In a Schlenk tube wrapped with aluminium foil, a solution of **15a** (37 mg, 56 μmol) in 1 mL CH_2Cl_2 was added to a suspension of $AgBF_4$ (11 mg, 56 μmol) in 1 mL CH_2Cl_2. After stirring for 16 h at RT, the mixture was filtered through Celite. The solvent was reduced to 0.3 mL under reduced pressure and the solution was overlaid with pentane. Colorless crystals of **19** were obtained after 5 days, which were washed with pentane and dried *in vacuo* (35 mg, 41 μmol, 73% yield). *Anal.* Calc. for $C_{45}H_{54}AgBF_4NOP \cdot 2.3CH_2Cl_2$: C, 54.32; H, 5.65; N, 1.34. Found: C, 54.33; H, 5.72; N, 1.36%. 2.2.19. [Rh(**15a**)Cl_3] (**21**)

To a solution of **15a** (16.4 mg, 25.0 μmol) in 0.7 mL CH_3CN was added a solution of $RhCl_3(H_2O)_3$ (6.6 mg, 25.0 μmol) in 0.3 mL CH_3CN at RT. The mixture was refluxed for 3h. Upon cooling to RT, the complex precipitated as an orange powder. After the solvent was removed under reduced pressure, the residue was purified by column chromatography over silica gel eluting with CH_2Cl_2 (TLC : $R_f = 0.34$), and then CH_2Cl_2–Et_2O (95:5) to give **21** as an orange solid (11.3 mg, 13.1 μmol, 52% yield). *Anal.* Calc. for $C_{45}H_{54}Cl_3NOPRh$: C, 62.47; H, 6.29; N, 1.62. Found: C, 62.35; H, 6.47; N, 1.49%. IR (KBr): *v* (cm^{-1}) 344, 358 (Rh–Cl), 1613 (C=N). $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$): δ 37.3 (d, $^1J_{PRh} = 105$ Hz). ^1H RMN (300 MHz, $CDCl_3$): δ 0.85 (s, 3H, H_8), 0.93 (s, 3H, H_{10}), 1.13 (s, 3H, H_9), 1.32 (s, 9H, $C(CH_3)_3$), 1.34 (s, 9H, $C(CH_3)_3$), 1.43 (s, 3H, $CH_{3xanthene}$), 1.58 (m, 1H, H_{5endo}), 1.90 (s, 3H, $CH_{3xanthene}$), 1.99–2.04 (m, 2H, H_{5exo}/H_{6exo}), 2.07 (m, 1H, H_4), 2.18 (m, 1H, H_{6endo}), 3.17 (d, 1H, $^2J_{HH} = 20.1$ Hz, H_{3endo}), 4.18 (d, 1H, $^2J_{HH} = 21$ Hz, H_{3exo}), 7.23 (d, 1H, $^4J_{HH} = 2.0$ Hz, H_{12}), 7.28 (d, 1H, $^4J_{HH} = 2.0$ Hz, H_{11}), 7.32 (m, 2H, H_{ar}), 7.40–7.55 (m, 4H, H_{ar}), 7.61 (dd, 1H, $^3J_{HP} = 10.2$ Hz, $^4J_{HH} = 2.1$ Hz, H_{14}), 7.69 (d, 1H, $^4J_{HH} = 1.9$ Hz, H_{13}), 7.87–7.96 (m, 4H, H_{ar}). $^{13}C\{^1H\}$

NMR (125.7 MHz, $CDCl_3$): 13.9 (broad s, C_8), 20.3 (s, C_9), 20.6 (s, C_{10}), 24.7 (broad s, $CH_{3xanthene}$), 27.3 (s, C_5), 31.4 (s, $2C(CH_3)_3$), 33.1 (s, C_6), 34.9 (s, $C(CH_3)_3$), 35.0 (s, $C(CH_3)_3$), 35.4 (broad s, $CH_{3xanthene}$), 35.5 (s, $C(CH_3)_2$), 43.2 (s, C_4), 47.1 (s, C_3), 53.6 (s, C_7), 58.8 (s, C_1), 117.8 (d, $J_{CP} = 53$ Hz, C_{ar}), 119.2 (s, C_{12}), 122.4 (s, C_{11}), 126.4 (s, C_{13}), 127.3 (s, C_{ar}), 127.8 (d, $J_{CP} = 12$ Hz, CH_{ar}), 128.3 (d, $J_{CP} = 11$ Hz, CH_{ar}), 128.9 (s, C_{ar}), 130.0 (s, C_{ar}), 130.4 (s, C_{14}), 131.1 (s, CH_{ar}), 131.4 (s, CH_{ar}), 133.4 (d, $J_{CP} = 7$ Hz, CH_{ar}), 133.9 (d, $J_{CP} = 7$ Hz, C_{ar}), 136.0 (d, $J_{CP} = 8$ Hz, CH_{ar}), 136.5 (s, C_{ar}), 145.8 (s, C_{ar}), 146.3 (s, C_{ar}), 149.2 (d, $J_{CP} = 6$ Hz, C_{ar}), 155.8 (d, $J_{CP} = 10$ Hz, C_{ar}), 201.5 (s, C_2).

2.3. Catalytic procedures

2.3.1. General procedure for palladium-catalyzed allylic alkylation with dimethyl malonate

A solution of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (0.9 mg, 2.5 μmol) and of ligand (4 or 6 μmol) in 1 mL THF was stirred for 20 min at RT. Alternatively, the catalyst solution was prepared by mixing together $AgBF_4$ (1 mg, 5 μmol) with $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (0.9 mg, 2.5 μmol) for 15 min, filtering on Celite and adding the ligand (4 μmol) to the filtrate. A solution of dimethyl sodiomalonate was prepared by allowing a solution of dimethyl malonate (132 mg, 1 mmol) in THF (1.5 mL) to react with a suspension of NaH (24 mg, 1 mmol). A solution of the substrate **16a–c** (0.5 mmol) in THF (1 mL) was added to the catalyst solution, followed by the nucleophile solution. The conversion was periodically monitored by GC. When the reaction was over, water (10 mL) was added and the organic phase was extracted with Et_2O (3×15 mL). The extract was dried over $MgSO_4$, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel with pentane–Et_2O (4:1 v/v). The alkylation products were identified by comparison with literature data: dimethyl (*E*)-(1,3-diphenylprop-2-en-1-yl)malonate (**17a**) [19], dimethyl (*E*)-(pent-3-en-2-yl)malonate (**17b**) [20], dimethyl (cyclohex-2-en-1-yl)malonate (**17c**) [21]. The ee values were measured by analytical chromatography; **17a**: HPLC, $t(R) = 9.75$ min, $t(S) = 13.40$ min; **17b**: GC, temperature 40 °C (1 min), then 40 → 95 °C (1 °C min^{-1}), then 95 °C (30 min), $t(S) = 71.2$ min, $t(R) = 71.7$ min; **17c**: GC, temperature 40 °C (1 min), then 40 → 130 °C (1 °C min^{-1}), then 0.1 °C min^{-1}, $t(S) = 97.6$ min, $t(R) = 98.0$ min.

2.3.2. General procedure for silver-catalyzed allylation of benzaldehyde

In a Schlenk tube wrapped with aluminium foil, a solution of AgF (9 mg, 71 μmol) and of ligand (43 μmol) in 4 mL CH_3OH was stirred for 20 min at RT. The temperature was lowered to −20 °C, and benzaldehyde (75 μL, 707 μmol) and allyltrimethoxysilane (120 μL, 707 μmol) were successively added with a syringe. The solution was stirred at −20 °C for 4 h, then the temperature was raised to room temperature. The mixture was stirred at this temperature for 20 h, and was then worked up following a reported procedure [22]. The crude 1-phenylbut-3-en-1-ol was purified by column chromatography on silica gel with pentane–Et_2O (4:1). The ee values were measured by GC: temperature 40 °C, 5 min, then 40 → 180 °C, 2 °C min^{-1}, $t(S) = 52.47$ min, $t(R) = 52.75$ min. The retention times had been determined with an authentic sample [91% ee, (*S*) configuration] synthesized following the silver-catalyzed procedure using (*S*)-Binap as chiral ligand [22].

2.3.3. General procedure for rhodium-catalyzed hydrosilylation of acetophenone

To a solution of **21** (9 mg, 10 μmol) in 1 mL $CDCl_3$ was added $AgBF_4$ (4 mg, 20 μmol). The mixture was stirred for 20 h at room temperature and filtered through Celite. After NMR analysis, the solvent was evaporated to dryness and the catalyst redissolved in 1 mL CH_2Cl_2. Alternatively, the catalyst solution was prepared by mixing together $[Rh(cyclooctadiene)Cl]_2$ (2.5 mg, 5 μmol) and ligand **15a** or **15b** (6.5 mg, 10 μmol) in 1 mL CH_2Cl_2 and stirring for 18 h at room temperature. To the catalyst solution was added acetophenone (117 μL, 1 mmol). The temperature was lowered to 0 °C and diphenylsilane (297 μL, 1.6 mmol) was slowly added. The solution was stirred for 1 h at 0 °C, and then for 30 h at RT. The conversion was monitored by TLC and ^1H NMR. The reaction was quenched by adding 1 mL CH_3OH. Hydrolysis of the silyl ether was performed by adding a methanolic solution of K_2CO_3 (1% w/w, 10 mL) and stirring for 4 h. The product was extracted with Et_2O (3×10 mL). The combined organic layers were washed with brine (3 mL), dried over anhydrous $MgSO_4$ and evaporated to dryness. The resulting oil was purified by column chromatography over silica gel eluting with *n*-hexane–Et_2O (95:5 → 80:20 v/v). The ee values were measured by GC: temperature 120 °C, $t(R) = 24.7$ min, $t(S) = 25.9$ min, using (*S*)-(−)-1-phenylethanol (Acros) as a reference.

2.4. X-ray crystallography

Single crystals suitable for X-ray diffraction analysis were obtained by cooling a saturated CH_3CN solution to −23 °C (***ent*-15b**), slow diffusion of pentane into a saturated solution in CH_2Cl_2 (**18**), slow diffusion of pentane into a saturated solution in toluene (**19**), or slow diffusion of *n*-hexane into a saturated CH_2Cl_2 solution (**21**). The X-ray data were collected on a KappaCCD diffractometer with Mo Kα graphite-monochromated radiation ($\lambda = 0.71073$ Å). Details of data collection parameters and refinements results are listed in Table 1. The structures were solved using direct methods. Hydrogen atoms were introduced as fixed contributors at calculated positions (C–H = 0.95 Å, B(H) = 1.3 Beqv). Final difference maps revealed no significant maxima. All calculations were done using the Nonius OpenMoleN package [23]. Neutral atom scattering factor coefficients and anomalous dispersion coefficients were taken from a standard source [24].

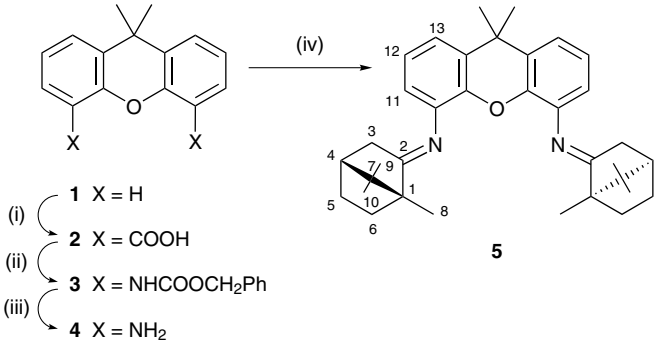
3. Results and discussion

3.1. Synthesis and analysis of the ligands

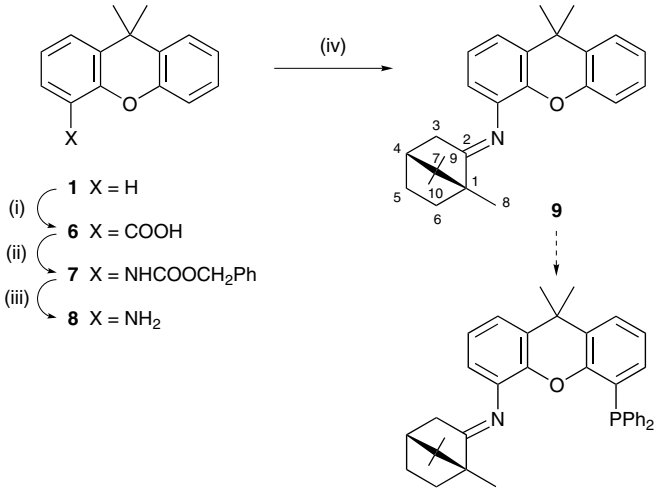
The diimine **5** was synthesized in four steps starting from 9,9-dimethyl-9*H*-xanthene **1** (Scheme 1). The first part of the synthetic scheme consisted in (i) double deprotonation of **1** in *ortho* position with an excess of *n*-butyllithium, followed by a nucleophilic attack of the dilithiated species onto CO_2; (ii) Curtius rearrangement using diphenylphosphorylazide; and (iii) basic hydrolysis leading to the diamine **4**. The final key step was the condensation of the amine functions of **4** with (1*R*)-camphor. It had been reported that the cheap and available titanium tetrachloride is an efficient catalyst for the synthesis of camphimines, when classical methods are unsuccessful because of steric hindrance on the ketone [25]. Indeed it has been used with success for the preparation of **5**, as well as that of other reported iminophosphines derived from camphor [7]. We optimized the condensation yield by employing an excess of camphor, and a large amount of $TiCl_4$ and triethylamine.



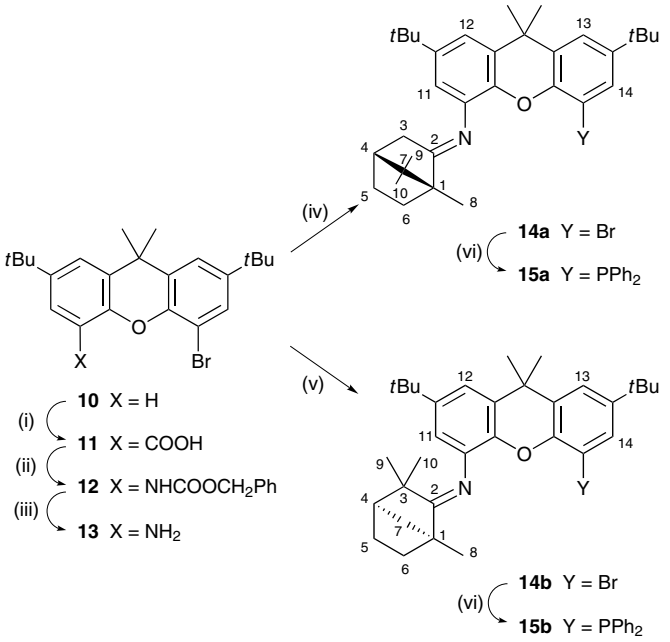
Scheme 1. Synthesis of the camphor-derived diimine ligand **5**. Reagents and conditions: (i) (a) *n*BuLi (2.5 equiv.), THF, −78 °C → RT; (b) CO_2, −78 °C → RT; (ii) diphenylphosphorylazide (2 equiv.), $PhCH_2OH$ (2 equiv.), NEt_3 (2 equiv.), $PhCH_3$, 100 °C; (iii) KOH, EtOH, reflux; (iv) (1*R*)-camphor (3 equiv.), $TiCl_4$ (5 equiv.), NEt_3 (20 equiv.), $PhCH_3$, reflux.

We have previously reported the X-ray structure of compound **5** [8]. The essential informations that it provided were (i) that the configuration of the imines is *E*, which is easily explained on steric grounds; and (ii) that the tricyclic 9,9-dimethylxanthene unit is planar in the unit cell. The question of whether 9,9-dimethylxanthene itself is also planar or not in solution has been addressed by Aizenshtat et al. [26]. They observed no influence of the temperature on its ^{1}H NMR spectrum; similarly, a variable-temperature analysis of **5** in the range −90 to 27 °C showed no major alteration of the NMR spectrum. The interpretation they proposed, i.e. that the tricycle is either planar or non-planar but rapidly inverting (butterfly motion) with a very low energy barrier, is suitable for **5**.

We expected to synthesize the iminophosphine ligand **15a** following a similar pathway, starting from the monocarboxylated derivative **6** (Scheme 2). The monofunctionalization of **1** proved to be a delicate step, because of the competitive formation of the *ortho*-dilithiated species that led to **2** upon reaction with CO_2. Indeed, using 1 equiv. *n*BuLi as a base gave **2** as the major product, whereas PhLi was found to be a better reagent, leading to **6** with an optimal yield (47%) when used in excess (2.5 equiv.). The three following steps were conducted in the same conditions as those depicted in Scheme 1, with better yields however, this being likely due to the conversion of only one chemical function instead of two (Curtius, **7**: 86%; basic hydrolysis, **8**: 86%; condensation with camphor, **9**: 66%). As mentioned previously [8], we were unsuccessful in transforming **9** into the iminophosphine shown Scheme 2: abstracting the



Scheme 2. Attempted synthesis of a camphor-derived iminophosphine from 9,9-dimethyl-9*H*-xanthene (**1**). (i) (a) PhLi (2.5 equiv.), THF, −78 °C → RT; (b) CO_2, −78 °C → RT; (ii) diphenylphosphorylazide (1 equiv.), $PhCH_2OH$ (1 equiv.), NEt_3 (1 equiv.), $PhCH_3$, 100 °C; (iii) KOH, EtOH, reflux; (iv) (1*R*)-camphor (1.5 equiv.), $TiCl_4$ (2.5 equiv.), NEt_3 (10 equiv.), $PhCH_3$, reflux.



Scheme 3. Synthesis of the iminophosphine ligands **15a** from 2,7-di-*tert*butyl-4,5-dibromo-9,9-dimethyl-9*H*-xanthene (**10**). Reagents and conditions: (i) (a) *n*BuLi (1 equiv.), THF, −78 °C; (b) CO_2, −78 °C → RT; (ii) diphenylphosphorylazide (1.1 equiv.), $PhCH_2OH$ (1.1 equiv.), NEt_3 (1.1 equiv.), $PhCH_3$, 100 °C; (iii) KOH, EtOH, reflux; (iv) (1*R*)-camphor (1.5 equiv.), $TiCl_4$ (2.5 equiv.), NEt_3 (10 equiv.), $PhCH_3$, reflux; (v) (1*S*)-fenchone (1.5 equiv.), $TiCl_4$ (7.5 equiv.), NEt_3 (30 equiv.), $PhCH_3$, reflux; (vi) (a) *n*BuLi (1.3 equiv.), THF, −78 °C; (b) PPh_2Cl (1.3 equiv.), −78 °C → RT.

proton in *ortho* position of xanthene necessitates to use *n*BuLi and the temperature to be raised to ca. 20 °C, these conditions leading to complete decomposition of **9**. Replacement of *n*BuLi by other deprotonating agents (*s*BuLi, *t*BuLi, PhLi) did not lead to any improvements.

Instead, the air-stable iminophosphine ligands **15a** and **15b** were synthesized in five steps starting from 2,7-di-*tert*-butyl-4,5-dibromo-9,9-dimethyl-9*H*-xanthene **10** (Scheme 3) [8]. The major change with regard to the synthetic schemes described above was that the organolithium reactive species involved in the first and in the last steps of the synthetic pathways were not obtained by abstraction of the *ortho* xanthene protons, but by bromide–lithium exchange that was run with *n*BuLi under milder conditions [27] (lower temperature). Several attempts to synthesize similar chiral iminophosphine derived from (+)-menthone, (+)-nopinone or (−)-myrtenal, using either $TiCl_4$ or other Lewis acids, were unsuccessful.

Our NMR data indicate that only the *E* stereoisomers of the camphor-derived imines **14a** and **15a** are present in solution, as in the X-ray structure of the diimine **5**. This statement is notably supported by the ^1H–^1H ROESY spectrum of **15a** recorded in CD_2Cl_2 at room temperature. It exhibits strong NOE cross-peaks between the signal of H_{11}, belonging to the xanthene backbone, and those of H_{3exo} and H_9 that belong to the chiral bicycle, whereas no NOE effect was observed between the signals of H_{11} and H_8.

By contrast, in fenchone or its derivatives, the steric hindrance generated by Me_8 on one side of the carbon-heteroatom double bond, and by Me_9 and Me_{10} on the other side, are of the same order of magnitude; for instance, the energy difference between the *E* and *Z* isomers of oximes derived from fenchone is less than 4 kJ mol^{-1} [28]. Indeed, both *E* and *Z* isomers of the fenchone-derived imines **14b** and **15b** are observed in solution, according to their NMR spectra recorded at room temperature. Several of the protons of each stereoisomer have accidentally identical chemical shifts, such as the aromatic protons H_{12}–H_{14}, and the *t*Bu protons. By contrast, the signal of H_{11} is split in two non-equivalent signals, a major, narrow doublet and a minor, broad signal which is shifted upfield by ca. 0.1 ppm (respectively at 6.62 and 6.55 ppm in compound **14b**, see Fig. 1). In general, the aliphatic protons belonging to the chiral bicycle exhibit large overlapping signals that cannot be easily distinguished, with the exception of the methyl signals of the major isomer. However, on the spectrum of **14b**, we could identify both H_8 signals as a singlet at 1.40 ppm (major isomer) and a broad, shielded singlet at 0.68 ppm. The $^{31}P\{^1H\}$ NMR spectrum of **15b** recorded at room temperature also displays a narrow major signal and a broad minor one (Fig. 2), corresponding also to both stereoisomers.

The analysis of **14b** by ^1H–^1H NOESY spectroscopy allows us to assign the signals of the major isomer to the *Z* configuration (drawn Scheme 3). Indeed, strong NOE cross-peaks are displayed Fig. 1 that indicate spatial proximity between H_{11} and the dimethylmethylene unit of the bicycle (H_9 and H_{10}). The (*Z*)/(*E*) ratio was calculated from the integration of the proton signals; it reached a value of 4 for compound **14b** and 9 for compound **15b**.

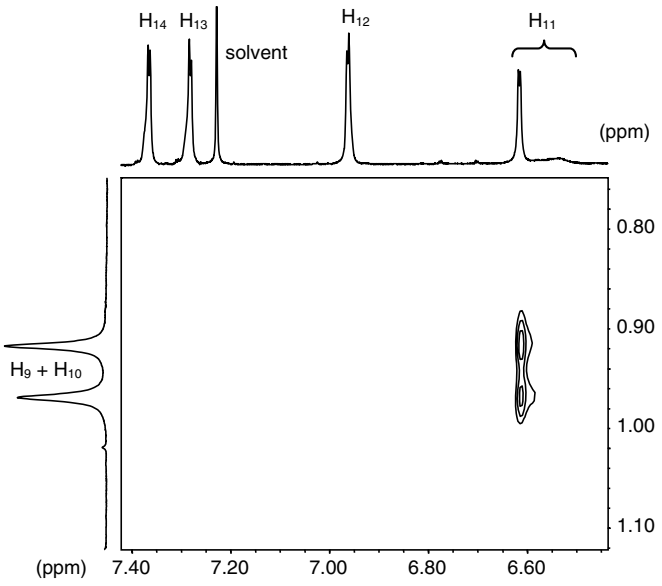


Fig. 1. Section of the ^{1}H–^{1}H NOESY spectrum of compound **14b** recorded in $CDCl_3$ at 298 K (500 MHz, $\tau_m = 450$ ms).

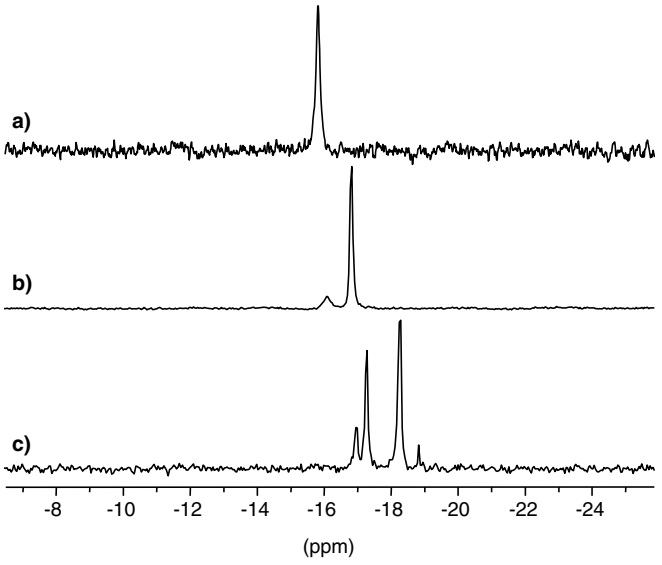

Fig. 2. $^{31}P\{^{1}H\}$ NMR spectra (121.5 MHz) of compound **15b** recorded (a) in CD_3CN at 333 K; (b) in $CDCl_3$ at 298 K; (c) in $CDCl_3$ at 243 K.

The broadness of some of the signals suggests that a chemical exchange process takes place in solution, and this assertion is supported by several elements. Various exchange cross-peaks between signals of the *Z* and *E* isomers are observed on the NOESY spectrum of **14b**, notably for H_8, H_9, H_{10}, H_{11} and for the xanthene methyl groups. Besides, the $^{31}P\{^{1}H\}$ NMR spectrum of **15b** in CD_3CN shows that the major and minor signals have coalesced into one singlet upon heating to 333 K (see Fig. 2; the spectra of **15b** at room temperature are practically identical in $CDCl_3$ and in CD_3CN). On the ^{1}H NMR spectrum recorded at 333 K in CD_3CN, the H_{11} signal also appears as a narrow, single averaged doublet. Those data can be interpreted as

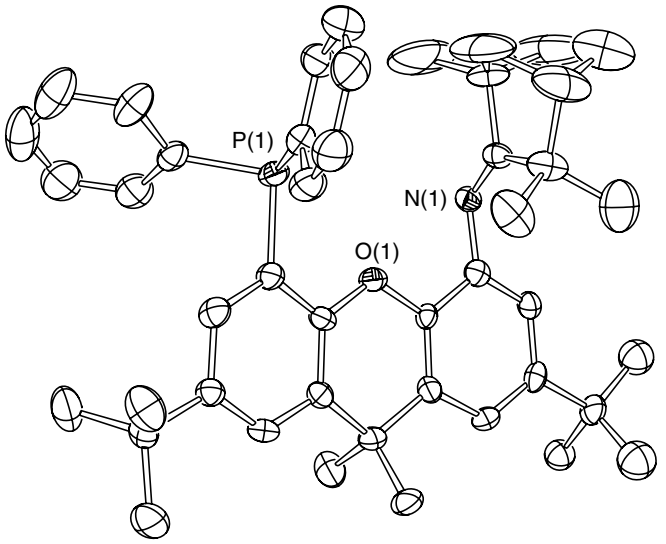

Fig. 3. ORTEP drawing of ligand ***ent*-15b** showing 50% probability thermal ellipsoids. Hydrogen atoms are omitted for clarity.

the result of a fast equilibrium between both isomers. Such isomerizations of imines have low energy barriers in comparison with alkenes [29]; this is in good agreement with our NMR observations at ambient and high temperature.

A decrease of the temperature also leads to important modifications of the phosphorus and proton NMR spectra of **15b**. Most of the ^{1}H NMR signals in CD_2Cl_2 broaden when the temperature is lowered, but even at 192 K those signals are still broad and overlapping. However, we can distinguish four large H_{11} signals of unequal intensity at 192 K between 6.3 and 6.6 ppm. Similarly, the $^{31}P\{^{1}H\}$ NMR spectrum recorded at 253 K in $CDCl_3$ exhibits four signals (Fig. 2), that result from a split of the two signals detected at room temperature. These observations can be interpreted as the result of a second, lower-energy fluxional process. It seems unlikely that it would be related to a butterfly motion of the xanthene backbone (supposing it would be non-planar in solution); if it were so, then we should probably observe similar modifications upon cooling of the NMR features of other compounds like **5**, and it is not the case (vide supra). We rather consider the low-temperature NMR spectra of **15b** as the result of a restricted rotation about the carbon-nitrogen single bond, because the xanthene backbone interacts sterically with Me_9 and Me_{10} in isomer *Z*, and with Me_8 in isomer *E*. Therefore, for each configuration of the imine, two atropoisomers are frozen at low temperature.

Single crystals of ***ent*-15b**, i.e. the enantiomer **15b** derived from (1*R*)-(−)-fenchone, were analyzed by X-ray diffraction. The quality of the structure was poor; however preliminary data X-ray were collected.[1] The solid state structure of ***ent*-15b** is represented Fig. 3.

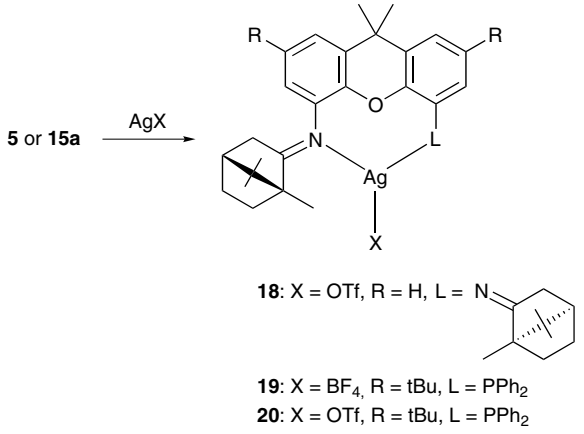
[1] Crystallographic data: crystal system triclinic, space group $P\bar{1}$, $V = 3811.6(4)$ Å^3, $a = 14.3556(7)$ Å, $b = 16.330(1)$ Å, $c = 16.9783(9)$ Å, $\alpha = 77.536(5)°$, $\beta = 81.951(5)°$, $\gamma = 80.606(5)°$, $Z = 4$.

3.2. Applications in metal coordination and metal-catalyzed organic reactions

In analogy with our previous studies with diphospholanes [5], we attempted to isolate palladium complexes from our ligands. [Pd(cyclooctadiene)Cl_2] did not react with ligand **5**, whereas a reaction with **15a** led to a mixture of several complexes that could not be separated. We also tried to isolate palladium π-allyl and π-cyclohexenyl complexes following the classical synthetic pathway that we had used with other xanthene-based ligands (withdrawal of chloro bridges of palladium π-allyl dimers with $AgBF_4$, followed by addition of ligand **5** or **15a**) [5]. Unfortunately, NMR monitoring of the coordination reactions revealed that all attempts had led to mixtures. Obviously the xanthene-based diimine and iminophosphine ligands do not fit the square-planar geometry of palladium (II), probably because of their very large bite angle; therefore they lead to mixtures of ill-defined complexes (e.g. coordination polymers) and to unsatisfactory catalytic results. Similar difficulties to generate bidentate Rh or Pt complexes with xanthene-derived P,N or N,N ligands were previously experienced by van Leeuwen et al. [30]. Hence, we chose other metal ions, whose electronic or geometric characteristics would be more adapted to our ligands.

Indeed, the synthesis of the silver (I) complexes [Ag(**5**)(OTf)] (**18**), [Ag(**15a**)(BF_4)] (**19**) and [Ag(**15a**)(OTf)] (**20**) was straighforward (Scheme 4). They were prepared by mixing a silver salt (AgX, X = OTf or BF_4) with 1 equiv. of the proper ligand in methylene chloride at room temperature, with good-to-excellent yields (**18**: 89%; **19**: 73%; **20**: 97%).

We undertook an X-ray diffraction analysis of complexes **18** and **19**; their ORTEP representations are shown on Figs. 4 and 5 respectively, and a selection of their bond distances and angles are given in Tables 2 and 3. For **18**, the unit cell contains one molecule, whereas for **19** two of them are present, which correspond to two conformers of the complex (vide infra). In all cases, the geometry of the complex is trigonal planar, which is not the most common



Scheme 4.

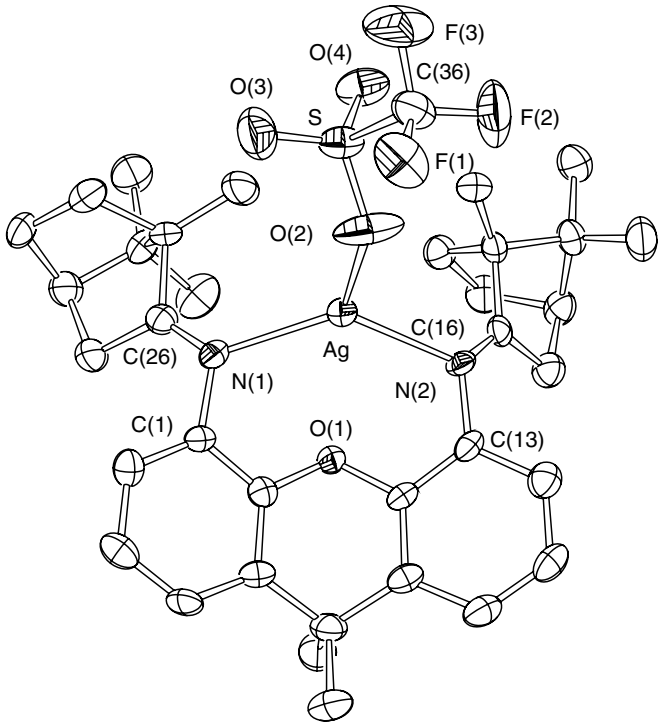


Fig. 4. ORTEP drawing of [Ag(**5**)(OTf)] (**18**) showing 50% probability thermal ellipsoids and the atom-numbering scheme. Hydrogen atoms and CH_2Cl_2 are omitted for clarity.

one among silver (I) complexes [31a]. The chiral ligands chelate the metal ion *via* their nitrogen or phosphorus donor atoms, but not *via* the xanthene oxygen atom; the third position is occupied by the triflate or tetrafluoroborate anion. As expected, the bite angle of the chiral ligand reaches higher values [**18**: 126.3(1)°; **19**: 123.6(1)° and 122.4(1)°] than in homologous diphospholane palladium complexes [5]. The xanthene backbone is tilted with regard to the coordination plane; as a consequence, in complex **18**, the diimine ligand **5** has lost its C_2 symmetry axis. The backbone is also folded along the O···CMe_2 axis, which results in a boat conformation of the central heterocycle. In all structures, the camphimines have retained their (*E*) configuration after coordination to the metal (assuming we do not consider Ag as a substituent for the determination of the absolute configuration). The Ag–N bond lengths (2.287(6)–2.351(4) Å) are within the lower range for silver complexes coordinated by Schiff bases [32], which suggests strong metal–ligand bonds.

In complex **18**, the small increase of the C=N bond lengths remains within the esd with regard to the free ligand (1.288(7) and 1.276(6) Å versus 1.258(4) and 1.268(4) Å). Similarly, coordination of an isothiazole to Ag^I only leads to a very slight increase of the nitrogen-carbon bond [33a]. In connection with this elongation, we observe a significant decrease of the C=N vibration wavenumber on the IR spectrum, from 1690 (**5**) to 1648 cm^{-1} (**18**). The Ag–O(2) bond length is also short (2.3415(4) Å) by comparison with other reported structures of η^1-OSO_2CF_3 silver (I) complexes (range 3.39–3.58 Å) [33].

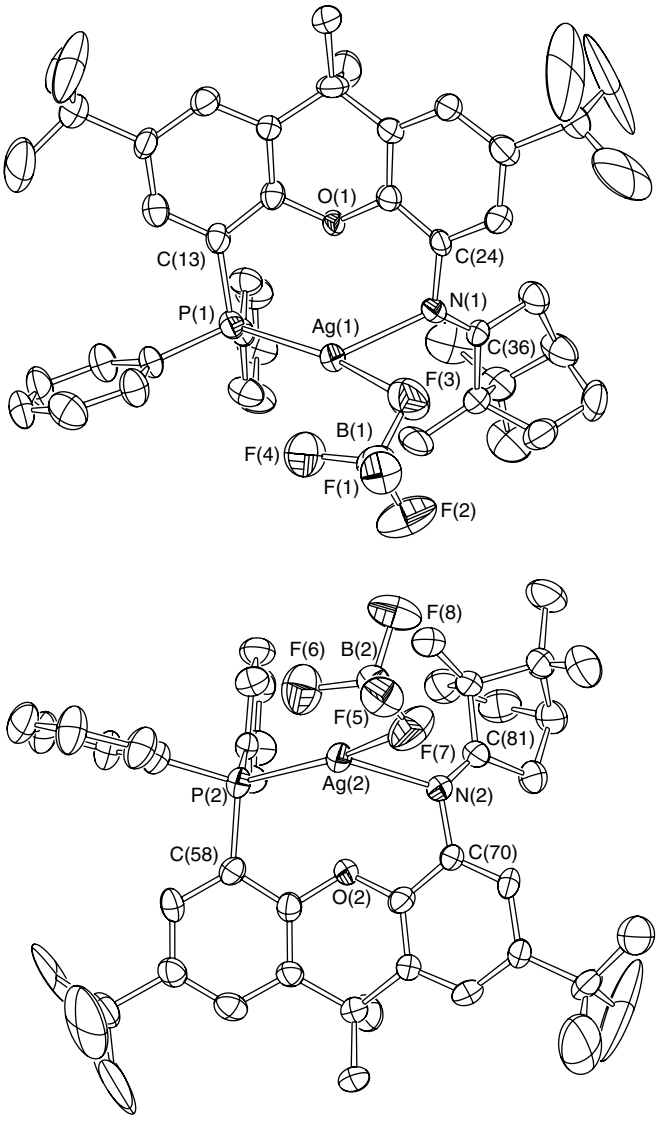

Fig. 5. ORTEP drawings of [Ag(**15a**)(BF_4)] (**19**) showing 50% probability thermal ellipsoids and the atom–numbering scheme. Both molecules present in the unit cell are represented.

Table 2
Selected bond lengths (Å) and angles (°) for [Ag(**5**)(OTf)] (**18**)

Ag–N(1)	2.310(4)	C(1)–N(1)	1.457(6)
Ag–N(2)	2.351(4)	C(26)–N(1)	1.288(7)

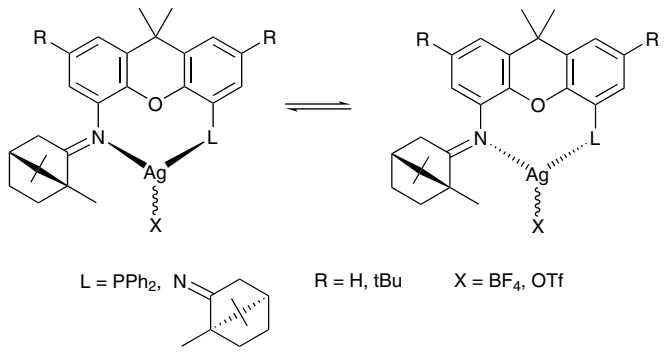
and the BF_4^- ligand are positioned *anti* with regard to the plane defined by Ag and C═N, whereas in the second one they are *syn* (Fig. 5). The trigonal planar geometry of the complexes is highly distorted, the η^1-BF_4 anion being located in pseudo-trans position with regard to the phosphorus donor atom. This tendency towards linearity is commonly observed in phosphine-coordinated silver complexes [34]. Comparison of the Ag–P (2.384(2) and 2.386(2) Å) and Ag–F bond distances (2.547(4) and 2.450(4) Å) with literature data [32,35] indicates that they are markedly short.

The ^1H and $^{13}C\{^1H\}$ NMR spectra of complex **18** in CD_2Cl_2 recorded at room temperature exhibit the narrow signals of an apparently C_2-symmetric diimine ligand. All the ^1H signals broaden upon cooling, and even at 178 K they are still broad and unresolved. This indicates that the complex is fluxional. A straightforward interpretation of this fluxionality is that the complex adopts in solution a conformation similar to the one observed in the solid state by crystallography, and that it undergoes a rapid conformational equilibrium (flip-flop interconversion [5], see Scheme 5). In this process, the metal-anion fragment rocks back and forth, which results here in apparent C_2-symmetry of the ligand. Besides, NOE cross-peaks detected on the ^1H–^1H ROESY spectrum between the aromatic H_{11} signal at 6.82 ppm, and the signals at 6.56 and 6.82 ppm of H_{3exo} and H_{3endo} that belong to the chiral bicycle, confirm the *E* configuration of the imines that was observed on the X-ray structure.



Scheme 5. Conformational equilibrium of the fluxional complexes **18**–**20**.

Analysis of the iminophosphine complexes **19** and **20** by variable-temperature ^{1}H NMR spectroscopy leads to similar conclusions. The room-temperature spectra exhibit narrow, averaged signals, and lowering the temperature leads to their broadening and splitting. In general the signals at low temperature are still broad and overlap; however, they could be identified for the H_{11} and H_{14} signals of **20** (Fig. 6), which are split into two signals of nearly equal intensity (integration ratio 53/47).

At 298 K, the $^{31}P\{^1H\}$ NMR signal of **19** in CD_2Cl_2 is a broad singlet at −5.8 ppm, whereas for **20** it appears as two doublets centered at −5.2 ppm, resulting from the coupling with both silver isotopes (^{107}Ag: $^1J_{PAg} = 642$ Hz; ^{109}Ag: $^1J_{PAg} = 741$ Hz). Cooling the solution of **19** gives rise to a broadening of the singlet and a splitting into two new singlets at 183 K (Fig. 7). Unlike other reported silver-phosphine complexes [36], no coupling with the silver nucleus appears at low temperature. Concerning **20**, its $^{31}P\{^1H\}$ NMR spectrum at 203 K consists of two pairs of doublets of equal intensity, one centered at −4.8 ppm ($^1J_{PAg} = 647$ and 747 Hz) and the other at −5.1 (2d, $^1J_{PAg} = 644$ and 744 Hz).

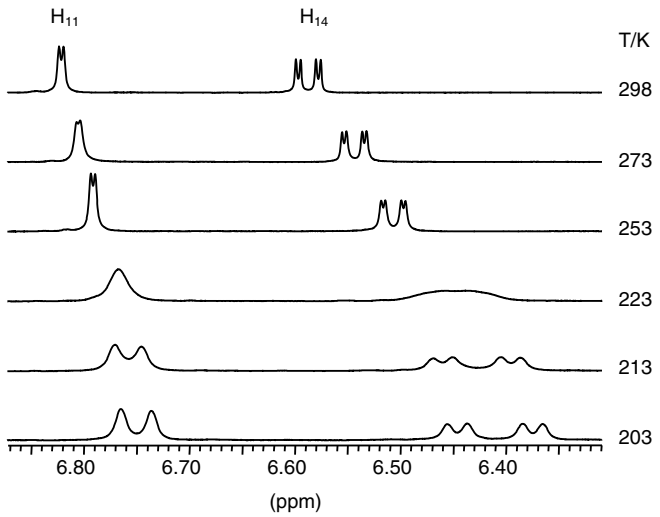


Fig. 6. Variable-temperature ^{1}H NMR spectra (500 MHz) of complex **20** in CD_2Cl_2: section of the aromatic region.

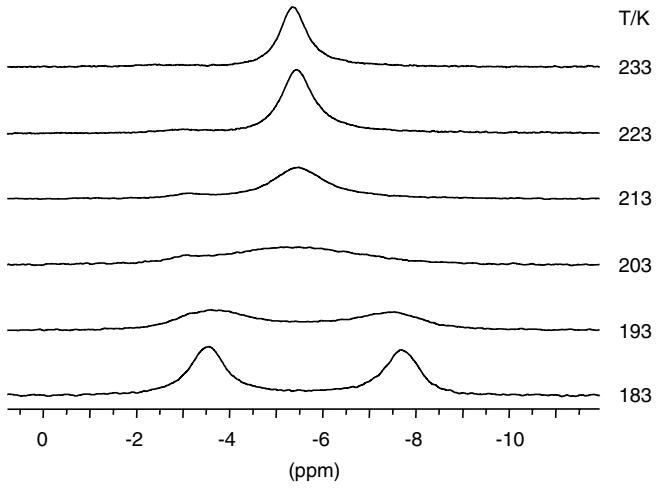

Fig. 7. Variable-temperature $^{31}P\{^1H\}$ NMR spectra (121.5 MHz) of complex **19** in CD_2Cl_2.

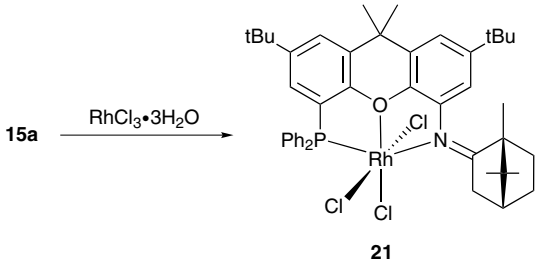
This fluxionality of complexes **19** and **20** is again reasonably explained by a conformational equilibrium between two conformers (Scheme 5). Each of the low-temperature signals of **19** or **20** shown in Figs. 6 and 7 corresponds to one of them, whereas at room temperature the equilibrium is fast and the signals are averaged. Indeed, in the solid state, both conformers of **19** were observed in the unit cell (vide supra). It is not surprising that they are in roughly equal proportion in solution, as long as in the X-ray structure there appeared to be no major differences in intramolecular steric interactions between the bicycle and the coordinating anion.

The rhodium (III) complex [Rh(**15a**)Cl_3] (**21**) was synthesized by refluxing $RhCl_3 \cdot 3H_2O$ with 1 equiv. of ligand **15a** in acetonitrile (Scheme 6). Partial hydrolysis of the imine function occurred upon coordination to Rh^{III}: some key NMR signals of an aminophosphine-coordinated complex were found on the ^{1}H NMR spectrum, such as an NH_2 signal that resonates at 6.36 ppm as a broad doublet ($^2J_{HRh} = 5$ Hz). This probably results from the enhancement of the electrophilicity of the coordinated imine; similarly, hydrolysis of an imine coordinated to Rh^I has been reported [37]. Nevertheless, complex **21** could be isolated in a pure form, although with moderate yield (52%), after purification by column chromatography over silica gel. By contrast, mixing ligand **5** with various rhodium sources ([Rh(cyclooctadiene)Cl]$_2$, $RhCl_3 \cdot 3H_2O$, $RhCl_3(CH_3CN)_3$) at room temperature did not lead to new Rh^I or Rh^{III} complexes.

Single crystals of complex **21** suitable for X-ray analysis were obtained. The X-ray structure is represented in Fig. 8, and a selection of its bond distances and angles is shown in Table 4. By contrast with the silver complexes, the chiral ligand is tridentate and meridional, coordinating the rhodium (III) cation by its oxygen atom in addition with its phosphorus and nitrogen donor atoms. Few examples of this coordination mode for xanthene-based or related ligands are reported in the literature [38]. The complex presents an expected distorted octahedral geometry [31b], with a large deviation from linearity of the N–Rh–P angle (163.16(8)°) due to the chelate effect. The fourth equatorial position and both axial positions are occupied by chloro ligands.



Scheme 6.

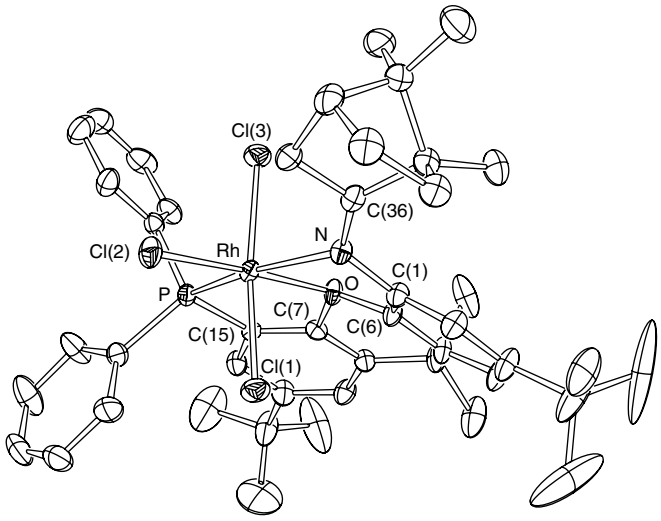


Fig. 8. ORTEP drawing of [Rh(**15a**)Cl_3] (**21**) showing 50% probability thermal ellipsoids and the atom-numbering scheme.

The X-ray structure reveals that the imine has isomerized upon coordination to Rh^{III}, the bridgehead methyl being now in *cis* position with regard to the aromatic xanthene cycle. We suppose that this isomerization is due to unfavorable steric interactions between the chloro ligand and this bridgehead methyl. However, steric repulsion also occurs between this methyl substituent and the backbone, so that the chiral bicycle lies above the equatorial plane and the backbone is bent below. As in the structures of the silver complexes, the xanthene tricycle is folded and the central cycle is in a boat conformation.

The oxygen atom is pyramidalized, as indicated by the sum of the Rh–O–C(6), Rh–O–C(7) and C(6)–O–C(7) bond angles (342°). The Rh–O bond length (2.128(2) Å) is very close to the value reported by van Leeuwen et al. for a Rh^{I}–xantphos complex (2.126(3) Å) [38b]. By comparison with tabulated data [32], the Rh–N bond length (2.178(3) Å) is rather long and the Rh–P (2.237(1) Å) and Rh–Cl (2.2922(9)–2.3322(9) Å) bond lengths are short; this is easily explained by the strong *trans* influence of $–PPh_2$ with regard to the other coordinating substituents [39]. The oxygen donor atom has a remarkably low *trans* influence, as indicated by the lower value of the Rh–Cl(2) bond distance (2.2922(9) Å) in comparison with the other rhodium–chloro distances. As in the silver complexes, the C=N bond undergoes an elongation upon coordination to rhodium (III) (1.298(5) Å versus 1.258(4) and 1.268(4) Å for the free ligand), in connection with a major shift ($-77\ cm^{-1}$) of the IR $\nu_{C=N}$ wavenumber.

It is remarkable that the ^1H NMR signals of the methyl groups borne by the xanthene tricycle in **21** have very different chemical shifts (1.43 and 1.90 ppm). This large $\Delta\delta$ value (0.47 ppm) is owed to the fact that one is frozen in axial position and the other in equatorial position. In comparison, $\Delta\delta$ is much lower in the fluxional silver complexes, where both positions exchange. The ^1H–^1H ROESY spectrum allows us to assign them, because the aromatic protons H_{12} and H_{13} display stronger NOE cross-peaks with the equatorial methyl that resonates at 1.90 ppm, than with the axial one that resonates at 1.43 ppm. The ROESY spectrum confirms also that the configuration of the imine is *Z* as in the X-ray structure: a close contact revealed by a NOE effect is found between H_8 (bridgehead methyl) and the aromatic proton H_{11}. In addition, no major modifications of the $^{31}P\{^1H\}$ or the ^1H NMR spectra were found when the solution was cooled to 213 K, indicating that complex **21** is not fluxional.

Catalytic tests were carried out either with preformed or with in situ-synthesized metal complexes. They consisted of asymmetric silver-catalyzed allylation of benzaldehyde (Scheme 7), rhodium-catalyzed hydrosilylation of acetophenone (Scheme 8), and palladium-catalyzed allylic alkylation (Scheme 9).

Yamamoto et al. have reported the catalytic addition of allyl silanes onto benzaldehyde [22]; their catalysts were prepared in situ by mixing silver fluoride with a chiral diphosphine. We first attempted to isolate a presumably active catalytic species from AgF and our ligand **15a**, and indeed the reaction run in methanol at room temperature yielded cleanly a new silver complex presumably formulated [AgF(**15a**)] which exhibited a $^{31}P\{^1H\}$ NMR signal centered at −3.8 ppm ($^1J_{PAg} = 641$ Hz and 737 Hz). Unfortunately, this species was far less stable than complexes **18**–**20**; it rapidly decomposed to a silver mirror even when the

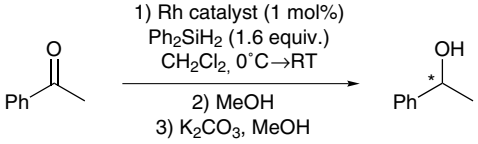
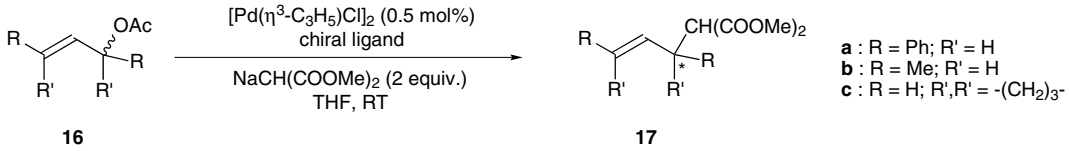


Scheme 8. Rhodium-catalyzed hydrosilylation of acetophenone.



Scheme 9. Palladium-catalyzed allylic alkylation.

solution was protected from air and light, and could not be analyzed further. Therefore, we ran the allylation reaction with catalysts prepared in situ following the procedure of Yamamoto et al., replacing the diphosphines with our ligands. The reaction was conducted in methanol at −20 °C for 4 h, then at room temperature for 20 h. The diimine ligand **5** led to a low ee (18%, *S* enantiomer) with a conversion of 68%, whereas the homoallylic alcohol was racemic with the iminophosphines **15a,b** (conversions 62% and 68%, respectively).

For complex **21**, we applied the hydrosilylation procedure described for trichloro rhodium precursors by Nishiyama et al., who first converted them into cationic species with silver tetrafluoroborate [40]. This step was slow (20 h reaction time); it led cleanly to a single species that exhibited a doublet at 38.3 ppm in $CDCl_3$ on a $^{31}P\{^1H\}$ NMR spectrum ($^1J_{PRh} = 95$ Hz). The catalytic reaction run afterwards was almost quantitative but sluggish (95% conversion within 30 h at RT), and very poorly selective (5% ee). We also prepared hydrosilylation rhodium catalysts in situ from **15a** or **15b** and from [Rh(cyclooctadiene)Cl]$_2$[41]; the 1-phenylethanol yield reached then 76% and 72% respectively after 30 h at RT, but the product was racemic.

Palladium-catalyzed allylic alkylations were conducted with catalysts synthesized in situ from $[PdCl(\eta^3\text{-}C_3H_5)]_2$ and a chiral ligand. With substrates **16a** and **16c**, no reaction was observed when we used the diimine ligand **5**. By contrast, the iminophosphine ligands **15a,b** led to good conversions and moderate enantioselectivities as shown in previously reported preliminary results (up to 36% ee) [8]. Catalytic tests run with substrate **16c** confirmed this trend (ligand **15a**: 77% yield, 16% ee (*S*); ligand **15b**: 27% yield, 19% ee (*R*) after 20 h reaction time). Burgess et al. have emphasized the importance of the ligand/palladium ratio in asymmetric catalysis with P,N ligands [42]. A L/Pd ratio superior to 1 can be detrimental to the ee, probably because of the presence of reactive intermediates where the Pd-allyl moiety is coordinated by the phosphorus atoms of two ligands with dangling nitrogen atoms. To avoid this drawback, we ran some catalytic tests on substrates **16a** and **16b** using a default of ligand **15b** (L/Pd = 0.8), but this did not alter the conversion or the ee. Addition of 1 mol% $AgBF_4$ as chloride scavenger was also attempted, in case the chloride ions present in solution would prevent the hemilabile imine functions to coordinate the metal. However, this led to a dramatic decrease of the reactivity without any improvement of the ee.

4. Conclusion

The chiral P,N and N,N ligands with a rigid xanthene backbone have been synthesized; they display a marked specificity towards the chelate coordination of some metal ions and not to others. Our ligands are not well adapted to the coordination of palladium (II), leading only to mixtures. In Pd-catalyzed allylic alkylation, the enantioselectivities obtained are unfortunately lower than those obtained with Duxantphos [4,5]. We note that in general the iminophosphine derived from the sterically encumbered fenchone is slightly more selective than the one derived from camphor. Incidentally, this steric congestion is also the cause of a dynamic coexistence in solution of both configurations of the free ligand **15b**.

By contrast with palladium (II), silver (I) is coordinated by our ligands in a N,N or P,N bidentate fashion with a wide bite angle; the ligands obviously fit the usual geometries of this metal ion. Those are to our knowledge the first reported silver complexes with wide bite-angle chelate ligands. A P,O,N tridentate coordination mode is observed in a rhodium (III) complex with the iminophosphine **15a**. This difference with the silver complexes is related to the octahedral geometry of the Rh complex, and also to the hard character (according to the Pearson theory) of Rh^{III} compared to Ag^I (d^6 versus d^{10} electronic configuration). Besides, a feature characteristic of the bidentate mode by opposition with the tridentate mode is the fluxionality of the complexes, the latter displaying more rigidity than the former. Although the catalytic performances of the Ag and Rh complexes were poor, the Ag complexes may find application in other processes involving similar chiral species, like the resolution of racemic alkenes [43].

addition to regulate smooth muscle relaxation, neurotransmission, and immune response alterations in NO production and metabolism. The NO participates in multiple pathological circumstances such as hypertension, cardiomyopathy, pulmonary disorders, arteriosclerosis and endotoxemia [4–6]. Three different heme-containing NO-synthases (NOS) encoded by different genes mediate a common reaction, which converts L-arginine and molecular oxygen to citrulline and NO. Nevertheless, while two NOS proteins are constitutive enzymes first characterized in neurons (nNOS or Type I NOS) and vascular endothelium (eNOS or Type III NOS) in macrophages and other cell types the NO generation occurs through a normally absent inducible (iNOS or Type II NOS) isoform [4–6]. Under normal physiological conditions the widely distributed nNOS and eNOS isoforms release low levels of NO required for neural transmission, regulation of the vascular tone and normal tissue homeostasis. In contrast, the expression of the iNOS enzyme in macrophages and other cell types exposed to bacterial lipopolysaccharide (LPS), interferon-γ (IFNγ) and other agents generates large and sustained quantities of NO, a hallmark of such critical situations as septic shock [7], renal damage, adult respiratory distress syndrome, diabetes, neurodegeneration and chronic inflammatory disease [5]. In this context while NO donor drugs are currently used to compensate the reduced L-arginine–NO pathway of patients suffering from hypotension and angina, two different therapeutical strategies have been used to counteract the damaging effect of NO overproduction [7,8]. While the first approach is based on aminoacid and non-amino acid NOS inhibitors with pharmacologically useful isoform selectivity (particularly for iNOS), the second alternative method involves the use of other molecules endowed with the ability to scavenge or remove the excess of NO generated during the septic shock or chronic inflammatory diseases [7,8]. Despite the fact that some selective NOS inhibitors are useful in animal models of septic shock, treatment with these agents is frequently accompanied by adverse side effects such as pulmonary hypertension and mortality [8]. Therefore the search for NO scavenger molecules with demonstrated pharmacological activity represents a true alternative to the use of NOS inhibitors in a broad spectrum of disease models [4–6].

Among these scavenger molecules are some metal-dithiocarbamates. Recent reviews have focused on novel aspects of the chemistry of dithiocarbamates including topics as diverse as electrochemistry, photoelectron spectroscopy and analytical applications (e.g., for the determination of metals in foodstuff, water and environmental samples) and highlighted the potential value of these compounds as useful NO trapping agents [9].

In this respect kinetic studies of the interaction of iron dithiocarbamate complexes with NO have been reported and a mechanism for the reaction proposed [10–13]. Nevertheless, the studies of thermodynamic equilibria between iron dithiocarbamate complexes with NO in aqueous solution are still scarce.

Reported data [9,14,15] have shown the stability of the bonds between copper(II) dithiocarbamates and nitric oxide. We have carried out for first time the thermodynamic studies in aqueous solution [16,17]. In a previous work [16], we have published the first report on the stable coordination in aqueous solution of NO to copper(II)–bis(dithiocarbamates). Coordinated NO in complexes such as $CuL_2(NO)$ and $CuL_2(NO)_2$ is not removed by purging the solution with Ar or air. Only when the solution containing both complexes is heated up to 333 K, the $CuL_2(NO)_2$ complex is dissociated to $CuL_2(NO)$, which is stable. NO coordinates instantaneously to copper(II) in $CuL_2(NO)$ and then a slow electron transfer of the unpaired electron of the NO reduces the Cu(II) to Cu(I). The thermodynamic stability of the complexes $CuL_2(NO)$ and $CuL_2(NO)_2$ (L = (dihydroxyethyl)dithiocarbamate), in aqueous solution was confirmed in the following work [17]. In this last work [17], the theoretical studies by means of SPARTAN'02 programs were carried out also to take into account the possibility of the direct attack of NO on S atom of the dithiocarbamate. However, the isomer with S–NO bond was found to be by 12.29 kcal/mol less exotermic than the Cu–NO bonded isomer in complex $CuL_2(NO)$ thus confirming the experimental data in the first work [16].

This paper deals with the thermodynamic study of copper(II) dithiocarbamates complexes with NO. These studies allowed us to determine the stability constants of the complex species presented in our system. From the speciation diagrams we can deduce that copper(II) dithiocarbamates is more effective to trap NO.

In this work, we have prepared new copper(II) dithiocarbamates: bis(4-piperidonedithiocarbamato)copper(II) $[Cu(Pdtc)_2]_2$ (**1**), bis(piperidinedithiocarbamato)copper(II) $[Cu(Ppdtc)_2]_2$ (**2**) and bis[(2-piperidinecarboxy)dithiocarbamato]copper(II) $Cu(Ppidtc)_2$ (**3**), which have been characterized. The X-ray structure of **1** and **2** were determined. Complexes **1** and **2** are not soluble in water so their interaction with nitric oxide has been carried by theoretical methods. Complex **3** is soluble in water, which allowed us to study their interaction with nitric oxide in aqueous solution and analyse the chemical speciation of the complexes formed.

Furthermore, in this work we have also studied spectrophotometrically the interaction of the previously prepared but not characterized, bis[*N*-(dithiocarboxy)sarcosine]-copper(II), $Cu(Sdtc)_2$ (**4**) [18] and bis[(dicarboxymethyl)dithiocarbamato]copper(II), $Cu(Idadtc)_2$ (**5**) [19] with nitric oxide in aqueous solution. The analyses of the experimental data were carried out by means of the LETAGROP-SPEFO and HYPERQUAD programs [20–22] and the stability constants of the complexes CuL_2NO and $CuL_2(NO)_2$ were determined.

In addition and based on the above-mentioned results, we have also carried out studies on the biological effects of these dithiocarbamates. We report herein the ability of **3**, **4**, **5** and the previously studied [17] bis[(dihydroxyethyl)dithiocarbamato]copper(II), $Cu(Deadtc)_2$ (**6**) to trap NO released in vitro either by the model donor agent

sodium nitroprusside (NPS) or produced by murine macrophages J774 cells activated by the simultaneous treatment with lipopolysaccharide(LPS) and interferon IFNγ.

2. Experimental

2.1. General remarks

Elemental analyses for carbon, hydrogen, nitrogen and sulfur were performed on Fisons EA 1108 CHNS-O instrument. The IR spectra were recorded in the 4000–450 cm^{-1} region using KBr Pellets on Bruker IF S55 spectrophotometer. The electronic spectra were recorded on a Cary 50 Varian and Shimadzu UV-2101PC spectrophotometer (spectrophotometric studies). The electrospray ionization (ESI) mass spectral measurement of the complex was carried out on a Micromass QUATTRO LC spectrometer. A solution of the complex (0.606 mM) was prepared in dimethylsulfoxide–acetonitrile 50:50 v/v. The FAB-MS were recorded using VGAutoSpec Micromass spectrophotometer.

Magnetic susceptibility measurements on polycrystalline samples were carried out in the temperature range 5–300 K with Quantum Design SQUID magnetometer. Diamagnetic corrections of the constituent atoms were estimated from Pascal's constants. Experimental susceptibilities were also corrected for the temperature-independent paramagnetism and the magnetization of the sample holder.

2.2. Materials

4-Piperidone monohydrate hydrochloride, piperidine, 2-piperidinecarboxylic acid, sarcosine, iminodiacetic acid, *N*,*N*-dihydroxyethylamine, carbon disulfide and copper metal were purchased from Sigma–Aldrich. Cupric acetate monohydrate was purchased from Fluka. Cupric chloride dehydrate, ammonia solution, nitric acid and sodium hydroxide were obtained from Merck. Potassium hydroxide was obtained from Panreac.

For the preparation of all aqueous solution bidistilled water was used.

Lipopolysaccharide (LPS) was obtained from Boehringer. The NO donnor sodium nitroprusside (NPS), Interferon γ (IFNγ), L-glutamine, sodium nitrite, sulfanilamide and *N*-(1-naphtyl)ethylendiamine were purchased from Sigma–Aldrich (Barcelona, Spain). Fetal bovine serum (FBS), Dulbeco's modified Eagle's medium (DMEM), antibiotics (penicillin, streptomycin), phosphate-buffered saline (PBS) and other tissue culture reagents were obtained from Gibco (Grand Island, NY).

2.3. Preparation of the bis(dithiocarbamato)copper(II) complexes

2.3.1. $[Cu(Pdtc)_2]_2$ (**1**)

An ammonia solution (20%, 4 ml, 0.04 mol) of 4-piperidone monohydrate hydrochloride (3 g, 0.02 mol) was prepared. To this solution cooled down to 0 °C, 3 ml (0.05 mol) of carbon disulfide dissolves in 10 ml of ethanol was added dropwise under stirring. Then, an aqueous solution of 7 g of $Cu(NO_3)_2 \cdot 3H_2O$ (0.03 mol) was added and a brown precipitate appeared. After collection by filtration, the precipitate was washed with water and dried by repeater washing with ether. The complex was crystallized by slow evaporation at room temperature from acetonitrile as solvent. Yield: 60%.

2.3.2. $[Cu(Ppdtc)_2]_2$ (**2**)

To an aqueous solution of piperidine (7.3 mmol), potassium hydroxide (0.8 g) and carbon disulfide (0.4 ml) were added. A yellow solution appeared to which an aqueous solution of cupric acetate monohydrate was added. The resulting brown precipitate was filtered off and washed with water and dried with ether. Single crystals were obtained by slow evaporation at room temperature using a mixture of ethanol and ether (50:50) as solvent. Yield: 54%.

2.3.3. $Cu(Ppidtc)_2$, probably $[Cu(Ppidtc)_2]_2$ (**3**)

In an aqueous solution of 6.46 g (0.05 mol) of 2-piperidinecarboxylic acid and 5.6 g (0.1 mol) of potassium hydroxide (1:2), 3 ml (0.05 mol) of CS_2 was added dropwise. To this solution an aqueous solution of 6.25 g (0.025 mol) of $CuSO_4 \cdot 5H_2O$ (2:1) was added dropwise and a brown precipitate appeared. The resulting brown precipitate was filtered off and washed with water and dried in a dessicator. Yield: 60%.

Elemental analyses for $[Cu(Pdtc)_2]_2$, $[Cu(Ppdtc)_2]$ and $Cu(Ppidtc)_2$ complexes are presented in Table 1.

The compound $Cu(Sdtc)_2$ was reported by Sakay [18], $Cu(Idadtc)_2$ by Hulanicki and Minczewska [19] and $Cu(Deadtc)_2$ was synthesized according to Radha et al. [23].

2.4. X-ray structure determination

X-ray data for single crystal of **1** and **2** complexes were collected with a Bruker Smart CCD and Bruker Nonius KAPPA CCD diffractometers, respectively, using monochromatic Mo Kα radiation ($\lambda = 0.71073$ Å). For **1**, the data were processed with SAINT [24] and corrected for absorption using SADABS [25]. The structure was solved by direct methods and refined by full-matrix least-squares techniques against F^2 using SHELXTL-NT 5.10 [26]. Data

Table 1
Elemental analyses of the copper(II) complexes

Complex	Elemental analysis: found (calculated %)			
	C	H	N	S
$[Cu(Pdtc)_2]_2$	34.99 (34.99)	3.89 (3.89)	6.80 (7.24)	31.11 (30.11)
$[Cu(ppdtc)_2]_2$	37.62 (37.55)	5.33 (5.22)	7.75 (7.30)	33.83 (33.37)
$Cu(Ppidtc)_2$	40.24 (40.88)	4.62 (4.90)	5.94 (5.75)	27.15 (27.37)

$[Cu(Pdtc)_2]_2 = C_{24}H_{32}O_4N_4S_8Cu_2$.
$[Cu(ppdtc)_2]_2 = C_{24}H_{40}N_4S_8Cu_2$.
$Cu(Ppidtc)_2 = C_{14}H_{20}O_4N_2S_4Cu$.

reduction and cell parameters refinements for **2** were carried out with the programs COLLECT [27] and DENSO [28]. The structure was solved using SIR-97 [29] and refined with SHELXL-97 [30] using full-matrix least-squares with anisotropic thermal parameters for all non-H atoms. Hydrogen atoms were placed at idealized positions. The PLATON [31] package of programs was used for absorption corrections (MultiScan option) and for molecular graphics generation. Both crystals **1** and **2** are laminar dark brown.

For **1** and **2**, a summary of the key crystallographic information is given in Table 2. For **1**, selected bond distances and angles are listed in Table 3. For **2**, due to the high value of *R*, the bond distances and angles are shown in Table S1.

2.5. Molecular modeling

In order to obtain the most stable conformation, calculations of molecular modeling for different compounds were carried out using molecular mechanics force field MM^+, which is an extension of MM2 developed by Allinger and Burker [32]. The geometries were optimized using the UFF force field [33]. Both MM^+ and UFF provide qualitative accounts of molecular geometry conformation and strain energy. The MM^+ calculations were made with the HYPERCHEM program [34] and conformations of all compounds were generated using molecular dynamics for each one with the following options: starting 0 K, simulation temperature 300 K, heat time 0.1 ps, run time 1 ps. These conformations are optimized using a Fletcher–Reeves (conjugate gradient) protocol with the standard tight converge criterion (RMS gradient = 0.01 kcal $Å^{-1}$ in vacuo).

Molecular mechanics calculations were made also using the UFF force field implemented in GAUSSIAN-03 W package [35].

Table 2
Summary of the crystallographic results for the complexes **1** and **2**

Complex	$[Cu(Pdtc)_2]_2$ (**1**)	$[Cu(ppdtc)_2]_2$ (**2**)
Empirical formula	$C_{24}H_{32}Cu_2N_4O_4S_8$	$C_{24}H_{40}Cu_2N_4S_8$

2.6. Equilibrium studies by electronic spectroscopy

The electronic spectra were recorded on a Shimadzu UV-2101 PC spectrophotometer.

A solution of copper(II) dithiocarbamate complexes and NO saturated aqueous solution were prepared by generating the gas from the reaction of metallic copper with 5 M nitric acid [2] using Schlenk techniques:

$$8HNO_3 + 3Cu \rightarrow 3Cu(NO_3)_2 + 4H_2O + 2NO$$

The gas was purified by passing it through five traps containing 50% NaOH solutions. The purified gas was bubbled in a Schlenk flask containing 20 ml of cold water. A thin Teflon hose was connected into the NO aqueous solution through the side arm of the flask. Teflon stopcocks were used to isolate each part of the Schlenk system when necessary. The whole system, tightly isolated from air, was previously deoxygenated by passing pure Ar for approximately 1 h [16,17]. Once the NO aqueous solution was obtained, the Schlenk flask was disconnected and then installed in a thermostated bath at 20 °C and the Teflon hose was connected to an Orion automatic microburet and purged with pure Ar. The concentrations of NO used for the calculations were made considering the reported concentration for saturated aqueous solution of NO (2.057 mM) at 20 °C [36]. The solutions of the bis(dithiocarbamato)copper(II) complexes **3**, **4** and **5**, respectively, were prepared in a 7.4 phosphate buffer solution (0.06 M). A number of 6–10 μl aliquots of the NO saturated aqueous solution thermostated at 20 °C were administered to the air tight flask containing the Cu(II) complex solution (**3**, **4** and **5**, respectively) using an Orion automatic microburette. The temperature of the cell was held at 20 °C with a Peltier controller system attached to the spectrophotometer. The same apparatus was used to administer the studied solution to the optical cell.

For a solution of $Cu(Ppidtc)_2$ (**3**) (48.5 μM) the electronic spectral data (19 absorbance values for each addition of NO solution within the range 420–476 nm at 20 °C) were processed using HYPERQUAD software [22].

For a solution of $Cu(Sdtc)_2$ (**4**) (76 μM) the electronic spectral data (16th absorbance values for each addition of NO solution within the range 348–436 nm at 20 °C) were processed using SPEFO version [20] of LETAGROP software [21].

For a solution of $Cu(Idadtc)_2$ (**5**) (52.1 μM) the electronic spectral data (33 absorbance values for each addition of NO solution within the range 348–436 nm at 20 °C) were processed using HYPERQUAD software [22].

2.7. Effect of dithiocarbamates on NO release in cell-free experiments

Stock solutions (30 mM) of copper(II) dithiocarbamates **3**, **4**, **5** and **6**, respectively, were prepared in PBS (pH 7.4) and sterilized using 0.2 μm Millipore filters. Sterile solutions of the NO donor SNP were prepared in DMEM (final concentration 30 mM) just before use. Aliquots of the SNP stock solution were dispensed into 96 well tissue culture plates containing either DMEM alone (to yield final concentrations of the donor in the range of 30–100 μM) or medium supplemented with copper(II) dithiocarbamates at final concentrations 10 μM. Culture plates containing the appropriate concentrations of SNP alone or in combination with copper(II) dithiocarbamates were placed (24 h) in a Haereus tissue culture incubator (5% CO_2 and 37 °C) and thereafter media were aspirated and used for nitrite determination (see below).

2.8. Effect of copper(II) dithiocarbamates on NO released by J774 murine macrophages stimulated with LPS and IFNγ

The J774 murine macrophage cell line characterized by the ability to express iNOS and generate large quantities of NO in response to the simultaneous stimulation with LPS and IFNγ [7,8,37,38] was donated by Dr. M. Fresno (CBM, Universidad Autónoma de Madrid). Cells were grown in 100 mm Falcon's tissue culture plates containing DMEM/10% fetal bovine serum (FBS) supplemented with L-glutamine (2 mM) and antibiotics (100 U/ml penicillin and 100 μg/ml streptomycin) and maintained at 37 °C in a 5% CO_2 incubator (Haerus). Cells from confluent cultures (65–75%) were detached form the plates, resuspended in serum depleted medium (DMEM/2% FBS) and aliquots (200 μl) containing equal number of cells ($\sim 25 \times 10^4$ cells) inoculated into 96-well tissue culture plates (Falcon). Cells were left untreated (controls) or stimulated (24 h) with a combination of LPS and IFNγ (final concentration 1 μg/ml and 100 U/ml, respectively) alone or in the presence of the indicated concentrations of the different copper(II) dithiocarbamates. After this period of time media were aspirated and used to measure total nitrite levels (see below) and the lack of cell toxicity determined by previously described methods (Mosman) [39].

2.9. Nitrite determinations

The ability of copper(II) dithiocarbamates to trap NO generated by chemical donors (NPS) or cytomix (LPS + IFNγ)-stimulated macrophages was evaluated by changes in the concentration of stable NO metabolites (nitrite + nitrate) in culture medium as determined by the Griess reaction [40]. Suitable aliquots (100 μl) of culture medium were mixed with an equal volume of Griess reagent (a 1:1 mixture of 1% sulfanilamide and 0.1% naphthylethylenediamine dihydrochloride in 2.5% H_3PO_4), incubated for 10 min at room temperature [40] and concentrations were determined at 550 nm in an EL-312 Microplate reader (Biotek Instruments, Winooski, VT). Sterile-filtered standard solutions of sodium nitrite (0–50 μM) were freshly prepared in culture medium and incubated in parallel with each experiment and comparable results were obtained using a nitrate reductase assay kit provided by Alexis Biochemicals (Laufelfingen, Switzerland).

2.10. Statistical methods

Results for nitrite concentrations are expressed as the means ± SEM from triplicate or quadruplicate cultures, and each experiment was repeated at least three times. The minimal effective doses and ED50 were determined with a software program based on a four-parameter logistic equation as previously described [40]. Statistical differences were examined using ANOVA and, as indicated, Student's *t*-test for comparison of the means. $P < 0.5$ was considered significant.

3. Results and discussion

3.1. Description of the structures of the complexes *1* and *2*

The crystallographic data of the complexes **1** and **2** are given in Table 2.

The structure of **1** is built up by centre-symmetric dimeric entities. Fig. 1 shows a perspective view of the dimeric unit showing the atomic numbering scheme of the complex.

For this compound, the distances Cu–S and Cu–S′ are 2.373 Å and 2.704 Å, respectively, in good agreement with the values found for the dimeric dithiocarbamates: $[CuS_2CN(Et)_2]_2$ [41] (Cu–S and Cu–S′: 2.327 Å and 2.844 Å, respectively) and $[CuS_2CN(CH_2Et)_2]_2$ [41] (Cu–S and Cu–S′: 2.322 Å and 2.740 Å, respectively).

The coordination sphere of copper(II) ions is described as a distorted square-pyramid. The basal coordination positions are occupied by four sulfur atoms belonging to two dithiocarbamate ligands.

Each bridging sulfur atom simultaneously occupies an equatorial coordination site on one copper(II) ion and an apical site on the other copper(II).

The axial Cu–S bond distance (2.7036(10) Å) is longer than the equatorial Cu–S ones. The Cu–S(2) bond length in [(2.373(10) Å] are longer in the Cu–S equatorial bond lengths because S(2) is a bridging atom. The bond angles S(2)–Cu(1)–S(4), S(3)–Cu(1)–S(5), 76.26(2)°, 76.52(2)°, respectively, are nearly the same.

The bridging network S(2)–Cu(1)–S(2)a is strictly planar owing to the inversion centre. These results are in good agreement with earlier determinations [41–43].

The overall geometry of the complex **2** (Fig. 2) is similar to complex **1**. However, because of the high values of *R* ($R = 0.1012$), the bond parameters (Table S1) are not accurate and should be treated with caution.

3.2. IR spectra

The most significant bands for the **1**, **2** and **3** complexes are given in Table 4. The bands in the range 1480–1510 cm^{-1} are attributed to the ν(C–N) (partial double bond) stretching vibration [17,41,44]. This position corresponds to a partial double bond character, and is recorded in the range previously reported for similar compounds [45–47]. The band in the range 940–1050 cm^{-1}, belonging to the ν(S–C) (partial double bond) stretching is considered indicative of dithiocarbamate acting as a bidentate ligand [44,48]. The band at 1588 cm^{-1} corresponds to antisymmetric carboxyl stretching frequencies of the non-complexed ionic COO^- in the ligand of the complex **3** [49]. The band at 1716 cm^{-1} in the complex **1** is assigned to

C=O stretching vibration of the no complexed ketonic group $–CH_2–CO–CH_2–$ of the ligand [47,50].

3.3. Electronic spectra

The most significant bands of the copper(II) complexes **1** and **3** are presented in Table 5. For complex **2** in DMSO, the values are similar to complex **1**. The most intense band at 273 nm is probably a band of the ligand; the band at 438 nm is a $\sigma(S) \rightarrow Cu(II)$ ligand to metal charge transfer in a planar CuS_4 (CuS_5 in pyc geometry) chromophore, and the band at 630–650 nm (shoulder) is a d–d band [51–54], in agreement with a planar CuS_4 geometry (monomers) or pyc CuS_5 geometry (dimers).

3.4. Magnetic properties

The magnetic behaviour of complexes **1** and **3** is shown in Figs. S1 and S2 by means of a $\chi_M T$ versus T plot (χ_M being the molar magnetic susceptibility). At room temperature both compounds give a value for $\chi_M T$ that is slightly lower then expected for two non-interacting Cu(II) ions (0.9 $cm^3\,mol^{-1}\,K$), and upon cooling $\chi_M T$ continuously decreases also for both compounds. This behaviour is indicative of the occurrence of weak antiferromagnetic interactions in **1** and **3**. The pattern of the curve for both compounds is very similar, thus although the structure of **3** is not known in solid state it must be very similar to that of **1**. Other polymerizations also are possible: $[Cu(Et_2dtc)]_4$ is tetramer [55]. The structure of **1**, Fig. 1, consist of dinuclear copper(II) entities bridged by μ-S atoms. The antiferromagnetic coupling for these complexes is due to spin cancellation through the S bridge atoms [56]. However, we have not been able to fit the magnetic data to the numerical expression for copper(II) dinuclear complexes. May be some paramagnetic impurities or intermolecular interactions are present in the polycrystalline samples which were measured, that make the data to deviate from the ideal model.

Table 5
Electronic data of the complexes **1** and **3**

Complex	λ/nm ($\varepsilon/M^{-1}\,cm^{-1}$)			Solvent
1	273 (50.000)	438 (24.450)	650 (2.400)	DMSO
3	273 (505)	433 (184)	630 (13.4)	water

3.5. Mass spectrometry

Complex **1** was further characterized by electrospray ionization (ESI) mass spectrometry. The ESI spectrum of the monomeric complex $[Cu(Pdtc)_2]_2$ obtained at $\Delta V = 20$ V is presented in Fig. 3. The main peak observed at m/z 411.5 is corresponding to $[Cu(Pdtc)_2]^+$. The presence of three ions is not in good agreement with the isotropic distribution of the Cu: Cu^{63} (69.2%); Cu^{65} (30.8%) [57]. Probably the other two peaks can be assigned to protonated ions, Table 6.

This result implies that the dimer in dimethylsulfoxide–acetonitrile solution is broken showing only the monomeric complex.

3.6. Molecular modeling

In Ref. [17], we have studied the interaction between NO and the bis[1-(2-hydroxyethyl)piperazinedithiocarbamato]-copper(II) by means of molecular mechanics and semi-empirical methods.

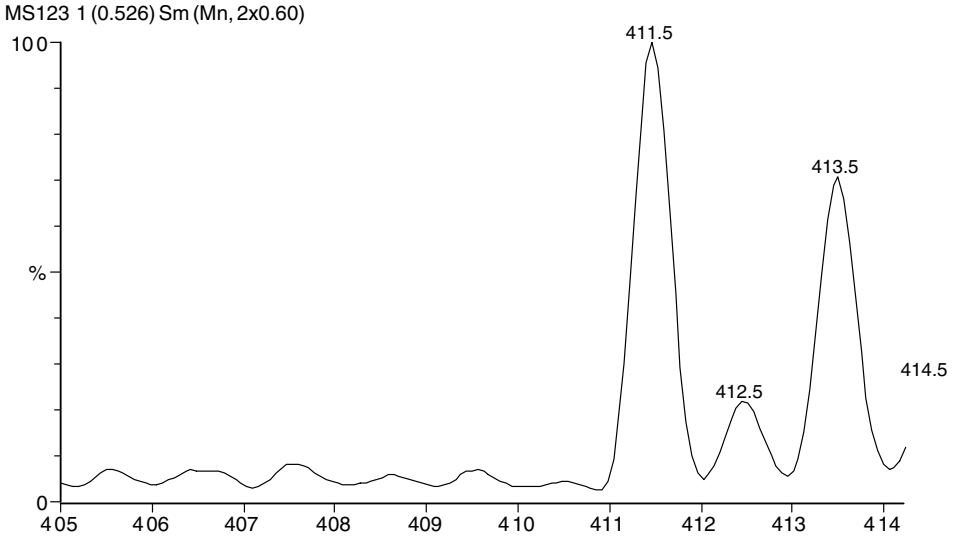

Fig. 3. ESI mass spectra of the monomeric complex of $[Cu(Pdtc)_2]_2$ obtained in 50:50 acetonitrile–dimethylsulfoxide; $\Delta V = 20$ V.

Table 6
Principal ions in the ESI spectra of the monomeric complex of $[Cu(Pdtc)_2]_2$

Complex	*m*/*z*	Relative abundance (%)	Assignment
$Cu(Pdtc)_2$	411.5	100	$[Cu(Pdtc)_2]^+$
	412.5	20	$[Cu(Pdtc)_2 + H]^{2+}$
	413.5	70	$[Cu(Pdtc)_2 + 2H]^{3+}$

Analogously, in this work we have studied in gaseous phase the interaction between NO and the monomeric complex $Cu(Pdtc)_2$, **M**, and the dimeric complex $[Cu(Pdtc)_2]_2$, **D**. Figs. 4 and 5 show the most stable confor-

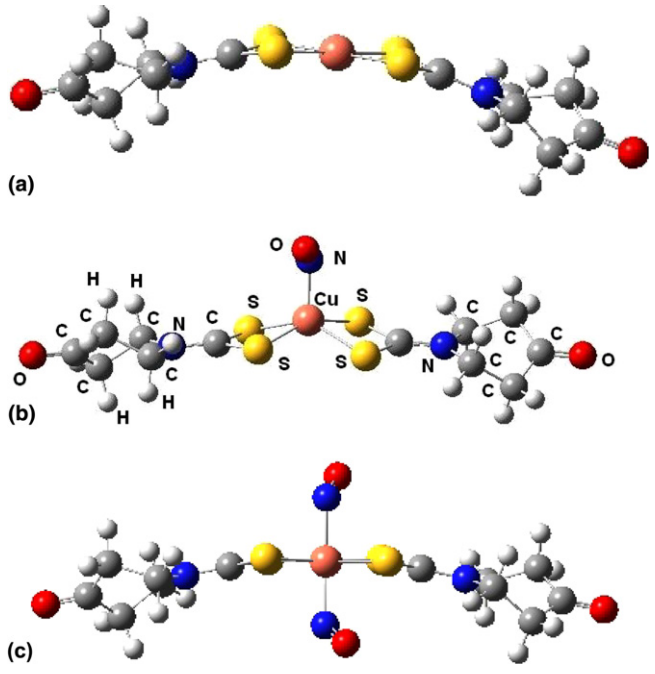

Fig. 4. Most stable conformations in gaseous phase for: (a) monomer **M**; (b) **M**(NO); and (c) **M**$(NO)_2$.

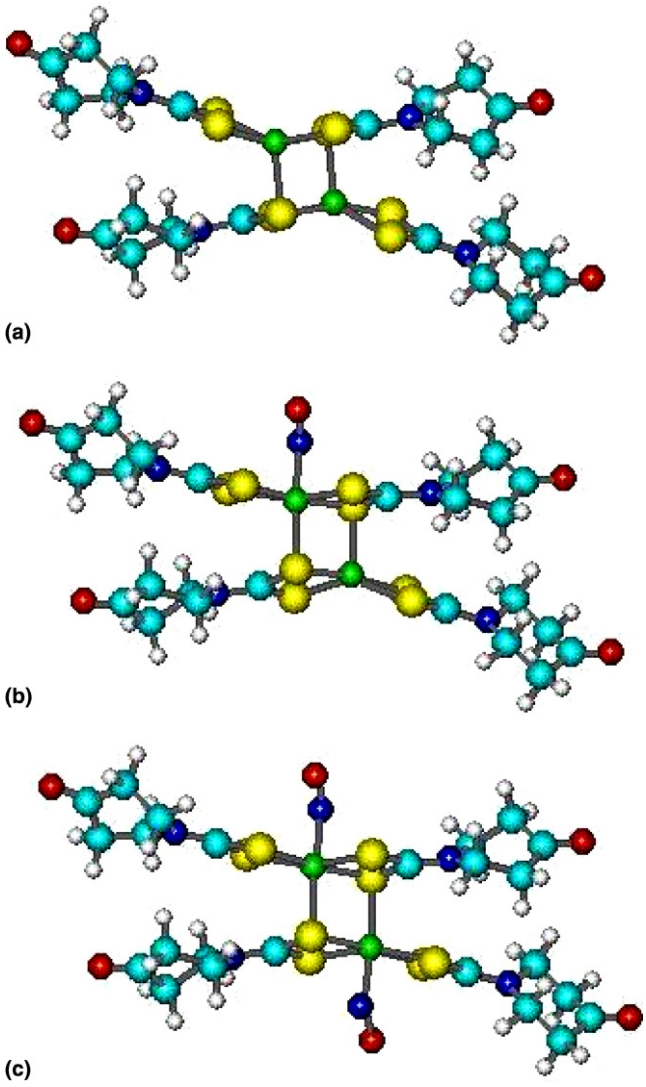

Fig. 5. Most stable conformations in gaseous phase for: (a) dimeric **D**; (b) **D**(NO); and (c) **D**$(NO)_2$.

mations in gaseous phase for the compounds **M** (4a), **M**(NO) (4b), **M**$(NO)_2$ (4c), **D** (5a), **D**(NO) (5b) and **D**$(NO)_2$ (5c), respectively, obtained by theoretical calculations. The most symmetrical conformations correspond to **M**$(NO)_2$ and **D**$(NO)_2$. It was found that in the dithiocarbamate complexes, the $[CuS_4]$ groups become more planar and they are coordinated to two molecules of nitric oxide.

A possibility of direct NO attack on S atom of the dithiocarbamate was also taken into account. For the monomeric complex **M**, the isomer with S–NO bond was found to be 12.29 kcal/mol less exothermic than the Cu–NO bond isomer M(NO). Also the complexes with S–NO bond are more distorted than the complexes containing Cu–NO bond. It was found in all cases, both for monomer and dimer that the bond angle Cu–NO is 120°, which indirectly shows that the charge transfer is metal to ligand which agree well with the previous experimental information [16].

3.7. Solution studies

A $Cu(Sdtc)_2$ (**4**) solution presents a maximum at 432 nm ($\log\varepsilon = 3.92$). With addition of a NO solution the maximum decreased in intensity and blue-shifted to 425 nm. At the same time a new band appears at 356 nm. Both bands correspond to LMCT transitions between the copper ion and dithiocarbamate and NO, respectively [16,51]. An isosbestic point is observed at 388 nm (Fig. 6), indicating that the reversible process is taking place. The blue shift variation of the absorbance from 432 nm (ratio Cu:NO = 1:0) to 425 nm (ratio Cu:NO = 1:2, curve 3, Fig. 6) and the red shift of the band at 356–360 nm (curve 3, Fig. 6) give two inflection points at 1:1 and 1:2 Cu:NO molar ratios, 388 and 390 nm, with formation of the complexes $Cu(Sdtc)_2(NO)$ and $Cu(Sdtc)_2(NO)_2$, respectively (Fig. 7). The experimental data were analysed by means of the SPEFO version [20] of the LETAGROP program [21]. The calculations indicate that **4** reacts stepwise with two moles of NO (Scheme 1, Table 7). The values of the stability constants and the species distribution diagram (Fig. 7) indicate that the complex corresponding to equilibrium (1) is thermodynamically more stable than the complex corresponding to equilibrium (2). The diagram also indicates that the complex 1:2 is formed from complex 1:1 (Fig. 7, Scheme 1 and Table 7). With excess of nitric oxide the complex $Cu(Sdtc)_2(NO)_2$ forms quantitatively (Fig. 7). The dithiocarbamate complex $Cu(Sdtc)_2$ is a versatile agent to capture the NO under physiological conditions (pH 7.4).

A $Cu(Ppidtc)_2$ (**3**) solution presents a maximum at 432 nm ($\log\varepsilon = 4.01$). With addition of a NO solution the maximum decreased in intensity and it is blue-shifted. At the same time a new band appears at 356 nm. An isosbestic point is observed at ≈382 nm, indicating that a reversible process is taking place. The experimental data were analysed using the HYPERQUAD program [22]. The stability constants for $Cu(Ppidtc)_2NO$ and $Cu(Ppidtc)_2(NO)_2$ complexes

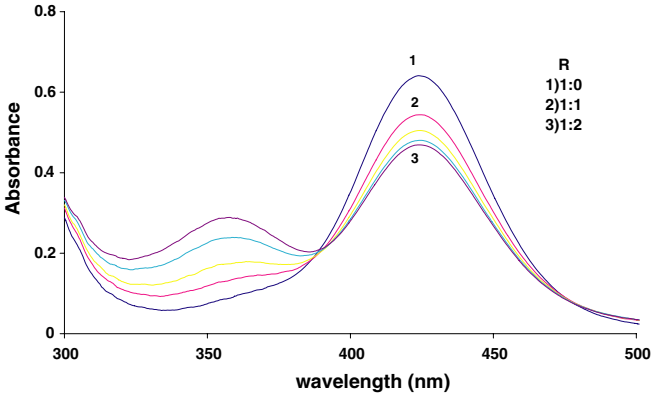

Fig. 6. UV spectra at 293 K for $Cu(Sdtc)_2$ (76 μM) with different additions of NO saturated aqueous solution: (1) $Cu(Sdtc)_2$:NO = 1:0. (2) $Cu(Sdtc)_2$:NO = 1:1. (3) $Cu(Sdtc)_2$:NO = 1:2.

$$Cu(Dtc)_2 + NO \overset{K_1}{\rightleftharpoons} Cu(Dtc)_2NO \quad A$$

$$Cu(Dtc)_2NO + NO \overset{K_2}{\rightleftharpoons} Cu(Dtc)_2(NO)_2 \quad B$$

Scheme 1. A: equilibrium (1); B: equilibrium (2).

Table 7
Stability constants of the $Cu(Dtc)_2NO$ and $Cu(Dtc)_2(NO)_2$ complexes

Complex	$\log K_1$	$\log K_2$	Reference
$Cu(Ppidtc)_2$	3.16(1)	2.61(1)	this work
$Cu(Sdtc)_2$	4.7(5)	3.9(6)	this work
$Cu(Idadtc)_2$	8.5(1)	2.4(1)	this work
$Cu(Deadtc)_2$	10.3(1)	2.2(1)	[17]

are given in Table 7. That values for $\log K_1$ indicate that the complex $Cu(Ppidtc)_2NO_2$ is weaker than the $Cu(Sdtc)_2NO$ complex.

Complex **5** presents a maximum at 432 nm ($\log\varepsilon = 4.09$) which decreased in intensity with the addition of a NO solution and is blue-shifted (curve 3, Fig. 8). This decrease was accompanied by the simultaneous appearance of a new

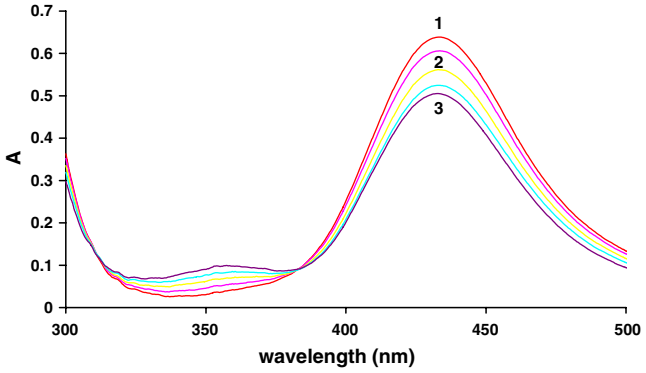

Fig. 8. Experimental UV–Vis spectrophotometric data for the Cu(Idadtc)$_2$/NO system at pH 7.4 and 20 °C. Concentration of the Cu(Idadtc)$_2$ complex (5.21 μM) and different ratios R = Cu(Idadtc)$_2$:NO (1), Cu(Idadtc)$_2$:NO 1:0; (2), Cu(Idadtc)$_2$:NO 1:1 (3); and Cu(Idadtc)$_2$:NO 1:2.

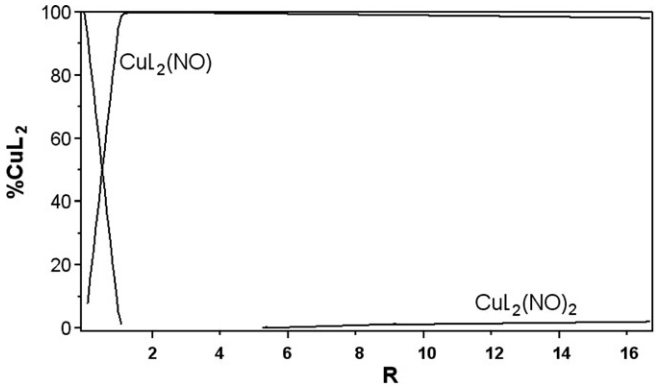

Fig. 9. Species distribution diagram for Cu(Idadtc)$_2$–NO system at pH 7.4 and 20 °C. Concentration of the Cu(Idadtc)$_2$ complex: 5.21 μM.

band at 352 nm which corresponds to a charge transfer transition between the copper ion of the dithiocarbamate complex and NO [16]. An isosbestic point is observed at ≈383 nm, batochromically shifted, by successive additions of NO to the Cu(Idadtc)$_2$ solution indicating that reversible processes are taking place. The experimental data analysed using the HYPERQUAD program [22] indicated that **5** reacts stepwise with two moles of NO (Scheme 1 and Table 7). Calculation of the stability constants for Cu(Idadtc)$_2$NO and Cu(Idadtc)$_2$(NO)$_2$ complexes allowed to obtain the values for logK_1, complex 1:1, equilibrium A in Scheme

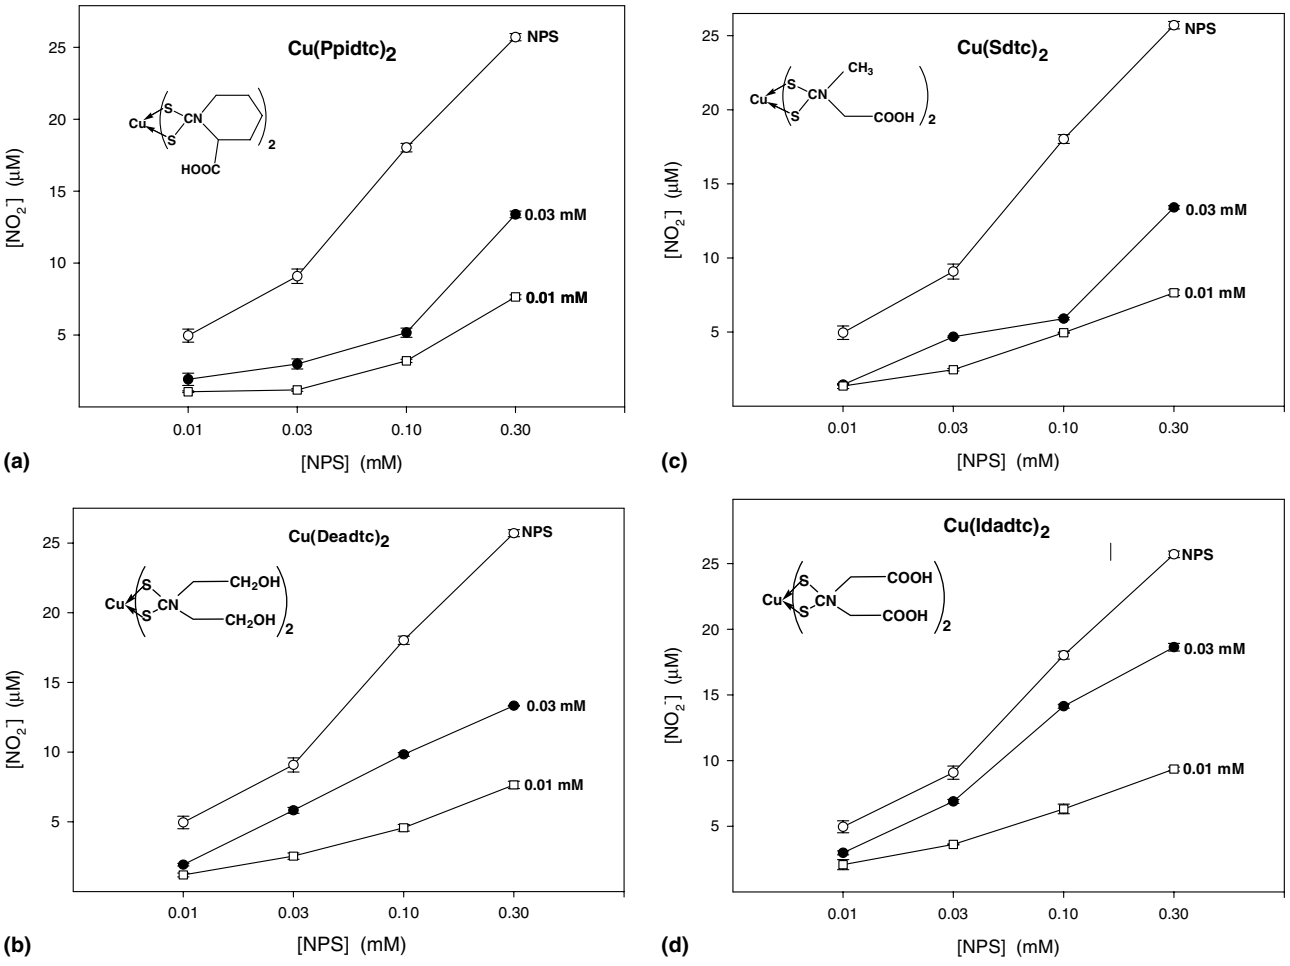

Fig. 10. Effect of copper(II) dithiocarbamates (at final concentrations of 10 and 30 μM) on nitrite levels present in culture media containing the NO-donnor NPS (final concentration). Each data point represents nitrite concentrations (means ± SEM) three different experiments using triplicate or quadruplicate wells per data point.

1, and $\log K_2$, complex 1:2, equilibrium B in Scheme 1 indicating that the complex 1:1 is much stronger than the complex 1:2. These data, together with the species distribution diagram (Fig. 9) indicate a stepwise process in which formation of the 1:2 complex requires that the complex 1:1 is practically formed in accordance with previous studies of our laboratory [16,17]. Similar behaviour with NO has the $Cu(Deadtc)_2$ complexes, with a higher value for $\log K_1$ [17] (Table 7).

3.8. The copper(II) dithiocarbamates reduce nitrite concentrations derived from the nitric oxide producing agent NPS

Since the complexes **3**, **4**, **5** (this work) and **6** [17] trap NO in aqueous solution, in the next set of experiments we explored their ability to trap NO generated by increasing concentrations (10–300 μM) of the specific NO-donor compound NPS (Fig. 10). Total nitrite levels were extremely low in wells containing DMEM alone, augmented in a concentration-dependent manner in cultures supplemented with NPS and significantly decreased in the presence of two different doses (10 μM or 30 μM) of the different copper(II) dithiocarbamates.

3.9. Effect of the copper(II) dithiocarbamates on the concentration of NO generated by cultured macrophages stimulated with LPS and IFNγ

Since the above-mentioned data demonstrate that copper(II) dithiocarbamate derivatives trap NO under cell-free conditions we performed additional experiments to test whether a similar activity was exerted in cytomix (LPS + IFNγ)-stimulated murine macrophages (Fig. 11). As expected nitrite concentrations were negligible in unstimulated cells (see control in Fig. 11) or cultures exposed only to the highest dose (300 μM) of copper(II) dithiocarbamate derivatives. In contrast, activation of

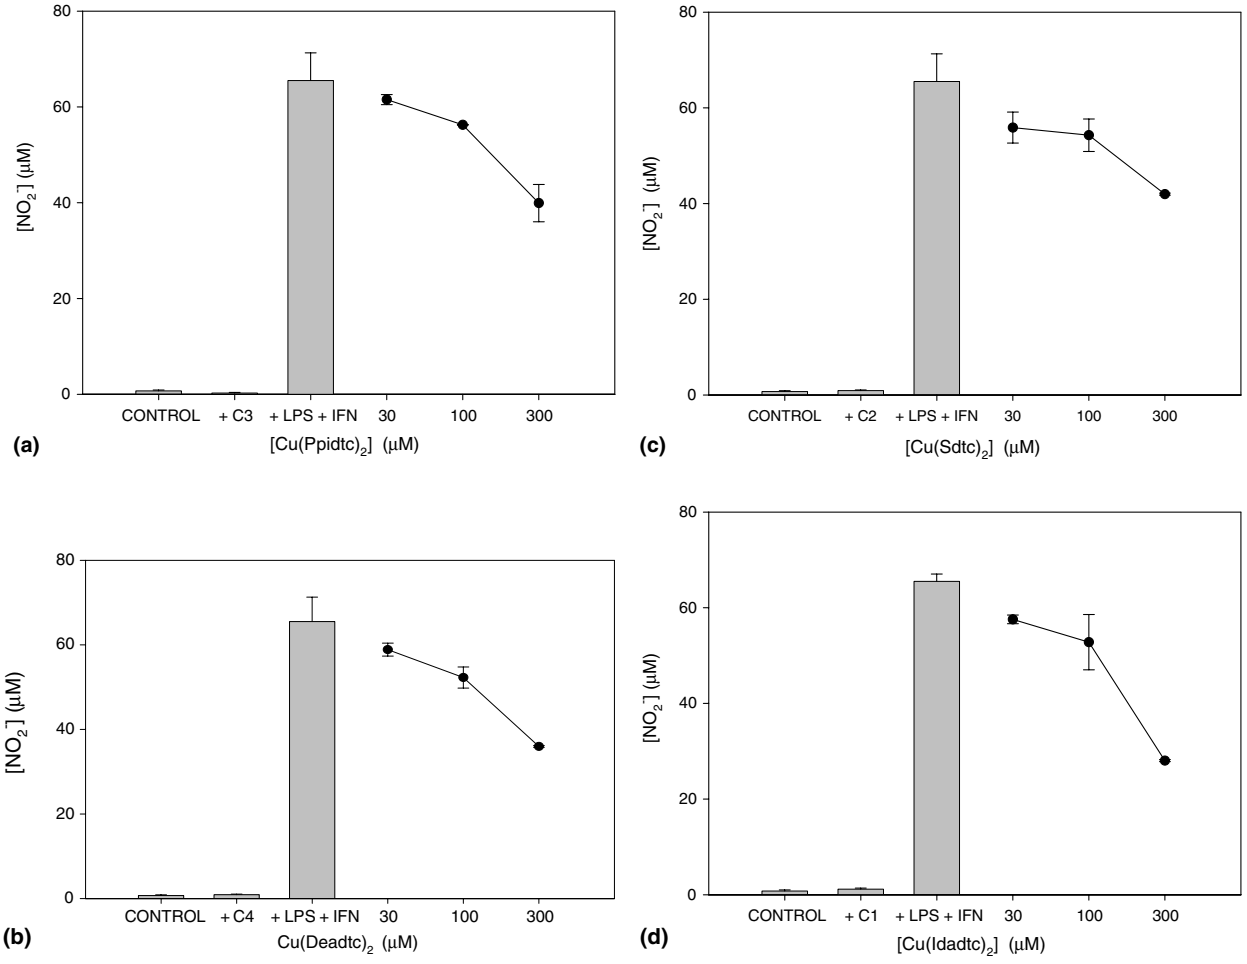

Fig. 11. Effect of increasing concentrations of copper(II) dithiocarbamates on NO production in control or cytomix (LPS and IFNγ) stimulated J774 murine macrophages. Macrophages were cultured (24 h) in the absence or presence of medium alone (controls), with citomix (LPS + IFNγ) alone or in the presence of three different concentrations (30–300 μM) of each Cu(II)dithiocarbamate. Each data point represents nitrite concentrations (means ± SEM) of three different experiments using triplicate or quadruplicate wells per data point. Additional groups of cells were treated with the highest dose (300 μM) of copper(II) dithiocarbamates alone.

macrophage iNOS by the simultaneous treatment (24 h) with cytomix (LPS and IFNγ) dramatically increased NO_2^- concentration (up to 65 μM) being these reaction dose-dependently reduced by the addition of cultures significantly reduced in the presence of graded doses of these copper(II) dithiocarbamates.

When considered together the data derived from experiments using chemical donors (SNP) or cytomix (LPS + IFNγ)-activated macrophages demonstrate that the different copper(II) dithiocarbamates studied are effective NO scavengers, which rapidly react with NO and prevent the formation of its stable oxidation product (NO_2^-) in aqueous solution.

This results confirm previous studies with Cu(ProDTC)$_2 \cdot 3H_2O$ [16].

4. Conclusions

Single crystals of **1** and **2** were prepared for the first time and characterized by X-ray diffraction. They are dimeric. For complex **2**, selected bond distance and bond angles are given in Supplementary material because of the high value of *R* (Table S1).

Complex **3** was also prepared for the first time.

The stability constants and speciation diagrams in aqueous solution of the Cu(Deadtc)$_2$–NO [17] and Cu(Idadtc)$_2$–NO systems indicate that these copper(II) dithiocarbamates have a great ability to trap NO under in physiologic conditions. The formation of the complexes $CuL_2(NO)$ and $CuL_2(NO)_2$ is successive.

The results for the Cu(Sdtc)–NO and Cu(Ppidtc)$_2$–NO systems indicate that the formation of the complexes $CuL_2(NO)$ and $CuL_2(NO)_2$ is simultaneous and therefore this dithiocarbamate copper(II) complex is more versatile to uptake and release NO in physiological conditions.

The species distribution diagrams in aqueous solution at physiological pH (7.4) also indicate that these copper(II) dithiocarbamates help to know the chemistry to regulate the NO in the tissues and to control its biological function.

Since NO yields stable oxidation products (mainly NO_2^- and lower levels of NO_3^-) in aqueous solution we also demonstrate that the copper(II) dithiocarbamates studied are able to decrease total nitrite concentrations produced by the model NO-donor NPS. Of further interest a similar decrease in the total nitrite concentrations was observed when the copper(II) dithiocarbamates were added to murine macrophages challenged with LPS and IFNγ to induce iNOS expression. These data support the potential application of copper(II) dithiocarbamates as therapeutic agents in animal models of septic shock. Verification of this possibility is currently under investigation in our laboratories.

the water molecules. Ross also lists the infrared spectra of the pseudo-alums formed from one divalent and one trivalent cation. Halotrichite has infrared bands at v_1, 1000 cm^{-1}; v_2, 480 cm^{-1}; v_3, 1121, 1085, 1068 cm^{-1}; v_4, 645, 600 cm^{-1}. Pickeringite the Mg end member of the halotrichite–pickeringite series has infrared bands at v_1, 1000 cm^{-1}; v_2, 435 cm^{-1}; v_3, 1085, 1025 cm^{-1}; v_4, 638, 600 cm^{-1} [11]. These minerals display infrared water bands in the OH stretching, 3400 and 3000 cm^{-1} region; OH deformation, 1650 cm^{-1} region; OH libration, 725 cm^{-1} region. Ross also reports a weak band at ~960 cm^{-1} which is assigned to a second OH librational vibration [11]. As with the infrared spectra, Raman spectra of alums are based on the combination of the spectra of the sulphate and water. Sulphate typically is a tetrahedral oxyanion with Raman bands at 981 (v_1), 451 (v_2), 1104 (v_3) and 613 (v_4) cm^{-1} [13]. Some sulphates have their symmetry reduced through acting as monodentate and bidentate ligands [13]. In the case of bidentate behaviour both bridging and chelating ligands are known. This reduction in symmetry is observed by the splitting of the v_3 and v_4 into two components under C_{3v} symmetry and three components under C_{2v} symmetry.

In this work we report the Raman and infrared spectra of two synthetic halotrichites and compare the spectra with that of the natural minerals.

2. Experimental

2.1. Synthesis of halotrichites

The synthetic halotrichites type minerals Pickeringite and Apjohnite were prepared from an ultra pure water solution. Saturated solutions of both components were shaken together with the solid sulphates contained in filter bag sacks and were placed on either side of a beaker, which contained the saturated solution. In the synthesis of pickeringite, 9.824 g of $Al_2(SO_4)_3 \cdot 18H_2O$ and 2.491 g of $MnSO_4 \cdot H_2O$ were contained in the two sacks, while in the synthesis of apjohnite, 13.027 g of $Al_2(SO_4)_3 \cdot 18H_2O$ and 4.818 g of $MgSO_4 \cdot 7H_2O$ were used. The double salt was left over a period of a week to crystallise out. The crystals were dried and collected by vacuum filtration and washed with ethanol and diethyl ether. The minerals were analysed by X-ray diffraction for phase purity and by electron probe using energy dispersive techniques for quantitative chemical composition.

2.2. Raman spectroscopy

The crystals of halotrichite were placed and oriented on the stage of an Olympus BHSM microscope, equipped with 10× and 50× objectives and part of a Renishaw 1000 Raman microscope system, which also includes a monochromator, a filter system and a Charge Coupled Device (CCD). Raman spectra were excited by a HeNe laser (633 nm) at a resolution of 2 cm^{-1} in the range between 100 and 4000 cm^{-1}. Repeated acquisition using the highest magnification was accumulated to improve the signal to noise ratio. Spectra were calibrated using the 520.5 cm^{-1} line of a silicon wafer. In order to ensure that the correct spectra are obtained, the incident excitation radiation was scrambled. Previous studies by the authors provide more details of the experimental technique [14–17]. Spectra at elevated temperatures were obtained using a Linkam thermal stage (Scientific Instruments Ltd., Waterfield, Surrey, England). Spectral manipulation such as baseline adjustment, smoothing and normalisation was performed using the GRAMS® software package (Galactic Industries Corporation, Salem, NH, USA).

2.3. Infrared spectroscopy

Infrared spectra were obtained using a Nicolet Nexus 870 FTIR spectrometer with a smart endurance single bounce diamond ATR cell. Spectra over the 4000–525 cm^{-1} range were obtained by the co-addition of 64 scans with a resolution of 4 cm^{-1} and a mirror velocity of 0.6329 cm/s. Spectra were co-added to improve the signal to noise ratio.

Band component analysis was undertaken using the Jandel 'PEAKFIT' software package, which enabled the type of fitting function to be selected and allows specific parameters to be fixed or varied accordingly. Band fitting was done using a Lorentz–Gauss cross-product function with the minimum number of component bands used for the fitting process. The Lorentz–Gauss ratio was maintained at values greater than 0.7 and fitting was undertaken until reproducible results were obtained with squared regression coefficient of R^2 greater than 0.995.

3. Results and discussion

The Raman spectra of synthetic apjohnite and pickingerite in the 950–1050 cm^{-1} region are shown in Fig. 1; the infrared spectra in the 525–1225 cm^{-1} region in Fig. 2; the Raman spectra in the 100–700 cm^{-1} region in Fig. 3; the Raman spectra in the 2700–3700 cm^{-1} region in Fig. 4 and the infrared spectra in the 2100–3700 cm^{-1} region in Fig. 5. The results of the analyses of the Raman and infrared spectra of synthetic apjohnite and pickingerite together with the results of the Raman spectra of natural halotrichite, wupatkiite and apjohnite are reported in Table 1.

The Raman spectrum of pickingerite displays an intense symmetric band at 984 cm^{-1} assigned to the v_1 $(SO_4)^{2-}$ symmetric stretching mode. A second very low intensity band is observed at 971 cm^{-1}. According to Ross, this band is a water librational mode. A comparison may be made with the Raman spectrum of halotrichite where a single Raman band at 995 cm^{-1} is observed with a low intensity band at 975 cm^{-1}. The Raman spectrum of synthetic apjohnite shows two resolved bands at 995 and 990 cm^{-1} with a third band at 975 cm^{-1}. The first two bands are

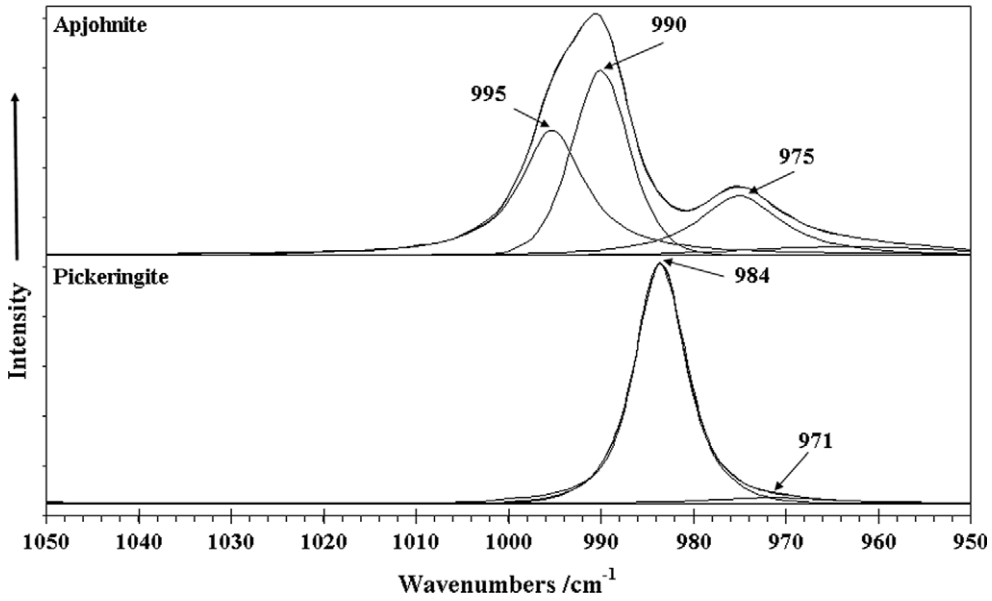

Fig. 1. Raman spectra of synthetic apjohnite and pickingerite in the 950–1050 cm^{-1} region.

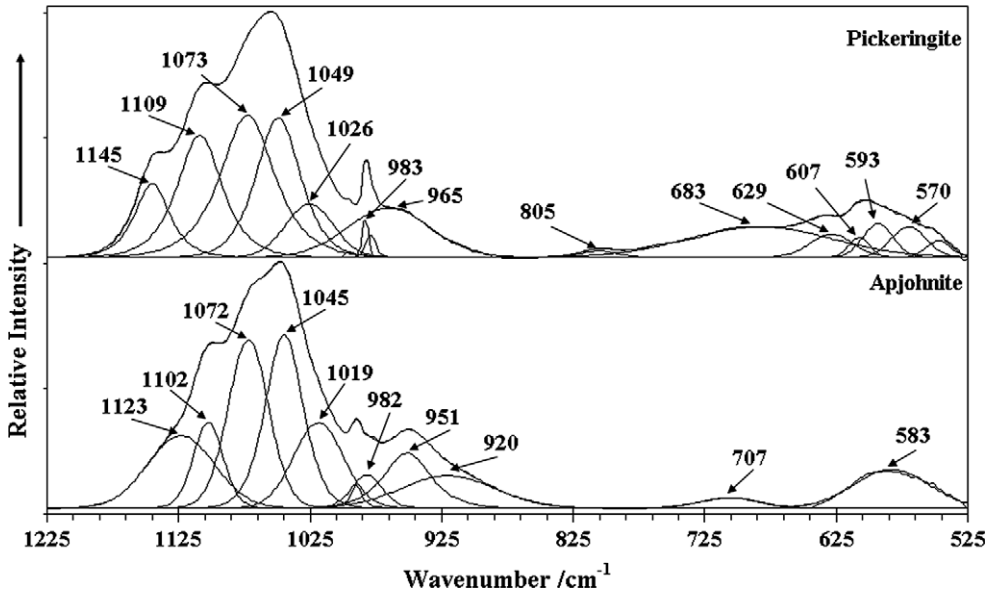

Fig. 2. Infrared spectra of synthetic apjohnite and pickingerite in the 525–1225 cm^{-1} region.

assigned to the v_1 $(SO_4)^{2-}$ symmetric stretching modes, whilst the latter band is assigned to the water librational mode. In comparison the Raman spectrum of the natural mineral apjohnite displays two bands at 997 and 991 cm^{-1}. A further comparison is made with the Raman spectrum of the cobalt alum wupatkiite where two bands are observed at 996 and 990 cm^{-1}. Both Ross and Griffith reported a single Raman band at 1006 cm^{-1}.

The infrared spectra of synthetic apjohnite and pickingerite are shown in Fig. 2. The spectra are complex with many overlapping bands. The band at 983 cm^{-1} (pickingerite) and 982 cm^{-1} (apjohnite) are assigned to the IR forbidden v_1 $(SO_4)^{2-}$ symmetric stretching mode. The bands at 965 and 951 cm^{-1} for pickeringite and apjohnite are ascribed to the water librational modes. The series of bands of pickingerite at 1145, 1109, 1073, 1049 and 1026 cm^{-1} and for apjohnite at 1123, 1102, 1072, 1045 and 1019 cm^{-1} for apjohnite are attributed to the v_3 $(SO_4)^{2-}$ antisymmetric stretching modes. The observation of multiple bands is in line with the concept of non equivalent sulphate anions in the pseudo-alum structure.

Alunogen ($Al_2(SO_4)_3 \cdot 18H_2O$) has an infrared band at 993 cm^{-1} and coquimbite ($Fe_2(SO_4)_3 \cdot 9H_2O$) a band at 1014 cm^{-1}. It is concluded that the higher wavenumber band at 995 cm^{-1} is attributable to the divalent cation (either Fe, Mg or Mn) and the second band at 990 cm^{-1} to the trivalent cation (Al) (see Fig. 1). However the relative intensities of apjohnite bands suggest otherwise. The

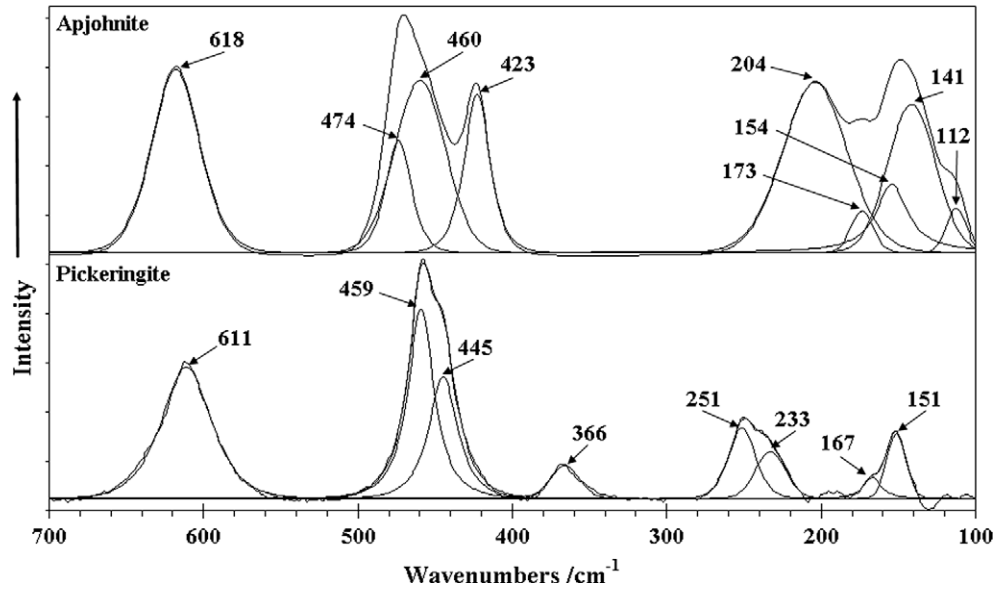

Fig. 3. Raman spectra of synthetic apjohnite and pickingerite in the 100–700 cm^{-1} region.

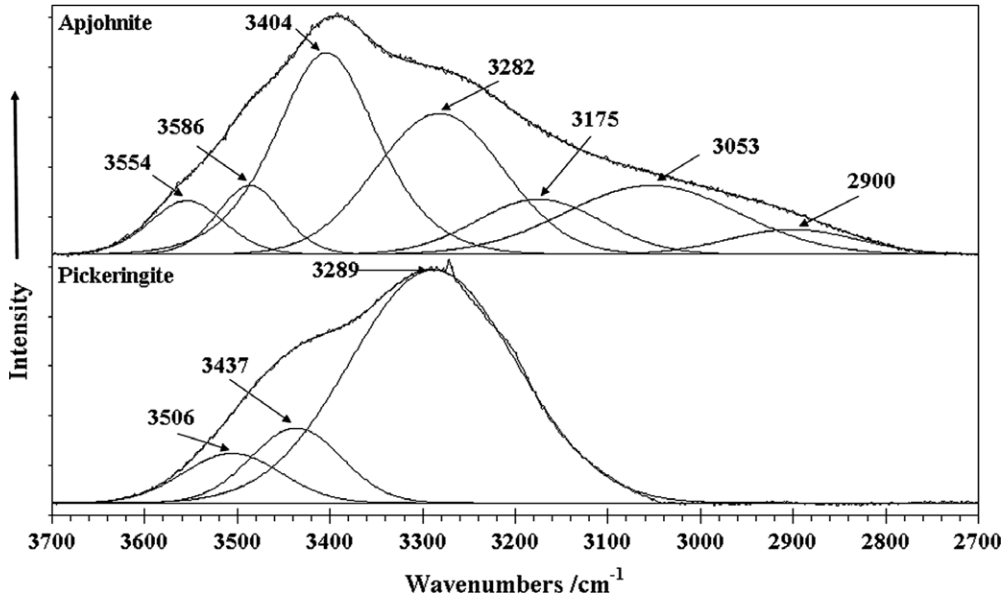

Fig. 4. Raman spectra of synthetic apjohnite and pickingerite in the 2700–3700 cm^{-1} region.

crystallographic data shows that there are four distinct sulphate groups with one of the sulphate groups coordinating the divalent cation. The relative intensity of the two bands at 995 and 990 cm^{-1} is ~3:1. Thus the lower wavenumber band is assigned to the sulphate coordinating to the divalent cation and the higher wavenumber band to the sulphates in the water hydration sphere of the aluminium. The infrared spectra of synthesised pickeringite and apjohnite show two weak bands at 983 and 965 cm^{-1} and at 982 and 951 cm^{-1}, respectively. The observation of two bands in both the Raman and infrared spectra supports the concept of two different sulphates associated with the hydration sphere of each cation. The bandwidths of the two bands at 996 and 990 cm^{-1} for natural halotrichite are 8.2 and 6.4 cm^{-1}. Similarly for wupatkiite the bandwidths of the two bands at 996 and 992 cm^{-1} in the 298 K spectrum are 7.8 and 6.4 cm^{-1}.

From a spectroscopic point of view, the situation of the Raman spectra of the v_1 $(SO_4)^{2-}$ symmetric stretching region is complex, since all these isomorphous minerals crystallise in a monoclinic space group $P2_1/c$ and four independently sulphate ions are present. In the unit cell, there are 16 anions in the primitive cell each located in the C_1 position. So additional numerous bands due to crystal effects are expected. There are four crystallographically independent sulphate ions. This will result in numerous band splittings, which may be more readily observed at 77 K. Hence it would be expected that each independent

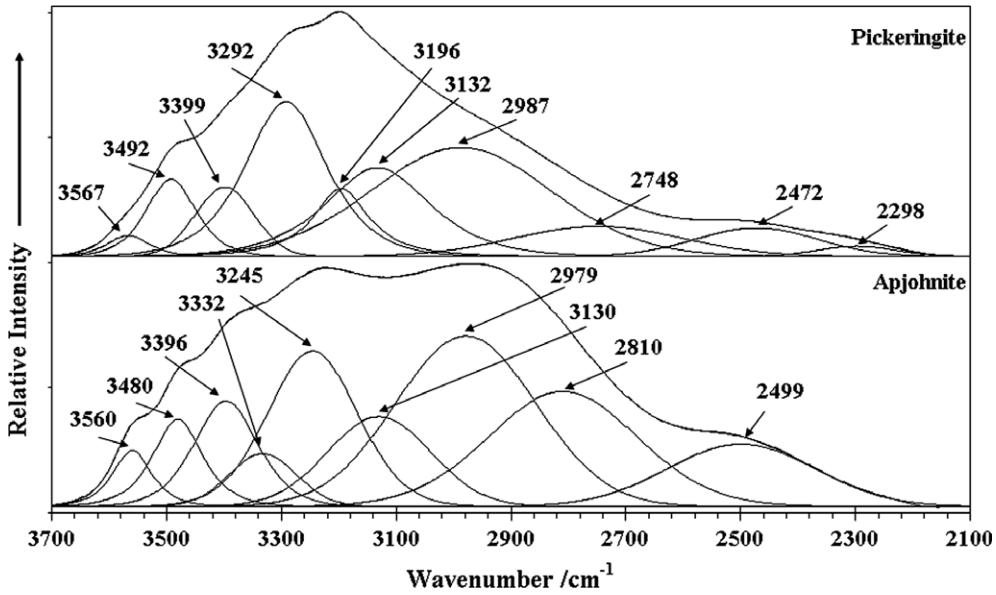

Fig. 5. Infrared spectra of synthetic apjohnite and pickingerite in the 2100–3700 cm^{-1} region.

sulphate anion would have its individual Raman spectrum. However accidental coincidence of the bands can occur, resulting in fewer bands than might be predicted. The Raman spectra of synthetic apjohnite and pickingerite show two very low intensity bands at 1141 and 1080 cm^{-1} and 1096 and 1058 cm^{-1}, respectively.

The antisymmetric stretching region of natural pseudo-alums is complex and is of low intensity in the Raman spectra. For halotrichite Raman bands are observed at 1148, 1112, 1091, 1070 and 1053 cm^{-1}. Raman bands are observed in similar positions for both wupatkiite and apjohnite. The number of bands observed in this region should reflect the number of sulphate anions in the primitive cell. Ross reported two infrared bands for pickeringite at 1085 and 1025 cm^{-1} and three bands for halotrichite at 1121, 1085 and 1068 cm^{-1} [18]. In obtaining the Raman spectra of the v_3 region for these pseudo-alums, some difficulty was experienced in obtaining high quality spectra because of low intensity throughput and high background, nevertheless some spectra were obtained.

The low frequency regions of synthetic pickingerite and apjohnite at 298 are shown in Fig. 3. For pickingerite two bands are observed at 459 and 445 cm^{-1} and for apjohnite three bands are observed at 474, 460 and 423 cm^{-1}. These bands are assigned to the v_2 bending modes. The Raman spectrum of the v_2 region of natural halotrichite shows two bands at 468, 424 and 390 cm^{-1}. The pickingerite spectrum has bands at 466, 427 and 396 cm^{-1}. Natural apjohnite shows two bands at 466 and 427 cm^{-1}. These two bands are well separated for halotrichite but overlap for the other two minerals. Infrared spectra of the minerals show two weak bands at 470 and 428 cm^{-1}. Ross reported one infrared band for halotrichite at 480 cm^{-1} and a band for pickeringite at 435 cm^{-1} [18]. There is good agreement between the infrared spectra reported by Ross and the Raman data reported here. Good band separation was obtained. Sodium sulphate shows three v_2 Raman bands at 435, 449 and 470 cm^{-1}. Basic aluminium sulphate (Al_{13} sulphate) shows three bands at 446, 459 and 496 cm^{-1}. The observation of three bands for synthetic halotrichites spectra supports the concept that (a) sulphate is of reduced site symmetry and (b) different sulphates exist around the water molecules coordinated to the two hydrated cations.

The v_4 mode is observed for natural halotrichite in the Raman spectrum at 298 K as a single band at 622 cm^{-1}. For wupatkiite, the band is observed at 619 cm^{-1} with a shoulder at 605 cm^{-1}. Apjohnite has a single Raman band at 617 cm^{-1}. Ross reports two v_4 modes in the infrared spectra at 645 and 600 cm^{-1} for halotrichite and 638 and 600 cm^{-1} for pickeringite [18]. The infrared spectrum of synthetic pickingerite shows low intensity bands at 683 (broad), 629, 607, 593 and 570 cm^{-1} and for apjohnite at 707 and 583 cm^{-1}. These bands are attributed to the v_4 bending modes. The infrared spectrum of natural halotrichite shows two bands at 632 and 595 cm^{-1}. A Wupatkiite Raman spectrum of this region is more complex with bands observed at 652, 626, 618, 606 and 589 cm^{-1}. The Raman spectrum of natural apjohnite shows good band separation in the v_4 region with bands at 650, 620, 605 and 590 cm^{-1} [13]. Sulphate typically is a tetrahedral oxyanion with bands at 981 (v_1), 451 (v_2), 1104 (v_3) and 613 (v_4) cm^{-1}. Some sulphates have their symmetry reduced through the formation of monodentate and bidentate ligands. In the case of bidentate formation both bridging and chelating ligands are known. This reduction in symmetry is observed by the splitting of the v_3 and v_4 into two components under C_{3v} symmetry and three components under C_{2v} symmetry. The observation that three or four bands are observed in the v_4 region of these halotrichites is attributed to the reduction of symmetry to C_{2v} or less, and the fact that four

crystallographically distinct sulphate groups are present in the structure, one acts as a unidentate towards the M^{2+} ion.

The Raman and infrared spectra of synthetic pickingerite and apjohnite in the OH stretching region are shown in Figs. 4 and 5, respectively. The Raman spectrum of pickingerite displays bands at 3506, 3437 and 3289 cm^{-1}. The Raman spectrum of synthetic apjohnite is more complex. Raman bands are observed at 3554, 3586, 3404 and 3282 cm^{-1}. Additional bands are observed at 3175, 3053 and 2900 cm^{-1}. The infrared spectrum as shown in Fig. 5 is complex with many overlapping broad bands. The bands show greater intensity when compared with the intensity of the Raman bands. Raman spectroscopy is not very sensitive to the measurement of water in gels, crystals and minerals. Nevertheless, the OH stretching region of water in these pseudo-alums can be determined. The OH stretching region of natural halotrichite is complex and shows five bands at 3452, 3369, 3255, 3166 and 2944 cm^{-1}. Similar spectra are observed for apjohnite and wupatkiite. A Wupatkiite Raman spectrum shows bands at 3499, 3414, 3234, 3111, 2989 and 2852 cm^{-1}. The absence of bands in both the infrared and Raman spectra for natural halotrichites around 3550 cm^{-1} suggests that no adsorbed water is present. The v_2 water-bending mode is extremely weak in Raman spectra of alums but is readily observed in the infrared spectra (Fig. 6). Infrared spectra of the halotrichites show a broad profile centred upon 1650 cm^{-1}. Bands for apjohnite may be resolved at 1679, 1654, 1616 and 1582 cm^{-1}. Bands for pickingerite may be resolved at 1676, 1669 and 1648 cm^{-1}. The observation of the high frequency v_2 mode of water is indicative of coordinated water which is strongly hydrogen bonded. The observation of the second IR band suggests a second type of water molecule is present. This water is involved with hydrogen bonding to the sulphate and hence is another cause of the reduction in symmetry of the sulphate ion, as supported by the single crystal X-ray structure of apjohnite.

4. Conclusions

Halotrichites are a pseudo-alums which can form a continuous series of solid solutions with pickingerite by the substitution of Mg for Fe^{2+}. Raman spectroscopy is a very powerful tool for the study of these types of minerals and because of the compositional variation differences in the Raman spectrum of halotrichites of different origins are observed. In situ Raman spectroscopy at 298 enabled the spectra of synthetic pseudo-alums: pickingerite and apjohnite to be obtained. Multiple antisymmetric stretching bands are observed as well as multiple bending modes suggesting a reduction in symmetry of the sulphate in the halotrichite structure. The symmetry of the sulphate as observed by the number of bands in the v_2, v_3 and v_4 modes, is essentially reduced to C_{2v}. Two types of sulphate are identified and are associated with the two principal kinds of sites in the structure, as expected from the X-ray diffraction study. The crystal structure of halotrichites shows four non-equivalent sulphate units, three of which are bonded to water molecules and one to the divalent cation. Raman spectroscopy identifies two sulphate symmetric stretching vibrations in line with the crystal structure.

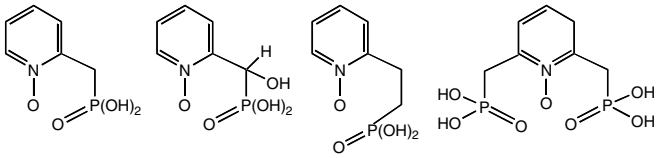
bifunctional 2-(methylphosphonic acid) pyridine *N*-oxides **1**-H_2 [16], **1′**-H_2 [16] and **2**-H_2 [17] and their coordination chemistry toward selected lanthanide ions. For example, **1**-H_2 and **1′**-H_2 form complexes $Er(\mathbf{1}\text{-}H^-)_3(\mathbf{1}\text{-}H_2)\cdot 8H_2O$ in which all four ligands act as bidentate chelates producing an eight-coordinate metal center [16]. The P–O and N–O groups also participate in the formation of an extensive 3D hydrogen bonding network. The ligand **2**-H_2, with its longer *exo*-ethyl phosphonic acid arm, forms a complex $Nd(\mathbf{2}\text{-}H^{-1})_3$. The solid-state structure contains chains along the *c*-axis in which the *N*-oxide does not participate in chelate formation on Er(III), but is involved in hydrogen bond interactions with phosphonic acid hydrogen atoms [17]. The differences between these ligands and their coordination properties has led us to explore the directed synthesis of the trifunctional ligand, 2,6-bis(methylphosphonic acid)pyridine *N*-oxide **3**-H_4, and its coordination chemistry with Nd(III). The results of that study are reported here.

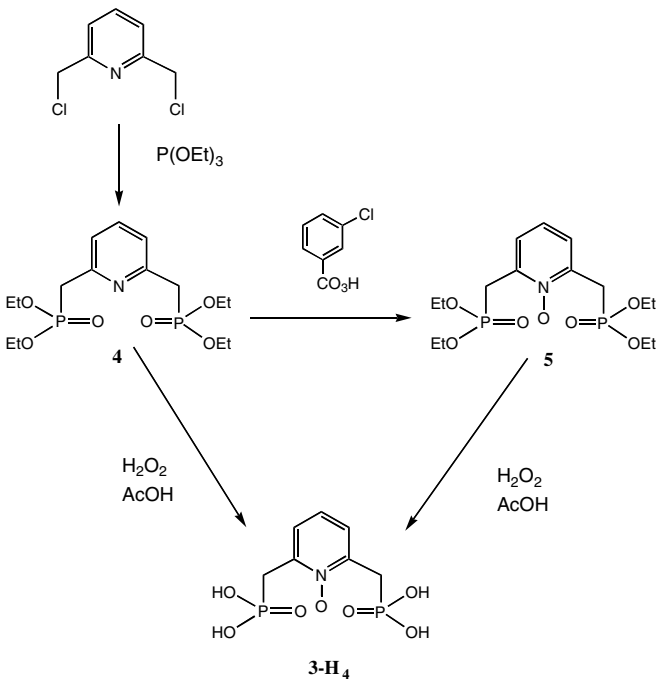


1-H_2 **1'-H_2** **2-H_2** **3-H_4**

2. Results and discussion

2.1. Synthesis and characterization of ligand

The target ligand, 2,6-bis(methylphosphonic acid)pyridine *N*-oxide, **3**-H_4, was prepared in good to fair overall yields by two related approaches that differ in the method of oxidation of the intermediate, 2,6-bis(diethylphosphonomethyl)pyridine (**4**) (Scheme 1). We have previously reported the synthesis of **4** from an Arbusov reaction between $P(OEt)_3$ and 2,6-bis(chloromethyl)pyridine [6] and under the conditions described there (140–150 °C, 4 h), **4** was obtained in 88% yield. We note here that performing the reaction at 150 °C for 7 h results in essentially quantitative formation of **4** with a single ^{31}P NMR resonance at δ 25.6. This ^{31}P NMR shift appears in the region expected for alkyl phosphonates, $RP(O)(OR)_2$ [18]. The direct oxidative hydrolysis of the ester **4** to the acid **3**-H_4 (Method 1) was examined by use of mixtures of glacial acetic acid and hydrogen peroxide. By this route, the oxidative conversion is only partially effective. Under the conditions described, about 65% of **4** remains unconverted after a typical reaction. Following extractive work up, the solid product is a mixture that contains ~93% **3**-H_4 and ~7% of the pyridine compound $[(HO)_2P(O)CH_2]_2C_5H_3N$, that is identified by its ^{31}P NMR resonance, δ 14. This mixture is difficult to separate, and this fact together with the unsatisfactory overall conversion led us to seek an alternate synthesis approach.



Scheme 1.

In our previous report [6], in which a synthesis for compound **5** was sought, we noted that when the oxidation of **4** with 3-chloroperbenzoic acid (70 °C, 16 h) was not carefully controlled, variable quantities of **3**-H_4 would also appear in samples of **5**. With the temperature sensitivity in mind, we performed here the N-oxidation of **4** with 3-chloroperbenzoic acid in $CHCl_3$ solution at 23 °C for 18 h (Method 2). This results in formation of **5** in 91% yield, which is a much improved yield compared to 47% obtained when the reaction is performed at elevated temperature. Characterization data obtained here for **5** are consistent with the data reported earlier. The subsequent hydrolysis of **5** with acetic acid/H_2O_2 solution is completed at 70 °C after ~17 h. The hydrogen peroxide is added to assist in the N-oxidation of any small quantities of **4** that remain in **5**. Simple work up normally provides pure **3**-H_4 in 90% yield. However, if small amounts of **4** or **5** are carried through, recrystallization from acetone/water or Et_2O/pentane solutions removes these impurities. The product is an analytically pure, white, crystalline solid obtained as a monohydrate. The NMR spectra are solvent dependent and ^{31}P and spectral data are provided for D_2O and d_6-DMSO solutions.

2.2. Synthesis of the complex

The 2:1 combinations of **3**-H_4 and $Nd(NO_3)_3$ in MeOH or $Nd(OH)_3$ in water produce clear solutions that deposit amorphous solids upon evaporation of the volatiles or addition of $CHCl_3$ to the reaction mixtures. Elemental analyses suggest formation of 2:1 ligand:metal complexes with varying degrees of solvation. However, when 2:1

combinations of **3-H**$_4$ and Nd(NO$_3$)$_3$ or Nd(OH)$_3$ in a minimum of water are heated in sealed glass tubes at 85 °C, blue-purple crystals of a complex Nd(**3-H**$_2^{2-}$)(**3-H**$_3^{1-}$)-(H$_2$O)$_{4/3}$ form and this complex has been characterized by single crystal X-ray diffraction analysis.

2.3. Crystallographic analysis of the complex

A diffraction quality crystal of the complex, obtained from the hydrothermal synthesis described above, was selected and its structure determined by single crystal X-ray diffraction techniques. One view of the asymmetric unit is shown in Fig. 1 and selected bond lengths are listed in Table 1. The formula for the asymmetric unit is Nd(**3-H**$_2^{2-}$)(**3-H**$_3^{1-}$)(H$_2$O)$_{4/3}$. The view of the asymmetric unit shown in Fig. 1 suggests that the Nd(III) ion is six coordinate; however, it is seven coordinate with the inner sphere coordination polyhedron best approximated as a mono-capped trigonal prism as shown in Fig. 2. The seventh oxygen atom position, O4A, not shown in the view of the asymmetric unit, results from bridge bonding with another asymmetric unit (see below). Both anionic ligands

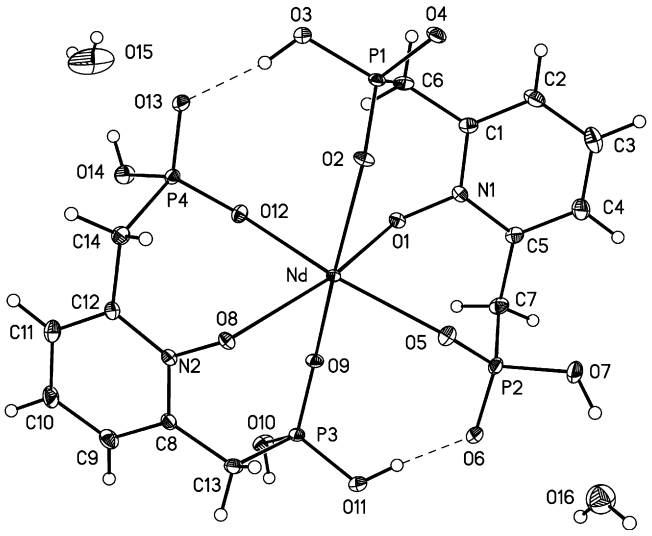


Fig. 1. Molecular structure and atom labeling scheme for the asymmetric unit Nd(**3-H**$_2^{2-}$)(**3-H**$_3^{1-}$)(H$_2$O)$_{4/3}$ (20% probability ellipsoids).

derived from the tetra-acid, **3-H**$_4$, are bonded to Nd(III) as tridentate chelates. One of the ligands exists as a symmetrical doubly deprotonated anion **3-H**$_2^{2-}$ while the second is a monoanion, **3-H**$_3^{1-}$. The **3-H**$_3^{1-}$ ligand symmetrically chelates to the Nd(III): Nd–O8N2 2.369(3) Å, Nd–O9P3 2.427(3) Å, Nd–O12P4 2.378(4) Å. The **3-H**$_2^{2-}$ ligand, on the other hand, displays more asymmetric binding in part because one phosphonate oxygen atom, O4, bridge bonds to a Nd(III) in a second asymmetric unit: Nd–O1N1 2.526(4) Å, Nd–O2P1 2.338(3) Å, Nd–O5P2 2.375(4) Å, Nd–O4(4/3 − x + y, 2/3 − x, z − 1/3) 2.340(4). The connectivity between asymmetric units is illustrated in Fig. 3. The resulting ···O4(4/3 − x + y, 2/3 − x, z − 1/3) Nd–O4–Nd(2/3 − y, −2/3 + x − y, 1/3 + z)··· and related interactions produce chains that spiral along the c direction of the unit cell and a view of the unit cell looking down the c-axis is shown in Fig. 4. The pyridine N–O bond lengths are equivalent as are the P–O bond lengths involving oxygen atoms coordinated to Nd(III): N1–O1 1.332(5) Å, N2–O8 1.323(5) Å; P–ONd avg. 1.501 ± 0.010 Å. The formally anionic oxygen atoms, O6 and O13, involved in hydrogen bonding to adjacent asymmetric units also display short P–O bond lengths: P2–O6 1.516(4) Å, P4–O13 1.494(4) Å. The unionized P–OH groups display longer P–O bond lengths: P1–O3 1.571(4) Å, P2–O7 1.551(4) Å, P3–O11 1.527(4) Å, P3–O10 1.559(4) Å, P4–O14 1.567(4) Å. There are two hydrogen-bond interactions within the asymmetric unit, O3H3···O13 1.73 Å (170°), O11H11···O6 1.62 Å (175°), that appear to help order the ligand chelation mode as indicated in Fig. 2. There is also an inter-asymmetric unit hydrogen bond between a phosphonic acid proton and the Nd coordinated pyridine *N*-oxide, O10H10···O1:1:77 Å (168°).

Finally, there is extensive hydrogen bonding involving phosphonic acid protons and lattice water molecules. The water molecules occupy columnar space generated by the spiral chains as depicted in Fig. 4. In that figure, the Nd(III) coordination polyhedra are shown in green, the phosphorus atom tetrahedral are shown in magenta, carbon atoms in the ligand backbone are shown as grey

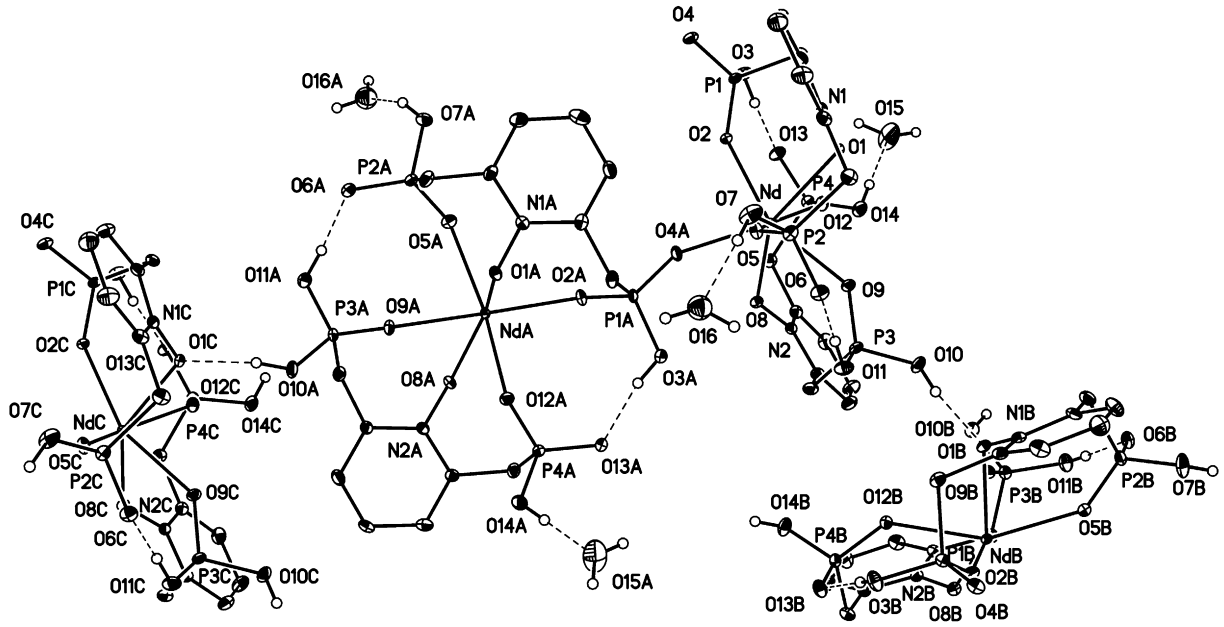

Fig. 3. View of the 1-D Chain structure for Nd(**3**-H_2^{2-})(**3**-H_3^{1-})$(H_2O)_{4/3}$: molecule A at $4/3 - x + y$, $2/3 - x$, $z - 1/3$; molecule B at $1/3 - y$, $x - y - 1/3$, $z - 1/3$; molecule C at $2/3 + x$, $1/3 + y$, $z - 1/3$.

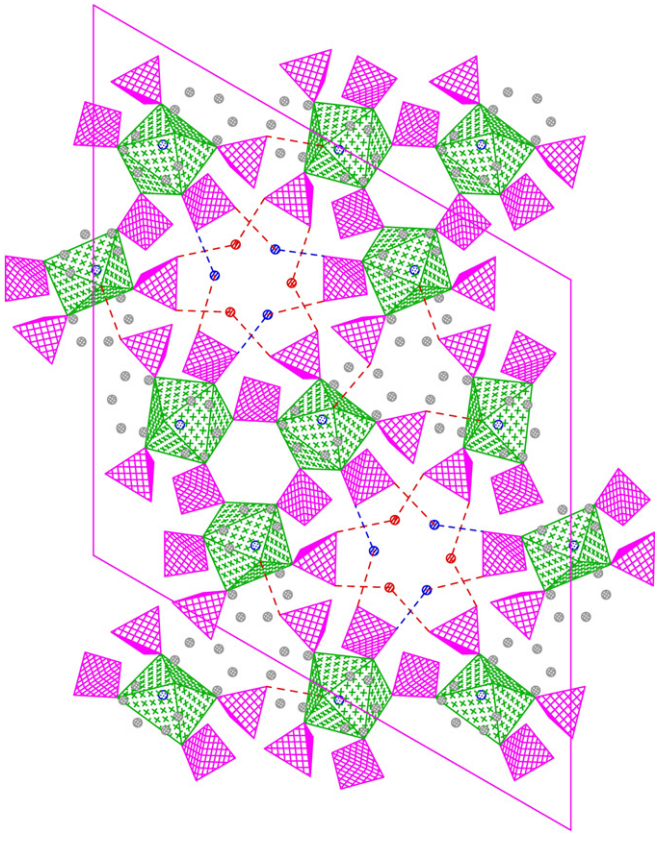

Fig. 4. View of the unit cell for Nd(**3**-H_2^{2-})(**3**-H_3^{1-})$(H_2O)_{4/3}$ looking down the *c*-axis. Seven coordinate Nd(III) polyhedra shown in green, four coordinate phosphate tetrahedra shown in magenta, ligand carbon backbone atoms shown in grey and water sites shown in red and blue. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

dots and the water oxygen atom positions O15, O15A, O15B are depicted in red and the disordered (three sites) O16 in blue. The resulting O···O non-bonded distances involved in the PO–H···OH_2 hydrogen bonds are shown in Fig. 5.

3. Conclusion

A high yield synthesis for the trifunctional phosphonic acid ligand **3-H$_4$** has been developed and this allows for the study of the coordination chemistry of the tetra-acid toward lanthanide ions without interference from competing chelation interactions with the impurity ligands **4**, **5** and $[(HO)_2P(O)CH_2]_2C_5H_3N$. The target ligand readily dissolves lanthanide hydroxides at 23 °C and forms amorphous 2:1 ligand/Ln(III) complexes that have variable elemental compositions due to easily lost lattice solvent molecules. However, hydrothermal synthesis conditions produce well-behaved crystalline solids and one of these complexes with Nd(III) has been structurally characterized. Single crystal X-ray diffraction analysis reveals formation of a bis-ligand complex in which both ligands act as tridentate chelates. A single P–O–Nd chain interaction and hydrogen bonding interactions link the asymmetric units in the unit cell. The strong chelation produced by anionic forms of **3-H$_4$** suggests utility as an acidic separations agent and such studies with uranium are in progress.

4. Experimental

4.1. General

The organic reagents were purchased from Aldrich Chemical Co. and organic solvents were obtained from VWR. The $Nd(NO_3)_3 \cdot 6H_2O$ was purchased from Ventron. All reactions were performed under dry conditions unless noted otherwise. Infrared spectra were recorded on a Mattson 2020 FT-IR and NMR spectra were obtained from Bruker FX-250 and JEOL-GSX400 instruments using Me_4Si (^1H and ^{13}C) and H_3PO_4 (^{31}P) as external shift standards. Downfield shifts are reported with $+\delta$. Elemental analyses were obtained from Galbraith Laboratories.

4.2. 4.2.1. Ligand synthesis Method 1

A sample of 2,6-bis[(diethylphosphono)methyl]pyridine (**4**) (8.0 g, 0.02 mole) *vide infra* in glacial acetic acid (40 mL) was combined with H_2O_2 (3.5 mL, 30%) and heated (70 °C, 8 h). The mixture was cooled, another portion of H_2O_2 (3.5 mL, 30%) was added and the mixture heated (70 °C, 18 h). Over this time, the solution becomes milky in appearance. The resulting mixture was then vacuum evaporated leaving a white powder that was vacuum dried (70 °C, 24 h) to remove traces of acetic acid residue. The dry powder was dissolved in water (40 mL) and poured into well-stirred acetone (500 mL). A precipitate formed immediately and the mixture was stored (−20 °C, 18 h). The solid was recovered by filtration in air, washed with acetone and vacuum dried. The solid was recrystallized twice from H_2O (min)/acetone mixtures: yield 1.8 g (28%).

4.2.2. Method 2

A sample of 2,6-bis(chloromethyl)pyridine [5,6] (8.0 g, 46 mmol) was added to $P(OEt)_3$ (80 mL) at once under a dry nitrogen atmosphere. The reaction mixture was heated (bath temp. 150 °C, 7 h) in a fashion so that the volatile EtCl that formed could escape through the top of a reflux condenser protected by a mercury bubbler. The reaction was cooled to 23 °C and excess $P(OEt)_3$ removed under vacuum leaving 2,6-bis[(diethylphosphono)-methyl]pyridine (**4**) as an orange oil (17.4 g). NMR ($CDCl_3$): $^{31}P\{^1H\}$ δ 25.6; ^1H δ 1.17 (t, $J = 7.0$ Hz, **C**$\mathbf{H}_3$), 3.26 (d, $J = 26.2$ Hz, **C**$\mathbf{H}_2$P), 3.95 (m, O**C**$\mathbf{H}_2$), 7.15 (d, $J = 3.8$ Hz), 7.47 (t, $J = 4.6$ Hz). A sample of **4** (17.0 g, 0.045 mol) and 3-chloroperbenzoic acid (9.0 g, 70–75%) were combined in $CHCl_3$ (80 mL) at 23 °C and stirred (18 h). A saturated solution of $NaHCO_3$ (300 mL) was added, stirred and the phases separated. The aqueous phase was washed with $CHCl_3$ (75 mL × 3) and the combined organic phases dried over anhyd. Na_2SO_4. Evaporation of the volatiles gave 2,6-bis[(diethylphosphono)methyl]pyridine *N*-oxide (**5**) as a colorless oil: yield, 16.2 g (91%). The oil slowly crystallized over several days (m.p. = 50–52 °C). NMR ($CDCl_3$): $^{31}P\{^1H\}$ δ 23.9; ^1H δ 0.86 (t, $J = 6.8$ Hz, **C**$\mathbf{H}_3$), 3.32 (d, $J = 21.8$ Hz, **C**$\mathbf{H}_2$P), 3.71 (m, O**C**$\mathbf{H}_2$), 6.88 (t, $J = 6.5$ Hz), 7.1 (d, $J = 7.1$ Hz); $^{13}C\{^1H\}$ δ 16.5 (d, $J = 6$ Hz, **C**H_3), 28.3 (d, $J = 140$ Hz; **C**H_2P), 63.2 (d, $J = 6.5$ Hz, O**C**H_2), 124.3, 125.8, 144.0. A sample of **5** (8.0 g, 0.02 mol) was dissolved in glacial acetic acid (20 mL) and H_2O_2 (3.6 mL, 30%) added. The mixture was stirred and heated (70 °C, 17 h). A milky solution formed during heating. The mixture was cooled, vacuum evaporated and a white powder collected that was further dried under vacuum (70 °C, 24 h). The dry powder was dissolved in water (40 mL) and the solution poured into well stirred acetone (500 mL). The combination produces a white precipitate and the mixture was cooled (−20 °C, 18 h). The solid was collected by filtration, washed with acetone and dried (70 °C, 24 h). 2,6-Bis(methylphosphonic acid)pyridine *N*-oxide (**3**) was recovered as a white solid: yield 5.1 g (90%), m.p. = 202–204 °C. NMR: ^{31}P $\{^1H\}$ (D_2O) δ 17.9, (d_6-DMSO) δ 19.3; ^1H (D_2O) δ 3.69 (d, 21.2 Hz, **C**$\mathbf{H}_2$), 7.72 (d, $J = 7.3$ Hz), 7.95 (t, $J = 7.6$ Hz); ^{13}C $\{^1H\}$ (d_6-DMSO) δ 35.2 (d, $J = 26.7$ Hz, **C**H_2), 130.2, 134.4, 150.3 (d, $J = 8.7$ Hz). *Anal.* Calc. for $C_7H_{11}NO_7P_2H_2O$ (301.128): C, 27.92; H, 4.35; N 4.65. Found: C, 27.79; H, 4.61; N 4.59%.

