].

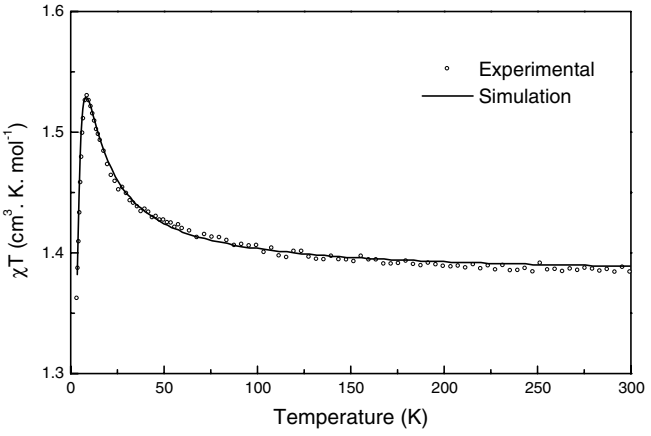

Fig. 7. The variation of $\chi_M T$ as a function of temperature for compound **1**. The symbols represent the experimental data and the continuous line represents the best fit to Eq. (2).

3.4. Thermal analysis

The results of thermogravimetric analysis for compound **1** are shown in Figs. 8 and 9. The compound was heated to 1000 °C, all relevant weight losses were complete by 600 °C. The TGA curve reveals that the polymer is stable up to 150 °C after which a weight loss due to the removal of one lattice-included methanol molecule and one half CO group occurs in the range 150–185 °C (observed loss 10.46%, theoretical loss 10.78%). The dTG curve indicates that the inflexion temperature occurred at 174.94 °C, Fig. 8. An endothermic peak is observed at the same temperature in the DTA curve with an enthalpy value equal to 165.25 kJ/mol, Fig. 9. A sharp weight loss of one PAB ligand is centered at 387.42 °C (observed loss 31.62%, theoretical loss 31.88%). The heat flow peak associated with the process reveals that it is endothermic with $\Delta H = 94.86$ kJ/mol. Loss of two coordinated methanol molecules occurred at a higher temperatures (489.20 °C) with $\Delta H = 29.78$ kJ/mol. The experimental and theoretical losses are 15.14% and 15.00%, respectively. Fragmentation of the PAB ligand further occurred at 550.73 °C with loss of 0.25$C_6H_4NH_2$ group ($\Delta H = 20.08$ kJ/mol). Material decomposition of the complex continues at higher temperature with the formation of nickel (II) oxide, Figs. 8 and 9.

3.5. Formation constant and thermodynamic parameters

The point-wise method [33,52,53] was used to calculate the dissociation constant of the *p*-aminobenzoic acid ligand, based on evaluation of the average proton number associated with the ligand n_A at different pH values, Table 4. On plotting the pK values versus $1/T$, straight lines are obtained with a slope of $\Delta H/2.303$ R, from which the ΔH

Table 3

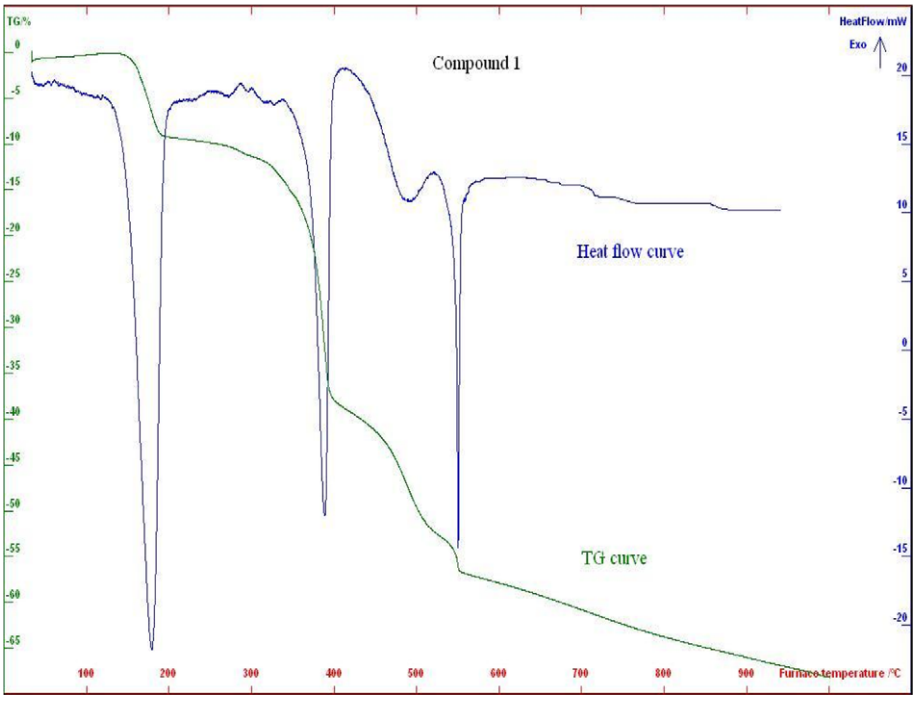

Fig. 9. TG and heat flow curves in the thermogravimetric analysis of **1**.

values (kcal mol^{-1}) are computed (Van't Hoff method). The free energy values ΔG (kcal mol^{-1}) are calculated using the equation $\Delta G = 2.303RT\,pK$, whereas the entropy term ΔS (eu) is given as $\Delta S = 10^3(\Delta H - \Delta G)/T$. The thermodynamics of ionization of *p*-aminobenzoic acid are evaluated in the temperature range 20–40 °C, Table 4. The pK_a values decrease with increasing temperature. The positive ΔH value indicates that the acid dissociation is an endothermic mechanism. The negative ΔS value in 50% ethanol is attributed to the presence of intermolecular hydrogen bonding with the solvent that promotes a higher degree of ordering [54].

Table 4
pK values and thermodynamic parameters for *p*-aminobenzoic acid in 50% ethanol–water

T (°C)	p$K_a \pm 0.03$	ΔG (kcal mol^{-1}) ± 0.04	ΔS (cal mol^{-1} K) ± 0.20
20	6.23	8.50	−16.00
25	6.18	8.43	−15.76
30	6.13	8.36	−15.53
35	6.10	8.32	−15.40
40	6.05	8.26	−15.19

ΔH (kcal mol^{-1}) $= 3.73 \pm 0.07$.

The stability constants of the nickel complexes can be calculated using the modified Bjerrum's method [33,53,55]. The pH measurements during titration of the solution of the chelating agent in the presence and absence of metal ions with alkali could be used to calculate the free ligand exponent (pA) and the degree of formation of the system (n). [A^{-2}] is the concentration of free ligand anion and n is the average number of moles of ligand bound per mole of metal ion. By plotting the values of n versus pA, $\log K_{f1}$ and $\log K_{f2}$ values are obtained at the pA values equivalent to 0.5 and 1.5, respectively, Table 5 [33,53]

$$[A^{-2}] = \frac{(2-a)C_A - [H^+] + [OH^-]}{\frac{2[H^+]^2}{K_1K_2} + \frac{[H^+]}{K_2}}$$

$$\overline{n} = \frac{1}{C_M}\left(C_A - \left[\frac{[H^+]^2}{K_1K_2} + \frac{[H^+]}{K_2} + 1\right][A^{-2}]\right)$$

The thermodynamic parameters for metal complexation are also listed in Table 5. The enthalpy of complexation, ΔH (kcal mol^{-1}) values were determined from the plot of $\log K_f$ versus $1/T$. Straight lines were obtained with a slope of $-\Delta H/2.303$ R. The free energy ΔG (kcal mol^{-1}) was calculated from the relation $\Delta G = -2.303RT \log K_f$. The entropy ΔS (eu) is given as $\Delta S = 10^3(\Delta H - \Delta G)/T$.

The negative values of ΔG indicate that the formation of 1:1 and 1:2 metal ligand complexes is a thermodynamically favored process. The high negative value of ΔH indicates that the enthalpy effect is more dominant than the entropy effect. In the case of PAB bridging two metal atoms, the highly unfavorable entropy due to steric effects can be overcome by the large stabilization energy from π–π interactions. The formation of a mononuclear *p*-aminobenzoate nickel complex has been confirmed by X-ray [29], while in the present studies the linear doubly bridged polymer has been obtained. During the synthesis of **1**, the initially formed mononuclear NiL_2, with L = PAB coordinated through the carboxylate group to Ni(II), acts as a ligand to another NiL_2 through the NH_2 group forming dinuclear and similarly trinuclear species until reaching a more thermodynamically stable situation by forming a 1D polynuclear complex. Thus, the system under equilibrium forms and breaks bonds, sifts through various possibilities until reaching the most stable product, complex **1**.

Table 5
$\log K_{f1}$ and ($\log K_{f2}$) values and thermodynamic parameters for the nickel complex with *p*-aminobenzoic acid in 50% ethanol–water

T (°C)	$\log K_{f1}$ ($\log K_{f2}$) ± 0.04	ΔG (kcal mol^{-1}) ± 0.06	ΔS (cal mol^{-1} K) ± 0.40
20	3.39(1.45)	−4.63(−1.98)	−17.44(−69.93)
25	3.24(1.21)	−4.42(−1.65)	−18.15(−71.04)
30	3.11(0.84)	−4.24(−1.14)	−18.75(−72.75)
35	3.08(0.69)	−4.20(−0.94)	−18.88(−73.42)
40	2.89	−3.94	−19.76

ΔH (kcal mol^{-1}) $= -9.83 \pm 0.20$ for K_{f1} and ΔH (kcal mol^{-1}) $= -22.83 \pm 0.40$ for K_{f2}.

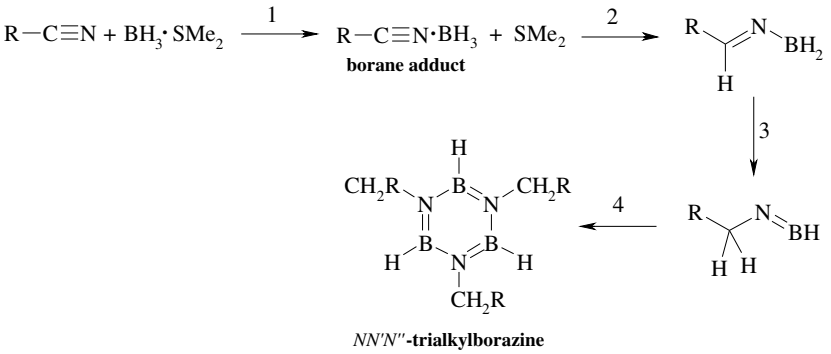

Scheme 1.

affording 35–40% *NN′N″*-triethylborazine [9]. In addition, a further 25–37% of the product distribution has been attributed to bicyclic compounds [10].

Complexes of borane with ethers (e.g., $BH_3 \cdot THF$ and $BH_3 \cdot OEt_2$) effectively convert nitriles to their corresponding amines after hydrolysis [3,4,11]. The reduction is, however, more sluggish with the dimethyl sulfide complex [12,13]. While the greater stability of the borane–dimethyl sulfide complex ($BH_3 \cdot SMe_2$) towards dissociation was cited as a reason for the retardation in reactivity, its stability towards decomposition and better handling characteristics are the reason for the choice of this complex in hydroboration and reduction reactions [13]. An improved procedure for enhancing the reactivity of the borane–dimethyl sulfide complex towards nitriles has been published and its general applicability toward nitrile reduction established [5,14]. Tetrabutylammonium borohydrides have also been used for the reduction of nitriles [15], while various strategies for the enhancement of the reactivity and selectivity of sodium borohydrides toward the reduction of nitrile compounds have also been developed [16].

The conventionally adopted method for investigating the reactivity of nitriles toward reduction by borane–Lewis base adducts has been the determination of residual hydridic hydrogen at the end of the reaction period [17]. This technique, while adequate for comparison of the relative reactivity of various boranes toward nitriles, cannot be used to determine precise kinetic and activation parameters. The applicability of infrared spectroscopy to the investigation of the hydroboration reaction has been demonstrated for some time in the literature [18–25]. Yet, ^{11}B NMR spectroscopy has not received much attention in the field of hydroboration kinetics, with the technique usually relegated to a qualitative role [26,27]. The non-destructive nature of the technique coupled with its real-time analysis, shows the potential of its use for the determination of kinetic data for various reactions. The aim of this investigation was, thus, to determine kinetic and activation parameters for the reduction of acrylonitrile using ^{11}B NMR spectroscopy.

2. Experimental

2.1. General

Borane dimethyl sulfide (1 M in dichloromethane, Sigma–Aldrich) was used without further purification. Acrylonitrile, propionitrile and benzonitrile (all Sigma–Aldrich) were dried by percolating over activated 3 Å molecular sieve before use. Nitrile and borane dimethyl sulfide solutions were diluted to the relevant concentrations with dichloromethane (Merck) distilled over calcium hydride.

Standard techniques for handling of air- and moisture-sensitive materials were used for handling syringes, needles, canulae, glassware, quartz NMR tubes and reagents [28,29].

2.2. Kinetic measurements

^{11}B NMR spectra were recorded at 160 MHz and referenced externally against $BF_3 \cdot OEt_2$ (0 ppm) on a Varian Unity Inova 500 spectrometer in 5 mm quartz tubes with proton decoupling (Waltz-16). A proton-coupled spectrum of the reaction was also recorded in order to identify reaction intermediates and products. A 1-min delay was allowed for mixing and temperature equilibration in the spectrometer, after which arrayed spectra were recorded at set time intervals. The temperature of the spectrometer was controlled at an accuracy of ±0.5 °C. The kinetic data were obtained by monitoring the signal area of the borane dimethyl sulfide peak with time. The following peaks were identified over time in the ^{11}B NMR spectrum: $BH_3 \cdot SMe_2$ [quartet, $\delta^{11}B = -20.3$ ppm, $J_{B-H} = 110$ Hz], $CH_2{=}CH{-}C{\equiv}N \cdot BH_3$ [quartet, $\delta^{11}B = -25.7$ ppm, $J_{B-H} = 104$ Hz] and vinylimino borane [triplet, $\delta^{11}B = -16.3$ ppm, $J_{B-H} = 111$ Hz], $EtC{\equiv}N \cdot BH_3$ [quartet, $\delta^{11}B = -26.2$ ppm, $J_{B-H} = 102$ Hz] and $C_6H_5C{\equiv}N \cdot BH_3$ [quartet, $\delta^{11}B = -25.8$ ppm, $J_{B-H} = 102$ Hz]. Also identified in the spectrum were impurities in the $BH_3 \cdot SMe_2$ solution [singlet, $\delta^{11}B = -10.9$ ppm; singlet, $\delta^{11}B = -13.5$ ppm; singlet, $\delta^{11}B = -17.3$ ppm; singlet, $\delta^{11}B = -15.4$ ppm; singlet, singlet, $\delta^{11}B = -23.2$ ppm; $\delta^{11}B = -29.2$ ppm].

The concentration dependence study of the reduction of acrylonitrile was carried out under pseudo-first-order conditions with the concentration of the nitrile in at least 10-fold excess over that of the borane. Pseudo-first-order rate constants were calculated from single-exponential kinetic traces of integral data from arrayed NMR spectra on Origin 5.0 software. The activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, were determined from temperature studies of k_2' over the temperature range 15–30 °C.

3. Computational modelling

Computational calculations were performed on Spartan '04 [30] computational software. The reaction profile was generated from the B3LYP/6-31G* [31–33] single point energies of SE/AM1-optimised geometries. Electrostatic charges and thermodynamic parameters were determined at the B3LYP/6-31G* level.

4. Results and discussion

No reduction was observed for the reaction involving borane dimethyl sulfide with propionitrile and benzonitrile. These compounds formed borane–nitrile adducts, $C_6H_5C{\equiv}N \cdot BH_3$ ($\delta^{11}B = -25.8$ ppm) and $CH_3CH_2C{\equiv}N \cdot BH_3$ ($\delta^{11}B = -26.2$ ppm), identifiable as quartets in the ^{11}B spectrum. Surprisingly, there are no NMR chemical shifts reported in the literature for these types of adducts. Both ^1H and ^{11}B NMR spectroscopy showed the equilibrium between the $Me_2S \cdot BH_3$ and the $RC{\equiv}N \cdot BH_3$ adducts to favour the former, with ^1H NMR investigation revealing $K = (7.45 \pm 0.20) \times 10^{-3}$ and $K = (1.16 \pm 0.02) \times 10^{-2}$ for $C_6H_5C{\equiv}N \cdot BH_3$ and $EtC{\equiv}N \cdot BH_3$, respectively. The weak equilibrium constants for nitrile–borane adduct formation may be responsible for the lack of reactivity, reduction in this case, of these two compounds. For reduction to occur, a stable adduct would first need to be formed.

It was, however, possible to monitor the kinetics of the reaction up to the first reduction of acrylonitrile (steps 1 and 2 in Scheme 1) through ^{11}B NMR spectroscopy (Fig. 1). The borane–nitrile adduct formed between acrylonitrile and BH_3 ($\delta^{11}B = -25.7$ ppm, $J_{B-H} = 107$ Hz) was completely depleted after 500 s and was generally present in such small concentrations that no meaningful kinetic data could be obtained for it. This is not surprising, as these have been reported to be unstable at room temperature [7]. It can, therefore, be concluded that borane–nitrile adduct formation and depletion are very fast processes. Kinetic investigation of the two hydride shifts prior to

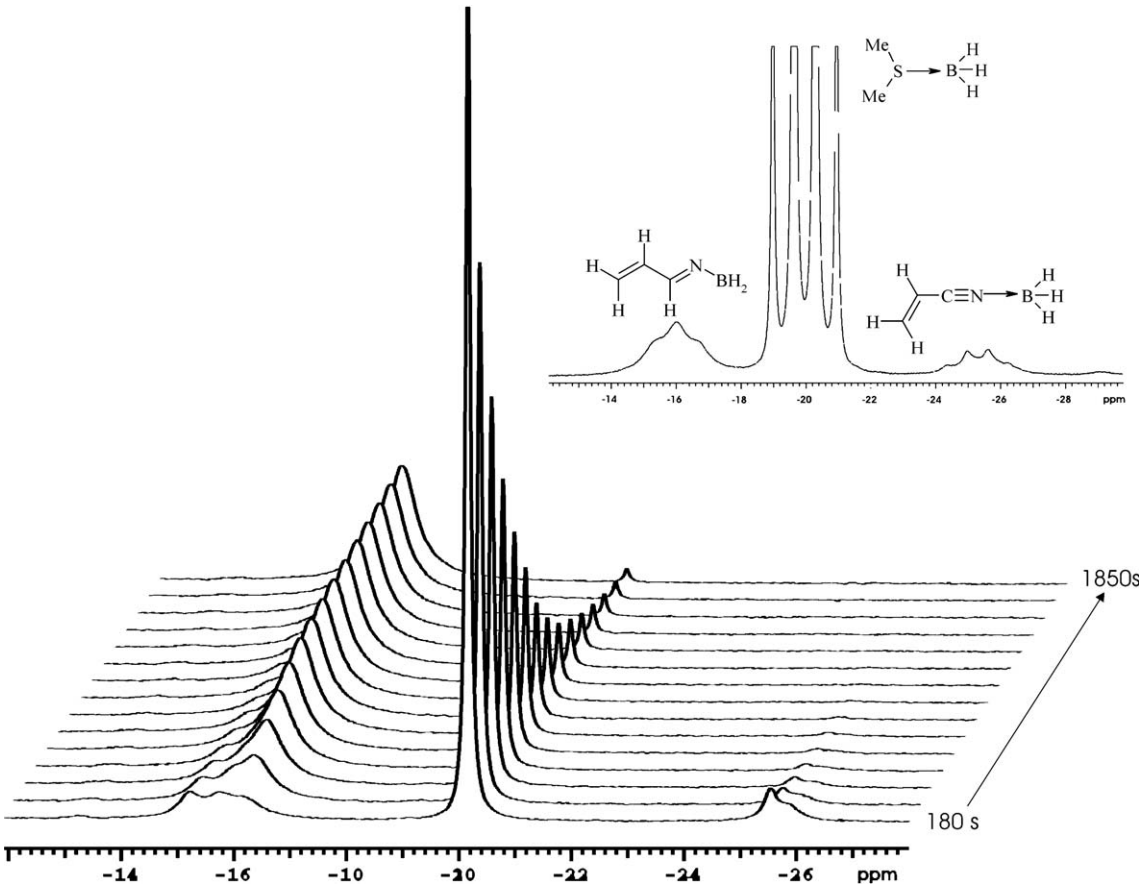

Fig. 1. Arrayed ^{11}B–{^1H} spectrum for reduction of acrylonitrile with borane dimethyl sulfide complex (0.16 M) in CH_2Cl_2 at 25 °C and ^{11}B spectrum (inset) showing species identified during reaction.

borazine formation (steps 3 and 4 in Scheme 1) was not possible owing to the polymerisation of the acrylonitrile. This polymerisation is expected under the reaction conditions of the study [34,35]. Analysis of the arrayed spectra shows that the reduction of acrylonitrile did not proceed to the borazine and carbozara stages. No peaks consistent with those reported for *NN′N″*-tri-*n*-alkylborazines [36] and carbozara derivatives [10] were identified in the ^{11}B NMR spectrum at the end of reaction. The relatively high field shift of the aldiminoborane indicates a shielded boron atom in a four-coordinate environment suggestive of a dimeric aldiminoborane species. This is supported by the literature precedents that show that aldiminoboranes are, in general, dimeric rather than monomeric [37–39].

4.1. Kinetic measurements

Pseudo-first-order rate constants, k_{obs}, for the reduction of acrylonitrile by the borane–dimethyl sulfide complex (0.16 M) at various concentrations (3–8 M) and temperatures (15–30 °C) were obtained from ^{11}B NMR arrayed experiments and subsequent integration of the borane and vinyliminoborane peaks. These resulted in the kinetic plot shown in Fig. 2.

A first-order exponential decay curve was then fitted over the data points for the depletion of the borane dimethyl sulfide complex in order to generate the pseudo-first-order rate constants, k_{obs}. These were then plotted against acrylonitrile concentration, resulting into a linear dependence of k_{obs} on the concentration of acrylonitrile with no meaningful *y*-intercept as shown in Fig. 3.

The results imply that k_{obs} can be expressed by

$$k_{obs} = k'_2[\text{acrylonitrile}]. \quad (1)$$

On the basis of the observed ^{11}B NMR data and kinetics, we propose the following pre-equilibrium mechanism that involves a dissociative step (Eqs. (2) and (3)):

$$BH_3 \cdot SMe_2 \rightleftharpoons BH_3 + SMe_2 \quad (2)$$

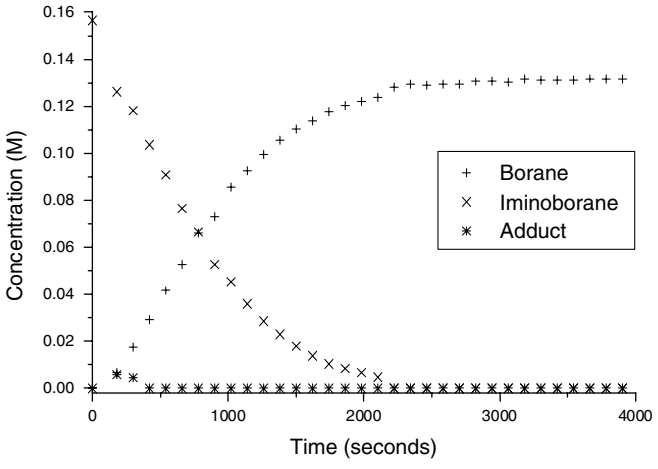

Fig. 2. Kinetic plot for reduction of acrylonitrile with borane dimethyl sulfide complex (0.16 M) in CH_2Cl_2 at 25 °C.

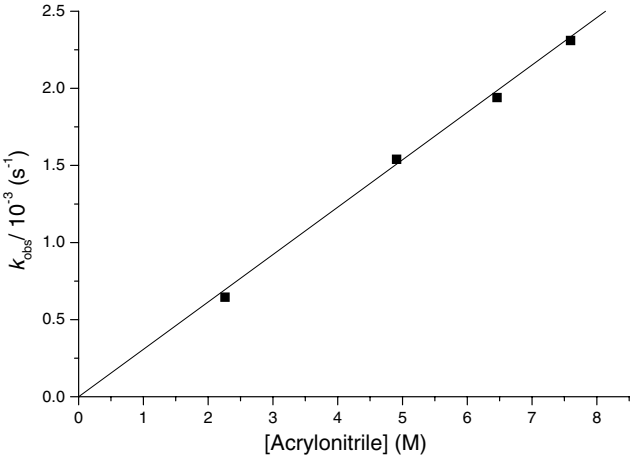

Fig. 3. Concentration dependence of k_{obs} on acrylonitrile concentration in the reduction of acrylonitrile with borane dimethyl sulfide complex (0.16 M) in CH_2Cl_2 at 25 °C.

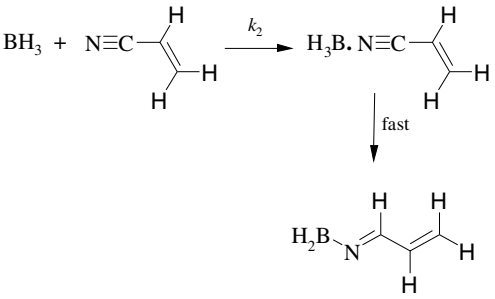

(3)

The rate for this mechanism can be expressed as shown in Eq. (4)

$$k_{obs} = \frac{k_1 k_2[\text{acrylonitrile}]}{k_{-1}[SMe_2] + k_2[\text{acrylonitrile}]}. \quad (4)$$

In the presence of excess dimethyl sulfide, $k_{-1}[SMe_2]$ becomes greater than k_2[acrylonitrile]. Hence, Eq. (4) reduces to Eq. (5) since $[SMe_2]$ is constant

$$k_{obs} = \frac{k_1 k_2}{k_{-1}[SMe_2]}[\text{acrylonitrile}] = k'_2[\text{acrylonitrile}]. \quad (5)$$

To determine whether the $BH_3 \cdot SMe_2$ complex obtained from Sigma–Aldrich had any excess SMe_2, ^1H NMR spectrum of the complex was determined. The integration of the relevant signals showed that free SMe_2 was present at an excess of 12.5%.

The rate constants obtained for acrylonitrile are summarised in Table 1.

The temperature dependence of the reduction of acrylonitrile was also investigated. Since Fig. 3 showed the absence of a reverse reaction, a single concentration (4.911 M) of acrylonitrile was investigated. The values of activation enthalpy, $\Delta H^{\neq}$, and activation entropy, $\Delta S^{\neq}$, were determined from the Eyring plot shown in Fig. 4; which shows a linear correlation over the investigated temperature range. The values of the activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, are tabulated in Table 1.

The negative $\Delta S^{\neq}$ value indicates that the overall mechanism of the reduction of acrylonitrile by $BH_3 \cdot SMe_2$ in the

Table 1
Kinetic data for the reduction of acrylonitrile in CH_2Cl_2

Temperature (°C)	$k'_2/10^{-3}$ ($M\ s^{-1}$)[a]	Thermodynamic data
15.0	0.47 ± 0.01	$\Delta H^{\neq} = 58 \pm 3$ kJ mol^{-1}
20.0	1.16 ± 0.04	
25.0	1.54 ± 0.04	
30.0	2.42 ± 0.09	$\Delta S^{\neq} = -71 \pm 10$ J K^{-1} mol^{-1}
k_1(25 °C)[b]	$(2.52 \pm 0.57) \times 10^{-3}$ s^{-1}	

[a] $k'_2 = k_2k_1/k_{-1}[SMe_2]$.
[b] From $[SMe_2]$ dependence study, [acrylonitrile] = 4.911 M.

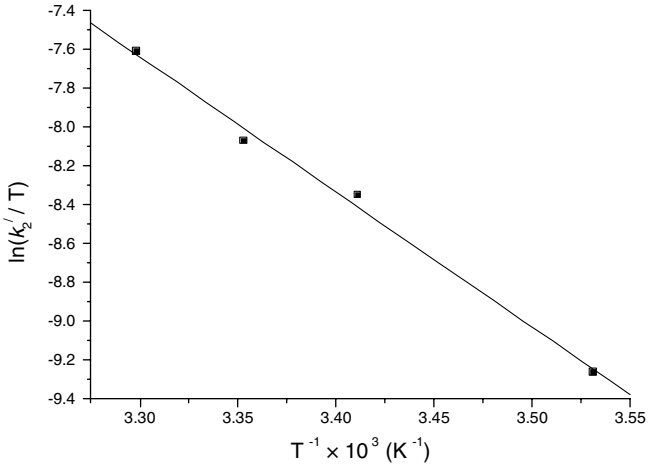

Fig. 4. Eyring plot illustrating the temperature dependence of k'_2 for the depletion of borane dimethyl sulfide complex (0.16 M) in the first step of the reduction of acrylonitrile in CH_2Cl_2.

presence of excess dimethyl sulfide is associative. The dissociation of the dimethyl sulfide prior to reduction has a positive entropy contribution, which must be smaller than the negative entropy contribution of the reduction process.

To test the mechanism further, Eq. (5) was expressed differently as shown in

$$\frac{1}{k_{obs}} = \frac{k_{-1}}{k_1k_2[\text{acrylonitrile}]}[SMe_2] + \frac{1}{k_1}. \quad (6)$$

This equation was used to analyse the k_{obs} data obtained when the acrylonitrile concentration was held constant (4.911 M) while that of excess dimethyl sulfide was varied from 0.019 to 0.193 M. Plotting $1/k_{obs}$ against $[SMe_2]$ resulted in the linear plot shown in Fig. 5. This confirms that the first step in the reaction sequence is the dissociation of the Lewis base from BH_3 as proposed in the mechanism.

4.2. Computational study

The reduction of acrylonitrile, propionitrile, hydrogen cyanide and benzonitrile was modelled at the B3LYP/6-31G* level of theory in order to account for the observed

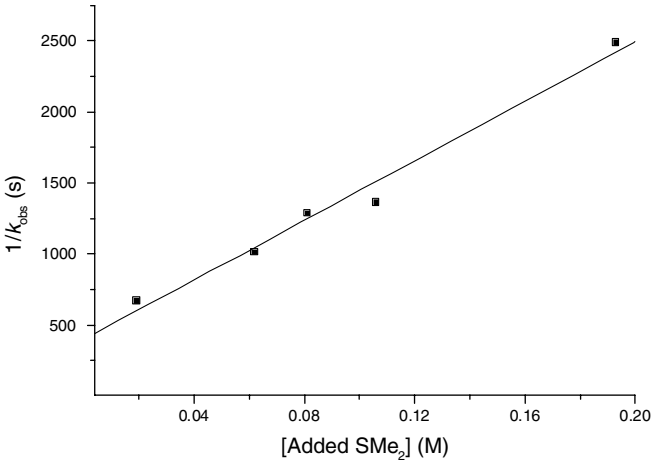

Fig. 5. Concentration dependence of k_{obs} on dimethyl sulfide concentration in the reduction of acrylonitrile with borane dimethyl sulfide complex (0.16 M) in CH_2Cl_2 at 25 °C.

reactivities. The energy profile for the reaction is depicted in Fig. 6 where, in contrast to the MNDO results of Ray and Chadha [40], there was no transition state found for the formation of a borane–nitrile adduct. The B3LYP calculations support the observation by Emeléus and Wade [7] that the stability of the borane–nitrile adducts affects their reactivities, with adduct of acrylonitrile and BH_3 being about 6–8 kJ mol^{-1} more stable than those of benzonitrile and propionitrile. A stable adduct is more likely to undergo step 2 of Scheme 1.

The concepts of absolute hardness, η, and electronegativity, χ^0, as defined by Eq. (7) can be revoked to explain the weakness of the BH_3 adducts of benzonitrile and propionitrile by accounting for the effect of the HOMO–LUMO gap [41].

$$\eta = \frac{(I-A)}{2} \quad \text{and} \quad \chi^0 = \frac{(I+A)}{2}. \quad (7)$$

Molecular orbital theory shows that $I = -E_{LUMO}$ and $A = -E_{HOMO}$ in eV such that combining η and χ^0 to determine the transfer of electron density possible from a Lewis base to a Lewis acid, ΔN as defined in Eq. (8), puts the stability of the nitrile–BH_3 adducts in perspective

$$\Delta N = \frac{(\chi^0_A - \chi^0_B)}{2(\eta_A + \eta_B)}. \quad (8)$$

The results in Table 2 show that acrylonitrile is the most similar to BH_3 in terms of hardness with a large degree of electron transfer to BH_3 in the nitrile–BH_3 adduct, thereby explaining the relative stability of the complex. Propionitrile, by contrast, is in fact harder than BH_3, implying a much larger HOMO–LUMO gap, with hardly any transfer of electron density. Though benzonitrile has a similar level of electron transfer to acrylonitrile, it is softer than BH_3 suggests a much larger HOMO–LUMO gap (the HOMO of acrylonitrile is 0.61 eV higher in energy than that of benzonitrile), which has implications for the ener-

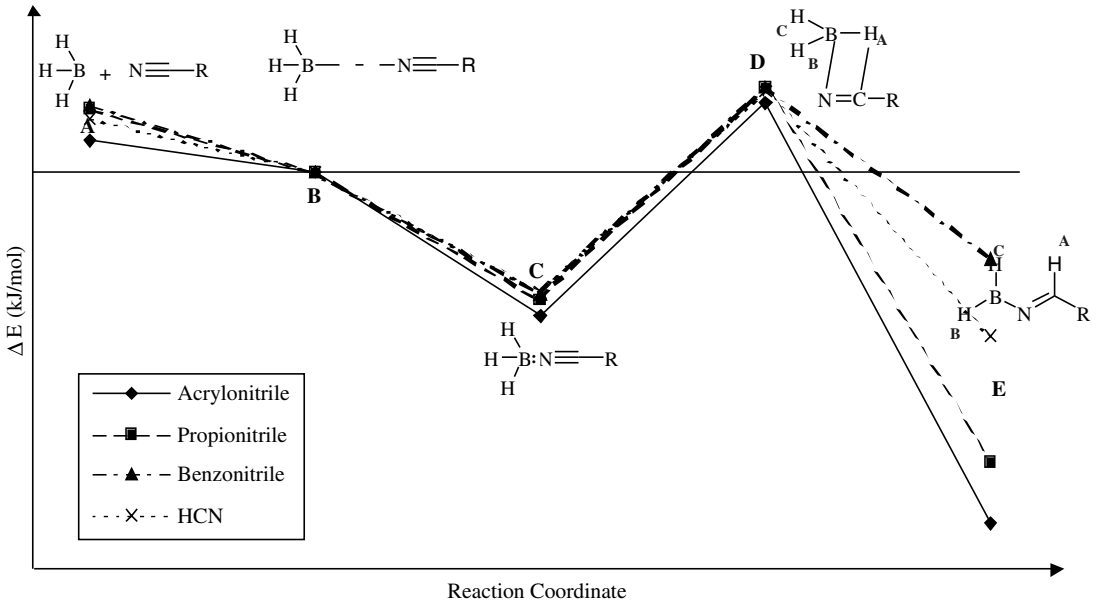

Fig. 6. B3LYP/6-31G* energy profile of stationary points for the reaction of BH_3 with acrylonitrile, propionitrile and benzonitrile.

Table 2
B3LYP/6-31G* calculated absolute hardness, absolute negativity and electron density transfer in adducts of selected nitriles with BH_3

	η (eV)	χ^0 (eV)	ΔN
BH_3	3.89	5.67	
$H_2C{=}CH{-}C{\equiv}N$	3.17	4.70	0.734
$C_6H_5{-}C{\equiv}N$	2.93	4.34	0.734
$H_3C{-}CH_2{-}C{\equiv}N$	4.83	3.93	0.550
$H{-}C{\equiv}N$	5.17	4.61	0.567

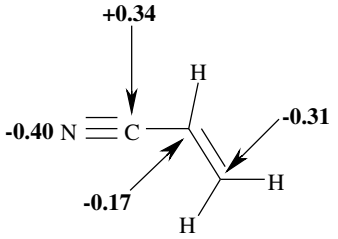

Fig. 7. B3LYP/6-31G* calculated electrostatic charge distribution in the acrylonitrile molecule.

getic requirements of adduct formation. Table 3 shows that the change in energy of complex formation, $\Delta_{complexation}E$, is greatest for the formation of the acrylonitrile–BH_3 adduct at -75.1 kJ mol^{-1}.

In addition to the relative stability of the adducts, depicted in Fig. 7, the activation energy requirements are critical for reduction to take place. As summarised in Table 3, the overall energy barriers ($\Delta_{activation}E$) for the reduction of propionitrile (42.7 kJ mol^{-1}), hydrogen cyanide (40.7 kJ mol^{-1}) and benzonitrile (42.3 kJ mol^{-1}) are higher than the energy barrier (34.7 kJ mol^{-1}) for the reduction of acrylonitrile. The B3LYP method gives a better account of the reaction with energy barriers calculated in the present work being substantially lower and, thus, more reasonable than those calculated by Ray and Chadha's MNDO study [40].

