As for the perfluorated manganese and technetium compounds the Re-C bond lengths progress from $C_6F_5ReO_3$ (2.081 Å) over $C_5F_5ReO_3$ (2.159 Å) to CF_3ReO_3 (2.171 Å). The Re–C bond lengths of [Re_2(η^5-C_5H_5)(μ-η^1:η^5-C_5H_4)-$(CO)_4$-(2,3,4,6-C_6F_4H)] [45] (2.19(1) Å) and [Re(η^6-C_5-Me_4CH_2)$(CO)_2$ (C_6F_5)][46] (2.20(1) Å) are longer than the calculated values for the C_6F_5 compound, thus indicating a strong rhenium–carbon bond. While no values for rhenium C_5F_5 or CF_3 compounds are available, the Ru–C bond lengths of 2.15–2.20 Å found by gas electron diffraction for Ru(η^5-C_5F_5)($\eta^5C_5Me_5$) [42] indicate that the bond lengths of the CF_3 and C_5F_5 compounds are well in the range of Re–C bonds. The O–Re–O angles of the C_6F_5 compound (111.5° and 111.1°) are smaller than those of the CF_3 compound (112.8 and 110.8) and the C_5F_5 (112.9° and 112.4°). The Re–O bond lengths are constant between 1.724 and 1.737 Å, comparing well with the calculated bond lengths of $FReO_3$ (1.720 Å) and CH_3ReO_3 (1.726 Å). A bond length of 2.16 Å has been obtained by SCF calculations for CF_3ReO_3 [23] comparing surprisingly well with the values obtained from the DFT and MP2 calculations here.

In order to discuss the relative stability of the group 7 trioxo compounds, we decided to calculate the reaction energy of the shown reaction (1):

$$LMO_3 + H_2 \rightarrow HMO_3 + HL \quad (1)$$

with L = O^-, F, CH_3, CF_3, C_5F_5 and C_6F_5 (see Table 4). This reaction should give some insight into the question whether electronegative ligands stabilise the ligand-to-metal bond or not. In addition the tetraoxo anions were taken into account as they are considered to be among the most stable group 7 compounds in the oxidation state +VII.

While the differences between the MP2 and BP86 values are small for the fluoride and methyl compounds, the difference between MP2 and BP86 is up to 24.2 kcal/mol for MnO_4^-. This is due to the well-known MP instabilities that frequently occur in calculations of first row transition

Table 4
The relative stability of LMO_3 compounds to $HMO_3 + H_2$ according to reaction (1) (in kcal/mol)

	Mn			Tc			Re

	MP2	1.756	109.9	121.0	−303.29506	0.01153

Distances (r) are given in Å, bond angles (α) and the dihedral angle (θ) are given in degrees. The absolute energies (E) and zero point vibrational energies (ZPE) are given in atomic units. All results in this table were obtained with basis set 1.

metals [35,36]. While the MnO_4^- compounds are favoured by about 100 kcal/mol over the HMO_3 compounds, the energy differences for the other compounds are quite small. While the manganese and technetium fluorides seem to be more favorable or more unfavorable according to the applied method, the rhenium fluoride compound is favoured over $HReO_3$. The methyl compounds are slightly less favoured (by up to 3 kcal/mol) than the HMO_3 compounds. CF_3MO_3 is around 10 kcal/mol less favorable than the hydrogen compound. For C_5F_5 and C_6F_5 alike the BP86 results suggest a stability close to the hydrogen compounds while the MP2 results suggest a higher stability than the hydrogen compound by 13–19 kcal/mol with a maximum for the technetium compound. In summary, the CF_3 compounds are the least stable compounds and the C_6F_5 and sometimes the C_5F_5 compounds have a slightly higher stability than the methyl compounds. An explanation for the low stability of the CF_3 compound might be that while O^-, F^-, C_5F_5 and C_6F_5 are involved in π-bonding and CH_3 is a σ-donor, CF_3 only acts as a σ-acceptor.

To illustrate the above findings a natural bond orbital analysis (NBO) was carried out (see Table 6). The charge of the metal atom obtained from the NBO analysis increases from manganese (0.78–1.02) over technetium (1.47–1.76) to rhenium (1.72–1.79). The metal charge is highest in the fluorides and lowest in the C_5F_5 and C_6F_5 compounds. The charge of the oxygen atoms remains almost constant for all neutral compounds at −0.27 for Mn, −0.44 for Tc and −0.53 for Re. In the methyl and C_6F_5 compounds the carbon bound to the metal atom has a substantial negative charge of −0.70 to −0.97 for CF_3 and −0.30 to −0.50 for C_6F_5. The bonded carbon atom of C_5F_5 is almost neutral. All other carbon ring atoms have positive charges. The population of d-orbitals of the metal atom increases from rhenium over technetium to manganese. As expected the fluorides have the lowest d-electron population on the metals. The s-orbital population seems almost unaffected by the change of ligands. The electron population on manganese is somewhat higher than expected just from considering the electron densities and is probably due to the smaller ionic radius of manganese where the charge of the nucleus acts stronger on the dense inner shell electrons than in technetium and rhenium with their more polarizable electron shell structure.

Table 6
Atomic charges and populations from NBO analyses for the group 7 trioxides (in units of e)

4. Conclusion

Group 7 (Mn, Tc, Re) LMO_3 complexes with perfluorated ligands (CF_3, C_5F_5 and C_6F_5) were investigated. While the CF_3 compounds are the least stable of the investigated molecules, the η^1-bonded C_5F_5 and C_6F_5 compounds of technetium and rhenium show a higher stability than the experimentally known methyl trioxo compounds of these metals. Calculations of C_5F_5 as well as for the experimentally unknown CH_3MnO_3 at the MP2 level lead to decomposition of the compounds, thus indicating that these compounds do not exist. The stabilization of C_6F_5 and C_5F_5 compared to CF_3 is due to π-bonding. The data for $C_6F_5MnO_3$ suggest that it is a promising candidate for synthesis and might be the first organyl-manganese trioxide.

Novel monomeric barium complexes as volatile precursors for chemical vapour deposition

Matthew R. Hill, Jennifer J. Russell, Nicholas K. Roberts *, Robert N. Lamb

Department of Surface Science and Technology, School of Chemistry, The University of New South Wales, Sydney NSW 2052, Australia

Received 31 March 2006; accepted 24 August 2006
Available online 10 September 2006

Abstract

A new range of barium complexes with single encapsulating ligands have been prepared for use in chemical vapour deposition (CVD). A novel pathway providing an unprecedented sequence of barium carbamates is reported. New dianionic bis β-ketoesterates and their barium, strontium and calcium derivatives were synthesised. High resolution mass spectrometry showed some barium derivatives to be monomeric, and preliminary testing indicated some volatility in these species. Calcium and strontium complexes were found to have nuclearities that varied according to their ionic radii relative to the chain length of the encapsulating ligand.

1. Introduction

Barium is important in the microelectronics and high temperature superconductor (HTSC) thin-film industries. Ferroelectric perovskites such as $BaTiO_3$ are key materials in the development of dynamic and non-volatile random-access memories [1–4], and research within the HTSC industry is largely focussed on films of yttrium barium cuprate ($YBa_2Cu_3O_{7-x}$) for the realisation of viable HTSC devices [5–8].

Development of a chemical vapour deposition route to these thin film materials has been hindered by a lack of barium precursors with sufficient volatility and stable vapour pressures. The dearth of suitable complexes arises from the chemistry and coordination proclivities of the Ba^{2+} ion, and in particular from its large size-to-charge ratio. The Ba^{2+} ion is exceptionally large, at 149 pm in diameter, and whilst this size creates useful distortion within a perovskite unit cell, it causes significant problems when making chemical vapour deposition (CVD) precursors. Many barium complexes have high coordination numbers (commonly 8–13), and tend to form oligomeric species via oxo-bridging to satisfy the high coordination number requirements of the large metal ion. Complexes of such high nuclearities are involatile, and their formation must be prevented if a volatile complex is desired. However, the relatively low ionic charge of the metal ion means that there would be insufficient coordination if anionic ligands were used alone. Thus, the synthesis of a ligand that engenders a volatile complex is not simple. This challenge has aroused strong interest over recent years, spawning many varying approaches. Fluorinated complexes have been particularly popular for enhancing the volatility of barium precursors for CVD [9–25]. A significant group of derivatives have been reported, but all are thwarted by the common problem of fluorine contamination in any thin films derived from these complexes [26–29]. As a consequence, volatile non-fluorinated complexes are highly sought after.

In various approaches to non-fluorinated barium CVD precursors, volatility has been imparted by the use of ligands with sterically demanding and/or neutral donor atoms. It has been found that sterically hindered barium derivatives of low coordination number are volatile, but they sublime

doi:10.1016/j.poly.2006.08.032

with significant concomitant thermal decomposition. This occurs regardless of the degree of steric hindrance that has been incorporated into the structure, in an attempt to inhibit the μ-oxo bridging to adjacent metal centres that is thought to initiate the decomposition. The use of sterically hindering components with appended neutral coordinative sites has been more successful in engendering volatile species. These ligands typically have two portions: the anionic component with sterically demanding groups, and a neutral coordinating component that is bound to the anionic component in varying manners, as exemplified in Fig. 1.

Compounds **1** [30] and **2** [31] represent unsuccessful attempts to create monomeric barium complexes. The spacing between the diketonate and oligoether moieties is unsuitable because strained four- or seven-membered rings would be enforced, upon the formation of monomeric species. Consequently the undesirable bridging to adjacent metal centres is actually more stable, and thus preferred. In contrast, compounds **3** [32–35] and **4** [36,37] are volatile complexes, each having two mono-anionic ligands with an appropriate spacing between the diketonate and oligoether components. Although these compounds are volatile, they sublime with substantial thermal decomposition, largely because the two separate ligands do not sufficiently cloak the large metal ion. The work of Studebaker et al. [29] is most significant in this field. They reported the ketoiminate **5** [29,38], where one encapsulating ligand was used to take best advantage of the increased stability afforded by the chelate effect. This increase in ligand sophistication improved the characteristics of prospective barium CVD complexes, but at the same time it increased the synthetic difficulty of preparing more advanced ligand systems.

It was clear to us that dianionic encapsulating ligands should be at the forefront of further research in this area. Exploration of new ligand systems, and the adaptation of earlier work in the attachment of donor chains to β-diketonates were of particular interest.

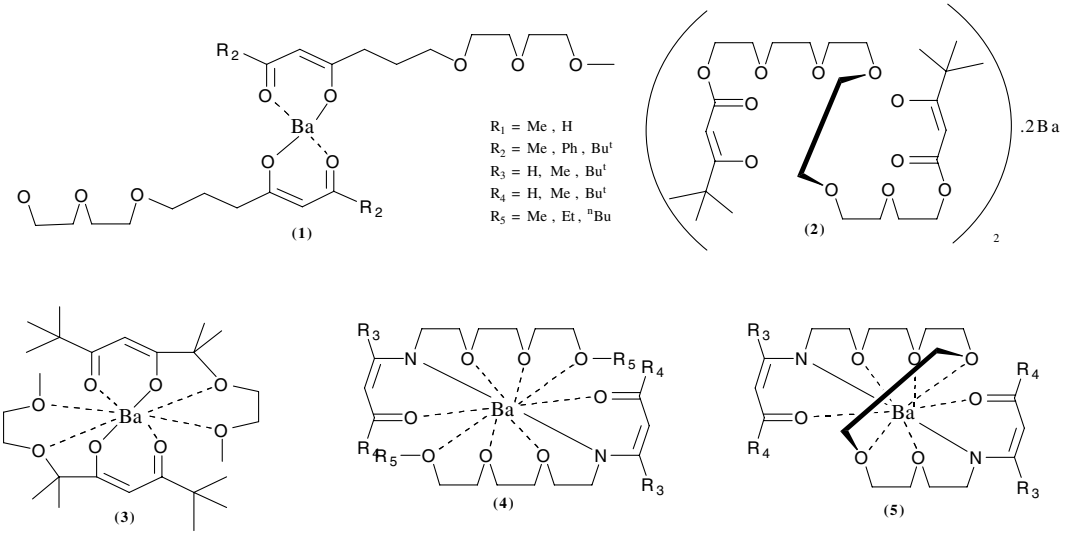
We report herein the synthesis of a class of encapsulated barium bis-carbamato complexes, and a new group of alkaline earth bis-ketoesterates that show promise for CVD applications.

2. Results and discussion

2.1. Barium carbamato complexes

Complexes of organic carbamates have been successfully applied as precursors to the SSCVD of a number of thin film materials, including MgO [39], ZnO [40], Sb_2O_3 [41], ZnS [42] and CdSe [43]. The synthesis of these complexes is comparatively simple, making the carbamato ligand an attractive proposition for barium CVD precursors. However, carbamates have not been applied as a ligand in barium chemistry, and in fact there have been, to date, no reports of any structurally characterised Ba, Sr, or Ca carbamato complex. A noteworthy observation from the organic carbamate complexes mentioned above was the agency of the trivalent nitrogen atom in providing an extra functionality. This extra branching simplified the assembly of all the requirements of a CVD ligand: the anionic component, the neutral donor polyether chain, and the sterically impeding alkyl group.

The general strategy adopted in the preparation of these complexes, as outlined in Scheme 1, was to prepare oligoether ligands of different chain lengths, terminated by secondary diamines **8** bearing various bulky or coordinating alkyl or aryl 'R' substituents. These amines afforded the complexes **9** through a CO_2 insertion reaction. The simple high yielding synthesis of the bromides **7** [44] at the start led directly to the secondary amines **8** by using the relevant primary amine in large excess [45]; this stratagem bypassed the extra steps of mono-protection, acylation, deacylation and alkylation that are usually employed to produce a mono-alkylated amine. The synthesis of the



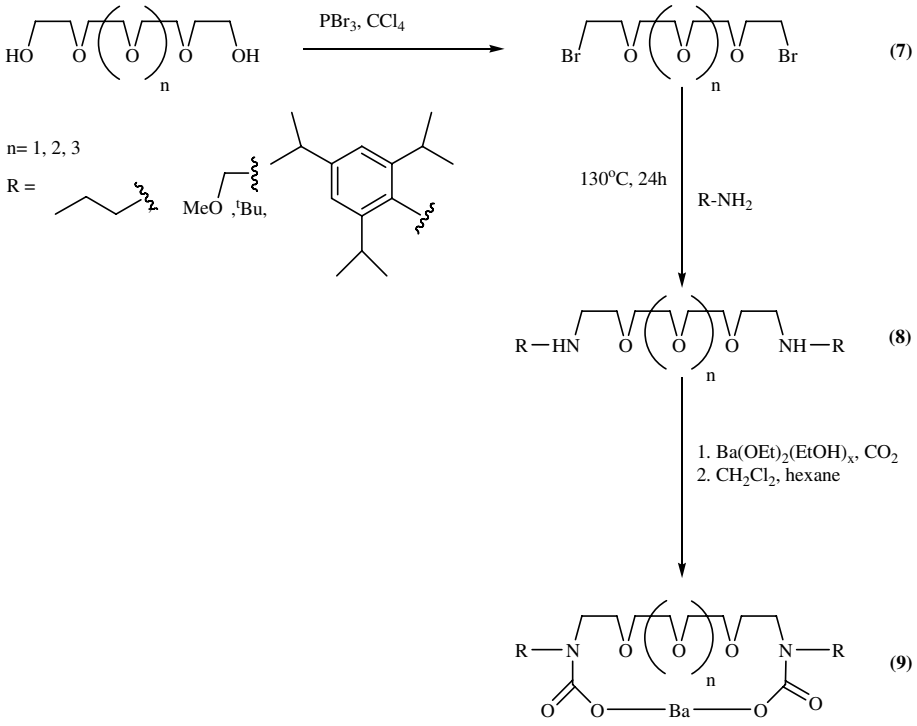


Fig. 1. Barium complexes **1** [30], **2** [31], **3** [32–35], **4** [36,37], and **5** [29,38].

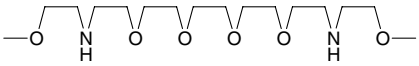
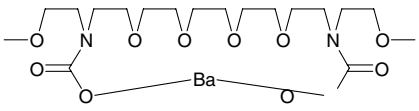
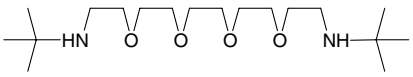
Scheme 1. Synthetic scheme for encapsulating barium carbamates.

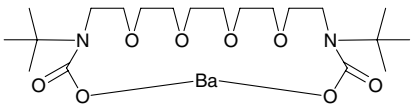
barium carbamates **9** proved to be more difficult. Their preparation was circumscribed by the strict reaction conditions necessary to prepare these compounds in preference to decomposition or other unwanted side reactions:

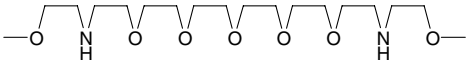
- Anhydrous conditions were needed to promote the formation of carbamates in preference to carbonates.
- Elevated temperatures were avoided as this could have resulted in decarboxylation.
- Commonly used insoluble barium sources (i.e. BaH_2, Ba/NH_3) were not reactive enough.

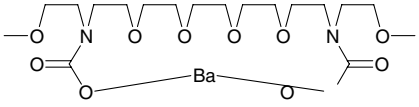


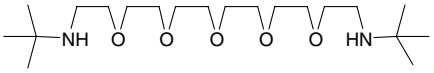


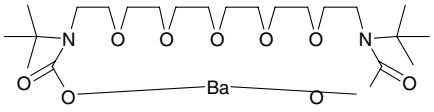


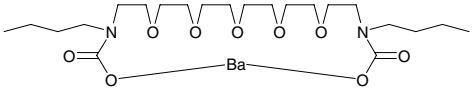












A soluble anhydrous barium source needed to be used, whose ligands would readily detach at room temperature without reacting with the CO_2 that is required to form the desired complexes. We found a reactive alkoxide $Ba(OEt)_2(EtOH)_x$, formed by reacting barium metal with excess dry ethanol, was suitable. The ethoxide ligand readily detached in the presence of the protonated, strongly chelating ligand **8** in CH_2Cl_2 solution, to release EtOH and an excellent yield of the barium carbamato complex **9**, which was isolated by precipitation with hexane.

Using this general method, a broad class of unprecedented encapsulating barium carbamato complexes were synthesised in excellent yields, as shown in Table 1. It was possible to prepare complexes that had varying degrees of steric hindrance and donor chain length. The volatility testing performed on the encapsulating carbamato complexes was disappointing, however, as it clearly revealed that these complexes were unsuitable for CVD. The typical thermogravimetric analysis shown in Fig. 2 indicated that these carbamates began to decompose immediately upon heating, and therefore did not possess sufficient thermal stability to remain intact at the necessary elevated temperatures. It was likely that the complexes were not actually monomeric in nature, but actually an interpenetrating web of carbamato ligands bridging between adjacent metal sites to form polymeric species.

Further reflections on the available coordination modes of the carbamate ligand group offer some insight into the problem. The coordination of a carbamato ligand group to a single barium ion in a mononuclear complex would entail the formation of either a strained four- or seven-membered ring (see Fig. 3), depending on whether the nitrogen atom of the carbamate is or is not coordinated. Furthermore, the carbonyl oxygen must, by default, point outwards, where it could participate in undesirable bridging to a neighbouring complex. Thus, mononuclear coordination of these carbamate ligands is probably unfavourable compared to bridging polymeric coordination. Previous examples of bridged bonding were evident in complexes **1** and **2**, where monomeric chelation would cause ring strain. Dimeric and polymeric species formed in preference, and these were likewise involatile.

Whilst extensive attempts at crystallising the barium carbamato species **9** for use in X-ray crystallography proved ultimately to be unsuccessful, some experimental evidence supported the proposed oligomeric/polymeric arrangement of these complexes. Firstly, the molecular ion was never observed in any mass spectrometric experiments, even under the gentlest of ionisation conditions.

Table 1
Summary of barium carbamato complexes and the ligands from which they were derived

Ligand (yield, identification)	Ba complex (yield, identification)
 (78%, **10**)	 (78%, **11**)
 (69%, **12**)	 (81%, **13**)
 (34%, **14**)	 (85%, **15**)
 (72%, **16**)	 (89%, **17**)
 (70%, **18**)	 (98%, **19**)

Instead, a complicated series of higher m/z ions were generally observed, which we ascribe to the presence of higher nuclearity species. Secondly, although the compounds were soluble in many polar organic solvents, the dissolution was initially very slow, even though the complexes ultimately proved to be highly soluble. Such a slow dissolution, apparently under kinetic control, could arise from the solvent progressively replacing oxo-bridging bonds. Although a painstaking experimental investigation might have revealed the structures of these complexes, we chose to direct our efforts instead to the synthesis of monomeric barium complexes as a potentially more fruitful area.

2.2. Barium β-diketonates

The β-diketonato moiety is the dominant ligand in the quest for volatile barium complexes. The ligand provides sites for the incorporation of sterically demanding groups, and points of attachment for neutral coordinative components. Also, β-diketonates impart good thermal stability to metal complexes. As shown earlier in Fig. 1, there have been some attempts at attaching neutral coordinative groups to these ligands, but these preliminary works have been limited in their scope and success.

One of our early approaches to making an encapsulating barium complex **23** is illustrated in Scheme 2. Whilst the phase transfer reaction afforded the diester **21** in fair yield, quite different conditions were required depending upon the length of the glycol portion. We think this was due to the tendency of the glycol chain to chelate about metal cations, thereby affecting reaction progress [46]. The propensity of the glycol chain to chelate metal atoms may have also been the reason that subsequent attempts to use Claisen condensations to prepare the diketonate **22** proved

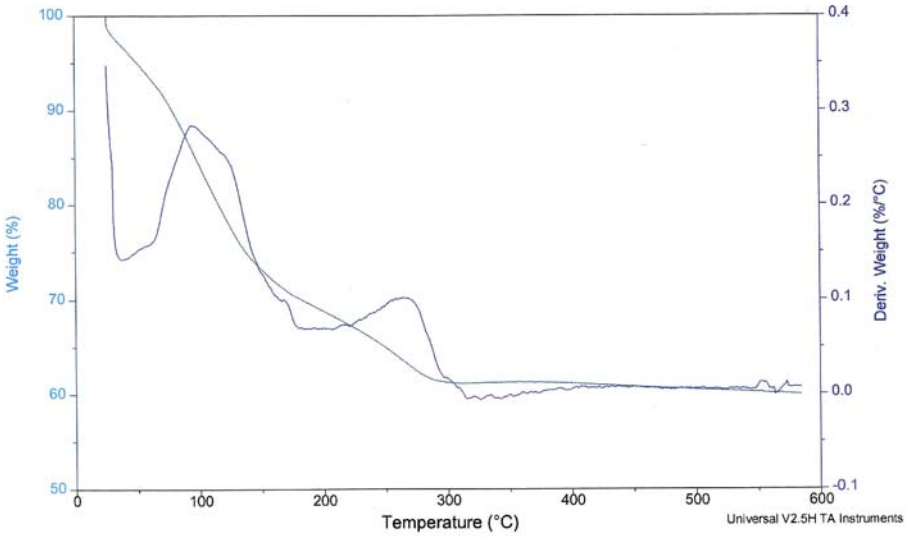


Fig. 2. A typical thermogravimetric analysis of a barium carbamato complex **19**.

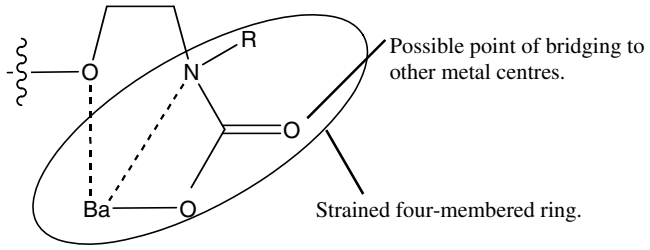

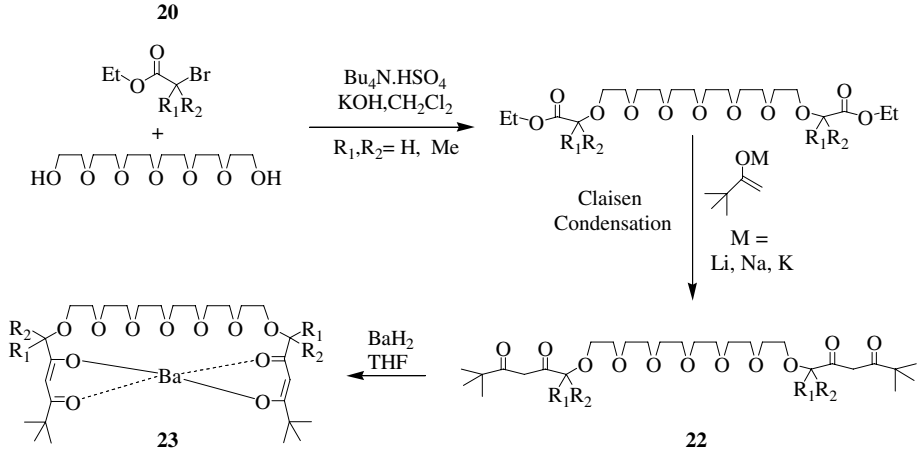

Fig. 3. The structural requirements of a monomeric barium carbamato complex.

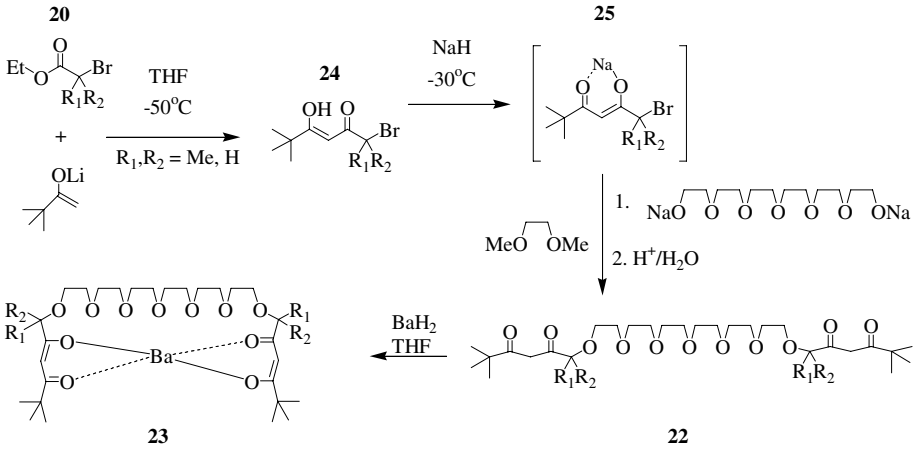
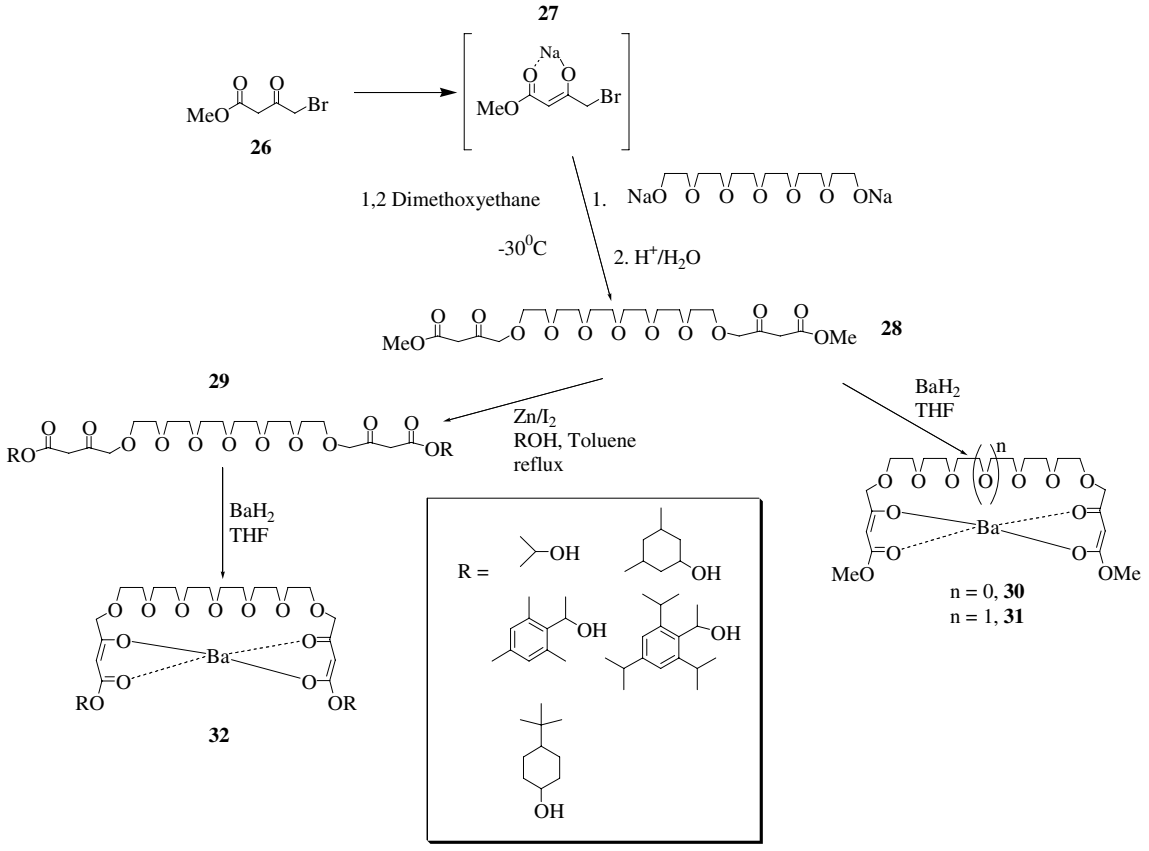


to be unsuccessful, even when a number of conditions and reagents were tried.

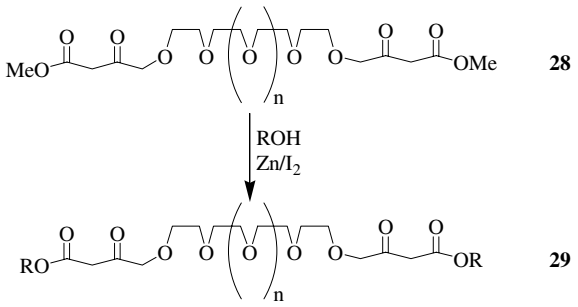
A simple means of circumventing the possible problems of hindering glycol chains in the formation of β-diketonates was to prepare the diketonate portion of the ligand before attaching the glycol component. Thus, the Claisen condensation to form the bromodiketone **24** proceeded well (Scheme 3), although care was needed to avoid exposure of some derivatives to light, which promoted bromine cleavage and the decomposition of **24**.



The next step of linking the bromo derivative to the glycol chain, to make **22**, was unsuccessful when we applied standard procedures [47]. Workup of the reaction mixture yielded unreacted glycol chains and self-condensed diketonate moieties. From this result we surmise that the reaction of the sodium chelate **25** with the glycolate salt is hindered by the two R groups α- to the bromine, so that intramolecular condensation of **25** is favoured over reaction with the glycolate. We attempted to attenuate the diketonate reactivity by forming its more covalent lithium salt, whilst boosting the glycolate reactivity by forming its potassium salt – but to no avail. Upon the failure of this approach, we reduced the steric crowding adjacent to the bromine atom, and did obtain successful intermolecular reaction with the glycolate salt. This modification is illustrated in Scheme 4.

Scheme 2. A proposed synthetic route to a diketonate complex of a single dianionic ligand.

Scheme 3. A second synthetic route to encapsulating barium diketonate complexes.



Scheme 4. The successful preparation of chelating diester barium complexes.

The successful synthesis of the dimethyl ester **28** (Scheme 4) has been reported previously [47]. Undoubtedly the resonance effect of the methoxy group helps stabilise the sodium β-diketonate complex **27**. Reactions of homologues of **28** with BaH_2 delivered the barium complexes **30** and **31** in good yields. The monomeric structure of each complex was confirmed by high resolution mass spectrometry. Whilst the ready synthesis of **28** is consistent with our ideas on steric hindrance, the resulting complexes **30** and **31** were not suitable for CVD precursors. They readily cleave off their oligo-ethylene oxide moiety when heated. Such behaviour was predictable, however, as these complexes lack sufficient steric shielding of the metal ion to isolate the barium atoms sufficiently from donor groups on neighbouring complexes.

Therefore, it was necessary to develop a method of introducing a sterically bulky component to the diester ligand. We sought a method of introducing a sterically

bulky group into the diester ligand other than α- to the oligoglycol attachment. The ester group in **28** offered a means of introducing such a group through a transesterification route. Transesterifications proceeded with moderate success in the presence of the Zn/I_2 heterogenous catalytic system. Illustrated below is a summary of these results.

28

29

In Table 2 the limitations of this approach are exposed. No transesterifications were successful in the presence of the longest hexaethylene glycol chain. The difficulty of performing conventional organic reactions on this length of glycol chain has been illustrated by the results outlined in Scheme 3 and 4. Shorter chain lengths produced several hindered species in moderate to good yield, yet attempts to perform transesterifications with desirable *tert*-butyl or fluorinated alcohols were unsuccessful. Also, it was necessary to use benzyl alcohols instead of bulky phenols, as it is known that phenyl alcohols undergo self-condensation reactions under the reaction conditions, to form coumarins [48].

Nevertheless, the successful transesterifications performed represented a novel approach to the synthesis of new prospective ligands for barium and other alkaline earth complexes. The results of attempted complexation reactions are listed in Table 3.

An appraisal of these results allows some conclusions to be drawn. It was not possible to form metal complexes with the bulky aromatic ligands **38** or **39**. Evidently, the sterically bulky components of these ligands were too large to allow effective coordination of a metal atom. The effect of steric bulk was more pronounced than expected, as the barium ion did not complex with any ligand containing groups more bulky than an isopropyl derivatisation; only **34** gave a reasonable yield (65% of **6**) by reaction with BaH_2.

The utility of ligands made by this route for our aim of barium ion complexation was not ideal. The transesterification method failed each time we tried to make the long ligand chain compounds that we thought were needed for stable barium complexation. The hypothesis that stable complexation of alkaline earth cations required a matching of cation size to ligand chain length was tested by comparing the strengths of calcium and strontium complexation with the barium results. In general we found that the short chain length ligands, which failed to complex with barium, did complex with calcium and strontium. Thus, **37** failed to react with barium, but gave the strontium complex **45** in

96% yield. However, bulky ligands **38** and **39** did not complex to strontium any more then they did to barium.

Synthesis of calcium complexes **40**, **41**, **43** and **44** provided some interesting results. The pentaethylene oxide complexes **41** and **43** were prepared using CaH_2 and were identified as $[LCa_2]^{2+}$ by high resolution mass spectrometry. This highlighted the result of a ligand being greater in length than required to gird the circumference of a single metal ion; an additional metal atom was needed to fulfill the available coordination sites. The shorter chain ligand **33** afforded the complexes **40** and **44**, but freshly prepared $Ca(O^iPr_2)_2$ reagent was required, as CaH_2 or Ca/NH_3 were not reactive enough. Mass spectrometry indicated a stoichiometry of the type Ca_3L_2. The Ca/L stoichiometric ratio was lower as the chain length was decreased.

The thermal properties of the limited accessible barium complexes in this system were measured (Fig. 4). It was notable that these complexes had a far greater thermal stability (ca. 175 °C) than the previously described carbamato derivatives. Above 175 °C the compounds decomposed continuously to residues of varying compositions. The percentage yields of residue were compared to an idealised yield expected if pure BaO had been formed (Table 4).

The pentaethylene oxide methyl ester **30** decomposed to a mass of residue greater than that expected if the material had decomposed to BaO. As decarboxylation of the ester groups on **30** is plausible, the formation of some $BaCO_3$ in the residue could account for the mass excess. In contrast, the longer chain ester complex **31** decomposed to a residue weight corresponding to BaO, so no generality can be drawn from these few results. The most interesting thermogravimetric result was that the isopropyl ester complex **6** gave half the weight of residue expected, as calculated for BaO. Evidently considerable barium was lost in volatile form, either due to volatility of **6** or of an intermediate pyrolysis product. Encouraged by this result we tested **6** under CVD conditions, but we found that it was not volatile enough to deliver sufficient material to the surface of the substrate. In another test the substrate was used cold, to collect a sample of the species delivered in the effluent stream from the hot Knüdsen cell. XPS analysis of the condensate showed that some **6** was present, but the spectra showed a low atomic abundance of barium, indicating significant thermal decomposition had occurred.

Table 4
Residues remaining following thermal decomposition of barium complexes

Complex	Percentage residue of BaO	Observed percentage residue
6	23.2	12.3
30	25.3	31.8
31	23.6	23.1

3. Summary and conclusions

The metal complexation studies reported represent significant advances in making a range of derivatives of barium, strontium and calcium, with some of the characteristics needed for CVD.

A novel synthetic scheme has been devised which afforded a sequence of barium carbamato complexes in relatively few steps, and in good yields. Preliminary characterisation of these complexes showed that they were neither monomeric nor volatile. Thermogravimetric analysis of the carbamato complexes revealed that none of the carbamato derivatives possessed sufficient thermal stability to be volatile, regardless of their structure.

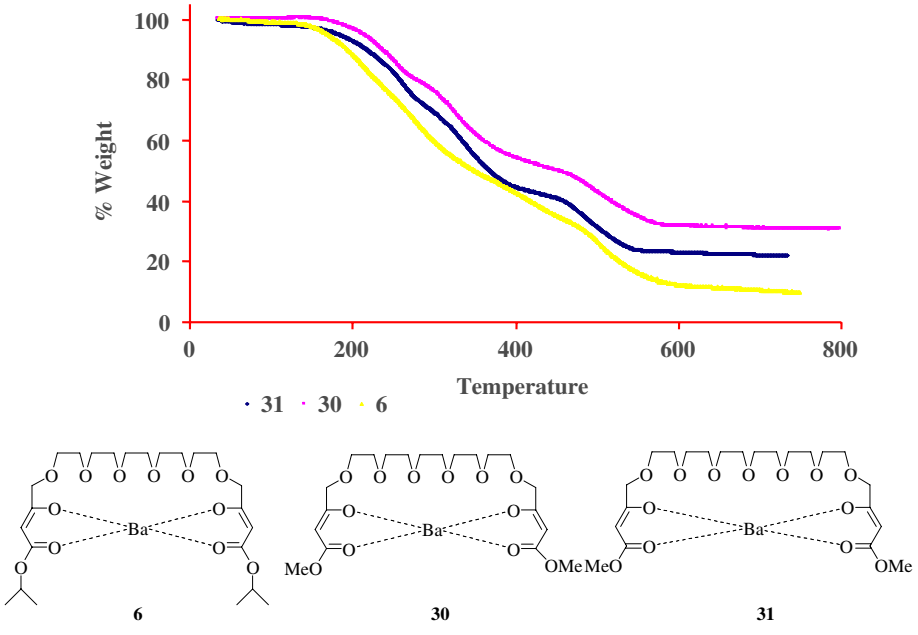

Fig. 4. Thermogravimetric analysis of barium diketonates.

A different approach yielded barium, calcium and strontium complexes of oligoethylene oxide β-ketoesterates. However, the ligands available for metal complexation turned out to be limited by the hindering nature of longer oligo-ethylene oxide components in preparative reactions, and there was in addition limited success in the transesterifications in the presence of long oligo-ethylene oxide chains. Also, of the ligands that could be successfully synthesised, those with highly hindered substituents did not form stable metal complexes. Significantly, high-resolution mass spectrometry of the compounds that could be made revealed that the strontium and barium analogues were monomeric, whereas calcium derivatives of various chain length ligands arranged themselves as either Ca_2L or Ca_3L_2. Repeated attempts to crystallise these complexes indicated that they were most likely non-crystalline in nature. Thermogravimetric analysis of these metal complexes showed they were more thermally stable compared to the class of carbamato complexes we made at first. The isopropyl-substituted barium complex **6** exhibited promising volatility during these analyses. However, the volatility was insufficient for useful barium-containing films to be grown.

4. Experimental

Infrared spectra were recorded as KBr disks and as neat liquids on a Perkin–Elmer 580B spectrometer. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AC300F spectrometer at 300 MHz. Solvents and reagents were purified by the literature methods. Attempts to record microanalytical data for compounds described within did not give the expected results because ligands containing oligoethylene oxide segments could not be distilled, even at reduced pressures and elevated temperatures, and hence could not be isolated in a sufficient purity. X-ray quality crystals of metal complexes could not be obtained, and hence similar purity problems hindered their elemental analysis. Instead, high resolution mass spectrometry was used to definitively confirm the identity of reported compounds. High resolution mass spectra were obtained by electrospray in positive ion mode with a capillary voltage of 50 V and an ion source temperature of 190 °C. Mass spectra of metal carbamate complexes could not be obtained due to their instability under ionisation. Meaningful data could not be obtained even with the most 'gentle' ionisation techniques including MALDI and electrospray. Ca, Sr and Ba complexes reported are moderately air sensitive, and rapidly hydrolyse when exposed to moist air. BaH_2 was purchased from Aldrich and was used as received.

4.1. 1,14-Dibromo-3,6,9,12-tetraoxatetradecane (*46*)

This compound was prepared by following a procedure previously reported [44,49]. A solution of PBr_3 (12.78 g, 4.70×10^{-2} mol) in CCl_4 (13 mL) was added dropwise to a solution of pentaethylene glycol (15.00 g, 6.30×10^{-2} mol) in CCl_4 (21 mL). The resulting mixture was then refluxed for 2 h. Ice (70 g) was added to the cooled solution. The organic layer was then washed with a saturated solution of $NaHCO_3$ (30 mL), water (30 mL) and dried over $MgSO_4$. Removal of volatiles in vacuo afforded a viscous yellow liquid, **73** (9.20 g, 40%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 3.43 (t, 4H, $2\times CH_2Br$), 3.62 (m, 12H, $3\times OCH_2CH_2O$), 3.77 (t, 4H, $2\times OCH_2CH_2Br$). ^{13}C NMR ($CDCl_3$) δ (ppm): 30.21 ($2\times CH_2Br$), 70.45 (OCH_2CH_2O), 70.56 (OCH_2CH_2O), 71.10 ($3\times OCH_2CH_2O$). These spectra were in good agreement with the literature [44,49].

4.2. 1,17-Dibromo-3,6,9,12,15-pentaoxaheptadecane (*47*)

A similar procedure to that for **46** was employed, using hexaethylene glycol (25.00 g, 8.90×10^{-2} mol) and PBr_3 (18.06 g, 6.7×10^{-2} mol) and delivered **47** as a very viscous pale yellow liquid (21.65 g, 60%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 3.42 (t, 4H, $2\times CH_2Br$), 3.61 (m, 16H, $4\times OCH_2CH_2O$), 3.76 (t, 4H, $2\times OCH_2CH_2Br$). ^{13}C NMR ($CDCl_3$) δ (ppm): 30.24 ($2\times CH_2Br$), 70.43 (OCH_2CH_2O), 70.47 (OCH_2CH_2O), 71.55 ($2\times OCH_2CH_2O$), 71.08 (OCH_2CH_2O). These spectra were in good agreement with the literature.

4.3. 1,17-Di(n-butylamino)-3,6,9,12,15-pentaoxaheptadecane (*18*)

This material was prepared by adaptation of a procedure first described by King et al. [45] To a mixture of powdered NaOH (0.98 g, 2.46×10^{-2} mol) in Et_2O (50 mL) **47** (5.00 g, 1.23×10^{-2} mol) and *n*-butyl amine (17.90 g, 2.45×10^{-1} mol) were added. The resultant mixture was refluxed for 24 h, and left overnight to cool. Precipitated NaBr was filtered off and the filtrate evaporated to dryness. Water was added to the resulting oily residue (20 mL). The aqueous solution was then extracted with dichloromethane for 48 h using a continuous liquid-liquid phase extraction setup. The organic phase was dried and the volatiles removed in vacuo to deliver a pale yellow liquid **18** (3.38 g, 70%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 0.87 (t, 6H, $2\times CH_3CH_2$), 1.31 (hextuplet, 4H, $2\times CH_3CH_2$), 1.43 (p, 4H, $2\times CH_2CH_2CH_3$), 1.71 (br s, 2H, $2\times NH$), 2.57 (t, 4H, $2\times CH_2CH_2CH_2CH_3$), 2.74 (t, 4H, $2\times NHCH_2$), 3.61 (m, 20H, $5\times OCH_2CH_2O$). ^{13}C NMR ($CDCl_3$) δ (ppm): 13.87 ($2\times CH_3CH_2$), 20.35 ($2\times CH_3CH_2$), 32.14 ($2\times CH_2CH_2CH_3$), 49.22 ($2\times CH_2CH_2CH_2CH_3$), 49.54 ($2\times NHCH_2$), 70.21 (OCH_2CH_2O), 70.41 ($2\times OCH_2CH_2O$), 70.48 (OCH_2CH_2O), 70.51 (OCH_2CH_2O). μ_{max}: 1115, 1455, 1654, 2925, 3315, 3521 cm^{-1}. Found, HRMS m/z 415.315367 $(M+Na)^+$. $C_{20}H_{44}N_2O_5Na$ requires 415.314793, $\Delta = 1.38$ ppm.

4.4. 1,17-Di(tert-butylamino)-3,6,9,12-tetraoxatetradecane (*12*)

By using a similar procedure to that for **18** with **46** (2.46 g, 6.76×10^{-3} mol), *tert*-butyl amine (10.00 g,

1.37×10^{-1} mol), powdered NaOH (0.54 g, 1.35×10^{-2} mol) and THF (30 mL), **12** was isolated as a clear orange liquid (1.63 g, 69%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.02 (s, 18H, $2 \times (CH_3)_3C$), 1.41 (br s, 2H, $2 \times NH$), 2.65 (t, 4H, $2 \times NHCH_2$) 3.57 (m, 16H, $4 \times OCH_2CH_2O$). ^{13}C NMR ($CDCl_3$) δ (ppm): 28.83 ($2 \times (CH_3)_3C$), 41.86 ($2 \times NHCH_2$), 49.84 ($2 \times (CH_3)_3C$) 70.09 (OCH_2CH_2O), 70.35 (OCH_2CH_2O), 70.45 (OCH_2CH_2O), 71.31 (OCH_2CH_2O). μ_{max}: 1107, 1467, 1639, 2947, 3321, 3546 cm^{-1}. Found, HRMS *m/z* 371.289013 $(M+Na)^+$. $C_{18}H_{40}N_2O_4Na$ requires 371.288578, $\Delta = 1.17$ ppm.

4.5. 1,17-Di(tert-butylamino)-3,6,9,12,15-pentaoxaheptadecane (16)

This compound was prepared in a similar fashion to **18** using **47** (2.76 g, 6.76×10^{-3} mol), *tert*-butyl amine (10.00 g, 1.37×10^{-1} mol), powdered NaOH (0.54 g, 1.35×10^{-2} mol) and THF (30 mL), yielding a **16** as a clear orange liquid (1.91 g, 72%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.09 (s, 18H, $2 \times (CH_3)_3C$), 2.73 (t, 4H, $2 \times NHCH_2$) 2.91 (br s, 2H, $2 \times NH$), 3.62 (m, 20H, $5 \times OCH_2CH_2O$). ^{13}C NMR ($CDCl_3$) δ (ppm): 28.65 ($2 \times (CH_3)_3C$), 41.89 ($2 \times NHCH_2$), 50.38 ($2 \times (CH_3)_3C$) 70.04 (OCH_2CH_2O), 70.17 (OCH_2CH_2O), 70.68 (OCH_2CH_2O), 70.97 (OCH_2CH_2O), 72.31 (OCH_2CH_2O). μ_{max}: 1107, 1468, 1643, 2951, 3321, 3535 cm^{-1}. Found, HRMS *m/z* 415.314869 $(M+Na)^+$. $C_{20}H_{44}N_2O_5Na$ requires 415.314793, $\Delta = 0.18$ ppm.

4.6. 1,17-Di(2-methoxyethylamino)-3,6,9,12-tetraoxatetradecane (10)

A mixture of **46** (0.84 g, 2.30×10^{-3} mol), 2-methoxy ethylamine (0.92 g, 4.60×10^{-2} mol) and powdered NaOH (0.18 g, 4.60×10^{-3} mol) in Et_2O (20 mL) were reacted similarly to that for **18** to afford a viscous orange liquid **10** (0.63 g, 78%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.93 (br s, 2H, $2 \times NH$), 2.78 (m, 8H, $4 \times NHCH_2$), 3.31 (s, 6H, $2 \times OCH_3$), 3.45 (t, 4H, $2 \times CH_3OCH_2$), 3.71 (m, 16H, $4 \times OCH_2CH_2O$). ^{13}C NMR ($CDCl_3$) δ (ppm): 49.19 ($2 \times NHCH_2$), 49.22 ($2 \times NHCH_2$), 58.68 ($2 \times CH_3O$), 70.29 (OCH_2CH_2O), 70.45 (OCH_2CH_2O), 70.51 (OCH_2CH_2O), 70.59 (OCH_2CH_2O), 72.04 (OCH_2CH_2O). μ_{max}: 1114, 1456, 1656, 2873, 3332, 3568 cm^{-1}. Found, HRMS *m/z* 375.247659 $(M+Na)^+$. $C_{16}H_{36}N_2O_6Na$ requires 375.247107, $\Delta = 1.47$ ppm.

4.7. 1,17-Di(2-methoxyethylamino)-3,6,9,12,15-pentaoxaheptadecane (14)

A procedure analogous to that for **18** using powdered NaOH (0.98 g, 2.46×10^{-2} mol), 2-methoxy ethyl amine (18.39 g, 2.45×10^{-1} mol), **47** (5.00 g, 1.23×10^{-2} mol), and Et_2O (50 mL) afforded **14** as a viscous orange liquid (1.65 g, 34%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.91 (br s, 2H, $2 \times NH$), 2.78 (m, 8H, $4 \times NHCH_2$), 3.32 (s, 6H, $2 \times OCH_3$), 3.46 (t, 4H, $2 \times CH_3OCH_2$), 3.62 (m, 20H, $5 \times OCH_2CH_2O$). ^{13}C NMR ($CDCl_3$) δ (ppm): 49.20 ($2 \times OCH_3$), 53.94 ($2 \times NHCH_2$), 58.66 ($2 \times CH_3O$), 70.20 (OCH_2CH_2O), 70.26 (OCH_2CH_2O), 70.42 (OCH_2CH_2O), 70.49 (OCH_2CH_2O), 70.56 (OCH_2CH_2O), 72.02 (OCH_2CH_2O). μ_{max}: 1117, 1456, 1655, 2875, 3329, 3531 cm^{-1}. Found, HRMS *m/z* 419.271333 $(M+Na)^+$. $C_{18}H_{40}N_2O_7Na$ requires 419.273217, $\Delta = 4.49$ ppm.

4.8. 3,6,9,12,15-Pentaoxaheptadecane 1,17-di(n-butylcarbamato) barium (II) (19)

Barium metal (0.25 g, 1.79×10^{-3} mol) was added to dry EtOH (30 mL) under N_2. Over a period of 5 min, the Ba metal dissolved with evolution of H_2. The solvent was then removed with a mechanical vacuum, with the solid being further dried at reduced pressure for an additional 3 h. The white solid was then dissolved in dry dichloromethane (30 mL) and **18** (0.77 g, 1.97×10^{-3} mol) was added. CO_2 was passed over the solution until its uptake was no longer evident. The solvent was then evaporated off and hexane (30 mL) added. The resulting precipitate was filtered off and dried in vacuo to deliver a tan solid **19** (1.18 g, 98%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 0.91 (t, 6H, $2 \times CH_3CH_2$), 1.35 (sextet, 4H, $2 \times CH_3CH_2$), 1.47 (p, 4H, $2 \times CH_2CH_2CH_3$), 2.60 (t, 4H, $2 \times CH_2CH_2CH_2CH_3$), 2.78 (t, 4H, $2 \times NHCH_2$), 3.65 (m, 20H, $5 \times OCH_2CH_2O$). μ_{max}: 1467, 1546, 1651, 2865, 2924, 3412 cm^{-1}.

4.9. 3,6,9,12-Tetraoxatetradecane 1,17-di(2-methoxyethylcarbamato) barium (II) (11)

Use of **10** (0.50 g, 1.42×10^{-3} mol), BaH_2 (0.18 g, 1.28×10^{-3} mol), EtOH (20 mL), dichloromethane (20 mL), hexane (20 mL), and CO_2 in a manner similar to that described for **19** gave **11** as a pale yellow solid (0.57 g, 78%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.93 (br s, 2H, $2 \times NH$), 2.78 (m, 8H, $4 \times NHCH_2$), 3.31 (s, 6H, $2 \times OCH_3$), 3.45 (t, 4H, $2 \times CH_3OCH_2$), 3.71 (m, 16H, $4 \times OCH_2CH_2O$). μ_{max}: 1464, 1543, 1644, 2854, 2951, 3455 cm^{-1}.

4.10. 3,6,9,12,15-Pentaoxaheptadecane 1,17-di(2-methoxyethylcarbamato) barium (II) (15)

A synthetic procedure similar to that for **19** delivered from Ba metal (0.49 g, (3.58×10^{-3} mol), EtOH (30 mL), **14** (1.54 g, 3.89×10^{-3} mol), CH_2Cl_2 (30 mL), CO_2 and hexane (30 mL), a pale yellow solid **15** (1.89 g, 85%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 2.80 (m, 8H, $4 \times NHCH_2$), 3.35 (s, 6H, $2 \times OCH_3$), 3.48 (t, 4H, $2 \times CH_3OCH_2$), 3.64 (m, 20H, $5 \times OCH_2CH_2O$). μ_{max}: 1462, 1547, 1643, 2854, 2923, 3426 cm^{-1}.

4.11. 3,6,9,12-Tetraoxatetradecane 1,17-di(tert-butylcarbamato) barium (II) (13)

A procedure similar to **19** using **12** (1.00 g, 2.87×10^{-3} mol), Ba metal (0.36 g, 2.58×10^{-3} mol), EtOH

(30 mL), dichloromethane (30 mL), hexane (30 mL) and CO_2 delivered **13** as a light brown solid (1.17 g, 81%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.07 (s, 18H, $2\times(CH_3)_3C$), 2.69 (t, 4H, $2\times NHCH_2$) 3.63 (m, 16H, $4\times OCH_2CH_2O$). μ_{max}: 1098, 1459, 1654, 2935, 3317, 3555 cm^{-1}.

4.12. 3,6,9,12,15-Pentaoxaheptadecane 1,17-di(tert-butylcarbamato) barium (II) (17)

By following a procedure similar to that for **19** using **16** (1.00 g, 2.55×10^{-3} mol), Ba metal (0.36 g, 2.58×10^{-3} mol), EtOH (30 mL), dichloromethane (30 mL), hexane (30 mL) and CO_2 **17** was isolated as a light brown solid (1.40 g, 89%). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.12 (s, 18H, $2\times(CH_3)_3C$), 2.77 (t, 4H, $2\times NHCH_2$), 3.67 (m, 20H, $5\times OCH_2CH_2O$). μ_{max}: 1113, 1471, 1654, 2935, 3308, 3521 cm^{-1}.

4.13. Bis(methyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianoate (48)

This compound was prepared according to Kellogg et al. [47]. To a suspension of 60% NaH in mineral oil (3.23 g, 7.70×10^{-2} mol), washed three times with hexane under N_2, 100 mL of dry 1,2-dimethoxyethane (DME) was added. The solution was cooled to −30 °C and methyl 4-bromo-3-oxobutanoate [50] (15.00 g, 7.70×10^{-2} mol) in DME (50 mL) added dropwise. After stirring for 20 min at −30 °C, a solution of the disodium salt of pentaethylene glycol, made by treatment of the glycol (9.16 g, 3.84×10^{-2} mol) in DME (50 mL) with NaH (3.23 g, 7.70×10^{-2} mol) was introduced dropwise, maintaining the temperature below 0 °C. At the completion of this addition, the resulting mixture was refluxed for 16 h. Workup with dilute HCl (2 M, 50 mL), extraction with CH_2Cl_2 (3×100 mL), drying over $MgSO_4$, followed by evaporation of the solvent delivered **48** as an orange oil (9.30 g, 78%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 3.54 (s, 4H, $2\times C(=O)CH_2C(=O)$), 3.62 (m, 20H, $5\times OCH_2CH_2O$), 3.72 (s, 6H, $2\times OCH_3$), 4.18 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 45.70 ($2\times C(=O)CH_2C(=O)$), 52.13 ($2\times OCH_3$), 70.36 ($5\times OCH_2CH_2O$), 76.07 ($2\times OCH_2C(=O)$), 167.38 ($2\times CH_3OC(=O)$), 201.80 ($2\times CH_2C(=O)$). μ_{max}: 1105, 1724, 2876, 3442 cm^{-1}. Found: HRMS *m/z* 489.195732 $(M+Na)^+$. $C_{20}H_{34}O_{12}Na$ requires 489.194796, $\Delta = 1.90$ ppm.

4.14. Bis(methyl)-5,8,11,14,17,20,23-heptaoxa-3,27-dioxo-hexacosadianoate (49)

By adapting the above procedure, using methyl 4-bromo-3-oxobutanoate (1.87 g, 9.57×10^{-3} mol), NaH (2×0.40 g, $2\times9.57\times10^{-3}$ mol), hexaethylene glycol (1.35 g, 4.79×10^{-3} mol) and DME (120 mL), **49** was isolated as a brown oil (1.14 g, 46%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 3.54 (s, 4H, $2\times C(=O)CH_2C(=O)$), 3.63 (m, 24H, $6\times OCH_2CH_2O$), 3.72 (s, 6H, $2\times OCH_3$), 4.18 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 45.50 ($2\times C(=O)CH_2C(=O)$), 52.22 ($2\times OCH_3$), 70.46 ($6\times OCH_2CH_2O$), 76.16 ($2\times OCH_2C(=O)$), 167.43 ($2\times CH_3OC(=O)$), 201.86 ($2\times CH_2C(=O)$). μ_{max}: 1439, 1747, 2875, 3516 cm^{-1}. Found: HRMS *m/z* 533.224086 $(M+Na)^+$. $C_{22}H_{38}O_{13}Na$ requires 533.221011, $\Delta = 5.80$ ppm.

4.15. Bis(methyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato barium (II) (30)

Metal complexes were prepared under Schlenk conditions. To a solution of **48** (1.00 g, 2.14×10^{-3} mol) in THF (30 mL) was added BaH_2 (0.40 g, 2.85×10^{-3} mol) and the resulting suspension was heated at reflux for 12 h under N_2. Excess BaH_2 was filtered from the brown solution, the solvent was removed in vacuo, followed by the addition of hexane (30 mL). The resulting pale brown precipitate was then filtered off and dried to afford **30** as a tan powder (1.27 g, 98%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 3.28 (s, 6H, $2\times OCH_3$), 3.47 (s, 2H, $2\times C(=O)CHC(=O)$), 3.64 (br s, 20H, $5\times OCH_2CH_2O$), 4.52 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 25.55 ($2\times OCH_3$), (49.39 $2\times(C(=O)-CHC(=O))$), 68.31 ($6\times OCH_2CH_2O$), 74.21 ($2\times CH_2O-CH_2C(=O)$), 170.11 ($2\times CH_3OC(=O)$), 181.68 ($2\times CH_2C(=O)$). μ_{max}: 1478, 1634, 2952, 3433 cm^{-1}. Found: HRMS *m/z* 603.108574 (M^+). $C_{20}H_{32}O_{12}Ba$ requires 603.102438, $\Delta = 10.20$ ppm.

4.16. Bis(methyl)-5,8,11,14,17,20,23-heptaoxa-3,27-dioxo-hexacosadianato barium (II) (31)

A mixture of **49** (2.00 g, 3.91×10^{-3} mol) and BaH_2 (0.70 g, 5.07×10^{-3} mol) in THF (50 mL) was heated at reflux overnight under N_2 and then cooled to room temperature. The resulting suspension was filtered, the solvent removed under vacuum and replaced by hexane (30 mL). A dark orange powder then formed, which was isolated as **31** (2.15 g, 85%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 3.48 (s, 6H, $2\times OCH_3$), 3.61 (br s, 24H, $6\times OCH_2-CH_2O$), 3.65 (s, 2H, $2\times C(=O)CHC(=O)$), 4.35 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 25.48 ($2\times OCH_3$), (49.45 $2\times(C(=O)CHC(=O))$, 70.44 ($6\times OCH_2CH_2O$), 76.53 ($2\times CH_2OCH_2C(=O)$), 170.02 ($2\times CH_3OC(=O)$), 181.91 ($2\times CH_2C(=O)$). μ_{max}: 1107, 1446, 1648, 2921, 3455 cm^{-1}. Found: HRMS *m/z* 647.127995 (M^+). $C_{22}H_{36}O_{13}Ba$ requires 647.128243, $\Delta = -0.40$ ppm.

4.17. Bis(2-propyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianoate (34)

This compound was prepared by the successful adaptation of a procedure outlined by Chavan and co-workers [48]. Compound **48** (1.00 g, 1.96×10^{-3} mol) was added to a mixture of zinc powder (0.55 g, 8.5×10^{-3} mol) and

a catalytic quantity of I_2 in isopropanol (30 mL), which was then heated to reflux for a period of 24 h. The resulting mixture was then cooled to room temperature, and dilute HNO_3 (20 mL) was added. The organic layer was separated and the aqueous layer extracted with Et_2O (3×50 mL). The combined organic extracts were dried over $MgSO_4$, filtered, and the solvent removed in vacuo to afford **34** as a yellow oil (1.31 g, 60%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 1.26 (d, 12H, $4 \times CH_3CH$), 3.49 (s, 4H, $2 \times C(=O)CH_2C(=O)$), 3.68 (m, 20H, $5 \times OCH_2CH_2O$), 4.24 (s, 4H, $2 \times CH_2OCH_2C(=O)$), 5.04 (septet, 2H, $2 \times CH_3CH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 21.60 ($4 \times CH_3$), 46.10 ($2 \times C(=O)CH_2C(=O)$), 69.00 ($2 \times CH_3CH$)), 70.33 ($5 \times OCH_2CH_2O$), 76.06 ($2 \times OCH_2C(=O)$), 166.49 ($2 \times CH_3OC(=O)$), 201.71 ($2 \times CH_2C(=O)$). μ_{max}: 1109, 1460, 1721, 2951, 3516 cm^{-1}. Found: HRMS m/z 545.256157 $(M+Na)^+$. $C_{24}H_{42}O_{12}Na$ requires 545.256848, $\Delta = -1.20$ ppm.

4.18. Bis(3,5-cyclohexyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianoate (35)

Compound **35** was prepared according to the method described for **34**. To a solution of **48** (1.98 g, 4.24×10^{-3} mol) in toluene (10 mL) was slowly added 3,5 dimethylcyclohexanol (1.20 g, 9.32×10^{-3} mol) in toluene (10 mL), followed by zinc powder (0.55 g, 8.48×10^{-3} mol) and a catalytic quantity of I_2. The mixture was heated to reflux overnight. After cooling, 2M HNO_3 (50 mL) was added, and the mixture extracted with CH_2Cl_2 (3×75 mL), the isolated crude mixture was purified using chromatography over silica gel (CH_2Cl_2) to give **35** as a brown oil (1.85 g, 59%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 0.92 (d, 12H, $4 \times CH_3CH$), 1.49 (m, 4H, $2 \times CHCH_2CH$), 1.62 (d, 8H, $4 \times CHCH_2CH$), 1.96 (d, 4H, $4 \times CH_3CH$), 3.48 (s, 4H, $2 \times C(=O)CH_2C(=O)$), 3.63 (m, 20H, $5 \times OCH_2CH_2O$), 4.18 (s, 4H, $2 \times CH_2OCH_2C(=O)$), 4.76 (s, 2H, $2 \times OCH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 19.05 ($4 \times CH_3CH$), 30.45 ($4 \times CHCH_3$), 39.61 ($4 \times CHCH_2CH$), 39.93 ($2 \times CHCH_2CH$), 46.12 ($2 \times C(=O)CH_2C(=O)$), 70.48 ($5 \times OCH_2CH_2O$), 74.13 ($2 \times CHO$), 76.19 ($2 \times OCH_2C(=O)$), 166.47 ($2 \times CH_3OC(=O)$), 201.88 ($2 \times CH_2C(=O)$). μ_{max}: 1109, 1460, 1723, 2950, 3440 cm^{-1}. Found: HRMS m/z 681.382761 $(M+Na)^+$. $C_{34}H_{58}O_{12}Na$ requires 681.382598, $\Delta = 0.22$ ppm.

4.19. Bis(4-tert-butylcyclohexyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianoate (37)

By following a procedure similar to that for **35**, chromatography over silica gel with light petroleum/ethyl acetate eluent (5:1) afforded 1.50 g of an orange liquid (47%), **37**, from **48** (1.00 g, 4.29×10^{-3} mol), 4-*tert*-butylcyclohexanol (1.34 g, 8.58×10^{-3} mol), Zn powder (0.56 g, 8.58×10^{-3} mol) and a catalytic amount of I_2 in toluene (30 mL). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 0.83 (s, 18H, $2 \times C(CH_3)_3$), 1.07 (m, 2H, $2 \times (CH_3)_3CH$), 1.19 (m, 4H, $2 \times CHCH_2CH$), 1.58 (m, 4H, $2 \times CH_2$), 1.77 (m, 2H, $2 \times CH_2$), 2.02 (s, 4H, $2 \times CH_2$), 3.46 (s, 4H, $2 \times C(=O)CH_2C(=O)$), 3.64 (m, 20H, $5 \times OCH_2CH_2O$), 4.11 (s, 2H, $2 \times OCH$), 4.20 (s, 4H, $2 \times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 26.11 ($2 \times (CH_3)_3CH$), 27.33 ($4 \times (CH_3)_3CH$), 30.35 ($2 \times CH_2$), 31.84 ($2 \times CH_2$), 46.08 ($2 \times CH_2$), 47.34 ($2 \times C(=O)CH_2C(=O)$), 50.68 ($2 \times OCH$), 65.75 ($2 \times CH_2$), 70.90 ($5 \times OCH_2CH_2O$), 72.64 ($2 \times CHO$), 76.23 ($2 \times OCH_2C(=O)$), 166.53 ($2 \times CH_3OC(=O)$), 206.94 ($2 \times CH_2C(=O)$). μ_{max}: 1116, 1460, 1721, 2955, 3431 cm^{-1}. Found: HRMS m/z 737.442976 $(M+Na)^+$. $C_{38}H_{66}O_{12}Na$ requires 737.444649, $\Delta = 2.27$ ppm.

4.20. Bis(1-(1,3,5-trimethylbenzyl)-ethyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianoate (38)

The transesterification of **38** was performed according to the method described above. Toluene (30 mL), Zn powder (0.36 g, 5.54×10^{-3} mol), **48** (1.29 g, 2.77×10^{-3} mol) and 1-(2,4,6-trimethylphenyl)-ethanol (1.00 g, 6.09×10^{-3} mol) gave **38** after chromatography over silica gel (1:1 EtOAc/CH_2Cl_2) as a pale brown liquid (1.54 g, 76%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 1.56 (d, 6H, $2 \times CH_3CH$), 2.23 (m, 18H, $6 \times CCH_3$), 3.48 (s, 4H, $2 \times C(=O)CH_2C(=O)$), 3.65 (m, 20H, $5 \times OCH_2CH_2O$), 4.16 (s, 4H, $2 \times CH_2OCH_2C(=O)$), 6.31 (q, 2H, $2 \times CHCH_3$), 6.80 (s, 4H, $4 \times ArH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 19.39 ($4 \times ArCH_3$), 20.28 ($2 \times ArCH_3$), 45.84 ($2 \times C(=O)CH_2C(=O)$), 61.62 ($2 \times CHCH_3$), 70.49 ($5 \times OCH_2CH_2O$), 76.13 ($2 \times OCH_2C(=O)$), 129.90 ($4 \times CH$), 133.64 ($4 \times CH_3C$), 135.82 ($2 \times CH_3C$), 137.09 ($2 \times CCH$), 166.18 ($2 \times CH_3OC(=O)$), 201.73 ($2 \times CH_2C(=O)$). μ_{max}: 1109, 1452, 1724, 2874, 3482 cm^{-1}. Found: HRMS m/z 753.383791 $(M+Na)^+$. $C_{40}H_{58}O_{12}Na$ requires 753.382148, $\Delta = 2.18$ ppm.

4.21. Bis(1-(1,3,5-triisopropylbenzyl)-ethyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianoate (39)

The use of **48** (0.43 g, 9.14×10^{-4} mol), Zn powder (0.12 g, 1.83×10^{-3} mol), 1-(2,4,6-triisopropylphenyl)-ethanol (0.50 g, 2.01×10^{-3} mol) and a catalytic quantity of iodine in toluene (20 mL) according to the method described above, followed by chromatography over silica gel (1:1 EtOAc/CH_2Cl_2) gave **39** as a dark orange liquid in 54% yield (0.44 g). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 1.21 (d, 36H, $2 \times CH_3CH$), 1.65 (d, 6H, $2 \times CHCH_3$), 2.82 (septet, 6H, $6 \times (CH_3)_2CH$), 3.49 (s, 4H, $2 \times C(=O)CH_2C(=O)$), 3.64 (m, 20H, $5 \times OCH_2CH_2O$), 4.18 (s, 4H, $2 \times CH_2OCH_2C(=O)$), 6.56 (q, 2H, $2 \times CHCH_3$), 7.00 (s, 4H, $4 \times ArH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 21.98 ($2 \times CHCH_3$), 23.77 ($12 \times CH_3CHAr$), 33.96 ($6 \times CH_3CHAr$), 46.05 ($2 \times C(=O)CH_2C(=O)$), 62.65 ($2 \times CHCH_3$), 69.46 ($5 \times OCH_2CH_2O$), 76.16 ($2 \times OCH_2C(=O)$), 128.22 ($4 \times CH$), 131.50

($4\times CH_3C$), 148.19 ($6\times CH_3C$), 166.38 ($2\times CH_3OC(=O)$), 201.66 ($2\times CH_2C(=O)$). μ_{max}: 1106, 1608, 1651, 1724, 2958, 3501 cm^{-1}. Found: HRMS *m/z* 921.570555 $(M+Na)^+$. $C_{46}H_{73}O_{12}Na$ requires 921.569849, $\Delta =$ 0.80 ppm.

4.22. Bis(2-propyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato barium (II) (**6**)

Barium hydride (0.25 g, 1.76×10^{-3} mol) was added to a solution of **34** (0.80 g, 1.41×10^{-3} mol) in dry THF (70 mL) and the resulting mixture was heated to reflux overnight. Excess BaH_2 was filtered off, and the solvent removed in vacuo. Hexane (30 mL) was added to the residue, causing **6** to precipitate out as a tan powder in 65% yield. ^1H NMR: (300 MHz, $CDCl_3$) δ (ppm): 1.24 (d, 12H, $2\times CH_3CH$), 3.64 (br s, 20H, $5\times OCH_2CH_2O$), 4.63 (s, 2H, $2\times C(=O)CHC(=O)$), 4.94 (s, 4H, $2\times CH_2OCH_2C(=O)$), 5.06 (heptet, 2H, $2\times CH_3CH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 21.91 ($4\times CH_3$), 46.23 ($2\times C(=O)CH_2C(=O)$), 68.65 ($2\times CH_3CH$)), 70.48 ($5\times OCH_2CH_2O$), 76.06 ($2\times OCH_2C(=O)$), 166.50 ($2\times CH_3OC(=O)$), 202.10 ($2\times CH_2C(=O)$). μ_{max}: 1450, 1645, 2960, 3440 cm^{-1}. Found: HRMS *m/z* 659.164837 (M^+). $C_{24}H_{40}O_{12}Ba$ requires 659.164596, $\Delta = 0.40$ ppm.

4.23. Bis(methyl)-5,8,11,14,17,20,23-heptaoxa-3,27-dioxo-hexacosadianato strontium (II) (**50**)

This pale yellow solid was isolated in a manner similar to that of **6**, with **49** (0.33 g, 6.46×10^{-4} mol) and $Sr(O^iPr_2)_2$ (0.20, 9.71×10^{-4} mol) being employed as reactants in 30 mL THF (0.35 g, 91%). ^1H NMR: (300 MHz, $CDCl_3$) δ (ppm): 3.48 (s, 6H, $2\times OCH_3$), 3.61 (br s, 24H, $6\times OCH_2CH_2O$), 3.65 (s, 2H, $2\times C(=O)CHC(=O)$), 4.37 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 25.51 ($2\times OCH_3$), 49.45 ($2\times(C(=O)CHC(=O))$), 70.38 ($6\times OCH_2CH_2O$), 76.52 ($2\times CH_2OCH_2C(=O)$), 170.01 ($2\times CH_3OC(=O)$), 184.87 ($2\times CH_2C(=O)$). μ_{max}: 1111, 1438, 1660, 2930, 3423 cm^{-1}. Found, HRMS *m/z* 619.111404 $(M+Na)^+$. $C_{22}H_{36}O_{13}SrNa$ requires 619.110505, $\Delta = 1.4$ ppm.

4.24. Bis(methyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato strontium (II) (**51**)

By adapting the method described for **50**, reaction of $Sr(O^iPr)_2$ (0.30 g, 1.46×10^{-3} mol)) and **48** (0.50 g, 1.07×10^{-3} mol) afforded 0.46 g of **51** (0.45 g, 78%) as a tan solid. ^1H NMR: ($CDCl_3$) δ (ppm): 3.48 (s, 6H, $2\times OCH_3$), 3.63 (br s, 24H, $6\times OCH_2CH_2O$), 3.68 (s, 2H, $2\times C(=O)CHC(=O)$), 4.41 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 25.42 ($2\times OCH_3$), 49.63 ($2\times(C(=O)CHC(=O))$), 70.89 ($6\times OCH_2CH_2O$), 76.69 ($2\times CH_2OCH_2C(=O)$), 168.31 ($2\times CH_3OC(=O)$), 183.45 ($2\times CH_2C(=O)$). μ_{max}: 1103, 1451, 1645, 2932, 3421 cm^{-1}. Found, HRMS *m/z* 553.102597 $(M+H)^+$. $C_{20}H_{33}O_{12}Sr$ requires 553.103765, $\Delta = 2.10$ ppm.

4.25. Bis(2-propyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato strontium (II) (**42**)

This tan solid was prepared from **34** (0.50 g, 8.6×10^{-4} mol), $Sr(O^iPr_2)_2$ (0.25 g, 1.21×10^{-3} mol) and THF (30 mL) in a manner similar to that for other metal complexes described above (0.48 g, 83%). ^1H NMR: (300 MHz, $CDCl_3$) δ (ppm): 1.21 (d, 12H, $2\times CH_3CH$), 3.64 (br s, 20H, $5\times OCH_2CH_2O$), 4.61 (s, 2H, $2\times C(=O)CHC(=O)$), 4.87 (s, 4H, $2\times CH_2OCH_2C(=O)$), 5.12 (heptet, 2H, $2\times CH_3CH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 21.86 ($4\times CH_3$), 46.27 ($2\times C(=O)CH_2C(=O)$), 68.91 ($2\times CH_3CH$)), 70.48 ($5\times OCH_2CH_2O$), 76.12 ($2\times OCH_2C(=O)$), 166.93 ($2\times CH_3OC(=O)$), 201.45 ($2\times CH_2C(=O)$). μ_{max}: 1115, 1450, 1654, 2955, 3469 cm^{-1}. Found: HRMS *m/z* 609.165994 (M^+). $C_{24}H_{40}O_{12}Sr$ requires 609.166543, $\Delta = 1.00$ ppm.

4.26. Bis(4-tert-butylcyclohexyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato strontium (II) (**45**)

Reaction of $Sr(O^iPr_2)_2$ (0.30 g, 1.45×10^{-3} mol) and **37** (0.80 g, 1.08×10^{-3} mol) in THF (30 mL) afforded **45** as a pale brown solid (0.83 g, 96%). ^1H NMR: (300 MHz, $CDCl_3$) δ (ppm): 0.85 (s, 18H, $2\times C(CH_3)_3$), 1.11 (m, 2H, $2\times(CH_3)_3CH$), 1.23 (m, 4H, $2\times CHCH_2CH$), 1.51 (m, 4H, $2\times CH_2$), 1.77 (m, 2H, $2\times CH_2$), 2.03 (s, 4H, $2\times CH_2$), 3.67 (m, 20H, $5\times OCH_2CH_2O$), 4.11 (s, 2H, $2\times OCH$), 4.26 (s, 4H, $2\times CH_2OCH_2C(=O)$), 5.09 (s, 2H, $2\times C(=O)CHC(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 26.12 ($2\times(CH_3)_3CH$), 27.51 ($4\times(CH_3)_3CH$), 30.35 ($2\times CH_2$), 31.87 ($2\times CH_2$), 46.11 ($2\times CH_2$), 47.39 ($2\times C(=O)CHC(=O)$), 50.68 ($2\times OCH$), 65.83 ($2\times CH_2$), 70.97 ($5\times OCH_2CH_2O$), 72.17 ($2\times CHO$), 76.51 ($2\times OCH_2C(=O)$), 166.51 ($2\times CH_3OC(=O)$), 207.35 ($2\times CH_2C(=O)$). μ_{max}: 1107, 1465, 1721, 2930, 3432 cm^{-1}. Found: HRMS *m/z* 801.343300 $(M+H)^+$. $C_{38}H_{65}O_{12}Sr$ requires 801.354750, $\Delta = 14.00$ ppm.

4.27. Bis(methyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato calcium (II) (**52**)

Compound **52** was isolated as a tan solid from **48** (0.50 g, 1.07×10^{-3} mol), CaH_2 (0.10 g, 2.20×10^{-3} mol) and THF (30 mL) in 78% yield (0.42 g). ^1H NMR: (300 MHz, $CDCl_3$) δ (ppm): 3.31 (s, 6H, $2\times OCH_3$), 3.48 (s, 2H, $2\times C(=O)CHC(=O)$), 3.63 (br s, 20H, $5\times OCH_2CH_2O$), 4.55 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 25.55 ($2\times OCH_3$), 49.45 ($2\times(C(=O)CHC(=O))$), 69.22 ($6\times OCH_2CH_2O$), 74.22 ($2\times CH_2OCH_2C(=O)$), 170.11 ($2\times CH_3OC(=O)$), 183.56 ($2\times CH_2C(=O)$). μ_{max}: 1455, 1621, 2937, 3450 cm^{-1}. Found: HRMS *m/z* 544.113984 $(M+Ca)^+$. $C_{20}H_{32}O_{12}Ca_2$ requires 544.114558, $\Delta = 1.05$ ppm.

4.28. Bis(4-tert-butylcyclohexyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato calcium (II) (**44**)

Compound **44** was isolated from **37** (0.81 g, 1.10×10^{-3} mol), CaH_2 (0.10 g, 2.20×10^{-3} mol) and THF (30 mL). The material was washed twice with heptane to deliver a pale brown solid (0.63 g, 72%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 0.85 (s, 18H, $2\times C(CH_3)_3$), 1.09 (m, 2H, $2\times(CH_3)_3CH$), 1.21 (m, 4H, $2\times CHCH_2CH$), 1.47 (m, 4H, $2\times CH_2$), 1.77 (m, 2H, $2\times CH_2$), 1.99 (s, 4H, $2\times CH_2$), 3.70 (m, 20H, $5\times OCH_2CH_2O$), 4.11 (s, 2H, $2\times OCH$), 4.29 (s, 4H, $2\times CH_2OCH_2C(=O)$), 5.03 (s, 2H, $2\times C(=O)CHC(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 26.12 ($2\times(CH_3)_3CH$), 27.49 ($4\times(CH_3)_3CH$), 30.36 ($2\times CH_2$), 31.88 ($2\times CH_2$), 46.12 ($2\times CH_2$), 47.28 ($2\times C(=O)CHC(=O)$), 50.32 ($2\times OCH$), 65.71 ($2\times CH_2$), 71.23 ($5\times OCH_2CH_2O$), 72.17 ($2\times CHO$), 76.49 ($2\times OCH_2C(=O)$), 166.51 ($2\times CH_3OC(=O)$), 203.55 ($2\times CH_2C(=O)$). μ_{max}: 1107, 1455, 1726, 2928, 3451 cm^{-1}. Found: HRMS m/z $(M+Ca)^{2+}$ 396.181644. $C_{38}H_{64}O_{12}Ca_2$ requires 396.181932, $\Delta=-0.80$ ppm.

4.29. Bis(2-propyl)-5,8,11,14,17,20-hexaoxa-3,22-dioxo-tetracosadianato calcium (II) (**41**)

This yellow powder (0.65 g, 77%) was isolated from **34** (0.80 g, 1.5×10^{-3} mol), CaH_2 (0.10 g, 2.34×10^{-3} mol) and THF (70 mL). ^{1}H NMR: ($CDCl_3$) δ (ppm): 1.26 (d, 12H, $2\times CH_3CH$), 3.65 (m, 20H, $10\times OCH_2$), 4.11 (s, 2H, $2\times C(=O)CHC(=O)$), 4.85 (s, 4H, $2\times CH_2OCH_2C(=O)$), 4.98 (heptet, 2H, $2\times CH_3CH$). ^{13}C NMR ($CDCl_3$) δ (ppm): 21.71 ($4\times CH_3$), 47.11 ($2\times C(=O)CH_2C(=O)$), 67.85 ($2\times CH_3CH$)), 69.88 ($5\times OCH_2CH_2O$), 71.84 ($2\times OCH_2C(=O)$), 172.84 ($2\times CH_3OC(=O)$), 202.29 ($2\times CH_2C(=O)$). μ_{max}: 1111, 1467, 1731, 2930, 3449 cm^{-1}. Found, HRMS m/z 300.087342 $(M+Ca)^{2+}$. $C_{24}H_{40}O_{12}Ca_2$ requires 300.088032, $\Delta=-2.30$ ppm.

4.30. Bis-(methyl)-5,8,11,14,17,-pentaoxa-3,19-dioxo-unacosadianoate (**53**)

A similar procedure to that employed for **48** was employed [47], using methyl 4-bromo-3-oxobutanoate (22.10 g, 1.13×10^{-1} mol), tetraethylene glycol (11.02 g, 5.68×10^{-2} mol), 1,2-dimethoxyethane (200 mL) and sodium hydride (5.46 g, 2.26×10^{-1} mol) delivering 15.09 g of a viscous brown liquid (63%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 3.52 (s, 4H, $2\times C(=O)CH_2C(=O)$), 3.62 (m, 16H, $4\times OCH_2CH_2O$), 3.70 (s, 6H, $2\times OCH_3$), 4.16 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 45.48 ($2\times C(=O)CH_2C(=O)$), 52.21 (OCH_3), 70.20 ($4\times OCH_2CH_2O$), 76.11 ($2\times OCH_2C(=O)$), 167.43 ($2\times CH_3OC(=O)$), 201.86 ($2\times CH_2C(=O)$). μ_{max}: 1107, 1710, 2865, 3421 cm^{-1}. Found: HRMS m/z 445.167998 $(M+Na)^+$. $C_{18}H_{30}O_{11}Na$ requires 445.168031, $\Delta=0.10$ ppm.

4.31. Bis(2-propyl)-5,8,11,14,17-pentaoxa-3,19-dioxo-unacosadianoate (**33**)

Zn powder (1.69 g, 2.60×10^{-2} mol), **53** (5.0 g, 1.20×10^{-2} mol), isopropanol (15 mL), I_2 (0.01 g) and toluene (30 mL) were refluxed for three days. A work up procedure similar to that for other transesterifications described above afforded a free flowing orange liquid **33** (4.60 g, 78%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 1.24 (d, 12H, $4\times CH_3CH$), 3.48 (s, 4H, $2\times C(=O)CH_2C(=O)$), 3.63 (m, 16H, $4\times OCH_2CH_2O$), 4.18 (s, 4H, $2\times CH_2OCH_2C(=O)$), 5.05 (septet, 2H, $2\times CH_3CH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 21.68 ($4\times CH_3$), 46.08 ($2\times C(=O)CH_2C(=O)$), 67.58 ($2\times CH_3CH$)), 70.51 ($5\times OCH_2CH_2O$), 76.93 ($2\times OCH_2C(=O)$), 166.49 ($2\times CH_3OC(=O)$), 201.93 ($2\times CH_2C(=O)$). μ_{max}: 1115, 1718, 2933, 3543 cm^{-1}. Found: HRMS m/z 501.230143 $(M+Na)^+$. $C_{22}H_{38}O_{11}Na$ requires 501.230635, $\Delta=0.90$ ppm.

4.32. Bis(4-tert-butylcyclohexyl)-5,8,11,14,17-pentaoxa-3,19-dioxo-unacosadianoate (**36**)

A procedure similar to that above using **53** (5.00 g, 1.18×10^{-2} mol), 4-*tert*-butylcyclohexanol (4.06 g. 2.60×10^{-2} mol), Zn powder (1.69 g, 2.60×10^{-2} mol) and a catalytic amount of I_2 in toluene (30 mL), afforded a very thick viscous orange liquid (6.14 g, 75%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 0.84 (s, 18H, $2\times C(CH_3)_3$), 1.17 (m, 2H, $2\times(CH_3)_3CH$), 1.26 (m, 4H, $2\times CHCH_2CH$), 1.78 (m, 4H, $2\times CH_2$), 1.99 (m, 2H, $2\times CH_2$), 2.14 (s, 4H, $2\times CH_2$), 3.45 (s, 4H, $2\times C(=O)CH_2C(=O)$), 3.67 (m, 16H, $4\times OCH_2CH_2O$), 4.11 (s, 2H, $2\times OCH$), 4.20 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 25.29 ($2\times(CH_3)_3CH$), 27.33 ($4\times(CH_3)_3CH$), 30.36 ($2\times CH_2$), 32.40 ($2\times CH_2$), 46.08 ($2\times CH_2$), 47.35 ($2\times C(=O)CH_2C(=O)$), 50.65 ($2\times OCH$), 65.73 ($2\times CH_2$), 70.19 ($4\times OCH_2CH_2O$), 71.01 ($2\times CHO$), 76.49 ($2\times OCH_2C(=O)$), 166.51 ($2\times CH_3OC(=O)$), 201.91 ($2\times CH_2C(=O)$). μ_{max}: 1117, 1463, 1725, 2970, 3451 cm^{-1}. Found: HRMS m/z 693.416948 $(M+Na)^+$. $C_{36}H_{62}O_{11}Na$ requires 693.418426, $\Delta=2.10$ ppm.

4.33. Bis(2-propyl)-5,8,11,14,17-pentaoxa-3,19-dioxo-unacosadianato calcium (II) (**40**)

To a solution of **33** (0.50 g, 1.04×10^{-3} mol) in THF (30 mL), freshly made $Ca(O^iPr)_2$ (0.20 g, 1.26×10^{-3} mol) was added. The resulting mixture was refluxed overnight, filtered, and the product precipitated from hexane (30 mL) to afford **40** as a pale brown solid (0.55 g, 50%). ^{1}H NMR: (300 MHz, $CDCl_3$) δ (ppm): 1.21 (d, 12H, $4\times CH_3CH$), 3.64 (m, 16H, $4\times OCH_2CH_2O$), 4.18 (s, 4H, $2\times CH_2OCH_2C(=O)$), 4.87 (s, 2H, $2\times C(=O)CHC(=O)$), 5.07 (septet, 2H, $2\times CH_3CH$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 21.73 ($4\times CH_3$), 47.21 ($2\times C(=O)CHC(=O)$), 67.55 ($2\times CH_3CH$), 70.55 ($5\times OCH_2CH_2O$),

76.93 ($2\times OCH_2C(=O)$), 166.49 ($2\times CH_3OC(=O)$), 201.95 ($2\times CH_2C(=O)$). μ_{max}: 1115, 1718, 2951, 3535 cm^{-1}. Found: HRMS *m/z* 536.170747 $(2M+Ca)^{2+}$. $C_{44}H_{72}O_{22}Ca_3$ requires 536.169012, $\Delta = 3.10$ ppm.

4.34. Bis(4-tert-butylcyclohexyl)-5,8,11,14,17-pentaoxa-3,19-dioxo-unacosadianato calcium (II) (**43**)

This compound was prepared in a manner similar to that for **40** using **36** (0.50 g, 7.45×10^{-4} mol), THF (30 mL), $Ca(O^iPr)_2$ (0.15 g, 9.47×10^{-4} mol) to afford **43** as a dark yellow powder (0.53 g, 68%). ^1H NMR: (300 MHz, $CDCl_3$) δ (ppm): 0.84 (s, 18H, $2\times C(CH_3)_3$), 1.15 (m, 2H, $2\times(CH_3)_3CH$), 1.28 (m, 4H, $2\times CHCH_2CH$), 1.78 (m, 4H, $2\times CH_2$), 1.99 (m, 2H, $2\times CH_2$), 2.19 (s, 4H, $2\times CH_2$), 3.49 (s, 2H, $2\times C(=O)CHC(=O)$), 3.71 (m, 16H, $4\times OCH_2CH_2O$), 4.10 (s, 2H, $2\times OCH$), 4.20 (s, 4H, $2\times CH_2OCH_2C(=O)$). ^{13}C NMR (76.6 MHz, $CDCl_3$) δ (ppm): 25.30 ($2\times(CH_3)_3CH$), 27.45 ($4\times(CH_3)_3CH$), 30.50 ($2\times CH_2$), 32.43 ($2\times CH_2$), 46.12 ($2\times CH_2$), 47.50 ($2\times C(=O)CH_2C(=O)$), 50.81 ($2\times OCH$), 65.73 ($2\times CH_2$), 70.21 ($4\times OCH_2CH_2O$), 71.01 ($2\times CHO$), 76.51 ($2\times OCH_2C(=O)$), 166.51 ($2\times CH_3OC(=O)$), 204.37 ($2\times CH_2C(=O)$). μ_{max}: 1111, 1465, 1710, 2965, 3451 cm^{-1}. Found: HRMS *m/z* 728.357415 $(2M+Ca)^{2+}$. $C_{72}H_{120}O_{22}Ca_3$ requires 728.356902, $\Delta = 0.70$ ppm.

Abstract

The rates of base catalysed hydrolysis of six *asym*-$[Co(dmptacn)X]^{n+}$ and six *asym*-$[Co(dmpmetacn)X]^{n+}$ complexes ($X = Br^-$, NO_3^-, $MeSO_3^-$, $CF_3SO_3^-$, Me_2SO, SO_4^{2-}) have been studied to explore the role of the leaving group and the formal charge on these complex ions in determining the effective site of deprotonation, at one of the four distinct α-CH_2 pyridyl sites or at an NH centre. The work corroborates the new pseudo-aminate mechanism established for the chloro derivatives. Deuterium exchange and proton NMR experiments have shown that the site of deprotonation is leaving group dependent, the first time this long-standing speculative idea has been proven. This work has also shown that the effect of improving the leaving group can override rate limiting deprotonation to the point where NH deprotonation, via the normal S_N1CB mechanism, operates rather than the rate limiting pseudo-aminate mechanism. The steric course of substitution has been determined and the reaction via NH deprotonation, enforced by employing an exceptionally good leaving group such as the triflate ion, has uncovered a non-retentive pathway leading to the previously unknown (and unstable) *sym* isomeric product. The steric course of substitution is shown to be mechanism dependent. For reaction via α-CH_2 deprotonation, which of the two arms is utilised proved quite leaving group dependent, although the specific proton on a particular 'arm' was always the same, consistent with the requirements of this new mechanism.

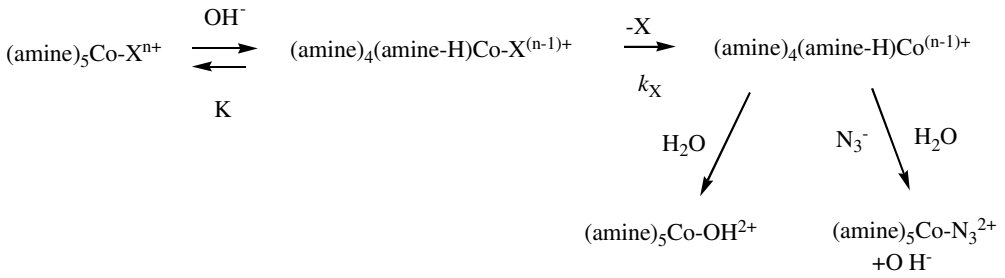
1. Introduction



When a $[(amine)_5CoX]^{n+}$ or $[(en)_2ACoX]^{n+}$ species is reacted in aqueous base containing a competing nucleophile such as N_3^-, both hydroxo and azido products are formed [1,2]. The relative amounts, and their stereochemistry, are closely independent of the nature of the leaving group [3–6], consistent with a mechanism that does not involve X at the product determining stage (Scheme 1).

Careful product distribution studies, however, have shown a slight but real dependence on the nature of X (and its charge) [7,8]. This has been interpreted in terms of a very short-lived five coordinate intermediate, in which X remains present in the ionic atmosphere; others believe there are no intermediates [8]. Another explanation is that base hydrolysis proceeds not by NH deprotonation at a single site but rather at multiple sites, in which case the relative rates of the alternative processes depend upon the leaving group X even if genuine pentacoordinate intermediates are involved, and the product distribution will accordingly reveal a leaving group dependence.

One approach to the resolution of this problem has been the design of complexes that bear a single NH centre [3,9]. This led to the examination of the *asym*-$[Co(dmptacn)Cl]^{2+}$ ion [10] and earlier [11] the *asym*-$[Co(dmpmetacn)Cl]^{2+}$ derivative (Figs. 1 and 2). Remarkably, for both ions base catalysed substitution of Cl^- was found to occur via deprotonation at an α-CH_2 centre, even for the dmptacn complex which bears a potentially deprotonatable NH site. Moreover, deprotonation proved to be rate limiting. Since normal base hydrolysis involves the cleavage of the

Scheme 1. The 'normal' S_N1CB mechanism for base catalysed substitution.

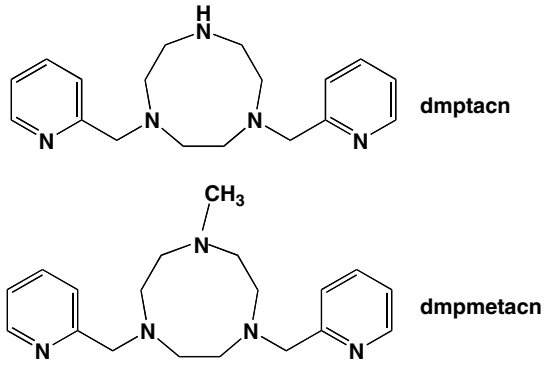

Fig. 1. Ligand structures.

metal-leaving group bond as the rate determining step, it was reasoned that improving the leaving group could force the *asym*-$[Co(dmptacn)X]^{n+}$ complex to base hydrolyse via the normal S_N1CB process, i.e., through deprotonation at NH rather than at the $-CH_2-$ centre.

Herein, we report the base hydrolysis kinetics, proton exchange experiments and product distributions for the reactions of a range of *asym*-$[Co(dmptacn)X]^{n+}$ and *asym*-$[Co(dmpmetacn)X]^{n+}$ complexes ($X = Cl^-$, Br^-, NO_3^-, SO_4^{2-}, Me_2SO, $CH_3SO_3^-$, $CF_3SO_3^-$) to explore the role of the leaving group in controlling the effective site of deprotonation in base catalysed substitution.

2. Experimental

All chemicals were AnalaR or an equivalent grade. Carbon-13 and proton NMR spectra were recorded with a Varian Unity Plus 400 MHz instrument at 20 °C. Solvents used were D_2O with dioxane as the internal reference (^{13}C, δ 69.27 relative to NaDSS), and Me_2SO-d_6 with the central peak of the CD_3 septet as the reference (^{13}C, δ 39.37 relative to $SiMe_4$). Full visible absorption spectra and absorbance–time traces were recorded with a HP8453 diode array vis–UV spectrophotometer thermostated to 25.00 ± 0.05 °C with use of a Lauda RM6 circulating water bath. Cation exchange media used were Dowex 50Wx2 (H^+ form, 200–400 mesh; Biorad) and SP-Sephadex C25 (Na^+ form; Pharmacia). Carbon dioxide free Milli-Q water was used for all physical measurements.

2.1. Complexes

The dmptacn and dmpmetacn complexes were prepared by identical methods as now described for dmptacn. The methyl ligand derivatives tended to be less water soluble. The complexes were characterised by elemental analyses (Table 1S), ^1H (Table 2S) and ^{13}C (Table 3S) NMR, and visible–UV (Table 4S) spectroscopy.

2.1.1. Asym-[Co(dmptacn)Cl](ClO4)2 and asym-[Co(dmptacn)OH2](ClO4)3

These were prepared and characterised as described previously [11]. The chloro complexes were converted to Cl^- salts by ion exchange on Dowex 50WX2 (H^+ form, 200–400 mesh) using a 0.1 M HCl wash, elution with 4 M HCl and rota-evaporation to dryness.

2.1.2. Asym-[Co(dmptacn)OS(CF3)O2](ClO4)2

Asym-[Co(dmptacn)Cl]Cl_2 (5 g) added slowly to neat CF_3SO_3H (25 mL; MMM Co., or Aldrich) was heated on

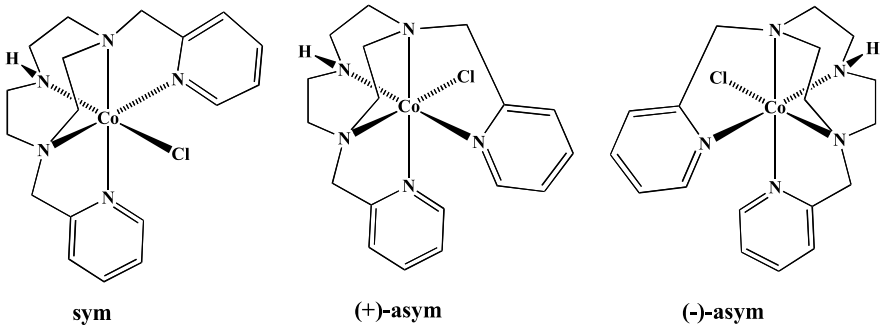

Fig. 2. The two geometric isomers of $[Co(dmptacn)Cl]^{2+}$, showing the enantiomers of the *asym* form.

a steam bath for 2 h while gently purging with dry N_2. The cooled product mixture was slowly poured into ice cold ether (800 mL), while well stirred. The resultant pink–orange solid was collected, washed with ether, dried and recrystallised from a minimum volume of water (ca. 20 °C) by filtering and diluting with a fifth volume of 5 M $HClO_4$ (50:50 ice/72% $HClO_4$). The crystals of *asym*-[Co(dmptacn)$OS(CF_3)O_2$]$(ClO_4)_2$ that deposited rapidly were collected, washed with ethanol and ether, and air dried. Yield: 7.2 g, 95%.

2.1.3. *Asym*-[Co(dmptacn)Br]$(ClO_4)_2$

This was prepared by heating *asym*-[Co(dmptacn)OH_2]$(ClO_4)_3$ (1 g) or *asym*-[Co(dmptacn)$OS(CF_3)O_2$]$(ClO_4)_2$ (1.5 g) in HBr (48%, 15 mL) on a steam bath for 3 h. The product was crystallised directly through the addition of 72% $HClO_4$ (5 mL), and recrystallised to purity from water as described for the triflato complex. Yield: 85%.

2.1.4. *Asym*-[Co(dmptacn)OSO_3H]$ZnCl_4$

Asym-[Co(dmptacn)$OS(CF_3)O_2$]$(ClO_4)_2$ (1.5 g) was reacted at ambient temperature in H_2SO_4 (15 mL, 98%) for 5 days. The crude product was purified by dilution with ice (200 g), absorption on and elution (f M HCl) from Dowex. The first band was the 1 + sulfato species which was crystallised by rotaevaporation of the HCl at <40 °C. It was recrystallised from a minimum volume of water by adding a fifth volume of 2 M 'H_2ZnCl_4' (2 M $ZnCl_2$ in 5 M HCl) and careful addition of iso–propanol. The red-purple crystals were collected, washed with iso–propanol and ether and air dried. Yield: 65%.

2.1.5. *Asym*-[Co(dmptacn)$OSMe_2$]$(ClO_4)_3$

Asym-[Co(dmptacn)$OS(CF_3)O_2$]$(ClO_4)_2$ (1.5 g) was heated for 30 min in Me_2SO (15 mL) at 60 °C and then cooled and poured slowly into ether (300 mL) containing *iso*–propanol (20 mL). The crude pink *asym*-[Co(dmptacn)-$OSMe_2$]$^{3+}$ salt so obtained was recrystallised from water as the perchlorate, as described for the triflato complex. Yield: 90%.

2.1.6. *Asym*-[Co(dmptacn)$OS(CH_3)O_2$]$(ClO_4)_2$

This was prepared and purified as described for the Me_2SO complex but using neat CH_3SO_3H (20 mL; Aldrich) as solvent and a longer reaction time (3 h). Yield: 85%.

2.1.7. *Asym*-[Co(dmptacn)ONO_2]$(ClO_4)_2$

Finely divided *asym*-[Co(dmptacn)Cl]Cl_2 (1 g) was stirred in 5 M HNO_3 (20 mL), which had been saturated with $Hg(NO_3)_2$, for 4 days at ambient temperature. Perchloric acid (5 mL) was added to the resultant suspension, and the mixture chilled for several hours. The collected product was recrystallised from water as described for the triflato complex. Yield: 74%.

2.1.8. d_4-*Asym*-[Co(dmptacn)$OS(CF_3)O_2$]$(ClO_4)_2$

This was synthesised from the perdeuterated chloro complex d_4-*asym*-[Co(dmptacn)Cl]Cl_2 as described for the normal triflato species. There was no H/D exchange observed under the conditions.

2.2. Recovery

All these expensive ligand complexes were recovered after all the physical measurements by ion exchange on Dowex; digestion of the combined eluates (in 3–4 M HCl) in neat triflic acid, after removal of the HCl through rota-evaporation, converted everything cleanly to the triflato complex which was isolated as described above. The deuterated complexes required back exchanging in 1 M NaOH prior to this treatment.

2.3. Buffer solutions

The buffers employed consisted of ethanolamine (0.40 M) solutions that had been partly neutralized (0.1–0.9 equiv.) with HCl, with the ionic strength adjusted to 2.00 M with NaCl. They were diluted 1:1 for use. The pH determinations were performed as described previously [10].

2.4. Hydrolysis kinetics

The kinetics of base hydrolysis were measured in a series of ethanolamine buffers employed previously [11,10,12] and also in NaOH/NaCl ($I = 1.0$ M) at 25.00 ± 0.05 °C. Spectrophotometric data were collected as full spectra (650–300 nm) versus time, in triplicate, and analysed as described previously. Sharp isosbestic points were observed for all reactions. Runs were performed in triplicate and at several pH values, and the results k(obsd)/[OH^-] averaged to provide k_{OH} data. The first order rates of acid hydrolysis were determined spectrophotometrically for the two triflate complexes in 0.1 M CF_3SO_3H by well established methods. Sharp isosbestic points were observed at 395, 440 and 544 nm for the base hydrolysis of *asym*-[Co(dmpmetacn)-$OS(CF_3)O_2$]$^{2+}$, and at 438 and 503 nm for acid hydrolysis. For the *asym*-[Co(dmptacn)$OS(CF_3)O_2$]$^{2+}$ complex in acid hydrolysis, the isosbestic points in acid were similar, at 432 and 504 nm.

2.5. Proton exchange

Samples (0.10 g) of [Co(dmptacn)X]$(ClO_4)_n$ and [Co-(dmpmetacn)X]$(ClO_4)_n$ ($X = CF_3SO_3^-, Me_2SO, CH_3SO_3^-$) were reacted in D_2O/0.1 M NaOD (20 mL) for ca. 3 s at 25 °C using an inverted Y-tube method (thermally pre-equilibrated Co in 10 mL of D_2O in one arm, 10 mL of 0.2 M NaOD in the other) and then rapidly acid quenched with 1 M $HClO_4$ (10 mL). Product (*asym*-[Co(dmptacn)-OH_2]$(ClO_4)_3$ or *asym*-[Co(dmpmetacn)OH_2]$(ClO_4)_3$) and recovered reactant were separated and isolated as described previously [11], and their ^1H and ^{13}C NMR spectra were recorded in Me_2SO-d_6. For several of the complexes the reactant was completely consumed and only the product (*asym–sym*-OH) was isolatable, as the aqua complex

mixture. In some cases the aqua product was converted back to the chloro species in hot HCl (4 h, 90 °C), or more conveniently by solid state anation (125 °C, 1 h) of $[CoL(OH_2)]Cl_3$ obtained directly off the ion exchange column after rotaevaporation of the HCl (L = dmptach or dmpmetacn); control experiments established that there was no H/D exchange under either set of conditions. The materials so obtained were routinely recrystallised from water as the perchlorate salts.

Control experiments were conducted on samples of *asym*-$[CoL(OH_2)](ClO_4)_3$ reacted in D_2O/OD^- for identical time periods.

2.6. Steric course of substitution

This was determined for each reaction by NMR as described previously [10,11]. The product was *asym*-$[Co(dmptacn)OH]^{2+}$ or *asym*-$[Codmpmetacn)OH]^{2+}$ in all cases, except for the reactions of the *asym*-$[Co(dmptacn)ONO_2]^{2+}$, *asym*-$[Co(dmptacn)OSMe_2]^{3+}$ and *asym*-$[Co(dmptacn)O_3SCF_3]^{2+}$ ions which, for the first time, revealed some *sym*-$[Co(dmptacn)OH]^{2+}$ product, Fig. 2,[1] clearly identified in both the ^1H and ^{13}C spectra as the component having exactly half the number of signals that the C_1 *asym* species showed.

3. Results and discussion

3.1. Syntheses

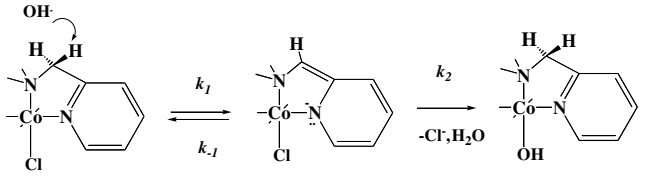
The *asym*-$[Co(dmptacn)X](ClO_4)_n$ and *asym*-$[Co(dmpmetacn)X](ClO_4)_n$ (X = Cl^-, OH_2) complexes have been fully characterised previously, through three X-ray structures and extensive 1D and 2D NMR studies [10,11,13]. There are two possible isomeric forms (Fig. 2) but until now only the *asym* form has been observed. The *asym* isomer is chiral; *asym*-$[Co(dmptacn)Cl]^{2+}$ has been optically resolved [10].

The remaining derivatives reported herein (X = $CF_3SO_3^-$, $CH_3SO_3^-$, NO_3^-, Me_2SO, Br^- and SO_4^{2-}) were synthesised by a range of established methods, with some modifications. The basic starting materials were the triflate complexes, made from the known [10,11] chloro derivatives (Cl^- salts) reacted in hot triflic acid. The isolated triflate complexes, as their triflate salts, were reacted in neat CH_3SO_3H, Me_2SO or H_2SO_4, or concentrated aqueous HBr, to give the corresponding substitution products [14], the last via anation of the first formed aqua complex [15]. The nitrato derivative was made by Hg(II) induced reaction of the chloro or bromo complex in strong NO_3^- media, analogously to the synthesis of related nitrato complexes [14]. Nitrato complexes have also been obtained by the solid state anation of the nitrate salts of the corresponding aqua species [1], or using the Ag^+ induced process for the chloro complex in strong HNO_3 [16].

3.2. Characterisation

All new compounds were analysed satisfactorily (some were hydrates; Table 1S, Supplementary data). The sulfato complexes, from aqueous 'H_2ZnCl_4', crystallised as their protonated forms which is unusual for bound sulfate, and likely reflects the propensity of $ZnCl_4^{2-}$ to selective crystallize 2+ cations. The ^1H and ^{13}C NMR spectra for all complexes (Tables 2S and 3S, Supplementary data) were clean, and indicative of the *asym* (C_1 symmetry) configuration, Fig. 2. There is the expected similarity amongst these spectra, and we note the NH resonance for the dmptacn compounds is quite X dependent. The essential characteristics of these spectra have been discussed in detail previously. The absorption maxima for the Vis–UV spectra are recorded in Table 4S, and again, they show the expected X dependence.

3.3. Acid hydrolysis of asym-$[Co(dmptacn)(OS(CF_3)O_2]^{2+}$ and asym-$[Co(dmpmetacn)(OS(CF_3)O_2)]^{2+}$



Since the discovery [15,17–20] and widespread use of the triflate ion $CF_3SO_3^-$ as a good leaving group in coordination chemistry, kinetic studies on the slower classic metal ion substitution systems, notably Cr(III), Os(III), Ru(III), Pt(IV), Co(III), Rh(III) and Ir(III), have shown that the metal-O(triflate) bond is acid hydrolysed rapidly, usually on the sec to min half-life time scale at 25 °C, and at a rate which is not especially metal ion dependent for the inert d^3 or d^6 electron configuration [7,15,17,18,21–26]. Many of these studies have involved the pentaammine complexes, $[M(NH_3)_5OS(CF_3)O_2]^{n+}$. The present study presents a quite different picture, with the *asym*-$[Co(dmptacn)OS(CF_3)O_2]^{2+}$ complex hydrolysing with a half-life of 6.9 h; the methyl-ligand derivative is even slower, $t_{1/2}$ 37 h, and clearly these rates are very slow by previously determined standards for a triflato complex. The $[Co(NH_3)_5OS(CF_3)O_2]^{2+}$ ion, for example [27,28], is 1000-fold more reactive than its dmptacn counterpart. As yet, there are no acid hydrolysis data for other leaving groups, within the tacn-derived pentadentate ligand systems, for further comparisons and analysis.

3.4. Base hydrolysis of asym-$[Co(dmpmetacn)X]^{2+}$

All seven dmpmetacn complexes must base hydrolyse by the recently discovered pseudo-aminate mechanism [11] since there are no NH protons available for the normal S_N1CB process. The origin of the base catalysis in these compounds is shown in Scheme 2.

A requirement of this mechanism is proton exchange at one of the four inequivalent α-pyridyl CH_2 protons during the act of base hydrolysis. This was demonstrated for the $[Co(dmpmetacn)Cl]^{2+}$ complex by showing that the

[1] The synthesis, characterization and kinetics of acid and base hydrolysis of the *sym* isomers will be reported separately.

Scheme 2. The pseudo-aminate mechanism for base catalysed substitution.

product for base hydrolysis in D_2O/OD^- had 1.0 D in the α-pyridyl methylenes, and that the *asym*-[Co(dmpmetacn)OD]$^{2+}$ product did not subsequently exchange at the α-CH_2 sites anywhere near rapidly enough to account for this [11]. Moreover, reactant recovered after about one $t_{1/2}$ of base hydrolysis contained negligible D, which showed that, once deprotonated, Cl^- loss was faster than reprotonation in the conjugate base intermediate ($k_2 \gg k_{-1}$; Scheme 2). This was a classic case of rate limiting deprotonation, confirmed by the large kinetic isotope effect observed (k_H/k_D ca. 4.5)

The specific rates of base hydrolysis for the seven *asym*-[Co(dmpmetacn)X]$^{n+}$ (and *asym*-[Co(dmptacn)X]$^{n+}$) complexes are presented in Table 1, along with the corresponding values [27–29] for the classic $[Co(NH_3)_5X]^{n+}$ ions. The simple pentaammine complexes clearly react via NH_3 deprotonation, although whether this is *cis*- or *trans*-X deprotonation is arguable; indeed, the deprotonation site may even be leaving group dependent. The order of reactivity is $CF_3SO_3^- > CH_3SO_3^- > Me_2SO > NO_3^- > Br^- > Cl^- > SO_4^{2-}$. For the dmpmetacn series of complexes, this order is largely retained, although the spread of values is much smaller. There are the 'slower' complexes, X = SO_4^-, Cl^- and Br^-, and the 'faster' reactants, X = NO_3^- and Me_2SO. The 'fastest' are the sulfonates, X = $CH_3SO_3^-$ and $CF_3SO_3^-$, and here there is an anomaly. The simple pentaammine complexes are more reactive, especially for the triflate ions where the rate difference exceeds 5000.

The rate comparison here is compounded by the fact that, in the pentaammine series, the deprotonation site is an NH_3 (*cis* or *trans* to the leaving group) [30,31], whereas for the dmpmetacn complexes, not only is the site of deprotonation different (at an α-pyridyl CH_2 centre), but the proton abstraction step is rate determining [11]. The variation in rate with leaving group therefore reflects the variation in acidity of the –CH_2-centre in question, whereas for the pentaammines, the observed k_{OH} value (=$k_X K$; Scheme 1) reflects both the acidity of the relevant NH_3 and the reactivity (k_X) of the conjugate base generated from it, which in turn is related to the Co–X bond strength for what are undoubtedly [5] dissociative reactions.

Sulfonates are known to enhance the acidity of *cis*-amines [32], and if the deprotonation site is at the *cis* ammine for the $[Co(NH_3)_5X]^{2+}$ complexes, as some believe [33], then this can account for the anomaly noted, with the (unsupported) assumption that the sulfonates do not affect the acidity of the α-pyridyl proton to the same extent. The other component of the anomaly is the Co–OS(CR)O_2 bond strength (R = CH_3 or CF_3). This bond has been regarded as generally weak, compared to that for other leaving groups under comparison, since in the acid hydrolysis reactions, also largely dissociative processes, the sulfonates are hydrolysed rapidly [23,24,27,28]. Consistent with this analysis, the *asym*-[Co(dmpmetacn)OS(CF_3)O_2]$^{2+}$ ion is extraordinarily unreactive in acid hydrolysis, with a $t_{1/2}$ of 37 h, compared to a $t_{1/2}$ of 29 s for [Co(NH_3)$_5$-OS(CF_3)O_2]$^{2+}$. We are, as yet, unsure of the origin of the relative inertness of the triflato complexes of the dmpmetacn and dmptacn ligands.

Table 1
Second-order rate constants (k_{OH}) for the base hydrolysis of *asym*-[Co(dmptacn)X]$^{n+}$, *asym*-[Co(dmpmetacn)X]$^{n+}$ and $[Co(NH_3)_5X]^{n+}$, I = 1.0 M (NaCl or $NaClO_4$), 25 °C

3.5. Base hydrolysis of *asym*-[Co(dmptacn)X]$^{n+}$

The regular S_N1CB mechanism (Scheme 1), for which the deprotonation–reprotonation equilibrium is fast compared to the rate of loss of X from the conjugate base, leads to the rate expression, $k_{OH} = k_X \cdot K$. Note that K *may* be X dependent but k_X certainly is, and a rough guide to the X dependence of k_X values are the acid hydrolysis rates, shown in parenthesis in Table 1. These range from 2×10^{-2} s^{-1} for $CF_3SO_3^-$ to 9×10^{-7} s^{-1} for SO_4^{2-}, a factor of ca. 2×10^4. On the other hand, for a rate limiting deprotonation mechanism (Scheme 2), $k_{OH} = k_1$, where k_1 measures the rate of proton abstraction from an active α-CH_2 site, and this is not anticipated to be strongly X dependent. For the *asym*-[Co(dmptacn)Cl]$^{2+}$ complex, the data suggested that reaction via the NH centre was negligible, perhaps at most 5% (i.e. >20:1 for the alternate reaction pathways). To switch this to, say, >1:20 would require an acceleratory factor of at least 400, for the NH over the CH deprotonation pathway. A change in the leaving group from Cl^- to $CF_3SO_3^-$ (10^4 based on k_s values, 10^6 based on k_{OH} values, Table 1) may have been sufficient to do this, but it was unlikely for any of the other leaving groups.

For the *asym*-[Co(dmptacn)X]$^{n+}$ series of complexes, the leaving group dependence of the k_{OH} values is not too dissimilar to that for the *asym*-[Co(dmpmetacn)X]$^{n+}$ series, with the dmpmetacn complexes being somewhat faster (1.2–18-fold). The glaring exception is the triflate complex of dmptacn, where the rate difference is 500-fold and in the reverse sense. Here clearly is the mechanism switch we were anticipating – from C–H deprotonation to N–H deprotonation. Indeed, the dmptacn triflato ion has close to the reactivity of the pentaammine analogue [21],[2] if one corrects for the intrinsic difference in Co-OS(CF_3)O_2 lability. The dmptacn complex is only 10-fold less reactive in base hydrolysis, but 1000-fold in acid hydrolysis, indicating that the triflate ion greatly enhances the acidity of the NH centre in the dmptacn complex (as it did for the CH centre in the dmpmetacn complex). In this sense the chemistry parallels that for other [32] [Co(pentaamine)OS(CF_3)O_2]$^{2+}$ ions.

3.6. Site of deprotonation

Previously we showed that only one particular CH proton was involved for the base catalysed hydrolysis of *asym*-[Co(dmpmetacn)Cl]$^{2+}$, and through extensive 1D and 2D NMR experiments we identified which was the one [11].

The deuteration experiments can show if the –CH– site of deprotonation varies, as the leaving group is varied, given that in the common *asym*-[Co(dmpmetacn)OH]$^{2+}$ product any differences in the CH_2 ^{1}H and ^{13}C signals would be clearly apparent, and we know [10,11] they are not scrambled amongst themselves in base.

It has been pointed out that the complex loses memory of the proton's origin because deprotonation of either proton in a particular 'arm' leads to the *same* conjugate base species, according to our pseudo-aminate mechanism [11]. Further, because the process is rate limiting, the leaving group is expelled before the conjugate base is reprotonated (Scheme 2). This means that, in OD^-/D_2O, the D can end up in one or other position (or both), irrespective of which proton was originally abstracted. By varying the leaving group this proposition can now be tested experimentally (vide infra).

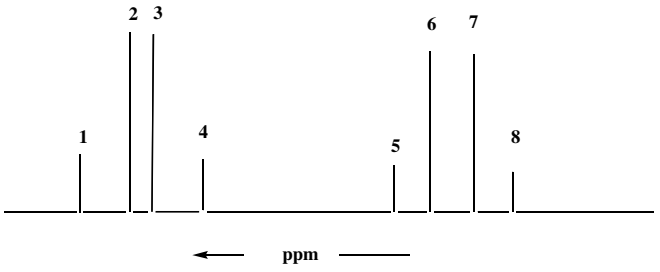
For the *asym*-[Co(dmptacn)Cl]$^{2+}$ complex the situation was similar [10] except here the loss of Cl^- from the conjugate base was competitive in rate with the rate of reprotonation, leading to a reduced kinetic isotope effect but one nonetheless that was significant, k_H/k_D ca. 2.0. The D-labelling experiments for this system were thus equivocal. However, with improved leaving groups it proved possible to increase the rate of loss of leaving group from the conjugate base to the extent that reprotonation of the conjugate base was not competitive. The reactions could be quenched at much shorter reaction times so that the subsequent exchange in the (same) *asym*-[Co(dmptacn)OH]$^{2+}$ product was no longer an issue. On the other hand, the risk was that reaction via a NH deprotonation is increased since the leaving group is much improved.

We tested four additional dmptacn complexes (X = Br^-, NO_3^-, Me_2SO, $CF_3SO_3^-$), and, as a control, two other dmpmetacn complexes (X = $CH_3SO_3^-$ and $CF_3SO_3^-$), both of which were expected to show the exchange of exactly 1.0 CH proton.

The results of deuteration studies aimed at establishing the site or sites of CH deprotonation are presented in Table 2. The results for the dmpmetacn complexes are:

(i) exactly 1.0 D is incorporated by each of the reactants,
(ii) both CH_2 sites ('arms') can be utilised simultaneously,
(iii) the proportion utilised from these two sites is leaving group dependent,
(iv) the proton which is exchanged in one or other of the 'arms' is exclusively one particular one (i.e. deprotonation is regioselective), and
(v) the protons involved are the same for all leaving groups.

The ^{1}H NMR spectra for the dmpmetacn systems are shown in Figs. 1S and 2S (Supplementary data). For X = $MeSO_3^-$ (Fig. 1S), analysis of the deuterated chloro complex derived from the aqua product reveals a 50:50 distribution of the 1.0 D between the two α-CH_2 sites. For the triflato complex, there is also 1.0 D incorporation, but predominantly at the higher field α-CH_2 site (Fig. 2S). There is an overlap of one of the residual CH protons in each of the AB quartets because of the small upfield isotopic shifts.



The results for the dmptacn complexes (Table 2) reveal exactly the same trends, although the actual α-CH_2 proton sites involved may be different (they have not all been assigned for the dmptacn complexes). The ^{1}H NMR spectra are shown for the products of base catalysed reaction of the Br^- and Me_2SO complexes in D_2O,OD^- are shown in Figs. 3S and 4S (Supplementary data). The former shows that the higher field α-CH_2 is the preferred deprotonation site (but not exclusively so), that only 1.0 D is incorporated, i.e. there is no reaction via the NH centre, and that the recovered reactant contains no D, confirming rate limiting deprotonation. The product for the reaction of the Me_2SO complex on the other hand has incorporated 0.5 D into each site.

These results show that of all these compounds hydrolyse exclusively by CH deprotonation; it is only the faster of the dmptacn (X = NO_3^- and $CF_3SO_3^-$) complex reactions that involve the NH centre to any extent. This result tends to strengthen the argument [10] for the slowest of them (X = Cl^- and SO_4^{2-}) reacting exclusively via the CH deprotonation route, even though we have not proven this using D labelling studies for these two complexes.

For 'normal' S_N1CB base hydrolysis where acidic amine centres are involved, multiple deprotonation sites can be argued to be a plausible reason for the small but real leaving group dependences of product distributions for

[2] Our experience is that the pentaamminetriflatocobalt(III) complex base hydrolyses much faster than the published data indicate.

Table 2
Fractional deuteration at the four α-CH_2 protons for the product of base catalysed hydrolysis of *asym*-$[Co(dmptacn)X]^{n+}$ and *asym*-$[Co(dmpmetacn)X]^{n+}$

[a] Reprotonation/deuteration competitive with loss of the Cl^- leaving group.
[b] This is entirely accounted for by the small amount of subsequent exchange in the product hydroxo complex (see[c]). The reaction is entirely via NH deprotonation, and the detectable amount of co-formed *sym*-$[Co(dmptacn)OH]^{2+}$ also appears to be undeuterated at the α-CH_2 sites (refer text).
[d] There is some 35% product which is not deuterated at any of the 4 α-CH_2 protons; this clearly is the NH deprotonation pathway, consistent with the appearance of some *sym*- $[Co(dmptacn)OH]^{2+}$ product together with the predominant *asym*-$[Co(dmptacn)OH]^{2+}$ (refer text).
[e] A trace of *sym*-$[Co(dmptacn)OH]^{2+}$ is also formed here, consistent with a small proportion of reaction via NH deprotonation.

reactants such as *cis*- and *trans*-$[Co(en)_2AX]^{n+}$ (where the *trans*-/*cis*-$[Co(en)_2A(OH)]^{2+}$ ratio defines the product distribution) and $[Co(NH_3)_5X]^{n+}$ ions reacted in H_2O/OH^-/N_3^- (where the $[Co(NH_3)_5N_3]^{2+}$/$[Co(NH_3)_5OH]^{2+}$ ratio defines the product distribution) [4,6]. This idea now has credence, given its clear demonstration for alternative acidic CH centres amongst *asym*-$[Co(dmptacn)X]^{n+}$ complexes (points (ii) and (iii) above), but ironically it is unlikely to be ever proven for simple pentaamine complexes unless examples of rate limiting deprotonation can be found.

Such an opportunity to test the leaving group dependence of the effective site of deprotonation has not presented itself in base hydrolysis studies, and this is the first time that it has been demonstrated.

3.7. D-exchange experiments

To confirm the switch in mechanism from CH to NH deprotonation for the base hydrolysis of the *asym*-$[Co(dmptacn)OS(CF_3)O_2]^{2+}$ complex we needed to show that all four CH_2 protons remained intact in OD^-/D_2O media.

Deuterium can be incorporated into an α-CH_2 site in more than one way. First, base catalysed H/D exchange can occur in the reactant without ligand substitution, such as happens with $[Co(tmptacn)]^{3+}$ [34]. This can mean a $[Co(dmptacn)OH]^{2+}$ product with between 0 and 4 D in the α-CH_2. This prospect can be checked by examining recovered reactant for D content in a partial base hydrolysis experiment. Second, the product hydroxo complex can exchange faster than it is formed, leading to between 1 and 4 D for base hydrolysis via α-CH_2 deprotonation, or between 0 and 4 D for reaction via NH deprotonation. Thirdly, if the rate of reprotonation of the conjugate base is comparable in rate to loss of the leaving group, the hydroxo product will still contain only 1.0 D if the same single site (1 of 4) is involved, but the magnitude of the kinetic isotope effect is reduced, as discussed previously [10]. Finally, if reaction via α-CH_2 deprotonation involves a conjugate base that reprotonates at a very slow rate compared to loss of the leaving group, the product will have exactly 1 D.

Fig. 3 shows the ^1H spectrum for the *asym*-$[Co(dmptacn)OH_2](ClO_4)_3$ complex derived from base hydrolysis of the *asym*-$[Co(dmptacn)ONO_2](ClO_4)_2$ complex in D_2O/OD^-. There is partial deuteration at both sites (much more at **b** than **a**), but less than 1.0 D in total at the methylenes; thus some undeuterated product is apparent, indicating about 35% reaction via the NH centre.

The results for the base hydrolysis of *asym*-$[Co(dmptacn)OS(CF_3)O_2]^{2+}$, the most reactive of all the complexes, are shown in Fig. 4 (and Table 2). The ^1H spectrum is that for regenerated *asym*-$[Co(dmptacn)Cl](ClO_4)_2$ complex, by HCl anation of the base hydrolysis product *asym*-d_n-$[Co(dmptacn)OD]^{2+}$, or solid state anation of *asym*-d_n-$[Co(dmptacn)OH_2]Cl_3$; control experiments showed that

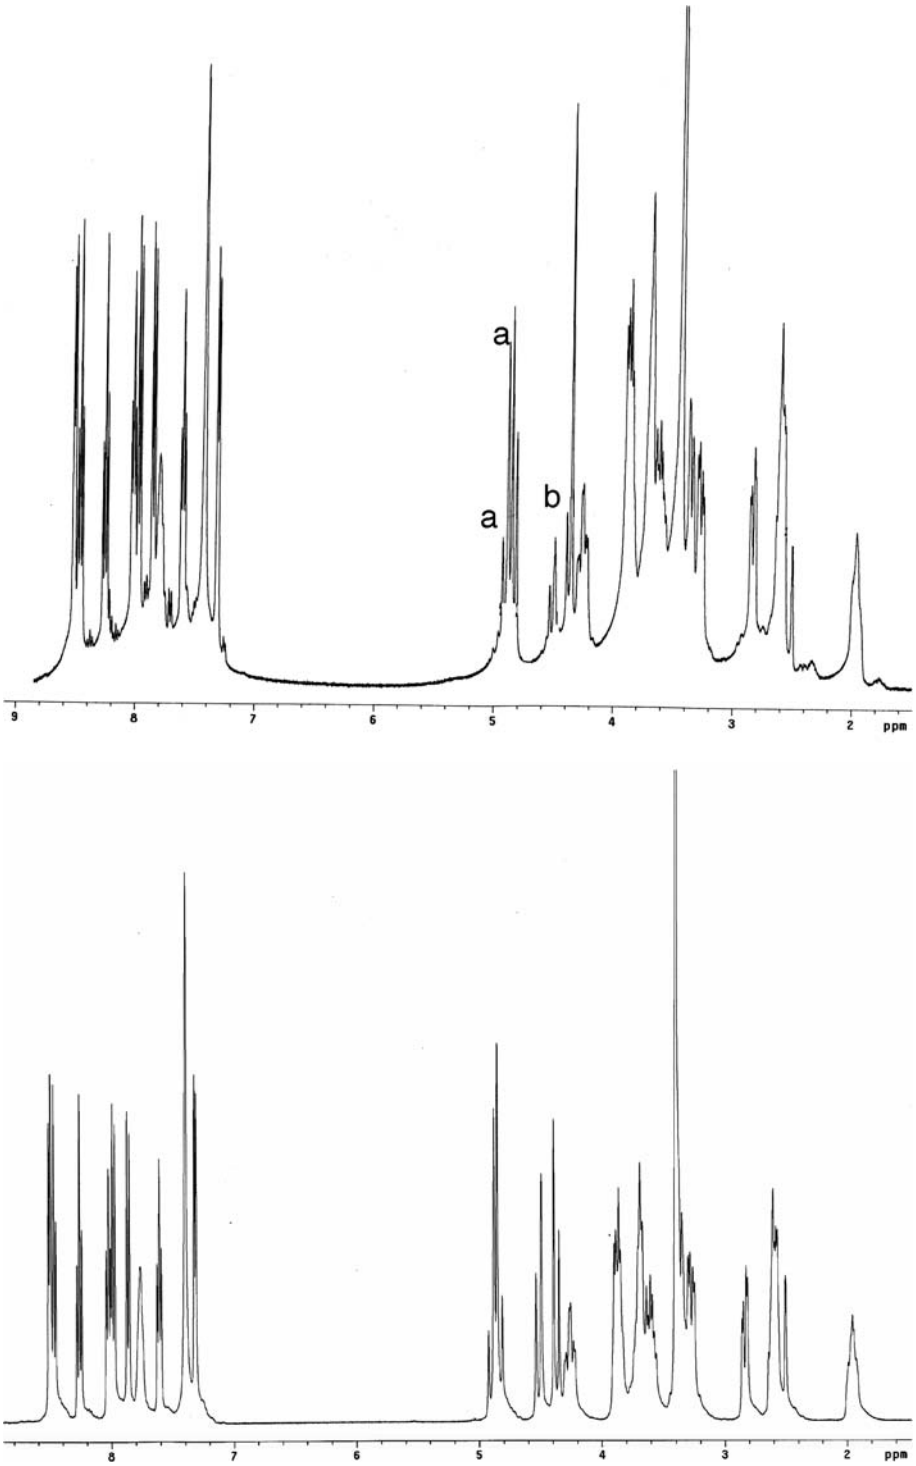

Fig. 3. Top: ^{1}H NMR spectrum of *asym*-[Co(dmptacn)OH_2]$(ClO_4)_3$ in Me_2SO-d_6 derived from the reaction of *asym*-[Co(dmptacn)ONO_2]$(ClO_4)_2$ in D_2O/OD^-: selective deuteration at the lower doublet of the upper α-CH_2 AB quartet (at b) is evident (δ ca. 4.5 ppm), leading to the CHD singlet to the right of b, and there is also a clear evidence of some undeuterated aqua product in this region since there is little deuteration at a. Bottom: the spectrum for authentic *asym*-[Co(dmptacn)OH_2]$(ClO_4)_3$.

these reactions occur without any H/D exchange at either of the –CH_2-sites. The spectrum for the authentic aqua complex is also given. The two sets of AB quartets for the α-pyridyl protons in the ^{1}H spectrum of the OD^-/D^+ cycled material are observed to be unchanged from those for authentic *asym*-[Co(dmptacn)Cl]$(ClO_4)_2$. Further, in the ^{13}C NMR spectrum (not shown) neither C signal, at δ 67.0 and 69.2 ppm, which correspond to the α-CH_2 resonances, is collapsed by D incorporation. It is concluded that the base hydrolysis reaction occurs exclusively via NH deprotonation, i.e., the normal S_N1CB mechanism. Consistent with this result, the rate of base hydrolysis

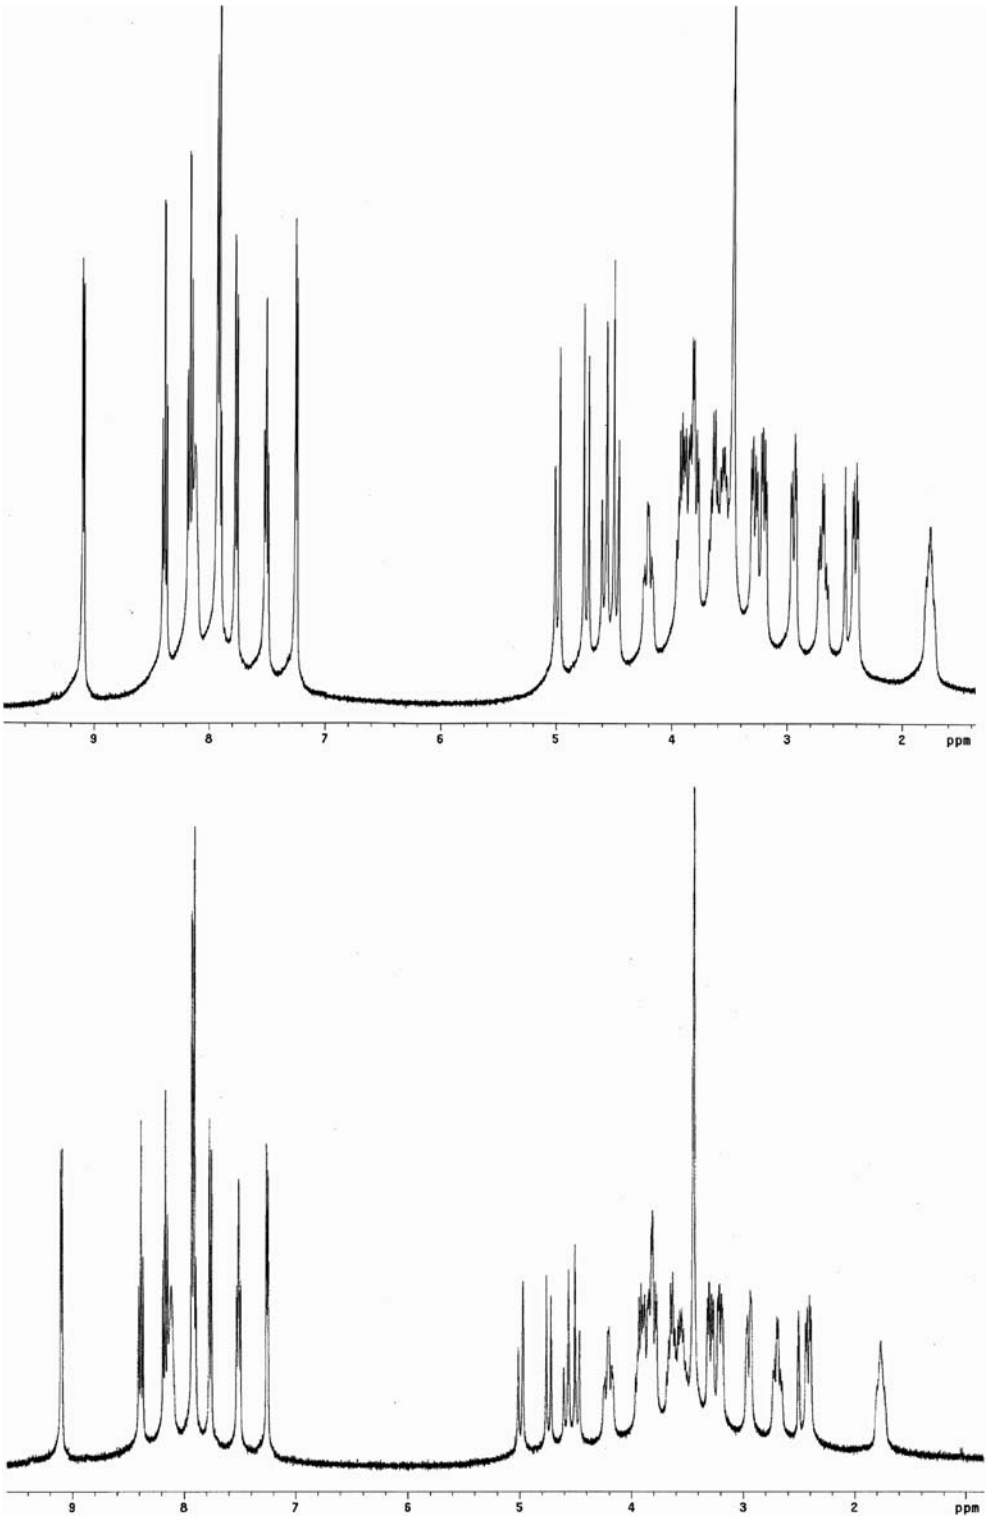

Fig. 4. ^{1}H NMR specta of *asym*-[Co(dmptacn)Cl](ClO$_4$)$_2$ in Me$_2$SO-d_6: Top: recovered from the reaction of *asym*-[Co(dmptacn)OS(CF$_3$)O$_2$](ClO$_4$)$_2$ in D$_2$O/OD$^-$ and Cl$^-$ reanation of the acidified product [Co(dmptacn)OH$_2$]$^{3+}$. Bottom: authentic *asym*-[Co(dmptacn)Cl](ClO$_4$)$_2$. No deuteration at any of the α-CH$_2$ sites (δ 4.5–5 ppm) is apparent.

of h_4-*asym*-[Co(dmptacn)OS(CF$_3$)O$_2$]$^{2+}$ and d_4-*asym*-[Co(dmptacn)OS(CF$_3$)O$_2$]$^{2+}$ measured for one particular buffer were identical, i.e. the kinetic isotope effect is zero (compare the corresponding chloro complexes where the rates differ by 100% [10]).

The reaction scheme involves a potentially reversible CH deprotonation, as believed to be so for the *asym*-[Co(dmptacn)Cl]$^{2+}$ complex, but for the [Co(dmptacn)X]$^{n+}$ species in general any observed rate comparison needs to recognise that the reprotonation reaction (k_{-1}) is common

to all species, while the loss of X from the intermediate $[Co(dmptacn\text{-}H)X]^{(n-1)+}$ ion will be strongly leaving group dependent.

3.8. Steric course of base hydrolysis

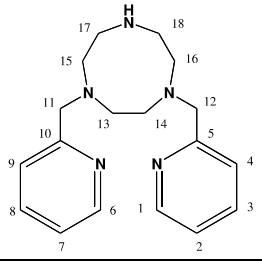
The base hydrolysis of the *asym*-$[Co(dmptacn)Cl]^{2+}$ and *asym*-$[Co(dmpmetacn)Cl]^{2+}$ complexes is completely retentive. Similarly, the optically resolved *asym*-$[Co(dmptacn)Cl]^{2+}$ ion involves a negligible loss in activity in a base hydrolysis/HCl anation cycle. Further, the regiospecifically D-labelled *asym*-$[Co(dmpmetacn)Cl]^{2+}$ ion involves no D-site scrambling in base hydrolysis. All these experiments exclude even the transient formation of the *sym* isomer (Fig. 2) en route to hydroxo product.

The base hydrolysis for all the *asym*-$[Co(dmpmetacn)X]^{n+}$ derivatives was also retentive. This fact served to highlight the anomaly now described for the corresponding dmptacn complexes. CH deprotonation is uniformly required for the dmpmetacn complexes, albeit which particular CH site is involved can depend upon the leaving group. The dmptacn complexes can however switch from CH to NH deprotonation, as this work has demonstrated, and we now report that such a switch results in a change of stereochemistry – the product for the base hydrolysis of the triflato complex is an 86:14 mixture of *asym*-/*sym*-OH – the first time a *sym* isomer has been observed in these ligand systems.

The *sym* isomer has been isolated and an independent study of the acid and base hydrolysis of *sym*-$[Co(dmptacn)Cl]^{2+}$ will be described elsewhere. We have been unable to make a *sym*-$[Co(dmpmetacn)X]^{n+}$ derivative as yet because this synthetic route does not work when the NH deprotonation mechanism is blocked through *N*-methylation.

Since we know through the D labelling experiments that the *asym*-$[Co(dmptacn)OS(CF_3)O_2]^{2+}$ complex hydrolyses entirely via NH deprotonation, we took the relative amount of *sym*-OH product in the base hydrolysis reactions of the other *asym*-$[Co(dmptacn)X]^{n+}$ complexes as a measure of what proportion of reaction went via CH deprotonation and what proportion via NH deprotonation. The results showed that only the very reactive triflato complex went via this route, although a little *sym*-OH product was observed for the NO_3^- (5%) and a trace for the Me_2SO complexes; the former translates to 35% reaction via the NH deprotonation route, if the 0% and 14% *sym*-OH product distributions truly characterise the two alternative reaction pathways, and this analysis is in accord with the D-labelling experiments (Table 2).

This important result also shows that the *asym*-$[Co(dmptacn)Cl]^{2+}$ complex does not hydrolyse via any significant NH deprotonation pathway since there is no *sym*-OH product. Some reaction via a NH deprotonation route was one of the two possibilities to account for the reduced kinetic isotope effect observed for this complex; the D labelling experiments [10] were ambiguous and could not resolve this issue.



3.9. Isotopic shifts in the ^{13}C NMR spectra

It is now well documented [35] that isotopic substitution of H by D results in readily discernible chemical shift variations in ^{13}C spectra [35]. We have utilised this in following proton exchange by ^{13}C NMR, assigning spectra, and have reported the effect for D substitution at both NH and CH centres [36–38].

Usually the replacement of NH by ND results in an upfield shift of ca.10 Hz at 100 MHz for an α-C centre. The effect is additive, and shifts (smaller) are also discernible for the β-C centre [37].

In the present work, we had occasion to examine these effects in greater detail by recording the ^{13}C NMR spectra for the unequal mixtures of d_4- and h_4-*asym*-$[Co(dmptacn)X]^{n+}$ ions ($X = Cl^-$ and OH_2), Fig. 5S (Supplementary data), and surprisingly observed both positive

Table 3
Isotopic shifts for ^{13}C signals between 1 and 5 bonds from the site of deuteration in the complexes *asym*-$[Co(dmptacn)X](ClO_4)_{2,3}$ ($X = Cl^-$, OH_2) in Me_2SO-d_6

Shifts (ppb) [a]					
Carbon	$^1\Delta$	$^2\Delta$	$^3\Delta$	$^4\Delta$	$^5\Delta$
Chloro complex

C1, C6				0, 0[b]	
C3, C8				0, 0[b]	
C2, C7					35, 30
C13, C14			115, 125[c]		
C15, C16			60, 55		
C17, C18		100, 100[e]		0, 0 [b,d]	
Aqua complex					
C11, C12	615, 700				
C5, C10		100, 95			
C4, C9			−40, −50		
C1, C6				0, 0[b]	
C3, C8				0, 0[b]	
C2, C7					35, 30
C13, C14			125, 120[d]		
C15, C16			60, 70		
C17, C18		100, 100[e]		0, 0[b,d]	

[a] Parts per billion. $^1\Delta$, $^2\Delta$ are 1-bond, 2-bond shifts, etc; e.g. for C–N–D it s a 2-bond shift; for this purpose multiple bonds are regarded as one bond. Upfield shifts are defined as positive.

[b] No special resolution techniques applied – ⩽1 Hz shifts would go undetected.

[c] These are compounded $^3\Delta$ and $^4\Delta$ shifts, but largely $^3\Delta$.

[d] Shift for C–D.

[e] Shift for N–D.

and negative shifts, the magnitude of which were not linearly correlated with the type of C nor the location of D substitution. Note that the shifts are for a 2D substitution at an α-CH_2; the numbers would be halved for a 1D substitution.

The shift results are summarised in Table 3. These data are for spectra run at normal rather than enhanced resolution; shifts of $\leqslant$1 Hz would not have been resolved.

A significant result is that the isotopic shifts can be carried across 5 or 6 bonds where the intervening C-backbone is aromatic, and the shifts are of both signs. For the saturated tacn part of the molecules, the shifts are all positive, and rapidly fall off with distance. It is not understood why the C13 and C14 shifts are twice as large as those for C15 and C16 that are also three bonds from the D. Possibly the C13 and C14 shifts are compounded by the 3-bond and 4-bond D substitution, although there is no evidence for a 4-bond shift for either C17 or C18.

A new approach to the relationship between bond energy and electronegativity

Derek W. Smith

Abstract

The familiar equation whereby Pauling related heteronuclear bond energies $D_{A–B}$ to the electronegativity difference $\Delta\chi$ ($=|\chi_A - \chi_B|$) and the homonuclear bond energies $D_{A–A}$ and $D_{B–B}$ has been the subject of critical scrutiny for at least half a century. A modification to this equation that combines the concepts of electronegativity and hardness/softness can be rewritten in terms of two quantities x and y, both having absolute significance. Both homo- and heteronuclear bond energies can be rationalised from these new equations. The quantities x are linearly related to Pauling electronegativities, while y appears to be a measure of an atom's intrinsic bonding potential, related to size and availability of valence orbitals.

Keywords: Bond energy; Bonding theory; Electronegativity; Hard–soft interactions

1. Introduction

Rationalising the relative strengths of chemical bonds is central to an understanding of chemical reactions. In a singly-bonded diatomic molecule AB, the bond energy is equal to the dissociation energy (distinctions between bond energies and bond enthalpies, and between measurements made at 0 and 298 K, need not concern us). In polyatomic molecules AB_n the experimentally determined bond dissociation energy is often invoked as a measure of bond strength, but the mean bond energy, i.e. the total atomisation energy divided by n, may be more relevant for comparative purposes. Heteronuclear single bond energies $D_{A–B}$ can be related to the homonuclear terms $D_{A–A}$ and $D_{B–B}$ by Pauling's bond energy

$$D_{A–B} = 1/2(D_{A–A} + D_{B–B}) + a(\chi_A - \chi_B)^2 \quad (1)$$

where χ_A and χ_B are the electronegativities of the atoms A and B respectively, and a is equal to 96.5 when all energies are expressed in kJ mol^{-1} (1 eV = 96.5 kJ mol^{-1}). Pauling [1] used Eq. (1) to establish the first scale of electronegativity. Since only relative – not absolute – values can be obtained from Eq. (1), Pauling initially assigned an arbitrary value of zero to hydrogen. In 1934, Mulliken [2] proposed – on sounder theoretical grounds than any of those underlying Eq. (1) – that the electronegativity of an atom was proportional to the arithmetic mean of its ionisation potential and electron affinity (the latter being defined as positive if the electron attachment is exothermic). Mulliken electronegativities are absolute values, and the clear relationship between Pauling and Mulliken electronegativities persuaded Pauling to add 2.05 to his original values, in order to eliminate the intercept on the linear plot between the two sets [1b]. These modified Pauling electronegativities have been treated as having absolute significance in, for example, discussions of electronegativity equalisation [3a] and group electronegativities [3b,4], and are still reproduced in contemporary undergraduate texts. However, it has long been known that Eq. (1) is of limited applicability. It gives poor results for molecules formed by the least electronegative elements, and for fluorides of most metallic elements the calculated bond energies are much too high. As pointed

doi:10.1016/j.poly.2006.09.013

out by Pritchard and Skinner [5], Pauling's electronegativities for the elements of Groups 1 and 2 were derived from the heats of formation of crystalline solids such as NaCl(s), and not from the dissociation energies of gaseous molecules like NaCl(g). In Allred's revised Pauling scale [6], values for elements like Na were determined from thermochemical data for crystalline chlorides and bromides. These manoeuvres can be justified on two grounds:

(i) Pauling insisted that the electronegativity of an atom 'represents the attraction of a neutral atom in a stable molecule for electrons' [7]. At room temperature and atmospheric pressure, molecules like NaCl(g) are unstable with respect to polymerisation to form crystalline solids.
(ii) The bonding in fluorides such as NaF(g) is mainly ionic, and their thermochemistry is better treated by Coulombic models; Eq. (1) is applicable for bonds that are predominantly covalent, with a smaller ionic contribution.

In recent years, Eq. (1) has been subjected to increasingly critical scrutiny. It has been argued [8,9] that it is valid only for a limited number of bonds where $\Delta\chi$ (i.e. $|\chi_A - \chi_B|$) is small. The following equation appears to work rather better:

$$D_{A\text{–}B} = 1/2(D_{A\text{–}A} + D_{B\text{–}B}) + a\Delta\chi \quad (2)$$

The use of the geometric mean $(D_{A\text{–}A}D_{B\text{–}B})^{1/2}$ in place of the arithmetic mean is also advantageous, and was preferred by Reddy et al. [8]. Pauling [10] noted that the geometric mean in Eq. (1) had advantages in dealing with, e.g., alkali metal hydrides, but did not use it in constructing his scale. Eq. (2) has the additional attraction that the electronegativity difference $\Delta\chi$ (and hence the electronegativities themselves) can be expressed in units of energy rather than $(\text{energy})^{1/2}$ as implied by Eq. (1) – unless the units of energy are deemed to reside in the constant a. However, it should be noted that Reddy et al. [8] invoked the bond energies of diatomic molecules such as SrCl(g), which are unstable with respect to disproportionation; the dissociation energy of SrCl(g) is rather less the mean bond energy in $SrCl_2$(g) and it can be argued that such molecules are excluded by Pauling's definition [7] from allegiance to Eq. (1). Murphy et al. [9] included in their analysis thermochemical data for molecular species such as the gaseous alkali metal halides and hydrides, which were known not to conform to Eq. (1) and were not invoked in the construction of either the traditional [1b] or revised [6] Pauling scales.

Eq. (1) can be modified [11] to give much better agreement with experimental bond energies using traditional Pauling electronegativities, while obviating a problem with units which troubled Murphy et al. [9]. Moreover, Eq. (1) and its variants have an advantage over Eq. (2) in dealing with metatheses of the type

$$AX + BY \rightarrow AY + BX \quad (3)$$

According to Eq. (2), such a reaction should always be thermoneutral ($\Delta H^o = 0$). But, as noted by Pauling [12], metatheses as in Eq. (3) are usually exothermic if $\chi_A < \chi_B < \chi_X < \chi_Y$. It can readily be predicted from Eq. (1) that for Reaction (3)

$$\Delta H^o = 2a(\chi_B - \chi_A)(\chi_X - \chi_Y) \quad (4)$$

This provides a valuable rationale for many synthetic strategies. For example, the reaction

$$R_3SnCl + R'Li \rightarrow R_3SnR' + LiCl \quad (5)$$

is driven thermodynamically by the highly exothermic enthalpy/free energy of formation of LiCl, where the most and least electronegative elements are brought into combination. The synthetic utility of Grignard reagents and metal hydrides such as $LiAlH_4$ can be similarly rationalised. However, Pearson [13] noted a number of cases where electronegativity considerations predict the wrong sign for ΔH^o. For example, the reaction

$$LiF(g) + CsI(g) \rightarrow LiI(g) + CsF(g) \quad (6)$$

should be exothermic since the least and most electronegative of all the elements – Cs and F respectively – are combined on the right hand side of Eq. (6). But – as was noted by Pearson [13] – the experimental ΔH^o for the reaction ion Eq. (6) is positive: standard thermochemical tabulations [14] lead to a value of $+51.6\ \text{kJ mol}^{-1}$ (Pearson [13], using older thermochemical data, gave $\Delta H^o = +71\ \text{kJ mol}^{-1}$). Pearson [13,15] – noting that cations and anions are respectively acids and bases in the Lewis sense – proposed that the thermochemistry of metathetic reactions is best explained in terms of the affinity of hard acids for hard bases, and of soft acids for soft bases, together with the enmity between hard-soft acid-base pairs. Thus Pauling stressed the attraction of opposites as optimising the strength of a chemical bond, while Pearson advocated 'like goes with like'. In an attempt to resolve this 'Pearson–Pauling paradox' [16], it was proposed [17] that the enthalpy of formation ΔH_f^o of a binary substance A_pB_q could be expressed as

$$-\Delta H_f^o(A_pB_q)/n = a[(x_A - x_B)^2 - (y_A - y_B)^2] \quad (7)$$

where $n = pn_A(=-qn_B)$, n_A and n_B being respectively the oxidation numbers of A and B. The parameter x was deemed to have the same meaning as the Pauling electronegativity χ, while y was tentatively related to the diffuseness of an atom's valence orbitals; a mismatch in y values would tend to weaken the bonding. While y is not a direct measure of hardness/softness, a plot of y against x effects an excellent demarcation between hard and soft acids. Soft acids/bases tend to be large ions formed by atoms of relatively high electronegativity. Eq. (7) permits the rationalisation of other thermochemical data, for example the effectiveness of binary fluorides as fluorinating agents, the thermal stabilities of oxides and the stabilisation of high/low oxidation states by fluorides/iodides respectively. Thus the Pauling and Pearson approaches can be reconciled.

2. An alternative approach

Further development of Eq. (7) permits new insights into the relative strengths of chemical bonds. It is easy – with the same notation as in Eqs. (1) and (2) – to derive Eq. (11) from Eqs. (8)–(10)

$$D_{A\text{–}A} = y_A^2 - x_A^2 \tag{8}$$

$$D_{B\text{–}B} = y_B^2 - x_B^2 \tag{9}$$

$$D_{A\text{–}B} = y_A y_B - x_A x_B \tag{10}$$

$$D_{A\text{–}B} - 1/2(D_{A\text{–}A} + D_{B\text{–}B}) = 1/2[(x_A - x_B)^2 - (y_A - y_B)^2] \tag{11}$$

For a gaseous molecular substance AB_n, the left hand sides of Eqs. (7) and (11) are identical; the right hand sides differ only in the units of x and y. From Eq. (7), only differences in the parameters x and y can be determined by analysis of experimental thermochemical data; x_H was set equal to the Pauling value of 2.1 and y_H was arbitrarily assigned a value of zero [17]. But in Eqs. (8)–(10), the x and y parameters assume an absolute significance, and homonuclear, singly-bonded diatomic molecules as well as heteronuclear AB_n are embraced. A fresh interpretation of bond energies in relation to electronegativity begins to emerge. Experimentally, the strongest homonuclear single bonds are H–H > C–C > B–B > S–S > Cl–Cl. These are all relatively small atoms (with covalent radii <1.05 Å) and of intermediate electronegativity (2.5 ± 0.5 on the traditional Pauling scale). The weakest homonuclear single bonds are formed by atoms of high electronegativity (F–F, O–O) and also by atoms of low electronegativity (Li–Li, etc.). These observations are consistent with Eqs. (8) and (9) if y is related to atomic size – small atoms having large values of y – and if x is close to zero for atoms around the middle of the electronegativity scale. Thus x is not to be identified with an absolute electronegativity; it is an absolute quantity linearly related to electronegativity in the Pauling/Mulliken sense. O and F are to be assigned large, positive values of x, while atoms of low electronegativity have negative values. The weakness of the F–F and O–O bonds is usually attributed in undergraduate texts to repulsion between lone pairs of electrons, although other explanations have been proposed [18,19]. We are dealing with covalent bonds in which pairs of electrons – one from each atom – are shared. It can be argued that x_A represents the balance between the willingness of A to contribute an electron to a shared pair, and its tendency to attract an electron from the other atom, as implied by the Mulliken definition of electronegativity (2). The weakness of the F–F bond is then attributed to the unwillingness of the fluorine atoms to share their unpaired electrons on an equal footing. An atom of low electronegativity such as lithium prefers to give than to receive or share, resulting in a weak Li–Li bond. The strongest homopolar bonds will result where x_A^2 is small (i.e. where x_A is close to zero, as in atoms of intermediate electronegativity) and y_A^2 is large(small atom). The strongest heteropolar bonds will be formed between small atoms where the product $x_A x_B$ is negative, i.e. one atom is of high and the other of low electronegativity. There is no need explicitly to invoke ionic-covalent resonance in these arguments.

2.1. Calculating scales of x and y

We now set out to determine numerical values of x and y from Eqs. (8)–(10), beginning with hydrogen and the halogens which form unequivocally singly bonded diatomic molecules. Regression analysis led to values for the ten x and y parameters for these five elements from the 15 experimental bond energies (taken from Ref. [9]). It was found

Table 1
Values of y and x for main group elements, with Pauling electronegativities χ_P from Eq. (12) and original Pauling values $\chi_P(o)$ from Ref. [1b]

Element	y	x	χ_P	$\chi_P(o)$
H	20.99 ± 0.32	0	2.18	2.1
F	27.55 ± 0.77	24.43 ± 0.91	3.84 ± 0.06	4.0
Cl	20.30 ± 0.67	12.91 ± 1.01	3.06 ± 0.07	3.0
Br	17.08 ± 0.62	9.99 ± 0.99	2.86 ± 0.07	2.8
I	13.49 ± 0.55	4.29 ± 0.95	2.47 ± 0.06	2.5
O	22.02 ± 0.29	18.52 ± 0.39	3.44 ± 0.03	3.5
S	17.00 ± 0.58	4.68 ± 1.02	2.50 ± 0.07	2.5
Se	14.99 ± 0.40	2.78 ± 0.70	2.37 ± 0.05	2.4
Te	13.39 ± 0.39	−0.63 ± 0.60	2.14 ± 0.04	2.1
N	18.63 ± 0.04	13.72 ± 0.07	3.11 ± 0.01	3.0
P	15.05 ± 0.91	−2.96 ± 1.39	1.98 ± 0.09	2.1
As	14.31 ± 0.49	−1.83 ± 0.75	2.06 ± 0.05	2.0
Sb	12.59 ± 0.40	−4.03 ± 0.61	1.91 ± 0.04	1.9
C	19.81 ± 0.02	5.96 ± 0.05	2.59 ± 0.01	2.5
Si	15.43 ± 0.26	−6.90 ± 0.40	1.71 ± 0.03	1.8
Ge	14.09 ± 0.38	−3.64 ± 0.59	1.93 ± 0.04	1.8
Sn	12.39 ± 0.85	−5.75 ± 1.84	1.79 ± 0.13	1.8
B	18.38 ± 0.14	−5.56 ± 0.21	1.80 ± 0.01	2.0

that x_H was equal to $+0.05 \pm 0.86$ (kJ mol^{-1})$^{1/2}$; in order to economise on parameters, x_H was arbitrarily set equal to zero, as in Pauling's original scale [1a]. With the remaining 9 parameters, the 15 experimental bond energies were reproduced with a mean error of 7.0 kJ mol^{-1}. Using the values of x and y thus obtained, the corresponding parameters for B, C, Si, Ge, Sn, N, P, As, Sb, O, S, Se and Te were calculated by regression analysis from experimental bond energies (again from Ref. [9]) for $D_{A–A}$ and $D_{A–X}$ (X = H, F, Cl, Br, I). For some elements, not all of these six values are available. For others, some of the bond energies given in Ref. [9] were not used:

(i) It has been argued [4] that C–F, N–F and O–F bond energies are enhanced by contributions from resonance structures such as $F^-O{=}F^+$; in the language of molecular orbital theory, this arises from interaction between filled π orbitals on the fluorine atoms and empty σ antibonding MOs. These bond energies were therefore rejected in the analysis.
(ii) The value of 235 kJ mol^{-1} quoted [9] for O–Br is evidently the dissociation energy of the BrO radical, and not the mean bond energy in Br_2O.
(iii) The figure of 211.7 kJ mol^{-1} for $D_{Te–Te}$ is too high – it exceeds the atomisation enthalpy of elemental Te by some 15 kJ mol^{-1}.

The $D_{A–A}$ values for A = C, Si, Ge and Sn are usually taken from the atomisation enthalpies of the elemental substances in the diamond-type structure. For the heavier elements at least, these may be enhanced by longer-range interactions; in other words, bands rather than bonds are more appropriate. There is evidence [20] that $D_{Si–Si}$ is about 20 kJ mol^{-1} smaller in silanes than in elemental silicon. Thus $D_{A–A}$ was ignored in the analysis for these elements.

3. Results and discussion

The final values by regression analysis of x and y for Main Group elements (excluding the most electropositive, metallic elements for which Eq. (1) is demonstrably inapplicable, for the reasons already outlined) are collected in Table 1. As illustrated in Fig. 1, there is an excellent linear correlation ($R = 0.989$) between the x parameters and traditional Pauling electronegativities χ_P [12] according to Eq. (12):

$$\chi_P = 2.18 + 0.068x \quad (12)$$

Values of χ_P thus obtained are given in Table 1. It is not to be inferred that x_A is to be identified with the electronegativity of the atom/element A; rather, the x parameters are quantities which can be linearly correlated with electronegativities. The same R value is obtained with Allred's revised Pauling values (6). With Allen's spectroscopic scale [21], the correlation coefficient R is only 0.970. However, the x and χ_P values in Table 1 fulfil some of Allen's criteria [9,21]:

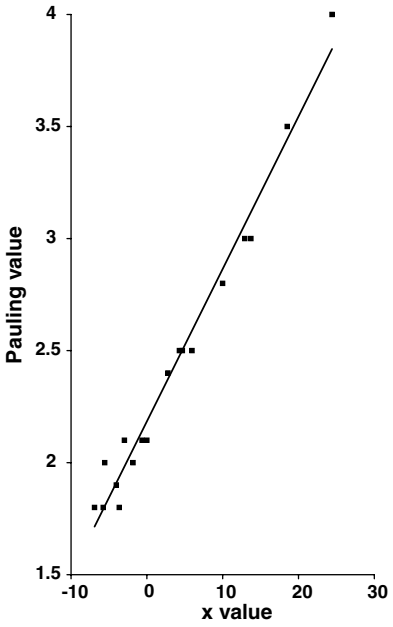

Fig. 1. Plot of x against traditional Pauling electronegativities from Ref. [1b].

(i) Silicon has the lowest x of all the metalloids; tin ought to be lower, but x_{Sn} is poorly determined, on account of the large experimental uncertainty in D(Sn–F).
(ii) We find $x_N > x_{Cl}$, though not within the limits of experimental uncertainty (it has been pointed out [22] that the argument set out in Ref. [9] for the higher electronegativity of N compared with Cl appears to be based on the erroneous proposition that N never exhibits the+5 oxidation state, while Cl(+7) is known).
(iii) The alternation between the second and third element in Group 14 – i.e. $\chi_{Si} < \chi_{Ge}$ – is apparent; this becomes less marked in Group 15 and has disappeared by Group 17.

We now look at trends in the parameter y. I tentatively propose that this measures the intrinsic bonding potential of an atom. It is primarily related to atomic size, and to the suitability in energy and radial extension of its valence orbitals. To some extent these variables parallel electronegativities. However, y_H is smaller than y_O or y_F. This may reflect that fact that hydrogen has only a single valence orbital, 1s, while oxygen and fluorine – even if only σ bonding is considered – can employ both 2s and 2p, and enjoy the benefits of hybridisation. But there is not a steady increase in y_A across the first short period; the discontinuity between C and N, and the abrupt increase between O and F are striking. Similar but less marked discontinuities are observed between Groups 14 and 15, and between Groups 16 and 17 among the heavier elements. An explanation for this behaviour may be found in considerations of exchange energy stabilisation in free atoms [23], which favours the

formation of atoms such as N and O (having more than one unpaired electron in their ground states) and thus lowers N–N and O–O bond energies. For heavier atoms such as I, spin–orbit coupling also affects homopolar bond energies.

4. Conclusions

It is widely believed that the familiar Pauling bond energy equation yields only *differences* in atomic electronegativities, which can be used to rationalise the relative strengths of heteronuclear bonds. The absolute – as opposed to relative – significance of Pauling electronegativities rests upon their linear relationship with Mulliken's values. This paper shows how absolute quantities x related to Pauling electronegativities can be derived from thermochemical data. These, together with the values of the 'intrinsic bonding potential' y, enable the rationalisation of the relative magnitudes of homonuclear as well as heteronuclear bond energies.

It is useful to compare the present treatment with other two-parameter models for the rationalisation of bond strengths. Drago and Wayland [24] separated the strength of the dative bond in a Lewis acid/base adduct into ionic and covalent components. Attempts to construct quantitative scales of hardness/softness focus on the principle that the hard-hard interaction is primarily ionic, while the soft-soft interaction is covalent [25,26]. The model proposed in the present paper differs from these, and from the traditional Pauling treatment, in that no ionic–covalent dichotomy needs to be invoked explicitly. The parameters are related to the atom's capacity to form covalent bonds by electron sharing, and the model is inappropriate for molecules (such as the alkali halides) where the bonding is predominantly ionic.

Obviously a two-parameter model will work better than one with only a single parameter. Is the superior performance of our model merely a statistical artifice, or do the x and y parameters have real meaning that can enrich our understanding of bond energies? The excellent correlation between the x values and Pauling electronegativities – which have largely stood the test of time – can scarcely be fortuitous, and the periodic trends in the y parameter can be rationalized rather well.

Abstract

The combination of electronic and vibrational spectra has been applied to correlate the spectral properties, with composition, structure and cation substitutions such as Mn, Fe, Ca and Zn for Mg in humites: norbergite, alleghanyite, leucophoenicite and sonolite with increasing number of silicate layers, 1, 2, 3 and 4. The observation of two broad bands in the visible range, near 550 and 450 nm (18 180 and 22 220 cm^{-1}) and one sharp band around 410 nm (24 390 cm^{-1}) is characteristic of Mn^{2+} in alleghanyite and leucophoenicite. The study of UV–Vis (electronic) spectral features confirms Mn as a major substituent in these two samples. Cation impurities like Zn and Ca as revealed from EDX analysis might be the cause for the absence of Mn-type spectrum in sonolite. The first observation is the near-infrared spectra of all four minerals in the first fundamental overtone OH-stretching mode are different and each mineral is characterized by its NIR spectrum. The feature in the range 7180–6600 cm^{-1} [1393–1515 nm or 1.39–1.52 μm] corresponds to the overtones of OH stretching vibrational modes of the humite groups observed in their IR spectra over the range, 3680–3320 cm^{-1}. The infrared spectra of the hydrous components of OH and SiO_4 groups in the mineral structure act as an aid to distinguish the minerals of the humite mineral group. A band at 541 cm^{-1} is assigned to MnO stretching mode.

1. Introduction

The humite minerals have been studied for almost 100 years [1–9]. Crystal structures were elucidated in the 1960s and 1970s [10–12,10,13–20]. The minerals are structurally analagous to olivine [21]. Much variation in the composition of the minerals is observed due to isomorphic substitution [21]. Many of the minerals contain manganese as the substituent [21–24]. No near-infrared spectroscopic studies of the minerals have been forthcoming. The humite minerals are a group of four homologues that are represented by the general formula nMg_2SiO_4. $Mg(OH,F)_2$ where $n = 1$ for norbergite, $n = 2$ for chondrodite, $n = 3$ for humite and $n = 4$ for clinohumite [25]. The humite group of minerals forms a morphotropic series with the mineral olivine and brucite. The members of this group differ not only by chemistry but by the number of olivine or silicate layers that are present between the brucite layers. There can be either one, two, three or four layers of the silicate layers between each brucite-like sheet. This has the effect of extending the unit cell of the minerals and affecting their symmetries.

The humite minerals are a homologous series of magnesium–ferrous–manganese orthosilicates whose structures are based on hexagonal closest-packed arrays of anions (O,F,OH) with octahedral and tetrahedral cation distributions related to that in forsterite. In humite there are 4 distinct octahedra; M(1)O6 and M(2)O6, like those in olivine, and M(2)O5(F,OH)1 and M(3)O4(F,OH)2, like those in

doi:10.1016/j.poly.2006.09.038

chondrodite. Ferrous Fe is ordered in equal amounts (approximately 0.1 Fe^{2+}) into the more distorted octahedra with 6 O ligands but avoids the less distorted octahedra with 1 or 2 (F,OH) ligands. In these closely packed orthosilicates, all anions are charge-balanced, and Fe^{2+} prefers the more distorted sites than those with the more polarizable ligands. In Mg/Fe olivines the M(1)O6 octahedron is significantly smaller but slightly more distorted than M(2)O6. A general mineralogy, chemistry and crystal structures of the humite series and Mn-analogues have been well-studied and summarized by Ribbe et al. [17,21,27]. A recent study of the structure of a natural chondrodite by neutron diffraction demonstrated that hydrogen is found to occupy the H1 site. The significance of hydrogen-bonding has been explained in humite structures containing varying amounts of OH, F and Ti [6]. A few spectroscopic studies are made on humite [26,28,29] and iron-rich clinohumites [30]. There are many studies reported on the vibrational modes of olivines by infrared and Raman spectroscopy [10–12,10,13–15].

Humites may contain Mg, Ca, Ti, Mn, Fe and Zn although only Mg, Mn and Ca form end members. These cations are ordered into the octahedral sites which vary in distortion, ligancy, size, and symmetry. A better understanding of the behaviour of cations substitution for Mg in humites is expected to provide a helpful guidance for spectral analysis of Mn-bearing minerals. It is our intention that makes the study of manganese humites and to compare with the Mg bearing humite.

Norbergite, $Mg_3(SiO_4)(OH,F)_2$ is a member of humite group. Humite group minerals possess silicate layers and oxide layers in their structures. The silicate layers and oxide layers have the same structure as olivine and brucite respectively. The Raman spectra of norbergite samples were investigated and explained the dependence of OH Raman bands on temperature and pressure [31]. The magnesium humites (norbergite, chondrodite, humite and clinohumite) have been studied and summarized [32]. Their manganese analogues (alleghanyite, leucophoenicite, sonalite, jerrygibbsite, ribbeite and manganhumite) have received less attention. They are, in general, less common, found in metamorphosed Mn-deposits. Alleghanyite, $Mn_5(SiO_4)(OH)_2$ species crystal structure was reported by Rentzeperis [33], a high Mg alleghanyite from Sterling Hill was described by Petersen et al. [34] and later crystal structure refinement report [35] shows cations in alleghanyite and all other humite group minerals are ordered in octahedral sites accordingly to size criteria, eventhough ligancy (O, OH, F) may be the controlling factor where charge balance and crystal-field effects are involved. Penfield and Warren [36] disclosed originally the mineral, leucophoenicite, $(Mn^{2+})_7(SiO_4)_3(OH)_2$ and its crystal structure solved by Moore [37,38] confirms edge-sharing, half-occupied, silicate tetrahedra and is structurally distinct from the humite group minerals. Later, the study of TEM images of leucophoenicite [39], supports the structure analysis done by Moore's structural report [37]. Sonlitnolite, $Mn_9^{2+}(SiO_4)_4(OH)_2$ was first described by Yoshinaga [40]. from eleven localities in Japan and crystal structure was discussed by Ribbe [32].

The expression of Mn humite minerals, their formula, number of silicate layers and symmetry class are described in Table 1. Previous studies have been based on the chemistry and structural analysis. No spectroscopic studies were included in previous research and this is why we are presenting this work. In this communication, we present the spectroscopic investigations of selected manganese humites (alleghanyite, leucophoenicite, sonalite) and Mg-humite for comparison.

2. Experimental

2.1. Minerals

The minerals used in this work listed in Table 1 were obtained on loan from The South Australian Museum and from the Mineralogical Research Company. The minerals have been analysed by X-ray diffraction for phase identification and by SEM together with electron probe analysis for chemical composition.

2.2. SEM and EDX analysis

For X-ray microanalysis (EDX), samples were embedded in araldite resin and polished with diamond paste on Lamplan 450 polishing cloth using water as a lubricant.

Table 1
Table of Mn-humite and Mg-humite minerals, their formula, number of silicate layers and symmetry class

Mineral name	Origin	Ideal formula	Formula calculated from EDX analysis	Silicate layers	Class
Norbergite	Franklin Limestone Quarry, Franklin, Sussex County, New Jersey	$Mg_3(SiO_4)(OH,F)_2$	$Mg_{2.80}Fe_{0.03}Ca_{0.01}(SiO_4)F_{1.19}(OH)_{0.49}$	1	orthorhombic
Alleghanyite	Hamayokokawa Mine, Tatuno Cho, Nagano Prefecture, Japan	$(Mn^{2+})_5(SiO_4)_2Mg(OH, F,)_2$	$Mn_{11.48}(SiO_4)_2(OH,F)_{3.48}$	2	monoclinic
Leucophoenicite	Parker Shaft, Franklin, Sussex County, New Jersey	$(Mn^{2+})_7(SiO_4)_3(OH)_2$	$Mn_{6.47}Mg_{0.19}Ca_{0.45}(SiO_4)_3(OH)_{2.22}$	3	monoclinic
Sonalite[a]	Franklin Limestone quarry, Franklin, Sussex County, New Jersey	$(Mn^{2+})_9(SiO_4)_4(OH,F)_2$	$Mn_{0.9}{}^{2+}$, $Zn^{2+}0.06$, $Ca_{0.03}{}^{2+}(SiO_4)_4(OH_{0.56}, F_{0.44})$	4	monoclinic

[a] Formula calculated from the data reported by Dunn [24].

Next, the samples were coated with a thin layer of evaporated carbon for conduction and examined in a JEOL 840A analytical SEM (JEOL Ltd., Tokyo, Japan) at 25 kV accelerating voltage. Preliminary analyses of the humite mineral samples were carried out on the FEI Quanta SEM using an EDAX microanalyser (FEI Company, Hillsboro, Oregon, USA), and microanalysis of the clusters of fine crystals was carried out using a full standards quantitative procedure on the JEOL 840 SEM using a Moran Scientific microanalysis system (Tokyo, Japan). Oxygen was not measured directly but calculated using assumed stoichiometries to the other elements analysed.

2.3. UV–Vis spectroscopy

UV–Vis spectrophotometer (Varian Cary 3, Melbourne, Australia), equipped with a Diffuse Reflectance Accessory (DRA) was employed to record the electronic spectra of the samples in the region between 200 and 900 nm (50 000–11 110 cm^{-1}). This technique allows the study of the reflectance spectra of the samples in the powder form. The DRA consists of a 73 mm diameter integrating sphere, featuring an inbuilt high performance photomultiplier. Sample was mounted on coarse filter paper by resuspending the sample and submerging the filter paper into the suspension. Initially a base line was recorded using two pressed polytetrafluoroethylene (PTFE) reference disks. Next, the sample was mounted flat over the sample port and the reflectance spectrum of the sample, relative to the reference disks, was collected by the integrating sphere. By placing the sample flat any specular components of reflectance should be directed out of the DRA entrance port, as the angle of incidence is 0°. The diffuse reflectance measurements were converted into absorption (arbitrary units) using the Kubelka-Munk function. Data manipulation was performed using Microsoft Excel.

2.4. NIR and infrared spectroscopy

NIR spectra were collected on a Nicolet Nexus FT-IR spectrometer with a Nicolet Near-IR Fibreport accessory in diffuse reflectance mode. A white light source was used, with a quartz beam splitter and TEC NIR InGaAs detector. Spectra were obtained from 11 000 to 4000 cm^{-1} (909–2500 nm) by the co-addition of 64 scans at a resolution of 8 cm^{-1}. A mirror velocity of 1.2659 m/s was used. The spectra were transformed using the Kubelka–Munk algorithm ($f(R_\infty) = (1 - R_\infty)^2/2R_\infty$) for comparison with absorption spectra.

Mid-infrared and NIR spectra were obtained using an FT spectrometer (Nicolet Nexus, Madison, Wisconsin, USA) with a ''smart endurance'' single bounce diamond ATR cell. Spectra over the 4000–500 cm^{-1} (2500–20,000 nm) range were obtained by the co-addition of 64 scans with a resolution of 4 cm^{-1} and a mirror velocity of 0.6329 cm/s.

The spectral manipulations of baseline adjustment, smoothing, and normalisation were performed using the Spectracalc software package GRAMS (Galactic Industries Corporation, NH, USA). Band component analysis was carried out using peakfit software (Jandel Scientific, Postfach 4107, D-40688 Erkrath, Germany). Lorentz–Gauss cross product functions were used through out and peak fit analysis undertaken until squared correlation coefficients with R^2 greater than >0.995 were obtained.

3. Results and discussion

3.1. SEM analysis

The EDX quantitative analyses were made on different areas of the samples. and selected one set of EDX spectra of humites studied in this work. The spectra were de-convoluted and calibrated to produce the chemical formula as given in Table 1. The analysis is in harmony with the accepted formula of humites. The data in the table shows Mg is major and Fe as minor impurity in norbergite where as other minerals are rich in manganese with minor inclusions of Mg, Ca, Zn and F. For sonalite, the chemical formula has been calculated from the analytical data reported for manganese humites, including sonalite originating from Franklin, New Jersey [24]. The sonolite mineral from the same origin is used in the present study.

3.2. UV–Vis (electronic) spectroscopy

For a given symmetry, transition metal ion can produce a characteristic absorption spectrum and spectra of minerals may be used to identify ions in unusual oxidation states and the symmetry of co-ordination states. The electronic spectra of iron group ions can be studied in the 200–900 nm region (50 000–11 110 cm^{-1}). The valency of manganese is two in most of the minerals. The ground state for Mn^{2+} (d^5) is ^6S which transforms into $^6A_{1g}$ in crystal field. The excited states of d^5 ions are quartet (^4G, ^4F,^4D,^4P) and doublet (^2I, ^2H,^2G,^2F,^2D,^2P, ^2S) terms. Thus sextet–quartet/sextet–doublet transitions result for d^5 ions and are called spin-forbidden transitions. Usually sextet–quartet transitions are observed and Mn^{2+} ion in octahedral co-ordination gives rise to two broad bands in the range 600–450 nm (16 665–22 220 cm^{-1}) and one sharp band around 400 nm (25 000 cm^{-1}) [41–43]. The study of UV–Vis spectroscopy of humites, reveals the electronic spectra for two samples, alleghanyite and leucophoenicite. It is not surprising to note the absence of a Mn-spectrum in norbergite since Mg is major cation. Whereas in sonolite the contribution by Mn is expected but surprisingly is absent in the spectrum. At least there are two reasons that can be reasonably accounted. The presence of Mn is very low when compared to the other two Mn-bearing humites. The other factor, for the suppression of the spectrum is due to the presence of cations like Zn and Ca. The contribution of cations, like Zn and Ca might be effective for masking

the Mn-type spectrum in sonolite ($Mn_{0.9}^{2+}Zn_{0.06}^{2+}$-$Ca_{0.03}^{2+}(SiO_4)_4(OH_{0.56}F_{0.44})$.

The electronic spectra of the two bivalent Mn-minerals; alleghanyite, $Mn_{11.48}(SiO_4)_2(OH,F)_{3.48}$ and leucophoenicite, $Mn_{6.47}Mg_{0.19}Ca_{0.45}(SiO_4)_3(OH)_{2.22}$ are shown in Fig. 1. The spectra of the two samples look alike but band positions differ only slightly. The observation of two broad bands in the visible range, near 550 and 450 nm (18 180 and 22 220 cm^{-1}) and one very sharp band around 410 nm (24 390 cm^{-1}) are characteristic of Mn^{2+} in these minerals. The first broad feature observed at 549 nm (18 215 cm^{-1}) is attributed to $^6A_{1g}(S) \rightarrow {}^4T_{1g}(G)$ transition and a similar broad band but relatively less intense at 453 nm (22 075 cm^{-1}) is identified as $^6A_{1g}(S) \rightarrow {}^4T_{2g}(G)$ transition. These transitions are shifted for leucophoenicite, at 558 (17 920 cm^{-1}) and 441 nm (22 675 cm^{-1}) with additional shoulder at 435 nm (22 990 cm^{-1}). For Mn-rich mineral, sursasite, bands at 580 nm (17 240 cm^{-1}) and 515 nm (19 420 cm^{-1}) are assigned to $^6A_{1g}(S) \rightarrow {}^4T_{1g}(G)$ and $^6A_{1g}(S) \rightarrow {}^4T_{2g}(G)$ transition respectively [44]. $^4A_{1g}(G)$ and $^4E_{1g}(G)$ states give rise to sharp bands because of these states are independent of crystal-field, *Dq* [45]. The sharp line like bands of alleghanyite in UV region at 413 nm (24 210 cm^{-1}) and 408 nm (24 510 cm^{-1}) are identified as independent crystal-field transitions and are assigned to $^6A_{1g}(S) \rightarrow {}^4A_{1g}(G)$ and $^6A_{1g}(S) \rightarrow {}^4E_{1g}(G)$ transitions respectively. An almost a similar feature is seen for leucophoenicite. These bands are shifted to higher wavenumbers in the UV region. Mn^{2+} in silicate melts and glasses consist of a band at 415 nm (24 095 cm^{-1}) and explained the cause of this band by two transitions, $^6A_{1g}(S) \rightarrow {}^4A_{1g}(G)$ and $^6A_{1g}(S) \rightarrow {}^4E_{1g}(G)$ [46]. The observation of splitting for the UV band at around 410 nm (24 390 cm^{-1}) shows with distinguishable energy may be explained by the distortion of octahedral symmetry of Mn^{2+} ions in both the minerals. The assignment of the Mn^{2+} bands in humites are presented in Table 2 alongwith the bands reported for Mn-bearing silicate [44].The variation in band positions with shifts to higher wavenumbers may be due to the presence of Mg and Ca in these minerals.