4.3. Coordination complexes

A sample of **3-H$_4$** (113 mg, 0.38 mmol) and $Nd(NO_3) \cdot 6H_2O$ (87.6 mg, 0.2 mmol) were dissolved in water (10 mL) and sealed in a pyrex tube. The tube was heated (85 °C, 24 h) and during this time frame blue-purple crystals began to deposit and continued to deposit on

4.4. Crystallography

Crystal data and refinement details for the structure determination are presented in Table 2. Data were collected in the ω scan mode in the θ range 1.62–27.49° on a crystal $0.46 \times 0.22 \times 0.22$ mm in size by using a Siemens R3m/V diffractometer equipped with a graphite monochromator using Mo Kα radiation ($\lambda = 0.71073$ Å). Crystal data parameters are summarized in Table 1. Calculations were performed with SHELXTL (VMS version) and the structure solved by direct methods. Full-matrix least-squares refinements were completed using appropriate neutral atom scattering factors and anomalous dispersion terms including anisotropic thermal parameters on the heavy atoms. Data were corrected for adsorption using semi-empirical psi-scans. The data collected included Friedel pairs and the model was refined in *R*3 (Flack parameter = 0.66 (2)). After all of the non-hydrogen atoms were included, the program suggests to provide for racemic twinning and this significantly improves the *R*-factors. The asymmetric unit is $NdP_4O_{14}N_2H_{19}C_{14}$ with 1 1/3 waters of crystallization. There are nine asymmetric units in the unit cell. The water molecule of 015 is in a fully occupied site but that of 016 has an occupation factor of 1/3. The arrangement of atoms about Nd is nearly centric but the intensities do not fit the *R*-3 space group.

5. Supplementary material

Supplementary crystallographic data are available free of charge from the Cambridge Crystallographic Data Centre, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 336033, email: deposit@ccdc.cam.ac.uk on request, quoting the deposit number 601867.

DMeDPQ TPT

Chart 1. Chemical structures of DMeDPQ and TPT.

of structurally characterized dicyanamide bridged discrete dinuclear compounds [2,13a,13b].

Although dicyanamide can mediate only weak interactions between paramagnetic metal centers [2–14], a few multidimensional dicyanamide-bridged compounds exhibit long range magnetic ordering [1]. Evidently, dicyanamide is also a promising building unit to derive magnetic materials.

It may be noted that the utilization of a new organic ligand may result in new types of topologies in the heteroleptic metal–dicyanamide family. As the blocking or bridging organic counterpart, although several ligands from polypyridine family has been used previously [1d], 6,7-dimethyl-2,3-di(2-pyridyl)quinoxaline (DMeDPQ) and 2,4,6-tri(2-pyridyl)-1,3,5-triazine (TPT) have still not been utilized. Herein, we report the syntheses, structures, and variable-temperature magnetic studies of a one-dimensional double chain compound, $[Mn^{II}(DMeDPQ)(\mu_{1,5}\text{-dca})_2]_n$ (**1**), and a discrete dinuclear compound, $[Mn_2^{II}(TPT)_2(\mu_{1,5}\text{-dca})_2(H_2O)_2](ClO_4)_2$ (**2**), derived from DMeDPQ and TPT, respectively (see Chart 1).

2. Experimental

2.1. Materials and physical methods

All the reagents and solvents were purchased from the commercial sources and used as received. Elemental (C, H, and N) analyses were performed on a Perkin–Elmer 2400 II analyzer. IR spectra were recorded in the region 400–4000 cm^{-1} on a Bio-Rad FTS40 spectrophotometer with samples as KBr disks. Variable-temperature (5–300 K) magnetic susceptibility measurements under fixed field strength of 1 T were carried out with a Quantum Design MPMS SQUID magnetometer.

2.2. Syntheses of $[Mn^{II}(DMeDPQ)(\mu_{1,5}\text{-dca})_2]_n$ (1) and $[Mn_2^{II}(TPT)_2(\mu_{1,5}\text{-dca})_2(H_2O)_2](ClO_4)_2$ (2)

The two complexes were synthesized in the same way and mixing the reactants in the same stoichiometric ratio as illustrated below for **1**, except using TPT instead of DMeDPQ for **2**.

To a stirred methanol solution (25 ml) containing DMeDPQ (0.156 g, 0.5 mmol) and $Mn(ClO_4)_2 \cdot 6H_2O$ (0.362 g, 1 mmol) was added an aqueous solution (5 ml) of sodium dicyanamide (0.178 g, 2 mmol). After stirring for 4 h, the yellow solution was filtered to remove any suspended particles and the filtrate was kept at room temperature for slow evaporation. After a few days, a yellow crystalline compound containing diffractable single crystals was deposited, collected by filtration and washed with methanol. Yield: 0.18 g (72%, in terms of DMeDPQ). *Anal.* Calc. for $C_{24}H_{16}MnN_{10}$: C, 57.7; H, 3.2; N, 28.0. Found: C, 57.6; H, 3.2; N, 27.9%. IR (KBr/cm^{-1}): dicyanamide: 2313, 2239, 2181. Data for **2**: color: yellow. Yield: 80% (in terms of TPT). *Anal.* Calc. for $C_{40}H_{28}Cl_2Mn_2N_{18}O_{10}$: C, 43.6; H, 2.6; N, 22.9. Found: C, 43.5; H, 2.6; N, 23.1%. IR (KBr/cm^{-1}): dicyanamide: 2329, 2235, 2192.

2.3. Crystal structure determination of $[Mn^{II}(DMeDPQ)(\mu_{1,5}\text{-dca})_2]_n$ (1) and $[Mn_2^{II}(TPT)_2(\mu_{1,5}\text{-dca})_2(H_2O)_2](ClO_4)_2$ (2)

Pertinent crystallographic data of these two complexes are summarized in Table 1. Diffraction data were collected on a NONIUS Kappa CCD (for **1**) and a Bruker SMART CCD (for **2**) diffractometer in the ω–2ϑ scan mode at 295 K using graphite monochomated Mo Kα radiation, having $\lambda = 0.71073$ Å. The structures were solved by direct and Fourier methods and refined by full-matrix least-squares methods based on F^2 using the programs SHELXS-97 and SHELXL-97 [15]. All non-hydrogen atoms were readily located and refined by anisotropic thermal parameters.

Table 1
Crystallographic data for **1** and **2**

Compound	**1**	**2**
Empirical formula	$C_{24}H_{16}MnN_{10}$	$C_{40}H_{28}Cl_2Mn_2N_{18}O_{10}$
Formula weight	499.41	1101.58

T (K)	295(2)	295(2)
λ (Mo Kα) (Å)	0.71073	0.71073
D_{calc} (g cm^{-3})	1.400	1.651
μ (mm^{-1})	0.591	0.772
F(000)	1020	558
2θ Range (°)	4.26–55	3.10–55
Total reflections	26602	28495
Unique reflections (R_{int})	5398 (0.0658)	5083 (0.0467)
R_1[a]/wR_2[b] ($I > 2\sigma(I)$ data)	0.0482/0.1108	0.0488/0.1373
R_1[a]/wR_2[b] (all data)	0.0934/0.1355	0.0737/0.1618

[a] $R_1 = [\sum\|F_o| - |F_c\|/\sum|F_o|]$.
[b] $wR_2 = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$.

The final least-squares refinements (R_1) based on [$I > 2\sigma(I)$] converged to 0.0482 for **1** and 0.0488 for **2**.

3. Results and discussion

3.1. Description of the structure of $[Mn^{II}(DMeDPQ)(\mu_{1,5}\text{-}dca)_2]_n$ (1)

An ORTEP representation of the asymmetric unit of **1** is shown in Fig. 1, while the coordination environment and the construction of one-dimensional double chain is shown in Fig. 2. Selected bond lengths and bond angles are listed in Table 2. The metal ion is hexacoordinated by DMeDPQ and dicyanamide anions. DMeDPQ behaves as bidentate chelating ligand through one quinoxaline nitrogen and one pyridyl nitrogen, while the other two nitrogen atoms remain uncoordinated. The remaining four positions are occupied by the nitrile nitrogens of four dicyanamide ligands. The other ends of two dicyanamides, bonded to a metal ion in *trans* positions, coordinate to two different manganese(II) centers to result in a one-dimensional chain propagated along the crystallographic *b* axis. The remaining two dca, which are in *cis* positions, make bridges to the adjacent metal ion of neighboring one-dimensional chain. As a result, an infinite one-dimensional double chain is generated by two single EE and two double EE dicyanamides. The geometry around the manganese(II) ion is distorted octahedral. The best equatorial plane is defined by the pyridyl nitrogen (N(7)) and three dicyanamide nitrogens (N(1C), N(6B), and N(4)) with the deviations of the ligand atoms and the metal center being, respectively, 0.023 Å (average) and 0.028 Å. The axial positions are occupied by the quinoxaline nitrogen (N(8)) and nitrile nitrogen (N(3)) of one double EE dca. The four Mn–N(dca) bond lengths [Mn–N(1C) = 2.187(2) Å, Mn–N(3) = 2.209(2) Å, Mn–N(4) = 2.214(3) Å, and Mn–N(6B) = 2.167(3) Å] are shorter than the metal–polypyridyl bond distances (Mn–N(7) = 2.2799(19) Å, Mn–N(8) = 2.3421(19) Å). These differences in bond lengths are in the range as observed for other Mn^{II}–dca systems [2a–c,4a,5a,5b]. Again, the *transoid* and *cisoid* angles vary, respectively, from 163.49(8)° to 176.32(19)° and from 71.67(6)° to 106.64(8)° indicative of distortion from O_h geometry.

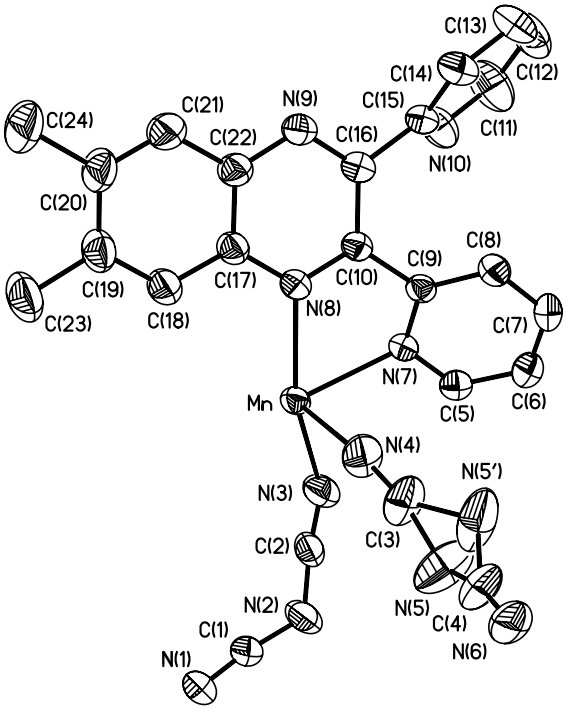

Fig. 1. ORTEP representation (40% thermal ellipsoids) of the asymmetric unit of **1**.

One single EE dca and one double EE dca link the metal ion in a nearly linear fashion with Mn–N–C angles of

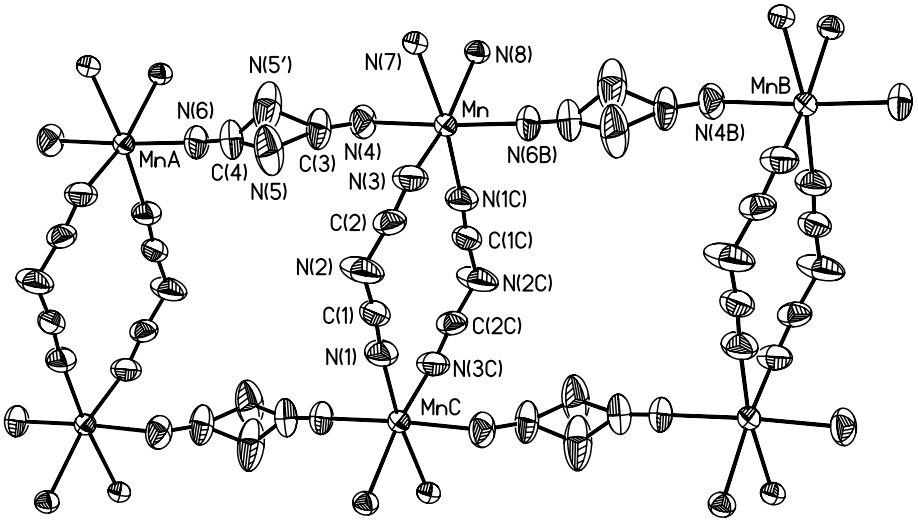

Fig. 2. Perspective view (40% thermal ellipsoids) of **1** demonstrating the coordination environment and construction of one-dimensional double chain. Except the donor centers, other atoms of the organic ligand (DMeDPQ) are omitted for clarity. Symmetry codes: Mn: x, y, z; MnA: x, $y-1$, z; MnB: x, $1+y$, z; MnC: $1-x$, $1-y$, $-z$.

M–N(4)–C(3)	149.1(3)

Symmetry code: as in Fig. 2.

172.9(2)° and 173.3(2)°. The other two dca coordinate in a significantly bent way having Mn–N–C angles of 135.5(2)° and 149.1(3)°. Due to the disorder of the amide nitrogen (N(5); N(5)···N(5′) = 1.07(3) Å) of the single EE dca, its C–N distances are larger than that in the double EE dca. However, the C≡N and C–N distances in either of the two crystallographically different dca anions are very similar (Table 2). In addition, the C–N–C angles (121.7(3)° and 116.4(5)°) indicate the pseudo C_{2v} symmetry of the dicyanamides.

3.2. Description of the structure of $[Mn^{II}_2(TPT)_2(\mu_{1,5}\text{-dca})_2(H_2O)_2](ClO_4)_2$ (**2**)

The structure of **2** (Fig. 3 and Table 3) shows that this is a discrete dinuclear complex where the metal centers are doubly bridged by two double EE dicyanamides. One triazine and two pyridine nitrogens of the multidentate heterocyclic ligand, TPT, coordinate to each of the two metal centers and hence block three coordination positions. Between the Mn–N(TPT) and Mn–N(dca) bond distances (2.235(2)–2.316(2) Å and 2.134(3)–2.181(2) Å, respectively), the former is significantly larger. Such differences in bond lengths have been observed previously in related compounds of manganese(II) [2a–c,4a,5a,5b]. The stereochemistry of the metal ion, due to the rigidity of the donor environment of TPT, deviates appreciably from ideal octahedron. In addition to the differences in the metal–ligand bond distances, the *transoid* angles (140.27(7)°, 167.17(10)°, and 172.97(9)°) and the wide range of *cisoid* angles (70.04(7)–118.29(11)°) are indicative of significant distortion of the coordination environment. While the deviations of the metal ion and the donor centers from the least-squares planes N(2)N(7)N(9)O(1) and N(1)N(2)N(3)N(9), the latter of which is a better square plane, are not very high (<0.08 Å), practically no plane is defined by N(1), N(3), N(7), and O(1) (deviations > 0.4 Å) which is indicative of significant distortion. All the bond distances and bond angles (Table 3) of the dicyanamide are within the usual ranges and are indicative of the pseudo C_{2v} symmetry. One end of the crystallographically equivalent dicyanamide is bonded almost linearly (Mn–N(9)–C(20) = 170.8(3)°), while the other end coordinates in a significantly bent way (Mn–N(7)–C(19) = 142.5(2)°).

3.3. Magnetic properties

Variable-temperature (5–300 K) magnetic behaviors at fixed field strength of 1 T of the two complexes are shown in Fig. 4 in the form of $\chi_M T$ versus T plots. For **1**, the $\chi_M T$ value at 300 K is 4.37 $cm^3\ mol^{-1}$ K, which is equal to the spin-only $\chi_M T$ value of high spin Mn^{II}. The $\chi_M T$ value (8.67 $cm^3\ mol^{-1}$ K) of **2** at 300 K is also practically equal to the theoretical value (8.75 $cm^3\ mol^{-1}$ K) for two non-correlated spins of $S_1 = 5/2$ and $S_2 = 5/2$. On lowering the temperatures, $\chi_M T$ values of both the complexes remain almost constant to ~50 K and then decrease rapidly to 5 K where the $\chi_M T$ values are 2.51 and 4.63 $cm^3\ mol^{-1}$ K for **1** and **2**, respectively. The profiles indicate the existence of a very weak antiferromagnetic interaction in both complexes. It may be mentioned that consistent data of magnetic susceptibilities of **1** and **2** are obtained with the samples from different preparations using the same method as described in Section 2.

Currently, no theoretical model exists to analyze the magnetic data of one-dimensional ladder compounds containing $S = 5/2$ ions. However, the system can be modelled as single EE dca bridged infinite chains that are subjected to interchain interactions through the double EE dicyanamides. In that case, the compound can be analyzed with Eq. (1), where $\chi_{1\text{-D}}$ represents the susceptibilities of infinite chain compounds [16] and zJ' implies, in molecular field approximation, the exchange interaction mediated through the double EE dicyanamides.

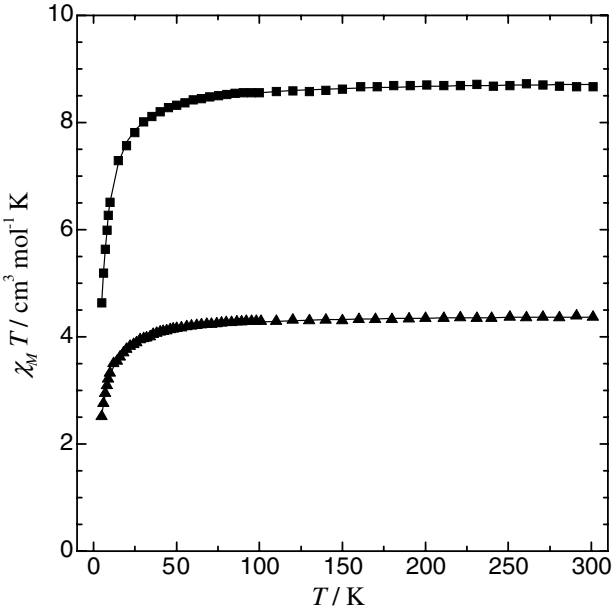

Fig. 4. Experimental (▲ for **1** and ■ for **2**) and calculated (——) $\chi_M T$ vs. T plots for **1** and **2**.

$$\chi_M = \frac{\chi_{1\text{-D}}}{1 - 2zJ'\chi_{1\text{-D}}/N\beta^2 g^2}, \tag{1}$$

where

$$\chi_{1\text{-D}} = \frac{N\beta^2 g^2 S(S+1)}{3kT}\,\frac{1+u}{1-u}$$

with

$$u = \coth\frac{2JS(S+1)}{kT} - \frac{kT}{2JS(S+1)}.$$

Taking the g value fixed at 2.0, least-squares fitting of the susceptibility data with Eq. (1) leads to an excellent simulation (Fig. 4) with $J = -0.12$ cm^{-1} and $zJ' = -0.13$ cm^{-1}; the agreement factor (R), defined as $[\sum\{(\chi_M T)_{obs} - (\chi_M T)_{calc}\}^2/\sum\{(\chi_M T)_{obs}\}^2]$, being 4.23×10^{-3}. Now, excluding single EE bridged centers, the number (z) of neighboring metal ions around a manganese(II) center is 1. Therefore, the value of J' becomes -0.13 cm^{-1}. Hence, the magnitudes (-0.12 and -0.13 cm^{-1}) of antiferromagnetic coupling through the single EE dca and double EE dca can be considered as almost equal. For the dinuclear complex **2**, the susceptibility data are well fitted (Fig. 4) with the theoretical equation derived from the Hamiltonian $\mathbf{H} = -2J\mathbf{S}_1 \cdot \mathbf{S}_2$. In this case, global minimization takes place with $J = -0.31$ cm^{-1}, $g = 2.0$ (fixed), and $R = 2.91 \times 10^{-3}$.

The susceptibility data of the double chain compound **1** can also be well fitted with the dinuclear model ($\mathbf{H} = -2J\mathbf{S}_1 \cdot \mathbf{S}_2$) converging with $J = -0.3$ cm^{-1}, $g = 2.0$ (fixed), and $R = 8.43 \times 10^{-3}$. Evidently, average J values for the two routes have been considered here. Again, consideration of the dinuclear model with molecular field

approximation results in global minimization with $J = -0.24\ \mathrm{cm}^{-1}$, $zJ' = -0.05\ \mathrm{cm}^{-1}$, $g = 2.0$ (fixed), and $R = 6.84 \times 10^{-3}$. Simulation of the experimental data of **1** with the three models mentioned above reveals that the J value of the double chain compound lies in the range -0.05 to $-0.24\ \mathrm{cm}^{-1}$. It may be noted that the observation of only a weak antiferromagnetic interaction in both compounds **1** and **2** is consistent with the magnetic properties of the previously reported examples of dicyanamide bridged manganese(II) compounds [2a–c,4a,5a,5b].

involve a room temperature dehydroxylation of the HAS_A form. We proposed that further substitution of $Si(OH)_4$ into HAS_A was driving the dehydroxylation [8] and it is this proposition that is tested further in the current research. We have used a combination of solution and solid-state structural techniques to provide evidence that the formation HAS_A is a prerequisite to the formation of HAS_B.

2. Experimental

2.1. Preparation of solutions

All reagents used were of the highest purity available. Solutions which included a wide range of concentrations of $Si(OH)_4$ (25–2000 μmol/L) applied across three molar ratios (0.5, 1.0, 2.0) of $Si(OH)_4$ to Al were prepared in PTFE phials and containers (Cowie Technology Ltd., UK) using ultrapure water (conductivity < 0.067 μS/cm, Elga UK) which included 100 mmol/L KNO_3 as background electrolyte and which were buffered at pH 6.0 with 25 mmol/L PIPES (piperazine-*N*,*N*′-bis-2-ethanesulphonic acid). Stock solutions of $Si(OH)_4$, up to a maximum concentration of 2.0 mmol/L, were prepared by cation exchange of Na_4SiO_4 and either diluted as required or used in the place of ultrapure water. Al was added from a freshly prepared 1 mol/L stock of $Al(NO_3)_3 \cdot 9H_2O$ in 1% HNO_3. An established method was used for the preparation of all HAS solutions [5] and all solutions were incubated at 20 °C for the requisite time period prior to sampling.

The precipitation experiments (see Fig. 1) involved the preparation of 20 mL volumes of 5 replicates of 21 different combinations of $Si(OH)_4$ and Al. These were aged for 24 h and then filtered through 0.1 μm polyvinylidene fluoride membrane filters (Durapore). For the ageing study (see Fig. 2) 100 mL volumes of 5 replicates of 4 preparations which included 800 μmol/L Al and either 800, 1100, 1500 or 2000 μmol/L $Si(OH)_4$ were aged for up to 500 h. These solutions were periodically sampled and filtered using syringe filters (Millipore) which incorporated the same 0.1 μm polyvinylidene fluoride membrane filters (Durapore). Analagous solutions of larger volume, 500 mL, were run in parallel and, following ageing for typically, 12, 72, 168 or 336 h, were filtered (0.1 μm membrane filtration) to collect significant quantities (>200 mg) of precipitate for subsequent solid-state analyses. For all studies, post-filtration [$Si(OH)_4$] were measured spectrophotometrically (λ_{max} 810 nm) as the reduced blue-molybdosilicic acid complex [9] and post-filtration [Al] by graphite furnace atomic absorption spectrometry (GFAAS) using a method developed in our laboratory [10].

2.2. Solid-state analyses

Solid phases collected by membrane filtration were dried to a constant weight at 37 °C and thereafter gently ground to a fine powder using an agate mortar and pestle. The elemental composition, structural identity and thermal chemistry of each of the solid phases were determined by electron microprobe analysis, solid-state NMR and thermogravimetric analysis, respectively, using methods which have been described in detail in recent publications [8,11].

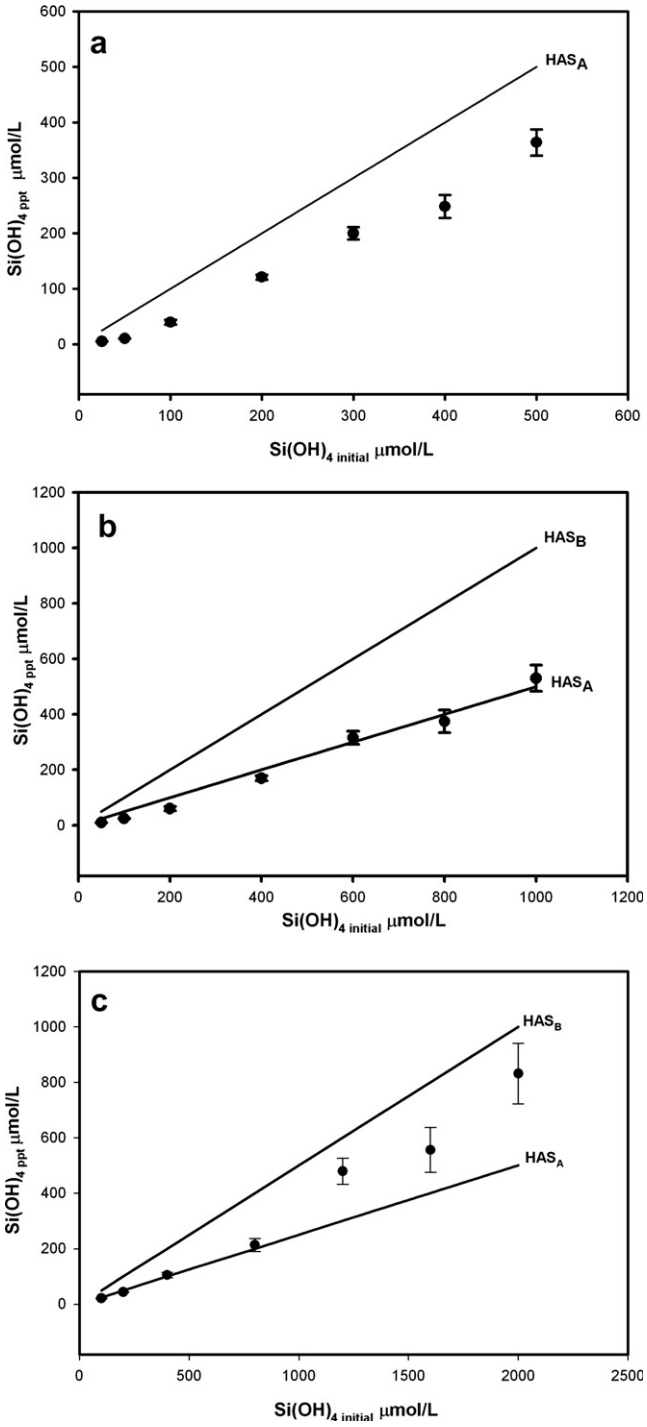

Fig. 1. The precipitation of $Si(OH)_4$ from solutions ($Si(OH)_{4\ ppt}$) in which the initial ratio of $Si(OH)_4$ to Al was (a) 1:2; (b) 1:1; (c) 2:1. Mean and SD are plotted, $n = 5$. Solid lines indicate the theoretical precipitation of $Si(OH)_4$ if all of the available Al were precipitated by the formation of HAS_A (a) and HAS_A or HAS_B (b,c).

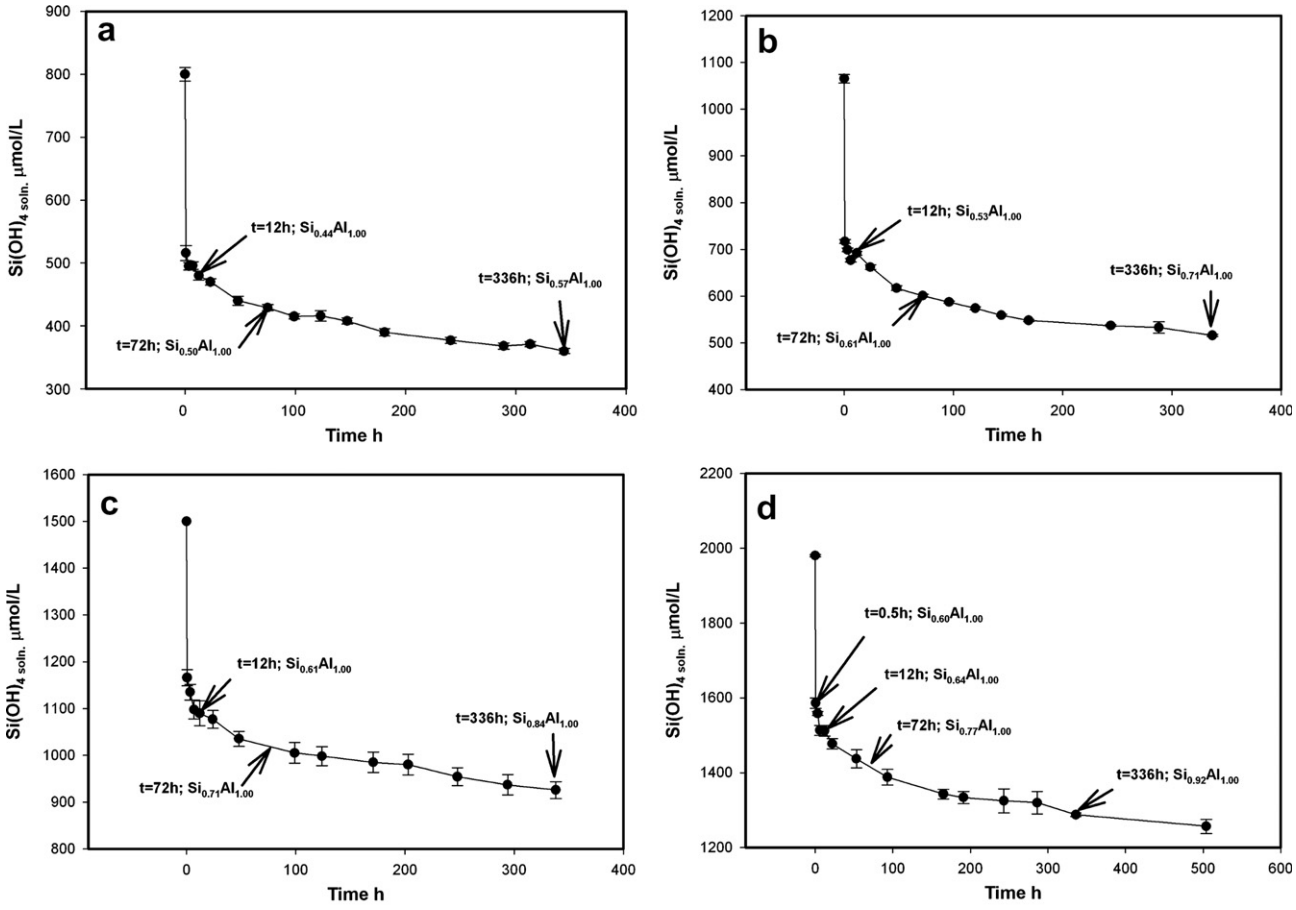

Fig. 2. The concentration of $Si(OH)_4$ remaining in solution ($Si(OH)_{4soln.}$) following the reaction of (a) 800; (b) 1100; (c) 1500; (d) 2000 μmol/L $Si(OH)_4$ with 800 μmol/L Al and ageing of the solutions at 20 °C for up to 500 h. Mean and SD are plotted, $n = 5$. The arrows indicate the times at which solid phases were collected and their relative contents of Si and Al determined by electron probe microanalysis.

3. Results

3.1. Precipitation of $Si(OH)_4$ by Al

$Si(OH)_4$ was precipitated within the 24 h period of ageing under each of the solution conditions which ranged from ca 25 μmol/L $Si(OH)_4$/50 μmol/L Al to ca 2000 μmol/L $Si(OH)_4$/1000 μmol/L Al. The proportion of available $Si(OH)_4$ precipitated in the former was ca 20% whereas this increased up to ca 100% in the latter. There was no Al post-filtration for any of the initial combinations of $Si(OH)_4$ and Al. When these filtration data were expressed according to the theoretical composition of the solid phase formed (i.e. either HAS_A or HAS_B) it was clear that the probable composition of precipitate depended upon the initial solution concentrations of $Si(OH)_4$ and Al and their ratio (Fig. 1). Thus for $Si(OH)_4$:Al ratios of 0.5 and 1.0 the filtration data predicted the formation of HAS_A whereas for a ratio of 2.0 the data predicted the formation of HAS_A at lower total concentrations (<1000 μmol/L $Si(OH)_4$) and HAS_B, or a mixture of HAS_A and HAS_B, at higher total concentrations (1000–2000 μmol/L $Si(OH)_4$) (Fig. 1).

3.2. Influence of ageing on the precipitation of $Si(OH)_4$ and the nature of the solid phase formed

Four different solution compositions were investigated over an ageing period up to 500 h (Fig. 2). The compositions were chosen to reflect a range of $Si(OH)_4$ to Al ratios over which the formation of either HAS_A or HAS_B was predicted [7].

3.2.1. 800 μmol/L $Si(OH)_4$:800 μmol/L Al

The $[Si(OH)_4]$ was rapidly reduced to ca 500 μmol/L within only 0.5 h ageing and thereafter continued to fall steadily before approaching a plateau $[Si(OH)_4]$ of ca 370 μmol/L after approximately 300 h ageing (Fig. 2a). There was no Al post-filtration and so ca 800 μmol/L Al resulted in the co-precipitation of ca 400 μmol/L $Si(OH)_4$ within 300–336 h. The Si:Al ratio of solid phases collected after 12 ($Si_{0.44}Al_{1.00}$), 72 ($Si_{0.50}Al_{1.00}$) and 336 h ($Si_{0.57}Al_{1.00}$) increased with ageing of solutions and mirrored the slow reductions in $[Si(OH)_4]_{soln.}$. Investigation of these three solid phases by TGA revealed a sharp exotherm at 191 °C at 12 h (Fig. 3) which was absent at 72 and 336 h. Each of

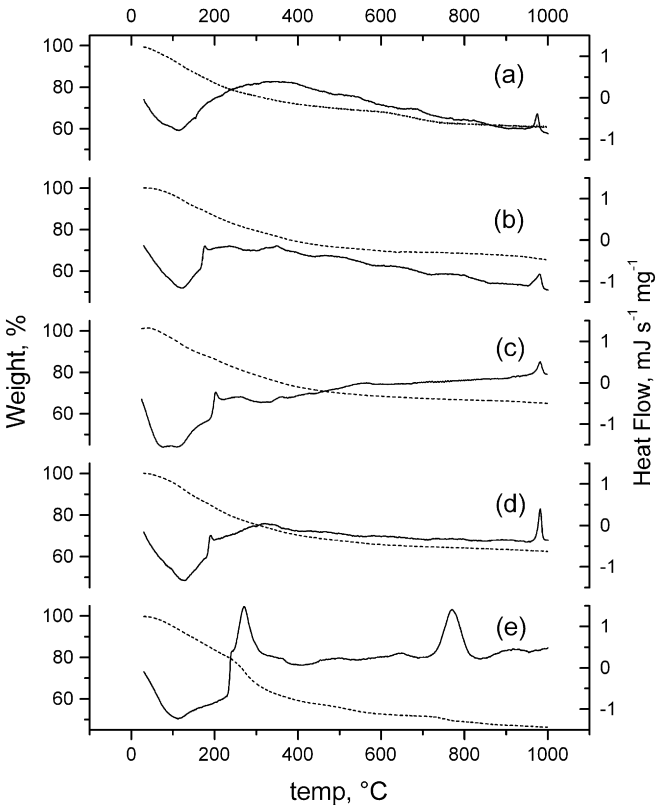

Fig. 3. Representative TGA–DSC plots of solid phases collected after 12 h ageing at 20 °C from PIPES-buffered solutions containing (a) 2000 μmol/L $Si(OH)_4$ and 800 μmol/L Al; (b) 1500 μmol/L $Si(OH)_4$ and 800 μmol/L Al; (c) 1100 μmol/L $Si(OH)_4$ and 800 μmol/L Al; (d) 800 μmol/L $Si(OH)_4$ and 800 μmol/L Al; (e) 800 μmol/L Al. Heat flows are indicated by solid lines and weight losses by dashed lines.

the solid phases revealed an endotherm at 115–120 °C and a sharp exotherm at ca 980 °C.

3.2.2. 1100 μmol/L $Si(OH)_4$:800 μmol/L Al

The initial $[Si(OH)_4]$ was rapidly reduced to ca 700 μmol/L within 0.5 h and continued to fall to ca 500 μmol/L after ageing for 336 h (Fig. 2b). There was no Al post-filtration and ca 800 μmol/L Al co-precipitated ca 400 μmol/L $Si(OH)_4$ within 0.5 h and 600 μmol/L $Si(OH)_4$ after 336 h. The Si:Al ratios of solid phases collected after 12 ($Si_{0.53}Al_{1.00}$), 72 ($Si_{0.61}Al_{1.00}$) and 336 h ($Si_{0.71}Al_{1.00}$) increased with ageing and again mirrored the reductions in $[Si(OH)_4]_{soln.}$. TGA of solid phases revealed a sharp exothermic peak at 204 °C in the precipitate collected after 12 h ageing (Fig. 3) which was not present in precipitates collected after 24, 72, 168 and 336 h. Each of the solid phases revealed an endotherm at 115–120 °C and a sharp exotherm at ca 980 °C.

3.2.3. 1500 μmol/L $Si(OH)_4$:800 μmol/L Al

The initial $[Si(OH)_4]$ was rapidly reduced to ca 1100 μmol/L within 0.5 h and thereafter fell less quickly and reached a plateau $[Si(OH)_4]$ of ca 930 μmol/L after 336 h (Fig. 2c). There was no Al post-filtration and ca 800 μmol/L Al co-precipitated ca 400 μmol/L $Si(OH)_4$ within 0.5 h and 600 μmol/L $Si(OH)_4$ after 336 h. The Si:Al ratios of solid phases collected after 12 ($Si_{0.61}Al_{1.00}$), 72 ($Si_{0.71}Al_{1.00}$) and 336 h ($Si_{0.84}Al_{1.00}$) increased with ageing and reflected the continued precipitation of $Si(OH)_4$ from the solutions. TGA of solid phases showed a small exotherm at 176 °C for the solid collected after 12 h (Fig. 3) which was not evident after 72 or 336 h. All three solid phases indicated endotherms at 115–120 °C and sharp exotherms at ca 980 °C.

3.2.4. 2000 μmol/L $Si(OH)_4$:800 μmol/L Al

The initial $[Si(OH)_4]$ was rapidly reduced to ca 1600 μmol/L within 0.5 h and continued to fall to ca 1300 μmol/L after more than 500 h ageing (Fig. 2d). There was no Al post-filtration and ca 800 μmol/L Al co-precipitated ca 400 μmol/L $Si(OH)_4$ within 0.5 h and ca 700 μmol/L $Si(OH)_4$ after 500 h. These changes in $[Si(OH)_4]_{soln.}$ were mirrored by increased Si:Al ratios of solid phases collected after 0.5 ($Si_{0.60}Al_{1.00}$), 12 ($Si_{0.64}Al_{1.00}$), 72 ($Si_{0.77}Al_{1.00}$) and 336 h ($Si_{0.92}Al_{1.00}$). TGA spectra for solid phases collected after 12, (Fig. 3) 72 and 336 h were identical and showed an endotherm at 115–120 °C and a sharp exotherm at ca 980 °C. Solid-state ^{27}Al MAS NMR of solid phases collected after 0.5, 72 and 336 h revealed two discrete shifts at 1.25 (Al^{VI}) and 55 (Al^{IV}) ppm and that the proportion of Al^{IV} to Al^{VI} increased with the age of the solid phase (Fig. 4a). Solid-state ^{29}Si MAS NMR (Fig. 4b) indicated a single shift, the peak of which increased from −83 to −89 ppm with increased age of the solid phase, which was generally indicative of Si in the vicinity of 1-2Al (Q^3(1-2Al)).

4. Discussion

The formation of HAS and their subsequent nucleation and growth towards aggregates which could be collected by 0.1 μm membrane filtration occurred in all combinations of concentrations of $Si(OH)_4$ and Al. For some of the combinations the precipitation cascade was sufficiently rapid to enable solid phases to be collected within only 0.5 h ageing. The experiments in which different combinations of initial concentration of $Si(OH)_4$ and ratio's of $Si(OH)_4$ to Al were aged for only 24 h appeared to demonstrate that within this time period the nature of the precipitate formed was finely balanced between three possible idealised forms;

$$Al(OH)_{3(s)} \leftrightarrow HAS_A \leftrightarrow HAS_B$$

In solutions in which the initial ratio of $Si(OH)_4$ to Al was 0.5 (the stoichiometry of HAS_A) the amount of $Si(OH)_4$ which was precipitated from solution was always less than would be expected if HAS_A was the only product (Fig. 1a). Post-filtration analyses of [Al] in each combination of initial $[Si(OH)_4]$ and $Si(OH)_4$ to Al ratio indicated that ca 100% of the available Al was co-precipitated and thus the solid phases formed for $Si(OH)_4$ to Al ratios of 0.5 must have included both $Al(OH)_{3(s)}$ and HAS_A. This indicated

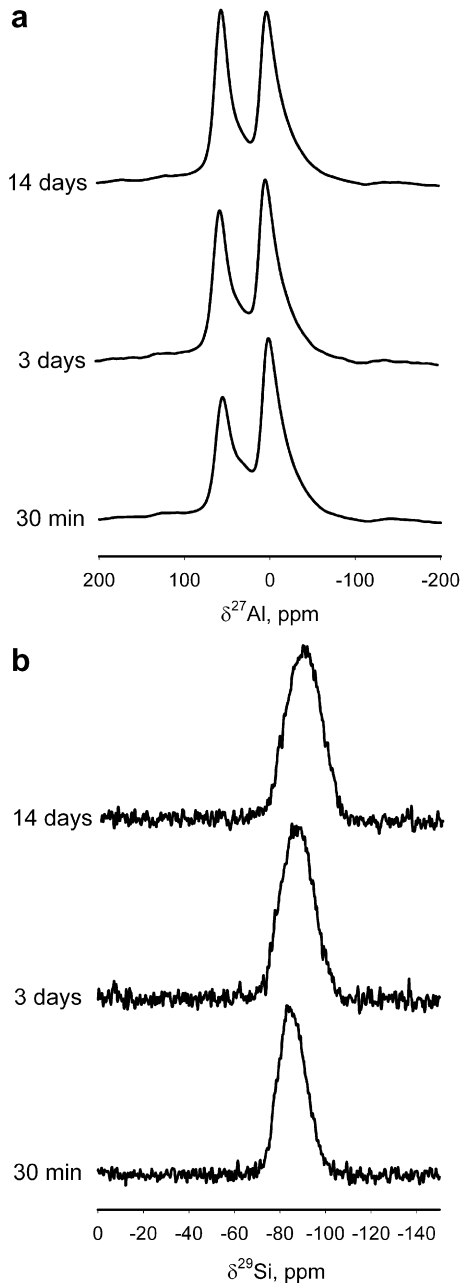

Fig. 4. Representative (a) ^{27}Al and (b) ^{29}Si NMR spectra of solid phases collected after 0.5, 72 and 336 h ageing at 20 °C from PIPES-buffered solutions containing 2000 μmol/L $Si(OH)_4$ and 800 μmol/L Al.

that while HAS_A was rapidly formed something prevented all of the theoretically possible $Si(OH)_4$ being incorporated into this phase within the 24 h period of ageing. The results of the precipitation experiments in which the initial ratio of $Si(OH)_4$ to Al was 1.0 (the stoichiometry of HAS_B) suggested that the 'something' was the residual $[Si(OH)_4]$ which followed the initial rapid formation of HAS_A (Fig. 1b). In these experiments the amount of $Si(OH)_4$ which was co-precipitated was in each case equivalent to what would have been expected from the formation of HAS_A (Fig. 1b). Thus HAS_A was the dominant solid phase formed under these conditions and the higher residual $[Si(OH)_4]$ which was due to the initial $Si(OH)_4$ to Al ratio of 1.0 was critical in ensuring that all of the available Al was incorporated into HAS_A. For example, if we compare the efficacy with which 800 μmol/L Al precipitated $Si(OH)_4$ in solutions in which the initial $Si(OH)_4$ to Al ratio was either 0.5 (Fig. 1a) or 1.0 (Fig. 1b) we find that 248.4 ± 20.9 μmol/L of $Si(OH)_4$ were precipitated in the former (ca 150 μmol/L $Si(OH)_4$ remained in solution) whereas 374.7 ± 40.8 μmol/L $Si(OH)_4$ were precipitated in the latter (ca 425 μmol/L $Si(OH)_4$ remained in solution). These results have demonstrated that for initial solution conditions of 800 μmol/L Al and 400 μmol/L $Si(OH)_4$ while HAS_A was the predominant solid phase formed the reaction was prevented from reaching completion (i.e. all $Al(OH)_{3(s)}$/$Si(OH)_4$ precipitated as HAS_A) by a limiting residual $[Si(OH)_4]$. However, when the initial $[Si(OH)_4]$ was 800 μmol/L the additional residual $Si(OH)_4$ ensured that all available $Al(OH)_{3(s)}$ reacted with $Si(OH)_4$ to give a solid phase consisting of ca pure HAS_A. By logical extension, an initial $Si(OH)_4$ to Al ratio of 1.0 should, theoretically, have been sufficient to allow the formation of HAS_B and yet there was little evidence that HAS_B was formed in these solutions during 24 h ageing (Fig. 1b). Thus while the residual $[Si(OH)_4]$ promoted the formation of HAS_A it was not sufficient to support the subsequent formation of HAS_B through the reaction of $Si(OH)_4$ with HAS_A. In these 24 h ageing experiments evidence for the formation of HAS_B was only obtained from those solutions in which the initial $Si(OH)_4$ to Al ratio was 2.0 (Fig. 1c). However, it was not simply the ratio of $Si(OH)_4$ to Al that was important since the evidence for the formation of HAS_B only became clear at initial $[Si(OH)_4] \geqslant 1200$ μmol/L (Fig. 1c). The results of the 24 h precipitation experiments appeared to suggest that the formation of HAS was dependent upon the combination of both the initial $[Si(OH)_4]$ and the $Si(OH)_4$ to Al ratio. In addition they afforded strong evidence that the formation of HAS_A was a prerequisite to the formation of HAS_B.

When the formation of HAS in solutions including 800 μmol/L Al and 800, 1100, 1500 or 2000 μmol/L $Si(OH)_4$ were investigated over time we found further evidence that HAS_A was a prerequisite to the formation of HAS_B. It was remarkable that in each of these conditions the initial $[Si(OH)_4]$ was reduced by ca 400 μmol/L within the first 0.5 h (Fig. 2a–d). This strongly suggested that regardless of the initial solution conditions the first step in the precipitation of HAS (or the co-precipitation of $Si(OH)_4$ by Al) was the formation of HAS_A. Electron microprobe analyses of the stoichiometries of the solid phases confirmed that HAS_A was the predominant solid phase formed during the first 12 h in solutions which included 800 μmol/L Al and 800, 1100 or 1500 μmol/L $Si(OH)_4$. Thereafter, ageing of solutions resulted in the further precipitation of $Si(OH)_4$ and its concomitant incorporation into solid phases such that after 336 h there was clear evidence of the formation of HAS_B in those solutions in which $Si(OH)_4$ had initially been present to excess

(Fig. 2b–d). The formation of HAS_B appeared to be most rapid in the presence of the greatest excess of $Si(OH)_4$ (Fig. 2d) and analyses of solid phases collected after only 0.5 h confirmed its presence in these rapidly formed precipitates. Solid-state ^{27}Al NMR indicated the presence of Al^{VI} and a significant component of Al^{IV} the latter only being found in HAS_B [7]. In addition solid-state ^{29}Si NMR did not indicate a significant shift at −78 ppm ($Q^3(3Al)$) which would normally be indicative of HAS_A [7]. The results of the NMR did not tally well with those of filtration (only 400 μmol/L $Si(OH)_4$ was co-precipitated at this time) or the electron microprobe as the Si:Al ratio of the solid phase collected after only 0.5 h was 0.60 and would normally be indicative of a phase composed primarily of HAS_A with, perhaps, some HAS_B. TGA of solid phases collected at 12h included exotherms in the region ca 175–200 °C for all conditions except that with the highest excess of $Si(OH)_4$ (Fig. 3). Exotherms in this temperature region have not hitherto been observed for solid phases collected from solutions with initial $Si(OH)_4$ to Al ratio's of $\geqslant 1.0$ [11]. However, the exotherms were not evident in solid phases collected from solutions after more than 12 h ageing. The initial presence and thereafter absence of exotherms in aged precipitates, including those collected from solutions which contained equimolar [$Si(OH)_4$] and [Al] and were likely to be composed of almost exclusively HAS_A, strongly suggested that the exothermic peaks were not characteristic of HAS_A but indicative of contaminating amounts of $Al(OH)_{3(s)}$. The latter being absent in precipitates collected from solutions with the highest excess of $Si(OH)_4$ and in precipitates collected from solutions after more than 12 h ageing.

We have investigated the mechanism of formation of HAS and provided further evidence of equilibria between $Al(OH)_{3(s)}$, HAS_A and HAS_B and, in particular, the role of $Si(OH)_4$ in determining which of these solid phases will predominate for any given solution conditions. We have shown that HAS_A is formed rapidly in solutions which include stoichiometric concentrations of $Si(OH)_4$ and Al (i.e. 1:2) though the reaction does not approach completion (i.e. Si:Al ratio of 0.5 in solid phase) in the absence of an excess of $Si(OH)_4$ in the 'equilibrated' solution (i.e. initial solution conditions of 1:1). We have observed that HAS_A was the likely initial product of the reaction of $Al(OH)_{3(s)}$ with $Si(OH)_4$ even in solutions in which $Si(OH)_4$ was present to significant excess and this supported the contention that HAS_A was the necessary precursor to HAS_B. The latter was not fully supported by the ^{29}Si NMR of the precipitate collected after only 0.5 h from solutions containing 2000 μmol/L $Si(OH)_4$ and 800 μmol/L Al since we did not observe a significant HAS_A-characteristic shift at −78 ppm. Future research on similar freshly precipitated solid phases should help to resolve this conundrum.

Finally TGA of the solid phases confirmed what we had believed to be true in our earlier study [11] that exotherms in the temperature region ca 175–300 °C were not characteristic of HAS_A but were actually indicative of the presence of residual $Al(OH)_{3(s)}$. In relation to the latter, we have investigated the thermal chemistry of $Al(OH)_{3(s)}$ prepared in the presence of PIPES and collected after only 12 h ageing. This solid phase was prepared as a control for the HAS phases. We observed two significant exotherms (Fig. 3e) one at ca 271 °C, similar to that seen previously [11] and a second at ca 771 °C which has not hitherto been observed. Remnants of the former were observed in several of the other solid phases collected after only 12 h (Fig. 3b–d) whereas the latter exotherm was absent from these precipitates. The significance of these exothermic peaks to the structure of $Al(OH)_{3(s)}$ formed in the presence of a pH buffer remain to be determined.

Acknowledgements

This research was funded by NERC. D.C. Apperley is thanked for all his help with the solid-state NMR which were obtained through the EPSRC solid-state NMR service at Durham. D. Plant is thanked for electron microprobe analyses which were carried out at the Electron Microprobe Facility at Manchester.

(**7**); *n*-Bu (**8**))] were obtained by reaction of di- and trialkyltin with 2,4,5-trifluoro-3-methoxybenzoic acid. All the complexes were characterized by elemental, IR, ^{1}H and ^{13}C NMR spectra analyses. Among them, complexes **1**, **3**, **7** and **8** are also characterized by X-ray crystallography diffraction analyses.

2. Experimental

2.1. Materials and measurements

Triphenyltin chloride, trimethyltin chloride, tri-*n*-butyltin chloride, dimethyltin dichloride, di-*n*-butyltin dichloride, diphenyltin dichloride and 2,4,5-trifluoro-3-methoxybenzoic acid were commercially available, and they were used without further purification. Dibenzyltin dichloride and tribenzyltin chloride were prepared by a standard method reported in the literature [12]. The melting points were obtained on a Kofler micro melting point apparatus and are uncorrected. Infrared-spectra were recorded on a Nicolet-460 spectrophotometer using KBr discs and sodium chloride optics. ^{1}H and ^{13}C NMR spectra were obtained on a Varian Mercury Plus 400 MHz NMR spectrometer. The chemical shifts are reported in ppm with respect to the references and are stated relative to external tetramethylsilane (TMS) for ^{1}H and ^{13}C NMR. Elemental analyses were performed with a PE-2400 II elemental apparatus.

2.2. Syntheses of the complex *1*–*8*

2.2.1. $[Ph_3SnO_2CC_6HF_3OCH_3]$ (*1*)

Under a dry nitrogen atmosphere, 2,4,5-trifluoro-3-methoxybenzoic acid (0.206 g, 1.0 mmol) and sodium ethoxide (0.068 g, 1.0 mmol) were added in benzene (20 ml) to a Schlenk flask and stirred for about 10 min, then triphenyltin chloride (0.385 g, 1.0 mmol) was added to the mixture. The stirring was continued for 12 h at 40 °C and then the solution was filtered. The filtrate was gradually evaporated until a solid product was obtained. The solid was recrystallized from ether–petroleum and a transparent colorless crystal of complex **1** was formed. Yield: 88%; m.p. 109–110. °C. *Anal.* Calc. for $C_{26}H_{19}F_3O_3Sn$: C, 56.25; H, 3.45. Found: C, 56.49; H, 3.34%. IR (KBr, cm^{-1}): ν_{as}(C=O) 1582, ν_s(C–O)1380, ν_{as}(Sn–C) 564, ν_s(Sn–C) 523, ν(Sn–O) 484. ^{1}H NMR ($CDCl_3$, ppm): δ 7.26–7.52 (m, 1H, $C_6HF_3OCH_3$), 7.49–7.80 (m, 15H, Sn–C_6H_5), 4.02 (s, 3H, OCH_3). ^{13}C NMR ($CDCl_3$, ppm): δ 168.24 (COO), 113.45, 129.00, 129.32, 129.64, 129.62, 130.61, 130.68, 130.75, 136.92, 137.16, 137.40, 137.80 (Ar–C), 62.36 (OCH_3).

2.2.2. $[(PhCH_2)_3SnO_2CC_6HF_3OCH_3]$ (*2*)

The procedure is similar to that of complex **1**. 2,4,5-Trifluoro-3-methoxybenzoic acid (0.206 g, 1.0 mmol), sodium ethoxide (0.068 g, 1.0 mmol) and tribenzyltin chloride (0.427 g, 1.0 mmol) were reacted for 12 h at 40 °C. Recrystallized from ether–petroleum, a transparent colorless crystal was formed. Yield: 77%; m.p. 123–125 °C. *Anal.* Calc. for $C_{29}H_{25}F_3O_3Sn$: C, 58.32; H, 4.22. Found: C, 58.72; H, 4.31%. IR (KBr, cm^{-1}): ν_{as}(C=O), 1590 ν_s(C–O) 1381, ν_{as}(Sn–C) 560, ν_s(Sn–C) 518, ν(Sn–O) 479. ^{1}H NMR ($CDCl_3$, ppm): δ 7.31–7.81 (m, 1H, $C_6HF_3OCH_3$), 7.23–7.52 (m, 15H, Sn–$CH_2C_6H_5$), 3.16 (s, 6H, Sn–$CH_2C_6H_5$), 4.03 (s, 3H, OCH_3). ^{13}C NMR ($CDCl_3$, ppm): δ 32.5 ($ArCH_2$), 112.85, 112.92, 129.76, 128.88, 129.15, 129.37, 130.29, 130.35, 136.74, 136.90, 137.20, 137.32 (Ar–C), 168.25(COO), 62.35 (OCH_3).

2.2.3. $[Me_3SnO_2CC_6HF_3OCH_3]$ (*3*)

The procedure is similar to that of complex **1**. 2,4,5-Trifluoro-3-methoxybenzoic acid (0.206 g, 1.0 mmol), sodium ethoxide (0.068 g, 1.0 mmol) and trimethyltin chloride (0.199 g, 1.0 mmol) were reacted for 12 h at 40 °C. Recrystallized from ether–petroleum, a transparent colorless crystal was formed. Yield: 87%; m.p. 104–106 °C. *Anal.* Calc. for $C_{11}H_{13}F_3O_3Sn$: C, 35.81; H, 3.55. Found: C, 35.80; H, 3.73. IR (KBr, cm^{-1}): ν_{as}(C=O) 1589, ν_s(C–O) 1372, ν_{as}(Sn–C) 555, ν_s(Sn–C) 530, ν(Sn–O) 488. ^{1}H NMR ($CDCl_3$, ppm): δ 7.25–7.80 (m, 1H, $C_6HF_3OCH_3$), 0.60–0.87 (m, 9H), 4.03 (s, 3H, OCH_3) ppm. ^{13}C NMR ($CDCl_3$, ppm): δ 167.46 (COO), 114.87, 138.75, 145.65, 148.02, 148.34, 152.35 (Ar–C), 62.36 (OCH_3), 14.27 (–CH_3).

2.2.4. $[n\text{-}Bu_3SnO_2CC_6HF_3OCH_3]$ (*4*)

The procedure is similar to that of complex **1**. 2,4,5-Trifluoro-3-methoxybenzoic acid (0.206 g, 1.0 mmol), sodium ethoxide (0.068 g, 1.0 mmol) and tri-*n*-butyltin (0.325 g, 1.0 mmol) were reacted for 12 h at 40 °C. Recrystallized from ether–petroleum, a transparent colorless crystal was formed. Yield: 78%. m.p. 163–165 °C; *Anal.* Calc. for $C_{20}H_{31}F_3O_3Sn$: C, 48.51; H, 6.31. Found: C, 48.71; H, 6.18%. IR (KBr, cm^{-1}): ν_{as}(C=O) 1586, ν_s(C–O) 1380, ν_{as}(Sn–C) 561, ν_s(Sn–C) 527, ν(Sn–O) 482. ^{1}H NMR ($CDCl_3$, ppm): δ 7.26–7.75 (m, 1H, $C_6HF_3OCH_3$), 0.83–1.54 (m, 27H, Sn–C_4H_9), 4.04 (s, 3H, OCH_3). ^{13}C NMR ($CDCl_3$, ppm): δ 167.46 (COO), 113.00, 138.68, 145.46, 145.85, 147.91, 148.02, 153.67 (Ar–C), 62.36 (OCH_3), 22.83, 31.773, 45.57 (–CH_2–), 14.27 (CH_3).

2.2.5. $[Ph_2Sn(O_2CC_6HF_3OCH_3)_2]$ (*5*)

The procedure is similar to that of complex **1**. 2,4,5-Trifluoro-3-methoxybenzoic acid (0.412 g, 2.0 mmol), sodium ethoxide (0.136 g, 2.0 mmol) and dimethyltin dichloride (0.219 g, 1.0 mmol) were reacted for 12 h at 40 °C. Recrystallized from ether–petroleum, a transparent colorless crystal was formed. Yield: 83%; m.p. 187–189 °C. *Anal.* Calc. for $C_{28}H_{18}F_6O_6Sn$: C, 49.23; H, 2.66. Found: C, 49.31; H, 2.86%. IR (KBr, cm^{-1}): ν_{as}(C=O) 1586, ν_s(C–O) 1378, ν_{as}(Sn–C) 559, ν_s(Sn–C) 525, ν(Sn–O) 488. ^{1}H NMR ($CDCl_3$, ppm): δ 7.15–7.72 (m, 12H, Sn–C_6H_5 and $C_6HF_3OCH_3$), 4.04 (s, 3H, OCH_3). ^{13}C NMR ($CDCl_3$, ppm): δ168.65 (COO), 112.42, 112.51, 129.56, 128.78, 129.35, 129.47, 130.49, 130.45, 136.64, 136.77, 137.40, 137.68 (Ar–C), 62.36 (OCH_3).

*2.2.6. [$(PhCH_2)_2Sn(O_2CC_6HF_3OCH_3)_2$] (**6**)*

The procedure is similar to that of complex **1**. 2,4,5-Trifluoro-3-methoxybenzoic acid (0.412 g, 2.0 mmol), sodium ethoxide (0.136 g, 2.0 mmol) and dibenzyltin dichloride (0.371 g, 1.0 mmol) were reacted for 12 h at 40 °C. Recrystallized from ether–petroleum, a transparent colorless crystal was formed. Yield: 85%; m.p. 192–194 °C. *Anal.* Calc. for $C_{30}H_{22}F_6O_6Sn$: C, 50.66; H, 3.12. Found: C, 50.45; H, 3.24%. IR (KBr, cm^{-1}): ν_{as}(C=O) 1589, ν_s(C–O) 1381, ν_{as}(Sn–C) 588, ν_s(Sn–C) 533, ν(Sn–O) 460. ^{1}H NMR ($CDCl_3$, ppm): δ 7.84–7.36 (m, 12H, $C_6HF_3OCH_3$ and $Sn–CH_2C_6H_5$), 3.29 (s, 4H, $Sn–CH_2C_6H_5$), 4.06 (s, 3H, OCH_3). ^{13}C NMR ($CDCl_3$, ppm): δ 168.05 (COO), 112.65, 112.32, 129.46, 128.58, 129.05, 129.17, 130.19, 130.15, 136.54, 136.70, 137.10, 137.22 (Ar–C), 32.6 ($ArCH_2$), 62.52 (OCH_3).

2.2.7. [$Me_2Sn(O_2CC_6HF_3OCH_3)_2$] (7)

The procedure is similar to that of complex **1**. 2,4,5-Trifluoro-3-methoxybenzoic acid (0.412 g, 2.0 mmol), sodium ethoxide (0.136 g, 2.0 mmol) and dibenzyltin dichloride (0.371 g, 1.0 mmol) were reacted for 12 h at 40 °C. Recrystallized from ether–petroleum, a transparent colorless crystal was formed. Yield: 85%; m.p. 192–194 °C. *Anal.* Calc. for $C_{18}H_{14}F_6O_6Sn$: C, 38.67; H, 2.52. Found: C, 38.65; H, 2.33%. IR (KBr, cm^{-1}): ν_{as}(C=O) 1587, ν_s(C–O)1379, ν_{as}(Sn–C) 586, ν_s(Sn–C) 532, ν(Sn–O) 461. ^{1}H NMR ($CDCl_3$, ppm): δ 7.26–7.60 (m, 2H, $C_6HF_3OCH_3$), 4.06 (s, 3H, OCH_3), 0.85–1.28 (m, 6H, $Sn–CH_3$). ^{13}C NMR ($CDCl_3$, ppm): δ 170.80 (COO), 113.29, 145.72, 147.10, 148.18, 149.53, 151.83 (Ar–C), 62.49 (OCH_3), 8.87 ($–CH_3$).

*2.2.8. [$n\text{-}Bu_2Sn(O_2CC_6HF_3OCH_3)_2$] (**8**)*

The procedure is similar to that of complex **1**. 2,4,5-Trifluoro-3-methoxybenzoic acid (0.412 g, 2.0 mmol), sodium ethoxide (0.136 g, 2.0 mmol) and di-*n*-butyltin dichloride (0.303 g, 1.0 mmol) were reacted for 12 h at 40 °C. Recrystallized from ether–petroleum, a transparent colorless crystal was formed. Yield: 80%; m.p. 117–119 °C. *Anal.* Calc. for $C_{24}H_{26}F_6O_6Sn$: C, 44.82; H, 4.07. Found: C, 45.0; H, 4.10%. IR (KBr, cm^{-1}): ν_{as}(C=O) 1579, ν_s(C–O)1373, ν_{as}(Sn–C) 586, ν_s(Sn–C) 537, ν(Sn–O) 462. ^{1}H NMR (CDCl, ppm): δ 7.27–7.62 (m, 2H, $Sn–C_6HF_3OCH_3$), 0.88–1.81 (m, 12H, $Sn–C_4H_9$), 4.06 (s, 3H, OCH_3). ^{13}C NMR ($CDCl_3$, ppm): δ 170.10 (COO), 113.19, 145.62, 146.87, 148.08, 149.33, 151.63 (Ar–C), 62.50 (OCH_3), 22.83, 31.75, 45.36 ($–CH_2–$), 14.28 (CH_3).

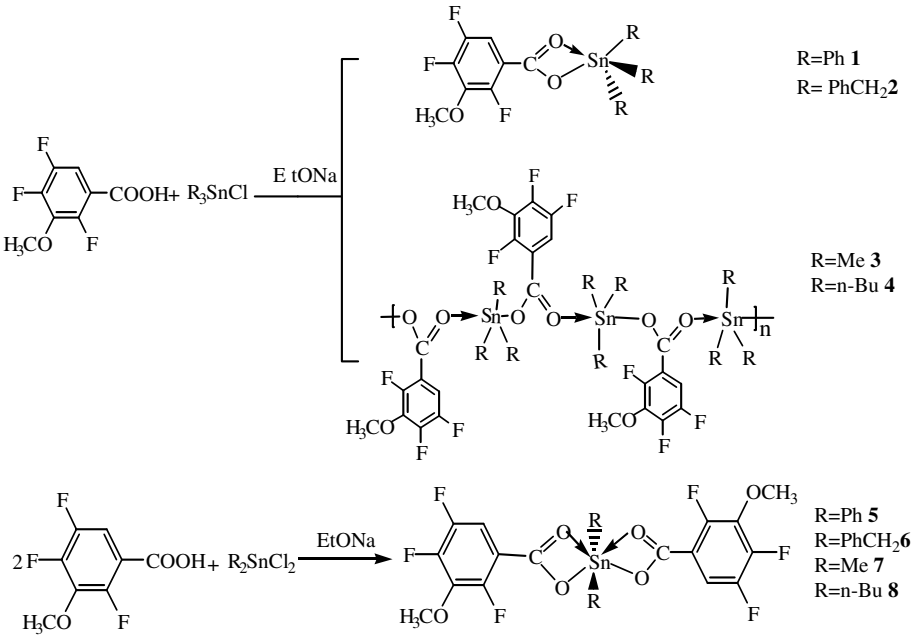
3. Results and discussion

3.1. Syntheses

The syntheses procedure is given in Scheme 1.

3.2. IR spectra

Comparing the IR spectra of the free ligand with complexes **1**–**8**, the explicit feature is the absence of a band in the region 3200–3500 cm^{-1}, which appears in the free ligand as the –OH stretching vibration, thus indicating metal-ligand bond formation through this site. The absorption in the region 460–488 cm^{-1}, which is absent in the spectrum of the free ligand, is assigned to the Sn–O stretching mode. All these values are consistent with those detected in a



Scheme 1.

number of organotin-oxygen derivatives [13,14]. In the organotin carboxylate complexes, IR spectroscopy can provide useful information concerning the coordinate formation of the carboxylate [15]. $\Delta v(v_{as}(COO)–v_s(COO))$, 202–217 cm^{-1}, are smaller than that of the free ligand, 341 cm^{-1}, but near to that in the sodium salt of the ligand, 200 cm^{-1}, which suggest the presence of bidentate chelating carboxylate groups [16]. This information is consistent with the analysis of related X-ray crystallography data.

3.3. NMR spectra

The ^1H NMR spectra show that the signal for the OH proton (10.89 ppm) in the spectrum of the ligand is absent in the spectra of the complexes, thus indicating the removal of the OH proton and the formation of Sn–O bonds. This is consistent with the IR data. Signals for the other groups appear in the same positions as in the ligand.

The ^{13}C NMR spectra of all the complexes shown a significant downfield shift of all carbon resonances compared with the free ligand. The shift is a consequence of electron density transfer from the ligand to the acceptor.

3.4. X-ray crystallographic studies

3.4.1. Crystal structure of $[Ph_3SnO_2CC_6HF_3OCH_3]$ (1)

The molecular structure of complex **1** is shown in Fig. 1 and selected bond lengths and angles are given in Table 1. As can be seen from Fig. 1, the complex possesses a monomeric structure, the Sn(1)–O(1) [2.076(3) Å] bond length lies in the range that has been reported as the Sn–O covalent bond length [2.054(3)–2.083(2) Å for Sn(1)–O(1)] [17a], which proves that the oxygen atoms are coordinated to the tin atoms by a strong chemical bond. The intramolecular distance [Sn(1)···O(2)] is 2.743(4) Å. Although the distance is considerably longer than the normal Sn–O covalent bond length, they lie in the range of Sn···O distances of (2.61–3.02 Å), which have been confidently reported for intramolecular bonds [17b,17c]. As the oxygen atom is involved in a weak coordinative interaction with tin along one of the tetrahedral faces, the structure distortion for the tin atom in complex **1** is best described as a capped tetrahedron.

Table 1
Selected bond lengths (Å) and angles (°) for **1**

Bond lengths			
Sn(1)–C(9)	2.130(4)	Sn(1)–O(1)	2.076(3)
Sn(1)–C(15)	2.123(5)	Sn(1)–O(2)	2.743(4)
Sn(1)–C(21)	2.133(5)		
Bond angles			
O(1)–Sn(1)–C(15)	108.19(16)	C(15)–Sn(1)–C(9)	112.57(19)
O(1)–Sn(1)–C(9)	97.24(16)	C(15)–Sn(1)–C(21)	116.14(19)
O(1)–Sn(1)–C(21)	112.47(15)	C(9)–Sn(1)–C(21)	108.69(18)
O(1)–Sn(1)–O(2)	52.18 (12)	C(9)–Sn(1)–O(2)	149.13(15)

As shown in Fig. 2, a pair of intermolecular C–H···F hydrogen bonds are recognized, which associate the discrete molecule into a dimer. The C–H···F distance is 2.557 Å, which is shorter than the sum of van der waals radii of H and F (2.67 Å) [18]. The C···F distance and the C–H···F angle are 3.343 Å and 142.5°, respectively.

The dimers of complex **1** are further linked by intermolecular C–H···F hydrogen bonds. As shown in Fig. 3, the C(13A) atom acts as a hydrogen-bond donor via the

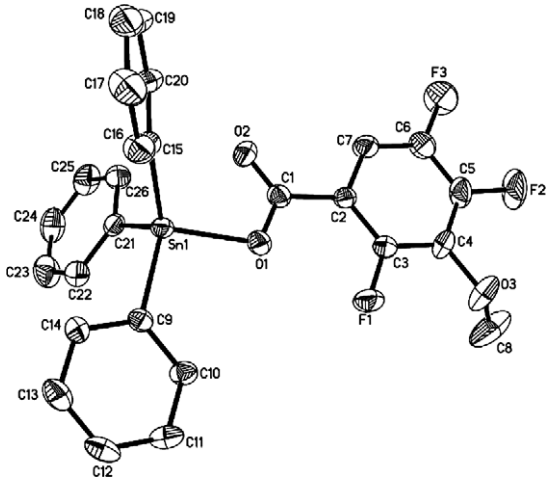


Fig. 1. Molecular structure of complex **1**.

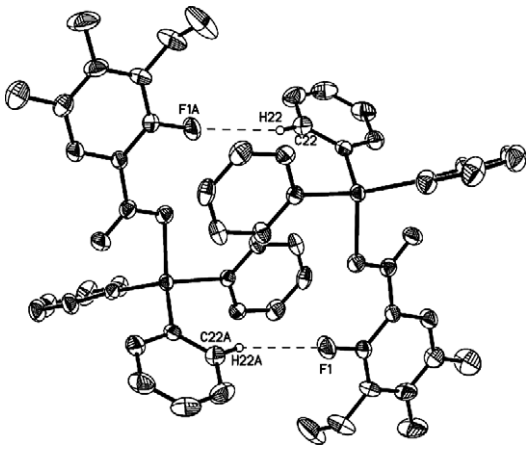

Fig. 2. Dimer structure of complex **1**.

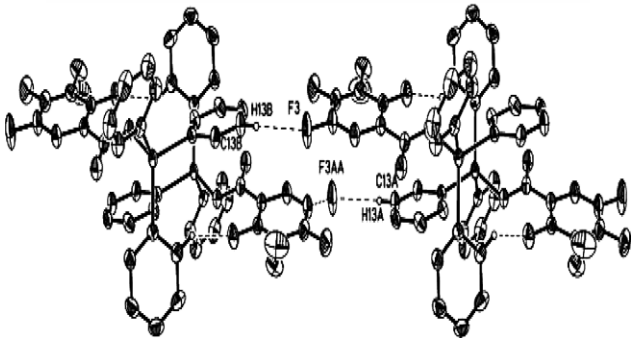

Fig. 3. 1D chain structure of complex **1**, propagation by weak C–H···F interactions.

H(13A) atom to the fluorine F(3AA) atom, and the C(13B) atom acts the same as C(13A), so the dimers form a 1D chain with a head-to-tail arrangement. The C···F and H···F distances and the C–H···F angle are 3.239 Å, 2.556 Å and 130.62°, respectively. The observed C–H···F distances are consistent with phenyl C–H···F interactions reported for various fluorobenzene complexes (2.36–2.86 Å) [19].

3.4.2. Crystal structure of $[Me_3SnO_2CC_6HF_3OCH_3]$ (3)

The molecular structure of complex **3** is shown in Fig. 4 and selected bond lengths and angles are given in Table 2. As can be seen from Fig. 4, the geometry of the tin center is a distorted trigonal bipyramid and the structure adopted in the solid state is *trans*-R_3SnO_2. The central tin atom is five-coordinated with the two O atoms [O(1) and O(2A)] occupying the axial sites, the angle of the axial ligands [O(1)–Sn(1)–O(2A)] is 174.93(9)°. Three methyl groups define the equatorial plane and the sum of the trigonal C–Sn–C angles is 356.7°. The carboxylate ligand bridges two symmetry-related Sn atoms and gives rise to the unequal Sn–O bond distances. This inequality is reflected in the C(1)–O bond distance, and the longer C(1)–O(1) [1.282(4) Å] is associated with the shorter Sn(1)–O(1) [2.120(3) Å] bond, which is shorter than other reported trimethylorganotin(IV) polymeric structures [2.14(1)–2.208(2) Å] [20a,21] and approaches the covalent radii of Sn and O (2.13 Å) [18]. The Sn(1)–O(2A) distance [2.668(3) Å] is longer than other reported complexes [21], but is far shorter than the sum of the van der Waals radii of Sn and O (3.68 Å) [18]. All these information indicate that Sn(1)–O(2) is a weak coordinate bond. The Sn-C distances [2.103(4)–2.114(4) Å] are consistent with those reported in other triorganotin(IV) carboxylates [17d,20a].

The intermolecular C=O → Sn coordination in **3** leads to infinite zigzag chains containing the tin centers and carboxyl groups [Fig. 5], which is consistent with another organotin(IV) complex that has been reported [20a]. Furthermore, the F(2) atom of the ligand in one chain and the F(2E) atom in another chain form an intermolecular non-bonding F···F interaction [Fig. 6], which is similar to that of the Cl···Cl interaction reported in the literature [21]. The F···F distance (2.820 Å) is a little longer than that has been reported (2.80 Å) [22], but is considerably shorter than the sum of the van der waals radii of two fluorine atoms (2.94 Å)[18]. The C(5)···F(2A) distance and C(5)–F(2)···F(2A) angle is 3.399 Å and 103.98° respectively. These 1D chains are further linked by intermolecular C–H···F hydrogen bonds, as shown in Fig. 7, the C(9) and C(9B) atoms act as a hydrogen-bond donors via H(9C) and H(9CB) atoms to phenyl F(2C) and F(2BA) atoms [Fig. 7] The C···F, F···H distance and the C–H···F angle are 3.522 Å, 2.631 Å and 148.2° respectively. The F···H distance (2.631 Å) and the C–H···F angle are bigger than the same type of measurements that are found in complex **1** (2.557 Å and 142.5°, 2.556 Å and 130.62°), but shorter than the sum of van der waals radii of H and F (2.67 Å) [18]. These intermolecular F···F and C–H···F interactions

3.4.3. Crystal structures of $[Me_2Sn(O_2CC_6HF_3OCH_3)_2]$ (7) and $[n\text{-}Bu_2Sn(O_2CC_6HF_3OCH_3)_2]$ (8)

The molecular structures of complexes **7** and **8** are shown in Figs. 8 and 10, and selected bond lengths and angles are given in Tables 3 and 4. The geometry at the central Sn atoms in both complexes of **7** and **8** is a skew-trapezoidal bipyramidal geometry. The four O atoms, which derive from two chelate carboxylate ligands, define the basal plane. The C–Sn–C angle [142.4(4)° for **7**, 147.5(2)° for **8**] lies in the range of C–Sn–C angles of 122.6–156.9° found for diorganotin derivatives in which the organo substituents do not adopt *cis*- or *trans*-geometries about the tin atom [23]. The carboxylate ligands chelate the Sn center with asymmetric Sn–O bond distances and this asymmetry is related to the shorter Sn–O bonds. The degree of asymmetry in the Sn–O bond distances is not equal to the difference between the Sn–O bond distances for two carboxylate

ligands (0.541 Å and 0.388 Å for **7**, 0.434 Å and 0.390 Å for **8**). The anisobidente mode of coordination of the carboxylate is also reflected in the disparity of the associated carbon–oxygen bonds. Although the Sn(1)–O(2) (2.656 Å for **7** and 2.562(3) Å for **8**) and Sn(1)–O(5) (2.506 Å for **7** and 2.531(4) Å for **8**) bonds are longer than the sum of the covalent radii of Sn and O (2.13 Å), they are nevertheless significantly below the sum of the van der waals radii of these atoms (3.68Å) [18].

The most interesting aspect of the structure concerns the intermolecular weak Sn···O and Sn···F interactions, which help in the construction of the dimer as shown in Figs. 9 and 11. The two weak Sn···O bond lengths are equal (3.121 Å for **7** and 3.097 Å for **8**), which is less than the sum of the van der Walls radii of Sn and O (3.68 Å) [18] and between those that have been reported in $[Et_2Sn(O_2CC_4H_3S)]$ (2.891 Å) and $Ph_2Sn(O_2CCH_2Cl)_2$ (3.552 Å) [24,25]. The interaction of Sn···F is similar to the Sn···Cl interaction that has been reported [26] and the distance is 3.635 Å for **7** and 3.638Å for **8**.

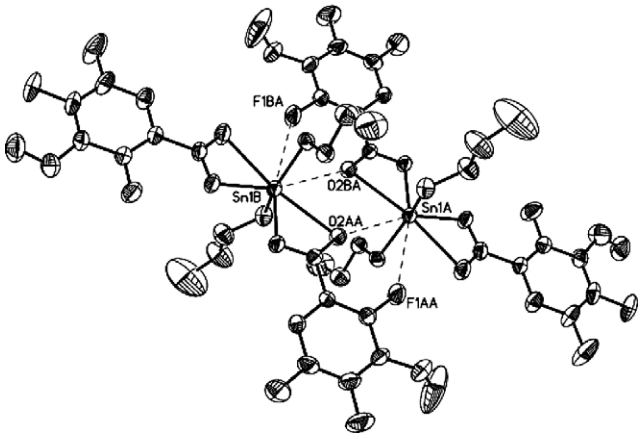

Fig. 11. The dimer structure of complex **8**.

Moreover, for complex **7** the dimers are connected into a 1 D chain through C–H···F hydrogen bonding. The C···F and H···F distances and the C–H···F angle are 3.312 Å, 2.612 Å and 130.01° respectively, these data are consistent with those found in the literature [19]. For complex **8**, we can find two types of shorter distances that are formed by the phenyl F and the methyl H. One is a little longer than the other. For the longer one, its C···F and H···F distances and the C–H···F angle are 3.511 Å, 2.607 Å and 157.06° respectively; and for the shorter one, its C···F and H···F distances and the C–H···F angle are 3.297 Å, 2.517 Å and 138.34° respectively. So a 1D chain structure in the solid state is propagated by two types of C–H···F weak interactions. Further, the C–H···F distance (2.517 Å) is the shortest among the above mentioned in this article.

4. X-ray crystallography

Crystals were mounted in Lindemann capillaries under nitrogen. All X-ray crystallographic data were collected on a Bruker SMART CCD 1000 diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at

298(2) K. A semi-empirical absorption correction was applied to the data. The structure was solved by direct methods using SHELXS–97 and refined against F^2 by full-matrix least squares using SHELXL–97. Hydrogen atoms were placed in calculated positions. Crystal data and experimental details of the structure determinations are list in Table 5.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structure analysis of the compounds have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 600461 **1**, 600462 **3**, 600459 **7**, 600460 **8**. Copies of these information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

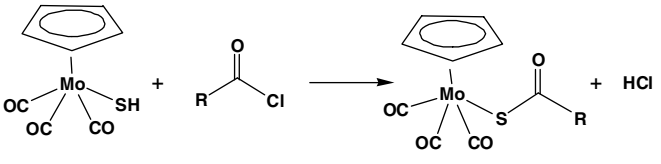
complexes to include molybdenum. The reaction between $CpMo(CO)_3SH$ and acid chlorides which gives the expected thiocarboxylate complexes $CpMo(CO)_3SCOR$ is discussed in this report.

2. Results and discussion

2.1. Synthesis and characterization

Treatment of the molybdenum hydrosulfido complex $CpMo(CO)_3SH$ with acid chlorides gave the thiocarboxylate complexes $CpMo(CO)_3SCOR$, **1**–**5** as shown in the following equation:



1 - 5

R= Me (**1**), CH_2Cl (**2**), Ph (**3**), 4-$C_6H_4NO_2$ (**4**), 3,5-$C_6H_3(NO_2)_2$ (**5**)

(1)

The resulting dark-red thiocarboxylate complexes, **1**–**5**, are air stable as solids. In solution, these complexes are quite unstable and they decompose to brown insoluble materials. In some experiments small amounts of the chloride complex $CpMo(CO)_3Cl$ were also obtained. Complexes **1**–**5** have been fully characterized by IR, ^1H NMR spectra, elemental analysis and by the single crystal X-ray structure determination of **3**. The IR spectra of **1**–**5** display three absorption bands in the range of 2048–2042, 1980–1971, and 1936–1942 cm^{-1}, respectively, for the terminal carbonyl ligands. These bands are lower than those observed for $CpMo(CO)_3SH$ (2039, 1963 cm^{-1}) [33,34], but similar to those observed for $CpMo(CO)_3S_2CSR$ (2050–2046, 1976, and 1951–1952 cm^{-1}) [35]. An additional distinctive absorption appears between 1644 and 1736 cm^{-1}, corresponding to the ketonic carbonyl group of the thiocarboxylate ligand. This value is higher than those observed for the analogous iron thiocarboxylates $CpFe(CO)_2SCOR$ (1590–1630 cm^{-1}), suggesting less electron density around the Mo center compared to that of Fe.

The ^1H NMR spectra of **1**–**5** show the expected signals of the Cp protons in the range 5.55–5.66 ppm. These resonances are found at lower field than the peak for $CpMo(CO)_3SH$ (4.55 ppm) and $CpMo(CO)_3(S_2CSR)$ (4.32 ppm), suggesting that the thiocarboxylate group is a stronger π-acceptor (or weaker σ-donor) ligand compared to the thioxanthate unit [35]. The peaks for the R-group of the thiocarboxylate ligands are shown in the expected ranges with the expected multiplicities.

2.2. Crystal structure

The molecular structure of **3** with the atom numbering scheme is shown in Fig. 1. Selected bond distances (Å) and angles (°) of **3** are presented in Table 1. The crystal lattice of **3** contains two crystallographically independent molecules. The Cp-ring is bonded to the molybdenum atom in a η^5-fashion with Mo–C bond distances ranging from 2.295(4) Å to 2.355(4) Å. The Mo–S bond distance 2.5191(10) Å is similar to that reported for $Mo(\kappa^2C,S\text{-}SCOPr^i)(\kappa S\text{-}SCOMe)(CO)_2(PMe_3)_2$, 2.511(4) Å [28]. The $Mo–C_{CO}$ bond distances (average of 1.986 Å) are in agreement with those found in $CpMo(CO)_3$-containing complexes. The C=O bond distance of the thiocarboxylate ligand of 1.214(5) Å is similar to that reported for $Mo(\kappa^2C,S\text{-}SCOPr^i)(\kappa S\text{-}SCOMe)(CO)_2(PMe_3)_2$ of 1.19(2) Å [28] and to that found in other complexes containing thiocarboxylate groups [22,26].

3. Experimental

3.1. General

Synthetic work was carried out under a dinitrogen atmosphere using Schlenk techniques. Tetrahydrofuran, diethyl ether, hexane, and dichloromethane were dried, distilled and stored under nitrogen. The reagent $CpMo(CO)_3SH$ was prepared as described previously [34,35]. Acid chlorides, molybdenum hexacarbonyl and sulfur were obtained commercially and were used as received.

Nuclear magnetic resonance (NMR) spectra were obtained on a Bruker spectrometer operating at 200 MHz with chemical shifts reported in ppm downfield from TMS, using the solvent residual peak as an internal reference. Infrared (IR) spectra were recorded on a Nicolet-Impact 410 FT-IR spectrometer in CH_2Cl_2 solutions. Elemental analyses were done at Laboratoire D'Analyse Élementaire, Universite de Montréal, Montréal, Québec, Canada. Melting points were reported on a Staurt Melting point apparatus (SMP3) and are uncorrected.

3.2. General procedure for the preparation of $CpMo(CO)_3SCOR$, 1–5

A diethyl ether solution of $CpMo(CO)_3SH$ (0.28 g, 1.00 mmol) was cooled to −78 °C. The respective acid chloride (1.10 mmol) was added as one portion. The cooling bath was removed and the solution was stirred for 2 h at room temperature. The volatiles were removed under vacuum and the resulting solid was redissolved in a minimum amount of dichloromethane and introduced onto a silica gel column made up with hexane. Elution with hexane removes the excess acid chlorides and with a 1:1 v:v ratio of diethyl ether:hexane gives an orange band. This band was collected and the volatiles were removed under vacuum. The resulting red solid was recrystallized from dichloromethane/hexane at 0 °C.

Found: C, 41.86; H, 1.87; N, 2.95; S, 7.02%.

3.2.5. $CpMo(CO)_3SCO\text{-}4\text{-}C_6H_3(NO_2)_2$ (5)

Yield: 87%. M.p.: 162–163 °C. IR (CH_2Cl_2, cm^{-1}): 2046 (s), 1977 (s), 1941 (s) (ν(C≡O)), 1710 (m) (ν(C=O)). ^{1}H-NMR ($CDCl_3$): 5.66 (s, 5H, C_5H_5), 8.33 (d, 2H, $C_6H_3(NO_2)_2$, $J_m = 3.1$ Hz), 8.67 (t, 1H, $C_6H_3(NO_2)_2$, $J_m = 3.1$ Hz). *Anal.* Calc. for $C_{15}H_9MoN_2O_8S$: C, 38.23; H, 1.50; N, 5.94; S, 6.80. Found: C, 37.75; H, 1.37; N, 5.45; S, 6.38%.

3.3. X-ray structure analysis

X-ray data of a dark red crystal of $CpMo(CO)_3SCOPh$ (**3**) were collected with an Oxford Gemini S diffractomer with a graphite monochromator λ(Mo Kα) = 0.71073 Å. The crystallographic data are presented in Table 2. The structure was solved by direct methods using SHELXS-97 [36] and refined by full-matrix least-square procedures on

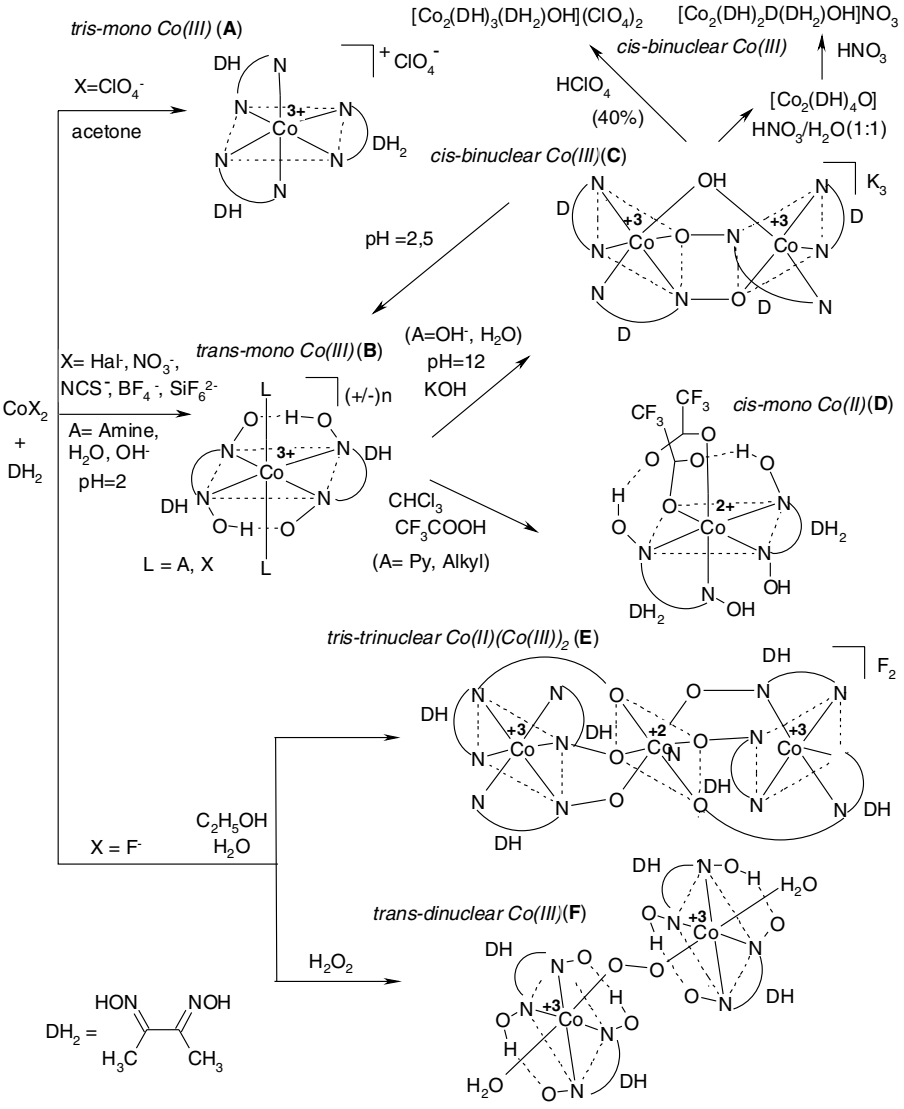

Scheme 1. Synthetic and structural flexibility of the Co/DH_2 system.

Taking into account that no examples with cobalt dimethylglyoxymate containing directly coordinated fluorine ion to the cobalt center were known, our previous investigations were focused in this direction. Our attempt to prepare such compounds was unsuccessful, instead non-trivial binuclear Co(III)-*trans* with a μ-peroxo bridge [11] (type F Scheme 1), and tris-trinuclear mixed-valence Co(II)-$(Co(III))_2$ [12] (type E Scheme 1) compounds were obtained using CoF_2 or HF as the fluorine sources. Exploiting these reagents directly in the synthesis has proven to have some serious drawbacks related to their toxic and corrosive properties. That is why our attention has now turned to the $Co(OTf)_2 \cdot 6H_2O$ ($CF_3SO_3^-$ or OTf^- – triflate) salt which is less toxic, chemically inert and contains a weakly coordinating anion with a fluorocarbon functionality. Within this context, we report hereafter on the synthesis and crystal X-ray structural characterization of three new complexes, one trinuclear tris-Co(II) and two *trans*-cobaloxime type Co(III) complexes prepared from a Co(II) triflate precursor.

2. Experimental

2.1. Materials

All chemicals were of reagent grade and used as purchased without further purification. $Co(CF_3SO_3)_2 \cdot 6H_2O$ was prepared according to [21], by dropwise treating of a water suspension of basic cobalt carbonate with a small excess of CF_3SO_3H (98%).

2.2. Synthesis

2.2.1. $[Co_3(\mu\text{-}DH)_6] \cdot 24H_2O$ (*I*)

Dimethylglyoxime (0.23 g, 0.002 mol) and $Co(CF_3SO_3)_2 \cdot 6H_2O$ (0.47 g, 0.001 mol) were dissolved in 10 ml of an ethanol/water (1:1) mixture and heated in a graphite crucible for 10 min at 70 °C. After cooling a brown solid was filtered out, washed with ethanol and dried in air. The yield was 43%. Single crystals suitable for X-ray

diffraction studies were obtained by recrystallization from water/ethanol (1:1) mixture.

Found: C, 22.63; H, 6.48; N, 12.82. Calc. for $C_{24}H_{90}Co_3N_{12}O_{36}$ (fw = 1299.87) C, 22.18; H, 6.98; N, 12.93.

UV–Vis, $\lambda_{max}(\varepsilon)$, $C = 1.2 \times 10^{-4}$ M, DMF: 432 nm (sh, 13 192), 268 nm (42 032) ($dm^3\ mol^{-1}\ cm^{-1}$).

IR (KBr, cm^{-1}): 500(s), 637(w), 733(w), 804(w), 973(m), 1071(s), 1130(w), 1214(s), 1383(w), 1495(w), 1558(w), 1627(m), 1742(w), 2852(w), 2923(m), 3435(s).

MS FAB(−), *m/z*: 864.5 (I, 100%) $[Co_3(DH)_6 - 3H]^-$, 749.3 (I, 22%) $[Co_3(DH)_5 - 3H]^-$, 403.7 (I, 8%) $[Co(DH)_3]^-$, 597.7 (I, 8%), 633.3 (I, 5%) $[Co_3(DH)_4 - 4H]^-$, 523.3 (I, 5%) $[Co_3(DH)_3]^-$, 461.5 (I; 4%) $[Co_2(DH)_3 - H]^-$, 287.5 (I; 3%) $[Co(DH)_2 - H]^-$.

2.2.2. $[Co(DH)_2Tu_2]CF_3SO_3$ (*II*)

Dimethylglyoxime (0.23 g, 0.002 mol) and $Co(CF_3SO_3)_2 \cdot 6H_2O$ (0.47 g. 0.001 mol) were dissolved in 10 ml of a methanol/water (1:1) mixture and heated in a graphite crucible for 10 min at 70 °C. The solution was then filtered to remove unreacted dimethylglyoxime. Thiourea (Tu) (0.15 g, 0.002 mol) solubilized in 5 ml methanol was finally added and the mixture was heated for an additional 10 min. After cooling a brown solid was filtered out, washed with ethanol and dried in air. The yield was 71%.

Found: C, 22.17; H, 3.59; N, 18.81. Calc. for $C_{11}H_{22}CoF_3N_8O_7S_3$ (fw = 590.48) C, 22.36; H, 3.73; N, 18.97.

2.3. Analyses and physical measurements

Elemental analyses were made by standard micromethods. Mass-spectrometric analyses were performed on an Analytical VG 7070 EQ instrument using the FAB method. UV–Vis spectra were obtained with Lambda 6 Perkin–Elmer spectrophotometer. IR spectra were recorded with KBr discs in the range 4000–400 cm^{-1} on a Perkin–Elmer spectrometer. UV–Vis spectra were obtained with Lambda 6 Perkin–Elmer spectrophotometer. Both ^1H (400 MHz) and ^{13}C NMR (100.6 MHz) measurements were carried out on a Bruker Avance 400 spectrometer, using DMSO as the solvent. Chloroform solution ESR spectra were obtained with a Bruker spectrometer, type ER100D, using DPPH as the reference. All spectra were recorded at 298 and 170 K, using a standard low temperature apparatus Bruker ER 4111VT. Magnetic susceptibility of powdered samples was obtained at 290 K using Oxford Instruments with a CF200 cryo-system and microbalance Cahn 2000. The equipment was previously calibrated with $HgCo(NCS)_4$ standard [22]. The magnetic measurement was corrected for cell and sample diamagnetic contributions [23].

2.3.1. X-ray crystallography

Diffraction data were collected at 130 K for **I** and **II** and at 293 K for **III** with a KM4CCD diffractometer using Mo Kα graphite-monochromated radiation. Crystallographic data and details of the refinement process are summarized in Table 1. The structures were solved by direct methods using the program SHELXS-97 [24]. Refinement and all further calculations were carried out using SHELXL-97 [25]. In the case of structure **I** refinement of the structure presented some problems. We localized quite straightforwardly two cobalt atoms at special positions, the DH ligand, four

water molecules (one is disordered over two positions) and all hydrogen atoms. However, the refinement converged poorly and there were two high residual peaks of ca. 6 and 4 e Å^{-3} on difference electron density maps which were initially difficult to explain. The highest peak was located at the Wyckoff position 1b of C_{3i} symmetry at a distance of 2.4 Å from six DH oxygen atoms. The second peak was located very close to the Co1 atom. Additionally, the displacement parameters of the Co2 atom were relatively high whereas the displacement ellipsoid of Co1 was strongly elongated in the z direction. To explain these features we assumed a disorder of the trinuclear complex molecules in the crystal lattice which can be described as follows. Trinuclear complex molecules in **I** are arranged into columns running along the [0 0 1] direction and only every second site of the C_{3i} symmetry along this direction is occupied by a Co2 atom. The 'unoccupied' C_{3i} sites are surrounded by six hydrogen bonded OH groups of the DH ligand. However, shifting the complex molecule along the z direction by 0.5c so that the Co2 atom is placed in the nearest unoccupied Wyckoff 1b site, does not substantially influence the intermolecular interactions of the complex molecules with the surrounding water molecules because after this transformation atoms of the DH and DH$_x$ ligand closely overlap (Fig. 1a) and the Co1′ atom is placed only 0.5 Å apart from Co1. We noticed that whereas [0 0 1] columns of the complex molecules should be ordered, there might be some faults in their distribution (i.e. their arrangement does not always obey the space group symmetry) giving rise to the observed crystal disorder. Therefore, the complex molecule was generated in this second alternative position, and introduced as a rigid group for further refinement. The sum of the occupancy factors of the minor and major positions of the complex molecule was kept equal to 1. The molecule in the minor position was refined isotropically and its final occupancy factor refined at 0.18. With these considerations, the structure refinement of **I** proceeded smoothly giving the results presented in Table 1. The triflate ion in **III** is disordered. This non-centrosymmetric ion is located at a crystallographic inversion center

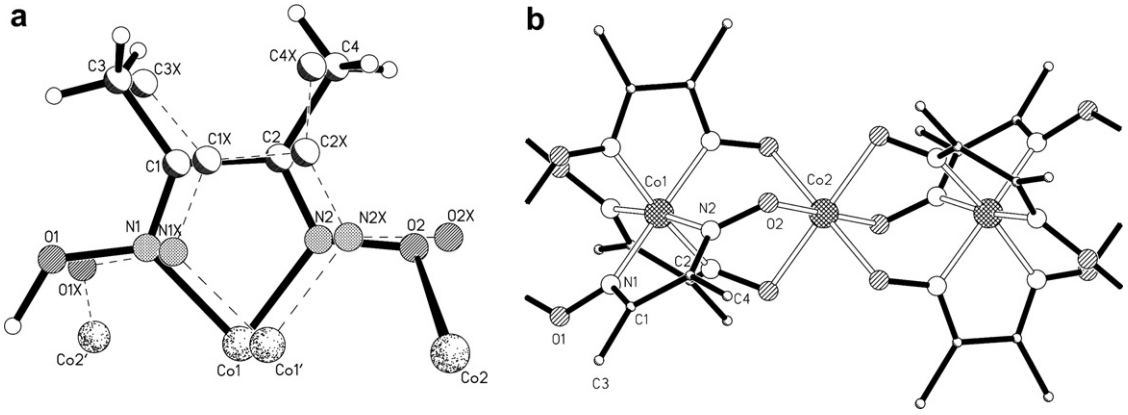

Fig. 1. (a) Drawing of the asymmetric part of the complex molecule in **I** showing disorder encountered in this crystal structure (the molecule with lower occupancy is presented with dashed lines) and (b) the complex molecule in **I** shown without disorder.

where it adopts two distinct orientations with O atoms overlapping with F atoms and C atoms overlapping with S atoms.

H-atoms were located from Fourier difference maps and refined isotropically. H-atoms from water molecules were also located from difference maps but their positions were kept fixed with $U_{iso} = 1.5U_{eq}$ of their carrier O atom. The non-H atoms were refined anisotropically, using weighted full-matrix least-squares on F^2. Selected bond lengths and angles for **II** and **III** are listed in Table 2.

3. Results and discussion

3.1. Mass-, IR and UV–Vis data

The complexes **I**–**III** have been prepared in good yields and characterized from analytical and physicochemical data (Sections 2.2.1–2.2.3). The elemental analysis data of **1** suggest a 1:2 stoichiometric ratio between cobalt and the DH-ligand, and a formula $[Co(DH)_2X_2]CF_3SO_3$ where X = Tu and Py for **II** and **III**, respectively. Their brick red or brown color suggests an octahedral stereochemistry. In the FAB(+) mass spectrum of **I** the highest mass species detected is the trinuclear dimethylglyoximate core $[Co_3(DH)_6 - 3H]^-$. An insignificant fragmentation with subsequent loss of the DH residue $[Co_3(DH)_5 - 3H]^-$, $[Co_3(DH)_4 - 4H]^-$, $[Co_3(DH)_3]^-$, and generation of bi- and mononuclear species $[Co_2(DH)_3 - H]^-$, $[Co(DH)_3]^-$, $[Co(DH)_2 - H]^-$ were also observed. No signal corresponding to the triflate anion was detected in FAB(−). In the case of **II** and **III**, the 100% intensive and the single signal in FAB(−) corresponds to the counter anion OTf^-. In the positive FAB spectra in both cases the signal corresponding to the $[Co(DH)_2]^+$ unit is present as well as its combination with one or two molecules of axial ligands.

Their UV–Vis spectra are also different, **II**–**III** have a relatively weak and featureless visible spectrum as do other octahedral *trans* Co(III) dimethylglyoximates, with an intensity that rises into the UV toward the general cobaloxime-type absorption at ca 263 and 222 nm for **II** and **III**, respectively (due to the intraligand (DH) π–π* transition). The second band at 281 and 250 nm (for **II** and **III**) is assigned to the corresponding apical ligands Tu or Py, molecules which are located in *trans* positions related to each other, and is due to the charge transfer from the axial ligands to the cobalt ion. No d–d transition bands of the metal are observed for **II**–**III**, which in most Co(III) complexes are assigned as $^1A_{1g} \rightarrow {}^1T_{1g}$ at between 476 and 625 nm [26]. In contrast the UV/visible spectrum of **I** contains a weak absorption at 432–614 nm (sh, broad band) characteristic of Co(II) d–d transitions and a maximum band at 268 nm, attributed to the intraligand DH π–π* transitions. Generally, the electronic spectra of octahedral Co(II) complexes show as a rule two main bands, one transition occurring in the 950–1540 nm range and the other in the 460–660 nm range [27] identified with $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transitions, respectively. No near IR measurements were made on our compounds.

In the IR spectrum of **I** the presence of water molecule are reflected by a strong absorption at 3434 nm. The C=N frequencies of coordinated dimethylglyoxime molecules are also present at 1627 nm. Two strong absorption bands at 1213 and 1070 nm are attributed to NO groups. The signal at 500 nm corresponds to Co–N bonds. No Co–O absorption bands were detected, probably due their presence in the field lower than 450 nm. The IR spectrum of **II** is more complicated and represents a combination of contributions from the cation and anion. In the solid state IR spectrum of **III** the triflate group causes absorption bands at 1269 cm^{-1}, 1032 ($\nu s(SO_2)$) and 635 cm^{-1} ($\delta s(SO_3)$) and which can be assigned to the uncoordinated counterion. The band at 515 cm^{-1} is assignable to the Co–N stretching frequency between cobalt and nitrogen atoms of dimethylglyoxime [28].

Taking into account the data of mass-, UV–Vis and IR data, the synthesized compounds were proposed to have an octahedral structure, as in simple cobaloxime type species. The different behavior of **I**, the missing bands in the IR spectra of characteristic OTf^- stretching bands, the absence of a triflate peak in the FAB(−) as well as the presence in the FAB(+) of the highest peak corresponding to a trinuclear dimethylglyoximate core indicate its non electrolytic and polynuclear nature, which was confirmed by its X-ray structure analysis.

3.2. NMR spectra

The ^1H NMR spectra of diamagnetic compounds **II** and **III** indicate their *trans*-configuration. The signals of methyl groups of DH residues in the ^1H NMR spectra are 2.37 and 2.31 ppm for **I** and **II**, respectively, which are shifted downfield compared to the "free" DH_2 molecule (1.48 ppm, D_2O). The presence of a large downfield singlet 17.55 (for **II**) and 18.16 ppm (for **III**) in the ^1H NMR is due to the two symmetrical intramolecular hydrogen bonds, and is

an indirect proof of the *trans*-type configuration. The coordination of apical ligands (Tu and Py) is well illustrated in the ^{1}H and ^{13}C NMR spectra (Sections 2.2.2 and 2.2.3). In the ^{1}H NMR, a downfield shift of about 0.87 ppm (for free Tu in DMSO, ^{1}H NMR, δNH 7.05 ppm; $\delta^{13}C$ (C=S) 183.81 ppm [29] and for studied compound **II** these values are 7.92 and 176.49 ppm, respectively) was observed for the N–H proton of Tu in **II** on its complexation with the cobaloxime core. An upfield shift of about 7.32 ppm is observed in the C=S resonance (^{13}C NMR $\delta^{13}C_{(C=S)}$ 176.49 ppm) of Tu (**II**) on its complexation. This is due to the lowering of the C=S bond order upon coordination and a shift of N → C electron density producing a partial double bond character in the C–N bond, as observed in other metal complexes of thiourea [30]. The presence of an aromatic proton in the region 7.59 –8.17 ppm (^{1}H NMR) is due to the coordinated pyridine molecule in **III**. The uncoordinated triflate anions give rise to a quartet system, 121.53 (q, $^{1}J_{CF} = 321.48$ Hz, CF_3), in the ^{13}C NMR spectra of both compounds.

3.3. Magnetic measurements and ESR spectra

Most cobalt(II) complexes of non-macrocyclic tetradentate ligands with nitrogen and/or oxygen donors are high-spin, five or six coordinate complexes [31].

The studied compound **I** $[Co_3(DH)_6]$ falls into the same category, its magnetic moment of $\mu_B = 4.3$ MB is quite comparable to the values expected (spin-only, 3.88 MB) and found (typically 4.3–5.2 MB) for high spin Co(II), but distinctly different from the value 1.73 MB characteristic to Co(II) with a low spin configuration [32]. The slight decrease in the value compared with literature data for high spin octahedral complexes of Co (II) could be due to the interaction with the other nuclei of cobalt, or with the bridging ligand.

No ESR signal for **I** in both the solid or in solution were observed at room temperature. The lack of a signal can be the result of fast spin-lattice relaxation times and strongly suggests the presence of a high-spin Co(II) complex [33–35].

3.4. Crystal structures

3.4.1. Compound *I*

The trigonal R-3 crystals of **I** are built from neutral, C_{3i} symmetrical trinuclear $[Co^{II}(DH)_3]_2Co^{II}$ molecules and water of crystallization (24 H_2O molecules per one complex molecule). Two $\{Co^{2+}(\mu\text{-}DH)_3\}$ units with cis-oriented DH^- groups are connected to the central Co^{II} ion via bridging oxygen atoms (Fig. 1b). Thus, both types of Co^{II} atoms have octahedral coordination, however their environment in the molecule is different. Co(2) is surrounded by six O atoms from six deprotonated oxime groups whereas Co(1) is coordinated by six N atoms from three DH^- units. the structure of this neutral molecule is very similar to that reported in [11] for the $[Co_2^{III}Co^{II}(DH)_6]^{2+}$ cation. The $(Co1–N)_{DH}$ distances are 1.892(4) and 1.919(4) Å and the $(Co2–O)_{DH}$ bond is 2.083(3) Å (Table 2). However the difference from [11] consists in that all three atoms of cobalt are Co(II).

In the crystal the $[Co^{II}(DH)_3]_2Co^{II}$ molecules are connected end-to-end by hydrogen bonds between their oxime OH groups into a polymeric structure running along the *z* axis (Fig. 2). Six hydrogen-bonded OH groups belonging to two molecules form a cyclic motif with the graph symbol $R_6^6(12)$ [36]. These hydrogen-bonded columns of $[Co^{II}(DH)_3]_2Co^{II}$ are immersed in the 3D hydrogen-bond network formed by four symmetry-independent water molecules. They join to this network by hydrogen bonds O3W–H···O2 and O4WB–H···O1 (Fig. 3). Molecules of crystal-water are joined among themselves by an elaborate system of hydrogen bonds, forming their own supramolecular system. Disorder of the water molecule OW4B can, to some extend, be related to the disorder of the complex molecules (see Section 2). The hydrogen-bond parameters are listed in Table 3.

3.4.2. Compound *II*

The crystals of **II** consist of non-centrosymmetric $[Co(DH)_2Tu_2]^+$ cations and $[CF_3SO_3]^-$ anions (Fig. 4). The complex cation shows an usual *trans*-octahedral configuration (4N2S) around the metal ion with the two

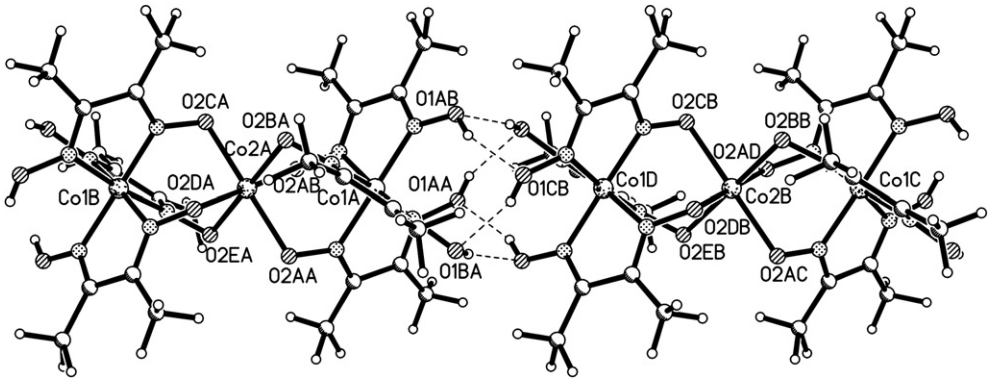

Fig. 2. Polymeric structure formed from hydrogen-bonded trinuclear complex molecules in **I**. Hydrogen bonds between OH groups are shown as dashed lines.

Symmetry code: (\$1) $-x+1/3, -y+2/3, -z-1/3$; (\$2) $-x+y, -x+1, z$; (\$3) $-y+1/3, x-y+2/3, z-1/3$; (\$4) $x-y+2/3, x+1/3, -z-2/3$; (\$5) $-x+y+1/3, -x+2/3, z-1/3$; (\$6) $-x+y-1/3, -x+1/3, z+1/3$.

DH-chelating units in the equatorial plane of the Co^{III} ion and the apical coordination sites occupied by two thiourea molecules. The coordination geometry for compound **II** is given in Table 2. The DH^- ligands in the cation are connected via two strong intramolecular hydrogen bonds O1–H1...O4 2.508(3) Å and O3–H3...O2 2.529(3) Å. The two thiourea moieties are differently situated relative to the complex equatorial plane: the S(2)C(9)N(5)N(6) unit is approximately perpendicular to this plane [dihedral angle equal to 87.6(1)°] whereas the S(1)C(10)N(7)N(8) unit shows a nearly parallel orientation [dihedral angle equal to 22.3(1)°]. The perpendicular orientation of the thiourea molecule in the complex cation is stabilized by the "bifurcated" intramolecular N6–H6...O1 and N6–H6...O4 hydrogen bonds with N...O distances of 3.180(3) and

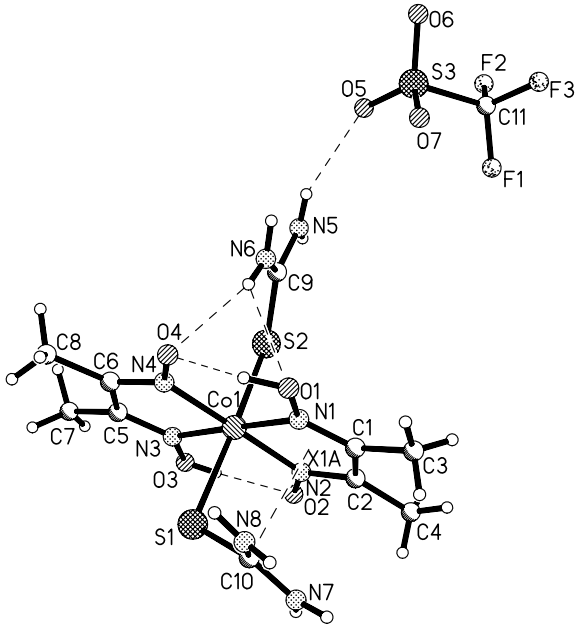

Fig. 4. Ortep drawing and atom labelling in **II**.

3.049(3) Å, respectively. In turn, the thiourea molecule in the parallel arrangement relative to the complex cation equatorial plane can be involved in an intramolecular π–π interaction with the π-delocalized chelate ring Co1 N1 N2 C1 C2, distance C10...X1A 3.001(3) Å (where X1A is the centre of the chelate ring). Similar orientations of the thiourea fragments in the $[Co(DH)_2Tu_2]$ units have already been noticed in some earlier reported structures of similar complexes [37–39].

The $[Co(DH)_2Tu_2]^+$ cations and $[CF_3SO_3]^-$ anions are connected in the crystal via numerous hydrogen bonds. Interaction of the amino groups from the S(1)C(11)N(7)-

Table 4

N(8) moiety with the oxygen atoms of the DH-units leads to the formation of an infinite centrosymmetric 1D network N7–H7B...O2$^{\#2}$ 2.844(3) Å, N8–H8B...O4$^{\#5}$ 2.956(3) Å. Hydrogen-bond interactions of thiourea molecules with the triflate anions generate a 3D hydrogen-bond network in the crystal. The hydrogen-bond geometry is given in Table 4.

3.4.3. Compound *III*

The crystals of **III** consist of centrosymmetric $[Co(DH)_2Py_2]^+$ cations and $[CF_3SO_3]^-$ anions (Fig. 5). The triflate ion is disordered around the inversion center located in the middle of the C–S bond. The complex cation shows a *trans*-octahedral configuration (6N) around the metal ion with the two DH-chelating units in the equatorial plane of the Co^{III} ion and apical sites occupied by the two pyridine ligands. The coordination geometry, which for compound **III** shows no unusual features, is given in Table 2. The pyridine molecule is nearly perpendicular to the equatorial plane of the complex cation with a dihedral angle equal to 88.6(1)°. The OH groups from two DH^- units are involved in typical strong O–H...O intramolecular hydrogen bonds and there are no other classical hydrogen-bond donors in **III**.

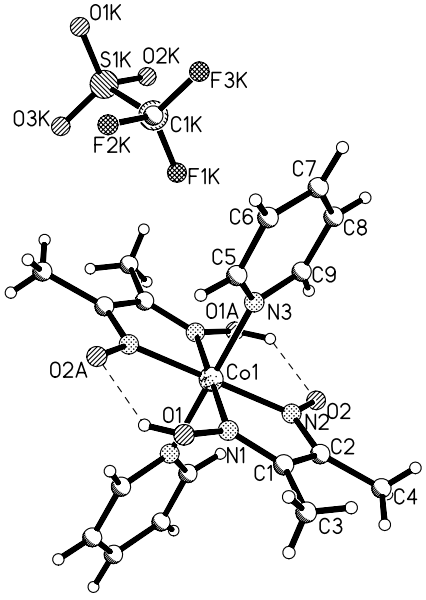

Fig. 5. Ortep drawing and atom labelling in **III**.

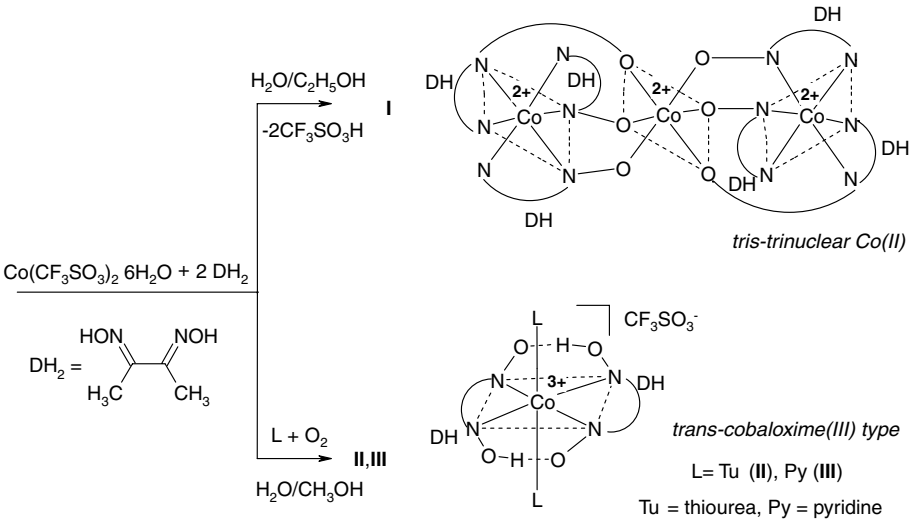
The crystal structures in **II** and **III** are different. In the first Tu fragments have an essential role in crystal formation. The $[Co(DH)_2Tu_2]^+$ cations and $[CF_3SO_3]^-$ anions are connected in the crystal via numerous hydrogen bonds. Interaction of the amino groups from the S(1)C(11)N(7)N(8) moiety with the oxygen atoms of the DH-units leads to the formation of the infinite centrosymmetric 1D network N7–H7B...O2$^{\#2}$ 2.844(3) Å, N8–H8B...O4$^{\#5}$ 2.956(3) Å. The last leads to the formation of infinite chains with various centre-symmetrical dimers motifs. Hydrogen-bond interactions of thiourea molecules with the triflate anions generate a 3D hydrogen-bond network in the crystal. The hydrogen-bond geometry is given in Table 4.

Only one type of dimer motive takes part in the formation of infinite centre-symmetrical dimer chains in**III**. The several short intermolecular C–H...O contacts with H...O distances less than 2.6 Å can be found. The shortest of them is between C5–H of the pyridine ring and O1 from the DH^- ligand C5...O1 3.171(5), C5–H5 0.91(4), H5...O1 2.45(5) Å and C5–H5...O1 136(4)°. This interaction generates (on principle different from **II**) centrosymmetric dimer-chains.

The X-ray structural analysis confirmed the identity of two types of complexes: trinuclear tris Co(II) and mononuclear *trans* cobaloxime compounds, obtained by using Co(II) trifluoromethanesulfonate as the starting material in the synthesis of dimethylglyoximate complexes (Scheme 2).

The assembling of the first system is due to the synthetic behavior of the TfO-anion, especially its leaving group ability and non-coordinating properties which provoke the coordination unsaturation of the central atom and evidently the tris-type structure. The formation of *cis*-cobaloxime seems to be a general feature of weakly coordinated and less strong anions like perchlorate, trifluoroacetate and triflate, and can be considered as an alternative way for the synthesis of *cis*-cobaloxime. If the *cis*-formation via the "rearrangement of *trans*-precursors" is governed by the destruction of the hydrogen-bonded system: by proton abstraction (compound **C** from Scheme 1) [5] or opposite their addition (compound **D** from Scheme 1) [8,9], in our case (**I**) as well as in [10 and 12] (compound **A** and **E**, respectively, from Scheme 1), this process occurs during the one pot reaction of the starting reagents (DH_2 and CoX_2, where $X^- = CF_3SO_3^-, ClO_4^-, F^-$). To the best of our knowledge this is the first report on structurally characterized Co(II) tris-cobaloxime.

When additional donor ligands (Py, Tu) are present during the reaction under similar conditions, exclusively mononuclear Co(III) *trans*-mixed-ligand cobaloxime



Scheme 2. Synthesis of compounds **I**–**III**.

complexes were obtained (**II**–**III**). The preference for a *trans*-conformation is probably due to the coordination saturation of the central atom with additional apical donors and the steric demand of bulky DH^- chelating ligands which are located in-plane and tailored with two intramolecular hydrogen bonds in a stable quasi-macrocyclic system. Although these complexes form from Co(II) salts, the central atom in **II** and **III** is oxidized to Co(III) by air oxygen during the reaction.

Generally, dimethylglyoxime can act not only as a "classical" bidentate ligand (via two nitrogen atoms), but also in a tridentate bridging manner (μ-ONN) or a double bridging tetradentate mode (μ^2-ONNO), giving rise to linear polynuclear (multimetal) systems. In complex **I** the DH_2 group exhibits a tridentate bridging behavior whereas in complexes **II** and**III** it acts as a typical bidentate chelating ligand.

4. Conclusions

Cobalt triflate has been found to be a useful starting material for the formation of two types of dimethylglyoximate species trinuclear tris- Co(II) and "classical" Co(III) octahedral *trans*-mononuclear structures. The identity of the compounds was confirmed by X-ray crystallography, elemental analysis, FAB mass spectrometry, ^1H and ^{13}C NMR, UV–Vis, IR and magnetochemistry. No oxidation of Co(II) starting precursors occurs during the assembling of non-trivial trinuclear tris-dimethylglyoximate species. This is the first report on structurally characterized Co(II) tris-cobaloxime.

environmental changes, which could be easily followed, for instance by optical spectroscopy [7b].

Oxomolybdenum(V) complexes were among the porphyrins studied in the past for both catalytic and analytical purposes [1–3,17–27]. One point of interest in these compounds is that they present ligand exchange behaviour similar to that encountered in the biochemical function of iron porphyrins. The main difference between the iron and molybdenum porphyrins is that in the molybdenum case the oxo ligand is placed in one of the two axial positions and that ligand exchange reactions are based on the ease of removal of the ligand placed at the *trans* position to this oxo ligand [1,28–31]. These reactions are usually redox ones, accompanied by oxidation or reduction of the metal, and sometimes can be photoassisted. In the last case the oxomolybdenum(V) porphyrins function as photoreducing agents [32,33].

In this context, we are interested in investigating the photoassisted ligand exchange reactions of oxomolybdenum(V) porphyrins, mainly in view of possible sensing applications, but also for the dechlorination of chlorinated pollutants. Herein, we study the photochemical behaviour of oxomolybdenum(V) porphyrins in different chemical environments and under different conditions. More specifically, we report on the photochemically-induced ligand exchange reactions of the ethoxy-oxo(TPP)Mo(V) complex mainly in chlorinated solvents and secondarily in non-chlorinated solvents.

2. Experimental

2.1. Materials

The starting chemicals were reagent grade and were used without further purification, except as noted. The basic type I alumina column was activated at 150 °C for a minimum of 24 h. H_2(TPP) and $Mo(CO)_6$ were the starting materials used for the synthesis of the dimer μ-oxo(TPP)-Mo(V) according to a slightly modified (dichloromethane was used instead of chloroform as eluant) Srivastava method [34,35]. The synthesis was performed under an argon stream atmosphere using Schlenk-tube techniques. The dimer was identified with FTIR and UV–visible spectroscopy and the spectra obtained were compared with the corresponding ones in the literature [28] (Fig. S1). Elution of the reaction mixture from the basic activated alumina column with dichloromethane, containing a small quantity of ethanol for stabilization, resulted in the formation of the ethoxy-oxo(TPP)Mo(V) complex, as was identified by UV–visible spectroscopy.

2.2. Instrumentation and physicochemical measurements

Absorption spectra were collected on a Perkin–Elmer Lambda 6 grating spectrophotometer and ε ($M^{-1}\,cm^{-1}$) measurements were performed in $CHCl_3$ solutions of 0.05×10^{-3} M. FTIR spectra were recorded on a Perkin–Elmer FT series 1760 spectrophotometer in KBr pellets. ESR spectra were obtained with a X-band Buker 220 SE spectrometer. GC analyses were conducted with a DANI 8521 gas chromatograph equipped with a flame ionization detector, using columns packed with Carbowax, 20 M, 5% on Chromosorb W-AW.

Solutions of the ethoxy-oxo complex with concentration 2.4×10^{-4} M in various solvents were initially prepared. More concentrated solutions of $\sim10^{-3}$ M of this complex were prepared only for detection reasons and it is explicitly stated when used. The solutions of the ethoxy-oxo complex were irradiated with a 500 W high-pressure Hg lamp (usually operated at 300 W) and the desired wavelength range (450–455 nm) has been selected with an ORIEL monochromator.

For the measurement of the quantum yield, e.g. of the photochemical conversion of the ethoxy-oxo complex to the chloro-oxo complex during the exposure at ~450 nm, the number of moles of photons absorbed was measured with radiometry at this wavelength and the number of moles of the ethoxy-oxo complex reacted was calculated from the corresponding UV spectra: initially (absorbance A_o at 450 nm) and after the irradiation (absorbance A at 450 nm), where A_o and A differ less than 10%. Repeated experiments indicated that this method for the determination of the quantum yield had an error of up to 20%.

3. Results and discussion

3.1. Photochemically-induced ligand exchange reactions

The first experimental evidence of photochemically-induced ligand exchange reactions of ethoxy-oxo(TPP)-Mo(V) porphyrin has been obtained during its elution with dichloromethane in a chromatographic column. The green solution of this porphyrin was unstable under laboratory light and it was converted to a brown species, which was identified with UV–visible spectroscopy as the chloro-oxo derivative. More specifically, it was noticed that the characteristic 452 nm peak of the ethoxy-oxo complex was significantly reduced under laboratory light and the characteristic 497 nm peak of the chloro-oxo complex was formed, along with all the other peaks of that complex mentioned in the literature [1,28] (see Fig. 1 and Table 1).

This photochemical reaction was further investigated under controlled conditions. It was found that photoexcitation of a dichloromethane solution of the ethoxy-oxo complex (concentration 2.4×10^{-4} M) in the Soret band region (450–455 nm) induced a ligand exchange reaction: the ethoxy ligand was replaced by the chloride one. UV–visible spectroscopy indicated that the ethoxy-oxo complex was completely (100%) converted to the chloro-oxo complex (after 340 s of illumination under the experimental conditions used), as shown in Fig. 1. The quantum yield of this photochemical reaction at 450 nm was $\sim38\times10^{-4}$ (Table 1). The reaction progress shown in this figure is similar to the one obtained through chloride anion addition to a

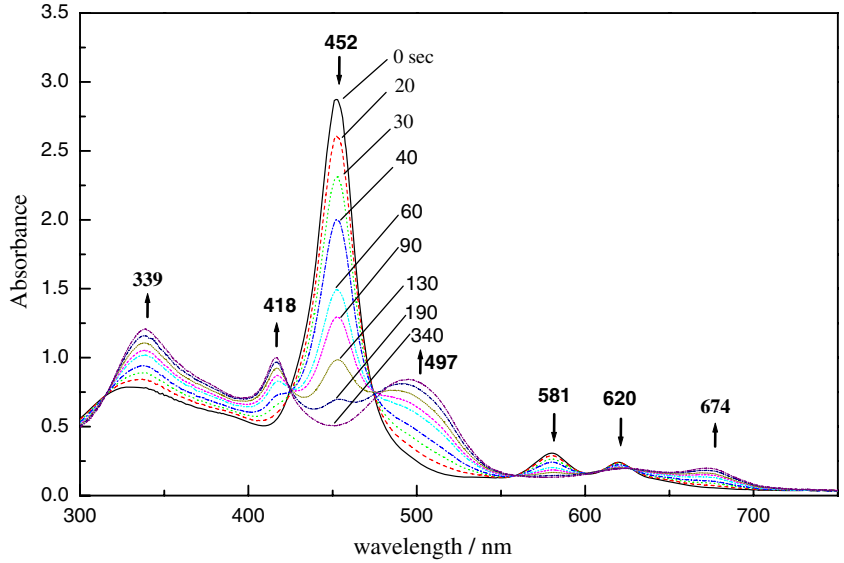

Fig. 1. UV–vis spectra evolution during Soret band irradiation of the ethoxy-oxo complex in dichloromethane. The ethoxy-oxo complex is completely converted to the chloro-oxo complex. (The exposure time is written on each spectrum.)

Table 1
(a) UV–vis absorption data and (b) quantum yields of photochemical reactions of molybdenum porphyrins[a]

(a)

Complex	Solvent	Wavelength (nm) ($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1})	Ref.
Ethoxy-oxo Mo(V)	dichloromethane	453(182), 540(3.5), 581(15.9), 620(10.9)	[1,28]
Chloro-oxo Mo(V)	dichloromethane	343(60), 417(3.3), 498(43), 628(8.6), 674(9.3)	[1,28]
Hydroxy-oxo Mo(V)	dichloromethane	464(90), 593(10.8), 635(8.4)	[1,28]
μ-Oxo Mo(V)	benzene	410(36), 444(59), 583(3.5), 617(4.2), 667(3.3)	[1,28]
Oxo Mo(IV)	dichloromethane	429(295), 480(2.43), 511(3.79), 553(17.2), 590(3.4), 640(1.2)	[1,23]

(b)

Initial complex	Solvent	Additive-concentration (%v/v)	Photochemically formed complex	Quantum yield ($\Phi \times 10^4$)
Ethoxy-oxo Mo(V)	dichloromethane		chloro-oxo Mo(V)	38 ± 8
Ethoxy-oxo Mo(V)	acetone		oxo Mo(IV)	13 ± 3
Ethoxy-oxo Mo(V)	tetrachloroethylene		chloro-oxo Mo(V)	2.5 ± 0.5
Ethoxy-oxo Mo(V)	acetone	CH_2Cl_2 (2.5%)	chloro-oxo Mo(V)	2.5 ± 0.5

[a] The concentration of the initial ethoxy-oxo complex was 2.4×10^{-4} M.

methoxy-oxo(TPP)Mo(V) solution, as has been reported before [23].

The observed photoassisted ligand exchange process may be explained on the basis of reactions (1)–(4). According to the literature [32,33], photolysis of the ethoxy-oxo(TPP)Mo(V) porphyrin is expected to induce primarily the reduction of the metalloporphyrin and the formation of ethoxy radicals according to the following equation:

$$Mo^{V}O(TPP)OEt + h\nu \rightarrow Mo^{IV}O(TPP) + CH_3CH_2O^{\cdot} \quad (1)$$

In agreement with this statement, irradiation of an acetone solution of the ethoxy-oxo complex (concentration 2.4×10^{-4} M) in the Soret band provided evidence that some amounts of the oxo(TPP)Mo(IV) complex are accumulated. In fact, Fig. 2 shows a decrease of the ethoxy-oxo complex absorption at 450 nm and the growth of a new band at 420 nm, which can be ascribed to the formation of the oxo-complex [1,23,28]. The quantum yield of this photochemical reaction at 450 nm was $\sim 13 \times 10^{-4}$ (Table 1).

Evidence for the formation of ethoxy radicals was obtained by irradiating ethoxy-oxo porphyrin solutions containing phenyl-*tert*-butylnitrone (PBN) as a spin trap [36a] in the cavity of an ESR spectrometer. This experiment was carried out in the presence of an excess of ethanol (2.5% v/v). The obtained spectrum reported in Fig. 3 consists of a triplet of doublets with the following values of the hyperfine splitting constants: $a_N = 14.2$ and $a_H = 2.5$ G. This spectrum is consistent with the formation of a paramagnetic adduct between PBN and the photogenerated ethoxy radical [36b].

Ethoxy radicals are powerful reducing agents [37] and they are expected to react with dichloromethane resulting in the ejection of Cl^-, in accordance with Eq. (2) [38–41]:

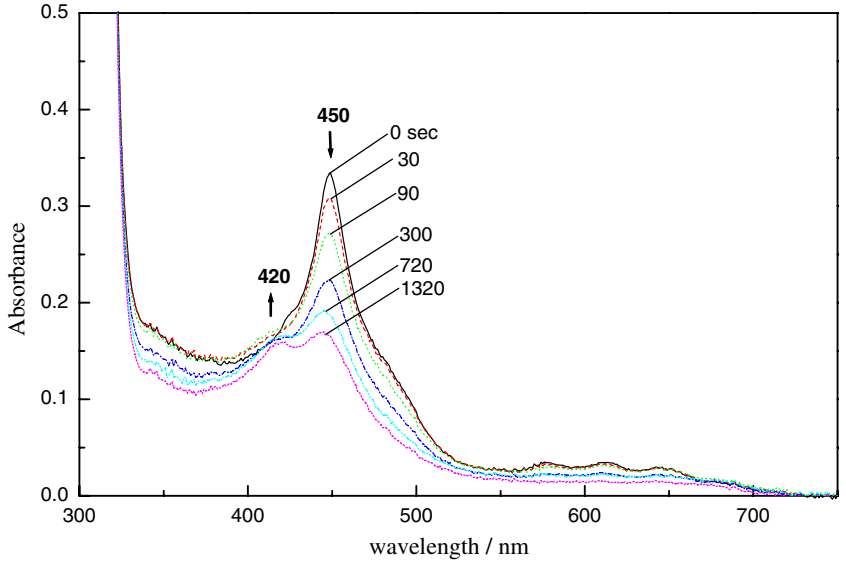

Fig. 2. UV–vis spectra progression during Soret band irradiation of the ethoxy-oxo complex in acetone. The ethoxy-oxo complex is converted to the oxo Mo(IV) complex. (The exposure times are shown.)

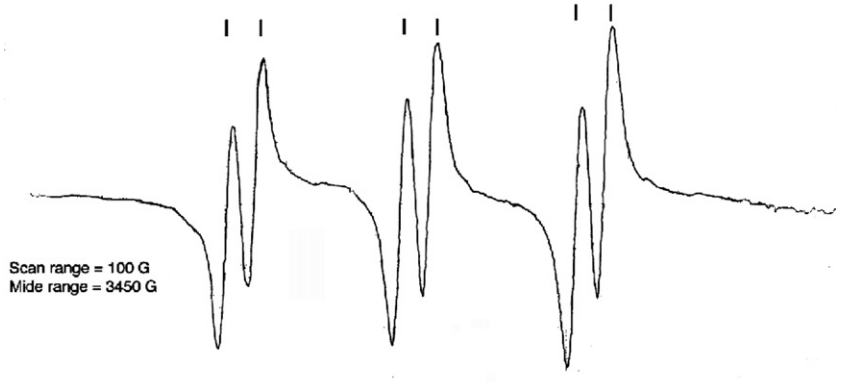

Fig. 3. ESR spectrum of the ethoxy-oxo complex ($\sim 10^{-3}$ M) in dichloromethane containing ethanol (2.5% v/v) and PBN that indicates the formation of a paramagnetic adduct between PBN and the photogenerated ethoxy radical.

$$CH_3CH_2O^{\cdot} + CH_2Cl_2 \rightarrow {}^{\cdot}CH_2Cl + Cl^- + H^+ + CH_3CHO \quad (2)$$

The formation of acetaldehyde through Eq. (2) was demonstrated by gas chromatographic analysis of irradiated dichloromethane solutions of the ethoxy-oxo complex (2.4×10^{-4} M) containing ethanol and water (2.5% v/v each). In fact, we were able to detect with GC analysis the acetal derivative of acetaldehyde, formed through its reaction with EtOH under acidic conditions. Chain propagation reactions that lead to further dechlorination of the ${}^{\cdot}CH_2Cl$ radical are also possible, as has been reported with other dechlorination photocatalysts [42]. The formation of chloride ions through Eq. 2 was verified indirectly by the formation of the chloro-oxo complex during reaction (3).

Thus, the dechlorination reaction (2) is likely to be followed by the equilibrium reaction (3), where Cl^- ions replace the ethoxy ligand of the porphyrin:

$$Cl^- + Mo^{V}O(TPP)OEt + H^+ \rightleftharpoons Mo^{V}O(TPP)Cl + EtOH \quad (3)$$

Reaction (3) has already been reported [23,43] but we also verified it: addition of HCl to the solution of the ethoxy-oxo complex resulted in ligand exchange and the formation of the chloro-oxo complex with the characteristic optical spectrum. We also noticed that the photochemically formed chloro-oxo complex was stable in the absence of light and it did not reconvert to the initial ethoxy-oxo complex, as observed from its optical spectrum.

The reduced complex formed by Eq. (1) is also able to react with dichloromethane, leading to the dechlorination of this solvent and to the formation of the chloro-oxo(TPP)Mo(V) complex according to the following equation:

$$Mo^{IV}O(TPP) + CH_2Cl_2 \rightarrow Mo^{V}O(TPP)Cl + {}^{\cdot}CH_2Cl \quad (4)$$

A similar behaviour has been previously reported for iron *meso*-tetraarylporphyrins and other iron porphyrins dissolved in CCl_4 or $CHCl_3$ [38–40,44].

In an alternative route, it is possible that the photoreduced complex is oxidized by oxygen forming the superoxide ion, O_2^-, which, in turn, has been reported to lead to dechlorination reactions [25,45–48]. This dechlorination pathway is expected to occur with lower efficiency, because the opposite redox reaction, the reduction of oxo(TPP)-molybdenum(V) porphyrins by the superoxide ion, has been reported to take place in similar systems [20].

As it has been already reported [1,33] for analogous compounds, the chloro-oxo complex did not undergo photochemically-induced ligand exchange reactions, a behaviour attributed to the high polarity of the axial coordination bond. It is generally known that the more ionic the axial coordination bond of an oxomolybdenum(V) complex the less readily the complex is photoreduced, because this bond is cleaved homolitically upon photoirradiation [1,33].

3.2. Effects of the reaction medium on the photoproduct formation

3.2.1. Homogeneous systems

The photoassisted ligand exchange reaction of the ethoxy-oxo metalloporphyrin was also investigated in tetrachloroethylene, in the presence of oxygen. Thus, a tetrachloroethylene solution of the ethoxy-oxo complex (concentration 2.4×10^{-4} M) was irradiated at the Soret band. The ethoxy-oxo complex was completely (100%) converted to the chloro-oxo complex after ~72 min exposure via the same photochemical ligand exchange reaction, as shown in Fig. 4. In this figure, two isosbestic points appear again, but these points are red shifted (at 384 and 467 nm) in comparison with the spectra obtained before in dichloromethane. On the other hand, the disappearance of the characteristic 450 nm peak of the ethoxy-oxo complex and the appearance of the characteristic 492 nm peak of the chloro-oxo complex shows an almost identical behaviour with the one observed in dichloromethane. Additionally, the photochemical reaction in tetrachloroethylene is significantly slower than in dichloromethane, since the quantum yield of the ligand exchange reaction in tetrachloroethylene ($\sim 2.5 \times 10^{-4}$) is almost one order of magnitude smaller than the one in dichloromethane (Table 1). Similar photochemical behaviour of the ethoxy-oxo complex was also observed in experiments with other chlorinated solvents, such as 1,2-dichloroethane and 1,2,4-trichlorobenzene.

The photoinduced ligand exchange process was also investigated in acetone containing a low percentage of a chlorinated solvent, to be compared with results obtained in pure acetone. Thus, an acetone solution of the ethoxy-oxo complex (2.4×10^{-4} M) containing dichloromethane (2.5% v/v) was irradiated at the Soret band. The ethoxy-oxo complex was converted to the chloro-oxo complex, but with lower efficiency than in pure dichloromethane. Indeed, the quantum yield was $\sim 2.5 \times 10^{-4}$, which is almost one order of magnitude smaller than the one in dichloromethane only (Table 1).

Spectral evidence indicates that the described photoassisted formation of the chloro-oxo metalloporphyrin occurs also when irradiation is carried out in the presence of a large excess of ethanol (molar ratio EtOH/complex ~220:1) in dichloromethane solution. This is a clear indication that equilibrium (3) remains shifted to the right despite the high concentration of the ethanol added. The high stability of the chloro-oxo complex in the presence of ethanol was confirmed by the finding that addition of ethanol

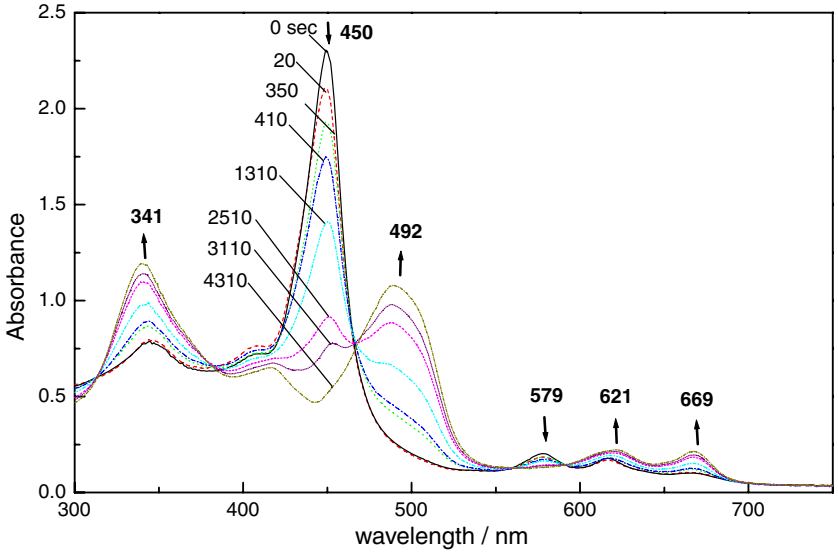

Fig. 4. UV–vis spectra evolution during Soret band exposure of the ethoxy-oxo complex in tetrachloroethylene. The ethoxy-oxo complex is completely converted to the chloro-oxo complex. (The exposure times are given; compare with data of Fig. 2.)

(0.5% v/v) to a dichloromethane solution of the photochemically obtained chloro-oxo complex (2.4×10^{-4} M) did not induce any spectral changes. An undesired consequence of these results is that the restoration of the initial ethoxy-oxo complex for initiating a new photocatalytic cycle is not possible by simple addition of ethanol in excess.

3.2.2. Biphasic systems

The results discussed so far indicate that the photochemical conversion of the ethoxy-oxo complex to its chloro-oxo derivative puts an end to the desired photoassisted ligand exchange process, due to the high stability of the chloro complex, also in the presence of an excess of ethanol. In the following, we demonstrate that the use of biphasic systems enables us to regenerate the starting ethoxy-oxo porphyrin, so inducing the photoassisted ligand exchange process in a cyclic manner.

Addition of ethanol and water (2.5% v/v each) to a dichloromethane solution of the photogenerated chloro-oxo complex (2.4×10^{-4} M) resulted in its quantitative conversion to the ethoxy-oxo derivative, as was observed with UV–visible spectroscopy (Fig. 5a). Under these conditions, water removes high amounts of Cl^- ions from the organic phase, where the metalloporphyrin complex is dissolved, favouring in this way the detachment of Cl^- from its axial position and the coordination of ethanol. Subsequently, Soret band irradiation for 170 min of the last solution resulted in the complete formation of the chloro-oxo

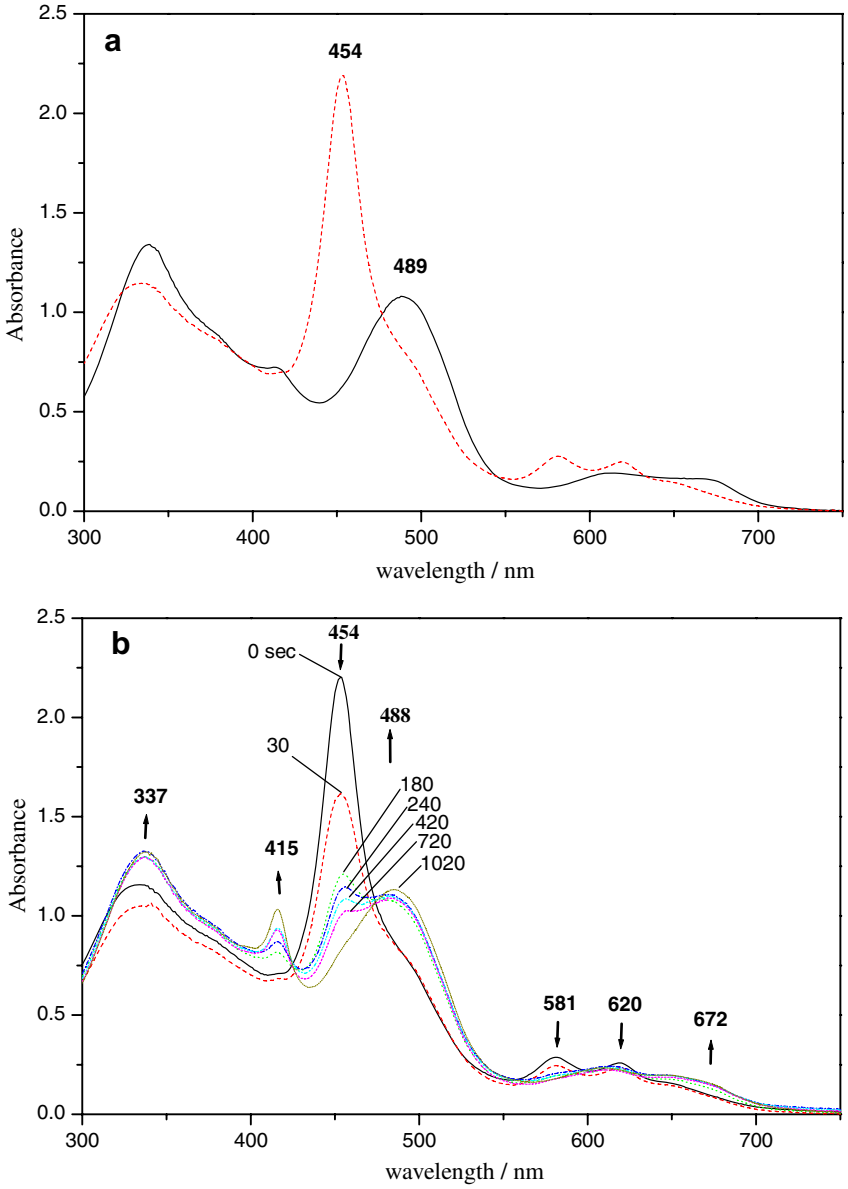

Fig. 5. UV–vis spectra progression during: (a) addition of ethanol and water (2.5% v/v each) to the photochemically converted chloro-oxo complex (2.4×10^{-4} M in dichloromethane), which resulted in the formation of the initial ethoxy-oxo complex; (b) Soret band irradiation (for 170 min) of the ethoxy-oxo complex formed in case (a), which resulted in the formation of the chloro-oxo complex.

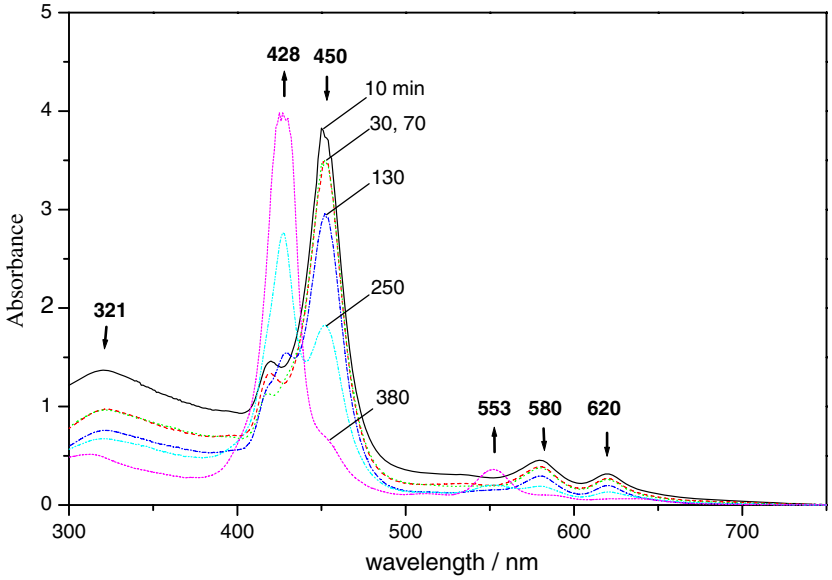

Fig. 6. UV–vis spectra evolution during Soret band exposure of a dichloromethane solution of the ethoxy-oxo complex (2.4×10^{-4} M) containing EtOH, H_2O and aqueous NaOH solution 1 M (2.5% v/v each). The ethoxy-oxo complex is completely converted to the oxo(TPP)Mo(IV) complex.

complex through the same photochemical ligand exchange route (Fig. 5b). In this case, the whole heterogeneous solution was irradiated, but in fact the organic phase was exposed and the UV–visible spectrum of this phase was obtained, as the small quantity of the added water occupied the bottom of the cell. In Fig. 5b, the complete disappearance of the characteristic 454 nm peak of the ethoxy-oxo complex and the appearance of the characteristic 488 nm peak of the chloro-oxo complex are presented.

Consequently, the formation of the biphasic system (dichloromethane/water with a major concentration of ethanol) of the ethoxy-oxo complex favours the photocatalytic inducement of the previous ligand exchange route. The photocatalytic cycles are terminated as soon as the whole quantity of ethanol in the organic phase is photooxidised. New catalytic cycles can be achieved by the biphasic system with addition of a further quantity of ethanol. Thus, the studied photoassisted ligand exchange process could be used for the dechlorination of pollutants upon addition of ethanol and water forming a biphasic system.

In order to increase the photocatalytic cycles of the photoassisted ligand exchange process, ethanol, water and NaOH were added to a dichloromethane solution of the ethoxy-oxo porphyrin. More specifically, ethanol, water and aqueous NaOH solution 1 M (2.5% v/v each) were added to a dichloromethane solution of the ethoxy-oxo complex (2.4×10^{-4} M). Subsequently, Soret band irradiation of the solution for 380 min led to the complete formation of the oxoMo(IV) complex, as was observed by UV–vis spectroscopy (Fig. 6). The formation of the hydroxy-oxo(TPP)Mo(V) complex, which could be expected in this case, was not observed (i.e. the major 464 nm peak of the hydroxy-oxo complex along with the other peaks of that complex were not observed, see Fig. 6 and Table 1). On the other hand, both the characteristic peaks at 428 and 553 nm of the oxoMo(IV) complex were obtained. Furthermore, detection of the acetal derivative in this irradiated biphasic system with GC analysis was not feasible, due to the predominant basic conditions. Therefore, in this last, quite complicated biphasic system, the photoassisted ligand exchange route was changed, as no chloro-oxo complex was observed. A possible explanation is that NaOH removes more effectively the Cl^- ions from the organic phase than water does. Nevertheless, further investigation on this system is necessary in order to clarify the picture.

4. Conclusions

In this contribution, the photoassisted ligand exchange reactions of ethoxy-oxo(TPP)Mo(V) porphyrin were studied. In this first investigation specific attention has been given to the formation of the photochemically inert chloro-oxo complex, which results in a net overall photoassisted ligand exchange reaction. This reaction is easily followed due to the characteristic UV–visible spectra evolution in different chlorinated solvents. Regeneration of the starting ethoxy-oxo complex and, thus, photocatalytic inducement of the ligand exchange route was not possible by simple addition of ethanol in excess, but only with the addition of water and ethanol in the reaction medium, where a biphasic system is formed. Further addition of NaOH changed the photoassisted ligand exchange route, and led to the formation of the oxoMo(IV) complex, instead of the chloro-oxo complex. The mechanistic details and the possible practical value of the described chemistry in bonded chlorine detection and dechlorination of pollutants appear worthy of further investigation.

RaaiR′ **1** α-NaiR′, **2** β-NaiR′ **3**

R′ = CH_3 (**a**), CH_2-CH_3 (**b**)

2. Experimental

2.1. Materials and methods

1-Alkyl-2-(naphthyl-α/β-azo)imidazoles (α-NaiR′, **2** and β-NaiR′ **3**; R′ = CH_3 (**a**), CH_2-CH_3 (**b**)) were prepared by the reported procedure [18]. $M(CO)_6$ (M = Cr, Mo) and $Me_3NO \cdot 2H_2O$ were Sigma–Aldrich reagents. Reactions were carried out under an extremely dry oxygen free atmosphere under Atmos bags (Sigma–Aldrich). THF and *n*-heptane were dried before use [21]. For the solution spectral studies spectroscopic grade solvents were used from Lancester, UK. Microanalyses (C, H, N) were performed using a Perkin–Elmer 2400 CHN elemental analyzer. Spectroscopic measurements were carried out using the following instruments: UV–VIS spectra, Lambda 25 Perkin–Elmer; IR spectra (KBr disk, 4000–450 cm^{-1}), RX-1 Perkin–Elmer; ^1H NMR and ^{13}C NMR spectra in $CDCl_3$ Bruker 300 MHz FT-NMR spectrometers in the presence of TMS as an internal standard. Emission was examined by a LS 55 Perkin–Elmer spectrofluorimeter at room temperature (298 K) in MeCN under degassed conditions. FAB-MS was collected from JEOL-AX 500. Electrochemical measurements were carried out with the use of a computer controlled EG&G PARC VersaStat model 250 Electrochemical instrument using a Pt-disk working electrode and Pt-wire auxiliary electrode under an inert (dry N_2) environment. The solution was IR compensated and the results were collected at 298 K. The reported results were referenced to Ag/AgCl in CH_2Cl_2 and were uncorrected for junction potential. [*n*-Bu_4N][ClO_4] was used as the supporting electrolyte.

2.2. Preparation of $Cr(CO)_4$(NaiR′) (**4**, **5** (Cr); **6**, **7** (Mo))

A representative case of [$Cr(CO)_4$(α-NaiMe)] (**4a**) is detailed below. To $Cr(CO)_6$ (60 mg, 0.27 mmol) dissolved in dry CH_2Cl_2 (10 cm^3) was added $Me_3NO \cdot 2H_2O$ (62 mg, 0.56 mmol) and the solution was stirred for 45 min. To the resulting yellow solution α-NaiMe (65 mg, 0.28 mmol) was added and the solution was stirred for 4 h. The colour of the solution changed from brown red to dark blue. Then the solvent was evaporated under low pressure and the crude product was passed down a neutral Al_2O_3 column. A blue portion was eluted with benzene:pet-ether (60–80°) (1:1 v/v). Removal of the solvent afforded the analytically pure product (**4a**) in 22% yield.