Table 3
B3LYP/6-31G* calculated energies for the reaction of selected nitriles with BH_3

Adduct	$\Delta_{complexation}E$ (kJ mol^{-1})	$\Delta_{activation}E$ (kJ mol^{-1})
$H_2C{=}CH{-}C{\equiv}N$	-75.1	34.7
$H_3C{-}CH_2{-}C{\equiv}N$	-64.3	42.7
$C_6H_5{-}C{\equiv}N$	-61.4	42.3
$H{-}C{\equiv}N$	-60.8	40.7
$H{-}C{\equiv}N$ [40]	-66.9	89.1

The B3LYP results for charge transfer (Table 4) bear out with those of Ray and Chadha [40] in that there is a reversal of charge in the nitrile–BH_3 adduct for the atoms that make up the borane and the nitrogen and carbon atoms in the nitrile. These transfers of charge are of the similar magnitude where 0.8 units of charge are transferred to the boron atom from the borane protons and the nitrogen and carbon atoms of the nitrile functionality.

An interesting question arises when considering the preference of reduction at the nitrile as opposed to the alkene functionality of acrylonitrile, especially in relation to Brown and Kortnyk's [5] observation that, in solution, nitriles are less reactive than alkenes towards hydroboration/reduction. A look into the distribution of electrostatic charge in the acrylonitrile molecule (Fig. 7) reveals that the nitrogen atom carries most of the electrostatic charge in the molecule and, as such, is the point most susceptible to electrophilic attack.

Table 4
Changes in electrostatic charges of atoms in the stationary points C (nitrile–BH_3 adduct) on the reaction surface

Atom	$H_2C{=}CH{-}C{\equiv}N$	$H_3C{-}CH_2{-}C{\equiv}N$	$C_6H_5{-}C{\equiv}N$	$H{-}C{\equiv}N$
B	0.79	0.78	0.82	0.74
H_A	−0.12	−0.11	−0.12	−0.11
H_B	−0.12	−0.11	−0.12	−0.11
H_C	−0.12	−0.11	−0.12	−0.11
N	−0.52	−0.56	−0.62	−0.53
C	0.17	0.22	0.27	0.20

Note. Original charge on the boron atom of the free borane is +0.30, thus if the boron atom gains 0.79 units of negative charge from acrylonitrile its final charge will be −0.49 in the borane–acrylonitrile adduct.

5. Summary

In summary, the results obtained in this study indicate that the overall reduction of acrylonitrile with $BH_3 \cdot SMe_2$ is associative. In addition, the importance of the dissociation of the dimethyl sulfide from borane to the reduction process has also been illustrated. The lack of reaction with propionitrile and benzonitrile at 25 °C can be attributed to lack of stability of their adducts as demonstrated by the low equilibrium constants for the formation of their adducts with borane and further illustrated in Fig. 6 in their higher energies than the acrylonitrile–borane adduct. Furthermore, these compounds would have higher activation barriers, as shown in Table 3.

The applicability of ^{11}B NMR spectroscopy to physical organic chemistry has been demonstrated. To our knowledge, this is the first time that a detailed mechanistic study of these types of complexes has been undertaken.

We chose the ligand L^1H, to get a carboxylato bridged manganese complex as there has been significant research interest in the chemistry of manganese carboxylato complexes owing to their relevance to the biological Mn sites [2,3] and the realisation of single-molecular magnets which are cluster complexes having abnormally large values of ground state spin [26,27]. Dinuclear manganese(II) complexes are of special attraction, since such systems are known to exist at the active centres of some manganese containing enzymes [28]. Recently, dinuclear units with one to three carboxylato bridges were suggested to be a plausible structure of the dinuclear sites in Mn catalases [28]. Using the same ligand, we have already reported one quasi-tetrahedral Cu_4 cluster and a helical-chain copper(II) complex [29], and two novel zinc(II) helical chain polymers in our earlier articles [30]. In the present case we get a rare double $\mu_{1,1}$-carboxylato bridged five coordinated dinuclear manganese(II) complex. On the other hand a salen type ligand L^2H_2 has been employed for the preparation of complex **2**. Though the ligand L^2H_2 is very similar with the ligand stated in our previous report [25], here we get a monomeric manganese(III) complex, which forms a dimer through hydrogen bonds.

The present paper describes the synthesis, spectral characterisation and crystal structures of two new Mn(II) and Mn(III) complexes using two different Schiff base ligands (L^1H and L^2H_2). The magnetic behaviour for **1** is driven by a weak antiferromagnetic interaction.

2. Experimental

2.1. Materials and measurements

Pyridine 2-carboxyldehyde, anthranilic acid (Aldrich), 1,3-diaminopropane, *o*-vanillin, manganese(II) nitrate tetrahydrate, manganese(II) perchlorate hexahydrate (Fluka), sodium thiocyanate, sodium azide(Aldrich) were used as received. The solvents used were of reagent grade.

Elemental analyses were carried out using a Perkin–Elmer 2400 II elemental analyser. The infrared spectra were recorded on a Perkin–Elmer FT-IR spectrophotometer with a KBr disc. The electronic spectrum was recorded (for complex **2**) on a Perkin–Elmer Lambda 40 (UV–Vis) spectrophotometer in methanol. Electrochemical study (for complex **2**) was performed on a CH600A cyclic voltammeter (CV) using tetrabutyl ammonium perchlorate (TBAP) as the supporting electrolyte. The magnetic measurement for **1** was carried out on polycrystalline sample using a Quantum Design SQUID MPMS-XL magnetometer in the temperature range 300–2K with an applied field of 3000G. The contribution of the sample holder was determined separately in the same temperature range and field. Diamagnetic corrections were estimated from Pascal's constants. Room temperature magnetic susceptibility was measured in vibrating sample magnetometer using mercury(tetrathiocyanato)cobaltate as the standard. As the complex **1** is insoluble, electronic spectrum and electrochemical study were not performed for this complex. Magnetic susceptibility for **2**, at room temperature was measured in a vibrating sample magnetometer using mercury(tetrathiocyanato)cobaltate as the standard. As complex **1** is insoluble, electronic spectrum and electrochemical studies were not performed for this complex.

2.2. Synthesis of ligands and metal complexes

2.2.1. $[C_5H_4NC{=}NC_6H_4(COOH)]$ (L^1H)

The Schiff base ligand (L^1H) was prepared by refluxing pyridine 2-carboxyldehyde (10 mmol) and anthranilic acid (10 mmol) in 50 ml of methanol for 30 min. The resulting brownish red solution containing the ligand was used without further purification.

2.2.2. $[(OMe)(OH)C_6H_3C{=}NCH_2CH_2CH_2N{=}CC_6H_3(OH)(OMe)]$ (L^2H_2)

The Schiff base ligand L^2H_2 was obtained by the condensation of *o*-vanillin (20 mmol) with 1,3-diaminopropane (10 mmol) in 50 ml methanol under refluxing conditions for 30 min. The resulting orange yellow solution of the ligand was used without further purification.

2.2.3. $[Mn_2(L^1)_2(NCS)_2]$ (**1**)

To a methanolic solution (20 ml) of manganese nitrate tetrahydrate (0.251 g, 1 mmol), the liquid Schiff base (L^1H) (2 mmol) was added, followed by the addition of a solution of sodium thiocyanate (0.081 g, 1 mmol) in a minimum volume of methanol with constant stirring for 30 min. The resulting mixture was kept in a refrigerator yielding light orange, hexagonal crystals suitable for X-ray diffraction after 15 days. The crystals were collected by filtration and air-dried. Yield – 60%. *Anal.* Calc. for $C_{28}H_{18}Mn_2N_6O_4S_2$: C,49.7; H, 2.7; N, 12.4. Found: C, 49.6; H, 2.6; N, 12.1%.

2.2.4. $[Mn(L^2)(N_3)(H_2O)]$ (2)

To a methanolic solution (15 ml) of manganese perchlorate hexahydrate (0.365 g, 1 mmol), a methanolic solution of the Schiff base (L^2H_2) (1 mmol) was added. Then a solution of sodium azide (0.065 g, 1 mmol) in a minimum volume of water was added with constant stirring. The resulting solution was stirred for 20 min at room temperature. Deep brown, hexagonal crystals suitable for X-ray diffraction were obtained after 9 days. The crystals were collected by filtration and air-dried. Yield – 72 %. *Anal.* Calc. for $C_{19}H_{22}MnN_5O_5$: C, 43.7; H, 4.9; N, 12.1. Found: C, 43.6; H, 4.8; N, 12.1%.

Caution. Perchlorate salts are potentially explosive and should be used in small quantities with much care.

2.3. X-ray crystallographic studies

X-ray single-crystal diffraction data for **1** and **2** were collected at low temperature (163(2) K) with a Nonius Kappa CCD diffractometer equipped with a normal

monochromatised focus X-ray tube having a molybdenum target. The data were collected using the COLLECT software (Nonius BV, 1997–2000) and then were processed through the DENZO reduction software (Otwinowski and Minor, 1997). The structures were solved and refined on F^2 using the SHELXTL software. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in the final refinement model in calculated positions with isotropic thermal parameters. Crystal structure and refinement data are summarised in Table 1.

3. Results and discussion

3.1. Description of the structures

3.1.1. $[Mn_2(L1)_2(NCS)_2]$ (1)

Fig. 1 shows the molecular structure of **1** with atom labelling scheme and the relevant bond lengths and angles are summarised in Table 2. The structure consists of a centro-symmetric dimer where each equivalent manganese atoms is associated with a terminal thiocyanate ligand and a tridentate Schiff base bonded through imine nitrogen, pyridine nitrogen and carboxylato oxygen (NNO) atoms. The two μ_2-carboxylato O-atoms bridge the two manganese centres and link the two halves of the dimer about a pseudo twofold symmetry axis which lies normal to the almost planar Mn_2O_2 rhombus. For a pentacoordinated metal centre, the distortion of the structure from trigonal bipyramidal (TBP) to square pyramidal (SP) can be evaluated by the Addision distortion index τ [31,32]: $\tau = |\beta - \alpha|/60°$, α and β being the two largest angles around the central atom; values for τ in perfect polyhedra are 1.0 for TBP and 0.0 for SP. Here, the five coordinated manganese(II) ions exhibit a distorted square pyramidal geometry ($\tau = 0.0603$) with the thiocyanate nitrogen occupying the apical sites and two bridging carboxylato oxygen, one pyridine and one imine nitrogen atoms of the coordinated

Symmetry operations used for equivalent atoms **A**: $1-x, -1/2+y, 1/2-z$ and **B**: $1-x, 1-y, 1-z$.

Schiff base ligands forming a good mean plane from which the manganese centres are deviated by 0.797 Å towards the thiocyanate ligand. The Mn…Mn separation (3.431 Å) and the bond distances and angles associated with Mn_2O_2 fragment are comparable to similar systems (Table 4, Scheme 1). The thiocyanate ligand is almost linear (N3–C14–S1 = 178.9(4)°) but it coordinates with the metal centre in bent fashion (C14–N3–Mn = 165.1(4)°).

3.1.2. *[Mn(L²)(N₃)(H₂O)] (2)*

The ORTEP presentation of **2** is shown in Fig. 2 and relevant bond lengths and angles are summarised in Table 2. The structure consists of two crystallographically independent six coordinated Mn(III) complexes labelled **A** and **B**. In both independent units **A** and **B**, the manganese(III) ion adopts a distorted octahedral geometry where the coordination sites of the Schiff base ligand, i.e. two imine nitrogen and two phenolic-oxygen atoms form an equatorial plane and the axial sites are occupied by the azido nitrogen atom and an oxygen atom from the coordinated water molecule. The square base of each octahedron is nearly planar with the Mn(III) centres being deviated by 0.077 and 0.064 Å from the mean plane containing the four basal atoms for **A** and **B**, respectively. The axial Mn–N and Mn–O bonds [2.228(3)–2.282(3) Å/2.176(2)–2.268(2) Å] are longer than the corresponding equatorial bonds [1.895(2)–2.057(3) Å/1.900(2)–2.070(3) Å] because of the Jahn Teller effect, as anticipated for high spin Mn(III) complexes. The azide group is almost linear with a N–N–N angle 179.3(4)°/177.8(5)°, indicating sp hybridisation of the central azide N-atom, and it connects with the Mn(III) centre in a bent fashion making an angle N4A–N5A–Mn1 = 127.9(2)°/N4B–N5B–Mn2 = 127.7(3)°. The three six membered rings, which are formed around each manganese centre, are puckered. Each hydrogen atom of the coordinated water molecule forms strong H-bonds with the non-coordinated methoxy oxygen and coordinated phenolato oxygen atoms of another similar mononuclear unit (i.e. **A** connected to **A** and **B** connected to **B**). In this way each mononuclear complex gives rise to a dimeric structure (**A**–**A**/**B**–**B**) (Fig. 3, Table 3). The distance between the two Mn atoms connected through H-bonding is 5.1092(8) Å.

3.2. Infrared spectra

The strong absorption bands corresponding to $\nu_{C=N}$ of the thiocyanato ligand for **1** and $\nu_{N=N}$ of the azido ligand for **2** appear at 2075 and 2029 cm^{-1}, respectively. The bands at 1626 and 1611 cm^{-1} for **1** and **2**, respectively, are attributable to $\nu_{C=N}$ (imine bond) and these bands shift to a lower frequency region compared to that obtained for the respective free ligands [at 1640 (L^1H) and 1633 cm^{-1} (L^2H_2)]. For complex **1**, the bands at 1412 and 1545 cm^{-1} are assigned to $\nu_s(CO_2)$ and $\nu_{as}(CO_2)$ vibrations. The difference of these two frequencies, Δ [$\Delta = \nu_s(CO_2) - \nu_{as}(CO_2) = 133\ cm^{-1}$] indicates the bridging coordination modes of the carboxylate group of the Schiff base [36]. Ligand coordination with the manganese ion is substantiated by two types of bands at 439(**1**), 445(**2**) cm^{-1} and 361(**1**), 371(**2**) cm^{-1}, corresponding to ν_{Mn-N} and ν_{Mn-O}, respectively. Some additional bands are obtained only in the spectrum of **2**, due to the presence of the coordinated water molecule. A broad absorption band around 3410 cm^{-1} appears due to the ν_{sym} and ν_{asym} vibration of

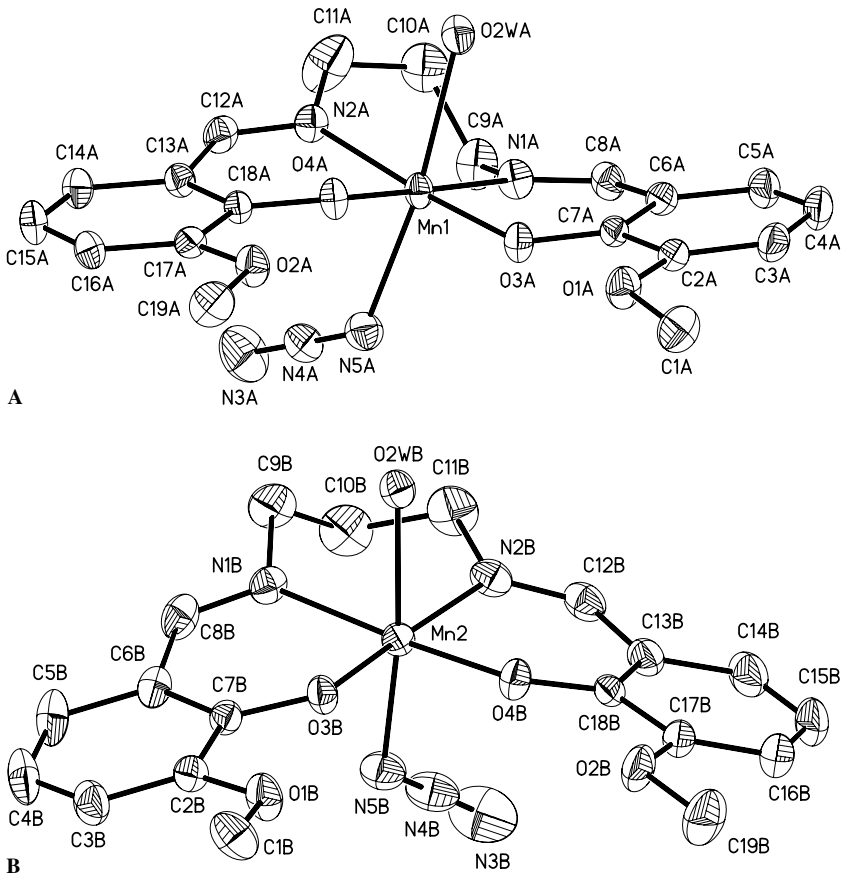

Fig. 2. Molecular view of **2** (**A** and **B**) with atom labelling and ellipsoids at 30% probability.

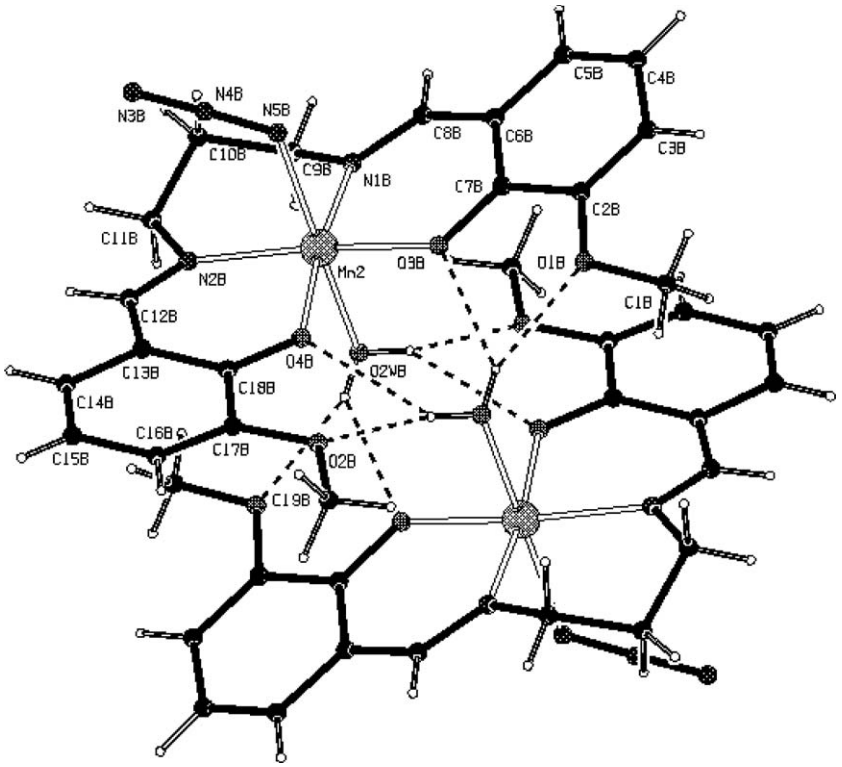

Fig. 3. Dimeric view of complex **2** through H-bonding (for the sake of clarity only one crystallographic unit, **B** is shown).

the OH group of the water molecule. The scissoring motion for the coordinated water appears at 1560 cm^{-1}.

3.3. Electronic spectrum

Complex **2** displays two strong absorption bands in the region 230 ($\varepsilon = 1100\ mol^{-1}\ cm^{-1}$) and 275 nm ($\varepsilon = 1150\ mol^{-1}\ cm^{-1}$), which can be assigned to charge transfer from the ligand to the Mn(III) centre. The spectrum also shows low-intensity absorption bands associated with d–d transitions in the range 490–500 ($\varepsilon = 390\ mol^{-1}\ cm^{-1}$) nm.

3.4. Electrochemical study

The cyclic voltammetry of complex **2** shows one irreversible oxidative and one irreversible reductive response at 1.33 and −0.42 V due to Mn(III)/Mn(IV) and Mn(II)/Mn(III) redox couples.

3.5. Magnetic studies

The overall magnetic behaviour of complex **1** corresponds to weak antiferromagnetically coupled systems (Fig. 4). At room temperature, $\chi_M T$ shows a value of 8.395 $cm^3\ K\ mol^{-1}$ which is as expected for two manganese(II) ions (8.655 $cm^3\ mol^{-1}\ K$ per two Mn(II) with $g = 2.0$). When the sample is cooled, the $\chi_M T$ value remains constant, and below approximately 80 K decreases quickly to 6.020 $cm^3\ K\ mol^{-1}$ at very low temperatures (5 K). The χ_M value increases continuously on cooling from 0.029 $cm^3\ mol^{-1}$ to reach a maximum value of 1.204 $cm^3\ mol^{-1}$ at 5 K. To determine the exchange parameters via the double η^1:μ-$O_{carboxylate}$ bridge, (Fig. 5) χ_MT was fitted to the equation Eq. (1) for an isotropically coupled pair of $S = 5/2$ ions [48], where N is Avogadro's number, μ_B is the Bohr magneton and k_B is the Boltzmann constant. The best fit parameters for reproducing satisfactorily the experimental data, as shown in Fig. 4, are $J_1 = -0.41 \pm 0.029\ cm^{-1}$, and $g = 2.0$ with $R = 3.2 \times 10^{-5}$ ($R = \sum_i(\chi T_{icalc} - \chi T_{iexp})^2 / (\chi T_{iexp})^2$).

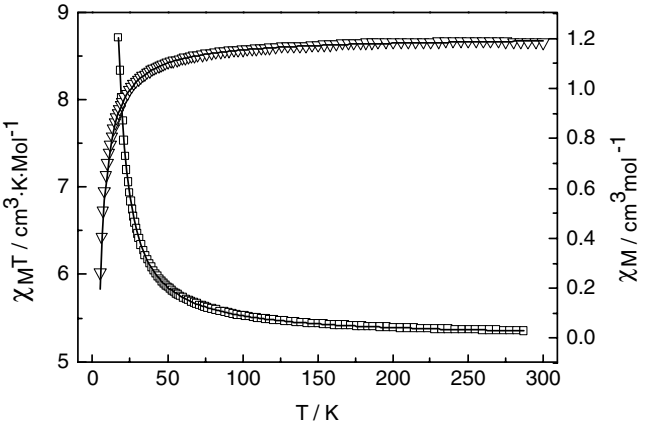

Fig. 4. Plot of the $\chi_M T$ product (△) and χ_M (□) vs. T for compound **1**. Solid line shows the best fit of the data (see text).

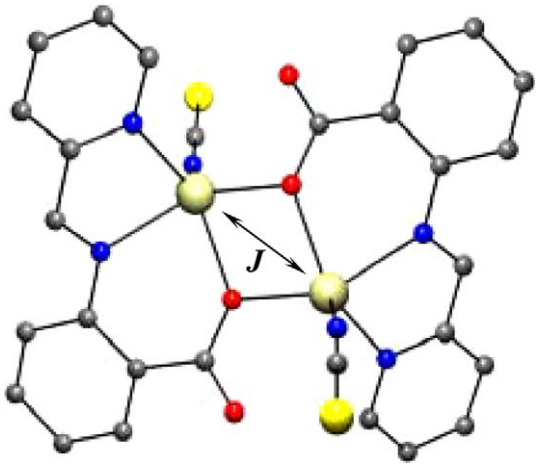

Fig. 5. Dinuclear structure of complex **1**. The schematic magnetic interaction is indicated.

It is well known that the magnetic coupling in M(II)-oxo bridged systems is mainly governed by the M–O–M angle [49]. In complex **1** this angle is close to 106.0°, which should correspond to a small and negative J value. The weak antiferromagnetic coupling found in complex **1** is compared to that previously reported in the literature for similar complexes [37,40] and also for complexes where two Mn(II) ions are bridged by two phenolate ligands [50–53]. This feature can be checked from Table 4, where the J value of $-0.41\ cm^{-1}$ for complex **1** matches those shown in this Table for complexes with similar M–O–M angles.

The X-band powder spectrum at room temperature is shown in Fig. 6. This spectrum is the addition of the spectra for $S = 1, 2, 3, 4$ and 5 excited states. Considering the small J value, all S states are populated at room temperature

$$\chi_M T = \frac{Ng^2\mu_B^2}{k_B} \cdot \frac{2\exp(J/k_B) + 10\exp(3J/k_B) + 28\exp(6J/k_B) + 60\exp(10J/k_B) + 110\exp(15J/k_B)}{1 + 3\exp(J/k_B) + 5\exp(3J/k_B) + 7\exp(6J/k_B) + 9\exp(10J/k_B) + 11\exp(15J/k_B)} \quad (1)$$

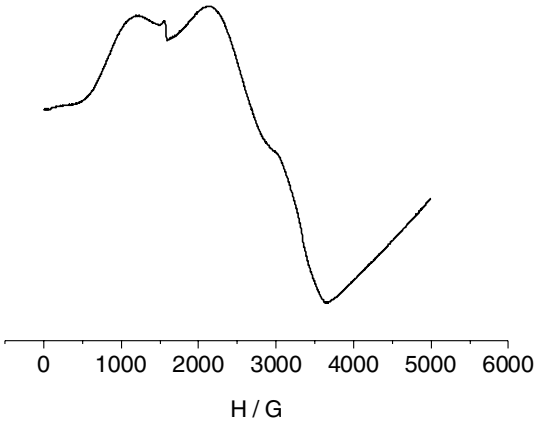

Fig. 6. EPR spectra of compound **1** at room temperature.

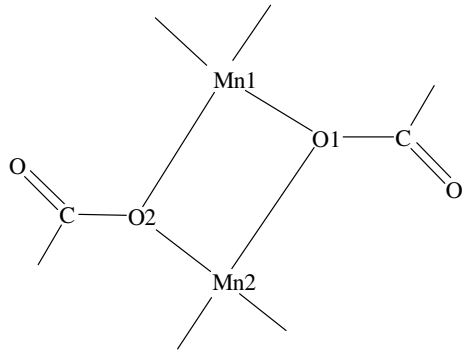
($E_{S=5} = -15J = -15 \times -0.39 \approx 6\ cm^{-1}$). Each state has its own D value, very small in manganese(II) complexes. This is the reason of the width of the spectrum (5000 G approximately).

The room temperature magnetic moment value for **2** is 2.64 BM and the value is very much consistent with that of other low spin manganese(III) complexes [54]. The value



Scheme 1.

indicates that there is no interaction between the two manganese centres connected through hydrogen bonds.

4. Conclusion

One dinuclear five coordinated Mn(II) complex and a mononuclear octahedral Mn(III) complex (**1** and **2**) are obtained from a tridentate and a tetradentate Schiff base, respectively. A very weak antiferromagnetic interaction has been observed for **1**. Complex **2** forms a dimer through

H bonds, but no significant magnetic interaction is found for this complex. In the case of **2**, there is no direct bonding between the two crystallographically independent monomeric units present in the lattice, and this may be due to the occurrence of two bulky methoxy groups in the coordinated Schiff base.

5. Supplementary data

CCDC-289532 (**1**) and 289533 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; e-mail: deposit @ccdc.cam.ac.uk].

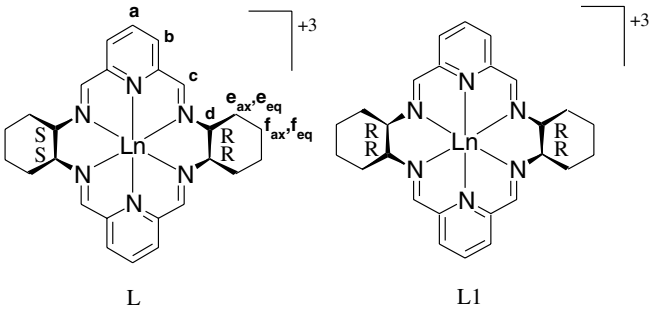

Scheme 1. The general structure and the labelling scheme of the Ln(III) complexes of the macrocycles L and L1.

complexes. In particular, it has been established that chirality of the tetraazamacrocycles strongly influences the properties of their complexes. The complexes of the *meso*-type tetraazamacrocycles differ from their chiral isomers not only in structure, but also in the reactivity and spectroscopic properties [8]. Typical examples of such tetraazameacrocyclic isomers are the *meso*- and chiral racemic *rac*-forms of 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene [8a,8c,8g]. In contrast, very few *meso*- and *rac*-isomers of the lanthanide(III) complexes with the larger hexaazamacrocycles are known [9], and their comparison is limited. In this report we present the synthesis and characterisation of a new series of lanthanide(III) complexes with the *meso*-hexaazamacrocycle L, and compare their structure, stability and paramagnetic NMR spectra with those of the analogous complexes of the isomeric chiral macrocycle L1.

2. Experimental

2.1. Synthesis

2,6-Diformylpyridine was obtained by oxidation of 2,6-pyridinedimethanol [10]. Macrocycle L was synthesised as described in Ref. [7]. All other reagents (Aldrich) were reagent grade and used as received.

2.1.1. Method A

A solution of 17 mmol of (+/−)-*trans*-1,2-diaminocyclohexane (1.941 g) in 5 mL of methanol was combined with a solution of 17 mmol of 2,6-diformylpyridine (2.297 g) in 165 mL of methanol and the mixture was refluxed for 48 h. The white precipitate of a mixture of 2 + 2 and 4 + 4 macrocycles was filtered off, washed with methanol and dried under vacuum. The combined product (3.523 g) was obtained in 97.2% yield. 256 mg of the above mixture (containing 0.45 mmol of L and 0.075 mmol of macrocycle 4 + 4, as determined by NMR integration of the sample) was suspended in 40 mL of dichloromethane and solution of the appropriate lanthanide nitrate hydrate (0.6 mmol) in 20 mL of methanol was added. The mixture was stirred for 1 h at room temperature. The dichloromethane was removed on rotary evaporator and the volume reduced to ca. 20 mL. The mixture was filtered to remove the unreacted 4 + 4 macrocycle and the volume of the filtrate was further reduced to 2–10 mL, depending on Ln(III) ion, until a new precipitate appeared. The mixture was placed in the freezer and the crystalline product obtained the next day was filtered, washed with small amount of cold methanol and dried under vacuum.

$LaL(NO_3)_3 \cdot 0.5H_2O$: Yield 67% (based on L). Required for: $C_{52}H_{62}N_{18}O_{19}La_2$ C, 41.06; H, 4.11; N, 16.58. Found: C, 41.13; H, 3.87; N, 16.76%. Electrospray MS (MeOH): *m/z* 690 $LaL(NO_3)_2^+$, 314 $LaL(NO_3)^{+2}$.

$YbL(NO_3)_3 \cdot 2.5H_2O$: Yield 31.86%. Required for: $C_{52}H_{70}N_{18}O_{23}Yb_2$ C, 37.60; H, 4.25; N, 15.18. Found: C,

37.87; H, 4.09; N, 14.91%. Electrospray MS (MeOH): *m/z* 724 $YbL(NO_3)_2^+$, 330 $YbL(NO_3)^{+2}$.

$LuL(NO_3)_3 \cdot 2.5H_2O$: Yield 41%. Required for: $C_{52}H_{70}N_{18}O_{23}Lu_2$ C, 37.51; H, 4.24; N, 15.14. Found: C, 37.73; H, 4.01; N, 14.89%. Electrospray MS (MeOH): *m/z* 725 $LuL(NO_3)_2^+$, 332 $LuL(NO_3)^{+2}$.

2.1.2. Method B

256 mg (0.6 mmol) of pure macrocyle L was suspended in 40 mL of dichloromethane and solution of the appropriate lanthanide nitrate hydrate (0.6 mmol) in 20 mL of methanol was added. The mixture was stirred for 1 h at room temperature to give a clear solution. The dichloromethane was removed on a rotary evaporator and the volume reduced (to ca. 10 mL for Eu(III) and Er(III), to ca. 2–3 mL for Yb(III)) until solid product started to appear. The mixture was placed in the freezer and the crystalline product obtained next day was filtered, washed with small amount of cold methanol and dried under vacuum. The properties of Eu(III), Er(III) and Yb(III) complexes obtained in this way were identical to those prepared according to method A.

2.2. Methods

The NMR spectra were taken on Bruker Avance 500 and AMX 300 spectrometers. The spectra were acquired using 200 ms to 2 s repetition times, depending on the kind of lanthanide ion studied. The chemical shifts were referenced to the residual solvent signal. The COSY and HMQC spectra were acquired using 256×1 K data points and zero filled to $1\text{ K} \times 1\text{ K}$ matrix. The isotropic shifts were calculated by using diamagnetic Lu(III) complexes as a reference. The resulting isotropic shifts were fit to Eq. (7) using a non-linear least squares fit of D_1 and D_2 parameters and the angle α determining the orientation of the principal axes of the magnetic susceptibility tensor within the symmetry plane of the complex. The calculations were accomplished by minimising the agreement factor: $R = [\sum(\delta_{obs}^{iso} - \delta_{dip}^{calc})^2 / \sum(\delta_{iso}^{obs})^2]^{0.5}$. The geometric factors for each proton were derived from the coordinates of the crystal structure of Sm(III) complex. The experimental isotropic shifts were treated as averaged shifts of pairs of protons such as a and a′, b and b′, etc. Electrospray mass spectra were obtained using Finnigan TSQ-700 instrument equipped with EST ion source. The elemental analyses were carried out on a Perkin–Elmer 2400 CHN elemental analyser.

2.3. X-ray data collection and structure determination

Crystals of both complexes were grown by slow evaporation of a methanol–chloroform solutions. The data were collected at 100 K using a KM4 CCD diffractometer and graphite-monochromated Mo Kα radiation generated from Diffraction X-ray tube operated at 50 kV and 35 mA. The images were indexed, integrated, and scaled using the Oxford Diffraction data reduction package [11]. The experimental details together with crystal data are given in Table 1. The structure was solved by the heavy atom method using SHELXS97 [12] and refined by the full-matrix least-squares method on all F^2 data [13]. The lattice parameters were calculated for refinement of positions of all measured reflections. The data were corrected for absorption [14].

Table 1
Crystal data and structures refinement for $[LaL(NO_3)_2(CH_3OH)](NO_3) \cdot (CH_3OH)$ and $[SmL(NO_3)_2(CH_3OH)](NO_3) \cdot (CH_3OH)$

Empirical formula	$C_{27}H_{33}N_8O_7La$, CH_4O, NO_3	$C_{27}H_{33}N_8O_7Sm$, CH_4O, NO_3

3. Results and discussion

3.1. Synthesis and stability of the complexes

The $[LnL](NO_3)_3 \cdot nH_2O$ complexes can be synthesized both from the pure macrocycle L [7] (method B) as well as from the mixture (method A) of L and another macrocycle that is a 4 + 4 condensation product. This mixture can be easily obtained in the condensation of racemic *trans*-1,2-diaminocyclohexane and 2,6-diformylpyridine [7]. In method A, the 4 + 4 macrocycle is separated from the methanol solution of the complex as poorly soluble product. This method is more practical, because it allows to omit the purification of L by fractional crystallisation. In both methods care should be taken to use relatively mild conditions and short reaction times, otherwise admixture

of lanthanide(III) complexes of L1 is obtained. In fact the L1 complexes were main product of the reaction, when the above mixture of macrocycles was refluxed for several days in methanol with the lanthanide(III) nitrates or chlorides (for this reason we were initially convinced that the above macrocyclic substrate L was a free form of chiral ligand L1). This observation indicates that the complexes of L1 are thermodynamically more stable. Presumably, they are formed as a result of hydrolytic cleavage of the Schiff base macrocycle L of RRSS configuration, and rearrangement of the diamine fragments into racemic *RRRR*/*SSSS* form of the more stable complexed macrocyle L1.

To further test this hypothesis, we have investigated the stability of pure $[LnL](NO_3)_3 \cdot nH_2O$ complexes in solution. The complexes are relatively stable in CD_3OD or $CD_3OD/CDCl_3$ 1:2 v/v solutions at room temperature. For instance the ^1H NMR spectrum of the Eu(III) complex obtained after 30 days indicates only traces of the EuL1 complex as well as of hydrolytic decomposition products such as dimeric μ-hydroxo complexes of L. The decomposition is somewhat more pronounced at elevated temperatures and in aqueous solutions. The hydrolytic decomposition is much faster for the complexes of L with heavier lanthanides, such as Yb(III), than for the complexes with lighter lanthanide(III) ions. The conversion of complexes of L into complexes of L1 is further accelerated by the presence of additional free lanthanide(III) nitrate. For instance almost complete transition of $[YbL](NO_3)_3$ into $[YbL1](NO_3)_3$ is observed when the $CD_3OD/CDCl_3$ 1:2 v/v solution of the former complex is heated at 50 °C in the presence of 2 equiv. of Yb(III) nitrate for 9 days (Supplementary Fig. 1). This experiment corresponds to reaction conditions under which impure products are obtained. The effect of excess of Ln(III) ion and elevated temperature is in accord with the hydrolytic mechanism of the rearrangement of L into L1. The formation of imine bond (accompanied by release of water molecule) is partially reversible and is catalysed by acids. For this reason, the reverse reaction is faster in the acidic conditions resulting form the hydrolysis of the free Ln(III) salt, in the presence of additional amount of water introduced with the lanthanide salts, or possibly is catalysed by the free Ln(III) ion itself. The transformation of $[LnL]^{3+}$ complexes into $[LnL1]^{3+}$ complexes is consistent with the fact that complexes of L are not formed in a template synthesis. In this synthesis only the complexes of L1 are obtained from the racemic form to the diamine. This preference for the chiral form of the hexaazamacrocycle is not observed in the case of derivatives of substituted ethylenediamines. In this case, mixtures of *meso* and chiral *rac* hexaazamacrocycles were obtained in reactions of racemic diamine templated by Ln(III), Ca(II) and Sr(II) ions [9].

The identity of the complexes has been confirmed by elemental analyses and mass spectra. The ESI-MS+ of methanol solutions of the $[LnL](NO_3)_3 \cdot nH_2O$ complexes show peaks at m/e corresponding to ions $[LnL](NO_3)^{+2}$ and $[LnL](NO_3)_2{}^{+}$. The presence of these species indicates axial coordination of nitrate anions rather than clusterisation of ions under the conditions of ESI-MS measurements. The binding of anions is also evident from titration of the $[LnL](NO_3)_3 \cdot nH_2O$ complex with sodium acetate monitored by NMR spectroscopy (vide infra).