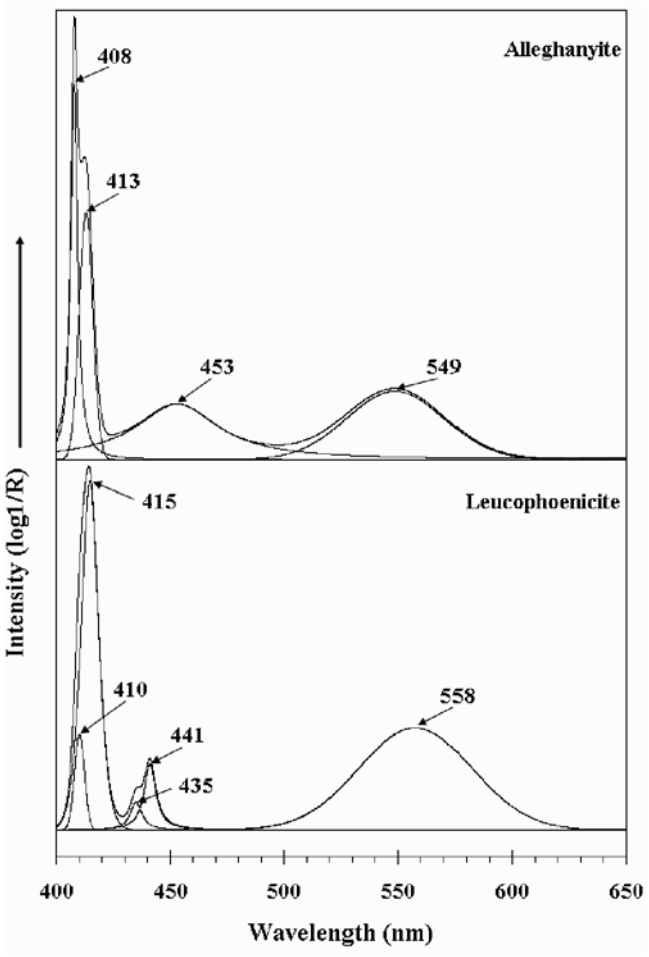

Fig. 1. UV–Vis reflectance spectra of alleghanyite and leucophoenicite in the 400–650 nm region.

3.3. NIR spectroscopy

Near-infrared spectra of Mn-humite mineral group covering a wide range in composition show diagnostic absorption bands related to vibrational processes involving hydroxyl units. Many of these absorption bands are relatively broad and overlapping. However, by the application of spectral analysis methods like continuum removal and derivate analysis permit minerals (under study) to be distinguished. The main spectral differences between the minerals

are illustrated in plots showing major absorption band centres and other spectral feature positions. The observed NIR spectral features may conveniently subdivide into three regions (Figs. 2–4): (a) the first region is the high wavenumber region 7400–6400 cm^{-1} (1351–1562 nm) (1.35–1.56 μm) attributed to the OH-stretching and bending modes (Fig. 2); (b) the 5650–4650 cm^{-1} (1770–2150 nm) (1.77–2.15 μm) region attributed to combination of OH and Si–OH modes shown in Fig. 3 and (c) the 4600–4000 cm^{-1} (2174–2500 nm) (2.17–2.50 μm) region assigned to the combination of the stretching and deformation modes of humite minerals and are related manganese(II) hydroxide and the spectra are shown in Fig. 4.

3.3.1. The 7400–6400 cm^{-1} (1351–1562 nm) (1.35–1.56 μm) spectral region

In this spectral region where the first overtones of the OH-stretching vibrations are shown for norbergite, alleghanyite, leucophoenicite and sonalite in Fig. 2. Norbergite, a single-layered silicate, shows unique spectrum at around 7180 $cm^{-1}$and the spectrum is resolved into one sharp peak at 7180 cm^{-1} (1393 nm) (1.39 μm)and two weak bands at 7165 and 7035 cm^{-1} (1396 and 1422 nm) (1.40 and 1.42 μm). These bands are shifted to lower wavenumbers and appear with distorted modes for the two-layered and three-layered alleghanyite and leucophoenicite minerals respectively. It may also be explained that the possible substitutions of cations of Mn/Zn/Ca/Fe for Mg are responsible for the complexity of bands in their spectra. The spectrum is more complicated for the four-layered sonolite and may be resolved into a series of overlapping bands. The first observation is the spectra of all the four minerals in the region 7400–6400 cm^{-1} (1351–1562 nm) (1.35–1.56 μm) are different and each mineral is characterized by NIR spectrum. Bands from 7180 to 6600 cm^{-1} (1393–1515 nm) (1.39–1.52 μm) correspond to the overtones of OH stretching vibrational modes of the humite groups shown in their IR spectra over the range, 3680–3320 cm^{-1} (Fig. 4). Bands appear as shoulders to the higher wavenumbers of the sharp peak at 7180 cm^{-1} (1393 nm) (1.39 μm) may be attributed to the combination of OH-stretching fundamental and MOH-deformation modes ($2 \times$ OH fundamental + OH deformation) [47]. These spectral features confirm range of compositional variations in humite group minerals. For example, M = Mg in sonalite, the weak shoulders at 7205 cm^{-1}

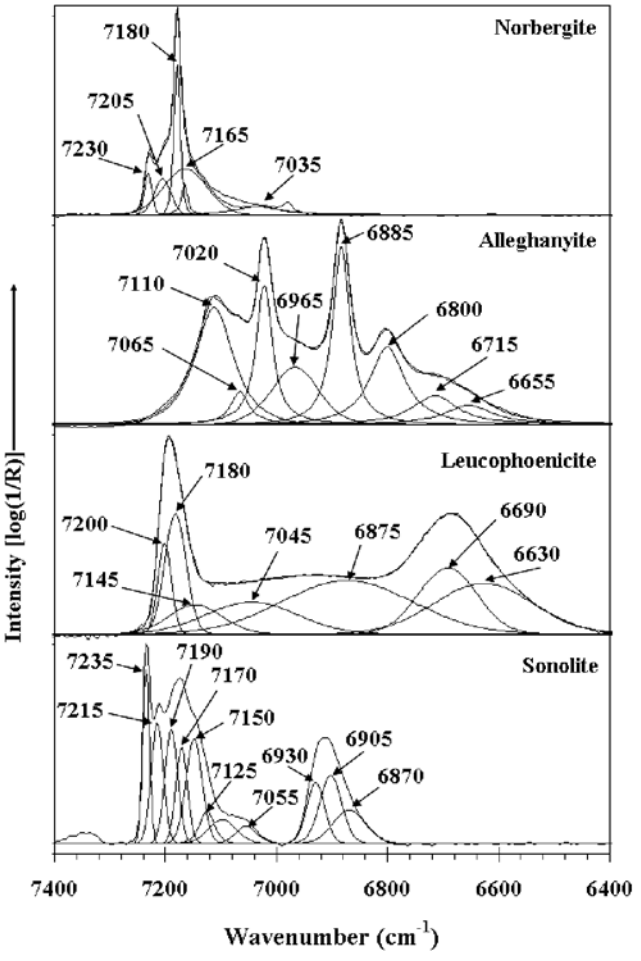

Fig. 2. NIR reflectance spectra of norbergite, alleghanyite, leucophoenicite and sonolite in the 7400–6400 cm^{-1} region.

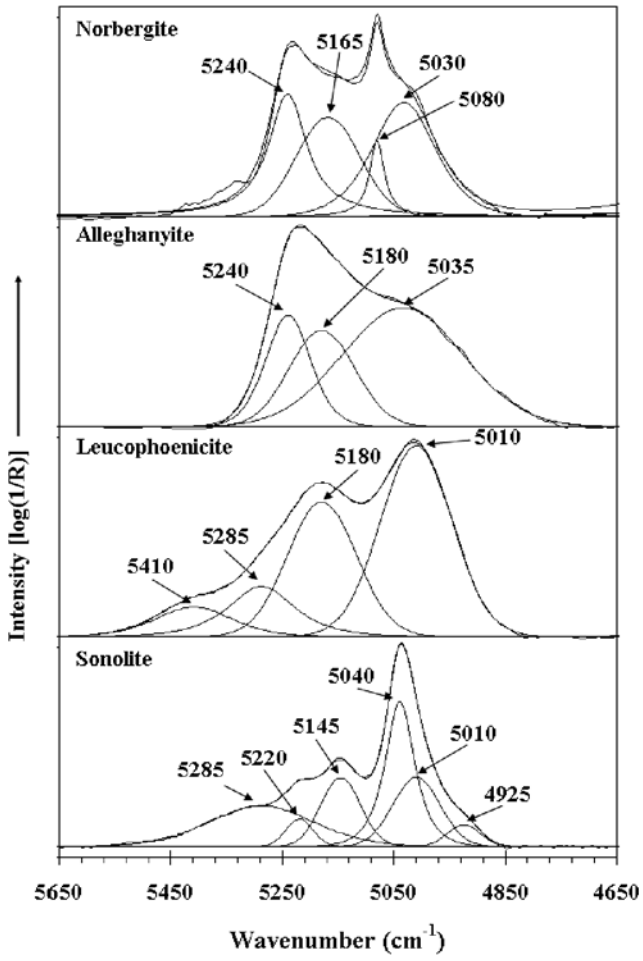

Fig. 3. NIR reflectance spectra of norbergite, alleghanyite, leucophoenicite and sonolite in the 5650–4650 cm^{-1} region.

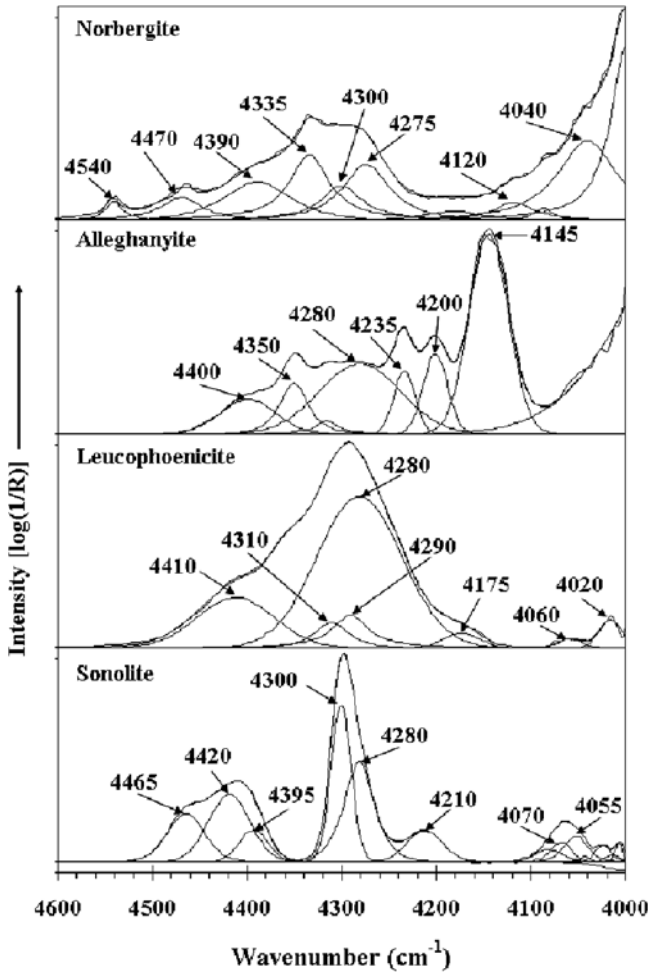

Fig. 4. NIR reflectance spectra of norbergite, alleghanyite, leucophoenicite and sonolite in the 4600–4000 cm^{-1} region.

(1388 nm) (1.39 μm) cm^{-1} might be the result of MgOH. The same band appears with variable band positions and intensity in other minerals. For alleghanyite, leucophoenicite and sonalite 'M' may be Mn/Ca/Zn that causes the change in intensity and positions of bands in the spectrum.

3.3.2. The 5650–4650 cm^{-1} (1770–2150 nm) (1.77–2.15 μm) spectral region

The 5650–4650 cm^{-1} (1770–2150 nm) (1.77–2.15 μm) spectral region (Fig. 3) shows a number of vibrational modes. The broad spectrum centred at 5200 cm^{-1} (1923 nm) (1.92 μm) is a common feature to the spectra of humites. Each spectrum is resolved into three peaks. The most pronounced band registered in all the spectra is near 5030 cm^{-1} (1988 nm) (1.99 μm) is probably due to the combination of OH and Si–OH modes [48]. The observation of the most intense band for Fe-humites at 5200 cm^{-1} (1923 nm) (1.92 μm) has been attributed to the combinational band of OH and Si–OH modes. For norbergite the main bands are located at 5240, 5165 and 5030 cm^{-1} (1908, 1936 and 1988 nm) (1.91, 1.94 and 1.99 μm) and alleghanyite displays almost similar spectrum with a little/minor variation of band positions. The intensity and position of the bands are variable in leucophoenicite and sonalite from one another. The complexity of bands increases with the order of silicate layers in humites. Thus Fig. 3 shows characteristic patterns due to SiO_4 units for single-layered (norbergite), two-layered (alleghanyite), three-layered (leucophoenicite) and four-layered (sonolite) of silicate layers between the brucite layers of humite groups. In particular, the spectrum of four-layered silicate mineral, sonolite shows four individual weak intensity bands at 5285, 5145, 5040 and 5010 cm^{-1} (1892, 1944, 1984 and 1996 nm) (1.89,1.94, 1.98 and 2.00 μm) and three-layered, leucophoenicite at 5410, 5285 and 5180 and 5010 cm^{-1} (1848, 1892, 1931 and 1996 nm) (1.85, 1.89, 1.93 and 2.00 μm) suggest the contribution of weak intensity bands by OH-stretching vibrations of hydroxyl groups.

3.3.3. The 4600–4000 cm^{-1} (2174 to2500 nm) (2.17–2.50 μm) spectral region

This spectral region results from combination of IR fundamental modes observed in the mid-IR range. Fig. 4 shows four main groups of bands at 4540, 4470, 4335, and 4120 cm^{-1} (2203, 2237, 2307 and 2427 nm) (2.20, 2.24, 2.31 and 2.43 μm) for norbergite and a similar series of bands exhibit by Fe-humites. Bands in the range, 4540–4470 cm^{-1} (2203–2237 nm) (2.20–2.24 μm) in humite minerals are the combination of fundamental bands due to Si–OH bonding [49]. The bands around 4500–4300 cm^{-1} (2222–2326 nm) (2.22–2.33 μm) appear due to the combinations of OH-stretching and M–OH bending modes, where M may be Mg, Mn, Al and/or Fe [50]. The observation of combination bands in NIR spectra for tourmalines shows bands at 4529, 4454, 4356 and 4238 cm^{-1} (2208, 2245, 2296 and 2360 nm) (2.21, 2.25, 2.30 and 2.36 μm) [51]. For the humite mineral group, three bands centred at 4300, 4200 and 4100 cm^{-1} (2326, 2381 and 2439 nm) (2.33, 2.38 and 2.44 μm) and same set of bands are displayed by norbergite and alleghanyite with minimal band position differences. Well resolved bands appear in leucophoenicite and sonalite near 4300 cm^{-1} (2326 nm) (2.33 μm) band. OH-bending mode is clearly resolved in humites near 756–724 cm^{-1}. The second band in the range 4300–4200 cm^{-1} (2326–2381 nm) (2.33–2.38 μm) is attributed to MnOH vibrations (combination of OH-stretching and M–OH-bending modes) [50]. The low wavenumber bands near 4100 cm^{-1} (2439 nm) (2.44 μm) may be attributed to (Mg/Ca/Zn)OH units. The shift of combination bands of OH-stretching and M–OH bending modes to lower wavenumbers in humite groups shows compositional variation and possible substitutions of Mn^{2+}, Fe^{2+}, Zn^{2+}, Ca^{2+} for Mg^{2+}.

3.4. Mid-IR spectroscopy

The mid-infrared spectra of the humite minerals are subdivided into three regions according to the observed features in their spectra.

(1) The 3750–3250 cm^{-1} region corresponds to OH-stretching vibrations.
(2) The 1100–500 cm^{-1}region corresponds to the various stretching and bending vibrations of SiO_4 units.

The spectra of OH-stretching region are shown in Fig. 5. The stretching and bending vibrations in the ranges, 1050–800 cm^{-1} and 750–500 cm^{-1} are shown in Fig. 6. The hydrous components of OH and SiO_4 groups in the mineral structure act as an aid to distinguish the humite group minerals by FTIR spectroscopy. This technique is a rapid one and most sensitive to identify the OH and SiO_4 groups in minerals. The spectra of the hydroxyl-stretching region of humites are shown in Fig. 5. Norbergite shows two bands at 3581 and 3572 cm^{-1} whereas the spectrum of alleghanyite shifts to lower wavenumbers with a splitting of the second band and the bands are 3528, 3484, 3495 and 3469 cm^{-1}. The three-layered leucophoenicite spectrum also moved further to a lower region at 3368, 3344, 3322 and 3284 cm^{-1}. The OH region of four-layered becomes complex and more number of bands resolved at 3679, 3642, 3542 and 3465 cm^{-1} for sonolite. The shift to lower

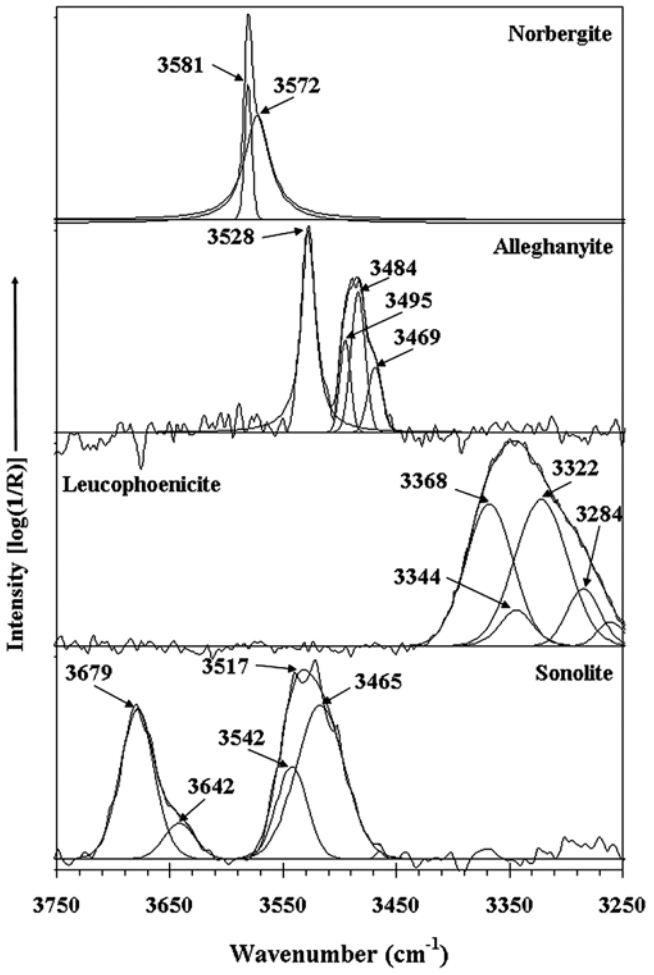

Fig. 5. IR reflectance spectra of norbergite, alleghanyite, leucophoenicite and sonolite in the 3750–3250 cm^{-1} region.

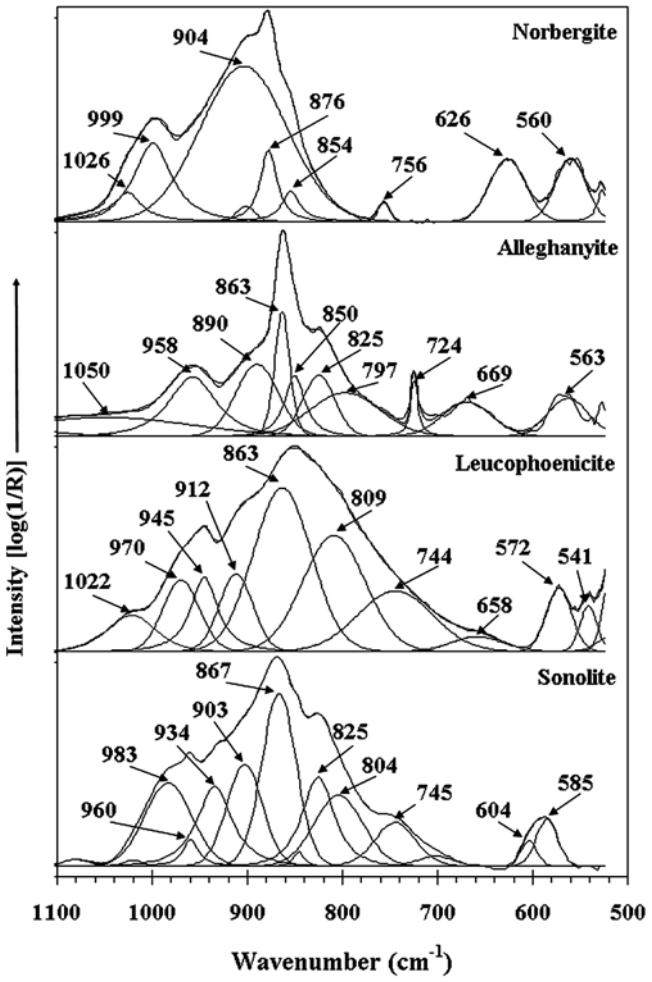

Fig. 6. IR reflectance spectra of norbergite, alleghanyite, leucophoenicite and sonolite in the 1100–500 cm^{-1} region.

energy of the spectrum might be the cause of cations like, Ca and Zn, besides Mn in sonolite. A set of six modes at 3685, 3650, 3571, 3561, 3411 and 3393 cm^{-1} have been reported in the OH fundamental stretching region of chondrodite from Keral Khondalite Belt, India [47]. Analysis of IR spectra of Mg-rich chondrodites having cation impurities like Fe, Ti shows various stretching and bending modes of (Mg–O) and (SiO_4) groups. The assignment of the observed vibrational modes for OH-stretching vibrations and SiO_4 stretching/bending vibrations in IR-spectra of humite minerals is presented in Table 3 and compared with data reported for chondrodites from different localities: (1) chondrodite from Keral Khondalite Belt, India [47], (2) sample originated from Limecrest Quarry, Newton, New Jersey, USA [52] and the mineral from UC, Berkeley, USA [53]. The reason for the difference in band positions of the OH-stretching vibrations is attributed to the strength of the hydrogen bond formed between the OH units of the brucite-like layer and the adjacent olivine layers. It is clear from their spectra (Fig. 5) the complexity of OH spectrum increases with number of silicate layers in humites. However, IR spectroscopy is able to differentiate the mineral group from one, two, three or four-layered of

silicates of humite mineral group, norbergite, alleghanyite, leucophoenicite, sonalite by the main OH bands observed at 3581, 3484 and 3322 cm^{-1} respectively with an exception to 3679 cm^{-1} in sonolite.

There are several investigations published on hydrous magnesium silicates and analyses present for stretching and bending modes of Mg–O and SiO_4 groups in the mid-infrared region [52–55]. Number of modes have been detected in the region 1100–500 cm^{-1} for the various compositions (Fig. 6). All the network modes concerned with SiO_4 stretching modes observed here in the range 1050–800 cm^{-1} are comparable with the modes reported in chondrodites (Table 3). Norbergite, a Mg-humite, gives rise to five mode at 1026, 999, 904, 876 and 854 cm^{-1}. The spectra of all Mn-bearing humites, were observed to have shifted to lower wavenumber. All the samples show a number of peaks on either side of the most intense peak centred near 876 cm^{-1}. The patterns look alike but show bands with varying intensities and band positions. Thus the main SiO_4 stretching mode centred near 876 cm^{-1}(Fig. 6) shows shift to lower wavenumber for Mn-bearing minerals, alleghanyite, leucophoenicite and sonalite. The spectra leucophoenicite and sonalite which are the minerals with three and four-silicate layers respectively show increased in complexity and overlapping bands. The M–OH deformation modes observed near 756 cm^{-1} and two weak bands near 680–500 cm^{-1} are the most probable result of SiO_4 bending vibrations and Mn–O vibrations.

4. Conclusions

The study of UV–Vis spectroscopy of humites, reveals the electronic spectra by two samples, alleghanyite and leucophoenicite. It is of surprise to see the absence of Mn-type spectrum in sonolite, even though the representative chemical formula obtained from EDX analysis shows the presence of manganese in the sample and may be accounted for the impurities like cations of Ca and Zn. The loss of the Mn-spectrum for sonolite, looks as if cation impurities like Ca and Zn are responsible $(Mn_{0.9}{}^{2+}Zn_{0.06}{}^{2+}Ca_{0.03}{}^{2+}(SiO_4)_4(OH_{0.56}F_{0.44}))$.

A pair of sharp bands of alleghanyite and leucophoenicite in UV region at around 410 nm (24 390 cm^{-1}) is identified as due to independent crystal-field transitions of Mn^{2+} ion and are assigned to $^6A_{1g}(S) \rightarrow {}^4A_{1g}(G)$ and $^6A_{1g}(S) \rightarrow {}^4E_{1g}(G)$ transitions. The observation of splitting (300 cm^{-1}) (5 nm) of the UV band shows with distinguishable energy may be explained by the distortion of octahedral symmetry of the Mn-bearing humites. The shift of combinational bands of OH-stretching and M–OH bending modes to lower wavenumbers in humite group minerals shows compositional variation and possible substitutions of Mn^{2+}, Fe^{2+}, Zn^{2+}, Ca^{2+} for Mg^{2+}. The humite mineral group is characterized by two OH-stretching vibrations over the range 3680–3320 cm^{-1}. A series of SiO_4 stretching modes displayed over the range, 1050–800 cm^{-1} symmetrically on either side of an intense peak centred near 876 cm^{-1} and the complexity of SiO_4 stretching and bending spectra increases with the number of silicate layers in Mn-bearing humite minerals.

Abstract

Nickel and copper complexes containing 1,3,5-benzenetricarboxylic acid, with a combination of selected N-donor ligands and Schiff bases, of the composition $Ni_3(bimz)_6(btc)_2 \cdot 12H_2O$ (**1**), $Ni_3(btz)_9(btc)_2 \cdot 12H_2O$ (**2**), $Ni_2(L_1)(btc) \cdot 7H_2O$ (**3**), $Ni_3(L_2)_2(Hbtc) \cdot 9H_2O$ (**4**), $Ni_2(L_3)(btc) \cdot 4H_2O$ (**5**), $Cu_2(L_4)(btc) \cdot 7H_2O$ (**6**), $[Cu_3(pmdien)_3(btc)](ClO_4)_3 \cdot 6H_2O$ (**7**) and $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$ (**8**); H_3btc = 1,3,5-benzenetricarboxylic acid, bimz = benzimidazole, btz = 1,2,3-benztriazole, L_1 = 2-[(phenylimino)methyl]phenol, L_2 = *N*,*N*′-bis-(salicylidene)propylenediamine, L_3 = 2-{[(2-nitrophenyl)methylene]amino}phenol, L_4 = 2-[(4-methoxy-phenylimino)methyl]-phenol, pmdien = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine, mdpta = *N*,*N*-bis-(3-aminopropyl)methylamine, have been synthesized. The complexes have been studied by elemental analysis, IR, UV–Vis spectroscopies, magnetochemical and conductivity measurements and selected compounds also by thermal analysis. The crystal and molecular structure of complex **8** was solved. The complex is trinuclear with btc^{3-}-bridge. The coordination polyhedron around each copper atom can be described as a distorted square with a $CuON_3$ chromophore formed by one oxygen atom of carboxylate and three nitrogen atoms of mdpta. The magnetic properties of **8** have been studied in the 1.8–300 K temperature range revealing a very weak antiferromagnetic exchange interaction with $J = -0.56\ cm^{-1}$ for $g = 2.13(9)$. The antimicrobial activities against selected strains of bacteria were evaluated. It was found that only complex **5** is able to inhibit the growth of *Staphylococcus* strains.

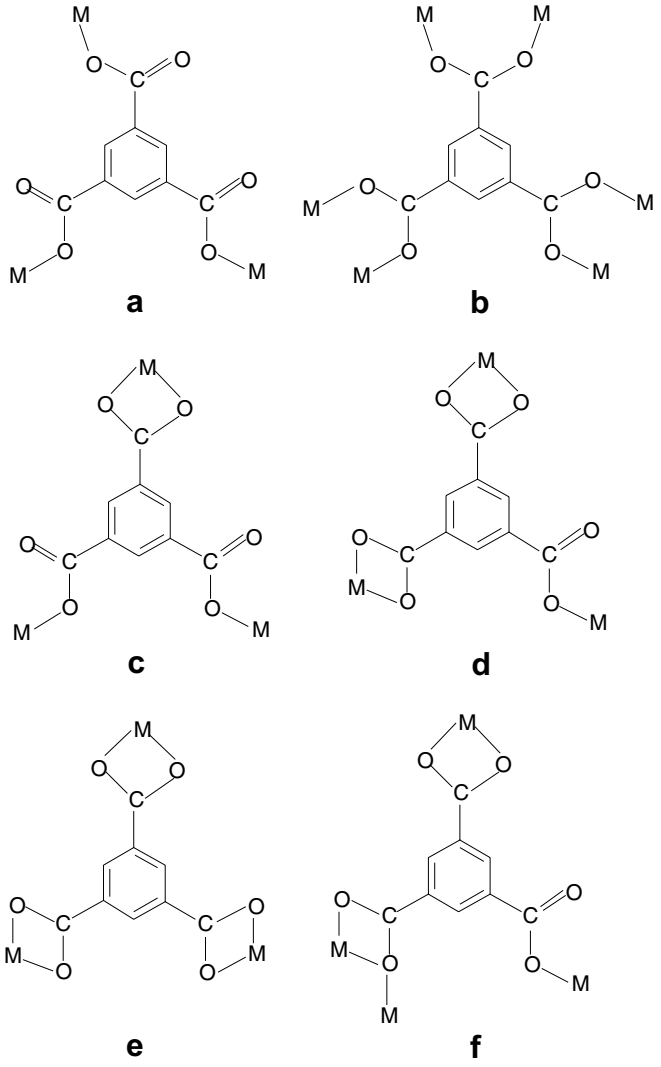
Keywords: Nickel(II); Copper(II); 1,3,5-Benzenetricarboxylic (trimesic) acid complexes; X-ray structure; Magnetic properties

1. Introduction

Transition metal complexes with N-donor ligands bridged by carboxylic acids are studied not only for interesting magnetic and spectral properties, but also as catalysts or nano-materials precursors and for applications in pharmaceutical industry for their potential antibacterial, antiviral and antitumour effects [1–3].



1,3,5-Benzenetricarboxylic acid (trimesic acid) is a tricarboxylic acid with potentially six oxygen donor atoms, which can be coordinated to the central atoms in different coordination modes. Transition metal complexes with the 1,3,5-benzenetricarboxylate anion which is not coordinated to central atom are rather rare [4,5]. Many polynuclear complexes with a btc bridge have been studied and different coordination modes of carboxylato groups have been proved by X-ray analysis: (a) tris-monodentate [6–8]; (b) tris-bidentate [9]; (c) chelating bidentate and bis-monodentate [10]; (d) chelating bis-bidentate and monodentate [11];

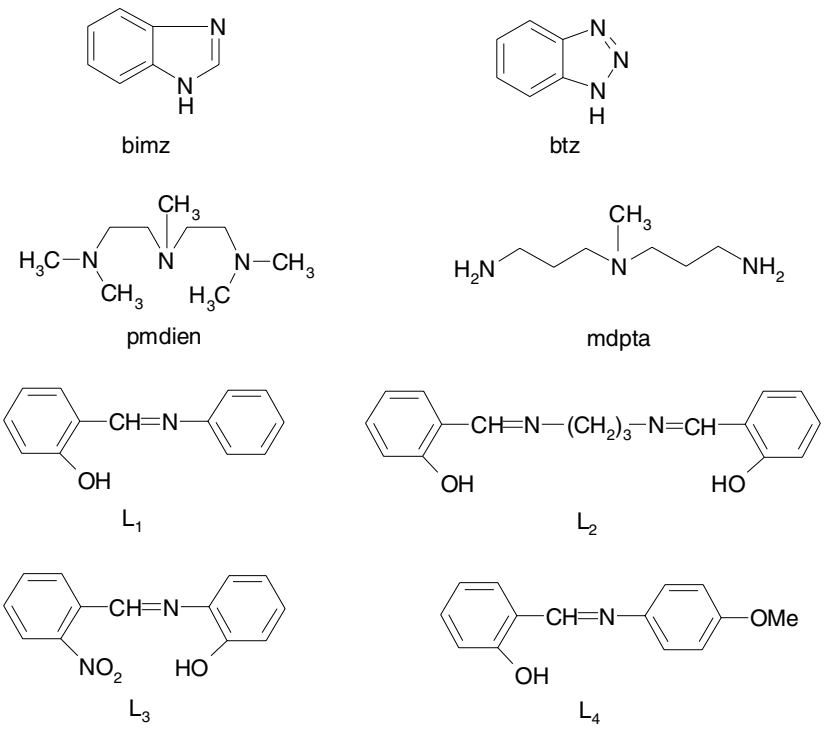
(e) chelating tris-bidentate [12]; chelating/bridging bidentate and monodentate [13] (see Scheme 1). Nickel complexes with btc in combination with tetraaza- and hexaazamacrocyclic ligands, pyridine derivatives or polybasic alcohols, have been prepared and structurally characterized [14–19]. The hydrothermal method has been used for the preparation of Mn, Co and Zn complexes with a $btcH^{2-}$ bridge. The structures consist of double stranded chains of dianions and dimeric units. Magnetic studies showed that a ferromagnetic interaction occurs in Mn and Co complexes [20]. Synthesis and study of copper complexes containing btc bridges and *N*-heterocyclic amines have been reported [21–23]. Comba et al. have prepared a copper complex; X-ray analysis confirmed that the btc^{3-} anion is situated outside the coordination sphere [24].

The aim of our work was the preparation and study of nickel and copper complexes containing a combination of btc^{3-} anion and selected N-donor ligands or Schiff bases in the coordination sphere (the used ligands are depicted in Scheme 2). The ligands were used to block coordination sites of the central atoms and to prevent formation of polymers. We prepared also trinuclear species and solved the X-ray structure of complex **8**. EPR and magnetic study of the complex proved that the benzenetricarboxylate bridge is not suitable for exchange interactions between the central atoms.

Scheme 1. Coordination modes of benzene-1,3,5-tricarboxylic acid (H_3btc).



2. Experimental

2.1. Materials and methods

All chemicals and solvents were supplied from Aldrich, Carlo Erba and Lachema (Czech Republic) and were used as received. Compound $Ni(Hbtc) \cdot 12H_2O$ was prepared by the reaction of $NiCO_3 \cdot 2Ni(OH)_2 \cdot 4H_2O$ (6.76 g, 30 mmol) and H_3btc (7.10 g, 20 mmol) in water (50 cm^3). The reaction mixture was refluxed for 5 h. After cooling, a green precipitate was filtered off, washed with water and dried in air. Schiff base L_2 was obtained by condensation of salicylaldehyde (4.18 cm^3, 20 mmol) with 1,3-diaminopropane (1.66 cm^3, 20 mmol) in ethanol (100 cm^3). Na_3btc was prepared by neutralization of H_3btc (2.1 g, 10 mmol) with NaOH (1.2 g, 30 mmol) in water (100 cm^3).

The C, H, N analyses were carried out on an EA 1108 instrument (Fisons). The content of nickel and copper was determined by chelatometric titration on murexid as an indicator. UV–Vis spectra were recorded on an UV–Vis Spectrometer Lambda 35 (Perkin–Elmer) and IR spectra on a FT-IR Spectrometer Spectrum One (Perkin–Elmer) using KBr pellets. The molar conductivity was measured on a Conductivity Meter LF 340 (WTW, Germany). Thermal analysis was performed on an Exstar (Seiko Instruments Inc.). Magnetochemical data at room temperature were obtained by the Faraday method. $Hg[Co(SCN)_4]$ was used as a calibrant. Magnetization measurements at a magnetic field of 0.5 T in the temperature range 1.8–300 K were performed using a Quantum Design SQUID-based MPMSXL-5-type magnetometer. The SQUID magnetometer was calibrated with a palladium rod sample (Materials Research Corporation, measured purity 99.9985%). The superconducting magnet was generally operated at a field strength ranging from 0 to 5 T. Corrections are based on subtracting the sample-holder signal and contribution χ_D estimated from Pascal constants (-401×10^{-6} cm^3 mol^{-1} per trimer). A temperature-independent paramagnetism of 60×10^{-6} cm^3 K mol^{-1} for the copper(II) ion was used. Additional magnetization measurements were made at 2 K in a magnetic field from 0 to 5 T. EPR spectra were recorded at 293 and 77 K on a Bruker ESP 300 spectrometer operating at X-band equipped with an ER 035M Bruker NMR gaussmeter and an HP 5350B Hewlett–Packard microwave frequency counter. The spectrum at 4.2 K was measured with an X-band Radiopan SE/X 2543 Spectrometer.

The antimicrobial activities of the complexes against *Staphylococcus aureus* CCM 3953, *Enterococcus faecalis* CCM 4224, *Escherichia coli* CCM 3954, *Pseudomonas*

Scheme 2. Structural formulas of used ligands.

aeruginosa CCM 3955, *Staphylococcus epidermidis*, *S. aureus* MRSA, *Enterococcus faecium* VRE and *Klebsiella pneumoniae* ESBL were estimated and expressed as minimal inhibitory concentrations MIC ($\mu g\,mL^{-1}$). The bacteria were inoculated into a liquid medium (Mueller–Hinton or Brain Heart Infusion broth). The test complexes were dissolved in DMSO and diluted by water. Solutions with concentrations 100–0.78 $\mu g\,mL^{-1}$ were used for testing. Bacteria were cultured for 24 h at 37 °C; then the growth of microorganisms was observed. When no growth of microorganisms was observed in the medium containing the lowest concentration of test materials, the MIC of the test material was defined at this point of dilution. All compounds were tested two times and results are given as an average of two independent experiments [25].

2.2. Syntheses

2.2.1. $Ni_3(bimz)_6(btc)_2 \cdot 12H_2O$ (**1**)

Bimz (0.47 g, 4 mmol), dissolved in ethanol (96%, 25 cm^3) was added to a suspension of $Ni(Hbtc) \cdot 12H_2O$ (0.48 g, 1 mmol) in water (50 cm^3). The reaction mixture was refluxed for 5 h. After cooling a violet-blue precipitate was filtered off, washed with small amounts of ethanol and dried at room temperature. Yield: 64%.

2.2.2. $Ni_3(btz)_9(btc)_2 \cdot 12H_2O$ (**2**)

A solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1 mmol) in water (25 cm^3) was mixed with a solution of Na_3btc (0.1 mol/dm^3, 3.3 cm^3). After addition of btz (0.24 g, 2 mmol) dissolved in hot water (25 cm^3) a violet-blue precipitate was formed. It was filtered off, washed with water and dried at room temperature. Yield: 56%.

2.2.3. $Ni_2(L_1)(btc) \cdot 7H_2O$ (**3**)

$NiCl_2 \cdot 6H_2O$ (0.24 g, 1 mmol) was dissolved in ethanol (25 cm^3). After addition of Schiff base L_1 (0.20 g, 1 mmol) a yellow-green solution was obtained. Triethylamine (0.14 cm^3, 1 mmol) was added and solution color changed to dark green. After addition of a solution of Na_3btc (0.1 mol/dm^3, 3.3 cm^3) a green precipitate was formed. It was filtered off, washed with water and ethanol and dried at room temperature. Yield: 44%.

2.2.4. $Ni_3(L_2)_2(Hbtc) \cdot 9H_2O$ (**4**)

$NiCl_2 \cdot 6H_2O$ (0.23 g, 1 mmol) was dissolved in ethanol (25 cm^3). After addition of a solution of Schiff base L_2 (0.2 mol/dm^3, 5 cm^3), a dark green solution was obtained. Triethylamine (0.14 cm^3) was added and the solution color turned brown-red. After addition of a solution of Na_3btc (0.1 mol/dm^3, 3.3 cm^3) a green precipitate was obtained. It was filtered off, washed with water and ethanol and dried at room temperature. Yield: 71%.

2.2.5. $Ni_2(L_3)(btc) \cdot 4H_2O$ (**5**)

$Ni(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1 mmol) was dissolved in ethanol (50 cm^3). After addition of Schiff base L_3 (0.49 g, 2 mmol) a brown-yellow solution was obtained. Triethylamine (0.28 cm^3) was added and the solution color turned dark red. After addition of a solution of Na_3btc (0.1 mol/dm^3, 3.3 cm^3) a brown precipitate was formed. It was

filtered off, washed with water and ethanol and dried at room temperature. Yield: 69%.

2.2.6. $Cu_2(L_4)(btc)\cdot 7H_2O$ (6)

$CuCl_2\cdot 2H_2O$ (0.17 g, 1 mmol) was dissolved in methanol (25 cm^3). After addition of Schiff base L_4 (0.23 g, 1 mmol) a brown-yellow solution was obtained. Triethylamine (0.14 cm^3) was added and the solution color turned dark brown. After addition of a solution of Na_3btc (0.1 mol/dm^3, 3.3 cm^3) a brown precipitate was obtained. It was filtered off, washed with water and ethanol and dried at room temperature. Yield: 77%.

2.2.7. $[Cu_3(pmdien)_3(btc)](ClO_4)_3\cdot 6H_2O$ (7)

Pmdien (0.21 cm^3, 1 mmol) was added to a solution of $Cu(ClO_4)_2\cdot 6H_2O$ (0.37 g, 1 mmol) in water (25 cm^3). After addition of Na_3btc solution (0.1 mol/dm^3, 3.3 cm^3), a dark blue precipitate was formed. It was filtered off, washed with ethanol and dried at room temperature. Yield: 56%.

2.2.8. $[Cu_3(mdpta)_3(btc)](ClO_4)_3\cdot 4H_2O$ (8)

Mdpta (0.32 cm^3, 2 mmol) was added to a solution of $Cu(ClO_4)_2\cdot 6H_2O$ (0.74 g, 2 mmol) in ethanol (50 cm^3) After addition of a solution of Na_3btc (0.1 mol/dm^3, 3.3 cm^3), a dark blue solution was obtained. Dark blue crystals were obtained in one week. The crystals were collected on a frit, washed with water and dried at room temperature. Yield: 48%.

2.3. X-ray crystallography

X-ray data were collected using a four circle κ-axis diffractometer Xcalibur™2 (Oxford Diffraction) equipped with a Sapphire2 CCD detector, a monochromator Enhance and a Cryojet cooler system, using Mo Kα radiation at 107 K. The CrysAlis program package (1.171.7 version) was used for data reduction. Details of the structure are discussed in Section 3.2.

3. Results and discussion

3.1. Physical techniques

The results of the elemental analyses and physico-chemical study are listed in Tables 1 and 2. The IR spectra of all the complexes show the characteristic bands of carboxylate groups in the region 1542–1614 cm^{-1} for the $\nu_{as}(COO^-)$ and 1350–1378 cm^{-1} for the $\nu_s(COO^-)$ vibrations. IR spectra of complexes containing Schiff bases (**3**–**6**) exhibit bands at 1614–1618 cm^{-1}, which can be assigned to the ν(C=N) vibrations. In the IR spectra of copper complexes **7** and **8** bands were found at 1096, 618 cm^{-1} and 1091, 624 cm^{-1} for **7** and **8**, which can be assigned to the $\nu_3(ClO_4)$ and $\nu_4(ClO_4)$ vibrations, typical for a non-coordinated perchlorate anion [26].

The nickel complexes have effective magnetic moments in the 2.73–3.72 B.M. range (per one Ni atom). For these complexes we can assume octahedral (**1**, **4**, **5**) or penta-coordinated (**2**, **3**) arrangements of donor atoms around

the central nickel atom. The large magnetic moments can be due to large orbital contributions expected for trigonal bipyramidal Ni(II) complexes with orbitally degenerate states [27]. If we assume a distorted octahedral arrangement for complexes **1**, **4** and **5**, the bands found in UV–Vis spectra in the 17 500–21 400 cm^{-1} and 22 900–28 000 cm^{-1} region can be assigned to the $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$ transitions, respectively [28]. The UV–Vis bands of complexes **2** (at 15 500, 27 400 cm^{-1}) and **3** (at 17 500, 27 100 cm^{-1}), can be assigned to the $^3E' \rightarrow {}^3E''$ and $^3E' \rightarrow {}^3A_2'$ transitions, respectively, when a trigonal-bipyramidal geometry is suggested [29].

TG curves of the complexes **3**–**5** (not shown) exhibit no plateau that could be assigned to thermally stable intermediates. The thermal decomposition is complete between 425 and 480 °C and the final product is NiO, which was confirmed by powder X-ray diffraction analysis.

The copper complexes exhibit effective magnetic moments in the 1.90–2.07 B.M. range (per one Cu atom). These values are in good agreement with the assumption of one unpaired electron of Cu(II) ion where an orbital contribution also occurs [30]. The UV–Vis absorption spectra of the copper complexes contain bands in the region 15 500–24 300 cm^{-1} and 28 100–33 700 cm^{-1}, belonging probably to d–d and CT transitions. Complex **6** could be polymeric and we can assume an octahedral or pentacoordinated arrangement of the chromophore. In complex **7** we can assume a similar arrangement of donor atoms around the central copper atom as in complex **8** (confirmed by single crystal X-ray analysis).

The complexes are insoluble in most common organic solvents except for complex **7**, which is soluble in dimethylformamide and water. The molar conductivity of complex **7** in dimethylformamide (10^{-3} mol dm^{-3}) is 218.1 S cm^2 mol^{-1}, which is a value typical for 3:1 electrolytes [31]. The perchlorate anions are situated outside the coordination sphere of the central copper atom.

The antimicrobial activities of the complexes were estimated and it was found that only complex **5** exhibits a very small activity against *S. aureus* CCM 3953, *S. epidermidis* and *S. aureus* MRSA for the maximum concentration used (100 μg mL^{-1}). The remaining complexes do not significantly inhibit the growth of the test organisms.

3.2. Crystal structure of $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$ (**8**)

The structure was solved by standard SHELX programs [32,33]. Crystal data and structure refinement is given in Table 3; selected bond and angles are listed in Table 4. It is apparent that the molecule (see Fig. 1) forms a trinuclear

Table 4
Selected bond lengths (Å) and angles (°) of $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$

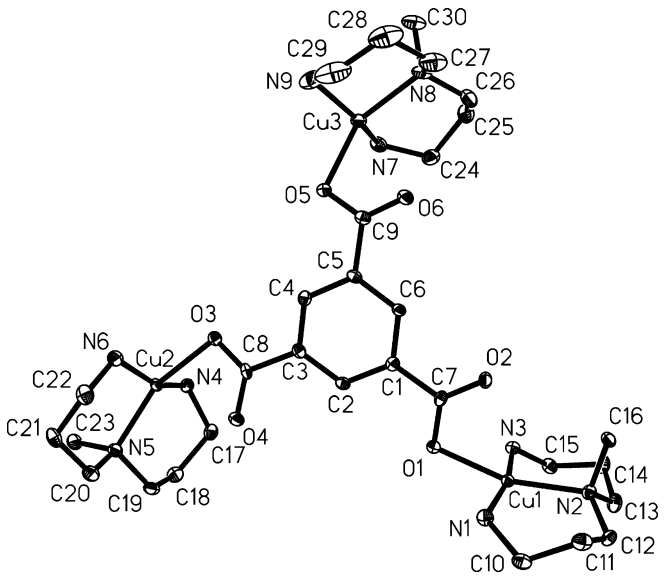

Fig. 1. Molecule of $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$. Thermal ellipsoids are drawn at 50% probability level. Perchlorate ions and solvating water molecules are omitted for clarity.

copper complex, containing three CuN_3O chromophores connected via a benzene-1,3,5-tricarboxylate bridge. The perchlorate anions and water molecules are out of the coordination sphere. The geometry of the chromophores is square planar (see Table 4), but with a significant tetrahedral distortion. The deviations from ideal CuN_3O planes (in Å) are for O-atoms: from 0.239(2) to −0.375(2); for N-atoms: from 0.081(2) to 0.582(3) and from −0.383(2) to −0.734(2). The dihedral angles between Cu(1)O(1)N(1)N(2)N(3) (**A**), Cu(2)O(3)N(4)N(5)N(6) (**B**) and Cu(3)O(5)N(7)N(8)N(9) (**C**) are: **A**–**B** 106.5(2)°; **A**–**C** 96.5(2)° and **B**–**C** 9.9(3)°.

The subsequent anisotropic refinement converged to a reasonable fit $R_1 = 0.0757$ for observed reflections $I > 3\sigma(I)$. However, Fourier maps in the vicinity of one of the ClO_4^- anions revealed a clear indication of some disorder. Even more convincing was the difference Fourier map in the same area. Another Cl position slightly shifted from the original one has been located. Moreover we could also localize a separate peak having a reasonable distance from that new Cl position. The vector between these two new atoms had the opposite direction with respect to one of original Cl–O bonds. This made it possible to deduce that the second position of ClO_4^- is related to the basic position by a rotation about 180° perpendicular to the original Cl–O bond. The remaining three new oxygen positions could not be localized so clearly because the rotation brings them too close the original ones.

The rigid body option of Jana 2000 has been used to make a final refinement [34]. One molecule with adjustable shape in the two above mentioned positions has been used. Together with the average geometry of ClO_4 we refined also translation and rotation parameters for each position and the site occupancies restricted by the complementary condition. The occupancy of the new position was refined to 0.235(2).

As the next step we have localized five possible positions for water molecules. Three of them were regularly distributed over the available space. Two remaining peaks, located in the vicinity of the disordered ClO_4^-, were not fully occupied and the refined occupancies were in a close relationship with those for the two positions of ClO_4^-. A more detailed analysis of O–O distances showed that the more occupied position of the water molecule makes too short a distances with oxygen atoms from the less occupied ClO_4^- position and vice versa.

Finally, the structure has been completed with the hydrogen atoms except for those belonging to water molecules. The H positions were restrained to keep an ideal geometry during the refinement.

3.3. EPR spectra and magnetic properties of $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$ (**8**)

The magnetic properties of the trimer were determined over the temperature range 1.8–300 K. Plots of the magnetic susceptibility and reciprocal magnetic susceptibility are given in Fig. 2. The magnetic dependence of the experimental and calculated $\chi_{Cu}T$ in the field (0.5 T) for the trimer (χ_{Cu} is the susceptibility value per one copper center) is shown in Fig. 3.

The Curie–Weiss behavior indicates a linear relation of the reciprocal magnetic susceptibility curve at higher temperatures (100–300 K) with a Curie constant $C = 0.426\ cm^3\ mol^{-1}\ K$ and Weiss-constant, $\theta = -1.74$ K and a small anomaly is observed only at the lowest temperatures. The compound reveals a magnetic behavior which is characteristic of antiferromagnetic spin coupling. The $\chi_{Cu}T$ values decreases gradually with lowering of the temperature, from $0.425\ cm^3\ mol^{-1}\ K$ at 300 K to $0.256\ cm^3\ mol^{-1}\ K$ at 1.8 K, and the effective magnetic moment from 1.85 B.M. at 300 K to 1.43 B.M. at 1.8 K.

The powdered sample of the complex indicates a rhombic deformed square-pyramidal EPR spectrum in

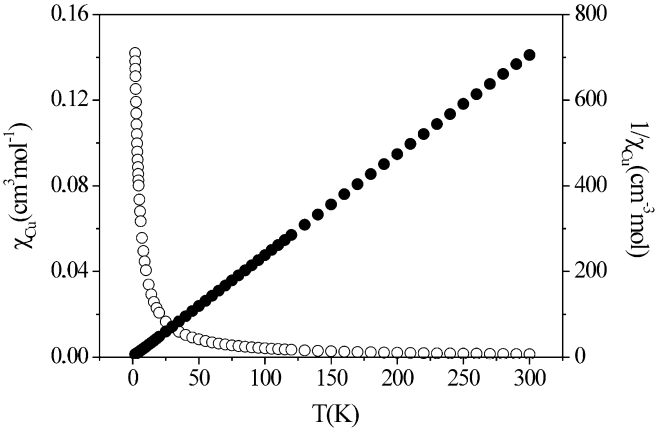

Fig. 2. Plots of the magnetic data χ_{Cu} (○) and $1/\chi_{Cu}$ (●) versus temperature for $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$.

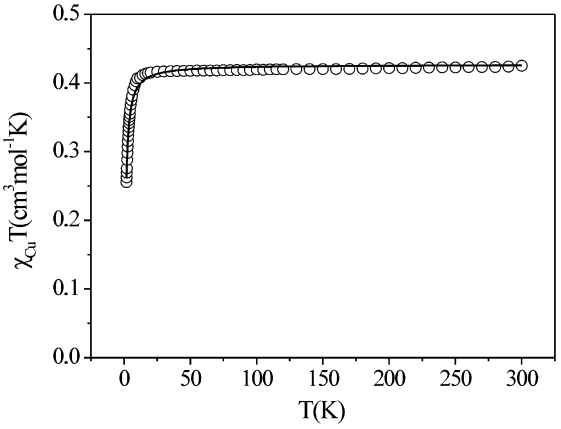

Fig. 3. Plots of the magnetic data $\chi_{Cu}T$ experimental (○) versus temperature for $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$. Full line represents the calculated curve (see text).

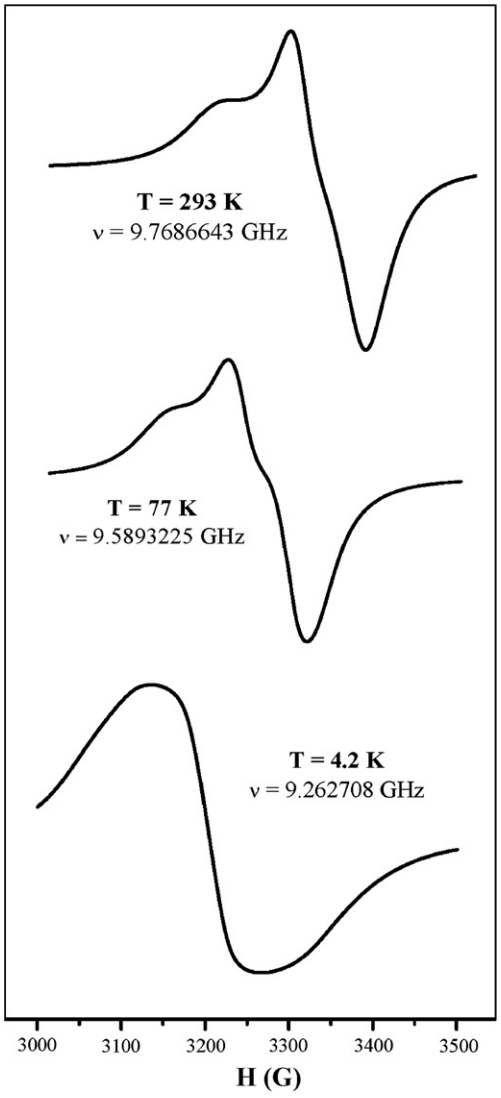

Fig. 4. X-band EPR spectra of a powdered sample of $[Cu_3(mdpta)_3(btc)](ClO_4)_3 \cdot 4H_2O$ at different temperatures.

the higher temperature region (Fig. 4) with spectroscopic splitting factors $g_1 = 2.17_8$, $g_2 = 2.11_8$, $g_3 = 2.07_0$ at 293 K and $g_1 = 2.17_4$, $g_2 = 2.11_9$, $g_3 = 2.06_8$ at 77 K.

At liquid helium temperature (4.2 K), an isotropic EPR signal with a single symmetric line only at $g = 2.06(1)$ with $\delta H_{pp} = 180$ G is observed.

X-ray analysis indicated that the Cu(II) centers form a regular triangle. An isotropic exchange model Hamiltonian of the trimer can be written as follows:

$$\widehat{H} = -2J(\widehat{S}_1\widehat{S}_2 + \widehat{S}_2\widehat{S}_3 + \widehat{S}_1\widehat{S}_3)$$

where $S_i = 1/2$, J is an exchange parameter.

A closed-form solution of the magnetic susceptibility derived from the susceptibility takes the form [35–39]:

$$\chi = \frac{Ng^2\mu_B^2}{4kT}\frac{1 + 5e^{3J/kT}}{1 + e^{3J/kT}}$$

where N, g, β, k and T have their usual meanings and both J and g factors were calculated in the fitting processes. The best least-squares fit (solid lines in Fig. 3) was obtained for the following values: $J = -0.56\ cm^{-1}$, $g = 2.13_9$ and $R = 4.79 \times 10^{-5}$.

$$R = \sqrt{\left\{\sum_{i=1}^{n}\left[(\chi_M^{exp})_i - (\chi_M^{calc.})_i\right]^2 \Big/ (\chi_M^{exp})_i^2\right\} \Big/ \sum_{i=1}^{n} 1 \Big/ (\chi_M^{exp})_i^2}$$

Abstract

Solution equilibrium studies on Cu(II)-, Ni(II)- and Zn(II)-*N*-Me-β-Alaninehydroxamic acid (*N*-Me-β-Alaha), -*N*-Me-α-alaninehydroxamic acid (*N*-Me-α-Alaha), -Imidazole-4-carbohydroxamic acid (Im-4-Cha), -*N*-Me-imidazole-4-carbohydroxamic acid (*N*-Me-Im-4-Cha) and -Imidazole-4-acetohydroxamic acid (Im-4-Aha) systems have been performed by pH-potentiometry, UV–Vis spectrophotometry, EPR, CD, ESI-MS and ^{1}H NMR methods. According to the results: (i) the amino-N atoms are more basic in *N*-Me-α-Alaha and *N*-Me-β-Alaha than the hydroxamate function, but the trend is just the opposite between the imidazole-N(3) and hydroxamate. (ii) The metal ion anchor is always the hydroxamate part in the amino acid derivatives, while it is always the imidazole-N(3) in the studied imidazolehydroxamic acids. (iii) The three studied *N*-Me derivatives do not form metallacrowns. Only hydroxamate type chelate is formed with *N*-Me-β-Alaha, but with *N*-Me-α-Alaha a new type of coordination mode (via amino-N and hydroxamate-O) also exists. *N*-Me-Im-4-Cha also forms a dinuclear complex, $[M_2L_3]$, with Cu(II) and Ni(II) (but not with Zn(II)). In this complex, one of the three ligands might bridge the two metal ions (five-membered hydroxamate-(O,O) plus five-membered (N_{im}, O_{carb}) bridging bis-chelating mode), while each of the additional two ligands binds to one metal. (iv) The two studied *N*–H derivatives, having dissociable proton on the hydroxamic-N, are able to form metallacrown species. A pentanuclear complex, $[M_5L_4H_{-4}]$, is exclusively formed above pH 4 between Cu(II) and Im-4-Aha. Interestingly, this 12-metallacrown-4 type complex, although together with various mononuclear binding isomers, appears also with Ni(II) and Zn(II). Unfortunately, the complexes of Im-4-Cha are not soluble in water at physiological pH at all.

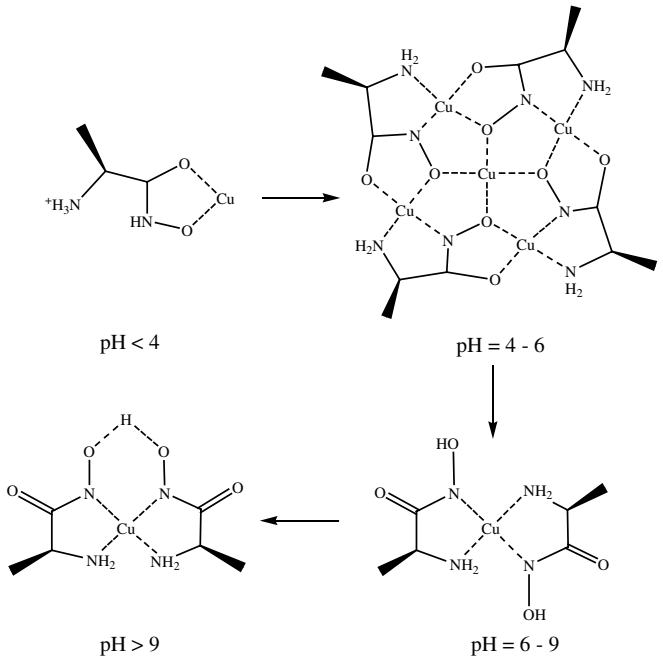
1. Introduction



Hydroxamic acids are among the most well studied compounds due to their significance in so many fields [1]. Natural hydroxamate-based compounds, siderophores, play a crucial role in microbial iron(III) storage and transport [1,2]. Hydroxamic acids are also capable for the inhibition of a wide variety of enzymes including matrix metalloproteinases [1–4] or ureases [5,6]. There is no doubt that the inhibitory effect is in correlation with chelation of the catalytic metal center by the hydroxamate function. However, metal complexation of hydroxamic acids depends on many factors, such as the presence of additional potential donor site(s). This is the reason why characterization of the

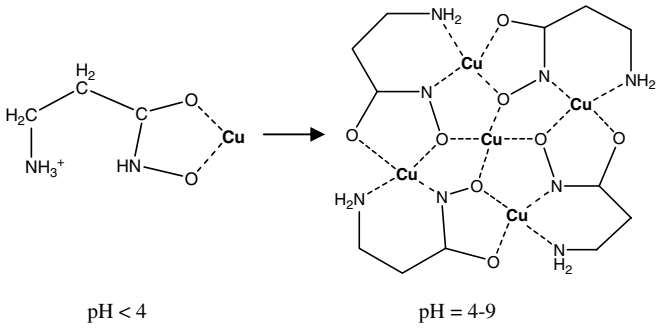
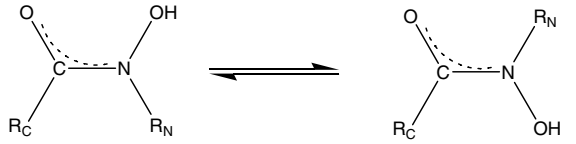
doi:10.1016/j.poly.2006.08.019



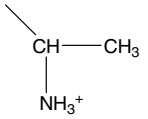
interaction between metal ions and various hydroxamates might provide useful information to understand inhibitory effect of such molecules.

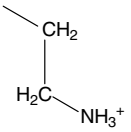
Hydroxamic acid derivatives of natural amino acids have also become into the focus of interest [7–16]. Some of them were prepared to chelate certain trace elements being essential in animal nutrition [12], or as potential metalloenzyme inhibitors [13]. However, the presence of the amino group may cause significant change in the coordination mode compared to that in simple hydroxamic acids. For example, when an amino group is situated in α-position to the hydroxamic moiety (like in α-alaninehydroxamic acid) the coordination to Cu(II) starts via the hydroxamate chelate, but as the pH is increased a metallacrown-type polynuclear species, in which each deprotonated ligand (LH_{-1}) is coordinated in bridging bis-chelating mode, plus one additional metal ion is accommodated in the formed cavity, appears between pH 4 and 6. Although, 15-metallacrown-5 type complexes were synthesized by Pecoraro and co-workers with α-derivatives [8], but in solution 12-metallacrown-4 type was proven by ESI-MS in recent works [10,11]. At pH ca. 6, where the conditional stability of the five-membered (N_{am}, N_{hydr}) chelate overpasses the stability of the five-membered hydroxamate-(O,O), the formation of (N_{am}, N_{hydr}), formation of 4N-coordinated bis-chelated mononuclear species becomes favoured. The four nitrogens remain co-ordinated at pH > 9 too, but, following the deprotonation of one of the coordinated hydroxamate groups, a hydrogen bond is formed between the two ligands [7,10,11]. The suggested bonding modes are the followings:

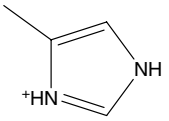
Although Zn(II) seems to prefer the hydroxamate oxygens somewhat over the nitrogens, a mixed coordination mode in Zn_2L_3 species was also suggested between α-amino acid derivatives and this metal ion [7,14]. Nickel(II) unambiguously prefers the five-membered (N_{am}, N_{hydr}) chelate over the hydroxamate type coordination as it was proved first for the nickel(II)–glycinehydroxamate square planar bis-complex by X-ray investigations [15].

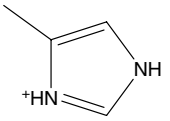


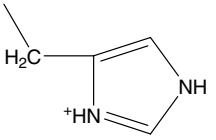
Hydroxamate oxygens of β-alaninehydroxamate start to coordinate to Cu(II) above pH 3, then a pentanuclear 12-metallacrown-4 (shown below) predominates above pH 4 [16].











Even a six-membered (N_{am}, N_{hydr}) chelate seems to be more stable than the five-membered hydroxamate (O,O) type one above pH 7 with Ni(II), therefore nitrogen-coordinated planar complex appears in this pH region. Zn(II) prefers hydroxamate type coordination with β-amino acid derivatives [7].

As it is shown above, the coordination behaviour of aminohydroxamic acids is determined highly by the amino-N and hydroxamate-N donors. But what is the situation with *N*-methyl derivatives of aminohydroxamic acids, where coordination via the hydroxamate-N is not possible? Do these derivatives realize only simple hydroxamate type coordination? This is an important question, because chelation of the active-site metal ion by hydroxamate function is thought to be a crucial factor for effective metalloenzyme inhibition by hydroxamate-based molecules [1]. Therefore, the present solution equilibrium study focuses on the complexation between Cu^{2+}, Ni^{2+}, Zn^{2+} ions (these metal ions are often included in the active centres of metalloenzymes) and *N*-methyl derivatives of aminohydroxamic acids, *N*-methyl-L-α-alaninehydroxamic acid (*N*-Me-α-Alaha), *N*-methyl-β-alaninehydroxamic acid (*N*-Me-β-Alaha). Besides, new compounds, imidazole-4-carbohydroxamic acid (Im-4-Cha), *N*-methyl-imidazole-4-carbohydroxamic acid (*N*-Me-Im-4-Cha) or imidazole-4-acetohydroxamic acid (Im-4-Aha), were also studied, in which the highly basic amino-nitrogen is replaced by the less basic imidazole-N donors. These compounds have been synthesized and investigated because of two reasons. Namely, the less basic imidazole donors might provide lower competitive effect to the hydroxamate-type chelation, but, on the other hand, an aromatic imidazole-ring can be involved more easily in non-covalent interactions (such as stacking interactions) than an amino function. Beside pH-potentiometry, UV–Vis, CD, EPR, ^{1}H NMR and ESI-MS measurements

Table 1
Formulae of the studied ligands

(*Z*) (*E*)

Ligands	R_C	R_N
L-*N*-Methyl-α-alaninehydroxamic acid (*N*-Me-α-Alaha)		–CH_3
N-Methyl-β-alaninehydroxamic acid (*N*-Me-β-Alaha)		–CH_3

N-Methyl-imidazole-4-carbo-hydroxamic acid (*N*-Me-Im-4-Cha)		–CH_3
Imidazole-4-acetohydroxamic acid (Im-4-Aha)		–H

were carried out in aqueous solution. The formulae of the studied ligands are summarized in Table 1. The results were always compared to the corresponding literature data of L-α-alaninehydroxamic acid (L-α-Alaha) and β-alaninehydroxamic acid (β-Alaha).

2. Experimental

2.1. Synthesis

All chemicals and solvents were of analytical grade and were used without further purification. Imidazole-4-acetic acid hydrochloride, imidazole-4-carboxylic acid was purchased from Aldrich, Z-L-α-alanine from Bachem, diciclohexylcarbodiimide (DCC) from Fluka. Methanol was dried under N_2 using magnesium while dry tetrahydrofurane was made under N_2 using Na wire and benzophenone. L-α-Alaha and β-Alaha were prepared as reported previously [17]. Imidazole-4-carbohydroxamic acid · HCl (Im-4-Cha) and *N*-methylimidazole-4-carbohydroxamic acid · HCl (*N*-Me-Im-4-Cha) were also prepared by using literature methods [18,19].

2.1.1. Z-protected L-α-Alanine methyl esther (*1*)

Z-Alanine (3.0 g, 13.4 mmol) in freshly distilled dry methanol (20 mL) was converted to Z-Ala-methyl esther bubbling dry hydrochloride gas for one hour in ice-bath. Solvent was evaporated in vacuo, affording the pure product as white crystals. Yield: 3.0 g, 97%. TLC: eluent: CH_2Cl_2:MeOH 9:1, R_f: 0.77. ^{1}H NMR (360 MHz, D_2O-DMSO-d^6 mixture): $\delta = 7.53$ (s, 5H, Ar–H), 5.23 (s, 2H, Ar–CH_2), 4.30 (q, 1H, Ala–CH), 3.84 (s, 3H, O–CH_3), 1.48 (d, 3H, Ala-CH_3).

2.1.2. Z protected N-methyl L-α-Alaninehydroxamic acid (*2*)

1 (1.7 g, 7.165 mmol) was reacted with a solution of *N*-methyl hydroxamine (658 mg, 7.88 mmol) in dry methanol (20 mL) and Na-methylate solution (4.15 mL, 3.23 M, 13.40 mmol) at 0 °C. After the reaction mixture was strirred overnight in ice bath, water (4 mL) and 2 M HCl solution was added to neutralize the mixture. Solvent was removed in vacuo and the residual oil was dissolved in water (5 mL). This solution was extracted with ethylacetate (3×15 ml). The organic phase was extracted with 0.2 M NaOH solution (4×50 mL) and the aqueous phase was acidified to pH 2 using 2 M HCl and extracted again with ethylacetate (2×20 mL). After drying on Na_2SO_4, evaporation of the solvent in vacuo yielded a colourless oil. Yield: 430 mg, 24%. TLC: eluent: CH_2Cl_2:MeOH 9:1, R_f: 0.52. ^{1}H NMR (360 MHz, D_2O and DMSO mixture): $\delta = 7.51$ (s, 5H, Ar–H), 5.19 (s, 2H, Ar–CH_2), 4.22 (q, 1H, Ala–CH), 3.32 (s, 3H, N–Me), 1.38 (d, 3H, Ala–CH_3).

2.1.3. N-Methyl-L-α-Alaninehydroxamic acid · HCl (N-Me-α-Alaha) (*3*)

2 (425 mg, 1.68 mmol) was dissolved in dry methanol (10 mL), acidified by using HCl in dry methanol and stirred under H_2 atmosphere for six hours in the presence of palladium charcoal (142 mg 10% Pd). After filtration the solvent was removed in vacuo affording a colourless oil. Yield: 178 mg, 90%. TLC: eluent: CH_2Cl_2:MeOH 9:1, R_f: 0.0, ^{1}H NMR (360 MHz, D_2O): $\delta = 4.58$ (q, 1H, Ala–CH), 3.35 (s, 3H, N–Me), 1.58 (d, 3H, Ala–CH_3). ^{13}C NMR (360 MHz, D_2O): $\delta = 169.57$ (C=O), 47.18 (Ala–CH), 36.17 (N–CH_3), 15.13 (Ala–CH_3).

2.1.4. Z protected N-methyl-O-benzyl-β-alaninehydroxamic acid (*4*)

O-Benzyl-*N*-methyl hydroxylamine hydrochloride (1.75 g, 10.1 mmol) was dissolved in dry methanol (20 mL), chilled, KOH (0.58 g, 10.1 mmol) was added as solid and the mixture was stirred for 15 min under N_2. KCl was filtered out and the solution kept at 0 °C. Z-β-Alanine (1.50 g, 6.73 mmol) was dissolved in dry tetrahydrofurane (40 mL) and chilled. Ethylchloroformiate (0.77 mL, 8.08 mmol) and *N*-methyl morpholine (0.96 ml, 8.75 mmol) were added. After 40 min of stirring at 0 °C the solid was filtered out and the solution dropwise added to the solution of the free hydroxylamine. The reaction

mixture was stirred under N_2 in ice-bath for two hours and for one hour at ambient temperature. The solvent was evaporated in vacuo resulting an oil, which was taken up in ethylacetate (50 mL), washed with the citric acid (0.5 M, 2 × 25 mL), $NaHCO_3$ (0.5 M, 2 × 25 mL) and brine (1 × 25 mL). It was dried on $MgSO_4$ and evaporated to dryness affording a colourless oil. (Yield: 1.0 g, 43%), TLC: eluent: CH_2Cl_2:MeOH 9:1, R_f: 0.85, ^{1}H NMR (360 MHz, D_2O): $\delta = 7.41$ (s, 5H, Ar–H), 5.09 (s, 2H, Ar–CH_2), 3.39 (t, 2H, Ala–CH_2), 3.19 (s, 3H, N–Me), 2.68 (t, 2H, Ala–CH_2).

2.1.5. *N*-Methyl-β-alaninehydroxamic acid · HCl (*N*-Me-β-Alaha) (**5**)

4 (250 mg, 0.73 mmol) was subjected to hydrogenolysis in methanol (10 mL), using palladium charcoal (75 mg, 10% Pd) and HCl solution (1.94 M, 0.65 mL) for four hours. After filtration and evaporation the solution afforded a colourless oil. (Yield: 78 mg, 90%). TLC: eluent: THF:MeOH:H_2O 5:5:1, R_f: 0.25, ^{1}H NMR (360 MHz, D_2O): $\delta = 3.27$ (t, 2H, Ala–CH_2), 3.24 (s, 3H, N–Me), 2.90 (t, 2H, Ala–CH_2), ^{13}C NMR (360 MHz, D_2O): $\delta = 170.28$ (C=O), 35.94 (Ala–CH_2–NH_2), 35.38 (N–CH_3), 28.85 (Ala–CH_2).

2.1.6. Imidazole-4-acetohydroxamic acid · HCl (Im-4-Aha) (**6**)

Imidazole-4-acetic acid hydrochloride (500 mg, 3.08 mmol) and hydroxylamine hydrochloride (630 mg, 9.2 mmol) were dissolved in dry methanol (10 mL) under N_2. At 0 °C dicyclohexylcarbodiimide (DCC) (950 mg, 4.6 mmol) was added. After stirred overnight in ice bath, the reaction mixture was filtered and the residue was evaporated to dryness in vacuo at 40 °C yielding a white foam. It was treated with water (7 mL) and ethanol (8 drops), filtered, washed with a small amount of cold water. The resulting solution was extracted with dichloromethane (6 × 15 mL). The aqueous phase was acidified to pH 2 by using 0.2 M HCl. Solvent was removed in vacuo yielding white crystals, which were recrystallised from ethanol affording white needles. (Yield: 110 mg, 25%). TLC: eluent: CH_2Cl_2:MeOH 9:1, R_f: 0.90. ^{1}H NMR (360 MHz, D_2O): $\delta = 8.66$ (s, 1H, imH^2), 7.38 (1H, imH^5), 3.73 (2H, im-CH_2). ^{13}C NMR (360 MHz, D_2O): $\delta = 167.01$ (C=O), 134.28 (im C^4), 126.01 (im C^2), 117.60 (im C^5), 28.09 (–CH_2–).

2.2. Potentiometric and spectroscopic studies

The exact concentration of the ligand stock solutions was determined by the Gran's method [19]. The Cu(II) and Ni(II) stock solutions were prepared from $CuCl_2$ and $NiCl_2$ (Reanal) dissolved in bi-distilled water. Zn(II) stock solution was made from ZnO (Reanal) dissolved in diluted HCl of known concentration (0.1 M). For the Cu(II), Ni(II) and Zn(II) stock solutions, the exact metal ion concentrations were checked gravimetrically by the use of quinolin-8-olate. The exact concentrations of the ligand stock solutions were determined by pH-potentiometry. The pH-potentiometric and the spectrophotometric measurements were carried out at an ionic strength of 0.2 M (KCl). Temperature was 25.0 ± 0.1 °C. Carbonate-free KOH solution of known concentration (0.2 M) was used as titrant. HCl stock solution was prepared from cc. HCl. The concentration was determined by pH-potentiometric titrations using the Gran's method [20]. Radiometer pHM 84 instrument equipped with Metrohm combined electrode (type 6.0234.110) was used for pH-potentiometric measurements with a Metrohm 715 Dosimat automatic burette. The electrode system was calibrated according to Irving et al. [21] and the pH-metric readings could, therefore, be converted into hydrogen concentration. The water ionization constant (pK_w) determined was 13.76 ± 0.01. All the pH-potentiometric titrations were performed over the pH range of 2–11 or until precipitation occurred. Initial volume of the samples was 3.00–5.00 mL. Ligand concentration was 2–4 mM and metal ion concentration varied in the range of 1–6 mM, the metal to ligand ratios were 1:1, 1:2 and 1:3. The samples were completely deoxygenated by bubbling purified argon for approx. 20 min before the measurements. The equilibrium calculations were performed by the PSEQUAD computer program [22]. A Perkin Elmer Lambda 25 or an Avantes fiber optic spectrophotometer equipped with 10 mm probe head by using 100 ms integration time and an average of 50 spectra were used to record the UV–Vis spectra for the Cu(II) and Ni(II) complexes in the range of 300–800 nm at all metal to ligand ratios studied, in the 1–6 mM metal ion concentration region. CD spectra for L-α-Alaha or L-*N*-Me-α-Alaha and their Cu(II) systems were obtained at 25 °C under a constant flow of nitrogen on a Jasco J-810 spectropolarimeter which was calibrated with an aqueous solution of (1*R*)-(−)-10-camphorsulfonic acid, ammonium salt. Measurements were carried out in water at different pH values, using 1 mm or 1 cm path length cuvettes in the 200–800 nm wavelength region. Spectra represent an average of 8–20 scans. All the solutions were freshly prepared using deionized water. Concentrations of the hydroxamates and their copper(II) complexes used to record CD spectra were 0.004 and 0.002 M, respectively. ^{1}H NMR measurements were made for L-*N*-Me-α-Alaha, *N*-Me-β-Alaha, Im-4-Aha, Im-4-Cha and *N*-Me-Im-4-Cha ligands and for their Zn(II) complexes on Bruker Advance AM 360 by using D_2O as solvent and TSP ((trimethylsilyl)-propionic acid-D4, sodium salt) as standard under the following conditions: metal to ligand ratio was 1:2 in all samples and the analytical concentration of the ligands was 0.005 M. By the study of the dependence of the chemical shifts from pD values between pD 2 and 11 0.1 M NaOD and DCl solutions were used. Magnetic measurements were carried out by using the Evans method [23] on a Bruker Advance II 300 MHz NMR spectrometer. Co-axial NMR tubes were used for the investigations where the inset contained the reference D_2O solution with 2% of *t*-BuOH and in the outer tube had the paramagnetic species dissolved in

D_2O containing 2% of *t*-BuOH. The concentration of the metal ion was 0.003 M at 1:2 metal to ligand ratio. All measurements were carried out without ionic strength. pD values, in range 2–10, were set up with D_2SO_4 or NaOD. Electrospray ionization time-of-flight mass spectrometric (ESI-TOF MS) analysis was made for the Cu(II)-*N*-Me-α-Alaha, -Im-4-Aha and -*N*-Me-Im-4-Cha, for Ni(II)-Im-4-Aha, -Im-4-Cha and -*N*-Me-Im-4-Cha, and Zn(II)-Im-4-aha and -*N*-Me-Im-4-Cha system on a Bruker BIOTOF II ESI-TOF instrument by using 0.006 M ligand concentration at 1:2 metal to ligand ratio at pH 6. The solutions were introduced directly into the ESI source by a syringe pump (Cole-Parmer Ins. Comp. type 74900.) at a flow rate of 2 μL/min. The temperature of drying gas (N_2) was 100 °C. The pressure of the nebulizating gas (N_2) was 30 psi. Voltages applied at the capillary entrance, capillary exit and the first and the second skimmers were −4500, 120, 40 and 30 V, respectively. The spectra were accumulated and recorded by a digitizer at a sampling rate of 2 GHz. The spectrometer was operated at unit mass resolution and was calibrated to sodium trifluoroacetate. Anisotropic X-band EPR spectra of frozen solutions were recorded at 120 K, using a Bruker EMX spectrometer after addition of ethylene glycol to ensure good glass formation. Copper(II) stock solution for EPR measurements were prepared from $CuSO_4 \cdot 5H_2O$ enriched with ^{63}Cu to get better resolution of EPR spectra. Metallic copper (99.3% ^{63}Cu and 0.7% ^{65}Cu) was purchased from JV Isoflex, Moscow, Russia for this purpose and converted into the sulfate.

3. Results and discussion

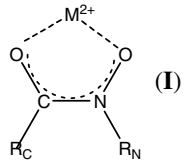
3.1. Acidity of the ligands

All the ligands studied have two dissociable protons in the totally protonated form (H_2L^+), one at the hydroxamic function, another one at the amino-N or imidazole-N. The dissociation constants have been determined by pH-potentiometric titrations and, together with the previously obtained values for L-α-Alaha and β-Alaha, are summarized in Table 2.

As it is known from the previous results for L-α-Alaha and β-Alaha [24], the two dissociation processes overlap in these two molecules. Consequently, the dissociation constants which can be obtained by pH-potentiometry are macroconstants and cannot be ascribed unambiguously to either of the acidic groups. The dissociation microconstants, characteristic of the acidity of the individual groups, were determined and the values showed that the NH_3^+ group is more acidic than the NHOH group in the α-derivative ($pK_{amino} = 7.48$, $pK_{hydr} = 7.90$), while the acidity sequence is the opposite in the β-Alaha ($pK_{amino} = 8.85$, $pK_{hydr} = 8.47$) [24]. In order to evaluate the acidity trend in the *N*-Me derivatives of these two aminohydroxamic acids, ^1H NMR titrations have been performed in the present work under the conditions given in Section 2. The pD-dependence of the chemical shifts (S.1) clearly demonstrates that the two processes overlap completely in *N*-Me-α-Alaha, but almost quite separated in *N*-Me-β-Alaha. By fitting the curves by the program SCIENTIST [25], the individual constants for the ammonium and hydroxamic functions of *N*-Me-α-Alaha were calculated ($pK_{amino} = 8.63(1)$, $pK_{hydr} = 8.28(1)$). If these values are compared to those for L-α-Alaha, one can conclude that, due to the electronic effect of the methyl substituent[1] and lack of the possibility for hydrogen bond formation, the acidity sequence is just the opposite in the *N*-Me-α-Alaha compared to L-α-Alaha.[2] In β-Alaha the NHOH is already more acidic than the amino group and replacement of *N*-H with *N*-Me makes the hydroxamic group even more acidic. As a result of this, the two dissociation processes of the *N*-Me-β-Alaha are almost separated and the pK_{a1} in Table 2 can be roughly assigned to the deprotonation process of the hydroxamic function, while the pK_{a2} to the dissociation of β-NH_3^+.

For the imidazole derivatives the NMR results suggest that the lower p*K* values in Table 2 belong to the dissociation of the protonated imidazole-N(3), while the higher ones to the hydroxamic functions. On the other hand, because the "side chain" imidazole-N(3) is less isolated in Im-4-Cha than in Im-4-Aha derivatives, the stronger mutual electronic effects result in the more significant increase in the acidities and decrease in p*K* values of the former molecule. Moreover, the exceptionally low pK_{a1} of Im-4-Cha also suggests the existence of hydrogen bond between the imidazole-N and hydroxamic-NH.

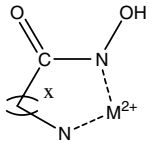
Table 2
Dissociation constants (p*K*)[a] of the studied ligands, $t = 25$ °C, $I = 0.2$ M (KCl)



Ligands	pK_{a1}	pK_{a2}
L-α-Alaha	7.34[b]	9.16[b]
N-Me-α-Alaha	7.61(2)	9.25(1)
β-Alaha	8.32[b]	9.59[b]
N-Me-β-Alaha	8.12(1)	9.88(1)
Im-4-Cha	3.76(3)	8.82(1)
N-Me-Im-4-Cha	5.06(3)	8.57(2)
Im-4-Aha	6.17(1)	9.05(2)

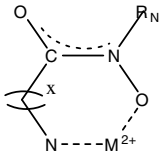
[a] Numbers in parenthesis indicated standard deviations.
[b] Ref. [23].

3.2. Metal complexation of the ligands



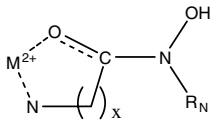
The ligands, shown in Table 1, are able to coordinate to a metal ion by different ways. Possibilities for the formation of chelates are summarized in Scheme 1.

[1] It is known from previous results that the change of *N*-H to *N*-Me substituent results in significant increase in the acidity (decrease of the p*K*) of the hydroxamic function. For example, pK_a for acetohydroxamic acid is 9.27, while for *N*-Me-acetohydroxamic acid is 8.70 [26].
[2] Since D_2O was used in the present work, the values in H_2O can be obtained by correction [27].



(I)

five-membered
hydroxamate-type chelate
(O,O)



(II)

x = 1 five-membered **($N_{am/im}$, N_{hydr})**
x = 2 six-membered **($N_{am/im}$, N_{hydr})**

(III)

x = 1 six-membered **($N_{am/im}$,O_{hydr})**
x = 2 seven-membered **($N_{am/im}$,O_{hydr})**

(IV)

x = 1 five-membered **($N_{am/im}$,O_{carb})**
x = 2 six-membered **($N_{am/im}$,O_{carb})**

Scheme 1.

Under certain conditions, formation of a chelate, which has the highest conditional stability, is the most favoured. If different chelates have comparable stabilities, mononuclear species with different bonding modes (binding isomers) or oligonuclear complexes (like interesting metallacrowns with amino acid derivatives [8,10,11,16]) can be formed. Structure (**II**) is not possible at all with the *N*-Me derivatives.

3.2.1. Cu(II), Ni(II) and Zn(II) complexes of N-Me-α-Alaha and N-Me-β-Alaha

Although the hydroxamate-type coordination (structure **I**) is the most probable, but, at least theoretically, structure **IV** is also possible with the mono-protonated form of these ligands. In order to obtain somewhat deeper insight into the bonding modes, the stability trends of these two chelates (Structures **I** and **IV**) were evaluated by using model ligands, acetohydroxamic acid (Aha), alanyl-glycine (Ala-Gly) and β-alanyl-glycine (β-AlaGly). Aha was used to model hydroxamate-(O,O) chelation. Assuming that there is no significant difference between the stability of (N_{am}, O_{carb}) chelates formed via terminal amino-N and peptide carbonyl-O donors of the peptides and via amino-N and hydroxamic carbonyl-O donors, the [CuL] complex of Ala-Gly was the model for the five-membered whereas that of β-AlaGly for the six-membered (N_{am}, O_{carb}) chelate. Since the amino-N donor atoms are protonated in the free ligands up to high pH, the metal ions must compete with protons for the binding sites. In such cases, only the pH-dependent conditional constants (K') indicate the metal binding capability of a specific site at a specific pH. To compare the stability of the different type of chelates with each other, the conditional constants for the monochelated metal complexes of the model ligands were calculated. The conditional stability constant can be defined as

$$K' = \beta_{ML}/\alpha_{H_i},$$

where β_{ML} are the corresponding overall stability constants taken from Refs. [26,28] and

$$\alpha_{H_i} = [L]\left(1 + \sum_{i=1}^{n} \beta_{H_iL} \cdot [H^i]\right),$$

where [L] stands for the totally deprotonated form of Aha, AlaGly or β-AlaGly; $n = 1$ for these model ligands and β_{H_iL} is the corresponding protonation constant (in the case of the peptides it is the protonation constant of the amino-N) taken from Refs. [26,28].

The calculated logarithmic K' values for different chelates with copper(II) as a function of pH are shown in Fig. 1.

As Fig. 1 clearly shows, the hydroxamate chelate (structure **I**) is preferred over the structure **IV** (it has the highest

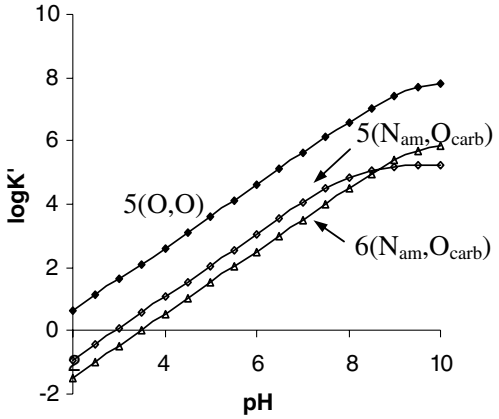


Fig. 1. Calculated pH-dependent logarithmic K' values for five-membered (O,O), five-membered (N_{am}, O_{carb}) and six-membered (N_{am}, O_{carb}) type chelates with copper(II) as a function of pH.

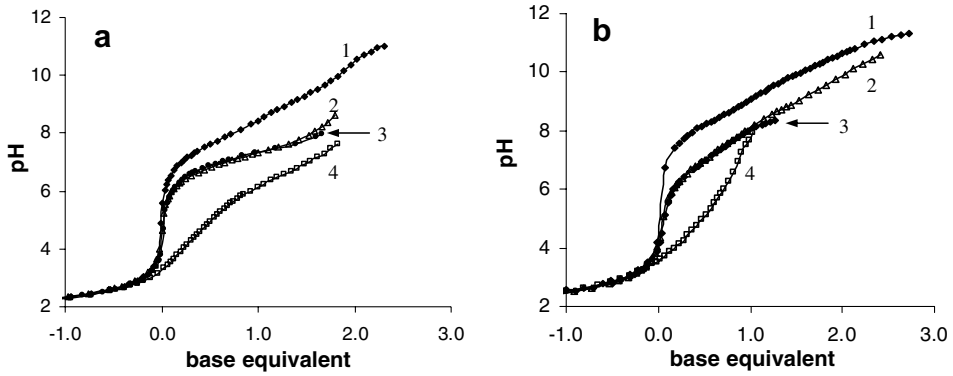

Fig. 2. pH-potentiometric titration curves registered for (a) *N*-Me-α-Alaha (**1**) and for Zn(II)- (**2**), Ni(II)- (**3**), and Cu(II)- (**4**) *N*-Me-α-Alaha systems and for (b) *N*-Me-β-Alaha (**1**) and for Zn(II)- (**2**), Ni(II)- (**3**), and Cu(II)- (**4**) *N*-Me-β-Alaha systems at metal to ligand ratio 1:2, $c_L = 4 \times 10^{-3}$ M.

log K' values) in the whole evaluated pH range. This means that the formation of (N_{am}, O_{carb}) chelate (either five-membered with *N*-Me-α-Alaha or six-membered with *N*-Me-β-Alaha) cannot be expected. Evaluation, made with the other two metal ions led to the same conclusion. Unfortunately, adequate models for the structure **III**, (N_{am}, O_{hydr})-type chelate, which can be formed only with a non-protonated ligand, could not be found.

During the experimental work, first pH-potentiometric titrations for the Cu(II)-, Ni(II)- and Zn(II)-*N*-Me-α-Alaha and -*N*-Me-β-Alaha systems have been performed. Representative titration curves recorded for the free ligands and at 1:2 metal to ligand ratios are shown in Fig. 2.

It is well demonstrated in Fig. 2a and b that these ligands start to interact with Cu(II) below pH 3, but with the other two metals, Ni(II) and Zn(II), only above pH 4. One equivalent of proton is displaced by a Cu(II) or Ni(II) ion from an *N*-Me-β-Alaha molecule before the precipitation starts, while in the presence of Zn(II), the second dissociable proton is released only in the pH-range where the free ligand itself dissociates. Moreover, UV–Vis spectra, recorded for Cu(II)-[3] and also for the Ni(II)-containing samples[4] are very similar to those obtained with acetohydroxamic acid [26]. It means that exclusive hydroxamate-type coordination (structure **I**) occurs with *N*-Me-β-Alaha. Stoichiometry of the complexes and the overall formation constants yielding the best fit of the pH-metric experimental data are given in Table 3. The numerous protonated mono- and bis-chelated complexes of *N*-Me-β-Alaha involve the dissociable proton on the non-coordinated amino group. The species [NiL_2H_{-1}] is most probably a mixed hydroxo complex.

Although, the hydroxamate-type coordination of the mono-protonated *N*-Me-α-Alaha (structure **I**) is assumed

Table 3
Overall stability constants (log β) for the Cu(II), Ni(II) and Zn(II) complexes of *N*-Me-α-Alaha and *N*-Me-β-Alaha, $t = 25$ °C, $I = 0.2$ M (KCl)

Ligand	Species	Cu(II)	Ni(II)	Zn(II)
			log β

	[ML]	8.86(3)	5.47(3)	5.43(4)
	[MLH_{-1}]		−3.50(6)	
	[ML_2H_2]	28.98(5)		
	[ML_2H]	22.7(4)	17.38(9)	
	[ML_2]	15.77(4)	9.78(4)	9.96(9)
N-Me-β-Alaha	[MLH]	16.71(3)	14.09(3)	14.04(4)
	[ML_2H_2]	31.97(8)	27.60(4)	27.60(4)
	[ML_2H]	23.5(1)	19.39(4)	19.43(6)
	[ML_2]		10.21(4)	10.1(3)
	[ML_2H_{-1}]		−0.11(3)	

(for the stoichiometrries and overall stability constants see Table 3), but the pH-metric experimental results suggest metal ion-induced deprotonation of both dissociable protons,[5] and also the spectroscopic results indicate unambiguously the involvement of the amino-N in the coordination of the non-protonated ligand. To demonstrate this, some UV–Vis spectra and CD spectra recorded for the Cu(II)-*N*-Me-α-Alaha system are presented in Figs. 3 and 4, respectively.

Although, the charge-transfer band with $\lambda_{max} = 380$ nm (Fig. 3) indicates the involvement of the hydroxamate function in the coordination, λ_{max} of the d–d band (see enlarged inset in Fig. 3) decreases continuously and at pH 6.77 (last measured pH before the precipitation) is significantly lower (ca. 620 nm) than the $\lambda_{max} = 650$ nm for the Cu(aceto-hydroxamate)$_2$ complex [26]. If the well-known Sigel–Martin's equation [29] and the parameters determined previously for the various types of donors [25,28] are used for

[3] Charge transfer band, characteristic for the hydroxamate-type interaction appears at ca. 380 nm and the minimum λ_{max} of the d–d band is 650 nm.

[4] One characteristic band at ca. 390 nm and another one at ca. 655 nm, assigned to $^1A_{1g} \rightarrow {}^1A_{2g}$ and $^1A_{1g} \rightarrow {}^1B_{1g}$ transitions, respectively, are reached by pH ca. 7 and remain unchanged until precipitation occurs.

[5] E.g. the dissociation constants (pK_{MLH}), which can be calculated for the MLH = ML + H process from the data of Table 3, are much less (6,30, 7.05, 6.88 for the Cu(II), Ni(II) and Zn(II) complexes, respectively) than pK_{amino} of the free-ligand.

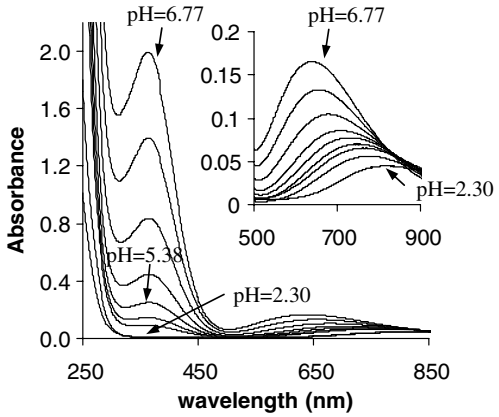

Fig. 3. Representative UV–Vis spectra registered for the Cu(II)-*N*-Me-α-Alaha as a function of pH at 1 to 2 metal to ligand ratio; $c_{Cu(II)} = 6 \times 10^{-3}$ M (inset: enlarged d–d part of the same spectra).

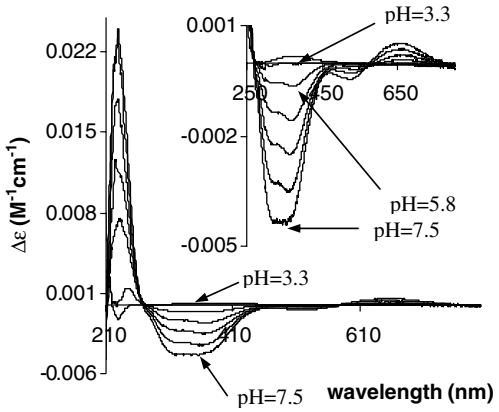

Fig. 4. Representative CD spectra registered for the Cu(II)-*N*-Me-α-Alaha as a function of pH at 1 to 2 metal to ligand ratio; $c_{Cu(II)} = 6 \times 10^{-3}$ M (inset: enlarged CD spectra in the range 250–800 nm).

estimating the absorption maximum, $\lambda_{max} = 620$ nm is obtained when equatorial coordination of three hydroxamate-O and one amino-N donors to a copper(II) ion is assumed.

CD spectra (Fig. 4) exhibit a positive Cotton effect in the 300–400 nm region at pH 3.31 (which is characteristic for hydroxamate type (O,O) coordination of this ligand [13]), but above pH 5 the Cotton effect turns to negative, which indicates a change in the coordination mode. This latter type of spectra can be found in the Cu(II)-L-α-Alaha system in the pH-range, where both nitrogen and oxygen donors are coordinated to the metal ion (see Section 1) [14]. To find whether any polynuclear complex in this pH-range in the Cu(II)-*N*-Me-α-Alaha system is formed, ESI-MS measurements at pH 6 were made but a mononuclear species, $[ML_2H]$, was only found ($m/z = 298$).

Based on the above findings, we can conclude that with a non-protonated *N*-Me-α-Alaha both the five-membered hydroxamate-(O,O) (structure **I**) and six-membered (N_{am}, O_{hydr}) (structure **III**) are formed and the mixed type coordination mode (**I** and **III**) in the bis-complex can be assumed.

3.2.2. Cu(II), Ni(II) and Zn(II) complexes of imidazole derivatives of aminohydroxamic acids, Im-4-Cha, N-Me-Im-4-Cha and Im-4-Aha

An aliphatic amino-N with high basicity in the α- or β-position is replaced by a much less basic, aromatic imidazole-N in the Im-4-Cha and Im-4-Aha derivatives. The effect of this change on the coordination mode(s) has been investigated by pH-potentiometry, UV–Vis, EPR, ^{1}H NMR and ESI MS methods. For the Cu(II)-containing systems magnetic measurements by using the Evans method [23] have also been performed. Out of the recorded pH-metric titration curves only a few examples are shown in Figs. 5a–c.

The titration curves registered before precipitation could be fitted best with the equilibrium models and stability constants shown in Table 4.

Figs. 5a–c clearly show that Cu(II) and Ni(II) are able to displace imidazole-NH even in the case of im-4-Cha where the free ligand itself dissociates already below pH 4 (for pK_a see Table 2). With this ligand, the displacement of imidazole-NH by Zn(II) (which prefers oxygen donors over nitrogen ones) seems questionable in Fig. 5a, but somewhat bigger effect was measured at 1:1 metal to ligand ratio. Also, a small but consequent difference between the chemical shift of the imidazole C(2)-H proton in the absence and presence of Zn(II) ion above pH 3 (see S.2) suggests a week coordination via the imidazole-N(3) of im-4-Cha with Zn(II) too. As a conclusion it may be stated that while the more basic amino-N does not, the less basic imidazole-N behaves as an anchor for Cu(II), Ni(II) or even for Zn(II) and the complex formation often starts at lower pH with imidazole derivatives compared to the amino-N containing counterparts. Most probably, chelate **IV** (which is not formed with the amino derivatives) is formed at the beginning of the interaction between these imidazole-containing ligands and Cu(II), Ni(II) or Zn(II). The first species found in most cases has a stoichiometry of [MLH], in which the proton is at the hydroxamic group. (Stability constant could not be calculated for [ZnLH] complexes of Im-4-Cha and Im-4-Aha.) Beside these similarities obtained with the three ligands, big differences between their metal complexation were also found.

With **Im-4-Cha** precipitation occurred at as low as pH 3 with Cu(II) and at pH 6–7 with Zn(II) and Ni(II) too, therefore a few species could only be detected before precipitation. To clarify the bonding modes, UV–Vis spectra for the Cu(II)- and Ni(II)-containing systems, furthermore EPR and magnetic measurements for the Cu(II)-containing ones have been performed before precipitation occurred. Looking at the visible spectra of the Ni(II) complexes, octahedral geometry is suggested up to pH 6 and continuous blue shift of the λ_{max} assigned to the $^3A_{2g} \rightarrow {}^3T_{1g}$ (655 nm at pH 2 and 605 at pH ca. 6) indicates increasing number of N-donor in the coordination sphere as the pH from 2 to 6 is increased. Taking into account these findings and also those with the analogues amino derivative, L-α-Alaha [8,10,11], first of all N-coordinated mono- and bis-complexes are suggested to form between Im-4-Cha and

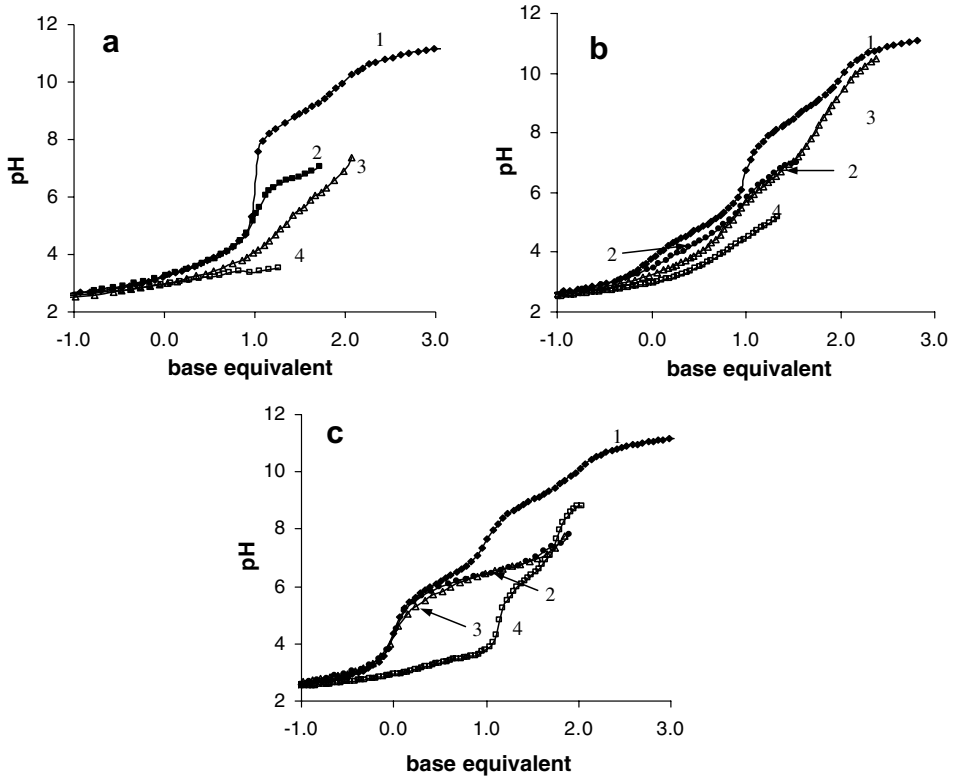

Fig. 5. pH-potentiometric titration curves registered for (a) Im-4-Cha (**1**) and for Zn(II)- (**2**), Ni(II)- (**3**), and Cu(II)- (**4**) Im-4-Cha systems; for (b) *N*-Me-Im-4-Cha (**1**) and for Zn(II)- (**2**), Ni(II)- (**3**), and Cu(II)- (**4**) *N*-Me-Im-4-Cha systems; for (c) Im-4-Aha (**1**) and for Zn(II)- (**2**), Ni(II)- (**3**), and Cu(II)- (**4**) Im-4-Aha systems at metal to ligand ratio 1:2, $c_L = 3 \times 10^{-3}$ M.

Table 4
Overall stability constants ($\log\beta$) for the Cu(II), Ni(II) and Zn(II) complexes of Im-4-Cha, *N*-Me-Im-4-Cha and Im-4-Aha, $t = 25$ °C, $I = 0.2$ M (KCl)

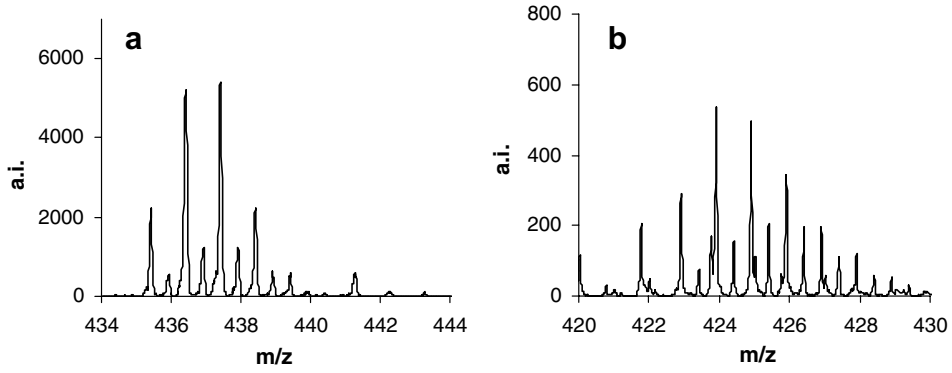
	[$M_5L_4H_{-4}$]	46.32(8)	8.8(2)	8.0(2)

Ni(II) below pH 6. Colour of the precipitate appeared just above 6, however, was already yellow, which is characteristic for planar complexes. With Cu(II), EPR results suggest the formation of EPR silent polynuclear complexes where the precipitation occurs. These findings suggest favoured formation of water-insoluble polynuclear species of Im-4-Cha with the studied metal ions. On the analogy of L-α-Alaha (see Section 1), formation of some metallacrown, at least with Cu(II), seems possible. The 91 experimental points registered before the precipitation resulted in slightly better fit (6.1×10^{-3} versus 6.7×10^{-3}) when [$Cu_6L_5H_{-5}$] compared to [$Cu_5L_4H_{-4}$] was involved in the calculation. As a consequence, stability constant for the former species is given in Table 4, but direct proof (including ESI-MS) for exact stoichiometry of the metallacrown species was not obtained.

Im-4-Aha, containing the side-chain imidazole donor in β-position relative to the hydroxamic function, forms somewhat more soluble complexes with Cu(II) and, as a consequence, a wider pH-range could be characterized in solution. All the stability constants calculated by fitting the pH-metric titration curves registered for the three systems before the precipitation are shown in Table 4. The pH-potentiometric results suggest only the formation of a very stable pentanuclear species in a wide pH-range with Cu(II) (see S.3), but much less stable Ni(II)- or Zn(II)-containing species are shown (see Fig. 5c). ESI-MS results obtained at pH 6 are in good agreement with this finding. Predominance of [$Cu_5L_4H_{-4}$]-type species ($\{[Cu_5L_4H_{-4}]H_{-1}\}^+$ with $m/z = 874$; $[Cu_5L_4H_{-4}]^{2+}$ with $m/z = 437$; $\{[Cu_5L_4H_{-4}]Cl\}^+$ with $m/z = 910$) was found.



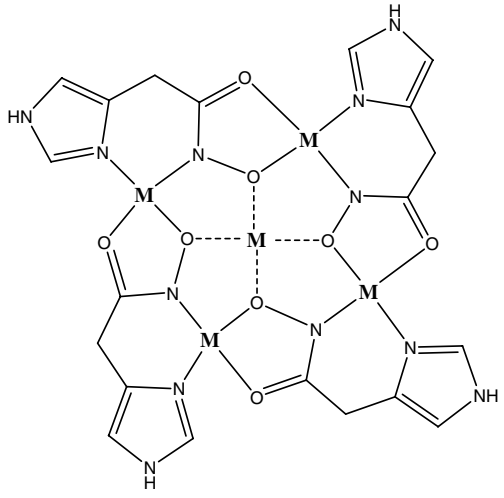


Fig. 6. ESI-MS spectra registered for the (a) Cu(II)-Im-4-Aha, and (b) Ni(II)-Im-4-Aha at pH 6 at 1 to 2 metal to ligand ratio, $c_L = 5 \times 10^{-3}$ M.

Interestingly, the pentanuclear species appears also with Ni(II) and Zn(II). However, because the stability of $[Ni_5L_4H_{-4}]$ and $[Zn_5L_4H_{-4}]$ is lower compared to the copper(II)-containing analogous species, they exist together with various bis- and tris-chelated mononuclear complexes ($[NiL_2H_2]^{2+}$ with $m/z = 170$; $[NiL_2H]^{+}$ with $m/z = 339$; $[NiL_2]K^{+}$ with m/z 377; $[NiL_3H_2]^{+}$ with $m/z = 480$; $[Ni_5L_4H_{-4}]^{2+}$ with $m/z = 424$ and $[ZnL_2H]^{+}$ with $m/z = 345$; $[ZnL_2]K^{+}$ with m/z 383; $[Zn_5L_4H_{-4}]^{2+}$ with $m/z = 438$). Representative parts of the spectra characteristic for the pentanuclear complexes with Cu(II) and Ni(II) are shown in Figs. 6a and b, respectively.

Taking the analogy with the Cu(II) complex of β-Alaha (see Section 1), the following 12-metallocrown-4 type bonding mode is suggested in the pentanuclear complexes with Im-4-Aha (Scheme 2).

***N*-Me-Im-4-Cha**, which is not able to form five-membered (N_{im}, N_{hydr}) chelate, realizes a five-membered (N_{im}, O_{carb}) one (**IV**) at the beginning of the complex formation as detailed above. This is unambiguous for example from the pH-metric results (see Fig. 5b) and it is also suggested for the Zn(II)-containing system by the ^{1}H NMR spectra (Fig. 7).

Scheme 2.

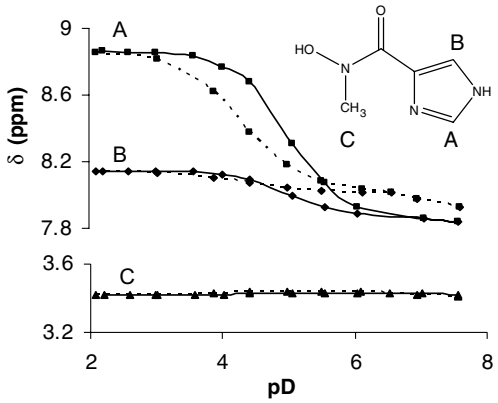

Fig. 7. pD dependence of the ^{1}H NMR chemical shifts recorded for *N*-Me-Im-4-Cha (continuous line) and Zn(II)-*N*-Me-Im-4-Cha (dashed line) system at 1 to 2 metal to ligand ratio, $c_L = 3 \times 10^{-3}$ M (letter A relates C(2)H, B for C(5)H, while C for CH_3 protons).

The chemical shift of the C(2)H proton is assumed to be sensitive to the metal ion coordination via imidazole-N(3), while C(5)H is expected to feel a strong coordination via the hydroxamate function. As it can be seen in Fig. 7 there is interaction with the involvement of imidazole-N(3) already from pD ca. 3, but strong interaction involving hydroxamate starts only at pD ca. 5 (probably after the deprotonation of the hydroxamic group with the formation of structure **III**).[6] In agreement with this result, ESI-MS spectra showed the formation of mononuclear bis-chelated complexes $[ZnL_2H_2]^{2+}$ ($m/z = 173$) and $[ZnL_2H]^{+}$ ($m/z = 345$). Unexpectedly, beside the mononuclear species ($[CuL_2H]^{+}$ with $m/z = 344$; $[CuL_2]K^{+}$ with $m/z = 382$; $[NiL_2H_2]^{2+}$ with $m/z = 170$); ($[NiL_2H]^{+}$ with $m/z = 339$; $[CuL_2]K^{+}$ with $m/z = 377$; $[NiL_3H_2]^{+}$ with $m/z = 480$), dinuclear species $[M_2L_3]^{+}$ (see Fig. 8) appeared (m/z values are 546 and 536 with Cu(II) and Ni(II), respectively).

[6] Structure **III** (instead of **IV**) is suggested, because the significantly more favoured deprotonation of the hydroxamic group from the complexes (pK_{ZnLH} and pK_{ZnL2H2}, which can be calculated from Table 4, are both ca. 6.2) compared to the free ligand ($pK = 8.57$) indicates metal ion induced dissociation of this proton.

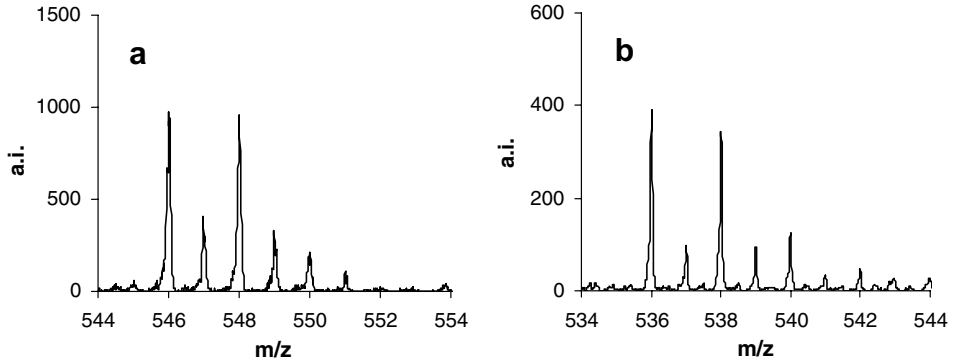

Fig. 8. ESI-MS spectra registered for the (a) Cu(II)-*N*-Me-Im-4-Cha, and (b) Ni(II)-*N*-Me-Im-4-Cha at pH 6 at 1 to 2 metal to ligand ratio, $c_L = 5 \times 10^{-3}$ M.

For Cu(II) this result is also supported by EPR, where the presence of a dimeric species is confirmed by the half field spectra (recorded both for sample with precipitate and filtrate) which shows 7 lines centred at $G \sim 4$ (Fig. 9).

Although stability constants could be calculated for $[Cu_2L_3]$, but the concentration of this species is quite small (see Fig. 10 for the concentration distribution curves). Most probably, the ratio of the dinuclear species is even lower with Ni(II), therefore its stability constant could not be calculated. Neither pH-potentiometric nor ESI-MS results indicated the formation of $[Zn_2L_3]$. Perhaps, the very low stability of the (N_{im}, O_{carb}) chelate compared to the hydroxamate one with Zn(II) causes that the dinuclear species can not be formed with this metal.

One possible structure of $[M_2L_3]$ can be that one of the three ligands binds two metal ions via two joined chelates, while ring stacking between two imidazole rings of the two other coordinating ligands exists (S.4).

All the above results are also supported by magnetic measurements. Magnetic measurements were carried out for the Cu(II)-Im-4-Cha, -*N*-Me-Im-4-Cha and -Im-4-Aha systems. Differences between the chemical shifts of *t*-BuOH in dia- and paramagnetic surroundings as a function of pD are shown in Fig. 11. (Mass magnetic susceptibilities calculated by the Evans's method [22] show completely the same profile, therefore are not shown here.)

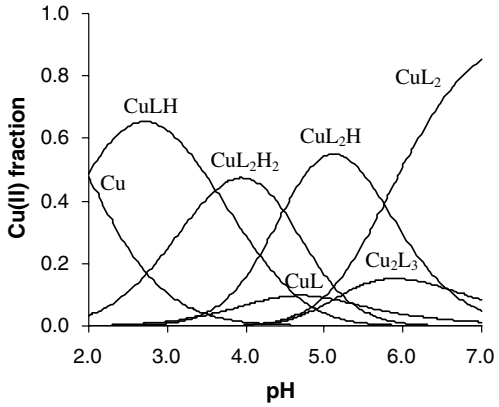

Fig. 10. Concentration distribution curves calculated for Cu(II)-*N*-Me-Im-4-Cha system at 1 to 2 metal to ligand ratio. $c_{ligand} = 4 \times 10^{-3}$ M.

As Fig. 11 reveals the chemical shift differences practically do not show pD dependence in the case of Cu(II)-*N*-Me-Im-4-Cha system, where only mononuclear species are formed (dotted line). Negligible dependence can be seen

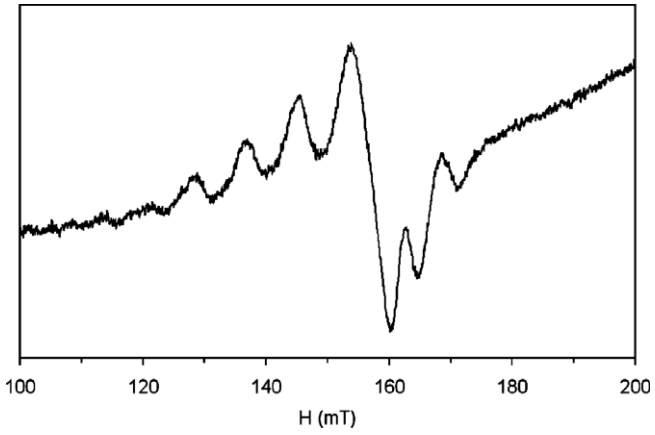

Fig. 9. Half field EPR spectra registered for Cu(II)-*N*-Me-Im-4-Cha system at 1 to 2 metal to ligand ratio, at pH ca. 6. $c_L = 3 \times 10^{-3}$ M, $T = 120$ K.

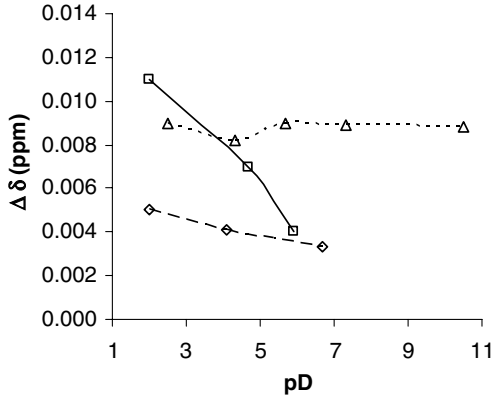

Fig. 11. pD dependence of the differences between the ^{1}H NMR chemical shifts of *t*-BuOH in dia- and paramagnetic surroundings for Cu(II)-*N*-Me-Im-4-Cha (dotted line), Cu(II)-Im-4-Aha (dashed line) and Cu(II)-Im-4-Cha (continuous line) at 1 to 2 metal to ligand ratio. $c_L = 3 \times 10^{-3}$ M.

for Cu(II)-Im-4-Aha (dashed line), but the values are measurably lower compared to that for the former system. This result indicates antiferromagnetic coupling between the copper centres in the latter system, where a metallacrown type polynuclear species with high stability exists. However, a continuous decrease of the $\Delta\delta$ values as a function of pD can be seen with Im-4-Cha (continuous line). This behaviour compared to those of the other two ligands may also led to the conclusion that following the formation of monomeric type complexes at low pD, polymerisation takes place in the Cu(II)-Im-4-Cha system.

4. Conclusion

When solution equilibrium results obtained for H^+, Cu^{2+}, Ni^{2+} and Zn^{2+} complexes of *N*-Me-β-Alaninehydroxamic acid (*N*-Me-β-Alaha), L-*N*-Me-α-Alaninehydroxamic acid (*N*-Me-α-Alaha), Imidazole-4-Carbohydroxamic acid (Im-4-Cha), *N*-Me-Imidazole-4-Carbohydroxamic acid (*N*-Me-Im-4-Cha) and Imidazole-4-Acetohydroxamic acid (Im-4-Aha) are summarized, the following conclusion can be drown: Although, coordination via the hydroxamate chelate is crucial for inhibition of a metalloenzyme (like an MMP or urease) by hydroxamate-based compounds, privilege of the hydroxamate-type (O,O)-coordination may not exist if the amino-N is in chelatable position to the hydroxamate-N in hydroxamic derivatives of α- and β-amino acids. Therefore, *N*-Me-α-Alaha and *N*-Me-β-Alaha have been synthesized and studied, where the hydroxamate-N is not able to coordinate. Only hydroxamate type coordination of *N*-Me-β-Alaha was found with all the three metals, but formation of additional six-membered chelate via the amino-N and hydroxamate-O is suggested parallel to the hydroxamate one in the case of *N*-Me-α-Alaha.

The less basic imidazole-N(3) was found to behave as anchor donor not only to Cu^{2+} and Ni^{2+}, but even to Zn^{2+}, although this latter metal ion prefers oxygen donors over nitrogen ones. By increasing the pH water insoluble polynuclear species have been found to form with Im-4-Cha. A pentanuclear metallacrown is exclusively formed above pH 4 between Cu(II) and Im-4-Aha. The stability of this species with Ni(II) and Zn(II) is significantly lower, and as a consequence, it appears together with various mononuclear bonding isomers in the Ni(II)-Im-4-Aha and Zn(II)-Im-4-Aha systems. Beside the mononuclear species a dinuclear complex, $[M_2L_3]$, was found in the Cu(II)- and Ni(II)-*N*-Me-Im-4-Cha. A possible bonding mode is that one of the three ligands bridges two metal ions, while each of the other two ligands binds to one metal. Stacking interaction between the imidazole rings of the latter two ligands might stabilize this species.

Synthesis, spectral characterization and photoluminescence properties of cadmium(II) complexes of *N*-[(2-pyridyl)methyliden]-α (or β)-aminonaphthalene (α- or β-NaiPy) and comparison with the complexes of 1-alkyl-2-(naphthyl-α (or β)-azo)imidazole. Single crystal X-ray structure of $[Cd(\beta\text{-NaiPy})_2(ONO_2)_2]$

Abstract

Cadmium(II) complexes of *N*-[(2-pyridyl)methyliden]-α (or β)-aminonaphthalene (α or β-NaiPy) and 1-alkyl-2-(naphthyl-α (or β)-azo)imidazoles (α- or β-NaiR) using Cl^-, ClO_4^- and NO_3^- as anions are spectroscopically characterized. Molar conductance data in nitromethane show that the chloro and nitrite compounds are non-conducting, while the perchlorate complexes are 1:2 electrolytes. The single crystal X-ray structure of $[Cd(N\text{-}\{(2\text{-pyridyl})methyliden\}\text{-}\beta\text{-aminonaphthalene})_2(ONO_2)_2]$ has been determined. The luminescence properties of Cd(II) complexes of α/β-NaiPy are studied and they exhibit ligand centered π–π^* emissions. Naphthylazoimidazoles and their cadmium complexes are non-fluorescent.

1. Introduction

Luminescent metal complexes are a potential field for applications in many areas such as light emitting devices (LEDs), design of optical materials and sensors [1]. Polypyridine complexes of transition and non-transition metals have been extensively used in this field [2–6]. The ligands carry the α-diimine function (–N=C–C=N–). Recent years have witnessed a great deal of interest in the synthesis of new ligands with a diimine group in the framework. The condensation of pyridine-2-carboxaldehyde with aromatic amine has synthesized a Schiff base in which the –N=C– group in the pyridine ring is conjugated with an exocyclic –C=N– group to form a diimine function [7–9]. Schiff bases synthesized from the condensation of naphthyl amines and pyridine-2-carboxaldehyde are scarce [10–12]. The naphthyl group is sterically more crowded, electronically labile and more delocalized than the phenyl group. Thus, the naphthyl substituent in Schiff bases may affect significantly the spectroscopic and photophysical properties of metal complexes compared to the properties of phenyl Schiff bases. In this article we wish to report the synthesis, spectral characterization and luminescence properties of *N*-[(2-pyridyl)methyliden]-α (or β)-aminonaphthalene (α- or β-NaiPy) complexes of Cd(II) using Cl^-, NO_3^- and ClO_4^- as anions. A comparison will be made with the structure and properties of 1-alkyl-2-(naphthylazo)imidazole complexes of Cd(II) under identical environments. Naphthylazoimidazole possesses the azoimine (–N=N–C=N–) chelating function, isoelectronic with the diimine (–N=C–C=N–) unit. A structural confirmation has been carried out for $[Cd(\beta\text{-NaiPy})_2(ONO_2)_2]$ by single crystal X-ray diffraction.

2. Experimental

2.1. Materials and measurements

α-Naphthylamine and β-naphthylamine were purchased from Thomas Baker & Co. Pyridine-2-carboxaldehyde was purchased from Lancaster Ltd., England. *N*-[(2-Pyridyl)-methyliden]-α (or β)-aminonaphthalene (α or β-NaiPy) were synthesized by equimolar condensation of pyridine-2-carboxaldehyde and naphthylamine in ethanol following a previously reported procedure [10]. 1-Alkyl-2-(naphthyl-α/β-azo)imidazoles (α/β-NaiR) were synthesized by a published procedure [13]. All other chemicals used were of A.R. quality and were used as received from SRL, India. The solvents were used after drying [14].

UV–Vis spectra were recorded using Lambda 25 Perkin–Elmer spectrophotometers and FT-IR spectra (KBr disc) were obtained from Spectrum RX-1 Perkin–Elmer (4000–450 cm^{-1}) and JASCO model 420 (4000–200 cm^{-1}) spectrophotometers. Microanalyses were collected from a Perkin–Elmer 2400 CHN elemental analyzer. ^1H NMR spectra were recorded on a Bruker 300 MHz FT NMR. Solution electrical conductivity was measured using a Systronics 305 digital conductivity meter. Luminescence properties were measured using a LS-55 Perkin–Elmer fluorescence spectrophotometer at room temperature (298 K) in CH_3CN solution with a 1 cm path length quartz cell.

The fluorescence quantum yield of the α- or β-NaiPy and their cadmium(II) complexes (**5**–**10**) was determined using Coumarin-120 laser dye as a reference with a known ϕ_R of 0.63 in MeCN. The complex and the reference dye were excited at 340 nm, maintaining nearly equal absorbance (~0.1), and the emission spectra were recorded from 350 to 600 nm. The area of the emission spectrum was integrated using the software available in the instrument and the quantum yield is calculated according to the following equation:

$$\phi_S/\phi_R = [A_S/A_R] \times [(Abs)_R/(Abs)_S] \times [\eta_S^2/\eta_R^2]$$

Here, ϕ_S and ϕ_R are the fluorescence quantum yield of the sample and reference, respectively. A_S and A_R are the area under the fluorescence spectra of the sample and the reference respectively, $(Abs)_S$ and $(Abs)_R$ are the respective optical densities of the sample and the reference solution at the wavelength of excitation, and η_S and η_R are the values of the refractive index for the respective solvent used for the sample and reference.

2.2. Preparation of the complexes

2.2.1. Synthesis of di-chloro-N-[((2-pyridyl)methyliden)-α-aminonaphthalene]cadmium(II), Cd(α-NaiPy)Cl_2] (5)

N-[(2-Pyridyl)methyliden)-α-aminonaphthalene] (0.25 g, 1.08 mmol) in MeOH (10 mL) was added dropwise to a methanolic solution (10 mL) of $CdCl_2$ (0.27 g, 1.18 mmol) at room temperature and the resulting mixture was stirred for 3 h. The solution colour turned yellow. The volume was reduced to half of its original volume by slow evaporation in air. Yellow crystals then separated. They were filtered, washed with water, water–MeOH (1:1, v/v). The product was then crystallized by diffusion of a CH_2Cl_2 solution into hexane. The yield was 0.28 g (74%).

2.2.2. Synthesis of dinitrito-N-[((2-pyridyl)methyliden)-α-aminonaphthalene]cadmium(II), [Cd(α-NaiPy)$_2$(NO_3)$_2$] (7)

N-[(2-Pyridyl)methyliden)-α-aminonaphthalene] (0.25 g, 1.08 mmol) in MeOH (10 mL) was added dropwise to a methanolic solution (10 mL) of $Cd(NO_3)_2 \cdot 4H_2O$ (0.17 g, 0.55 mmol) at room temperature and the resulting mixture was stirred for 3 h. The volume of yellow solution was reduced to half of its original volume by slow evaporation in air. The solution was then kept in a refrigerator, maintaining the temperature at 5 °C. The bright yellow crystalline product was then recrystallized from MeOH–H_2O (1:1, v/v) and dried over $CaCl_2$. The yield was 0.22 g, 64%. [Cd(β-NaiPy)$_2$(NO_3)$_2$] (**8**) was prepared similarly and the yield was 70%.

2.3. Synthesis of bis-[1-methyl-2-(naphthyl-α-azo)-imidazole]cadmium(II) perchlorate, [Cd(α-NaiMe)$_2$]-(ClO$_4$)$_2$ (**15a**)

1-Methyl-2-(naphthyl-α-azo)imidazole (0.25 g, 1.06 mmol) in MeOH (15 mL) was added dropwise to a methanolic solution (25 mL) of $Cd(ClO_4)_2 \cdot 6H_2O$ (0.50 g, 1.19 mmol) at room temperature and the resulting mixture was stirred for 1 h. The solution was then filtered and kept undisturbed for a week. Orange crystals appeared on the wall of the beaker. The bright crystalline product was then recrystallized by diffusion of a CH_2Cl_2 solution into hexane. The yield was 0.25 g, 60%.

Other compounds were prepared following an identical procedure and isolated in yields of 55–70%.

2.4. Crystallographic data collection and refinement of [Cd(β-NaiPy)$_2$(ONO$_2$)$_2$] (**8**)

Crystals were grown by slow evaporation of a methanol solution of the reaction mixture of Cd(NO$_3$)$_2$ and β-NaiPy in 1:1 molar proportion **8**. Crystal parameters and refined data are summarized in Table 1. The data (0.20 × 0.15 × 0.10 mm) were collected in a CCD area detector fine focus sealed tube at 294 K using graphite monochromated (Mo Kα radiation, λ = 0.71073 Å). Unit cell parameters were determined from least-squares refinement of setting angles with 2θ in the range $4.42 \leqslant 2\theta \leqslant 56.60°$. Of 9984 collected data, 3622 with $I > 2\sigma(I)$ were used for structure solution. The hkl ranges are $-39 \leqslant h \leqslant 15$, $-18 \leqslant k \leqslant 20$, $-22 \leqslant l \leqslant 16$. Reflection data were recorded using the ω scan technique. Data were corrected for Lorentz polarization effects and for linear decay. Semi-empirical absorption corrections based on ψ-scans were applied. The structure was solved by the direct method using SHELXS-97 and successive difference Fourier syntheses. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed geometrically and refined using the riding model. In the final difference Fourier map the residual minima and maxima −0. 237, 0.418 e/Å^3 were evaluated using SHELXL-97. All calculations were carried out using SHELXL-97 [15], ORTEP-32 [16] and PLATON-99 [17] programs.

[a] $R_1 = \sum|F_0 - F_c|/\sum F_0$.
[b] $wR_2 = \left[\sum w(F_0^2 - F_c^2)/\sum wF_0^4\right]^{1/2}$, $w = 1/[\sigma^2(F^2) + (0.0424P)^2]$.

3. Results and discussion

3.1. The synthesis and formulation

Two series of *N*,*N*′-chelating ligands are used in this work (Scheme 1) containing azoimine (–N=N–C=N–) and diimine (–N=C–C=N–) functions. *N*-[(2-Pyridyl)-methyliden)-α-aminonaphthalene] (α-NaiPy, **1** and β-NaiPy, **2**) are selected for the diimine system. 1-Alkyl-2-(naphthyl-α/β-azo)imidazoles (α-NaiR, **3** and β-NaiR, **4**; R = Me (**3a**/**4a**), Et (**3b**/**4b**)) belong to the azoimine system.

The complexes were synthesized by reacting a methanol solution of the ligand and different cadmium(II) salts in a

Scheme 1.

1:1 mole ratio for $CdCl_2$ and a 1:2 mole proportion for $Cd(NO_3)_2 \cdot 6H_2O$ or $Cd(ClO_4)_2 \cdot 6H_2O$ (other molar ratios of $CdCl_2$:ligands such as 1:2 or 1:3 also separated complexes of composition identical to the 1:1 mole ratio). Upon slow evaporation of the reaction mixture, yellow to orange crystals were deposited on the wall of the beaker, which were separated by filtration and dried over $CaCl_2$. Microanalytical data support the composition, Cd(α-NaiPy)Cl_2 (**5**)/Cd(β-NaiPy)Cl_2 (**6**), $[Cd(\alpha\text{-NaiPy})_2(ONO_2)_2]$ (**7**)/$[Cd(\beta\text{-NaiPy})_2(ONO_2)_2]$ (**8**), $[Cd(\alpha\text{-NaiPy})_2](ClO_4)_2$ (**9**)/$[Cd(\beta\text{-NaiPy})_2](ClO_4)_2$ (**10**). Molar conductance measurements suggest that the compounds **5**–**8** are non-conducting in nitromethane and support coordinated Cl^- and NO_3^- while **9** and **10** show 1:2 conductivity ($\Lambda_M = 120$–$135\ \Omega^{-1}\ mol^{-1}\ cm^{-1}$). This implies that the complexes **5**, **6** and **9**, **10** are four coordinated while **7** and **8** are six coordinated. Infrared spectra of **7** and **8** exhibit strong stretches at 1420, 1390, 1380 cm^{-1}, which are in agreement with coordinated O–NO_2 [18–20]. $\nu(ClO_4)$ appears in complexes **9** and **10** as a sharp single stretch at *ca.* 1090 and a weak stretch at 625 cm^{-1}. The strong stretches at *ca.* 1610 cm^{-1} in the complexes suggest the presence of ν(C=N) on comparing with reported data [7–9].

The IR stretching frequencies of naphthylazoimidazole–Cd(II) complexes are assigned on comparing with the free ligand data [10]. All the bands have not been assigned and some significant stretching frequencies are set out. The ν(N=N) values are shifted to lower frequency by 10–20 cm^{-1} compared to the free ligand value, which supports coordination of azo-N to Cd(II). Cd(NaiR)Cl_2 (**11, 12**) show two ν(Cd–Cl) at *ca.* 324 and *ca.* 298 cm^{-1}. $\nu(ClO_4)$ of $[Cd(NaiR)_2](ClO_4)_2$ (**15**, **16**) appear at 1082–1091 cm^{-1} with a weak stretch at 624–627 cm^{-1}. $\nu(NO_3)$ of $[Cd(NaiR)_2](NO_3)_2$ (**13**, **14**) appears at 1380–1390 cm^{-1} as a sharp strong stretch which is in agreement with ionic NO_3 nature [13,14]. Molar conductivities of **13**–**16** also support a 1:2 electrolytic nature.

The electronic spectra of the Cd(NaiPy) complexes (**5**–**10**) show a weak absorption at 400–460 nm ($\varepsilon \sim 800$–$1500\ M^{-1}\ cm^{-1}$) along with intense absorptions in the UV region at *ca.* 350 nm and *ca.* 270 nm ($\varepsilon \sim 10^4\ M^{-1}\ cm^{-1}$). These intense transitions may be assigned to intraligand charge transfer (n–π* and π–π*) transitions. The longer wavelength weak transition may be due to a d^{10}(Cd) to π* state of the diimine function (MLCT). The UV–Vis spectra of the Cd-NaiR complexes (**11**–**16**) show weak bands at 410–455 for LMCT and an intense transition below 400 nm which corresponds to intraligand transitions.

The ^1H NMR spectra are recorded in $CDCl_3$ solution for **5**–**8** and **11**–**14**. Data are given in Table 3. The assignment has been made on the basis of spin–spin interactions, and on comparing with the free ligand values [21,22]. Pyridyl-2-(naphthylmethylene)amines exhibit a singlet most downfield which has been assigned to –HC=N–(7H) at 8.75–8.78 ppm. Other signals around 7.7–8.5 ppm refer to pyridine-H (3-H–6-H), and naphthyl signals appear at 7.2–7.6 ppm [10–12]. In the complexes the NMR signals are in general downfield shifted. Of them, the pyridyl protons (3-H to 6-H) are shifted to downfield by >0.5 ppm from that of the free ligand data [6]. The naphthyl protons (8-H to 15-H) remain almost undisturbed.

In the Cd-NaiR complexes (**11**–**16**), the imidazole protons (4-, 5-H) show signals at 7.3–7.4 ppm that are 0.3–0.4 ppm downfield shifted, while the naphthyl protons are insignificantly shifted compared to the free ligand data [21,22].

3.2. Molecular structure of $[Cd(\beta\text{-NaiPy})_2(ONO_2)_2]$ (8)

An ORTEP view of complex **8** is shown in Fig. 1. The Cd center is in a distorted octahedral position surrounded by an N_4O_2 coordination sphere. Each β-NaiPy acts as a diimine type bidentate *N*,*N*′ chelator (*N*,*N*(pyridine); *N*′,*N*(naphthyl)) and NO_3 serves as an O donor ligand. A

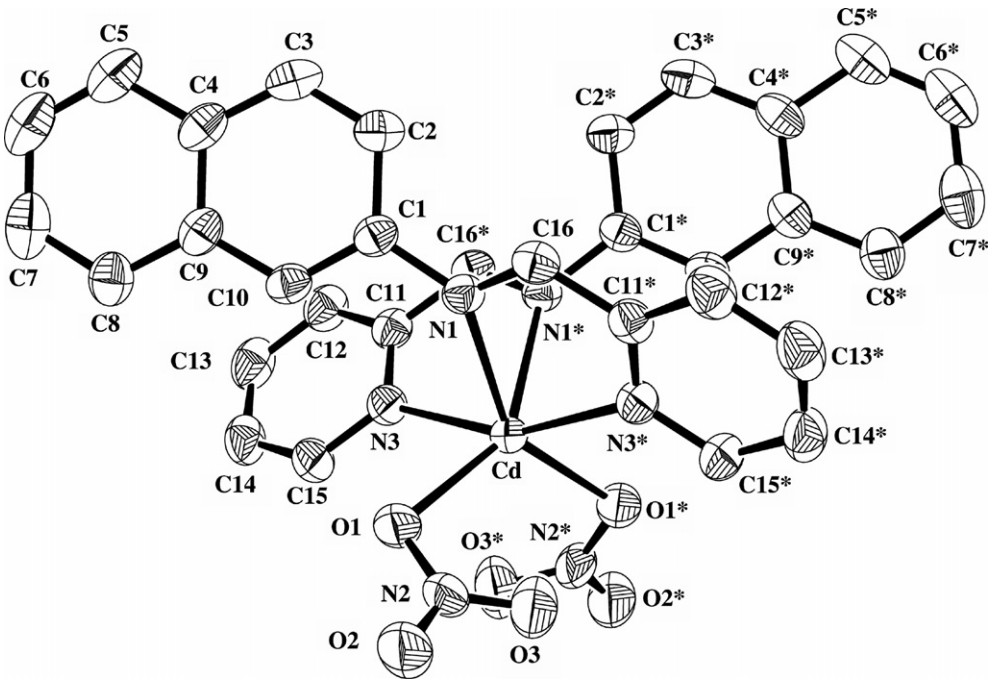

Fig. 1. Molecular structure of $[Cd(\beta\text{-NaiPy})_2(ONO_2)_2]$ (50% probability ellipsoids).

crystallographic 2-fold rotation axis passes through Cd. Bond parameters (Table 2) suggest a longer Cd–N(naphthyl) bond [Cd–N(1) (naphthyl) 2.465(2) Å] than Cd–N(pyridine) bond [Cd–N(3)(pyridine), 2.305(2) Å] and a reasonable chelate angle (N(3)–Cd–N(1), 69.99(7)°). The bond parameters are significantly different from Zn(II) complexes of β-NaiPy. The metric parameters are Zn–N(pyridine) 2.0870(18), Zn–N(naphthyl) 2.2027(17) Å and chelate angle, N(pyridine)–Zn–N(naphthyl) 77.68(7)° in $[Zn(\beta\text{-NaiPy})(N_3)(1,1\text{-}N_3)]_2$ [20], and Zn–N(pyridine) 2.115(9), Zn–N(naphthyl), 2.287(1) Å and N(pyridine)–Zn–N(naphthyl) 94.35(3)° in $[Zn(\beta\text{-NaiPy})_2(ONO_2)_2]$ [23]. $[Ag(\beta\text{-NaiPy})_2](ClO_4)$ shows rather closer metric parameters to Cd(II) than that of the Zn(II) complexes: Ag–N(pyridine), 2.325(3), 2.241(3), Ag–N(naphthyl), 2.318(3), 2.455(3) Å and N(pyridine)–Ag–N(naphthyl), 73.00(9)°, 71.87(10)° [24]. The difference in the structural parameters between Zn(II) and Cd(II) complexes may be explained in view of their position in the periodic table and hence their atom size; Cd(II) > Zn(II). The Cd and Ag are 4d block elements and hence their metric parameters may be comparable. The ligand is planar. The pendant naphthyl ring makes a dihedral angle of 38.32° with the chelated diimine motif. The Cd–O bond distance is 2.3220(19) Å which is expectedly longer than the Zn–O bond length (2.090(2) Å) of the analogous complex, $[Zn(\beta\text{-NaiPy})_2(ONO_2)_2]$ [23]. The angles extended by other donor centers around Cd(II) are in support of a distorted octahedral geometry (Table 2).

Table 2
Selected bond lengths (Å) and bond angles (°) of $[Cd(\beta\text{-NaiPy})_2(ONO_2)_2]$ (**8**)

Cg(3) where Cg(1) is N(3), C(11), C(12), C(13), C(14), C(15); Cg(2) is C(1), C(2), C(3), C(4), C(9), C(10) and Cg(3) is C(4), C(5), C(6), C(7), C(8), C(9)) π–π interactions between pyridyl and naphthyl rings incorporate a robust character to the molecule and lead to the formation of a 3-D supramolecular geometry.

3.3. Photoluminescence properties

No emission originating from metal-centered and MLCT or LMCT excited states are expected for the Cd(II) complexes, since the Cd(II) ion is difficult to oxidize or reduce due to its d^{10} configuration. Thus, the emission observed (Fig. 4 and Table 3) in the complexes is tentatively assigned to the (π–π*) intraligand fluorescence. The luminescence spectra of the ligands in $CHCl_3$ exhibit an emission at 431 (α-NaiPy) and 406 nm (β-NaiPy) at 298 K upon excitation at 330 nm. At 77 K these compounds show an emission at 455 nm (α-NaiPy) and 448 nm (β-NaiPy). Naphthylazoimidazoles (NaiR) are non-luminescent under identical conditions. It is interesting that the Cd(II) complexes show a higher intensity than that of the free ligand value. It has been reported that the metal

ions can enhance or quench the fluorescence emission of pyridine containing compounds [25–27]. In the absence of metal ions the fluorescence of the ligand is probably quenched by the occurrence of a photoinduced electron transfer (PET) process due to the presence of a lone pair of electrons on the nitrogen atoms. Such a PET process is prevented by the complexation of NaiPy with metal ions; thus the fluorescence intensity may be greatly enhanced by the coordination to Cd(II). The chelation of the ligand increases rigidity and reduces the loss of energy by thermal vibrational decay. At low temperature (77 K) the complexes show a bright greenish-blue emission and have been red shifted by 40–50 nm from the emission in solution at 298 K. This is probably caused by intermolecular interactions in the frozen conditions that effectively decreases the energy gap.

4. Supplementary data

CCDC No. 600511 contains the supplementary crystallographic data for $[Cd(\beta\text{-NaiPy})_2(ONO_2)_2]$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223 336 033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

A new zeolite-immobilized hybrid catalyst Cu(MeO-salen)-NaY has been prepared by encapsulating [Cu(MeO-salen)(H_2O)] (**1**) [where MeO-salenH_2 = *N*,*N*′-(ethylene)-bis-(3-methoxysalicylaldimine)] in a NaY zeolite matrix. The hybrid material has been characterized by UV–Vis, IR and EPR spectrometry and by X-ray powder diffraction analysis. The pristine complex [Cu(MeO-salen)(H_2O)] (**1**) has also been synthesized and characterized by all the spectrometric methods mentioned above as well as by single crystal X-ray diffraction analysis. A brilliant color change (green to red) has been observed when the complex [Cu(MeO-salen)(H_2O)] (**1**) is immobilized in the zeolitic matrix. X-ray powder diffraction analysis of Cu(MeO-salen)-NaY reveals that the structural integrity of the mother zeolite in the hybrid material remains intact upon immobilization of the complex. The coordination geometry around the Cu^{II} ion in [Cu(MeO-salen)(H_2O)] is found to be square pyramidal. Spectroscopic studies indicate that coordination geometry of the complex undergoes a significant distortion when it is entrapped in the zeolite cavity. While Cu(MeO-salen)-NaY shows excellent catalytic activity and product selectivity in the hydroxylation of phenol and 1-naphthol, [Cu(MeO-salen)(H_2O)] (**1**) remains virtually catalytically inactive in these reactions.

1. Introduction

The ease with which nature performs many of the difficult chemical transformations essential to the life process has long been admired by synthetic chemists. By judicious choice of active sites (in many cases metal complexes) and supports (proteins) nature has built up an impressive array of enzymes that catalyze various reactions such as partial oxidation of unactivated hydrocarbons, electron transfer, etc. in a regio- and stereo-controlled way [1]. In the life process nature selectively generates only that which is necessary in its various activities, producing no undesired waste and side products. In a laboratory, we seldom have such control over reactions. Arguably to attain the success in reproducing life process reactions perfectly in the laboratory is extremely difficult, if not impossible, but mimicking them to a certain extent can increase the efficacy of chemical processes remarkably in comparison to the processes that we follow today. A group of enzymes, for example oxygenase, activate dioxygen to oxidize various kinds of organic substrates into their oxygenates. The metal ions in many of these enzymes act as active centers. Copper, iron and manganese are often found in the active centers in these enzymes [1]. Considerable efforts have been directed to prepare the synthetic mimic of the active center of these unique naturally occurring catalysts to study their catalytic activity in the laboratory [2,3]. Metal complexes of porphyrins, phthalocyanines and Schiff bases that mimic the active center of enzymes have been employed as

doi:10.1016/j.poly.2006.08.018

catalysts in studying many oxidation reactions, but they lose their catalytic activity during the reaction because of the formation of inactive species like μ-oxo dimers or degradation of the complex itself due to oxidation of the ligands. In living systems the protein cavity in which the active center is encapsulated in fact protects the enzymes from undesired dimerization and degradation of ligands. In order to increase the stability and reactivity of synthetic metal complexes they can be encapsulated in a porous matrix [4–7]. Zeolites or molecular sieves structurally resemble enzymes. They are solids with internal networks of linked channels, which open into wider cages or pores. For example, NaY, being a large pore zeolite, has a supercage size of ca. 13 Å. In addition to this it has sodalite cages (diameter ~7 Å). However, the size of the window through which a molecule can enter into the supercage is ca. 8 Å. These cages and/or pores may be used for directing a reaction by immobilizing an active site (usually a metal complex). It is well known that a porous matrix like a zeolite, etc. shows spectacular shape selectivity in catalytic reactions [8]. Heterogenization of a homogeneous catalysts in a porous solid support, in this way, makes the hybrid materials industrially important because the new catalysts: (a) can be easily separated from the reaction mixture and reused with minimum loss of activity; (b) are much more robust than their homogeneous counterparts [9]. The catalysts prepared by immobilizing a metal complex in a porous matrix have shown enhanced catalytic efficacy in comparison to their corresponding homogeneous counterparts [10–12]. Besides, studies on the photochemical and photophysical properties of ruthenium complexes encapsulated in zeolite matrices have been undertaken by several groups [13–15]. It has been found that the photochemical and photophysical properties of neat metal complexes change dramatically upon immobilization in a zeolite matrix. Sykora *et al*. showed that the zeolite immobilized $[Ru(bpy)_n(bpz)_{3-n}]^{2+}$ complex (where bpz is 2,2′-bipyrazine and bpy is 2,2′-bipyridine) can be used to store solar energy by photochemical reactions [13]. Immobilization of certain types of organic compounds in zeolite matrices has demonstrated striking color changes [16]. Recently, organic dye molecules have been immobilized in a zeolite or a molecular sieve to prepare sensors [17,18].

In many metalloenzymes copper(II) ions act as the active center [19–21]. Galactose oxidase is one such mononuclear copper containing enzyme that catalyses stereospecific oxidation of alcoholic or phenolic compounds. The coordination environment of Schiff base complexes of copper(II), for example [Cu(salen)] [salenH_2 = *N*,*N*′-(ethylene)-bis-(salicylaldimine)], mimic the coordination environment of the copper(II) ion of galactose oxidase (Chart 1). Although in recent times attempts have been made to encapsulate copper complexes in a zeolite matrix to mimic this type of enzyme, emphasis has rarely been given to understand the stereo-electronic properties of the copper(II) Schiff base complexes after immobilization [22]. Knowledge regarding the structure of the immobilized

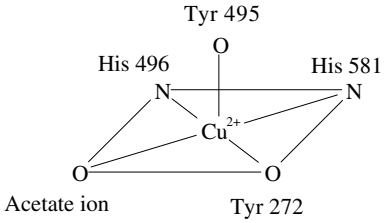

Chart 1.

complex is certainly important to delineate the mechanism of the catalytic reactions and to design new catalysts of this kind. Here we report the synthesis of [Cu(MeO-salen)(H_2O)] (**1**) [MeO-salenH_2 = *N*,*N*′-(ethylene)-bis-(3-methoxy-salicylaldimine)], its X-ray crystal structure, immobilization of complex **1** in a NaY zeolite matrix and the characterization as well as catalytic efficacy in oxidation reactions.

2. Experimental

2.1. Materials

NaY zeolite was procured from Tosoh Corporation, Japan. The ligand, MeO-salenH_2, was prepared from 3-methoxy-salicylaldehyde by condensation with 1,2-ethanediamine following the standard procedure [23,24]. All other chemicals were of AR/GR quality.

2.1.1. Synthesis of [Cu(MeO-salen)(H_2O)] (1)

A solution of $Cu(NO_3)_2 \cdot 3H_2O$ (0.489 g) (2 mmol) in methanol (20 mL) was slowly added to a methanolic solution of MeO-salenH_2 (0.648 g) (2 mmol) with constant stirring. A green precipitate was formed in 30 min on stirring the mixture. The product thus obtained was recrystallized from methanol. X-ray quality green single crystals were obtained on slow evaporation of a methanolic solution of the complex.

2.1.2. Incorporation of copper(II) in NaY

$Cu(NO_3)_2 \cdot 3H_2O$ (4 g), dissolved in 100 ml of H_2O, was stirred continuously for 5 h with NaY (4 g) in suspension. The white zeolite turned blue during the stirring. The solid mass was filtered and washed thoroughly with a copious amount of deionized water and dried under vacuum to give a light blue powder of Cu–NaY. The zeolite thus produced was then used for the immobilization work. Calcination of Cu–NaY was avoided to arrest the migration of copper(II) ions from the vicinity of the supercage.

2.1.3. Immobilization of [Cu(MeO-salen)] in NaY

To prepare Cu(MeO-salen)-NaY, 1 g of Cu–NaY zeolite was mixed with 3 g of MeO-salenH_2 and placed in a closed round-bottom flask containing dry N_2 and heated at 140 °C for an hour with occasional stirring. During heating the mixture turned green. The mixture was then cooled, pulverized and finally subjected to soxhlet extraction with

methanol and acetone. The green solid produced after extraction was then stirred with portions of fresh acetonitrile several times for washing. Interestingly on washing with acetonitrile the green mass transformed to a red solid. This was then collected by filtration and dried in air. This species hereinafter will be designated as Cu(MeO-salen)-NaY.

2.2. X-ray crystallography

2.2.1. Crystal data

$C_{18}H_{20}CuN_2O_5$, $M = 407.91$, orthorhombic space group P_{nma}, $Z = 4$, $a = 9.261(2)$, $b = 24.712(5)$, $c = 7.510(4)$ Å, $V = 1718(1)$ Å^3, $\lambda = 0.71069$ Å, $D_{calc} = 1.576$ gcm^{-3}, $F_{000} = 844$, green block crystal, dimensions = $0.75 \times 0.60 \times 0.23$ mm, $T = 296$ K.

2.2.2. Structure determination

Of the 2402 reflections which were collected on a Rigaku AFC7S diffractometer with graphaite monochromated Mo Kα radiation, 2017 were unique ($R_{int} = 0.010$) with $I > -10.00\sigma(I)$. The structure was solved by direct methods SIR 92 [25]. The non-hydrogen atoms were refined anisotropically and hydrogen atoms were included but not refined. The final cycle of full-matrix least-squares refinement was converged with unweighted and weighted agreement factors of

$$R = \sum \left(F_O^2 - F_C^2\right) \Big/ \sum F_O^2 = 0.099$$

$$R_w = \left[\sum w\left(F_O^2 - F_C^2\right)^2 \Big/ \sum w\left(F_O^2\right)^2\right]^{1/2} = 0.120$$

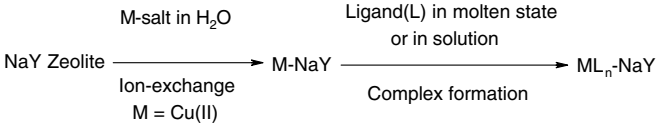
$$R_1 = \sum \| F_O| - |F_C| \| \Big/ \sum |F_O| = 0.035 \text{ for } I > 2.00(I)$$

2.3. Physical measurements

Infrared and electronic spectra were measured on a Perkin–Elmer 783 and a Hitachi U 3400 spectrophotometer, respectively. EPR spectra were measured on a Varian E-112 spectrometer at room temperature. The X-ray powder diffraction measurements were made on a PW 1730/1710 Philips X ray diffractometer. The copper content of the sample was estimated by a Varian Techtron AA-575ABQ atomic absorption spectrophotometer. The catalytic reaction products were analyzed by a Hewlett–Packard 5880A gas chromatograph equipped with an FID detector. Other measurements were undertaken as reported previously [26].

2.4. Catalytic reactions

The catalytic reactions were undertaken in a glass batch reactor. In a typical reaction 1 g of the substrate was taken in 10 mL of H_2O, 50 mg of the catalyst was added to it and this was equilibrated at a temperature of 45 °C in an oil-bath. 1 mL of a 30% H_2O_2 solution was added to this with continuous stirring. The products were collected at different time intervals and were identified and quantified by GC and verified by GC–MS.



3. Results and discussions

3.1. Preparation and chromotropism

The immobilization of the complex in a zeolite matrix was done by a "ship-in-the-bottle" synthesis technique [6]. The flexible Schiff base ligand (in the molten state) was allowed to react with Cu–NaY (Scheme 1). It is expected that the Cu(MeO-salen) complex will be formed in the supercage as well as on the surface of the Y zeolite. As the complex is neutral only a weak force such as a van der Waals interaction is operative here to catch hold of the complex on the surface of the zeolite. It seems soxhlet extraction with CH_3CN effectively washes the hybrid material but some complex molecules might remain on the surface of the zeolite. Nevertheless complex molecules formed inside the zeolite supercage will be retained after washings. Therefore, it can be postulated that the complex molecules are mostly being physically trapped inside the supercage of the zeolite. A sharp color change (light blue to green) of Cu–NaY was observed on mixing with the molten ligand. On washing (soxhlet) with CH_3CN the green colored crude of Cu(MeO-salen)-NaY catalyst turns to a red powder. Although it is well known that organic molecules often show chromotropism when they are entrapped in a porous matrix [16], such chromotropism of inorganic complexes has rarely been observed when they are immobilized in zeolite matrices [10–12,22]. The total copper content in Cu(MeO-salen)-NaY is given in Table 1. The number of metal complexes formed per supercage of NaY is calculated to be ca. 3. The carbon and nitrogen analysis agrees well with these results.

3.2. X-ray structure of [Cu(MeO-salen)(H_2O)] (1)

An ORTEP [27] diagram of the complex [Cu(MeO-salen)(H_2O)] (**1**) along with the atom numbering scheme

Scheme 1.

Table 1
Elemental analyses for complex **1** and Cu(MeO-salen)-NaY

Species	Copper(II) content (wt%)	Cu-Schiff base concentration (mol/g)
[Cu(MeO-salen)(H_2O)] (**1**)	15.2[a] (15.58[b])	
Cu(MeO-salen)-NaY	1.325[a]	2.1×10^{-4}

[a] AAS.

Table 2
Selected bond lengths (Å) and angles (°) for complex **1**

Bond lengths (Å)			
Cu–O(1)	1.934(1)	Cu–N(1)	1.959(2)
Cu–O(1*)	1.934(1)	Cu–N(1*)	1.959(2)
Cu–O(3)	2.369(2)		
Bond angles (°)			
O(1)–Cu–O(1*)	90.39(8)	N(1)–Cu–N(1*)	82.7(1)
O(1)–Cu–N(1)	92.24(7)	O(1*)–Cu–N(1)	167.69(8)
O(1)–Cu–N(1*)	167.69(8)	O(1*)–Cu–N(1*)	92.24(7)

is given in the Fig. 1. Selected bond lengths and angles of the complex are listed in Table 2. The coordination geometry around the copper ion is found to be square pyramidal. Two nitrogen atoms of the azomethine groups of the ligand and the two oxygen atoms of the phenoxo groups of the salicylaldehyde occupy the four coordination sites of the copper(II) ion. The fifth coordination site is occupied by the oxygen atom of the aquo ligand present in the complex **1**. Comparison of the ORTEP diagram of complex **1** with the coordination environment of copper in galactose oxidase shows a close resemblance between them. Single crystal X-ray analysis of galactose oxidase (EC 1.1.3.9) reveals that the apical coordination sites of the mononuclear copper (II) moiety in this enzyme are occupied by two nitrogen atoms of histidine moieties (His 581 and His 496) and two oxygen atoms, one from an acetate ion and another one from a tyrosine moiety (Tyr 272), while the axial site is occupied by an oxygen atom of Tyr 495 (Chart 1) [28].

3.3. X-ray powder diffraction

X-ray powder diffraction measurements have been carried out for Cu(MeO-salen)-NaY. Comparison of the XRD pattern of Cu(MeO-salen)-NaY with the standard pattern of NaY shows no appreciable change in peak positions as well as in the relative intensities of the diffraction lines. This indicates that the crystallinity of the zeolitic matrix remained intact upon immobilization of the inorganic complex.

3.4. Thermal analysis

The simultaneous TG-DTA profiles of complex **1** and the catalyst Cu(MeO-salen)-NaY are shown in Figs. 2a and 2b, respectively. The TG curve for complex **1** shows a significant loss of weight in the temperature range 200–350 °C where the corresponding DTA curve shows a broad exothermic peak with a small kink at ca. 276 °C. The exothermic peak indicates the decomposition of the complex moiety (Fig. 2a). The TG curve of Cu(MeO-salen)-NaY shows that the sample starts to lose its weight from a little above the ambient temperature and the curve shows continuous significant weight loss up to ca. 400 °C (Fig. 2b). As the Cu(MeO-salen)-NaY catalyst contains a large amount of loosely bound H_2O molecules in the zeolite cavities, weight loss starts from a very low temperature where virtually no endothermic peak is observed in the corresponding DTA curve. Nevertheless a broad exothermic peak is observed in DTA curve of the catalyst which corresponds well with the decomposition of the copper(II) Schiff base complex present in the catalyst.

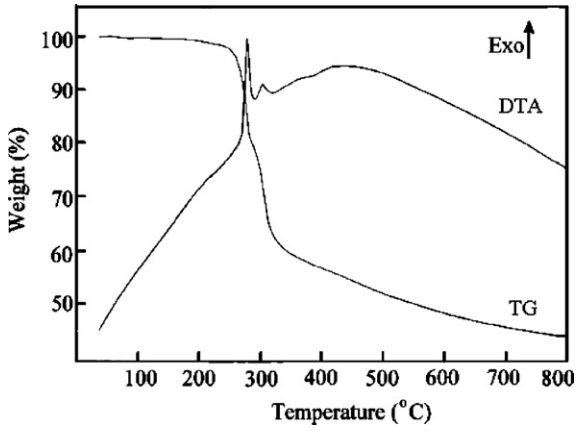

Fig. 2a. TG-DTA profile of [Cu(MeO-salen)(H_2O)] (**1**) [Sample weight: 5.002 mg. Rate of heating: 10 °C/min; Standard: α-Al_2O_3].

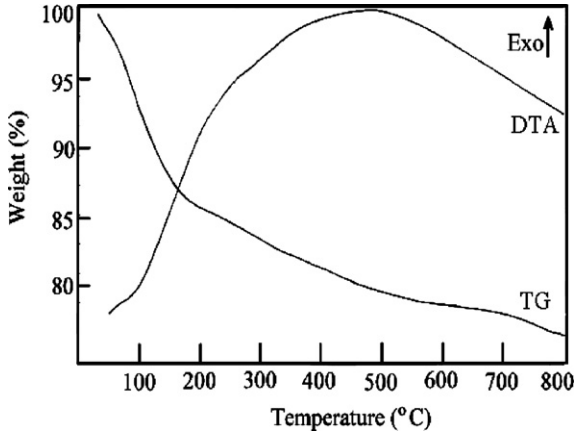

Fig. 2b. TG-DTA profile of Cu(MeO-salen)-NaY catalyst [Sample weight: 10.134 mg. Rate of heating: 10 °C/min; Standard: α-Al_2O_3].

3.5. IR spectroscopy

IR spectral studies of the pristine complex, [Cu(MeO-salen)(H_2O)] and Cu(MeO-salen)-NaY have been undertaken to understand the integrity of the copper(II) Schiff base complex in the zeolite matrix (Fig. 3). Complex **1** shows a sharp band in the range 1630–1650 cm^{-1}, attributable to the azomethine group of the Schiff base ligand [29]. This band in the free ligand appears at frequencies higher by ~10 cm^{-1}. An intense band in the range 1400–1300 cm^{-1} is assigned to the ν(C–O) band of the methoxy group of the ligand [29]. The IR spectrum of Cu(MeO-salen)-NaY shows the presence of all prominent bands for the azomethine group as well as for the C–O vibration of the ligand, appearing in the region 1650–1300 cm^{-1}. As no zeolitic IR band appears in this region of the spectra, except for the band for HOH bending of H_2O at 1650 cm^{-1} that disappears upon careful drying of the catalyst, this may be considered as evidence of the formation of the complexes inside the zeolitic matrix. The vibration bands of the host zeolite obscured the IR bands of the complex in other regions. The IR spectrum of Cu(MeO-salen)-NaY shows an intense band at ca. 1031 cm^{-1} attributable to the asymmetric stretching of the Al–O–Si chain of the zeolite. The symmetric stretching and bending bands of the Al–O–Si framework of the zeolite appear at ca. 732 and 454 cm^{-1}, respectively [30].

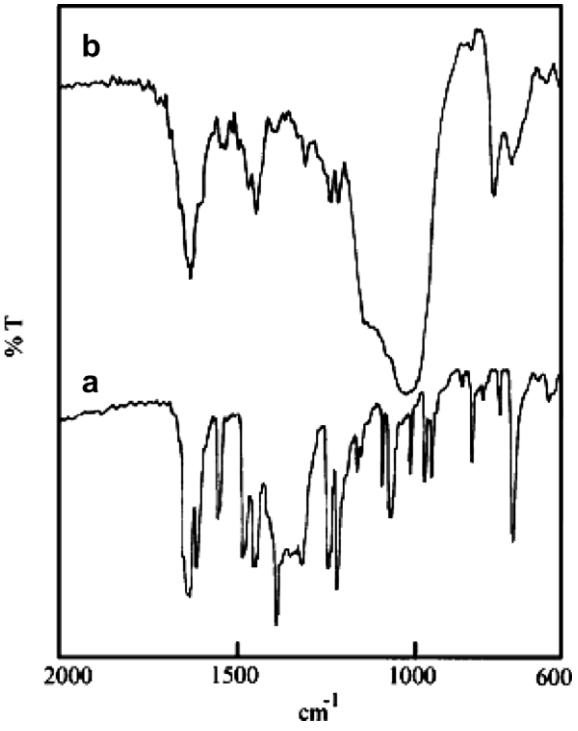

Fig. 3. IR spectra of [Cu(MeO-salen)(H_2O)] (**1**) (a) and Cu(MeO-salen)-NaY catalyst (b).

3.6. UV–Vis spectroscopy

The electronic spectra of the species [Cu(MeO-salen)-(H_2O)] (**1**) and Cu(MeO-salen)-NaY have been measured in the solid state (Fig. 4). The pristine complex, [Cu(MeO-salen)(H_2O)] shows two clear absorption maximum at ca. 17 699 cm^{-1} and 27 397 cm^{-1} whereas the catalyst Cu(MeO-salen)-NaY shows these two peaks at ca. 18 282 cm^{-1} and 27 248 cm^{-1}. All the species show highly intense charge transfer bands in the higher energy region at ca. 35 971 cm^{-1}. The free copper(II) ion has a term symbol ^2D. When the free ion acquires a definite geometry on complex formation the ^2D term splits into several energy states. The splitting of the d-orbitals is related to the stereochemical properties of the complex. It is well established that a Schiff base copper(II) complex with D_{4h} or D_{2h} symmetry can show three/four transitions depending on the metal ligand geometry it acquires on complex formation [31]. The electronic spectrum in the present case is not so well resolved, therefore a D_{4h} symmetry is assumed in all the systems. The transition for $^2B_{1g} \rightarrow {}^2E_g$ (ΔE_{xz}) is expected to be relatively more intense than the other peaks. Gersmann and Swalen assigned the peak maximum observed in the range 18 000–21 000 cm^{-1} to the $^2B_{1g} \rightarrow {}^2B_{2g}$ (ΔE_{xy}) transition and the peak observed in the range 23 100–31 000 cm^{-1} corresponds to the $^2B_{1g} \rightarrow {}^2E_g$ transition for various copper(II) complexes [32]. Lewis et al. also assigned the lower energy band to be due to the $^2B_{1g} \rightarrow {}^2B_{2g}$ transition [33]. The value for the $^2B_{1g} \rightarrow {}^2E_g$ transition could also be estimated from the spin Hamiltonian parameter, which is calculated to be 28 000 cm^{-1}. Therefore it is possible that this higher energy band might sometimes be obscured by the charge transfer band. Indeed in many cases it appears difficult to assign the observed

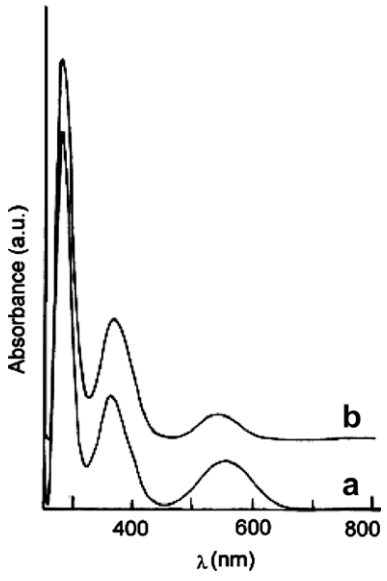

Fig. 4. UV–Vis spectra of [Cu(MeO-salen)(H_2O)] (**1**) (a) and Cu(MeO-salen)-NaY catalyst (b).

peaks to any one of the transitions. In our case two clear excitation bands for $^2B_{1g} \rightarrow {}^2B_{2g}$ (ΔE_{xy}) and $^2B_{1g} \rightarrow {}^2E_g$ (ΔE_{xz}) were observed in the range 18 282–17 699 cm^{-1} and 27 397–27 248 cm^{-1}, respectively. The $^2B_{1g} \rightarrow {}^2B_{2g}$ (ΔE_{xy}) transition is blue shifted on immobilization of the complex in the NaY matrix. The shifting of the $^2B_{1g} \rightarrow {}^2B_{2g}$ band to the higher energy region clearly demonstrates that the in-plane ligand field interaction is becoming stronger on immobilization of the complex in the NaY matrix than in its pristine state.

3.7. EPR studies

The EPR spectra for [Cu(MeO-salen)(H_2O)] (**1**) and Cu(MeO-salen)-NaY have been measured (Fig. 5). Spectral parameters have been calculated using the method of Kneubuhl [34a]. The principal g values calculated using the usual procedure are in agreement with those reported for zeolite immobilized copper Schiff base systems [34b]. It has been observed that for all copper systems $g_\parallel > g_\perp > 2.0023$, suggesting that the unpaired electron occupies the $d_{x^2-y^2}$ orbital, which is characteristic of a tetragonally elongated Cu^{II} system. Hyperfine coupling due to the metal ion, A_{Cu} (for ^{63}Cu, $I = \frac{3}{2}$) was resolved in the case of Cu(MeO-salen)-NaY. These values are given in Table 3. For Cu(MeO-salen)-NaY the $g_\parallel$ and $g_\perp$ values are found to be 2.244 and 2.053, respectively. The $A_\parallel$ value of Cu(MeO-salen)-NaY is calculated to be 145 G from the EPR spectra (Table 3). [Cu(MeO-salen)(H_2O)] also shows an axial EPR spectrum with $g_\parallel$ and $g_\perp$ equal to 2.209 and 2.044 but the hyperfine coupling is not resolved in this case. Immobilization of the complex in the NaY matrix has a significant effect on both the $g_\parallel$ and $g_\perp$ values. The variation in the $g_\parallel$ value on immobilization could be interpreted as being due to the change in the coordination environment around the copper (II) ion. The increase in the $g_\perp$ value could be correlated with distortions from the square planarity of the N_2O_2 chromophore around the copper(II) ion (vide infra).

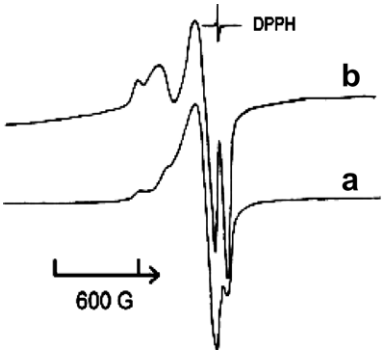

Fig. 5. EPR spectra of [Cu(MeO-salen)(H_2O)] (**1**) (a) and Cu(MeO-salen)-NaY catalyst (b).

Table 3
EPR spectral parameters

Species	$g_\parallel$	$g_\perp$	$A_\parallel$ (Gauss)	$A_\parallel$ ($\times 10^{-4}$ cm^{-1})
[Cu(MeO-salen)(H_2O)] (**1**)	2.209	2.044	200	203
Cu(MeO-salen)-NaY	2.244	2.053	145	159

3.8. Ground-state wave function and bonding parameters

The MO coefficients have been calculated using the ligand field approach adopted by Maki and McGarvey for Schiff base complexes with D_{4h} or D_{2h} symmetry [35,36]. Group theoretical consideration and proper linear combinations of ligand orbitals with the d-orbitals of the copper (II) ion affords the following antibonding wave functions [35,37]:

$$B_{1g} = \alpha d_{x^2-y^2} - \frac{1}{2}\alpha'\left[-\sigma_x^{(1)} + \sigma_y^{(2)} + \sigma_z^{(3)} - \sigma_y^{(4)}\right] \tag{3.1}$$

$$B_{2g} = \beta d_{xy} - \frac{1}{2}\sqrt{(1-\beta^2)}\left[p_y^{(1)} + p_x^{(2)} - p_y^{(3)} - p_x^{(4)}\right] \tag{3.2}$$

$$A_{1g} = \gamma d_{3z^2-r^2} - \frac{1}{2}\sqrt{(1-\gamma^2)}\left[-\sigma_x^{(1)} + \sigma_y^{(2)} + \sigma_z^{(3)} - \sigma_y^{(4)}\right] \tag{3.3}$$

$$E_g \begin{cases} = \delta d_{xz} - \sqrt{(1-\delta^2)}\left(\frac{p_z^{(1)} - p_z^{(3)}}{\sqrt{2}}\right) & \text{(a)} \\ = \delta d_{yz} - \sqrt{(1-\delta^2)}\left(\frac{p_z^{(2)} - p_z^{(4)}}{\sqrt{2}}\right) & \text{(b)} \end{cases} \tag{3.4}$$

Overlap is included only for the B_{1g} state, where α and α' are related:

$$\alpha^2 + \alpha'^2 - 2\alpha\alpha' S = 1 \tag{3.5}$$

Here S is the overlap integral. For Schiff base ligands the value of S is 0.093 [35]. The B_{1g} and A_{1g} states account for the σ bonding to the copper (α and α'). The B_{2g} state represents the in-plane π bonding (β). δ is the coefficient for the MO E_g representing the out-of-plane π bonding and α' is the coefficient for ligand orbitals forming the B_{1g} orbital. Since α, α', β and δ are MO coefficients, their values must be less than or equal to unity. They must be greater than 0.5 otherwise they will have no significance on the degree of covalency in the bonding. The extent of the departure of these coefficients from unity measures the extent of delocalization of the metal electrons due to metal-ligand bonding, hence the extent of covalency. When an unpaired electron is interacting with a magnetic field,the spin Hamiltonian could be expressed as

$$\hat{H} = g_\parallel \beta H_z S_z + g_\perp \beta (H_x S_x + H_y S_y) + A_\parallel S_z I_z + A_\perp (S_x I_x + S_y I_y) \tag{3.6}$$

When the wave function for B_{1g} is applied to the above Hamiltonian, the following EPR spectral parameters can be obtained [35–37]:

$$g_\parallel = 2.0023 - \left(\frac{8\lambda}{\Delta E_{xy}}\right)[\alpha^2\beta^2 - f(\beta)] \tag{3.7}$$

where

$$f(\beta) = \alpha\alpha'\beta S + \frac{1}{2}\alpha\alpha'\beta(1-\beta^2)^{1/2}T(n) \quad (3.8)$$

$$g_\perp = 2.0023 - \left(\frac{2\lambda}{\Delta E_{xz}}\right)[\alpha^2\beta^2 - f(\beta)] \quad (3.9)$$

where

$$f(\beta) = \alpha\alpha'\delta^2 S + \frac{1}{\sqrt{2}}\alpha\alpha'\delta(1-\delta^2)^{1/2}T(n) \quad (3.10)$$

$$A_\parallel = P\left\{\alpha^2\left(\frac{4}{7}+k\right) - 2\lambda\alpha^2\left[\frac{4\beta^2}{\Delta E_{xy}} + \left(\frac{3}{7}\right)\frac{\delta^2}{\Delta E_{xz}}\right]\right\} \quad (3.11)$$

where $P = 2\gamma_{Cu}\beta_e\beta_N\langle d_{x^2-y^2}|r^{-3}|d_{x^2-y^2}\rangle = 0.036\ cm^{-1}$, γ_{Cu} is the magnetogyric ratio, β_e is the Bohr magneton and β_N is the nuclear magneton of ^{63}Cu. The constant k corrects for the Fermi contact term of excited configurations of Cu. The constant $T(n)$ is an integral over the ligand functions and results from the calculation of the matrix elements of the Hamiltonian with the wave functions. Based on these equations, α can be approximately evaluated using the following equation [32]:

$$\alpha^2 = \frac{A_\parallel}{P} + (g_\parallel - 2) + \left(\frac{3}{7}\right)(g_\perp - 2) + 0.04 \quad (3.12)$$

Here, 0.04 approximates the various integrals by an average value.

When π-bonding is present it is necessary to simplify Eqs. (3.7)–(3.10) (unless nuclear and ligand hyperfine structure provide extra data) by ignoring overlap and the small terms in $T(n)$. This leads to expressions previously derived by Stevens [38]:

$$g_\parallel = 2 - \left(\frac{8\lambda\alpha^2\beta^2}{\Delta E_{xy}}\right) \quad (3.13)$$

$$g_\perp = 2 - \left(\frac{2\lambda\alpha^2\delta^2}{\Delta E_{xz}}\right) \quad (3.14)$$

The α values (the d-orbital coefficients for the b_{1g} molecular orbital representing in-plane σ-bonding) were evaluated from Eq. (3.12), whereas the values of α' (the metal d-orbital coefficients for the b_{1g} molecular orbital representing in-plane σ-bonding) were calculated from Eq. (3.5). The values of β (the metal d-orbital coefficients for the b_{2g} molecular orbital representing in-plane π-bonding) were calculated from Eq. (3.13) using the ΔE_{xy} value from electronic spectra whereas δ values were calculated using Eq. (3.14). The MO coefficients were obtained by using the value of $-828\ cm^{-1}$ for λ, the spin–spin coupling constant and $0.036\ cm^{-1}$ for P, dipolar interaction term for a free copper(II) ion (Table 4).

3.9. Catalytic reactions

The oxidation of phenol and 1-naphthol were carried out to test the catalytic efficiency of the prepared catalyst. The results of the reactions are given in Table 5. In both the reactions the hybrid catalyst showed good catalytic activity. It is interesting to note that neither the green species of impure Cu(MeO-salen)-NaY(imp.), nor the Cu-exchanged mother zeolite (Cu–NaY) exhibited any noticeable catalytic activity. The pristine [Cu(MeO-salen)(H_2O)] complex also shows no catalytic activity in solution in the above mentioned oxidation reactions (Table 5). It should be noted that atomic absorption spectroscopic analysis shows copper is not leaching out during oxidation reactions as no copper was detected in the liquid phase of the reaction mixture after completion of the reaction. Hydroxylation of phenol using this catalyst affords two products, viz. catechol and hydroquinone, instead of the three expected products (catechol, hydroquinone and benzoquinone) whereas hydroxylation of 1-naphthol gives selectively only 1,4-naphthoquinone in lieu of three possible products (1,4-naphthoquinone, 1,4-dihydroxy-naphthalene and 1,2-dihydroxy-naphthalene). This clearly demonstrates

Table 4
Electronic d–d transitions and MO coefficients

Species	α^2	α'^2	β^2	ΔE_{xy} (cm^{-1})	δ^2	ΔE_{xz} (cm^{-1})
[Cu(MeO-salen)(H_2O)] (**1**)	0.835	0.250	0.740	17699	0.866	27397
Cu(MeO-salen)-NaY	0.741	0.354	0.897	18282	0.992	27248

Table 5
Catalytic performance of Cu(MeO-salen)-NaY, Cu-NaY and [Cu(MeO-salen)(H_2O)] (**1**)

Catalyst	Reaction time (h)	Conversion (% mass)					
		Phenol			1-Naphthol		
		BQ[a]	CAT[a]	HQ[a]	1,4-NQ[a]	1,4-DHN[a]	1,2-DHN[a]
Cu(MeO-salen)-NaY	3		7.9	4.5	20.5		
	6		11.7	6.2	80.7		
Cu-NaY	6	No detectable activity					
[Cu(MeO-salen)(H_2O)] (**1**)	6	No detectable activity					

[a] BQ, benzoquinone; HQ, hydroquinone, CAT, catachol, 1,4-NQ, 1,4-naphthoquinone, 1,4-DHN, 1,4-dihydroxynaphthalene, and 1,2-DHN, 1,2-dihydroxynaphthalene.

that [Cu(MeO-salen)(H_2O)] on immobilization in a NaY matrix not only shows remarkable catalytic activity in the hydroxylation reactions of phenol and 1-naphthol but also exhibits excellent product selectivity.

4. Conclusion

It is evident from this study that the copper(II) Schiff base complex, [Cu(MeO-salen)(H_2O)] (**1**), which possesses a square pyramidal geometry undergoes a severe distortion in its coordination environment on immobilization in a NaY matrix. The shifting of the $^2B_{1g} \rightarrow {}^2B_{2g}$ band to shorter wavelength in electronic spectra of the catalyst, Cu(MeO-salen)-NaY (red) in comparison to the pristine complex or [Cu(MeO-salen)(H_2O)] (green), indicates that the axial ligand field around the copper(II) ion is weaker in the former [39]. This may be due to loss of the aquo ligand of the complex **1** to give rise to a square planar moiety during entrapment of the complex in the NaY supercage. EPR spectra are in accord with this as the $g_{\|}$ value of the catalyst is higher than that of complex **1** (Table 3) [39,40]. The lower value of the calculated MO coefficient α^2 for the catalyst also suggests that the covalency of the in-plane ligand is increased on immobilization. As a result we observed the chromotropism (color change) in the complex when it is immobilized in the NaY matrix. The concomitant tetrahedral distortion in the CuO_2N_2 chromophoric moiety of the entrapped complex in NaY matrix is also evident as the catalyst shows a higher value of $g_{\perp}$ in comparison to the corresponding value for the complex **1** [41]. In addition the value of MO coefficients β^2 and δ^2, which represents the π-bonding, is higher in the case of catalyst than the pristine complex **1** (Table 4). This indicates that the complex undergoes tetrahedral distortion on entrapment. Interestingly while the pristine complex does not show any catalytic activity towards oxidation reactions, its immobilized variety does. Evidently the copper(II) Schiff base becomes reactive when it suffers distortion. Although more complex and dynamic situations are encountered in metalloproteins, it is tempting to mention that the blue copper protein shows greater reactivity where the active copper(II) site possesses an intermediate coordination environment between square planar and tetrahedral [21]. It is apparent from this study that a square planar copper(II) complex moiety with its two vacant axial positions facilitates nucleophilic attack by the oxidant to enhance the catalytic activity of the hybrid materials in the oxidation reactions. Flexibility of the diamine backbone of Schiff base ligand and fine tuning of the stereoelectronic structure of the complex by introducing different substitutions in the ligand are the crucial factors that govern the reactivity of the Cu^{II} complex.

Available online 9 September 2006

Abstract

Mixed ligand complexes having the formulae $Cu(RPO)_2Py_2$, $Cu(RPO)_2Im_2$ and $Cu(DBO)_2Py_2$ [RPO = resacetophenone oxime, DBO = 2,4-dihydroxybenzophenone oxime, Py = pyridine and Im = imidazole] have been synthesized and characterized by UV–Vis, IR, ESR, cyclic voltammetry and magnetic susceptibility methods. Absorption studies revealed that each of these octahedral complexes is an avid binder of calf thymus DNA. The apparent binding constants for mixed ligand complexes are in order of 10^4–10^5 M^{-1}. Based on the data obtained in the DNA binding studies a partial intercalative mode of binding is suggested for these complexes. The nucleolytic cleavage activity of the adducts was carried out on double stranded pBR322 circular plasmid DNA by using a gel electrophoresis experiment in the presence and absence of oxidant (H_2O_2). All the metal complexes cleaved supercoiled DNA by hydrolytic and oxidative paths. The oxidative path dominates the hydrolytic cleavage. The hydrolytic cleavage of DNA is evidenced from the control experiments showing discernable cleavage inhibition in the presence of the hydroxyl radical inhibitor DMSO or the singlet oxygen quencher azide ion.

Keywords: Mixed ligand copper(II) complexes; Oximes; Aromatic bases; CT DNA; Binding interaction; Hydrolytic cleavage

1. Introduction

Oximes are widely recognized ligands [1–5]. Transition metal complexes with O-hydroxy aromatic oximes (e.g. salicylaldoxime (SAO)) have attracted much attention, as they exist as *cis* and *trans* geometrical isomers. Copper complexes are known to assume *trans* structures while cobalt complexes have *cis* structures. We have investigated several cobalt complexes with O-hydroxy carbonyl Schiff bases (tetradentate ligands) containing additional hydroxyl groups [6]. Such additional groups have been exploited to anchor the complexes on a polymer support [7].