In analogous reactions treatment of $Cr(CO)_6$ with two molar equivalents of $Me_3NO \cdot 2H_2O$ and an equimolar quantity of α-NaiEt, β-NaiMe and β-NaiEt afforded the complexes [$Cr(CO)_4$(α-NaiEt)] (**4b**) (yield, 29%; blue), [$Cr(CO)_4$(β-NaiMe)] (**5a**) (yield, 35%; green) and [$Cr(CO)_4$(β-NaiEt)] (**5b**) (yield, 30%; green). Microanalytical data are as follows: *Anal.* Calc. for [$Cr(CO)_4$(α-NaiMe)] (**4a**), $C_{18}H_{12}N_4O_4Cr$, C, 54.00; H, 3.00; N, 14.00. Found: C, 53.88; H, 3.04; N, 14.08%. *Anal.* Calc. for [$Cr(CO)_4$-(α-NaiEt)] (**4b**): $C_{19}H_{14}N_4O_4Cr$, C, 55.07; H, 3.38; N, 13.53. Found: C, 55.00; H, 3.30; N, 13.64%. *Anal.* Calc. for [$Cr(CO)_4$(β-NaiMe)] (**5a**): $C_{18}H_{12}N_4O_4Cr$, C, 54.00; H, 3.00; N, 14.00. Found: C, 54.08; H, 3.08; N, 14.05%. *Anal.* Calc. for [$Cr(CO)_4$(β-NaiEt)] (**5b**): $C_{19}H_{14}N_4O_4Cr$, C, 55.07; H, 3.38; N, 13.53. Found: C, 55.02; H, 3.34; N, 13.46%.

2.3. Preparation of [$Mo(CO)_4$(α-NaiMe)] (**6a**)

To $Mo(CO)_6$ (60 mg, 0.23 mmol) dissolved in dry CH_2Cl_2 (10 cm^3) was added $Me_3NO \cdot 2H_2O$ (52 mg, 0.47 mmol), and the solution was stirred for 45 min. To the resulting solution α-NaiMe (54 mg, 0.23 mmol) was added and the solution was stirred for a further 5 h. The colour of the solution changed from brown red to dark blue. Then the solvent was evaporated under reduced pressure and the crude product was passed down a neutral Al_2O_3 column. A blue portion was eluted with benzene: pet-ether (1:1, v/v). Removal of the solvent afforded the analytically pure dark blue product [$Mo(CO)_4$(α-NaiMe)] (**6a**) in 43% yield.

In analogous reactions treatment of $Mo(CO)_6$ with two molar equivalents of $Me_3NO \cdot 2H_2O$ and an equimolar quantity of α-NaiEt, β-NaiMe and β-NaiEt afforded the complexes [$Mo(CO)_4$(α-NaiEt)] (**6b**) (yield, 30%; blue), [$Mo(CO)_4$(β-NaiMe)] (**7a**) (yield, 44%, green) and [$Mo(CO)_4$(β-NaiEt)] (**7b**) (yield, 40%, green). Microanalytical data are as follows: *Anal.* Calc. for [$Mo(CO)_4$-(α-NaiMe)] (**6a**), $C_{18}H_{12}N_4O_4Mo$, C, 48.65; H, 2.70; N, 12.61. Found: C, 48.60; H, 2.64; N, 12.68%. *Anal.* Calc. for [$Mo(CO)_4$(α-NaiEt)] (**6b**): $C_{19}H_{14}N_4O_4Mo$, C, 49.78; H, 3.06; N, 12.23. Found: C, 49.84; H, 3.11; N, 12.14%. *Anal.* Calc. for [$Mo(CO)_4$(β-NaiMe)] (**7a**): $C_{18}H_{12}N_4O_4$ Mo, C, 48.65; H, 2.70; N, 12.61. Found: C, 48.62; H, 2.74; N, 12.56%. *Anal.* Calc. for [$Mo(CO)_4$(β-NaiEt)] (**7b**): $C_{19}H_{14}N_4O_4Mo$, C, 49.78; H, 3.06; N, 12.23. Found: C, 49.72; H, 3.10; N, 12.28%.

3. Results and discussion

3.1. Synthesis

The equimolar reaction of α/β-NaiR′ and $M(CO)_6$ (M = Cr, Mo) under stirring conditions in dry CH_2Cl_2 in the presence of two equivalents of Me_3NO under a nitrogen environment for a period of 4–6 h has synthesized blue or green complexes in 25–45% yield. The ligands, 1-alkyl-2-(naphthyl-α/β-azo)imidazoles (α-NaiR′, **1**; β-NaiR′, **2** and R′ = -CH_3 (**a**), CH_2-CH_3 (**b**)), are N, N′ chelating systems where N and N′ refer to N(imidazole) and N(azo) donor centres, respectively. Use of Me_3NO has reduced the reaction time to one-tenth of the reaction time in its absence and also increases the yield of the product from <5% to >20%. The composition of the complexes, *cis*-[$M(CO)_4$(NaiR′)] (M = Cr (**4** for α-NaiR′ and **5** for β-NaiR′); Mo (**6** for α-NaiR′ and **7** for β-NaiR′)), has been supported by microanalytical and spectroscopic data. We have attempted to crystallize these complexes but failed to get a good quality diffracting crystals. We have attempted to synthesize the complexes *cis*-[$M(CO)_2$(NaiR′)$_2$] and [M(NaiR′)$_3$] using an excess of the ligands and Me_3NO, but in each experiment (at varied temperature and solvent) we get only an intractable brown solid

$$M(CO)_6 + 2Me_3NO + \alpha/\beta\text{-NaiR}' \rightarrow [M(CO)_4(\alpha/\beta\text{-NaiR}')] + 2CO_2 + 2Me_3N \quad (1)$$

The complexes are soluble in solvents of different polarity, from benzene to acetonitrile, chloroform, dichloromethane. Solutions of *cis*-[$M(CO)_4$(α-NaiR′)] (**4** and **6**) are blue while those of *cis*-[$M(CO)_4$(β-NaiR′)] (**5** and **7**) are green. They are non-electrolytes and are diamagnetic.

3.2. Spectroscopic characterization

3.2.1. FT-IR and mass spectra

FT-IR spectra were taken in KBr discs and in CH_2Cl_2 solution. The carbonyl stretching frequencies of the complexes are presented in Table 1. The spectra show three or four bands (three bands appear in the intensity ratio 1:2:1, where intensity is compared from the area measurement using the ORIGIN 6.0 program). The spectra in solution (CH_2Cl_2) show ν(CO) at 2–15 cm^{-1} higher frequency than that of KBr-phase data. The mean value of the three or four ν(CO) in these cases is lower ($\Delta\nu$(CO) = 15–25 cm^{-1}) than that of $M(CO)_4$(2-PAP) (2-PAP = 2-(phenylazo)pyridine) [4]. This supports weaker π-acidity of naphthylazoimidazoles than that of phenylazopyridine. On comparing with the spectral pattern and frequency of CO stretching of [$M(CO)_4$(2-PAP)] [4] and [$M(CO)_4$(RaaiR′)] [12] (RaaiR′ = 1-alkyl-2-(arylazo)imidazole), the present complexes are assigned to *cis*-tetracarbonyl complexes with octahedral coordination where the ligand NaiR′ binds as a bidentate chelating agent. The ν(N=N) and ν(C=N) bands appear at 1390–1400 and 1590–1600 cm^{-1} respectively. The mass fragmentation by FAB-MS of the complexes supports the expected fragmentation pattern of M^+, $(M-CO)^+$, $(M-2CO)^+$, $(M-3CO)^+$, $(M-4CO)^+$ (Table 1). This information also helps us to identify the tetracarbonyl complexes of NaiR′.

3.2.2. UV–Vis spectra and emission properties

Benzene solutions of the complexes are either blue (α-NaiR′ complexes, [$M(CO)_4$(α-NaiR′)] (**4**, **6**)) or green (β-NaiR′ complexes, [$M(CO)_4$(β-NaiR′)] (**5**, **7**)). The spectra show three or four high intense ($\varepsilon \sim 10^4$) bands within 350–625 nm (Figs. 1 and 2). The main band around 600 nm shifts to shorter wavelength on going from the less polar CH_2Cl_2 to a more polar solvent (MeCN). In d^6-

octahedral complexes of the M(0)-state, the lowest energy electronic transition is from a filled metal d orbital to the unoccupied lowest energy π^* orbital of the ligand, and the transition in this case is rightly defined as a MLCT transition. Other transitions <400 nm are intraligand (n–π^*/π–π^*) transitions (ILCT) and have been verified with free ligand data [22]. [$M(CO)_4$(β-NaiR′)] show ILCT at longer wavelength (370–385 nm) compared to [$M(CO)_4$(α-NaiR′)] (330–340 nm). This suggests that [$M(CO)_4$(α-NaiR′)] has a better ground state stability than [$M(CO)_4$(β-NaiR′)] while the excited state energy is more or less same as these complexes.

The photoluminescence properties of the complexes (**4**–**7**) were studied at room temperature (298 K) in benzene (Figs. 1 and 2). The ligands are photo-inactive both at room temperature and low temperature. The emission is observed upon excitation at shorter wavelength 330–380 nm (Table 2). The absorptions <400 nm are assigned to n–π^*/π–π^* transitions. Thus, the emission observed in the complexes is tentatively assigned to (π–π^*) intraligand fluorescence. In the absence of metal ions, fluorescence of the ligand is probably quenched by the occurrence of a photoinduced electron transfer (PET) process due to presence of a lone pair of nitrogen atoms. Such a PET process is prevented by the complexation of ligand with metal ions; thus the fluorescence intensity may be enhanced by the coordination to a metal ion. However, naphthylazoimidazole complexes of Ru(II) (d^6), Os(II) (d^6) or Pt(II) (d^8) [23–25] do not exhibit emission properties. Fluorescence activity of [$M(CO)_4$-(NaiR′)] may be due to the presence of CO. The high π-acidity of CO may be important to maintain a population at an excited state and hence the emission property.

3.2.3. ^1H and ^{13}C NMR spectra

The ^1H NMR spectra (Table 3) were assigned on comparing with free ligand values [22]. An important observation is the downfield shifting of the imidazole protons, 4- and 5-H, by 0.4–0.7 ppm. 4-H is shifted by 0.6–0.7 ppm compared to the shift of 5-H of 0.4–0.5 ppm. This supports the coordination of the imidazole-N (N(3)) to the metal centre. Naphthyl protons (6-H to 13-H) experience small perturbations and the chemical shift data are comparable with free ligand data [22]. The 1-alkyl group shows the usual splitting pattern: 1-Me is a singlet (4.00–4.1 ppm); 1-CH_2-CH_3 shows quartet for the –CH_2– group (4.6–4.7 ppm, $J = 10.0$ Hz) and triplet for the –CH_3 group (1.6–1.7 ppm, $J = 8.0$ Hz). [$M(CO)_4$(β-NaiR′)] show a downfield singlet at 8.4 (for M = Cr) and 8.8 ppm (for M = Mo) which corresponds to the 6-H signal. While the other protons show reverse information, i.e., protons in [$Mo(CO)_4$(NaiR′)] (**6**, **7**) show a marginal upfield shifting by 0.02–0.1 ppm with reference to [$Cr(CO)_4$(NaiR′)] (**4**, **5**).

The ^{13}C NMR spectra are complicated due to a large number of C centres (data are collected in the Supplementary material, Table 4). The assignment has been done by comparing with the spectra of the free ligands [22]. The DEFT study has also distinguished the primary, secondary, tertiary and quaternary C centres. The most downfield signals, observed between 190 and 220 ppm, are due to C in CO. Mo(CO) complexes show higher chemical shift data than the Cr(CO) system. The lowest δ is observed at 42–45 ppm and is assigned to N(1)–CH_3 or N(1)–CH_2–C-centres.

3.2.4. Electrochemistry

The electrochemical properties of the complexes were investigated by cyclic voltammograms (CV) in 0.1 M [*n*-Bu_4N][ClO_4] in CH_2Cl_2 solution at a scan rate of 50 mV S^{-1}. All CV data were collected under a nitrogen environment and potentials are expressed with reference to Ag/AgCl. The results are collected in Table 2. All of the compounds show two oxidations and two reductions. By analogy with similar types of α-diimine complexes [1]

Table 2

and [M(CO)$_4$(2-PAP)] (2-PAP = 2-(phenylazo)pyridine) [4] we suggest that the oxidation is primarily a metal-centred electron extraction. In every case the first oxidation on scan reversal shows a cathodic peak at a potential difference >100 mV to that of the anodic peak and supports quasireversibility (Fig. 3) of the voltammogram. The second oxidation ($M^+ \rightarrow M^{2+}$) in most of the complexes is irreversible in nature and the cathodic peak does not appear at all on scan reversal. [M(CO)$_4$(α-NaiR′)] shows a higher M^+/M^0 redox potential than that of [M(CO)$_4$(β-NaiR′)]. The reduction is referred to electron accommodation to the π^* MO of the chelated NaiR′. The first reduction in each case appears at a more positive potential than that of the free ligand [22], reflecting the stabilization

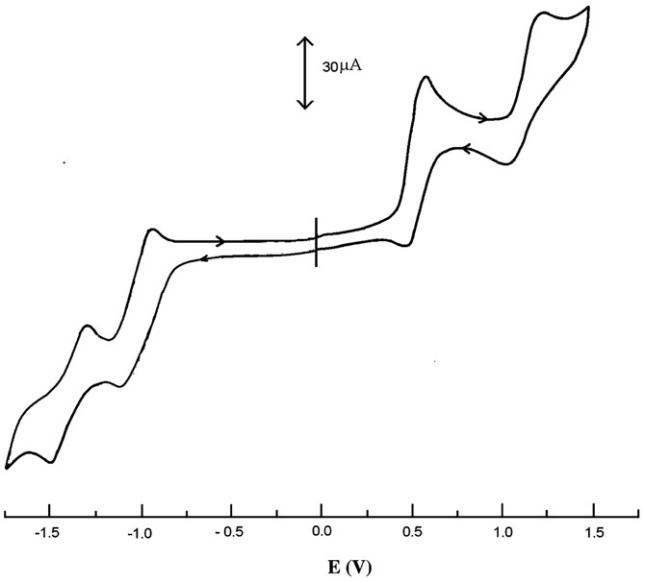

Fig. 3. Cyclic voltammogram of *cis*-[Cr(CO)$_4$(β-NaiEt)] in CH_2Cl_2 using a Pt-disk working electrode, Pt-auxiliary electrode, Ag/AgCl reference and [*n*-Bu_4N][ClO_4] supporting electrolyte.

of the π^* MO upon coordination. The reduction potential follows α-NaiR′ > β-NaiR′ and Mo > Cr. On considering the literature data of NaiR′ complexes [22–25], the reduction is referred to azo/azo$^-$ and azo$^-$/azo$^=$, which appear at a more negative potential than that of analogous 2-(phenylazo)pyridine complexes. This is due to higher π-acidity of pyridine compared to imidazole [13] and higher electronic susceptibility of the naphthyl group compared to the phenyl group [26].

4. Conclusion

Cis-[M(CO)$_4$(α/β-NaiR′)] (M = Cr(0), Mo(0); α/β-NaiR′ = 1-alkyl-2-(naphthyl-α/β-azo)imidazole) are characterized by different spectroscopic tools (FT-IR, UV–Vis, Mass, ^{1}H and ^{13}C NMR). The mass fragmentation pattern shows successive removal of CO. The ligands belong to the π-acidic azoimine family and stabilize efficiently Cr(0) and Mo(0) oxidation states. The cyclic voltammogram gives two metal centred oxidations, M^+/M^0 and M^{2+}/M^+, and two ligand centred reductions, azo/azo$^-$ and azo$^-$/azo$^=$. The complexes exhibit π–π^* emission; *cis*-[M(CO)$_4$(α-NaiR′)] emits at a higher energy than *cis*-[M(CO)$_4$(β-NaiR′)].

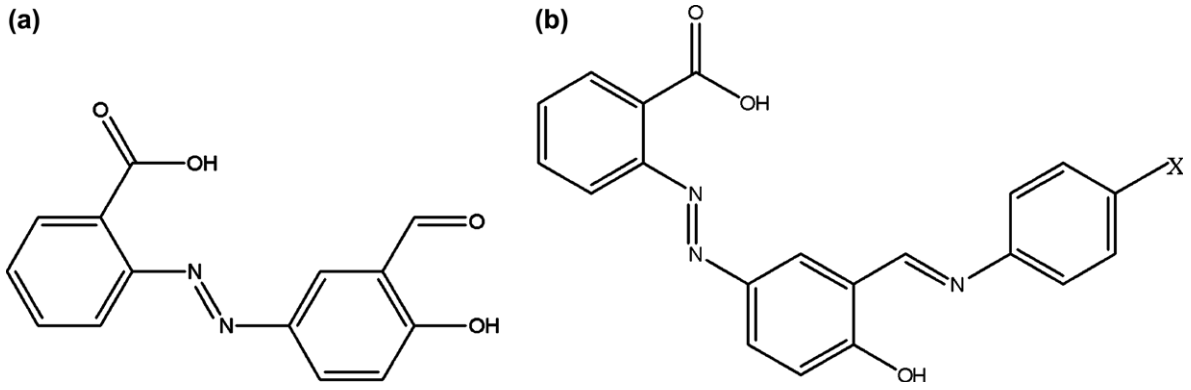

Fig. 1. Generic structure of the ligand. *Abbreviations*. (a) LHH′ (pre-ligand) (b) L^1HH': X = –CH_3; L^2HH': X = –Br, L^3HH': X = –Cl, L^4HH': X = –OCH_3, where H and H′ represent hydroxy and carboxylic acid H atoms, respectively.

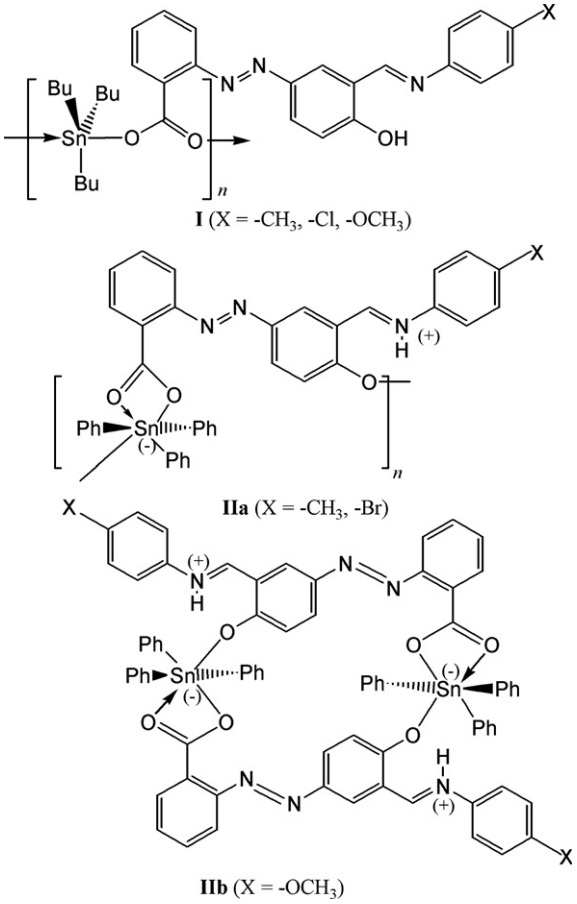

Scheme 1. Structural motifs in $R_3Sn[O_2CC_6H_4\{N{=}N(C_6H_3\text{-}4\text{-}OH\text{-}(C(H){=}NC_6H_4X\text{-}4))\}\text{-}o]$ complexes.

solid state, the three investigated tri-*n*-butyltin(IV) complexes (X = –Cl [4], –OCH_3 [5] or –CH_3 [6]) have the motif **I** structure. The complexes are one-dimensional polymers in which the two carboxylate O atoms of a single benzoate ligand bridge the adjacent $SnBu_3$ groups. The Sn atom has a slightly distorted *trans*-Bu_3SnO_2 trigonal-bipyramidal coordination geometry with O atoms from two different carboxylate ligands occupying the axial positions. In contrast to the tri-*n*-butyltin(IV) analogues, the carboxylate ligands in the triphenyltin(IV) complexes (X = –Br or –CH_3 [1]) were found to exist in a zwitterionic form as a result of the coordination of the phenoxide O atom to a Sn atom. Two structural motifs, **IIa** and **IIb**, were found. In motif **IIa**, a polymeric *trans*-Ph_3SnO_2 configuration was observed where the adjacent $SnPh_3$ moieties are bridged by a single carboxylate ligand through a carboxylate O atom and the phenoxide O atom. The pattern then continues indefinitely. Each Sn atom has a slightly distorted trigonal-bipyramidal coordination geometry with the carboxylate and phenoxide O atoms from two different carboxylate ligands occupying the axial positions. On the other hand, a subtle modification of the X-substituent in the ligand framework (from –CH_3 or –Br to –OCH_3) results in discrete cyclic centrosymmetric dimers where two $SnPh_3$ entities are bridged by two carboxylate anions through their carboxylate and phenoxide O atoms (motif **IIb**) [1]. Despite the dimerization instead of polymerization, the coordination geometry about the Sn atom is virtually the same as that found in motif **IIa**. The triorganotin(IV) complexes of the type $R_3Sn[O_2CC_6H_4\{N{=}N(C_6H_3\text{-}4\text{-}OH(C(H){=}NC_6H_4X\text{-}4))\}\text{-}o]$, particularly the tri-*n*-butyltin(IV) complexes, were screened for larvicidal activity against the second larval instar of the *Aedes aegypti* and *Anopheles stephensi* mosquito [4,5] as well as for embryo toxicity against the sea urchin (*Paracentrotus lividus* and *Sphaerechinus granularis*) early developmental stages [7]. These compounds have shown promise as larvicides but were found to be toxic against the sea urchin.

Given the synthetic and structural importance and the potential biological activity of the $R_3Sn[O_2CC_6H_4\{N{=}N(C_6H_3\text{-}4\text{-}OH(C(H){=}NC_6H_4X\text{-}4))\}\text{-}o]$ class of complexes, it is of interest to explore the chemistry of the analogous complexes of these ligands with Bz_3Sn(IV). The present contribution details the preparation and spectroscopic characterization of four complexes of this type, viz. $Bz_3Sn[O_2CC_6H_4\{N{=}N(C_6H_3\text{-}4\text{-}OH(C(H){=}NC_6H_4X\text{-}4))\}\text{-}o](OH_2)$ (X = –CH_3, –Br, –Cl, –OCH_3). The crystal structures of two aqua complexes, $Bz_3Sn[O_2CC_6H_4\{N{=}N(C_6H_3\text{-}4\text{-}OH(C(H){=}NC_6H_4X\text{-}4))\}\text{-}o](OH_2)$ (X = –Cl, –OCH_3), are also reported.

2. Experimental

2.1. Materials

Bz_3SnOH was prepared as described by Sisido et al. [8]. The solvents used in the reactions were of AR grade and were dried using standard procedures. Toluene was distilled from sodium benzophenone ketyl. The ligands, 2-{(*E*)-4-hydroxy-3-[(*E*)-4-(aryl)iminomethyl] phenyldiazenyl}benzoic acids, $L^{1-4}HH'$, were prepared and characterized as described in our earlier report [4]. The compound $Bz_3SnLH \cdot OH_2$ (where $LH = O_2CC_6H_4(N{=}N(C_6H_3\text{-}4\text{-}OH\text{-}5\text{-}CHO)\text{-}o)$ [9]) has been included for the convenience of the discussion.

2.2. Physical measurements

Carbon, hydrogen and nitrogen analyses were performed with a Perkin–Elmer 2400 series II instrument. IR spectra in the range 4000–400 cm^{-1} were obtained on a BOMEM DA-8 FT-IR spectrophotometer with samples investigated as KBr discs. The ^1H, ^{13}C and ^{119}Sn NMR spectra were recorded on a Bruker AMX 400 spectrometer and measured at 400.13, 100.62 and 149.18 MHz, respectively. The ^1H, ^{13}C and ^{119}Sn chemical shifts were referred to Me_4Si set at 0.00 ppm, $CDCl_3$ set at 77.0 ppm and Me_4Sn set at 0.00 ppm, respectively. The Mössbauer spectra of the complexes in the solid state were recorded using a Model MS-900 spectrometer in the acceleration mode with a moving source geometry. A 10 mCi $Ca^{119m}SnO_3$ source was used and counts of 30,000 or more were accumulated for each spectrum. The spectra were measured at 80 K using a liquid-nitrogen cryostat. The velocity was calibrated at ambient temperature using a composition of $BaSnO_3$ and tin foil (splitting 2.52 mm s^{-1}). The resultant spectra were analyzed using the Web Research software package.

2.3. Synthesis of the tribenzyltin(IV) complexes

A typical method is described below.

2.3.1. Synthesis of $Bz_3SnLH \cdot OH_2$ (1)

Compound **1** was synthesized by reacting LHH′ (0.38 g, 1.40 mmol) and Bz_3SnOH (0.58 g, 1.41 mmol) in 50 ml of anhydrous toluene in a 100 ml flask equipped with a Dean-Stark moisture trap and water-cooled condenser. The reaction mixture was refluxed for 8 h and filtered while hot. The filtrate was collected and the volatiles were removed using a rotary evaporator. The residue was dried in vacuo, washed with hexane thoroughly, extracted into benzene and filtered. The crude product was obtained after evaporation and this was then recrystallized from benzene to yield dark-red crystals of the desired product. Yield: (0.36 g, 39%); m.p.: 73–75 °C. *Anal.* Calc. for $C_{35}H_{32}N_2O_5Sn$: C, 61.85; H, 4.70; N, 4.12. Found: C, 61.48; H, 4.53; N, 4.29%. IR (cm^{-1}): 1659 $\nu(OCO)_{asym}$. ^1H NMR ($CDCl_3$): 11.3 (brs, 1H, OH, D_2O exchangeable), 9.78 (s, 1H, C(H)=O), 2.68 (s, 6H, CH_2: Bz_3Sn), 6.72–7.60 (complex multiplets, 22H, remaining ligand and Bz_3Sn protons) ppm. ^{13}C NMR ($CDCl_3$): 196.5 (C(H)=O), 174.9 (CO_2), not detected (C–OH), 24.2 (CH_2: Bz_3Sn), 116.3–161.2 (complex nature of the remaining ligand and Bz_3Sn carbon signals which could not be identified with certainty owing to poor signal to noise ratio) ppm. ^{119}Sn Mössbauer: $\delta = 1.04$, $\Delta = 2.51$ mm s^{-1}, $\rho = 2.4$.

The other tribenzyltin(IV) complexes (**2**–**5**) were prepared by reacting Bz_3SnOH with the appropriate ligand (L^1HH'–L^4HH') following an analogous procedure. The characterization and spectroscopic data of the complexes are given below.

2.3.2. $Bz_3SnL^1H \cdot OH_2$ (2)

Orange-red crystals of compound **2** was obtained from a benzene–hexane mixture (1:3 v/v). Yield: 79%; m.p.: 96–98 °C. *Anal.* Calc. for $C_{42}H_{39}N_3O_4Sn$: C, 65.62; H, 5.11; N, 5.46. Found: C, 65.42; H, 4.83; N, 5.49%. IR (cm^{-1}): 1619 $\nu\ (OCO)_{asym}$. ^1H NMR ($CDCl_3$): 13.1 (brs, 1H, OH, D_2O exchangeable), 8.45 (s, 1H, C(H)=N), 2.69 (s, 6H, CH_2: Bz_3Sn), 2.42 (s, 3H, CH_3), 6.70–8.10 (26H, remaining ligand and Bz_3Sn protons) ppm. ^{13}C NMR ($CDCl_3$): 174.9 (CO_2), 164.5 (C–OH), 160.8 (C(H)=N), 24.3 (CH_2: Bz_3Sn), 20.9 (CH_3), 151.9, 145.7, 144.9, 138.6, 137.3, 131.3, 129.9, 129.1, 128.6, 128.3, 127.8, 127.2, 124.5, 120.9, 118.9, 118.1, 117.8 (remaining ligand and Bz_3Sn carbon signals) ppm. ^{119}Sn NMR (δ, ppm): −10.5. ^{119}Sn Mössbauer: $\delta = 1.39$, $\Delta = 3.07$ mm s^{-1}, $\rho = 2.2$.

2.3.3. $Bz_3SnL^2H \cdot OH_2$ (3)

Red crystals of compound **3** were obtained from a benzene–hexane mixture (1:3 v/v). Yield: 64%; m.p.: 72–74 °C. *Anal.* Calc. for $C_{41}H_{36}BrN_3O_4Sn$: C, 59.09; H, 4.35; N, 5.04. Found: C, 60.19; H, 4.26; N, 5.18%. IR (cm^{-1}): 1619 $\nu\ (OCO)_{asym}$. ^1H NMR ($CDCl_3$): 13.5 (brs, 1H, OH, D_2O exchangeable), 8.43 (s, 1H, C(H)=N), 2.63 (s, 6H, CH_2: Bz_3Sn), 6.70–7.99 (26H, remaining ligand and Bz_3Sn protons) ppm. ^{13}C NMR ($CDCl_3$): 173.4 (CO_2), 164.1 (C–OH), 162.3 (C(H)=N), 24.3 (CH_2: Bz_3Sn), 151.9, 146.6, 145.8, 138.5, 132.5, 131.4, 129.9, 129.5, 129.3, 128.8, 127.9, 127.0, 124.6, 122.8, 120.8, 118.8, 118.2, 117.6 (remaining ligand and Bz_3Sn carbon signals) ppm. ^{119}Sn NMR (δ, ppm): −9.82. ^{119}Sn Mössbauer: $\delta = 1.27$, $\Delta = 2.76$ mm s^{-1}, $\rho = 2.2$.

2.3.4. $Bz_3SnL^3H \cdot OH_2$ (4)

Red crystals of compound **4** were obtained from a toluene–hexane mixture (1:3 v/v). Yield: 49%; m.p.: 71–73 °C. *Anal.* Calc. for $C_{41}H_{36}ClN_3O_4Sn$: C, 62.43; H, 4.59; N, 5.33. Found: C, 62.01; H, 4.49; N, 5.40%. IR (cm^{-1}): 1617 $\nu(OCO)_{asym}$. ^1H NMR ($CDCl_3$): 13.6 (brs, 1H, OH, D_2O exchangeable), 8.49 (s, 1H, C(H)=N), 2.69 (s, 6H, CH_2: Bz_3Sn), 6.70–8.05 (26 H, remaining ligand and Bz_3Sn protons) ppm. ^{13}C NMR ($CDCl_3$): 173.2 (CO_2), 163.9 (C–OH), 162.2 (C(H)=N), 24.3 (CH_2: Bz_3Sn), 151.7, 146.1,

145.8, 139.8, 138.4, 132.8, 131.2, 129.9, 129.4, 129.2, 128.6, 127.8, 126.8, 124.5, 122.2, 118.7, 117.9, 117.5 (remaining ligand and Bz_3Sn carbon signals) ppm. ^{119}Sn NMR (δ, ppm): −10.2. ^{119}Sn Mössbauer: $\delta = 1.14$, $\Delta = 2.99$ mm s^{-1}, $\rho = 2.6$.

2.3.5. $Bz_3SnL^4H \cdot OH_2$ (5)

Red crystals of compound **5** were obtained from a benzene–hexane mixture (1:3 v/v). Yield: 75%; m.p.: 74–76 °C. *Anal.* Calc. for $C_{42}H_{39}N_3O_5Sn$: C, 64.30; H, 5.01; N, 5.36. Found: C, 64.50; H, 4.89; N, 5.28%. IR (cm^{-1}): 1617 $\nu(OCO)_{asym}$. ^1H NMR ($CDCl_3$): 14.1 (brs, 1H, OH, D_2O exchangeable), 8.53 (s, 1H, C(H)=N), 3.84 (s, 3H, OCH_3), 2.69 (s, 6H, CH_2: Bz_3Sn), 6.70–8.03 (26 H, remaining ligand and Bz_3Sn protons) ppm. ^{13}C NMR ($CDCl_3$): 173.2 (CO_2), 164.3 (C–OH), 159.5 (C(H)=N), 55.5 (OCH_3), 24.3 (CH_2: Bz_3Sn), 151.9, 145.8, 140.5, 138.6, 131.3, 130.3, 129.9, 129.2, 128.6, 128.4, 126.8, 124.5, 122.3, 119.1, 117.9, 117.7, 114.7 (remaining ligand and Bz_3Sn carbon signals) ppm. ^{119}Sn NMR (δ, ppm): −10.48. ^{119}Sn Mössbauer: $\delta = 1.39$, $\Delta = 3.13$ mm s^{-1}, $\rho = 2.3$.

2.4. X-ray crystallography

Crystals of compounds **4** and **5** suitable for an X-ray crystal-structure determination were obtained from a toluene–hexane and a benzene–hexane solution, respectively, by slow evaporation of the solvent at room temperature. All measurements were made at low temperature on a Nonius KappaCCD diffractometer [10] with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) and an Oxford Cryosystems Cryostream 700 cooler. Data reduction were performed with HKL DENZO and SCALEPACK [11]. The intensities were corrected for Lorentz and polarization effects, and an empirical absorption correction based on the multi-scan method [12] was applied. Equivalent reflections were merged. The data collection and refinement parameters are given in Table 1. Views of the molecular structures are shown in Figs. 3 and 4. The structures were solved by direct methods by using SIR-92 [13]. For each structure, the non-hydrogen atoms were refined anisotropically. The water ligand and phenoxy H atoms were placed in positions indicated by the difference electron density map and their positions were allowed to refine together with individual isotropic displacement parameters. All remaining H atoms in each structure were placed in geometrically calculated positions and refined using a riding model where each H atom was assigned a fixed isotropic displacement parameter with a value equal to $1.2U_{eq}$ of its parent atom ($1.5U_{eq}$ for the methyl group in **5**). The refinement of each structure was carried out on F^2 using full-matrix least-squares procedures, which minimized the function $\sum w(F_o^2 - F_c^2)^2$. A correction for secondary extinction was applied in the case of complex **5**. One reflection, whose intensity was considered to be an extreme outlier, was omitted from the final refinement of **4**. All calculations were performed using the SHELXL-97 [14] program.

3. Results and discussion

3.1. Synthetic aspect

Recently, we have investigated the reaction of Bz_3SnCl with sodium 2-[(*E*)-2-(3-formyl-4-hydroxyphenyl)-1-diazenyl]benzoate, LHNa (Fig. 1a) in anhydrous methanol. The reaction proceeded via debenzylation and oxidative decarbonylation [15]. This reaction afforded a cyclic dinuclear dibenzyltin(IV) complex, $[Bz_2\{O_2CC_6H_4\{N(H)=N=(C_6H_3\text{-}4(=O)\text{-}5\text{-}O)\}\text{-}o\}Sn]_2$ (Fig. 2) instead of the polymeric Me_3Sn(IV) [16] and Bu_3Sn(IV) [4] as well as the monomeric Ph_3Sn(IV) [9] analogues. In a similar way, the reactions of Bz_3SnCl with sodium 2-{(*E*)-4-hydroxy-3-[(*E*)-4-(aryl)iminomethyl]phenyldiazenyl}benzoates, L^1H-Na–L^4HNa (Fig. 1b) were attempted under identical

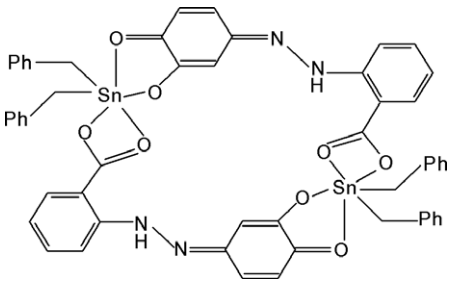

Fig. 2. Cyclic dibenzyltin(IV) complex: $[Bz_2\{O_2CC_6H_4\{N(H)\text{–}N=(C_6H_3\text{-}4(=O)\text{-}5\text{–}O)\}\text{-}o\}Sn]_2$.

reaction conditions, in the expectation of obtaining the corresponding $Bz_3Sn(IV)$ derivatives. Instead, the work-up of the reaction mixture yielded crystals of the same cyclic dibenzyltin(IV) dimer, i.e. $[Bz_2\{O_2CC_6H_4\{N(H)\text{—}N{=}(C_6H_3\text{-}4(=O)\text{-}5\text{-}O)\}\text{-}o\}Sn]_2$. The melting point, microanalytical, spectroscopic and crystallographic data of the two products were identical. In the latter reactions, cleavage of the H–C=N–Ar part from the ligand molecule and simultaneous debenzylation was noticed. At present, however, the exact mechanism of the cleavage/rearrangement is not clearly understood. On the other hand, attempted reactions of the free acids (LHH′ (pre-ligand) and L^1HH'–L^4HH') with Bz_3SnOH in anhydrous toluene afforded the desired products $Bz_3SnLH \cdot OH_2$ and $Bz_3SnL^{1-4}H \cdot OH_2$ in moderate to good yields, respectively. Attempted crystallization of these $Bz_3Sn(IV)$ complexes from an anhydrous benzene-methanol mixture again afforded crystals of the dimeric dibenzyltin complex (Fig. 2). Hence, the crystallization attempts were made using anhydrous benzene, benzene–hexane or toluene–hexane.

3.2. Spectroscopy

The diagnostically important infrared absorption frequencies for the carboxylate antisymmetric [ν_{asym}(OCO)] stretching vibration of the complexes are given in Section 2. The assignment of the symmetric [ν_{sym}(OCO)] stretching vibration band could not be made owing to the complex pattern of the spectra. The assignment of the band is based on comparison with the spectra of the free ligands. The antisymmetric [ν_{asym}(OCO)] stretching vibrations for the uncomplexed ligands have been detected at 1733 cm^{-1} in LHH′ [9] and around the 1725 cm^{-1} region for $L^{1-4}HH'$ [4]. In the complexes, the carbonyl stretching frequencies are found to be shifted to lower wavenumber, which is ascribed to carboxylate coordination in accordance with earlier reports [1,4,17,18].

The ^1H and ^{13}C NMR data of LHH′ and $L^{1-4}HH'$ have been reported earlier [4,9] and the conclusions drawn from the ligand assignments were then subsequently extrapolated to the complexes owing to the data similarity for at least a few signals. The ^1H NMR integration values were completely consistent with the formulation of the products. Individual assignments of the ^1H and ^{13}C signals of the tribenzyltin(IV) moiety and most parts of the ligand skeleton could not be made owing to serious signal overlap resulting in complex patterns. The ^{119}Sn NMR chemical shifts of the tribenzyltin(IV) complexes (**2**–**5**) in $CDCl_3$ solution are listed in Section 2.3. The complexes exhibit a single sharp resonance at around −10.0 ppm, suggesting that the complexes are isostructural in solution. The ^{119}Sn NMR resonances fall within the range from +55.0 to −25.0 ppm, which is usually indicative of four-coordinate tribenzyltin(IV) species in solution [19]. This indicates that the five-coordinate structure of the solid (see X-ray discussion, vide infra) breaks up in solution [20], presumably by loss of the water ligand.

The Mössbauer results from the complexes are listed in Section 2.3. The ratio of the quadrupole splitting (Δ) value to the isomer shift (δ) value ($\rho = \Delta/\delta$) can be used to distinguish between the different coordination states of the central tin atom [21]. Tin compounds which are four coordinate have ρ values less than 1.8 while ρ values larger than 2.1 would indicate compounds with greater than four coordination. Complexes **2**–**5** (slightly lower in the case of **1**) have similar δ and Δ parameters, and the ρ values are greater than 2.1 suggesting that the complexes are isostructural with a coordination number greater than four. Trigonal-bipyramidal triorganotin(IV) complexes with organic groups in the equatorial plane [22] have been reported to have Δ values between 3.00 and 4.00 mm s^{-1}. This value has also been found to change as a function of the axial bond distances [22]. The tribenzyltin(IV) complexes in the present investigation exhibited Δ values of ~3.00 mm s^{-1} which correspond with a trigonal-bipyramidal geometry around the tin atom with equatorial benzyl groups, [20,23–25] and is in agreement with the structures determined by X-ray crystallography (see Section 3.3).

3.3. X-ray crystallography

The crystal structures of complexes **4** and **5** are very similar and the principal geometric parameters do not differ significantly (Table 2). In contrast to the polymeric tri-*n*-butyltin(IV) [4–6] and polymeric and dimeric triphenyltin(IV) [1] analogues (Scheme 1), both of the tribenzyltin(IV)

complexes, **4** and **5**, exhibit the same monomeric *trans*-R_3SnO_2 structural motif, as illustrated in Figs. 3 and 4. The structures are also shown in Scheme 2 for clarity. The Sn atom has a slightly distorted trigonal-bipyramidal coordination geometry with equatorial benzyl groups and the axial positions occupied by an O atom from the carboxylate ligand and the O atom from the water ligand. A monomeric structure with a similar mode of coordination and geometry about the Sn atom was observed in the triphenyltin(IV) complex of the pre-ligand i.e. $Ph_3Sn[O_2CC_6H_4(N{=}N(C_6H_3$-4-OH-5-CHO))-*o*$](OH_2)$ [9]. The carbonyl O atom of the carboxylate ligand in **4** and **5** also coordinates very weakly to the Sn atom with long Sn···O(2) distances of 3.056(2) and 3.008(2) Å, respectively. Although the Sn···O(2) distances are well inside the sum of the van der Waals radii of the Sn and O atoms (ca. 3.6 Å), there does not appear to be any major distortion of the principal trigonal bipyramidal Sn-coordination geometry as a result of this contact. A similar additional weak Sn···O coordination was also observed in the structures of related polymeric $[R_3SnLH]_n$ (R = ^{n}Bu, Ph) derivatives [1,4–6]. The Sn atom coordination geometry found for complexes **4** and **5** is in good agreement with that

inferred from ^{119m}Sn Mössbauer spectroscopy (see Section 3.2).

In complexes **4** and **5**, the phenoxy H atom forms an intramolecular hydrogen bond with the imine N atom, thereby creating a loop with a graph set motif [26,27] of S(6). The H atoms of the water ligand form intermolecular hydrogen bonds with the phenoxy O atom of one neighbouring molecule and with the weakly coordinating carboxylate O atom of a different neighbouring molecule (Table 3). The former interaction links the molecules into extended chains which run parallel to the [0 1 0] direction and can be described by a graph set motif of C(14). The

ligands (L) of the general formula Ln(β-diketonate)$_3$L, for which impressive photoluminescence properties have been demonstrated [18]. For the diketonate ligand, we have chosen 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate (hfac) because of its low vibrational coupling with Eu(III) emission [9,19–21], enhanced thermal stability and volatility of the resulting lanthanide complexes when compared with its non-fluorinated analogs [22]. Our choice of ligand L is 2,4,6-tri(2-pyridyl)-1,3,5-triazine (tptz), a bulky aromatic compound featuring three 2-pyridyl rings fixed on a central 1,3,5-triazine platform [23]. Lanthanide complexes with tptz ligand have first been introduced by Durham et al. [24]. Recently a number of structurally characterized lanthanide complexes were reported [16,25–28], including the very first tptz adduct of a lanthanide β-diketonate reported by us [16]; tptz acts as a terdentate ligand in these structurally characterized complexes, coordinating the lanthanide ion with one of the three pyrazine N atoms and the N atoms on the *ortho*-substituted pyridyl groups. The remaining N atoms allow for further coordination to other metals, transition metals in particular [29]. Thus, structurally sophisticated multinuclear heterometallic complexes may be envisioned, whose magnetic and photophysical properties are of fundamental interest and practical significance.

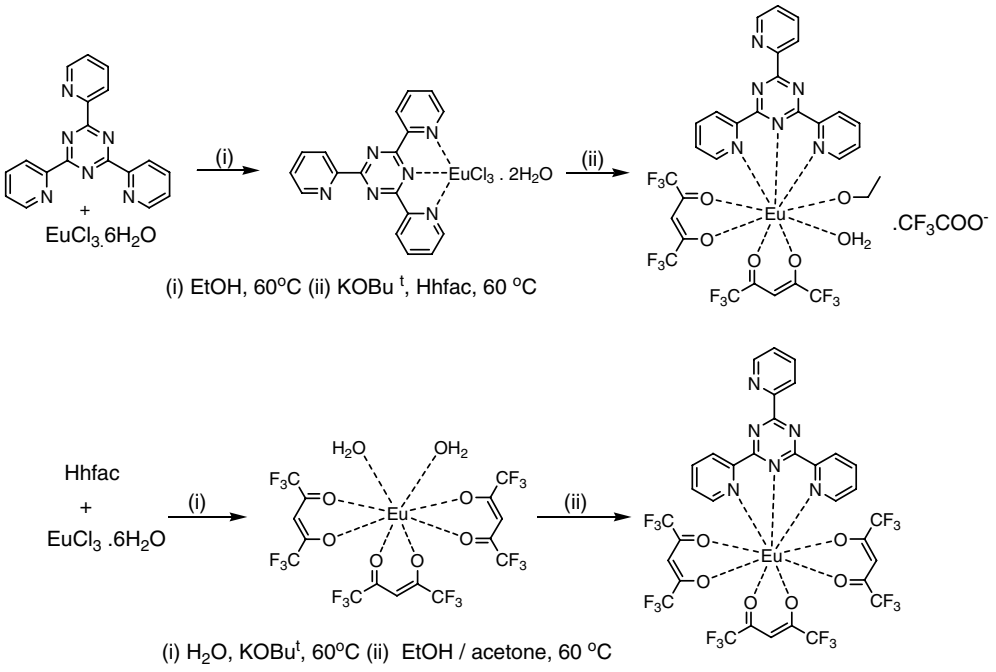
By adopting a procedure used previously for the synthesis of Eu(dbm)$_3$(tptz) (dbm = dibenzoylmethanate) [16], in which a tptz complex with the starting $EuCl_3$ hydrate was prepared followed by the substitution of Cl^- for the diketonate ligands, an unexpected complex formulated as [Eu(hfac)$_2$(H_2O)(EtOH)(tptz)][$CF_3CO_2^-$] (**1**) was obtained. The complex planned for, Eu(hfac)$_3$(tptz) (**2**), was subsequently produced by using the more traditional route of making the hydrated lanthanide diketonate first, followed by the replacement of the aqua ligands by tptz. Here the synthesis, structural characterization by single-crystal X-ray diffraction, and photoluminescence studies of these two new Eu(III) complexes are reported (Scheme 1).

2. Experimental

$EuCl_3 \cdot 6H_2O$ (99.9%), 2,4,6-tri(2-pyridyl)-1,3,5-triazine (98%), 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (98%), and potassium *tert*-butoxide (95%) were purchased from Aldrich and used without further purification. A slightly modified procedure for the recently reported Eu(dbm)$_3$(tptz) was adopted [16]. Elemental analysis (CHN) was performed by Numega Resonance Laboratory, San Diego, California.

2.1. Synthesis of [Eu(hfac)$_2$(H_2O)(EtOH)(tptz)][$CF_3CO_2^-$] (1)

A mixture of tptz (0.312 g, 1.00 mmol) and $EuCl_3 \cdot 6H_2O$ (0.366 g, 1.00 mmol) in 20 mL of absolute ethanol was stirred at 60 °C for 10 min to afford a clear solution. To this solution was added over 10 min a solution of $KOBu^t$ (0.336 g, 3.00 mmol) and Hhfac (0.624 g, 3.00 mmol) in 10 mL of absolute ethanol, and the resulting mixture was stirred at 60 °C for 1 h under nitrogen, and then at room temperature for 3 h. The mixture thus obtained was filtered, and the solid was washed with copious de-ionized water to remove KCl. The crude product was dissolved in acetone, and the solution was dried over anhydrous $MgSO_4$. The filtrate was collected, from which a pale yellow solid was obtained upon removal of the solvent. Recrystallization from ethanol:acetone (v/v 1:1) produced a crystalline solid as the analytically pure product (0.64 g, 61%). *Anal.* Calc.



Scheme 1. Synthesis of [Eu(hfac)$_2$(H_2O)(EtOH)(tptz)][$CF_3CO_2^-$] (**1**) and Eu(hfac)$_3$(tptz) (**2**).

for $C_{32}H_{22}N_6O_8F_{15}Eu$: C, 36.41; H, 2.10; N, 7.96. Found: C, 36.33; H, 2.06; N, 8.09%.

2.2. Synthesis of Eu(hfac)$_3$(tptz) (2)

Using a modified literature [11], $Eu(hfac)_3(H_2O)_2$ was first prepared. Briefly, Hhfac (0.624 g, 3.0 mmol) was added to a solution of $KOBu^t$ (0.336 g, 3.0 mmol) in H_2O (10 mL). The resulting clear solution was stirred for 10 min at room temperature and then added to an aqueous solution of $EuCl_3 \cdot 6H_2O$ (0.366 g 1.0 mmol in 10 mL H_2O). The mixture was stirred at 60 °C for 30 min under nitrogen and then for 2.5 h at room temperature. The mixture was filtered, and the precipitate was washed with cold de-ionized water (2 × 100 mL) and dried under vacuum at room temperature for 12 hr. If necessary, the product can be recrystallized from acetone:ethanol (v/v 1:1).

To a solution of $Eu(hfac)_3(H_2O)_2$ (0.808 g, 1.0 mmol) in acetone (15 mL) was added tptz (0.312 g, 1.00 mmol) in ethanol (15 mL). The mixture was stirred at 60 °C for 0.5 h and then overnight at room temperature. The mixture was filtered, and the filtrate was allowed to evaporate at room temperature to afford analytically pure product (0.73 g, 67%). *Anal.* Calc. for $C_{33}H_{15}N_6O_6F_{18}Eu$: C, 36.52; H, 1.39; N, 7.74. Found: C, 36.65; H, 1.36; N, 7.80%.

2.3. X-ray structure determinations

Single crystals of both compounds suitable for X-ray diffraction studies were obtained by slow evaporation of their saturated solutions in ethanol:acetone (v/v 1:1) at room temperature over several days.

The crystals were mounted on a glass fiber in a random orientation and cooled to −93 °C in a stream of nitrogen gas controlled with Cryostream Controller 700. Data collection was performed on a Bruker SMART CCD 1000 X-ray diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), operating at 50 kV and 30 mA over 2θ ranges of 2.58–50.00°. No significant decay was observed during the data collection.

Data were processed on a Pentium PC using the Bruker AXS Crystal Structure Analysis Package, Version 5.10 [30]. Neutral atom scattering factors were taken from Cromer and Waber [31]. The raw intensity data were integrated using the program SAINT-Plus and absorption corrections were applied using program SADABS. The structure was solved by direct methods. Full-matrix least-square refinements minimizing the function $\sum W(F_o^2 - F_c^2)$ were applied to the compound. All non-hydrogen atoms were refined anisotropically. All of the water hydrogen atoms and the hydroxyl hydrogen atoms were located gradually

in difference Fourier map, while the rest hydrogen atoms were calculated, and their contributions were included in the structure factor calculations. Details on data collection and structure refinements are given in Table 1.

2.4. Photophysical studies

Electronic absorption spectra in dichloromethane solutions were recorded on a Perkin Elmer Lambda 10 spectrophotometer. Photoluminescence studies were carried out using a Fluorolog-3 fluorometer. The measured fluorescence in the visible range was excited by the light from a Xe-Arc lamp and detected with a photo multiplier tube at an angle of 90° to the incident beam. Photoluminescent quantum yields were measured and calculated using cresyl violet perchlorate ($\Phi = 0.54$ in methanol) [32] or rhodamin 6G (95% in ethanol) [33] as the standards. Corrections were made for the instrumental parameters and differing refractive indices of the solvents used [34,35]. The experimental uncertainty for the quantum efficiency calculations is 10%.

3. Results and discussion

Most of the lanthanide β-diketonates reported were synthesized either by an one-pot synthesis in which the lanthanide starting material, a β-diketone, and a selected neutral ligand are reacted in the presence of a suitable base or by first making the electrically neutral β-diketonate hydrates, followed by substitution of the aqua ligand(s) for neutral ligands of a different type [8,36]. However, adventitious hydrolysis producing unexpected lanthanide oxo/hydroxo complexes has been observed in both syntheses [37]. We noted recently that introducing the neutral Lewis base ligand prior to the introduction of the β-diketonate ligand is an effective approach to suppressing the formation of the hydrolysis products [16]. Subsequently, this procedure was utilized for the successful production of a number of tptz adducts with various lanthanide β-diketonates [17].

Surprisingly, when the same procedure was applied for the synthesis of $Eu(hfac)_3(tptz)$, a complex formulated as $[Eu(hfac)_2(H_2O)(EtOH)(tptz)][CF_3CO_2^-]$ (**1**) was instead isolated in good yield. Only two diketonate ligands are incorporated into the coordination sphere, although the initial molar ratios of Eu(III) to HFA is 1:3. Charge balancing is provided by $CF_3CO_2^-$ whose formation is also worth noting since it was not present in the starting materials. This *in situ* formation of $CF_3CO_2^-$ is not unprecedented; it has been observed by other researchers as the result of hfac decomposition via the reverse reaction of Claissen condensation, a process facilitated by a base in the presence of trace amount of water [38,39]. In the present case, the uncoordinated N atoms of tptz may serve as the base catalyst for the decomposition of the third HFA that is used for Eu(III) coordination.

The tptz adduct initially planned for, $Eu(hfac)_3(tptz)$ (**2**), was subsequently synthesized by using the more traditional approach. $EuCl_3 \cdot 6H_2O$ was reacted with three equivalents of Hhfac/base to form $Eu(hfac)_3(H_2O)_2$, whose aqua ligands were then substituted for tptz under mild conditions.

Both **1** and **2** are air-stable and readily soluble in solvents such as acetone, chloroform, and dichloromethane, but sparingly soluble in alcohols. Product purification was facile by recrystallization from a mixture of acetone and ethanol. Satisfactory microanalysis results (CHN) were obtained for both compounds.

The molecular structures of **1** and **2** · EtOH were established by single crystal X-ray diffraction, and are shown in Figs. 1 and 2, respectively. The Eu(III) of **1** is coordinated by two hfac, one tptz, one H_2O, and one EtOH, whereas the coordination of **2** features three hfac and one tptz ligands. In both cases, the coordination polyhedron may be best described as a distorted square antiprism monocapped by the middle coordinating N atom [N(1)]. For complex **1**, the charge-balancing $CF_3CO_2^-$ is hydrogen-

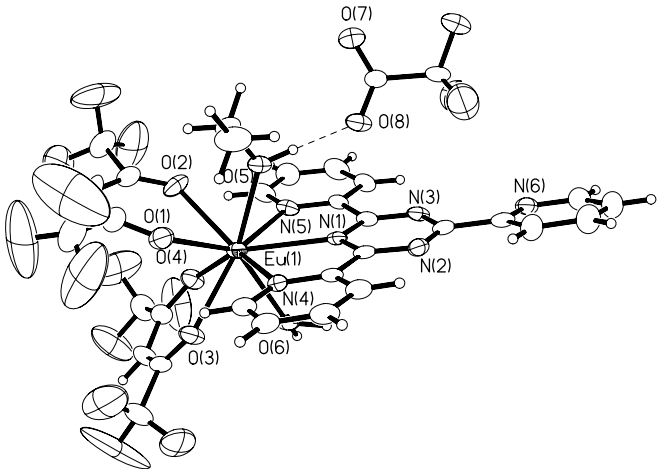

Fig. 1. An ORTEP view of the crystal structure of $[Eu(hfac)_2(H_2O)(EtOH)(tptz)][CF_3CO_2^-]$ (**1**). Thermal ellipsoids are drawn at the 50% probability level.

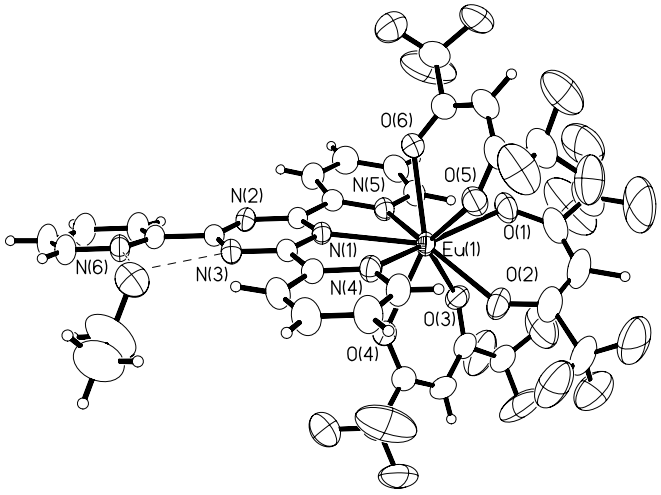

Fig. 2. An ORTEP view of the crystal structure of $Eu(hfac)_3(tptz) \cdot EtOH$ (**2**). Thermal ellipsoids are drawn at the 50% probability level.

bonded with the OH group of the Eu(III)-bound EtOH. For **2** · EtOH, there is a molecule of EtOH, hydrogen-bonded to the metal free N3 and N6 of the tptz ligand. The Eu–O(hfac) distances of **1** range from 2.390(3) Å to 2.450(3) Å, with an average of 2.420(8) Å. For **2** · EtOH, the corresponding values are from 2.354(2) Å to 2.503(2) Å, with an average of 2.411(4) Å. These distances are within the range reported for similar complexes [9,13,40,41]. The tptz ligand is nearly coplanar in both complexes. The Eu–N(1) bond distance is 2.534(3) Å and 2.539(2) Å for **1** and **2**, respectively. These values, indicated in bold face in Table 2, are the shortest of the three, consistent with the findings made with previously reported lanthanide-tptz complexes [16,25,28].

As compared with previously reported tptz adducts of europium β-diketonates, a number of structural features of **1** and **2** merit further discussions. The Eu–N1 distances [2.534(3) Å for **1** and 2.539(2) Å for **2**] are noticeably shorter than those of Eu(β-diketonate)$_3$(tptz). The corresponding values are 2.580(7) Å (tta, thinoyltrifluoroacetone), 2.607(3) Å (btfa, 4,4,4-trifluoro-1-phenyl-1,3-butanedione), 2.618(11) Å (ba, 1-benzoylacetone), and 2.676(2) Å (dbm, dibenzoylmethane) [16,17]. They are even shorter than those of Eu(tptz)Cl_3(MeOH)$_2$ [2.555(4) Å] and Eu(tptz)-$(NO_3)_3(H_2O)$ [2.576(2) Å] whose Eu(III) ions are situated in a less sterically congested environment [25,28]. This observation may be rationalized in terms of the electron withdrawing power of the fluorinated ligands; hfac is less reactive toward the Eu(III) center due to the relatively low electron density on its O atoms. As a result, the net positive charge of the lanthanide ion with hfac coordination is probably more than when non-fluorinate ligands are utilized. A corollary is that tptz ligand is more strongly bound to Eu(III) in the case of hfac coordination, resulting in a shorter Eu–N distance.

The preoccupation of part of the coordination sphere by the bulky tptz ligand in the synthesis of **1** may have prevented the coordination of three hfac ligands, particularly so if the relatively weak coordinating ability of the hfac ligand is considered. A similar observation was made in the synthesis of Yb(hfac)$_2$(NO_3)(terpy) (terpy = 2,2′:6′,2″-terpyridine) where Yb(III) ion is coordinated to two hfac ligands instead of three due to the preoccupation of the metal center by terpy, which has a similar steric bulk of coordination to that of tptz [42].

Table 2
Selected bond distances (Å) and angles (°) of [Eu(hfac)$_2$(H_2O)(EtOH)-(tptz)][$CF_3CO_2^-$] (**1**) and Eu(hfac)$_3$(tptz) · EtOH (**2** · EtOH)

3.1. Electronic spectroscopic and photoluminescence studies

The electronic absorption spectra obtained for **2** and its ligands (Hhfac and tptz) in dichloromethane are shown in Fig. 3. Tptz shows absorption bands at 247 nm and 282 nm, whereas a strong absorption is shown at 275 nm for Hhfac. The spectrum of **2** (λ_{max} = 295 nm) contains essentially the combined ligand absorptions, but with slight red shifts due to metal complexation. Complex **1** displays almost identical ligand-based absorption in the range of 225–350 nm.

The electronic excitation and photoluminescence of **1** and **2** were studied in dichloromethane solution at room temperature, and they exhibit very similar properties. Only the spectra of **2** are shown in Fig. 4. The excitation spectrum resembles its absorption spectrum, confirming that the energy transfer occurs from the ligands to the Eu(III) ion. Five narrow emission peaks are observed in the range 570–715 nm, characteristic of Eu(III)-originated luminescence.

The photoluminescence quantum yields of **1** and **2** were determined to be 52% and 60%, respectively. The maximum excitation wavelength of the title complexes (295 nm) is very close to the maximum absorption wave-

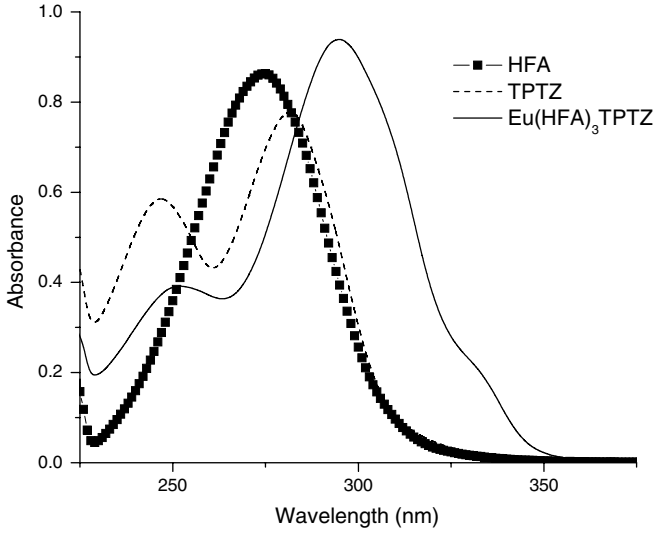

Fig. 3. Absorption spectra of Hhfac, tptz, and **2** in dichloromethane solution.

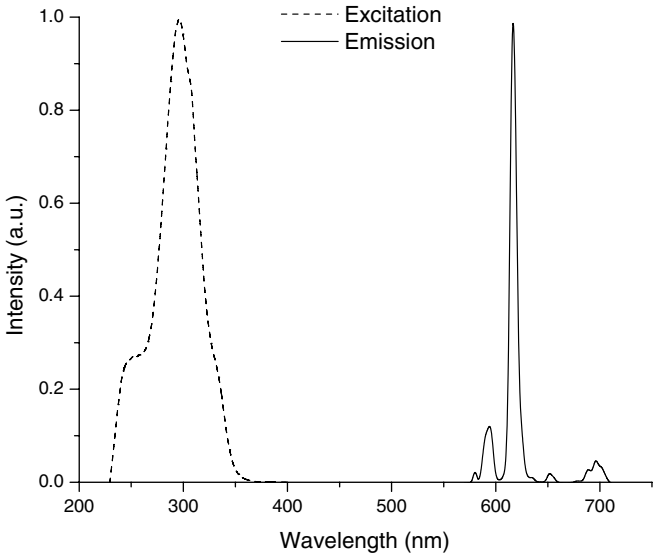

Fig. 4. Excitation (—) and emission (–) spectra of **2** in dichloromethane solution.

lengths of both Hhfac (275 nm) and tptz (282 nm). As such, both ligands are presumably responsible for the ligand-mediated energy transfer, resulting in effective population of the Eu(III) $^5D_0$ emissive state and high quantum yields of light emission. Thus, tptz ligand not only saturates the coordination sphere but also enhances the ligand-mediated energy transfer. This may be the reason why the quantum yield observed for **1** is still high despite the presence of luminescence–quenching water and ethanol ligands. In fact, the two complexes reported here possess the highest quantum yields among all the reported Eu(III)-hfac complexes, lending further support to the significant role(s) of tptz. In comparison, the photoluminescence quantum yields for $Eu(dbm)_3(tptz)$, $Eu(ba)_3(tptz)$, $Eu(tta)_3(tptz)$, and $Eu(btfa)_3(tptz)$ were found to be 17.4, 15.5, 40.2, and 69.7%, respectively [17]. In these cases, the energy transfer was believed to be mainly mediated by the β-diketonate ligands as the excitation wavelengths match the absorption spectra of the corresponding β-diketonate ligands. The comparably high values for $Eu(tta)_3(tptz)$ and $Eu(btfa)_3$-(tptz) may be the result of a better energy match between the ligand singlet and triplet excited states and/or a better energy match between the ligand triple excited state and the metal ion's resonance levels [7,14], with the tptz ligand providing additional advantages of site-protection.

4. Summary

Two new europium β-diketonates featuring 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate and 2,4,6-tri(2-pyridyl)-1,3,5-triazine, a rigid neutral ligand were synthesized. These two complexes, formulated as $[Eu(hfac)_2(H_2O)(EtOH)(tptz)][CF_3CO_2^-]$ (**1**) and $Eu(hfac)_3(tptz)$ (**2**), were structurally characterized using single crystal X-ray diffraction. The difference in the composition and structure between these two complexes is caused by simply reversing the order of ligand (Hhfac and tptz) addition during the complex synthesis. Both complexes display bright photoluminescence characteristic of Eu(III) ion. Both ligands are believed to be responsible for the high quantum yields observed.

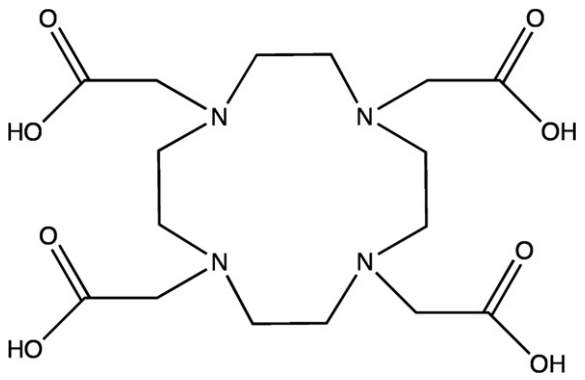

Fig. 1. 1,4,7,10-tetraazacyclo-dodecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA). Note the pendant acetic acid 'arms'.

Innovative Technology Labmaster 100 Dry Box and standard Schlenk techniques. Gallium trichloride (99.9%), ammonium acetate and ethanol (chromatography grade) were purchased from Sigma. DOTA was purchased from Strem Chemicals (Toronto, Canada). Water was distilled and deionized to 18.6 MΩ using a Barnstead Diamond RO Reverse Osmosis machine coupled to a Barnstead Nano Diamond ultrapurification machine. An Agilent 1100 HPLC with manual injection and automated fraction collector was fitted with a Zorbax C_{18} analytical column for purification. Inductively Coupled Plasma (ICP) was conducted on a Perkin–Elmer ELAN 6100. Nuclear magnetic resonance was carried out on a Bruker 300 MHz machine. Electrospray mass spectrometry was performed on a Schimadzu LCMS-2010 A system at a cone voltage of 4.5 kV. Infrared spectra were recorded on a Nicolet Magna-IR 850 Series II spectrophotometer as KBr pellets.

2.1. Synthesis and characterization

0.12 g (0.68 mmol) of $GaCl_3$ was dissolved in 66.5 ml of 0.2 M ammonium acetate buffer (pH 5.0). To this solution was added a 55 ml solution of DOTA (0.68 mmol, (5 mg/ml)) in 0.2 M ammonium acetate buffer (pH 5.0). The resulting mixture was heated at 95 °C for 25 min. The volume was reduced in vacuo to approximately 10–15 ml. The solution was filtered (0.45 μM, Fisher) and then purified using reverse phase HPLC: (A) 100% for 5 min then (B) 100% for 10 min. (A) 0.2 M ammonium acetate (pH 5.0); (B) 100% ethanol. Complex **1** eluted with a retention time of $T_r = 7.81$ min. The retention time for uncomplexed DOTA under these conditions was noted as $T_r = 7.21$ min. A fivefold excess of ice-cold acetone was added to the combined Gallium-DOTA fractions and the solution filtered and allowed to stand at 4 °C. Colorless rod shaped crystals formed after ~24 h. ES-MS *m*/*z*: 470.85 ($M + H^+$), calculated 470.7 for $GaC_{16}H_{25}N_4O_8$. ^1H NMR (300 MHz, D_2O): δ 3.73–3.65(d), δ 3.44–3.31(d), δ 2.7(t), δ 2.24(s), δ 2.0(m). 2.2. Determination of crystal structure

Structural measurements were performed on a Bruker-AXS SMART-CCD diffractometer at low temperature (90 K) using graphite-monochromated Mo Kα radiation ($\lambda_{Mo\ K\alpha} = 0.71073$Å). The structures were solved by direct methods. All non-hydrogen atoms were refined anistropically. After all of the non-hydrogen atoms were located, the model was refined against F^2, initially using isotropic and later anisotropic thermal displacement parameters.

Table 1

Largest difference in peak and hole (e Å^{-3})	1.425 and −0.599

Hydrogen atoms were introduced in calculated positions and refined isotropically. Lattice water hydrogens were not observed in the difference Fourier maps. Neutral atom scattering coefficients and anomalous dispersion corrections were taken from the *International Tables*, volume C. All calculations were performed using SHELXTL crystallographic software packages [8]. Selected bond lengths and angles are given in Table 1. Crystallographic details have been summarized in Table 2.

2.3. Thermogravimetric analysis (TGA)

Thermal analysis was performed on a TA instruments TGA Q500 using 5–11 mg samples placed on platinum pans and run under a nitrogen atmosphere (50 mL/min). The temperature was ramped from ~25 to 400 °C at a rate of 5 °C/min. Analysis was performed using the TA instruments Universal Analysis 2000 software program.

3. Results and discussion

3.1. Synthesis of 1

Complex **1** was obtained by reaction of stoichiometric equivalents of gallium chloride with the DOTA ligand in aqueous solution at acidic pH (pH 5) to prevent the formation and precipitation of $Ga(OH)_3$. Separation of the targeted compound from unreacted material or gallium impurities was achieved by HPLC with the new complex exhibiting a retention time of $T_r = 7.81$ min. Single crystals suitable for X-ray crystallography were obtained after purification by concentrating an aqueous solution of **1** in vacuo until initial precipitation was observed. Water was then added drop-wise with vigorous stirring until complete redissolution was observed. The solution was then filtered and ~five equivalents of ice-cold acetone, by volume, was added. Upon addition of the acetone, the borosilicate glass flask was sealed and placed at 4 °C. Suitable crystals, as colorless rods, were obtained after approximately 24 h. The presence of gallium in the crystals was determined prior to X-ray structure determination by removing and dissolving some of the crystals in water and performing ICP (data not shown) and electrospray mass spectrometry (Section 3.3; Figs. 4 and 5).

3.2. Structural characterization

The structure of **1** displaying an asymmetric unit and numbering scheme is shown in Fig. 2. It was solved in space group *C*2*c* with monoclinic symmetry. Selected bond lengths and angles are given in Table 1.

The gallium coordination sphere consists of a N_2O_4 donor set. The equatorial plane is composed of two DOTA nitrogens from the ring and two oxygens from the pendant carboxylate arms. The plane formed by the coordinated N_2O_2 set is slightly distorted with a torsional angle of 5.38°.

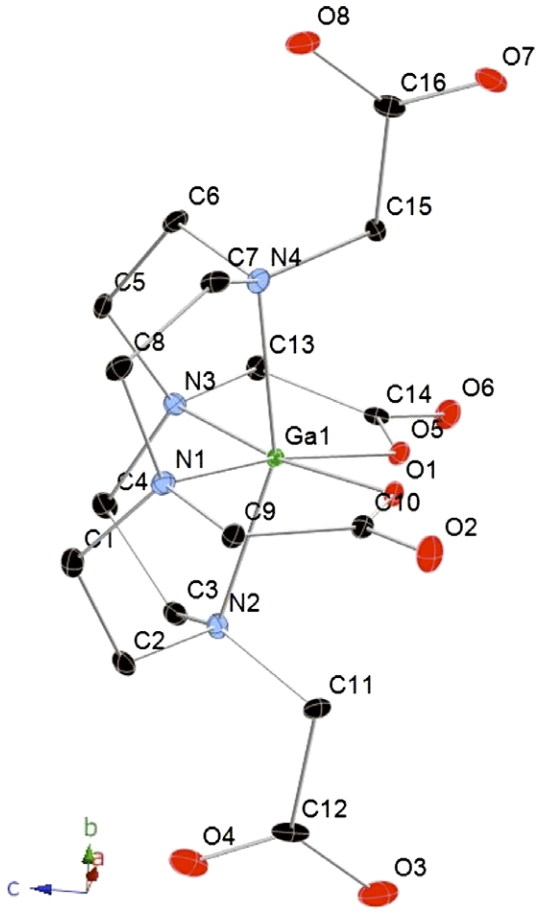

Fig. 2. ORTEP structure of **1** looking down the *a* axis. Hydrogen atoms and waters of crystallization have been omitted for clarity.

DOTA ring nitrogens complete the distorted octahedral geometry about the metal centre by occupying the axial positions. The distortion from perfect linearity predicted by a perfect octahedral geometry is best demonstrated by the angle created by the two axial nitrogens and gallium [N2–Ga1–N4] noted as 156.48°. Equatorial Ga–N bond lengths are also slightly shorter than those observed for the *trans* Ga–N bonds (Table 1). The gallium–oxygen bond lengths are shorter again at 1.940 Å [Ga1–O1] and 1.929 Å [Ga1–O5]. While two of the four-carboxylate 'arms' of the DOTA ligand are directly involved in metal coordination, the two remaining 'arms' are uncoordinated. One of the uncoordinated arms remains a carboxylic acid moiety and the hydrogen was assigned in the crystal structure [O3–H3 0.819 Å]. The angle produced by C12–O3–H3 is 109.4° consistent with the tetrahedral nature of a C–OH moiety. For the remaining carboxylic 'arm' a hydrogen atom could not be found and a deprotonated conjugate base is predicted. This serves to balance the charge of the trivalent gallium to leave an overall neutral complex and is consistent with a peptide modified DOTA structure described by Mäcke et al., where they also predicted the uncoordinated carboxylate to be deprotonated [9]. This arrangement is further corroborated by electrospray mass spectrometry conducted and described herein (Section 3.3).

Complex **1** packs to produce alternating ABAB layers of asymmetric units along the crystallographic *b* axis. The units align to optimize the arrangement of the 'dangling' carboxylate/carboxylic acid arms (see Fig. 3). Within each individual layer the pendant carboxylate moieties of each individual asymmetric unit are connected through intermolecular hydrogen bonding between the uncoordinated carboxylate groups to lattice water molecules to give a one-dimensional chain structure. In addition H-bonding between each AB layer is facilitated through intermolecular H-bonding with lattice water molecules producing an overall 2D supramolecular system such as we have described before for copper systems [10]. While lattice water hydrogen atoms were not found, oxygen–oxygen bond distances and angles characteristic of such contacts can infer H-bonding e.g. [O(4)···O(91w) 2.789 Å, O(8′)···O(91w) 2.720 Å, O(4)···O(91w)···O(8′) 130.76°] (Fig. 4) [11].

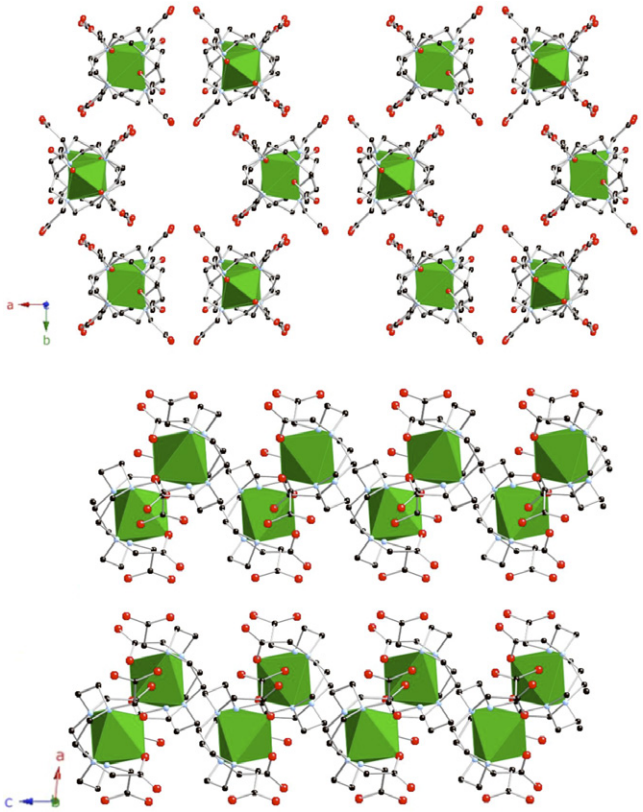

Fig. 3. (a) Packing of **1** looking down the *c* axis and (b) longing down the *b* axis. Lattice waters and hydrogen atoms removed for clarity.

3.3. Electrospray mass spectrometry

Electrospray mass spectrometry was conducted on an aqueous solution of redissolved crystals of **1** (Fig. 5). Briefly, crystals were removed using a Pasteur pipette and dried on filter paper. The crystals become powdered on standing and were then retrieved and redissolved in 18.6 MΩ water.

The data illustrates the presence of complex **1** in an aqueous environment and demonstrates that complex **1** can be isolated and redissolved without ionization. It also corroborates what is noted from the X-ray analysis, namely the formation of a resonance stabilized carboxylate species forming to balance charge and produce a neutral complex, as indicated by the fact that the electrospray indicates a formula containing 25 hydrogen atoms [$C_{16}H_{25}N_4O_8Ga$], consistent with the loss of three hydrogens from the DOTA ligand. This is as expected for a complex with DOTA given the predicted kinetic and thermodynamic stability of similar metal-DOTA complexes [4]. This stability is important if gallium is to be incorporated into anti-cancer or diagnostic bioconjugates to work in an aqueous environment.

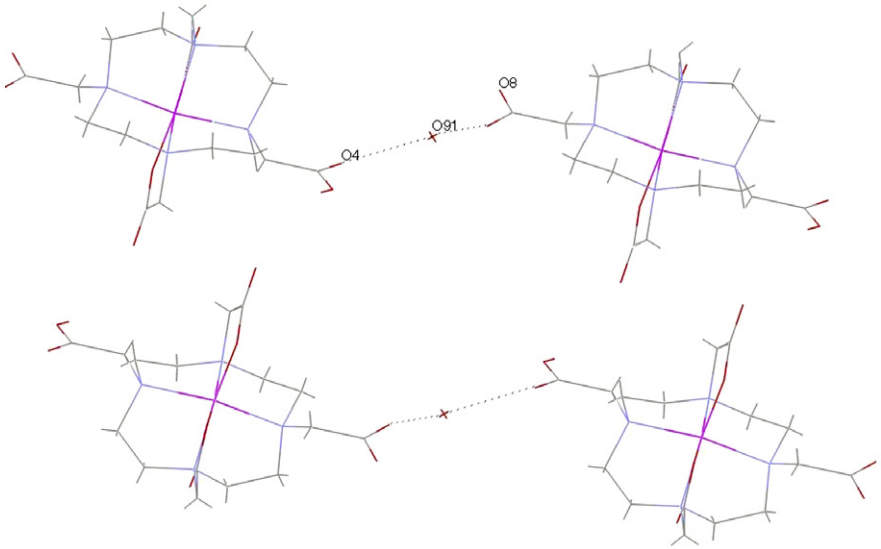

Fig. 4. Packing of **1** looking down the *c* axis indicating H-bonding between asymmetric units facilitated through lattice water molecules. Additional lattice waters omitted for clarity.

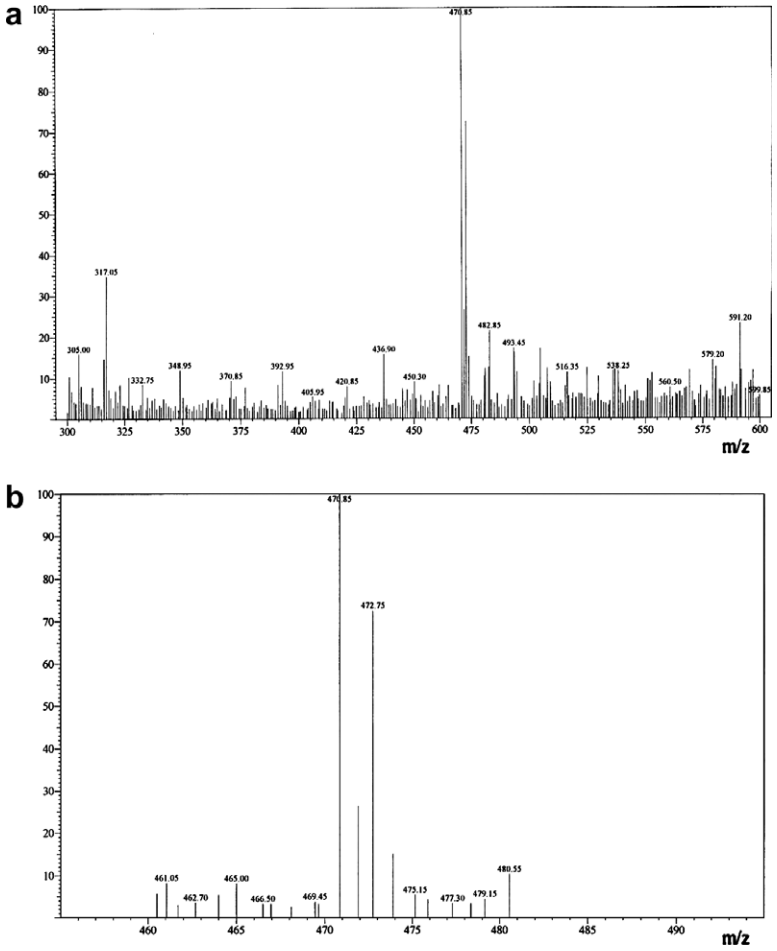

Fig. 5. Electrospray mass spectrum for **1**. (a) 300–600 m/z range and (b) 460–480 m/z range to show isotopic pattern. The theoretical isotopic pattern of 470 (100%): 471 (29.4 %): 472 (69.8): 473 (13.3 %) for **1** can be clearly observed.

3.4. Thermal properties of *1*

Complex **1** is stable in air at ambient temperature. TGA was carried out to examine the thermal stability of **1**. The samples were ramped from ~25 to 400 °C at a rate of 5 °C/min. The TGA curve can be seen in Fig. 6.

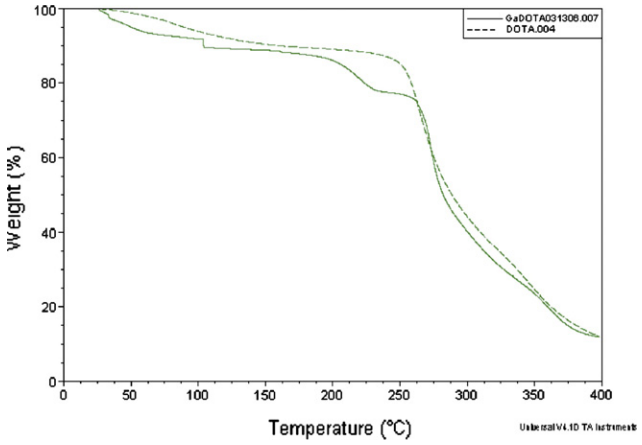

Fig. 6. TGA curve for **1** (solid line) and uncomplexed DOTA (dotted line). ICP was performed on a sample of **1** used to conduct TGA studies to confirm gallium prior to run.

There is no indication of there being any appreciably stable intermediate between the temperatures investigated. However, a slight inflection point at ca. 200 °C is evident and occurs after a mass loss of ~12.5% consistent with the departure of 7 waters of crystallization. The remainder of the trace is consistent with the loss of the remaining water molecules (presumably more extensively involved in hydrogen bonding within **1** consistent with the crystallography) and subsequent complex decomposition beginning at ~270 °C. This can be rationalized as the 'break-up' of the organic DOTA moiety. This is consistent with a TGA trace obtained for the uncomplexed DOTA ligand and indicates that complexation of the metal cation does not confer any greater thermal stability to DOTA.

4. Conclusions

We have successfully synthesized and characterized, both in solution and in the solid state, the Ga(III) chelate complex **1**. The species crystallizes with a high degree of hydration, which plays a role in H-bond interactions producing an ornate 2D supramolecular structure. Most importantly for our work is the fact that the complex is

stable in aqueous solution as indicated by electrospray mass spectrometry. This is vital if these systems are to be conjugated to delivery vectors and transported in vivo. We are currently extending our synthetic approach to look at ruthenium and rhenium complexes with DOTA and incorporation of these complexes into thiamin and folic acid based bioconjugates.

Acknowledgements

This work was supported by funds from Syracuse University. The authors wish to thank Colin Fuss at the Centre for Environmental Science and Engineering at Syracuse University for conducting the ICP experiments and Professor Karin Ruhlandt-Senge for use of a Innovative Technology Labmaster 100 Dry Box for weighing of the $GaCl_3$.

Appendix A. Supplementary material

Crystallographic data (CIF file) for complex **1** has been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 606649. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax + 44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or via the internet www.ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.06.039.

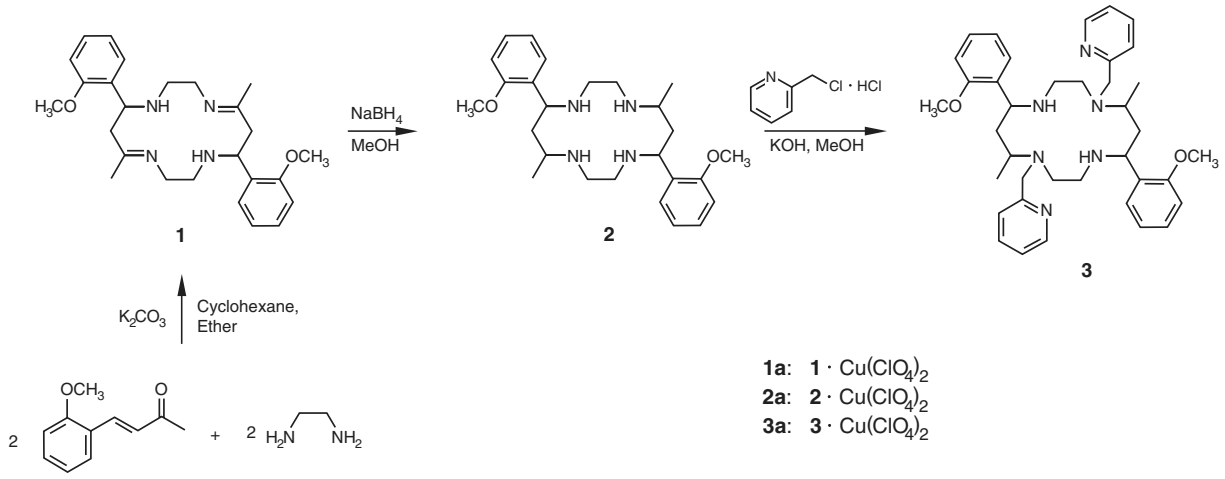

Scheme 1. Synthesis of the tetraaza macrocycles and specification of complexes studied.

N-linked 2-picolyl groups. Both, the crystal structures of all the uncomplexed macrocycles **1**–**3** and the respective Cu(II) complexes have been solved and comparatively discussed to reveal structural consequences on the coordination behavior. Thus, the present study will serve as a useful example of cyclam-type co-ordination chemistry being supplement to the known structures of related cyclams and cyclam complexes that differ in the absence of the methoxy substituents, respectively, anisyl pendants, or show other structural modifications [21–29].

2. Experimental

Caution: Although we did not encounter any problems, perchlorate salts of metal complexes containing organic ligands and solvents are potentially explosive and should be handled only in small quantities and with great caution!

2.1. General methods and materials

Melting points (uncorrected) were taken on a heating stage microscope (Rapido, Dresden). The IR spectrum (ν in cm^{-1}) was recorded on a Perkin–Elmer 1600 FT-IR instrument. NMR spectra (δ in ppm, J in Hz, Me_4Si as internal standard) were obtained with Bruker Avance DPX 400 (^1H: 400 MHz, ^{13}C: 100.6 MHz). The mass spectrum (ESI) was determined on a Hewlett–Packard HP 59987 A instrument.

Reactions were monitored by thin-layer chromatography (TLC) carried out on Merck silica gel 60 F254 coated plates. All reagents were commercial products and were utilized without further purification. The solvents used were purified or dried by common literature procedures [30].

2.2. Synthesis of the macrocycles

2-Methoxybenzylideneacetone was obtained from 2-methoxybenzaldehyde and acetone according to the literature [31].

2.2.1. 7,14-Bis(2-methoxyphenyl)-5,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-5,12-diene (*1*)

Prepared from 2-methoxybenzylideneacetone and ethylenediamine with anhydrous potassium carbonate in cyclohexane–diethyl ether (1:2) following the literature procedure [27]. Recrystallization form chloroform–diethyl ether yielded 80% yellowish crystals; m.p. 144–145 °C (literature [32] m.p. 143–145 °C).

2.2.2. 7,14-Bis(2-methoxyphenyl)-5,12-dimethyl-1,4,8,11-tetraazacyclotetradecane (*2*)

Synthesized by treatment of **1** with $NaBH_4$ in dry ethanol and workup according to the literature [32] which yielded 92% colourless crystals; m.p. 197–198 °C (literature [32] m.p. 198–199 °C).

2.2.3. 4,11-Bis(2-pyridylmethyl)-7,14-bis(2-methoxyphenyl)-5,12-dimethyl-1,4,8,11-tetraazacyclotetradecane (*3*)

To a stirred solution of **2** (1.0 g, 2.43 mmol) and sodium hydroxide (0.44 g, 11.0 mmol) in water (20 cm^3) was added dropwise a solution of picolyl chloride hydrochloride in methylene chloride (20 cm^3). The mixture was stirred for 10 h at 25 °C. The organic phase was separated and the aqueous phase extracted with three 50 cm^3 portions of methylene chloride. The combined organic phases were evaporated under reduced pressure and the remaining oil crystallized from ethanol to give a colorless solid with m.p. 236–238 °C (yield: 82%). *Anal.* Calc. for $C_{38}H_{50}N_6O_2$ (FW = 622.85): C, 73.28; H, 8.09; N, 13.49. Found: C, 73.03; H, 8.19; N, 13.41%. IR (KBr): 3252, 2966, 2934, 2895, 2834, 2817, 1597 (s), 1588 (s), 1491 (s), 1472 (s), 1434 (s), 1364, 1274, 1237, 1135, 1084, 1050, 1029, 786, 766 (s), 756 (s) cm^{-1}. ^1H NMR ($CDCl_3$): $\delta = 0.96$ (s, 3H, CH_3), 0.98 (s, 3H, CH_3), 1.60–1.66 (m, 2H, C*H*–CH_3), 1.93 (b, 2H, NH), 2.29–2.90 (m, 12H, CH_2), 3.81 (s, 6H, OCH_3), 3.83 (m, 2H, NC*H*-Ar), 4.05 (s, 4H, CH_2-Ar), 6.86 (d, $J = 8.4$, 2H, Ar-H), 6.93 (m, 4H, Ar-H), 7.11 (d, $J = 6.8$, 2H, Ar-H), 7.20 (m, 2H, Ar-H), 7.59 (t,

$J = 3.6$, 2H, Ar-H),7.71 (d, $J = 7.2$, 2H, Ar-H), 8.47 (d, $J = 3.6$, 2H, Ar-H). ^{13}C NMR ($CDCl_3$): $\delta = 13.8$ (CH_3), 40.5, 44.6 (CH*C*H$_2$CH, N*C*H$_2$*C*H$_2$N), 54.0, 54.6 (*C*HCH$_3$, *C*HAr), 55.3 (OCH_3), 56.1 (N*C*H$_2$Ar), 110.4, 120.7, 121.6, 123.2, 127.2, 127.4, 132.6, 157.1, 161.4 (Ar). MS (ESI): $m/z = 622$ (M^+).

2.3. Preparation of the $Cu(ClO_4)_2$ complexes

To a stirred solution of the corresponding macrocycle (0.7 mmol) in methanol (20 cm^3) was added $Cu(ClO_4)_2 \cdot 6H_2O$ (0.26 g, 0.7 mmol). The precipitate which had formed during 4 h was collected, washed with methanol and dried under vacuum.

1 $\cdot$ *Cu(ClO$_4$)$_2$ (**1a**)*: violet crystals (yield: 91%). *Anal.* Calc. for $C_{26}H_{36}Cl_2CuN_4O_{10}$ (FW = 699.04): C, 44.67; H, 5.19; N, 8.01. Found: C, 44.41; H, 5.21; N 7.94%. MS(ESI): $m/z = 598$ [M − ClO$_4^-$].

2 $\cdot$ *Cu(ClO$_4$)$_2$ (**2a**)*: dark-pink crystals (yield: 93%). *Anal.* Calc. for $C_{26}H_{40}Cl_2CuN_4O_{10}$ (FW = 703.07): C, 44.42; H, 5.37; N, 7.97. Found: C, 44.22; H, 5.78; N 7.91%. MS(ESI): $m/z = 601$ [M − ClO$_4^-$].

3 $\cdot$ *Cu(ClO$_4$)$_2$ (**3a**)*: blue crystals (yield: 95%). *Anal.* Calc. for $C_{38}H_{50}Cl_2CuN_6O_{10}$ (FW = 885.03): calcd. C, 51.56; H, 5.69; N, 9.49. Found: C, 51.45; H, 5.72; N, 9.38%. MS(ESI): $m/z = 783$ [M − ClO$_4^-$].

2.4. X-ray crystallography

In a general procedure, the addition of $Cu(ClO_4)_2 \cdot 6H_2O$ to an equimolar solution of the respective ligand (**1**–**3**) in methanol yielded the complexes **1a**–**3a** as amorphous powders. Further crystallization from selected solvents produced crystals suitable for X-ray crystallographic analysis. Crystallographic data of the complexes and those of the free ligands are summarized in Table 1.

X-ray diffraction studies of **1**, **2**, **2a**, **3** $\cdot$ 2CHCl$_3$ and **3a** were carried out on a Bruker-AXS APEX2 diffractometer with a CCD area detector (Mo Kα; $\lambda = 0.71073$ Å, graphite monochromator): frames were collected at $T = 93$ K or 103 K with ω and ϕ rotation at 5 or 10 s per frame. The measured intensities were reduced to F^2 and corrected for absorption with SADABS (SAINT-NT [33]). Structure solution, refinement and data output were carried out with the SHELXTL program package [34]. All non-hydrogen atoms were refined anisotropically. With the exception of the amino hydrogens in the structures **3a**, **2** and **3** all other hydrogens were included in the models in calculated positions and were refined as constrained to bonding atoms. The X-ray diffraction data collection of **1a** were collected on a CAD4 diffractometer in the ω–2θ scan mode (Cu Kα; $\lambda = 1.5418$ Å, graphite monochromator). The SHELXS-97 program was applied for structure solution, while the SHELXL-97 was used for structure refinement [35]. All data were corrected for Lorentz and polarization effects.

3. Results and discussion

3.1. Synthesis

The macrocyclic **1** (Scheme 1) was synthesized via the cyclocondensation route [36] starting form 2-methoxybenzylideneacetone and ethylenediamine [32]. Subjection of **1** to a sodium borohydride reduction yielding the substituted cyclam **2** [32]. Reaction of **2** with picolyl chloride hydrochloride and sodium hydroxide gave the cyclam derivative **3**. The complexes **1a**, **2a** and **3a** were prepared from the respective macrocycles (**1**–**3**) with $Cu(ClO_4)_2 \cdot 6H_2O$ in methanolic solution.

3.2. X-ray structural study

In order to investigate, how complex formation mutually affects molecular conformations, we performed both crystal structure determination of the free macrocyclic ligands and their complexes with Cu(II) perchlorate.

Crystal data and selected experimental details are summarized in Table 1. Perspective views of the structures including the numbering schemes of relevant atoms are shown in Figs. 1, 3, 5, 7, 9 and 11. Packing illustrations are presented in Figs. 2, 4, 6, 8, 10 and 12. Geometric parameters of the co-ordinative interactions are given in Table 2.

3.2.1. Crystal structure of *1* and *1a* [*1* $\cdot$ *Cu(ClO$_4$)$_2$*]

The X-ray crystallographic analysis of the macrocyclic diimine **1** yields the orthorhombic space group $P2_12_12_1$. Obviously, under the chosen conditions of crystal growing spontaneous optical resolution occurs, so that a given crystal consists of molecules of the same absolute configuration, which is *R*,*R* or *S*,*S* at the chiral centers C(1) and C(6) (Fig. 1a). The mean planes of the two C-N=C–C ring fragments are oriented at an angle of nearly 50° to each other inducing a boat-like conformation which forces the two exocyclic methyl groups into a *syn*-diequatorial arrangement. The aromatic rings are inclined with an angle of 40.9° towards each other. Moreover, as illustrated by the space filling model (Fig. 1b), partial collapsing of the intramolecular cavity leaves only a small 'hole' of approximately 2.6×2.8 Å being defined by the four nitrogen atoms. The fact, that neither significant conventional hydrogen bonds [37] nor weak directional contacts like C–H$\cdots\pi$ [38,39] and $\pi\cdots\pi$ interactions [40,41] are found in the crystal structure suggests that the strongly bent and compact shape of the molecule follows close-packing requirements. Thus, the crystal packing of **1** (Fig. 2) is characterized by an intensive nesting of molecules with the methoxy substituents and the voids of adjacent molecules gearing together.

Crystallization of the complex **1a** from acetonitrile/H_2O yields violet crystals of the non-centrosymmetric space group *Pn*. Due to the presence of a glide plane, the crystal

consists of a racemic mixture of stereoisomers of the configuration *R*,*R* and *S*,*S* while the meso *R*,*S*-stereoisomer has not been found in the crystalline form. The amino hydrogens H(1′) and H(3′) of **1a** are located on one side of the macrocycle. Since they contact to the ether oxygens of the anisyl residues, their methoxy groups exhibit a *syn*-arrangement (Fig. 3). Another interesting structural feature of **1a** can be seen in the highly distorted coordination sphere of the copper ion, which is reflected by unequal Cu–O bond lengths and the O–Cu–O angle that deviates significantly from linearity (163.6°). The Cu–O distances of 2.574(10) and 2.976(11) Å also indicate rather weak coordination of the anions to the copper center. The Cu–N(sp^2) distances [1.975(11), 1.979(11) Å] and the Cu–N(sp^3) bond lengths [1.966(12), 2.032(10) Å] are in the same order of magnitude. The high degree of conformational distortion can be attributed to the different binding behavior of the two perchlorate anions. One of them is

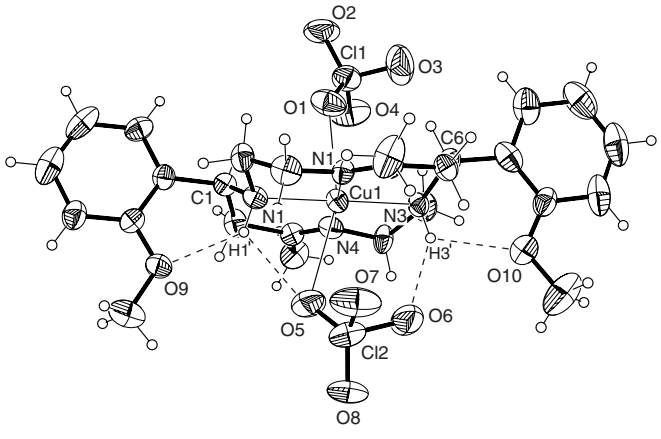

Fig. 3. Molecular structure of **1** · $Cu(ClO_4)_2$ with atom labelling of relevant atoms and displacement ellipsoids at the 40% probability level. Only one site of the disordered perchlorate ions is displayed. Broken lines represent hydrogen bond type contacts.

primarily associated to the ligand via intramolecular N–H···O contacts (O···H 2.243, 2.302 Å), while the other one is involved in intermolecular C–H···O hydrogen bonding (O···H 2.495, 2.664 Å) [42,43]. The crystal packing of **1a** is composed of molecular layers running parallel to the crystallographic B-plane (Fig. 4). They are held together by weak C–H···O hydrogen bond type contacts (O···H 2.49 Å) and π···π stacking interactions between the aromatic groups. The interlayer association is accomplished by the perchlorate ions that form weak interactions to arene and methylene hydrogens.

Previous papers have been published on metal complexes formed by the unsubstituted diphenyl analogue of **1** [21,29]. The crystal structure of the $Ni(ClO_4)_2$ complex [29], in which the diimine ligand has the same chirality as in **1a**, shows that the absence of the methoxy groups does not much effect the molecular conformation. On the other hand, the Ni(II) cation induces significant changes in coordination behavior compared to the Cu(II) in **1a**. Only one of the perchlorate ions occupies an axial position with both N–H groups oriented towards the opposite side of the NiN_4 plane, forming N–H···O hydrogen bonds to oxygen atoms of different perchlorate ions. Thus, a totally different molecular assembly within the crystal results.

3.2.2. Crystal structure of **2** and **2a** [**2** · $Cu(ClO_4)_2$]

The macrocyclic tetraamine **2** yields colorless crystals of the monoclinic space group $P2_1/n$ with two molecules within the unit cell. The torsion angles along the macroring are all ±*gauche* and *anti*. Although not all of them adopt idealized values (−66.0°, 175.4°, −175.2°, 69.6°, 168.3°, −168.8°, 72.8°), the macrocycle shows a regular, less strained conformation (Fig. 5). With the exception of the axial amino hydrogens H(2′), which for sterical reasons are not associated, all other strong donors and acceptors are involved in intramolecular hydrogen bonding. Two of the N–H bonds are directed towards the ring center, which opens the possibility of forming asymmetrical bifurcated hydrogen bonds [37] of the N–H···N type [N(1)–H(1′)···N(2) 2.32 Å, 135.0°; N(1)–H(1′)···N(2A) 2.57 Å, 110.7°], thus giving a cyclic four-membered hydrogen bond motif inside the macroring. As a consequence, van der Waals type interactions primarily contribute to the stabilization of the columnar packing mode of compound **2** (Fig. 6). Former investigations have shown that reduction of the unsubstituted diphenyl analogue of the diimine **1** yields the three possible stereo isomeric tetraazacyclotetradecanes in ca. 85:15:1 ratio [44,45]. The major product,

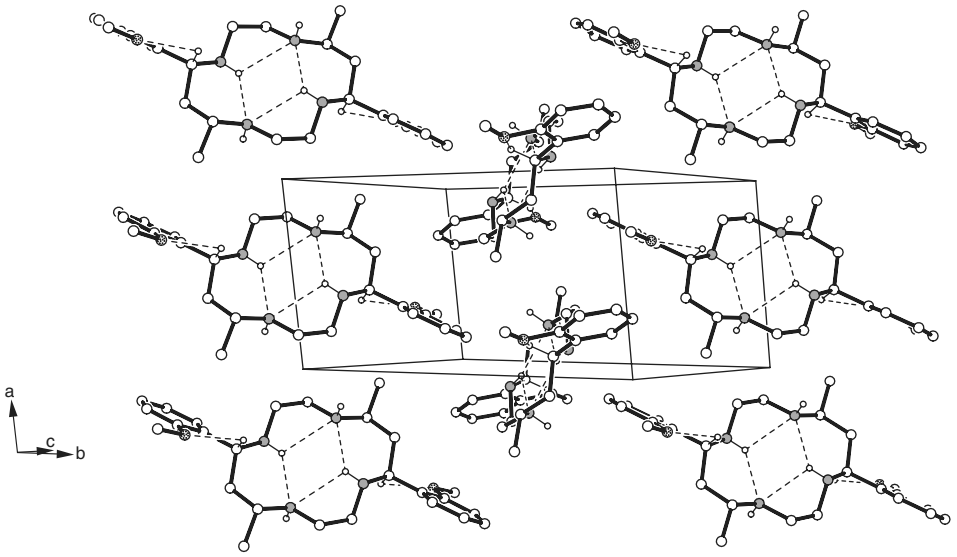

Fig. 6. Packing structure of **2**. Non-relevant hydrogen atoms are omitted for clarity.

which has been characterized by X-ray analysis [46] agrees with the configuration found for **2**.

Crystallization of complex **2a** from acetonitrile/H_2O yields crystals of the monoclinic space group $P2_1/c$ with two crystallographically independent halves of molecules in the asymmetric unit of the cell (Fig. 7), i.e. the copper atoms are located on crystallographic inversion centers (1/2, 1/2, 0 and 1, 0, 0). In both molecules, the anions are disordered over two sites. The Cu(II) exhibits an elongated octahedral coordination environment with the axial positions being occupied by one oxygen atom of each perchlorate ion. In one of the complexes, the Cu–O distance is rather long [2.562(3) Å] indicating only a weak binding, while in the second complex the respective bond is 2.363(4) Å. The Cu–N bond lengths [2.015(4)–2.038(3) Å] are within the expected range [7]. The six-membered chelate rings of the complex molecules adopt a distorted chair-like conformation with the anisyl and methyl substituents in equatorial positions, whereas the five-membered chelate rings are twisted. The aromatic units are arranged nearly perpendicular (88.4°, 86.7°) with respect to the CuN_4-plane. Although the independent molecules have similar conformations, they deviate in their mode of interactions. In molecule 1, the atom H(1′) forms an intramolecular bifurcated hydrogen bond [37] to the oxygens O(2) (2.245 Å) of the perchlorate anion and O(5) (2.225 Å) of

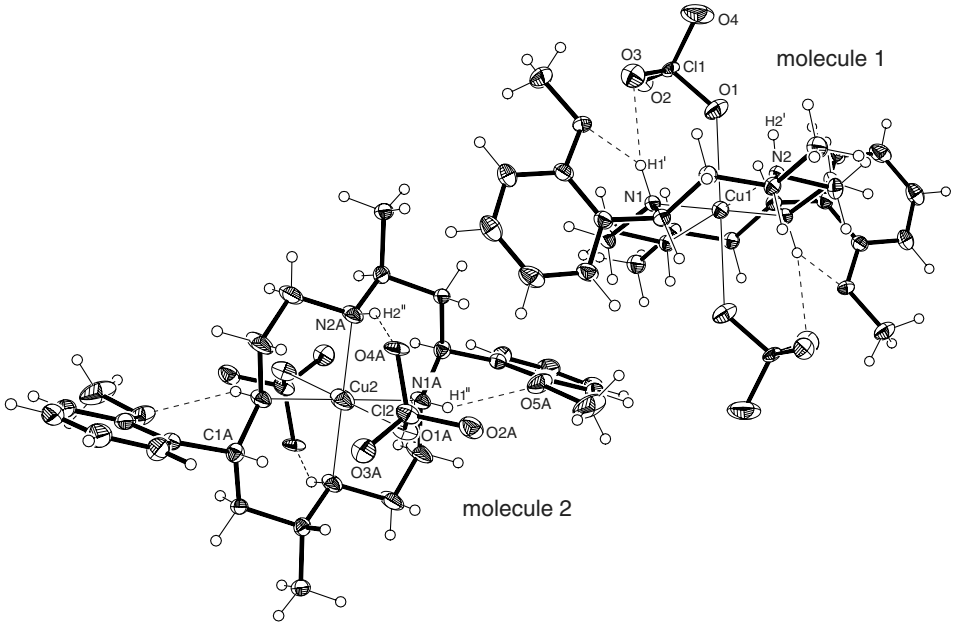

Fig. 7. Molecular structure of **2** · $Cu(ClO_4)_2$ with numbering of relevant atoms and displacement ellipsoids at the 40% probability level. Only one site of the disordered perchlorate ions is displayed. Broken lines represent hydrogen bond type contacts.

the anisyl group, while H(2′) remains free. In molecule 2, all amino hydrogens participate in intramolecular hydrogen bonding [H(1″)···O(1A) 2.284 Å, H(2″)···O(4A) 2.196 Å]. The packing of the crystals consists of infinite molecular chains extending in direction of the crystallographic *c*-axis (Fig. 8). Within these chains, the basal planes of consecutive molecules are titled to each other with an angle of 52.5° thus allowing formation of intermolecular C–H···O hydrogen bonds (O···H 2.200, 2.562 Å) between the anions and methyl groups of the ligands.

3.2.3. Crystal structure of $\mathbf{3}\cdot 2CHCl_3$ and **3a** [$\mathbf{3}\cdot Cu(ClO_4)_2$]

Crystals of compound **3**, suitable for diffraction experiments, could only be obtained as 1:2 (host:guest) solvent complex with chloroform (space group $P\bar{1}$). The unit cell of the crystal contains one complex entity (Fig. 9) with the solvent molecules associated via C–H···N hydrogen bond type interactions [42,43] with the pyridyl nitrogen [N(3)···H(1G) 2.37 Å]. Also in the present case, intramolecular contacts contribute to the molecular conformation. The hydrogen atom attached to N(2), the position of which could be gained from the difference electron density map, is directed towards the interior of the ring, and its well-defined N–H···N geometry suggests the existence of a weak hydrogen bridge to N(1) [N(2)–H(2′)···N(1) 2.25 Å, 137.7°]. The packing structure of the solvent complex of

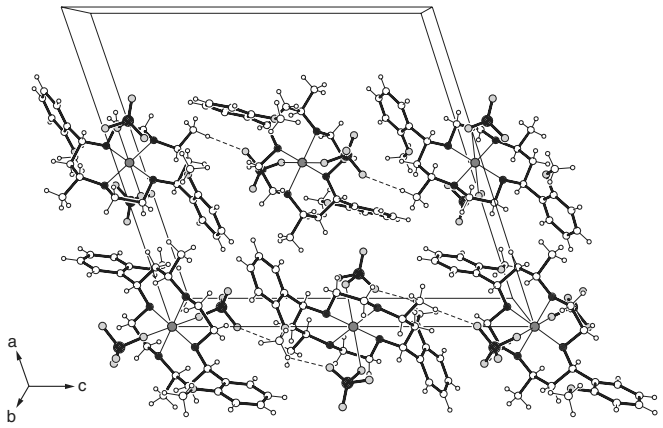

Fig. 8. Packing illustration of $\mathbf{2}\cdot(ClO_4)_2$.

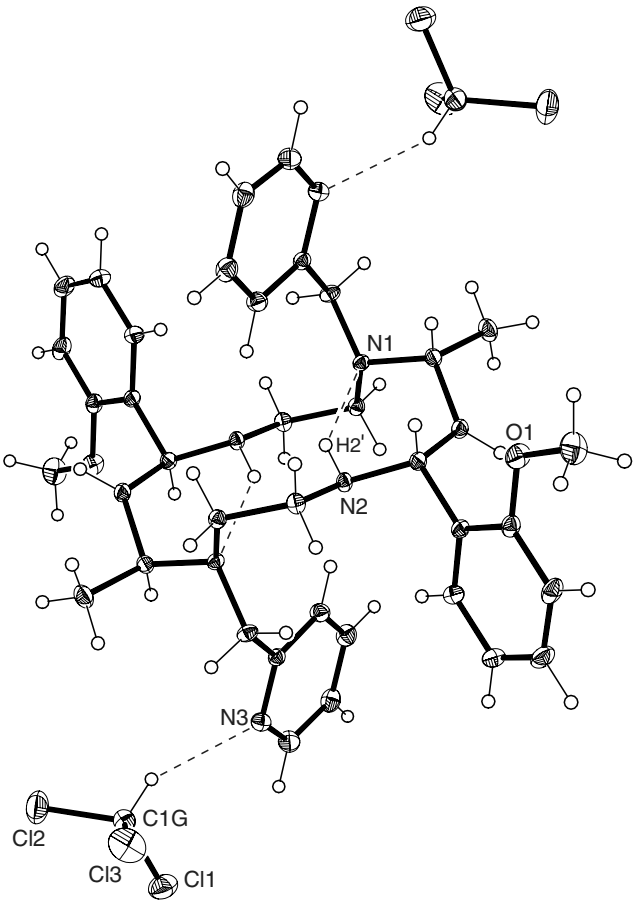

Fig. 9. Perspective view of the host–guest unit $\mathbf{3}\cdot CHCl_3$ (1:2) with numbering of relevant atoms and displacement ellipsoids at the 40% probability level. Hydrogen bond type contacts are displayed as broken lines.

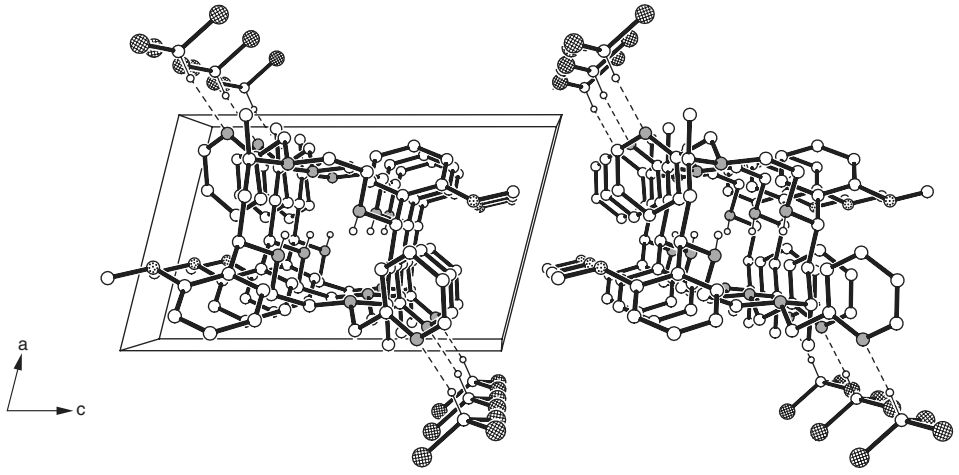

Fig. 10. Packing diagram of $\mathbf{3}\cdot CHCl_3$ (1:2). Non-relevant hydrogen atoms are omitted for clarity.

3 is composed of discrete **3** · $CHCl_3$ 1:2 aggregates stacked in a columnar array along the crystallographic *b*-axis (Fig. 10). Within the stacks, the host molecules are associated by aromatic edge-to-face (C–H···π) contacts [38,39] with the electron deficient pyridyl residues acting as donors and the electron-rich anisyl groups as hydrogen bond acceptors. The distance between the *para* C–H hydrogen of the pyridine and the ring centroid of the anisyl is 2.53 Å, while the C–H···centroid angle is 152.2°.

The Cu(II) complex **3a** yields blue crystals of the monoclinic space group $P2_1/n$ when crystallized from methanol. The asymmetric unit of the cell contains one half of the molecule with the copper atom located on the symmetry center 1/2, 1, 0. Different from structures **1a** and **2a**, the perchlorate ions of **3a** are not involved in complexation (Fig. 11). Instead, the nitrogen atoms of the two pyridylmethyl substituents occupy the apical sites of the octahedral coordination polyhedron. The axial Cu–N distances are 2.517(1) Å, whereas the equatorial Cu–N bonds are 2.036(1) and 2.106(1) Å. For steric reasons, the planes of the pyridyl residues are inclined at an angle of 54.3° with respect to the CuN_4 basal plane. Although rich in strong hydrogen bond acceptors, the anions show only poor association. Obviously, shielding of the amino hydrogens by the 2-picolyl units prevents effective hydrogen bonding to the counter ions. The same co-ordination behavior is also found in reported structures of copper(II) complexes having a similar pyridyl-substituted cyclam framework but differ in the mode of substitution [25–28]. It is also interesting to compare the structure of **3a** with the crystal structure of the copper(II) complex of the *N*-acetyl diphenyl substituted cyclam derivative reported previously [24]. In this structure, the charged carboxylate oxygens act as apical coordination sites of the *trans*-octahedral coordination environment of Cu(II). In addition, two ethanol molecules are hydrogen bonded to the two coordinated carboxyl oxygens thus preventing further intermolecular contacts.

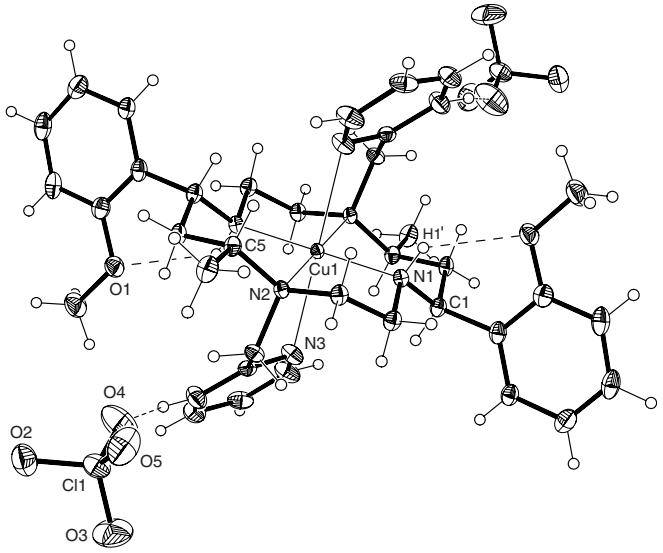

Fig. 11. Molecular structure of **3** · $Cu(ClO_4)_2$ with numbering of relevant atoms and displacement ellipsoids at the 40% probability level. Broken lines represent hydrogen bond type interactions.

The packing structure of **3a** is characterized by two-dimensional layers of complex cations which are stacked along the crystallographic *c*-axis (Fig. 12). The arrangement is stabilized by perchlorate ions, which fill the interstitial spaces between the layers and bridge the cations by weak C–H···O contacts (O···H 2.34–2.58 Å) [42,43]. Aromatic π···π interactions [40,41] are formed within the layers. The interacting aryl groups are displaced relative to each other, showing centroid–centroid distances of 4.50 Å for the phenyl rings and 4.30 Å for coordinated pyridyl

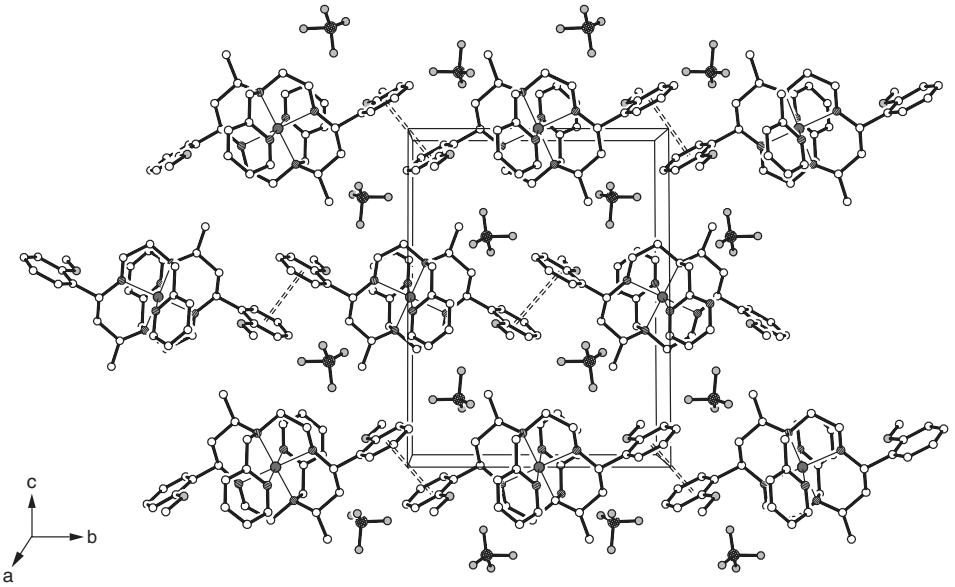

Fig. 12. Packing illustration of **3** · $Cu(ClO_4)_2$ with aromatic π–π interactions depicted as broken double lines. All hydrogen atoms are omitted for clarity.

fragments. Other types of non-covalent cation–cation interactions are not observed in the crystal.

4. Conclusion

A comparative structural study involving a designed series of cyclam type derivatives **1**–**3** that feature a different degree of saturation, and thus flexibility of the macroring, different number of functional appendages, and thus power of coordination, including their respective complexes with Cu(II) perchlorate has been reported.

X-ray crystal structures of the uncomplexed macrocycles **1**–**3** reveal that steric shielding caused by the ring substituents prevents the amino hydrogens from forming effective non-covalent bonding between molecules. Instead, these donors are either free or are used for intramolecular hydrogen bonding. The unsaturated diimine macrocycle **1** crystallizes in a non-centrosymmetric crystal structure. According to the given space group, a selected crystal contains molecules of the same absolute configuration and therefore is optically active. The strongly distorted geometry with a nearly complete collapsing of the macrocyclic cavity means that no intramolecular hydrogen bonds are present. In the case of **2**, two of the amino hydrogens are directed to the interior of the macrocycle giving a four-membered system of bifurcated hydrogen bonds, which is also found in crystal structures of related cyclam derivatives [22,23]. Intramolecular hydrogen bonding of the *N*-substituted macrocyclic ring is also found in the 1:2 inclusion compound of **3** with chloroform. However, only two bent N–H···N hydrogen bonds are present giving the molecule a pseudo-tricyclic structure.

In the complexes **1a**–**3a**, the metal center exhibits a more or less distorted octahedral coordination environment in which the four macroring nitrogens define the equatorial coordination sites of the polyhedron. Nevertheless, the ligand molecules show marked differences in their complexing behavior. The cyclam-based copper(II) complexes **2a** and **3a** show centrosymmetric molecular structures in the solid state. As expected, the apical coordination sites in **2a** are occupied by the oxygen atoms of two perchlorate anions [47]. A second oxygen of each anion forms an intramolecular N–H···O hydrogen bond to the complexed macroring. The presence of two *N*-substituted chelating pyridine containing pendants in the macrocycle **3** affects a different mode of coordination of the complex **3a** which is now of the CuN_6 type. As a result, its crystal structure consists of discrete complex cations and perchlorate anions which are cross-linked by weak C–H···O hydrogen bonds. The fact that the gross structure of **3a** corresponds to reported copper(II) complexes of related pyridyl-substituted cyclams [25–28] suggests rather robust conformational behavior of the macroring, including the pyridyl side arms, even in the presence of other potentially co-ordinating pendants such as the anisyl residues in **3a**, indicating particular co-ordinative interaction of this system. Similar to the uncomplexed diimine macroring **1**, the crystal structure of the respective complex **1a** has also an enantiomorphous configuration attributed to the *R*,*R* or *S*,*S* configuration at the chiral C atoms. Obviously, the reduced number of strong hydrogen bond donors, which is only half of those found in the complexes **2a** and **3a** and which determine the degree of cation–anion interactions, results in a less symmetric boat-like geometry of the complexed macrocycle.

Thus, only the pyridine containing pendants in **3a** proved effective in coordination of the metal ion while the uncomplexed macrocycle **3** yielded an inclusion compound with chloroform, also indicating a special ability relating to this series of compounds.

5. Supplementary data

Full details of the crystal structure analyses of **1**, **2**, **3**, **1a, 2a** and **3a** have been deposited with the Cambridge Crystallographic Data Centre (CCDC Nos. 288907–288909 and 288904–288906, respectively). Copies may be obtained free of charge on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax (int. code): +44 1223 336 033, e-mail: deposit@ccdc.cam.ac.uk].

hydrophobic core have been shown to promote binding in aqueous environments.

Herein, we describe the synthesis and structure of mononuclear, octahedral zinc(II) complexes of the tetradentate DAHC derivative *cis*-3,5-*bis*[(2-pyridinyleneamin]-*trans*-hydroxycyclohexane (DDOP) [13], with both nitrate and triflate as anions. Complexation of a series of amino acid substrates with these complexes was examined using isothermal titration calorimetry, revealing that the nature of the counterion has an important influence not only upon the solid state supramolecular architecture, but also upon interactions with other molecules in solution.

2. Results and discussion

2.1. Ligand/complex design overview

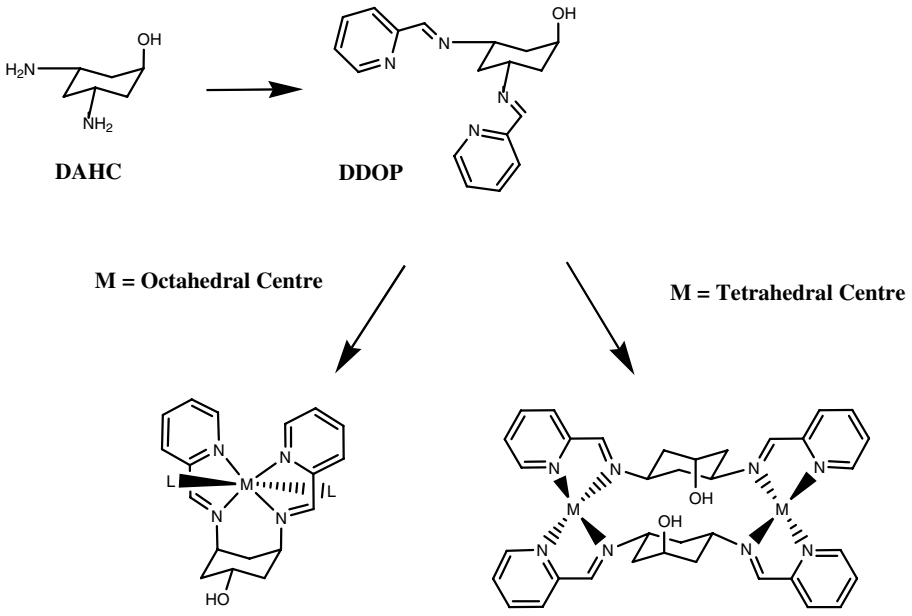
DDOP is synthesised from DAHC by a simple Schiff base derivatisation using 2-pyridinecarbaldehyde [13], yielding a more highly pre-organised ligand with a tetradentate (or *bis*-bidentate) donor set. The aromatic rings increase the system's rigidity, strengthening the hand of the ligand and reducing the influence of anions, solvent and metal centres on the outcome of the complexation. Furthermore, they provide a hydrophobic surface capable of participating in π-stacking or other van der Waals interactions.

Despite the rigidity of the donor set, the conformational flexibility of the cyclohexane backbone gives this derivative two possible coordination modes depending upon the preferences of the metal centre (Scheme 1); either a dinucleating, *bis*-bidentate chelator with tetrahedral metal centres, or a tetradentate mononucleating coordination pocket for octahedral, square pyramidal or square planar centres. In the mononuclear case, coordination of an octahedral metal centre leaves two vacant coordination sites which may be filled by solvent molecules, counterions or other co-ligands. In this way, the use of various anions and solvents may influence the shape, hydrogen bonding and packing properties of the complex, or allow bridging to form multinuclear aggregates; while the hydrophobic environment around the zinc centre may encourage substrate binding in aqueous environments.

2.2. Synthesis and crystal structure

Complexes **1** and **2** were synthesised in high yields by simply mixing the ligand with a small excess of the appropriate zinc(II) salt in methanol, and crystallising by slow diffusion of diethyl ether into the methanolic solution. Predictably, the highly preorganised nature of the tetradentate coordination pocket resulted in similar mononuclear complex cations. Interestingly, however, there is one significant difference between the two complexes. In **1**, the water ligand is arranged *anti* to the DDOP alcohol group, whereas in **2** it is arranged *syn* (Fig. 1).

In most other respects, the geometries of the two complexes are highly similar. Both show a slight opening of the ligand "arms" away from a parallel orientation, as demonstrated by a large N–Zn–N angle between the pyridyl nitrogens, and a smaller angle between the imine nitrogens (Table 1). Significantly shorter bond lengths show that axial ligation is stronger to the softer water O-donor than to the harder anions, with this effect being more pronounced in the triflate complex, **2**, and both complexes have an O–Zn–O angle that deviates from the ideal 180°. However, in **2** the equatorial Zn–N bond lengths are slightly longer than in 1, while Zn–O distances are shorter.



Scheme 1. The parent amine DAHC, Schiff base ligand DDOP, and its two coordination modes.

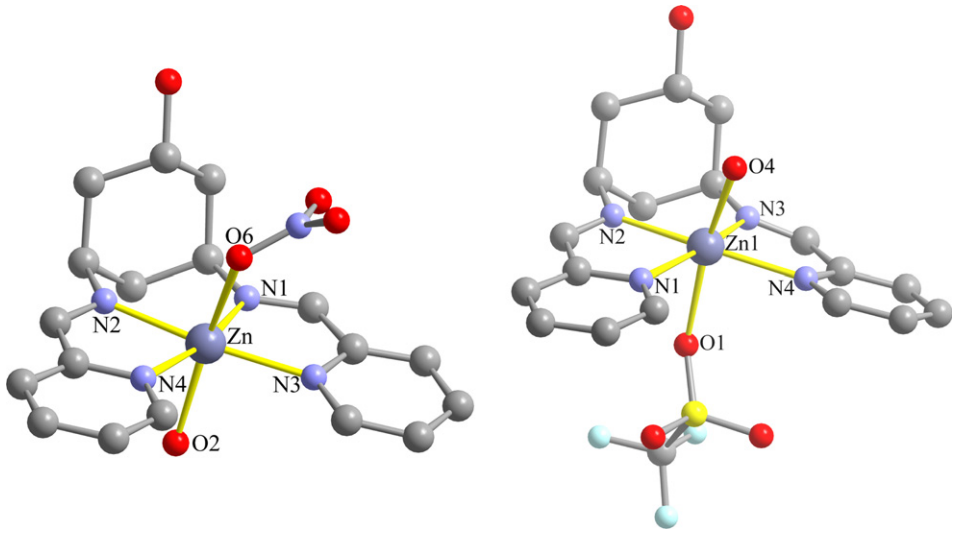


Fig. 1. The complex cations in $[Zn(DDOP)(NO_3)(H_2O)](NO_3)$ (**1**, left), and $[Zn(DDOP)(OTf)(H_2O)](OTf)$ (**2**, right), showing the *anti* and *syn* arrangements of the water ligand respectively. C is grey; F, pale blue; N, blue; O, red; S, yellow; Zn, blue grey. Hydrogen atoms are omitted for clarity. This colour scheme is retained in all figures. (For interpretation of references in colour in this figure legend, the reader is referred to the web version of this article.)

Table 1
Selected bond lengths and angles in $[Zn(DDOP)(H_2O)(NO_3)](NO_3)$ (**1**) and $[Zn(DDOP)(H_2O)(OTf)](OTf)$ (**2**)

		Compound **1**		Compound **2**	
Bond distances (Å)	DDOP	N(1)–Zn	2.110(2)	N(1)–Zn	2.133(2)
		N(2)–Zn	2.136(2)	N(2)–Zn	2.123(2)
		N(3)–Zn	2.136(2)	N(3)–Zn	2.145(2)
		N(4)–Zn	2.125(2)	N(4)–Zn	2.140(2)
	Water ligand	O(2)–Zn	2.173(2)	O(4)–Zn	2.107(2)
	Coordinated anion	O(6)–Zn	2.280(2)	O(1)–Zn	2.240(2)
Bond angles (°)	Pyridyl-N	N(4)–Zn–N(3)	113.77(8)	N(1)–Zn–N(4)	114.81(6)
	Imine-N	N(1)–Zn–N(2)	88.77(8)	N(2)–Zn–N(3)	88.05(6)
	Oxygen	O(2)–Zn–O(6)	164.67(8)	O(4)–Zn–O(1)	166.66(6)

Furthermore, the Zn atom is substantially displaced (0.131 Å) from the N4 plane in **2**, while in **1** it is almost perfectly coplanar (0.006 Å displacement).

The change in position of the water ligand observed in **2** has a significant impact on the long range ordering of the crystal structure, with a change from a 2-dimensional hydrogen bonded network in **1** to isolated hydrogen bonded dimers in **2**. In **1**, hydrogen bonded layers of complex cations and nitrate counterions run parallel to the crystallographic *ab* plane (Fig. 2). These layers are constructed by hydrogen bonds between the water ligand of one cation and the nitrato ligand of the next, and further interactions between nitrate counterions, DDOP alcohol groups and water ligands (for distances and angles see Table 2). Association of the layers to form the crystal may occur through π-stacking interactions, with aromatic systems from alternate layers taking an alignment close to that of a classic slipped π–π stack [14], with a long centroid–centroid distance (3.97 Å) and shorter atom to atom contacts (3.52 Å).

In **2**, the hydrogen bonded dimers consist of two complex cations and two triflate counterions, while the shorter D . . . A distances and near-ideal (180°) D–H . . . A angles imply that the hydrogen bonds are stronger in this system (Table 2). Each cation has its water ligand and DDOP alcohol group bridged by hydrogen bonding interactions with two oxygens from a triflate anion to form a "half-dimer"; these halves are connected by hydrogen bonds between the water ligands and DDOP alcohol groups of the two complex cations. The participation of the water ligand in two strong hydrogen bonding interactions explains the relatively large displacement of the zinc atom from the N_4 plane, with the hydrogen bonds and strong Zn–O coordinate bond acting to pull the metal centre out of position in the absence of any counteracting hydrogen bonds to the coordinated triflate anion. This apparent influence of hydrogen bonding over the metal coordination environment suggests that it may be a factor in the positioning of the water ligand. For example, the wider separation of the oxygens in the triflate anion (≈2.4 Å compared with 2.1 Å) may allow it to form a strong hydrogen bonded bridge between the alcohol group and water ligand in **2**, making the *syn* arrangement more favourable. Another factor may be the larger size of the triflate anion, which

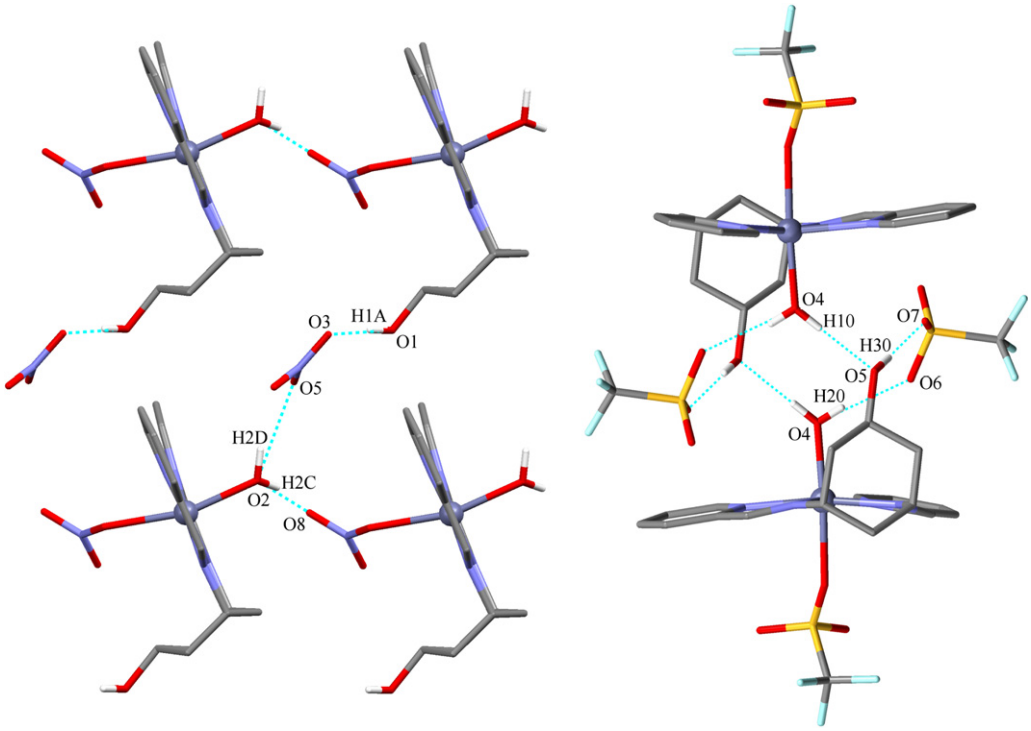

Fig. 2. Assembly of a hydrogen bonded layer in [Zn(DDOP)(NO_3)(H_2O)](NO_3) (**1**, left), and a hydrogen bonded dimer in [Zn(DDOP)(H_2O)(OTf)](OTf) (**2**, right). Hydrogen bonds are shown heavy atom to heavy atom as bright blue dotted lines, selected hydrogens are shown in white. (For interpretation of references in colour in this figure legend the reader is referred to the web version of this article.)

Table 2
Hydrogen bond lengths and angles in [Zn(DDOP)(H_2O)(NO_3)](NO_3) (**1**) and [Zn(DDOP)(H_2O)(OTf)](OTf) (**2**), calculated using PLATON [15]

	H-bonding atoms	D–H (Å)	H···A (Å)	D···A (Å)	D–H···A (°)

	O(5)–H(30)···O(7)	0.76(3)	1.97	2.730(3)	177(4)

in the *anti* arrangement could make an unfavourable steric clash with the DDOP cyclohexane backbone.

2.3. Solution chemistry

The overall structure of **1** and **2**, with four equatorial N-donors and an axial water ligand, is reminiscent of the zinc cyclams. ^{1}H NMR measurements in deuterated methanol indicated that the basic mononuclear, tetradentate chelated structure of the cations was retained upon dissolution, as revealed by the cyclohexane protons which provide an excellent conformational probe. This, coupled with the hydrophobic surface offered by the aromatic system, suggested that these molecules had potential as molecular recognition agents. Using isothermal titration calorimetry (ITC) [16] we analyzed the binding properties of the two metal complexes against a series of amino acids. Serine, tyrosine and histidine offered an interesting spectrum of coordinating amino acids to gauge the effect of the nitrate and triflate on the metal centre's ability to bind the substrates. In all cases it was shown that binding constants to the triflate complex **2** were considerably higher than the corresponding nitrate complex **1**. In the both the serine and tyrosine binding experiments the interactions were highly endothermic. This phenomenon is characteristic of hydrophobic interactions through the expulsion of solvent/counter anions from the receptor surface and substrate environs. For example, serine, when complexed with **2** afforded an endothermic interaction, $\Delta H \approx +2.71$ kcal mol^{-1}. The nitrate species **1**, gives a smaller positive ΔH of $\sim$0.85 kcal mol^{-1}. The substantially lower endothermic interaction observed could be assigned to the ineffective expulsion of the strongly coordinating nitrate anion.

However, for both complex **1** and **2**, the ITC traces (Fig. 3) indicate the coordination of two histidine amino acids to the zinc metal centre. While binding of the first histidine is endothermic (for complex **2**, $\Delta H \approx +0.94$ kcal

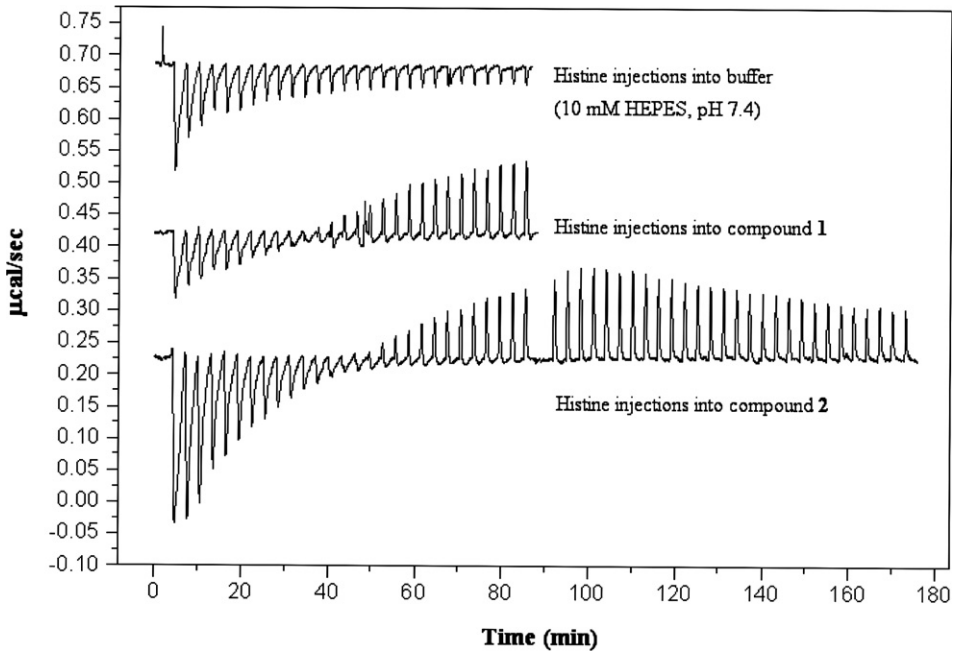

Fig. 3. ITC traces showing the binding of histidine to compounds **1** and **2**, indicating a two centre binding mode with endothermic followed by exothermic binding.

mol^{-1}), binding of the second is an exothermic process (for complex **2**, $\Delta H \approx -5.1$ kcal mol^{-1}). It appears that binding must occur above and below the planar platform via the imidazole moiety, giving an octahedral species reminiscent of the 6-coordinate iron centre observed in some haemoglobins [17]. This is because: (i) zinc has previously been shown to form 6-coordinate imidazole complexes in aqueous solution [18]; while (ii) any 5-coordinate possibilities would first require hydrolysis of one arm of the DDOP ligand to free a donor site, or, improbably, dissociation of this tetradentate chelating ligand. It should be noted that Schiff bases are generally considered relatively stable to hydrolysis [19], and furthermore such a transformation would be endothermic [20]. The two centre binding observed with histidine is probably due to the higher affinity for zinc of the softer imidazole N-donor, which unlike the carboxylic acid O-donors of the other amino acids is capable of displacing water as well as the counterions.

The two complexes were also tested against a series of phosphates, but the binding constants were negligible. The large solvent exposed areas around the metal centre probably contribute to the poor affinity of these polar substrates. Improved hydrophobic shielding would potentially increase the binding affinity for more hydrophilic substrates.

3. Conclusions

A change of anion from nitrate to triflate induces a change in the positioning of the coordinated anion in an octahedral zinc(II) complex. This change appears to result from the triflate anion's larger size and contrasting hydrogen bonding properties, which in the solid state favour formation of a *syn* complex, with a corresponding change from a 2D hydrogen bonded network to isolated hydrogen bonded dimers. In addition, the non-coordinating nature of the triflate anion in solution increases the ability of the zinc complex to bind amino acid substrates, giving it the potential for further development as a molecular recognition agent.

4. Experimental

4.1. Materials, methods and instrumentation

The ligand DDOP was synthesised by reaction of *cis*-3,5-diamino-*trans*-hydroxycyclohexane with 2-pyridinecarbaldehyde [13]. All other reagents and solvents were purchased (Fisher/Lancaster/Riedel-de Haën/Aldrich) as AR grade and used without further purification. Deuterated solvents were obtained from Aldrich. All complexations were performed in the ambient atmosphere. Infra-red spectra were measured with Jasco FTIR-410 and Bruker TENSOR 27 spectrometers and ^{1}H NMR measurements were performed using Bruker DPX-400 and Avance-400 spectrometers. X-ray diffraction data were collected using Nonius Kappa-CCD and Bruker CCD-1000 diffractometers with Mo Kα radiation and a graphite monochromator. Isothermal titration calorimetry was performed using Microcal MCS and VP-ITC titration microcalorimeters.

4.2. Preparation of $[Zn(DDOP)(H_2O)(NO_3)](NO_3)$ (**1**)

$Zn(NO_3)_2 \cdot 6H_2O$ (0.0675 g, 0.227 mmol) in methanol (5 mL) was added to a solution of DDOP (0.070 g, 0.226 mmol) in methanol (20 mL) and the resulting clear, colourless solution was stirred for 2 h at room temperature.

Evaporation of solvent *in vacuo* to a volume of ≈4 mL, followed by diffusion of ether into the methanolic solution yielded **1** as large colourless crystals in around 24 h (0.0714 g, 0.138 mmol, 61%). ^{1}H NMR (400 MHz, CD_3OD): δ 9.09 (d, 2H), 8.78 (s, 2H), 8.32 (*p*td, 2H), 8.06 (d, 2H), 7.93 (m, 2H), 4.51 (m, 2H), 4.26 (tt, 1H), 2.16 (m, 4H), 1.92 (*p*td, 2H). IR (KBr disc) cm^{-1}: 3415 s, 2922 w, 1641 m, 1603 m, 1385 s, 1329 s, 1068 m, 781 m. Elemental analysis for $C_{18}H_{22}N_6O_8Zn$, actual (expected) %: C, 42.00 (41.92); H, 4.25 (4.30); N, 15.89 (16.29).

4.3. Preparation of [Zn(DDOP)(H$_2$O)(OTf)](OTf) (2)

$Zn(CF_3SO_3)_2 \cdot 6H_2O$ (0.103 g, 0.283 mmol) in methanol (≈1 mL) was added to a solution of DDOP (0.073 g, 0.234 mmol) in methanol (2.5 mL). After stirring for around 1 h at room temperature, diffusion of ether into the methanolic solution yielded colourless crystals of **2** in less than 24 h (0.138 g, 0.20 mmol, 85%). ^{1}H NMR (400 MHz, CD_3OD): δ 9.09 (d, 2H), 8.80 (s, 2H), 8.23 (*p*td, 2H), 8.08 (d, 2H), 7.97 (m, 2H), 4.50 (m, 2H), 4.22 (tt, 1H), 2.16 (m, 4H), 1.93 (*p*td, 2H). IR (KBr disc) cm^{-1}. Elemental analysis for $C_{20}H_{22}F_6N_4O_8S_2Zn$, actual (expected) %: C, 34.75 (34.82); H, 3.11 (3.21); N, 7.96 (8.12).

4.4. Single-crystal structure determination

Suitable single crystals of **1** and **2** were mounted on the end of a thin glass fiber using Fomblin oil or epoxy glue. X-ray diffraction intensity data were measured at 150 K on a Nonius Kappa-CCD diffractometer, **1**, and at 193 K on a Bruker CCD-1000 diffractometer, **2**, in both cases using molybdenum radiation [λ(Mo Kα) = 0.7107 Å]. Structure solution and refinement for **1** was carried out with SHELXS-97 [21] and SHELXL-97 [22] via WinGX [23], and for **2** with SHELXTL [24]. Corrections for incident and diffracted beam absorption effects were applied using empirical methods [25]. Both compounds crystallized in the space group $P2_1/n$, as determined by systematic absences in the intensity data, intensity statistics and the successful solution and refinement of the structures. Both structures were solved by a combination of the Patterson method and difference Fourier syntheses and refined against F^2 by the full-matrix least-squares technique, with all non-hydrogen atoms refined anisotropically. Hydrogen atoms of alcohol groups and water ligands were found objectively on a Fourier difference map and were refined in the isotropic approximation, while other hydrogen atoms were calculated using the riding model. Crystal data, data collection parameters and refinement statistics for **1** and **2** are listed in Table 3.

4.5. Isothermal titration calorimetry

Isothermal titration calorimetry (ITC) experiments were used to measure the binding of the two complexes to various substrates, and were performed at 25 °C (298 K) using Microcal MCS and VP-ITC titration microcalorimeters. In order to minimize mixing heat effects caused by differences in solution composition, the substrates and zinc complexes were both dissolved in freshly prepared HEPES buffer (pH = 7.4) before each titration experiment. All solutions prior to experiments were degassed before being added to the calorimeter cell. The substrates, at a concentration of 5.0 mM, were injected in 10 μL increments into the reaction cell (cell volume 1.31–1.41 mL) containing **1** or **2** at a concentration of ≈0.25 mM, until there occurred a saturation of the macrocyclic cavity. A 250 μL injection syringe with 310–400 rpm stirring was used to give a series of 10 μL injections at 3-min intervals. Control experiments for heats of mixing and dilution were performed under identical conditions and used for data correction in subsequent analysis. Data acquisition and subsequent non-linear regression analysis were done in terms of a simple binding model using the Microcal ORIGIN software package.

Table 3

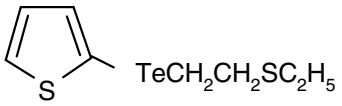
Waal's radii. The mercury complex $[HgCl_2(\mathbf{L})]$ decomposes on crystallization resulting in Th_2TeCl_2 (Th = 2-thienyl), which has been characterized by single crystal X-ray diffraction. The results of these investigations are reported in this paper.



L

2. Experimental

The C and H analyses were carried out with a Perkin–Elmer elemental analyzer 240 C. Tellurium was estimated using a flame atomic absorption spectrometer (Perkin–Elmer, Analyst 100). Mercury was determined by the cold vapour AAS method. The ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker Spectrospin DPX-300 NMR spectrometer at 300.13 and 75.47 MHz, respectively. IR spectra, in the range 4000–250 cm^{-1}, were recorded on a Nicolet Protége 460 FT-IR spectrometer as KBr pellets. The conductance measurements were made in acetonitrile (concentration ~1 mM) using an ORION conductivity meter model 162. The molecular weights (concentration ~5 mM) in chloroform were determined with a Knauer vapour pressure osmometer model A0280. The melting points determined in open capillary are reported as such.

2.1. X-ray crystallography

The data for **1** and **5** were collected (at 120 K) on an Enraf Nonius Kappa CCD area detector diffractometer, with ϕ and ω scans chosen to give a complete asymmetric unit. Cell refinement [12,13a] corresponds to a monoclinic cell for both **1** and **5**. The dimensions of both are given in Table 1 along with other experimental parameters. Absorption correction was applied [12,13]. The structures of both **1** and **5** were solved by direct methods [14] and refined using the WINGX version [15] of SHELX-97 [16]. Hydrogen atoms were included in idealized positions with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. Non-hydrogen atoms were treated anisotropically. In **1**, the 64/36 disorder in the (C_4H_3S) group was successfully modelled by placing restraints on distances and thermal parameters within the group. The final cycle of full-matrix least-squares refinement for **1** was based on 16484 observed (3034 independent) reflections (2550 for $F^2 > 4\sigma(F^2)$) and 126 variable parameters, and converged (largest parameter shift was 0.001 times its esd). The molecular structure of **1** is displayed as an ORTEP diagram in Fig. 1. Its selected bond lengths and angles are given in Table 2. The final cycle of full-matrix least-squares refinement for **5** was based on 945 observed reflections (918 for $F^2 > 4\sigma(F^2)$) and 54 variable parameters, and converged (largest parameter shift was 0.001 times its esd). The disorder in the (C_4H_3S) group was also successfully modelled by placing restraints on distances and thermal parameters. The crystal and structure refinement data for **5** are given in Table 1. Selected bond lengths and bond angles are given in Table 3. The molecular structure of **5** is displayed as an ORTEP diagram in Fig. 2.

Table 1
Crystal data and structure refinement for **1** and **5**

Compound	**1**	**5**
Empirical formula	$C_8H_{12}S_2Cl_2PdTe$	$C_8H_6S_2Cl_2Te$

2.2. Synthesis of 1-ethylthio-2-[2-thienyltelluro]ethane (*L*)

A 2-thienyl lithium solution (5.0 cm^3 of 1.0 M solution in THF) was added to elemental tellurium (0.63 g, 5.0 mmol) taken in dry THF (25 cm^3) at 0 °C in a Schlenk tube. The mixture was stirred at this temperature for 1.5 h (tellurium was dissolved) after which it was cooled to −78 °C. 2-Chloroethyl ethyl sulfide (0.62 g, 5.0 mmol) was added with constant stirring at −78 °C. The mixture was allowed to come to room temperature slowly over ~12 h, after which it was poured into 100 cm^3 of ice cold

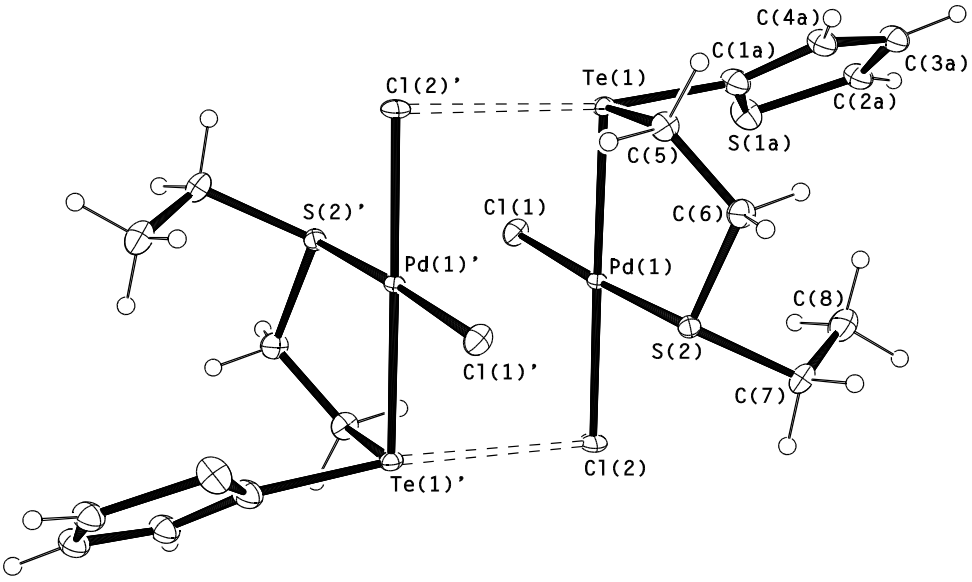

Fig. 1. Molecular structure of $[PdCl_2(\mathbf{L})]$ (**1**).

water. The ligand **L** was extracted into chloroform ($3 \times 50\ cm^3$) from the aqueous mixture. The combined chloroform extract was washed with brine (saturated solution of NaCl) ($2 \times 10\ cm^3$), dried over Na_2SO_4 and evaporated under reduced pressure on a rotary evaporator to give **L** as a red oil. Yield, 70%. ^1H NMR (δ versus TMS, $CDCl_3$, 25 °C): 1.19 (t, 3H, H_1), 2.52 (t, 2H, H_4), 2.92–2.99 (m, 4H, H_3 and H_2), 6.90–6.93 (bm, 1H, H_7), 7.37–7.38 (bd,1H, H_6), 7.42–7.44 (bd, 1H, H_8). $^{13}C\{^1H\}$ NMR (δ versus TMS, $CDCl_3$, 25 °C): 10.5 (C_4), 14.5 (C_1), 25.2 (C_2), 33.1 (C_3), 128.7 (C_6), 134.2 (C_7), 141.3 (C_8), 142.7(C_5). IR (KBr, cm^{-1}): 3455mb, 2958m, 2924w, 1580s, 1483s, 1386w, 1324w, 1281m, 1256s, 1170m, 1046m, 872m, 816w, 706s, 622m, 512m, 463w.

2.3. Synthesis of $[PdCl_2(\mathbf{L})]$ (**1**)

To a solution of **L** (0.08 g, 0.25 mmol) made in 10 cm^3 of acetone was added $Na_2[PdCl_4]$ (0.07 g, 0.25 mmol) dissolved in 10 cm^3 of water. The resulting mixture was stirred

for 2 h at room temperature and poured into 100 cm^3 of water. The complex was extracted into chloroform (4×25 cm^3). The extract was dried over anhydrous sodium sulfate, concentrated to ~10 cm^3 on a rotary evaporator and mixed with hexane (20 cm^3). The resulting yellow solid (**1**) was filtered, washed with hexane and dried *in vacuo*. It was recrystallized from a chloroform–hexane mixture (1:1). Yield, 80%; m.p. 94 °C (d). *Anal.* Calc.: C, 20.12; H, 2.51; Te, 26.75. Found: C, 20.10; H, 2.65; Te, 26.05%. Λ_m: 4.80 Ω^{-1} cm^2 mol^{-1}. Mol. wt.: 611.0 (477.00). ^{1}H NMR (δ versus TMS, $CDCl_3$, 25 °C): 1.36 (t, 3H, H_1), 3.09–3.63 (bm, 6H, H_4, H_3 and H_2), 7.16 (m, 1H, H_7), 7.63–7.71 (m, 2H, H_6 and H_8). $^{13}C\{^1H\}$ NMR (δ versus TMS, $CDCl_3$, 25 °C): 20.2 (C_4), 13.3 (C_1), 30.0 (C_2), 42.0(C_3), 129.3 (C_6), 135.2 (C_7), 139.7(C_8), 142.7(C_5). IR (KBr, cm^{-1}): 3435 mb, 3067w, 2960m, 2924s, 1623w, 1448m, 1406m, 1390m, 1260m, 1212s, 1102m, 1048m, 970w, 887w, 842m, 792vw, 715s, 464w, 326sh, 303sh, 292sh, 279sh, 246sh, 234vs.