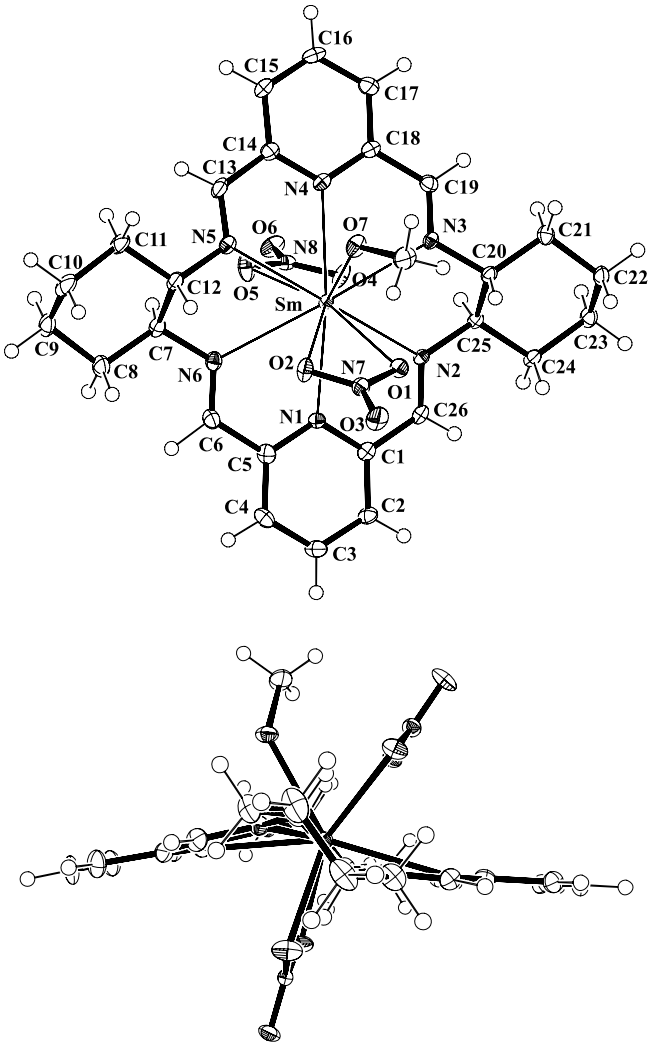

Fig. 1. Front and side view of the complex cation $[SmL(NO_3)_2(CH_3OH)]^+$.

4. Crystal structure of $[SmL(NO_3)_2(CH_3OH)](NO_3) \cdot CH_3OH$ and $[LaL(NO_3)_2(CH_3OH)](NO_3) \cdot CH_3OH$ complexes

Crystals of $[SmL(NO_3)_2(CH_3OH)](NO_3) \cdot CH_3OH$ and the isomorphic $[LaL(NO_3)_2(CH_3OH)](NO_3) \cdot CH_3OH$ complexes have been obtained by slow evaporation of the $[LnL](NO_3)_3 \cdot nH_2O$ solutions in chloroform/methanol mixture. The asymmetric unit of the samarium(III) complex is composed of the complex cation $[SmL(NO_3)_2(CH_3OH)]^+$, nitrate anion and additional methanol molecule. The samarium(III) ion is coordinated in the centre of the macrocycle by six nitrogen atoms of the ligand L (Fig. 1, Table 2). The coordination sphere of Sm(III) is

completed by axial ligands: on one side of the macrocycle by bidentate nitrate anion and on the other side by bidentate nitrate anion and methanol molecule. The coordination sphere of the Sm(III) ion defines irregular polyhedron. The $[SmL(NO_3)_2(CH_3OH)](NO_3)CH_3OH$ complex represents a rare example of the 11-coordinate samarium(III) ion, which prefers smaller coordination numbers. On the other hand, this coordination number is not unusual for the larger La(III) ion and was previously observed for the La(III) complexes with hexaazamacrocycles [2]. The fact that the La(III) and Sm(III) complexes are isostructural is not expected for the hexaazamacrocyclic complexes. For this class of compounds the larger La(III) ion typically has higher coordination number than the ions belonging to the middle of the series of lanthanide(III) ions [2]. The structure of the Sm(III) and La(III) $[LnL](NO_3)_3 \cdot nH_2O$ complexes is different to that of the $[LnL1](NO_3)_3 \cdot nH_2O$ complexes [3d]. The latter complexes are 10-coordinate and have two bidentate axial nitrate anions bound in axial position. The most striking difference is that the Sm(III) complex of L is 11-coordinate, while the L1 complex of the larger Nd(III) ion is 10-coordinate. This difference results from different steric requirements of the two isomeric macrocycles and reflects the influence of the structure of the macrocyclic equatorial ligand on the axial ligation.

The macrocycle L in its La(III) and Sm(III) complexes adopts flatter conformation in comparison with the free form [7], but it preserves some features of the stepped conformation (Fig. 1). In the free form the two pyridine rings are placed on two parallel planes separated by 5.37 Å, while in the complexed form these two rings are inclined at 13.38° for Sm(III) and 13.70° for La(III) complexes, respectively and are closer to being positioned in one plane. This angle between the pyridine rings describes also the overall bending of the macrocycle.

The hexaazamacrocycles adopt their conformation to the size and coordination requirements of the coordinated lanthanide(III) ions [2]. This is achieved by combination of various degree of bending and helical twisting of the macrocycle. In the case of nitrate derivatives of the lanthanide(III) complexes with the isomeric chiral macrocycle L1, practically no bending is observed and the helical twist determines the macrocycle conformation. It should be noted that helical twist of the hexaazamacrocyle is usually observed also for the achiral macrocycles, e.g., for the derivatives of ethylenediamine and 2,6-diacetylpyridine [2]. In this way chiral complexes are formed from macrocycles devoid of stereogenic centres. In the case of L, however, the *RR* and *SS* configuration of the two diaminocyclohexane rings imposes C_s symmetry of the macrocycle. For this reason, the $[LnL](NO_3)_3 \cdot nH_2O$ complexes exhibit no helical twist. This is manifested, e.g., by the angle formed between the two vectors defined by the opposite pairs of diamine nitrogen atoms N2N3 and N5N6 which is close to zero (0.68°). This twist is even better reflected by the improper torsion angle C2C4C15C17 equal to 1.87°. For 13 out of 86 structures [15] of related complexes of lanthanide and transition metal ions with hexaaza and hexaoxaaza macrocyles containing two pyridine rings, this angle was close to zero (less than 3°). The majority of these complexes exhibit various degrees of helical twist; for the remaining 73 structures this angle varies from 5° to 88.66° including values of 22.73° and 27.83° for the Nd(III) and Tm(III) complexes of macrocyle L1. The helical twist can be also measured by the torsional angle determined by two C–N bonds of the opposite pyridine fragments. In the present case this angle is nonzero (6.8°), this value results from the stepped conformation and not from helical twist.

4.1. ^1H NMR spectroscopy

The investigated compounds give rise to eight signals of intensity 1:2:2:2:2:2:2:2 in their ^1H NMR spectra (Table 3), and seven signals in ^{13}C NMR spectra. The number of resonances corresponds to effective C_{2h} symmetry of the $[LnL](NO_3)_3 \cdot nH_2O$ complexes. This symmetry results from fast on the NMR time scale, dynamic exchange of axial ligands on the two sides of the macrocycle, accompanied by conformational averaging of the C_s-symmetric structure of the macrocycle L observed for the solid state. For this latter symmetry 16 ^1H NMR signals should be observed. Similar dynamic averaging of the axial ligation of macrocyclic lanthanide complexes was observed previously [3c,16]. The exchange process is slowed down at 183 K as indicated by doubling of some resonances and observation of more complicated spectra. Unfortunately, line broadening did not allow for detailed analysis of the spectra recorded at low temperatures.

Table 3
^{1}H NMR chemical shifts of the $[LnL(NO_3)_3]\cdot nH_2O$ complexes ($CD_3OD/CDCl_3$ 1:2 v/v solution, 298 K)

The spectra of $CD_3OD/CDCl_3$ 1:2 v/v solutions of the paramagnetic Ce(III), Pr(III), Nd(III), Eu(III) and Yb(III) $[LnL](NO_3)_3\cdot nH_2O$ complexes were assigned on the basis of COSY and HMQC experiments (Fig. 2, Supplementary Fig. 2). In the remaining cases the signals were assigned on the basis of the linewidth dependence on the reverse sixth power of the proton–Ln(III) distance [17]. Analysis of crystal structures of $[LnL](NO_3)_3\cdot nH_2O$ complexes enables calculation of the relative ratios of linewidths, increasing in the order $\mathbf{f}_{eq}$, **a**, $\mathbf{f}_{ax}$, **b**, $\mathbf{e}_{eq}$, $\mathbf{e}_{ax}$, **c**, **d** (see Scheme 1 for the labelling).

The chemical shifts of the various paramagnetic $[LnL](NO_3)_3\cdot nH_2O$ complexes span a wide range of values (Table 3), reflecting differences in magnetic properties of these ions. There is an interesting comparison between

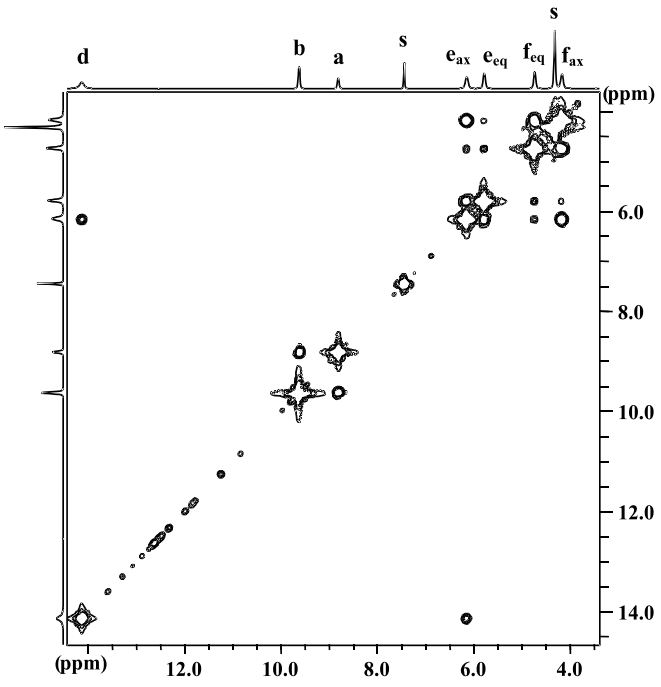

Fig. 2. The COSY spectrum ($CD_3OD/CDCl_3$ 1:2 v/v solution, 298 K) of $[NdL(NO_3)_3]\cdot 3H_2O$ complex.

the spectra of $[LnL](NO_3)_3\cdot nH_2O$ and the isomeric $[LnL1](NO_3)_3\cdot nH_2O$ complexes measured in the same solvent (Fig. 3). In the case of diamagnetic La(III) and Lu(III) derivatives the spectra are almost identical. This is a consequence of the fact that L and L1 are isomers and despite the difference in configuration of chiral carbon atoms the chemical nature of the two compounds is similar. In the case of Eu(III) derivatives (Fig. 3), as well as in the case of Ce(III), Pr(III), Nd(III), and Sm(III)), the overall spectral patterns of the two types of complexes bear some similarity, but the differences in the shift values are clear. Yet in the case of Tb(III), Dy(III), Ho(III), Er(III), Tm(III) and Yb(III) derivatives completely different spectral patterns are observed for the complexes of L and the corresponding complexes of L1 (Fig. 3, Supplementary Fig. 1).

In paramagnetic metal complexes the observed nucleus experiences additional shift, called the isotropic shift, δ_{iso}, that arises from the interaction of the nuclear and electronic spins [17]. In the case of lanthanide complexes this paramagnetic shift is often called lanthanide induced shift (LIS). The isotropic shift can be separated into through-space dipolar contribution (called also pseudocontact) δ_{dip} and through-bonds contact contribution δ_{con}:

$$\delta_{iso} = \delta_{dip} + \delta_{con}. \quad (1)$$

In the case of lanthanide complexes [18] the dipolar contribution is given by:

$$\delta_{dip} = C_j G, \quad (2)$$

where constant C_j depends on the Ln(III) ion, while G contains the information about crystal field parameters of the complex and geometric factors G' determined by position in space of given nucleus.

The contact shift is given by the formula [19,20]:

$$\delta_{con} = A\langle S_z\rangle/\gamma\hbar B_0 = A'\langle S_z\rangle, \quad (3)$$

where A is the hyperfine coupling constant, and $\langle S_z\rangle$ is the spin expectation value.

An estimation of the contact and dipolar contributions to the paramagnetic shift can be made on the basis of the Reilley method [21], which combines the Eqs. (1)–(3) into:

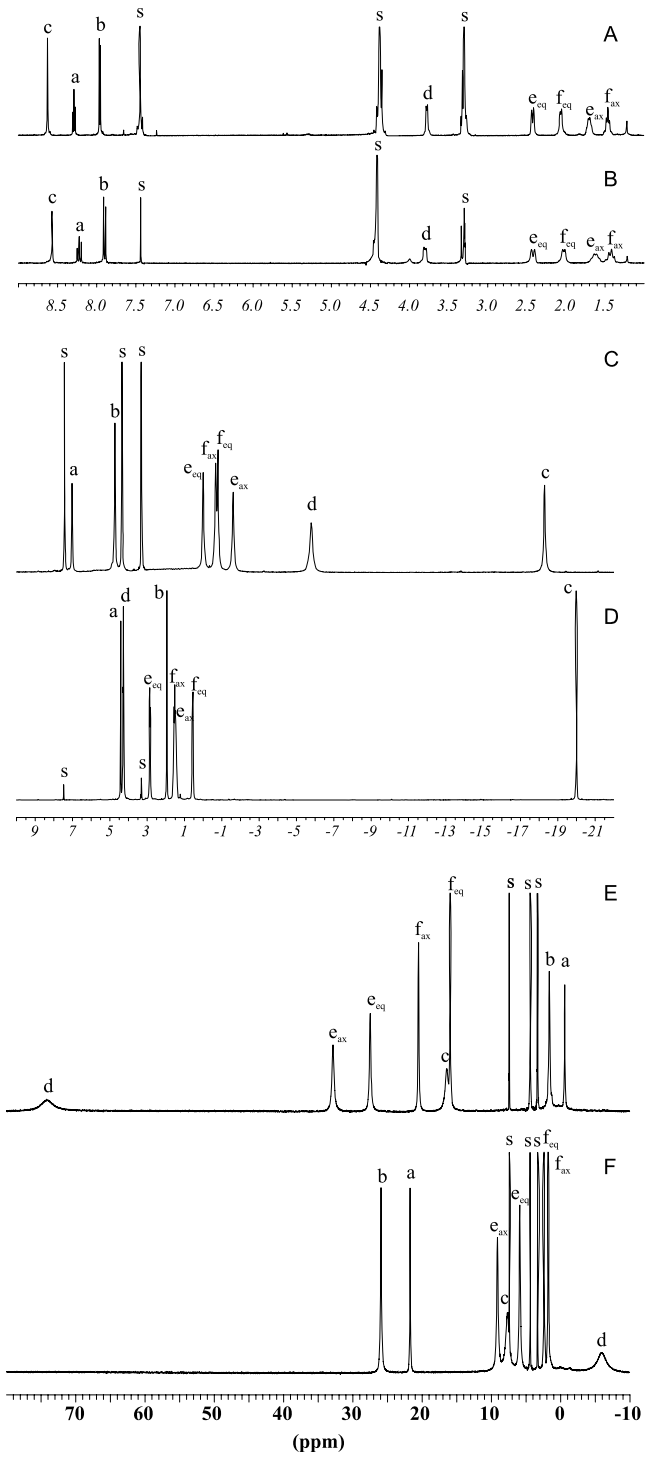

Fig. 3. The comparison of the ^{1}H NMR spectra ($CD_3OD/CDCl_3$ 1:2 v/v solution, 298 K) of complexes of L and L1: (A) $[LaL(NO_3)_3]\cdot 0.5H_2O$; (B) $[LaL1(NO_3)_3]$; (C) $[EuL(NO_3)_3]\cdot 2H_2O$; (D) $[EuL1(NO_3)_3]$; (E) $[ErL(NO_3)_3]\cdot 2H_2O$; (F) $[ErL1(NO_3)_3]$.

$$\delta_{ij}/C_j = G_i + A'_i\langle S_z\rangle_j/C_j, \quad (4)$$

$$\delta_{ij}/\langle S_z\rangle_j = A'_i + G_iC_j/\langle S_z\rangle_j, \quad (5)$$

where index i denotes given nucleus and index j refers to series of lanthanide ions. In the idealised situation of the exactly isostructural series of Ln(III) complexes, the crystal field parameters, geometrical factors and hyperfine coupling constants are equal in each complex and hence are the constants G and A'. Since the values of $\langle S_z\rangle$ and C_j are known [18–20], the linear fit of the Eq. (5) or Eq. (6), written for a set of Ln(III) complexes, gives the constants G and A' for each position. The crystal-field dependent method described above was refined into so called crystal-field independent approach based on analysis of shifts of two given protons along the lanthanide series [22–24]. In this method the crystal field parameters are factored out, and the ratios of geometric factors, $R_{ik} = G'_i/G'_k = G_i/G_k$, of nuclei i and k, are obtained in the linear fit of the equation:

$$\delta_{ij}/\langle S_z\rangle_j = (A'_i - R_{ik}A'_k) + R_{ik}\delta_{kj}/\langle S_z\rangle_j. \quad (6)$$

For series of isostructural Ln(III) complexes plots according to dependence (6) should be linear even when crystal field parameters are not constant along the series.

In order to check the isostructurality of the series of lanthanide(III) complexes of L in solution, the isotropic shifts were fit to Eqs. (4) and (5). As often observed, the plots according to Eq. (5) give better correlation in comparison with those based on Eq. (4). The plots based on Eq. (5) show three branches corresponding to series Ce(III)–Eu(III), Tb(III)–Ho(III) and Tm(III)–Yb(III) (Fig. 4). The points for Tb(III) (and to a lesser degree for Dy(III)) lie on the intersection of the first two branches, so alternatively they can be included in the second branch. In the case of plots corresponding to position **a** and **b** the first two branches are very close, giving the false impression of a correlation along the Ce(III)–Ho(III) series (Fig. 4). Each observed branch corresponds to a series of isostructural complexes. The presence of the first branch is in full agreement with the X-ray crystal data indicating that the La(III) and Sm(III) complexes are isomorphous.

The ''breaks'' observed in the middle of lanthanide ion series are often observed [17,22–24], and are ascribed to the abrupt change of the geometry of the complexes related to the gradual decrease of the ion radius. This change usually corresponds to the variation of coordination number. In the present case, the ''breaks'' reflect at least two changes of axial ligation along the series of lanthanide(III) complexes of the macrocycle L. The lighter lanthanides Ce–Eu form 11-coordinate complexes described above. The next series of Tb–Ho complexes are likely to lose coordinated solvent molecule and form 10-coordinate complexes with two bidentate nitrate anions on the two sides of the macrocyle. The coordination number is further decreased for the Tm(III) and Yb(III) complexes, e.g., as a result of coordination of monodentate nitrate anion or replacement of bidentate nitrate anion by solvent molecule. The correlation concerning two experimental points (Tm(III) and Yb(III)) is not meaningful, so these two complexes may further vary in geometry.

The data for Sm(III) complexes were not taken into account in the analysis, since the isotropic shifts as well as $\langle S_z\rangle$ value of Sm(III) exhibit the largest relative errors,

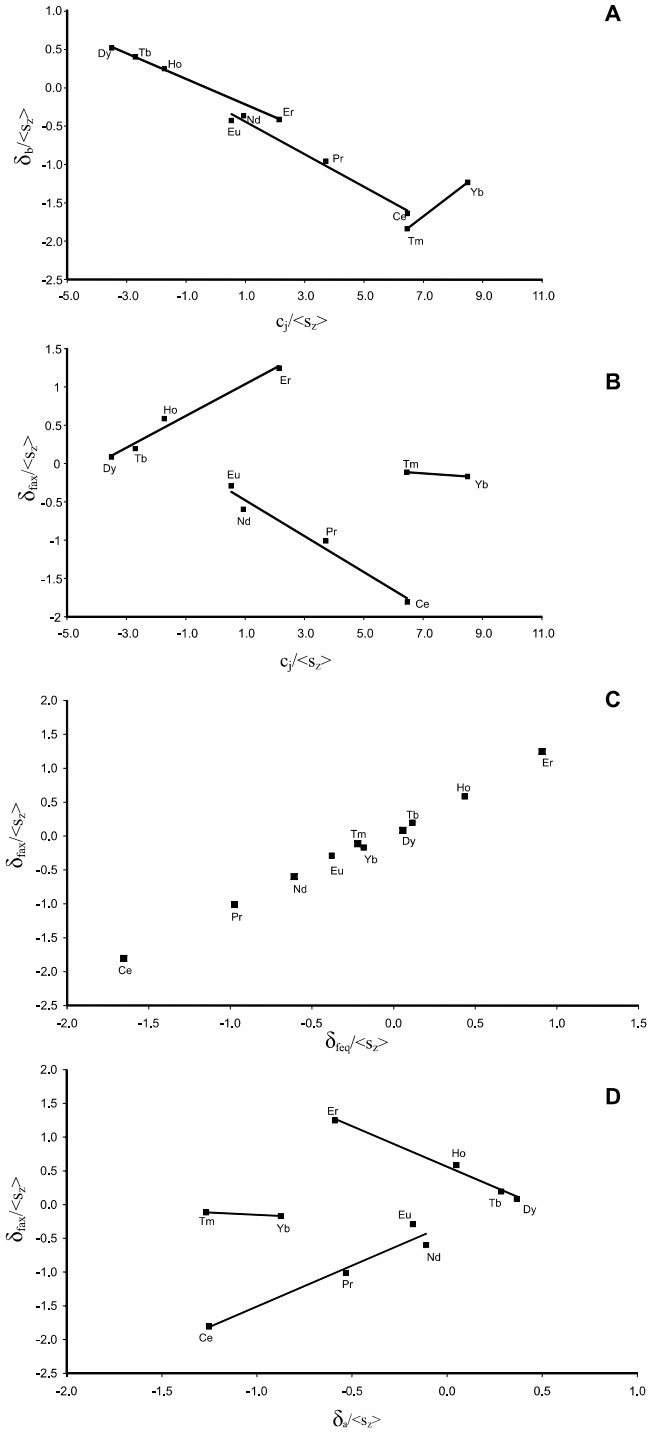

Fig. 4. Plots of $\delta_{ij}/\langle S_z\rangle_j$ vs. $C_j/\langle S_z\rangle_j$ for protons **b** (plot **A**) and $\mathbf{f}_{ax}$ (plot **B**) in the $[LnL](NO_3)_3 \cdot nH_2O$ complexes ($CD_3OD/CDCl_3$ 1:2 v/v solution, 298 K). Plots of $\delta_{ij}/\langle S_z\rangle_j$ vs. $\delta_{kj}/\langle S_z\rangle_j$ for the pairs of protons $i = \mathbf{f}_{ax}$, $k = \mathbf{f}_{eq}$ (plot **C**) and $i = \mathbf{f}_{ax}$, $k = \mathbf{a}$ (plot **D**) in the $[LnL](NO_3)_3 \cdot nH_2O$ complexes ($CD_3OD/CDCl_3$ 1:2 v/v solution, 298 K).

and as often observed [17], the data for Sm(III) complexes exhibit larger deviations in the plots. The data for Gd(III) complexes were also not analysed, because the severe broadening of the lines precluded observation and assignment of NMR signals.

The calculated values of G and A' (Table 4) allow in turn calculation of the dipolar and contact contributions to the isotropic shifts on the basis of Eqs. (2) and (3), respectively. The contact contribution dominates the paramagnetic shifts of the $[EuL](NO_3)_3 \cdot 2H_2O$ complex, in particular, the large contact shift −23.43 ppm of the azomethine proton is similar to the corresponding shift of $[EuL1](NO_3)_3$ complex [3a]. The G values are very different for the series of complexes of L and L1 of the heavier lanthanide ions, reflecting the very different dipolar contributions.

The results discussed above were verified using a crystal-field independent method [22–24]. When the shifts of pairs of remote protons, e.g., the pair of protons **a** and $\mathbf{f}_{ax}$ are analysed on the basis of the Eq. (6) (Fig. 4) similar breaks are obtained in the plots to those observed for plots based on Eq. (5). Thus the crystal-field independent method confirms the presence of structural changes. On the other hand, for the pairs of neighbouring protons, such as the pair of signals $\mathbf{f}_{ax}$ and $\mathbf{f}_{eq}$ (Fig. 4), linear plots following the Eq. (6) are obtained for the whole series of paramagnetic lanthanide ions. These correlations reflect parallel changes of geometric factors for the pairs of close nuclei [3a], rather than the presence of one series of isostructural complexes.

The shifts of $[YbL(NO_3)_3]_2 \cdot 2.5H_2O$ complex are expected to be dominated by dipolar contribution. The dipolar shift [17] is given by the Eq. (7):

$$\delta_{dip} = D_1 G_1 + D_2 G_2 = \frac{(\bar{\chi} - \chi_{zz})}{2N}\left\langle \frac{1 - 3\cos^2\theta}{r^3} \right\rangle + \frac{(\chi_{xx} - \chi_{yy})}{2N}\left\langle \frac{\sin^2\theta\cos 2\varphi}{r^3} \right\rangle, \quad (7)$$

where χ_{xx}, χ_{yy} and χ_{zz} are the principal components of magnetic susceptibility tensor and r, θ and φ are polar coordinates of the given nucleus. The ^{1}H NMR spectrum of this complex is rather unusual, because all the signals are in practically diamagnetic region −0.24 to 6.06 ppm. For other macrocyclic Yb(III) complexes a wide range of sizable paramagnetic shifts is observed [3a,3b, 3e,25,26], e.g., for the $[YbL1](NO_3)_3$ complex of ligand L1 the signals span the 0.55–25.84 ppm range. The small range of paramagnetic shifts of $[YbL](NO_3)_3 \cdot 2.5H_2O$ indicate small magnetic anisotropy of Yb(III) ion in this complex. The values of magnetic anisotropy parameters D_1 and D_2 have been varied in the computer simulation of Eq. (7) to obtain the best agreement between the calculated dipolar shifts and the experimental isotropic shifts. The values obtained for D_1 and D_2 were −500 and 260 ppm × Å^3, respectively, indeed much smaller than the values obtained for the related $[YbL1(NO_3)_3]_2$ complex. A satisfactory agreement factor ($R = 0.097$) was obtained in the calculation. The magnetic z axis is rotated by $\alpha = 19°$ from the direction perpendicular to the macrocycle plane. Similar values ($D_1 = -540$ ppm Å^3, $D_2 = 190$ ppm Å^3, $\alpha = 15°$ and $R = 0.084$) were obtained in a simplified calculations taking into account only one quarter of the macrocycle.

Table 4

On the other hand the range of paramagnetic shifts is larger for the acetate (−23.73 to 28.06 ppm) and mixed acetate/nitrate (−10.40 to 23.84 ppm) Yb(III) complexes of L. These complexes were generated in solution during titration of the $[YbL](NO_3)_3 \cdot 2.5H_2O$ complex with sodium acetate monitored by NMR spectroscopy. Analogous complexes were observed during titration of Eu(III) derivative (Supplementary Fig. 3). Addition of 1 equiv. of acetate results in formation of a mixture containing $[LnL](AcO)(NO_3)^+$ species. The addition of two or more equivalents of acetate leads to complete formation of $[LnL](AcO)_2^+$derivatives. The formation of these complexes is easily observed, since, as previously noticed [3b,25,26], the NMR spectra of macrocyclic complexes of paramagnetic Ln(III) ions strongly depend on axial ligation. The formation of mixed acetate/nitrate species is not accompanied by doubling of the number of lines observed for analogous complexes of L1 [3b]. This difference reflects faster exchange of axial ligands for the complexes of L, resulting in higher effective symmetry, as discussed above.

5. Conclusions

The crystal structures of La(III) and Sm(III) complexes of the macrocycle L show 11-coordinate metal ion bound in the centre of the macrocycle. The NMR results confirm that the complexes of L with the lighter lanthanide(III) ions are isostructural, but the complexes with heavier lanthanides differ in axial ligation. The comparison of complexes of the *meso*-macrocycle L with the complexes of the chiral isomeric macrocycle L1 shows the effect of the configuration of the stereogenic carbon atoms on the properties of lanthanide(III) complexes. The main differences are:

1. The complexes of the macrocycle L are thermodynamically less stable.
2. The steric requirements of L are related to higher coordination number of the bound Ln(III) ion.
3. The macrocycle L adopts bent conformation in its Ln(III) complexes, while L1 adopts helically twisted conformation.
4. The chemical shifts of the complexes of L and L1 with the same paramagnetic Ln(III) are drastically different as a result of completely different dipolar contribution to the paramagnetic shift.

analyzer. Infrared spectra were recorded as KBr pellets in the range 4000–200 cm^{-1} on Pye–Unicam SP-3-300 spectrophotometer. The melting points were determined with a Gallenkamp electrically heated apparatus. ^1H NMR were recorded on a JEOL AL-300 FT spectrometer operating at a frequency of 300 MHz using $CDCl_3$ as solvent with TMS as internal reference. ^{13}C NMR spectra were recorded at a frequency of 200 MHz using $CDCl_3$ as solvent and TMS as an internal reference. ^{31}P NMR spectra were recorded on a Bruker ACP-300 spectrometer operating at a frequency of 121.5 MHz with $(CH_3O)_3P$ as external reference set at zero value.

2.2. Preparation of ligand (Hbztsc)

To a solution of thiosemicarbazide (2.5 g, 0.027 mol) in hot distilled water (50 mL) and glacial acetic acid (5 mL), was slowly added benzophenone (4.99 g, 0.027 mol) dissolved in methanol (30 mL). The contents were refluxed for 30 h. and the clear solution containing yellowish orange oily layer, was poured in a beaker and stirred vigorously with a glass rod. The yellow solid formed was dried and recrystallised using methanol. Slow evaporation of the solution gave clear yellow crystals. (25%, m.p. 160–162 °C). *Anal.* Calc. for $C_{14}H_{13}N_3S$: C, 65.79; H, 5.09; N, 16.45. Found: C, 65.66; H, 4.93; N, 16.25%. Main IR peaks (KBr, cm^{-1}): ν(N–H) 3412 s, 3346 s, 3247 m, (–NH_2–) 3151 s (–NH–); 1608b, 1437b ν(C=N) + δNH_2 + ν(C=C); 1070 s, 1026 s, 846 s (thioamide moiety). ^1H NMR ($CDCl_3$, δ ppm) 8.68 (–N^2H), 7.81 s, 6.45 sb (N^1H_2), 7.27–7.61 m (Ph). ^{13}C NMR ($CDCl_3$, δ ppm, J, Hz): 178.8 (C^1); 151.0 (C^2); 136.3, 131.0 (C^3); 130.3, 130.23 (C^6); 129.86, 127.7 ($C^{4,8}$); 128.4 ($C^{5,7}$).

2.3. Synthesis of complexes

2.3.1. [CuCl(η^1-S-Hbztsc)(PPh_3)$_2$] · CH_3CN (1)

To a solution of CuCl (0.025 g, 0.25 mmol) in dry acetonitrile (15 mL) was added solid Hbztsc (0.064 g, 0.25 mmol) and the contents were stirred for 3 h at room temperature. During stirring, a yellow solid formed was separated. To this solid suspended in acetonitrile was added PPh_3 (0.132 g, 0.50 mmol) and stirring was continued for further 1 h followed by refluxing for 10 min. Clear light yellow solution formed was filtered and allowed to evaporate at room temperature. Slow evaporation of solution gave clear light yellow crystals. Complex is soluble in chloroform, dichloromethane and hot acetonitrile (60%, m.p. 182–184 °C). *Anal.* Calc. for $C_{50}H_{43}ClCuN_3P_2S \cdot CH_3CN$: C, 67.83; H, 5.00; N, 6.08. Found: C, 67.58; H, 5.04; N, 5.52%. Main IR peaks (KBr, cm^{-1}): ν(N–H) 3336 s, 3238 m (–NH_2–), 3144 m (–NH–); 1602 m, 1585 sh ν(C=N) + $\delta(NH_2)$ + ν(C=C); 1072 s, 1024 s, 841 s (thioamide moiety); 1093 s ν(P–C_{Ph}). ^1H NMR ($CDCl_3$, δ ppm) 9.11 b (–N^2H), 8.57 s, 6.91 s (–N^1H_2), 7.29–7.69 m (Ph + PPh_3). ^{13}C NMR ($CDCl_3$, δ ppm, J, Hz) 176.9 (C^1); 157.9 (C^2); 136.3, 131.1 (C^3); 130.4 (C^6); 129.8, 127.8 ($C^{4,8}$); 128.6 ($C^{5,7}$); 133.9 (*i*-C, PhP); 133.9 (*o*-C, $J_{P-C} = 15.1$, PhP); 129.4 (*p*-C, PhP); 128.4 (*m*-C, $J_{P-C} = 8.8$, PhP). ^{31}P NMR ($CDCl_3$, δ ppm): −112.16 ppm, $\Delta\delta(\delta_{complex} - \delta_{ligand}) = 0.991$ ppm. Compound **2** was prepared in the similar manner.

2.3.2. [CuBr(η^1-S-Hbztsc)(PPh_3)$_2$] · CH_3CN (2)

Crystals were grown from an acetonitrile solution at room temperature. Complex is soluble in chloroform, dichloromethane and hot acetonitrile (61%, m.p. 184–186 °C). *Anal.* Calc. for $C_{50}H_{43}BrCuN_3P_2S \cdot CH_3CN$: C, 64.70; H, 4.76; N, 5.80. Found: C, 64.82; H, 5.15; N, 5.31%. Main IR peaks (KBr, cm^{-1}): ν(N–H) 3344 s, 3236m (–NH_2–), 3157 m (–NH–); 1602 s, 1585 m ν(C=N) + $\delta(NH_2)$ + ν(C=C); 1025 s, 837 s (thioamide moiety); 1091 s ν(P–C_{Ph}). ^1H NMR ($CDCl_3$, δ ppm) 9.02 b (–N^2H), 8.46 s (–N^1H_2), 7.20–7.66 m (–N^1H_2 + Ph + PPh_3). ^{13}C NMR ($CDCl_3$, δ ppm, J, Hz) 176.6 (C^1); 151.7 (C^2); 136.3, 131.1 (C^3); 130.4 (C^6); 129.5, 127.8 ($C^{4,8}$); 128.5 ($C^{5,7}$); 133.4 (*i*-C, PhP), 133.9 (*o*-C, $J_{P-C} = 14.7$, PhP),129.4 (*p*-C, PhP), 128.4 (*m*-C, $J_{P-C} = 9.1$, PhP). ^{31}P NMR ($CDCl_3$, δ ppm): −112.73, $\Delta\delta(\delta_{complex} - \delta_{ligand}) = 0.427$ ppm.

2.3.3. [CuI(η^1-S-Hbztsc)$_2$] (3)

To a solution of CuI (0.025 g, 0.13 mmol) in dry acetonitrile (20 mL) was added solid Hbztsc (0.067 g, 0.26 mmol) and contents were stirred for 4 h. Clear yellow solution was filtered and allowed to evaporate at room temperature. Slow evaporation of solution gave clear

yellow crystalline needles. Complex is soluble in chloroform, dichloromethane and hot acetonitrile. (68.5%, m.p. 210–212 °C). *Anal.* Calc. for $C_{28}H_{26}CuIN_6S_2$: C, 47.92; H, 3.71; N, 11.98. Found: C, 48.53; H, 3.84; N, 11.81%. Main IR peaks (KBr, cm^{-1}): ν(N–H) 3390 s, 3346 s, 3223 m (–NH_2–) 3149 s (–NH–); 1595 sh, 1583 m, 1500 m ν(C=N) + δ(NH) + ν(C=C); 1072 s, 1026 s, 831 s (thioamide moiety). ^{1}H NMR ($CDCl_3$, δ ppm), 8.78 s (–N^2H), 8.06 sb (–N^1H_2), 7.28–7.60 m (N^1H_2 + Ph).

2.4. X-ray crystallography

Suitable light yellow crystals of Hbztsc and compounds **1**, **2** and **3** were mounted on an automatic Enraf Nonius CAD-4 diffractometer equipped with graphite monochromator and Mo Kα radiation ($\lambda = 0.71073$ Å). The unit cell dimensions and intensity data were measured at 93 K for Hbztsc, **1**, **2** and 100 K for **3**. The structures were solved by direct methods and refined by full matrix least squares method based on F^2. All nonhydrogen atoms were refined anisotropically using XCAD-49 (data reduction) and SHELXL. The hydrogen atoms were calculated using structure factor calculations in their idealized positions. The crystallographic data is summarized in Table 1.