Investigation on DNA interactions and cleavage activity of metal complexes with oximes are quite limited [8]. In light of the above and in continuation of our on going research work [9,10] on metal–DNA interactions herein we describe the synthesis characterization, DNA binding and cleavage activity of copper(II) complexes with resacetophenone oxime (2,4-dihydroxyacetophenone oxime) and 2,4-dihydroxybenzophenone oxime and their pyridine and imidazole adducts.

2. Experimental

2.1. Chemical

2,4-Dihydroxybenzophenone and resacetophenone were purchased from Merck, and metals used in the preparation of the complexes are of reagent grade. The solvents used in the synthesis of the ligands and metal complexes were distilled before use. All other chemicals were of AR grade and were used without further purification. Agarose, used in gel

electrophoresis, was purchased from Sigma–Aldrich, Calf thymus DNA and plasmid pBR322 were purchased from Genie Biolabs, Bangalore, India.

2.2. Instrumentation

The elemental analyses were performed using a Perkin–Elmer 2400 CHNS elemental analyzer. Magnetic moments were determined in the polycrystalline state on a PAR model-155 vibrating sample magnetometer operating at field strength of 2–8 kG. High purity Ni metal (saturation moment 55 emu/g) was used as standard. The molar conductance of the complexes in DMF (10^{-3} M) solution was measured at 28 ± 2 °C with a systronic model 303 direct-reading conductivity bridge. The electronic spectra were recorded in DMF with a Schimadzu UV-160A spectrophotometer. FT-IR spectra were recorded in the range 4000–50 cm^{-1} with a Bruker IFS 66V in KBr and polyethylene medium. ESR spectra were recorded on Varian E-122 X-band spectrophotometers at liquid nitrogen temperature in DMF. The voltammetric measurements were performed on Bio-Analytical Systems (BAS), CV-27 assembly in conjunction with an *X–Y* recorder. Measurements were made on the degassed (N_2 bubbling for 5 min) solution in DMF (10^{-3} M) containing 0.1 M tetraethyl ammonium perchlorate as the supporting electrolyte. The three-electrode system consisted of a glassy carbon (working), platinum (auxiliary) and Ag/AgCl (reference) electrodes. UV–Vis spectra were recorded on a Tech-Comp UV-8500 instrument.

2.3. DNA binding experiments

A solution of CT DNA in 0.5 mM NaCl/5 mM Tris–HCl (pH 7.0) gave a ratio of UV absorbance at 260 and 280 nm, A_{260}/A_{280} of 1.8–1.9, indicating DNA was sufficiently free of protein. A concentrated stock solution of DNA was prepared in 5 mM Tris–HCl/50 mM NaCl in water, pH 7.0 and the concentration of CT DNA were determined by UV absorbance at 260 nm after 1:100 dilutions (in 250 μM in NP). The molar absorption coefficient was taken as 6600 M^{-1} [11]. Stock solutions were stored at 4 °C and were used after no more than four days. Doubly distilled water was used to prepare the buffer solutions. Solution were prepared with the appropriate copper complexes (35 μM of a 1.0 mM solution in DMF), CT DNA (diluted from a 1 mg/ml solution), NaCl (final concentration 50 mM) and Tris–HCl buffer (pH 7.0, final concentration 50 mM) and diluted with H_2O to a total volume of 1 ml. After equilibration (ca. 10 min), the spectra were recorded against an analogous blank solution containing the same concentration of DNA/NaCl and Tris–HCl buffer.

The data were then fitted to Eq. (1) to obtain the intrinsic binding constant, K_b [12]

$$[DNA]/(\varepsilon_a - \varepsilon_f) = [DNA]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_a - \varepsilon_f), \quad (1)$$

where ε_a, ε_f and ε_b are the apparent free and bound metal complex extinction coefficients, respectively. A plot of $[DNA]/(\varepsilon_a - \varepsilon_f)$ versus [DNA] gave a slope of $1/(\varepsilon_b - \varepsilon_f)$ and a *Y*-intercept equal to $1/K_b(\varepsilon_a - \varepsilon_f)$, K_b is the ratio of the slope to the *Y*-intercept.

2.4. Assay of nuclease activity

A DMF solution containing the metal complexes (1 μl of 1 mM) was taken in a clean eppendroff tube and plasmid DNA (1 μl of 0.10 μg/ml) was added. The contents were incubated for 2 h at 37 °C and loaded on 1% agarose gel after mixing 5 μl of loading buffer (0.25% bromophenol blue + 25% xylenecyanol + 30% glycerol sterilized distilled). Electrophoresis was performed at constant voltage (80 V) until the bromophenol blue reached to 3/4 of the gel. Then the gel was stained for 10 min by immersing it in ethidium bromide solution. The gel was then de-stained for 10 min by keeping it in sterile distilled water and the plasmid band was visualized by viewing the gel under a transilluminator and photographed. The efficiency of the DNA cleavage was measured by determining the ability of the complex to form open circular (OC) or nicked circular (NC) DNA from its supercoiled (SC) form by quantitatively estimating the intensities of the bands using the *Vilber Lourmat* (V 99.01) Gel Documentation System. The reactions were carried out under hydrolytic conditions. A control experiment was done in presences of hydroxyl radical scavenger DMSO and singlet oxygen quencher azide ion.

3. Preparation

3.1. Preparation of ligands

Resactophenone oxime (RPO) and 2,4-dihydroxybenzophenone oxime (DBO) ligands were prepared by the reaction of hydroxylammoniumchloride ($NH_2OH \cdot HCl$) with resacetophenone and 2,4-dihydroxybenzophenone, respectively.

Hydroxylammoniumchloride (0.03 mol) and resacetophenone (0.03 mol) were taken in 50% aqueous methanol or 2,4-dihydroxybenzophenone (0.03 mol) in benzene solvent. The resulting mixture was acidified with a few drops of glacial acetic acid and refluxed for 2–3 h. The precipitated compound was filtered, washed with cold water dried under vacuum and recrystallized from aqueous ethanol.

The infra red spectrum of RPO and DBO shows strong and broad bands due to hydrogen-bonded phenolic OH at 2′-position in the region 3000–2800 cm^{-1}. They also exhibit two separate OH bands due to oxime OH at 3237, 3137 cm^{-1} and phenolic OH at 3400, 3350 cm^{-1}, respectively, in addition to >C=N stretching at 1598, 1588 cm^{-1}, respectively. The ^1H NMR spectra of RPO and DBO were recorded in DMSO-d_6 solvent. RPO shows signals at 2.22 (s, 3H), 6.42–7.21 (m, 3H), 9.15 (s, 1H) 10.85 (s, 1H) and 11.79 (s, 1H) assigned to $–CH_3$, $–C_6H_3$,

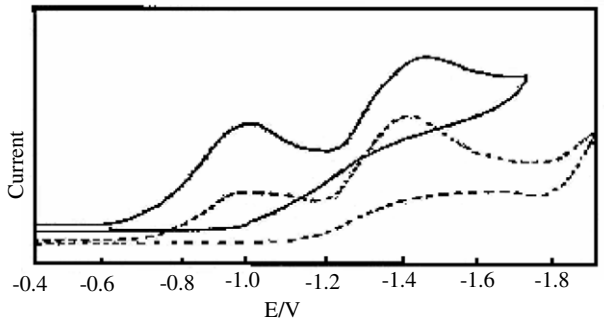

Fig. 1. Cyclicvoltametric profile diagram of RPO (------) and DBO (——).

ortho phenolic OH, *para* phenolic OH and =N–OH (oxime), respectively. Signals corresponding to $-C_6H_3$, $-C_6H_5$, two phenolic OH's and oxime-OH are, respectively, observed in the NMR spectrum of DBO at 6.30–6.45 (m, 3H), 7.22–7.80 (m, 5H), 10.09–10.42 broad (2H) and 12.45 (s, 1H) δ values, respectively. The mass spectrum of RPO shows a molecular ion peak at 167 (m/z) corresponding to its molecular weight. The other important peaks at m/z 150 and 135 are due to loss of –OH and $-CH_3$ from the molecular ion peak. A peak at 121 corresponds to the formation of the $HOC_6H_3NCH_3^+$ ion. The mass spectrum of DBO shows peaks at 229, 213, 183 and 108 corresponding to the molecular ion ($M^{+\cdot}$), $M^{+\cdot}-16$, $HOC_6H_3N–Ph^{+\cdot}$ and  , respectively.

The presence of only cathodic peaks [−1.35 and −1.83 (RPO); −1.42 and −1.87 V (DBO)] in cyclicvoltammograms (Fig. 1) of the ligands suggest an irreversible reduction of the azomethine group. Each peak corresponds to a one electron reduction. A possible mechanism (Scheme 1) is proposed for the reduction of these ligands.

3.2. Synthesis of cuproxime complexes and their pyridine and imidazole adducts

Cuproximes were prepared by mixing copper(II) chloride (4.3 g, 0.025 mol) and oxime [RPO (0.05 mol) or DBO (0.05 mol)] in a 1:2 ratio in 50% aqueous ethanolic medium. The reaction mixture was stirred for 30 min, and the precipitate formed was filtered, washed with hot water and cold methanol. The complexes were dried at 110 °C.

The copper(II) complex (1.5 g) of RPO or DBO was placed in a schlenk tube and dissolved in pyridine (3 ml). The solution was stirred magnetically for 30 min and *n*-hexane (25 ml) was added. After standing for 3–4 days, the dark green product that formed was washed with water and *n*-hexane and dried under reduced pressure over $CaCl_2$.

Cuproxime of RPO (0.01 mol) was placed in a 250-ml round bottom flask. Imidazole (0.05 mol) dissolved in CH_2Cl_2 was added to the contents of the flask. The reaction mixture was refluxed on a water bath for 2 h. On cooling the dark green precipitate that formed was filtered, washed with cold hexane and dried under vacuo over $CaCl_2$.

4. Results and discussion

The present ligands contain two functional groups viz., oxime and phenolic groups (Fig. 2). The ligands and their metal complexes (both the cuproximes and their adducts) are stable at room temperature, are non-hygroscopic, soluble partially in methanol, ethanol and easily soluble in dimethylformamide. The colour, melting point, analytical data, molar conductance and magnetic moment data are summarized in Table 1. Elemental analysis supports the present composition of the complexes. The molar conductivity data suggest that the complexes are non-electrolytes. The magnetic moment values of the complexes indicate the

presence of one unpaired electron. The copper salicylaldoxime complex [$Cu(SAO)_2$] is used for comparative studies.

The electronic spectral data of the metal complexes are given in Table 2. The spectral data of the complexes are dominated by intense intra-ligand (π–π^*) and charge transfer (CT) bands. The presence of a single d–d band may be attributed to the symmetric nature of the ligand field. In the electronic spectra of the mixed ligand complexes, d–d bands are observed in the high-energy region (Table 2) due to Jahn–Teller distortion observed in octahedral complexes.

The broad band in the IR region 3000–2800 cm^{-1} in RPO and DBO are absent in the corresponding copper chelates suggesting the deprotonation of the 2′-OH phenolic group due to formation of a covalent bond between the copper and phenolic oxygen. Strong bands observed at 1598 and 1588 cm^{-1} assigned to >C=N– stretching vibration in the ligands are shifted to lower frequency in the complexes revealing the participation of the azomethine nitrogen in chelation. The non-ligand bands observed in the far IR spectra of the metal complexes are assigned to ν(M–N) (265, 271 and 289 cm^{-1}) ν(M–O) (576, 589 and 595 cm^{-1}) stretching vibrations. Additional bands observed (1610–1600, 1540–1520, 260–220, 245–230 cm^{-1}) in the IR spectra of the mixed ligand complexes are presumably due to the binding of bases (pyridine/imidazole) to copper via nitrogen donor atoms, preferably in axial positions.

Oxime OH stretching vibrations are observed at a lower frequency in the chelates (3221 and 3128 cm^{-1}), indicating the involvement of oxime OH in strong hydrogen bonding which leads to the formation of a stable 5-membered ring structure. Observance of three evenly distributed bands in the 620–450 cm^{-1} region is characteristic of a *trans*-structure for the complexes [13]. IR spectral data together with electronic and magnetic moment data suggest a *trans* square planar structure for the cuproximes and a *trans* octahedral structure for the mixed ligand copper(II) complexes (Fig. 3a and b).

ESR spectra of all the complexes are recorded in DMF solvent at liquid nitrogen temperature (LNT). The ESR spectra of the copper(II) complexes exhibit a set of four well-resolved peaks in the low field region and a weaker signal in high field region, corresponding to $g_\parallel$ and $g_\perp$, respectively (Fig. 4). The $g_\parallel$ and $g_\perp$ values are 2.245, 2.019 for $Cu(RPO)_2$ and 2.218, 2.015 for $Cu(DBO)_2$, respectively. The trend observed, $g_\parallel > g_\perp > 2.02$, for the present copper complexes is typical of a copper(II) (d^9) ion in axial symmetry with the unpaired electron present in the $d_{x^2-y^2}$ orbital. The $g_\parallel$ value of the parent complexes being less than 2.3 is indicative of significant covalent bonding

[14,15] in the complexes. The orbital reduction parameters data ($K_{\|} > K_{\perp}$) in Table 3 suggest that the present complexes have out-of-plane π-bonding [16].

Massacesi et al. [17,18] reported $g_{\|}$ values in the range 2.3–2.4 for complexes containing copper–oxygen bonds and 2.2–2.3 for complexes containing copper–nitrogen bonds. The present copper oxime complexes have $g_{\|} = 2.2$–2.4 in conformity with both Cu–O and Cu–N bonds in the cuproximes and their adducts.

The P values for a complex containing N_2O_2 donor atoms fall in the range 0.022–0.029 cm^{-1} [19]. The P values for the mixed ligand complexes are consistent with bonding of copper with nitrogen and oxygen donor atoms [20].

The redox behavior of these complexes has been investigated by cyclic voltammetry at a glassy carbon electrode. Table 4 gives the electrochemical data obtained at a glassy carbon electrode in DMF solution. The cathodic peak current function values were found to be independent of the scan rate. Repeated scans, as well as different scan rates showed that dissociation does not take place. Fig. 5 shows the profile of $Cu(RPO)_2Py_2$ and $Cu(DBO)_2Py_2$ complexes at 50 mV s^{-1} scan rates.

The copper complexes are redox active and show a cyclic voltammetric response in the potential range of 0.35–0.60 V which is assignable to the reduction peak of Cu(II)/Cu(I). All these complexes exhibit quasi-reversible behavior [21] as indicated by the non-equivalent current

intensity of cathodic and anodic peaks ($i_c/i_a = 0.512$–0.322 V). All complexes have a large separation between the anodic and cathodic peaks (100–250 mV) indicating the quasi-reversible character. The ΔG° values of the mixed ligand complexes are greater than the parent complexes, showing that these complexes are more stable than their parent complexes.

The $E_{1/2}$ values of the adducts and complexes are comparable with other complexes showing nuclease activity [22]. The $E_{1/2}$ values of the parent complexes and mixed ligand complexes are high suggesting that the complexes undergo a more facile redox change which is the requirement for DNA cleavage [23].

4.1. Electronic absorption titrations

The binding interaction of the copper complexes with DNA was monitored by UV–Vis spectroscopy. The absorption spectra of the copper complexes are compared with and without CT DNA. In the UV region spectra, all the copper(II) complexes exhibit an intense absorption band around 280 nm which is attributed to an n–π^* or π–π^* transition. With increasing concentration of CT DNA, the absorption bands of the complexes are affected, resulting in the obvious tendency of hyperchromism or hypochromism with a hypsochromic shift (1–4 nm). The change in absorbance values with increasing amount of CT DNA were used to evaluate the intrinsic binding constant K_b for the present complexes (Table 5).

In the presence of increasing amounts of CT DNA, the UV–Vis absorption of $Cu(RPO)_2$ and $Cu(DBO)_2$ showed

Table 5
Effect of CT DNA on the absorbance bands and binding constant of the copper complexes and adducts

Complex	λ_{max} (nm)		$\Delta\lambda$ (nm)	H (%)	K_b (M^{-1})
	Free	Bound			
I	341	342.5	1.5	−16.6	2.5×10^4
II	276.0	274.5	1.5	−12.8	3.8×10^5
III	275.5	274.2	1.3	+11.8	2.6×10^4
IV	274.5	272.4	2.1	+12.4	2.1×10^5
V	287.1	284.8	2.3	−15.6	9.9×10^5
	357.0	345.2	12.8	−23.2	
VI	291.5	290.2	1.3	+4.8	1.4×10^4
	325.5	324.2	1.3	+0.5	

hypsochromic shifts (λ_{max}: 1.0 ± 0.5 nm) and hypochromism [hypochromicity: 12.8% for Cu(RPO) and 15.4% for Cu(DBO)]. While the mixed ligand complexes showed hypsochromic (λ_{max}: 1.0 ± 0.5 nm) and hyperchromism [hyperchromicity: +11.8%, +12.4% and +4.8%]. The change in hypochromic to hyperchromic shift from parent complex to mixed ligand complexes suggests that the type of binding mode is different (Fig. 6). This may be attributed to a change in structure from square planar (parent) to octahedral nature (adducts). The binding nature in the mixed ligand complexes is significant due to π-stacking or a hydrophobic interaction of the aromatic pyridine or imidazole bases. The binding constants of the parent complexes are sufficiently high, possibly due to their square planar nature [24]. A strong binding constant for II and V compared with I may be attributed to the presence of an extra OH group in complexes II and V, while V has the highest binding constant, which may be due to an increased π-stacking interaction facilitated by the presence of extra phenyl rings [25].

4.2. Nuclease activity

Gel electrophoresis experiments using pBR322 circular plasmid DNA were performed with the ligands and their complexes in the presence and absence of H_2O_2 as an oxidant. At micro-molar concentrations, for 2 h incubation periods, the ligands exhibit no significant cleavage activity in the absence or presence of oxidant (H_2O_2). The nuclease activity is greatly enhanced by the incorporation of copper ion in the respective ligands. The nuclease activity of the complexes was also investigated in the presence of a free radical scavenger, dimethylsulfoxide (DMSO) and a singlet oxygen quencher, azide ion (NaN_3).

From Fig. 7a it is evident that the complexes cleave DNA more efficiently in the presence of an oxidant. This may be attributed to the formation of hydroxyl free radicals. The production of a hydroxyl radical due to the reaction between the metal complex and oxidant may be explained as shown below [26].

$$(L)Cu^{2+} + H_2O_2 \rightarrow (L)Cu^{3+} + OH + OH^{\cdot}$$

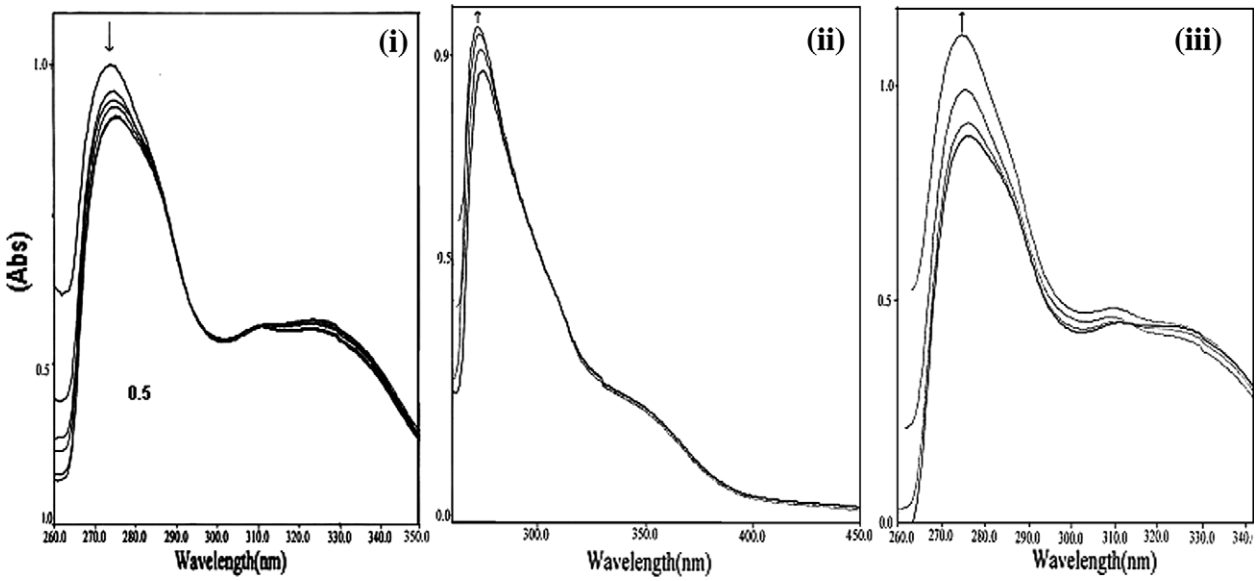

Fig. 6. Variation in absorption spectra of: (i) $Cu(RPO)_2$, (ii) $Cu(RPO)_2Py_2$, and (iii) $Cu(RPO)_2Im_2$ in the absence and presence of increasing amounts of DNA. [CuL] = 35 μM. Arrows show the absorbance changes upon increasing the DNA concentration.

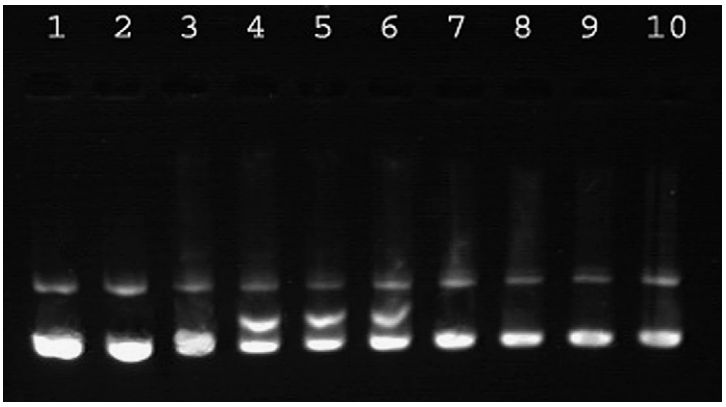

Fig. 7b. Gel electrophoresis diagram for reactions done in the control experiment with an incubation time of 60 min at 37 °C in dark condition with NaN_3 (1 mM) and DMSO (4 μl): Lane 1: DNA; lane 2: DNA + DBO; lane 3: DNA + $CuCl_2$; lane 4: DNA + $[Cu(DBO)_2]Py_2$; lane 5: DNA + $[Cu(DBO)_2]$-Py_2 + DMSO(4 μl); lane 6: DNA + $[Cu(DBO)_2]Py_2$ + NaN_3 (1 mM); lane 7: DNA + RPO; lane 8: DNA + $[Cu(RPO)_2]Py_2$; lane 9: DNA + $[Cu(RPO)_2]$-Py_2 + DMSO(4 μl); and lane 10: DNA + $[Cu(RPO)_2]Py_2$ + NaN_3.

These $OH^{\cdot}$ free radicals participate in the oxidation of the deoxyribose moiety, followed by hydrolytic cleavage of the sugar phosphate backbone [27]. The more pronounced nuclease activity of these adducts in the presence of oxidant as compared to the parent complexes (Fig. 7a, lanes 6–9, 12 and 13) may be due to the increased production of hydroxyl radicals. Even in the absence of oxidant, the mixed ligand complexes exhibit significant DNA cleavage activity when compared to the parent complexes (e.g. lanes 4, 6 and 8). This may be due to the ability of the mixed ligand complexes to associate with DNA, facilitated by aromatic bases (hydrophobic interaction) leading to fair nucleolytic cleavage. From Table 6 it is clear that the percentage of cleavage activity in the presence of oxidant (H_2O_2) follows the order $Cu(RPO)_2Py > Cu(DBO)_2Py > Cu(RPO)_2Im_2$.

The nuclease activity of the complexes has also been investigated in the presence of a free radical scavenger (dimethylsulfoxide) and a singlet oxygen quencher (azide ions). To this end, standard scavengers of reactive oxygen intermediates were included in the electrophoresis process (Fig. 7b). Quantification of the gel afforded the data given in Table 7. Azide (lanes 6 and 10) inhibits to some extent, indicating the involvement of a singlet oxygen in the cleavage activity. The hydroxyl radical scavenger, dimethylsulfoxide (lanes 5 and 9) diminishes the nuclease activity of the compound, which is indicative of the involvement of the hydroxyl radical in the cleavage process. Nuclease activity of the complexes is not completely diminished either in the presence of free radical scavenger or in the presence of singlet oxygen quencher. This means that some DNA is cleaved by other than an oxidative mechanism, possibly by a discernable hydrolytic path.

Table 7
DNA cleavage of pBR 322 by the copper(II)–pyridine adducts (1 mM) in the presence of potential inhibitors (Fig. 7b)

Complex	Percentage of form I	Percentage of form II	Percentage of form III
DNA	87.6	12.4	ND
DBO	85.4	14.6	ND

5. Conclusions

Reports on DNA interactions of copper complexes of polypyridyl and phenanthroline mixed ligand complexes are numerous in the literature, those of interactions of metal oximates and of mixed ligand copper complexes with oximes and aromatic bases have not been investigated so far. In this study, we have attempted to unravel the DNA interactions and cleavage activity of mixed ligand copper complexes. The increase in binding constants of copper complexes II and V compared with the $Cu(SAO)_2$ complex (I) may be due to formation of a strong hydrogen bonding interaction between the coordinated ligands (RPO and DBO). The mixed ligand complex with imidazole appears to be a better DNA binding agent than the corresponding pyridine analogue, possibly due to the additional free nitrogen atom that may facilitate to strengthen the DNA interaction via hydrogen bonding. Since the complexes are found to cleave DNA even in the presences of free radical scavenger (DMSO) and singlet oxygen quencher (NaN_3) these complexes may also be regarded as hydrolytic cleavage agents.

Abstract

Attempted crystallization of $(H_2IMes)RuCl_2(P(CH_2CH_2R_{f8})_3)(=CHPh)$ (H_2IMes = 1,3-dimesityl-4,5-dihydroimidazol-2-ylidene; $R_{f8} = (CF_2)_7CF_3$) in air affords dark red needles of the octahedral ruthenium(III) salt $[H_3IMes]^+$ *trans*-$[RuCl_4(P(CH_2CH_2R_{f8})_3)_2]^-$, which is structurally characterized. Only crystal structures of square planar adducts of fluorous alkylphosphines have been determined to date. The bond lengths and angles associated with the cation and $RuCl_4L_2$ core are similar to those in related compounds. The lattice exhibits fluorous domains unlike those in square planar complexes, and the ponytail conformations are analyzed in detail. The NC*H*N proton of the cation is hydrogen bonded to two chloride ligands of the anion, and the CH_2CH_2 "backside" is directed at two chloride ligands of another anion, leading to non-fluorous channels in the lattice.

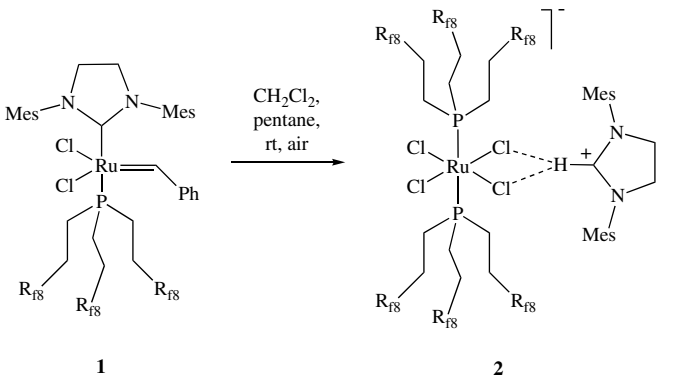
Keywords: Fluorous; Phosphine; Ruthenium; Crystal structure; Conformation; Helices; Grubbs' catalyst

1. Introduction

With the emergence of fluorous chemistry over the last decade [1], the structures of highly fluorinated sp^3-hybridized segments of atoms have taken on additional significance. Interestingly, in 1997 only two compounds could be located in the Cambridge Crystallographic Database that featured six or more consecutive CF_2 groups [2,3]. Since then, this number has grown appreciably. However, crystalline fluorous molecules still remain somewhat of a rarity. In our research group, all compounds containing R_{fn} segments with $n \geqslant 6$ are structurally characterized as a matter of course ($R_{fn} = (CF_2)_{n-1}CF_3$).

Crystal structures of several metal complexes of fluorous alkylphosphines have been reported [4–6]. Most of these feature square planar metals with two *trans* donor ligands – either fluorous monophosphines [4] or chelating pincer ligands [5]. All exhibit discrete fluorous domains, thereby providing solid state analogies to the commonly observed spontaneous separations of liquid fluorous and organic phases. In this paper, we describe a distinctly new type of fluorous bis(trialkylphosphine) complex, an anionic octahedral ruthenium(III) species, and its crystallographic characterization. The unusual structural and lattice packing properties are analyzed in detail.

2. Results



Analogs of Grubbs' second generation catalyst with fluorous trialkylphosphines have recently been reported [7]. A CH_2Cl_2 solution of one of these, $(H_2IMes)RuCl_2(P(CH_2CH_2R_{f8})_3)(=CHPh)$ (**1**; H_2IMes = 1,3-dimesityl-4,5-dihydroimidazol-2-ylidene), was layered with pentane. As shown in Eq. (1), the sample was allowed to slowly concentrate in air. Dark red needles formed, and X-ray data were collected as described in Table 1 and Section 4.

1 **2**

(1)

Refinement gave the unexpected structure depicted in Fig. 1(top). The crystalline material proved to be the salt **2**, with a protonated H_2IMes or dihydroimidazolinium cation, and an octahedral 17-valence-electron ruthenium(III) bis(phosphine) tetrachloride anion. The NC*H*N proton of the $[H_3IMes]^+$ moiety could be located and refined. It was hydrogen bonded to two chloride ligands (*H*–Cl and C–Cl distances, 2.68(5) and 3.455 Å; sum of hydrogen and chlorine van der Waals radii [8], 2.95 Å). The resulting C–H–Ru vector defined a C_2 symmetry axis. The crystal was free of disorder, and the quality of the structure solution was much higher than with many fluorous metal complexes. Key metrical parameters are summarized in Table 2.

The conformations of the $CH_2CH_2R_{f8}$ segments of the symmetry-equivalent phosphine ligands were analyzed. As can be seen in Fig. 1 (bottom), the one starting at C21 (terminating at C30) exhibited an "all-*anti*" conformation, as quantified by the torsion angles summarized in Table 2. The one starting at C11 (terminating at C20) exhibited an initial *anti* CH_2–CH_2–CF_2–CF_2 unit (torsion angle 160.6°), followed by a gauche CH_2–CF_2–CF_2–CF_2 unit (torsion angle 78.8°), and then *anti* CF_2–CF_2–CF_2–CF_2 units (torsion angles 156.3–169.8°). The one starting at C1 also exhibited initial *anti* CH_2–CH_2–CF_2–CF_2 and *gauche* CH_2–CF_2–CF_2–CF_2 units (torsion angles 166.0° and 80.3°), and included a single gauche CF_2–CF_2–CF_2–CF_2 unit (C6–C7–C8–C9; torsion angle 53.3°). These conformations bring two ponytails from one phosphorus in van der Waals contact with one from the other phosphorus, as illustrated in Fig. 2. The van der Waals radius of fluorine is 1.40 (Pauling value)–1.47 Å [8], and the closest intramolecular fluorine–fluorine contact is 2.908 Å (F15A–F24A).

With respect to packing, consider the cation first. As shown in Fig. 3 (top), the CH_2CH_2 "backside" of the dihydroimidazolinium moiety is directed at the two non-hydrogen-bonding chloride ligands of another anion (C–Cl distances 3.706 and 3.744 Å; calculated H–Cl distances, 3.125 and 3.150 Å). This creates non-fluorous channels that propagate throughout the lattice, as illustrated in Fig. 3 (bottom). Two chloride ligands peek out of the fluorous domains in one set of channels (alternating between those that participate in hydrogen bonding and those that do not). The cations emerge from the fluorous regions in another set (alternating between those with the NC*H*N proton pointing up to hydrogen bond to the next anion, and those with the proton pointing down to bond to the anion below). In the fluorous domains, the closest intermolecular fluorine–fluorine contact is 2.681 Å (F14A–F5B).

3. Discussion

3.1. Related ruthenium and imidazolium species

Ruthenium(III) complexes of the general formula Q^+ *trans*-$[RuCl_4L_2]^-$ have been known for some time. One of the first was reported by Stephenson and Wilkinson [9]. They observed that when a red solution of the diamagnetic ruthenium(II) complex $RuCl_2(CO)(pyr)_2$ was allowed to "age" and treated with excess pyridine, the orange paramagnetic ruthenium(III) salt $[pyrH]^+$ *trans*-$[RuCl_4(CO)(pyr)]^-$ could be isolated in 40% yield. Reactions with excesses of phosphines led to species of the formula $[R_3PH]^+$ *trans*-$[RuCl_4(PR_3)_2]^-$ (**Ia**,**b**; Fig. 4). The scope of these reactions was subsequently expanded [10].

Later, imidazolium salts of related complexes with DMSO and imidazole ligands were isolated, as exemplified by **IIa** in Fig. 4 [11]. The crystal structure of **IIa** has not been described, but that of the diamagnetic 18-valence-electron iridium homolog **IIb** has [12,13]. A short contact between one protonated nitrogen of the cation and a

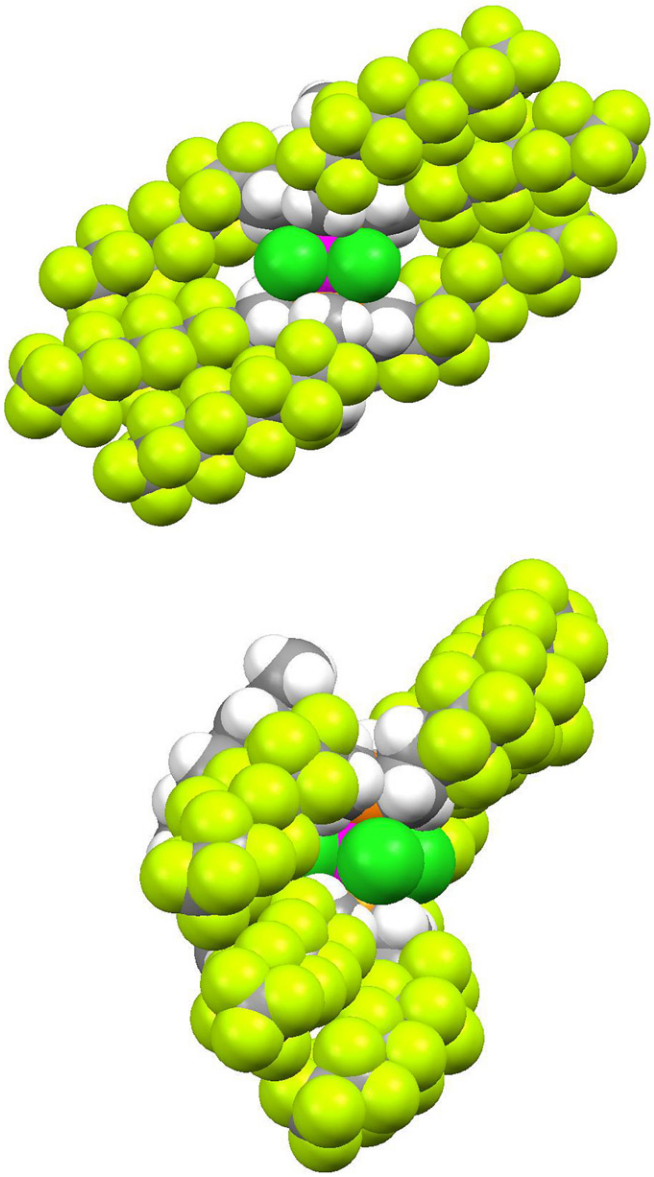
F(25A)–C(25)–C(26)–F(26B)	175.3(3)	F(27B)–C(27)–C(28)–F(28B)	−52.5(4)	F(29B)–C(29)–C(30)–F(30C)	−172.8(5)

chloride ligand was noted (3.21(1) Å). The crystal structure of the analogous ruthenium complex with a thiazole ligand and thiazolium cation, **IIc**, has also been reported [14]. The closest contact between the protonated nitrogen and a chloride ligand in **IIc** is 4.18 Å.

To our knowledge, only two salts with anions of the formulae $[RuCl_4(PR_3)_2]^-$ have been structurally characterized, **Ic** and **Id** (Fig. 4) [15,16]. Both feature polymetallic cations that do not allow the possibility of hydrogen bonding, and were obtained in low yield in the course of exploratory synthetic studies. Despite the lack of hydrogen bonding, these represent the best available structural models for the ruthenium core in **2**. Complex **Ic** exhibits ruthenium–chlorine bond lengths of 2.361(4)–2.367(4) Å, ruthenium–phosphorus bond lengths of 2.372(5) Å, and bond angles between *cis* atoms ranging from 88.2(2)° to 91.8(2)°. The corresponding values for **Id** are 2.350(1)–2.365(1) Å, 2.417(1) Å, and 87.58(5)–94.01(4)°. These compare very closely to the ruthenium–chlorine bond lengths (2.3620(8)–2.3686(8) Å), ruthenium–phosphorus bond lengths (2.3713(9) Å), and bond angles between *cis* atoms (86.93(4)–91.82(3)°) in **2**.



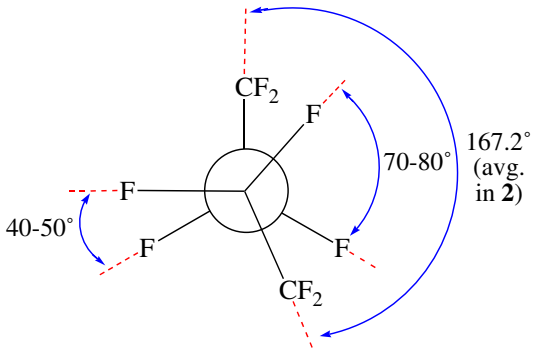


Fig. 2. Space filling representations of **2**: top, from the side of the chloride ligands that do not hydrogen bond to the cation; bottom, top view rotated counter-clockwise about a vertical axis.

There are an enormous number of structurally characterized imidazolium salts that exhibit hydrogen bonding. To our knowledge, no crystal structures containing protonated H_2IMes have been determined. However, there are at least two crystal structures that contain the dehydrogenated analog, protonated IMes [17–19]. One of these exhibits hydrogen bonding between the NC*H*N proton and a phenolate anion [17,18]. Interestingly, a CH=CH proton of the five membered ring interacts with the π cloud of a phenolate anion of a neighboring ion pair. This is reminiscent of the double-faced interaction of the $[H_3IMes]^+$ moiety in Fig. 3 (top). The other structure involves hydrogen bonding to a thiolate ligand of an aluminum-based anion [19]. The C⋯N distances in these compounds (1.330(3)–1.343(2) Å) are slightly longer than in **2** (1.308(4) Å), consistent with delocalization of the nitrogen lone pairs over a more extensive unsaturated framework.

3.2. Conformational and preparative aspects

It is now well-established that the lowest energy (*anti*) conformations of *n*-perfluoroalkanes and perfluoroalkyl groups exhibit C–C–C–C torsion angles somewhat less than those of *n*-alkanes (ca. 166° versus 180°), as illustrated by **III** [20,21]. This relieves certain electrostatically repulsive interactions, and leads to new attractive interactions [21]. Accordingly, the torsion angles of the *anti* CF_2–CF_2–CF_2–CF_2 segments of **2** (Table 2) average 167.2°. This imparts a slight twist, and the twists propagate with the same clockwise or counter-clockwise sense to give helical $(CF_2)_n$ moieties. As expected from **III**, the average torsion angles of the *anti* F–CF_2–CF_2–F segments in **2** (168.1°) are also somewhat less than their counterparts in *n*-alkanes (180°). Furthermore, the torsion angles of the *gauche* F–CF_2–CF_2–F segments generally fall into two regimes, one of ca. 40–50° and the other of ca. 70–80°.

III

As can be seen in Fig. 2, the two ponytails from each phosphorus atom that pack nearly in van der Waals contact exhibit the opposite helical chirality. The third adjacent ponytail, originating from the other phosphorus atom, contains the unique gauche CF_2–CF_2–CF_2–CF_2 segment. Helical relationships between ponytails from different molecules were not examined. Recently, the helical nature of fluorous ponytails has been exploited in supramolecular phenomena [22,23], and shown to persist in solution through VCD measurements [24].

Three square planar complexes containing *trans* fluorous trialkylphosphines have been structurally characterized: *trans*-$RhCl(CO)(P((CH_2)_2R_{f6})_3)_2$ [4a,4b], the iridium analog *trans*-$IrCl(CO)(P((CH_2)_2R_{f6})_3)_2$ [4a], and *trans*-$PtCl_2(P((CH_2)_2R_{f6})_3)_2$ [4e]. In the first two, which are isostructural, four of the ponytails are approximately coplanar, with two extending in an all-*anti* conformation from each phosphorus atom perpendicular to the coordination plane – one above and one below. As shown in Fig. 5 (left stack), the remaining two ponytails extend on a common side of the plane of the other four, and contain *gauche* CH_2–CF_2–

CF_2–CF_2 linkages. They are splayed in a manner that allows a sandwich-like fit with two comparable chains of a second molecule, leaving a rather flat backside (right stack, Fig. 5). The *anti*/*gauche* sequences within the ponytails of the platinum complex are identical, but the P–M–P conformation differs, resulting in a different packing arrangement.

This study adds to growing number of cases where a small amount of an interesting and unexpected inorganic complex, obtained by serendipity, could be unambiguously characterized due to the ease of modern crystallographic techniques. Perhaps analogous oxidation products will be obtained from other ruthenium(II) metathesis catalysts in the future. Although the syntheses of the ruthenium(III) tetrachloride complexes in Fig. 4 often proceed in modest yields, it is highly probable that an efficient, directed synthesis of **2** or a salt with an alternative cation could be achieved. While this would be beyond the scope of the present work, it should be noted that ruthenium(III) complexes – including several imidazolium salts of *trans*-$[RuCl_4L_2]^-$ anions – have gained prominence as anti-cancer agents [25]. Species such as **2** would have distinctly different phase and redox properties that could be beneficial with respect to physiological transport and the proposed mechanisms of activation [25].

4. Experimental

Crystallography: A CH_2Cl_2 solution of **1** [7] was layered with pentane and kept in air at room temperature. After 4 d, dark red needles were taken to a Nonius KappaCCD diffractometer for data collection as outlined in Table 1. Cell parameters were obtained from 10 frames using a 10° scan and refined with 12225 reflections. Lorentz, polarization and empirical absorption corrections [26] were applied. The space group was determined from systematic absences and subsequent least-squares refinement. The structure was solved by direct methods. The parameters were refined with all data by full-matrix-least-squares on F^2 using SHELXL-97 [27]. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atom H41C was located and refined isotropically. Other hydrogen atoms were fixed in idealized positions using a riding model. Scattering factors were taken from the literature [28]. The unanticipated structure **2** exhibited a twofold symmetry axis.

Abstract

Two new diamagnetic, mononuclear and aminated porphyrin complexes of O,O-*trans*-Cd (**3**-*trans*) and O,S-*cis*-Cd (**4**-*cis*) have been synthesized and characterized by ^1H, ^{13}C NMR spectroscopy. The crystal structures of (acetato)(N-2-furancarboxamido-*meso*-tetraphenylporphyrinato)cadmium(II) [Cd(N-NHCO-2-C_4H_3O-tpp)(OAc); **3**-*trans*] and (acetato)(N-2-thiophenecarboxamido-*meso*-tetraphenylporphyrinato)cadmium(II) [Cd(N-NHCO-2-C_4H_3S-tpp)(OAc); **4**-*cis*] were determined. The coordination sphere around Cd^{2+} is a distorted square-based pyramid in which the apical site is occupied by a bidentate chelating OAc^- group for **3**-*trans* and **4**-*cis*. The plane of three pyrrole nitrogen atoms [i.e., N(1), N(2), N(4) for **3**-*trans* and N(1), N(2), N(3) for **4**-*cis*] strongly bonded to Cd^{2+} is adopted as a reference plane 3N. The N(3) and N(4) pyrrole rings bearing the 2-furancarboxamido (Fr) and 2-thiophenecarboxamido groups in **3**-*trans* and **4**-*cis*, respectively, deviate mostly from the 3N plane, thus orienting separately with a dihedral angle of 33.4° and of 31.0°. In **3**-*trans*, Cd^{2+} and N(5) are located on different sides at 1.06 and −1.49 Å from its 3N plane, while in **4**-*cis*, Cd^{2+} and N(5) are also located on different sides at 1.04 and −1.53 Å from its 3N plane. An attractive electrostatic interaction between the Cd^{2+} and $O(4)^-$ atoms in furan stabilizes the O,O-*trans* conformer of **3**. A repulsive electrostatic interaction between Cd^{2+} and $S(1)^+$ destabilizes the O,S-*trans* conformer of **4**. Both of these repulsive and the mutually attractive interactions between $S(1)^+$ and $O(3)^-$ atoms favor the O,S-*cis* rotamer of **4** both in the vapor phase and in low polarity solvents. NOE difference spectroscopy, HMQC and HMBC were employed for the unambiguous assignment of the ^1H and ^{13}C NMR resonances of **3**-*trans* and **4**-*cis* in $CDCl_3$ at 20 and −50 °C.

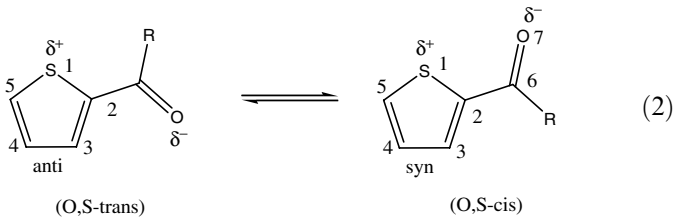
1. Introduction



There have been numerous investigations on the rotational equilibrium between the two *anti* and *syn* planar isomers of 2-acyl-furans and -thiophenes (i.e., R = H, CH_3, Et, Pr^i, pentan-3-yl, Bu^t, Cl, F, Bu^tO) [1–6]

(O,S-trans) (O,S-cis) (2)

Group charge density calculations reveal that both oxygen atoms in 2-acyl-furans of the *syn* form, being strongly charged, face increasing repulsive electrostatic interactions (see Eq. (1)). However, in the thiophene carbonyl derivatives, the S atom is positively charged and consequently there is an attractive electrostatic interaction between the S and O atoms in *cis* form (see Eq. (2)) [1]. The major factor determining the stability or instability of the *cis*-isomer is a repulsive electrostatic interaction between the two oxygen atoms for furan carbonyl and an attractive electrostatic interaction between the sulfur and oxygen atoms for the thiophene carbonyl. The O,O-*trans* form has a relatively low dipole moment and is favored in the gas phase or in low polar solvents with dielectric constants (ε) smaller than 5. In a more polar medium, the O,O-*cis* isomer with a higher dipole moment (μ) is favored due to a stronger solute–solvent interaction; as a result the O,O-*cis* form in 2-acyl-furans can be more stable than the O,O-*trans* isomer in solution when the energy difference ΔE ($=E_{syn}-E_{anti}$) is relatively small and $\Delta\mu$ ($=\mu_{syn}-\mu_{anti}$) is large in the gas phase. In the case of the thiophene-2-carbonyl derivative, the more polar O,S-*cis* conformation is found to be more stable in the vapor phase; the *cis* form also predominates in solutions of different polarity; the amount of O,S-*cis* isomer increases slightly with solvent polarity. The energy differences (ΔE) between the rotamers are 4–13 kJ/mol, but the barrier to rotation is ca. 42 kJ/mol [1].

The preparation of *N*-substituted-*N*-aminoporphyrin has been described by three groups [7–11]. In *N*-substituted-*N*-aminoporphyrin, when the H atom of NH_2 is replaced either by the 2-furoncarboxyamino ligand or by the 2-thiophenecarboxyamino group, two new free aminated porphyrins are formed, namely N-2-furancarboxamido-*meso*-tetraphenylporphyrin (N-NHCO-2-C_4H_3-OHtpp; **1**) and N-2-thiophenecarboxamido-*meso*-tetraphenylporphyrin (N-NHCO-2-C_4H_3S-Htpp; **2**) [tpp = dianion of *meso*-tetraphenylporphyrin], which are derivatives of 2-acyl-furans and -thiophenes, respectively. A thorough review of the literature shows that there is no prior report on the metal complexes of **1** and **2**. The lack of previous work on metal complexes of these two ligands prompted us to undertake the synthesis and structural studies of the Cd(II) complexes. Metallation of these aminated porphyrins could lead to mononuclear metal complexes in which the metal is coordinated to four porphyrinic N atoms. Cd(II) is a diamagnetic ion and maintains the d^{10} electron configuration which minimizes intrinsic coordination geometry preferences while favoring coordination by softer ligands. In this paper, we describe the X-ray structural investigation on the metallation of **1** and **2** leading to mononuclear complexes of (acetato)(N-2-furancarboxamido-*meso*-tetraphenylporphyrinato)cadmium(II) [Cd(N-NHCO-2-C_4H_3O-tpp)(OAc); **3**] and (acetato)(N-2-thiophenecarboxamido-*meso*-tetraphenylporphyrinato)cadmium(II) [Cd(N-NHCO-2-C_4H_3S-tpp)(OAc); **4**], respectively. This metallation introduces the metal electrostatic interaction between the Cd(II) atom and the heteroatom of the ring in **3** and **4** as the diamagnetic Cd(II) is just located in the vicinity of the furonylcarboxamido (or thiophenecarboxamido) group in **3** (or **4**). We try to figure out how the metal electrostatic effect influences the O,O-Cd and O,S-Cd conformers of **3** and **4**, respectively. These metal electrostatic effects could be applied to explain the various conformations of thallium(III), bismuth(III) and tin(IV) porphyrin complexes with O,O and O,S rotamers.

2. Experimental

2.1. N-NHCO-2-C_4H_3O-Htpp (1) [9]

A mixture of NaN_3 (1.00 g, 1.54×10^{-2} mol) in distilled water (2 cm^3) and 2-furoyl chloride (2.5 mL, 2.54×10^{-2} mol) was stirred for 30 min. After concentration, the residue was dissolved in CH_2Cl_2 and filtered to remove excess NaN_3 and NaCl. The CH_2Cl_2 layer contained 2-furancarbonyl azide ($C_4H_3OCON_3$). A solution of Zn(tpp) (0.30 g, 1.36×10^{-3} mol) and the above $C_4H_3OCON_3$ in CH_2Cl_2 (100 cm^3) in a stoppered 250 mL Erlenmeyer flask was left for ca. 24 h in the sunlight. To this solution was then added 0.5 N HCl (250 cm^3) with vigorous shaking for 0.5 h. The organic layer, green in color, was separated, solid ammonium carbonate was added to it, and then dried with anhydrous Na_2SO_4. The excess $(NH_4)_2CO_3$ and Na_2SO_4 were removed by filtration. After concentration, the residue was dissolved in a minimum of CH_2Cl_2 and chromatographed on silica gel (50.00 g, 70–230 mesh). The dimensions of the silica gel column were 1.5×17 in. The desired compound was eluted with ethyl acetate (EtOAc)–CH_2Cl_2 [1:9 (v/v)] as a dark purple band on silica gel. Removal of the solvent and recrystallization from CH_2Cl_2–MeOH [1:2 (v/v)] gave the purple solid N-NHCO-2-C_4H_3O-Htpp (**1**) (0.165 g, 2.28×10^{-4} mol, 46.8%), which was again dissolved in CH_2Cl_2 and layered with CH_3OH to get purple crystals for single crystal X-ray analysis. ^{1}H NMR (599.95 MHz, $CDCl_3$, 20 °C): δ 9.12 [d, H_β(10,19), ^3J(H–H) = 4.4 Hz], H_β(a,b) represents two equivalent β-pyrrole protons attached to carbons a and b, respectively; 8.90 [d, H_β(9,20), ^3J(H–H) = 4.8 Hz]; 8.88 [s, H_β(4,5)]; 8.35 [bs, *o*′-H(34,44) and *o*′-H(38,40)], where *o*-H = *ortho* protons; 8.28 [d, *o*-H(26,28), ^3J(H–H) = 6.6 Hz]; 8.19 [d, *o*-H(22,32), ^3J(H–H) = 6.6 Hz]; 8.09 [s, H_β(14,15)]; 7.78–7.82 (m) for *meta* and *para* protons; 5.79 [s, Fr-H_5]; 4.69 [q, Fr-H_4, ^3J(Fr-H_4, Fr-H_5) = 1.8 Hz and ^3J(Fr-H_4, Fr-H_3) = 3.6 Hz]; 1.35 [s, Fr-H_3], where Fr = 2-furancarboxamido. MS (FAB): M^+

724 (calcd for $C_{49}H_{33}N_5O_2$: 724). UV/Vis spectrum, λ (nm) [$\varepsilon \times 10^{-3}$ (M^{-1} cm^{-1})] in CH_2Cl_2: 429 (246.6), 541 (10.2), 582 (10.2), 638 (7.8).

2.2. Preparation of N-NHCO-2-C_4H_3S-Htpp (2) [9]

A mixture of NaN_3 (1.00 g, 1.54×10^{-2} mol) in distilled water (2 cm^3) and 2-thiophenecarbonylchloride (2.5 mL) was stirred for 20 min. After concentration, the residue was dissolved in CH_2Cl_2 and filtered to remove excess NaN_3 and NaCl. The CH_2Cl_2 layer contains 2-thiophenecarbonyl azide ($C_4H_3SCON_3$). A solution of Zn(tpp) (0.27 g, 3.04×10^{-4} mol) and the above $C_4H_3SCON_3$ in CH_2Cl_2 (200 cm^3) in a stoppered 250 mL Erlenmeyer flask was left for ca. 8 h in the sunlight. To this solution was then added 0.5 N HCl (250 cm^3) with vigorous shaking for 0.5 h. The organic layer was separated, solid ammonium carbonate added to it, and then dried with anhydrous Na_2SO_4. The excess $(NH_4)_2CO_3$ and Na_2SO_4 were removed by filtration. After concentration, the residue was dissolved in a minimum of CH_2Cl_2 and chromatographed on silica gel (100.00 g, 70–230 mesh). The dimensions of the silica gel column were 1.5×17 in. The desired compound was eluted with ethyl acetate (EtOAc)–CH_2Cl_2 [1:4 (v/v)] as a dark brown band on silica gel. Removal of the solvent and recrystallization from CH_2Cl_2–MeOH [1:2 (v/v)] gave the purple solid of N-NHCO-2-C_4H_3S-Htpp (**2**) (0.17 g, 2.06×10^{-4} mol, 68%) which was again dissolved in CH_2Cl_2 and layered with CH_3CN to get purple crystals for single crystal X-ray analysis. ^{1}H NMR (599.95 MHz, $CDCl_3$, 20 °C): δ 9.10 [d, H_β(10,19), ^3J(H–H) = 4.2 Hz]; 8.87 [d, H_β(9,20), ^3J(H–H) = 4.2 Hz]; 8.85 [s, H_β(4,5)]; 8.36 [bs, *o*′-H(34,44) and *o*′-H(38,40)], where *o*-H = *ortho* protons; 8.25 [d, *o*-H(22,32), ^3J(H–H) = 7.2 Hz]; 8.16 [d, *o*-H(26,28), ^3J(H–H) = 7.2 Hz]; 8.06 [s, H_β(14,15)]; 7.75–7.80 (m) for *meta* and *para* protons; 5.85 [dd, S-H_5, ^3J(S-H_4, S-H_5) = 5.0 Hz and ^4J(S-H_3, S-H_5) = 1.2 Hz], where S = 2-thiophenecarboxamido; 5.43 [dd, S-H_4, ^3J(S-H_3, S-H_4) = 3.8 Hz and ^3J(S-H_4, S-H_5) = 5.0 Hz]; 3.47 [dd, S-H_3, ^3J(S-H_3, S-H_4) = 3.8 Hz and ^4J(S-H_3, S-H_5) = 1.2 Hz]; −0.35 (s, NH). MS (FAB): M^+ 740 (calcd for $C_{49}H_{33}N_5OS$: 740). UV/Vis spectrum, λ (nm) [$\varepsilon \times 10^{-3}$ (M^{-1} cm^{-1})] in CH_2Cl_2: 430 (278), 541 (21.8), 583 (21.7), 639 (19.4).

2.3. Preparation of Cd(N-NHCO-2-C_4H_3O-tpp)(OAc) (3)

A mixture of N-NHCO-2-C_4H_3O-Htpp (**1**) (76 mg, 0.1 mmol) in CH_2Cl_2 (5 cm^3) and $Cd(OAc)_2 \cdot 2H_2O$ (69 mg, 0.3 mmol) in MeOH (2 cm^3) were refluxed in CH_3CN (20 cm^3) for 3 h. After concentration, the residue was dissolved in CH_2Cl_2 and washed with distilled water to remove excess $Cd(OAc)_2 \cdot 2H_2O$. The CH_2Cl_2 layer was concentrated to dryness affording a blue precipitate, which was recrystallized from toluene–hexane [1:3 (v/v)] yielding a dark blue solid of **3** (51 mg, 0.0548 mmol, 55%). Compound **3** was redissolved in CH_2Cl_2 and layered with toluene to afford blue crystals for single-crystal X-ray analysis. ^{1}H NMR (599.95 MHz, $CDCl_3$, 20 °C): δ 8.89 [s, H_β(2,3)]; 8.76 [d, H_β(14,35), ^3J(H–H) = 4.5 Hz]; 8.73 [d, H_β(13,36), ^3J(H–H) = 4.5 Hz]; 8.61 [s, H_β(24,25)]; 8.62 [d, *o*-H(22,29), ^3J(H–H) = 6.6 Hz]; 8.40 [d, *o*-H(18,33), ^3J(H–H) = 6.6 Hz]; 7.75–7.86 (m, *meta* and *para* protons); 5.72 (s, Fr-H_5); 5.20 (s, Fr-H_4); 4.37 (s, Fr-H_3); 0.17 (s, OAc-Me), −0.99 (s, NH). ^{1}H NMR (599.95 Hz, $CDCl_3$, −50 °C): δ 8.96 [s, H_β(2,3)]; 8.76 [d, H_β(14,35), ^3J(H–H) = 4.2 Hz]; 8.73 [d, H_β(13,36), ^3J(H–H) = 7.8 Hz]; 8.70 [s, H_β(24,25)]; 8.64 [d, *o*-H(22,29), ^3J(H–H) = 7.8 Hz]; 8.48 [d, *o*-H(18,33), ^3J(H–H) = 7.2 Hz]; 8.42 [d, *o*′-H(11,40), ^3J(H–H) = 4.8 Hz]; 8.20 [d, *o*′-H(7,44), ^3J(H–H) = 7.2 Hz]; 7.75–7.91 (m, *meta* and *para* protons); 5.74 (s, Fr-H_5); 5.24 [d, Fr-H_4, ^3J(H–H) = 1.8 Hz]; 4.52 (s, Fr-H_3); 0.18 (s, OAc-Me); −1.12 (s, NH). ^{13}C NMR (150.87 MHz, 20 °C, $CDCl_3$): δ 154.0 [s, C_α(1,4)]; 153.9 [s, C_α(15,34)]; 152.2 [s, C_α(12,37)]; 150.2 [s, C_α(23,26)]; 134.11 [s, C_β(2,3)]; 134.06 [s, C_β(13,36)]; 131.5 [s, C_β(14,35)]; 123.9 [s, C_β(24,25)]; 121.9 [s, C_m(16,17)]; 152.2 [s, Fr–CO]; 141.8 [s, Fr–C_2]; 108.7 [s, Fr–C_3]; 110.2 [s, Fr–C_4]; 143.5 [s, Fr–C_5]; 176.3 [s, OAc-CO]; 18.9 [s, OAc-Me]. MS (FAB): $(M-OAc)^+$ 834 (calcd for $C_{49}H_{31}CdN_5O_2$: 834). UV/Vis spectrum, λ (nm) [$\varepsilon \times 10^{-3}$ (M^{-1} cm^{-1})] in CH_2Cl_2: 442.0 (233.1), 619.1 (17).

2.4. Preparation of Cd(N-NHCO-2-C_4H_3S-tpp)(OAc) (4)

Compound **4** was prepared in the same way as described for **3** in a 52% yield using N-NHCO-2-C_4H_3S-Htpp (**2**). Compound **4** was dissolved in CH_2Cl_2 and layered with toluene to obtain blue crystals for single-crystal X-ray analysis. ^{1}H NMR (599.95 MHz, $CDCl_3$, 20 °C):δ 8.89 [s, H_β(4,5)]; 8.76 [d, H_β(10,19), ^3J(H–H) = 4.2 Hz]; 8.72 [d, H_β(9,20), ^3J(H–H) = 4.2 Hz]; 8.63 [s, H_β(14,15)]; 8.60 [d, *o*-H(38,40), ^3J(H–H) = 7.2 Hz]; 8.40 [d, *o*-H(34,44), ^3J(H–H) = 6.6 Hz]; 7.74–7.86 (m, *meta* and *para* protons); 6.34 [d, S-H_5, ^3J(H–H) = 4.8 Hz]; 5.57 [t, S-H_4, ^3J(H–H) = 4.2 Hz]; 2.99 [d, S-H_3, ^3J(H–H) = 3 Hz]; 0.15 (s, OAc-Me), −1.23 (s, NH). ^{1}H NMR (599.95 MHz, $CDCl_3$, −50 °C): δ 8.95 [s, H_β(4,5)]; 8.75 [d, H_β(10,19), ^3J(H–H) = 3.6 Hz]; 8.71 [s, H_β(14,15)]; 8.70 [d, H_β(9,20), ^3J(H–H) = 3.6 Hz]; 8.61 [d, *o*-H(38,40), ^3J(H–H) = 7.0 Hz]; 8.47 [d, *o*-H(34,44), ^3J(H–H) = 7.0 Hz]; 8.42 [s, *o*′-H(22,32)]; 8.18 [d, *o*′-H(26,28), ^3J(H–H) = 7.2 Hz]; 7.76–7.90 (m, *meta* and *para* protons); 6.42 [d, S-H_5, ^3J(H–H) = 4.8 Hz]; 5.56 [t, S-H_4, ^3J(H–H) = 4.2 Hz]; 2.69 [d, S-H_3, ^3J(H–H) = 3 Hz]; 0.17 (s, OAc-Me), −1.42 (s, NH). ^{13}C NMR (150.87 MHz, 20 °C, $CDCl_3$): δ 154.0 [s, C_α(3,6)]; 149.8 [s, C_α(13,16)]; 152.2 (s) and 153.9 (s) for C_α(1,8) and C_α(11,18); 134.2 [s, C_β(4,5)]; 134.1 [s, C_β(9,20)]; 131.7 [s, C_β(10,19)]; 124.0 [s, C_β(14,15)]; 121.9 [s, C_m]; 155.5 [s, S-CO]; 131.4 [s, S-C_2]; 126.5 [s, S-C_3]; 126.0 [s, S-C_4]; 130.1 [s, S-C_5]; 176.6 [s, OAc-CO]; 18.9 [s, OAc-Me]. MS (FAB): $(M-OAc)^+$ 851 (calcd for $C_{49}H_{32}CdN_5OS$: 851). UV/Vis spectrum, λ (nm) [$\varepsilon \times 10^{-3}$ (M^{-1} cm^{-1})] in CH_2Cl_2: 432.9 (235.9), 543.0 (9.79), 584.0 (11.6), 639.0 (14.3).

2.5. NMR spectroscopy

Proton and ^{13}C NMR spectra were recorded at 599.95 and 150.87 MHz, respectively, on Varian Unity Inova-600 spectrometers locked on deuterated solvent, and referenced to the solvent peak. Proton NMR is relative to CD_2Cl_2 or $CDCl_3$ at $\delta = 5.30$ or 7.24 and ^{13}C NMR to the center line of CD_2Cl_2 or $CDCl_3$ at $\delta = 53.6$ or 77.0. The temperature of the spectrometer probe was calibrated by the shift difference of the methanol resonance in the ^1H NMR spectrum. HMQC (heteronuclear multiple quantum coherence) was used to correlate protons and carbon through one-bond coupling and HMBC (heteronuclear multiple bond coherence) for two- and three-bond proton–carbon coupling. Nuclear Overhauser effect (NOE) difference spectroscopy was employed to determine the ^1H–^1H proximity through space over a distance of up to about 4 Å.

The positive-ion fast atom bombardment mass spectrum (FAB-MS) was obtained in a nitrobenzyl alcohol (NBA) matrix using a JEOL JMS-SX/SX 102A mass spectrometer. UV/Vis spectra were recorded at 20 °C on a HITACHI U-3210 spectrophotometer.

2.6. X-ray crystallography

Table 1 presents the crystal data for $\mathbf{3}\cdot C_6H_5CH_3$ (*trans*) and $\mathbf{4}\cdot CH_2Cl_2$ (*cis*). Measurements were taken on a Bruker AXS SMART-1000 diffractometer using monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). Empirical absorption corrections were made for **3**-*trans* and **4**-*cis*. The structures were solved by direct methods (SHELXTL-97) [12] and refined by the full-matrix least-squares method. The furan group within **3**-*trans* is disordered with an occupancy factor of 0.6 for O(4)C(51) and 0.4 for O(4′)C(51′). These two atoms [i.e., O(4),C(51)] were refined with isotropic displacement parameters for **3**-*trans*. All non-hydrogen atoms except the above two atoms for **3**-*trans* were refined with anisotropic thermal parameters, whereas all hydrogen atoms were placed in calculated positions and refined with a riding model. Table 2 lists selected bond distances and angles for both $\mathbf{3}\cdot C_6H_5CH_3$ (*trans*) and $\mathbf{4}\cdot CH_2Cl_2$ (*cis*).

3. Results and discussion

3.1. Molecular structures of $\mathbf{3}\cdot C_6H_5CH_3$ and $\mathbf{4}\cdot CH_2Cl_2$

Using a d^{10} metal, namely cadmium(II), the new complexes $\mathbf{3}\cdot C_6H_5CH_3$ and $\mathbf{4}\cdot CH_2Cl_2$ were synthesized. The synthetic strategy is outlined in Scheme 1. During the metallation of free bases **1** and **2** with $Cd(OAc)_2$ (Scheme 1), the soft acid Cd^{2+} prefers to retain one OAc^- ligand and coordinate to the N–H proton [i.e., H(2A)] of **1** and **2** to form six-coordinate complexes **3** and **4**. The molecular frameworks are depicted in Fig. 1a for **3** and in Fig. 1b for **4**.

Scheme 1.

The bond distance (Å) of Cd(1)–O(1) is 2.302(4), Cd(1)–O(2) = 2.325(4), and the mean Cd(1)–N(p) = 2.287(4) Å for **3**; for **4**, the values are Cd(1)–O(1) = 2.289(3), Cd(1)–O(2) = 2.291(3) and the mean Cd(1)–N(p) = 2.286(3) Å (Table 2). The cadmium–nitrogen bond distances [Cd(1)–N(1) = 2.247(3), Cd(1)–N(2) = 2.296(4) and Cd(1)–N(4) = 2.318(4) Å of **3**; Cd(1)–N(1) = 2.277(3), Cd(1)–N(2) = 2.278(3) and Cd(1)–N(3) = 2.303(3) Å of **4**] are comparable to those of Cd(1)–N(p) = 2.301(5) Å in Cd(N–NHCO-C_6H_5-tpp)(OAc) [11]. The Cd(1)···N(3) distance of 2.606(4) Å for **3** [or Cd(1)···N(4) distance of 2.617(3) for **4**] is longer than 2.301(5) Å but is significantly shorter than the sum of the van der Waals radii of Cd and N (3.15 Å) [13]. This longer Cd···N(3) contact in **3** [or Cd···N(4) in **4**] may be viewed as a secondary intramolecular interaction. This kind of secondary interaction was earlier observed for both Cd(N-NHCOC_6H_5-tpp)(OAc) with Cd(1)···N(4) = 2.612(5) Å [11] and [Cd(H_3daps)Cl_4]$CH_3CN \cdot 0.25H_2O$ [H_4dap = 2,6-bis(1-salicyloylhydrazonoethyl)pyridine] with Cd···N(6) = 2.74(1) Å [14]. Most chemists seem to consider this secondary interaction between the metal ion and the fourth N as a weak bond in *N*-substituted porphyrin metal complexes. Furthermore, N(1), N(2) and N(4) [or N(1), N(2) and N(3)] are bonded strongly as well as covalently to the Cd atom in **3** [or **4**]. Thus the Cd(II)–2-furancarboxyamido-*meso*-tpp (**3**) and N-2-thiophenecarboxyamido-*meso*-tpp (**4**) structures are quite similar to metal(II) *N*-substituted porphyrin complexes with three strong and one weaker metal–N bond [11,15]. Compound **3** is an O,O-*trans* conformer in the solid phase with a dihedral angle of Ψ [O(3)–C(47)–C(48)–O(4)] = −174.17° and thus we are able to assign it as **3**-*trans*. Compound **4** is an O,S-*cis* conformation (i.e., **4**-*cis*) in the solid phase with Ψ [O(3)–C(47)–C(48)–S(1)] = 1.59°. The geometry around Cd^{2+} is described as a distorted square-based pyramid in which the apical site is occupied by a bidentate chelating OAc^- group in **3**-*trans* and **4**-*cis*. Fig. 2 shows the actual porphyrin skeleton of **3**-*trans* and **4**-*cis*.

We adopt the plane of three strongly bound pyrrole nitrogen atoms [i.e., N(1), N(2) and N(4) for **3**-*trans* and N(1), N(2) and N(3) for **4**-*cis*] as a reference plane, 3N. In **3**-*trans* (or **4**-*cis*), Cd^{2+} and N(5) are located on different sides at 1.06 (or 1.04) and −1.49 Å (or −1.53 Å) from its 3N plane, respectively (Fig. 2). The N(3) and N(4) pyrrole rings bearing the 2-furancarboxamido (Fr) and 2-thiophenecarboxamido groups in **3**-*trans* and **4**-*cis*, respectively, deviate mostly from the 3N plane, thus orienting separately with a dihedral angle of 33.4° and of 31.0°, whereas small angles of 0.7°, 18.5° and 23.7° occur with N(1), N(4) and N(2) pyrrole for **3**-*trans*

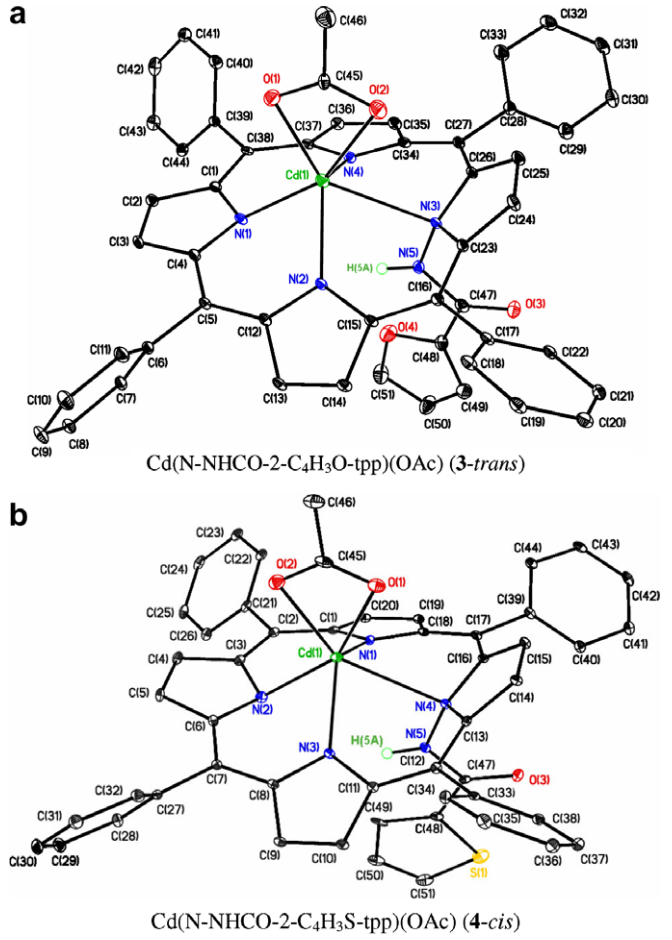

Fig. 1. Molecular configuration and atom-labelling scheme for (a) $3 \cdot C_6H_5CH_3$ (*trans*) and (b) $4 \cdot CH_2Cl_2$ (*cis*), with ellipsoids drawn at 30% probability. Hydrogen atoms, solvent $C_6H_5CH_3$ for $3 \cdot C_6H_5CH_3$ (*trans*) and CH_2Cl_2 for $4 \cdot CH_2Cl_2$ (*cis*) are omitted for clarity.

and the corresponding angles are 18.2°, 23.5° and 17.6° with N(2), N(1) and N(3) pyrrole for **4**-*cis*. In **4**-*cis*, such a large deviation from planarity for the N(4) pyrrole is also reflected by observing a 7.7–10.2 ppm upfield shift of the C_β(C14, C15) at 124.0 ppm compared to 131.7 ppm for C_β(C10, C19), 134.1 ppm for C_β(C9, C20) and 134.2 ppm for C_β(C4, C5). In **3**-*trans*, a similar deviation is also found for N(3) pyrrole by observing a 7.6–10.2 ppm upfield shift of C_β(C24, C25) at 123.9 ppm compared to 134.11 ppm for C_β(C2, C3), 134.06 ppm for C_β(C13, C36) and 131.5 ppm for C_β(C14, C35).

It is noted that the ionic radius for the metal ion increases from 0.82 Å for Zn^{2+} with a coordination number (CN = 5) to 1.09 Å for Cd^{2+} (CN = 6). Because of the larger size of Cd^{2+}, Cd(1), O(2) and O(1) lie 1.06, 2.88 and 3.24 Å, respectively, above the 3N plane in **3**-*trans*, compared to 1.04 Å for Cd(1), 2.92 Å for O(1) and 3.16 Å for O(2) in **4**-*cis* [cf. 0.65 Å for Zn^{2+} in Zn(N-Me-tpp)Cl] (Fig. 2) [16].

The dihedral angles between the mean plane of the skeleton (3N) and the planes of the phenyl groups are 57.6° [C(9)], 32.1° [C(20)], 32° [C(31)] and 56.4° [C(42)] for

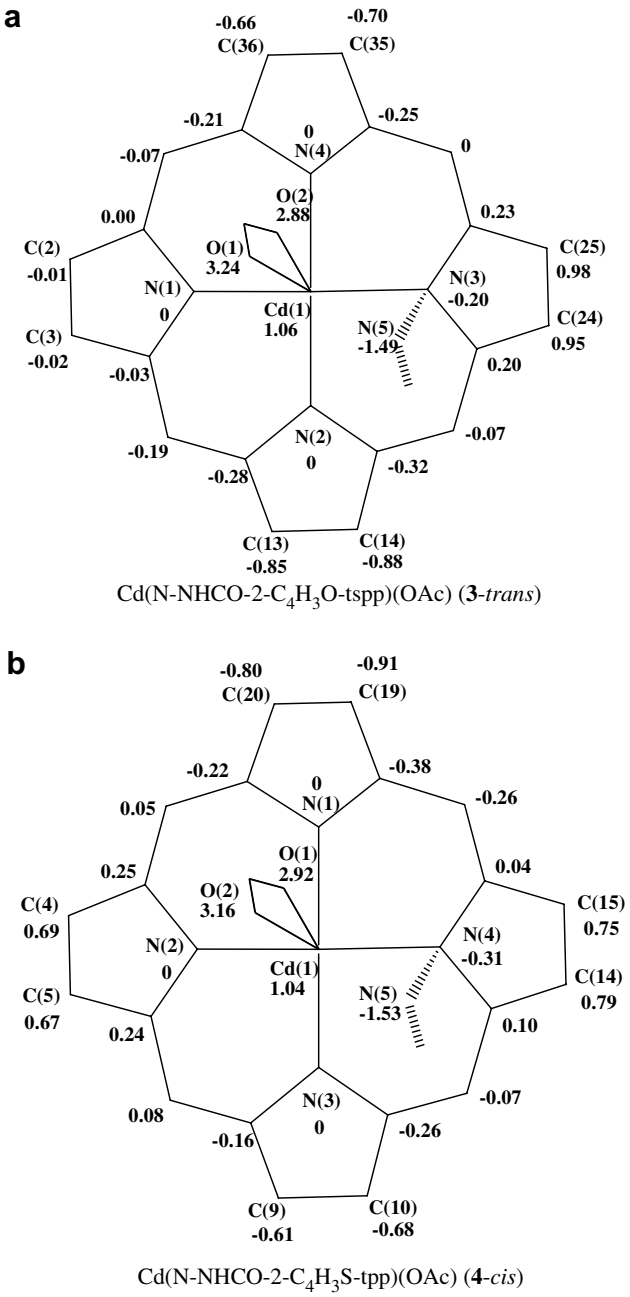

Fig. 2. Diagram of the porphyrinato core ($C_{20}N_4$, Cd, furan, thiophene and OAc) of (a) **3**-*trans* and (b) **4**-*cis*. The values represent the displacement (in Å) of the atoms from the 3N plane [i.e., N(1), N(2), N(4) for **3**-*trans* and N(1)–N(3) for **4**-*cis*].

3-*trans* and the corresponding angles are 44.7°, 42.9°, 34.3° and 35.7° for **4**-*cis*.

3.2. ^1H and ^{13}C NMR spectroscopy data of **3**-trans and **4**-cis in $CDCl_3$

The singlet at −0.35 ppm was assigned to NH protons [i.e., H(2A) and H(5A)] for **2** at 20 °C. Moreover, the signal arising from the NH protons [i.e., H(2A) and H(5A)] of **1** was not observed at 20 °C. At −90 °C, traces of water were

frozen from solution of **1** in CD_2Cl_2. Thus, the frozen water inhibits intermolecular proton exchange between water and NH protons of **1** and allows the observation of a broad singlet for the NH proton at −0.61 ppm ($\Delta\nu_{1/2} = 23$ Hz). Upon metallation, there were no signal of NH (in pyrrole) [i.e., H(1A) for **3** and H(2A) for **4**] for metal porphyrins **3** and **4**. The ^{1}H NMR spectrum of **3** (or **4**) in $CDCl_3$ (Figs. 3 and 4) showed a sharp singlet at $\delta = -0.99$ (or −1.23) ppm ($\Delta\nu_{1/2} = 4$ Hz) for the NH proton at 20 °C. These NMR data for **3** (or **4**) suggest that the NH proton [i.e., H(5A)] bound to N(5) undergoes rapid intermolecular proton exchange with water at 20 °C.

Complexes **3**-*trans* and **4**-*cis* were characterized by ^{1}H (Figs. 3 and 4) and ^{13}C NMR spectra. In solution, the molecule has effective C_s symmetry with a mirror plane running through the N(5)–N(3)–Cd(1)–N(1)–O(1)–O(2) unit for **3**-*trans* or the N(5)–N(4)–Cd(1)–N(2)–O(1)–O(2) unit for **4**-*cis* (Fig. 1). There are four β-pyrrole protons H_β, four β-pyrrole carbons C_β, four α-pyrrole carbons C_α, two different *meso* carbons C_{meso} and two phenyl-C_1 carbons for these two complexes. In **4**-*cis*, the doublet at 8.76 ppm is assigned to $H_\beta(10,19)$ with $^3J(H–H) = 4.2$ Hz, and the other doublet at 8.72 ppm with $^3J(H–H) = 4.2$ Hz is due to $H_\beta(9,20)$ (Fig. 3a). The singlet at 8.89 ppm is assigned to $H_\beta(4,5)$ and the other singlet at 8.63 ppm is due to $H_\beta(14,15)$ (Fig. 3a). In **3**-*trans*, the doublet at 8.76 ppm is due to $H_\beta(14,35)$ with $^3J(H–H) = 4.5$ Hz and the other doublet at 8.73 ppm is due to $H_\beta(13,36)$ with $^3J(H–H) = 4.5$ Hz (Fig. 4a). The singlet at 8.89 ppm is assigned to $H_\beta(2,3)$ and the other singlet at 8.61 ppm is due to $H_\beta(24,25)$ (Fig. 4a).

Fig. 3 depicts the representative ^{1}H spectra for **4**-*cis* in $CDCl_3$ at 20 and −50 °C. At 20 °C, the rotation of the phenyl group along C_1–C_{meso} [C(17)–C(39) or C(12)–C(33)]

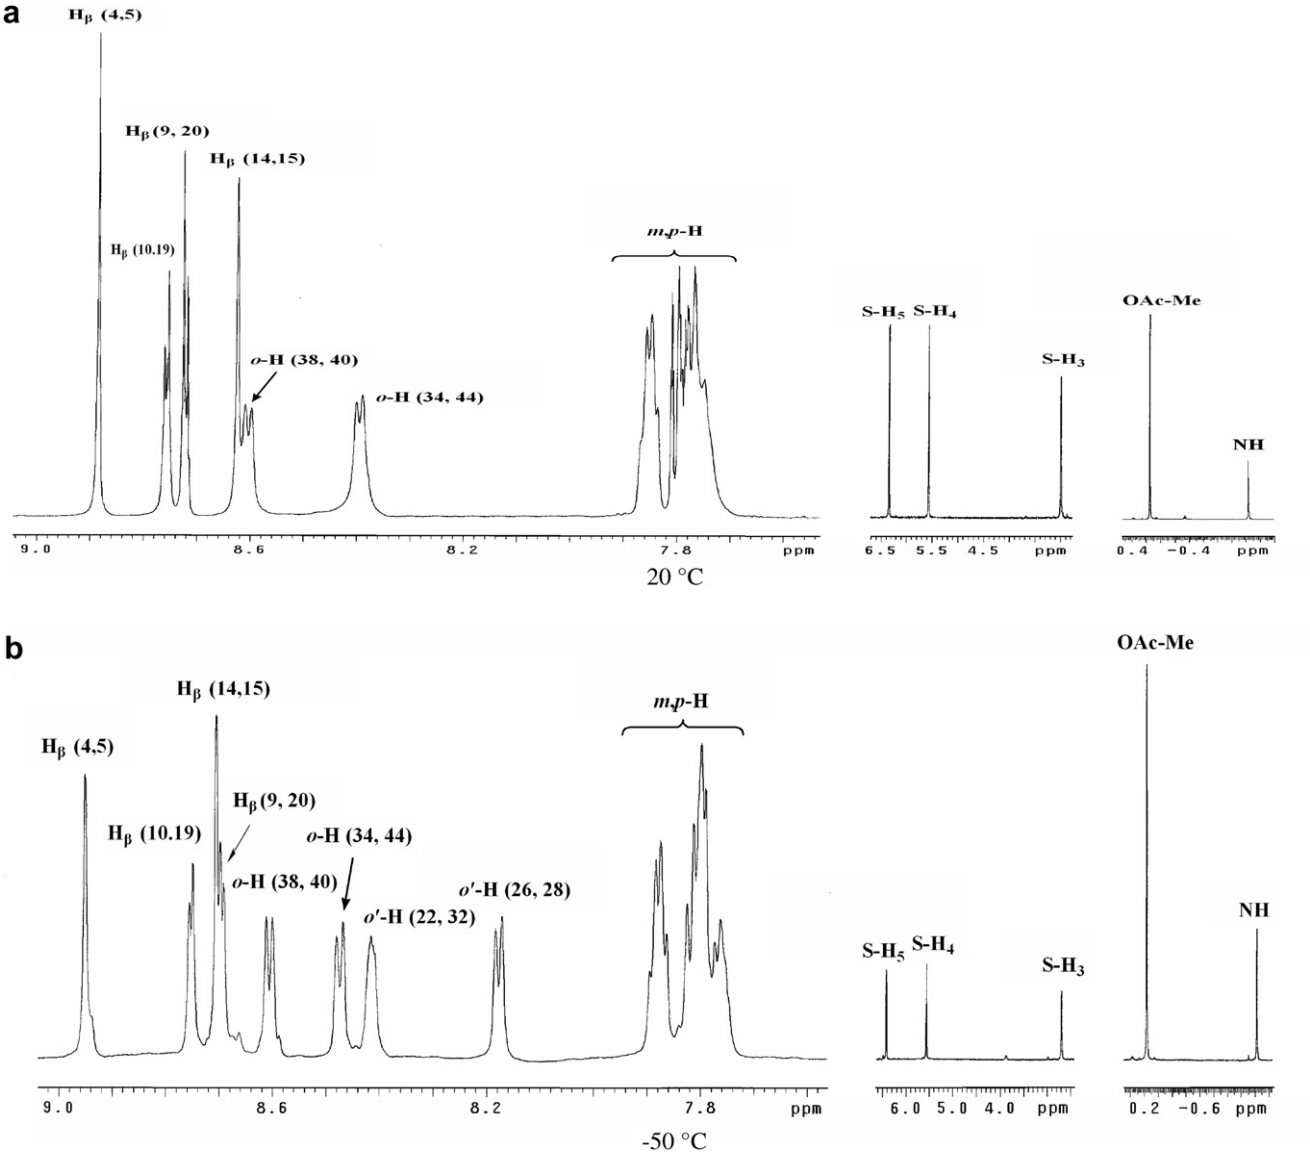

Fig. 3. ^{1}H NMR spectra for **4**-*cis* at 599.95 MHz in $CDCl_3$: (a) 20 °C, (b) −50 °C, where S = 2-thiophenecarboxamido.

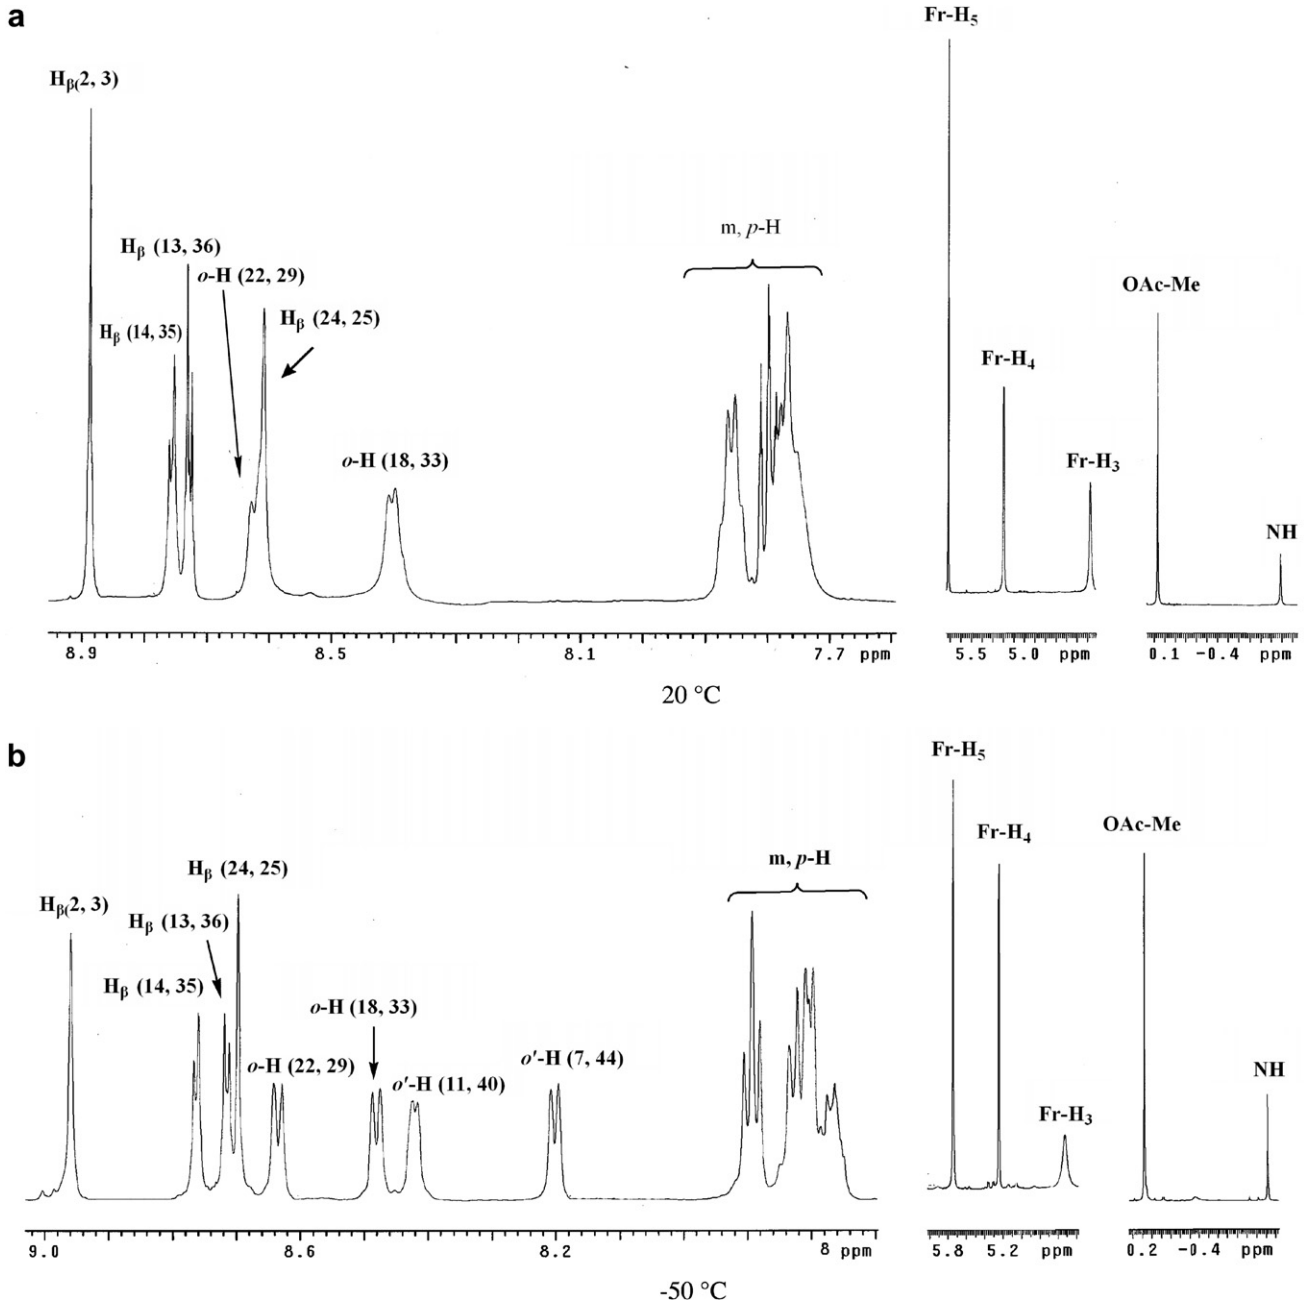

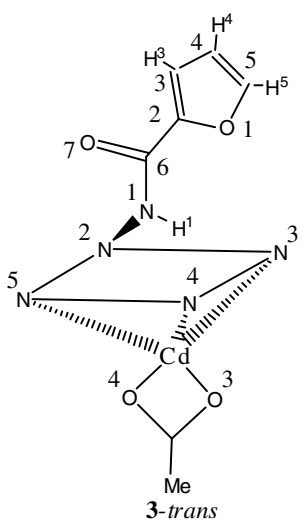

Fig. 4. ^{1}H NMR spectra for **3**-*trans* at 599.95 MHz in $CDCl_3$: (a) 20 °C, (b) −50 °C, where Fr = 2-furancarboxamido.

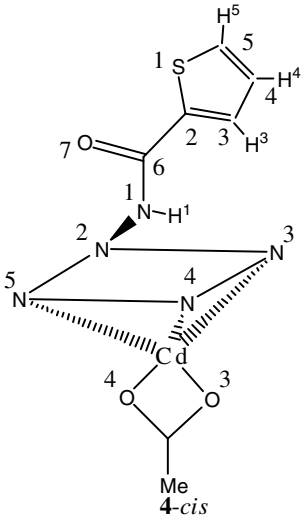

bond is slow. This slow rotation is supported by the two singlets at 8.60 and 8.40 ppm due to *o*-H(38,40) and *o*-H(34,44), respectively (Fig. 3a). Moreover, the rotation of the phenyl group along C(7)–C(27) [or C(2)–C(21)] bond for **4**-*cis* is at the intermediate exchange region. In this intermediate exchange region, the signals are broadened beyond detection. Hence, no signals of *o*′-H(22,32) and *o*′-H(26,28) for **4**-*cis* have been observed at 20 °C (Fig. 3a). At −50 °C, this rotation is extremely slow. Hence, the rate of intramolecular exchange of the *ortho* protons for **4**-*cis* in $CDCl_3$ is also extremely slow. The doublet at 8.61 ppm is assigned to *ortho* protons *o*-H(38,40) with ^3J(H–H) = 7.0 Hz (Fig. 3b). The other doublet at 8.47 ppm is due to *ortho* protons *o*-H(34,44) with ^3J(H–H) = 7.0 Hz. Likewise, the singlet at 8.42 ppm is due to *ortho* proton *o*-H(22,32). The corresponding doublet at 8.18 ppm is due to *o*-H(26,28) with ^3J(H–H) = 7.2 Hz (Fig. 3b). The interpretation of these data were confirmed by the NOE difference spectroscopy for **4**-*cis* in $CDCl_3$ at 20 and −50 °C.

In a similar fashion, the rotation for the phenyl group of **3**-*trans* in $CDCl_3$ at 20 °C along C(27)–C(28) [or C(16)–C(17)] bond is slow and the rotation along C(38)–C(39) [or C(5)–C(6)] is at the intermediate exchange region. Hence, the ^{1}H resonances for the *ortho* protons of **3**-*trans* were observed as two sets of doublets: one doublet at 8.62 ppm is assigned to *ortho* protons *o*-H(22,29) with

^3J(H–H) = 6.6 Hz and the other doublet at 8.40 ppm is due to *ortho* protons *o*-H(18,33) with ^3J(H–H) = 6.6 Hz (Fig. 4a). Moreover, no signals of *o*′-H(11,40) and *o*′-H(7,44) of **3**-*trans* have been detected at 20 °C (Fig. 4a). However, for *ortho* protons, at −50 °C, the rotation of phenyl group along the C_1–C_{meso} bond in **3**-*trans* is extremely slow, which is evident from the appearance of the four doublets at 8.64 [*o*-H(22,29)], 8.48 [*o*-H(18,33)], 8.42 [*o*′-H(11,40)], and 8.20 [*o*′-H(7,44)] ppm due to four different *ortho* protons of the aromatic ring (Fig. 4b).

Due to the ring current effect, upfield shifts for the ^{1}H resonances of S-H_5, S-H_4 and S-H_3 for **4** with the O,S-*cis* conformer in $CDCl_3$ at −50 °C are $\Delta\delta = -1.21$ [from 7.63 (obtained from 2-acetylthiophene) to 6.42 ppm], −2.13 (from 7.69 to 5.56 ppm) and −4.44 ppm (from 7.13 to 2.69 ppm), respectively (Fig. 3b). Qualitatively, as the distance between the geometrical center (C_t) of the 4N plane and axial protons gets smaller, the shielding effect becomes larger. In **4**-*cis*, the distance for $C_t\cdots$S-H_3, $C_t\cdots$S-H_4 and $C_t\cdots$S-H_5 increases from 3.235, 5.738 to 7.066 Å, individually. As the S-H_3 proton of **4**-*cis* is closer to C_t, the shielding gets larger for this S-H_3. A similar ring current effect is also observed for **3**-*trans*. The occurrence of weak intramolecular hydrogen bonding between one amino hydrogen [H(5A)] and the furan oxygen [O(4)] in O,O-*trans* of **3** is reflected in the long N(5)–H(5A)$\cdots$O(4) (furan) bond distance of 2.358 Å and acute N(5)–H(5A)$\cdots$O(4) (furan) angle of 104.35° (Fig. 1a) [6]. The hydrogen bonding results in a downfield shift of 0.24 ppm for the NH proton which resonances from −1.23 ppm for **4**-*cis* (O,S-*cis*-Cd) to −0.99 ppm for **3**-*trans* (O,O-*trans*-Cd) in $CDCl_3$ at 20 °C (Figs. 3 and 4). This intramolecular H-bonding and electrostatic attraction between $Cd(1)^{2+}$ and $O(4)^-$ restricts the rotation of the furan group along the C(48)–C(47) bond. Thus, as the temperature is increased from −50 °C to 20 °C for **3**-*trans* in $CDCl_3$, Fr-H_3 rotates a degree slightly closer to C_t and a minimum upfield shift of −0.15 ppm was observed for the ^{1}H resonances of Fr-H_3 from 4.52 to 4.37 ppm (Fig. 4).

X-ray diffraction analysis unambiguously confirms that **3**-*trans* and **4**-*cis* have a chelating bidentate OAc^- ligand in the solid phase. Notably, the ring current effects seldom exceed 10 ppm in ^{1}H NMR [17] and 2 ppm in ^{13}C NMR [18]. Hence, the ring current contribution is relatively less important in determining the ^{13}C chemical shifts than proton shifts. The ^{13}C NMR chemical shifts were shown to be a useful tool for diagnosing the nature of acetate ligands, whether unidentate or bidentate in diamagnetic complexes. Unidentate acetate ligands were located at 20.5 ± 0.2 and 168.2 ± 1.7 ppm and bidentate acetate ligands at 18.0 ± 0.7 and 175.2 ± 1.6 ppm [17]. The methyl and carbonyl chemical shifts of the acetate group in **3**-*trans* (or **4**-*cis*) at 20 °C in $CDCl_3$ are separately located at 18.9 (or 18.9) and 176.3 (or 176.6) ppm confirming that the acetate is chelating bidentately and is coordinated to the cadmium atom in **3**-*trans* (or **4**-*cis*) in the solution phase. The difference in chemical shifts for the CO group to be characteristic of either uni- or bidentate acetates are definitely out of the range of the shielding effect of a porphyrin.

NBO group net charges over O(4), O(3) and Cd(1) in **3** (O,O-*trans*-Cd; **3**-*trans*) are −0.473, −0.626 and 1.674, respectively (Table 3). In **3**-*trans*, a weakly repulsive electrostatic interaction between the two oxygen atoms [i,e., $O(3)^-$ and $O(4)^-$] and a strongly attractive electrostatic force between the cadmium [$Cd(1)^{2+}$] and oxygen atom [$O(4)^-$] are two major factors explaining the *trans* conformer of **3** which dominates both in the solid phase and in low polar solvents at low temperature. Group charges for S(1), O(3) and Cd(1) in **4** (O,S-*cis*-Cd; **4**-*cis*) are 0.490, −0.634 and 1.676, respectively (Table 3). In **4**-*cis*, a moderately electrostatic attraction between the sulfur [$S(1)^+$] and oxygen atom [$O(3)^-$] and weakly repulsive electrostatic force between the cadmium [$Cd(1)^{2+}$] and sulfur [$S(1)^+$] are two major factors determining that the *cis* conformer of **4** is favored both in the solid and in low polarity solvents at low temperature.

4. Conclusion

We have investigated two new, diamagnetic and mononuclear cadmium(II) *N*-substituted-*N*-aminoporphyrin complexes **3**-*trans* and **4**-*cis* which exist in O,O-*trans* and O,S-*cis* conformers, respectively, and their X-ray structures have been established. We also demonstrate how the electrostatic repulsive and attractive forces influence the favorable conformers in the case of **3**-*trans* and **4**-*cis*. Both the electrostatic attraction between Cd^{2+} and $O(4)^-$ and the N–H$\cdots$O (furan) H-bond interaction stabilized the O,O-*trans* form of **3**-*trans* in $CDCl_3$ at −50 °C. Both the electrostatic repulsion between Cd^{2+} and $S(1)^+$ and the attractive interaction between $S(1)^+$ and $O(3)^-$ stabilize the O,S-*cis* conformer of **4**.

Abstract

1-Alkyl-2-(naphthyl-α/β-azo)imidazole (α-NaiR **1**; β-NaiR, **2**) react with $[Os(H)(Cl)(CO)(PPh_3)_3]$ in THF and synthesise $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**3**, **4**). The X-ray structure of $[Os(H)(CO)(PPh_3)_2(\alpha\text{-NaiEt})](PF_6)$ (**3c**) shows a distorted octahedral geometry. Other spectroscopic studies (IR, UV–Vis, NMR) support the stereochemistry of the complexes. Addition of Cl_2 in MeCN to **3** or **4** gives $[Os(Cl)(CO)(\alpha/\beta\text{-NaiR})(PPh_3)_2](PF_6)$ (**5**, **6**), which were characterized by spectroscopic studies. The redox properties of the complexes show Os(III)/Os(II), Os(IV)/Os(III) and azo reductions.

1. Introduction

Polypyridyl complexes of ruthenium and osmium are an active area of current research [1–7]. There are a number of M–polypyridine complexes which bear M–H bonds (M = Ru, Os) [8]. The functional group is the diimine, –N=C–C=N–, and the key feature of these heterocycles is their π-acidity. Recent years have witnessed a great deal of interest in the synthesis of new ligands in the framework of the diimine function (–N=C–C=N–) or the functional modification to design an isoelectronic chelating motif. We have been engaged for the last few years in the design of the azoimine function (–N=C–C=N–) which is a functional modification of the diimine unit. We have synthesized the azoimidazole in the azoimine family [9,10]. Imidazole and its derivatives are chosen because of their chemical and biological ubiquity [11], whilst the azo group enhances the π-acidity and is responsible for photochromism [12], pH—responsive and redox activity of the molecules [3]. It is important to stabilize M–H bonds in the presence of a π-acidic chelating framework in the complexes [13–15].

In this work we have used 1-alkyl-2-(naphthyl-α/β-azo)-imidazoles (α/β-NaiR) as a chelating azoimine function [10,16]. We have synthesized $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})]^+$, an osmium-hydrido-carbonyl compound, and the structure has been established by single crystal X-ray diffraction study in one case. The complexes have been reacted with chlorine in acetonitrile. The products, $[Os(Cl)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](ClO_4)$, were characterised by spectroscopic and electrochemical techniques.

α-NaiR(**1**) β-NaiR(**2**)

H (**a**), Me (**b**), CH_2CH_3 (**c**), CH_2Ph (**d**)

2. Results and discussion

2.1. Synthesis and formulation

The reaction of $[Os(H)(Cl)(CO)(PPh_3)_3]$ and 1-alkyl-2-(naphthyl-α/β-azo)imidazoles (α-NaiR (**1**), β-NaiR (**2**) where R = H (a), Me (b), CH_2CH_3 (c), CH_2Ph (d)) in dry THF under dinitrogen yielded a dark red coloured solution. On evaporation of the solvent to half of its original volume and addition of NH_4PF_6, a dark precipitate appeared after cooling in a deep freezer for overnight. The formulation of the complex, $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**3** for α-NaiR; **4** for β-NaiR) is supported by microanalytical data (see Section 3). Although two geometrical isomers (**3** and **3′** or **4** and **4′**) are possible [CO *trans* to N(azo) or N(imidazole)] we have isolated only one isomer, CO *trans* to N(imidazole) (**3** and **4**). The complexes, **3** and **4**, are diamagnetic and show 1:1 conductivity in acetonitrile solution ($\Lambda_M = 90$–$105\ \Omega^{-1}\ mol^{-1}\ cm^2$). The reaction of α/β-NaiH and $[Os(H)(Cl)(CO)(PPh_3)_3]$ also gave dark coloured crystalline compounds in the presence of NH_4PF_6, but their solubility was too low to carry out any spectral measurements, thus they were not studied further. Reaction of $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ with Cl_2 in MeCN gave red coloured $[Os(Cl)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**5**, **6**) in high yield (>70%). The hydrido complexes (**3**, **4**) can be regenerated from the chloro complexes (**5**, **6**) by refluxing with $NaBH_4$ in EtOH for 2 h. The formation of hydrido complexes from **5**/**6** has been confirmed by elemental and spectral analysis.

2.2. Molecular structure

The X-ray structure of $[Os(H)(CO)(PPh_3)_2(\alpha\text{-NaiEt})](PF_6)$ (**3c**) is shown in Fig. 1; selected bond parameters are listed in Table 1. The molecule consists of a central Os atom surrounded by six coordination centers and the arrangement is distorted octahedral. The atomic arrangement involves two *trans*-phosphine, a chelated 1-ethyl-2-(naphthyl-α-azo)imidazole (α-NaiEt), hydrido (H^-) and a CO within the OsP_2N_2CH coordination sphere. The H^- is located *trans* to the azo-N coordination. The α-naphthyl ring is inclined at an angle of 46.07(11)° with respect to the chelate ring (Os, N(1), C(2), N(2), N(8)). The *trans*-phosphine angle, P(1)–Ru–P(2) of 167.29 (2)° lies in the range of reported data [17,18]. The steric crowding of phenyl and naphthyl groups may provide this large deviation from the perfect *trans*-angle value. The chelate angle N(1)–Os–N(8) is 74.49(8)°. Other angles about Os define the distorted octahedral geometry.

There is no statistically significant difference in the two Os–N bonds; Os(1)–N(8), [(N8) is azo-N] is 2.1117(19) Å and Os(1)–N(1) (N(1) is imidazole) is 2.109(2) Å. The –N=N– bond length is 1.306(3) Å and is longer than the free ligand azo distance (1.267(3) Å) [16] which is in support of $d\pi(Os) \rightarrow \pi^*(azo)$ charge transmission. The

		N(8)–Os(1)–H(1)	168.5(10)

Os–H is *trans* to the Os–N=N-(azo) group. The *trans effect* of the Os–H bond may cause elongation of the –N=N– bond. The *trans* Os–H bond enhances the charge transfer to the N=N function and causes the increase in the N=N distance. The Os–C and C–O bond lengths are 1.855(3) and 1.160(3) Å, respectively. The observed Os–P distances, 2.3916(7), 2.3670 (7) Å, are short in the series of $Os(PPh_3)$ chemistry [17,18].

The intramolecular hydrogen bonding interaction generates a supramolecule. A hydrogen bonded dimer serves as a motif (Fig. 2). An F atom in PF_6^- acts as a bridging agent between two complex units. A bifurcated hydrogen bond [(naph)C(14)–H(14)–F(6)(PF_5)–H(27)–C(27)(PPh_3): C(14)–H(14a), 0.95; H(14a)–F(6), 2.520(2); C(14)–F(6), 3.231(3) Å; ∠C–H–F, 132.0° and C(27)–H(27a), 0.95; H(27a)–F(6), 2.400(1); C(27)–F(6), 3.319(3) Å and ∠C–H–F 163.0°] bridges two molecules and forms a supracyclic dimer. PPh_3 protons form several hydrogen bonding interactions with F–P(F_5) and form a 3-D arrangement.

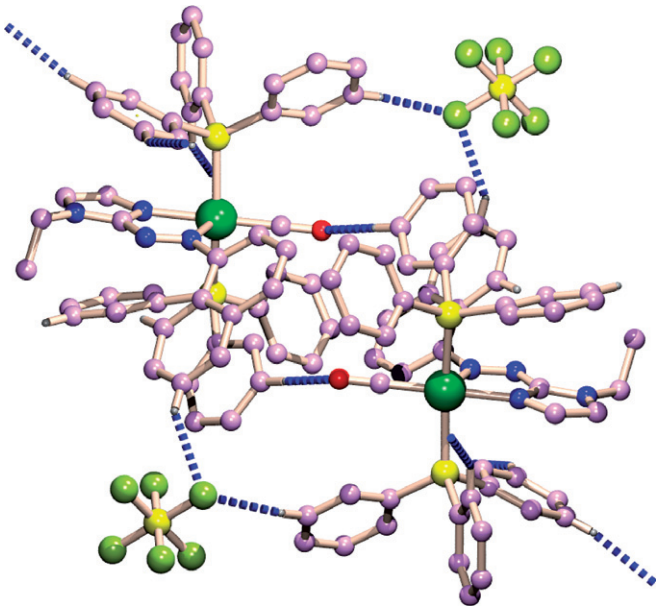

Fig. 2. H-Bonded dimer showing the C–H---F---H–C unit.

2.3. Spectra and bonding

The complexes $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**3**,**4**) show a sharp stretch at 1920–1940 cm^{-1}, which corresponds to ν(CO). The ν(Os–H) band is observed at ca. 2080–2100 cm^{-1}. Other significant vibrations are ν(N=N) and ν(C=N) at 1350–1380 and 1560–1580 cm^{-1}, respectively. The azo stretching is significantly shifted to the lower frequency region compared to the free ligand value (1400–1410 cm^{-1}) [16] and is in support of back donation, $d\pi Os(II) \rightarrow \pi^*$(azo). The single crystal structure determination in one of the complexes also supports a retro-bonding process (vide supra). For the chlorinated complexes (**5**/**6**) ν(CO) is shifted to 1960–1970 cm^{-1} which is higher than the precursor complexes (**3**/**4**). This is corroborated with the absence of σ-donation of Os–H to the Os–CO motif.

The electronic spectra of the complexes **3** and **4** in MeCN show two high intensity transitions at 310–350 and 410–440 nm and these are assigned to ligand-centred charge transfer transitions. An intense broad band at 490–505 nm (Table 2) (Fig. 3), absent in the free ligand, is obviously assigned to a $d\pi(Os) \rightarrow \pi^*$(azoimine) transition [10]. The solution spectra of **5** and **6** show blue shifting by 10–30 nm compared to the hydrido analogues, **3** and **4** respectively.

The ^1H NMR spectra of the complexes are taken in $CDCl_3$ (the proton numbering pattern is shown in Scheme 1) and have been assigned (Table 3) on the basis of spin-spin interactions and on comparison with the free ligand values [10,16]. The X-ray structure determination aids the unambiguous assignment of the protons. The most significant observation is the appearance of a triplet Os–H signal at −9.55 to −9.65 ppm ($^2J_{P-H} = 22$–25 Hz) for $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$. Imidazole protons 4- and 5-H appear as a broad singlet at 7.2–7.3 and 7.0–7.1 ppm, respectively. The singlet nature of the imidazole protons may be due to rapid proton exchange on the NMR time scale. 1-R signals of (α/β)-NaiR in $[Os(H/Cl)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})]^+$ appear at their usual position [16]; 1-Me appears as a singlet at 4.10–4.15 ppm; 1-CH_2–CH_3 gives a quartet at 4.45–4.50 ppm, ($J = 8.0$ Hz) and a triplet at 1.5 ppm ($J = 8.0$ Hz) for –CH_2– and –CH_3, respectively; 1-CH_2–(Ph) gives a singlet at 5.65–5.75 ppm. PPh_3 shows multiplets at 7.2–7.4 ppm.

2.4. Electrochemistry

The redox data are summarised in Table 2. $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**3**, **4**) and $[Os(Cl)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**5**, **6**) show two successive redox responses (Fig. 4) in MeCN solution with a Pt-working electrode (+ve to Ag/AgCl) between 0.0 and 1.8 V. The voltammogram is quasireversible in nature as is evident from the peak-to-peak separation data (for a reversible

Table 2

6c	356(3.68), 468(5.07), 512(6.19)	0.78(120)	1.36(180)	−0.77(170), −1.32[b]
6d	336(4.94), 356(5.44), 505(3.44)	0.80(130)	1.36(170)	−0.78(160), −1.37[b]

[a] Solvent MeCN, Pt-disk working electrode, Ag/AgCl reference electrode, Pt wire auxiliary electrode, [*n*-Bu_4N][ClO_4] supporting electrolyte. $E^1_M = 0.5(E_{pa} + E_{pc})$, V for Os(III)/Os(II) couple, E^2_M for Os(IV)/Os(III) couple in unit of V, $\Delta E_p = |E_{pa} - E_{pc}|$, mV; E_{pc} (cathodic-peak-potential), E_{pa} (anodic-peak-potential).
[b] E_{pc} (cathodic-peak-potential).

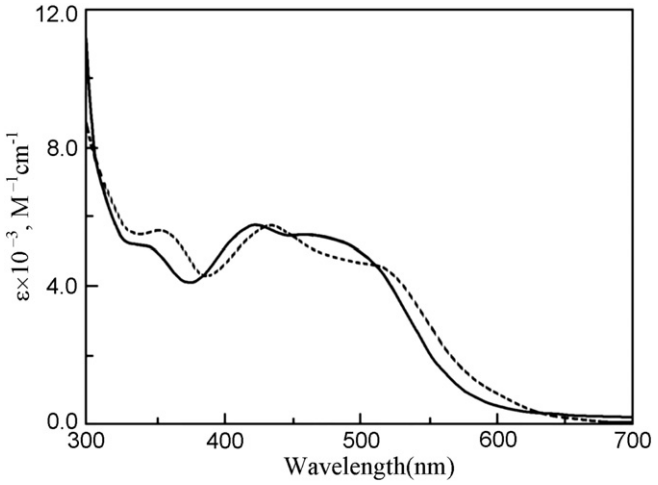

Fig. 3. Absorption spectra of [Os(H)(CO)(PPh_3)$_2$(α-NaiEt)](PF_6)] (**3c**) (—) [Os(Cl)(CO)(PPh_3)$_2$(α-NaiEt)](PF_6)] (**5c**) (- - -) (in acetonitrile).

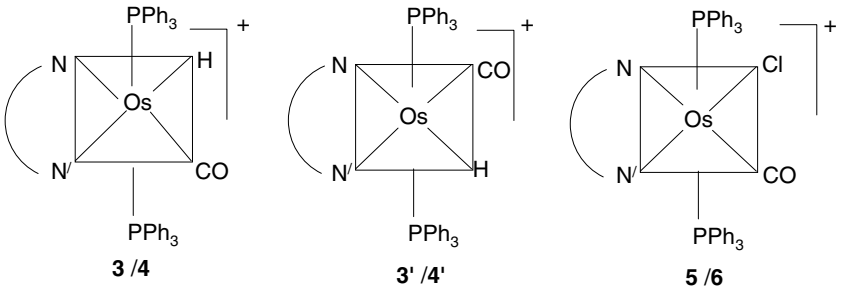

cyclic voltammogram ΔE_p is 60 mV and in the present complexes $\Delta E_p > 120$ mV and is quasi-reversible). The nature of the voltammogram does not change with scan rate (50–250 mV S^{-1}). Os(II) can sequentially exhibit Os(III)/Os(II) and Os(IV)/Os(III) redox processes at positive to Ag/AgCl reference electrode. Thus, two redox couples are referred to metal centred oxidations: Os(III)/Os(II) and Os(IV)/Os(III). Redox couples of [Os(H)(CO)(PPh_3)$_2$(α/β-NaiR)](PF_6) (**3**, **4**) at 0.6–0.70 and 1.1–1.3 V are shifted to 0.7–0.8 and 1.2–1.4 V, respectively, in [Os(Cl)(CO)(PPh_3)$_2$(α/β-NaiR)](PF_6) (**5**, **6**). The effect of the electron withdrawing Cl in the latter complexes may be the reason for this redox shifting.

On scanning to the negative direction (0 to −1.8 V), two redox responses are observed (Fig. 4). First response is quasireversible ($\Delta E_p \geqslant 120$ mV) and the second one appears at <−1.2 V which is irreversible in nature. Ligand reduction of azoimidazole complexes appears at negative potential [16b]. The chelated ligand belongs to the azoimine family and can accommodate two electrons centred at the azo group (–N=N–). On comparing with the literature [13,16,19], the reductive responses may be due to accommodation of electrons in the azo dominated function [–N=N]/[–N⁻–N–]$^-$ and [–N⁻–N]$^-$/[–N–N–]$^{2-}$.

3. Experimental

3.1. Materials

The 1-alkyl-2-(naphthyl-α/β-azo)imidazoles were synthesized following a previously published procedure [16]. [Os(H)(Cl)(CO)(PPh_3)$_3$] was also prepared by a reported method [20]. Imidazole and all other organic chemicals and inorganic salts were available from Sisco Research Lab,

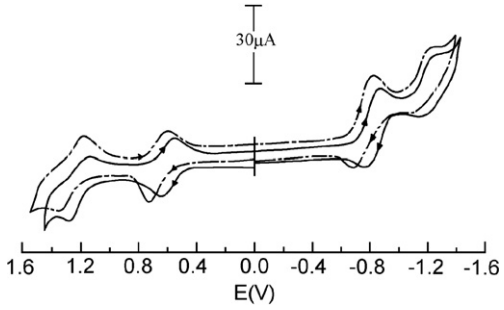

Fig. 4. Cyclic voltammogram of $[Os(H)(CO)(PPh_3)_2(\alpha\text{-NaiEt})](PF_6)$ (**3c**) (—); $[Os(Cl)(CO)(PPh_3)_2(\alpha\text{-NaiEt})](PF_6)$ (**5c**) (– – –) in acetonitrile using a Pt-working electrode and a Ag/AgCl reference electrode.

Mumbai, India. The purification of acetonitrile and preparation of *n*-tetra-butylammonium perchlorate $[n\text{-}Bu_4N][ClO_4]$ for the electrochemical work were done as reported before [9]. Dinitrogen was purified by bubbling through an alkaline pyrogallol solution. All other chemicals and solvents were of reagent grade and were used without further purification. Commercially available SRL silica gel (60–120 mesh) was used for column chromatography.

3.2. Physical measurements

Microanalytical data (C, H, N) were collected on a Perkin–Elmer 2400 CHNS/O elemental analyzer. Spectroscopic data were obtained using the following instruments: UV–Vis spectra, Perkin–Elmer; model Lambda 25. IR spectra (KBr disk, 4000–450 cm^{-1}), Perkin–Elmer; model RX-1. ^{1}H NMR spectra, Bruker (AC) 300 MHz FTNMR spectrometer. Molar conductances were measured using a Systronics conductivity meter 304 model using ca. 10^{-3} M solutions in acetonitrile. Electrochemical measurements were performed using computer-controlled PAR model 250 VersaStat electrochemical instruments with Pt-disk electrodes. All measurements were carried out under a nitrogen environment at 298 K with reference to Ag/AgCl in acetonitrile using $[n\text{-}Bu_4N][ClO_4]$ as the supporting electrolyte. The reported potentials are uncorrected for junction potentials. Magnetic properties were measured using a PAR-155 vibrating sample magnetometer fitted with a Walker scientific magnet. EPR spectra were recorded on a Varian E-109C spectrometer.

3.3. Synthesis of $[Os(H)(CO)(PPh_3)_2(\alpha\text{-NaiMe})](PF_6)$ (*3b*)

To a suspension of $[Os(H)(Cl)(CO)(PPh_3)_3]$ (0.250 g, 0.230 mmol) in dry THF (20 ml) 1-methyl-2-(naphthyl-α-azo)imidazole (α-NaiMe) (0.065 g, 0.28 mmol) was added in the same solvent (10 ml). The solution was stirred and refluxed for 15 h under dinitrogen. The orange red solution turned deep red. It was then cooled and filtered. The filtrate was then evaporated slowly in air to half of its original volume. A THF solution (5 ml) of NH_4PF_6 (0.2 g) was added into this solution and the resulting solution was kept in a deep freezer overnight. A dark precipitate appeared which was filtered, washed with cold THF and then dried in a $CaCl_2$ desiccator in vacuo. Purification was carried out by column chromatography over a silica gel column prepared in benzene. The desired red band was eluted by acetonitrile. It was then evaporated and dried over $CaCl_2$ in vacuo. The yield was 0.16 g (63%).

The other complexes were prepared following an identical procedure. The yield varied between 55% and 65%. Microanalytical data: Calc. (found) for $C_{51}H_{43}N_4OF_6P_3Os$ (**3b**): C, 54.44 (54.35); H, 3.82 (3.76); N, 4.98 (5.11%). For $C_{52}H_{45}N_4OF_6P_3Os$ (**3c**): C, 54.82 (54.95); H, 3.95 (3.88); N, 4.92 (5.01%). For $C_{57}H_{47}N_4OF_6P_3Os$ (**3d**): C, 56.99 (56.89); H, 3.92 (3.86); N, 4.67 (4.63%). For $C_{51}H_{43}N_4OF_6P_3Os$ (**4b**): C, 54.44 (54.39); H, 3.82 (3.78); N, 4.98 (4.94%).

For $C_{52}H_{45}N_4OF_6P_3Os$ (**4c**): C, 54.82 (54.78); H, 3.95 (3.98); N, 4.92 (4.94%). For $C_{57}H_{47}N_4OF_6P_3Os$ (**4d**): C, 56.99 (57.05); H, 3.92 (3.94); N, 4.67 (4.71%).

3.4. Reaction of $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (3, 4) with Cl_2 in MeCN

To a MeCN solution of $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$, a few drops of Cl_2 saturated MeCN was added and the resulting solution was stirred. The solution colour changed immediately from red to red-violet. The volume was reduced by slow evaporation and addition of NH_4PF_6 separated out crystalline compounds. A red-violet band was separated by chromatography. The eluent was evaporated to dryness, then the dark mass was water washed and dried over $CaCl_2$. Microanalytical data of the complexes support the composition $[Os(Cl)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ and conductivity data ($\Lambda_M = 100$–$110\ \Omega^{-1}\ cm^2\ mol^{-1}$) suggests a 1:1 electrolyte.

$$[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})]^+ \xrightarrow{Cl_2 \text{ in MeCN}} [Os(Cl)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})]^+$$

Microanalytical data: Calc. (found) for $C_{51}H_{42}N_4OClF_6P_3Os$ (**7b**): C, 52.83 (52.79); H, 3.62 (3.59); N, 4.83 (4.80%). For $C_{52}H_{44}N_4OClF_6P_3Os$ (**7c**): C, 53.22 (53.24); H, 3.75 (3.76); N, 4.77 (4.78%). For $C_{57}H_{46}N_4OClF_6P_3Os$ (**7d**): C, 55.41 (55.38); H, 3.73 (3.71); N, 4.54 (4.52%). For $C_{51}H_{42}N_4OClF_6P_3Os$ (**8b**): C, 52.83 (52.87%); H, 3.62 (3.64%); N, 4.83 (4.86%). For $C_{52}H_{44}N_4OClF_6P_3Os$ (**8c**): C, 53.22 (53.19); H, 3.75 (3.73); N, 4.77 (4.79). For $C_{57}H_{46}N_4OClF_6P_3Os$ (**8d**): C, 55.41 (55.36); H, 3.73 (3.69); N, 4.54 (4.52%).

3.5. X-ray crystal structure determination

Crystals of $[Os(H)(CO)(PPh_3)_2(\alpha\text{-NaiEt})](PF_6)$ (**3c**) were grown by slow diffusion of a CH_2Cl_2 solution of the complex into hexane. The prismatic red crystal was of dimensions $0.20 \times 0.10 \times 0.10$ mm. Data were collected using a CCD area detector rotating anode radiation source and a confocal optics monochromator of Mo-Kα radiation ($\lambda = 0.71073$ Å) at 93(2) K. Data collections were performed in the 2θ range 3.1–52.74° Absorption corrections were carried out by the multiscan process. Out of a total of 30,568 reflections, 9226 unique data (8451 of $I > 2\sigma(I)$) were used for the structure determination. Data reduction were carried out using Crystalclear 1.3.6 (Rigaku Corporation). The structure solution and refinement were carried out using the programs SHELXS-97 [21] and SHELXL-97 [22]. The structure was solved by direct method and refined by full-matrix least-squares refinement based on F^2. All non-hydrogen atoms were refined anisotropically. The hydridic H atom was fixed at a distance of 1.60 Å from the metal [23]. Crystal parameters and refinement results are summarized in Table 4.

Table 4
Summarised crystallographic data for $[Os(H)(CO)(PPh_3)_2(\alpha\text{-NaiEt})](PF_6)$

Empirical formula	$C_{52}H_{45}F_6N_4OP_3Os$
Formula weight	1139.03
Crystal system	monoclinic
Space group	$P2(1)/n$
a (Å)	12.0841(14)
b (Å)	25.549(3)
c (Å)	15.7643(18)
β (°)	103.684(3)
Size (mm^3)	$0.20 \times 0.10 \times 0.10$
V (Å^3)	4728.8(9)
λ (Å)	0.71073
$\rho_{calc.}$ ($Mg\ m^{-3}$)	1.600
Z	4
T (K)	93(2)
μ Mo-Kα (mm^{-1})	2.865
Total reflection collected	30 568
Unique reflections (R_{int})	9226(0.0287)
Refined parameters	609
Largest differences in peak and hole (e Å^{-3})	2.151 and −0.763
R[a] ($I > 2\sigma(I)$)	0.0235
wR[b]	0.0500
Goodness-of-fit[c]	1.043

[a] $R = \sum|F_o - F_c|/\sum F_o$.
[b] $wR = [\sum w(F_o^2 - F_c^2)/\sum wF_o^4]^{1/2}$ where $w = 1/[\sigma_2(F_o^2) + (0.0183P)^2 + 4.1609P]$, where $P = (F_o^2 + 2F_c^2)/3$.
[c] Goodness-of-fit (GOF) is defined as $[w(F_o^2 - F_c^2)/(n_0 - n_p)]^{1/2}$ where n_0 and n_p denote the number of data and variables, respectively.

4. Conclusion

1-Alkyl-2-(naphthyl-α/β-azo)imidazole (α/β-NaiR, **1** and **2**) has been reacted with $[Os(H)(Cl)(CO)(PPh_3)_3]$ in THF to synthesise $[Os(H)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**3**, **4**). The structure of the complexes has been determined by spectroscopic data (FTIR, UV–Vis, ^{1}H NMR) and redox activity was examined by cyclic voltammetry. Single crystal X-ray diffraction measurement in the case of $[Os(H)(CO)(PPh_3)_2(\alpha\text{-NaiEt})](PF_6)$ confirmed the structure. Cl_2 (in MeCN) addition to the hydrido-Os compounds (**3**, **4**) has synthesized $[Os(Cl)(CO)(PPh_3)_2(\alpha/\beta\text{-NaiR})](PF_6)$ (**5**, **6**).

Abstract

Seven bis(ligand) Co(III) complexes {$[CoL^1_2]NO_3 \cdot H_2O$ (**1**), $[CoL^1_2]Cl \cdot 2H_2O$ (**2**),$[CoL^1_2]ClO_4$ (**3**), $[CoL^2_2]NO_3$ (**4**), $[CoL^2_2]Cl \cdot 2H_2O$ (**5**), $[CoL^3_2]Br \cdot 2H_2O$ (**6**), $[CoL^3_2]ClO_4 \cdot H_2O$ (**7**)} of three thiosemicarbazone ligands {pyridine-2-carbaldehyde-N(4)-*p*-methoxyphenyl thiosemicarbazone [HL^1], pyridine-2-carbaldehyde-N(4)-2-phenylethyl thiosemicarbazone [HL^2] and pyridine-2-carbaldehyde-N(4)-(methyl),N(4)-(phenyl) thiosemicarbazone [HL^3]} were synthesized and physico-chemically characterized. All complexes are assigned octahedral geometries on the basis of spectral studies. The ligands deprotonate and coordinate by means of pyridine nitrogen, azomethine nitrogen, and thiolate sulfur atoms. The single crystal X-ray structures of HL^3 and two nitrate compounds are discussed. The structural studies corroborate the spectral characterization.

1. Introduction

Schiff bases and their transition metal complexes are of much interest in inorganic chemistry and have been studied extensively. Thiosemicarbazones and their metal complexes are very promising compounds among Schiff bases, due to their beneficial biological applications [1]. It is known that the biological activity of the thiosemicarbazones varies with the N(4) substituent as well as the ketone or aldehyde from which they are derived [2,3]. There are reports that the presence of alkyl groups at the terminal N(4) position can considerably increase their activity [4]. Domag et al. [5] had reported that thiosemicarbazones possess antitubercular activity and after that many papers on the pharmacology of these compounds appeared, indicating that they have wide inhibitory activity against smallpox [6] and several kinds of tumors [7]. They can also be used as pesticides [8] and fungicides [9–12]. The presence of various donor atoms and ability to change the denticity depending on the reaction conditions and starting reagents make thiosemicarbazones of various aldehydes and ketones a special category among organic ligands [13].

Due to the pronounced antibacterial, antimalarial, antitumor and antileukaemic activity of heterocyclic thiosemicarbazones and their metal complexes, these compounds have been attractive to a large number of research groups in recent years [14–22]. Pyridine-2-carbaldehyde thiosemicarbazone and its substituted derivatives and their metal complexes are important members in this series. A large number of complexes of different metals with the above ligands have been studied and biological activities of some of them have been explored [23,24]. In an earlier paper [25] we have reported the synthesis and crystal structure of one of the three present ligands, namely

pyridine-2-carbaldehyde N(4)-phenylethyl thiosemicarbazone (HL^2). Chattopadhyay et al. [26] have reported cobalt(III) complexes of the type $[CoL_2]X$ (X = Cl, SCN and N_3) where L is a deprotonated pyridine-2-carbaldehyde thiosemicarbazone. Here we report the synthesis and characterization of a novel ligand pyridine-2-carbaldehyde N(4)-methyl N(4)-phenyl thiosemicarbazone (HL^3) and the cobalt(III) complexes of three pyridine-2-carbaldehyde based thiosemicarbazones. In order to characterize these compounds unequivocally we report the molecular and crystal structures of HL^3 and two complexes, $[CoL^1_2]NO_3$ and $[CoL^2_2]NO_3$.

2. Experimental

Pyridine-2-carbaldehyde (Aldrich) and *p*-anisidine (Fluka) were used as received. Cobalt(II) nitrate hexahydrate, cobalt(II) chloride hexahydrate, cobalt(II) perchlorate hexahydrate (Merck) were used as supplied. 4-Methyl-4-phenyl-3-thiosemicarbazide was prepared as reported previously [27] and solvents were purified by standard procedures before use. *Caution!* Perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled with care.

2.1. Synthesis of ligands

The thiosemicarbazone ligands (Scheme 1) were obtained by adopting and modifying a reported procedure of Scovill [27]. The synthesis and crystal structure of HL^2 have been published earlier [25].

2.1.1. Synthesis of HL^1

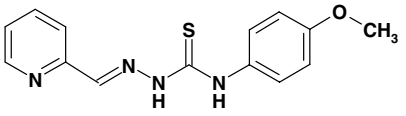
A solution of 1.00 g (5.52 mmol) of 4-methyl-4-phenyl-3-thiosemicarbazide in 5 ml of MeCN was refluxed with 0.679 g (5.52 mmol) of 4-methoxyaniline (*p*-anisidine) and 0.591 g (5.52 mmol) of pyridine-2-carbaldehyde for 1.5 h. The solution was chilled (overnight) and the crystals that separated were collected and washed well with MeCN. Yield: 58%. The compound was recrystallized from ethanol and dried *in vacuo* over P_4O_{10}.

2.1.2. Synthesis of HL^3

A solution of 1.00 g (5.52 mmol) of 4-methyl-4-phenyl-3-thiosemicarbazide in 5 ml of MeCN was mixed with 0.591 g (5.52 mmol) of pyridine-2-carbaldehyde. The solution was heated at reflux for 1 h, chilled (overnight) and the crystals that separated were collected and washed well with MeCN. Yield: 64%. The compound was recrystallized from ethanol and dried *in vacuo* over P_4O_{10}. Single crystals of XRD quality were obtained by slow evaporation of an ethanol solution of the compound.

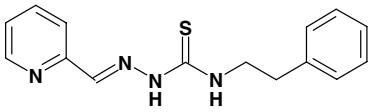
All analytical and spectroscopic data of the ligands are in good agreement with the expected values.

2.2. Synthesis of complexes



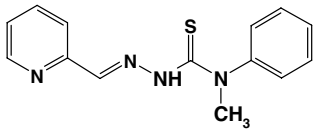
All complexes were prepared by the following general method. To a hot methanolic (20 ml) solution of thiosemicarbazone (0.5 mmol), 0.5 mmol of the cobalt(II) salt dissolved in 10 ml hot methanol was added. The mixture was refluxed for 2 h and allowed to stand for two days at room temperature. The compound formed was filtered, washed with water, methanol and ether. It was then dried *in vacuo* over P_4O_{10}. XRD quality single crystals of **1** and **4** were obtained by the slow evaporation of their methanol solutions.

2.3. Physical measurements



Elemental analyses were carried out using a Vario EL III CHNS analyzer at SAIF, Kochi, India. Infrared spectra were recorded on a Thermo Nicolet, AVATAR 370 DTGS model FT-IR spectrophotometer with KBr pellets and the ATR technique at SAIF, Kochi, India. Electronic spectra were recorded on a Cary 5000 version 1.09 UV–Vis–NIR spectrophotometer using a solution in chloroform.

2.4. X-ray crystallography



The crystallographic data and structure refinement parameters for the compounds are given in Table 1. The

data of HL^3 and **1** were collected using a Bruker Smart Apex CCD diffractometer equipped with graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation, while compound **4** was diffracted by CrysAlis CCD, Oxford Diffraction Ltd. with graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation at the National Single Crystal X-ray Diffraction Facility, IIT, Bombay, India. The trial structure was solved using SHELXS-97 [28] and refinement was carried out by full-matrix least-squares on F^2 (SHELXL) [28]. The molecular graphics employed were ORTEP-III [29] and PLATON [30].

3. Results and discussion

The colors and partial elemental analysis data of all the complexes are listed in Table 2. All the complexes are brown in color and soluble in solvents like methanol, ethanol, chloroform and DMF. They are found to be diamagnetic which confirms oxidation to cobalt(III) during the preparation, as has been found previously with heterocyclic N(4)-substituted thiosemicarbazones, and hence corresponds to a d^6 ion in a strong field [31]. The molar conductivities of 10^{-3} M DMF solutions of the complexes indicate

Table 2

[a] Molar conductivity of 10^{-3} M DMF solution, in Ω^{-1} cm^2 mol^{-1}.

that they are 1:1 electrolytes. The partial elemental analysis data and conductance measurement data are consistent with the general formulation of the complexes as $[CoL_2]X$, where X = NO_3, Cl, Br and ClO_4. For the compounds **1**, **5** and **7**, the elemental analysis data matches with the stoichiometry containing one molecule of water of crystallization/lattice water, two molecules in the case of **2** and **6**, whereas no water molecules are present in **3** and **4**. The relevant bond lengths and bond angles of HL^3, $[CoL_2^1]NO_3 \cdot H_2O$ (**1**) and $[CoL_2^2]NO_3$ (**4**) are listed in Table 3. The asymmetric unit of **4** contains three molecules, only one of which is discussed.

3.1. Crystal structure of HL^3

The molecular structure of HL^3, with the atom numbering scheme, is given in Fig. 1. Its existence in the thione form is confirmed by the C=S bond length of 1.6750(14) Å [32]. The molecule exists in the *E* conformation about the N2–N3 bond as evidenced by the C6–N2–N3–C7 dihedral angle of 177.66(16)°. The intramolecular hydrogen bond N3–H1N3···N1 and the intermolecular hydrogen bond C6–H6···N2* facilitate this geometry. The core thiosemicarbazone moiety C6, N2, N3, C7, S1, N4 is in a plane with a maximum deviation of −0.0576(15) Å for the N2 atom and makes an angle of 16.79(8)° with the pyridyl ring. The phenyl ring plane is almost perpendicular {85.38(8)°} to this thiosemicarbazone plane. Relevant C–H···π and Cg···Cg interactions are given in Table 4.

3.2. Crystal structures of $[CoL_2^1]NO_3 \cdot H_2O$ (**1**) and $[CoL_2^2]NO_3$ (**4**)

The molecular structures of **1** and **4** along with the atom numbering schemes are given in Figs. 2 and 3. The metal

Cg(1) = N1, C1, C2, C3, C4, C5			
CH···π interactions			
X–H(I)–Res(1)···Cg(J)	H···Cg (Å)	X···Cg (Å)	X–H···Cg (°)
C(14)–H(14B) [1]···Cg(2)[a]	2.95	3.7088	137
Equivalent position codes: a = $1-x$, $-y$, $2-z$			
Cg(2) = C(8), C(9), C(10), C(11), C(12), C(13)			

Cg = Centroid, α = dihedral angles between planes I and J, β = angle Cg(1)–Cg(J).

centers in both the complexes possess an octahedral geometry with two deprotonated ligands. The Co(III) ion is coordinated in a *meridional* fashion [33–35] using pairs of *cis* pyridyl nitrogen, *trans* azomethine nitrogen and *cis* thiolate sulfur atoms from two monoanionic ligands. This coordination results in four five membered chelate rings in both complexes. The bond angles suggest a distorted octahedral coordination geometry in both complexes. The dihedral angle formed by the mean planes of the bicyclic chelate systems of each of the ligands is 89.75(13)° in **1** and 83.45(1)° in **4**. In **1**, each bicyclic chelate system, Co1, S1, C7, N3, N2, C6, C5, N1 and Co1, S2, C21, N7, N6, C20, C19, N5, are approximately planar as evidenced by the maximum deviation of −0.057(7) Å for C6 and 0.080(7) Å for C21, respectively. In **4**, the bicyclic chelate system Co1, S1, C7, N3, N2, C6, C5, N1 is approximately planar with a maximum deviation of 0.06297 Å for N1, though its counterpart Co1, S2, C22, N7, N6, C21, C20, N5 show a distortion as evidenced by the maximum deviation of 2.12988 Å for C22. These results suggest the distortion in the octahedral geometry is more in **4** compared to **1**.

On complexation the ligand HL^2 undergoes structural reorientation to coordinate the metal in a NNS manner in **4**. The azomethine nitrogen was in the *E* configuration with both pyridyl nitrogen and sulfur atoms in its metal free form of the ligand, but now is in the *Z* form with both the other donor atoms. The C–S bond length increases to 1.732(6) Å [C7–S1] and 1.776(8) Å [C22–S2] from 1.6849(13) Å in HL^2. The N3–C7 bond length also changes from 1.3587(16) Å to 1.329(6) Å [1.292(8) Å for N7–C22] due to enolization of the ligand for coordination after deprotonation. The Co–S and Co–N bond lengths in both complexes are comparable. The Co–$N_{azomethine}$ bond lengths are shorter compared to Co–$N_{pyridine}$ bond lengths, indicating the greater strength of former bonds compared to the latter.

The molecules of **1** and **4** are packed in a 'face to face' manner within the unit cell, as is evident from Fig. 4 for the case of **1**, a result of diverse hydrogen bonding and C–H···π ring interactions (Tables 5 and 6). The 'face to face' arrangement is along the *b* axis for the case of **1**

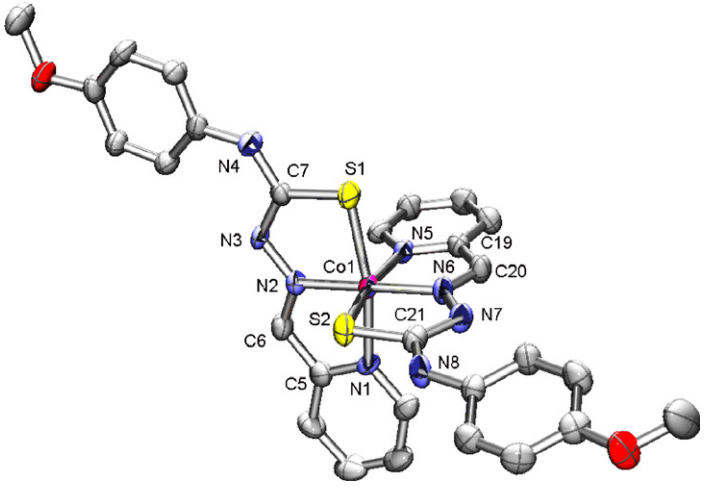

Fig. 2. ORTEP diagram for the compound $[CoL^1_2]NO_3$ (**1**) with 50% probability ellipsoids. Hydrogen atoms and the nitrate ion are omitted for clarity.

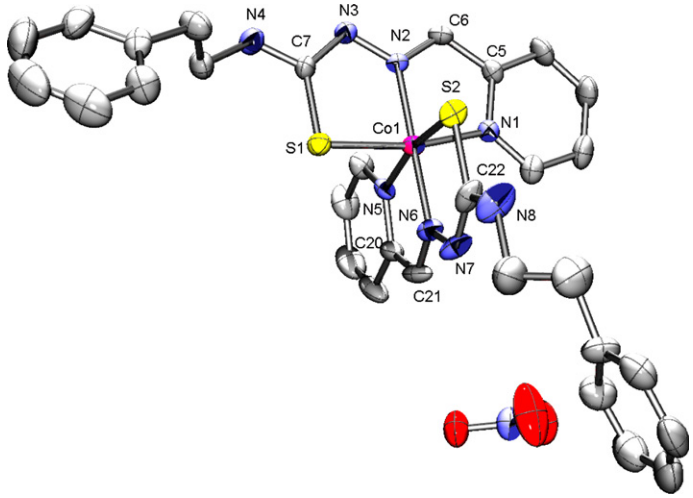

Fig. 3. ORTEP diagram for the compound $[CoL^2_2]NO_3$ (**4**) with 25% probability ellipsoids. Hydrogen atoms are omitted for clarity.

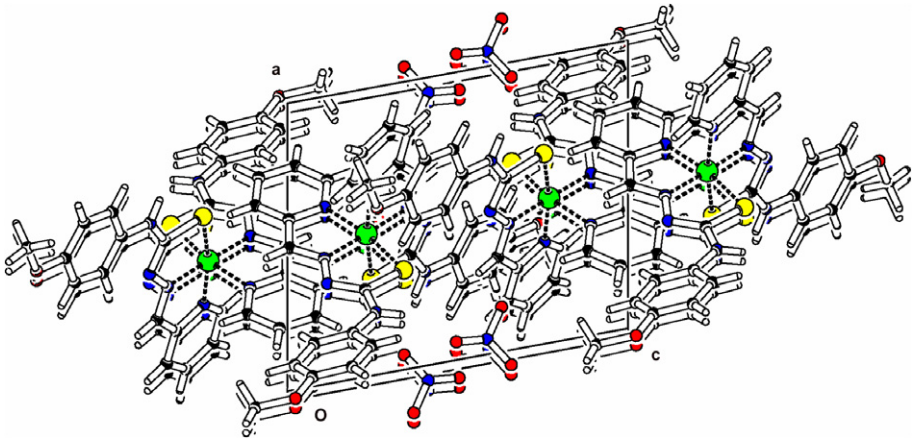

Fig. 4. A view of the molecule $[CoL^1_2]NO_3$ (**1**) along the *b* axis showing face to face packing in the unit cell.

and along the *c* axis for the case of **4** (Fig. 5). Since the latter contains three different molecules in the asymmetric unit, a large number of diverse interactions are present compared to those present in **1**. However, no significant π···π interactions are found in the packing of **4**. The relevant hydrogen bonding interactions of **1** and **4** along with HL^3 are listed in Table 7.

3.3. Infrared spectra

The characteristic IR bands (50–4000 cm^{-1}) for the free ligands (HL^1, HL^2 and HL^3) differ from those of their complexes and provide significant indications regarding the bonding sites of the ligands. IR spectral assignments of the ligands and the complexes are listed in Table 8. A medium band in the range 3129–3158 cm^{-1} in the free ligands due to the $\nu(^2N–H)$ vibration disappears in the spectra of complexes, providing strong evidence for ligand coordination around the cobalt(III) ion in its deprotonated form.

Equivalent position codes: a = x, y, z; b = x, $1+y$, z; c = $1-x$, $1/2+y$, $-z$.
Cg(1) = Co1, S1, C7, N3, N2; Cg(2) = Co1, S2, C7, N7, N2; Cg(3) = Co1, N1, C20, C6, N2; Cg(4) = Co1, N1, C5, C6, N2; Cg(7) = C10, C26, C27, C13, C14, C15.

Bands ranging from 1600 to 1350 cm^{-1} suffer significant shifts in the spectra of the complexes, which can be attributed to ν(C=C) and ν(C=N) vibration modes, and their mixing patterns are different from that in the spectra of the ligands. The positive shift of bands corresponding to ν(C=N) in the range 1584–1590 cm^{-1} in the free ligands to 1602–1614 cm^{-1} in the complexes is consistent with the coordination of the azomethine nitrogen to the central Co(III) ion [36,37]. Medium bands at ca. 439–450 cm^{-1} corresponding to ν(Co–N) further support azomethine nitrogen coordination [38,39]. The enolization of the ligands is supported by the increase in ν(N–N) by 58–115 cm^{-1}. The bands in the ranges 1307–1334 and 779–897 cm^{-1} due to ν(C=S) and δ(C=S), respectively, of the free ligands are shifted to lower values, indicating coordination of the thiolate sulfur to the Co(III) ion. The downward shift of the bands in the complexes corresponding to ν(C=S) and δ(C=S) in the free ligands can be attributed to a change of bond order and strong electron delocalization upon chelation [40]. Medium bands in the range at 375–385 cm^{-1} are assignable to ν(Co–S) [41]. A positive shift corresponding to out-of-plane bending vibrations of the pyridine ring in the free ligands (613–622 cm^{-1}) to higher frequencies (617–635 cm^{-1}) in the complexes is confirmative of pyridine nitrogen coordination to the cobalt(III) ion [42]. Medium bands at ca. 255–268 cm^{-1} corresponding to $\nu(Co–N_{pyridyl})$ point towards the coordination of the pyridyl nitrogen to the cobalt(III) ion [43].

The perchlorate complexes **3** and **7** show single broad bands at 1120 and 1123 cm^{-1} and strong bands at 620 and 625 cm^{-1}, indicating the presence of ionic perchlorate [44]. The bands at 1120 and 1123 cm^{-1} are assignable to $\nu_3(ClO_4)$ and unsplit bands at 620 and 625 cm^{-1} assignable to $\nu_4(ClO_4)$. Moreover, no bands assignable to ν_1(930 cm^{-1}) or ν_2(460 cm^{-1}) are observed in their spectra. This, along with unsplit ν_3 and ν_4 bands, show the exclusive presence of a non-coordinated perchlorate group having C_{3v} symmetry and it is supposed to be descended from T_d symmetry due to lattice effects [45].

In the spectra of the complexes **1** and **4** the absence of the combination bands ($\nu_1+\nu_4$) in the region 1700–1800 cm^{-1} rules out the possibility for a coordinated

nitrato group. The presence of bands at ca. 840 (ν_2), 1384 (ν_3) and 706 cm^{-1} (ν_4) for **1** and bands at 725, 1384 and 842 cm^{-1} for **4** clearly points out the uncoordinated nature of the nitrate group [46]. According to Stefov et al., coordinated water should exhibit bands at 825, 575 and 500 cm^{-1}. The absence of bands in these regions in the spectra of complexes **1**, **2**, **5**, **6** and **7** shows that the water molecules are not coordinated but are present as lattice water [47].

3.4. Electronic spectra

The electronic spectral assignments of the ligands and their complexes are given in Table 9. The electronic spectra of spin paired trivalent cobalt complexes of approximate O_h symmetry have the following assignments of d–d bands: ν_1: $^1T_{1g} \leftarrow {}^1A_{1g}$; ν_2: $^1T_{2g} \leftarrow {}^1A_{1g}$; ν_3: $^3T_{1g} \leftarrow {}^1A_{1g}$; ν_4: $^3T_{2g} \leftarrow {}^1A_{1g}$ [45]. The ν_1 bands are assigned values ~19 646–21 052 cm^{-1} and $\nu_2 \sim 25\,000$ cm^{-1}. The band

HL^3				30948	42796
$[CoL^3_2]Br \cdot 2H_2O$ (**6**)	20576	25063	17953	31408	43212
$[CoL^3_2]ClO_4 \cdot H_2O$ (**7**)	20534	25000	17422	31396	43096

assigned to v_2 is a combination band between it and the more intense $S \rightarrow Co^{III}$ charge-transfer bands. Very weak bands at ~16393–17953 cm^{-1} correspond to spin forbidden $^3T_{2g} \leftarrow {}^1A_{1g}$ transitions. From the spectra it can be concluded that two well separated high energy bands corresponding to spin allowed singlet → singlet transitions have been observed with the occasional presence of low energy spin forbidden bands.

Abstract

A tetranitrile monomer was synthesized by nucleophilic aromatic substitution of *N*,*N*′-bis(2-hydroxyethyl)-4,13-diaza-18-crown-6 onto 4-nitrophthalonitrile. A series of polymeric metal-free and metallophthalocyanine (M = 2H, Zn, Cu, Co and Ni) polymers was prepared by polymeric tetramerization reaction of the tetranitrile monomer with proper materials. The electrical conductivities of the polymeric phthalocyanines measured as gold sandwiches were found to be $\sim 10^{-9}$–10^{-4} S cm^{-1} in a vacuum and in argon. The extraction ability of the metal-free polymeric phthalocyanine was evaluated in tetrahydrofuran using several alkali metal picrates such as Li^+, Na^+, K^+ and Cs^+. The extraction affinity of the metal-free polymeric phthalocyanine for K^+ was found to be highest in the heterogeneous solid–liquid phase extraction experiments. The disaggregation property of the metal-free polymeric phthalocyanine was investigated with sodium, potassium and ammonium ions and methanol. All the novel compounds were characterized by using elemental analysis, UV–Vis, FT-IR, NMR and MS spectral data and DTA/TG.

1. Introduction

Phthalocyanines have found practical applications in a wide range of high technology fields such as nonlinear optics, photosensitizers, gas sensors, catalysts, liquid crystals, optical data storage, sensitizers for photodynamic therapy of cancer, electrodes in fuel cell, photoelectric conversion materials in solar cells, and laser service substances, among others [1–3]. A great number of remarkable applications of phthalocyanines arise from their unique 18π electron conjugated aromatic cloud, which makes them present high thermal and chemical stability and remarkable photoelectric properties [4].

A combination of a phthalocyanine with a polymer or incorporation of a phthalocyanine into a polymer is a powerful tool for designing materials with interesting properties [5]. Polymeric phthalocyanines were mainly prepared via polycyclotetramerization reactions of bifunctional monomers such as various nitriles [6–21] or tetracarboxylic acid derivatives [22–25] in the presence of metal salts or metals. We have previously synthesized novel phthalocyanines carrying various macrocyclic groups and polymeric phthalocyanines [26].

In the present work, metal-free and metallophthalocyanine polymers which contain ethyleneoxy diaza-18-crown-6 moieties were synthesized and characterized. The electrical conductivities of the polymers as Au/MPc/Au sandwiches in a vacuum and in argon atmosphere were examined. The viscosity properties of all the polymers and alkali

metal extraction ability and disaggregation property of the metal-free polymeric phthalocyanine were investigated.

2. Experimental

2.1. Materials

Phosphorus pentoxide (P_2O_5), 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU), ethyl alcohol, *n*-pentanol, dimethylformamide (DMF), tetrahydrofuran (THF), chloroform, dichloromethane, petroleum ether, quinoline, sulphuric acid, hydrochloric acid, pyridine, acetone, 1,2-bis(2-iodoethoxy)ethane, sodium iodide, sodium thiosulfate, acetonitrile, sodium carbonate, dioxane, ethylene oxide, methanol, 1,2-(2-aminoethoxy)ethane were received from Merck and used as supplied. Cesium carbonate (Cs_2CO_3) was received from Merck and used after drying in oven at 250 °C for 36 h. All organic solvents were dried and purified as described by Perrin and Armarego [27]. 4-Nitrophthalonitrile was synthesized as described in the literature [28]. 1,10-Diaza-18-crown-6 was synthesized according to the literature [29].

2.2. Measurements

Melting points of the compounds were determined with an electrothermal melting point apparatus and were uncorrected. ^{1}H NMR spectra were recorded on a Varian Mercury Plus 300 MHz spectrometer with $CDCl_3$ as solvent and tetramethylsilane as the internal standard. ^{13}C NMR spectra were recorded on a Varian Mercury Plus 75 MHz spectrometer with $CDCl_3$ as the solvent and tetramethylsilane as the internal standard. Transmission IR spectra of samples were recorded on a FTIR spectrophotometer (Shimadzu FTIR-8201 PC) with the samples in KBr pellets. Optical spectra in the UV–Vis region were recorded with a model Shimadzu 1601 UV–Vis spectrometer using standard cuvettes with a fixed 1 cm pathlength at room temperature. The d.c. conductivity was measured by a Autolab 30 Voltammetry-FRA 2 frequency analyser. The frequency range was of 100 Hz–1 MHz and applied amplitude (rms) was 10 mV. Mass spectra were measured on a Varian MAT 711 and on Micromass Quatro LC/ULTIMA LC-MS MS spectrometers. The elemental analysis of the compounds was determined on a CHNS-932 LECO instrument. The metal contents of the metallophthalocyanine polymers were determined with a Unicam 929 AA spectrophotometer in solutions prepared by decomposition of the metallophthalocyanines in conc. sulfuric acid and conc. nitric acid solution followed by digestion in conc. hydrochloric acid solution and deionize water. Differential thermal analysis (DTA/TG) was performed on a Linseis L81 instrument in air atmosphere with a heating rate of 10 °C/min in a temperature range of 50–750 °C. Intrinsic viscosities of freshly prepared dilute solutions of phthalocyanine polymers were measured in conc. H_2SO_4 at 25 °C by use of an Ubbelohde viscometer.

2.3. Synthesis

2.3.1. Preparation of N,N′-bis(2-hydroxyethyl)-4,13-diaza-18-crown-6 (3)

A mixture of 1,10-diaza-18-crown-6 (3 g, 11.44 mmol) and methanol (20 mL) was charged into a 250-mL three-necked flask on ice-bath. Ethylene oxide (2.7 mL) was cooled to −20 °C and then added dropwise into the reaction flask over a period of 10 min. After adding, ice-bath was changed with oil-bath. The reaction mixture was refluxed first for 4 h with a condenser which was cooled to −20 °C and then 3 more hours with an ordinary condenser under nitrogen atmosphere at 65–70 °C. The reaction was ended and the solvent, methanol, was evaporated. The residue was distilled under vacuum at 200–210 °C (0.10-mm Hg) to yield pale yellow product. Refractive index of the product was 1.4937 at 20 °C. After the product was cooled to −10 °C, some part of the product was precipitated as white crystals. They were mechanically separated from the mother liquor; m.p., 49–51 °C.

Compound **3**: yield, 2.88 g (72%). *Anal.* Calc. for $C_{16}H_{34}N_2O_6$: C, 54.84; H, 9.78; N, 7.99. Found: C, 55.01; H, 9.64; N, 8.12%. 2.3.2. Preparation of N,N′-bis (2-oxyethyl-phthalonitrilo)-4,13-diaza-18-crown-6 (5)

A mixture of 4-nitrophthalonitrile (2.47 g, 14.28 mmol) and dry DMF (10 mL) was charged into a 200-mL three-necked flask and stirred at room temperature under nitrogen inert atmosphere. *N*,*N*′-Bis(2-hydroxyethyl)-4,13-diaza-18-crown-6 (2.5 g, 7.14 mmol) was added to the solution and the temperature was increased up to 50 °C. Powdered Cs_2CO_3 (7.12 g, 21.42 mmol) was added to the system in five equal portions at 45 min intervals with efficient stirring and the reaction system was stirred at the same temperature (50 °C) for 7 days. Aliquots were taken and checked periodically for completeness of the reactions and observed by thin layer chromatography (TLC) (8:2 chloroform:methanol). The reaction system was cooled and poured into ice-water and then mixed for 3 h. The mixture was extracted with chloroform (4 × 50 mL) and

organic phase was dried over $MgSO_4$. Chloroform was evaporated and oily brown crude product was obtained. The yield was recrystallized from a mixture of ethanol:diethyl ether (3:1; v/v) and dried again under vacuum over P_2O_5. The final brown solid **5** was soluble in chloroform, DMF, DMSO, pyridine, THF and dichloromethane.

Compound **5**: yield, 3.96 g (92%); m.p., 156 °C. *Anal.* Calc. for $C_{32}H_{38}N_6O_6$: C, 63.77; H, 6.36; N, 13.94. Found: C, 63.94; H, 6.22; N, 13.65%. 2.3.3. Preparation of metal-free polymeric phthalocyanine (*6*)

A mixture of compound **5** (0.602 g, 1 mmol), *n*-pentanol (5 mL) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (0.155 g, 1 mmol) was placed in a standard Schlenk tube under nitrogen atmosphere and degassed several times. The temperature was gradually increased up to 90 °C and degassed again with nitrogen. Then the reaction mixture was stirred at 145 °C for 12 h. After the reaction mixture was cooled and decanted, the residue was stirred with methanol:petroleum ether mixture (10 mL, 1/1; v/v). The product **6** was filtered off, washed with DMF, methanol, acetone and diethyl ether and dried in air. The final dark green solid **6** was soluble in H_2SO_4, hot pyridine and poorly soluble in chloroform, dichloromethane and THF.

Compound **6**: yield, 0.43 g; m.p. >300 °C. *Anal.* Calc. for $(C_{128}H_{154}N_{24}O_{24})_n$ (2411.16): C, 63.72; H, 6.43; N, 13.93. Found: C, 63.48; H, 6.65; N, 14.12%. IR (KBr): ν_{max} (cm^{-1}): 3275 (N–H), 3055 (aromatic =CH), 2970–2840 (CH_2), 2223 (C≡N), 1642 (—C=N—), 1598 (aromatic —C=C—), 1469, 1380, 1265 (Ar–O–C), 1130–1040 (CH_2–O–CH_2), 1030, 960, 853, 682 and 530 cm^{-1}. ^{1}H NMR (pyridine-d_5): $\delta = 8.42$–8.18 (m, br, 96H, ArH), 4.34 (t, J 7.15 Hz, 64H, N–CH_2–CH_2O–Ar), 3.54 (s, 128H, –OCH_2-CH_2O), 3.22 (t, J 6.52 Hz, 128H, NCH_2CH_2O), 2.87 (t, J 7.15 Hz, 64H, NCH_2CH_2O–), 2.57 (t, J 6.52 Hz, 128H, NCH_2CH_2O). MS (FAB positive), m/z: 9645.87 $[M + 1]^+$.

2.3.4. Preparation of Zn-containing polymer (*7*)

A mixture of bisphthalonitrile compound **5** (0.602 g, 1 mmol), zinc acetate dihydrate [$Zn(CH_3COO)_2 \cdot 2H_2O$] (0.112 g, 0.5 mmol) and amyl alcohol (5 mL) was put in a flask and the temperature was increased up to 160 °C. DBU (0.08 g, 0.08 mL, 0.5 mmol) was added dropwise with a syringe to the system at the same temperature. The reaction was treated at 160 °C for 12 h under reflux and nitrogen atmosphere. After cooling, 10 mL of methanol–water mixture (1:1, v/v) was added to the system and stirred for 45 min. The crude product was filtered and washed with methanol, DMF, distilled water, petroleum ether and acetone. The final green product **7** was dried under vacuum over P_2O_5 at 100 °C.

Compound **7**: yield, 0.40 g; m.p. >300 °C. *Anal.* Calc. for $(C_{128}H_{156}N_{20}O_{32}Zn)_n$ (2549.05): C, 60.24; H, 6.16; N, 10.98; Zn, 2.56. Found: C, 60.45; H, 6.37; N, 10.69; Zn, 2.67%. IR (KBr): ν_{max} (cm^{-1}): 3390 (imide N–H), 3054 (aromatic =CH), 2990–2789 (CH_2), 1770 (sym. C=O), 1720 (asym. C=O), 1640 (—C=N—), 1598 (aromatic —C=C—), 1485, 1421, 1326, 1254 (Ar–O–C), 1160–1040 (C–O–C), 957, 842 and 650 cm^{-1}.

2.3.5. Preparation of Cu-containing polymer (*8*)

A mixture of bisphthalonitrile compound **5** (0.602 g, 1 mmol), $Cu(CH_3COO)_2 \cdot H_2O$ (0.100 g, 0.5 mmol) and amyl alcohol (3 mL) was put in a flask. The temperature was increased up to 160 °C and degassed three times under nitrogen atmosphere. Then, DBU (0.08 mL, 0.08 g, 0.5 mmol) was added drop by drop with a syringe into the system. The reaction was treated at 160 °C for 12 h under reflux and nitrogen atmosphere. The reaction mixture was cooled, diethyl ether–methanol mixture (5 mL, 1:1) was added and stirred for 1 h. The mixture was filtered and the solid part was washed with distilled water, DMF, ethanol and diethyl ether. The final product **8** was dried under vacuum over P_2O_5 at 100 °C.

Compound **8**: yield, 0.38 g; m.p. >300 °C. *Anal.* Calc. for $(C_{128}H_{156}N_{20}O_{32}Cu)_n$ (2548.05): C, 60.28; H, 6.17; N, 10.98; Cu, 2.49. Found: C, 60.51; H, 6.43; N, 11.17; Cu, 2.26%. IR (KBr): ν_{max} (cm^{-1}): 3360 (imide N–H), 3062 (aromatic =CH), 2980–2853 (CH_2), 1774 (sym. C=O), 1713 (asym. C=O), 1636 (—C=N—), 1601 (aromatic —C=C—), 1493, 1428, 1330, 1262 (Ar–O–C), 1155–1020 (C–O–C), 964, 856 and 590 cm^{-1}.

2.3.6. Preparation of Co-containing polymer (*9*)

A mixture of bisphthalonitrile compound **5** (0.602 g, 1 mmol), dry quinoline (2 mL) and $CoCl_2 \cdot 6H_2O$ (0.120 g, 0.5 mmol) was kept in a flask and degassed three times with nitrogen. The reaction mixture was treated at 220 °C under reflux and nitrogen inert atmosphere. After 24 h of stirring, the reaction mixture was cooled and then diethyl ether (25 mL) was added and then filtered off. The solid part was washed with methanol:diethyl ether mixture (20 mL, 1:1), DMF, hot ethanol, acetone and filtered off. The final product **9** was dried under vacuum over P_2O_5 at 100 °C. The final green product **9** was soluble in H_2SO_4 and poorly soluble in pyridine.

Compound **9**: yield, 0.31 g; m.p. >300 °C. *Anal*. Calc. for $(C_{128}H_{156}N_{20}O_{32}Co)_n$ (2544.05): C, 60.39; H, 6.18; N, 11.00; Co, 2.32. Found: C, 60.17; H, 6.41; N, 11.23; Co, 2.64%. IR (KBr): ν_{max} (cm^{-1}): 3400 (imide N–H), 3048 (aromatic =CH), 2920–2796 (CH_2), 1776 (sym. C=O), 1718 (asym. 2.3.7. Preparation of Ni-containing polymer (*10*)

A mixture of bisphthalonitrile compound **5** (0.602 g, 1 mmol), dry quinoline (1.5 mL) and $NiCl_2 \cdot 6H_2O$ (0.122 g, 0.5 mmol) was charged in a standard Schlenk tube and degassed three times with nitrogen. The temperature was increased up to 220 °C and treated for 24 h under reflux and nitrogen inert atmosphere. The system was cooled to room temperature and methanol:water (10 mL, 1:1; v/v) mixture was added to the system and stirred at room temperature for 1 h. The product was filtered off and washed with DMF, methanol, distilled water, petroleum ether. The final green product **10** was dried under vacuum over P_2O_5 at 100 °C. The product **10** was soluble in H_2SO_4 and poorly soluble in pyridine.

Compound **10**: yield, 0.37 g; m.p. >300 °C. *Anal*. Calc. for $(C_{128}H_{156}N_{20}O_{32}Ni)_n$ (2543.05): C, 60.40; H, 6.18; N, 11.01; Ni, 2.31. Found: C, 60.64; H, 6.06; N, 11.35; Ni, 2.52%. IR (KBr): ν_{max} (cm^{-1}): 3413 (imide N–H), 3043 (aromatic =CH), 2925–2875 (CH_2), 1772 (sym. C=O), 1710 (asym. C=O), 1642 (—C=N—), 1605 (aromatic —C=C—), 1513, 1420, 1325, 1257 (Ar–O–C), 1160–10430 (C–O–C), 974, 846 and 610 cm^{-1}.

2.3.8. The conversion of cyano end groups of the metal-free polymeric phthalocyanine into imido groups (*6a*)

A sample of the metal-free polymeric phthalocyanine (**6**) (150 mg) was dissolved in a minimum volume of H_2SO_4 (96 wt%) at room temperature. After 3–4 h of stirring, the reaction mixture was filtered. The filtrate was poured into excess amount of ice-water mixture. The dark green crude product was washed with distilled water until the washings were neutral. Then the final product **6a** was washed with ethanol and diethyl ether and dried under vacuum over P_2O_5 at 100 °C.

Compound **6a**: yield, 0.12 g; m.p. >300 °C. Elemental analyses (for imide end groups): *Anal*. Calc. for $(C_{128}H_{158}N_{20}O_{32})_n$ $(2487.14)_n$: C, 61.77; H, 6.40; N, 11.26. Found: C, 61.89; H, 6.26; N, 11.54%. IR (KBr): ν_{max} (cm^{-1}): 3385 (imide N–H), 3310 (N–H), 3050 (aromatic =CH), 2980–2852 (CH_2), 1772 (sym. C=O), 1720 (asym. C=O), 1629 (—C=N—), 1596 (aromatic —C=C—), 1508, 1491, 1448, 1324, 1242 (Ar–O–C), 1151–1040 (C–O–C), 975, 940–840, and 543 cm^{-1}.

2.3.9. Metal analysis of the polymeric phthalocyanines

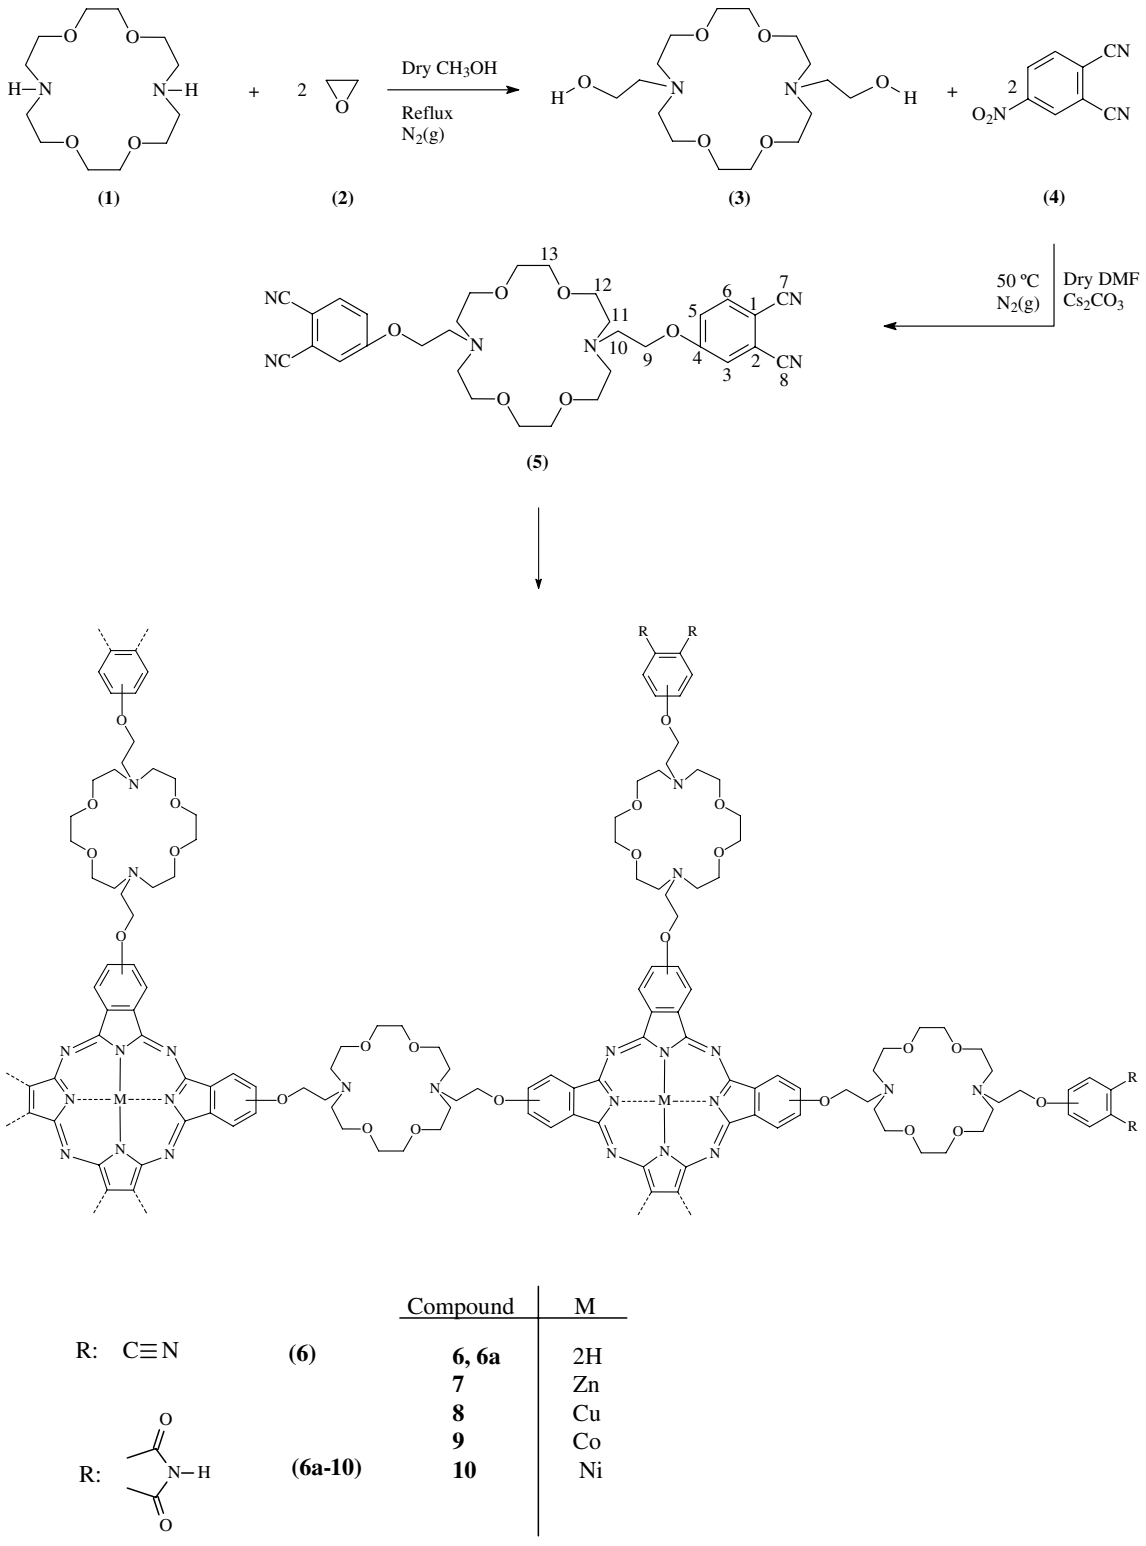
A sample of the metallophthalocyanine polymers (**7**–**10**) (10 mg) was added into concentrated sulfuric acid (2.5 mL) and conc. nitric acid (3.5 mL). The mixture was heated for 2 h at 160 °C in an oil-bath. The solution was firstly digested in conc. HCl acid solution and then diluted with deionize water (500 mL). The determination of metal ions was conducted by atomic absorption measurements.

Table 1
Alkaline metal picrate extractions for **6**[a] under solid/liquid two-phase conditions

Metal ion	Extractability of the metal-free polymeric phthalocyanine (**6**) (%)[b]	λ_{max} (nm) of metal picrate
Li^+	6.01 ± 0.01	362
Na^+	77.17 ± 0.01	356
K^+	94.25 ± 0.01	364
Cs^+	22.16 ± 0.01	354

[a] Temperature 25 ± 1 °C; THF phase (10 mL), [picrate] = 3.0×10^{-3} M; host molecule = 20 mg.
[b] Average and standard deviation for three independent measurements.

2.3.10. Measurement of the alkali metal-binding properties of the polymeric metal-free phthalocyanine



The extraction properties of **6** were investigated under solid–liquid phase condition by using alkali metal picrates (Li^+, Na^+, K^+ and Cs^+) as substrates and measuring by UV–Vis the amounts of picrate in THF phase before and after treatment with polymers in suspension. Suspensions were prepared by mixing 25 mg of the polymeric metal-free phthalocyanine (**6**) and the alkali metal picrate solutions as described in previous article [26g]. The prepared suspensions were put in plastic bottles and shaken vigorously for 24 h at room temperature. Results and experimental conditions are reported in Table 1. In the absence of host **6**, blank experiment, no metal ion picrate extraction was detected. The extractability was determined based on the absorbance of picrate ion in the THF suspensions. The extractability was calculated by using the following equation:

$$E(\%) = [(A_0 - A)/A_0] \times 100$$

where A_0 is the absorbance in the absence of ligand. A denotes the absorbance in THF suspension phase after extraction.

3. Results and discussion

The synthesis of the *N*,*N*′-bis(2-hydroxyethyl)-4,13-diaza-18-crown-6 (**3**) was performed by starting with 4,13-diaza-18-crown-6 (**1**) and ethylene oxide (**2**) in methanol (Scheme 1). The yield (72%) was higher than the known procedure (51%) [29] and the product was partly solid (m.p., 49–51 °C) while it was said to be oily in the literature reference. Elemental analysis and mass spectral data of **3** were satisfactory: 350.25(1.8) $[M]^+$. In ^1H NMR ($CDCl_3$) spectrum of **3**, NH group of compound **1** disappeared as expected. ^1H NMR spectrum of **3** showed new signal at $\delta = 4.43$ (s, broad, 2H, OH) and also the proton-decoupled ^{13}C NMR spectrum of **3** indicates the presence of primary alcohol carbon atoms at $\delta = 60.14$ (NCH_2CH_2OH) and 56.43 (NCH_2CH_2OH), respectively. The IR spectrum of **3** was easily verified with the disappearance of N–H and

Scheme 1. Synthesis of new polymeric phthalocyanine polymers substituted with diaza-18-crown-6 macrocycles through ethyleneoxy bridges.

presence of O–H stretching vibrations at 3327 cm^{-1}. The difference between the IR spectra of **1** and **3** is clear from the absence of characteristic vibrations such as N–H. 4-Nitrophthalonitrile (**4**) was treated with **3** in the presence of Cs_2CO_3in DMF to afford tetranitrile monomer **5** with high yield (92%). Final purification of tetranitrile derivative **5** by recrystallization afforded **5** for which elemental analysis and EI mass spectral data were satisfactory: 602.58 $[M]^+$. In ^1H NMR spectrum of **5**, OH group of compound **3** disappeared as expected. The disappearance of OH and the presence of Ar–O–C at 1260 cm^{-1} and the presence of C≡N functional group at 2230 cm^{-1} in the IR spectrum

of compound **5** confirm the formation of desired compound **5**.

The metal-free phthalocyanine polymer was synthesized by heating mixture of **5**, DBU and amyl alcohol in a Schlenk tube [30]. The transition metal complexes were prepared from the tetracyano compound **5** and the corresponding metal salt in proper solvent (Scheme 1).

The molecular weights of the polymers could not be determined using traditional methods because of their poor solubility in organic solvents, but by comparison of the IR absorption bands of the end groups with those of the bridging groups [15,31]. On the other hand, according to the FAB mass spectra analysis of **6** using the soluble part (~80%) of **6** in pyridine, we can say that **6** is a tetramer molecule. The ^{1}H NMR spectrum of the soluble part of the **6** in pyridine-d_5 displayed broad signals, and the protons of the phthalocyanine core were invisible, even at elevated temperatures. This effect was attributed to strong aggregation of the molecules.

The IR spectra of metal-free **6**, **6a** and metallophthalocynaine polymers (**7**–**10**) are very similar. The significant difference is the presence of ν(N–H) vibrations of the inner phthalocyanine core which are assigned to a weak band at 3275 cm^{-1} in the metal-free molecule. These bands disappear in the spectra of the metallophthalocyanine polymers. These bands are especially beneficial for characterization of metal-free phthalocyanine polymers, as there is little frequency dependence on ring substitution and they are not overlapped by strong tetranitrile monomer absorptions [10]. The end groups of the metal-free phthalocyanine polymer were cyano groups (2223 cm^{-1}) while the end groups of the metallophthalocyanine polymers were imido groups (~1776–1710 cm^{-1}). The existence of imido groups in the case of metallophthalocyanine polymers was attributed to the presence of the moisture during work-up and the hydrated metal salts. There was little shift to longer wavelength numbers in most of the IR bands of the metal complexes with respect to the metal-free analogues [10,32].

The elemental analyses of the metal-free and metallophthalocyanine polymers (**6**, **6a**, **7**–**10**) were satisfactory.

The metal-free (**6**) and metallo polymers (**7**–**10**) gave typical UV–Vis absorptions spectra of phthalocyanines (Table 2). As it can bee seen in Table 2 there is a shoulder at the slightly higher energy sides for all products. The presence of shoulders in the UV–Vis spectra of the all polymers corresponds to the aggregated or non-aggregated species in conc. sulfuric acid. Metal-free phthalocyanine polymer (**6**) decomposes slowly by hydrolysis in conc. H_2SO_4, which is demonstrated by a decrease of the absorption coefficient at longer wavelengths. Metal-containing polymers (**7**–**10**), however, were stable. When going from organic solvents to concentrated H_2SO_4, the long-wave absorption band underwent a significant bathochromic shift, which is due to degradation and weak protonation of the phthalocyanine ring at the *meso* nitrogen atoms. The intensity of these absorptions also decreased. The UV–Vis spectrum of **6** was obtained in pyridine and conc. H_2SO_4. The electronic absorption spectrum of **6** in pyridine at room temperature is shown in Fig. 1. There were the split Q-band as expected and there were two strong bands in the visible region [33]. The split Q-band which is characteristic for metal-free phthalocyanines observed at λ_{max} 706 and 672 nm with a shoulder at 640 nm, indicating the monomeric species; the monomeric species with D_{2h} symmetry shows two intense absorptions at around 700 nm [34,35]. On the other hand, such split Q-band absorptions in pyridine are due to $\pi \Rightarrow \pi^*$ transition of this fully conjugated 18π electron systems [26a]. In the case of a H_2SO_4 solution of **6**, the primary band in the visible region was broadened and shifted to longer wavelength (104 nm). In all cases the intensities in the UV (Soret band transition) and Vis (Q-band transition) were $I_{UV}/I_{Vis} \leqslant 1$ (Table 2). This result indicates the absence of poly(isoindolinine) co-units in all of the polymeric phthalocyanines (**6**–**10**).

Disaggregation of the metal-free polymeric phthalocyanine (**6**), followed by changes in the visible spectra after the addition of methanol, several alkali and NH_4^+ cation, constitute an effective route for characterizing the complexation behavior of the ethyleneoxy diaza-18-crown-6 peripheral substituents. Firstly, we clarified whether methanol has any effect or not on the visible spectrum of **6**. For this purpose, different amounts of methanol were added to the solution of **6** in pyridine. As can be seen in Fig. 1 decreases in the intensities of Q bands were observed in the visible absorption spectrum of **6** with increasing the amounts of methanol. This can be due to the dilution. Then the different concentration of metal salts (e.g. $NaNO_3$, KNO_3, NH_4NO_3) solutions in methanol (1.0×10^{-3} M)

Table 2
Wavelength and relative absorbance intensities of the UV–Vis spectra of the polymeric phthalocyanines

7	Zn	H_2SO_4	850 (2.88)	819[b] (2.40)	736 (1.12)	619 (0.26)	458 (2.24)	365 (1.95)	327 (1.51)	297 (1.38)		0.48
8	Cu	H_2SO_4	832 (1.20)	775[b] (0.78)	732 (0.52)	617 (0.19)	430 (0.85)	412 (0.35)	338 (0.69)	304 (1.10)		0.92
9	Co	H_2SO_4	816 (1.74)	755[b] (0.89)	720 (0.55)	663 (0.08)	391 (2.40)	377 (1.45)	326 (2.14)	292 (2.45)		1.41
10	Ni	H_2SO_4	816 (2.51)	758[b] (0.79)	719 (0.52)	639 (0.33)	460 (2.57)	414 (2.24)	378 (2.00)	297 (2.88)		1.14

[a] Intensity ratio of absorption B bands at λ = 274–304 nm and Q bands at λ = 719–850 nm (C = 1.0×10^{-4} g/L in H_2SO_4, 1.0×10^{-3} g/L in pyridine).
[b] Shoulder.

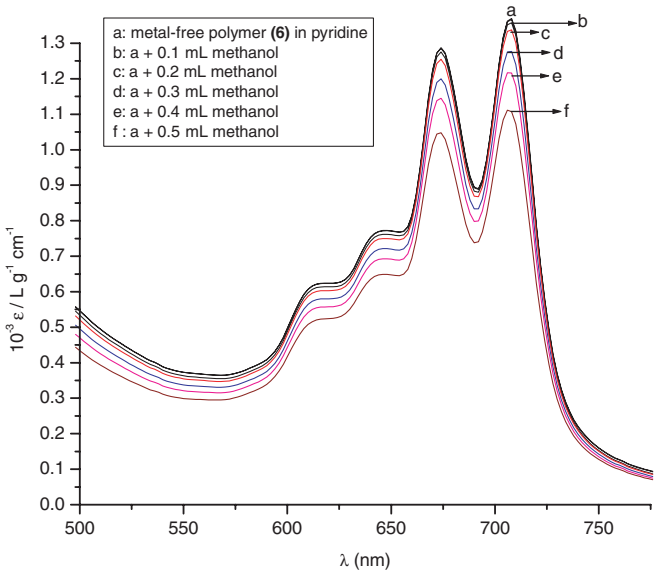

Fig. 1. Changes in the visible spectra of **6** in pyridine (1.0×10^{-3} g/L) after the addition different amounts of methanol.