2.4. Synthesis of [$PtCl_2$(**L**)] (**2**)

$K_2[PtCl_4]$ (0.10 g, 0.25 mmol) was dissolved in 10 cm^3 of water and mixed with a solution of **L** (0.08 g, 0.25 mmol) in 10 cm^3 of acetone. The resulting mixture was stirred for 3 h at room temperature and poured into 100 cm^3 of water. The complex was extracted into chloroform (4×25 cm^3). The extract was dried over anhydrous sodium sulfate, concentrated to ~10 cm^3 on a rotary evaporator and mixed with hexane (20 cm^3). The resulting light yellow colored compound (**2**) was filtered, washed with hexane and recrystallized from a chloroform–hexane (2:1) mixture. Yield, 78%; m.p. 84 °C (d). *Anal.* Calc.: C, 16.92; H, 2.12; Te, 22.54. Found: C, 16.17; H, 2.26; Te, 23.01%. Λ_m: 5.30 Ω^{-1} cm^2 mol^{-1}. Mol. wt.: 602.0 (565.68). ^{1}H NMR (δ versus TMS, $CDCl_3$, 25 °C): 1.43 (t, 3H, H_1), 3.00–3.48 (bm, 6H, H_4, H_3 and H_2), 7.14–7.19 (m, 1H, H_7), 7.60–7.65 (m, 2H, H_6 and H_8). $^{13}C\{^1H\}$ NMR (δ versus TMS, $CDCl_3$, 25 °C): 17.1, 18.9 (C_4), 11.1, 11.5 (C_1), 29.9, 30.5 (C_2), 39.9, 40.4 (C_3), 127.3 (C_6), 132.9 (C_7), 137.1 (C_8), 142.7 (C_5). IR (KBr, cm^{-1}): 3436mb, 3072w, 2961m, 2923m, 2853w, 2360vs, 2338vs, 1620w, 1448w, 1390m, 1214m, 1048w, 951w, 892w, 842m, 717s, 463w, 320mb, 299mb, 245sh, 232vs.

2.5. Synthesis of [$Ag(L)_2][ClO_4]$ (**3**)

A solution of $AgClO_4$ (0.1 g, 0.58 mmol) in 15 cm^3 of dry methanol was stirred under a dry nitrogen atmosphere in the absence of light. It was mixed with a solution of **L** (0.34 g, 1.16 mmol) in 10 cm^3 of chloroform. The mixture was stirred at room temperature for 1 h. A pink colored complex precipitated, which was filtered, washed well with acetone (3×10 cm^3) followed by cold chloroform (3×10 cm^3) and dried *in vacuo*. It was recrystallized with acetonitrile. Yield, 72%; m.p. 108 °C (d). *Anal.* Calc.: C, 23.80; H, 2.97; Te, 31.64. Found: C, 24.13; H, 3.01; Te, 32.06%. Λ_m: 35.90 Ω^{-1} cm^2 mol^{-1}. ^{1}H NMR (δ versus TMS, $CDCl_3$, 25 °C): 1.34 (t, 3H, H_1), 2.81 (m, 3H, $2H_2 + 1H_3$), 2.96 (m, 1H, $1H_3$), 3.24–3.25 (m, 2H. H_4), 6.99–7.00 (m, 1H, H_7), 7.43–7.48 (m, 2H, H_6 and H_8). IR (KBr, cm^{-1}): 3460mb, 2958m, 2923w, 1630w, 1584s, 1487s, 1460m, 1391w, 1285m, 1249s, 1178m, 1092vs, 816m, 622s, 512w, 463w.

2.6. Synthesis of [$CuBr(L)]_2$ (**4**)

To a solution of **L** (0.14 g, 0.50 mmol) in 10 cm^3 of chloroform was added Cu_2Br_2 (0.07 g, 0.50 mmol) dissolved in 10 cm^3 of nitromethane. The resulting mixture was stirred under an inert atmosphere for 2 h at room temperature, after which the solution was filtered through celite. The clear filtrate was concentrated to ~10 cm^3 on a rotary evaporator and mixed with hexane (20 cm^3). The resulting white solid was filtered, washed with hexane, dried *in vacuo* and stored under inert conditions. Complex **4** was recrystallized from a chloroform–hexane mixture (1:1). Yield, 62%; m.p. 82 °C (d). *Anal.* Calc.: C, 21.66; H, 2.70; Te, 28.79. Found: C, 22.26; H, 2.01; Te, 28.92%. Λ_m: 6.80 Ω^{-1} cm^2 mol^{-1}. Mol. wt.: 857 (887) ^{1}H NMR (δ versus TMS, $CDCl_3$, 25 °C): 1.32–1.39 (t, 3H, H_1), 2.92–2.96 (m, 2H, H_4), 2.67–2.77 (m, 4H, H_3 and H_2), 6.95–6.98 (m, 1H, H_7), 7.45–7.47 (m, 1H, H_6), 7.68–7.70 (m, 1H, H_8). $^{13}C\{^1H\}$ NMR (δ versus TMS, 25 °C): 19.9 (C_4), 13.9 (C_1), 29.0 (C_2), 33.8 (C_3), 129.0 (C_6), 134.6 (C_7), 141.9 (C_8), 141.0(C_5). IR (KBr, cm^{-1}): 3430mb, 3062m, 2960m, 2920s, 1447m, 1386s, 1324w, 1256m, 1213vs, 1078w, 1046w, 943w, 872vw, 840s, 793m, 706vs, 464s, 336s.

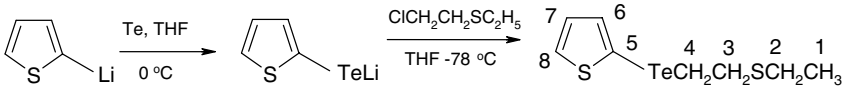
2.7. Reaction of $HgCl_2$ with **L**

$HgCl_2$ (0.15 g, 0.55 mmol) dissolved in acetone (20 cm^3) was mixed with a solution of **L** (0.16 g, 0.55 mmol) made in chloroform (20 cm^3). The resulting mixture was stirred at room temperature until the ligand **L** was consumed (as monitored by TLC). The solvent was removed from the mixture on a rotary evaporator. The resulting residue was dissolved in 20 cm^3 of chloroform and filtered through celite. The filtrate was concentrated to 10 cm^3 on a rotary evaporator and mixed with 20 cm^3 of hexane. A white complex was separated, filtered, dried *in vacuo* and kept at 0 °C for recrystallization from a chloroform–hexane (1:1) mixture. White crystals of bis(thienyl) tellurium(IV) chloride (**5**) resulted which were characterized by single crystal X-ray diffraction. Yield, 23 %. *Anal.* Calc.: C, 26.33; H, 1.64; Te, 33.59. Found: C, 26.19; H, 1.57; Te, 32.75%. ^{1}H NMR (δ versus TMS, DMSO-d_6, 25 °C): 6.91–6.94 (m, 1H, H_2), 7.78–7.79 (d, 1H, H_3), 8.14–8.15 (d, 1H, H_1).

3. Results and discussion

Ligand **L** has been synthesized according to Eq. (1), given below, as red brown oil, which is stable under ambient conditions but starts decomposing after three weeks

with the precipitation of a white insoluble powder (tellurium dioxide). It is soluble in common organic solvents such as chloroform, dichloromethane and acetone, but insoluble in hexane. Its complexes are also soluble in common organic solvents such as chloroform and dichloromethane and are stable under ambient conditions, except **4** which disproportionates easily into Cu(II) species:



(1)

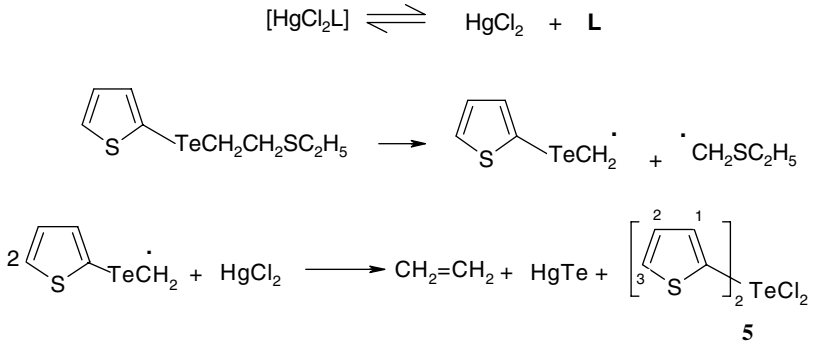
The mercury complex of **L** decomposes on crystallization resulting in Th_2TeCl_2 (Th = 2-thienyl), probably by mechanism shown in Scheme 1, which is supported by the decomposition of $[HgBr_2L]$ reported earlier [17]. Complex **5** was characterized by X-ray diffraction studies on its single needle shaped transparent crystals, which are sparingly soluble in chloroform but easily dissolve in dimethylsulfoxide. The free radical $C_2H_5SCH_2^{\cdot}$ combines to give the semi-solid $C_2H_5SCH_2CH_2SC_2H_5$ [^{1}H NMR (δ versus TMS, $CDCl_3$, 25 °C): 1.34 (t, 3 H, CH_3 of Et), 2.56–2.64 (q, 2H, CH_2 of Et), 2.73–2.96 (m, 2H, CH_2); $^{13}C\{^1H\}$ NMR (δ versus TMS, $CDCl_3$, 25 °C): 14.5 (CH_3 of Et), 23.5 (CH_2 of Et), 30.0 (CH_2)]. HgTe (0.1 g) was digested with 20 cm^3 of $HCl + HNO_3$ (3:1). The solution, after suitable dilution, was subjected to the appropriate AAS measurement. *Anal*. Calc.: Hg, 61.12; Te 38.87. Found: Hg, 60.23; Te, 39.90%.

The molar conductance values, Λ_M of the complexes **1**–**4** in acetonitrile at ~1 mM concentration level have been determined. The found values for all the complexes except **3** are much lower than the values expected for a 1:1 electrolyte. This suggests that they all are non-electrolytes except **3**, which is found to be 1:1 electrolyte. The molecular weight of **2** determined in chloroform by the vapour pressure osmometric method was found to be very close to the value calculated from its molecular formula, whereas in the case of **1** the difference between found and calculated values of molecular weight was found to be of the order which does not rule out some kind of molecular association. Thus, no appreciable molecular dissociation or association of **2** in solution is indicated by molecular weight measurements. The molecular weight of **4** was found to be nearly double the value calculated from the formula [CuBrL], supporting its dimeric nature.

In the IR spectrum of **1** the bands observed at 326 and 303 cm^{-1} may be assigned to a *cis* Cl–Pd–Cl system. This is supported by the single crystal structure of **1**. In the IR spectrum of **2** the bands at 320 cm^{-1} may be assigned to *cis* Cl–Pt–Cl of a square planar complex. The Te–C (aliphatic) stretching vibrations in the IR spectra of **1** and **2** are observed around 463 cm^{-1}. In the IR spectrum of **3** two bands appear at 1092 and 622 cm^{-1}, which show the presence of ionic ClO_4^-, i.e. outside the coordination sphere. In the IR spectrum of **4**, there is no band around 300 cm^{-1}, which indicates the absence of terminal Cu–Br, therefore it may have a bromo bridged structure if **L** is presumed to be in a bidentate mode.

3.1. NMR spectra

In the ^{1}H NMR spectrum of **L**, signals for the protons of the two $-CH_2$ groups attached to sulfur are merged together and give a multiplet at 2.92–2.99 ppm. The CH_2 protons attached to Te appear as a triplet at 2.52 ppm. The protons of the thienyl group viz. H_7, H_6 and H_8 appear separately, the first one as a broad multiplet and the other two as broad doublets. In the ^{1}H NMR spectrum of **1** the signals of H_1 appear as a multiplet and are deshielded by ~0.18 ppm as compared to free **L**. The signals due to H_2 and H_3 also merge with that of H_4. The broad multiplet between 3.09 and 3.63 is due to six protons of three $-CH_2$ groups. All the



Scheme 1.

CH_2 protons, therefore, appear deshielded by at least 0.6 ppm as compared to those of free ligand **L**. The protons of the thienyl group viz. H_6 and H_8 merge together and appear as a multiplet at 7.63–7.71 ppm. The H_7 proton also appears as a multiplet but is upfield compared to H_6 and H_8. The ^{1}H NMR spectrum of **2** is essentially the same as that of **1**. All CH_2 protons merge together and appear deshielded by up to ~0.52 ppm as compared to those of free **L**. The Te–CH_2 signal in the ^{1}H NMR spectrum of **3** shows a downfield shift of ~0.7 ppm (with respect to that of **L**), whereas an upfield shift (~0.1 ppm) is noticed in the signal of protons attached to sulfur, suggesting that the binding of **L** with metal takes place at least through Te. In the case of d^{10} metal ions, deshielding of protons associated with the donor site on coordination is not always observed, therefore the involvement of sulfur in coordination in **3** cannot be ruled out on this basis. Also in the ^{1}H NMR spectrum of **4** the Te–CH_2 signal appears deshielded by ~0.4 ppm as compared to that of free **L**. The two signals due to CH_2–S–CH_2 merge together and show an upfield shift of ~0.25 ppm with respect to those of **L**. The shifts observed in the proton signals of the thienyl group are virtually insignificant in the spectra of both **3** and **4**, indicating that the thienyl sulfur is not involved in any type of bonding. A conclusion similar to that of **3** may also be drawn about the coordination mode of **L** in **4**. Thus, the overall picture emerging from the proton NMR is that **L** coordinates through its Te with all four metals and in the case of **1** and **2** coordination via S also appears to exist but it cannot be predicted on the basis of ^{1}H NMR unequivocally in the case of **3** and **4** as CH_2 protons linked to S are found to be shielded, which may be because metal ions in both the complexes are d^{10} systems, and with them such an observation is not uncommon.

In the carbon-13 NMR spectra of **1** and **2**, the CH_2–Te signal exhibits a deshielding of ~8–9 ppm as compared to that of free ligand **L**, thereby supporting the ligation of **L** through Te. The downfield shifts (with respect to **L**) in the signals of C_2 and C_3 in the spectra of both the complexes are ~4 and 7–8 ppm, respectively, indicating ligation through sulfur also along with Te, as evidenced by the single crystal structure of **1**. In the carbon-13 NMR spectrum of **2**, two signals for each carbon atom appear, which may be due to the ^{13}C–^{195}Pt coupling. The shifts observed on complexation in the signals of the thienyl ring carbon atoms of **L** are almost insignificant. In the carbon-13 NMR spectrum of **4** the CH_2–Te signal also appears with a deshielding (~9.5 ppm) as compared to that of free **L**. Signal of C_2 also gets deshielded by ~3.8 ppm on the formation of **4**. These observations indicate that **L** coordinates in a bidentate mode with Cu in **4**. The shifts observed in the signals of all other carbon atoms are insignificant, which implies that the ligation of **L** is not through the thienyl sulfur. The carbon-13 NMR spectrum of **3** could not be recorded due to inadequate solubility.

3.2. Crystal structure

The molecular structure of **1** is shown in Fig. 1. Pd has a square planar geometry with **L** ligating in a bidentate mode. The Pd(1)–Cl(1) bond (2.322(1) Å) is shorter than Pd(1)–Cl(2) (2.38(1) Å) due to the *trans* influence of Te, but both are consistent with the values of 2.287(3) and 2.352(3) Å reported for a Pd-complex of (4-MeC_6H_4 $TeCH_2CH_2$-2-(C_5H_4N)) [18] and the values of 2.3160(7) and 2.3915(7) Å for a Pd-complex of N-{2-(4-methoxyphenyltelluro)ethyl} pyrrolidine [19]. The square planar geometry around palladium is supported by Cl(1)–Pd(1)–Cl(2), S(2)–Pd(1)–Cl(2) and Te(1)–Pd(1)–Cl(1) bond angles (94.46(4)°, 177.27(4)° and 86.83(3)°, respectively). The Pd–Te bond length of 2.504 Å observed for **1** is shorter than the sum of the respective covalent radii of 2.63 Å [1.31 Å (Pd(II)) and 1.32 Å (Te)] [20]. Similarly, the Pd–S bond length of 2.273(1) Å is also comparable with the sum of the respective covalent radii, 2.33 Å [1.31 Å (Pd(II)) and 1.02 Å (S)] and consistent with the earlier literature reports of 2.38 Å [21]. The single crystal structure of a Pd(II) complex of (Te, S) ligand 4-$MeOC_6H_4TeCH_2CH_2$ SEt has been reported earlier [8]. The various bond lengths of this Pd–(Te, S) ligand complex [Pd–Cl, 2.316(4)/2.344(3); Pd–Te, 2.492(13); Pd–S, 2.268(4) Å] are consistent with those of **1** and suggest that the donor ability of Te is little affected by replacing the substituted phenyl group with the thienyl group. The interesting feature of the crystal structure of **1** is the intermolecular interactions between Te (coordinated to Pd) and Cl and sulfur and Cl. The Te–Cl distance (3.401 Å) is shorter than sum of van der Waal's radii (3.81 Å). The S–Cl distance 3.488 Å is also shorter than sum of van der Waal's radii (3.55 Å). The Pd–Pd distance between the two molecules is 3.4156(6) Å, greater than the sum of van der Waal's radii (3.26 Å). Thus, these interactions result in the formation of dimeric units in the crystal, which dissociate in solution as the molecular weight of **1** is not found to correspond to a dimeric moiety. However, when all secondary interactions are of the Te–Cl type, the Pd–Pd distance between the molecules in the crystal is lowered below the sum of van der Waal's radii [23]. The C–C bond lengths and bond angles of the thiophene rings are found to be normal. The Te–C(1a) bond length, 2.10(2) Å, is shorter than the Te–C(5) bond length, 2.147(4) Å, but both are consistent with the earlier reported values [22] of 2.116(20) and 2.158(30) Å, respectively. Fig. 2 shows an ORTEP diagram of **5**. The structure of **5** is typical of that of a tellurium(IV) compound (saw-horse type). The geometry around Te, with a Cl(1)–Te(1)–Cl(1) angle of 178.06° and a C(1)–Te(1)–Cl(1) angle of 88.58°, can be best described as pseudo tetrahedral (trigonal bipyramidal with a stereochemically active lone pair on one corner of the triangle). The two Te–Cl bond lengths are same, 2.480(1) Å and are longer than the sum of the covalent radii, 2.36 Å. However they are somewhat shorter than the axial Te–Cl bond lengths, 2.499(3) and 2.525(4) Å reported earlier in the case of a $RR'TeCl_2$ type compound [24]. Thus, the

bonding in the Cl–Te–Cl system may be described in terms of a 3c–4e bond. The Te–C bond length in **5**, 2.151(3) Å, is longer than Te–C(aryl) of **1** but closer to its Te–C(alkyl) value, in spite of the fact that Te is in the +IV oxidation state in **5**.

emission quantum efficiency (η) by protecting the metal ion from the luminescence quencher such as O–H and N–H oscillators [5].

The spectroscopic properties of the 2-acyl-1,3-indandione complexes have been only moderately studied. Up to now, the main investigation about rare earth complexes with 2-acyl-1,3-indandiones have been concerned with complexation investigation and luminescence properties of these systems in solution [6–9]. They made a correlation between the intensity parameter η for the Eu^{3+}-complexes, which was defined as the ratio between the intensity of the $^5D_0 \rightarrow {}^7F_2$ and $^5D_0 \rightarrow {}^7F_1$ transitions, and dielectric constant of the solvents and the average polarizability of the ligand molecules. However, to the best of our knowledge, so far, no detailed studies of luminescence, including intensity parameters and ligand-to-metal energy transfer processes in solid state and X-rays structural information on these kinds of complexes have been reported yet.

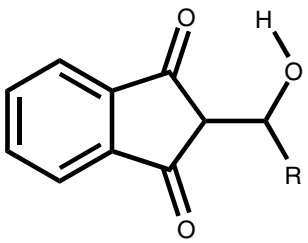
The present work is devoted to the synthesis, characterization and study of the photoluminescence behavior of seven trivalent Eu^{3+}-complexes $[Eu(ACIND)_3(H_2O)_2]$ and $[Eu(ACIND)_3(TPPO)_2]$ (where ACIND is stands for the ligands 2-acetyl-1,3-indandionate (AIND), 2-isovaleryl-1,3-indandionate (ISOVIND) or 2-benzyl-1,3-indandionate (BIND) in solid state with 2-acyl-1,3-indandionates (Fig. 1). X-ray crystal structure of the $[Eu(ISOVIND)_3 \cdot (H_2O)\text{-}(EtOH)]$ complex is also presented, which, to our knowledge, it is the first report on structural analysis of a complex with the 2-acyl-1,3-indandione ligand. An analysis of the intramolecular energy transfer processes for these compounds was also performed by theoretical methods.

2. Experimental

2.1. Materials and methods

Carbon and hydrogen contents were determined by usual microanalytical procedures using an elemental analyzer model CHN 2400 (Perkin–Elmer). Infrared spectra were recorded in the range from 4000 to 400 cm^{-1} in KBr pellets by using a Bomem model MB102 FTIR spectrophotometer. TG analysis were performed with a TG-50 thermobalance (Shimadzu) by using platinum crucibles with 2 mg of sample, under a dynamic nitrogen atmosphere (50 mL min^{-1}) and a heating rate of 10 °C min^{-1}. Excitation and emission spectra at room (~298 K) and liquid nitrogen temperatures were collected at an angle of 22.5° (front face) in a spectrofluorimeter (SPEX-Fluorolog 2) with double grating 0.22 m monochromator (SPEX 1680), and a 450 W Xenon lamp as excitation source. Luminescence decay curves were measured using a phosphorimeter SPEX 1934D accessory coupled to the spectrofluorimeter.

All reagents diethyl phthalate, acetone, methyl isobutyl ketone, acetophenone and Eu_2O_3 were purchased from Aldrich Chemical Co., $EuCl_3 \cdot 6H_2O$ were prepared according to Ref. [10] by reaction between europium oxide and hydrochloric acid.



R= CH_3, $CH_2CH(CH_3)_2$, C_6H_5

Fig. 1. Structural formula of the 2-acyl-1,3-indandione ligands.

2.2. Synthesis of the ligands

2-Acetyl-1,3-indandione (AIND), 2-isovaleryl-1,3-indandione (ISOVIND) and 2-benzoyl-1,3-indandione (BIND) ligands were synthesized using a method reported by Kilgore and co-workers [11]. Firstly, sodium ethoxide was formed by reacting 5.7 g (0.25 mol) of sodium with 12 mL (0.25 mol) of dried ethanol in benzene (200 mL), under stirring. A mixture of 55.5 g (0.25 mmol) of diethyl phthalate and the appropriate methyl ketone (acetone, isopropyl methyl ketone or acetophenone) was added, and refluxed at 80 °C for 6 h. After that, the solvent was evaporated under reduced pressure to give a yellow precipitate, which was diluted in 1 L of water and it was allowed to stand overnight. After acidifying with hydrochloric acid a yellow oil was produced, which after 24 h yield a solid product. This product was filtered, dried and recrystallized in methanol to give compound in 40% yield.

Anal. Calc. for AIND, $C_{11}H_8O_3$: C, 70.20; H, 4.30. Found: C, 69.48; H, 4,35%. 2.3. Synthesis of the hydrated Eu^{3+}-complexes

The preparation method of europium indandionate complexes were similar to those used in Ref. [12]. Sodium 2-acetyl-1,3-indandionate was prepared by neutralizing 1.0 g (5.3 mmol) of the ligand 2-acetyl-1,3-indandione with NaOH (1 mol L^{-1}) using deionized water and pH adjusted to 7. To the resulting solution was added dropwise an aqueous solution of $EuCl_3 \cdot 6H_2O$ (0.5 g, 1.4 mmol), forming immediately a yellow precipitated that was filtered, washed with water and dried under vacuum to give the desired product (yields ~90%). The same procedure, was

used to synthesize hydrated Eu^{3+}-complex with 2-isovaleril-1,3-indandionate and 2-benzoyl-1,3-indandionate ligands. In the case of the hydrated Eu^{3+}-complex with ISOVIND, a single crystal suitable for X-ray structure analysis was obtained by slow evaporation from an ethanol solution. The compositions of the complexes were confirmed by elemental analysis:

2.4. Synthesis of the Eu^{3+}-complexes with TPPO

Europium complexes with TPPO as a second kind of ligand were synthesized using the correspondent hydrated $[Eu(ACIND)_3(H_2O)_2]$ complexes as precursors. A solution of TPPO (0.37 g, 1.3 mmol) in acetone (10 mL) was added to a solution of $[Eu(ACIND)_3(H_2O)_2]$ (0.5 g, ~0.6 mmol) in acetone (20 mL), and the mixture was stirred for 2 h at room temperature. After solvent evaporation, a precipitated was produced, which was filtered, washed with ethanol and dried in vacumm. Yield: ~80%. The compositions of the complex systems were confirmed by elemental analysis and IR data: *Anal.* Calc. for $[Eu(AIND)_3(TPPO)_2]$, $C_{69}H_{51}EuO_{11}P_2$: C, 65.25; H, 4.05. Found: C, 64.93; H, 4.11%.IR (KBr, cm^{-1}): 3107m, 1558s, 1531s, 14317s, 1396s, 1342m, 1227m, 1120m, 1080w, 1037m, 862m, 820s, 777s, 725s, 659m, 430m. For $[Eu(ISOVIND)_3(TPPO)_2]$, $C_{78}H_{69}EuO_{11}P_2$: C, 67.09; H, 4.98. Found: C, 67.04; H, 5.27%. For $[Eu(BIND)_3(TPPO)_2]$, $C_{84}H_{57}EuO_{11}P_2$: C, 69.28; H, 3.95. Found: C, 69.06; H, 3.83%. IR (KBr, cm^{-1}): 3055w, 1687m, 1620s, 1589s, 1490m, 1452s, 1425s, 1340m, 1164m, 1121m, 1020w, 743m, 696m, 636m, 540s.

2.5. X-ray structure determination of $Eu(ISOVIND)_3(H_2O)(EtOH)$

A suitable crystal of the $Eu(ISOVIND)_3(H_2O)(EtOH)$ complex for X-ray diffraction was obtained dissolving the complex in a mixture of ethanol and water in a ratio 3/1 (v/v). The resulting solution was kept in stand by for a week, resulting in yellow hexagonal crystals. A crystal of this compound was mounted in a Enraf-Nonius CAD4 diffractometer with graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å), at 293 K. The structure was solved by direct methods using the SIR92 program [13] and refined by full-matrix least-squares methods on F^2 by the SHELX97 program package [14]. The hydrogen atoms for the water molecule was found in the Fourier difference map, and refined with U equal to 1.3 times the U_{eq} of the Ow. All others non-hydrogen atoms were refined anisotropically and the hydrogen atoms position were calculated in ideal geometry with thermal parameters equal to 1.5 times the U_{eq} of the attached C atom for the methyl groups and 1.2 for the others. Crystallographic data for the $Eu(ISOVIND)_3(H_2O)(EtOH)$ complex are shown in Table 1.

3. Results and discussion

IR spectra of the complexes as compared to the free indandione ligands show a displacement of the C=O stretching to lower frequencies (about 70 cm^{-1}), suggesting that the indandionate ligands are coordinated through oxygen atoms. In the case of the complexes $Eu(ACIND)_3(TPPO)_2$, the displacement of the P=O stretching from 1190 cm^{-1} in the free TPPO ligand to 1170 cm^{-1} in the compounds provides good evidence that the coordination of the TPPO to europium ion is also occurring through oxygen atom.

$w = 1/\sigma^2(F_o^2) + 0.0517P)^2$ where $P = (F_o^2 + 2F_c^2)/3$.

Thermogravimetric curves for the $[Eu(ACIND)_3(H_2O)_2]$ complexes exhibited similar profiles (figure not shown). The curves show a first weight loss in the range from 120 to 190 °C, which is assigned to the release of two water molecules coordinated to the Eu(III) ion. For [Eu(ISOVIND)$_3$(H_2O)(EtOH)] complex the first weight loss corresponds to 6.8%, which agrees to the release of one water and one ethanol molecule. The complexes with the TPPO ligand present no weight loss until 230 °C, confirming the anhydrous character of these complexes.

3.1. Structure of [Eu(ISOVIND)$_3$(H_2O)(EtOH)]

X-ray analysis reveals that eight oxygen atoms are coordinated to the central europium ion (six from the bidentate ISOVIND ligand, one from the water molecule and another from the ethanol). A key feature of the structure described herein is that, to the best of our knowledge, it is the first example of a rare earth coordination compound with a 2-acyl-1,3-indandionate ligand to be reported. The carbon atoms –CH_2 and –CH_3 from the ligands (2-acyl-1,

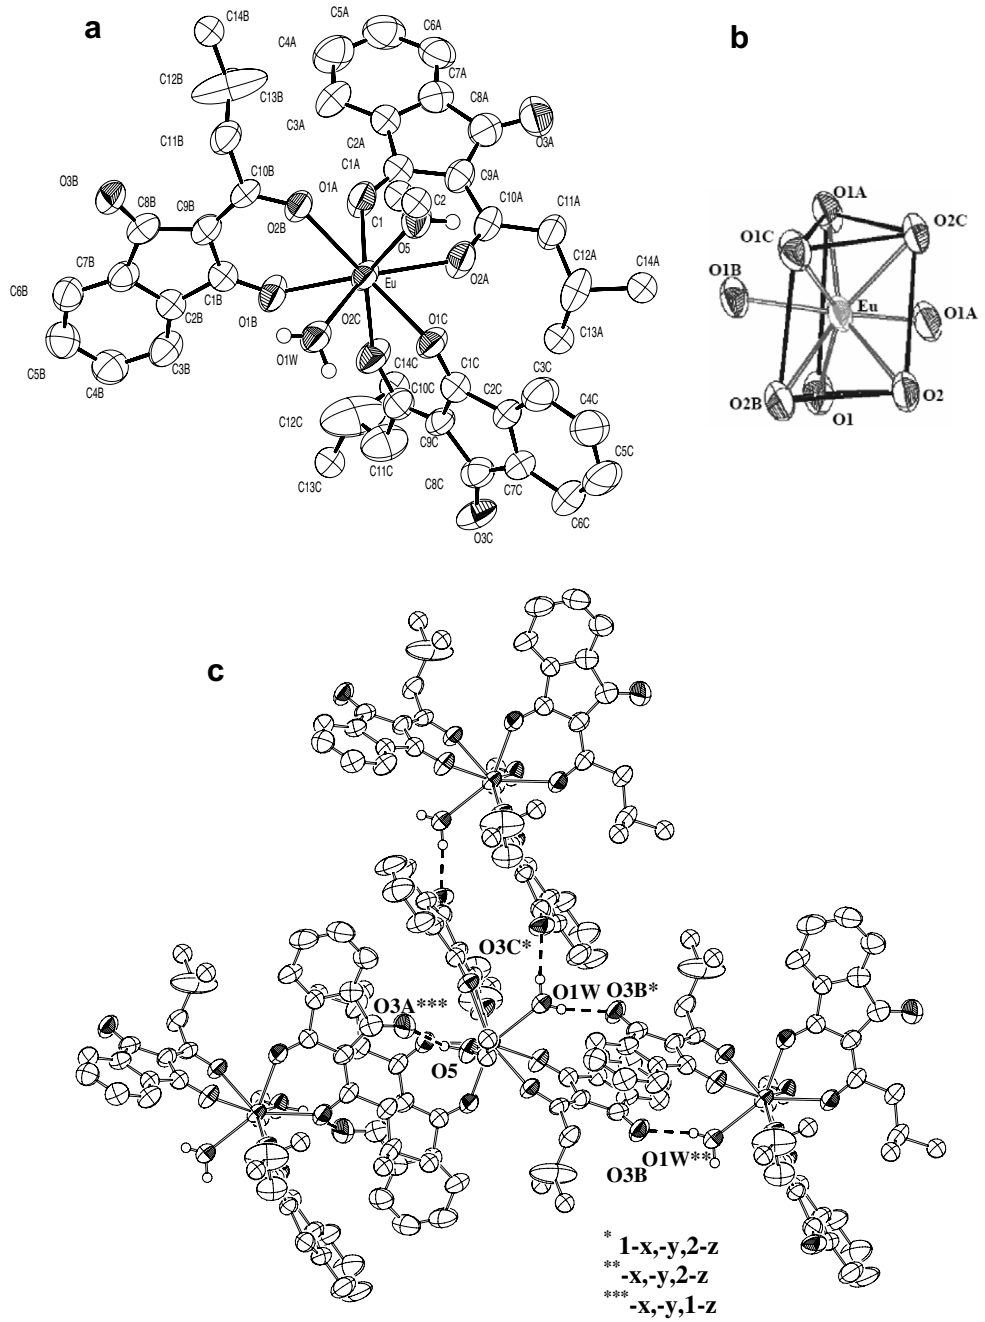

Fig. 2. (a) ORTEP drawing (50% of probability) displaying the X-ray structure of [Eu(ISOVIND)$_3$(H_2O)(EtOH)] complex; the thermal disordered methyl carbon atoms are arbitrary taken with Ueq equal to 0.05. (b) Coordination polyhedron of Eu^{3+} ion and (c) Molecules of [Eu(ISOVIND)$_3$(H_2O)(EtOH)] complex showing intermolecular H-bonding connections as dashed lines.

3-indandionate and ethanol) presents disorder by the thermal vibration. An ORTEP drawing displaying the molecular structure, with the methyl carbon atoms assuming an isotropical displacement supposition, the coordination polyhedron of the Eu(III) ion, and representation of the intermolecular hydrogen bonds in $[Eu(ISOVIND)_3(H_2O)(EtOH)]$, are presented in Fig. 2.

The geometrical arrangement of the oxygen atoms in the first coordination sphere can be described as a bicapped trigonal prism presenting a site symmetry close to C_{2v} (Fig. 2b). The Eu–O distances fall into two distinct ranges where those including O atoms from ISOVIND are shorter (Eu–O ~ 2.40 Å) than those from neutral aqua and ethanol ligands, which present Eu–O distances of 2.422(5) and 2.447(4) Å, respectively (Table 2). It is also important to observe in the crystal structure of $Eu(ISOVIND)_3(H_2O)(EtOH)$ that the hydrogen bond scheme (Table 2) gives rise to a supermolecular polymer (Fig. 2c). The water molecule coordinated to the Eu^{3+} ion is simultaneously hydrogen-bonded to two uncoordinated carbonyl oxygen atom of ISOVIND of two adjacent molecules (symmetry operation $\bar{1}$), and the OH from ethanol is connected to the third CO group of ISOVIND through O–H···O hydrogen bonds. The O_{water}–H···$O_{carbonyl}$ hydrogen bonds are similar to those found for rare earth complexes with aliphatic β-diketonate ligands reported in the literature [15].

Excitation spectra of the europium complexes with 2-acyl-1,3-indandione ligands, recorded at 77 K in the spectral range 250–590 nm (Fig. 3) were obtained with emission monitored at $^5D_0 \rightarrow {}^7F_2$ hypersensitive transition around

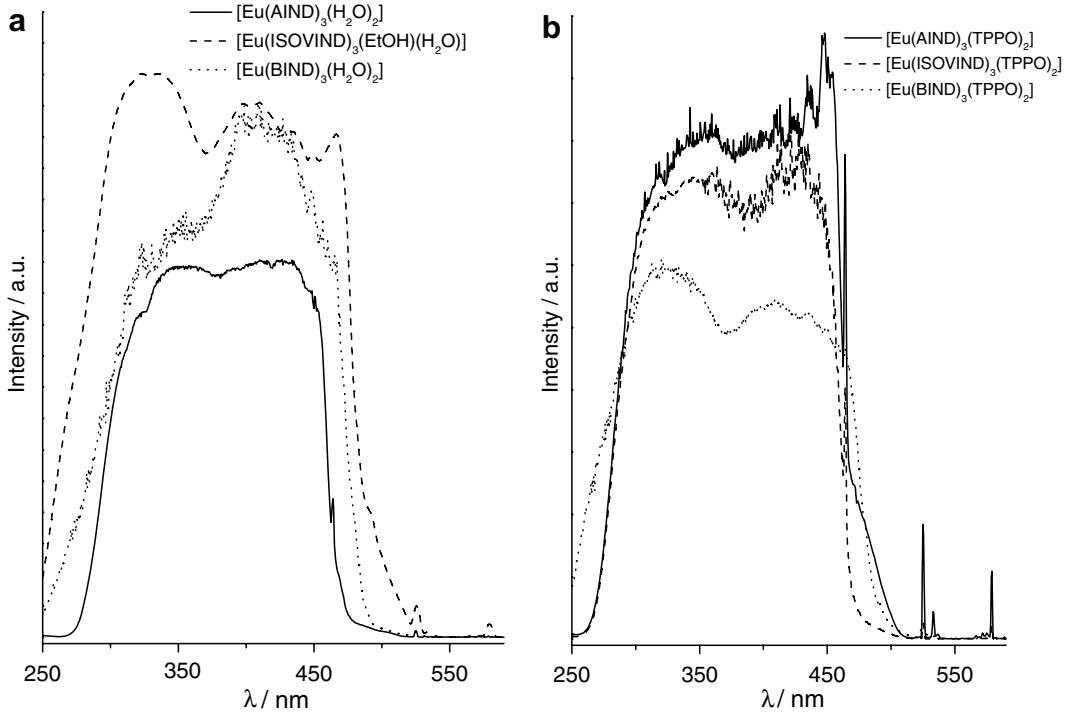

Fig. 3. Excitation spectra of (a) $[Eu(ACIND)_3 \cdot (H_2O)_2]$ and (b) $[Eu(ACIND)_3 \cdot (TPPO)_2]$ complexes in solid state, at 77 K. The spectra were recorded with emission monitored at 612 nm.

612 nm. These spectra present a strong broad band between 270 and 470 nm assigned to the photoexcitation process of the Eu(III) ion via the $S_0 \rightarrow S_1$ transition. The excitation spectra also exhibit narrow bands assigned to the 4f–4f transitions from the $^7F_0$ ground level to the excited states. However, these bands are less intense than those bands corresponding to the $S_0 \rightarrow S_1$ transition. This result gives evidence of europium luminescence sensitization through intramolecular energy transfer from the 2-acyl-1,3-indandione ligands.

Photoluminescence spectra of the hydrated complexes and those with the TPPO ligand, at 77 K, are displayed in Fig. 4. The emission spectra show characteristic $^5D_0 \rightarrow {}^7F_J$ ($J = 0$–4) transitions of Eu(III), with the hypersensitive $^5D_0 \rightarrow {}^7F_2$ transition (at 612 nm) as the most prominent one. The local-ligand field splitting is particularly evident for $^5D_0 \rightarrow {}^7F_{1-4}$ transitions, presenting Stark $(2J + 1)$-components, indicating that the Eu^{3+} ion occupies a site with low symmetry [16,17]. It is observed that, in general, emission spectra of complexes with TPPO present different profiles from the respective hydrated compounds, reflecting changes in the chemical environment around the Eu^{3+} ion. It is also important to mention that the emission spectra of all europium complexes do not exhibit ligand centered transitions, indicating that there is an efficient intramolecular energy transfer from the indandionate ligands to the Eu^{3+} ion.

In order to get further information on the chemical environment of the Eu^{3+} ions in these complexes, experimental intensity parameters Ω_λ ($\lambda = 2$ and 4), radiative rates (A_{0J}) for the $^5D_0 \rightarrow {}^7F_2$ and $^5D_0 \rightarrow {}^7F_4$ transitions and emission quantum efficiency (η) were determined (Table 3) according to Refs. [16,18].

Experimental intensity parameter Ω_2 exhibits values around 40×10^{-20} cm^2 for the hydrated complexes, suggesting the presence of a highly polarizable chemical environment around the Eu^{3+} ion [5]. These values are as high as those presented for europium complexes containing aliphatic β-diketonate, such as TTA and DBM-europium complexes [3]. It is also observed a decrease in Ω_2 for complexes with TPPO as compared to the hydrated ones. This result may be a consequence of steric hindrance due to phenyl groups that belong to the TPPO ligand.

Comparing the values of η for the complexes containing the TPPO ligand with their respective hydrated compounds, it is concluded that indeed a substitution of water

molecules in the first coordination sphere of the Eu^{3+} ion by the TPPO ligand occurs. This result reflects a decrease in the non-radiative rates (A_{nrad}) that is a consequence of the absence of O–H oscillators present in coordinated water molecules, which causes multiphonon deactivation process in the Eu^{3+} ion [5].

Theoretical structure for the [Eu(ISOVIND)$_3$(H_2O)-(EtOH)] complex was calculated using the Sparkle/AM1 model [16]. The result obtained agrees with those determined by X-rays diffraction (Fig. 2), indicating that the Sparkle/AM1 model has also proved to be very useful in predicting coordination geometries of the Eu-indandionate complexes.

Theoretical quantum yield, q, for [Eu(ISOVIND)$_3$-(H_2O)(EtOH)] was calculated according to the procedure described in Refs. [4,19]. The calculated values of transfer (W_{ET}) and back-transfer (W_{BT}) rates between ligand and Eu^{3+} ion levels are the following: $S_1 \rightarrow {}^5D_2$, $W_{ET} = 4.42 \times 10^6\ s^{-1}$; $S_1 \rightarrow {}^5D_1$, $W_{ET} = 1.30 \times 10^{10}\ s^{-1}$; $S_1 \rightarrow {}^5D_0$, $W_{ET} = 9.5 \times 10^9\ s^{-1}$; $T \rightarrow {}^5D_1$, $W_{ET} = 5.45 \times 10^9\ s^{-1}$ ($W_{BT} = 4.95 \times 10^9\ s^{-1}$); $T \rightarrow {}^5D_0$, $W_{ET} = 6.16 \times 10^9\ s^{-1}$ ($W_{BT} = 1.37 \times 10^6\ s^{-1}$). The back-transfer ($W_{BT}$) rates ${}^5D_J \rightarrow S_1$ are negligible. Consequently, there are two probable intramolecular energy transfer processes as operative channels from ISOVIND to the Eu^{3+} ion in [Eu(ISOVIND)$_3$-(H_2O)(EtOH)]: (**1**) $S_0 \rightarrow S_1 \rightarrow T \rightarrow ({}^5D_1, {}^5D_0) \rightarrow {}^7F_J$ and (**2**) $S_0 \rightarrow S_1 \rightarrow ({}^5D_1, {}^5D_0) \rightarrow {}^7F_J$. Besides, the value of q (8.0%) is close to $\eta = 8.6\%$, indicating that an efficient energy transfer from indandionate ligands to the Eu^{3+} ion in fact occurs.

4. Conclusions

It has been demonstrated that the first structurally characterized Eu^{3+}–(2-acyl-1,3-indandione) complex indicated that their coordination to the metal ion occurs in similar form as for aliphatic β-diketonates. Our results indicate that an efficient ligand-metal ion energy transfer process occurs for the Eu–(2-acyl-1,3-indandione) complexes, and that the channels (**1**) and (**2**) are the most probable ones involved in photoluminescent mechanism for [Eu(ISOVIND)$_3$(H_2O)-(EtOH)] complex.

ucts (from Alfa and Aldrich) and were used without further purification. Solvents were of reagent grade and were purified by the usual methods. *Caution*: Although no problems were encountered during the course of this work, attention is drawn to the potentially explosive nature of the perchlorate salts.

2.2. Synthesis of the macrocycle L

The synthesis of L was achieved following the literature method [5]. To a refluxing suspension of Ba(II) chloride dihydrate (1.22 g, 5 mmol) and 2,6-diformylpyridine (1.35 g, 10 mmol) in methanol (200 ml), a solution of diethylenetriamine (1.08 ml, 10 mmol) was added dropwise. The mixture was refluxed for 3 h and cooled to 0 °C. Sodium tetrahydroborate (1.52 g, 40 mmol) was added, and after 30 min a second portion (0.76 g, 20 mmol) was added. The mixture was stirred for 10 h at room temperature, and after that it was concentrated to dryness under reduced pressure. The crude solid was extracted with chloroform (3 × 100 ml) and a brown oil was obtained. It was dissolved in methanol and hydrobromic acid was added dropwise until acid pH. The tetrahydrobromide salt of the ligand L^1 was isolated.

Anal. Calc. for $C_{22}H_{36}N_8$ (molecular weight: 412.58): C, 64.1; H, 8.8; N, 27.2. Found: C, 64.2; H, 8.7; N, 27.1%. Yield: 65%. 2.3. Synthesis of the metal complexes: general procedure

The appropriate metal salt (0.25 mmol in a 1:1 or 0.5 mmol in a 2:1 M:L molar ratio) was dissolved in acetonitrile (10 mL) and added to a stirred solution of the ligand L (0.1031 g, 0.25 mmol) in acetonitrile (20 mL). The solution was stirred for 2 h and concentrated in a rotary evaporator until ca. 5–6 mL remained. The product obtained was filtered off and dried. In both cases the same dinuclear complexes were obtained and the data gathered here belong to the 2:1 procedure.

2.4. Physical measurements

Elemental analyses were performed in a Carlo-Erba EA microanalyser. Infra-red spectra were recorded as KBr discs on a Bruker IFS-66V spectrophotometer. The L-SIMS mass spectra were recorded using a Micromass Autospec spectrometer using 3-nitrobenzyl alcohol as the matrix. Conductivity measurements were carried out in 10^{-3} mol dm^{-3} acetonitrile solutions at 20 °C using a WTW LF3 conductivitymeter. The ^1H NMR spectra were recorded on a Bruker 500 MHz, and $CDCl_3$ was used as the solvent. Solid state electronic spectra were recorded on a Hitachi 4–3200 spectrophotometer using $MgCO_3$ as the reference. Magnetic studies were determined at room temperature on a vibration sample magnetometer (VSM) Digital Measurement System 1660 with a magnetic field of 5000 G.

2.5. Crystal structure determination

By slow recrystallisation from acetonitrile, crystals of the compounds $[Ni_2L(NO_3)_2](NO_3)_2$, $[Cu_2L(NO_3)_4]$ and

$[Cu_2L(ClO_4)_4]$, suitable for X-ray diffraction, were obtained. The details of the X-ray crystal data and the structure solution and refinement are given in Table 1. Measurements were made on a Bruker SMART CCD 1000 area diffractometer. All data were corrected for Lorentz and polarization effects. Empirical absorption corrections were also applied for all the crystal structures obtained [6]. Complex scattering factors were taken from the program package SHELXTL [7]. The structures were solved by direct methods, which revealed the position of all non-hydrogen atoms. All the structures were refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters for all non-hydrogen atoms. The hydrogen atoms were located in their calculated positions and refined using a riding model (see Scheme 1).

investigated, and the complexation was performed by mixing acetonitrile solutions of both ligand and metal salt. In all cases, the products isolated were the dinuclear complexes, $[Co_2L](NO_3)_4 \cdot H_2O$, $[Ni_2L(NO_3)_2](NO_3)_2 \cdot H_2O$, $[Cu_2L(NO_3)_4] \cdot 4H_2O$, $[Co_2L](ClO_4)_4 \cdot 4H_2O$, $[Ni_2L](ClO_4)_4 \cdot CH_3CN$ and $[Cu_2L(ClO_4)_4] \cdot 5H_2O$. Crystalline products were obtained upon evaporation of the solutions.

The complexes appear to be air stable; they are soluble in acetonitrile, dimethylformamide and dimethylsulfoxide and insoluble in water, methanol, ethanol and chloroform. They were characterized by elemental analysis (C, N, H), molar conductivity, mass spectrometry, IR spectroscopy, magnetic measurements, UV–Vis spectroscopy and X-ray diffraction for $[Ni_2L(NO_3)_2](NO_3)_2$, $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$ complexes.

3.1. Crystal structures

Blue prisms of $[Ni_2L(NO_3)_2](NO_3)_2$, $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$, were obtained by slow recrystallization of the complexes in acetonitrile. The details of the X-ray crystal structure solution and refinement for all complexes are given in Table 1. The molecular structure and selected bond lengths relating to the coordination environment of the metals are given in Figs. 1–3 for $[Ni_2L(NO_3)_2](NO_3)_2$, $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$, respectively.

The $[Ni_2L(NO_3)_2](NO_3)_2$ crystal structure is consistent with the cationic complex $[Ni_2L(NO_3)_2]^{2+}$ and two non-coordinated nitrate anions. In $[Ni_2L(NO_3)_2]^{2+}$, the structure shows two metal atoms endocyclically coordinated into the macrocyclic cavity, each one situated in opposite sides of the ligand hole in a N_4O_2 environment. The metal ions are bonded to one pyridine group, three secondary amine nitrogen atoms – two adjacent from one side of the macrocyclic framework and the third from the other side – and two oxygen atoms from one asymmetric bidentate nitrate group. As is usual in this kind of structure, the distortion from octahedral geometry is due to the small bite of the bidentate nitrate ligand O(1N)–Ni(1)–O(2N), 60.06(5)°. The other two nitrate ions are positioned outside the primary metal coordination sphere, showing a hydrogen bond contact with N(2)–H(2A), where the N(2)–H(2A)···O(4N) distance is 2.298 Å. The shorter bond length corresponds to the pyridine nitrogen atom, Ni–N1, 1.995(1) Å, the average value for the Ni–N_{amine} bond lengths being 2.134 Å, similar to that found in other similar octahedral Ni(II) complexes [8].

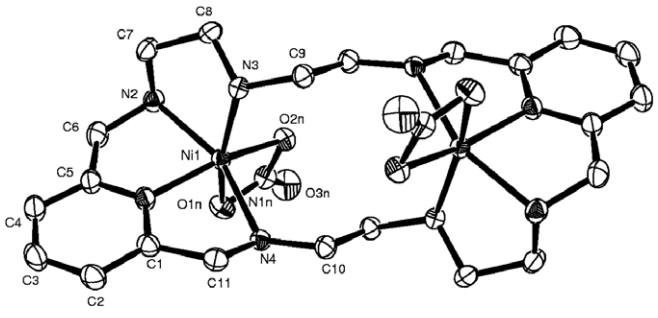

Fig. 1. Crystal structure of $[Ni_2L(NO_3)_2](NO_3)_2$; Selected bond lengths (Å) and angles (°): N(1)–Ni(1) 1.9949(14), N(2)–Ni(1) 2.1138(14), N(3)–Ni(1) 2.0967(14), N(4)–Ni(1) 2.1904(13), O(1N)–Ni(1) 2.1794(14), O(2N)–Ni(1) 2.1136(12), N(1)–Ni(1)–N(3) 101.89(6), N(1)–Ni(1)–N(2) 79.06(6), N(3)–Ni(1)–N(2) 83.97(5), N(1)–Ni(1)–O(2N) 156.89(5), N(3)–Ni(1)–O(2N) 100.23(5), N(2)–Ni(1)–O(2N) 96.75(5), N(1)–Ni(1)–O(1N) 97.15(6), N(3)–Ni(1)–O(1N) 159.36(5), N(2)–Ni(1)–O(1N) 91.96(6), O(2N)–Ni(1)–O(1N) 60.06(5), N(1)–Ni(1)–N(4) 78.54(6), N(3)–Ni(1)–N(4) 101.21(5), N(2)–Ni(1)–N(4) 157.59(5), O(2N)–Ni(1)–N(4) 103.63(5), O(1N)–Ni(1)–N(4) 90.25(5).

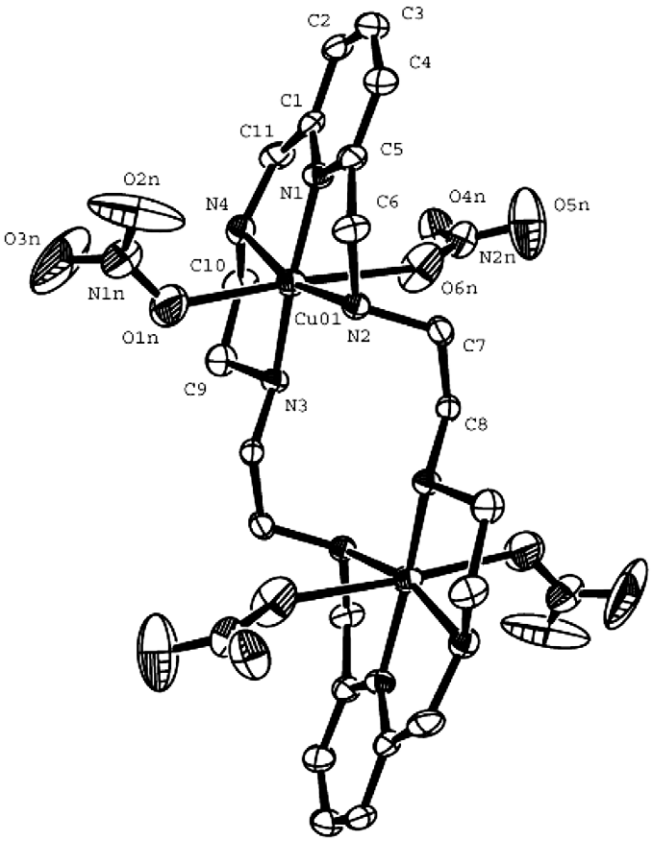

Fig. 2. Crystal structure of $[Cu_2L(NO_3)_4]$; Selected bond lengths (Å) and angles (°): N(1)–Cu(01) 1.914(6), N(2)–Cu(01) 2.072(5), N(3)–Cu(01)#1 2.024(5), N(4)–Cu(01)#1 2.018(5), O(1N)–Cu(01) 2.339(7), O(6N)–Cu(01) 2.626(7), Cu(01)–N(4)#1 2.018(5), Cu(01)–N(3)#1 2.024(5), N(1)–Cu(01)–N(4)#1 81.2(3), N(1)–Cu(01)–N(3)#1 161.3(2), N(4)#1–Cu(01)–N(3)#1 86.5(2), N(1)–Cu(01)–N(2) 82.6(2), N(4)#1–Cu(01)–N(2) 163.8(2), N(3)#1–Cu(01)–N(2) 109.3(2), N(1)–Cu(01)–O(1N) 105.2(3), N(4)#1–Cu(01)–O(1N) 91.9(3), N(3)#1–Cu(01)–O(1N) 89.2(3), N(2)–Cu(01)–O(1N) 91.8(3), N(1)–Cu(01)–O(6N) 79.2(3), N(4)–Cu(01)–O(6N) 87.1(3), N(3)–Cu(01)–O(6N) 87.4(3), N(2)–Cu(01)–O(6N) 38.63(3).

The copper(II) crystal structures show the neutral compound $[Cu_2LX_4]$ ($X = NO_3^-$ or ClO_4^-) with similar gross features for both cases. The crystal structures confirm the presence of dinuclear endomacrocyclic complexes, where the metal atoms are six coordinated by four donor nitrogen atoms from the macrocyclic backbone, similar to that described above for the nickel complex, and two oxygen atoms from two monodentate anions, nitrate for

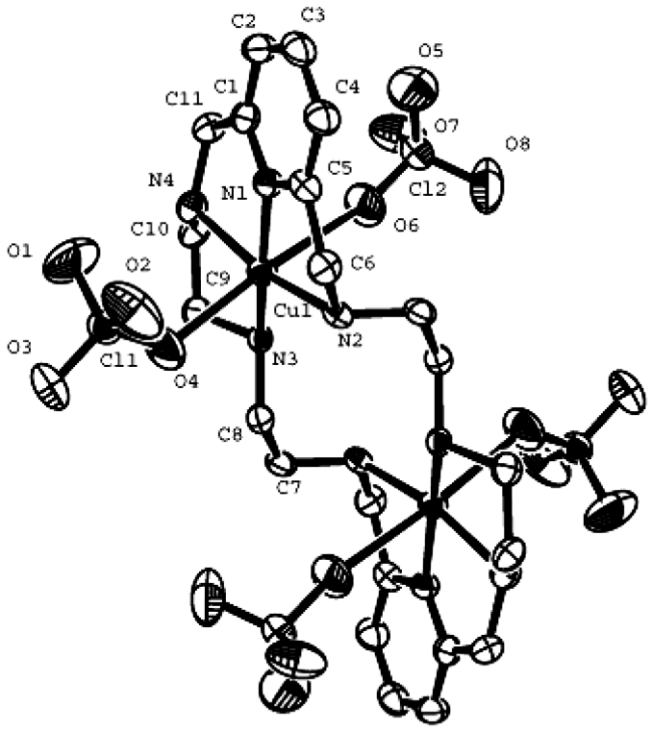

Fig. 3. Crystal structure of $[\mathbf{Cu_2L(ClO_4)_4}]$; Selected bond lengths (Å) and angles (°). Cu(1)–N(1) 1.921(4), Cu(1)–N(3) 2.016(4), Cu(1)–N(4) 2.018(4), Cu(1)–N(2) 2.090(4), Cu(1)–O(4) 2.414(4), Cu(1)–O(6) 2.617(4), N(1)–Cu(1)–N(3) 162.24(16), N(1)–Cu(1)–N(4) 81.73(17), N(3)–Cu(1)–N(4) 86.44(15), N(1)–Cu(1)–N(2) 82.51(16), N(3)–Cu(1)–N(2) 109.33(15), N(4)–Cu(1)–N(2) 164.12(16), N(1)–Cu(1)–O(4) 104.30(15), N(3)–Cu(1)–O(4) 89.78(15), N(4)–Cu(1)–O(4) 94.74(16), N(2)–Cu(1)–O(4) 87.33(16), N(1)–Cu(1)–O(6) 83.76(14), N(3)–Cu(1)–O(6) 82.79(14), N(4)–Cu(1)–O(6) 55.70(14), N(2)–Cu(1)–O(6) 94.16(14).

$[Cu_2L(NO_3)_4]$ and perchlorate for $[Cu_2L(ClO_4)_4]$. A tetragonally distorted octahedral geometry is observed in both complexes where the oxygen atoms are situated in axial positions giving rise to two different and longest distances to the metal atoms, O(1N)–Cu(1) 2.339(7) and O(6N)–Cu(1) 2.626(7) Å, for the nitrate complex and Cu(1)–O(4) 2.414(4) and Cu(1)–O(6) 2.617(4) Å for perchlorate derivative. The basal plane is provided by the four nitrogen amino atoms from the ligand, the deviation from planarity of the square base for these structures being 0.1079 for $[Cu_2L(NO_3)_4]$ and 0.1117 Å for the $[Cu_2L(ClO_4)_4]$ complex. The pyridine ring again provides the strongest bond to the copper metal, Cu–N1, 1.914(6) and 1.921(4) Å for $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$, respectively, shorter than the Cu–N_{amine} bond lengths, which have average values of 2.038 and 2.041 Å for the nitrate and perchlorate complexes, respectively. Both sorts of distances are shorter than that found for other similar octahedral Cu(II) complexes [8].

The three complexes described have a markedly step conformation, and in all cases the dihedral angle between the pyridine groups from the macrocyclic backbone is 0°, showing that there is no twisting in the ligand molecules; nevertheless the planes containing the pyridinic rings are 1.54, 3.28 and 3.66 Å apart for $[Ni_2L(NO_3)_2](NO_3)_2$, $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$, respectively.

The crystal structures show that there is no significant interaction between the metal ions, they are 5.58, 5.48 and 5.44 Å away from each other, for $[Ni_2L(NO_3)_2](NO_3)_2$, $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$, respectively.

3.2. Spectroscopic and magnetic studies

The presence of water molecules was confirmed by the appearance in the IR spectra of an intense broad band centered at ca. 3400 cm^{-1}. The ν(C=N) and ν(C=C) bands from the pyridine ring appear at 1592, 1575 and 1454 cm^{-1} in the free ligand, and they undergo a shift toward higher frequencies on complexation, appearing at 1610, 1580 and 1450 cm^{-1} in the IR spectra of the complexes, suggesting an interaction between the metal and the pyridine nitrogen atoms [9,10]. The secondary amine stretches in the region 3100–3300 cm^{-1} are split and/or shifted relative to that in the free macrocycle, suggesting coordination to the metal ion.

The IR spectra of all the complexes show the presence of several bands in the region associated with nitrate and perchlorate vibrations, suggesting coordination to the metal ion [11–13]. However, the spectra of the nitrate complexes show also an intense band at 1380 cm^{-1} due to the presence of ionic nitrate, and in some perchlorate complexes a band at 1100 cm^{-1}, attributable to the asymmetric Cl–O stretching mode of the perchlorate anions, is observed. This result is supported by the X-ray crystallographic studies, which show the presence of coordinated and ionic counterions in $[Ni_2L(NO_3)_2](NO_3)_2$. The X-ray crystal studies of $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$ show all counterions coordinated to the metals, but some of them can probably be displaced by the Br^- ion of the KBr disc.

Molar conductivity data, measured at room temperature using acetonitrile as the solvent, showed the presence of ionic and coordinated counterions, since they are in the range reported in that solvent for 2:1 and 3:1 electrolytes for nitrate and perchlorate complexes, respectively [14]. It seems that two nitrate ions remain in the inner coordination sphere in the nitrate complexes whilst only one perchlorate ion is coordinated to the metal ions in solution, in accordance with the different coordinative capacity between nitrate and perchlorate anions. This is in agreement with the results obtained from the IR and X-ray studies.

The L-SIMS mass spectra of the complexes confirm in most cases the dinuclear nature of the complexes, as they feature peaks attributable to the dinuclear species $[M_2L(X)]$, $[M_2L(X)_2]$ or $[M_2L(X)_3]$, ($X = NO_3^-$ or ClO_4^-).

The diffuse reflectance spectra were measured at room temperature for all complexes. The solid state electronic spectra of the Co(II) complexes $[Co_2L](ClO_4)_4 \cdot 4H_2O$ and $[Co_2L](NO_3)_4 \cdot H_2O$ are very similar and they show five bands at 8636, 15300, 18000, 19685 and 21552 cm^{-1} for $[Co_2L](NO_3)_4 \cdot H_2O$ and 8803, 11000, 16200, 18100 and

21 786 cm^{-1} for $[Co_2L](ClO_4)_4 \cdot 4H_2O$, indicative of a high spin distorted trigonal bipyramidal arrangement for the metal ions [15]. The electronic spectra of $[Ni_2L](ClO_4)_4 \cdot CH_3CN$ and $[Ni_2L(NO_3)_2](NO_3)_2 \cdot H_2O$ show bands at 10 460 cm^{-1} (ν_1), 17 420 cm^{-1} (ν_2) and 28 328 cm^{-1} (ν_3) and 10 850 (ν_1), 17 130 (ν_2) and 27 430 cm^{-1} (ν_3), respectively. These values are typical of octahedral Ni(II) complexes and they can accordingly be attributed to $^3T_{2g} \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$, transitions [16]. This result is in agreement with the X-ray crystal structure of the $[Ni_2L(NO_3)_2](NO_3)_2 \cdot H_2O$ complex, which presents the metal ion in a distorted octahedral environment.

For $[Cu_2L(ClO_4)_4] \cdot 5H_2O$ and $[Cu_2L(NO_3)_4] \cdot 4H_2O$ the electronic reflectance spectra show one broad band at 17 241 and 16 639 cm^{-1}, respectively, as expected for octahedrally coordinated Cu^{II} complexes [17,18].

The value of the room temperature magnetic moments of the compounds $[Ni_2L](ClO_4)_4 \cdot CH_3CN$ (5.1 BM), $[Ni_2L(NO_3)_2](NO_3)_2 \cdot H_2O$ (5.6 BM), $[Cu_2L(ClO_4)_4] \cdot 5H_2O$ (2.8 BM) and $[Cu_2L(NO_3)_4] \cdot 4H_2O$ (3.0 BM) lie within the range usually observed for octahedral Ni(II) and Cu(II) complexes [19]. The magnetic moment values obtained for $[Co_2L](ClO_4)_4 \cdot 4H_2O$ and $[Co_2L](NO_3)_4 \cdot H_2O$ are indicative of the presence of dinuclear five coordinated Co(II) complexes, with values of 5.9 and 6.2 BM, respectively [20].

The magnetic susceptibility results support the evidence of the reflectance spectra obtained for all the transitional metal complexes and are compatible with the crystal structures obtained for the complexes $[Ni_2L(NO_3)_2](NO_3)_2$, $[Cu_2L(NO_3)_4]$ and $[Cu_2L(ClO_4)_4]$.

4. Conclusions

The complexation capacity of the 24-membered octaazamacrocyclic ligand L in a 1:1 and 2:1 metal:ligand molar ratio towards the transitional metal ions Co(II), Ni(II) and Cu(II) has been investigated. Probably, because the ligand L has a large enough cavity to give rise to dinuclear endomacrocyclic complexes with these ions, the attempts to obtain mononuclear complexes were unsuccessful and dinuclear complexes were always obtained. The nitrate and perchlorate metal complexes of Ni(II) and Cu(II) present a distorted N_4O_2 octahedral environment, the metal being coordinated by a pyridine group, three secondary amine nitrogen atoms from the macrocyclic ligand and oxygen atoms from the nitrate or perchlorate anions. The spectroscopic studies reveal that the Co(II) complexes exhibit a five coordinated environment.

of peroxo-bridged compounds with amino acids and peptides serving as co-ligands, synthesized by us, proved to be powerful oxidant of bromide at near neutral pH [21–23].

Bromination of organic substrates, particularly aromatics, has been attracting considerable contemporary interest [24–31] mainly due to the commercial importance of such compounds [32]. Since the traditional bromination methods require the use of elemental bromine and solvents which are environmentally hazardous [33], there has been a continued search for alternative benign catalytic systems which can mimic the biological bromoperoxidase in the synthesis of brominated organics. Bromoperoxidases (VBPO), involved in the biosynthesis of brominated marine natural products, catalyze bromination by using H_2O_2 and bromide salts instead of Br_2 [34,35]. A large number of model systems mimicking the enzymatic activity have been developed [35–41], focusing mainly on vanadium and peroxovanadium compounds, particularly to elucidate the mechanistic details of the enzyme function which is yet to be fully understood. Contrary to natural V-BPO which is most efficient at pH 5.5–7 several model complexes were found to be catalytically active in acid medium [35–38, 40–42] which limits their utility as effective catalyst. By itself, H_2O_2 is capable of oxidizing bromide in highly acidic medium (pH < 3) but is ineffective in solution at pH > 5.0. Oxidation of bromide by hydrogen peroxide has been reported to be catalyzed by tungstate(VI) systems in acidic medium [42]. A tungstate-exchanged layered double hydroxide has also been studied as a heterogeneous catalyst in oxidative bromination of olefines by H_2O_2system [31,32]. However, examples of well-defined synthetic heteroligand peroxotungstate compounds displaying activity in oxidative bromination is scanty in literature [43] despite the number of such compounds known.

In view of the above observations in the present work we endeavored to establish rational synthetic routes to new oxo-bridged peroxotungsten complexes containing dipeptide as co-ligand, with appropriate characteristics of solubility and stability. We were particularly interested to examine whether such dinuclear compounds could act as oxidant of bromide with good activity at physiological pH, an essential requirement of a biomimetic model. Reported in this paper are the first synthesis, characterization of oxo bridged dinuclear complexes, $Na_2[W_2O_3(O_2)_4(gly\text{-}gly)_2]\cdot 3H_2O$ (**1**) and $Na_2[W_2O_3(O_2)_4(gly\text{-}leu)_2]\cdot 3H_2O$ (**2**), and studies on their stability and bromination activity. We have also investigated the bromination activity of the complex, $Na_2[W_2O_3(O_2)_4(cystine)]\cdot 4H_2O$ (**3**), synthesized previously by us.

2. Materials and methods

The chemicals used were all reagent grade products. The sources of chemicals are given below: sodium tungstate, cysteine (CDH, New Delhi, India); tungstic acid, (Himedia Laboratories, Mumbai, India); glyclyl-peptides (Sigma–Aldrich Chemical Company); hydrogen peroxide (30%) (Ranbaxy, New Delhi, India); phenol red (from *Aspergillus niger*); potassium bromide, potassium dihydrogen phosphates, sodium and potassium hydroxides (SD fine chemicals, Mumbai, India). The complex, $Na_2[W_2O_3(O_2)_4(cystine)]\cdot 4H_2O$ (**3**) was prepared by methods reported earlier [20]. The water used for solution preparation was deionised and distilled.

2.1. Synthesis of peroxotungsten complexes, $Na_2[W_2O_3(O_2)_4(gly\text{-}gly)_2]\cdot 3H_2O$ (*1*) and $Na_2[W_2O_3(O_2)_4(gly\text{-}leu)_2]\cdot 3H_2O$ (*2*)

In a typical reaction H_2WO_4 (0.25 g, 1.0 mmol) was added to 10 ml of 30% H_2O_2 (88.2 mmol) contained in a 250 ml beaker. The mixture was kept in an ice bath and stirred slowly until all the solids dissolved and a clear solution was obtained. To this solution dipeptide (1.0 mmol) was added. The pH of the clear solution was recorded to be 1.6. The pH of the reaction mixture was adjusted to ca. 2.5 by adding sodium hydroxide (46.0 mmol). On adding pre-cooled acetone (ca. 50 ml) to the above solution under continuous stirring, a white pasty mass separated out. After allowing it to stand for about 15 min in the ice bath, the supernatant liquid was decanted and the residue was treated repeatedly with acetone under scratching until it became a microcrystalline solid. The product was separated by centrifugation, washed with cold acetone and dried in vacuo over concentrated sulfuric acid. In the solid state these complexes were found to be stable for several weeks stored dry at <20 °C but tended to be hygroscopic at ambient conditions and decomposed in a few days.

Anal. Calc. for $Na_2[W_2O_3(O_2)_4(gly\text{-}gly)_2]\cdot 3H_2O$ (**1**): Na, 5.06; W, 40.52; O_2^{2-}, 14.09; C, 10.57; N, 6.16; H, 2.20. Found: Na, 4.98; W, 40.13; O_2^{2-}, 13.86; C, 10.35; N, 5.90; H, 2.23%. Yield: approximately 38%.

Anal. Calc. for $Na_2[W_2O_3(O_2)_4(gly\text{-}Leu)_2]\cdot 3H_2O$ (**2**): Na, 4.50; W, 36.07; O_2^{2-}, 12.54; C, 18.82; N, 5.49; H, 3.52. Found: Na, 4.42; W, 35.88; O_2^{2-}, 12.32; C, 18.76; N, 5.40; H, 3.20%. Yield: approximately 37%.

2.2. Elemental analysis

The compounds were analyzed for C, H, and N at the Regional Sophisticated Instrumentation Centre (RSIC), North Eastern Hill University, Shillong, India. The total peroxide content was determined by adding a weighed amount of the compound to a cold solution of 1.5% boric acid (W/V) in 0.7 M sulfuric acid (100 ml) and titration with standard Cerium(IV) solution [44]. Tungsten was determined gravimetrically [45] as $BaWO_4$. The values are given as % by weight of the compounds from which the ratios of W:peroxide are derived.

2.3. Physical and spectroscopic measurements

Spectra in the visible and ultraviolet region were recorded in a Cary Model Bio 100 spectrophotometer,

equipped with a peltier controlled constant temperature cell. The absorbance values are denoted as A_{592} at the wavelength indicated. The infrared (IR) spectra were recorded with samples as KBr pellets in a Nicolet Model Impact 410 FT-IR spectrophotometer and also in a Perkin–Elmer Model 983 spectrophotometer. The spectra were recorded at ambient temperatures by making pressed pellets of the compounds. The ^{1}H NMR spectra were recorded in deuterated chloroform in a Varian EM-390 90 MHz spectrophotometer using TMS as the internal standard. HPLC analyses were performed using a Waters Tm 2487 dual λ detector and assayed at fixed wavelengths using a C_{18} column (Nova-Pak C_{18}, 3.9 × 150 mm, Waters). Magnetic susceptibilities of the complexes were measured by the Gouy method, using Hg[Co(NCS)] as the calibrant. Molar conductance measurements were made at ambient temperature using Systronics Conductivity meter 306. Thermo gravimetric analysis was done in Mettler Toledo Star system at a heating rate of 5 °C/min under the atmosphere of nitrogen using aluminum pan.

2.4. Measurements of bromination activity in solution

The method of de Boer et al. [46] of introducing four bromine atoms into the molecule of phenol red (ε^{433} mmol = 19.7) to form bromophenol blue (ε^{592} mmol = 67.4) was used to measure bromination activity. Phenol red acts as an efficient trap of active bromine species without influencing the rate of reaction until it is exhausted. The reaction mixture contained phosphate buffer (50 mM, pH 5.5), KBr (0.5 M) and phenol red (0.1 mM). The redox activity was tested by adding a measured amount of aliquot from solution of the synthesized compound (1 mM), and by monitoring the possible change in absorbance at 592 nm at 30 °C. The volume of the reaction mixture was kept at 25 ml. Aliquots were transferred to the spectrophotometer immediately after mixing.

2.5. Bromination of organic substrates and product analysis

In a representative procedure, organic substrate (0.5 mmol) was added to a solution of acetonitrile: water (1:1) (3 ml) containing KBr (1.5 mmol). A weighed amount of solid peroxotungstate complex **1** (0.25 mmol) was then added to the reaction mixture at room temperature under continuous stirring. The stirring was continued for ca. 1 h. Reaction products as well as unreacted organic substrates were then extracted with diethyl ether and dried over anhydrous Na_2SO_4. Products were then separated by TLC and HPLC. ^{1}H NMR spectroscopy and melting point determinations were made to interpret the products.

In order to isolate the tungsten species remaining after the completion of the reaction, the following method has been adopted. After extraction of the organic reaction product, the aqueous part of the reaction mixture was transferred to a 250 ml beaker. Keeping the solution in an ice bath, pre cooled acetone was added with constant stirring until a colorless pasty mass separated out. After allowing it to stand for 10 min in an ice bath, the supernatant liquid was decanted off and the residue was treated repeatedly with acetone under scratching until it became white microcrystalline solid. The product was separated by centrifugation, washed with cold acetone and dried in vacuo over concentrated sulfuric acid.

3. Results and discussion

3.1. Synthesis and characterization

The reaction of tungsten with H_2O_2 is highly sensitive to pH and it is known that a number of peroxotungsten species are formed in solution with slight variation of pH of the reaction medium [12,15]. The methodology for the successful synthesis of the white microcrystalline dinuclear peroxotungstate compounds **1** and **2** was based on the reaction of H_2WO_4 with 30% H_2O_2 and the respective ligand in an aqueous acidic medium. Since one of our primary aims was to isolate complexes with a $[WO(O_2)_2]_2O$ moiety which has been reported to exist in an acidic solution [15], the pH of the reaction medium was strategically maintained at <3. Thus the use of acidic pH and choice of the ancillary ligand appeared to be essential parameters for achieving success of the synthesis of the dimeric title compounds. The factors such as maintenance of required time and temperature at ⩽4 °C were found to be equally important for achieving the desired syntheses. We have earlier synthesized such oxo-bridged dimeric compounds, $A_2[W_2O_3(O_2)_4(\text{cystine})]\cdot 4H_2O$ (A = Na and K) by adopting a similar synthetic strategy [20]. Our attempts to isolate analogous dinuclear compounds in the presence of some other ligand systems such as proline, glutamic acid, asparatic acid, thioglycolic acid etc. were unsuccessful. At a relatively higher pH of ca. 5.5 and using Na_2WO_4 as source of tungsten(VI), monomeric diperoxotungsten complexes were obtained in each of these cases. This suggests that the chosen dipeptide ligands may have a role in stabilizing the products.

The title compounds were diamagnetic in nature as was evident from the magnetic susceptibility measurement in conformity with the presence of tungsten(VI) in each case. From the elemental analysis data, the ratio of 1:2 was obtained for W:peroxide, while W:co-ligand ratio was ascertained to be 1:1 in each of the complexes. The elemental analysis results and molar conductance values obtained from measurement at ambient temperature were in complete agreement with the formulation of the complex species as $Na_2[W_2O_3(O_2)_4(\text{gly-gly})_2]\cdot 3H_2O$ (**1**) and $Na_2[W_2O_3(O_2)_4(\text{gly-Leu})_2]\cdot 3H_2O$ (**2**), respectively.

Each of the title compounds displayed characteristic spectral patterns in the infra-red region involving absorptions due to co-ordinated peroxide, amino acid or dipeptide ligand and lattice water (Table 1). The strong absorption at ca. 960 cm^{-1} was consistent with the presence of a terminally bonded W=O group in each case [15,16]. For the dinuclear W–O–W unit the antisymmetric

Table 1
The structurally significant IR bands of the compounds **1** and **2**

S. no.	Compound	IR bands					
		ν(W=O)	ν(O–O)	ν(W_2O)	ν_{as}(W–O_2)	ν_s(W–O_2)	ν_{sym}(W_2O)
1	$Na_2[W_2O_3(O_2)_4(gly\text{-}gly)_2]\cdot 3H_2O$ (**1**)	952	843	770	612	531	410
2	$Na_2[W_2O_3(O_2)_4(gly\text{-}leu)_2]\cdot 3H_2O$ (**2**)	949	845	767	613	534	415

and symmetric stretchings were expected in the 750–770 and 500 cm^{-1} regions [15,16], respectively. In the spectra of the complexes **1** and **2**, a prominent band at ca. 770 cm^{-1} and another weak intensity band appearing at ca. 410 cm^{-1} attributable to $\nu_{asym}(W_2O)$ and $\nu_{sym}(W_2O)$ modes gave clear indication of the presence of a bridging oxo group in each of them. The presence of side-on bound peroxo ligand in the compounds, was evident from the observance of the expected ν(O–O), ν_2 and ν_3 modes which involve metal-oxygen stretches of W–O_2 vibrations in the range of ca. 850, ca. 610 and ca. 530 cm^{-1}, respectively.

IR spectroscopy is immensely useful and informative for the characterization of heteroligand peroxometal complexes since it provides information not only about co-ordination of peroxo but also ligand groups when compared with the spectra of the free ligands. The characteristic shifts of heteroligand bands that occur upon co-ordination compared to the spectra of the free ligand reveal the bonding sites in the co-ordinated ligands. The spectra of the complexes **1** and **2** exhibited two distinct bands in the range of 1680–1660 cm^{-1} and 1630–1590 cm^{-1} which have been assigned to ν(C=O) (amide) and ν_{as}(COO) of the co-ordinated peptide ligands [47–49]. The position of ν(C=O) band in the complexes almost remained unaltered compared to its position in free ligand which indicated that the amide group was not taking part in co-ordination. The broadening of the band was probably owing to their participation in hydrogen bonding. Co-ordination through N-atom of the amide group was unlikely as evident from the spectra because such co-ordination is known to cause considerable decrease in the peptide carbonyl stretching frequency which was not observed in case of these compounds [50,51]. The ν_s(COO) vibration of the free ligands were observed in the range of 1410–1400 cm^{-1} in the IR spectra [47]. A medium intensity band with some broadening observed in the range of 1395–1405 cm^{-1} region was assigned to ν_s(COO) of the unidentate carboxylate group (ν_{as}–$\nu_s \approx 300$ cm^{-1}) [47]. The broadening of the band was probably caused by its mixing with the C–N stretching of amide group expected to occur in this region [49]. The spectra showed N–H stretching bands of coordinated peptide residue at 3300–3100 cm^{-1} region as expected from the –N^+H_3 group. N–H deformation modes (1520–1600 cm^{-1}) in their position and pattern in the spectra of the complexes significantly remained unaltered compared to the free ligand. Based on these observations it may be inferred that the dipeptide ligands, occurring as zwitterions in the complexes, co-ordinate to tungsten(VI) through carboxylate group. The presence of lattice water in each of the complexes **1** and **2** was indicated by the strong ν(OH) absorptions displayed at 3500–3400 cm^{-1}. However, the bending mode of water could not be assigned with certainty as it occurred in the carbonyl frequency region.

Depending on the pH of the reaction solution and the nature of the metal, a ligand like an amino acid or a simple peptide can act as mono, bi or tridentate ligand with different combinations of donor sites, viz., terminal amino and carboxylate groups [52] as well as amide groups in peptides and can occur in complexes in either neutral zwitterionic form or anionic form. In addition, they are known to form bridges between metal atoms leading to the formation of dinuclear or polynuclear structures. In the present study, the low pH apparently favored the co-ordination of dipeptides in their neutral zwitterionic form to the two W(VI) centers through carboxylate groups thereby stabilizing the $[WO(O_2)_2]_2O$ moiety and leading to the synthesis of the desired complexes **1**and **2**. Hydrogen bonding between the side chains is likely to stabilize the complex species in the solid state. Based on these observations a structure of the type shown in Fig. 1 has been proposed for complexes **1** and **2**, which is shown for the glycyl-glycine complex as a representative.

3.2. Stability of the complexes in solution

The stability of the compounds in an aqueous solution of pH 3.5, which is the pH attained by the solution on dissolution of the compounds, has been studied by estimating the peroxide content and molar conductances at different time intervals for any possible change. The investigations revealed that their peroxide content and molar conductance values (261 Ω^{-1} cm^2 mol^{-1} for **1** and 257 Ω^{-1} cm^2 mol^{-1} for **2**) remained unaltered for over a period of 12 h and oxygen was not released on dissolution of the complexes in

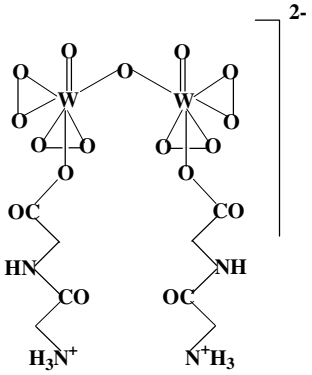

Fig. 1. Proposed structure of the dinuclear peroxotungstate compounds shown with $Na_2[W_2O_3(O_2)_4(gly\text{-}gly)_2]\cdot 3H_2O$ as representative.

water. The compounds were also found to be stable at pH 7.0 as well as at pH 8.0. The high stability of the compounds in solution at acidic as well as physiological pH is likely to be a consequence of the additional stability imparted by the heteroligands.

3.3. Thermal analysis

Thermo gravimetric analysis data of the compounds provided crucial information regarding composition of the compounds and their thermal stability. It has been evident from the TG and DTG curves (Fig. 2) that after the initial dehydration, the compounds **1** and **2** undergo multistage decomposition up to a final decomposition temperature of 550 °C.

The first stage of decomposition occurs at 40–100 °C with the liberation of the outer sphere water molecules from the complexes (Table 2). The observed weight loss of 5.4% and 5.0% for the complexes **1** and **2**, respectively are in good agreement with the calculated values (Table 2). Another decomposition stage observed in the temperature region of 110–200 °C for complex **1** and 90–160 °C for complex **2** with a corresponding weight loss of 13.2% and 11.5%, respectively is characteristic of complete loss of co-ordinated peroxo groups from the complexes [17]. It seems likely that the nature of the heteroligand has a specific effect on the thermal stability of the complexes, though not a large one, as reflected in the variation in their decomposition temperatures with respect to the loss of peroxide. Absence of peroxo group in the decomposition product was confirmed from the infrared spectral analysis. Mention must be made that some peroxotungstate and peroxomolybdate compounds containing amino acids as co-ligands were reported to behave in a similar manner losing their peroxide completely on heating [17].

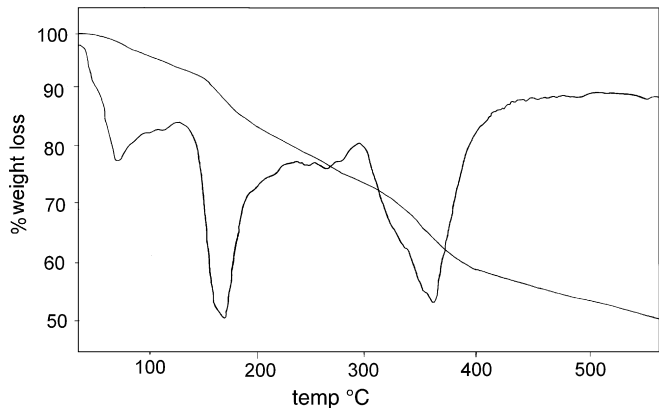

Fig. 2. TG and DTG plot of $Na_2[W_2O_3(O_2)_4(gly\text{-}gly)_2]\cdot 3H_2O$ (**1**).

The total weight loss which occurred during the course of the overall decomposition process on heating the compounds up to a final temperature of 550 °C was recorded to be 48.08% for complex **1**, which is in good agreement with the theoretically calculated value of 49.15% for the complete loss of the components viz, lattice water, co-ordinated peroxide, and the glycyl-glycine ligands. The remaining dark brown sticky residue after heating up to 550 °C was found to be a hydrated oxotungstate species as indicated by the IR spectrum which displayed the characteristic ν(W=O) and ν(OH) absorptions and was devoid of bands attributable to peroxo and the dipeptide ligands of the original compounds.

3.4. Redox activity of the complexes in bromination reaction

The bromination of phenol red to its tetra brominated product, bromophenol blue was used to measure the bromination activity of the complexes **1**–**3** in solution. Addition of freshly prepared aqueous solution of each of the compounds **1**–**3**, at concentrations indicated (Table 3), to the standard reaction of bromide in phosphate buffer with phenol red as trap for oxidized bromine resulted in gradual color change of the solution from yellow to blue. The spectrum recorded showed a peak at A_{592} characteristic of the product bromophenol blue and a decrease in absorbance of the peak at A_{433} due to loss of phenol red (Fig. 3). The data in Table 3 show that the dinuclear complexes **1**–**3** possess bromination activity.

A similar reaction when carried out in absence of phenol red displayed a peak at 262 nm with a shoulder at 237 nm on addition of solutions of compounds. Addition of phenol red to this solution resulted in the decrease in A_{262} nm and a peak at 592 nm appeared indicating the formation of bromophenol blue. The 262 nm peak, therefore, represents a bromination competent oxidized species of bromide, probably an equilibrium mixture of BrOH, Br_2 and Br_3^- as proposed earlier [34].

It was of significance to note that the bromination activity of each of the dimeric tetraperoxo complexes with two oxo-bridged diperoxotungsten units were recorded to be limited

Table 2

2. $Na_2[W_2O_3(O_2)_4(gly\text{-}leu)_2]\cdot 3H_2O$ (**2**)	0.1	0.18	10.9	1.88
3. $Na_2[W_2O_3(O_2)_4(cystine)]\cdot 4H_2O$ (**3**)	0.1	0.19	11.2	1.94

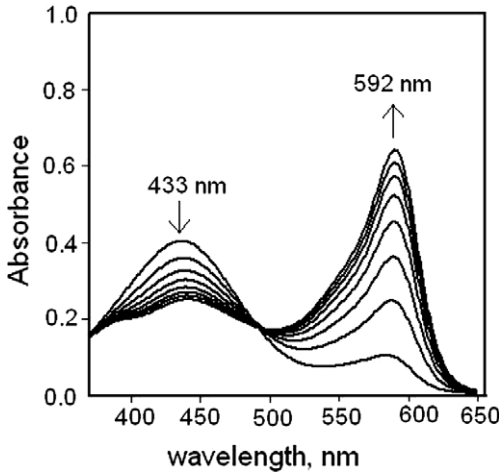

Fig. 3. Bromination activity with dinuclear peroxotungstate compound **1**. The spectrum recorded immediately after adding the compound solution to the reaction mixture. Spectral changes at 2 min interval. The reaction mixture contained phosphate buffer (0.05 M, pH 5.5), KBr (0.5 M), phenol red (0.1 mM) and compound **1** (0.05 mM).

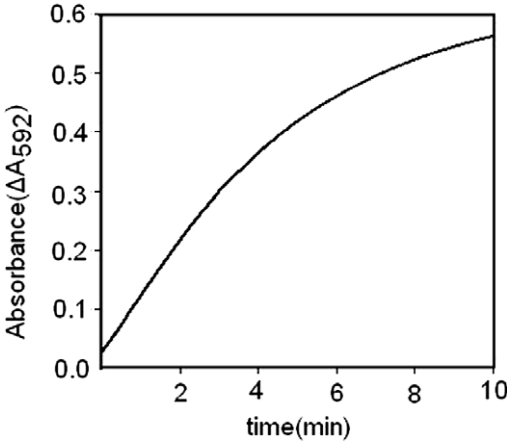

Fig. 4. The increase of absorbance at 592 nm indicating the rate of bromination with compound **1**. The reaction mixture contained phosphate buffer (0.05 M, pH 5.5), KBr (0.5 M), phenol red (0.1 mM) and compound **1** (0.05 mM).

to ca. 50% of that expected on the basis of the total number of peroxo groups present in the complexes (Table 3). Decrease or increase in concentrations of the compound, substrate or KBr in the reaction solution had no effect on this feature. The consistently observed stoichiometry of 2:1 for bromine transferred: peroxotungsten compound cause us to infer that only one of the peroxo groups of a diperoxotungsten moiety of the tetraperoxotungsten complex would be active in bromide oxidation.

The effect of H_2O_2 on the bromination reaction under standard assay conditions was tested. While the initial addition of H_2O_2 (0.5 mM) to the reaction solution had no observable effect on the initial rate of bromination (Fig. 4), it was quite intriguing to note a revival of the bromination activity on addition of H_2O_2 (0.5 mM), after bromination to a spent reaction mixture which contained excess bromide and substrate. It is thus plausible that an inactive tungsten intermediate formed after completion of the bromination process probably combines with peroxide in presence of excess H_2O_2 to regenerate the respective starting dimeric tetraperoxo tungstate complex giving rise to a catalytic cycle. Exogenous hydrogen peroxide is therefore required to maintain the tungsten complexes in their tetraperoxo forms in order to obtain a catalytic cycle.

The bromination activity of the compounds was surprisingly, found to be maximum at pH 7.5, unlike in the case of peroxovanadate catalyzed oxidative bromination where the rate was reported to increase monotonously with increasing acidity of the reaction medium [53]. We have obtained the data in Table 3 at pH 5.5 since the use of this method is limited to pH range near 5.0 in order to achieve conversion from phenol red (pK_a 7.9) to bromophenol blue (pK_a 4.0). Omission of phosphate buffer from the reaction medium did not alter the bromination activity of the complexes. This indicated that the presence of phosphate was not essential for such activity of the peroxotungsten compounds.

Efficacy of the complexes in mediating bromination of organic substrates in presence of bromide in aqueous-organic media has been explored. Bromination of several activated aromatics into their corresponding bromo-organics took place in moderate yields in presence of the dinuclear pW complexes (Table 4) at ambient temperature. Reactions were carried out in the absence of buffer. Preferential bromination at either *ortho* or *para* positions of the aromatic ring leading to mono substitution indicate an electrophilic bromination mechanism. That the brominating species was 'Br^+' and not a '$Br^{\bullet}$' in these reactions was further evident from the ring substituted products obtained from the substrate, 2-methoxy toluene (Table 4). Bromination through radical reaction would have produced benzyl bromide instead of bromo-methoxy toluene.

In order to ascertain the nature of the inactive intermediate formed in solution and to rationalize the reaction sequence the product isolated from the aqueous extract

of the reaction mixture, after completion of the reaction, was subjected to IR and elemental analysis. IR spectrum of the compound resembled closely the spectrum of the original starting complex showing the presence of peroxo group, bridging as well as terminal oxo groups and co-ordinated dipeptide. Elemental analysis results suggested the presence of one peroxo group per W(VI) indicating the formation of a monoperoxotungsten species. It thus appears that the dimeric complex remains intact throughout the course of the bromination process where two of its peroxo groups participate, leading to the formation of a dimeric peroxotungsten compound with two heteroligand monoperoxo moieties bonded through an oxo group. It is interesting to note that we could also isolate an analogous dimeric mono peroxotungsten species from a separate experiment involving complex **1** (0.5 mM) and KBr (2.0 mM) under standard assay condition with phenol red omitted from the reaction medium. This observation is consistent with the proposal which implicates formation of a monoperoxotungsten intermediate which is inactive in bromination.

A scheme of reactions, shown in Fig. 5, is proposed which satisfactorily describes the principal features of our results. The dimeric compounds react with bromide to yield oxidized bromine species, proposed to be an equilibrium mixture of BrOH, Br_2 and Br_3^-, with concomitant formation of dinuclear intermediate which is likely to possess two monoperoxotungsten units with the oxo-bridge retained (reaction a). Transfer of the bromine atom to the substrate AH from the bromination competent oxidised bromine intermediate takes place (reaction b). In the presence of excess H_2O_2 the diperoxo intermediate combines with peroxide to regenerate the starting tetraperoxo ditungstate complex giving rise to a catalytic cycle (reaction c). To us it appears that bromide would attack an edge-bound peroxo group in preference to a hepta co-ordinated tungsten centre as observed in some other redox processes involving peroxo compounds of W(VI) and Mo(VI) [13,14,43].

Formation of an inactive monoperoxo intermediate from a catalytically active diperoxotungsten or molybdenum complex during oxygen-atom transfer reactions mediated by such complexes is not unprecedented [13,14]. A monoperoxo Mo(VI) has been implicated as an intermediate in the mechanisms proposed by Reynolds et al. [43] as well as by Butler and co-workers for the Mo(VI) and W(VI) catalyzed bromide oxidations [42]. It is also relevant in this context that during one of our previous studies involving redox activity of the complex **3** with respect to reduced glutathione (GSH), only two of the peroxo groups out of four peroxides present per molecule of the complex were found to be involved in oxidation [20]. These considerations fortify our proposed mechanism.

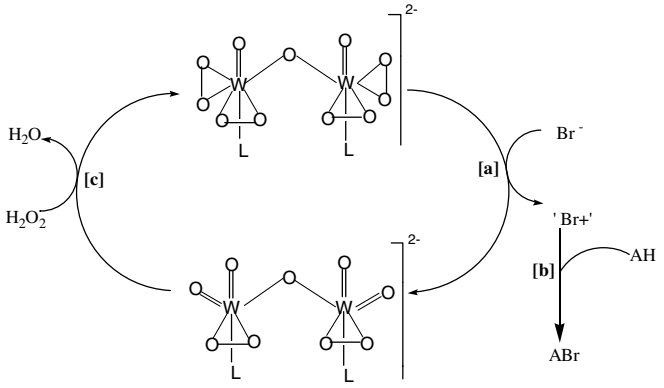

Fig. 5. Schematic representation of reactions occurring with dinuclear tetraperoxotungsten(VI) compounds (L = cystine, gly-gly or gly-leu). (a) reaction of the complex with bromide to yield oxidized bromine and an intermediate postulated as a diperoxotungsten species having two monoperoxotungsten units with the oxo-bridge retained; (b) transfer of bromine from the active species to acceptor AH; (c) in presence of excess H_2O_2 the diperoxo intermediate combines with peroxide to regenerate the starting tetraperoxo tungstate complex giving rise to a catalytic cycle. No attempt is made to show the exact stoichiometry of the reaction.

The observed reaction pattern is in accord with the earlier suggestions that for a peroxotungsten complex to be active in oxidation an oxo-diperoxo configuration may be a prerequisite [13]. This feature is however, in contrast to the findings that diperoxo-vanadate compounds with only η^2-peroxo groups in its co-ordination sphere were catalytically incompetent in bromide oxidation at neutral pH [23,53]. A dinuclear peroxovanadate with a μ-peroxo group, on the other hand was highly active in bromination at physiological pH [21–23,53]. The proposed reaction pathway conferred the status of a bromide oxidant, at physiological pH, on the VOOV group [21–23,53]. The mechanisms of bromide oxidation mediated by pW and pV compounds, tested by us, thus appear to be distinctly different. It is not completely clear however, as to why a η^2-peroxo group of diperoxotungsten(VI) species is highly reactive in oxidative bromination while a diperoxovanadate species with similar edge-bound peroxo groups is ineffective in bromination at near neutral pH.

4. Conclusion

In summary, with the examples of the newly synthesized dinuclear complexes the present investigation has

established that it is possible to isolate the oxo-bridged tetraperoxotungstate(VI) species formed in solution into solid state, through complexation with specific ligands under appropriate experimental conditions. A noteworthy observation of the present investigation, which may also be of biochemical importance, is the high stability of the compounds in solution at a wide range of pH values particularly at acidic pH. Undoubtedly, the most notable aspect of the present study is the finding that the newly synthesized complexes besides being stoichiometric reagents for bromide oxidation in aqueous medium, also acted as a catalyst for the same reaction when used in conjunction with H_2O_2 at neutral pH. Isolation of the diperoxoditungsten(VI) species as reaction intermediate lends support to the proposed mechanism. Information generated from the present investigation may find relevance in the context of designing safer biomimetic redox catalysts for organic bromination.

no inert μ-OH polymer complexes [19–22] must be present in order to avoid dramatic decreases in reaction rate. The existence of an important degree of outer-sphere hydrogen-bonding in the previous steps to the substitution reactions is clear in all cases [21,23,24], and the play of the anionic phosphate groups is considered crucial [25–28].

The use of inert octahedral d^6 complexes has been initiated by the use of Pt(IV) complexes. Nevertheless, their reactivity has always been associated with a Pt(II) reduced form, followed by the coordination to nitrogen donors of the purine bases [29–31]. The use of much more classical inert t_{2g}^6-type complexes, such as those derived from Co(III), has been explored in very few cases [21,32–37]. The problems arising from the charge of the initial dichloro complexes, as well as the extraordinary inertness of their t_{2g}^6 octahedral coordination sphere are crucial in the scarcity of their use. Furthermore, the stability of the complexes at physiological pH is drastically reduced, and the formation of inert μ-OH polymer species dominant [38]. The behaviour of *cis*-tetraamine Co(III) complexes is fundamentally different from the platinum or palladium complexes in a crucial fact: coordination of the oxo groups of the phosphate groups is highly favoured instead of the purine base nitrogens. As a consequence, the kinetic reactivity of this complexes has been generally associated with the enhancement of the hydrolytic cleavage of the phosphate esters by an extra hydroxo ligand attached to the Co(III) centre at pH $\geqslant$ 8 [38–42]. The interest in the initial substitution processes leading to this reactivity is great, but the difficulties encountered have not allowed what, in principle, represents an easy study. The careful choice of a proper and wide pH range for the study of the substitution processes is not trivial either, although it has been used in some relevant cases [43]. One has to accept that the *quality* of the data obtained is bound to be lower in these cases than for the typical situation where only a margin of one unit in pH is used.

The use of *cyclam*-type ligands represents an important way to sort some of the inherent problems arising from the use of the above mentioned inert Co(III) complexes. Functionalization of the amine groups by carboxylates can induce important changes in the overall charge of the complex [44,45], and the possibility of outer-sphere interactions between the added groups and the polynucleotide chains cannot be neglected [46]. The *cis* geometry of the tetraamine ligand can be forced by the use of the smaller *cyclen* analog. In these three circumstances, the existence of already immense number of substituted DOTA type ligands has to be taken into account [44,47]. Finally, conjugate-base catalyses has been observed for the substitution processes of this type of complexes. This is a favourable aspect in view of the extraordinary inertness of the centre and the kinetic stability of the possible μ-OH polymers formed at physiological pH [48–52].

In view of these facts we present in this paper the study of the substitution processes of the water bound to the *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ complex by 5′AMP and 5′IMP at different pH values. The study of the process is accompanied by a parallel monitoring of the substitution by chloride and inosine (INO), in order to obtain information about the specific factors influencing phosphate substitution. ^{31}P NMR monitoring of the reactions indicate that the process is clean, and that no hydrolysis of the phosphate esters is observed at pH $\leqslant$ 7.0. The stability of the final phosphatosubstituted cobaltocomplex is demonstrated and a further intramolecular process leading to the partial chelate formation of a *O*(phosphato)-*N*(nucleoside) species proved. The importance of these facts can be envisaged in view of the interactions of these type of complexes with polynucleotide chains.

2. Results and discussion

2.1. Aqua and chloro complexes

cis-$[Co(H_2O)_2(tren)]^{3+}$ and *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ complexes have been prepared *via* triflate solvolysis [53,54] from the corresponding dichloro precursors [51,55]. The partially substituted chloroaqua derivatives are obtained from the dichloro complexes *via* the spontaneous hydrolysis of one of the chloride ions in aqueous medium [49]. Table 1 collects the electronic spectral relevant data used for their characterization. The values are in good agreement with the published above mentioned data, despite the difficulties encountered given their high conjugate-base hydrolytic reactivity. Potentiometric and UV–vis titrations, using SPECFIT [56], were carried out for the determination of the pK_a values corresponding to the two cobalt-bound aquo ligands. Both set of independently obtained data produced reasonable agreement between them and the values given in the literature for these systems [57,58].

Given the fact that the reactivity involved in the studies to be carried out comprehends the $[Co(H_2O)_2(N)_4]^{3+}$/$[CoCl(H_2O)(N)_4]^{2+}$/$[Co(OH)(H_2O)(N)_4]^{2+}$/$[CoCl(OH)(N)_4]^{+}$-{$(N)_4$ = tetraamine ligand} mixtures, the determination of the pK_a value of the *cis*-$[CoCl(H_2O)(cyclen)]^{2+}$ species was also pursued. Unfortunately, the fast hydrolysis of

Table 1
UV–Vis spectral data for the series of complexes prepared as a function of the pH of the medium used (perchlorate or triflate salts unless stated) for the substitution kinetic measures

Species	pH	$\lambda(\varepsilon)$/nm (M^{-1} cm^{-1})	
cis-$[CoCl(H_2O)(tren)]^{2+}$	0	535 (138)	375 (155)
cis-$[Co(H_2O)_2(tren)]^{3+}$	1	505 (107)	350 (99)
cis-$[Co(OH)(H_2O)(tren)]^{2+}$	6.5[a]	510 (100)	356 (105)
cis-$[Co(OH)_2(tren)]^{+}$	8.5[a]	517 (105)	366 (115)
cis-$[CoCl(H_2O)(cyclen)]^{2+}$	0.3 (HCl)	534 (205)	374 (171)
cis-$[CoCl(OH)(cyclen)]^{+}$	12.5 (1.0 M NaCl)	544 (207)	360 (201)
cis-$[Co(H_2O)_2(cyclen)]^{3+}$	1	502 (177)	358 (134)
cis-$[Co(OH)(H_2O)(cyclen)]^{2+}$	7.1[b]	526 (179)	358 (124)
cis-$[Co(OH)_2(cyclen)]^{+}$	12.5[b]	548 (164)	360 (150)

[a] pK_{a1} = 5.44, pK_{a2} = 7.70.
[b] pK_{a1} = 5.66, pK_{a2} = 8.14.

the cobalt-bound chloro ligand cannot be avoided under the titration conditions (see appropriate entry in Table 1), as for the simple tetraamminocobalt(III) complexes [59]. The process results in the formation of the dihydroxo complex in major quantities, even in the presence of 1.0 M of chloride ions. An apparent value of about 6.4 was estimated from a non-rigorous SPECFIT fitting of the UV–vis titration data to an equilibrium involving the four relevant species, indicated above, in 1.0 M NaCl.

UV–vis monitoring substitution of H_2O by Cl^- on the complexes containing *tren* and *cyclen* tetraamines showed a good retention of isosbestic points at high acidity. These correspond solely to the process of formation of the monochloro cobaltocomplex, as expected from the data available in the literature [50,51]. Furthermore, treatment of the dichloro complexes in 1 M chloride solution at higher pH (up to 5.0) produced solely mixtures of diaquo and monochloro complexes, which indicates that under the conditions of the studies, only the formation of the mono-substituted chloro complex has to be considered [49]. In *cis*-$[Co(H_2O)_2(tren)]^{3+}$ the two water molecules occupy geometrically distinct positions, while nitrogen-based isomerism leads the two aqua ligands in *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ also inequivalent in the isolated *syn*,*anti* complexes [48]. The relative lability of the two non-chelated ligands in these complexes has already been established, and a base-catalysed mechanism, even at relatively low pH found to be operative for both *tren* and *cyclen* derivatives [48]. In view of these facts the kinetic experiments were designed to study only the $[Co(H_2O)_2(tren)]^{3+}/[CoCl(H_2O)(tren)]^{2+}$ and $[Co(H_2O)_2(cyclen)]^{3+}/[Co(OH)(H_2O)(cyclen)]^{2+}/[CoCl(H_2O)(cyclen)]^{2+}$ product systems, where the different acidity of the aqua ligands has been established [50,60]. For these systems the operation of the internal alternative base-catalysed substitution mechanism from the hydroxo complexes has to be considered [61,62].

2.2. Nucleoside and nucleotide complexes

The complexation of these biologically relevant ligands to the Co(III) complexes has only been studied for the *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ system, given the simpler characteristics of its substitution processes [50]. In view of the possible hydrolysis of nucleotides by this complex at physiological pH [38–40,63], the stability of the diaquacomplex at pH 7 was monitored. In all cases only the mono and dihydroxo derivatives were detected, the formation of other type of polymers were not observed by UV–vis, except for experiments carried out at high complex concentrations and/or more alkaline conditions. Even in these conditions, decreasing pH back to 7 produced the immediate and quantitative reappearance of the aquahydroxo complex, *cis*-$[Co(OH)(H_2O)(cyclen)]^{2+}$. This allowed us to study the substitution reactions without the problems derived from the existence of very stable and inert μ-OH polymeric forms that have been detected for some Pd(II) and Pt(II) model systems at physiological pH [11,64]. The values of the pK_a for the different ligands used in the study (Chart 1) have also to be considered. Literature values for the $H(INO)^+/INO/(INO–H)^-$ system are 1.1 and 8.8, while they are 3.8 and 6.2 for the $H_2(5'AMP)/H(5'AMP)^-/(5'AMP)^{2-}$ system, and 2.4 and 6.4 for the $H_2(5'IMP)/H(5'IMP)^-/(5'IMP)^{2-}$ equilibria [65,66]. Given the fact that for the nucleotide systems the mono/deprotonated equilibrium lies in the margin of pH used in this study, the values of the pK_a for these ligands were determined potentiometrically at the relevant ionic strength (1.0 M), Table 2 collects the determined data.

The nature of the nucleotide-substituted complexes has been studied *via* ^{31}P NMR spectroscopy; Table 2 collects the data obtained for the experiments carried out at different $[H^+]$ and in conditions of excess of ligand or cobaltocomplex. The data for the blank experiment carried out with phosphate as entering ligand is revealing, and agree with a cobalt-bound varying mixture of $H_2PO_4^-$ and HPO_4^{2-} [5,67,68]. At acidic pH, and with 25-fold excess phosphate, the formation of both the mono and bisphosphato complexes has to be considered. The set of data collected, with two ^{31}P NMR signals in the monodentate phosphate zone agree with this fact only if the two positions have become equivalent. Although, the signals could also be associated to two inequivalent monophosphato complexes, due to the initial *syn*/*anti* isomerism of the equatorial amines, the absence of two more signals corresponding to the bisphosphato derivative does not agree with this supposition, unless only this derivative has been formed. In this respect it is important to note that only a signal is observed when the experiment is carried out with cobalt complex in excess (Table 2 third entry), and at the same position that one of the signals observed in the systems with excess phosphate. As a whole, these observations seem to indicate that under the conditions of the experiment the two inequivalent *syn*/*anti* aqua ligand positions in *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ become equivalent when both are substituted by phosphate. Intramolecular hydrogen bonding between the phosphato ligand and the equatorial amine protons probably forces a symmetrical

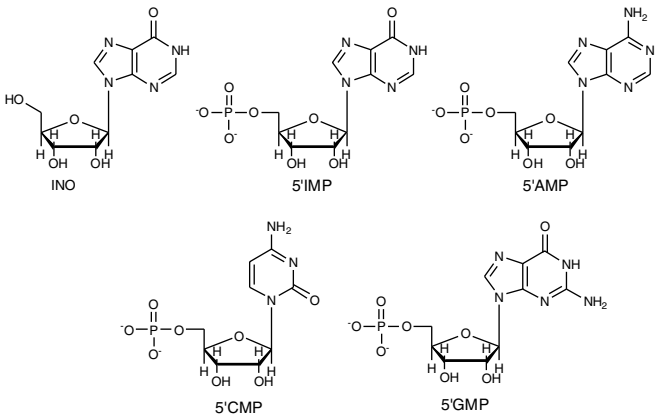

Chart 1.

syn/*syn* isomerism of the bisphosphato complex and a preferential phosphate substitution of the aqua ligand *cis* to the equatorial amine with *syn* arrangement in the initial *syn*/*anti* complex (Fig. 1) [52,60,61]. The signal at 11 ppm at pH 4.0 is associated to the monophosphato complex and its disappearance with time to give a new signal at 20 ppm is assigned to a bridged Co^{III}-*O*(HPO_2)*O*-Co^{III} species [68]. For the experiment at pH 5.3 the same signal disappears by formation of phosphato bridged species, favoured by the excess of cobalt complex, that includes some chelate-bridging, μ-κ^2-PO_4, geometries (30 ppm zone) given the higher pH [39,43]. Finally, the spectrum at pH 9.0 shows only a signal at 26 ppm attributable to the simple chelate [Co(κ^2-PO_4)(cyclen)] complex [65].

For the nucleotide derivatives the set of ^{31}P NMR signals at pH 5.0 and 7.0 do not have any resemblance with the blank reactivity pattern seen for the phosphato derivatives. Hydrolysis of the ligand is evidently not taking place, despite that found for similar systems described [38,39]. For the experiments carried out with excess 5′AMP ligand, the formation of the mono and bis derivatives might be envisaged from the data collected in Table 2. On standing, a further wide signal in the 19 ppm region appears that we associate to some sort of bridged complex as indicated before. For the experiments run for 5′AMP and 5′IMP with excess cobalt only a signal (monosubstituted complex) at 14 ppm appears just after mixing, and a further signal, much less intense at 15 ppm, is made evident as time increases (Figure S1); thus, this signal cannot be due to bis-

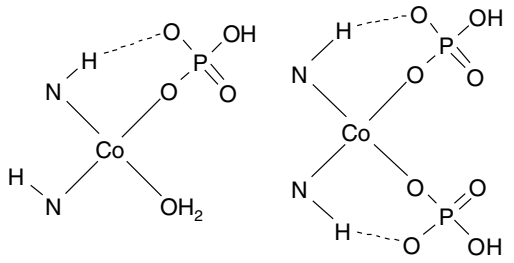

Fig. 1.

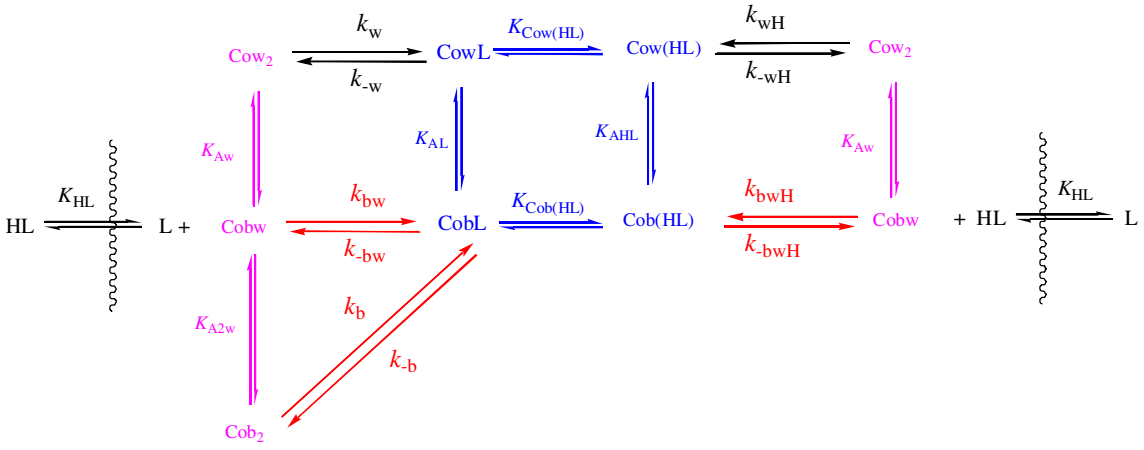
complexes. Possible phosphato bridged complexes cannot be considered either, given the fact that the chemical shift is expected at lower fields [68]. An equilibrium mixture with a chelate, or bridged, complex involving both one of the phosphate oxo groups and some other donors of the nucleotide can be held responsible for this fact [69]. The chemical shift of the phosphato group is not expected to be greatly affected and the formation process is expected to be concentration independent (*vide infra*). Some control experiments carried out with 5′CMP and 5′GMP also show this set of two signals in the monophosphato complex region, in good agreement with the above mentioned assumption.

As a whole, the studies indicate that the chemistry of the substitution processes on *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ by nucleotides at physiological pH does not involve hydrolysis of the ligands on coordination. No signals in the 30 ppm zone of the ^{31}P NMR spectrum are detected, a clear indication of the lack of the μ-κ^2-PO_4 complexes expected from hydrolysed phosphate at this pH [43]. The complexes, though, evolve to the formation of *O*(phosphato)-*N*(nucleoside) species.

2.3. Substitution kinetics

Once the nature of the complexes has been established, the full sequence of the kinetics of the reactions at physiological pH has to be considered. In principle the careful determination of the pK_a values of the diaquacobalt complexes and the entering ligands should enable an easy study. Nevertheless, these systems are surprising labile for a Co(III)–amine complex, expected to react fairly slowly at the pH range used [38,70]. The study of the substitution reactions of H_2O by chloride in *cis*-$[Co(H_2O)_2(tren)]^{3+}$ or *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ is acidity-dependent even at fairly high $[H^+]$ values, implying that an internal conjugate-base reaction mechanism is operative on the aqua-complexes even at acidic pH [48,50,52,61,62]. Scheme 1 (left side) corresponds to the set of possible reaction paths operating for the substitution process by a ligand (**L**) on the substrates



Scheme 1.

derived from the complex *cis*-$[Co(H_2O)_2(tetraamine)]^{3+}$, **Cow**$_2$, at different acidities. That is, in the fully protonated form of the tetraamine *tren* or *cyclen* ligands (**Co**≡{Co(tren)}$^{3+}$ or {Co(cyclen)}$^{3+}$) or in the form containing a reactive internal base-conjugated tetraamine (**Co**$^-$≡{Co(tren-H)}$^{2+}$ or {Co(cyclen-H)}$^{2+}$) produced from proton transfer to coordinated hydroxo ligands of the inert complexes [61,62]. The acid–base equilibria to be considered in the range of pH in which the experiments were carried out are the following:

$$k_{on} = \frac{\{k_{wH}\}[H^+]^2 + \{k_w k_{HL} + k_{bwH} k_{Aw}\}[H^+] + \{k_{bw} K_{Aw} K_{HL}\} + \{k_b K_{Aw} K_{A2w} K_{HL}\}(1/[H^+])}{\{[H^+] + K_{HL}\}\{[H^+] + K_{Aw}\}} \quad (1)$$

$$k_{off} = \frac{\{k_{-wH}/K_{Cow(HL)})\}[H^+]^2 + \{k_{-w} + k_{-bwH} K_{AHL}/K_{CowHL}\}[H^+] + \{k_{-bw} K_{AL}\} + \{k_{-b} K_{AL}\}(1/[H^+])}{([H^+] + K_{AL})} \quad (2)$$

$$k_{on}\{[H^+]K_{HL}^{-1} + 1\}\{[H^+] + K_{Aw}\} = \{k_{wH}K_{HL}^{-1}\}[H^+]^2 + \{k_w + k_{bwH}K_{Aw}K_{HL}^{-1}\}[H^+] + \{k_{bw}K_{Aw}\} + \{k_b K_{Aw} K_{A2w}\}(1/[H^+]) \quad (3)$$

$$k_{off}([H^+] + K_{AL}) = \{k_{-wH}/K_{Cow(HL)})\}[H^+]^2 + \{k_{-w}k_{-bwH}K_{AHL}/K_{CowHL}\}[H^+] + \{k_{-bw}K_{AL}\} + \{k_{-b}K_{AL}\}(1/[H^+]) \quad (4)$$

Co$(H_2O)_2$/**Co**$(OH)(H_2O)$ ≡ **Cow**$_2$/**Cobw**;
K_{Aw} producing reactive **Co**$^-$**w**$_2$

Co$(OH)(H_2O)$/**Co**$(OH)_2$ ≡ **Cobw**/**Cob**$_2$;
K_{A2w} producing reactive **Co**$^-$**bw**

Co(H_2O)L;/**Co**(OH)L ≡ **CowL**/**CobL**;
K_{AL} producing reactive **Co**$^-$**wL**

Whenever the ligand **L** can further be involved in an acid–base equilibrium, at the pH used for the experiments (as is the case for the 5′IMP and 5′AMP ligands) species **HL** has also to be considered. The parallel reaction scheme showed on the right of Scheme 1 applies, related through the corresponding deprotonation equilibria.

Only the k_w/k_{-w} and k_{wH}/k_{-wH} paths corresponds to a spontaneous process, while the k_{bw}/k_{-bw}, k_{bwH}/k_{-bwH} and k_b/k_{-b} reactions correspond to internal base catalysed processes, as indicated for equivalent systems [50,52,61]. The possible k_{bH}/k_{-bH} term, derived from **Cob**$_2$ plus **HL** reactivity, should not be considered given the fact that pH requirements for **Cob**$_2$ do not allow for the existence of **HL**. For the full reaction scheme the rate law can be written as $k_{obs} = k_{on} \times [L]_{total} + k_{off}$. The expression for k_{on} can be derived as in Eq. (1), taking into account that the amount of **Cob**$_2$ in negligible under the pH conditions used. For k_{off} Eq. (2) applies, if the concentrations of **Cow(HL)** and **Cob(HL)** are considered negligible, given the increased acidity of the coordinated HL ligand.

Fig. 2 represents typical plots of k_{obs} *versus* $[L]_{total}$ for the systems studied. From the plots of $k_{on}\{([H^+]K_{HL}^{-1} + 1)([H^+] + K_{Aw})\}$ (Eq. (3)) or $k_{off}\{[H^+] + K_{AL}\}$ (Eq. (4)) *versus* $[H^+]$ (or $[H^+]^{-1}$), shown in Figs. 3 and S2, the values of the specific combinations of rate and equilibrium constants involved in the different reaction $[H^+]$-dependent paths can be derived [14]. It is clear that data have errors much larger than those derived from the mathematical treatment, only the relative weight of the acidity-dependent contributions can be considered. The choice of the plot *versus* $[H^+]$ or $[H^+]^{-1}$ has been done according to the range of acidity values used, as indicated in Tables 3 and 4 that collect the relevant data calculated using the pK_{Aw} and pK_{HL} values in Tables 1 and 2. A value of pK_{AL} of 6.4 has been estimated (see Section 2.1) for $[CoCl(H_2O)(cyclen)]^{2+}$/$[CoCl(OH)(cyclen)]^+$, and the value has been used for all the rest of the $[CoL(H_2O)(tetraamine)]^{n+}$/$[CoL(OH)(tetraamine)]^{(n-1)+}$ equilibria.

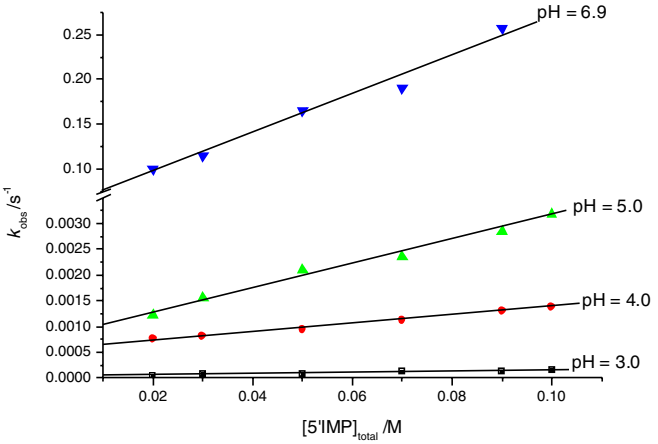


Fig. 2. Plot of k_{obs} *vs.* $[5'IMP]_{total}$ for the substitution on *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ at 21 °C, $I = 1.0$ M ($NaClO_4$) and different acidities.

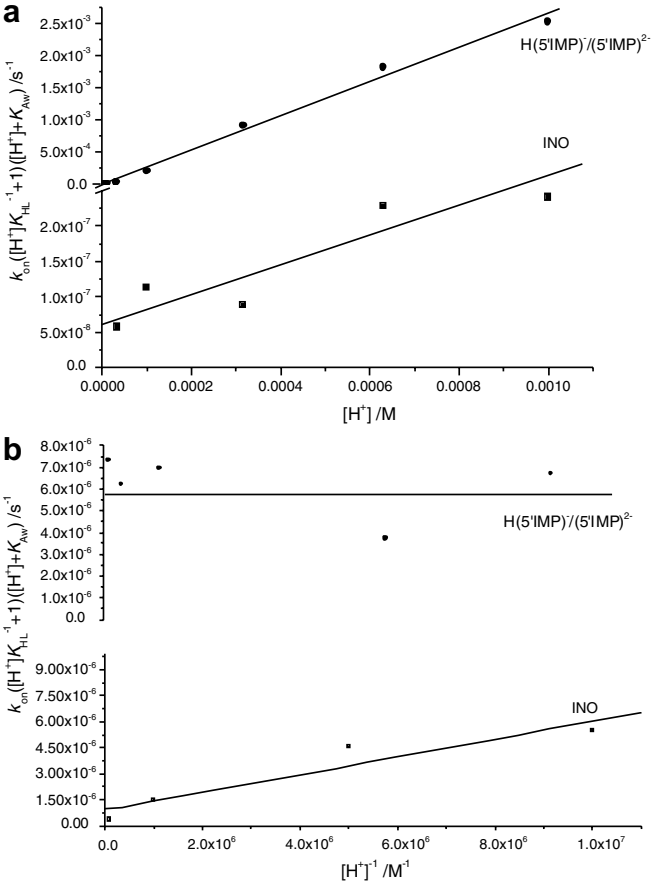

Fig. 3. Plots of $k_{on}\{([H^+]K_{HL}^{-1}+1)([H^+]+K_{Aw})\}$, for the *cis*-$[Co(H_2O)_2$-(cyclen)$]^{3+}$ plus the hypoxanthine nucleoside and nucleotide derivatives, *vs.* $[H^+]$ (a) or $[H^+]^{-1}$ (b) according to Eq. (3), at the pH range indicated in Table 3 ($T = 21$ °C, $I = 1.0$ M ($NaClO_4$)).

The chloride substitution reaction on the *tren* cobalt complexes has only contribution from the spontaneous path down to pH 4. For the complex having the more acidic *cyclen* ligand the path derived from the first internal base-catalysed is active in the same pH range. Despite the fact that the concentration of the **Cob**$_2$ species is very low ($K_{A2w} = 10^{-8.14}$) under the conditions used the k_b/k_{-b} internal base-catalysed path is also active for this complex at the pH range used. Nevertheless, its contribution to the process is ca. 5 orders of magnitude lower, which could be considered an indicative of the concerted internal conjugate-base process that necessarily forces a hydroxo ligand (a much better Lewis-base ligand) out of the coordination sphere of the cobalt.

On moving to the similar substitution process on *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ by inosine, the nucleoside is found active in the same reaction paths detected for the chloride anion at the working pH. The values calculated for the rate constants show, however, surprising differences with respect to the chloride substitution process. Spontaneous substitution is 1–2 orders of magnitude larger, while the contribution to substitution of the two conjugate-base paths are reduced by the same degree. Given the neutral charge of the INO entering ligand at the working pH, a variety of factors on these dissociatively activated substitutions, such as the existence of hydrogen-bonded outer-sphere complexes involving the cyclic amines and the biologically relevant ligands [2,71–73], have to be held responsible of the unexpected trend. Equilibrium constants are definitively larger than for the chloride ligands, in good agreement with the nature of the nitrogen donor groups [16,23,74,75].

As for the substitution processes by 5′AMP and 5′IMP on *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$, the main contribution corresponds to the spontaneous process on **Cow**$_2$, k_w, and/or the internal conjugate-base generated for the k_{bwH} path, both being kinetically undistinguishable by proton ambiguity. The reaction rate of the path related to the internal conjugate-base generated from **Cobw** is five orders of magnitude lower. The reverse reaction is only active *via* the latter producing a *partial* equilibrium constant of ca. 200, in good agreement with the preference of phosphate to water of the cobalt(III) centre [76,77]. The values found for the substitution rate constants are practically the same for the two systems, indicating the fairly equivalent nature of the phosphate entering groups.

Given the dissociatively activated character of the process studied, the difference on the values corresponding to the rate constants for the nucleoside and nucleotide substitution processes in the second column of Table 3 has to be related to a large value of k_{bwH}. The non-innocent outer-sphere hydrogen bonded complex between the **Cobw** and **HL** species, can be held responsible for this large increase, as in many of the reactivity associated with biologically relevant ligands [45]. In this case {**Cobw**;**HL**} and {**Cow**$_2$;**L**} would be undistinguishable, but the former will enable a very active internal conjugate-base pathway that can explain the enormous acceleration observed.

Finally the mentioned slow appearance of a second ^{31}P NMR signal at ca. 15 ppm, related to the presence of a system where both the phosphate and the purine base are attached to a Co(III) centre, has to be considered. The

[b] At 25 °C.
[c] Non-applicable for chloride and inosine substitution at this pH range.
[d] The pH range used for the measures does not allow for the determination of these values.

UV–vis monitored experiments showed irregular small drifts in the final absorbance readings, which were independent of the concentration of the nucleotides, and were associated to an intramolecular process. As expected from the small intensity of this ^{31}P NMR signal, the amplitude of these changes are very small making difficult its proper quantification. This observation is of great importance, and further studies are underway. Substitution of the last available ligand in the coordination sphere of the cobalt should render the complex unreactive towards hydrolysis of the phosphate group [15].

3. Conclusions

The study of the substitution of water by chloride and biologically relevant ligands has been carried out with cobaltocomplexes containing *cyclen* and *tren* tetraamine ligands. These ligands enable both the stability of the metal complex and the actuation of fast conjugate-base pathways even at physiological pH. The lability and stability of the inert skeleton of the complex permit the rapid dissociation of any polymeric μ-OH species appearing in the medium, the substitution reactivity becoming much simpler. The kinetic processes for the substitution of water by nucleotides are seen to be dominated by a concerted conjugate-base path on the hydrogen bonded outer-sphere complexes formed between *cis*-$[Co(OH)(H_2O)(cyclen)]^{2+}$ and the monoprotonated nucleotide. As a whole, comparison of the data for the full set of ligands used in this study indicates that the reaction paths are common to all processes, as expected for a dissociatively activated process.

^{31}P NMR monitoring of the experiments indicates that the substitution processes are clean and that no phosphate hydrolysis is observed at pH $\leqslant$ 7.0, which represents a

striking difference with most of the studies carried out on Co(III) complexes with this type of ligands. The formation of a phosphate-purine base chelated complex is observed in the experiments, after the initial formation of the phosphato monosubstituted *cis*-[Co(*O*PO$_2$Onucleoside)-(H$_2$O)(cyclen)]$^{2+}$ complex. This represents a promising way into the reactivity of this type of complexes, given the absence of any other hydroxo ligand attached to the cobalt centre capable of promoting the expected phosphate hydrolysis.

4. Experimental

4.1. Compounds

The chlorides of dichlorotetraaminecobalt complexes, *cis*-[Co(Cl)$_2$(tetraamine)]Cl, have been prepared according to the published procedures [51,55]. The perchlorate salts of the aquachlorocomplexes, *cis*-[CoCl(H$_2$O)(tetraamine)]$^{2+}$, were also prepared following literature procedures, except that an excess of NaClO$_4$ was used instead of ammonium sulfate [49]. The diaquacomplexes, *cis*-[Co(H$_2$O)$_2$(tetraamine)]$^{3+}$, were prepared *via* triflate solvolysis [53,54] from the corresponding dichloro precursors. The resulting solid from the triflate solvolysis (3 g) was dissolved in 20 cm^3 of water and after 1–2 h the solution was cooled at 0 °C and NaClO$_4$ or triflic acid were added. On standing the corresponding perchlorates or triflates of the diaquacomplexes crystallize; the complexes were characterized by their UV–vis spectra (Table 1) and elemental analyses. *Anal.* Calc. for [Co(H$_2$O)$_2$(tren)](CF$_3$SO$_3$)$_3$: C, 15.7; N, 8.14. Found: C, 16.0; N, 8.32%. *Anal.* Calc. for [Co(H$_2$O)$_2$-(cyclen)](CF$_3$SO$_3$)$_3$ · H$_2$O: C, 18.0, N, 7.65. Found: C, 18.0; N, 7.47%. ^{13}C NMR (D$_2$O, 0.1 M HClO$_4$) indicated that the complexes have the expected *syn*/*anti* form as derived from the number of spectral signals [52], 60.20, 56.82, 52.72, 50.70 and 122.6 (q) ($^1J_{CF} = 315$ Hz).

Controlled pH solutions were achieved by addition of HClO$_4$ (pH 0–3), NaOH (pH 11–13) or using MES and HEPES buffers (pH 4–7) [78]. As a general rule the buffer (pH 4–7) concentration was 0.05 M, and the final pH was adjusted *via* de addition of HClO$_4$ or NaOH solutions until the desired reading in the pH metre (4–7 range). Ionic strength was fixed to 1.0 M by the addition of the calculated volume of NaClO$_4$ solutions.

4.2. Instruments

All the ^{31}P NMR spectra were recorded in H$_2$O on a Bruker DRX 250 instrument (101.25 MHz) of the Serveis Científico-Tècnics de la Universitat de Barcelona or on a Bruker Avance 500 instrument (202.46 MHz) of the Institut Català d'Investigació Química; using capilar tubes or coaxial insets containing H$_3$PO$_4$ (D$_2$O) or trimethylphosphite (CD$_3$COCD$_3$) as references. UV–vis spectra were carried out on HP8452A or Cary50 instruments.

4.3. pK_a titrations

Potentiometric titrations of the different diaquacomplexes, *cis*-[Co(H$_2$O)$_2$(tetraamine)]$^{3+}$, and the relevant ligands, 5′AMP and 5′IMP, were carried out in order to determine their acidity constants under the conditions of the study, i.e. $I = 1.0$ M (NaClO$_4$). For the cobalt complexes, their solutions in water (ca. 1×10^{-2} M) were transferred to a 50 cm^3 cell and thermostated at 25 °C; addition of small amounts of standard 0.1 M NaOH produced successive e.m.f. readings on a Metrohm 713 pH meter (glass and Ag/AgCl reference electrodes). For nucleotides the solutions (ca. 1×10^{-2} M) were prepared in aqueous 0.01 M NaOH and transferred to a 50 cm^3 cell thermostated at 25 °C; addition of small amounts of standard 0.01 M HClO$_4$ produced successive e.m.f. readings on the same instrument. Argon was bubbled through the solution during the experiment to avoid the presence of CO$_2$. The general technique is the same as that described in the literature [79].

Spectrophotometric titrations [80] of the cobalt tetraamine complexes produced changes in the UV–vis spectrum with pH which indicated also the presence of two distinct processes. Samples were titrated on a thermostated (25 °C) vessel and circulated to a UV–vis cell inside the spectrophotometer, basically with the same procedure indicated for the potentiometric titrations. The pK_a values were derived by the use of the SPECFIT program [56].

4.4. Kinetics

The reactions were followed by UV–vis spectroscopy in the full 250–700 nm range. Runs with $t_{1/2} > 170$ s were recorded on an HP8452A or a Cary 50 instrument equipped with a thermostated multicell transport; for runs with $t_{1/2} < 7$ s an Applied-Photophysics stopped-flow instrument connected to a J&M TIDAS spectrophotometer was used. Kinetics with intermediate $t_{1/2}$ were measured on a Hi-Tech SFA rapid mixing accessory connected to the HP8452A or J&M TIDAS instruments. Observed rate constants were derived from absorbance *versus* time traces at the wavelengths where a maximum increase and/or decrease of absorbance was observed. No dependence of the observed rate constant values on the selected wavelengths was detected, as expected for reactions where a good retention of isosbestic points is observed. The general kinetic technique is that previously described [11,81], in all cases the cobaltocomplex concentration was maintained at $(2–3) \times 10^{-3}$ M. In most of the experiments the observed absorbance *versus* time traces behaved as first-order producing reproducible rate constants within a 5% error. In some of the kinetic experiments with nucleotides a secondary change in the final absorbance was observed. Its quantification indicated its independence of the entering ligand concentration, although no definite values could be extracted (see Section 2.3). Table S1 (supporting information) collects all the obtained k_{obs} values for all the

complexes studied as a function of the starting complex, entering ligand, entering ligand concentration, pH and temperature.

phase [14–18]. The results showed that most of these complexes still undergo photochromism upon complexation. In some cases the complexes could show reversible photoreactions even with the S atoms of the thiophene rings from the ligand being coordinated to the metal center, which is generally considered to suppress the free movement of the thiophene groups during photocyclization. As a continuous work, we reported herein the syntheses and photochromism of two novel copper(II) polymers with BM-2-PTP or closed-BM-2-PTP. [Cu(closed-BM-2-PTP)Cl_2] (**2**) was found to be a mixture containing two conformers with a ratio of 1:1 by X-ray crystallographic analysis, and showed effective photoreaction in the crystalline state upon irradiation.

2. Experimental

2.1. General methods

Unless otherwise indicated, all starting materials were obtained from commercial suppliers (Aldrich, Tokyo Kasei Chemicals and Wako Chemicals) and were used without further purification. Infrared spectra were recorded as KBr disks on JASCO FT-IR 8000 and FT/IR-430 spectrometers. Absorption spectra in the crystalline state were measured by diffuse reflection using the Kubelka–Munk method on a SHIMADZU UV-2450 spectrometer, and barium sulfate was used as a reference. Photoirradiation was carried out using a 150 W Xe lamp, and monochromatic light was obtained by passing the light through a monochromator.

2.2. Syntheses

2.2.1. Closed-BM-2-PTP

BM-2-PTP was synthesized as reported elsewhere [18]. A CH_2Cl_2 solution of BM-2-PTP was irradiated with 340 nm light which resulted in a blue solution, chromatography over silica gel (1% NMe_3/CH_2Cl_2) afforded closed-BM-2-PTP as a deep blue powder. *Anal.* Calc. for $C_{25}H_{16}F_6N_2S_2$: C, 57.46; H, 3.09; N, 5.36. Found: C, 57.56; H, 3.12; N, 5.24%. IR (KBr pellet): 3056 (w), 2857 (w), 1624 (m), 1581 (m), 1566 (m), 1552 (m), 1458 (m), 1433 (m), 1341 (s). UV–Vis (solid state) $\lambda_{max} = 350$ nm, $\lambda_2 = 610$ nm: after irradiation with 610 nm light (solid state) $\lambda_{max} = 350$ nm, after irradiation with 350 nm light (solid state) $\lambda_{max} = 530$ nm.

2.2.2. [Cu(BM-2-PTP)Cl_2] (**1**)

A solution of BM-2-PTP (15.9 mg, 30 μmol) in benzene (3 mL) was layered with a solution of $CuCl_2$ (3.9 mg, 30 μmol) in THF (3 mL). After standing at room temperature for 1 week, purple block crystals were obtained at the interface between the two solutions. *Anal.* Calc. for $C_{25}H_{16}Cl_2CuF_6N_2S_2$: C, 45.70; H, 2.45; N, 4.26. Found: C, 45.36; H, 2.50; N, 4.28%. IR (KBr pellet): 3058 (w), 2919 (w), 1600 (m), 1566 (m), 1495 (m), 1468 (m), 1430 (m), 1273 (s), 1060 (m), 1028 (m), 637 (m). UV–Vis (solid state) $\lambda_{max} = 340$ nm: after irradiation with 340 nm light (solid state) $\lambda_{max} = 620$ nm. Complex **1** is insoluble in common solvents due to its polymeric structure.

2.2.3. [Cu(closed-BM-2-PTP)Cl_2] (**2**)

Closed-BM-2-PTP (10.4 mg, 20 μmol) and $CuCl_2$ (2.7 mg, 20 μmol) were dissolved in 4 mL acetone. The mixture was introduced into a narrow-diameter glass tube and layered with a hexane solution. After standing at room temperature for 1 week, dark blue block crystals were obtained at the interface between the two solutions. *Anal.* Calc. for $C_{25}H_{16}Cl_2CuF_6N_2S_2$: C, 45.70; H, 2.45; N, 4.26. Found: C, 45.39; H, 2.49; N, 4.16%. IR (KBr pellet): 3056 (w), 2857 (w), 1626 (m), 1599 (m), 1566 (m), 1498 (w), 1474 (w), 1430 (s), 1341 (s). UV–Vis (solid state) $\lambda_{max} = 535$ nm, $\lambda_2 = 630$ nm: after irradiation with 535 nm light (solid state) $\lambda_{max} = 335$ nm. Complex **2** is insoluble in common solvents due to its polymeric structure.

2.3. X-ray data collection and structure solutions and refinements

Diffraction data for complexes **1** and **2** were collected on a Quantum CCD area detector coupled with a Rigaku MSC Mercury CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71070$ Å). The intensity data were collected at 150 K and 220 K for complexes **1** and **2**, respectively, using the multi-scan technique, and a total of 2994 and 2951 reflections were collected for complexes **1** and **2**, respectively. The linear absorption coefficient μ for Mo Kα radiation was 12.57 and 8.22 cm^{-1}, respectively.

The structures were solved by direct methods followed by subsequent Fourier calculations [20]. The non-hydrogen atoms were refined anisotropically. The final cycle of the full-matrix least-squares refinement was based on 2404 and 2712 observed reflections and 174 and 190 variable parameters for complexes **1** and **2**, respectively, converged with the unweighted and weighted agreement factors of $R = \sum\|F_o| - |F_c\|/\sum|F_o|$ and $R_w = [\sum w(F_o^2 - F_c^2)^2/\sum w(F_o^2)^2]^{1/2}$. The atomic scattering factors and anomalous dispersion terms were taken from the International Tables for X-ray Crystallography, vol. IV [21]. All calculations were performed using the teXsan crystallographic software package [22]. Details of the X-ray experiments and crystal data are summarized in Table 1. Selected bond lengths and bond angles are given in Table 2.

3. Results and discussion

3.1. Structural characterizations

The crystal structures of complexes **1** and **2** were determined by X-ray crystallographic analyses. Each Cu(II) of complex **1** is coordinated linearly by two N atoms from different ligands and two chloride anions, showing a slightly distorted square planar geometry (Fig. 1). The Cu atom lies

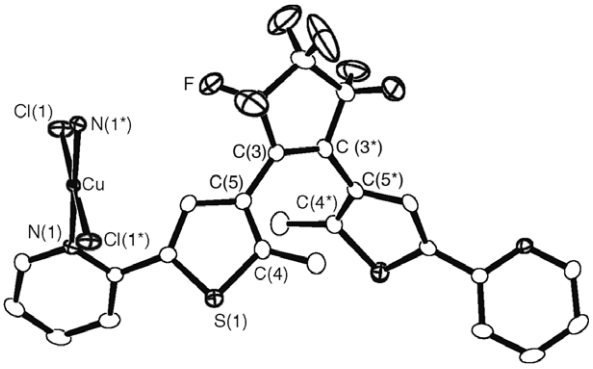

Fig. 1. Crystal structure of **1**, ORTEP view with an atomic labelling scheme, showing 50% thermal ellipsoids. Symmetric code: * $-x$, $1-y$, $-z$.

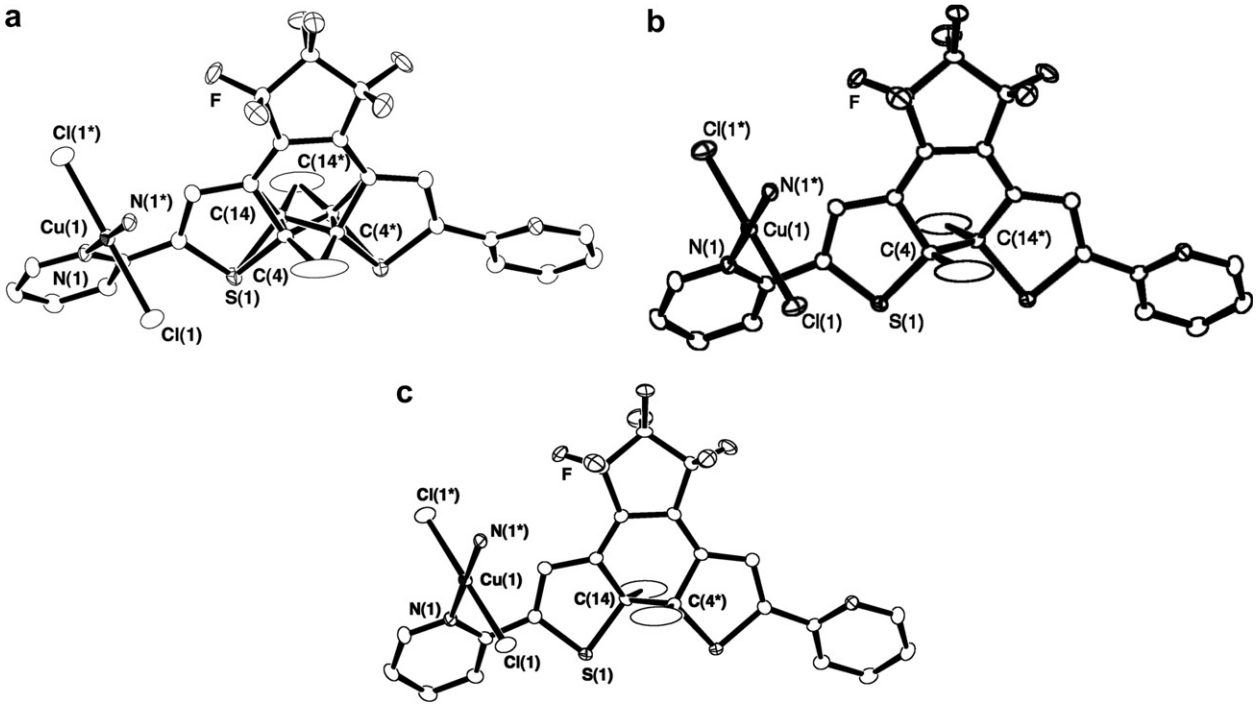

Fig. 2. Crystal structure of **2**, ORTEP view with an atomic labelling scheme, showing 50% thermal ellipsoids. (a) Complex **2** showing two conformers; (b) conformer A; (c) conformer B; symmetric code: * $1-x$, $-y$, $1-z$.

inside the plane constructed by N(1), N(1*), Cl(1) and Cl(1*), and the two pyridyl rings of the ligands are essentially perpendicular [N(1*)–Cu(1)–Cl(1) = 89.20(8)° and N(1*)–Cu(1)–Cl(1*) = 90.80(8)°] to the equatorial plane [Cl(1)Cu(1)Cl(1*)]. The bond lengths of Cu–N and Cu–Cl are 1.992(3) Å and 2.2378(9) Å, respectively, and fall within the normal range of $[Cu(py)_xCl_2]$ complexes [23–28]. Moreover, the two thienyl rings in complex **1** adopt an antiparallel configuration and the distance between the two reactive carbons C(4) and C(4*) is 3.394(6) Å, which is shorter than those of the metal free ligand [3.486(4) Å] and Ag(I) complexes with same ligand [3.548(1)–3.632(5) Å] [18], suggesting possible photoreactivity in the solid state. On the other hand, the mean torsion angle between the thiophene and perfluorocyclopentene rings [C(3*)–C(3)–C(5)–C(4) and C(3)–C(3*)–C(5*)–C(4*)] is 55.36°, larger than those of the Ag(I) complexes [48.43–53.35°].

The structures of complexes **2** and **1** are essentially the same except the dihedral angels between the pyridyl rings and the N(1)N(1*)Cl(1)Cl(1*) plane differ. It is noted that complex **2** has either a *R*,*R* or *S*,*S* asymmetric structure, with the ratio of two conformers A/B = 1/1 (Fig. 2). The bond distances between reactive carbons C(4) and C(14*)/C(14) and C(4*) in the two conformers are the same, 1.53(1) Å, a value which is usual for a single bond.

Both complexes **1** and **2** form 1-D infinite polymeric chains where two adjacent BM-2-PTP or closed-BM-2-PTP molecules are bridged by Cu(II) via two N atoms from pyridyl rings. The nearest distance between adjacent 1-D chains is ca. 8.32 Å and ca. 6.90 Å for complexes **1** and **2**, respectively, indicating no interaction between neighboring chains (Fig. 3).

3.2. Photochromism in the crystalline phase

The photoirradiation process of closed-BM-2-PTP and Cu(II) complexes were followed by electronic spectroscopy. The absorption spectra in the crystalline state were measured by diffuse reflection using barium sulfate as the reference and are illustrated in Figs. 4–6.

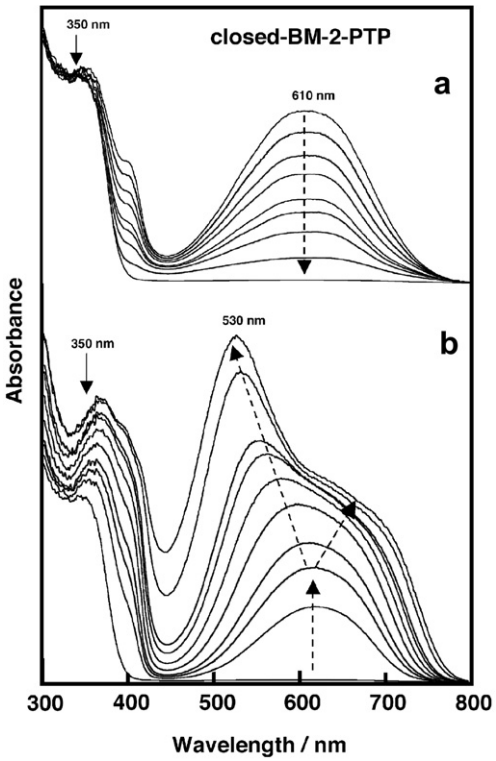

Fig. 4. Absorption spectral changes of closed-BM-2-PTP: (a) irradiated with 610 nm light; (b) irradiated with 350 nm light.

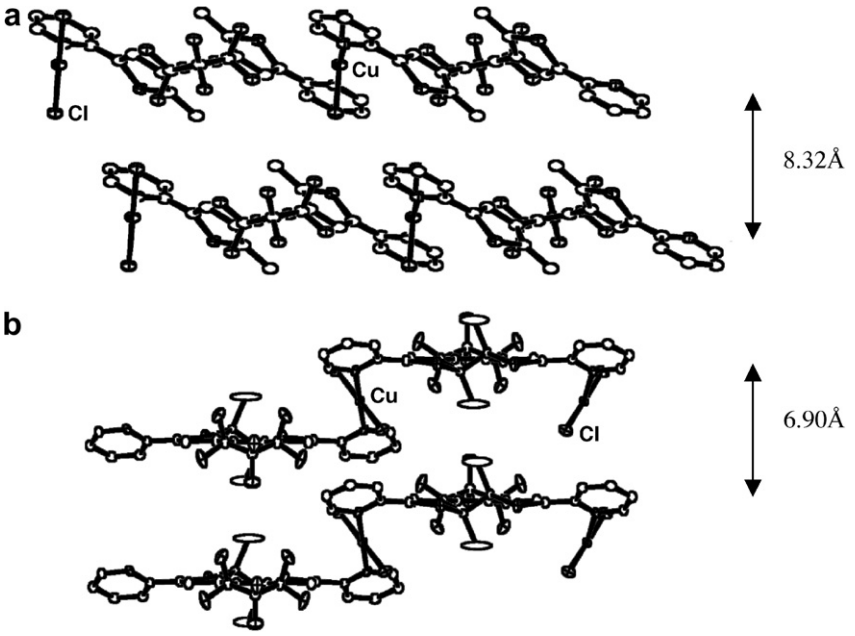

Fig. 3. Packing structures of complexes **1** and **2**.

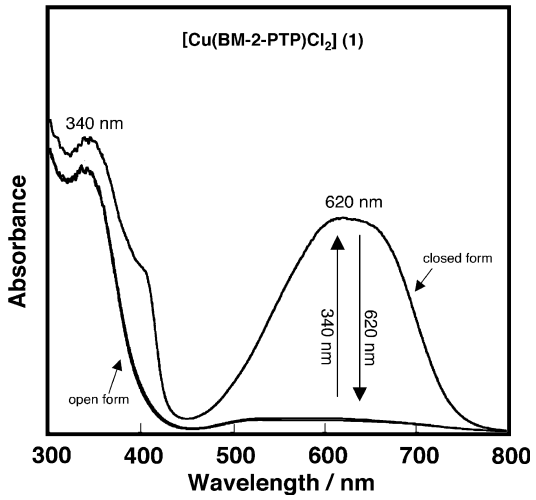

Fig. 5. Absorption spectral changes of complex **1**.

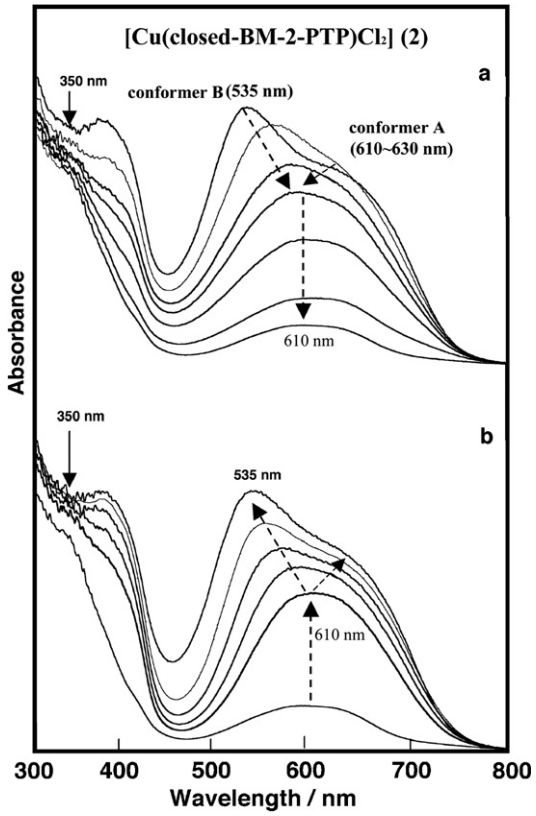

Fig. 6. Absorption spectral changes of complex **2**: (a) irradiated with 535 nm light; (b) irradiated with 335 nm light.

3.2.1. Photochromism of closed-BM-2-PTP

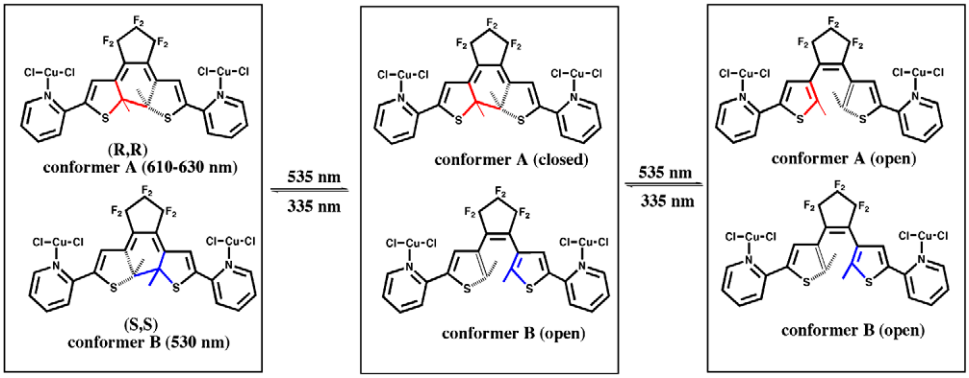
Photochromism of closed-BM-2-PTP was observed in the solid state, as shown in Fig. 4. Before irradiation the blue powder of closed-BM-2-PTP has λ_{max} values of 610 nm and ca. 350 nm. The 610 nm peak is characteristic of the closed-ring conformer but it is much longer than the λ_{max} value (580 nm, [18]) of the closed-ring form obtained by irradiation of BM-2-PTP. Upon irradiation with 610 nm light the λ_{max} value of 610 nm gradually flattened accompanying the pale blue color being bleached completely, which is attributed to a change to the corresponding open form. However, upon irradiation with 350 nm light the regenerated absorption peak of 610 nm shifted to shorter wavelength to give a broad absorption spectrum with a peak at 530 nm and a shoulder at 610–630 nm. Also, the color changed to purple, distinctive from the initial blue of closed-BM-2-PTP. These unexpected spectral changes indicated that the structure of closed-BM-2-PTP is changed after one cycle of coloration/decoloration. Before irradiation only one conformer was detected in closed-BM-2-PTP, which showed a 610 nm peak in the visible region, but during photocyclization it is possible for the ligand to form two conformers because the diarylethene undergoes a photochemical conrotatory cyclization [29]. The cyclization might contain two steps according to the changes of the absorptions: (1) the open-ring form was first converted to the corresponding closed-ring form which has an absorption peak at 610 nm; (2) with prolonged irradiation part of the conformer was gradually changed to another conformer and finally forms a mixture of two species which resulted in the different absorption peaks observed at 530 nm and 610–630 nm, respectively. This assumption is consistent with the previous work reported by Yamaguchi et al., who separated the two conformers by means of HPLC and found one isolated isomer was changed to the mixture of two diastereomers after irradiation [29].

3.2.2. Photochromism of complex *1*

Complex **1** displays normal photochromism in the crystalline state as expected. Fig. 5 shows its spectral changes. Similarly to the free ligand (BM-2-PTP) and Ag(I) complexes with BM-2-PTP, complex **1** has a maximum absorption at 340 nm before irradiation. After photoirradiation with 340 nm light, the purple color turned blue, accompanying a new strong absorption at 620 nm which appeared due to the formation of the closed form. The blue species reverted to their initial color by irradiation with 620 nm light, indicative of reversible photochromic behavior in the crystalline phase. Compared with the free ligand, the λ_{max} value of complex **1** increased as much as 40 nm and the maximum absorption is also longer than those of the Ag(I) complexes with BM-2-PTP [18].

3.2.3. Photochromism of complex *2*

Fig. 6 shows the quite different photochromism of complex **2** from that of complex **1**. Before irradiation the blue complex **2** shows a broad absorption spectrum with a λ_{max} value of 535 nm (conformer B) and a shoulder at 610–630 nm (conformer A). Irradiation with visible light of 535 nm leads to the disappearance of the 535 nm peak and the formation of an new absorption peak at 610 nm. With prolonged irradiation of visible light the intensity of the 610 nm peak gradually flattened, accompanying the



Scheme 1. Photochromism of complex **2** in the crystalline phase.

color fading completely due to the transformation of the closed to open isomer. When the open isomer was exposed to UV (335 nm) light, the intensity of the 610 nm peak increased and then this absorption peak gradually shifted to 535 nm and 610–630 nm, with the color turning from blue to purple. These spectral changes show clearly that complex **2** displays reversible photochromism in the crystalline state. The spectral changes during the photocyclization of complex **2** are very similar to those of the cyclizative transformation of the ligand.