3. Results and discussion

3.1. Synthesis and infrared spectroscopy

Reaction of copper(I) chloride/copper(I) bromide with benzophenone thiosemicarbazone (Hbztsc, Ph_2C=N–NH–C(=S)–NH_2) in the molar ratio of 1:1 in MeCN formed an insoluble product of stoichiometry {CuX-(Hbztsc)} which after addition of two moles of PPh_3 yielded a monomeric tetrahedral complex [CuX(Hbztsc)(PPh_3)$_2$] (X = Cl, **1**; Br, **2**) (Scheme 1). Reaction of copper(I) iodide with Hbztsc in the presence of two moles of PPh_3 did not form similar complex, rather it formed a known cubane complex, {$Cu_4I_4(PPh_3)_4$}. However copper(I) iodide with Hbztsc in MeCN in the absence of PPh_3, formed a trigonal complex [CuI(Hbztsc)$_2$] (**3**). All these complexes have melting points in the range of 182–210 °C. Complexes **1** and **2** are readily soluble in chloroform while **3** is sparingly soluble.

The IR spectra of ligand (Hbztsc) shows ν(N–H) in the range of 3412–3247 cm^{-1} (–NH_2) and at 3151 s (–NH–). In all the complexes, ν(N–H) ranges from 3390–3236 cm^{-1} (–NH_2) and 3160–3140 cm^{-1} (–NH–). It suggests the neutral monodentate (η^1-S) nature of ligand Hbztsc. The thioamide bands ν(C–S) + ν(C–N) appear in the range of 846–1085 cm^{-1} in Hbztsc. These modes appear in the region of 830–1090 cm^{-1} in the complexes. Medium to broad peaks appear at 1608 b, 1473 b cm^{-1} in free ligand corresponding to ν(C=N), δ(NH_2) and ν(C=C). However, they appear in the range of 1500–1605 cm^{-1} in all the complexes. A characteristic ν(P–C_{Ph}) peak at 1093 s cm^{-1} in (**1**) and 1091 s cm^{-1} in (**2**) confirms the presence of PPh_3 in the coordinated form in the complexes.

3.2. Crystal structures of ligand and complexes *1–3*

The atomic numbering schemes for molecular structures of ligand and complexes **1**, **2** and **3** are shown in Figs. 1–4 and the selected bond lengths and angles are given in Table 2.

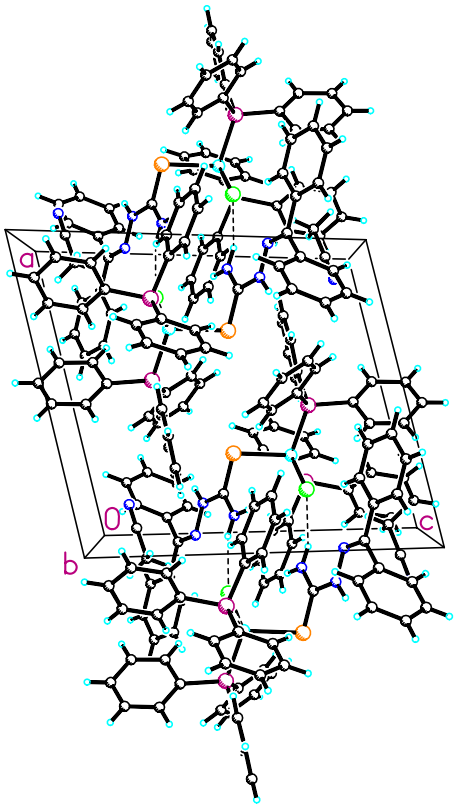

Fig. 2b. Packing diagram of [CuCl(η^1-S-Hbztsc)(PPh_3)$_2$] · CH_3CN (**1**).

3.2.1. Ligand

The ligand (Hbztsc) crystallized in the monoclinic space group *C*2/*c*. The S and the hydrazinic N(3) atoms are *trans* with respect to C(1)–N(2) bond and thus ligand has *E* configuration. The C(1)–S bond distance, 1.6866(17) Å is close to a double bond, and comparable with ca.1.69 Å in salicylaldehyde thiosemicarbazone and 2-hydroxyacetophenone [43,44]; other bonds, C(2)–N(3), C(1)–N(1), C(1)–N(2), N(2)–N(3) are also comparable with the literature data

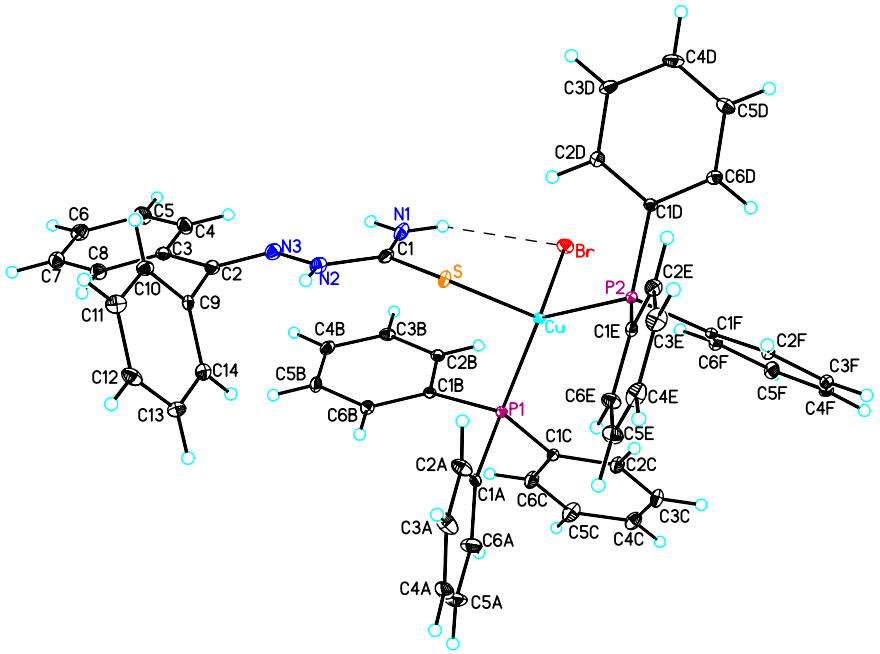

Fig. 3a. The structure of $[CuBr(\eta^1\text{-S-Hbztsc})(PPh_3)_2]\cdot CH_3CN$ (**2**) with numbering scheme.

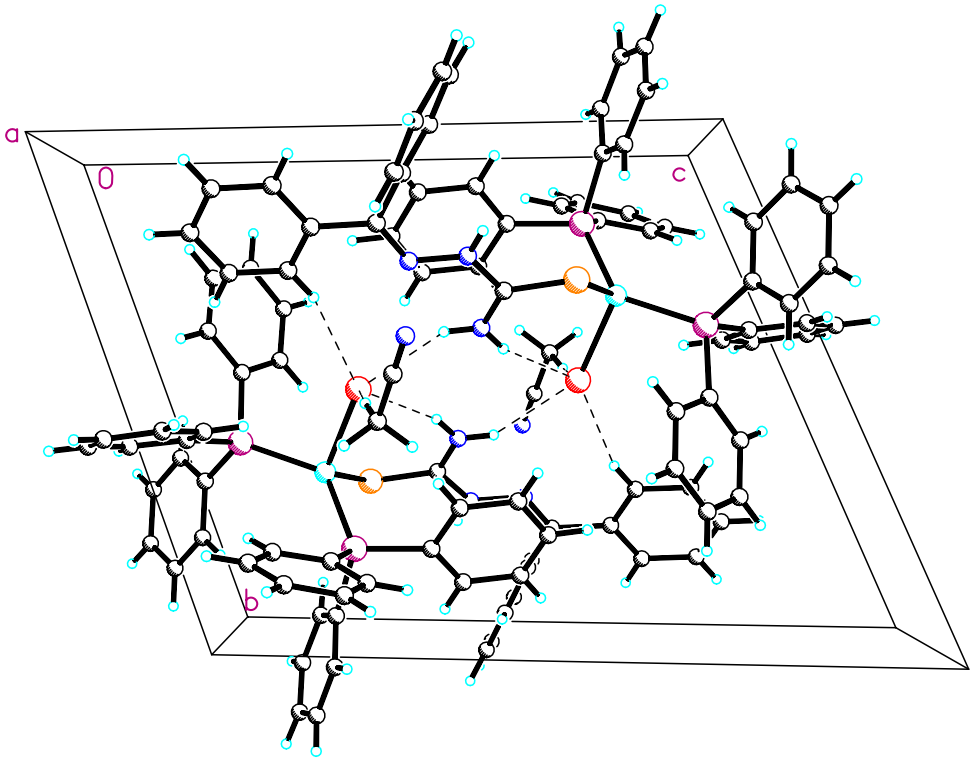

Fig. 3b. Packing diagram of $[CuBr(\eta^1\text{-S-Hbztsc})(PPh_3)_2]\cdot CH_3CN$ (**2**).

[43–45]. There is a moderately strong intermolecular N(1)–H(1B)···S* bond [2.49 Å] {cf. sum of van der Waals radii of H and S, 3.0 Å [46]} and a long range C–H_{Ph}···S intermolecular hydrogen bonding leading to formation of dimer as shown in Fig. 1b.

3.2.2. Complexes *1–3*

Complexes **1** and **2** have the triclinic space groups, while complex **3** has monoclinic space group. The E-configuration of free ligand is unchanged in the complexes. In complex **1**, copper is bonded to one S atom of the ligand

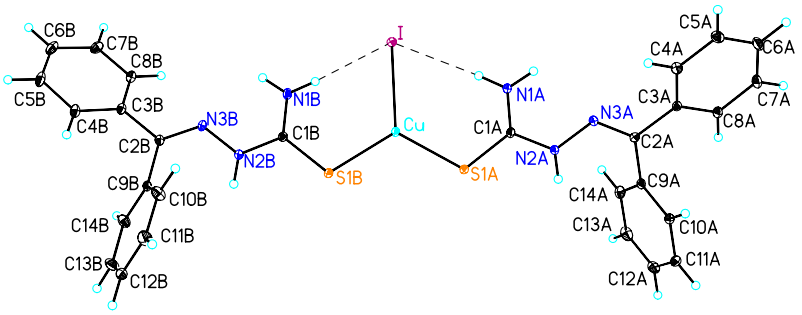

Fig. 4a. The structure of $[CuI(\eta^1\text{-S-Hbztsc})_2]$ (**3**) with numbering scheme.

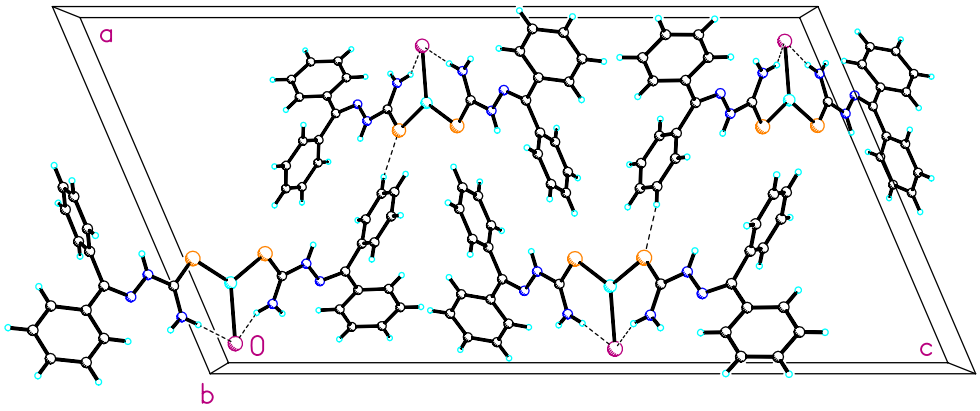

Fig. 4b. Packing diagram of $[CuI(\eta^1\text{-S-Hbztsc})_2]$ (**3**).

(Hbztsc) with Cu–S bond distance of 2.3606(8) Å; two P atoms from PPh_3 ligands {Cu–P(1), 2.2665(8) Å; Cu–P(2), 2.2505(8) Å}, and one chlorine atom at Cu–Cl bond distance of 2.3757(7) Å. Complex **2** has similar bond parameters, viz., Cu–S, 2.3542(17) Å; Cu–P(1), 2.2749 (17) Å; Cu–P(2), 2.2552(16) Å; Cu–Br, 2.4863(12) Å. The angles around Cu lie in the ranges, 102.55(3)–126.00(3)° and 99.49(6)–131.56(4)° in compounds **1** and **2**, respectively, with P(2)–Cu–P(1) being the largest, and P(2)–Cu–X {X = Cl, Br} being the smallest. This reveals a distorted tetrahedral geometry around Cu atom in both the complexes. Finally in complex **3**, each Cu is bonded to two S atoms of two Hbztsc ligands with Cu–S distances of 2.2269(7), 2.2321(7) Å, and to one iodine atom with Cu–I bond distance of 2.5441(4) Å. The angles around Cu range from 118.95(2)° to 121.42(2)°, indicating a trigonal geometry around copper center. The C–S bond distances in these complexes are marginally longer vis-à-vis free ligand, and reveal weakening of pπ–pπ bond. It may be noted that trends of variation in Cu–P, Cu–S and C–S distances are analogous to the literature values [19,21,24a]. The absence of PPh_3 in trigonal planar complex **3** makes a stronger Cu–S bond. Further, Cu–X distances in the complexes are much less than the sum of the ionic radii of Cu^+ and X^- (Cu^+, Cl^-, 2.58 Å; Cu^+, Br^-, 2.73 Å; Cu^+, I^-, 2.97 Å [46]).

In the solid state, amino (–HN^1H) hydrogen atom of thiosemicarbazone is involved in hydrogen bonding in all the complexes (Table 3). In complex (**1**), one hydrogen of amino group is engaged in intramolecular –$HN^1H\cdots$Cl hydrogen bonding while other hydrogen is involved in intermolecular –$HN^1H\cdots$Cl hydrogen bonding forming a dimer (Fig. 2b). Similar trend of bonding is seen in complex **2** except for the presence of additional long range C–H_{Ph}(Hbztsc)$\cdots$Br contact resulting in the formation of 8 membered ring in the center of the dimer. Two molecules of CH_3CN are present as solvent of crystallization per unit cell in the crystal packing but are not involved in any sort of hydrogen bonding at all and also do not appear in the analysis (Fig. 3b). However, in complex **3**, one hydrogen of amino group is engaged in intramolecular –$HN^1H\cdots$I hydrogen bonding while other hydrogen remains free. In addition, long range intermolecular C–H_{Ph}(Hbztsc)$\cdots$S hydrogen bonding is present forming a dimer (Fig. 4b).

A comparison of P–Cu–P, S–Cu–X and Cu–S–C bond angles is made for various Cu^I-complexes with analogous thiosemicarbazones (Table 4). The groups at C^2 carbon appear to play significant role in affecting the above angles which are correlated with the electronegativity of halogen atoms. When py, H (**4**–**6**) [24a] ; and Ph, H (**7**, **8**) [24a] are bonded to C^2 carbon, angles Cu–S–C and S–Cu–X increase with change in X from chloride to iodide; and the corresponding P–Cu–P bond angles decrease. The halogens are engaged in intramolecular –$N^2H\cdots$X, or –$N^1H_2\cdots$X hydrogen bonds and strengths of these bonds obviously vary with the electronegativity of halogen atoms. Chart 3 exhibits how the amino and imino hydrogen atoms

are involved in hydrogen bonding with halogens. A stronger $-N^2H\cdots X$ or $-N^1H_2\cdots X$ hydrogen bond shortens the Cu–S–C bond angle, which leads to opening of P–Cu–P angle. The trend for *p*-HOC_6H_5, H groups (**9**, **10**) [21] bonded to C^2 is similar except for S–Cu–X which decreased and this may be due to the packing effect or presence of solvent of crystallization. Due to rigidity of isatin groups (**11**, **12**) [19], the above trends are less significant.

The most significant observation is found when two Ph groups are bonded to C^2 carbon. Both Cu–S–C and S–Cu–X angles increase as noted for above complexes. However, P–Cu–P angle increases with change in halide from chloride (121°) to bromide (131°) in complexes **1** and **2**, unlike the expected decreasing trend. The increased P–Cu–P bond angle in complex **2** is due to the steric effect of two Ph groups at C^2 carbon with large bromide group. In case of still bulky iodide group in complex **3**, this steric effect becomes very large and this explains lack of formation copper(I) iodide complex containing PPh_3 ligands similar to **1** or **2**.

3.3. NMR spectroscopy

The ^1H NMR of ligand Hbztsc in $CDCl_3$ shows a singlet at 8.68 ppm (N^2H), which shifted downfield to 9.11 ppm in complex **1**, 9.02 ppm in complex **2** and 8.78 ppm in complex **3**. This is in accordance with the coordination behaviour of thiosemicarbazones [24a], and its presence in the spectra of complexes indicates that N^2H protons are not deprotonated. The N^1H_2 protons of free ligand Hbztsc exhibit two sets of signals, one broad peak (unresolved) at 6.45 ppm and a doublet at 7.81 ppm. This can be attributed to the restricted rotation about C^1–N^1 bond axis due to delocalization of lone pairs of electrons on N^1H_2 nitrogen. A pair of broad signals corresponding to N^1H_2 protons appear downfield at 6.91 ppm and 8.56 ppm in complex **1**. However, a single broad signal is observed at 8.47 ppm in complex **2** and 8.06 ppm in complex **3**. The second signal is probably obscured by the protons of phenyl rings. This may be attributed to intermolecular as well as intramolecular $-HN^1H\cdots X$ (X = Cl, Br, I) hydrogen bonding in the solid state which may be operative even in the solution phase. The phenyl protons in free ligand show a series of multiplets in the region of 7.27–7.61 ppm. Ph_3P signals in the complexes merged with the signals of phenyl protons of ligand and show a series of doublets and multiplets in the region of 7.29–7.69 ppm in **1** and 7.20–7.66 ppm in **2**. In complex **3**, phenyl protons appeared unchanged at 7.28–7.60 ppm.

The ^{13}C NMR spectra provide more convincing information about the monodentate behaviour of Hbztsc moiety in the complexes. The C^1 carbon signal appears at δ 176.9 ppm in **1** and at δ 176.5 ppm in **2**, which are upfield relative to the free ligand (δ 178.8 ppm). Further, C^2 carbon signal at δ 157.9 ppm in **1** and δ 151.7 ppm in **2** shifts downfield relative to the free ligand (δ 150.98 ppm), the former carbon showing more pronounced shift. This behaviour is similar to that observed for related complexes

Table 3

(**8**) (Hbtsc = Benzaldehyde thiosemicarbazone) [24a]; [CuBr(L)$(PPh_3)_2$] (**9**), [CuI(L)$(PPh_3)_2$] (**10**) (L = 4 hydroxybenzaldehyde thiosemicarbazone) [21]; [CuBr(H_2istsc)$(PPh_3)_2$] (**11**); [CuI(H_2istsc)$(PPh_3)_2$] (**12**) (H_2istsc = Isatin-3-carbaldehyde thiosemicarbazone) [19].

[24a]. C^3 carbon in free ligand shows a pair of low intensity signals at δ 136.3 ppm and δ 131.0 ppm. This can be attributed to the fact that the two phenyl rings at C^2 carbon in the free ligand as well as in complexes are not coplanar rather at an angle with respect to each other. Thus carbon atoms of two phenyl rings at C^2 carbon are in different chemical environments due to different spatial arrangement of phenyl rings, also revealed by the X-ray structure of the ligand (Fig. 1a). Similarly, $C^{4,8}$ and C^6 carbon atoms show pairs of signals at δ 129.8, 127.7 ppm and δ 130.3, 130.2 ppm, respectively. A single broad signal at δ 128.4 ppm is observed for $C^{5,7}$ carbons. Similar signals are observed for ligand ring carbons (C^3,$C^{4,8}$,$C^{5,7}$,C^6) in the complexes **1** and **2** showing no significant shift. Various signals due to *ipso* carbon, *ortho*, *meta* and *para* carbons of phosphine ligands are well resolved in both the complexes. The *i*-C, *ortho*, *meta* and *para* carbon signals of Ph rings of

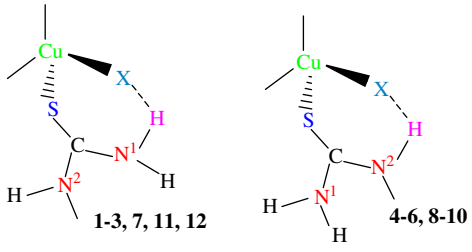

Chart 3.

PPh_3 in **1** appear as separate and are similar to the corresponding signals in **2**.

The ^{31}P NMR signal of free Ph_3P appears at −113.153 ppm. A single broad signal is observed in the complexes **1** and **2** indicating the equivalence of two PPh_3 groups. This signal shifted downfield to −112.16 ppm in **1** and −112.73 ppm in **2** with coordination shifts ($\delta_{complex} - \delta_{ligand}$) of 0.99 and 0.43 ppm, respectively. Such low coordination shifts can be attributed to the equilibrium between coordinated PPh_3 and the free PPh_3 in the solution phase, and similar behaviour was observed in the literature [24b].

4. Supplementary material

Supplementary data is available from CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 12336033; e-mail: deposit@ccdc.cam.ac.uk, or on the web www.ccdc.cam.ac.uk) on request quoting the deposition number CCDC 297906 for (**1**), 297907 for (**2**), 297908 for (**3**) and 297909 for Hbztsc.

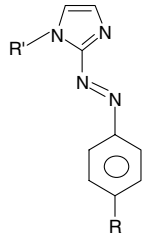
self-assembly of metal, bidentate azoimine blocker and pseudohalide, we have been successful in isolating and characterizing tetranuclear complexes with the formula $[Cu(RaaiR')(N_3)_2]_4$ [RaaiR′; R = H (**3**), Me (**4**); R′ = Me (**a**), Et (**b**)]. The structure has been confirmed by a single crystal X-ray diffraction study of $[Cu(HaaiMe)(N_3)_2]_4$ (**3a**). Variable temperature magnetic measurements of **3a** show the occurrence of ferromagnetic ($J_1 = +25.3\ cm^{-1}$) and antiferromagnetic ($J_2 = -4.7\ cm^{-1}$) interactions through the double and single end-on azido bridges, respectively. Addition of excess of RaaiR′ to the respective tetranuclear copper(II) complex in 2-methoxy ethanol has enabled the cluster to be split into a mononuclear copper(II) complex of the composition $[Cu(RaaiR')_2(N_3)_2]$. The structure and magnetism are detailed below.

2. Results and discussion

2.1. The complexes

The complexes are synthesized by the reaction of 1-alkyl-2-(arylazo)imidazole (RaaiR′), $Cu(OAc)_2 \cdot H_2O$ and NaN_3 in MeOH in a 1:1:2 mole proportion at 298 K. The ligand is an unsymmetric, N,N′-bidentate chelator where N and N′ refer to N(imidazole) and N(azo) donor centres, respectively. The azide (N_3^-) is a bridging ligand showing its versatile coordination motifs. The composition, $[Cu(RaaiR')(N_3)_2]_4$ (R = H (**3**), Me (**4**); R′ = Me (**a**), (**b**)) has been confirmed by X-ray crystal structure determination of one of the compounds, $[Cu(HaaiMe)(N_3)_2]_4$ (**3a**). The tetranuclear cluster is dissociated into a mono-copper complex, $[Cu(RaaiR')_2(N_3)_2]$ (**5**, **6**) upon addition of excess of RaaiR′ to a 2-methoxy ethanol solution of the complex. The structure of the mononuclear copper(II) compound has also been established by X-ray structure study in one case, $[Cu(HaaiEt)_2(N_3)_2]$ (**6a**), and by comparing with previously reported results [16].



RaaiR′

R = H (**a**), Me (**b**); R′ = Me (**1**), Et (**2**)

2.2. Spectral studies

Infrared spectral data were assigned on comparing with the free ligand data and on comparing with $[Cu(RaaiR')_2(N_3)_2]$ [16]. The most significant observation is the appearance of strong sharp stretches at 2069–2082, 2045–2050 and 2026–2028 cm^{-1} for **3** and **4**. These correspond to $\nu_{asym}(N_3)$. This supports a bridging end-on type binding of N_3 in the complexes **3** and **4** [9,11,22]. Moderately intense stretchings at 1583–1598 and 1438–1448 cm^{-1} are due to ν(C=N) and ν(N=N), respectively [14].

Because of the insolubility of the complexes in common organic solvents, the electronic spectra of the complexes have been recorded in *N*,*N*-dimethyl formamide (DMF) solution in the UV–Vis region (200–900 nm). The complexes (**3**, **4**) exhibit four weak transitions around 715, 585, 475 and 450 nm. The position and intensity of the bands may not only be of d–d origin rather an admixture of d–d and MLCT ($d\pi(Cu) \rightarrow \pi^*$(ligand)) transitions. The bands $\leqslant$400 nm are presumably due to intra-ligand π–π^* and n–π^* transitions.

2.3. Crystal structures

2.3.1. $[Cu(HaaiMe)(N_3)_2]_4$ (**3a**)

The X-ray structure (Fig. 1) reveals that complex **3a** is a neutral tetranuclear copper(II) derivative, comprising a dimer-of-dinuclear copper(II) subunits. Selected bond lengths and angles are given in Table 1. There are two crystallographically unique copper(II) environments; one of them is a five-coordinated square-based pyramid with a CuN_5 donor set and other is a six-coordinated distorted octahedral CuN_6 type. The dinuclear core unit is generated by a two $\mu_{1,1}$-N_3 bridging scheme. Dimerisation of the dinuclear motif is carrying out by $\mu_{1,1}$-N_3-group bridging. Thus, an arrangement of four copper atoms is formed. Each copper centre has been chelated with a HaaiMe ligand in which the ligand acts as an unsymmetric bidentate N,N′-donor type where N(imidazole) and N(azo) refer to N and N′, respectively.

The atomic groups Cu(1), N(5), C(13), N(7), N(8) and Cu(2), N(1), C(3), N(3), N(4) constitute two chelate planes of mean deviation $\leqslant$0.02 Å. The pendant phenyl ring makes a dihedral angle of about 8° with the chelating

Symmetry code: $2-x, 1-y, 1-z$.

plane. The chelate angles of —Cu—N=N—C=N— are N(1)–Cu(2)–N(4), 69.54(9)°, N(5)–Cu(1)–N(8), 68.75(10)°. From the respective basal plane, the Cu(1) and Cu(2) centres are moved in same direction by −0.168(1) and −0.123(1) Å. These two planes are inclined at a dihedral angle of 87.22(10)°. In the dinuclear motif the bridging unit Cu_2N_2 is a four armed distorted plane of mean deviation ~0.02 Å. The Cu–N distances in the Cu_2N_2 unit reveal the distortion of the tetraatomic cycle: Cu(1)–N(1), 2.017(2); Cu(2)–N(1), 2.051(2); Cu(1)–N(12), 1.973(2); Cu(2)–N(12), 1.980(2) Å. The bridge angles are 100.60(11)° and 104.71(12)°. The other two angles (N(9)–Cu(1/2)–N(12)) are 77.77(10)° and 76.82(10)°. The chelate and bridge planes are inclined at an angle of 76.30(13)°. Double bridged azide groups are inclined at an acute angle with the bridge plane [N(9)–N(10)–N(11) makes 55° and N(12)–N(13)–N(14) makes 15° angle with Cu_2N_2]. The single-bridged azido group [N(15)–N(16)–N(17)] lies at an angle of 61° with the Cu_2N_2 motif. Dimerisation of the dicopper core generates the Cu_2N bridge unit (Cu(2_a)*–N(15)–Cu(1)) (* symmetry: $2-x, 1-y, 1-z$) of angle 106.59(12)°. The geometrical arrangement reflects the distorted orientation of the groups around the bridge. In the CuN_6 arrangement the donor centres are as follows: chelating HaaiMe gives two N-donor centres; three end-on azido bridged-N centres and a terminal azido-N donor. The bond parameters around the CuN_6 coordination environment shows a distorted octahedral arrangement. In the TBP CuN_5, the triangular base is constituted by N(8), N(13), N(15), Cu(1) and apical positions are occupied by N(9) and N(5). The azido bridge angles in the dinuclear copper(II) unit (Cu(1)–$\{\mu_{1,1}$-$N_3\}_2$–Cu(2)) are 100.60(11)° and 104.72(12)° and lie in the range of reported values [9,11,27]. The bridge angle has a major effect on the spin-exchange phenomena (evaluated from the exchange parameter J). Planarity of the Cu_2N_2 unit, chelate angle of the capping agent, dihedral angle between two coordination planes, steric and electronic factors of the ligand significantly control the magnetic properties of the complexes. The two dinuclear copper(II) cores (Cu(1)···Cu(2) unit) are bridged by a $\mu_{1,1}$-N_3 group in an inverted fashion (Cu(1) of core-1 is bridged by $\mu_{1,1}$-N_3 to Cu(2a)* (* symmetry: $2-x, 1-y, 1-z$) of core-2 and vice versa) to constitute an eight-member ring. The Cu(1)···Cu(2) distance is 3.13 Å and is similar to reported azido bridged (end-on) dicopper complexes [13] but shorter than oxobridged (Cu–O–Cu) phenolato compounds [7a]. In the single azido bridged (Cu(1)–$\{\mu_{1,1}$-$N_3\}$–Cu(2_a)*) (* symmetry: $2-x, 1-y, 1-z$) dinuclear copper(II) unit the Cu···Cu separation is 3.59(2) Å and is longer than the double azido bridged dicopper unit.

There are three types of (azido) N_3-groups present in the tetranuclear copper(II) unit: two N_3-units bridge two Cu(II)-centres in the dimeric core; one N_3-function serves to bridge two dimer cores and the last N_3-unit coordinates as a monodentate donor with one of the two copper centres in the dimer. Other N-donor centres are N(imidazole) and N(azo) from the chelated HaaiMe. Out of them, the N(azo) requires considerably more room than the other N-donors [23]. There are at least two steric reasons for this. First, the N(azo) belongs to an exocyclic N=N along with a pendant aryl group; thus the van der Waals repulsion will be greater than N(imidazole). Second, the N(azido) has larger s-character compared to N(azo) and thus N(azo) is more space demanding. The Cu–N(azo) distances are the longest in the series and are Cu(1)–N(8), 2.639(1) and Cu(2)–N(4), 2.632(3) Å. However, the Cu–N(azo) distances are less than the sum of the van der Waals radii of Cu(II) and N(azo) [24]. This implies a covalent interaction of N(azo) and Cu(II). Cu(II) has some preference to bind to N(imidazole) [25] compared to N(azo) and is shortened by 0.6 Å. The azido bond lengths lie in the range 1.12–1.21 Å. The azo N=N distances in the two chelated HaaiMe of the dimer are N(3)–N(4), 1.260(3) and N(7)–N(8), 1.243(4) Å, which are near to the free ligand value (1.250(1) Å) [26].

2.4. Magnetic study

The variable temperature magnetic susceptibility data for complex **3a** was recorded between 300 and 2 K. A plot of $\chi_M T$ versus T for the four copper(II) ions is shown in Fig. 2. At 300 K, the $\chi_M T$ value is 1.64 $cm^3\ mol^{-1}$ K, which

is close to that expected for four uncoupled spins, with $g = 2.09$. The value increases slightly on lowering the temperature and reaches a maximum (1.83 $cm^3\ mol^{-1}\ K$) at 22 K. Below this temperature $\chi_M T$ decreases to a value of 1.38 $cm^3\ mol^{-1}\ K$ at 2 K. The shape of this curve indicates dominant ferromagnetic coupling until 22 K and below this temperature $\chi_M T$ decreases from 1.8 to 1.4 $cm^3\ mol^{-1}\ K$, which is the signature of antiferromagnetic exchange and/or the presence of the ZFS of the ground state. To analyze the magnetic pathways it is necessary to schematize them as is shown in Fig. 3. This scheme matches with the structure that, as indicated above, can be considered as a dimer of dimers. The J_1 corresponds to the double end-on azido bridges with an equatorial–equatorial (short–short) coordination mode, whereas J_2 corresponds to the single end-on azido bridge, but in equatorial–axial (short–long) coordination mode. Thus, considering these two different J values, the analysis of the experimental susceptibility values has been performed using the following expression:

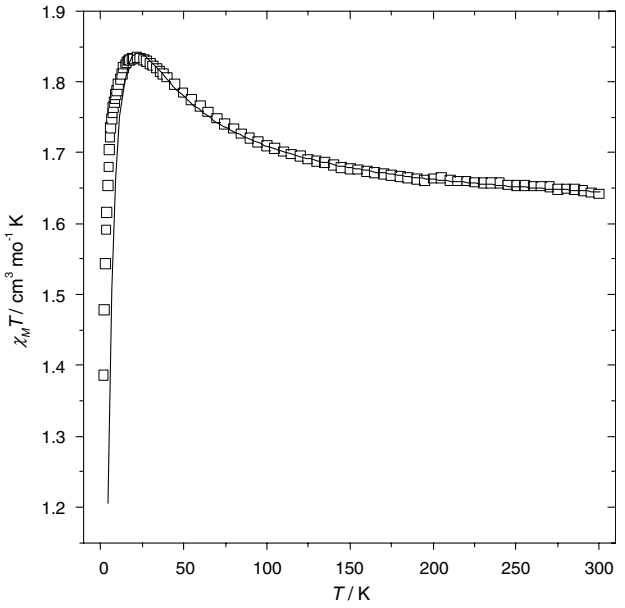

Fig. 2. Plot of the $\chi_M T$ vs. T data for complex **3a**. Solid line represents the best fit (see text).

$$\chi_M = Ng^2\beta^2/KT[A/B], \quad (1)$$

where $A = [30\exp(-E_1/kT) + 6\exp(-E_2/kT) + 6\exp(-E_3/kT) + 6\exp(-E_4/kT)]$, $B = 5[\exp(-E_1/kT) + 3\exp(-E_2/kT) + 3\exp(-E_3/kT) + 3\exp(-E_4/kT) + \exp(-E_5/kT) + \exp(-E_6/kT)]$.

E_n values can be obtained using the Kambe method from the Hamiltonian:

$$H = -J_1(S_1 \cdot S_2 + S_3 \cdot S_4) - J_2(S_1 \cdot S_3 + S_2 \cdot S_4)$$
$$E_1 = (-J_1 - J_2)/2, \quad E_2 = (-J_1 + J_2)/2,$$
$$E_3 = (J_1 + J_2)/2, \quad E_4 = (J_1 - J_2)/2,$$
$$E_5 = (J_1 + J_2)/2 + (J_1^2 + J_2^2 - J_1J_2)^{1/2},$$
$$E_6 = (J_1 + J_2)/2 - (J_1^2 + J_2^2 - J_1J_2)^{1/2}$$

where J_i parameters correspond to those given in Fig. 4. The best fit parameters found are: $J_1 = +25.3\ cm^{-1}$, $J_2 = -4.7\ cm^{-1}$, $g = 2.07$ and $R = 1.6 \times 10^{-4}$, where $R = \sum[(\chi_M T)_{exp} - (\chi_M T)_{cal}]^2 / \sum(\chi_M T)^2_{exp}$. Attempts to fit the experimental data introducing D, zJ' or θ parameters in the expression (1) did not improve the R factor.

The values of the superexchange parameters are $J_1 = +25.3\ cm^{-1}$ and $J_2 = -4.7\ cm^{-1}$ which are typical for such Cu(II) complexes with these structural features. The bonding pattern of Cu–(N_3)–Cu is unique in this example, having one single end-on and double end-on azide bridging, and is different from so far reported end-on azido bridged Cu(II) complexes (Table 2). Indeed, for the equatorial–equatorial coordination mode (such as in the J_1 pathway), the magnetic behavior of copper-azide bridged complexes in end-on mode is well-known [28–35] and the general trends of their magnetic properties are well-correlated to the structural parameters of the bridge (mainly Cu–N_{azide}–Cu angle). Currently, the end-on or ($\mu_{1,1}$) double bridges are usually associated with ferromagnetic behavior [5], although for angles out of the range 96–104° the interaction can be antiferromagnetic [27,36]. However, for azido anions bridging in an end-on fashion at the axial–equatorial position (such in the J_2 case, Fig. 3), the reported J values are always small and they can be ferromagnetic or antiferromagnetic [37–42], depending on the Cu–N distance and the τ parameter ($\tau = 0$ for square pyramidal or elongated octahedral geometries and

[a] OBISDIEN = 1,13-dioxa-4,7,10,16,19,23-hexaazacyclotetracosane; *t*-bupy = 4-*tert*-butylpyridine; (tbz = bis(2-benzimidazolyl)propane; DMPDT = 2,5-bis-((pyridylmethy1)thio)thiadiazole; 4-Etpy = 4-ethylpyridine; 3-ampy = 3-aminopyridine; Meinic = methylisonicotinate; HL^1 = 1-(2-hydroxybenzyl)-1,5-diazacicloctane; bpm = bis(pyrazol-1-yl)methane; L^2 = 1,2,4,5-tetrakis-(1,4,7-triazacyclonon-1-ylmethyl)benzene, terpy = 2,2′:6,2″-terpyridine; SE = result from the condensation of *N*,*N*-dimethylethylenediamine with salicylaldehyde; H_2oxen = *N*,*N*′-bis(2-aminoethyl)oxamide; hppz = homopiperazine; L^3 = 2-(pyrazol-1-yl-methyl)pyridine; Me-L^4 = 2-(3-methylpyrazol-1-ylmethyl)pyridine. L^5 and L^6 are obtained from the condensation of 2-pyridylaldehyde with aniline and *p*-chloroaniline, respectively.

$\tau = 1$ for trigonal bipyramidal geometry). Thus, the J_2 value of $-4.7\ cm^{-1}$ (small for copper(II) ions), can be unequivocally assigned to the monobridge azido ligand (equatorial–axial). The two J values found in **3a** match with those shown in Table 2.