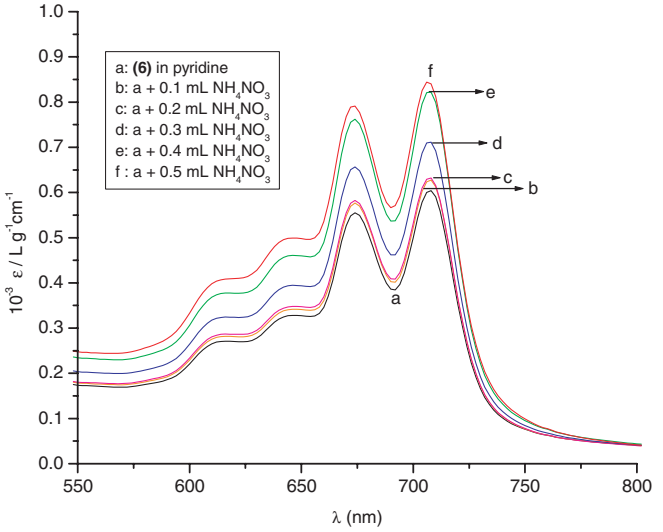

Fig. 2. Changes in the visible spectra of **6** in pyridine (1.0×10^{-3} g/L) after the addition of NH_4NO_3 solutions in methanol (1.0×10^{-3} M).

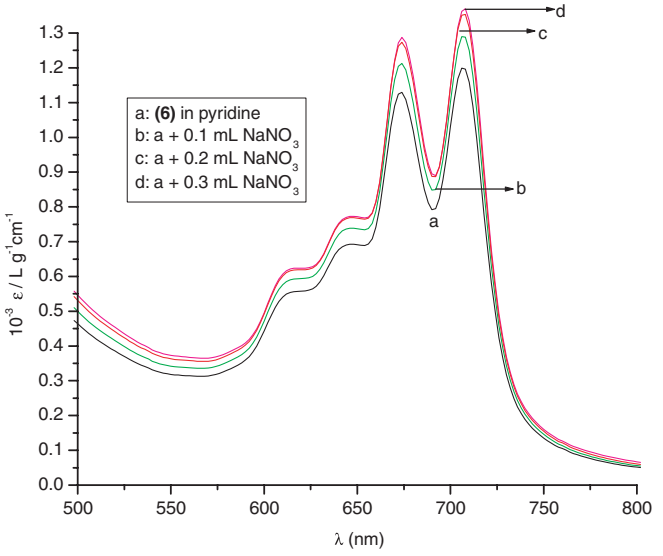

Fig. 3. Changes in the visible spectra of **6** in pyridine (1.0×10^{-3} g/L) after the addition of $NaNO_3$ solutions in methanol (1.0×10^{-3} M).

were added to the solution of the metal-free polymeric phthalocyanine (**6**) in pyridine (1.0×10^{-3} g/L). When we added $NaNO_3$, KNO_3 and NH_4NO_3 solutions to the metal-free polymeric phthalocyanine (**6**) solution caused a dramatic change due to disaggregation in the visible spectrum of **6** even in spite of dilution effect of methanol. This observation can be attributed to the disaggregation of **6** by trapped Na^+, K^+ and NH_4^+ ions in the diaza-18-crown-6 units, the radius cavity of which is harmonious with these ions and there is no intermolecular complexation between the phthalocyanine units [36] (Figs. 2–4).

The intrinsic viscosities of dilute solutions of polymers were measured by means of Ubbelohde viscometer. The intrinsic viscosities of all polymers were similar (Table 3). Fig. 5 shows the viscosities of polymers as a function of polymer concentration, and indicates that viscosities decreased depending on polymer concentration. This behavior can be explained by two effects: (1) degradation of the polymers and (2) weakly protonation of the four bridging nitrogen atoms at the periphery of each phthalocyanine polymer and the nitrogen atoms of the diaza-18-crown-6 units. On the other hand, there were linear decreasing in the case of **7** and **9** while polynomial decreasing in the case of **6**, **8** and **10** (Fig. 5). It can be probably due to lower stability of **6**, **8** and **10** than those of others, **7** and **9**.

The structure of the polymers was an Au/MPc/Au sandwich in the configuration commonly used for the electrical conductivity measurements [37]. To prepare the samples, powdered materials were pressed at a load of 2 tons for 3 min into disk-shaped compacts with a thickness of 0.45–0.60 mm. The d.c. conductivity was measured by a Autolab 30 Voltammetry-FRA 2 frequency analyser. The frequency range was of 100 Hz–1 MHz and applied amplitude (rms) was 10 mV. The electrical conductivities of the polymers were measured in a vacuum and in argon atmosphere. Table 3 shows the d.c. electrical conductivities of polymers **6**, **6a**, **7**–**10**. These values correspond to semi-conductive materials as encountered in number-substituted phthalocyanine derivatives [26g]. The conductivity values obtained under an argon atmosphere were higher than those of under vacuum for all polymers probably due to absorbed oxygen in argon [38].

The thermal stability of the phthalocyanine polymers (**6**–**10**) was determined by thermal analysis. Due to high thermal stability of the phthalocyanine core, cleavage of the substituent macrocycles takes place first and then the main decomposition occurs above 400 °C [39]. But, the crown ether units are not stable at temperatures above 300 °C even under inert conditions [40]. The initial decomposition temperature decreased in the order **7** > **9** > **10** > **8** > **6** (Table 4).

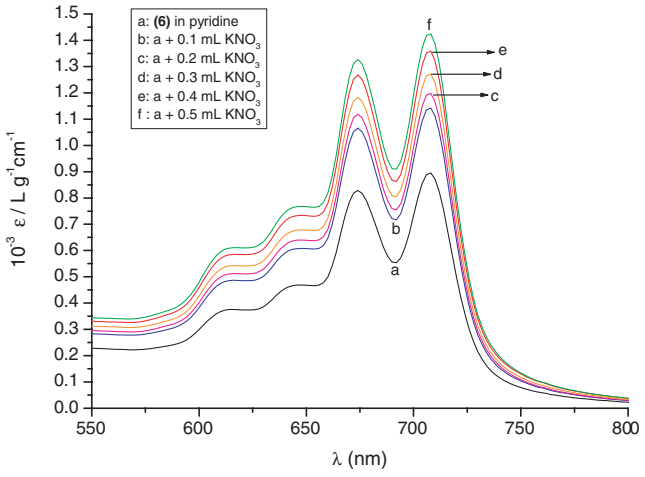

Fig. 4. Changes in the visible spectra of **6** in pyridine (1.0×10^{-3} g/L) after the addition of KNO_3 solutions in methanol (1.0×10^{-3} M).

Table 3
Electrical conductivity and intrinsic viscosities of the polymeric phthalocyanines at room temperature

Compound	M	Conductivity (S cm^{-1})		Pellet thickness (mm)	Intrinsic viscosity, η (H_2SO_4)
		In argon	In vacuum		
6	2H	1.12×10^{-7}	9.76×10^{-8}	0.55	0.75
6a	2H	1.83×10^{-7}	1.01×10^{-7}	0.45	
7	Zn	1.05×10^{-7}	7.48×10^{-8}	0.60	0.67
8	Cu	3.06×10^{-7}	6.28×10^{-7}	0.45	0.89
9	Co	2.70×10^{-8}	8.77×10^{-8}	0.55	0.62
10	Ni	2.88×10^{-4}	1.56×10^{-5}	0.60	0.89

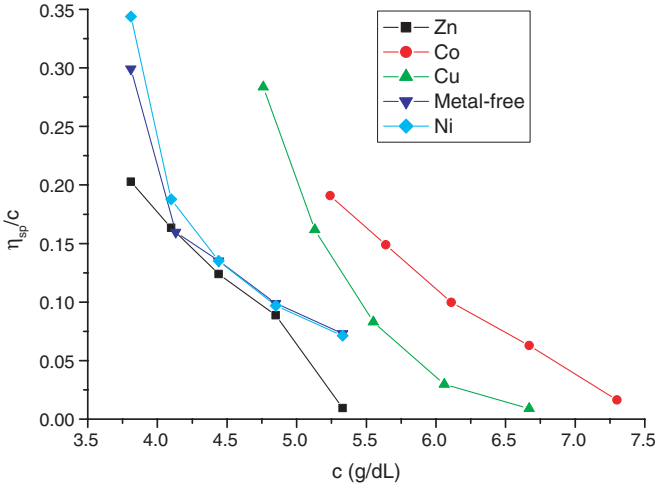

Fig. 5. Intrinsic viscosities of the polymeric phthalocyanines.

Cu-containing polymer **8** was the most rapidly degraded metallophthalocyanine while Zn-, Ni- and Co-containing metallophthalocyanine polymers showed good thermal stability under working conditions.

The alkali metal-binding ability of diaza-18-crown-6 units containing polymers were evaluated. Due to their insolubility, heterogeneous phase extraction of alkali metal picrates from THF solutions to the solid metal-free polymer was investigated. Picrate was used as counter anion for all compounds. The results can be seen in Table 1. Examinations of the data reveal the following results: (a) the tendency of binding alkali picrates goes parallel with the increase in the ionic diameter except for Cs^+ and (b) the highest extraction affinity of **6** was determined as 94.25% for K^+. The extraction affinity of **6** for Li^+, Na^+, K^+, Cs^+ were determined as 6.01%, 77.17%, 94.25% and 22.16%, respectively. The highest extraction affinity in the case of K^+ is probably due to the more compatibility of K^+ with macrocyclic unit than the other ions.

Table 4
Thermal properties of the polymeric phthalocyanines

Compound	M	Initial decomposition temperature in °C	Main decomposition temperature in °C
6	2H	335	475
7	Zn	400	675
8	Cu	350	590
9	Co	360	660
10	Ni	355	625

4. Conclusions

We have presented the synthesis and characterization of polymeric phthalocyanines with diaza-18-crown-6 ethyleneoxy bridges. The metal-free phthalocyanine polymer (**6**) and metallophthalocyanine polymers were prepared using a tetranitrile monomer and proper materials. Zn-, Ni- and Co-containing polymers showed good thermal stability while Cu-containing and the metal-free polymers were the most rapidly degraded. The electrical conductivities of the polymeric phthalocyanines measured as gold sandwiches were found to be 10^{-9}–10^{-4} S cm^{-1} *in vacuo* and argon. The extraction ability of **6** was evaluated in THF by using several alkali metal picrates and the highest extraction affinity was observed for K^+. The intrinsic viscosity of the metal-free polymer and metallophthalocyanine polymers were similar. The metal-free polymeric phthalocyanine (**6**) had a clear disaggregation tendency with the addition of KNO_3, $NaNO_3$ and NH_4NO_3.

Abstract

A novel phosphite-based hetero-polyoxomolybdate, $[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$, has been isolated and structurally characterized. The most striking feature of this polyanion is the presence of peripheral phosphite groups linked to the MoO_6 octahedra. In the solid state, this cluster shows strong hydrogen bonding interactions that apparently play a key role in its stabilization and isolation from solution.

1. Introduction

Polyoxometalates (POM) are discrete polyanionic fragments of early transition metal oxides, specially vanadium, molybdenum and tungsten, which usually adopt highly symmetrical structural motifs. The introduction of heteroatoms such as P, As, Sb, Se or Bi in polyoxometalates leads to higher versatility in the chemical properties and molecular structures. Although the research on POM chemistry [1–3] began more than hundred years ago, they reached great importance from the second half of the 20th century and up to this date. The great interest of this subject is justified because the large structural variety and tunable chemical and physical properties make POM very attractive candidates which can be used in very different fields such as catalysis [4,5] (homogeneous and heterogeneous), electrochemistry [6], electrochromism [7], conductivity [8], magnetism [9–11] or medicine [12,13] (anti-viral and anti-tumoral agents).

The controlled formation of polyoxometalates, and specially the rational directed synthesis of specific structures presents a major challenge, attending to the large number of factors which must be considered relevant in their synthesis: temperature, molecular ratio M/X, the nature of the solvent, pH value or the nature of the counter ions. In the search for novel structural motifs, some different synthetic strategies from normal solution techniques have successfully been employed, as hydrothermal methods [14,15].

Although their great structural diversity, from the well-known Keggin and Dawson-Wells structures to giant nanosized clusters [16], all polyoxometalates are formed from a relatively low number of highly symmetrical MO_x polyhedrons, usually octahedral or tetrahedral, and in some cases pentacoordinated square-based pyramids, where the corners of the polyhedra are occupied by oxygen atoms. On the contrary, polyoxometalates possessing pyramidal lone electron pair atoms in its structure are quite rare, although some examples have been described with elements such as P^{III}, As^{III}, Sb^{III}, Se^{IV} or Bi^{III} [17–20]. Most of these are coming from the search for aminoacid-bound polyanions, where the pyramidal lone electron pair atom resides in the center of a hexagonal ring of V, Mo or W octahedra, lying slightly above the plane defined by the

doi:10.1016/j.poly.2006.08.030

metal atoms, with the three oxygen atoms of the $[H_nX^{III}O_3]^{-3+n}$ $(0 < n < 3)$ unit acting as bridges between the metal centers.

Using the flexibility of the hexameric core of Mo(VI) octahedra, which appears to be a recurrent structural motif in POM chemistry, in this work we report the synthesis and structural characterization of a novel phosphite-based polymolybdate, that exhibits for the first time terminal pyramidal lone electron pair units. Due to this peculiar feature, $[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$ can only be isolated in the presence of strong hydrogen bonding interactions, promoted in this case by ethylendiamine molecules.

2. Experimental

2.1. Synthesis

All reagents were of commercial grade and used without further purification.

$Na(H_2en)_4[Mo_6(PO_3)(HPO_3)_3O_{18}]\cdot 3H_2O$ (**1**) was synthesized as yellow block-like crystals in 40% yield (based on Mo, 1.7 mmol). Two solutions were prepared separately: (A) $Na_2MoO_4\cdot 2H_2O$ (0.4 g; 1.7 mmol) and NH_4VO_3 (0.2 g; 1.7 mmol) in 7 mL of water and (B) $Ni(OAc)_2$ (0.35 g; 1.4 mmol) and ethylenediamine (3 mL) in 3 mL of water. Solution (B) is added to solution (A) and the mixture is stirred for 10 min. After that a 50% (wt%) H_3PO_3 aqueous solution is prepared "in situ" and slowly added, pH of the solution was controlled very carefully, the solution presented violet color and a starting pH value of 11, after the acid addition the solution presented a pH value of 6.6 and its color had turned to dark green. The resulting dark green solution was filtered to remove any solid in solution and was left to stand at room temperature. After several days the block-like pale-yellow crystals of **1** were collected by filtration and separated by hand. The IR spectrum of compound **1** exhibited a pattern of bands at 1621(m), 1520(m), 1455(w), 1327(w), 1088(s), 1031(s), 910(s), 669(m), 592(w), 561(w) and 503(w) cm^{-1} (see Table 1).

2.2. Physical measurements

A yellow plate-like single crystal with dimensions $0.3\times 0.1\times 0.3$ mm was mounted on a glass fiber for indexing and intensity data collection at room temperature on a Siemens SMART KappaCCD diffractometer equipped using graphite-monochromated Mo Kα radiation ($\lambda =$ 0.71073 Å). Direct methods were used to solve the structure and to locate the heavy atoms (SIR-97) [21]. The remaining atoms were found from successive difference maps and refined against F^2 with a full-matrix least-squares algorithm using SHELXL-97 [22]. The final cycle of refinement, including the atomic coordinates, anisotropic thermal parameters (all metal and phosphorus atoms), and isotropic thermal parameters (all oxygen, carbon and nitrogen atoms), converged at $R_1 = 0.0528$ and $wR_2 = 0.1135$. Crystallographic data are summarized in Table 2.

3. Results and discussion

$[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$ was obtained in good yield as $Na(H_2en)_4[Mo_6(PO_3)(HPO_3)_3O_{18}]\cdot 3H_2O$ (**1**). It is the main product from the reaction of an aqueous solution of $Na_2MoO_4\cdot 2H_2O$, NH_4VO_3, $Ni(OAc)_2$ and ethylenediamine in the presence of the H_3PO_3 acid with strict control of the pH value during the reaction. Usually, this type of

reactions yield reduced heteropolymolybdates, with the phosphite getting oxidized to phosphate $(PO_4)^{3-}$ [23]. Surprisingly, in the mild conditions we use (room temperature during all the process) the phosphorus atoms maintain its oxidation state in the final compound. We attempted many times to obtain compound **1** in the absence of NH_4VO_3 and $Ni(OAc)_2$, two reagents that do not appear in compound **1**, but we did not succeed in the isolation of this polyanion. Therefore, these reagents must participate somehow in the process. It is difficult to explain their role in the reaction, though. NH_4VO_3 is probably involved in the control of the pH value and the Ni^{2+} ions in the given concentration of free ethylenediamine in solution. It is important to remark that ethylenediamine molecules are crucial in the stabilization of the final structure through hydrogen bond interactions which links the polyanionic clusters leading to the final packing.

The structure of **1** contains $[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$ anions, surrounded by protonated ethylendiamine and solvent molecules. The structure of polyanion (Fig. 1) consists of a six-membered ring of MoO_6 octahedra, which alternate in sharing edges and corners. A central phosphite group is present with its phosphorus atom located slightly above the plane of six molybdenum atoms. The most striking feature of this new polymolybdate resides in the existence of other three terminal phosphite groups on one side of the ring, capping the edge-sharing Mo dimers with two oxygen atoms, with the free oxygen atom from each group perpendicular to the ring, forming a basket-like structure. The lone pair of the central phosphite group also points towards same side of the ring as the peripheral phosphite groups. The octahedral coordination of the Mo atoms is completed with two terminal oxo groups, one equatorial on the plane of the ring, and the other on the opposite side of the ring with respect to the phosphite groups. The polyanion is highly symmetric with a molecular threefold axis running through the central phosphorus atom, perpendicular to the plane defined by the Mo atoms.

The Mo–O distances to the phosphite oxygen atoms (2.402 Å $\leqslant d \geqslant$ 2.186 Å) are larger than the rest of Mo–O distances (1.881 Å $< d <$ 1.986 Å). All phosphorus atoms present the same trigonal pyramid geometry, with all P–O distances in a 0.03 Å range and all O–P–O angles in a 4.06° range. Only the terminal O atoms from the phosphite appear protonated, according to the bond-valence sum calculation [24]. Taking this into account, the overall charge for the polyanion is −9. Therefore, the ethylendiamine molecules must be protonated, for electroneutrality. The presence of one Na atom was revealed by elemental analysis, and its position in the structure was assigned to the only peak surrounded exclusively by O atoms, with no interactions with any ethylendiamine unit.

It is important to state the existence of significant hydrogen bonding interactions in the structure. The strongest ones involve oxygen atoms of the peripheral phosphite groups and hydrogen atoms protonated ethylendiamine cations (Fig. 2). This also dictates the conformation of the ethylendiamine molecules. Two of them present a *cis* conformation. Terminal oxygen O28 is chelated by one ethylendiamine unit, with O···N distances 2.794(13) and 2.791(12) Å to N5 and N6, respectively. Terminal oxygen O29 interact with the other ethylendiamine in *cis*

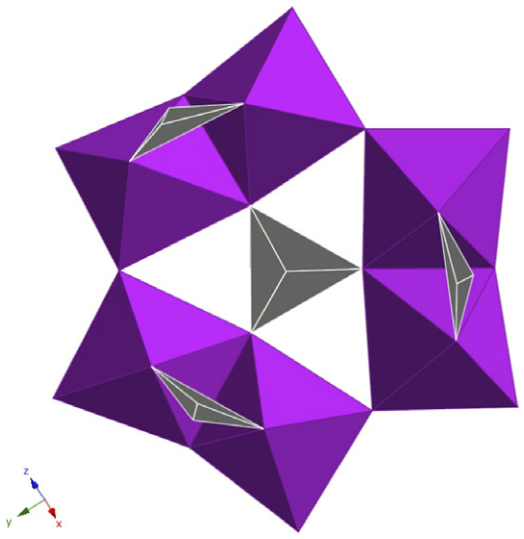

Fig. 1. Polyhedral representation of the polymolybdate anion. The MoO_6 octahedra are shown in violet and the PO_3^{3-} and HPO_3^{2-} groups in grey. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

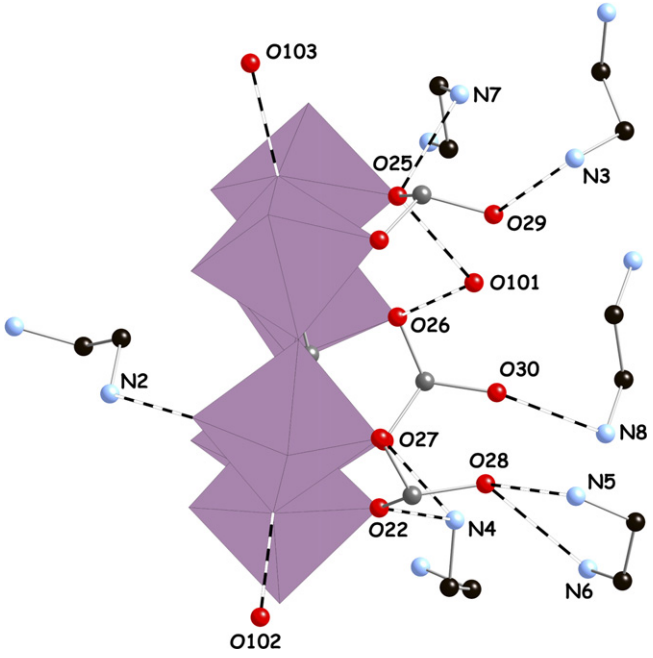

Fig. 2. Representation of the shortest hydrogen bonding interactions (dashed lines) between a $[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$ polyanion and its surroundings in the crystal structure of **1**. The balls represent molybdenum (violet), phosphorus (grey), oxygen (red), nitrogen (blue), carbon (black) (H atoms omitted for the sake of clarity). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

(O29···N3 = 2.684(11) Å) that connects to adjacent anions through the N4···O22 and N4···O27 contacts (2.688(11) and 2.742(11) Å, respectively). Terminal oxygen O30 shows a close contact (O30···N8 = 2.691(11) Å) to an ethylendiamine group, that exhibits *trans* configuration. This cation also links to adjacent anions through the slightly longer N7···O7 and N7···25 hydrogen bonds (2.842(12) and 2.869(11) Å, respectively). Finally, the remaining ethylendiamine shows stronger interactions with the opposite side of the anions, for a shortest distance of 2.777(13) Å (O2···N2). The water molecules play also an important role in the H bonding network. Water O101 shows contacts at 2.701(11) and 2.771(12) Å to oxygen atoms from phosphite groups (O26 and O25, respectively). The other two water molecules, on the contrary, bind core oxo groups: O102···O13 = 2.745(12) Å and O103···O15 = 2.754(12) Å. All these contacts, along with many other ones below 2.9 Å, create a complex 3D H-bonding network, showing a layered pseudo-hexagonal packing for the polyanions. Two types of layers can be distinguished running perpendicular to the *a* axes with a repeating pattern ...AB... (Fig. 3).

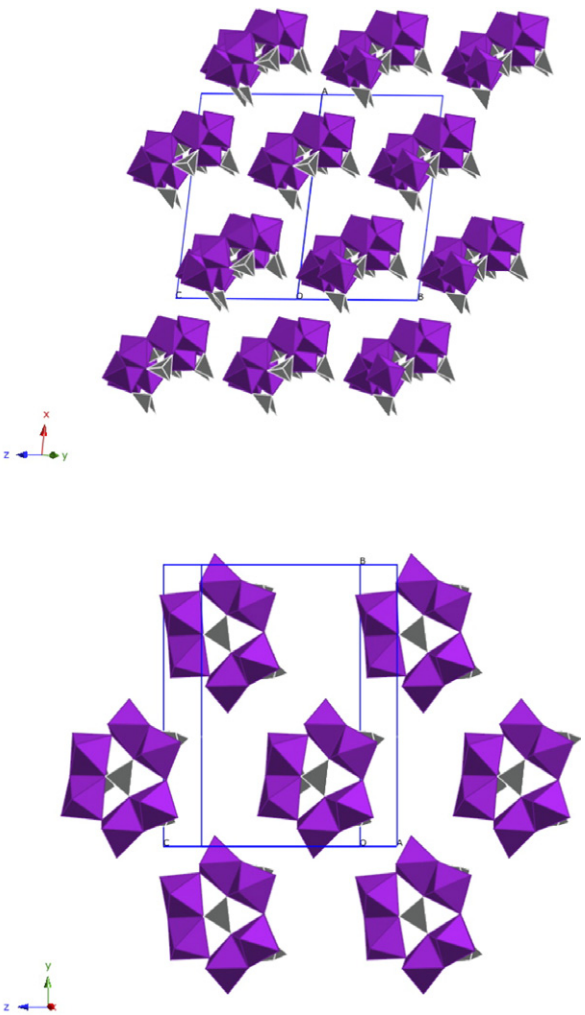

Fig. 3. (Top) View of the anionic layers of $[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$ units and their packing along the *a* axis. (Bottom) View of the pseudo-hexagonal packing on the *bc* plane. The color code is the same as in Fig. 1. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

In addition to their influence in determining the crystal structure, the O···N interactions between phosphite and ethylendiamine groups should also favor the stability of this compound in solution, allowing for its crystallization. As mentioned before, this is the first example of a POM with terminal phosphite groups, and the presence of so many, strong and varied interactions of these groups with the surrounding cations evidence that they are an important factor for its stability.

The structure of the $[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$ cluster is reminiscent of other similar structures, with several differences: on one hand, all other structures possess only one central pyramidal lone electron pair unit, with the three capping positions occupied either by carboxylate [17,18], organoarsonate [25,26], or tetrahedral $[X^{VI}O_4]^{2-}$ groups (X = S, Se) [19,20]. In most cases the cluster appears partially reduced, and in all cases the cluster is in its anionic form.

All attempts to dissolve **1** in any common organic or inorganic solvent failed, even in mixtures of them. Acid or basic solutions are able to dissolve the solid, but the cluster does not exist in solution as proven by mass spectroscopy, and cannot be recovered anymore.

4. Conclusions

In this paper we report the synthesis and structural characterization of a novel phosphite based polyoxometalate with formula $[Mo_6(PO_3)(HPO_3)_3O_{18}]^{9-}$. It is important to remark that few POMs with pyramidal lone electron pair atoms in their structure have been previously described and, in addition, **1** is the first example where such trigonal pyramidal polyhedra appear as terminal groups. A strong hydrogen bonded network stabilizes this POM in the solid state. As chemistry interest is moving from molecular to supramolecular organizations, this cluster is a clear example of how supramolecular chemistry can indeed expand the reach of molecular species. The poor solubility of **1** could now be improved by exchange of ethylendiamine by other ligands, able to participate in hydrogen bonded networks to assure its stability. Then, **1** could be used as building block in other reactions, either as ligand towards transition metal cations, or even as a source of hexa-vacant Keggin-type structure $[Mo_6(PO_3)O_{18}]$, by removal of the very labile phosphite groups. Such species would have 12 terminal oxygen atoms, which are strong basic sites susceptible to be attacked by electrophilic species in condensation reactions.

Trinuclear Schiff base complexes with uranium(V) and copper(II) or zinc(II) ions

Lionel Salmon, Pierre Thuéry, Michel Ephritikhine *

Service de Chimie Moléculaire, DSM, DRECAM, CNRS URA 331, Laboratoire Claude Fréjacques, Bat. 125, CEA/Saclay, 91191 Gif-sur-Yvette, France

Received 12 June 2006; accepted 23 August 2006
Available online 30 August 2006

Abstract

Treatment of the uranium(IV) complexes $[\{ML^1(py)\}_2U^{IV}]$ (M = Cu, Zn; L^1 = *N*,*N*′-bis(3-hydroxysalicylidene)-1,3-propanediamine) with silver nitrate in pyridine led to the formation of the corresponding cationic uranium(V) species which were found to be thermally unstable and were converted back into the parent U^{IV} complexes; no electron transfer was observed in solution between the U^{IV} and U^V compounds. In the crystals of $[\{ML^1(py)\}_2U^{IV}][\{ML^1(py)\}_2U^V][NO_3]$, the neutral U^{IV} and cationic U^V species are clearly identified by the distinct U–O distances. Similar reaction of $[\{ZnL^2(py)\}_2U^{IV}]$ [L^2 = *N*,*N*′-bis(3-hydroxysalicylidene)-1,4-butanediamine] with $AgNO_3$ gave crystals of $[\{ZnL^2(py)\}U^V\{ZnL^2(py)_2\}][NO_3]$ but the copper counterpart was not isolated. Crystals of $[\{ZnL^1(py)\}_2U^V][OTf]\cdot THF$ ($OTf = OSO_2CF_3$) were obtained fortuitously from the reaction of $[Zn(H_2L^1)]$ and $U(OTf)_3$.

1. Introduction

We recently reported on the synthesis, crystal structure and magnetic behaviour of a series of trinuclear Schiff base complexes of general formula $[\{ML^i(py)_x\}_2An^{IV}]$ (M = Cu, Zn; An = Th, U) where the central actinide(IV) ion is surrounded by the eight oxygen atoms of two hexadentate bicompartmental Schiff base ligands L which are orthogonal to one another and contain a Cu^{II} or Zn^{II} ion in their inner N_2O_2 cavity [1,2]. We were interested in studying the corresponding uranium(V) derivatives $[\{ML^i(py)_x\}_2U^V]^+$ for two reasons. The synthesis of such complexes is somewhat challenging because of the instability of U^V versus U^{IV} and U^{VI}, but a number of pentavalent uranium compounds with oxygen ligands have been isolated [3–7], since the discovery of the alkoxides $U(OR)_5$ [8]. The isolation of the $[\{ML^i(py)_x\}_2U^V]^+$ complexes, first examples of heteronuclear compounds associating 3d and $5f^1$ ions, would permit to determine the nature of the magnetic interaction between these ions. The presence of a single f electron on the U^V ion could facilitate the elaboration of a general theoretical model to describe the magnetic susceptibility of a 4f or 5f ion which possesses a first-order orbital momentum. Here we present our attempts to synthesize the compounds $[\{ML^i(py)_x\}_2U^V][NO_3]$ [M = Cu or Zn; L^1 = *N*,*N*′-bis(3-hydroxysalicylidene)-R with R = 1,3-propanediamine ($i = 1$) or 1,4-butanediamine ($i = 2$)] by oxidation of the parent uranium(IV) complexes with $AgNO_3$; these reactions afforded crystals of $[\{ML^1(py)\}_2U^{IV}][\{ML^1(py)\}_2U^V][NO_3]\cdot 4py$ (M = Cu, Zn) and $[\{ZnL^2(py)\}U^V\{ZnL^2(py)_2\}][NO_3]\cdot py$ which were characterized by X-ray diffraction analysis. We also describe the crystal structure of $[\{ZnL^1(py)\}_2U^V][OTf]\cdot THF$ ($OTf = OSO_2CF_3$) which was obtained fortuitously from the reaction of $[Zn(H_2L^1)]$ and $U(OTf)_3$. However, the unsuccessful synthesis of the pure $Cu^{II}_2U^V$ compounds precluded the magnetic properties to be investigated.

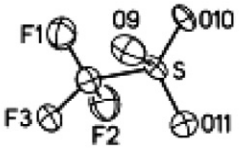
2. Results and discussion



2.1. Synthesis of the complexes

In the presence of one equivalent of $AgNO_3$ in pyridine at 20 °C, $[\{CuL^1(py)\}_2U^{IV}]$ was partially transformed into the uranium(V) derivative $[\{CuL^1(py)\}_2U^{V}][NO_3]$; no electron transfer was detected by NMR spectroscopy between the U^{IV} and U^{V} complexes. Total conversion of U^{IV} into U^{V} required the addition of three equivalents of the silver salt and after usual work-up, $[\{CuL^1(py)\}_2U^{V}][NO_3]$ was isolated as a black powder in 28% yield. While the ^1H NMR spectrum did not show the presence of impurities, the elemental analyses were not satisfactory and attempts to purify the product were unsuccessful. The uranium(V) complex was found to be sensitive to heat, being converted back into the U^{IV} congener. Dark brown crystals of the mixed-valence compound $[\{CuL^1(py)\}_2U^{IV}][\{CuL^1(py)\}_2U^{V}][NO_3]\cdot 4py$ were deposited from a pyridine solution at 80 °C. The synthesis of $[\{ZnL^1(py)\}_2U^{V}][NO_3]$ was easier than that of the copper analogue, not requiring an excess of $AgNO_3$, and this $Zn_2^{II}U^{V}$ complex proved to be stable, up to 80 °C, towards the $U^{V}\rightarrow U^{IV}$ reduction. However, it was not obtained analytically pure; a refluxing pyridine solution of the complex deposited dark brown crystals of $[\{ZnL^1(py)\}_2U^{IV}][\{ZnL^1(py)\}_2U^{V}][NO_3]\cdot 4py$. In contrast, oxidation of $[\{ZnL^2(py)\}_2U^{IV}]$ was totally achieved upon addition of one equivalent of $AgNO_3$ in pyridine, and dark brown crystals of the stable, analytically pure, uranium(V) compound $[\{ZnL^2(py)\}U^{V}\{ZnL^2(py)_2\}][NO_3]\cdot py$ were isolated in 80% yield. Unfortunately, the copper analogue of this $Zn_2^{II}U^{V}$ complex was not obtained in a pure form. As previously noted with uranium(V) amide compounds, the factors, steric and electronic, which determine the stability of the +5 oxidation state of uranium are not well understood [4].

Treatment of $[Zn(H_2L^1)]$ with $U(OTf)_3$ in pyridine afforded a mixture of the dinuclear and trinuclear uranium(IV) complexes $[\{ZnL^1(py)_x\}U^{IV}(OTf)_2]$ and $[\{ZnL^1(py)_x\}_2U^{IV}]$. This result is not surprising since oxidation reactions of trivalent uranium complexes by alcohols and phenols have some precedents [9–11]. Heating the mixture under reflux gave dark yellow crystals of $[Hpy][\{ZnL^1(py)\}_2U^{IV}][OTf]$ together with a few dark brown crystals of $[\{ZnL^1(py)\}_2U^{V}][OTf]\cdot THF$; this latter uranium(V) complex likely resulted from oxidation by adventitious traces of air.

2.2. Crystal structures of the complexes

The crystal structures of the M_2U complexes permit, after the couple of dithiolene compounds $[U(C_8H_8)(dddt)_2]^{n-}$

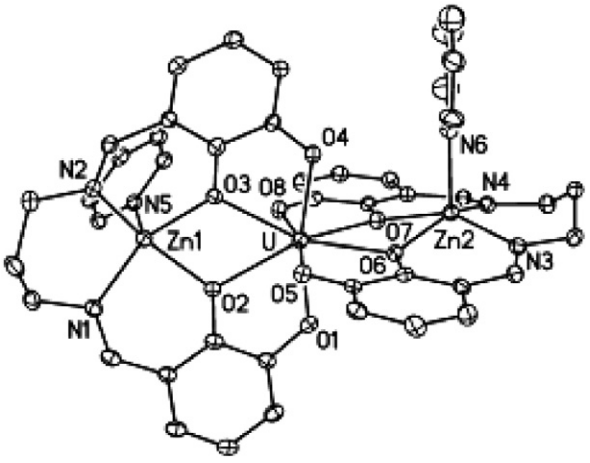


Fig. 2. View of $[\{ZnL^1(py)\}_2U^{V}][OTf]$. The hydrogen atoms are omitted for clarity. Displacement ellipsoids are drawn at the 20% probability level.

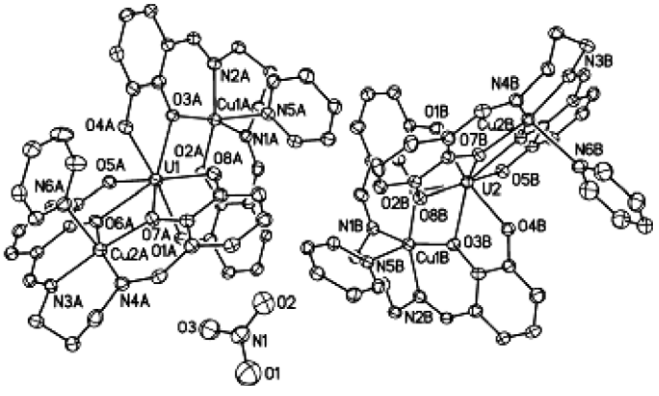

Fig. 1. View of $[\{CuL^1(py)\}_2U^{IV}][\{CuL^1(py)\}_2U^{V}][NO_3]$. The hydrogen atoms are omitted for clarity. Only one position of the disordered pyridine molecule is represented. Displacement ellipsoids are drawn at the 20% probability level.

($n = 1$ or 2; dddt = 5,6-dihydro-1,4-dithiin-2,3-dithiolate) [12], a direct comparison of analogous U^{IV} and U^{V} derivatives. All the trinuclear compounds adopt the same structure which has already been described with the series of $[\{ML^{i}(py)_x\}_2An^{IV}]$ complexes. The 3d ions occupy the inner N_2O_2 cavities of the bicompartmental Schiff base ligands and are found in a square-pyramidal or octahedral coordination mode, depending on whether one or two pyridine molecules are attached to them; the uranium atom is inside the dodecahedron defined by the oxygen atoms of the L^{i} ligands, which form two orthogonal trapeza, O1–O2–O3–O4 and O5–O6–O7–O8. Views of $[\{CuL^{1}(py)\}_2U^{IV}]$-$[\{CuL^{1}(py)\}_2U^{V}][NO_3]$, $[\{ZnL^{1}(py)\}_2U^{V}]$ [OTf] and of the cation $[\{ZnL^{2}(py)\}U^{V}\{ZnL^{2}(py)_2\}]^{+}$ are shown in Figs. 1–3, respectively; selected bond lengths and angles are listed in Table 1.

The crystals of $[\{ML^{1}(py)\}_2U^{IV}][\{ML^{1}(py)\}_2U^{V}]$-$[NO_3]\cdot 4py$, isomorphous for M = Zn and Cu, are

composed of discrete neutral and cationic trinuclear complexes $[\{ML^1(py)\}_2U]^{0,+1}$, nitrate ions and solvent molecules. The attribution of the electronic charge, 0 or +1, and consequently the uranium oxidation state, +4 or +5, to the complexes labelled A and B, respectively, is unambiguous in view of the distinct geometrical parameters; this clear differentiation is in agreement with the absence of electron transfer observed in solution. The bond lengths and angles in the neutral complexes A are essentially the same as those found in the previously reported structures of $[\{CuL^1(py)\}U^{IV}\{CuL^1\}]\cdot py$ and $[\{ZnL^1(py)\}_2U^{IV}]\cdot 2.5py$ [1]. The geometrical parameters in $[Hpy][\{ZnL^1(py)\}_2U^{IV}][OTf]$ are also quite similar, except the U–O4 distance which is larger because of the presence of an hydrogen bond between O4 and the pyridinium cation [N7···O4 2.535(5) Å, N7–H···O4 173°]. However, the U–O distances in the cationic species B are systematically shorter than the corresponding U–O distances in the neutral counterparts A, in agreement with the variation in the radii of the U^{IV} and U^V ions [13]; this shortening is more important for the U–O_t distances between the metal and the terminal oxygen atoms O1, O4, O5 and O8 (ca. 0.11 Å) than for the U–O_b distances between the metal and the bridging oxygen atoms O2, O3, O6 and O7 (ca. 0.05 Å). Moreover, the average U–O, U–O_b and U–O_t distances in complex B of $[\{ZnL^1(py)\}_2U^{IV}][\{ZnL^1(py)\}_2U^V][NO_3]\cdot 4py$ are quite identical to those measured in the uranium(V) cations of $[\{ZnL^1(py)\}_2U^V][OTf]\cdot THF$ and $[\{ZnL^2(py)\}U^V\{ZnL^2(py)_2\}][NO_3]\cdot py$. Comparison of the structure of the latter with that of the uranium(IV) analogue $[\{ZnL^2(py)\}_2U^{IV}]\cdot 2py$ [2] shows the same differences between the U^{IV}–O and U^V–O distances. The coordination geometry of the 3d ions is not significantly affected by changing the oxidation state of uranium in the $[\{ML^i(py)\}_2U]^{0,+1}$ complexes. In particular, the average M–O and M–N distances in complexes A and B of $[\{ML^1(py)\}_2U^{IV}][\{ML^1(py)\}_2U^V][NO_3]$ are identical, with values of 1.950 and 1.997 Å for M = Cu and 2.03 and 2.07 Å for M = Zn, respectively. As observed with the uranium(IV) compounds $[\{ML^i(py)\}_2U^{IV}]$, the length of the diimino chain of L^i has practically no influence on the environment of the U^V ion, while the Zn···U distances slightly increase by ca. 0.04 Å when passing from L^1 to L^2.

3. Experimental

3.1. General

All reactions were carried out under argon (<5 ppm oxygen or water) using standard Schlenk-vessel and vacuum-line techniques or in a glove box. Solvents were dried by standard methods and distilled immediately before use; deuterated pyridine (Eurisotop) was distilled over NaH and stored over 3 Å molecular sieves. The ^1H NMR spectra were recorded on a Bruker DPX 200 instrument and referenced internally using the residual protio solvent resonances relative to tetramethylsilane ($\delta = 0$). Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany). The complexes $[Zn(H_2L^1)]$, $[\{ML^i(py)_x\}_2U]$ [1,2] and $U(OTf)_3$ [14] were synthesized as previously described.

3.2. Syntheses

3.2.1. Reaction of $[\{CuL^1(py)\}_2U^{IV}]$ and $AgNO_3$

(a) An NMR tube was charged with $[\{CuL^1(py)\}_2U^{IV}]$ (10.0 mg, 0.0087 mmol) and $AgNO_3$ (1.5 mg, 0.0087 mmol) in pyridine-d_5 (0.4 mL). After 1 h at 20 °C, the spectrum indicated that 60% of the uranium(IV) complex were converted into the uranium(V) derivative $[\{CuL^1(py)\}_2U^V][NO_3]$. ^1H NMR spectrum (pyridine-d_5, 23 °C): −12.20 (4H, –CH_2–), 5.65, 10.32 and 25.54 (3 × 4H, aromatic H), 101.20 (8H, NCH_2). Further addition of 2 equiv. of $AgNO_3$ (3.0 mg, 0.0174 mmol) led to the complete formation of the uranium(V) complex. Dark brown crystals of $[\{CuL^1(py)\}_2U^{IV}][\{CuL^1(py)\}_2U^V][NO_3]\cdot 4py$ were obtained after heating the mixture at 80 °C for 5 days. The uranium(IV) complex was the sole species detected in solution after prolonged heating at 110 °C.

(b) A flask was charged with $[\{CuL^1(py)\}_2U^{IV}]$ (80.0 mg, 0.075 mmol) and $AgNO_3$ (38.1 mg, 0.225 mmol) in pyridine (15 mL). After stirring for 2 days at 20 °C, the Ag precipitate was filtered off, the solution was evaporated to dryness, leaving a black powder of $[\{CuL^1(py)\}_2U^V][NO_3]$ which was washed with pyridine (5 mL) and dried under vacuum (25 mg, 28%). The ^1H NMR spectrum does not show the presence of impurities but the elemental analyses suggest contamination with $AgNO_3$. *Anal.* Calc. for $C_{44}H_{38}N_7O_{11}Cu_2U$: C, 43.81; H, 3.15; N, 8.13. Found: C, 39.46; H, 3.18; N, 9.48%.

3.2.2. Reaction of $[\{ZnL^1(py)\}_2U^{IV}]$ and $AgNO_3$

(a) An NMR tube was charged with $[\{ZnL^1(py)\}_2U^{IV}]$ (10.0 mg, 0.0087 mmol) and $AgNO_3$ (1.5 mg, 0.0087 mmol) in pyridine-d_5 (0.4 mL). The spectrum indicated the quantitative formation of $[\{ZnL^1(py)\}_2U^V][NO_3]$. ^1H NMR spectrum (pyridine-d_5, 23 °C): 1.29 (4H, –CH_2–), 3.25 (8H, NCH_2), 5.65 (4H, CH=N), 5.90, 8.36 and 8.66 (3 × 4H, aromatic H). The uranium(V) compound was stable up to 80 °C, but was converted into the U^{IV} congener upon heating at 110 °C. Dark brown crystals of $[\{ZnL^1(py)\}_2U^{IV}][\{ZnL^1(py)\}_2U^V][NO_3]\cdot 4py$ were obtained after heating at 110 °C for 5 days.

(b) A flask was charged with $[\{ZnL^1(py)\}_2U^{IV}]$ (120.0 mg, 0.104 mmol) and $AgNO_3$ (17.8 mg, 0.104 mmol) in pyridine (15 mL). After stirring for 12 h at 20 °C, the Ag precipitate was filtered off, the solution was evaporated to dryness, leaving a black powder of $[\{ZnL^1(py)\}_2U^V][NO_3]$ which was washed with pyridine (5 mL) and dried under vacuum (57 mg, 45%). Satisfactory elemental analyses were not obtained. *Anal.* Calc. for $C_{44}H_{38}N_7O_{11}Zn_2U$: C, 43.68; H, 3.14; N, 8.11. Found: C, 41.38; H, 3.34; N, 9.06%.

3.2.3. Reaction of $[\{ZnL^2(py)\}_2U^{IV}]$ and $AgNO_3$

An NMR tube was charged with $[\{ZnL^2(py)\}_2U^{IV}]$ (10.0 mg, 0.0085 mmol) and $AgNO_3$ (1.5 mg, 0.0085 mmol) in pyridine-d_5 (0.4 mL). The spectrum indicated the quantitative formation of $[\{ZnL^2(py)\}_2U^{V}][NO_3]$. ^{1}H NMR spectrum (pyridine-d_5, 23 °C): 1.27 (8H, –CH_2–), 3.20 (8H, NCH_2), 5.65 (4H, CH=N), 6.05, 8.55 and 8.81 (3 × 4H, aromatic H). Dark brown crystals of $[\{ZnL^2(py)\}U^{V}\{ZnL^2(py)_2\}][NO_3]\cdot py$ were obtained after heating at 60 °C for 5 days (9.0 mg, 80%). The elemental analyses are in agreement with the formula $[\{ZnL^2(py)\}U^{V}\{ZnL^2(py)_2\}][NO_3]$. *Anal.* Calc. for $C_{51}H_{47}N_8O_{11}Zn_2U$: C, 46.51; H, 3.57; N, 8.51. Found: C, 46.38; H, 3.72; N, 8.69%.

3.2.4. Reaction of $[Zn(H_2L^1)]$ and $U(OTf)_3$

An NMR tube was charged with $[Zn(H_2L^1)]$ (5.0 mg, 0.013 mmol) and $U(OTf)_3$ (9.1 mg, 0.013 mmol) in pyridine (0.4 mL). After 30 min at 20 °C, the spectrum showed the formation of the dinuclear $[\{ZnL^1(py)_x\}U^{IV}(OTf)_2]$ and trinuclear $[\{ZnL^1(py)_x\}_2U^{IV}]$ uranium(IV) species in the relative proportions of 50:50. ^{1}H NMR spectrum of $[\{ZnL^1(py)_x\}U^{IV}(OTf)_2]$ (pyridine-d_5, 23 °C): −14.27 (2H, –CH_2–), −10.11 (4H, NCH_2), 21.13, 45.25 and 97.87 (3 × 2H, aromatic H); ^{1}H NMR spectrum of $[\{ZnL^1(py)_x\}_2U^{IV}]$ (pyridine-d_5, 23 °C): −9.45 (4H, –CH_2–), −7.72 (8H, NCH_2), 0.10 (4H, CH=N), 5.44, 14.92, and 24.97 (3 × 4H, aromatic H). Prolonged heating of the solution at 110 °C led to the formation of dark yellow crystals of $[Hpy][\{ZnL^1(py)\}_2U^{IV}][OTf]$ together with few dark brown crystals of $[\{ZnL^1(py)\}_2U^{V}][OTf]\cdot THF$.

3.3. Crystallography

The data were collected at 100(2) K on a Nonius Kappa-CCD area detector diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The crystals were introduced into glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from 10 frames, then refined on all data. The data (φ-scans) [15] were processed with HKL2000 [16]. The structures were solved by Patterson map interpretation or by direct methods with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97 [17]. Absorption effects were corrected empirically with the program DELABS in PLATON [18]. All non-hydrogen atoms were refined with anisotropic displacement parameters, except when specified below. Special details are as follows.

$[\{CuL^1(py)\}_2U^{IV}][\{CuL^1(py)\}_2U^{V}][NO_3]\cdot 4py$. The pyridine molecule bound to Cu2B is disordered over two positions sharing the nitrogen and *para*-carbon atoms, which have been refined with occupancy parameters constrained to sum to unity. All non-hydrogen atoms were refined with anisotropic displacement parameters, except for those of one badly resolved solvent pyridine molecule, which has been refined with a common isotropic displacement factor for the six atoms. Three pyridine molecules

have been refined as idealized hexagons and two of them were affected with a 0.5 occupancy parameter in order to retain acceptable displacement factors. Some restraints on displacement parameters were applied for the atoms of the nitrate ion, seemingly affected with unresolved disorder. Some short C···C and H···H contacts involving the badly resolved, partially occupied pyridine molecules indicate the presence of unresolved disorder or the presence of positions which cannot be occupied simultaneously.

$[\{ZnL^{1}(py)\}_2U^{IV}][\{ZnL^{1}(py)\}_2U^{V}][NO_3]\cdot 4py$. This compound is isomorphous with the copper analogue and the same problems arising from disorder are present. All non-hydrogen atoms were refined with anisotropic displacement parameters, except for those of two badly resolved solvent pyridine molecules, which have been refined as idealized hexagons with a common isotropic displacement factor and an occupancy parameter of 0.5 each in order to retain an acceptable value for the displacement factor. Some restraints on displacement parameters were applied for the atoms of the nitrate ion, seemingly affected with unresolved disorder, for some atoms of one of the bridges in the Schiff base B and for some atoms of the pyridine molecules. Some short C···C and H···H contacts involving the badly resolved, partially occupied pyridine molecules indicate the presence of unresolved disorder or the presence of positions which cannot be occupied simultaneously.

$[\{ZnL^{1}(py)\}_2U^{V}][OTf]\cdot THF$. Restraints on displacement parameters were applied for the oxygen and fluorine atoms of the trifluoromethanesulfonate counter-ion and for the atoms of the THF solvent molecule.

$[Hpy][\{ZnL^{1}(py)\}_2U^{IV}][OTf]$. The hydrogen atom bound to the pyridinium nitrogen atom N7 was found on a Fourier-difference map.

The carbon-bound hydrogen atoms were introduced at calculated positions (except for those of the disordered pyridine molecules in $[\{ML^{1}(py)\}_2U^{IV}][\{ML^{1}(py)\}_2U^{V}][NO_3]\cdot 4py$). All hydrogen atoms were treated as riding atoms with an isotropic displacement parameter equal to 1.2 times that of the parent atom. Crystal data and structure refinement details are given in Table 2. The molecular plots were drawn with SHELXTL [19].

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 610524–610528. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Platinum complexes of the type [Pt(*cis*-1,4-DACH)(L)$_2$]X, where *cis*-1,4-DACH = *cis*-1,4-diaminocyclohexane; L = adenine (ade) (**1**), hypoxanthine (hyp) (**2**), 9-methylguanine (9-megua) (**3**), cytosine (cyt) (**4**), or 1-methylcytosine (1-mecyt) (**5**); and X = SO_4 or Cl_2 groups, were synthesized and characterized by elemental analysis and by ^{1}H, ^{13}C, and ^{195}Pt nuclear magnetic resonance spectroscopy. The crystals of [Pt(*cis*-1,4-DACH)(9-megua)$_2$]SO_4[9-megua-H]$_2SO_4$ (**3**) and [Pt(*cis*-1,4-DACH)(1-mecyt)$_2$]$Cl_2 \cdot 6H_2O$ (**5**) were also subjected to single-crystal X-ray diffraction. The base/PtN4 coordination plane dihedral angles were 74.55° and 85.61° in complex **3** and 78.12° and 81.80° in complex **5**. The platinum had distorted square planar geometry in both complexes; the two adjacent corners were occupied by the two nitrogen atoms of *cis*-1,4-DACH, and the other two corners were occupied by the two N7 atoms of 9-megua in complex **3** and the two N3 atoms of 1-mecyt in complex **5**. The *cis*-1,4-DACH, which has a unique twist-boat configuration, formed a seven-member chelating ring with platinum, which led to considerable strain during bidentate *cis*-1,4-DACH binding. Cations of both complexes **3** and **5** adopted C_2 molecular symmetry. These adducts were the models for the intrastand cross-links that were relevant to the binding of the Pt(II) antitumor drugs to DNA.

1. Introduction

Undesirable side effects and acquired drug resistance limit the clinical effectiveness of cisplatin and its second-generation analog carboplatin [1–6]. Consequently, a third-generation of platinum (Pt) complexes have been developed with 1,2-diaminocyclohexane (DACH) [7–14] as its ligand; these complexes exhibit activity against cisplatin-resistant tumors [15–17]. The DACH-Pt analogs ormaplatin [18] and oxaliplatin [19] and the liposome-entrapped *cis*-bis(neodecanoato)(*trans*-1(*R*),2(*R*)-DACH)-Pt(II) have shown promise in clinical trials [20]. In our laboratory, we have expanded on this research by developing a new class of Pt complexes that have *cis*-1,4-DACH as the carrier ligand [21–25].

Substantial evidence has shown that Pt-based antitumor drugs have DNA as their primary target and block DNA replication as their primary mechanism of action [26–28]. The most frequent DNA adduct of cisplatin is the d(GpG) intrastrand N7, N7 crosslink, which accounts for roughly 60% of these adducts [29,30]. The second most abundant DNA adduct of cisplatin is the d(ApG) intrastrand N7, N7 crosslink, which accounts for approximately 20–30% [31]. Another, less frequent adduct involves N3 of cytosine in cytidine-rich DNA regions [32–34]. Hambley et al. reported a [Pt^{II}(hmp)Cl_2] with homopiperazine as the non leaving amine ligand to interact stereospecifically with DNA to form mostly bifunctional interstrand, and substantially intrastrand adduct [35].

The X-ray structures of all possible cisplatin-bound nucleic acid base adducts have been reported [28–30], providing insight into the structural changes that occur on platination [36–41]. However, little is known about the antitumor Pt complexes containing *cis*-1,4-DACH. *cis*-1,4-DACH exists in three isomeric forms: axial/equatorial (chair), diequatorial (boat), and diaxial (twist-boat) (Fig. 1). Most common is the chair (axial/equatorial) conformation, in which the disposition of the two NH_2 groups is highly unfavorable to chelation. However, in the diaxial (twist-boat) conformation, the molecule can chelate to a metal ion. As shown in our previous studies of the crystal structure of Pt complexes [21–24], *cis*-1,4-DACH assumes the twist-boat conformation in these complexes to facilitate its binding to Pt to form a seven-member chelating ring.

These complexes have shown great clinical promise. The findings that [Pt(*cis*-1,4-DACH)Cl_2] exhibits more in vitro cytotoxicity than either cisplatin or tetraplatin [21] and also has substantial in vivo activity in Pt-DACH-resistant L1210 leukemia cell lines suggest that differences in shape or conformation are important in eliciting the antitumor activity of (*cis*-1,4-DACH)-Pt complexes [24,42]. This marked level of activity also supports the notion that these novel Pt complexes are neither a cisplatin- nor a [Pt(1*R*, 2*R*-DACH)Cl_2]-type analog but rather a system that incorporates properties of both. Although the mechanism underlying the antitumor reactivity has not been established [43], obvious possibilities include the processes of mono- or diadduct formation, recognition and repair, and translation. Hence, *cis*-1,4-DACH-Pt adducts are models for the intrastrand cross-links that are relevant to the binding of Pt antitumor drugs to DNA [44,45].

Here, we report the synthesis and characterization of nucleobase complexes containing *cis*-1,4-DACH-Pt and the crystal structures of [Pt(*cis*-1,4-DACH)(9-methylguanine)$_2$]SO_4[9-methylguanine-H]$_2SO_4$ and [Pt(*cis*-1,4-DACH)(1-methylcytosine)$_2$]$Cl_2 \cdot 6H_2O$ adducts.

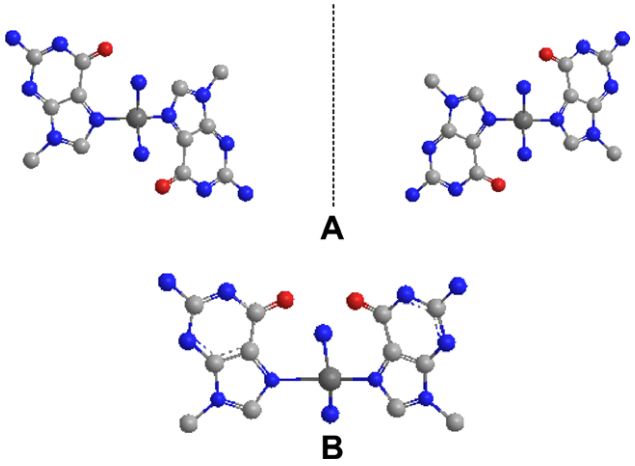

Fig. 1. Structures of [Pt(*cis*-1,4-DACH)$(L)_2$] complexes (from which the cyclohexyl ring has been omitted for clarity) showing the possible relative orientations of the methylguanine ligands. The ligands can be arranged so that they are related by a C_2 axis, which generates an enantiomeric pair (A), or by a mirror plane (B).

2. Experimental

2.1. Chemicals

Adenine (ade), hypoxanthine (hyp), 9-methylguanine (9-megua), cytosine (cyt), and 1-methylcytosine (1-mecyt) were purchased from Aldrich Chemical Co. (Milwaukee, WI). 1,4-DACH in an 80% *cis* and 20% *trans* mixture was purchased from TCI Organics, Portland, OR. K_2PtCl_4 was purchased from Johnson Mathey (Searbrook, NH). Silver nitrate, *N*,*N*-dimethylformamide (DMF), and potassium chloride were purchased from Fisher Scientific Co. (Houston, TX).

2.2. Physical measurements

Elemental analyses were performed by Robertson Microlit Laboratories Inc. (Madison, NJ). ^1H, ^{13}C, and ^{195}Pt nuclear magnetic resonance (NMR) spectra were recorded at 43.055 MHz using a Bruker 300-MHz spectrometer with a 5-mm tunable probe. Chemical shifts were measured relative to an external standard of 2.2 M Na_2PtCl_6 in D_2O at 0.00 ppm.

2.3. Preparation of Pt complexes

[Pt(*cis*-1,4-DACH)(SO_4)] and [Pt(*cis*-1,4-DACH)Cl_2] were synthesized as described previously [22–25].

2.3.1. [Pt(*cis*-1,4-DACH)$(ade)_2$]$SO_4 \cdot 2H_2O$ (**1**)

[Pt(*cis*-1,4-DACH)$(SO_4)H_2O$] (0.42 g; 1.00 mmol) was dissolved in 25 mL of water, after which ade (0.23 g; 1.70 mmol) in 10 mL of water was added. The reaction mixture was stirred at 40 °C for 96 h. The clear, pale yellow solution that formed was filtered, concentrated to 5 ml, and then treated with acetone to induce precipitation. The resultant solid product was washed with cold water and acetone and dried over P_2O_5 under a vacuum. The yield was 67%. *Anal.* Calc.: C, 27.00; H, 3.93; N, 23.62. Found: C, 27.35; H, 3.87; N, 23.91%. ^1H NMR [δ, ppm in D_2O]: C_2H, 8.21; C_8H, 8.29. ^{13}C NMR [δ, ppm in D_2O]: C_2, 152.91; C_4, 154.67; C_5, 115.89; C_6, 150.92; C_8, 143.65. ^{195}Pt NMR: δ −2565 ppm.

2.3.2. [Pt(*cis*-1,4-DACH)$(hyp)_2$]$SO_4 \cdot 2H_2O$ (**2**)

Complex **2** was prepared in the same way as complex **1**. The yield was 75%. *Anal.* Calc.: C, 27.62; H, 3.45; N, 20.14. Found: C, 27.32; H, 3.10; N, 19.87%. ^1H NMR (δ, ppm in D_2O): C_2H, 8.86; C_8H, 8.95. ^{13}C NMR [δ, ppm in DMSO-d_6]: C_2, 154.02; C_4, 156.03; C_5, 116.24; C_6, 145.58; C_8, 141.09. ^{195}Pt NMR: δ −2590 ppm.

2.3.3. [Pt(*cis*-1,4-DACH)$(9\text{-megua})_2$]SO_4-[9-megua-H]$_2SO_4$ (**3**)

Complex **3** was prepared in the same way as complex **1**, but it was further redissolved in a minimum volume of water filtered and kept for slow evaporation at room

temperature. The colorless crystals obtained were filtered, washed with cold water, and dried under a vacuum. The yield was 60%. *Anal*. Calc.: C, 30.96; H, 3.78; N, 26.49. Found: C, 30.89; H, 3.95; N, 26.67%. ^{1}H NMR [δ, ppm in D_2O]: C_8H, 7.87; CH_3, 3.53. ^{13}C NMR [δ, ppm in D_2O]: C_2, 154.87; C_4, 157.46; C_5, 113.53; C_6, 151.65; C_8, 142.42; CH_3, 30.89. ^{195}Pt NMR: δ −2479 ppm.

2.3.4. *[Pt(cis-1,4-DACH)(cyt)$_2$]SO$_4$ · 2H$_2$O (**4**)*

Complex **4** was prepared in the same way as complex **1**. The yield was 72%. *Anal*. Calc.: C, 25.33; H, 4.22; N, 16.89. Found: C, 25.45; H, 4.43; N, 16.91%. ^{1}H NMR [δ, ppm in D_2O]: C_5H, 6.03; C_6H, 7.50. ^{13}C NMR [δ, ppm in D_2O]: C_2, 156.37; C_4, 166.67; C_5, 94.89; C_6, 144.03. ^{195}Pt NMR: δ −2695 ppm.

2.3.5. *[Pt(cis-1,4-DACH)(1-mecyt)$_2$]Cl$_2$ · 6H$_2$O (**5**)*

[Pt^{II}(1,4-DACH)Cl$_2$] (0.38 g; 1.00 mmol) was suspended in 25 mL of water, after which 1-mecyt (0.22 g; 1.76 mmol) in 10 mL of water was added. The reaction mixture was stirred at 40 °C for 48 h. A clear solution was obtained, which was filtered and concentrated to 5 mL under reduced pressure. The solution was then treated with acetone to induce precipitation. The resultant solid product was washed with cold water and acetone and then dried under a vacuum. The product was subsequently redissolved in a minimum volume of water kept for slow evaporation at room temperature. The colorless crystals obtained were filtered, washed with cold water, and dried in a vacuum. The yield was 60%. *Anal*. Calc.: C, 28.83; H, 4.84; N, 16.81. Found: C, 28.78; H, 4.76; N, 16.58%. ^{1}H NMR [δ, ppm in D_2O]: CH_3, 3.43; C_5H, 5.71; C_6H, 7.59. ^{13}C NMR [δ, ppm in D_2O]: C_2, 156.23; C_4, 165.97; C_5, 94.85; C_6, 148.64; CH_3, 38.49. ^{195}Pt NMR: δ −2650 ppm.

2.4. Crystallographic measurements

X-ray crystallographic data were collected with a single-crystal X-ray diffractometer (AFC5S; Rigaku), and data collection and reduction software (TEXSAN *Single Crystal Structure Analysis Software* 5.0; Molecular Structure Corporation, The Woodlands, TX) [46]. Crystals suitable for analysis were mounted on the tip of a glass fiber. Data collection and refinement parameters are summarized in Table 1. The data were corrected for Lorentz and polarization effects and for absorption.

The crystal structures of complexes **3** and **5** were resolved, refined, and plotted directly by using the software contained in the SHELXTL 6.10 program library [47]. For complexes **3** and **5**, the Pt atoms were shown to sit on a

crystallographic twofold axis, so that only half of the DACH ring and one of the N-base ligands were unique. In complex **3**, all nonhydrogen atoms were refined with anisotropic displacement parameters, except for the carbon atoms of the *cis*-1,4-DACH ring, which were disordered; this disorder could not be resolved. Because the configurations of the solid-state structures of complexes **3** and **5** are chiral, the possibility that the space group was *Cc* rather than *C*2/*c* was considered for both. For complex **3**, no acceptable solution could be obtained using the Patterson map or direct methods for the space group *Cc*. Attempts to remove the center of symmetry from the *C*2/*c* solution were not successful and gave no refineable solution. For complex **5**, the structure was resolved and refined in *Cc*, but the data obtained did not support anisotropic refinement of all nonhydrogen atoms, some of which were non-positive definite. Additionally, the data for complex **5** indicated that it was a racemic twin. Given these findings, the centrosymmetric space groups were chosen in both cases as the best solutions. Consequently, the bond distances and angles associated with those group as reported here should be viewed with caution. Furthermore, the [Pt(*cis*-1,4-DACH)(9-megua)$_2$]SO_4 complex cocrystallized with [9-megua-H]$_2SO_4$. In addition to two water molecules of solvation, the crystal structure of complex **3** contained additional water molecules that could not be refined satisfactorily. The contribution of the additional water molecules of solvation was taken into account by using the squeeze routine in the PLATON X-ray data refinement software package [48] where a total of 126e was found in the void volume of the crystal. A structural analysis of complex **5** showed the presence of three oxygen atoms attributable to the lattice waters of crystallization, giving an overall formula of six water molecules per Pt complex.

For both complexes **3** and **5** hydrogen atoms were calculated in ideal positions (i.e., riding model), and F^2 was refined using all reflections. The weighted *R* factors (*wR*) and goodness-of-fit determinations were based on F^2. Conventional *R* factors were based on *F*, with *F* set to zero for negative F^2. *R* factors based on F^2 were statistically about twice as large as those based on *F*, and *R* factors based on all data were expected to be even larger. Selected bond distances and angles for complex **3** are shown in Table 2 and for complex **5** in Table 3.

3. Results and discussion

3.1. Characterization of complexes

Scheme 1 shows the synthetic route and structure of the Pt complexes **1**–**5**. These complexes were all characterized by elemental analysis and ^{1}H, ^{13}C, and ^{195}Pt NMR spectroscopy.

The theoretical values obtained from the elemental analyses were in good agreement with the actual findings. The singlets observed in the range of −2565 to −2695 ppm in the ^{195}Pt NMR spectra were assignable to the Pt–N4 system and were similar to those of related square planar Pt(II) complexes that had four nitrogens as donor atoms [49]. In ^{1}H NMR spectra, the peaks corresponding to the C_8H protons of ade, hyp, and 9-megua shifted downfield by 0.2, 0.7, and 0.3 ppm, respectively, in complexes **1**–**3** compared with the corresponding ligands, which indicated the coordination of N7 to the Pt atom. In complexes **4** and **5**, a downfield shift of 0.1 ppm in the C_5H proton peaks of cyt and 1-mecyt compared with the corresponding ligands indicated the coordination of Pt to N3.

The proton-decoupled ^{13}C NMR spectra of purine and pyrimidine bases were obtained from the Integrated Spectral Data Base System for Organic Compounds for comparison with the spectra we obtained. In complexes **1**–**3**, a downfield shift of 3.35–3.71 ppm was observed at C_5 and an upfield shift of 3.18–4.52 ppm at C_8 compared with free ligands, ade, hyp, or 9-megua. In complexes **4** and **5**, an upfield shift of 3.09–3.54 ppm was observed at C_2 and of 1.00–1.20 ppm at C_4 compared with cyt and 1-mecyt. These identical shifts in both substituted and unsubstituted purine and pyrimidine base complexes support the notion that N7 and N3 are binding sites in the purine and pyrimidine bases, respectively. Scheme 1 shows the general structure of complexes **1**–**5**.

L = adenine (ade), hypoxanthine (hyp), 9-methyl guanine (9-megua), cytosine (cyt), 1-methylcytosine (1-mecyt)

X = SO_4, H_2O or 2Cl

Scheme 1.

3.2. X-ray crystal structures

The X-ray crystal structure of complex **3** is shown in Fig. 2a and of complex **5** in Fig. 2b. respectively. Selected bond lengths and bond angles for each compound are given in Tables 2 and 3, respectively. The Pt atom in both complexes had a distorted square planar geometry, with the angles mostly deviating from the expected values of 90° and 180°. A longer bite distance in the chelating ligand (*cis*-1,4-DACH) caused the distortion. The two adjacent corners of the Pt plane were occupied by two nitrogen atoms of the *cis*-1,4-DACH molecule, while the other two positions were occupied by the N7 atoms of two 9-megua moieties in complex **3** and the N3 atoms of two 1-mecyt moieties in complex **5**. *cis*-1,4-DACH, which exists in a unique twist-boat configuration, formed a 7-member chelating ring with the Pt atom.

The N–Pt–N angle in the *cis*-1,4-DACH-Pt region expanded to 97.1° in complex **3** and to 97.8° in complex **5** because of geometric constraints imposed by the ligands. However, the same bond angle in the cisplatin adducts is about 90°, as reported previously for complexes $[Pt(NH_3)_2(9\text{-ethylguanine})_2]SO_4$ (93.2°),[1] $[Pt(NH_3)_2(9\text{-ethylguanine})_2][Pt(CN)_4]$ (87.8°) [49], $[Pt(NH_3)_2(9\text{-ethylguanine})(1\text{-methylcytosine})](ClO_4)_2$ (90.0°) [50], and *cis*-$[Pt(NH_3)_2(9\text{-methyladenine})(9\text{-ethylguanine})](NO_3)_2$ (88.9°) [48]. The expansion of this bond angle was compensated for by contraction of the N(7)–Pt–(N41) and N(3)–Pt–N(13) bond angles to 87° in complex **3** and to 85.7° in complex **5**. The average Pt–N bond lengths of 2.033(8) Å [51] in complexes **3** and **5** were within the range normally observed for cisplatin-nucleobase adducts [48].[1]

The dihedral angles between the purine or pyrimidine ligands and the Pt coordination plane (9-megua 1/Pt–N4 = 74.54° and 9-megua 2/Pt–N4 = 85.61° in complex **3** and 1-mecyt 1/Pt–N4 = 78.12° and 1-mecyt 2/Pt–N4 = 81.80° in complex **5**) were large and prevented any substantial intracomplex base-to-base interaction. In analogous complexes, one of the nucleobase rings forms

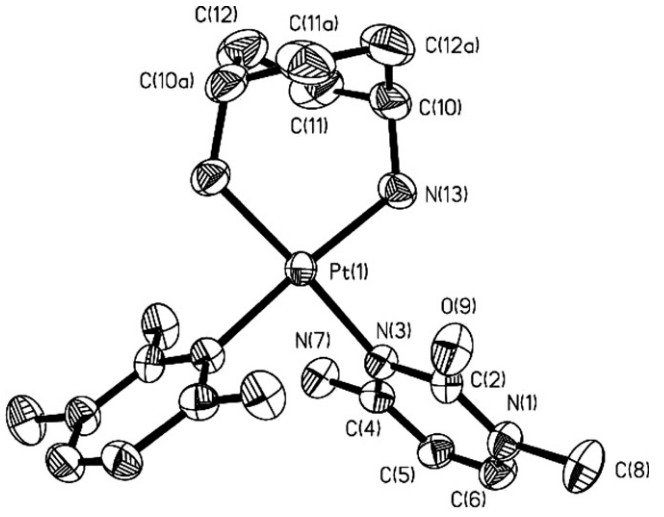

Fig. 2b. ORTEP representation of the structure of complex **5**. [Pt(*cis*-1,4-DACH)(1-mecyt)$_2$]Cl_2 and hydrogen atom are omitted for clarity.

[1] The average values of ESD are calculated via the Scatter formula:

$$\sigma = \left[\sum_{i=1}^{i=N} (d_i - d)^2 \Big/ (N-1)\right]^{1/2}$$

They are thus external estimates of the ESD based on an individual measurement.

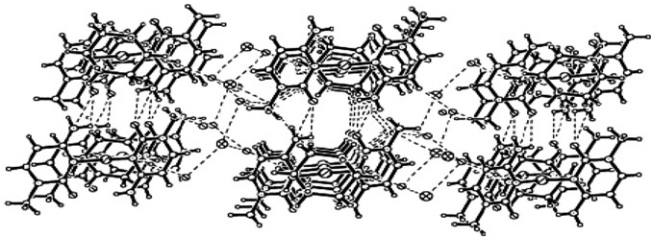

Fig. 3b. A view of the molecular packing of [Pt(*cis*-1,4-DACH)-(1-mecyt)$_2$]Cl_2.

a smaller angle (~50°) with the Pt plane, leading to internal hydrogen bonds [44,45]. Views of the molecular packing of both crystals structures are shown in Fig. 3. In the cations of complexes **3** and **5**, the purine or pyrimidines nucleobases are coordinated to Pt at their N7 and N3 locations, respectively.

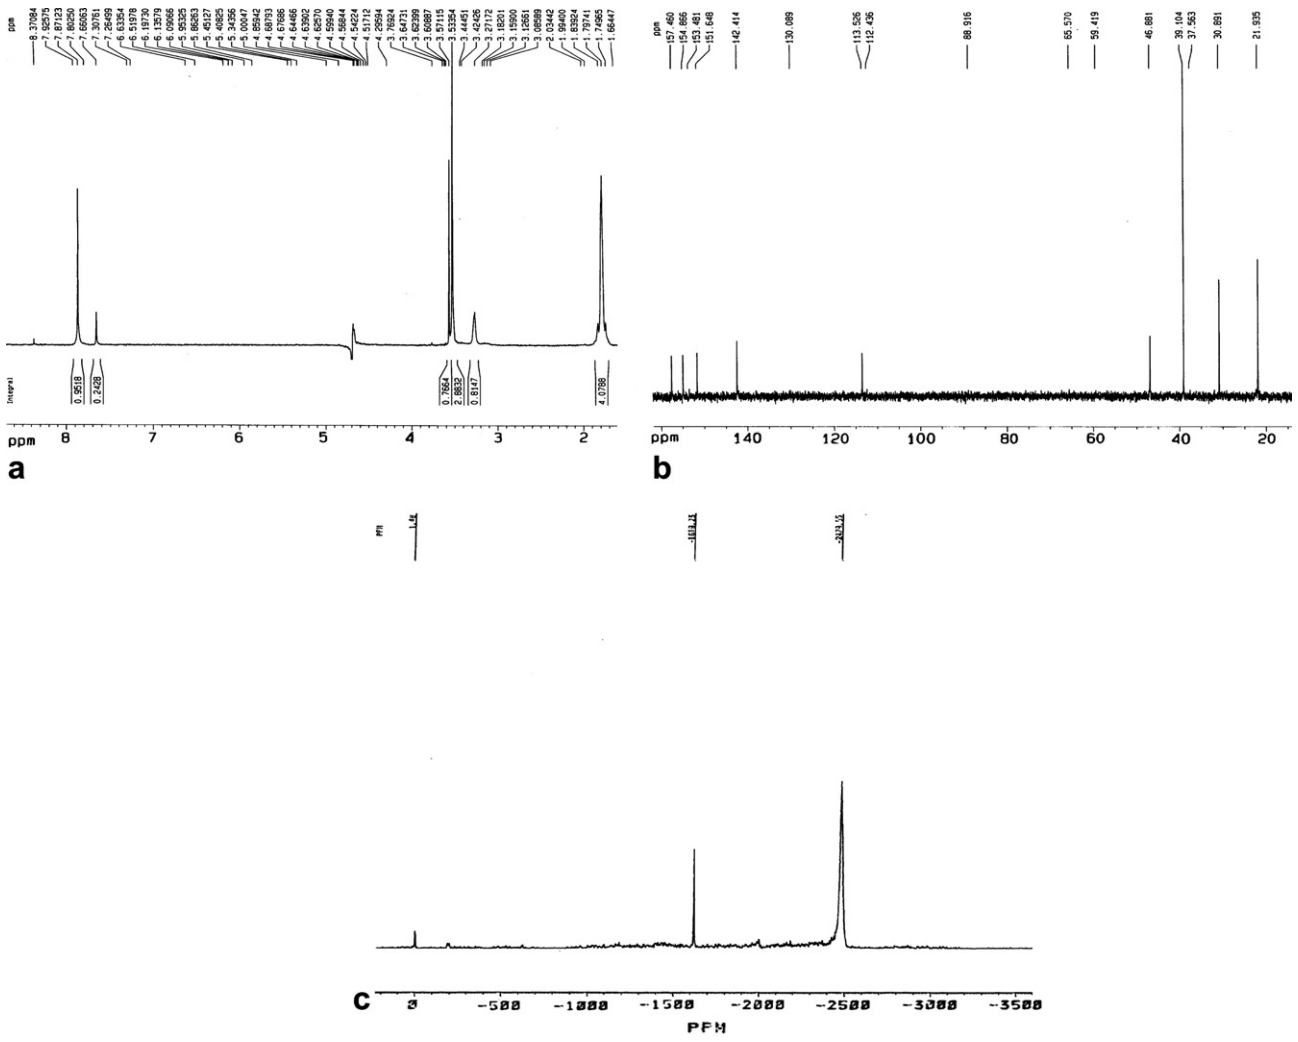

Fig. 4. NMR spectra of [Pt(*cis*-1,4-DACH)(9-megua)$_2$]SO_4[9-megua-H]$_2SO_4$. (a) ^{1}H NMR. (b) ^{13}C NMR. (c) ^{195}Pt NMR.

The starting (*cis*-1,4-DACH)$PtCl_2$ and the planar nucleobase ligands are not chiral because they both contain mirror planes of symmetry. However, when the nucleobase and ligands are attached to Pt, as they are in Fig. 1, they are oriented so that the overall resulting complex has either a C_2 or a mirror symmetry. The latter is not observed in the figure, meaning that the complexes have C_2 symmetry and are thus chiral. Because the reaction methodology began with nonchiral starting materials, the expected product was a racemic mixture of the two enantiomeric forms, as shown in Fig. 1a. The crystallographic determination of such systems can be ambiguous, given that the data often allow for refinement in either a centrosymmetric space group, in which the molecule sits on a crystallographic C_2 axis, or in a noncentrosymmetric space group, in which no crystallographic symmetry is imposed but noncrystallographic C_2 symmetry is still present the molecule. For the determinations of **3** and **5**, both possibilities were considered. The refinements proceeded best in the centrosymmetric space group $C2/c$, which represented racemic mixtures. For complex **3**, refinement could also be performed in the noncentrosymmetric Cc group, but full anisotropic refinement was not possible without some atoms becoming nonpositive definite. The structure of complex **5** could not be resolved in the Cc group. Presumably, in solution, free rotation about the Pt–N bonds occurs so that the isolation of a single enantiomer is not feasible (see Fig. 4).

Different mapping techniques have demonstrated that the reaction product both in vitro and in vivo involves loss of two chloride ions and binding of platinum to the N7 atoms of two adjacent guanines or adjacent adenine/guanine bases [52]. Theses type of interactions inhibit shielding the adduct from nucleotide excision repair, replication, and interfere with transcription by recruting essential transcription factors from their native binding sites [53–57]. It has been shown by NMR and X-ray studies that when cisplatin or *cis*-dichloro-*trans*-diacetato-ammine-cyclohexylamineplatinum(IV) (JM216) binds to adjacent guanine residues on duplex DNA, it distorts the double helix by causing a bend towards the major groove and a widening and flattening of the minor groove [58–62]. Significant differences in the effectiveness of ethylenediamine-platinum and 1,2-diaminocyclohexane-platinum (1,2-DACH-Pt) adducts in inhibiting transformation efficiency in a repair-deficient strain of *Escherichia coli* suggest that carrier ligand effects on resistant cell lines arise from differences in the ability of certain Pt-DNA adducts to inhibit other process, such as replication or transcription [59,60]. In this context a series of Pt(II)- and Pt(IV)-DNA adducts with cisplatin, 1,2-diaminocyclohexane, 1,4-diaminocylohexane, and homopiperazine have been synthesized and structurally and spectroscopically characterized and their different orientation are reported in their crysytal structures [48,49,63–66]. These structural distortions and differences in carrier ligand effect in turn likely affect the ability of the platinum drugs to block DNA replication and transcription [67,68].

4. Conclusions

In our continuous effort to investigate any correlation between anticancer activity and the DNA adduct profile, which may contribute to the understanding mechanism of action of such platinum based anticancer agents, that are structurally and functionally distinct from cisplatin prompted us to report here the synthesis and characterization of Pt(II) diadducts with DNA bases. Additionally, the crystal structures of [Pt(*cis*-1,4-DACH)(9-megua)$_2$]SO_4-[9-megua-H]$_2SO_4$ (**3**) and [Pt(*cis*-1,4-DACH)(1-mecyt)$_2$]-$Cl_2 \cdot 6H_2O$ (**5**) were determined by X-ray crystallography.

Abstract

Treatment of $[M(H_2L^i)]$ with UCl_4 in pyridine led to the formation of the dinuclear complexes $[ML^i(py)UCl_2(py)_2]$ and/or $[Hpy][ML^i(py)UCl_3]$ [L^i = *N*,*N*′-bis(3-hydroxysalicylidene)-R, R = 1,2-phenylenediamine ($i = 1$), R = *trans*-1,2-cyclohexanediamine ($i = 2$), R = 2-amino-benzylamine ($i = 3$), R = 1,3-propanediamine ($i = 4$), R = 2,2-dimethyl-1,3-propanediamine ($i = 5$); M = Cu or Ni]. The crystal structures show that the 3d and 5f ions occupy, respectively, the N_2O_2 and O_4 cavities of the Schiff base ligand, the U^{4+} ion adopting a dodecahedral or pentagonal bipyramidal configuration in the neutral and anionic complexes, respectively.

1. Introduction

Polynuclear complexes containing both d- and f-block transition metals attract much attention for their interesting magnetic behaviour [1] and their potential in the development of molecular-based materials with controlled properties [2,3]. Most studies were devoted to copper(II)–gadolinium(III) (3d–4f) complexes in which both ferro- [4–8] and antiferromagnetic [9,10] interactions have been observed. When the lanthanide(III) ion, Ln^{3+}, is different from gadolinium, the presence of a first-order orbital momentum complicates the analysis of the magnetic properties which are governed by both the thermal population of the Stark components of the 4f ion and the 3d–4f interaction. The nature of this interaction could be determined by subtracting the sole contribution of the lanthanide ion, which is reflected by the magnetic behaviour of isostructural derivatives in which the paramagnetic 3d ion, i.e. Cu^{2+}, has been replaced by a diamagnetic ion, i.e. Zn^{2+} [11,12]. In the last past years, the first compounds containing both 3d and 5f ions have been isolated [13–18]. In addition to the challenge of their synthesis, such complexes are attractive for their magnetic properties which, by comparison with those of the 3d–4f derivatives, would reflect the greater spatial extension of the 5f orbitals. We have prepared a series of trinuclear compounds of general formula $[\{ML^i(py)\}_2U]$ (M = Cu, Zn) which differ by the length of the diimino chain of the Schiff base ligand L and whose magnetic properties were found to be dependent on the Cu···U distance [15,16]. With L^6 = *N*,*N*′-bis(3-hydroxysalicylidene)-2-methyl-1,2-propanediamine, we succeeded in isolating the first strictly dinuclear compound of paramagnetic 3d and 5f ions, $[CuL^6(py)U(acac)_2]$, from an equimolar mixture of $[Cu(H_2L^6)]$ and $U(acac)_4$ [17]. This dinuclear compound was the sole to have been obtained pure since the use of the other Schiff base ligands led invariably to the straightforward formation of the Cu_2U complexes. Here we present the crystal structure of new CuU and NiU compounds in this family which were synthesized by using UCl_4 instead of $U(acac)_4$ as the uranium precursor. Unfortunately, attempts to isolate and characterize the ZnU analogues were unsuccessful, precluding any magnetic studies.

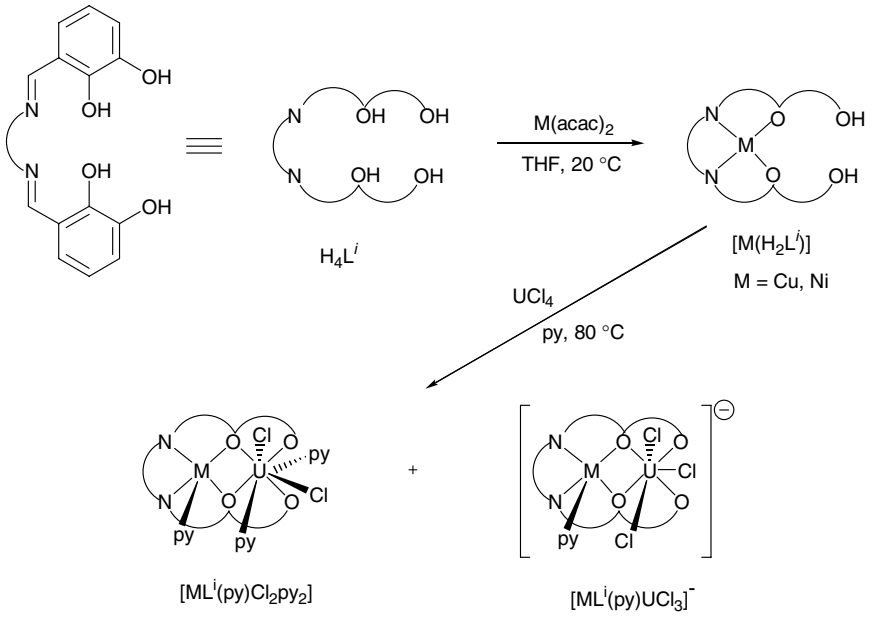
2. Results and discussion



2.1. Synthesis of the complexes

The Schiff bases H_4L^i [L^i = *N*,*N*′-bis(3-hydroxysalicylidene)-R, R = 1,2-phenylenediamine ($i = 1$), R = *trans*-1,2-cyclohexanediamine ($i = 2$), R = 2-amino-benzylamine ($i = 3$), R = 1,3-propanediamine ($i = 4$), R = 2,2-dimethyl-1,3-propanediamine ($i = 5$)] are represented in Scheme 1. Reactions of $[M(H_2L^i)]$ (M = Cu, Ni or Zn) with one equivalent of $U(acac)_4$ in refluxing pyridine afforded directly the trinuclear compounds $[\{ML^i(py)\}_2U]$, without it being possible to isolate the $[ML^i(py)U(acac)_2]$ intermediates [15,16]. Similar treatment of $[M(H_2L^i)]$ (M = Cu, Ni) with UCl_4 in place of $U(acac)_4$ afforded the dinuclear compounds $[ML^i(py)UCl_2(py)_2]$ and/or $[Hpy][ML^i(py)UCl_3]$ (Scheme 2). The synthesis of these complexes is likely favoured by the retention of the chloride ion on the metal centre while reactions with $U(acac)_4$ lead to the irreversible elimination of acacH. The orange microcrystalline powder of $[CuL^1(py)UCl_2(py)_2]$ (**1**) was obtained in 97% yield by treatment of $[Cu(H_2L^1)]$ with UCl_4 in pyridine at 80 °C, while similar reaction of $[Cu(H_2L^2)]$ gave a mixture of green crystals of $[CuL^2(py)UCl_2(py)_2]$ (**2**) and orange crystals of $[Hpy][CuL^2(py)UCl_3]$. Under the same experimental conditions, the anionic compounds $[Hpy][CuL^i(py)UCl_3]$ [$i = 3$ (**3**), 4 (**4**) and 5 (**5**)] were the sole products isolated from $[Cu(H_2L^i)]$, as dark brown ($i = 3$), dark yellow ($i = 4$) and light green ($i = 5$) crystals. Similar reactions of $[Ni(H_2L^i)]$ ($i = 3$, 5) and UCl_4 led to the formation of the anionic complexes $[Hpy]_2[NiL^3(py)_2UCl_3][NiL^3(py)UCl_3]$ (**6**) and $[Hpy][NiL^5(py)UCl_3]$ (**7**).

As mentioned in Section 1, the nature of the Cu–U or Ni–U interaction in these dinuclear compounds can be determined by comparison of their magnetic properties with those of the ZnU analogues. Unfortunately, reactions of $[Zn(H_2L^i)]$ ($i = 2$–5) with UCl_4 gave insoluble powders which could not be fully characterized. Only the products obtained from $[Zn(H_2L^1)]$ were soluble in pyridine but, surprisingly, the ^1H NMR spectra revealed the presence of two compounds with a dissymmetric structure, all the protons of the Schiff base ligands being magnetically unequivalent.

Scheme 1. The H_4L^i Schiff bases.

Scheme 2. Synthesis of the complexes.

Obviously, the ZnU analogue of **1** was not formed and, in the absence of crystallographic analysis, these complexes have not been identified.

2.2. Crystal structures of the complexes

Crystals of **1**·2py, **2**·2py, **3**·1.25py, **4**, **5**·py, **6**·1.5py and **7**·py suitable for X-ray diffraction analysis were obtained by crystallization from pyridine. Views of **1** and **4** are shown in Figs. 1 and 2, respectively, and selected bond lengths and angles are listed in Table 1. The asymmetric unit of **2**·2py contains two independent enantiomer molecules, $[Cu[(R,R)\text{-}L^2](py)UCl_2(py)_2]$ and $[Cu[(S,S)\text{-}L^2](py)\text{-}UCl_2(py)_2]$ (see Section 4.3), and the asymmetric unit of **3**·1.25py contains two identical independent molecules. In all the CuU complexes **1**–**5**, the copper and uranium atoms occupy, respectively, the N_2O_2 and O_4 cavities of the Schiff base ligand and are bridged by the two oxygen atoms O(2) and O(3) of the salicylidene fragments; the Cu^{2+} ions adopt a square pyramidal coordination mode, being displaced from the N_2O_2 base towards the pyridine ligand by 0.20–0.27 Å. In the neutral compounds **1** and **2**, the U^{4+} ion is bound to two chloride ions and two nitrogen atoms of pyridine ligands and is found in a dodecahedral environment defined by the two trapezia O(1)–O(2)–O(3)–O(4) and Cl(1)–N(3)–Cl(2)–N(4) intersecting at an angle of 89.43(9)° in **1** and 89.47(17) and 89.83(17)° in **2**. The anionic complexes **3**, **4** and **5** differ by the displacement of the two pyridine ligands with a chloride ion, and the seven coordinate uranium atom is in a pentagonal bipyramidal configuration with Cl(1) and Cl(3) in apical positions. The charge is compensated with that of a pyridinium ion which is hydrogen bonded to a pyridine nitrogen atom in **3** (in which the pyridinium ions are disordered, Section 4.3) or to one phenoxide oxygen atom in **4** or **5** [N(4)···O(4) 2.828(6) Å, N(4)–H···O(4) 166° in **4**, N(4)···O(1) 2.667(9) Å (pyridinium proton not found) in **5**]. The length of the diimino chain of L^i and the configuration of the U^{4+} ion in complexes **1**–**5** have no major influence on the U–O distances, which average 2.44(3) Å [bridging O(2) and O(3)] and 2.25(3) Å [terminal O(1) and O(4)], and on the O(2)–U–O(3) and O(1)–U–O(4) angles which vary from 59.3(2) to 62.4(3)° and from 164.0(3) to 167.7(2)°, respectively; these values are quite identical to those found in the series of $[\{CuL^i(py)\}_2U]$ compounds. However, as also observed in the trinuclear complexes, the length of the diimino chain of L^i has a marked effect on the coordination of the 3d metal, in particular the N(1)–Cu–N(2) and O(2)–Cu–O(3) angles which are, respectively, ca. 10° smaller and 6° larger in **1** and **2** than in **3**, **4** and **5**. In relation to these variations, the Cu..U distances increase by passing from L^1 and L^2 to L^3, L^4 and L^5, with average values of 3.541(7) and 3.632(15) Å. The mean values of the U–Cl bond lengths, 2.73(2) Å in **1** and **2** and 2.68(2) Å in **3**, **4** and **5**, are among the largest reported in the Cambridge Structural Database (CSD, Version 5.27) [19].

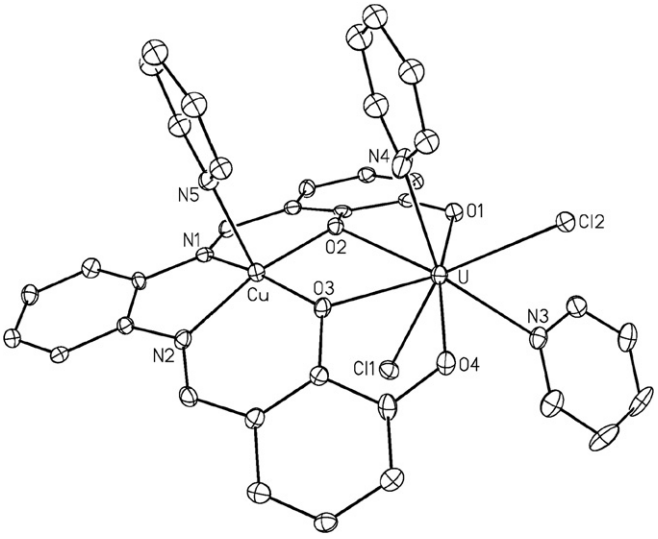


Fig. 1. View of complex **1**. The hydrogen atoms are omitted for clarity. Only the principal component of the disordered pyridine molecules is represented. Displacement ellipsoids are drawn at the 30% probability level.

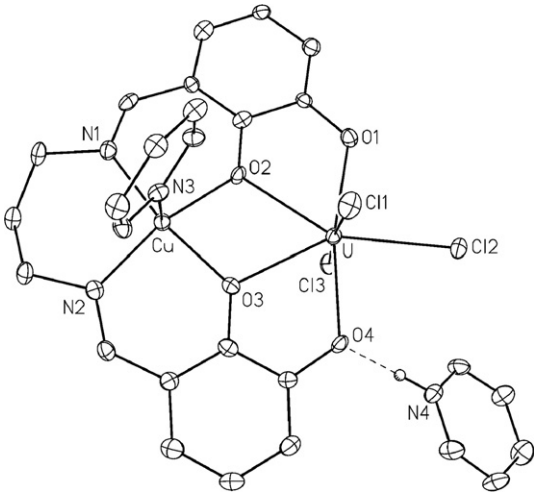

Fig. 2. View of complex **4**. The hydrogen atoms (except the pyridinium one) are omitted for clarity. The hydrogen bond is shown as a dashed line. Displacement ellipsoids are drawn at the 30% probability level.

Crystals of **6**·1.5py contain two different anionic complexes $[NiL^3(py)_2UCl_3]^-$ and $[NiL^3(py)UCl_3]^-$, denoted A and B, respectively. The distinct configurations of the Ni atom, octahedral in A and square pyramidal in B, have no influence on the Ni–O(2,3) and Ni–N(1,2) distances. In fact, the 3d ion in complex A is in the mean plane of the N_2O_2 cavity [distance to the plane 0.026(3) Å] while it is out of this plane in complex B, by 0.364(3) Å; however, the Ni–O and Ni–N distances are not shorter in A than in B because of the enlargement of the N_2O_2 cavity, in relation with the variation of the N–Ni–N and N–Ni–O angles which are larger in A than in B, by ca. 5° and 2°, respectively.

Comparison of the structures of **6** (complex B) and **3**, and of **7** and **5**, which are isomorphous, indicate that the

[a] Values for the two independent molecules.
[b] Values for complexes A and B (see text); Ni–N(4) in complex A 2.236(7) Å.
[c] α is the dihedral angle between the two halves of the MO(2)O(3)U bridging core.

coordination geometry of the U^{4+} ion is quite identical in all the complexes. However, the Ni–O and Ni–N(1,2) distances are larger than the corresponding Cu–O and Cu–N distances, by ca. 0.04 Å, whereas the radius of the Ni^{2+} ion is 0.02 Å smaller than that of Cu^{2+} [20]. The Ni^{2+} ion is more displaced than Cu^{2+} from the N_2O_2 plane, by ca. 0.35 versus 0.25 Å, and the Ni–N(py) distances of 2.026(7) and 2.048(6) Å are much smaller than the average Cu–N(py) distance of 2.29(2) Å. The same variations in the structural parameters of the square pyramidal Ni^{2+} and Cu^{2+} ions were observed in the trinuclear complexes [{NiL^5(py)}$_2$U] and [{CuL^5(py)]U[CuL^5}].

3. Conclusion

The difficulty in obtaining strictly dinuclear CuU and ZnU complexes from reactions of [M(H_2L^i)] (M = Cu, Ni or Zn) with U(acac)$_4$ arises from the straightforward formation of the corresponding trinuclear compounds [{ML^i(py)}$_2$U]. Replacement of U(acac)$_4$ with UCl_4 permitted to prepare CuU and NiU complexes, either as neutral or anionic derivatives [ML^i(py)UCl_2(py)$_2$] and [Hpy][ML^i(py)UCl_3], but the unsuccessful isolation and characterization of the ZnU analogues precluded any studies of the Cu–U or Ni–U exchange interaction.

4. Experimental

4.1. General

All reactions were carried out under argon (<5 ppm oxygen or water) using standard Schlenk-vessel and vacuum-line techniques or in a glove box. Solvents were dried by standard methods and distilled immediately before use; deuterated pyridine (Eurisotop) was distilled over NaH and stored over 3 Å molecular sieves. The ^{1}H NMR spectra were recorded on a Bruker DPX 200 instrument and referenced internally using the residual protio solvent resonances relative to tetramethylsilane (δ 0). Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany).

The Schiff bases H_4L^i (i = 1–5) were synthesized by published methods [21]. The acac compounds M(acac)$_2$ (Cu, Ni and Zn) (Aldrich) were used without purification; UCl_4

was prepared as previously reported [22]. The complexes $[M(H_2L^i)]$ were synthesized in THF by reaction of H_4L^i with 1 equiv. of $M(acac)_2$.

4.2. Syntheses

The complexes can be divided into two series of general formula $[ML^i(py)UCl_2(py)_2]$ and $[Hpy][ML^i(py)UCl_3]$. One example in each series, **1** and **4**, has been characterized by its elemental analyses; all the complexes or their solvates were characterized by X-ray diffraction analysis.

4.2.1. $[CuL^1(py)UCl_2(py)_2]$ (*1*)

A flask was charged with $[Cu(H_2L^1)]$ (150 mg, 0.37 mmol) and UCl_4 (139 mg, 0.37 mmol) in pyridine (25 mL). The reaction mixture was heated at 80 °C for 12 h; the brown-orange powder of **1** was filtered off, washed with pyridine (20 ml) and dried under vacuum (340 mg, 97%).

The complex could not be characterized by its ^{1}H NMR spectrum because of its insolubility in organic solvents. *Anal.* Calc. for $C_{35}H_{27}N_5O_4Cl_2CuU$: C, 44.05; H, 2.83; N, 7.34. Found: C, 43.89; H, 3.03; N, 7.49%. Crystals of **1**·2py were obtained by heating a suspension of **1** in pyridine at 80 °C.

4.2.2. $[CuL^2(py)UCl_2(py)_2]$ (*2*) and $[Hpy][CuL^2(py)UCl_3]$

An NMR tube was charged with $[Cu(H_2L^2)]$ (6.0 mg, 0.0144 mmol) and UCl_4 (5.5 mg, 0.0144 mmol) in pyridine-d_5 (0.4 mL). Immediately, at 20 °C, a brown powder precipitated and the ^{1}H NMR indicated the presence of two species A and B in the relative proportions of 2:1. The tube was heated at 80 °C and the NMR spectrum showed the presence of both species in relative proportions 1:1. Prolonged heating at 80 °C led to the crystallization of a mixture of light green platelets of $[CuL^2(py)UCl_2(py)_2]\cdot 2py$ (**2**·2py) and orange platelets of $[Hpy][CuL^2(py)UCl_3]$.

^{1}H NMR of species A: 15.35, 18.29 and 41.61 (3×2 H, aromatic H). ^{1}H NMR of species B: 16.57 and 42.79 (4 H + 2 H, aromatic H). Broad signals at −16.1, −12.8, −6.2 and 1.4 are attributed to the protons of the cyclohexyl rings of both compounds; a signal at δ 21.2 can be attributed to the Hpy proton.

4.2.3. $[Hpy][CuL^3(py)UCl_3]$ (*3*)

An NMR tube was charged with $[Cu(H_2L^3)]$ (5.0 mg, 0.0118 mmol) and UCl_4 (4.5 mg, 0.0118 mmol) in pyridine-d_5 (0.4 mL). The tube was heated at 80 °C for 1 d and the spectrum indicated the presence of the sole complex **3**. Prolonged heating at 80 °C led to the crystallization of dark brown platelets of **3**·1.25py.

^{1}H NMR (pyridine-d_5, 23 °C): −16.5, −6.84, 1.32 and 12.29 (4×1 H, Ph of the diimino chain), 17.52 and 18.15 (2×1 H, aromatic H), 23.12 (3 H, aromatic H and pyH), 40.23 (2 H, aromatic H), 106.2 and 107.8 (2×1 H, NCH_2).

4.2.4. $[Hpy][CuL^4(py)UCl_3]$ (*4*)

(a) An NMR tube was charged with $[Cu(H_2L^4)]$ (5.0 mg, 0.0133 mmol) and UCl_4 (5.1 mg, 0.0133 mmol) in pyridine-d_5 (0.4 mL). After heating at 80 °C for 5 d, the spectrum indicated the presence of the sole complex **4** which crystallized as dark yellow platelets.

^{1}H NMR (pyridine-d_5, 23 °C): −25.59 (2 H, CH_2) 10.46, 19.69 and 44.10 (3×2 H, aromatic H), 93.42 and 116.90 (2×2 H, NCH_2).

(b) A flask was charged with $[Cu(H_2L^4)]$ (50 mg, 0.13 mmol) and UCl_4 (50 mg, 0.13 mmol) in pyridine (15 mL). The reaction mixture was heated for 6 h at 80 °C; the brown powder of **4** was filtered off, washed with pyridine (10 mL) and dried under vacuum (55 mg, 47%). *Anal.* Calc. for $C_{27}H_{25}N_4O_4Cl_3CuU$: C, 36.94; H, 2.85; N, 6.39. Found: C, 36.81; H, 3.05; N, 6.59%.

4.2.5. $[Hpy][CuL^5(py)UCl_3]$ (*5*)

An NMR tube was charged with $[Cu(H_2L^5)]$ (5.0 mg, 0.0124 mmol) and UCl_4 (4.7 mg, 0.0124 mmol) in pyridine-d_5 (0.4 mL). The tube was heated at 80 °C for 12 h and the NMR spectrum of the limpid dark brown solution indicated the presence of the sole complex **5**. Prolonged heating at 80 °C led to the crystallization of light green needles of **5**·py.

^{1}H NMR (pyridine-d_5, 23 °C): −10.83 (6 H, Me) 10.34, 19.28 and 43.14 (3×2 H, aromatic H), 110.7 (4 H, NCH_2); a signal at δ 20.02 can be attributed to the Hpy proton.

4.2.6. $[Hpy]_2[NiL^3(py)_2UCl_3][NiL^3(py)UCl_3]$ (*6*)

An NMR tube was charged with $[Ni(H_2L^3)]$ (5.0 mg, 0.0119 mmol) and UCl_4 (4.5 mg, 0.0118 mmol) in pyridine-d_5 (0.4 mL). After 30 min at 20 °C, the spectrum of the red solution showed the formation of **6** as the sole product. Prolonged heating at 80 °C led to the crystallization of orange platelets of **6**·1.5py.

^{1}H NMR (pyridine-d_5, 23 °C): −13.37, −4.59, −0.52 and 13.72 (4×1 H, Ph of the diimino chain), 18.91 and 29.16 (2×2 H, aromatic H), 29.29 (1 H, Hpy), 35.60 and 35.92 (2×1 H, aromatic H), 94.9 (2 H, NCH_2).

4.2.7. $[Hpy][NiL^5(py)UCl_3]$ (*7*)

An NMR tube was charged with $[Ni(H_2L^5)]$ (5.0 mg, 0.0125 mmol) and UCl_4 (4.8 mg, 0.0125 mmol) in pyridine-d_5 (0.4 mL). After 30 min at 20 °C, the spectrum of the dark green solution containing a small quantity of green powder showed the formation of **7** together with another unidentified compound. Light green crystals of **7**·py were deposited after heating at 80 °C for 2 d.

^{1}H NMR (pyridine-d_5, 23 °C): −7.14 (6 H, Me); 12.28, 22.25 and 38.55 (3×2 H, aromatic H), 99.6 (4 H, NCH_2).

4.2.8. Reaction of $[Zn(H_2L^1)]$ and UCl_4

An NMR tube was charged with $[Zn(H_2L^1)]$ (5.0 mg, 0.0122 mmol) and UCl_4 (4.6 mg, 0.0122 mmol) in pyridine-d_5 (0.4 mL). After 30 min at 20 °C, the spectrum of the orange-red solution showed the signals of two

complexes denoted A and B, in relative proportions of 50:50. Complex B was the sole complex in solution after 24 h at 80 °C.

^{1}H NMR (complex A): −35.07, −16.25, −10.80, −7.42, −6.54 and −0.15 (6 × 1 H, Ph of the diimino chain and CH=N), 17.89, 18.76, 21.97, 34.08, 36.06 and 89.77 (6 × 1 H, aromatic H).

^{1}H NMR (complex B): −28.23, −23.50, −15.96 and −10.80 (4 ×1 H, Ph of the diimino chain), −8.78 and −6.23 (2 × 1 H, CH=N), 12.30, 20.81, 25.70, 29.50, 35.53 and 40.62 (6 × 1 H, aromatic H).

4.3. Crystallography

The data were collected at 100(2) K on a Nonius KappaCCD area detector diffractometer [23] using graphite-monochromated Mo Kα radiation (λ 0.71073 Å). The crystals were introduced in glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from 10 frames, then refined on all data. A 180° φ-range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed to 28 or 30 mm. The data were processed with HKL2000 and DELABS [24]. The structures were solved by direct methods with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97 [25]. Absorption effects were corrected empirically with the program HKL2000 DELABS in PLATON [26]. All non-hydrogen atoms were refined with anisotropic displacement parameters, unless specified below. The carbon-bound hydrogen atoms were introduced at calculated positions in all compounds (except for some disordered parts). All hydrogen atoms were treated as riding atoms with an isotropic displacement parameter equal to 1.2 (NH, CH, CH_2) or 1.5 (CH_3) times that of the parent atom. Specific details are as follows:

Compound **1**·2py. Two of the metal-bound pyridine molecules are disordered over two sites, sharing only atom N(4) in the first molecule, and N(5) and the *para* carbon atom in the second. The disordered components were affected with occupancy factors constrained to sum to unity; these factors appeared to be identical (and were then constrained to be so) for the components of the two molecules which are nearly parallel to one another. The disordered carbon atoms were refined isotropically, with some restraints on bond lengths and displacement parameters.

Compound **2**·2py. The space group $P2_1/c$ used for the seemingly isomorphous compound **1**·2py would be correct for most of the structure, in particular for the metal atoms, but it does not permit a good refinement of some parts of the structure such as the pyridine molecules, even with the use of restraints. Moreover, it can be ruled out with reasonable confidence on the basis of systematic extinctions, in spite of the low crystal quality. The solution adopted corresponds to the chiral space group $P2_1$ with two independent molecules in the asymmetric unit, which constitute an enantiomorph pair. The case of non-centrosymmetric racemates was investigated in detail, but that of the even more surprising racemates crystallizing in chiral space groups (i.e. containing only proper symmetry elements) seems to be illustrated by only 17 organic structures in the CSD [27]. In the present case, the presence of a pseudo-inversion centre is found with an 83% fit only by the program ADDSYM [26] and the passage from a centrosymmetric to a chiral space group could be due to the different positions of the coordinated pyridine molecules in the two complexes. Restraints on displacement parameters have been applied for some badly behaving atoms, particularly in the solvent molecules. Crystals of the compound [Hpy][CuL^2(py)UCl_3] were also obtained from the same preparation, but it was only possible to get a rough model of the structure due to the lack of crystals of sufficient quality.

Compound **3**·1.25py. Three pyridine molecules are disordered, one around a symmetry center and the others over two positions which have been refined with occupancy parameters constrained to sum to unity. Several locations for the pyridinium proton (which has not been found) are thus possible. Three pyridine molecules have been refined as idealized hexagons. The disordered carbon atoms have been refined isotropically and restraints have been applied for some badly behaving atoms in the pyridine molecules. Several short contacts indicate that some of the disordered pyridine positions cannot be occupied simultaneously with their equivalent through the symmetry centre.

Compound **4**. The pyridinium hydrogen atom has been found on a Fourier-difference map.

Compounds **5**·py and **7**·py. The pyridinium hydrogen atom was not found in either of these two isomorphous compounds. Restraints on displacement parameters have been applied for five atoms of the pyridine molecules in **7**. The absolute structure was determined, with Flack parameter values of −0.007(7) and −0.003(6) for **5** and **7**, respectively, [28].

Compound **6**·1.5py. Two pyridine molecules are disordered around a symmetry centre, one of them being further disordered over two positions which have been refined with occupancy parameters of 0.5. Several locations for the pyridinium proton (which has not been found) are thus possible, with two short N···N contacts indicating possible hydrogen bonds. Some restraints have been applied for some atoms in the more badly resolved pyridine molecules.

Crystal data and structure refinement parameters are given in Table 2. The molecular plots were drawn with SHELXTL [29].

5. Supplementary material

CCDC No. 614903–614909 contains the supplementary crystallographic data for **1**–**7**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk, or from the Cambridge Crystallographic Data Centre, 12 Union

Abstract

Single crystal X-ray structure determinations are described for salts of 5,6,14,15-dibenzo-1,4-dioxa-8,12-diazacyclopentadeca-5,14-diene (L^1) (mono-protonated, as its $F_3CSO_3^-$ ('tfs') salt, and diprotonated, as its nitrate salt) and 5,6,17,18-dibenzo-1,4-dioxa-8,11,15-triazacyclooctadeca-5,17-diene (L^2) (diprotonated, as its tfs salt), defining their protonic hydrogen atom distributions and conformations. In $(L^1H)(tfs)$, an NH group is protonated, the associated hydrogen atoms interacting one within the cation to the other NH group, the other with a tfs oxygen atom. In $(L^1H_2)(NO_3)_2$ (two phases), both NH groups are protonated; in each case, although one NH_2^+ group is oriented so that one of its hydrogen atoms is directed within the ring to the adjacent oxygen atom, there is a competing interaction with a nitrate oxygen atom. All other NH_2^+ hydrogen atoms interact with nitrate oxygen atoms. In $(L^2H_2)(tfs)_2$, the peripheral NH groups are protonated, the protonic hydrogen atoms interacting with tfs anions disposed above and below the macrocycle, making a tight $[(L^2H_2)(tfs)_2]$ cluster.

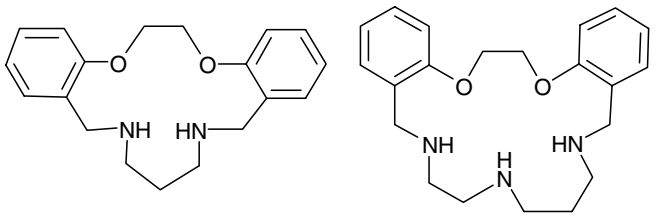
1. Introduction

A continuing theme in our prior studies has been the design and synthesis of macrocyclic ligands for metal-ion recognition. For example, we have undertaken a number of such studies employing series of mixed-donor macrocycles for which the 15-membered, O_2N_2-system 5,6,14,15-dibenzo-1,4-dioxa-8,12-diazacyclopentadeca-5,14-diene (L^1), and the 17-membered O_2N_3-system, 5,6,17,18-dibenzo-1,4-dioxa-8,11,15-triazacyclooctadeca-5,17-diene (L^2), may be considered to be the parent rings [1,2]. In these studies parameters such as the macrocyclic ring size, its donor atom set, the spacing between donor atoms and the presence of substituents on the nitrogen donor atoms were all varied in a systematic manner while the nature of the interaction with a range of first-row transition and post-transition metal ions was monitored. Such a strategy has resulted in a number of examples of significant metal ion discrimination being observed within the above metal ions series [3–5].



Attempts by us to extend studies of the above type to the trivalent lanthanoid ions were not successful. When we endeavoured to prepare complexes of L^1 and L^2 by reacting them with europium(III) nitrate or trifluoromethanesulfonate (≡ 'triflate' ≡ $F_3CSO_3^-$ ≡ tfs) in ethanol, the crystalline materials isolated were shown by single crystal X-ray studies in three cases to be simply salts of the diversely protonated ligands.

The above behaviour parallels recently reported results [6] describing attempts to form complexes of L^1 with the sodium salts NaX (X = picrate, ClO_4, BF_4, PF_6, SCN,

doi:10.1016/j.poly.2006.08.023

and BPh_4). These studies also resulted in the isolation of metal-free protonated ligand salts of the corresponding anions; the respective products were shown to be mono- and hemi-protonated derivatives containing a diversity of cation···anion interaction types. In view of this, we now wish to augment this record with further structural results for cyclic derivatives of this type, two of which involve diprotonated species. These thus extend the array of forms and types found for such systems, as well as aiding an understanding of the anion binding therein.

L^1 L^2

2. Experimental

The three protonated salts, $(L^1H)(tfs)$, $(L^1H_2)(NO_3)_2$ (two phases) and $(L^2H_2)(tfs)_2$, were obtained on the addition of europium(III) nitrate to a solution of the corresponding free ligand, on a 1:1 millimolar scale, in a few mL of hot ethanol. Colorless crystals of the (europium-free) relevant salts were obtained on allowing the solutions to stand and slowly evaporate at ambient temperature.

2.1. Structure determinations

Initially, unique room-temperature single-counter diffractometer data sets were measured ($2\theta/\theta$ scan mode; monochromatic Mo Kα radiation, $\lambda = 0.7107_3$ Å, $2\theta_{max} = 50°$; T ca. 295 K), yielding N independent data, used without absorption correction in the refinements, N_0 with $I > 3\sigma(I)$ being considered 'observed', refining anisotropic displacement parameter forms for the non-hydrogen atoms, $(x, y, z, U_{iso})_H$ being also refined or constrained at estimates, supported by difference map evidence. The determinations were of indifferent quality and, material for two of the materials having been preserved, redeterminations were undertaken with the advent of a 'low'-temperature CCD facility, full spheres of data being measured (Bruker AXS instrument, ω-scans, $2\theta_{max} = 50°$; T ca. 153 K), $N_{t(otal)}$ reflections being merged (R_{int} cited) after 'empirical'/multi-scan absorption correction (proprietary software), the 'observed' criterion being $F > 4\sigma(F)$. Conventional residuals, R, R_w are cited on $|F|$ at convergence (weights $= (\sigma^2(F) + 0.0004F^2)^{-1}$). Neutral atom complex scattering factors were employed within various versions of the Xtal 3.x program system [7]. Pertinent results are given below and in the figures, the latter showing 20% (295 K), 50% (153 K) probability amplitude displacement ellipsoids for the non-hydrogen atoms, hydrogen atoms having arbitrary radii of 0.1 Å; individual variations in procedure are cited as 'variata'. Full *cif* depositions, which follows a further refinement cycle on F^2, reside with the Cambridge Crystallographic Data Base, CCDC 611987-611990.

2.1.1. Crystal/refinement data

2.1.1.1. $(L^1H)(tfs)$. $C_{20}H_{25}F_3N_2O_5S$, $M = 462.5$, triclinic, space group $P\bar{1}$ (C_i^1, No. 2), $a = 12.485(3)$, $b = 10.365(2)$, $c = 9.275(2)$ Å, $\alpha = 87.03(1)$, $\beta = 69.62(2)$, $\gamma = 89.28(2)°$, $V = 1124$ Å^3. D_c $(Z = 2) = 1.36_7$ g cm^{-3}. $\mu_{mo} = 2.0$ cm^{-1}; specimen: $0.20 \times 0.60 \times 0.25$ mm; $N = 3926$, $N_0 = 2506$; $R = 0.060$, $R_w = 0.065$. $(x, y, z, U_{iso})_H$ refined. Single-counter instrument, T ca. 295 K.

Comment. Displacement parameters were high on the anion components, no disorder being resolvable.

2.1.1.2. $(L^1H_2)(NO_3)_2$. $C_{19}H_{26}N_4O_8$, $M = 438.4$, triclinic, space group $P\bar{1}$.

2.1.1.2.1. Z = 2 form. $a = 12.525(5)$, $b = 10.207(5)$, $c = 9.229(4)$ Å, $\alpha = 68.06(4)$, $\beta = 75.31(3)$, $\gamma = 80.21(4)°$, $V = 1055$ Å^3. $D_c = 1.38_0$ g cm^{-3}. $\mu_{Mo} = 1.1$ cm^{-1}; specimen: $0.08 \times 0.24 \times 0.55$ mm. $N = 3691$, $N_0 = 1489$; $R = 0.073$, $R_w = 0.071$. $(x, y, z, U_{iso})_H$ constrained. Single counter instrument, T ca. 295 K.

2.1.1.2.2. CCD instrument, T ca. 153 K.

2.1.1.3. $(L^2H_2)(tfs)_2$. $C_{23}H_{31}F_6N_3O_8S_2$, $M = 655.6$. Monoclinic, space group $P2_1/c$ ($C_{2/h}^5$, No. 14), $a = 12.080(4)$, $b = 18.530(6)$, $c = 12.810(4)$ Å, $\beta = 95.758(5)°$, $V = 2853$ Å^3. D_c $(Z = 4) = 1.52_2$ g cm^{-3}. $\mu_{Mo} = 2.8$ cm^{-1}; specimen: $0.19 \times 0.09 \times 0.05$ mm; 'T'$_{min/max} = 0.82$. $N_t = 21\,677$, $N = 4830$ ($R_{int} = 0.10$), $N_0 = 2972$; $R = 0.064$, $R_w = 0.080$. $(x, y, z, U_{iso})_H$ constrained. CCD instrument, T ca. 153 K.

3. Results and discussion

In the recent report [6] mentioned above, the structural characterization of the metal-free products crystallized from methanol solutions of the sodium salts (NaX) and L^1 were described. In these studies ratios of NaX:L^1 of 1:1 were employed for the reactions in the presence of picrate and BPh_4 counterions (=X), yielding for the picrate, $(HL^1)(pic)$, and for BPh_4, $(H_2L_3^1)(BPh_4)_2$. The latter was not structurally characterized but was shown to yield $(HL)(BPh_4)$ on recrystallization from acetonitrile and the structure of this product was obtained. This latter product was also obtained when the synthesis was carried out directly in acetonitrile. For $X = ClO_4$, BF_4, PF_6, SCN, ratios of NaX:L^1 of 1:2 were employed, with the products in these cases having novel $(HL_2^1)X$ stoichiometries.

In the present work, the results of our single crystal X-ray structure determinations are in general consistent

with the above formulations. In our case the crystallization of L^1 or L^2 with europium(III) nitrate or triflate in 1:1 ratio from ethanol yielded unsolvated products of type $(HL^1)(tfs)$, $(H_2L^1)(NO_3)_2$ and $(H_2L^2)(tfs)_2$. All three are metal free and the first two show a generally higher degree of protonation for L^1 (with one exception). This is consistent with the use of the trivalent lanthanoid species, which are more acidic than the group 1 metal ions in solution. A

Carbon atoms are denoted by number only; the three values in each entry are for (**L^{1}H**)(tfs); $(L^1H_2)(NO_3)_2$ ($Z = 2$ form); $(L^1H_2)(NO_3)_2$ ($Z = 4$ form; two cations). θ is the interplanar dihedral angle between the pair of aromatic C_6 ring planes; n' denotes the alternate ligand segment.
[a] In the $Z = 4$ (triclinic) nitrate, for $n = 1$, 2 read $n = 3$, 4.

consequence of the lower ratio of X to protonated ligand in the ClO_4, BF_4, PF_6, SCN arrays, in which, as in all arrays under discussion, the ring NH groups are protonated rather than O, is a propensity toward hydrogen-bonding either within the macrocycle (NH···N or NH···O) or between adjacent macrocycles (NH···N). Despite the differing degree of protonation between the compounds of Ref. [6], the macrocycle conformations of the L^1 arrays are similar throughout, as indicated persuasively by Fig. 10 of this reference.

In the structure of (L^1H)(tfs), (Fig. 1, Tables 1 and 2), one formula unit, devoid of crystallographic symmetry, comprises the asymmetric unit of the structure, containing the only singly protonated cation of the present array of compounds. The macrocycle conformation (Fig. 1, Table 2) is the same as that found in the previous study [6]. Hydrogen-bonding is found from the protonated NH_2^+ (21) grouping, the hydrogen atoms being disposed so that one H(21C) is directed toward the unprotonated N(11) with a longer distance across the ring toward O(28) [N(21), H(21C)···O(28) 3.021(3), 2.5, Å]. The other hydrogen atom, H(21D), interacts with one of the tfs anion oxygen atoms so that an ion-pair is formed.

Remarkably, the specimen defined at low-temperature for $(L^1H_2)(NO_3)_2$ differs from that occurring at room-temperature, the former having two independent formula units devoid of crystallographic symmetry comprising the asymmetric unit of the structure (153 K, $Z = 4$), while the other (295 K, $Z = 2$) has one. Both forms are triclinic, $P\bar{1}$, each with a short axis ca. 9.1 Å; both have overlapping cation strings, running along a in the $Z = 2$ form, and the bc cell diagonal in the $Z = 4$ form. The most immediately obvious difference lies in the disposition of the anions, the two independent nitrate groups lying quasi-parallel to the short cell axis in the $Z = 2$ form, while in the $Z = 4$ form nitrate groups 2, 3 are thus disposed, with nitrate 1 quasi-normal to the axis (Figs. 2 and 3). The macrocycle conformations are similar throughout the three independently defined specimens (Table 2) and different to that of the less heavily protonated forms discussed previously. Within the macrocycle, the conformation of the C_3 string between the pair of nitrogen atoms is now such that the NH···N intra-cation

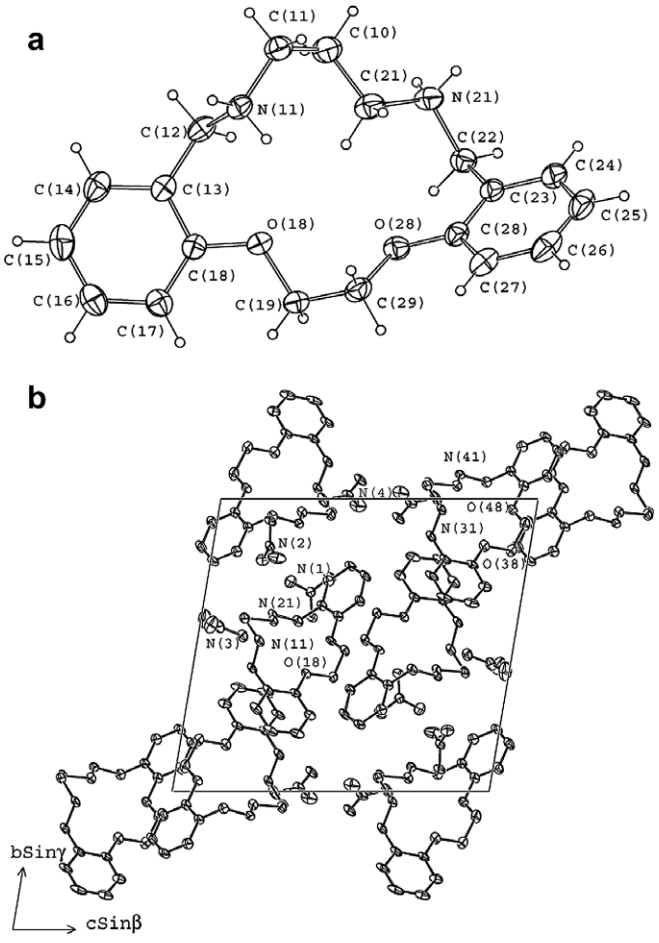

Fig. 2. (a) The $(L^1H_2)^{2+}$ cation in $(L^1H_2)(NO_3)_2$ ($Z = 2$ form). (b) Unit cell contents of $(L^1H_2)(NO_3)_2$ ($Z = 2$ form) projected down a.

interactions found in the mono-protonated forms are no longer feasible. The nitrogen atoms of each ring are oriented so that for each there is still indeed an '*endo*'-NH hydrogen atom, but its proximity to the associated oxygen atom is now appreciably closer. In the $Z = 2$ form, all NH hydrogen atoms interact with the nitrate groups, two of these with nitrate 1 with a pair of such anions related by a simple translation along the short axis, thus generating a strand of alternating anions and cations in that dimension,

O(19)–30–29–28	−79.2(5)	θ	69.6(2)

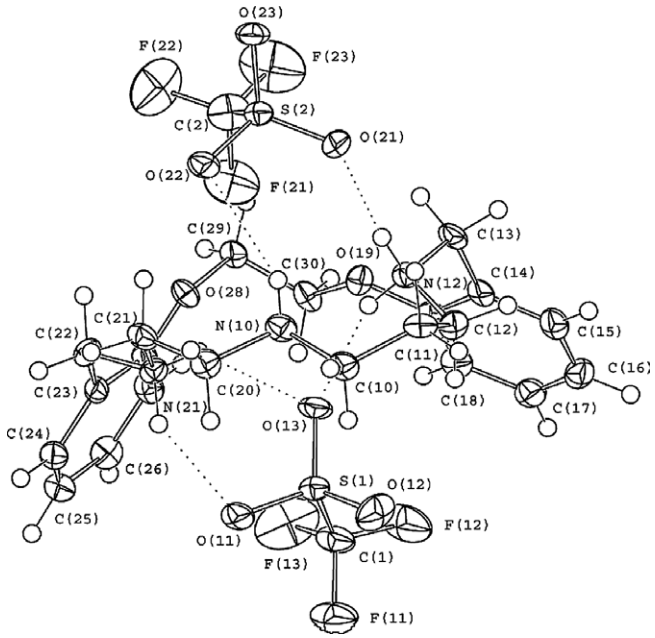

Fig. 4. The $[(L^2H_2)(tfs)_2]$ aggregate.

with similar inversion related interactions with nitrate 2 linking the cations along b, resulting in a two-dimensional web. The dispositions in the $Z = 4$ form are rather similar, nitrates 3 linking cations 1 along a, with nitrates 1, 2 linking in the other dimensions to cations 2, and nitrates 4 linking cations 2 along a.

In $(L^2H_2)(tfs)_2$, the cation is also diprotonated, the protonic hydrogen atoms being associated with the peripheral rather than the central nitrogen atom, which has none of the protonic hydrogen atoms in its near vicinity, similarly true of the macrocycle oxygen atoms; one formula unit, devoid of crystallographic symmetry, comprises the asymmetric unit of the structure. Here the interactions between cation and anion are tight and unambiguously confined within the asymmetric unit, forming a cluster $[(L^2H_2)(tfs)_2]$ with anion 1 approaching to one side of the macrocycle, O(11) interacting with H(21D) and O(13) with H(12D, 21C), and anion 2 from the other side, O(21) interacting with H(12C) and O(22), less strongly, with the central NH hydrogen atom H(10) (Tables 1 and 3, Fig. 4).

4. Concluding remarks

The present results extend the known protonated forms of the O_2N_2-donor macrocycle L^1 as well as providing a comparative structure of a related protonated O_2N_3-donor structure. They also show that under the conditions employed, the affinities of L^1 and L^2 for protons are higher than for europium(III). Further, they provide insight into the modes of anion binding in such macrocyclic species, a topic of much current interest [8,9] with implications for a range of biological, sensing, separation (including ion exchange and solvent extraction) applications.

Abstract

Two novel compounds of the formulae $[\{Cu(phen)_2\}_2(\mu\text{-}C_2O_4)][Cu(phen)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]_2 \cdot 8H_2O$ (**1**) and $[\{Cu(bpy)_2\}_2(\mu\text{-}C_2O_4)][Cu(bpy)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]_2 \cdot 0.5bpy \cdot 7H_2O$ (**2**) (phen = 1,10-phenanthroline, bpy = 2,2′-bipyridine) have been prepared and characterized by single crystal X-ray diffraction, IR spectroscopy and magnetic susceptibility measurements. The molecular structure of both **1** and **2** consists of a discrete $Cu^{II}Cu^{II}$ oxalate-bridged dinuclear $[\{Cu(L)_2\}_2(\mu\text{-}C_2O_4)]^{2+}$ cation (**A** unit) and two $Cu^{II}Nb^{V}$ oxalate-bridged dinuclear $[Cu(L)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]^{-}$ anions (**B** units) (L = phen, bpy). In **1** a crystallographic inversion centre is located in the middle of the oxalate bridge of the **A** unit, whereas in **2** an analogous inversion centre is missing. In the **A** units the copper(II) atoms adopt a tetragonally elongated octahedral coordination with the equatorial planes being perpendicular to the mean planes of the oxalate bridge and parallel to each other. In both structures, similar one-dimensional motifs are generated through the ligand stacking interactions, with a difference that one free bipyridine molecule, present in **2**, intercalates into one of the motifs. It is shown that the phenanthroline ligand, due to its ability of stacking through the central aromatic ring, causes longer intermolecular Cu···Cu distances than the bipyridine ligand. The magnetic susceptibility measurements (1.8–290 K) show the ferromagnetic exchange interaction between the copper(II) atoms in the **A** units of both compounds, with $J = +5.9\ cm^{-1}$ and $+7.9\ cm^{-1}$ for **1** and **2**, respectively (J – the exchange parameter in the isotropic spin Hamiltonian $\mathbf{H}_{INT} = -J\mathbf{S}_1 \cdot \mathbf{S}_2$).

1. Introduction

The use of tris(oxalato)metallates, $[M^{III}(C_2O_4)_3]^{3-}$ (M^{III} = Cr, Fe, Ru, V), in the synthesis of new homo- or heterometallic oxalate-bridged complex systems is constantly growing. In the reactions of these anions with organic and inorganic cations different structure types resulted ranging from discrete polynuclear metal species [1–3] to polymeric one- (1D) [4,5], two- (2D) [6–13] or three-dimensional (3D) [14–16] assemblies. In these investigations the scientists have been trying to couple two or more paramagnetic metal centres using the oxalate $C_2O_4^{2-}$ anion, due to its ability of exhibiting a bis(bidendate) bridging coordination mode and to mediate the magnetic exchange interaction between metal ions. In general, the magnetic properties of these systems follow their structure types.

Within the discrete molecules ferro- or antiferromagnetic exchange interactions have been found [1–3]. The 1D structure of $[K(18\text{-crown-6})][Mn(H_2O)_2Cr(C_2O_4)_3] \cdot 0.5(18\text{-crown-6})$ (18-crown-6 = $C_{12}H_{24}O_6$) shows the ferromagnetic coupling within the chains as well as between the

chains reaching the bulk ferromagnetic ordering below 3.5 K [5]. The long-range magnetic order has been detected for the 2D honeycomb layered structured compound of the composition $A[M^{II}M^{III}(C_2O_4)_3]$ (A = organic monocation; M^{II} = Mn, Fe, Co, Ni, Cu, Zn, V; M^{III} = Cr, Fe, Ru, V). Ferro- or ferrimagnets are formed depending on metal ion, with T_c values in the range 5–14 K for $[M^{II}Cr^{III}(C_2O_4)_3]^-$ [6,8,10], and 13 K for $[Fe^{II}Ru^{III}(C_2O_4)_3]^-$ [11,12]. Compounds $A[V^{II}V^{III}(C_2O_4)_3]$ and $A[V^{II}V^{III}(C_2O_4)_3(H_2O)_2]$ order as ferrimagnets at 11 and 30 K, respectively [13]. A series of compounds $[Fe^{II}Fe^{III}(C_2O_4)_3]^-$ behave as ferrimagnets with T_c in the range 33–48 K [9]. The long-range ferromagnetic order with T_c up to 6.6 K within the 3D structures of tris(oxalato)metallates was found for a series of compounds $[Z^{II}(bpy)_3][ClO_4][M^{II}Cr^{III}(C_2O_4)_3]$ (Z^{II} = Ru, Fe, Co, Ni; M^{II} = Mn, Fe, Co, Ni, Cu, Zn) [16].

In relation to the study with tris(oxalato)metallates we have extended the investigations to the complex oxotris(oxalato)niobate(V) anion, $[NbO(C_2O_4)_3]^{3-}$, investigated earlier in our laboratory [17]. Unexpectedly, in the reaction of this anion with $CuCl_2 \cdot 2H_2O$ and ethanol solution of 1,10-phenanthroline we have isolated $[\{Cu(phen)_2\}_2(\mu\text{-}C_2O_4)][Cu(phen)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]_2 \cdot 8H_2O$ (**1**), and in the reaction with $[Cu(bpy)_3]Cl_2 \cdot 6H_2O$ the compound $[\{Cu(bpy)_2\}_2(\mu\text{-}C_2O_4)][Cu(bpy)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]_2 \cdot 0.5bpy \cdot 7H_2O$ (**2**) has formed. Both compounds contain $Cu^{II}Cu^{II}$ and $Cu^{II}Nb^{V}$ oxalate-bridged dinuclear units with a ferromagnetic spin-exchange interaction within the former.

2. Experimental

2.1. Materials

All reagents used in the syntheses were purchased from commercial sources and applied without further purification. Synthesis of $(NH_4)_3[NbO(C_2O_4)_3] \cdot H_2O$ and $[Cu(bpy)_3]Cl_2 \cdot 6H_2O$ was performed according to the methods in the literature [18–20].

2.2. Synthesis of the complexes

2.2.1. $[\{Cu(phen)_2\}_2(\mu\text{-}C_2O_4)][Cu(phen)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]_2 \cdot 8H_2O$ (*1*)

To an aqueous solution (10 mL) of $(NH_4)_3[NbO(C_2O_4)_3] \cdot H_2O$ (0.106 g, 0.238 mmol) an aqueous solution (5 mL) of $CuCl_2 \cdot 2H_2O$ (0.081 g, 0.477 mmol) and an ethanol solution (5 mL) of phen (0.189 g, 0.953 mmol) were added dropwise by stirring at room temperature. Immediately, the reaction mixture became cloudy forming a blue precipitate, which was removed by filtration. Almost at the same time two kinds of single crystals started to grow up: blue needles of $[Cu(phen)(C_2O_4)H_2O] \cdot H_2O$ [21] and light green polyhedral crystals of **1**. They were separated mechanically. The green crystals of **1** were washed with water and dried in air. The yield was 0.046 g, 17% (based on Nb). *Anal.* Calc. for $C_{110}H_{80}Cu_4Nb_2N_{16}O_{38}$ (M_r = 2673.88): C, 49.41; H, 3.02; N, 8.38. Found: C, 49.72; H, 3.12; N, 8.51%. IR $\tilde{\nu}/cm^{-1}$: 3422 (m, br), 3060 (w), 1735 (w), 1710 (vs), 1692 (vs), 1647 (sh), 1630 (vs), 1585 (m), 1517 (m), 1493 (w), 1453 (w), 1427 (s), 1401 (s), 1362 (s), 1341 (m), 1295 (m), 1250 (m), 1223 (w), 1153 (w), 1142 (w), 1105 (w), 1090 (w), 1035 (w), 1001 (w), 943 (m), 906 (m), 868 (sh), 853 (s), 802 (m), 793 (m), 724 (s), 651 (w), 644 (w), 541 (w), 475 (w), 428 (w), 397 (w), 364 (w), 333 (w).

2.2.2. $[\{Cu(bpy)_2\}_2(\mu\text{-}C_2O_4)][Cu(bpy)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]_2 \cdot 0.5bpy \cdot 7H_2O$ (*2*)

After mixing an aqueous solution (10 mL) of $(NH_4)_3[NbO(C_2O_4)_3] \cdot H_2O$ (0.104 g, 0.234 mmol) and an aqueous solution (10 mL) of $[Cu(bpy)_3]Cl_2 \cdot 6H_2O$ (0.166 g, 0.234 mmol) the resulting blue solution became cloudy and a blue precipitate formed. The reaction mixture was left for 24 h when the precipitate was removed by filtration. The filtrate was allowed to concentrate slowly at ambient conditions. In the period of five days blue polyhedra-like single crystals of **2** were obtained, which were filtered off, washed with water and dried in air. The yield was 0.086 g, 58% (based on Cu). *Anal.* Calc. for $C_{99}H_{82}Cu_4Nb_2N_{17}O_{37}$ (M_r = 2541.80): C, 46.78; H, 3.25; N, 9.37. Found: C, 46.48; H, 3.22; N, 9.34%. IR $\tilde{\nu}/cm^{-1}$: 3425 (m, br), 3074 (w), 1730 (sh), 1711 (vs), 1687 (vs), 1648 (sh), 1631 (s), 1598 (s), 1493 (m), 1474 (m), 1443 (s), 1376 (s), 1316 (m), 1301 (w), 1286 (sh), 1242 (w), 1178 (w), 1160 (w), 1101 (w), 1060 (w), 1045 (w), 1029 (m), 1014 (w), 933 (m), 904 (m), 801 (m), 792 (m), 775 (s), 734 (m), 650 (w), 633 (w), 543 (w), 482 (w), 421 (w), 397 (w), 362 (w), 339 (m).

2.3. Physical measurements

Elemental analyses for C, H and N were carried out using a Perkin–Elmer Model 2400 microanalytical analyser.

Infrared spectra were recorded as KBr pellets on an ABB Bomem FT model MB 102 spectrometer in the 4000–200 cm^{-1} region.

The magnetic data for **1** and **2** were collected on a commercial SQUID magnetometer (MPMS-5, Quantum Design). The measurements were performed in the temperature range 1.8–290 K for the applied magnetic field of 1 T. The field dependence of the magnetic moments was checked up to 5 T and both compounds showed linearity up to more than 1 T; therefore, the susceptibilities analyzed here are field-independent. Prior to any calculation, the measured data were corrected against the sample holder's contribution. Diamagnetic corrections for the constituent atoms were estimated from the Pascal's constants [22] and found to be -1389×10^{-6} cm^3 mol^{-1} (**1**) and -1034×10^{-6} cm^3 mol^{-1} (**2**). The magnetic susceptibilities were also corrected for the temperature-independent paramagnetism (60×10^{-6} cm^3 mol^{-1} per Cu^{II}) [23].

2.4. X-ray crystallographic study

Suitable single crystals of **1** and **2** were selected and mounted on an Enraf-Nonius Kappa CCD diffractometer. All data were collected by graphite monochromated Mo-Kα radiation ($\lambda = 0.71073$ Å) at 200 K. Crystals of dimensions small enough (ca. $0.12 \times 0.1 \times 0.1$ mm) to avoid errors generated by the absorption of the X-rays in the samples were chosen. Data reduction and determination of the unit cell parameters were performed using the DENZO-SCALEPACK program [24].

Both structures were solved and refined by the SHELXS-97 and SHELXL-97 programs [25,26]. The majority of non-hydrogen atoms were found by direct methods and the rest of them were located from subsequent difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic thermal displacement parameters (ADP) and hydrogen atoms were treated with isotropic thermal displacement parameters. Hydrogen atoms from phenanthroline or bipyridine moieties were placed in the calculated positions and restrained to ride on the atoms to which they were bonded, with $U_{iso}(H) = 1.2U_{eq}(C)$. Starting positions of hydrogen atoms from crystal water molecules were located by the M. Nardelli algorithm [27] implemented in the WINGX program [28]. Later on, the crystal water molecules were treated as rigid groups [O–H distances of 0.84 Å, H–O–H angles of 104°, $U_{iso}(H) = 1.2U_{eq}(O)$], leaving rotations of the molecules to be free. To improve convergence of the last refinement cycles, few additional restraints were added. For compound **2** we found that the O34, C56, C57 and C58 atoms possess somewhat unusual (elongated) ADP parameters. Details on crystallographic structural analyses of compounds **1** and **2** are summarized in Table 1.

3. Results and discussion

3.1. Molecular structures

Both compounds **1** and **2** contain one oxalate-bridged $Cu^{II}Cu^{II}$ unit (**A**) and two oxalate-bridged $Cu^{II}Nb^{V}$ units (**B**) (Figs. 1 and 2). In **1**, there is a crystallographic inversion centre in the middle of the oxalate bridge of the **A** unit; in this way, just one half of the **A** unit and only one of the two **B** units are symmetrically independent (Fig. 1). In **2**, the lack of an analogous crystallographic centre of symmetry in the **A** unit, results in crystallographic independency of all atoms, in the **A** unit as well as in both of the **B** units (**B1** and **B2**). Units of the **A** type possess an approximate $2/m$ molecular symmetry in both compounds.

In **1** and **2** the copper(II) atoms (d^9 configuration) are octahedrally coordinated by four nitrogen atoms from the two phenanthroline or bipyridine ligands, respectively, and by two oxygen atoms from the bridging oxalate groups. In addition to the expected trigonal distortion (three bidendate ligands), a tetragonal elongation in the Cu environment is also observed. In the **A** unit of **1**, the O4 and N3 atoms are connected to the Cu1 atom at distances that are in average for 0.29 Å larger than for the other four atoms (Table 2). Thus, Cu1 is located in a tetragonally elongated coordination environment with the four-fold axis roughly matching the Cu1–O4 and Cu1–N3 bonds direction. With respect to the **A** unit of **2**, the Cu1–N2 and Cu1–O3 bond lengths are in average for 0.26 Å larger than the other four [around Cu1] and the Cu2–O5 and Cu2–N6 bond lengths are in average for 0.23 Å larger than the others [around Cu2] (Table 1), confirming a tetragonally elongated coordination of the Cu atoms. Tetragonal elongation of the ligand field is very frequent for copper(II) ions [23] and this is a nice example of the Jahn-Teller effect; the system with an orbitally degenerate ground state (^2E_g, for a perfect octahedral ligand field) spontaneously undergoes a tetragonal distortion reaching the orbitally non-degenerate $^2B_1$ ground state. More precisely, the Cu1 atom in **1** and the Cu1 and Cu2 atoms in **2** are parts of the *cis*-CuN_4O_2 chromophores, which cannot be described in a perfect octahedral symmetry; since, the observed elongations are consequences of a pseudo Jahn-Teller effect [30]. Anyway, these elongations enable us to identify the topology and the type of the atomic Cu orbitals ($d_{x^2-y^2}$ or d_{z^2}) that should be considered as the main parts of the magnetic orbitals, i.e. the orbitals carrying one unpaired electron (spin). In tetragonally elongated environments, $d_{x^2-y^2}$ should be singly occupied [23,30]. The lobes of the $d_{x^2-y^2}$ orbital should be oriented toward the 4 nearest atoms in the coordination environment of Cu atoms. Therefore, the magnetic orbital of the Cu1 atom in **1** should lie in the mean plane of the N1, N2, N4 and O3 atoms and due to the crystallographic centre of symmetry,

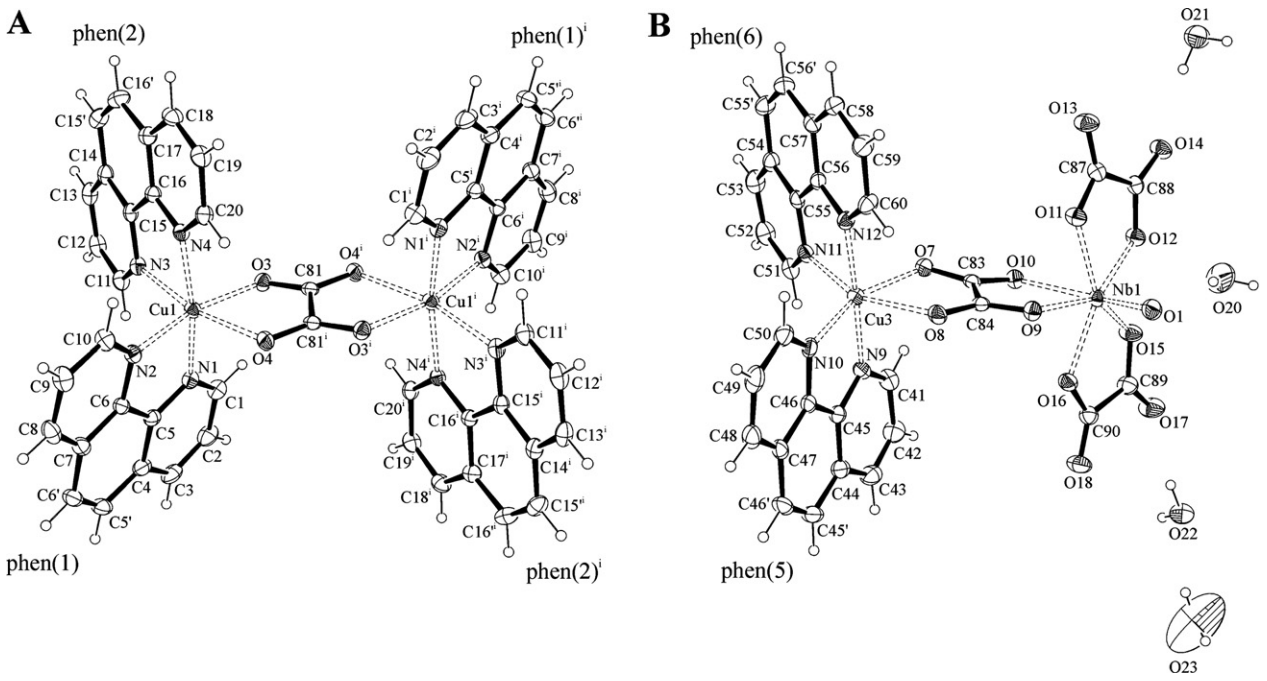

Fig. 1. ORTEP-III drawings [29] of the molecular structure of **1** with atom numbering scheme [symmetry code: (i) $1-x, -y, -z$].

the magnetic orbital of the $Cu1^{i}$ atom should lie in the mean plane of the $N1^{i}$, $N2^{i}$, $N4^{i}$ and $O3^{i}$ atoms [symmetry code: (i) $1-x, -y, -z$]. The magnetic orbitals of Cu1 and $Cu1^{i}$ in the **A** unit are therefore parallel to each other and both of them perpendicular to the plane of the bridging oxalate group. They are also parallel with the planes of phen(1) and phen(1)^{i} and perpendicular to the planes of phen(2) and phen(2)^{i}. The intramolecular distance $Cu1\cdots Cu1^{i}$ in **1** is 5.6193(5) Å. In **2**, the magnetic orbital of the Cu1 atom should lie in the mean plane of the N1, N3, N4 and O4 atoms, while the magnetic orbital of the Cu2 atom should lie in the mean plane of the N5, N7, N8 and O6 atoms. Again, the magnetic orbitals turn out to be parallel to each other and perpendicular to the plane of the bridging oxalate group. They are parallel with the planes of bpy(2) and bpy(4) and perpendicular to the planes of bpy(1) and bpy(3). The intramolecular distance $Cu1\cdots Cu2$ in **2** is 5.6340(7) Å, i.e. only for 0.015 Å larger than the analogous distance in **1**.

In regard to the **B** units, tetragonal elongations of the coordination geometry around the Cu atoms are in both compounds more questionable, because the pairs of the largest bond lengths are not necessarily those that are oppositely oriented (Table 2, Figs. 1 and 2). Anyway, the largest bond length in each particular coordination environment around Cu comprises one of the oxygen atoms from the bridging oxalate group, i.e. O8 (from the **B** unit of **1** and the **B1** unit of **2**) or O20 (from the **B2** unit of **2**). Also, the three shortest bond lengths are always made up by three nitrogen atoms from phenanthroline or bipyridine ligands, i.e. N9, N10 and N12 (from the **B** unit of **1** and the **B1** unit of **2**) and N13, N14 and N16 (from the **B2** unit of **2**). The remaining nitrogen atoms [N11 and N15] are those that are oppositely oriented to the O8 and O20 atoms, respectively, having in average for 0.13 Å larger bond lengths toward the Cu atoms than the three shortest ones. Therefore, it can be still assumed that a tetragonal elongation driven by the Jahn-Teller effect is present in the observed Cu atom environments. The remaining oxygen atoms from the bridging oxalate groups [O7 and O19] are connected to the Cu atoms at comparably large distances (Table 2). If the $d_{x^2-y^2}$ orbital is still the one with the highest energy, it should remain the main part of the magnetic orbitals of the Cu3 and Cu4 magnetic centres. Therefore, in one magnetic centre (Cu3) this orbital should lie in the mean plane of the N9, N10 and N12 atoms and in the other one (Cu4) this orbital should lie in the mean plane of the N13, N14 and N16 atoms. In both cases, the orbitals are perpendicular to the plane of the bridging oxalate groups, parallel with one phenanthroline (bipyridine) ligand [phen(5) or bpy(5) for Cu3 and bpy(7) for Cu4] and perpendicular to the other phenanthroline (bipyridine) ligand [phen(6) or bpy(6) for Cu3 and bpy(8) for Cu4].

The environments of the Nb atoms in the **B** units of **1** and **2** are similar to those previously observed in other compounds containing the $[NbO(C_2O_4)_3]^{3-}$ entities [18,19]. The relevant Nb–O bonds are listed in Table 3. Six oxygen atoms from the three oxalate ligands and one oxo-oxygen atom comprise the coordination number seven around Nb, in distorted pentagonal–bipyramidal geometry, where one of the oxalate groups serves as a bridge between the Nb and Cu atoms. The equatorial plane of the pentagonal bipyramid around Nb1 is defined by the O9, O11, O12, O15 and O16 atoms, whereas a similar plane for Nb2 in **2** is defined by the O21, O23, O24, O27 and O28 atoms. The oxo-oxygen atoms [O1 or O2] are located in the

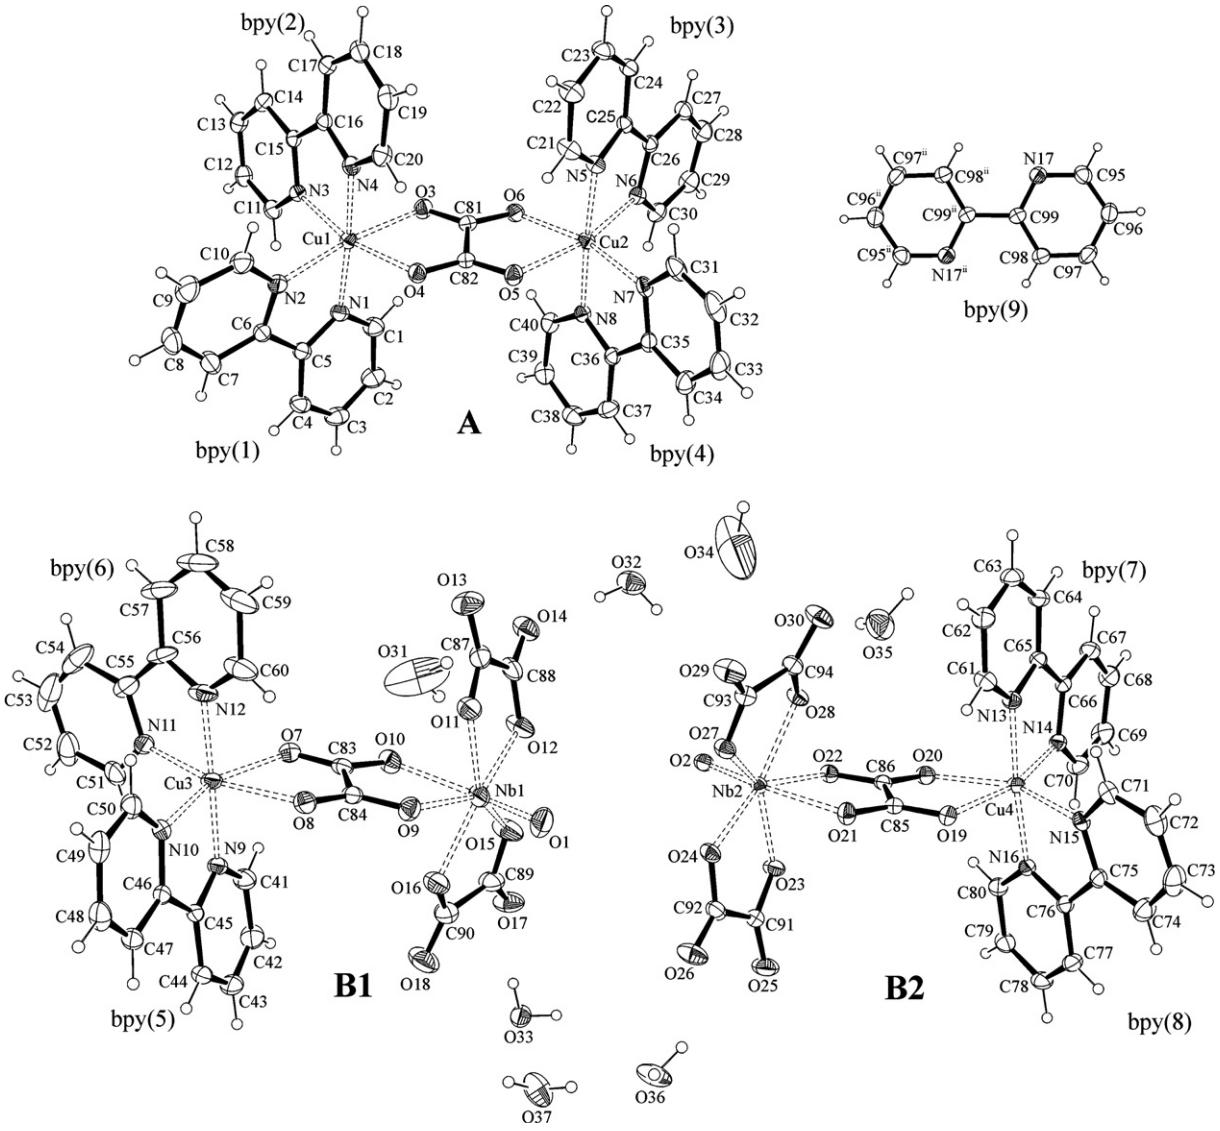

Fig. 2. ORTEP-III drawings [29] of the molecular structure of **2** with atom numbering scheme [symmetry code (ii): $1-x$, $1-y$, $1-z$].

apices of the pentagonal bipyramids and are at the shortest interatomic distances from Nb, confirming a double-bond character of the Nb=O bond. The other apices of the coordination polyhedra around Nb are occupied by the oxygen [O10 or O22] atoms from the bridging oxalate groups. These atoms have the largest Nb–O bond lengths and are just diametrically opposite to the O8 and O20 atoms (inside

the bridging oxalate ligands) that are at the largest distances from the Cu atoms (Figs. 1 and 2, Table 3).

The Nb atoms are in the diamagnetic +5 oxidation state. This is naturally understood from the charge neutrality requirements, but could be also verified by the method of bond-valence parameters given by Brese and O'Keeffe [31]. This method associates the valence of a bond between two atoms, v_{ij}, with the corresponding bond length, d_{ij}, according to the relation:

$$v_{ij} = \exp[(R_{ij} - d_{ij})/0.37] \quad (1)$$

The bond-valence parameter, R_{ij}, should not depend on the structure, but on the type of the atoms connected by a chemical bond only. The sum of all bond valences over the atoms in a coordination polyhedron should be equal to the oxidation state of the central atom. Using a value of 1.911 for R_{ij}, as found for the Nb^{V} and O combination [31], the calculation leads to the bond valence sum of 4.98, 4.96 and 4.94 for Nb1 in **1**, Nb1 in **2** and Nb2 in **2**, respectively. The values corroborate well with the assigned oxidation states of the Nb atoms. Therefore, the dinuclear $Cu^{II}Nb^{V}$ units (**B** units) are the systems containing just one spin (magnetic centre) located on the Cu^{II} atoms.

3.2. Crystal structures

The **A** and **B** units in both **1** and **2** are joined together by specific packing forces into the overall crystal structures. Among the competitive factors, stacking interactions of the aromatic systems seem to have structurally the most significant role. Several types of stacking interactions can be anticipated in both structures: the interactions between two neighbouring **A** units (**A**–**A**), the interactions between two neighbouring **B** units (**B**–**B**) and those appearing between two units of different type (**A**–**B**).

3.2.1. Stacking and C–H···π interactions in *1*

The stacking interactions between the phenanthroline ligands in **1**, classified according to the **A**–**A**, **B**–**B** or **A**–**B** types, and related parameters are listed in Table 4.

The first type (**A**–**A**) involves two phenanthroline ligands [phen(1) and phen(1)^{iii}] mutually related through the centre of symmetry *i* placed in the origin of the unit cell (Fig. 3). Due to this symmetry, the mean planes of the two stacked phenanthroline ligands are parallel ($\Theta = 0$, Table 4) with the distance between them being equal to 3.395(2) Å. However, the distance between their centres of gravity is considerably larger [4.010(2) Å, Table 3], since the ligands are shifted along their mean planes. Actually, the π···π stacking interaction acts between the central aromatic rings of the phenanthroline ligands, and the distance between the centres of gravity of the central rings [3.614(2) Å] is closer to the distance between the mean planes of the two ligands than to the distance between the centres of gravity of the phenanthroline ligands in the whole (Table 4). The existence of two mutually independent crystallographic centres of symmetry, i.e. *i* placed at the origin [connecting two **A** units *via* phen(1)···phen(1)^{iii} interaction] and *i*′ placed in the middle of the **A** unit [coordinates (1/2, 0, 0)] results in a one-dimensional motif extruding along the crystallographic *a* axis (Fig. 3).

The structurally similar stacking interactions connecting the **B** units into another one-dimensional motif are shown in Fig. 4. The interaction phen(5)···phen(5)^{ii} acts through the centre of symmetry *i*″ located at the coordinates (1/2, 1/2, 1/2) and the interaction phen(6)···phen(6)^{iv} connects two units through the centre of symmetry *i*‴ located at the coordinates (0, 1/2, 0). Thus formed one-dimensional motif of the **B** units extrudes in the direction [1, 0, 1]. Again,

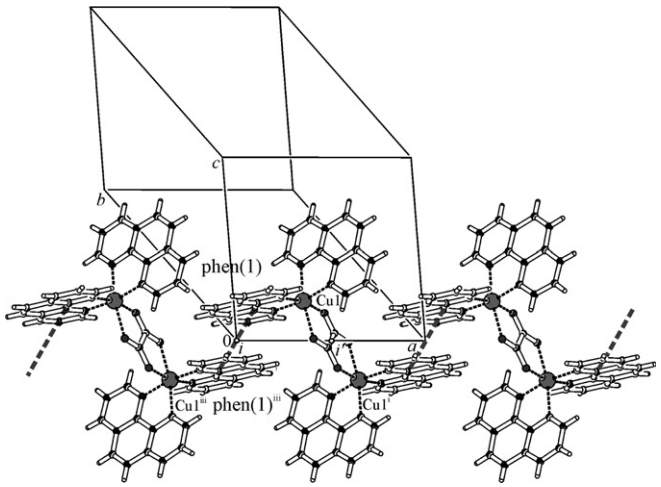

Fig. 3. One-dimensional structural motif in **1** generated by the **A**–**A** type of the phenanthroline stacking interaction (gray dashed lines). Labels and symmetry codes refer to those given in Fig. 1 and Table 4.

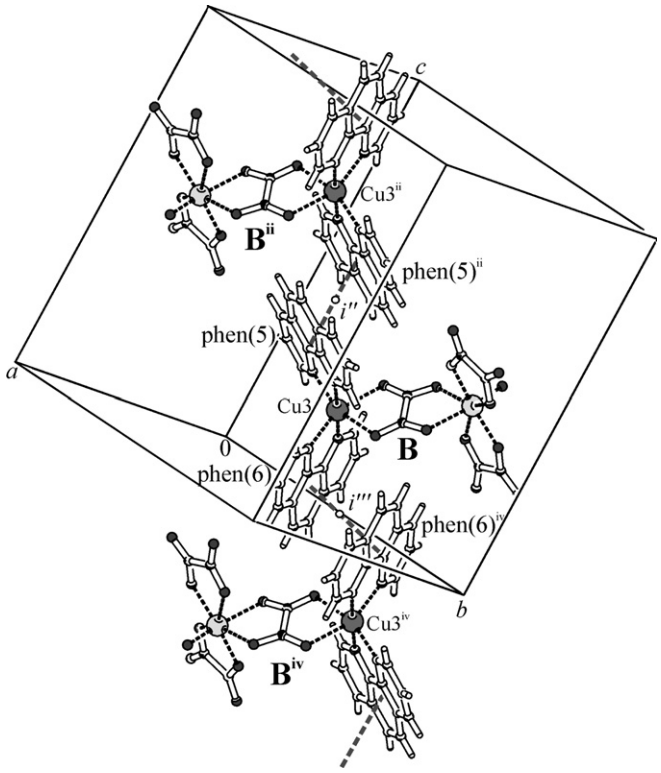

Fig. 4. One-dimensional structural motif in **1** generated by the **B**–**B** type of the phenanthroline stacking interaction (gray dashed lines). Labels and symmetry codes refer to those given in Table 4.

the phenanthroline ligands are mutually shifted in such a way that the central 6-membered aromatic rings are actually located one above another.

In the third type of stacking interactions (**A**–**B**) there is no centre of symmetry between the phenanthroline ligands. This interaction is actually a part of a more complex supramolecular embrace of two phenanthroline ligands from one **A** unit [phen(1) and phen(2)] and two phenanthroline ligands from one **B** unit [phen(5) and phen(6)] (Fig. 5). The phen(2) ligand tends to be parallel with phen(5) (stacking interaction), although the angle between their mean planes is 13.30(7)° (Table 4). The aromatic ring π(4) [N3–C11–C12–C13–C14–C15] from phen(2) is located above the aromatic rings π(8) [C44–C45–C46–C47–C46′–C45′] and π(9) [N10–C46–C47–C48–C49–C50] from phen(5) (Fig. 5). The distances π(4)···π(8) and π(4)···π(9) are 3.706(2) Å and 3.730(2) Å, respectively. These values are smaller than the distance from the centre of gravity of phen(2) to the mean plane of phen(5) (Table 4). In this supramolecular **A**–**B** embrace, three C–H···π interactions: C3–H3···π(11), C49–H49···π(3) and C50–H50···π(2) also appear (Fig. 5). The geometrical parameters for all C–H···π contacts found in the crystal structure are given in Table 5 (using criteria that H···π < 3.4 Å and C–H···π > 100°). The last three interactions listed [C59–H59···π(4)^{v}, C59–H59···π(5)^{v} and C60–H60···π(5)^{v}] actually connect a different **A**–**B** pair, i.e. the **B** unit and one **A**^{v} unit which is translated by one period in the negative direction of the *a* axis [symmetry code: (v) $-1+x, y, z$].

The shortest Cu···Cu intermolecular distance generated by a stacking or C–H···π interaction (Tables 4 and 5) is the one between the Cu1 and Cu3 atoms, having a value of 7.0091(5) Å (**A**–**B** supramolecular embrace, Fig. 5 and Table 4). The next higher value [8.6616(5) Å] is specific for the Cu3···Cu1^{v} contact [**A**–**B** pair in which the **A** unit

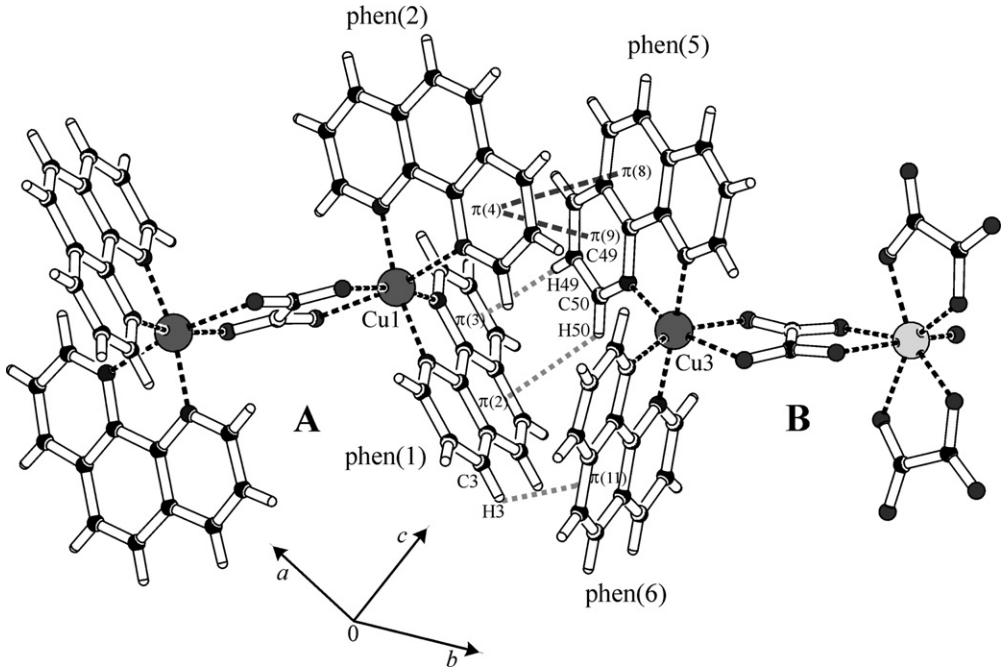

Fig. 5. The **A**–**B** type of supramolecular embrace in **1** made by phenanthroline ligands from two different types of constituents. Three π···π interactions [parts of the phen(2)···phen(5) stacking interaction given in Table 4] are shown by dark dashed gray lines, three C–H···π interactions (first three rows in Table 5) are shown by light dotted gray lines.

Table 5
C–H ···π interactions with Cu···Cu intermolecular distances in compound **1**

Interaction[a]	H ···π (Å)	C ···π (Å)	C–H···π (°)	Cu···Cu (Å)[b]
C3–H3···π(11)	3.198(4)	3.594(4)	107.8(2)	7.0091(5)
C49–H49···π(3)	2.543(4)	3.276(4)	135.9(2)	7.0091(5)
C50–H50···π(2)	3.161(3)	3.793(3)	126.8(2)	7.0091(5)

C59–H59···π(5)^{v}	3.121(3)	3.723(3)	124.0(2)	8.6616(5)
C60–H60···π(5)^{v}	2.967(4)	3.658(4)	132.3(2)	8.6616(5)

[a] π(11) = C54–C55′–C56′–C57–C56–C55; π(3) = N2–C6–C7–C8–C9–C10; π(2) = C4–C5–C6–C7–C6′–C5′; π(4) = N3–C11–C12–C13–C14–C15; π(5) = C14–C15–C16–C17–C16′–C15′.
[b] Distance between two Cu atoms to which phen ligands involved in the C–H···π interaction are coordinated; Symmetry code: (v) $-1+x, y, z$.

is translated in the negative direction of the *a* axis], realized through the C–H···π interactions only (Table 5). Therefore, the intermolecular distances between two Cu atoms related through the typical centrosymmetric stacking interactions (Figs. 3 and 4) are just the third, fourth and fifth ones in this range, with the values of 8.8147(5), 9.0199(5) and 9.2116(5) Å, respectively.

3.2.2. Stacking and C–H···π interactions in **2**

The stacking interactions of the bipyridine ligands in **2** are listed in Table 6. Several types of stacking interactions can be distinguished. The first one connecting two **A**-type units actually involves three bipyridine molecules: bpy(1) from an **A** unit, bpy(1)^{ii} from the symmetry-related unit [symmetry code: (ii) $1-x, 1-y, 1-z$] and one free bipyridine molecule [bpy(9)] which intercalates between bpy(1) and bpy(1)^{ii} (Fig. 6). The centre of symmetry of bpy(9) coincides with the crystallographic centre of symmetry *i* located at the position (1/2, 1/2, 1/2). The distance between the centres of gravity of bpy(1) and bpy(9) is 3.710(2) Å, whereas the distance from the centre of gravity of bpy(9) to the mean plane of bpy(1) is 3.346(2) Å. These values are just one half of the values representing the relevant parameters for the bpy(1)···bpy(1)^{ii} pair (Table 6, first row). The angle between the mean planes of bpy(1) and bpy(9) is 5.64(9)°. The second type of stacking interaction connecting the **A** units is realized through the crystallographic centre of symmetry *i*′ located in the vicinity of bpy(3), at the coordinates (1/2, 1, 0) (Table 6, second row). Two independent crystallographic centres of

Table 6
Stacking interactions with Cu···Cu intermolecular distances in compound **2**

Interaction bpy(*i*)··· bpy(*j*)	Type	*d* (Å)[a]	Θ (°)[b]	bpy(*i*)$_{\perp}$ (Å)[c]	Cu···Cu (Å)[d]

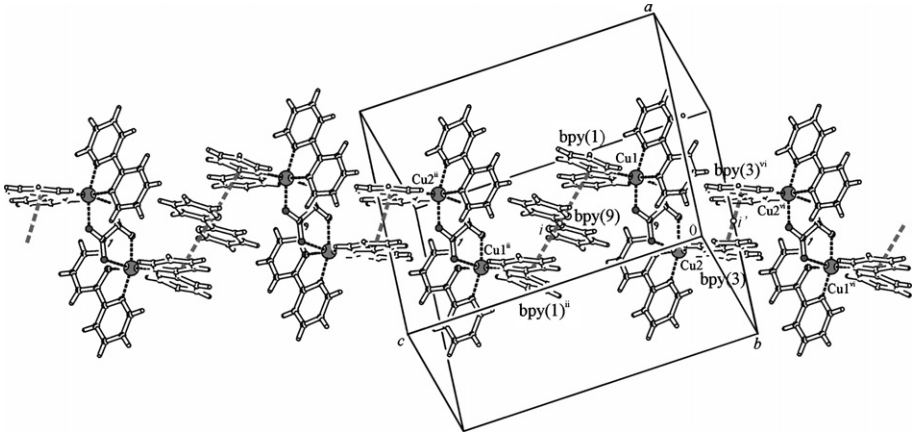

Fig. 6. One-dimensional structural motif in **2** generated by two bipyridine stacking interactions of the **A**–**A** type (gray dashed lines). bpy(9) intercalates between bpy(1) and bpy(1)^{ii}. Labels and symmetry codes refer to those given in Fig. 2 and Table 6.

symmetry generate one-dimensional motif extruding along the crystallographic direction $[0,-1,1]$ (Fig. 6). The motif is very similar to that one encountered for the **A** units in the crystal structure of **1** (Fig. 3), but with an additional free bipyridine molecule intercalating in every other bpy···bpy interaction. Due to this intercalation, a crystallographic centre of symmetry in the middle of the **A** unit can not exist [bpy(3) and bpy(4) are not symmetry related to bpy(1) and bpy(2), respectively], and this causes a lower symmetry of the **A** unit in **2** in comparison with the **A** unit in **1**.

Stacking interactions involving the **B** units in **2** are similar to the corresponding interactions appearing in the crystal structure of **1**. However, a difference arises from the fact that in the structure of **2** two symmetry independent **B** units exist, resulting in three different stacking interactions of the **B**–**B** type, i.e. **B1**–**B2**, **B1**–**B1** and **B2**–**B2** (Table 6). The **B1**–**B2** interaction connects two symmetrically independent **B** units (Table 6, third row). A small angle between the mean planes of the stacked bipyridine ligands and a relatively small difference between the d and bpy(i)$_\perp$ values show that this structural motif is almost centrosymmetric and that the bipyridine molecules on the whole are involved in the **B1**–**B2** stacking interaction. The **B1**–**B1** and **B2**–**B2** stacking interactions are strictly centrosymmetric because they operate across the crystallographic centres of symmetry i'' and i''' [located at the positions $(1,1/2,1/2)$ and $(0,1,0)$, respectively], as well as across the centres of symmetry at their symmetry equivalent positions [in Fig. 7, the i''' centre of symmetry is shown at the position (1, 0, 0)]. These three stacking interactions connect **B1** and **B2** units in a one-dimensional motif which extrudes in the direction $[0,1,1]$ (Fig. 7) and is structurally very similar to that of the **B** units in the crystal structure of **1** (Fig. 3).

The last two stacking interactions from Table 6 (**A**–**B1** and **A**–**B2**) are actually parts of two more complex supramolecular embraces (Fig. 8) and both of them are similar with the **A**–**B** embrace encountered in the crystal structure of **1** (Fig. 5). The **A**–**B1** embrace involves bpy(1) and bpy(2) from the **A** unit and bpy(5) and bpy(6) from the **B1** unit, while the second embrace (**A**–**B2**) involves bpy(3) and bpy(4) from **A** and bpy(7) and bpy(8) from **B2**. Since a centre of symmetry in the middle of the **A** unit can not exist, the **B** units embraced on each side of the **A** unit must be symmetrically independent, as well. Stacking interactions bpy(2)···bpy(5) and bpy(4)···bpy(7) listed in Table 6 do not involve the bipyridine molecules on the whole, but only one of their two pyridyl rings. This is the reason why the differences between the d and bpy(i)$_\perp$ values for this stacking interactions are so large. The π(3) and π(10) rings are stacked in the first interaction [π(3) = N3–C11–C12–C13–C14–C15, π(10) = N10–C46–C47–C48–C49–C50] and the π(7) and π(14) rings are stacked in the second interaction [π(7) = N7–C31–C32–C33–C34–C35, π(14) = N14–C66–C67–C68–C69–C70], as shown in Fig. 8. The distance between the centres of gravity of π(3) and π(10) is 3.973(2) Å, whereas the corresponding distance for π(7) and π(14) is 3.636(2) Å.

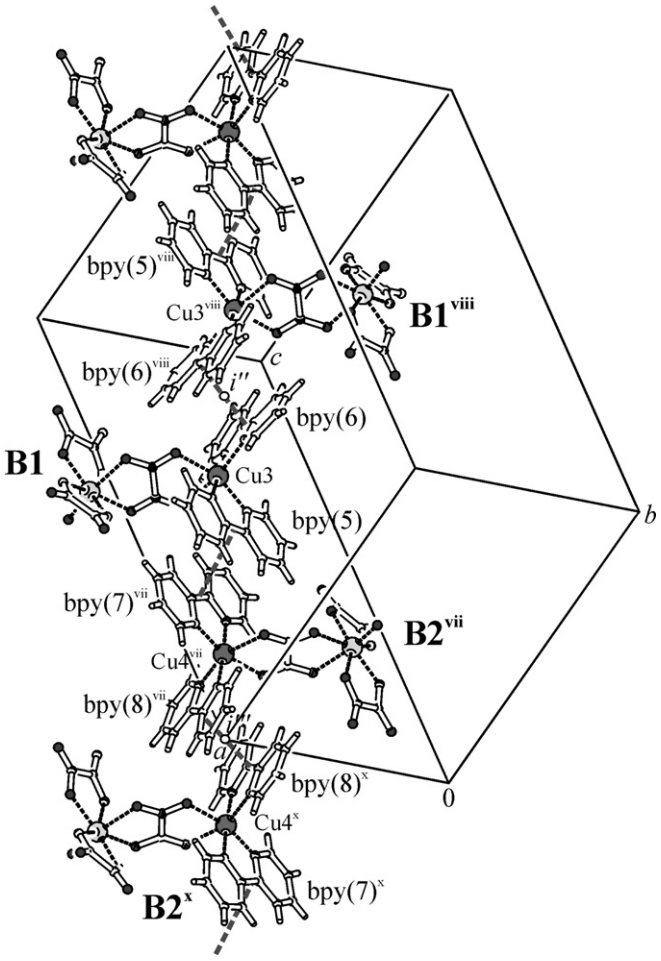

Fig. 7. One-dimensional structural motif in **2**, generated by three bipyridine stacking interactions of the **B**–**B** type (gray dashed lines). Labels and symmetry codes refer to those given in Table 6, except the symmetry code (x): $1-x$, $1-y$, $-z$. The bpy(8)^{vii}···bpy(8)^{x} contact is symmetry equivalent with the bpy(8)···bpy(8)^{ix} contact listed in Table 6.

In Fig. 8, beside mentioned stacking interactions, the three C–H···π interactions involved in the **A**–**B1** and **A**–**B2** supramolecular embraces are also shown. All C–H···π interactions appearing in the structure (with criteria H···π < 3.4 Å and C–H···π > 100°) are listed in Table 7. Comparing C–H···π interactions in **2** with those in **1** (Table 5) it can be observed that interactions involving the C49–H49 and C50–H50 bonds occur in both cases. The **A**–**B1** and **A**–**B2** embraces (Fig. 8) define the intermolecular Cu1···Cu3 and Cu2···Cu4 distances of 7.6973(9) and 7.0632(8) Å, respectively (Tables 6 and 7). Beside mentioned, there is one more C–H···π interaction between the **B2** unit and one **A** unit located one step further along the chain formed by the **A**–**A** stacking interactions shown in Fig. 6. This interaction defines a Cu4···Cu1^{vi} distance of 8.7355(9) Å. The interaction C28–H28···π(4)^{vi} (Table 7, sixth row) actually connects two units of the **A** type [the C28–H28 bond is from the bpy(3) ligand, whereas the

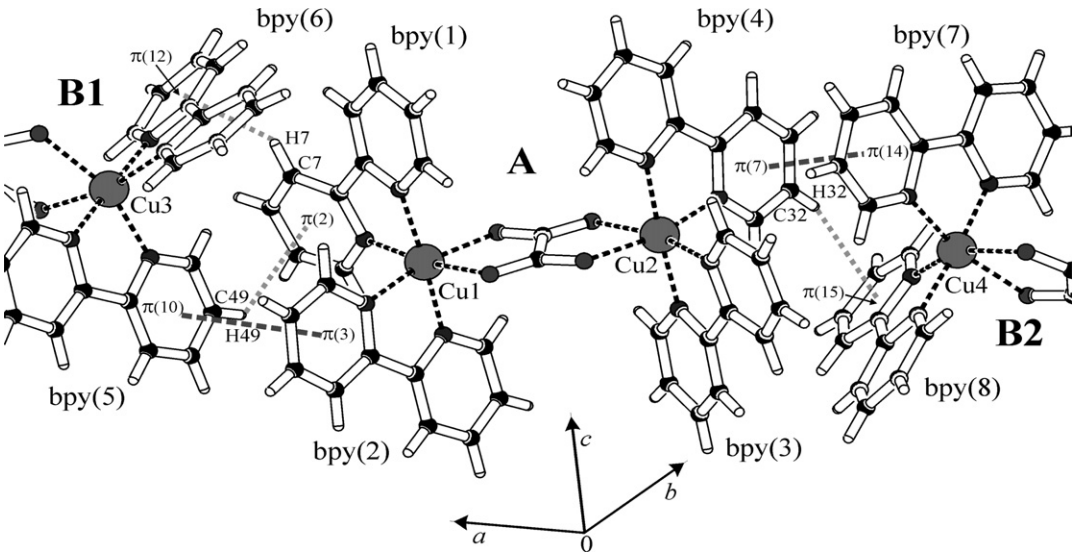

Fig. 8. Two **A**–**B** supramolecular embraces in **2**, made by four bipyridine ligands from two different types of constituents. Two π···π interactions [parts of the bpy(2)···bpy(5) and bpy(4)···bpy(7) stacking interactions given in Table 6] are shown by dark dashed gray lines, while three C–H···π interactions (first three rows in Table 7) are shown by light dotted gray lines.

Table 7
C–H···π interactions with Cu···Cu intermolecular distances in compound **2**

Interaction[a]	H···π (Å)	C···π (Å)	C–H···π (°)	Cu···Cu (Å)[b]
C7–H7···π(12)	2.994(4)	3.748(4)	139.2(2)	7.6973(9)
C49–H49···π(2)	3.238(4)	3.276(4)	135.9(2)	7.6973(9)
C50–H50···π(2)	3.266(4)	3.918(3)	129.0(2)	7.6973(9)
C32–H32···π(15)	2.847(4)	3.670(4)	148.0(2)	7.0632(8)
C79–H79···π(3)^{vi}	3.001(4)	3.671(4)	130.3(2)	8.7355(9)
C28–H28···π(4)^{vi}	2.697(4)	3.586(4)	160.4(2)	9.7606(1)
C97–H97···π(8)^{ii}	3.172(4)	3.886(4)	135.1(2)	

[a] π(12) = N12–C56–C57–C58–C59–C60; π(2) = N2–C6–C7–C8–C9–C10; π(15) = N15–C71–C72–C73–C74–C75; π(3) = N3–C11–C12–C13–C14–C15; π(4) = N4–C16–C17–C18–C19–C20; π(8) = N8–C36–C37–C38–C39–C40.

[b] Distance between two Cu atoms to which phen ligands involved in the C–H···π interaction are coordinated; Symmetry codes: (vi) $1-x, 2-y, -z$; (ii) $1-x, 1-y, 1-z$.

π(4) ring is from the bpy(2) ligand], therefore it superimposes on the one-dimensional stacking motif of the **A** units (Fig. 6). This contact defines the intermolecular Cu2···Cu1^{vi} distance of 9.7606(1) Å. The last C–H···π interaction noted in Table 7 involves the C97–H97 bond from the free bipyridine [bpy(9)] molecule, so the intermolecular Cu···Cu distance is not defined [bpy(9) is not coordinated to any of the Cu atoms]. These last C–H···π interactions given in Table 7 generate longer intermolecular Cu···Cu distances than the **A**–**B1** or **A**–**B2** supramolecular embraces or any of the stacking interactions given in Table 6 [with the exception of the bpy(1)···bpy(1)^{ii} interaction which involves the intercalated bpy(9) molecule]. This is an important difference as compared with the analogous analysis of the Cu···Cu intermolecular distances in **1**.