As noted before, X-ray crystallographic analyses revealed complex **2** to be a racemic mixture of *R*,*R* and *S*,*S* enantiomer pairs. This is due to closed-BM-2-PTP because diarylethene undergoes a photochemical conrotatory cyclization producing two enantiomers originating from two asymmetric carbon atoms. Yamaguchi and Kodani once reported such mixtures and investigated their photoreactions in solution by introducing a chiral substituent into the diarylethene [29,30]. It was found that one isolated enantiomer shows normal cycloreversion, while during cyclization it is easily transferred to a mixture of two enantomers in solution. Yamaguchi et al. also examined a diarylethene system containing two conformers wherein two open isomers transformed into closed-ring isomers independently upon irradiation to give two absorptions in the visible region [31,32]. We could not separate the two enantiomers because of the insolubility of complex **2** in common solvents, so no direct evidence was obtained to prove the absorption features of complex **2**. However, the above-mentioned previous works are agreeable with our assumptions. It is tentatively considered that conformers A and B in complex **2** display photochromism independently in the crystalline phase. The original absorption of 535 nm and 610–630 nm of complex **2** should be assigned to the coexistence of two conformers. In cycloreversion the two conformers convert to the corresponding open isomers separately. The disappearance of the 530 nm absorption indicated conformer B (535 nm) changed to the corresponding open form first. While with irradiation of 335 nm light, conformer A (610–630 nm) was reverted to the closed-form which regenerated the absorption of 610 nm, as shown in Scheme 1.

Further investigation on the crystal structure of the open form of complex **2** was not successful due to the poor quality of the single crystal after irradiation. In spite of the limited evidence it is indicated clearly that the two types of ring-closed forms in complex **2** are photoreactive and both isomers display photocycloreversion reactions in the crystalline phase. The photogenerated ring-open form of complex **2** is packed in an antiparallel conformation [33]. We reported Rh(II) complexes with *cis*-dbe showed photocyclization in the crystalline state where three conformations coexisted in one crystal [16], and Irie and co-worker's group also proved a mixture of dithienylethene in the open form could undergo reversible photochromism in the solid state [34,35]. The findings obtained here evidence that two ring-closed photoactive isomers coexist in one crystal and the mixture undergoes photochromic reactions effectively in the crystalline phase.

4. Conclusions

Two novel Cu(II) single crystals were prepared by the reaction of $CuCl_2$ with BM-2-PTP in the open or closed form. Their structures were characterized by X-ray crystallographic analyses and their photoreactivities were investigated in the crystalline phase. It has been demonstrated that both complexes possess a similar coordination environment but display quite different photoreactions, which are attributed to the distinct photoresponsive patterns of BM-2-PTP and closed-BM-2-PTP. It was proved by X-ray crystallographic analyses that a mixture of closed-ring conformers could undergo photochromic reactions in the crystalline phase. It is suggested that two closed-ring conformers in complex **2** are both photoactive and the photogenerated ring-opening form adopts an antiparallel conformation. The mechanism of the photochromism of complex **2** is tentatively concluded as two conformers displaying photoreactions independently. It is hoped that this work will be helpful for accumulating evidence to clarify the rule of photocycloreversion reactions in the crystalline phase.

with azodicarboxylic and acetylenic esters [32], oxime-phosphazene derivatives with alkyl and acyl substituents [33,34], polymers from 4-formylphenoxy [35,36], maleic [37] and 3,4-methylenedioxyphenoxy substituents [38].

In this paper, we have prepared oxime-cyclophosphazenes from hexakis(4-formylphenoxy)cyclotriphosphazene and hexakis(4-acetylphenoxy)cyclotriphosphazene, and have studied their reactions with benzyl and benzoyl halides such as benzyl chloride, benzenesulfanoyl chloride, benzoyl chloride, 4-methoxybenzoyl chloride and 2-chlorobenzoyl chloride. We hope that this original work is potentially an useful addition to the literature and can lead to some high polymer works.

2. Experimental

2.1. General remarks

Solvents and other liquids used in the experimental works were dried by conventional methods. Hexachlorocyclotriphosphazene [$N_3P_3Cl_6$] (**1**) was recrystallized from hexane. Other chemicals were used as purchased. Hexakis(4-formylphenoxy)cyclotriphosphazene (**2**) and hexakis(4-acetylphenoxy)cyclotriphosphazene (**8**) were prepared as described by Carriedo and et al. [25]. The reactions of [$N_3P_3Cl_6$] with the phenols were carried out under the dry nitrogen.

The IR spectra were recorded on an ATI Unicam Mattson 1000 FTIR spectrometer. ^1H, ^{13}C and ^{31}P NMR spectra were recorded using a Bruker DPX-300 spectrometer operating at 300.13, 75.46 and 121.49 MHz, respectively. The ^1H and ^{13}C NMR chemical shifts were measured using $SiMe_4$ as an internal standard and the ^{31}P chemical shifts were measured using 85% H_3PO_4 as an external standard. Chemical shifts downfield from the standard were assigned positive δ values. Microanalysis was carried out by a LECO 932 CHNS-O apparatus.

2.2. Synthesis of compound 2

A mixture of **1** (10.34 g, 29.74 mmol), 4-hydroxybenzaldehyde (22.05 g, 180.56 mmol) and K_2CO_3 (50.00 g, 361.76 mmol) was stirred in THF (250 mL) at 0 °C and then reacted at ambient temperature for 48 h. The solvent was removed under vacuum. The residue was extracted with CH_2Cl_2 (4 × 75 mL). After the solvent was removed, a white solid **2** formed in 92% (23.57 g) yield. IR (cm^{-1}): 1706 $\nu_{C=O}$, 1184 $\nu_{P=N}$, 962 ν_{P-O-C}. ^1H NMR (in $CDCl_3$-d, for numbering see Scheme 2, coupling constants J (Hz), is.: isomer, s: singlet, w: weak): 7.10 (d) H^2 ($^4J_{POCCH}$: 8.50), 7.60 (d) H^3 ($^5J_{POCCCH}$: 8.56), 9.90 (s) H^5; H^2:H3:H^5 = 2:2:1. ^{13}C NMR: 121.60 C^2, 131.40 C^3, 134.14 C^4, 154.80 C^1, 190.83 C^5.

2.3. Synthesis of compound 3

A mixture of **2** (20.00 g, 23.21 mmol) and hydroxylaminehydrochloride (10.00 g, 143.90 mmol) was refluxed in pyridine (15 mL) for 3 h. After the reaction was complete, the mixture was allowed to cool and was slowly poured into water (100 mL) and reprecipitated twice from water. The white solid **3** was washed with alcohol and dried at 50 °C in a vacuum. Yield: 83% (18.33 g). IR (cm^{-1}): 3340 ν_{OH}, 1187 $\nu_{P=N}$, 949 ν_{P-O-C}. ^1H NMR (in acetone-d): 6.86 (d) H^2 ($^4J_{POCCH}$: 8.45), 7.28 (d) H^3 ($^5J_{POCCCH}$: 8.50), 7.96 (s) H^5, 10.17 (s) H^6, 7.20 (w) H^2 (is.), 7.77 (w) H^3 (is.); H^2:H^3:H^5:H^6 = 2:2:1:1. ^{13}C NMR: 121.50 C^2, 121.33 C^2 (is.), 129.00 C^3, 129.37 C^3 (is.), 131.00 C^4, 131.00 C^4 (is.), 148.19 C_5, 151.70 C^1.

2.4. Reaction of 3 with benzyl chloride

A solution of 0.70 mL (0.77 g, 6.08 mmol) benzyl chloride in acetone (10 mL) was slowly added dropwise to a stirred and cooled (0–5 °C) mixture of **3** (0.80 g, 0.84 mmol) and K_2CO_3 (2.00 g, 14.47 mmol) in acetone (30 mL). The reaction was carried out at room temperature for 1 h and then was refluxed for 48 h. After the reaction was complete, the precipitate was filtered off and the solvent was removed. An oily product was obtained. It was dissolved in a very small amount of acetone and was precipitated with hexane. The solvent was removed under vacuum over 96 h. A white solid **4** formed. Yield: 66% (0.83 g). IR (cm^{-1}): 1183 $\nu_{P=N}$, 1024 ν_{N-O-C}, 952 ν_{P-O-C}. ^1H NMR (in DMSO-d): 6.95 (d) H^2, 7.2–7.6 (m) H^3, H^8, H^9, H^{10}, 8.30 (s) H^5, 5.20 (s) H^6. ^{13}C NMR: 150.95 C^1, 148.49 C^5, 147.60 C^5 (is.), 137.79 C^7, 137.85 C^7 (is.), 129.64 C^4, 129.28 C^4 (is.), 128.78 C^9, 128.69 C^{10}, 128.63 C^8, 128.32 C^3, 121.31 C^2, 121.00 C^2 (is.), 76.04 C^6. (The solvents could not be removed completely, so there are very very weak peaks at 0.8 and 1.3 ppm.)

2.5. Reaction of 3 with benzenesulfanoyl chloride

A solution of 0.55 mL (0.76 g, 4.29 mmol) benzenesulfanoyl chloride in acetone (10 mL), **3** (0.60 g, 0.63 mmol) and Et_3N (2 mL) in acetone (30 mL) was used for **4**. The reaction was carried out at room temperature for 12 h and then was refluxed for 48 h. Compound **5** was obtained. The orange colour solid **5** was washed with alcohol and dried at 50 °C in a vacuum for 48 h. Yield: 68% (0.36 g). IR (cm^{-1}): 2230 ν_{CN}, 1188 $\nu_{P=N}$, 950 ν_{P-O-C}. ^1H NMR (in DMSO-d): 7.15 (d) H^2, 7.85 (d) H^3. ^{13}C NMR: 152.88 C^1, 135.07 C^3, 121.99 C^2, 118.85 C^4, 109.37 C^5.

2.6. Reaction of 3 with 1-napthalenesulfanoyl chloride

A solution of 1.00 g (4.41 mmol) 1-napthalenesulfanoyl chloride in acetone (10 mL), **3** (0.60 g, 0.63 mmol) and Et_3N (2 mL) in acetone (30 mL) was used for **4**. The reaction was carried out at room temperature for 12 h and then was refluxed for 60 h. Compound **5** was obtained. The orange colour solid **5** was washed with alcohol and dried at 50 °C in a vacuum for 48 h. Yield: 85% (0.45 g).

2.7. Reaction of **3** with benzoyl chloride

A solution of 0.55 mL (0.66 g, 4.73 mmol) benzoyl chloride in acetone (10 mL), **3** (0.60 g, 0.63 mmol) in acetone (30 mL) and Et_3N (2 mL) was used for the preparation of **6** for **4**. The reaction was carried out at room temperature for 12 h. After the reaction was complete, the precipitate was filtered off, the liquid mixture was slowly poured into water (100 mL) and the solid product was obtained. It was reprecipitated twice from water, then it was dissolved in hot alcohol and any impurities were filtered off. The white solid **6** was crystallized from alcohol and dried at 50 °C in a vacuum for 48 h. Yield: 27% (0.25 g). IR (cm^{-1}): 3410 ν_{OH}, 1746 $\nu_{C=O}$, 1181 $\nu_{P=N}$, 1082 ν_{N-O-C}, 955 ν_{P-O-C}. ^1H NMR (in DMSO-d): 6.90–8.30 (m) H^2, H^3, H^8, H^9, H^{10}, H^{12}, H^{13}, 8.90 (s) H^5, H^{15}, 11.30 (s) H^{16}. ^{13}C NMR: 167.80 C^6, 163.55 C^5, 157.32 C^{15}, 153.28 C^1, 152.27 C^{11}, 135.00 C^{10}, 134.00 C^4, 132.00 C^{14}, 128.08–129.7 C^3, C^7, C^8, C^9, C^{13}, 121.95 C^2, 121.67 C^{12}.

2.8. Synthesis of compound **7**

A mixture of **1** (7.00 g, 20.13 mmol), 4-hydroxyacetophenone (16.72 g, 122.80 mmol) and K_2CO_3 (34.00 g, 245.99 mmol) was refluxed in acetone (250 mL) for 3 h. The solvent was evaporated in a vacuum and the residue was extracted with CH_2Cl_2 (4 × 75 mL). After the evaporation of the solvent in a vacuum, a white solid **7** formed in 87% (16.50 g) yield. IR (cm^{-1}): 1685 $\nu_{C=O}$, 1188 $\nu_{P=N}$, 949 ν_{P-O-C}. ^1H NMR (in DMSO-d): 7.05 (d) H^2, 7.85 (d) H^3, 2.45 (s) H^6, H^2:H^3:H^6 = 2:2:3. ^{13}C NMR: 27.04 C^6, 120.96 C^2,131.20 C^3, 134.54 C^4, 153.27 C^1, 197.00 C^5.

2.9. Synthesis of compound **8**

Hydroxylaminehydrochloride (4.50 g, 64.75 mmol) and **7** (10.00 g, 10.57 mmol) were used for the preparation of **8**, as for **3**. After the reaction was complete, the mixture was allowed to cool and the mixture was slowly poured into water (100 mL) and reprecipitated twice from water. The white solid **8** was obtained in 99% (10.89 g) yield. IR (cm^{-1}): 3460 ν_{OH}, 1208 $\nu_{P=N}$, 960 ν_{P-O-C}. ^1H NMR (in DMSO-d): 6.85 (d) H^2, 7.50 (d) H^3, 2.10 (s) H^6, 11.25 (s) H^7, H^2:H^3:H^6:H^7 = 2:2:3:1. ^{13}C NMR: 11.90 C^6, 120.93 C^2, 127.36 C^3, 134.64 C^4, 150.39 C^1, 152.51 C^5.

2.10. Reaction of **8** with benzyl chloride

A solution of 0.50 mL (0.55 g, 4.34 mmol) benzyl chloride in acetone (10 mL), **8** (0.60 g, 0.58 mmol) and K_2CO_3 (2.00 g, 14.47 mmol) in acetone (30 mL) was used for the preparation of **9**, as for **4**. The oily product **9** was obtained and dried under vacuum for 48 h. Yield: 80% (0.60 g). IR (cm^{-1}): 3295 ν_{OH}, 1183 $\nu_{P=N}$, 1014 ν_{N-O-C}, 955 ν_{P-O-C}. ^1H NMR (in DMSO-d): 11.30 (s) H^{18}, 6.85 H^2, 7.70 (m) (H^3, H^9, H^{10}, H^{11}, H^{13}, H^{14}), 5.20(s) H^7, 2.10 (s) H^{17}, 2.15 (s) H^6. ^{13}C NMR: 153.97 C^{16}, 152.48 C^5, 150.76 C^{12}, 150.31 C^1, 138.25 C^8, 134.66 C^{15}, 133.44 C^4, 128.79 C^{10}, 128.48 C^{11}, 128.22 C^9, 127.73 C^{14}, 127.37 C^3, 120.95 C^2, C^{13}, 75.94 C^7, 12.82 and 11.88 C^{17}, C^6.

2.11. Reaction of **8** with benzoyl chloride

A solution of 0.70 mL (0.74 g, 5.22 mmol) benzoyl chloride in acetone (10 mL), **8** (0.60 g, 0.58 mmol) and Et_3N (2 mL) in acetone (30 mL) was used for the preparation of **10**, as for **4**. The reaction was carried out at room temperature for 12 h and then was refluxed for 24 h. After the reaction was complete, the mixture was allowed to cool and the mixture was slowly poured into water (100 mL) and reprecipitated twice from water. The white solid **10** was crystallized from alcohol. Yield: 88% (0.85 g). IR (cm^{-1}): 1747 $\nu_{C=O}$, 1173 $\nu_{P=N}$, 1063 ν_{N-O-C}, 962 ν_{P-O-C}. ^1H NMR (in DMSO-d): 7.10 (d) H^2, 7.75 (d) H^3, 8.01 (d) H^9, 7.70 (t) H^{11}, 7.50 (t) H^{10}. ^{13}C NMR: 163.40 C^7, 163.19 C^5, 151.75 C^1, 151.78 C^1 (is.), 134.12 C^{11}, 132.6 C^4, 132.40 C^4 (is.), 129.60 C^9, 129.35 C^{10}, 129.18 C^3, 128.87 C^8, 121.32 C^2, 14.64 C^6.

2.12. Reaction of **8** with 4-methoxybenzoyl chloride

A solution of 0.70 g (4.10 mmol) 4-methoxybenzoyl chloride in acetone (10 mL), **8** (0.60 g, 0.58 mmol) and Et_3N (2 mL) in acetone (30 mL) was used for the preparation of **11**, as for **4**. The reaction was carried out at room temperature for 24 h. The white solid **11** was washed with hot alcohol and acetone. Yield: 80% (0.85 g). IR (cm^{-1}): 1741 $\nu_{C=O}$, 1210 $\nu_{P=N}$, 1023 ν_{N-O-C}, 951 ν_{P-O-C}. ^1H NMR (in DMSO-d): 6.87 (d) H^{10}, 7.12 (d) H^2, 7.70 (d) H^3, 7.90 (d) H^9, 2.43 (s) H^6, 3.85 (s) H^{12}. ^{13}C NMR: 163.79 C^7, 162.83 C^5, C^{11}, 151.72 C^1, 151.78 C^1 (is.), 132.22 C^4, 132.40 C^4 (is.), 131.73 C^9, 129.07 C^3, 121.25 C^2, 120.88 C^8, 114.58 C^{10}, 55.93 C^{12}, 14.52 C^6.

2.13. Reaction of **8** with 2-chlorobenzoyl chloride

A solution of 0.60 mL (0.82 g, 4.73 mmol) 2-chlorobenzoyl chloride in acetone (10 mL), **8** (0.60 g, 0.58 mmol) and Et_3N (2 mL) in acetone (30 mL) was used for the preparation of **12**, as for **4**. The reaction was carried out at room temperature for 12 h and then was refluxed for 8 h. The white solid **12** was washed with hot alcohol. Yield: 76% (0.82 g). IR (cm^{-1}): 1741 $\nu_{C=O}$, 1210 $\nu_{P=N}$, 1032 ν_{N-O-C}, 953 ν_{P-O-C}. ^1H NMR (in DMSO-d): 7.10–7.88 H^{Ar}, 2.42 (s) H^6. ^{13}C NMR: 14.99 C^6, 121.33 C^2, 151.77 C^1, 162.75 C^5, 163.83 C^7, 133.95 C^9, 132.38 C^4, 131.92 C^{11}, 131.53 C^8, 131.28 C^{13}, 129.33 C^{10}, 129.22 C^3, 127.87 C^{12}.

3. Results and discussion

The reaction of **1** with 6 equivalent of 4-hydroxybenzaldehyde and 4-hydroxyacetophenone in the presence of K_2CO_3 in THF gave hexakis(4-formylphenoxy)cyclotriphosphazene (**2**) and hexakis(4-acetylphenoxy)cyclo-

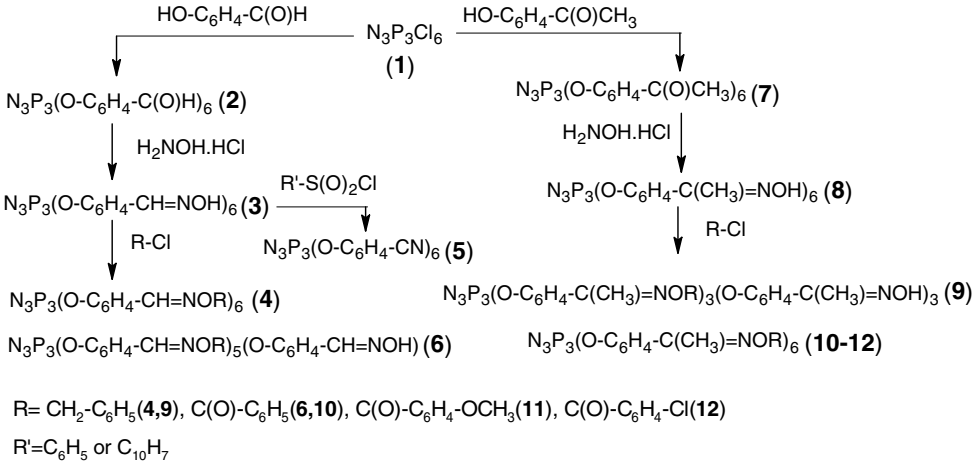
triphosphazene (**7**). Oxime compounds hexakis(4-[(hydroxyimino)methyl]phenoxy)cyclotriphosphazene (**3**) and hexakis(4-[(1)-*N*-hydroxyethaneimidoyl]phenoxy)cyclotriphosphazene (**8**) were synthesized from the reactions of **2** and **7** with hydroxlaminehydrochloride in pyridine, respectively.

Hexa and pentasubstituted compounds were obtained from the reaction of hexakis(4-[(hydroxyimino)methyl] phenoxy)cyclotriphosphazene (**3**) with benzyl chloride and benzoyl chloride in acetone (in the presence of K_2CO_3 for benzyl chloride, and Et_3N for benzoyl chloride) via replacement of all the oxime protons with benzyl and benzoyl groups, respectively. However, the oxime groups on **3** rearranged to nitrile (**5**) in the reaction of **3** with benzenesulfanoyl chloride and 1-napthalenesulfanoyl chloride via dehydration of the oximes [39,40]. Compound **5** was previously synthesized by Carriedo. $N_3P_3(OC_6H_4\text{-}CN)_6$ was directly obtained from the reaction of $N_3P_3Cl_6$ with 4-cyanophenol and characterized by elemental analysis and ^1H, ^{13}C and ^{31}P NMR spectra (25). The analysis results of **5** are in good accordance with the literature values (25). Similar compounds, $N_3P_3(OPh)_5(OC_6H_4\text{–}CN\text{–}p)$ and $N_3P_3(OC_6H_4\text{–}R\text{–}4)_5(OC_6H_4\text{–}CN\text{–}4)$ (R=H or ^{t}Bu), were synthesized by Allcock et al. [41] and Carriedo et al. [42], respectively. Hexasubstituted compounds were obtained from the reactions of **8** with benzoyl chloride, 4-methoxybenzoyl chloride and 2-chlorobenzoyl chloride. A trisubstituted compound was obtained from the reaction of **8** with benzyl chloride in acetone (in the presence of K_2CO_3 for benzyl chloride, and triethylamine for benzoyl chloride, 4-methoxybenzoyl chloride and 2-chlorobenzoyl chloride). The reactions are shown in Scheme 1. All the products were generally obtained in high yields. Pure and defined products could not be obtained from the reaction of **3** with 4-methoxybenzoyl chloride and 2-chlorobenzoyl chloride.

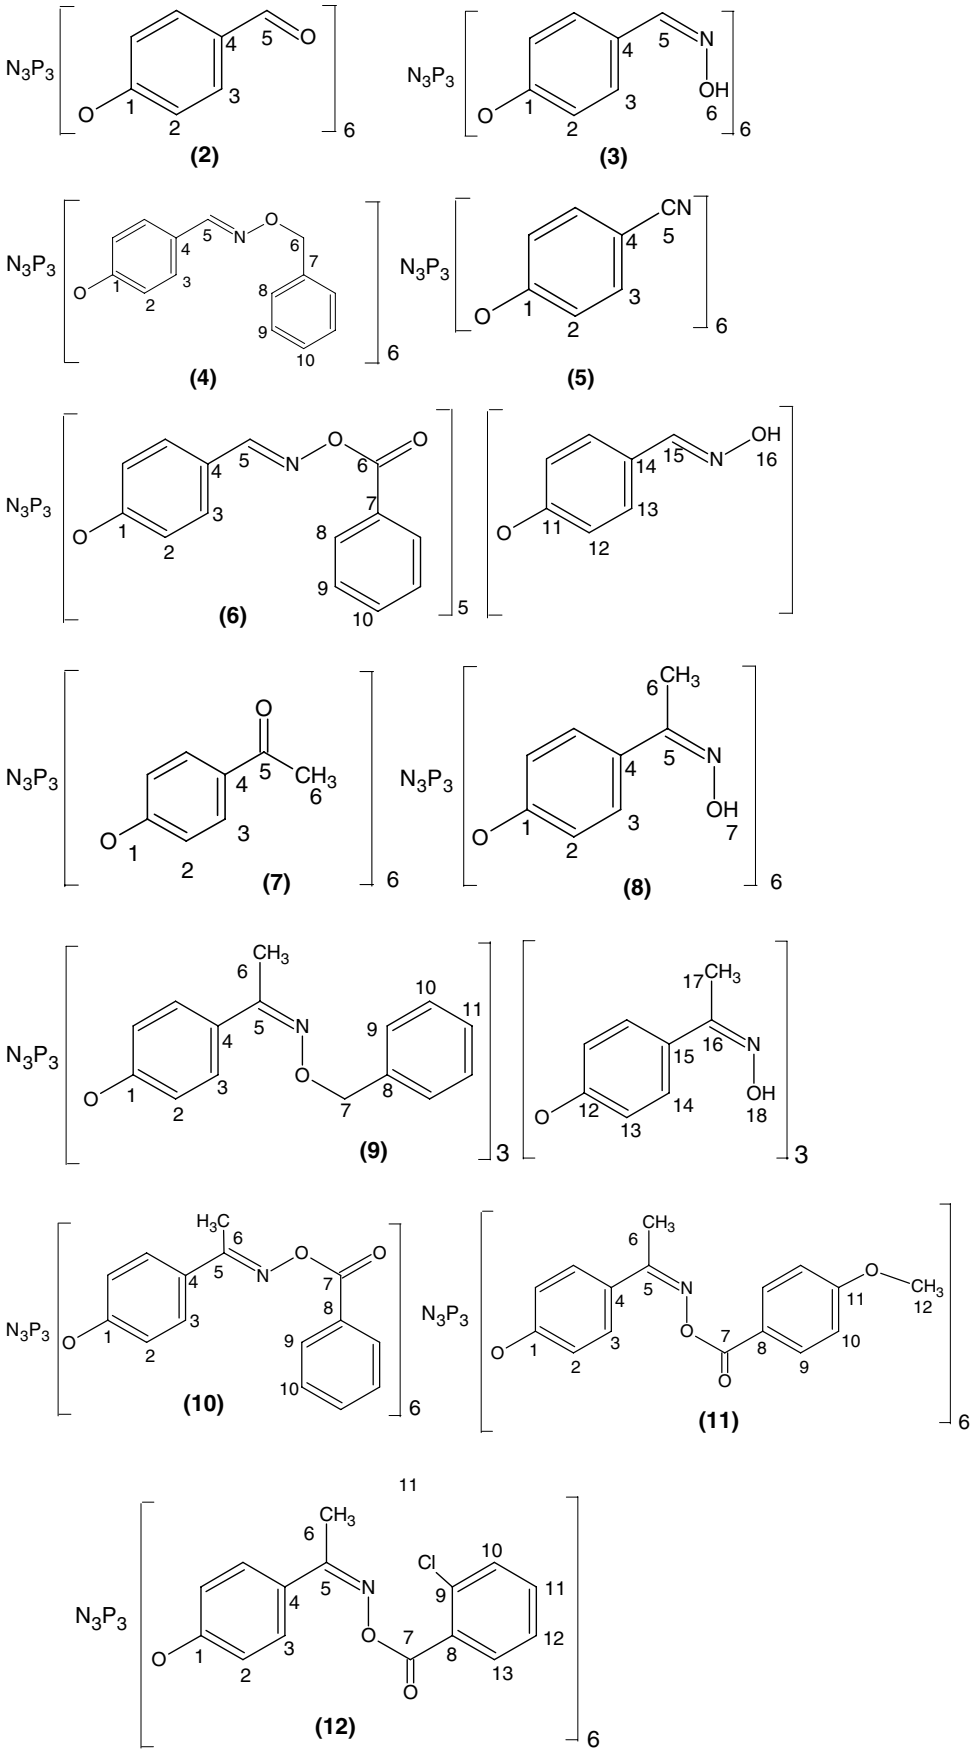
The structures of the compounds were defined by elemental analysis, IR and ^1H, ^{13}C and ^{31}P NMR spectroscopy (structures **2**–**12** are shown in Scheme 2). Physical properties and analytical data for **2**–**12** are shown in Table 1. Compounds **2**–**12** were synthesized in high yields except for **4** and **6**. The solvents used for the purification of compounds **4**, **5**, **6** and **9** could not be removed completely, so weak peaks of trace amounts of solvents were observed at 0.8 and 1.3 ppm for **4**, 1.3 and 2.4 ppm for **5**, 0.8, 1.3 and 4.4 ppm for **6** and **9** in the ^1H NMR spectra. Similarly, solvent peaks were observed at 18 and 25 ppm for **4**, 20 and 29 ppm for **5**, 19 and 57 ppm for **6** and 8 and 30 ppm for **9** in the ^{13}C NMR spectra. Thus the presence of these trace amounts of solvent affect the elemental analysis, in particular the carbon value.

The characteristic stretching peaks in the IR spectra of the phosphazenes have been assigned in the experimental section. The P=N stretching vibrations, which are observed between 1173 and 1210 cm^{-1}, are characteristic of cyclophosphazenes. Compared to **1**, which appeared at 1218 cm^{-1}, these peaks are shifted to longer wavelengths for **2**–**12**. The OH stretching vibrations in the IR spectra of **3**, **6**, **8** and **9** indicate oxime compounds. While **3** and **8** are initial oximes, all hydrogen atoms of the OH groups of **6** and **9** could not be replaced by the benzoyl and benzyl substituents, respectively.

The NMR data for **2**–**12** are presented in the experimental section. The ^{31}P NMR shifts of **2**–**12** change between 7.51 and 17.21 ppm. Although there is only one peak in the ^{31}P NMR spectra of **1**, **2**, **5**, **6**, **7**, **9**, **10** and **12** at 20.12, 8.33, 7.51, 8.36, 8.05, 9.00, 8.88 and 8.84 ppm, respectively, two peaks, with very weak second signals, are observed at $\delta = 17.21$, 17.26, $\delta = 8.67$, 8.57, $\delta = 9.04$, 9.01 and $\delta = 8.89$, 8.79 ppm for **3**, **4**, **8** and **11**, respectively. It is assumed that the weak peaks are due to the *cyn* and *anti* isomerism of the –C=N– groups. The effects of the *cyn* and *anti* isomerism are also observed in the ^{13}C NMR spectra of **3**, **4** and **11**. This data demonstrates that compounds **3**, **4**, **8** and **11** consist of a mixture of two isomers, but the others have one isomer. Although there are different phosphorus environments in the molecule of **6**, the main peak is observed as a singlet. It is understood that the phosphorus peaks are not affected by these changes because the substituted groups are far away from the phosphorus atoms.



Scheme 1. General pathway of the reactions.



Scheme 2. The structures of the compounds **2**–**12**.

The ^{1}H and ^{13}C NMR data also confirm the structures of **2**–**12** (Scheme 2). In the ^{1}H NMR spectra (Table 1), the OH protons are observed at 10.17, 11.30, 11.25 and 11.30 ppm for **3**, **6**, **8** and **9**, respectively. It is understood from the integral intensities that there are six OH protons in **3** and **8**, which are the original oxime-phosphazenes, one OH proton in **6** and three OH protons in **9**. This observation for **6** and **9** indicates that benzoyl or benzyl groups have not replaced all the OH protons in **3** and **8**. The aldehyde proton for **2** appears at 9.90 ppm. The azomethine protons for **3**, **4** and **6** are observed at 7.96 (H^5), 8.30 (H^5) and 8.90 (H^5, H^{15}) ppm, respectively. The aromatic protons for all the compounds appear between 6.85 and 8.30 ppm.

Table 2
The ^{31}P NMR data of **1**–**12**

	Major isomer		Minor isomer	
	ppm	Rel. intensity (%)	ppm	Rel. intensity (%)
1	20.12			
2	8.33			
3	17.21	82	17.26	18
4	8.67	62	8.57	38
5	7.51			
6	8.36			
7	8.05			
8	9.04	79	9.01	21
9	9.00			
10	8.88			
11	8.89	79	8.79	21
12	8.84			

Detailed ^{13}P NMR spectral data are shown in Table 2. The aldehyde carbon atom for **2** and the ketone carbon atom for **7** are observed at 190.83 and 197.00 ppm, at the lowest downfield position of the carbon atoms. Compared to **3** and **8**, the azomethine carbon atoms in the substituted moiety of the molecules are shifted to lower downfield for compounds **6**, **10**, **11** and **12**, except for **4** and **9** in which the benzyl group releases an electron to the molecule. The azomethine resonances do not change or show very little change in the non-substituted moiety of **9**.

4. Conclusion

Hexa and pentasubstituted compounds were obtained from the reaction of hexakis(4-[(hydroxyimino)methyl]-phenoxy)cyclotriphosphazene (**3**) with benzyl chloride and benzoyl chloride via replacement of all the oxime protons with benzyl and benzoyl groups, respectively. However, the oxime groups in **3** rearranged to nitrile (**5**) in the reaction of **3** with benzenesulfanoyl chloride and 1-napthalenesulfanoyl chloride via dehydration of the oxime groups. Hexasubstituted compounds were obtained from the reactions of **8** with benzoyl chloride, 4-methoxybenzoyl chloride and 2-chlorobenzoyl chloride. A trisubstituted compound was obtained from the reaction of **8** with benzyl chloride. Pure and defined products could not be obtained from the reaction of **3** with 4-methoxybenzoyl chloride and 2-chlorobenzoyl chloride.

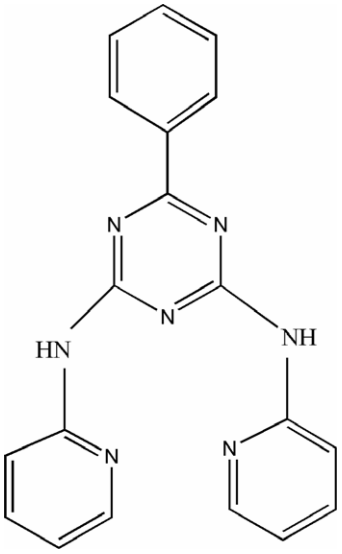

Chart 1. *N*,*N*′-di(2-pyridyl)-2,4-diamino-6-phenyl-1,3,5-triazine(dp dapt).

association running along the 1D open channels. A recent report described a discrete ice-like hexameric water cluster stabilized by a cyano-bridged trimetallic complex [16,17]. Here, the hexameric water cluster is unique and unlike the previously published hexamer water clusters [16–22]. There is mounting evidence of the presence of ordered water clusters in the active clefts of proteins such as dimeric haemoglobin, crambin, actinidin and carbonic anhydrase, however, positional information for the waters and their nature is still preliminary [16,17]. As water molecules play an important role in contributing to conformation, stability, function and dynamics of biomacromolecules, the new 1D water clusters arrays may provide insight into the hydrogen-bonding motif of the aqueous environment in living systems and enhance understanding of the 1D water morphologies.

2. Experimental

2.1. Materials and physical measurements

The new ligand *N*,*N*′-di(2-pyridyl)-2,4-diamino-6-phenyl-1,3,5-triazine was synthesized according to the literature method [15]. All other reagents and solvents employed were commercially available and used as received without further purification. Infrared spectra on KBr pellets were recorded on a Nicolet 170SX FT-IR spectrophotometer in the range 4000–400 cm^{-1}. Electronic spectra were taken on a Cary 300 Bio UV–Vis spectrophotometer in the range 200–800 nm at ambient temperature. Elemental analysis was conducted with a Perkin–Elmer model 240C instrument. Fluorescence experiments used a HITACHI F-4500 Fluorescence spectrophotometer and were measured in methanol. Thermal analysis was performed on a NETZSCH STA 449C microanalyzer in a nitrogen atmosphere at a heating rate of 10 °C min^{-1}.

2.2. Synthesis of $\{[Cu(dpdapt)(Hhbd)]\cdot 6H_2O\}_n$ (1)

A methanol suspension (15 mL) of dpdapt (68.2 mg, 0.2 mmol) was added slowly dropwise to methanol (15 mL) dissolved Cu(Hhbd) (42.3 mg, 0.22 mmol). The resulting mixture was stirred for 30 min and then filtered. The aqua filtrate solution was transferred a tube and evaporated at room temperature. After two months, deep blue crystals were obtained. Yield: 65%. *Anal.* Calc. for $C_{23}H_{31}CuN_7O_{11}$ (645.09): C, 41.78; H, 4.74; N, 14.83. Found: C, 41.91; H, 4.70; N, 14.72%. IR spectrum (cm^{-1}): 3425(w), 2923(w), 1640(s), 1592(m), 1502(w), 1469(s), 1429(s), 1381(s), 1242(w), 1195(w), 1157(w), 1023(w), 891(w), 821(w), 773(m), 703(w), 633(w), 525(w).

2.3. Synthesis of $[Cu(dpdapt)(SO_4)]\cdot 2H_2O$ (2)

$CuSO_4\cdot 5H_2O$ (50.0 mg, 0.2 mmol) was dissolved in methanol (15 mL) and mixed with a methanol suspension (15 mL) of dpdapt (68.2 mg, 0.2 mmol) and then stirred for 1 h. Diffused in Et_2O after filtration, finally blue crystals were produced. Yield: 59%. *Anal.* Calc. for $C_{19}H_{19}CuN_7O_6S$ (537.01): C, 42.50; H, 3.57; N, 18.26. Found: C, 42.32; H, 3.43; N, 18.38%. IR spectrum (cm^{-1}): 3493(w), 2925(w), 1636(s), 1587(s), 1502(m), 1469(s), 1434(s), 1242(w), 1195(w), 1162(w), 977(w), 867(w), 832(w), 770(m), 696(w), 634(w), 517(w), 432(w).

2.4. Synthesis of $[Cu(dpdapt)(oxa)]\cdot H_2O$ (3)

Cu(oxa) (30.3 mg, 0.2 mmol) was dissolved in methanol (15 mL) and mixed with a methanol suspension (15 mL) of dpdapt (68.2 mg, 0.2 mmol) and then stirred for 2 h. Green crystals **3** were obtained after the mixture was allowed to stand at room temperature for a month. Yield: 60%. *Anal.* Calc. for $C_{21}H_{17}CuN_7O_5$ (510.96): C, 51.16; H, 3.07; N, 19.89. Found: C, 51.33; H, 2.94; N, 19.73%. IR spectrum (cm^{-1}): 3411(w), 2913(w), 1665(s), 1573(m), 1510(w), 1466(s), 1385(s), 1269(w), 1240(w), 1202(w), 1157(w), 1115(w), 1059(w), 1023(w), 779(m), 706(w), 627(w), 524(w).

2.5. Crystallographic data collection and structure determination

Single-crystal X-ray diffraction of complexes **1**, **2** and **3** were performed on a BRUKER SMART 1000 CCD diffractometer equipped with a graphite crystal monochromator situated in the incident beam for data collection. Crystallographic data were collected with Mo Kα radiation ($\lambda = 0.71073$ Å) for the three complexes at 296(2) K. The structures were solved by direct methods and refined by full-matrix least-squares method on F^2 values using SHELXL 97 and SHELXL 97 programs, respectively [23,24]. Single crystal X-ray structural analysis shows the hydroxyl group might lie on one of the two adjacent methylenes, which would present the hydroxyl group disordered in a half-occupied position in complex **1**. All non-hydrogen atoms

were refined with anisotropic displacement parameters. Hydrogen atoms of all water molecules in complex **1** were not visible in the difference Fourier map. In complexes **2** and **3**, the hydrogen atoms of the lattice water molecules could be trustfully inferred from analysis of the difference Fourier map. Crystal data, data collection and refinement parameters for three complexes are shown in Table 1, and selected bond lengths and bond angles are listed in Table 2.

3. Results and discussion

3.1. Description of the crystal structures

A single crystal X-ray structural analysis shows **1** crystallizes in monoclinic space group C_2/c. Each copper atom has a slightly distorted [CuN_3O_2] trigonal bipyramid geometry. Owing to the symmetry of the ligand, each copper atom lies on a two-fold axis in the subunit (Fig. 1). The

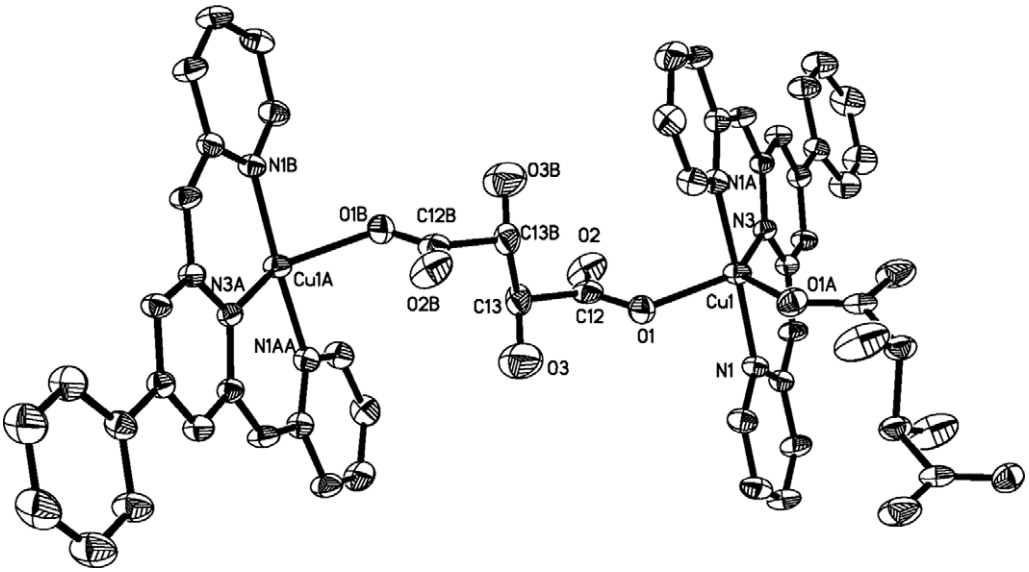

Fig. 1. Repeat unit of the infinite coordination polymer of **1**. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms and water molecules are omitted for clarity.

copper (II) ion is coordinated to three nitrogen atoms from the dpdapt ligand, and two oxygen atoms from two different Hhbd dianions. The two pyridyl rings of the dpdapt ligand are nearly coplanar with a dihedral angle of ca. 4.5°. It is worthwhile to note that the Hhbd dianions bridge copper centers to create a 1D polymeric chain running along the *a* axis with an adjacent Cu···Cu distance of 8.957(2) Å. The dpdapt ligands lie on both sides of this 1D chain in an antiparallel fashion. Interestingly, these 1D polymeric chains self-assemble to generate a 2D

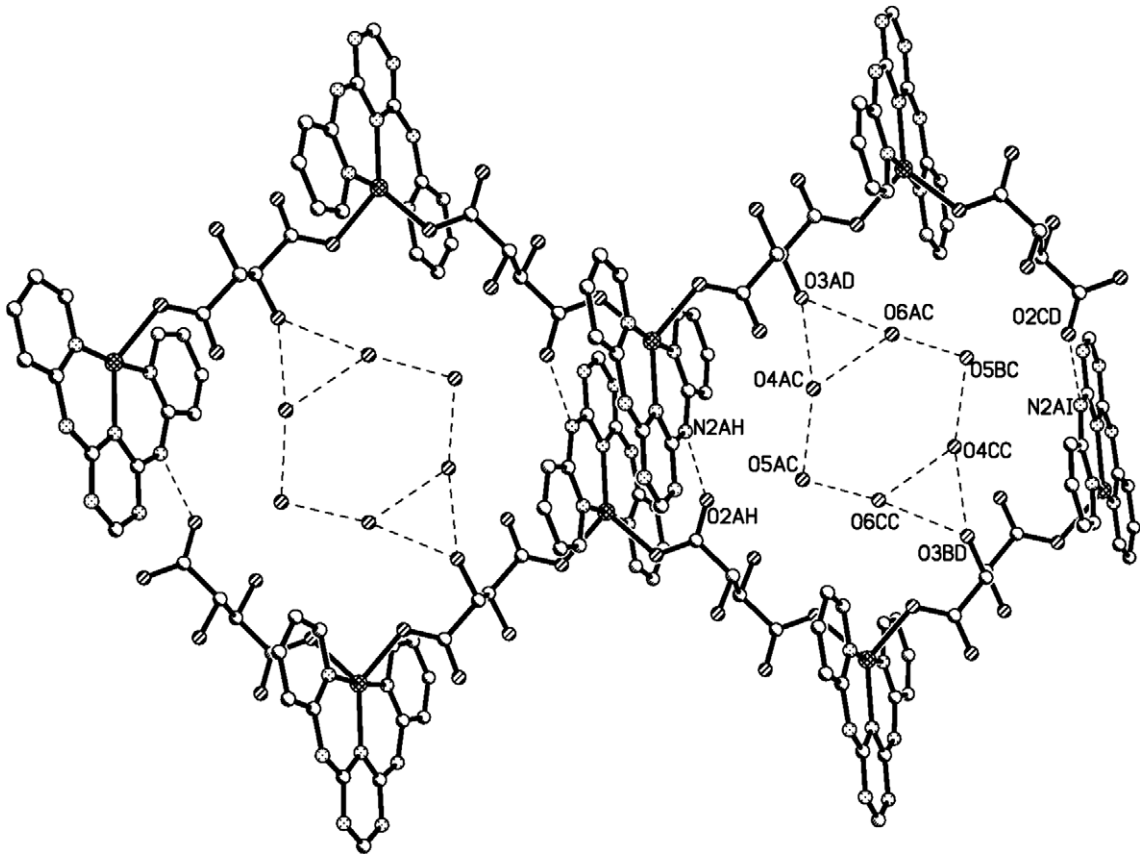

Fig. 2. View of the 2D supramolecular structure of complex **1** self-assembled by hydrogen bonds and π–π stacking interactions.

supramolecular architecture under the direction of hydrogen bonding (N_{amido}–H···$O_{carbonyl}$, 2.832(4) Å) and π–π stacking interactions between the pyridyl and triazine ring with a center-to-center distance of 3.55 Å and with a dihedral angle of ca. 2.7° (Symmetry code: $-x$, $-y$, $-z$) (Fig. 2). There are also significant hydrogen bonds involving hydroxyl oxygen atoms (O3AD, O3BD) of the dicarboxylate ligands and aqua oxygen atoms (O4AC, O6AC, O4CC, O5AC, O5BC, O6CC) from lattice water molecules. These observed hydrogen bonding interactions, with the donor–acceptor distances, are shown in Tables 2 and 3. These interactions generate the final 3D framework that feature 1D open channels (14.626 × 15.110 Å) when viewed along the *c* axis (Fig. 3).

The most remarkable feature in **1** is that these 1D channels are occupied by six water molecules, which are associated by strong O–H···O hydrogen bonds into cyclic centrosymmetric hexamers that adopt a hexagon configuration (Fig. 4(a)). The geometric parameters of the hexamers are summarized in Table 3. The average distance between the oxygen atoms is 2.838(6) Å, which is very similar to the O···O distance of 2.85 Å in liquid water [25]. Unlike the previously reported hexamer clusters [16–22], here it is noteworthy that the water hexamer clusters are self-assembled along the channels by interhexamer O6···O6 hydrogen bonds to give extended 1D arrays consisting of six-membered rings of water (Fig. 4(a)). When viewed down the crystallographic *c* axis, more interestingly, an adjacent hexameric water cluster is not complete superposition but is in a slipped stacking mode (Fig. 4(b)).

Additionally, the hydrogen bonding between water molecules and the hydroxyl oxygen atoms of dicarboxylate ligands plays an important role in contributing to the stability of the 1D hexameric water cluster arrays. This supramolecular association of water molecules in arrays is presumably enforced by the shape and the condition of the interior of the host's channel. These results further illustrate the structural diversity possible for water clusters and the sensitive dependence of their structures on the nature of their environment.

Table 3

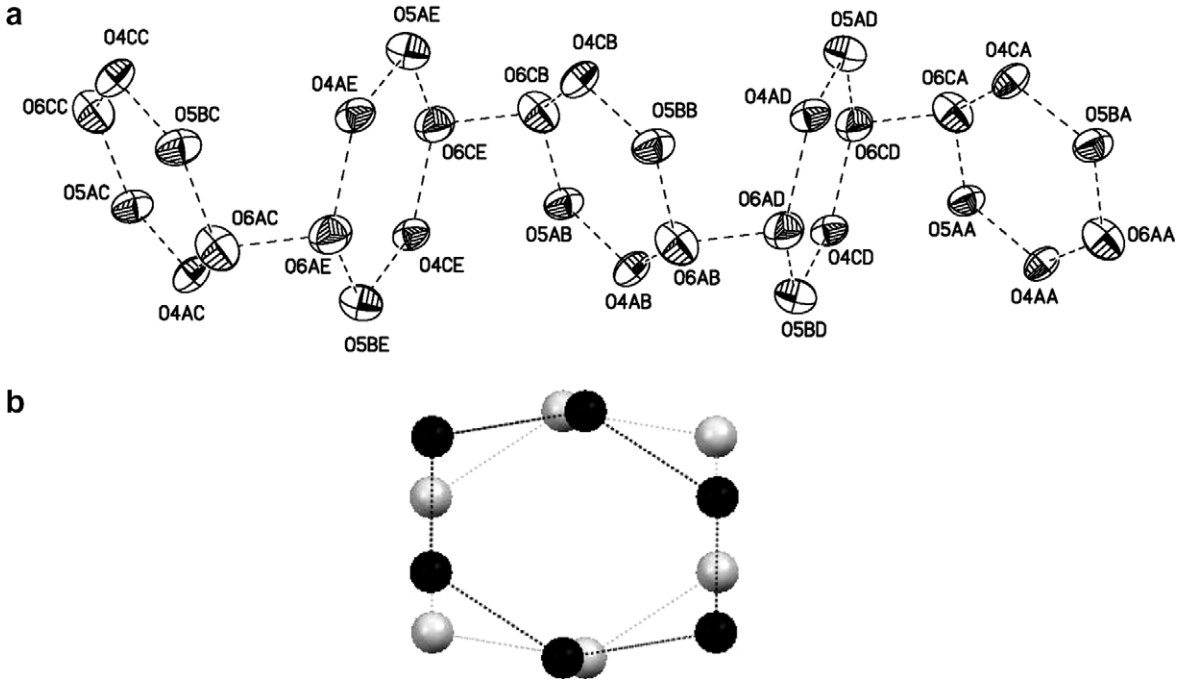

Fig. 4. (a) Extended 1D array consisting of six-membered rings of water molecules in the 3D framework of complex **1**. The hydrogen bond O···O distances [Å]: O5AB···O4AB, 2.783(9); O4AB···O6AB, 2.844(5); O6AB···O5BB, 2.887(5). (b) View of hexameric water cluster array in the 1D open channels of complex **1**. Black and grey represent the different array of an adjacent cyclic $(H_2O)_6$ cluster. Dotted lines show the hydrogen bonding between water molecules.

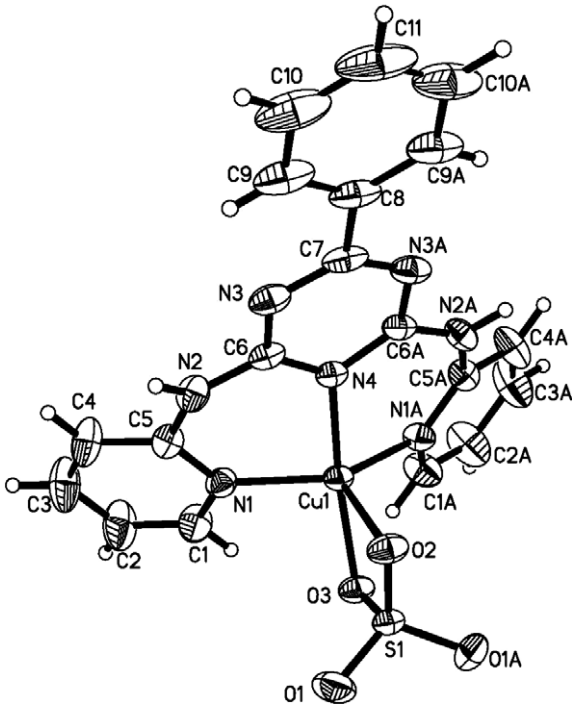

Fig. 5. ORTEP view of $[Cu(dpdapt)(SO_4)]\cdot 2H_2O$ (**2**) with 30% probability ellipsoids. The water molecules are omitted here.

The molecular structure of **2** is shown in Fig. 5. The complex crystallizes in the orthorhombic space group *Pnnm*. The Cu1 is five-coordinate being bonded in a bidentate fashion to two oxygen atoms (O2, O3) of the sulfate dianion and in a tridentate fashion to one triazine-N atom (N4) and two pyridine-N atoms (N1, N1A). The two pyridyl rings of the dpdapt ligand are non-coplanar with a dihedral angle of ca. 52.2°. In mononuclear $[Cu(dpdapt)(SO_4)]\cdot 2H_2O$, the bond angles N1–Cu1–N1A (130.4(5)°), N1A–Cu1–O2 (114.5(8)°) and O2–Cu1–N1 (114.5(8)°) add up to approximately to 360° and the angle N4–Cu1–O3 is close to 180°, so the coordinated geometry of the central copper can be described as a distorted trigonal bipyramid configuration, Cu1, N1, N1A, O2 forming the equatorial plane and N4, O3 occupying the axial positions. The lattice water molecules act as a hydrogen bond donor/acceptor, forming hydrogen bonds with the oxygen atoms of the sulfate anion and the amido nitrogen atoms (as shown in Table 2), to give rise to a 2D network structure in the *ac* plane as shown in Fig. 6.

Complexes **3** and **1** have the same crystal system and different space group, and complex **3** displays a $P2_1/n$ space group. The central copper(II) is five-coordinate being bonded in a bidentate fashion to two oxygen atoms (O1, O2) of an oxalate dianion and in a tridentate fashion to one triazine-N atom (N3) and two pyridine-N atoms (N1, N7) (Fig. 7). The dihedral angle between the two pyridyl ring planes of the dpdapt ligand is 38.9°. The bonds distance to the terminal triazine N3 (Cu1–N3) is 1.954(3) Å and the distance with the pyridyl donors N1 and N7 are 2.013(3) and 2.068(3) Å, respectively. The average Cu–N bond length is observed to be 2.011(9) Å, which is longer than that of **1**. Both Cu–N bond lengths are typical of those found for five-coordinate Cu(II)-μ-

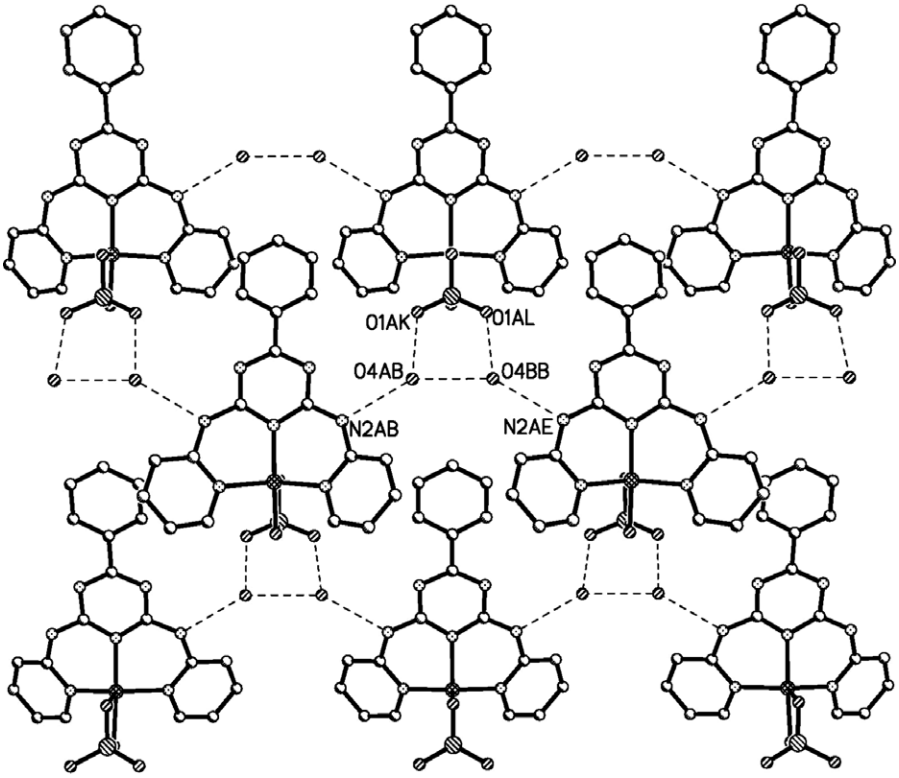

Fig. 6. View of the 2D network of $[Cu(dpdapt)(SO_4)] \cdot 2H_2O$ (**2**) constructed through two kinds of hydrogen bonds (O–H···O, N–H···O) in the *ac* plane.

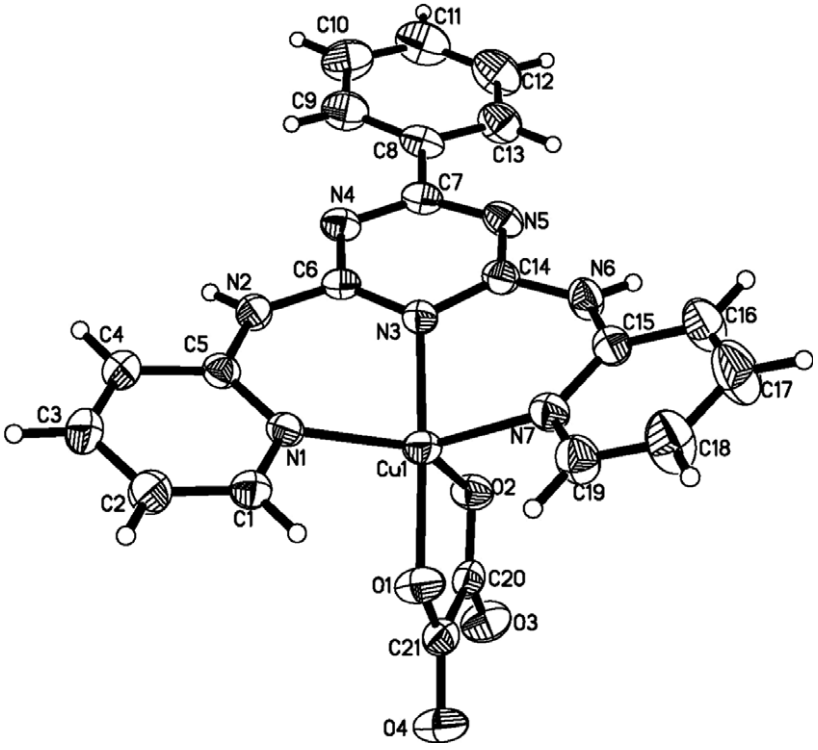

Fig. 7. Perspective view of the coordination environment of the copper atom in the complex $[Cu(dpdapt)(oxa)] \cdot H_2O$ (**3**). Thermal ellipsoids are drawn at the 30% probability level. One water molecule is omitted here.

pmea analogues [26]. The adjacent monomeric entity is interconnected through hydrogen bonding interactions involving the oxygen atoms of the lattice water molecule and the oxalate dianion and the amido nitrogen atoms (Table 2), to generate a 2D wavelike network in the *ac* plane (Fig. 8).

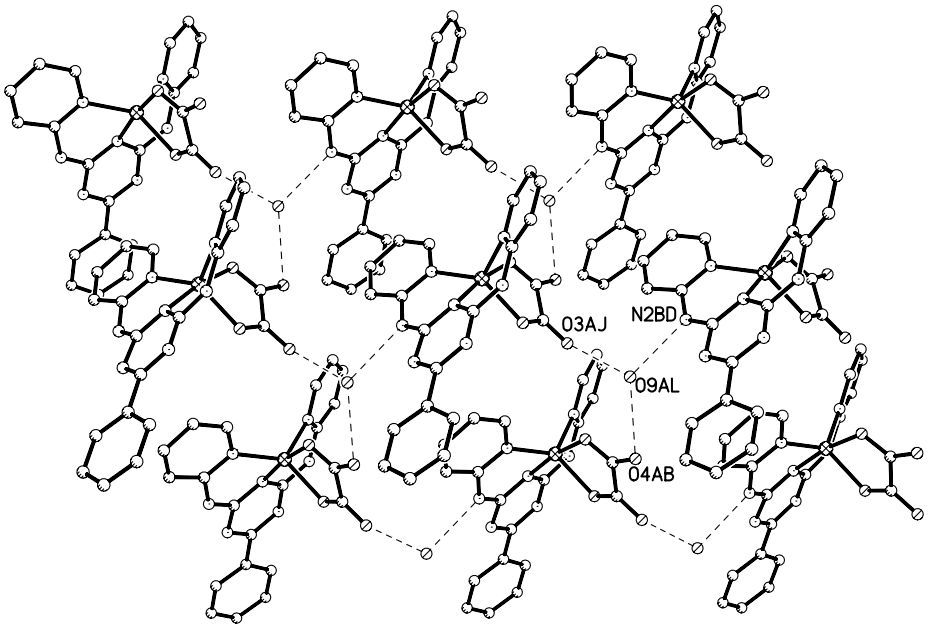

Fig. 8. View of the 2D supramolecular network of [Cu(dpdapt)(oxa)]·H_2O (**3**) formed by hydrogen bonds (O9AL–H···O3AJ, 2.687(5) Å, O9AL–H···O4AB, 2.855(5) Å; N2BD–H···O9AL, 2.730(5) Å). The hydrogen atoms of the lattice water molecules and the organic ligand are omitted for clarity here.

Although the structures of **1**, **2** and **3** exhibit the coordination character of the dpdapt ligand in part, the framework structures of the three complexes are rare for inorganic triazine compounds. To the best of our knowledge only one dimeric unit of a transition-metal complex based on 1,3,5-tris(2-pyridyl)triazine (tpt) has been reported [27], but no solvent molecules effect and π–π interactions were discussed. Additionally, in our previous works, two complexes have been reported [15], which show ladder and layer frameworks via intermolecular and intramolecular hydrogen bonds, respectively. However, we discuss here the action of guest solvent molecules in constructing the three complexes. There are hexameric, dimeric and one water molecule located in the lattices of complexes **1**, **2** and **3**, respectively. It is the water molecules that extend complexes **2** and **3** into 2D supramolecular networks. While in **1**, water molecules form a hexagon configuration in the adjacent 1D polymeric chains, Furthermore, the individual water hexamer self-assembles 1D chains by interhexamer hydrogen bonds, which exert a great influence on extending the architecture of complex **1**.

3.2. Spectroscopic properties

The IR spectra of the three complexes were performed as KBr pellets in the range 4000–400 cm^{-1}. In complex **1**, the bands around 1425 and 1496 cm^{-1} for the ligand dpdapt, attributed to the C=N groups, are shifted to 1469 and 1592 cm^{-1}. In complex **2**, the corresponding bands for the C=N groups are shifted to 1469 and 1587 cm^{-1}, the bands corresponding to SO_4^{2-} are at 634 cm^{-1}. The corresponding bands for the C=N groups for **3** are shifted to 1466 and 1573 cm^{-1}, respectively. Furthermore, the spectra exhibit ν_{as}(OCO) and ν_s(OCO) vibrations of the carboxylate groups that occur at 1640 and 1381 cm^{-1} for **1** and 1665 and 1385 cm^{-1} for **3**. $\Delta[\nu_{as}(OCO)-\nu_s(OCO)] > 200$ cm^{-1} for complexes **1** and **3**, and the value reveals that the carboxylate is coordinated in a monodentate fashion, which is consistent with the results of the X-ray analysis. These data confirm the involvement of acid radical ligands and ligand dpdapt in the copper complexation. The UV–Vis spectra of the complexes are recorded in methanol and are characterized by several spectral regions. The absorption bands in the range 260–285 nm for the dpdapt ligand are ligand-centered (LC) due to π–π^* transitions. The peak at 300 nm for complexes **1**, **2** and **3** is due to the d–d transition and the low-energy bands at 300, 302 and 297 nm are assigned to metal-to-ligand charge transfer transitions (MLCT) [28,29]. This slight shift of absorption bands of the complexes relative to that of dpdapt is caused by the effect of metal-to-ligand charge transfer transitions.

The luminescence data were obtained in methanol at room temperature. It was reported that the dpdapt ligand showed a strongest emission peak at 375.4 nm with an excitation peak at 330.0 nm [15]. The emission bands for complexes **1**, **2** and **3** can be attributed to intraligand fluorescent emission of the coordinated dpdapt ligand. The emission peak for complex **1** is at 310.8 nm, for complex **2** at 330.6 nm and for complex **3** at 320.2 nm, and their emission spectra show strong peaks at 448.6, 414.2 and 423.6 nm, respectively. Compared with the excitation–emission spectrum of the ligand, obvious enhancement of the fluoroscence intensities is realized in complexes **1**, **2** and **3**; the emission bands for three complexes are red-shifted. This drastic shift can be attributed to the strong hydrogen-bonding interactions between the water

molecules and the nearby O atoms of acid radical ligands that change the donor–acceptor character of the dpdapt moieties. These peaks of the emission spectra are probably assigned to intramolecular charge transfer (ICT) transitions [30].

3.3. Thermogravimetric analysis

Thermogravimetric analysis (TGA) for complexes **1**, **2** and **3** were recorded under a nitrogen atmosphere. The TGA result for complex **1** shows an initial weight loss of 16.07% at about 200 °C, corresponding to the removal of six water molecules per formula unit (16.35% calculated). Heating above 500 °C results in complete collapse of complex **1** accompanied by a rapid mass change as the organic component burns off. The two water molecules in complex **2** are lost at about 115 °C with mass loss of 5.39% (5.72%, calculated). Heating above 450 °C leads complete collapse of complex **2**. Complex **3** loses its one water molecule at about 118 °C, leading to a 3.32% loss of the formula unit (3.53%, calculated). The complete collapse of **3** is showed above 470 °C.

4. Conclusion

In summary, we have successfully synthesized three copper (II) complexes by the combination of coordination bonds, hydrogen bonds and π–π interactions. Importantly, this type of ligand contains functional groups capable of O–H···X (X = N, O) hydrogen bonds and supporting π–π interactions that sustain supramolecular architectures. Complex **1** self-assembles a 1D polymeric chain by dicarboxylate bridges and exhibits a 3D framework with 1D open channels, while complexes **2** and **3** show 2D wavelike networks constructed through two kinds of hydrogen bonding (O–H···O, N–H···O) interactions. We anticipate SO_4^{2-} and $C_2O_4^{2-}$ could play the same role as in the complexes $[C_4N_2H_{12}][Ni_3F_2(SO_4)_3(H_2O)_2]$ [31] and $\{Zn(ox)(py)_2H_2O\}_n$ [32], in which acid radical ligands link adjacent metal ions, acting as bridges. However, in complexes **2** and **3**, two kinds of acid radical ligands display a chelate coordination mode. Interestingly, in **1** the host framework encapsulates cyclic $(H_2O)_6$ clusters that are connected into 1D arrays along the 1D open channels. These unique water cluster arrays may be important in understanding the hydrogen-bonding motifs responsible for the anomalous character of water in living systems, as well as in the study of synthetic models, useful in theoretical and computational studies.

area-detector diffractometer. Intensity data sets were collected using Mo Kα radiation ($\lambda = 0.71073$ Å) through the program COLLECT [22]. Correction for Lorentz-polarization effects, peak integration and background determination was carried out with the program DENZO [23]. Frame scaling and unit cell parameters refinement were performed with the program SCALEPACK [23]. Numerical absorption correction was performed by modelling the crystal faces [24]. Crystallographic data at 293 and 100 K are listed in Table 1.

Both structures were solved in the monoclinic symmetry, space group $P2_1/n$ at 293 K and $P2_1/a$ at 100 K, according to the automated search for space groups available in Wingx [25]. Copper and sulfur atoms were located using direct methods with the program SHELXS-97 [26]. The oxygen atoms and the organic moieties were found from successive difference Fourier calculations using SHELXL-97 [27]. For the room temperature phase, all H atoms were located by difference Fourier syntheses after several cycles of least-squares refinements. H–O and H–H distances, within water molecules, were restrained to 0.96(2) and 1.48(2) Å, respectively. C–H and H–H distances within the disordered organic moiety were also constrained to 0.97(2) and 1.58(4) Å, respectively, so that the H–C–H angles fitted the ideal value of a tetrahedral angle. In the low temperature phase, the aqua H atoms and H atoms bonded to N atoms were located in a difference Fourier map and their positions and isotropic displacement parameters were refined. H–O and H–H distances, within water molecules, were restrained to 0.96(2) and 1.48(2) Å, respectively. H atoms bonded to C atoms were positioned geometrically (the C–H bonds were fixed at 0.97 Å) and allowed to ride on their parent atoms. Atomic scattering factors were taken from the International Tables for Crystallography [28]. The atomic coordinates and isotropic displacement parameters appear in Table 2. Bond distances and angles calculated from the final atomic coordinates, as well as probable hydrogen bonds, are given in Tables 3 and 4.

2.3. Thermal behaviour

Differential scanning calorimetry at low temperature was performed with a SETARAM DSC131 instrument for temperatures ranging from 133 to 315 K at a rate of 5 K min^{-1}. A polycrystalline sample of 22.23 mg was placed in a hermetic aluminium cell in nitrogen atmosphere.

The measurements of the complex's electric permittivity, ε^*, were performed with an impedance analyzer Hewlett–Packard 4192 A LF in the frequency range from 100 Hz to 1 MHz. Crystals of the title compound were crushed and pressed to dense and translucent pellets (8 mm in diameter; 0.75 mm in thickness) at a pressure of 200 MPa. Both planar faces of these pellets were coated with silver paint and the pellets were then sandwiched between metal electrodes, which were also coated with silver paint. The measurements were carried out in a vacuum between 120 and 360 K.

[a] U_{eq} is defined as one-third of the trace of the orthogonalized U_{ij} tensor.

Thermogravimetric (TG) measurement was performed with a Rigaku Thermoflex instrument under flowing air, with a heating rate of 15 °C h^{-1} from ambient temperature to 900 °C. A powdered sample, 96.01 mg, was spread evenly in a large platinum crucible to avoid mass effects.

Temperature-dependent X-ray powder diffraction (TDXD) was performed with a powder diffractometer combining the curved-position-sensitive detector (CPS120) from INEL and a high temperature attachment from Rigaku. The detector was used in a semi-focusing arrangement by reflection (Cu Kα_1 radiation, $\lambda = 1.5406$ Å) as described elsewhere [29]. The thermal decomposition of the title compound was carried out in flowing air with a heating rate of 7 °C h^{-1} from ambient temperature to 610 °C.

3. Results and discussion

3.1. Crystal structures

3.1.1. Structure at room temperature

A projection of the structure of the title compound is presented in Fig. 1. The structure consists of a hydrogen-bonded network involving $Cu(H_2O)_6$ octahedra, SO_4 tetrahedra and the disordered protonated diamine. The Cu atoms, lying in a special position on a centre of inversion, are coordinated by four water oxygens forming a slightly distorted square plane. The Cu–OW1 and Cu–OW2 distances are 1.974(2) and 1.980(2) Å, respectively (Table 3). The coordination sphere of the Cu^{2+} cation is completed by two symmetry-equivalent water-molecule oxygen atoms located above and below the square plane. The Cu–OW3 distance of 2.395(2) Å is strongly elongated so that the coordination polyhedron around the copper cation can be described as a strongly distorted octahedron. The Cu ions in this compound display the so-called (4 + 2) type of coordination that has often been observed, which is consistent with a Jahn–Teller distortion. The distances within the $[Cu(H_2O)_6]^{2+}$ octahedron are comparable to those observed in other compounds [30–32]. As it can be seen in Figs. 1 and 2, these octahedra are isolated from one another with a shortest Cu–Cu distance value of 6.953 Å. They are stacked along the *a* and *c* axes while they alternate along the *b* axis.

The dabco groups are located around inversion centres at (1/2 0 1/2) and (0 1/2 0), while all their atoms are located in general positions. Thus, the molecule adopts two possible orientations. The C atoms are distributed between two positions related by the symmetry centre, with a refined site occupancy factor equal to 0.5. It is the consequence of the fact that the internal symmetry of the protonated diamine does not contain any inversion centre. The organic moieties are stacked along the *a* and *c* axes (as for the $Cu(H_2O)_6$ octahedra). The organic and inorganic cations alternate along the [1 0 1] direction so that they form mixed cationic layers parallel to *a*–*c* plane. There is no hydrogen bond between the cationic entities. Within the dabcodiium cations, the N–C distances and the C–N–C angles range from 1.353(7) to 1.602(7) Å and from 100.7(4) to 116.2(4)°, respectively (Table 3).

As it is seen in other organically templated metal sulfates, the sulfur atom has four oxygen atoms coordinating to form a slightly distorted tetrahedron. In fact, the S–O distances range from 1.464(3) to 1.478(2) Å and the O–S–O angles vary from 108.1(2) to 110.7(2)° (Table 3). These tetrahedra are isolated and they are stacked in the *a*–*c* plane to form anionic layers alternating with the cationic layers previously described. These anions are connected to the cations via N–H···O and OW–H···O hydrogen bonds. Three oxygen atoms belonging to the SO_4

tetrahedra are involved in two hydrogen bonds accepting two water hydrogen atoms, while the O1 atom is involved in the N–H···O bond accepting only one hydrogen atom from the organic moiety (Fig. 3). The intermolecular N–H···O bond has a value equal to 2.659(3) Å and the OW–H···O hydrogen bond lengths vary from 2.716(3) to 2.947(3) Å with a mean D···O distance value of 2.766 Å (Table 4). A similar crystal structure is observed in the nickel related phase [21].

3.1.2. Structure at low temperature (100 K)

In the low temperature phase, which crystallizes in the $P2_1/a$ space group, the crystal structure consists of isolated $[Cu(H_2O)_6]^{2+}$, SO_4^{2-} and fully ordered $(C_6H_{14}N_2)^{2+}$ ions linked together by a hydrogen-bonding network (Fig. 4).

At 100 K, the copper ion is coordinated by six water molecule oxygen atoms and also displays the so-called (4 + 2) type of coordination due to the Jahn–Teller effect. In fact, four Cu–OW distances are almost equal while the two others are substantially longer (Table 3). The $Cu(OW)_6$ polyhedra are not connected and they are separated with a shortest Cu–Cu distance of 6.741 Å, which is shorter than that found in the room temperature phase (Cu–Cu = 6.953 Å). This result can be due to the dabco ordering which probably leads to a decrease of the mean volume of the amino group. The Cu^{2+} octahedron is surrounded by six sulfate tetrahedra connected via hydrogen bonds in a bidentate fashion to the octahedron (Fig. 5).

The $[dabcoH_2]^{2+}$ cations are staked along the [1 0 1] direction and they alternate with the inorganic cations

unit of the low temperature phase (Fig. 7) reveals that the oxygen atoms of each sulfate anion participate as acceptors in hydrogen bonds, through H atoms bonded to N atoms and water-molecule hydrogen atoms. The donor···acceptor bond distances range from 2.623(4) to 2.947(4) Å ($\langle D\cdots O\rangle = 2.754$ Å) and the D–H···O angles vary between

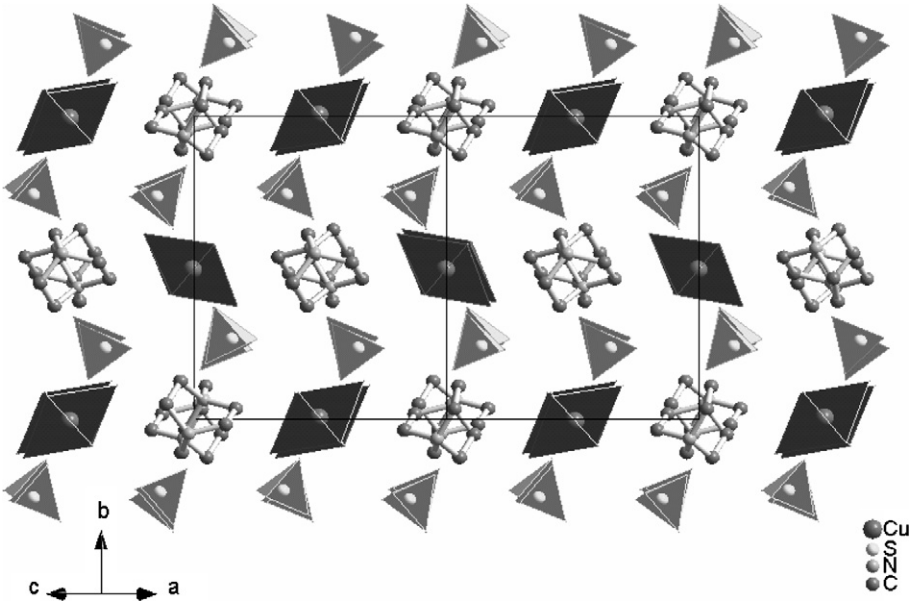

Fig. 6. A projection of the structure of the title compound at 100 K along the [1 0 1] direction. H atoms are omitted for clarity.

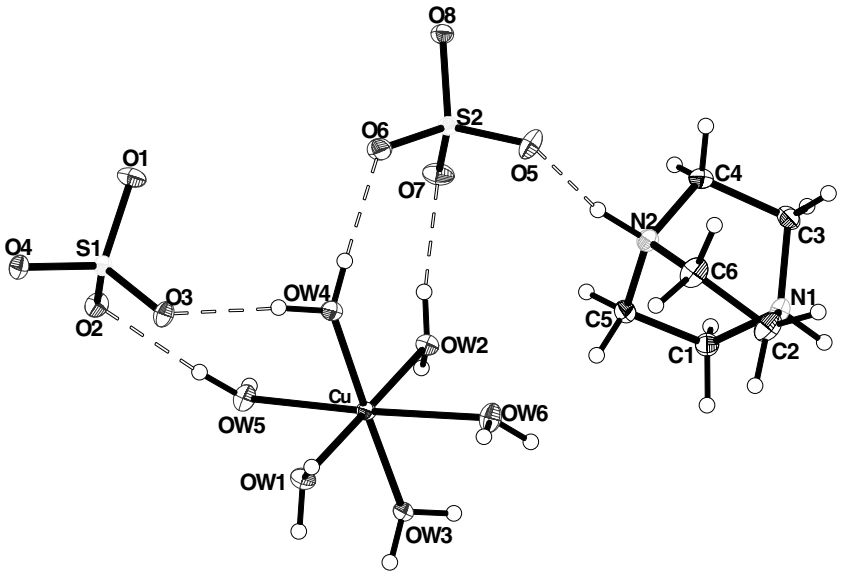

Fig. 7. A part of the crystal structure at 100 K showing the asymmetric unit and atom numbering. Displacement ellipsoids are drawn at the 50% probability level. Hydrogen bonds are represented by dashed lines.

162(5) and 179(6)°, with a mean value 173.07° (Table 4). It should be noted that the hydrogen bonds at low temperature are slightly stronger than those at 293 K ($\langle D\cdots O\rangle =$ 2.766 Å). At 100 K, O1 and O5 accept only one dabcodium hydrogen atom while all the other oxygen atoms belonging to the SO_4 tetrahedra are involved in two hydrogen bonds accepting two water hydrogen atoms, as in the structure solved at 293 K.

3.2. Thermal behaviour

3.2.1. Differential scanning calorimetry

Differential scanning calorimetry (DSC) curves of a powdered sample of the title compound, between 133 and 315 K, including heating and cooling processes are shown in Fig. 8. The thermal changes of $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$ are reversible in the measured temperature range. Only one observed heat anomaly at 265.7/281.8 K (heating–cooling) clearly indicates a first order phase transition. The characteristic thermodynamic values have been determined as follows:

Increasing temperature	Decreasing temperature
T_o (onset) $= 265.7 \pm 0.3$ K	T_o (onset) $= 281.8 \pm 0.3$ K
T_s (peak) $= 268.9 \pm 0.3$ K	T_s (peak) $= 276.0 \pm 0.3$ K
$\Delta H = 4.50$ kJ mol^{-1}	$\Delta H = -4.30$ kJ mol^{-1}
$\Delta S = 16.72$ J mol^{-1} K^{-1}	$\Delta S = 15.59$ J mol^{-1} K^{-1}

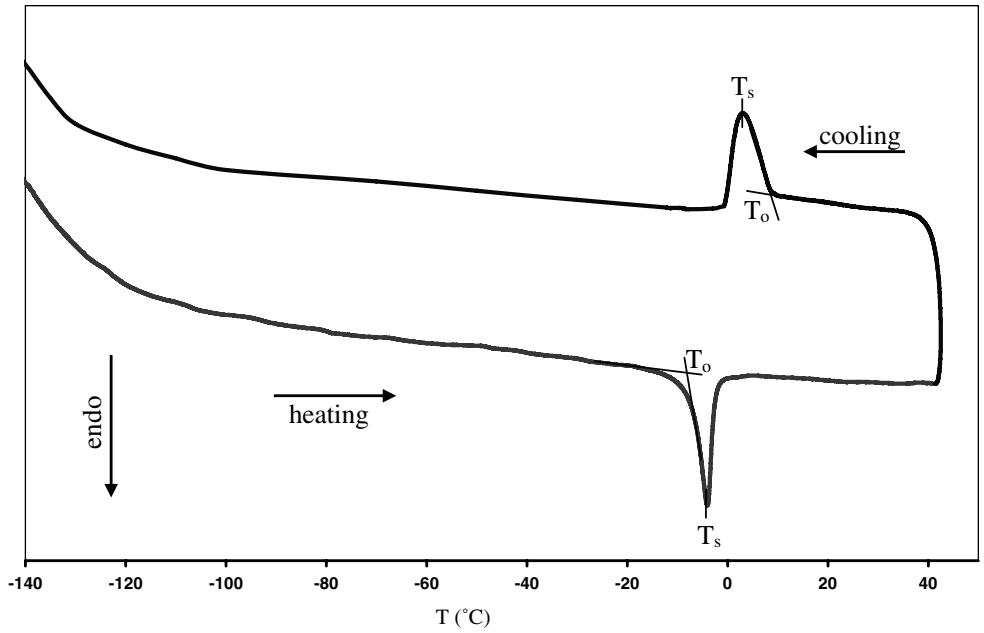

Fig. 8. DSC curves obtained upon heating and cooling $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$.

The entropy change (ΔS) accompanying the first order transition is equal to 16.72 J mol^{-1} K^{-1} which suggests an order–disorder mechanism for this transition, as expected from the crystal structure analyses.

3.2.2. Dielectric properties

The electrical data measured as an impedance Z^* have been converted into permittivity ε^* using the relation, $\varepsilon^* = 1/iwC_0Z^*$ where C_0 is the vacuum capacitance [33]. The temperature dependence of the real part of the complex permittivity, ε', at several frequencies is presented in Fig. 9. A transition is characterized by a weak increase of ε' from 5.8 to 7 (for all frequencies). The observed dielectric anomaly at about 262 K confirms the transition observed by differential scanning calorimetry at about the same temperature. The behaviour of the real part of the dielectric permittivity is similar to that reported by Bednarska-Bolek et al. for the $(C_5H_{10}NH_2)SbCl_6 \cdot (C_5H_{10}NH_2)Cl$ crystal [34] so that the phase transition is expected to be of the prototype-ferroelastic nature. In order to make clear whether the

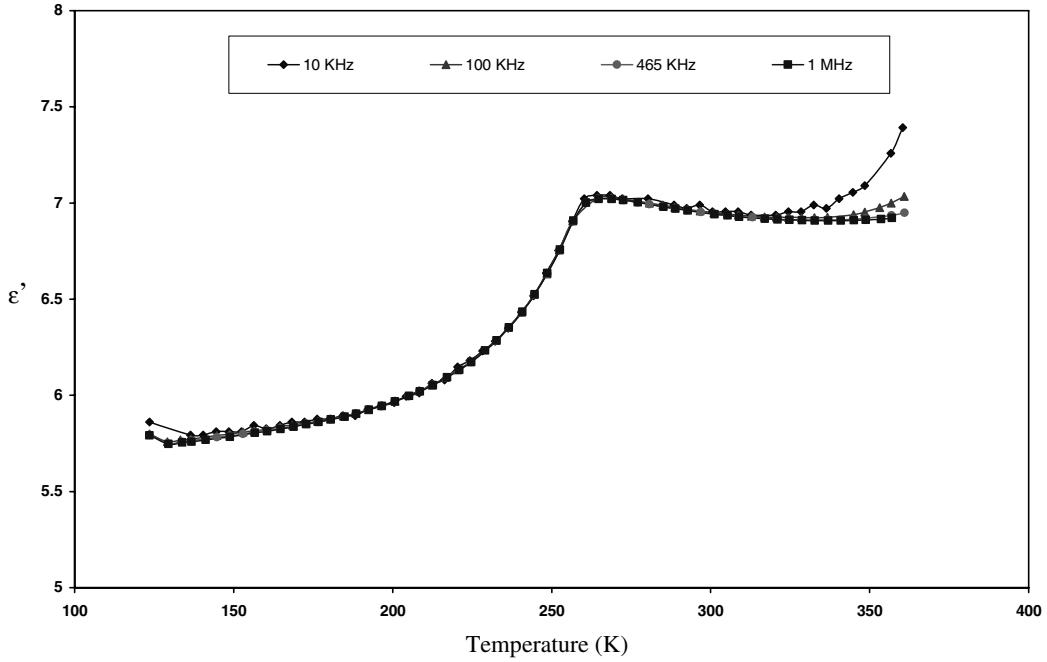

Fig. 9. Temperature dependence of ε' at different frequencies.

265 K transition is a ferroelastic transition or not, some photographs using an optical polarization microscope have been made below and above the phase transition temperature.

3.2.3. Polarizing microscope observations

The optical observations of $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$ were carried out over a wide temperature range by means of the Leitz optical polarization microscope (ortholux2-pol type). Fig. 10 shows photographs of a title compound crystal upon heating from 233 to 293 K. No ferroelastic domain structure is observed below and above the transition temperature. These results evidence that the material undergoes only an order–disorder phase transition.

3.2.4. Thermal decomposition

The thermogravimetry curve and the three-dimensional representation of the powder diffraction patterns obtained during the decomposition of $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$ under flowing air are shown in Figs. 11 and 12, respectively. The thermal decomposition of the title compound takes place in several steps. In the first stage, the compound loses 4.5 water molecules in the temperature range 66–100 °C (observed weight loss, 17.01%; calculated weight loss, 16.95%). In the second step of decomposition (temperature range 122–150 °C) the compound loses the remaining 1.5 water molecules. The TDXD plot shows that the anhydrous phase, obtained after the complete dehydration of the title compound, is amorphous to X-rays until 200 °C. At this temperature some diffraction lines emerge from the background. A few lines disappear at about 250 °C while the remaining ones are observed up to 300 °C. Analysis of the last peaks reveals that it is the pattern of $Cu(NH_4)_2(SO_4)_2$ [ICDD No., 18-090]. Then $Cu(NH_4)_2(SO_4)_2$ is formed together with a second phase at the beginning of the decomposition of the anhydrous phase $(dabcoH_2)Cu(SO_4)_2$. It is supposed that the unknown phase corresponds to a crystallized variety of the anhydrous dabcodiium copper sulfate. Indeed, a similar thermal behaviour has already been observed for anhydrous lanthanum potassium oxalate [35], anhydrous potassium yttrium squarate [36] and piperazinediium copper sulfate [20]. Unfortunately, the low quality of the powder data of the

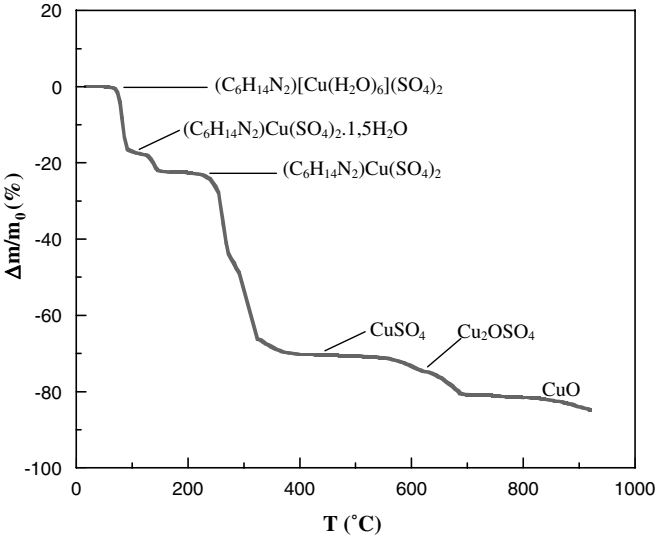

Fig. 11. TG curve for the decomposition of $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$ in air (15 °C h^{-1}).

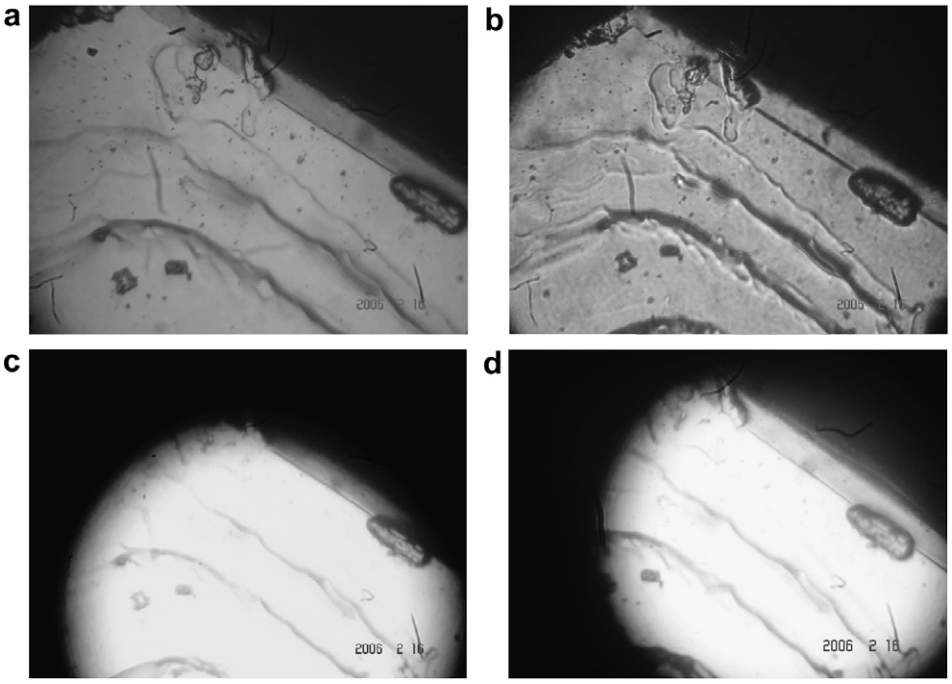

Fig. 10. Photographs of a $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$ crystal upon heating: (a) 233, (b) 253, (c) 273 and (d) 293 K.

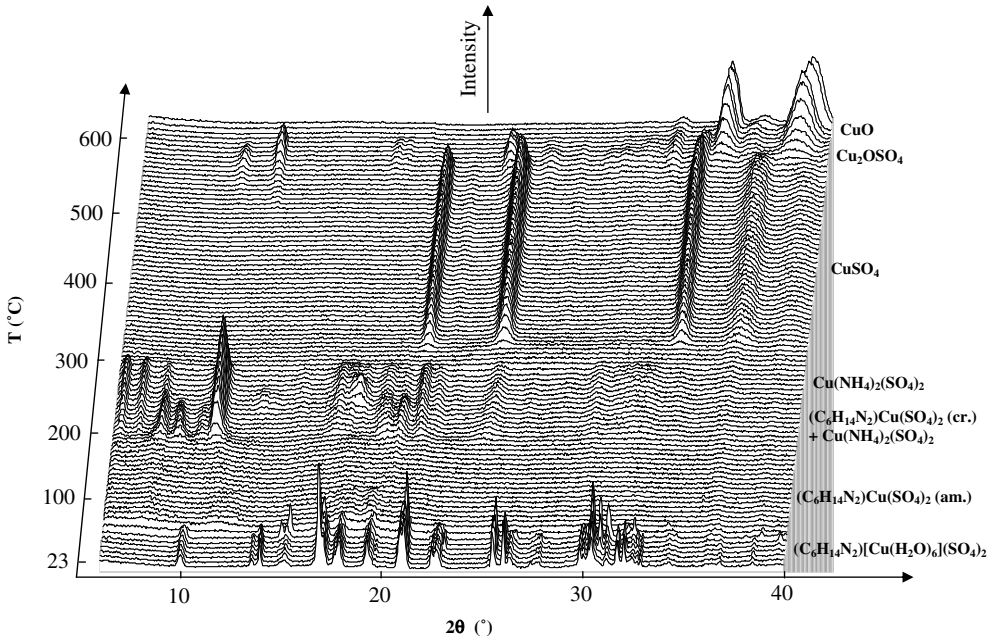

Fig. 12. TDXD plot for the decomposition of $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$ in air (7 °C h^{-1} from 18 to 610 °C; counting time of 3600 s per pattern).

anhydrous phase did not allow further structural investigations on the compound. The end of the decomposition of $Cu(NH_4)_2(SO_4)_2$ leads to anhydrous copper sulfate. It decomposes, at 560 °C, into Cu_2OSO_4 as evidenced on the TDXD plot and by the weight loss of 74.96% (calculated weight loss, 74.99%) observed on the TG curve at the inflection. The last transformation corresponds to the formation of copper oxide, CuO, which crystallise immediately after the beginning of the decomposition of Cu_2OSO_4.

4. Concluding remarks

The first copper(II) sulfate templated by 1,4-diazabicyclo[2.2.2]octane, $(C_6H_{14}N_2)[Cu(H_2O)_6](SO_4)_2$, has been prepared and characterized. The crystal structures at 293 and 100 K have been resolved by X-ray single-crystal diffraction data. Crystallographic studies show that it crystallizes with monoclinic symmetry (space group $P2_1/n$ and $P2_1/a$ at room temperature and 100 K, respectively). Both phases exhibit similar crystal structures consisting of Cu^{2+} cations octahedrally coordinated to six water molecules, sulfate tetrahedra and dabcodiium cations (disordered at room temperature) linked by hydrogen bonds only. A structural phase transition, due to the ordering of the dabcodiium cation, is detected by differential scanning calorimetry and confirmed by dielectric studies. The dabcodiium templated copper sulfate undergoes an order–disorder phase transition of the first order at about 265.7/281.8 K on heating cooling runs. Optical observations show that no domain structures are distinguished in both phases. The thermal decomposition of the precursor, studied by TG and TDXD, proceeds through several stages giving rise to copper oxide.

Acknowledgements

Grateful thanks are expressed to Dr. T. Roisnel (Centre de Diffractométrie X, Université de Rennes I) for the assistance in single-crystal X-ray diffraction data collection and Professor Régnault Von der Mühll (ICMCB-CNRS Université Bordeaux 1) for the optical observations.

Appendix A. Supplementary data

Further details of the crystal structure investigations at 293 and 100 K can be obtained from the Cambridge Crystallographic Data Center. The deposition numbers are respectively CCDC Nos. 607328 and 607329. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.07.010.

prepared **1**/$Pd(OAc)_2$ and **2** were carried out. In general, complex **2** results in lower efficiency compared with that of in situ prepared **1**/$Pd(OAc)_2$.

It is well-known that halide-coordinated palladium complexes such as $[(\eta^4\text{-}C_4Ph_4)PdBr_2]_2$ are always present in dimeric form with two bridging halides [6]. The bonding of the chelating acetate toward palladium atom in **2** is seemingly weak resulting in replacement by a stronger ligand such as halide. It leads naturally to an energetically favorable form, a dimeric complex. Herein, we report the preparation of a new unusually large sized palladium dimeric compound and its catalytic activity in Suzuki reactions.

2. Results and discussion

2.1. Preparation and characterization of a palladium dimer 3

A new and unusually large-sized palladium dimeric compound, $\{(\mu\text{-}PPh_2CH_2PPh_2)Co_2(CO)_4(\mu,\eta\text{-}(t\text{Bu})_2PC{\equiv}CC_6H_4\text{-}\kappa C^1)Pd(\mu\text{-}Cl)\}_2$ (**3**), was obtained in good yield from the treatment of **2** with LiCl in toluene at 25 °C for 72 h (Scheme 3).

The identity of **3** was confirmed by spectroscopic means as well as X-ray diffraction methods (Table 1). Interestingly, the spectroscopic data of **3** exhibit two distinct sets of signals for its constructed units, $(\mu\text{-}PPh_2CH_2PPh_2)Co_2(CO)_4(\mu,\eta\text{-}(t\text{Bu})_2PC{\equiv}CC_6H_4\text{-}\kappa C^1)$. These two components are not magnetically equivalent. In ^{1}H NMR, two sets of doublets appear at 8.52 and 8.69 ppm, which correspond to the adjacent protons of the orthomatallated arene. Another two sets of multiplets signals observed at 3.34 and 3.50 ppm are assigned to two distinct sets of methylene protons of **3**. The ^{31}P NMR spectrum displays two sets of singlets at 82.87 and 84.40 ppm assigned to two phosphorous atoms coordinated to Pd. In addition, two sets of multiplets at 38.00 and 41.43 ppm correspond to the coordinated dppm ligand. The ^{13}C NMR data also support the account that the two constructed components of **3** are not in the same magnetical environment. The ORTEP diagram for **3** is depicted in Fig. 1. As shown, it is a doubly chloride-bridged palladium dimer. The original chelating acetate ligand was removed from **2**. The four atoms, Pd_2Cl_2, are arranged in a diamond shape and almost coplanar. The conformation of the rest of the dimer is almost unaltered from its counterpart in **2**. Two isomeric forms of **3** might

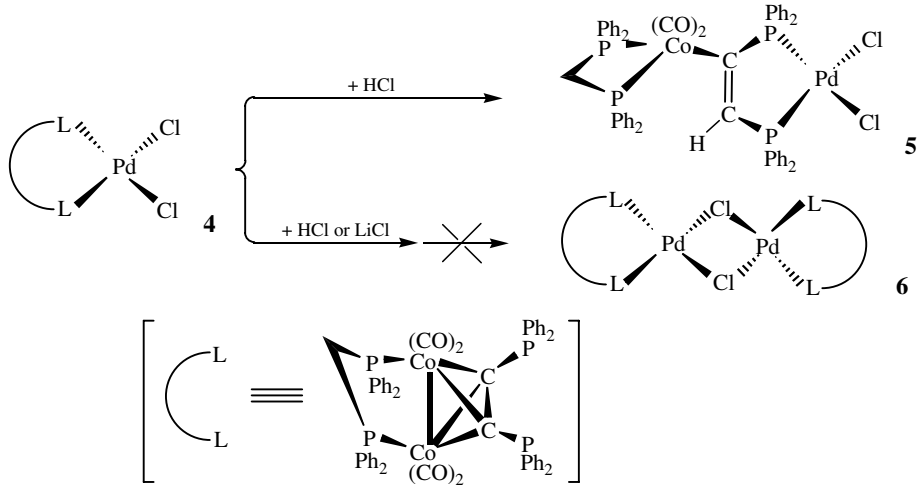
be presented in solution. Crystal structure of **3** only represents one of the two isomeric forms.

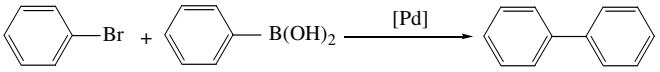
The authors have previously reported the preparation of a novel palladium complex *cis*-dichloride(1,2-bis(diphenylphosphino)vinyl-P,P′,C)palladium(II)–(bis(diphenyl phosphino)methane-P,P′)cobaltacarbonyl (**5**). It was obtained from the treatment of $(\mu\text{-}Ph_2PCH_2PPh_2)Co_2(CO)_4$-$((\mu,\eta\text{-}Ph_2PC{\equiv}CPPh_2)\text{-}\kappa^2P,P')PdCl_2$ (**4**) with hydrochloric acid (Scheme 4) [7]. This complex can be regarded as an unique derivative of the well known compound, $PdCl_2$(dppe) [8]. Nevertheless, there was no sign of forming a doubly chloride-bridged palladium dimer **6** from the reaction of **4** with LiCl.

2.2. Suzuki reactions using 2

Palladium-catalyzed Suzuki reactions of bromobenzenes with phenylboronic acid were carried out by employing **2** as a catalyst precursor (Scheme 5). The general procedures for the catalytic reactions under investigation are described as follows. A suitable Schlenk tube was charged with 1.0 mmol of bromobenzene, 1.5 mmol of phenylboronic acid, 1.0 ml THF, 3.0 mmol KF and 1.0 mol% of **2**. The reaction mixture was stirred at 60 °C for 3–19 h followed by a work-up (Diagram 1). A satisfactory result was obtained only when the reaction time was 19 h.



Scheme 4.



Scheme 5.

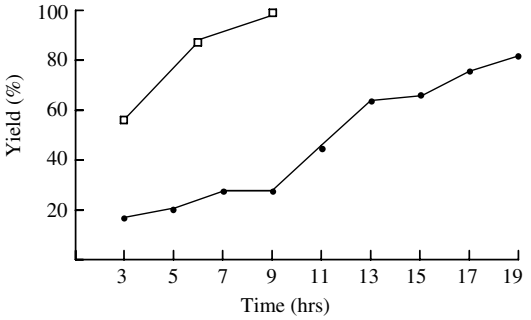


Diagram 1. The dependence of yield of the Suzuki coupling reactions employing **2** (in ●) and **3** (in □) on reaction hours.

Subsequently, the impact of various solvents used in the reaction was evaluated. As shown, the reaction rate is greatly affected by the kind of solvent used (Table 2). For instance, the coupling reaction was ineffective when DMF was used (entry 4). However, the yield was greatly improved when 1,4-dioxane was employed as solvent (entry 5).

It is well-known that the choice of a base is crucial to the success of a palladium-catalyzed Suzuki reaction [9]. Therefore, the influences of the bases used on the reactions were examined (Table 3). As shown, excellent yields were observed when alkaline metal fluorides such as KF and CsF (entries 1and 2) as well as NaO^{t}Bu and K_3PO_4 (entries 4 and 6) were used as bases. The yields were lower when NaOH and K_2CO_3 were employed as bases under the same reaction condition (entries 3 and 5). Amine derived bases such as morpholine, NEt_3 and piperidine failed to promote the reactions resulting in very low yields (entries 7–9).

[b] Isolated yield; average of two runs.

2.3. Suzuki reactions using 3

For comparison, the same Suzuki reactions were carried out by employing **3** as the catalyst precursor. The general procedures for the catalytic reactions under investigation are described as follows. A suitable Schlenk tube was charged with 1.0 mmol of bromobenzene, 1.5 mmol of phenylboronic acid, 1.0 ml THF, 3.0 mmol KF and 0.5 mol% of **3**. The reaction mixture was stirred at 60 °C for 3–9 h followed by a work-up. As shown in Diagram 1, the catalytic efficiencies were much better than in the

Table 4

[b] Isolated yield; average of two runs.

Table 6
Suzuki coupling reactions under various substrate/**3** ratios[a]

Entry	**3** (mmol%)	Yield (%)[b]
1	0.5	99.1
2	0.25	97.3
3	0.1	91.2
4	0.05	85.9

[a] *Condition*: 1.0 mmol bromobenzene, 1.5 mmol phenylboronic acid, 3.0 mmol CsF, 60 °C, 1.0 ml 1,4-dioxane, 6 h.
[b] Isolated yield; average of two runs.

previous case when **2** was employed. With **3** it takes a shorter reaction time to reach the same conversion. As known, the halide bridging bond is intrinsically weak in dimer. It is ready to break and form an unsaturated palladium monomer. The latter is presumably an active species that promptly accepts the oncoming substrate(s) for further catalytic reaction.

The effect of the solvent used was evaluated as well (Table 4). The procedures for Suzuki reactions were the same as previously mentioned. Again, the best yield was observed using 1,4-dioxane as a solvent (entry 5). It is in accord with the previous case (Table 2).

The influences of the bases used on the reactions were examined next (Table 5). As shown, excellent yields were observed when alkaline metal fluorides KF and CsF were used as bases (entries 1 and 2). Other bases, especially amines, were much less effective (entries 3–9).

The Suzuki coupling reactions with various substrate/catalyst loading ratios (0.5–0.05 mol% **3**) were also examined (Table 6). A reasonable yield was achieved even when 0.05 mol% **3** was employed.

The following table shows the results from the **3**-assisted Suzuki cross-coupling reactions (Table 7). The catalytic performance was good for the substrate with electron-withdrawing group (entries 6–8). Nevertheless, the efficiency was low for the substrate with electron-donating group (entries 2 and 3). It is consistent with the general observation for the palladium-catalyzed Suzuki reaction.

Table 7
Suzuki coupling reactions employing **3** under various substrate[a]

Entry	Subtract	Temperatue (°C)	Yield (%)[b]
1		50 60	83.9 89.7
2		50 60	14.7 62.8

[a] *Conditions*: 1.00 mmol phenylbromide, 1.50 mmol phenylboronic acid, 3.00 equiv. CsF, 0.05 mol% **3**, 1.0 mL 1,4-dioxane, 5 h, 50 °C.
[b] Averaged by two runs; isolated yield.

3. Concluding remarks

We have demonstrated that the Suzuki reactions of aryl bromides with phenylboronic acid could be carried out catalytically with two novel palladium complexes **2** and **3**. The catalytic performance is better with **3** probably due to its readiness to form the unsaturated active monomer.

4. Experimental

4.1. General

All manipulations were carried out under a dry nitrogen atmosphere. All solvents including deuterated solvents were purified before use. All separations of the products were performed by Centrifugal Thin Layer Chromatography (CTLC, Chromatotron, Harrison model 8924). ^{1}H NMR spectra were recorded (Varian VXR-300S spectrometer) at 300.00 MHz; chemical shifts are reported in ppm relative to internal $CHCl_3$ or CH_2Cl_2. ^{31}P and ^{13}C NMR spectra were recorded at 121.44 and 75.46 MHz, respectively. Some other routine ^{1}H NMR spectra were recorded on Gemini-200 spectrometer at 200.00 MHz or Varian-400 spectrometer at 400.00 MHz. Mass spectra were recorded on JOEL JMS-SX/SX 102A GC/MS/MS spectrometer. Elemental analyses were obtained on Heraeus CHN-O-S-Rapid.

4.2. Synthesis of 3

A 100 cm^3 round-bottomed flask was charged with 1.00 mmol (1.025 g) (μ-$PPh_2CH_2PPh_2$)$Co_2(CO)_4$(μ,η-(tBu)$_2$PC$\equiv$CC_6H_4-κC^1)Pd(μ-OAc) **2** and one molar equivalent of LiCl (0.0424 g) as well as 15 ml of toluene. The mixture was stirred at 25 °C for 72 h. Subsequently, purification of products using centrifugal thin-layer chromatography (CTLC) was carried out. The first band, brown in color, was eluted out by a mixture solvent of

CH_2Cl_2/ethyl acetate (10/1). It was identified as the title compound $\{(\mu\text{-}PPh_2CH_2PPh_2)Co_2(CO)_4(\mu,\eta\text{-}(t\text{Bu})_2PC{\equiv}CC_6H_4\text{-}\kappa C^1)Pd(\mu\text{-}Cl)\}_2$ (**3**). The yield of **3** is 75% (0.1503 g, 0.750 mmol).

3: ^{1}H NMR (C_6D_6, δ/ppm): 1.37 (t, $J_{P-H} = 30.0$, 36H, $-C(CH_3)_3$), 3.34, 3.50 (m, 2H, dppm), 6.71–7.46 (m, 46H, arene), 8.52 (d, $J_{H-H} = 6.8$, 1H, *o*-hydrogen of the orthometallated arene), 8.69 (d, $J_{H-H} = 7.2$, 1H, *o*-hydrogen of the orthometallated arene); ^{13}C NMR (C_6D_6, δ/ppm): 30.5 (d, 12C, $C(CH_3)_3$), 39.0 (d, 4C, $C(CH_3)_3$), 40.8 (s, 2C, CH_2), 73.8 (d, 4C, $PhC{\equiv}CP(t\text{-}Bu)_2$), 124.6–146.9 (m, 56C, arene), 146.0 (s, 2C, *ipso* of arene), 158.4 (d, 2C, *ipso* of arene), 202.8–207.0 (m, 8C, CO); ^{31}P NMR (C_6D_6, δ/ppm): 38.0 (dd, $J_{P-P} = 109.9$, 2P, dppm), 41.4 (t, $J_{P-P} = 86.1$, 2P, dppm), 82.9 (s, 1P, $P(t\text{-}Bu)_2$), 84.4 (s, 1P, $P(t\text{-}Bu)_2$). *Anal.* Calc. for **3**: C, 41.60; H, 4.07. Found: C, 41.59; H, 4.04%. M.S.: *m*/*z* 696 (M^+).

4.3. General procedures for the Suzuki cross-coupling reactions

Suzuki cross-coupling reactions were performed according to the following procedures. Complex **3** (10.02 mg, 0.005 mmol), boronic acid (0.183 g, 1.500 mmol) and potassium fluoride (0.174 g, 3.0 mmol) were placed into a 20 ml Schlenk flask. The flask was evacuated and backfilled with nitrogen before adding THF (1 ml) and bromobenzene (0.11 ml, 1.000 mmol). The solution was stirred at 60 °C for 6 h. Subsequently, excess amount of water was added and the product was extracted with ether (2×30 ml). The combined organic extracts were dried over anhydrous $MgSO_4$ and concentrated under vacuum. The crude residue was purified by flash chromatography on silica gel or gas chromatography.

4.4. X-ray crystallographic studies

Suitable crystals of **3** were sealed in thin-walled glass capillaries under nitrogen atmosphere and mounted on a Bruker AXS SMART 1000 diffractometer. Intensity data were collected in 1350 frames with increasing ω (width of 0.3° per frame). The absorption correction was based on the symmetry equivalent reflections using SADABS program. The space group determination was based on a check of the Laue symmetry and systematic absences, and was confirmed using the structure solution. The structure was solved by direct methods using a SHELXTL package [10]. All non-H atoms were located from successive Fourier maps and the hydrogen atoms were refined using a riding model. Anisotropic thermal parameters were used for all non-H atoms and fixed isotropic parameters were used for H atoms.[1] Crystallographic data of **3** are summarized in Table 1.

[1] The hydrogen atoms were ride on carbons or oxygen atoms in their idealized positions and held fixed with the C–H distances of 0.96 Å.

[11] and hexacatenar 4,4′-disubstituted 2,2′-bipyridines [12] as ligands.

In this paper we report on the structural features of bis-dithiocarboxylate complexes of zinc. The focus of this study is on the role of 2,5-disubstituted thiophene as a chain-director being part of a dithiocarboxylate ligand and whether this can have an effect on the liquid-crystalline properties of zinc complexes. Unlike *p*-substituted dithiobenzoate ligands that afford linear rods, the presence of thiophene results in the formation of small kinks in the chains. An interesting field of recent research deals with bent-shaped molecules that can exhibit either columnar or lamellar mesophases [13]. The 2,5-disubstituted thiophene derivatives reported by Swager [14] displayed an antiparallel bent-rod structure resulting from the disubstituted thiophene and alkyl chains. However, a hexagonal columnar phase was observed because of the symmetrically substituted benzene molecules at the end of the chains. There is some controversy over claims that 2,5-disubstituted 5-membered heterocycles display bent-core and not conventional calamitic liquid crystal behaviour.

In this study, thiophene-containing ligands is used in four coordinated complexes of zinc and the structural features resulting from the five-membered thiophene rings should display a ''step-rod'' type of structure. In addition, the thiophene unit can electronically affect the coordination properties of dithiocarboxylato ligands by π-delocalization in a similar fashion as observed in thienyl carbene complexes [15].

2. Experimental

2.1. General

All commercially available chemicals were used as received. Solvents were dried and distilled under nitrogen prior to use. Diethyl ether, tetrahydrofuran and hexane were distilled from sodium metal, with benzophenone as indicator in the case of the etheral solvents. Dichloromethane was distilled from phosphorus pentoxide. Thiophene was purified as described by Spies and Angelici [16]. Reactions were performed in an inert atmosphere of either nitrogen or argon using standard Schlenk and vacuum-line techniques. Column chromatography was carried out under a nitrogen atmosphere using silica gel (particle size 0.063–0.200 nm) as stationary phase. All other reagents were purchased from commercial suppliers and used without further purification. All NMR spectra were recorded in degassed deuterated chloroform on a Bruker ARX-300 spectrometer. Chemical shifts were referenced to chloroform. ^{1}H and ^{13}C NMR spectra were measured at 300.133 and 75.469 MHz, respectively. Infrared spectra were recorded on a Perkin–Elmer Spectrum RX1 FT-IR spectrophotometer with a NaCl cell using hexane as solvent. Melting points were recorded on a hot stage Gallenkamp melting point apparatus and are uncorrected. Liquid-crystalline properties were examined on a differential scanning calorimeter (DSC) Q 100 V8.2 Build 268 and Hot-stage Polarising Optical Microscope (POM) Olympus BX60 equipped with a Linkam THMS600 hot stage and a Linkam TMS93 programmable temperature controller.

2.2. Synthesis

2.2.1. Synthesis of the 5-alkyl-2-thiophenedithiocarboxylate ligands ($RTCS_2^-$)

(a) Preparation of 2-alkylthiophene (RT). The procedure used was similar to the one described by Brandsma [17]. *n*-Butyl lithium (15.6 ml, 25.0 mmol) was added to a mixture of THF (50.0 ml) and hexane (30.0 ml), which was cooled to −20 °C. Thiophene (1.68 g, 20.0 mmol) was introduced over 10 min with cooling between 0 °C and 10 °C. The cooling bath was removed and the mixture allowed to warm to room temperature. The alkyl bromide (2.74 g for butyl bromide, 20.0 mmol) was added in one portion without external cooling. The temperature of the solution was raised to 50 °C and kept at this temperature for a further 30 min. The rest of the procedure was carried out in air. Ice water (100 ml) was added with vigorous stirring. Two separate layers formed and were separated. Two further extractions of the aqueous phase with 20 ml diethyl ether gave a combined organic solution that was dried over anhydrous $MgSO_4$. The mixture was concentrated in a rotary evaporator to afford the crude product. Yield = 2.38 g; 85% for R = butyl and in the range 78–89% for the other R groups.

(b) Preparation of 5-alkyl-2-thiophenedithiocarboxylic acid ($RTCS_2H$). *n*-Butyl lithium (12.5 ml, 20.0 mmol) was added to a solution of THF (50.0 ml) and hexane (30.0 ml), which was cooled to −20 °C. 2-Alkyl thiophene (R = butyl, 2.38 g, 17.0 mmol) was introduced over 10 min with cooling between 0 °C and 10 °C. The cooling bath was removed and the mixture warmed to room temperature while being stirred for a further 10 min. The solution was cooled to 0 °C and copper(I) bromide (0.1 g) added. Carbon disulfide (1.29 g, 17.0 mmol) was added drop-wise to the stirred mixture. The colour of the reaction mixture changed to deep-red. The cooling bath was removed and the mixture was allowed to reach room temperature while stirring was continued for a further 1 h. Ice water (100.0 ml) was added followed by dilute hydrochloric acid (20.0 ml, 1 mol/dm^3). The organic layer was separated in air and the product extracted into diethyl ether (70.0 ml) and washed with 2 × 50.0 ml of water. The product was dried over $MgSO_4$ and the solvent removed *in vacuo*. Yield = 3.30 g; 89.8% for R = butyl and in the range of 69–90% for the other R groups.

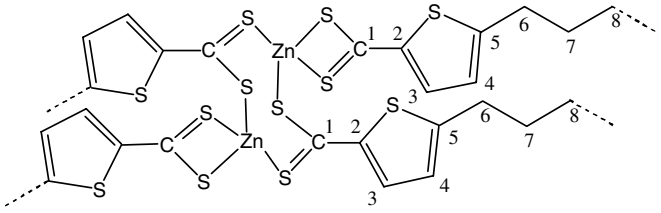
(c) Preparation of sodium 5-alkyl-2-thiophenedithiocarboxylate ($RTCS_2Na$). Sodium metal (0.35 g, 15.28 mmol) was added over 10 min to vigorously stirred methanol (50.0 ml). When all the sodium had dissolved, additional (20.0 ml) methanol was added. 5-Alkyl-2-thiophenedithiocarboxylic acid (for R = butyl, 3.30 g, 15.28 mmol) was added over 5 min to the mixture and left stirring for

30 min. The solvent was removed under reduced pressure, affording the sodium 5-alkyl-2-thiophenedithiocarboxylate as an orange-brown solid. Yield = 3.09 g (85%) for R = butyl and in the range 72–88% for the other R groups.

2.2.2. Synthesis of the bis-5-alkyl-2-thiophenedithiocarboxylato complexes $[Zn_2(S_2CTR)_4]$

The procedure was similar to that of Adams et al. [9], who prepared dithiobenzoate complexes. A colourless solution of $ZnCl_2$ (0.41 g, 3.0 mmol) in water (10.0 ml) was added to a stirred solution of sodium 5-alkyl-2-thiophenedithiocarboxylate (for R = butyl, 1.55 g, 6.5 mmol) in water (25.0 ml) at room temperature. The colour of the solution turned orange-brown and the mixture was left to stir for 3 h. The mixture was concentrated to 25.0 ml on a rotary evaporator and 20.0 ml of methanol was added. The precipitate was separated by filtration and dried. The product, an oily solid, was purified on a silica gel column with hexane as the initial eluent. The first fraction, on evaporation, afforded an oily red liquid that consisted of a mixture of organic products containing carbon disulfides. The desired product was eluted from the column with a solvent mixture hexane:CH_2Cl_2 (1:1). Orange powder was obtained on evaporation of the solvent. Yield = 0.49 g, 33% for R = butyl and in the range 29–37% for the other R groups.

Five complexes, tetra(5-alkyl-2-thiophenedithiocarboxylato)dizinc(II), $[Zn_2(S_2CTR)_4]$, were synthesized by using different alkyl bromide derivatives as precursors, C_4H_9 (**1**), C_6H_{13} (**2**), C_8H_{17} (**3**), $C_{12}H_{25}$ (**4**) and $C_{16}H_{33}$ (**5**). The atomic numbering scheme used for the NMR data is shown below



*Complex **1**:* Orange solid; m.p. 132 °C; Yield: 33%. ^{1}H NMR (δ/ppm in $CDCl_3$; J/Hz): 7.87 (d, 2H, H3, $J = 3.9$), 6.83 (d, 2H, H4, $J = 3.6$), 2.82 (t, 4H, H6, $J = 7.5$), 1.66 (m, 4H, H7), 1.42 (m, 4H, H8), 0.92 (t, 6H, H9, $J = 7.2/7.5$). ^{13}C NMR (δ/ppm in $CDCl_3$): 208.0 (C1), 161.8 (C2), 153.9 (C5), 134.6 (C3), 127.5 (C4), 33.2, 29.8, 22.1, 13.7 (C6–C9).

*Complex **2**:* Orange solid; m.p. 119 °C; Yield: 46%. ^{1}H NMR (δ/ppm in $CDCl_3$; J/Hz): 7.87 (d, 2H, H3, $J = 3.9$), 6.83 (d, 2H, H4, $J = 3.9$), 2.81 (t, 4H, H6, $J = 7.5$), 1.69 (m, 4H, H7), 1.30 (m, 12H, H8–H10), 0.87 (t, 6H, H11, $J = 6.7$). ^{13}C NMR (δ/ppm in $CDCl_3$): 207.0 (C1), 162.5 (C2), 148.7 (C5), 135.2 (C3), 128.0 (C4), 31.8, 31.5, 31.4, 29.0, 22.9, 14.4 (C6–C11).

*Complex **3**:* Orange solid; m.p. 102 °C; Yield: 52%. ^{1}H NMR (δ/ppm in $CDCl_3$): 7.87 (d, 2H, H3, $J = 3.9$), 6.82 (d, 2H, H4, $J = 3.9$), 2.80 (t, 4H, H6, $J = 7.5/7.8$), 1.69 (m, 4H, H7), 1.26 (m, 20H, H8–H12), 0.87 (t, 6H, H13, $J = 6.7/7.0$). ^{13}C NMR (δ/ppm in $CDCl_3$; J/Hz): 207.5 (C1), 162.1 (C2), 148.3 (C5), 134.8 (C3), 127.6 (C4), 31.8, 31.1, 30.6, 29.2, 29.1, 29.0, 22.6, 14.0 (C6–C13).

*Complex **4**:* Orange solid; m.p. 84 °C; Yield: 38%. ^{1}H NMR (δ/ppm in $CDCl_3$): 7.85 (d, 2H, H3, $J = 3.9$), 6.81 (d, 2H, H4, $J = 3.9$), 2.79 (t, 4H, H6, $J = 7.5$), 1.68 (m, 4H, H7), 1.23 (m, 36H, H8–H16), 0.85 (t, 6H, H17, $J = 6.2/7.0$). ^{13}C NMR (δ/ppm in $CDCl_3$; J/Hz): 206.8 (C1), 161.6 (C2), 134.3 (C5), 128.8 (C3), 127.5 (C4), 35.7, 31.9, 31.1, 30.9, 29.7, 29.6, 29.4, 29.2, 29.0, 26.4, 22.7, 14.1 (C6–C17).

*Complex **5**:* Orange solid; m.p. 52 °C; Yield: 32%. ^{1}H NMR (δ/ppm in $CDCl_3$; J/Hz): 7.86 (d, 2H, H3, $J = 3.9$), 6.82 (d, 2H, H4, $J = 4.1$), 2.80 (t, 4H, H6, $J = 7.5$), 1.67 (m, 4H, H7), 1.24 (m, 52H, H8–H20), 0.86 (t, 6H, H21, $J = 6.5/6.7$). ^{13}C NMR (δ/ppm in $CDCl_3$): 207.4 (C1), 161.5 (C2), 153.9 (C5), 134.2 (C3), 127.5 (C4), 31.9, 31.3, 31.1, 30.8, 30.7, 30.5, 29.8, 29.7, 29.6, 29.5, 29.3, 29.2, 29.0, 26.4, 22.7, 14.1 (C6–C21).

2.3. Crystallography

Re-crystallization from a saturated dichloromethane solution layered by hexane gave red needles of **2** suitable for X-ray diffraction studies. Data were collected at 20 °C by means of a combination of ϕ and ω scans on a Bruker (Siemans) P4 diffractometer, fitted with a SMART [18] 1K CCD detector, using graphite-monochromated, Mo Kα radiation. Semi-empirical absorption corrections, derived from multiple scanning of equivalent reflections, were applied using SADABS [18]. All hydrogen atom positions were obtained from a difference Fourier map and were refined. All non-hydrogen atoms were refined with anisotropic displacement parameters, all hydrogen atoms were refined with isotropic displacement parameters. Cell refinement and data reduction were performed using SAINT [18]. The structure was solved using SHELXTL [18] and refined using SHELXTL and SHELXL97 [19]. Structure graphics were prepared using ORTEP-3 [20], POV-RAY [21] and Mercury [22] software. Crystal data and other experimental procedures and refinement parameters are given in Table 1.

3. Results and discussion

Five complexes of the type $[Zn_2(S_2CTR)_4]$ (where T = 2,5-disubstituted thiophene, R = alkyl group; C_4H_9 (**1**), C_6H_{13} (**2**), C_8H_{17} (**3**), $C_{12}H_{25}$ (**4**), $C_{16}H_{33}$ (**5**)) were synthesized via a four-step reaction route as shown in Scheme 1.

The sodium 5-alkyl-2-thiophenedithiocarboxylate precursors were synthesized according to the literature procedures [17]. The final step was similar to that used by Adams

Table 1
Crystal data and structure refinement data for $[Zn_2(S_2CTC_6H_{13})_4]$ (**2**)

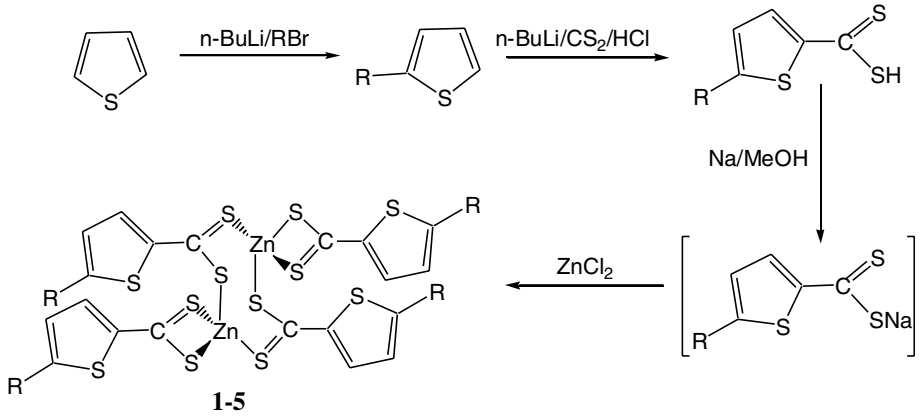
Largest difference in peak and hole (e Å^{-3})	0.272 and −0.401

et al. for the preparation of the corresponding dithiobenzoate complexes [9]. It was also possible to obtain the products in a one-pot procedure by executing the first two steps at low temperature in THF and without the acidification. Solid zinc chloride was added in small portions to a −50 °C solution of the *in situ* prepared 5-alkyl-2-thiophenedithiocarboxylate. On removing the reaction mixture from a cold bath, the colour of the solution changed to red-brown. The solvent was removed under reduced pressure and purification was accomplished as previously described. The products **1**–**5** were obtained as orange powders and afforded red needles on re-crystallization. The complexes were characterized by NMR spectroscopy.

The chemical shifts recorded in the ^{1}H NMR spectra of **1**–**5** are all comparable, as one would expect from the very similar ligands in these complexes. Compared to thiophene, the signals assigned to H3 are 0.90 ppm (av.) more downfield than the corresponding protons in thiophene. The chemical shifts of the ^{1}H and ^{13}C NMR resonances in the spectra of thiophene are found for C2/C5 at 7.20 and 124.9 ppm and for C3/C4 at 6.96 and 126.7 ppm [23]. This demonstrates the electronic involvement of the thiophene ring in the complexes and reflects strong electron withdrawing effects of the coordinated and chelating carbon disulfide moieties. By contrast, the alkyl substituents in the 5-position display an inductive effect on the thiophene ring and the signal for H4 is shifted slightly upfield compared to the corresponding value in thiophene. Support for these results are found in the ^{13}C NMR spectra of the complexes with the coordinating-CS_2 (C1) carbon at 207 ppm and the thiophene *ipso*-carbon (C2) at 162 ppm, respectively. The infrared spectra of all the complexes are very similar and display peaks at 1046 and 980 cm^{-1} that were assigned to the C–S stretching frequencies of the dithiocarboxylate groups. Usually, the stretching frequencies of dithiocarboxylate complexes of Ni(II) and Zn(II) are observed between 900 and 1100 cm^{-1} [24].

3.1. Crystal structure of $[Zn_2(S_2CTC_6H_{13})_4]$ (2)

Crystals of **2** were grown from refrigerated solutions of **2** in dichloromethane and hexane using the solvent layering technique. The structure of **2** was confirmed by single crystal X-ray crystallography. An ORTEP + POV-Ray plot of the geometry of **2** with displacement ellipsoids set at 50% probability, is presented in Fig. 1. Computer generated



Scheme 1.

models [22] of two views of the structure of **2** are shown in Fig. 2 and a packing diagram in Fig. 3. Selected bond lengths and bond angles are listed in Table 2. Unlike the monomeric structure of $[Zn(S_2CPh)_2]$ [4] which displays a distorted tetrahedral geometry around the zinc, the structure for **2** is similar to those observed for 4-butyloxy and 4-octyloxy dithiobenzoates [9] and the dithio- [11] and diselenocarbamates [25]. Two zinc ions and four ligands form the structural unit. Each zinc ion has one bidentate dithiocarboxylate ligand, while the other two ligands bridge between the two zinc ions to form an eight membered ring.

One sulfur atom of one of the two chelate rings of two $[Zn(S_2CTC_6H_{13})_2]$ molecules is also coordinated through a lone electron pair to the second zinc centre. This represents a significantly longer Zn–S bond length of

S(5)–Zn(1)–S(1)	134.47(3)	C(12)–S(5)–Zn(1)	93.72(9)
S(5)–Zn(1)–S(4)	67.62(2)		

[a] The corresponding bond lengths and angles in thiophene are C2–S/C5–S 1.714(1) Å, C2–C3/C4–C5 1.370(2) Å, C3–C4 1.423(2) Å; C2–S–C5 = 92.2(1)°, S–C2–C3/S–C5–C4 = 111.5(3)°, C2–C3–C4/C5–C4–C3 = 112.5(3)° [26].

2.8840(8) Å (compared to an average value of 2.3926(8) Å for the other four Zn–S distances) in **2**. The geometry of sulfur atoms surrounding the zinc atom resembles a distorted trigonal bipyramidal rather than a square pyramidal structure (Fig. 2a). This is evident from three equidistant Zn–S bond distances (Zn–S1, Zn–S4#1 and Zn–S5) representing the equatorial plane of the trigonal bipyramid and the two longer Zn–S distances (Zn–S2 and Zn1–S4) for the sulfur atoms in the axial positions. As a result of the strain caused by the four-membered dithiocarboxylate chelate rings, the sulfur atoms are one in the axial and the other in an equatorial position. In the monomeric structure of $[Zn(S_2CPh)_2]$ the S–Zn–S′ angle of a chelate ring was 77°, giving a highly distorted tetrahedral geometry. The S2–Zn1–S4 angle in **2** is 167.7° and those in the equatorial plane 102.8°, 117.8° and 134.5° compared to a value of 172.4° and values of 102.5°, 115.3° and 140.5°, respectively, for the axial and equatorial positions in $[Zn_2(4\text{-bdtb})_4]$ (bdtb = butyloxydithiobenzoato) [9].

The C–S distance, C12–S4, of the bridging sulfur atoms of the dimeric structure in **2** is significantly longer than the other C–S distances which are comparable with the C–S distances in monomeric $[Zn(S_2CPh)_2]$ [4]. Important differences are observed in the bond distances of the thiophene rings compared to thiophene [26] and can be explained by electron delocalization outwards towards the coordinating CS_2-moiety compared to delocalization within the unsubstituted thiophene ring. Whereas the C–S distances and those of the double bonds in the rings are the same, the C3–C4 as well as the C14–C15 bond distances are significantly shorter in **2** compared to the corresponding distance in thiophene (1.423(2) Å).

The main structural difference between **2** and the linear, rod-like structures of the 1,4-substituted dithiobenzoates is the orientation of the alkyl chains with respect to the thiophene–metal–thiophene core that emerges for **2** as a consequence of the 2,5-disubstituted five-membered thiophene rings. This causes a step in the chain of the ligand and is shown in Fig. 2b. The packing pattern (Fig. 3) shows the appearance of ordered rods in the solid state.

3.2. Thermal behaviour

The thermal properties of the complexes were preliminarily examined by differential scanning calorimeter (DSC). Mesophases and liquid crystal phases can be inferred from DSC measurements by detecting the enthalpy change that is associated with a phase transition. Complexes **1**, **2** and **5** showed sharp single endothermic peaks whereas **3** and **4** showed two broad peaks, one small and one medium endothermic peak during melting.

The thermogram of $[Zn_2(S_2CTC_8H_{17})_4]$ (**3**) showed two endothermic peaks, at 69 °C and 102 °C. The first peak at 69 °C is regarded as a crystal–crystal transition. The peak at 102 °C is ascribed to the melting point of the complex. Sometimes multiple endothermic events might represent transitions from one crystalline state to another crystalline state, which occur when the substance exist in different molecular packing in the solid state at different temperatures [27]. Complex **4** showed two endothermic peaks. The melting points of **1**–**5** from DSC are given in Table 3.

Table 3
Melting points of **1**–**5** and analogue $[Zn(S_2CC_6H_4OR)_2]$ complexes[a]

Complex	Chain length	Melting point (°C)	$[Zn(S_2CC_6H_4OR)_2]$ R	Melting point[b] (°C)
1	C_4H_9	132	C_4H_9	172, (201)
2	C_6H_{13}	119	C_6H_{13}	155, (194)
3	C_8H_{17}	102	C_8H_{17}	147, (184), 140(N-SmC)
4	$C_{12}H_{25}$	84		
5	$C_{16}H_{33}$	52		

[a] See reference [9].
[b] The first value represents K-N and the values in brackets N-I phases unless stated otherwise.

The trend in the melting points is a steady linear decrease as the alkyl chain length of the complexes increased. We ascribe the decrease in melting point with increasing chain length to greater disorder resulting from less favourable interactions of longer alkyl chains in the packing of the rods in the solid state. Similar results have been reported earlier for metal alkanoates [28]. It is of interest to note that the alkyloxy dithiobenzoate complexes have higher melting points compared to the alkyl thiophene dithiocarboxylate complexes [9].

Two complexes, **5** that displayed a sharp endothermic peak and **4** that gave two broad endothermic peaks, were also examined by Hot-stage Polarising Optical microscopy. Complex **5** directly melted to the isotropic liquid without showing any mesophases. Complex **4**, when looking at the sample between crossed polarizers, gave an impression that there was a mesophase present above 80 °C. However, careful examination revealed that the birefringence observed was not due to a mesophase but due to tiny crystals floating in an isotropic melt. Cooling of the samples resulted in simple crystallization without forming any mesophases. Therefore complexes **4** and **5** are not liquid crystalline. By contrast, most alkyloxydithiobenzoate complexes of zinc(II) displayed a nematic phase while a smectic phase only appeared for the C_8 to C_{10} homologues [9].

determined the chemistry of the copper(I) octa-nuclear cluster compounds has now also become biologically relevant [3]. However, due to difficulties in producing single crystals and often to inabilities in distinguishing similar clusters by conventional spectroscopic methods only one structure for each of the first two classes of clusters have been crystallographically characterized, $\{Cu_4[S_2P(O^iPr)_2]_4\}$ [4] and $\{Cu_6[S_2P(OEt)_2]_6\}$ [5], and a limited number of octameric structures, $\{Cu_8[S_2P(OR)_2]_6(\mu_8\text{-}X)\}$, R = Et, ^{n}Pr and ^{i}Pr, $X = S^{2-}$, Cl^- and Br^-, have been reported [5,6].

We have previously shown that solid-state NMR (^{31}P CP/MAS and static ^{65}Cu) in combination with copper K-edge EXAFS studies can be successfully used for characterizing the polycrystalline poly-nuclear copper(I) *O,O′*-dialkyldithiophosphate cluster compounds [6c,7]. The EXAFS data for the polycrystalline compounds, $\{Cu_8[S_2P(OR)_2]_6(\mu_8\text{-}S)\}$ with R = Et, ^{n}Pr, ^{i}Pr, ^{n}Bu, ^{i}Bu and ^{i}Am, have shown that copper cores are 'equally distorted' and the $[Cu_8(S_2P)_6(S_{centre})]$ units in these structures are independent of the size and the branching in the alkyl chains of the ligands [6c,7b]. The actual number of different copper sites in the octanuclear clusters with R = ^{n}Bu and ^{i}Bu has been revealed by the ^{65}Cu NMR studies, showing the presence of two different copper sites [7b,7c]. Possible intra-molecular motions were discussed in terms of the size and branching of the hydrocarbon chains, as reasons for the different ^{65}Cu NMR responses of the systems with R = Et, ^{n}Pr and ^{n}Bu [6c,7c].

The dithiophosphate ligand shells in the octanuclear clusters were found to contain three chemically different phosphorus sites in the cases of R = ^{n}Bu and ^{i}Bu while only one site was observed in the ^{31}P CP/MAS NMR spectra for the compounds with shorter hydrocarbon chains, R = Et, ^{n}Pr [6c,7b,7c].

As we have previously described, ^{31}P chemical shift tensor parameters (estimated from the intensities of the spinning sidebands in ^{31}P CP/MAS NMR spectra) can also be used for the assignment of the coordination mode (bridging or terminal) of *O,O′*-dialkyldithiophosphate ligands adsorbed on the surface of synthetic sphalerite, galena and chalcocite [8,7d]. In previous studies of chalcocite we have shown that the adsorption of potassium *O,O′*-dialkyldithiophosphate ligands (alkyl = Et or ^{i}Bu) leads to the formation of surface compounds such as Cu_6L_6 with $L = [S_2P(OEt)_2]$ [7d] or a mixture of $Cu_8L_6(S)$ and Cu_6L_6 with $L = [S_2P(O^iBu)_2]$ [7b] and a possible role of the disulfide (of the dithiophosphate) at the mineral surfaces has been discussed.

In the early 1970s Fuerstenau et al. showed that when a disulfide is added as a collector (instead of a dithiophosphate salt), chalcocite floated completely even at pH 13.4 [9] but the chemistry of the processes was not investigated. Recently, it has been suggested that copper(II) ions at a chalcocite surface may react with disulfide molecules forming hydrophobic copper(I) *O,O′*-dialkyldithiophosphate species which promote the flotation processes [7b,10].

Herein, we report the solid-state ^{31}P CP/MAS- and static ^{65}Cu NMR data for polycrystalline octa-nuclear dithiophosphate cluster compounds with R = ^{i}Pr and ^{i}Am and show differences and similarities to the NMR data for other *alkyl*-analogues, with particular reference to R = ^{n}Bu and ^{i}Bu. The ^{65}Cu transverse relaxation time, T_2, which indicated significant differences in the motions present, was determined at ambient temperature. The second part of the paper comprises the copper K-edge EXAFS and ^{31}P NMR data for $\{Cu_4[S_2P(O^iPr)_2]_4\}$ and $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ in acetone and CH_2Cl_2 solutions, comparing for the first time the structures in the liquid- and solid-state for these types of clusters. In addition, we show the ^{31}P NMR responses of synthetic chalcocite surfaces treated independently with a potassium *O,O′*-di-iso-amyldithiophosphate collector, $K[S_2P(O^iAm)_2]$, and the corresponding disulfide-$[S_2P(O^iAm)_2]_2$, and discuss the formation of the copper(I)-di-*i*-amyldithiophosphate species on the mineral surfaces.

2. Experimental

2.1. Materials

Potassium *O,O′*-dialkyldithiophosphate ligands: $K[S_2P(O^iPr)_2]$ and $K[S_2P(O^iAm)_2]$, the commercial collectors *Danafloat 245K* and *656K*, respectively, were provided by CHEMINOVA AGRO A/S and used as received. Synthetic chalcocite, Cu_2S, was obtained from STREM CHEMICALS. The structural identity of the chalcocite was confirmed using X-ray powder diffraction data.

2.1.1. Synthesis and characterization of the polycrystalline copper(I) O,O′-dialkyldithiophosphate cluster compounds

$\{Cu_4[S_2P(O^iPr)_2]_4\}$, $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ and $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$. The polycrystalline cluster compounds were obtained by following the methods of Kokotailo et al. [4] and Matsumato et al. [6b], respectively, and were characterized as reported elsewhere [7b].

$[S_2P(O^iAm)_2]_2$ was isolated using the following procedure: a concentrated alcoholic solution of iodine was added dropwise to a concentrated aqueous solution of potassium *O,O′*-di-*i*-amyldithiophosphate salt, $K[S_2P(O^iAm)_2]$, until a pale-yellow oil was obtained. The two phases were separated and the organic one was characterized by $^{31}P\{^1H\}$ NMR. No additional ^{31}P signals were observed in the ^{31}P NMR spectrum, showing that no secondary synthesis products were formed. Details about the preparation of the disulfide have been reported elsewhere [11].

2.1.2. Surface formed compounds

(a) One gram of synthetic chalcocite (Cu_2S) powder was immersed in an aqueous solution (50 ml) of $K[S_2P(O^iAm)_2]$ at pH 9.2 (borate buffer) and kept, under stirring, for 30 min. The ligand was dissolved in deionized water and after conditioning the samples were centrifuged at 4000 rpm for 5 min, rinsed with deionized water, centrifuged once more, and dried

in a vacuum desiccator. In this study, a 10 mmol dm^{-3} $K[S_2P(O^iAm)_2]$ aqueous solution was used. The procedure was repeated using a dilute aqueous solution of KOH to adjust the pH to 9.2 (instead of the borate buffer) and no change in the ^{31}P CP/MAS NMR spectra was observed. The synthetic chalcocite had a specific surface area of about 1 m^2/g.

(b) One gram of synthetic chalcocite (Cu_2S) powder was mixed with a droplet (0.0137 g) of $[S_2P(O^iAm)_2]_2$ and carefully stirred for about 5 min and then transferred to a rotor for subsequent NMR measurements.

3. Methods

All experiments were performed at ambient temperature (298 K).

3.1. ^{31}P CP/MAS NMR

Solid-state ^{31}P magic-angle-spinning (MAS) NMR spectra were recorded at 145.73 MHz on a Varian/Chemagnetics InfinityPlus CMX-360 ($B_0 = 8.46$ T) spectrometer with cross-polarization (CP) from the protons and proton decoupling [12]. The CP mixing time was 3 ms. The ^1H 90° pulse width was 5 μs. 32 (for the pure compounds) and 12 000–20 000 signal transients (for the surface compounds) were accumulated with 3 s relaxation delays. The samples were packed in standard ZrO_2 rotors: 4 mm for the pure cluster compounds and 7.5 mm for the surface compounds. To increase the reliability of the simulations of the chemical shift anisotropy parameters, the ^{31}P NMR spectra were obtained at three different spinning frequencies (in the range 3–6 kHz).

The compounds were additionally studied using a single pulse experiment with a proton-decoupled acquisition. The ^1H 90° pulse width was 5 μs and 6 s relaxation delays were used. No changes in the spectra in comparison to the ^{31}P CP/MAS NMR data were observed.

By analyzing the intensities of the spinning sidebands in the ^{31}P spectral patterns, the CSA parameters, δ_{aniso} and η, for the copper(I) *O*,*O*′-dialkyldithiophosphate cluster compounds were estimated. A simulation program in the Mathematica front-end was used for this purpose. The calculations involved the integrated intensities of the spinning sidebands, the Larmor resonance frequency, the spinning frequency and the noise level variance [13].

The liquid-state ^{31}P NMR spectra were recorded on the same spectrometer using a 10 mm broadband 'liquid' probe and a single-pulse experiment with and without proton decoupling. The ^1H 90° pulse width was 15 μs and 512 signal transients were accumulated with a 2 s relaxation delay. The samples were dissolved either in acetone or CH_2Cl_2.

All solid/liquid state ^{31}P NMR data were externally/internally referenced to 85.5% H_3PO_4 [14].

3.2. Static ^{65}Cu NMR

The ^{63}Cu and ^{65}Cu isotopes both have spin $I = 3/2$ and large quadrupole moments. Despite the lower natural abundance of the ^{65}Cu-isotope, it was preferred in this study since its resonance frequency falls in a spectral window that is relatively free from signals for isotopes of other elements and the effects of quadrupolar interactions are slightly smaller. Excitation at a single frequency was insufficient to excite whole central-transition spectra because of the width of the powder line-shapes, and they were therefore acquired by repeatedly stepping the carrier frequency by 100 kHz, retuning the probe and acquiring a new set of data, before finally adding all the sub-spectra together [15].

The solid-state ^{65}Cu NMR spectra of the compounds were recorded for three applied magnetic field strengths: 7.05, 9.4 and 14.1 T, using Bruker CXP-300, Bruker MSL-400 and Chemagnetics Infinity CMX-600 spectrometers with reference frequencies of 85.20, 113.62 and 170.40 MHz, respectively. The spectra were acquired using Bruker 5 (at 14.1 T) and 7 mm static probes, and spin-echo pulse-sequence experiments. At 7.05 T, the radio-frequency field strength, B_1, was 125 kHz, the pulse timings were (1.0 μs – τ – 1.0 μs, $\tau = 20$ μs) with 0.5 s relaxation delays, and 40 960 transients were averaged per resonance offset. At 9.4 T, B_1 was 116 kHz, and the same experimental timings and number of transients as those for 7.05 T were used. At 14.1 T, B_1 was 125 kHz, the pulse timings were (1.1 μs – τ – 1.1 μs, $\tau = 15$ μs) with a pulse delay of 40 ms, and 50 000 transients were averaged per resonance offset. The energy-level splittings that are utilized in NMR are smaller at lower magnetic field strengths, and the resulting weaker signal strengths are reduced further by the broader width of spectra such as those studied here. The range of transmitter frequencies used at the two lower field strengths was therefore limited to those in the region of line-shapes with smaller quadrupolar coupling constants and therefore narrower widths. All ^{65}Cu NMR spectra were externally referenced to a secondary standard of powdered CuCl at 0 ppm [16].

The NMR data were processed with the FID data left-shifted to the echo maximum prior to FT (giving a half echo). The second-order quadrupolar line-shapes for the central transition of ^{65}Cu nuclei, including chemical shift anisotropy (CSA) contributions where necessary, were simulated using the DMfit program [17]. The errors were estimated by changing a parameter's value when all of the other parameter values were kept constant. Furthermore, the ^{65}Cu NMR spectra were simulated using the SIMPSON simulation program [18] to confirm independently the NMR parameters obtained by DMFit.

The spin–spin transverse-relaxation time T_2 was measured at 14.1 T using a carrier frequency of 170.40 MHz and the relevant experimental conditions described above, by varying the value of τ.

3.3. EXAFS

About 20 mg of each compound, $\{Cu_4[S_2P(O^iPr)_2]_4\}$ and $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$, were dissolved in 2 cm^3 dry acetone to give an edge step in the transition mode of approximately one unit in the logarithmic intensity ratio. The copper K-edge EXAFS measurements were performed at the wiggler beam line I811 at the MAXII Synchrotron, the MAX Laboratory, Lund University, Sweden. The EXAFS station was equipped with a Si[1 1 1] double crystal monochromator and higher-order harmonics were reduced by detuning the second monochromator crystal to reflect 50% of the maximum intensity at the end of the scans. The internal energy calibration was made with a copper metal foil with the first inflection point assigned to 8980.3 eV [19]. Two scans (with a recording time of 90 min for each scan) were averaged to give good data quality in the k range 2–14 $Å^{-1}$ (k^3-weighted data). Calculated model functions using ab initio calculated phase and amplitude parameters obtained by the FEFF7 and GNXAS programs were curve-fitted in k-space [20].

The EXAFSPAK and GNXAS program packages were used for the data treatment. The final data analyses were performed by means of the GNXAS code in order to obtain the best possible splines [21,22]. The GNXAS code is based on the calculation of the EXAFS signal and a subsequent refinement of the structural parameters [22]. The GNXAS method accounts for multiple scattering (MS) paths, with correct treatment of the configurational average of all the MS signals to allow the fitting of correlated distances and bond distance variances (Debye–Waller factors). A correct description of the first coordination sphere of a studied compound has to account for asymmetry in the distribution of the ion–solvent distances [23]. Therefore the Cu–S two-body signals associated with the first coordination shells were modelled with Γ-like distribution functions that depend on four parameters, namely, the coordination number N, the average distance R, the mean-square variation σ, and the skewness β. The β term is related to the third cumulant C_3 through the relation $C_3 = \sigma^3\beta$. However, the β term was negligible for all distances of importance in this study. R is the first moment of the function $[4\pi/g(r)^2]dr$.

The standard deviations given for the refined parameters in Table 4 were obtained from k^2-weighted least squares refinements of the EXAFS function $\chi(k)$, and do not include systematic errors in the measurements. These statistical error estimates provide a measure of the precision of the results and allow various reasonable comparisons, including the significance of relative shifts in the distances. However, the variations in the refined parameters, including the shift in the E_0 value (for which $k = 0$), using different models and data ranges, indicate that the absolute accuracy of the distances given for the separate complexes is within ±0.01 to 0.02 Å for well-defined interactions. The 'standard deviations' given in the Table 4 have been increased accordingly to include the estimated additional effects of systematic errors.

3.4. Surface-area determination

A chalcocite sample was degassed at 575 K overnight and nitrogen adsorption measurements were performed on a Micromeritics ASAP 2010 instrument. The specific surface area was calculated using the BET equation [24].

4. Results and discussion

4.1. Solid-state studies on copper(I) O,O′-dialkyldithiophosphate cluster compounds (alkyl = ^{i}Pr and ^{i}Am)

4.1.1. ^{31}P CP/MAS NMR studies

The ^{31}P CP/MAS NMR spectra of the octa-nuclear copper(I) di-*iso*-propyl- and di-*iso*-amyldithiophosphate cluster compounds, $\{Cu_8[S_2P(OR)_2]_6(\mu_8\text{-}S)\}$ where R = ^{i}Pr and ^{i}Am, **1** and **2**, are shown in Figs. 1 and 2a, respectively. Both compounds display three ^{31}P NMR centre-band resonance lines with isotropic shifts at 103.8, 94.5, 93.2, for **1**, and 100.6, 98.3 and 96.7 ppm for **2** (see insets),

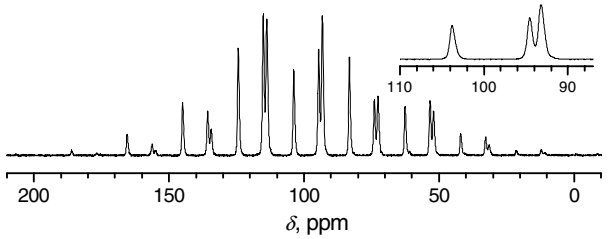

Fig. 1. ^{31}P CP/MAS NMR spectrum (at 8.46 T) of the polycrystalline $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ (**1**); 32 signal transients. 3 kHz spinning frequency. The expanded centre-band region is shown in the inset.

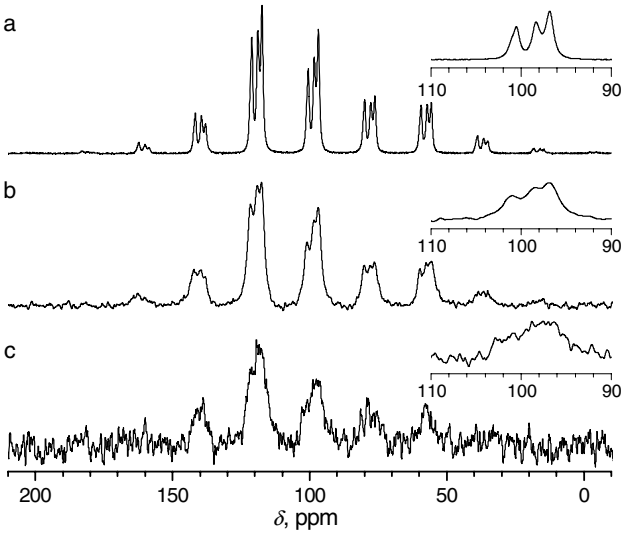

Fig. 2. ^{31}P CP/MAS NMR spectrum (at 8.46 T) of the polycrystalline $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$ (**2**), 32 signal transients (a); a chalcocite sample treated with a 10 mmol dm^{-3} aqueous solution of $K[S_2P(O^iAm)_2]$, 20 000 signal transients (b); and a chalcocite sample treated with the $[S_2P(O^iAm)_2]_2$, 12 000 signal transients (c); 3 kHz spinning frequency. The expanded centre-band regions are shown in the insets.

and relative integrated intensities of all sidebands close to 1:1:1 (for both cases). This indicates that the PO_2S_2 tetrahedra in the ligands are additionally distorted by different orientations of the hydrocarbon chains, and that the phosphorus sites in both clusters are chemically equivalent in pairs.

The symmetry of the electronic environments around each P-site can be estimated from the ^{31}P chemical shift anisotropy (CSA) parameters, δ_{aniso} and η, using the definitions: $\delta_{aniso} = \delta_{zz} - \delta_{iso}$; $\delta_{iso} = (\delta_{xx} + \delta_{yy} + \delta_{zz})/3$, where δ_{xx}, δ_{yy} and δ_{zz} are the principal values of the chemical shift tensor, $|\delta_{zz} - \delta_{iso}| \geqslant |\delta_{xx} - \delta_{iso}| \geqslant |\delta_{yy} - \delta_{iso}|$ and $\eta = (\delta_{yy} - \delta_{xx})/\delta_{aniso}$. The ^{31}P CSA parameters for these clusters were estimated from the intensities of the spinning sidebands, which flank the centre-bands at $\delta_{iso} \pm k(\nu_r/\nu_0) \times 10^6$ ppm, (ν_0 is the Larmor resonance frequency for the ^{31}P nuclei, ν_r is the sample spinning frequency and $k = 1,2,3\ldots$) and are shown in Tables 1 and 2, respectively.

In the known single crystal structure of the *iso*-propyl cluster, $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\} \cdot CH_2Cl_2$ [5], there are three crystallographically different P sites and indeed three phosphorus sites were observed in the ^{31}P CP/MAS NMR spectrum of **1**. Three isotropic resonance lines have also been observed for the octa-nuclear copper(I) clusters with R = ^{i}Bu [7b] and ^{n}Bu [7c]. Therefore, three isotropic resonances were also expected for the cluster compound with R = ^{i}Am, **2**, as the chemically similar octameric compounds with bulky alkyl groups are likely to show similar ^{31}P NMR responses.

The most de-shielded ^{31}P-resonances in **1** (103.8 ppm) have an asymmetric chemical shift tensor with η close to one. An interesting fact is that the isotropic chemical shift of these phosphorus sites in **1** coincides with that of the least de-shielded phosphorus sites in the corresponding potassium salt (see Table 1), but the results of the deconvolution procedure and the following ^{31}P CSA calculations revealed very different ^{31}P CSA parameters. Therefore, isotropic chemical shifts alone must be used with a precaution in assignments of the solid-state ^{31}P NMR spectra of dialkyldithiophosphate compounds.

Recent ab initio calculations of ^{31}P chemical shift tensors in a model fragment, $[PO_2S_2]^-$, have shown that negative

values of δ_{aniso} (and $0 < \eta < 1$) correspond to similar relatively large S-P-S bond angles, which are characteristic of bridging-type bonding, while positive values of δ_{aniso} reveal a terminal-type bonding [25]. These conclusions were also confirmed by ^{31}P CSA experimental data for mononuclear nickel(II)-, bi- and tetranuclear zinc(II)-, polynuclear Pb(II)- and Cd(II)-, and for the copper(I) tetra-, hexa- and octa-nuclear *O*,*O*′-dithiophosphate cluster compounds [7,25,26]. The ^{31}P CSA parameters for the phosphorus sites in the ionic potassium salts (δ_{aniso} larger than −100 ppm and $\eta \sim 0$) are very different from the ^{31}P CSA for the P sites in the two octa-nuclear copper(I) cluster compounds (δ_{aniso} varies between −56 and −69 ppm and $0.2 < \eta < 0.9$), which is an indication that the phosphorus sites belong to bridging-type ligands in the cluster compounds. It is notable that the most de-shielded phosphorus sites in both cluster compounds are characterized by the most asymmetric chemical shift tensors (observed in the values of the η-parameter). A similar trend was observed in the ^{31}P CP/MAS NMR spectra of other octanuclear copper(I) cluster compounds with R = ^{n}Bu and ^{i}Bu [7b,7c].