2.4.1. Reaction of excess ligand with $[Cu(RaaiR')(N_3)_2]_4$

To a 2-methoxy-ethanol solution of the tetranuclear complex, an excess of the ligand (the same ligand as is present in the tetranuclear copper(II) complex) was added and stirred for a few minutes. Upon addition of water to this solution a brown product was separated. It was then purified by recrystallisation from the mixture of methanol and 2-methoxy ethanol (1/1 v/v). Infrared spectra of the complex show a sharp single band at an average of $2045\ cm^{-1}$. This supports the presence of terminal N_3-bonding. Moderately intense stretchings at 1585–1595 and 1440–1450 cm^{-1} are referred to ν(C=N) and ν(N=N), respectively. These complexes are non-conducting and sufficiently soluble in common organic solvents like chloroform, dichloromethane and acetonitrile. The UV–Vis spectra are recorded in acetonitrile solution and show weak absorptions at 706–730 and 570–580 nm. The structural confirmation has been carried out in one case by a single crystal X-ray structure study and is given below in detail. Room temperature (298 K) magnetic data of mononuclear complexes **5** and **6** show the typical values of $\chi_M T$ for one unpaired electron (d^9), around 0.4 $cm^3\ mol^{-1}$ K.

2.4.2. $Cu(HaaiEt)_2(N_3)_2\cdot C_3H_8O_2$ (**6a**$\cdot C_3H_8O_2$)

Crystals are obtained on slow evaporation of a mixture of 2-methoxy ethanol and a methanol solution of $[Cu(HaaiEt)_2(N_3)_2]_4$ and HaaiEt (in excess). An ORTEP view of $Cu(HaaiEt)_2(N_3)_2\cdot C_3H_8O_2$ is shown in Fig. 4. Selected bond lengths and angles are given in Table 3. In the discrete molecule, copper(II) is surrounded by two ligands and two azido groups. The ligand serves as an unsymmetric N,N′-chelating agent (N refers to imidazole-N and N′ refers to azo-N donor centres) and two ligands chelate in a manner to give *cis*-N,N and *trans*-N′,N′ arrangements. Two N_3^- coordinate in a *cis*-fashion around Cu(II). Thus, the coordination sequence of azides, imidazole-N(N) and azo-N(N′) describe a *cis–cis–trans* stereochemical orientation. The geometry of the copper ion is an axially elongated octahedron; the equatorial plane is formed by two imidazole-N (each from an individual ligand) and two azido-N

donor centres. The two axial positions are occupied by two azo-N donor centres of two HaaiEt. The N–Cu–N bond angles subtended by the chelating ligands are N(1)–Cu–N(12), 70.28(10)° and N(5)–Cu–N(13), 69.60(12)° which are close to the precursor tetranuclear copper(II) compound. The arylazoimidazole moiety is almost planar with a deviation from the least square plane <0.04 Å. The chelate rings constitute good planes (mean deviation ~0.03 Å). The pendant aryl ring makes small a dihedral angle with the chelate plane and lie in the range 7–8°. The proposed molecular planes in the octahedral geometry are found to be heavily distorted in this structure. The distortion in CuN_6 coordination is supported from the bond parameters of the structures (Table 3).

There are three types of N-donor centres: N(imidazole), N(azo) and N(azido). Usually Cu–N(azo) distances are longer than the other distances and lie in the range of 2.6–2.7 Å. The reasons of more space of N(azo) have been accounted for earlier (see above) [23–25]. The structural distortion is not only of electronic origin (Jahn–Teller distortion for d^9, Cu(II)) but also arises from the steric effect of N-donor centres. The lowering in overall symmetry is manifested by the elongation of axial bonds and the two N(azo) donor centres occupy two axial positions. There is a small difference (~0.01 Å) between two Cu–N(imidazole) distances [Cu(1)–N(1), 2.003(3); Cu(1)–N(5), 2.018(3) Å]. The sum of the equatorial bond angles (plane is constituted by two imidazole-N and two azido-N donor centres) at Cu is 360.31°. It shows that the metal ion is essentially in the mean plane. A significant deviation from the *trans* angle is observed for the two axial N-donors, more than that of the equatorial N-donors in the chelated fragment Cu(HaaiEt). In the equatorial plane the *trans* angles are >170° [N(1)–Cu(1)–N(7), 176.16(14)°; N(2)–Cu(1)–N(5), 174.63(15)°]. The axial ∠N–Cu–N is >150° [N(12)–Cu(1)–N(13), 152.30(10)°]. The large deviation (~35°) from the *trans* angle (180°) is undoubtedly from the combined contribution of short chelate angle, lifting of the inherent degeneracy of the d^9 configuration and the steric requirement of azo-N centres. The azido bond lengths and angles are within the range for reported data [9–13]. The azo, N=N, distances lie between 1.26–1.27 Å which is longer than the free ligand value (1.250(1) Å) [26].

3. Experimental

3.1. Materials

$Cu(OAc)_2 \cdot H_2O$, NaN_3 were purchased from Sisco Research Lab, India, and 1-alkyl-2-arylazoimdazoles (RaaiR′) were prepared following the literature procedures [20]. All other chemicals and solvents were analytical reagent grade. Solvents were used after drying. For spectral studies solvents of spectroscopic grade were purchased from Lancaster, UK. The reaction conditions have been set up following the procedure of synthesis of $[Mn(MeaaiEt)(N_3)_2]_n$ [14].

Caution! Azido complexes of transition metal ions containing organic ligands are potentially explosive. Only a small amount of material should be prepared, and it should be handled with care.

3.2. Physical measurements

Microanalyses (C, H, N) were performed using a Perkin–Elmer 2400 CHNO/S elemental analyzer. Copper analyses were carried out by iodometric titration [43]. Spectroscopic measurements were carried out using the following instruments: UV–Vis spectra, reflectance spectra, JASCO UV–Vis/NIR model V-570; IR spectra (KBr disk, 4000–200 cm^{-1}), JASCO FT-IR model 420. The room temperature magnetic moment was measured using a vibrating sample PAR-155 magnetometer at 298 K. Molar conductances (Λ_M) were measured in a Systronics conductivity meter 304 model using ca. 10^{-3} M solutions in MeOH. The magnetic susceptibility of a powdered sample was measured using a SQUID Magnetometer in the temperature range 300–2 K at an applied field of 0.1 T. The contribution of the sample holder was determined separately in the same temperature range and field. Diamagnetic corrections were estimated from Pascal's constants. The magnetic susceptibility was fitted by least square techniques.

3.3. Syntheses

3.3.1. *[Cu(HaaiMe)(N3)2]4 (**3a**)*

A solution of 1-methyl-2-(phenylazo)imidazole (HaaiMe) (0.045 g, 0.24 mmol) in methanol (10 ml) was added dropwise to a stirred solution of $Cu(OAc)_2 \cdot H_2O$ (0.05 g, 0.25 mmol per copper) in MeOH (10 ml) at 298 K. The greenish brown solution was stirred for 15 min. NaN_3 (0.033 g, 0.51 mmol) in MeOH (10 ml) was

added to this solution. The colour changed from greenish brown to red brown. The solution was filtered and left undisturbed for a few days. The dark brown crystalline compounds were collected, washed with aqueous methanol (1:1, v/v) and finally with ether. It was dried in vacuo. Yield was 0.063 g (74%). The microanalytical data of the two complexes is as follows, $[Cu(HaaiMe)(N_3)_2]_4$ (**3a**): *Anal.* Calc. for $C_{40}H_{40}N_{40}Cu_4$: C, 35.97; H, 2.99; N, 41.97; Cu, 19.05. Found: C, 35.86; H, 3.05; N, 41.84; Cu, 18.91%. $[Cu(MeaaiMe)(N_3)_2]_4$ (**3b**) (yield, 65%). *Anal.* Calc. for $C_{44}H_{48}N_{40}Cu_4$: C, 37.98; H, 3.45; N, 40.28; Cu, 18.28. Found: C, 37.89; H, 3.39; N, 40.37; Cu, 18.14%. $[Cu(HaaiEt)(N_3)_2]_4$ (**4a**) (yield, 67%). *Anal.* Calc. for $C_{44}H_{48}N_{40}Cu_4$: C, 37.98; H, 3.45; N, 40.28; Cu, 18.28. Found: C, 37.92; H, 3.51; N, 40.33; Cu, 18.17%. $[Cu(MeaaiEt)(N_3)_2]_4$ (**4b**) (yield, 72%). *Anal.* Calc. for $C_{48}H_{56}N_{40}Cu_4$: C, 39.83; H, 3.87; N, 38.73; Cu, 17.57. Found: C, 39.89; H, 3.81; N, 38.68; Cu, 17.45%.

3.3.2. Reaction of HaaiMe with $[Cu(HaaiMe)(N_3)_2]_4$

To a well-stirred suspension of $[Cu(HaaiMe)(N_3)_2]_4$ (**3a**) (0.1 g, 0.30 mmol) in 2-methoxy ethanol (5 ml), a small excess to one equivalent (with reference to per copper atom) of HaaiMe (0.60 g, 0.32 mmol) in methanol (10 ml) was added and stirred continuously for 30 min. By this time the solution colour changed to brown violet. It was then filtered through a G-4 crucible, to reject any residue, and left undisturbed for slow evaporation. Dark coloured crystals appeared after a week. These were then filtered, washed with cold methanol and dried in vacuo over $CaCl_2$. Yield was 0.09 g (58%). $[Cu(HaaiMe)_2(N_3)_2]$ (**5a**): *Anal.* Calc. for $C_{20}H_{20}N_{14}Cu$: C, 35.97; H, 2.99; N, 41.97; Cu, 19.05. Found: C, 35.86; H, 3.05; N, 41.84; Cu, 18.91%.

$[Cu(MeaaiMe)_2(N_3)_2]$ (**5b**) (yield, 55%). *Anal.* Calc. for $C_{22}H_{24}N_{14}Cu$: C, 37.98; H, 3.45; N, 40.28; Cu, 18.28. Found: C, 37.89; H, 3.39; N, 40.37; Cu, 18.14%. $[Cu(HaaiEt)_2(N_3)_2]$ (**6a**) (yield, 60%). *Anal.* Calc. for $C_{22}H_{24}N_{14}Cu$: C, 37.98; H, 3.45; N, 40.28; Cu, 18.28. Found: C, 37.92; H, 3.51; N, 40.33; Cu, 18.17%. $[Cu(MeaaiEt)_2(N_3)_2]$ (**6b**) (yield, 58%). *Anal.* Calc. for $C_{24}H_{28}N_{14}Cu$: C, 39.83; H, 3.87; N, 38.73; Cu, 17.57. Found: C, 39.89; H, 3.81; N, 38.68; Cu, 17.45%.

3.4. Crystallographic data collection and refinement of the structure

Good quality and stable to X-ray crystals for both the complexes were collected from slow evaporation of synthetic mixtures in methanol and 2-methoxy ethanol. Data were collected with a Siemens SMART CCD diffractometer using fine focus sealed graphite-monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). Unit cell parameters were determined from least-squares refinement of setting angles of 6529 reflections at 293 K for $[Cu(HaaiMe)(N_3)_2]_4$ (**3a**) and 7195 reflections for $[Cu(HaaiEt)_2(N_3)_2]\cdot C_3H_8O_2$ (**6a**) at 294 K. Data were collected with 2θ in the range $4.04 \leqslant 2\theta \leqslant 56.54°$ (for **3a**) and $2.6 \leqslant 2\theta \leqslant 56.6°$ (for **6a**).

Table 4
Summarized crystallographic data for **3a** and **6a** · $C_3H_8O_2$

Compound	**3a**	**6a** · $C_3H_8O_2$
Empirical formula	$C_{40}H_{40}N_{40}Cu_4$	$C_{25}H_{32}N_{14}O_2Cu$
Formula weight	1335.32	624.19

Reflection number total	31 861	35 918
Unique reflections	6529	7195
R_1[a] $[I > 2\sigma(I)]$	0.0444	0.0652
wR_2[b]	0.0970	0.1322
Goodness-of-fit	0.92	0.83

[a] $R = \sum(|F_o - F_c|)/\sum|F_o|$.
[b] $wR = [\sum w(F_o^2 - F_c^2)/\sum w(F_o)^2]^{1/2}$, $w = 1/[\sigma^2(F_o)^2 + (0.0462P)^2]$ for **3a** and $w = 1/[\sigma^2(F_o)^2 + (0.0659P)^2]$ for **6a**, where $P = ((F_o)^2 + 2(F_c)^2)/3$.

A summary of the crystallographic data and structure refinement parameters is given in Table 4. Reflection data were recorded using the ω scan technique. Data were corrected for Lorentz polarization effects and for linear decay using the SAINT program. Semi-empirical absorption corrections based on ψ-scans were applied. The structure was solved by direct methods using SHELXS-97 [44,45] and successive difference Fourier syntheses. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed geometrically and refined using the riding model. In the final difference Fourier map the residual maxima and minima were 0.396 and −0.206 for **3a** and 0.313 and −0.230 for **6a**.

4. Conclusion

In this research we demonstrate the synthesis of tetranuclear $[Cu(RaaiR')(N_3)_2]_4$ complexes from the reaction of $Cu(OAc)_2\cdot H_2O$, RaaiR′ and NaN_3 in a 1:1:2 mole ratio. Addition of RaaR′ (a slight excess of one equivalent) to a 2-methoxy ethanol solution of the tetranuclear compound has degraded it to a mono-copper compound of composition, $[Cu(RaaiR')_2(N_3)_2]$. In each case, the structural confirmation has been done by X-ray diffraction studies. The tetranuclear arrangement has been achieved by end-on sharing of N_3-groups in the dimers in which six-coordinated CuN_6 and five-coordinated CuN_5 units are associated via two end-on-N_3 bridging groups. IR spectra also distinguish the bonding pattern. Variable temperature magnetic susceptibility measurement (300–2 K) shows both anti- and ferromagnetic interactions for $[Cu(HaaiMe)(N_3)_2]_4$.

Acknowledgements

Financial support from the Council of Scientific and Industrial Research, and Department of Science and Technology, New Delhi are gratefully acknowledged. C.S. also acknowledges UGC for providing him a Visiting Associateship to I.I.Sc., Bangalore. M.S.F. is also grateful for the grant given by the Spanish Ministerio de Ciencia y Tecnologia (Programa Ramon y Cajal). Our sincere thanks are due to Prof. J. Ribas, Universitat de Barcelona, Spain for his helpful discussion on magnetism of the complexes.

Appendix A. Supplementary material

UV–Vis and infrared spectral data are submitted in Supplementary Table. Crystallographic data for the structures have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 249036 for $Cu(HaaiEt)_2(N_3)_2 \cdot C_3H_8O_2$ and 249037 for $[Cu(HaaiMe)(N_3)_2]_4$. elimination of RH is accompanied by formation of binuclear and polynuclear compounds containing bridging bpy ligand in which both pyridyl rings are 3-metallated [19].

We were using some dimeric rhodium(II) complexes ($[Rh_2(RCOO)_2(N–N)_2(H_2O)_2](RCOO)_2$ and $[Rh_2X_2(RCOO)_2(N–N)_2]$ where R = H, CH_3, Me, Et, *n*-Bu, PhCH(OH), X = Cl^-, Br^-, I^- and N–N = 2,2′-bipyridine or 1,10-phenanthroline) as very active homogeneous hydrogenation catalysts of ketones [20] and olefins [21]. The reaction takes place in basic methanolic solutions. In order to understand better reactivity of these catalytic systems we have decided to investigate 'in situ' generated catalysts using ^1H and ^{13}C NMR. The NMR experiments were run in the solution of $[Rh_2\{\mu\text{-}(S)\text{-}PhCH(OH)COO\}_4(H_2O)_2]$ (**1**) and $[Rh_2(\mu\text{-}CH_3COO)_4(H_2O)_2]$ with 2,2′-bipyridine and 4,4′-dimethyl-2,2′-bipyridine in CD_3ONa/CD_3OD as well as $[Rh(bpy)_2]Cl$ (**2**) in the same CD_3ONa/CD_3OD solution. ^1H and ^{13}C NMR experiments for **1** in the solution of CD_3ONa/CD_3OD have shown that C–H bond activation in the coordinated bpy ligand takes place. As a result of this reaction H–D exchange occurs. To our knowledge this is the first example of deuterium exchange of **H3,3′**-protons in 2,2′-bipyridine complexes of rhodium.

2. Experimental

The complexes $[Rh_2\{\mu\text{-}(S)\text{-}PhCH(OH)COO\}_4(H_2O)_2]$ (**1**) [22], $[Rh_2(\mu\text{-}CH_3COO)_4(H_2O)_2]$ [23], and $[Rh(bpy)_2]Cl$ (**2**) [24] were prepared according to the published methods. The CD_3ONa/CD_3OD solutions were prepared by dissolving sodium metal in oxygen-free CD_3OD. NMR experiments were performed using the following conditions: Na:Rh molar ratio = 20:1–60:1; [Rh] = 10^{-2} M–4×10^{-2} M; bpy: Rh molar ratio = 2:1; temperature = 25–50 °C. All manipulations were performed under Ar. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM400 and AMX300 spectrometers. ^{13}C NMR spectra were performed using ca. 50 000–60 000 scans. Chemical shifts are reported in ppm relative to tetramethylsilane, using the residual solvent proton resonance (methanol, $\delta = 3.31$ ppm) as an internal standard. The procedure with **1** as a starting compound was as follows: the appropriate amount of **1** and bpy was placed in NMR tube, and the tube was filled with argon. Then the known amount of CD_3ONa/CD_3OD solution was added under argon to the NMR tube. The solid reagents dissolve over a period of about 15–30 min at room temperature to give a deep violet solution. At this moment the measurements of the NMR spectra have been started. In the case of 4,4′-Me_2-bpy the solution of the ligand in CD_3ONa/CD_3OD was prepared first. Then this solution was transported under argon to the NMR tube containing the known amount of **1**. Again NMR measurements were started when the solution turned deep violet. The procedure with **2** was analogous. In the case of this reaction the solution of ligand in CD_3ONa/CD_3OD was added to the tube containing rhodium complex **2**.

3. Results and discussion

Dissolution of $[Rh_2\{\mu\text{-}(S)\text{-}PhCH(OH)COO\}_4(H_2O)_2]$ – bpy mixture (bpy: Rh molar ratio = 2:1) in the CD_3ONa/CD_3OD as a solvent (under Ar) affords a violet solution over a period of about 10–30 min which depends mainly on the temperature. At higher temperatures (50 °C) it takes about 10 min to get the violet colour. The NMR spectra of the resultant solutions exhibit two general characteristic features:

(i) At the beginning of reaction there are four signals present in the "bipyridine region": **H6,6′** (8.66 ppm, d $^3J_{5,6} = 5.6$ Hz); **H3,3′** (8.28 ppm, d, $^3J_{3,4} = 8.0$ Hz); **H4,4′** (7.93 ppm, t, $^3J_{3,4} = {}^3J_{4,5} = 8.0$ Hz); **H5,5′** (7.44 ppm, dd, $^3J_{4,5} = 8.0$ Hz, $^3J_{5,6} = 5.6$ Hz). The doublet due to **H3,3′** protons is slowly diminishing during the reaction and finally completely vanishes. The substitution is completed within 2–3 days at room temperature, and within 0.5–1 h when the solution is heated at 50 °C. At the same time, the signal due to 4,4′-protons (δ 7.93 ppm) undergoes transformation from triplet to doublet (exhibiting the fine structure due to H–D coupling) and the signals due to the 5,5′ – and 6,6′ – protons remain essentially unchanged (Fig. 1).

Under analogous reaction conditions, free bpy is unreactive. These observations are in accord with complete

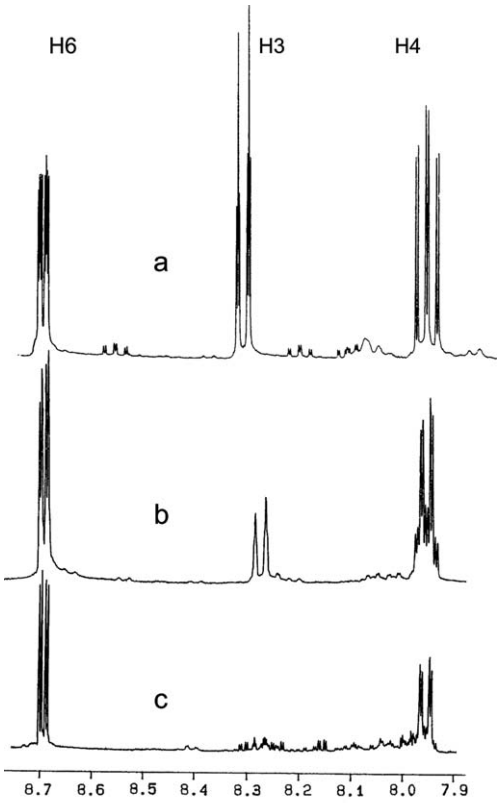

Fig. 1. A part of ^1H NMR spectrum measured in the time of reaction. (a) 20 min after adding CD_3ONa/CD_3OD solution to the solution of **1** with bpy in CD_3OD. (b) Spectrum recorded after 10 h of reaction and (c) final spectrum after two days of reaction. Reaction was made at 298 K.

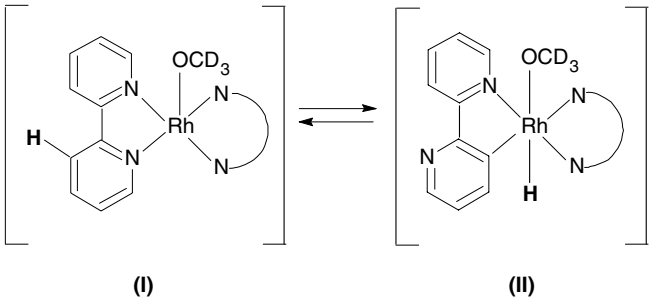
exchange of the 3,3′ protons for deuterium. This exchange has been also followed using ^{13}C NMR. After complete exchange of **H3,3′** protons the **C3,3′** resonance at 122.7 ppm also decreases and finally disappears due to the lack of the Nuclear Overhauser Effect and the new, very low intensity triplet centered at 122.2 ppm appears (Fig. 2).

The slight shift towards a higher field is due to the isotope effect. During the diminishing of **H3,3′** resonances several new, low intensity signals in the "bipyridine region" are observed. Two of them are shifted towards higher fields; 6.84 ppm (d) and 6.64 ppm (dd). The analogous patterns with similar chemical shifts have been observed for well defined $[Ir(Hbpy\text{-}C^3,N')(bpy\text{-}N,N')_2]^{3+}$ in $Me_2SO\text{-}d_6$ (6.8 ppm (d) and 7,16 ppm (dd)) [16] and for $[Ir(bpy\text{-}C^3,N')^{-}(bpy\text{-}N,N')_2]^{2+}$ in 50% D_2O – 50% $Me_2SO\text{-}d_6$ (6.8 ppm (d) and 7.12 ppm (dd)) [15], for some Pd cyclometallated complexes with 6- substituted bipyridine (the observed chemical shifts were 6.73 and 6.84 ppm for H5, and 7.29 and 7.33 for H4 protons in complexes of the type $[Pd(L)(PPh_3)Cl]\cdot HBF_4$ [25], or in similar platinum(II) complexes [26]. Therefore we suggest that complexes of the type (**II**) (see Scheme 1) are formed during H–D exchange reaction.

(ii) During the deuterium exchange reaction several hydride resonances appear. They have been observed in the range of −14 to −28 ppm. The number and intensity of the signals in hydride region are strongly dependent upon the reaction temperature. Hydride signals at higher fields (about −26 to −28 ppm) are observed only at low temperatures, below −60 °C. The most stable Rh hydride resonance is a doublet at −15.94 ppm ($^1J_{Rh-H} = 27.5$ Hz). It can be assigned to the orthometallated Rh(III) complex



(I) (II)

Scheme 1.

which should be kinetically inert due to the d^6 electronic configuration of the central atom (Fig. 3).

It must be emphasized that the only hydrogen source are coordinated 2,2′-bipyridine ligands because the experiments have been performed under Ar and in solution of CD_3ONa in CD_3OD. The process of hydride formation is rather slow and the time after which hydride resonances can be observed depends strongly on the reaction conditions (especially on the temperature of reaction). At 50 °C the −15.94 ppm resonance is observed after about 5–10 min. Within this period of time the solution becomes violet, suggesting the formation of the square planar Rh(I) compounds [24] which may undergo oxidative addition giving hydrido complexes of Rh(III). The hydride signals are of very low intensity as compared to the very strong resonances of the 2,2′-bipyridine protons of the "main" rhodium complex present in solution. The hydride resonances are approximately four times less intense than signals at 6.64 ppm and 6.84 ppm characteristic for complexes obtained in the reaction of "roll over metallation" [25,26].

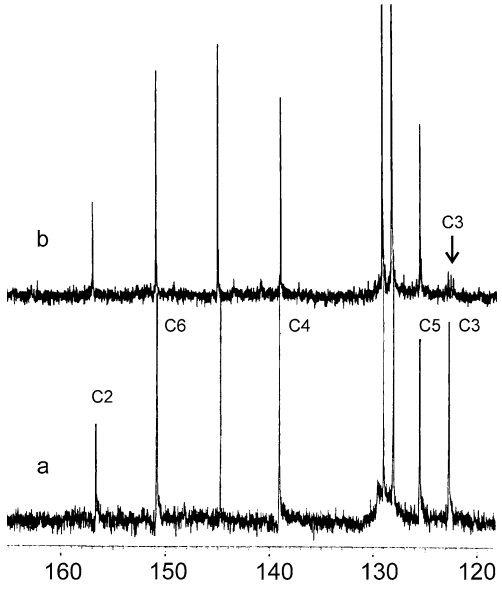


Fig. 2. Fragment of ^{13}C NMR spectrum for the same solution as in Fig. 1. (a) The beginning of the reaction and (b) spectrum recorded after complete exchange of **H3,3′** protons.

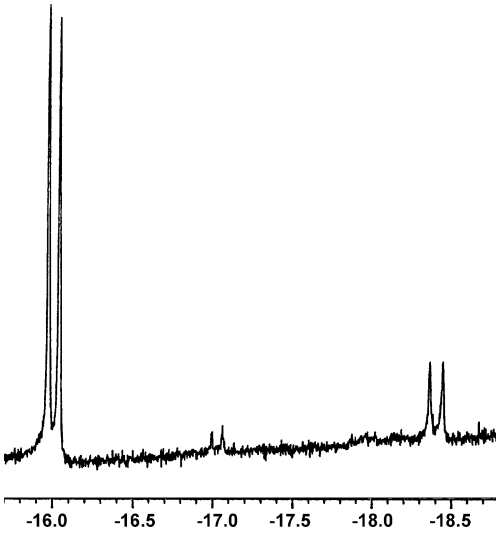

Fig. 3. 3 Part of ^1H NMR spectrum in "hydride" region. The doublet at −15.94 ppm ($J_{Rh-H} = 27.5$ Hz) belongs to the most stable hydrido complex.

The chemical shifts observed for hydride resonances in these "in situ" experiments are; −13.97 ppm (d, $^1J_{Rh-H} = 27.2$ Hz) and −15.94 ppm (d $^1J_{Rh-H} = 27.5$ Hz). The signal at −13.97 ppm (always present at the beginning of experiment) slowly decreases while the −15.94 ppm doublet is growing. This higher field signal is present in the spectrum until the **H3,3′–D3,3′** exchange is completed. The observed chemical shifts and coupling constants are quite similar to those reported for some rhodium(III) complexes with ethylenediamine as a chelating ligand [27]: $\delta = -16.3$ to −22.6 ppm; $^1J_{Rh-H} = 19$ to 30 Hz.

Above observations strongly suggest that oxidative addition reaction according to the Scheme 1 takes place.

In the first step of the reaction the carboxylate bridges are broken and coordination of the [OCD_3^-] anions and 2,2′-bipyridine occurs. It has been recently confirmed for [$Pt(bpy)_2$] complex in aqueous alkaline solution that at these conditions an attack of OH^- at the metal center takes place [37]. As a result of this reaction, a six-coordinate rhodium(III) hydride (abbreviated as (**II**)) is formed, and it should play the crucial role as a kinetically inert intermediate in the deuterium exchange reaction. We postulate that at this step of the reaction hydride resonances in NMR spectra are observed. The analogous pathway have been postulated for the cyclometallation of [$Pt(Me)_2$(6-R-bpy)], where R = alkyl or aryl [26].

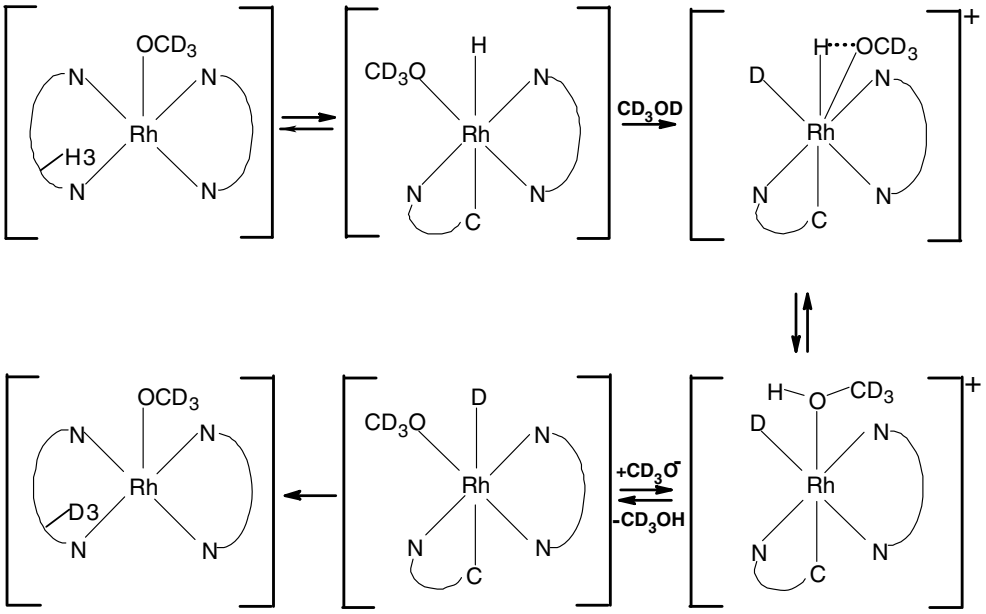
In order to simplify the system under investigation we have prepared [$Rh(bpy)_2$]Cl (**2**) [24]. The ^{1}H NMR (300 MHz) spectrum of this complex (10^{-2} M) in CD_3ONa/CD_3OD solution (under Ar) exhibits only one hydride resonance of low intensity at −15.94 ppm (d, $^1J_{Rh-H} = 27.4$ Hz). As in the case of "in situ" reactions for this compound **H3,3′–D3,3′** exchange is also observed (the **H3,3′** doublet ($\delta = 8.29$ ppm) and 122.6 ppm resonance in ^{13}C are lowering their intensities with time). Square planar complexes of the type $[Rh(bpy)_2]^+$ are well known [24,28–33] and have been used in some interesting catalytic reactions as for instance: hydrogen production [29,30], wgsr [33], selective hydrogenation of ketones and hydrogenation of ketones with isopropanol as a hydrogen source [34,35].

On the basis of NMR experiments we postulate one of the possible mechanisms of the **H3,3′–D3,3′** exchange in the system under investigations (Scheme 2).

As it has been mentioned earlier during the "in situ" reactions several hydride resonances are observed which suggest a few different rhodium species (all signals are of low intensity). It is well known that $[Rh(bpy)_2]^+$ forms several different species which is pH and concentration dependent [24]. These species may form different hydrides.

We would like to emphasize that when the reaction mixture is heated to 50 °C for a long period of time (several hours) **H4,4′–D4,4′** and **H5,5′–D5,5′** exchange has also been observed. This suggests that other exchange mechanisms are also possible, as was proposed for ruthenium compound with bpy [3,36].

In order to establish how substituents in bpy influence the reactivity of H–D exchange we performed the "in situ" reaction of **1** with 4,4′-Me_2-bpy. We have noticed unexpectedly that in this case there were no H–D exchange reaction in bpy rings. However this system shows considerable activity of methyl protons towards the H–D exchange reaction, although under similar reaction conditions free 4,4′-Me_2-bpy is unreactive. During the reactions no hydrides have been observed. Therefore the mechanism of this exchange should be different from that proposed for 2,2′-bipyridine.



Scheme 2.

magnetic coupling. The magnetic properties vary as a function of the rotation of the magnetic plane about the N–N bond [12b].

The present work describes the synthesis, structural characterization and magnetic properties of three triple-helicates. The general formula of Ni(II) triple-helicates is $[Ni_2(L^i)_3]\cdot(ClO_4)_4\cdot(H_2O)_3$ $(i = 1, 2)$, where L^1 and L^2 are 1,4-bis(2-pyridyl)-1-amino-4-methyl-2,3-diaza-1,3-butadiene and 2,5-bis(2-pyridyl)-3,4-diaza-2,4-hexadiene (Scheme 1), respectively, and the Mn(II) triple-helicate is $[Mn_2(L^1)_3]\cdot(ClO_4)_4\cdot(H_2O)_3$. The crystal structure of L^1 is also presented.

2. Experimental

2.1. Materials and synthesis

All the starting chemicals were of AR grade and used as purchased without further purification.

Caution! Although not encountered in our experiments, readers are cautioned about the potentially explosive nature of the perchlorate and azido complexes. Only a small amount of the material should be prepared, and it should be handled with care.

Ligands. The L^1 and L^2 ligands were prepared according to the literature procedures [14–17]. Recrystallization of L^1 from an ethanol solution afforded yellow crystals suitable for X-ray analysis.

*$[Ni_2(L^1)_3]\cdot(ClO_4)_4\cdot 3H_2O$ (**1**)*. A methanol solution (2 mL) of nickel(II) perchlorate hexahydrate (0.146 g, 0.4 mmol) was added with continuous stirring into 10 mL methanol solution of L^1 (0.144 g, 0.6 mmol). Slow evaporation of the resulting reddish-orange solution at room temperature yielded reddish-orange crystals within 1 week. The crystals were filtered off, washed quickly with water and ethanol, and dried in air. Yield: (0.137 g) 53.4%. $C_{39}H_{45}N_{15}Ni_2Cl_4O_{19}$ (Fw: 1287.12). *Anal.* Calc. C, 36.40; H, 3.52; N, 16.32. Found: C, 36.17; H, 3.66; N, 16.45%. Main IR bands (cm^{-1}): 3354m, 3208m, 1661vs, 1593m, 1421m, 1376m, 1100vs, 1021sh, 793m, 780m, 747m.

*$[Ni_2(L^2)_3]\cdot(ClO_4)_4\cdot 3H_2O$ (**2**)*. Crystals of **2** were obtained by the same method as for **1**, using L^2 instead of L^1. Slow evaporation of the reaction solution at room temperature yielded reddish-orange crystals of **2** within 1 week. Yield: (0.115 g) 44.7%. $C_{42}H_{48}N_{12}Ni_2Cl_4O_{19}$ (Fw: 1284.14). *Anal.* Calc. C, 39.37; H, 3.78; N, 13.13. Found: C, 39.55; H, 3.74; N, 13.26%. Main IR bands (cm^{-1}): 3079m, 2924m, 1659vs, 1596m, 1444m, 1375m, 1334m, 1261m, 1095 vs, 1020m, 776m, 745m.

*$[Mn_2(L^1)_3]\cdot(ClO_4)_4\cdot 3H_2O$ (**3**)*. A methanol solution (4 mL) containing L^1 (0.072 g 0.3 mmol) was added into one arm of an H-shaped tube and manganese(II) perchlorate hexahydrate (0.073 g 0.2 mmol) in the same solvent (2 mL) was added into the other arm, and then about 20 mL of methanol was carefully added so that the bridge of the tube was filled. Slow diffusion between the two solutions afforded orange crystals of **3** within 1 week. Yield: (0.095 g) 74.3%. $C_{39}H_{45}N_{15}Mn_2Cl_4O_{19}$ (Fw: 1279.58). *Anal.* Calc. C, 36.65; H, 3.55; N, 16.45. Found: C, 37.15; H, 3.69; N, 16.16%. Main IR bands (cm^{-1}): 3349m, 3213m, 1656vs, 1589m, 1417m, 1373m, 1098vs, 1017sh, 795m, 780m, 744m.

2.2. Physical measurements

Elemental analyses (C, H, N) were performed on an Elementar Vario EL analyzer. IR spectra were recorded on a Nicolet Magna-IR 750 spectrometer equipped with a Nic-Plan Microscope. Magnetic properties of the complexes **1**, **2** and **3** were carried out on a Quantum Design PPMS-9 magnetometer. Diamagnetic corrections were made with Pascal's constants [18].

2.3. Crystallographic studies

Diffraction intensity data of the single crystals were collected at room temperature on a Bruker Smart APEX CCD diffractometer (**1**), a Rigaku RAXIS RAPID IP diffractometer (**2**) and a Nonius Kappa CCD diffractometer (L^1 and **3**), all equipped with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Empirical absorption corrections were applied using the SORTAV program [19] (for L^1 and **3**), the SADABS program (for **1**) [20] and the ABSCOR program (for **2**) [21]. All structures were solved by the direct method and refined by the full-matrix least-squares method on F^2 with anisotropic thermal parameters for all non-hydrogen atoms [22]. Hydrogen atoms were located geometrically and refined using the riding model. Pertinent crystallographic data and structure refinement parameters are summarized in Table 1. The diffraction intensity of **3** was very weak with poor resolution, and the measured maximum 2θ angle was only 37.05°. To confirm the structure, the powder XRD pattern of **3** was measured on a Rigaku D/MAX-2000 diffractometer using graphite-monochromated Cu Kα radiation ($\lambda = 1.5418$ Å), and compared with that calculated from the single-crystal data.