Taking into consideration the intermolecular Cu···Cu distances generated by the strictly centrosymmetric stacking interactions (first three interactions shown in Table 4 for **1** and the second, fifth and sixth ones in Table 6 for **2**), it can be observed that the corresponding distances are by ca. 1.4 Å longer in **1** than in **2**. This elongation is probably connected with the possibility that the saturation of the π···π stacking interaction with the central aromatic rings exists in phenanthroline, but not in the bipyridine ligands. The additional aromatic rings probably induce a characteristic shift of the neighbouring phenanthroline ligands in the direction of their mean planes, and hence the elongation of the corresponding intermolecular Cu···Cu distance.

3.2.3. Comparison of crystal packing and hydrogen bonds in *1* and *2*

The analyses of stacking interactions in both compounds show two types of one-dimensional infinite structural motifs: the **A**-type (Figs. 3 and 6) and **B**-type arrangements (Figs. 4 and 7). Both types extrude in the different space directions and are sufficient for building up the entire three-dimensional crystalline frameworks. The directions of the **A**-type motifs (as well as the directions of **B**-type) in **1** and **2** are not identical because the unit cells are different (they are chosen to be Niggli reduced cells [32] in both cases). The fact that **2** contain fewer centres of symmetry than **1**, causes the Niggli reduced cells to be different. Nevertheless, the similarity of the unit cells can be observed by comparison of their volumes (Table 1); the volume of the unit cell of **2** is roughly two times larger than that of **1**. Due to two main differences in the packing of mentioned one-dimensional motifs (formed by stacking interactions), some differences in the residual volumes (solvent accessible areas) can be expected. One of the differences is that the structure of **2** hosts one additional free bipyridine molecule (one half per formula unit), and the

other one is that the phenanthroline ligand generates longer intermolecular contacts (as seen through the Cu···Cu distances) than bipyridine. The residual volumes in both structures are occupied by crystal water molecules. Although some of them have similar positions in both structures, the orientations of hydrogen atoms are different. So, the motifs generated by the hydrogen bonds in two structures are not comparable. The relevant parameters for the observed hydrogen bonds in **1** and **2** are listed in Tables 8 and 9, respectively.

3.3. Infrared spectra

The IR spectra of **1** and **2** show characteristic absorption bands of bidentate and bis(bidentate) bridging oxalate groups beside those originating from 1,10-phenanthroline in **1**, and 2,2′-bipyridine in **2**. The absorption bands of weak to medium intensity that occur in the region 3500–3400 cm^{-1} for both complexes, are consistent with the presence of the crystal H_2O molecules. Several strong-intensity absorptions indicate the presence of the bidentate and bis(bidentate) oxalate ligand: ν_{as}(CO) found at 1735, 1710 and 1692 cm^{-1} for **1** and at 1730, 1711 and 1687 cm^{-1} for **2**, ν_s(CO) at 1362 and 1250 cm^{-1} for **1** and at 1376 and 1242 cm^{-1} for **2** as well as δ(OCO) at 793 and 792 cm^{-1} for **1** and **2**, respectively, are consistent with the bidentate oxalate group, whereas ν_{as}(CO) at 1630 and 1631 cm^{-1} for **1** and **2**, respectively, ν_s(CO) at 1295 and 1301 cm^{-1} for **1** and **2**, respectively, beside δ(OCO) found at 802 cm^{-1} for **1** and at 801 cm^{-1} for **2**, are in agreement with the position of corresponding absorptions in oxalate-bridged dinuclear copper(II) complexes [33,34]. Among the other absorption bands in the IR spectra, those located at 943 cm^{-1} and 933 cm^{-1} for **1** and **2**, respectively, are easily recognized as ν(NbO). The relative position of these bands (a higher wave number for **1** than for **2**) is in agreement with the corresponding bond lengths [a shorter Nb=O bond length in **1** (1.1697(2) Å) in comparison to the one in **2** (1.709(3) Å)].

3.4. Magnetic properties

The temperature dependences of $\chi_M T$ for **1** and **2** are shown in Fig. 9. The values of $\chi_M T$ for **1** and **2** at temperatures above 120 K are constant with an average of 1.73 and 1.79 $cm^3\,mol^{-1}\,K$ for **1** and **2**, respectively. This corresponds to the effective magnetic moment per molecule $\mu = 3.72\beta$ for **1** and $\mu = 3.78\beta$ for **2**, where β is the Bohr

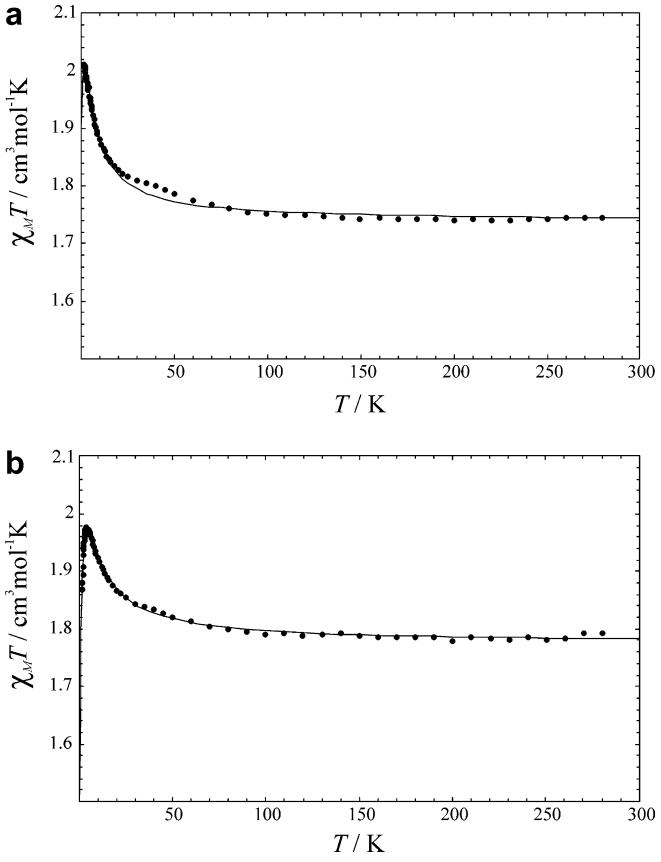

Fig. 9. Temperature dependence of $\chi_M T$ for compounds **1** (a) and **2** (b); the solid lines represent the curves of the best fit.

magneton. Generally, the spin-only value of the magnetic moment for four uncoupled Cu^{II} ions is $\mu = \beta\sqrt{4 \cdot g_{Cu}^2 S_{Cu}(S_{Cu}+1)}$. The measured values correspond to $g = 2.15$ for **1** and $g = 2.17$ for **2**. On cooling the samples below 50 K, the product $\chi_M T$ increases for both compounds, reaching for **1** a maximum value of 2.02 $cm^3\,mol^{-1}K$ at 1.8 K and for **2** a maximum value of 1.98 $cm^3\,mol^{-1}K$ at 5 K, upon what a decrease of $\chi_M T$ for **2** appears. The reciprocal magnetic susceptibility χ^{-1} vs. T plot shows a strong linear dependence above 100 K for both compounds. The Weiss constants ($\Theta = -0.1 \pm 0.1$ for **1** and $\Theta = 0.0 \pm 0.6$ for **2**) point to a negligible long-range order (Θ is determined from high-temperature region, i.e. >120 K). Consequently, the observed magnetic behaviour should be analysed on the molecular level.

Based on the structures, it is reasonable to suppose that magnetic measurements can be explained by the behaviour of a pair of spins $S = 1/2$ coupled *via* the isotropic Heisenberg interaction J [the $Cu^{II}Cu^{II}$ units (**A** type units), $\mathbf{H}_{INT} = -J\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$], and by the uncoupled spins $S = 1/2$ coming from the Cu^{II} ions of the $Cu^{II}Nb^{V}$ units (**B** type units). The Nb^{V} atoms do not contribute to the paramagnetic susceptibility of the compounds as already mentioned. As there are two **B** type units per one **A** type for both structures, the supposed formula for the molar magnetic susceptibility is:

$$\chi' = \chi_{di} + 2\chi_{Curie} \tag{2}$$

wherein the first term is the Bleaney and Bowers expression for the $Cu^{II}Cu^{II}$ dinuclear unit [23]:

$$\chi_{di} = \frac{2Ng^2\beta^2}{kT(3 + e^{-J/kT})} \tag{3}$$

and the second term is a Curie law for $S = 1/2$:

$$\chi_{Curie} = \frac{Ng^2\beta^2}{4kT} \tag{4}$$

A positive interaction parameter J in the first term can explain the observed increase of $\chi_M T$ in the process of cooling. In that case (ferromagnetic interaction) a more populated ground state is the triplet state having a higher spin quantum number S, and hence a higher magnetic moment $\mu_{eff}[\chi T \propto (\mu_{eff})^2]$. A relatively good fit of the susceptibility measurements with the Eq. (2) can be obtained for **1**, but not for **2**, mainly because of the evident decrease of the experimental values for $\chi_M T$ below 5 K (Fig. 9). This decline can be attributed to the additional intermolecular magnetic exchange interaction or to the zero-field splitting on the triplet states of the $Cu^{II}Cu^{II}$ dimer [23]. Zero-field splitting is usually explained in the literature by mutual perturbations caused by lowering of the magnetic centre symmetry and spin–orbit interaction [23]. Because the $Cu^{II}Cu^{II}$ units in both compounds have approximately the same type of molecular symmetry ($C2/m$) there is no reason for the existence of zero-field splitting in one type of compound and not in the other. So, it seems more probable that the observed decrease in the experimental $\chi_M T$ curve for **2** is caused by the weak intermolecular magnetic exchange interactions. Because there are several different intermolecular structural contacts realized by the stacking or C–H$\cdots\pi$ interactions in the crystal structures (Tables 4–7) it is impossible to assign the unique exchange interaction parameter to every particular type of contacts; the final expression for the magnetic susceptibility would become overparameterized. For this reason, the effects of intermolecular magnetic exchange interactions are included in the mean field approximation [35]:

$$\chi = \frac{\chi'}{1 - \frac{zJ'}{Ng^2\beta^2}\chi'} \tag{5}$$

introducing only one parameter (zJ'). The nonlinear fit of the $\chi_M T$ vs. T experimental curves using Eq. (5) gave the following results for the parameters: $J = +5.9(1)$ cm^{-1}, $g = 2.15(1)$, $zJ' = -0.01(1)$ cm^{-1} for **1** and $J = +7.9(2)$ cm^{-1}, $g = 2.17(1)$, $zJ' = -0.10$ (1) cm^{-1} for **2**. The discrepancy factors R, defined as $R = \sum[(\chi_M T)_{obsd.} - (\chi_M T)_{calcd.}]^2 / \sum[(\chi_M T)_{obsd.}]^2$, equal 1.2×10^{-5} and 1.5×10^{-5} for **1** and **2**, respectively. The intermolecular exchange parameter zJ' is antiferromagnetic in both cases: almost zero for **1** and very small for **2**. As shown in the crystal packing analyses, the most frequently observed intermolecular structural motif (between all encountered) is a centrosymmetrical stacking of phenanthroline or bipyridine ligands attached to the neighbouring **A** or **B** units. It is also shown that the intermolecular Cu$\cdots$Cu distances generated by this type of stacking are for ~1.5 Å larger in **1** than in **2**, due to the possibility for stacking of the central aromatic rings in the phenanthroline molecules. This structural difference could be the explanation for the larger zJ' parameter observed for **2** than for **1**. If this assumption is correct, the additional antiferromagnetic exchange interaction should be mediated across the stacked bipyridine ligands. In the literature, there are no much evidences on this kind of mediation of the magnetic exchange interaction. The only exception is the compound [Cu-(acac)(Me_2bpy)-(NCS)] (acac = acetylacetonate; Me_2bpy = 4,4′-dimethyl-2,2′-bipyridine) where the interaction of $J = -0.84$ cm^{-1} was observed [36].

A more reliable parameter that can be extracted from the fitting procedure in the presented magnetochemical analyses of **1** and **2** is the intramolecular magnetic exchange parameter J, the one that couples two Cu^{II} magnetic centres inside the **A** unit into a spin-coupled $Cu^{II}Cu^{II}$ dimer. In both compounds this parameter turns out to be positive, indicating a ferromagnetic interaction between the Cu^{II} ions across the bridging oxalate units. This is not surprising because such behaviour was already encountered in the literature [37] and it corroborates well the theoretical predictions based on DFT calculations [38]. These predictions claim that the ferromagnetic exchange interactions of strength up to 10 cm^{-1} are possible for mutually parallel orientation of the magnetic

orbitals on each Cu^{II} magnetic centre, both perpendicular on the mean plane of the oxalate bridge [38]. The analysis of the molecular geometry of the **A** units in both compounds has shown exactly this kind of orbital topology (see Section 3.1).

4. Conclusion

The oxotris(oxalato)niobate(V) $[NbO(C_2O_4)_3]^{3-}$ ion has been used for the first time as the starting substance for the construction of complex oxalate compounds with oxalate-bridged metal ions. Namely, compounds **1** and **2** contain $Cu^{II}Cu^{II}$ oxalate-bridged $[\{Cu(L)_2\}_2(\mu\text{-}C_2O_4)]^{2+}$ cation (**A** unit) and two $Cu^{II}Nb^{V}$ oxalate-bridged $[Cu(L)_2(\mu\text{-}C_2O_4)NbO(C_2O_4)_2]^{-}$ anions (**B** units). Both substances crystallize in the triclinic space group $P\bar{1}$; in **1** a crystallographic inversion center is located in the middle of the oxalate bridge, in **2** an analogous inversion center is missing. One-dimensional motifs present in both structures have been generated by the ligand stacking interactions. The observed ferromagnetic interaction between copper(II) atoms in the **A** units of both compounds is the consequence of the suitable topology of the magnetic orbitals located on the copper(II) ions.

Abstract

Three copper(II) complexes derived from 2-(hydroxymethyl)pyridine (LH) have been synthesised and a comparative X-ray investigation of their respective crystal structures undertaken. In the absence of added base, LH reacts with copper(II) chloride or nitrate to yield the five-coordinate $[Cu(LH)_2Cl]Cl$ and six-coordinate $[Cu(LH)_2(NO_3)_2]$ species. In the chloro complex the coordination geometry is distorted trigonal bipyramidal, with the pyridyl nitrogens occupying the axial position and two hydroxyl oxygens from the bidentate ligands together with a chloro group occupying the equatorial sites. The structure of the nitrate species, published previously, has been reinvestigated at low temperature in order to specify the weak interactions in the crystal; it contains two molecules of bidentate LH bound *trans* in the equatorial plane while monodentate nitrato ligands occupy the axial sites. In each of these complexes the hydroxyl protons act as hydrogen bond donors, interacting with the non-coordinated chloride anion in $[Cu(LH)_2Cl]Cl$ and the coordinated nitrato groups in $[Cu(LH)_2(NO_3)_2]$ to form bridged, hydrogen-bonded, copper(II)-organic arrays in each case; offset face-to-face π-stacking in the latter produces a two dimensional structure. Further weak CH···Cl, CH···O interactions stabilise both arrangements. The X-ray structure of the complex $[Cu(L)_2]\cdot 4H_2O$ containing the deprotonated ligand is also described. The presence of the latter results in the above hydrogen bonding arrangements being 'switched off' and instead a new two-dimensional network involving bridging tetrameric water clusters hydrogen bound to adjacent ligand hydroxo groups to give extended sheets is generated; offset face-to-face π-stacking occurs between sheets to yield a three dimensional array.

1. Introduction

The design and synthesis of extended metallo assemblies, particularly those with interesting topologies and/or potential technological applications have received much recent attention [1–3]. As part of these studies, increasing interest has been shown in the weak interactions linking metal complex units in the solid state and such investigations now form a major part of the current activity within the crystal engineering field. In this context, the effect of coordinated ligand protonation/deprotonation on the resulting crystal framework structures has received somewhat less attention, although a number of literature examples do exist [4]. In such systems, it is sometimes possible to 'switch' hydrogen bonding by subtle variation of the pH of the reaction solution used to form the product, resulting in a significant topological change in the framework material isolated.

In the present study, we have investigated the effect of protonation/deprotonation behaviour on the crystal geometries of three copper(II) complexes generated from 2-(hydroxymethyl)pyridine (LH) under different pH conditions.

Thermodynamic data for the copper(II) complexes of LH have been reported previously [5–11] and detailed IR studies have also been undertaken [12]. Two LH ligands have been well documented to bind in a bidentate fashion to copper(II) to form 5-membered chelate rings via their N,O donor atoms. In the absence of added base, each LH remains protonated forming either a five- or six-coordinate species, depending on the counter anion present. This leaves each alcohol hydrogen free to act as a proton donor [13,14]. In addition to a number of copper(II)/carboxylate derivatives [13], one structure with nitrate as the counter anion [14] has been reported. However, at higher pHs LH is known to deprotonate in the presence of this metal ion to form $[Cu(L)_2]\cdot 4H_2O$, in which two deprotonated ligands (L) bind to the copper in a *trans* square planar arrangement [5–12]. Two further copper(II) structures derived from LH have been reported; the first contains a cubane-like Cu_4O_4 motif with bridging succinate [15] and another has the composition $[Cu(L)(NCS)]_2$ and incorporates a μ-alkoxo bridge [16]. The former structure forms interesting nanoporous 2D sheets which stack via π–π interactions between pyridyl units. We now report a synthetic and X-ray study of the complex structures and crystal arrangements present in three copper(II) complexes derived from 2-(hydroxymethyl)pyridine (LH).

2. Experimental

Reagents and solvents were purchased from commercial sources and were used without further purification. Positive ion electrospray ionisation mass spectra were obtained on a Finnigan LCQ-8 spectrometer with the sample dissolved in methanol/water. Microanalyses were obtained at the Department of Chemistry, TU Dresden.

2.1. Complex synthesis

2.1.1. $[Cu(LH)_2Cl]Cl\cdot H_2O$

$CuCl_2\cdot 2H_2O$ (0.782 g, 4.58 mmol) in ethanol (30 mL) was mixed with 2-(hydroxymethyl)pyridine (1.013 g, 9.28 mmol) in ethanol (20 mL) (indicator paper indicated a pH of ~5). The resulting dark green solution was stirred for 30 min. Green-blue crystals of the title compound were obtained by slow diffusion of ether vapour into the resulting solution over 5 d. A crystal from this crop was used for the X-ray structure determination. The remaining crystals were collected, washed with diethylether then allowed to dry in air. ESI-MS: *m*/*z* 280 $[Cu(L)(LH)]^+$. Yield: 0.952 g (56%). *Anal.* Calc. for $C_{12}H_{16}CuCl_2N_2O_3$: C, 38.87; H, 4.35; N, 7.56. Found: C, 38.62; H, 4.12; N, 7.50%.

2.1.2. $[Cu(LH)_2(NO_3)_2]$

This complex was prepared by a modification of a previously reported synthetic procedure [10]. $Cu(NO_3)_2\cdot 2.5H_2O$ (0.477 g, 2.05 mmol) in ethanol (10 mL) was added to 2-(hydroxymethyl)pyridine (0.448 g, 4.11 mmol) in ethanol (10 mL) (indicator paper indicated a pH of ~5). The resulting dark green solution was stirred for 3 h at 40 °C. Blue crystals of the title compound were obtained by slow diffusion of diethyl ether into the resulting solution over 3 d. A crystal from this crop was used for the X-ray structure determination. The remaining crystals were collected, washed with diethylether then allowed to dry in air. Yield: 0.516 g (62%); ESI-MS: *m*/*z* 280 $[Cu(LH)(L)]^+$; *m*/*z* 343 $[Cu(LH)_2NO_3]^+$. *Anal.* Calc. for $C_{12}H_{14}CuN_4O_8$: C, 35.52; H, 3.48; N, 13.81. Found: C, 35.52; H, 3.34; N, 13.82%.

2.1.3. $[Cu(L)_2]\cdot 4H_2O$

This complex was prepared by a modification of a reported synthesis for a related complex [10]. $CuCl_2\cdot 2H_2O$ (0.393 g, 2.31 mmol) in ethanol (20 mL) was mixed with 2-(hydroxymethyl)pyridine (0.504 g, 4.62 mmol) in ethanol (10 mL). The resulting dark green solution was stirred for 3 h (40 °C) and then adjusted to pH 10 with tetraethylammonium hydroxide. The dark violet solution was allowed to evaporate slowly at ambient temperature over 10 d. Violet crystals formed and one of these was used directly for the X-ray determination. The remainder were washed with diethylether then allowed to dry in air. ESI-MS: *m*/*z* 280 $[Cu(L)(LH)]^+$. Yield: 0.675 g (83%). *Anal.* Calc. for $C_{12}H_{20}CuN_2O_6$: C, 41.01; H, 5.74; N, 7.97. Found: C, 41.05; H, 5.74; N, 8.04%. Substitution of $Cu(NO_3)_2\cdot 2.5H_2O$ or $CuSO_4\cdot 5H_2O$ (in 10 mL of water) in the required stoichiometry for $CuCl_2\cdot 2H_2O$ in this procedure also gave the above product in satisfactory yield in each case.

2.2. X-ray structure determinations

We determined a low temperature X-ray structure of $[Cu(LH)_2(NO_3)_2]$ as part of the present study, but note that it is a redetermination of the reported structure obtained at room temperature [14]. While the results from this and our determination are quite similar, in view of our structure being obtained at low temperature we have included brief details of its determination along with those of the other two (new) structures obtained in the present study.

Data for $[Cu(LH)_2(NO_3)_2]$ were collected at 150(2) K with ω scans to approximately 56° 2θ using a Bruker SMART 1000 diffractometer employing graphite-monochromated Mo Kα radiation generated from a sealed tube (0.71073 Å). For $[Cu(LH)_2Cl]Cl$ and $[Cu(L)_2]\cdot 4H_2O$ data were collected at 150(2) K with φ and ω scans to approximately 66° 2θ using a Bruker-Nonius APEX2-X8-FR591 diffractometer employing graphite-monochromated Mo Kα radiation generated from a rotating anode (0.71073 Å). Data integration and reduction were undertaken with SAINT

and XPREP [17] and subsequent computations were carried out using the WINGX-32 graphical user interface [18]. Structures were solved by direct methods using SIR97 [19]. Multi-scan empirical absorption corrections were applied to data sets using the program SADABS [20]. Data were refined and extended with SHELXL-97 [21]. Non-hydrogen atoms were refined anisotropically. Carbon-bound hydrogen atoms were included in idealised positions and refined using a riding model. Oxygen-bound hydrogen atoms that were structurally evident in the difference Fourier map were included and refined with bond length and angle restraints.

ORTEP depictions of the crystal structures are provided in Figs. 1, 3 and 5. Schematic depictions are given in Figs. 2, 4, 6, 7 and 1S in the ESI†. Hydrogen bonding information is given in Table 1. Where applicable, additional details relating to the X-ray crystal structure refinement are given below and in the ESI† (along with tables of selected bond lengths and angles).

2.3. Crystal structure and refinement data

$$R_1 = \sum ||F_o| - |F_c|| / \sum |F_o| \quad \text{for} \quad F_o > 2\sigma(F_o)$$

$$\text{and} \quad wR_2 = \left\{ \sum [w(F_o^2 - F_c^2)^2] / \sum [w(F_c^2)^2] \right\}^{1/2}$$

where $w = 1/[\sigma^2(F_o^2) + (AP)^2 + BP]$, $P = (F_o^2 + 2F_c^2)/3$ and A and B are listed with the crystal data for each structure.

2.3.1. [Cu(HL)$_2$Cl]Cl

2.3.3. [Cu(L)$_2$] · 4H$_2$O

Formula $C_{12}H_{20}CuN_2O_6$, $M = 351.84$, monoclinic, space group: $C2/m$(#12), $a = 13.4460(14)$, $b = 7.1130(7)$, $c = 8.2370(7)$ Å, $\beta = 110.674(6)°$, $V = 737.07(12)$ Å^3, $D_c = 1.585$ g cm^{-3}, $Z = 2$, crystal size 0.130 by 0.114 by 0.094 mm, colour purple, habit multiface, temperature = 150(2) K, λ(Mo–Kα) = 0.71073 Å, μ(Mo–Kα) = 1.510 mm^{-1}, T(SADABS)$_{min,max} = 0.789$, 0.868, $2\theta_{max} = 71.00$, hkl range −19 to 19, −10 to 9, −13 to 12, $N = 7562$, $N_{ind} = 1388$ ($R_{merge} = 0.0293$), $N_{obs} = 1242(I > 2\sigma(I))$, $N_{var} = 71$, residuals: $R_1(F) = 0.0373$, $wR_2(F^2) = 0.0844$, Goodness-of-fit (all) = 1.056, $A = 0.0298$, $B = 1.5883$, $\Delta\rho_{min,max}$: −0.661, 0.756 e$^-$ Å^{-3}.

3. Results and discussion

The 2:1 reaction of 2-(hydroxymethyl)pyridine (LH) with copper(II) chloride in ethanol at pH ~5 resulted in a colour change from dark green to blue-green. Slow diffusion of diethyl ether vapour into the resulting solution resulted in the formation of blue crystals of stoichiometry Cu(LH)$_2$Cl$_2$ suitable for X-ray analysis. In accord with related prior work, it was envisaged that ligand LH would remain in its protonated form on coordination at this pH and this was thus found to occur. The resulting structure is presented in Fig. 1.

The copper(II) ion is 5-coordinate and adopts a distorted trigonal bipyramidal geometry with the two pyridyl nitrogen donors occupying the axial positions. Two hydroxyl oxygens and a chloride ligand occupy the equatorial positions; the N(1)–Cu–N(1) and O(1)–Cu–Cl(1) bond angles are 173° and 136°, respectively. The second chloride ion is not coordinated, but is hydrogen bound to two hydroxyl protons belonging to different (adjacent) complex units. This bonding motif is perpetuated throughout the lattice to yield a one-dimensional polymeric structure (Fig. 2). Related 'bound' hydroxy to chloride hydrogen bond interactions also occur in the structures of copper(II) chloride complexes of the related ligands, 2-(2-hydroxyethyl)pyridine and 2,6-bis(hydroxymethyl)pyridine [22–24]. In the present structure, adjacent one-dimensional polymer chains also interact weakly via C–H⋯Cl interactions with the separation between Cl(1) and H(2) being

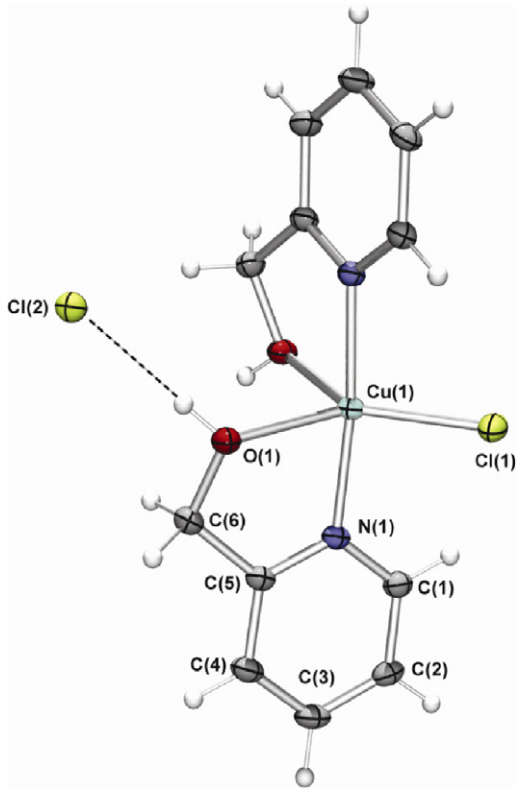

Fig. 1. An ORTEP plot of $[Cu(LH)_2Cl]Cl$ shown with 50% probability ellipsoids. Dashed line indicates a hydrogen bond.

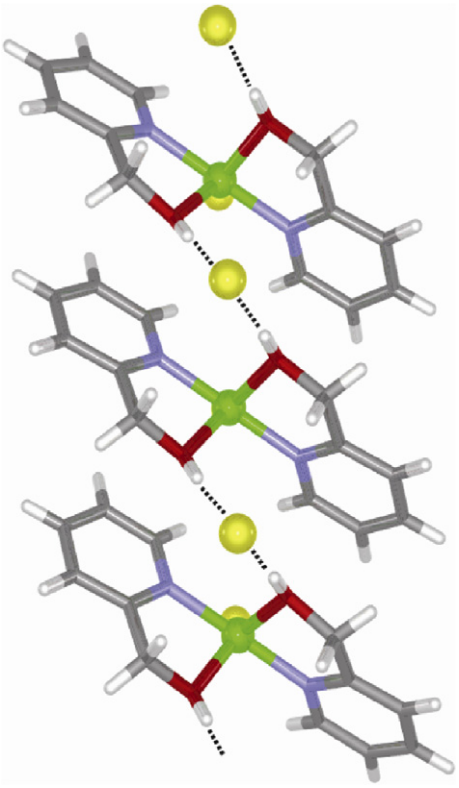

Fig. 2. View of the one-dimensional polymer formed via hydrogen bonding interactions between the hydroxy protons and the chloride anions (projection down the *b*-axis).

2.85 Å. A projection down the *a*-axis showing these interactions is given as Fig. 1S in the ESI. Two C–H to Cl–M distances occur C(1)–H(1)···Cl(1) and C(4)–H(4)···Cl(1) and range between 2.73 and 2.85 Å; both are shorter then the sum of van der Waals radii for hydrogen and chlorine (2.95 Å) [25].

In a similar fashion, the 2:1 reaction of LH with copper(II) nitrate in ethanol (also at pH ~5) resulted in a colour change to blue-green and slow diffusion of diethyl-ether vapour into this solution gave blue crystals of stoichiometry $Cu(LH)_2(NO_3)_2$ suitable for X-ray analysis. In contrast to the structure of the chloride derivative discussed above, the copper(II) ion in this case is octahedral with two nitrate anions occupying the axial positions and the equatorial positions occupied by *trans* bidentate LH ligands. This change in coordination from six to five may reflect the stronger binding of chloride (and hence its ability to donate electron density) over nitrate for latter first row transition metal ions such as copper(II). Again the hydroxyl proton acts as a hydrogen donor, in this case interacting with an oxygen from coordinated nitrate in an adjacent complex such that an infinite one-dimensional polymer is generated (Fig. 4). Similar O–H···O interactions are present in the literature structures of the related species $[Cu(LH)_2(CH_3CHBrCO_2)_2]$ and $[Cu(LH)_2(saccharato)_2]$ [13]. In the present structure pyridyl rings from each one-dimensional polymer chain π–π stack in an offset face to face arrangement with adjacent chains (~3.58 Å) forming an extended two-dimensional structure.

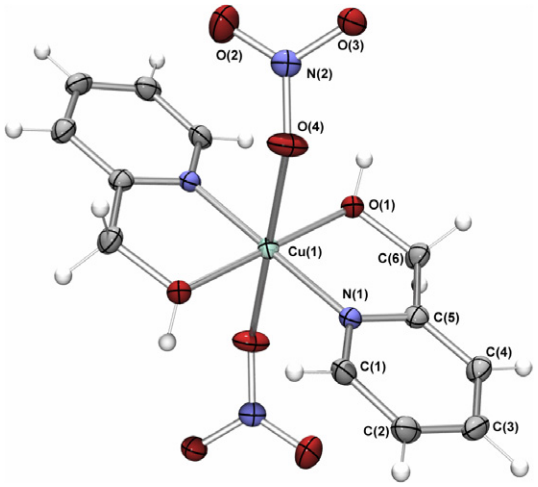

Fig. 3. An ORTEP plot of $[Cu(LH)_2(NO_3)_2]$ shown with 50% probability ellipsoids.

The addition of tetraethylammonium hydroxide to an ethanol solution of either of the above complexes to pH ~10, or indeed adjusting the pH of a solution of LH and copper(II) acetate or sulfate to this value leads to a colour change to deep purple. Slow evaporation of the resulting solution in each case led to the isolation of purple crystals (of identical habit and unit cell) of the previously reported complex $[Cu(L)_2]\cdot 4H_2O$. The X-ray structure of this product is presented in Fig. 5.

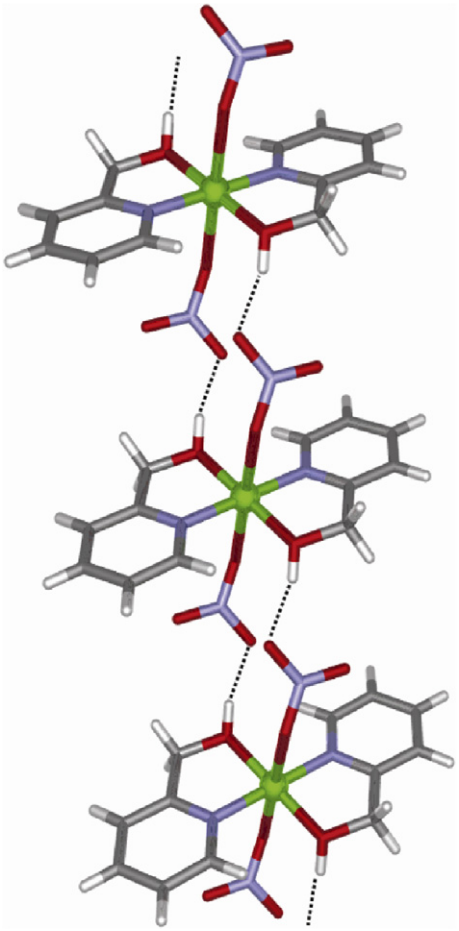

Fig. 4. A segment of the one-dimensional polymer formed by hydrogen bonding interactions in $[Cu(LH)_2(NO_3)_2]$; π-π interactions between chains (not shown) form two-dimensional sheets.

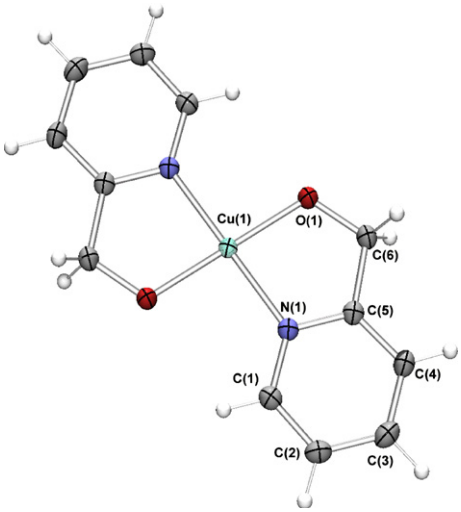

Fig. 5. An ORTEP plot representation of $[Cu(L)_2]\cdot 4H_2O$ shown with 50% probability ellipsoids. Solvent water molecules are omitted for clarity.

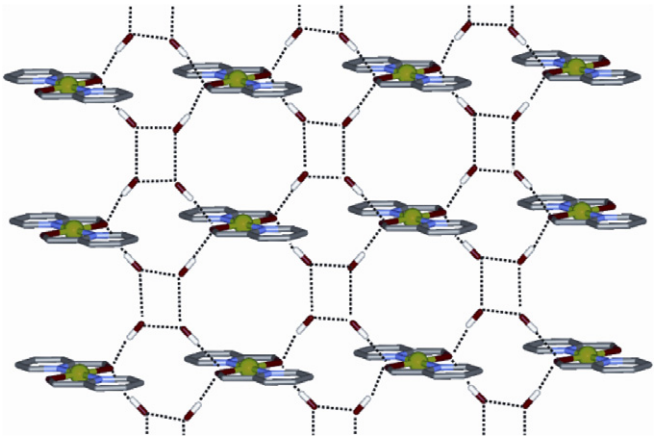

Fig. 6. A schematic representation of a segment of the two-dimensional hydrogen bonded arrangement in $[Cu(L)_2]\cdot 4H_2O$; π–π interactions between sheets (see Fig. 7) result in an infinite three-dimensional network. Hydrogen bonds are indicated by dashed lines.

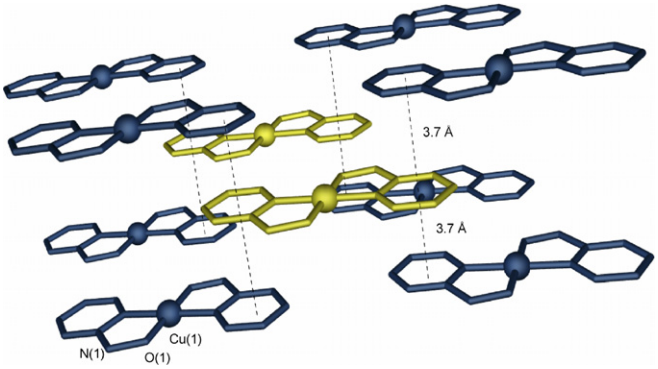

Fig. 7. Offset face-to-face π–π interactions in $[Cu(L)_2]\cdot 4H_2O$. Each of the two-dimensional sheets (blue) interact with adjacent sheets (yellow) via π–π interactions [ring centroid–ring centroid ~3.7 Å] resulting in the formation of an infinite three-dimensional network. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

In this case, the structure reveals that $[Cu(L)_2]\cdot 4H_2O$ has a square planar coordination geometry with the deprotonated (bidentate) 2-(hydroxymethyl)pyridine ligands coordinated mutually *trans*. As a consequence, bound oxygen atoms capable of acting as hydrogen bond acceptors have replaced the bound OH hydrogen bond donors in $[Cu(LH)_2Cl]Cl$ and $[Cu(LH)_2(NO_3)_2]$. This results in a change in the simple hydrogen bond patterns observed in the latter complexes to a more complicated arrangement in the former complex (Figs. 6 and 7).

A four-water hydrogen-bonded cluster is present in the structure which acts as a hydrogen bond donor to each of the deprotonated hydroxo atoms in $[Cu(L)_2]\cdot 4H_2O$ to form an infinite one-dimensional tape (see Fig. 6). In the tetrameric water cluster, each water molecule is involved in the formation of three hydrogen bonds, two of which are water–water interactions and one is with a metal complex hydroxo oxygen. Within the cluster, the four oxygen atoms in the tetramer are coplanar and the hydrogen atoms [H(7); H(8a) of O(2)] are at an angle of 32° above and below the ring. The average hydrogen bond distance within the water tetramer is 2.73 Å and is similar to the previously reported calculated value of 2.743 Å for a discrete water

tetramer [26]. Overall, the above water cluster/metal complex-containing tapes are linked via individual complex molecules such that infinite two-dimensional sheets result (Fig. 6).

Each of the two-dimensional sheets depicted in Fig. 6 interact further with adjacent sheets via offset face-to-face π–π interactions (~3.7 Å), resulting in the formation of an infinite three-dimensional network (Fig. 7). Thus, anion substitution in the reaction solution has resulted in a switch from a one-dimensional polymer in the case of $[Cu(LH)_2Cl]Cl$ to a two-dimensional polymer in the case of $[Cu(LH)_2(NO_3)_2]$ and a pH change involving either system results in the formation of the three-dimensional network found in $[Cu(L)_2]\cdot 4H_2O$.

4. Concluding remarks

The present study reports an investigation of the complex structures and crystal arrangements present in three copper(II) complexes derived from 2-(hydroxymethyl)pyridine. The study illustrates the manner by which 'pH switching' of a proton donor to a proton acceptor in the reaction solution used to synthesise the corresponding copper(II) complexes results in significant additional complexity in the resulting crystal network in the latter case.

Abstract

Hexanuclear Zr(IV) oxo carboxylate derivatives of the general formula $[Zr_6O_4(OH)_4(OOCR')_{12}]$ ($R' = Bu^t$ (**1**), $C(CH_3)_2Et$ (**2**)) were synthesized from $Zr(OR)_4$ ($R = Pr^i$, $C(CH_3)_2Et$) and appropriate organic acids ($HOOCR'$, $R' = Bu^t$, $C(CH_3)_2Et$) in a molar ratio 1:2. The crystal structures of **1** and **2** were solved in the centrosymmetric $R\bar{3}$ space group. Zirconium atoms form hexanuclear Zr(IV) clusters, linked by 4:4 system of μ_3-oxo/hydoxo bridges and stabilized by *syn–syn* carboxylate groups. Each of the metal ions is surrounded by eight oxygen atoms derived from four μ_3-O; oxo/hydroxo bridges, and four μ-O; carboxylate ones. Analysis of crystallographic and spectroscopic data suggests that four protons migrate between eight oxide bridges of the $[Zr_6O_4(OH)_4(OOCR')_{12}]$ cluster. Thermogravimetric and temperature variable (VT IR) studies have been carried out in order to determine the thermal behaviors of **1** and **2**.

1. Introduction

Synthesis and properties of zirconium oxo clusters have been studied extensively in search for the novel type inorganic–organic hybrid polymers [1,2], and precursors of solid-state materials used mainly in sol–gel, but also in chemical vapor deposition methods (CVD) [2–5]. The reaction of $Zr(OR)_4$ with organic acids ($HOOCR'$) yields the multinuclear oxo complexes regardless of the molar ratio employed [6–10]. Kickelbick et al. reported that the reaction of Zr(IV) alkoxides with corresponding organic acids, using the molar ratio 1:4, proceeded with formation of carboxylate derivatives of general formulas $[Zr_6(OH)_4O_4(OMc)_{12}]$ and $[Zr_4O_2(OMc)_{12}]$ [7,8]. In the structure of $[Zr_6(OH)_4O_4(OMc)_{12}]$, zirconium atoms (coordination number 8) form hexanuclear clusters linked by μ_3-oxo and μ_3-hydroxo bridges, which are stabilized by 12 methacrylate ligands. Three of them chelate the Zr(IV) atoms, while the remaining nine carboxylate groups participate in *syn–syn* bridges. The hydrogen atoms of the bridging groups have not been located, however, analysis of Zr–O bond distances and the charge balance indicates the presence of four μ_3-OH groups [6]. A similar type of clusters has also been detected in structures of $[Zr_6(OH)_2O_6(OOCHPh_2)_{10}(phen)_2]$ and also $[Ti_6O_8(\eta^5\text{-}C_5H_5)_6]$ (in this case, the formation of $[Ti(IV)_4Ti(III)_2O_8]$ clusters was postulated) [11,12]. Crystals of other complexes: $[Zr_4O_2(OMc)_{12}]$, $[Zr_6O_2(OPr^i)_{16}(OOC\text{–}C_{10}H_6O)_2]$, $[Zr_6O_2(OMe)_4(OBu^n)_2(OMc)_{14}]$, $[Zr_6O_2(OBu^n)_{10}(OMc)_{10}]$, have been obtained with a 6–15 folds excess of the organic acid ($HOOCR'$, $R' = C_{10}H_6OH$, $CMe{=}CH_2$) [6–8,13]. When Zr/carboxylate ligand ratio was increased from 1:2 to 1:3, as for $[Zr_4O_2(OMc)_{12}]$, the structure of cluster opened up and a distorted butterfly arrangement was formed [6]. The application of sterically varied carboxylic acids

doi:10.1016/j.poly.2006.08.025

(HOOCR′; R′ = H, CH_3, Pr^i, Bu^t, CH_2Bu^t) in the reaction with zirconium(IV) alkoxides (molar ratio 1:1) leads to the formation of the following products: $[Zr_4O_2(O_2CH)_2(OPr^i)_{10}]$, $[Zr_3O(O_2CCH_3)_5(OPr^i)_5]$, $[Zr_2(OPr^i)_6(O_2CPr^i)_2]_2$, $[Zr_2O(O_2CBu^t)(OPr^i)_7](HOPr^i)_2$, $[Zr_2O(O_2CH_2Bu^t)_2(OPr^i)_6](HOPr^i)$ [9].

A series of multinuclear Ti(IV) oxo carboxylate derivatives with oligomeric ring-shape molecules were synthesized through the reaction of branched acids (HOOCR′, R′ = Bu^t, $C(CH_3)_2Et$) with titanium(IV) alkoxides in a molar ratio 1:2 [14]. Therefore, the aim of the reported research was the synthesis and structural characterization of the novel multinuclear Zr(IV) oxo carboxylate derivatives, obtained in a reaction between $Zr(OR)_4$ (R = Pr^i, $C(CH_3)_2Et$) and HOOCR′ (R′ = Bu^t and $C(CH_3)_2Et$). Thermal behavior of synthesized compounds was studied using thermogravimetric analysis and variable temperature (VT IR) spectroscopy.

2. Results and discussion

Hexanuclear Zr(IV) oxo carboxylate derivatives were prepared in the reaction of the respective zirconium alkoxide ($Zr(OR)_4$, R = Pr^i, $C(CH_3)_2Et$) with the twofold excess of the organic acid (HOOCR′ (R′ = Bu^t, or $C(CH_3)_2Et$)) at room temperature under Ar atmosphere. Considering the literature data [7], the above reaction can be illustrated by the overall equation (1).

$$6Zr(OR')_4 + 20RCOOH \xrightarrow{RT,\ Ar} [Zr_6O_4(OH)_4(OOCR)_{12}] + 8RC(O)OR' + 16R'OH \quad (1)$$

where R′ = Pr^i, $C(CH_3)_2Et$, R = Bu^t, $C(CH_3)_2Et$.

Initially the reaction mixture became turbid, but after 12 h the clear solution was formed. The colorless crystals, suitable for single crystal X-ray studies, were grown by slow evaporation (glovebox, RT) of the solvent after 1 day. Results of elemental analysis suggest the formation of the complex of general formula $[Zr_6O_4(OH)_4(OOCR')_{12}]$ (R′ = Bu^t (**1**), $C(CH_3)_2Et$ (**2**)). The obtained compounds were insoluble in aliphatic and sparingly soluble in aromatic solvents. Although synthesized complexes are relatively stable in the air and not sensitive to the moisture, they were stored at room temperature and under the argon atmosphere during all experiments.

3. X-ray crystallographic structures

Single crystals X-ray analysis revealed that **1** and **2** crystallize in the centrosymmetric $R\bar{3}$ (no. 148) space group for the series of crystals, for which diffraction data were collected at 293 K (Table 1). The structures of these compounds consist of hexanuclear $[Zr_6(\mu_3\text{-}O)_8]^{12+}$ clusters where six equivalent metal ions are arranged in the corners of an octahedron (Fig. 1). Consequently, in all the investigated structures the $[Zr_6(\mu_3\text{-}O)_8]^{12+}$ cluster symmetry was C_{3i}. Since two oxygen atoms (O1) were located on the threefold axis, they were related only by the center of symmetry, and are chemically and structurally identical. The other six oxygen atoms (O2) are related to each other by both the threefold axis and the center, therefore being chemically and structurally equivalent. According to above data, the 2:6 distributions of structurally different oxygen bridges was detected in the cluster as a consequence of the molecular symmetry. That problem is discussed further in the IR spectroscopy section of the paper. The cluster might be constituted by both oxo and hydroxy groups bridging the metal ions. For six Zr^{4+} centers, the electrostatic compensation would require four bridges of each type, besides 12 carboxylate ligands present in the structure. Therefore, the neutral cluster should be built with 4:4 systems of oxo/hydroxy bridges. Contrary to that, the molecular symmetry requirements imposed by the crystal structure allow only 6:2 or 8:0 composition of the bridges. The question of their nature is even more convoluted, since the crystallographic data have shown no trace of any peak that would correspond to the hydrogen atoms belonging to hydroxyl groups. If the cluster is built with eight oxo bridges, the total electric charge of the cluster would be −4, while for eight hydroxyl groups it would be +4.

The crystal structure determination at 293 K did not reveal any additional ions in the crystal lattice that would compensate the non-zero charge of the cluster ion. Considering the previous reports [6] we assumed a mixed architecture with the 4:4 ratio of the O/OH bridges, what has to be consistent with the 6:2 structural constraints on the cluster composition. In this case, the two identical O1 atoms positioned on the threefold axis are related by the center of symmetry and could be either oxo or hydroxy bridges, while the remaining six have to be of identical chemical nature due to the crystallographic symmetry. Only the assumption that four protons migrate between six oxygen (O2) bridging groups permits the explanation of this problem. The oxo/hydroxy ratio within that set is 2:4 in case of two axial oxo bridges, and 4:2 for the axial hydroxyls, respectively. The statistical disorder, imposed by the crystallographic symmetry requirements, would result in 2/3 or 1/3 of hydrogen bound to each of those six bridges. The lack of clear peaks corresponding to the hydrogen atoms of OH groups on the electron density maps indicates their statistical disordering, further supporting the proposed hypothesis. However, no conclusions could be derived for the distribution of two types of oxygen bridges in the studied cluster. In order to improve the quality of crystal structures, the low temperature (at 103 and 123 K) X-ray diffraction studies have been carried out. The cluster architecture and symmetry was identical to that found at 293 K. It is interesting that results of the structure determination were worse than those obtained at room temperature (unpublished results). That may be explained by the observed changes in the stability of crystals with the decrease of the temperature (Fig. 3).

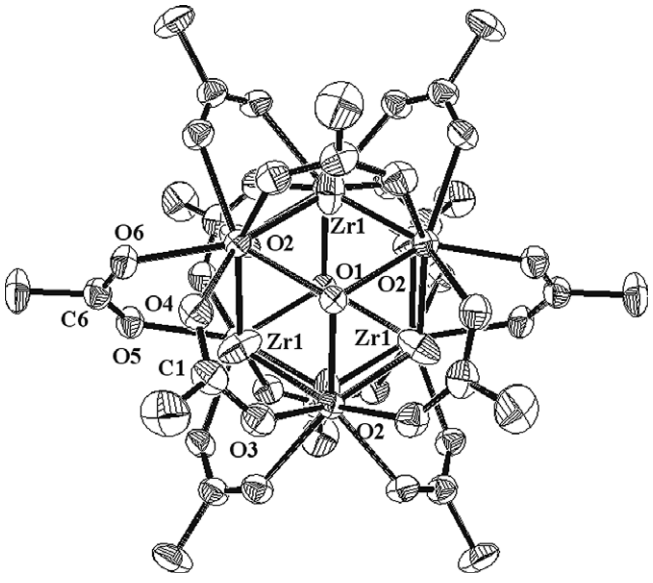

Fig. 1. Perspective view of the $[Zr_6O_4(OH)_4(OOCBu^t)_{12}]$ (**1**) cluster along the threefold axis coinciding with O1–O1′ direction. For clarity, the branched hydrocarbon groups of the carboxylates are not shown.

The distances between atoms within $[Zr_6O_4(OH)_4(OOCR')_{12}]$ cluster and in the coordination sphere of central cation are listed in Table 2. The average Zr1–Zr1 distances within **1** and **2** clusters are 3.510 Å and are similar to the analogous average distances in $[Zr_6(OH)_4O_4(OMc)_{12}]$ cluster [6]. The metal atoms of the octahedron are linked by μ_3-O bridges, which form the $\{Zr_6(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4\}$ clusters stabilized by twelve *syn–syn* bridges of carboxylate ligands. Each of Zr(IV) ions (coordination number 8) is surrounded by four oxygen atoms of μ_3-O/μ_3-OH bridges and four of carboxylato bridges μ-O(OOC). Oxygen atoms of oxo-bridges show two types of neighborhood: (a) O1 (2×) – where all Zr1–O1 distances are identical, and (b) O2 (4×) – where the narrow differences variation in the length of these bonds are noticed (Table 2). The bridging oxygen atoms are located slightly above each Zr_3 face of that octahedron. In **1** the deviations of the oxygen atoms from the best Zr_3 planes are 0.6807 and 0.6808 Å for O1 and O2 atoms, respectively. In **2**, the analogous deviations are 0.6766 and 0.6695 Å for O1 and O2 atoms, respectively. Trimethylacetate ligands of **1** form the asymmetric bridges, where the length of shorter Zr–O bonds varies in the range 2.202(7)–2.209(7) Å, and longer ones 2.232(7)–2.236(7) Å (C–O distances range 1.254(11)–1.260(12) Å, and 1.277(12)–1.279(11) Å). The presence of two non-equivalent carboxylate groups was also detected in the cluster of **2**. The length of Zr–O and O–C bonds being (a) Zr1–O3 = 2.210(5) Å, C1–O3 1.269(8) Å, and Zr1–O4 2.206(5) Å, C6–O4 1.262(8) Å and (b) Zr1–O5 2.224(5) Å, C6–O5 1.286(8) Å, and Zr1–O6 2.234(5) Å, C6–O6 1.281(8) for the stronger and weaker coordinated μ-OOC bridges, respectively.

Comparison of **1** and **2** crystallographic data with $[Zr_6(OH)_4O_4(OOCMc)_{12}]$ [6] reveled the clear differences in clusters structure, and their packing in the crystal lattice. The assignment of the bridging oxygen atoms to μ_3-O and μ_3-OH groups was possible basing on the analysis of Zr–O distances in $[Zr_6(OH)_4O_4(OOCMc)_{12}]$ (2.060–2.095 Å for μ_3-O, and 2.170–2.410 Å for μ_3-OH [6]). Significant differences in the Zr-(μ-OH) and Zr-(μ-O) bond length were also detected in other type of $[Zr_6(\mu\text{-}O)_n(\mu\text{-}OH)_m]$ cores [15]. Crystallographic data of **1** and **2** exhibited that the length of Zr-(μ_3-O/OH) bonds vary from 2.123(9) to 2.151(8) and from 2.128(5) to 2.138(6) Å, respectively (Table 2). Therefore, the use of criterion mentioned above for identification of μ_3-O and μ_3-OH groups in the structure of studied compounds is difficult. These differences are to small to determine which oxygen atoms may be attributed to oxo or hydroxo groups in the assumed $[Zr\text{-}(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4]$ core. The centrosymmetric space group and the narrow range of Zr-(μ_3-O/OH) bond length, detected for **1** and **2**, suggest that the migration of protons between oxygen bridges should be assumed. The way of carboxylate ligands association is a next difference between the structure of $[Zr_6(OH)_4O_4(OOCMc)_{12}]$ (chelating and bridging connections [6]) and the structures reported in this paper. The large, branched carboxylate ligands form only *syn–syn* bidendate bridges, stabilizing the $\{Zr\text{-}(\mu_3\text{-}O)\}^{4-}$ clusters. Moreover, their packing in the crystal lattice is different. Kickelbick and Schubert reported that in $[Zr_6(OH)_4O_4(OOCMc)_{12}]$ lattice six clusters are arranged in rings, which form large

voids parallel to the *c*-axis [6]. The clusters in the structures of **1** and **2** also form rings, but interior of each of them is filled by additional seventh cluster (Fig. 2).

3.1. ^{13}C NMR characterization of Zr(IV) multinuclear oxo carboxylates

Solid-state ^{13}C NMR spectra of **1** and **2** crystalline powders were registered in order to determine the structural differences between the studied compounds (data deposited as a supplementary material). Analysis of these data revealed no significant differences in chemical shifts of methyl, methylene, and quaternary carbon in ^{13}C NMR spectra of studied compounds. Simultaneously, the clear differences were noticed for resonance signals of carbon atoms of coordinated carboxylate groups. The splitting of carboxylate carbon signals were detected in spectra **1** and **2** between 183 and 185 ppm. According to structural data and literature reports [14,16], their chemical shift is characteristic for carbons of bidendate carboxylate groups, which form *syn–syn* bridges. Splitting of these signals suggests the presence of a non-symmetrical carboxylate ligand in $[Zr_6(OH)_4O_4(OOCR')_{12}]$ clusters. Studies of ^{13}C NMR spectra of **1** and **2** in [D$_6$] benzene solutions show clear similarities in the chemical shifts of the resonance signals with their analogues in solid-state spectra (e.g. δ C (COO) $\cong$ 184 ppm in the solid state and $\delta \cong 185$ ppm in solution). This fact shows that $[Zr_6O_4(OH)_4(OOCR')_{12}]$ are stable and their structure does not change even in the solution. Simultaneously, signals from protons of OH or OD groups were not registered.

3.2. Infrared spectroscopy studies

The problems with identification of OH groups caused that cluster structure of **1** and **2** were also characterized by the infrared spectroscopy. IR spectra were recorded between 98 and 350 K, and the wavenumbers of absorption bands with their assignation are listed in Table 3.

Weak bands, which were found at 3672 and 3668 cm^{-1}, in spectra of **1** and **2**, respectively, can be attributed to stretching vibrations (ν(OH)) of bridging OH groups not involved in hydrogen bonds [15,17,18]. No bands corresponding to OH groups forming hydrogen bonds have been found. According to literature reports, the formation of hydrogen bonds results in the shift of the ν(OH) band towards lower wavenumbers, between 3150 and 3550 cm^{-1} [17]. The detection of bands assigned to stretching modes of OH groups (in spectra of **1** and **2**) confirms the presence of hydroxo groups in their structure. Possible effects associated with the protons migration in $[Zr_6O_4(OH)_4(OOCR')_{12}]$ clusters could be visible between 400 and 1000 cm^{-1}. That is the region, where bands corresponding to libration modes of OH groups, stretching vibrations of M-(μ_3-O/OH) bridges, as well as bending and rocking modes of carboxylate groups can be detected [17,19–21]. Analysis of spectra registered at room temperature (RT) exhibited the presence of middle intensity bands at 728 and 724 cm^{-1} for **1** and **2**, respectively. Considering results of previous studies, the frequencies mentioned above were attributed to asymmetric vibrations of the equivalent Zr-(μ_3-O) bridges [21]. In spectra registered at liquid nitrogen temperature (LNT), the splitting of this band was observed (Table 3, Fig. 3b). The proton migration effects caused that in spectra registered at room temperature the splitting of these bands was not observed. Simultaneously, the restrictions of proton migration between oxygen bridges at liquid nitrogen temperature

Table 3
Wavenumbers (cm^{-1}) for the vibrations of carboxylate groups and oxo bridges (Zr–O–Zr) in LNT spectra of $[Zr_6O_4(OH)_4(OOCR')_{12}]$ (where R = Bu^t (**1**), $C(CH_3)_2Et$ (**2**))

(LNT) and the formation non-equivalent Zr-(μ_3-O/OH) bridges contribute to their splitting. Concluding, the results of IR and X-ray structure determination, give therefore the consistent basis for hypothesis of the proton migration occurring between six oxygen (O2) bridges.

Bands attributed to υ_{as}(COO) and υ_s(COO) vibrations have been detected in IR spectra of **1** and **2** between 1563–1570 cm^{-1} and 1416–1425 cm^{-1} (Table 3). Values of the $\Delta[\upsilon_{as}(COO) - \upsilon_s(COO)]$ parameter, being 147–145 cm^{-1}, are characteristic for bidendate carboxylate groups participating in *syn–syn* bridges [21–23]. Single bands, descended from asymmetric and symmetric vibrations of groups, indicate that all carboxylate groups form equivalent interactions in $[Zr_6O_4(OH)_4(OOCCR)_{12}]$ clusters. The presence of chelating and bridging carboxylate ligands, as in the case of $[Zr_6O_4(OH)_4(OMc)_{12}]$ [6], should result in the significant splitting of these bands. Absorption bands, which were detected between 400 and 700 cm^{-1}, can be attributed to COO bending and rocking vibrations of COO groups (Table 3). Considering previous reports, absorption bands at 650–680 cm^{-1} and 418–480 cm^{-1} were assigned to the bending (δ(OCO)) and rocking (ρ(COO)) vibrations of carboxylate group respectively [21,22]. Data presented in Table 3 show the clear differences in the frequency and splitting of bands descended from OCO bending vibrations. These spectral effects can be explained by the differences in the strength of Zr-(μ-O) carboxylate ligand bonds in the structure of synthesized compounds at low temperatures.

The frequency changes of bands assigned to stretching modes of OH, COO groups, and Zr-(μ_3-O/OH) bridges in spectra registered at RT and LNT indicate the possible

changes in the structure of $[Zr_6O_4(OH)_4(OOCCR)_{12}]$ clusters. These effects were studied using the variable temperature IR (VT IR) spectroscopy. Obtained results have been presented as a dependence between frequency ν(OH) and ν_{as}(Zr(O/OH)Zr) modes versus temperature (Fig. 3). According to these data, the frequency of these vibrations revealed the stepwise changes; first step about 103 K and the other one near 173 and 240 K, respectively. Above effects can be assigned to the phase transitions associated with dynamical changes in the structure **1** and **2** [24,25]. The migration of protons and the rotational disorder of Bu^t or $C(CH_3)_2Et$ groups in the crystal lattice are main factors causing the mentioned changes and explain difficulties in the precise determination of **1** and **2** crystal structure at low temperatures (103 or 123 K).

3.3. Thermal stabilities of studied Zr(IV) carboxylate derivatives

The thermal decomposition pathway of Zr(IV) multinuclear oxo carboxylates was studied using thermogravimetric methods (TGA/DTA) over the temperature range 298–873 K. The thermolysis of **1** proceeds in four endothermic steps, with maxima at 485, 668, 742, and 783 K (data deposited as a supplementary material). The weight loss of 61.0% indicate that decomposition of this compound proceed with complete conversion of this compound to ZrO_2 (calculated weight loss 61.0%) in the whole temperature range. Although **2** form a similar type of the structure as **1**, its thermal decomposition proceeds in two endothermic stages at 493 and 793 K. The sample weight lose (65.0%) indicates the complete conversion of **2** to zirconium oxide (calculated weight loss 64.1). The weak and broad stage which was noticed at 343–473 K can be assigned to the sublimation process. Experiments, with application of the cooling finger of sublimation chamber, exhibited that **2** sublimes between 373 and 453 K. IR spectra of sublimation products proved its occurrence. For **1** that process was not observed. Formation of ZrO_2 as the main decomposition product of **1** and **2** has been confirmed using IR and X-ray diffraction (XRD) methods. Analysis of XRD data proved the formation of ZrO_2 monoclinic form (literature data [26]: 28.18 ($\bar{1}11$), 31.47 (111), 34.15 (002), 34.42 (020), 35.30 (200), 49.30 (022), 50.13 (220); experimental: 28.18 ($\bar{1}11$), 31.46 (111), 34.15 (002), 34.42 (020), 35.30 (200), 49.30 (022), 50.12 (220)). The results of thermogravimetric analysis could be correlated with crystallographic data for **1** and **2**. The structure of **1** is characterized by the strong bridging interactions of carboxylic groups with Zr(IV) cations. Also, one of the Bu^t moieties revealed no rotational disorder and participated in the efficient intra-molecular interactions. Consequently, sublimation of that compound was not observed, while the thermal decomposition starts at 485 K. The cluster of **2** is stable, since its architecture is similar to that found in **1**. The significant rotational disorder of all hydrocarbon moieties results in weaker intra-molecular interactions and sublimation was detected at ~395 K.

4. Conclusions

Two multinuclear zirconium(IV) oxo carboxylates, $[Zr_6O_4(OH)_4(OOCR')_{12}]$ ($R' = Bu^t$ (**1**), $C(CH_3)_2Et$ (**2**)) were prepared in a direct reaction of Zr(IV) alkoxides with the suitable branched organic acids in the molar ratio 1:2, and characterized by elemental analysis, IR, ^{13}C NMR and single crystal X-ray diffraction techniques.

X-ray studies revealed that independently from the kind of Zr(IV) alkoxides ($Zr(OPr^i)_4$ or $Zr(OC(CH_3)_2Et)$ and organic acid used in the synthesis, a similar type of structure is formed. The structures of **1** and **2** consist of centrosymmetric clusters, composed of six zirconium(IV) atoms linked by 4:4 system of μ_3-oxo/hydoxy bridges and stabilized by *syn–syn* carboxylate bridges. Analysis of crystallographic and IR data suggests that four protons migrate between eight of Zr-(μ_3-O) bridges of the $[Zr_6O_4(OH)_4(OOCR')_{12}]$ cluster. The migration effects and the rotational disorder of Bu^t or $C(CH_3)_2Et$ groups in the crystal lattice are the main factors causing the dynamical changes of the structure of**1** and **2**, in the temperature range 98–293 K.

Results of thermal analysis revealed the significant differences in thermal stability of **1** and **2**, although studied compounds form a similar type of the crystallographic structure. In both cases thermolysis of these compounds proceed with their complete conversion to ZrO_2 (monoclinic form).

5. Experimental

5.1. Materials and methods

The studied compounds were synthesized at room temperature under argon atmosphere, using standard Schlenk line and glovebox techniques. $Zr(OR)_4$ ($R = Pr^i$, $C(CH_3)_2Et$) and Bu^tCOOH, $Et(CH_3)_2CCOOH$ (Aldrich) were used as received. The reactions were carried in the mixture of *n*-hexane and Pr^iOH used as a solvent. Both solvents were distilled and stored over the molecular sieves.

Infrared (IR) spectra were recorded on Perkin–Elmer Spectrum 2000 spectrometer within range 400–4000 cm^{-1} with a medium slit width and peak resolution of 4.0 cm^{-1}. The samples of analyzed compounds were studied as a powder dispersed in a KBr pellet. Variable temperature IR spectra were registered between 98 and 353 K using the SPECAC variable temperature cell. Solid-state ^{13}C NMR spectra were registered on Bruker AMX 300. The solution ^{1} and ^{13}C NMR spectra ([D_6]-benzene) were recorded using a 5 mm solution probe on Varian Gemini 200. Thermogravimetric analysis (TGA/DTA) was carried out using SDT 2960 TA Instruments, in nitrogen atmosphere between 298 and 873 K at a ramp rate 3 K^{-1}. X-ray diffraction (XRD) data were collected with a Philips

X'PERT diffractometer; 2Θ ranges 30–80°, Cu Kα radiation and sample spinning (step size – 0.1°, program. res. slit – 0.5, measuring time – 11 s per point).

5.2. Reaction of $Zr(OR)_4$ ($R = Pr^i$, $C(CH_3)_2Et$) with organic acids (RCOOH; $R = Bu^t$ (**1**), $t(CH_3)_2C$ (**2**))

$Zr(OR)_4$ ($R = Pr^i$, $C(CH_3)_2Et$) (1 g of $Zr(OPr^i)_4$ (2.58 mmol) or 1.13 g of $Zr(OC(CH_3)_2Et$ (2.58 mmol)) was added dropwise to a solution of organic acid (0.42 g; 5.16 mmol **1**, and 0.6 g; 5.16 mmol **2**) in the 3 cm^3 of mixture of *n*-hexane and Pr^iOH or $Et(CH_3)_2COH$ (1:1), and stirred for 24 h. Crystals were grown by slow evaporation of the reaction mixture under argon atmosphere (glovebox). The colourless crystals were obtained after 1 day.

5.3. $Zr_6O_8(OOCBu^t)_{12}$ (**1**)

Yield: 61%. The % Zr was gravimetrically determined as ZrO_2. Anal. Calc. for $C_{60}H_{108}O_{32}Zr_6$: C, 38.15; H, 5.75; Zr, 29.0. Found: C, 37.33; H, 6,18; Zr, 28.50%. IR (KBr, cm^{-1}): 1568 (ν_{as}(COO)); 1424 (ν_s(COO)); 729 (ν_{as}(Zr–O–Zr)); 680 (ν_s(Zr–O–Zr)), 607 (δ(OCO)); 481 (ρ(OCO)); ^{13}C NMR (solid-state, δ, ppm) 28.4 ($CH_3(Bu^t)$); 39.7 and 39.9 ($C(Bu^t)$); 183.9 and 184.5 (COO).

5.4. $Zr_6O_8(OOCC(CH_3)_2Et)_{12}$ (**2**)

Yield: 67%. Anal. Calc. for $C_{72}H_{132}O_{32}Zr_6$: C, 42.03; H, 6.42; Zr, 26.6. Found: C, 41.77; H, 6.89; Zr, 25.70%. IR (KBr, cm^{-1}): 1560 and 1566 (ν_{as}(COO)); 1413 (ν_s(COO)); 726 (ν_{as}(Zr–O–Zr); 678 (ν_s(Zr–O–Zr)), 631 and 598 (δ(OCO)); 482 (ρ(OCO)); ^{13}C NMR (solid-state, δ, ppm) 10.0 (CH_3(Et)); 33.1 (CH_2(Et)); 39.7 ($C(Bu^t)$); 43.2 ($CH_3(Bu^t)$); 183.9 and 184.3 (COO).

5.5. X-ray structure data

The diffraction data were collected at 293 K for the single crystals ($0.10 \times 0.08 \times 0.06$ mm **1**, $0.20 \times 0.17 \times 0.15$ mm **2**) using Oxford Diffraction KM4 CCD diffractometer, Mo Kα radiation $\lambda = 0{,}71073$ Å. The reflections have been measured with $\omega - 2\theta$ method. The numerical absorption correction was applied for **1** and **2** (RED167 package of programs, Oxford Diffraction, 2000). Structures of **1** and **2** were solved by the direct methods and refined with full-matrix least-squares procedure on F^2 using SHELX-97 program package [27]. Details of the data collection and structure refinement are presented in Table 1. Crystal data have been deposited with CCDC (deposition numbers CCDC 278496 and 278497 for **1** and **2**, respectively).

Abstract

The present work deals with a class I mixed valence trinuclear complex $[Co^{II}(\mu\text{-}OAc)_2(\mu\text{-}L)_2Co_2{}^{III}(NCS)_2]$ (**1**) formed by partial aerial oxidation (H_2L = 1,7-bis(2-hydroxyphenyl)-2,6-diazahepta-1,6-diene). The terminal $Co^{III}N_3O_3$ centres exhibit a uniform facial arrangement of both N_3 and O_3 donor sets and the Co^{II} centre is coordinated to six oxygen atoms. Variable temperature magnetic susceptibility measurement reveals that the intermediate Co(II) paramagnetic centre undergoes a very weak spin exchange ($\theta = -6.39$ K, antiferromagnetic) interaction with the two terminal Co(III) diamagnetic centres over the range 300–2 K. A three line EPR spectra at 4 K was characterized with highly anisotropic g tensors and the one line broad spectra at 300 K indicates the strong influence of temperature on the metal spin states, consistent with a high spin Co(II) complex. Two anodic responses appeared at +0.85 ($Co^{2+} \rightarrow Co^{3+}$, reversible) and +1.7 V ($Co^{3+} \rightarrow Co^{4+}$, irreversible) corresponding to one and two electron transfer oxidation respectively. Another reversible signal attributed to $Co^{3+} \rightarrow Co^{2+}$ reduction occurred at −0.5 V, associated with a two electron stoichiometry. Compound **1** reacted with hydrazine to form a square planar orange-red $[Co^{II}(L)]$ species, **2**. Inter conversion between **1** and **2** involves electron exchange coupled with proton transfer.

1. Introduction

Cobalt complexes based on quadridentate bis(salicylidene) Schiff base ligands, preserve substantial interest relevant to vitamin B_{12} models [1–4] as well as biomimetic catalysts [5–7]. The concerned ligands also draw considerable attention in view of their fascinating μ^2-bridging ability of the phenoxo oxygen atoms affording high nuclearity complexes which could act as promising candidates to offer valuable insight into various natural electron transfer events [8]. High nuclearity coordination complexes thus achieved by this kind of compartmental ligands along with other appropriate coligands provide tractable examples to rationalize magnetic exchange phenomenon [9,10] emerging from temperature dependent interactions between the spin states of individual magnetic centres. Use of bis(salicylidene) ligands with polymethylene spacers of varying flexibility allow us to regulate their electronic and steric demands which of course in association with metal preferences could effectively modulate structural versatility enlightening spin and valence change phenomena.

The unique potentiality of simple ligands has prompted us to synthesize high nuclearity cobalt(II) complexes in the presence of ancillary NCS ligands and to study their electron transfer as well as spin exchange behaviours. Our attempt with 1,7-bis(2-hydroxyphenyl)-2,6-diazahepta-1,6-diene as a representative of the bis(salicylidene) family furnished a novel Co^{III}–Co^{II}–Co^{III} mixed valence octahedral trinuclear species.

Herein we report the synthesis, spectroscopic characterizations, structure, magnetic properties and redox behaviour of the trimer. We also noted that the trimer undergoes spontaneous chemical reduction.

2. Experimental

2.1. Materials and physical measurements

The ligand H_2L was synthesized by condensation of 1,3-diaminopropane with salicaldehyde in dry methanol following the literature method [11]. All other chemicals were of reagent grade and were used as received. Solvents were dried and distilled prior to use. The IR spectra were recorded on KBr pellets with a Perkin–Elmer RXI FT-IR spectrometer. A Perkin–Elmer 2400 II elemental analyzer was used for microanalysis. FAB mass spectra (matrix, 3-nitrobenzyl alcohol) was done with a JEOL JMS600 spectrometer. Electrochemical measurements were performed under a dinitrogen atmosphere using a PAR model Versastat-2 electrochemical analyzer with a platinum working electrode. The supporting electrolyte was tetraethylammonium perchlorate (TEAP), and the potentials were referenced to the saturated calomel electrode (SCE) without junction correction. X-band EPR spectra in solid and solution states were recorded using a Bruker 300E spectrometer. Variable temperature magnetic susceptibility measurement was performed using a cryogenic S600 SQUID magnetometer.

2.2. Preparation of complexes

2.2.1. Synthesis of $[Co^{II}(\mu\text{-}L)_2(\mu\text{-}OAc)_2Co_2{}^{III}(NCS)_2]\cdot 2CH_3CN$ ($\mathbf{1}\cdot 2CH_3CN$)

To a solution of $Co(OAc)_2\cdot 4H_2O$ (0.05 g, 0.200 mmol) in methanol (25 ml), NH_4SCN (0.01 g, 0.133 mmol) was added and vigorously stirred for 15 min. A yellow solution of the ligand H_2L (0.038 g, 0.133 mmol) in methanol (5 ml) was then added slowly to the metal solution. The resulting brown solution turned green on stirring in air for 3 h. It was then filtered and solvent removal from the filtrate under reduced pressure gave a green residue which was washed twice (10 ml each) with hexane to remove excess ligand, if any. The green mass was dried in vacuum over fused $CaCl_2$, and subsequent recrystallization from acetonitrile solution afforded the crystalline green complex. Yield: 0.062 g (88% based on metal salt). (Anal. Calc. for $C_{44}H_{44}Co_3N_8O_8S_2$: C, 50.10; H, 4.21; N, 10.63. Found: C, 50.16; H, 4.17; N, 10.67%.)

Alternatively, to an orange-red solution of **2** (0.136 g, 0.400 mmol) in 10 ml methanol, a methanolic solution (25 ml) containing $Co(OAc)_2\cdot 4H_2O$ (0.05 g, 0.200 mmol) and NH_4SCN (0.03 g, 0.400 mmol) was added dropwise over a period of 10 min with continuous stirring. The resulting solution turned green on stirring in air for 4 h. It was then filtered and solvent removal from the filtrate under reduced pressure gave a green residue which was washed thrice (10 ml each) with cold water to remove excess of reagents, if any. The green mass was dried in vacuum over conc. H_2SO_4, and subsequent recrystallization from acetonitrile afforded the crystalline green complex. Yield: 0.304 g (72% based on **2**). It has been observed that the reaction time can be considerably reduced to 2 h upon purging dioxygen gas into the reacting solution.

2.2.2. Synthesis of $[Co^{II}L]$ (**2**)

To a green solution of $\mathbf{1}\cdot 2CH_3CN$ (0.300 g, 0.285 mmol) in dichloromethane (60 ml) was added 50% hydrazine hydrate (0.016 g, 0.320 mmol) solution. It was stirred for 45 min at room temperature whereupon the solution gradually turned reddish brown. The resulting solution was stripped of solvent under reduced pressure. The deep brown residue thus obtained was freshly dissolved in dichloromethane (25 ml) and extracted five times with water (50 ml each). On performing subsequent extractions, the colour of the dichloromethane part became intense orange-red in colour. The orange product was then isolated by solvent evaporation and dried in vacuum over fused $CaCl_2$. Yield: 0.158 g (82% based on $\mathbf{1}\cdot 2CH_3CN$). (Anal. Calc. for $C_{17}H_{16}CoN_2O_2$: C, 60.13; H, 4.75; N, 8.26. Found: C, 60.17; H, 4.72; N, 8.32%.)

Alternatively, the concerned ligand H_2L (0.086 g, 0.300 mmol) was dissolved in dry methanol (10 ml), followed by dropwise addition of a methanolic solution (20 ml) containing $Co(OAc)_2\cdot 4H_2O$ (0.038 g, 0.150 mmol) at ambient temperature under stirring. This was continued for 3 h under the passage of dinitrogen gas, which resulted in an orange brown solution. Stripping of solvent furnished an orange brown residue which was washed with *n*-hexane to remove unreacted ligand, if any, and further with cold water to ensure no metal substrate was present. The orange-red complex thus obtained was dissolved dichloromethane and recrystallized by slow evaporation. The product finally was dried over fused $CaCl_2$. Yield: 0.038 g (75% based on metal salt).

2.3. X-ray crystallography

Dark green single crystals of $\mathbf{1}\cdot 2CH_3CN$ were obtained by slow evaporation of solvent from an acetonitrile solution. Data were collected at $T = 130(2)$ K on a Siemens SMART CCD area-detector diffractometer equipped with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å, rotating anode source) in the range $1.64° \leqslant \theta \leqslant 28.29°$. All the data were corrected for Lorentz polarization and absorption using the SADABS [12] routine. The structure was generated by direct methods using SHELXS-97 [13] followed by successive Fourier synthesis and refined by full matrix least squares based on F^2 with SHELXL-97 [14]. Anisotropic displacement parameters were assigned to all non-hydrogen atoms. Hydrogen atoms were inserted at calculated positions; the hydrogen atoms of acetonitrile solvent molecules were not introduced in the model. Significant crystal data are collected in Table 1.

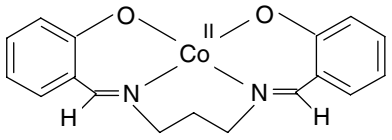
3. Results and discussion

3.1. Synthesis of compounds

Facile condensation of salicylaldehyde and 1,3-diaminopropane in a 2:1 molar ratio respectively, afforded a neutral condensate, 1,7-bis(2-hydroxyphenyl)-2,6-diazahepta-1,6-diene (general abbreviation H_2L, where H atoms are dissociable phenolic hydrogens) which has been employed as a tetradentate chelating ligand in the present work.

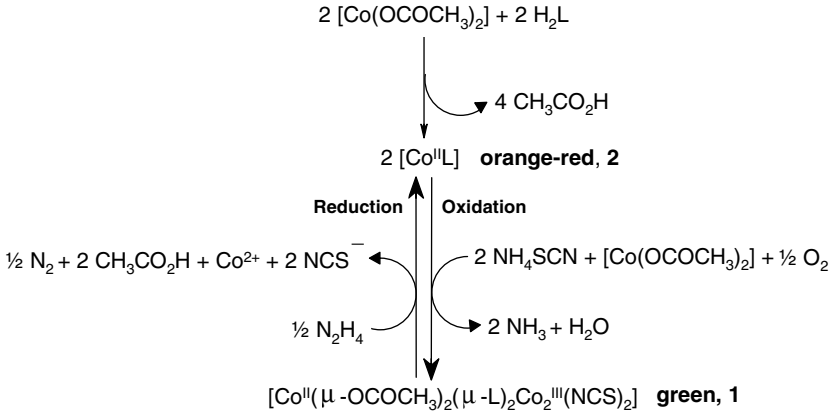


H_2L

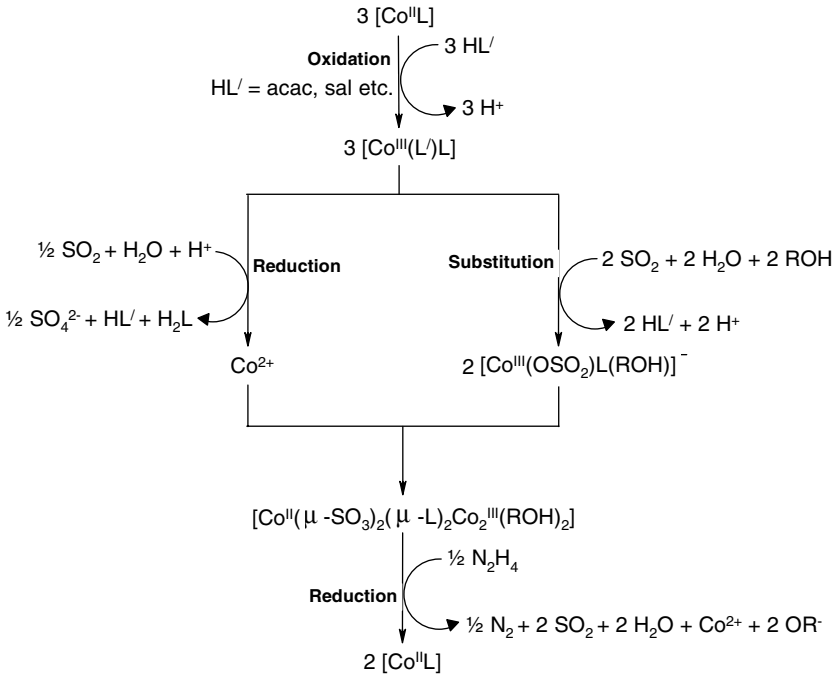
In order to synthesize a high nuclearity cobalt-H_2L complex, we reacted 1 mol of H_2L with a 2:2 methanolic mixture of $Co(OAc)_2$ and NH_4SCN, under magnetic stirring at ambient temperature. Subsequent crystallization of the product from acetonitrile solution gave green crystals of the trimeric mixed valence cobalt complex $[Co^{II}(\mu\text{-}OAc)_2(\mu\text{-}L)_2Co_2{}^{III}(NCS)_2]$ (**1**) as authenticated from its X-ray structure determination. In this process the yield of the complex is only ~45%.

We revisited the reaction in search of the concerned oxidizing agent and the appropriate stoichiometries of the metal and ligands to increase the yield of the product. The reaction when carried out under dinitrogen atmosphere only ended up with no formation of the desired product which logically tempted us to believe that atmospheric oxygen acts here as an external oxidant. Subsequently we carried out the reaction (in air) in a 3:2:2 mol ratio of metal, H_2L and NH_4SCN respectively in methanol solution under stirring at ambient conditions. The modified strategy indeed worked excellently and the yield of the product reached even up to 88% after recrystallization from acetonitrile solvent. The stoichiometric equivalents of the ingredients is presented in Eq. (1)

$$3[Co^{II}(OAc)_2] + 2H_2L + 2NH_4SCN + 1/2\,O_2 \rightarrow [Co^{II}(\mu\text{-}OAc)_2(\mu\text{-}L)_2Co_2{}^{III}(NCS)_2] + 2NH_4OAc + 2HOAc + H_2O \quad (1)$$



It could be assumed that the reaction was initiated via the formation of a four coordinated mononuclear Co(II) species as the first possible intermediate $[Co^{II}L]$ (**2**) which reacts further with $Co^{II}(OAc)_2$ in the presence of NH_4SCN and ultimately aerial oxidation generates the desired trimer.



2

To examine the validity of the proposed reaction pathway, we tried to trap the reactive intermediate (**2**), but did not succeed, instead an orange-red coloured complex was isolated by hydrazine reduction of **1**. Potency of N_2H_4 as a reducing agent lies in its unique proton cum electron donor ability involving the reaction $1/2\,N_2H_4 \rightarrow 1/2\,N_2 + 2H^+ + 2e$. Liberated protons cleave the μ^2-OAc linkages of **1** and the Co^{III} centres suffer reduction by consuming the electrons. The outcome of the chemical events is the formation of **2**. Interestingly, the reaction of $[Co^{II}L]$ (**2**) and $Co(OAc)_2$ in a 2:1 mol ratio respectively in methanol in the presence of NH_4SCN (2 mol) afforded the green coloured trimer, **1** (Scheme 1). The reaction has been carried out in air, and under dinitrogen atmosphere the reaction did not occur. Therefore, in the presence of a proton donating agent like ammonium salt, dioxygen from the air is reduced to water via the following reaction, $2NH_4{}^+ + 1/2\,O_2 + 2e \rightarrow 2NH_3 + H_2O$ where the $[Co^{II}L]$ complex acts as a one electron donor and subsequently is oxidized to the complex, $[Co^{II}(\mu\text{-}OAc)_2(\mu\text{-}L)_2Co_2{}^{III}(NCS)_2]$ (**1**).

It is important to note that the only known structurally characterized trimeric mixed valence complex [15] with the H_2L type ligand is $[Co^{II}(\mu\text{-}SO_3)_2(\mu\text{-}L^1)_2Co_2{}^{III}(Pr^nOH)_2]$ (L^1 is a derivative of L where two aldimine protons have been replaced by two methyl groups) and this sulfito bridged trimer was obtained by partial reduction [15] of the corresponding Co^{III} precursor by SO_2 (Scheme 2). Thus both partial oxidation and reduction of Co^{II} and Co^{III} precursors respectively, provide different efficient routes to prepare Co^{III}–Co^{II}–Co^{III} trimers incorporating H_2L/H_2L^1 types of di-Schiff bases.

Scheme 1.

Scheme 2.

3.2. Crystal structure

The asymmetric unit of **1** consists of one neutral $[Co(\mu\text{-}OAc)_2(\mu\text{-}L)_2Co_2(NCS)_2]$ molecule and two acetonitrile solvent molecules. The structure of the complex is depicted in Fig. 1 and selected bond distances and angles are listed in Table 2. The cobalt(III) and cobalt(II) centres are linked by one acetate ion and two phenoxo oxygen atoms of L^{2-}, forming an μ-acetato–bis(μ^2-phenoxo) bridged Co^{III}–Co^{II} motif. Another Co^{III} centre is again bonded with the Co^{III}–Co^{II} motif via a similar bridging segment and generates the Co^{III}–Co^{II}–Co^{III} core.

Co1 has a six-coordinate octahedral geometry in which O1, O2, N4 and N3 atoms of the deprotonated di-Schiff base (L^{2-}) constitute the equatorial plane and N1 and O8 atoms of isothiocyanate and acetate ligands respectively, define the axial direction. The geometry is distorted with an average twist angle of 52.5°. The equatorial plane deviates by only 0.01 Å from the best fit mean plane. One of the two salicyldimine chelate rings (O1, C11, C12, C13, C14, C15, C16, C17 and N3) makes a dihedral angle of 34.5° with the $Co1N_2O_2$ equatorial plane. Likewise, the other salicyldimine ring is inclined by 28.1° with the $Co1N_2O_2$ plane. The trimethylene spacer of L^{2-} adopts a boat configuration with a "V-angle" of 121.1° (180° represents a planar arrangement) [16]. The coordination environment around Co3 is very similar to that of Co1. It (Co3) also sits in a pseudooctahedral environment in which the L^{2-} ligand occupies the equatorial positions (O3, O4, N6 and N5 atoms) and the two apical positions are coordinated by the oxygen atom (O6) of bridging acetate and by an isothiocyanato nitrogen (N2). The average twist angle of the

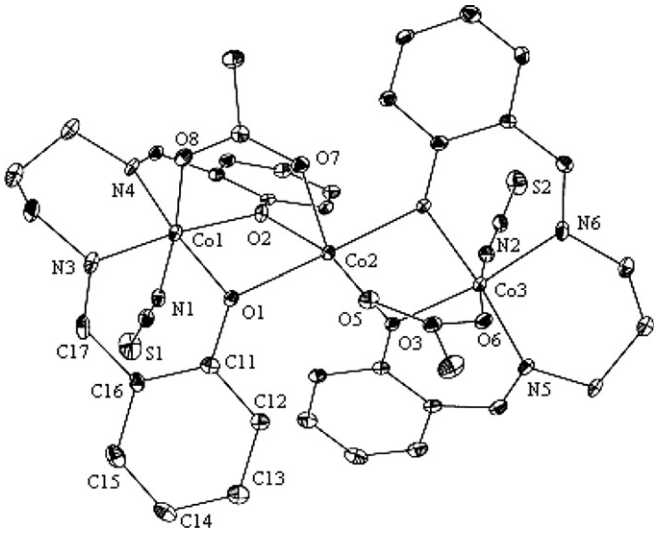


Fig. 1. A perspective view (25% probability thermal ellipsoids) and atom labelling scheme of $[Co(\mu\text{-}OAc)_2(\mu\text{-}L)_2Co_2(NCS)_2]$ (**1**). Hydrogen atoms and solvent molecules are omitted for clarity.

octahedron is 51.7°. The four donor atoms of L^{2-} describe a satisfactory plane with average mean deviation of 0.02 Å. Two chelated salicyldimine rings make an average dihedral angle of 30.1° with the equatorial $Co_3N_2O_2$ plane. Like Co1, the trimethylene spacer of L^{2-} adopts a boat configuration with a corresponding "V-angle" of 119.5°. A notable feature in the individual CoN_3O_3 environments is a uniform *facial* disposition of both N_3 and O_3 donor sets, maximizing the back-bonding effect. The central Co2 atom is coordinated by phenoxo oxygen atoms (O4 and O1) along the axial direction and the equatorial plane is defined by two acetato (O5 and O7) and two other phenoxo (O2 and O3) oxygen donors. The asymmetric coordination is evident from exclusive *cis* orientations of μ^2-phenoxo oxygen pairs of each of individual L^{2-} ligands and the acetate oxygen donors. In contrast, a *trans* orientation of the μ-sulfito oxygen donors (axially coordinated) around the central Co^{II} atom in the $[Co^{II}(\mu\text{-}SO_3)_2(\mu\text{-}L^1)_2Co_2{}^{III}(Pr^nOH)_2]$ complex [15], is consistent with an inversion symmetry. The $Co2O_6$ octahedral motif is deformed with an average twist angle of 53.3° and the equatorial plane deviates considerably by 0.31 Å from the best fit mean plane.

The average of Co1–O and Co1–N distances are 1.894 Å and 1.909 Å, almost identical to the concerned bond lengths observed for the Co3 atom ($(Co3\text{–}O)_{av} = 1.897$ Å, $(Co3\text{–}N)_{av} = 1.909$ Å). The average bond distance between the central Co2 atom and equatorial oxygen donors (~2.08 Å) is longer than that of the Co2-axial phenoxo oxygen atoms (~2.05 Å), pertinent to ground state distortion. The bond lengths between Co2 and four phenoxo oxygen atoms span the range 2.046–2.137 Å, whereas bond lengths between Co2 and two acetate oxygen atoms lie in the range 2.021–2.033 Å, i.e. on average the Co2–O-(phenoxo) length is ~0.06 Å longer than the Co2–O(acetate) length, attributed to differing bridging modes of the two bridging ligands. All the six Co2–O distances are averaged at 2.059 Å which is significantly longer than the Co(1/3)–O lengths by ca. 0.17 Å, substantiating the fact that the bivalent Co2 atom has a larger radius compared to terminal trivalent cobalt atoms. The Co1···Co2 and Co2···Co3 intra-atomic separations are 3.046(6) and 3.055(5) Å respectively, which could presumably restrict intra-metal spin exchange through mutual interactions. The bridging angles Co1–O1–Co2, Co1–O2–Co2, Co2–O3–Co3 and Co2–O4–Co3 are 100.9°, 98.4°, 98.0° and 101.5°, which indicate non-colinear Co^{III}–O–Co^{II} fragments, not suitable for any significant electronic exchange. This impression has been confirmed by a variable temperature magnetic susceptibility study, discussed later.

3.3. IR spectra

The trimeric mixed valence complex exhibits several distinguishable resonances consistent with the coordination geometry, revealed from structure determination. Vibrationally active acetate ligands display antisymmetric and symmetric stretching vibrations at 1561 and 1410 cm^{-1} respectively. The difference in frequency, Δ ($\nu_{as}(COO^-) - \nu_s(COO^-)$) is 151 cm^{-1} (163 cm^{-1} for free acetate ion), indicating the presence of a deprotonated carboxylate group

coordinated to metal centres in a bridged bidentate fashion [17]. Monodentate N-bound isothiocyanate groups are characterized with an intense signal at 2100 cm^{-1}. The characteristic imine (C=N) stretch of the chelated ligand appears at 1630 cm^{-1} and the red shift of this C=N absorption of about 15 cm^{-1} on going from the free H_2L ligand to the complex suggests a weak π-accepting ability of the coordinated ligand.

3.4. Electrochemistry

Aiming to investigate the electron transfer events of **1**, a cylic voltammetry experiment was performed in acetonitrile solution within the potential range (+2) to (−1) V versus the saturated calomel electrode (SCE) at ambient temperature. The voltammogram of **1** is represented in Fig. 2.

The complex displayed a reversible oxidative response (couple I) at +0.85 V with characteristic anodic (E_{pa}) and cathodic (E_{pc}) peak potentials at +0.89 and +0.81 V respectively. The reversible signal is attributed to the $Co^{2+} \rightarrow Co^{3+}$ oxidation. The ratio of the observed and calculated coulomb accounts for a single electron change ($\mathbf{1} \rightarrow \mathbf{1}^{+}$), obtained from constant potential coulometry at a potential ca. 0.150 V more positive than the $E_{1/2}$ value of the concerned couple which is near to unity (0.97) and confirms one electron oxidation. The relevant electron transfer is represented in Eq. (2)

$$[Co^{III}–Co^{I}–Co^{III}] \rightarrow [Co^{III}–Co^{III}–Co^{III}]^{+} + e \quad (2)$$

The second oxidation reaction (couple II) was commenced at ca. +1.7 V in the anode sweep whereas no response at the counter cathode sweep was observed. The response is assigned to an oxidation of Co(III) to Co(IV) (Eq. (3)). This oxidation is expected to occur at high positive potential due to the relative destabilization of Co^{4+} with respect to Co^{3+} in a N_3O_3 donor environment and electrochemical irreversibility possibly arises from the lability of the Co^{4+} centres on the voltammetric time scale. A two electron stoichiometry of couple II was determined from differential pulse voltammogram (DPV) measurement by direct comparison of the peak height with respect to that of couple I. Irreversibility remains persistent regardless of variable scan rates (0.05–1.0 V s^{-1})

$$[Co^{III}–Co^{III}–Co^{III}]^{+} \rightarrow [Co^{IV}–Co^{III}–Co^{IV}]^{3+} + 2e \quad (3)$$

One of the reviewers suggested that ligand (L^{2-}/NCS^{-}) oxidation might be an alternative event at this potential instead of metal oxidation and the authors need to furnish further evidences (experimental and literature) in support of this assignment.

We did some relevant experiments to re-account the responsible chemical transformation associated with the oxidative response at +1.7 V. Firstly, the monocondensate of salicaldehyde and 1,3-diaminopropane was previously characterized [18] to be redox inactive. Likewise, a voltammetric study of the ligand H_2L in dry acetonitrile solvent over the accessible potential range did not record any signal. Secondly, to verify whether NCS^{-} is redox active, though it is a very remote chance from a theoretical standpoint, we prepared an analogous complex $[Co^{II}(\mu\text{-}OAc)_2(\mu\text{-}L)_2Co_2^{III}(N_3)_2]$ from suitable reagents which expectedly displayed a similar voltammogram (like **1**) attesting the fact that neither of the ancillary ligands (NCS^{-}/N_3^{-}) participate in oxidation. Finally, conclusive evidence in favour of metal oxidation was obtained from a low temperature EPR study of a coulometrically oxidized solution of **1**, performed at a constant potential (+1.85 V). The resulting deep brown solution was silent to EPR and consequently ruled out any possibility of ligand stabilized cationic radical formation via oxidation, which would otherwise respond to EPR with a g value close to the characteristic spin only value (2.002) of a free electron. This observation is in agreement with the electrochemically generated $Co_2^{IV}Co^{III}$ ionic species in which effective spin coupling between the two Co(IV) paramagnets takes place through the intervening diamagnetic Co(III) centre. In addition to the above supportive experimental facts, a literature survey reveals a series of μ^2-acetato-μ^3-oxo based Co(III) trimers [19] undergoing one electron reversible oxidation at ~+1.25 V to mixed valence $[Co_2^{III}Co^{IV}]^{2+}$ species, confirmed by a controlled electrolysis method. Another recently reported Co(IV) complex, $[Co_4O_4(O_2CR)_2(bpy)_4]^{3+}$ is stabilized through a cubane framework [20] supported by acetate groups. Search for stabilizing electronic effects in the authenticated complexes revealed the common presence of a predominantly oxygen rich donor environment around Co(IV) involving bridging oxo ($\mu\text{-}O^{2-}$, σ cum π donor) and bridging acetato ($\mu\text{-}OAc^{-}$, σ donor) moieties along with nitrogenous donors. The structures are characterized with the occurrence of a di(μ^2-oxo)dicobalt motif, a neccessary stabilizing feature. The complex examined in this work bears some resemblance both in terms of structural and electronic aspects to the reported complexes, thereby providing the opportunity to stabilize the $[Co_2^{IV}Co^{III}]^{3+}$ species as happened in practice. On a conspectus of the

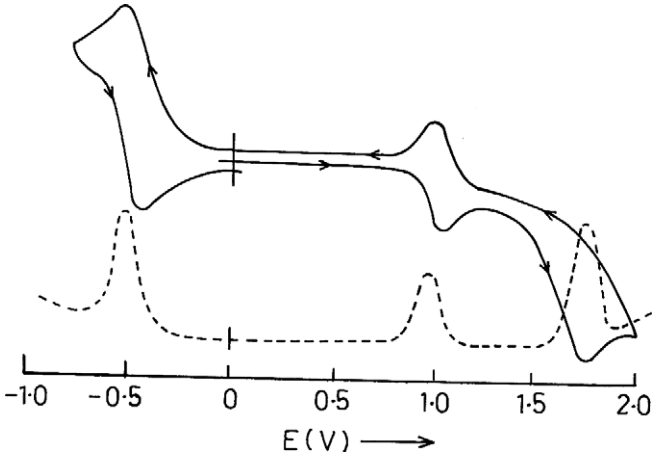

Fig. 2. Cyclic voltammogram of **1** at room temperature in MeCN solvent.

aforecited evidences, the assignment seems to be established.

The reductive response (couple III) occurring at −0.5 V ($\Delta E_p = 90$ mV) is ascribed to a $Co^{3+} \rightarrow Co^{2+}$ transformation. DPV is suggestive of a two electron transfer and the metal valence change associated with couple III is stated in Eq. (4)

$$[Co^{III}–Co^{II}–Co^{III}] + 2e \rightarrow [Co^{II}–Co^{II}–Co^{II}]^2 \quad (4)$$

3.5. Magnetic properties

Magnetic susceptibility of **1** in the polycrystalline state was measured over the temperature range 300–2 K. The magnetic moment at room temperature (300 K) is 5.06μ_B, corresponding to that of a monomeric complex having a cobalt(II) ion in a high spin octahedral environment. The value is higher than the spin only value of high spin cobalt(II) (3.87μ_B; $\mu_S = [4S(S+1)]^{1/2}$; $S = 3/2$) but closer to the value expected for the situation where the contribution of orbital angular momentum [21] is taken into account (5.20μ_B; $\mu_S = [L(L+1) + 4S(S+1)]^{1/2}$; $L = 3$; $S = 3/2$). The observed magnetic moment is in good agreement with the magnetic moment of a non-spin coupled Co(III) ($S = 0$)–Co(II) ($S = 3/2$)–Co(III) ($S = 0$) system, as established from the equation $\mu^2 = \sum \mu_i^2$, where μ_i is the magnetic moment of the individual metal centres of homonuclear polymetallic species [22].

To verify the nature of the spin exchange phenomenon, variable temperature magnetic susceptibility measurement will be of interest indeed. The temperature dependence of the magnetic susceptibility is small as revealed from the linear nature of $1/\chi_M$ versus T graph (Fig. 3), with a correlation constant of 0.999. The data could be fitted to a typical Curie–Weiss model for a $S = 3/2$ system with $\theta = -6.39$ K and $C = 3.24$ cm^3 K mol^{-1}. The magnetic moment remains virtually independent of temperature in the higher temperature range, there being a marginal drop from 5.06μ_B at 300 K to 4.79μ_B at 50 K due to the orbital contribution of the excited E_g states [23]. However, below 50 K, there is a steady decrease in the magnetic moment to a value of 2.76μ_B at 2 K, consistent with significant zero-field splitting leading to an unequal population of the Kramers doublet. Accordingly, it is not unrealistic to assume that the spin exchange interaction (antiferromagnetic) between the variable valence metal atoms is very small and **1** behaves as a high spin monomeric Co(II) species in the solid state throughout the temperature domain.

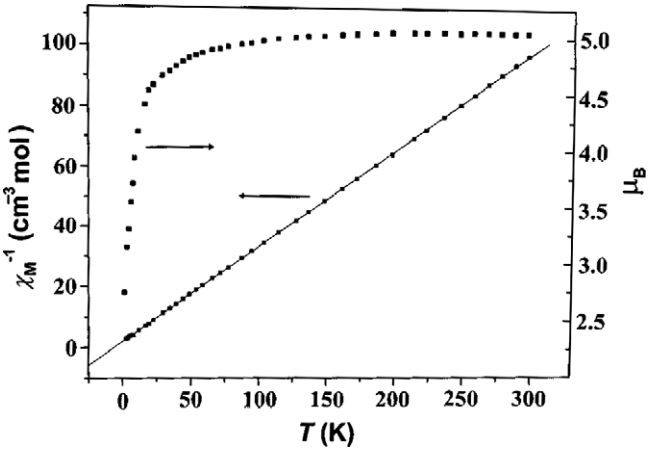

Fig. 3. Variation of χ_M^{-1} with temperature.

3.6. EPR spectra

The X-band EPR spectrum of a polycrystalline powder sample of **1** at 4 K is displayed in Fig. 4. For a $S = 3/2$ spin system (HS Co^{2+}, d^7), the zero field perturbation splits the energy levels into two doublets, $m_s = |\pm 3/2\rangle$ and $|\pm 1/2\rangle$. The nature of the spectrum could be assigned to the transitions between the ground state Kramers doublet with a highly anisotropic g-factor ($g_x = 4.33$, $g_y = 3.27$ and $g_z = 1.99$), which is believed to originate from the involvement of an excited doublet with an effective spin of 3/2 [24]. The spectrum is broad and overlapping in nature at 77 K, thereby eliminating any possibility to resolve the individual g_x and g_y components of the $g_\perp$ absorption. However, the obtained g values are indicative of a weak rhombic distortion, consistent with other high spin Co(II) species. Under axial symmetry the degeneracy of the $^4T_{2g}$ ground state splits into $^4A_{2g}$ and ^4E_g levels and the lower lying term then splits in course of spin–orbit coupling into Kramers doublets, whose zero field splitting energy is larger than the energy of the microwave radiation ($g\beta H$) used for the X-band EPR technique [25]. Owing to the above fact, only the transitions involving the lowest Kramers doublet ($\pm 1/2$) could be expected and indeed has been experimentally found. No hyperfine structure arising from an electron-

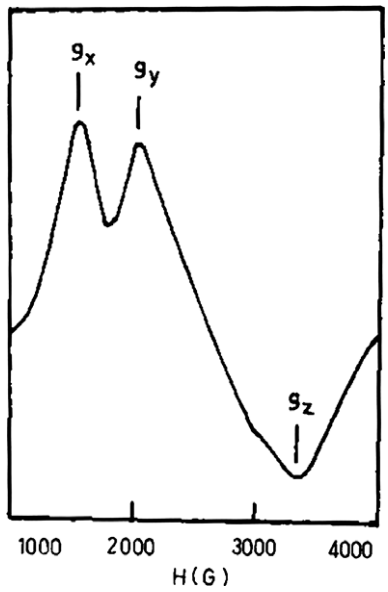

Fig. 4. EPR diagram of complex **1** in the polycrystalline state at 9.1 GHz and 4 K.

nucleus interaction for the ^{59}Co isotope (100% abundance, $I = 7/2$) is observed in the spectrum. The observation corroborates the weak nature of the spin exchange interaction in **1** as otherwise evident from variable temperature magnetic susceptibility measurement ($|\theta| = 6.39$ K). The EPR spectrum in a frozen (4 K) dichloromethane/toluene (2:1) glass also follows a similar pattern ($g_x = 4.29$, $g_y = 3.31$ and $g_z = 2.02$) as observed for a polycrystalline powder sample at 4 K, strongly indicating the retainment of the coordination environment both in solid and solution phases. The powder EPR spectrum recorded at 300 K is fortunately characterized by a single broad line with a centre field g value of 2.60. The single line spectrum could arise from substantial overlapping of the individual g-tensors which could be apparently attributed to considerably fast spin-lattice relaxation processes, thereby significantly reducing the lifetime of the concerned spin doublets [26].

4. Chemical reduction of the trimer: isolation of the product and spectroscopic evidence

The chemically accessible formal potential of the Co^{3+}/Co^{2+} reduction couple of **1** has tempted us to examine the reductive susceptibility and we have successfully used hydrazine hydrate which reduced the trimer in dichloromethane solution furnishing an orange-red complex, characterized with the help of various spectroscopic techniques and magnetic susceptibility measurement. All the results of the spectroscopic investigations confirm the orange-red complex to be a monomeric, square planar, neutral Co(II) species incorporating L^{2-} chelation. The relevant chemical transformation is depicted in Scheme 1 (vide supra).

UV–Vis spectra of **2** in dichloromethane solution exhibits a lowest energy band maximum at 675 nm followed by a moderate intensity absorption at 500 nm. The other characteristic feature of the spectrum occurred at 378 nm and is believed to be associated with a charge transfer process. The remaining band maxima appearing near and below 300 nm are due to the intraligand transitions, very similar with the absorption of the free H_2L ligand. In the IR spectrum, the prominent imine (C=N) stretch of the chelated ligand appeared at 1620 cm^{-1}, red shift of this vibration by 10 cm^{-1} on going from **1** to **2** suggests a better π-accepting ability of the coordinated ligand in the latter complex, which might stem from superior back-donation from low valent metal to $\pi^*_{C=N}$ orbitals. The ligand did not show any O–H stretching band, confirming the deprotonated oxygen (phenoxo) binding to the metal. Disappearance of characteristic vibrational signals of acetate and NCS groups logically lead us to recognize **2** as a cobalt(II) derivative incorporating only L^{2-} coordination. A cyclic voltammetric study of **2** reveals an irreversible one-electron oxidative response in both coordinating (MeCN) and non-coordinating (DCM) solvents, attributed to a $Co^{2+} \rightarrow Co^{3+}$ transformation at +0.80 V versus SCE. The signal appeared at a lower potential compared to the relevant couple in **1** because of superior stabilization of Co^{3+} ($3d^6$) in a square planar coordination. The X-band EPR spectrum in powder at 77 K is characterized with a broad single line signal. Individual g tensors considerably merge into each other and effectively exhibit a g_{av} absorption at 2.51. Powder susceptibility measurement of **2** was done at room temperature and corresponds to a one electron paramagnetic moment of 2.26μ_B. In general magnetic moments of square planar Co(II) complexes fall in the range 2.1–2.9μ_B, owing to a significant orbital contribution to the spin only magnetic moment [27,28]. The composition of **2** was established convincingly from a FAB mass spectrum, with a maximum molecular ion peak at $m/z =$ 339 which is in very good agreement with the calculated mass of 339.26. Very recent structural elucidation of [*N*,*N*′-bis(2-hydroxynaphthylmethylene)-1,3-propanediaminato]cobalt(II) [29] confirms the square planar geometry of **2** beyond doubt.

5. Conclusion

The bis(salicylidene) based schiff base ligand afforded a new Co^{III}–Co^{II}–Co^{III} trinuclear complex via partial aerial oxidation of a Co^{II} precursor. The coordination is completed by bridging acetate and monodentate N-bound isothiocyanate ions. Structure determination reveals a uniform facial disposition of N_3 and O_3 donor atoms around the terminal Co^{III} centres, augmenting the ligand field strength compared to the $Co^{II}O_6$ environment. Variable temperature magnetic susceptibility and EPR studies authenticate **1** as a valence trapped species in both solid and solution phases. Cyclic voltammogram of **1** reveals prominent oxidative and reductive signals ascribed to $Co^{2+} \rightarrow Co^{3+}$, $Co^{3+} \rightarrow Co^{4+}$ and $Co^{3+} \rightarrow Co^{2+}$ transformations and interestingly the latter two processes involve a formal two-electron transfer. Chemical reduction of **1** by hydrazine furnished a square planar $[Co^{II}L]$ species, **2**.

Abstract

The new ball-type bisphthalocyanines [metal-free **6**, Zn(II) **7** and Co(II) **8**] were synthesized from the corresponding 4,4′-[1,1′-methylenebis(naphthalene-2,1-diyl)]bis(oxy)di-phthalonitrile **4**, which can be obtained from the reaction of 4-nitrophthalonitrile (**2**) with 1,1′-methylenedinaphthalen-2-ol **3**. A novel clamshell type bisphthalocyanine **5** was synthesized from compound **4** and 4,5-bis(hexylthio)phthalonitrile **1**. The novel compounds have been characterized by elemental analysis, UV/Vis, IR, ^{1}H NMR and MALDI-TOF Mass spectroscopies. The electrochemical and spectroelectrochemical measurements showed the formation of various mixed-valence oxidation and reduction species, due to the strong intramolecular interactions between the two phthalocyanine rings, especially in the ball-type phthalocyanines. The conduction properties of the compounds have been examined by d.c. and impedance spectroscopy measurements as function of temperature and frequency. D.c. conductivity, measured between 290 and 480 K, is thermally activated with the activation energy ranging between 0.62 and 0.84 eV. The a.c. results gave a power law behaviour, $\sigma_{a.c.} = A(T)\omega^s$, in which the frequency exponent s decreases with temperature for **6**, **7** and **8**. The bulk resistance of the samples was derived from complex impedance spectra. It was found that the bulk resistance shows a typical negative temperature coefficient of resistance, decreasing with a rise in temperature, like that of a semiconductor.

1. Introduction

Phthalocyanines (Pcs) have been the subject of great interest in areas such as semiconductors, chemical sensors, liquid crystals, molecular metals, catalysis, electrochromism and non-linear optics [1,2]. While the parent molecules have a number of useful properties, considerable effort has focused on the design of novel structures which may show improved or novel characteristics. In this respect, the attention of investigators has been attracted to binuclear Pcs linked by various kinds of bridges, i.e., lanthanoid and actinoid sandwich dimmers [3–6], covalently linked cofacial dimmers [7–9], planar homo- and

doi:10.1016/j.poly.2006.08.039

hetero-dimers sharing a common aromatic ring or linked by other units [10–14] and linear dimers linked by flexible alkyl chains [15,16]. A strong interaction between the halves of the molecule was usually detected in electronic absorption spectra and by electrochemistry. Due to intermolecular and/or intramolecular interactions between the Pc rings, the Q bands were usually much broader than in the monomers, or split. Moreover, since the redox couples observed in monomeric species may split into two couples, the spectra of mixed-valence species have been recorded. It was suggested that electron cloud overlap is important for strong interactions.

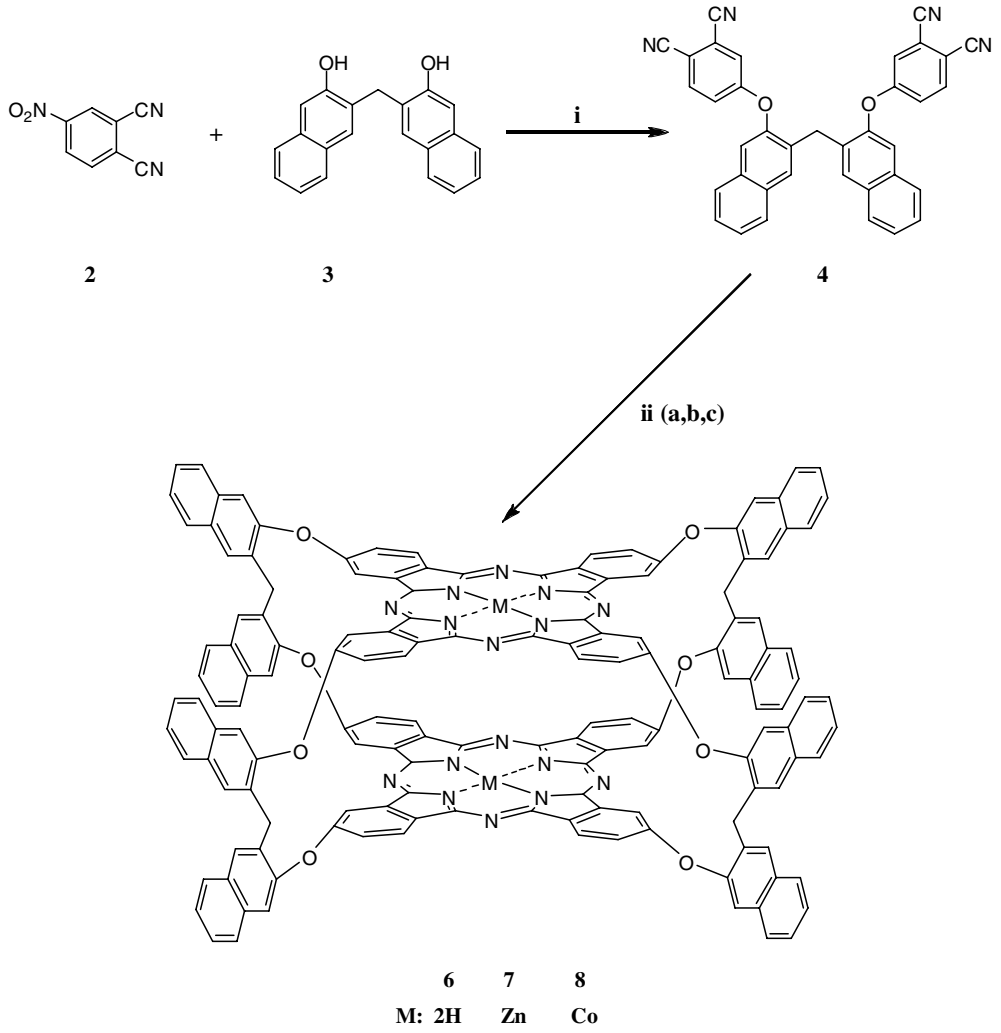
We have reported recently on the synthesis, characterization and electrical, electrochemical and gas sensing properties of a novel sandwich dilutetium tetra Pc [17–19], a cyclic borazine derivative containing three phthalocyaninato Zn(II) macrocycles [20] and a ball-type four *t*-butylcalix[4]arene bridged binuclear Zn(II) Pc [21]. These novel compounds showed interesting electrical, electrochemical and/or electrochromic properties.

Many Pc dimers and multimers, having various kinds of linkage, have been reported to date. These dimers and multimers, especially those with rigid cofacial configurations, usually show spectroscopic, electrochemical and electrical properties which differ significantly from the parent monomers. Although the first synthesis of ball-type binuclear Pcs has been reported by Zefirov's group [22], no detailed study on the electrochemistry, spectroelectrochemistry and electrical properties of this type of Pcs has yet been carried out. In this paper, we present the first detailed study on the preparation, characterization, spectroelectrochemical and electrical properties of some new metal-free and metallophthalocyanines of the clamshell or ball type (Schemes 1 and 2).

Scheme 1. (i) Li, pentan-1-ol, N_2, 180 °C.

2. Experimental

The starting materials **1** and **2** were synthesized by the methods described previously in the literature [23]. Compound **3** was used as supplied commercially. IR spectra were recorded on a Shimadzu FTIR-8300 spectrophotometer as KBr pellets. Electronic spectra were recorded on a Shimadzu UV-1601 spectrophotometer. Elemental analyses were performed by the Instrumental Analysis Laboratory of Tubitak – Ankara. ^{1}H NMR spectra were recorded in *d*-chloroform, *d*-dimethylsulfoxide and *d*-acetone with a Mercury-Vx 400 MHz instrument. Mass spectra were acquired in linear and reflectron modes with an average of 50 and 100 shots on a Voyager-DE™ PRO MALDI-TOF mass spectrometer (Applied Biosystems, USA) equipped with a nitrogen UV-Laser operating at 337 nm.



2.1. Synthesis

2.1.1. 4,4′-[1,1′-Methylenebis (naphthalene-2,1-diyl)]-bis(oxy)diphthalonitrile (**4**)

A mixture of **3** (0.60 g, 2 mmol) and **2** (0.69 g, 4 mmol) in 20 mL dimethylsulfoxide (DMSO) was stirred at room temperature under argon. K_2CO_3 (0.828 g, 6 mmol) was added into the mixture over a period of 2 h. After stirring the reaction mixture for a further 24 h, the undissolved salt was removed by filtration. The reaction mixture was poured into water (100 mL) and stirred. The precipitate was filtered and washed with water. The residue was chromatographed by silica gel and eluted with CH_2Cl_2 (DCM). Yield; 1.0 g (91%). Compound **4** is soluble in chloroform, tetrahydrofuran (THF) and acetone. Mp: 268 °C. *Anal.* Calc. for $C_{37}H_{22}N_4O_2$: C, 80.13; H, 4.00; N, 10.10. Found: C, 79.93; H, 3.92; N, 9.95%; IR (KBr pellet) ν, cm^{-1}: 3074 (Ar–H), 2231 (C≡N), 1566–1587 (C=C), 1245–1282 (Ar–O–Ar); ^{1}H NMR (*d*-acetone) δ 8.32 (d, $J = 8.19$ Hz, 2H), 7.92 (d, $J = 8.58$ Hz, 2H), 7.82 (d, $J = 2.34$ Hz, 2H), 7.70 (d, $J = 8.58$ Hz, 2H), 7.56 (m, 4H), 7.10 (brs, 2H), 6.92 (d, $J = 2.34$ Hz, 2H), 6.86 (dd, $J = 8.78$ Hz, $J = 2.34$ Hz, 2H), 4.95 (s, 2H) ppm.

2.1.2. [8,8′-Bis-2,2′(9′,10′,16′,17′,23′,24′-hexylthiophthalocyaninyl)methylendioxynaphthalene] (**5**)

A mixture of compound **1** (1.08 g, 3 mmol) and compound **4** (0.276 g, 0.5 mmol) in 1.5 mL of dry amyl

Scheme 2. (i) K_2CO_3, DMSO; (ii) a: Li, pentan-1-ol, N_2, 170 °C; b: $Zn(CH_3COO)_2 \cdot 2H_2O$, 280 °C; c: $Co(CH_3COO)_2 \cdot 4H_2O$, 280 °C.

alcohol was heated in a sealed tube at 80 °C under N_2. After addition of elemental lithium (0.030 g, 4.32 mmol) the reaction mixture was stirred at 180 °C for 6 h. After cooling to room temperature, the dark green mixture was diluted with methanol (10 mL) to precipitate the product and it was filtered. After having been washed successively with hot water, hot ethanol (3×20 mL), and then hot methanol (3×20 mL) to remove the unreacted organic materials, it was dried *in vacuo* (60 °C). The crude product was purified by column chromatography with silica gel, eluting with chloroform. Yield: 204 mg (15%). This compound is soluble in chloroform, DCM, THF and dimethylformamide (DMF). Mp > 350 °C. *Anal.* Calc. for $C_{157}H_{192}N_{16}O_2S_{12}$: C, 69.32; H, 7.11; N, 8.24; S, 14.15. Found: C, 69.03; H, 7.31; N, 8.53; S, 13.95%. MS (MALDI-TOF): *m/z* 2721 $[M+H]^+$, IR (KBr pellet) *ν*, cm^{-1}: 3357 (–NH), 3060 (arom.-CH), 2925–2858 (aliph.-CH_2), 1651–1591 (C=C), 1232 (Ar–O–Ar); UV–Vis (CH_2Cl_2), nm (log ε): 730 (5.149), 690 (5.406), 645 (5.470), 330 (5.733); ^1H NMR (*d*-chloroform): δ, ppm 8.21–7.1 (m, 30H, arom.), 3.79–3.75 (m, 2H, Ar–CH_2), 2.90–2.95 (m, 120H, aliph.-CH_2), 1.63 (m, 36H, –CH_3).

2.1.3. [8,8′-Tetrakis-bis-(2′,10′,16′,24′-phthalocyaninyl) methylendioxynaphthalene] (6)

A suspension of compound **4** (0552 g, 1 mmol) in 1.5 mL of dry amyl alcohol was heated in a sealed tube at 80 °C under N_2. After addition of elemental lithium (0.035 g, 5.043 mmol) to the reaction mixture, a dark green colour appeared in 15 min. The reaction mixture was stirred at 170 °C for 8 h. After cooling to room temperature, methanol (20 mL) was added to precipitate the product, which was then filtered. The residue was washed successively with first hot water then with hot methanol and diethyl ether before drying it *in vacuo* (70 °C). The residue was coarsely fractionated on a silica gel column eluting with chloroform and a gradient of chloroform-methanol up to 5% methanol. Yield: 55 mg (10%). This compound is soluble in THF, DMF. Mp > 350 °C. *Anal.* Calc. for $C_{148}H_{84}N_{16}O_8$: C, 80.28; H, 3.82; N, 10.12. Found: C, 80.07; H, 3.65; N, 10.05%; MS (MALDI-TOF): *m/z* 2215

$[M+H]^+$, IR (KBr pellet) ν, cm^{-1}: 3321 (>NH), 3059 (arom.-CH), 2941 (aliph.-CH_2), 1655–1589 (C=C), 1383–1229 (Ar–O–Ar); UV–Vis (DMSO), nm ($\log\varepsilon$): 710 (5.174), 680 (5.336), 630 (5.398), 325 (5.693); ^1H NMR (*d*-chloroform): δ, ppm 8.18–6.80 (m, 72H, arom.), 4.80 (m, 8H, Ar–CH_2).

2.1.4. [8,8′-Tetrakis-bis-(2′,10′,16′,24′-phthalocyaninato-dizinc(II))methylendioxynaphthalene] (7)

A mixture of compound **4** (0552 g, 1 mmol) and $Zn(OAc)_2\cdot 2H_2O$ (0.200 g, 1.2 mmol) was powdered in a quartz crucible and heated in a sealed glass tube for 3 min under a dry N_2 atmosphere at 280 °C. After cooling to room temperature, 5 mL of DMF was added to the residue to dissolve the product. The reaction mixture was precipitated by adding water. The precipitate was filtered, multiply washed first with hot water and then with hot ethanol in order to eliminate the unreacted starting materials, and dried *in vacuo*. Then, the crude product was washed with methanol, ethanol, acetonitrile and acetone for 12 h respectively in a soxhlet apparatus. The residue was coarsely fractionated on a silica gel column eluting with chloroform and a gradient of chloroform–THF up to 100% THF. Yield: 57 mg (9.75%). This compound is soluble in chloroform, DCM, THF, DMF and DMSO Mp > 350 °C. *Anal.* Calc. for $C_{148}H_{80}N_{16}O_8Zn_2$: C, 75.93; H, 3.44; N, 9.57. Found: C, 75.82; H, 3.24; N, 9.65%; MS (MALDI-TOF): *m*/*z* 2337 $[M+H]^+$, 2355 $[M+H_2O+H]^+$, IR (KBr pellet) ν, cm^{-1}: 3059 (arom.-CH), 2925 (aliph.-CH_2), 1655–1591 (C=C), 1232 (Ar–O–Ar); UV–Vis (CH_2Cl_2), nm ($\log\varepsilon$): 730 (5.545), 700 (5.488), 635 (5.100), 375 (5.362), 325 (5.510); ^1H NMR (*d*-chloroform): δ, ppm 8.25–6.50 (m, 72H, arom.), 4.80–4.70 (m, 8H, Ar–CH_2).

2.1.5. [8,8′-Tetrakis-bis-(2′,10′,16′,24′-phthalocyaninato-dicobalt(II))methylendioxynaphthalene] (8)

A mixture of compound **4** (0.200 g, 0.337 mmol) and $Co(OAc)_2\cdot 4H_2O$ (0.130 g, 0.522 mmol) was powdered in a quartz crucible and heated in a sealed glass tube for 5 min under a dry N_2 atmosphere at 280 °C. After cooling to room temperature, a blue-green reaction product was obtained, isolated and purified using the same procedure as explained above for **7**. Yield: 45 mg (7.75%). This compound is soluble in chloroform, DCM, THF, DMF and DMSO. Mp > 350 °C. *Anal.* Calc. for $C_{148}H_{80}N_{16}O_8Co_2$: C, 76.35; H, 3.46; N, 9.63. Found: C, 76.3; H, 3.51; N, 9.61%; MS (MALDI-TOF): *m*/*z* 2327 $[M+H]^+$, IR (KBr pellet) ν, cm^{-1}: 3063 (arom.-CH), 2934 (aliph.-CH_2), 1653–1591 (C=C), 1275–1232 (Ar–O–Ar); UV–Vis (CH_2Cl_2), nm ($\log\varepsilon$): 690 (5.632), 627 (5.033), 343 (5.556).

2.2. Electrochemical and spectroelectrochemical measurements

The cyclic voltammetry (CV) and controlled potential coulometry (CPC) measurements were carried out with a Princeton Applied Research Model VersaStat II potentiostat/galvanostat controlled by an external PC and utilizing a three-electrode configuration at 25 °C. The working electrode was a Pt plate with a surface area of 0.10 cm^2. The surface of the working electrode was polished with a H_2O suspension of Al_2O_3 before each run. The last polishing was done with a particle size of 50 nm. A Pt wire served as the counter electrode. A saturated calomel electrode (SCE) was employed as the reference electrode separated from the bulk of the solution by a double bridge. The ferrocene/ferrocenium couple (Fc/Fc^+) was also used as an internal standard. Electrochemical grade tetrabutylammonium perchlorate (TBAP) in extra pure DMSO and DCM was employed as the supporting electrolyte at a concentration of 0.10 mol dm^{-3}. High purity N_2 was used for deoxygenating the solution for at least 20 min prior to each run and to maintain a nitrogen blanket during the measurements. For CPC studies, a Pt gauze working electrode (10.5 cm^2 surface area), Pt wire counter electrode separated by a glass bridge and SCE as a reference electrode were used. The spectroelectrochemical measurements were carried out by an Agilent Model 8453 diode array spectrophotometer equipped with a potentiostat/galvanostat and utilizing a three-electrode configuration of a thin layer quartz spectroelectrochemical cell at 25 °C. The working electrode was a transparent Pt gauze. A Pt wire counter electrode separated by a glass bridge and a SCE reference electrode separated from the bulk of the solution by a double bridge were used.

2.3. Electrical conductivity and impedance measurements

For the electrical characterization, conductivity and impedance measurements, ten-finger interdigital gold electrodes with 50 μm gap were deposited photolithographically on pre-cleaned corning glass substrate. Prior to the vacuum evaporation, the glass substrates were thoroughly cleaned ultrasonically. Thin films of the compounds were obtained by spin-coating chloroform solutions of the products over the electrode arrays to obtain devices suitable for d.c. conductivity and impedance measurements. The materials were dissolved in extra pure grade chloroform at concentrations of $\sim 5\times 10^{-4}$ M for all the compounds. Fifty microlitres of such solutions were added with a glass pipette onto the IDT structure held onto spinner (Speciality Coatings Systems Inc., Model P6700 Series). The substrate spun at 200 rpm for 10 s and the solvent evaporated during this period, producing a homogeneous film of the phthalocyanine derivatives. The substrate temperature was kept constant at 293 K during deposition of the materials over the electrodes. Current–voltage (*I*–*V*) measurements were performed in a vacuum of 10^{-3} mbar between 290 and 480 K by using a Keithley 617 electrometer. Dc conductivity values were calculated from the measured current–voltage (*I*–*V*) characteristics by using the relation $\sigma_{d.c.} = [I\cdot d/V(2n-1)l\cdot h]$, where I is the measured current, V is the bias voltage, d is the electrode spacing, n is the number of electrode finger pairs, l is the overlap length of the electrode

fingers and *h* is the thickness of the electrodes. A.c. conductivity and low signal impedance spectra measurements were carried out with a Keithley 3330 LCZ meter in the frequency range 40 Hz to 100 kHz in the temperature range 290–480 K. During the measurement the temperature of the sample was controlled with a Leybold LTC 60 temperature controller. The conductivity data were recorded using an IEEE 488 data acquisition system incorporated to a personal computer.

3. Results and discussion

3.1. Synthesis

The synthesis of bisphthalodinitriles is based on the reaction of diols with an excess of compound **2** (DMF or DMSO in the presence of K_2CO_3 as a base, at 20 °C for 60–96 h) [24,25]. Our key starting material is compound **4** which can be obtained via the reaction of compound **2** and **3**, in dry DMSO in the presence of K_2CO_3, in a yield 91%. The metal-free clamshell-type Pc, **5** was also obtained by the reaction of compound **4** with **1** using the statistically mixed condensation method in dry *n*-penthanol and in the presence of lithium as a catalyst (Scheme 1).

A new ball-type metal-free Pc **6** was prepared by the reaction of compound **4** with lithium in dry *n*-penthanol. Compound **4** was also tetramerized to ball-type **7** and **8** (Scheme 2).

Elemental analysis, IR, ^{1}H NMR, MASS and UV/Vis spectra confirmed the proposed structures of the compounds. A diagnostic feature of Pc formation from compound **4** was the disappearance of the sharp intense CN vibration band at 2231 cm^{-1} in IR spectrum. The spectra of compounds **4**–**8** showed Ar–O–Ar peaks at 1225–1285 cm^{-1}, C=C (in phenyl and naphthalene rings) peaks at 1560–1655 cm^{-1}, aromatic CH peaks at 3060–3070 cm^{-1} and aliphatic CH_2 and CH_3 peaks at 2860–2945 cm^{-1}. The weak band around 3320–3360 cm^{-1} for **5** and **6** can be attributed to the N–H stretching frequency of the metal-free inner core.

The UV–Vis spectra of **5** in DCM and **6**, **7** and **8** in DMSO showed characteristic absorptions between 627 and 730 nm in the Q-band region (Table 1). The Q band observed for the compounds was attributed to the $\pi \rightarrow \pi^*$ transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the Pc ring. The other bands (B) in the UV region at 325–375 nm were observed due to the transitions from the deeper π levels to the LUMO. The spectra of **5** and **6** involved a double Q band, which is quite typical for metal-free Pc. The characteristic double Q band for each metal-free Pc was barely evident even at 10^{-7} mol dm^{-3} concentration. The Q band S_1 emission is still observed but with an unusually broad spectrum [26–29]. In addition, a third band at the blue side of the double Q band for each metal-free complex was observed. These bands, in addition to the broadness of the spectra, are indicative of intramolecular coupling between the Pc rings in these complexes. The compounds **7** and **8** show characteristic absorptions around 600 and 730 nm in the Q band region. As expected, well splitting of the Q band in the spectrum of $[ZnPc]_2$, **7**, was observed. This can be attributed to strong intramolecular interactions between the Pc rings, probably due to the ball-type cofacial structure. Although the Q band in the spectrum of **8** is not split, a well-defined absorption at 627 nm can be attributed to intramolecular interactions.

Table 1
UV–Vis data for the phthalocyanines

Compound	λ/nm ($\log\varepsilon$/dm^3 mol^{-1} cm^{-1})
5[a]	730 (5.149), 690 (5.406), 645 (5.470), 330 (5.733)
6[b]	710 (5.174), 680 (5.336), 630 (5.398), 325 (5.693)
7[b]	730 (5.545), 700 (5.488), 635 (5.100), 375 (5.362), 325 (5.510)
8[b]	690 (5.632), 627 (5.033), 343 (5.556)

[a] In DCM.
[b] In DMSO.

The ^{1}H NMR spectra were also in good correlation with the structure of the synthesized compounds. In the ^{1}H NMR spectrum of compound **4**, which was taken in *d*-acetone, the phenyl protons appeared at 7.92 ppm (d), 7.82 ppm (d) and 6.86 ppm (dd), naphthalene protons at 8.32 ppm (d), 7.70 ppm (d), 7.56 ppm (m), 7.10 ppm (brs) and 6.92 ppm (d) and CH_2 protons at 4.95 ppm (s). In the ^{1}H NMR spectra of **5**, **6** and **7**, which were taken in *d*-chloroform, the aromatic protons appeared at 8.25–6.45 ppm (m) and Ar–CH_2 peaks at 4.80–4.70 ppm (m). In addition, in the ^{1}H NMR spectrum of **5**, the –CH_3 protons at the end of the chain appeared at 1.65 ppm and aliphatic –CH_2– protons at 2.90–2.95 ppm. In the ^{1}H NMR spectra of **5** and **6**, NH protons could not be observed, probably due to the broad nature of these peaks in the presence of intense resonances of the Pc ring [30].

A 3,5-dinitrobenzoic acid (DNB) MALDI matrix was used and prepared in chloroform at a concentration of 20 mg/mL for **5** and α-cyano-4-hydroxycinnamic acid was prepared in chloroform at a concentration of 20 mg/mL for **6**. MALDI samples were prepared by mixing sample solutions (4 mg/mL) with the matrix solution (1:10 v/v) in a 0.5 mL eppendorf® microtube. Finally 1 μL of this mixture was deposited on the sample plate, dried at room temperature and then analyzed. The protonated molecular ion peak of the ligand was observed at 2721 Da together with some fragment ion peaks. The mass difference between these peaks corresponding to 84 Da mass resulted from cyclohexane elimination from the ligand at the side groups.

In the MALDI-MS spectrum of **6**, beside the cyclohexane elimination, two main fragment ions were observed at 1491 and 1226 Da mass, resulting from breakage of the bond between the oxygen and aromatic ring which exist in the core of the ligand.

For compound **6**, a protonated molecular ion peak was observed at 2215 Da. This value exactly overlaps with the mass of **6** calculated theoretically from its elemental composition. Beside the protonated molecular ion peak of the complex, two other intense and one low intensity peaks were observed with 282 Da mass differences from each other and the protonated molecular ion peak. These peak masses indicate a fragmentation resulting from the protonated molecular ion of the complex with a 282 Da mass loss from both sides of the complex. This fragment indicates that the leaving group could be $C_{21}H_{14}O$, which exists as an end group in the chemical structure of **6**.

3-Indole acrylic acid (IAA) MALDI matrix was used and prepared in chloroform at a concentration of 20 mg/mL for **7**. The peak group representing the protonated molecular ion of the complex was observed starting with 2330 Da mass and finishing with 2338 Da, following each other by 1 Da mass differences. This type of mass distribution results from the isotopic mass distribution of carbon (mainly ^{13}C) and the isotopes of zinc in the metal complex. These peaks resulted from water adduct, side chain eliminations (oxygen leaving). This indicated that the complex was more stable under the MALDI matrix conditions and also under the laser energy.

2,5-Dihydroxybenzoic acid (DHB) MALDI matrix was used and prepared in chloroform at a concentration of 20 mg/mL for **8**. The positive ion MALDI-MS spectrum of **8** ($C_{148}H_{80}N_{16}O_8Co_2$) is given in Fig. 1. The peak group representing the protonated molecular ion of **8** was observed starting with 2325 Da mass and finishing with 2330 Da, following each other by 1 Da mass differences, as in **7**, from the isotropic mass distribution.

3.2. Electrochemistry and spectroelectrochemistry

The redox properties of the complexes were examined by cyclic and differential pulse voltammetry, and CPC in DMSO/TBAP or DCM/TBAP. A summary of the relevant electrochemical data is given in Table 2. Typical cyclic and differential pulse voltammograms for **8** are shown in Fig. 2. The CPC studies showed that all the redox processes for the complexes, except the reduction couples of **5**, involve

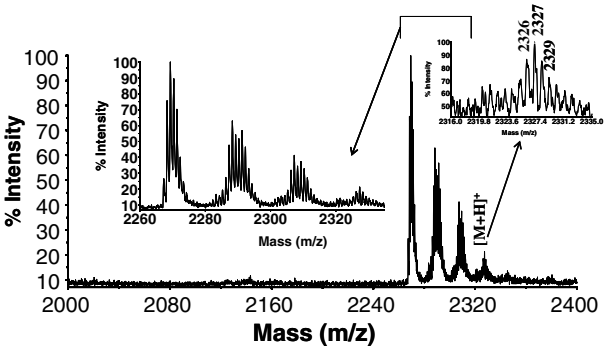


Fig. 1. Mass spectra of **8** (reflectron).

[a] Potentials are reported with respect to the SCE. Half-wave potentials in DCM *vs.* Fc/Fc^+ couple correspond approximately with the above **5** data minus 0.45 V. Half-wave potentials in DMSO *vs.* Fc/Fc^+ couple correspond approximately with the above **6**, **7** and **8** data minus 0.50 V. $E_{1/2}$ values were measured by cyclic voltammetry [$E_{1/2} = (E_{pa} + E_{pc})/2$] or differential pulse voltammetry. The peak separation values ($\Delta E_p = E_{pa} - E_{pc}$) are reported at 0.100 V s^{-1}. ΔE is the potential difference between the first oxidation and first reduction potentials. It represents the HOMO–LUMO gap for **5**, **6** and **7**, but the charge transfer transition for **8** involving redox-active metal centers. ΔE_s indicates mixed-valence splitting energy for the relevant split redox couples.

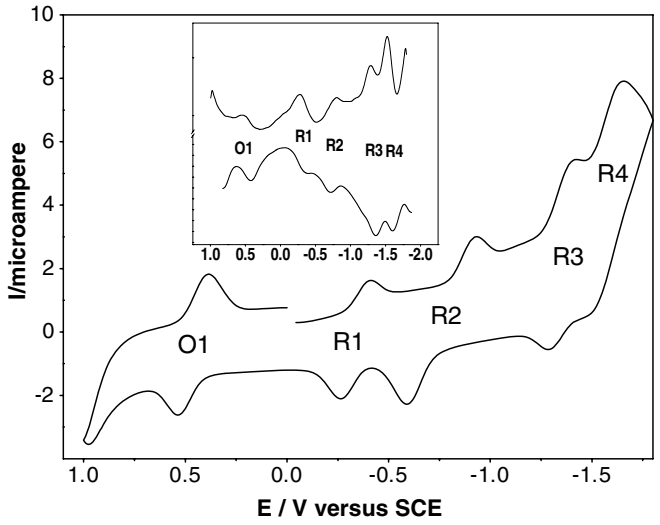

Fig. 2. Cyclic and differential pulse voltammograms of **8** at 0.100 V s^{-1} in DMSO/TBAP solution.

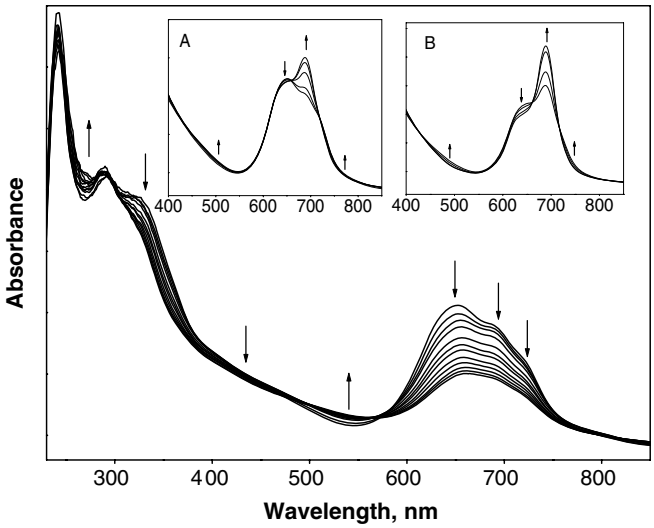

Fig. 3. UV–Vis spectra of **5** and spectral changes during its first oxidation, first reduction (inset A) and second reduction (inset B) in DCM/TBAP solution.

the transfer of one electron. The number of electrons transferred in each reduction process of **5** was found to be two. The spectroelectrochemical properties were also examined by recording the UV–Vis spectral changes during the stepwise reductions and oxidations of the complexes.

The CV of **5** gave two one-electron quasi-reversible oxidation couples and three two-electron quasi-reversible reduction couples within the potential limits of the DCM/TBAP medium. The two one-electron oxidation couples may be attributed to the stepwise oxidation of the two Pc rings in **5**, and thus to the formation of mixed valence $[H_2Pc(-2) \cdot H_2Pc(-1)]^{+}$ species in the first step and doubly oxidized $[H_2Pc(-1)]_2^{2+}$ species in the second step, probably due to intramolecular cofacial electronic coupling between the two Pc rings. No splitting was observed in the two-electron reduction processes. Thus, there is no stabilization of the mixed-valence anion radical species. The involvement of two electrons in each reduction process of **5** should suggest that the two Pc rings are reduced simultaneously. This may be due to uncoupling of cofacial conformations prior to or/and simultaneously with the first reduction process. In that case, the coupling between the halves of the molecule is not important enough to cause the splitting of the reduction processes. This type of electrochemical behaviour was observed previously for a clamshell-type binuclear Pc, permitting only the observation of mixed-valence ring-oxidized species [31]. In order to provide additional support for the assignment of the redox processes, spectroelectrochemical measurements were also carried out. The UV–Vis spectra of the original **5** and the spectral changes recorded during its first oxidation, first reduction and second reduction in DCM/TBAP are shown in Fig. 3. The spectrum of **5** is considerably broad with three Q band absorptions at 645, 689 and 728 nm. We should note that the splitting of the Q band into three bands were more noticeable in the absence of TBAP. The presence of TBAP in spectroelectrochemical measurements caused a decrease in the absorption ratio of 645 nm/689 nm. TBAP probably causes a decrease in the intramolecular coupling between the Pc rings, due to possible changes in the cofacial clamshell conformation, as reported previously [31]. However, the spectrum recorded in DCM/TBAP was highly similar in the maximum absorption values to that in DCM, with just small differences. In dimeric Pcs, intramolecular coupling between the rings causes a band at the red side of the characteristic Q band, at around 630 nm. Thus, the band at 645 nm in the broad spectrum of metal-free Pc **5** may be attributed to the cofacial intramolecular coupling. Furthermore, there was an increase in the absorption at 689 nm while the absorption at around 645 nm decreases during the stepwise controlled potential electrolyis of a solution of **5** at potentials slightly more negative than the first and second reduction potentials (insets A and B in Fig. 3). This presumably arises from the decrease in intramolecular coupling, as a result of the repulsion between the negatively charged Pc rings. Upon the third reduction, in contrast to the first and second reductions, there was a decrease in absorption of all the bands. This may be due to decomposition of the doubly reduced species under the conditions of electrolysis at a considerably negative constant potential. Upon the first oxidation, the absorption of all the three bands at the Q band region decreased. However, the absorption in some regions below 576 nm increased, and well-defined isosbestic points were obtained at 315, 456 and 576 nm. The spectrum obtained after the first oxidation was still broad at the Q band region. This is characteristic for ring-oxidized mixed-valence species [31]. The broadness may suggest that intramolecular coupling between the Pc rings is still remarkable after the first oxidation. The second oxidation to the fully oxidized $[H_2Pc(-1)]_2^{2+}$ species occurs at

considerably positive potentials. Unfortunately, probably for this reason, well-defined spectral changes for the second oxidation could not be obtained.

The metal-free ball-type complex, **6** displayed four one-electron quasi-reversible reduction couples and two one-electron reversible oxidation couples (Table 2). The stepwise one-electron processes imply the existence of mixed-valence first- and second-reduced, and first-oxidized species. The half-wave potentials of these processes and the relevant electrochemical data are given in Table 2. All the redox processes for **5** and **6** are ligand-based since these complexes are metal-free. The voltammetric behaviour of the ball-type **6** is remarkably different from the clamshell-type **5**, especially on the reduction side. In contrast to **5**, the formation of stable mixed-valence first- and second-reduced species is observed for **6**, in addition to the formation of mixed-valence first-oxidized species, as a result of the splitting of the Pc(-2)/Pc(-3) and Pc(-3)/Pc(-4) redox couples. It may be concluded that the binding of two Pc rings at two sides in the ball-type **6** causes stronger intramolecular cofacial coupling, compared to the clamshell-type **5**. Moreover, the first oxidation of **6** occurs at a potential 400 mV less positive with respect to that of **5**, while the first reductions of the complexes occur at relatively approximate potentials. The difference between the first oxidation and the first reduction potentials in these complexes corresponds to the HOMO–LUMO gap. As a result, the HOMO–LUMO transition is remarkably narrower for **6** (1.54 V for **5** and 1.06 V for **6**). This should be also due to the strong electronic coupling and the splitting of molecular orbitals. The UV–Vis spectra of the original **6** and the well-defined spectral changes during its stepwise controlled potential electrolysis for reduction and oxidation couples provided additional support for these comments. Fig. 4 shows the UV–Vis spectra of the original **6** and typical well-defined spectral changes during its first reduction, first oxidation and second oxidation. The UV–Vis spectrum of the original **6** gave a split Q band with two strong absorptions at 630 and 680 nm, and a shoulder at 710 nm. In this spectrum, in addition to the clear splitting into three bands, the absorption at 630 nm, corresponding to the intramolecular coupling in binuclear Pcs is remarkably higher than those at 680 and 710 nm. During the first reduction process, the general spectral change is the decrease in the absorption ratio of $A(630)/A(680)$. This behaviour may be attributed to the decrease in coupling, due to the negative charge of Pc rings and thus to the repulsion forces. However, in contrast to **5**, the coupling is still not negligible since the absorption band at around 630 nm has a considerable value (Fig. 4). Furthermore, it was observed that the absorption band at around 630 nm was still a remarkable value compared to that at 680 nm, even after the third reduction process. Upon the first oxidation of **6**, the absorption at 680 nm increases while a slight decrease in absorption at 630 nm is observed (inset A in Fig. 4). After the second oxidation, the peak at 630 nm peak is still higher than the peak at 680 nm (inset B in Fig. 4). This may be due to the delocalization of the positive charge on the whole molecule.

The CV of the ball-type $[ZnPc]_2$ **7** displayed quasi-reversible four one-electron reduction and a one-electron oxidation processes (Table 2). These redox processes should also be associated with the presence of mixed-valence first- and second-reduced, and first-oxidized species. Fig. 5 shows the UV–Vis spectra of the original complex **7** and the spectral changes during the first, second (inset A) and third (inset B) reductions in DMSO/TBAP. The well-split Q band and the presence of a shoulder at 635 nm in the spectra of the original complex indicate strong intramolecular coupling between the two Pc rings. During the first reduction, the absorption at 700 nm increases with a blue shift to 686 nm, and a sharp decrease in the absorption at

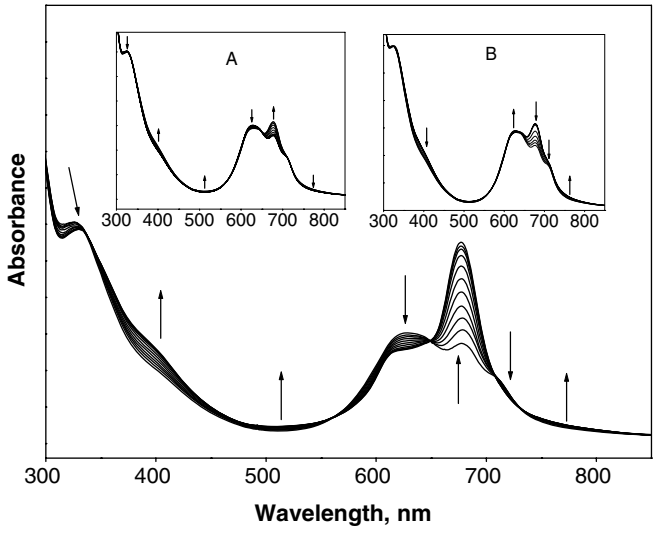

Fig. 4. UV–Vis spectra of **6** and spectral changes during its first reduction, first oxidation (inset A) and second oxidation (inset B) in DMSO/TBAP solution.

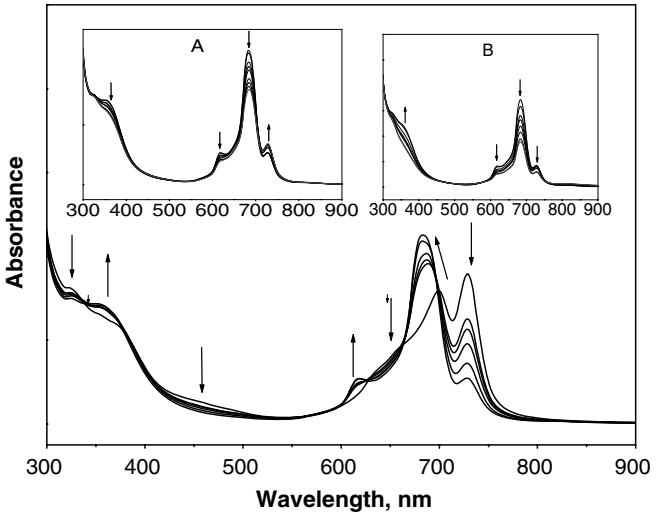

Fig. 5. UV–Vis spectra of **7** and spectral changes during its first, second (inset A) and third reduction (inset B) in DMSO/TBAP solution.

730 nm without any shift is observed. In the meantime, the absorption of the shoulder at 635 nm decreases and a sharp peak at 620 nm appears, indicating the decrease in coupling. These spectral changes with the changes around the soret band are associated with well-defined isosbestic points at 700, 664, 627, 582, 375 and 340 nm. During the second reduction process, there was a decrease in the absorption of the peaks at 355, 686 and 620 nm, and an increase in the absorption of the peak at 730 nm (inset A in Fig. 5). Upon the third reduction, the absorption of the B band at around 360 nm increases while the absorption of the other peaks around the Q band decreases (inset B in Fig. 5). In contrast to **6**, after the reduction processes, the absorption at around 630 nm was considerably lower compared to the absorption at 686 nm, indicating negligible coupling for the reduced species. This may be due to the relatively higher repulsion forces and the increase in the distance between the two Pc rings during the reduction processes. Upon the first oxidation, similar spectral changes with those of the first reduction were observed with the formation of slightly different isosbestic points.

Compound **8** also displayed four quasi-reversible one-electron reduction and a one-electron oxidation processes in DMSO/TBAP (Fig. 2 and Table 2). However, the nature of these redox processes should be different, compared to those of **6** and **7**. It is clear from the previous studies that the Co(II) metal center is redox-active in metallo Pcs [32]. In addition, its redox behaviour strongly depends on the presence or absence of coordinating solvent or supporting electrolyte ions. Previous reports on the electrochemistry of Co(II) Pcs clearly suggested that both the first reduction and first oxidation processes in these complexes are metal-based in polar coordinating solvents such as DMSO and DMF. Since compound **8** is a binuclear cofacial complex, and thus involves two Co(II) centers, the oxidation and the first two reductions probably correspond to $[Co(II)Pc(-2)\cdot Co(III)Pc(-2)]^{+}/[Co(II)Pc(-2)]_2$, $[Co(II)Pc(-2)]_2/[Co(II)Pc(-2)\cdot Co(I)Pc(-2)]^{-}$ and $[Co(II)Pc(-2)\cdot Co(I)Pc(-2)]^{-}/[Co(I)Pc(-2)]_2^{2-}$ redox processes, respectively. On the other hand, the third and fourth reductions should be related to the splitting of the Pc(-2)/Pc(-3) couple, and thus is ligand-based, corresponding to $[Co(I)Pc(-2)]_2^{2-}/[Co(I)Pc(-2)\cdot Co(I)Pc(-3)]^{3-}$ and $[Co(I)Pc(-2)\cdot Co(I)Pc(-3)]^{3-}/[Co(I)Pc(-3)]_2^{4-}$ redox processes, respectively. In contrast to the data in this study and in the articles about Nap- and Ant[CoTRNPc]$_2$ [33,34], it was reported previously that neither the Co(II)/Co(III) nor Co(II)/Co(I) redox couples are split in a coordinating solvent such as DMF or DMSO for some planar and cofacial binuclear Co(II) Pcs [35,36]. The different behaviour was assigned to insufficient intramolecular coupling for splitting, rearrangement to a less coupled conformation prior to electron transfer and/or axial coordination of solvent molecules to the cobalt atoms, which may be sterically hindered in the cofacial complexes. The splits observed in this study may be attributed to the interactions between the two cobalt centers, which are probably held in close proximity by the cofacial ligand geometry, resulting in overlap of their d_{z^2} orbitals along the cobalt–cobalt axis. The UV–Vis spectrum of original **8** and the spectral changes during its reduction and oxidation processes are given in Fig. 6. Surprisingly, the spectra of **7** and **8** are different. In contrast to **7**, the Q band in the spectrum of **8** is not split. This may result from the difference in coordinative properties in axial positions of the metal centers in **7** and **8**. Another alternative or additional reason for the difference may be less intramolecular coupling in **8** compared to **7**. However, complex **8** displays a peak as a shoulder at 627 nm, indicating the presence of intramolecular coupling. The spectroelectrochemical measurements in solution have a vital importance in confirming the assignment of the redox processes in the Pcs, especially in cobalt Pcs. Upon first reduction (Fig. 6a), the formation of Co(I) species is indicated by the appearance of a new absorption at 488 nm, associated with a metal-to-ligand charge transfer (MLCT) from Co(I) to the Pc ring [37,38]. During the second reduction, the absorption of the newly formed MLCT peak continues increasing while the Q band absorption at 690 nm decreases (Fig. 6b). In the meantime, a shoulder at the red side of the main peak at 690 nm appears. Therefore, the spectrum of the mixed-valence Co(II)/Co(I) species obtained during the first reduction is different from that of the fully reduced Co(I)/Co(I) species obtained during the second reduction. The Co(II)/Co(I) mixed-valence species has a much weaker MLCT band. This implies that the added first electron may be delocalized over the extended ring system. This type of behaviour was observed previously for the (-1)-bridged binuclear [CoTRNPc]$_2$ [35]. Upon the third reduction, the MLCT peak at 488 nm decreases, in contrast to the first and second reduction processes (Fig. 6c). This is probably due to the ring reduction and formation of mixed-valence ring-reduced species. The formation of mixed-valence Co(II)/Co(III) species is indicated by the appearance of a new absorption at 485 nm, associated with MLCT from Co(III) to the Pc ring (Fig. 6d). The shift in the Q band absorption from 690 nm to 697 nm also provides additional support for a metal-based first oxidation. The spectrum of the mixed-valence Co(II)/Co(III) species is different from that of classical $[Co(III)Pc(-2)]^{+}$ cation radical species. Generally, a new peak at around 480 nm does not appear during the first oxidation of mono Pcs [39].

The mixed-valence splitting values for the various redox couples of metal-free clamshell-type **5** and ball-type **6**, **7** and **8** are within the range of 0.23–0.44 V, indicating the existence of various stable mixed-valence species. The Pc(-1)/Pc(-2) mixed-valence species of **6** appears to be more stable than that of **5**. This should arise from the ball-type rigid structure of **5**, leading to strong intramolecular cofacial interactions. It appears that for the ball-type **7**, Pc(-2)/Pc(-3) mixed-valence species are much more stable than the Pc(-3)/Pc(-4) mixed-valence species. Similarly, Co(II)/Co(I)

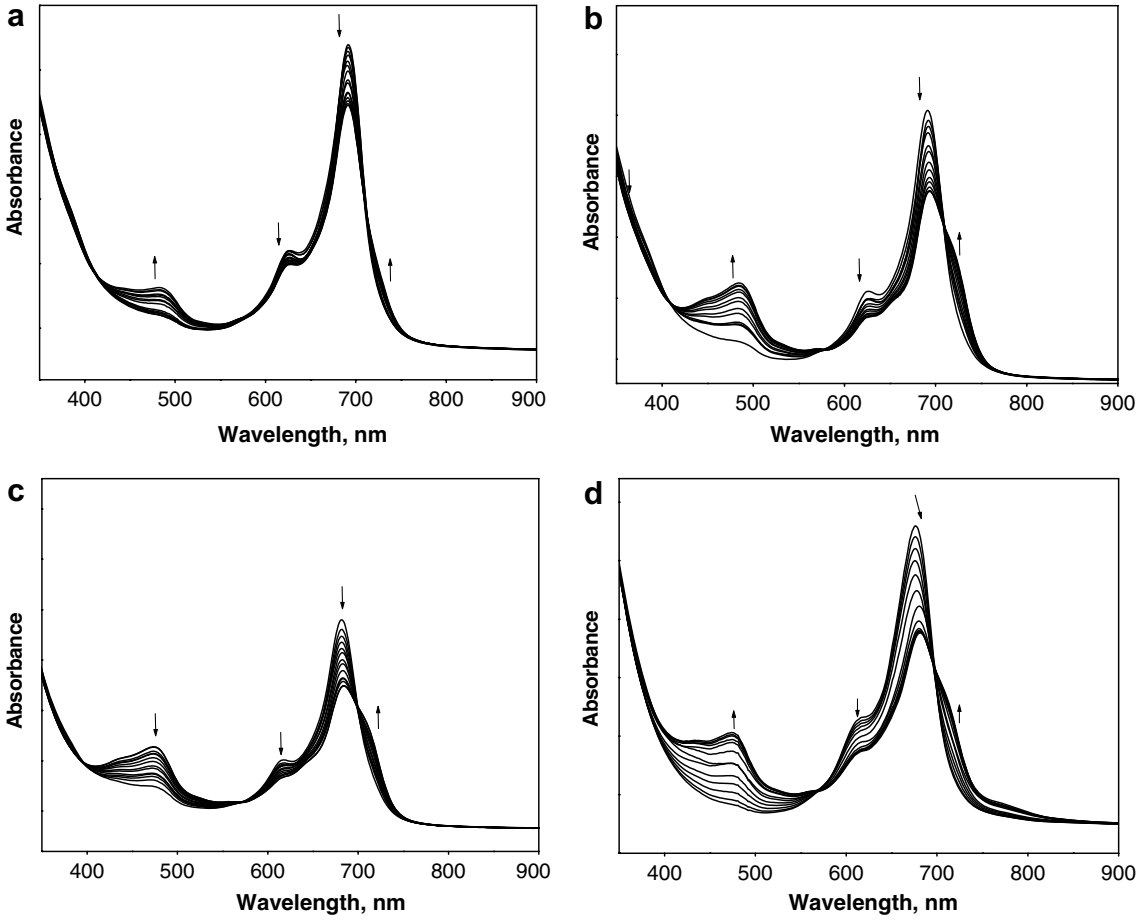

Fig. 6. UV–Vis spectra of **8** and spectral changes during its redox processes in DMSO/TBAP solution: (a) The first reduction; (b) the second reduction; (c) the third reduction; (d) the first oxidation.

mixed-valence species of ball-type **8** are more stable than its Pc(-2)/Pc(-3) mixed-valence species.

3.3. Electrical conductivity and impedance spectroscopy

To obtain valuable information on the processes taking place in the film of the compounds, the temperature dependence of the d.c. electrical conductivity was examined. A conduction mechanism frequently observed in Pc thin film is thermally activated conduction. The value of the thermal energy of electrical conduction, E_A, calculated from the curves $\ln \sigma_{d.c.} = f(1/T)$, ranged between 0.38. and 0.91 eV. The calculations were made by taking into account the expression;

$$\sigma_{d.c.} = \sigma_0 \exp(-E_A/kT) \quad (1)$$

where E_A is the thermal activation energy of the electrical conduction, T is temperature, k is Boltzmann's constant and σ_0 is a parameter depending on the semiconductor nature. The linear dependence in the Arrehenius plot suggests the presence of only one conduction mechanism, assuming that the dominant levels are the conduction and valence bands in the temperature range of 290–480 K for the films of the compounds. Among the ball type compounds investigated, the metal-free Pc of ball type, **6**, showed the lowest electrical conductivity, especially at high temperature. It should be noticed that the d.c. conductivity of compounds **7** and **8** are nearly of the same order, even at high temperatures. It is well established that the electrical conductivities of phthalocyaninato and related compounds depend very much upon the central metal atom, the nature of substituent groups, overlap of the π-electron systems between the pc molecules and the stacking arrangement of the molecules. The lowest conductivity for compound **6** suggests that the central metal atom does play a dominant role in charge transfer of the ball type Pc thin film. The higher conductivity of **7** and **8** can be attributed to the decrease of the separation distance between the Pc macrocycles, because of the inserted metal atom. A comparison of the d.c. conductivities of metal-free Pc of clamshell type, **5**, and metal-free Pc of ball type, **6**, indicates that **5** has a higher conductivity than **6** for all temperatures. The higher conductivity of **5** can be expected here due to the differences in the stacking arrangement of the Pc molecules. This difference in arrangement may result in altering the interaction of the π-electron systems between the different molecules, which may affect the electrical conductivity of the Pc.

The electrical behaviour of the materials is often characterized in terms of complex impedance spectra. The impedance spectroscopy technique is based on analyzing the a.c. response of a system to a sinusoidal excitation and subsequent measurements of impedance as function of the frequency of sinusoidal excitation. The analysis of the impedance data may allow an estimation of the values of circuit elements which are directly related to the material properties, e.g, the bulk resistance, the grain boundary resistance, the double-layer capacitance, etc. Fig. 7a shows the measured complex impedance spectra (Cole–Cole plot) of the compounds recorded in the frequency range 40–100 kHz at room temperature. The room temperature impedance spectra of the compounds are characterized by the appearance of semicircular shaped arcs. It was observed that temperature has a strong effect on the impedance spectra of the compounds. As temperature rises, the semicircular arcs transform into full semicircles. Fig. 7b shows the impedance spectra of the compounds at 430 K. A simple semicircle in the Cole–Cole plot is considered to result when the electrical processes in the materials arise basically due to the contribution from the bulk material. In the simple semicircle case, the measured impedance data can be modelled as an equivalent electrical circuit comprising of a capacitor, C, in parallel with a resistor, R_1, in series with another resistor, R_2. The series resistance in the equivalent circuit represent the ohmic losses in the experimental set-up and electrode sheet resistance. The parallel resistance is the bulk resistance of the coating material. The values of R_1 and R_2 can be obtained from the intercept of the spectrum on the real axis at low and high frequencies, respectively. The values of bulk resistance for all the compounds have been estimated from the complex impedance spectra as a function of temperature. A monotonic decrease in R_1 was observed with the rise in temperature. This observation suggest that the increase of temperature lowers the barrier for charge transport.

The frequency dependence of conductivity can also give information about the conduction mechanism in the film. It is known that [40] when the localized states are randomly distributed, the a.c. conductivity depends on frequency as

$$\sigma_{ac} \propto \omega^s \tag{2}$$

where ω is the angular frequency, and the frequency exponent, s, is a material dependent constant. When the conductivity of the compounds is measured by using the a.c. technique, the trend observed is essentially the same found for d.c. conductivities: **5** > **7** > **8** > **6**. These results for ac conductivity are in agreement with the observed d.c. conductivity. Fig. 8 shows the measured a.c. conductivity of the compounds in the frequency range, 40–10^5 Hz at 355 K. A similar frequency dependence is also observed for other temperatures. Fig. 8 indicates that the a.c. conductivity obeys the relation $\sigma_{ac} = A\omega^s$, where A is a constant. Many mechanisms can be operative for charge transport in Pc compounds. Different conduction mechanisms can lead to ω^s type of behaviour for a.c. conductivity, but it is not easy to decide which mechanisms are responsible for the observed conduction. The variation of the exponent s with temperature gives information about the conduction mechanism. The values of the frequency exponent s, estimated from the slopes of the curves in Fig. 8, were found to be less than unity for all the compounds, which is consistent with the general behaviour of Pc films [41]. The exponent s calculated from the slopes

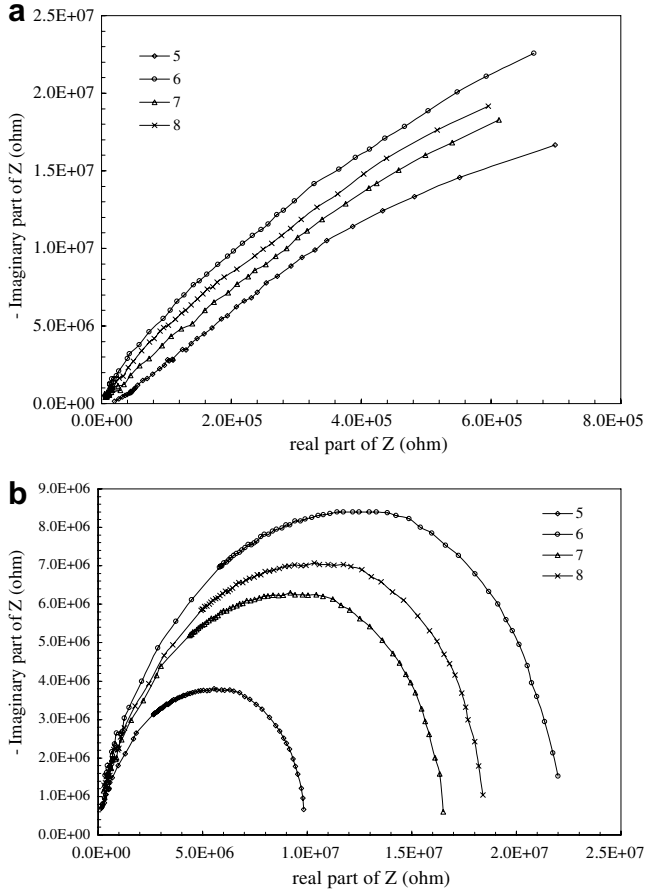

Fig. 7. Impedance spectra of the compounds (a) at room temperature (b) 430 K.

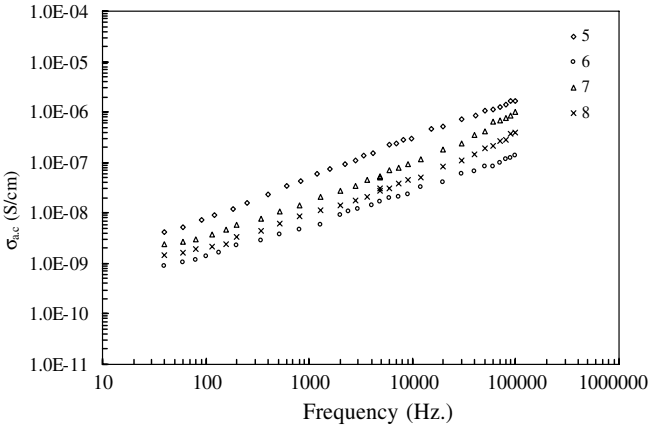

Fig. 8. The frequency dependence of the a.c. conductivity of films of the compounds at 355 K.

of Fig. 8 is temperature dependent and decreases with increasing temperature for the compounds **6**, **7** and **8**. A temperature independent frequency exponent *s*, with a value of ~0.78, was observed for **5**. It is observed that the values of *s* lie in the range 0.76–0.82. The observed behaviour of *s* for **5** allows the conclusion that the Quantum Mechanical Tunelling model (QMT) is a possible conduction mechanism. According to this model the conduction occurs by means of thermally assisted QMT. The QMT model predicts a temperature independent *s* with a constant value around 0.8, which is given by

$$s = 1 - \frac{4}{\ln(\omega\tau_0)} \tag{3}$$

where ω is the angular frequency and τ_0 the characteristic relaxation time of the carrier

The temperature independent frequency exponent *s* for **5** is consistent with the prediction of the QMT model. It was also observed that *s* is definitely a function of temperature for compounds **6**, **7** and **8**, and shows a general tendency to increase with decreasing temperature. The decrease in *s* with temperature cannot be explained by the QMT model. In the case of compounds **6**, **7** and **8** a hopping conduction process, which was developed by Eliot [42], is applicable. According to this model, a charge carriers hops between sites over the potential barrier separating them, rather than tunnelling through the barrier. The expression for conductivity in this model [43] is given by

$$\sigma_{ac}(\omega) = \frac{\pi^2 N^2 \varepsilon}{24}\left(\frac{8q^2}{\varepsilon W_{OB}}\right)^6 \frac{\omega^s}{\tau_0^\beta} \tag{4}$$

where ε is the dielectric constant, W_{OB} the optical band gap, τ_0 a characteristic relaxation time, *q* electronic charge, and *N* is the spatial density of defect states. The frequency exponent *s* for this model is evaluated as

$$s = 1 - \beta = 1 - 6k_B T/W_{OB} \tag{5}$$

where k_B is Boltzmann's constant. Therefore, according to the Correlated Barrier Hopping (CBH) model, *s* should be temperature dependent. A comparison of the experimentally determined *s* values with the prediction of the CBH model suggest that the dependence of the exponent *s* on temperature is in agreement with the prediction of the CBH model for compounds **6**, **7** and **8**.

Abstract

A convenient synthetic method for the preparation of organothiomethylpyridine ligands 2-($RSCH_2$)C_5H_4N (R = Ph ($\mathbf{L}^1$), Me ($\mathbf{L}^2$)), 2-MeS–6-Me-C_5H_3N ($\mathbf{L}^3$), and 2-MeS–4-Me-C_5H_3N ($\mathbf{L}^4$) via the initial lithiation of substituted 2-picolines followed by the nucleophilic reaction with a diorganyldisulfide is described. The complexes [$PtBr_2$L] (L = $\mathbf{L}^1$–$\mathbf{L}^4$) have been prepared in good to high yields as yellow solids with low solubility in organic solvents. The solid state structures of the complexes have been determined, showing the spatial arrangement of the complexes to depend significantly upon varying substituents within the ligand. The complexes undergo oxidation by bromine to form the tetravalent complexes [$PtBr_4$(L)] (L = $\mathbf{L}^1$–$\mathbf{L}^4$). The solid state structures of [$PtBr_4$($\mathbf{L}^2$)] and [$PtBr_4$($\mathbf{L}_4$)] have been determined, and shown to be monomeric with the ligand chelating the platinum centre.

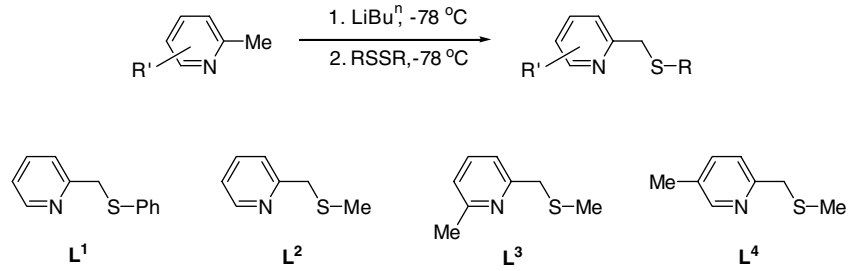
Keywords: Platinum; Mixed donor ligands; Pyridine; Thioether; X-ray crystal structures



1. Introduction

The coordination chemistry of platinum(II) containing thio-, seleno- and telluroether ligands has been well established [1–3]. In contrast, reported platinum(IV) complexes containing N– and S– (or Se–) donor ligands are fewer [4–9]. Pyridylthioether ligands are a class of simple and fundamental heteroleptic ligands [10], and we have recently prepared a number of Pt(II) and Pd(II) chloride complexes, including Pd(II) complexes that facilitate Heck catalysis, containing the mixed donor ligands 2-($RECH_2$)C_5H_4N (RE = MeS, PhS, MeSe) and investigated their behaviour in solution using DFT calculations [11]. Comparison of the solid state structures of [MCl_2{2-($PhSCH_2$)C_5H_4N}] (M = Pd, Pt) and results from theoretical studies of solution processes indicate that the Pt–S bond is stronger than Pd–S, consistent with the softer Lewis acidity of platinum compared with palladium. Similar trends in bond distances in isomorphous structures of palladium and platinum complexes containing homoleptic and heteroleptic ligands have been observed and theoretical calculations have been performed [12–16].

There are several known methods for preparing thioether–pyridine heteroleptic ligand systems [17–25]. Reported methods of synthesis tend to be specific for the individual target molecule. However, an early report of the isolation of 2-($PhSCH_2$)-3-Me-C_5H_3N on reaction of 2,3-$Me_2C_5H_3N$ with $LiBu^n$ and PhSSPh [20] indicates the potential for development of a simple generic method. Herein, we describe the application of this method for the preparation of previously reported ligands $\mathbf{L}^1$–$\mathbf{L}^3$ [17,20,25] and the new ligand $\mathbf{L}^4$, that illustrates versatility

Scheme 1. Synthesis of substituted pyridyl thioether ligands, $\mathbf{L}^1$–$\mathbf{L}^4$.

in the range of substitution on the pyridyl ring and in the thioether group (Scheme 1). The synthesis and characterisation of Pt(II,IV) bromide complexes of ligands $\mathbf{L}^1$–$\mathbf{L}^4$ are described, allowing a systematic investigation into the effects of ligand, in particular the effect of adding a methyl group to the pyridyl ring in the 6-position, using single crystal X-ray diffraction studies.

2. Experimental

2.1. Materials and methods

All reactions were performed under argon gas using standard Schlenk techniques. Platinum(II) chloride was obtained as a loan from Johnson Matthey and was used without purification. All solvents were degassed prior to use. Infra-red spectra were recorded as KBr pressed discs on a Bruker IF55 Infra-red Spectrometer. Mass spectra of the complexes were recorded on a Kratos Analytical Concept ISQ mass spectrometer. ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded on a Varian Mercury Plus NMR spectrometer operating at 299.9 and 75.4 MHz in deuterated dimethylsulfoxide or deuterated chloroform and referenced to the residual resonances of the solvent (δ 2.33 and 7.25 ppm (^{1}H), respectively, 77.0 ppm (^{13}C{^{1}H} in $CDCl_3$)). Microanalyses (C, H, N, S) were determined by The Microanalysis Service, Central Science Laboratory, University of Tasmania.

2.2. Syntheses of ligands $\mathbf{L}^1$–$\mathbf{L}^4$

2.2.1. 2-(Phenylthiomethyl)pyridine ($\mathbf{L}^1$)

A solution of LiBu^n (6.00 mL of a 1.6 M hexane solution) was added dropwise to a stirred solution of 2-picoline (1.0 mL, 10.1 mmol) in Et_2O (25 mL) at −78 °C. The reaction was allowed to warm to ambient temperature, after which it was added dropwise to a stirred solution of diphenyl disulphide (2.36 g, 10.8 mmol) in THF (35 mL) at −78 °C. The solution was allowed to warm to room temperature and stirred for 12 h. Water was then added and the aqueous layer extracted with Et_2O (3 × 30 mL). The organic phase was dried (Na_2SO_4), and the solvent removed in a vacuum resulting in an oil. The product was purified by passing through a silica plug (5% Et_2O in petroleum spirit (b.p. 40–60 °C)) to give a yellow oil (0.96 g, 47%). *Anal.* Calc. for $C_{12}H_{11}NS$: C, 71.60; H, 5.51; N, 6.96; S, 15.93. LSIMS (*m*/*z*) 152 $(M - H)^+$ [$^{12}C_8H_{11}{}^{14}N^{32}S_{152}$].

2.3. Syntheses of complexes [$PtBr_2L$] ($L = \mathbf{L}^1$ (**1**), $\mathbf{L}^2$ (**2**), $\mathbf{L}^3$ (**3**), $\mathbf{L}^4$ (**4**))

Sodium bromide (0.827 mmol) and $PtCl_2$ (0.376 mmol) were refluxed in MeCN (30 mL) for 24 h. The light brown solution was filtered and the appropriate ligand (0.381 mmol) was added. The mixture was allowed to stir at room temperature (16 h). The MeCN volume was reduced in a vacuum (ca. 1 mL) and Et_2O added to afford an off-white precipitate. The solid was collected and washed with Et_2O, yielding the desired compound.

[$PtBr_2(\mathbf{L}^1)$] (**1**) (69%). *Anal.* Calc. for $C_{12}H_{11}Br_2NPtS$: C, 25.91; H, 1.99; N, 2.52. IR (KBr, cm^{-1}): 2957(s), 2910(m), 1616(s), 1481(w), 1394(m), 1311(w), 1269(s), 1032(m), 980(w), 956(m), 829(m), 563(w), 443(w).

2.4.3. [$PtBr_4(\mathbf{L}^4)$] (**8**)

The procedure used was as for [$PtBr_4(\mathbf{L}^1)$] using $\mathbf{L}^4$ (73%). *Anal.* Calc. for $C_8H_{11}Br_4NPtS$: C, 14.39; H, 1.66; N 2.10. Found: C, 14.87; H, 1.84; N, 2.17%. ^{1}H NMR (299.9 MHz, DMSO-d_6, 25 °C) δ: 9.20 (m, 1H, C_5H_4N), 7.84 (m, 1H, C_5H_4N), 7.63 (m, 1H, C_5H_4N), 5.12, 4.93 (AB spin system, 2H, CH_2), 2.69 (s, $J_{Pt-H} = 18.0$ Hz, 3H, CH_3), 2.51 (s, 3H, CH_3). IR (KBr, cm^{-1}): 2959(m),

2903(m), 1597(m), 1571(m), 1459(s), 1433(m), 1398(s), 1367(s), 1316(m), 1297(w), 1202(w), 1171(m), 1118(m), 1038(m), 970(s), 852(w), 779(s).

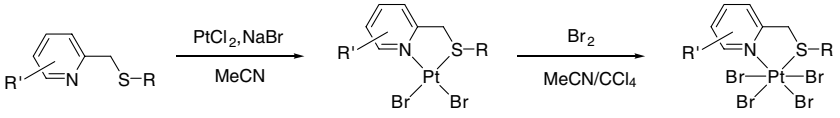
2.5. X-ray crystallographic studies

Suitable crystals for X-ray diffraction studies of $[PtBr_2L]$ ($L = \mathbf{L}^1$ (**1**), $\mathbf{L}^2$ (**2**), $\mathbf{L}^3$ (**3**), $\mathbf{L}^4$ (**4**)) and $[PtBr_4(\mathbf{L}^2)]$ were grown from $MeNO_2/Et_2O$ (vapour diffusion). Full spheres of CCD area-detector diffractometer data for all complexes were measured (Bruker AXS, ω-scans, monochromatic Mo Kα radiation, $\lambda = 0.7107_3$ Å, T ca. 153 K), N_{total} reflections merging to N unique (R_{int} cited) after 'empirical'/multiscan absorption correction (proprietary software), N_o with $F > 4\sigma(F)$ being considered "observed" and used in the full matrix least squares refinements. $(x, y, z, U_{iso})_H$ were refined for **2a** only, constrained in the remainder. Neutral atom complex scattering factors were employed within the context of the XTAL 3.7 program system [26]. Pertinent results are given above and in the tables and figures, the latter showing 50% probability amplitude displacement envelopes for the non-hydrogen atoms, hydrogen atoms having arbitrary radii of 0.1 Å.

3. Results and discussion

3.1. Synthesis of ligands

Lithiation of the α-carbon of a substituted pyridine using $LiBu^n$ affords the carbanion which then undergoes a nucleophilic substitution reaction with an appropriate diorganyl disulfide to afford the desired heteroleptic substituted pyridyl thioether compounds, $\mathbf{L}^1$–$\mathbf{L}^4$, in 47–87% yield (Scheme 1). This is a relatively simple and efficient "one-pot" synthesis, suitable for both MeSSMe and PhSSPh. The ligands, including the new ligand $\mathbf{L}^4$, were characterised using ^1H and $^{13}C\{^1H\}$ NMR spectroscopy, EI mass spectrometry, and elemental analysis.



The room temperature ^1H NMR spectra of the methylthioether ligands, $\mathbf{L}^3$ and $\mathbf{L}^4$, are as expected and show no obvious trends upon substitution of the pyridyl ring compared with the spectrum of $\mathbf{L}^2$. The aromatic protons are observed as resonances between 6.98 and 8.36 ppm; methylene protons can be seen as a sharp singlet at 3.79 and 3.75 ppm for $\mathbf{L}^3$ and $\mathbf{L}^4$, respectively. The SMe moiety is observed as a singlet at 2.04 ppm for $\mathbf{L}^3$ and $\mathbf{L}^4$, respectively, while the second singlet, observed at 3.79 and 2.33 ppm, corresponds to the methyl substituent on the pyridyl ring at the 6- and 4-position, respectively.

The $^{13}C\{^1H\}$ NMR spectra of $\mathbf{L}^3$ and $\mathbf{L}^4$ exhibit resonances in the range of 158.5–120.2 ppm for the aromatic carbon atoms. The methylene carbons are observed at 40.2 and 40.1 ppm, while the resonance corresponding to the methyl substituent of the sulfur is observed at 15.4 ppm for both ligands. Another signal corresponding to the methyl substituent on the pyridyl ring occurs at 24.6 ppm and 21.3 ppm for $\mathbf{L}^3$ and $\mathbf{L}^4$, respectively.

3.2. Synthesis of $[PtBr_2L]$ and $[PtBr_4L]$ complexes

Treatment of $PtBr_2$ (formed in situ from $PtCl_2$ and NaBr) with a slight excess of **L** in MeCN afforded the complexes $[PtBr_2L]$ ($L = \mathbf{L}^1$ (**1**), $\mathbf{L}^2$ (**2**), $\mathbf{L}^3$ (**3**),$\mathbf{L}^4$ (**4**)) as pale yellow solids in 69–87% yield (Scheme 2). The compounds are stable to air and moisture and have limited solubility in organic solvents. LSI mass spectra of the complexes exhibit an ion, corresponding to $[M + Na]^+$, where the sodium atom entered the matrix from slight contamination of starting material. The mass spectrum of $[PtBr_2\mathbf{L}^1]$ exhibits an additional ion at m/z 553, corresponding to the ion $[M - Br+L]^+$. The $[PtBr_4L]$ complexes ($L = \mathbf{L}^1$ (**5**), $\mathbf{L}^2$ (**6**), $\mathbf{L}^3$ (**7**), $\mathbf{L}^4$ (**8**)) were prepared in good yield (67–75%) by treatment of $[PtBr_2L]$ in MeCN with a solution of Br_2/CCl_4 at room temperature for 30 min (Scheme 1). The complexes are air stable orange powders, with very limited solubility, thus making characterisation difficult.