4.1.2. Static ^{65}Cu NMR studies

The static ^{65}Cu NMR spectra of **1** and **2** obtained at 7.05, 9.4 and 14.1 T are shown in Figs. 3 and 4, respectively, together with simulations. Table 3 summarizes the

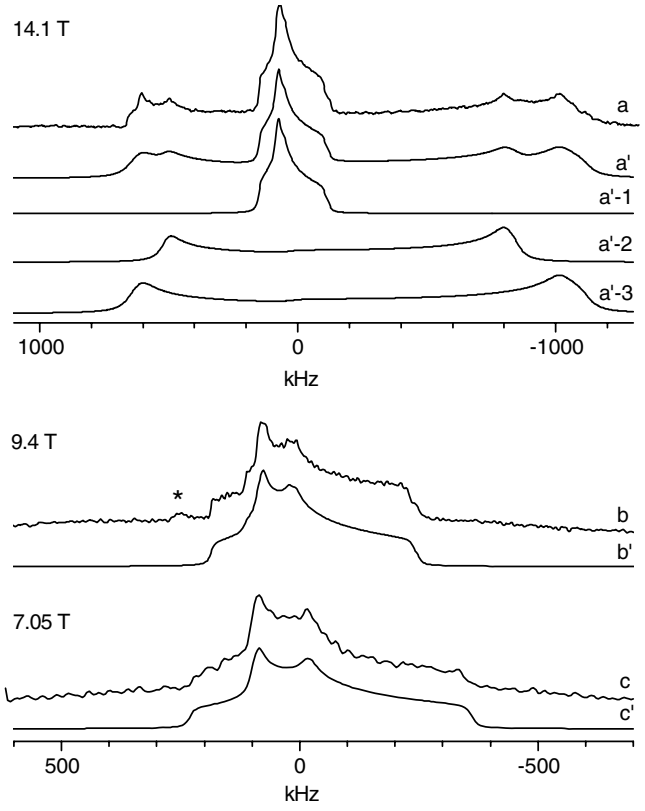

Fig. 3. Solid-state static ^{65}Cu NMR spectra (at 14.1, 9.4 and 7.05 T) of the polycrystalline $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ (a-c), together with simulations (a′-c′); a′-1, a′-2 and a′-3 show the individual line-shapes used in a′. The broad components were not visible at 9.4 and 7.05 T. The probe background (at 9.4 T) is denoted with an asterisk.

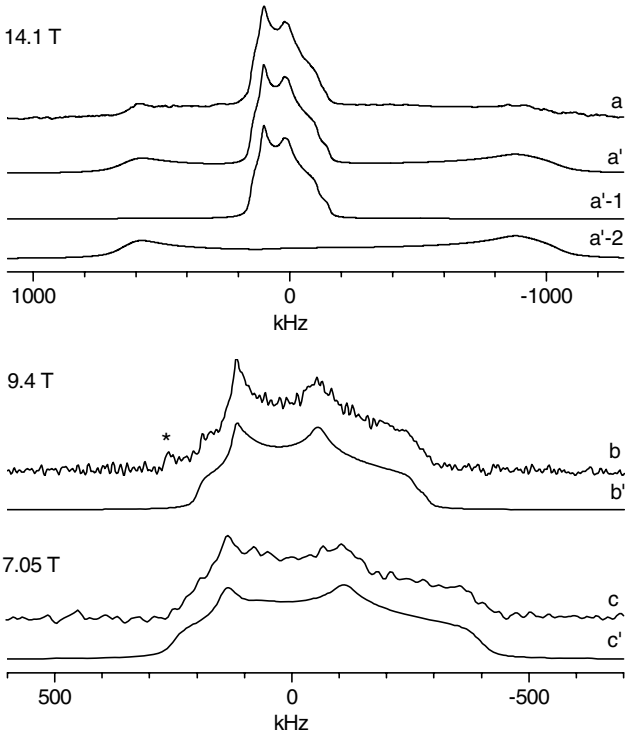

Fig. 4. Solid-state static ^{65}Cu NMR spectra (at 14.1, 9.4 and 7.05 T) of the polycrystalline $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$ (a-c), together with simulations (a′-c′); a′-1 and a′-2 show the individual line-shapes used in a′. The broad component was not visible at 9.4 and 7.05 T. The probe background (at 9.4 T) is denoted with an asterisk.

NMR parameters that were used to simulate the static ^{65}Cu NMR spectra of these two compounds and those for the ^{i}Bu-analogue, $\{Cu_8[S_2P(O^iBu)_2]_6(\mu_8\text{-}S)\}$, previously reported [7b]. These parameters describe two interaction tensors: the quadrupolar interaction (described by the quadrupolar coupling constant, $C_Q = e^2Qq/h$, and its asymmetry parameter, $\eta_Q = (V_{XX} - V_{YY})/V_{ZZ}$, where eQ is the nuclear electric quadrupolar moment, $eq = V_{ZZ}$, and $|V_{XX}| \leqslant |V_{YY}| \leqslant |V_{ZZ}|$ are the elements of the diagonalised EFG tensor) and the ^{65}Cu chemical shift (with an isotropic term δ_{iso}, and anisotropic terms δ_{CS} and η_{CS}). The spectra at 14.1 T for both compounds reveal the presence of more than one quadrupolar line-shape, which are substantially overlapped since the differences in isotropic chemical shift are much smaller than the quadrupolar line-widths, as expected. The relative orientations of the two interaction tensors for **1** and **2** are reflected in the angle parameters used in the simulations (see Table 3).

The static ^{65}Cu NMR spectrum of **1** at 14.1 T reveals three quadrupolar line-shapes with relative integrated intensities close to 1:1:2 (Fig. 3a and Table 3). The presence of such line-shapes with different characteristics (see Table 3) is an indication of the presence of at least three copper sites with different electric field gradients (EFG), although similarities in the local geometries for all copper sites, $[CuS_3\cdots S_{centre}]$, were expected to result in similar line-shapes and therefore similar EFG's. The line-shape for the copper sites with $\delta_{iso} = 460$ ppm has a noticeable

Table 3

nd – not detected.
– does not affect the line shape.

^{65}Cu CSA contribution and cannot be simulated exclusively by a quadrupolar interaction tensor, while for the copper sites with $\delta_{iso} = 170$ and 100 ppm, where the electric field gradient is very large, the simulations do not require such a combination of interactions.

In the crystal structure of $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\} \cdot CH_2Cl_2$ [5] there are four structurally non-equivalent copper sites in tetrahedral arrangements of the $[CuS_3\cdots S]$-type. However, singularities of only three second-order quadrupolar line-shapes are well delineated (Fig. 3a) in spite of the expected overlap of four similar quadrupolar patterns. The corresponding integrated intensities in the simulations of these sites, however, allow the spectrum to be considered as a superposition of the central transitions of the four copper sites ($CuS_3\cdots S$). Furthermore, data show that very small differences in the local geometry of the copper sites in **1** are producing large differences in the quadrupolar parameters (with a change in C_Q from 15.7 to 47.1 MHz), with corresponding differences in the electronic charge distribution.

The data presented in Fig. 3 for **1** are a useful illustration of the importance of studies involving multiple magnetic field strengths. Simulations of the smaller C_Q line-shape using the high-field data alone would not only provide an inaccurate value for C_Q but also an η_Q close to unity. The lower-field data show quite different line-shapes that are characteristic of tensors where $\eta_Q < 1$. At lower field-strengths, the chemical shift interaction is weaker but the second-order quadrupolar interaction terms are stronger. Such data therefore tends to provide useful information on quadrupolar interactions, with higher-field data being more useful for determining chemical shift tensors. The accuracy of the parameters used to describe the narrower line-shapes (of **1** and **2**) is increased by comparing powder spectra obtained at multiple magnetic field strengths and a fit for all three fields for both compounds cannot be achieved without including the CSA component. This component, however, is expected to be less significant for the broad line-shapes and therefore it was not included in their simulations. The sloping background intensities visible in the spectra acquired at lower magnetic field strengths are caused by these broad line-shapes and to a lesser extent the quadrupolar satellites, and are an effect of the limited sweep range.

The ^{65}Cu NMR spectrum of **2** reveals only two quadrupolar line-shapes with relative integrated intensities close to 1:1 (see Fig. 4a and Table 3) suggesting the existence of two types of site with equal-sized populations. Similar to the ^{65}Cu NMR data of $\{Cu_8[S_2P(OR)_2]_6(\mu_8\text{-}S)\}$ with R = ^{i}Bu and ^{n}Bu [7b,7c], the two quadrupolar line-shapes in the ^{65}Cu NMR spectrum of $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$ cluster are substantially overlapped and the narrower line-shape is again additionally perturbed by a considerable ^{65}Cu CSA contribution ($\delta_{CS} = 400$ ppm).

It is somewhat surprising that the copper sites in these copper clusters, all of which have an almost 'rigid' closest chemical environment of the $CuS_3\cdots S$-type, display different numbers of copper sites that are also characterized by very different quadrupolar parameters. Such differences are caused by different EFG's at the copper nuclei that are determined by differences in the local charge distributions, and are therefore sensitive to the bonding characteristics. The large differences in C_Q described above are indicative of significant differences in the bonding or bond-strengths at the different sites, which result in such differences in the ^{65}Cu spectra of these chemically very similar copper sites.

4.1.3. ^{65}Cu spin-echo decay constants, T_2, for the copper(I) O,O′-di-i-propyl- and O,O′-di-i-amyldithiophosphate cluster compounds

An NMR study of the dynamical behaviour of a system can be performed by measuring the spin-echo peak

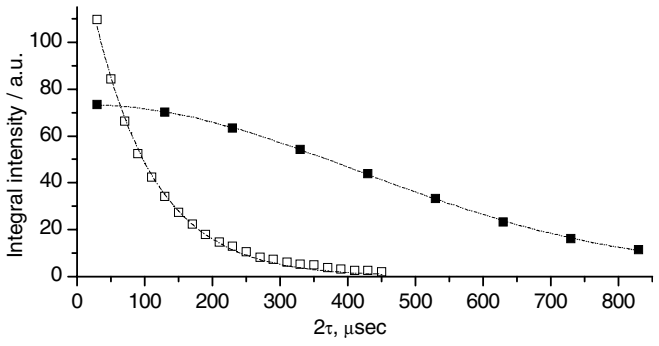

Fig. 5. ^{65}Cu NMR transverse relaxation decays (T_2) for the polycrystalline $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ (filled squares) and $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$ (open squares) measured using a spin-echo pulse sequence. Broken lines are fits with T_2 of 590 (Gaussian) and 90 μs (exponential).

intensity, since the spin-echo experiment refocuses the effects of inhomogeneous broadening [27]. Fig. 5 shows the intensities of the ^{65}Cu NMR spin-echo signals of **1** and **2** at 14.1 T (at the carrier frequency of powdered CuCl, at 0 ppm) plotted versus the spin-echo delay time, τ. The magnetization decay is Gaussian (Eq. (1)) for **1** with $T_2 = 590 \pm 10$ μs and exponential (Eq. (2)) for **2** with $T_2 = 90 \pm 10$ μs:

$$M = M_0 \exp\left(\frac{-(2\tau)^2}{(T_2)^2}\right); \quad (1)$$

$$M = M_0 \exp\left(\frac{-2\tau}{T_2}\right) \quad (2)$$

In general, the decay of the spin echo intensity of a nucleus is a complex, many-site variable that involves couplings between neighbouring sites and fluctuations in the interactions affecting the precession frequency of the nucleus. In other words, it contains information about the surroundings of the nuclei of interest and through the T_2 value (its nature and magnitude) can reveal the nature of the dynamic processes in the system. (We use the characteristic decay in the magnetization measured using the spin-echo experiment as an operational definition of T_2 although there are both secular and non-secular terms which can contribute to the measured time and not all the secular terms will necessarily be refocussed by the pulse used here [28]. The sources of the decay cannot usually be determined, but some studies chose to define T_2 as the decay resulting from effects of homonuclear coupling, and use T_2' for the overall decay caused by the different contributing effects [29].) Whilst a full variable temperature study is needed to assure the details of the relaxation behaviour in the systems discussed here, the different functions describing the decay in **1** and **2** clearly indicate different dynamics (motions) in the two samples. A Gaussian T_2 decay (predominantly due to the dipole–dipole broadening [30]) is usually observed in cases with no motion on the NMR time scale that affect the resonance signal [30]. When there are motions (vibrational or/and rotational, and/or inhomogeneous spin fluctuations) present the T_2 undergoes a crossover from Gaussian to exponential. Although T_2 is short for compounds **1** and **2**, the substantially shorter T_2 for **2** indicates that there is motion in **2** that is causing additional relaxation, probably longitudinal relaxation (characterized by a time constant, T_1) and, since $T_1 \geqslant T_2$, [30] T_2 is considerably reduced.

We have recently reported (in the case of ^{65}Cu in the $\{Cu_8[S_2P(O^nBu)_2]_6(\mu_8\text{-}S)\}$ cluster compound) that a type of movement/motion of the structure, originating in the ligand tails, is most likely to be the reason for the observed exponential decay (with $T_2 = 160$ μs) and for the relatively weak spin-echo signal [7c].

For octa-nuclear copper(I) *O*,*O*′-dialkyldithiophosphate structures, it has been proposed that the main factors determining the overall motions/vibrations are the number of methylene groups (CH_2) (giving more flexibility of the structures and hence producing motions in the ligand tails) and the positional vibrations of the S_{centre} (due to the available 'free space' in the copper core cavities) [7c]. The T_2 value of 590 μs for **1** and the observed Gaussian decay indicate that some of the intra-molecular dynamic processes, present in the octa-nuclear cluster with R = ^{i}Am, **2**, are less effective or absent in the octa-nuclear cluster with R = ^{i}Pr (i.e. **1**). It is most likely that the absence of CH_2-groups in the ligand hydrocarbon chains of **1** is the reason for the more 'rigid environments' of the copper atoms in the cube. Therefore, considerably weaker fluctuations in the EFG's at the copper positions are expected, and hence a slower decay of the magnetization of the ^{65}Cu NMR echo signals is observed (and a Gaussian T_2 of 590 μs is determined).

For the case of **2**, the T_2 value of 90 μs and the observed exponential decay of the magnetization, indicate that different dynamic processes are dominating. The presence of two CH_2-groups in the hydrocarbon chains (none for R = ^{i}Pr) would allow a certain flexibility in the structure, and therefore fluctuations in the EFG's could arise, decreasing the value of T_2. Similar effects that could shorten further the relaxation time are intermolecular motions (together with intra-molecular motions). These are fairly likely to exist in **2**, due to its considerably larger ligands (in comparison to those in **1**) and the possible geometric positions in which the 12 hydrocarbon chains could exist. There is a possibility that some motions are hindered or enhanced in **2** by steric factors rather than electronic effects, but this could only be confirmed by low-temperature experiments.

It is worth noting that although the EXAFS data for the two compounds, have shown that the mean Cu–S, Cu···S_{centre} and Cu···Cu distances for both compounds are 2.285, 2.64 and 2.99 Å (which means that the two copper cores are very similar), this method only provides information about the average distances. There is therefore a possibility that the local surroundings of the copper sites in the two compounds are slightly dissimilar and that the observed shortening of T_2 is due to fluctuating EFG's (which are causing T_1 (and T_2) relaxation) that are experienced by some of the copper sites in the cubes more strongly than by others, and hence dominate the overall decay of the echo intensity in **1** and **2**.

4.2. Liquid-state EXAFS and ^{31}P NMR studies on copper(I) O,O′-di-iso-propyldithiophosphate cluster compounds with different nuclearity

There is very little known about the structures of the poly-nuclear copper(I) dialkyldithiophosphate compounds in solution, while numerous data for the mononuclear copper(II) dialkyldithiophosphate complexes have been reported [31]. In principle, it is accepted that the structures in the solid-state will be the same as those in solutions if there are no specific interactions with the solvents and no chemical decomposition occurs. $^{31}P\{^1H\}$ NMR data only for $\{Cu_4[S_2P(O^iPr)_2]_4\}$ and $\{Cu_6[S_2P(OEt)_2]_6\}$ compounds in $CDCl_3$ have been briefly reported together with the single crystal data for these compounds [5]. It is known that

$Zn_4L_6(Se)$ ($L = [Se_2P(OPr)_2]$) decomposes in solution to a monomer and a dimer, which are themselves in a dynamic equilibrium [32a]. The octanuclear copper(I) cluster with a similar ligand ($L = [Se_2P(O^iPr)_2]$) in a CH_2Cl_2 solution has shown only one resonance line in the $^{31}P\{^1H\}$ NMR [32b]. In this study we use EXAFS spectroscopy to investigate the structures of $\{Cu_4[S_2P(O^iPr)_2]_4\}$ and $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ in solution, comparing the results to the EXAFS data for these compounds in the solid-state.

EXAFS is a lattice-independent structure method, which provides information about the structure around the absorbing atom in the sample (in this case, copper) and a correct description of the first coordination sphere of the studied compound is obtained when the distribution of the ion–solvent distances is taken into account. The raw EXAFS data for **1** and $\{Cu_4[S_2P(O^iPr)_2]_4\}$ in acetone solutions and in the solid-state are shown in Fig. 6a, the fitted Fourier transforms in Fig. 6b, and the refined structure parameters are summarized in Table 4. Solid-state EXAFS data are shown for comparison in Table 4 and the individual fits for all data are provided in the Supporting information. The cluster compounds in the solid-state display similar EXAFS functions with small differences between the two types of structures.

The average Cu···Cu, Cu–S, Cu···S_{centre} bond distances for **1** in an acetone solution and in the solid-state are almost identical (within the error limits). The mean Cu–S bond distance is 2.285 Å for the solid-state and 2.289 Å for the acetone solution. The mean Cu···Cu distances are 2.99 Å and 3.01 Å, respectively. Such a similarity between the solid- and liquid-state data is also observed in the mean Cu···Cu and Cu–S bond distances for the tetrameric copper(I) structure with the same ligand: the mean Cu–S bond distances are 2.265 and 2.262 Å, respectively, while the corresponding Cu···Cu bond distances are 2.82 and 2.84 Å. This shows that the structures around the copper(I) ions in both poly-nuclear cluster compounds, $\{Cu_4[S_2P(O^iPr)_2]_4\}$ and $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$, are principally identical in the solid- and liquid-states. Interactions with this solvent did not lead to any initiation of a decomposition process or formation of other copper(I) dithiophosphate species. If such products were formed then the structural parameters obtained would not be similar to those found for the compounds in the solid-state.

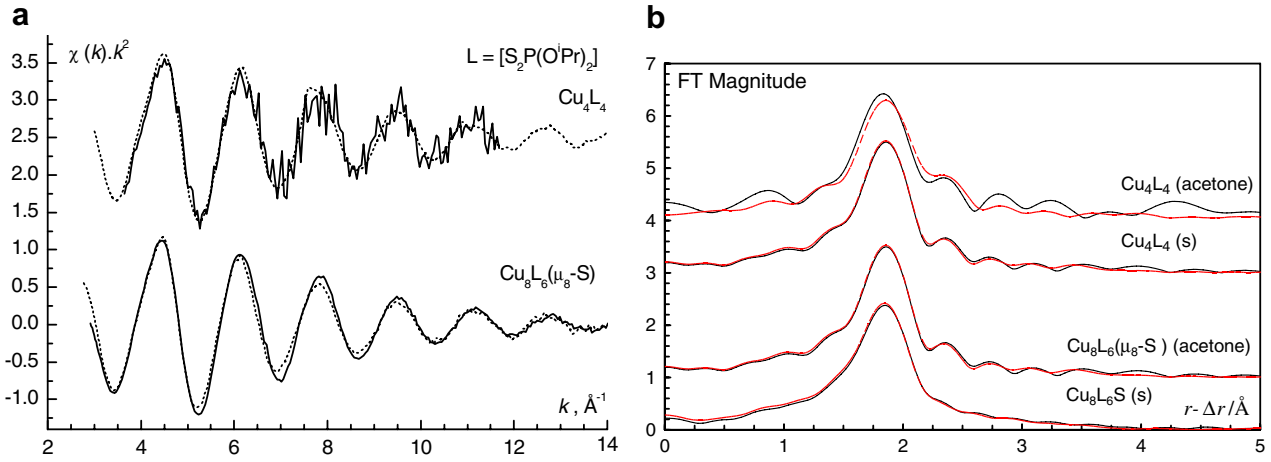

Fig. 6. (a) Raw copper K-edge EXAFS data of $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ in the solid-state and in an acetone solution (no offset) and of $\{Cu_4[S_2P(O^iPr)_2]_4\}$ in the solid-state and an acetone solution (offset +2.5), broken lines – solid-state and solid lines – acetone solutions; (b) fitted Fourier transforms of $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ in the solid-state (no offset) and in an acetone solution (offset +1.0) and of $\{Cu_4[S_2P(O^iPr)_2]_4\}$ in the solid-state (offset +3.0) and in an acetone solution (offset +4.0), solid black lines – experimental data and broken red lines – model; (s) indicates data in the solid-state.

Acetone	2.84(3)	0.024(3)	3	2.262(5)	0.0055(5)	3			

[a] Data are taken from Ref. [6c].

The two acetone solutions were further studied by ^{31}P NMR and the data are shown in Table 1. Both compounds display a single ^{31}P NMR resonance line with isotropic shifts at 98.6 ppm. An isotropic chemical shift of 97.4 ppm was recorded for both when the samples were dissolved in CH_2Cl_2. The effect of the concentration was studied by taking several measurements with different sample concentrations in both solvents, and no differences in the aforementioned ^{31}P isotropic shifts were detected. It has been reported that in the absence of acid–base interactions between a solvent and a solute (which cause a change in the connectivity at the phosphorus), solvent effects (due to some inter-molecular interactions between the solute and the solvent) [27]) on phosphorus chemical shifts in the M-*O*,*O*′-dialkyldithiophosphate compounds (M = Zn, Hg, Pb, As, Sb and Bi) are small, typically from 1 to 2.2 ppm [33]. Therefore, the slightly different chemical shifts observed for the compounds in the two different solvents used clearly show that the PO_2S_2 tetrahedra in the two different clusters have very similar characteristics, and show ^{31}P NMR spectra that are averaged by the molecular tumbling to a single resonance line at the same chemical shift.

These results are not surprising when the ^{31}P CP/MAS NMR is considered in more detail with the crystallographic data for the systems. The corresponding isotropic ^{31}P chemical shifts for the two compounds in the solid-state together with their mean value for each compound are also shown in Table 1. These averages (97.2 and 98.0 ppm) are very close to the positions of the lines found in the liquid-state ^{31}P NMR spectrum and are therefore good indicators of the shifts in those spectra. In previous studies, we have reported ^{31}P NMR data for monomeric and dimeric zinc(II) *O*,*O*′-dialkyldithiophosphate complexes (in the solid-state, in acetone and chloroform solutions, and in melts) and differences of about 2–3 ppm between the expected isotropic chemical shifts (based on the solid-state data) and isotropic chemical shifts in the liquid-state (or melts) were observed [26a]. Therefore, the above difference of 0.8 ppm in the chemical shifts is likely to result in very similar or identical isotropic chemical shifts in liquid-state ^{31}P NMR spectra of these systems even though the exact value(s) cannot be predicted. When the crystal structures of the corresponding solid cluster compounds were analysed (by averaging all P–O and P–S bond distances and corresponding bond angles in the PO_2S_2 tetrahedra in each structure) it was found that the average bond distances in the P-tetrahedra differ by less than 0.01 Å for the two clusters and the differences in the corresponding average bond angles are less than 0.4°. These data are therefore very similar and are unlikely to cause the occurrence of two different isotropic chemical shifts in a ^{31}P NMR spectrum (where the accuracy of the data is limited to 0.1 ppm).

All of our attempts to record $^{63/65}Cu$ NMR spectra of the compounds in acetone or CH_2Cl_2, were unsuccessful, probably due to significantly distorted tetrahedral configurations of the copper sites [34].

4.3. Characterization of synthetic chalcocite surfaces when treated with K[S$_2$P(O^{i}Am)$_2$] and [S$_2$P(O^{i}Am)$_2$]$_2$: ^{31}P NMR studies

The ^{31}P CP/MAS NMR spectra of synthetic chalcocite samples treated with a 10 mM aqueous solution of the collector, $K[S_2P(O^iAm)_2]$ and with the oxidized collector, $[S_2P(O^iAm)_2]_2$, are shown in Figs. 2b and c, respectively. In both cases, a broad (about 8 ppm) centre-band resonance at about 100 ppm, flanked by the spinning sidebands is observed. No changes in the spectra were observed when a single pulse ^{31}P NMR experiment was conducted on these samples and no resonance lines corresponding to the phosphorus sites in the disulfide (at 85.0 ppm, see Table 2) were detected.

The spinning sideband patterns for the two samples are very similar and also resemble that for the pure cluster compound **2** (compare to Fig. 2a). Results of a de-convolution procedure and the following CSA simulations reveal that the ^{31}P CSA parameters (together with δ_{iso}) are similar (within the confidence limits) to those for **2**. The phosphorus sites on the collector-treated chalcocite surface and on the disulfide-treated surface show negative values of δ_{aniso} between −62 and −72 ppm and both correlate with the values of δ_{aniso} between −62 and −70 ppm for **2**, discussed above. This confirms the presence of only bridging-type coordination in the di-*i*-amyldithiophosphate species formed on the mineral surface. Furthermore, it can be concluded that treatments with a collector or an oxidized collector (disulfide in this case) both result in the formation of the same type of copper(I) *O*,*O*′-dithiophosphate species on the surface of synthetic chalcocite, and in the case of the *O*,*O*′-di-*i*-amyldithiophosphate derivative the dominant species have the $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$ type structure. These data correlate well with our previous studies of chalcocite surfaces (treated with $K[S_2P(O^iBu)_2]$ as a collector) where a mixture of $\{Cu_8L_6(S)\}$ and $\{Cu_6L_6\}$ species ($L = [S_2P(O^iBu)_2]$) on the mineral surface was detected [7b].

The fact that no traces of disulfides were observed in the ^{31}P NMR spectra of any of the collector treated Cu_2S samples in our previous and current studies, and that the disulfide-treated surfaces do not show the presence of adsorbed disulfide, show that the disulfide is quantitatively reduced and complex bound by copper ions to the corresponding copper(I) dithiophosphate cluster species formed at the chalcocite surface. However, such a reduction process must be accompanied by a corresponding oxidation process. Our preliminary adsorption studies of disulfide on synthetic sphalerite (ZnS) activated by copper(II), and Cu_2O surfaces, show that the corresponding copper(I)–dithiophosphate species are formed on the sphalerite surface and that the disulfide remains almost un-altered on the Cu_2O surface. The observations indicate that the model of interaction of the collector with the mineral surface should be re-considered with respect to the properties of the metal-sulfur containing mineral surfaces.

An interesting vibration spectroscopy study of the interaction between some sulfide minerals and *O*,*O*′-diethyldithiophosphate ions (DTP) in aqueous solutions was reported in 1994 [35]. The formation of disulfide at the mineral surfaces is ascribed as a result of a red-ox process between the *O*,*O*′-diethyldithiophosphate ions and highly oxidizing species such as $S_2O_8^{2-}$ and/or $S_2O_7^{2-}$, which are likely to exist on the surfaces of sulfide minerals that are characterized by short S···S distances (less that 3.6 Å) [35]. A relationship between the shortest S···S distance in the sulfide mineral and the type of product formed at the mineral surface (metal–dithiophosphate complex or disulfide) was proposed and for the surface of chalcocite (which has a longer S···S distance of 3.71 Å [36]) only the formation of ''CuDTP''-species was predicted and detected. This fact can also explain the absence of disulfide on the chalcocite surface (as reported in this study), based on the crystallographic characteristics of the mineral.

As the formation of $S_2O_8^{2-}$ and or $S_2O_7^{2-}$ ions at the chalcocite surface is very unlikely, a possible explanation of the disulfide–surface interactions at the mineral surface is that a process of involving the simultaneous oxidation of the sulfide ions at the surface occurs when the disulfide at the chalcocite surfaces is reduced to dithiophosphate ions. This can also be considered for the copper(II)-activated sphalerite surface even though the exact distribution of copper atoms at the surface is not known. The disulfide is not strong enough to oxidize the S^{2-} to SO_3^{2-} or SO_4^{2-} ions but poly-sulfur ions can probably still be formed. Similar oxidation processes on the surface of Cu_2O are not expected due to the chemical properties of O^{2-} ions. If only the copper ions were involved in the red-ox reaction between the disulfide and the chalcocite surface then the ''Cu-DTP'' species would have been formed at the surface of the Cu_2O treated with disulfide. More detailed studies involving different concentrations of the disulfide and further studies on the adsorption processes at different surfaces are, indeed, needed to reveal the actual interaction process between the collector and/or disulfide, and the chalcocite.

5. Conclusions

The polycrystalline $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ and $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$ cluster compounds were synthesized and characterized by solid-state ^{31}P CP/MAS and static ^{65}Cu (at multiple magnetic field strengths) NMR. The ^{31}P and ^{65}Cu isotropic and anisotropic chemical shifts and ^{65}Cu quadrupolar interaction parameters for the cluster compounds were estimated by simulating the experimental NMR spectra. Three different quadrupolar line-shapes were detected in the solid-state static ^{65}Cu NMR spectrum of $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ while only two were distinguishable in the case of $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$. The dithiophosphate ligand shells show a chemical equivalence in pairs of the six phosphorus sites (in both cases). Significantly different short transverse relaxation time constants, T_2, of 590 μs (Gaussian) and 90 μs (exponential), were determined for the octanuclear copper(I) cluster compounds, $\{Cu_8[S_2P(O^iPr)_2]_6(\mu_8\text{-}S)\}$ and $\{Cu_8[S_2P(O^iAm)_2]_6(\mu_8\text{-}S)\}$, respectively. The difference was ascribed to effects originating in the alkyl chains, despite the chemically identical local environment for all the copper sites, $[CuS_3\ldots S_{centre}]$.

The structural appearances of poly-nuclear cluster compounds $\{Cu_4L_4\}$ and $\{Cu_8L_6(S)\}$ ($L = S_2P(OR)_2$ with $R = {}^iPr$) in acetone solutions were examined by copper K-edge EXAFS and liquid-state ^{31}P NMR. It was determined that these structures are in principle the same in the solid-state and in the acetone solutions, and show identical ^{31}P isotropic chemical shifts in the liquid-state (acetone and CH_2Cl_2).

The adsorption mechanism of potassium *O*,*O*′-di-*iso*-amyldithiophosphate and of the corresponding disulfide on synthetic chalcocite surfaces were examined by means of solid-state ^{31}P NMR. From these data, it is concluded that which species are formed at the mineral surfaces is independent of the form of the dithio-ligand (a potassium salt or a disulfide). The ^{31}P chemical shift data (both isotropic chemical shifts and CSA's) for the species formed on the synthetic chalcocite surfaces were used to assign these species to a phase with a $\{Cu_8L_6(S)\}$ type structure, $L = S_2P(O^iAm)_2$.

Acknowledgements

The work was financed by Agricola Research Centre at Luleå University of Technology. The Varian/Chemagnetics Infinity CMX-360 spectrometer was purchased with a grant from the Swedish Council for Planning and Coordination of Research (FRN) and further upgraded with a grant from The Foundation to the memory of J.C. and S.M. Kempe. ^{65}Cu NMR measurements were initiated during a Framework 5 Marie Curie Training program at the University of Warwick, UK. The EXAFS data were carried out at MAXLab, University of Lund, and supported by The Swedish Research Council and The Wallenberg Foundation. The MAXLab, Lund University, is gratefully acknowledged for allocation of beam-time and putting laboratory facilities at our disposal. MAXLab is supported by The Swedish Research Council and The Knut and Alice Wallenbergs Stiftelse, and additional support was made by The Crafoordska Stiftelse and The Faculty of Science & Technology, Norwegian University of Science & Technology. We are grateful to Marshall Hughes, Organic Mass Spectroscopy Facility in the CSL at University of Tasmania, for the FAB-mass measurements of the cluster compounds. The authors also acknowledge *CHEMINOVA AGRO A/S* for dithiophosphate reagents. RD thanks the Leverhulme Trust for support. We thank Dr. Andy Howes, University of Warwick, UK for discussions and we are grateful for the support from Dr. Stefan Carlson at the MAXLab.

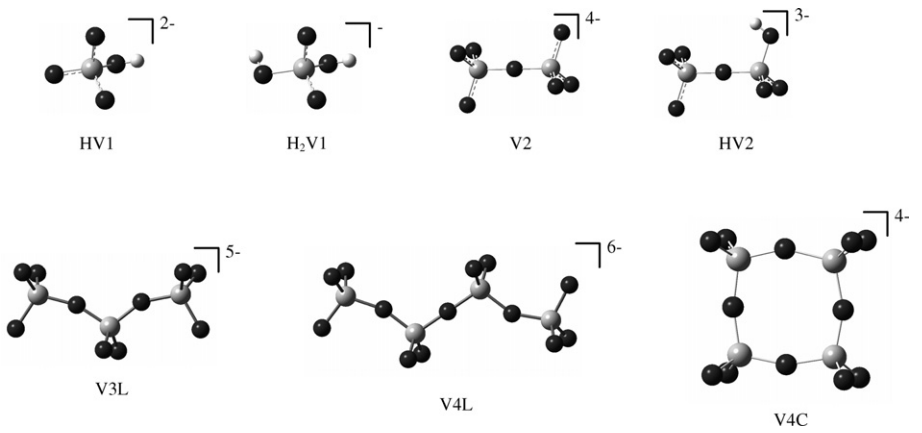

Fig. 1. Schematic structures of the main species in vanadate aqueous solutions (adapted from Refs. [3,4]) HVO_4^{2-} (HV1), $H_2VO_4^-$ (H_2V1), $V_2O_7^{4-}$ (V2), $HV_2O_7^{3-}$ (HV2), $V_3O_{10}^{5-}$ (V3L), $V_4O_{13}^{6-}$ (V4L) and $V_4O_{12}^{4-}$ (V4C).

it should be emphasized that not only hydrophobic interactions will lead to an association between a guest molecules and CD. Ionic solutes, such as non-associated inorganic salts, can also be involved in these complexes [13–15].

The present paper intends to fill this gap, and report conductance measurements and diffusion coefficients for vanadium (V) in aqueous solutions of β-cyclodextrin (β-CD) at 298.15 K. These studies are complemented and supported by nuclear magnetic resonance (NMR) spectroscopic studies in order to identify the dominant species involved in the diffusion and conductivity processes. To obtain a better understanding of the structure of the chemical species formed, we have complemented these studies using molecular mechanics calculations. Finally, a model to calculate the association constant between vanadium (V) and β-CD has been developed and the association constant estimated.

2. Experimental

2.1. Reagents

Ammonium monovanadate (Merck, *pro analysi*, >99%) was used without further purification. β-CD was purchased from Sigma (*pro analysi* >99%), and had a water content 13.1% as verified from thermal analysis.

Aqueous solutions were prepared using bi-distilled (diffusion measurements) or Millipore-Q (conductance measurements) water, and D_2O (NMR spectroscopy).

All solutions were freshly prepared before each experiment.

2.2. Diffusion measurements

Diffusion coefficients were measured with an open-ended capillary cell. The apparatus assembled for use with the open-ended capillary cell in this laboratory is essentially the same as previously reported [16]. The cell has two vertical capillaries, each closed at one end by a platinum electrode and positioned one above the other with the open ends separated by a distance of about 14 mm.

The upper and lower tubes, initially filled with solutions of concentrations $0.75c$ and $1.25c$, respectively, were surrounded with a solution of concentration c. This ambient solution was contained in a glass tank ($200 \times 140 \times 60$) mm immersed in a thermostat at 298.15 K. The tank was divided internally by Perspex sheets and a glass stirrer created a slow lateral flow of ambient solution across the open ends of the capillaries. Experimental conditions were such that the concentration at each of the open ends was equal to the ambient solution value c. That is the physical length of the capillary tube coincided with the diffusion path, such that the boundary conditions described in the literature [16] to solve Fick's second law of diffusion are applicable. As a consequence, the so-called Δl-effect [16] is reduced to negligible proportions. In contrast to a manual apparatus, where diffusion is followed by measuring the ratio of resistances of the top and bottom tubes, $w = R_t/R_b$, by an alternating current transformer bridge, in our automatic apparatus w was measured by a Solartron digital voltmeter (DVM) 7061 with 6 1/2 digits. A Bradley Electronics Model 232 power source supplied a 30 V sinusoidal signal of 4 kHz (stable up to 0.1 mV) to a potential divider that applied a 250 mV signal to the platinum electrodes at the top and bottom capillaries. By rapidly (<1 s) measuring the voltages V' and V'' from top and bottom electrodes to the central electrode at ground potential, the value $w = R_t/R_b$ was then calculated from the DVM reading.

To measure the differential diffusion coefficient, D, at a given concentration c, a "top" solution of concentration $0.75c$ and a "bottom" solution of concentration $1.25c$ were prepared, each in a 2 L volumetric flask. The "bulk" solution of concentration c was produced by mixing accurately measured volumes of 1 L of "top" solution with 1 L of "bottom" solution. The ammonium monovanadate solutions were prepared by heating to 353.15 K and then allowing them to cool to 298.15 K. The glass tank and the two capillaries were filled with solution c, immersed in the

thermostat, and were allowed to come to thermal equilibrium. The quantity $TR_{inf} = 10^4/(1 + w)$ was then measured very accurately. Here $w = R_t/R_b$ is the electrical resistance (R) ratio for solutions of concentration c of the top (t) and bottom (b) diffusion capillaries at infinite time. $TR = 10^4/(1 + w)$ is the equivalent at any time t.

The capillaries were filled with "top" and "bottom" solutions, which were allowed to diffuse into the "bulk" solution. Resistance ratio readings were taken at recorded times, beginning 1000 min after the start of each experiment. The diffusion coefficient was evaluated using a linear least-squares procedure to fit the data, followed by an iterative process which uses 20 terms of the expansion series of the solution of Fick's second law for the present boundary conditions. The theory developed for this cell has been described previously [16].

2.3. Conductance measurements

Solution electrical resistances were measured with a Wayne-Kerr model 4265 Automatic LCR meter at 1 kHz. A Shedlovsky-type conductance cell was used. Cell constants ($\approx$0.1417 ($\pm$0.0001) cm^{-1}) were determined from measurements with KCl (reagent grade, recrystallized, and dried) using the procedure and data of Barthel et al. [17]. Measurements were made at 298.15 ± 0.01 K. Solutions were always used within 12 h after preparation.

In a typical experiment a vanadium (V) solution (of concentration around 5 mM) was placed in the conductivity cell; then, aliquots of the β-CD solution (dissolved in ammonium monovanadate solution of the same concentration as that in the conductivity cell, to maintain a constant NH_4VO_3 concentration throughout the experiment) were added in a stepwise manner using a micropipette. The concentration of β-CD was varied from 0 to 8 mM. The conductance of the solution was measured after each addition. All solutions were freshly prepared just before each experiment.

2.4. NMR measurements

The ^1H, ^{13}C and ^{51}V NMR spectra were obtained on a Varian UNITY-500 NMR spectrometer (at 499.824, 125.692 and 131.404 MHz, respectively). The ^1H NMR spectra were recorded using spectral widths of 5000 Hz, acquisition times of 5 s, pulse delays of 5 s and about 320 pulses. The residual water signal was reduced by using the Presat sequence. The ^{13}C NMR spectra were obtained using proton-decoupling techniques taking advantage of the nuclear Overhauser effect due to the low intensity of the signals as a consequence of the bound ligand; spectral widths of 30000 Hz, acquisition times of 1 s, pulse delays of 10 s and about 5000 pulses were employed. The methyl signal of *tert*-butyl alcohol was used as internal reference for ^1H ($\delta = 1.3$) and ^{13}C ($\delta = 31.2$) relative to TMS. The ^{51}V NMR spectra were obtained using $VOCl_3$ ($\delta = 0$) as external reference, typically with spectral widths of 80000 Hz, acquisition times of 0.04 s, pulse delays of 0.02 s and about 16000 pulses. Slow exchange is confirmed in this system since in the ^1H and ^{13}C NMR spectra distinct signals appear for bound and free ligand.

2.5. Molecular mechanics studies (MM2)

Molecular mechanic studies are a valuable tool to interpret atom or ion dynamics of solute/solvent interactions in molecular systems involving large numbers of molecules or ions [18]. The calculations presented in this study were performed using the MM+ molecular mechanics force field, with a Polak–Ribiere algorithm having a convergence limit o 0.2 kJ/A mol, performed on a 3.2 MHz Pentium 4 workstation with HyperChem v6.

3. Results and discussion

3.1. NMR spectra of NH_4VO_3 in aqueous solutions of β-cyclodextrin

The ^{51}V NMR spectrum of a D_2O solution of NH_4VO_3 5×10^{-3} M (pH $\approx$ 7.5) shows four signals that can be assigned to tetrahedral monovanadate, divanadate, tetravanadate and pentavanadate [19]. In the presence of β-cyclodextrin (1×10^{-3} M), the slow equilibrium between oligomeric species is slightly changed and in the ^{51}V NMR spectra of solutions of NH_4VO_3/β-cyclodextrin (pH $\approx$ 7.5) in D_2O, in addition to the tetrahedral monovanadate (V_1), divanadate (V_2), tetravanadate (V_4) and pentavanadate (V_5) ions, it is possible to identify one additional signal ($\delta = -542$ ppm), that can be assigned to complex species formed between vanadate (V) and β-cyclodextrin. These species are also detected in the ^1H NMR spectra and in the ^{13}C NMR spectra for solutions with higher β-cyclodextrin concentrations.

When β-cyclodextrin is added to the vanadate solution, the signals due to oligomeric species V_1 and V_2 and V_4 decrease in intensity, and the spectra indicate the formation of the complex species. ^{51}V chemical shifts of complexes detected with β-cyclodextrin, suggest the presence of octahedral metal centres [3,19–21] in the complex (Fig. 2 and Table 1).

Mixtures of ammonium vanadate and β-cyclodextrin, in aqueous solution, show two additional sets of ^1H and ^{13}C signals, whose intensities depend on concentration and molar ratios, which are assigned to the complexed forms, in addition to those of the free ligand which is always present in excess.

Regarding the ^{13}C NMR spectra, the high frequency shifts relative to the free ligand observed upon binding ($\Delta\delta$) for carbinol carbon nuclei C-2 and C-3 are characteristic of the involvement of OH-2 and OH-3 groups in complexation as follows: for C-1, C-2, C-3 and C-5 two signals for bound ligand are detected in each case, which $\Delta\delta$ are 2.22 and 0.22 ppm, 8.79/11.26 and 7.89 ppm and 11.74, 10.23/7.75 ppm, and 1.55 and 0.38 ppm, respectively. For

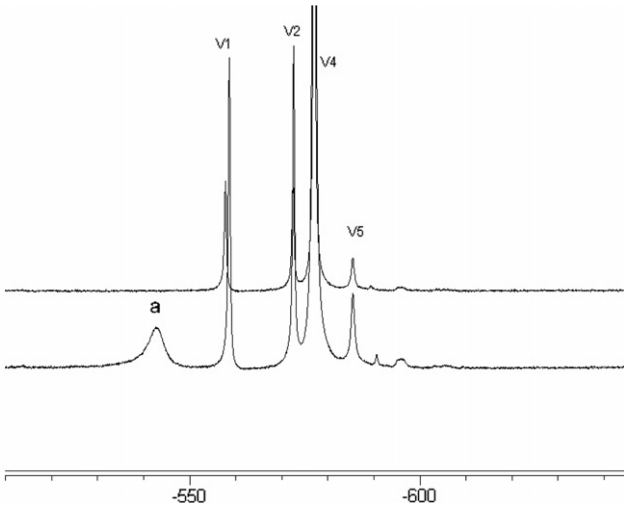

Fig. 2. ^{51}V NMR spectra (131.404 MHz) of a 5 mM solution of NH_4VO_3 (top) and a 5 mM:1 mM solution of NH_4VO_3/β-CD (bottom), pH ≈ 7.5, 298.15 K.

Table 1
Concentrations of vanadate species[a,b] obtained from ^{51}V NMR at 298.15 K

	V_1	V_2	V_4	V_5	CD2V
NH_4VO_3[c]	0.48	0.53	3.69	0.30	0.0
NH_4VO_3/β-cyclodextrin[d]	0.47	0.52	3.28	0.26	0.47
NH_4VO_3/β-cyclodextrin[e]	0.40	0.49	1.87	0.06	2.17
NH_4VO_3/β-cyclodextrin[f]	0.32	0.30	1.00	0.05	3.33
NH_4VO_3/β-cyclodextrin[g]	0.36	0.25	0.84	0.03	3.52

[a] The concentration of all the vanadate species are shown as vanadium atom concentration in millimolar dm^{-3} units and are obtained the ^{51}V integrals. Ionic strength was not controlled.

[b] V_1, monomeric vanadate; V_2, dimeric vanadate; V_4, tetrameric vanadate; V_5, pentameric vanadate; CD2V complex possessing octahedral centres.

[c] 5 mmol dm^{-3} solution, pH ≈ 7.5.

[d] 5.0:1.0 mmol dm^{-3} solution, pH ≈ 7.5.

[e] 5.0:5.6 mmol dm^{-3} solution, pH ≈ 7.5.

[f] 5.0:10.0 mmol dm^{-3} solution, pH ≈ 7.5.

[g] 5.0:13.0 mmol dm^{-3} solution, pH ≈ 7.5.

C-4 and C-6 only one signal is detected for bound ligand in each case, for which $\Delta\delta$ values are 0.15 and 0.56 ppm, respectively, presumably due to the superposition of the remaining signals with those of the free ligand. Similarly, in the ^1H NMR spectra, the protons H-2 and H-3 undergo a significant chemical shift, which is to high frequencies. Although the two signals relative to bound ligand are not observed for H-2, due to superposition with those of the free ligand, two signals for bound ligand are detected for H-3 ($\Delta\delta$ 0.67 and 0.52 ppm).

Thus, the coordination sites of the ligand should involve the (2,3)-diol group of two glucose moieties from different β-CD units, since the diol coordination requirements for an octahedral complex can only be fulfilled with four hydroxyl groups and the cyclic structure of the β-cyclodextrin does not allow four coordination sites in the same cyclodextrin molecule.

All these findings, associated with the fact that the two ligand molecules are magnetically equivalent, points to the conclusion that the two sets of bound ligand detected in the ^1H and ^{13}C NMR spectra are due to two 2:1 (ligand: metal) diastereoisomers (CD2V) differing in the relative configuration of O-2 and O-3 around the octahedral metal centre. Complexes have been characterized of Mo(VI) and W(VI) with α-hydroxyacids and sugar acids in aqueous solution having similar geometry [22,23].

3.2. Molecular mechanics analysis

From molecular mechanics, vanadium (V) coordination through oxygen 2 and 3 of a glucose residue from both β-CD rings with vanadium (V) induces just small conformational reorientation in all glucose rings of both β-CD molecules, but the main effect appears to be the tilting of one β-CD molecule relative to the other. Starting with both β-CD in a "in plane" situation, the MM+ geometry minimization always leads to a perfect octahedral coordination in vanadium (V) with the two β-CD molecules displaced by 45° (Fig. 3).

The energy variations before and after the vanadium coordination also support the 2:1 ratio of β-cyclodextrin/octahedral vanadium. The sum of the vacuum energies calculated for an isolated set of two β-cyclodextrin and an octahedral vanadium ($V(=O)_2(OH)_4$) is 890.2 kJ/mol and the calculated energy for the two β-cyclodextrin coordinated with an octahedral vanadium is 874.5 kJ/mol, showing a very small beneficial effect in the final coordination compound. The perfect octahedral coordination at vanadium

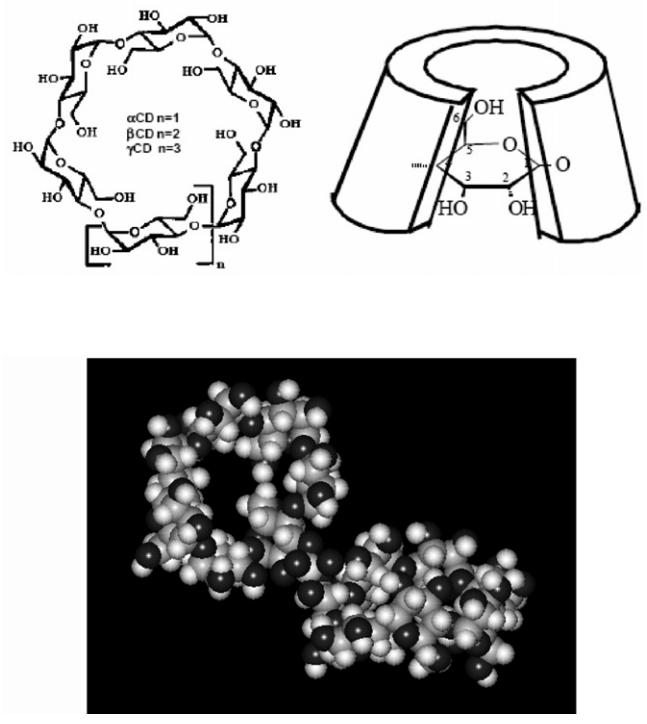

Fig. 3. 3D minimized structure of the 2:1 β-CD/vanadium complex.

and the energy calculations both point to 2:1 ratio β-cyclodextrin/octahedral vanadium (V) complexation, in agreement with the NMR data.

3.3. Electrical conductivity

Fig. 4 shows the effect of the β-CD on the molar conductivity of aqueous solutions of NH_4VO_3 at 298.15 K. The molar conductivity (Λ) was calculated using

$$\Lambda = (\kappa - \kappa_0)/(c \times 1000) \quad (1)$$

where κ and κ_0 are specific conductances of solution and water, respectively, and c is the ammonium vanadate concentration. The molar conductivity of the ammonium vanadate solution decreases with the addition of β-CD, providing further evidence for complexation between the NH_4VO_3 and β-CD. As a consequence, an appreciable fraction of the transport of NH_4VO_3 may occur via these larger aggregates, which will lead to high resistance to motion through the liquid and, consequently, a lower mobility and a decrease in the conductivity, as found; that is, the complexes are less effective as charge carriers (the ion mobility is decreased upon complexation). From the analysis of Fig. 4, it is also possible to conclude that no plateau of molar conductivity as a function of [β-CD] is reached at $[\beta\text{-CD}]/[NH_4VO_3] < 2$, which is a further evidence that no 1:1 complexation is occurring.

3.4. Diffusion coefficients of NH_4VO_3 in aqueous solutions of β-cyclodextrin

Tables 2 and 3 show the experimental diffusion coefficients with ammonium monovanadate solutions of concentrations from 1×10^{-3} to 5×10^{-2} M at 298.15 K alone, and in the presence of β-cyclodextrin. These results are the average of three experiments performed on consecutive days. Good reproducibility was observed, as seen by the small standard deviations of the mean, S_{Dav}. Previous papers [24,25] reporting data obtained with our conductivity cell have shown that the inaccuracy of our results should be close to the imprecision, giving therefore an experimental uncertainty 1–2%.

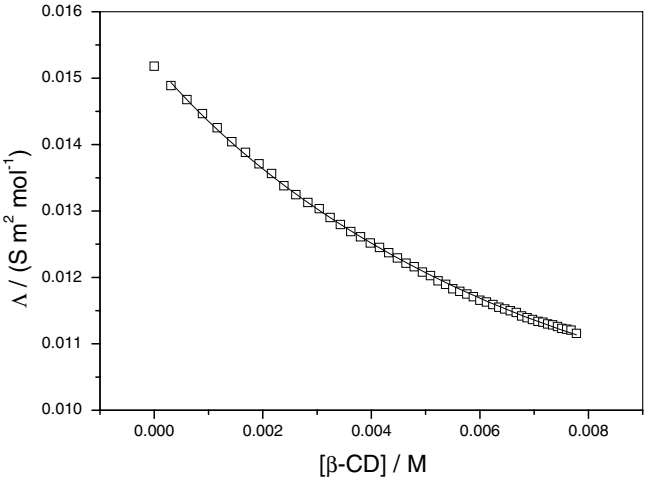

Fig. 4. Dependence of the molar conductivity of the NH_4VO_3 (4.907 mM) on the β-cyclodextrin concentration, at 298.15 K. Solid lines represent molar conductivities predicted by Eq. (9) using the parameters shown in Section 3.5.

Table 2
Diffusion coefficients, D, of NH_4VO_3 in aqueous solutions at 298.15 K at different concentrations, c (see Ref. [3])

c (M)	D (10^{-9} m^2 s^{-1})[a]	TR_{inf}[b]	S_{Dav} (10^{-9} m^2 s^{-1})[c]
0.001	1.264	5 000.5	0.018
0.003	1.203	4 999.8	0.009
0.005	1.174	5 000.0	0.003
0.008	1.147	5 000.1	0.006
0.010	1.135	5 000.2	0.010

0.030	1.110	5 011.1	0.007
0.050	1.090	4 995.5	0.008

[a] Mean value of D_{exp} in three experiments.
[b] $TR_{inf} = 10^4/(1 + w)$, where $w = R_t/R_b$ is the resistance ratio of top and bottom capillaries.
[c] S_{Dav} is the standard deviation of the mean of three experiments.

Table 3
Diffusion coefficients, D[a], of NH_4VO_3 in aqueous solutions of β-cyclodextrin (0.001 M) at different concentrations, c, and the standard deviations of the means, S_{Dav}

c (mol dm^{-3})	$T = 298.15$ K		
	D (10^{-9} m^2 s^{-1})[a]	S_{Dav} (10^{-9} m^2 s^{-1})[b]	$\Delta D/D$ (%)[c]
0.001	1.046	0.003	−17.2
0.01	1.058	0.002	−6.8
0.02	1.072	0.005	−3.9
0.05	1.112	0.001	+2.0

[a] D is the mean diffusion coefficient for three experiments.
[b] S_{Dav} is the standard deviation of that mean.
[c] $\Delta D/D$ represent the relative deviations between the diffusion coefficients of NH_4VO_3 at the specified concentration in 0.001 M β-cyclodextrin, D, and that of the NH_4VO_3 in water, D (Table 2).

From Table 2, the decrease of the diffusion coefficient of ammonium monovanadate in aqueous solutions with increasing concentration strongly suggests the presence of new species (e.g., $V_4O_{12}^{4-}$) resulting from condensation of the salt. The decrease of D with concentration may be explained by assuming those species have a lower mobility than other anions because of their size. The eventual onset and formation of ion pairs upon increasing concentration may also contribute to the decrease of D with concentration [24].

The β-cyclodextrin molecules exert a significant influence on the diffusion of ammonium monovanadate in the various aqueous solutions ($c \leqslant 0.05$ M). Under the present experimental conditions, i.e., $[NH_4VO_3]/$[carbohydrate] ratio values $\geqslant 1$ and dilute solutions, the motion of the solvent and the change of parameters such as viscosity, dielectric constant and degree of hydration with concentration, can be neglected. With a concentration gradient in a solution with exactly the same salt

concentration as that in the above solution of NH_4VO_3 but now with identical concentrations of β-cyclodextrin, we observe that the diffusion coefficient D is lower. Assuming that D [25] is a product of kinetic (molar mobility coefficient of a diffusing substance, U_m) and thermodynamic factors ($c\partial\mu/\partial c$, where μ represents the chemical potential), we suggest that both factors decrease, when we pass from a solution of pure NH_4VO_3 to a mixed solution having both NH_4VO_3 and β-cyclodextrin. In fact, the decrease of the kinetic factor is confirmed by the conductance results at 298.15 K (Table 3). Thus, two different effects can control the diffusion process: the ionic mobility and the gradient of the chemical potential. Based on these measurements, in conjunction with the conductance measurements, we conclude that, over the concentration range studied (Table 3), the diffusion of NH_4VO_3 in aqueous solutions at 298.15 K appears to be affected by complexation or aggregate formation between vanadate ions and β-cyclodextrin. This supports the above NMR, conductance, and MM2 studies. For the same concentrations, the observed deviations in diffusion coefficients for NH_4VO_3 in the presence and absence of β-cyclodextrin, are lower than obtained for conductance. Possibly, the slight decrease of the gradient of the chemical potential with concentration can explain this behaviour. These considerations should be taken into account when studying the corrosion of dental alloys containing vanadium.

3.5. Determination of association constants

According to the discussion of the NMR experimental results (see Section 3.1), the interaction between NH_4VO_3 (V) and β-cyclodextrin (CD) leads to a 2:1 (CD:V) complex, CD_2V. Assuming that such complexation occurs in a two-step model, the equilibrium equations can be written as:

$$CD + V \rightleftharpoons CDV \quad (2)$$

$$CDV + CD \rightleftharpoons CD_2V \quad (3)$$

The stability of the association complexes, CDV and CD_2V, can be described in terms of association constant, K_{11} and K_{21}, respectively.

$$K_{11} = C_{CDV}/(C_{CD,f} \cdot C_{V,f}) \quad (4)$$

$$K_{21} = C_{CD2V}/(C_{CD,f} \cdot C_{CDV}) \quad (5)$$

According to the law of conservation of mass:

$$C_{V,f} = C_{V,t} - C_{CDV} - C_{CD2V} \quad (6)$$

and

$$C_{CD,f} = C_{CD,t} - C_{CDV} - 2C_{CD2V} \quad (7)$$

where $C_{V,t}$ and $C_{CD,t}$, and $C_{V,f}$ and $C_{CD,f}$ represent the total (t) and free (f) concentrations of V and β-CD, and C_{CDV} and C_{CD2V} are the concentrations of 1:1 and 2:1 associate species, respectively.

Considering the CD concentration range where the free vanadium, $C_{V,f}$, and the free β-cyclodextrin, $C_{CD,f}$, are in equilibrium with the complexes, CDV and CD_2V, the observed specific conductance, κ, can be expressed as:

$$\kappa = \kappa_V + \kappa_{CDV} + \kappa_{CD2V} \quad (8)$$

where κ_V, κ_{CDV} and κ_{CD2V} are ammonium monovanadate and the associate compounds (1:1 and 2:1) specific conductances.

Taking into account the definition of molar conductivity, $\Lambda = \kappa/(C \cdot 1000)$ and from combination of Eqs. (4)–(8) gives, after some algebra, the following expression for the observed molar conductivity:

$$\Lambda = \frac{\Lambda_V + \Lambda_{CDV}K_{11}C_{CD,f} + \Lambda_{CD2V}K_{11}K_{21}C_{CD,f}^2}{1 + K_{11}C_{CD,f} + K_{11}K_{21}C_{CD,f}^2} \quad (9)$$

where Λ is the observed molar conductivity.

Least-square fits were performed using in-house written soft-ware based on the Gnuplot®. The fitting results are: $K_{11} = 98\ (\pm 2)\ M^{-1}$, $K_{21} = 440\ (\pm 5)\ M^{-1}$, $\Lambda_V = 0.0152\ (0.002)\ S\ m^2\ mol^{-1}$, $\Lambda_{CDV} \to 0$, $\Lambda_{CD2V} = 0.0112\ (0.003)\ S\ m^2\ mol^{-1}$ and $R = 2.20 \times 10^{-8}\ S^2\ m^4\ mol^{-2}$. The application of the model (Eq. (9)) to the experimental results shows that: (a) $K_{11} < K_{21}$, indicating that the formation of 2:1 stoichiometric complexes predominates rather than the 1:1, and (b) the fitting is independent of Λ_{CDV} when this value is lower than $1 \times 10^{-6}\ S\ m^2\ mol^{-1}$ and approaches to zero. This latter result suggests that the concentration of CD-V complexes affecting specific conductance, κ_{CDV}, can be neglected; that is, the concentration of CD-V species can also be neglected, which is in agreement with the results presented in (a) and the NMR results where no complex 1:1 is detected.

4. Conclusions

We have measured diffusion coefficients, electrical conductivity, obtained NMR spectral data for ammonium monovanadate in aqueous solutions of β-cyclodextrin, and have complemented these studies with molecular mechanics calculations. In the presence of this carbohydrate, the diffusion behaviour of ammonium monovanadate can be explained by formation of complexes in small concentrations. These species are suggested to be responsible by the decrease of the free energy gradient driving the diffusion process and the mobility factor. From the conductivity data, the presence of this carbohydrate decreases the mobility of the ammonium monovanadate.

2. Experimental

2.1. General methods

Microanalytical (C, H, N) data were obtained with a FLASH EA 1112 Series CHNS Analyzer. A SHIMADZU 3101- PC UV/VIS/NIR spectrophotometer was used to record the electronic spectra. Infrared spectra were recorded on KBr pellets with a JASCO-5300 FT-IR spectrophotometer. The variable temperature (90–305 K) magnetic susceptibility measurements were performed using the Faraday technique with a setup comprising a George Associates Lewis Coil force magnetometer, a CAHN microbalance, and an Air Products cryostat. $Hg[Co(NCS)_4]$ was used as the standard. Diamagnetic correction (-630×10^{-6} cgsu) for $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]$ calculated from Pascal's constants [12] was used to obtain the molar paramagnetic susceptibilities.

2.2. Materials

2,6-Diformyl-4-methylphenol (dfp) was prepared according to the reported procedure [13]. L-Tyrosine and sodium hydroxide were procured from Acros India and used as received. Solvents were purified by standard methods. All other chemicals used were of analytical reagent grade and used without further purifications.

2.3. Synthesis of $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]\cdot 10H_2O$ (1)

To a solution of L-tyrosine (0.18 g, 1 mmol) in ethanol–water mixture (3:1, 40 mL) was added NaOH (0.04 g, 1 mmol) and 2,6-diformyl-4-methylphenol (0.082 g, 0.5 mmol). The reaction mixture was stirred for 1 h at room temperature. To the resulting Schiff-base (H_3L), formed *in situ*, was added $CuSO_4\cdot 5H_2O$ (0.25 g, 1 mmol), and stirred again for another 12 h at room temperature. The resulting dark green solution was filtered and the filtrate on slow evaporation yielded green crystals of **1**. The crystals lose water molecules on exposure to atmosphere (taken out from mother liquor) at room temperature (as is evidenced from TGA studies and loss of single-crystallinity). Yield after water loss 55%. IR (KBr, cm^{-1}): 3391, 1641, 1552, 1516, 1452, 1367, 1321, 1242, 1084, 1045, 885, 858, 810, 765, 542. *Anal*. Calc. for $C_{54}H_{48}N_4O_{16}Cu_4$ (after water loss): C, 51.35; H, 3.83; N, 4.44. Found: C, 50.98; H, 3.95; N, 4.18%. UV/Vis [*N*,*N*-dimethylformamide; λ_{max}/nm (ε)]: 652 (348), 378 (14,951).

2.4. X-ray crystallography

Since the crystals of compound $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]\cdot 10H_2O$ (**1**) lose water molecules once out of mother liquor at ambient conditions, the crystals of **1** were cooled immediately to 100(2) K after removing from the mother liquor. The data were collected on a Bruker SMART APEX CCD area detector system [λ(Mo–Kα) = 0.71073 Å], graphite monochromator, 2400 frames were recorded with an ω scan width of 0.3°, each for 20 s, crystal-detector distance 60 mm, collimator 0.5 mm. The data were reduced using SAINTPLUS [14] and a multi-scan absorption correction using SADABS [14] was performed. The structure was solved by direct methods; structure solution and refinement were done using the programs of SHELX-97 [15]. All non-hydrogen atoms were refined anisotropically. One of the water molecules (O(11)) shows disorder over two positions with equal occupancy. Water hydrogen atoms (except that of O(11)) were located in the differential Fourier maps and their positions were refined using isotropic thermal parameters. Additional details of the data collection parameters and refinement are collected in Table 1. The final Fourier difference synthesis showed minimum and maximum peaks of −0.363 and +0.774 e Å^{-3}.

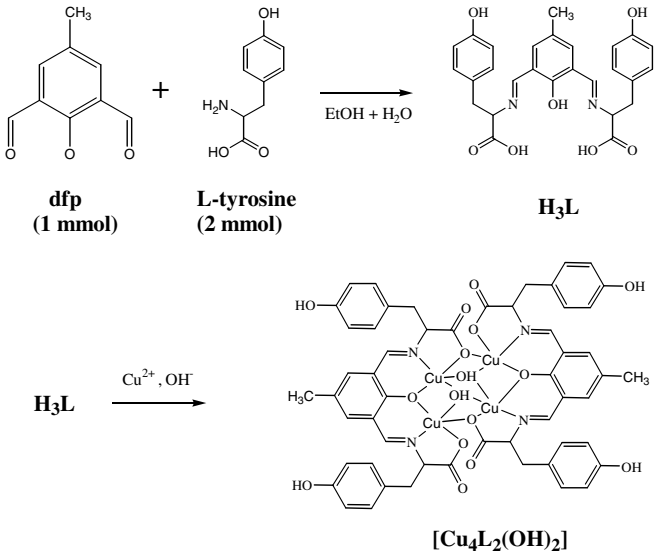
3. Results and discussion

3.1. Synthesis

The ligand H_3L, formed *in situ*, by Schiff base condensation (Scheme 1), was reacted with copper(II) sulfate pentahydrate and NaOH at room temperature in ethanol–water mixture to afford the tetra-nuclear complex $[Cu^{II}_4L_2(OH)_2]\cdot 10H_2O$ (**1**) in moderate yield. The two OH^- groups, that act as bridging ligands per tetra-nuclear complex, seems to originate from the sodium hydroxide used in this synthesis. Deprotonation of the Schiff base ligand (removal of three protons per ligand) can also be caused by the added hydroxide ions.



Scheme 1.

3.2. Description of the structure

The complex $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]$ can be formulated as $\{[Cu_2(C_{27}H_{23}N_2O_7)(OH)]\}_2$ in **1**; the centrosymmetric molecule being formed by two binuclear units, one of which is the crystallographic asymmetric unit (along with 5 water molecules). The crystal structure of the tetra-nuclear complex $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]$ in $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]\cdot 10H_2O$ (**1**) with the atom numbering scheme is shown in Fig. 1. Two binuclear units related by the center of symmetry are bridged by two hydroxide oxygen atoms O(8) and O(8)#1 (#1 $= -x+2, -y+1, -z+1$) and as a result form a tetranuclear structure. In the binuclear unit, the two copper centers are also bridged by endogenous phenolic oxygen. The coordination geometries of Cu(1) and Cu(2) in the crystallographically unique unit are slightly different. The coordination geometry of Cu(1) is square pyramidal with the basal co-ordination plane provided by O(1), O(2)and N(1) of the same binuclear unit and O(8)#1 from the adjacent binuclear unit. The axial co-ordination site is occupied by an hydroxide oxygen O(8). {Cu(1)–O(8) 2.3484(19) Å}. Atom Cu(1) deviates by 0.1074(10) Å toward the axial ligand O(8) from the equatorial co-ordination plane. The geometry of Cu(2) can also be described as distorted square pyramidal although the axial bond length is large compared to that of Cu(1). The oxygen atom O(2)#1 of the carboxylate group of the adjacent binuclear unit satisfies the fifth coordination of Cu(2) with a long axial distance of Cu(2)–O(2)#1 2.711(2) Å. The small difference in co-ordination geometries around Cu(1) and Cu(2) is also reflected in the respective bond distances. For example, Cu(2)–O(1) [1.9216(17) Å] is shorter than Cu(1)–O(1) [1.9442(17) Å].

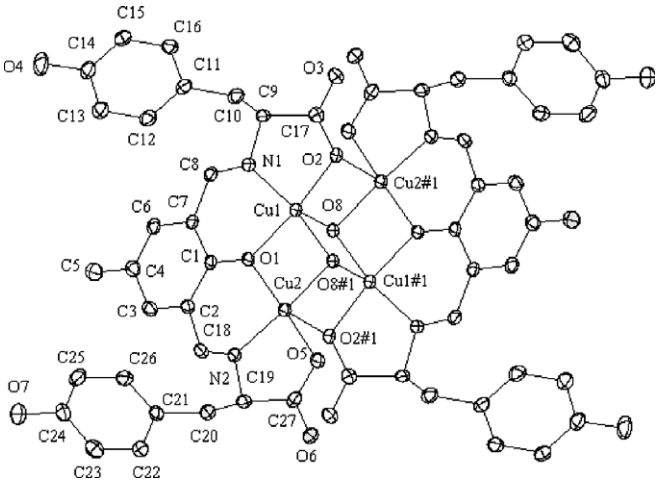


Fig. 1. Thermal ellipsoid plot of the structure of $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]$ in **1**. Hydrogen atoms have been omitted for clarity. Atoms with additional label #1 are related to each other by symmetry operations: #1 $-x+2, -y+1, -z+1$.

Although we have used a chiral amino acid L-tyrosine as starting material, it has undergone racemization under the reaction conditions. As a result, both the chiral carbons present in a particular dimer have opposite absolute configurations and the compound crystallizes in an achiral space group $P\bar{1}$ (C(9) and C(19)#1-(S) and C(19) and C(9)#1-(R)). Similar racemization phenomena have been reported previously [16].

The geometry of the centro-symmetric Cu_4O_4 central core of the molecule can be described as a 'double-open' face shared dicubane with two missing vertices (Fig. 1). One of the two cubanes may be outlined by three four-membered rings: (a) O(1)–Cu(1)–O(8)#1–Cu(2), (b) Cu(2)–O(8)#1–Cu(1)#1–O(2)#1 (c) Cu(1)–O(8)#1–Cu(1)#1–(O8) (#1 $= -x+2, -y+1, -z+1$). The two open cubanes are related by a crystallographic centre of symmetry located at the centroid of the face (c). A Cu_4N_6 defective dicubane-type motif with two missing vertices has been reported in the case of azido bridged 1D molecular railroad copper complex [17].

The most striking feature of the crystal structure of **1** is that, all five crystal water molecules, located in the asymmetric unit, are involved in forming a supramolecular acyclic water nonamer $(H_2O)_9$. This can be described as an "S" shaped water hexamer $(H_2O)_6$ connecting a near linear water trimer $(H_2O)_3$ as shown in Fig. 2 (left). Water nonamer is formed from the water molecules O(9)–O(13), located in the asymmetric unit. The O(11) water is disordered over two symmetry related positions (O(11) and O(11)#8), (#8 $-x, -y+2, -z+1$).

Infantes and Motherwell reported the patterns of water clusters within the Cambridge Structural Database (CSD) and classified them as discrete rings and chains, infinite chains and tapes, and layer structures [18]. According to their CSD search, there was only one discrete quasi-planar cyclic water nonamer known until 2002 [18]. Later, in 2005, Ghosh and Bharadwaj described a discrete open zig-zag water nonamer in an inorganic molecular crystalline hydrate [19]. Extended chain-like arrangement based on a $(H_2O)_9$ cluster is not known (CSD search until 2003)

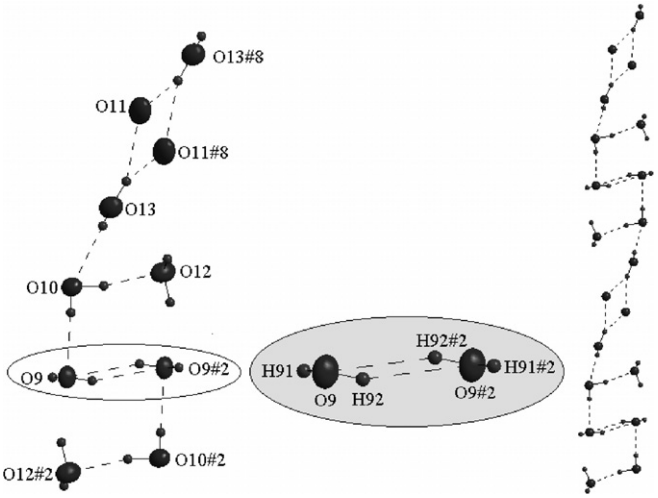

Fig. 2. Left: Water nonamer cluster consisting of a near linear water trimer and an "S" shaped water hexamer that incorporates a cyclic water dimer (highlighted in an ellipsoid). O(11) water is disordered over two positions. Middle: cyclic water dimer is highlighted separately. Right: water nonamer undergoes further hydrogen bond linking to a chainlike structure. Atoms with additional labels #2 and #8 are related to each other by symmetry operations: #2 $-x$, $2-y$, $2-z$; #8 $-x$, $2-y$, $1-z$.

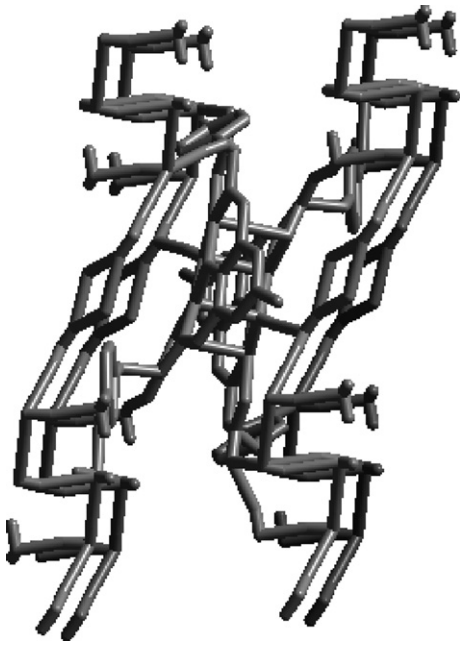

Fig. 3. $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]$ complex exhibiting its hydrogen bonding interactions with four surrounding water chains of $(H_2O)_9$ clusters.

[20]. The water nonamer, in the present study, undergoes hydrogen bond linking into an infinite chain through out the crystal lattice that extends along crystallographic *c* axis (Fig. 2, right). Very recently, Mascal et al. have published an essay on water oligomers in crystalline hydrates by choosing 17 random recent publications that describe unprecedented assemblies of water molecules and compared these structures against those already in the CSD [21]. However, the context of water nonamer is not discussed in this article.

The water nonamer, in the present case, features an inbuilt "cyclic" water dimer (O(9) and O(9)#2, Fig. 2, highlighted) of locally C_i symmetry. This dimer is formed by two O(9) water molecules which are related by a symmetry operation.

The stabilization of such $(H_2O)_9$ and $(H_2O)_2$ clusters in a molecular crystalline host is facilitated by suitable hydrogen bonding environment around the water structure. Indeed, the water chains are supported/anchored by the tetra-nuclear copper complex $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]$ in the crystal of **1** via O–H···O type hydrogen bonding interactions. Each $\{Cu_4\}$ complex connects four different water chains as shown in Fig. 3. Similarly, each water nonamer is anchored by six surrounding $\{Cu_4\}$ complexes (see Supplementary material). The hydrogen bonding parameters for the water nonamer are described in Table 2 and its interactions with the host (copper complex) are provided as Supplementary material (S-Table 3).

Table 2
Geometrical parameters of hydrogen-bonds (Å, °) in water nonamer (see Fig. 2)

D–H···A	*d*(D···H)	*d*(H···A)	*d*(D···A)	L(DHA)
O10–H101···O12	0.94(5)	1.74(4)	2.669(4)	167(3)
O10–H102···O9	0.82(4)	2.03(4)	2.848(3)	178(5)
O13–H132···O10	0.84(4)	2.10(5)	2.901(4)	158(9)
O13–H131···O11	0.89(4)	2.01(6)	2.822(6)	150(9)
O13–H131···O11#8	0.89(4)	2.16(7)	2.931(7)	144(9)
O9–H92···O9#2	0.70(3)	2.08(3)	2.747(5)	160(4)

Atoms with additional labels #2 and #8 are related to each other by symmetry operations specified in the caption of Fig. 2.

3.3. Magnetic studies

To evaluate the singlet–triplet energy separation ($-2J$), variable temperature magnetic study of the complex **1** (after solvent loss) was performed in the temperature range of 90–305 K. Despite the tetranuclear structure, the experimental magnetic susceptibility values were fitted [22] to the Bleaney–Bower's equation with a Curie type of impurity of $S = 0.5$ as shown in Fig. 4. The best fit of the magnetic data to this equation yielded $2J = -217\ cm^{-1}$, $g = 2.019$ and a TIP value of $60 \times 10^{-6}\ cm^3\ mol^{-1}$ (see Supplementary materials for magnetic details). This result may be interpreted in terms of a predominant magnetic interaction through the endogenous phenolic oxygen atom O(1) (and O(1)#1), the intra- and inter-dimer magnetic interactions through the exogenous hydroxide oxygen atom contributing little to the magnetic susceptibility (see also Fig. 1). The phenolic oxygen atom O(1) is bound to three atoms and has lone-pair electrons. On the other hand, the exogenous hydroxide oxygen atom is bound to four atoms and therefore has no lone-pair of electrons. It is likely that each bond involving the bridging oxygen with sp^3-hybridized orbitals is almost perfectly localized so that no spin-exchange interaction is operative.

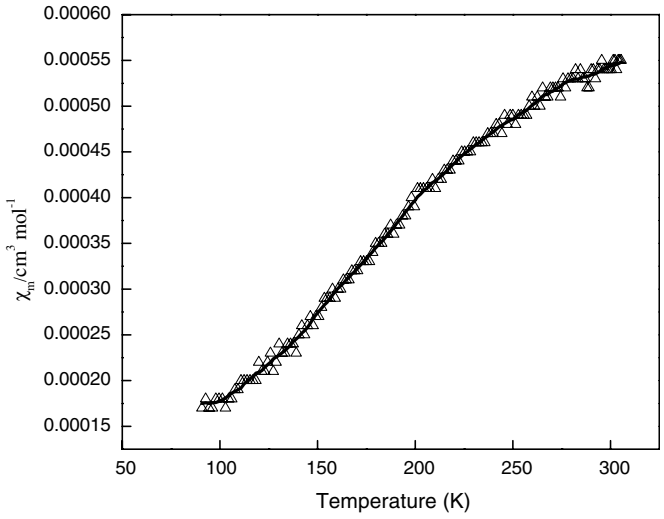

Fig. 4. Magnetic susceptibility data plotted in the form of χ_M (Δ) vs. T for complex **1** in the temperature range 90–305 K. The theoretical fit to the experimental data is shown by solid line.

3.4. TGA studies

Compound $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]\cdot 10H_2O$ (**1**) looses all ten lattice water molecules once the relevant crystals are taken out from mother liquor at room temperature (298 K). This is consistent with elemental analysis of the crystals dried at room temperature (see Synthesis of **1**). This why, the TGA curve shows almost flat feature upto ~200 °C. The loss of crystal water molecules at ambient conditions (once the crystals are removed from mother liquor) could be due to the fact that all these crystal water molecules (O(9) through O(13), see S-Figs. 2–4 in Supplementary section) are involved in forming a high energy form of water cluster. At ~250 °C, the curve show a sharp loss that corresponds to the loss of two OH^- groups of the complex $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]$ (for TGA curve, see S-Fig. 10 in Supplementary section).

4. Conclusions

We have described synthesis and characterization of a new tetra-nuclear copper(II) complex $[Cu_4(C_{54}H_{46}N_4O_{14})(OH)_2]\cdot 10H_2O$ (**1**) that features an unusual form of water nonamer, which in turn, congregates to a chainlike extended structure through-out the crystal. This is rare example of an extended water structure based on an odd numbered water cluster. The hydrogen bonding donor/acceptor sites of the copper complex in the crystal lattice provide a surrounding that stabilizes such high energy form of water nonamer inscribing a "transition state" water dimer.

Acknowledgements

We thank DST, Government of India, for financial support (Project No.: SR/S1/IC-18/2002). The National X-ray Diffractometer facility at University of Hyderabad by the Department of Science and Technology, Government of India, is gratefully acknowledged. We are grateful to UGC, New Delhi, for providing infrastructure facility at University of Hyderabad under UPE grant. We thank Professor M.V. Rajasekharan for helpful discussions. We are grateful to Professor A.R. Chakravarty of IISc. Bangalore for providing the variable temperature magnetic susceptibility data. C.P.P. and S.S. thank UGC, New Delhi for their fellowships.

Appendix A. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 286027 for compound **1**. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk). Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.07.008.

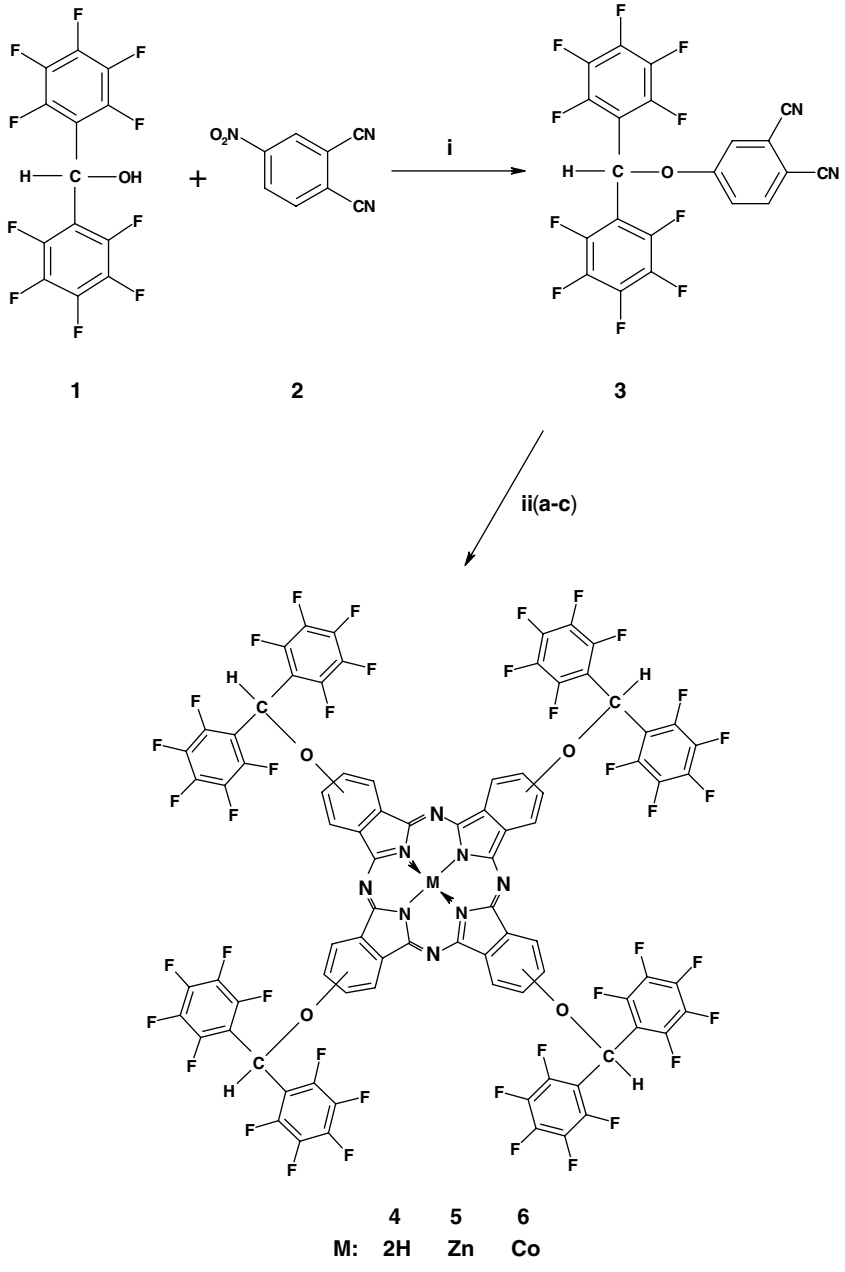
properties of some fluoro-substituted Pcs. In the case of electron-withdrawing peripheral fluorine substituents, Pcs can be dissolved even in polar aprotic solvents and become good electron donors for use as chemical sensors [9,10,12].

In this paper, we report the preparation of some new bis(pentafluorophenyl)methoxyl substituted Pc derivatives, and their spectral, electrochemical, spectroelectrochemical and electrical properties (Scheme 1).

2. Experimental

The starting material 4-nitrophthalonitrile **2** was synthesized by the methods described previously in the literature [13]. Bis(pentafluorophenyl)methanol **1** was used as supplied commercially. Routine IR and UV–vis spectra were recorded on a Shimadzu FTIR-8300 spectrophotometer as KBr pellets and a Shimadzu UV-1601 UV–vis spectrophotometer, respectively. Elemental analyses were performed by the LECO CHNS 932. Mass spectra of 4-[bis(pentafluorophenyl)methoxy]phthalonitrile **3** and Pc derivatives **4–6** were obtained by using the Agilent LC/MSD-TOF spectrometer and Micromass Quattro LC–MS/MS spectrophotometer respectively. ^{1}H NMR and ^{19}F NMR spectra were obtained on a Varian Mercury-V × 400 MHz spectrophotometer.



Scheme 1. (i) K_2CO_3, CH_3CN; (ii) a: Li, pentan-1-ol; b: $Zn(CH_3COO)_2 \cdot 2H_2O$, DMAE; c: $Co(CH_3COO)_2 \cdot 4H_2O$, DMAE.

2.1. Synthesis

2.1.1. 4-[Bis(pentafluorophenyl)methoxy]phthalonitrile (3)

A mixture of bis(pentafluorophenyl)methanol **1** (1.00 g, 2.74 mmol), 4-nitrophthalonitrile **2** (0.47 g, 2.74 mmol) and K_2CO_3 (1.14 g, 8.24 mmol) was heated for 24 h, refluxing in dry acetonitrile (40 mL) under argon. The cooled reaction mixture was filtered off and the filtrate evaporated to dryness under vacuum in a rotary evaporator. After being dried under vacuum, the yellowish viscous product was isolated with column chromatography over silica gel using chloroform as the eluent. The second fraction, which is targeted, was eluted with $CHCl_3$. On evaporation of the solvent, a white product was obtained (Scheme 1). The compound **3** is readily soluble in $CHCl_3$, CH_2Cl_2, acetone, THF, MeOH and EtOH. Yield: 0.822 g (61%), m.p. 128 °C. *Anal*. Calc. for $C_{21}H_4F_{10}N_2O$: C, 51.45; H, 0.82; N, 5.71. Found: C, 51.71; H, 0.81; N, 5.69%. MS (LC/MSD-TOF, APCI), *m/z*: 490 $[M]^+$, IR (KBr pellet) *ν*, cm^{-1}: 3090 (Ar–H), 2923–2854 (alkyl ≻CH), 2233 (C≡N), 1242 (C–O–C); ^1H NMR (*d*-$CDCl_3$): $\delta = 6.94$ (s, 1H, ≻CH), 7.24 (d, 1H, Ar–H), 7.33 (d, 1H, Ar–H), 7.76 (d, 1H, Ar–H). ^{19}F NMR (*d*-$CDCl_3$): δ (ppm) = −141.2 (d, *o*-fluoro), −149.9 (t, *p*-fluoro), −159.6 (q, *m*-fluoro).

2.1.2. Tetrakis[bis(pentafluorophenyl)methoxy]-2H-phthalocyanine (4)

Compound **3** (0.245 g, 0.5 mmol) was added to 5 mL pentan-1-ol and heated to dissolve. An excess of Li wire was subsequently added to the solution. As the Li was added, a large quantity of gas was evolved and the reaction mixture turned to dark green. The mixture was heated at reflux under nitrogen for 5 h [10]. On cooling, 30 mL of AcOH/H_2O (1:1-v/v) was added to the mixture and stirred for 20 min at the room temperature. The resulting waxy green Pc phase was separated from the mixture. The Pc product which remained in the flask was washed with water three times, and the residue was dried under vacuum to give tarry green Pc (Scheme 1). The crude Pc **4** was treated with three portions of 30 mL of ($CHCl_3$/H_2O – 3:1) (v/v) mixture. After the separation of the $CHCl_3$ phases, the $CHCl_3$ extracts were then combined, dried with anhydrous Na_2SO_4, and the total volume was evaporated to dryness using a rotary evaporator. The purification of the aimed Pc was carried out on silica gel column with $CHCl_3$. Compound **4** is soluble in $CHCl_3$, CH_2Cl_2, THF, EtOH, MeOH, DMSO and DMF. Yield: 0.085 g (34%). *Anal*. Calc. for $C_{84}H_{18}F_{40}N_8O_4$: C, 51.39; H, 0.92; N, 5.71. Found: C, 52.02; H, 0.89; N, 5.83%. MS(LC–MS/MS, ES+) *m/z*: 1963 $[M]^+$, IR (KBr pellet) *ν*, cm^{-1}: 3297 (NH), 3073 (Ar–H), 2948–2893 (alkyl ≻CH), 1236 (C–O–C). UV–vis (DMSO) *λ*, nm (log *ε*): 700(4.72), 674(4.75), 650(4.67), 326(5.03); ^1H NMR (*d*-$CDCl_3$) *δ*: 7.41–7.96 (m, 3H, Ar–H), 6.99 (s,1H, ≻CH), −8.2 (br s, 2H, NH).

2.1.3. Tetrakis[bis(pentafluorophenyl)methoxy]-phthalocyaninato zinc(II) (5)

Compound **3** (196 mg, 0.4 mmol) and $Zn(CH_3COO)_2 \cdot 2H_2O$ (22 mg, 0.10 mmol) were mixed in dry 2-*N*-*N*-dimethylaminoethanol (DMAE) (1 mL) in a glass tube. After being degassed with a vacuum, the mixture was sealed, and heated at 150–160 °C for 5 h to give a symmetrical substituted Pc (Scheme 1). After being cooled, the reaction mixture was poured into 100 mL of ethanol and the dark green precipitate was separated by centrifuging. The product was dissolved in DMF and precipitated with a mixture of $CHCl_3$ and acetone. After filtration, the precipitate was washed successively with boiling acetic acid, water and ether, and dried under vacuum. Compound **5** is soluble in DMSO and DMF, and partly soluble in acetone, MeOH and EtOH. Yield: 0.065 g (32%). *Anal*. Calc. for $C_{84}H_{16}F_{40}N_8O_4Zn$: C, 49.79; H, 0.80; N, 5.53. Found: C, 50.56; H, 0.83; N, 5.49%. MS(LC–MS/MS, ES+) *m/z*: 2026 $[M]^+$, IR (KBr pellet) *ν*, cm^{-1}: 3087 (Ar–H), 2925–2883 (alkyl ≻CH), 1242 (C–O–C); UV–vis (DMSO) *λ*, nm (log *ε*): 698(4.84), 641(4.35), 356(4.78); ^1H NMR (DMSO-d_6): $\delta = 7.94$–7.63 (m, 3H, Ar–H), 6.81 (s, 1H, ≻CH). ^{19}F NMR (DMSO-d_6): δ(ppm) = −143.2 (d, *o*-fluoro), −156.5 (t, *p*-fluoro), −163.2 (q, *m*-fluoro).

2.1.4. Tetrakis[bis(pentafluorophenyl)methoxy]-phthalocyaninato cobalt(II) (6)

A mixture of compound **3** (0.089 g, 0.18), $Co(CH_3COO)_2 \cdot 4H_2O$ (0.011 g, 0.045 mmol) and DMAE (0.5 mL) was heated and stirred at 150–160 °C for 6 h in a sealed glass tube under argon to afford symmetrical Pc (Scheme 1). After cooling to room temperature, the reaction mixture was treated with ethanol and a dark blue precipitate was separated by centrifuging. The product was dissolved in DMF and precipitated with a mixture of $CHCl_3$ and acetone. After filtration, the precipitate was washed several times with boiling AcOH, water and EtOH to obtain the targeted Pc. The dark blue product was dried under vacuum. Compound **6** is soluble in DMSO and DMF. Yield: 0.014 g (16%). *Anal*. Calc. for $C_{84}H_{16}F_{40}N_8O_4Co$: C, 49.95; H, 0.80; N, 5.55. Found: C, 49.08; H, 0.83; N, 5.62%. MS(LC–MS/MS, ES+) *m/z*: 2021 $[M + 1]^+$, IR (KBr pellet) *ν*, cm^{-1}: 3085 (Ar–H), 2927–2884 (alkyl ≻CH), 1244 (C–O–C); UV–vis (DMSO) *λ*, nm (log *ε*): 675(4.77), 320(4.99).

2.2. Electrochemical and spectroelectrochemical measurements

The cyclic voltammetry (CV) and controlled potential coulometry (CPC) measurements were carried out with a Princeton Applied Research Model VersaStat II potentiostat/galvanostat controlled by an external PC and utilizing a three-electrode configuration at 25 °C. The working electrode was a Pt plate with a surface area of 0.10 cm^2. The surface of the working electrode was polished with a H_2O

suspension of Al_2O_3 before each run. The last polishing was done with a particle size of 50 nm. A Pt wire served as the counter electrode. A saturated calomel electrode (SCE) was employed as the reference electrode and was separated from the bulk of the solution by a double bridge. The ferrocene/ferrocenium couple (Fc/Fc^+) was also used as an internal standard. Electrochemical grade tetrabutylammonium perchlorate (TBAP) in extra pure dimethylsulfoxide (DMSO) was employed as the supporting electrolyte at a concentration of 0.10 mol dm^{-3}. High purity N_2 was used for deoxygenating the solution for at least 20 min prior to each run and to maintain a nitrogen blanket during the measurements. For controlled potential chronocoulometry (CPC) studies, a Pt gauze working electrode (10.5 cm^2 surface area), Pt wire counter electrode separated by a glass bridge, and a SCE as a reference electrode were used. The spectroelectrochemical measurements were carried out with an Agilent Model 8453 diode array spectrophotometer equipped with a potentiostat/galvanostat and utilizing a three-electrode configuration of a thin layer quartz spectroelectrochemical cell at 25 °C. The working electrode was transparent Pt gauze. A Pt wire counter electrode separated by a glass bridge and a SCE reference electrode, separated from the bulk of the solution by a double bridge, were used.

2.3. Dc and impedance spectral measurements

Spin coated thin films of the compounds were prepared on a glass substrate fitted with interdigitated (IDT) gold electrodes for electrical characterization. Before vacuum evaporation, the glass substrates were thoroughly cleaned ultrasonically and then coated with 100 Å of chromium followed by 1200 Å of gold in a Leybold Univex 450 coater system. The film was patterned photolithographically and etched to provide 10 fingers pairs of electrodes having a width of 100 μm, spaced 100 μm from the adjacent electrodes. The finger overlap distance was 5 mm. DMF was used as the solvent. The reason for using DMF as the solvent is the good solubility of the compounds in DMF. The compounds were dissolved in DMF at concentrations of 5×10^{-3} M for all compounds. Twenty microlitres of such solutions were added with a glass pipette onto the IDT structure held on a spinner (Speciality Coatings Systems Inc., Model P6700 Series). The substrate was spun at 2000 rpm for 20 s and then the films were dried at 60 °C under vacuum for 2 h to evaporate the solvent. Dc conductivity measurements were performed between 290 K and 440 K using a Keithley 617 electrometer. Impedance spectroscopy measurements were carried out with a Keithley 3330 LCZ meter in the frequency range 40–10^5 Hz, and in the temperature range 290–440 K. A close cycle liquid helium cryostat was used to allow electrical characteristics to be measured over a wide temperature range. The temperature of the samples was controlled with a Leybold LTC 60 temperature controller during the measurements. The conductivity data were recorded using an IEEE 488 data acquisition system incorporated into a personal computer.

3. Results and discussion

3.1. Synthesis

The main precursor, molecule **3**, for the synthesis of bis(pentafluorophenyl)methoxyl substituted Pcs was obtained by a nitro displacement reaction [3,14] of 4-nitrophthalonitrile (**2**) and bis(pentafluorophenyl)methanol (**1**). The peripherally substituted Pc derivatives were prepared from the phthalonitrile derivative **3** with Li in pentan-1-ol [10] or with metal acetates [$Zn(OAc)_2 \cdot 2H_2O$ or $Co(OAc)_2 \cdot 4H_2O$] in DMAE by a cyclotetramerization reaction.

The central metal ions and the peripheral substituents on the Pc ring effect the solubility of the MPcs. Perfluoro-substituted compounds have a tendency for high solubility in polar solvents. This situation may be interpreted with the extreme electronegativity of the fluorine atom. Both the metal-free **4** and Zn(II) Pc **5** were soluble in strong and medium polar solvents such as DMSO, DMF, EtOH and MeOH, while the Co(II)-Pc (**6**) was soluble only in strong solvents, e.g. DMSO and DMF. On the contrary to Pcs **5** and (**6**), the metal-free one **4** also showed solubility in less polar solvents such as $CHCl_3$, CH_2Cl_2 and THF.

The IR spectra were derived from potassium bromide disks. The existence of C≡N groups was apparent from a single peak at 2233 cm^{-1} in the spectrum of **3**. The formation of phthalocyanines from the dinitrile derivative was verified by the disappearance of the C≡N stretching vibration band at 2233 cm^{-1}. The IR spectra of **4**–**6** showed similar characteristics, except for metal-free **4** which showed a peak at 3297 cm^{-1}, assigned to NH groups of the inner core.

The UV–vis spectra of **4**–**6** in DMSO show characteristic absorptions between 700 and 675 nm in the Q-band region. As expected, no splitting of the Q-band in the spectra of the MPcs (M: Zn, Co) was observed while the metal-free Pc **4** showed the expected Q band splitting. The Q band observed for all Pc compounds was attributed to the $\pi \rightarrow \pi^*$ transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the Pc ring. The λ_{max} value of the fluorinated compounds were slightly shifted to shorter wavelengths [8–10]. The other bands in the UV region at 326 nm for **4**, 356 nm for **5** and 320 nm for **6** were observed due to transitions from the deeper π levels to the LUMO (Fig. 1).

The ^1H NMR spectra are also consistent with the proposed structures. The ^1H NMR spectrum of **3** in *d*-$CDCl_3$ exhibited signals for the aromatic protons around 7.24–7.76 ppm as three doublets, and a peak for the >CH proton of the aliphatic group at 6.94 ppm as a singlet. However, the aromatic and aliphatic protons in Pcs **4** and **5** appeared as multiplets at 7.96–7.41, 7.94–7.63 ppm, and as singlets at

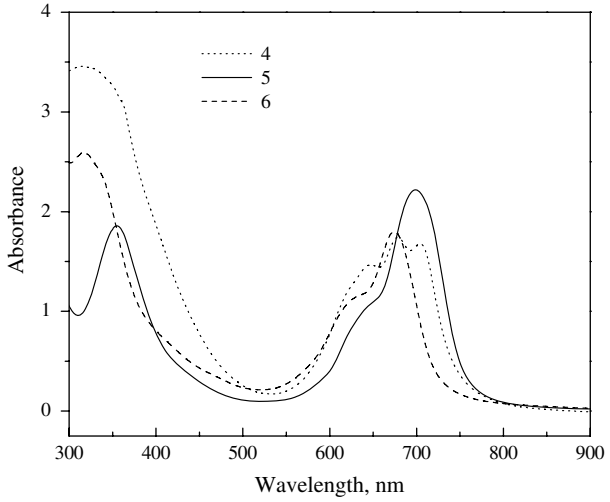


Fig. 1. UV–vis spectra of **4**–**6** in DMSO.

6.99, 6.81 ppm, respectively. The internal NH protons of metal-free Pc **4** were confirmed as a broad signal at −8.2 ppm.

A close investigation of the ^{19}F NMR spectra of compounds **3** and **5** confirmed the proposed structures. These compounds displayed signals due to $F_{2,6}$, F_4 and $F_{3,5}$ at δ: −141.2, −149.9 and −159.6 ppm, and −143.2, −156.5 and −163.2 ppm, respectively. The F_4 signal appeared as a triplet due to $F_{3,5}$ coupling, the $F_{2,6}$ signals appeared as a doublet and the $F_{3,5}$ signals as a quartet in both compound. Thus, the ^{19}F NMR measurements provided additional support for the structures of the fluorinated compounds **3** and **5** [15].

In addition to these supportive results for the structures, the mass spectra of compounds **3**–**6** gave the characteristic molecular ion peaks at *m/z*: 490 $[M]^+$, 1963 $[M]^+$, 2026 $[M]^+$ and 2021 $[M+1]^+$, respectively, from which the proposed structures were confirmed.

3.2. Electrochemistry and spectroelectrochemistry

Cyclic voltammetry of **4**–**6** was carried out on a platinum working electrode in DMSO. Controlled-potential coulometry studies showed that the redox processes monitored for these compounds generally involves the transfer of one electron. Voltammetric data of the compounds are presented in Table 1. It should be noted that as the third reductions occurred at very negative potentials, it was not possible to determine correctly the number of electrons transferred. However, on the basis of the studies reported previously for mono Pcs [16], it can be assumed that the third reduction for each compound involves the transfer of one electron.

Compound **4** displayed three quasi-reversible reduction waves at $E_{1/2} = -0.53$ V, $E_{1/2} = -0.93$ V and $E_{1/2} = -1.89$ V versus SCE, with considerably high anodic to cathodic peak separations (Fig. 2). These Pc ring-based redox processes were examined as a function of potential

Table 1
Voltammetric data for **4**–**6**

Compound	Redox couple	$E_{1/2}$[a] (V) vs. SCE and Fc/Fc^{+}[b]	ΔE_p[c] (V)
4	Pc(-2)/Pc(-3)	−0.53 (−1.03)	0.30
	Pc(-3)/Pc(-4)	−0.93 (−1.43)	0.42
	Pc(-4)/Pc(-5)	−1.89 (−2.39)	0.18
5	Pc(-2)/Pc(-3)	−0.67 (−1.17)	0.30
	Pc(-3)/Pc(-4)	−1.04 (−1.54)	0.44
	Pc(-4)/Pc(-5)	−1.94 (−2.44)	0.12
6	Co(III)/Co(II)	0.43 (−0.07)	0.06
	Co(II)/Co(I)	−0.43 (−0.93)	0.30
	Pc(-2)/Pc(-3)	−0.83 (−1.33)	0.54
	Pc(-3)/Pc(-4)	−1.39 (−1.89)	0.06

[a] $E_{1/2} = (E_{pa} + E_{pc})/2$ at 0.100 V s^{-1}.
[b] The values in parenthesis indicate the potentials vs. Fc/Fc^{+}.
[c] $\Delta E_p = E_{pa} - E_{pc}$ at 0.100 V s^{-1}.

scan rate in order to determine the mode of mass transport. The peak currents for the processes Ic, IIc and IIIc increased in direct proportion to the square root of the scan rate between 0.025 and 1.00 V/s, thus suggesting that the relevant reactions are controlled by diffusion. Compound **5** shows similar voltammetric behaviour to **4**. It also showed three one-electron, quasi-reversible reduction waves at $E_{1/2} = -0.67$ V, $E_{1/2} = -1.04$ V and $E_{1/2} = -1.94$ V versus SCE (Fig. 3). These reduction processes are probably ligand based since zinc is not redox active in Pc complexes. The first reduction processes of **4** occur at potentials slightly less negative than those of **5**. This can be attributed to the difference in the polarizing power of central metal and the hydrogens. The first two ring reduction processes for main group Pcs are generally separated by about 0.4–0.5 V. The third reduction occurs 0.8 V more negative than the second reduction. The separation between the second and the third reductions is smaller with more polarizing ions such as Zn(II) [16]. The redox potentials measured for **4** and **5** are consistent with the general

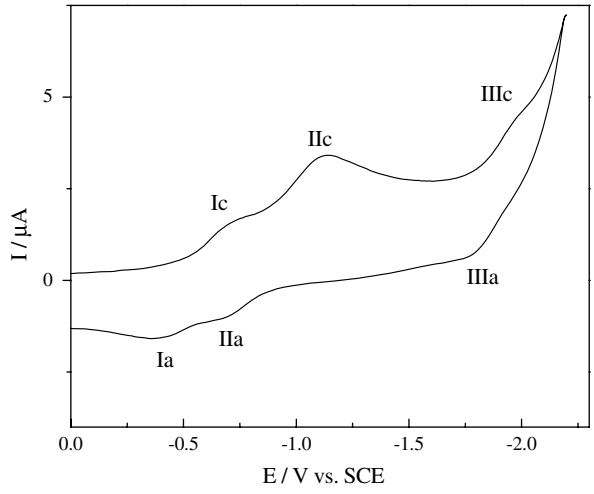

Fig. 2. Cyclic voltammogram of **4** at 0.100 V s^{-1} in DMSO/TBAP solution.

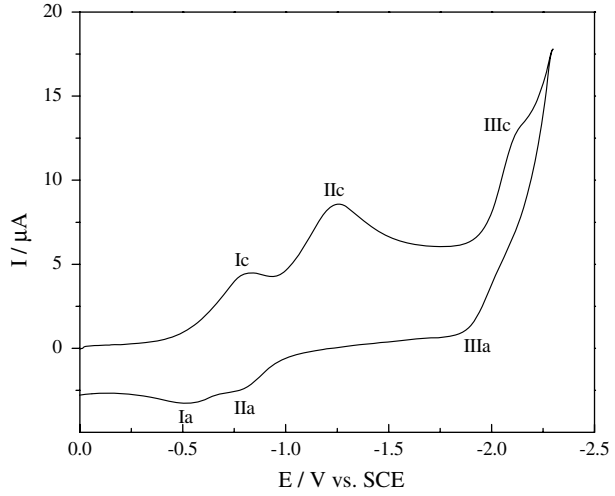

Fig. 3. Cyclic voltammogram of **5** at 0.100 V s^{-1} in DMSO/TBAP solution.

redox characteristics reported previously for similar Pcs. The first ring reduction potentials of **4** and **5** are less negative as compared with those given for unsubstituted Pcs in the literature [16]. This positive potential shift can be attributed to the electron withdrawing effect of the fluorine atoms in **4** and **5**. Therefore, it was possible to observe the third reductions for **4** and **5**, which cannot be monitored generally. On the other hand, the first oxidation could not be observed for **4** and **5**, probably for the same reason, positively shifted potentials.

A typical voltammogram for **6** is shown in Fig. 4. The voltammetric behaviour of **6** is different from those of **4** and **5**. It indicates three one-electron reduction processes at $E_{1/2} = -0.43$ V, $E_{1/2} = -0.83$ V and $E_{1/2} = -1.39$ V versus SCE, and a one-electron oxidation process at $E_{1/2} = 0.43$ V versus SCE. If the transition metal ion concerned has no accessible d orbital levels lying between the HOMO and LUMO gap of a Pc species, then its redox chemistry will appear very much like that of a main group Pc species. Nickel, copper, zinc and some other MPcs behave in this fashion, with the M(II) central ion being unchanged as the MPc unit is either oxidized or reduced. However, some species vary their electrochemical behaviour according to their environment, i.e., the oxidation of Co(II)Pc(-2) can lead to $[Co(III)Pc(-2)]^+$ or $[Co(II)Pc(-1)]^+$ depending on whether there are any available suitable coordinating species that would stabilize the Co(II) center. Such electrochemistry, especially of Co(II)Pc(-2) and Fe(II)Pc(-2) is split into two sections, that referring to donor solvents and that referring to non-donor solvents. The main difference lies in whether the metal or the ring is oxidized first. Donor solvents strongly favor Co(III)Pc(-2) by coordinating along the axis to form six coordinate species. If such donor solvents are absent, then oxidation to Co(III) is inhibited and ring oxidation occurs first. Thus, the first oxidation and the first reduction processes of **6** are probably metal based and correspond to Co(II)Pc(-2)/$[Co(III)Pc(-2)]^+$ and Co(II)Pc(-2)/$[Co(I)Pc(-2)]^-$, respectively, while the second and third reductions are ring based, since the voltammetric measurements were carried out in DMSO/TBAP.

In order to provide additional support for the identification of the redox processes of **5** and **6**, spectroelectrochemistry of these complexes was also studied. Typical absorption spectra for the neutral **5** and its electrochemically generated species are shown in Fig. 5. Fig. 6a shows the UV–vis spectral changes of complex **5** during the controlled potential reduction of the complex at −0.87 V versus SCE. Upon reduction, a decrease in the absorption of the Q band centered at 700 nm and its broadening towards the red region is observed. This is accompanied by an increase in absorption at the region, 500–600 nm. Isosbestic points are observed at 337, 372, 606 and 732 nm. These spectral changes are characteristic for the formation of Zn(II)Pc(-3) species [17,18]. The well-defined spectral

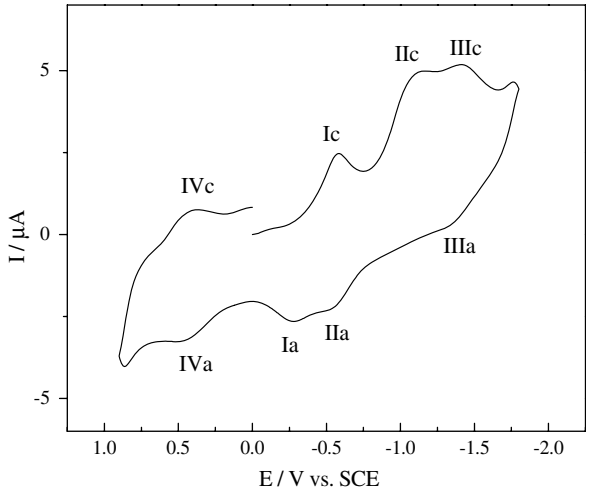

Fig. 4. Cyclic voltammogram of **6** at 0.100 V s^{-1} in DMSO/TBAP solution.

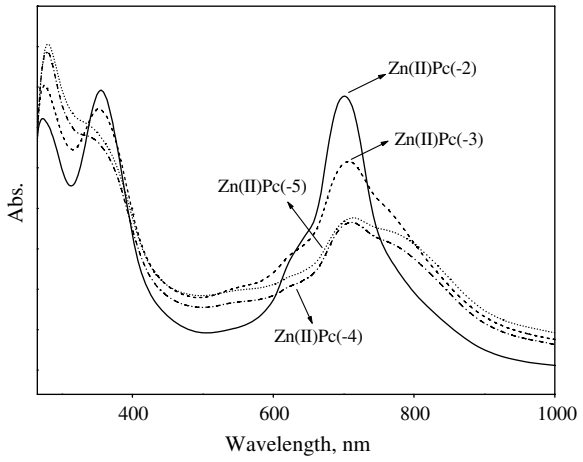

Fig. 5. UV–vis spectra of **5** and its electrochemically generated reduced species.

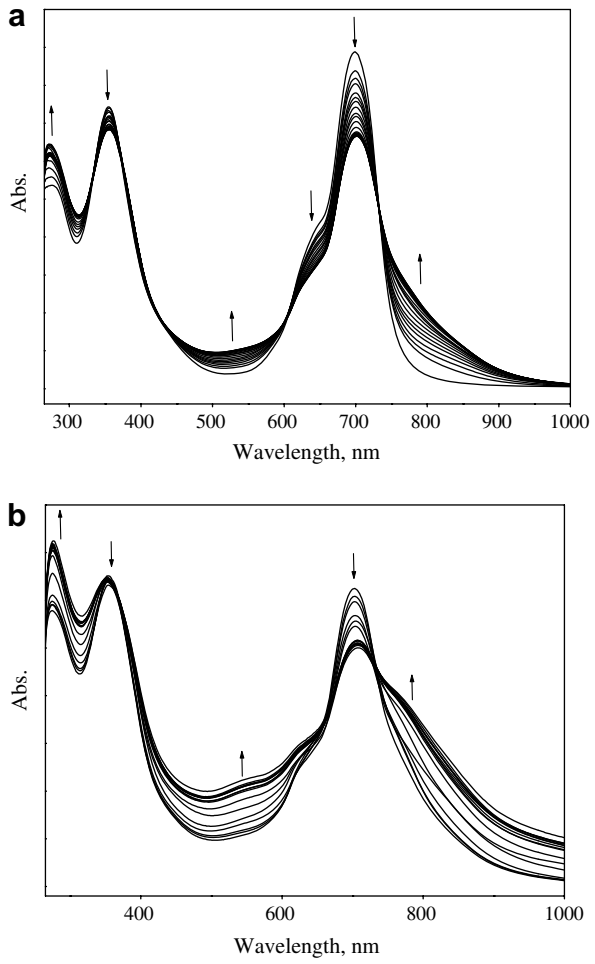

Fig. 6. UV–vis spectral changes during (a) the first reduction; (b) the second reduction of **5**.

changes during the second reduction of **5** with an applied potential of −1.40 V versus SCE are shown in Fig. 6b. Similar spectral changes continue with the formation of well-defined isosbestic points at 374, 666 and 730 nm. The appearance of a new broad absorption band with low intensity at 544 nm is also characteristic for ring reduction. The first and second reduction processes were chemically reversible on the spectroelectrochemical time scale and the nearly original spectrum of the neutral compound **5** was obtained upon reoxidation. It could be concluded that the species produced during the first and second reduction processes remained stable throughout the measurement. The final spectra obtained after the controlled potential electrolysis of **5** at −2.10 V versus SCE is given in Fig. 5. Unfortunately, the third reduction process was not chemically reversible on the spectroelectrochemical time scale although it was quasi-reversible during the cyclic voltammetric measurement. Reoxidation of the triply reduced species did not generate compound **5** with its original spectrum. This is probably due to the fact that the third reduction process occurs at considerably negative potentials, and decomposition of the complex may occur when the potential is held constant at a considerably negative potential.

Fig. 7 represents the UV–vis spectra of the neutral **6** and its electro-generated species. Fig. 8a shows the UV–vis spectral changes of **6** during its first reduction at −0.70 V versus SCE. The Q band absorption at 673 nm and the intensity of the shoulder at 623 nm decrease, while a new intense band at 480 nm appears and the absorption at the red region of the Q band increases during the controlled-potential electrolysis. This reduction process has well-defined isosbestic points at 393, 568 and 703 nm. The new band at 480 nm is typical for Co(I)Pc(-2) species, and thus suggests that the first reduction of **6** occurs at the metal center [19,20]. Upon reduction at −1.2 V versus SCE, the Q band absorption goes on decreasing without shift, and the absorption of the new band also decreases (Fig. 8b). These spectral changes are accompanied by an increase in the absorption at the red region of the Q band with isosbestic point at 396, 570 and 701 nm, which is characteristic for Pc ring reduction [21]. The spectral changes observed during the third reduction process corresponding to couple III were also typical for ring reduction. The final spectra of the species electrochemically generated after third reduction is shown in Fig. 7. Although the first and second reduction, and the first oxidation processes were chemically reversible, the third reduction process was not reversible on the spectroelectrochemical timescale, and the original species could not be obtained upon reoxidation of the triply reduced species. This is also probably due to decomposition after reduction. Fig. 8c shows the spectral changes during oxidation of **6**. The original Q band absorption at 673 nm increases with a clear shift to 683 nm while the absorption of the shoulder at 623 nm decreases slightly and the absorption in the 500–600 nm region increases. These spectral changes result in isosbestic points at 418, 612 and 728 nm, typical of a Co(II)Pc(-2)/Co(III)Pc(-2) redox process [20].

3.3. Dc and impedance spectral measurements

To gain more valuable information on the processes taking place in the films, the temperature dependence of the direct current conductivity was examined during heating and cooling processes. Measurements were carried out in an ambient vacuum ($<10^{-3}$ mbar). In the current–voltage (I–V) measurements symmetrical currents at positive and negative polarization as well as an ohmic contact behaviour were found. The conductivity values of the films were calculated from the slopes of the measured I–V characteristics. It was found that the conductivity of the films were reversible for temperature cycling. The measured dc conductivity data of the prepared films were plotted as $\ln\sigma(T)$ versus $1/T$. This plot indicated that the compounds are semiconducting in nature. A linear relationship in conductivity variations are observed for **4**–**6** in the temperature range 290–440 K. The slopes of these plots are determined and used to evaluate the activation energies and the data are presented in Table 2. The general trend, for the order of electrical conductivities, observed in the whole temperature range for these compounds are $\sigma_{dc}(2H) > \sigma_{dc}(Co) \approx \sigma_{dc}(Zn)$. The observed electrical conductivities of the compounds are found to be $\sim 10^2$ times higher compared to their parent Pcs. Differences in the order of the electrical conductivities in this case are mainly due to the electron withdrawing effect of fluorine atoms. The electron withdrawing bis(pentafluorophenyl) substituents decreases the separation distance between the Pc macrocycles. The smaller interplanar spacing between the molecules as well as favorable intermolecular stacking are expected to lead to greater overlap between the π-electron orbitals of both macrocycles. This result is significant because it strongly suggests that the overlap of π-electron orbitals plays a major role in the electrical conduction behaviour. The highest conductivity in metal free Pc **4** indicates that the transport of charge carriers is through the ligands, and not through the metal ions.

The trend observed in the ac electrical conductivity was the same as the dc conductivity ($\sigma_{ac}(2H) > \sigma_{ac}(Co) \approx \sigma_{ac}(Zn)$). Fig. 9 shows the dependence of ac conductivity on frequency for the compounds at 350 K. As can be seen from Fig. 9, the frequency has a pronounced effect on the measured ac conductivity. The frequency dependence of the conductivity follow a universal power law for all the compounds [22],

$$\sigma_{ac}(\omega) = A\omega^s \quad (1)$$

where ω is the angular frequency, A and the frequency exponent s are material dependent constants. In general, ac conductivities are not equal to dc conductivities. Several mechanisms can be operative for ac conduction in molecular materials. In the case of ac conductivity, the measured conductivity depends not only the conductivity of the material, but also on capacitance. When the impedance of the sample becomes purely resistive the ac conductivity equals the dc conductivity. The interpretation of the

Table 2
The dc conductivity and activation energy values of the compounds

Compound	σ_{dc290} (S/cm)	σ_{dc400} (S/cm)	E_a (eV)
4	4.4×10^{-8}	1.3×10^{-4}	0.81
5	1.6×10^{-9}	5.1×10^{-5}	0.77
6	1.2×10^{-9}	4.0×10^{-5}	0.78

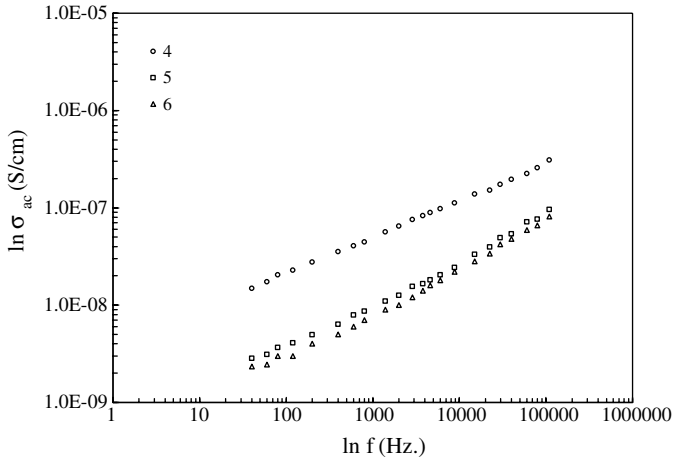

Fig. 9. The dependence of ac conductivity on frequency for **4**–**6** at 350 K.

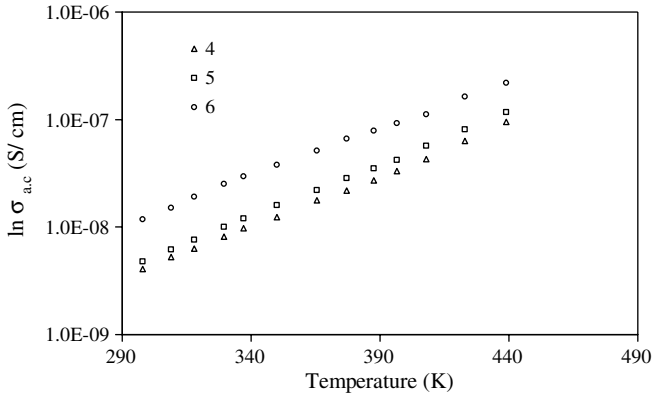

Fig. 10. The temperature dependence of the ac conductivity at a constant frequency of 15 kHz for **4**–**6**.

measured ac conductivity data should be focused on the hopping processes. The hopping model, which was developed by Eliot, assumes that charge carriers hop between sites over the potential barrier separating them, rather than tunnelling through the barrier [23]. This model gives an ac conductivity which can be expressed to a first-order approximation as

$$\sigma_{ac}(\omega, T) = \frac{n\pi^3 N^2 \varepsilon\varepsilon_0 \omega}{24} R_\omega^6 \quad (2)$$

where ε is the dielectric constant of the material, ε_0 that of free space, N is the spatial density of defect states, $n = 1$ for a single electron $n = 2$ for hopping of two electrons and R_ω is the hopping distance. The temperature dependent frequency exponent s for this model is given by,

$$s = 1 - \beta = 1 - 6k_B T/W_M \quad (3)$$

where W_M is the optical band gap, k_B is the Boltzman's constant and T is temperature. The variation of frequency exponent, s, with temperature gives information on the specific mechanism involved. The values of s have been calculated from the slope of $\ln \sigma_{ac}(\omega)$ versus $\ln \omega$ graphs. Our calculations showed that s is definitely a function of temperature for all compounds. The comparison of the experimentally determined s values with the prediction from the hopping model suggest that the dependence of exponent s on temperature is in agreement with the prediction of the hopping model for these compounds. However, the decrease in frequency exponent s with increasing temperature is not evident for the hopping model. In addition to the behaviour of s, the temperature dependence of the measured ac conductivity has to be considered. Eq. (2) can be rewritten in the form

$$\sigma_{ac}(\omega, T) = BC^{T/Q} \quad (4)$$

where $C = 1/\omega\tau_0$, B denotes all other temperature-independent parameters and $Q = W_M/6k_B$. According to Eq. (4), since C and Q are independent of the temperature, the slope of the $\ln \sigma_{ac}(\omega, T)$ versus T graph should be constant. Fig. 10 shows the temperature dependence of the measured ac conductivity at constant frequency (15 kHz). The linear relationship between σ_{ac} and T confirms that the charge carrier transport occurs via hopping processes.

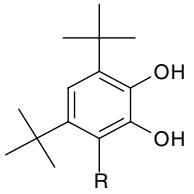
antifungal effect of copper ions has been known for many years since the Bordeaux mixture was first used at the end of 19th century for the treatment of downy mildew of vines [19]. In this connection it is of interest to study various aspects of copper (II) coordination chemistry of SHD derivatives and its antifungal activities.

Recently, we have studied the interaction of a series of SHD derivatives with silver (I), copper (II), cobalt (II) and nickel (II) ions in aqueous ethanol solutions [20–25]. In these studies, the experimental data on the quantitative aspects of complexation equilibrium for metal ions forming complexes with the above-stated ligands in aqueous ethanol solutions were obtained by potentiometric titration. Potentiometric investigation of the equilibria in the systems containing metal (II) ions and SHD derivatives allowed us to recognize that complexes were formed, and to find out their composition and stability, thus allowing one to select optimal conditions for synthesizing the complexes. Continuing with our research program concerning the coordination chemistry and biological activity of SHD derivatives, we report herein the synthesis and characterization of Cu (II) complexes with 3,5-di(*tert*-butyl)-1,2-benzenediol (**I**), 4,6-di(*tert*-butyl)-1,2,3-benzentriol (**II**) and sulfur-containing SHD derivatives such as 4,6-di(*tert*-butyl)-3-(2-hydroxyethylsulfanyl)-1,2-benzenediol (**III**) and 2-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]-acetic acid (**IV**):



I – R=H

II – R=OH

III – R=SCH_2CH_2OH

IV – R=SCH_2COOH

We have also reported the synthesis of an Ag (I) complex with one of the ligands, 2-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]acetic acid, which acts as a potentially antimicrobial substance [20]. Since our earlier work had revealed that Ag (I) complexation leads to enhancement of the antifungal activity of this ligand, we were motivated to explore whether there is a similar trend in the case of the Cu (II) complexes of the SHD derivatives.

In deciding on the subjects of our investigation, we also took into account that one of the key factors leading to a broad spectrum of antimicrobial activities of some transition metal complexes with *O*-coordinated ligands may be related to a direct interaction or complexation of the metal ion with biological ligands due to the ability of the *O*-coordinated ligand in this complex to be readily substituted by an *S*-coordinated bioligand [26,27]. Most bioligands contain the potential target sites for the inhibition of microbial growth by these metal complexes that reportedly might be the *S*-containing residues of proteins. In this connection it is of interest to study the structure–activity correlation in antifungal activities of the Cu (II) complexes with the aforesaid SHD ligands.

The solid Cu (II) complexes were characterized by means of elemental analysis, XRD, TG/DTA, FT-IR, ESR and XPS. However, a full structural analysis could not be performed because no single crystals suitable for X-ray diffraction studies were obtained. A special investigation showed that most of the metal complexes formed with the sterically hindered *o*-diphenol derivatives containing one or two *tert*-butyl groups were hard to crystallize [20–25,28]. Therefore, our notion of the coordination modes of the Cu (II) complexes reported here was formed on the basis of findings provided by other physico-chemical methods.

We also estimated the antifungal activities of the Cu (II) complexes as compared with those of the respective free ligands. Among the test microorganisms there were two plant pathogenic fungi (*Fusarium sp.*, *Botrytis cinerea*).

2. Experimental

2.1. Materials and methods

Chemicals were purchased from commercial sources and were used without further purification. The SHD derivatives were prepared according to [5,7,29–32]. The preparation of the Cu (II) complexes is described later.

Infrared spectra of the solids (the ligands **I**–**IV** and the synthesized Cu (II) complexes) were recorded with a Spectrum 1000 spectrophotometer in the wavelength range 4000–400 cm^{-1} at room temperature, using nujol mulls of the ligands and the complexes, and polyethylene windows.

Thermal analysis was performed with a derivatograph OD-103 MOM. TG/DTA measurements were run in the air between 20 and 450 °C (5 °C min^{-1}).

Elemental analyses were carried out according to standard methods by the Microanalytical Laboratory, Bioorganic Chemistry Institute, National Academy of Sciences, Belarus. Copper and sulfur determinations were carried out using an atomic emission spectrometer with an inductively coupled plasma excitation source (Spectroflame Modula). A sample of a Cu (II) complex was decomposed on treatment with $HNO_3 + H_2O_2$ using a Milestone mls 1200 mega microwave digestion system. After the complex had been decomposed, the contents of metal and sulfur in the resulting solution were determined.

XRD studies were made with an HZG 4A diffractometer ($Co_{K\alpha}$ radiation, MnO_2-filter). An XPS study was performed with an ES-2401 spectrometer. Sample surface etching with Ar^+ was employed. Core level energies were calibrated by the C 1s line with $E_B = 284.6$ eV.

ESR spectra of polycrystalline samples were measured on ERS-220 X-band spectrometer (9.45 GHz) at room temperature and at 77 K, using 100-kHz field modulation; *g* factors were quoted relative to the standard marker DPPH ($g = 2.0036$).

The molar conductances of 10^{-3} M solutions of the Cu (II) complexes in acetonitrile were measured at 20 °C using a TESLA BMS91 conductometer (cell constant 1.0).

2.2. Synthesis of the Cu (II) complexes with sterically hindered o-diphenol derivatives

Based on our previous findings [21–25], the conditions were created to purposefully provide the preferential formation of a complex with a Cu (II):L ratio of 1:2. A solution of the Cu (II) salt was added in small portions to the ligand solution under continuous stirring, so that the complexation always took place with an excess of ligand present. The preparation followed a common procedure. A solution of 0.050 mmol $Cu(CH_3COO)_2 \cdot H_2O$ in 10 ml of water was added dropwise to a colorless solution of 0.100 mmol of **I**–**IV** dissolved in 10 ml of ethanol (molar ratio Cu (II):L = 1:2). It must to be taken into account that these ligands are redox active when producing their complexes with transition metal ions, especially with copper (II), in order to prevent the production of the oxidized forms of the ligands (in particular, *o*-semiquinones, as was shown in [28,33]). Because of this, argon was bubbled through the solutions (pH $\leqslant$ 6) during the synthesis to ensure the absence of oxygen. The reaction vessel was shielded from light. Colored precipitates of the Cu (II) complexes formed instantaneously. After 1.5 h stirring, they were collected on membrane filters (JG 0.2 μm), washed with ethanol and water, and dried *in vacuo* (yield > 70%).

2.3. Antifungal activities

Antifungal activities of the compounds were tested according to a method reported elsewhere [34]. The following test microorganisms (collection of Department of Microbiology, Belarusian State University) were used: *Aspergillus niger*, *Fusarium sp.*, *Penicillium lividum*, *Mucor sp.*, *B. cinerea*. The compounds were dissolved in DMSO and diluted in Sabouraud liquid medium to yield working solutions of the test complexes of concentration 100 μg mL^{-1}. The complexes, which were insoluble in DMSO, were ground to a fine powder and then suspended in the solvent. A solution of the compound was thoroughly mixed with the sterilized medium, and the mixture poured on glass Petri dishes. After solidification of the medium, the plates were inoculated with a small piece of micelial block of each test fungus cut out from the outer margin of the culture grown on a basal medium. The inoculated plates were incubated at 25 °C whereupon the linear growth of the fungal colony was measured in two directions at right angles to each other after 72 h, and the average of three replicates was taken as the diameter of the colony in millimeters. The concentration of DMSO in the medium did not affect the fungal growth. The degree of inhibition of radial growth (RI) was calculated as follows [35]: RI=100(C–T)/C (%), where T is the mean value of the diameter of the fungal colonies in the presence of a given concentration of each compound, and C is the mean value of the diameter of the fungal colonies in the absence of the same compound, measured under the same conditions. The results were confirmed in three independent experiments.

3. Results and discussion

All the complexes were characterized by X-ray patterns of their own, differing significantly from that of the respective ligands. The elemental analyses data for the complexes Cu (II) with **I**–**IV** are in agreement with the general formula $Cu(L)_2$.

The low solubility of most of these complexes in common organic solvents hinders their study in solution. All the complexes were insoluble in water, ethanol, diethyl ether, nitromethane and chloroform, and only $Cu(L^I)_2$ and $Cu(L^{III})_2$ were soluble in acetonitrile. The low values of the molar conductivity in acetonitrile for the complexes $Cu(L^I)_2$ (Λ_{mol}=8.9 Ω^{-1} cm^2 mol^{-1}) and $Cu(L^{III})_2$ (Λ_{mol}=4.5 Ω^{-1} cm^2 mol^{-1}) indicate them being essentially non-electrolytes in this solvent [36]. Thus, the conductivity data suggest that the ligands, in particular **I** and **III**, may be coordinated to the Cu (II) ion as uninegatively charged ligands.

3.1. Thermal studies

Thermal analyses in air flow with identification of the final products by X-ray powder diffraction has shown all the complexes to be anhydrous and unsolvated, because their DTA curves lack any endothermic peaks over a wide range from 60 to 150 °C. A summary of the results is given in Table 1.

Most of the complexes behaved very similarly on thermal analysis and generally showed two stages of decomposition, except for $Cu(L^{IV})_2$ (three stages). These stages correspond to the maximal weight losses. Taking the $Cu(L^I)_2$ complex as an example, the TGA curve shows that

Table 1
TG/DTA data for decomposition of the Cu (II) complexes to form CuO

Complex	Temperature (°C)	Process	% Weight loss	
			Found	Calc.
$Cu(L^I)_2$	160–390	exothermic	83.42	84.27
$Cu(L^{II})_2$	180–310	exothermic	84.13	85.21
$Cu(L^{III})_2$	170–390	exothermic	87.06	87.91
$Cu(L^{IV})_2$	190–410	exothermic	87.58	88.41

the maximal two-stage weight loss of 83.42% from 160 to 390 °C corresponds to the loss of two ligand molecules in the $Cu(L^I)_2$ complex (Calc. 84.27%): $Cu(L)_2 \rightarrow CuO$. The agreement between the experimental and theoretical weight losses for the above processes confirms the formulas of the Cu (II) complexes.

3.2. Infrared spectra

To specify the coordination modes in the Cu (II) complexes, we used IR spectroscopy (Table 2).

In the spectra of **I** and **II** there are two bands at 3200–3550 cm^{-1}, indicating the presence of intermolecular hydrogen bonds involving hydroxyl groups [37]. As for the spectra of $Cu(L^I)_2$ and $Cu(L^{II})_2$, there is only one broad band in that region, which allows one to suggest that **I** and **II** coordinate as κ^2O,O-ligands in the singly deprotonated form. The bands at 1200–1050 cm^{-1} in the spectra of **I** and **II**, assigned to the vibrations of the C–O band, are shifted towards lower frequencies in the spectra of $Cu(L^I)_2$ and $Cu(L^{II})_2$, indicating Cu (II) being coordinated with the hydroxyls of **I** and **II**. The strong band at 1463 cm^{-1} in the $Cu(L^{II})_2$ spectrum may be due to the radical-anionic ligand form being present [38].

IR spectral assignments of ligands **III** and **IV** and their Cu (II) complexes in the regions 3200–3550 cm^{-1} and 1200–1020 cm^{-1} are in much the same fashion as above mentioned. The shift of the bands at 1000–760 cm^{-1}, assigned to C–S bond vibrations, to the short-wave region in the spectrum of this complex suggests that the sulfur is involved in the complexation. In the spectrum of **IV** the band corresponding to the stretching vibrations of C=O in the carboxyl group is observed at 1690 cm^{-1}. It is absent in the spectrum of $Cu(L^{IV})_2$, but new bands at 1550 and 1600 cm^{-1} appear, which are characteristic of $-COO^-$ group vibrations [37]. The shift of the stretching vibration frequencies for the carboxylic group is indicative of the hydrogen ions therein being substituted by Cu (II) in the two coordinated ligand molecules.

It should be noted that in the spectra of all the complexes under study there are bands in the region of 470–580 cm^{-1} which may be assigned to the stretching vibrations of the Cu–O bond. As Cu–S stretching vibration frequencies are usually below 400 cm^{-1}, they could not be registered with the instrument employed here to register IR spectra.

Table 2
IR spectral assignments (cm^{-1}) of the ligands and the Cu (II) complexes

Compound	ν(–OH)	ν(C–S)	ν(COO^-)	ν(C–O)	ν(Cu–O)
L^I	3461			1105	
	3264				
$Cu(L^I)_2$	3484			1091	510
L^{II}	3540			1182

	3339	848		1004	
$Cu(L^{III})_2$	3399	826		1064	477
		770		1010	
L^{IV}	3545	1030		1163	
	3447	775		1117	
	3349			1027	
$Cu(L^{IV})_2$	3377	1000	1602	1159	488
		767	1574		

3.3. ESR spectra

The ESR parameters of the Cu (II) complexes are presented in Table 3. The ESR spectra of complexes $Cu(L^I)_2$ and $Cu(L^{II})_2$ at room temperature were not observed, but all the complexes are characterized by the spectra at 77 K.

The ESR spectra of $Cu(L^I)_2$, $Cu(L^{II})_2$ and $Cu(L^{III})_2$ compounds in the polycrystalline state (77 K) are typical axial spectra (Fig. 1) with $g_\parallel$ and $g_\perp$ features at about 2.28–2.30 and 2.03–2.04. The geometric parameter G, which is a measure of the exchange interaction between the copper (II) centers in the polycrystalline compound, is calculated using the equation $G = (g_\parallel - 2.0023)/(g_\perp - 2.0023)$ [39]. The geometric parameter G for the complexes $Cu(L^I)_2$, $Cu(L^{II})_2$ and $Cu(L^{III})_2$ appears to be greater than 4, which shows that there are no magnetic exchange interactions between the copper (II) centers [40]. The solid state ESR spectra of all these complexes at 77 K are quite similar

Table 3
ESR parameters of Cu (II) complexes

Complex	$A_\parallel$	$g_\parallel$	$g_\perp$	$g(R^\cdot)$	g_1	g_2	g_3	G
$Cu(L^I)_2$	178	2.285	2.0278					11.09
$Cu(L^{II})_2$	171	2.278	2.0331	2.0043				8.95
$Cu(L^{III})_2$	145	2.297	2.0407					7.67
$Cu(L^{IV})_2$					2.230	2.111	2.0228	

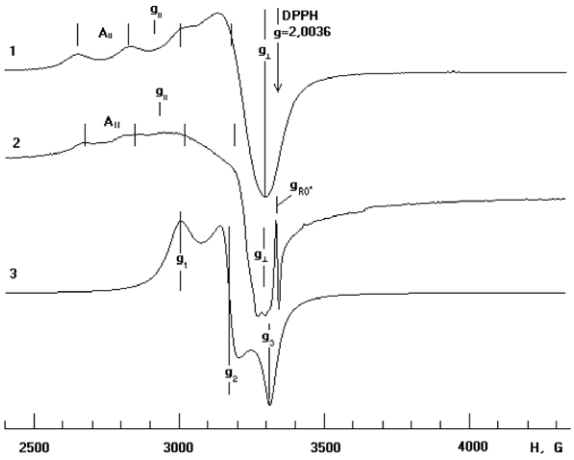

Fig. 1. ESR spectra of compounds $Cu(L^I)_2$ (**1**), $Cu(L^{II})_2$ (**2**) and $Cu(L^{IV})_2$ (**3**) in the polycrystalline state at 77 K.

and exhibit axially symmetric g-tensor parameters with $g_{\|} > g_{\perp} > 2.0023$. These data indicate that the copper site has a $d_{x^2-y^2}$ ground state, characteristic of square planar stereochemistry [41,42]. This structure of the complex agrees with the data of the elemental analysis for the aforesaid Cu (II) complexes.

The ESR spectrum of the $Cu(L^{IV})_2$ complex apparently shows rhombic symmetry ($g_1 = 2.230$; $g_2 = 2.111$; $g_3 = 2.0228$), which indicates the existence of partial mixing of the d_{z^2} orbital into the $d_{x^2-y^2}$ magnetic orbital [43]. Although it is impossible to obtain accurate molecular values from polycrystalline ESR spectra, it is possible to distinguish unambiguously between $d_{x^2-y^2}$ and d_{z^2} as ground states. Thus, the observed g-values ($g_{\|} > g_{\perp} > 0$) and the value of $R=(g_2 - g_1)/(g_3 - g_2)$ of 0.74 suggest a predominantly $d_{x^2-y^2}$ ground state [40].

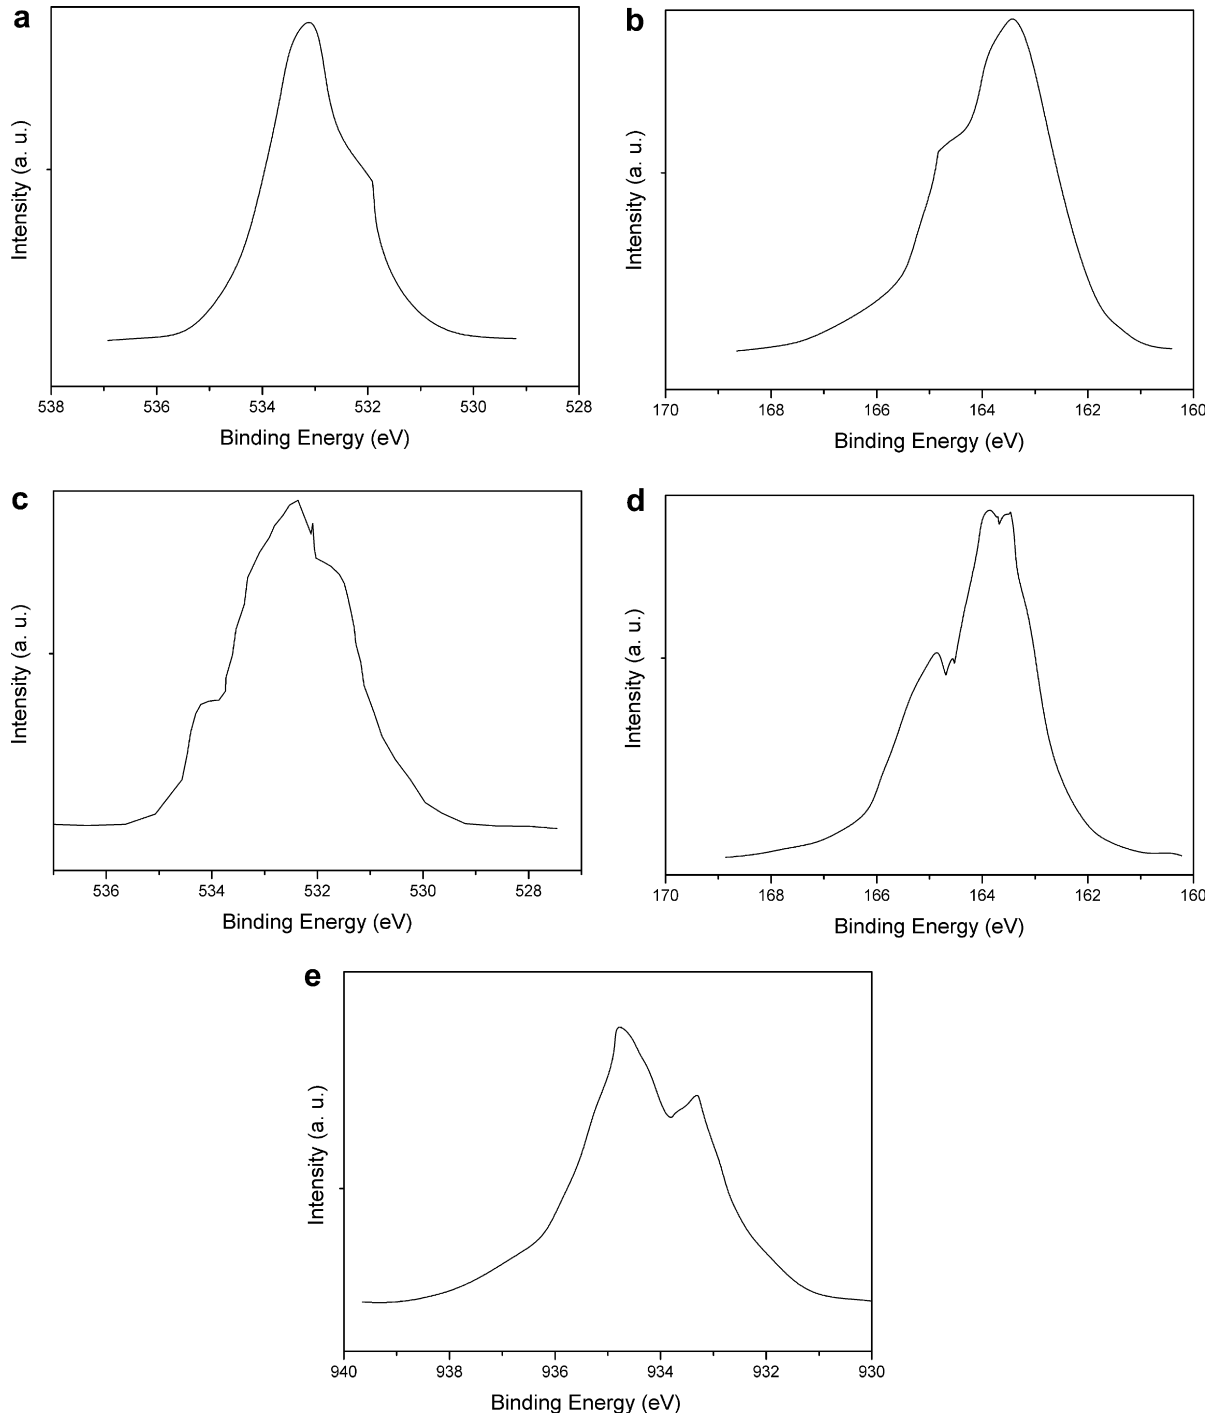

Fig. 2. The X-ray photoelectron spectra: (a) O 1 s core level spectrum of free **III** ligand; (b) S 2p core level spectrum of free **III** ligand; (c) O 1 s core level spectrum of $Cu(L^{III})_2$; (d) S 2p core level spectrum of $Cu(L^{III})_2$; (e) Cu 2p core level spectrum of $Cu(L^{III})_2$.

According to [44], $g_{\|}$ values less than 2.3 indicate considerable covalent character of M–L bonds (Table 3). The smaller $A_{\|}$ value for complex $Cu(L^{III})_2$ has been attributed to the high covalency of the Cu–S bonding [45].

It should be noted that the ESR spectrum of the $Cu(L^{II})_2$ complexes differ from those of $Cu(L^{I})_2$, $Cu(L^{III})_2$ and $Cu(L^{IV})_2$ by the presence of narrow singlet signals with a *g*-factor near 2 (Table 3). On the basis of the *g*-factor values (respectively, 2.0043 and 2.0045), it may be suggested that these radicals are phenoxyl ones. In the free crystalline ligands no stabilized radicals are registered. Concentration of phenoxyl radicals in the $Cu(L^{II})_2$ complex is about 4–8×10^{15} g^{-1}, thus they may be assumed to form during the synthesis of the complexes. No stabilized radicals being present in the $Cu(L^{I})_2$, $Cu(L^{III})_2$ and $Cu(L^{IV})_2$ complexes is evidence of the possibility of redox reactions on complexation, apparently depending on the ligand nature and on the conditions in which the complexation takes place [33].

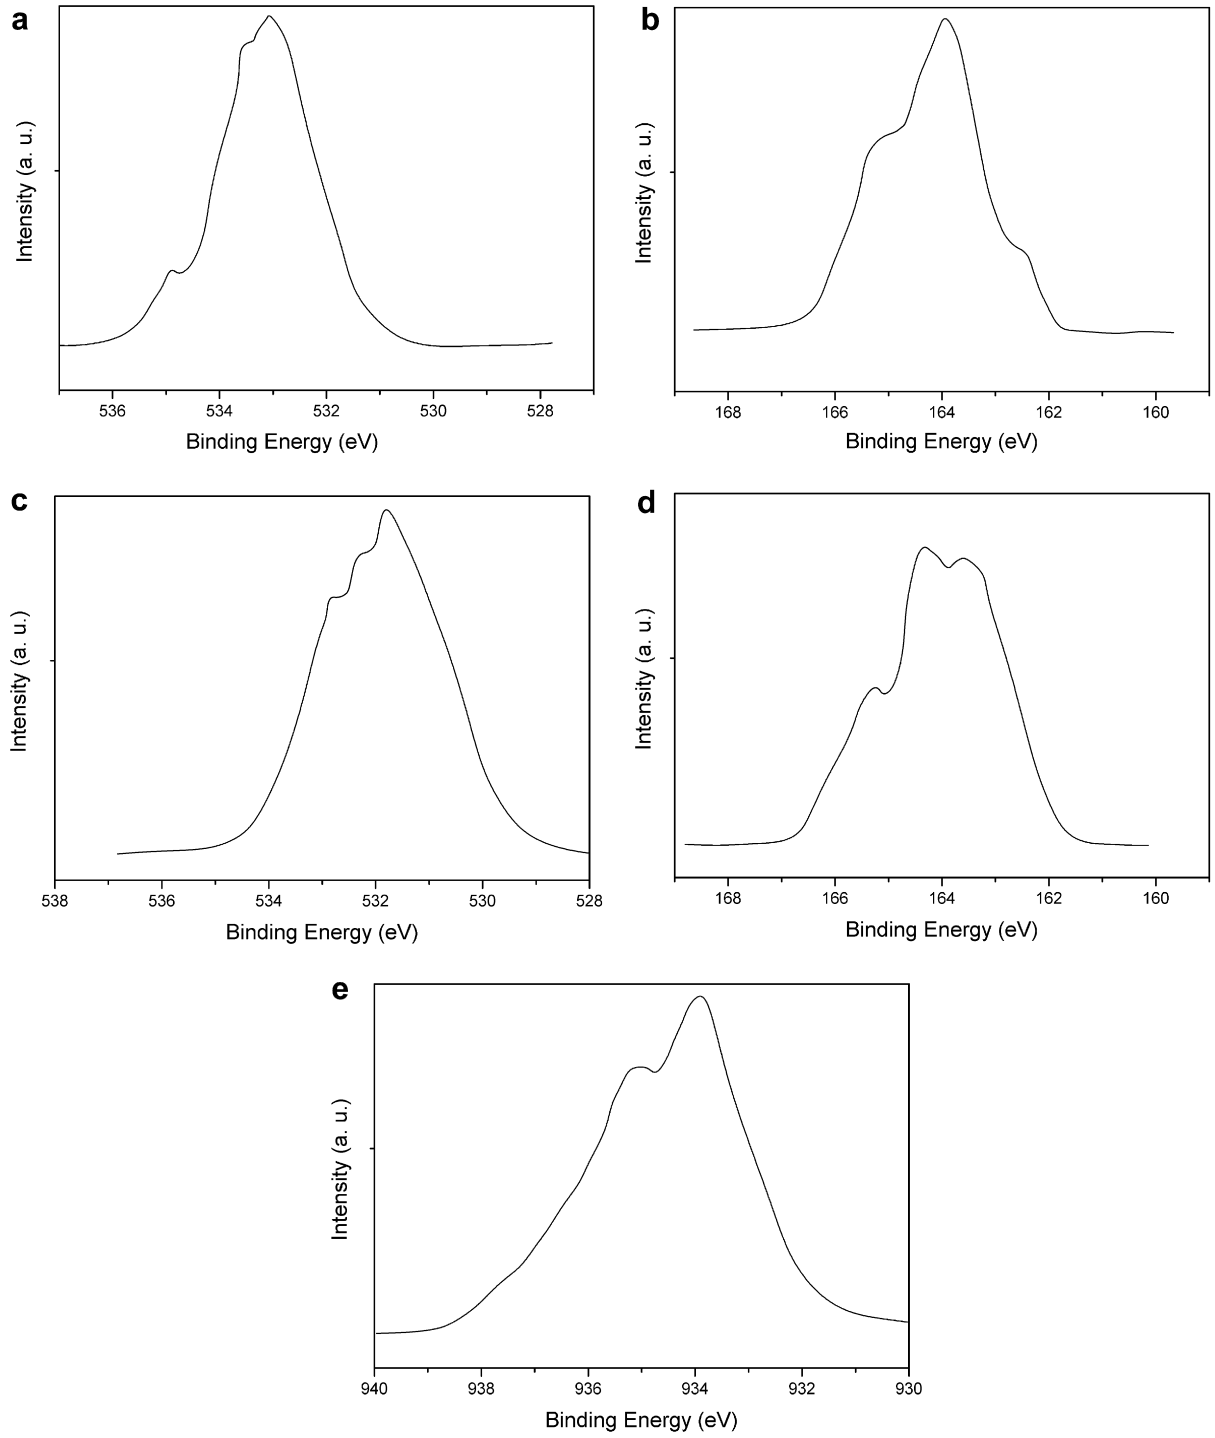

Fig. 3. The X-ray photoelectron spectra: (a) O 1 s core level spectrum of free **IV** ligand; (b) S 2p core level spectrum of free **IV** ligand; (c) O 1 s core level spectrum of $Cu(L^{IV})_2$; (d) S 2p core level spectrum of $Cu(L^{IV})_2$; (e) Cu 2p core level spectrum of $Cu(L^{IV})_2$.

Table 4
Antifungal activities of the free ligands **I**–**IV** and their Cu (II) complexes expressed as radial inhibition of mycelial growth (RI, %)

Compound	RI (%)				
	Aspergillus niger	*Fusarium sp.*	*Mucor sp.*	*Penicillium lividum*	*Botrytis cinerea*
L^{I}	65	100	100	80	100
$Cu(L^{I})_2$	35	80	0	75	50
L^{II}	100	100	100	75	100
$Cu(L^{II})_2$	75	80	100	60	100
L^{III}	50	60	0	60	100
$Cu(L^{III})_2$	75	95	25	75	100
L^{IV}	80	100	0	75	100
$Cu(L^{IV})_2$	80	100	50	80	100
Nystatin	80	90	100	90	60
Terbinafine	100	80	25	40	60

3.4. X-ray photoelectron spectra

Unfortunately, we failed to register the spectra of polycrystalline samples of $Cu(L^{I})_2$ and $Cu(L^{II})_2$ complexes, because the latter undergo decomposition under the conditions in which the spectra are registered.

In the case of $Cu(L^{III})_2$ and $Cu(L^{IV})_2$, the Cu 2p core level spectra are spin split into two peaks, respectively, at 934.7, 933.3 eV (Fig. 2e) and at 935.4, 934.4 eV (Fig. 3e). In the Cu (II) compounds, the Cu 2p energy is 934–935.5 eV, and for Cu (I) it is 932.1 eV [46]. Thus, the copper energy state in these complexes is Cu(II).

The S 2p core level spectra of $Cu(L^{III})_2$ and $Cu(L^{IV})_2$ have three distinct peaks each (respectively, Figs. 2d and 3d). The increased binding energies of S 2p and decreased electron density in the Cu(II) complexes in comparison with the parent ligands (respectively, Figs. 2b and 3b) may be indicative of the S atom being involved in forming the coordination core in the Cu(II) complexes.

The increased binding energies of O 1 s in the Cu(II) complexes (Figs. 2c and 3c) in comparison with the parent ligands (Figs. 2a and 3a) suggest the electron donating properties of the hydroxyl group and its coordination to Cu (II). The binding energy being decreased from 534.9 to 533.3 eV and from 533.6 to 532.7 eV may be related to the carboxylate anion being formed in $Cu(L^{IV})_2$ complex (Fig. 3a and c) [46].

3.5. Antifungal activities

Inhibition values of the free ligands and their Cu (II) complexes are listed in Table 4. It should be emphasized that antifungal tests of these compounds were first performed here. Commonly used antifungal drugs Nystatin and Terbinafine were tested as positive controls.

Most of the compounds (both the free ligands and the complexes) exert pronounced antifungal activities ($RI \geqslant 70\%$), which in a number of cases were comparable with those of Nystatin and Terbinafine or even higher. Except for the $Cu(L^{II})_2$ complex, all of them have the highest inhibitory properties ($RI = 100\%$) against *B. cinerea*.

The highest activity ($RI = 100\%$) is characteristic of both ligand **II** against *A. niger* and ligands **I, II**, **IV** and the $Cu(L^{IV})_2$ complex against *Fusarium sp*. Ligands **I**, **II** and $Cu(L^{II})_2$ complex are the best antifungal agents against *Mucor sp.* The most active compounds against *P. lividum* are ligand **I** and $Cu(L^{IV})_2$ complex.

$Cu(L^{I})_2$ and $Cu(L^{II})_2$ complexes, formed by κ^2O,O-ligands, exhibit inhibitory activity comparable to or lower than that of the free ligands. In spite of the activity becoming somewhat lower, the results obtained merit notice, because it is known that the presence of Cu (II) ions may substantially decrease the toxic effect of the ligands [17,18]. According to [47,48], ligands may be more reactive with the microelements necessary for fungal nutrition. Along with this explanation, the authors [49–51] suppose that the reduced activity of the compounds against fungi can be attributed to their inability to form hydrogen bonds through the *O*-donor groups with the active centres of the cell constituents.

It is evident that $Cu(L^{III})_2$ and $Cu(L^{IV})_2$ complexes, formed, respectively, by κ^2O,S- and κ^2O,O,S-ligands, exhibit inhibitory activity comparable to or higher than that of the free ligands. $Cu(L^{III})_2$ is more potent than the parent ligand towards *A. niger* and *Fusarium sp.*, as well as $Cu(L^{III})_2$ and $Cu(L^{IV})_2$, which show higher antifungal potency than the parent ligands towards *P. lividum* and *Mucor sp.* It is common knowledge that chelation could enhance the lipophilic character of central metal atoms which subsequently favours its penetration through the lipid layers of the cell membrane.

4. Conclusion

During the past decade the importance of *o*-diphenol-based (or catechol-based) metal complexes in biology has become evident. Because these ligands are redox active, it must be taken into account when producing their complexes with transition metal ions, especially with copper (II), in order to prevent the production of the oxidized forms of ligands (in particular, *o*-semiquinones, as was shown in [28,33]). We have synthesized several Cu (II) complexes with some SHD derivatives, which seem to be promising for the study of their antifungal activities. Our investigation shows that we have managed to avoid oxidation of the ligands **I**, **III** and **IV** on their complexation with

Cu (II) ions, and it was only for ligand **II** that stabilized phenoxyl radicals were found to be present in a very small amount. It should be noted that their presence in $Cu(L^{II})_2$ had no marked enhancing effect on the antifungal activities of the latter compared with that of the parent ligand **II**. In general, most of the compounds tested show a broad spectra of antifungal activities, which in a number of cases were comparable with those of Nystatin and Terbinafine, or were even higher. These facts may be of interest in the design of new effective drugs and agents against plant pathogenic fungi.

a methylene chloride/*n*-hexane mixture and compound **2** has been isolated as colourless crystals. Yield: 0.51 g (65%). M.p. 218 °C.