3. Results and discussion

3.1. Crystal structure of ligand L^1

The structure of L^1 is illustrated in Fig. 1, and selected bond distances and bond angles are listed in Table 2. The L^1 ligand crystallizes in an orthorhombic system with two crystallographically independent molecules included in the asymmetric unit. Each pyridylimine unit is planar and adopts a *transoid* conformation with respect to the Py–C bond to minimize the repulsive force of the electronic interactions between the lone pairs of N(pyridyl) and N(imine) [10a]. The two pyridylimine fragments in each molecule are also in *transoid* positions with respect to the central N–N bond to minimize the repulsive force between the amine group and the methyl group, but due to the rotational flexibility of the N–N bond, the relative orientation of two pyridylimine fragments is variable. For one set, the dihedral angle between the two pyridylimine fragments is 174.89° and the C–N–N–C torsion angle is 176.49°. For the other set, both angles are 180°, due to the presence of a crystallographic inversion center in the middle of the N–N bond. The centrosymmetry leads to a statistical disorder of the two substituent groups: both the amine group and the methyl group occupy the position of the X1 atom with occupancies of 0.5.

3.2. Crystal structure of the complexes

Crystal structure analyses revealed that complexes **1**, **2** and **3** are isomorphous and consist of cationic binuclear triple helicates with crystallographic C_3 symmetry. As shown in Fig. 2, the powder XRD pattern of **3** is in good agreement with those calculated from the single-crystal data of **1** and **3**, confirming that the single-crystal structural

analysis of **3** is reasonable despite of the poor diffraction resolution.

3.2.1. $[Ni_2(L^1)_3]\cdot(ClO_4)_4\cdot 3H_2O$ (**1**)

The structure of **1** is illustrated in Fig. 3a, and selected bond distances and bond angles are listed in Table 3. In comparison with the "free" ligand, the ligand L^1 in complex **1** exhibits no appreciable differences in the N–N, C–C and C–N distances, but the conformation is completely different. The pyridine ring rotates by ca. 180° around the Py–C bond to place the pyridyl nitrogen and the imine nitrogen on the same side, so each pyridylimine group can act as a bidentate bite site. The pyridylimine groups are rotated around the N–N bond so that the C–N–N–C torsion angle and the dihedral angles between the two planar pyridylimine groups become 81.18° and 72.66°, respectively, giving rise to a twisted spiral conformation for the whole ligand.

Symmetry code A: $-x+1$, $y+1/2$, $-z+3/2$.

The spiral twist induces chirality to the ligand, and three equivalent ligands wrap around two metal ions to yield a binuclear triple helicate (*M*-configured with *ΔΔ* metal centers in Fig. 2a) with a C_3 symmetry and a 3-fold axis along the two central Ni(II) ions. In the binuclear cation, each nickel(II) ion is ligated by three pyridylimine groups and adopts the octahedral geometry with a trigonal distortion and with the Ni–N distances in the narrow range of 2.07–2.09 Å. The Ni···Ni distance spanned by the triple N–N bridges is 3.679(1) Å, and the Ni–N–N–Ni torsion angle is 46.94°. The perchlorate ions and water molecules lie among the binuclear cations without any indication of hydrogen bonding. The nearest Ni···Ni distance between neighboring binuclear units is 7.9 Å between Ni1 and Ni2 ($-x$, $1-y$, $1-z$).

3.2.2. $[Ni_2(L^2)_3]\cdot(ClO_4)_4\cdot 3H_2O$ (**2**)

The structure of **2** is depicted in Fig. 3b. The bond distances and bond angles (Table 3) are similar to those in **1**, and the Ni···Ni distance spanned by the triple N–N bridge is 3.683(2) Å. The major differences lie in the twist of the diazine ligands. The C–N–N–C and Ni–N–N–Ni torsion angles are 87.37° and 50.11°, respectively, and the dihedral angles between the two planar pyridylimine groups is 72.0°.

3.2.3. $[Mn_2(L^1)_3]\cdot(ClO_4)_4\cdot 3H_2O$ (**3**)

Complex **3** is isostructural with complexes **1** and **2**. As expected, the Mn–N distances (av. 2.22 Å) are longer than the Ni–N distances in **1** and **2**. The Mn···Mn distance spanned by the triple N–N bridge is 3.95 Å. The C–N–N–C and Mn–N–N–Mn torsion angles are 99.9° and 49.1°, respectively, and the dihedral angles between the two planar pyridylimine groups is 75.6°.

3.3. Magnetism

The magnetic susceptibilities of complexes **1** and **2** were measured in the 5–300 K temperature range and are shown in Figs. 4 and 5, respectively. At 300 K, the experimental $\chi_M T$ values are 2.23 and 2.04 emu mol^{-1} K for **1** and **2**, respectively, which correspond to the spin-only value expected for two high-spin Ni(II) ions. Upon cooling, the $\chi_M T$ products decrease monotonically, and the χ_M values increase continuously to maxima of 0.099 emu mol^{-1} at 10 K and 0.054 emu mol^{-1} at 17 K for **1** and **2**, respectively. These observations indicate that an antiferromagnetic interaction is operative between the Ni(II) ions linked by the triple N–N bridges.

The data were fitted to the expression derived from the isotropic spin-coupling Hamiltonian $H = -J\hat{S}_1\hat{S}_2$ [23]

$$\chi_M = \frac{2Ng^2\beta^2}{kT}\frac{1+5\exp(2J/kT)}{3+5\exp(2J/kT)+\exp(-J/kT)}.$$

The simulations resulted in $J = -2.97$ with $g = 2.13$ and $J = -5.40$ cm^{-1} with $g = 2.07$ for **1** and **2**, respectively. Although several helical binuclear Ni(II) complexes with open-chain diazine bridges have been structurally characterized previously [10c,15,17,24], to our knowledge, only one of them, $[Ni_2(pahox)_3]\cdot(ClO_4)_4\cdot 4H_2O$ (pahox = butanedione-monoxime picolinamide hydrazone), has been investigated with variable-temperature magnetic measurements, and it was found to exhibit a weaker magnetic interaction [24]. Selected structural and magnetic data of the compound together with those of the present compounds are collected in Table 4. As can be seen, the difference in the magnitude of the magnetic interaction seems to be due to the different Ni–N–N–Ni torsion angles: larger magnetic exchange parameters are associated with larger torsion angles, although larger torsion angles lead to larger Ni···Ni distances.

The thermal variation of magnetic susceptibility for complex **3** is shown in Fig. 6. At room-temperature the experimental $\chi_M T$ value is 8.90 emu mol^{-1} K for **3**, which corresponds to the spin-only value expected for two high-spin Mn(II) ions. Upon cooling, the $\chi_M T$ product increases smoothly to 14.41 emu mol^{-1} K at 2 K. This behavior is consistent with a ferromagnetic interaction between the two metal centers linked by the triple N–N bridges. The field dependent magnetization data was measured at 2 K (Fig. 7), and the magnetization ($9.93N\beta$) at 5.5 T is very close to the saturation value. It is noted that the magnetization curve is in good agreement with that calculated from the Brillouin function for $S = 5$, suggesting a high spin ground state for the binuclear complex due to the ferromagnetic interaction.

The thermal variation of magnetic data were fitted to a simple isotropic exchange expression for two $S = 5/2$ spin states, derived from the exchange Hamiltonian $H = -J\hat{S}_1\hat{S}_2$ [25].

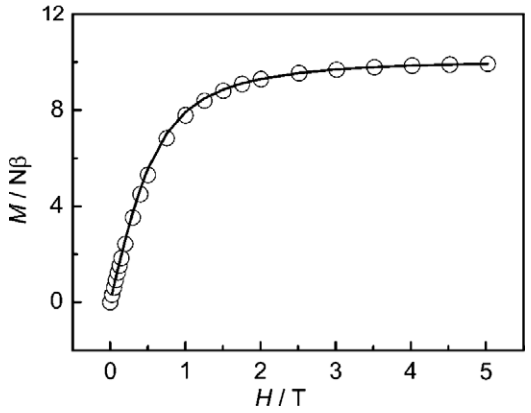

Fig. 7. Field dependence of magnetization of **3**; the solid line represents the best fit to the Brillouin function for $S = 5$, $g = 2.0$ at 2 K.

The deduced expression of the magnetic susceptibility is

$$\chi_M = \frac{2Ng^2\beta^2}{kT}\,\frac{55 + 30e^{5x} + 14e^{9x} + 5e^{12x} + e^{14x}}{11 + 9e^{5x} + 7e^{9x} + 5e^{12x} + 3e^{14x} + e^{15x}},$$

where $x = J/kT$. A reasonable data fit (Fig. 5) was obtained for $J = 1.24\ cm^{-1}$ and $g = 2.0$. The magnetic exchange in Mn(II) systems can also be related to the M–N–N–M torsion angles: the magnetic interaction in **3** is ferromagnetic ($J = 1.04\ cm^{-1}$). It is consistent with that for the reported $[Mn_2(pahap)_3]\cdot(ClO_4)_4\cdot 5H_2O$ (pahap = picolinamideazine) [15], in which the torsion angles (av. 44.2°) are close to that (49.1°) in **3**, but contrasts with the reported double helicate $[Mn_2(pahox)_2Cl4]\cdot H_2O$ [24], where the magnetic coupling is antiferromagnetic and the torsion angles are much larger (av. 86.2°). It seems that the magnetic differences might arise from the difference in the M–N–N–M torsion angles. With these limited data, however, it is unwarranted to conclude any unambiguous magneto-structural correlations. Other structural factors such as the coordination geometry around the metal ions may also contribute to the observed magnetic interactions. Complexes **1**–**3** and related binuclear triple helicates (**4** and **5**, Table 4) have comparable M–N–N–M angles and coordination environments, but the signs of the magnetic interactions for Ni(II) and Mn(II) are opposite, reflecting the significant influence of the different magnetic orbitals and exchange pathways involved for Ni(II) and Mn(II) in these triply diazine-bridged systems.

4. Conclusion

By employing open-chain diazine ligands with two bidentate pyridylimine groups, we successfully obtained three binuclear triple helicates with Ni(II) and Mn(II). In these complexes, three bis(bidentate) diazine ligands with a spiral conformation wrap around two metal cations, resulting in triple helicates with C_3 symmetry. Magnetic investigations revealed that the intramolecular magnetic interactions through the triple diazine bridges are antiferromagnetic for the Ni(II) triple helicates but ferromagnetic for the Mn(II) triple helicate. It seems that the magnetic interactions for the Ni(II) compounds are mainly dependent upon the degree of the twist of the ligands about the N–N bond. Further experimental and theoretical studies are needed to obtain more precise correlations.

Perkin–Elmer FT-IR Espectrum One, as KBr pellets. UV spectra of 0.1 mM solutions were obtained with a UNICAM UV 300 and mass spectra were obtained with a VG Autospec mass spectrometer operating in the electron Impact (EI) mode and liquid secondary iron mass spectrometry (LSIMS) mode. Elemental compositions were analysed with a Perkin–Elmer 2400B. 4-(2-Thienyl)-1,3-dithiol-2-thione [20], 4-(3-thienyl)-1,3-dithiol-2-thione [20] and 4-(*p*-cyanophenyl)-1,3-dithiole-2-thione [18,20] were prepared by published methods. Electrochemical measurements were recorded on a EG&G 273 model and carried out in dry CH_2Cl_2 under argon using $[n\text{-}NBu_4]PF_6$ (0.1 M) as a background electrolyte, with a Pt disk electrode versus SCE (values in V).

2.2. 4-(2-Thienyl)-1,3-dithiole-2-one (*1*)

To a solution of 4-(2-thienyl)-1,3-dithiol-2-thione (216 mg, 1 mmol) in MeCN (10 ml) was added $Hg(OAc)_2$ (414 mg, 1.3 mmol). The mixture was refluxed for 6 h and after cooling the solvent was completely removed in vacuo. Purification was carried out by column chromatography (silica, CH_2Cl_2). The resulting solution was carefully washed with sat. Na_2CO_3 and water. After drying (Na_2SO_4) the solvent was evaporated in vacuo to afford a yellow solid. Yield: 85%. *Anal*. Calc. for $[C_7H_4OS_3]$: C, 41.93; H, 2.01; S, 47.92. Found: C, 41.95; H, 2.42; S, 47.52%. IR (KBr, cm^{-1}): ν(C=O) 1638. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.30–7.28 (m, 1H, *H_5-thienyl*), 7.07–7.03 (m, 2H, *$H_{3,4}$-thienyl*), 6.73 (s, 1H, *H_5-dithiole*) ppm. *m/z* (EI^+): 200 ($[M]^+$, 16%), 136 (100%).

2.3. 4-(3-Thienyl)-1,3-dithiole-2-one (*2*)

This compound was prepared as described for **1** using 4-(3-thienyl)-1,3-dithiol-2-thione (216 mg, 1 mmol). Yellow solid. Yield: 80%. *Anal*. Calc. for $[C_7H_4OS_3]$: C, 41.93; H, 2.01; S, 47.92. Found: C, 41.54; H, 2.40; S, 47.49%. IR (KBr, cm^{-1}): ν(C=O) 1628. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.42–7.18 (m, 1H, *H_2-thienyl*), 7.30–7.23 (m, 2H, *$H_{4,5}$-thienyl*), 6.77 (s, 1H, *H_5-dithiole*) ppm. *m/z* (EI^+): 200 ($[M]^+$, 100%), 172 ($[M–C–O]^+$, 52%), 140 ($[M–C–O–S]^+$, 12%).

2.4. [M{S_2C_2H-(*p*-CN-C_6H_4)}(dppe)], M = Ni (*3*), Pd (*4*)

4-(*p*-Cyanophenyl)-1,3-dithiole-2-thione (47 mg, 0.2 mmol) was suspended in MeOH (20 ml) under argon atmosphere. KOH (0.5 ml, 1 M in MeOH) was added and the reaction mixture was refluxed until the thione was dissolved (3 h). After cooling $[NiCl_2(dppe)]$ (106 mg, 0.2 mmol) or $[PdCl_2(dppe)]$ (115 mg, 0.2 mmol) was added. The reaction mixture was stirred for 24 h and the precipitate was subsequently collected by filtration and washed with diethyl ether. M = Ni (**3**), green solid. Yield: 45%. *Anal*. Calc. for $[C_{35}H_{29}NNiP_2S_2]$: C, 64.90; H, 4.51; N, 2.16; S, 9.90. Found: C, 64.68; H, 4.86; N, 2.09; S, 10.01%. IR (KBr, cm^{-1}): ν(C≡N) 2218, ν(C=C) 1597. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.80–7.66 (m, 10H), 7.46–7.36 (m, 14H), 7.30 (s, 1H), 2.38 (d, 4H, $J = 17.4$ Hz) ppm. $^{31}P\{^1H\}$ NMR: AB system $\delta_A = 58.6$, $\delta_B = 57.9$ ppm ($J_{AB} = 46.5$ Hz). *m/z* ($LSIMS^+$): 647 ($[M]^+$, 100%). M = Pd (**4**), orange solid. Yield: 65%. *Anal*. Calc. for $[C_{35}H_{29}NP_2PdS_2]$: C, 60.39; H, 4.20; N, 2.01; S, 9.21. Found: C, 59.99; H, 4.15; N, 1.96; S, 9.21%. IR (KBr, cm^{-1}): ν(C≡N) 2213, ν(C=C) 1599. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.84–7.73 (m, 10H), 7.52–7.40 (m, 14H), 7.20 (d, 1H, $J = 3.6$ Hz), 2.53 (d, 4H, $J = 20.7$ Hz) ppm. $^{31}P\{^1H\}$ NMR: AB system $\delta_A = 51.7$, $\delta_B = 51.6$ ppm (J_{AB}=36.1 Hz). *m/z* ($LSIMS^+$): 695 ($[M]^+$, 100%).

2.5. [M{S_2C_2H-(2-C_4H_3S)}(dppe)], M = Ni (*5*), Pd (*6*)

4-(2-Thienyl)-1,3-dithiole-2-one (**1**) (50 mg, 0.25 mmol) was suspended in EtOH (10 ml) under argon atmosphere, for M = Pd in THF (10 ml). NaOEt (2 ml, 0.4 M in EtOH) was added and the reaction mixture was refluxed until the ketone was dissolved (1.5 h). After cooling $[NiCl_2(dppe)]$ (132 mg, 0.25 mmol) or $[PdCl_2(dppe)]$ (144 mg, 0.25 mmol) was added. The reaction mixture was stirred for 24 h and then the solvent was reduced in vacuo to 5 ml. Hexane or diethyl ether (20 ml) was added to precipitate the corresponding compound which was filtered off. Purification was carried out by column chromatography. M = Ni (**5**), (silica, 60 ethyl acetate/40 hexane), green solid. Yield: 15%. *Anal*. Calc. for $[C_{32}H_{28}NiP_2S_3]$: C, 61.05; H, 4.45; S, 15.26. Found: C, 60.68; H, 4.06; S, 14.88%. IR (KBr, cm^{-1}): ν(C=C) 1633. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.77–7.70 (m, 8H), 7.45–7.19 (m, 12H), 6.92 (m, 2H), 6.84 (m, 1H), 6.72 (m, 1H), 2.35–2.27 (m, 4H) ppm. $^{31}P\{^1H\}$ NMR: AB system $\delta_A = 58.0$, $\delta_B = 57.5$ ppm ($J_{AB} = 34.8$ Hz). *m/z* ($LSIMS^+$): 628 ($[M]^+$, 100%), 431 ($[S(dppe)^+]$, 72%). M = Pd (**6**), (silica, dichloromethane), purple solid. Yield: 49%. *Anal*. Calc. for $[C_{32}H_{28}P_2PdS_3]$: C, 56.71; H, 4.13; S, 14.18. Found: C, 56.40; H, 4.43; S, 13.68%. IR (KBr, cm^{-1}): ν(C=C) 1634. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.77–7.68 (m, 9H), 7.37–7.33 (m, 11H), 6.99 (m, 1H), 6.89–6.83 (m, 2H), 6.72 (m, 1H), 2.42 (d, 4H, $J = 15.3$ Hz) ppm. $^{31}P\{^1H\}$ NMR: AB system $\delta_A = 50.9$, $\delta_B = 50.7$ ppm ($J_{AB} = 26.7$ Hz). *m/z* ($LSIMS^+$): 676 ($[M]^+$, 100%), 506 ([Pd(dppe)], 18%), 429 ([S(dppe)], 32%).

2.6. [M{S_2C_2H-(3-C_4H_3S)}(dppe)], M = Ni (*7*), Pd (*8*)

4-(3-Thienyl)-1,3-dithiole-2-one (**2**) (50 mg, 0.25 mmol) was suspended in THF (15 ml). NaOEt (2 ml, 0.4 M in EtOH) was added and the reaction mixture was refluxed until the ketone was dissolved (1.5 h). After cooling $[NiCl_2(dppe)]$ (132 mg, 0.25 mmol) or $[PdCl_2(dppe)]$ (144 mg, 0.25 mmol) was added. The reaction mixture was stirred for 24 h and then the solvent was reduced in

vacuo to 5 ml. Hexane (20 ml) was added to precipitate the corresponding compound which was filtered off. M = Ni (**7**), green solid. Yield: 44%. *Anal*. Calc. for [$C_{32}H_{28}NiP_2S_3$]: C, 61.05; H, 4.45; S, 15.26. Found: C, 60.67; H, 4.48; S, 14.84%. IR (KBr, cm^{-1}): ν(C=C) 1629. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.77–7.61 (m, 10H), 7.44–7.37 (m, 10H), 7.19–7.13 (m, 2H), 7.00 (m, 1H), 6.93 (s, 1H), 2.30 (d, 4H, $J = 13.2$ Hz) ppm. $^{31}P\{^1H\}$ NMR: AB system $\delta_A = 57.8$, $\delta_B = 57.6$ ppm ($J_{AB} = 34.1$ Hz). *m/z* (LSIMS$^+$): 628 ([M]$^+$, 100%), 431 ([S(dppe)$^+$], 25%). M = Pd (**8**), brown solid. Yield: 90%. *Anal*. Calc. for [$C_{32}H_{28}P_2PdS_3$]: C, 56.71; H, 4.13; S, 14.18. Found: C, 56.40; H, 4.21; S, 13.76%. IR (KBr, cm^{-1}): ν(C=C) 1638. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ 7.80–7.71 (m, 8H), 7.43–7.35 (m, 12H), 7.21 (m, 2H), 7.03 (m, 1H), 6.85 (m, 1H), 2.43 (d, 4H, $J = 15.3$ Hz) ppm. $^{31}P\{^1H\}$ NMR: δ 50.5 (s) ppm. *m/z* (LSIMS$^+$): 676 ([M]$^+$, 100%), 476 (52%), 291 (72%).

2.7. Crystallographic studies

Crystals suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into dichloromethane solutions. A summary of the fundamental crystal and refinement data of compounds **4** and **6** is given in Table 3. The crystals were mounted on a glass fiber with inert oil and centered on a Bruker Nonius Kappa CCD diffractometer in the case of **4** and on a Bruker-Siemens Smart CCD diffractometer in **6** using monochromated Mo Kα radiation ($\lambda = 0.7107$ Å), scan type θ–2θ. The diffraction frames were integrated using the SAINT [21] package and corrected for absorption with SORTAV [22,23] or SADABS [24] programs. The structures were solved by direct methods using SHELXS [25]. Full-matrix least squares refinement was carried out using SHELXTL [26] minimising $\omega(F_o^2 - F_c^2)^2$. Hydrogen atoms were included using a riding model. Weighted *R* factors (R_w) and all goodness-of-fit *S* values are based on F^2; conventional *R* factors (*R*) are based on *F*.

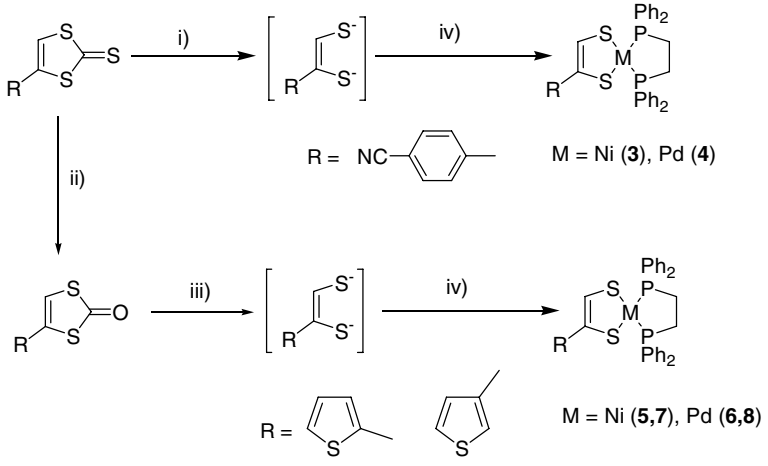
3. Results and discussion

Deprotection of 4-(*p*-cyanophenyl)-1,3-dithiole-2-thione [18,20], 4-(2-thienyl)-1,3-dithiole-2-one (**1**) and 4-(3-thienyl)-1,3-dithiole-2-one (**2**) with a base in MeOH or in THF (to improve the solubility) leads to the formation in situ of the corresponding dithiolate salts. Curiously the formation of the dithiolates takes place starting from the thione (Scheme 1, (i)) in the case of *p*-cyanophenyl, though in the case of 2- and 3-thienyl the transformation is on the corresponding ketone, in order to improve the electrophilicity around the C atom in the 2 position, necessary as a previous reaction. Subsequent addition of [$NiCl_2$(dppe)] and [$PdCl_2$(dppe)] followed by purification work-up afforded the heteroleptic complexes as shown in Scheme 1.

The spectroscopic data of all the dithiolenes are in agreement with their formulation. In the ^1H NMR spectra, the proton of the S_2C_2H unit appears as a doublet or multiplet, possibly due to the coupling of this proton with the P atom in the *trans* position. More illustrative are the $^{31}P\{^1H\}$ NMR spectra, most of them show an AB system around 58 ppm for Ni complexes and 51 ppm for Pd complexes. This AB system is due to the closed resonances of the two inequivalent phosphorous atoms because of the lack of symmetry of the dithiolene ligand used in this work. The LSIMS$^+$ mass spectra exhibit the molecular peaks in all cases.

Crystals of the palladium complexes [Pd{S_2C_2H-(*p*-CN-C_6H_4)}(dppe)] (**4**) and [Pd{S_2C_2H-(2-C_4H_3S)}(dppe)] (**6**) were grown by slow diffusion of diethyl ether into a dichloromethane solution of each complex. Perspective drawings of the structures are shown in Figs. 1 and 2 respectively. Bond distances and angles are collected in Tables 1 and 2 and crystallographic data are collected in Table 3.

The crystalline structure of the two compounds is similar to that of other group 10 metallo-1,2-enedithiolate complexes [8,27–33]. Compound **6** crystallises as the water



Scheme 1. Synthesis of heteroleptic dithiolene complexes.

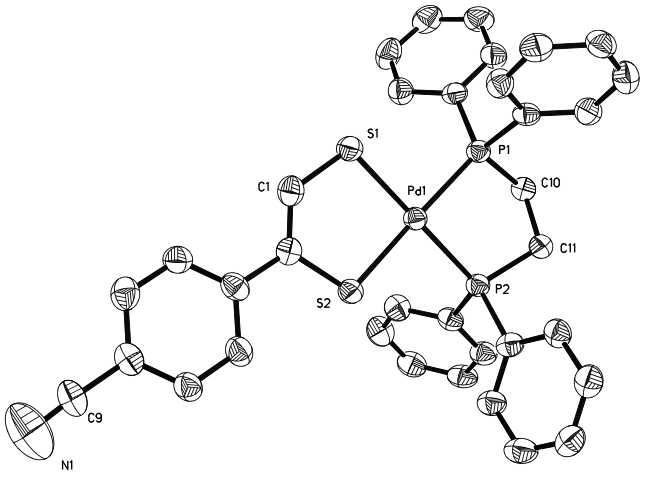


Fig. 1. Crystal structure of [Pd{S_2C_2H-(*p*-CN-C_6H_4)}(dppe)] (**4**). Thermal ellipsoids are drawn at the 50% probability level and H atoms have been omitted for clarity.

solvate with two independent molecules per unit cell. The P–Pd–P angles are very similar in both complexes, [P(1)–Pd(1)–P(2) = 86.09(5)° in **4** and P(1)–Pd(1)–P(2) = 85.00(6)°, P(4)–Pd(2)–P(3) = 84.71(6)° in **6**] as occurs with the S–Pd–S angles [S(1)–Pd(1)–S(2) = 88.34(5)° in **4** and S(1)–Pd(1)–S(2) = 89.31(5)°; S(5)–Pd(2)–S(4) = 88.48(6)° in **6**]. The metallo-1,2-enedithiolate consists of a planar five-membered ring in the two cases with the palladium atom deviating slightly from the least squares planes, 0.0143(6) Å in **4** and 0.0387(7), 0.0571(14) Å in the two independent molecules of **6**. The substituents *p*-cyanophenyl in **4** and 2-thienyl in **6** are also coplanar with the metallo-1,2-dithiolene unit with smaller torsion angles in the case of the two molecules of complex **6** [C(33)–C(34)–

[a] $R_1(F) = \sum\|F_o| - |F_c\|/\sum|F_o|$.
[b] $\varpi R_2(F^2) = [\sum[\varpi(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]^{1/2}$; $w^{-1} = [\sigma^2(F_o^2) + (\alpha P)^2 + bP]$, where $P = [\max(F_o^2, 0) + 2F_c^2]/3$.
[c] $S = [\sum[\varpi(F_o^2 - F_c^2)^2]/(n-p)]^{1/2}$, where *n* is the number of reflections and *p* the number of refined parameters.

C(35)–S(6) = 9.1° and C(1)–C(2)–C(3)–S(2) = 9.5° in **6** and C(2)–C(3)–C(8)–S(2) = 13° in **4**]. The Pd–S bond lengths are in the range of other Pd-dithiolene complexes [31,34–37]. The C–C bonds in the dithiolene unit are best described as double bonds [C(1)–C(2) = 1.329(6) Å in **4** and C(1)–C(2) = 1.341(8), C(33)–C(34) = 1.338(10) Å in **6**] while the C–C bonds in the bisphosphine dppe are single bonds. One of the molecules in compound **6** shows some disorder in the thiophene ring between *syn* and *anti* conformers with respect to the proton of the dithiolene unit (S_2C_2H), in an equal distribution, while the thiophene in the other molecule displays a *syn* conformation.

*Electrochemical properties of complexes **3**–**8***. Cyclic voltammetry experiments display in all the new complexes one reversible one-electron oxidation due to the dithiolene unit, except in the case of the palladium complex **4** which shows an irreversible oxidation (Table 4). In the case of complexes **3** and **6** an additional irreversible oxidation process is observed at $E_{(ox)} = 1.07$ V (**4**) and 0.59 V (**6**), which can be assigned to a second oxidation of the dithiolenes (see Table 4).

Table 4
Cyclic voltammetric data for complexes **3**–**8** (V vs. SCE, Pt disk electrode in 0.1 M of NBu_4PF_6)

Compound	**3**	**4**	**5**	**6**	**7**	**8**
$E^1_{1/2}$	+0.39v	+0.52v(i)	+0.42v	+0.39v	+0.408v	+0.38v
$E^2_{1/2}$	+1.16v(i)			+1.11v(i)		

4. Concluding remarks

We have presented the synthesis and complete characterisation of heteroleptic nickel and palladium dithiolenes via deprotection of the corresponding starting thiones and subsequent addition of the metallic derivatives with 1,2-bis(diphenylphosphino)ethane as an ancillary ligand. The X-ray analyses of two Pd-dithiolenes show a planar five-membered ring involving the metallic center and the dithiolene unit.

2. Experimental

2.1. Physical measurements

The chemicals used were obtained from the following sources: triethylenetetramine from S.D. Fine Chem., India. 2-Hydroxy acetophenone from Spectrochem, Mumbai, India. Copper(II) perchlorate hexahydrate was prepared by treating Copper(II) carbonate with 1:1 $HClO_4$ and crystallized after concentration on water bath. All other chemicals and solvents were reagent grade materials and were used as received without further purification. The elemental analyses (C, H, N) were performed with a Perkin–Elmer model 240 C elemental analyzer. ^1H and ^{13}C NMR spectra of the ligand were obtained on a Bruker AC 200 NMR spectrometer using TMS as the internal standard. ^1H NMR spectra of the complex were collected on a 250 MHz Bruker DXR 250 spectrometer. In all cases, the protio-solvent signal was used as reference and chemical shifts were quoted on the δ scale (down field shifts are positive). IR spectra were recorded on a Perkin–Elmer 883 spectrophotometer. The solution electrical conductivity and electronic spectra were obtained using a Unitech type U131C digital conductivity meter with a solute concentration of about 10^{-3} M and a Shimadzu UV 3100 UV–Vis–NIR spectrophotometer, respectively. The room temperature magnetic susceptibilities in the solid state were measured using a home built Gouy balance fitted with a polytronic d.c. power supply. The experimental magnetic susceptibilities were corrected for the diamagnetic response using Pascal's constants [10]. Magnetic measurements were carried out at the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (ca. 40 mg) using a Quantum Design MPMS XL-5 SQUID susceptometer operating at a constant magnetic field of 1 T between 2 and 300 K. The experimental magnetic moment was corrected for the diamagnetic contribution from the sample holder. X-band and EPR measurements (9.7857 GHz) were performed at various temperatures on powdered samples a Bruker Spectrometer (ESR 300E), working with an oxford liquid helium cryostat for variable temperature.

2.2. Preparation of H_3L

A solution of triethylenetetramine (3.7 g, 25.32 mmol) in methanol (25 ml) was dropwise added to a methanolic solution (25 ml) of 2-hydroxyacetophenone (10.2 g, 74.90 mmol) with stirring at room temperature. The yellow solution was then refluxed for 5 h. The solvent was evaporated in air. The yellow solid was separated by filtration through G4 sintered bed and washed thoroughly with hexane and water. Finally, the isolated compound was dried in vacuo over P_4O_{10}. Yield 9.3 g (75%), m.p. 184–186 °C. *Anal.* Calc. for $C_{30}H_{36}N_4O_3$: C, 71.97; H, 7.25; N, 11.19. Found: C, 71.51; H, 7.62; N, 11.49%. Mass spectrum (EI): m/z 500 ($M^+ = L^+$). 2.3. Preparation of $1 \cdot 4H_2O$

To the solution of H_3L (0.50 g, 1.00 mmol) in acetonitrile (20 ml) was added aqueous solution of NaOH (0.12 g, 3.00 mmol) followed by aqueous solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.74 g, 2.00 mmol) with magnetic stirring in air at ambient temperature. The reaction mixture was then stirred for two more hours. The resulting dark green color solution was then left for evaporation in the air. The dark green color crystals separated out were isolated and dried in vacuo. Yield: 0.56 g (75%). *Anal.* Calc. for $C_{31}H_{42}N_4O_{10}Cu_2$: C, 49.13; H, 5.58; N, 7.39; Cu, 16.77. Found: C, 49.41; H, 5.48; N, 7.51; Cu, 17.12%. IR (KBr, cm^{-1}): $\nu = 3395$(b), 2920(b), 1590(s), 1531(s), 1441(s), 1338(s), 1242(s), 1113(s), 850(s), 747(s). Molar conductance, Λ_M: (MeCN solution) 45 ohm^{-1} cm^2 mol^{-1}. UV–Vis spectra [λ_{max}, nm (ε, l mol^{-1} cm^{-1})]: (MeCN solution) 635 (338), 395 (2700), 366 (6886), 309(8627). Room temperature μ_{eff} (tot.): 2.29 μ_B; μ_{eff}/Cu: 1.62 μ_B.

2.4. Preparation of **2**

To the solution of H_3L (0.50 g, 1.00 mmol) in acetonitrile (20 ml) was added aqueous solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.74 g, 2.00 mmol) with magnetic stirring in air at room temperature. The resulting blue violet solution was then stirred for 1hour and left in the air for solvent evaporation. The dark blue violet solid that separated out was filtered washed with water and dried in the vacuo. Yield: 0. 37 g (70%). *Anal.* Calc. for $C_{14}H_{24}N_4O_9CuCl_2$: C, 31.91; H, 4.59; N, 10.63; Cu, 12.06. Found: C, 32.13; H, 4.48; N, 10.85; Cu, 12.37%. IR (KBr, cm^{-1}): $\nu = 2928$(b), 1607(vs), 1589(s), 1323(s), 1091(s), 963(s), 738(s). Molar conductance, Λ_M: (MeCN solution) 235 ohm^{-1} cm^2 mol^{-1}. UV–Vis spectra [λ_{max}, nm (ε, l mol^{-1} cm^{-1})]: (MeCN solution) 567 (290), 351 (8445), 268 (27 265), 239 (30 605). Room temperature μ_{eff} 1.75 μ_B.

2.5. X-ray crystallographic procedures for $1 \cdot 4H_2O$ and **2**

Suitable crystals of $1 \cdot 4H_2O$ and **2** were grown from acetonitrile/H_2O and acetonitrile/dichloromethane solution of the complexes, respectively, at room temperature over a period of 5–10 days. The single crystal data were collected on Bruker-Nonius Mach3 CAD4 X-ray diffractometer that uses graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) by ω-scan method. The structure was solved by direct methods and refined by least-square methods on F^2 using SHELX-97 [11]. Non-hydrogen atoms were refined anisotropically and hydrogen atoms on C-atoms were fixed at calculated positions and refined using a riding model. Whereas H-atoms on water molecules in $1 \cdot 4H_2O$ could not be located. The details of crystal data are given in Table 1. The selected bond lengths are summarized in Table 2.