The ^1H NMR spectra for all complexes exhibit a second-order spectrum with an AB spin system for the methylene protons between 5.64 and 4.43 ppm. Resonances corresponding to the pyridyl protons are observed as various multiplets between 9.69 and 7.10 ppm. The methyl protons in **2**–**4** are observed as singlets between 2.49 and 2.32 ppm which are further downfield than those of the analogous chloride complexes because of the increased *trans*-effect of the bromide ligand. Variable temperature ^1H NMR studies of $[PtBr_2\mathbf{L}^2]$ were used to investigate the effect of changing halide ligands on the *E*-inversion process. The coalescence temperature of the methylene protons in $[PtBr_2\mathbf{L}^2]$ (150 °C) is slightly lower than that for the analogous $[PtCl_2\mathbf{L}^2]$ complex (157 °C) [11], and has previously been observed for platinum halide complexes containing dithioether ligands, being explained in terms of the increased *trans*-influence of the heavier halide [27]. The ^1H NMR spectra of the Pt(IV) complexes **5**–**8** were similar

Scheme 2. Synthesis of $[PtBr_2L]$ (**1**–**4**) and $[PtBr_4L]$ (**5**–**8**) complexes.

to those of the Pt(II) complexes in that a second-order AB spin coupling pattern was observed for the methylene protons of the ligand. All other features of the spectra were as expected with aromatic protons observed in the typical region, and the methyl protons of complexes **6**, **3** and **4** being observed as singlets between 2.70 and 2.04 ppm.

*3.3. Structures of [$PtBr_2(L^1)$] (**1**), [$PtBr_2(L^2)$] (**2**), [$PtBr_2(L^3)$] (**3**), [$PtBr_2(L^4)$] (**4**), [$PtBr_4(L^2)$] (**6**), and [$PtBr_4(L^4)$] (8)*

All of the Pt(II) complexes (Figs. 1–8, and Tables 1 and 2) crystallise with the asymmetric unit comprised of a monomeric species with distorted square planar geometry for platinum. The Pt–S bond distances in all the [$PtBr_2L$] complexes (2.238(2)–2.250(3) Å) are comparable to those observed in [$PtBr_2(PhS(CH_2)_2SPh)$] (2.249(3), 2.248(3) Å) [28]. Similarly, the Pt–N bond distances (2.033(6)–2.058(4) Å) are comparable to those found in complexes such as [$PtBr_2(Me_2$-phen)] (Me_2-phen = 2,9-dimethyl-1,10-phenanthroline) (2.049(7), 2.058(9) Å) [29]. The Pt–Br bond distances in the complexes [$PtBr_2L$] range from 2.4220(9) to 2.4630(9) Å and are typical, with the shortest bond associated with the bromine atom *trans* to the pyridyl nitrogen and the longest associated with the bromine atom *trans* to the sulfur atom, the latter values also comparable with those of [$PtBr_2(PhS(CH_2)_2SPh)$] (2.430(1), 2.434(1)) [28].

The effect of changing the halide from Cl to Br in the coordination sphere about the platinum can be seen by comparing the structures of the analogous complexes [$PtCl_2(L^1)$] and [$PtBr_2(L^1)$] [11] (see also Table 2). Increases in Pt–S and Pt–N bond distances in [$PtBr_2(L^1)$] (2.2423(11) and 2.058(4) Å, respectively), compared to those of the complex [$PtCl_2(L^1)$] (2.235(1) and 2.034(3) Å, respectively), are consistent with the increased *trans*-influence of the bromide ligand. The strain of the two complexes appears comparable, with the puckering of the five-membered chelate

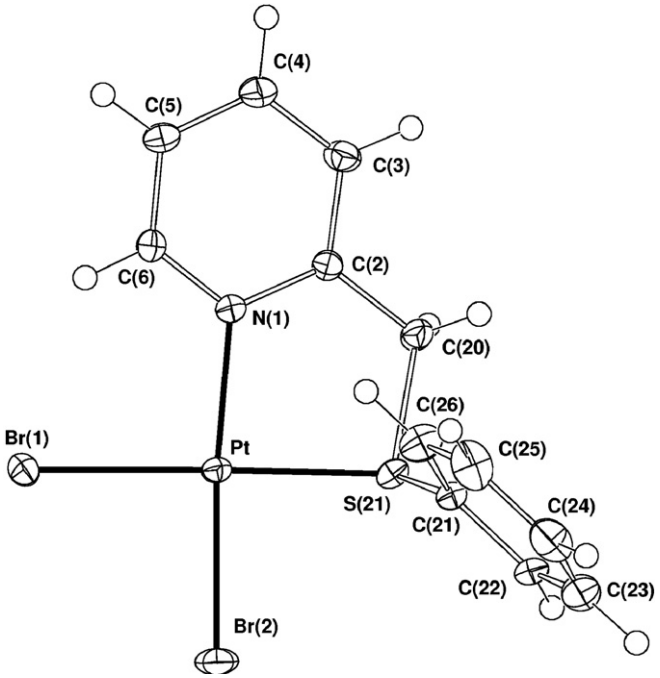


Fig. 1. Molecular projection of [$PtBr_2(L^1)$] (**1**).

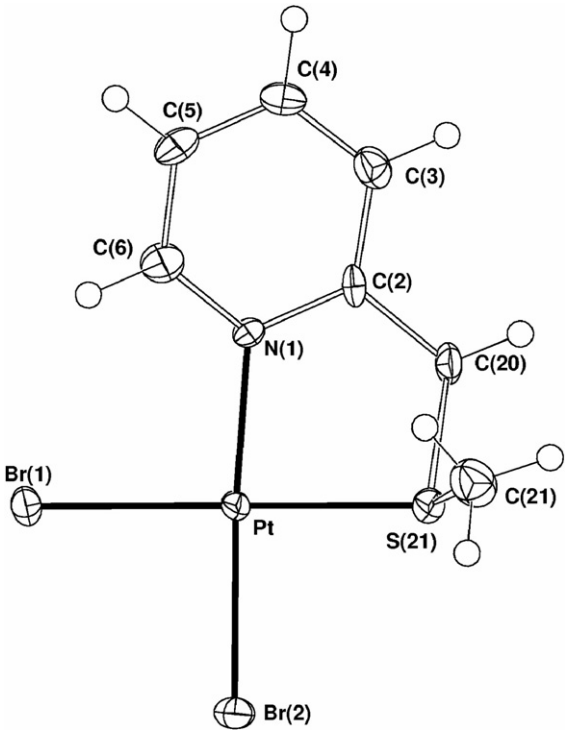

Fig. 2. Molecular projection of [$PtBr_2(L^2)$] (**2**).

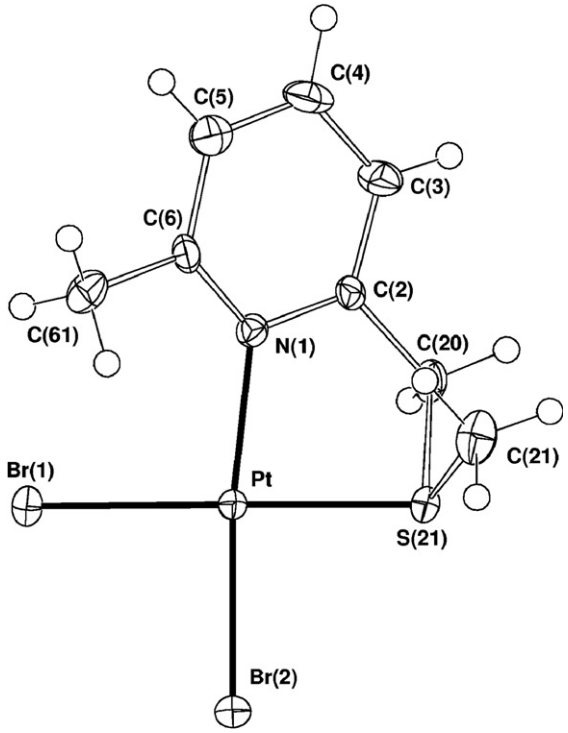

Fig. 3. Molecular projection of [$PtBr_2(L^3)$] (**3**).

rings being similar, as are the associated atom deviations from the C_5N plane (the coordination plane in most cases is somewhat puckered). Changes in the Pt–S and Pt–N bond distances are negligible, despite the variation in *trans*-influence of the bromide atoms.

Variation of the thioether substituent from Ph to Me has little to no effect on bond lengths within the coordination environment of the platinum, but there are subtle effects on the bond angles and strain within the molecule. These are evident in the parameters of Table 2, where data for the present compounds is marshalled comparatively with other relevant data from the literature. The slightly more acute 'bite' angle of the methylthioether complex, **2** (Fig. 2), compared to the phenylthioether complex, **1**, is accompanied by an increase in the strain of the chelate ring, most evident in the differences in associated torsion angles (Table 2). The decrease in the bite angle in complex **2** (85.8(2)°) is offset by a relaxation of all other bond angles about the platinum except the Br(1)–Pt–Br(1) angle which is slightly more acute for the methylthioether complex (89.57(3)°; cf. 90.06(2)° for complexes **2** and **1**, respectively).

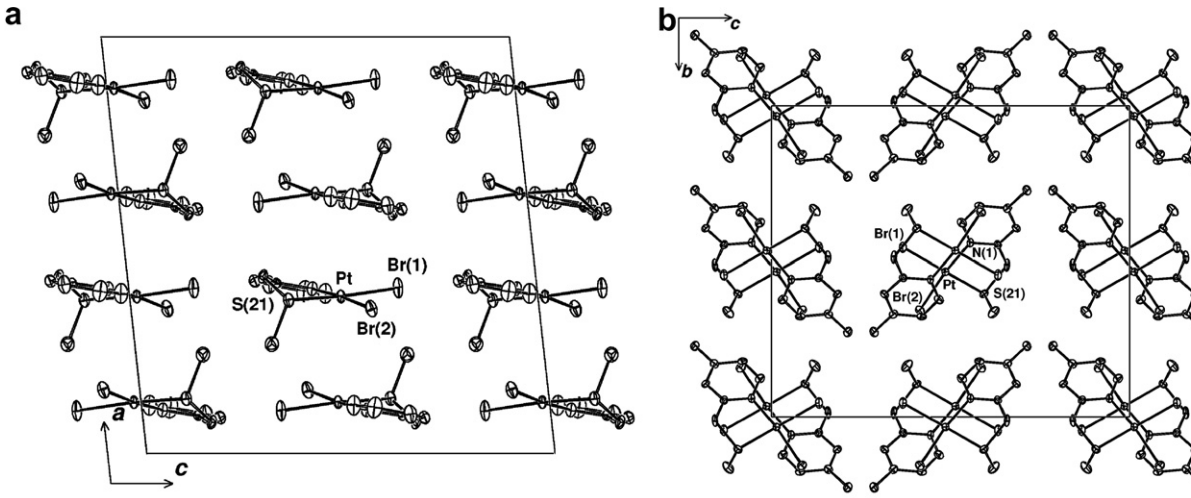

Fig. 5. (a,b). Unit cell contents of **2** and **4**, projected down *b* and *a*, respectively. (The closest Pt···Pt contacts in these structures are 4.2234(7), 3.7364(6) Å, respectively.)

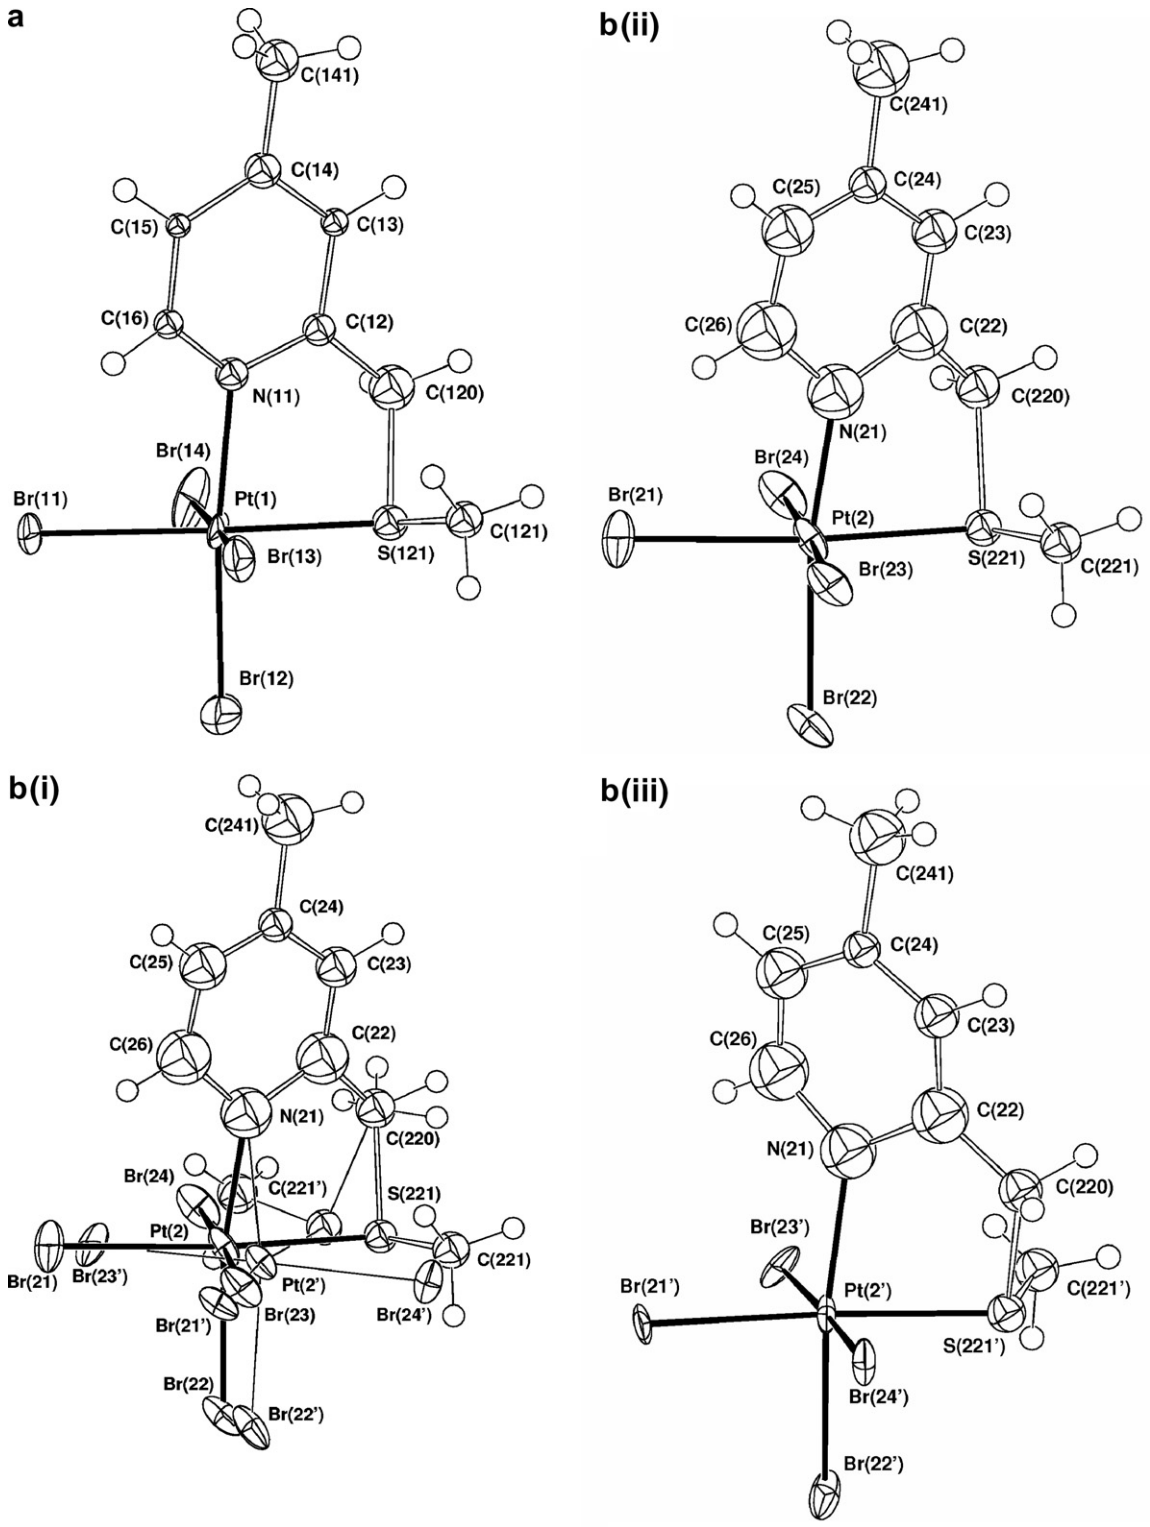

Fig. 7. Molecular projections of $[PtBr_4(\mathbf{L}^4)]$ (**8**). (a) Molecule 1. (b) Molecule 2: (i) the disordered composite and (ii, iii) the two deconvoluted components.

The addition of a methyl moiety at the 6-position of the pyridyl ring dramatically changes the overall shape of the molecule from that of the complex containing the unsubstituted ligand, the effects paralleling that previously observed in the counterpart *t*-butyl substituted palladium(II) chloride analogues (Table 2) [30]. This is most strongly evidenced in the changes in torsion angles in the chelate ring which in turn bring about a dramatic twist in the MX_2 array relative to the pyridine plane (Table 2). There is a lengthening of the Pt–N bond distance in **3** compared to that in **2** (2.055(7), 2.034(7) Å, respectively), associated with an increase in the Br(1)–Pt–N(1) bond angle

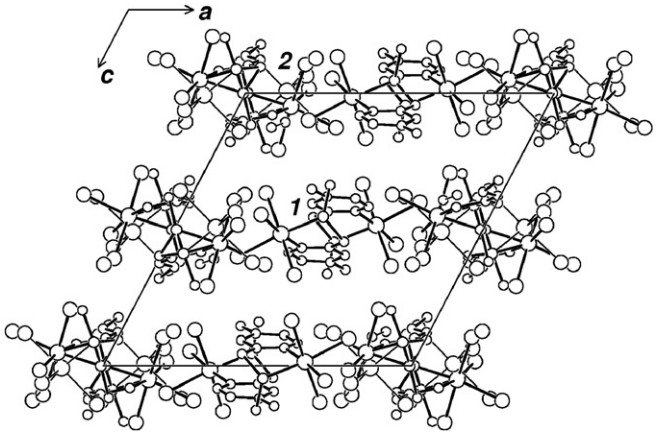

Fig. 8. Unit cell contents of $[PtBr_4(\mathbf{L}^4)]$ (**8**), projected down *b*.

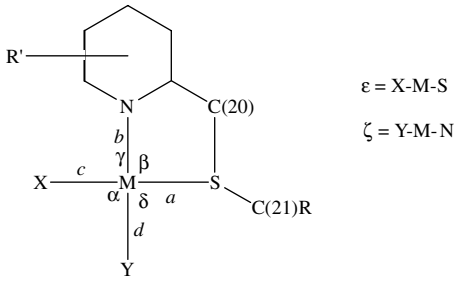
(96.7(2), 94.5(2)°, respectively) because of steric interactions between the 6-methyl substituent of the pyridyl ring and the *cis* bromine atom. A concomitant of the lengthened Pt–N bond is a decrease in the bite angle of the ligand (83.7(2)° (**3**), 85.8(2)° (**2**)). When the substitution of the ligand occurs at the 4-position of the pyridyl ring, the overall shape of the complex (**4**, Fig. 4) resembles that of **2** where the ligand is unsubstituted, suggesting that the change in the structure of **3** is due mostly to the increased steric strain brought on by the addition of the methyl substituent at the 6-position rather than electronic differences in the complexes. Interesting stackings of the planar components of the molecules are observed (Fig. 5).

The Pt(IV) complex $[PtBr_4(\mathbf{L}^2)]$ (**6**) crystallises in the orthorhombic space group $Pna2_1$ with the asymmetric unit comprised of a monomeric species containing distorted octahedral geometry (Fig. 6). Bond distances and angles are listed in Table 3. The Pt–N bond distance of $[PtBr_4(\mathbf{L}^1)]$ (2.101(10) Å) is also shorter than that in $[PtBrMe_3$(2,6-bis(*p*-tolylthiomethyl)pyridine)] (2.311(6) Å) [4], and again can be attributed to the different *trans*-influence that the methyl group has on the nitrogen centre compared to the bromide atom. The five-membered chelate ring in $[PtBr_4(\mathbf{L}^2)]$ is significantly more puckered than observed in the structure of $[PtBr_2(\mathbf{L}^2)]$, with the sulfur atom out of the Pt–N(1)–C(2)–C(21) plane (χ^2 19) by 0.68(2) Å, which may be attributed to the increased steric hindrance between the lone pair of electrons on the sulfur atom with the bromine atoms due to the increased coordination number of the platinum. The large ring puckering is reflected in the larger than ideal Br(4)–Pt–S(21) bond angle (93.99(9)°) and the smaller than ideal Br(3)–Pt–S(21) bond angle (86.49(9)°). The ligand bite angle (N(1)–Pt–S(21)) at 83.6(3)° is significantly smaller than that seen in the $[PtBr_2(\mathbf{L}^2)]$ complex (85.8(2)°) but is consistent with the lengthening of the Pt–N and Pt–S bonds associated with the higher coordination number. The Pt–S bond distance in $[PtBr_4(\mathbf{L}^2)]$ (2.329(3) Å) is longer than in $[PtBr_2(\mathbf{L}^2)]$, consistent with an increase in the coordination number of the platinum. However, it is also shorter relative to the Pt–S bond distances of $[PtBrMe_3(Me_2N(CH_2)_2SC_6H_4$-Me-4)] (2.437(3) Å) [8] and $[PtBrMe_3$(2,6-bis(*p*-tolylthiomethyl)pyridine)] (2.419(4) Å)[4] which can be attributed to the difference in *trans* influence of the methyl compared to the bromide group.



Crystals of $[PtBr_4(\mathbf{L}^4)]$ (**8**) were small and data of an unsatisfactory quality, with, further, a disordered model resulting in an inferior determination, replicated in a later study on an instrument of more recent manufacture and

at a lower temperature. Two independent molecules, devoid of crystallographic symmetry comprise the asymmetric unit of the structure. One is ordered, refining unproblematically, albeit with isotropic displacement parameter forms for S, C, N. The other comprises a pair of disordered superimposed components (Fig. 7), the disorder resolvable in all atoms except MeC_5H_3NC, occupancies refining to 0.605(9) and complement. The disorder is a consequence of co-crystallisation at site 2 of molecules differing in the orientation of the S–Me group. Although the geometries are imprecise, with the chelate rings of similar conformations in molecules 1 and the two components of molecule 2 (one component of the latter being of opposite chirality) (Table 2), it is interesting to find that the chelate ring conformation is somewhat different to that found in $[PtBr_4(L^2)]$ (**6**), best appreciated by observation of the pendant S–Me disposition. Disorder is not resolved in the aromatic ring of molecule 2, although its displacement parameters are high, perhaps because of the constraint of parallel packing of the aromatic planes in the lattice (Fig. 8), their being some tendency for the molecules to be disposed in sheets.

4. Conclusions

A relatively simple generic synthetic method has been developed for the preparation of substituted pyridyl thioether ligands, one of the most fundamental heteroleptic ligand systems. The solid-state structures of a number of $PtBr_2L$ complexes containing pyridyl thioether ligands were elucidated. The deviation from ideal square planar geometry is influenced by the substitution of a methyl group at the 6-position of the pyridyl ring. The electronic effects of the methyl group have minimal effect on the structure. Variation of the thioether substituent from Ph to Me has little to no effect on bond lengths within the coordination environment of the platinum, but there are subtle effects on the bond angles and strain, with the square planar geometry becoming less tetrahedrally distorted and the distance between the sulfur atom and the chelate ring becoming greater in the thiomethyl complex $[PtBr_2(L^2)]$. It is hoped that such investigations into the effect of ligand variation on the structure of the compounds will help to understand what characteristics influence their catalytic activity.

Abstract

Three Pd(II) complexes $[Pd_2(\mu\text{-}Cl)_2\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]\cdot 0.25CH_2Cl_2$ (**1**), $[Pd\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]\cdot 4CHCl_3$ (**2**) and $[PdCl_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ (**3**) have been synthesized by the reactions of $1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10}$ with $PdCl_2$ in acetonitrile, cyanophenyl and dichloromethane, respectively. A fourth complex, $[PdI_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ (**4**), was obtained by a ligand exchange reaction through the substitution of the Cl^- of complex **3** with I^-. All four complexes have been characterized by elemental analysis, FT-IR, ^1H and ^{13}C NMR spectroscopy and X-ray structure determination. Single crystal X-ray determination showed that the carborane cage, *nido* for **1**, **2** and *closo* for **3**, **4**, was coordinated bidentately to the Pd atom through the two P atoms, and the geometry at the Pd atom was square-planar in all the complexes.

1. Introduction

Bidentate ligands have played an important role in the development of catalytic applications of metal organic complexes [1]. Two of the fundamentals for these catalysts are that two *cis*positions of the metal center are available to perform the reaction, and bidentate phosphines have already been demonstrated to be very convenient for this sort of catalysis [2]. The influence of substitution at the cluster carbon atoms in *o*-carborane by electron rich element phosphorus has been of interest to us. Among of the derivatives of *o*-carborane, the *closo* diphosphine $1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10}$ and the *nido* $[7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}]^-$ anion degraded from the *closo* species are two typical bidentate phosphine ligands [3,4]. Because the two phosphorus atoms bonded to the two adjacent carbon atoms of the *o*-carborane are fixed by the geometry of the carborane skeleton in an eclipsed conformation at *cis* positions, a stable complex can be formed through a five-membered chelating ring between the ligand and a metal atom. Several Pd(II) complexes with *closo* or *nido* carborane diphosphine ligands, such as $[PdCl_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]\cdot CH_2Cl_2$ [5], $[PdClMe(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]\cdot CH_2Cl_2$ [6], $[PdBr_{1.133}Cl_{0.867}(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]\cdot CH_2Cl_2$, $[PdBr_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]\cdot CH_2Cl_2$ and $[PdBrCl_{0.541}Me_{0.459}(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]\cdot CHCl_3$ [7], where the structures have been characterized by X-ray diffraction, have been reported. Considering the importance of Pd as a metal in catalysis, we are also interested in this kind of complex and reported a Pd(II) complex with the formula $[PdCl(PPh_3)\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}]\cdot 1.25CH_2Cl_2$ [8]. Recently, we investigated the reactions of the *closo* diphosphine ligand with $PdCl_2$ in three different solvents and obtained three Pd(II) complexes with the formula $[Pd_2(\mu\text{-}Cl)_2\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]\cdot 0.25CH_2Cl_2$ (**1**), $[Pd\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]\cdot 4CHCl_3$ (**2**) and $[PdCl_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ (**3**). By using a ligand exchange reaction, we have also obtained the complex $[PdI_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ (**4**). All the complexes were characterized by elemental analysis, FT-IR, ^1H and ^{13}C NMR spectroscopy and X-ray structure determination.

2. Experimental

2.1. Reagents and techniques

All the reactions were carried out under an atmosphere of dry, oxygen-free dinitrogen. Some subsequent manipulations were performed in the air. Solvents were dried with suitable drying agents, distilled under dinitrogen and deoxygenated prior to use. 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ was prepared according to the literature procedure [3]. All chemicals were purchased and used as received. Infrared spectra were recorded in the range 400–4000 cm^{-1} from KBr pellets on a Nicolet-460 FT-IR spectrophotometer. Elemental analysis (C, H) was carried out with a Perkin–Elemer 2400 II elemental analyzer. The ^1H and ^{13}C NMR were recorded on a Varian Mercury 400 spectrometer in $CDCl_3$ solution with tetramethylsilane (TMS) as an internal standard at 400.15 and 100.63 MHz, respectively. The ^{13}C spectra are broadband proton decoupled. The chemical shifts are reported in parts per million with respect to the references and are stated relative to external TMS for ^1H and ^{13}C NMR.

2.2. Synthetic procedures

2.2.1. Preparation of $[Pd_2(\mu\text{-}Cl)_2\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]\cdot 0.25CH_2Cl_2$ (1)

$PdCl_2$ (18.8 mg, 0.10 mmol) and 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (51.2 mg, 0.10 mmol) were added to 10 ml acetonitrile and the mixture was refluxed for 6 h under the protection of dry N_2. The yellow solid that formed was filtered off, washed with acetonitrile, and dried in vacuum (26.4 mg, 41.0%). M.p. 278–279 °C. A crystal suitable for X-ray diffraction was obtained from a dichloromethane–*n*-hexane solution. FT-IR ν_{KBr} (cm^{-1}): 3052 m, 2540 m, 1435 m, 1098 m, 741 m. ^1H NMR (400.15 MHz, $CDCl_3$): −2.1 ppm (2H, B–H–B); ^{13}C NMR (100.63 MHz, $CDCl_3$): 124–131 ppm (48C), 76.5 ppm (4C). *Anal.* Calc. for $C_{52.25}H_{60.5}B_{18}Cl_{2.50}P_4Pd_2$: C, 47.96; H, 4.66; Found: C, 47.82; H, 4.71%.

2.2.2. Preparation of $[Pd\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]\cdot 4CHCl_3$ (2)

$PdCl_2$ (18.8 mg, 0.10 mmol) was added to a solution of 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (102.4 mg, 0.20 mmol) in 10 ml cyanophenyl and stirred for 10 h under the protection of dry N_2. The yellow solid that formed was filtered off, and dried in vacuum (42.7 mg, 38.5%). M.p. 236–237 °C. A crystal for X-ray diffraction was grown from a chloroform solution layered with ether. FT-IR ν_{KBr} (cm^{-1}): 3042 m, 2560 m, 1423 m, 1108 m, 735 m. ^1H NMR (400.15 MHz, $CDCl_3$): −2.13 ppm (2H, B–H–B); ^{13}C NMR (100.63 MHz, $CDCl_3$): 125–132 ppm (48C), 77.1 ppm (4C). *Anal.* Calc. for $C_{56}H_{64}B_{18}Cl_{12}P_4Pd$: C, 42.37; H, 4.06; Found: C, 42.30; H, 4.00%.

2.2.3. Preparation of $[PdCl_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ (3)

$PdCl_2$ (18.8 mg, 0.10 mmol) was added to a solution of 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (51.2 mg, 0.10 mmol) in 10 ml dichloromethane. The mixture was refluxed for 3 h under the protection of dry N_2, and concentrated to 5 ml, and then 20ml *n*-hexane was added to precipitate the solid. Yield: 53.8 mg, 78.0%. M.p. 291–292 °C. A crystal suitable for X-ray diffraction was obtained from a CH_2Cl_2 solution after partial evaporation the solvent. FT-IR ν_{KBr} (cm^{-1}): 3000 m, 2600 m, 1433 m, 1080 m, 755 m. ^1H NMR (400.15 MHz, $CDCl_3$): 7.2–7.6 ppm (20H); ^{13}C NMR (100.63 MHz, $CDCl_3$): 124–132 ppm (24C), 76.3 ppm (2C). *Anal.* Calc. for $C_{26}H_{30}B_{10}Cl_2P_2Pd$: C, 45.26; H, 4.38; Found: C, 45.40; H, 4.32%.

2.2.4. Preparation of $[PdI_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ (4)

KI (1.0 mmol, 166 mg) was added to the dichloromethane solution obtained from the preparation of complex **3**. The suspension was refluxed for 5 h under the protection of dry N_2, and then filtered. The yellow filtrate was concentrated to 5 ml, and 20 ml *n*-hexane was added to precipitate the solid. Yield 43.2 mg, 49.5%. M.p. 261–262 °C. A crystal suitable for X-ray diffraction was obtained from a dichloromethane–*n*-hexane solution. FT-IR ν_{KBr} (cm^{-1}): 3030 m, 2590 m, 1445 m, 1090 m, 727 m. ^1H NMR (400.15 MHz, $CDCl_3$): 7.2–7.6 ppm (20H); ^{13}C NMR (100.63 MHz, $CDCl_3$): 125–133 ppm (24C), 77.3 ppm (2C). *Anal.* Calc. for $C_{26}H_{30}B_{10}I_2P_2Pd$: C, 35.78; H, 3.47; Found: C, 35.60; H, 3.38%.

2.3. X-ray crystallography data collection and processing

The collection of crystallographic data for the four complexes was carried out on a Bruker Smart-1000 CCD diffractometer, using graphite-monochromatized Mo-Kα radiation ($\lambda = 0.71073$ Å) at 298(2) K. The structures were solved by direct method and expanded using Fourier difference techniques with the SHELXTL-97 program package [9]. The solvent CH_2Cl_2 in complex **1** was disordered and partially occupied atoms were refined with isotropic displacement parameters, whilst the remaining non-hydrogen atoms were refined anisotropically by full-matrix least-squares calculations on F^2. All the H atoms were located in a difference Fourier map and thereafter refined isotropically, except the bridge H atoms of the *nido* carborane skeleton. These bridge H atoms were refined isotropically with fixed *U* values. Details of the crystal parameters, data collection and refinement are summarized in Table 1.

was first disclosed by Teixidor's group in 1993 [4]. Based on the result, much research work has been done relevant to this area by this group [10–13], and many complexes containing the *nido*-[7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$]$^-$ anion, such as Ru [14], Rh [15], Au [16,17], Ag [18] and Ni, Pd and Pt [8], have been reported. By treatment of $PdCl_2$ with the *closo* diphosphine ligand 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ in a molar ratio 1:1 in acetonitrile under refluxing conditions, we obtained a binuclear Pd complex with the formula [Pd_2-(μ-Cl)$_2${7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$}$_2$]$\cdot$ 0.25CH_2Cl_2 (**1**), in which the *closo* structure of the carborane skeleton was also degraded. When the $PdCl_2$:carborane diphosphine ligand ratio was changed to 1:2 with the conditions otherwise the same, the same product was obtained, indicating that the ratio of the reactants has no influence on the result of this reaction. However, when the reaction was carried out with the starting material $PdCl_2$ and 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ with a molar ratio 1:2 in cyanophenyl, the complex [Pd{7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$}$_2$]$\cdot$ 4$CHCl_3$ (**2**) was obtained, in which the two Cl ions of the initial $PdCl_2$ were substituted by the *nido* carborane diphosphine anion [7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$]$^-$. The reactions are shown in Scheme 1. From these results, it seemed that the solvent could play an important role in the formation process of the complexes.

Scheme 1. The reactions for the preparation of complexes **1** and **2**.

In strong nucleophilic solvents, such as ethanol [8], acetonitrile and cyanophenyl, the *closo* carborane skeleton could be degraded in the reactions of Pd compounds with the *closo* ligand. However, in mild nucleophilic solvents, for example dichloromethane, the *closo* structure of the carborane could be preserved [6,7]. The complex $[PdCl_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]\cdot CH_2Cl_2$ could be obtained by the reactions of the *closo* ligand with $[PdCl_2(cod)]$ in CH_2Cl_2 or $[PdCl_2(PhCN)_2]$ in toluene [5]. Here, we revised the method for the preparation of this complex. By using $PdCl_2$ as the initial material to react with the *closo* ligand in dichloromethane under refluxing conditions, we also obtained this complex. This result further confirmed the conclusion that a mild nucleophilic solvent could avoid the degradation of the *closo* diphosphine ligand. The corresponding PdI_2 complex $[PdI_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ (**4**) was obtained through the substitution of Cl^- in $[PdCl_2(1,2\text{-}(PPh_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10})]$ with I^- under refluxing conditions in CH_2Cl_2 after several hours. The bromide derivative could also be afforded by this type of ligand exchange reaction, although the process was more difficult than that for the preparation of complex **4** (refluxing for 8 days) [7].

3.2. Spectral characterization

All the complexes were characterized by FT-IR, ^1H and ^{13}C NMR spectroscopy. The IR spectra of these complexes were very similar to each other and exhibited absorptions characteristic of terminal B–H vibrations at about 2540–2600 cm^{-1}in the four complexes, which are in the normal range for B–H vibrations of 2625–2450 cm^{-1} [19]. The absorptions at 3052, 3042, 3000 and 3030 cm^{-1} might be attributed to the ν_{C-H} stretching vibration of the benzene rings. Several peaks were found from 1695 to 1410 cm^{-1}, which might be assigned to $\nu_{C=C}$ stretching vibrations. The peak at ca. 1400 cm^{-1} was the in-plane deformation mode of the benzene ring, and the peak at ca. 1100 cm^{-1} was the absorption of $\nu_{C(phenyl)-P}$, which was a little shifted in keeping with phosphorus coordination to the carborane moiety. The absorption at approximately 740 cm^{-1} showed the existence of cage deformation. The ^1H NMR spectra (400.15 MHz) of these complexes displayed a complex pattern of resonances at about 7.1–7.6 ppm which could be attributed to the phenyl-H of the PPh_2 groups. A resonance at ca. −2.1 ppm is the bridge H atom of B–H–B [4]. In the ^{13}C NMR spectra (100.63 MHz), a resonance at ca. $\delta = 130$ ppm could be assigned to the benzene ring C atoms, and a resonance at ca. $\delta = 77$ could be assigned to the carbon atom of carborane cage (Cc) [20].

3.3. Crystallographic data of the complexes

Crystal structures of the four complexes are shown in Figs. 1–4, respectively. Selected bond lengths and angles are given in Table 2. Complex **1** crystallizes in the monoclinic space group *C*2/*c*, containing four formula units in the unit cell and the disordered solvent CH_2Cl_2. The molecular structure of complex**1** is symmetrical and the symmetry transformations used to generate equivalent atoms are $-x+1/2,\ -y+3/2,\ -z+2$. Two Cl atoms bridge the two same Pd[7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$] units. The dihedral angel between central plane formed by the $[Pd_2Cl_2]$ unit and the side P(1)Pd(1)P(2) plane is only 3.3°, indicating that these two planes are almost parallel to each other. The Pd–Cl distance, 2.394(3) Å, is almost equal to the bond length of 2.405(5) Å in $[Pd_2(\mu\text{-}Cl)_2\{7,8\text{-}(P^iPr_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]$ [12], but slightly longer than the average distance of 2.338(2) Å in $[PdCl(PPh_3)\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}]\cdot 1.25\ CH_2Cl_2$ [8]. The two Pd–P bonds (2.233(2) and 2.236(2) Å) and the P–Pd–P angle (85.23(8)°) are all consistent with the average values 2.238 Å and 87.0(1)° in $[Pd_2(\mu\text{-}Cl)_2\{7,8\text{-}(P^iPr_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]$. The average distances of P–Cc, 1.817 Å, and

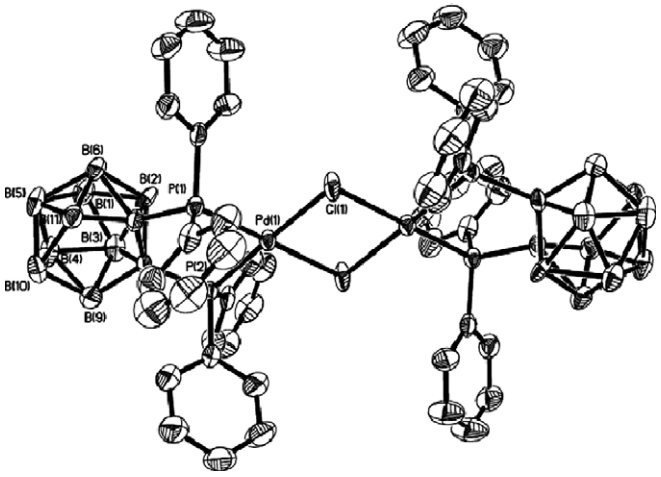

Fig. 1. Perspective view of complex unit of **1**. The H atoms are omitted for clarity.

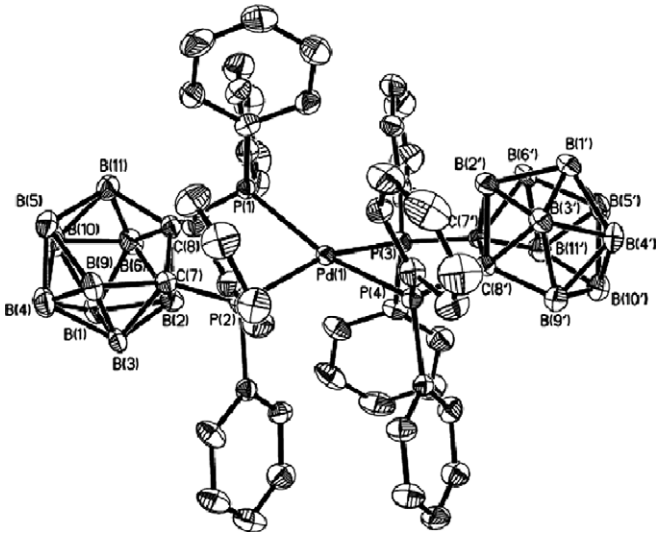

Fig. 2. Perspective view of complex unit of **2**. The H atoms are omitted for clarity.

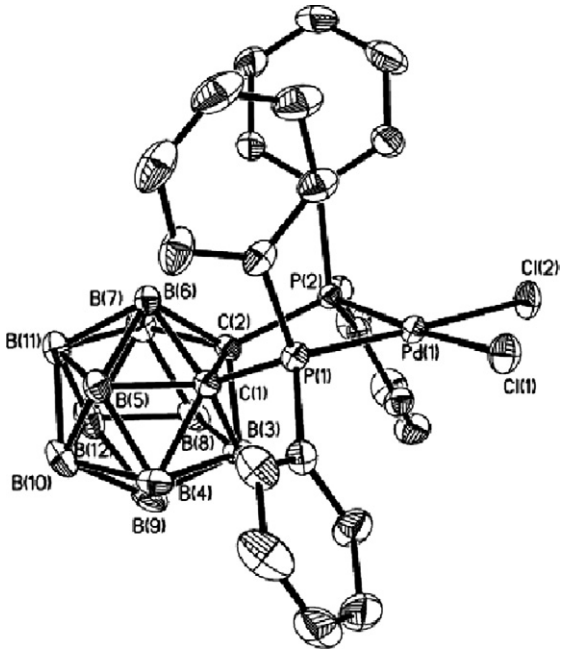

Fig. 3. The crystal structure of complex **3**. The H atoms are omitted for clarity.

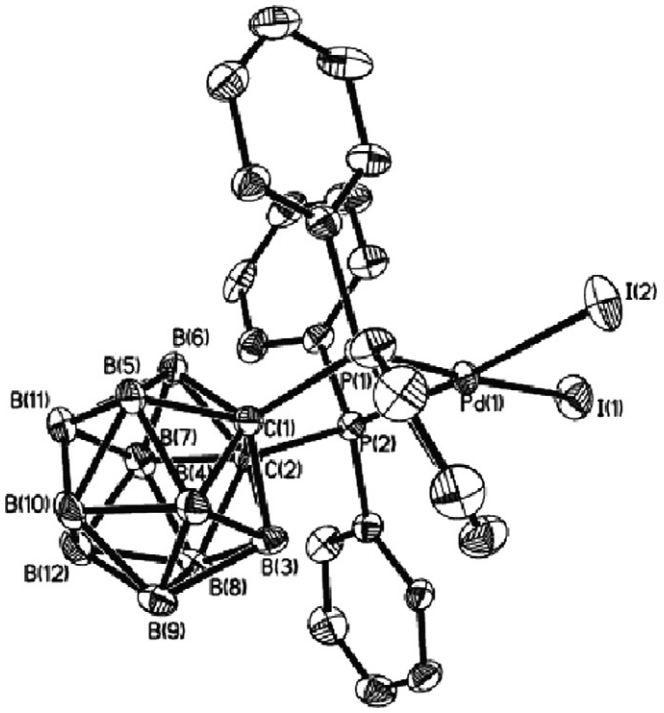

Fig. 4. The crystal structure of complex **4**. The H atoms are omitted for clarity.

Cc–Cc, 1.556(13) Å, are slightly shorter than the corresponding distances, 1.87 and 1.61(2) Å, in $[NMe_4]$-[7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$] · CH_3CH_2OH [10], implying that coordination of the ligand to the Pd atom has an influence on these bond lengths.

Complex **2** also contains four formula units in the unit cell and the solvent $CHCl_3$, and crystallizes in the monoclinic space group *P*2(1)/*c*. The central Pd atom is coordinated to four P atoms coming from two *nido* carborane diphosphine anions [7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}]^-$. The geometry at the Pd atom is seriously distorted square-planar with a mean deviation from the P(1)P(2)P(3)P(4)Pd(1) plane of 0.3141 Å, and the angles around Pd (Table 2) deviate much from the values for a regular square-planar coordination mode. The distances of the four Pd–P bonds are almost equal to each other, and the average value of 2.362 Å is obviously longer than those in complex **1**, which can be attributed to the steric effect of the two ligands. The angles of P(1)–Pd(1)–P(2), 82.63(7)°, and P(3)–Pd(1)–P(4), 82.86(7)°, are slightly smaller than the value of 85.23(8)° in $[Pd_2(\mu\text{-}Cl)_2\{7,8\text{-}(P^iPr_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}_2]$. As for the other parameters in complex **2**, such as the distances of P–Cc and Cc–Cc as listed in Table 2, no noticeable differences have been found on comparison to those in complex **1**.

Symmetry transformations used to generate equivalent atoms for complex **1**: $-x+1/2$, $-y+3/2$, $-z+2$.

As for complex **4**, the Pd atom is also four coordinate, in which two positions are occupied by the *closo* carborane diphosphine 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$, and the other two come from two I atoms in *cis* positions, fulfilling the slightly distorted square-planar coordination. The mean derivation from the P(1)P(2)Pd(1)I(1)I(2) plane is only 0.0258 Å. The two I–Pd bond lengths are 2.622(7) and 2.614(7) Å, which are comparable to the analogous distances of 2.6649(8) and 2.6446(10) Å in [PdI_2(dppe)] [21]. The I–Pd–I angle of 91.74(2)° is almost equal to Cl–Pd–Cl angle of 91.94(4)° in complex **3**. Other bond lengths and angles in the coordination sphere of [PdI_2(1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$)] agree well with the corresponding values in [$PdCl_2$(1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$)]·CH_2Cl_2 [5]. Comparison of the configuration of the *closo* carborane diphosphine ligand in complex **4** with that in the free 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ ligand reveals differences. In the free ligand the P(1)–C(1)–C(2)–P(2) torsion angle is 10.6(3)° [22], while this angle in complex **4** is only 0.6(5)°. This data indicates that coordination of the ligand to Pd(II) alters the symmetry of the ligand. On comparison to that in the free *closo* ligand, the symmetry of the ligand in the complex **4** closely approaches C_{2v}.

4. Conclusions

In this paper we have reported four Pd(II) complexes containing *closo* or *nido* carborane diphosphine ligands, which were obtained by the reactions of the *closo* ligand 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ with $PdCl_2$ in different solvents or by a ligand exchange reaction. The results indicate that the solvent plays an important role in these reactions, both for the degradation of the *closo* carborane skeleton and for the formation process of the complexes.

Abstract

Three new dinuclear copper(II) compounds: $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CH)_2]$ (**1**), $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_3)_2]$ (**2**) and $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_2CH_3)_2]$ (**3**) have been synthesized and characterized crystallographically and spectroscopically. Compounds **1**, **2** and **3** consist of a dinuclear unit in which both Cu(II) ions are connected through two end-on azido bridges providing a distorted square pyramidal geometry with a CuN_4O chromophore. The Cu···Cu separations are 3.195, 3.200 and 3.247 Å for compounds **1**, **2** and **3**, respectively. The magnetic properties have been measured in the range from 5 to 300 K and correlated with the molecular structures. All three compounds show a medium to weak ferromagnetic exchange interactions between the Cu(II) ions dominated by the bridging azido ligands, with a singlet-triplet splitting (J) of 63.3, 63.8 and 5.1 cm^{-1}, for compounds **1**, **2** and **3**, respectively. A large zero-field splitting of about 0.4 cm^{-1} is observed in the EPR for compounds **1** and **2**.

1. Introduction

Recently, the synthesis of pseudohalide bridged compounds, N_3^-, NCS^-, NCO^-, continue being the great interest subject, and intensive investigations have taken place as a result of their diverse structures and applications in magnetic materials [1]. The use of a variety of different bridging ligand has afforded an interesting array of molecular systems with a new architecture. Therefore, it is essential to choose appropriate bridges to rationally design magnetic systems with desirable property [2]. Among them, the azide anion has received the major attention owing to its versatility as a ligand and the wide variety of magnetic behaviours [1–20]. The magnetic characters of the azido-bridged compounds are readily predicted in view of its binding pattern: the most common bridging modes of azide are the end-on ($\mu_{1,1}$-N_3, EO) [2–4,9,10] and the end-to-end ($\mu_{1,3}$-N_3, EE) fashions [2,4–8], which generally lead to ferromagnetic and antiferromagnetic interactions, respectively. However, the end-on bridging does result in antiferromagnetism; the critical angle for accidental orthogonality is ≈108.5°, when the bridging angle exceeds a critical value [11–14]. This correlation is valid only for basal–basal coordination, sometimes also applied to basal–apical coordination mode, which may lead to confusion [1d]. In the basal–apical type of compounds, usually the coupling is very small as the magnetic orbital describing the single electron is mainly of a $d_{x^2-y^2}$ type lying in the basal plane of the

doi:10.1016/j.poly.2006.09.073

metal center and has only a small contribution on the axis perpendicular to the basal plane [15]. The magnetic behaviour for three compounds having doubly bridged azido ligands, in the basal–basal mode for compounds **1** and **2** and in the basal–apical mode for compound **3**, predicts a medium (compounds **1** and **2**) to a weak (compound **3**) ferromagnetic coupling [1]. Based on structural considerations, the end-on bridge is responsible for a ferromagnetic route.

In this study, the synthesis, X-ray crystal structures, spectroscopic and magnetic properties of three dinuclear copper(II) compounds, $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CH)_2]$ (**1**), $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_3)_2]$ (**2**) and $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_2CH_3)_2]$ (**3**) (dpyam = di-2-pyridylamine), all containing bridging azide anions, are reported.

2. Experimental

2.1. Materials and measurements

The di-2-dipyridylamine was purchased as commercial chemicals from Aldrich. All reagents are commercial grade materials and were used without further purification. Elemental analyses (C, H, N) were determined on a Perkin–Elmer PE 2400 CHNS/O Analyzer.

IR spectra were recorded on a Perkin–Elmer Spectrum One FT-IR spectrophotometer as KBr disc in the 4000–450 cm^{-1} spectral range. Solid-state (diffuse reflectance) electronic spectra were measured as polycrystalline samples on a Perkin–Elmer Lambda2S spectrophotometer. The X-band powder EPR spectra were obtained on polycrystalline samples at room temperature and 77 K with a JEOL RE2X electron spin resonance spectrometer. Magnetic susceptibility measurements (5–300 K) were carried out using a Quantum design MPMS-5S SQUID magnetometer (measurements carried out at 0.1 mT). Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.

Caution: Azido complexes of transition metal ions containing organic ligands are potentially explosive. Only a small amount of material should be prepared and handled with care.

2.2. Syntheses

2.2.1. $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CH)_2]$ (1)

The ligand dpyam (0.17 g, 1 mmol), dissolved in methanol/DMF (20/5 ml) and a solid of $Cu(O_2CH)_2 \cdot nH_2O$ (0.31 g, 2 mmol) were mixed together, followed by addition of an aqueous solution of NaN_3 (0.065 g, 1 mmol, in 2 ml) with continuous stirring. The green solution was slowly evaporated at room temperature until brownish crystals of **1** separated. Yield ca. 80%. *Anal*. Calc. for $C_{22}H_{20}Cu_2N_{12}O_4$: C, 41.06; H, 3.13; N, 26.12. Found: C, 40.90; H, 2.96; N, 26.32%.

2.2.2. $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_3)_2]$ (2)

Compound **2** synthesized from $Cu(O_2CCH_3)_2 \cdot nH_2O$ (0.364 g, 2 mmol) and NaN_3 (0.650 g, 1 mmol) in a similar procedure as **1**. The green solution was slowly evaporated at room temperature until brownish-green crystals of **2** separated. Yield ca. 70%. *Anal*. Calc. for $C_{24}H_{24}Cu_2N_{12}O_4$: C, 42.92; H, 3.60; N, 25.02. Found: C, 42.60; H,3.36; N, 25.32%.

2.2.3. $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_2CH_3)_2]$ (3)

Compound **3** synthesized from $Cu(OH)_2$ (0.195 g, 2 mmol), $NaO_2CCH_2CH_3$ (0.192 g, 2 mmol) and NaN_3 (0.650 g, 1 mmol) in a similar procedure as **1**. The resulting green solution was allowed to stand at room temperature. Green crystals appeared. Yield ca. 70%. *Anal*. Calc. for $C_{26}H_{28}Cu_2N_{12}O_4$: C, 44.63; H, 4.03; N, 24.02. Found: C, 44.89; H, 3.90; N, 24.00%.

2.3. Crystallography

The X-ray single-crystal data for the three compounds were collected at 273 K for compounds **1**, **2** and at 293 K for **3**, respectively, on a 1 K Bruker SMART CCD area-detector diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at a detector distance of 4.5 cm and swing angle of $-30°$. A hemisphere of the reciprocal space was covered by combination of three sets of exposures; each set had a different ϕ angle (0°, 88°, 180°) and each exposure of 40 s covered 0.3° in ω. Data reduction and cell refinements were performed using the program SAINT [21]. An empirical absorption correction by using the SADABS [22] program was applied, which resulted in transmission coefficients ranging from 0.741 to 1.000 for compound **1**, 0.608 to 1.000 for compound **2** and 0.818 to 1.000 for compound **3**. The structures were solved by direct methods and refined by full matrix least-squares method on $(F_{obs})^2$ with anisotropic thermal parameters for all non-hydrogen atoms using the SHELXTL-PC V 6.12 software package [23]. All hydrogen atoms were located in a difference Fourier map and refined isotropically, except H atoms of acetate (compound **2**) and propionate anions (compound **3**) which were fixed geometrically with the HFIX utility. The molecular graphics were created by using SHELXTL-PC [23] package. The crystal and refinement details for three compounds are listed in Table 1.

3. Results and discussion

3.1. Crystal structure of $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CH)_2]$ (1)

The structure of compound **1** consists of neutral dinuclear entities. Each of them results from the pairing of two mononuclear units related via an inversion centre. A view of the dinuclear species is given in Fig. 1. Relevant bond distances and angles are reported in Table 2. Each copper(II) ion has a markedly distorted square pyramidal

geometry with a high τ value of 0.38. The structure index is defined as $\tau = (\beta - \alpha)/60$, where β and α are the largest coordination angles, $\tau = 0$ for square pyramidal (SP) and $\tau = 1$ for trigonal bipyramidal (TBP) geometry [24,25], of the CuN_4O chromophore, with two nitrogen atoms of the two bridging azide ligands (Cu–N distances 1.991(1), 2.143(1) Å), a nitrogen of the dpyam ligand (Cu–N distance 1.988(1) Å) and an oxygen atom of the formato ligand (Cu–O distance 2.014(1) Å) forming the basal plane. The axial site of each copper(II) atom is occupied by another nitrogen atom of the dpyam ligand (Cu–N distance 2.129(1) Å) which is slightly shorter than the equatorial bond, Cu(1)–N(4), indicating an unusual square pyramidal geometry found in compound **1**. The copper(II) atoms of the compound are linked through a double azido bridges in an end-on bridging mode from the equatorial position of one copper chromophore to the equatorial position of the other one. The tetrahedral twist of the square base

defined by a dihedral angle between the CuN_2 and CuNO planes is at a quite high value of 34.0° and consequently, the copper atom is displaced 0.36 Å from its individual plane. The Cu···Cu separation is 3.195 Å, while the Cu–N_{azido}–Cu bridging angle is 101.1(1)°, which is an usual angle of azide bridges in most metal compounds [26–28]. The dpyam ligand is slightly folded, as the value of the dihedral angle between the planar pyridine rings is 4.9°. An oxygen atom of the formato ligand is at a distance of 2.945(1) Å from the copper(II) atom, which is slightly too long to be considered as a semi-coordination bond.

The crystal lattice is stabilized by hydrogen bonding between the amine N and an oxygen atom of neighboring formato group with a N···O contact of 2.829(7) Å leading to the formation of the 2D network. Details of the hydrogen bonding are listed in Table 2.

3.2. Crystal structure $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_3)_2]$ (**2**)

The structure of **2** (Fig. 2) consists of a dinuclear unit $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_3)_2]$ in which the copper(II)

atoms are bridged by two azido ions in an end-on fashion. Each of them results from the pairing of two mononuclear units related via an inversion centre. Relevant bond distances and angles are reported in Table 3.

The five-coordinate CuN_4O chromophore around the copper(II) ion consists of two nitrogen atoms of two bridging azide ligands (Cu–N distances 1.997(2), 2.143(2) Å), two nitrogen atoms of a dpyam ligand (Cu–N distances 1.987(2), 2.120(2) Å) and an oxygen atom of an acetato ligand (Cu–O distance 1.967(2) Å). The largest basal angles angle are 172.1(1)° and 143.3(1)°, the distortion parameter τ in this case is 0.48, so the geometry can be described as an extremely distorted square pyramidal geometry with the axial site Cu(1)–N(2), both copper(II) ions of the compound are linked through a double azido bridges in an end-on bridging mode from the equatorial position of one copper chromophore to the equatorial position of the other one. The tetrahedral twist of the square base defined by a dihedral angle between the CuN_2 and CuNO planes is at a high value of 36.0° and consequently, the copper atom is displaced 0.36 Å from its individual plane. The Cu···Cu separation is 3.200(1) Å, while the Cu–N_{azido}–Cu bridging angle is 101.2(1)°. An oxygen atom of the acetato ligand is at a distance of 2.997(2) Å from the copper(II) atom, which is also too long to be considered as a semi-coordination bond. The crystal lattice is stabilized by hydrogen bonding between the amine N and an oxygen atom of neighboring formato group with a N···O contact of 2.864(9) Å leading to the formation of the 2D network. Details of the hydrogen bonding are listed in Table 3.

3.3. Crystal structure of $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_2CH_3)_2]$ (3)

Compound **3** is made up of one-half $[Cu(dpyam)(\mu_{1,1}\text{-}N_3)(O_2CCH_2CH_3)]^+$ moiety, which the other half being symmetry related via a centre of symmetry. This unit depicted in Fig. 3. Selected bond distances and angles are reported in Table 4. Each copper(II) ion is five coordinated in the form of distorted square pyramidal geometry ($\tau = 0.30$) of the CuN_4O chromophore (see Fig. 4c). The square base comprises two nitrogen atoms of the dpyam ligand (Cu–N distances 2.011(1), 1.999(1) Å), an oxygen atom of the propionato ligand (Cu–O distance 1.960(1) Å) and a nitrogen atom of the azido ligand (Cu–N distance 2.006(1) Å), with a tetrahedral twist between the CuN_2 and CuNO planes of 21.0°. The coordination of the apical position is formed by a nitrogen atom from another azido anion (Cu–N distance 2.348(1) Å). Both copper(II) atoms of the compound are linked through a double azido bridge in an end-on bridging mode from the equatorial position of one copper chromophore to the axial position of the other one. Both square bases are parallel in a partial face-to-face manner. The copper atom is displaced 0.16 Å from the square plane. The Cu···Cu separation is 3.247 Å, while the Cu–N_{azido}–Cu bridging angle is 96.2(1)°. The dpyam ligand is non-planar, a dihedral angle of 17.3° occurs between the individual pyridine rings and the dpyam bite angle is 89.2(1)°. An oxygen atom of the propionato ligand is at a distance of 2.848(1) Å from the copper(II) atom, which is too long to be considered as a semi-coordination bond. The hydrogen bonding involving the amine N and an oxygen atom of acetato group with a N···O contact of 2.796(7) Å. leads to the formation of the 2D network. Details of the hydrogen bonding are listed in Table 4.

3.4. Spectral characterization

3.4.1. Electronic and IR spectra

The IR spectra show an intense absorption peak at 2062, 2060 and 2047 cm^{-1} for compounds **1**, **2** and **3**, respectively, which can be assigned to the $\nu_{as}(N_3)$ stretching vibration of the azide ligand in the end-on coordination mode. The strong bands at 1581, 1340 cm^{-1} for **1**, 1567 and 1402 cm^{-1} for **2** and 1555, 1426 cm^{-1} for **3** are assigned to the $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ modes of the carboxylate group within a dinuclear species.

The electronic diffuse reflectance spectrum of **3** shows an asymmetric broad band at 14 890 cm^{-1} and low-energy

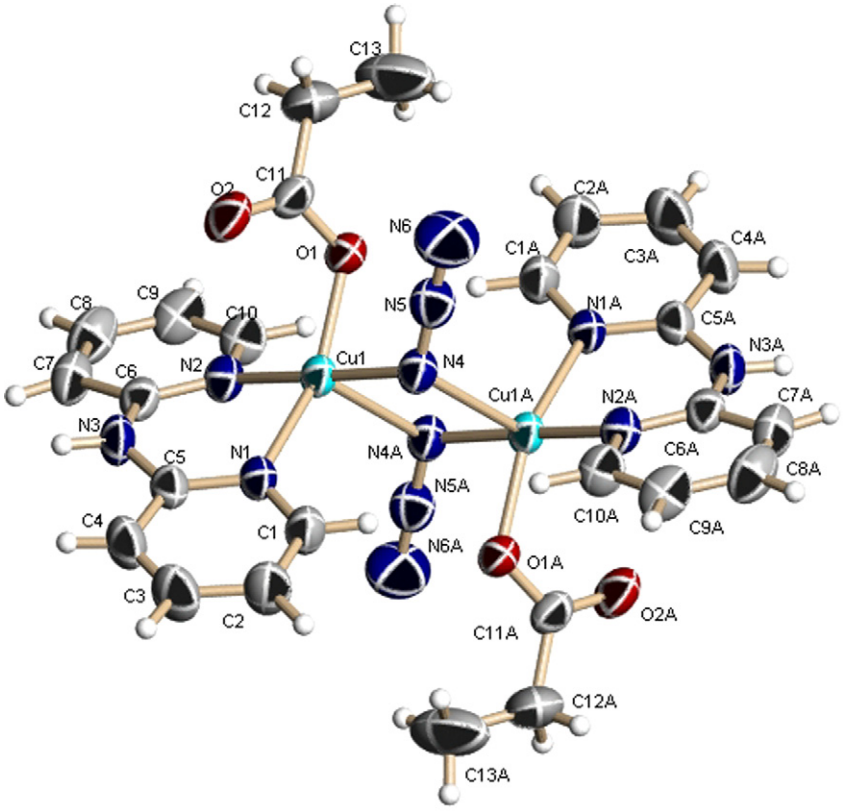

Fig. 3. ORTEP 50% probability plot of $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_2CH_3)_2]$ (**3**).

Hydrogen bonds	D–H	H···A	D···A	D–H···A
N(3)–H(5)···O(2) [1/2 − x, 1/2 + y, 1/2 − z]	0.86	1.93	2.796(7)	177

shoulder at 11 580 cm^{-1}. This feature is consistent with the distorted square pyramidal geometry and the d_{z^2}, d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ and $d_{xy} \rightarrow d_{x^2-y^2}$ transitions, respectively. Incase of compounds **1** and **2**, the spectrum shows two bands with nearly equal intensity at 12 980 and 9660 cm^{-1} (for compound **1**) and 12 580 and 9690 cm^{-1} (for compound **2**). The unusual apparent at low frequencies in **1** and **2** arises due to large tetrahedral twist of the square base and a shorter axial bond distance as compared to those of **3**. However, both bands of **1** and **2** are assigned to be the $d_{xy}, d_{yz}, d_{xz} \rightarrow d_{x^2-y^2}$ and $d_{z^2} \rightarrow d_{x^2-y^2}$ transitions [29].

3.4.2. EPR and magnetic properties

The EPR spectra of compounds **1** and **2** were recorded as a polycrystalline powder at RT and 77 K from 0 to 800 mT at X-band frequency ($h\nu = 0.325$ cm^{-1}).

The observed EPR spectrum of compound **1** and **2** reveals typical triplet spectra with a zero-field splitting parameter $D < h\nu$. The spectra are almost identical for both

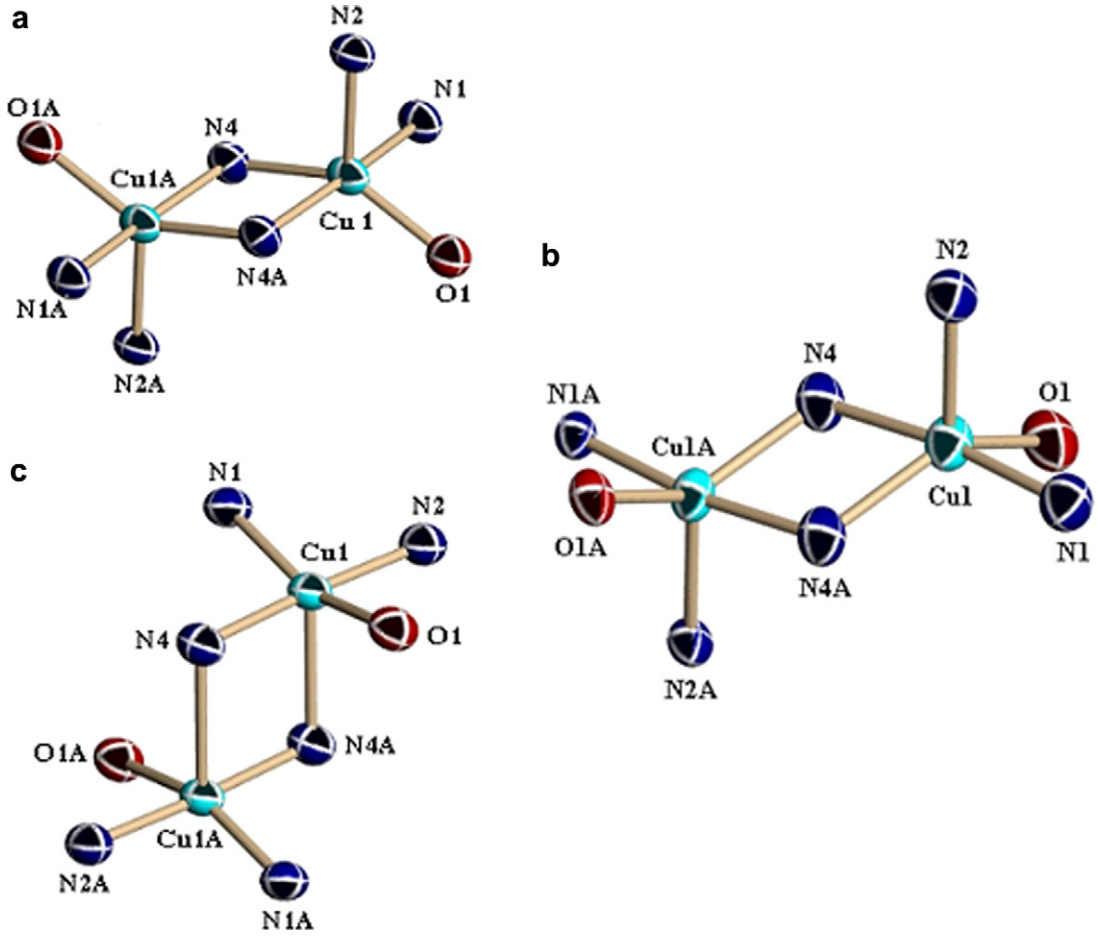

Fig. 4. The chromophore of (a) $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CH)_2]$ (**1**), (b) $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2(O_2CCH_3)_2]$ (**2**) and (c) $[Cu_2(dpyam)_2(\mu_{1,1}\text{-}N_3)_2\text{-}(O_2CCH_2CH_3)_2]$ (**3**).

compounds and hardly no change is observed at RT and 77 K. Two representative EPR spectra are given as Fig. 5 (compound **1** at RT) and Fig. 6 (compound **3** at RT). Others are given as supplementary material. Compound **1** shows very broad absorptions (at RT) at 110, 250 and 460 mT (110, 275 and 490 mT for compound **2**), which are too broad for assignment and/or simulation. A rough estimate for the zero-field splitting is 0.4 cm^{-1}. The sharp weak absorptions at around 320 mT are from monomeric impurity.

The EPR spectrum of compound **3** was recorded at RT and 77 K from 220 to 420 mT, and both show an axial $S = 1/2$ spectrum with a $g_\perp$ of 2.09 and unresolved $g_\parallel$ of 2.26. These values are in agreement with a $d_{x^2-y^2}$ ground state [29].

At RT a very weak half-field signal is observed at 160 mT, typical for dinuclear species. However, at 77 K this signal is not observed. The observed EPR spectra are in agreement with the magnetic behaviour of the three compounds (vide infra).

The magnetic susceptibility of all three compounds has been measured from 5 to 300 K. The magnetic properties of the compounds are depicted in Figs. 7–9, for compounds **1**–**3**, respectively, in the form of μ_{eff} versus T plots for one copper(II) ion. Compounds **1** and **2** show a very similar magnetic behaviour. At 300 K the μ_{eff} is 1.89 μ_B per copper ion for compound **1** (1.84 μ_B, for **2**), which is somewhat

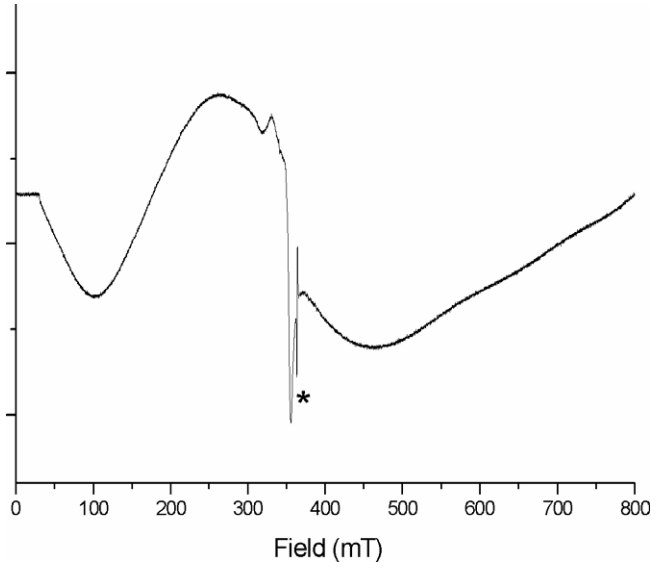

Fig. 5. EPR spectrum of compound **1** at RT (the starred peak is the internal reference, DPPH).

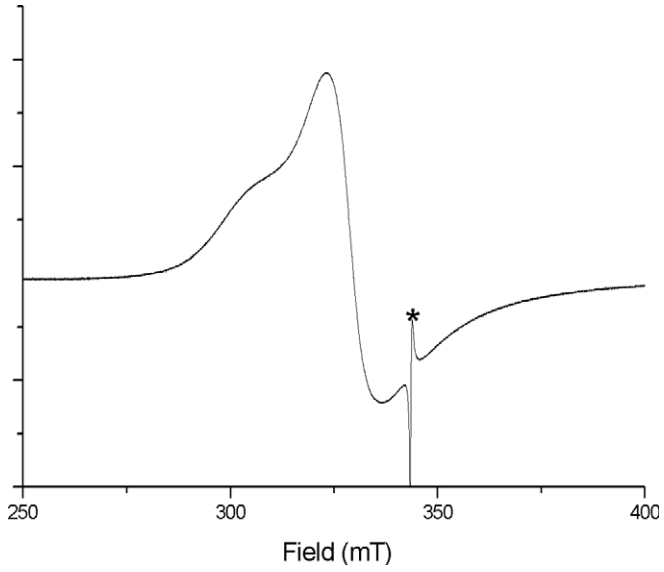

Fig. 6. EPR spectrum of compound **3** at RT (the starred peak is the internal reference, DPPH).

above the spin-only value for a single uncoupled spin $S = 1/2$ copper(II) centre. Upon cooling it raises gradually to reach 2.02 and 2.04 μ_B, at around 25 K, for compounds **1** and **2**, respectively. This behaviour is typical for medium to strong ferromagnetically coupled copper(II) dinuclear compound. Below that temperature, μ_{eff} then diminishes till a value around 1.92 μ_B for compound **1** (2.00 μ_B for **2**) at 5 K, which may originate from intermolecular antiferromagnetic interactions, or from the paramagnetic impurities present in the samples (vide infra).

The magnetic properties of compound **3** differ from that of compounds **1** and **2**. At 300 K the μ_{eff} is 1.74 μ_B per copper ion for compound **3**, which is about the spin-only value calculated for an uncoupled spin $S = 1/2$ copper(II) centre. Upon cooling, this value stays almost constant till about 50 K, where it increases gradually to reach 1.86 μ_B, at

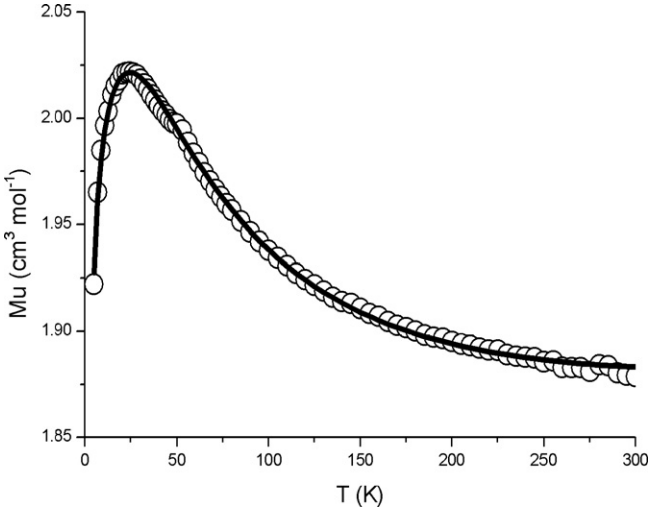

Fig. 7. A plot of the temperature dependence of μ_{eff} vs. T per Cu(II) ion for compound **1**. The solid line represents the calculated curve (see text).

5 K (see Fig. 8). This magnetic behaviour is typical for very weak ferromagnetically coupled copper(II) ions in a dinuclear compound.

The theoretical expression for the magnetic susceptibility for two interacting $S = 1/2$ centers, based on the general Hamiltonian [30] is: $H_{ex} = -JS_1S_2$, in which the exchange parameter J, is negative for antiferromagnetic and positive for ferromagnetic interaction. The magnetic data were fitted to the equation given in the literature for dinuclear copper compounds ([30], p. 132):

$$\chi_m = (2Ng^2\beta^2)[kT - (2zJ'/(3 + \exp(-J/kT)))]^{-1} \times [3 + \exp(-J/kT)]^{-1}(1 - p) + \chi_p p + \mathrm{TIP},$$

in which N, g, β, k and T have their usual meanings.

The parameter p denotes the fraction of paramagnetic impurity in the sample and zJ' refers to the interaction between neighbouring dinuclear identities. A temperature

independent paramagnetism (TIP) was also considered and fixed at 60×10^{-6} per copper ion. The fit was accomplished by minimisation of $R = \sum(\chi_m \cdot T_{calc} - \chi_m \cdot T_{obs})^2/(\chi_m \cdot T_{obs})^2$ by least-squares procedure. The best fit was obtained for compound **1** with the following values: $J = 63.3\ cm^{-1}$, $g = 2.06$, $zJ' = -3.3\ cm^{-1}$, $p = 0.04$, with a final R of 2.0×10^{-4} (see solid line in Fig. 7). For compound **2** these values are $J = 63.8\ cm^{-1}$, $g = 2.05$, $zJ' = -0.8\ cm^{-1}$, $p = 0.01$, with a final R of 9.0×10^{-5} (see solid line in Fig. 8). For compound **3** these values are $J = 5.1\ cm^{-1}$, $g = 2.02$, $zJ' = -2.2\ cm^{-1}$, $p = 0.06$, with a final R of 1.5×10^{-3} (see solid line in Fig. 9). These values are in agreement with the structural results (see Section 4).

3.4.3. Comparison of structures and magnetic properties

The compounds together with a number of related dinuclear copper(II)-azido compounds are listed in Table 5 in which two copper(II) atoms are bridged through two bridging azide anions with the basal–basal coordination; $[Cu_2(N_3)_2(4\text{-Etpy})_4(NO_3)_2]$ (**13**) and $[Cu_2(N_3)_2(3\text{-mpy})_4(NO_3)_2] \cdot C_2H_5OH$ (**14**) [15], and basal–apical mode; $[Cu(terpy)(N_3)(H_2O)]_2(PF_6)_2$ (**4**) and $[\{Cu(terpy)(N_3)\}_2](PF_6)_2$ (**9**) [9], $[Cu(bipy)(N_3)_2]_n$ (**5**) ($s = 0.06$) [34], $[Cu(dpp)(N_3)_2]_n$ (**6**) ($s = 0.12$) [31], $[Cu(aepi)(N_3)_2]_2$ (**7**) ($s = 0.15$) [2], $[L_2(N_3)_2Cu_2]$ (**8**) ($s = 0.18$) [33], $[Cu(L^1)(N_3)]_2$ (**10**) ($s = 0.02$), $[Cu(L^2)(N_3)]_2$ (**11**) ($s = 0.17$) and $[Cu(L^3)(N_3)]_2$ (**12**) ($s = 0.26$) [33]. For compounds with the basal–basal coordination, **13** and **14** are strong ferromagnetic with the high J values of 230.1 and 223.2 cm^{-1}, corresponding to the small θ angles of 98.2° and 97.5°, respectively (<108.5°) [11–14]. The present compounds **1** and **2** which involve the larger θ angles, 101.1° and 101.2°, respectively (<108.5°) reasonably provide a weaker ferromagnetic coupling. In addition, the marked distortion in Cu(II) geometry of both compounds may also be responsible for the lower J values of **1** and **2**, lower than expected, leading to a medium strong ferromagnetic interaction. In the case of basal–apical bridging fashion as in other remaining compounds in Table 5 including the present compound **3**, θ is not the determining factor of magnetic nature [15]. Their magnetic properties are weak ferromagnetic, compounds **3**, **8** and **12**, or weak antiferromagnetic interaction, compounds **4**–**7** and **9**–**11**. In these compounds the bridges connect an equatorial site with a high spin density to an apical site which has a weak spin density explaining the weak interaction observed.

4. Conclusion

In this paper we have presented the synthesis and magnetic study of three new azido-bridged copper(II) compounds with dpyam. The coordination geometry around each copper(II) ion is distorted square pyramidal for all three compounds. The azide ions in the compounds bridge two copper centers through one nitrogen atom (end-on bridging mode). Both azido bridges in compounds **1** and **2** involve the basal–basal coordination while each bridging N atom in compound **3** occupies an equatorial position on Cu1 and an axial position on Cu1A. The strong magnetic interaction requires good σ orientation of magnetic orbitals and superexchange properties of bridging ligand. In the basal–basal type of compounds **1** and **2**, the magnetic orbital is $d_{x^2-y^2}$ for copper center directed toward the bridging azido ligand corresponding to a medium strong ferromagnetic interaction, but a reduction of the ferromagnetic contribution will be observed when the geometry becomes distorted. The overlap of the orbitals thus becomes weaker and also such interaction becomes weaker. For compound **3**, the coupling is very small as the magnetic orbital of a $d_{x^2-y^2}$ type lying in the basal plane of the copper center and has only a small contribution on the axis perpendicular to the basal plane. All three compounds display a dominant ferromagnetic behaviour, but the magnitude of the exchange interaction is much smaller in the case of **3**.

Abstract

A new complex, $\{[CuL(\mu_{1,5}\text{-dca})(dca)]\}_n$ (**1**), has been synthesized from the reaction of $Cu(NO_3)_2 \cdot 3H_2O$, *N*,*N*-diethyl-1,2-ethanediamine (L) and sodium dicyanamide (Nadca) in aqueous medium. Single crystal X-ray analysis reveals that the complex has a 1D infinite zigzag chain structure in which copper(II) ions are bridged by single dicyanamide ligands in an end-to-end fashion. The chains propagate parallel to the crystallographic *b*-axis and they are stacked one upon another along the *c*-axis. The coordination environment of the copper(II) centers are distorted square-pyramidal. Of the four coordination sites of the basal plane of the square-pyramid, two are occupied by the nitrogen atoms of the diamine and the remaining two sites are occupied by the terminal nitrogen atoms of the bridging dca groups. One terminal nitrogen atom of a monodentate dca group occupies the apical position of the coordinated polyhedra. [CuL(dca)] units are then connected to each other through a $\mu_{1,5}$-dca bridge to form 1D chains. The variable temperature magnetic susceptibility measurements evidenced weakly antiferromagnetic interactions ($J = -0.35\ cm^{-1}$) in $\{[CuL(\mu_{1,5}\text{-dca})(dca)]\}_n$ (**1**).

Keywords: Dicyanamide; Copper diamine complex; 1D chain; Antiferromagnetic; X-ray crystal structure

1. Introduction

Pseuohalide bridged transition metal containing coordination polymers have long been studied for their interesting magnetic properties [1,2]. Recently, the larger pseudohalide ligand dicyanamide $[N(CN)_2]^-$ (dca) has attracted a lot of attention due to the discovery of long-range magnetic ordering in the 3D systems α-$M(dca)_2$, M = Cr, Mn, Fe, Co, Ni, Cu [3–5]. In this context, variability of the coordination modes of the dca ligand is particularly interesting, which allows the preparation of compounds with various kinds of architectures: mononuclear, polynuclear, as well as 1D, 2D and 3D networks [6]. The copper(II) ion often adopts a five-coordinated structure due to plasticity of its coordination geometry. Quite a few 1D compounds have been reported in which pseudohalogens connect adjacent metal ions along the chain due to the flexibility in the coordinating ability of the copper(II) ions [1,7,8]. 1D chain compounds, $\{[CuL1(\mu_{1,5}\text{-dca})(dca)]\}_n$ with L1 = 2,2′-bipyridine or 2,2′-bipyridylamine have been reported where copper(II) ions are bridged by a single $\mu_{1,5}$-dca group [9–11]. While a weak antiferromagnetic coupling between copper(II) centers has been observed for the complexes with 2,2′-bipyridine, no significant magnetic coupling was observed in $\{[Cu(2,2'\text{-bipyridylamine})(\mu_{1,5}\text{-dca})(dca)]\}_n$. Magnetic interactions through dca bridges are generally weak but their nature, *i.e.* ferromagnetic or antiferromagnetic cannot

doi:10.1016/j.poly.2006.08.037

be easily predicted due to the need of successful theoretical models to analyze the magneto-structural correlations of these systems which thus deserve more studies. As a result, studies on dca bridged compounds have received intense attention in recent times [6,12–14]. Particularly, 1D chain compounds with a linear or zigzag geometry are of current interest in magnetochemistry and condensed matter physics due to the possibility of generating Haldane gap type systems and single chain magnets [15–17].

In the present study, we report the synthesis, X-ray crystal structure and magnetic study of a new 1D infinite chain compound $\{[CuL(\mu_{1,5}\text{-dca})(dca)]\}_n$ ([L = *N*,*N*,-diethyl-1,2-ethanediamine)] (**1**).

2. Experimental

2.1. General

Copper(II) nitrate trihydrate (Aldrich) and sodium dicyanamide (Aldrich) were used without further purification. All other chemicals used were of AR grade. The instruments used for measurements were reported earlier [18].

2.2. Synthesis of $\{[CuL(\mu_{1,5}\text{-dca})(dca)]\}_n$ (1)

$Cu(NO_3)_2 \cdot 3H_2O$ (0.25 mmol, 60 mg) and *N*,*N*-diethyl-1,2-ethanediamine (0.25 mmol, 27 mg) were dissolved together in 10 ml of water, which produced immediately a blue colored solution. To this, an aqueous solution of dca (0.5 mmol, 44 mg) was added with stirring. The resulting solution was then filtered and allowed to evaporate slowly at room temperature. Deep blue rhomboid crystals of complex (**1**) appeared in 10 days. The crystals were filtered, washed with water and dried in air (Yield 85%). *Anal*. Calc. for $C_{20}H_{32}Cu_2N_{16}$: C, 38.5; H, 5.1; N, 35.9. Found: C, 38.2; H, 4.7; N, 35.3%. IR spectra (KBr): ν_s(C≡N), 2140; ν_{as}(C≡N), 2220; ν_s(C≡N) + ν_{as}(C≡N), 2260; ν_{as}(C—N), 1380 cm^{-1}.

2.3. X-ray crystallography

2.3.1. Crystal data

$C_{10}H_{16}N_8Cu$, $M =$ 311.84, monoclinic, space group $P2_1/n$, $a = 7.3479(2)$, $b = 12.2358(4)$, $c = 32.6615(11)$ Å, $\beta = 91.1491(5)°$, $V = 2935.92(16)$ Å^3, $Z = 8$, $D_{calc} = 1.411$ g cm^{-3}, $F_{000} = 1288$, $\mu = 1.489$ mm^{-1}, green block crystal, dimensions = 0.35 × 0.35 × 0.10 mm, $T = 296.1$ K.

2.3.2. X-ray single crystal structure determination of (1)

A rectangular blue single crystal of complex (**1**) was selected for collecting X-ray data. All measurements were made on a Rigaku AFC7 diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71070$ Å) equipped with a Rigaku Mercury CCD detector. Of the 22 392 reflections that were collected, 12 388 ($R_{int} = 0.030$) were unique. The collected intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction was also employed. Data were collected and processed using the CRYSTALCLEAR (Rigaku) program [19]. The structures were solved by direct methods (SIR 97) [20] and expanded using Fourier techniques. Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically. Hydrogen atoms were refined using the riding model. The final cycle of full-matrix least-squares refinement was converged with unweighted and weighted agreement factors of 0.0568 and 0.2098, respectively. All calculations were carried out using CRYSTALSTRUCTURE [21], CRYSTALS [22] and PLATON [23]. The molecular graphics software used were ORTEP III [24] and MERCURY [25].

3. Results and discussion

3.1. X-ray structure of complex (1)

The ORTEP diagram of the asymmetric unit of (**1**) with the atom numbering scheme is shown in Fig. 1. Selected bond lengths and angles of complex (**1**) are listed in Table 1. The geometry around the copper centers could be described as distorted square-pyramidal with the basal planes defined by two nitrogen atoms of coordinated diamine and two terminal nitrogen atoms of the bridging dca ligand (N1, N2, N11, N14 for Cu1; N6, N7, N13, $N16^i$ for Cu2), while the coordinated nitrogen atoms of the monodentate dca ligand occupy the apical positions (N3 and N8) (symmetry operation i = $x, y - 1, z$). The crystal structure of complex (**1**) is characterized by [CuL($\mu_{1,5}$-dca)(dca)] units linked into 1D polymeric chains where one dca anion connects the copper(II)ion of the symmetry related unit in an end-to-end bridging mode. The chains propagate parallel to the crystallographic *b*-axis while they are stacked one upon another along the crystallographic *c*-axis (Fig. 2). The chains are connected with each other through strong H-bonds between amine hydrogen and terminal nitrogen atoms of the monodentate dca ligand (*vide infra*). The $\{N(CN)_2\}^-$ ligands present in complex (**1**) are bent around the amide nitrogen atom through an angle *ca.* 124°. The trigonality index τ (=$(\phi_1 - \phi_2)/60$, where ϕ_1, ϕ_2 are the two largest L–M–L angles of the coordination sphere) has been calculated for the penta-coordinated copper sites [26]. The τ values are found to be 0.46 and 0.35 for Cu1 and Cu2, respectively, confirming the square-pyramidal character of both the copper sites ($\tau = 0$ infers a perfect square-pyramid, and a $\tau = 1$, a perfect trigonal bipyramid). This is also apparent in the large variation of the basal N–Cu–N (*trans*) angles (176.1–148.4° for Cu1, 173.2–152.4° for Cu2). The Cu–N (basal) bond distances in complex (**1**), ranging between 1.971(4)–2.202(6) Å for Cu1 and 1.975(5)–2.121(4) Å for Cu2 (Table 1), are consistent with the corresponding values reported for analogous copper(II) systems [27,28]. The shortening of the Cu–N basal bond lengths in comparison to the Cu–N(apical) lengths [1.955(6)–2.185(5)] Å is a result of the Jahn–Teller

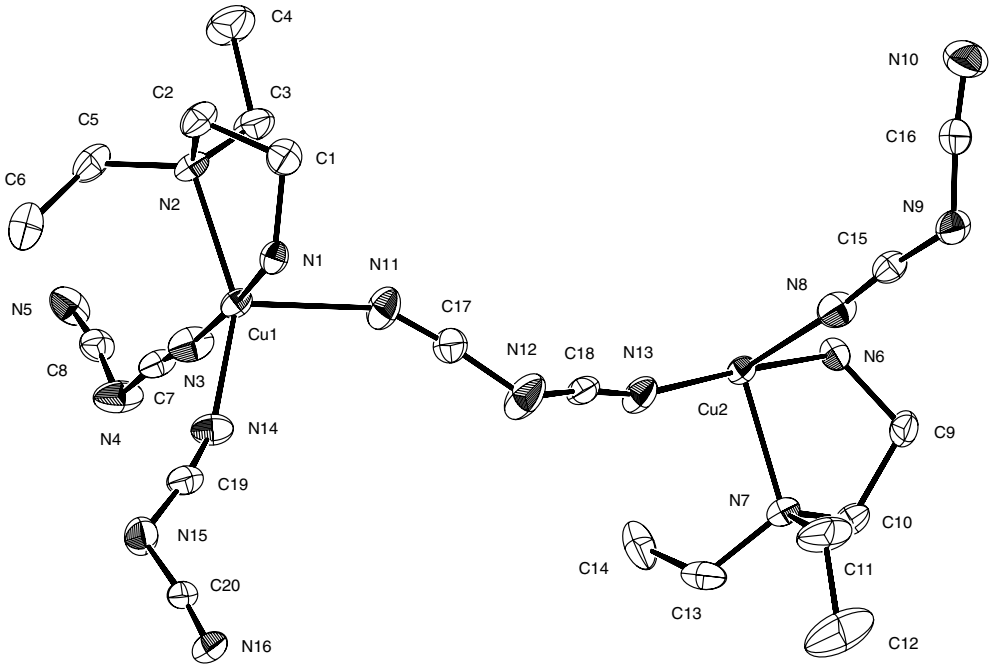

Fig. 1. ORTEP diagram of complex (**1**) showing the atom numbering scheme.

effect for the d^9 configuration of the Cu^{II} ion in a square-pyramidal environment. The Cu···Cu distances in complex (**1**) were *ca.* 8.054–8.314 Å which are rather long to have effective magnetic coupling.

Fig. 2 shows H-bonded infinite 1D zigzag chains of $\{[CuL(\mu_{1,5}\text{-dca})(dca)]\}_n$ (**1**) that extend along the crystallographic *b*-axis. Intermolecular N–H···N hydrogen bonds, N1···N5^{ii} 2.982(16) Å, H1···N5^{ii} 2.050 Å, N1–H1···N5^{ii}

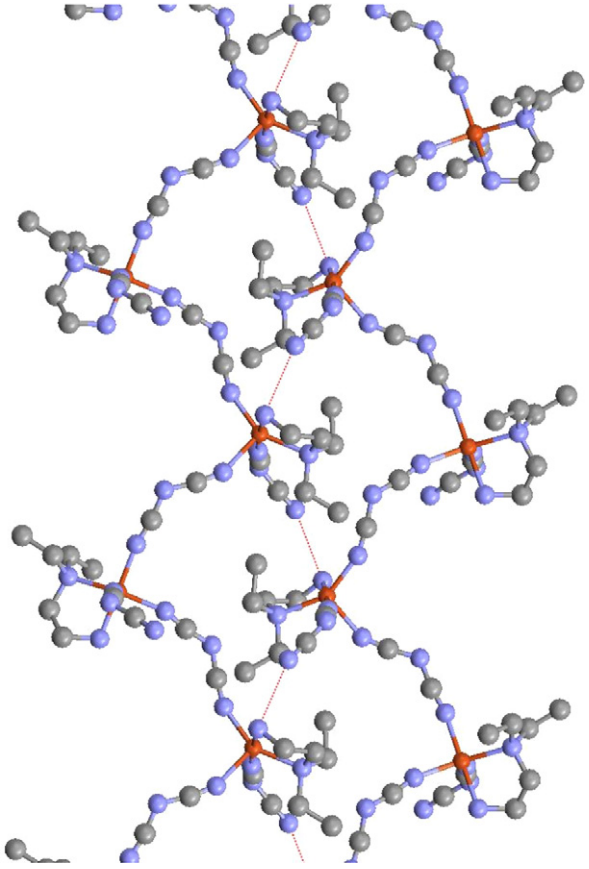

Fig. 2. Diagram showing stacking of 1D chains of complex (**1**). Red dotted lines denote the H-bonding as discussed in the text. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

166.24° interlink the chains via the amine hydrogen and terminal nitrogen atoms of the monodentate dca ligands (symmetry operation ii = $1/2 - x, 1/2 + y, 1/2 - z$).

3.2. Magnetic study

The temperature dependence of the molar magnetic susceptibility, χ_M, for complex (**1**) in the 2–290 K temperature range was measured with a superconducting quantum interference device (SQUID) magnetometer, under magnetic fields of 1 T and it is shown in Fig. 3. The $\chi_M T$ value (per Cu^{2+} ion), 0.44 $cm^3\ mol^{-1}$ K, at 290 K for complex (**1**) is slightly higher than the expected value for an isolated magnetically uncoupled copper(II) ion ($\chi_M T = 0.37$ $cm^3\ mol^{-1}$ K for $g = 2.0$). Upon cooling the $\chi_M T$ value of complex (**1**) remains almost unchanged until *ca.* 40 K, and then decreases rapidly to reach 0.38 $cm^3\ mol^{-1}$ K at around 2 K, which clearly indicates that the magnetic interaction between the copper(II) ions is antiferromagnetic.

In order to explain the magnetic properties of complex (**1**), a simple case of an isotropic infinite chain model that is provided by an array of equally spaced copper(II) ions bridged through $\mu_{1,5}$-dca ligands with $S = 1/2$ local spins has been considered. The spin Hamiltonian of such a system can be written as $H = -J \sum \hat{S}_{Ai} \cdot \hat{S}_{Ai+1}$. For an infinite 1D chain system no analytical method is available to determine the energies of low-lying states and magnetic susceptibility. However, a numerical expression that may be used to fit the magnetic susceptibility data is given by Estes et al. [29]:

$$\chi_M = \frac{Ng^2\beta^2}{kT} \frac{0.25 + 0.074975x + 0.075235x^2}{1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3} \quad (1)$$

where $x = |J|/kT$. Fitting of the magnetic susceptibility data with Eq. (1) yielded the parameter values $J = -0.35(0.04)$ cm^{-1}, $g = 2.2(0.1)$, with an agreement factor $R = 1.8 \times 10^{-8}$. Fig. 3 shows the result of this fit. As can be seen in Fig. 3, the χ_M versus T curve does not go through a rounded maximum for complex (**1**), a feature which is usually observed for a bulk antiferromagnetic systems. This indicates the complex $\{[Cu_2L_2(\mu_{1,5}\text{-dca})_2(dca)_2]\}_n$ (**1**) does not show any long-range ordering up to 2 K. T_{max}, the temperature at which χ_M becomes a maximum could be calculated for a bulk antiferromagnetic system using Bonner and Fisher's equation [30], $kT_{max}/|J| = 0.641$. T_{max} in the case of complex (**1**) is found to be 0.57 K. Hence, we did not reach a low enough temperature to observe a folded-knee type χ_M versus T plot for complex (**1**). The magnetic interaction for single end-to-end dicyanamido zigzag 1D chain compounds *viz.* $\{[Cu(2,2'\text{-bipyridine})(\mu_{1,5}\text{-dca})(dca)]\}_n$ ($J = -0.10$ cm^{-1}) and $\{[Cu(pyim)(\mu_{1,5}\text{-dca})(H_2O)]\}_n$ ($J = -0.35$ cm^{-1}) [pyim = 2-(2-pyridyl)-imidazole] is antiferromagnetic [9–11]. However, the magnetic interaction in linear 1D chains of an octahedral copper(II) complex bridged by tricyanomethanide is reported to be ferromagnetic [31].

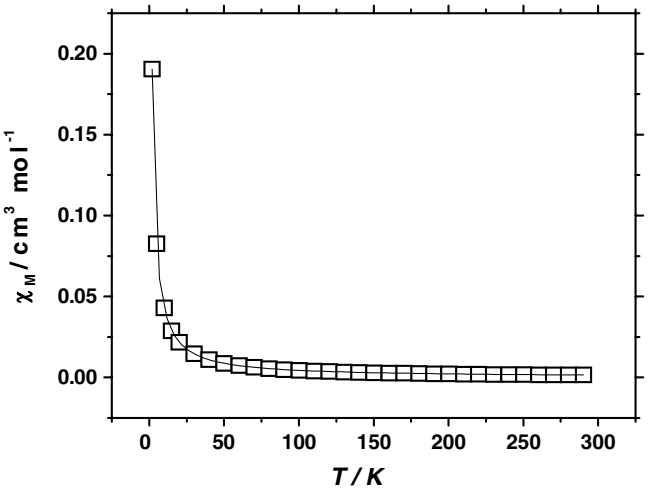

Fig. 3. χ_M vs. T (□) plot for complex (**1**). Solid lines represent the best fit of the data with the model described in the text.

4. Conclusion

Summarizing the above discussion we can conclude that we have synthesized a new 1D infinite zigzag chain compound, $\{[CuL(\mu_{1,5}\text{-dca})(dca)]\}_n$. The magnetic measurement shows that the coupling between copper(II) ions is antiferromagnetic. Dicynamide in this case also is found to be a weak antiferromagnetic coupler as reported earlier [9–11,32]. The result is, however, not inconsistent with the theoretical prediction based on extended Hückel calculations [33].

5. Supplementary materials

CCDC 609951 contains the supplementary crystallographic data for (**1**). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Three new metal–radical complexes of the formula $[M(NITm\text{-}Py)_2(N_3)_2(DMSO)_2]$ [M = Cu(II) **1**, Ni(II) **2**, Co(II) **3**; NITmPy = 2-(3′-pyridyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide] were synthesized and characterized structurally as well as magnetically. Three complexes are three-spin complexes in which two NITmPy radical ligands are coordinated to the metal ion through the nitrogen atoms of the pyridyl rings. The magnetic behaviors of the three complexes are investigated. Complexes **1** and **2** show ferromagnetic interactions while antiferromagnetic coupling is predominant for complex **3**. The magnetic properties are analyzed in connection with their structures and the magnetic exchange mechanism is discussed.

1. Introduction

In the field of molecular-based magnetic materials, the coordination of paramagnetic metal ions with organic radical molecules has become a very promising strategy. By employment of this strategy, a large number of metal–radical complexes with various structures have been synthesized and magnetically characterized [1–5]. Some of these complexes show spontaneous magnetization with T_c up to 46 K [6].

It has been a pursuing goal to obtain new bulk molecular-based magnets with a high critical temperature and this has been directed in the preparation of 2D and even 3D metal–radical complexes [7–9]. However, recently some intense interesting discrete molecules have been prepared by using the metal–radical approach. Rey et al. have reported that the reaction of $Cu(hfac)_2$ with nitronyl nitroxide leads to a molecular cluster exhibiting a molecular spin transition [10]; Koga and coworkers have obtained cobalt(II) complexes with *N*-*tert*-butylnitroxides showing interesting magnetic relaxation behavior in frozen solution [11]. On the other hand, discrete metal–radical complexes with a definite geometry are good candidates for the fundamental studies of magneto-structural correlations, especially how the structural factors affect the metal–radical interactions. Such investigation is necessary not only for understanding the magnetic exchange mechanism between the metal and organic radical but also for guiding the design of new organic radical ligands for the development of novel molecular magnetic materials [12]. With this in mind, here we report three new coordination complexes involving nitronyl nitroxide ligands and azide, namely, $[M(NITmPy)_2(N_3)_2(DMSO)_2]$ [M = Cu(II), Ni(II), Co(II); NITmPy = 2-(3′-pyridyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide].

2. Experimental

2.1. General

All reagents were purchased from commercial sources and were used as received. 2-(3′-Pyridyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide (NITmPy) was prepared by the literature method [13]. Elemental analyses for C, H and N were carried out with a Perkin–Elmer 240 elemental analyzer. The infrared spectra were recorded in KBr pellets in the range 4000–400 cm^{-1} on a Bruker Tensor 27 IR spectrometer. Variable-temperature magnetic susceptibilities were measured on a MPMS XL-7 SQUID magnetometer. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms.

2.2. Synthesis

$[Cu(NITmPy)_2(N_3)_2(DMSO)_2]$ (**1**): A methanol solution (10 mL) of NaN_3 (0.026 g, 0.4 mmol) was added to a methanol solution (20 mL) of $Cu(NO_3)_2 \cdot 3H_2O$ (0.0483 g, 0.2 mmol) and NITmPy (0.0936 g, 0.4 mmol). After the resulting blue solution was stirred for 2 h, 5 mL of DMSO was added. Further stirring for another 1h gave rise to a blue solution. Dark blue single crystals suitable for X-ray analysis were obtained by slow evaporation at room temperature after two weeks. Yield 0.100 g (67%). *Anal.* Calc. for $C_{28}H_{44}N_{12}CuO_6S_2$: C, 43.50; H, 5.70; N, 21.75. Found: C, 42.86; H, 5.76; N, 21.43%. IR data (KBr, cm^{-1}): $\nu = 2040$ (s), 1600 (m), 1397 (s), 1320 (s).

$[Ni(NITmPy)_2(N_3)_2(DMSO)_2]$ (**2**): This complex was prepared by a procedure similar to that for **1**, using $Ni(NO_3)_2 \cdot 6H_2O$ instead of $Cu(NO_3)_2 \cdot 3H_2O$. Yield 0.076 g (50%). *Anal.* Calc. for $C_{28}H_{44}N_{12}NiO_6S_2$: C, 43.77; H, 5.73; N, 21.89. Found: C, 44.40; H, 5.52; N, 20.89%. IR data (KBr, cm^{-1}): $\nu = 2042$ (s), 1605 (m), 1370 (s), 1323 (s).

$[Co(NITmPy)_2(N_3)_2(DMSO)_2]$ (**3**): This complex was prepared by a procedure similar to that for **1**, using $Co(CH_3COO)_2 \cdot 4H_2O$ instead of $Cu(NO_3)_2 \cdot 3H_2O$. Yield 0.046 g (30%). *Anal.* Calc. for $C_{28}H_{44}N_{12}CoO_6S_2$: C, 43.76; H, 5.73; N, 21.88. Found: C, 43.91; H, 5.65; N, 21.11%. IR data (KBr, cm^{-1}): $\nu = 2041$ (s), 1610 (m), 1375 (s), 1325 (s).

2.3. X-ray crystallographic study

Single crystal X-ray diffraction data for complexes **1** and **3** were collected on a Bruker SMART 1000 CCD diffractometer employing graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), while those of complex **2** were collected using a Bruker SMART APEXII CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structures were solved by direct methods and refined by full matrix least-squares on F^2 using SHELXS 97 [14] and SHELXL 97 [15] programs, respectively. Non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed in calculated positions and refined isotropically using a riding model. The crystallographic data for complexes **1**–**3** are listed in Table 1, and selected bond lengths and angles are listed in Table 2.

3. Results and discussion

3.1. Description of the crystal structures

3.1.1. *[Cu(NITmPy)$_2$(N$_3$)$_2$(DMSO)$_2$] (**1**)*

An ORTEP drawing of **1** is shown in Fig. 1. The whole molecule is centrosymmetric and two paramagnetic radical ligands NITmPy are *trans*-coordinated to the copper(II) ion. The copper(II) ion is located in a 4 + 2 coordination environment in which the basal plane is formed by two nitrogen atoms (N(1), N(1A)) from the pyridyl rings of the NITmPy ligands with a Cu–N bond length of 2.040(2) Å and another two nitrogen atoms (N(4), N(4A)) from two azido ligands with a Cu–N bond length of 1.997(2) Å. The apical positions are occupied by two oxygen atoms (O(3), O(3A)) from two DMSO molecules with a Cu–O bond distance of 2.454 Å, which is significantly longer than the basal distances. The dihedral angle between the pyridyl ring and nitroxide group (O(1)–N(2)–C(6)–N(3)–O(2)) is 28.6°. The shortest contact between nitroxide groups is 4.044 Å. It should be noted that the closest contact is observed between the oxygen atom (O(2)) of the nitroxide group and the carbon atom (C′(3)) belonging to an adjacent molecule (O(2)–C′(3) = 3.357 Å) (shown in Fig. 2).

3.1.2. *[Ni(NITmPy)$_2$(N$_3$)$_2$(DMSO)$_2$] (**2**) and [Co(NITmPy)$_2$(N$_3$)$_2$(DMSO)$_2$] (**3**)*

Complexes **2** and **3** are isostructural and an ORTEP drawing of the molecular structure with the atomic labelling is shown in Fig. 3. The metal ion is located on an inversion center and adopts a distorted octahedral geometry. It is bound to two nitrogen atoms from the pyridyl rings of radical ligands and two oxygen atoms from DMSO molecules in the basal plane in addition to two azide ligands occupying the apical positions. The metal–N(pyridyl) bond distances are 2.103(2) and 2.159(2) Å for **2** and **3**, respectively, and the metal–O(DMSO) bond distances are 2.103(2) for **2** and 2.140(2) Å for **3**, whereas the metal–N(azido) bond distances are 2.067(2) and 2.084(2) Å for **2** and **3**, respectively, which are shorter than those of the basal plane. Thus, contrary to complex **1**, the metal ions of complexes **2** and **3** are in an axially compressed octahedral geometry. The dihedral angles between the pyridyl rings and NO–C–NO moieties are 27.5° and 28.2° for **2** and **3**, respectively. The shortest contacts between nitroxide groups are 4.102 and 4.144 Å for **2** and **3**, respectively. Similarly, the observed closest contacts between the oxygen atom of the nitroxide group and the carbon atom of an adjacent molecule are 3.395 and 3.380 Å for complexes **2** and **3**, respectively.

3.2. Magnetic properties and discussion

The temperature dependence of the magnetic susceptibilities for the three complexes was measured in the temperature range 1.8–300 K with an applied field of 2000 G. Fig. 4 shows the variation of the molar magnetic susceptibility in terms of the reciprocal of χ_M and μ_{eff} for complex **1**. The value of the effective magnetic moment μ_{eff} is 2.91 μ_B at 300 K, close to the spin-only value (3.0 μ_B) expected for three uncorrelated $S = 1/2$ spins with $g = 2.00$. As the temperature is lowered, the μ_{eff} value gradually increases and reaches a maximum of 3.41 μ_B at 7.0 K, then it decreases quickly. The variation of χ_M with temperature obeys the Curie–Weiss law as there is linear relationship between $1/\chi_M$ and T. The corresponding Curie constant (C) and Weiss constant (Θ) are found to be 1.08 $cm^3\,K\,mol^{-1}$ and 4.31 K. These results are characteristic of a system with a ferromagnetic interaction. Previous experimental and theoretical results have showed that the nitronyl nitroxide group of the radical has a large positive spin density, while large negative spin density is located on the sp^2 carbon atom bridging two NO groups, and there is weak alternative delocalization on the pyridyl ring [16,17]. This will lead to magnetic coupling between the metal ion and the

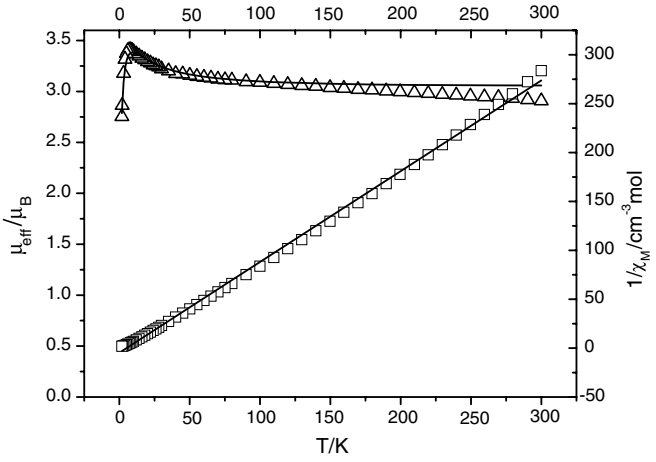

Fig. 4. Plot of $1/\chi_M$ (□) and μ_{eff} (△) vs. T for complex **1**. The solid line corresponds to the best theoretical fits.

NITmPy radical through the pyridyl ring, and NITmPy radical ligands through space. For complex **1**, according to the crystal structure, there are mainly three kinds of magnetic interactions, namely: (i) Cu(II) interacting with the coordinated NITmPy radical; (ii) magnetic coupling between neighboring NITmPy radicals through the NO···C pathway (3.357 Å); (iii) interaction between neighboring NO groups of NITmPy radicals through space (4.044 Å). The magnetic coupling between neighboring NO groups should be a weak antiferromagnetic interaction due to a rather large separation (4.044 Å) [18–20]. The magnetic interaction between neighboring NITmPy radicals through the NO···C pathway should be a weak ferromagnetic interaction because the closest contact involves the oxygen atom (O(2)) of an uncoordinated NO group which carries a large positive spin density and the carbon atom (C′(3)) of the adjacent NITmPy radical that carries a small negative spin density (O(2)···C′(3) = 3.357 Å) and these two atoms carrying opposite signs of the spin density alternate leading to ↑N″(3)–O″(2)↑···↓C′(3)–↑C′(4)–↓C′(6)–↑N′(3)–↑O′(2)···↓C(3), which matches McConnell's criteria [21]. The last two kinds of magnetic interactions should dominate at low temperature. Consequently, the experimental data was fitted to Eq. (1), derived from the spin Hamiltonian $\widehat{H} = -2J\sum(\widehat{S}_{Cu}\widehat{S}_R + \widehat{S}_{Cu}\widehat{S}_R)$. Considering the magnetic behavior at low temperature, the mean-field approximation, zJ', was introduced.

$$\chi_{tri} = \frac{N\beta^2}{4kT}\frac{g_3^2 + g_2^2\exp(-2J/kT) + 10g_1^2\exp(J/kT)}{1 + \exp(-2J/kT) + 2\exp(J/kT)} \quad (1)$$

$$\chi_M = \chi_{tri}/[1 - \chi_{tri}(2zJ'/Ng^2\beta^2)]$$

with

$$g_1 = (2g_{rad} + g_{Cu})/3$$

$$g_2 = (4g_{rad} - g_{Cu})/3$$

$$g_3 = g_{Cu}$$

The best fitting leads to $J = 7.43\ cm^{-1}$, $zJ' = -0.47\ cm^{-1}$, $g_{Cu} = 2.02$, $g_{rad} = 2.0$ (fixed), and $R = 1.13\times10^{-3}$ (R value is defined as $\sum[(\chi_M)_{obs} - (\chi_M)_{calc}]^2/\sum[(\chi_M)_{obs}]^2$). The fitting results indicate the magnetic interaction between copper(II) and the coordinated NITmPy radical is a ferromagnetic interaction.

The magnetic susceptibility data of complex **2** in form of $1/\chi_M$ and μ_{eff} versus T plots are given in Fig. 5. At room temperature, the μ_{eff} value is 3.92 μ_B, which is slightly higher than the expected value (3.79 μ_B) for isolated $S_{Ni} = 1$ and two $S_{rad} = 1/2$ spins. This value smoothly increases upon cooling and reaches a maximum of 4.37 μ_B at 8.0 K, and then decrease rapidly to 1.8 K. The magnetic susceptibility data follows the Curie–Weiss law with $C = 1.92\ cm^3\ K\ mol^{-1}$ and $\Theta = 2.85$ K. The results suggest a ferromagnetic interaction between the nickel(II) ion and NITmPy radical. Based on the crystal structure, the present magnetic system is similar to that of complex **1**. The magnetic interactions between neighboring NO groups of NITmPy radicals through space (4.102 Å) lead to weak antiferromagnetic interactions and the magnetic coupling between neighboring NITmPy radicals through the NO···C pathway (3.395 Å) results in weak ferromagnetic interactions. Therefore, the magnetic behavior of complex **2** can be explained by a theoretical expression (2) deduced from the spin Hamiltonian $\widehat{H} = -2J\sum(\widehat{S}_{Ni}\widehat{S}_R + \widehat{S}_{Ni}\widehat{S}_R)$, where J represents the magnetic interaction between the Ni(II) ion and the coordinated NITmPy radical. The weak antiferro- and ferromagnetic interactions and the zero field splitting of the nickel(II) ion were considered in the mean-field approximation as zJ'.

$$\chi_M = \frac{N\beta^2}{2kT}\frac{(g_{Ni} + g_R)^2(5 + e^{-4x}) + 4g_{Ni}^2e^{-2x}}{5 + 3e^{-4x} + e^{-6x} + 3e^{-2x}} \quad (2)$$

$$\chi_{total} = \chi_M/[1 - \chi_M(2zJ'/Ng^2\beta^2)]$$

The best fit to the experimental magnetic data gives following parameters: $g_{Ni} = 2.12$, $g_{rad} = 2.0$ (fixed), $J = 3.61\ cm^{-1}$, $zJ' = -0.31\ cm^{-1}$, $R = 1.0\times10^{-2}$. The fitting results show the nickel(II) ion is ferromagnetically coupled with the NITmPy radical ligand.

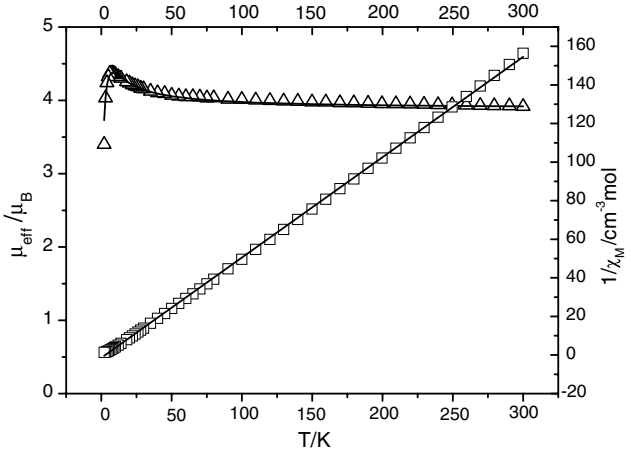

Fig. 5. Plot of $1/\chi_M$ (□) and μ_{eff} (△) vs. T for complex **2**. The solid line represents the best theoretical fits.

The magnetic behavior of complex **3** is shown in Fig. 6. The value of the μ_{eff} at 300 K is 5.57 μ_B, which is obviously larger than that expected for non-interacting $S_{Co} = 3/2$ and two $S_{rad} = 1/2$ spins (4.58 μ_B), indicating an unquenched orbital contribution. It can be seen that, with decreasing temperature, the μ_{eff} value continuously decreases to reach a minimum of 4.83 μ_B at 16.0 K and then it slightly increases to reach a small peak with a value of 4.87 μ_B at 6.0 K and finally decreases down to 4.39 μ_B at 1.8 K. Above 45 K, the magnetic data can be fitted to the Curie–Weiss law with $C = 4.09\ \mathrm{cm^3\ K\ mol^{-1}}$ and $\Theta = -15.68$ K. The results imply there exist an antiferromagnetic interaction between the cobalt(II) ion and NITmPy radical. Using Eq. (3) [22] with $g_{rad} = 2.0$, this leads to $g_{Co} = 2.67$, which is a reasonable value for octahedral high-spin cobalt(II) complexes [23].

$$C = \frac{N\beta^2}{3k}[2g_{rad}^2 S_{rad}(S_{rad}+1) + g_{Co}^2 S_{Co}(S_{Co}+1)] \quad (3)$$

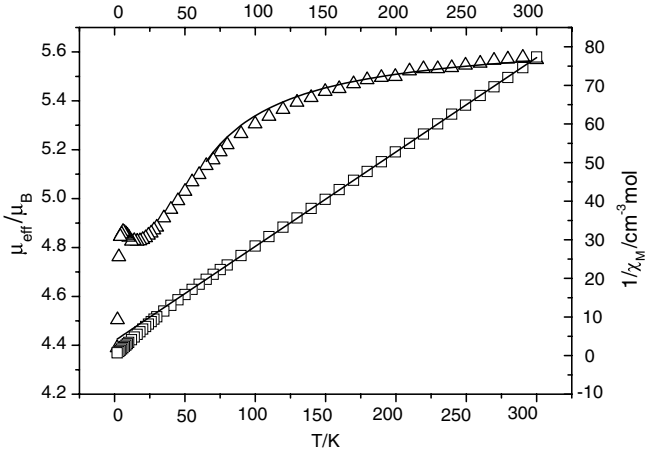
Similarly, there exist weak antiferromagnetic interactions between neighboring NO groups of NITmPy radicals through space (4.144 Å) and ferromagnetic coupling between neighboring NITmPy radicals through the NO···C pathway (3.380 Å). The latter can be confirmed by an observed small peak at lower temperature in the plot of μ_{eff} versus T. The strict analysis of magnetic data for cobalt(II) complexes need to consider the effects of spin-orbit coupling and zero-field splitting. Moreover, at low temperature, the octahedral cobalt(II) energy levels become largely depopulated, until eventually a single Kramer doublet is occupied. Therefore it is very difficult to find an elaborate model incorporating all of these to fit the magnetic data at low temperature. However, according to Sinn [24], the higher temperature magnetic data (above 70 K) may be approximately interpreted by the isotropic spin Hamiltonian. Thus the magnetic data above 70 K can be analyzed with Eq. (4) derived from the Hamiltonian $\widehat{H} = -2J\sum(\widehat{S}_{Co}\widehat{S}_R + \widehat{S}_{Co}\widehat{S}_R)$, where J represents the magnetic interaction between the Co(II) ion and the coordinated NITmPy radical. The expression of the magnetic susceptibility is given below:

$$\chi_M = \frac{N\beta^2}{4kT} \times \frac{35g_1^2 + 10g_2^2\exp(-5x) + g_3^2\exp(-8x) + 10g_4^2\exp(-3x)}{3 + 2\exp(-5x) + \exp(-8x) + 2\exp(-3x)} \quad (4)$$

with $\chi = J/kT$, $g_1 = (3g_{Co} + 2g_R)/5$, $g_2 = (11g_{Co} + 4g_R)/15$, $g_3 = (5g_{Co} - 2g_R)/3$, $g_4 = g_{Co}$.

The best fit for the magnetic data (70–300 K) leads to $g_{Co} = 2.66$, $g_{rad} = 2.0$ (fixed), $J = -6.18\ \mathrm{cm^{-1}}$, $R = 1.0 \times 10^{-4}$. The fitting results show that the exchange coupling between the Co(II) ion and NITmPy radical is weakly antiferromagnetic.

The magnetic studies of the three complexes show that the copper(II) and nickel(II) ions are ferromagnetically coupled with the coordinated NITmPy radical ligands while an antiferromagnetic interaction is observed between the cobalt(II) ion and NITmPy radial ligand. This may be understood by a spin polarization mechanism [16,17,21,25–28] or the orbital symmetry [29,30]. According to spin polarization analysis (Scheme 1), the ferromagnetic interactions between the metal and radical in complexes **1** and **2** are anticipated. This is just in agreement with the above fitting results on basis of the experimental magnetic data. For complex **3**, the spin polarization mechanism cannot explain its magnetic behavior. However, based on the orbital symmetry, the cobalt(II) ion of complex **3** has two magnetic orbitals with σ symmetry ($d_{x^2-y^2}, d_{z^2}$), which are orthogonal to the magnetic orbital (π^*) of the radical, leading to a ferromagnetic interaction, and one magnetic orbital with π symmetry (either of d_{xy}, d_{xz}, d_{yz}) that will be able to overlap with the magnetic orbital of the radical leading to antiferromagnetic coupling. The observed antiferromagnetic coupling in complex **3** can be attributed to the good overlap of the magnetic orbitals which is capable of overcoming the ferromagnetic component. The observed weak magnetic coupling between the metal ion and NITmPy radical is consistent with the reported magnetic exchange [31–34] of pyridine substituted nitroxide–metal complexes due to the small spin density on the nitrogen atom.



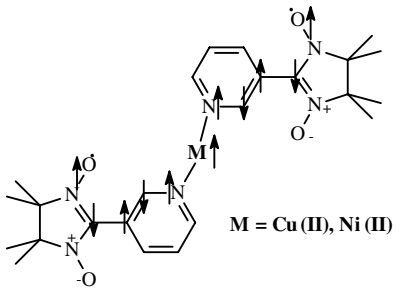


Fig. 6. Plot of $1/\chi_M$ (□) and μ_{eff} (△) vs. T for complex **3**. The solid line represents the best theoretical fits (70–300 K).

Scheme 1. Spin polarization mechanism for intramolecular ferromagnetic coupling in complexes **1** and **2**.

4. Conclusion

We have successfully obtained three new metal–radical complexes **1**–**3** of the formula $[M(NITmPy)_2(N_3)_2(DMSO)_2]$ [M = Cu(II), Ni(II), Co(II)]. For the three complexes, the crystal structural analyses indicate that two NITmPy radical ligands are coordinated to the metal ions via the nitrogen atoms of the pyridyl rings to afford the three-spin complexes. Ferromagnetic interactions are observed in complexes **1** and **2**, whereas an antiferromagnetic interaction dominates in complex **3**. A spin polarization mechanism and orbital symmetry are used to explain the magnetic coupling for complexes **1** and **2**, and **3**, respectively.

5. Supplementary material

CCDC 612405, 612406 and 612407 contains the supplementary crystallographic data for **1**, **3** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Compounds $[Cu(L_1)_2]$ (**1**) and $[Cu(L_2)_2]$ (**2**), where L_1 and L_2 are Schiff base ligands of 4-aminoantipyrine and substituted salicylaldehydes, were synthesized and characterized using various spectroscopic techniques such as elemental analysis, UV–Vis, IR, and NMR. The single crystal X-ray structures for L_1, L_2, and their corresponding Cu(II) complexes assembled in a 1:2 metal to ligand ratio were analyzed for their various weak H-bonding and dimeric association. The structural analysis of compounds **1** and **2**, being the first crystal structures in this series, deserves special attention to help further the understanding in this area of structure–reactivity correlation studies. Further these compounds, composed of very similar chemical composition with a small difference in the substituent on the salicylaldehyde moiety, influenced through various weak inter- and intramolecular H-bonding and C–H$\cdots\pi$ interactions, rearrange the geometry around Cu(II) from a tetrahedrally distorted square planar geometry in $[Cu(L_1)_2]$ (**1**) to square planar in $[Cu(L_2)_2]$ (**2**). Steric strain imposed by the methyl substitution on the 4-aminoantipyrine moiety of the Schiff base ligand, causing this small change of the Cu(II) geometry, along with various weak interactions is analyzed in detail.

1. Introduction

Schiff bases of 4-aminoantipyrine and its complexes are known for their variety of applications in the area of catalysis [1,2], clinical applications [3], and pharmacology [4]. New kinds of chemo-therapeutic agents containing Schiff bases have gained significant attention among biochemists [1] and of those aminopyrines are commonly administered intravenously to detect liver disease [3] in clinical treatment. Hence a systematic understanding on the structure–reactivity correlation has warranted synthesis and characterization of a variety of Schiff base complexes containing different 2-hydroxy aromatic moieties such as furan-2-aldehyde, thiophene-2-aldehyde [4], and pyrrole-2-carboxaldehyde [5], etc. Thus there are a number of reports on compounds based on aminopyridine Schiff bases, though accounts of their crystal structures are limited. The salicylaldehyde based SAAP [6] and pyrrole based HPAP [5] Schiff base ligands and their Cu(II) [7] and lanthanum (Pr, Nd, Gd, Dy, Y, U) complexes [8,9] have been reported already. Although there are many compounds in the literature, our search on the CCDC shows no crystal structure has been reported so far and the structures of those entire complexes are elucidated only with spectroscopic evidence. With this in view, the present report accounts for the synthesis of two antipyrine Schiff base ligands L_1 and L_2 (Fig. 1) and their Cu(II) complexes $[Cu(L_1)_2]$ (**1**), and $[Cu(L_2)_2]$ (**2**), with a special impetus on their structural investigations. Further, the structural

analysis in the present report explores that the weak interactions introduced by varying the substitution on the salicylaldehyde unit, modify the Cu(II) geometry from a tetrahedrally distorted square planar to a distorted square planar geometry.

2. Experimental

2.1. Materials

$Cu(CH_3COO)_2 \cdot H_2O$, 4-aminoantipyrine, 2,4-dihydroxybenzaldehyde, and 3,5-dichlorosalicylaldehydes were purchased from Aldrich & Co. All these chemicals were used as received without any further purification.

2.2. Synthesis

2.2.1. Preparation of the ligands: $L_1 \cdot MeOH$

A 1:1 equimolar methanolic solution of 4-aminoantipyrine (0.406 gm, 0.001 mol) and 2,4-dihydroxybenzaldehyde (0.276 gm, 0.001 mol) were mixed and gently heated for 2 h with constant stirring. The characteristic yellow precipitate obtained by Schiff base condensation was filtered out and kept for crystallization, dissolving in methanol. Fine yellow crystals obtained upon slow evaporation at room temperature were characterized, including single crystal X-ray diffraction. L_1: 4-{[(1*Z*)-(2,4-dihydroxyphenyl)methylene]-amino}-1,5-dimethyl-2-phenyl-1,2-dihydro-3*H*-pyrazol-3-one. NMR data (δ, *Methanol-d_4*): 13.55 (br s, –OH, 1H), 9.63 (s, CH=N, 1H), 7.56–7.20 (m, Ar phenyl, 5H), 6.40–6.31 (m, Ar, 3H), 3.14 (s, N–CH_3, 3H), 2.35 (s, C–CH_3, 3H). IR data (KBr, cm^{-1}): 3500–2900 (weak, br), 1615 (st, intense), 1586 (s, br). UV–Vis [CH_3CN, λ_{max}, nm, (ε, M^{-1}, cm^{-1})], 336 (3030), 422 (2840). ES [MSI] Calc for $C_{19}H_{21}N_3O_4$ (m/z+H^+) = 323.34. Found = 324.26. *Anal.* Calc. for $C_{19}H_{21}N_3O_4$: C, 64.21; H, 5.95; N, 11.82. Found: C, 63.86; H, 5.56; N, 12.25%.

2.2.2. Synthesis of L_2

4-{[(1*Z*)-(3,5-dichloro-2-hydroxyphenyl)methylene]amino}-1,5-dimethyl-2-phenyl-1,2-dihydro-3*H*-pyrazol-3-one. The above synthetic procedure was repeated for L_2 appropriately adapting 3,5-dichlorosalicylaldehyde in place of 2,4-dihydroxybenzaldehyde. NMR data (δ, $CDCl_3$): 14.3 (br s, OH, 1H), 9.75 (s, CH=N, 1H), 7.55-7.26 (m, Ar 7H), 3.23 (s, N-CH_3,3H), 2.45 (s, C–CH_3,3H). IR data (KBr, cm^{-1}) 3639–2593 (br), 1665 (sharp, st), 1589 (sharp, st). UV–Vis [CH_3CN, λ_{max}, nm, (ε, M^{-1}, cm^{-1})], 345 (3000), 380 (2800). ES [MSI] Calc for $C_{18}H_{15}Cl_2N_3O_2$ (m/z) = 375.05; Found = (m/z+H^+) = 376.25; (m/z+Na^+) = 398.24. *Anal.* Calc. for $C_{18}H_{15}Cl_2N_3O_2$; C, 57.46; H, 4.02; N, 11.17. Found: C, 57.5; H, 3.95; N, 11.0%.

2.2.3. Preparation of complexes $[Cu(L_1)_2]$ (**1**), and $[Cu(L_2)_2]$ (**2**)

The Schiff base ligand L_1 (0.071 gm, 0.002 mmol), dissolved in chloroform, was mixed with an ethanolic solution of $[Cu(CH_3COO)_2] \cdot H_2O$ (0.199 gm, 0.001 mmol) and allowed to stir continuously. The immediate color change from green to dark red indicates complexation. Upon slow evaporation at room temperature, the dark red crystals were obtained in 48 h. $[Cu(L_1)_2]$ (**1**): UV–Vis [CH_3CN, λ_{max}, nm, (ε, M^{-1}, cm^{-1})], 364 (1980), 509 (80). ES [MSI] Calc for $CuC_{36}H_{30}N_6O_6$ (m/z+H^+) = 708.18. Found = 708.30. *Anal.* Calc. for $CuC_{36}H_{30}N_6O_6$: C, 61.05; H, 4.55; N, 11.88. Found: C, 61.5; H, 4.48; N, 11.36%. $[Cu(L_2)_2]$ (**2**): The above procedure was repeated for **2** adapted for L_2 with a 1:2 $Cu(CH_3COO) \cdot H_2O$: L_2 ratio. UV–Vis [CH_3CN, λ_{max}, nm, (ε, M^{-1}, cm^{-1})], 359 (6970), 427 (1300), 531 (300). ES [MSI] Calc for $CuC_{36}H_{28}Cl_4N_6O_4$ (m/z+H^+) = 814.02. Found = 814.02. *Anal.* Calc. for $CuC_{36}H_{28}Cl_4N_6O_4$: C, 53.11; H, 3.46; N, 10.32. Found: C, 52.99; H, 3.97; N, 10.20%.

2.3. Physical measurements

Microanalysis of the complexes was done using a Perkin–Elmer PE 2400 series II CHNS/O elemental analyzer. IR spectra were recorded using KBr pellets (1% w/w) on a Perkin–Elmer Spectrum GX FT-IR spectrophotometer. Electronic spectra were recorded on a Schimadzu UV 3101PC spectrophotometer. Mass analyses were performed using electron spray ionization (ESI) technique on a Waters Q Tof-micro mass spectrometer. ^1H NMR spectra were recorded on a Bruker Avance DPX 200 FT-NMR spectrometer. Chemical shifts for proton resonances are reported in ppm (δ) relative to tetramethylesilane.

2.4. X-ray crystallography

A summary of the crystallographic data and details of data collection for L_1, L_2 and **1**, **2** are given in Table 1. Selected bond distances and bond angles for compounds **1** and **2** are given in Table 2. In each case, a crystal of suitable size was selected from the mother liquor and immersed in partone oil, then mounted on the tip of a glass fiber and cemented using epoxy resin. Intensity data for all three crystals were collected using Mo Kα (λ = 0.71073 Å) radiation on a Bruker SMART APEX diffractometer equipped with a CCD area detector. The data integration and reduction were processed with SAINT [10] software. An empirical

absorption correction was applied to the collected reflections using SADABS [11]. The structures were solved by direct methods using SHELXTL [11b] and were refined on F^2 by the full-matrix least-squares technique using the SHELXL-97 [12] package. Graphics are generated using ORTEP. Packing and H-bonding diagrams are generated by PLATON [13] and MERCURY [116]. In all the four compounds, non-hydrogen atoms were refined anisotropically until convergence was reached and hydrogen atoms attached to all carbon atoms were geometrically fixed using the program SHELXTL.

3. Results and discussion

3.1. Spectral investigation

The Schiff base ligands L_1 and L_2 are yellow in color and are soluble in almost all organic solvents, such as methanol, acetonitrile, chloroform, acetone, DMF and DMSO, and the corresponding metal complexes $[Cu(L_1)_2]$ (**1**) and $[Cu(L_2)_2]$ (**2**) obtained with a 1:2 metal ligand ratio are found to be dark red in color. The electronic spectra for both these ligands behave very similarly and show two characteristic bands at 336–360 nm and 420 nm representing intra ligand charge transfer transitions. The corresponding metal complexes **1** and **2** exhibit a characteristic d-d band at 500–530 nm with a broad spectral feature. While the position of λ_{max} is attributable to the square planar geometry, the broadness of the spectral pattern can be attributed to the degree of distortion in the geometry. The three characteristic IR signals for L_1 and L_2, corresponding to (i) OH; (ii) C=O, C=N; (iii) phenolate oxygen C···O, were analyzed. The broad IR signal centered at 3430 cm^{-1} obtained for both the free ligands L_1 and L_2 can be ascribed to the OH functional groups. The compounds **1** and **2** show sharp and intense peaks in the range of 1572–1589 cm^{-1} and 1616–1665 cm^{-1} which can be attributed to $\nu_{CH=N}$ and $\nu_{C=O}$ stretching modes respectively. The characteristic peak at 9.6–9.75 δ in the ^{1}H NMR spectrum further confirms the azomethine CH=N condensation. The disappearance of the OH peak and the significant shift in the $\nu_{C=N}$ stretching frequency in **1** and **2**, with respect to the corresponding free ligands, indicate the complexation with the Cu(II) center. The shift in the azomethine peak by 10–15 cm^{-1} in the IR spectra indicates its involvement in coordination. The IR signal observed at

1616–1665 cm^{-1}, representing the C=O group attached to the antiypyrine five-membered ring remains unchanged in compounds **1** and **2** with respect to the free ligands, symbolizing that it is not involved in the coordination.

3.2. Crystal structure and molecular association

3.2.1. Structure of L_1

The Schiff base ligand L_1 crystallizes in the monoclinic space group $P2_1/c$, along with methanol as a solvent of crystallization. Fig. 2a–c represents the ORTEP diagram for L_1, its dimeric association and the intermolecular C–H···N interaction through molecular pairs along the *c*-axis, respectively. The *meta*-dihydroxy substituted salicylyl phenyl ring C11–C16 is almost in the same plane (mean plane deviation 12.89°), while the phenyl ring C1–C6 of the antipyrine moiety is tilted by 49.67° with respect to the central five-membered ring. The mode of molecular packing influenced through the mode of H-bonding is dictated by variation in the substitutions on the salicyl phenyl ring.

As depicted in Fig. 2b, the molecules are oriented in such a way that the C18 methyl group of the antipyrine ring is aligned towards the azomethine N3, making strong intermolecular C–H···N interactions forming molecular pairs along the *c*-axis [C(18)–H(18A)···N(3); H(18A)···N(3) = 2.58 Å C(18)···N(3) = 3.536(2) Å, ∠C(18)–H(18A)···N(3) = 171°, symmetry code: $1-x, -1/2+y, 1/2-z$]. H18C from the same methyl group is involved in an intermolecular C–H···O interaction with the exocyclic ketonic oxygen of the antipyrine ring along the *b*-axis [C(18)–H(18C)···O(1); H(18C)···O(1) = 2.41 Å, C(18)···O(1) = 3.358(2) Å, ∠C(18)–H(18C)···O(1) = 167° symmetry code: $x, -1+y, z$] which is well within the range in the review articles reported by Steiner [15a] and Nangia [15b]. In addition to the C–H···N interaction, the lattice methanolic OH acts as both donor and acceptor through O–H···O hydrogen bonding with the molecular pairs (Fig. 2b) of the L_1 moiety from either side creating a layered hydrogen bonded motif. The O–H···O hydrogen bonding parameters, with the symmetry code, between the lattice methanol with ketonic oxygen O1 of the antipyrine ring and the phenolic hydrogen H2A of the ligand moiety are as follows: O(4)–H(4A)···O(1); H(4A)···O(1) = 1.86 Å; O(4)···O(1) = 2.671(2) Å, ∠O(4)–H(4A)···O = 171°, symmetry code: $1-x, -1/2+y, 3/2-z$ and O(2)–H(2A)···O(4):H(2A)···O(4) = 1.85 Å, O(2)···O(4) = 2.665(2) Å, ∠O(2)–H(2A)···O(4) = 171°, symmetry code: $x, 5/2-y, -1/2+z$. In addition to this intermolecular hydrogen bonding, intramolecular O–H···N and C–H···O interactions also exist for the stabilization of the ligand moiety, incorporating the methanol molecule in the crystal lattice (Fig. 2c).

3.2.2. Structure of L_2

Ligand L_2 crystallizes in monoclinic space group $P2_1/n$ with four molecules in the unit cell. Fig. 3a and b represents the ORTEP diagram and their dimeric association of L_2. In L_2, the *ortho* and *para* positions of the phenyl ring, with respect to the OH group, are substituted by Cl1 and Cl2 respectively. The dichloro substituted "sal" phenyl ring (C11–C16) is in the same plane, while the phenyl ring C1–C6 of the antipyrine moiety is tilted by 36.64° with respect to the central five-membered ring. The tilt of the phenyl group (C1–C6) with respect to central five-membered ring can be attributed to various molecular interactions involved in the packing pattern.

The molecules are packed along the *ac*-plane with a slight offset in adjacent layers to make an effective dimeric

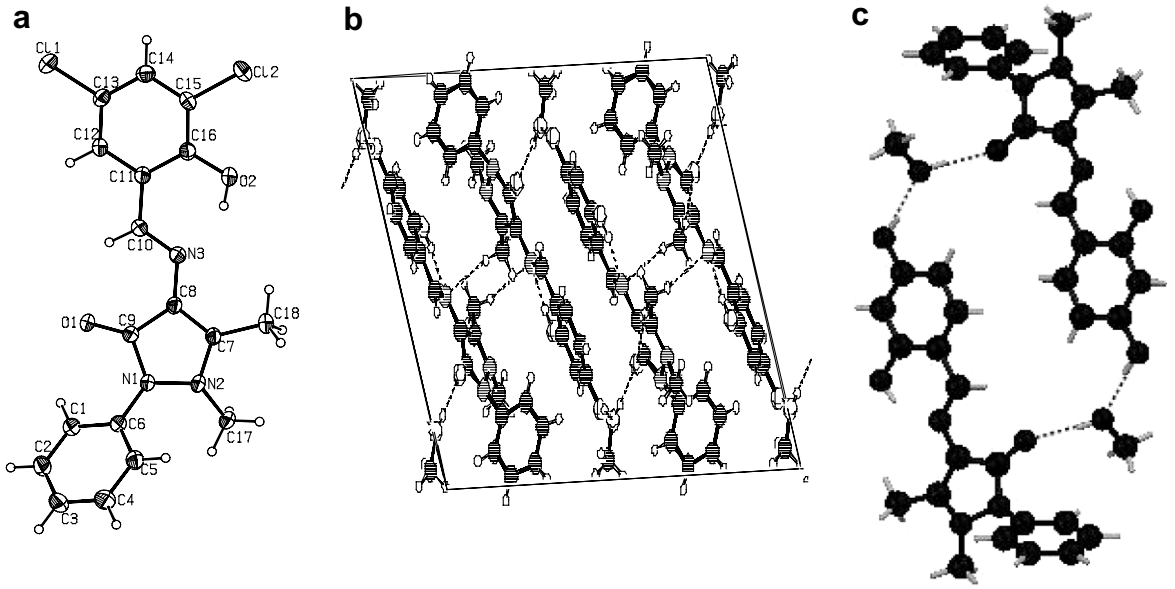

Fig. 2. (a) ORTEP diagram with the atom numbering for L_1, (b) intermolecular CH···N interaction mediated molecular pairs and (c) dimeric association through methanol.

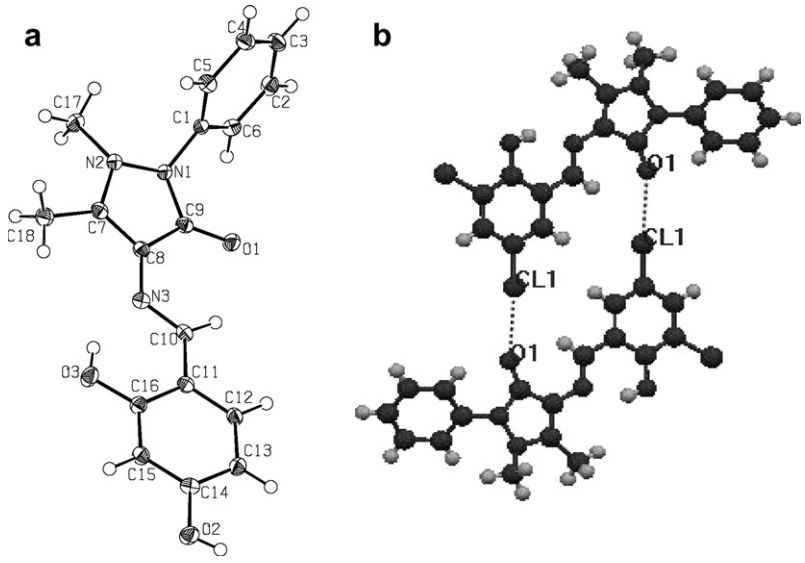

Fig. 3. (a) ORTEP diagram with the atom numbering for L_2 and (b) dimeric association of L_2.

association via a C=O···Cl interaction. The close up view of the dimeric association via the C=O···Cl interaction between a centro-symmetric pair is shown in Fig. 3b. Thus, Cl1 attached to the "sal" phenyl ring makes contact with the exocyclic ketonic oxygen O1 of the five-membered antipyrine ring with an O···Cl distance of 3.010 Å and angle ∠C=O···Cl of 158.12°, which is well within the range reported earlier [15c]. The observed O···Cl distance (3.010 Å) is shorter than the sum of the Van der Waals radii for Cl and O (3.2 Å) and this short contact is due to the partial positive and negative charge residing on Cl1 and O1 respectively. Further, the O···Cl short contacts observed in pentachloronitrobenzene by Tanaka et al. [15d] and 2-chloro-4,6-dinitrophenol by Andersen et al. [15e] also support a similar mode of interaction with partial negative and positive charges between the O and Cl atoms at a distance 3.01 Å and 3.054 Å, respectively. Intramolecular O–H···N H-bonding between the phenolic hydrogen H2 and N3 (O(2)–H(2)···N(3):H(2)···N(3) = 1.87 Å; O(2)···N(3) = 2.597(2) Å; ∠O(2)–H(2)···N(3) = 148°) and a C–H···O interaction (C(10)–H(10)···O(1):H(10)···O(1) = 2.28 Å; C(10)···O(1) = 2.972(3) Å and C(10)–H(10)···O(1) = 130°) between H10 and the exocyclic ketonic oxygen O1 of the five-membered ring are also observed, and these intramolecular H-bonding interactions have an effect on the conformation of the molecule, including the tilt of the phenyl ring with respect to the five-membered ring.

3.2.3. Structure of $[Cu(L_1)_2]$ (1)

An ORTEP view of the neutral Cu(II) complex, **1** with the atom numbering scheme is shown in Fig. 4. The metal center possesses a tetrahedrally distorted square planar geometry with N2O2 donor atoms coordinating from two different Schiff base ligands L_1. Even though the ligand is tridentate in nature, it binds the Cu(II) ion, in a bidentate fashion through the deprotonated phenolic oxygen of the phenyl ring and nitrogen of the azomethine group, leaving

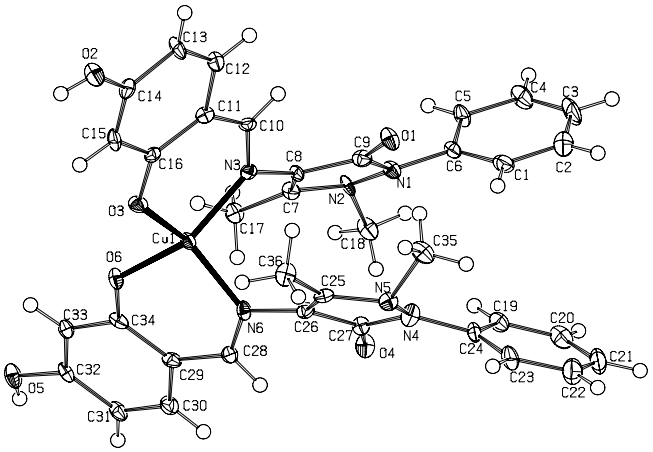

Fig. 4. ORTEP diagram of *1* with the atom numbering scheme.

the antipyrine exocyclic ketonic oxygen O4 and O1 free. The steric strain imposed by the methyl substitution on the antipyrine moiety restricts the ligand towards bidentate coordination from its tridentate nature. The Cu–N distances (Cu1–N3 = 1.967(3) Å; Cu1–N6 = 1.953(3) Å) and Cu–O distances (Cu1–O3 = 1.887(3) Å; Cu1–O6 = 1.924(3) Å) are well within the range reported for related Schiff base complexes of Cu(salen) [16,17]. The *cis* angles subtended by the six-membered chelate ring with Cu(II) from each ligand [O3–Cu1–N3 = 95.95(13)°, O6–Cu1–N6 = 94.07(13)°, N6–Cu1–N3 = 99.23(13)°, O3–Cu1–O6 = 91.78(12)°] deviate only marginally from the ideal square planar value. However, the trans angles [N6–Cu1–O3 = 145.30(13)° and O6–Cu1–N3 = 143.74(13)°] at the Cu(II) center deviate significantly from an ideal square planar geometry, indicating a tetrahedral bias to the Cu(II) coordination. This may be due to the steric constraints imposed by the methyl groups attached to the five-membered antipyrine ring towards the right approach of

the ligand moiety for metal coordination. This is further strengthened by the mean plane involving the "sal" units from different ligands, which are twisted relative to each other by approximately 58.09° and make angles of 28.86° (C11–C16 and O3) and 37.89° (C29–C34 and O6) with respect to the N2O2 mean plane. The N and O atoms show considerable deviation from the mean plane involving N2O2; *trans* N and O from a different ligand moiety (N3 and O6) are displaced in the downward direction (−0.540 Å and −0.625 Å) while N6 and O3 are in the opposite direction (0.494 Å and 0.540 Å) with Cu(II) contained well within the coordination plane (0.015 Å). It is pertinent to note that such distortions in the Cu(II) geometry of blue copper proteins [18–20] and Cu(salen) [21,22] complexes with tetrahedrally distorted square planar geometry are reported to deserve importance in view of catalytic activity.

The packing diagram viewed down the *a*-axis with various H-bonding interactions in **1** is depicted in Fig. 5. The molecules are aligned as layers along the *b*-axis by strong intermolecular O–H···O interactions, between adjacent molecules via the phenolic hydrogen H5 (from O5) of each coordinated ligand moiety with the ketonic oxygen O1 of the five-membered antipyrine moiety. These hydrogen bonded layers are further cross linked along the *c*-axis generating the bilayer by another intermolecular O–H···O H-bonding between the phenolic hydrogen H2 of the second ligand with the coordinated "sal" oxygen O2 [O(2)–H(2)···O(6):H(2)···O(6) = 1.97 Å, O(2)···O(6) = 2.701(4) Å, ∠O(2)–H(2)···O(6) = 147°]. Intermolecular C–H···O interactions between the bilayers creates a two dimensional H-bonded network in the *bc*-plane [C(17)–H(17A)···O(3):H(17A)···O(3) = 2.51 Å, C(17)···O(3) = 3.323(5) Å, ∠C(17)–H(17A)···O(3) = 142° and C(22)–H(22)···O(2):H(22)···O(2) = 2.43 Å, C(22)···O(2) = 3.340(6) Å,∠C(22)–H(22)···O(2) = 167°]. In addition to the above mentioned intermolecular H-bonding, intramolecular C–H···O H-bonding also exist between the methyl hydrogens H18A and H35A from different ligands with the ketonic oxygens O4 and O1 respectively (C(18)–H(18A)···O(4):H(18A)···O(4) = 2.49 Å; C18···O(4) = 3.364(6), ∠C(18)–H(18A)···O(4) = 151° and C(35)–H(35A)···O(1):H(35A)···O(1) = 2.31 Å, C(35)···O(1) = 3.242(6) Å and ∠C(35)–H(35A)···O(1) = 162°). Thus, the ketonic oxygen O1 and O4 from the two different ligand moieties may be orienting the preferential hydrogen bonding mode rather than coordination with the metal center to impose a tetrahedrally distorted square pyramidal geometry around the Cu(II) center.

3.2.4. Structure of $[Cu(L_2)_2]$ (2)

Compound **2** crystallizes in the centrosymmetric space group $C_{2/c}$ with Cu(II) sitting on a twofold axis. An ORTEP view of the neutral Cu(II) complex with the atom numbering scheme is shown in Fig. 6. The metal center possesses a distorted square planar geometry with N2O2 donor atoms coordinating from two different Schiff base ligands. The Cu(II) ion occupies a special position and coordinates with two symmetry related ligand moieties in a bidentate fashion through the deprotonated phenolic oxygen and nitrogen of the azomethine group, leaving the antipyrine exocyclic ketonic oxygen free. The Cu–N distance (Cu1–N3 = 1.9567(17) Å) and Cu–O distance (Cu1–O2 = 1.8878(14) Å) are well within the range reported for related Schiff base complexes [16,17]. The *cis* angles subtended by the six-membered chelate ring with Cu(II) from each ligand [O2–Cu1–N3 = 90.75(6)°, O(2)a–Cu(1)–N(3) = 93.63(6)°] are within the close range of an ideal square planar value, while the *trans* angles [O(2)a–Cu(1)–O(2) = 154.31(9)° and N(3)a–Cu(1)–N(3) = 160.18(10)°] at the Cu(II) center deviate from square planar geometry, indicating a distorted square planar geometry for the Cu(II) coordination. This can be attributed to the six-membered metal-chelate ring formation by the ligand moiety around Cu(II) and the ligand steric constraints imposed by the methyl groups attached to the five-membered antipyrine ring towards the closer approach for metal coordination. The mean

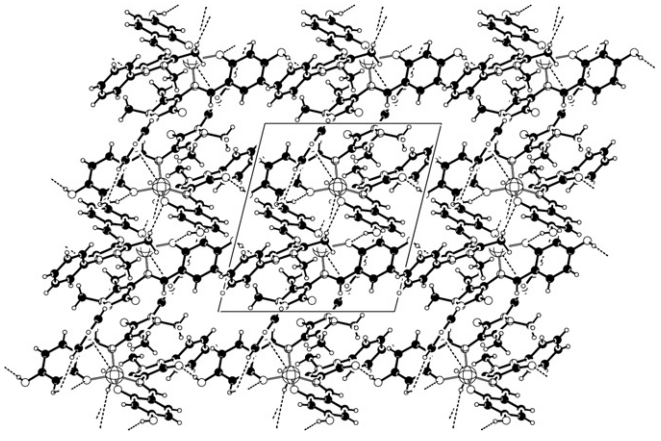

Fig. 5. Packing diagram of **1** viewed down the *a*-axis with various H-bonding interactions.

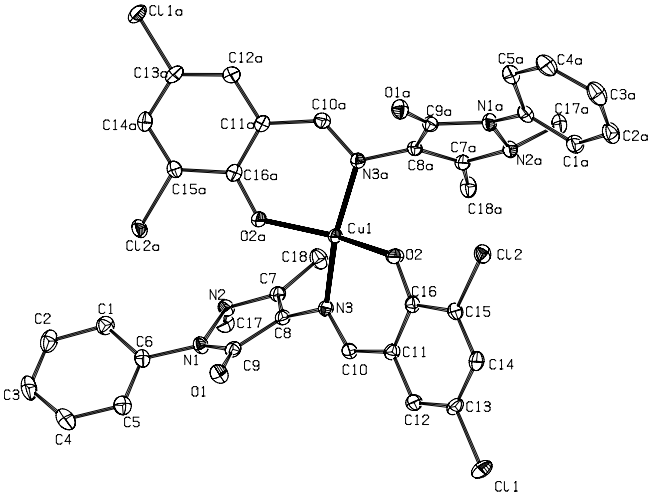

Fig. 6. ORTEP diagram of **2** with the atom numbering scheme. (Hydrogen atoms are omitted for clarity.)

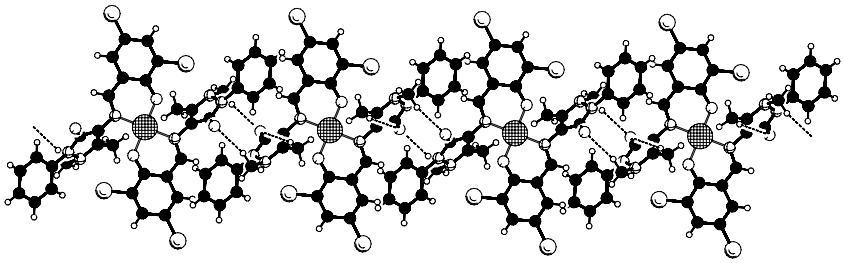

Fig. 7. Packing diagram of **2** viewed down the *b*-axis showing the hydrogen bonding interactions.

plane involving the "sal" units of symmetry related ligands are twisted relative to each other by 34.43° and make a 17.15° angle (angle of C11–C16 and O2) with respect to the N2O2 mean plane, which is comparatively less in **2** indicating much less distortion from the square planar geometry. The Cu(II) atom is contained well in the square base, the *trans* oxygens and *trans* nitrogens coordinated to it from the twofold related ligands are displaced by 0.729° and 1.789° respectively in opposite directions.

A packing diagram of compound **2** viewed down the *b*-axis with hydrogen bonding interactions is shown in Fig. 7. As depicted in the packing, the molecules are arranged in layers along the *c*-axis. The aligned adjacent molecules within the layers are bridged via intermolecular C–H···O hydrogen bonding between the methyl hydrogens H17C and H18C of the five-membered antipyrine ring with the exocyclic ketonic oxygen O1 from either side of the symmetry allied ligand moiety. Details pertinent to the hydrogen bonding interactions and symmetry code are: C(17)–H(17C)···O(1):H(17C)···O(1) = 2.38 Å; C(17)···O(1) = 3.303(3) Å; ∠C(17)–H(17C)···O(1) = 160°, symmetry code: $-x$, $1-y$, $-z$ and C(18)–H(18C)···O(1):H(18C)···O(1) = 2.57 Å; C(18)···O(1) = 3.502(3); ∠C(18)–H(18C)···O(1) = 163°, symmetry code; x, $1+y$, z. The layers along the *c*-axis are also involved in weak C–H···π interactions [23] between the antipyrine phenyl ring and azomethane hydrogen H10, showing the effective closer approach and orientation of the neighboring molecules. Pertinent C–H···π interactions with the symmetry code are C10–H10···Cg1:H10···Cg1 = 2.94 Å, C10···Cg1 = 3.609(2) Å and ∠C10–H10···Cg1 = 130°, symmetry code = $-x$, $1-y$, $-z$, where Cg1 is the centroid of the phenyl ring (C1–C6). In the crystal structures of 5-dimethylnaphthalene [23b] and Resorcinol [23c] the observed CH···π distances range from 2.87 Å to 2.99 Å and 2.77 Å to 2.92 Å which are comparable with the present report for a weak C–H···π contact.

4. Conclusion

In conclusion, we have synthesized two important antipyrine Schiff base ligands and their Cu(II) complexes. The single crystal X-ray structures of **1** and **2**, being the first in the series of this type of compound, illustrate that the mode of weak H-bonding interactions and steric effect imposed by the methyl group has a profound influence on the Cu(II) geometry in **1** and **2**, rearranging from tetrahedrally distorted square planar geometry into distorted square planar.

Abstract

Four new mixed ligand nickel(II) complexes viz., $[Ni(tren)(phen)](ClO_4)_2$ (**1**), $[Ni(tren)(bipy)](ClO_4)_2$ (**2**), $[Ni(SAA)(PMDT)]\cdot 2H_2O$ (**3**) and [Ni(SAA)(TPTZ)] (**4**) (tren = tris(2-aminoethylamine), phen = 1,10-phenanthroline, bipy = 2,2′-bipyridine, SAA = salicylidene anthranilic acid, PMDT = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine, TPTZ = 2,4,6-tri(2-pyridyl)-1,3,5-triazine) have been synthesized and characterized by means of elemental analysis, spectroscopic, magnetic susceptibility and cyclic voltammetric measurements. Single crystal X-ray analysis of $[Ni(tren)(phen)](ClO_4)_2$ (**1**) and $[Ni(SAA)(PMDT)]\cdot 2H_2O$ (**3**) has revealed the presence of a distorted octahedral geometry. Superoxide dismutase activity of these complexes has also been measured.

Keywords: Mixed ligand nickel(II) complexes; Magnetic susceptibility; Single crystal X-ray analysis; Superoxide dismutase activity

1. Introduction

Recently, Ni-containing superoxide dismutase (NiSOD) was isolated from several *Streptomyces* species [1]. The enzymatic activity of NiSOD [2] however is on the same high level as that of Cu–ZnSOD at about $10^9\ M^{-1}\ S^{-1}$ per metal center. The superoxide radical (O_2^-) is an inevitable byproduct of aerobic metabolism which if not eliminated may cause significant cellular damage; consequently, the superoxide radical has been implicated in numerous medical disorders [3]. To avoid such harmful consequences, all oxygen metabolizing organisms possess metalloenzymes known as superoxide dismutases (SODs). SODs are dedicated to keep the concentration of O_2^- in controlled low limits thus protecting biological molecules from oxidative damage. These SODs disproportionate the toxic O_2^- radical to molecular oxygen and hydrogen peroxide [4]. All SODs employ the two-step ping-pong mechanism shown in Eqs. (1) and (2), where M is a redox active metal center capable of both oxidizing and reducing superoxide

$$M^{ox} + O_2^- \rightarrow M^{red} + O_2 \quad (1)$$

$$M^{red} + O_2 + 2H^+ \rightarrow M^{ox} + H_2O_2 \quad (2)$$

X-ray crystallographic studies [5] of NiSODs from *Streptomyces* species have illustrated the nature of the enzyme active site. In both structures, the square pyramidal coordination geometry exhibited by the Ni center in the oxidized form ($NiSOD_{ox}$) is converted to a square-planar geometry in the reduced state ($NiSOD_{red}$), as the axial imidazole group derived from the His1 residue dissociates upon metal ion reduction. The four equatorial ligands include two thiolates from Cys2 and Cys6 in a *cis* arrangement, the deprotonated amide of the Cys2 backbone, and the N-terminal $-NH_2$ group of His1.

The preparation and study of structural models can lead to the understanding of fundamental mechanistic aspects of the enzyme as well as to the development of structure–activity relationships.

In the continuation of our work [6] on polyamines, polypyridyl and salicylideneanthranilic acid containing complexes, here we report the synthesis and characterization of new mixed ligand nickel(II) complexes viz., $[Ni(tren)(phen)](ClO_4)_2$ (**1**), $[Ni(tren)(bipy)](ClO_4)_2$ (**2**),

[Ni(SAA)(PMDT)]·$2H_2O$ (**3**) and [Ni(SAA)(TPTZ)] (**4**). Single crystal X-ray analysis of **1** and **3**, spectral, redox properties and superoxide dismutase activity of these complexes have also been described.

2. Experimental

2.1. Materials and methods

$Ni(ClO_4)_2 \cdot 6H_2O$, *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDT), 2,4,6-tri(2-pyridyl)-1,3,5-triazine (TPTZ) (Aldrich Chemicals), $NiCl_2 \cdot 6H_2O$, 1,10-phenanthroline, 2,2′-bipyridine, methanol, acetonitrile (S.D. Fine Chemicals) and tetrabutylammonium perchlorate (Acros Chemicals) were used as purchased. The Schiff base (SAA) was prepared as described in our earlier publication [6f]. Elemental analyses were performed on an Elementar Vario EL III, Carlo Erba 1108 elemental analyzer. FAB mass spectra were recorded on a JEOL SX 102/DA 6000 mass spectrometer using xenon (6 kV, 10 mA) as the FAB gas. The magnetic susceptibility data were recorded on a Gouy balance at room temperature using mercury(II) tetrathiocyanato cobaltate(II) ($\chi_g = 16.44 \times 10^{-6}$ cgs unit) as the calibrant. The effective magnetic moment was calculated per Ni(II) atom from the equation $\mu_{eff} = 2.83\sqrt{\chi_M T}$ B.M., where χ_M is the molar magnetic susceptibility corrected for diamagnetism of the constituent atoms [7]. UV–Vis spectra were recorded on a Shimadzu UV–Vis 160 spectrophotometer in quartz cells. A BAS-100 Epsilon electrochemical analyzer was used for the cyclic voltammetric experiment in DMSO solution of the complex containing tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. The three electrodes measurement was carried out at 298 K under nitrogen atmosphere with a platinum working electrode, a platinum wire auxiliary electrode and a silver/silver chloride reference electrode (Ag/AgCl). The SOD activities were evaluated using alkaline DMSO as a source of superoxide radicals (O_2^-) and nitro blue tetrazolium chloride (NBT) as a scavanger [6f,6d].

2.2. Synthesis of the complexes

2.2.1. Preparation of [Ni(tren)(phen)]$(ClO_4)_2$ (1) and [Ni(tren)(bipy)]$(ClO_4)_2$ (2)

To a MeOH solution (10 mL) of $Ni(ClO_4)_2 \cdot 6H_2O$ (1.0 mmol, 0.365 g) a MeOH solution (10 mL) of tren (1.0 mmol, 0.146 g) was added with stirring for 10 min. To the above reaction mixture, a MeOH solution (10 mL) of phen (1.0 mmol, 0.198 g) was added and the stirring was continued for 30 min at 25 °C. After completion of the reaction, the precipitate thus formed was collected by filtration and was dissolved in MeOH:MeCN (1:1 v/v) for recrystallization. After two days of slow evaporation light pink crystals were collected and washed with MeOH . These were dried in air at room temperature and stored in $CaCl_2$ desiccator. Yield, 70%. *Anal.* Calc. for $C_{18}H_{26}N_6NiCl_2O_8$ (**1**): C, 37.03; H, 4.45; N, 14.40. Found: C, 37.55; H, 5.00; N, 14.35%. FAB Mass found: 383. Calc.: 385.17. Complex **2** was synthesized as described above by employing bipy (1.0 mmol, 0.156 g) in place of phen. Yield, 75%. *Anal.* Calc. for $C_{16}H_{26}N_6NiCl_2O_8$ (**2**): C, 34.33; H, 4.65; N, 15.02. Found: C, 34.23; H, 4.50; N, 15.42%. FAB Mass found: 360. Calc.: 361.14.

2.2.2. Synthesis of [Ni(SAA)(PMDT)]·$2H_2O$ (3) and [Ni(SAA)(TPTZ)] (4)

To a MeOH solution (10 mL) of $NiCl_2 \cdot 6H_2O$ (1.0 mmol, 0.237 g), a MeOH solution (10 mL) of the potassium salt of SAA (1.0 mmol, 0.241 g) was added with stirring for 10 min. To the above reaction mixture, a MeOH solution (10 mL) of PMDT (1.0 mmol, 0.173 g) was added and the stirring was continued for 30 min at 25 °C. After completion of the reaction, the dark red reaction mixture was filtered to remove any solid impurities and left for slow evaporation. After two days of slow evaporation dark red crystals were collected and washed with MeOH. These were dried in air at room temperature and stored in $CaCl_2$ desiccator. Yield, 70%. *Anal.* Calc. for $C_{23}H_{38}N_4O_5Ni$ (**3**): C, 58.31; H, 7.18; N, 11.83. Found: C, 57.61; H, 7.56; N, 11.58%. FAB Mass found: 473. Calc.: 473.27. Complex **4** was synthesized as described above by employing TPTZ (1.0 mmol) in place of PMDT. Yield, 75%. *Anal.* Calc. for $C_{32}H_{23}N_7O_3Ni$ (**4**): C, 62.71; H, 3.75; N, 16.00. Found: C, 61.12; H, 4.19; N, 15.54%. FAB Mass found: 611. Calc.: 612.31.

Caution! Perchlorate salts of metal complexes are potentially explosive and should be handled with great care.

2.3. X-ray crystallography

Crystals suitable for single crystal X-ray analysis for the complexes [Ni(tren)(phen)]$(ClO_4)_2$ (**1**) and [Ni(SAA)(PMDT)]·$2H_2O$ (**3**) were grown by slow evaporation of the reaction mixture at room temperature. The single crystals of **1** and **3** were mounted on a glass fiber and used for data collection (Table 1). Crystal data were collected on an Enraf-Nonius $MACH_3$ diffractometer using graphite monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). The crystal orientation, cell refinement and intensity measurements were made using the program CAD-4PC performing ψ-scan measurements. The structures were solved by direct methods using the program SHELXS-97 [8] and refined by full-matrix least-squares techniques against F^2 using SHELXL-97 [9]. All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were geometrically fixed and allowed to refine using a riding model.

3. Results and discussion

3.1. Synthesis

All the present mixed ligand nickel(II) complexes have been synthesized by the following sequential routes:

For complexes **1** and **2**

$$[Ni(C)(H_2O)_n] + D \rightarrow [Ni(C)(D)] \quad (6)$$

C = SAA, D = PMDT/TPTZ

The target complexes were prepared in a good yield. These complexes were characterized by microanalysis and further characterized by FAB^+ mass spectrometry.

3.2. Crystal structures

Complexes **1** and **3** have been characterized by the single crystal X-ray diffraction technique. The ORTEP views of the complexes are shown in Figs. 1 and 2. Crystallographic data (Table 1), selected bond angles and distances are given in Tables 2 and 3. Complex **1** crystallizes in the orthorhombic system. The structure of **1** was solved in *Pbca* space group, whereas **3** crystallizes in the triclinic $P\bar{1}$ space group. The coordination geometries of complexes **1** and **3** are distorted octahedral. Significant deviation from 90° of the bond angles involving the chelation is observed (Tables 2 and 3). In complex **1** one tetradentate ligand (tren) and

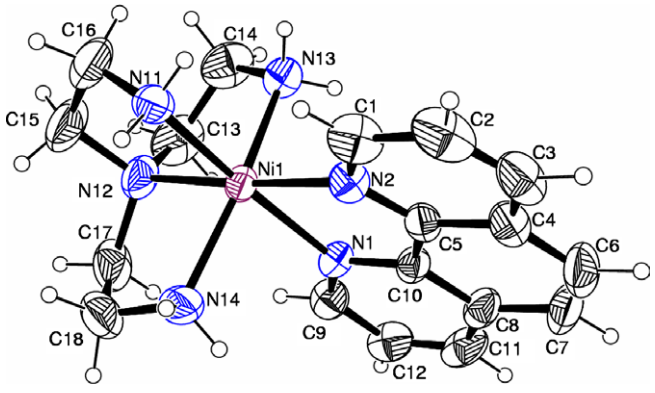

Fig. 1. ORTEP diagram of the complex $[Ni(tren)(phen)]^{2+}$ (**1**).

one bidentate ligand (phen) are coordinated with the nickel(II) center. The coordination sites in the complexes are the tetradentate tris(2-aminoethylamine) group Ni–N(11) = 2.113(2) Å, Ni–N(12) = 2.105(3) Å, Ni–N(13) = 2.129(2) Å, Ni–N(14) = 2.102(3) Å and heterocyclic N of the phen Ni–N(1) = 2.187(2) Å and Ni–N(2) = 2.083(2) Å. Individual, mean bond distances and angles within the coordination polyhedron compare well with those found in other octahedral complexes of Ni(II) involving N-donor atoms [10]. The coordination geometry is distorted from octahedral as ascertained by the observed τ value of 0.059 (the structural index is defined as $\tau=(\beta-\alpha)/60$

where α and β are the largest coordination angles, β = N(2)–Ni(1)–N(12) 176.5° and α = N(11)–Ni(1)–N(1) 172.9°), such a type of octahedral geometry was observed in similar Ni(II) complexes ($\tau = 0.07$) [11].

In complex **3**, the crystal structure consists of a mononuclear neutral moiety with two water molecules. The coordination sites in complex **3** are the tridentate PMDT group Ni–N(1) = 2.211(3) Å, Ni–N(2) = 2.130(3) Å, Ni–N(3) = 2.327(3) Å and tridentate Schiff base (SAA) containing ONO donors Ni–O(1) = 1.996(3) Å, Ni–N(4) = 2.058(3) Å, Ni–O(2) = 2.015(3) Å. The geometry of the $Ni^{II}N_4O_2$ coordination polyhedron is appreciably elongated and minimally distorted octahedral as ascertained by the observed τ value of 0.06 (β = N(4)–Ni–N(2) 177.27° and α = O(1)–Ni–O(2) 173.41°). The nickel–nitrogen and nickel–oxygen lengths for the octahedral $[Ni(SAA)(PMDT)]\cdot 2H_2O$ (**3**) are comparable to that found in similar types of nickel(II) octahedral complexes [12].

3.3. Magnetic measurements

The magnetic susceptibility measurements in the solid state show that the present complexes are paramagnetic at room temperature. The observed magnetic moments of these complexes are in the range expected for spin-free d^8 systems. The observed magnetic moment values of $[Ni(tren)(phen)](ClO_4)_2$ (**1**), $[Ni(tren)(bipy)](ClO_4)_2$ (**2**), $[Ni(SAA)(PMDT)]\cdot 2H_2O$ (**3**) and [Ni(SAA)(TPTZ)] (**4**) are 3.05, 2.95, 3.22 and 3.25 B.M., respectively. The magnetic moment values (μ_{eff}) lie within the range normally found for other nickel(II) complexes [13].

3.4. Ligand field spectra

The room temperature ligand field spectra (electronic spectra) of these complexes have been recorded in 100% DMSO solution. One representative ligand field spectra is shown in Fig. 3 and band positions are presented in Table 4. These complexes, very similar to one another, show three strong absorptions ($^3A_{2g} \rightarrow {}^3T_{2g}$, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$, $^3A_{2g} \rightarrow {}^3T_{1g}(P)$) and one weak absorption, characteristic of regular octahedral nickel(II) complexes [14]. Experimental absorption maxima corresponding to these three transitions are given in Table 4. Although the presence of distortions ($^3A_{2g} \rightarrow {}^3T_{2g}$, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$, $^3A_{2g} \rightarrow {}^3T_{1g}(P)$) from the ideal octahedral geometry about the Ni atoms is demonstrated by the structural results (X-ray data).

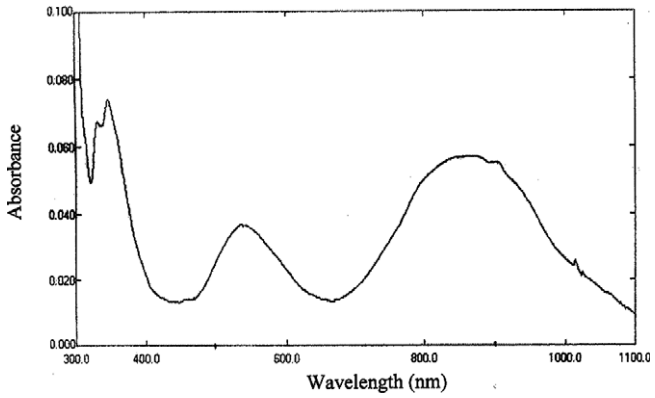

Fig. 3. The UV–Vis spectrum ($0.003\ mol^{-1}\ dm^{-3}$) of [Ni(SAA)-(PMDT)]·$2H_2O$ (**3**) in DMSO.

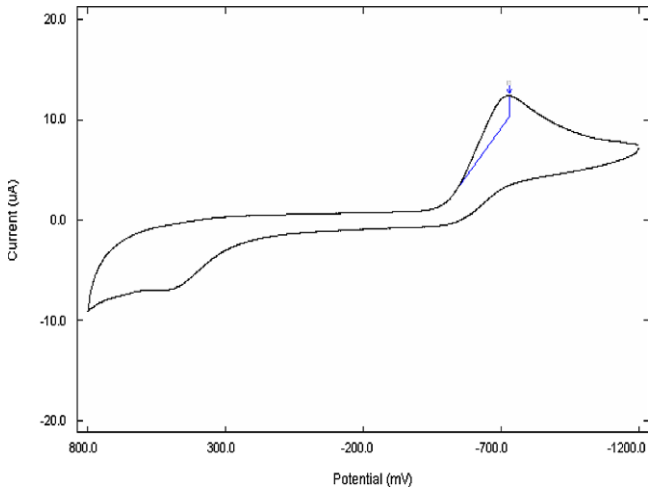

Fig. 4. Cyclic voltammogram ($0.003\ mol^{-1}\ dm^{-3}$) of [Ni(tren)(phen)]·$2H_2O$ (**1**) in DMSO (0.1 M TBAP as supporting electrolyte, scan rate: 500 mV/s).

However, band shapes and positions (assigned on the basis of O_h symmetry) and the ligand field parameter Dq ($3A_{2g} \rightarrow 3T_{2g}$, lowest energy transition) and B (Racah parameter) values, calculated according to the averaged environment rules, are in the range found for octahedrally coordinated nickel(II) ions [15].

3.5. Electrochemistry

Cyclic voltammetry of the present complexes was recorded in DMSO with TBAP as a supporting electrolyte. A representative voltammogram is shown in Fig. 4. The redox processes assigned as Ni(II)/Ni(I) couples are fully irreversible. The voltammograms of these complexes consist of two well-separated peaks, one cathodic potential (E_{pc}) and one anodic potential (E_{pa}). In these complexes reduction waves are observed at more negative potentials. Such type of electrochemistry for six-coordinate nickel(II) complexes is reported by Patra and Mukherjee [16]. The redox potential values for the nickel(II) complexes are presented in Table 5. The pertinent redox couples are represented in the following electron transfer series (Eq. (7)).

$$Ni^{II} \underset{+e^-}{\overset{e^-}{\rightleftharpoons}} Ni^{I} \qquad (7)$$

Table 5
CV Results (in V) for the Ni(II) complexes in different media[a]

[Ni(SAA)(TPTZ)] (**4**)	−0.76	0.45

[a] Reference electrode: Ag/AgCl. Auxiliary electrode: platinum wire. Working electrode: platinum.

3.6. SOD activity

The superoxide dismutase activities for the present complexes have been measured. These complexes exhibit significant catalytic activity towards the dismutation of superoxide anions. Superoxide was enzymatically supplied from alkaline DMSO and SOD activity was evaluated by the NBT assay [6d,6f] following the reduction of NBT to MF^+ kinetically at 560 nm. The concentration causing 50% inhibition of NBT reduction is called IC_{50}. The observed IC_{50} values of the present complexes are comparable with the earlier reported values for copper(II) complexes [6c]. The catalytic activity of NiSOD [2], however, is on the same high level as that of Cu, ZnSOD at about $10^9\ M^{-1}\ s^{-1}$ per metal center. [Ni(tren)(phen)]$(ClO_4)_2$ (**1**) shows highest SOD activity ($IC_{50} = 40\ \mu mol\ dm^{-3}$) where

Table 4
Absorption maxima, Dq, β, B and $\beta°$ of the octahedral Ni(II) complexes (ν_{max} in cm^{-1})

Complex	$^3A_{2g} \rightarrow {}^3T_{2g}$ (ν_1)	$^3A_{2g} \rightarrow {}^3T_{1g}$(F) ($\nu_2$)	$^3A_{2g} \rightarrow {}^3T_{1g}$(P) ($\nu_3$)	ν_2/ν_1	Dq	β	B	$\beta°$
[Ni(tren)(phen)]$(ClO_4)_2$ (**1**)	11170	19050	24400	1.70	1117	0.64	663	36
[Ni(tren)(bipy)]$(ClO_4)_2$ (**2**)	11100	19000	24500	1.71	1110	0.66	680	34

[Ni(SAA)(TPTZ)] (**4**)	11580	18570	29700	1.60	1158	0.87	902	13

$15B = (\nu_2 + \nu_3) = -3\nu_1$; $\beta = B/Bo$ [Bo (free ion) = 1030]; $\beta° = (1 - \beta) \times 100$.

as [Ni(SAA)(TPTZ)] (**4**) shows lowest SOD activity ($IC_{50} = 58$ μmol dm^{-3}) and the remaining complexes show intermediate values i.e., [Ni(tren)(bipy)]$(ClO_4)_2$ (**2**) shows an IC_{50} value of 48 μmol dm^{-3} and [Ni(SAA)(PMDT)]·$2H_2O$ (**3**) shows an IC_{50} value of 43 μmol dm^{-3}.

4. Conclusion

In this paper, we have described the synthesis and characterization of four new mononuclear nickel(II) complexes [Ni(tren)(phen)]$(ClO_4)_2$ (**1**) [Ni(tren)(bipy)]$(ClO_4)_2$ (**2**), [Ni(SAA)(PMDT)]·$2H_2O$ (**3**) and [Ni(SAA)(TPTZ) (**4**). Complexes **1** and **3** were structurally characterized by single crystal X-ray analysis. Magnetic moment values and spectral data of these complexes have shown a paramagnetic nature of the nickel(II) centre. Superoxide dismutase activity of these complexes was also measured and discussed.

5. Supplementary material

CCDC 298991 and 298970 contain the supplementary crystallographic data for [Ni(tren)(phen)]$(ClO_4)_2$ (**1**) and [Ni(SAA)(PMDT)]·$2H_2O$ (**3**). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac. uk.

Acknowledgments

Our grateful thanks are due to the National Diffraction Facility, X-ray Division and RSIC (SAIF), IIT Mumbai for single crystal data collection and e.p.r. measurements, respectively. The Head RSIC, Central Drug Research Institute, Lucknow is also thankfully acknowledged for providing analytical and spectral facilities. Financial assistance from UGC [Scheme No.F.30-76/2004(SR)] New Delhi is also thankfully acknowledged.

Abstract

The iron complexes with the phenoxyalkanoic acids 3,4-D, 2,3-D and 2,4,5-T in the presence or not of a nitrogen donor heterocyclic ligand, phen, were prepared and characterized. Interaction of Fe(III) with phenoxyalkanoic acids and phen leads to dinuclear neutral complexes while the absence of phen favours trinuclear cationic or tetranuclear neutral forms. The crystal structure of hexakis(2,3-dichlorophenoxyacetato)tris(methanol)oxotri-iron(III) chloride–methanol(1/3), $[Fe_3O(2,3\text{-}D)_6(MeOH)_3]Cl \cdot 3MeOH$ (**2**), and tetrakis(dimethyl-sulfoxide)octakis(2,4,5-trichlorophenoxyacetato)dioxotetra-iron(III) methanol(1/2)–water(1/1)–dimethylsulfoxide(1/0.8), $\{[Fe_4O_2(2,4,5\text{-}T)_8(dmso)_4] \cdot 2MeOH \cdot H_2O \cdot 0.8dmso\}$ (**3**), have been determined and refined by least-squares methods using three-dimensional Mo Kα data.

Magnetic data of the trimer show antiferromagnetic interaction. The ground state of the system is $S = 1/2$ with a small percentage of $S = 5/2$ paramagnetic impurity $\rho = 0.7\%$. For the tetramer, the magnetic data suggest antiferromagnetically coupled system with $S = 0$ ground state, while for the dimer, $\{[Fe_2OCl_2(3,4\text{-}D)_2(phen)_2] \cdot H_2O \cdot 3.5MeOH\}$ a very strong antiferromagnetic exchange interaction between the two ions has been observed. The fitting results give an exchange interaction of $J = 254.1\ cm^{-1}$, with $S = 0$ ground state with a small amount of paramagnetic $S = 5/2$ impurity ($\rho = 0.3\%$).

1. Introduction

In the bioinorganic area, iron hydroxo- and oxo-bridged dinuclear complexes represent synthetic models of the active sites of various non-heme iron proteins [1–10]. Dinuclear Fe(III) complexes are known in neutral and cationic form [11–14]. Binuclear compounds have been isolated in the presence of chelating nitrogen donor ligands. This class of compounds can be characterized by the presence of [Fe_2-(μ-O)] core while carboxylato groups can also bridge the two metal ions e.g. $[Fe_2O(O_2CMe)_2Cl_2(bpy)_2]$ [11], $[Fe_2O(O_2CCH_2Cl)_2(H_2O)(bpy)_2](NO_3)_2$ [12], $[Fe_2O(O_2CCF_3)_2(Me_2bpy)_4](ClO_4)_2$ [13], $[Fe_2O(O_2CPh)_2(phen)_4]Cl_2$ [14].

Oxo-centered, carboxylate-bridged trinuclear iron complexes [15–18] having the [Fe_3-(μ-O)] core have been characterized in mixed valence $Fe(III)_2Fe(II)$ neutral [17] or homovalence $Fe(III)_3$ mono-cationic clusters with the general formula $[Fe_3O(O_2CR)_6(solvent)_3](X)_{0\text{ or }1}$ [16]. The triangular oxo centered structure was confirmed in 1965 and since then attention has focused on various properties in the solid state. The monocationic complexes which contain three high-spin iron(III) centers, were some of the first metal clusters to which interesting magnetic exchange behavior were observed, e.g. spin frustration, while the

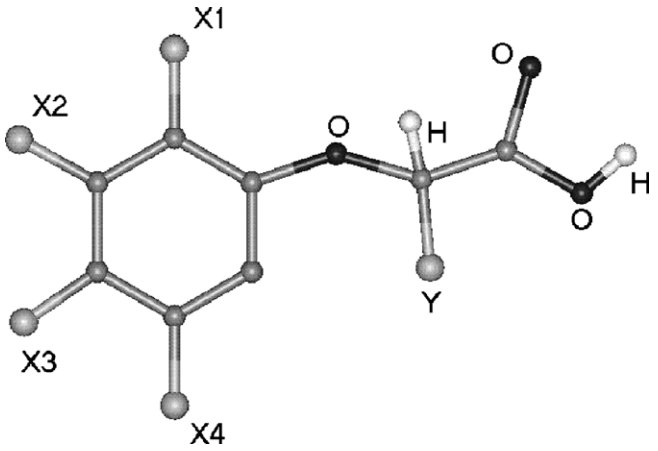
doi:10.1016/j.poly.2006.09.002



neutral complexes display intriguing temperature-dependent mixed-valence behavior and have been examined by many physical techniques.