Path c: A suspension of anhydrous K_2CO_3 (1.10 g, 8 mmol), 18-crown-6 (0.1 g, 0.38 mmol as a catalyst) and bis-thiourea **1** (0.94 g, 1.6 mmol) in benzene solution (70 mL) was stirred at room temperature for 15 min. To the resulting potassium salt, a benzene (30 mL) solution of $ClCH_2C(O)OCH_3$ (0.35 g, 3.2 mmol) was added dropwise whilst stirring vigorously. The mixture was stirred at room temperature for a further 2 h, then the K_2CO_3 precipitate was filtered off and the solvent was removed in vacuo. The residue was recrystallized from a benzene/*n*-hexane mixture and compound **2** was isolated as colourless crystals. Yield: 0.30 g (59%). M.p. 218 °C. ^{1}H NMR ($CDCl_3$): $\delta = 1.25$ (d, $^3J_{H,H} = 5.1$ Hz, 6H, CH_3), 1.38 (d, $^3J_{H,H} = 5.1$ Hz, 6H, CH_3), 4.81 (d. sept, $^3J_{POCH} = 11.2$ Hz, $^3J_{H,H} = 5.1$ Hz, 2H, OCH), 7.15 (m, 2H, AA′ of AA′XX′, C_6H_4), 7.36 (m, 2H, XX′ of AA′XX′, C_6H_4), 11.97 (s, 2H, NH) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): 64.8 (t, $^3J_{POCH} = 11.2$ Hz) ppm. IR: $\tilde{\nu} = 3240$ (NH), 1648 (C=N), 1020, 980, 945 (POC), 648, 620 (P=S) cm^{-1}. *Anal.* Calc. for $C_{13}H_{20}N_3O_2PS$ (313.36): C, 49.83; H, 6.43. Found: C, 49.89; H, 6.56%.

2.2. Synthesis of [K(18-crown-6)L] (5)

A suspension of **2** (0.16 g, 0.5 mmol), 18-crown-6 (0.16 g, 0.6 mmol) and KOH (0.08 g, 1.5 mmol) in acetone solution (15 mL) was stirred at room temperature for 15 min, then the precipitate was filtered off. The solvent was removed in vacuo. The residue was recrystallized from a methylene chloride/*n*-hexane mixture and compound **5** was isolated as a colourless powder. Yield: 0.19 g (63%). M.p. 218 °C. ^{1}H NMR ($CDCl_3$): 1.25 (d, $^3J_{H,H} = 6.2$ Hz, 6H, CH_3), 1.30 (d, $^3J_{H,H} = 6.2$ Hz, 6H, CH_3), 3.62 (s, 24H, OCH_2), 4.77 (d. sept, $^3J_{POCH} = 9.7$ Hz, $^3J_{H,H} = 6.1$ Hz, 2H, OCH), 6.99 (m, 2H, AA′ of AA′XX′, C_6H_4), 7.20 (m, 2H, XX′ of AA′XX′, C_6H_4) ppm. ^{1}H NMR (d_6-acetone): 1.22 (d. d, $^3J_{H,H} = 6.1$ Hz, 12H, CH_3), 3.66 (s, 24H, OCH_2), 4.69 (d. sept, $^3J_{POCH} = 11.3$ Hz, $^3J_{H,H} = 6.1$ Hz, 2H, OCH), 6.76 (m, 2H, AA′ of AA′XX′, C_6H_4), 7.13 (m, 2H, XX′ of AA′XX′, C_6H_4) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): 62.1 (t, $^3J_{POCH} = 9.7$ Hz) ppm. $^{31}P\{^1H\}$ NMR (d_6-acetone): 61.6 (d. t, $^3J_{POCH} = 10.8$ Hz, $^2J_{PNH} = 8.0$ Hz) ppm. IR: $\tilde{\nu} = 3288$ (NH), 1624 (C=N), 1108 (COC), 992, 964, 948 (POC), 618, 584 (P=S) cm^{-1}. *Anal.* Calc. for $C_{25}H_{43}KN_3O_8PS$ (615.21): C, 48.76; H, 7.04; N, 6.82. Found: C, 48.73; H, 7.07; N, 6.79%.

2.3. Synthesis of O,O′-diisopropyl-(1-{[(diisopropoxyphosphorothio) amino]carbonothioyl}imidazolidine-2-ylidene)amidothiophosphate (8)

A suspension of anhydrous K_2CO_3 (1.38 g, 10 mmol), 18-crown-6 (0.1 g, 0.38 mmol as a catalyst) and bis-thiourea **6** (1.35 g, 2.5 mmol) in acetonitrile solution (50 mL) was stirred at room temperature for 4 h, then the K_2CO_3 precipitate was filtered off. To the filtrate, containing potassium salt **7**, (δ_P 66.0 ppm, CH_3CN), an acetonitrile (50 mL) solution of iodine (0.64 g, 2.5 mmol) was added dropwise whilst stirring vigorously. The mixture was stirred at room temperature for a further 3 h, then the formed white precipitate was filtered off and the solvent was removed in vacuo. The residue was recrystallized from a methylene chloride/*n*-hexane mixture and compound **8** was isolated as colourless crystals. Yield: 0.69 g (55%). M.p. 95 °C. ^{1}H NMR (C_6D_6): 1.43-1.50 (m, 24H, CH_3), 3.23 (m, 2H, AA′ of AA′XX′, NCH_2), 4.10 (m, 2H, XX′ of AA′XX′, NCH_2), 4.84 (d. sept, $^3J_{POCH} = 10.8$ Hz, $^3J_{H,H} = 6.2$ Hz, 2H, OCH), 5.06 (d. sept, $^3J_{POCH} = 10.8$ Hz, $^3J_{H,H} = 6.2$ Hz, 2H, OCH), 8.64 (s, 1H, N*H*CH_2), 12.65 (d, $^3J_{PNH} = 12.2$ Hz, 1H, NHP) ppm. ^{31}P NMR (C_6D_6): 59.2 (d. trip, $^3J_{POCH} = 10.6$ Hz, $^2J_{PNH} = 11.5$ Hz, 1P), 62.0 (t, $^3J_{POCH} = 10.8$ Hz, 1P) ppm. IR: $\tilde{\nu} = 3250$ (NH), 1650 (C=N), 1020, 1000, 975 (POC), 610 (P=S) cm^{-1}. *Anal.* Calc. for $C_{16}H_{34}N_4O_4P_2S_3$ (504.61): C, 38.09; H, 6.79. Found: C, 38.04; H, 6.77%.

2.4. Physical measurements

Infrared spectra (Nujol) were recorded on a Specord M-80 spectrometer in the range 400–3600 cm^{-1}. NMR spectra were obtained on a Varian Unity-300 NMR spectrometer at 25°C. ^{1}H, ^{31}P and $^{31}P\{^1H\}$ spectra were recorded at 299.948 and 121.420 MHz, respectively. Chemical shifts are reported with reference to $SiMe_4$ (^{1}H) and H_3PO_4 (^{31}P). Elemental analyses were performed on a Perkin–Elmer 2400 CHN microanalyser. *N*-Thiophosphorylated thioureas **1** and **6** were prepared according to the previously described methods [2,10].

2.5. Crystal structure determination and refinement

The X-ray diffraction data for the crystals of **2** and **8** were collected on a Enraf-Nonius CAD4 automatic diffractometer using graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation ($T = 293(2)$ K). The stability of the crystals and the experimental conditions were checked every 2 h using three control reflections, while the orientation was monitored every 200 reflections by centering two standards. The structures were solved by direct method using the SIR [12] program and refined by full-matrix least-squares using the program SHELXL-97 [13]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated and refined as riding atoms. All calculations were performed on a PC using the WinGX [14] program. Cell parameters, data collection and data reduction were performed on an Alpha Station 200 computer using the MOLEN [15] program. All figures were made using the program PLATON [16].

Some crystal data of **2**: $C_{13}H_{20}N_3O_2PS$; $M = 313.35$; space group $P2_1/n$ (No. 14); dimensions $0.40 \times 0.35 \times 0.30$ mm, $a = 11.245(2)$ Å, $b = 9.564(1)$ Å, $c = 15.243(2)$ Å;

$\beta = 92.69(6)°$; $V = 1637.5(4)$ Å^3, $D_{calc} = 1.27$ Mg m^{-3}, $Z = 4$, μ(Mo Kα) = 0.3 mm^{-1}; $F(000) = 664$, $\theta_{max} = 26.3°$. A total of 3429 unique reflections were measured, of which 2276 were with $I > 2\sigma(I)$. The structure converged with $R = 0.0382$, $R_w = 0.0968$. Some crystal data of **8**: $C_{16}H_{34}N_4O_4P_2S_3$; $M = 504.62$; space group $P2_1/n$ (No. 14); dimensions $0.40 \times 0.40 \times 0.35$ mm, $a = 10.418(5)$ Å, $b = 8.734(3)$ Å, $c = 29.616(7)$ Å; $\beta = 96.20(2)°$; $V = 2679(2)$ Å^3, $D_{calc} = 1.25$ Mg m^{-3}, $Z = 4$, μ(Mo Kα) = 0.420 mm^{-1}; $F(000) = 1072$, $\theta_{max} = 26.3$. A total of 4533 unique reflections were measured, of which 2463 were with $I > 2\sigma(I)$. The structure converged with $R = 0.0690$, $R_w = 0.1905$.

3. Results and discussion

3.1. Synthesis

Earlier it has been shown by us [11] that thiophosphorylated bis-thiourea (**1**) oxidation (Scheme 1, path a), leads to elimination of the thiophosphoric acid isothiocyanate molecule and to thiophosphorylated imine formation (**2**). In the present work we have established that thiourea **1** interaction with bases in benzene solution brings similar results (Scheme 1, path b). However, in the latter case 2–3 days are required for completion of the process.

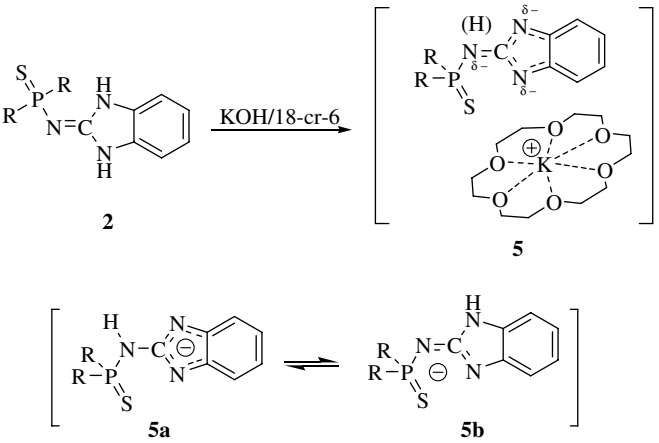
It is known that the reactions of chloranhydrides, amides and monochloracetic acid ethers with *N*-thiophosphorylated thioureas lead to iminothiazolidine-4-on *N*-(thio)phosphorylated derivatives [3]. Bis-thiourea **1**, under similar conditions, does not form cyclic *S*-alkylation products, only imine **2** and isothiocyanate were isolated from the reaction mixture.

As a possible scheme of processes, one can assume reactive carbodiimide formation with subsequent intramolecular cyclization and isothiocyanate molecule elimination.

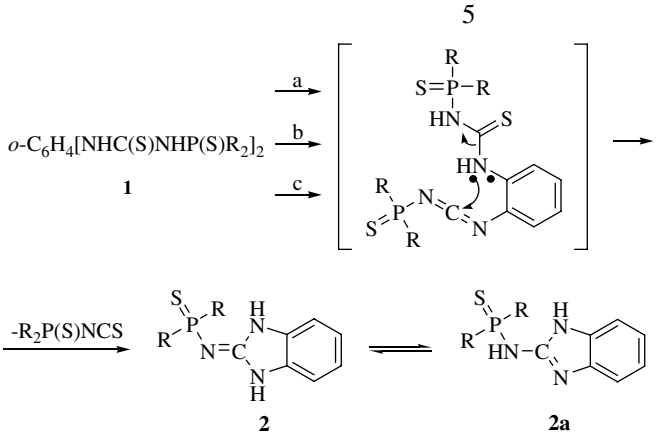
An electron acceptor effect of a thiophosphoryl substituent in combination with an opportunity of negative charge delocalization within the N–C=N fragment and the benzimidazolic cycle gives acidic properties. The reaction of **2** with KOH in acetone solution in the presence of 18-crown-6 has allowed the isolation of the potassium salt with $[K^+(18\text{-crown-6})L^-]$ composition as a colourless fine-crystalline solid, insoluble in water. Based on data of IR, ^{1}H and ^{31}P NMR spectroscopy and microanalysis, the structure **5** was ascribed to this salt (Scheme 2).

Bis-thiourea (**6**), containing an ethylenediamine fragment, behaves in the oxidation reaction differently: under KOH treatment it converts into salt (**7**), which does not experience any further transformations. In the IR spectrum of compound **7** there are no absorption bands in the range which is characteristic for the C=N bond. The NMR ^{31}P{^{1}H} spectrum of the salt **7** contains a signal with a chemical shift of 66.0 ppm, that is typical for such a kind of structure. Under iodine treatment on a salt **7** solution, an imidazolidine cycle (**8**) forms, but the process proceeds without isothiocyanate molecule elimination (Scheme 3).

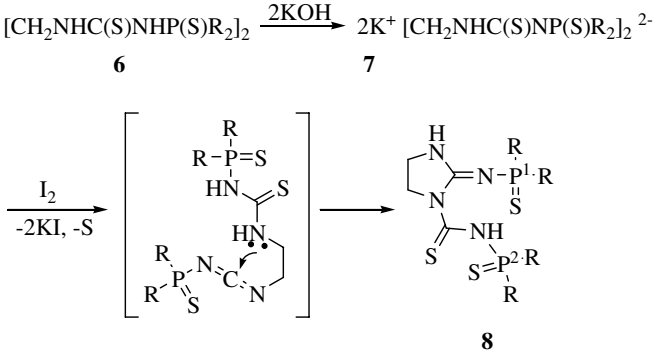
Thiourea fragment preservation in the molecule of **8** is explained by the greater nucleophility of the imidazolidine fragment nitrogen atom in comparison with the benzo-analogue **2**. Electronic density delocalization in the conjugated



Scheme 2.



Scheme 1. R = O*i*-Pr. Reagents: (a) I_2, $2NEt_3$ (–[S], $–2NEt_3 \cdot HI$); (b) K_2CO_3/18-crown-6 ($–K_2S$); (c) $ClCH_2C(O)OCH_3$, $1/2(K_2CO_3$/18-crown-6) ($–HSCH_2C(O)OCH_3$, –KCl).



Scheme 3.

benzimidazolimine cycle makes the existence of a product of isocyanate addition to compound **2** unfavorable.

3.2. IR and NMR spectroscopy

The IR spectrum of **2** contains an absorption band for a C=N group at 1648 cm^{-1}. There are triplets at 64.8 ppm ($CDCl_3$) ($^3J_{POCH}$ 11.2 Hz) and 63.6 ppm (d_6-acetone) ($^3J_{POCH}$ 11.1 Hz) in the ^{31}P NMR spectrum, corresponding to the imidothiophosphate environment of phosphorus. Thus, in contrast with the phosphoryl analog reported in [6], the phosphorylimido form **2** is the major prototropic form both in the crystal and in solution. There are no spectral signs of the phosphorylamido form **2a** found in NMR spectra.

In the ^1H NMR spectrum of the benzimidazole **2**, the C_6H_4 moiety gives a AA′XX′ system which corresponds to symmetrical substitutions in the benzene ring. Protons of the NH-groups show up in the ^1H NMR spectrum as a singlet at 11.97 ppm, due to the deshielding effect of the benzene ring and H bond formation. The isothiocyanate (*i*-PrO)$_2$P(S)NCS has been found in the reaction mixture by IR and ^{31}P NMR spectroscopy (δ_P 43.0 ppm; ν(N=C=S) 2000 cm^{-1}).

The ^1H NMR spectrum of the salt **5** in $CDCl_3$ contains a singlet signal of 18-crown-6 OCH_2 groups at 3.62 ppm, with the intensity corresponding to 24 protons in comparison with signals of O*i*-Pr and C_6H_4 moieties. Low-frequency shift of the C=N band in the IR spectrum of compound **5** confirms the conjugated anion formation.

For the anion there are two possible prototropic forms, which differ from one another by the mode of negative charge delocalization (Scheme 2). In the form **5a** the negative charge is delocalized within the conjugated bicyclic system, whilst in the form **5b** the exocyclic CNPS fragment takes part in the delocalization.

^1H NMR spectra recorded for $CDCl_3$ and d_6-acetone solutions do not show the resonance of the NH proton. It could be due to fast proton exchange in solution between the forms **5a** and **5b**. In the ^{31}P NMR spectrum, recorded in d_6-acetone, a phosphorus signal has the shape of a doublet of triplets with $^2J_{PH}$ 8.0 Hz, which also confirms the formation of the form **5a** in solution (Scheme 2). The ^{31}P NMR spectrum recorded in $CDCl_3$ shows a triplet signal for the phosphorus atom with a characteristic constant $^3J_{POCH}$ of 9.7 Hz. The fact that the signal is not split by the proton of the neighbouring NHP group is a consequence of increasing of proton exchange rate in $CDCl_3$ media and of partial equilibrium shift to the form **5b**. In the ^1H NMR spectra of the salt **5** the C_6H_4 moiety gives a AA′XX′ spin system regardless of the solvent nature.

Another confirmation of **5a** form prevalence is the high-field shift of the phosphorus atom signal in ^{31}P NMR spectra, at 2.7 ppm ($CDCl_3$) and 3.2 ppm (d_6-acetone) with respect to neutral benzimidazole **2**. Quite contrary to that, the deprotonated forms of the *N*-acylamidophosphates $[RC(X)NP(Y)(OR')_2]^-$ (X, Y = O, S) have significant low-field shift of the signals in ^{31}P spectra due to delocalization of the negative charge in the XCNPS moiety [1].

The $^{31}P\{^1H\}$ NMR spectrum of **8** contains two singlet signals of equal intensity, with chemical shifts of 62.0 and 59.2 ppm, corresponding phosphorus atoms in imidothiophosphate (P^1) and amidothiophosphate (P^2) environments, respectively. In the NMR ^{31}P spectrum, without decoupling from protons, they represent a triplet and a doublet of triplets with characteristic $^3J_{POCH}$ and $^2J_{PNH}$ constants. A shift of the signal of the P^2NH group proton up to 12.65 ppm in the NMR ^1H spectrum specifies the preservation of the $N^4H\cdots N^3$ hydrogen bond in solution. The ^1H NMR spectrum of **8** contains a double set of isopropoxyl group signals; NCH_2 protons of the imidazolidine cycle exhibit an AA′XX′ system.

3.3. Crystal structure of 2

According to the X-ray data (Fig. 1), the five-membered $N^1C^2N^3C^4C^5$ cycle in a molecule of **2** is planar with maximal deviation of atoms from this plane with distances which do not exceed the experimental error (0.01(2) Å). It is an interesting fact that the P=S bond is practically in the covered eclipsed conformation with the rather double N=C bond. The molecule of **2** in a crystal forms two types of hydrogen bonds: intramolecular and intermolecular. The intramolecular hydrogen bond is formed by a proton of the NH-group and a sulfur atom. Parameters of the intramolecular hydrogen bond are as followed: $d(N^4–H^4)$ 0.80(2) Å, $d(H^2\cdots S^1)$ 2.52(3) Å, $d(N^4\cdots S^1)$ 3.151(2) Å, $\angle(N^3–H^3–S^1)$ 136(2)°. As a result of this bonding a six-membered cycle $S^1P^1N^2C^3N^3H^3$ having the "envelope" conformation forms: the $P^1N^2C^2N^3H^3$ moiety is planar with a maximal deviation for atom N^2 of 0.033(2) Å, atom S^1 is deviated from this plane with a distance of 0.5509(9) Å. Intermolecular hydrogen bonds $N^1–H^1\cdots N^{2'}$ $(1-x, 1-y, -z)$ lead to centrosymmetric dimer formation in the crystal. The bonds have the following parameters: $d(N^1–H^1)$ 0.81(2) Å, $d(H^1\cdots N^{2'})$ 2.12(2) Å, $d(N^1\cdots N^{2'})$ 2.922(2) Å, $\angle(N^1–H^1\cdots N^{2'})$ 173(3)°.

3.4. Crystal structure of 8

In the crystal of compound **8** (Fig. 2) there is an imidazolidine-2-imine planar fragment. Bonds at the C^3 atom in a cycle are not equivalent. The lone-pair of electrons of the N^2 nitrogen atom is in conjugation only with the C=N bond, while the N^1 atom is under thiocarbonylic group acceptor influence. The five-membered cycle $C^1C^2N^1C^3N^2$ in a molecule of **8** is planar with maximal deviation of atoms from this plane with distances 0.016(7) Å. As in **2**, the thiophosphoryl group is coplanar with the five-membered cycle. Deviations of sulfur, phosphorus and imine nitrogen atoms from the $C^1–C^2–N^1–C^3–N^2$ plane are 0.166(2), −0.166(1) and 0.028(4) Å, respectively. An exocyclic *N*-thiophosphorylthioamide fragment is in a conformation with a *syn*-arrangement of $S^3–C^4$ and $N^4–P^2$ bonds,

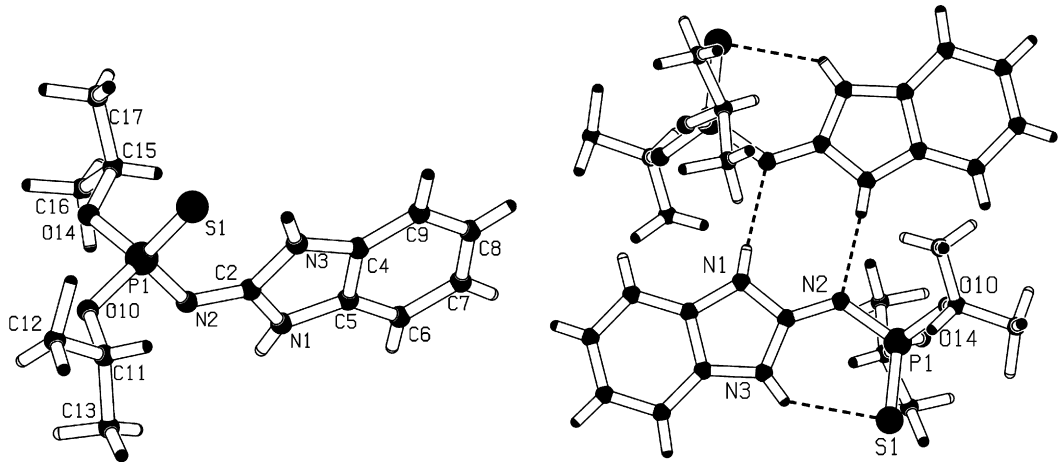


Fig. 1. Molecular drawing of **2** (left); hydrogen bonding between two molecules (right). Selected bond distances (Å), bond angles (°) and torsion angles (°) of **2**: S^1–P^1 1.9400(9), P^1–N^2 1.622(2), N^2–$C^3$1.317(3), N^1–C^3 1.352(3), N^4–C^3 1.361(3), P^1–N^2–C^2 126.8(2), S^1–P^1–N^2–C^3 −24.7(2), P^1–N^2–C^3–N^4 7.3(4).

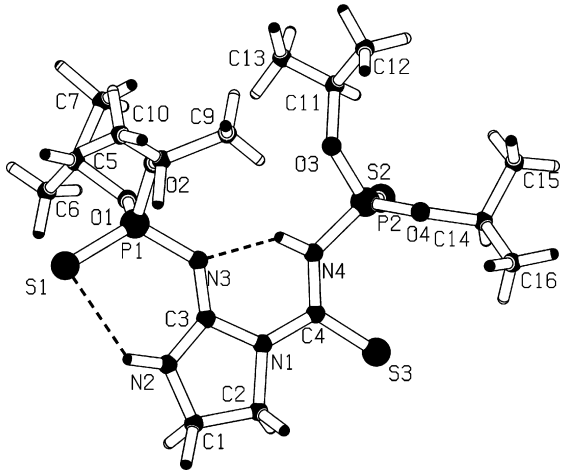

Fig. 2. Molecular drawing of **8**. Selected bond distances (Å), bond angles (°) and torsion angles (°) of **8**: S^1–P^1 1.938(2), P^1–N^3 1.626(5), N^3–C^3 1 1.294(6) N^1–C^3 1.402(4), N^2–C^3 1.397(6), N^2–C^1 1.438(8), N^1–C^2 1.471(6), N^1–C^4 1.399(5), S^2–P^2 1.918(2), P^2–N^4 1.680(3), N^4–C^4 1.351(6), S^4–C^4 1.651(5), $S^1P^1N^3$ 118.7(2), $S^2P^2N^4$ 116.2(1), $P^1N^3C^3$ 128.1(4), $P^2N^4C^4$ 127.8(3), $P^2N^4C^4$–S^4 8.7(7), $S^1P^1N^3C^3$ 21.9(5), $S^2P^2N^4C^4$ 63.3(5), $P^1N^3C^3N^2$ −9.4(8).

typical for such compounds [1]. The fragment S^3–C^4–N^4–P^2 belongs to the five-membered cycle plane. Maximal deviation from the C^1–C^2–N^1–C^3–N^2 plane for the phosphorus atom is −0.122(1) Å.

There are intramolecular hydrogen bonds, $N^2H\cdots S^1$ and $N^4H\cdots N^3$, in molecule **8**. Parameters of the intramolecular hydrogen bonds are as followed: $d(N^2$–$H^2)$ 0.86 Å, $d(H^2\cdots S^1)$ 2.60 Å, $d(N^2\cdots S^1)$ 3.224(6) Å, $\angle(N^2$–H^2–$S^1)$ 134.8° and $d(N^4$–$H^4)$ 0.86 Å, $d(H^4\cdots N^3)$ 1.91 Å, $d(N^4\cdots N^3)$ 2.616(6) Å, $\angle(N^4$–H^4–$N^3)$ 138.2°. These result in the formation of two six-membered cycles $N^3C^3N^1C^4N^4H^4$ and $S^1P^1N^3C^3N^2H^2$. Both of them have the "envelope" conformation, as in structure **2**. The $N^3C^3N^1C^4N^4$ fragment is planar with the maximum deviation of atom C^4 with a distance of 0.033(5) Å, and atom H^4 is deviated from this plane with a distance of 0.20 Å. The $S^1H^2N^2C^3N^3$ fragment is also planar within the limits of 0.038 Å (the maximum deviation of the H^2 atom), P^1 is deviated with a distance 0.302(1) Å.

4. Conclusion

It has been established that the bis-thiourea *o*-$C_6H_4[NHC(S)NHP(S)(O\textit{i}\text{-}Pr)_2]_2$ (**1**) undergoes cyclization with elimination of a molecule of diisopropylthiophosphoric acid isothiocyanate and with formation of a derivative of phosphorylated benzimidazole **2**. The cyclization process accelerates significantly upon using oxidants or alkylation agents. In contrast to the analogue with a phenylene bridging fragment, the bis-thiourea $[CH_2NHC(S)NHP(S)(O\textit{i}\text{-}Pr)_2]_2$, upon treatment with a base, converts into a salt, which oxidation with iodine affords the iminoimidazolidine **8**, containing the *N*-thiophosphorylthiourea fragment. Thiophosphoryl isothiocyanate elimination does not occur whilst cyclization is the case.

The synthesized compounds **2** and **8** contain neighbouring PS, CN, CS groups and acidic NH protons. All these make them interesting as polyfunctional ligands, capable of forming chelate complexes with d-metal cations.

We have been interested in the design, synthesis and investigation of polynuclear manganese complexes, especially based on pivalic acid [19–21]. In this paper, we report the synthesis, crystal structures and characterization of two new manganese pivalates, namely homo-valent $[Mn_3^{III}O\text{-}(O_2CCMe_3)_6(Im)_3](Me_3CCO_2)\cdot 0.5Me_3CCO_2H$ (**1**) and mixed-valent $[Mn_2^{III}Mn^{II}O(O_2CCMe_3)_6(1\text{-MeIm})_3]$ (**2**) (where Im = imidazole, 1-MeIm = 1-methylimidazole) complexes.

2. Experimental

2.1. Materials and methods

Starting materials were purchased from commercial sources and used without further purification. $[Mn_6O_2(O_2CCMe_3)_{10}(Me_3CCO_2H)_4]$ was prepared by the reported procedure [22]. The infrared spectra were recorded on a Perkin–Elmer Spectrum One spectrometer using KBr pellets in the region 4000–400 cm^{-1}. TG analyses were carried out on a Mettler-Toledo TA 50 in dry nitrogen (60 ml min^{-1}) at a heating rate of 5 °C min^{-1}.

2.2. Synthesis of complexes

2.2.1. Synthesis of $[Mn_3O(O_2CCMe_3)_6(Im)_3](Me_3CCO_2)\cdot 0.5Me_3CCO_2H$ (1)

Imidazole (1.25 g, 18.36 mmol) and pivalic acid (5.4 g, 52.89 mmol) were dissolved in water (4 ml) and stirred. Then, to this solution was added $MnCl_2\cdot 4H_2O$ (0.8 g, 4.06 mmol) followed by adding solid $KMnO_4$ (0.25 g, 1.58 mmol) in small portions to give a brown homogeneous solution. Finally, this solution was heated at 60 °C for 1 h and then was left to stand overnight at r.t. The microcrystalline precipitate was filtered off, washed with hexane and dried in air. Single crystals suitable for X-ray analysis were obtained by recrystallization of **1** from MeCN. Yield (after recrystallization): 0.36 g (30%). *Anal.* Calc. for $C_{93}H_{160}Mn_6N_{12}O_{32}$: C, 48.82; H, 7.05; N, 7.35. Found: C, 48.65; H, 7.04; N, 7.38%. IR (KBr, cm^{-1}) 3159m, 3067m, 2960m, 2872m, 1609vs, 1570m, 1547m, 1510m, 1482s, 1458m, 1405s, 1370s, 1358s, 1329m, 1224s, 1148w, 1098w, 1069m, 958w, 938w, 895w, 836w, 786m, 751m, 655m, 625m, 598m, 562w.

2.2.2. Synthesis of $[Mn_3O(O_2CCMe_3)_6(1\text{-MeIm})_3]$ (2)

Complex $[Mn_6O_2(O_2CCMe_3)_{10}(Me_3CCO_2H)_4]$ (0.5 g, 0.28 mmol) and $KMnO_4$ (0.05 g, 0.31 mmol) were dissolved in 1-MeIm (2 ml). The mixture was heated at 90 °C for an hour and then the reaction was allowed to cool. After two days this mixture was extracted with diethyl ether. On the next day, from the diethyl ether extracts, crystals suitable for X-ray analysis formed. The crystals were filtered off and washed with cold diethyl ether. Yield: 0.27 g (31.03%). *Anal.* Calc. for $C_{84}H_{144}Mn_6N_{12}O_{26}$: C, 48.79; H, 7.02; N, 8.13. Found: C, 47.78; H, 6.80; N, 8.15%. IR (KBr, cm^{-1}) 3129m, 2958s, 2926sh, 2869sh, 1608br.vs, 1538m, 1526m, 1482s, 1457m, 1411vs, 1370s, 1358s, 1286w, 1227s, 1110s, 1024w, 956w, 932w, 893w, 831m, 788m, 762w, 733w, 695m, 656m, 615m, 599m.

2.3. X-ray crystallography

Diffraction data were collected at 153 K for **1** and **2** with a Stoe Mark II Imaging Plate Diffractometer using Mo Kα graphite-monochromated radiation. Crystallographic data and details of the refinement process are summarized in Table 1. The structures were solved by direct methods using the program SHELXS-97 [23]. Refinement and all further calculations were carried out using SHELXL-97 [24]. H-atoms were located from Fourier difference maps and refined isotropically; their thermal parameters were kept fixed with $U_{iso} = 1.5U_{eq}$ of their carrier O and N atoms. In both structures some of methyl groups in the pivalate fragments are disordered over two positions with occupancies 0.50 ± 0.10. Non-hydrogen atoms were refined anisotropically, using weighted full-matrix least-squares on F^2.

2.4. Magnetic measurements

Magnetic susceptibility and magnetization data of powdered samples of compounds **1** and **2** were collected on a MPMS Quantum Design SQUID magnetometer (XL-5) in the temperature range of 300–1.8 K and at applied magnetic fields up to 5 T. The samples were placed in a saran foil bag for compound **1** and in a gelatine capsule for compound **2**. A straw was used as the sample holder. Data were corrected for the experimentally determined diamagnetism of the sample holder and the diamagnetic contributions of the samples, which were estimated from Pascal's constants. The Levenberg–Marquardt least-squares fitting algorithm, in combination with MAGPACK [25], was used to model the experimental magnetic susceptibility and magnetization data.

3. Results and discussion

3.1. Synthesis and preliminary characterization

The reaction of manganese(II) chloride with $KMnO_4$, imidazole and an excess of pivalic acid in a small amount of water leads to the formation of $[Mn_3O(O_2CCMe_3)_6(Im)_3](Me_3CCO_2)\cdot 0.5Me_3CCO_2H$ (**1**). This method of preparing oxo-bridged manganese complexes by the oxidation of Mn(II) ions using MnO_4^- ions in the presence of carboxylate ligands and aromatic amines was first used by Lis for the synthesis of a dodecanuclear complex [26] and then largely developed by Christou et al. [6,27]; it is a very useful synthetic route to design Mn complexes with higher oxidation states (Mn^{III}, Mn^{IV}). Moreover, the largest manganese carboxylate cluster, a Mn_{30} complex [28], was also obtained from this type of comproportionation reaction. The synthesis of the mixed-valence compound $[Mn_3O(O_2CCMe_3)_6(1\text{-MeIm})_3]$ (**2**) was performed by the

interaction of the hexanuclear mixed-valent $[Mn^{II}_4Mn^{III}_2O_2(O_2CCMe_3)_{10}(Me_3CCO_2H)_4]$ cluster with $KMnO_4$ in 1-methylimidazole.

The IR spectra of complexes **1** and **2** have strong and broad bands in the 1609–1546 and 1369–1357 cm^{-1} region, which are due to asymmetric and symmetric vibrations, respectively, of the coordinated carboxylate groups [29,30] of the pivalate ligand. The broad bands with medium intensity in the 3159–3067 cm^{-1} region can be ascribed to the absorption frequencies of the N–H vibration of Im and O–H vibration of solvate pivalic molecules in compound **1**.

Thermal analysis of **1** and **2** has been performed in a nitrogen atmosphere in the temperature range 25–600 °C. For **1** the first weight loss of 19.05% from 110 to 210 °C corresponds to the loss of a half molecule (per formula unit) of solvate pivalic acid, one molecule of the uncoordinated pivalic anion and one imidazole molecule (calculated 19.25%). On further heating, the decomposition of remaining organic ligands takes place in two unidentified steps with total weight loss of 61.08% and is completed below 500 °C to give the expected oxide (observed 19.95%, calculated 20.00%). It is interesting to note that the mixed-valent oxo-centered trinuclear compound **2** decomposes to the final products below 275 °C, a much lower temperature compared to the above mentioned homo-valent compound **1**. The first weight loss of about 4.54% occurred at 110 °C, which corresponds to the loss of a half molecule (per formula unit) of 1-MeIm (calculated 3.97%). A further weight loss of 30.25% occurred between 130 and 210 °C, which agrees with calculated values of 29.62% for the release of the remaining 1-MeIm molecules and one molecule of pivalate ligand. The decomposition of the pivalate ligands was completed at ca. 275 °C (the weight loss is 40.55%) with the observed remaining weight percentage of 24.58%.

3.2. Crystal structures

3.2.1. The structure of $[Mn_3O(O_2CCMe_3)_6(Im)_3](Me_3CCO_2)\cdot 0.5Me_3CCO_2H$ (1)

The crystal structure of **1** consists of two independent $[Mn_3O(O_2CCMe_3)_6(Im)_3]^+$ cations (molecules **A** and **B**), two $Me_3CCO_2^-$ anions and a neutral Me_3CCO_2H molecule (Fig. 1). The structure of cation **A** is shown in Fig. 2. Selected bond distances and angles for **1** are listed in Table 2. Three Mn(III) atoms form a nearly equilateral triangle with an oxygen atom in the center. The Mn···Mn distances within the triangle are all very similar (3.260 ± 0.006 Å). The central μ_3-oxygen atom is slightly displaced from the Mn_3 triangular plane (0.015(2) Å for molecule **A** and 0.019(2) Å for molecule **B**). The Mn–(μ_3-O) bond distances are in the range of 1.879(2)–1.890(2) Å (Table 2). Four oxygen atoms from the bridging carboxylate groups and a terminal imidazole nitrogen atom additionally complete coordination at each Mn(III) atom. The Mn–O_{carb} bond distances range from 1.923(2) to 2.186(3) Å, and the Mn–N bond distances lie in the range of 2.011(3)–2.026(3) Å. Thus, the manganese coordination geometry can be regarded as a slightly distorted octahedron. The configuration, bond distances and bond angles of molecules **A** and **B**

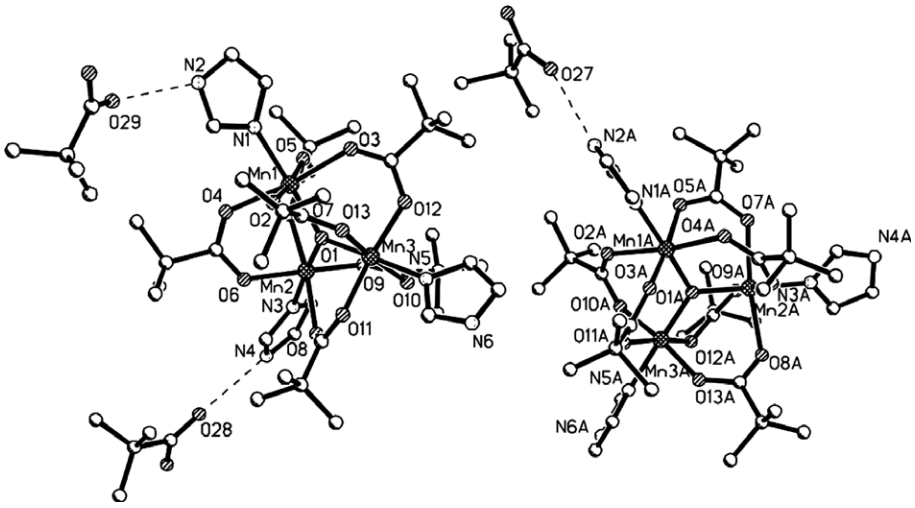

Fig. 1. View of the structure of complex **1** (molecule **A**, left; molecule **B**, right). Hydrogen bonds are shown as dashed lines. Hydrogen atoms are omitted for clarity.

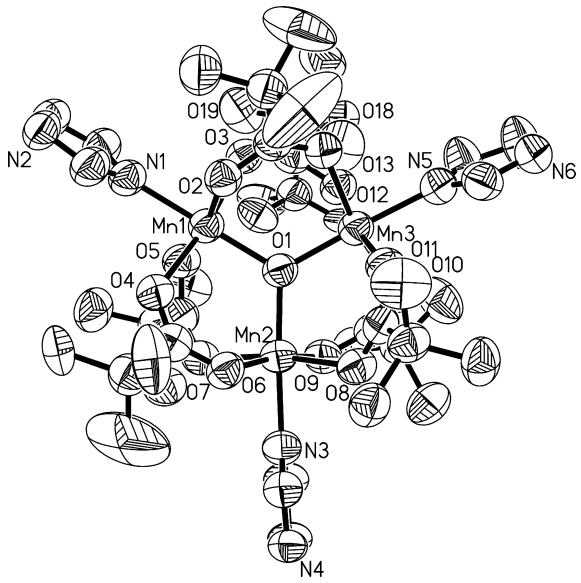

Fig. 2. View of the structure of molecule **A** in compound **1.** Hydrogen atoms are omitted for clarity.

are in a good agreement with the data in earlier investigated structures of oxo-centered trinuclear manganese(III) carboxylate complexes [13–15] (Table 3).

The presence of the uncoordinated carboxylic group of pivalic acid and the solvate acid molecule as well as of the N–H group of imidazole ligand results in an extensive hydrogen-bonded network in complex **1**. It is interesting to note that in this crystal structure the formation of centrosymmetric motifs consisting of four trinuclear clusters is observed. The packing of molecules in the crystal structure along the [0 0 1] direction is shown in Fig. 3a. In addition, these centrosymmetric motives are connected by hydrogen bonds N–H···O (2.636(4)–2.866(4) Å) between carboxyl oxygen atoms of pivalic acid and nitrogen atoms of Im, as well as by hydrogen bonds O–H···O of 2.556(4) Å, forming zig-zag chains (Fig. 3b). Finally, a 3D supramolecular architecture is formed in compound **1**. The parameters of all intermolecular hydrogen bonds are listed in Table 4.

3.2.2. The structure of $[Mn_3O(O_2CCMe_3)_6(1\text{-}MeIm)_3]$ (**2**)

X-ray diffraction analysis revealed that complex **2** consists of two independent molecules (**A** and **B**) of the trinuclear oxo-centered $[Mn_3O(O_2CCMe_3)_6(1\text{-}MeIm)_3]$ cluster in the unit cell. The structure of molecule **B** is shown in Fig. 4. Selected bond distances and angles for **2** are listed in Table 5. Each Mn atom adopts a slightly distorted octahedral geometry and is coordinated by an oxygen atom of the central triangle, four oxygen atoms from bridging pivalate ligands, and a terminal 1-MeIm nitrogen atom. The central μ_3-oxygen atom is slightly displaced from the Mn_3 triangular plane (0.029(2) Å for molecule **A** and 0.028(2) Å for molecule **B**). The Mn···Mn distances are in the range of 3.220(2)–3.408(2) Å, and the Mn(2)···Mn(3) distances of 3.220(2) and 3.312(2) Å for **A** and **B** molecules, respectively, are significantly shorter than the Mn(1)···Mn(2) (average value 3.391 Å) and Mn(1)···Mn(3) (average value 3.406 Å) distances. Based on the neutral charge of the $[Mn_3O(O_2CCMe_3)_6(1\text{-}MeIm)_3]$ cluster, the Mn oxidation states in this complex are given as $[Mn^{III}_2Mn^{II}O]^{6+}$. As expected for its lower oxidation state, the position of the Mn(II) atom can be assigned on the basis of its longer metal–μ-oxygen and metal–ligand bond distances compared with the Mn(III) atoms (Table 3). From these data Mn(1) is readily assigned as the Mn^{II} center, whereas Mn(2) and Mn(3) atoms are Mn^{III} centers. The Mn^{III}–O(1) bond distances are in the range 1.800(4)–1.848(4) Å, which is in agreement with the common basic carboxylate type seen for the above mentioned trinuclear manganese(III) complex **1** and other trinuclear manganese(III) carboxylate complexes (Table 3). For manganese(II) atoms these distances are significantly longer and

equal to 2.128(5) Å for Mn(1)–O(1) and 2.170(4) Å for Mn(1A)–O(1A). The four Mn–O_{carb} distances around manganese(III) atoms are in the range of 1.947(5)–2.174(5) Å, and the Mn^{III}–N distances (2.060(6)–2.064(5) Å) are quite similar to those found in **1**. As expected for a typical manganese(II) atom, Mn–O_{carb} bond distances are found in the range of 2.129(5)–2.207(5) Å, which is slightly longer than those for Mn^{III} atoms. The Mn^{II}–N distance of 2.251(6) Å at Mn(1) and Mn(1A) is also longer than that for the trivalent manganese atom (2.256(6) Å). The Mn–O(1)–Mn angles range from 116.6(2)° up to 125.4(2)° and differ slightly from the analogous angles which were found in a Mn_3O cluster with imposed C_2 symmetry [9].

In contrast to **1**, in which an extensive network of hydrogen-bonding interactions is observed due to the presence of the uncoordinated carboxyl group of pivalic acid and the NH group of imidazole, aromatic C–H$\cdots\pi$ interactions [31–33] embracing 1-methylimidazole rings enhance the structural stability in compound **2**. Because the 1-MeIm heterocycles are not all parallel with each other, the aromatic–aromatic interactions in compound **2** are either edge-to-face interactions or T-shaped orientations. In addition to the aromatic C–H$\cdots\pi$ interactions, five 1-MeIm heterocycles from six heterocycles (heterocycles are marked as follows: N1 ∩ N2 is cycle N1C1N2C2C3, N3 ∩ N4–N3C5N4C6C7, etc.) exhibit five contacts, each between aliphatic C–H of the methyl group and the π-cycle of another molecule (Table 6). Note that all six 1-MeIm heterocycles are involved in such interactions forming a 3D network in compound **2** (Fig. 5). The heterocycle N5A ∩ N6A forms with the N1A ∩ N2A heterocycle two types of C–H$\cdots\pi$ contacts, one exhibiting aromatic–aromatic edge-to-face interaction having a centroid–centroid distance of 4.468 Å and plane angle of 24.47° between the aromatic heterocycles, and the other being an aliphatic–aromatic interaction between the hydrogen (H12E) of the methyl group (C12) and imidazole cycle (N1A ∩ N2A) with the shortest interatomic distance of 2.835 Å. Further, the cycle N1A ∩ N2A interacts with N1 ∩ N2 forming an edge-to-face contact with the centroid–centroid distance of 4.242 Å (plane angle 31.69°) and the aliphatic–aromatic interaction of 3.032 Å (a typical aliphatic–aromatic interaction is in the range of 2.79–3.05 Å [32]). The third edge-to-face interaction is found between cycles N1 ∩ N2 and N5 ∩ N6 (centroid–centroid distance 4.374 Å, plane angle 24.22°) and there is

a contact with 2.848 Å distance formed by the C–H of the methyl group (C12) and the π-cycle (Table 6). The next C–H···π interactions consisting of the edge-to-face contact (centroid–centroid distance 4.250 Å, plane angle 18.11°) and aliphatic–aromatic contact (2.952 Å) are found between N5 ∩ N6 and N3 ∩ N4 heterocycles. There is further close C–H···π contact with distance of 2.999 Å between heterocycle N3 ∩ N4 (C6) and N3A ∩ N4A (C7–H7A), which is probably more of a T-shaped interaction based on the interplane angle of 68.64°. It is noted that there is only the aliphatic–aromatic C–H···π interaction of 2.986 Å between the heterocycle N3A ∩ N4A and the neighboring heterocycle N5A ∩ N6A (the centroid–centroid distance is 5.953 Å and plane 86.72°).

3.3. Magnetic properties

The magnetic susceptibility χ_{Mol} between 1.9 and 300 K of the trinuclear, μ_3-oxo-bridged manganese(III) compound **1** was determined. In Fig. 6, the temperature dependence of the inverse molar susceptibility χ^{-1}_{Mol} is depicted. Above 55 K, the data can be fitted to the Curie–Weiss expression with a Weiss constant $\theta = -147$ K which is indicative of antiferromagnetic exchange interactions. The thermal dependence of the molar susceptibility, plotted as $\chi_{Mol}T$ versus T is shown in Fig. 7. The $\chi_{Mol}T$ value at 300 K is 8.14 emu K mol^{-1}, which is a little below the calculated value of 9 emu K mol^{-1} for three non-interacting manganese(III) ions ($S = 2$, $g = 2$). The decrease of $\chi_{Mol}T$ with decreasing temperature suggests overall antiferromagnetic exchange interactions. A simulation based on the model proposed by Borrás-Almenar et al. [25] using the isotropic Heisenberg–Dirac–Van Vleck term, $\widehat{H}_O = -2\Sigma_{i,f}J_{if}\widehat{S}_i\widehat{S}_f$, as the leading part of the exchange spin Hamiltonian, was applied. Thereby and in correspondence with the structural data, the compound is regarded as an isosceles triangle and consequently, two different exchange coupling constants are considered: J between Mn(3)–Mn(1) and Mn(3)–Mn(2) and J^* between Mn(1) and Mn(2). However, as shown in a theoretical study by Brechin et al. [34], there is a high density of different energy levels close to the ground state and also the total S value of the ground state depends strongly on the ratio J/J^*, hence it is a quite complex situation. Taking the data of the temperature dependence of the magnetic susceptibility and the magnetization data which are measured at 1.85 K (Figs. 7 and S1), a simulation of the experimental data revealed the following parameters: $J = -7.5$ cm^{-1}, $J^* = -5.2$ cm^{-1}, $D = 15.5$ cm^{-1} and $g = 2.1$. With these parameters, the $\chi_{Mol}T$ versus T data can be simulated fairly well. On the basis of the same parameter set, also the magnetization data can be approached reasonably well,

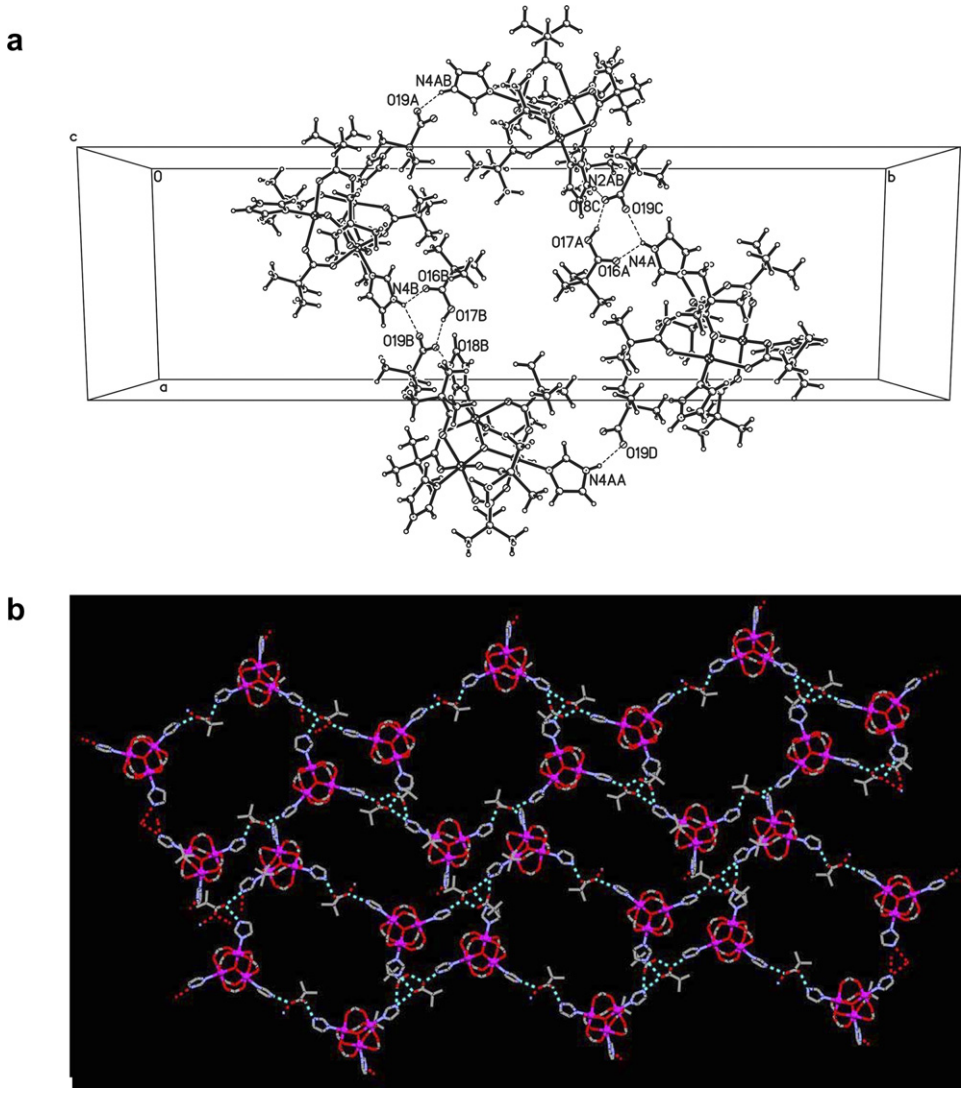

Fig. 3. (a) A fragment of the crystal structure in compound **1.** Hydrogen bonds are shown as dashed lines. (b) Perspective view of the crystal structure along the *b* axis. Hydrogen bonds are shown as dashed lines, the methyl groups of the coordinated pivalic acid are omitted for clarity.

especially if one notes the complex configuration of multiple states lying close to the ground-state. Overall, a ground state with $S = 0$ but with energetically close lying states with $S = 1$ and $S = 2$ can be anticipated.

For the trinuclear mixed-valence compound **2**, the temperature dependence of the inverse molar susceptibility χ_{Mol}^{-1} between 1.9 and 300 K is depicted in Fig. 8. A fit above 55 K of the data to the Curie–Weiss expression gives a Weiss constant $\theta = -140$ K, which is indicative of antiferromagnetic exchange interactions. In Fig. 9 the thermal dependence of the molar susceptibility, plotted as $\chi_{\mathrm{Mol}}T$ versus T, is shown. The experimentally determined room

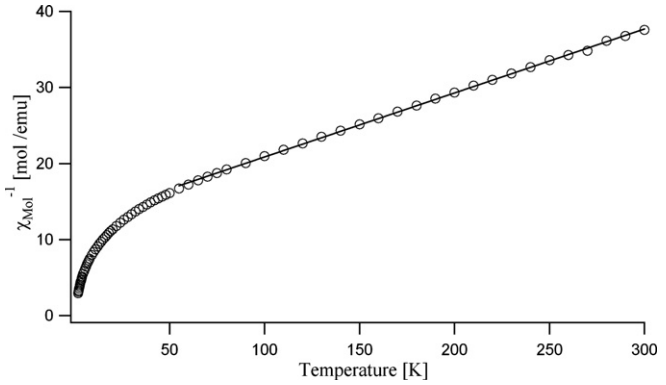

Fig. 6. The inverse molar susceptibility χ_{Mol}^{-1} vs. T for compound **1**. The solid line represents a linear fit to the data from 55 to 300 K, giving a Weiss constant $\theta = -147$ K.

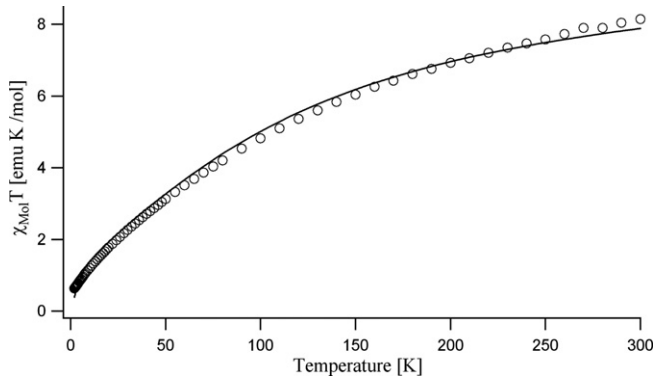

Fig. 7. Plot of the $\chi_{Mol}T$ product vs. T of compound **1** in an applied field of 1 kG. The solid curve represents a simulation from 2 to 300 K with the parameters $J = -7.5\ cm^{-1}$, $J^* = -5.2\ cm^{-1}$, $D = 15.5\ cm^{-1}$ and $g = 2.1$ (see text).

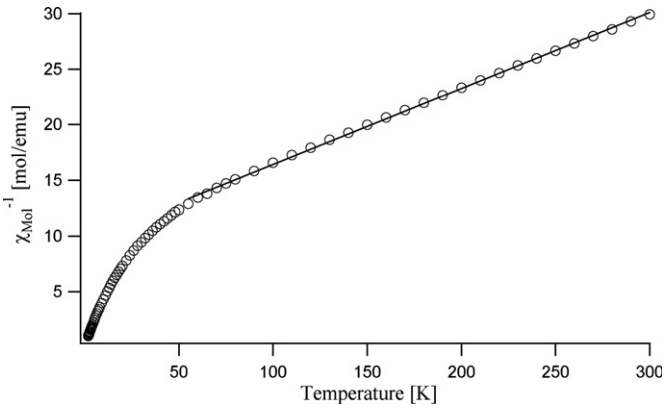

Fig. 8. The inverse molar susceptibility χ_{Mol}^{-1} vs. T for compound **2**. The solid line represents a linear fit to the data from 55 to 300 K, giving a Weiss constant $\theta = -140$ K.

temperature value $\chi_{Mol}T$ of 10.0 emu K mol^{-1} is in good agreement with a calculated value of 10.38 emu K mol^{-1} for the non-interacting two manganese(III) ions ($S = 2$, $g = 2$) and one manganese(II) ion ($S = 5/2$, $g = 2$). With decreasing temperature the $\chi_{Mol}T$ values drop slowly, which suggests overall antiferromagnetic exchange interactions. For the simulation of the data [25], two different exchange interactions have been considered: J between the Mn(II) ($S = 5/2$) and the two Mn(III) ($S = 2$) centers, and J^* between the two Mn(III) centers. The parameters found for the best simulation of the experimental data

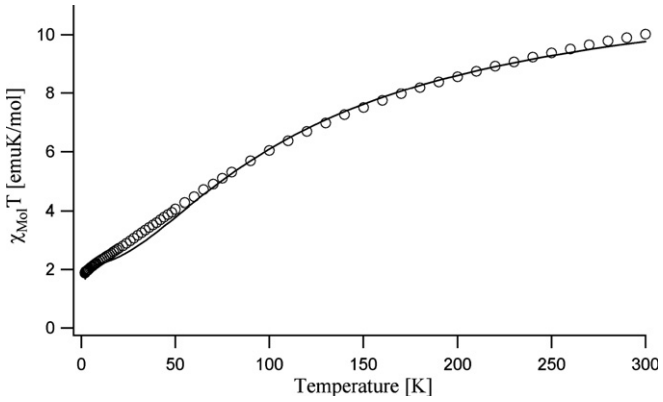

Fig. 9. Plot of the $\chi_{Mol}T$ product vs. T of compound **2** in an applied field of 1 kG. The solid curve represents the fit from 2 to 300 K with the parameters $J = -7.0\ cm^{-1}$, $J^* = -1.6\ cm^{-1}$, $D = -1.6\ cm^{-1}$ and $g = 2.2$ (see text).

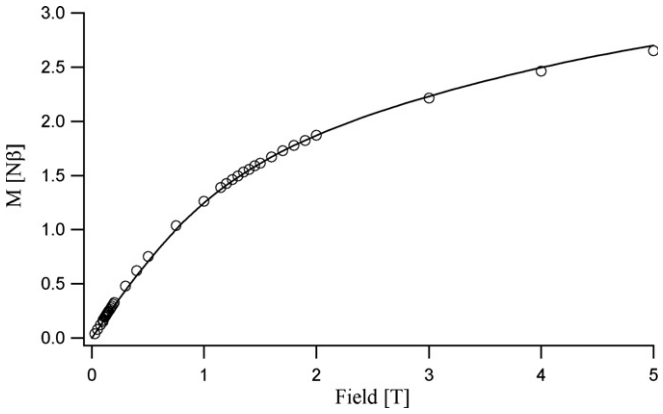

Fig. 10. Field dependence of the magnetization of compound **2** measured at $T = 1.85$ K. The solid curve represents the fit with the parameters $J = -7.0\ cm^{-1}$, $J^* = -1.6\ cm^{-1}$, $D = -1.6\ cm^{-1}$ and $g = 2.2$ (see text).

are: $J = -7.0\ cm^{-1}$, $J^* = -1.6\ cm^{-1}$, $D = -1.6\ cm^{-1}$ and $g = 2.2$. Moreover, with the same parameter set, a fairly good simulation of the magnetization data, measured at 1.85 K (see Fig. 10), has been obtained. At a magnetic field of 5 T, M_{sat} is not yet reached but a value close to 3 Nβ can be estimated. Accordingly, this would be consistent with a total ground state spin value of $S = 3/2$. This result is in accordance with a related detailed study by Ribas et al. [11].

4. Conclusions

In summary, we have synthesized and structurally characterized two new μ-oxo trinuclear manganese carboxylate complexes with imidazole and 1-methylimidazole ligands. One of them, complex $[Mn_3O(O_2CCMe_3)_6(Im)_3](Me_3CCO_2) \cdot 0.5Me_3CCO_2H$ (**1**) is a homo-valent Mn^{III}_3O cluster, which has been synthesized by comproportionation reaction of manganese(II) chloride with $KMnO_4$, imidazole and an excess of pivalic acid, whereas complex $[Mn_3O(O_2CCMe_3)_6(1\text{-}MeIm)_3]$ (**2**), which is a mixed-valent $Mn^{III}_2Mn^{II}O$ cluster, was isolated by the reaction of hexanuclear mixed-valent $[Mn^{III}_4Mn^{III}_2O_2(O_2CCMe_3)_{10}(Me_3CCO_2H)_4]$ with $KMnO_4$ in 1-methylimidazole. The trinuclear nature of these complexes has been compared to that of the previously reported μ-oxo trinuclear manganese carboxylates. The magnetic properties of **1** and **2** were studied by variable-temperature susceptibility measurements. The results reveal that both compounds are antiferromagnetically coupled, spin-frustrated triangular systems exhibiting weak to moderate exchange coupling constants.

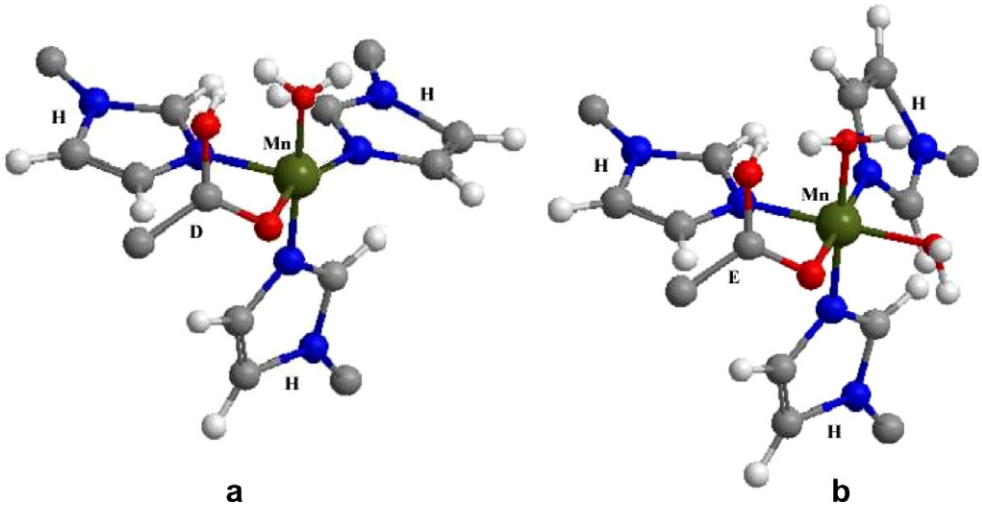

Fig. 1. Active site structure for Mn–SOD (a) and Mn(II)oxlate-oxidase (b).

molecules. The active site structures for other mononuclear manganese enzymes are not known with certainty, but based on their analogous iron enzymes, a square-pyramidal arrangement of two histidines, a glutamate and two water molecules has been proposed for Mn(II)dioxygenase [11] and an active site structure similar to the iron-containing soybean lipoxygenase has been proposed for the manganese lipoxygenase enzyme [12]. According to Minor et al. [13], the iron in iron-lipoxygenase, is coordinated to three nitrogens of histidine residues, one oxygen of a monodentate isoleucine and one oxygen of a weakly coordinated asparagine. A water molecule forming a hydrogen bond with the non-coordinated carboxylate oxygen of isoleucine, completes the distorted octahedral coordination sphere. A common structural feature found in most of the above proteins and enzymes is the presence of one or more carboxylate derived from aspartate/glutamate/isoleucine or asparagine side chains of the protein. These carboxylates act as a bridge between metal ions present in the binuclear manganese containing enzyme and also are suggested to play an important role for structural holding and proton transfer via hydrogen-bonding interactions in proteins [14]. The role of hydrogen bonding in the stabilization of structures as well as in the functions of various metalloproteins is well known in biochemistry [15].

There are several examples of mononuclear and binuclear manganese carboxylate complexes where the hydrogen atoms of the ligand alcohol groups, the bridging aqua or the lattice water molecules form inter/intramolecular hydrogen bonds with coordinated carboxylate groups available in the literature [16], but manganese carboxylate complexes with hydrogen bonds involving pyrazole groups are limited in number. In light of the importance of hydrogen bonded carboxylate and the limited examples of manganese carboxylate complexes with hydrogen bonded pyrazole, we have undertaken the synthesis, structural and SOD activity studies of some manganese carboxylate complexes in the present paper.

2. Experimental

2.1. Materials

All manipulations were carried out under nitrogen atmosphere using standard Schlenk tube techniques unless otherwise stated. The required organic solvents were carefully purified and distilled under nitrogen prior to use, by the literature method [17]. $MnCl_2 \cdot 4H_2O$ (reagent grade) was purchased from E. Merck. Other reagents were of the highest grade commercially available and were used without further purification. 3,5-*i*-Pr_2pzH [$Pz^{iPr2}H$] (**1**), KHB(3,5-*i*-$Pr_2pz)_3$ [Tp^{iPr2}] (**2**), [18] KHB(3-Ph,5-$Mepz)_3$ [$Tp^{Ph,Me}$] (**3**) [19] and Tp^{iPr2}MnCl (**4**) [20] were synthesized by the literature methods.

2.2. Physical methods

IR spectra were obtained on a Thermo Nikolet Nexus FT-IR spectrometer in KBr and FD-MS spectra were obtained on a Hitachi M-80 mass spectrometer. Room temperature magnetic susceptibility measurements were done on a Cahn Faraday magnetic susceptibility balance. The X-ray data collection and processing for **5** and **6** were performed on a Rigaku RAXIS-IV imaging plate area detector with Mo Kα radiation ($\lambda = 0.71070$ Å). In the reduction of data, Lorentz and polarization corrections, and empirical absorptions were made [21]. The structure analysis was performed on an IRIS O2 (Silicon Graphics) using the teXsan structure solving program system obtained from the Rigaku Corp., Tokyo, Japan [22]. Neutral scattering factors were obtained from the standard source [23]. The structures were solved by a combination of direct methods (SHELXS-86) [24] and Fourier synthesis (DIRDIF 94) [25]. Least-squares refinements were carried out using SHELXS-97 [24] linked to teXsan. All non-hydrogen atoms were refined anisotropically. Diffraction data for complex **7** were recorded at −80 °C with a Bruker

Smart CCD diffractometer. Emperical absorption corrections were applied. The structure was solved by Patterson methods and refined anisotropically with the SHELX program suite. Hydrogen atoms involved in hydrogen bonding were obtained by refinement, not by fixing the position. Single crystal diffraction studies for **8** and **10** were carried out on a Bruker Smart CCD diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å) in a sealed tube at 25 °C. Crystal structures were solved by direct methods and in anisotropic approximation refined using the SHELX TL package [26,27]. Hydrogen atoms were constrained by the rigid model.

2.3. Synthesis of complexes

2.3.1. *[(Pz^{iPr2}H)$_4$Mn(NO$_2$–OBz)$_2$] (**5**)*

(0.197 g, 1.00 mmol) $MnCl_2 \cdot 4H_2O$ and (0.604 g, 4.00 mmol) Pz^{iPr2}H were stirred in 25 mL CH_2Cl_2 and 5 mL CH_3OH for 1 h. To this solution was added a 5 mL acetonitrile solution of sodium *p*-nitrobenzoate (0.378 g, 2.00 mmol) and the reaction mixture was stirred for 12 h at room temperature. The mixture was filtered over celite and the solvent was evaporated to dryness. The compound was dissolved in 5 mL CH_3CN and colorless crystals were obtained at −20 °C (yield 84%). *Anal.* Calc. (%) for $C_{50}H_{72}N_{10}O_8Mn$: C, 60.26; H, 7.28; N, 14.06. Found: C, 60.09; H, 7.31; N, 13.72%. IR (KBr, cm^{-1}), *ν*(NH of pyrazole) 3211, ν_{as}(COO) 1576, ν_s(COO) 1473, $\mu_{eff} = 5.75$ BM at 295 K.

2.3.2. *[(Pz^{iPr2}H)$_4$Mn(F–OBz)$_2$] (**6**)*

(0.197 g, 1.00 mmol) $MnCl_2 \cdot 4H_2O$ and (0.604 g, 4.00 mmol) Pz^{iPr2}H were stirred in 30 mL CH_2Cl_2 and 5 mL CH_3OH for 1 h. A 5 mL acetonitrile solution of sodium *p*-fluorobenzoate (0.324 g, 2.00 mmol) was added to this solution and stirred for 12 h. The mixture was filtered over celite and the solvent was evaporated to dryness. The compound was dissolved in 5 mL acetonitrile and colorless crystals were obtained by slow cooling at −20 °C (Yield 80%). *Anal.* Calc. (%) for $C_{50}H_{72}N_8O_4F_2Mn$: C, 63.72; H, 7.70; N, 11.89. Found: C, 63.49; H, 7.67; N, 11.44%. IR (KBr, cm^{-1}) *ν* (NH of pyrazole) 3297, ν_{as}(COO) 1570, ν_s(COO) 1442, $\mu_{eff} = 5.78$ BM at 295 K.

2.3.3. *[Tp^{Ph,Me}Mn(OAc)Pz^{Ph,Me}H] (**7**)*

KTp^{Ph,Me} (0.521 g, 1.00 mmol) was stirred with $Mn(OAc)_2 \cdot 4H_2O$ (0.245 g, 1.00 mmol) and 1.0 equivalent of Pz^{Ph,Me}H (0.158 g, 1.00 mmol) in 25 mL dichloromethane and 5 mL methanol for 2 h. The mixture was filtered through celite and the filtrate was dried under vacuum. The colorless powder was dissolved in a mixture of dichloromethane and acetonitrile (1:1 ratio) and crystals were obtained by cooling the solution at −20 °C (Yield 65%). *Anal.* Calc. (%) for $C_{42}H_{41}BMnN_8O_2$: C, 66.76; H, 5.47; N, 14.83. Found: C, 66.56; H, 5.39; N, 14.90%. IR (KBr, cm^{-1}), *ν*(BH) 2539, ν_{as}(COO) 1572, ν_s(COO) 1435, $\mu_{eff} = 5.68$ BM at 295 K.

2.3.4. *[Tp^{iPr2}Mn(Cl)Pz^{iPr2}H] (**8**)*

$MnCl_2 \cdot 4H_2O$ (0.197 g, 1.00 mmol), KTp^{iPr2} (0.504 g, 1.00 mmol) and Pz^{iPr2}H (0.761 g, 5.00 mmol) were stirred in 25 mL CH_2Cl_2 and 5 mL CH_3OH for 1 h. The mixture was filtered over celite and the solvent was evaporated to dryness under vacuum. The compound was dissolved in 5.0 mL pentane and 3.0 mL ether. Colorless crystals were obtained from the filtrate at −20 °C in 85% yield. *Anal.* Calc. for $C_{36}H_{62}N_8BClMn$: C, 61.05; H, 8.82; N, 15.82; Cl, 5.00. Found: C, 61.12; H, 8.83; N, 15.97; Cl, 4.80%. IR (KBr, cm^{-1}) *ν*(BH) 2548, *ν*(NH of pyrazole) 3292, *ν*(CN of pyrazole) 1560, $\mu_{eff} = 5.70$ BM at 295 K.

2.3.5. *[Tp^{iPr2}Mn(F–OBz)] (**9**)*

To a 30 mL toluene solution of **4** (0.489 g, 0.882 mmol), was added a 10 mL acetonitrile solution of sodium *p*-fluorobenzoate (0.143 g, 0.882 mmol) and the reaction mixture was stirred for 16 h. The mixture was filtered over celite and the solvent was evaporated under vacuum. A colorless microcrystalline solid was obtained by slow cooling of an acetonitrile solution at −20 °C in 45% yield. *Anal.* Calc. (%) for $C_{34}H_{51}N_6BFO_2Mn$: C, 61.82; H, 7.78; N, 12.27. Found: C, 61.65; H, 7.90; N, 12.07%. IR (KBr, cm^{-1}), *ν*(BH) 2541, ν_{as}(COO) 1600, ν_s(COO) 1469, $\mu_{eff} = 5.83$ BM at 295 K, FD–MS (*m*/*z*) = 660.

2.3.6. *[Tp^{iPr2}Mn$_2$(μ-FOBz)$_3$(Pz^{iPr2}H)$_2$] (**10**)*

$MnCl_2 \cdot 4H_2O$ (0.168 g, 0.855 mmol), complex **4** (0.474 g, 0.855 mmol), sodium *p*-fluorobenzoate (0.419 g, 2.57 mmol) and Pz^{iPr2}H (0.260 g, 1.71 mmol) in a mixture of toluene and acetonitrile (1:1) were stirred for 12 h at room temperature. The mixture was filtered over celite and the solvent was evaporated to dryness. Colorless crystals were obtained by slow cooling of acetonitrile solution at −20 °C in 65% yield. *Anal.* Calc. (%) $C_{66}H_{90}N_{10}BF_3O_6Mn_2$; C, 61.11; H, 6.99; N, 10.79. Found: C, 60.85; H, 6.95; N, 10.85%. IR(KBr, cm^{-1}), *ν*(BH) 2538, ν_{as}(COO) 1594, ν_s(COO) 1469, $\mu_{eff} = 5.90/Mn^{2+}$ BM at 295 K.

3. Results and discussion

The reaction of $MnCl_2 \cdot 4H_2O$ with four equivalents of pyrazole **1** and two equivalent of sodium *p*-nitrobenzoate/sodium *p*-fluorobenzoate gave six coordinated mononuclear

$$MnCl_2.4H_2O + 4\ \text{eq. Pz}^{iPr2}\text{H} + 2\ \text{eq. NaOBzX} \longrightarrow (\text{Pz}^{iPr2}\text{H})_4\text{Mn(X-OBz)}_2$$

(X= NO_2, **5**)
(X= F, **6**)

Scheme 1.

manganese high spin complexes **5** $\{C_{50}H_{72}N_{10}O_8Mn\}$ and **6** $\{C_{50}H_{72}N_8O_4F_2Mn\}$ (Scheme 1). Selected bond distances and bond angles are listed in Table 1 and crystallographic data in Table 2. The Thermal ellipsoid view of the crystal structures for complexes **5** and **6** are given in Figs. 2 and 3, whereas the structure showing intramolecular hydrogen bonding and CH_3–π interactions for these complexes are given in Figs. 4 and 5, respectively. The coordination environment and geometry in complexes **5** and **6** are very similar. As shown in the X-ray structures, both complexes are six coordinated with a distorted octahedral geometry. The manganese–nitrogen and manganese–oxygen bond distances (Table 1) for **5** and **6** are nearly the same. The Mn–N bond distances are slightly longer than the Mn–N bond distances in Mn–Tp^{iPr2} complexes [28]. Also the Mn–O bond distances of coordinated *p*-nitrobenzoate/*p*-fluorobenzoate are slightly longer than the reported manganese carboxylate complexes having the Tp^{ipr2} ligand [28]. In both these complexes, the pyrazole as well as the benzoate groups are behaving as monodentate ligands; the *p*-nitrobenzoate/*p*-fluorobenzoate are coordinated to manganese by only one oxygen atom. The uncoordinated oxygen atom of each benzoate group forms intramolecular hydrogen bonds with two N–H hydrogen atoms attached to the pyrazole rings of $Pz^{iPr2}H$. The different values of the N–O bond distances (O2–N12, 2.833 (3); O2–N22 is 2.873(3) Å in **5** and O2–N12, 2.803 (2); O2–N22 is 2.831(3) Å in **6**), clearly indicate that the hydrogen bonding is stronger in complex **6** than in complex **5**. Besides the existence of intramolecular hydrogen bonding, both of these complexes exhibit a CH_3–π interaction between the CH_3 group of $Pz^{iPr2}H$ and the benzene ring of *p*-nitrobenzoate/*p*-fluorobenzoate as can be judged from the distances between the hydrogen and the centroid of the ring, 3.022 Å in **5** and 3.217 Å in **6** (Figs. 4 and 5). The presence of CH_3–π as well as the π–π stacking interaction is not uncommon in metal complexes [16h]. Several manganese benzoate complexes having Tp ligands have been reported [28], but mononuclear six coordinated manganese carboxylate complexes with intramolecular hydrogen bonding are not very common, except for some octahedral manganese (II) carboxylate complexes [29]. The presence of intramolecular hydrogen bonding as well as a CH_3–π interaction may be responsible for the stability of these complexes, as both are stable under air in the solid as well as in solution state, and they do not react with O_2 or CO_2.

When $Mn(OAc)_2 \cdot 4H_2O$ was allowed to react with $Tp^{Ph,Me}$ in the presence of pyrazole ($Pz^{Ph,Me}H$) (Scheme 2), a five coordinated intramolecular hydrogen bonded manganese (II) complex **7** $\{C_{42}H_{41}BMnN_8O_2\}$ was isolated. As shown in Fig. 6 (Thermal ellipsoid view), the manganese is coordinated with three nitrogen of the $Tp^{Ph,Me}$ ligand. The Mn–N bond distances in complex **7** (Table 1) are very similar to the Mn–N bond distances present in the mononuclear benzoate complex of manganese with Tp^{iPr2} (Mn1–N1, 2.195(4) Å; Mn1–N2, 2.277(4) Å; Mn1–N3, 2.161(3) Å) [28b] but longer than the Fe–N bond distances

(Fe1–N1, 2.2626(15) Å; Fe1–N2, 2.0745(15) Å; Fe1–N3, 2.0855(16) Å) in a mononuclear iron acetate complex with Tp^{Ph2} [30]. The Mn–N bond distance of the coordinated $Pz^{Ph,Me}H$ (Mn1–N7, 2.234 (18) Å) is similar to the Fe–N bond distance with 3,5-diphenylpyrazole (Fe1–N4, 2.2347 (17) Å), but shorter than the Mn–N bond distance with $Pz^{iPr2}H$ coordination (Mn1–N4, 2.304 (4) Å). The acetate behaves as a monodendate ligand in **7** where one oxygen atom is bonded with the manganese center and the other oxygen atom forms a hydrogen bond with the proton lying on the nitrogen of $Pz^{PhMe}H$ coordinated at the apical position to the manganese ion. The carboxylate oxygen from asparate in Mn–SOD is also bound to the manganese unidentately as is the acetate anion in complex **7**. The existence of a hydrogen bond in complex **7** is clearly established on the basis of the location of the hydrogen bond with mean bond distances of Ha–O2, 1.909 Å and Ha–N8, 0.859 Å. The presence of a hydrogen bond also affects the appearance of the ν(NH) band in the IR spectrum of the complex as the free $Pz^{PhMe}H$ gives the band at 3180 cm^{-1}. The short distance of the carbonyl oxygen (O_2) of the acetate anion from the nitrogen of neutral pyr-

azole (N8) (O2–N8 bond, 2.76 Å), also suggest the presence of hydrogen bonding in **7**.

The Mn–O bond distance (Mn1–O1, 2.0240 (16) Å) is very similar to the Mn–O bond distance in a mononuclear hydrogen bonded manganese benzoate complex (Mn1–O1, 2.043(4) Å) [28b] but larger than the Fe–O1 bond distance in a mononuclear hydrogen bonded iron acetato complex (Fe–O1, 1.9634 (14) Å) [30]. The geometry of this complex is trigonal bipyramidal with one nitrogen (N2) from Tp^{PhMe} and N7 of the neutral pyrazole in apical positions.

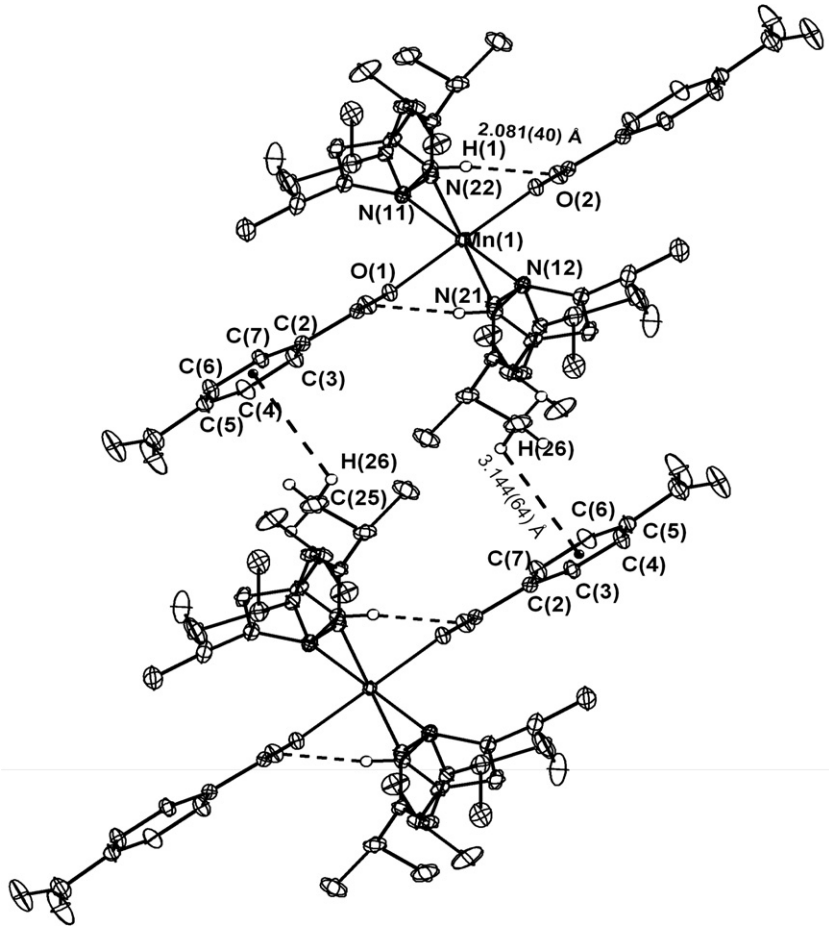

Fig. 4. Molecular structure showing intramolecular hydrogen bonding and CH_3–π interactions in complex **5**.

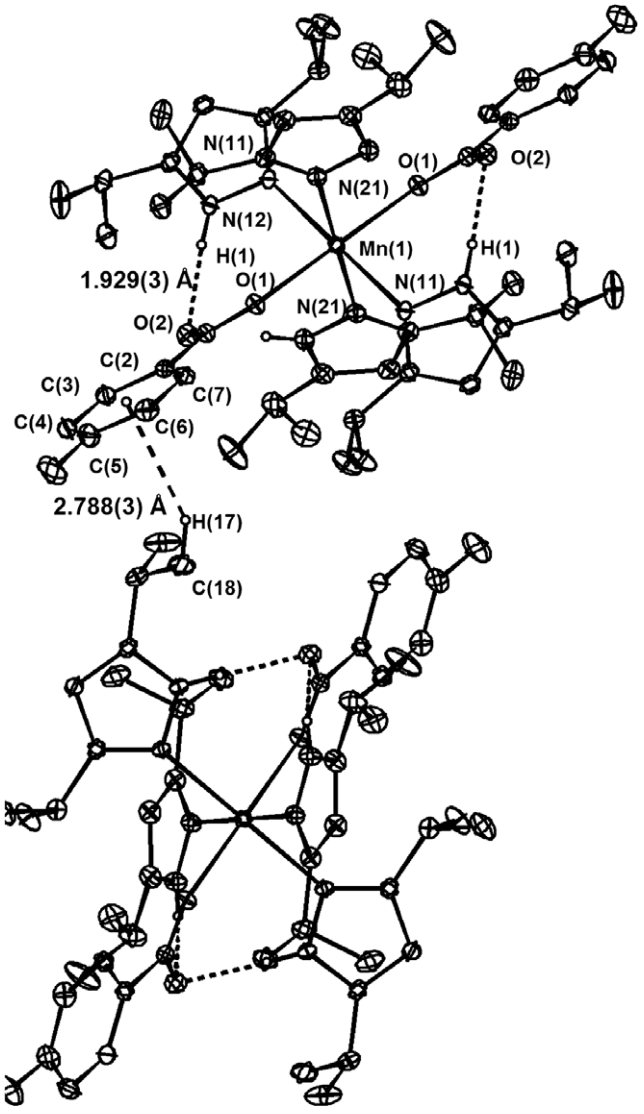

Fig. 5. Molecular structure showing intramolecular hydrogen bonding and CH_3–π interactions in complex **6**.

In another set of experiments, we have prepared $Tp^{iPr2}MnClPz^{iPr2}H$, $\{C_{36}H_{62}N_8BClMn\}$ (**8**) as a starting material for the preparation of other various manganese complexes. Complex **8** was prepared by the reaction of $MnCl_2 \cdot 4H_2O$ with KTp^{iPr2} in the presence of 1.5 equivalents of $Pz^{iPr2}H$, as shown in Scheme 3. Complex **8** is a mononuclear high spin manganese (II) species. As shown in the crystal structure (Fig. 7), it is five coordinate having a N_4Cl ligand donor set with a distorted geometry. The Mn1–Cl1 bond distance is 2.4193 Å, which is longer than the Mn–Cl bond distance in $Mn_2Cl_4(O{-}C_6H_4{-}p\text{-}CH_3)_2^{-2}$ (2.32 Å) [31] and [MnTPPCl](K222)] (2.364 Å) [31c], but similar to the Mn–Cl terminal bond distance in LMn_2Cl_2Br (2.411 Å) [31b]. The distances between manganese and nitrogens of the coordinated Tp^{iPr2} slightly differ from each other (Mn1–N1, 2.2425 (19) Å; Mn1–N3, 2.1507 Å; Mn1–N5, 2.164 (2) Å) and are considerably longer than the distances reported for $[Mn(HB(3,5\text{-}Mepz)_3)]^{+2}$ (1.96–1.98 Å) [32] and 2.05–2.23 Å in $[Mn_2O(O_2(CH_3)_2)(HB(pz)_3)_2] \cdot CH_3CN$ [33].

Using the literature method [20] we have prepared the complex $Tp^{iPr2}MnCl$, $\{C_{34}H_{51}N_6BFO_2Mn\}$ (**4**) by reacting $MnCl_2 \cdot 4H_2O$ and KTp^{iPr2} in a 1:1 ratio, to act as a starting material for the synthesis of complexes **9** $\{C_{34}H_{51}N_6BFO_2Mn\}$ and **10** $\{C_{66}H_{90}N_{10}BF_3O_6Mn_2\}$. Complex **9** was prepared by the reaction of **4** with one equivalent of sodium *p*-fluorobenzoate (Scheme 4). The spectroscopic characterization revealed that the benzoate group coordinates in a bidentate fashion. Although the crystal structure of **9** could not be determined, based on other spectroscopic data and the X-ray structure of a five coordinate cobalt fluorobenzoate complex with Tp^{iPr2} [34], we infer that **9** is also a monomeric five coordinate Mn(II) complex.

We have also succeeded in synthesizing an unsymmetrical fluorobenzoate bridged binuclear manganese (II) complex. The reaction of **4** with **1**, $MnCl_2 \cdot 4H_2O$ and sodium

$$Mn(OAc)_2.4H_2O + KTp^{Ph,Me} + Pz^{Ph,Me}H \longrightarrow Tp^{Ph,Me}Mn(OAc)Pz^{Ph,Me}H$$

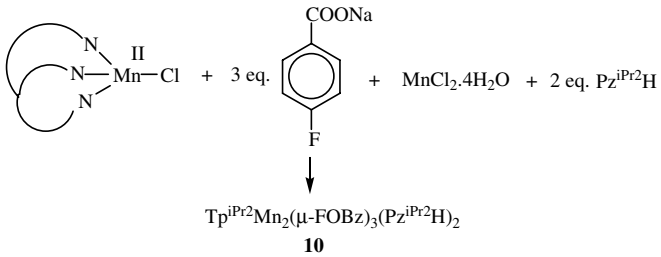
9

Scheme 4.

p-fluorobenzoate in mixed solvent (toluene:acetonitrile in a 1:1 ratio) gave complex **10** (Scheme 5). The presence of an IR band at 3297 cm^{-1} (due to the *v*N–H stretching band) in the IR spectrum of this complex suggested the existence of pyrazole in the protonated form. The molecular structure of **10** was determined by X-ray crystallography and its Thermal ellipsoid view is given in Fig. 8. As shown in Fig. 8, both manganese (II) ions are in the same environment. The two manganese (II) ions are bridged with three fluorobenzoate groups in an unsymmetrical manner with a Mn–Mn separation of 3.732(4) Å. Like the previously reported benzoate bridged binuclear manganese complex by Osawa et al. [35], in complex **10** both manganese ions are also in an octahedral environment and two of the μ-fluorobenzoate groups are symmetrically bridging, whereas the third one adopts a unique coordination mode i.e., only one oxygen from the carboxylate serves as a bridging ligand, while the other one binds to Mn2 terminally. A structurally similar (μ-carboxylato)$_3$ unit has been reported in a linear trinuclear manganese(II) carboxylato complex [36]. The Mn–Mn separation found in complex **10** is 3.732(4) Å, which is close to 3.739(2) Å [37] and 3.612(2) Å [38] in (μ-aqua)(bis(μ-carboxylato)dimanganese(II)) complexes but shorter than 4.034(2) Å in a symmetrical tris(μ-carboxylato)$_3$ complex [39]. The short metal–metal distance in **10** reflects the unusual nature of the tris(μ-fluorobenzoato)$_3$ unit with one oxygen atom from a fluorobenzoate group acting as a bridging ligand. The magnetic susceptibility of the powdered sample is 8.34 BM per mol. Efforts were also made for the successful removal of one bridging fluorobenzoate without disturbing the manganese bimetallic core, but the reaction of **10** with one equivalent of NaOH in toluene resulted in the formation of a mononuclear manganese (II) fluorobenzoate complex similar to **9**, in contrast to the pyrazole adduct as reported by Osawa et al. [35]. The resultant complex is five coordinated with a N_3O_2 ligand donor set and the fluorobenzoate group is coordinated to the manganese bidentately.



10

Scheme 5.

3.1. Superoxide dismutase activity studies

The complexes **5**–**8** and **10** were tested for their SOD activity using xanthine–xanthine oxidase–nitro blue tetrazolium (NBT) methods [40], as the coordination number around manganese in these complexes is close to the coordination number around the manganese in manganese-containing SOD enzyme [1] and also they have intramolecular hydrogen bonding, except in complexes **8** and **10**. The test was performed separately in duplicate for each compound in 3 ml of 50 mM potassium phosphate buffer (pH 7.4) at 25 °C in the absence of EDTA. The reaction mixture was prepared as follows:

Fifty micromoles of NBT, 50 μM xanthine, 1000 U/ml catalase and 0.04 U/ml xanthine oxidase were used to produce superoxide ions in solution. The formation of diformazan was monitored at 560 nm wavelength. The IC_{50} value in Fig. 9 means the concentration of the complex which exerts SOD activity equivalent to one unit of native SOD. Out of these tested complexes only complex **7** exhibited IC_{50} values

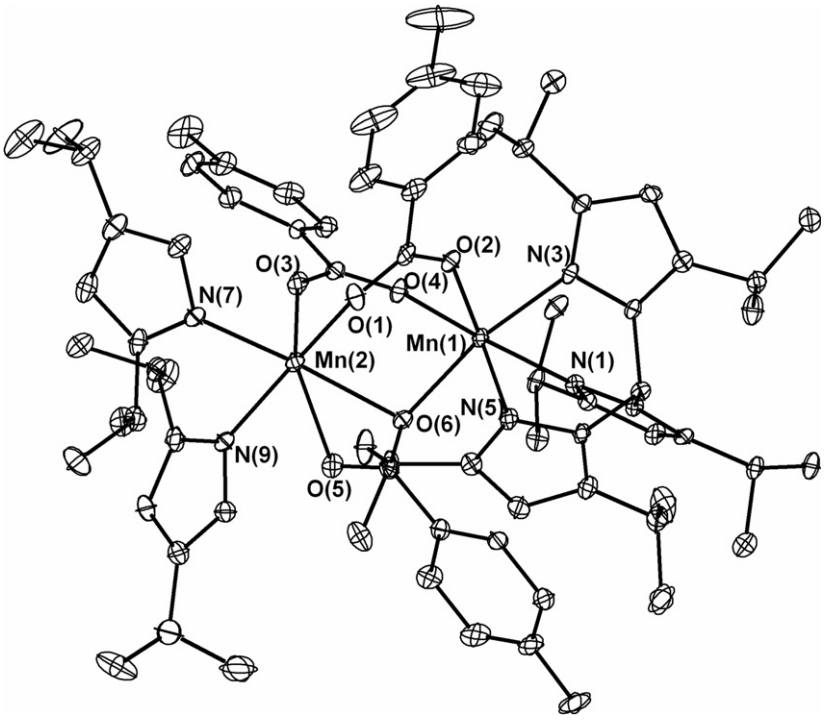


Fig. 8. Thermal ellipsoid view of complex **10** drawn at the 50% probability level. All hydrogen atoms have been omitted for clarity.

at 3.5 μM concentration (Fig. 9), clearly indicating that this may be a suitable model for a SOD mimic. The SOD activity value for **7** is much better than the previously reported SOD model complexes screened by the NBT method under the same conditions [41], but lower than the SOD model complex reported by Kitajima et al. [28b]. Also the ability of complex **7** to disproportionate O_2^- is comparatively better than the most active systems based on salen or porphyrin ligands reported by several workers [42]. The better SOD activities of complex **7** may be attributable to the very close structural similarities of this complex with the active site of native Mn–SOD.

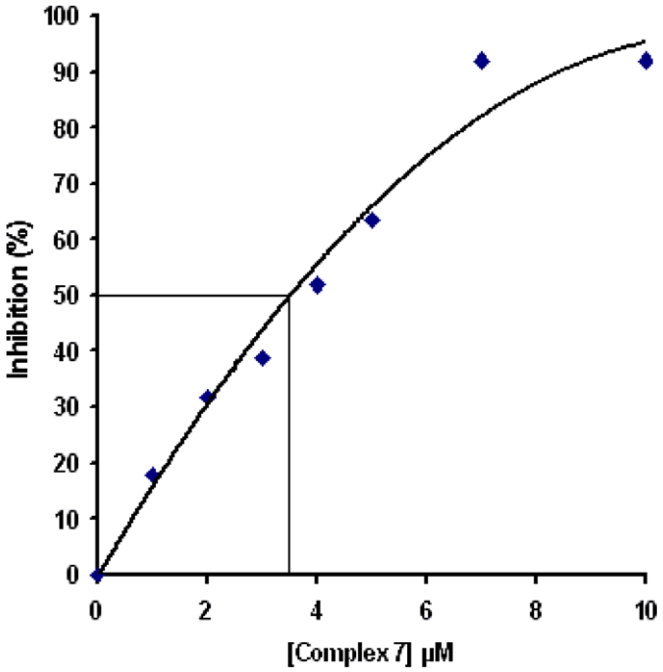

Fig. 9. SOD activity of complex **7** in xanthene oxidase-NBT assay.

4. Conclusion

We have reported several manganese carboxylate complexes, both with hydrogen as well as non-hydrogen binding, having five and six coordination numbers. The results presented in this paper demonstrated that different coordination modes of the carboxylate groups are possible simply by changing the supporting nitrogen donor ligands. It is possible to get the hydrogen bonded carboxylate complexes simply by adding the corresponding pyrazole to the reaction mixture as demonstrated in the formation of complex **7**, or by using pyrazole as a supporting ligand in the reaction as shown by the preparation of complexes **5** and **6**. The reaction of $Pz^{iPr2}H$ with $MnCl_2 \cdot 4H_2O$ and sodium *p*-nitrobenzoate/sodium *p*-fluorbenzoate resulted in the formation of octahedral complexes with intramolecular hydrogen bonding and CH_3–π interactions. The SOD activity studies on complexes **5**–**8** and **10** suggested that complex **7** seems to be a good model mimic of the native Mn–SOD enzyme as complex **7** has a suitable active site structure as well as intermolecular hydrogen bonding.

5. Supporting data

The crystallographic data have been deposited with the CCDC. Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on requesting,

quoting the deposition numbers CCDC 293641–293644 and CCDC 293653, e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk.

of two or more phthalonitrile derivatives with different substituents, isolation of each isomer is hardly possible, and the yield of the desired product could be very low [1,13,14]. Some unsymmetrical structures have been acquired by making use of boron subphtalocyanines [15].

Many binuclear phthalocyanines have been synthesized and various properties have been reported in last decade [16]. In our previous study, starting from a tetracyano compound with 12-membered dioxa-dithia macrocycles, in which oxygen and sulfur atoms are diagonally positioned, it has been possible to prepare either polymeric or dimeric phthalocyanines over iminoisoindoline compounds with subphthalocyanine [17] using the statistically mixed method [18]. In applications phthalocyanines are usually prepared by depositing the phthalocyanine molecules as thin films onto an appropriate substrate, using different methods (LB technique, high vacuum evaporation, spin coating, etc.). While the phthalocyanine thin films are used for the fabrication of practical devices, their electrical (d.c. and a.c.) properties must be taken into account. For example, to produce any device whose active layer is made of phthalocyanine films, we need to know the effect of the temperature on both a.c. and d.c. electrical properties of the film, so as to carry out an accurate design. The aim of this study is to synthesize binuclear octaphthalocyanine and dimeric phthalocyanine with six ferrocenyl groups. For this purpose, nitro-substituted dimeric phthalocyanine **3** was reacted with unsymmetric **4**, NaOH solution and activated zinc powder in THF to obtain **5**. In the second step, using hydrazine hydrate as a reductant, amine-substituted dimeric phthalocyanine **6** was synthesized from nitro-substituted dimeric phthalocyanine **3**. Finally, using ferrocenylaldehyde, **7** was prepared. The electrical properties of **3**, **5** and **6** were examined.

2. Experimental

2.1. Synthesis

All chemicals used were of reagent grade. All solvents were dried and purified as described by Perrin and Armarego [19]. The solvents were stored over molecular sieves. Soluble derivatives with eight alkylthio substituents have been synthesized through cyclotetramerization of 4,5-bis(hexylthio)phththalonitrile which has been prepared directly from the 4,5-dichloro compound with hexanethiol [20]. 4-Nitrophthalonitrile **2** was synthesized by the method described previously in the literature [21]. The progress of the reactions was monitored by thin layer chromatography (TLC). Column chromatography was used for purification of the complexes.

Elemental analyses were performed on a LECO CHNS 932 instrument. ^{1}H NMR spectra were determined with a Varian UNITY INOVA 500 MHz NMR spectrometer. IR spectra were recorded as KBr disks in the range of 400–4000 cm^{-1} on a SHIMADZU FTIR-8300 spectrometer. The electronic absorption spectra were measured in $CHCl_3$ for compounds **4**, **5** and DMSO for **3**, **6** with a UNICAM UV2-100 UV/VISIBLE spectrometer. Zinc, cobalt and iron contents in the digested mixture were determined on a Thermo X-Series/X7 ICP-MS. Before the ICP-MS measurements, compound **5** and **7** were digested with HNO_3.

2.2. [5′-6′-Bis(17′,25′,32′-trinitro-phthalocyaninyl)-(1,4,7,10-tetrathia-12-crown)dicobalt(II)] (3)

A mixture of **1** (0.062 g, 0.142 mmol), 4-nitrophthalonitrile **2** (0.150 g, 0.853 mmol) and $CoCl_2 \cdot 6H_2O$ (0.067 g, 0.284 mmol) was refluxed in amyl alcohol under argon for 6 h. The reaction mixture was cooled down to room temperature and precipitated by adding methanol. After filtration, the product was washed with methanol, chloroform and acetone. This compound was soluble in tetrahydrofuran (THF), dimethylformamide (DMF) and dimethylsulfoxide (DMSO). Yield: 75 mg (33%). UV–Vis (DMSO, λ_{max}/nm ($\log\varepsilon$)): 337 (5.090), 430(sh) (4.080), 642(sh) (4.610) and 682 (4.77). IR (KBr pellet) ν/cm^{-1}: 3060, 2983, 2923, 2858, 1620, 1523, 1344, 1260, 1090, 902, 742. *Anal*. Calc. for $C_{68}H_{30}N_{22}S_4O_{12}Co_2$: C, 51.56; H, 1.84; N, 19.55; S, 8.04. Found: C, 51.72; H, 1.70; N, 19.49; S, 7.95%.

2.3. [3-Nitro-9,10,16,17,23,24-hexakis(hexylthio)-phthalocyaninato Zn(II)] (4)

A well-powdered mixture of **2** (0.173 g, 1 mmol) and 4,5-bis(hexylthio) phthalonitrile (1.442 g, 4 mmol) were dissolved in dry DMF (3 mL) in a tube. Zinc(II) acetate (0.878 g, 4 mmol) was added to this solution and the mixture was sealed and heated at 170–180 °C for 6 h. to give an unsymmetrical substituted Pc. The reaction mixture was cooled down to room temperature and precipitated by adding methanol. After filtration, the dark green product was washed with methanol and purified by column chromatography (silica gel) with $CHCl_3$. Yield: 514 mg (39%). UV–Vis ($CHCl_3$, λ_{max}/nm ($\log\varepsilon$)): 337 (4.780), 363 (4.860), 440 (4.263), 638 (4.613) and 710 (5.269). IR (KBr pellet) ν/cm^{-1}: 3058, 2983, 2923, 2858, 1618, 1265, 902, 742; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 0.88 (s, 18H, –CH_3), 1.92–2.16 (m, 36H, –CCH_2), 2.22 (br, 12H, SCH_2), 2.62 (br s, 12H, –$SCCH_2$), 6.70–8.20 (m, 9H, Ar-H). *Anal*. Calc. for $C_{68}H_{87}N_9S_6O_2Zn$: C, 61.86; H, 6.64; N, 9.55. Found: C, 61.58; H, 6.77; N, 9.39%.

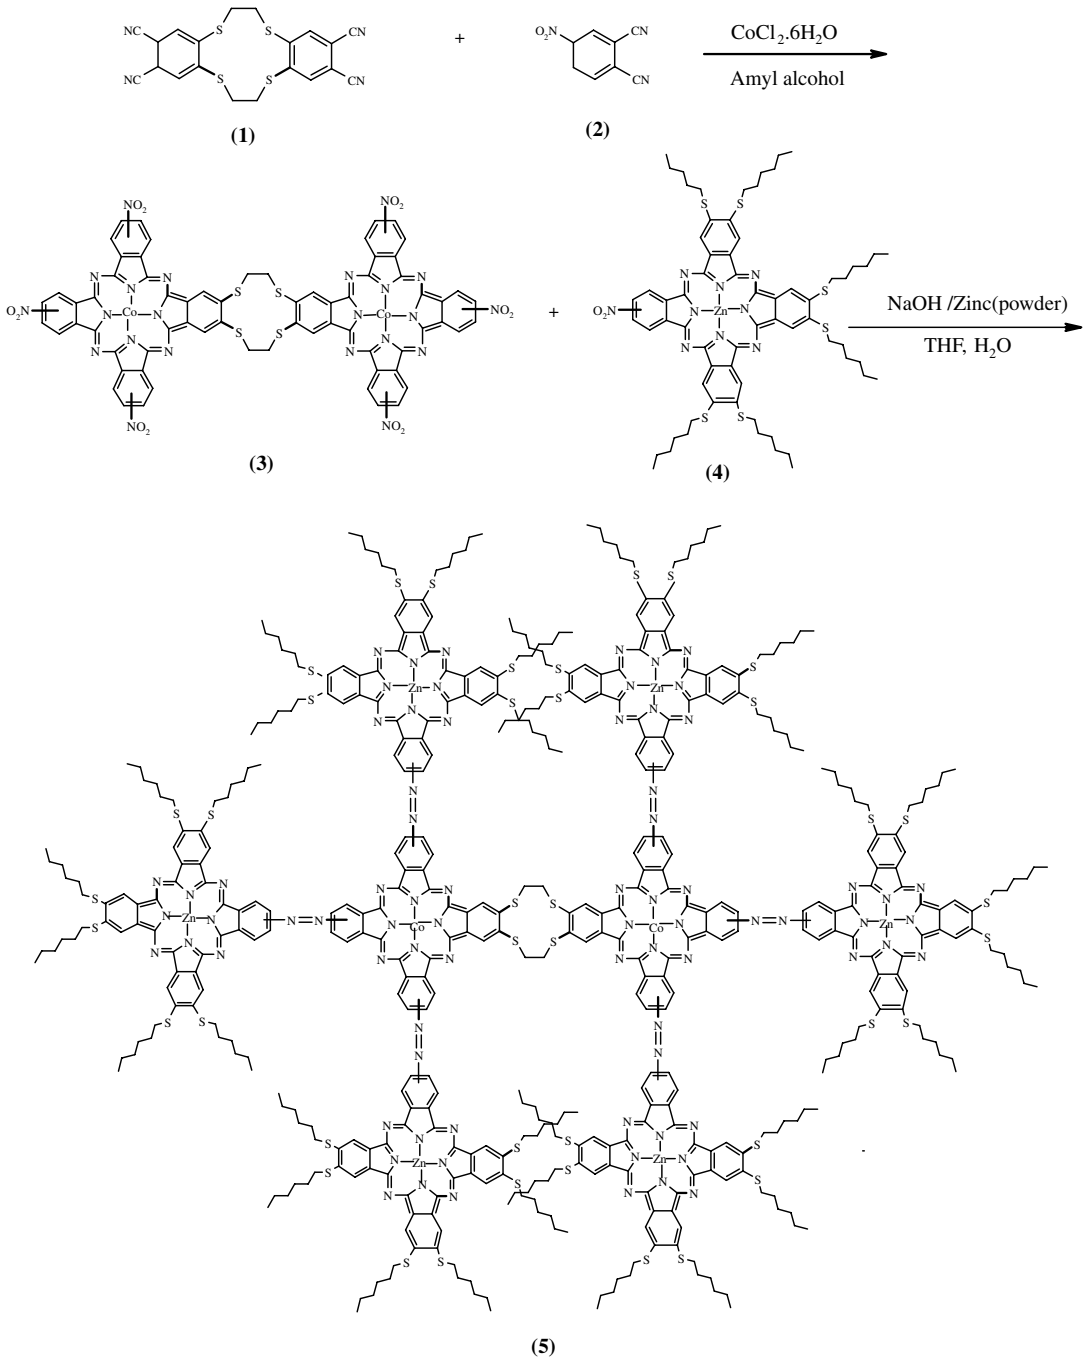
2.4. {17,25,32,17′,25′,32′-Hexakisazo-69,69′-hexakis[74′,75′,81′,82′,88′,89′(hexylthio)-phthalocyaninyl-hexazinc(II)]-[bis-phthalocyaninatodicobalt(II)]} (5)

Compound **3** (0.064 g, 0.040 mmol) and compound **4** (0.320 g, 0.243 mmol) were dissolved in THF. A solution of NaOH (1 mL, 0.268 M) and activated zinc powder were added to the reaction mixture and refluxed for 24 h, after which time the solvent was evaporated under

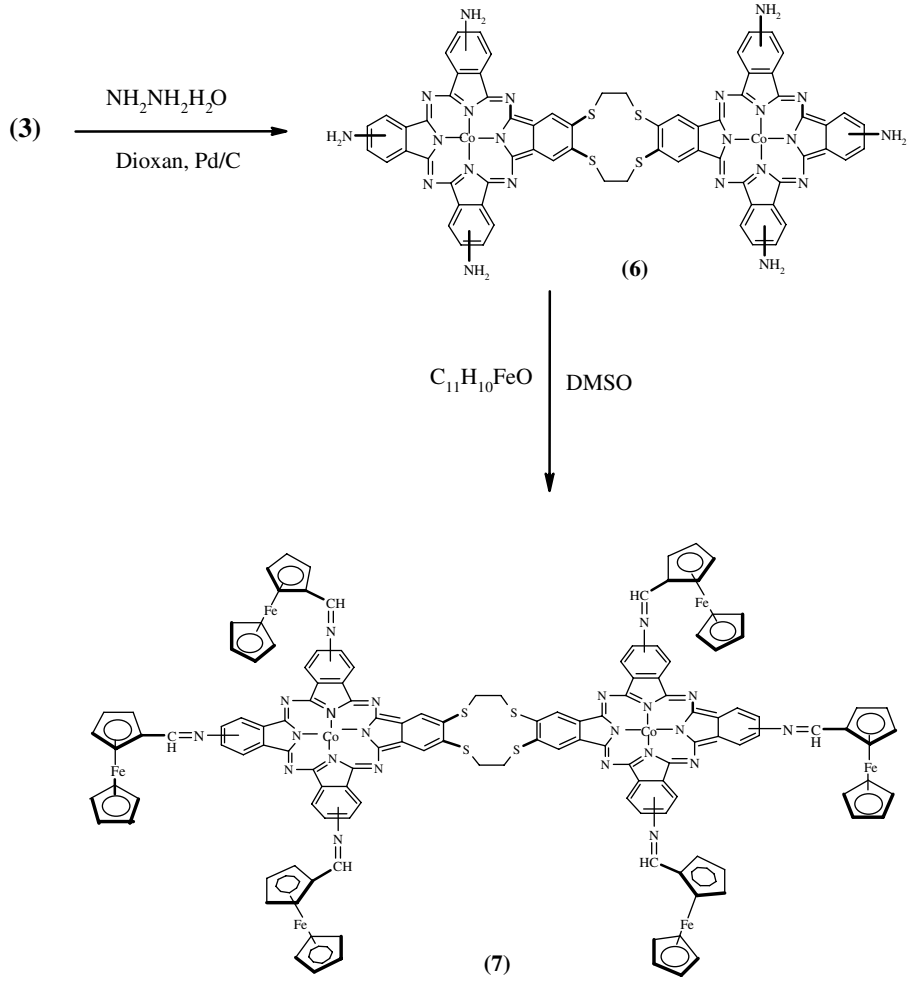
reduced pressure (Scheme 1). After filtration, the dark green product was washed with methanol and purified by column chromatography (silica gel) with $CHCl_3$. Compound **5** is soluble in chloroform, dichloromethane, dimethylformamide and dimethylsulfoxide. Yield: 10 mg (28%). UV–Vis (DMSO, λ_{max}/nm ($\log\varepsilon$)): 290 (5.039), 364 (4.473) and 700 (4.968). IR (KBr pellet) ν/cm^{-1}: 3058, 2983, 2923, 2858, 1610, 1575, 1440, 1265, 1090, 902, 742 *Anal*. Calc. for $C_{476}H_{552}N_{76}S_{40}Co_2Zn_6$: C, 61.79; H, 6.93; N, 7.69; S, 17.58. Found: C, 62.05; H, 7.13; N, 7.18; S, 17.19%. ICP-MS (Zn, Co): *Anal*. Calc. for $C_{476}H_{552}N_{76}S_{40}Co_2Zn_6$: Zn, 4.21; Co, 1.31. Found: Zn, 4.25; Co, 1.36%.

2.5. [5,6,5′,6′-Bis(17′,25′,32′-trisamino-phthalocyaninyl)-(1,4,7,10-tetrathia-12-crown) dicobalt(II)] (6)

A mixture of **3** (0.030 g, 0.019 mmol), hydrazine hydrate (8 mL) and a catalytic amount of 10% Pd/C was refluxed in dry dioxan (30 mL) under an argon atmosphere for 24 h (Scheme 2). The reaction mixture was cooled and quickly suction filtered. The filtrate was evaporated to dryness



Scheme 1. Synthesis of Co(II) and Zn(II) binuclear octaphthalocyanine **5**.



Scheme 2. Synthesis of dimeric phthalocyanine with six ferrocenyl groups **7**.

under vacuum and washed with methanol, THF and acetone. The dark green product was dried in vacuum. This compound is soluble in DMF and DMSO. Yield: 21.2 mg (79%). UV–Vis (DMSO, λ_{max}/nm ($\log\varepsilon$)): 358 (4.952), 643 (4.710) and 716 (4.897). IR (KBr pellet) ν/cm^{-1}: 3447, 3417, 3060, 2983, 2923, 2858, 1620, 1560, 1540, 1420, 1344, 1260, 1090, 902, 742. *Anal*. Calc. for $C_{68}H_{42}N_{22}S_4Co_2$: C, 57.79; H, 2.97; N, 21.81; S, 8.36. Found: C, 58.01; H, 2.79; N, 21.60; S, 9.18%.

2.6. [5,6,5′,6′-Bis(17′,25′-32′-tris-ferrocenylimin-phthalocyaninyl)(1,4,7,10-tetrathia-12-crown)dicobalt(II)] (7)

Compound **6** (0.015 g, 0.011 mmol) was dissolved in dry DMSO (0.022 g, 0.106 mmol) of ferrocenylaldehyde and a catalytic amount of *p*-toluene sulfonic acid were added to this solution and refluxed for 12 h (Scheme 2). The reaction mixture was cooled down to room temperature and methanol (20 mL) was added. After filtration, the dark green product was washed with methanol, DMF and acetone. This compound was insoluble in any solvent. Yield: 21.35 mg (75%). IR (KBr pellet) ν/cm^{-1}: 3050, 2923, 2858, 1602, 1569, 1460, 1420, 1390, 1340, 1265, 1090, 902, 820, 742. *Anal*. Calc. for $C_{134}H_{90}N_{22}S_4Fe_6Co_2$: C, 62.13; H, 3.48; N, 11.90; S, 4.95. Found: C, 62.28; H, 3.55; N, 11.62; S, 4.70%. ICP-MS (Fe, Co): *Anal*. Calc. for $C_{134}H_{90}N_{22}S_4Fe_6Co_2$: Fe, 12.98; Co, 4.56. Found: Fe, 12.90; Co, 4.65%.

2.7. Electrical characterization

For the electrical characterization, an interdigital comb structure with 100 μm gap on glass substrate was used. Thin films of compounds were obtained by the spin-coating method. A close-cycle liquid helium cryostat was used to allow electrical characteristics to be measured over a wide temperature range. DC conductivity measurements were performed between 295 and 400 K by using a Keithley 617 electrometer. AC conductivity measurements were carried out with a Keithley 3330 LCZ meter in the frequency range 40 Hz–100 kHz. in the temperature range from 295 to 400 K. During the measurement the temperature of the sample was controlled with a Leybold LTC 60 temperature controller. All the measurements were performed under 10^{-3} mbar in the dark. Both the d.c. and a.c. conductivity data were recorded using an IEEE-488 data acquisition system incorporated to a personal computer.

3. Results and discussion

3.1. Synthesis and characterization

Initial compounds **1**, **2** and 4,5-bis(hexylthio)phthalonitrile were available from an earlier study. Before the synthesis of **5**, the nitro-substituted dimeric Co(II) phthalocyanine **3** was prepared by reaction of **1**, **2** and cobalt(II) chloride in amyl alcohol.

In the second step, **2** was reacted with 4,5-bis(hexylthio)-1,2-dicyanobenzene and zinc(II) acetate in DMF to obtain unsymmetric Zn(II) phthalocyanine **4** [22]. This compound was purified by column chromatography (silica gel) with $CHCl_3$. The new compound **5** was prepared by the reaction of **3** and **4** with NaOH solution and activated zinc powder in THF. This compound was purified by column chromatography (silica gel) with $CHCl_3$. Peripheral nitro substituents on the Pc offer a number of possibilities to obtain reactive binding sites, such as reduction to an amine. For this purpose, hydrazine hydrate was used as the reductant. In order to demonstrate the reactivity of the amino groups in the hexaamino substituted dimeric Pc **6**, its condensation with ferrocenylaldehyde was carried out to furnish a new Pc with six ferrocenyl groups, **7**. Since this compound was insoluble, its structure was determined by elemental analysis, ICP-MS and IR spectroscopy.

The IR spectra of **3**, **4** and **5** were taken as KBr pellets. The stretching peaks at 2983 and 2858 cm^{-1} confirmed the presence of –CH and $–CH_3$ groups, respectively, for compounds **3**, **4** and **5**. The stretching peaks at around 1523–1344 cm^{-1} in the spectrum of **3** indicated the presence of a $–NO_2$ group that disappeared in the case of the amine-substituted Pc **6**. The presence of $–NH_2–$ in the structure of **6** was observed at 3447–3417 cm^{-1}. The C–S–C ether chain was characterized by an absorption at 1090 cm^{-1} for all the dimeric compounds. The stretching peaks at 1620–1575 cm^{-1} confirmed the presence of N=N groups for **5**. Comparison of the IR spectral data of compound **6** and **7** clearly indicates the conversion of the NH_2 groups to ferrocenylaldehyde groups by the disappearance of the NH_2 band at 3447–3417 cm^{-1} and the appearance of a new bands at 1569 and 1602 cm^{-1} in **7**.

The ^1H NMR data were taken in *d*-chloroform. In the ^1H NMR analysis of **4** aromatic protons appeared as multiplets at 6.70–8.20 ppm. The protons of $–CH_3$ groups at the end of the aliphatic chain appeared at 0.88 ppm for **4**. In the spectra of **4**, the $–CCH_2C–$ protons in the long aliphatic chain are at 1.92–2.16 ppm and the $–SCH_2$ group protons neighbouring an aromatic ring appear at 2.22–2.62 ppm. The UV–Vis absorption spectra of the phthalocyanine system exhibited characteristic Q and B bands. All of them showed typical electronic spectra with two strong absorption regions, one in the UV region at about 330 nm (B band), which is attributed to transitions from the deeper π levels to the LUMO. The other band was observed in the visible region at 670–720 nm (Q band) with a weaker satellite band around 600–650 nm [23] which indicated the aggregation. The characteristic Q band for all the compounds was ascribed to the $\pi–\pi^*$ transition from the highest occupied molecular orbital (HUMO) to the lowest unoccupied molecular orbital (LUMO). The band broadening that accompanied the exciton (or Davydon coupling) effects changes the visible region [24]. In the spectra of **3** and **6**, the Q bands shift from 682 to 716 nm. This is because of the electron-donating ability of the amino group [25]. A significant absorption for **3** was observed at 430 nm, corresponding to the electron-donor capacity of the nitro group, while the absorption disappeared at this position for **5** (Fig. 1).

Since compound **7** was insoluble, the UV–Vis spectra of this compound could not be taken. The ICP-MS measurements were done to determinate of the quantities of metals (Zn, Co and Fe) in the phthalocyanine structures for **5** and **7**. The results are given in Section 2. ICP-MS measurements provided additional support for the molecular structure of **5** and **7**.

3.2. DC conductivity measurement

The temperature dependence of the dark d.c. conductivity was obtained by the rapid cooling method which allows the avoidance of the influence of a sorption-desorption process. The measurements of direct current (d.c.) conductivity for **3**, **5** and **6** were carried out in the temperature range 290–400 K in a vacuum ($\leqslant 10^{-3}$ mbar). The variations of d.c. conductivity with temperature for the three compounds are plotted in Fig. 2. The plots indicated that **3**, **5** and **6** are semiconducting in nature. A good linear relationship in conductivity variations is observed (a region ascribed to a different activation energy corresponding to a different dominant excitation in the Arrehenius plots

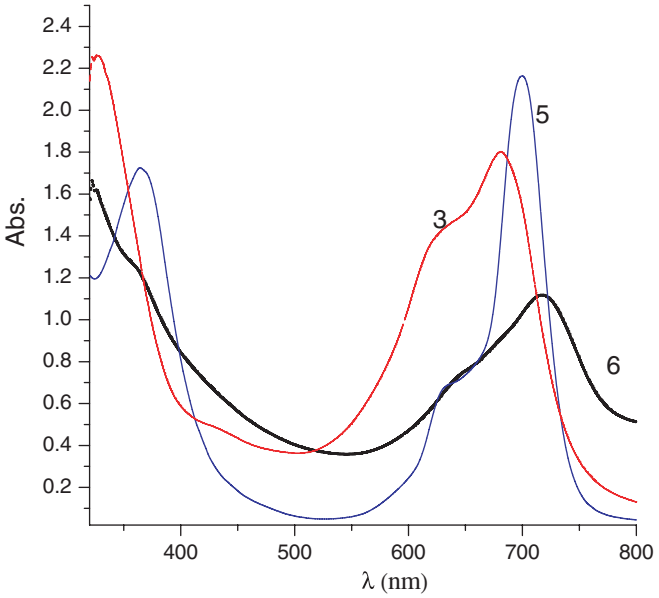


Fig. 1. UV–Vis spectra of **3** (3.06×10^{-5} M in DMSO), **5** (2.33×10^{-5} M in $CHCl_3$) and **6** (4.70×10^{-6} M in DMSO).

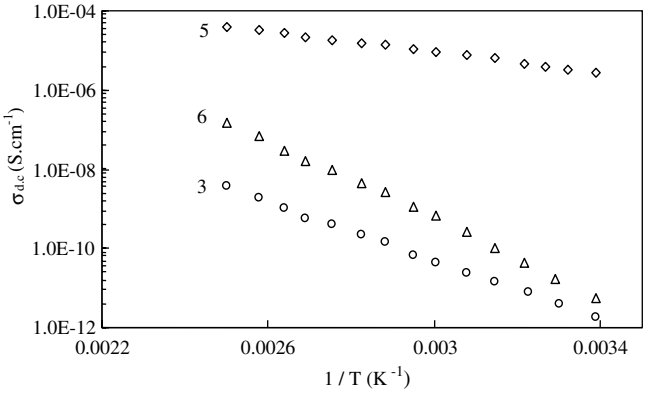

Fig. 2. Dependence of d.c. conductivity on the inverse of temperature for spin coated films of compounds **3**, **5** and **6**.

was not observed). In this case, the variation of the measured conductivity for the **3**, **6** and **5** films exhibit an exponential dependence on temperature and can be expressed as follows:

$$\sigma_{\mathrm{d.c.}} = \sigma_0 \exp(-E_A/kT) \quad (1)$$

where E_A is the activation energy, T is temperature, k is Boltzmann's constant and σ_0 is a constant of proportionality. The value of the activation energy was derived from the slope of the $\log \sigma_{\mathrm{d.c.}}$ versus $1/T$ graph and is 0.74 eV for compound **3**, 0.95 eV for compound **6** and 0.26 eV for compound **5**. Fig. 2 also shows that conductivity values at room temperature as well as at higher temperatures are different. The observed electrical conductivity values for **3**, **5** and **6** are 1.8×10^{-12} S/cm, 2.8×10^{-6} S/cm and 5.6×10^{-12} S/cm, respectively. The reduction of the electron withdrawing $-NO_2$ groups to electron donor $-NH_2$ groups was found to increase 3 times the electrical conductivity of the nitro substituted dimeric Co(II) phthalocyanine **3**. Whereas the azo coupling was found to increase the electrical conductivity by 10^6 times in comparison to dimeric Co(II) phthalocyanine **3**. A possible reason for the observed semiconducting property and improved electrical conductivity in **6** compared to **3** could be due to the smaller size of the amino group with respect to the nitro group. The smaller size of the amino group leads to stacking of the molecule with a smaller intermolecular distance resulting in greater π-electron interactions between the phthalocyanine molecules, thus providing a pathway for charge carriers. The higher conductivity of **5** can be expected due to the nature of the azo coupling and differences in the stacking arrangement of phthalocyanine molecules. This difference in arrangement may result in altering the interaction of π electron systems between the different molecules, which may affect the electrical conductivity of the phthalocyanine. Achar and Lokesh [26] studied the electrical properties of metal (II) tetranitro phthalocyanines of cobalt, nickel and copper. They found that an amine group substituent on the peripheral benzene ring of phthalocyanine molecule causes an increase in the electrical conductivity.

3.3. AC conductivity and impedance measurements

The ac conductivity and impedance spectral measurements were performed in the temperature range of 295–400 K and frequencies between 40 and 10^5 Hz.

Fig. 3 shows the frequency dependence of the imaginary part of impedance, loss spectra, for the films at different temperatures.

While a monotonic decrease in $Z''(f)$ can be noticed without any peak at low temperatures, with an increase of temperature, the spectra exhibits peaks at unique frequencies. A monotonic decrease in the loss spectra without any peaks up to 350 K means there is no current dissipation in this temperature region. The appearance of peaks at certain frequencies indicates the presence of an electrical

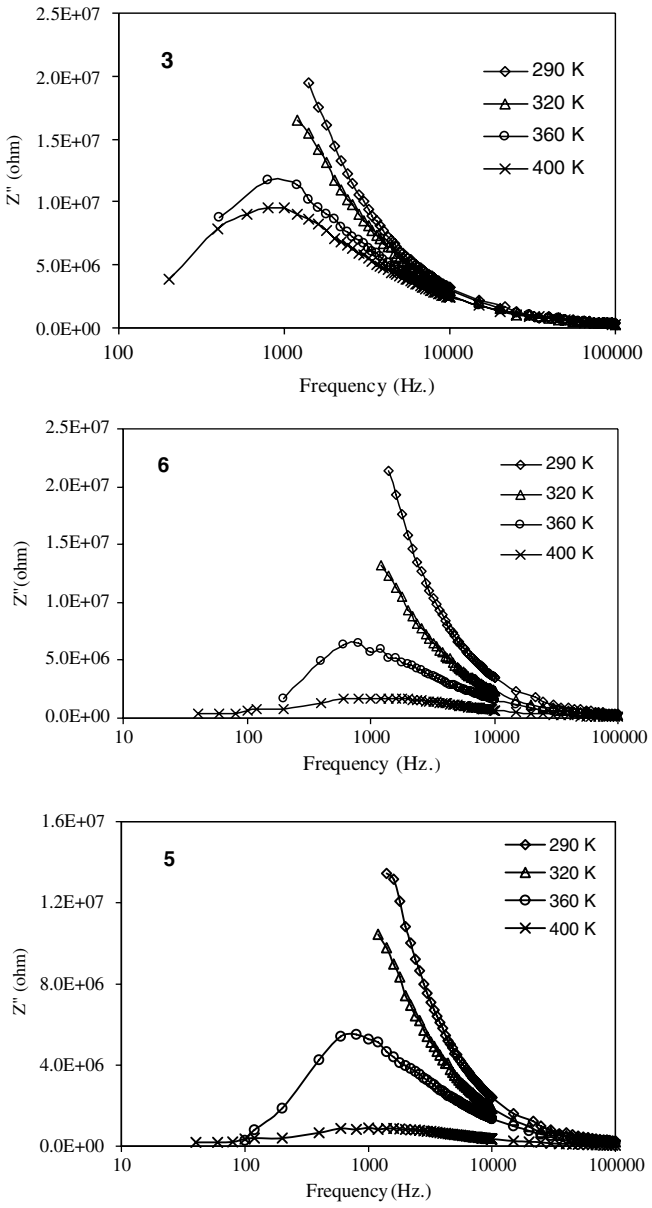

Fig. 3. Plot of the imaginary part of impedance with frequency for the films of **3**, **5** and **6**.

relaxation phenomenon in the films. It is noticed that the broadening of the $Z''(f)$ peaks is very obvious at higher temperatures. The observed broadening of the peaks with an increase in temperature suggests the presence of an electrical processes with a spread of relaxation time. The relaxation processes in the film may possibly be due to the presence of electron/immobile species at low temperatures and defects at higher temperatures. Further, the magnitude of $Z''(f)$ decreases gradually and it merges finally in the high frequency region. This behaviour can be attributed to the accumulation of space charge in the materials.

A considerable number of experimental results concerning the frequency dependent conductivity of a large variety of phthalocyanine materials can be found in the literature [27,28]. Room temperature a.c. behaviour of the compounds in the frequency range, 40–10^5 Hz is shown in Fig. 4. The effect of the reduction the nitro group to amines and azo coupling on the alternating current electrical conductivity can be seen clearly. The order of ac conductivities observed for these compounds are **5** > **6** > **3** for all frequencies investigated. These results for ac conductivity are in agreement with the observed d.c. conductivity. Fig. 4 also reveals that frequency has a pronounced effect on the measured ac conductivity for **3** and **6**. The frequency dependence of the conductivity follows a universal power law for compounds **3** and **6**, Fig. 4

$$\sigma_{\text{a.c.}}(\omega) = A\omega^s \tag{2}$$

where ω is the angular frequency, A and the frequency exponent s are material dependent constants. This type of a.c. conduction has been explained on the basis of two distinct mechanisms for carrier conduction.

One of them is quantum mechanical tunnelling (QMT) model. According to this model the conduction occurs by means of thermally assisted QMT. The other model, which is also known as correlated barrier hopping (CBH) model, is based on the concept of charged defects and in this bipolarons hop between two charged defect states D^+ and D^- over the barrier separating them, rather than tunnelling through the barrier. In these two models, the frequency exponent s is found to have two different trends with temperature and frequency [29]. The QMT model predicts a temperature independent s with a constant value around 0.8 which is given by

$$s = 1 - \frac{4}{\ln(\omega\tau_0)} \tag{3}$$

where ω is the angular frequency and τ_0 the characteristic relaxation time of the carrier. The values of s have been calculated from the slope of $\ln\sigma_{\text{ac}}(\omega)$ versus $\ln\omega$ graphs. Our calculations showed that s is definitely a function of temperature for compounds **3** and **6** and shows a general tendency to increase with decreasing temperature. The decrease in s with temperature is in contradiction with the QMT model. Therefore, it is apparent from the derived values of the index s that the conduction mechanism in **3** and **6** cannot be explained by the QMT model. In the case of **3** and **6** the hopping conduction process, which was developed by Elliot [29], is applicable. According to this model, the charge carriers hop between sites over the potential barrier separating them rather tunnelling through the barrier. The CBH model gives an ac conductivity which can be expressed to a first-order approximation as

$$\sigma_{\text{ac}}(\omega) = \frac{\pi^2 N^2 \varepsilon}{24}\left(\frac{8q^2}{\varepsilon W_{\text{OB}}}\right)^6 \frac{\omega^s}{\tau_0^\beta} \tag{4}$$

where ε is the dielectric constant, W_{OB} the optical band gap, τ_0 a characteristic relaxation time, q the electronic charge, k_{B} the Boltzmann's constant and N is the spatial density of defect states. The frequency exponent s for this model is evaluated as

$$s = 1 - \beta = 1 - 6k_{\text{B}}T/W_{\text{OB}} \tag{5}$$

The CBH model, in contrary to the QMT model, predicts a temperature-dependent s value which increases with decreasing temperature. The comparison of the experimentally determined s values with the prediction of the CBH model suggests that the dependence of the exponent s on temperature is in agreement with the prediction of the CBH model for compounds **3** and **6**.

A completely different frequency dependence was observed for compound **5**. The frequency dependence of a.c. conductivity at selected temperatures is shown in Fig. 5. It is clear from Fig. 5 that the a.c. conductivity for the spin coated film of compound **5** is frequency independent for all the temperature investigated.

Results indicate that the interpretation of the measured a.c. conductivity of compound **5** involves a number of difficulties; one of these is the contribution of the d.c. part. All the classical models based on the pair approximation deal only with pure a.c. conductivity, whereas the measured values include the d.c. limit. Therefore, any interpretation which is based on a model derived from the pair approximation has to exclude the d.c. limit somehow from the measured quantities. Conclusion of this topic is out of scope of this work.

4. Conclusions

In this study a new octaphthalocyanine **3** and a dimeric phthalocyanine with six ferrocenyl groups, **7**, were synthesized. The structures of these compounds were determined by elemental analysis, ICP-MS, IR, UV–Vis and ^{1}H NMR spectroscopy. Alternative current and direct current conductivity in thin films of compounds **3**, **5** and **6** at temperatures between 295 and 400 K were investigated. Well defined straight lines were obtained from the $\ln \sigma_{\mathrm{d.c.}}$ versus $1/T$ plots suggesting the presence of only one conduction mechanism in the whole temperature range for all compounds. While the frequency dependence of conductivity of the films of **3** and **6** is represented by the form ω^s, a frequency independent conductivity was observed for compound **5** above room temperature. A detailed analysis of the behaviour of **5** will be presented in a future paper.

trinuclear [(bpy)Co(μ-OOCMe)$_3$Co(μ-OOCMe)$_3$Co(bpy)] [10], tetranuclear [Co$_4$(μ$_2$-OOCCF$_3$)$_2$(μ$_3$-OH)$_4$(bpy)$_4$] [17], binuclear compounds [Co$_2$(μ-Cl)$_2$(phen)$_2$](PF$_6$)$_2$ · 2Et$_2$O [18], [(phen)$_2$Co(μ-Cl)$_2$CoCl$_2$] · Et$_2$O [19] and [Co$_2$-(μ-N$_3$)$_2$(N$_3$)$_2$(dmph)$_2$] (dmph = 2,9-dimethyl-1,10-phenanthroline) [20]. In these compounds the Co–Co distances are relatively short, generally in the range 3.0–3.5 Å. Much longer distances were found in complexes with polycarboxylato bridging ligands: OOCRCOO (R = alkylene, arylene), e.g.: [Co$_2$\{μ-C$_6$H$_2$(COO)$_4$-1,2,4,5\}(N–N)$_4$] (N–N= bpy, phen and their derivatives) [21], [Co\{μ-C$_6$H$_2$(COO)$_2$-(COOH)$_2$-1,2,3,4,5\}(phen)(H$_2$O)]$_n$ [22], [Co$_2$\{μ-OOCCH=CHCOO\}$_2$(phen)$_2$]$_n$ [23]. In this paper, we present the X-ray structure, electronic, IR and ^{1}H NMR spectra and magnetic properties of a dinuclear Co(II) acetate complex [Co$_2$(μ-OAc)$_2$(OAc)$_2$(μ-H$_2$O)(phen)$_2$] with a structure similar to that of metalloenzymes.

2. Experimental

Reagents and solvents (pro analysis) were purchased from the Polish company POCH and were used as received. Infrared spectra (KBr pellets) were recorded with a Bruker IFS 113v, ^{1}H NMR spectra on a Bruker AMX 300 and a Bruker Avance 500. The temperature dependence of the magnetic susceptibility was measured with a Quantum Design MPMS-XL-5 SQUID susceptometer operating at a magnetic field of 0.5 T in the temperature range 2.5–300 K. The susceptibilities were corrected for the diamagnetism of the constituent atoms using Pascal's constants [24]. Elemental analysis was performed with a Vario EL3 CHN analyzer.

2.1. Synthesis and characterization of [Co$_2$(μ-OAc)$_2$(OAc)$_2$(μ-H$_2$O)(phen)$_2$]

To a hot solution of Co(CH$_3$COO)$_2$ · 4H$_2$O (0.04882 g, 2 mmol) in water (1.0 cm^3) was added a solution of 1,10-phenanthroline C$_{12}$H$_8$N$_2$ · H$_2$O (0.3964 g, 2 mmol) in DMF (1.5 cm^3). The reaction mixture was stirred at 75 °C for 15 min. The orange solution was cooled to room temperature and left for 3 h. The orange product was isolated and recrystallized from methylene chloride and vacuum dried. Yield: 0.5933 g (81%). *Anal.* Calc. for C$_{32}$H$_{30}$Co$_2$N$_4$O$_9$: C, 52.47; H, 4.13; N, 7.65; found. C, 52.33; H, 4.25; N, 7.28%.

IR (in KBr, cm^{-1}): 3432 vs (ν_{OH}), 3053 w (ν_{CH}), 3003 w (ν_{CH}), 2928 w (ν_{CH}), 2851 vw (ν_{CH}), 2086 w, 1993 w, 1955 w, 1619 vs ($\nu^{as}_{COOH} + \nu_{OH}$), 1537 sh, 1515 m, 1419 vs (ν^{s}_{COOH}), 1348 m, 1335 m, 1222 w 1209 vw, 1140 m, 1115 vw, 1103 m, 1045 w, 1015 w, 916 w, 894 w, 868 m, 849 m, 841 m, 775 w, 727 s, 653 s, 641 w, 614 w, 556 vw, 493 vw, 423 vw. UV–Vis [reflectance spectrum, cm^{-1}]: 8750, 16600, 19500, 21400, 26000, 38000. ^{1}H NMR [CD$_2$Cl$_2$, ppm] 64.23 (4H, ^{2,9}H), 38.61 (4H, ^{3,8}H), 22.18 (4H, ^{5,6}H), 7.62 (4H, ^{4,7}H), 1.24 (2H, H$_2$O), −0.52 (12H, CH$_3$).

2.2. X-ray crystallography study

All measurements of the crystal were performed at low temperature using an Oxford Cryosystem device on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo Kα radiation. Accurate cell parameters were determined and refined by a least-squares fit of the strongest reflections. The data were corrected for Lorentz and polarization effects. No absorption correction was applied. Data reduction and analysis were carried out with the Oxford Diffraction, Poland (formerly Kuma Diffraction Wroclaw, Poland) programs. The structure was solved by direct methods (program SHELXS97 [25]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL97 [26] programs. Non-hydrogen atoms were refined with anisotropic vibrational parameters; hydrogen atoms of organic ligands were included from the geometry of the molecules and H atoms of aqua ligands were located from difference density maps and were refined with isotropic vibrational parameters.

3. Results and discussion

Complex [Co$_2$(μ-OOCCH$_3$)$_2$(OOCCH$_3$)$_2$(phen)$_2$(μ-OH$_2$)] (**1**), crystallizes in the monoclinic crystal system, $P2(1)/c$ space group. Crystallographic data are given in Table 1 and selected bond distances and angles are listed in Table 2.

Data on hydrogen bonds are presented in Table 3, an ORTEP plot of the complex is depicted in Fig. 1 and the stacking of the 1,10-phenanthroline ligands in the solid is

shown in Fig. 2. The ^1H NMR spectra of complex were investigated in CD_2Cl_2 in the range 223–298 K and in D_2O at 298 K. The ^1H NMR spectrum at 233 K is shown in Fig. 3. The magnetic susceptibility of complex **1** was measured in the temperature range 2.5–300 K. The temperature dependencies of the magnetic susceptibilities and effective magnetic moments of $[Co_2(\mu\text{-}OOCCH_3)_2(OOCCH_3)_2(phen)_2(\mu\text{-}OH_2)]$ are shown in Fig. 4.

Compound **1** was prepared by the reaction of cobalt(II) acetate with 1,10-phenanthroline in organic solvents (dimethylformamide, 1,4-dioxane). It is soluble in polar organic solvents and water. The X-ray structure shows that complex **1** has a structure similar to that of other dinuclear cobalt(II) compounds with carboxylato and nitrogen ligands. The Co(II) central atoms are bridged by two acetate anions and a water molecule and have octahedral coordination. The other coordination sites are occupied by terminal acetato ligands and 1,10-phenanthroline molecules, which are coordinated in nearly perpendicular planes. The nitrogen atoms are bound with the central atoms in trans positions to the bridging acetato ligands and water molecule. The structure of complex **1** is stabilized by strong hydrogen bonds formed by the water molecule with uncoordinated oxygen atoms of acetato ligands (d(O3–O7) = 2.566(3) Å and d(O3–O8) = 2.542(3) Å) and by weak C–H···O intra- and intermolecular hydrogen bonds (Table 3). The crystal structure of compound **1** is also stabilized by stacking of 1,10-phenanthroline ligands. The shortest distances between carbon atoms of two phenanthroline ligands vary in the range 3.34–3.70 Å (Fig. 2). The Co1–Co2 distance is equal to 3.574 Å, thus it is considerably greater than that in dicobalt methane monooxygenase hydroxylase (3.1 and 3.0 Å for protomers 1 and 2), but similar to the Fe–Fe distance (3.3 Å) in the reduced methane monooxygenase hydroxylase protomers and nearly the same as in dimanganese protomer 1 (3.5 Å) [3].

The presence of strong hydrogen bonds as well as bridging bidentate and terminal monodentate acetato ligands in the solid state was confirmed by the IR spectra of the complex in KBr and nujol mull. The monodentate CH_3COO ligands form such strong hydrogen bonds with the bridging

Symmetry transformations used to generate equivalent atoms: $1 + x$, $-1/2 - y$, $1/2 + z$ and x, $-1/2 - y$, $-1/2 + z$.

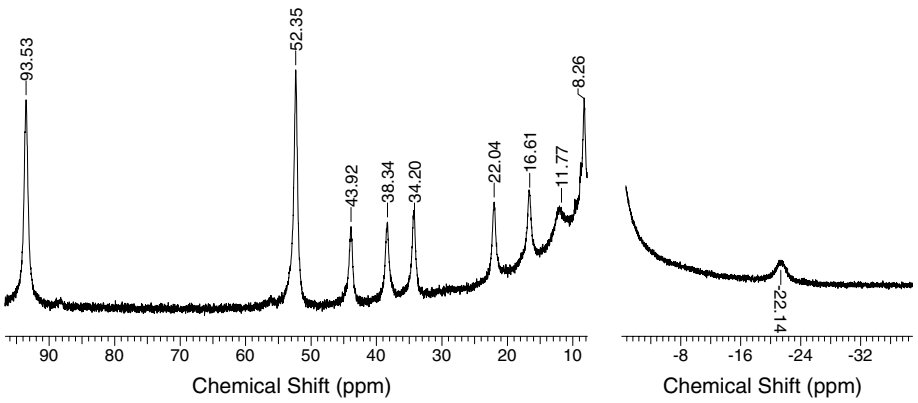

Fig. 3. The ^{1}H NMR spectrum of $[Co_2(\mu\text{-}OOCCH_3)_2(OOCCH_3)_2(phen)_2(\mu\text{-}OH_2)]$ in CD_2Cl_2 at 233 K.

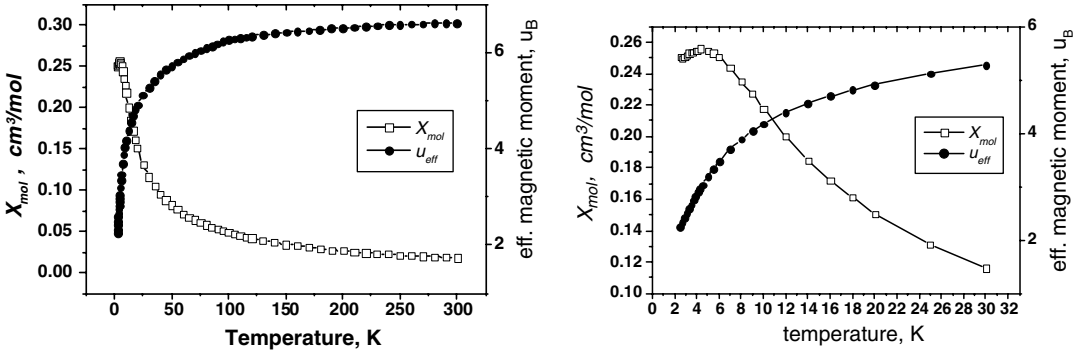

Fig. 4. Susceptibility and effective magnetic moment per dimer vs. temperature of complex $[Co_2(\mu\text{-}OOCCH_3)_2(OOCCH_3)_2(phen)_2(\mu\text{-}OH_2)]$.

H_2O ligand that the difference between the symmetrical and asymmetrical stretching vibration of the carboxylate group $\Delta\nu = \nu_{as}(COO) - \nu_s(COO) = 200\ cm^{-1}$ is approximately the same as for the bidentate bridging CH_3COO ligand. Therefore, only one broad $\nu_{as}(COO)$ and one $\nu_s(COO)$ band is observed in the IR spectrum of $[Co_2(\mu\text{-}OOCCH_3)_2(OOCCH_3)_2(phen)_2(\mu\text{-}OH_2)]$. The $\delta(OH)$ band is present at the same frequency as $\nu_{as}(COO)$, 1619 cm^{-1}.

In the reflectance electronic spectrum of the complex the $^4T_{2g} \leftarrow {}^4T_{1g}$ transition is observed at 8750 cm^{-1}. This band is symmetrical, thus the ^4T terms are not split owing to the lowering of the symmetry of the complex from O_h to C_{2v} for the $[CoN_2O_4]$ chromophore. However, the splitting of the term $^4T_{1g}(P)$ is observed because in the region of the transition $^4T_{1g}(P) \leftarrow {}^4T_{1g}$, 18 500–21 700 cm^{-1}, two bands are present, at 19 500 cm^{-1} and 21 400 cm^{-1}. Shoulders observed at 16 600 cm^{-1} and 18 800 cm^{-1} are most probably caused by spin forbidden $^2T_{1g}$, $^2T_{2g} \leftarrow {}^4T_{1g}$ and spin allowed $^4A_{2g} \leftarrow {}^4T_{1g}$ transitions, respectively.

The proton NMR spectra of the complex in CD_2Cl_2 were investigated in the temperature range 223–298 K. In the spectrum at 298 K, only five signals (assigned to the acetate and phen ligands) were found. Thus, at room temperature all the acetate groups are equivalent and both phenanthroline ligands become symmetrically coordinated with the Co(II) atoms, because the bridging and terminal acetate ligands interchange rapidly. The signals observed at 64.23, 38.61, 22.18, 7.62 and −0.52 ppm are assigned to the methyl groups of the acetato ligands and to the ^{2,9}H, ^{3,8}H, ^{5,6}H and ^{4,7}H protons of the bpy molecule, respectively. At lower temperatures the signals first broaden, then coalesce into three broad peaks. At 233 K and lower temperatures, separate resonances are observed: 2 for the methyl groups of acetate (at 93.53 pm – bridging and 52.35 pm – terminal) and 8 for the asymmetrically coordinated 1,10-phenanthroline ligands (at 43.92, 38.34, 34.20, 22.04, 16.61, 11.77, 8.26 and −22.14 ppm) with a ratio of methyl:methyl:aromatic signals equal to 3:3:1 (Fig. 3). Thus, at low temperatures the complex in CD_2Cl_2 solution has the same structure as in the solid state.

The relatively sharp signal at 298 K observed at 1.24 ppm is probably caused by a small amount of water contained in CD_2Cl_2. The resonance of coordinated water should be observed in the region where signals of solvent and its impurities are present. Therefore, it was not possible to determine the proton chemical shift of the aqua ligand. It is probable that at room temperature a fast exchange of protons between the aqua ligand and free water proceeds.

The ^{1}H NMR spectrum of the complex in D_2O solution shows the presence of three cobalt complexes with phenanthroline, namely complexes with Co:phen ratios equal to 1:1, 1:2 and 1:3. Phenanthroline signals for the 1:1 complex were observed at 76.76 (^{2,9}H), 41.05 (^{3,8}H), 34.11 (^{5,6}H) and

18.96 (^{4,7}H) ppm, for the 1:2 compound at 85.00 (^{2,9}H), 43.85 (^{3,8}H), 32.89 (^{5,6}H) and 16.72 (^{4,7}H) ppm and for the 1:3 complex at 106.15 (^{2,9}H), 50.15 (^{3,8}H), 33.52 (^{5,6}H) and 17.48 (^{4,7}H) ppm. The chemical shift for these complexes are nearly the same as for the appropriate 1,10-phenanthroline complexes with a chloride counter ion in D_2O. Thus, most likely, they form aqua complexes, although coordination of acetate ligands cannot be excluded. The methyl groups signal in D_2O was observed at 2.56 ppm The Co(phen)$_3$:Co(phen)$_2$:Co(phen):Co ratio in a solution of $[Co_2(OAc)_4(phen)_2(H_2O)]$ in D_2O is approximately equal to 1:4:15:6. These data indicate that in water solutions cobalt(II) complexes with Co:N–N ratios of 1:1 and 1:2 (N–N = phen, bpy and their derivatives) are labile and the heteroligand $[Co(N–N)_2X_2]^{m+}$ and $[Co(N–N)X_4{}^{n+}]$ as well as the homoligand $[Co(N–N)_2{}^{2+}]$ complexes are at equilibrium.

The dependences of magnetic susceptibility and effective magnetic moment of a polycrystalline sample of complex $[Co_2(OAc)_4(phen)_2(H_2O)]$ on temperature are shown in Fig. 4. Each Co(II) ion in this compound is octahedrally coordinated but the symmetry is axial due to rather strong distortions of the coordination spheres. The lowering of the symmetry is strong enough to remove the orbital degeneracy of the $^4T_{1g}$ ground state. Similar properties are shown by analogous Co(II) complexes containing *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine instead of 1,10-phenanthroline and other dinuclear Co(II) compounds: $[Co_2(\mu\text{-}OOCMe)_2(OOCMe)_2(\mu\text{-}H_2O)(Me_2NCH_2CH_2NMe_2)_2]$, $[Co_2(\mu\text{-}OOCCH_3)_3\{OC(NH_2)_2\}(Me_2NCH_2CH_2NMe_2)_2]^+$, $[Co_2(\mu\text{-}OOCCH_3)_2\{\mu\text{-}ONHC(=O)CH_3\}\{OC(NH_2)_2\}(Me_2NCH_2CH_2NMe_2)_2]^+$, $[Co_2(\mu\text{-}OOCCH_3)\{\mu\text{-}ONC(=O)CH_3\}_2(Me_2NCH_2CH_2NMe_2)_2]^+$ and $[Co_2(\mu\text{-}OOCR)_2(\mu\text{-}bhmp)]^+$ [2,5–9]. Therefore, the magnetic properties of the complex $[Co_2(OAc)_4(phen)_2(H_2O)]$ (**1**) can be explained assuming that the isotropic Heisenberg Hamiltonian is appropriate in this case [24,27]. The influence of the angular momentum is incorporated into the *g* tensors. Complex **1** shows a distinct maximum in χ_M at 4.5 K.

Calculations of χ_M were performed according to the method described in [24,27]. Satisfactory agreement of the calculated susceptibility with experimental data were obtained for average value $g = 2.1$ and $J = -2.1\ cm^{-1}$. These data exhibit that an antiferromagnetic interaction in this complex is stronger than in the dinuclear Co(II) complexes with three carboxylato bridges [2,5]. Thus, the antiferromagnetic interaction via three atoms of the carboxylic group is weak. This indicates that a considerably stronger antiferromagnetic interaction takes place via the O atom of the bridging water molecule. The effective magnetic moment of complex **1** (per dimer) at 300 K is equal to 6.62 μ_B and is somewhat lower than the spin-only value and considerably lower than the magnetic moments of compounds $[Co_2(\mu\text{-}OOCMe)_2(OOCMe)_2(\mu\text{-}H_2O)(Me_2NCH_2CH_2NMe_2)_2]$ and $[Co_2(\mu\text{-}OOCCH_3)_2\{\mu\text{-}ONHC(=O)CH_3\}\{OC(NH_2)_2\}(Me_2NCH_2CH_2NMe_2)_2]^+$ [2,5]. It decreases with diminishing temperature to 2.02 μ_B at 2 K.

4. Conclusions

Reaction of $Co(OOCCH_3)_2 \cdot 4H_2O$ with 1,10 phenanthroline in organic solvents gives the dinuclear complex $[Co_2(\mu\text{-}OAc)_2(OAc)_2(\mu\text{-}H_2O)(phen)_2]$ (**1**). Its structure and physicochemical properties have been investigated. The compound crystallizes in the monoclinic space group $P2(1)/c$. The Co–Co distance (3.574 Å) is similar to the Fe–Fe distance in the reduced methane monooxygenase hydroxylase and almost the same as in manganese monooxygenase. The Co(II) central atoms have an octahedral coordination, they are bridged by two acetate anions and a water molecule. The other coordination sites are occupied by terminal acetato ligands and 1,10-phenanthroline molecules, which are coordinated in nearly perpendicular planes. The structure of the complex is stabilized by strong hydrogen bonds formed by the water molecule with uncoordinated oxygen atoms of the acetato ligands and by weak C–H···O intra-and intermolecular hydrogen bonds. The crystal structure of compound **1** is also stabilized by stacking of the 1,10-phenanthroline ligands. The shortest C–C distances between two phenanthroline ligands vary in the range 3.34–3.70 Å. The complex exhibits antiferromagnetic exchange, the maximum in χ_M is observed at 4.5 K. The calculated value of the isotropic exchange parameter $J = -2.1\ cm^{-1}$. The proton NMR spectrum indicates that the structure of the complex in CD_2Cl_2 solution at low temperatures (223–243 K) is the same as in the solid state with symmetrically coordinated 1,10-phenanthroline ligands, however, at room temperature the bridging and terminal acetate ligands fast interchange. In water solution, the complex dissociates giving compounds with different Co:phen ratios.

5. Supplementary material

Crystallographic data for the structure reported in this paper (excluding structure factors) have been deposited at the Cambridge Crystallographic Data Centre and allocated the deposition number CCDC 604443. wide variety of conditions. Different routes can be found for the synthesis of cycles, however previous studies suggest thiosemicarbazones are typical substrates to undergo ring closure processes to afford the corresponding formation of 1,2,4-triazole (I) and 1,3,4-thiadiazole (II) derivatives, normally in the presence of a metallic salt (see Scheme 1) [13].

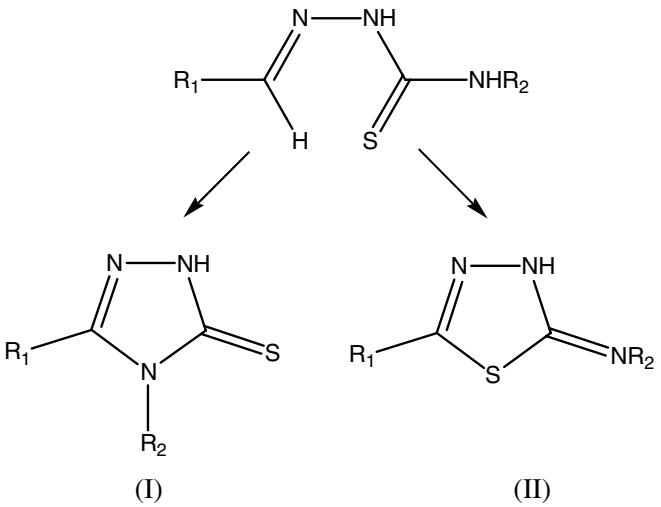
1,2,4-Triazol-3-thiones, as well as their corresponding thiosemicarbazones, can present in solution a *thione-thiol* tautomerism, whereas in the solid state they are present only in the thione form. The latter are very versatile, being able to form mono-, di- and polynuclear metal complexes as a result of two different coordination modes: as a monodentated ligand through the sulfur atom or as a bidentate bridge through the sulfur and a nitrogen atoms [14]. The presence of the soft thione donor group allows the stabilization of metal ions in low oxidation states such as Cu^{+}, Ag^{+}, Au^{+}. In addition, the pharmaceutical and industrial applications of some thiosemicarbazones increase the interest in this research field.

We have previously reported complexes containing thiosemicarbazone derivatives of 2-pyridinformamide and some transition and non-transition metals [15], nevertheless there are only a few reports on thiosemicarbazones complexes with Ag(I) [16,17]. Unexpectedly, there have been no X-ray structure determinations of Ag(I) thiosemicarbazone complexes until recently, with the publication of $[Ag_6(L^1H)_6]$ (L^1 = thiosemicarbazone of salicylaldehide) [18]. In order to extend our studies, in this work we described the preparation of a new silver(I) complex, $[Ag(E124tazt)]_6$ (**1**) (HE124tazt = 4-ethyl-5-pyridin-2-yl-2,4-dihydro-[1,2,4]triazol-3-thione), resulting from the cyclization 2-pyridinformamide *N*-4-ethylthio semicarbazone, HAm4E (Fig. 1), in the presence of Ag(I).



Scheme 1. Cyclization process of a thiosemicarbazone.

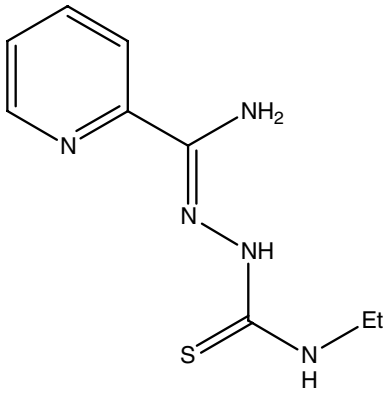


Fig. 1. Structure of 2-pyridinformamide *N*-4-ethylthiosemicarbazone, HAm4E.