3. Results and discussion

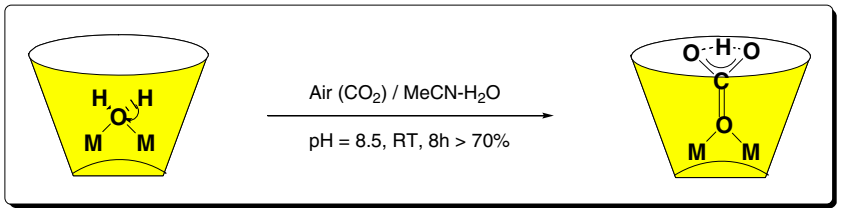
3.1. Syntheses and characterization

The μ-bis(tetradentate) ligand H_3L was synthesized by the known imidazolidine ring formation reaction with 2-hydroxy acetophenone and triethylenetetramine in 3:1 molar ratio under reflux for 5 h, and isolated in the solid form following a modified Bailer route [12]. The resulting Schiff base incorporated an imidazolidine ring from the

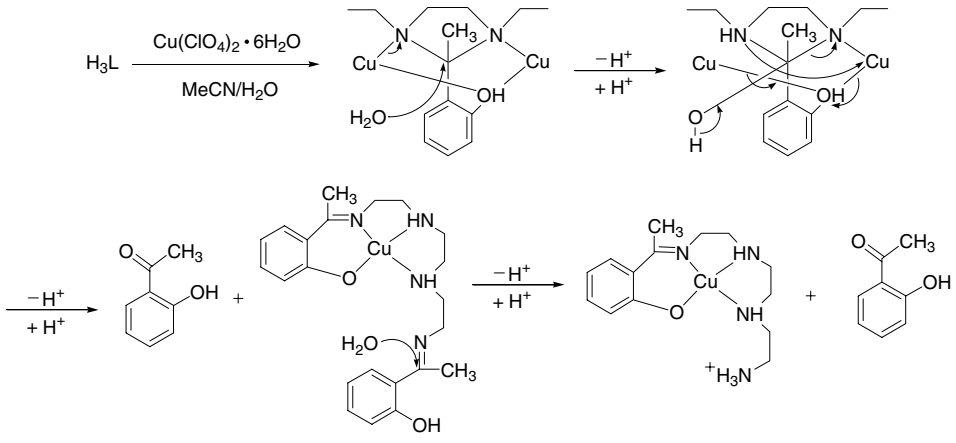
reaction of the third ketone with the two inner adjacent secondary amine nitrogens of trine [13]. In the IR spectrum of the ligand H_3L, the phenolic O–H stretching of the two terminal rings are observed at 3443 cm^{-1}. The C=N stretching frequency is observed at 1616 cm^{-1}. In the EI-MS of the ligand, the molecular ion peak (m/z) was observed at 500, confirming the formation of the desired imidazolidine ring containing ligand. In ^1H NMR spectra the characteristic central methyl protons and terminal methyl protons both appear as singlets at 1.38 and 2.21 ppm, respectively. The signals due to aromatic ring protons were observed in the 6.74–7.40 ppm region. The hydrogens on the imidazolidine backbone appeared as a complex set of overlapping triplet resonance signals at 2.74–2.80 ppm. The characteristic central methyl carbon and terminal methyl carbons appear at 14.51 and 26.58 ppm, respectively, in ^{13}C NMR spectra. The imidazolidine ring carbon at the hydroxyphenyl substitution appears at 116.83 ppm. The imine carbon appears at 164.29 ppm. Both ^1H and ^{13}C NMR data are comparable with the literature values [14,15]. The reaction of H_3L with $Cu(ClO_4)_2 \cdot 6H_2O$ in air leads to complex $\mathbf{1} \cdot 4H_2O$ after fixation and transformation of carbon dioxide, possibly resulting from the initial formation of the corresponding dinuclear complex with vacant coordination sites. Utilization of methylimine ligand (H_3L) instead of the corresponding (unsubstituted) imine ligand increases the ease of substitution of the apical bridging ligands in dicopper complexes. We have found that the aqua bridged complex, $[Cu^{II}_2(\mu\text{-}L)(\mu\text{-}H_2O)]ClO_4$, which represents the starting point of this investigation, fixes carbon dioxide in the form of the $\mu\text{-}\eta^2 : HCO_3^-$ bridged complex $\mathbf{1} \cdot 4H_2O$ in nearly quantitative yield (Scheme 2). The product was identified by IR spectroscopy and X-ray crystal structure analysis. Any carbonate bridged complex was not obtained at this pH. In moderate basic medium the fixation of carbon dioxide as hydrogencarbonate is possible when a nucleophilic M–OH unit attacks the electrophilic carbon atom of the CO_2 molecule. A proposed mechanism for the formation of $\mathbf{1} \cdot 4H_2O$ is suggested in Scheme 2. Possibly the bridged aqua ligand is activated by two Lewis-acidic Cu^{II} centers, favouring its deprotonation to give the μ-OH intermediate. Bridging water, which has no access for nucleophilic attack to the imidazolidine carbon and imine carbon of L^{3-}, is responsible for CO_2 activation.

The aqua bridged complex, formed initially in solution, thus exhibits remarkably high affinity for CO_2. The hydrogencarbonate group is generated in situ by reaction of atmospheric CO_2 without the need of bubbling CO_2 into the solution. On the other hand if a water molecule is present as a terminal ligand, it can hydrolyze the central imidazolidine part and terminal salicylimine end of the ligand. Attack of H_2O to the tertiary carbon of the imidazolidine ring and protonation of one imidazolidine nitrogen may be responsible for the ring hydrolysis. Further attack of H_2O to one of the imine bond gives the mononuclear complex $[Cu^{II}(HL^1)] \cdot 2ClO_4$ (**2**) with the loss of second 2-hydroxyacetophenone molecule as shown in Scheme 3.

The dicopper complex is bridged by endogenous L^{3-} and by the oxygen atom of an exogenous hydrogencarbonate. Only one $\mu\text{-}\eta^1 : \eta^1\text{-}O,O'$-hydrogencarbonate bridged



Scheme 2.



Scheme 3.

dicopper(II) complex has been reported till date [16]. Complex $\mathbf{1}\cdot 4H_2O$ is the first example where the hydrogencarbonate bridges between two copper centers through the single oxygen of one C=O group. Four possible bridging modes for hydrogencarbonate/carbonate bridged dinuclear metal systems are shown in Scheme 4. Mode A for hydrogencarbonate is reported for the first time in $\mathbf{1}\cdot 4H_2O$.

Complex $\mathbf{1}\cdot 4H_2O$ is obtained from the reaction of H_3L with $Cu(ClO_4)_2\cdot 6H_2O$ and NaOH (pH 8.5) in 1:2:3 molar ratio in acetonitrile–water (1:1 vol) at room temperature in air. In MeCN the solution conductivity measurement ($45\ \Omega^{-1}\ cm^2\ mol^{-1}$, 28 °C) shows non-electrolytic behavior, confirming the nature of the bridging group as HCO_3^-. The IR spectrum of the complex showed a strong absorption band at $1590\ cm^{-1}$ which is the characteristic stretching vibration of ν(C=O) of this group [17]. Fixation of atmospheric CO_2 as CO_3^{2-} or HCO_3^- bridged dinuclear or polynuclear Cu^{II} complexes has been described previously [18]. A broad peak at $3395\ cm^{-1}$ is due to uncoordinated water molecules. Of all dicopper compounds made from ligands related to H_3L, $\mathbf{1}\cdot 4H_2O$ is only the third example featuring a single exogenous oxygen bridging ligand (Scheme 5) [19,20] and the first example for any kind of neutral oxygen bridging reported till date.

Electronic spectra of the complex in acetonitrile solutions show several intense absorption bands in the visible region. A strong broad band at 635 nm region with molar extinction coefficient of $340\ l\ mol^{-1}\ cm^{-1}$ is characteristic of d–d transitions. Higher intensity charge transfer transitions are obtained at 395, 366 and 309 nm with molar extinction coefficients of 2700, 6885 and $8625\ l\ mol^{-1}\ cm^{-1}$, respectively.

Complex **2** was obtained as a blue violet solid in 70% yield from the reaction of H_3L with $Cu(ClO_4)_2\cdot 6H_2O$ in 1:2 molar ratio in air and in absence of base (pH 6) in MeCN–water mixture at room temperature. The complex behaves as a 1:2 electrolyte in acetonitrile solution ($\Lambda_M = 235\ ohm^{-1}\ cm^2\ mol^{-1}$). The IR spectrum of the complex showed strong absorption bands at 2928 and $1607\ cm^{-1}$, characteristic of the ν(NH) and ν(C=N) stretching vibrations. The strong unsplit band for $\nu(ClO_4^-)$ at around $1091\ cm^{-1}$ suggests no coordination of perchlorate ions [17]. The electronic spectra of the complex shows a d–d transition band at 567 nm with molar extinction coefficient of $290\ l\ mol^{-1}\ cm^{-1}$ and several charge transfer transitions in the 351–239 nm range with molar extinction coefficient of 8455–$30605\ l\ mol^{-1}\ cm^{-1}$. The structure of **2** shows that during the reaction, the ligand H_3L undergoes copper(II) mediated imidazolidine ring and one terminal imine bond hydrolysis simultaneously. It is interesting to note that the corresponding bis(amide) ligand is stable towards this type of coordination driven hydrolysis reaction [21].

3.2. X-ray structure of $[Cu_2^{II}(L)(HCO_3)]\cdot 4H_2O$ ($\mathbf{1}\cdot 4H_2O$) and $[Cu^{II}(HL^1)]\cdot 2ClO_4$ (**2**)

The molecular structure of $\mathbf{1}\cdot 4H_2O$ (Fig. 1a) consists of two Cu^{II} ions chelated and bridged by one L^{3-} ligand, which are related by a crystallographic plane of symmetry.

The bridging moieties of this ligand are one μ-η^1:η^1-*N*,*N*′-imidazolidine fragment and the single oxygen of the central phenoxide group, the imine N-atoms and the oxygen from terminal phenoxide groups completing the donation from L^{3-}. In addition, the metals are bridged by one μ-η^2-HCO_3^- group, which completes the triply bridging motif in the dicopper complex. Thus, each Cu^{II} ion exhibits a distorted square pyramidal ($\tau = 0.28$) [22] coordination geometry (N_2O_3) where the two N-atoms (imine and amine) and two O-atoms (terminal and bridging phenoxide groups, respectively) form the basal square plane and the C=O oxygen from the hydrogencarbonate ligand occupies the fifth (apical) coordination position. Bridging of hydrogencarbonate within a dicopper system by a C=O single oxygen is very uncommon.

Each *meridional* half of the ligand L^{3-} forms one five-membered (N–Cu–N) and two six-membered (N–Cu–O) chelate rings. The chelate bite angles are 86.1(2)° for the five-membered ring and 92.8(2)° (terminal phenoxide) and 90.1(2)° (bridging phenoxide) for the six-membered rings. The bond distances from Cu^{II} to the bridging oxygen atoms are 1.978(4) (phenolate) and 2.307(6) Å (hydrogencarbonate). The Cu···Cu distance is 3.210(6) Å, which is in the normal range for other molecules with a triply bridging motif [23,24]. The Cu–O–Cu bond angles for bridging phenol and hydrogencarbonate are 108.4(3)° and 88.2(3)°, respectively. The Cu–N_{imine} and Cu–N_{amine} distances are distinctly different; the longer Cu–N_{amine} distance (2.092(5) Å) compared to that of the Cu–N_{imine} bond (1.947(6) Å) is mainly due to the different states of

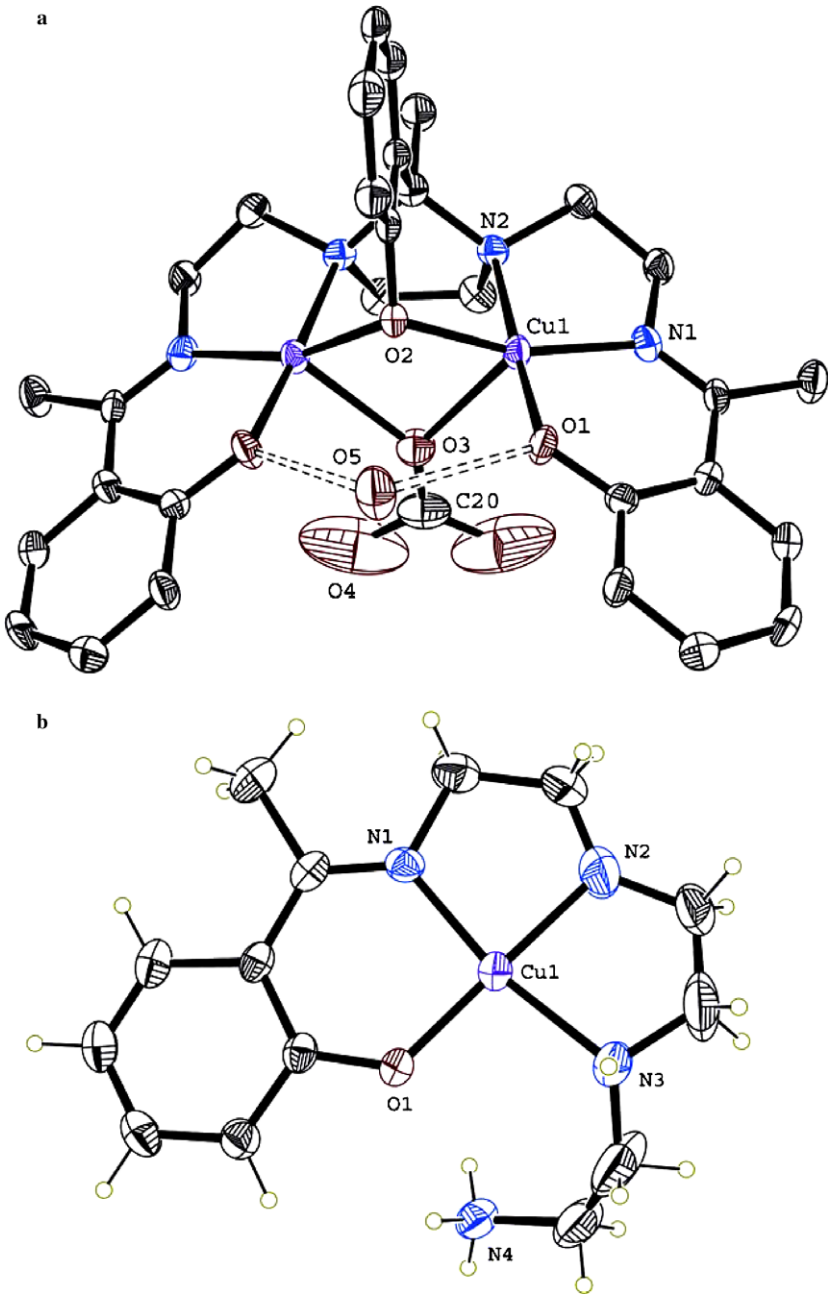

Fig. 1. Labeled ORTEP view of $\mathbf{1} \cdot 4H_2O$ with H-bond indicated as dashed lines (a), and cationic part of **2** (b). Ellipsoids are drawn at 30% probability. Hydrogen atoms are omitted for clarity in (a).

hybridization of the coordinating N atoms in the molecule. The Cu–N_{amine} distance is in the usual range for a bivalent metal ion and is not longer due to their participation in bridging. The C=O distance (1.240(15) Å) of the bridging hydrogencarbonate moiety is short in comparison to other reported C=O(carbonate) bridged dicopper complexes, proving the enhanced double-bond character of the carbon–oxygen bond in complex $\mathbf{1} \cdot 4H_2O$ [18b,25]. The other C–O distance in this moiety (C20–O4) is 1.319(13) Å, whereas all the O–C–C angles are close to 120°. It is difficult to establish the presence of the proton attached to the hydrogencarbonate group. This is inferred by inspection of the C–O bond distances, and is required to ensure the charge balance within the system. To the best of our knowledge, this is the first reported structure of a neutral dicopper system bridged by hydrogencarbonate through one single oxygen atom. The average C–C and C–N bond distances fall in the usual range. There are two water molecules of crystallization within the crystal lattice. The first water molecule O(5) shows intramolecular interactions with both the terminal phenolic oxygen atoms O(1) and O(2) (Fig. 1a) [O(5)···O(1)/O(2) = 2.773(3) Å]. The hydrogen bonded water molecule provides a pseudo macrocyclic ligand environment around two copper(II) centers

(Fig. 1a). The second water molecule is further hydrogen bonded to the first one at a distance O(5)···O(6) = 2.740(3) Å, which is in the range found in regular ice (2.74–2.85 Å) [26]. The molecules of $[Cu_2(L)(HCO_3)]\cdot 4H_2O$ units form an extended array by a combination of π···π, C–H···O and O–H···O hydrogen bonds [27], leading to the formation of a 3D network with zigzag hydrophilic layers along the (0 1 0) direction (Fig. 2a). The guest water molecules occupy the interlayer space of dicopper complexes and form an intricate hydrogen bond scheme. According to the structural data, they belong to either of two categories: (i) tightly bonded molecules, anchored to the network by one or more hydrogen bonds involving the terminal phenol oxygen atoms; and (ii) loosely bonded molecules showing only contacts with other water molecules.

The molecular structure of **2** (Fig. 1b) shows a mononuclear complex of copper(II) in square planar N_3O environment of the hydrolyzed zwitterionic ligand H_2L^{1+}.

The donor atoms consist of three nitrogens (one imine and two amine) and one phenolic oxygen. The tetradentate ligand H_2L^{1+} forms two five membered (N–Cu–N) and one six membered (N–Cu–O) chelate rings with bite angles of 86.0(3)°, 84.0(4)° and 94.7(2)°, respectively. The three chelate planes around the copper(II) ion are almost planar with maximum deviations of 0.051 Å at atom O(1) for the O(1)C(2)C(1)C(7)N(1)Cu(1) ring, −0.088 Å at atom C(9) for the N(1)C(8)C(9)N(2)Cu(1) ring and −0.032 Å at atom C(11) for the N(2)C(10)C(11)N(3)Cu(1) ring. The $Cu–O_{phenol}$ bond length [1.884(5) Å] is comparable to those observed in other four coordinate Cu^{II} complexes [28]. As for complex **2**, the $Cu–N_{imine}$ distance (1.953(6) Å) is shorter than the average $Cu–N_{amine}$ distances (2.038(8) Å) due to the different states of hybridization of the coordinating N_{amine} atoms in the molecule. The bond near the pendant $-NH_3^+$ moiety [Cu(1)–N(3)] features the longer distance (2.074(8) Å) compared to the Cu(1)–N(2) distance (2.002(8)) of the other amine nitrogen atom. The C–C and C–N bond distances fall in the usual range. The uncoordinated pendant $-NH_3^+$ group of the complex shows three hydrogen bonds; one with the coordinated phenolic oxygen and two with oxygen atoms of the two uncoordinated perchlorate molecules, respectively. Of the three hydrogen bonds, that with the coordinated

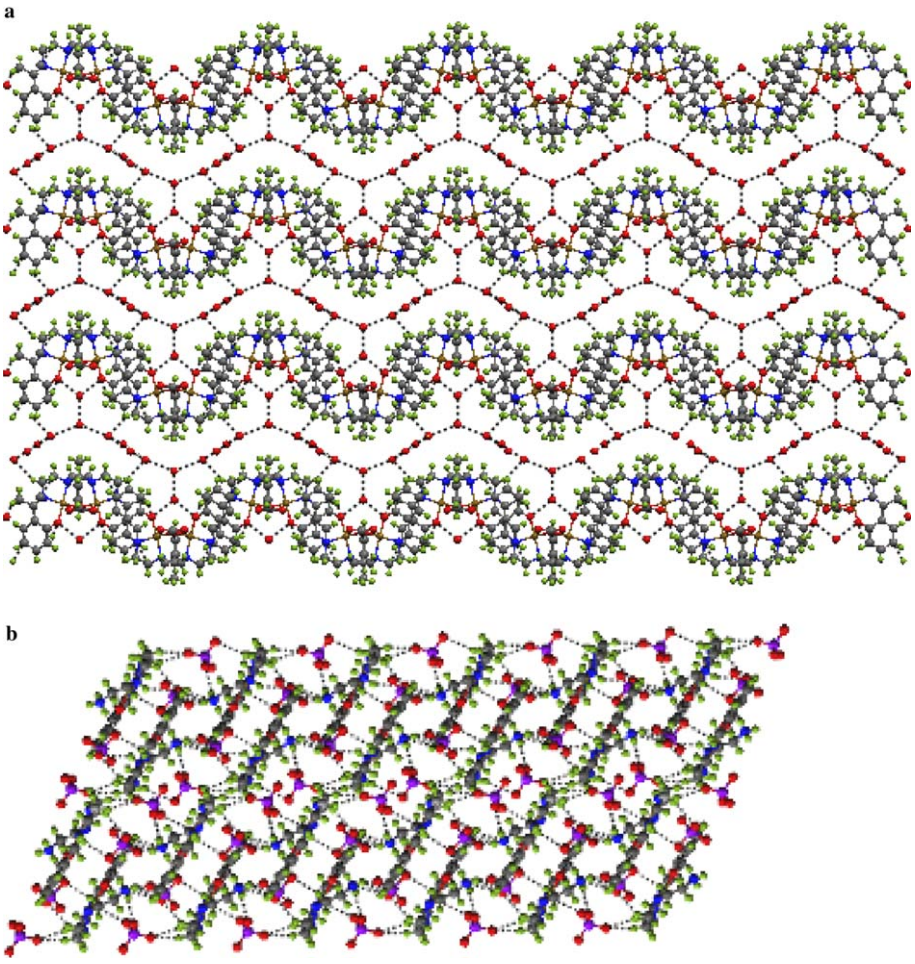

Fig. 2. (a) View of the packing of $\mathbf{1}\cdot 4H_2O$ along the (0 1 0) direction; guest water molecules give hydrogen bonded zigzag layers between the dinuclear units. (b) View of the packing of **2** along the (0 1 0) direction showing the formation of a 3D network with a step structure.

phenol (O(1)) is the shortest (with a N–H···O distance of 2.705 Å). The three observed hydrogen bonds again confirm the cationic nature of the pendant $-NH_3^+$ arm. The $[Cu^{II}(HL^1)]\cdot 2ClO_4$ units also form an extended array by a combination of C–H···O and O–H···O hydrogen bonds between the perchlorate anions and the ethylene backbone of the ligand, leading to the formation of a 3D network with a step structure along the (0 1 0) direction (Fig. 2b).

3.3. Magnetochemistry of $[Cu^{II}_2(L)(HCO_3)]\cdot 4H_2O$ ($\mathbf{1}\cdot 4H_2O$)

Bulk magnetization measurements on complex $\mathbf{1}\cdot 4H_2O$ under a constant magnetic field of 1 T were performed in the 2–300 K temperature range. The $\chi_M T$ versus T plot (Fig. 3) remains almost constant in almost all temperature range and only drops at a very low temperature, indicating that the magnetic exchange between Cu^{II} centers is very weak and antiferromagnetic.

A fit to the Bleaney-Bowers equation (for the Hamiltonian $H = -JS_1S_2$) provided a coupling constant of $J = -1.2\ cm^{-1}$. This is in contrast with the (much more significant) ferromagnetic nature of the coupling observed within a pair of carbonate bridged dimers previously reported with a ligand very similar to H_3L [18b]. The ferromagnetism in the latter case was explained, with help of DFT calculations, in terms of the counter-complementary effect between the various bridging moieties linking the Cu^{II} ions. However, in the present case, the coordination number and geometries of the metals are very different, and therefore, it is not possible to establish any analogy. This fit produced TIP and g values of $251\times 10^{-6}\ cm^3\ mol^{-1}$ and 1.94, respectively. The latter is slightly lower than expected for Cu^{II} and it could be due to an experimental error. A more reliable value ($g = 2.15$) could be obtained from variable temperature X-band solid state EPR (Fig. 4), as calculated from the rhombic signals $g_1 = 2.23$, $g_2 = 2.14$ and $g_3 = 2.08$. The existence of a signal even at 8 K is consistent with the very weak antiferromagnetic coupling existing between both Cu^{II} signals. The solution behavior of $\mathbf{1}\cdot 4H_2O$ was investigated by means of room temperature ^1H NMR in d_4-MeOH. The spectrum (Fig. 5) is similar to that obtained for a previously reported complex of H_3L, featuring bridging acetate instead of hydrogencarbonate.

For complex $\mathbf{1}\cdot 4H_2O$, however, the spectrum is much broader, to the point that many peaks escape detection. For this reason, only the peaks corresponding to the $-CH_3$ groups could be assigned in the present spectrum. A very broad peak, the integration of which is much larger than any other peak in the spectrum is attributed to exchangeable protons. This presumably reflects the fact that the antiferromagnetic coupling in $\mathbf{1}\cdot 4H_2O$ is weaker

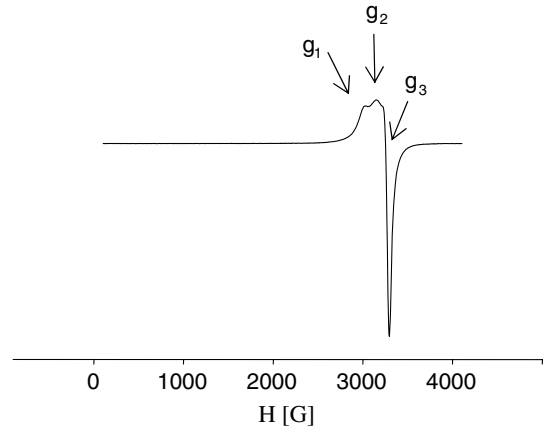

Fig. 4. Solid state powder EPR spectra (X-band) of $[Cu^{II}_2(L)(HCO_3)]\cdot 4H_2O$ ($\mathbf{1}\cdot 4H_2O$) at 8 K.

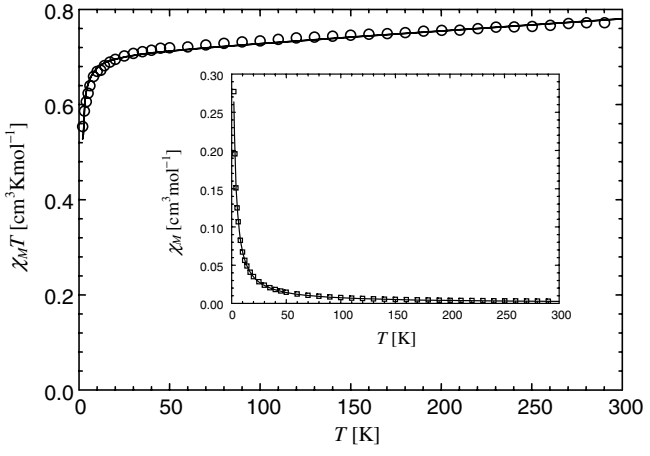

Fig. 3. Plot of $\chi_M T$ vs. T per molecule of $[Cu^{II}_2(L)(HCO_3)]\cdot 4H_2O$ ($\mathbf{1}\cdot 4H_2O$). The solid line is a fit to the experimental data using the Bleaney-Bowers equation. (Inset) Representation of experimental (squares) and calculated (solid line) χ_M vs. T data for ($\mathbf{1}\cdot 4H_2O$).

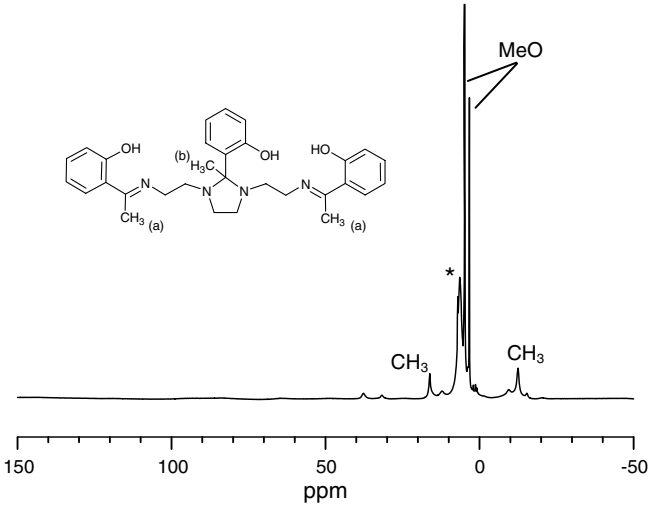

Fig. 5. Room temperature 250 MHz ^1H NMR spectrum of $[Cu^{II}_2(L)(HCO_3)]\cdot 4H_2O$ ($\mathbf{1}\cdot 4H_2O$) in d_4-MeOH. The signal labelled as '*' is attributed to exchangeable protons.

and also suggests that the solid state structure is maintained in solution (see Fig. 5).

4. Concluding remarks

In conclusion, we have described a ligand system that in the presence of Cu^{II} undergoes, depending on the pH conditions, either atmospheric CO_2 fixation and coordination upon formation of a dinuclear complex, or ligand hydrolysis leading to a mononuclear complex. The results presented here represent the first synthesis, structural description and magnetic characterization of a HCO_3^- neutral single oxygen bridged $Cu^{II}\cdots Cu^{II}$ complex. The magnetic coupling between the Cu^{II} ions is very weak and antiferromagnetic. This new $[Cu_2^{II}]$ complex shows a $[Cu_2(\mu\text{-imidazolidine})]^{4+}$ core and, currently, we are engaged in synthesizing analogues complexes of other 3d and 4d metal ions to scrutinize the effect that the nature of the exogenous bridging moiety has on the molecular structure and magnetism of new complexes.

Appendix A. Supplementary materials

Further details of the structure determinations, including atomic coordinates, bond lengths and bond angles and thermal parameters of all non-hydrogen atoms for the structure are available on request as supplementary material from The Director, Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk) (CCDC deposition Nos. 283579 and 283580). Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.04.005.

above-mentioned connectivity-based indices and indices based on topological distances (Wiener's type indices) there are indices that use explicitly the electronic structure of the molecule, [21–23] or are obtained by the combination of basic topological indices [24,25]. Needless to say, the topological indices are frequently highly intercorrelated, [26] and can be interpreted in various ways in terms of elementary molecular properties (size and shape of a molecule, molecular volume or surface, etc.) [27].

Our expectation that topological indices should work for the estimation of stability constants of coordination compounds is not based only on their wide application in all branches of chemistry. There are many approaches aimed at systematic or ad hoc estimation of the stability of coordination compounds, ranging from molecular mechanics [28–31] and molecular dynamics [32], to the methods based on the continuous distribution of solvent [33,34] or on the overlapping-sphere volume [35,36]. The variety of methods employed indicates that the stability of coordination compounds is determined by many, often unrelated, factors: electronic (strength of the metal—ligand bond), stereochemical (mode of coordination) and sterical (conformational). Thermodynamic stability is also dependent on the energy of solvation (hydration) of the metal, ligand and the complex, etc. In such a complex situation it seems appropriate to rely on holistic models, like the models based on topological indices.

In our preliminary work on molecular graph models [37,38], we have found that the estimates of stability constants of copper(II) chelates with amino acids were fairly well correlated on topological indices, the connectivity indices [39] proved to be among the best. The results, however, also suggest that the estimate depends on the molecular species (constitutional formula). In order to propose a model of general validity, in this paper we aim to study the influence of the constitutional formula, from which a molecular graph is derived, on the success of the estimate. For this purpose, we chose copper(II) complexes of amino acids and diaminoethane, along with their derivatives, divided into four sets. Also, we directed our efforts to the mono- and (binary and ternary) bis-complexes of those ligands.

2. Methods

The calculations of topological indices were performed with a program system DRAGON 2.1, written by Todeschini and coworkers, [40] that is capable of yielding 262 topological indices in a single run, along with many other molecular descriptors.

The connectivity matrix was constructed with the program CORINA, [41] developed by J. Sadowski, C.H. Schwab and J. Gasteiger.

Preliminary calculations have, however, shown that generally the most consistent results were obtained with the Randić index $^3\chi^v$ (*the valence molecular connectivity index of the 3rd order*):

$$^3\chi^v = \sum_{\text{path}} \{\delta(i)\delta(j)\delta(k)\delta(l)\}^{-0.5} \quad (1)$$

where $\delta(i)$, $\delta(j)$, δ(k) and $\delta(l)$ are weights (valence-delta values) of vertices (atoms) i, j, k and l making up the path of length 3 (three consecutive chemical bonds) in a vertex-weighted molecular graph [39,42]. The valence-delta value, $\delta(i)$, of a vertex i is defined by:

$$\delta(i) = [Z^v(i) - H(i)]/[Z(i) - Z^v(i) - 1] \quad (2)$$

where $Z^v(i)$ is the number of valence electrons belonging to the atom i, $Z(i)$ is its atomic number and $H(i)$ is the number of hydrogen atoms attached to the atom i. For instance, delta values for primary, secondary, tertiary and quaternary carbon atoms are, 1, 2, 3 and 4, respectively; for oxygen in an OH group it is equal to 5, and for the NH_2 group $\delta(N) = 3$. (It has to be pointed out that $^3\chi^v$ is only a member of the family of valence connectivity indices, $^n\chi^v$, which differ from each other by path length, i.e. the number of factors $\delta(i)$'s in the summation term.)

In this paper four kinds of molecular formulas (graphs) were used for the calculation of the index $^3\chi^v$. Besides the graphs of free ligands (L models), we also used the graphs of their chelates in various representations (Figs. 1, 3 and 5). Graphs with or without two additionally bound water molecules were denoted with b, and were used in ML^{aq} and ML models, respectively. If an additional ligand coordination is proposed for a complex, the new graph is constructed and marked with a c, and was used in the ML^{cor} models instead of the corresponding graph b. For the sake of simplicity, only the graphs of mono-chelates are given in Figs. 1, 3 and 5, while the graphs of the corresponding bis-complexes that were used in ML_2, ML_2^{aq} and ML_2^{cor} models can be derived from them in a straightforward manner, assuming the maximum coordination number of copper is six.

Regression calculations, including the leave-one-out procedure of cross validation, *cv*, were done by the CROMRsel program [43]. The standard error of cross validation estimate is defined as:

$$SE_{cv} = \left(\sum \Delta X^2/N\right)^{0.5} \quad (3)$$

where ΔX and N denote *cv* residuals and number of reference points, respectively.

3. Results

3.1. Chelates of 1,2-diaminoethane and its derivatives

As the first test for our approach we have chosen a set consisting of 14 copper(II) mono- and bis-complexes of 1,2-diaminoethane and its *N*-alkylated (**2**–**6**), *N*,*N*′-dialkylated (**7**–**10**) and *C*-substituted (**11**–**14**) derivatives (Table 1). All experimental $\log\beta_1$ ($\log K_1$) and $\log\beta_2$ values were selected from the literature, and were determined with the same method (potentiometry) under the same experimental conditions ($T = 298$ K, $I = 0.5$ mol L^{-1}).

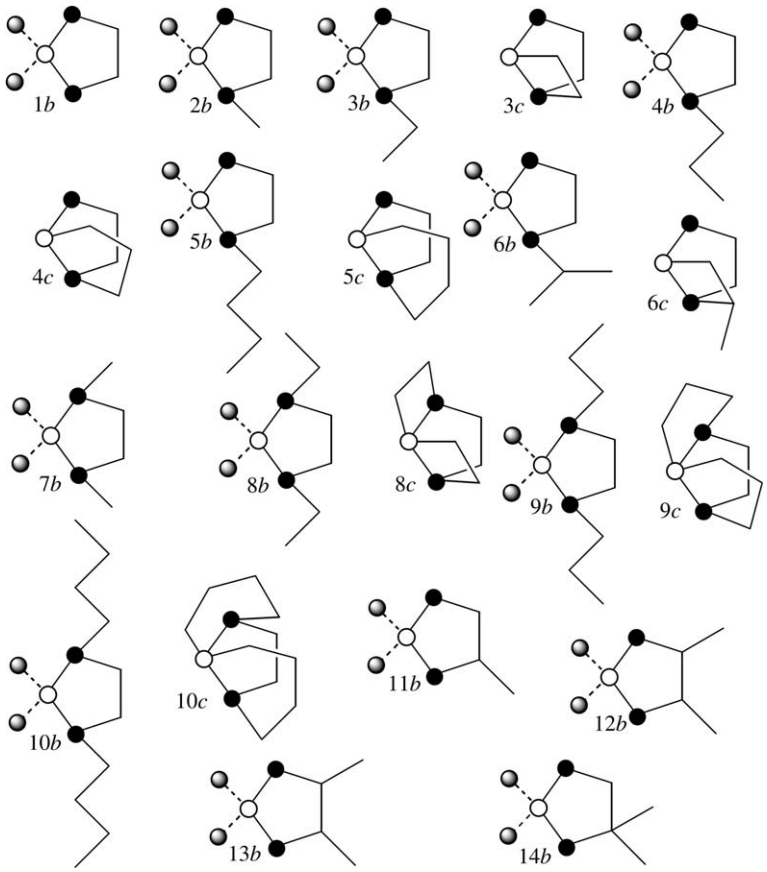

Fig. 1. The three kinds of molecular graphs of copper(II) mono-complexes of 1,2-diaminoethanes, as used in ML (*b*, without bonded H_2O), ML^{aq} (*b*, with bonded $2H_2O$) and ML^{cor}(*c*) models. Heteroatoms are marked with ○ (Cu), ● (N), ◍ (O).