The tetranuclear oxide-bridged carboxylate compounds includes three types of butterfly motif [19–23], the "bent" with the pyramidal μ_3-O ions on the same side or on the opposite sides of the fused Fe_3 planes [22–27] or "planar" [28–30] while examples having the rectangular core have also been reported [31]. In this class of compounds cationic e.g. $[Fe_4(OHO)(OH)_2(O_2CMe)_4(phen)_4](ClO_4)_3$, $[Fe_4O_2(O_2CPh)_7(phen)_2](ClO_4)$ [31], $[Fe_4O_2(O_2CMe)_7(bpy)_2]X$ {X = ClO_4 [19], Cl [20]}, $[Fe_4O_2(O_2CEt)_7(bpy)_2]X$ {X = ClO_4 [21], PF_6 [22]}, neutral e.g. $[Fe_4O_2(O_2CPh)_8(phen)_2]$ [31], $[Fe_4O_2Cl_2(O_2CMe)_6(bpy)_2]$ [23], or anionic $[NBu_4^n][Fe_4O_2(O_2CMe)_7(bpy)_2]$ [23] homovalence Fe(III) clusters have been reported. The formation of trinuclear or tetranuclear compounds is absolutely dependent of the solvent used. The use of methanol leads to the formation of the trinuclear species while from dmso or dmf solvents the tetranuclear compounds have been isolated.

The magnetic study of di-, tri- or tetranuclear Fe(III) clusters have shown that the presence of $Fe(III)_x$-O core leads to antiferromagnetically coupled behavior and/or the presence of spin frustration effects [32–42].

Our interest is focused on the interaction of metal ion with carboxylato ligands. We have initiated studies on the co-ordination chemistry of herbicide carboxylate agents with Cu(II), Mn(II), Mn(III), Ni(II) and d^{10} ions in an attempt to examine their mode of binding and possible biological relevance. Phenoxyalkanoic acids interact with metal ions to form complexes which have been shown to have diverse stereochemistries and biological interest [43–47].

In this paper, we report the synthesis, characterization and the magnetic behavior of binuclear, trinuclear and tetranuclear Fe(III) carboxylato compounds with the commercial auxin herbicides, 2,3-D = 2,3-dichlorophenoxy-acetic acid, 3,4-D = 3,4-dichlorophenoxy-acetic acid and 2,4,5-T = 2,4,5-trichlorophenoxy-acetic acid (Scheme 1) in the presence or not of phen = 1,10-phenanthroline.

Scheme 1. General formula of alkanoate ligands used. 2,4,5-T: X_1 = Cl, X_2 = H, X_3 = Cl, X_4 = Cl, Y = H. 3,4-D: X_1 = H, X_2 = Cl, X_3 = Cl, X_4 = H, Y = H. 2,3-D: X_1 = Cl, X_2 = Cl, X_3 = H, X_4 = H, Y = H.

We also report the molecular and the crystal structures of hexakis(2,3-dichloro-phenoxyacetato)tris(methanol)oxotri-iron(III)Chloride–methanol(1/3), $[Fe_3O(2,3\text{-}D)_6(MeOH)_3]Cl \cdot 3MeOH$ (**2**), and tetrakis(dimethyl-sulfoxide)octakis(2,4,5-trichloro-phenoxyacetato)dioxotetra-iron(III) methanol(1/2)–water(1/1)–dimethylsulfoxide(1/0.8), $\{[Fe_4O_2(2,4,5\text{-}T)_8(dmso)_4] \cdot 2MeOH \cdot H_2O \cdot 0.8dmso\}$ (**3**).

2. Experimental

2.1. Reagents and techniques

The chemicals for the synthesis of the compounds were used as purchased. Acetonitrile (CH_3CN) was distilled from calcium hydride (CaH_2) and CH_3OH from magnesium (Mg) and was stored over 3 Å molecular sieves. Diethyl ether, anhydrous grade, dimethylformamide = dmf and dimethylsulfoxide = dmso were used without any further purification. 3,4-D, 2,3-D, 2,4,5-T, phen and $FeCl_3 \cdot 6H_2O$ were purchased from Aldrich Co. All chemicals and solvents were reagent grade.

Infrared spectra (200–4000 cm^{-1}) were recorded on a Perkin–Elmer FT-IR 1650 spectrometer with samples prepared as KBr pellets. UV–Vis spectra were recorded on a Shimadzu-160A dual beam spectrophotometer. Room temperature magnetic measurements were carried out by Faraday's method using mercury tetrathiocyanatocobaltate(II) as a calibrant. Variable-temperature magnetic susceptibility measurements were carried out on powdered samples in the 3–300 K temperature range, using a Quantum Design SQUID susceptometer in a 0.1 kG and 1.0 kG applied magnetic field. Magnetization measurements were carried out at different temperatures in the range 1.8–6 K and in the field range 0–5 T. C, H and N elemental analysis were performed on a Perkin–Elmer 240B elemental analyzer, Fe was determined by atomic absorption spectroscopy on a Perkin–Elmer 1100B spectrophotometer. Electric conductance measurements were carried out with a WTW model LF 530 conductivity outfit and a type C cell, which had a cell constant of 0.996. This represents a mean value calibrated at 25 °C with potassium chloride. All temperatures were controlled with an accuracy of ±0.1 °C using a Haake thermoelectric circulating system.

2.2. Synthetic procedures

2.2.1. Synthesis of the dichlorobis[(3,4-dichlorophenoxy)acetato]bis(1,10-phenanthroline)-oxodiiron(III) $\{[Fe_2OCl_2(3,4\text{-}D)_2(phen)_2] \cdot H_2O \cdot 3.5MeOH\}$ (**1**)

3,4-D (2.22 g, 10 mmol) was dissolved in CH_3OH (20 cm^3) and NaOH (0.40 g, 10 mmol) was added. After 30 min stirring $FeCl_3 \cdot 6H_2O$ (2.7 g, 10 mmol) in CH_3OH (15 cm^3) and phen (1.80 g, 10 mmol) in CH_3OH (10 cm^3) were added drop wise. The reaction mixture was refluxed for 1 h. The red-green solution was reduced in volume and left for slow evaporation. Small green crystals of

{[Fe_2OCl_2(3,4-D)$_2$(phen)$_2$]·H_2O·3.5MeOH} (**1**) suitable for X-ray structure determination were deposited in a week. Yield 45%. (Fw = 1127.19). *Anal*. Calc. for $C_{43.50}H_{40}Cl_6Fe_2N_4O_{11.50}$ requires: C, 46.35; H, 3.55; N, 4.97; Fe 9.91. Found: C, 46.40; H, 3.35; N, 4.95; Fe 9.87%. IR: ν_{max}/cm^{-1} ν_{phen}(C=N):1649(vs); $\nu_{as}(CO_2)$: 1610, 1580(vs); $\nu_{sym}(CO_2)$:1426 (vs) (KBr pellet); UV–Vis: λ(nm)(ε, $dm^3\,mol^{-1}\,cm^{-1}$), dmso solution: 650(63); 530(100); 480(2450).

2.2.2. Hexakis(2,3-dichloro-phenoxyacetato)-tris(methanol)oxotri-iron(III) Chloride-methanol (1/3), [Fe_3O(2,3-D)$_6$(MeOH)$_3$]Cl·3MeOH (2)

2,3-D (2.22 g, 10 mmol) was dissolved in CH_3OH (15 cm^3) and NaOH (0.4 g, 10 mmol) was added. After 30 min stirring $FeCl_3\cdot 6H_2O$ (1.35 g, 5 mmol) in CH_3OH (10 cm^3) were added drop wise. The orange-yellow solution was reduced in volume and left for slow evaporation. Orange-yellow crystals of [Fe_3O(2,3-D)$_6$(MeOH)$_3$]Cl·3MeOH (**2**) suitable for X-ray structure determination were deposited in a week. Yield 30%. (Fw = 1731.37). *Anal*. Calc. for $C_{54}H_{54}Cl_{13}Fe_3O_{25}$ requires: C, 37.46; H, 3.12; Fe, 9.67. Found: C, 37.50; H, 3.08; Fe, 9.59%. IR: ν_{max}/cm^{-1} $\nu_{as}(CO_2)$: 1626, 1578(vs); $\nu_{sym}(CO_2)$:1425 (s) (KBr pellet).

2.2.3. Synthesis of the tetrakis(dimethyl-sulfoxide)-octakis(2,4,5-trichloro-phenoxyacetato) dioxotetrairon(III) methanol(1/2)-water(1/1)- dimethylsulfoxide(1/0.8), {[Fe_4O_2(2,4,5-T)$_8$(dmso)$_4$]·2MeOH·H_2O·0.8dmso} (3)

2,4,5-T (2.25 g, 10 mmol) was dissolved in CH_3OH/dmso 4:1 (20 cm^3) and NaOH (0.4 g, 10 mmol) was added. After 30 min stirring $FeCl_3\cdot 6H_2O$ (1.35 g, 5 mmol) in CH_3OH/dmso 1:1 (15 cm^3) was added drop wise. The reaction mixture was stirred for 1 h and reduced in volume under vacuum and left for slow evaporation. Red-brown crystals of {[Fe_4O_2(2,4,5-T)$_8$(dmso)$_4$]·2MeOH·H_2O·0.8dmso} (**3**), suitable for X-ray structure determination were deposited in a week. Yield 40%. (Fw = 2748.22). *Anal*. Calc. for $C_{75.6}H_{70.8}Cl_{24}Fe_4O_{33.8}S_{4.8}$ requires: C, 33.04; H, 2.57; Fe, 8.12. Found: C, 33.14; H, 2.46; Fe, 8.26%. IR: ν_{max}/cm^{-1} $\nu_{as}(CO_2)$: 1628(s), 1614(vs), 1591(vs); $\nu_{sym}(CO_2)$: 1422(vs) (KBr pellet); UV–Vis: λ(nm)(ε, $dm^3\,mol^{-1}\,cm^{-1}$), dmso solution: 553(95); 468(150).

2.3. X-ray crystallography data and processing

An orange-yellow parallelepiped crystal of [Fe_3O(2,3-D)$_6$(MeOH)$_3$]Cl·3MeOH (**2**) with approximate dimensions $0.10\times0.20\times0.50$ mm, and an red-brown one of {[Fe_4O_2(2,4,5-T)$_8$(dmso)$_4$]·2MeOH·H_2O·0.8dmso} (**3**), with approximate dimensions $0.20\times0.30\times0.50$ mm were mounted in air. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite monochromated Mo radiation. Crystal data and parameters for data collection are reported in Table 1. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11° < 2\theta < 23°$ for **2** and **3**. Intensity data were recorded using θ–2θ scan. Three standard reflections monitored every 97 reflections, showed <3.0% intensity fluctuation and no decay. Lorentz, polarization and ψ-scan absorption correction were applied using Crystal Logic software. Scattering Factors were taken from the International Tables for X-ray Crystallography [48]. The structures of **2** and **3** were solved by Direct methods using the programs SHELXS-86 [49], and refined by full-matrix least-squares techniques on F^2 with SHELXL-97 [50].

Further crystallographic details for **2**: $2\theta = 45.5°$, scan speed 2.0°/min, scan range $2.3 + x\alpha_1\alpha_2$ separation, reflections collected/unique = 10015/9603 [$R_{int} = 0.0466$], 882 parameters refined, R_1/wR_2 (for all data) = 0.0806/0.1713, $[\Delta\rho]_{max}/[\Delta\rho]_{min} = 1.029$ and -0.669, $[\Delta/\sigma]_{max} = 0.003$. All hydrogen atoms were introduced at calculated positions as riding on bonded atoms. All non-H atoms were refined anisotropically, including the solving methanols for which no-H atoms were included in the refinement. Further crystallographic details for **3**: $2\theta = 50°$, scan speed 6.0°/min, scan range $1.6 + \alpha_1\alpha_2$ separation, reflections collected/unique/used = 6946/6661 ($R_{int} = 0.0557$)/6661, 648 parameters refined, R_1/wR_2 (for all data) = 0.1762/0.3119, $[\Delta\rho]_{max}/[\Delta\rho]_{min} = 0.937/-0.505$ e/Å^3, $[\Delta/\sigma]_{max} = 0.006$. All hydrogen atoms were introduced at calculated positions as riding on bonded atoms. All non-H atoms were refined anisotropically, except for the solvent molecules which were refined isotropically.

3. Results and discussion

3.1. Synthesis of the complexes

(a) The synthesis of the binuclear complex has been achieved via the reaction of $FeCl_3 \cdot 6H_2O$ with the sodium salt of the ligand in the presence of phen. The reaction involves deprotonation of the ligand using NaOH or CH_3ONa as base, e.g.,

$$C_6H_3Cl_2\text{-}OCH_2COOH + CH_3ONa \rightarrow C_6H_3Cl_2\text{-}OCH_2COONa + CH_3OH$$

$$2C_6H_3Cl_2\text{-}OCH_2COONa + 2FeCl_3 + 2NaOH + 2phen \rightarrow [Fe_2OCl_2(C_6H_3Cl_2\text{-}OCH_2COO)_2(phen)_2] + 4NaCl + H_2O$$

The complex is green crystalline solid soluble in dmf, dmso.

(b) The synthesis of the trinuclear complex has been achieved via one step reaction of $FeCl_3 \cdot 6H_2O$, NaOH, and 2,3-D that results in the formation of the cationic complex,

$$6C_6H_3Cl_2\text{-}OCH_2COOH + 8NaOH + 3FeCl_3 \rightarrow [Fe_3O(C_6H_3Cl_2\text{-}OCH_2COO)_6(MeOH)_3]Cl + 8NaCl + 7H_2O$$

The complex is orange-yellow crystalline solid soluble in dmf, dmso.

(c) The synthesis of the tetranuclear complex has been achieved via the reaction of $FeCl_3 \cdot 6H_2O$ with the sodium salt of the ligand in CH_3OH/dmso. The reaction involves deprotonation of the ligand using NaOH or CH_3ONa as base, e.g.,

$$C_6H_2Cl_3\text{-}OCH_2COOH + CH_3ONa \rightarrow C_6H_2Cl_3\text{-}OCH_2COONa + CH_3OH$$

$$8C_6H_2Cl_3\text{-}OCH_2COONa + 4FeCl_3 + 4\ NaOH \rightarrow [Fe_4O_2(2,4,5\text{-}T)_8(dmso)_4] + 12NaCl + 2H_2O$$

The complex is red-brown crystalline solid soluble in dmf, dmso.

3.2. IR spectroscopy

IR spectroscopy was used as an additional technique to distinguish the structural similarities of the compounds with the same nuclearity as well as the coordination mode of the carboxylato ligands. The overall patterns of all compounds of the same number of metal ions, bi-, tri- and tetra-Fe(III) ions are almost identical supporting analogous structure. Bands of phen in the 1650–1600 cm^{-1}, attributed to ring stretching vibrations, shift to higher frequencies upon chelation in binuclear compounds. Similar shifts occur for the bands between 1250 and 1100 cm^{-1}, while those between 1050 and 700 cm^{-1} shift to lower frequencies with splitting of the band at ~850 cm^{-1} (an out-of-plane C–H deformation).The very strong bands at 1610 and 1580 (**1**), 1624 and 1575 (**2**) and 1614 and 1591 cm^{-1} (**3**) are assigned to the ν_{as}(COO) bidendate mode and the strong bands at 1426 (**1**), 1425 (**2**) and 1422 cm^{-1} (**3**) are assigned to the ν_s(COO) bidentate mode of the carboxylate ligands, respectively. The existence of two types of carboxylato ligands (monodentate, bidentate bridge) in tetranuclear compound **(3)** is reflected in its IR spectrum by the appearance of two ν_{as}(COO) bands at 1628 (monodentate) and 1614 and 1591 cm^{-1}(bidentate bridge); the two ν_s(COO) bands most probably coincide at 1422 cm^{-1}

3.2.1. Description of the structure $[Fe_3O(2,3\text{-}D)_6(MeOH)_3]Cl \cdot 3MeOH$ (2)

Complex **2** crystallizes in the triclinic space group $P\bar{1}$. A structural diagram of the complex appears in Fig. 1. Selected bond distances and angles are given in Table 2.

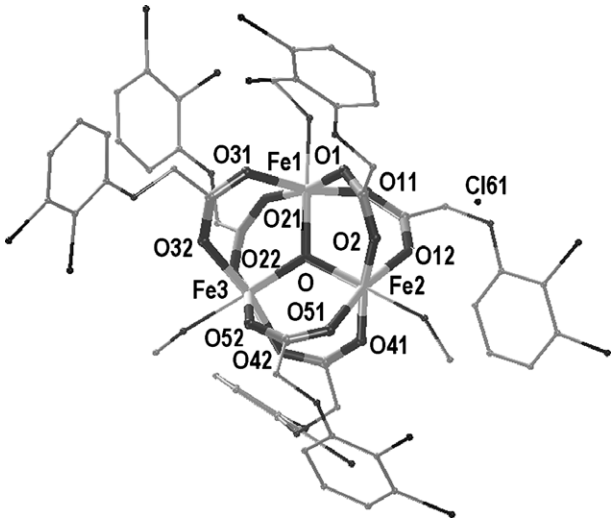

Fig. 1. A diagram of the structure of $[Fe_3O(2,3\text{-}D)_6(MeOH)_3]Cl \cdot 3MeOH$ (**2**).

Table 2
Selected bond distances (Å) and angles for complex **2**

Bond distances (Å)			
Fe(1)–O	1.914(4)	Fe(2)–O(12)	2.026(4)
Fe(1)–O(31)	2.002(4)	Fe(2)–O(51)	2.030(4)
Fe(1)–O(11)	2.006(4)	Fe(2)–OM2	2.046(4)
Fe(1)–O(21)	2.016(4)	Fe(3)–O	1.895(4)
Fe(1)–O(1)	2.022(4)	Fe(3)–O(52)	1.999(4)
Fe(1)–OM1	2.055(4)	Fe(3)–O(22)	2.022(4)
Fe(2)–O	1.917(4)	Fe(3)–O(42)	2.039(4)
Fe(2)–O(41)	2.001(4)	Fe(3)–O(32)	2.039(4)
Fe(2)–O(2)	2.008(4)	Fe(3)–OM3	2.094(4)
Bond angles (°)			
Fe(1)–Fe(3)–Fe(2)	60.08	Fe(2)–Fe(1)–Fe(3)	60.16
Fe(1)–Fe(2)–Fe(3)	59.76	Fe(1)–O–Fe(2)	119.4(2)
Fe(3)–O–Fe(1)	120.0(2)	Fe(3)–O–Fe(2)	120.6(2)
Separations			
Fe(1)...Fe(2)	3.309	Fe(1)...Cl	6.041
Fe(2)...Fe(3)	3.311	Fe(2)...Cl	7.422
Fe(3)...Fe(1)	3.298	Fe(3)...Cl	8.709

The compound is a Fe_3O description. It carries a positive charge. The Fe(1)–O = 1.914(4) Å and Fe(2)–O = 1.917(4) Å distances are almost the same, but the Fe(3)–O = 1.895(4) Å distance is slightly shorter . Again comparing the Fe–O (MeOH) distances, we can see that the bond lengths of Fe(1)–OM1 = 2.055(4) and Fe(2)–OM2 = 2.046(4) are very close, while the Fe(3)–OM3 distance of 2.094(4) Å is obviously longer than the former two. The triangle composed of the Fe(1), Fe(2) and Fe(3) atoms is very close to an equilateral triangle, with Fe(1)...Fe(2) Fe(2)...Fe(3) and Fe(3)...Fe(1) distances of 3.309 Å, 3.311 Å and 3.298 Å, respectively. The Fe(1)–Fe(3)–Fe(2), Fe(2)–Fe(1)–Fe(3) and Fe(1)–Fe(2)–Fe(3) angles are 60.08°, 60.16° and 59.76°, respectively. The central oxygen atom O lies on the Fe(1)Fe(2)Fe(3) plane (0.009 Å). The Fe(III) coordination geometry is slightly distorted octahedron with a terminal methanol oxygen atom, an oxygen atom in the center of the triangle and any other four oxygen atoms from the bridging carboxylate groups completing the coordination to each metal atom.

3.2.2. Description of the structure $[Fe_4O_2(2,4,5\text{-}T)_8(dmso)_4]\cdot 2MeOH\cdot H_2O\cdot 0.8dmso$ (3)

Complex **3** crystallizes in the monoclinic space group $C2/c$ and displays crystallographically imposed C_2 symmetry. A structural diagram of the complex appears in Fig. 2. Selected bond distances and angles are given in Table 3.

The tetranuclear molecule contains a $[Fe_4(\mu_3\text{-}O)_2]^{8+}$ core comprising four Fe(III) ions with a "butterfly" disposition and a μ_3-O^{2-} ion bridging each Fe_3 "wing". Ions Fe(1) and Fe(1′) $[1-x, y, 1.5-z]$ occupy the "hinge" or "body" sites, and Fe(2) and Fe(2′) $[1-x, y, 1.5-z]$ occupy the "wing-tip" sites. Both oxide ions, O and O $[1-x, y, 1.5-z]$, lie slightly out of their respective Fe_3 planes by 0.30 Å with sum of angles of 352.25°. The dihedral angle between the two Fe_3 planes is 158.34°. Thus, the core can be considered as two edge-sharing Fe_3 triangular units with the oxygen atoms out of their Fe_3 planes. Peripheral ligation is provided by eight RCO_2^- groups. The body/wing-tip Fe_2 pairs are bridged by six μ_2-carboxylate groups in syn–syn modes, while two monodentate carboxylate ligands, are coordinated to each of the two body metal ions Fe(1) and Fe(1′).

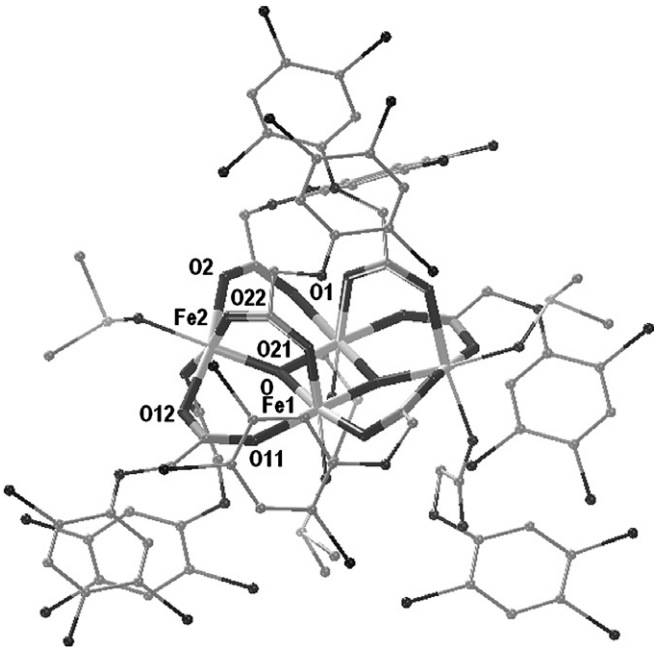

Fig. 2. A diagram of the structure of $[Fe_4O_2(2,4,5\text{-}T)_8(dmso)_4]\cdot 2MeOH\cdot H_2O\cdot 0.8dmso$ (**3**).

Table 3
Selected bond distances (Å) and angles for complex **3**

Bond distances (Å)			
Fe(1)–O	1.917(9)	Fe(2)–O	1.875(8)
Fe(1′)–O	1.919(10)	Fe(2)–O(31)	1.988(9)
Fe(1)–O(41)	2.015(9)	Fe(2)–O(2)	2.009(12)
Fe(1)–O(1)	2.023(9)	Fe(2)–O(51)	2.030(8)
Fe(1)–O(21)	2.039(9)	Fe(2)–O(22)	2.054(9)
Fe(1)–O(11)	2.059(10)	Fe(2)–O(12)	2.084(11)
Bond distances (°)			
O–Fe(1)–O	82.0(4)	O–Fe(2)–O(51)	176.5(4)
O–Fe(1)–O(1′)	170.8(4)	O(31)–Fe(2)–O(22)	172.4(4)
O(41)–Fe(1)–O(21)	168.2(4)	O(2)–Fe(2)–O(12)	168.0(4)
O–Fe(1)–O(11)	175.6(4)	Fe(2)–O–Fe(1′)	124.9(5)
Fe(1)–O–Fe(1′)	97.9(4)	Fe(2)–O–Fe(1)	129.4(5)
Separations			
Fe(1)...Fe(2)	3.363	Fe(1)...Fe(1′)	2.893(5)
Fe(1)...Fe(2′)	3.431	Fe(2)...Fe(2′)	6.038

The metal ions are octahedrally coordinated, their chromophores being FeO_6. The Fe...Fe separations fall into two types. The body/body separation, Fe(1)...Fe(1′), is short (2.893 Å) because these metal ions are bridged by two oxides. The wing-tip/body Fe...Fe separations can be distinguished into two types, those bridged by one (Fe(l)–Fe(2), 3.431 Å) and those bridged by two carboxylate groups (Fe(1)...Fe(2), 3.363 Å). Finally, the wing-tip/wing-tip separation (Fe(2)...Fe(2′), 6.038 Å) is the longest as expected. The "body"-Fe to μ_3-*O* distances are actually the same 1.918 Å and 1.919 Å, whereas the "wing-tip"-Fe to μ_3-*O* distance is slightly shorter 1.874 Å. This symmetry is also reflected in the bond angles at the triply bonding oxide atoms: the Fe(1)–O–Fe(1′) and Fe(2)–O–Fe(2′) angles (97.84° and 82.02°, respectively) are much smaller than the other Fe(1)–O–Fe(2) angles (124.93° and 129.48°). Compound **3** belongs in the family of structurally characterized tetranuclear Fe(III) clusters containing the "butterfly"-type $[Fe_4\mu_3\text{-}O_2]^{8+}$ core [22–31] and the third example having only carboxylato ligands [31]. Comparison of the structural parameters of **3** and those of the other members of the Fe(III) "butterfly" family, shows a noticeable structural difference of the body core that shows an idealized rhombic geometry.

The bridging ligands are bound to two Fe(III) metal ions in a symmetric fashion [Fe(1)–O(1) = 2.022(4) Å, Fe(2)–O(2) = 2.008(4) Å, O(1)–C(1) = 1.281(18) Å, O(2)–C(1) = 1.250(19) Å, Fe(1)–O(11) = 2.059(10) Å, Fe(2)–

O(12) = 2.084(11) Å, O(11)–C(11) = 1.267(15) Å, O(12)–C(11) = 1.273(19) Å]. Each unidentate carboxylato ligand is bound to Fe(III) ion through O(31) in a distance of Fe(2)–O(31) = 1.988(9) Å while the uncoordinated carboxylato oxygen [O(32)–C(31) = 1.25(2) Å] is H-bonded to the water molecule of crystallization [O(32)...Ow(1) = 2.780 Å].

3.3. Magnetic measurements

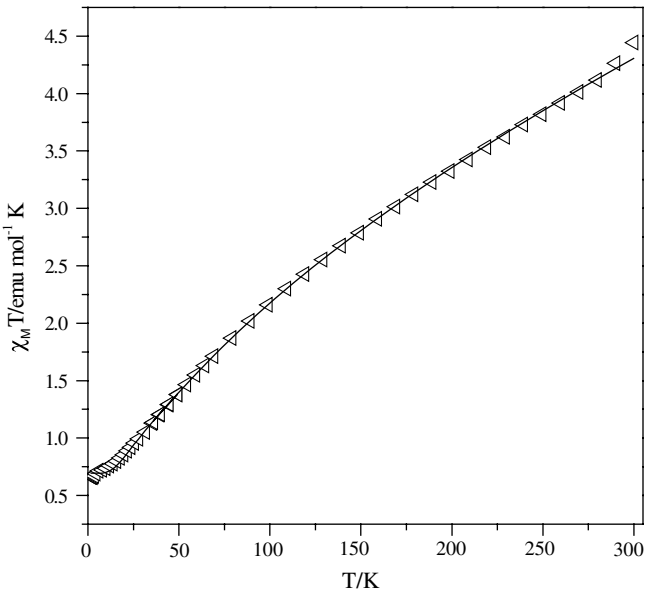
3.3.1. Magnetic study of the Fe3 system

The temperature dependence of the molar magnetic susceptibility of complex $[Fe_3O(2,3\text{-}D)_6(MeOH)_3]Cl \cdot 3MeOH$ (**2**), in the form of $\chi_M T$, is shown in Fig. 3.

The product $\chi_M T$ (4.5 emu mol^{-1} K at 300 K) decreases steadily with decreasing temperature, reaching the value of 0.66 emu mol^{-1} K at 1.75 K. The room-temperature $\chi_M T$ product is appreciably lower than expected for three uncoupled $S = 5/2$ spins (13.1 emu mol^{-1} K) and clearly reveals the antiferromagnetic behavior of the complex **2** while the low-temperature $\chi_M T$ data does not extrapolate to zero as temperature approaches 0 K as expected for odd-number of interacting half-integer spins. In order to investigate the magnetic behavior of the trinuclear system, a spin-only Heisenberg–Dirac–van Vleck (HDvV) Hamiltonian formalism was used and a C_{2v} point-group symmetry was assumed for the system (Scheme 2).

$$H = J_1(S_1 \cdot S_2 + S_1 \cdot S_3) + J_2(S_2 \cdot S_3) \quad (1)$$

The energies of the spin states as functions of the exchange integrals J_1 and J_2 were derived by using the Kambe [52] vector-coupling approach,



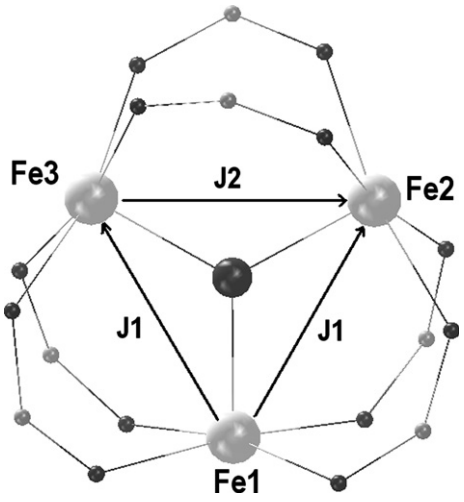


Fig. 3. The temperature dependence of the molar magnetic susceptibility of complex **2**, in the form of $\chi_M T$ vs. T is represented with the open triangles while the solid line represents the best theoretical fit. See text for details.

Scheme 2. Magnetic interactions of **2**.

$$\frac{2E(S_T, S_{23})}{J_2} = \alpha S_T(S_T + 1) + (1 - \alpha)S_{23}(S_{23} + 1) \quad (2)$$

where $S_{23} = S_2 + S_3$ and $S_T = S_1 + S_{23}$ and $\alpha = J_1/J_2$.

Although the point-group symmetry of our system is C_{3v}, no satisfactory fitting was obtained by assuming $J_1 = J_2 = J$. This happens because of the topology of the magnetic ions (an ideal equilateral triangle) which leads to non-preferred spin vector alignment (when the exchange interactions are antiferromagnetic). Having in mind that the interactions are antiferromagnetic, the energy of the spin states depends on S_{23} and in our case the term J_1/J_2 for some *discrete* values could lead to accidental degeneracy and other interesting phenomena of spin frustration. Fig. 4 displays (a) the dependence of the term $\alpha = J_1/J_2$ with the low lying energy levels of the trinuclear system and (b) the case of spin frustration for the value of $\alpha = 0.27$ and 0.57 where the energy levels, in the form of (S_T, S_{23}), (5/2, 0)–(3/2, 1) and (3/2, 1)–(1/2, 2), respectively are accidentally degenerate (FR points). When $\alpha = 1$, the energy of the spin states does not depend on the intermediate spin S_{23} and the ground state is given by two degenerate spin doublets, arising from $S_{23} = 2$ and $S_{23} = 3$. The ground state of the system is (a) $S = 5/2$ for $0 < \alpha < 0.27$; (b) $S = 3/2$ for values $0.27 < a < 0.57$, (c) $S = 1/2$ for values $a > 0.57$, while only the value of the intermediate spin quantum number S_{23} changes for $a > 1$ (Fig. 4).

A fit to the data of Fig. 3 gives $J_1 = 49.5$ cm^{-1}, $J_2 = 66.3$ cm^{-1} ($\alpha = 0.75$), and $g = 2.0$ fixed, with a small percentage of $S = 5/2$ paramagnetic impurity $\rho = 0.7\%$. According to the obtained ratio-parameter, α, a vertical solid line was drawn in Fig. 4 where its cross-sections with the energy levels show the low-lying energy spectrum of the system. For clarification reasons a second graph in Fig. 4 shows the energy difference of the low lying energy states of the system according to the fitting results.

Applying the term $D(S_z^2 - 1)$ to the above magnetic model resulted in no net improvement of the quality of the fit. The value of $D = 0.2$ cm^{-1} was obtained but reveals

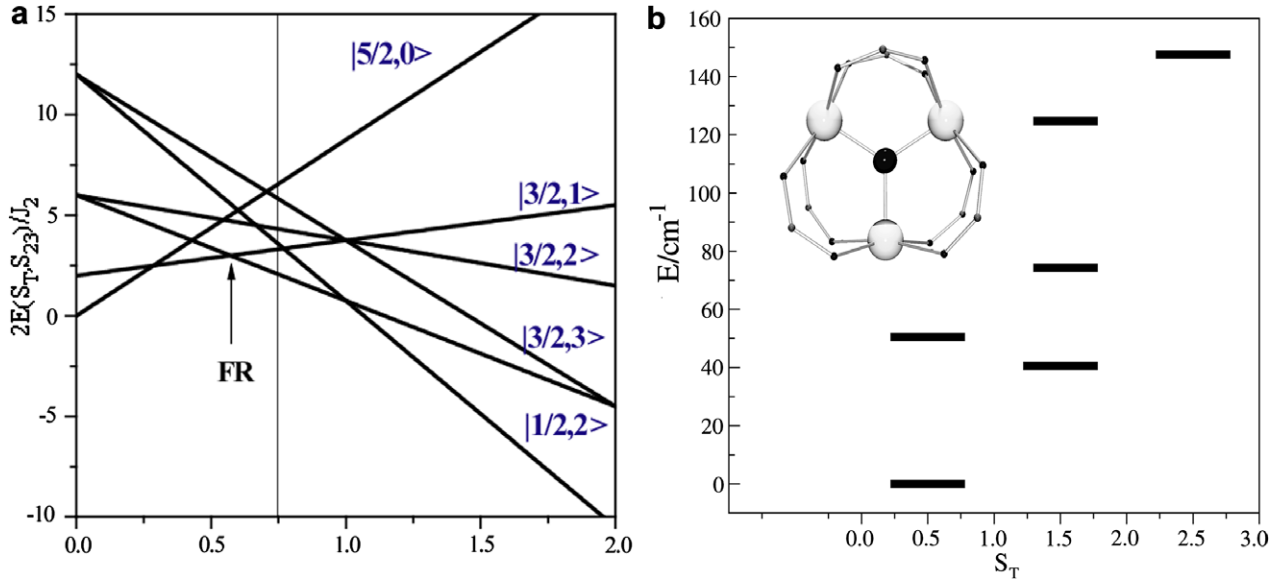

Fig. 4. (a) Dependence of some selective energy levels on the parameter $\alpha = J_1/J_2$; (b) the energy difference of the low lying energy states of the system according to the fitting results (see text for details).

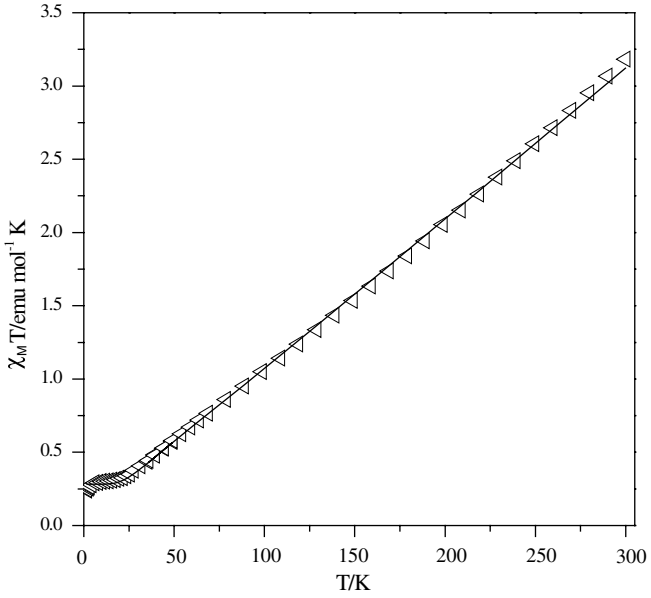
that it does not play an important role in the magnetic behavior of the system in the low-temperature range.

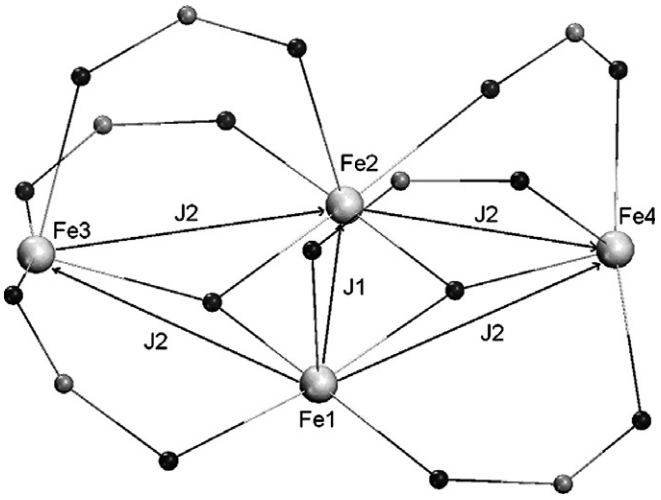
An alternative explanation for the magnetic behavior of complex **2a** retaining its idealized trigonal symmetry in the presence of non-Heisenberg exchange contributions [53–55] is given at the supporting information (Figure 1S).

3.3.2. Magnetic study of the Fe4 system

The room-temperature value of the susceptibility data in the form of $\chi_M T$ is 3.2 emu mol^{-1} K lower than the value expected for four uncoupled 5/2 spins. The values of $\chi_M T$ decrease monotonically with decreasing temperature until a plateau of 0.3 emu mol^{-1} K in the temperature range 17–1.8 K; the residual $\chi_M T$ value is due to a percentage of paramagnetic impurity (Fig. 5).

The data suggest antiferromagnetically coupled system with $S = 0$ ground state. For this complex a total of five exchange parameters J_{ij} are required to cover each possible pairwise exchange interaction between Fe^{III} atoms *i* and *j*; a sixth parameter J_{34} (the numbering scheme is the same as that shown in Scheme 3 is assumed to be zero, given the large distance involved (Fe(3)–Fe(4)) 6.038 Å). However, the main exchange interaction pathway will be via the μ_3-O^{2-} bridges, not the alkanoate bridges, so that from the magnetism viewpoint, the core symmetry is reduced and only three J values are required, $J_{13} = J_{24} = J_{wb}$, $J_{23} = J_{14} = J^*_{wb}$, and $J_{12} = J_{bb}$, where b = body and w = wing-tip. In fact, consideration of the Fe–O and Fe–O–Fe distances and angles in (Table 3) shows that the almost same pyramidality of O(1) and O(2) has a minor influence on these structural parameters and a 2J model appropriate for C_{2V} symmetry, i.e., $J_{wb} = J^*_{wb}$, thus does not appear unreasonable. The Hamiltonian formalism given in Eq. (3) was used to fit the data taking into account a small percentage of $S = 5/2$ paramagnetic impurity (ρ).





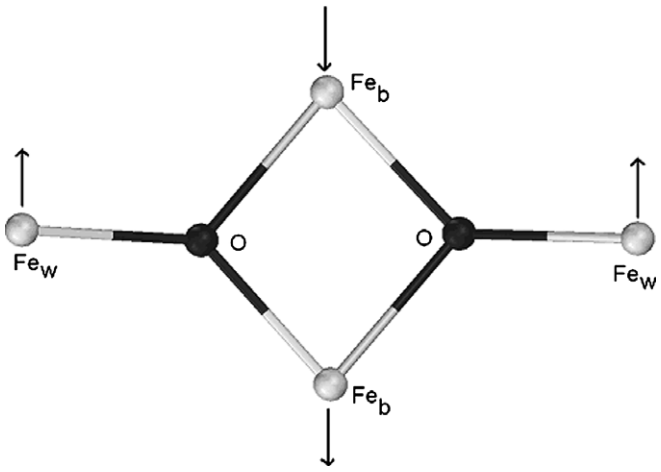


Fig. 5. The temperature dependence of the molar magnetic susceptibility of complex **3**, in the form of $\chi_M T$ vs. T is represented with the open triangles while the solid line represents the best theoretical fit. See text for details.

$$H = J_{bb}(S_1 \cdot S_2) + J_{wb}[(S_1 + S_2)(S_3 + S_4)] \quad (3)$$

The obtained fitting parameters are $J_{bb} = 5.6\ cm^{-1}$, $J_{wb} = 69.7\ cm^{-1}$, $g = 2.0$, and $\rho = 1\%$. The energy difference between the $S = 0$ ground state and the first excited $S = 1$ state is 69 cm^{-1}. An error-surface plot for the fitting shows that while the value of J_{wb} is well determined by the fitting procedure, the value of J_{bb} is not; since J_{wb} is so much stronger than J_{bb} and since there are four J_{wb} interactions and only one J_{bb}, the spin-manifold energies are primarily determined by J_{wb}, making the precise value of

Scheme 3. Magnetic interactions of **3**.

Scheme 4. The spin alignments in **3**.

J_{bb} indeterminate. Thus, a large range of J_{bb} values give essentially equally good fits of the data, although the quoted J_{bb} values give the lowest fitting error. Tetranuclear butterfly iron(III) complexes, and related [30–33] species, are regarded as examples exhibiting spin frustration [34–40]. The strong antiferromagnetic J_{wb} interactions frustrate the weaker J_{bb} interaction leading to the $S = 0$ ground state via the spin alignments shown pictorially in Scheme 4; i.e., the Fe_b spins are parallel in the ground state even though the J_{bb} parameter is most likely negative (antiferromagnetic) [41,42].

A further verification for the amount of paramagnetic impurity is given at the supporting information (figure 2S).

3.3.3. Magnetic study of the Fe2 system

A diagram of the complex $[Fe_2OCl_2(3,4\text{-}D)_2(phen)_2] \cdot H_2O \cdot 3.5MeOH$ (**1**) appears in Fig. 6. Due to low quality of the crystal the structural features[1] of the compound **1** will be used as supporting information in order to define the overall magnetic behavior of the dimmer. Two bidentate alkanoato ligands in *syn–syn* mode and a $\mu\text{-}O^{2-}$ group form bridges between iron atoms separated by 3.159 Å. The distorted octahedral geometry around each Fe(III) is completed with one chelating phen ligand and a chloride ion. The Fe(III)–O–Fe(III) angle of 122.55° and Fe(III)...Fe(III) separation fall in the range 120–124° and 3.090–3.160 Å reported for analogous compounds [11]. The structure is similar with that reported by Vincet et al. [51] while the dinuclear core has been observed in a series of Fe(III) cationic units [11–14].

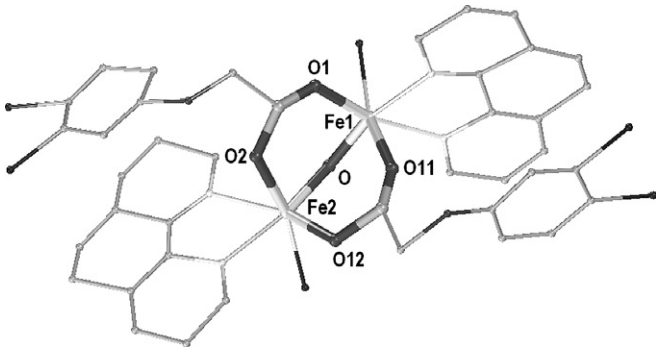

Fig. 6. The dimeric molecule of $\{[Fe_2OCl_2(3,4\text{-}D)_2(phen)_2] \cdot H_2O \cdot 3.5MeOH\}$ (**1**).

The room-temperature value of the susceptibility data in the form of $\chi_M T$ is 0.6 emu mol^{-1} K extremely lower than the value expected for two uncoupled 5/2 spins, which

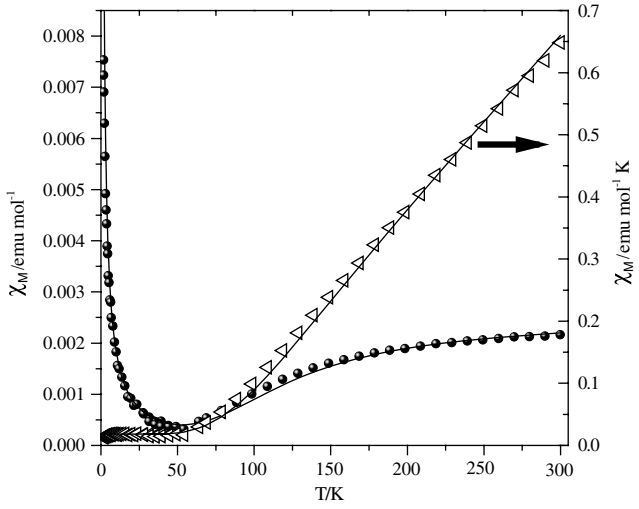

Fig. 7. The temperature dependence of the molar magnetic susceptibility of complex **1**, in the form of $\chi_M T$ vs. T (open triangles) and χ_M vs. T (solid cycles) is represented with the open triangles while the solid lines represents the best theoretical fit. See text for details.

[1] Empirical formula: $C_{43.50}H_{40}Cl_6Fe_2N_4O_{11.50}$; Fw: 1127.19; $T = 298$ K; Crystal sys.: monoclinic; space group: $P2_1/c$; $a = 15.03(4)$ Å; $b = 23.40(6)$ Å; $c = 18.02(4)$ Å; $\alpha = 90.00°$; $\beta = 120.66(5)°$; $\gamma = 90.00°$; $V = 5452(24)$ Å^3; $Z = 4$; D_{calc}: 1.373 Mg/m^3; Final R indices $[I > 2\sigma(I)]$: $R_1 = 0.1788$, $wR_2 = 0.3888$; R-factors based on F^2 are statistically about twice as large as those based on F, and R-factors based on all data will be even larger.

reveals the very strong antiferromagnetic exchange interaction between the two ions (Fig. 7).

The values of $\chi_M T$ decrease monotonically with decreasing temperature until a plateau of 0.02 emu mol^{-1} K in the temperature range 53–1.8 K; the residual $\chi_M T$ value is due to a percentage of paramagnetic impurity which is better shown in the χ_M data (also shown in the same figure) as a curie tail. The fitting results (solid lines in the same figure) gave an exchange interaction $J = 254.1$ cm^{-1} with a small amount of paramagnetic $S = 5/2$ impurity ($\rho = 0.3\%$).

A further verification for the amount of paramagnetic impurity comes from the plot of the reduced magnetization $M/N\mu_B$ vs the external magnetic field at 2 and 4 K (Figure 3S). The nonzero magnetization, although the ground state is $S = 0$, is in accordance with the small percentage of paramagnetic impurity found in the susceptibility data.

4. Conclusion

The structural characterization of bi-, tri- and tetranuclear Fe(III) complexes confirms the ability of alkanoato ligands to give a variety of multinuclear complexes. The formation of binuclear compounds is driven by the presence of chelating phen neutral ligands while the formation of trinuclear or tetranuclear compounds is absolutely dependent of the solvent used. The use of methanol leads to the formation of the trinuclear species while from dmso or dmf solvents the tetranuclear compounds have been isolated. The magnetic behavior of all nuclearities show antiferromagnetic exchange interaction with the ground state of the binuclear and tetranuclear compounds $S = 0$ and for the trinuclear one $S = 1/2$.

Abstract

Three mononuclear *cis*-dioxovanadium(V) complexes of tridentate thiosemicarbazones derived from 5-methyl-3-formylpyrazole (MPA) and *N*(4)-methyl/ethyl/dimethyl thiosemicarbazide have been synthesized and characterized. Single crystal X-ray analyses were performed with $[VO_2L^1]$ (**1**), $[VO_2L^2]$ (**2**) and $[VO_2L^3]$ (**3**), where L^1, L^2 and L^3 denote the [1 + 1] thiosemicarbazone mono-anions derived from MPA and *N*(4)-substituted methyl/ethyl/dimethyl thiosemicarbazide respectively. In all the complexes the vanadium atom is in a distorted square pyramidal geometry with a N_2SO_2 chromophore. The interesting finding in the work is that in complexes **1** and **2**, the thioimine nitrogen unusually participates in coordination whereas in **3** it is the azomethine nitrogen (quite usual) which is involved in the coordination process.

1. Introduction

The coordination chemistry of vanadium is of great current interest because of the discovery of its presence in abiotic as well as biotic systems. The element is present in some sea squirts [1,2]; mushrooms [3,4] and vanadium containing enzymes such as nitrogenase [5] and haloperoxidases [6], etc. Vanadium(V) complexes are known as potent inhibitors of various enzymes. Another important impetus to the coordination chemistry of vanadium in the context of medical applications has arisen from the ability of vanadium complexes to promote the insulin mimetic activity in pathophysiological state of diabetes mellitus in humans [7–10]. This biological and catalytic relevance of vanadium has prompted the synthesis of numerous model vanadium compounds containing O, N donor ligands, whose spectroscopic, magnetic and redox properties have been widely investigated [11–21]. Some other vanadium complexes of O, N donor ligands have been reported in recent times [22]. Although a volume of work has enriched the vanadium chemistry dealing with heterocyclic thiosemicarbazones [23], up until now, little research has centered on vanadium chemistry with thiosemicarbazones having pyrazole as the heterocyclic part. Therefore, considering the broad spectrum of potentially useful biological implications and the catalytic activity of the metal ion complexes with 5-methyl-3-formyl pyrazole thiosemicarbazones, this communication reports the synthesis, spectroscopic and

X-ray crystallographic characterization of three dioxovanadium(V) complexes with 5-methyl-3-formylpyrazole-*N*(4)-methyl/ethyl/dimethyl thiosemicarbazones HL^1, HL^2 and HL^3 respectively. We have reported earlier the synthesis and coordinating behaviour of HL^1 towards the Ni(II) ion [24]. As an extension of the work, we have used the same ligand (HL^1) along with two other similar ligands to study dioxovanadium chemistry in a NNS donor environment. In our previous work [24], we have noticed that the tridentate ligand, HL^1 out of two neighbouring nitrogen atoms – the azomethine and the thioimine – utilizes the azomethine one as one of the donor sites. This common observation is also extensively reported by other authors [23,25] engaged in studies on the coordination behaviour of heterocyclic thiosemicarbazone ligands towards transition metal ions. The peculiarity of this work is that instead of the azomethine nitrogen the unexpected thioimine nitrogen exhibits coordination in HL^1 and HL^2, whereas HL^3 behaves as usual utilizing its azomethine nitrogen as one of the donor atoms. This is quite a novel observation.

2. Experimental

2.1. Reagents and starting materials

Solvents and reagents were obtained from commercial sources and used without further purification unless otherwise stated. *N*(4)-Methyl-3-thiosemicarbazide; *N*(4)-ethyl-3-thiosemicarbazide; *N*(4)-dimethyl-3-thiosemicarbazide were purchased from Aldrich Chemicals, USA. Ethanol was purified using the established method [26].

2.2. Preparation of the ligands HL^1, HL^2, HL^3

All three ligands were synthesized following the same method as reported earlier for HL^1 [24]. *N*(4)-Ethyl-3-thiosemicarbazide and *N*(4)-dimethyl-3-thiosemicarbazide were used instead of *N*(4)-methyl-3-thiosemicarbazide for HL^2 and HL^3 respectively.

HL^1: Yield: ~70%; mp: 201 °C; CHN: (Found: C, 43.54; H, 5.82; N, 34.69%. Calculated for $C_7H_{11}N_5S$: C, 42.63; H, 5.59; N, 35.53); ν_{max}/cm^{-1} 3300, 3190, 1620, 1565, 1040, 865; ^1H NMR δ (d_6-DMSO) 2.26 (3H, s), 2.85 (3H, d), 6.34 (1H, s), 7.95 (1H, s), 8.50 (1H, s), 11.32 (1H, s); $m/z = 197$ (M^+, 100%).

HL^2: Yield: ~67%; mp: 194 °C; CHN: (Found: C, 46.55; H, 5.97; N, 32.86%. Calculated for $C_8H_{13}N_5S$: C, 45.49; H, 6.16; N, 33.17) ν_{max}/cm^{-1} 3300–3210, 1622, 1538, 1027, 837; ^1H NMR δ (d_6-DMSO) 1.06 (3H, t), 2.20 (3H, s), 3.21 (2H, m), 6.33 (1H, s), 7.61 (1H, s), 11.28 (1H, s); $m/z = 211$ (M^+, 53%).

HL^3: Yield: ~69%; mp: 194 °C; CHN: (Found: C, 46.55; H, 5.97; N, 32.86%. Calculated for $C_8H_{13}N_5S$: C, 45.49; H, 6.16; N, 33.17). ν_{max}/cm^{-1} 3300–3200, 1611, 1024, 865; ^1H NMR δ (d_6-DMSO) 2.25 (3H, s), 3.08 (6H, s), 6.24 (1H, s), 8.06 (1H, s), 10.79 (1H, s); $m/z = 211$ (M^+, 82%).

2.3. Preparation of the complexes

2.3.1. Preparation of complex *1*

To a solution of HL^1 (0.447 g, 2.27 mmol) in hot purified ethanol (15 cm^3) was added $VO(acac)_2$ (0.601 g, 2.27 mmol). The green mixture was refluxed for 3 h at water bath temperature, within which time the mixture turned greenish yellow. This mixture was kept at room temperature for slow evaporation. The yellow crystals so formed were filtered off after 72 h, washed with ethanol:water (1:1 v/v) and dried over anhydrous $CaCl_2$. Yield ca. 76%. Yellow crystals of complex **1**, suitable for X-ray diffraction studies were grown by slow evaporation of an ethanolic solution at room temperature.

2.3.2. Preparation of the complexes *2* and *3*

These two complexes were prepared using a similar method as described for **1** employing HL^2 and HL^3 as the ligand respectively. Yields ca. 72% (for **2**) and ca. 69% (for **3**). Pale yellow crystals of **2** and deep orange crystals of **3** suitable for X-ray crystallographic studies were isolated by slow evaporation of an ethanolic solution of the complexes at room temperature.

2.4. Physical measurements

Carbon, hydrogen and nitrogen contents of the ligands HL^1, HL^2 and HL^3 and of the V(V) complexes were determined with a Perkin–Elmer CHNS/O analyzer 2400 at IACS, Kolkata. The molar conductance values of the complexes were measured in DMF solution with a Systronic Model 304 digital conductivity meter. The electronic spectra of the complexes in acetonitrile solution and the diffuse reflectance spectra of the complexes were recorded on a Hitachi model U-3501 spectrophotometer. IR spectra were recorded on a Perkin–Elmer model 883 infrared spectrophotometer. ^1H NMR spectra of the aldehyde and the ligands were recorded in d_6-DMSO with a Bruker AM 300 L (300 MHz) superconducting FTNMR. Mass spectra of the ligands were done with JEOLJMS-AX 500 mass spectrometer. Cyclic voltammetry was carried out using Sycopel model AEW2 1820 F/S instrument. The measurements were performed at 300 K in acetonitrile solution containing 0.2 M TEAP as the supporting electrolyte and 10^{-3}–10^{-4} M of the V(V) complexes, deoxygenated by bubbling with nitrogen. The working, counter and reference electrodes used were a platinum wire, a platinum coil and an SCE.

2.5. Crystallographic measurements

A summary of crystallographic data is given in Table 1. Complete tabulations of crystallographic data, bond lengths and angles, atomic coordinates, thermal parameters and completely labelled ball and stick diagrams are available as supporting information. Data were obtained using a Bruker SMART diffractometer at 293(2) K (for **1**), 93(2) K (for **2**) and 295(2) K (for **3**). Unit cell dimensions

were refined by use of the settings of 25 accurately determined reflections, widely separated in reciprocal space. Intensities were measured by ω-scans. A total of 2064 reflections for **1**, 5153 reflections for **2** and 10008 reflections for **3** were collected. The data were averaged ($R_{int} = 0.031\%$ for complex **1**, $R_{int} = 0.0\%$ for complex **2** and $R_{int} = 0.0454\%$ for complex **3**). The structures were solved by direct methods and subsequent Fourier syntheses were used to determine the remaining non-hydrogen atomic positions.

Intensities were collected for Lorentz and polarization effects, and empirical absorption corrections were applied based on a set of ψ-scans. Calculations for **1** and **2** were carried out using Bruker SHELXTL and Bruker SAINT for **3** (data reduction), SHELXL-97 (absorption correction, structure solution or refinement and molecular graphics). The structures were solved using direct methods and refined on F^2 using full matrix least squares techniques with anisotropic displacement factors for all non-hydrogen atoms. Positions of the hydrogen atoms were calculated from the geometry of the molecular skeleton and their thermal displacement parameters were refined isotropically on a group-wise basis. Selected bond lengths and angles are reported in Table 3. H-Bonding distances and angles are shown in Tables 3a and b.

3. Results and discussion

3.1. Characterization of the ligands HL^1, HL^2 and HL^3

The elemental analyses (C, H and N) and IR spectral data [characteristic bands (cm^{-1}) at 3300–3260 (ν_{NH}), 1575 ($\nu_{CH=N}$), 1095 (ν_{N-Pz}), 1000 ($\nu_{C=S}$)] are in good agreement with the structures in Fig. 1. The absence of any band in the 2600–2200 cm^{-1} region of the IR spectra of the free ligands suggests the absence of any thiol tautomer in the solid state [27,28].

3.2. ^1H NMR spectra of the ligands

The ^{1}H NMR spectra (δ_H ppm) in d_6-DMSO at 300 MHz of the ligand HL^1, HL^2 and HL^3 give singlets at δ 2.26 (3H), δ 2.20 (3H) and δ 2.25 (3H) assignable to C_5–CH_3 (ring pz) and singlets at δ 6.34 (1H), δ 6.33 (1H) and δ 6.24 (1H) due to C_4–H (ring pz) respectively. A narrow split doublet at δ 2.85 ($J = 6$ Hz, 3H) for HL^1 is ascribed to the terminal N–CH_3; a narrow-split multiplet at δ 3.21 (2H) and triplet at δ 1.06 ($J = 6.5$ Hz, 3H) for HL^2 are ascribed to terminal NCH_2CH$_3$ and NCH$_2$CH_3 respectively and a singlet at δ 3.08 (6H) for HL^3 is ascribed

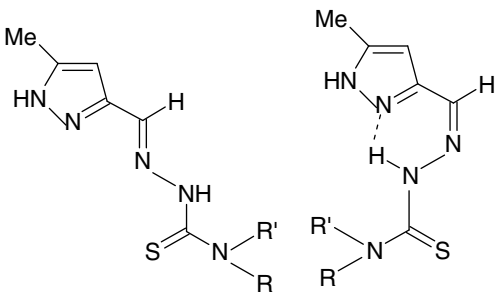

Fig. 1. Structure of the ligands: R = Me, R′ = H in HL^1; R = Et, R′ = H in HL^2; R = Me, R′ = Me in HL^3.

to terminal $N(CH_3)_2$. A slightly broad singlet at δ 7.95 (1H) for HL^1, at δ 7.61 (1H) for HL^2 and a singlet at δ 8.06 (1H) for HL^3 are ascribed to the azomethine proton of the ligand. A singlet at δ 11.32 (1H) for HL^1, at δ 11.28 (1H) for HL^2 and at δ 10.79 (1H) for HL^3 confirm the presence of azomethine NH in all three ligands.

3.3. Characterization of the complex species

The V(V) complexes have been prepared employing a V(IV) starting material such as $VO(acac)_2$. Molecular dioxygen from air serves as the oxidant during the course of the reaction. All the complexes gave satisfactory C, H, N analyses (Table 2) and are diamagnetic in nature. The molar conductance values of the complexes in DMF classify them as non-electrolytes [29].

3.3.1. IR spectra of the complexes

A comparative study of the IR spectral data of the reported complexes with those of the uncomplexed ligand gives meaningful information regarding bonding sites of the ligand molecules. The IR spectra of the complexes show a broad band spanning in the 3400–2900 cm^{-1} region, probably arising from the H-bonding between one of the V=O groups with one pyrazole N atom. The IR band appearing at 1573 cm^{-1} in the free ligand HL^1, HL^2, HL^3 spectra (CH=N) has been observed to shift towards a lower wavenumber by 25–30 cm^{-1} in the IR spectra of **1**, 15–20 cm^{-1} for **2** and by 35–40 cm^{-1} for **3**, due to involvement of the azomethine nitrogen [30] in bonding. In addition, a strong two-band pattern in the 960–840 cm^{-1} region is the signature of the *cis*-dioxovanadium(V) moiety [31] which may be assigned to symmetric and asymmetric ν(O=V=O) vibrations of the *cis*-VO_2 group [32].

An intense strong band at ca. 850 cm^{-1} characteristic for $\nu_{C=S}$ in all three ligands are found to suffer downfield shifts (ca. 80–100 cm^{-1}) after complexation in all the complexes. This indicates that the sulfur atom of the C=S in its deprotonated thiol form functions as the coordination site [30].

3.3.2. Solution spectra of the complexes

A DMF solution of the complexes record spectral data around 34364 cm^{-1} for **1**, 34350 cm^{-1} for **2** and two bands, one around 33350 cm^{-1} and the other around 24250 cm^{-1}, for **3**. Thus for all the complexes, the intense absorption band around 34000 cm^{-1} corresponds to an intraligand transition whereas the additional band for **3** around 24250 cm^{-1} is assignable to a L–V (dπ) LMCT band [33].

3.3.3. ^1H NMR spectra of the Complexes

The ^1H NMR spectral data (δ ppm) of **1**–**3** in d_6-DMSO at 300 MHz give singlets at δ 2.32 (3H), 2.32 (3H) and δ 2.30 (3H) assignable to C_5–CH_3 (Ring Pz) and singlets at δ 6.66 (1H), δ 6.66 (1H) and δ 6.63 (1H) ascribed to C_4–*H* (Ring Pz) respectively. A narrow split doublet at δ 2.95 ($J = 6$ Hz, 3H) for **1** is ascribed to the terminal NCH_3, a narrow split multiplet at δ 3.43 (2H) and triplet at δ 1.18 ($J = 6.5$ Hz, 3H) for **2** are ascribed to terminal NCH_2CH_3 and NCH_2CH_3 respectively, a narrow split singlet at δ 3.26 (6H) for **3** is ascribed to the terminal $N(CH_3)_2$. A slightly broad singlet at δ 8.15 (1H) in **1**, at δ 7.73 (1H) in **2** and appearance of a singlet at δ 8.46 (1H) in **3** is ascribed to the azomethine proton. Thus although the azomethine CH proton appears downfield (compared to the corresponding free ligand) in all the complexes, that in **3** undergoes the maximum downfield shift. This indicates that in **3** the CH azomethine proton, being nearby to the azomethine nitrogen donor center, feels maximum reduction in electron density. In **1** and **2** the azomethine CH proton is quite far from the thioimine nitrogen donor center and hence causes less reduction in electron density around CH. The absence of a singlet around δ 11.3 in **1**, δ 11.1 in **2** and δ 10.8 in **3** confirms the enethiolization process prior to complexation followed by deprotonation during complexation. This is also evident from the X-ray crystal structure studies.

3.3.4. Electrochemistry

Cyclic voltammograms of **1** and **3** were measured in acetonitrile within the potential window +0.20 to −1.5 V. The complexes display irreversible single step one electron responses around −0.78 V vs. SCE corresponding to V(V)/V(IV) reduction. The electrochemical study of **2** could not be performed because of its very poor solubility in the said solvent.

3.3.5. Structure description

The molecular structures of **1**–**3**, including the atom labelling, are shown in Fig. 3a–c respectively (atom labels of **2** appear in lower case in Fig. 3b). Their selected bond lengths and angles are given in Table 3a and b. The $[VO_2L^x]$, $x = 1$–3 unit of the complexes is neutral and mononuclear. In each complex, the unit cell comprises of four molecules. The V atom in each complex is coordinated

Table 2
Analytical data and pertinent physico-chemical properties of the complexes

Complex	Colour	%C	%H	%N	$\Lambda_M\ \Omega^{-1}\ cm^2\ mol^{-1}$ (in DMF)
$[VO_2L^1]$	pale yellow	30.08(30.11)	3.58(3.59)	25.07(25.09)	31
$[VO_2L^2]$	yellow	32.76(33.01)	4.09(4.15)	23.89(24.25)	35
$[VO_2L^3]$	yellow	32.76(33.01)	4.09(4.15)	23.89(24.25)	34

Elemental analyses found (calc.).

to two nitrogen atoms, one thiolato sulfur and two terminal oxo groups. Out of the two nitrogen donor atoms, the pyrazolyl nitrogen is common in all the cases. The other nitrogen is the thioimine (N1 for **1**, N2A/2B for **2**) and the azomethine (N3 for **3**) one.

The thiosemicarbazone molecule functions as singly deprotonated tridentate ligand. The deprotonation is accompanied by tautomerization to the iminothiolate form. The coordination geometry around the V atom in all the three complexes is best described as square pyramidal with a slight distortion towards a trigonal bipyramidal geometry. The Schiff base ligand is coordinated meridionally, occupying the three equatorial positions. The remaining equatorial position is occupied by one of the two oxo groups (O2). The apical position is satisfied by another oxo group (O1). The τ parameters of the complexes (0.20 for **1**, 0.18 for **2** (unit-A), 0.26 for **2** (unit-B) and 0.14 for **3**) also support their square pyramidal geometry. [34,35] The maximum distortion toward trigonal bipyramidal geometry occurs in **2** (unit-B). All the bond angles comprising the adjacent donor atoms in the basal plane and V as well as any one donor atom, V and O1 i.e., O_1VO_2, SVO_1, N_1VO_1 (for **1**, **2**), N_2VO_1 (for **3**), N_3VO_1 (for **1**, **3**) and N_2VO_1 (for **2**) are increased from the ideal value of 90° (Table 3b) because of the shifting of the V-atom from the square plane toward the apical oxygen (O1). The V-atom is shifted from the square plane upward through a distance of 0.560 Å in **1**, 0.569 Å in **2** (unit-A), 0.568 Å in **2** (unit-B) and 0.559 Å in **3**.

The average V=O distances 1.623 Å in **1**, 1.632 Å in **2** and 1.614 Å in **3**, being slightly longer than the normal V=O double bond length of 1.595 Å, indicate that the oxygens are involved in weak hydrogen bonding interactions [36]. The V–N(1) and V–N(3) distances 2.055 and 2.048 Å in **1**, V–N(2A) and V–N(1A) distances 2.071 and 2.050 Å in **2**, V–N(3) and V–N(2) distances 2.184 and 2.043 Å in **3** are in accordance with literature values for V–N distances [36,37].

The asymmetric unit in **2** contains two independent molecules; however, there are conformational differences between them. The vanadium atoms, being separated by a distance of 5.515 Å in the two units A and B, are

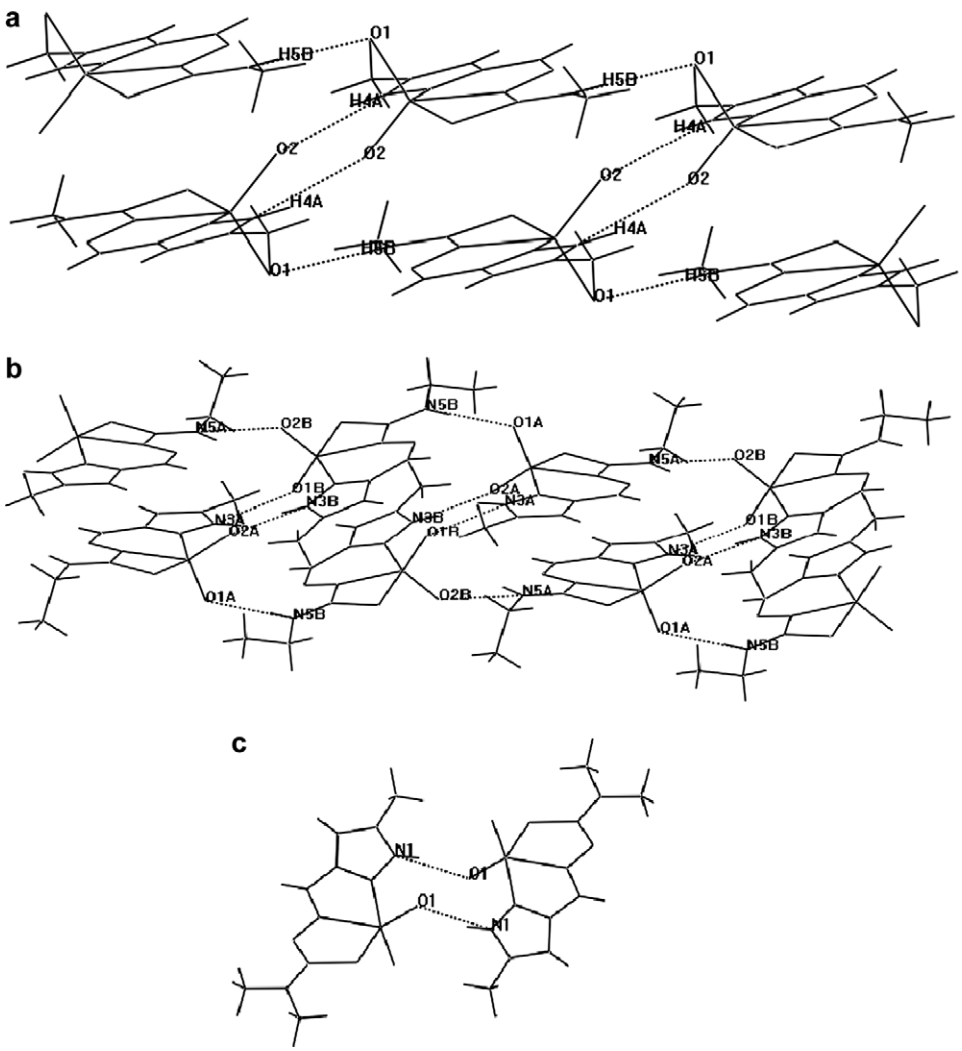

Fig. 2. (a) H-bonding in **1**; (b) H-bonding in **2**; (c) H-bonding in **3**.

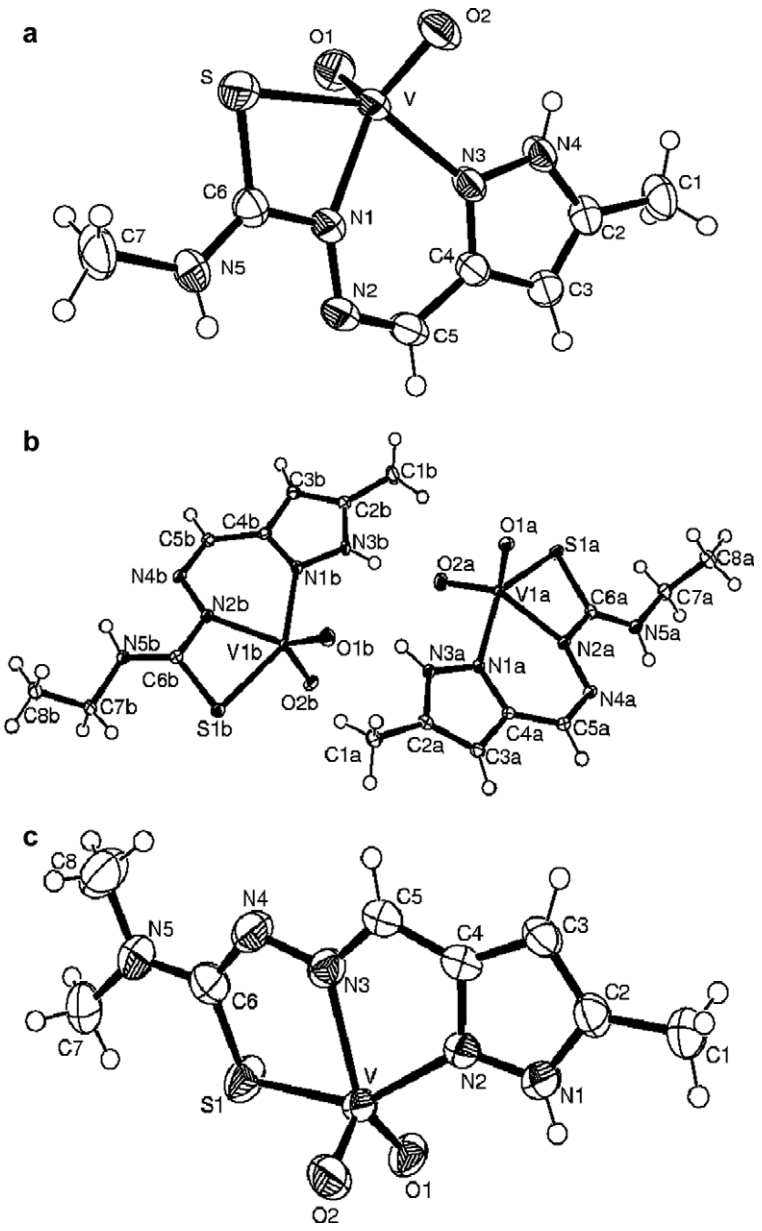

Fig. 3. (a) Molecular structure and atom-numbering scheme for **1** with thermal ellipsoids drawn at the 50% probability level; (b) molecular structure and atom-numbering scheme for **2** with thermal ellipsoids drawn at the 50% probability level. Two equivalent molecules in the asymmetric units, A and B are shown; (c) molecular structure and atom-numbering scheme for **3** with thermal ellipsoids drawn at the 50% probability level.

deviated downward by 0.315 Å and upward by 0.240 Å from the mean plane forming a skew conformation at C1B and C8B and eclipsed at C1A and C7A. The units A and B are joined by weak intermolecular hydrogen bonding.

In case of **1**, C1, C2, C3, C4, N3, N4, C5, N2, N1, C6, S are roughly in the same plane (with a maximal deviation of 0.063 Å) with the vanadium atom shifted by 0.317 Å out of that plane towards O1 [32]. Due to that latter deviation the conformation of the six-membered chelate ring containing V, N3 C4, C5, N2 and N1 atoms is concluded to be an envelope at V. Cremer and Pople [38] puckering analysis shows that the four membered chelate ring containing V, N1, C6 and S atoms also adopts an envelope conformation, but in that case on C6 (with a deviation of 0.111 Å) from the mean plane containing V, S and N1 atoms.

In the case of **2**, C1A/1B, C2A/2B, C3A/3B, C4A/4B, N1A/1B, N3A/3B, C5A/5B, N4A/4B, N2A/2B, C6A/6B and S1A/1B [A for unit-A and B for unit-B] are roughly in the same plane [with a maximal deviation of 0.059 Å for unit-A and 0.056 Å for unit-B]. The vanadium atom is shifted upward by 0.315 Å [for unit-A]/downward by 0.242 Å [for unit-B] out of that plane towards O1A (for unit-A)/O2B (for unit-B). Thus the six-membered chelate ring encompassing V1A/1B, N1A/1B, C4A/4B, C5A/5B, N4A/4B and N2A/2B atoms is enveloped at the vanadium center in each case. Cremer and Pople [38] puckering analysis shows that the four membered chelate ring containing

		S1B–V1B–O2B	101.58(5)		
		S1B–V1B–N1B	145.92(4)		
		S1B–V1B–N2B	67.42(4)		
		O1B–V1B–O2B	109.08(6)		
		O1B–V1B–N1B	97.01(6)		
		O1B–V1B–N2B	130.44(6)		
		O2B–V1B–N1B	100.07(6)		
		O2B–V1B–N2B	120.32(6)		
		N1B–V1B–N2B	78.97(6)		

V1A/1B, N2A/2B, C6A/6B and S1A/1B (unit-A and B) also looks like an envelope on C6 (A and B) with a deviation of 0.067 Å (for unit-A)/0.021 Å (for unit-B) from the mean plane containing the V1A/1B, S1A/1B and N2A/2B atoms.

In the case of **3**, C1, C2, C3, C4, N1, N2, C5, N3, N4, C6 and S1 are roughly in the same plane (with a maximal deviation of 0.200 Å) with the vanadium atom shifted by 0.354 Å out of that plane towards O2. Because of this deviation, the conformation of the five-membered chelate ring containing V, C4, C5, N3 and N2 atoms is proposed to be an envelope at V. The other five membered chelate ring containing V, N3, N4, C6 and S1 atoms is also in an envelope conformation on C6 (with a deviation of 0.204 Å) from the mean plane containing the V, N3, N4 and S1 atoms.

Complex **1** is stabilized through a network of weak H-bond interactions (Fig. 2a). The details are presented in Table 4. The H-bond distances between N3B and O2A [2.708 Å] and O1B and N3A [2.748 Å] support a weakly H-bonded structure in **2** (Fig. 2b, Table 4). Similarly the H-bond distance between N1 and O1 in **3** is 2.77 Å, which also indicates the presence of weak H-bonding (Fig. 2c, Table 4).

Table 4
Details of hydrogen bond distances (Å) and angles (°)

Complex	D–H···A	*d* (D–H)	*d* (H···A)	*d* (D···A)	∠(DHA)
1	N4–H4A···O2	0.8500	1.97	2.760(3)	151

4. Conclusion

We have prepared three V(V) complexes employing *N*(4)-mono/disubstituted pyrazole derived thiosemicarbazone ligands. In the case of *N*(4)-monosubstituted (HL^1 and HL^2) ligands, the unexpected thioimine nitrogen and not the expected azomethine nitrogen functions as one of the donor sites, whereas for the *N*(4)-disubstituted ligand (HL^3), the expected azomethine nitrogen acts as the donor site. The coordinating behaviour of similar types of *N*(4)-substituted aldehydo thiosemicarbazone ligands so far reported, in general, establishes that it is the azomethine nitrogen which functions as one of the donor sites toward transition metal ions. This peculiar coordinating behaviour of the thioimine nitrogen is unique for these *N*(4)-monosubstituted pyrazole derived ligands toward V only.

Abstract

Two new inorganic–organic coordination networks based on a versatile and unsymmetric building block 5-(4-pyridyl)-1,3,4-oxadiazole-2-thione (Hpot) and inorganic Co^{II} and Cd^{II} salts have been synthesized in mixed solvent media and structurally characterized by single-crystal X-ray diffraction analysis. Crystal Hpot (**1**) was obtained from methanol solution. Reaction of $Co(NO_3)_2 \cdot 6H_2O$ with Hpot afforded a neutral two-dimensional (2-D) porous coordination polymer $\{[Co(pot)_2] \cdot 6H_2O\}_n$ (**2**) with a (4,4) network, which shows a 3-D supramolecular network through O–H···O weak interactions. While substituting the transition metal ions used in **2** with $Cd(NO_3)_2 \cdot 6H_2O$, a neutral 2-D coordination polymer $[Cd_2(pot)_4]_n$ (**3**) with a (6,3) network which further extended to a 3-D supramolecular structure through versatile hydrogen bonds C–H···X (X = O, N and S) was obtained. It is remarkable that the building block "pot" anion exhibits versatile coordination modes in complexes **2** and **3**. These results indicate that the versatile nature of this rigid unsymmetric ligand, together with the coordination preferences of the metal centers, plays a critical role in construction of novel coordination polymers. The properties of gas absorption, magnetism and luminescence of **2** and **3** have been investigated and discussed in detail.

Keywords: Coordination complexes; Gas adsorption; Magnetism; Luminescence; Unsymmetric ligand; 5-(4-Pyridyl)-1,3,4-oxadiazole-2-thione; 5-(4-Pyridyl)-1,3,4-oxadiazole-2-thiol

1. Introduction

In recent decades, the construction of metal–organic coordination architectures has witnessed tremendous growth because of their intriguing structures and potential properties [1–4]. Most efforts have focused on using symmetric ligands (e.g., 4,4′-bipyridine and their analogues) [5,6]. However, the use of unsymmetrical ligands is still rare, though a few unsymmetrical ligands have been reported, for example, 2,3′-bipyridine, 2,4′-bipyridine and 3,4′-bipyridine and their analogues [7]. In this respect, our research has focused on designing new unsymmetrically bridging ligands and investigating their self-assemblies with metal centers. The adoption of unsymmetrically bridging ligands is expected to lead to a broader palette of coordination polymers that can be achieved with symmetric ligands. It is anticipated that unsymmetrical ligands can be assembled around metal centers in diverse arrangements, consequently resulting in unprecedented structural features and novel properties.

In our attempt to investigate the design and control of the self-assemblies of metal–organic frameworks (MOFs), we have successfully developed and constructed the intriguing MOFs based on the unsymmetric rigid or flexible ligands [8]. In this work, we synthesized a new unsymmetric rigid bridging ligand 5-(4-pyridyl)-1,3,4-oxadiazole-2-thione (Hpot), which probably results in the versatile structure of supermolecules or coordination polymers and their desired properties. It has characteristics based on the fol-

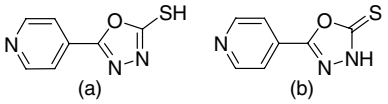

Chart 1. Configuration of Hpot ligand.

lowing advantages: (i) it has two possible configurations (*thione* and *thiol*, see Chart 1), which possesses versatile modes that will lead to novel topological architectures; (ii) it has three potential binding sites. An oxadiazole containing sulfide group exhibiting a variety of coordination modes usually makes the ligand anionic and the framework neutral which gives higher thermal stabilities. The sulfide group generally prefers to coordinate to a soft metal such as Cd(II) [8b]. Meanwhile, the free sulfide groups in the complexes often act as chemical interaction sites, which is attractive for developing new catalytic systems (for example, the moiety can catalyse the transfer of oxygen atoms to produce hydroxy groups) [9]. A pyridyl-type group that is able to satisfactorily complete the coordination sphere of the metal center usually leads to the formation of novel coordination polymers [10]; (iii) it has a strong capability of forming hydrogen bonding interactions that play an important role in the assembly of supramolecular compounds. To the best of our knowledge, this unsymmetric multifunctional building block containing a sulfide group and oxadiazole anion mode is first developed in the process of self-assembly of coordination polymers and supramolecular compounds. Herein, we report the synthesis, characterization and structures of two novel metal complexes with the "pot" ligand, $\{[Co(pot)_2]\cdot 6H_2O\}_n$ (**2**) and $[Cd_2(pot)_4]_n$ (**3**), in which versatile coordination modes of pot were observed. Additionally, the properties of gas adsorption, magnetism and fluorescence for complexes **2** and **3** have also been observed.

2. Experimental

2.1. Materials and physical measurements

The reagents and solvents employed were commercially available and used as received without further purification. The C, H and N microanalyses were carried out with a Perkin–Elmer 240 elemental analyzer. The FT-IR spectra were recorded from KBr pellets in the range 4000-400 cm^{-1} on a Bruker spectrometer. ^1H NMR spectra were recorded on a Bruker ARX-300 NMR spectrometer at 300.132 MHz using DMSO-d_6 as the solvent at room temperature; the DMSO-d_6 signal was used to lock the field and all chemical shifts are given relative to tetramethylsilane (TMS). Thermogravimetric analysis (TGA) data were collected with a Perkin–Elmer TGS-2 analyzer in a N_2 flow at a heating rate of 20 °C min^{-1}. The emission/excitation spectra were recorded on an Edinburgh FLS920 spectrometer equipped with a continuous Xe900 xenon lamp and an nF900 nanosecond flash lamp. The variable-temperature magnetic susceptibilities were measured on a Quantum Design SQUID susceptometer operating at a magnetic field of 0.1 T between 2 and 300 K. The diamagnetic corrections were evaluated from Pascal's constants for all the constituent atoms. Magnetization measurements were carried out at low temperature (2 K) in a 0–5 T range. Gas adsorption measurements were carried out with a Micromeritics ASAP 2010 surface area and porosimetry system. The gas adsorption tests of the desolvate **1** were obtained from the N_2 gas adsorption at 77 K with a volumetric adsorption apparatus. After **2** (712.6 mg) was placed at 80 °C under vacuum for 40 h, the sample had a weight loss of 19.2% ($6H_2O$) for **2**, in agreement with the TGA results.

2.2. Synthesis of the ligand 5-(4-pyridyl)-1,3,4-oxadiazole-2-thione (Hpot, 1)

The ligand Hpot was obtained by the modified literature method [11]. Yield: 78%. Mp: 272 °C. ^1H NMR (300 MHz, DMSO-d_6): $\delta = 8.8$ (d, 2H), 7.8 (d, 2H), 3.4 (br, 1H). IR (KBr, cm^{-1}): ν 3434 (br), 3087 (w), 3032 (m), 2401 (br), 1841 (br), 1596 (s), 1553 (m), 1493 (w), 1420 (w), 1365 (s), 1330 (m), 1309 (w), 1234 (m), 1200 (s), 1149 (s), 1084 (m), 1073 (w), 1051 (s), 1007 (s), 892 (m), 829 (s), 722 (m), 692 (m), 556 (s), 514 (m). ESI-MS (ESITOF N_2): m/z 180 (M+1). *Anal.* Calc. for $C_7H_5N_3OS$: C, 46.92; H, 2.81; N, 23.45. Found: C, 46.80; H, 2.80; N, 23.52%.

2.3. Synthesis of $\{[Co(pot)_2]\cdot 6H_2O\}_n$ (2)

To a solution of Hpot (34 mg, 0.2 mmol) in DMF (10 mL) was added a dilute aqueous solution of NaOH (0.1 M, 2 mL) with stirring to adjust the pH value of the mixture to ca. 7. Then, a water solution (5 mL) of $Co(NO_3)_2\cdot 6H_2O$ (29 mg, 0.1 mmol) was added slowly to the above solution under refluxing conditions for ca. 10 min. The resultant orange solution was filtered after cooling to room temperature. Block purple single-crystals suitable for X-ray diffraction were obtained by slow evaporation of the solvents within one week in 75% yield. *Anal.* Calc. for $C_{14}H_{24}CoN_6O_{10}S_2$: C, 30.06; H, 4.32; N, 15.02. Found: C, 29.95; H, 4.31; N, 15.07%. IR (cm^{-1}): 3408 (br) (ν_{O-H} for H_2O), 1534 (m), 1490 (s), 1424 (s) (skeletal vibrations for pyridyl ring), 1590 (s), 1549 (m), 1200 (s), 1051 (s) (skeletal vibrations for oxadiazole ring).

2.4. $[Cd_2(\mu_2\text{-}pot)_2(\mu_3\text{-}pot)_2]_n$ (3)

Hpot (35 mg, 0.2 mmol) was dissolved in DMF (20 mL). To the above solution was added a dilute aqueous solution of NaOH (0.1 M, 2 mL). A solution of $Cd(NO_3)_2\cdot 6H_2O$ (31 mg, 0.1 mmol) was added to the mixture and a large amount of yellow precipitate formed immediately. The slurry mixture was further vigorously stirred under heating for ca. 30 min, and then filtered after cooling to room temperature. The yellow powdered product was collected and washed with anhydrous methanol. The light-yellow filtrate

was allowed to stand at room temperature, and yellow block single-crystals suitable for X-ray diffraction were obtained by evaporation of the solvents within two weeks. Total yield: 75%. *Anal.* Calc. for $C_{28}H_{16}Cd_2N_{12}O_4S_4$: C, 35.87; H, 1.72; N, 17.93. Found: C, 35.74; H, 1.71; N, 18.00%. IR (cm^{-1}): 1536 (m), 1487 (s), 1425 (s) (skeletal vibrations for pyridyl ring), 1582 (s), 1550 (m), 1185 (s), 1040 (s) (skeletal vibrations for oxadiazole ring).

2.5. X-ray crystallography

Single-crystal X-ray diffraction measurements of **1**–**3** ($0.29 \times 0.09 \times 0.07$ mm, $0.43 \times 0.25 \times 0.24$ mm and $0.25 \times 0.25 \times 0.22$ mm for **1**, **2** and **3**, respectively) were carried out with a Bruker Smart APXII CCD diffractometer equipped with a graphite crystal monochromator situated in the incident beam for data collection at 293(2) K. Data collections were performed with Mo Kα radiation ($\lambda = 0.71073$ Å) by the ω-scan mode. No evidence was found for crystal decay during the data collection of complexes **1**–**3**. All the measured independent reflections were used in the structural analysis, and semi-empirical absorption corrections were applied using the SADABS program. The program SAINT [12] was used for integration of the diffraction profiles. All the structures were solved by direct methods using the SHELXS program of the SHELXTL package and refined with SHELXL [13]. Metal atoms were located from the *E*-maps and other non-hydrogen atoms were located in successive difference Fourier syntheses. The final refinement was performed by full-matrix least-squares methods with anisotropic thermal parameters for all the non-hydrogen atoms on F^2. All the hydrogen atoms were first found in difference electron density maps, and then placed in the calculated sites and included in the final refinement in the riding model approximation with displacement parameters derived from the parent atoms to which they were bonded. A summary of the crystallographic data and structure refinements are listed in Table 1.

Table 1
Crystallographic data and structure refinements for **1**–**3**

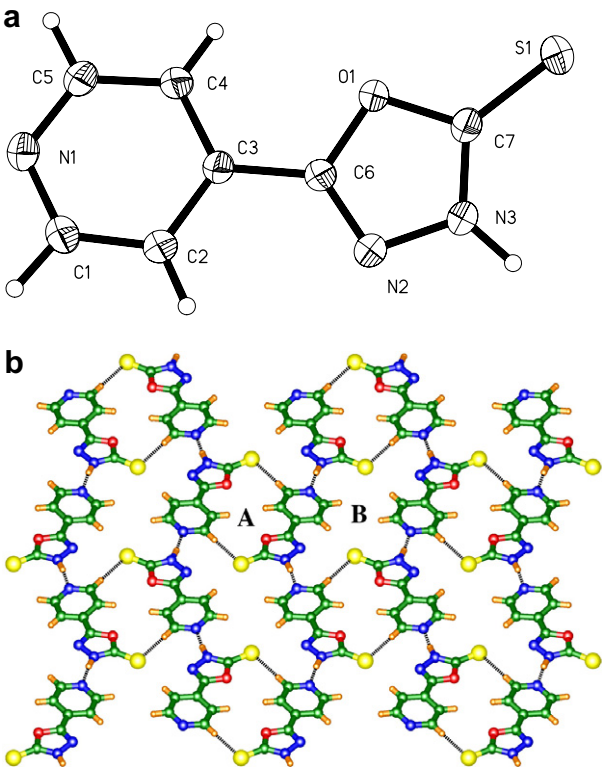
3. Results and discussion

3.1. Preparation of compounds 2 and 3

Compounds **2** and **3** were obtained as neutral molecular complexes in the water system by the combination of Hpot with cobalt and cadmium salts, respectively. Compound **2** could also be isolated according to the same synthetic procedure, but using $CoSO_4$ or $Co(OAc)_2$ as the source of cobalt (confirmed by X-ray diffraction, IR spectra and elemental analyses). A similar case was also observed for the Cd^{II} complex, which indicates that the final products are independent of the counter-anions of the metal salts. Complexes **2** and **3** have 2:1 ligand:metal compositions. Indeed, in these specific self-assembly processes, the products do not depend on the ligand-to-metal ratio (the results were confirmed by X-ray diffraction, IR spectra and elemental analyses). However, increasing the metal-to-ligand ratio results in a somewhat higher yield and crystal quality. Complexes **2** and **3** are air stable and can retain their structural integrity at room temperature for a considerable length of time. Furthermore, the building block "pot" adopts versatile coordination modes in these complexes, which is discussed in detail below.

3.2. Description of 1

Single X-ray analysis of compound **1** reveals that there is one molecule of Hpot in the asymmetric unit (Fig. 1a). The pyridyl and oxadiazole groups are almost co-planar. A pair of Hpot ligands, each using the oxadiazole and pyridyl nitrogen atoms, forms one donor and accept hydrogen bond (N(3)–H(3)···N(1) 2.732(2) Å) in the head–tail form, resulting in one-dimensional hydrogen-bonded chains [14,15]. Between the adjacent hydrogen-bonded chains, each Hpot molecule further forms two donor–acceptor hydrogen bonds (C(5)–H(5)···S(1) 3.852(1) Å) with the thione sulfur of an adjacent oxadiazole ring to another pyridyl ring, resulting in a two-dimensional hydrogen bonded layer along the (0 1 1) plane. These chains align parallel but right about to each other to form a nearly planar supramolecular layer. Two types of hydrogen-bonded patterns A–D, notated as $R_2^2(16)$ and $R_6^6(30)$, are observed in this 2-D array (Fig. 1b). The layers are further extended into a three-dimensional supramolecular array via offset π–π aromatic stacking interactions with a face-to-face distance of ca. 3.54 Å between oxadiazole and pyridyl rings (see Fig. S1).



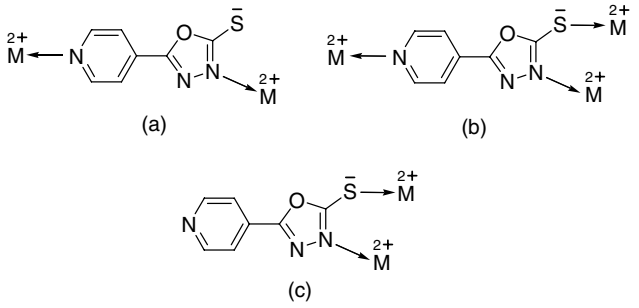


Fig. 1. (a) View of the structure of the free ligand Hpot **1**. (b) 2-D supramolecular network extended by hydrogen bonds along the (0 1 1) plane in **1**. The black dashed-lines stand for hydrogen bonds.

3.3. Description of the crystal structure of $\{[Co(pot)_2(H_2O)_2]\cdot 6H_2O\}_n$ (**2**)

Single X-ray analysis reveals that complex **2** possesses a two-dimensional (2-D) framework constructed of Co(II) centers and "pot" ligands. It is very interesting that the "pot" ligands adopt a μ_2 bridging mode (nitrogen atoms from the pyridyl and oxadiazole groups) in this case, as shown in Scheme 1a. The local coordination environment around the cobalt(II) ion (Fig. 2a) shows that the cobalt sits on a center of symmetry, and each six-coordinate cobalt center is in a perfect octahedron formed by two identical oxadiazole groups (Co(1)–N(1) = 2.158(2) Å) and two pyridine nitrogen atoms (Co(1)–N(3) =

Scheme 1. Coordination modes of ligand "pot" anion.

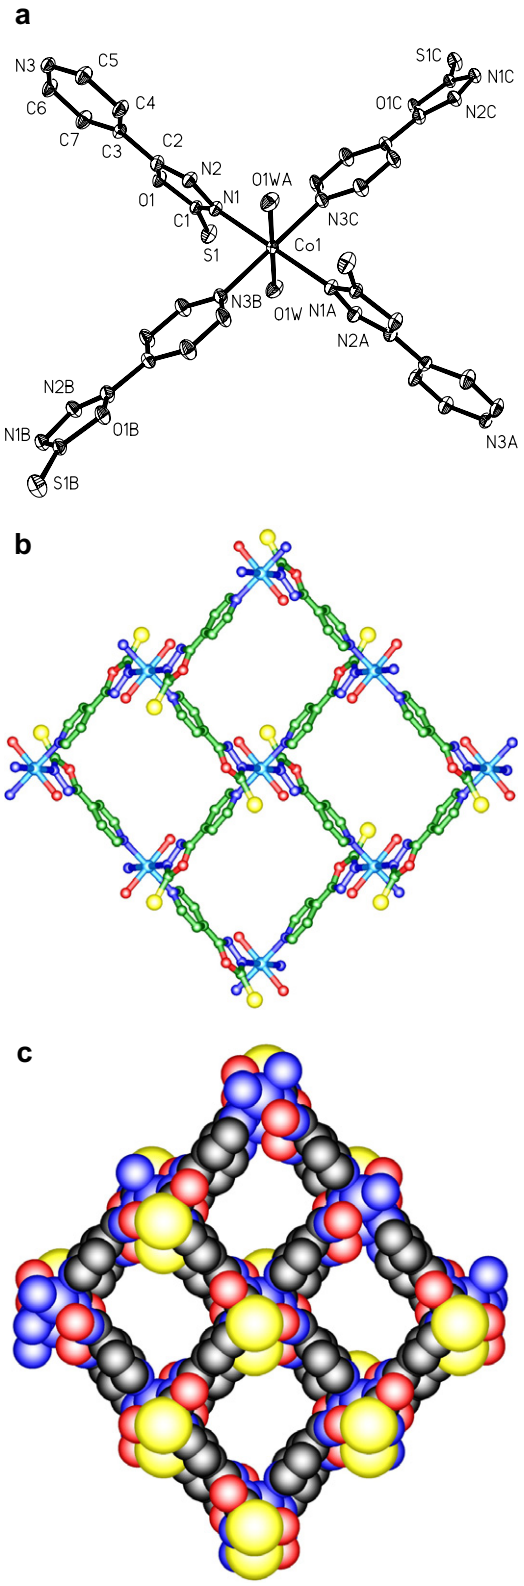

Fig. 2. (a) Local coordination environment around the metal atom for **2** (hydrogen atoms are omitted for clarity). (b) The rhombic grid structure along the *a*-axis for **2**. (c) Space-filling views of the *bc*-plane for **2**. The rhombic grids have the same dimensions with a side length of 10.183 Å and a diagonal measurement of about 12.697 × 15.924 Å (guest water molecules are omitted for clarity).

2.175(3) Å). In addition, two water molecules (Co(1)–O(1w) = 2.101(2) Å) occupy axial positions of the octahedron (see Table 2). Each "pot" ligand in **2** alternately employs its oxadiazole nitrogen atom and pyridine nitrogen atom to coordinate to two cobalt ions, and each cobalt center connects four "pot" ligands. Thus, four cobalt ions and four "pot" ligands form a coplanar tetragon with a side length of 10.183 Å and a diagonal measurement of about 12.697 × 15.924 Å, based on the metal–metal distances. The four cobalt ions lie in the same plane; each subtended "pot" ligand stands up or down the plane. The coplanar shape of the tetragon is understandable, because the "pot" ligand has a rigid linear structure. Such a macrocyclic tetragon (the internal angles of each tetragon are 102.86° and 77.14°) is further extended through the "pot" ligand and metal ions into a 2-D (4,4) neutral network with rhombic grids (Fig. 2b). It is noteworthy that all the cobalt ions in the 2-D frameworks are located in the same plane (see Fig. S2).

[i]Symmetry code for **2**: a, $-x$, $-y+2$, $-z+1$; b, $-x+1/2$, $y-1/2$, $-z+1/2$; c, $x-1/2$, $-y+5/2$, $z+1/2$.
[ii]Symmetry code for **3**: a, x, $y+1$, z; b, $x+1$, y, z; c, $x-1$, y, z.

The most intriguing feature of the structure for **2** is that there is no interpenetration between adjacent layers. These layers are stacked along the *a*-axis with an ABAB sequence, offset by approximately $0.25(b+c)$ along the *bc*-plane so that large channels are created with a square cross-section of ca. 7 Å × 7 Å, as illustrated in Fig. 2c. The stacking separation between two adjacent sheets is ca. 6.37 Å, and the shortest intersheet Co···Co distance is 9.008 Å. The disordered water molecules (6 per formula unit) are incorporated in the channels and the interlayer regions, which yield a variety of hydrogen bonds, and in turn enhance the stability of the apertures [16]. The crystal structure of **2** is similar to previous works that do not have interpenetrations between adjacent layers and can provide large void spaces to accommodate solvent molecules or ions [17,18], but it is very different from those with diverse interpenetrations filling the void space [19–22]. An analysis of the voids of **2** shows 37.7% of the space empties after the removal of these solvents.

3.4. $[Cd_2(\mu_2\text{-}pot)_2(\mu_3\text{-}pot)_2]_n$ (**3**)

The polymeric structure of **3** was revealed by X-ray single-crystal structure determination and has a neutral 2-D network structure. There are two cadmium ions and four distinct "pot" ligands in each asymmetric unit. In the structure of **3**, the Cd(1)^{II} center coordinates to two nitrogen atoms of oxadiazole groups from two distinct "pot" ligands, two sulfur atoms of oxadiazole groups from two different "pot" ligands, and one pyridyl nitrogen donor, as shown in Fig. 3a. The local coordination geometry around the Cd(1)^{II} atom can be best described as a greatly distorted trigonal bipyramid, in which one nitrogen atom and one sulfur atom from two distinct oxadiazole groups occupy the axial positions (Cd(1)–N_{oz} = 2.379(5) Å, Cd(1)–S(3) = 2.826(2) Å) (see Table 2). The Cd1^{II} center lies approximately in the trigonal least-squares plane defined by N(4)–S(3)–N(6)^{i} (i = x, $y+1$, z) with a deviation of 0.318 Å. Two nitrogen atoms and one sulfur atom are in the equatorial plane (Cd(1)–N(6A) = 2.196(4) Å; Cd(1)–N(4) = 2.290(5) Å; Cd(1)–S(3) = 2.5295(15) Å). In the equatorial plane, the bond angles of N_{py}–Cd(1)–S(3), N_{oz}–Cd(1)–S(3) and N_{py}–Cd(1)–N_{oz} are 101.74(14)°, 123.23(13)° and 134.94(18)°, respectively. Similarly, the coordination geometry of the Cd(2)^{II} metal ion is also a greatly distorted trigonal bipyramid (Fig. 3a), in which the axial positions are occupied by one nitrogen atom and one sulfur atom from two different oxadiazole groups. The Cd(2)^{II} center deviates by ca. 0.336 Å from the base plane defined by N(12)^{i}–S(1)–N(10) (i = $x+1$, y, z), which is slight larger than that of Cd(1)^{II}. In the equatorial plane, the bond lengths of Cd(2)–N_{oz}, Cd(2)–N_{py} and Cd(2)–S, and the bond angles of N_{py}–Cd(2)–S(1), N_{oz}–Cd(2)–S(1) and N_{py}–Cd(2)–N_{oz} are almost equal to that of Cd1, respectively. That is, it is noteworthy that there are two kinds of bridging modes of "pot" ligands in **3**, in which one kind of "pot" ligand shows N atoms and S atoms from

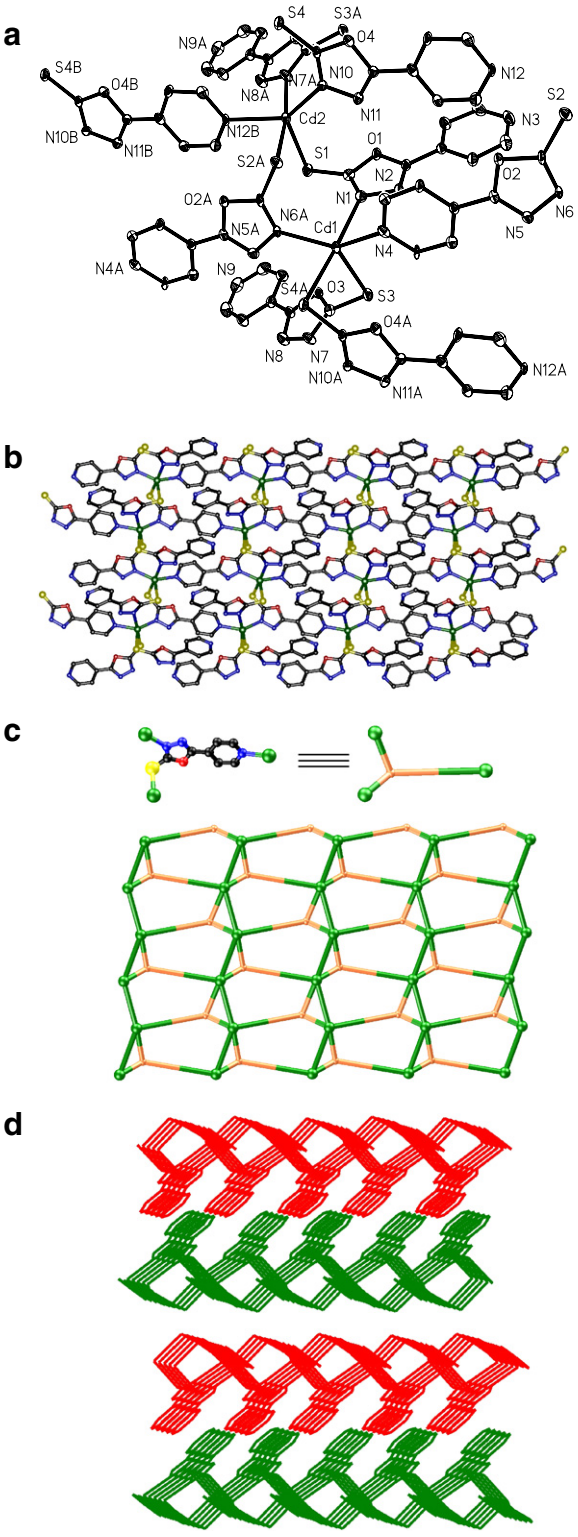

Fig. 3. (a) Local coordination environment around the metal atom for **3** (hydrogen atoms are omitted for clarity). (b) 2-D coordination network along the *c*-axis (hydrogen atoms are omitted for clarity). (c) The simplified 2-D (6,3) network (orange spheres: 3-connected ligand mode). (d) The stacking paragraph in A(−A)A(−A) along the *b*-axis (hydrogen atoms are omitted for clarity).

oxadiazole groups bridging two cadmium ions, that is a 2-connect ligand (Scheme 1c); the another kind of "pot" ligand shows not only N atoms and S atoms from oxadiazole groups coordinating to two Cd^{II} ions, but also N atoms from pyridine groups bridging a third cadmium ion, that is a 3-connect ligand (Scheme 1b). Thus, two "pot" ligands and three Cd(II) ions form a triangle with three side lengths of 5.195 Å, 10.415 Å and 10.094 Å based on the metal–metal distances. The triangle is further extended to a 2-D (6,3) framework with adjacent triagons through sharing Cd(II) ions and "pot" ligands (Fig. 3b and c).

Analysis of the crystal packing of **3** indicates that these 2-D coordinated sheets are closely stacked along the *a*-axis with an A(−A)A(−A) sequence, offset by approximately 0.5 $(y + z)$ along the (0 1 1) plane, as depicted in Fig. 3d. Such a closed packing mode leaves no free space to accommodate guest molecules. The shortest inter-sheet Cd···Cd separation is 6.666(2) Å. As shown in Table 3, there are some hydrogen bonding interactions, H···X (X = O, N and S) separations are in the 2.53–2.84 Å range with C···X (X = O, N and S) distances in the region of 2.892–3.781 Å, and the range of bond angles is between 167° and 171°, being in the normal range of such interactions [15]. These different kinds of hydrogen bonding C–H···X (X = O, or N, or S) weak interactions extend these 2-D layers into a 3-D supermolecular pattern, and in turn further stabilize the 3-D supramolecular packing (see Fig. S3).

3.4.1. Thermogravimetric analysis

To investigate the high thermal stability of the coordination complexes, thermogravimetric analyses (TGA) were conducted to determine the thermal stability of complexes **2** and **3**. TGA of complexes **2** and **3** was performed under a flow of nitrogen gas from room temperature to 700 °C at a heating rate of 20 °C min^{-1}. For **2**, the first weight loss of 19.20% (calcd: 19.30%) from 50 to 120 °C corresponds to the loss of six lattice water molecules per formula unit. Subsequently, the second weight loss of 6.51% (calcd: 6.43%) from 120 to 175 °C corresponds to the loss of two coordinated water molecules per formula unit. The final weight 74.11% (calcd: 74.27%) corresponds to a framework of $[Co(pot)_2]$. Decomposition of the complex begins at 205 °C and ends at 410 °C. The final decomposed product hardly loses any weight upon further heating from 410 to 700 °C. For **3**, a weight loss is not obviously observed in the temperature range 125–170 °C. Subsequently, a slight weight loss occurs in the range 170–210 °C. Decomposition of the complex begins at 210 °C and ends at 420 °C. The final decomposed product hardly loses any weight upon further heating from 420 to 700 °C.

Table 3
Hydrogen bond geometries in the crystal structure of **3**

Complex	D–H···A	D···A (Å)	H···A (Å)	∠D–H···A (°)
3[i]	C(7)–H(7A)–N(9)[a]	3.509(9)	2.59	171
	C(18)–H(18A)–N(3)[b]	3.511(1)	2.59	170
	C(28)–H(28)–S(2)[c]	3.781(7)	2.84	167

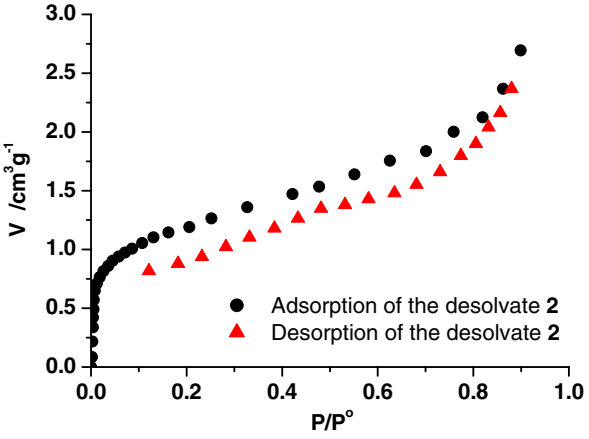

Fig. 4. Gas adsorption isotherms for the anhydrous **2** (the circle stand for the adsorption of the desolvate **2**; the triangle does the desorption of the desolvate **2**).

3.4.2. Gas adsorption isotherm

In view of the microporosity of the complex, the porous compound **2** with channels is investigated for gas adsorption measurements. The gas adsorption isotherms for desolvate **2** were at low levels (1.01 mL/g) with $0.1P_0$ (P_0 = saturation pressure), but were at much higher levels (2.40 mL/g) with $0.9P_0$ (Fig. 4). The pore size distributions of desolvate **2** were calculated and the data were fitted to a Horvath–Kawazoe differential pore volume (HK) plot [23]. The HK plot showed one peak at about 8.2 Å for the desolvate **2**, which agrees with the results of X-ray analysis, and the deviations compared with the crystal structural results should be ascribed to the irregular shapes of the channels [24].

3.4.3. Magnetism property

The magnetic property of complex **2** in the form of $\chi_M T$ versus T plots (χ_M is the molar magnetic susceptibility for one Co^{II} ion) and $M/N\beta$ versus H at 2 K (inset) are shown in Fig. 5. $\chi_M T$ values at 300 K are 3.20 $cm^3\ mol^{-1}$ K for **2**, which are larger than that expected for the spin-only case ($\chi_M T = 1.87\ cm^3\ mol^{-1}$ K, $S = 3/2$), indicating that an important orbital contribution is involved. The $\chi_M T$ values continuously decrease from room temperature to 0.90 $cm^3\ mol^{-1}$ K at 2 K for **2**. The reduced molar magnetization ($M/N\beta$) per Co^{II} tends to $2.3N\beta$ for **2**. The Co···Co distance in complex **2** is 10.183 Å, and the torsion angle between the pyridyl ring and oxadiazole is 5.98°, which avoids any delocalized π-pathway between the Co^{II} ions. As a consequence of these structural features, possible magnetic pathways in **2** are almost non-existent, and thus the magnetic coupling must be almost nil. A quantitative interpretation of the magnetic data are not straightforward because of the orbital degeneracy of octahedral Co^{II}. As indicated by Antolini et al. [25], in non-coupled Co^{II} complexes, the small temperature dependence of down to ca. 100 K rules out any possibility of relevant antiferromagnetic interactions which might in principle also reduce the room-temperature effective magnetic moment. The observed decrease of $\chi_M T$ at lower temperatures can be attributed to the thermal depopulation of the excited Kramer's doublets originated by spin-orbit and low symmetry splitting of $^4T_{1g}$ of the Co^{II} ion.

3.4.4. Fluorescent property

The fluorescence properties and potential applications as light-emitting diodes (LEDs) of aromatic organic molecules, organic polymers and MOFs have been investigated [26]. Construction of MOFs by the judicious choice of building blocks and metal ions can be an efficient method for obtaining new electroluminescent materials, due to the higher thermal stability of MOFs and the ability to alter the emission wavelength of organic materials [27]. The luminescent properties of the free ligand Hpot and its metal complex **3** have been investigated in the solid state. In their solid-state spectra, Hpot exhibits one emission maximum at 346 nm and complex **3** shows one emission peak that is red-shifted to 492 nm (Fig. 6); however, enhancement of fluorescence intensity was not observed. In a word, the emission color of free Hpot is significantly

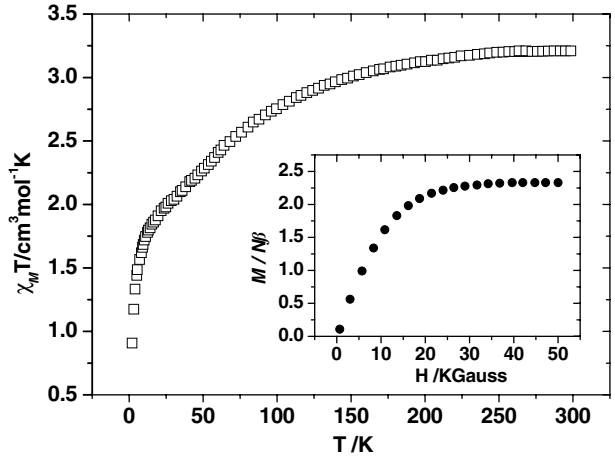

Fig. 5. Plots of the temperature dependence of $\chi_M T$ for **2**. Inset: plot of the reduced magnetization ($M/N\beta$) vs. H at 2 K for **2**.

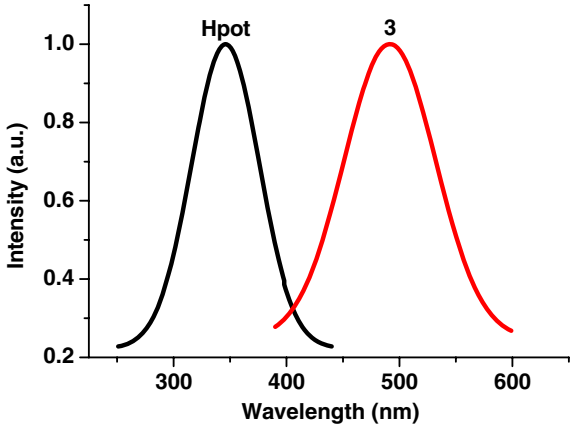

Fig. 6. Photoinduced emission spectra of Hpot and complex **3** in the solid state at room temperature.

affected by its incorporation into the complexes containing metal ions.

4. Conclusions

Two novel 2-D inorganic–organic coordination networks were generated from the multidentate organic ligand 5-(4-pyridyl)-1,3,4-oxadiazole-2-thione (Hpot) and inorganic Co^{II} and Cd^{II} salts. This work demonstrates that the rigid and unsymmetric "pot" anion is capable of coordinating to metal centers with N_{py}, N_{oz} or S donors groups and exhibits versatile coordination modes, which plays a very important role in the properties of these new materials. We are currently extending this result by preparing other new multifunctional ligands of this type with different coordination groups. It is anticipated that this new type of organic ligand will result in a variety of coordination polymers or supramolecules with unique structural features and interesting properties.

Abstract

The reaction of α-benzoinoxime, H_2BNO with $FeCl_3$ in the presence of Et_3N as a base gives the mononuclear Fe(III) complex, $Fe(HBNO)_3$ (**1**). Treatment of **1** with a methanolic solution of KOH at room temperature leads to a dinuclear Fe(III)–Fe(III) complex, $[Fe(HBNO)_2OH]_2$ (**2**). The complexes were initially characterized on the basis of their elemental, mass and thermal analyses. The IR studies were useful in assigning the coordination mode of the benzoinoxime ligand to the iron metal. In addition, the presence of a hydroxo-bridge in the dimeric complex **2** is inferred from the IR spectral studies. Room-temperature Mössbauer studies indicated octahedral, high-spin iron(III). Variable-temperature magnetic susceptibility measurements supported the existence of the μ-dihydroxo-bridging structure core, $Fe^{III}(\mu\text{-}OH)_2Fe^{III}$ in the dinuclear complex **2**. Theoretical modelling of the magnetic data indicated a weak antiferromagnetic spin exchange between the iron(III) centers ($J = -8.35\ cm^{-1}$, $g = 2.01$, $\rho = 0.02$ and $TIP = 1.7 \times 10^{-4}\ cm^3\ mol^{-1}$ for $H = -2JS_1 \cdot S_2$). The electronic spectra of the complexes revealed two bands due to d–d transitions and one band assignable to an oxygen (p_π) → Fe($d_{\pi*}$) LMCT transition observed in each complex. An additional charge-transfer transition, assignable to μ-hydroxo(p_π) → Fe($d_{\pi*}$), was observed for the dimeric complex **2**. The structural and vibrational behaviors of these complexes have been elucidated with quantum mechanical methods.

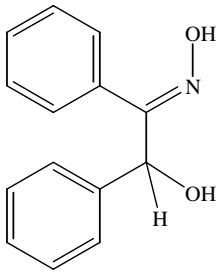
1. Introduction



The importance of iron as an essential element can be estimated by the wide range of iron proteins and enzymes playing different roles in biological systems. Proteins containing non-heme iron centers are widely spread in nature. They perform a broad range of functions, especially activating dioxygen for the oxidation of various substrates [1]. Dinuclear iron complexes in particular have biological relevance since they give valuable information about the binding mode of dioxygen to the iron sites of proteins involved in its transport and activation. They provide structural models for dinuclear sites in several proteins involved in oxygen storage of hemerythrin and oxygen activation of methanemonooxygenase [2–4]. Efforts to model these proteins have simulated the study of complexes containing Fe(μ-O)$_2$Fe and Fe(μ-OH)$_2$Fe cores [5–7]. In addition, these systems were treated as models for understanding the magnitude of exchange coupling interactions between the two iron centers and its relation to geometrical parameters [8]. Studies of some diiron complexes have shown that the oxo-bridge is responsible for strong antiferromagnetic coupling ($-50 > J > -200\ cm^{-1}$) and those complexes with hydroxo, alkoxo, phenoxo-bridges are weakly coupled ($0 > J > -30\ cm^{-1}$) [6,8–10].

We reported previously the synthesis and characterization of dinuclear chromium and molybdenum complexes containing oxo and hydroxo-bridged ligands [11,12]. In the present work, we describe the preparation and characterization of two new iron(III) complexes of the

α-benzoinoxime ligand. The coordination properties of the complexes were studied using FTIR, electronic and Mössbauer techniques. A magneto-structural correlation has been studied by variable-temperature magnetic susceptibility and theoretical modelling of the magnetic data. Semi-empirical theoretical calculations (MM+ and parameterized PM3) have been used to predict the most favored geometry for each complex.

α-benzoinoxime ligand (H_2BNO)

2. Experimental

Ferric chloride, $FeCl_3 \cdot 6H_2O$, and α-benzoinoxime, H_2BNO, were used as purchased from Aldrich chemical Co. Inc. Solvents were dried according to standard procedures.

Variable-temperature (10–300 K) magnetic susceptibility measurements were obtained with an Oxford Faraday magnetometer. Mössbauer measurements were carried out on a multichannel analyzer in constant acceleration mode. ^{57}Co in a Rh matrix (20 mc) was used as a radioactive source and was held at room temperature. The isomer shift was expressed relative to an iron metal absorber. Infrared spectra (4000–400 cm^{-1}) were recorded as KBr pellets on a Thermo Nicolet Nexus 670 FTIR spectrometer. The thermal analyses (TGA–DTA) were carried out under nitrogen with a heating rate of 10 °C/min using a Perkin–Elmer thermal analyzer. The electronic absorption spectra (190–1100 nm) were measured on a Cary 50 spectrophotometer. Samples were run on 10^{-4} M solutions in DMSO. Elemental analyses were performed using a Perkin–Elmer 2400 CHN elemental analyzer. The semi-empirical calculations in this study have been carried out using the Hyperchem 6.01 program package [13]. The Polak–Ribiere version of the conjugate gradient method was used in all energy minimization calculations with a coverage criterion less than 0.001 kcal mol^{-1} $Å^{-1}$. First and separately the benzoinoxime ligand was optimized and the results obtained have been applied for the oxime ligand in each calculation thereafter. The values of Fe–O and Fe–N bond lengths and Fe–O–Fe bond angle in the literatures were used as the starting inputs [6,14–17]. Initial optimization of different geometries of the complexes was performed with molecular mechanics (MM+). The geometry was further refined using parameterized PM3 method. Available parameters for Fe metal were implemented in the PM3 semi-empirical method [18]. The parameterized PM3 was used for the geometry optimization of the complexes under study. Theoretical harmonic vibrational frequencies are related to the experimental fundamentals by the optimum scaling factor λ, determined through a least-squares procedure, given by $\lambda = \sum_i^{all} \omega_i^{theor} \nu_i^{expt} / \sum_i^{all} (\omega_i^{theor})^2$, where ω_i^{theor} and ν_i^{expt} are the ith theoretical harmonic and ith experimental fundamental frequencies (in cm^{-1}) [19]. The molecular root mean square error (rms) was calculated by the square root of the sum over all the modes of Δ_{min} given in Ref. [19], where Δ_{min} is the minimized residual for each mode.

2.1. Synthesis of tris(benzoinoximato)iron(III), $Fe(HBNO)_3$ (1)

A solution of triethylamine (0.2 mL) in ethanol (5 mL) was added dropwise to an ethanolic solution (30 mL) of α-benzoinoxime, H_2BNO (0.38 g, 1.67 mmol) with stirring at room temperature. To the resulting solution, was added an ethanolic solution (10 mL) of $FeCl_3 \cdot 6H_2O$ (0.15 g, 0.55 mmol) and the mixture was heated at 70 °C for 18 h. The purple residue was separated from the reaction medium and then washed with cold absolute ethanol and dried. The residue was dissolved in dichloromethane. Chromatographic separation on a neutral Al_2O_3 column eluted with CH_2Cl_2–ether (90:10% v/v) gave $Fe(HBNO)_3$ as a purple band. Purple microcrystals of the complex were obtained by slow evaporation of the solvent with a flow of argon. The crystals were dried in a vacuum overnight. The product was obtained in 0.35 g (87%) yield.

Anal. Calc. for $C_{42}H_{36}FeN_3O_6$ (MW = 734.62): C, 68.67; H, 4.94; N, 5.72. Found: C, 68.50; H, 5.10; N, 5.77%. TGA, % weight loss (temp. °C): 61.22 (75–210), 23.26 (213–436).

2.2. Synthesis of μ-dihydroxobis{bis(benzoinoximato)-iron(III)}, $[Fe(HBNO)_2(\mu\text{-}OH)]_2$ (2)

To a solution of $Fe(HBNO)_3$ (0.5 g, 0.68 mmol) in 10 mL CH_3CN was added 5 mL CH_3OH solution of KOH (0.04 g, 0.71 mmol), and the mixture was stirred for 36 h. The color of the solution turned red and was dried in vacuum. The residue was washed with hot ethanol (95%) to remove KHBNO. Then the residue was redissolved in CH_2Cl_2 and subjected to chromatography on silica gel column with CH_2Cl_2–ether (80:20% v/v). The red band was eluted and collected. A dark red solid was obtained from the eluent by slow evaporation of the solvent with a flow of argon. The solid product was dried in a vacuum overnight. The product as a red solid was obtained in 64% (0.23 g) yield.

Anal. Calc. for $C_{56}H_{50}Fe_2N_4O_{10}$ (MW = 1050.74): C, 64.01; H, 4.80; N, 5.33. Found: C, 63.92; H, 4.77; N, 5.29%. TGA, % weight loss (temp. °C): 46.41 (61–152), 29.27 (154–326), 10.50 (328–480).

3. Results and discussion

The stoichiometric reaction between α-benzoinoxime, H_2BNO and $FeCl_3$ in the presence of triethylamine as a base has yielded the monomeric complex $Fe(HBNO)_3$ (**1**). Addition of OH^- to complex **1** at room temperature afforded the dimeric product **2**. Chromatographic analyses of both complexes have indicated one isomeric form for each complex.

The complexes were initially characterized on the basis of their elemental analyses, mass spectra and thermal analyses (TGA, DTA). The parent ion peak (*m*/*z*) was observed in the mass spectra at 734 and 1051 for complexes **1** and **2**, respectively. The thermal analyses (TGA, DTA) of complex **1** showed a weight loss of 61.22% in the temperature range 75–210 °C, corresponding to the loss of two molecules of benzoinoxime ligand. The mass loss of 23.26% in the temperature range 213–436 °C, corresponds to two phenyl groups and one OH of the third benzoinoxime ligand. For the dimeric complex **2**, three endothermic peaks were observed. The mass loss of 46.41% in the temperature range 61–152 °C corresponds to two benzoinoxime ligands and two OH groups. The other weight losses of 29.27% and 10.50% in the temperature ranges 154–326 and 328–480°C, respectively, are due to gradual decomposition of the organic fragments of the other benzoinoxime ligands.

The primary ligand, α-benzoinoxime, showed characteristic IR bands at 3326, 1670 and 950 cm^{-1} due to the OH, C=N and N–O stretching vibrations of the oxime group. These bands are observed for complex **1** at 3421 (OH), 1625 (C=N), 1089 and 1024 cm^{-1} (N–O). The C=N stretching vibration has shifted by 45 cm^{-1} to lower frequency. In contrast, the bands corresponding to OH and N–O stretches have shifted to higher frequencies with respect to the parent ligand. Such behavior is evidently indicates that the α-benzoinoxime ligands coordinate to the iron metal through the nitrogen atom of the oxime group [11,20]. The presence of two bands for the N–O stretching vibration indicates different types of N–O groups [21,22]. Consequently, the peaks at 1089 and 1024 cm^{-1} are assigned to free N–O and hydrogen-bonded N–O, respectively.

The infrared spectrum of complex **2** revealed two strong absorptions at 968 and 913 cm^{-1} that are not present in the spectrum of the monomeric complex $Fe(HBNO)_3$. In addition, no band between 800 and 850 cm^{-1} attributable to an oxo bridged structural unit is observed in the IR spectrum of the dimeric complex $[Fe(HBNO)_2OH]_2$ [5,10,23]. Furthermore, the similarity in the absorption peaks due to coordinated benzoinoxime ligand in both the monomeric and the dimeric complexes rules against any type of benzoinoximate bridging in the dimer. Therefore, the bands at 968 and 913 cm^{-1} in the $[Fe(HBNO)_2OH]_2$ dimer are assigned to a vibrational mode associated with the $Fe_2(OH)_2^{4+}$ structural unit. Consistent with this assignment, the infrared spectra of $[Fe(pic)_2OH]_2$ and $[Cr(HBNO)(BNIM)OH]_2$ showed bands due to $Fe_2(OH)_2^{4+}$ and $Cr_2(OH)_2^{4+}$ at 950 and 970 cm^{-1}, respectively [10,12]. Similarly to the monomeric complex **1**, a peak due to stretching vibration of oxime OH is observed at 3422 cm^{-1} for the dimeric complex. An additional peak was observed at 3599 cm^{-1} which is assigned to the

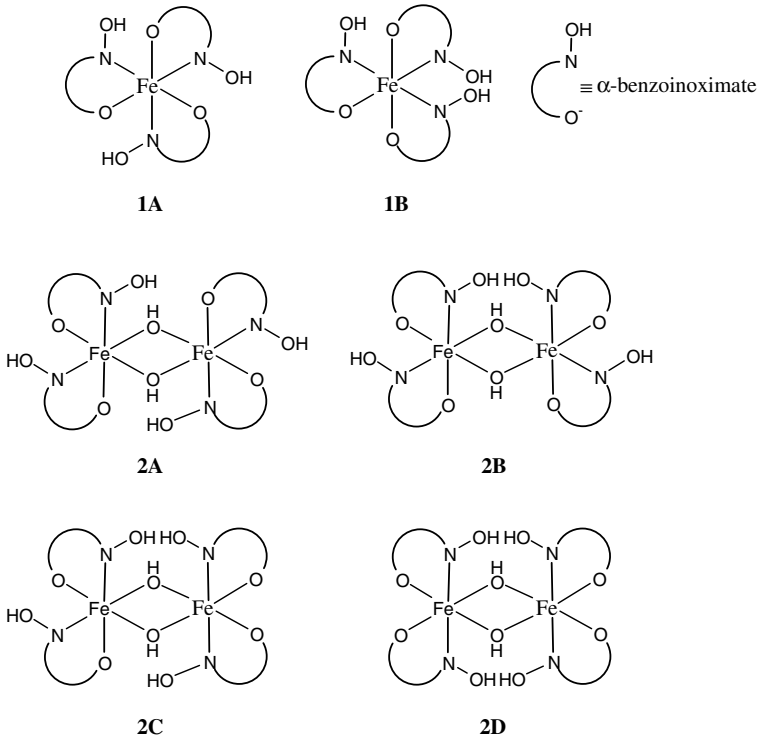

Fig. 1. Chemical structures for complexes **1** and **2** used for semi-empirical calculations.

bridging OH stretch. Finally, bands indicative of two types of N–O groups were observed at 1117 and 1080 cm^{-1} (free N–O) and at 1052 and 1024 cm^{-1} (hydrogen-bonded N–O). Usually, oxime complexes show two N–O bands in the range 1190–1260 and 1071–1110 cm^{-1} for strongly hydrogen-bonded species, whilst in free and weakly hydrogen-bonded species the N–O absorption occurs at ca. 1150 and 1020 cm^{-1} [21,22,24].

The monomeric complex **1** is expected to have two geometrical isomers; facial **1A** and meridional **1B** (Fig. 1), but only one isomer is obtained as indicated by the chromatographic analysis. Now the question is whether the $Fe(HBNO)_3$ has a facial or meridional configuration. Also, the dimeric complex **2**, is expected to adopt one of four geometrical isomers; **2A**, **2B**, **2C** or **2D** (Fig. 1). The spectroscopic techniques gave no information about the geometry of the complex. Hence, it was considered worthwhile to model the complexes using molecular mechanics MM+ and PM3 calculations, especially with the lack of structural analysis due to the poor quality of the crystals obtained.

The PM3 calculated results for each structure are summarized in Table 1. It can be seen that for the $Fe(HBNO)_3$ complex, the facial geometry **1A** is more stable than the meridional one **1B** by 3.8 kcal/mol. These results are in agreement with the structure of the $Co(BMO)_3$ complex, whose structure is characterized with a facial configuration by X-ray diffraction analysis [25]. For the dimeric complex **2**, the energy calculated for **2A** is more stable than those for the other configurations.

The most favored structures for the monomeric and dimeric iron(III) complexes based on semi-empirical PM3 geometry optimization are shown in Fig. 2. In both structures, the benzoinoxime ligand is coordinated to Fe(III) with the oxime nitrogen atom and the deprotonated alcoholic oxygen atom.

The observed and calculated vibrational frequencies for configurations **1A** and **2A** are compared in Table 2. The optimized scale factors determined for **1A** and **2A** are 0.998407 and 0.997745, respectively. The calculated harmonic vibrational frequencies compare well with fundamental experimental frequencies. The calculated root mean square error (rms) per molecule is 70.8 and 64.4 cm^{-1} for **1A** and **2A**, respectively. The rms values compare very well with those reported for vibrational frequency calculations using MP2-fc/631G(d) (rms = 63) and MP2-fc/631G(d,p) (rms = 61) [15].

The magnetic susceptibility data measured for $Fe(HBNO)_3$ revealed a magnetic moment of 5.86 B.M. at 300 K, which is close to the spin-only value (5.92) of high-spin Fe(III). The magnetic moment showed no significant temperature-dependence over the temperature range 300–10 K. Such behavior is indicative of a monomeric, octahedral high-spin Fe(III) complex [23].

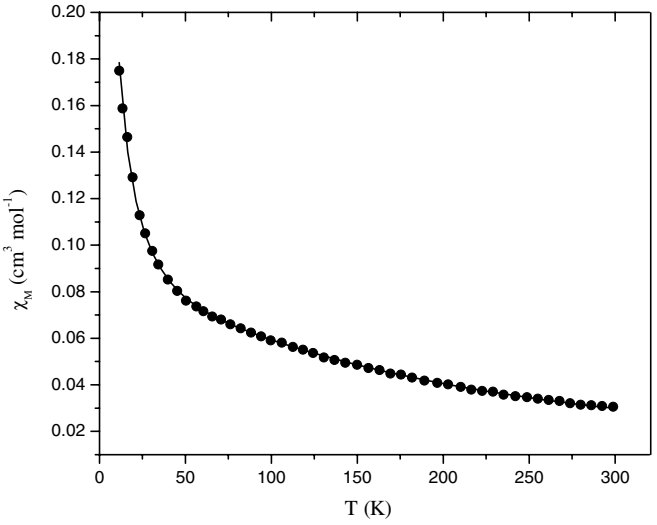

Fig. 3. Temperature dependence of the molar paramagnetic susceptibility, χ_m, curve for $[Fe(HMNO)_2OH]_2$. The solid line represent the least-squares fit of the data to the theoretical equation given in the text.

Magnetic susceptibility data for $[Fe(HBNO)_2OH]_2$ indicate a weak intramolecular antiferromagnetic spin exchange interaction. Both the magnitude and temperature dependence of the magnetic susceptibility typify the behavior of an $S_1 = S_2 = 5/2$ dimer [26]. The effective magnetic moment drops from 8.55 B.M. per molecule at ~300 K to 4.01 B.M. at ~11 K. The data were analyzed with the spin–spin interaction model based on the exchange Hamiltonian($\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2$). The molar paramagnetic susceptibility of an $S_1 = S_2 = 5/2$ exchange coupled Fe(III)–Fe(III) dimer is given by the following equation [27,28]:

$$\chi_M = \frac{2N\beta^2 g^2}{kT}\left[\frac{\chi'}{\chi''}\right](1-\rho) + \frac{2.19g^2}{T}\rho + \mathrm{TIP}$$
$$\chi' = [(55 + 30\exp(-10J/kT) + 14\exp(-18J/kT) + 5\exp(-24J/kT) + \exp(-28J/kT)]$$
$$\chi'' = [11 + 9\exp(-10J/kT) + 7\exp(-18J/kT) + 5\exp(-24J/kT) + 3\exp(-28J/kT) + \exp(-30J/kT)] \quad (1)$$

where, ρ gauges the amount of magnetically dilute ferric impurities and the other terms have their usual meanings. A non-linear least-squares fit to 51 experimental data points yielded $J = -8.35 \pm 0.2\ cm^{-1}$, $g = 2.01 \pm 0.02$, $\rho = 0.02 \pm 0.01$ and $\mathrm{TIP} = 1.7 \times 10^{-4} \pm 0.02\ cm^3\ mol^{-1}$ with $R = 8.29 \times 10^{-4}$. The fit is illustrated in Fig. 3. The value of the coupling constant J is in good agreement with the values reported for other dihydroxo-bridged Fe(III) dimers [6,10,29]. They exhibited coupling constants in the range of -7 to $-11\ cm^{-1}$. In contrast, oxo-bridged Fe(III) dimers are invariably characterized by a coupling constant near $-100\ cm^{-1}$ [30].

The Mössbauer spectrum of the dimeric complex **2** at 298 K is shown in Fig. 4. The spectrum consists of a single symmetric quadrupole doublet with $\Delta E_Q = 0.87$ mm/s and $\delta = 0.43$ mm/s. The values of the quadrupole splitting, ΔE_Q, and the isomer shift, δ, are consistent with the formulation of a complex containing high-spin Fe(III) and are similar to the Mössbauer parameters reported for number of dihydroxo-bridged diiron(III) dimers [30–32].

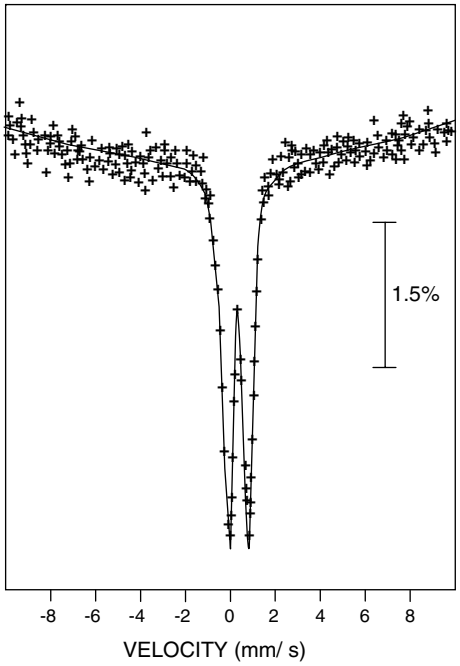

Fig. 4. Room-temperature Mössbauer spectrum of $[Fe(HMNO)_2OH]_2$.

The electronic absorption spectra recorded for the two complexes and the parent ligand as well in DMSO solution over the range 190–1100 nm are summarized in Table 3. The parent ligand displayed two absorptions at 284 and 405 nm corresponding, respectively, to the intraligand π–π^* and n–π^* transitions. The electronic spectra of the Fe(III) complexes are characterized by a band that can

Table 3
The electronic absorption data for α-benzoinoxime and its iron(III) complexes recorded in DMSO

Compound	λ, nm ($\log\varepsilon$)
H_2BNO	284 (2.7), 405[a] (1.5)
$Fe(HBNO)_3$	305 (4.1), 480[a] (3.3), 609 (1.2), 794 (1.0)
$[Fe(HBNO)_2OH]_2$	304 (3.9), 496[a] (3.4), 563 (3.2) 825 (1.1), 935 (1.2)

[a] Shoulder.

be assigned to a ligand-based π–π^* transition, which is normally the most intense band in the higher energy region of the spectra. Both complexes displayed a band that can be assigned to a charge-transfer transition from p_π orbitals of the oxime alcoholic oxygen atom to the half-filled $d_{\pi*}$ orbitals of the Fe(III) metal [32,33]. This band is observed at 480 nm for monomeric complex **1**, and at 496 nm for dimeric complex **2**. The red shift of this charge-transfer band for the dimeric complex with respect to the monomeric complex may explain the colors of the DMSO solutions of the two complexes (solutions of complexes **1** and **2** have purple and red colors, respectively). Two low-energy transitions ($\log\varepsilon \leqslant 1.2$) were observed in the spectra of both complexes and most probably are due to spin-forbidden d–d transitions. They have been assigned to the $^6A_1 \rightarrow {}^4T_1$ and $^6A_1 \rightarrow {}^4T_2$ transitions of high-spin Fe(III) [34]. The dominant feature of the spectrum of the dimeric complex **2** is an intense transition observed at 563 nm ($\log\varepsilon = 3.2$), which is absent in the spectra of both the monomeric complex and the parent ligand itself. This transition can be assigned to a charge-transfer transition from p_π orbitals of the hydroxo-bridged oxygen atom to $d_{\pi*}$ orbitals of the Fe(III) metal. Consistence with this assignment, a similar transition was observed for number of dihydroxo-bridged Fe(III) complexes [32,35].

Abstract

A series of S-alkylated derivatives of 2-thiohydantoins, containing two 5-(3-pyridylmethylene)-3,5-dihydro-4*H*-imiazole-4-one fragments joined by polymethylene bridges with different numbers of carbon atoms, was synthesized. The title (5*Z*,5′*Z*)-2,2′-(alkane-α,ω-diylsulfanyldiyl)bis(5-(3-pyridylmethylene)-3,5-dihydro-4*H*-imidazol-4-ones) (**L**) were obtained by alkylation of 5-(3-pyridylmethylene)-3-phenyl-2-thiohydantoine by 1,2-dibromoethane, 1,6-dibromohexane or 1,10-dibromodecane in DMF in the presence of potassium carbonate. The complexes of ligands **L** with $CoCl_2 \cdot 6H_2O$ have been synthesized. It is shown that, regardless of the **L**:$CoCl_2$ ratio, complexes with **L**$CoCl_2$ composition are obtained in all cases. The structure of the cobalt(II) chloride complex with (5*Z*,5′*Z*)-2,2′-(ethane-1,2-diyldisulfanyldiyl)bis(5-(3-pyridylmethylene)-3-phenyl-3,5-dihydro-4*H*-imidazol-4-one) was determined by means of the RSA method. The cobalt atom in this complex has a tetrahedral ligand environment and it is coordinated by two chloride anions and two nitrogen atoms of pyridine fragments, forming a 19-membered metallocycle. Electrochemical investigations of the synthesized ligands and complexes have been made by CVA and RDE methods. It is established that the first stage of reduction for the complexes takes place on the metal, whereas the first stage of oxidation takes place on the coordinated chloride-anions.

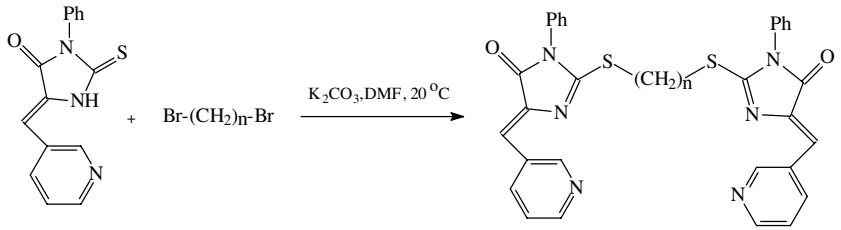
1. Introduction

Recently we have reported the synthesis and structural and electrochemical investigation for a series of 2-alkylthio-(5-pyridylmethylene)-3,5-dihydro-4*H*-imidazol-4-ones [1,2] and (5*Z*,5′*Z*)-2,2′-(alkane-α,ω-diyldisulfanyldiyl)bis-(5-(α-pyridylmethylene)-3,5-dihydro-4*H*-imidazol-4-one) [3] complexes with $CoCl_2$. Some of these complexes demonstrated the capability to react reversibly with molecular oxygen [2] and to catalyze the alkene epoxidation reactions [2,4].

In this work we describe the synthesis of 4H-imidazol-4-one derivatives **1**–**3**, which contain two 5-(β-pyridylmethylene)-3,5-dihydro-4*H*-imidazol-4-one fragments, joined by polymethylene bridges with different numbers of carbon atoms, and the results of their reactions with cobalt(II) chloride.



2. Result and discussion

2.1. Synthesis of the ligands and their complexes

Compounds **1**–**3** were obtained by 5-(3-pyridylmethylene)-3-phenyl-2-thiohydantoine alkylation by different α,ω-dibromoalkanes in DMF:

1, n = 2 (68%)
2, n = 6 (80%)
3, n = 8 (72%)

Based on the literature data, S-alkylated derivatives of 2-thiohydantoins are capable of forming coordination compounds in the reactions with transition metal salts, in which the metal ions coordinate with either or both nitrogen and sulfur atoms [5–12].

To obtain the target coordination compounds the method of slow diffusion of a ligand (**1**–**3**) solution in CH_2Cl_2 into a $CoCl_2 \cdot 6H_2O$ solution in EtOH or CH_3CN was used.

Complexes with composition 1:1 ($\mathbf{L} \cdot CoCl_2$) or 2:1 [$\mathbf{L} \cdot (CoCl_2)_2$] *a priori* would be expected as a result of $CoCl_2$ interaction with the examined ligands **1**–**3** (the collective designation "**L**" will be used below). Nevertheless, regardless of the **L**:$CoCl_2$ ratio, complexes **4**–**6** with $\mathbf{L}CoCl_2$ composition were obtained in all cases (according to elemental analysis and RSA data, complexes also contain additional solvents molecules). All the complexes are poorly soluble in EtOH and CH_3CN, but reasonably soluble in DMF and DMSO:

4, n = 2 (97%)
5, n = 6 (95%)
6, n = 10 (90%)

IR spectra of complexes **4**–**6** show C=O, C=N and C=C group absorption bands at 1730–1640 cm^{-1}, a shifted to lower frequencies when compared to the initial ligands.

In the electronic spectra of ligands **1**–**3** there are only the adsorptions bands in the UV-region due to π–π^* and n–π^* transitions. The spectrum of $CoCl_2 \cdot 6H_2O$, having the metal ion in an octahedral ligand environment, involves three bands of d–d transitions with moderate intensity in visible region (at 500–700 nm) (Table 1). UV–Vis spectra of the complexes **4**–**6** are characterized by lowering of the ligand bands intensities in the UV region, and a shift of the d–d transition bands in the visible region and a decrease of their intensity compared to $CoCl_2 \cdot 6H_2O$ (see Table 1 and Fig. 1). Such spectra are conformed to a tetrahedral coordination environment of the Co(II) ions. All the complexes have very similar electronic spectra, which permit the assumption that their structures are analogous. The tetrahedral configuration of the metal ion in the case of complex **2** was confirmed by RSA data.

2.2. Molecular and crystal structure of *4*

The structure of complex **4** was established by X-ray diffraction. The molecular structure of complex **2**, together with the atom numbering scheme and the selected geometric parameters, is shown in Fig. 2. Crystals available for structural investigation were made by slow diffusion of an ethanolic solution of $CoCl_2 \cdot 6H_2O$ to the solution of ligand **1** in CH_2Cl_2. Crystallographic data and structure

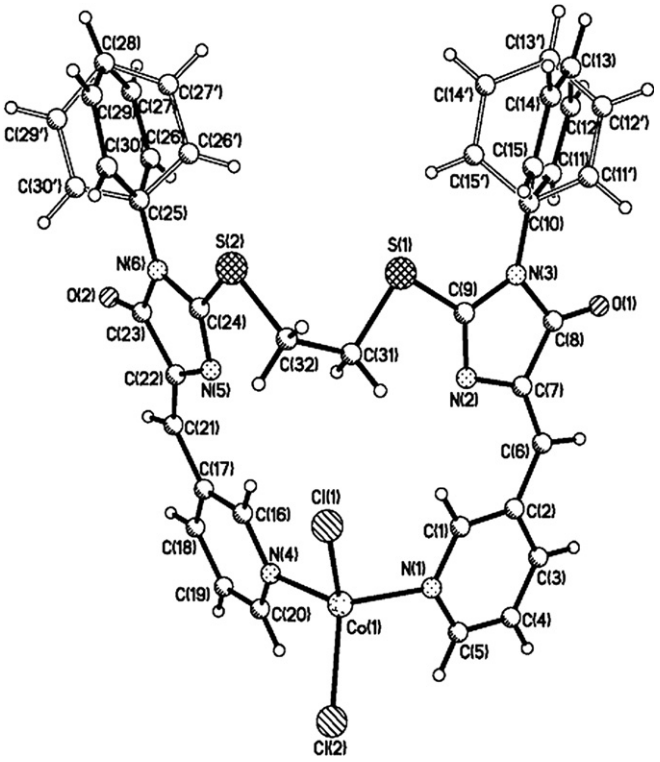

Fig. 2. Molecular structure of **4**. Thermal ellipsoids are given at the 50% probability level.

refinement details are given in Table 2; selected bond lengths and angles – in Table 3. The coordination geometry of the cobalt(II) atom represents a distorted tetrahedron. The metal atom is surrounded by two chloride anions and two nitrogen atoms of pyridine fragments forming a 19-membered metallocycle. This is the first example of a structurally characterized cobalt complex in which a bidentate organic ligand forms such chelate ring upon coordination. The imidazolone and phenyl rings in the ligand fragment are planar and practically coplanar. The phenyl rings in the organic ligand fragment are disordered (see Fig. 2). The two-carbon bridge between the sulfur atoms is orientated to the coordinated cobalt atom; this fact perhaps may be explained by the absence of any repulsion between the phenyl rings at N(3) [N(6)] and H_2C–S-groups in this case.

In the crystal structure of complex **4** additional molecules of methylene chloride and ethanol are present (Fig. 3). The disordered solvate CH_2Cl_2 and EtOH molecules occupy vacancies along the *a*-axis of the crystal.

2.3. Electrochemistry

Compounds **1**–**6** were studied by cyclic voltammetry (CV) and rotating disk electrode (RDE) voltammetry on a glassy-carbon (GC), Pt, and, in some cases, Au electrodes in DMF solutions in the presence of 0.05 M Bu_4NClO_4 as the supporting electrolyte. The electrochemical oxidation and reduction potentials are given in Table 4.

Ligands **1–3** are apparently oxidized primarily at the sulfur-containing fragment, and reduced at the O=C–C=C system, analogous of 2-methylthio-5-(pyridylmethylene)-dihydro-4*H*-imidazol-4-ones [2].

All complexes **4–6** are oxidized at less positive potentials compared to the corresponding ligands (see Figs. 4 and 5). Its first oxidation peaks at ~1.2 V presumably correspond to oxidation of Cl^- anions. The second oxidation peaks are due to oxidation of the organic ligand fragment. Anodic oxidation on a rotating disk electrode gives two-electron

	−2.16[b]			
Complex **5**	−1.25/0.03[a]	−0.88	1.28	1.27 (2)
			1.54	1.53 (1.6)
Ligand **3**	−1.28	−1.22 (2)	1.52	
	−1.98	−1.94 (1.6)		
Complex **6**	−1.25/0.04[d]	−1.08 (2.8)	1.22	1.19 (2)
		−1.83 (5.4)	1.52	

Experimental conditions: DMF, 0.05 M Bu_4NClO_4; CV, 200 mV s^{-1}; RDE, 20 mV s^{-1}; 2800 min^{-1}. The number of electrons transferred in the step, which was determined on a rotating disk electrode by comparing with the one-electron oxidation wave of ferrocene, is given in parentheses.

[a] Peak is not detected without electrolysis at 1.25–1.30 V.

[b] Low-intensity peak.

[c] Peak is better observable on Au electrode.

[d] The reverse peak corresponding to desorption of Co^0 increases with accumulation at the potential of the first reduction wave.

waves for the first stage of oxidation and the one-electron waves for the second stage.

In the cathodic region, the two-electron reduction peaks for complexes **4**–**6** are near to the first peaks of the free ligands reduction, but with an anodic dissolution peak of Co^0 in the reverse scan of the CV curve at 0.02–0.04 V (Fig. 5). The intensity of the latter peak increases −1.30 V. This fact means that the initial stage of reduction occurs "to the metal ions", and independently to either

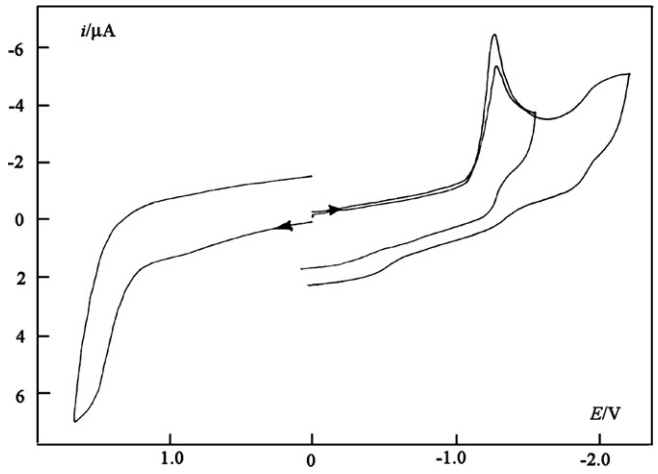

Fig. 4. Cyclic voltammogram of ligand **4** (DMF, 0.05 M Bu_4NClO_4, 10^{-3} M).

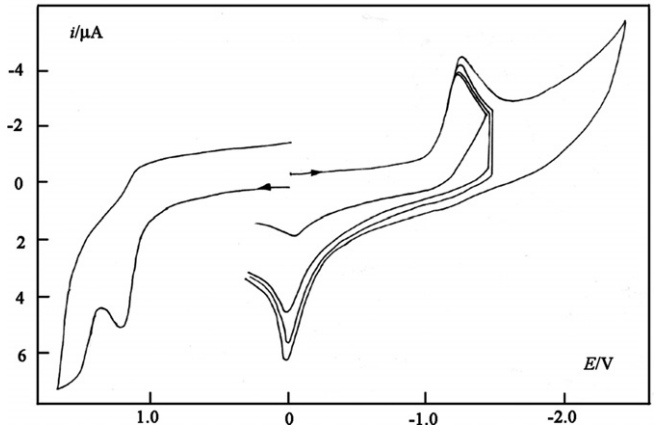

Fig. 5. Cyclic voltammogram of complex **6** (DMF, 0.05 M Bu_4NClO_4, 5×10^{-4} M).

coordinated metal atoms. Note, that the reduced forms of the complexes with a shorter polymethylene bridge between sulfur atoms are more stable than complex **6**, containing the $S(CH_2)_{10}S$-fragment: for the last compound an anodic dissolution peak of Co^0 is observed on the first scan of the CVA curve, whereas for complexes **4** and **5** the said peak is displayed with a marked intensity only under electrolysis at a potential of −1.25 V.

Hereby, complexes **4**–**6** undergo a two-electron reduction "at the metal" in the first step, accompanied by deposition of metallic cobalt on the electrode surface, and are oxidized first at coordinated chloride anions. Both oxidation and reduction first stages are two-electron irreversible processes.

3. Experimental

The starting 2-thioxo-3-phenyl-5-(3-pyridylmethylene)-imidazol-4-one was synthesized from phenyl isothiocyanate, glycine and 3-pyridine carboxaldehyde according to [13].

NMR spectra were registered on a Varian-XR-400 recorder (400 MHz for ^{1}H and 100 MHz for ^{13}C). IR spectra were obtained in Nujol on an IR200 (ThermoNicolet, USA) IR-spectrometer; UV–Vis spectra on a Perkin–Elmer λ-25 spectrometer.

Electrochemical studies were carried out on a PI-50-1.1 potentiostat. Glassy-carbon (2 mm in diameter), Pt (3 mm), or Au (1 mm) disks were used as the working electrodes; a 0.05 M Bu_4NClO_4 solution in DMF served as the supporting electrolyte; Ag/AgCl/KCl(satd.) was used as the reference electrode. All measurements were carried out under argon; the samples were dissolved in the pre-deaerated solvent. Dimethylformamide (high-purity grade) was purified by successive refluxing and vacuum distillation over anhydrous $CuSO_4$ and P_2O_5.

3.1. (5Z,5′Z)-2,2′-(Alkane-α,ω-diyldisylfanyldiyl)bis-(5-(3-pyridylmethylene)-3,5-dihydro-4H-imidazol-4-ones) (typical procedure)

α,ω-Dibromoalkane (0.05 mol) was added to a stirred mixture of 2-thioxo-3-phenyl-5-((*Z*)-3-pyridylmethylene)-2-imidazol-4-one (0.1 mol) and dried K_2CO_3 (0.15 mol) in 50 ml of DMF. The resulted mixture was stirred for 2 h at room temperature, then 50 ml of water was added. The formed precipitate was collected, washed with diethyl ether and recrystallized from ethyl acetate.

*3.2. Synthesis of coordination compounds from ligands **1** to **3** and $CoCl_2$ (typical procedure)*

To a solution of 0.068 mmol of ligand **1**, **2** or **3** in CH_2Cl_2 (placed in a glass tube with approximately 1 cm diameter) pure CH_3CN or EtOH (2 ml) was slowly added, in order to form a diphasic system. Then a solution of 0.068 mmol $CoCl_2 \cdot 6H_2O$ in 2–3 ml of CH_3CN or EtOH was added down the tube side, without mixing the ligand and salt solutions. Thereafter the tube was covered and kept for crystal solid precipitation. The solid was filtered and dried in air. All elemental analysis and melting points are given for the complexes obtained from the CH_3CN/CH_2Cl_2 mixture.

Abstract

New dichloride platinum(II) complexes with 5-methyl-1,2,4-triazolo[1,5-*a*]pyrimidin-7(4*H*)-one (HmtpO) have been synthesized and characterized by thermal analysis, infrared and ^{1}H, ^{13}C, ^{15}N, ^{195}Pt NMR spectroscopy. X-ray crystal structures of *cis*-$PtCl_2(NH_3)$-(HmtpO) (**1**) and *cis*-$PtCl_2(HmtpO)_2 \cdot 4H_2O$ (**2b**) were determined to $R = 0.0332$ and $R = 0.0802$, respectively. In both complexes the Pt(II) ions have a square-planar geometry with two adjacent corners being occupied by two nitrogens of HmtpO molecules for **2b** or NH_3 and HmtpO molecules for **1**, whereas the remaining adjacent corners are occupied by two chloride anions. Spectroscopic data confirm the square planar geometry with N(3) bonded HmtpO, S-bonded dimethylsulfoxide and two *trans* chloride anions for *trans*-$PtCl_2(dmso) \cdot 4H_2O$ (**3**).

Keywords: Platinum complex; 1,2,4-Triazolo[1,5-*a*]pyrimidine derivative; Dimethylsulfoxide; Multinuclear NMR; X-ray structure

1. Introduction

Cisplatin is one of the most commonly used anticancer drugs in the treatment of testicular, ovarian, bladder and head and neck cancer [1,2]. Despite the great success of treating certain kinds of cancer there are several side-effects, and both intrinsic and acquired resistance limit the organotropic profile of the drug [3].

There is a continuing interest in development of new platinum complexes, which are less toxic and have a broader activity spectrum. Variation in the nature of the amine can have a significant effect on the activity and toxicity of these complexes. Several platinum complexes with N-heterocyclic ligands, such as imidazole, thiazole, pyridine and purine derivatives, have been reported [4–7].

Triazolopyrimidine derivatives revealed structures similar to purine, differing from it by the presence of a pyrimidine nitrogen atom in a bridgehead position, and the lack of the acidic H-proton in the five-membered ring [8,9]. Triazolopyrimidine derivatives display a great versatility in their interaction with metal ions, because they can bind metal ions through different sites. Reported studies of triazolopyrimidine complexes display an appreciable variability in their molecular structure. There are examples of mono-, di- and multinuclear structures, which exhibited the central ion and inorganic anions influence on the complex's geometry [10–15]. Nevertheless, when triazolopyrimidines act monodentately to the platinum(II) ion, the preferred binding position appears to be N(3) [12,14]. Mononuclear platinum(II) species such as: *cis*-$PtCl_2$-$(HmtpO)_2 \cdot 2H_2O$ [13], *cis*-$[Pt(HmtpO)_2(NH_3)_2](NO_3)_2 \cdot 2H_2O$ [10] and *trans*-$PtCl_2(dmso)(dmtp)$ [14] revealed N(3) coordinated heterocycles. Polymeric compounds are usually obtained due to N(1) and N(3) coordination [16],

doi:10.1016/j.poly.2006.09.010

whereas dimers with eight-member rings are formed for the N(3), N(4) bridging mode [10]. The exceptions were complexes with 4,5,6,7-tetrahydro-5,7-dioxo-1,2,4-triazolo[1,5-*a*]pyrimidine (H_2tpO_2), where the bidentate ligands were linked through the exocyclic oxygen O(7) and endocyclic nitrogen N(1) [17].

It was recently demonstrated that the coordination compounds with 1,2,4-triazolo[1,5-*a*]pyrimidine revealed biological activity [13,18–21]. Some transition metal complexes with triazolopyrimidines significantly inhibited in vitro cell growth of the epimastigote [19] and Gram(+) and Gram(−) bacteria. The antitumor activity studies (in vitro) of *cis* platinum(II) compounds with the triazolopyrimidine ligands, 5-methyl-1,2,4-triazolo[1,5-*a*]pyrimidin- 7(4*H*)-one (HmtpO) [13], 5,7-diterbutyl-1,2,4-triazolo[1,5-*a*]pyrimidine (dbtp) [20] and 5,7-diphenyl-1,2,4-triazolo[1,5-*a*]pyrimidine (dptp) [20], indicate a moderate antiproliferative activity against the cells of rectal, breast and bladder cancer.

Following this research line, we have tried to synthesize new platinum(II) compounds, which will reveal activity similar to cisplatin, but have an additional functional group, where they could be linked to carrier substances. Therefore, for our studies we have chosen 5-methyl-1,2,4-triazolo[1,5-*a*]pyrimidin-7(4*H*)-one, with a structure similar to the purine ring existing in DNA, as a ligand for platinum(II). In this paper, we present the results on the synthesis and molecular structure characterization of the novel compounds: *cis*-$PtCl_2$(HmtpO)(NH_3) (**1**), *cis*-$PtCl_2(HmtpO)_2 \cdot H_2O$ (**2a**) and *trans*-$PtCl_2$(HmtpO)(dmso) $\cdot 4H_2O$ (**3**).

2. Experimental

2.1. Materials

Dipotassium tetrachloroplatinum(II), 5-methyl-*s*-triazolo[1,5-*a*]pyrimidine-7-ol (98%), potassium hexafluorophosphate (98%), tetraethylammonium chloride hydrate and tetraphenylphosphonium chloride (98%) were purchased from Aldrich, whereas the inorganic salts and organic solvents of analytical grade were from POCh Gliwice (Poland).

2.2. Instrumentation

The content of C, H, N was determined by elemental semi-microanalysis, Pt spectrophotometrically as H_2PtCl_6 on a Specord M40 Carl Zeiss Jena ($\lambda = 400$ nm). Thermogravimetric analyses were performed with a SDT-2960 TA Instrument (samples – 5 mg, heating range 25–1000 °C, heating rate 3.5 deg/min, N_2 atmosphere). IR spectra were measured with a Perkin–Elmer Spectrum-2000 FT-IR spectrometer, using KBr (400–4000 cm^{-1}) and polyethylene discs (100–400 cm^{-1}). The $^1H\{^{13}C\}$ HSQC, $^1H\{^{13}C\}$ HMBC and $^1H\{^{15}N\}$ HMQC spectra were performed with a Varian INOVA-500 NMR spectrometer equipped with an inverse Nalorac Z-gradient shielded probe. The solvent was dmso-d_6, the concentrations of the saturated solutions were ca. 0.01–0.05 M and the temperature was 298 K. The reference standard was TMS for ^1H and ^{13}C, CH_3NO_2 (external) for ^{15}N and K_2PtCl_6 (external) for ^{195}Pt.

The ^{13}C CPMAS spectra were performed with a Bruker AMX 300 MHz spectrometer using a Bruker MAS-VTN500SB BL4 probe head and 4 mm zirconia rotors, at 296 K.

2.3. Preparation of the platinum(II) complexes

Cis-$PtCl_2(dmso)_2$ [22] and $K[PtCl_3(NH_3)]$ [23] were prepared from K_2PtCl_4 by the known method.

Cis-$PtCl_2(NH_3)$(HmtpO) (**1**): To a solution of $K[PtCl_3(NH_3)]$ (0.050 g, 0.13 mmol) in 10 cm^3 of water, a solution of HmtpO (0.0210 g, 0.13 mmol) in 5 cm^3 of 1 M HCl was added. Reaction mixture was stirred at room temperature for 12 h. The yellow precipitate was filtered, washed with water, acetone, diethyl ether and dried in vacuum. Yield 0.0270 g (48%). *Anal.* Calc. for $C_6H_9Cl_2N_5OPt$: Pt, 45.0; C, 16.6; N, 16.2; H, 2.1. Found: Pt, 44.6; C, 16.7; N, 16.0; H, 1.8%.

Cis-$PtCl_2(HmtpO)_2 \cdot H_2O$ (**2a**): A suspension of K_2PtCl_4 (0.100 g; 0.26 mmol) in 5 cm^3 of water was treated with HmtpO (0.0798 g; 0.53 mmol) in 8 cm^3 of 1 M HCl and the reaction mixture stirred at room temperature for 48 h. The yellow precipitate was filtered, washed with water, acetone, diethyl ether and dried in vacuum. Yield 0.0456 g (30%). *Anal.* Calc. for $C_{12}H_{14}Cl_2N_8O_3Pt$: Pt, 33.4; C, 24.7; N, 19.2; H, 2.4. Found: Pt, 33.0; C, 24.3; N, 19.1; H, 2.6%. The thermal analysis confirmed detachment of water molecule (95–140 °C, weight calc. 3.35%, exp. 3.65%). Further decomposition proceeds in several endothermal stages and leads to metallic platinum above 885 °C. By slow crystallization of **2a** from a mixture of HCl and water (1:3 v/v), single crystals of **2b** suitable for X-ray structure analysis were obtained.

Trans-$PtCl_2(dmso) \cdot 4H_2O$ (**3**): A solution of HmtpO (0.036 g; 0.23 mmol) in 5 cm^3 of 1 M HCl was dropped to a solution of *cis*-$PtCl_2(dmso)_2$ (0.100 g, 0.23 mmol) in 10 cm^3 water–ethanol mixture. The reaction mixture was stirred at room temperature for 24 h. The filtrate was left for crystallization and after 3 days a yellow precipitate was filtered off, washed with ethanol, acetone, diethyl ether and dried in vacuum. Yield 0.0443 g (34%). *Anal.* Calc. for $C_8H_{20}Cl_2N_4O_6SPt$: Pt, 34.4; C, 17.0; N, 9.9; H, 3.6. Found: Pt, 34.1; C, 17.1; N, 9.4; H, 3.9%. The content of solvated water molecules in **3** has been confirmed by thermogravimetric analyses. The first endothermic step in the range 83–272 °C corresponds to the mass loss in the TG curves which can be correlated with detachment of 4 water molecules and dimethylsulfoxide (calc. 26.38%, exp. 26.87%). The next endothermic processes (275–820 °C) can be related to decomposition of **3** leaving platinum as a final product.

2.4. X-ray structure determination

Pale yellow crystals of *cis*-$PtCl_2(NH_3)$(HmtpO) (**1**) and *cis*-$PtCl_2(HmtpO)_2 \cdot 4H_2O$ (**2b**) were obtained by slow evaporation from a mixture of HCl and water. Complex **1** crystallized in monoclinic space group $P2_1/c$, whereas complex **2b** crystallized in the triclinic $P\bar{1}$ space group. The X-ray data for **1** and **2b** were collected at 293(2) K with an Oxford Sapphire CCD diffractometer, using Mo Kα radiation ($\lambda = 0.71073$ Å) and the ω–2θ method. The shape-based numerical absorption correction was applied with minimum and maximum transmissions of 0.04914 and 0.39687 for **1** and 0.17132 and 0.55792 for **2b**. The structure was solved by Patterson methods and refined with the full-matrix least-squares method on F2 with the use of the SHELX-97 program package [24]. The data collection and refinement processes are summarized in Table 1. The residual peaks tabulated for **2b** are positioned 1.16 Å from Cl(1) and 0.86 Å from Pt(1), respectively, therefore not indicating any missing atoms. The fractional coordinates of **1**, **2b** and selected bond lengths and angles are presented in Table 4.

2.5. Cytotoxic activity

The antiproliferative activity in vitro against HCV29T (bladder cancer) and T47D (breast cancer) cell lines were performed by using the SRB test as described [20].

3. Results and discussion

3.1. NMR spectroscopy

We have measured ^{1}H, ^{13}C and ^{15}N NMR spectra for **1**, **2a** in solution but not for **3** due to the low solubility of this complex in dmso-d_6 and another solvents. The ^{1}H NMR chemical shifts of the studied complexes are listed in Table 2. The spectra exhibit a singlet at 2.41 (**1**), 2.40 (**2a**) and 2.31 ppm (**3**) for the methyl group and singlets from H(2), H(6) (5.99–8.61 ppm) and H(4) (13.55–13.66 ppm) (Table 2). All signals from H(2), H(6) and H(4) are shifted towards lower fields due to coordination of the triazolopyrimidine ligand. This effect being more expressed for H(2) (0.27–0.44 ppm) and H(4) (0.36–0.44 ppm) than H(6) (0.17–0.26 ppm) (Table 2), suggests slightly stronger deshielding of H(2) and H(4). Therefore the monodentate coordination of HmtpO via N(3) can be proposed, because in the case of the bridging mode (N(3), N(4)), the coordination shifts were bigger (ca. 0.88 ppm) [25]. Additionally, the ^{1}H NMR spectrum of **1** exhibited a broad signal for the NH_3 protons ($\delta =$ 4.06 ppm), which confirms its coordination [26–29].

Coordination sites of the heterocyclic ring were determined by ^{1}H{^{15}N} HMQC spectra of the complexes. In

[a] Data from ^{13}C CPMAS NMR.
[b] The signal was not observed in the spectrum.

the ^{15}N NMR spectra four resonances at: −112.7, −257.3, −251.3, −157.8 for **1** and: −112.1, −257.8, −253.5, −157.9 ppm for **2a** were detected (Fig. 1, Table 3). In comparison to the free ligand spectrum, the shielding effect of N(1), N(3) and N(8) in the complexes is evident, while the biggest coordination shift was observed for N(3) (Δ_{coord} = 91–92 ppm) (Table 3). The strong shielding effect of N(3) is an unambiguous result of N(3) coordination in solution.

^{13}C NMR spectra of **1** and **2a** were recorded, while for **3** no peaks were detectable, due to the low solubility of the latter complex. The signals were assigned by a heterocorrelation ^{1}H–^{13}C technique and data are listed in Table 2. The coordination effect has an impact on C(2) and C(3a) signals which are shielded by 0.7–1.9 ppm in relation to free HmtpO, while C(5) and C(6) resonances are detected 0.7–6.5 ppm towards the low field (Table 2) which can be explained by the deshielding effect of the metal due to coordination via N(3).

A spectrum for complex **3** was measured in the solid phase and data are listed in Table 2. It should be noted that this is the first report of a ^{13}C CPMAS spectrum of HmtpO and one of its platinum(II) complexes. The spectrum presents a similar pattern of coordination shifts as observed in solution (Table 2), which indicates HmptO coordination via N(3). However, the coordination shift of the C(6) signal is larger (maximum 6.5 ppm).

^{195}Pt NMR spectra of **1** and **2a** were measured in dmso-d_6 and data are listed in Table 3. The signals of the *cis*-dichloro complexes were observed at −2089 (**2a**) and −2116 (**1**). These values are at lower field than those

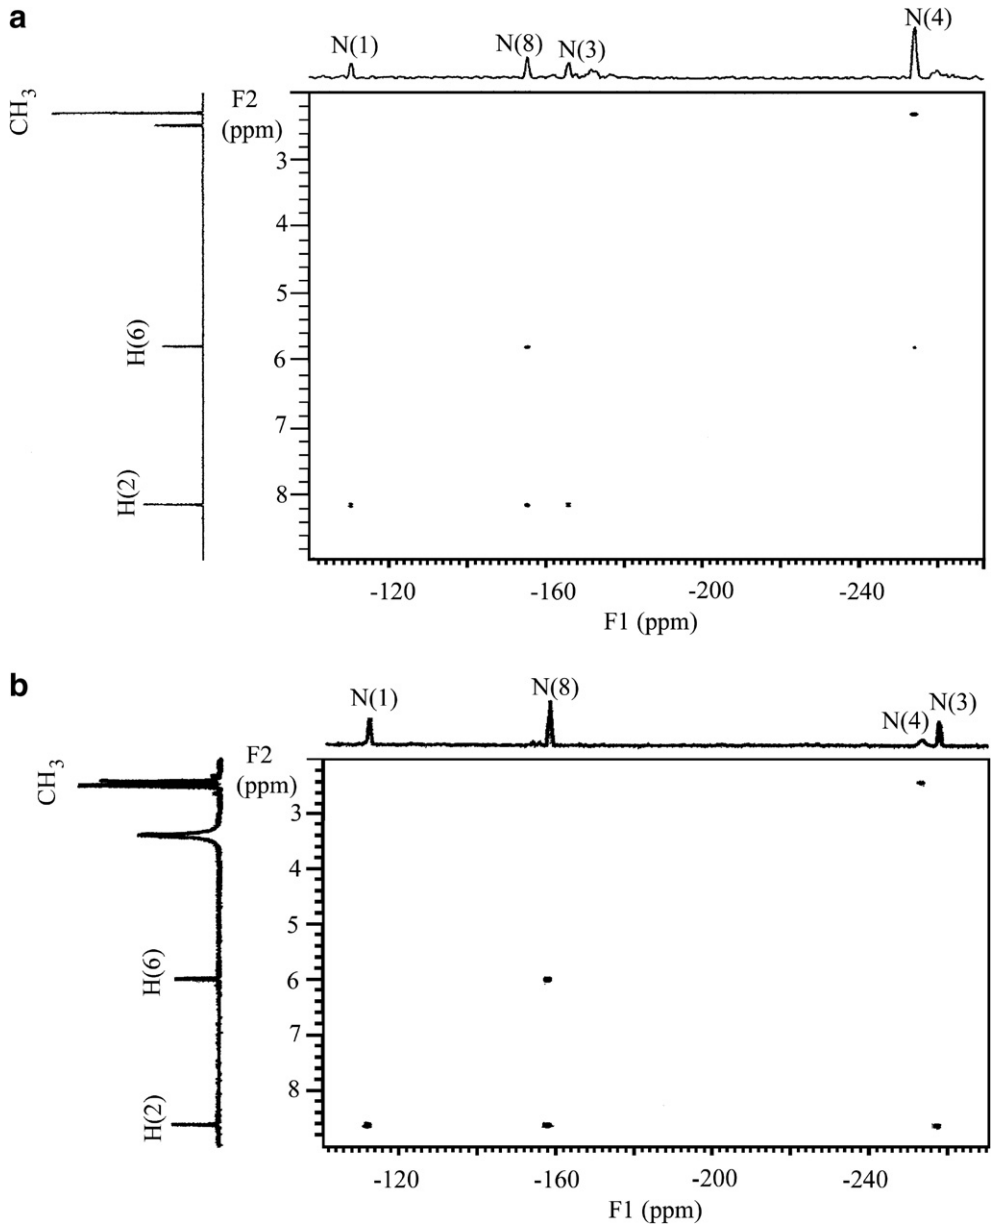

Fig. 1. $^{1}H\{^{15}N\}$ NMR spectra of (a) HmptO; (b) *cis*-$[PtCl_2(HmtpO)_2]\cdot H_2O$ (**1**).

(**1**) *cis*-$PtCl_2$(HmtpO)(NH_3)	−112.7 (−1.9)	−257.3 (−91.6)	−251.3 (+1.4)	−157.8 (−2.5)	−2116 (−492)
(**2a**) *cis*-$PtCl_2(HmtpO)_2 \cdot H_2O$	−112.1 (−1.3)	−257.8 (−92.1)	−253.5 (+0.8)	−157.9 (−2.6)	−2089 (−465)

[a] The ^{195}Pt NMR values in parentheses exhibit the chemical shift related to K_2PtCl_4 ($\delta = -1624$ ppm).

reported in the literature for complexes containing amines. This chemical shift range was also observed for other PtN_2Cl_2 chromophore systems [30–32]. In case of Pt(II) complexes containing amines the chemical shifts of ^{195}Pt were noted at: −2188 ppm (Me_2NH), −2224 ppm (*i*-$PrNH_2$), −2104 ppm (NH_3), −2184 ppm (1-adamantanamine), −2235 ppm (cyclobutyloamine) (in dmf-d_7) [33], whereas for *cis*-pyridine derivatives the chemical shifts were between −1998––2021 ppm (in $CDCl_3$) [34]. However, the resonances for the complexes with triazolopyrimidine derivatives are observed at lower field than those reported in the literature for complexes containing aromatic amines. The low field shift of ^{195}Pt signals can be related to a smaller σ electron donation effect in triazolopyrimidine ligands than in aliphatic amines complexes. This phenomenon can cause a reduction of electron density on the Pt(II) nuclei, resulting in its deshielding and larger ^{195}Pt signal coordination shift.

3.2. IR spectra

Absorption bands of ν(C=O) stretching vibrations at 1724 (**1**), 1709 (**2a**), 1714 cm^{-1} (**3**) upon coordination were shifted towards higher frequencies (max. 23 cm^{-1}). In addition, the two most characteristic bands of pyrimidine and imidazole ring skeleton vibrations after coordination appeared at higher frequencies by 18–30 cm^{-1} and 11–19 cm^{-1}, respectively. A similar effect has been already found for other complexes with N(3) coordinated triazolopyrimidine derivatives [13,14,20].

Table 4
Selected bond lengths (Å) and angles (°) for *cis*-$PtCl_2(NH_3)$(HmtpO) (**1**) and *cis*-$PtCl_2(HmtpO)_2 \cdot 4H_2O$ (**2b**)

Bond/angle	**1**	**2b** Ligand I	**2b** Ligand II
Pt(1)–N(3)	2.022(4)	2.059(8)	2.052(9)
Pt(1)–N(21)	2.029(5)		
Pt(1)–Cl(1)	2.2667(15)	2.276(3)	
Pt(1)–Cl(2)	2.2971(16)	2.290(3)	
C(2)–N(3)	1.355(7)	1.355(14)	1.350(13)
N(3)–C(3A)	1.323(6)	1.293(13)	1.286(12)
N(3)–Pt(1)–N(21)	91.7(2)	92.2(3)	
N(3)–Pt(1)–Cl(1)	176.13(13)	178.9(2)	87.6(2)
N(21)–Pt(1)–Cl(1)	87.30(16)		
N(3)–Pt(1)–Cl(2)	89.57(14)	87.8(3)	179.3(2)
N(21)–Pt(1)–Cl(2)	177.49(16)		
Cl(1)–Pt(1)–Cl(2)	91.60(7)	92.30(14)	
C(3A)–N(3)–Pt(1)	129.7(3)	124.3(8)	127.7(7)
C(2)–N(3)–Pt(1)	125.6(3)	126.8(8)	124.9(7)

In the spectrum of **3**, two new intensive absorption bands were detected at 1135 and 1024 cm^{-1}, which can be assigned to ρ_{CH3} rocking vibrations and ν_{SO} stretching vibration, respectively [22,35]. Similar bands were noted in the spectra of *trans*- and *cis*-$PtCl_2$(thiazole)(dmso) where S-bonded dmso was postulated (1150 and 1140 cm^{-1}, respectively) [29,36]. Recently, we have found a ν_{SO} band in the spectra of *trans*-$PtCl_2$(dmso)L complexes (L = 1,2,4-triazolo[1,5-*a*]pyrimidine or its 5,7-disubstituted derivatives), at similar frequencies (1142–1147 cm^{-1}) [14].

From group theory calculations, for a C_{2v} coordination sphere geometry ($PtCl_2N_2$) two of each stretching vibrations of Pt–Cl and Pt–N should of A_1 and B_1 type, all active in IR spectra. Far-IR spectra of complexes **1**–**3** exhibit one broad band of medium intensity, which can be assigned to Pt–Cl vibrations (A_1) (332–342 cm^{-1}). In the spectra of **1** and **2a** the second band appeared as a shoulder, due to coincidence with the ligand normal oscillations. However, the frequencies of the ν(Pt–Cl) bands in the spectra of the studied complexes were in the range characteristic for the *cis* geometry. In the case of platinum(II) complexes with HmtpO one broad band was reported at 330 cm^{-1} [13]. Similar complexes with 1-(2-aminophenyl)isoquinoline derivatives exhibit the band in the range 328–335 cm^{-1} [7], whereas those with substituted benzimidazole derivatives between 337 and 312 cm^{-1}, which is consistent with the values reported in this work [37].

3.3. Crystal structure of *cis*-$PtCl_2(NH_3)$(HmtpO) (**1**)

The crystal structure of **1** is formed by *cis*-$PtCl_2(NH_3)$-(HmtpO) units. The atom numbering scheme of **1** is shown in Fig. 2.

The coordination sphere of **1** is formed by the ammine and HmtpO ligand bonded in *cis* positions and two chloro ligands. The rms deviation of the atoms from the best PtN_2Cl_2 plane is 0.05 Å. The HmtpO ligand is coordinated via the N(3) atom, the Pt–N distance being 2.022(4) Å. The ammonia N(21) atom forms a 2.029(5) Å bond to platinum(II). The chloro ligands form Pt–Cl(1) and Pt–Cl(2) bonds of 2.267(2) and 2.297(2) Å, respectively, as expected for such bonds. The slight elongation of Pt–Cl2 might result from the *trans* influence of the ammine ligand and the steric effect of the HmtpO ligand being stronger than that of the ammine ligand. That conclusion is supported by the observed value of the N(3)–Pt(1)–Cl(2) angle 89.6(1)°, slightly larger than that of 87.3(2)° found for N(21)–Pt(1)–Cl(1).

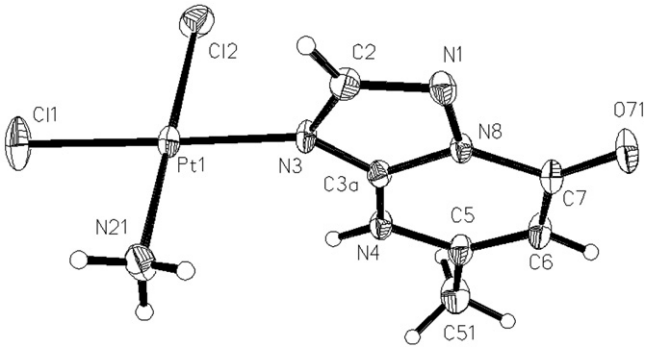

Fig. 2. Molecular structure of compound **1** as determined from X-ray diffraction data.