2. Results and discussion

2.1. Synthesis

The reaction of $AgNO_3$ in H_2O/MeOH with the 2-pyridinformamide *N*-4-ethylthiosemicarbazone, HAm4E, led to the formation of $[Ag(E124tazt)]_6$ (**1**) (HE124tazt = 4-ethyl-5-pyridin-2-yl-2,4-dihydro-[1,2,4]triazol-3-thione), the structure of which contains a heterocyclic ring formed during the reaction. The formation of this kind of heterocyclic ring depends on the structure of the starting thiosemicarbazone, thus 1,2,4-triazole and 1,3,4-thiadiazole heterocyclic rings can both be formed from 2-pyridinformamide thiosemicarbazones derivatives. In particular HAm4E (Fig. 1) forms a 1,2,4-triazol-3-thione, the presence of a substituent on the N(4) nitrogen atom being a decisive factor for the regiochemistry of the cyclization.

The proposed cyclization mechanism suggests nucleophilic attack of the N5 thioamide on the azomethine carbon, with the elimination of a molecule of NH_3 (see Scheme 2) [14].

The preparation of HAm4E was carried out by reducing 2-cyanopyridine in the presence of *N*-4-ethylthiosemicarbazide, as described previously [15]. In the presence of silver(I) ions, HAm4E undergoes a cyclization process (see Scheme 3) to give a silver complex containing the deprotonated 4-ethyl-5-pyridin-2-yl-2,4-dihydro-[1,2,4]triazol-3-thiolato, E124tazt. The final compound is stable at room temperature, is not light sensitive and is insoluble in water or commonly used organic solvents.

2.2. Crystal structure of *1*

Single-crystal X-ray diffraction analysis indicates that the silver complex crystallizes in the trigonal space group $R\bar{3}c$. The crystal structure determination reveals that the asymmetric unit contains a silver(I) ion bonded to an E124tazt molecule through its sulfur atom. The space group symmetry generates a hexanuclear cluster, whose structure consists of six silver atoms and six deprotonated triazole-3-thione ligands. The deprotonation of the ligands

on coordination is evident in the observed C–S bond distance of 1.726(5) Å instead the typical value of 1.671 Å for C=S [19]. Fig. 2 shows the molecular structure of the silver complex. Relevant interatomic bond distances and angles are given in Table 1.

The Ag_6S_6 central core is formed by two six-membered Ag_3S_3 rings linked together by 6 alternating NCS and SCN bridges (Fig. 3). The two six-membered Ag_3S_3 rings adopt a chair configuration, the silver atoms being coordinated to a triazole nitrogen and two sulfur atoms. The Ag–N bond distance is 2.225(4) Å, similar to those found in the complexes of Ag(I) and nitrogen-containing heterocyclic ligands [20,21]. Each thiolate sulfur atom bridges asymmetrically two silver atoms with Ag–S bond lengths of 2.4296(13) and 2.5984(14) Å, in the same range as other polynuclear silver complexes [18,22–24].

In both Ag_3S_3 rings, Ag(I) shows a trigonal planar coordination geometry (S1–Ag1–$S1^b$, 105.36; S1–Ag1–$N13^e$, 106.48; $N13^e$–Ag1–$S1^b$, 147.64°) with the metal atom lying 0.091(2) Å out of the NS_2 plane. However if the Ag···Ag interaction between rings (2.9996 Å) is considered, the resulting coordination polyhedron can be described as a highly distorted tetrahedron (S1–Ag1–$S1^b$, 105.36, $Ag1^e$–Ag1–$N1^e$, 83.94°) or, alternatively, as a trigonal pyramid.

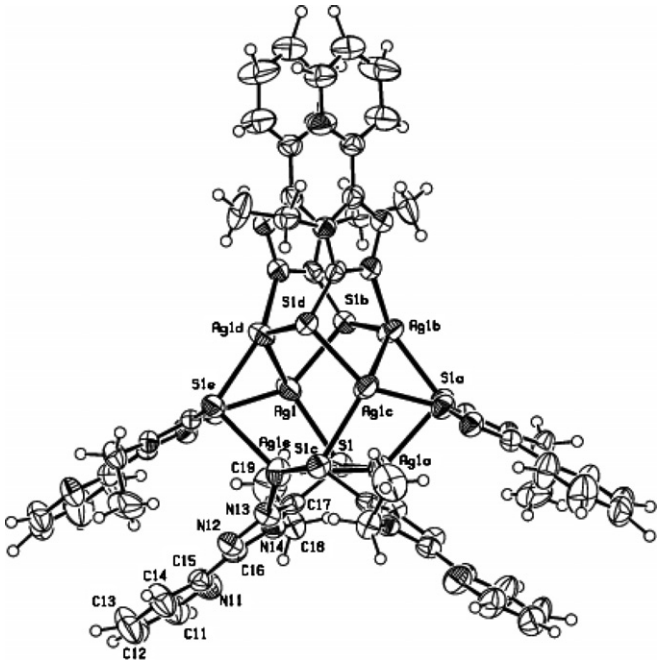

Fig. 2. Perspective view of **1**, showing 50% probability ellipsoids for the non-hydrogen atoms and the numbering scheme of the atoms in the molecule. Symmetry codes are given in Table 1.

In the Ag_6S_6 central core, the six silver atoms build a distorted octahedron formed by two parallel Ag_3 triangles, which adopt a staggered conformation [Ag···Ag distance of 3.8931(8) Å] and inter-ring distances of 3.6190(9) and 2.9996(9) Å. The Ag···Ag separation of 2.9996(9) Å is very close to that in metallic silver [2.889(6) Å], shorter than the sum of the van der Waals radii of two silver atoms (3.44 Å), suggesting the existence of some interaction between the

silver atoms. Although the closed d^{10} configuration of silver(I) appears to prevent any intermetallic bonding in silver(I) complexes for Ag···Ag distances longer than 2.705(1) Å [25], many complexes with definitive Ag···Ag attractive forces, known as argentophilic interactions, have been reported [26–28].

The bond distances within the ligand are similar to those of other triazole-3-thione and 2-pyridyl derivatives, although the intra-triazole ring bond distances suggest some multiple bond character and delocalization of electronic density. These ligands are almost planar with an angle of 5.2 (3)° between the pyridine and triazole rings. In **1**, both ligands show an antiparallel arrangement, displaying intramolecular π–π stacking interactions between the triazole- and pyridine rings, with centroid–centroid separations of 3.593 and 3.959 Å, respectively (Table 2). Intermolecular π–π stacking interactions are also responsible of the formation of 2D polymers. These two-dimensional nets

are stacked together along the crystallographic c axis generating hexameric parallel channels with crystallographic symmetry 3 (Fig. 4).

2.3. DFT calculations

In order to explore the nature of the Ag···Ag interactions from a theoretical point of view, quantum chemical investigations have been carried out using DFT methods. The structure optimization resulted in an excellent reproduction of the experimentally observed structural parameters (see Table 1). Therefore, the contribution of atomic orbitals (AOs) to molecular orbitals (MOs) has subsequently been studied by means of a Mulliken population analysis. The result, illustrated as the calculated density of states for all atoms versus silver atoms only, is given in Fig. 5.

The Ag valence orbitals (essentially 3d) are active between the energy level of the highest occupied molecular orbital (HOMO, at −3.7 eV) and −9.5 eV, which refers to about 100 occupied MOs. The maximum contribution of Ag, approx. 50% of the total DOS for all atoms, is observed for HOMO-41 (at −6.9 eV, i.e. 3.2 eV below the HOMO level). All MOs involving Ag d-orbitals have been analyzed with respect to the metal–metal contacts. This procedure revealed an essentially non-bonding (or weakly

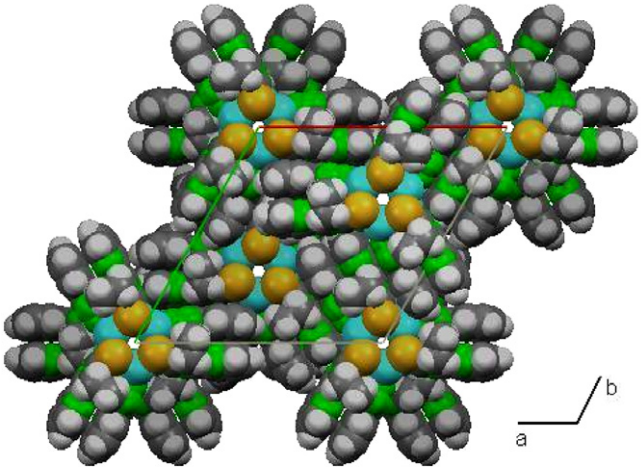

Fig. 4. The drawing of the packing diagram reveals the pattern of the array in the *ab* plane of **1**. Symmetry codes are given in Table 2.

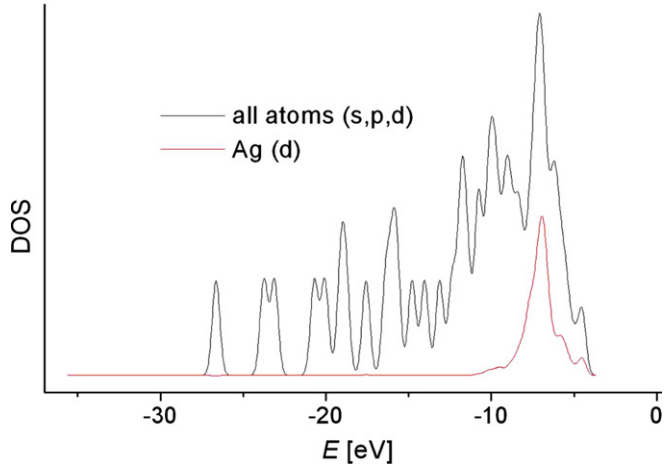

Fig. 5. Density of states (DOS) of the valence shell MOs (i.e. with contributions from C, N: 2s,2p; S: 3s,3p; Ag: 3d,4s) for the calculated $[Ag(E124tazt)]_6$. The solid line shows DOS considering all atoms, the dashed line refers only to the Ag d-orbital contribution; the latter represents essentially both the whole Ag valence orbital contribution (4s negligible) and the whole d-orbital contribution of all atoms (C, N, S d-contribution negligible).

antibonding) Ag···Ag situation for most of the respective MOs, with the exception of one MO (HOMO-56 at −7.3 eV, 36% Ag d-contribution) that clearly represents σ-bonds between Ag $d_{x^2-y^2}$ orbitals along all of the three short Ag···Ag contacts. Two further MOs (HOMO-63 and HOMO-64, both at −7.3 eV, 36% or 37% Ag d-contribution) show two or one such binding contacts involving d_{z^2} orbitals, besides one weakly antibonding or two weakly bonding ones, respectively. The quoted MOs are visualized in Fig. 6.

Preliminary neglecting the participation of orbitals of further atoms at the three MOs, one counts two electrons in each of these MOs to contribute to the binding Ag–Ag interactions. This denotes 2/3 e^- per Ag–Ag contact in HOMO-56, 1 e^- for each of the two binding Ag–Ag contacts in HOMO-64 and 2 e^- for one binding Ag–Ag contact in HOMO-63. The total number of two electrons per Ag–Ag contact which results from this crude estimation has to be reduced to an amount of ca. 2/3 electrons (36…37% of 2) per Ag–Ag contact according to the population analyses.

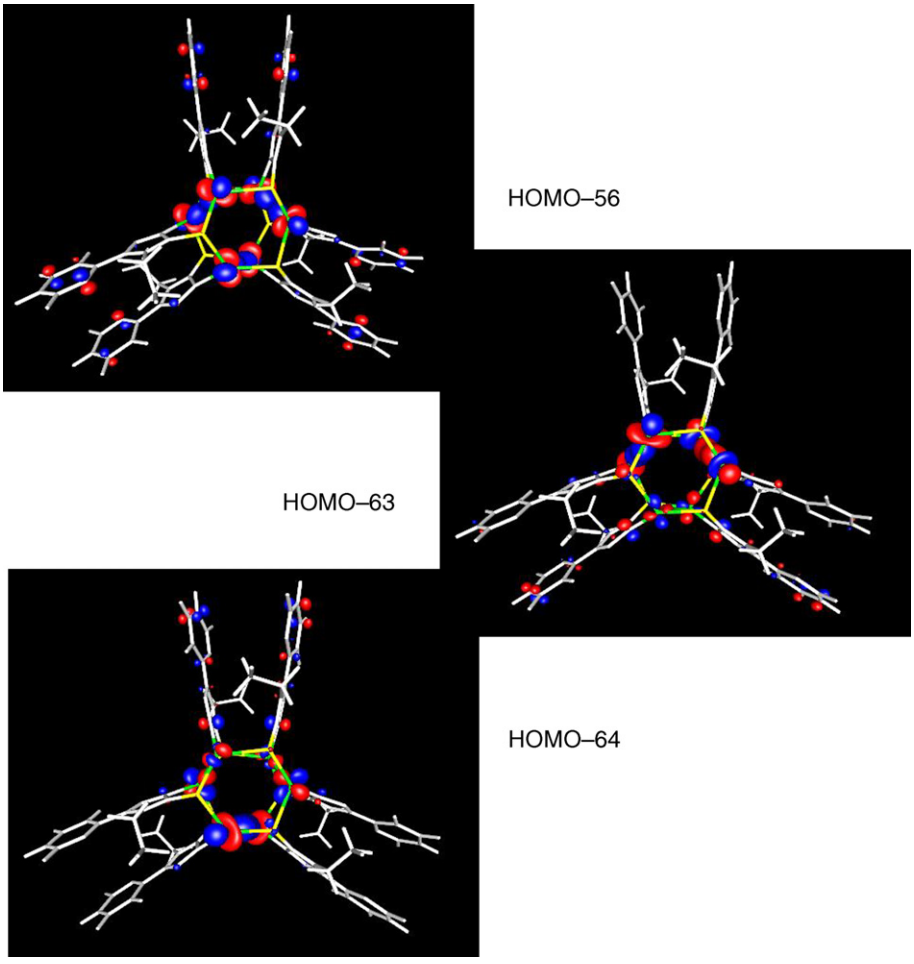

Fig. 6. Stick representation of the calculated $[Ag(E124tazt)]_6$ with visualization of the three MOs that show $d_{x^2-y^2}$–$d_{x^2-y^2}$ binding interactions between adjacent Ag atoms. For clarity, only Ag atoms (black) and S atoms (medium grey) are represented darker. Electron densities are drawn to 0.25 e^- Å^3.

2.4. Spectroscopic characterization

The IR spectrum of **1** shows absorption bands at 1588, 995 and 789 cm^{-1}, assigned to ν(C=N), ν(NN) and ν(CS), respectively. The absence of bands in the 3500–3000 cm^{-1} region due to NH stretching modes, supports the suggested cyclization of HAm4E, with elimination of NH_3 (Scheme 2) and deprotonation of the ligand in the thiol form. The bands at 346 and 304 cm^{-1} can be assigned to the vibrations ν(Ag–N) and ν(Ag–S), indicating the involvement of these atoms in the coordination [17].

The poor solubility of the complex only allows a ^1H NMR spectrum to be recorded. The spectrum shows signals assigned to the pyridine ring in the range of 8.71–7.50 ppm. The disappearance of the signal of the NH_2 group is in agreement with the cyclization of the thiosemicarbazone and the absence of an NH signal indicates the deprotonation of HE124tazt. The peaks corresponding to the ethyl group at 4.61 and 3.39 ppm are slightly shielded compared to those from HAm4E due to formation of the triazol group [15].

2.5. Luminescence measurements

It is known that most luminescence silver(I) compounds show their luminescence properties at low temperature, whereas only few of them are luminescent at room temperature [29]. Preliminary luminescence experiments on **1** as a nujol mull at room temperature are shown in Fig. 7.

Although the free ligand shows no luminescence, the spectra of **1** show two broad emission signals with shoulders at ~425 (shoulder at ~393 nm) and ~390 nm (shoulder at ~447 nm) upon excitation at 250 (curve a) and 350 nm (curve c), respectively. An unusual emission formed by two components at ~388 and ~410 nm was found upon excitation at 275 nm (curve b). This kind of dual emission could suggest the presence of different weakly coupled relaxation channels in **1**, as found in other compounds containing d^{10} metal centres [30,31]. Further investigations are being carried out to clarify this question.

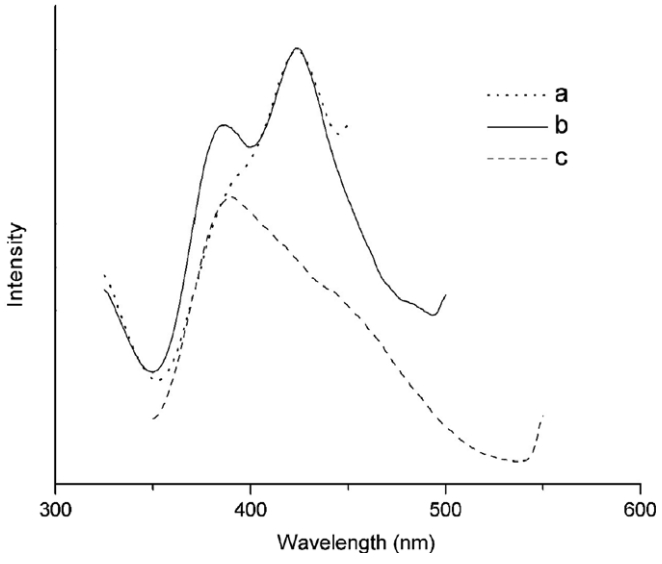

Fig. 7. Emission spectra of **1** as nujol mulls at room temperature. $\lambda_{exc} = 250$ nm (a); $\lambda_{exc} = 275$ nm (b); $\lambda_{exc} = 350$ nm (c).

3. Conclusions

A new air-stable silver triazol-3-thiolato complex, **1**, was synthesized and fully characterized, including X-ray crystal structure determination. The formation of **1** occurs through an oxidative cyclization of 2-pyridine *N*-4-ethyl thiosemicarbazone to 4-ethyl-5-pyridin-2-yl-2,4-dihydro-[1,2,4]triazol-thione, promoted by the presence of silver(I) ions. The X-ray crystal structure studies show the stabilization of the whole structure by π–π stacking interactions. DFT calculations that were carried out to study the nature of the Ag–Ag interaction, reveal that three of the MOs with Ag atomic orbital contributions clearly show d–d–σ-bonding. The approximate number of electrons involved in these Ag–Ag interactions is two. Preliminary luminescence experiments show fluorescence emission for **1** at room temperature. Upon excitation at 275 nm an unusual emission with two components is found, suggesting weak coupled relaxation channels. Further work on this subject is in progress.

4. Experimental

All commercials reagents were used as supplied. HAm4E was prepared according to the literature [15].

4.1. Synthesis of *1*

A solution of $AgNO_3$ (17 mg, 0.1 mmol) in H_2O (3 ml) was added to a solution of HAm4E (22 mg, 0.1 mmol) in MeOH (7 ml) and stirred for 30 min. The final clear yellow solution was kept in the dark and allowed to evaporate to give an orange product which was dissolved in DMF and overlayed with diethyl ether. Colourless single crystals suitable for a X-ray analysis of **1** were obtained.

Elemental analysis: *Anal.* Calc. for $C_{54}H_{54}Ag_6N_{24}S_6$: C, 34.5; H, 2.9; N, 17.9; S, 10.2. Found: C, 35.0; H, 3.2; N, 18.1; S, 9.7%. IR (ν_{max}/cm^{-1}): 1588 ν(C=N), 995 ν(NN), 789 ν(CS), 346 ν(Ag–N), 304 ν(Ag–S).

^1H NMR (DMSO-d_6, ppm): 8.71 (1H, d, H1); 7.98 (1H, m, H3); 7.93 (1H, d, H4); 7.50 (1H, m, H2); 4.61 (2H, s, CH_2), 3.39 (3H, s, CH_3).

4.2. Physical methods

Elemental analyses were performed with a Carlos Erba 1108 microanalyzer. NMR spectra were obtained from d^6-DMSO solutions with a Bruker AMX 300 spectrometer. Chemical shifts are reported in parts per million downfield from Me_4Si. IR spectra were recorded as KBr disks (4000–400 cm^{-1}) or polyethylene-sandwiched Nujol mulls (500–

100 cm^{-1}) with a Bruker IFS-66v spectrometer. Luminescence spectra were recorded at room temperature as Nujol mulls between quartz plates with a Varian Cary Eclipse Fluorescence Spectrophotometer.

4.3. X-ray crystallography

Crystals of **1**, grown in a mixture DMF/Et_2O, were mounted on glass fibers and were used for data collection. Reflections were obtained with a Bruker SMART CCD 1000 diffractometer. The data were processed with SAINT [32] and corrected for absorption using SADABS [33]. The structures were solved by direct methods [34], which revealed the position of all non-hydrogen atoms. They were refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [35]. The hydrogen atoms were located from difference syntheses in their calculated positions, and were refined using a riding model. Atom scattering factors were taken from the International Table for X-ray Crystallography [36]. Crystal and refinement data are listed in Table 3.

4.4. Methods of the DFT investigations

The calculations using density functional theory (DFT) methods [37] were performed with the program system TURBOMOLE [38] (RIDFT program [39], Becke–Perdew functional (B–P-86) [40]). Basis sets were of TZVPP quality (triple zeta valence plus multiple polarization functions) [39b]. Relativistically corrected effective core potentials (ECP) were used for the Ag atoms (ECP-28) [41]. All geometry optimizations were performed without symmetry restrictions (C_1 symmetry), therefore convergence into local minimum structures can be assumed and is confirmed by an excellent agreement of the structural parameters with the experimentally observed data. Values given in Table 1 are average values of the slightly varying structural parameters, resulting without symmetry restrictions.

Table 3
Crystal data and structure refinement for **1**

Empirical formula	$C_{54}H_{54}Ag_6N_{24}S_6$
Colour, habit	colourless, prism
Formula weight	1878.79
Temperature (K)	293(2)
Crystal size (mm)	$0.14 \times 0.11 \times 0.10$
Crystal system	trigonal
Space group	$R\bar{3}c$ (no. 167)
Unit cell dimensions	
a (Å)	22.8293(14)
b (Å)	22.8293(14)
c (Å)	23.294(3)
α (°)	90(0)
β (°)	90(0)
γ (°)	120(0)
Volume (Å^3)	10513.8(16)
Z	6
Density (Mg/m^3)	1.780
Absorption coefficient (mm^{-1})	1.876
θ Range for data collection (°)	1.78–26.41
Index ranges	$-24 \leqslant h \leqslant 0$
	$0 \leqslant k \leqslant 28$
	$0 \leqslant l \leqslant 28$
Reflections collected	40437
Independent reflections (R_{int})	2412, 0.0391
Data/parameters	2412/136
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0392$
	$wR_2 = 0.0917$
R indices (all data)	$R_1 = 0.0856$
	$wR_2 = 0.1009$
Goodness-of-fit	0.890
Largest diffraction peak/hole (e Å^{-3})	0.454/−0.960

Appendix A. Supplementary material

Crystallographic data for the structure reported in this paper (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as Supplementary Publication No. CCDC-605304. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223/336 033. E-mail: deposit@ccdc.cam.ac.uk). Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.07.028.

Aims and Scope

Polyhedron will publish original, fundamental, experimental and theoretical work of the highest quality in all the major areas of inorganic chemistry. These include synthetic chemistry, coordination chemistry, organometallic chemistry, bioinorganic chemistry, and solid-state and materials chemistry. Papers should be complete pieces of work, and the inclusion of results from spectroscopic and/or physical techniques is encouraged. Papers merely reporting the preparation and X-ray structural characterization of only a single compound will not be considered appropriate unless the compound and its structure are particularly interesting.

Similarly, papers concerned solely with stability constants determined by potentiometric titration data unsupported by other e.g. spectroscopic techniques will not be acceptable nor will solvent extraction data unless supported by other data of interest to inorganic chemists. Unnecessary fragmentation of work is not acceptable.

In addition Polyhedron publishes specially commissioned review articles (Polyhedron Reports) and collections of original research papers (Polyhedron Symposia-in-Print) of appropriate timeliness.

Publication Information: Polyhedron (ISSN 0277-5387). For 2006, volume 25 is scheduled for publication. Subscription prices are available upon request from the Publisher or from the Regional Sales Office nearest you or from this journal's website (http://www.elsevier.com/locate/poly). Further information is available on this journal and other Elsevier products through Elsevier's website (http://www.elsevier.com). Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by standard mail (surface within Europe, air delivery outside Europe). Priority rates are available upon request. Claims for missing issues should be made within six months of the date of dispatch.

Aims and Scope

Polyhedron will publish original, fundamental, experimental and theoretical work of the highest quality in all the major areas of inorganic chemistry. These include synthetic chemistry, coordination chemistry, organometallic chemistry, bioinorganic chemistry, and solid-state and materials chemistry. Papers should be complete pieces of work, and the inclusion of results from spectroscopic and/or physical techniques is encouraged. Papers merely reporting the preparation and X-ray structural characterization of only a single compound will not be considered appropriate unless the compound and its structure are particularly interesting.

Similarly, papers concerned solely with stability constants determined by potentiometric titration data unsupported by other e.g. spectroscopic techniques will not be acceptable nor will solvent extraction data unless supported by other data of interest to inorganic chemists. Unnecessary fragmentation of work is not acceptable.

In addition Polyhedron publishes specially commissioned review articles (Polyhedron Reports) and collections of original research papers (Polyhedron Symposia-in-Print) of appropriate timeliness.

Publication Information: Polyhedron (ISSN 0277-5387). For 2006, volume 25 is scheduled for publication. Subscription prices are available upon request from the Publisher or from the Regional Sales Office nearest you or from this journal's website (http://www.elsevier.com/locate/poly). Further information is available on this journal and other Elsevier products through Elsevier's website (http://www.elsevier.com). Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by standard mail (surface within Europe, air delivery outside Europe). Priority rates are available upon request. Claims for missing issues should be made within six months of the date of dispatch.

Aims and Scope

Polyhedron will publish original, fundamental, experimental and theoretical work of the highest quality in all the major areas of inorganic chemistry. These include synthetic chemistry, coordination chemistry, organometallic chemistry, bioinorganic chemistry, and solid-state and materials chemistry. Papers should be complete pieces of work, and the inclusion of results from spectroscopic and/or physical techniques is encouraged. Papers merely reporting the preparation and X-ray structural characterization of only a single compound will not be considered appropriate unless the compound and its structure are particularly interesting.

Similarly, papers concerned solely with stability constants determined by potentiometric titration data unsupported by other e.g. spectroscopic techniques will not be acceptable nor will solvent extraction data unless supported by other data of interest to inorganic chemists. Unnecessary fragmentation of work is not acceptable.

In addition Polyhedron publishes specially commissioned review articles (Polyhedron Reports) and collections of original research papers (Polyhedron Symposia-in-Print) of appropriate timeliness.

Publication Information: Polyhedron (ISSN 0277-5387). For 2006, volume 25 is scheduled for publication. Subscription prices are available upon request from the Publisher or from the Regional Sales Office nearest you or from this journal's website (http://www.elsevier.com/locate/poly). Further information is available on this journal and other Elsevier products through Elsevier's website (http://www.elsevier.com). Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by standard mail (surface within Europe, air delivery outside Europe). Priority rates are available upon request. Claims for missing issues should be made within six months of the date of dispatch.

Unnecessary fragmentation of work is not acceptable.

In addition Polyhedron publishes specially commissioned review articles (Polyhedron Reports) and collections of original research papers (Polyhedron Symposia-in-Print) of appropriate timeliness.

Publication Information: Polyhedron (ISSN 0277-5387). For 2006, volume 25 is scheduled for publication. Subscription prices are available upon request from the Publisher or from the Regional Sales Office nearest you or from this journal's website (http://www.elsevier.com/locate/poly). Further information is available on this journal and other Elsevier products through Elsevier's website (http://www.elsevier.com). Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by standard mail (surface within Europe, air delivery outside Europe). Priority rates are available upon request. Claims for missing issues should be made within six months of the date of dispatch.

Aims and Scope

Polyhedron will publish original, fundamental, experimental and theoretical work of the highest quality in all the major areas of inorganic chemistry. These include synthetic chemistry, coordination chemistry, organometallic chemistry, bioinorganic chemistry, and solid-state and materials chemistry. Papers should be complete pieces of work, and the inclusion of results from spectroscopic and/or physical techniques is encouraged. Papers merely reporting the preparation and X-ray structural characterization of only a single compound will not be considered appropriate unless the compound and its structure are particularly interesting.

Similarly, papers concerned solely with stability constants determined by potentiometric titration data unsupported by other e.g. spectroscopic techniques will not be acceptable nor will solvent extraction data unless supported by other data of interest to inorganic chemists. Unnecessary fragmentation of work is not acceptable.

In addition Polyhedron publishes specially commissioned review articles (Polyhedron Reports) and collections of original research papers (Polyhedron Symposia-in-Print) of appropriate timeliness.

Publication Information: Polyhedron (ISSN 0277-5387). For 2006, volume 25 is scheduled for publication. Papers

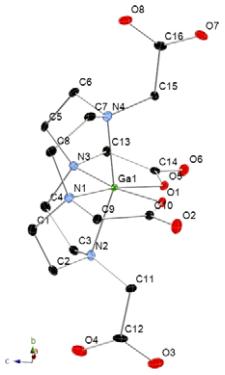
Nerissa A. Viola, Randy S. Rarig Jr., Wayne Ouellette, Robert P. Doyle

Polyhedron 25 (2006) 3457

Synthesis, structure and thermal analysis of the gallium complex of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA)

The reaction of gallium chloride with DOTA at room temperature in aqueous solution affords the complex [Ga(HDOTA) · 5.5H_2O] (**1**), which is characterized by single-crystal X-ray spectroscopy, electrospray mass spectrometry and thermal gravimetric analysis. Gallium displays 6-coordinate distorted octahedral geometry within a puckered macrocyclic DOTA framework. The equatorial plane comprises two nitrogens of the DOTA ring and two oxygens from two of the four pendant carboxylic acid groups. The axial positions are comprised of the remaining two transannular nitrogens of the DOTA ring.

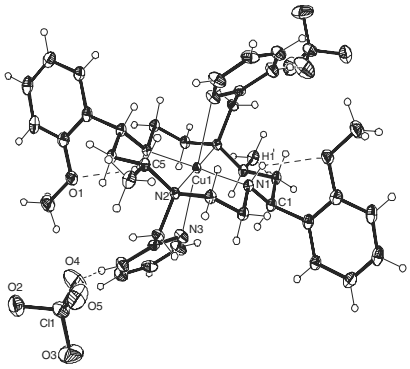


Thomas Schönherr, Wilhelm Seichter, Edwin Weber

Polyhedron 25 (2006) 3463

Complexes of pendant-armed cyclam derivatives with copper(II) perchlorate: Synthesis and crystal structures

Preparation and X-ray crystal structures of a designed series of cyclam type macrocyclic ligands that feature a different degree of saturation and number of functional appendages of the macroring, including corresponding complexes with Cu(II) perchlorate are reported and comparatively discussed. Dependent on the nature of the compound, transanular, pendant arm and anion involving conventional and weaker H bond contacts are shown to be operating in the formation of the crystal structures.

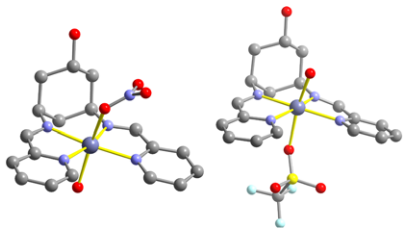


John Fielden, Patrick T. Gunning, De-Liang Long, Margaret Nutley, Arkady Ellern, Paul Kögerler, Leroy Cronin

Polyhedron 25 (2006) 3474

Anion control of isomerism, crystal packing and binding properties in a mononuclear zinc complex

Mononuclear zinc(II) complexes of the tetradentate pyridyl N-donor ligand *cis*-3,5-*bis*-[2-pyridinyleneamin]-*trans*-hydroxycyclohexane (DDOP) have been synthesised with nitrate and triflate counterions. The nature of the anion is seen to exert a significant influence on the arrangement of the axial ligands, construction of the solid state hydrogen bonded networks, and the ability to bind amino acid substrates.



Garima Singh, Ajai K. Singh, John E. Drake, Michael B. Hursthouse, Mark E. Light

Polyhedron 25 (2006) 3481

1-Ethylthio-2-[2-thienyltelluro]ethane (**L**) a new (Te, S) ligand: Synthesis and complexation with Ag(I), Cu(I), Pd(II) and Pt(II) – Single crystal structures of [$PdCl_2$(**L**)] and bis(thienyl) tellurium(IV) chloride

1-Ethylthio-2-[2-thienyltelluro]ethane(**L**) and its complexes [$PdCl_2$(**L**)] (**1**), [$PtCl_2$(**L**)] (**2**), [Ag(**L**)$_2$][ClO_4] (**3**) and [CuBr(**L**)]$_2$ (**4**) were synthesized. [$HgCl_2$(**L**)] on crystallization decomposes giving Th_2TeCl_2 (**5**) [Th = 2-thienyl]. **L** and **1**–**4** exhibit characteristic ^{1}H and ^{13}C NMR spectra. Single crystal structures of **1** and **5** were solved. The Pd–Te, Pd–S and Pd–Cl bond lengths are 2.5040(4), 2.273(1) and 2.322(1)/2.380(1) Å, respectively, in square planar **1**. Intermolecular weak interactions exist in **1** between Te/S and Cl [Te–Cl/S–Cl 3.401/3.488 Å]. Complex **5** has a saw-horse type structure [Te–Cl, 2.480(1) Å].

Synthesis and luminescent properties of Eu^{3+}-complexes with 2-acyl-1,3-indandionates (ACIND) and TPPO ligands: The first X-ray structure of Eu–ACIND complex

Europium complexes presenting general formulas [Eu(ACIND)$_3$(H_2O)$_2$] and [Eu(ACIND)$_3$(TPPO)$_2$] have been synthesized and characterized. In these formulas ACIND stands for the 2-acyl-1,3-indandionate ligands. The [Eu(ISOVIND)$_3$(H_2O)(EtOH)] complex was also prepared and its structure determined by single crystal X-ray analysis. Photoluminescence properties suggest an efficient ligand-to-metal intramolecular energy transfer process.

Co(II), Ni(II) and Cu(II) metal complexes with a N_8 azamacrocyclic ligand

Hydrated nitrate and perchlorate salts of the transitional metal ions Co^{2+}, Ni^{2+} and Cu^{2+} have been used to investigate the coordination capability of the octaaza macrocycle L derived from 2,6-diformylpyridine and diethylenetriamine. The synthesis of the metal complexes was carried out in 1:1 and 2:1 metal:ligand molar ratios, but dinuclear complexes were obtained in all cases. The complexes have been characterized by elemental analysis, molar conductivity, mass spectrometry, IR spectroscopy, diffuse reflectance and magnetic measurements. The crystal structures of [$Ni_2L(NO_3)_2$](NO_3)$_2$, [$Cu_2L(NO_3)_4$] and [$Cu_2L(ClO_4)_4$] have been determined.

Absence of phosphate hydrolysis in the nucleotide substitution reaction on *cis*-$[Co(H_2O)_2(cyclen)]^{3+}$ at physiological pH: Importance of hydrogen-bonding and conjugate base-catalysis

cis-$[Co(Cl)_2(tetraamine)]^+$ complexes are in the chloroaqua/chlorohydroxo forms under physiological conditions. Substitution studies with nucleotides indicate that the processes correspond to a simple reaction, producing final stable mixtures of monodentate *O*-phosphato and chelate *O*-phosphato-*N*-nucleotide forms. No hydrolytic cleavage of the phosphato-nucleoside bond has been observed.

Syntheses, structures and photochromism of two novel copper(II) complexes with 1,2-bis(2′-methyl-5′-(2″-pyridyl)-3′-thienyl)perfluorocyclopentene

Two novel Cu(II) complexes with photochromic BM-2-PTP or closed-BM-2-PTP were prepared and characterized. Both complexes displayed reversible photochromism in the crystalline phase upon appropriate photoirradiation. [Cu(closed-BM-2-PTP)Cl_2] (**2**) was revealed to exist as a mixture of two photoactive conformers by X-ray crystallographic analysis and displayed distinct absorption changes from [Cu(BM-2-PTP)Cl_2] (**1**) during its photoreaction.

Association between ammonium monovanadate and β-cyclodextrin as seen by NMR and transport techniques

The paper presents data concerning NMR and transport data of association between β-cyclodextrin (β-CD) and ammonium monovanadate. These properties are markedly influenced by the presence of β-CD. Data from NMR spectroscopy and molecular mechanics calculations show that these effects are due to strong interactions between this carbohydrate and vanadate (2:1 complexes).

Polyhedron 25 (2006) 3611

Synthesis, structure and properties of novel *N*-thiophosphorylated derivatives of 1,3-dihydro-2*H*-benzimidazol-2-imine and imidazolidine-2-imine

N-Thiophosphorylated thioureas are of interest as complexing agents and precursors for the synthesis of heterocycles containing exocyclic phosphorylic groups. Thus a number of reactions with their participation, leading to phosphor-containing iminothiazolidines, iminooxazolidines and thiophosphoryl-(phosphonyl)aminothiozoles formation have been reported. With the presence of two thiourea fragments occupying α,β positions in a molecule, it is reasonable to expect interesting transformations leading to cyclic structures.

A coumarin based fluorescent photoinduced electron transfer cation sensor

We wish to report 4-[(Bis(pyridin-2-ylmethyl)-amino)methyl]-7-methoxychromen-2-one, **1**, as a fluorescent photoinduced electron transfer cation sensor that is capable of indicating the presence of Zn^{2+}, Cd^{2+} and Pb^{2+} ions via a fluorescence signal. Log binding constants, β, for these metal ions have been measured, and were found to be 6.10 ± 0.4, 6.37 ± 0.3, and 5.67 ± 0.3, respectively.

Structural characterization of a series of new Cu-dipeptide complexes in solid state and in solution

Four new Cu(II)-dipeptide complexes were synthesized and studied in solid state and in solution. They were characterized by infrared, electronic and EPR spectroscopic techniques. The crystal structure of $[Cu(gly\text{-}val)] \cdot \frac{1}{2}H_2O$, [Cu(val-gly)], [Cu(val-phe)] and [Cu(phe-phe)] was determined by X-ray diffraction methods.

Monomers, chains, ladders, and two-dimensional sheets: Structural diversity in six new compounds of Zn(II) with 4,4′-bipyridine

Six new zinc(II)–4,4′-bipyridine coordination polymers with diverse structural topologies are reported. The versatility of bipy as a spacer ligand when assembling transition metal ions into coordination polymers is illustrated, providing examples of monomeric, linear chain, zig-zag chain, ladder, and two-dimensional network structures.

Polyhedron 25 (2006) 2616

Structural identification of the factors that prevent an electronic spin-state crossover in $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ (pz = pyrazolyl ring)

In contrast to other $Fe[(p\text{-}R\text{-}C_6H_4)\text{-}B(3\text{-}Mepz)_3]_2$ (R = I, —C≡C—H, —C≡C—$SiMe_3$, or —C≡C—C_6H_5) derivatives, magnetic, Mössbauer spectral, and X-ray crystallographic studies clearly demonstrate that $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$ remains high spin down to 4 K. Analysis of the data indicate that the degree of twisting of the pyrazolyl rings from ideal C_{3v} coordination symmetry (see figure) explains the lack of the spin-state crossover for $Fe[(C_6H_5)B(3\text{-}Mepz)_3]_2$.

Polyhedron 25 (2006) 2623

Synthesis of heterobinuclear Cu(II)—Zn(II) complexes derived from lateral macrobicyclic tricompartmental ligands: Spectral, electrochemical and kinetic studies

Spectral, electrochemical and kinetic studies of heterobinuclear Cu(II)—Zn(II) complexes were carried out and compared with homobinuclear Cu(II) complexes. Cyclic voltammetric studies show quasireversible one electron reduction wave due to the reduction of Cu(II) to Cu(I) and Zn(II) ion does not undergo reduction. The catalytic activities of the complexes increase with increase in macrocyclic ring size. Macrocyclic ring size influences the spectral, electrochemical and catalytic properties of the complexes.

Synthesis and characterization of mercury(II) complexes of selones: X-ray structures, CP MAS and solution NMR studies

Mercury(II) complexes of selones (L) having the general formulae, $[L_2HgCl_2]$, $[L_3HgCl]Cl$ and $[L_4Hg]Cl_2$ have been prepared and characterized by elemental analysis, IR and NMR (^1H, ^{13}C, ^{15}N, ^{77}Se, ^{199}Hg) spectroscopy. The complex of dichloro-bis(*N-isopropyl*-imidazolidine-2-selone-S)mercury(II), has been characterized by X-ray crystal analysis. The principal components of the ^{77}Se and ^{199}Hg shielding tensors were determined from solid-state NMR data.

Syntheses, characterisation and structure of new diazoketiminato chelates of palladium(II) incorporating a tridentate (*N*,*N*,*N*) azo ligand

Transition metal complexes incorporating polydentate azo ligands are demonstrated to possess interesting electron transfer behaviour and photophysical properties due to the presence of a low lying azo-π^* orbital. This work describes the synthesis and structure of new Pd(II) complexes of a delocalised tridentate (*N*,*N*,*N*) ligand forming a six membered diazoketiminato chelate.

Polyhedron 25 (2006) 2655

Structures and XPS studies of several 3d–4f cyano-bridged Ln^{III}–Fe^{III}/Co^{III} heterometallic complexes

We have newly carried out the crystal structure determination of several 3d–4f cyano-bridged bimetallic assemblies, $Ln(DMF)_4(H_2O)_3Co(CN)_6 \cdot H_2O$ (DMF = *N*,*N*′-dimethylformamide; Ln = Tb, Dy, Ho and Er) and X-ray photoelectron spectroscopy (XPS) studies of several analogous 3d–4f complexes, $Ln(DMF)_4(H_2O)_3M(CN)_6 \cdot H_2O$ (Ln = Ce, Nd, Sm, Gd, Tb, Dy, Ho and Er; M = Co and Fe) systematically. The results revealed that the reasons for photo-induced magnetization of Nd^{III}–Fe^{III} or Co^{III} complexes could be attributed to characteristic bent structures around cyano-bridges and gradual shifts of binding energies of Ln $4d_{3/2}$ peaks being closed to mixed-valence states.

Copper(II) complexes of sterically hindered Schiff base ligands: Synthesis, structure, spectra and electrochemistry

The synthesis, structure and spectral and redox behaviour of copper(II) complexes of sterically constrained N_3, N_3S_2 and N_2S_2 ligands are described. In the crystal structure of one of the complexes the CuN_3Cl_2 chromophore possesses a distorted square pyramidal coordination geometry. The replacement of isopropyl groups in this complex by the less sterically demanding methyl groups leads to a decreased geometric distortion. The interesting electrochemical behavior of the complexes has been explained based on a square scheme.

Reactions of neodymium(II) iodide with organohalides

The reactions of NdI_2 with organohalides PhX, $C_7H_{15}X$, *cyclo*-$C_6H_{11}X$, *t*-BuX (X = Cl, Br, I) in THF afford mainly the respective hydrocarbons R–H. Chlorotrimethylsilane is converted into Me_3SiH, $Me_3SiSiMe_3$ and $Me_3SiO(CH_2)_4CH_3$. The interactions of NdI_2 with alkyl halides in benzene result in alkylation of the solvent to give the mono- and disubstituted products R-Ph and $R_2C_6H_4$. Treatment of benzyl chloride by NdI_2 without solvent causes the oligomer $PhCH_2$-(p-$C_6H_4CH_2)_{28}C_6H_4CH_2Cl$ formation.

Complexes with lignin model compound vanillic acid. Two different carboxylate ligands in the same dinuclear tetracarboxylate complex $[Cu_2(C_8H_7O_4)_2(O_2CCH_3)_2(CH_3OH)_2]$

Two different carboxylate anions were found in the dinuclear copper(II) tetracarboxylate $[Cu_2(C_8H_7O_4)_2(O_2CCH_3)_2(CH_3OH)_2]$ (heterocarboxylate). The compound decomposes outside mother-liquid, by replacement of methanol with water molecules. EPR spectra and $\mu_{eff} < 1.73$ BM confirm the dinuclear cage structure of the decomposed complex. The compound is compared to a related homocarboxylate complex $[Cu_2(C_8H_7O_3)_4(H_2O)_2]$. In the EPR spectra of this complex, six signals of the triplet state $S = 1$ (H_{z1}, H_1 (H_{x1}, H_{y1}), H_2 (H_{x2}, H_{y2}), H_{z2}) are observed.

Selective one-pot synthesis of copper nanorods under surfactantless condition

Selective evolution of copper nanorods has been achieved from alkaline $CuSO_4$ solution using a specific concentration of glucose but spherical particles become the sole product above or below the critical concentration.

Polyhedron 25 (2006) 2353

Coordination modes of 3-hydroxypicolinic acid (OH-picH): Synthesis and characterization of cadmium(II) complexes. Crystal and molecular structures of $[CdX(OH\text{-}pic)(OH\text{-}picH)(H_2O)]_2$ X = Cl^-, Br^-

The cadmium(II) chloride and bromide react almost instantaneously with 3-hydroxypicolinic acid in water solution giving isostructural dinuclear complexes of general formula $[CdX(OH\text{-}pic)(OH\text{-}picH)(H_2O)]_2$; X = Cl^-, Br^- which is established by the X-ray structural analysis and also supported by the thermal analysis. These compounds are not stable in solutions and NMR spectral analysis revealed the presence of cadmium(II) 3-hydroxypicolinate as the only cadmium(II) compound in solution. Although, the synthesis conditions permit also a formation $Cd(OHpic)_2$, apparently the packing forces in the solid state yield to the title complexes.

Polyhedron 25 (2006) 2363

Coordination compounds in a pentacyclic aromatic system from 2-aminobenzothiazole derivatives and transition metal ions

The syntheses and structural analyses of coordination compounds derived from 2-(2-benzothiazolylamino)benzothiazole (**1**), 2-(2-aminobenzothiazolylamino)benzoxazole (**2**) and 2-(2-benzothiazolylamino)benzimidazole (**3**) with Co(II), Ni(II), and Zn(II) acetates and ligand **1** with Hg(II) acetate are reported. Three different geometries for the metal atoms were found: a distorted tetrahedron (for ML_2 Co, Ni, Zn and Hg), a square pyramid [for Co and Ni in $NiL_2(MeOH)$] and an octahedron for $Ni(L)(OAc)(MeOH)_2$.

Polyhedron 25 (2006) 2375

Synthesis, structure, and reactivity of some new dipyridyl and diamine-bridged dinuclear oxomolybdenum(VI) complexes

Some new diimine and diamine-bridged dinuclear Mo(VI) complexes of the general formula $[(MoO_2L)_2(\mu\text{-}N\text{–}N)]$ along with their common mononuclear precursor $[MoO_2L(C_2H_5OH)]$ have been synthesized and structurally characterized by X-ray crystallography. The ONO donor ligand (LH_2) is 2-hydroxy benzoylhydrazone of 2-hydroxybenzaldehyde and the bridging (μ-N–N) ligands are 4, 4′-bipyridine(4,4′-bpy), *trans*-1,2-bis(4-pyridyl) ethene (bpe), *trans*-1,2-bis(4-pyridyl) ethane (bpa) and *p*-phenylenediamine (ppda).

Polyhedron 25 (2006) 2383

2-(*N*,*N*-Dimethylamino)ethylselenolates of cadmium(II): Syntheses, structure of $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$ and their use as single source precursors for the preparation of CdSe nanoparticles

Cadmium selenolates, $[Cd(SeCH_2CH_2NMe_2)_2]$ and $[Cd_3(OAc)_2(SeCH_2CH_2NMe_2)_4]$, have been prepared and characterized. The structure of the latter has been established by X-ray crystallography. Thermolysis of $[Cd(SeCH_2CH_2NMe_2)_2]$ in a mixture of solvents (HDA/TOPO) or in a furnace gave CdSe nanoparticles which were characterized by UV–Vis, photoluminescence, X-ray diffraction and electron microscopy.

Polyhedron 25 (2006) 2392

Substitution derivatives of the heteronuclear cluster $RuOs_3(\mu\text{-}H)_2(CO)_{13}$: Disubstituted group 15 derivatives

The structures in the solid state and solution state of tertiary group 15 ligand disubstituted derivatives of the heteronuclear cluster $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ are examined. A number of isomeric structural types have been identified. In solution, most of these isomers are rapidly interconverting via hydride migrations. Substitution appears to be directed electronically to the ruthenium vertex, although steric hindrance appears to drive subsequent isomerisation via migration of the second group 15 ligand.

Polyhedron 25 (2006) 2407

Bathochromic effect of trifluoromethyl-substituted 2-naphthalen-1-yl-pyridine ligands in color tuning of iridium complexes

The iridium complexes, $(4\text{-fnapy})_2Ir(acac)$ and $(5\text{-fnapy})_2Ir(acac)$, were prepared and their X-ray crystal structures were determined. Compared to $Ir(napy)_2(acac)$, the introduction of trifluoromethyl-substituted ligands resulted in remarkable bathochromic effect. The trifluoromethyl group has a stronger influence on lowering the LUMO levels.

Polyhedron 25 (2006) 2415

A crystallographic and kinetic study of the formation of the tricyanonitrido(pyridine-2-carboxylato-κN,κO)rhenate(V) ion, [ReN-(η^2-pic)$(CN)_3]^{2-}$

The substitution reaction between [ReN-$(H_2O)(CN)_4]^{2-}$ and pic$^-$ (pyridine-2-carboxylato anion) resulted in the substitution of the aqua and cyano ligands to form the [ReN-(η^2-pic)$(CN)_3]^{2-}$ complex. The two consecutive reactions were kinetically investigated with the fast aqua substitution resulting in a rate constant of $1.92(5) \times 10^{-1}$ M^{-1} s^{-1} at 40.3 °C. A rate constant of $1.84(2) \times 10^{-2}$ s^{-1} at 80 °C was obtained for the second, slower cyano substitution. The negative entropy of activation of −133.4(3) J K^{-1} mol^{-1} for the slow reaction points to associative activation.

Polyhedron 25 (2006) 2447

Uranyl (1,3-diphenylpropane-1,3-dionato) complexes with *N*-adamantylacetamide and azacyclononanone: Synthesis, spectroscopy, luminescence and crystal structures

The synthesis and characterization of uranyl 1,3-diphenylpropane-1,3-dionato (benzoylacetonate, ba) complexes with *N*-adamantylacetamide, 2-azacyclononanone and triphenylphosphine oxide, with general formula $UO_2(ba)_2L$ are described. They were characterized by infrared, Raman and emission spectroscopies. All complexes are luminescent, presenting the characteristic uranyl vibronic spectrum. The crystal structures of the *N*-adamantylacetamide and 2-azacyclononanone were determined. All complexes are heptacoordinated and all neutral ligands bond through an oxygen atom. In the case of the *N*-adamantylacetamide complex there are two independent molecules in the asymmetric unit cell. Both structures are reported.

Polyhedron 25 (2006) 2465

Thermodynamics of thermal decomposition of group 13 metal trihalide adducts with piperidine: A combined theoretical and experimental study

Three major decomposition pathways of complexes formed by MX_3 (M = Al, Ga; X = Cl, I) and piperidine (pip) have been theoretically considered at the B3LYP/LANL2DZ(d,p) level of theory. Hydrogen gas elimination with formation of gaseous $MX_3 \cdot$ pyridine complexes becomes thermodynamically favorable above 500 K and is expected as a primary thermolysis product of $MX_3 \cdot$ pip. Alternative routes, which include dissociation into components or hydrogen halide elimination, require much higher temperatures. This theoretical conclusion is in qualitative agreement with present experimental thermolysis study of the $GaCl_3 \cdot$ pip complex.

Molecular engineering of coordination pockets in chloro-tris-phenoxo complexes of titanium(IV)

The preparation and characterisation of chloro-tris-phenoxo complexes of titanium(IV) in which coordination pockets are produced by varying the substituent in the 2-position of the phenoxo ligand phenyl ring is described. Collapse of the pockets in these complexes and some nitrogen tied-back anologues is determined using bipyridyl and pyridine ligands.

Polyhedron 25 (2006) 2093

Two halide exchange in copper(II) halide dimers: (4,4′-bipyridinium)$Cu_2Cl_{6-x}Br_x$

The presence of N–H···X and C–H···X hydrogen bonding interactions between the 4,4′-bipyridinium dications and $Cu_2X_6^{2-}$ dimers force short X···X contacts between the dimers with X···X distances of 3.645–3.690 Å. In this manner, alternating AFM magnetic chains are formed with alternating exchange pathways: the intradimer exchange coupling, J_2, and the X···X pathway, J_1. Magnetic studies indicate that these systems behave as chains with quite strong coupling, with $|J_1| > |J_2|$. The AFM coupling increases monotonically as the bromide content increases.

Trinuclear Cu(II) complexes containing peripheral ketonic oxygen bridges and a μ_3-OH core: Steric influence on their structures and existence

Two trinuclear copper(II) complexes, $[(CuL^1)_3(\mu_3\text{-fOH})](ClO_4)_2$ (**1**) and $[(CuL^2)_3(\mu_3\text{-OH})](ClO_4)_2 \cdot 0.75H_2O$ (**2**), where HL^1 and HL^2 are two tridentate Schiff base ligands derived from mono condensation of 1-benzoylacetone with 1,2-ethanediamine and 1,2-propanediamine, respectively, and a mononuclear complex, $[Cu(bn)(pn)]ClO_4$ (**3**), where bn = 1-benzoylacetonato and pn = 1,3-propanediamine, have been synthesized and structurally characterized. Variable-temperature magnetic susceptibility measurements reveal antiferromagnetic coupling in complexes **1** and **2**.

Polyhedron 25 (2006) 3095

Synthesis, characterization, catalytic oxidation and biological activity of ruthenium(III) Schiff base complexes derived from 3-acetyl-6-methyl-2H-pyran-2,4(3H)-dione

A series of paramagnetic low spin Ru(III) complexes of the type $[RuX_2(EPh_3)_2(L)]$ (where X = Cl or Br; E = P or As; L = monobasic bidentate Schiff base ligands) have been synthesized and characterized. The catalytic efficiency of one of the ruthenium complexes (**10**) was determined in the case of oxidation of primary and secondary alcohols into their corresponding aldehydes and ketones in the presence of *N*-methylmorpholine-*N*-oxide(NMO) as co-oxidant. Further, the in vitro toxicity of these complexes was tested against the growth of bacterial species viz., *Staphylococcus aureus* (209p) and *Escherichia Coli* ESS (2231).

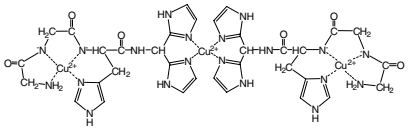
Polyhedron 25 (2006) 3173

Potentiometric and spectroscopic studies on the copper(II) and zinc(II) complexes of bis(imidazol-2-yl) derivatives of tripeptides

Copper(II) and zinc(II) complexes of the tripeptides containing chelating bis(imidazol-2-yl)methyl agents at the C-termini were studied. The formation of stable ML and ML_2 complexes was detected with a tridentate coordination of the ligands resulting in macrochelates. For GlyIleGly-BIMA and GlyGlyHis-BIMA polynuclear species exist in basic solution.

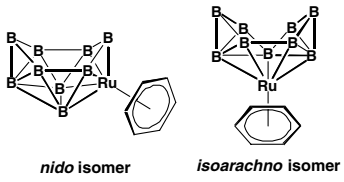


R. Bruce King, John Hagel

Polyhedron 25 (2006) 3183

The role of the metal formal oxidation state in metallaborane structures relating to *closo*/*isocloso* and *nido*/*isonido* pairs

The metal formal oxidation state increases by two units in a *closo* → *isocloso* or *nido* → *isonido* structural transformation, generally involving diamond–square–diamond processes relating to internal metal oxidative addition reactions. More exotic "*isoiso*" structures are found for metallaboranes containing metals exhibiting relatively high oxidation states such as molybdenum, tungsten, and rhenium.



Heera Krishna, Setharampattu S. Krishnamurthy, Munirathinam Nethaji

Polyhedron 25 (2006) 3189

An unexpected entry into the silver(I) chemistry of diphosphazane ligands: Crystal and molecular structures of $[Ag\{Ph_2PN(Pr^i)PPh_2\}(CF_3SO_3)]_2$, $[Ag\{Ph_2PN(Pr^i)PPh(OC_6H_3Me_2\text{-}2,6)\}_2]PF_6$, and $[Ag_3(\mu\text{-}Cl)_2\{Ph_2PN(R)PPh_2\}_3]PF_6$ (R = H, Pr^i)

The reactions of AgX (X = Cl, NO_3 or CF_3SO_3) with diphosphazane ligands of the type $X_2PN(R)PXY$ give mononuclear, binuclear and trinuclear silver(I) complexes which exhibit different coordination numbers and geometries as revealed by single crystal X-ray diffraction studies.

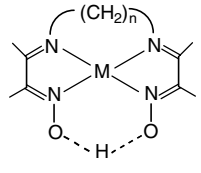
Polyhedron 25 (2006) 2710

Effect of metal ions and length of alkylene bridge on the strength of hydrogen bonds in diiminedioxime cobalt(III) and nickel(II) complexes

Comparison of crystal structures for diiminedioxime (BnH_2 and EnH_2) complexes of Co(III) and Ni(II) indicates that introduction of a propylene bridge opposite the hydrogen bond imposes no significant constraint but the ethylene bridge impose significant constraint. Hence the O—O distance of $[Co(EnH)Cl_2]$ is much longer than those for $[Co(BnH)(NO_3)_2]$ and $[Co(BnH)Cl_2]$.



M	n	O-O distance (Å)	
Co^{3+}	2	2.708	
Co^{3+}	4	2.434	$[Co(BnH)(NO_2)_2]$
		2.423	$[Co(BnH)Cl_2]$
Ni^{4+}	4	2.432	

Kyoung-Tae Youm, Jaejung Ko, Moo-Jin Jun

Polyhedron 25 (2006) 2717

Non-classical hydrogen bonds (C–H···X, X = Cl and N) induced 3D architecture: Trigonal bipyramidal ferric complex, $[Fe(btp)Cl_3]_n$ (btp = 2,6-bis(*N*1-1,2,4-triazolyl)-pyridine)

The reaction of $FeCl_3 \cdot 6H_2O$ with btp afforded the trigonal bipyramidal ferric complex, $[Fe(btp)Cl_3]_n$ (**1**) consisting of three chloride ligands and two nitrogen atoms of btp. Interestingly, in **1**, a 3D architecture is induced by non-classical C–H···Cl and C–H···N hydrogen bonds between 1D zigzag chains in which btp ligands bind ferric ions through coordination bonds.

Polyhedron 25 (2006) 2198

Crystal structures and magnetic properties of two new phosphate-metal complexes: $[Cu_2(bpy)_2(\mu,\eta^2\text{-}HPO_4)(\mu,\eta^1\text{-}H_2PO_4)(\mu,\eta^2\text{-}H_2PO_4)]_n$ and $[Cu_4(phen)_4(\mu_3,\eta^2\text{-}HPO_4)_2(\mu,\eta^2\text{-}H_2PO_4)_2(H_2PO_4)_2](H_2O)_4$

Two novel dinuclear-based polynuclear and tetranuclear Cu(II) compounds with mixed $H_xPO_4^{(3-x)-}$ bridges (x = 1, 2), $[Cu_2(bpy)_2(\mu,\eta^2\text{-}HPO_4)(\mu,\eta^1\text{-}H_2PO_4)(\mu,\eta^2\text{-}H_2PO_4)]_n$ (**1**) and $[Cu_4(phen)_4(\mu_3,\eta^2\text{-}HPO_4)_2(\mu,\eta^2\text{-}H_2PO_4)_2(H_2PO_4)_2](H_2O)_4$ (**2**) have been synthesized and characterized as well as the magnetic properties discussed. Both Cu(II) ions in a dimeric unit in **1** are in a distorted square pyramidal environment and linked by $\mu,\eta^2\text{-}HPO_4$ and $\mu,\eta^1\text{-}H_2PO_4$ ligands. In case of **2**, each Cu(II) ion displays a distorted square-pyramidal geometry, with two $\mu_3,\eta^2\text{-}HPO_4$ groups and two $\mu,\eta^2\text{-}H_2PO_4$ groups bridging, and two non-bridging H_2PO_4 groups.

UV–visible and synchronous fluorescence spectroscopic investigations of the complexation of Al(III) with caffeic acid, in aqueous low acidic medium

The interactions between aluminium (III) ions and caffeic acid in aqueous solution, at pH 5 and 6.5 were investigated. The complexes were characterized by electronic absorption and synchronous fluorescence spectroscopies combined with chemometrics methods. The stoichiometry composition and stability constants of complexes have been determined.

Polyhedron 25 (2006) 2223

Ruthenium(III) complexes of dipicolinic acid with PPh_3/$AsPh_3$ as co-ligand: Synthesis and structural characterization

New hexa-coordinated Ru(III) complexes of the type $[Ru(dipic)(EPh_3)_2X]$ have been synthesized by reacting 2,6-pyridinedicarboxylic acid (dipicolinic acid, H_2dipic) with the appropriate starting complexes $[RuX_3(EPh_3)_3]$ (where X = Cl, Br; E = P, As). The ligand behaves as tridentate dibasic chelate. Single-crystal X-ray analysis of the complex $[Ru(dipic)(PPh_3)_2Cl]$ revealed that the coordination environment around ruthenium metal consists of an NO_2P_2Cl octahedron with dipicolinic acid occupying equatorial plane.

Low-temperature (100 K) crystal structures of pentaaqua(5-nitrosalicylato) complexes of magnesium(II), zinc(II), cobalt(II) and nickel(II): A π–π stacked and hydrogen bonded 3D supramolecular architecture

Reactions of metal chloride or sulfate and the sodium salt of 5-nitrosalicylic acid (5-nsa) in aqueous solution result in isomorphous complexes of type $[M(H_2O)_5(5\text{-nsa})]^+$ $(5\text{-nsa})^- \cdot H_2O$ [M = Mg (**1**), Zn (**2**), Co (**3**), Ni (**4**)] in the solid state. The metal-bonded cationic moiety and the non-ligating anionic one are engaged in π-stacking interactions. The anchoring of the individual ionic subunits through π–π stacking and extensive hydrogen bonding results in a 3D supramolecular architecture.

Facile synthesis of Cu(II) complexes of mono-condensed N,N,N donor Schiff base ligands: Crystal structure, spectroscopic and magnetic properties

Four new copper(II) complexes of the general formula $CuLN_3ClO_4$, where L represents four similar tridentate N,N,N donor Schiff base ligands, have been synthesized in a very convenient way and structurally characterized. Two of the complexes consist of double basal–apical end-on (EO) azide bridged dinuclear Cu^{II} complexes and are antiferromagnetically coupled through the azido bridges. The third one is a perchlorate bridged one-dimensional Cu^{II} chain; two such chains are connected by hydrogen bonds. It shows two different magnetic interactions through the two kinds of hydrogen bonds; one is antiferromagnetic and the other is ferromagnetic. The fourth compound consists of 1-D chains in which the Cu^{II} ions are alternately bridged by single EO and end-to-end (EE) azido ligands. From a magnetic point of view it is a ferromagnetic dinuclear complex coupled through the EO bridge only.

Polyhedron 25 (2006) 2318

Anion-templating self-assembly of $[Cu_2(OMe)_2]^{2+}$ SBUs depending on the size of the anion in the solid state

The $[Cu_2(OMe)_2]^{2+}$ secondary building units (SBUs) are self-assembled into 3D cages or an infinite 1D coordination polymer depending on whether the counter-anion exerts a size-templating effect or not. Small anions of $[BF_4]^-$ and $[ClO_4]^-$ make two SBUs interconnect each other with four btp (=2,6-bis(*N*1-1,2,4-triazolyl)pyridine), leading the anion-encapsulated 3D cages. Meanwhile the triflate anion ($[OTf]^-$) does not induce a cage structure, leading instead to an infinite 1D coordination polymer.

Zn(II)-azide complexes of diimine and azoimine functions: Synthesis, spectra and X-ray structures

Two series of Zn(II)-azido complexes of diimine (—N=C—C=N—) and azoimine (—N=N—C=N—) are described. The ligands belong to α/β-naphthyl-(2-pyridylmethylene)-amine (diimine) and 1-alkyl-2-(naphthyl-α/β-azo)imidazoles (azoimine). The complexes are structurally characterized. The diimine system has end-on azido bridged ligands and the azoimine system gives terminal azido bridged complexes. They exhibit high intense ligand centered emissions.

Polyhedron 25 (2006) 1884

Capillary electrophoretic separation and kinetic study of inert copper(II) complexes of 1,8-bis(methylphosphonate) derivative of cyclam

Pentacoodinated *pc*-$[Cu(L)]^{2-}$ and octahedral *hx*-$[Cu(L)]^{2-}$ complexes and the free ligand dianion $(H_2L)^{2-}$ were successfully separated by means of CE. The method was used for evaluation of isomerization kinetics of the pentacoordinated isomer to the octahedral species. The isomerization was proved to be a highly energetically inconvenient process.

Polyhedron 25 (2006) 1893

Synthesis, characterization and spectroscopic and electrochemical studies of new axially coordinated cobalt(III) salen (salen=*N*,*N*′-bis-(salicylidene)-1,2-ethylenediamine) complexes. The crystal structure of $[Co^{III}(salen)(aniline)_2]$-$ClO_4$

Cobalt(III) complexes with some potentially tetradentate salen Schiff-bases as equatorial ligands and with different axial amine ligands were synthesized in situ and characterized by IR, ^1H NMR and elemental analysis. Electronic structure calculations indicate metal–ligand charge transfer transitions between 420 and 440 nm. The cyclic voltammetry of the complexes show that the axial amine ligands affect reduction potentials of Co(III) in the order of changes of their pK_a. In the crystal structure of $[Co(salen)(aniline)_2]ClO_4$ cobalt(III) center is six coordinated surrounded by an equatorial tetradentate salen ligand and two aniline axial ligands and ClO_4^- acts as a counter ion.

The reactions of *arachno*-$[B_9H_{14}]^-$ and *nido*-$[B_9H_{12}]^-$ with acids: Preparation and structures of chlorononaborates

The unidentified product from the hydride abstraction reaction between $[B_9H_{14}]^-$ and BCl_3 that produces $B_{10}H_{14}$, $[HBCl_3]^-$, and H_2 was previously thought to possess a polymeric structure, but has been shown to consist of a mixture of singly-, doubly- and triply-chlorinated analogues of *arachno*-$[B_9H_{14}]^-$. X-ray diffraction analyses indicate that these species co-crystallize in the solid state. These problems of disorder prompted us to prepare the analogous singly-substituted cluster $[B_9H_{13}Cl]^-$ by a different route. This species was obtained from the reaction between *nido*-$[B_9H_{12}]^-$ and anhydrous HCl, and its structure was also determined by X-ray analysis.

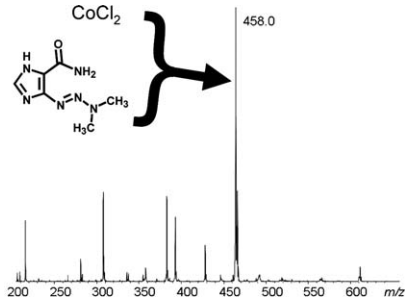
Electrospray ionization mass spectrometric study on the coordination behavior of dacarbazine towards transition metal ions

The complexation properties of the antitumor drug dacarbazine were studied by comparison of electrospray ionization mass spectra of isolated transition metal complexes and in situ-formed ones.

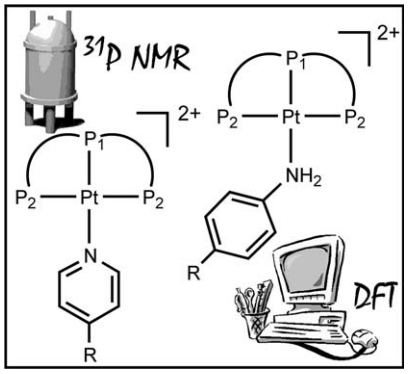


Marco Bortoluzzi, Giuliano Annibale, Giampaolo Marangoni, Gino Paolucci, Bruno Pitteri

Polyhedron 25 (2006) 1979

^{31}P NMR and DFT studies on square-planar bis(diphenylphosphinoethyl)phenylphosphine (triphos) complexes of Pt(II) with pyridines and anilines

The complexes $[Pt(triphos)(4\text{-R-py})](ClO_4)_2$ and $[Pt(triphos)(4\text{-R-an})](ClO_4)_2$ {4-R-py = *para*-substituted pyridines; 4-R-an = *para*-substituted anilines} were prepared starting from $[PtCl(triphos)]ClO_4$. The correlations between the pK_a of the pyridines and anilines and the $^1J_{Pt-P}$ couplings of the complexes are pointed out and informations about the structural and electronic properties of some of these derivatives, obtained with DFT calculations, are reported.



B. Machura, R. Kruszynski

Polyhedron 25 (2006) 1985

Synthesis, crystal, molecular and electronic structure of the $[Re(NO)Cl_2(PPh_3)(PPh_2py\text{-}P,N)]$ complex

The reaction of the $[ReCl_3(NO)(PPh_3)(OPPh_3)]$ complex with diphenyl(2-pyridyl)phosphine (PPh_2py) has been examined and a novel $\{ReNO\}^6$ rhenium nitrosyl – $[Re(NO)Cl_2(PPh_3)(PPh_2py\text{-}P,N)]$ has been obtained. The compound has been studied by IR, UV–Vis spectroscopy and X-ray crystallography. The molecular orbital diagram of $[Re(NO)Cl_2(PPh_3)(PPh_2py\text{-}P,N)]$ has been calculated with the density functional theory (DFT) method. The spin-allowed singlet–singlet electronic transitions of $[Re(NO)Cl_2(PPh_3)(PPh_2py\text{-}P,N)]$ have been calculated with the time-dependent DFT method, and the UV–Vis spectrum of the title compound has been discussed on this basis.

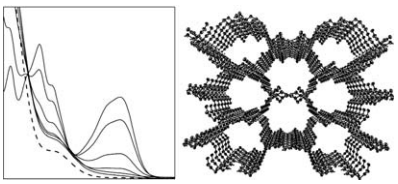
Polyhedron 25 (2006) 2007

Crystal engineering and magnetic properties of a 2D cyano-bridged $Ni^{II}Fe^{II}$ network formed through reduction of ferricyanide

Reaction of potassium ferricyanide with a mixture of nickel(II) chloride and *trans*-1,2-diaminocyclohexane (L) produces both a ferrocyanide ($[Ni^{II}L_2]_2[Fe^{II}(CN)_6]\cdot 5H_2O$ (**1**)) and a ferricyanide ($[Ni^{II}(L)_2]_3[Fe^{III}\text{-}(CN)_6]_2\cdot 2H_2O$ (**2**)) compound. From spectrophotometric titration, it has been established that the diamine is responsible for the reduction of ferricyanide to ferrocyanide. The factors that affect the formation of the two compounds as well as crystal engineering and magnetic properties of the ferrocyanide analogue, **1**, have been described. The structure of **1** consists of a two-dimensional cyano-bridged square grid network which is self-assembled into three-dimensions due to hydrogen bonding interactions.



Nebebech Belai, Michael T. Pope

Polyhedron 25 (2006) 2015

Synthesis and structural characterization of new organotin derivatives of polyoxotungstates via transmetallation and coupling reactions

Insertion of $\{RSn\}^{3+}$ into polyoxoytungstate structures by displacement of transition metal centers has been demonstrated with the chiral Tourné–Zonnevijlle anions and with $[Ce(W_5O_{18})_2]^{9-}$. Robust coupling of polyoxotungstates is achieved by the use of $\{Sn(CH_2)_nSn\}^{6+}$ as linkers.

Polyhedron 25 (2006) 2026

Electronic properties of mixed valence iron(II,III) dinuclear complexes with carboxylate bridges

Two mixed valence dinuclear iron(II,III) complexes with carboxylate bridges of the type $[Fe_2L_2(H_2O)_4](NO_3)(H_2O)_3$, where L = Schiff base derived from an α-amino acid (glycine or L-isoleucine) and 5-bromosalicylaldehyde have been prepared and characterised by different spectroscopic techniques, magnetic susceptibility, conductivity, and electrochemical measurements. The existence of the mixed valence species was corroborated by Mössbauer spectroscopy and electrochemical measurements. Temperature dependence of the reciprocal molar susceptibility indicates a weakly antiferromagnetically coupled system ($-J \sim 0.17$ and 0.14 cm^{-1}). The conproportionation constant values, at 298 K, are approximately 3.7×10^4 and 5.4×10^4. The obtained values are in agreement with a moderate electron coupling between the redox sites.

Polyhedron 25 (2006) 2033

The first silver catechol complexes: Crystal structures of triphenylphosphine stabilized silver tetra-bromo and tetra-chloro-catechols

The solid-state structures of the first verifiable silver complexes containing bound catechol ligands, $Ag(Br_4C_6(OH)O)(Ph_3P)_2$ and $Ag(Cl_4C_6(OH)O)(Ph_3P)_2$, are reported. In both complexes, only one of the catechol oxygens is coordinated to the silver along with the *ortho*-halogen, which forms the chelate ring with the metal. Additional hydrogen bonding is observed between the catechol groups to form a dimeric species in the solid state.

Polyhedron 25 (2006) 627

Unique copper ion catalyzed hydrolytic cleavage of C–N(2) bond of thiosemicarbazide

An unusual hydrolysis of C–N(2) bond of thiosemicarbazide is reported by $[Cu(2,2'\text{-bpy})X_2] \cdot xH_2O$ and $[Cu(\phi_3P)_2(CH_3CN)_2]ClO_4$ complexes. Thiocyanate, the hydrolytic product coordinates to Cu ion, $[Cu(2,2'\text{-bpy})(NCS)_2]$ and $[Cu(\phi_3P)_2(NCS)]_2$ are formed, respectively.

Polyhedron 25 (2006) 635

Design and syntheses of blue luminescent zinc(II) and cadmium(II) complexes with bidentate or tridentate pyridyl-imidazole ligands

A series of luminescent Zn(II) and Cd(II) complexes have been prepared based on three differently π-conjugated ligands, 2-(2-pyridyl)-imidazole (HL1), 2-(2-pyridyl)-benzimidazole (HL2) and 2,6-bis(benzimidazol-2yl)-pyridine (H_2L3). The spectra of the complexes with the ligands show the same rule. The structures of $Zn(L2)_2 \cdot H_2O$, $[Cd(L2)_2 \cdot (H_2O)_2] \cdot 2DMSO$, $Zn(HL2)_2$ and $Cd(HL3)_2$ have been established by X-ray crystallography. They display a blue luminescence and have high luminescence quantum efficiency. A theoretical study is consistent with the experimental results.

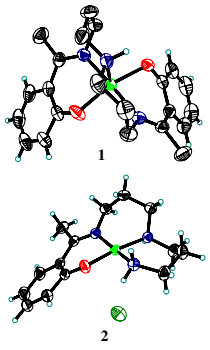
Polyhedron 25 (2006) 671

Synthesis, characterization and X-ray crystal structures of $[Ni(Me\text{-}sal)_2dpt]$ and [Ni(Me-sal)dpt]Cl

The synthesis, characterization, and single-crystal X-ray diffraction studies for two new Ni(II) complexes, $[Ni(Me\text{-}sal)_2dpt]$ (**1**) and [Ni(Me-sal)dpt]Cl (**2**), with penta- and tetradentate ligands $H_2(Me\text{-}sal)_2dpt$ and H(Me-sal)dpt containing N_3O_2 and N_3O donor sets, respectively, are reported. The coordination polyhedron about the Ni(II) center in complex (**1**) is best described as distorted trigonal bipyramidal and that of complex (**2**) as distorted square planar containing a "half unit" ligand, (Me-sal)dpt.



Danuta Kroczewska, Barbara Kurzak, Julia Jezierska

Polyhedron 25 (2006) 678

The role of the carboxylic group in the copper(II) mixed-ligand complexes of DL-aspartic acid-β-hydroxamic acid and polyamines

Stability of the mixed-ligand complexes with tridentate amines as a primary ligand and DL-aspartic acid-β-hydroxamic acid as a secondary ligand, their absorption and EPR spectra indicate a five-coordinate structure of the formed complexes. H-Asp-β-ha coordinates to $[Cu(A)]^{2+}$ by the carboxylate group in addition to the amino nitrogen (glycine-like coordination) in acidic and neutral pH. At higher pH the hydroxamate ligand is coordinated by N_{amino} and $N_{hydrox.}$ donor atoms.

Polyhedron 25 (2006) 695

Structural relationships in the homologous series of alkyltriphenylstannane compounds of formula $Ph_3Sn(CH_2)_{n-1}CH_3$, with *n* even and in the range 4–14 and 18

The solid state structures of several compounds in the homologous series of alkyltriphenylstannanes of general formula $Ph_3Sn(CH_2)_{n-1}CH_3$ have been determined. For *n* in the range 4–10 the structures are monoclinic with space group $P2_1/c$. For *n* greater than 10 they are, instead, triclinic with space group $P\bar{1}$. The structural difference between the two classes is attributable to a change in the degree of control over the packing of the molecules exerted by the triphenylstannyl entity on the one hand and the alkyl chain on the other.

Polyhedron 25 (2006) 747

Role of electronic factors in the formation of anionic complexes of tellurium(IV): Crystal structure of bis(4-methylbenzoylmethyltriphenylphosphonium) hexabromotellurate(IV)

Interaction of $(4\text{-}XC_6H_4COCH_2)_2TeBr_2$ with $(4\text{-}XC_6H_4COCH_2)Ph_3PBr$ gives the 1:1 adduct $[(4\text{-}XC_6H_4COCH_2)Ph_3P]^+[(4\text{-}XC_6H_4COCH_2)_2\text{-}TeBr_3]^-$ in the initial step when X = H or Me. A methoxy substituent (X = MeO) in any of the reactants, however, promotes the cleavage of Te–C bonds and bis(4-substitutedbenzoylmethyltriphenylphosphonium) hexabromotellurates(IV) are isolated. The crystal structure of $[(4\text{-}MeC_6H_4COCH_2)Ph_3P]_2[TeBr_6] \cdot CH_2Cl_2$ shows close C–H···Br/Cl contacts among the ions and solvated molecules, and supramolecular extended arrays of ionic molecular units formed by means of solvated head-to-tail linkers are identified.

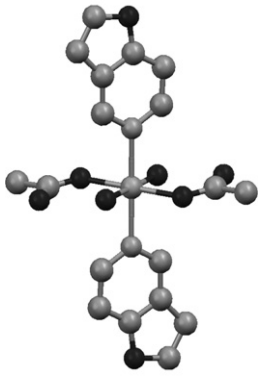
Polyhedron 25 (2006) 3261

Heteroleptic nickel(II) complexes formed from N-donor bases, carboxylic acids and water: Magnetostructural correlations

Four nickel(II) complexes with the general formula $[Ni(L^1)_2(L^2)_2(H_2O)_2]$, where L^1 = 2-methylimidazole, 1,2-dimethylimidazole, *iso*-quinoline and furo[3,2-*c*]pyridine, L^2 = formate and acetate, have been prepared and their structures determined by single-crystal X-ray diffraction techniques. All complexes show magnetic behavior typical for zero-field splitting systems. The axial parameter of the zero-field splitting, *D*, adopts moderately negative values and it correlates with the axial distortion of the coordination polyhedron.



Bikshandarkoil R. Srinivasan, Christian Näther, Sunder N. Dhuri, Wolfgang Bensch

Polyhedron 25 (2006) 3269

Cation–anion interactions in bis(±)*trans*-2-aminocyclohexylammonium tetrathiotungstate, 1,7-diazonia-4-aza-heptane tetrathiotungstate and 1,5-diazonia-9-aza-nonane tetrathiotungstate

The structures of the title complexes consist of tetrahedral tetrathiotungstate anions which are linked to the partially protonated organic ammonium cations with the aid of weak hydrogen bonding interactions. A comparative study of the structural features of several tetrathiotungstates is presented and the interactions between the organic ammonium cation and the tetrathiotungstate anion are discussed in terms of the magnitude of Δ, the difference between the longest and the shortest W–S bond distances.

Polyhedron 25 (2006) 3278

Crystal structure, magnetism and spectroscopy of two strongly antiferromagnetically coupled dinuclear Cu(II) paddlewheel-like compounds with 4-azabenzimidazole as a ligand

Two paddlewheel-like dinuclear compounds, $[Cu_2(azab)_4Cl_2]Cl_2(CH_3OH)_3$ (**1**) and $[Cu_2(azab)_4Br_2]Br_2(H_2O)_{1/2}$ (**2**) (in which azab = 4-azabenzimidazole), have been synthesized. Characterization is done by X-ray crystallography, infrared spectroscopy and EPR. Also the magnetic susceptibility of both compounds are investigated and obtained a strong antiferromagnetic interaction between the Cu(II) ions.

Preparation, structure and ethylene polymerization/oligomerization behavior of 2-carbethoxy-6-iminopyridine-based transition metal complexes

The synthesis, characterization and ethylene polymerization/oligomerization of a series of transition metal complexes with the formula {2-carbethoxy-6-[1-[(2,6-dimethylphenyl)imino]-ethyl]pyridine}$_n$$MCl_2$ [M = Mn(II) (**8**), Fe(II) (**9**), Co(II) (**10**), Cu(II) (**11**), Zn(II) (**12**), n = 1; Ni(II) (**13**), n = 2]; {2-carbethoxy-6-[1-[(2,4,6-trimethylphenyl)imino]ethyl]pyridine}-MCl_2 [M = Fe(II) (**14**), Co(II) (**15**), Ni(II) (**16**)]; {2-carbethoxy-6-[1-[(2,6-diethylphenyl)-imino]ethyl]pyridine}MCl_2 [M = Fe(II) (**17**), Co(II) (**18**), Ni(II) (**19**)] have been reported. The systematic studies are focused on the relationship between the catalytic activity of these complexes for ethylene polymerization/oligomerization and the electronic property of central metal, the ligand structure, as well as the reaction conditions.

Polyhedron 25 (2006) 3312

Synthesis, structure and properties of ternary copper(II) complexes of ONO donor Schiff base, imidazole, 2,2′-bipyridine and 1,10-phenanthroline

Three new complexes [Cu(SAA)(ImH)] (**1**), [Cu(SAA)(bipy)] CH_3CN (**2**), [Cu(SAA)(phen)] (**3**) were characterized by elemental analysis, magnetic susceptibility, X-band e.p.r., electronic spectroscopy and cyclic voltammetry. Single crystal X-ray analysis of (**1**) has revealed the presence of a distorted square planar geometry (N_2O_2) and (**2**) has revealed the presence of a distorted square pyramidal (4+1) geometry. In both structures the ONO Schiff base occupies the basal plane. Magnetic susceptibility measurements at room temperature were in the range 1.79 ± 0.01 BM. Superoxide dismutase (SOD) activity of the present complexes were also measured and discussed.

Further insight into the mechanism of formation of hydroxyaluminosilicates

When the kinetics of formation of hydroxyaluminosilicates (HAS) were investigated we obtained the first direct experimental evidence that the formation of HAS_A, an HAS with a Si:Al ratio of 0.5, was a prerequisite to the formation of HAS_B, an HAS with a Si:Al ratio of 1.0. We also found that the interconversions between $Al(OH)_{3(s)}$, HAS_A and HAS_B were critically dependent upon the concentration of silicic acid ($Si(OH)_4$) with the rapid formation of HAS_A being favoured when $[Si(OH)_4] = [Al]$ and the rapid formation of HAS_B being favoured when $[Si(OH)_4] \gg [Al]$.

Triprolinium 12-phosphomolybdate: Synthesis, crystal structure and properties of $[C_5H_{10}NO_2]_3[PMo_{12}O_{40}] \cdot 4.5H_2O$

This new organic–inorganic salt, hereafter **I**, has been synthesized and characterized by means of elemental analyses, IR spectrum, PNMR, ^{13}C NMR and single-crystal X-ray diffraction. The crystal structure consists of $[PMo_{12}O_{40}]^{3-}$ units linked together with $C_5H_{10}NO_2^{1+}$ cations and hydrogen bonded waters. The L-prolines retain their chirality and the zig-zag arrangement of the Keggin units bears some resemblance to the DNA strands.

N-rac-(5,7,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,14(1)-diene)copper(II): Structures of the perchlorate salt and a trinuclear tetracyanonickelato-bridged compound

The cation of *N-rac*-(5,7,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,14(1)-diene)copper(II) perchlorate has twofold symmetry with $Cu–N_{amine}$ = 1.994(1) and $Cu–N_{imine}$ = 1.969(1) Å, and with weak off-axis interactions with perchlorate oxygen atoms, Cu–O = 3.017(1) Å. The structure is compared with those of homologues with 14–18 ring-members. The tetracyanonickelate(II) compound has a trinuclear tetracyanonickelate-bridged cation with mean $Cu–N_{amine}$ = 2.009(3), mean $Cu–N_{imine}$ = 1.974(3), $Cu–N_{cyano}$ = 2.298(2) Å and $Cu–N_{cyano}{=}C$ = 142.1(2)°.

Crystal structures and unusual solution behaviour of diastereomeric aluminium and gallium complexes of chiral amines $[Me_3M \cdot RR^*NH]$

Six highly air and moisture sensitive diastereomeric adducts of trimethylaluminium and gallium have been formed from reaction with the three commonly used chiral secondary amines; ((*S*)-Ph(Me)CH)(PhCH$_2$)NH, (*R*,*R*)-Ph(Me)CH$_2$NH and (*S*)-Ph(Me)CH(CH$_2$CH=CH$_2$)NH, and their structures determined by single crystal X-ray diffraction. They were all found to be four coordinate monomers crystallising in the space group $P2_12_12_1$. Investigation of their solution structures by multinuclear and variable temperature NMR indicated that in contrast to the others (*S*,*R*)-$[Me_3Al \cdot HN(CHMePh)(CH_2Ph)]$ appeared to form two different isomers in toluene solution.

Low-spin iron(III) Schiff-base complexes with symmetric hexadentate ligands: Synthesis, crystal structure, spectroscopic and magnetic properties

The paper describes the synthesis and characterization of four new iron(III) complexes with two hexadentate Schiff-base ligands having N_4O_2 donor sets. In all cases, the molecular structure is built up by complex cations $[Fe(L)]^+$ and counter anions, ClO_4^- or BF_4^-. The mononuclear entities are organized into infinite 1D chains as a result of the hydrogen-bonding interactions established between the secondary amine functions of the Schiff-base ligand and counterions. Spectroscopic studies as well as temperature dependent magnetic properties indicate that all four iron(III) complexes are in low-spin electronic configuration.

Polyhedron 25 (2006) 1271

A novel polymeric Cu(II) assemblage and a monomeric Ni(II) complex from a new easy-to-prepare flexible polytopic ligand: Synthesis, structural and magnetic studies

The difference in coordination behavior of one new flexible polytopic ligand $\mathbf{H_2L}$ ($\mathbf{L} = C_{16}H_{14}N_6O_2$) has been examined with Cu(II) and Ni(II) acetate. It leads to the formation of a polynuclear pentacoordinated Cu(II) assemblage and a mononuclear four coordinated Ni(II) complex. The polynuclear copper complex exhibits strong antiferromagnetic behavior at low temperature with $J = -327\ cm^{-1}$.

Mono- and di-*N*-acetamidomethylated derivatives of *bis*(L-alaninato)copper(II): Characterization and nucleolytic property. Crystal structure of *bis*[*N*,*N*-di-(*N*′-methylacetamido)-L-alaninato]copper(II)

Mono- and di-*N*-acetamidomethylated derivatives of Cu(L-ala)$_2$. Crystal structure determination of the latter ($R_1 = R_2 = CH_2NH(C{=}O)CH_3$) shows intra- and intermolecular hydrogen bonding of the *N*-methylacetamido substituents. The former derivative ($R_1 = H$; $R_2 = CH_2NH(C{=}O)CH_3$), which dissolves readily in water, cleaves DNA more efficiently than Cu(L-ala)$_2$. Both complexes are additionally characterized by electron impact mass spectrometry.

Polyhedron 25 (2006) 1348

Synthesis, crystal, molecular and electronic structure of the $[ReCl_4(pzH)(PPh_3)]$ and $[ReCl_4(pyz)(PPh_3)]$ complexes

The reactions of the $[ReCl_4(PPh_3)_2]$ complex with pyrazole (pzH) and pyrazine (pyz) have been examined and two novel Re(IV) compounds – $[ReCl_4(pzH)(PPh_3)]$ (**1**) and $[ReCl_4(pyz)(PPh_3)]$ (**2**) – have been obtained. The compounds have been studied by IR, UV–Vis spectroscopy and X-ray crystallography. The electronic structures of **1** and **2** have been calculated with the density functional theory (DFT) method. The spin-allowed quartet–quartet electronic transitions of **1** and **2** have been calculated with the time-dependent DFT method, and the UV–Vis spectra of the title compounds have been discussed on this basis. From magnetic studies a small, negative value of *J* obtained confirms the occurrence of weak antiferromagnetic interactions between the rhenium centers in the crystal lattice.

Polyhedron 25 (2006) 1399

Structural characterization of a thiazoline-pyrazole ligand and its complexes with cobalt(II) and copper(II)

The thiazoline derivative 2-(pyrazol-1-yl)-2-thiazoline (PyTn) yields two novel complexes, $[CoCl_2(PyTn)_2] \cdot 2H_2O$ and $[\{CuCl(PyTn)\}_2(\mu\text{-}Cl)_2]$, by reaction with $CoCl_2 \cdot 6H_2O$ and $CuCl_2 \cdot 2H_2O$, respectively, in ethanol-water solution. The crystal structure of the cobalt(II) complex reveals a distorted octahedral geometry around cobalt(II) ion, whereas the copper(II) complex presents a structure consisting of two square pyramids linked by one edge.

Formation of manganese(II) complexes of substituted thiosemicarbazones derived from 2-benzoylpyridine: Structural and spectroscopic studies

Three manganese(II) complexes of 2-benzoylpyridine-3-tetramethyleneiminyl thiosemicarbazone (HBpypTsc), 2-benzoylpyridine *N*(4)-cyclohexyl thiosemicarbazone (HBpychTsc) and 2-benzoylpyridine *N*(4)-phenylthiosemicarbazone (HBpyphTsc) were synthesized and physico-chemically characterized by means of partial elemental analyses, molar conductance measurements, magnetic measurements, electronic, infrared and EPR spectral studies. The three complexes were given the formulae as $[Mn(BpypTsc)_2]$ (**1**), $[Mn(BpychTsc)_2] \cdot H_2O$ (**2**), $[Mn(BpyphTsc)_2]$ (**3**). The structure of the compound **1** has been solved by single crystal X-ray crystallography and was found to be distorted octahedral.

Polyhedron 25 (2006) 1415

Synthesis and characterization of some new mixed pentafluorophenyl organoantimony-(III and V) derivatives

Compounds of the type $(C_6F_5)_nSb(III)R_{3-n}$ [R = CH_3, $C_6H_4CH_3$-*p*, C_6H_5] have been synthesized by using grignard reactions and their oxidative addition reactions with Cl_2 or Br_2 carried out, which afford corresponding $(C_6F_5)_nSb(V)R_{3-n}X_2$ [X = Cl or Br] derivatives. The compounds were characterized by the micro-analysis, IR, NMR (^1H, ^{13}C and ^{19}F) and FAB mass analysis.

Polyhedron 25 (2006) 2824

Dynamic pseudo Jahn–Teller distortion in a compressed octahedral CuO_6 complex

The coordination sphere of *cis*-$[Cu(C_8H_7O_3)_2(H_2O)_2]$ at 115 K, with three rhombic coordination axes, differs importantly from the room temperature one, where compressed axial axes were determined. The MSDA analysis confirms the vibrational disorder in the structure at high temperature, and its gradual freezing by decreasing temperature. These results are in agreement with the EPR data that also show the reversibility of this change. Based on the EPR data, a $\{d_{z^2}\}^1$ ground state is proposed, although the room temperature spectrum suggests a $\{d_{x^2-y^2}\}^1$ ground state, but with a small g_3 value (close to g_e).

Polyhedron 25 (2006) 2829

Silver(I)-barbital based frameworks: Syntheses, crystal structures, spectroscopic, thermal and antimicrobial activity studies

Three Ag^{I}-barb coordination polymers have been reported. $Na_3[Ag_3(\mu\text{-barb})_6]$ is a 3D mixed-metal complex, while $\{[Ag_2(\mu\text{-barb})_2][Ag_2(\mu\text{-en})_2] \cdot 5H_2O\}_n$ contains the barb dianion and features 2D grid-type layers, which are further connected by extensive hydrogen bonds resulting in a 3D framework with open channels. $[Ag(barb)(\mu\text{-bpe})]_n$ consists of 1D helical chains connected by hydrogen bonds between barb ligands to form 2D supramolecular sheets, which are further linked by aromatic π–π stacking interactions into a 3D network. The barb ligand has been shown to be able to exhibit different coordination modes. Different coordination modes of barb are seen in $Na_3[Ag_3(\mu\text{-barb})_6]$ and $\{[Ag_2(\mu\text{-barb})_2][Ag_2(\mu\text{-en})_2] \cdot 5H_2O\}_n$. Antimicrobial studies of the title complexes were also performed. While barb and the other coligands did not show any significant antimicrobial activity, complexes **1**–**3** exhibited a wide spectrum of antimicrobial activity against selected bacteria and fungi.

Polyhedron 25 (2006) 2915

Synthesis and single crystal structure of a three coordinate complex of mercury(II) with 1-(ethylthio)-2-(diphenylphosphino) ethane (**L**) prepared by a new simple method

The (P, S) ligand 1-(ethylthio)-2-(diphenylphosphino) ethane (**L**) is synthesized in good yield by reacting Ph_2PLi with CH_3CH_2-SCH_2CH_2Cl. Its complexation with Cu(I), Hg(II) and organometallic species of Ru(II) are explored. The single crystal structure of Hg(II) complex of **L** has been determined. It is found to be a three coordinate species. The geometry of Hg can be best described as trigonal planar. The Hg(1)–P(1) bond length is 2.415(1) Å and the Hg–Br bond lengths are 2.5152(6) and 2.5952(6) Å. There exists a weak secondary interaction between Hg and the S donor site of the ligand.

Cation supported self-assembly of coordination polymers, $[(H_2en)(ntpMCl_2)]_n$ ($M = Zn^{II}$, Cd^{II}, Hg^{II}) involving the tripodal acid, ntp: X-ray crystal structure and DNA binding studies on zinc helicate

A first report on the self-assembly of novel coordination polymers of the type, $[(H_2en)(ntpMCl_2)]_n$ [$M = Zn^{II}$, Cd^{II}, Hg^{II}] resulting due to deprotonation of ntp, present as the zwitterion $[NH^+(CH_2CH_2COOH)_2$-$(CH_2CH_2COO)^-]$ in aqueous medium, by en leading to the formation of the ditopic anion ntp^{2-}, suggesting that H_2en^{2+} acts as a cation template. The coordination polymers thus resulted involve $[ntpMCl_2]^{2-}$ as building units stabilized via hydrogen bonding interactions. X-ray analyses on $[(H_2en)(ntpZnCl_2)]_n$ features four coordinate Zn^{2+} defined by two oxygen donors from ntp^{2-} ligands and two chloride anions.

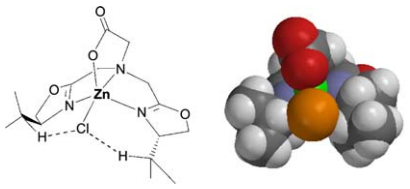
Polyhedron 25 (2006) 3025

Synthesis of a bis(oxazoline)-*N*-carboxylate ligand and its Zn(II) complex that shows C–H···Cl hydrogen bonding

A novel N_3O-type chelate and its Zn(II) complex are synthesized. The chelate is a branched type N_3O ligand, (*S*,*S*)-[Bis{(4-isopropyl-4,5-dihydrooxazol-2-yl)methyl}amino]acetic acid sodium salt, which was synthesized through a stepwise introduction of the oxazoline rings. The Zn(II) complex shows C–H···Cl–Zn hydrogen bonding both in the solid and solution states. A single crystal X-ray analysis of the Zn(II) complex supports the C–H···Cl–Zn hydrogen bonding, showing a microchannel structure.



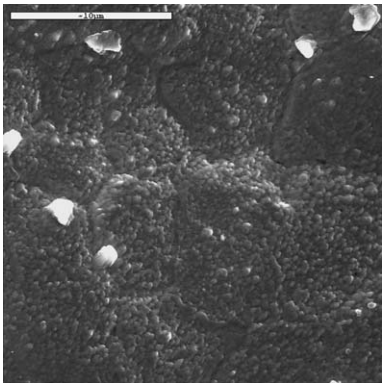
C-H---Cl Hydrogen bonding both in the solid and solution states

Russell Binions, Claire J. Carmalt, Ivan P. Parkin

Polyhedron 25 (2006) 3032

Antimony oxide thin films from the atmospheric pressure chemical vapour deposition reaction of antimony pentachloride and ethyl acetate

The reaction of antimony pentachloride and ethyl acetate under atmospheric pressure chemical vapour deposition conditions leads to the production of antimony (III) oxide thin films on glass and gas sensor substrates. Scanning electron microscopy (SEM) indicated that an island growth mechanism predominated. X-ray photoelectron spectroscopy (XPS) revealed binding energy shifts of 20.6 eV for O 2s and 35.4 eV for Sb 4d. The films were X-ray amorphous. Energy dispersive X-ray analysis (EDXA) and electron probe microanalysis (EPMA) gave coherent elemental compositions indicating that single phase Sb_2O_3 was made, with negligible impurity levels. The films showed little optical reflectance (~10%) and 65–75% total transmission from 400 to 800 nm. Gas sensing experiments indicated that the films responded best to a reducing gas at 400 °C.

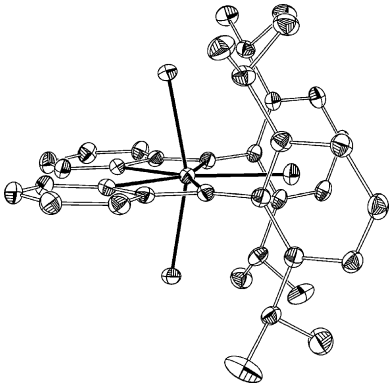


Markku Talja, Mika Polamo

Polyhedron 25 (2006) 3039

Configurational isomerism in crystalline bis-(amidopyridine)trichloro complexes of tantalum(V)

The structures of tantalum amidopyridine complexes were studied by X-ray diffraction. The seven-coordinated mononuclear bis-(amidopyridine) complexes displayed configurational isomerism in the crystalline state. Distortions in the coordination polyhedra around the Ta center were evaluated.

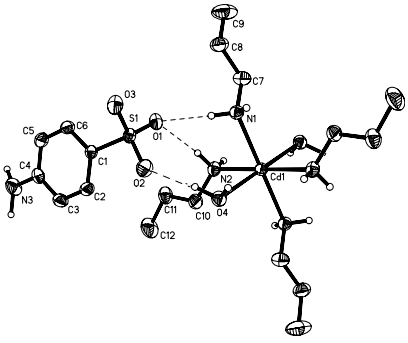


Ping Liu, Zhao-Xun Lian, Jiwen Cai

Polyhedron 25 (2006) 3045

Solid–vapor reaction properties of copper(II) and cadmium(II) sulfonates with amines

Copper(II) and cadmium(II) sulfonates react with amine vapors and form stable mono-amine-coordinated complexes. Single crystals can grow in situ via the solid–vapor reaction process.

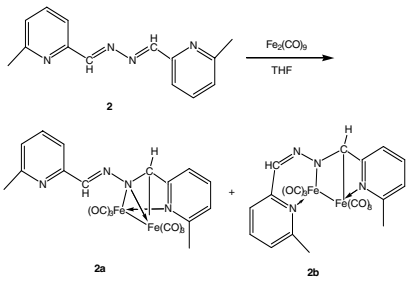


Chih-Yu Wu, Yi Chen, Shiau-Yi Jing, Chen-Shiang Lee, Joydev Dinda, Wen-Shu Hwang

Polyhedron 25 (2006) 3053

Reactions of diiron nonacarbonyl with pyrrolyl-, pyridyl- and thienyl-substituted azines: N—N bond cleavage, cyclometallation and C=N σ and π-bonding

The reactions of pyrrolyl, pyridyl and thienyl azines with $Fe_2(CO)_9$ yielded various types of diironhexacarbonyl complexes with different coordination modes, which resulted from (1) N—N bond cleavage, (2) cyclometallation, (3) diaza-bridge coordination, (4) σ- and π-imine bridge coordination and (5) π-imine bridge coordination of the ligand.

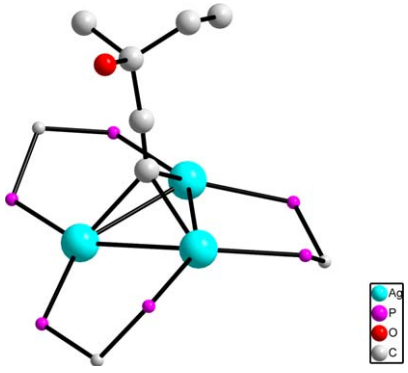


Raquel Aroz, Fabian Mohr, Elena Cerrada, Edward R.T. Tiekink, Mariano Laguna

Polyhedron 25 (2006) 3066

One-pot self-assembly of trinuclear silver(I) clusters containing propargyl alcohols and bis(diphenylphosphino)methane (dppm) ligands

A simple, safe and high yielding one-pot procedure for the synthesis of trinuclear silver(I) acetylide clusters containing propargyl alcohols HC≡CCRR′OH (R = R′ = H, Me; R = Me, R′ = Et) and dppm ligands is presented. The X-ray crystal structure of *rac*-$[Ag_3\{\mu_3\text{-}\eta^1\text{-}C{\equiv}CC(Me)(Et)OH\}(\mu\text{-dppm})_3](NO_3)_2 \cdot CH_2Cl_2$ was determined and the luminescence properties of the complexes were studied.



Jian-Sheng Xu, Yue-Tao Zhang, Guang-Hua Li, Ying Mu, Shou-Hua Feng

Polyhedron 25 (2006) 3071

Constrained geometry tetramethylcyclopentadienyl-phenoxy titanium complexes: Synthesis, structures and catalytic properties for ethylene polymerization

The synthesis of a new bidentate ligand, 1-(2-methoxyphenyl)-2,3,4,5-tetramethyl-cyclopentadiene (**1**), as well as its corresponding constrained geometry titanium complex, 2-tetramethylcyclopentadienyl-phenoxytitanium dichloride [(TCP)$TiCl_2$, **2**], was described. Complex **2** was synthesized by reaction of $TiCl_4$ with the lithium salt of **1**, followed by CH_3Cl elimination at 65 °C. Molecular structures of **2** and a known complex, 2-tetramethylcyclopentadienyl-6-methyl-phenoxytitanium dichloride [(TCMP)$TiCl_2$, **IVd**], were determined by single-crystal X-ray diffraction. When activated with Al^tBu_3 and $Ph_3C^+B(C_6F_5)_4^-$, complex **2** exhibits moderate catalytic properties for ethylene polymerization.

Preface 821

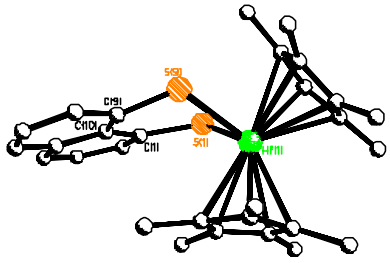
Papers

Stuart D. Robertson, Alexandra M.Z. Slawin, J. Derek Woollins

Polyhedron 25 (2006) 823

The preparation and characterisation of a series of group IV metallocene dithiolato complexes containing a naphthalene backbone

Metathesis reactions lead to $(Cp)^{*}_{2}MS_2C_{10}H_6$ [M = Ti, Zr, Hf] which are isomorphous allowing a comparison of the structural parameters.

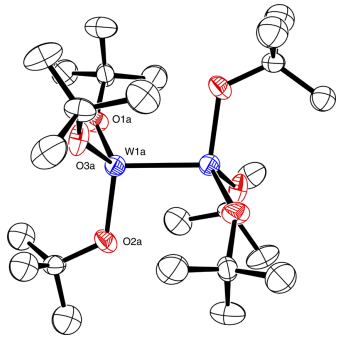


Malcolm H. Chisholm, Judith C. Gallucci, Carl B. Hollandsworth

Polyhedron 25 (2006) 827

Crystal and molecular structure of $W_2(OBu^t)_6$ and electronic structure calculations on various conformers of $W_2(OMe)_6$

The X-ray crystal structure of $W_2(OBu^t)_6$ is reported. The structure reveals 1.5 dimers in the asymmetric unit. One of the dinuclear molecules is highly disordered with respect to the W–W vectors. The alkoxide ligands are found in the common one distal, two proximal arrangement. DFT (ADF 2003.02) computational studies on several conformers of the model compound $W_2(OMe)_6$ reveal that there is little energetic difference between conformers of different proximality in the gas phase.

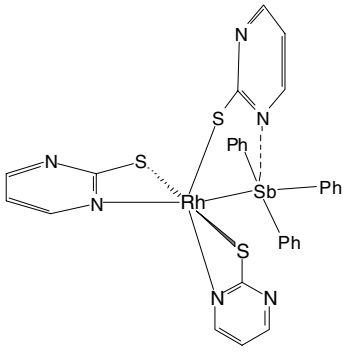


Renzo Cini, Gabriella Tamasi, Sandra Defazio, Maddalena Corsini, Francesco Berrettini, Alessandro Cavaglioni

Polyhedron 25 (2006) 834

Unusual hetero-atomic RhSCNSb(Rh) coordination ring: Synthesis and X-ray structure of [Rh($\underline{N}^1$,$\underline{S}^2$-2-thiopyrimidinato)$_2$($\underline{N}^1$(Sb),$\underline{S}^2$-(Rh)-2-thiopyrimidinato){Sb(C_6H_5)$_3$}] and long time sought structure of *mer*-[$RhCl_3$-{Sb(C_6H_5)$_3$}$_3$]

The reaction of [$RhCl_3(SbPh_3)_3$] with 2-thio-1,3-pyrimidine (Htpym) in ethanol produces crystalline [$Rh(tpym)_3(SbPh_3)$] that contains two $tpym^-$ N,S-chelating anions and a $tpym^-$ S-monodentate anion; this latter donates via a N atom to the Sb atom. The X-ray structure of [$RhCl_3(SbPh_3)_3$] shows that the chloride anion *trans* to Sb is significantly activated towards dissociation, an event that gives a rationale to the formation of [$RhCl_2(Ph)(SbPh_3)_3$] previously reported from this laboratory.

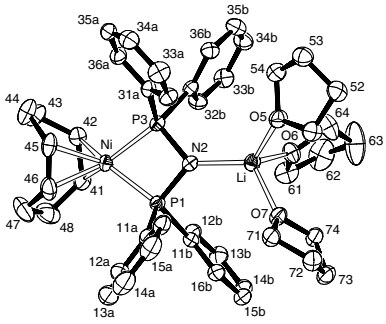


Musa Said, David L. Hughes, Manfred Bochmann

Polyhedron 25 (2006) 843

Synthesis and structures of diphosphinoamide complexes of nickel, palladium and platinum

The syntheses and single-crystal X-ray structures of bimetallic Ni–Li, Ni–Sn, Ni–Si, Pt–Li and Pt–Si complexes are described, based on the [amidobis(phosphine)]$^-$ anion as bridging ligand. The structures are based on MP_2N four-membered rings, the geometric parameters of which proved rather insensitive to changes in the N-main group element bond.

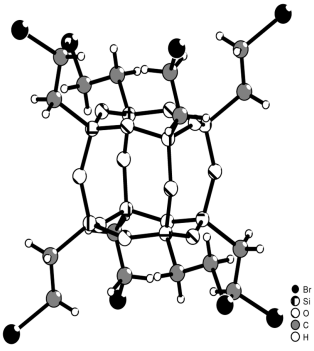


Ewan A. Drylie, Christopher D. Andrews, Meredith A. Hearshaw, Cristina Jimenez-Rodriguez, Alexandra Slawin, David J. Cole-Hamilton, Russell E. Morris

Polyhedron 25 (2006) 853

Synthesis and crystal structures of bromo- and ester-functionalised polyhedral silsesquioxanes

Two new functionalised octasilsesquioxanes have been prepared using octavinylsiloxane as the starting material. 1,3,5,7,9,11,13,15-octakis[ethylbromide]octasiloxane has been prepared by radical-initiated addition of HBr across the vinyl group and 1,3,5,7,9,11,13,15-octakis[methylpropanoate]octasiloxane has been prepared by direct methoxycarbonylation using a Pd(0) catalyst. Crystal structures of both compounds have been determined.

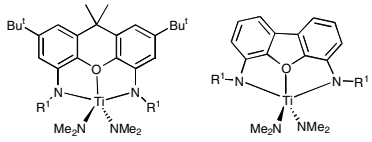


Robin M. Porter, Andreas A. Danopoulos

Polyhedron 25 (2006) 859

Dimethylxanthene- and dibenzofuran-diamido complexes of titanium

Tridentate dialkylamido- and diarylamido-ligands based on the dimethylxanthene and dibenzofuran backbones have been synthesised and used to prepare titanium dialkylamides and alkyls.

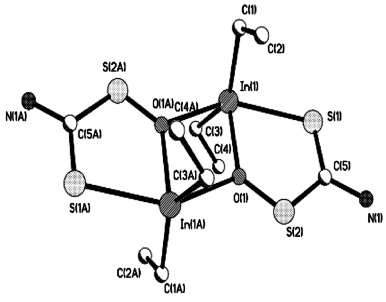


Mohammad A. Malik, Mohammad Afzaal, Paul O'Brien, Madeleine Halliwell

Polyhedron 25 (2006) 864

Synthesis of novel mixed indium(III) chalcogenolato complexes: Potential precursors for indium chalcogenides

Three new mixed chalcogenolato indium compounds have been synthesised and their structures determined by X-ray crystallographic method.

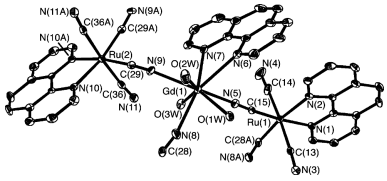


Juan-Manuel Herrera, Svetlana G. Baca, Harry Adams, Michael D. Ward

Polyhedron 25 (2006) 869

Syntheses and structures of two- and three-dimensional cyanide-bridged coordination networks derived from crystallization of diimine-tetracyanoruthenate anions with gadolinium(III) cations

Crystallisation of the cyanometallate complexes $[Ru(phen)(CN)_4]^{2-}$ and $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ (phen = 1,10-phenanthroline; bpym = 2,2′-bipyrimidine) with Gd(III) species affords two-dimensional or three-dimensional coordination networks based on Ru–CN–Gd bridges.

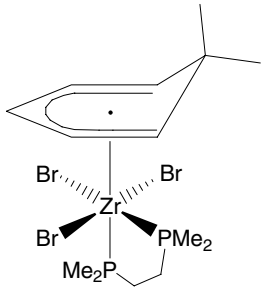


Atta M. Arif, Rehan Basta, Richard D. Ernst

Polyhedron 25 (2006) 876

Syntheses and characterization of mono-(6,6-dimethylcyclohexadienyl) complexes of titanium and zirconium

The reaction of $Ti(6,6\text{-dmch})_2$ with 1,2-$C_2H_4Cl_2$ led to the formation of the one-dimensional chloride-bridged polymer, $[Ti(6,6\text{-dmch})Cl_2]_n$, with a four-legged piano stool geometry (dmch = dimethylcyclohexadienyl). A mono(6,6-dmch) complex of zirconium, $Zr(6,6\text{-dmch})Br_3(dmpe)$, was isolated from the reaction of $Zr(6,6\text{-dmch})_2Br_2$ with dmpe (1,2-dimethylphosphinoethane).

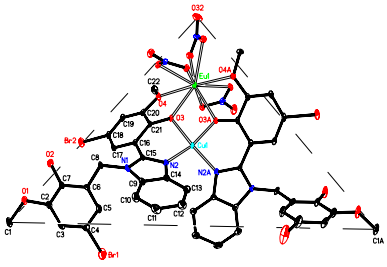


Xiaoping Yang, Richard A. Jones, Rachel J. Lai, Abdul Waheed, Michael M. Oye, Archie L. Holmes

Polyhedron 25 (2006) 881

Supramolecular assembly of nanometer-sized heterobimetallic 3d–4f complexes formed with benzimidazole based N,O-donor ligands

New heterobimetallic Cu–Ln complexes formed with benzoimidazole based N,O-donor ligands exhibit supramolecular 3D-networks via C–H··· O and CH···π interactions.

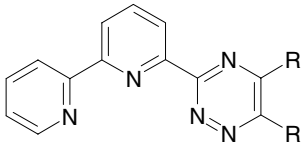


Michael G.B. Drew, Mark R.St.J. Foreman, Andreas Geist, Michael J. Hudson, Frank Marken, Virginia Norman, Michael Weigl

Polyhedron 25 (2006) 888

Synthesis, structure, and redox states of homoleptic d-block metal complexes with bis-1,2,4-triazin-3-yl-pyridine and 1,2,4-triazin-3-yl-bipyridine extractants

Cobalt(II), copper(II), iron(II), manganese(II), nickel(II) and zinc(II) form six-coordinate octahedral 1:2 complexes with triazinyl bipyridines. These metal complexes have been studied by crystallographic, electrochemical and theoretical methods.

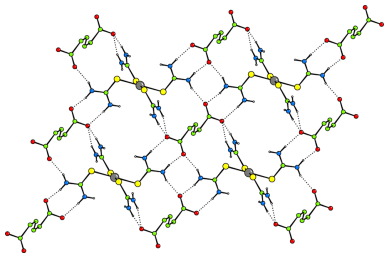


Philip A. Gale, Mark E. Light, Roberto Quesada

Polyhedron 25 (2006) 901

Formation and X-ray crystal structures of neutral 3D networks by charge-assisted hydrogen bonds between tetrakis(thiourea)-platinum(II) complexes and dicarboxylates

Complex salts of the tetrakis(thiourea)-platinum(II) cation and dicarboxylates are shown to be adequate molecular building blocks for the synthesis of three dimensional networks through charge-assisted hydrogen bonds.

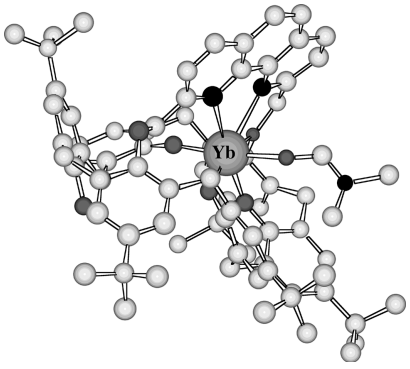


Jan P.W. Eggert, Jack M. Harrowfield, Ulrich Lüning, Brian W. Skelton, Allan H. White

Polyhedron 25 (2006) 910

Lanthanide(III) ion coordination by a concave reagent

Structural characterisation of the Yb(III) complex of a phenanthroline-bridged calix[6]-arene shows the ligand cavity to act as a receptor for another complex molecule rather than a bound ligand.

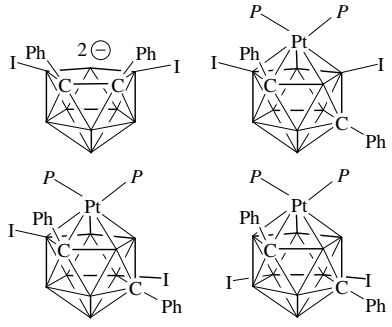


David Ellis, Rhona M. Garrioch, Georgina M. Rosair, Alan J. Welch

Polyhedron 25 (2006) 915

Isomerisation following the platination of $[7,8\text{-}Ph_2\text{-}9,11\text{-}I_2\text{-}7,8\text{-}\textit{nido}\text{-}C_2B_9H_7]^{2-}$

9-substituted- and 9,11-disubstituted-7,8-nido-diphenylcarboranes have been prepared and the latter platinated to afford three C atom isomerised species.

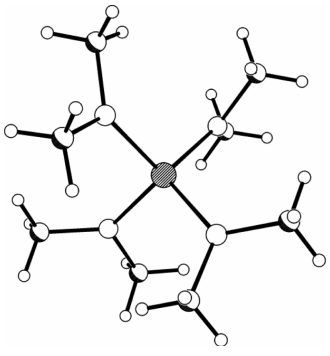


Morag E. Davie, Thomas Foerster, Simon Parsons, Colin Pulham, David W.H. Rankin, Bruce A. Smart

Polyhedron 25 (2006) 923

The crystal structure of tetrakis(dimethyl-amino)titanium(IV)

Although $Ti(NMe_2)_4$ has S_4 symmetry in the gas phase, in the solid state it has C_1 symmetry in order to avoid the formation of short methyl–methyl contacts.

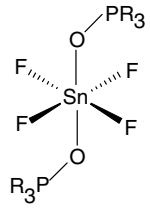


Martin F. Davis, William Levason, Gillian Reid, Michael Webster

Polyhedron 25 (2006) 930

Synthesis and characterisation of tin(IV) fluoride complexes of phosphine and arsine oxide ligands

The pseudooctahedral complexes $[SnF_4L_2]$ (L = Ph_3PO, Ph_3AsO, Me_3PO, Me_3AsO) and $[SnF_4(L–L)]$ (L–L = $Ph_2P(O)CH_2P(O)Ph_2$, *o*-$C_6H_4(P(O)Ph_2)_2$, *o*-$C_6H_4(P(O)Me_2)_2$) have been prepared and the X-ray crystal structures of *trans*-$[SnF_4(OPMe_3)_2]$, $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}] \cdot CH_2Cl_2 \cdot H_2O$ and $[o\text{-}C_6H_4(P(O)Ph_2)_2] \cdot CH_2Cl_2$ have been determined. The structural and NMR spectroscopic data on $[SnX_4L_2]$ (X = F, Cl, Br or I) show that SnF_4 is the strongest Lewis acid in the series towards hard Lewis bases.

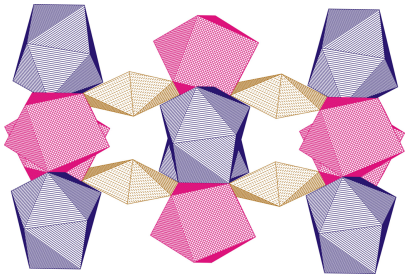


Thomas Gelbrich, Terence L. Threlfall, Susanne Huth, Eva Seeger

Polyhedron 25 (2006) 937

Structures of racemic lithium tartrate hydrates

A systematic study of the structures of LiM tartrate hydrates (M = Li, Na, K, Rb, Cs, NH_4) shows the occurrence of two- or three-dimensional coordination or hydrogen-bonded networks. Their similarities and differences are highlighted.

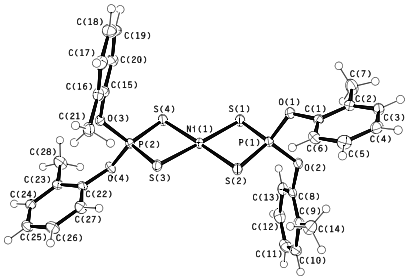


Ann L. Bingham, John E. Drake, Mark E. Light, Manisha Nirwan, Raju Ratnani

Polyhedron 25 (2006) 945

Synthesis, spectroscopic characterization and structural studies of nickel complexes of *O*,*O*′-diaryl(dibenzyl) dithiophosphates: Crystal structures of $Ni[S_2P(OC_6H_4CH_3\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4CH_3\text{-}m)_2]_2$ and $Ni[S_2P(OCH_2Ph)_2]_2$

Purple-coloured, tetra-coordinated Ni(II) complexes, $Ni[S_2P(OR)_2]_2$ (R = *o*-, *m*-, *p*-OC_6H_4Me, Ph and CH_2Ph) have been obtained by reaction of $NiCl_2$ with salts of corresponding *O*,*O*′-diaryl(dibenzyl) dithiophosphates and characterized by elemental analysis, UV, IR, ^1H, and ^{31}P NMR spectroscopy. The crystal structures of $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$ and $Ni[S_2P(OCH_2Ph)_2]_2$ are also described.

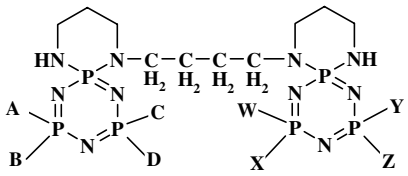


Simon J. Coles, David B. Davies, Robert J. Eaton, Adem Kılıç, Robert A. Shaw, Gönül Yenilmez Çiftçi

Polyhedron 25 (2006) 953

Structural and stereogenic properties of spiro- and ansa-substituted 1,3-propanedioxy derivatives of a spermine-bridged cyclotriphosphazene

Reaction of the achiral spermine-bridged cyclotriphosphazene compound (A-Z = Cl) with 1,3-propanediol at different molar ratios in THF gives various spiro- and ansa-derivatives with different stereogenic properties, i.e., racemates for unsymmetrically-substituted derivatives and meso, diastereoisomeric or achiral forms for symmetrical substitution.

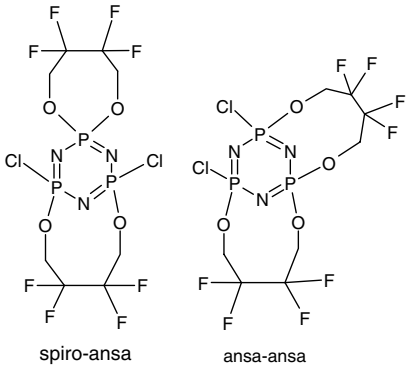


Serap Beşli, Simon J. Coles, David B. Davies, Robert J. Eaton, Adem Kılıç, Robert A. Shaw

Polyhedron 25 (2006) 963

Competitive formation of spiro and ansa derivatives in the reactions of tetrafluorobutane-1,4-diol with hexachlorocyclotriphosphazene: A comparison with butane-1,4-diol

Six products were isolated from the reaction of the sodium derivative of $HOCH_2CF_2CF_2CH_2OH$ with $N_3P_3Cl_6$: the mono-spiro compound, $N_3P_3Cl_4(OCH_2CF_2CF_2CH_2O)$ and its ansa isomer, the di-spiro derivative, $N_3P_3Cl_2(OCH_2CF_2CF_2CH_2O)_2$ and its spiro–ansa and ansa–ansa isomers (displayed) and a tri-spiro compound $N_3P_3(OCH_2CF_2CF_2CH_2O)_3$.

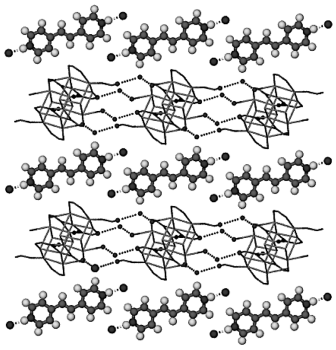


Xiao-Li Zhao, Thomas C.W. Mak

Polyhedron 25 (2006) 975

Supramolecular assembly of some polynuclear silver(I) complexes with encapsulated acetylenediide dianion and potentially exo-bidentate ligands

Five new $C_2@Ag_n$-containing complexes (bpe-$H_2 \cdot 2H_2O)[Ag_8(C_2)(CF_3CO_2)_8(H_2O)_2] \cdot 2H_2O$ (**1**), $[Ag_{14}(C_2)_2(C_2F_5CO_2)_{10}(H_2O)_4(bpe)] \cdot H_2O$ (**2**), $[Ag_7(C_2)(CF_3CO_2)_2(cba)_3]$ (**3**), $[Ag_7(C_2)$-$(C_2F_5CO_2)_5(cbaH)(H_2O)_2]$ (**4**) and $(imH)_3$-$[Ag_8(C_2)(CF_3CO_2)_9] \cdot H_2O$ (**5**) have been shown to exhibit a variety of supramolecular structures. Complex **1** provides the first example of a layer-type inclusion complex constructed with $C_2@Ag_n$ polyhedra.

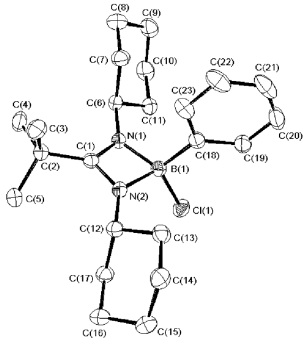


Michael Findlater, Nicholas J. Hill, Alan H. Cowley

Polyhedron 25 (2006) 983

Amidinate-substituted boron halides: Synthesis and structure

The synthesis and molecular structures of novel boron-substituted amidinates are reported. The unprecedented carbodiimide insertion into a boron–nitrogen bond is also discussed.

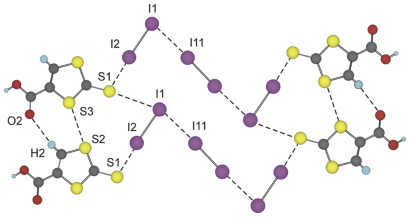


Peter J. Skabara, Rory Berridge, Neil Bricklebank, Helena Lath, Simon J. Coles, Peter N. Horton

Polyhedron 25 (2006) 989

Self-assembly of halogen adducts of ester and carboxylic acid functionalised 1,3-dithiole-2-thiones

New halogen adducts of 1,3-dithiole-2-thione-4-carboxylic acid and dimethyl 1,3-dithiole-2-thione-4,5-dicarboxylate have been prepared and characterised by X-ray crystallographic studies. The adducts feature an array of intramolecular and intermolecular close contacts involving chalcogen–chalcogen, chalcogen–halogen and halogen–halogen interactions.

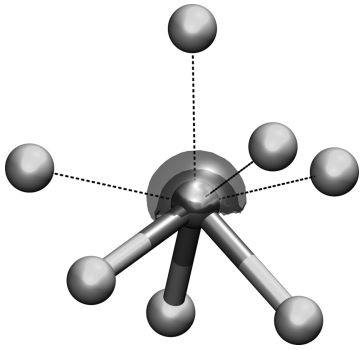


I. Abrahams, D.Z. Demetriou, E. Vordemvenne, K. Mustarde, D.M. Benoit

Polyhedron 25 (2006) 996

Lone pair effects in trihalo-stannate and -plumbate anions in the crystal structures of $Sr(MX_3)_2 \cdot 5H_2O$ (M = Sn, X = Cl, Br; M = Pb, X = Br): A joint crystallographic and electronic structure calculation approach

Electronic structure calculations in combination with X-ray crystallography have been used to examine valence electron pair distribution in $Sr(MX_3)_2 \cdot 5H_2O$ (M = Sn, X = Cl, Br; M = Pb, X = Br) and total energy minimisation methods used to predict the structure of $Sr(PbCl_3)_2 \cdot 5H_2O$.

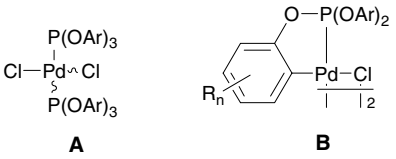


Robin B. Bedford, Michael Betham, Simon J. Coles, Peter N. Horton, María-José López-Sáez

Polyhedron 25 (2006) 1003

The influence of steric bulk on the geometry of triarylphosphite-based palladacycles and their tricyclohexylphosphine adducts

An exploration of the role of steric bulk on the synthesis and geometries of both simple triarylphosphite palladium (II) complexes (**A**) and their dimeric orthometallated counterparts (**B**).

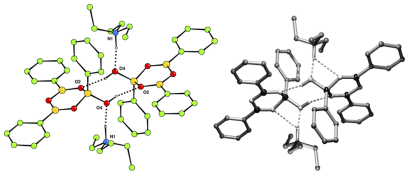


Michael A. Beckett, Simon J. Coles, Mark E. Light, Lars Fischer, Ben M. Stiefvater-Thomas, K. Sukuma Varma

Polyhedron 25 (2006) 1011

Synthesis and X-ray characterization of the organotriboroxinate salts $[Me_3NCH_2CH_2OH][Ph_4B_3O_3]$ and $[NEt_3H][Ph_3B_3O_3(OH)]$, and the X-ray structure of the triarylboroxine, $(4\text{-}MeOC_6H_4)_3B_3O_3$

The synthesis and characterization of the organotriboroxinate salts $[Me_3NCH_2CH_2OH][B_3O_4Ph_4]$ and $[NEt_3H][B_3O_3Ph_3(OH)]$ are reported. The latter contains the first example of a hybrid inorganic/organic triboroxinate anion, and exists in the solid-state as a dimer with H-bond ion-pair interactions between anions and cations and additional anion-anion H-bond interactions.

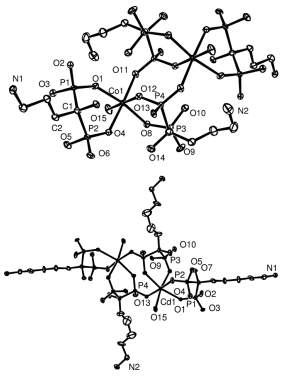


Siud Pui Man, Majid Motevalli, Stuart Gardiner, Alice Sullivan, John Wilson

Polyhedron 25 (2006) 1017

Structural studies on new metal derivatives of osteoporosis therapeutic aminohydroxyalkylidenebisphosphonic acids with C_4 and C_6 aminoalkyl chains

Hydrothermal reactions between the bisphosphonic acid 6-amino-1-hydroxy-1,1-hexylidene bisphosphonic acid and divalent hydrated metal nitrates of cobalt, nickel or zinc, afforded mononuclear dichelate products. Similar reactions using manganese or cadmium gave dinuclear products with chelate bridging as well as chelate terminal bisphosphonate ligands. The reaction between 4-amino-1-hydroxy-1,1-butylidene bisphosphonic acid and hydrated cobalt nitrate gave a dinuclear product. The C_6 alkylammonium chains in dinuclear compounds display supramolecular structure directing effects which are different from those in related compounds with C_4 alkylammonium chains.

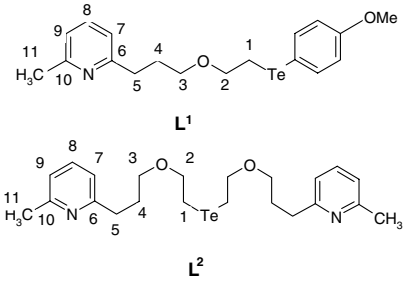


Sumit Bali, Ajai K. Singh, John. E. Drake, Mark. E. Light

Polyhedron 25 (2006) 1033

Multidentate hybrid organotellurium ligands 1-(4-methoxyphenyltelluro)-2-[3-(6-methyl-2-pyridyl)propoxy]ethane ($\mathbf{L}^1$) 2-methyl-6-{3-[2-({2-[3-(6-methyl-2-pyridyl)propoxy]ethyl}telluranyl)ethoxy]propyl}pyridine ($\mathbf{L}^2$) and their metal complexes: Formation of 20-membered metallomacrocycle by $\mathbf{L}^1$

1-(4-Methoxyphenyl-telluro)-2-[3-(6-methyl-2-pyridyl)propoxy]ethane ($\mathbf{L}^1$) 2-methyl-6-{3-[2-({2-[3-(6-methyl-2-pyridyl)propoxy]ethyl}-telluranyl)ethoxy]propyl}pyridine ($\mathbf{L}^2$) and their complexes $[PdCl_2(\mathbf{L}^1)]_2$ (**1**), $[PtCl_2(\mathbf{L}^1)]_2$ (**2**), $[HgBr_2(\mathbf{L}^1)]$ (**3**), $[PdCl_2\ (\mathbf{L}^2)]_2$ (**6**), $[PtCl_2(\mathbf{L}^2)]_2$ (**7**) and $[(PdCl_2)_3(\mathbf{L}^2)_2]$ (**8**) have been synthesized and characterized by IR, ^1H and ^{13}C NMR spectra. **3** on crystallization from acetone:hexane (2:1) mixture gives $MeOC_6H_4HgBr$ (**4**) and $[RTe^+–HgBr_2]Br^-$ (R = $–CH_2CH_2OCH_2CH_2CH_2$-(2-(6-CH_3–C_5H_3N))) (**5**).The crystal structures of **1**, **2** and **4** are solved. **1** and **2** are 20-membered metallomacrocycles and do not dissociate in solution. The crystals of **1** and **2** have chloroform and benzene, respectively, in the lattice whereas **4** is a linear ArHgBr type species. The Pd/Pt in **1** and **2** has square planar geometry. The Pd–Te and Pd–N bond lengths in **1** are 2.530(1)/2.5313(9) and 2.097(4) and 2.101(4) Å, respectively.

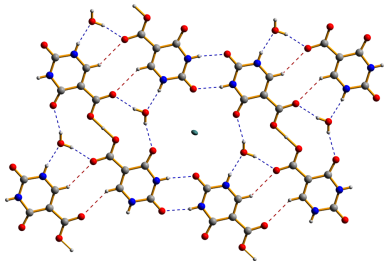


Gary S. Nichol, William Clegg

Polyhedron 25 (2006) 1043

Classical hydrogen bonding and weaker C–H···O interactions in complexes of uracil-5-carboxylic acid with the alkali metals Na–Cs

Five alkali metal complexes of the organic acid uracil-5-carboxylic acid, all synthesised from aqueous solution, are presented. Crystal structure analysis showed that hydrogen bonding is important in all compounds, with chain, sheet and tape motifs being formed. C–H···O hydrogen bonding, although weaker, also has a major role to play in most of the structures.

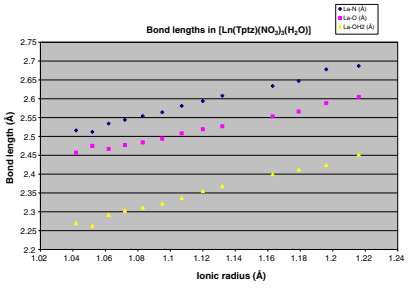


Simon A. Cotton, Vilius Franckevicius, Mary F. Mahon, Li Ling Ooi, Paul R. Raithby, Simon J. Teat

Polyhedron 25 (2006) 1057

Structures of 2,4,6-tri-α-pyridyl-1,3,5-triazine complexes of the lanthanoid nitrates: A study in the lanthanoid contraction

The structures of 20 new lanthanoid complexes all containing the 2,4,6-tri-α-puridyl-1,3,5-triazine ligand have been determined crystallographically. The majority of the complexes have the formula $[Ln(tptz)(NO)_3(H_2O)] \cdot 2EtOH$, with the two ethanol molecules hydrogen bonded to the complex. The lanthanoid ions are 10 co-ordinate and an analysis of the metal–ligand bond lengths is consistent with the lanthanide contraction across the series.



Michael J. Carr, Andreas Franken, Ramón Macías, John D. Kennedy

Polyhedron 25 (2006) 1069

Twelve-vertex polyhedral carbaborane chemistry. Isostructural cations and anions: The 'globule–globule' salt $[H_3NCH_2C_2B_{10}H_{11}]$-$[H_3CCH_2CB_{11}H_{11}]$

Chemistry associated with attempts to synthesise the salt $[H_3NCH_2C_2B_{10}H_{11}]^+$ $[H_3CCH_2CB_{11}H_{11}]^-$, of which the anions and cations are isostructural, are described.

Preface 203

Papers

Sherrika D. Daniel, Jean-Sébastien M. Lehn, James D. Korp, David M. Hoffman

Polyhedron 25 (2006) 205–210

Syntheses and X-ray structures of cerium amide complexes

The complexes $Ce(TMP)_3$ (TMP-H = 2,2,6,6-tetramethylpiperidine), $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$, and $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ were synthesized. The alkoxide ligand in $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$ originated from the THF solvent. There is evidence to suggest the presence of a weak Ce–vinyl group interaction in the structure of $[Ce(\mu\text{-}OCH{=}CH_2)(TMP)_2]_2$. $Ce(TMP)_3$ and $Ce[N\text{-}t\text{-}Bu(SiMe_3)]_3$ are trigonal planar monomers in the solid state.

Polyhedron 25 (2006) 211–218

Synthesis and molecular structure of mixed alkyne-cyclopentadienyl clusters via the ionic coupling of $[Os_3(CO)_9(R_2C_2)]^{2-}$ with $[Ru(\eta^5\text{-}C_5H_5)(MeCN)_3]^+$ and the reaction $[Os_3RuH(\eta^5\text{-}C_5H_5)(CO)_{10}(MeCN)]$ with alkynes (R_2C_2) (R = Me, Ph)

The coupling reaction of the dianion $[Os_3(CO)_9(R_2C_2)]$ (R = Me, Ph) with two equivalents of the monocation $[Ru(\eta^5\text{-}C_5H_5)(CH_3CN)_3]^+$ affords the neutral clusters $[Os_3Ru_2(CO)_9(R_2C_2)(\eta^5\text{-}C_5H_5)_2]$. These clusters exhibit a capped pseudo-octahedral $Os_3Ru_2C_2$ core, with the alkyne bonded parallel to the hinge bond of the capped butterfly metal geometry in a $\mu_4\text{-}\eta^2$ manner. Similarly, reaction of the activated cluster $[Os_3RuH(\eta^5C_5H_5)(CO)_{10}(MeCN)]$ with RCCR (R = Me, Ph) affords the related clusters $[Os_3RuH(CO)_9(\eta^5\text{-}C_5H_5)(R_2C_2)]$.

Polyhedron 25 (2006) 224–234

Complexes of the heavier alkaline earth metals containing β-diketiminato and iodide ligand sets

A series of mixed ligand complexes of calcium, strontium, and barium containing β-diketiminato and iodide ligands has been synthesized and characterized. Dimers or tetramers were obtained, which were connected through bridging iodide ligands. Depending on the steric bulk of the nitrogen atom substituents and the metal ion, η^5-, η^2-, or μ-η^2:η^5-β-diketiminato ligand coordination modes were observed. The combined results suggest that β-diketiminato ligands are strongly coordinating for group 2 metal ions, and are effective at stabilizing mixed ligand complexes toward redistribution equilibria.

DFT calculations of NMR $J_{C–H}$ coupling constants: An additional tool to characterize the α-agostic interaction in high oxidation state M-alkylidene complexes (M = Re, Mo and Ta)

DFT calculations have been used to calculate the spin–spin $J_{C–H}$ coupling constants for the C–H alkylidene bond in Re(≡CR)(=CHR)(X)(Y), Mo(=NR′)(=CHR)(X)(Y) and Ta($C_5R'_5$)(=CHR)(X)(Y), where the experiment suggests a weak agostic interaction for Re and Mo and a strong agostic interaction for Ta. The calculated $J_{C–H}$ are in good agreement with the experiment when the IGLO basis sets are used. The calculations reproduce that $J_{C–H}$ is lower for the *syn* than for the *anti* isomer. They also show that $J_{C–H}$ depends on the metal even in the absence of agostic interaction.

Thioether coordinated metalloenediynes: Syntheses, structures and thermal reactivity comparison

The d^{10} species of these novel thioether coordinated metalloenediynes have distorted but near tetrahedral geometries with weak thioether coordination, while the d^9 and d^8 species are likely *trans* tetragonal and square planar, respectively. Remarkably, the latter structures exhibit Bergman cyclization temperatures ~25 °C *lower* than their tetrahedral counterparts, and on the order of 50–100 °C lower than that expected for complexes with *trans* geometries. This chemical behavior derives from the fluxionality of the thioether linkage and an unusual *trans* to pseudo *cis* conformational change during upon heating.

Theoretical studies of π-loading and structural diversity in Cp_3MX (M = Zr, Hf; X = H, CH_3, OR, NR_2) compounds

DFT calculations have been used to explore the bonding and geometric preferences of Cp_3MX (M = Zr, Hf; X=H, CH_3, OR, NR_2) compounds containing σ-donor and π-donor X ligands. The compounds with a σ-only X ligand were found to be more stable as the "**3-5**" isomer, while the compounds with a π-donor X ligand were more stable as the "**2-5,1-1**" isomer. This stability difference is explained using molecular orbital theory.

A dendrimer-based Co_{32} nanocluster: Synthesis and application in diameter-controlled growth of single-walled carbon nanotubes

We report the synthesis and characterization of a dendrimer-based Co_{32} nanocluster molecule and its use as uniform-size catalytic seed for diameter-controlled growth of single-walled carbon nanotubes.

Polyhedron 25 (2006) 591–598

Synthesis and structure of gold(III) complexes of asymmetric dithiolene ligands

Four square planar $[Au(dithiolene)_2]^-$ complexes have been synthesized and characterized; they comprise Au(III) bound to two asymmetrically substituted ene-1,2-dithiolates and both *cis* and *trans* isomers are present in solution. Each complex undergoes an oxidation and a reduction, the potentials of which correlate with the electron withdrawing nature of the dithiolene.

Polyhedron 25 (2006) 599–612

Improved synthetic methods to mixed-donor thiacrown ethers

A series of azathia- and azaoxathiacrown ether macrocycles have been prepared in good yields via the use of *N*-boc-bis(2-chloroethyl)amine as a precursor; this route minimises undesirable side reactions and facilitates subsequent deprotection to the free cyclic amine.

Polyhedron 25 (2006) 613–625

Mixed 3d/4d and 3d/4f metal clusters: Tetranuclear $Fe^{III}_2M^{III}_2$ (M^{III} = Ln, Y) and $Mn^{IV}_2M^{III}_2$ (M = Yb, Y) complexes, and the first Fe/4f single-molecule magnets

Mixed 3d/4d and 3d/4f tetranuclear complexes have been synthesized, comprising Fe_2Ln_2, Fe_2Y_2, Mn_2Yb_2 and Mn_2Y_2 clusters. The compounds were prepared by using triethanolamine, pyridine-2,6-dimethanol, or methanolysis conditions. The Fe_2Ln_2 (Ln = Ho^{III}, Dy^{III}) were found to be single-molecule magnets (SMMs) by low temperature, single crystal hysteresis studies, and these complexes thus represent the first mixed-metal Fe/Ln SMMs to be discovered.

Polyhedron 25 (2006) 1

Syntheses and characterization of two novel heptanuclear trigonal prismatic $LnNi_6$ clusters with different terminal ligands

Two novel heptanuclear trigonal prismatic $LnNi_6$ clusters with the same $[LnNi_6(Gly)_6(\mu_3\text{-}OH)_3]$ core but different terminal aromatic ligands were prepared.

The new $Ru(NBD)Cl_2$(substituted-2,2′-biquinoline) complexes. Synthesis and characterization

The syntheses of three complexes having the general formula $Ru(NBD)Cl_2L$ (with L = 2,2′-biquinoline derivative) are described. Their spectroscopic properties are analyzed showing slight dependence with the complexes conformation, which is modulated, by the 3,3′-substitued position on the 2,2′-biquinoline ligand.

N-phthaloylglycinato complexes of cobalt, nickel, copper and zinc

Cobalt(II), zinc(II), copper(II) and nickel(II) complexes of *N*-phthaloylglycinato (Nphgly) ligands are synthesised and characterised. The cobalt and zinc complexes have composition $[M(Nphgly)_2(H_2O)_4]2H_2O$ and are iso-structural with octahedral geometry around the metal. A copper complex with composition $[Cu(Nphgly)_2(py)_3]$ where (py = pyridine) has a square pyramidal structure. Similar nickel complex has composition of $[Ni(Nphgly)_2(py)_3\text{-}1.3H_2O]$ has a trimeric H-bonded network.

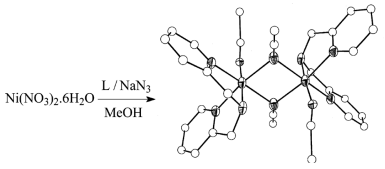
Polyhedron 25 (2006) 25

Synthesis, structure and magnetic properties of two end-on double azido bridged nickel(II) dinuclear entities incorporating *N*,*N*,*N*-coordinating tridentate reduced Schiff base ligands

The reaction of $Ni(NO_3)_2 \cdot 6H_2O$ with *N*,*N*,*N*-coordinating reduced Schiff base ligands in methanol in the presence of excess azide afforded $\mu_{1,1}$-N_3 bridged dinuclear nickel(II) complexes in excellent yields. Variable temperature magnetic susceptibility measurements confirm the ferromagnetic behavior of the complexes.



Ramesh Kapoor, Anuradha Pathak, Pratibha Kapoor, Paloth Venugopalan

Polyhedron 25 (2006) 31

Studies on cobalt(II) complexes with *N*,*N*,*N*′,*N*′-tetraethylpyridine-2,6-dicarboxamide(L^1) containing PF_6^-, BF_4^-, ClO_4^- and NO_3^- anions: X-ray crystal structures of $[Co(L^1)_2(CH_3CN)](PF_6)_2$ and $[Co(L^1)_2(H_2O)_2](X)_2 \cdot H_2O$ ($X = PF_6^-, ClO_4^-$)

Octahedral cobalt(II) complexes $[Co(L^1)_2(CH_3CN)](PF_6)_2$ (**1**) and $[Co(L^1)_2(H_2O)_2](X)_2$ ($X = PF_6^-$ (**2**), BF_4^- (**3**), ClO_4^-, (**4**), NO_3^- (**5**)) have been prepared; the composition of the product is dependent upon the reaction medium. The ligands use either ONO or ON donor atoms depending upon the steric demands. Compounds **2** and **4** are structurally similar and the lattice water is involved in the formation of chains by hydrogen bonding between different structural units.

Polyhedron 25 (2006) 43

The coordination behaviour of two structural isomeric ligands towards cadmium (II): Synthesis, spectroscopic characterization and crystal structures

Two thiazoline/indazole derivative ligands, 2-(indazol-1-yl)-2-thiazoline (TnInA) and 2-(indazol-2-yl)-2-thiazoline (TnInL) and their Cd(II) complexes were synthesized and characterized by physical measurements. The X-ray crystal structures of TnInA, TnInL, $[Cd(NO_3)_2(TnInA)_2]$ and $[Cd(NO_3)_2(TnInL)_2]$ have also been determined. The geometry around the cadmium atoms can be described as a triangulated dodecahedron.

Polyhedron 25 (2006) 52

Synthesis, characterization and crystal structures of a bidentate indazole–thiazine derivative ligand and its cobalt (II) and cadmium (II) metal complexes

A novel thiazine/indazole derivative ligand *N*-(5,6-dihydro-4H-1,3-thiazin-2-yl)indazole (InTz) and its cobalt (II) and cadmium (II) complexes were synthesized and characterized by physical measurements. The X-ray crystal structures of InTz, cobalt complex and cadmium complex have also been determined. The geometry around the metallic atoms can be described as a distorted octahedron for cobalt complex and as a distorted dodecahedron for cadmium complex.

Polyhedron 25 (2006) 61

Structural, antimicrobial and spectral studies of copper(II) complexes of 2-benzoylpyridine *N*(4)-phenyl thiosemicarbazone

A series of five Cu(II) complexes of 2-benzoylpyridine *N*(4)-phenyl thiosemicarbazone (HL) with a general formula [CuLX], except the perchlorate complex were prepared. The complexes were characterized by means of spectroscopic methods. The antimicrobial studies shows that the copper complexes were active against *Vibrio cholerae* O1 and *Salmonella paratyphi*. Single crystal XRD studies revealed the chloro complex to be a chlorine bridged dimer and the thiocyanato complex with a distorted square planar geometry.

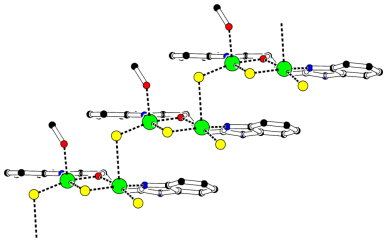
Polyhedron 25 (2006) 81

Crystal structure, magnetism and spectroscopy of a dinuclear Cu(II) compound with a chiral ligand; $Cu_2(SL)(\mu\text{-}Cl)(Cl)_2(CH_3OH)$ (HSL = *S*-1,2-bis(benzimidazol-2-yl)-1-hydroxyethane)

A new dinuclear Cu(II) compound with a chiral ligand, $Cu_2(SL)(\mu\text{-}Cl)(Cl)_2(CH_3OH)$ (in which HSL = *S*-1,2-bis(benzimidazol-2-yl)-1-hydroxyethane) displaying a strong antiferromagnetism of $J = -348$ cmis reported.



Prasad P. Phadnis, Sandip Dey, Vimal K. Jain, M. Nethaji, Ray J. Butcher

Polyhedron 25 (2006) 87

Synthesis, spectroscopy and structures of *o*-diphenylphosphinobenzoic acid complexes of diorganotin (IV), palladium (II) and platinum (II)

The reactions of diorganotin oxides and palladium (II) and platinum (II) precursors with *o*-diphenylphosphinobenzoic acid ([PPh_2-(o-C_6H_4COOH)], LH) have been investigated and a variety of complexes have been isolated and characterized by elemental analyses, IR, NMR (H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ and $^{119}Sn\{^1H\}$) and UV–Vis spectroscopy. The stereochemistry of these complexes has been deduced from spectroscopic data. The structures of $[\{Bu_2Sn(OOC\text{-}C_6H_4PPh_2)\}_2O]_2$ and $[Pt(O_2CC_6H_4PPh_2)_2]$ have been established by X-ray crystallography.

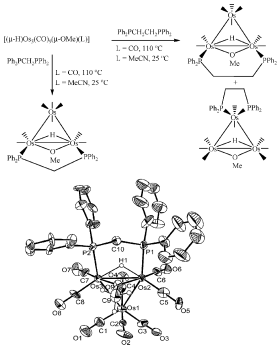
Polyhedron 25 (2006) 95

Reactions of $[(\mu\text{-}H)Os_3(CO)_{10}(\mu\text{-}OMe)]$ and $[(\mu\text{-}H)Os_3(CO)_9(\mu\text{-}OMe)(MeCN)]$ with dppm, dppe, dppp, and PPh_2H: X-ray crystal structures of $[(\mu\text{-}H)Os_3(CO)_8(\mu\text{-}OMe)(\mu_2\text{-}\eta^2\text{-}dppm)]$ and $[(\mu\text{-}H)Os_3(CO)_9(\mu\text{-}OMe)(PPh_2H)]$

The reactions of $[(\mu\text{-}H)Os_3(CO)_{10}(\mu\text{-}OMe)]$ (**1**) and its monoacetonitrile derivative $[(\mu\text{-}H)Os_3(CO)_9(\mu\text{-}OMe)(MeCN)]$ with diphosphines (dppm, dppe and dppp) and monophosphine (PPh_2H) are described. The structures of the products formed depend on the phosphine used. The crystal structures of two new compounds are reported.



Gabino A. Carriedo, F.J. Garcia Alonso, Carlos Diaz Valenzuela, Maria Luisa Valenzuela

Polyhedron 25 (2006) 105

Synthesis and thermal decarbonylation of $W(CO)_5$ complexes supported by nitrile, pyridine or phosphine ligands to poly-spirophosphazene random copolymers carrying O–C_6H_5–CO_2Pr groups

Phosphazene copolymers carrying nitrile, pyridine and phosphine ligands have been synthesized by sequential substitution from $[NPCl_2]_n$. Their reactions with $[W(MeOH)(CO)_5]$ gives the corresponding tungsten carbonyl complexes, that undergo a complete decarbonylation below 300 °C forming metal containing species that have a stabilizing effect on the polymeric matrices.

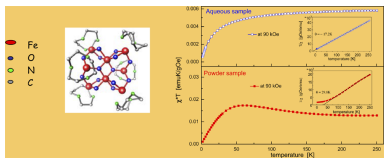
Polyhedron 25 (2006) 113

Investigations of the stability of $\{[(tacn)_6Fe_8(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)\}Br \cdot 8H_2O$ (Fe_8) cluster in aqueous solution by spectroscopic and magnetic methods

We report on the characterization of the single molecular magnet (SMM) $\{[(tacn)_6Fe_8\mu_3\text{-}O_2(\mu_2\text{-}OH)_{12}]Br_7(H_2O)]\}Br \cdot 8H_2O$, tacn = 1,4,7-triazacyclononane in aqueous solution. Spectroscopic and magnetic measurements evidence the lack of stability of the complex in aqueous solution.

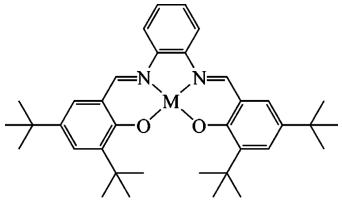


Michael P. Weberski Jr., Craig C. McLauchlan, Christopher G. Hamaker

Polyhedron 25 (2006) 119

Synthesis and X-ray structural characterization of M(3,5-^{t}Bu$_2$-salophen) (M = Cu, VO)

The synthesis, spectroscopic properties, and X-ray crystal structures of the copper (II) and vanadyl complexes of *N*,*N*′-phenylenebis(3,5-di-*tert*-butylsalicylideneimine) are reported.



M = Cu^{2+}, $[VO]^{2+}$

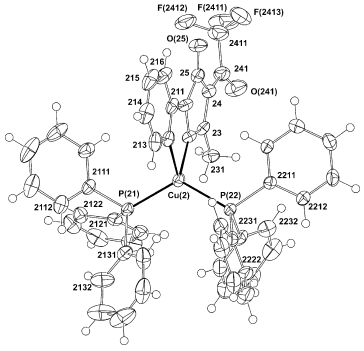
Polyhedron 25 (2006) 124

Copper(I) monophosphine complexes with functionalized acylpyrazolonate ligands: Syntheses of heterobimetallic Cu–Zn and Cu–Ru adducts

New phosphino–copper(I) acylpyrazolonate derivatives have been synthesized and characterized in the solid state and solution. They are monomeric compounds where the acylpyrazolonates act as O_2- or N_2-donor ligands depending on their substituents. In the latter case, the ligand is also able to coordinate other metal centres through the carbonyl arms, affording heterobimetallic derivatives.

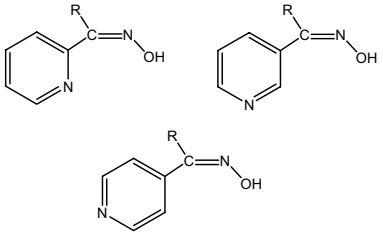


Constantinos J. Milios, Theocharis C. Stamatatos, Spyros P. Perlepes

Polyhedron 25 (2006) 134

The coordination chemistry of pyridyl oximes

This paper reviews the coordination chemistry of pyridyl oximes. The immense structural diversity of the pyridyloximate complexes stems from the ability of these ligands to exhibit a great variety of coordination modes. The products range from simple mononuclear metal complexes to heterometallic clusters and polymeric metallosupramolecular arrays. Aspects of the activation of 2-pyridyl oximes by 3d-metal centers are also detailed.



Cui-Juan Wang, Yao-Yu Wang, Hai-Rui Ma, Hui Wang, Qi-Zhen Shi, Shie-Ming Peng

Polyhedron 25 (2006) 195

A novel ligand *N*,*N*′-di(2-pyridyl)-2,4-diamino-6-phenyl-1,3,5-triazine (dpdapt) and its complexes: $[Cu(dpdapt)Cl_2]$ and $[Cu(dpdapt)(NO_3)(H_2O)] \cdot NO_3 \cdot H_2O$

A new ligand, dpdapt, and two crystalline polymorphic forms, $[Cu(dpdapt)Cl_2]$ (**1**) and $[Cu(dpdapt)(NO_3)(H_2O)] \cdot NO_3 \cdot H_2O$ (**2**), have been synthesized. The molecular structures of **1** and **2** were established by single-crystal X-ray diffraction studies. DFT calculations have been used to gain some insight about the coordination behavior of dpdapt and complex **1**.