Table 1
Stability constants ($\log\beta_1$ and $\log\beta_2$) of copper(II) mono- and bis-complexes with 1,2-diaminoethane and its derivatives

No.	Ligand	$\log\beta_1$	$\log\beta_2$	Reference
1	1,2-Diaminoethane	10.76	20.13	[50]
2	*N*-methyl-1,2-diaminoethane	10.55	19.11	[50]
3	*N*-ethyl-1,2-diaminoethane	10.19	18.57	[50]
4	*N*-propyl-1,2-diaminoethane	9.98	18.14	[50]
5	*N*-butyl-1,2-diaminoethane	9.94	18.21	[50]
6	*N*-isopropyl-1,2-diaminoethane	9.07	16.52	[50]
7	*N*,*N*′-dimethyl-1,2-diaminoethane	10.47	18.1	[51]
8	*N*,*N*′-diethyl-1,2-diaminoethane	9.30	15.62	[51]
9	*N*,*N*′-dipropyl-1,2-diaminoethane	8.79	14.34	[51]
10	*N*,*N*′-dibutyl-1,2-diaminoethane	8.67	13.51	[51]
11	1,2-Diaminopropane	10.78	20.06	[52]
12	(*R*,*S*)-2,3-diaminobutane	10.72	20.06	[52]
13	(*R*,*R*)-2,3-diaminobutane	11.39	21.21	[52]
14	2-Methyl-1,2-diaminopropane	10.53	19.58	[52]

Linear regression of $\log\beta_1$ on the connectivity index $^3\chi^v$ shows a distinct improvement of the results as the formula becomes more realistic; ML is a better representation than L, and ML^{aq} than ML (Table 2). Even better estimates were obtained when an additional coordination of the alkyl chains was proposed for all the *N*-substituents, except methyl. In this model, denoted as ML^{cor}, ligands **1**, **2**, **7** and **11**–**14** were assumed to be bidentate, **3**–**6** terdentate and **8**–**10** tetradentate (Fig. 1). The ML^{cor} model (No. 4, Fig. 2) proved to be the best; *r* rises to 0.903 and SE_{cv} drops to 0.38 $\log\beta$ units. Absolute values of cv residuals were in range from 0.00 (**5**) to 0.94 (**13**), which is very close to the range of model 3 (0.01–1.03 $\log\beta$ units), but substantially better than the range of model 2 (0.02–1.42 $\log\beta$ units), and especially of model 1 (0.07–1.48 $\log\beta$ units). The worst estimates for all the models were yielded for complexes **6**, *N*-isopropyl-1,2-diaminoethane, and **13**, (*R*,*R*)-2,3-diaminopropane, in contrast to its meso-isomer **12**, with the $\log\beta_1$

values reproduced in an absolute error range from 0.2 (model 4) to 0.75 $\log\beta$ units (model 1). It is interesting to note that model 4 equally well reproduced *b* and *c* set of molecules in terms of SE_{cv}, in contrast to models 2 and 3 with $SE_{cv}(b)/SE_{cv}(c)$ values of 1.59 and 1.37, respectively. (In models ML and ML^{aq} $SE_{cv}(c)$ stands for complexes for which an additional coordination in ML^{cor} model is proposed.)

In Table 2 seven models for the copper(II) bis-complexes with 1,2-diaminoethanes are also referred. Beside L, ML_2, ML_2^{aq} and ML_2^{cor} models (5–8), we checked the models based on the graphs of mono-complexes (9–11) for estimation of $\log\beta_2$ values. The best model proved to be model 11 ($r = 0.930$, $SE_{cv} = 0.93$ $\log\beta$ units), but the difference to other models is rather small. The two second to best are models 6 and 10, which yielded the same statistical parameters ($r = 0.918$, $SE_{cv} = 1.03$ $\log\beta$ units), and similar absolute cv residual range (0.03–2.21, 0.01–2.19 and 0.12–2.02 $\log\beta$ units for model 6, 10 and 11, respectively). Moreover, the models do not equally well reproduce *b* and *c* set of molecules. $SE_{cv}(b)/SE_{cv}(c)$ equals 1.63, 1.33, 2.00 and 1.62 for models 6, 7, 9 and 10, respectively. Models based on the ML^{cor} representation, however, yielded opposite trends; $SE_{cv}(b)/SE_{cv}(c)$ is 0.57 and 1.56 for model 8 and 11, respectively.

3.2. Chelates of aliphatic amino acids and N-alkylated glycines

The second set consists of altogether 11 ligands (Table 3): glycine (**1**), its seven *N*-alkylated and *N*,*N*-dialkylated derivatives (**5**–**11**) and three amino acids with alkylic side chains (**2**–**4**). All experimental values were obtained with the same method (potentiometry) and under the same experimental conditions ($T = 298$ K, $I = 0.1$ mol L^{-1}), except for leucine complexes, which were studied at $I = 0.01$ mol L^{-1}. In the ML^{cor} models, an additional coordination is assumed for complexes **7**–**11** (Fig. 3). The estimates for mono-complexes (Table 4) show a small difference between the models based on the assumption of ML, ML^{aq} or ML^{cor} structures. Model 14 appears to be the best, and the other two models yield equally good estimates; model 13 is superior to model 15 in terms of SE_{cv}, but model 15 is better than model 13 in terms of *r* and SE The best model in terms of absolute cv residual values is, however, model 13 (0.03–0.71 $\log\beta$ units), and this is slightly better than the residuals obtained by the "best" model 14 (0.00–0.74 $\log\beta$ units). The ML^{cor} model (No. 15) gave a $SE_{cv}(b)/SE_{cv}(c)$ value close to 1 (0.74), but model 13 yielded an even better value (1.20), in contrast to $SE_{cv}(b)/SE_{cv}(c) = 0.45$ for model 14.

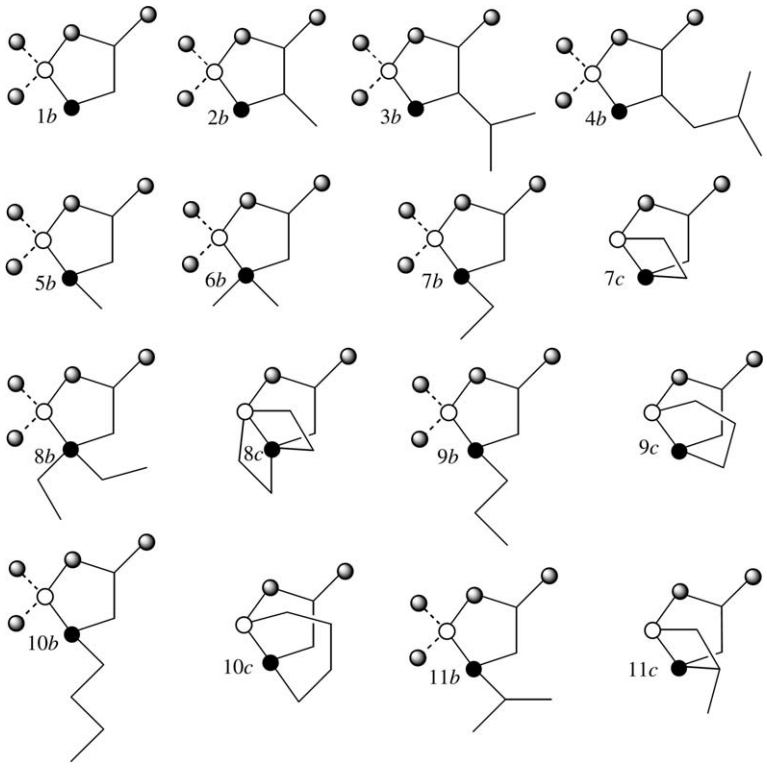

Fig. 3. The three kinds of molecular graphs of copper(II) mono-complexes of aliphatic amino acids and their *N*-alkylated derivatives; as used in ML (*b*, without bonded H_2O), ML^{aq}(*b*, with bonded $2H_2O$), and ML^{cor}(*c*) models. Heteroatoms are marked with ○ (Cu), ● (N), ◕ (O).

For the bis-complexes of this set of ligands, the same kinds of models are checked as for diaminoethane complexes (Table 4). The model based on the ML_2^{cor} representation (No. 19, Fig. 4), proved to be the best, and next to it are models 18 (ML_2^{aq}) and 21 (ML^{aq}). The best model (No. 19) also yielded a substantially better range of absolute cv residual values (0.03–0.88 $\log\beta$ units) than for the other two models (0.02–1.33 and 0.02–1.22 $\log\beta$ units, for models 18 and 21, respectively). The best $SE_{cv}(b)$/$SE_{cv}(c)$ values, 0.85 and 0.90, were obtained for models 19 and 20, respectively.

3.3. Chelates of naturally occurring amino acids

As a representative set for copper(II) chelates with naturally occurring amino acids, we choose glycine (**1**) followed by three alkylic (**2**, **4**, **6**), two hydroxy (**3**, **5**), two aromatic (**7**, **8**) and one sulfur-containing amino acid (**9**), Table 5. Stability constants were determined under the same experimental conditions ($T = 298$ K, $I = 0.05$ mol L^{-1}). The representation with additional coordination (*c*) was applied to ligands with hydroxy, aromatic, and sulfanyl groups (**3**, **5**, **7**, **8**, **9**, Fig. 5). In our decision, we were directed by the proposed ability of the side chains to interact with the central atom. The experimental findings support the assumed interactions of the hydroxy and aromatic group with the copper(II) in coordination compounds [44–46]. For methionine (**9**) the experimental findings are contradictory, because there is no evidence for Cu–S interactions in complexes of methionine [47], but such an interaction is observed in blue copper proteins [48]. Thus, for methionine complexes we proposed a

9	Methionine	7.85	14.53	[58]

structure with an apically bonded terminal aliphatic C-atom, reflecting sterical interactions of the bulky —S—CH_3 group with copper (9*c*, Fig. 5).

For the ML complexes, the best results were obtained for the ML^{cor} model (26, Table 6), which yielded $r = 0.888$ and $SE_{cv} = 0.08$ $\log\beta$ units (Fig. 6). Surprisingly, three other models yielded the same SE_{cv} values (0.11 $\log\beta$ units), and very slight differences in the values of the correlation coefficients ($r = 0.766$–0.771). The model 26 also reproduces the best experimental $\log\beta_1$ values, yielding absolute cv residuals from 0.01 to 0.14 $\log\beta$ units. It is significantly better than the other models, e.g. model 25 yielded 0.03–0.23 $\log\beta$ units. The quotient $SE_{cv}(b)/SE_{cv}(c)$ is close for all the models; it equals 1.2, 1.0 and 0.8 for models 24, 25 and 26, respectively.

For the bis-complexes, fairly good results were yielded by ML_2^{cor} and ML^{cor} models; $r = 0.786$, $SE_{cv} = 0.15$ $\log\beta$ units and $r = 0.743$, $SE_{cv} = 0.16$ $\log\beta$ units for models 30 and 33, respectively (Table 6). Assuming rather high standard errors of the slope for the other models, only models 30 and 33 appeared to be acceptable. They also have a similar range of absolute cv residual values, 0.01–0.32 vs. 0.00–0.35 $\log\beta$ units. In all the models, the worst estimate was yielded for serine (**3**). The same holds true for mono-complexes. The $SE_{cv}(b)/SE_{cv}(c)$ value is close to 0.8 for all the models.

3.4. Mixed complexes of naturally occurring amino acids

As the final proof of validity of our approach, we chose a set of 16 $\log\beta_2$ values for mixed (ternary) complexes of naturally occurring amino acids (Table 7). We derived two composite indices obtained by addition or subtraction

of the $^3\chi^v$ indices for two chelate rings, ML and MA, constituting a mixed complex (MLA), assuming $^3\chi^v(\mathrm{ML}) > {}^3\chi^v(\mathrm{MA})$. There are many possibilities to draw a graph of a mixed complex in terms of additional coordination, thus we took into account only the combinations referred in Table 7. Bivariate linear regression (35, Table 8) based on additional coordination representation, yielded better statistical parameters, which are comparable to the parameters for binary complexes ($r = 0.786$, $SE_{cv} = 0.15$, model 30). The values of absolute cv residual are in the range 0.01–0.33 $\log\beta$ units, with the highest residual value for the mixed complex of serine and threonine (**11**). This again shows superiority of the ML^{cor} to ML model.

4. Discussion

The results presented above and summarized in Table 9, show that the $\log\beta_1$ values are reproduced, in terms of SE_{cv}, within the range 0.08–0.38, and $\log\beta_2$ values from 0.15 to 0.93 $\log\beta$ units. These results, referred to the best regression for a set, show also that generally the best results were obtained with the models based on the ML^{cor} (ML_2^{cor}) representation; the sole exception being model 14 (Table 4), based on the ML^{aq} representation. In spite of this, there is a small difference between the estimates obtained with the

ML^{cor} and ML^{aq} models for the complexes of diaminoethanes and *N*-alkylated glycines. However, the very high superiority of the ML^{cor} models for complexes of naturally occurring amino acids should be explained by the higher affinity of the groups in the amino-acids side chains to the apical position. It is noteworthy that no model systematically reproduced a better *b* or *c* molecular subset, indicating that there is no substantial difference in molecules of both subsets.

The less successful reproduction of $\log\beta_2$ values has to be attributed mostly to the fact that they were generally determined with a higher error than the first constants. It is noteworthy that the difference between experimental values for $\log\beta$s amounts up to 0.3, although measured in the same way [49]. In judging the success of the estimate, one has also to keep in mind the range of experimental values ($\log\beta^{min}$–$\log\beta^{max}$) in the set. Taking as a measure of success the estimate quotient $SE_{cv}/(\log\beta^{max}–\log\beta^{min})$, models referred in Table 9 gave a quotient in the range from 0.12 to 0.26, with the same mean value (0.19) for both ML and ML_2 complexes.

The comparison of the best regressions in this paper with our previously published estimates obtained by the overlapping spheres (OS) method, [34–36] Table 9, clearly shows the quality of the results is virtually the same for both methods, in terms of SE_{cv} and the absolute cv residual range. This finding speaks in favor of the method based on topological indices, for the OS method is much more complicated. Internal comparison of the estimates shows that OS and $^3\chi^v$ methods often differ much more to each other than to the experimental results, pointing out that they would not be considered as equivalent. The reason for such a discrepancy, especially in the values of residuals, should be found in the fact there are some complexes whose stability constants are very hard to reproduce. For the $^3\chi^v$ method these are complexes of (*R*,*R*)-2,3-diaminobutane, *N*-isopropyl-1,2-diaminoethane, *N*,*N*′-diethylglycine, *N*-isopropylglycine and serine. For the OS models, the worst were reproduced for complexes of 1,2-diaminoethane, *N*,*N*′-dimethyl-1,2-diaminoethane, *N*-isopropylglycine and serine. Obviously, the OS method better reproduces the stability constants of the complexes of optical isomers, (*R*,*S*)- and (*R*,*R*)-2,3-diaminobutane, but *N*-isopropylglycine and serine were poorly reproduced by both methods.

A substantial improvement of the estimates was obtained by averaging the results of both methods (Table 9); SE_{cv}

dropped to 0.07–0.38 and 0.16–0.70 $\log\beta$ units for mono- and bis-complexes, respectively. The maximum error dropped even more; for the most poorly reproduced (bis-diaminoethane) complexes it descended from 2.02 ($^3\chi^v$, **13**) and 1.97 (OS, **7**) to 1.37 $\log\beta$ units (**10**). For the amino acid complexes, however, the complexes of *N*-isopropylglycine (**11**), and serine (**3**) were again reproduced worst.

As a conclusion of this paper, it can be stated that methods based on the topological indices fairly well reproduces the stability constants of coordination compounds, usually with an error less than 0.5 $\log\beta$ units. However, caution should be taken for the ''anomalous'' behavior of some ligands. The results should be substantially bettered by averaging the results obtained by other methods. Thus, the development of such a combinative approach will be the aim of our further research.

spectra were obtained in DMSO-d_6 solutions at 50 °C with a Varian Mercury 400 BB (400 MHz) spectrometer using TMS (^{1}H) and $VOCl_3$ (^{51}V) as reference compounds. The circular dichroism spectra were recorded using a Jasco J-20 recording spectropolarimeter.

2.2. X-ray investigations

The structure of **7** was determined. Crystal data and refinement details are provided in Table 1. Data for the **7** complex were obtained with Mo Kα radiation using a Nonius-Kappa CCD diffractometer. Structure was solved using direct methods with SHELXS-97 [16] and refined by full-matrix least-squares using the SHELXL-97 [17] with anisotropic thermal parameters for the non-hydrogen atoms. Analysis utilized the program PLATON [18]. Hydrogen atoms bonded to C and O atoms were included in calculated positions. Selected bond lengths and bond angles are listed in Table 2.

Table 1
Crystal data and structure refinement for **7**

Moiety formula	$C_{26}H_{34}N_4O_6V_2 \cdot 2H_2O$
Formula weight	636.48
Temperature (K)	293(2)
Wavelength (Å)	0.71073
Crystal system	monoclinic
Space group	$P2_1/c$
Unit cell dimensions	
a (Å)	9.7420(3)
b (Å)	6.7430(2)
c (Å)	20.6960(8)
β (°)	94.903(1)
Volume (Å^3)	1354.55(8)
Z	2
D_{calc} (g cm^{-3})	1.561
Absorption coefficient (mm^{-1})	0.747
$F(000)$	664
Crystal size (mm)	$0.25 \times 0.20 \times 0.15$
θ Range for data collection (°)	3.00–27.50
Limiting indices	$-12 \leqslant h \leqslant 12$, $-7 \leqslant k \leqslant 8$, $-26 \leqslant l \leqslant 26$
Reflections collected/unique [R_{int}]	5347/2968 [0.028]
Completeness to $\theta = 27.45$ (%)	95.2
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	2968/2/214
Goodness-of-fit on F^2	1.165
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0609$, $wR_2 = 0.1658$
R indices (all data)	$R_1 = 0.0770$, $wR_2 = 0.1725$
Extinction coefficient	0.026(5)
Largest difference in peak and hole (e Å^{-3})	0.313 and −0.533

Table 2
Selected bond lengths (Å) and bond angles (°) for **7**

V1–O1	1.610(3)	O2–V1–N1	156.59(13)
V1–O2	1.665(2)	O2–V1–N2	94.06(14)

V1–N1	2.219(3)	O3–V1–N2	156.00(15)
V1–N2	2.097(4)	N1–V1–N2	77.25(13)
V1–O2′	2.396(3)	O1–V1–O2′	171.25(13)
O1–V1–O2	106.95(15)	O2–V1–O2′	77.28(12)
O1–V1–O3	102.12(15)	O3–V1–O2′	84.57(12)
O1–V1–N1	95.37(14)	N1–V1–O2′	79.67(10)
O1–V1–N2	93.61(17)	N2–V1–O2′	78.31(14)
O2–V1–O3	98.46(12)	V1–O2–V1′	102.72(12)

The sign ′ denotes atom at $1 - x$, $-y$, $1 - z$.

2.3. Complexes

The complexes were prepared by methods analogous to the literature procedure of Root et al. [19]. Typically, 10 mmol of (*S*)-(+)-2-(aminomethyl)pyrrolidine in 10 ml of absolute ethanol was added with stirring to a freshly filtered solution of triethyl vanadate (10 mmol) in 250 ml of absolute ethanol producing a suspension of an intermediate. Then to that suspension was added slowly the desired aromatic *o*-hydroxyaldehyde (salicylaldehyde or its 5-methyl, 5-methoxy, 4,6-dimethoxy, 5-bromo, 5-nitro derivatives or 2-hydroxy-1-naphtaldehyde) or the *o*-hydroxyketone (2-hydrocyacetophenone, 2-hydroxybenzophenone or 1-hydroxy-2-acetonaphtone). After refluxing and stirring for 2 (aldehydes) or 10 h (ketones) the separated yellow solids were filtered off, washed several times with ethanol and Et_2O and then dried. Crystals suitable for X-ray analysis were obtained by slow crystallization of **7** from DMSO.

2.3.1. *N-(salicylidene)-(S)-(2-pyrrolidinylmethyl)amine dioxovanadium(V) (**1**)*

Yield: 60%. *Anal.* Calc. for $C_{12}H_{15}N_2O_3V$: C, 50.3; H, 5.3; N, 9.8. Found: C, 50.4; H, 5.3; N, 9.8%. 3. Results and discussion

3.1. Crystal and molecular structure of 7

The crystal of **7** is built from two kinds of dimeric complex molecules $\mathbf{A}_2$ and $\mathbf{B}_2$ and water molecules. An ORTEP diagram illustrating the molecular structure of **7** is given in Fig. 2. The figure shows that vanadium(V) ion is six-coordinated through three bonds to oxo groups and through bonds to the tridentate Schiff base ligand. The six-coordination illustrates the strong propensity of vanadium to increase its coordination number via dimerisation of two pentadentate monomers. The geometry of the coordination environment resembles two edge shared octahedrons that are significantly distorted. The separation of O1 from V1 (1.610(3) Å) (Table 2) is typically for V=O which is not involved in donor–acceptor interactions [19–23]. The O2, V1, O2′, V1′ atoms are situated in edges of a parallelogram with the acute O2–V1–O2′ angle of 77.3(1)°. The tridentate ligand is coordinated meridionally, its oxygen (O3) and pyrrolidine ring nitrogen (N2) occupy axial positions. The six-membered chelate ring defined by V1, O3, N1, C1, C6, C7 atoms is planar (maximal deviation of plane defining atoms does not exceed 0.029 Å). In the final stage of anisotropic refinement conformation disorder of pyrrolidine and five-membered chelate rings was recognized. Two conformations of each of these rings could be distinguished. The disorder of C12, common for pyrrolidine and five-membered chelate rings, and of C11 of the pyrrolidine ring, is displayed in Fig. 2. Both the chelate and pyrrolidine five-membered rings adopt in **B** twist (half-chair) but in **A** the envelope conformations. The refined site occupancy values of 0.552(14) for C11B and C12B and of 0.447(14) for C11A and C12A indicate that the crystal of **7** is a solid solution of **B** (55%) and **A** (45%). These arrangements and the priority sequence rules of Cahn et al. [24] allow to assign the absolute configuration of C12A to *R* and that of C12B to *S*. The ligand sites in conformation isomers **A** and **B** are diastereotopic and therefore the crystal of **7** may be considered as a solid solution of two

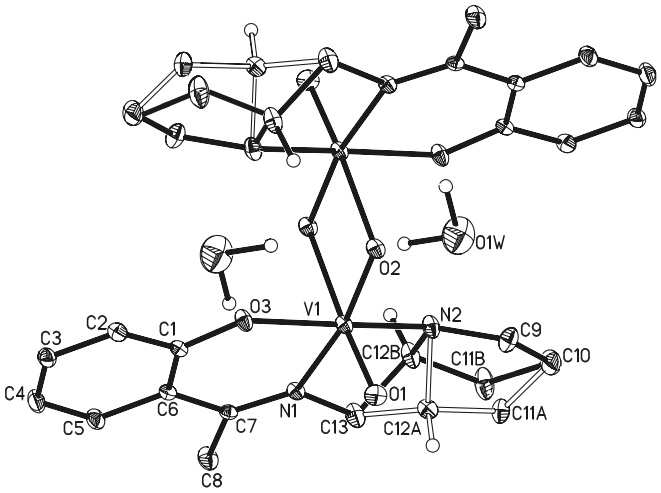

Fig. 2. An ORTEP drawing of the crystal structure of **7** with the atomic numbering scheme. H atoms, except those which are bound to C12A, C12B and of water molecules, are omitted for clarity. Displacement ellipsoids are drawn at the 10% probability level. The disordered conformation of five-membered ring is indicated by bonds drawn as parallel lines.

covalent diastereomers. A rare case of two diastereomers in one crystal was demonstrated earlier by Fulwood et al. [25] who resolved the crystal structure of the monooxovanadium(V) Schiff base complex solvate [VO(sal-L-ala)Bu^s]Bu^{s}OH. The steric demand of the space group symmetry prevents the inversion of rings so that only the most stable form of the molecule should be present in the crystal. The inconsistency of the crystal structure with that demand seems to be the result of sufficient similarity of **A** to **B** molecules, which quantified by the Kitaigorodski's isosterism coefficient [26] is $\varepsilon = 1 - v_{no}/v_o = 0.761 \pm 0.003$ (where v_{no} and v_o represent the non-overlap and overlap volumes of **A** and **B** molecules calculated on the basis of the average volumes of elements derived [27] from the analysis of the Cambridge Structural Database). The obtained ε value is somewhat smaller than the lower limit value of the reported 0.8–1 range [26] required for formation of a solid solution from two kinds of molecules. Partial transformation of **B** into **A** induced by crystallization occurs probably at the expense of the crystallization energy.

The diffraction experiment (due to its time and space averaging character) sees the structure of the crystal of **7**, containing the 45:55 mixture of two (**A** and **B**) conformers, centrosymmetric.

3.2. Spectroscopic studies

IR spectra of non-solvated complexes show a single band in the 3196–3233 cm^{-1} region designated to the N–H stretching mode of the coordinated secondary amino group, two bands in the 1585–1650 cm^{-1} range associated with ν(C=N) and ν(C=C) vibrations, two bands in the 839–936 cm^{-1} range which may be assigned to asymmetric and symmetric vibrations of VO_2 group. By analogy to the dissociation of the $[VO_2(1,2\text{-pnSal})]_2$ [19] and $[VO_2(MeenSal)]_2$ [20] dimers in DMSO solutions, which are weakly associated in the solid state [19,21], we felt it was likely that also the related dimeric complex **7** associated in the crystal through elongated O2–V1′ and O2′–V1 bonds (2.393(3) Å), and also the **1**–**6**, **8**–**10** complexes, are dissociated in DMSO at 50 °C to form monomeric compounds. In contrast to a single transition observed in the ^{51}V NMR spectrum of $[VO_2(1,2\text{-pnSal})]_2$ [19] and of $[VO_2(MeenSal)]_2$ [20] the **1**–**10** complexes exhibit two transitions in DMSO-d_6, one in the range from −532 to −539 ppm and the other approximately 8 ppm at higher field. The large separation of two ^{51}V resonances may be explained as the result of diastereomeric splitting which amounts ca. 7.5 ppm when the chiral centre containing asymmetric carbon atom is separated from the chiral vanadium centre by two bonds [28] like C12 from V1 in **7**. Intensities of ^{51}V NMR signals, as measured by areas they enclose, are in the ratios 3:1 for both **7** and **10** and in a greater number to one for the remaining compounds. The chemical shifts of both transitions from −531 to −556 ppm are in a range observed for five-coordinated V(V) complexes with similar O_3N_2 donor sets [19,20]. Since crystal structure conformations are generally good guides to conformational preferences in solution [29] we assigned two ^{51}V resonance signals to **A** and **B** diastereomers which were found in the crystal of **7**.

Chemical shifts, signal multiplicities and coupling constants of protons bonded to aromatic carbon atoms are comparable with the ^{1}H NMR data for related dioxovanadium(V) Schiff base complexes derived from analogous aromatic hydroxycarbonyl compounds and different diamines [20]. Protons of both five-membered rings of **1**–**10** give two sets of signals as illustrated in the part of the spectrum of the **5** compound (Fig. 3). Ratio's of signal intensities for corresponding protons from these sets are comparable with the **B**:**A** molar ratio's determined from ^{51}V NMR spectra. Two resonance signals of the ethylidene methyl group are observed in the spectra of **7** and **10** compounds. The integrated intensity ratio of these signals (3.24:1 for **7**, 3.45:1 for **10**) closely correlates with the molar ratio of **B**:**A** diastereomers in DMSO solution. Since the methyl group is not disordered two signals of its protons may be attributed to the van der Waals effect which result in a lower field shift of one of the signals relative to the other due to shorter H(C8) ⋯ H(C13) contact separation in **B** (stronger low field shift) than in **A**.

The methylene protons of the =N—CH_2—CH fragment have been analysed as two AB subspectra of the ABX system and the computations yield the values of a geminal coupling constant J_{AB} = 14–15 Hz, and vicinal couplings

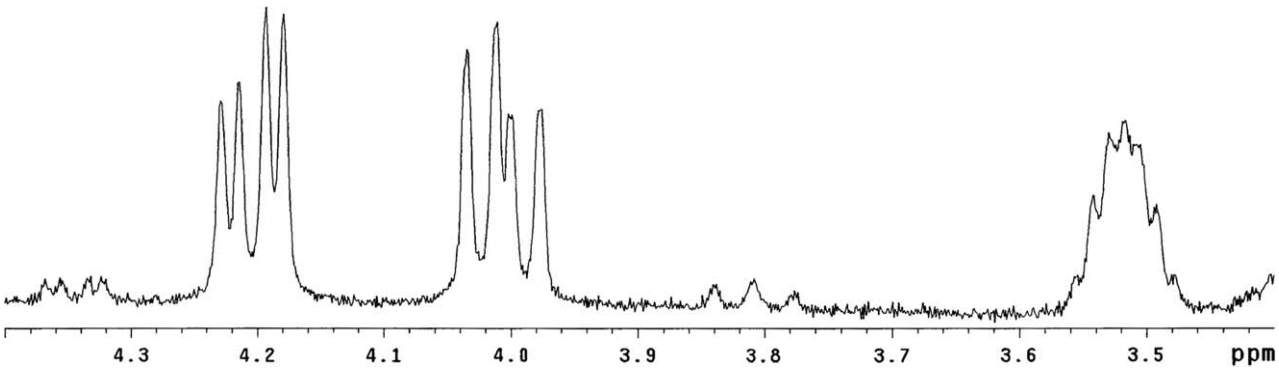

Fig. 3. Part of the ^{1}H NMR (400 MHz) spectrum of **5**.

$J_{AX} = 8$–10 Hz and $J_{BX} = 5$–6 Hz. The methine proton produces a seven-line multiplet (Fig. 3) with relative intensities of its components about 1:2:3:4:3:2:1 and this multiplicity may be interpreted as a triplet ($^3J = 10$ Hz) of triplets ($^3J = 5$ Hz) on the basis of first-order approximation. At 50 °C the AB system is in the region of slow exchange and the equilibrium constant $K = [\mathbf{B}]\backslash[\mathbf{A}]$ can be determined by integration of the separate resonance signals for **A** and **B**, particularly of NH, =N—CH_2 and CH_3—C=N protons. From the equation $-\Delta G^0 = RT \ln K$ the difference in free energy of the two conformations of **A** and **B** molecules is obtained. Its negative values $\Delta G^0(323) = -3.157 \pm 0.003$ kJ mol^{-1} for **10** and $\Delta G^0(323) = -3.325 \pm 0.003$ kJ mol^{-1} for **7** indicate that the compounds favour the twist conformation of both five-membered chelate rings.

The circular dichroism data for the complexes in DMSO are summarized in Section 2. Basing on the assumption that sign of the Cotton effect reflects the conformation of the five-membered chelate ring of a Schiff base complex [30] it may be concluded that the positive sign of all CD bands for **1**–**5** and **9** complexes is consistent with a high predominance of **B** form in DMSO solutions of complexes derived from aromatic hydroxyaldehydes.

3.3. Conclusions

A series of new Schiff base vanadium(V) complexes incorporating the pyrrolidine fragment have been obtained. The successfully determined structure of **7** is one of the rare case of vanadium complexes for which there are two diastereomers in one crystal and they appear in the diffraction experiment as one disordered molecule. The ratio of the diastereomer **B**, possessing the asymmetric carbon atom in the same absolute configuration as the parent (*S*)-(+)-2-(aminomethyl)pyrrolidine, to the diastereomer **A**, containing the corresponding carbon atom in *R* configuration, being 55:45 for the crystal of **7** changes to 3:1 in its DMSO solution and to a higher predominance of **B** over **A** in solutions of all of the remaining complexes. The free energy change value of transformation of *S*-diastereomer into its *R* analog in DMSO solution is particularly low for **7** and **10** complexes containing ethylidene substituent attached to the aromatic ring.

4. Supplementary material

Supplementary crystallographic data are available from the CCDC, Union Road, Cambridge CB2 1EZ, UK on request quoting the deposition number CCDC 292426 (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk).

planar and/or axial positions: a frame of distorted octahedron is always available, although different visible spectrophotometric behaviour is recorded in event of planar or axial entrance of the donors in substitution of pre-existing water oxygen. Visible spectrophotometric response is then fundamental, since both calorimetric and stability data are usually unable to discriminate among equatorial and axial positions of donor groups, as well known.

As previously observed by various authors [4–6], a red shift in the visible λ_{max} position of a copper(II) complex appears when a donor group is located in an axial position, that is the so-called "pentammine effect". In our context of copper(II)–ligand interaction in aqueous solution, a "*red shift*" is the shift towards higher wavelengths (shorter energies) of the visible absorption maximum occurring when an equatorially co-ordinated copper(II) complex (λ_{max1}) acquires a donor in an axial position (λ_{max2}): the corresponding red shift is simply expressed as $\Delta\lambda_{max} = \lambda_{max2} - \lambda_{max1}$. Oxygen of water is considered as a donor, since its contribution to the ligand field of a copper(II) aqueous ion is quantitatively known [1,5]. The red shift is defined for each axial donor by means of a simple normalisation, $\Delta\lambda_{max}/n$, with $n = 2$ for a complex having two donors along the z-axis.

In this study we attempted to obtain reliable discriminating evidences, using literature findings as well, in order to formulate a simple spectrum–structure correlation test to hypothesize an axial co-ordination in a copper(II) complex. Since visible absorption spectra discussed in many papers were recorded without explicit reference to the chemical speciation, that is without strictly considering stability aspects and overlapping of the species, we are forced to exclude many potential axially co-ordinated copper(II) complexes by our treatment. The equation developed in [1] (see also Refs. therein), providing a link between the λ_{max} value of a copper(II) complex and its equatorial co-ordination environment, should now help us in seeking discriminating visible spectrophotometric features to formulate a well-documented hypothesis of axial co-ordination for copper(II) ion. In this connection, a series of visible spectra were recorded on copper(II)–2,2′-bipyridine system (various metal-to-ligand ratios and pH were tested), since this bidentate ligand is known for its ability to co-ordinate copper(II) in axial position as well. Copper(II) complex formation with L-aspartic acid (a potential tridentate ligand) was also investigated by combined pH-metric and visible spectrophotometric techniques to check the eventual axial co-ordination. The study is moreover strengthen by a computer-assisted calculation procedure, based on the Lambert–Beer law, which allow us to calculate a visible spectrum for each of the complexes formed in solution (almost those reaching a significant percentage of formation). As a consequence, the spectrum–structure correlation is thought on single species, avoiding the significant errors due to the presence of two or more species at the same pH value.

2. Experimental

2.1. Chemicals

2,2′-Bipyridine (bipy, H_2L^{2+}, 99.5%) was a BDH AnalaR product and L-aspartic acid (asp, H_3L^{+}, 99%) was a Merck product, both employed without any further purification.

The copper(II) chloride stock solution was standardized by means of complexometric titrations with EDTA, in the presence of the metallochromic indicator murexide. Standard solutions of NaOH, KOH, HCl and HNO_3 were prepared by diluting concentrated Merck ampoules and were standardised against potassium hydrogenphthalate or sodium carbonate, respectively. Grade A glassware and deionised and twice distilled water were used for all solutions. The ionic strength was adjusted to 0.1 M by addition of KCl. The purity of acid–base active reagents ($\geqslant$99%) was checked by pH-metric titrations followed potentiometrically.

2.2. Electromotive force measurements

The potentiometric measurements of pH were performed at $T = (25.0 \pm 0.1)$ °C and ionic strength $I = 0.1$ M (KCl) with an Amel 338 potentiometer equipped with a combined glass electrode provided by Metrohm (Switzerland), model 6.0222.100, internal Ag/AgCl reference electrode (filling electrolyte: 3 mol/l KCl). The couple was calibrated in $-\log[H_3O^+]$ units (pH) employing alkalimetric titrations of hydrochloric acid with standard, carbonate free, potassium hydroxide. The ionic strength of the calibrating solutions was the same as that of solutions being examined. The alkalimetric titrations were carried out in a stream of purified nitrogen. Temperature control was achieved by means of liquid circulation from a thermo cryostat (model D1-G Haake). The concentration ranges examined was from 3 to 6 mM for C_M (C means analytical concentration). The metal-to-ligand molar ratios were from 1:1 to 1:3 for Cu^{2+}–2,2′-bipyridine and from 1:1 to 1:5 for Cu^{2+}–L-aspartic acid.

2.3. Spectrophotometric measurements

The visible spectrophotometric determinations were carried out with a Jasco V-550 UV/Vis spectrophotometer from 400 to 800 nm (optical path length 1.000). The solution being examined was transferred from the potentiometric to an optical cell using a peristaltic pump in order to record spectra as a function of the pH value of the solution, avoiding any equilibrium inconvenience. The metal concentration and the metal-to-ligand molar ratios were the same with regard to potentiometric determinations.

2.4. Data analysis and calculations

The stability constants of the complexes are expressed by the general formula: $\beta_{pqr} = [Cu_pL_qH_r]/[Cu]^p[L]^q[H]^r$ (all over the paper charges of complexes are omitted for sake of

simplicity); their values were refined by means of the BSTAC [7] program, which minimizes the error squares sum on electromotive force values and takes into account eventual variations of ionic strength among and/or during titrations.

Spectrophotometric data were analysed by means of the least squares computer program MOLEX [8], which calculates the values of molar absorptivity (ε_λ/dm^3 mol^{-1} cm^{-1}) by using experimental spectra (absorbance, A, versus wavelength, λ/nm), analytical concentrations of each reagent and the chemical model (stoichiometric coefficients, $p\ q\ r$, and known stability constant values of all complexes) as input. After the calculation of the species distribution, the spectra are estimated for each complex formed in solution, only leaving out the species formed in negligible amount, by assuming the additivity of the absorbance in the investigated concentration range (Lambert–Beer law). No assumptions on the shape of the curves nor on the nature of electronic transitions are taken into account by the calculation program.

In all calculations the hydrolysis of copper(II) ion [9] was considered.

3. Results

3.1. Complexes of 2,2′-bipyridine

First, the formation constant of the dimer $Cu_2L_2H_{-2}$ (2 2 −2 using $p\ q\ r$ indexes) with 2,2′-bipyridine has been re-calculated using pH-metric data (alkalimetric titrations of acidified Cu/L mixtures): we found ($T = 25$ °C, $I = 0.1$ M) $\log\beta_{22-2} = 5.59 \pm 0.02$ (uncertainty is expressed as ±SD). The agreement with the value previously estimated (5.68 ± 0.04 [10]) is good. The refinement has been performed assuming as fixed the values of $\log\beta_{pqr}$ related to the following species [11]: CuL ($\log\beta_{110} = 8.12$), CuL_2 ($\log\beta_{120} = 13.63$) and CuL_3 ($\log\beta_{130} = 17.0$); protonation constant values were from Ref. [10] (see also Refs. therein).