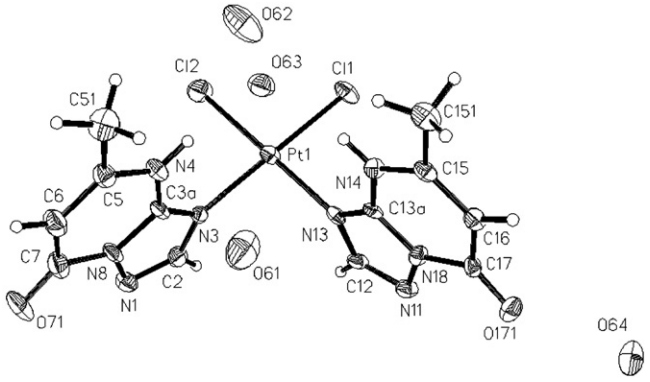

Fig. 3. Molecular structure of compound **2b** as determined from X-ray diffraction data.

The HmtpO ligand is planar, the rms deviation of the atoms from the best plane is 0.0127 Å. However, there is a slight bend of the ring system along the N(8)–C(3a) bond, the angle between the triazole ring and pyrimidine ring planes being 1.1(4)°. The HmtpO ring system is almost perpendicular to the PtN_2Cl_2 plane, the dihedral angle being 88.97°.

The intermolecular interactions in the crystal lattice include a network of hydrogen bonds formed by all donor N–H groups of the ligands. The ammine ligand N(21) forms H-bonds to Cl(2) $[-x+1, y+1/2, -z+3/2]$, O(71) $[x+1, y, z]$ and Cl(1) $[x, -y+1/2, z+1/2]$ atoms (N···Cl/O distances of 3.430, 3.103 and 3.244 Å, respectively). N(1)–H participates in the 2.904 Å contact with N(4) $[x, -y+1/2, z+1/2]$. The C(2)–H and C(6)–H groups form almost linear interactions to chloride ions, C(2)···Cl(2) $[1-x, -y, 2-z]$ and C(6)–H(6A)···Cl(2) $[-x, 0.5+y, 1.5-z]$ being 3.579(6) and 3.551(6) Å, respectively. The corresponding H(2A)···Cl(2) and H(6A)···Cl(2) distances are 2.67 and 2.64 Å, while the C(2)–H(2A)···Cl(2) and C(6)–H(6A)···Cl(2) angles are 165.9° and 167.5°, respectively. Such C–H···Cl interactions have been reported for other complexes of 1,2,4-triazolo-[1,5-*a*]pyrimidines [14] and indicate the significant polarization of these C–H bonds.

3.4. Crystal structure of *cis*-$PtCl_2(HmtpO)_2 \cdot 4H_2O$ (**2b**)

Cis-$PtCl_2(HmtpO)_2 \cdot 4H_2O$ molecules form the crystal structure of **2b**. The atom numbering scheme is shown in Fig. 3.

The structure of the new form of *cis*-$[PtCl_2(HmtpO)_2] \cdot 4H_2O$ (**2b**) was solved in the triclinic $P\bar{1}$ space group. A similar X-ray structure of $[PtCl_2(HmtpO)_2]$ dihydrate was solved in the monoclinic $P2_1/c$ space group with poor diffraction data [13]. However, the authors reported problems with the refinement of the second HmtpO ligand and explained the poor data quality by crystal dehydration during the experiment. Analysis of that paper revealed that one of the HmtpO ligands had a significant disorder, which resulted in its isotropic refinement and large values of the reported atomic displacement parameters, being 5 times the average value for the other HmtpO ligand. Also, authors commented that the poor quality data did not allowed any discussion of the ligand geometry [13]. Therefore, we decided to re-determine the structure of **2b** because of its biological significance and compare it with the structure of **1**. The crystal of **2b** was taken out from the solution and immediately mounted on the diffractometer for a fast experiment with the CCD detector. The reported structure contains four independent water molecules, two of which reveal slightly larger atomic displacement parameters than the other two. That might indicate the ability of the crystal to partially dehydrate and also a possible change of the lattice symmetry. However, the analysis of the experiment does not reveal the possible choice of the monoclinic cell corresponding to the dihydrated complex [13]. Furthermore, the quality of the new triclinic form of the hydrated *cis*-$[PtCl_2(HmtpO)_2] \cdot 4H_2O$ structure (**2b**) reported here is much better than that of the monoclinic form determined by the other authors [13]. Partial dehydration would be consistent with the difficulties of getting high quality diffraction data, we tried several crystals (with relatively high R_{int}), as reported by the other group [13].

Similar to the lower quality complex structure, the coordination sphere is formed by two *cis* chloride ions and two HmtpO ligands bonded to the Pt atom via N(3) atoms [13]. The Pt(1)–Cl(1) and Pt(1)–Cl(2) distances observed in **2b** are 2.276(3) and 2.290(3) Å, respectively and are similar to the analogous distances in complex **1**. The Pt(1)–N(3) and Pt(1)–N(13) distances are 2.059(8) and 2.052(9) Å, respectively and are slightly longer than those found in **1**. The HmtpO ligands are oriented in the same way with respect to the chloride ligands (Fig. 3). Such a position results from the pair of H-bonds formed by the N(4)–H groups to water O(63).

The HmtpO ligands are planar, the rms deviation of the atoms from the best plane is 0.013 and 0.019 Å for the N(1)–N(8) and N(11)–N(18) ligands, respectively. The dihedral angle between the best planes of these two ligands is 70.3(2)°. The corresponding value reported for the

Table 5
Structural differences between mononuclear Pt(II) complexes with triazolopyrimidines

Compounds	Bond distances (Å)		Angles (°)		Ref.
	Pt–N(3)	Pt–Cl	L–Pt–N(3)	Pt–N(3)–C(3A)	
cis-$PtCl_2(HmtpO)_2 \cdot 2H_2O$	2.00(2) 1.98(2)	2.278 (6) 2.274(8)	91.7(4) 89.7(7) 178.5(6) 177.3(4)	129(1) 130(2)	[13]
cis-$[Pt(NH_3)_2(HmtpO)_2](NO_3)_2 \cdot 2H_2O$	2.018(8) 2.012(8)		88.0(3) 90.9(3) 90.6(3) 90.7(3) 176.6(3) 176.3(3)	127.0(6) 129.5(7)	[25]
trans-$PtCl_2$(dmtp)(dmso)	2.048(5)	2.295(2) 2.303(2)	87.63(15) 89.2(2) 176.9(2)	[a]	[14]

[a] Data unavailable.

monoclinic form [13] was 79.8°, and has been strongly affected by the reported HmtpO ring disorder. The dihedral angles formed between the coordination PtN_2Cl_2 plane and HmtpO ring systems are 82.0(2) and 73.4(2)° for N(1)–N(8) and N(11)–N(18) ligands, respectively. The bend of the HmtpO ring system along the N(8)–C(3a) bond is similar to that detected in **1**. The dihedral angle between the triazole ring and pyrimidine ring planes are 1.2(8) and 2.2(6)° for N(1)–N(8) and N(11)–N(18) ring systems.

The intermolecular interactions include the network of H-bonds formed by N(1)–H(1A)···O(64) $[-x-1,-y,-z+1]$, N(4)–H(4A)···O(63) and N(14)–H(14A)···O(63), the corresponding N···O distances being 3.025(2), 2.788(2) and 2.854(2) Å. The water molecules also interact with other waters and chloride ions, although lack of hydrogen atoms in the model does not allow a discussion of the details of those interactions. One C–H···Cl interaction was found, that is analogous to those described for **1**. That is C(12)–H(12A)···Cl(1) $[-x,-y,1-z]$ with a C···Cl distance of 3.693(11) Å and C–H···Cl angle of 173.2°. The series of stacking interactions between the ring systems of the neighboring molecules complete the packing interactions.

Table 5 presents the main structural differences between known mononuclear Pt(II) complexes with triazolopyrimidines. Careful interpretation has shown that the Pt–N and Pt–Cl distances are not significantly different, but the Pt–N bond seems slightly longer when it is in a *trans* position to the chloro ligands. These results indicate that the *trans* influence of the chloro and triazolopyrimidine ligands is very similar and it might be greater for chloro ligands. However, more X-ray data are needed to determine with a bigger probability that the *trans* impact of the chloro ligands is larger than the influence of the heterocyclic ligands.

3.5. Cytotoxic activity

Many transition metals complexes with triazolopyrimidines show significant antitumor activity [13,20]. We have observed high activity of similar platinum(II) complexes with analogs of HmtpO (e.g 5,7-diphenyl-1,2,4-triazolo[1,5-*a*]pyrimidine (dptp) and 5,7-diterbutyl-1,2,4-triazolo[1,5-*a*]pyrimidine (dbtp) [20]). The in vitro antiproliferative activity of the studied platinum compounds **1**, **2a** was determined against two human cell lines: T47D (breast cancer) and HCV29T (bladder cancer). However, the obtained results indicate that studied platinum complexes are not cytotoxic in the concentration range 0.1–100 μg/ml.

4. Conclusion

The molecular structure and antiproliferative activity in vitro of mononuclear platinum(II) complexes with HmtpO were studied. The observed coordination mode via N(3) may be regarded as representative for triazolopyrimidines and analogous to N(9) complexation in purine. The crystal structures of **1**, **2b** indicate that the Pt(II) ion has a square planar geometry with N(3) bonded HmtpO, N-bonded second ligand (NH_3 (**1**) and HmtpO (**2b**)) and two *cis* chloride anions.

The results of the human cancer cell lines treatment with the new platinum(II) complexes confirm lower cytotoxicity of these compounds than cisplatinum in the concentration range 0.1–100 μg/ml.

5. Supplementary material

CCDC 276404 and 276405 contain the supplementary crystallographic data for **1** and **2b**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Nickel(II) complexes of di-, tri- and tetra-peptides built up from Asp and/or Glu residues have been studied by potentiometric, UV–Vis and circular dichroism spectroscopic methods. The stoichiometry of the complexes are the same as in the case of common oligopeptides, but the presence of the side chain carboxylate groups results in differences in their stabilities and coordination modes. The presence of the β-carboxylate groups increases the metal binding affinity of the peptides in all cases. This is due to the coordination of the first, second and third aspartic acid residue in the case of the NiL, $NiH_{-1}L$ and $NiH_{-2}L$ complexes, respectively. The high negative charge of Asp_4 suppresses the metal ion coordination of the third amide function, therefore the $NiH_{-3}L$ complex does not form with this tetrapeptide. In the case of peptides containing glutamic acid, no stability enhancement appears because there is only a weak interaction between the nickel(II) ion and the γ-carboxylate group, which is not able to compensate the disfavoured effect of the increasing negative charge of the complexes.

1. Introduction

Nickel is an essential element for many bacteria, plants and probably plays role in the metabolism of higher organisms. Although a deficiency disease for nickel in humans has not been identified, there is substantial evidence for the essential status of nickel [1]. On the other hand, nickel(II) ion is one the most frequent causes of allergic contact dermatitis (ACD) [2]. Dermatitis may be persistent in certain occupations and can result in sick leave or even an inability to work [3]. The initial step of antigen formation in ACD is commonly considered to be a covalent binding of an electrophilic hapten with the nucleophilic residue of proteins or other molecules in the skin [4]. Nickel ions have been shown to dissolve in sweat [5], and in contrast to classical haptens, metal ions do not form stable covalent protein modifications. They are rather known to produce geometrically highly defined coordination complexes with four or six donor atoms such as nitrogen or oxygen in amino acid side chains of appropriate proteins or peptides. Formation of these complexes is reversible and allows the exchange of the allergenic metal ions between different acceptor sites [6,7]. The most common oxygen donor groups in the side chain are the carboxylate groups of aspartic or glutamic acid residues, moreover the aspartic acid residue is part of the active site of biologically significant substances, such as thymopoietin, fibrinopeptide A, angiotensin II, Cu,Zn-superoxide dismutase and transketolase enzymes. Studies of tri-, tetra- and penta-peptides mimicking the active site of these biomolecules demonstrated the important role of the side chain carboxylate groups [8–16].

In our previous paper [17], equilibrium and spectroscopic results on the copper(II) complexes of di-, tri- and tetra-peptides built up from Asp and/or Glu residues

doi:10.1016/j.poly.2006.09.014

were studied. In accordance with expectations, it was found that the presence of two to five carboxylate functions generally results in enhanced metal binding ability of the ligands and it is especially true for the oligopeptides of aspartic acid. The presence of N-terminal aspartic acid enhances the stability of CuL with a β-alanine-like (NH_2,β-COO^-) coordination mode. In the case of AspAsp (Asp_2) and AspAspAsp (Asp_3) the (NH_2,N^-,β-COO^-) and (NH_2,N^-,N^-,β-COO^-) coordination modes will be favoured, which contain (5,6) and (5,5,6)-joined chelate ring systems, respectively. The outstanding stability of the latter binding mode and the high negative charge of the corresponding species suppress metal ion coordination of the third amide function of AspAsp-AspAsp (Asp_4).

Less data on the nickel(II) complexes of aspartic acid containing peptides is available. The results obtained from studies on nickel(II) complexes of tri- and tetra-peptide segments of thymopoietin (ArgLysAspVal, ArgLysAsp and ArgLys(Arg)Asp) [9] as well as Asp-AspAsp and a series of tetra-peptides containing one or two Asp or one Glu residue [18] were reported. These results reveal that similarly to copper(II) complexes, the β-carboxylate group of the Asp residue enhances the stability of the complexes, especially for peptides containing Asp on the N-termini. These ligands are coordinated tridentately to nickel(II) ions resulting in formation of octahedral NiL complexes at a lower pH range and NiL_2 for excess of ligands. The formation of the $NiH_{-1}L$ complex is considerable only for tetra-peptides containing the Asp residue in the second position. In other cases its amount is not significant or it is not detectable because of the cooperative deprotonation of the amide nitrogens. The cooperativity is especially high for tri- or tetra-peptides containing Asp in the third position. The formation of a stable $NiH_{-2}L$ complex with (NH_2,N^-,N^-,β-COO^-) coordination hinders the deprotonation of the third amide. The appearance of $NiH_{-3}L$ was not observed in the nickel(II)–thymopoietin segments systems [9], although its formation is supposed above pH 9 (about 0.5 log unit higher pH compared to the nickel(II)–tetraalanine [11] system) for the tetra-peptides containing one or two aspartic residues [18]. The presence of a side chain carboxylate group of glutamic acid, however, has a much smaller effect on the complex formation processes; they are very similar to those of tetraalanine.

In this paper we report the results obtained from the systematic investigations of nickel(II)-complexes of di-, tri- and tetra-peptides containing two or more aspartic and/or glutamic acids (Asp_2, Glu_2, AspGlu, GluAsp, Asp_3, Glu_3, Asp_4) by potentiometric, UV–Vis and circular dichroism (CD) spectroscopic techniques. Our goal was to study the influence of β- and γ-carboxylate groups as well as the effect of increased negative charge of the ligands on the complex formation processes of nickel(II)–ligand systems.

2. Experimental

2.1. Materials

The peptides AspGlu, GluAsp, Asp_2, Glu_2, Asp_3, Glu_3, Asp_4 and Ala_3 were purchased from Bachem and their purities checked by TLC (thin layer chromatography) and HPLC (high performance liquid chromatography) methods. Concentrations of the peptide stock solutions were determined by potentiometric titrations. A stock solution of nickel(II) chloride was prepared from analytical grade reagents and the concentration was checked gravimetrically *via* the precipitation of the oxinate.

2.2. Potentiometric studies

The pH-potentiometric titrations in the pH range 2.5–11.5 were performed on 3 cm^3 samples in the concentration range 2×10^{-3}–8×10^{-3} mol dm^{-3} at metal ion to ligand ratios ranging between 1:3 and 2:1. The measurements were made with a MOLSPIN pH meter equipped with a 6.0234.100 combined electrode (Metrohm) and a MOL-ACS microburette controlled by a computer.

The titrations were performed with a carbonate free stock solution of potassium hydroxide of known concentration. During the titration argon was bubbled through the samples to ensure the absence of oxygen and carbon dioxide, and to stir the solutions. All pH-potentiometric measurements were carried out at a constant ionic strength of 0.2 M KCl and at a constant temperature (298 K). The number of experimental points reached around 50–70 data (cm^3 – pH) for each titration curve. The pH readings were converted into hydrogen ion concentration as described earlier [19]. Protonation constants of the ligands and the overall stability constants ($\log\beta_{pqr}$) of the complexes were calculated by means of general computational programs, PSEQUAD [20] and SUPERQUAD [21], using Eqs. (1) and (2).

$$pM + qH + rL \rightleftharpoons M_pH_qL_r \quad (1)$$

$$\beta_{pqr} = \frac{[M_pH_qL_r]}{[M]^p[H]^q[L]^r} \quad (2)$$

2.3. Spectroscopic measurements

UV–Vis spectra of the nickel(II) complexes were recorded on a Hewlett Packard HP 8453 diode array and on a Perkin–Elmer Lambda 25 double beam spectrophotometer in the same concentration range as used for pH-potentiometry.

CD spectra of the nickel(II) complexes were recorded on a JASCO J-81 spectropolarimeter using 1 or 10 mm cells in the 200–800 nm range in the same concentration range as used for potentiometry. CD spectra of the individual species were calculated by the same general program

(PSEQUAD) as used for the evaluation of potentiometric measurements.

3. Results and discussion

3.1. Acid–base properties of the ligands

All the ligands contain one amino and two to five carboxylate donor functions. The pK values of the ligands [17] and the stability constants of the corresponding nickel(II) complexes are collected in Tables 1 and 2. The complexes with the same stoichiometry have different charges; therefore the charges are not shown.

The highest pK values belong to the protonation equilibria of the terminal amino groups, while the lowest and intermediate values correspond to the protonation of the terminal and side chain carboxylate donor functions, respectively [17].

3.2. Nickel(II) complexes of the dipeptides

It can be seen from Tables 1 and 2 that mostly 1:1 complexes are formed, some bis(ligand) complexes exist only with the dipeptides. The stoichiometry of the complexes formed in the Ni(II)–Asp_2 and Ni(II)–Gly_2 systems is the same, the only difference is the formation of the protonated NiLH species in the first case. The coordination modes of the complexes, however, are different. The NiL and NiL_2 complexes of Gly_2 contain (NH_2,CO) coordination modes in 5-membered chelates, while Asp_2 is able to coordinate as a tridentate ligand in the same complexes. The β-carboxylate group of the first Asp residue can be involved in the coordination beside the amino and carbonyl functions both in the NiL and NiL_2 complexes, resulting in the higher stability of these complexes for Asp_2. The visible absorption spectra support the octahedral geometry showing three absorption maxima at 380, 630, 1050 and at 370, 610, 980 nm for the NiL and NiL_2 complexes of Asp_2, respectively.

The amino acid like coordination favours the deprotonation of the amino nitrogen, therefore these complexes form not only in higher concentrations, but also at lower pH (see Fig. 1). A similar effect of the aspartic acid residue on the N-termini was observed for tetra-peptides AspAlaAlaAla, AspAlaAlaAsp [18] and AspArgValTyr [12]. The higher stability of [NiL] complexes is reflected in the higher values of $\log\beta[\mathrm{NiL}] - \mathrm{p}K_{\mathrm{amino}}$ compared to other dipeptides, on the other hand the higher $\log(K_1/K_2)$ (Table 1) values of AspAsp and AspGlu also support the enhancement of stability of the mono(ligand) complexes, hindering the coordination of a second ligand to form bis(ligand) complexes.

An increase of pH results in the formation of the species $NiH_{-1}L$ above pH 8. The coordination mode is (NH_2,N^-,COO^-) in both cases, but in the case of Asp_2 beside or instead of the C-terminal carboxylate group, the β-carboxylate group of the second aspartic acid residue can be coordinated, increasing the stability of the complex. On the other hand, the amino acid like coordination in the NiL complex hinders the deprotonation of the amide nitrogen. These two effects probably compensate each other, thus there is no difference in the pK_1(amide) values of the two ligands Asp_2 and Gly_2. However, the deprotonation of amide nitrogens in the bis(ligand) complexes of Asp_2 is shifted to a higher pH range (see pK(NiL_2/$NiH_{-1}L_2$) and pK($NiH_{-1}L_2$/$NiH_{-2}L_2$) values in Table 1).

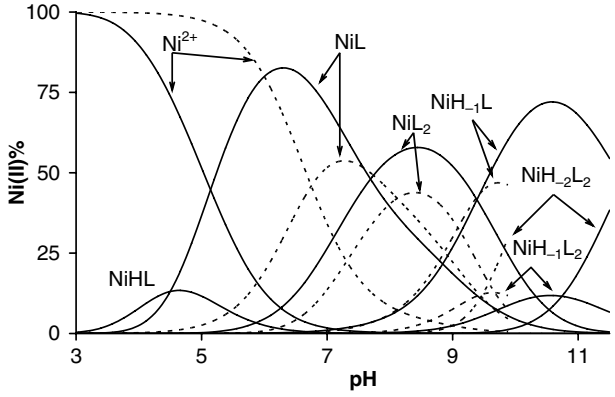

Fig. 1. Species distribution of the complexes formed in the nickel(II)–Asp_2 system (solid line; $c_{Ni(II)} = 2\times10^{-3}$ M. $c_L = 4\times10^{-3}$ M) as a function of pH. Dotted lines are for complexes with Gly_2 ($c_{Ni(II)} = 2\times10^{-3}$ M. $c_L = 4\times10^{-3}$ M).

Among these dipeptides, the complex formation of Glu_2 is the simplest. Only NiL, $NiH_{-1}L$ and NiL_2 complexes are formed, which is followed by precipitation above pH 9. The coordination mode is similar to Gly_2 complexes ((NH_2,CO), (NH_2,N^-,COO^-) and $2(NH_2,CO)$, respectively) but their stabilities are lower. This suggests that γ-carboxylate groups of Glu residues are not included in the complex formation, and the increased negative charge of the ligands even disfavours complex formation. As a consequence the deprotonation of the amide nitrogen for the NiL complex of Glu_2 occurs at a similar pH as in the case of Gly_2. The charges of the complexes $NiH_{-1}L_2$ and $NiH_{-2}L_2$ of Glu_2 would be −5 and −6, respectively, and there are no other factors to compensate this unfavourable effect. Therefore these complexes are not formed in the Ni(II)–Glu_2 system and precipitation occurs at a lower pH than in the case of Gly_2.

The metal binding affinity of AspGlu and GluAsp is between Asp_2 and Glu_2. It is well demonstrated in Fig. 2, where the metal binding ability of the four dipeptides built up from Asp and/or Glu residues is compared to that of Gly_2. We calculated the theoretical distribution of nickel(II) ions between Gly_2 and XaaYaa dipeptide

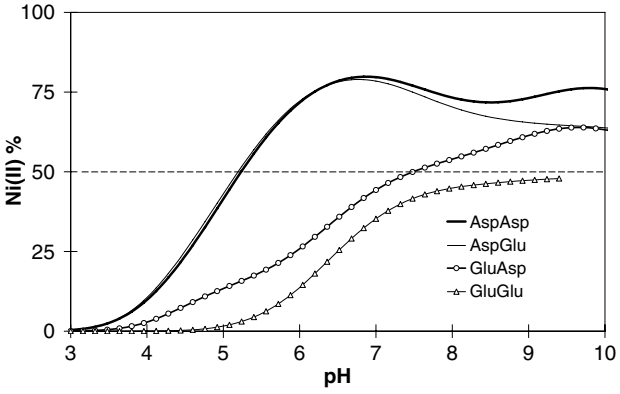

Fig. 2. The total amount of dipeptide complexes formed in the ternary systems containing Ni(II)–Gly_2 and one of the dipeptides of Asp_2, AspGlu, GluAsp and Glu_2 as a function of pH ($c_{Ni(II)} = c_{GlyGly} = c_B = 4.0\times10^{-3}$ M).

(Xaa = Asp or Glu, Yaa = Asp or Glu) and the total amount of complexes of XaaYaa dipeptides is depicted in Fig. 2. This figure unambiguously shows, that the stability enhancement for the species NiL (pH = 4–8.5) is highest and is almost the same for Asp_2 and AspGlu, which comes from the formation of the (NH_2,β-COO^-)-chelate at the N-terminus, as was discussed above. On the other hand, the high stability of (NH_2,N^-,β-COO^-) coordinated $NiH_{-1}L$ complexes resulted in the increase of the total amount of complexes of AspAsp and GluAsp at higher pH (pH = 8.5–10) because of the presence of aspartic acid residues on the C-termini. As a consequence, the metal binding affinity of AspGlu is similar to Asp_2 in the pH range 4–8.5, and decreases following the deprotonation of the amide nitrogen. The metal binding affinity of GluAsp is rather low in the acidic pH range, but increases with the deprotonation of the amide nitrogen, which could be promoted by the binding of the β-carboxylate group of the C-terminal Asp residue.

3.3. Nickel(II) complexes of Asp_3, Glu_3 and Asp_4

Complex formation of Asp_3 and Glu_3 is compared in Fig. 3. It can be seen that Asp_3 is a more effective metal binding ligand. Asp_3 is able to bind to nickel(II) below pH 4, resulting in the formation of the NiHL complex, in which one of the carboxylate groups is protonated. In the case of Glu_3, however, the complex formation processes start only above pH 5. It is clear from Table 2 that only 1:1 complexes are considered as the major species both in equimolar solution and in the presence of a slight excess of ligand. In contrast to earlier data [18] the formation of bis(ligand) complexes was not detected in these cases. These results can be explained by the high negative charge and the size of the ligands, which disfavours the bis(ligand) complex formation (the charge of the NiL_2 complex would be −6 for Asp_3, Glu_3 and −8 for Asp_4).

The fact that in the Ni(II)–Asp_3 system around physiological pH range 80% of the metal ion is bound in the species NiL, shows the enhanced stability of this complex. In the case of Glu_3 there is (NH_2,CO) coordination, while for Asp_3 (NH_2,β-COO^-) coordination is suggested. The latter "β-alanine" like coordination has a remarkable stabilizing effect. However, this coordination mode is not able to hinder the deprotonation of the first amide nitrogen, because the coordination of the second Asp residue is favoured. At the same time, the deprotonation of the second amide nitrogen is suppressed in the case of Asp_3. This process occurs at pH 8 in the Ni(II)–Glu_3 system and pH 9 in the Ni(II)–Asp_3 system. In the first case the species $NiH_{-1}L$ form only in a very low concentration, which indicates that the deprotonation and coordination of the amide nitrogens take place almost cooperatively. This is reflected in the pK_1(amide) and pK_2(amide) values too, which are similar to those of Gly_3 and Gly_4. However, the deprotonation of the two amide functions of Asp_3 takes place in well-separated processes. In this case the formation of $NiH_{-1}L$ is favoured owing to the coordination of the second β-carboxylate group and shifts the formation of the species $NiH_{-2}L$ to higher pH than in the Ni(II)–Glu_3 system. These findings are in good agreement with the earlier published data on similar peptide complexes [18].

It can be seen in Fig. 4, that the complex formation processes of Asp_4 are very similar to those of Asp_3. One more protonated species, NiH_2L, is also formed with this ligand, but all the others are the same regarding either their stoichiometries or coordination modes.

The deprotonation of the first and second amide functions of Asp_4 are less separated than those of Asp_3. Similar to the Cu(II) containing systems [17], the stabilizing role of the binding of β-carboxylate functions are lower because of the size of the ligand. Namely Asp_4 has altogether five carboxylate functions and four of them are present as non-coordinating side chains, loosening the binding strength in the $NiH_{-1}L$ species. Another important feature of the complex formation processes between Ni(II) and Asp_4 comes from the lack of deprotonation and coordination of the third amide function similarly to the Cu(II)–Asp_4 system. However, a notable difference between the copper(II) and nickel(II) containing systems can be concluded

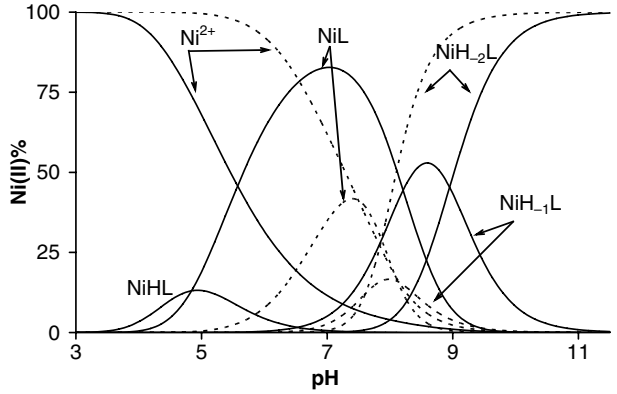

Fig. 3. Species distribution of the complexes formed in the nickel(II)–Asp_3 system (solid line; $c_{Ni(II)} = c_L = 4 \times 10^{-3}$ M) and in the nickel(II)–Glu_3 system (dotted line; $c_{Ni(II)} = c_L = 4 \times 10^{-3}$ M) as a function of pH.

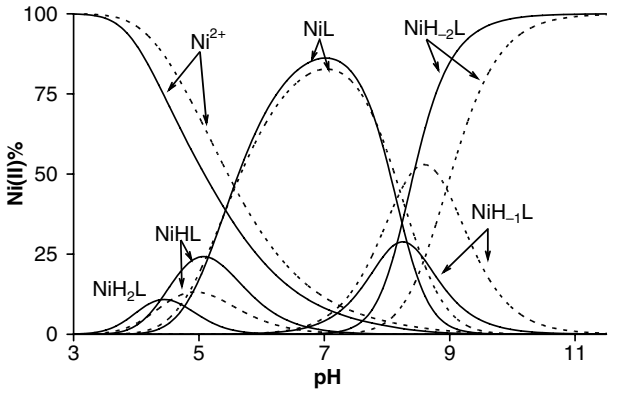

Fig. 4. Species distribution of the complexes formed in the nickel(II)–Asp_4 system (solid line; $c_{Ni(II)} = c_L = 4 \times 10^{-3}$ M) as a function of pH. Dotted lines are for complexes with Asp_3 ($c_{Ni(II)} = c_L = 4 \times 10^{-3}$ M).

from the literature data. In the case of Cu(II), all the tetra- and penta-peptides containing an aspartyl residue in the third position behave like tripeptides, the β-carboxylate group occupies the fourth coordination site of the metal ion and prevents the binding of the subsequent amino acid residues [8–10,24]. On the other hand, this was not observed for the Ni(II)-complexes of AlaAspAspAla, AlaAspAlaAsp and AlaAlaAspAsp. The deprotonation and coordination of the third amide function of these tetra-peptides, containing one or two aspartic acid residues take place, but at higher pH than in the case of Gly_4 [23] or Ala_4. The pK_3 values are 8.29 for AlaAlaAspAla and 9.65–9.70 for the peptides containing two aspartic acid residues [18]. These data demonstrate that the presence of a single aspartic acid in the second or/and third position is not able to prevent the deprotonation of the amide nitrogen and formation of $NiH_{-3}L$ species. On the other hand, the more aspartic acid residues present in the tetra-peptides the higher is the pK_3(amide). This means that the increasing negative charge of the ligand also disfavours the complex formation and $NiH_{-3}L$ does not form in the Ni(II)–Asp_4 system.

In acidic and neutral solution, similarly to the dipeptides, these ligands form octahedral complexes. However, the formation of the $NiH_{-2}L$ complexes is accompanied by significant changes in the visible absorption and CD spectra. The spectral parameters of $NiH_{-2}L$ species are collected in Table 3, and they indicate the square planar geometry of these Ni(II) complexes.

It is clear that the spectra of Asp_3 and Asp_4 are similar to each other, but they are completely different from those of Glu_3, Gly_3 or Ala_3. These similarities and differences can be best explained by the similarities and differences in the binding modes of the ligands. Namely, in the case of Glu_3 only the (NH_2,N^-,N^-,α-COO^-)-coordination mode can exists in the form of (5,5,5)-membered joined chelate rings, similarly to Gly_3. For Asp_4 the donor atoms are the same, but the C-terminal carboxylate could be replaced by the β-carboxylate residue in the form of a (5,5,6)-membered chelate. This results in the difference of CD extrema for the N^-(amide)–Ni(II) charge transfer transition and for the d–d transition both in the CD and visible absorption spectra. The similarity of the spectra of Asp_3 and Asp_4 reflects that for Asp_3 the (NH_2,N^-,N^-,β-COO^-)-coordination mode is preferred over the common "tripeptide like" coordination mode of $NiH_{-2}L$ complexes.

Table 3
Visible and CD spectral parameters of the $NiH_{-2}L$ complexes

Ligand	Vis $\lambda_{max}(\varepsilon)$ [nm(M^{-1} cm^{-1})]	CD $\lambda_{max}(\Delta\varepsilon)$ [nm(M^{-1} cm^{-1})]	
		$N^- \rightarrow$ Ni(II)	d–d
Asp_3	440(265)	232(−5.08)	492(−2.60) 422(+0.88)
Asp_4	438(229)	234(−12.19)	499(−2.10) 426(+1.55)
Glu_3	428(102)	249(+7.34)	474(−3.43)
Gly_3 [22]	427(197)		
Ala_3		248(+4.21)	473(−2.33)

4. Conclusion

The potentiometric and spectroscopic data obtained for nickel(II) complexes of di-, tri- and tetra-peptides containing two to four aspartic and/or glutamic acid residues reveal that side chain carboxylate functions have a significant impact on the complex formation processes of peptides. On the one hand the coordination of the β-carboxylate group enhances the stability of complexes and on the other hand the increase of negative charge of the ligands hinders, and moreover prevents, the formation of complexes characteristic of the nickel(II) common oligopeptide systems.

The presence of N-terminal aspartic acid enhances the stability of NiL complexes in all cases, and the tridentate binding of ligands results in complex formation processes at a lower pH range. The formation of bis(ligand) complexes is also significant for dipeptides (especially Asp_2, AspGlu), but in the case of larger tri- and tetra-peptides the existence of bis(ligand) complexes was not detected because of their high negative charges.

Aspartic acid in the second position stabilizes the $NiH_{-1}L$ complexes and the binding of the (NH_2,N^-,β-COO^-) donor set can be supposed. The presence of aspartic acid in the third position, however, promotes the deprotonation of the second amide nitrogen and formation of $NiH_{-2}L$ complexes. As a consequence, in the case of the ligands built up from aspartic acids alone, the effect of aspartic acid in the first, second and third position may compensate each other. It means that the deprotonation of the first amide nitrogen of Asp_2 takes place around the same pH as that of Glu_2 or Gly_2, and it is different from either AspGlu or GluAsp. Similarly, for Asp_3, the deprotonation of amide nitrogens occurs in well-separated steps, in contrast to Glu_3 and Gly_3 [22] or AlaAlaAspAla and AlaAspAspAla [18], where these processes are cooperative. In the case of Asp_4 the effect of the first aspartic acid is expressed in the enhanced stability of NiL complexes, but the second and third aspartic acid have smaller impact on the deprotonation processes of the amide nitrogens; the pK(amide) values are much closer to those of Gly_4 [23] or Ala_4 [11]. These latter facts are probably caused by an increase of negative charge of the ligand.

The high negative charge of the ligands influences above all the complex formation processes of tri- and tetra-peptides. These effects are as follows:

(i) Bis(ligand) complexes do not form in the case of Asp_3, Glu_3 and Asp_4 in contrast to Gly_3 and AspAlaAlaAla.
(ii) The stabilizing effect of the side chain carboxylate group is smaller for $NiH_{-1}L$ and $NiLH_{-2}$ complexes of Asp_4.

(iii) The deprotonation of the third amide nitrogen cannot be observed in the case of Asp_4, in contrast to Gly_4 and Ala_4 or tetra-peptides containing one or two aspartic acid.

Abstract

Ten copper(II) complexes {$[CuL^1Cl]$ (**1**), $[CuL^1NO_3]_2$ (**2**), $[CuL^1N_3]_2 \cdot 2/3H_2O$ (**3**), $[CuL^1]_2(ClO_4)_2 \cdot 2H_2O$ (**4**), $[CuL^2Cl]_2$ (**5**), $[CuL^2N_3]$ (**6**), $[Cu(HL^2)SO_4]_2 \cdot 4H_2O$ (**7**), $[Cu(HL^2)_2](ClO_4)_2 \cdot 1/2EtOH$ (**8**), $[CuL^3Cl]_2$ (**9**), $[CuL^3NCS] \cdot 1/2H_2O$ (**10**)} of three NNS donor thiosemicarbazone ligands {pyridine-2-carbaldehyde-*N*(4)-*p*-methoxyphenyl thiosemicarbazone [HL^1], pyridine-2-carbaldehyde-*N*(4)-2-phenethyl thiosemicarbazone [HL^2] and pyridine-2-carbaldehyde *N*(4)-(methyl), *N*(4)-(phenyl) thiosemicarbazone [HL^3]} were synthesized and physico-chemically characterized. The crystal structure of compound **9** has been determined by X-ray diffraction studies and is found that the dimer consists of two square pyramidal Cu(II) centers linked by two chlorine atoms.

Keywords: Thiosemicarbazone; Cu(II) complex; Pyridine-2-carbaldehyde; Crystal structure

1. Introduction

The coordination chemistry involving heterocyclic thiosemicarbazones has been interesting research area in the last 30 years because of their well-documented biological activities. Thiosemicarbazone derivatives have considerable antibacterial, antimalarial, antiviral and antitumor activities [1]. Complexation of such thiosemicarbazone ligands with metal ions has been found to produce synergistic effects on the antiproliferative activities of the parent ligands [2]. It has been reported that copper(II) complexes of heterocyclic *N*(4)-substituted thiosemicarbazones exercise bio-activity through a mechanism involving either inhibition of the enzyme ribonucleotide reductase, or creation of lesions in DNA strands. Studies have also shown that, for these ligands, nature of substitution on the terminal N(4) atom is crucial for the antifungal activity [3].

Pyridine-2-carbaldehyde thiosemicarbazone was the first α-(*N*)-heterocyclic carboxaldehyde thiosemicarbazone, reported to have carcinostatic effects [4]. This thiosemicarbazone ligand coordinates to the metal ions in both the anionic (L^-) and neutral (HL) forms. The anionic L^- form is usually present in $[CuLX]_2$ dimers in which, the metal centers can either be bridged through the thiolate sulfur or the non-thiosemicarbazone co-ligand X (X = Cl, N_3, NCS, etc.) [5]. It is reported that the formation of complexes with S-bridge or X-bridge depends on the nature of the non-thiosemicarbazone ligands. However, the actual underlying reasons for the formation of S- over X-bridged systems are not clear to date [6]. On the basis of these findings, the present communication reports on the optimal conditions for synthesis of ten copper(II) complexes with three ligands, viz., pyridine-2-carbaldehyde *N*(4)-paramethoxyphenyl thiosemicarbazone (HL^1), pyridine-2-carbaldehyde *N*(4)-phenethyl thiosemicarbazone (HL^2) and pyridine-2-carbaldehyde *N*(4)-methyl *N*(4)-phenyl thiosemicarbazone (HL^3) and their characterization

by physicochemical methods, together with X-ray crystal structure of one of the copper compounds, viz. $[CuL^3Cl]_2$.

2. Experimental

2.1. Materials

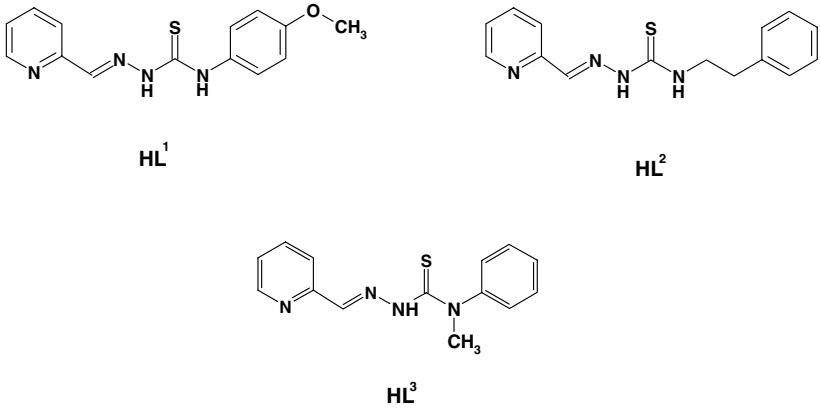
Pyridine-2-carbaldehyde (Aldrich), 2-phenylethylamine (Fluka) and *p*-anisidine (Fluka) were used as received. The metal salts copper(II) nitrate trihydrate, copper(II) chloride dihydrate, copper(II) acetate monohydrate, copper(II) perchlorate hexahydrate, copper(II) sulphate pentahydrate, sodium azide and potassium thiocyanate (Merck) were used as supplied. 4-Methyl-4-phenyl-3-thiosemicarbazide was prepared as reported previously [7] and solvents were purified by standard procedures before use. *Caution!* Azide and perchlorate complexes of metals with organic ligands are potentially explosive and should be handled with care.

2.2. Synthesis of ligands

The thiosemicarbazones were obtained by adopting and modifying a reported procedure of Scovill et al. [7]. The synthesis and crystal structure of HL^1 have been published earlier [8]. The structure of the three ligands are given in Scheme 1.

2.2.1. Synthesis of HL^1 and HL^3

HL^1 was synthesized by refluxing a solution of 1.00 g (5.52 mmol) of 4-methyl-4-phenyl-3-thiosemicarbazide in 5 ml of MeCN with 0.679 g (5.52 mmol) of 4-methoxyaniline (*p*-anisidine) and 0.591 g (5.52 mmol) of pyridine-2-carbaldehyde for 1.5 h. HL^3 was synthesized by a similar procedure without the addition of an amine. The solutions were chilled (overnight) and the crystals that formed were collected and washed well with MeCN. The compounds were recrystallized from ethanol and dried *in vacuo* over P_4O_{10}.



We have reported the syntheses of ligands HL^1 and HL^3 along with the crystal structure of HL^3 recently [9].

2.3. Synthesis of complexes

Refluxing/stirring of alcoholic solution of the ligand with the alcoholic/ aqueous alcoholic solution of the corresponding copper salt yielded the compounds **1**, **2**, **4**, **5**, **7**, **8** and **9** whereas compounds **3**, **6** and **10** were prepared by the metathetical displacement of acetate ion by azide and thiocyanate ion, respectively. Complexes **1**, **5** and **9** were synthesized by refluxing (1 h) 1.5 mmols each of the respective ligands dissolved in 20 ml hot ethanol with 1 mmol of $CuCl_2 \cdot 2H_2O$. In a similar method, complexes **4** and **8** were synthesized by using respective ligands and $Cu(ClO_4)_2 \cdot 6H_2O$ whereas complex **2** was obtained by stirring a hot solution of HL^1 (1.5 mmol) in ethanol (20 ml) with $Cu(NO_3)_2 \cdot 3H_2O$ (1.5 mmol). For the synthesis of **3**, **6** and **10**, the acetate complexes were first prepared by refluxing (15 min) 1.5 mmols each of the respective ligands dissolved in 20 ml hot ethanol with 1.5 mmol of $Cu(OAc)_2 \cdot H_2O$ and the acetate ion was then displaced by azide ion (**3**, **6**) and thiocyanate ion (**10**) by using NaN_3 and KCNS, respectively. The complex **7** was prepared by refluxing (4 h) a mixture of HL^2 (1.5 mmol) and $CuSO_4 \cdot 5H_2O$ (1.5 mmol) in a mixture of ethanol (20 ml) and water (20 ml). Upon evaporation of the solvent, the complexes were precipitated as green or brown solids. The complexes formed were filtered, washed with water, ethanol and ether and dried *in vacuo* over P_4O_{10}.

2.4. Physical measurements

Elemental analyses of the ligand and the complexes were done on a Heracus elemental analyzer at CDRI, Lucknow, India, and on a Vario EL III CHNS analyzer at SAIF, Kochi, India. The IR spectra were recorded on a Thermo Nicolet AVATAR 370 DTGS model FT-IR Spectrophotometer with KBr pellets at SAIF, Kochi. Electronic spectra were recorded on a Cary 5000, version 1.09 UV–Vis–NIR Spectrophotometer from a solution in $CHCl_3$. The EPR spectra of the complexes were recorded on a Varian E-112 Spectrometer using TCNE as the standard at SAIF, IIT, Bombay, India. The magnetic susceptibility

Scheme 1. The thiosemicarbazones HL^1, HL^2 and HL^3.

measurements were carried out at the Indian Institute of Technology, Roorkee, India, at room temperature in the polycrystalline state on a PAR model 155 Vibrating sample magnetometer at 5 kOe field strength. The molar conductances of the complexes in dimethylformamide solutions (10^{-3} M) at room temperature were measured using a direct reading conductivity meter.

2.5. X-ray crystallography

Single crystals of compound **9** of X-ray diffraction quality were grown from its methanol solution by slow evaporation at room temperature in air. The crystallographic data and structure refinement parameters are given in Table 1. The data were collected using a CrysAlis CCD, Oxford Diffraction Ltd., version 1.171.29.2 with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation on a triclinic single crystal of dimension $0.25 \times 0.20 \times 0.20$ mm with $P\bar{1}$ symmetry at the National Single Crystal X-ray Diffraction Facility, IIT, Bombay, India. The unit cell dimensions and intensity data were measured at 293 K. Empirical absorption correction was done using spherical harmonics, implemented in SCALE3 ABSPACK scaling algorithm. The trial structure was solved using SHELXS-97 [10] and refinement was carried out by full-matrix least squares on F^2 (SHELXL) [10]. Molecular graphics employed were ORTEP-III [11] and PLATON [12].

Largest difference peak and hole (e Å^{-3})	0.410 and −0.215

3. Results and discussion

In all the compounds except **7** and **8** the thiosemicarbazones deprotonate and chelate in thiolate form as evidenced by the IR spectra. The elemental analyses suggest the general empirical formula [CuLX] where X = Cl, NO_3, N_3, ClO_4 and NCS for complexes except **7** and **8**, but the complex **7** turned out to be $[Cu(HL)SO_4]$ and complex **8** to be $[Cu(HL)_2](ClO_4)_2$ with the perchlorate ion out of the coordination sphere. The complexes are appreciably soluble in methanol, ethanol, DMF and DMSO.

The colors, partial elemental analyses, molar conductivities and magnetic susceptibilities of the metal complexes are shown in Table 2. The green and brown colors are common to complexes involving thiosemicarbazone coordination due to the sulfur-to-metal charge-transfer bands, which dominate their visible spectra [13]. The molar conductivity values of the compounds **1**, **2**, **3**, **5**, **6**, **7**, **9** and **10** in 10^{-3} M solution in DMF show that they are non-conductors [14] indicating that the anion and the ligand are coordinated to the central copper(II). But the molar conductivity values of compounds **4** and **8** suggest that they are 2:1 electrolytes. The magnetic susceptibilities at room temperature per copper atom of the complexes except **6**, **8** and **10** suggest interaction between metal centers [15].

3.1. Crystal structure of $[CuL^3Cl]_2$ (9)

The molecular structure of the compound **9** along with atom numbering scheme are given in Fig. 1. The asymmetric unit is formed by one half of the molecule and the other half is related by a center of inversion in the Cu(1)–Cl(1)–Cu(1a)–Cl(1a) ring. The coordination geometry at each Cu(II) is square pyramidal. The ligand HL^3 coordinates the metal in a tridentate manner through its pyridyl nitrogen, azomethine nitrogen and thiolate sulfur, after enolization and deprotonation, to form the basal plane along with one chlorine atom. The basal chlorine atom takes the axial position of the adjacent monomer like its counterpart to result in two distorted square pyramids. The Cu–Cu separation is found to be 3.5330(11) Å. The τ value [16] of 0.139 at metal centers indicates slight distortion from perfect square pyramidal geometry. Thus, the two metal centers are bridged via chlorine atoms resulting in the formation of four five membered rings in which one copper atom is shared by two fused rings. A four membered ring involving the copper atoms and the chlorine atoms is also formed. The five membered ring Cu(1), N(1), C(5), C(6), N(2) is approximately planar with a maximum deviation of 0.0135(18) Å for C5, but Cu(1), N(2), N(3), C(7), S(1) ring is slightly distorted as evidenced by the maximum deviation of 0.1349(18) Å for C7; likewise for their counterpart rings. The four membered ring Cl(1), Cu(1), Cl(1a), Cu(1a) makes an angle of 83.62(3)° with the mean plane of bicyclic

[a] Molar conductivity of 10^{-3} M DMF solution, in Ω^{-1} cm^2 mol^{-1}.

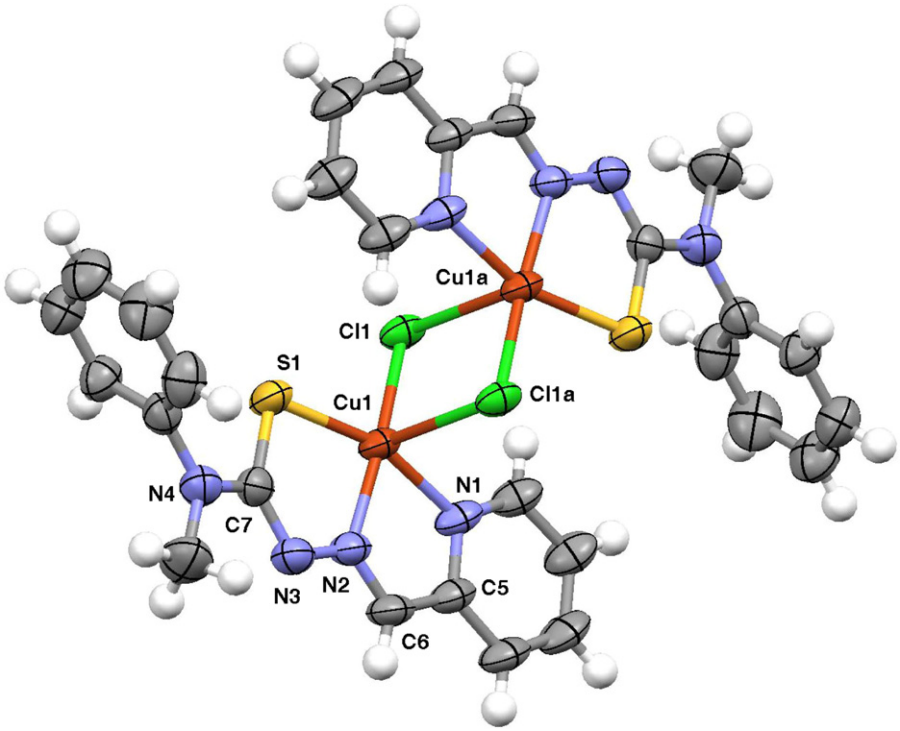

Fig. 1. ORTEP diagram of $[CuL^3Cl]_2$ (**9**) in 50% probability ellipsoids.

chelate system N(1), C(5), C(6), N(2), N(3), C(7), S(1), Cu(1) which is slightly distorted from planarity with a maximum deviation of −0.1979(18) Å for C5. Relevant bond lengths and angles are featured in Table 3. The bridging chlorine atoms are positioned at distances of 2.2587(7) Å for Cl(1) and 2.7245(12) Å for Cl(1a) and make an angle of 90.20(3)° at each metal centers and are in agreement with previous reports [17,18]. The Cu–$N_{azomethine}$ bond length [1.9784(14) Å] is lesser by 0.0541(19) Å compared to Cu–$N_{pyridine}$, indicates the strength of former bond than the latter [18,19].

The ligand HL^3 suffers a structural reorientation upon complexation. The N3 and C5 atoms were in *Z* configuration about the azomethine bond in its metal free form of ligand, is now in *E* form to coordinate the metal as NNS donor ligand. Coordination lengthens the thiosemicarbazone moiety's C(7)–S(1) bond length by 0.0645(22) Å and shortens N(3)–C(7) by 0.0384(18) Å, suggesting deprotonation after enolization. A comparison of the changes in bond lengths and angles are given in Table 3.

The molecules are packed along the *a*-axis directed by the C3–H3···Cl1 intermolecular hydrogen bonding interaction (Table 4). This intermolecular hydrogen bond links the molecules to form one-dimensional polymeric chains (Fig. 2). The aromatic π···π stacking interactions between pyridyl rings (symmetry code: $2 - x$, $1 - y$, $1 - z$ and a Cg–Cg distance of 3.8896 Å) reinforces crystal structure cohesion in molecular packing in the crystal lattice.

3.2. Infrared spectra

The IR bands most useful for the determination of the mode of coordination are presented in Table 5. The far IR assignments are shown in Table 6. The strong bands at 3310 and 3374 cm^{-1} in the spectra of HL^1 and HL^2 have been assigned to $\nu(^4N–H)$. In the complexes these bands shift to both higher and lower energies, suggesting differences in hydrogen bonding of N(4)H between the uncomplexed and complexed thiosemicarbazone [20]. A medium band in the range 3129–3158 cm^{-1} in the free ligands due to $\nu(^2N–H)$ vibration disappears in the spectra of complexes except **7** and **8**, providing a strong evidence for the ligand coordination around copper(II) ion in the deprotonated form. In the spectra of **7** and **8**, $\nu(^2N–H)$ bands appear at 3219 and 3206 cm^{-1}, respectively, but ν(S–H) band at 2570 cm^{-1} is absent showing that the ligand is in the thione form in these complexes [21]. The intense bands at 1584, 1586 and 1590 cm^{-1} in the spectra of HL^1, HL^2, and HL^3, respectively have been assigned to ν(C=N) of the thiosemicarbazone moiety. These bands are shifted to lower energies in the spectra of the complexes (1553–1573 cm^{-1}), indicating azomethine nitrogen coordination [22]. The presence of bands in the 402–415 cm^{-1} range is assigned to $\nu(Cu–N_{azomethine})$ agree well with previous studies of metal complexes of 2-formylpyridine *N*(4)-substituted thiosemicarbazones [23]. Strong bands found at 1024–1079 cm^{-1} in the ligands are assigned to the ν(N–N) band of the thiosemicarbazone. The increase in the frequency of this band in the spectra of complexes is due to the increase in the bond strength, again confirming the coordination via the azomethine nitrogen [24]. For the complexes containing the anionic ligands, a second band due to ν(N=C) is often resolved, but a number of complexes show only a single, broad band for both ν(C=N) and ν(N=C) modes [25]. The complexes **1**, **2**, **3**, **4**, **5**, **6**, **9** and **10** show bands corresponding to ν(N=C) in the range 1588–1615 $cm^{-1}$where as these bands are not present in the spectra of the complexes **7** and **8**.

The two bands appearing at the frequencies 1334, 1324 and 1307 cm^{-1} [ν(CS) + ν(CN)] and 837, 897 and 779 cm^{-1} (thioamide IV band), respectively, in the spectra of HL^1, HL^2, and HL^3 have been shifted to lower frequencies in the ranges 1289–1367 and 773–897 cm^{-1}, respectively indicating coordination of the thione/thiolato sulfur [26]. The presence of new bands in the range 323–344 cm^{-1} which is assignable to ν(Cu–S) is another indication of sulfur coordination which is found to be consistent with earlier reports [27]. Coordination of the pyridine nitrogen is indicated by a positive shift of the in-plane ring deformation band at 613, 622 and 614 cm^{-1} in the spectra of HL^1, HL^2, and HL^3 to 617–646 cm^{-1} in the spectra of the complexes. Out-of-plane ring deformation bands at 401, 406, and 421 cm^{-1} in the spectra of HL^1, HL^2 and HL^3 are also shifted to higher frequencies [28]. Pyridine nitrogen coordination is further proved by strong bands observed in the region 262–313 cm^{-1} assignable to ν(Cu–N) of pyridine ring as suggested by Clark and Williams [29]. Based on the above spectral evidences, it is confirmed that the ligands HL^1, HL^2, and HL^3 are tridentate, coordinating via the azomethine nitrogen, the pyridyl nitrogen and thione/thiolate sulfur.

The chloro complex **1** shows ν(Cu–Cl) band at 304 cm^{-1}, which is similar to its assignment for terminal chloro ligands in other thiosemicarbazone complexes [30]. In the chloro complexes **5** and **9**, the strong bands observed at 329 and 315 cm^{-1} together with bands at 162 and 164 cm^{-1} have been assigned to the ν(Cu–Cl) in a bridging mode [18]. The crystal structure of **9** confirms the presence of two bridging chlorine atoms.

The nitrato complex **2** has two strong bands at 1287 and 1412 cm^{-1} with a separation of 125 cm^{-1} corresponding to ν_1 and ν_4 and a medium band at 1016 cm^{-1} corresponding to ν_2 of the nitrato group indicating the presence of a terminal monodentate nitrato group [31]. The $\nu_1 + \nu_4$combination bands considered as diagnostic for the monocordinated nitrato group are observed at 1734 and

$[CuL^3NCS] \cdot 1/2H_2O$ (**10**)	413	297	325			314	

The azido complexes **3** and **6** show sharp bands at 2056 and 2038 cm^{-1} and strong bands at 1243 and 1356 cm^{-1}, respectively. These are assigned to ν_a and ν_s of the coordinated azido group. The broad bands observed at 647 cm^{-1} for both complexes are assigned to δ(N–N–N). ν(Cu–N_{azido}) bands are observed at 446 and 435 cm^{-1}, respectively, for **3** and **6**.

The perchlorate complexes **4** and **8** show single broad bands at 1121 cm^{-1} and strong bands at 626 and 624 cm^{-1}, indicating the presence of ionic perchlorate. The bands at 1121 cm^{-1} are assignable to $\nu_3(ClO_4)$ and the unsplit bands at 626 and 624 cm^{-1} assignable to $\nu_4(ClO_4)$. In the spectrum of the compound **4**, a medium band at 926 cm^{-1} may be due to $\nu_1(ClO_4)$ suggesting that ionic perchlorate is distorted from tetrahedral symmetry due to lattice effects or hydrogen bonding by the NH functions of the coordinated ligand [34]. However, no band assignable to $\nu_1(ClO_4)$ is observable in the spectrum of compound **8**. This along with unsplit ν_3 and ν_4 bands show exclusive presence of non-coordinated perchlorate group.

For the sulfato complex **7**, strong bands at 1116 and 1028 cm^{-1} are assignable to ν_3 of the mono coordinated sulfato group. Medium bands at 939 cm^{-1} (ν_1) and 644 cm^{-1} (ν_4) further confirm the unidentate behaviour of sulfato group [31].

Thiocyanato complex **10** exhibits a strong and sharp band at 2079 cm^{-1}, a weak band at 773 cm^{-1} and another weak band at 484 cm^{-1} which can be attributed to ν(CN), ν(CS) and δ(NCS), respectively. These values are typical for N-bonded thiocyanate complexes. A medium band at 325 cm^{-1} corresponds to ν(Cu–$N_{thiocyanato}$) vibrations which is in agreement with the reported values [35].

3.3. Electronic spectra

The electronic absorption spectra are often very helpful in the evaluation of results furnished by other methods of structural investigation. The tentative assignments of the significant electronic spectral bands of ligands and their copper(II) complexes are presented in Table 7. The electronic spectra in $CHCl_3$ solution of HL^1, HL^2 and HL^3 show the following intraligand absorption maxima: for HL^1, two bands corresponding to $\pi \rightarrow \pi^*$ of the pyridyl ring, benzene ring and imine function of the thiosemicarbazone moiety are observed at 42 730 and 38 760 cm^{-1}; the $n \rightarrow \pi^*$ transitions of the pyridyl ring and imine function of the thiosemicarbazone moiety are observed at 30 770 cm^{-1}; for HL^2, these bands are observed at 42 190, 36 630 and 30 960 cm^{-1}, respectively, and for HL^3 they are observed at 43 290, 38 610 and 30 840 cm^{-1} [36]. The

$\pi \rightarrow \pi^*$ transitions are not significantly altered on complex formation. In the spectra of the complexes in chloroform solutions the $n \rightarrow \pi^*$ transitions associated with the pyridine ring observed above 30 000 cm^{-1} in the spectra of the thiosemicarbazones are shifted to higher energies, the blue shift indicating coordination *via* the pyridyl nitrogen [17]. Strong bands in the range 22 880–24 040 cm^{-1} observed in the spectra of all Cu(II) complexes are assigned to $S \rightarrow Cu$ and $py \rightarrow Cu$ charge-transfer bands [26]. For the chloro complexes **1** and **5**, the $Cl \rightarrow Cu(II)$ charge transfer bands are found at 27 700 and 29 150 cm^{-1}, respectively, and band at 27 850 cm^{-1} in the spectrum of nitrato complex (**2**) is attributable to nitrato $O \rightarrow Cu(II)$ ligand to metal charge transfer transition [37].

The spectra of the complexes **1**, **3**, **5**, **6**, **7**, **9** (Fig. 3) and **10** exhibit weak d–d bands centered around 16 000 cm^{-1}, that of **2** and **4** are at *ca.* 15 000 cm^{-1}. For a square planar complex with $d_{x^2-y^2}$ ground state, three transitions are possible $d_{x^2-y^2} \rightarrow d_{z^2}$, $d_{x^2-y^2} \rightarrow d_{xy}$ and $d_{x^2-y^2} \rightarrow d_{xz}, d_{yz}$ ($^2A_{1g} \leftarrow {}^2B_{1g}$, $^2B_{2g} \leftarrow {}^2B_{1g}$ and $^2E_g \leftarrow {}^2B_{1g}$) and square pyramidal complexes have the $d_{x^2-y^2} \rightarrow d_{xz}, d_{yz}$ and $d_{x^2-y^2} \rightarrow d_{z^2}$ transitions [38–40]. Since the four d orbitals lie very close together, each transition cannot be distinguished by their energy and hence it is very difficult to resolve the bands into separate components. The broad band observed at 16 780 cm^{-1} in the electronic spectrum of the complex **8** is assigned to $^2E_g \leftarrow {}^2T_{2g}$ transition [41,42]. However, results obtained from electronic spectra do not permit a structural diagnosis free of uncertainty.

3.4. EPR spectra

The copper(II) ion, with a d^9 configuration, has an effective spin of $S = 1/2$ and is associated with a spin angular momentum, $m_s = \pm 1/2$, leading to a doubly degenerate spin state in the absence of a magnetic field. In a magnetic field the degeneracy is lifted between these states and the energy difference between them is given by $E = h\nu = g\beta H$, where h is Planck's constant, ν is the microwave frequency for transition from $m_s = +1/2$ to $m_s = -1/2$, g is the Lande splitting factor (equal to 2.0023 for a free electron), β is the Bohr magneton and H is the magnetic field. For the case of a $3d^9$ copper(II) ion, the appropriate spin Hamiltonian assuming a B_{1g} ground state is given by

$$\widehat{H} = \beta[g_{\|}H_zS_z + g_{\perp}(H_xS_x + H_yS_y)] + A_{\|}I_zS_z + A_{\perp}(I_xS_x + I_yS_y)$$

The EPR spectra of the complexes in the polycrystalline state at 298 K, in solution at 298 and 77 K were recorded in the X band, using 100 kHz field modulation and the g factors were quoted relative to the standard marker TCNE ($g = 2.00277$). EPR spectral assignments of the copper(II) complexes along with the spin Hamiltonian and orbital reduction parameters are given in Table 8.

The EPR spectra of compounds **8** and **10** in the polycrystalline state (298 K) show only one broad signal at 2.0762 and 2.0765, respectively, due to dipolar broadening and enhanced spin lattice relaxation. The spectra of the compounds **2**, **3**, **4**, **5**, **6**, **7** and **9** show typical axial behavior with slightly different $g_{\|}$ and $g_{\perp}$ values. The spectrum of compound **1** gives three g values *viz.* g_1, g_2 and g_3 which indicate rhombic distortion in its geometry. The geometric parameter G, which is a measure of the exchange interaction between the copper centers in the polycrystalline compound, is calculated using the equation: $G = (g_{\|} - 2.0023)/(g_{\perp} - 2.0023)$ for axial spectra and for rhombic spectra, $G = (g_3 - 2)/(g_{\perp} - 2)$ and $g_{\perp} = (g_1 + g_2)/2$. If $G > 4$, exchange interaction is negligible and if it is less than 4, considerable exchange interaction is indicated in the solid complex [43]. In all the copper(II) complexes $g_{\|} > g_{\perp} > 2.0023$ and G value within the range 2.08–4.49 are consistent with a $d_{x^2-y^2}$ ground state [44]. The solution spectra of complexes were recorded in DMF at 298 K. They are isotropic in nature with well-resolved four hyperfine lines (Fig. 4). The hyperfine splitting is due to the interaction of the electron spin with the copper nuclear spin (^{63,65}Cu, $I = 3/2$). The spectra of all the complexes in DMF at 77 K are axial with four copper hyperfine lines in both the parallel and perpendicular regions (Fig. 5). In addition the spectra of some of the complexes show five nitrogen superhyperfine lines in the high field component. For the spectra of all the complexes in frozen DMF the $g_{\|} > g_{\perp}$ values rules out the possibility of trigonal bipyramidal structures for which $g_{\perp} > g_{\|}$ is expected. The binuclear nature of **2**, **3**, **4**, **7** and **9** was confirmed by the presence of half-field signals ($\Delta M_s = \pm 2$) at *ca.* 1600 G (Fig. 6). However, for **5**, the half-field signal at *ca.* 1600 G is not well resolved. The EPR parameters $g_{\|}$, $g_{\perp}$, g_{av}, $A_{\|}$(Cu) and $A_{\perp}$(Cu) and the energies of d–d transition were used to evaluate the bonding parameters α^2, β^2 and γ^2, which may be regarded as measures of the covalency of the in-plane σ bonds, in-plane π bonds, and out-of-plane π bonds, respectively. The value of in plane sigma bonding parameter α^2 was estimated from the following expression:

$$\alpha^2 = -A_{\|}/0.036 + (g_{\|} - 2.0023) + 3/7(g_{\perp} - 2.0023) + 0.04$$

Fig. 4. EPR spectrum of **8** in DMF solution at 298 K.

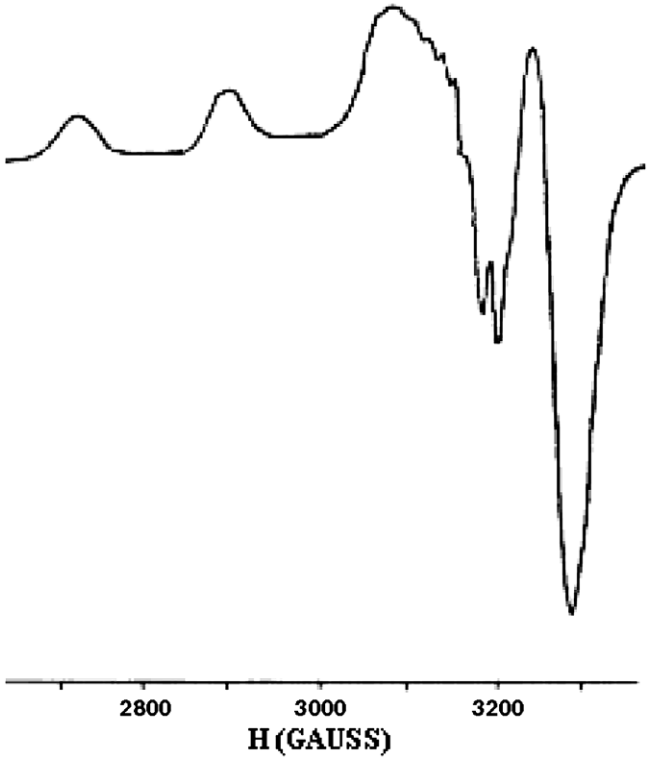

Fig. 5. EPR spectrum of **5** in DMF solution at 77 K.

The orbital reduction factors $K_{\parallel} = \alpha^2\ \beta^2$ and $K_{\perp} = \alpha^2\gamma^2$ were calculated using the following expressions [18]:

$$K_{\parallel}^2 = (g_{\parallel} - 2.0023)\Delta E(\mathrm{d}_{xy} - \mathrm{d}_{x^2-y^2})/8\lambda_0$$

$$K_{\perp}^2 = (g_{\perp} - 2.0023)\Delta E(_{\mathrm{d}_{xz,yz}} - \mathrm{d}_{x^2-y^2})/2\lambda_0$$

where λ_0 is the spin orbit coupling constant and has the value -828 cm^{-1} for a copper(II) d^9 system.

According to Hathaway [45], $K_{\parallel} = K_{\perp} = 0.77$ for pure σ bonding and $K_{\parallel} < K_{\perp}$ for in-plane π bonding, while for out-of-plane π bonding $K_{\parallel} > K_{\perp}$. In all the copper(II) complexes, it is observed that $K_{\parallel} < K_{\perp}$ which indicates the presence of significant in-plane π bonding. Furthermore, α^2, β^2 and γ^2 have values less than 1 which is expected

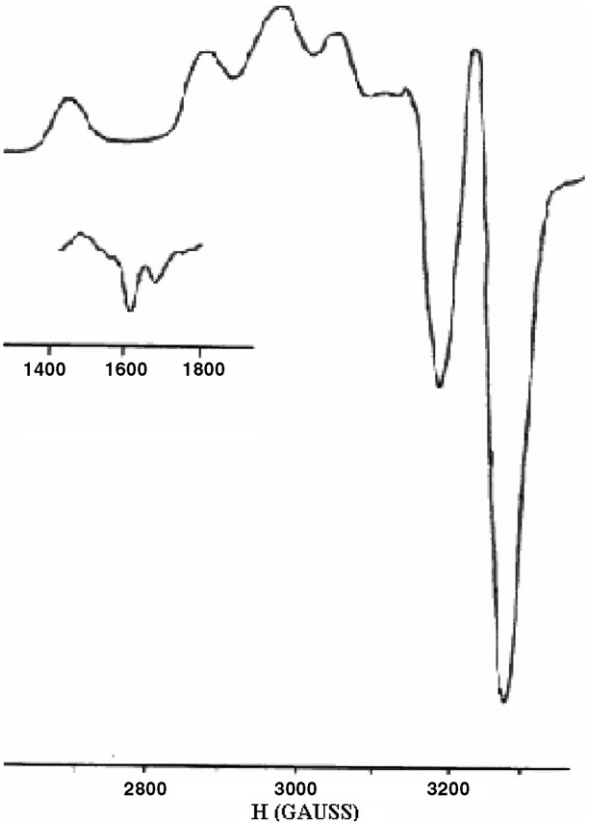

Fig. 6. EPR spectrum of **2** in DMF solution at 77 K.

for 100% ionic character of the bonds and become smaller with increasing covalent bonding. The evaluated values of α^2, β^2 and γ^2 of the complexes are consistent with both strong in plane σ and in plane π bonding. The $g_{\|}$ values are nearly the same for all the complexes indicating that the bonding is dominated by the thiosemicarbazone moiety.

The fact that the $g_3/g_{\|}$ values are less than 2.3 is an indication of significant covalent bonding in these complexes [46]. The Fermi contact hyperfine interaction term K may be obtained from [47]:

$$K = A_{iso}/P\beta^2 + (g_{av} - 2.0023)/\beta^2$$

where P is the free ion dipolar term and its value is 0.036. K is a dimensionless quantity, which is a measure of the contribution of s electrons to the hyperfine interaction. The K values obtained for all the complexes are in agreement with those estimated by Assour [48] and Abragam and Pryce [49].

Abstract

Three copper(II) complexes of salicylaldehyde N(4)-phenyl thiosemicarbazone (H_2L^1) and two copper(II) complexes of N(4)-cyclohexyl thiosemicarbazone (H_2L^2) have been synthesized and characterized by different physicochemical techniques like magnetic studies and electronic, infrared and EPR spectral studies. The complexes $[(CuL^1)_2] \cdot \frac{1}{2}H_2O$ (**1**) and $[(CuL^2)_2]$ (**4**) having dimeric structure. The thiosemicarbazones bind to the metal as dianionic ONS donor ligand in all the complexes, except in the complex $[Cu(HL^1)_2] \cdot H_2O$ (**2**). In complex **2**, the ligand moieties are coordinated as monoanionic (HL^-) ones. Two of the complexes $[CuL^1dmbipy] \cdot H_2O$ (**3**) and $[CuL^2dmbipy]$ (**5**) have been found to possess the stoichiometry [CuLB], where B = 4,4′-dimethyl-2,2′-bipyridine (dmbipy). The coordination geometry around copper(II) in **5** is trigonal bipyramidal distorted square based pyramidal (TBDSBP), as obtained by X-ray diffraction studies.

Keywords: Salicylaldehyde; Phenyl thiosemicarbazide; Cyclohexyl thiosemicarbazide; Copper(II) complexes; 4,4′-Dimethyl 2,2′-bipyridine; X-ray crystallography

1. Introduction

Thiosemicarbazones of aromatic *o*-hydroxyaldehydes and ketones have recently attracted considerable attention because of their potential biological properties. These aromatic thiosemicarbazones most often coordinate as the dianion on deprotonation of the ring hydroxyl group and loss of the N(2) hydrogen of the thiosemicarbazone moiety to form mononuclear as well as binuclear metal complexes. Such types of tridentate ONS donor thiosemicarbazones and their copper complexes have been studied in recent years owing to their pharmacological interest [1]. Spectral and structural studies of a series of biologically active heterocyclic base adducts of copper(II) complexes of salicylaldehyde N(4)-substituted thiosemicarbazones have been reported [2]. Similarly, the binuclear copper(II) complexes of N(4)-substituted thiosemicarbazones have also been investigated recently [3,4]. Here, we also report the synthesis, spectral, structural and EPR studies of some mono- and bi-nuclear complexes of two salicylaldehyde N(4)-substituted thiosemicarbazones.

2. Experimental

2.1. Materials

All compounds used for the synthesis of the thiosemicarbazone ligands were purified by standard methods and solvents were purified by distillation. 4,4′-Dimethyl-2,2′-bipyridine (dmbipy) (Sigma Aldrich) and $Cu(OAc)_2 \cdot H_2O$ (Fluka) were used as received.

2.2. Synthesis of the ligands and their copper(II) complexes

Salicylaldehyde N(4)-phenyl and N(4)-cyclohexyl thiosemicarbazones (H_2L^1 and H_2L^2, respectively) were synthesized by the earlier reported method [2,5] (Fig. 1).

2.2.1. $[(CuL^1)_2]\cdot\frac{1}{2}H_2O$ (**1**)

This complex was synthesized by refluxing an ethanolic solution of H_2L^1 (1 mmol, 0.271 g) with an aqueous solution of $Cu(OAc)_2\cdot H_2O$ (1 mmol, 0.1996 g) for 4 h. The complex formed was filtered, washed with ethanol and finally with ether and dried over P_4O_{10} in vacuo.

2.2.2. $[Cu(HL^1)_2]\cdot H_2O$ (**2**)

This complex was synthesized by refluxing an ethanolic solution of H_2L^1 (2 mmol, 0.542 g) with an aqueous solution of $Cu(OAc)_2\cdot H_2O$ (1 mmol, 0.1996 g) for 4 h. The complex formed was filtered, washed with ethanol and finally with ether and dried over P_4O_{10} in vacuo.

2.2.3. $[CuL^1dmbipy]\cdot H_2O$ (**3**)

This complex was synthesized by refluxing an ethanolic solution of H_2L^1 (1 mmol, 0.271 g) and heterocyclic base dmbipy (1 mmol, 0.184 g) with an aqueous solution of $Cu(OAc)_2\cdot H_2O$ (1 mmol, 0.1996 g) for 4 h. The complex formed was filtered, washed with ethanol and finally with ether and dried over P_4O_{10} in vacuo.

2.2.4. $[(CuL^2)_2]$ (**4**)

This complex was prepared by a similar method of the complex **1** by using H_2L^2.

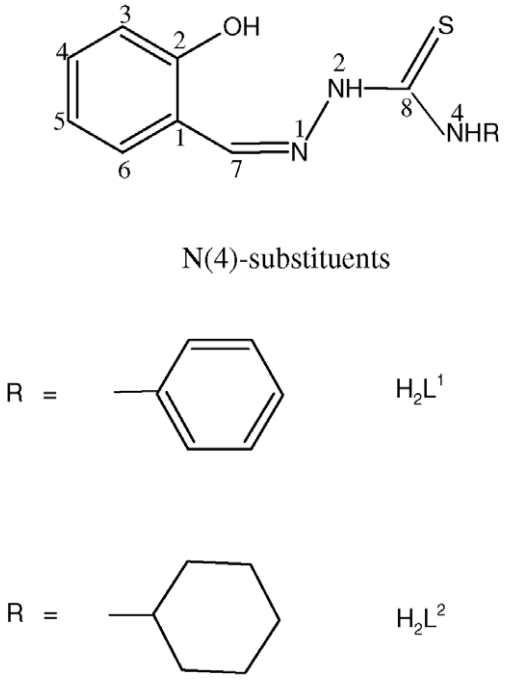

Fig. 1. Formulae of thiosemicarbazone ligands.

2.2.5. $[CuL^2dmbipy]$ (**5**)

The complex **5** was prepared by a similar method of the complex **3** by using H_2L^2.

2.3. Physical measurements

Elemental analyses were performed on a Vario ELIII elemental analyzer at SAIF, Cochin University of Science and Technology, Kochi 22, India. Magnetic susceptibility measurements were performed on a Vibrating Sample Magnetometer using $Hg[Co(SCN)_4]$ as a calibrant. Diamagnetic corrections for various atoms and structural units were computed from Pascal's constants. The FT-IR spectra were recorded on a Thermo Nicolet AVATAR 370 DTGS FTIR spectrometer using KBr pellets in the range 4000–400 cm^{-1} at SAIF, Cochin University of Science and Technology, Kochi 22, India and far IR spectra were recorded in the range 500–50 cm^{-1} on a Nicolet Magna 550 FT-IR spectrophotometer using polyethylene pellets at SAIF, IIT, Bombay, India. Electronic spectra of the ligands and the complexes were recorded on a GENESYS™ 10 Series spectrophotometers in DMF solvent. The EPR spectra were recorded on a Varian E-112 spectrometer using TCNE as the standard at SAIF, IIT, Bombay, India.

2.4. X-ray crystallography

A dark green crystal of the compound **5** having approximate dimensions $0.35\times0.30\times0.30$ mm was sealed in a

glass capillary. The X-ray diffraction data were measured at room temperature (293 K), data acquisition and cell refinement were done using the Argus (Nonius, MACH3 software) [6]. The Maxus software package (Nonius) was used for data reduction [7]. The structure was solved by direct methods and full-matrix least-squares refinement using SHELX 97 [8] package. The positions of all the non-hydrogen atoms were included in the full-matrix least-squares refinement using SHELX 97 program and all the hydrogen atoms were fixed in calculated positions. There were two potentially solvent accessible areas that can be spotted by PLATON [9]. However, we could not figure out any chemically reasonable solvent molecules in the void. Hence program SQUEEZE had been applied and the new file formed has been without solvent molecule. The structure of the compound **5** was plotted using the program DIAMOND Version 3.0 [10]. The final refinement cycle was based on all 5041 independent reflections and 313 variables, the $R_1 = 0.0586$, $wR_2 = 0.1291$. The crystallographic data and structure refinement parameters for the complex at 293 K are given in Table 1.

3. Results and discussion

3.1. Synthesis of the complexes

The complexes **1** and **4** were readily formed by refluxing ethanolic solutions of their respective ligand and $Cu(OAc)_2 \cdot H_2O$ in 1:1 ratio. The complex **2** was formed by using the ligand H_2L^1 and $Cu(OAc)_2 \cdot H_2O$ in 1:2 ratio. The complexes **3** and **5** were prepared by adding their respective ligands, metal salt and polypyridyl base 4,4′-dimethyl 2,2′-bipyridine (dmbipy) in 1:1:1 ratio. After double deprotonation, thiosemicarbazones coordinate as tridentate ligands in the thiolate form (L^{2-}) in all the complexes, except in complex **2**. In complex **2**, it is coordinated as monoanionic (HL^-) form. The elemental analyses of the complexes are in agreement with the general formula $[(ML)_2]$ (for complexes **1** and **4**); $[M(HL)_2]$ (for complex **2**) and [MLB] (for the complexes **3** and **5**) (Table 2). An X-ray quality single crystal of the compound **5** was obtained by slow evaporation of its ethanol solution over a period of 7 days.

Magnetic moments of the complexes were calculated from magnetic susceptibility measurements. The complexes **2**, **3** and **5** exhibit magnetic moments in the range 1.5–1.9 BM, which are close to the spin-only value. The magnetic moments of the complexes **1** and **4** at room temperature were found to be at ca. 1.25 BM. This low magnetic moments may arise due to the antiferromagnetic spin-spin interaction between the neighboring Cu(II) centers [11].

3.2. X-ray diffraction studies of the compound [CuL^2dmbipy]

The molecular structure of the compound **5** along with atom numbering scheme is given in Fig. 2 and selected bond lengths and bond angles are summarized in Table 3. Compound **5** crystallizes in the monoclinic space group $C2/c$. The copper atom in [CuL^2dmbipy] (**5**) is coordinated by phenolato oxygen, O(1), azomethine nitrogen, N(1), thiolato sulfur, S(1), of the thiosemicarbazone and the pyridine nitrogen, N(4) and N(5) of bipyridine derivative and is having an approximately trigonal bipyramidal geometry in which the equatorial positions are occupied by S(1), O(1) and N(5) and the axial positions by N(1) and N(4) [Cu(1)–N(1), 1.951(4) Å, Cu(1)–N(4), 2.016(4) Å] with the N(1)–Cu(1)–N(4) angle of 177.94(16)° being close to the 'ideal' value of 180° which is usual for such systems. In a five-coordinate system, the angular structural parameter (τ) is

used to propose an index of trigonality. The value of τ is defined by an equation represented by $\tau = (\beta - \alpha)/60$, where β is the greatest basal angle and α is the second greatest angle; τ is 0 for rectangular pyramidal forms and 1 for trigonal bipyramidal forms [12,13]. However, in the case of the five-coordinate system, the structure varies from near regular trigonal bipyramidal (RTB) to near square based pyramidal (SBP). The value of τ for the compound **5** is 0.35, indicates that the coordination geometry around Cu(II) is best described as trigonal bipyramidal distorted square based pyramidal (TBDSBP) [14] with copper displaced 0.2174 Å above the N(1), N(4), S(1) and O(1) coordination plane and towards the elongated apical N(5) atom, at a larger distance of 2.226(5) Å. This value is larger than the normal Cu–N bond lengths reported [15,16]. One of the reasons for the deviation from an ideal stereochemistry is the restricted bite angle imposed by both the L^{2-} and dmbipy ligands. The bite angle around the metal viz, N(4)–Cu(1)–N(5) of 77.23(18)° may be considered normal, when compared with an average value of 77° cited in the literature [17–19]. The O(1)–Cu(1)–N(5) bond angle, 96.36(16), and S(1)–Cu(1)–N(5) bond angle, 106.84(12), indicate a slight tilting of the axial Cu(1)–N(5) bond in the direction of the O(1)–Cu(1) bond and away from S(1)–Cu(1) bond. The dihedral angle formed by the least square plane Cg(4) and Cg(5) is 6.13° for the compound **5**. Ring puckering analyses and least-square plane calculations show that the Cg(3) ring comprising of atoms Cu(1), O(1), C(1), C(6), C(7) and N(1) adopts a screw-boat conformation and Cg(7) ring comprising of atoms C(9), C(10), C(11), C(12), C(13) and C(14) adopts a chair conformation.

Fig. 3 shows the contents of the unit cell along the *b* axis. The assemblage of molecules in the respective manner in the unit cell is resulted by the H bonding, π–π and CH–π interactions as depicted in Table 4. The centroid Cg(4) is involved in π–π interaction with pyridyl ring of the neighboring unit at the distance of 3.7197 Å, the CH–π interactions of the rings Cg(6) and Cg(1) with the neighboring molecules and also intermolecular hydrogen bonding interactions between N(3)–H(3N) and S(1) contribute stability to the unit cell packing.

3.3. IR and electronic spectra

The infrared spectral data of the complexes **1**–**5** are presented in Table 5 with their tentative assignments. On coordination of azomethine nitrogen, ν(C=N) shifts to lower wavenumbers by 10–20 cm^{-1}, as the band shifts from 1613 cm^{-1} in the uncomplexed thiosemicarbazone spectrum to ca. 1596 cm^{-1} in the spectra of the complexes. In all the five Cu(II) complexes, another strong band is found at ca. 1530–1555 cm^{-1}, which may be due to the newly formed ν(N=C) bond, resulting from enolization of the principal thiosemicarbazone ligand. Coordination of azomethine nitrogen is confirmed with the presence of new bands in the range 420–470 cm^{-1}, assignable to ν(Cu–N) for these complexes. For complexes **1**–**5**, ν(Cu–N) bands are at ca. 427 cm^{-1}. The ν(N–N) of the thiosemicarbazones H_2L^1 and H_2L^2 are found at 1149 and 1111 cm^{-1} respectively. The increase in the frequency of this band in the spectra of the complexes, due to the increase in the bond strength, again confirms the coordination *via* the azomethine nitrogen [20]. The decrease in the stretching frequency of C–S bond from ca. 865 cm^{-1} in the thiosemicarbazones by 50–70 cm^{-1} upon complexation indicates coordination *via* its thiolate sulfur. The presence of a new band in the 320–340 cm^{-1} range assignable to ν(Cu–S), is another indication of the involvement of sulfur coordination. In all the five complexes, except in the complex **2**, phenolic oxygen coordinated to copper by loss of the OH proton. A new band in the range 380–395 cm^{-1} in the spectra of the complexes **3** and **5** are assignable to ν(Cu–O). The IR spectra of the complexes **3** and **5** display bands characteristic of coordinated heterocyclic base [21].

The electronic spectra of the complexes in DMF solution are presented in Table 6. Each thiosemicarbazone and its copper(II) complexes have a ring $\pi \rightarrow \pi^*$ bands in the range 32 000–38 000 cm^{-1} and $n \rightarrow \pi^*$ bands in the range 28 000–32 000 cm^{-1}. Two ligand to metal charge transfer bands are found in 24 000–28 000 cm^{-1} range. In accordance with studies of previous copper(II) thiosemicarbazone complexes [22,23], the higher energy bands in the range 26 000–27 000 cm^{-1} is assigned to $S \rightarrow Cu^{II}$ transitions. The bands in the

24 000–25 000 cm^{-1} range are assignable to phenoxy O → Cu^{II} transitions [24]. Each complex has a d–d combination band in the range 14 000–16 000 cm^{-1}, which appears as a weak shoulder on the intraligand and charge transfer bands.

3.4. EPR spectra

The EPR parameters obtained for the compounds in the polycrystalline state at 298 K and in DMF solution at 77 K are presented in Tables 7 and 8.

The EPR spectra of compounds **1**–**5** in the polycrystalline state at room temperature shows different types of geometrical species. The compounds **1**, **3** and **4** show isotropic spectra with only one broad signal at $g = 2.059$, 2.070 and 2.129, respectively. Spectrum of compound **2** gives three *g* values indicating rhombic distortion in its geometry. The values g_1 and g_2 are very close to each other in compound **2**, which means that the rhombic distortion is very small. The spectrum of the compound **5** shows a typical axial one with well-defined $g_\parallel$ and $g_\perp$ values at 2.195 and 2.063, respectively. The geometric parameter *G*, which is a measure of the exchange interaction between the copper centers in the polycrystalline compound, is calculated using the equation: $G = (g_\parallel - 2.0023)/(g_\perp - 2.0023)$ for axial spectra and for rhombic spectra $G = (g_3 - 2.0023)/(g_\perp - 2.0023)$, where $g_\perp = (g_1 + g_2)/2$. If $G < 4.0$ considerable exchange interaction is indicated in the solid complex [25,26]. The *G* value for the compounds **2** and **5** in polycrystalline state at 298 K are 3.55 and 3.17, respectively. In all the copper(II) complexes $g_\parallel > g_\perp > 2.0023$ and *G* values within the range 2.5–4.0 are consistent with a $d_{x^2-y^2}$ ground state.

$[CuL^2dmbipy]$ (**5**)	2.98	0.75	0.81	0.93		0.61	0.70	114		

[a] Expressed in units of (cm).
[b] Parameter $R = (g_2 - g_1)/(g_3 - g_2)$.

The parameter R {R=$(g_2 - g_1)/(g_3 - g_2)$ for rhombic systems} calculated for the compound **2** is 0.125, i.e., $R < 1$, indicating a $d_{x^2-y^2}$ ground state of the copper(II) ion [27,28]. From the g value of a transition metal complex, we can obtain very important information about the structure of the complex.

The EPR spectra of all the compounds in frozen DMF solution at 77 K are axial. Moreover, they show well defined four hyperfine lines in the parallel region corresponding to the electron spin–nuclear spin interaction ($^{63,65}Cu$, $I = 3/2$). The fourth copper hyperfine line is expected to overlap with the high field component ($g_\perp$). However, the half field signal corresponding to the dimer was not observed for the compounds **1** and **4**. In all these compounds, $g_\parallel > g_\perp > 2$, corresponding to the presence of an unpaired electron in the $d_{x^2-y^2}$ orbital [29,30]. For a Cu(II) complex, $g_\parallel$ is a parameter sensitive enough to indicate covalence. For a covalent complex, $g_\parallel < 2.3$. Here also,

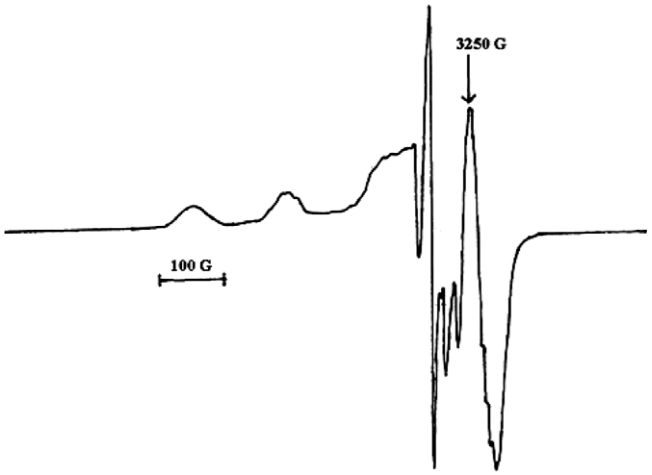

Fig. 4. EPR spectra of the compound **4** in DMF solution (at 77 K).

all the five complexes are covalent in nature. In solution at 77 K, $g_{\|}$ values (2.16–2.19) are almost the same for all the compounds, which indicate similar bonding nature in all of them [31]. In compound **4**, well resolved spectra with four copper hyperfine lines and three superhyperfine lines due to the azomethine nitrogen are observed in DMF (Fig. 4).

The EPR parameters $g_{\|}$, $g_{\perp}$, g_{av}, $A_{\|}$(Cu) and $A_{\perp}$(Cu) and energies of d–d transitions were used to evaluate the bonding parameters α^2, β^2 and γ^2, which may be regarded as measures of covalency of the in-plane σ bonds, in-plane π bonds and out-of-plane π bonds, respectively [32].

The value of in-plane σ bonding parameter α^2 was estimated from the expression [33,34],

$$\alpha^2 = -A_{\|}/0.036 + (g_{\|} - 2.00277) + 3/7(g_{\perp} - 2.00277) + 0.04$$

The following simplified expressions were used to calculate the bonding parameters [35,36]:

$$K_{\|}^2 = (g_{\|} - 2.00277)E_{d\text{–}d}/8\lambda_0$$

$$K_{\perp}^2 = (g_{\perp} - 2.00277)E_{d\text{–}d}/2\lambda_0$$

where $K_{\|} = \alpha^2\beta^2$ and $K_{\perp} = \alpha^2\gamma^2$, $K_{\|}$ and $K_{\perp}$ are orbital reduction factors and λ_0 represents the one electron spin–orbit coupling constant which equals $-828\ cm^{-1}$.

Hathaway [37] pointed out that, for pure σ bonding, $K_{\|} \approx K_{\perp} \approx 0.77$, and for in-plane π bonding, $K_{\|} < K_{\perp}$; while for out-of-plane π bonding $K_{\perp} < K_{\|}$. In all the complexes it is observed that $K_{\|} < K_{\perp}$which indicates the presence of significant in-plane π bonding. The values of the bonding parameters α^2, β^2 and $\gamma^2 < 1.0$ (value of 1.0 for 100% ionic character) indicate significant in-plane π bonding and in-plane σ bonding.

The Fermi contact hyperfine interaction term K may be obtained from [38]

$$K = A_{iso}/P\beta^2 + (g_{av} - 2.00277)/\beta^2$$

where P is the free ion dipolar term and its, value is 0.036. K is a dimensionless quantity, which is a measure of the contribution of s electrons to the hyperfine interaction and is generally found to have a value of 0.30. The K values obtained for all the complexes are in good agreement with those estimated by Assour [39] and Abragam and Pryce [40]. The empirical factor $f = g_{\|}/A_{\|}$ (cm^{-1}), is an index of tetrahedral distortion. In all the five compounds, f falls in the range 114–119 cm corresponding to a copper(II) center with medium distortion [41].

Abstract

New diazaphospholes and diazaphosphorinanes (**1**–**12**) were synthesized and characterized by ^{1}H, ^{13}C, ^{31}P NMR, mass and IR spectroscopy and elemental analysis. The factors which affect the $^{2,3}J$(P,X) (X=H, C) coupling constants in compounds **1**–**12** were considered. The ring size and the hybridization are parameters which change the ^{2}J(PNH) coupling constant in the sequence benzodiazaphospholes > diazaphospholes > diazaphosphorinanes. Also, attention was paid to exocyclic substituent effects. Asymmetric diazaphospholes **5**–**8** indicate two different $^{2}J(P,C)_{aliphatic}$ values, and the more deshielded carbon atom has a higher coupling constant. The crystal structures of compounds **7** and **10**–**12** were determined by X-ray crystallography. Hydrogen bonds produce a 2D framework for compound **10**, which is composed of two symmetrically independent molecules. Compounds **7**, **11** and **12** exist as a polymeric chain, 2D framework and centrosymmetric dimer, respectively, which are made by hydrogen bonds.

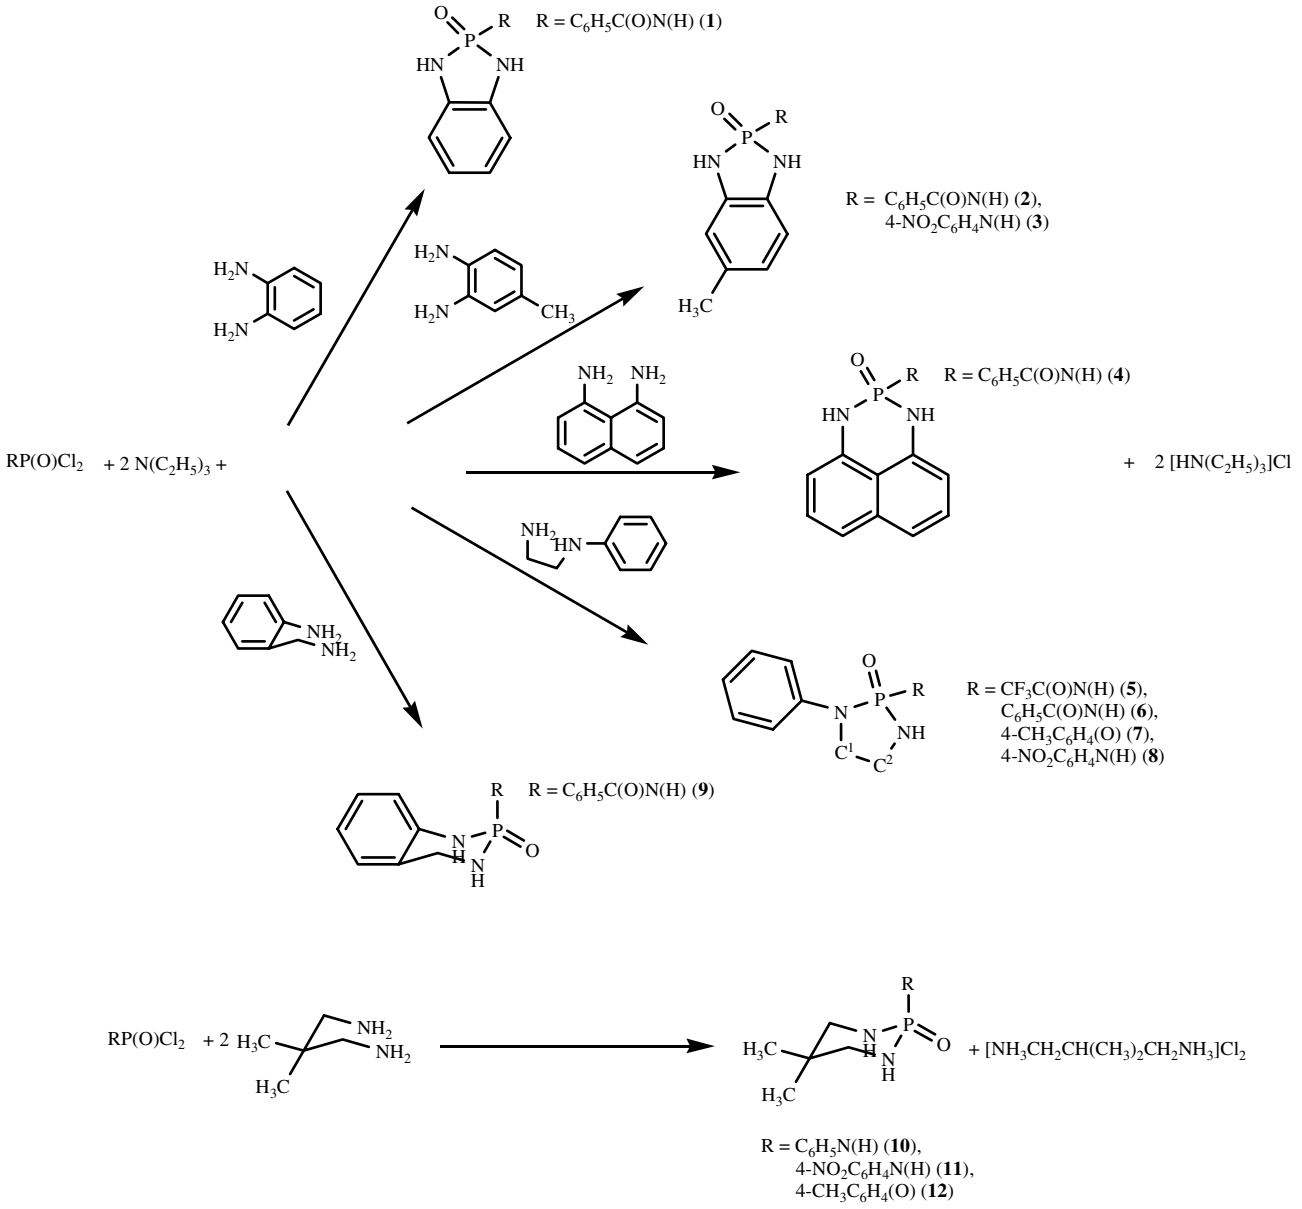
Keywords: Diazaphospholes; Diazaphosphorinanes; NMR; X-ray crystallography

1. Introduction

Diazaphospholes and diazaphosphorinanes are considered as important compounds due to their great applications in chemistry and medicine [1,2]. So far, a few structures [3,4] and coupling constant assignments of these compounds have been reported [3]. Stereochemistry, P–C coupling constants in 1,3,2-benzodiazaphospholes [5] and 2-oxo-, 2-thio-diazaphosphorinanes have been presented [6]. Phosphorus–hydrogen coupling constants in some diazaphospholes with three coordinated phosphorus atoms were studied [7]. To further investigate this area, the new diazaphospholes and diazaphosphorinanes **1**–**12** were synthesized and characterized to find effective parameters for $^{2,3}J$(P,X) coupling constants (X = H, C).



2. Experimental

2.1. Spectroscopic measurements

NMR spectra of compounds **1**–**12** were obtained from their prepared solutions, which must be fresh. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker (Avance DRS) 500 spectrometer. ^{1}H and ^{13}C, and ^{31}P chemical shifts were determined relative to tetramethylsilane (TMS) and 85% H_3PO_4 as external standards, respectively, and HSQC ^{1}H–^{15}N spectra to external TMS and CH_3–NO_2 standards. Infrared (IR) spectra were recorded on a Shimadzu model IR-60 spectrometer. Elemental analysis was performed using a Heraeus CHN-O-RAPID apparatus. High-resolution Mass spectra were obtained with a Shimadzu model QP-1100EX spectrometer (EI, 20 eV).

Scheme 1. The preparation of compounds **1**–**12**.

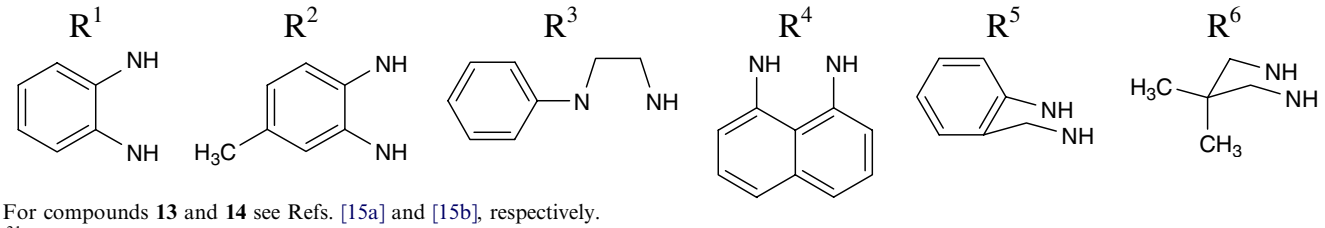
2.2. Syntheses

Syntheses of compounds **1**–**12** were performed by the reaction of *N*-benzoyl- [8], *N*-trifluoroacetyl- [9], *N*-phenyl- [10] and *N*-4-nitrophenyl- [11] phosphoramidic dichloride and (4-tolyl)-dichlorophosphate [12] with the corresponding amines in the presence of an HCl scavenger (triethylamine or an excess amount of the corresponding diamine).

2.3. X-ray measurements

X-ray data were collected on a Bruker SMART 1000 CCD single crystal diffractometer. Routine Lorentz and polarization corrections were applied and an absorption correction was performed using the SADABS program [13]. The structures were refined with SHELXL-97 [14] by full-matrix least-squares on F^2.

3. Results and discussion



3.1. NMR study

Several new diazaphospholes and diazaphosphorinanes **1**–**12** (Scheme 1) were synthesized to study effective parameters for $^{2,3}J$(P,X) coupling constants (X = H, C).

The effect of ring size on ^2J(PNH): Although the variation of the ^2J(PNH) coupling constant in acyclic phosphoramidates has been considered (in the range of 4–12 Hz) [15–17], less attention has been paid to diazaphospholes and diazaphosphorinanes. The ^{1}H NMR spectrum of

[a,b] For compounds **13** and **14** see Refs. [15a] and [15b], respectively.
[a] ^{31}P chemical shift was not reported in Ref. [15a].

compound **1** shows a doublet at 8.58 ppm with a high value $^{2}J(PNH)$ coupling constant (17.9 Hz) for two equivalent NH protons and a doublet at 9.96 ppm with $^{2}J(PNH) = 8.4$ Hz for the amidic proton. Also, in diazaphospholes **2** and **3**, the two non-equivalent NH protons (of the ring) indicate two high value $^{2}J(PNH)$ coupling constants, Table 1. Compound **4** shows a drastically reduction ($^{2}J(PNH) = 5.0$ Hz) on increasing the ring size (from five to six). ^{1}H NMR spectra of diazaphospholes **5**–**8** show $^{2}J(PNH)$ values in the range 13.1–15.3 Hz, which are reduced in comparison with compounds **1**–**3**. A further reduction was obtained by increasing the ring size in cyclic aliphatic compounds **10**–**12**, Table 1. A major part of the observed changes more likely results from conformational averaging of the orientation of bond vectors in the six-member rings when compared with the more fixed orientation of bond vectors in the five-member rings.

The effect of hybridization on $^{2}J(PNH)$: In compounds **1**–**3** the endocyclic nitrogen atoms of the NH groups are bonded to the carbon atoms with sp^2 hybridization in five-membered rings, but in compounds **5**–**8** they are bonded to sp^3 carbon atoms. $^{2}J(PNH)$ in compounds **5**–**8** are lower than those of compounds **1**–**3**. In molecule **9**, possessing two various NH groups, one of the two NH protons is bonded to a $C(sp^2)$ atom and the other to $C(sp^3)$ in a six-membered ring. The ^{1}H NMR spectrum shows two different coupling constants, $^{2}J(PNH) = 5.7$ Hz (sp^2) and $^{2}J(PNH) = 4.6$ Hz (sp^3).

The effect of the substituent on $^{2}J(PNH)$: A comparison of the benzodiazaphospholes **1**–**3**, **13** and **14** indicates a substituent effect (of the exocyclic group) on $^{2}J(PN_{endocyclic}H)$, in the range of 18.0 Hz (for **1** with a $C_6H_5C(O)NH$ moiety) to 11.2 Hz (for **14** with a Cl substituent), Table 1. Furthermore, in diazaphospholes **5**–**8**, the highest value of $^{2}J(PNH)$ is observed for compound **5** with a $CF_3C(O)N(H)$ electronegative moiety.

$^{3}J(PNCH)$ coupling constants: In the asymmetric diazaphospholes **5**–**8**, four H atoms of the $–CH_2CH_2–$ moiety appear at different chemical shifts with various $^{3}J(PNCH)_{aliphatic}$ coupling constants. Two benzylic protons of diazaphosphorinane **9** are diastereotopic and have different $^{3}J(PNCH)$ coupling constants depending on the dihedral angles with the P atom. ^{1}H NMR spectra of

Table 2
The intensities of $C_6H_5CN^+$ ($m/z = 103$) and other fragments in mass spectra of compounds **1**, **2**, **4**, **6** and **9** (the numbers in parentheses are intensities of these fragments)

Compound	$C_6H_5CN^+$	Amidophosphoric acid	Amidophosphoric acid–H_2O
1	69	170(100)	152(59)
2	100	184(14)	166(2)
4	100	220(65)	202(45)
6	100	184(9)	166(3)
9	100	198(55)	180(21)

compounds **10**–**12** show two different signals for H_{axial} and $H_{equatorial}$. The torsion angles of P–N–C–H_{axial} and P–N–C–$H_{equatorial}$ are about ±70° and ±170°, respectively, obtained from X-ray crystallography. Considering the Karplus equation [18], the values 24.8, 25.1 and 26.7 Hz are related to $^3J(PNCH_{equatorial})$ values in **10**–**12**. These values are larger than $^3J(PNCH)$ values for acyclic phosphoramidates [15–17]. For H_{axial}, the coupling with the P atom was not observed.

Ring size influence on $^2J(P,C)_{aromatic}$: Similar to the $^2J(PNH)$ value, high values for $^2J(P,C)_{aromatic}$ were observed for diazaphospholes **1**–**3** (about 14.0 Hz) which are larger than the values of acyclic phosphoramidates [19].

Deshielded carbon atoms and $^2J(P,C)$: In compounds **5**–**8**, two different signals (and two different $^2J(P,C)$ values) appear for the aliphatic carbon atoms (C^1 and C^2, Scheme 1) and the deshielded C^1 atoms show high values for $^2J(P,C)$ due to the effect of the phenyl ring.

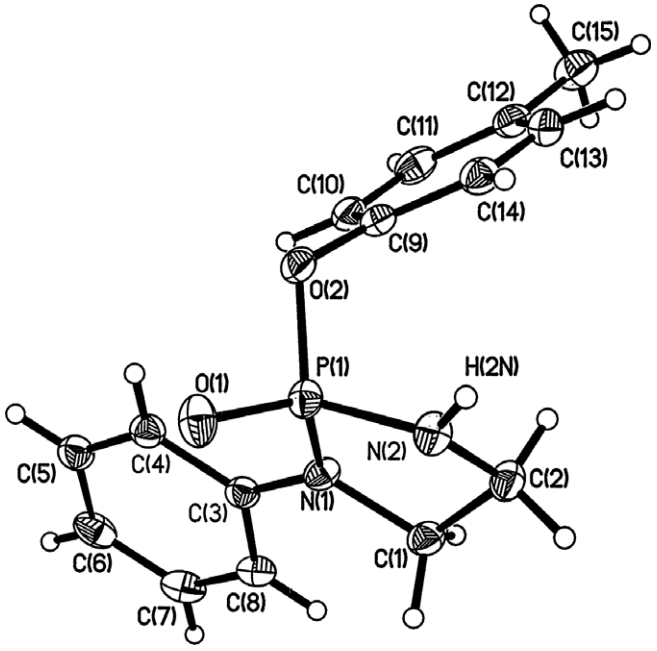

Fig. 2. Molecular structure and atom-labelling scheme for compound **7**, $(4\text{-}CH_3\text{-}C_6H_4O)P(O)[NHCH_2CH_2N(C_6H_5)]$ (50% probability ellipsoids).

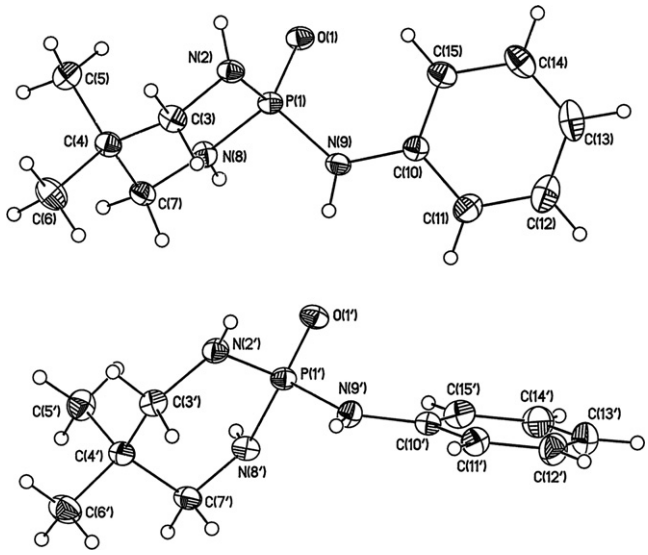

Fig. 3. Molecular structure and atom-labelling scheme for compound **10**, $C_6H_5N(H)P(O)[NHCH_2C(CH_3)_2CH_2NH]$ (50% probability ellipsoids).

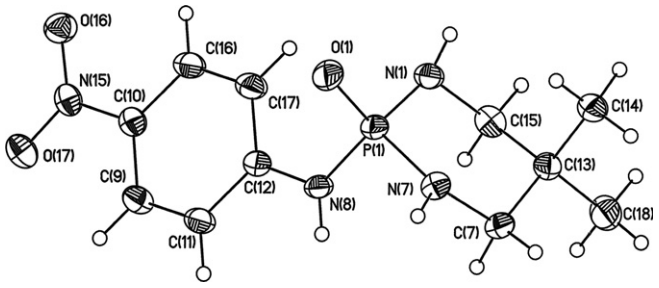

Fig. 4. Molecular structure and atom-labelling scheme for compound **11**, $4\text{-}NO_2\text{-}C_6H_4N(H)P(O)[NHCH_2C(CH_3)_2CH_2NH]$ (50% probability ellipsoids).

Substituent effect on $^2J(P,C)$: In compounds **5**–**8**, both $^2J(P,C^1)$ and $^2J(PNH)$ coupling constants vary with different substituents in the following order: $CF_3C(O)N(H) > C_6H_5C(O)N(H) > 4\text{-}CH_3C_6H_4\text{–}O > 4\text{-}NO_2\text{-}C_6H_4NH$. Similarly, the highest value of $^2J(P,C^2)$ was revealed for compound **5** with the $CF_3C(O)N(H)$ substituent. $^2J(P,C^2)$ values were observed in the sequence $CF_3C(O)N(H) > C_6H_5C(O)N(H) > 4\text{-}NO_2\text{–}C_6H_4NH > 4\text{-}CH_3C_6H_4\text{–}O$.

$^{2,3}J(P,C)_{aliphatic}$: In compounds **10**–**12**, $^{3}J(P,C)_{aliphatic} > {}^{2}J(P,C)_{aliphatic}$. Also, $^{2}J(P,C)_{aliphatic}$ in compound **7** is greater than that of compound **12**, due to the ring size effect.

^{31}P NMR study: In diazaphospholes with a five-membered ring heterocycle, the P atoms are more deshielded than those of diazaphosphorinanes with a six-membered ring (Table 1). By considering the high value coupling constants in diazaphospholes, it seems that the deshielded phosphorus atoms in diazaphospholes have a significant interaction with the H atoms.

2D HSQC ^{1}H–^{15}N: The 2D HSQC ^{1}H–^{15}N spectrum for **3** (Fig. 1) indicates the endocyclic N atoms are observed at 59.4 and 60.1 ppm, and NO_2 and NH nitrogen atoms in the 4-$NO_2C_6H_4NH$ moiety are at 75.0 and 75.2 ppm. The spectra of compounds **10**–**12** showed that the aliphatic N atoms appear upfield (at about 20 ppm) and the aromatic N atoms of C_6H_5NH and 4-$NO_2C_6H_4NH$ groups (in **10**, **11**) are downfield (at 61.4 and 75.4 ppm, respectively).

4. Mass spectroscopy investigation

Mass spectra of compounds with the general formula $C_6H_5C(O)N(H)P(O)R$ (**1**, **2**, **4**, **6** and **9**) show a fragment ion at $m/z = 103$, which in compounds **2**, **4**, **6** and **9** are base peaks, and is assigned to $PhCN^+$. In earlier work, Lapidot and Samuel reported on the pyrolysis of *N*-benzoyl phosphoramidates that led to PhCN and the related amidophosphoric acids [20]. Mass spectra of these compounds also show the presence of related amidophosphoric acid cations, with high intensity. In compound **1**, the cation $\overline{(P(O)(OH)(2\text{-}NH\text{-}C_6H_4\text{-}NH)^+)}$ is the base peak. It is assumed that the fragmentation pathway contains P–N cleavage and P–O formation and then the rearranged molecule is cleaved in a pseudo McLafferty mechanism to PhCN and the related amidophosphoric acid cations, see Scheme 2 for compound **1**. The m/z values and the intensities of the amidophosphoric acid fragments of these compounds are given in Table 2. In the next step, a water molecule is removed from the amidophosphoric acid.

4.1. X-ray crystallography

Single crystals of **7** were obtained from a mixture of methanol/acetonitrile and those of **10**–**12** from a mixture of methanol/n-heptane, at room temperature. The structures of these compounds are shown in Figs. 2–5, respectively. Crystallographic data and structure refinement parameters are listed in Table 3 and selected bond lengths and angles are presented in Table 4. The hydrogen bonding data are given in Table 5.

The nitrogen atom environments in the structure of **7** are nearly planar. The sum of the surrounding angles around N(1) and N(2) are slightly lower than sp^2 angles, 358.38° and 356.31°, respectively. P–N bonds in this molecule are smaller than a P–N single bond (1.77 Å) [21]; also, $P–N_{aliphatic}$ (1.614 Å) is stronger than $P–N_{aromatic}$ (1.672 Å). The angle P(1)–O(2)–C(9) is 121.92(12)° (sp^2 angle). Compound **10** exists as two independent molecules (**10** and **10′**) in the crystal lattice. The endocyclic nitrogen atoms in compounds **10**–**12** are distorted from planarity. The deviations from planarity in these structures are larger than that of diazaphosphole **7** and previously reported phodsphoramidates [19,22]. The sum of the angles around the endocyclic N atoms in compounds **10**–**12** (that are in the range of 352.76°–338.59°) are lower than those of diazaphosphole **7**. The exocyclic nitrogen atoms of aniline and nitroaniline groups are relatively planar. P–N bonds in these molecules are in the range 1.6708(15)–1.6192(12) Å (smaller than a P–N single bond). The P=O bond lengths in these molecules are slightly longer than the PO double bond length (1.45 Å) [21]. This bond is in an equatorial position. The equatorial preference for the P=O bond was previously observed by Bentrude [23] and was attributed to the overlap of the endocyclic nitrogen p-orbital with the P–N(exocyclic) anti-bonding orbital.

Hydrogen bonds: Compound **7** forms an infinite zigzag chain via an intermolecular –P=O…H–N– hydrogen bond. In diazaphosphorinane **10**, each independent molecule is connected to its symmetrically similar molecule via two equal –P=O…H–N– hydrogen bonds and produces a centrosymmetric dimer in the crystal lattice, P(1)–

O(1)...H(2N)–N(2) and P(1′)–O(1′)...H(8N′)–N(8′) hydrogen bonds in **10** and **10**′. These dimeric aggregates are connected to each other to form a 2D polymer. Each dimer of **10** is connected to two dimers of **10**′ by two equal P(1)–O(1)...H(9N′)–N(9′) H-bonds and then connected to the two other dimers of **10**′ by two other equal P(1′)–O(1′)...H(9N)–N(9) H-bonds. Therefore, one dimer of **10** is placed between four dimers of **10**′ and vice versa, Fig. 6. Furthermore two weak P(1′)–N(8′)...H(8N)–N(8) and P(1)–N(2)...H(2N′)–N(2′) H-bonds are produced in the packing. Compound **11** exists as a two dimensional polymer in the crystal lattice via –P=O...H–N– and –N–O...H–N– hydrogen bonds. Compound **12** forms centrosymmetric dimers via two equal P(1)–O(1)...H(1N)–N(1) hydrogen bonds and these dimers are connected via a weak H-bonds, P(1)–O(2)...H(2N)–N(2).

Abstract

Two crystal structures of Eu^{III} complexes with CDTA (*trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetate), $[C(NH_2)_3]_3[Eu_2(CDTA)_2(H_2O)_2]ClO_4 \cdot 7H_2O$ (**I**) and $[C(NH_2)_3][Eu(CDTA)(H_2O)] \cdot 2.375H_2O$ (**II**), are presented. Both structures are polymeric and the central metal ions are eight-coordinate. The first coordination sphere of each Eu^{III} cation contains five carboxylate oxygen atoms, two nitrogen ones and a water molecule. For **I**, as well as for water solutions of the Eu^{III}–CDTA complex at various pH values, the spectroscopic (UV–Vis) properties were investigated.

1. Introduction

Lanthanide polyaminopolycarboxylate chelates play an important role both in fundamental investigations and in several areas of practical applications. They are used, among others, as shift reagents in NMR spectroscopy [1], contrast agents in MRI imaging [2], structural probes [3] and luminescent tags in immunoassays [4]. This family of compounds has been epitomized by complexes of Ln^{III} with the ethylenediaminetetraacetate (EDTA) anion, which have been extensively studied both in solution e.g. [5] and in the solid state e.g. [6] and now may serve as a kind of standard when the structure, spectroscopic and/or thermodynamic properties of lanthanide polyaminopolycarboxylates are discussed. It is therefore of interest to find how the properties are altered when the $EDTA^{4-}$ skeleton is modified. In this work we present a study of two Eu^{III} complexes with such a ligand, i.e. *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetate (CDTA). The investigations of Ln^{III}–CDTA complexes carried out so far have been focused to a great part on their properties in aqueous solutions and included thermodynamic as well as spectroscopic aspects. Their stability constants are higher by an order or two of magnitude, depending on the lanthanide, than those of the EDTA complexes [7], and generally saying, they are thermodynamically stable [8]. The spectroscopic studies have revealed that in solutions of Eu^{III}–CDTA complexes an equilibrium exists between two different species, nine- and eight-coordinate, the dissimilarity between them consisting of a different number of coordinated water molecules (three or two) [9]. The average number of these molecules has been found to be 2.3–2.6 and is a little lower than that found in water solutions of the EDTA complexes (2.6–2.8) [5f,5h].

Because of difficulties connected with growing of monocrystals of adequate quality, structural data for Ln^{III}–CDTA complexes are scarce. To the best of the authors' knowledge only three crystal structures of these complexes have been published. Two of them, $NH_4[Ln(CDTA)(H_2O)_2] \cdot 4.5H_2O$ ($Ln = Gd^{III}$, Ho^{III}), are monomeric and isostructural [10,11] whereas in the third one, $Na[Eu(CDTA)(H_2O)] \cdot 4H_2O$ [12], dimeric anions of $[Eu(CDTA)–\mu\text{-}(H_2O)_2–Eu(CDTA)]^{2-}$ are formed. For the last system luminescence properties were also reported. In all these complexes the Ln^{III} ions are eight-coordinate.

In the crystal, the coordination surrounding of Ln^{III} ion is unambiguously defined, therefore the spectra of the

doi:10.1016/j.poly.2006.09.031

crystals may be a good starting point for interpretation of spectral data of solution systems. The paucity of such data has motivated us to attempt the preparation of Eu^{III}–CDTA complexes in the crystalline state, to study their crystal structures and spectroscopic properties and to compare the latter with the analogous properties of Eu^{III}–CDTA complexes in solution.

2. Experimental

2.1. Materials

Solutions for spectroscopic measurements: A stock solution of europium chloride was prepared by dissolving Eu_2O_3 (99.99%; Standford materials) in 2 mol dm^{-3} hydrochloric acid. The Eu^{III} ion concentration was determined complexometrically using xylenol orange as an indicator. The stock solution of H_4CDTA (98%; Lancaster) was prepared by half-neutralization with NaOH. The pH of the 1:1.1 Eu^{III}–CDTA solutions was adjusted by a carbonate-free NaOH water solution.

Crystal preparations: An aqueous solution of equimolar quantities of europium perchlorate and H_4CDTA was heated at ca. 80 °C. Next, solid $[C(NH_2)_3]_2CO_3$ was added until the pH value was 5. Large colourless crystals of $[C(NH_2)_3]_3[Eu_2(CDTA)_2(H_2O)_2]ClO_4 \cdot 7H_2O$ (**I**) were formed during slow evaporation. The other crystals, $[C(NH_2)_3][Eu(CDTA)(H_2O)] \cdot 2.375H_2O$ (**II**), were obtained as follows: a suspension of Eu_2O_3 and H_4CDTA was heated at ca. 80 °C. After dissolution of the substrates, the solution was alkalized with $[C(NH_2)_3]_2CO_3$ to a final pH value of 3, and left for crystallization.

2.2. X-ray study

Appropriate crystals were cut from larger ones and mounted on a Kuma KM4 diffractometer equipped with a CCD counter. The collected data were corrected for polarization, Lorentz and absorption, the last calculated from the crystal habit captured from photo scans. Both crystals turned out to be twinned. The twinning of crystal **I** was pseudo-merohedral; this was brought about by the fact that the unit cells spanned by vectors **a**, **b**, **c**, and **a**, **a**–**b**, **a**–**c** have very similar lattice constants. The fraction of the first twin component found from the refinement was 0.676(1). The twinning matrix in **II** was (−1/2 −1/2 0/ −3/2 1/2 0/ −1/2 1/2 −1) with the result that only reflections with $h + k$ even overlapped. The structure of **I** was solved and refined against all reflections, while that of **II** was solved using one twin component and refined against both. The positions of Eu were found from Patterson maps, the rest of the non-H atoms from difference Fourier

maps. The positions of the C- and N-bonded hydrogen atoms were calculated geometrically. The refinement was full-matrix with all ordered non-H atoms anisotropic. The oxygen atoms from disordered water molecules (in **II**) were refined isotropically and C- and N-bonded H atoms were constrained to 1.2 times the factors of the relevant C atoms. Because of twinning and partial overlapping of some reflections the precision of the structure determination of **II** unfortunately deteriorated. Our several attempts to find an untwinned sample failed and therefore we decided to solve and refine the structure against the twin data. The large volume of the asymmetric part seems upsetting. However we could not find a cell with smaller volume and herein we present the best model of twinning and the crystal structure which we have been able to find. Both structures were solved and refined by SHELXS97 [13] and SHELXL97 [14], respectively, and the program DIAMOND [15] was used for the molecular graphics. The data concerning the crystal parameters, data collection and refinement details are presented in Table 1.

3. Spectroscopy

3.1. UV–Vis measurements

Electronic absorption spectra were recorded on a Cary 500 UV–VIS–near-IR spectrophotometer. The solutions were measured at room temperature. Only spectra of **I** were recorded because we could not obtain a good sample of **II**. The absorption spectra of **I** were measured at 293 and 30 K (in an Oxford CF 1204 continuous flow helium cryostat). The oscillator strengths (P) were determined using the equation:

$$P = 4.32 \times 10^{-9}(cd)^{-1} \int A(\sigma)\,\mathrm{d}\sigma$$

where c is the concentration of the Eu^{III} ion in M, d is the length of the optical way in cm and $A(\sigma)$ is the absorbance as the function of the wavenumber in cm^{-1}. The P values were not corrected for the population of the $^7F_1$ state at room temperature. Corrected emission spectra were measured on a SLM Aminco 500 spectrofluorometer at 293 and 77 K. For luminescence, the Eu^{III} ion was excited with a wavelength of 394 nm.

4. Results and discussion

4.1. Structure

Both structures are built up from polymeric complex chains, guanidinium cations, water of crystallization (partially disordered in **II**), and, in the case of **I**, also perchlorate anions. The polymeric chains are composed of europium cations, *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetate (CDTA) anions and water molecules coordinated to europium. Each polymer unit (mer) contains a Eu^{III} cation and a CDTA anion which is coordinated to the metal through its four carboxylate oxygen atoms and two nitrogen atoms, filling thus six coordinate sites. The seventh site is occupied by a water molecule. Apart from that each mer donates one of its carboxylate oxygen atoms to the first coordination sphere of an Eu^{III} ion in a neighbouring mer (accepting at the same time an analogous O atom from the other neighbour). In this way infinite polymeric chains are formed and the europium cations are eight-coordinate. In **I** there are two symmetry independent Eu sites, and accordingly two different mers. In **II** the number of symmetry independent Eu sites is 4. Nevertheless, superimposition of all six mers (Fig. 1) shows that their conformations are very similar, the difference being only in small variations of bond lengths and angles. The Eu–O and Eu–N distances (see Table 2) are similar to those found in the europium dimeric complex with CDTA, $Na[Eu(CDTA)H_2O]\cdot 4H_2O$ [12], however the Eu–OH_2 bond distances are significantly longer in the present structures. The Eu–OH_2 average distances are 0.125 Å (compound **I**) and 0.103 Å (compound **II**) longer than in the quoted dimer. These variations may be caused by different modes of interaction of guanidinium and sodium cations with the CDTA moiety, because these cations induce different hydrogen bond networks. In both presented structures the shortest bonds are those involving carboxylate O atoms, the Eu–OH_2 ones are longer, and the

Symmetry transformations used to generate equivalent atoms: $^{i}-x-1, y, z$; $^{j}-x+1, y-1, z$.

Eu–N ones are the longest. As far as the conformation of the ligand is concerned, two subsets of methylenecarboxylate groups may be discerned. In each CDTA ligand two such groups are almost parallel. In **II** the angles between the least-squares fitted planes of such planes (namely C13 and C23, C33 and C43, C51 and C63, C71 and C83; the methylenecarboxylate groups are labelled after their central C atoms) are in the range 0.6–10.0°. In **I** the relevant angles differ more: the planes of the groups C1 and C12 are mutually twisted by 21.0°, whereas the groups C21 and C34 are twisted by only 4.5°. The other pairs are twisted by 54.9° and 59.7° in **I**, and 60.1–70.5° in **II**. Apart from that it may be noticed that the C–O bonds are generally longer when the O atom is coordinated to Eu, although the difference between the C–O lengths with O atoms coordinated and uncoordinated falls often within the range of experimental error. The approximate symmetry of all Eu first coordination spheres in both structures is C_2 (after neglecting the difference between the water and the bridging carboxylate O atoms); the axis passes through the center of the cyclohexyl ring, Eu and the bisector of the relevant water–Eu–bridging O atom angle. It is noteworthy that in the presented crystals the CDTA ligand behaves in a way

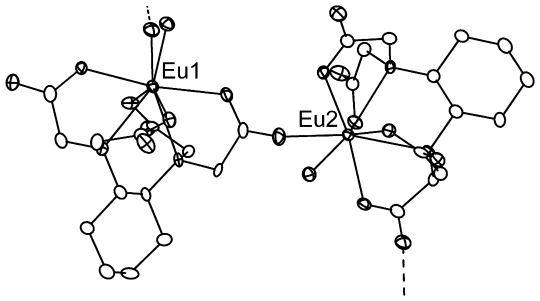

Fig. 2. A fragment of the polymeric chain in **I**.

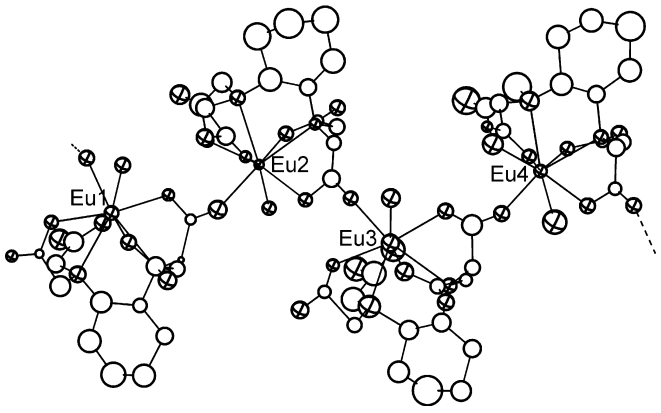

Fig. 3. A fragment of the polymeric chain in **II**.

different to that of its analogue, i.e. ethylenediaminetetraacetate (EDTA). The Eu^{III}–EDTA complexes are monomeric, and the europium cation is nine-coordinate [6d,6e,6f], contrary to the polymeric structures with eight-coordinate Eu ions in the present structures. Fragments of the polymeric complex chains are presented in Figs. 2 and 3.

5. Spectroscopic results

For the $^{7}F_0 \rightarrow {}^{5}D_0$ transition in **I** we were able to observe one peak at 17245 cm^{-1} at room temperature while at 30 K two components at 17241 and 17234 cm^{-1} appeared. The ground ($^{7}F_0$) and emitting ($^{5}D_0$) states of the europium ion are non-degenerate, therefore the number of peaks observed in the range 578–582 nm indicates the number of various chemical surroundings of the Eu^{III} ion. Accordingly we may assume existence of two different europium sites at 30 K and of one site at room temperature. In the absorption spectrum of a related compound, $[C(NH_2)_3][Eu(EDTA)(H_2O)_3]$, only one $^{7}F_0 \rightarrow {}^{5}D_0$ peak was observed at a very similar energy, 17252 cm^{-1} at room temperature [16] and 17243 cm^{-1} at 77 K. Also in the $^{7}F_0 \rightarrow {}^{5}D_1$ and $^{7}F_0 \rightarrow {}^{5}D_2$ transitions the number of components in the spectrum recorded at 77 K is greater than that found in the spectrum taken at 293 K. For the low local symmetry of the Eu^{III} ion in each symmetry independent site the number of the components should be 3 and 5, respectively. At room temperature the number of crystal

field levels in the absorption spectrum for $^7F_0 \rightarrow {}^5D_1$ and $^7F_0 \rightarrow {}^5D_2$ are actually 3 and 5, whereas in the low temperature (30 K) transitions 5 and 7 crystal field components in the range 19 050–19 120 and 21 390–21 550 cm^{-1}, respectively, may be seen (Fig. 4). This may suggest that between 293 and 100 K (taking into account the structural data reported above) a phase transition occurs. The oscillator strengths found in **I** at 293 and 30 K are presented in Table 3. Inspection of these data reveals somewhat anomalous behaviour of these quantities. Namely, the intensities of all the presented transitions increase on lowering the temperature. Such a change might be attributed to a phase transition in the case of $^7F_0 \rightarrow {}^5D_0$ and $^7F_0 \rightarrow {}^5D_2$. The most surprising thing is, however, the anomalous growth of the intensity of the $^7F_0 \rightarrow {}^5D_1$ transition, which is more than twice as intense as theoretically predicted [17]. Such an increase cannot be explained by thermal population of the $^7F_1$ state, which would account only for the loss of approximately 20 % of the intensity at room temperature. The reasons for this phenomenon are unclear, and perhaps need more detailed investigations, which however lie outside the scope of the present paper.

The splitting of the bands may also be observed in emission spectra at 77 K. At room temperature the transition $^5D_0 \rightarrow {}^7F_0$ was unsplit, whereas the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$ transitions had 3 and 4 discernible components. At 77 K the number of observed components was 2 for $^5D_0 \rightarrow {}^7F_0$, 6 for $^5D_0 \rightarrow {}^7F_1$ and 7 for $^5D_0 \rightarrow {}^7F_2$.

The results presented above may serve as a background for the interpretation of the spectroscopic properties of water solutions of the Eu^{III}–CDTA system. These properties remain essentially the same in the pH range between 3.5 and 9. The most significant changes in the absorption spectra are observed above pH 10. In Fig. 4 the absorption spectra of Eu^{III}–CDTA solutions at pH 7.40 and 11.0 have been juxtaposed. For both solutions two maxima at 17 250 and 17 239 cm^{-1} may be observed for the $^7F_0 \rightarrow {}^5D_0$ transition, which confirms the equilibrium of nine- and eight-coordinate isomers, as was previously reported at pH = 6.0 [9]. These values are similar both to the maximum found in the crystal at room temperature and to the analogous maxima found in solutions of the Eu^{III}–EDTA complex (17 254 and 17 240 cm^{-1}) [16]. There is another similarity that perhaps should be mentioned. Namely, the most intense crystal field components in the $^7F_0 \rightarrow {}^5D_2$ transition in both solutions very closely match the analogous components in the spectrum of **I** at room temperature.

Table 3
Oscillator strength values (P) of the Eu^{III} complexes with CDTA

Complex	$^7F_0 \rightarrow {}^5D_0$ $P \times 10^8$	$^7F_0 \rightarrow {}^5D_1$ $P \times 10^8$	$^7F_0 \rightarrow {}^5D_2$ $P \times 10^8$
Eu–CDTA pH 5.26	1.20	1.61	5.90
Eu–CDTA pH 7.40	1.25	1.62	5.34
Eu–CDTA pH 9.16	1.18	1.52	6.20
Eu–CDTA pH 11.0	0.59	1.50	11.4
Crystal $T = 293$ K	0.50	1.44	3.35
Crystal $T = 30$ K	1.38	3.20	11.0

The most remarkable changes may be observed in the values of the oscillator strengths (Table 3). The P value of the transition $^7F_0 \rightarrow {}^5D_0$ remains practically constant up to approximately pH = 9 and then decreases by about half, reaching a value very similar to that calculated for **I**

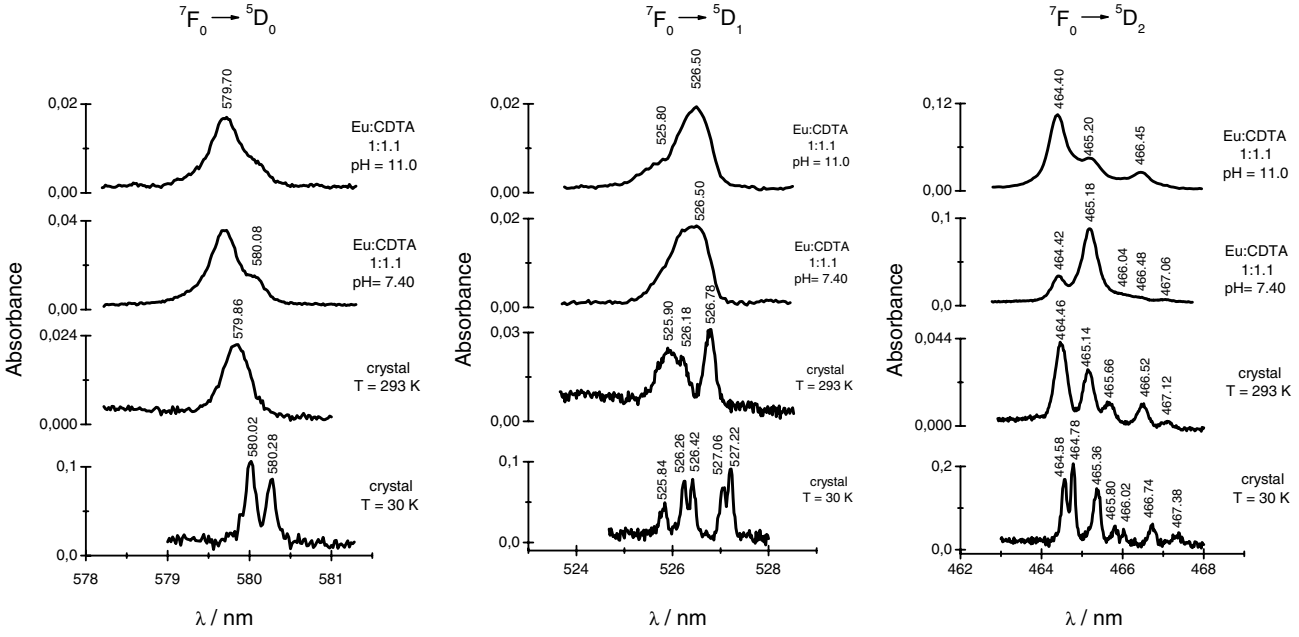

Fig. 4. Absorption spectra of the $^7F_0 \rightarrow {}^5D_{0,1,2}$ transitions of Eu^{III} complexes with CDTA in solution: $c_{Eu} = 44.1$ mM, $d = 5$ cm and in the monocrystal $c_{Eu} = 2.49$ M, $d = 0.102$ cm.

at room temperature. The magnetic-dipole allowed transition $^7F_0 \rightarrow {}^5D_1$ in the solutions and in **I** at 293 K is constant with the *P* value close to the theoretical value [17]. The intensity of the hypersensitive $^7F_0 \rightarrow {}^5D_2$ transition is, out of the three presented ones, the most affected by changes in the europium ion first coordination sphere. The oscillator strength of this band, like that of $^7F_0 \rightarrow {}^5D_0$, does not change essentially up to pH ≈ 9, and then, contrary to the latter transition, doubles at pH = 11. These changes may reflect the alterations within the first coordination sphere of the Eu^{III} ion, consisting of partial substitution of coordinated water molecules by hydroxy anions [5c,5d] and/or formation of a polymeric species [18]. The *P* values for the solutions are greater than in **I** at 293 K, because of molecular dynamics around the metal ion in solutions.

6. Conclusions

The presented results suggest that the CDTA anion behaves in a somewhat different way in comparison to EDTA as far as the structural aspects are concerned. Namely CDTA shows a more pronounced tendency to form polymeric structures with lanthanides. Apart from that the coordination numbers of all Eu^{III}–CDTA complexes are eight while in all known crystal structures of Eu^{III}–EDTA systems the Eu^{III} ion is nine-coordinate. The spectroscopic properties of the presented Eu^{III}–CDTA systems in water solutions rather closely resemble those of related Eu^{III}–EDTA ones. For instance for Eu^{III} complexes with both ligands the $^7F_0 \rightarrow {}^5D_{0,1,2}$ transitions lie at very similar energies. The $[Eu(CDTA)(H_2O)_{3\ or\ 2}]^-$ species remain stable up to pH ≈ 9, then partial hydrolysis and/or polymerization take place. The spectra of $[C(NH_2)_3]_3[Eu_2(CDTA)_2(H_2O)_2]ClO_4 \cdot 7H_2O$ at various temperatures reveal a phase transition in the crystal.

Abstract

The compounds, 2,6-bis(3,5-dimethylpyrazol-1-ylmethyl)pyridine ($_{Me}$NNN) (**L1**) and 2,6-bis(3,5-ditertbutylpyrazol-1-ylmethyl)pyridine ($_{tBu}$NNN) (**L2**), react with either $[Pd(NCMe)_2Cl_2]$ or [Pd(COD)ClMe] to form the mononuclear palladium complexes $[Pd(_{Me}NNN)Cl_2]$ (**1**), [Pd($_{Me}$NNN)ClMe] (**2**), $[Pd(_{tBu}NNN)Cl_2]$ (**3**) and [Pd($_{tBu}$NNN)ClMe] (**4**). Reactions of **1**, **2** and **4** with the halide abstractor, $NaBAr_4$ (Ar = 3,5-$(CF_3)_2C_6H_3$), led to the formation of stable tridentate cationic species $[Pd(_{Me}NNN)Cl]^+$(**5**), $[Pd(_{Me}NNN)Me]^+$ (**6**) and $[Pd(_{tBu}NNN)Cl]^+$ (**7**) respectively. The analogous carbonyl linker cationic species $[Pd\{(3,5\text{-}Me_2pz\text{-}CO)_2\text{-}py\}Cl]^+$ (**9**) and $[Pd\{(3,5\text{-}^tBu_2pz\text{-}CO)_2\text{-}py\}Cl]^+$ (**10**), prepared by halide abstraction of the neutral complexes $[Pd\{(3,5\text{-}Me_2pz\text{-}CO)_2\text{-}py\}Cl_2]$ and $[Pd\{(3,5\text{-}^tBu_2pz\text{-}CO)_2\text{-}py\}Cl_2]$ by $NaBAr_4$, were however less stable with $t_{1/2}$ of 14 and 2 days respectively. Attempts to crystallize **1** and **3** from the mother liquor resulted in the isolation of the salts $[Pd(_{Me}NNN)Cl]_2[Pd_2Cl_6]$ (**11**) and $[Pd(_{tBu}NNN)Cl]_2[Pd_2Cl_6]$ (**12**). Although when complexes **1**–**4** were reacted with modified methylaluminoxane (MMAO) or $NaBAr_4$, no active catalysts for ethylene oligomerization or polymerization were formed, activation with silver triflate (AgOTf) produced active catalysts that oligomerized and polymerized phenylacetylene to a mixture of *cis-transoidal* and *trans-cisoidal* polyphenylacetylene.

Keywords: (Pyrazolylmethyl)pyridine; Bidentate palladium complexes; Tridentate ligand coordination; Cationic palladium complexes; Phenylacetylene; Polymerization

1. Introduction

Multidentate nitrogen based ligands, such as 2,6-bis(organylimino)pyridine and 2,6-bis(pyrazol-1-ylmethyl)-pyridine late transition metal complexes, are good catalysts for the oligomerization and polymerization of olefins [1]. Other nitrogen based ligands such as bidentate α-diimine are also known to form cationic Ni and Pd complexes that polymerize or oligomerize olefins depending on the steric bulk of the ligand backbone [2]. These cationic α-diimine Ni and Pd complexes are often prepared by direct halide abstraction using silver or alkali metal salts of a very weakly coordinating or non-coordinating counter ion. It has been established that the presence of strongly coordinating ligands compete with the monomer for the vacant coordination site in the active catalyst [3]. It is therefore essential to have a weakly coordinating ligand that would not compete with the incoming monomer for the vacant site of the metal and yet would protect the metal in the absence of the substrate.

Recently we have used 2,6-bis(pyrazol-1-ylcarbonyl)pyridine palladium dichloride complexes as catalyst precursors for ethylene polymerization [4]. The ligands in these precursors are potentially tridentate but only coordinate in a bidentate mode through one pyrazolyl and the pyridine nitrogen atoms leaving the second pyrazolyl unit uncoordinated.

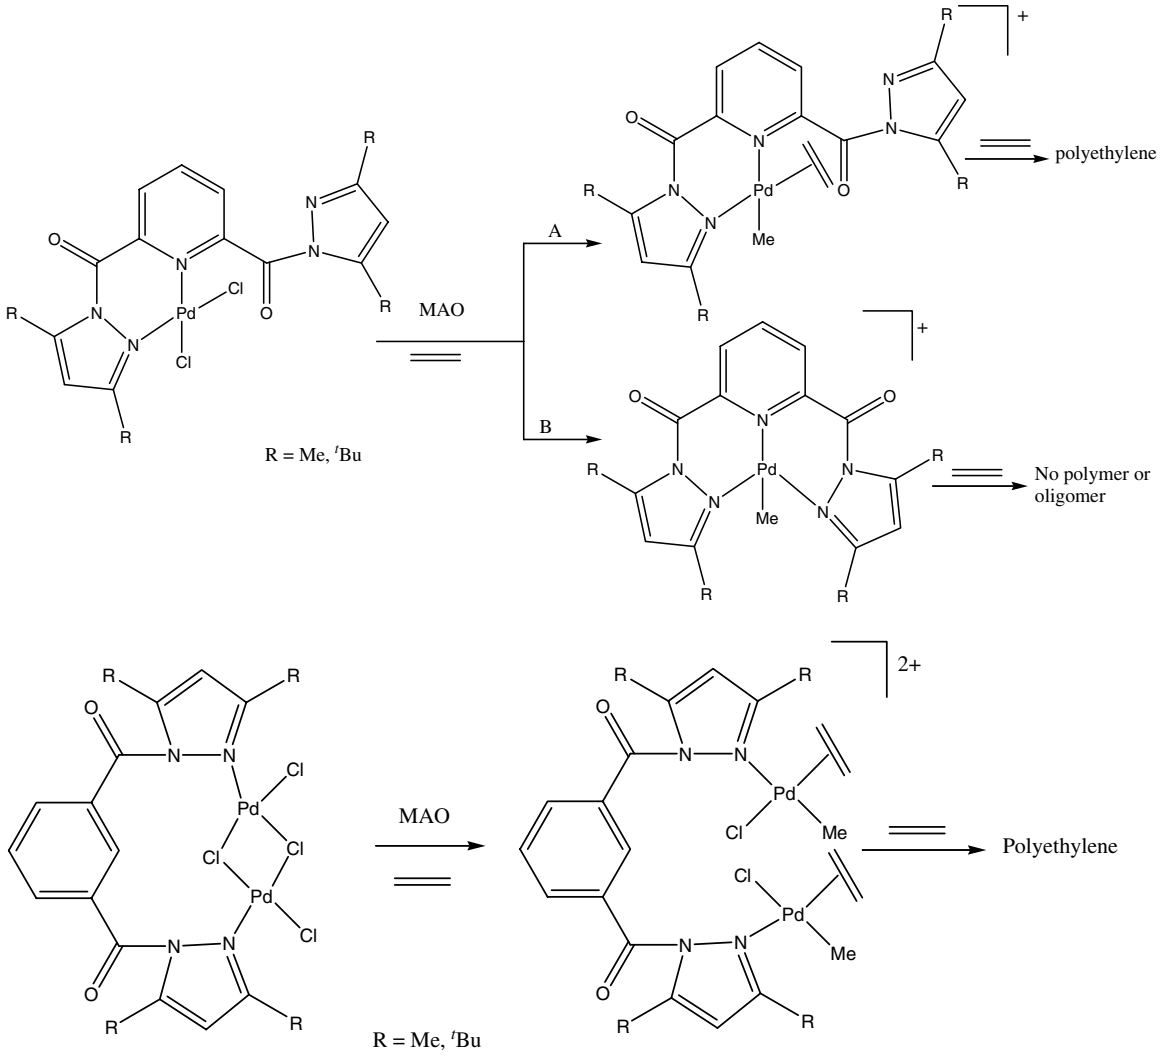
doi:10.1016/j.poly.2006.09.007



When the complexes are reacted with methylaluminoxane (MAO) as co-catalysts, they form active catalysts for the polymerization of ethylene to give high density polyethylene (HDPE) [4]. However, the expected activity in comparison with our previous catalysts generated from 1,3-bis(pyrazol-1-yl)benzene [5a] is considerably lower, possibly due to the potential of 2,6-bis(pyrazol-1-ylcarbonyl)pyridine to bind in a tridentate coordination mode upon removal of a chloride (Scheme 1). This is likely to result in the ethylene monomer competing with the second pyrazolyl unit in coordinating to the vacant site on the metal in the catalyst (Scheme 1, route B).

The stability of the carbonyl linker catalysts was also found to be lower than the bis(pyrazole)palladium(II) catalysts [5b] and in an attempt to produce more stable catalysts we have replaced the carbonyl linker with a methylene group. Some of the chemistry of 2,6-bis(pyrazol-1-ylmethyl)pyridine have earlier been explored by Steel et al. [6] and others [7]. In a report by Steel et al. [6a] a palladium dichloride complex with this ligand system was formulated as a trinuclear complex with three ligand units. We found 2,6-bis(pyrazol-1-ylmethyl)pyridine to complex with palladium dichloride fragments in a bidentate fashion; bonding through one pyrazolyl nitrogen and the pyridine nitrogen, with the second pyrazolyl unit uncoordinated. The latter coordinates to the palladium metal upon chloride abstraction. These findings and attempts to use the palladium complexes as ethylene and phenylacetylene polymerization catalysts are described in this paper.

2. Experimental

2.1. Materials and instrumentation

Synthetic and ^{1}H NMR experimental manipulations were performed under a nitrogen atmosphere using standard Schlenk techniques and glove box. All solvents were of analytical grade and were dried and distilled prior to use. Toluene and dichloromethane were dried and distilled from sodium/benzophenone and P_2O_5 respectively.

Scheme 1.

2,6-Bis(chloromethyl)pyridine, tetrabutylammonium bromide, silver triflate and phenylacetylene (98%) were obtained from Sigma–Aldrich and used as received. $NaBAr_4$ ($Ar = 3,5\text{-}(CF_3)_2C_6H_3$) was obtained from Boulder Scientific and used as received. The starting materials 3,5-ditertbutylpyrazole [8], [Pd(COD)MeCl] [9,10] and 2,6-bis(3,5-dim-ethylpyrazol-1-ylmethyl)pyridine (**L1**) [6a] were synthesized following the literature procedures. The NMR spectra were recorded on a Varian Gemini 2000 instrument (^1H at 200 MHz and ^{13}C at 50.1 MHz) at room temperature. The chemical shifts are reported in δ (ppm) and referenced to the residual $CHCl_3$ in the NMR solvent. Coupling constants are measured in Hertz (Hz). Elemental analyses were performed by the micro analytical laboratory at the University of Cape Town, South Africa, as a service. Polymer molecular weights were determined by gel permeation chromatography on a Waters 600E instrument equipped with a Waters differential refractometer detector (THF, at 30 °C, rate = 1.0 mL/min) and PL–MIXED-C…™ columns, using polystyrene standards.

2.2. Synthesis of ligands and palladium complexes

2.2.1. 2,6-{(3,5-^{t}Bu$_2$pzCH$_2$)$_2$py} (*L2*)

A mixture of 2,6-bis(bromomethyl)pyridine (1.00 g, 3.79 mmol) and 3,5-di-*tert*-butylpyrazole (1.36 g, 7.58 mmol) in benzene (40 mL), 40% aqueous NaOH (12 mL) and 40% aqueous tetrabutylammonium bromide (10 drops) was refluxed for 18 h. The organic layer was then separated, and evaporated *in vacuo*. The crude product was washed with water (40 mL) to afford an analytically pure compound **L2** as a white solid. Yield = 1.38 g (75%). ^1H NMR ($CDCl_3$): δ 1.23 (18H, s, ^{t}Bu, pz); 1.31 (18H, s, ^{t}Bu, pz); 5.55 (4H, s, CH_2); 5.93 (2H, s, 4H-pz); 6.32 (2H, d, 3,5H-py, $^3J_{HH} = 8.0$); 7.46 (1H, t, 4H-py, $^3J_{HH} = 8.0$). *Anal.* Calc. for $C_{29}H_{45}N_5$: C, 75.16; H, 9.72; N, 15.12. Found: C, 75.01; H, 9.55; N, 15.43%.

2.2.2. [Pd($_{Me}$ÑÑN)Cl$_2$] (*1*)

To a solution of **L1** (0.11 g, 0.39 mmol) in CH_2Cl_2 (20 mL) was added $[Pd(NCMe)_2Cl_2]$ (0.10 g, 0.39 mmol). The pink solution was stirred for 12 h and the product precipitated by addition of hexane (20 mL) to give a pink solid. Yield = 0.10 g (56%). ^1H NMR ($CDCl_3$): δ 2.45 (6H, s, CH_3, pz); 2.51 (6H, s, CH_3, pz); 5.85 (2H, d, CH_2, $^2J_{HH} = 15.2$); 5.93 (1H, s, 4H-pz); 6.17 (2H, d, CH_2, $^2J_{HH} = 15.0$); 6.28 (1H, s, 4H-pz); 8.11 (2H, d, 3,5H-py, $^3J_{HH} = 8.4$); 8.26 (1H, t, 4H-py, $^3J_{HH} = 8.4$). *Anal.* Calc. for $C_{17}H_{21}N_5PdCl_2$: C, 43.22; H, 4.44; N, 14.83. Found: C, 43.31; H, 4.10; N, 14.91%.

2.2.3. [Pd($_{Me}$ÑÑN)MeCl] (*2*)

To a solution of **L1** (0.30 g, 1.07 mmol) in Et_2O (20 mL) was added a solution [Pd(COD)ClMe] (0.27 g, 1.07 mmol) in Et_2O (20 mL). A light yellow precipitate was formed immediately. The mixture was stirred for 3 h, filtered and the material isolated recrystallized from CH_2Cl_2–hexane to give a light yellow solid. Yield = 0.31 g (68%). ^1H NMR ($CDCl_3$): δ 0.97 (3H, s, CH_3,Pd–Me); 2.34 (6H, s, CH_3, pz); 2.49 (6H, s, CH_3, pz); 5.68 (2H, d, CH_2, $^2J_{HH} = 15.4$); 5.74 (d, 2H, CH_2, $^2J_{HH} = 15.4$); 5.91 (2H, s, 4H-pz); 8.08 (1H, t, 4H-py, $^3J_{HH} = 8.4$); 8.15 (2H, d, 3,5H-py, $^3J_{HH} = 8.2$). ^{13}C NMR ($CDCl_3$): δ −7.4; 12.3; 14.9; 52.6; 108.2; 125.3; 141.7; 143.2; 151.8; 152.0. *Anal.* Calc. for $C_{18}H_{24}N_5PdCl \cdot CH_2Cl_2$: C, 42.53; H, 4.85; N, 13.06. Found: C, 42.31; H, 4.77; N, 11.64%.

2.2.4. [Pd($_{tBu}$ÑÑN)Cl$_2$] (*3*)

To a solution of $[Pd(NCMe)Cl_2]$ (0.20 g, 0.78 mmol) in CH_2Cl_2 (20 mL) was added **L2** (0.36 g, 0.78 mmol). The clear orange solution was stirred for 24 h after which an equal volume of hexane was added and kept at −4 °C to afford compound **3** as a yellow solid. Single crystals suitable for X-ray analysis were obtained by slow evaporation of $CDCl_3$ used as ^1H NMR solvent. Yield = 0.35 g (71%). ^1H NMR ($CDCl_3$): δ 1.27 (9H, s, ^{t}Bu, pz); 1.34 (9H, s, ^{t}Bu, pz); 1.41 (9H, s, ^{t}Bu, pz); 1.75 (9H, s, ^{t}Bu, pz); 5.72 (1H, d, CH_2, $^2J_{HH} = 18.6$); 5.78 (1H, d, CH_2, $^2J_{HH} = 15.4$); 5.92 (1H, s, 4H-pz); 5.97 (1H, s, 4H-pz); 6.23 (1H, d, CH_2, $^2J_{HH} = 15.6$); 7.01 (1H, d, CH_2, $^2J_{HH} = 19.0$); 7.44 (2H, d, 3,5H-py, $^3J_{HH} = 8.0$); 7.69 (1H, t, 4H-py, $^3J_{HH} = 8.0$). ^{13}C NMR ($CDCl_3$): δ 30.1; 30.2; 30.6; 31.1; 31.4; 31.8; 32.0; 33.0; 56.4; 56.7; 100.8; 104.3; 122.9; 124.0; 140.4; 153.2; 154.0; 155.2; 162.0; 164.3; 164.6. *Anal.* Calc. for $C_{29}H_{45}N_5PdCl_2 \cdot 0.5CH_2Cl_2$: C, 52.33; H, 6.59; N, 10.17. Found: C, 52.72; H, 7.08; N, 10.26%.

2.2.5. [Pd($_{tBu}$ÑÑN)MeCl] (*4*)

Compound **4** was prepared according to the procedure for **2** using **L2** (0.21 g, 0.45 mmol) and [Pd(COD)MeCl] (0.12 g, 0.45 mmol). Yield = 0.17 g (60%). ^1H NMR ($CDCl_3$): δ 1.03 (3H, s, CH_3, Pd–Me); 1.23 (9H, s, ^{t}Bu, pz); 1.35 (9H, s, ^{t}Bu, pz); 1.41 (9H, s, ^{t}Bu, pz); 1.61 (9H, s, ^{t}Bu, pz); 5.35 (1H, d, CH_2, $^2J_{HH} = 18.6$); 5.53 (1H, d, CH_2, $^2J_{HH} = 15.0$); 5.93 (1H, s, 4H-pz); 5.95 (1H, s, 4H-pz); 6.11 (1H, d, $CH_2{}^2J_{HH} = 15.4$); 6.87 (1H, d, CH_2, $^2J_{HH} = 19.2$); 7. 21 (2H, d, 3,5H-py, $^3J_{HH} = 8.0$); 7.69 (1H, t, 4H-py, $^3J_{HH} = 8.0$). ^{13}C NMR ($CDCl_3$): δ 30.1; 30.4; 30.6; 31.1; 31.5; 32.6; 55.7; 100.3; 103.8; 121.8; 122.2; 138.5; 152.8; 153.7; 162.1. *Anal.* Calc. for $C_{30}H_{48}N_5PdCl$: C, 58.06; H, 7.80; N, 11.28. Found: C, 58.10; H, 8.32; N, 10.13%.

The synthesis of **6** and **7** are described as examples of how the cationic complexes were prepared.

2.2.6. [Pd($_{Me}$ÑÑN)Me]BAr$_4$ (*6*)

To a solution of **2** (0.05 g, 0.11 mmol) in CH_2Cl_2 (10 mL) was added a solution of $NaBAr_4$ (0.10 g, 0.11 mmol) in CH_2Cl_2 (10 mL) and stirred for 10 min. The resultant mixture containing Pd black was filtered over Celite to give a clear solution. Hexane (20 mL) was added to the filtrate and kept at −4 °C to afford colourless single crystals suitable for X-ray analysis. Yield = 0.15 g (30%). ^1H NMR ($CDCl_3$): δ 1.09 (s, 3H, CH_3, Pd–Me); 2.30

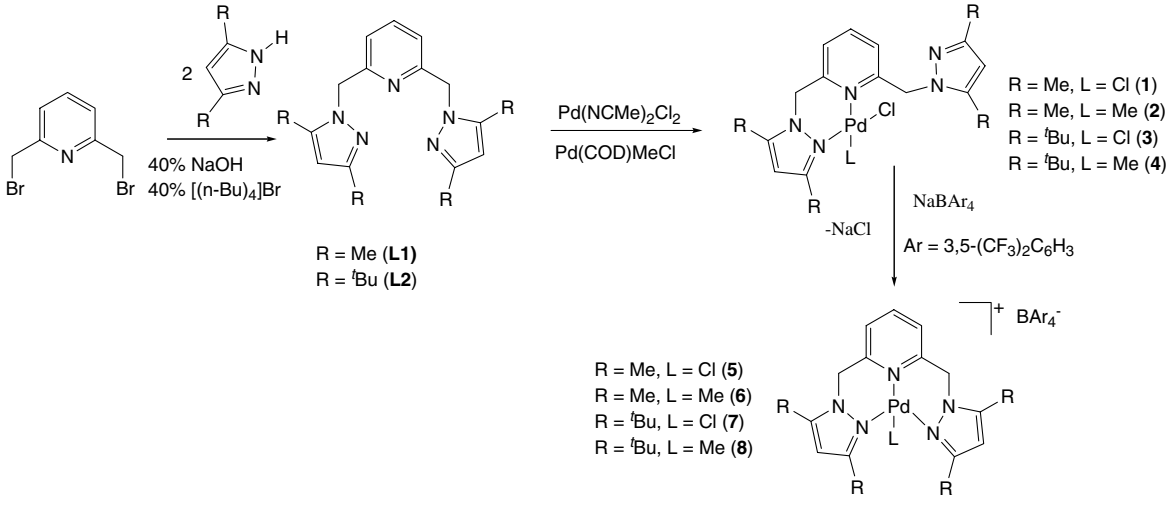
(6H, s, CH_3, pz); 2.35 (6H, s, CH_3, pz); 5.14 (2H, d, CH_2, $^2J_{HH} = 15.0$); 5.70 (2H, d, CH_2, $^2J_{HH} = 15.0$); 5.95 (2H, s, 4H-pz); 7.22 (2H, d, 3,5H-py, $^3J_{HH} = 8.0$). 7.55 (1H, t, 4H-py, $^3J_{HH} = 8.2$); 7.49 (4H, s, H_p, BAr_4); 7.68 (8H, s, H_o, BAr_4). *Anal.* Calc. for $C_{50}H_{36}BF_{24}N_5Pd$: C, 46.92; H, 2.73; N, 5.47. Found: C, 47.45; H, 2.48; N, 5.48%.

2.2.7. $[(_{tBu}\hat{N}\hat{N}N)PdCl]BAr_4$ (7)

This compound was synthesized according to the procedure described for **6** using **3** (0.09 g, 0.13 mmol) and $NaBAr_4$ (0.12 g, 0.13 mmol) which gave **7** as a crystalline orange solid. Yield = 0.11 g (58%). ^{1}H NMR ($CDCl_3$): δ 1.43 (18H, s, ^{t}Bu, pz); 1.52 (18H, s, ^{t}Bu, pz); 5.68 (2H, d, CH_2, $^2J_{HH} = 15.2$); 6.08 (2H, s, 4H-pz); 6.21 (2H, d, CH_2, $^2J_{HH} = 15.2$); 7.27 (2H, d, 3,5H-py, $^3J_{HH} = 8.0$); 7.50 (1H, t, 4H-py, $^3J_{HH} = 8.0$); 7.49 (4H, s, H_p, BAr_4); 7.68 (8H, s, H_o, BAr_4). *Anal.* Calc. for $C_{59}H_{57}BF_{24}N_5PdCl$: C, 49.05; H, 3.98; N, 4.85. Found: C, 49.51; H, 4.00; N, 4.97%.

2.3. Phenylacetylene oligomerization and polymerization

In a typical experiment, a solution of AgOTf (0.05 g, 0.2 mmol) in a 20 mL mixture of CH_2Cl_2 and MeCN (1:1) was added to a complex solution of **1** (0.05 g, 0.1 mmol) in CH_2Cl_2 (20 mL). A white precipitate of AgCl formed immediately, the mixture was stirred for 5 min and filtered to give a yellow solution of the active catalyst. To this solution was added 50 equiv. of phenylacetylene monomer (0.64 mL, 5 mmol). The yellow solution gradually turned dark red and was stirred for a further 1 h. After the reaction period, the solution was evaporated to dryness to afford a dark brown crude product, which was dissolved in minimum amount of CH_2Cl_2 and the polymer precipitated from methanol (40 mL). This was dried and weighed to obtain the percent polymer. The methanol solution was allowed to evaporate to dryness to obtain the oligomer fractions. Both the oligomers and polymers were characterized by of ^{1}H NMR spectroscopy and gel permeation chromatography.



2.4. X-ray crystallography

Crystal evaluation and data collection for **3**, **5**, **6**, **11** and **12** were performed on a Bruker CCD-1000 diffractometer with Mo Kα ($\lambda = 0.71073$ Å) radiation and the diffractometer to crystal distance of 4.9 cm. The initial cell constants were obtained from three series of ω scans at different starting angles. The reflections were successfully indexed by an automated indexing routine built in the SMART program. The absorption correction was based on fitting a function to the empirical transmission surface as sampled by multiple equivalent measurements [11]. The structures were solved by direct methods and refined by least-squares techniques using SHELXTL program [11]. All non-hydrogen atoms were refined with anisotropic displacement coefficients. All hydrogen atoms were included in the structure factor calculation at idealized positions and were allowed to ride on the neighbouring atoms with relative isotropic displacement coefficients.

3. Results and discussion

3.1. Synthesis of bis(pyrazol-1-ylmethyl)pyridine palladium complexes

Compound 2,6-bis(3,5-ditertbutylpyrazol-1-ylmethyl)-pyridine ($_{tBu}\hat{N}\hat{N}N$) (**L2**) was prepared in good yields (75%) via phase transfer catalyzed alkylation of 3,5-ditertbutylpyrazole and 2,6-bis(bromomethyl)pyridine following the literature procedure [6a] described for the synthesis of 2,6-bis(3,5-dimethylpyrazol-1-ylmethyl)pyridine ($_{Me}\hat{N}\hat{N}N$) (**L1**). Compounds **L1** and **L2** reacted with either $[Pd(NCMe)_2Cl_2]$or [Pd(COD)ClMe] to produce the corresponding complexes **1**–**4** in moderate to good yields (Scheme 2).

Scheme 2.

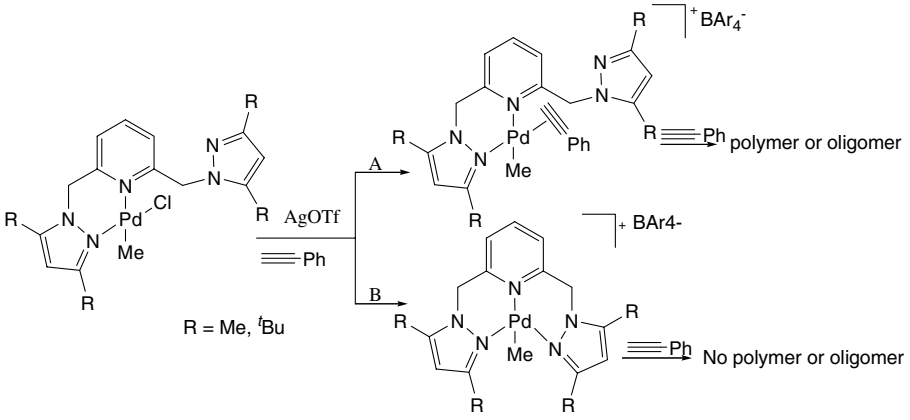
The ^{1}H NMR spectra of **L1** and **L2** gave signature peaks of the four CH_2 linker protons as singlets at 5.28 and 5.55 ppm respectively and typical peaks of methyl and tertbutyl at 2.25 and 2.51 ppm and 1.21 and 1.31 ppm respectively. These peaks were diagnostic in the next step to confirm that complexation of the ligands with the palladium salts had occurred. On complexation of **L1** and **L2**, the CH_2 linker protons appeared as AB quartets. In complexes **1** and **2** these signals are between 5.68–6.17 ppm (**L1** singlet, 5.28 ppm) confirming the presence of diastereotopic protons in axial and equatorial positions. This inequality arises from different chair and boat conformations that depict the existence of restricted rotations in the complexes hence the protons could be subjected to different contributions from the ring currents from the pyrazole or pyridine groups on the NMR time scale. A similar spectrum has been reported for the related Cu complex, $[Cu\{(Me_2pz\text{-}CH_2)_2py\}(PPh_3)]ClO_4$, [7a] in which the CH_2 linker protons were observed as AB quartets at 4.75 and 5.25 ppm.

In complexes **3** and **4**, the CH_2 linker protons appeared as four distinct AB quartets with geminal coupling constants ranging from 15.4 to 19.2 Hz. This highlights the increased restricted rotation in **3** and **4** arising from the more sterically demanding ditertbutyl groups. The large peak separation of the signals ($\Delta\delta = 1.38$ ppm), however, is rather unusual. A smaller peak separation between the CH_2 linker protons ($\Delta\delta = 0.70$ ppm) of the related Ru complex of **L1**, $[Ru\{(\eta^6\text{-}C_6H_6)(Me_2pz\text{-}CH_2)_2py\}]PF_6$, [12] has been reported. Recently Cavell and co-workers reported even a smaller peak separation ($\Delta\delta = 0.07$ ppm) for geminal coupling of the bridging methylene protons of $[Pd(_{t\mathrm{Bu}}\hat{C}\hat{N}C)Me]BF_4$; a feature attributed to the slow inversion of the complex [13]. In contrast to our results, Cavell and co-workers found that in the chloro analogue, $[Pd(_{t\mathrm{Bu}}\hat{C}\hat{N}C)Cl]BF_4$, the methylene protons appear as a singlet at 5.69 ppm probably as a consequence of the lower *trans* effect of the Cl^-, which reduces the $Pd\text{–}N_{(py)}$ bond length and gives the ligand backbone greater ability to undergo unhindered rotation [13]. The ^{1}H NMR spectra of **3** and **4** could be used to diagnose the bidentate bonding mode of compound **L2** in these complexes. For example in **3** one set of peaks at 1.41 and 1.75 ppm for tertbutyl protons and 5.92 ppm for the pyrazolyl ring proton were assigned to the bound pyrazolyl unit while peaks at 1.27 and 1.34 and 5.97 ppm were due to the 'dangling' pyrazolyl unit. This assignment is consistent with the solid state structure of **3** (*vide infra*). Similar spectra have been reported for compounds $[Ru\{(\eta^6\text{-}C_6H_6)(Me_2pz\text{-}CH_2)_2py\}]PF_6$ [12] and $[Pd\{(3,5\text{-}{}^tBu_2pz\text{-}CO)_2py\}Cl_2]$ [4].

3.2. Reactions of complexes *1–4* with $NaBAr_4$

In attempts to generate catalysts for the oligomerization or polymerization of ethylene, 8 mg of complexes **2** and **4** were reacted with either stoichiometric equivalent of $NaBAr_4$ or 1000-fold excess of modified methylaluminoxane (MMAO) in the presence of excess ethylene. We did not observe the formation of oligomers or polymers of ethylene as expected. In subsequent experiments performed on a preparative scale (Scheme 2), ^{1}H NMR spectroscopic analyses suggested the formation of cationic species in which the ligands bind in a tridentate fashion upon chloride abstraction. These cationic species, $[Pd(_{\mathrm{Me}}\hat{N}\hat{N}N)Cl]^+$ (**5**), $[Pd(_{\mathrm{Me}}\hat{N}\hat{N}N)Me]^+$ (**6**) and $[Pd(_{t\mathrm{Bu}}\hat{N}\hat{N}N)Cl]^+$ (**7**), were isolated as BAr_4^- salts and the structures of **5** and **6** (Figs. 2 and 3 respectively) confirmed the tridentate ligand coordination deduced from the spectroscopic data.

Recently we reported that $[Pd\{(3,5\text{-}Me_2pz\text{-}CO)_2py\}Cl_2]$ and $[Pd\{(3,5\text{-}{}^tBu_2pz\text{-}CO)_2py\}Cl_2]$ can be activated with methylaluminoxane (MAO) as co-catalyst to catalyze the polymerization of ethylene [4]. The inability of the cationic species generated from **2** and **4** to promote ethylene polymerization can be attributed to the strong coordination of the 'dangling' arm of the pyrazolyl unit in **2** and **4**, which blocks the vacant coordination site created upon chloride abstraction from the metal centre necessary for the coordination of the ethylene monomer. In the carbonyl linker analogues used to catalyze the polymerization of ethylene [4], it is likely that upon activation with MAO, similar tridentate cationic species are formed but under a high ethylene pressure, one of the coordinated pyrazolyl units dissociates from the Pd centre to allow the ethylene to coordinate and undergo subsequent insertion to form polyethylene (Scheme 1, route A). This behaviour is necessitated by the weaker binding ability of the pyrazolyl units in the carbonyl linker analogues. However, even when **6** and **7** were subjected to ethylene pressures up to 50 atm, there was no formation of polyethylene; an observation which highlights the strength of the $Pd\text{–}N_{(pz)}$ bonds in **6** and **7** relative to the binding affinity of the ethylene monomer.



3.3. Oligomerization and polymerization of phenylacetylene

The binding affinity of the monomer is important since in experiments using phenylacetylene instead of ethylene, we did observe the formation of oligomers and polymers of phenylacetylene (Table 1). The active catalysts were generated by reacting complexes **1–4** with AgOTf as halide abstractor in a mixture of CH_2Cl_2 and MeCN (3:1). The ability of catalysts generated from **1** to **4** to oligomerize and polymerize phenylacetylene therefore highlights the significance of the reactivity and the binding affinity of the incoming monomer in displacing or competing with one of the $Pd\text{–}N_{(pz)}$ bonds prior to coordination to the metal centre (Scheme 3, route A). However, the low percentage conversions observed for catalysts **1–4** (36–55%) compared to 90% conversion [10] obtained for the carbonyl linker and bis(pyrazole)palladium(II) complexes under similar conditions suggests the possibility of a competing deactivation pathway. This could arise from the formation of the inactive cationic tridentate species (Scheme 3, route B) which blocks monomer coordination. This argument

Table 1
Phenylacetylene oligomerization and polymerization data[a]

Entry	Catalyst	% Conversion[b]	M_w[c]	M_n[c]	M_w/M_n[c]	% *cis*[d]

[h] Oligomer fraction.

Scheme 3.

also supports the slow initiation process observed with systems **1**–**4** as opposed to rapid initiation observed with simple pyrazole and carbonyl linker pyrazolyl palladium complexes [14].

Generally catalysts **1** and **2** bearing methyl substituents on the pyrazolyl ligand showed higher activity than the tertbutyl analogues **3** and **4** (Table 1, entries 1–4). It is likely that the bulkier tertbutyl group hinders monomer coordination resulting in low product yields. We have examined the structurally characterized complexes **3**, **5**, **6**, **11** and **12** from the point of view of the ligand solid angles expressed in percentage of the metal coordination sphere shielded by each ligand. Such an approach provides a quantitative measure of the steric bulk of the ligands [15]. The tridentate ligands in **5**, **6** and **11** shield on average 59.6(10)% of the palladium coordination sphere. The κ^3-($_{t\text{Bu}}\hat{\text{N}}\hat{\text{N}}\hat{\text{N}}$) ligand in **12** shields an enormous 70.1% of the central metal, and the difference of over 10% from its methyl analogue is very significant in terms of dynamic behaviour. As a reference, even ca. 1% changes in the value of a ligand solid angle can affect the ligand's coordination mode [16]. However, it is interesting to note the size of the κ^2-($_{t\text{Bu}}\hat{\text{N}}\hat{\text{N}}\text{N}$) ligand in **3**; the shielding percentage of this ligand is only 51.0%, and thus the flexibility of ($_{t\text{Bu}}\hat{\text{N}}\hat{\text{N}}\text{N}$) can play a major role in the kinetics of the system. Time dependent polymerization experiments with catalyst **1** (Table 1, entries 1, 5 and 6) showed little variation in the percent conversion of monomer after 60 min. This is a typical feature involving catalyst decomposition with time [17] and in our case would suggest active catalysts forming tridentate species via route B in Scheme 3.

The stereochemistry of the polymers was determined by ^{1}H NMR spectroscopy. A typical ^{1}H NMR spectrum of polymers obtained showed a sharp singlet at 5.85 ppm for the vinylic protons, and broad singlets at 6.65 and 6.91 ppm corresponding to the phenyl *ortho* and *meta* protons respectively. From the ^{1}H NMR data, it is evident that all the polymers were a mixture of *cis-transoidal* and

trans-cisoidal [18] with the percentage *cis* content ranging from 44 to 80 (Table 1, entries 1–4). The *cis* and *trans* content of the polyphenylacetylene formed were established by the NMR method reported by Perec et al. [18a] and the formula to calculate the *cis* and *trans* content of the polymer is included as a footnote in Table 1. However, there was no clear dependence of the polymer stereochemistry with respect to catalyst structure.

GPC analysis showed the presence of both oligomers ($M_w = 620$–860) and low molecular weight polymers ($M_w = 2062$–3444) (Table 1, entries 1–4, 7 and 9). For example analysis of the crude products from catalysts **2** (Table 1, entry 7) gave a bimodal distribution GPC trace corresponding to oligomers of average M_w of 684 and polymers of average M_w of 3613. Upon purification of this product, the oligomers (methanol soluble fraction) and polymers (methanol insoluble) gave average M_w of 860 and 3444 respectively.

Table 2
Selected ^{1}H NMR signals and half lives ($t_{1/2}$) of the cationic complexes **5**–**10** in $CDCl_3$

Compound	^{1}H NMR ($CDCl_3$, ppm)				$t_{1/2}$ (days)
	CH_2	4H-pz	$_R$pz (R = Me or ^{t}Bu)	4H-py	
5	5.25, 5.95	5.99	2.35, 2.57	7.27	>30
6	5.14, 5.70	5.95	2.30, 2.35	7.55	>30
7	5.74, 6.31	6.07	1.41, 1.66	7.40	>30
8	5.68, 6.21	6.08	1.41, 1.52	7.50	>30

10		6.57	1.17, 1.76	8.01	2

3.4. Stability of cationic and neutral species of *1–4*

Following the attempts to establish the ability of **2** and **4** to produce active catalysts for ethylene polymerization as described above, we investigated the stability of the cationic species with CH_2 and CO linkers using complexes **1**–**4**, [Pd{(3,5-Me_2pz-CO)$_2$py}Cl_2] and [Pd{(3,5-^{t}Bu$_2$pz-CO)$_2$py}Cl_2]. In a typical experiment, **1** (6 mg, 0.012 mmol) and $NaBAr_4$ (12 mg, 0.012 mmol) were placed in a J-Young NMR tube and about 0.4 mL $CDCl_3$ added and the reaction followed by ^{1}H NMR spectroscopy. In all cases the cationic species of **1**–**4** were formed within 10 min but reactions of the CO linker analogues took up to 4 h to go to completion. The stability of the cationic species [Pd($_{Me}$ÑÑN)Cl]$^+$ (**5**), [Pd($_{Me}$ÑÑN)Me]$^+$ (**6**), [Pd($_{tBu}$ÑÑN)Cl]$^+$ (**7**), [Pd($_{tBu}$ÑÑN)Me]$^+$ (**8**), [Pd{(3,5-Me_2pz-CO)$_2$py}Cl]$^+$ (**9**) and [Pd{(3,5-^{t}Bu$_2$pz-CO)$_2$py}Cl]$^+$ (**10**) also varied. By using the proton peaks of the BAr_4^- counter ion in these salts as internal standard, we established that species **5**–**8** were stable for 30 days without any signs of decomposition while the carbonyl linker counterparts, **9** and **10**, had $t_{1/2}$ of 14 and 2 days respectively (Table 2). The low stability of **9** and **10** may arise from the effect of the carbonyl group in reducing the donor ability of the pyrazolyl nitrogen atoms in **9** and **10** compared to the cations with methylene linkers, **5**–**8**. The stability of the cationic species **5**–**8** might explain why reactions of **1**–**4** with either MMAO or $NaBAr_4$ did not result in the production of active ethylene polymerization catalysts.

Another interesting observation made during attempts to grow crystals of complexes **1**–**4** is that the species that crystallized depended on the procedure used. Attempts to

grow crystals of **1** and **3** directly from the mother liquor (reaction mixture) gave crystals of tridentately bound cationic species with $[Pd_2Cl_6]^{2-}$ as counter ion (**11** and **12**) within 7 days. On the other hand, when **3** was precipitated out initially from the reaction mixture and subsequently re-dissolved in CH_2Cl_2, crystals of **3** were obtained. Crystals of **3** were dissolved in $CDCl_3$ and monitored for 21 days by ^1H NMR but showed no signs of forming the cationic species **12**. It is not clear what causes the formation of **11** and **12** from the reaction mixture which does not occur when **1** and **3** are first isolated and re-dissolved in CH_2Cl_2. However, both **11** and **12** crystallized with solvent molecules and rapidly lost solvent when crystals were removed from the mother liquor and became insoluble. It was therefore difficult to further characterize these materials.

3.5. Molecular structure determination by single crystal X-ray crystallography

Single crystals suitable for X-ray analysis of complexes **3** and **5** were grown by slow evaporation of the dichloromethane solvent at room temperature while crystals of **6** were grown by slow diffusion of hexane into dichloromethane at −4 °C. In other attempts to obtain crystals of **1** and **3**, cationic tridentate palladium complexes $2[(_{Me}\hat{N}\hat{N}\hat{N})PdCl]^+$ (**11**) and $2[(_{tBu}\hat{N}\hat{N}\hat{N})PdCl]^+$ (**12**) with $[Pd_2Cl_6]^{2-}$ counter ions were obtained as described earlier.

Crystallographic data for **3**, **5**, **6**, **11** and **12** are presented in Table 3, while selected bond lengths and angles are given in Table 4. Solid state structures of **3**, **5**, **6**, **11** and **12** are shown in Figs. 1–5 respectively. The five palladium complexes contain the central metal in a slightly distorted

square planar geometry. In the structure of **3** (Fig. 1) the nitrogen atom, N5, of the free pyrazolyl unit is directed away from the palladium metal. It is therefore evident that the rotation about the CH_2 linker in the κ^2-2,6-{(3,5-^{t}Bu$_2$pzCH$_2$)$_2$py} ligand yields a κ^3-2,6-{(3,5-^{t}Bu$_2$pzCH$_2$)$_2$py} ligand in the cationic species **12** (Fig. 5). The $[Pd_2Cl_6]^{2-}$ in the structures of **11** and **12** occupies a crystallographic inversion centre with the two cationic palladium complexes residing on each side of the anion. The spatial arrangement of the cationic palladium moieties in **11** and **12** is such that the Pd–Cl bonds of the cationic complexes are facing away from the central $[Pd_2Cl_6]^{2-}$ unit.

The average bond lengths of the Pd–$N_{(pz)}$ of 2.026(3), 2.015(11), 2.026(11), 2.012(5) and 2.029(2) Å of complexes **3**, **5**, **6**, **11** and **12** respectively are all slightly shorter than the average Pd–N(pz) bond length of 2.06(9) Å obtained by averaging 607 bonds in 229 relevant complexes reported to the Cambridge Structural Database (CSD) [19] but the difference is not statistically significant because of the high uncertainties for the average Pd–$N_{(pz)}$ bond length of 2.06(9) Å.

The average Pd–N(pz) distance of 2.015(11) Å in **5** is somewhat shorter than that in **6** (2.036(11) Å), however the difference is not statistically significant. On the other

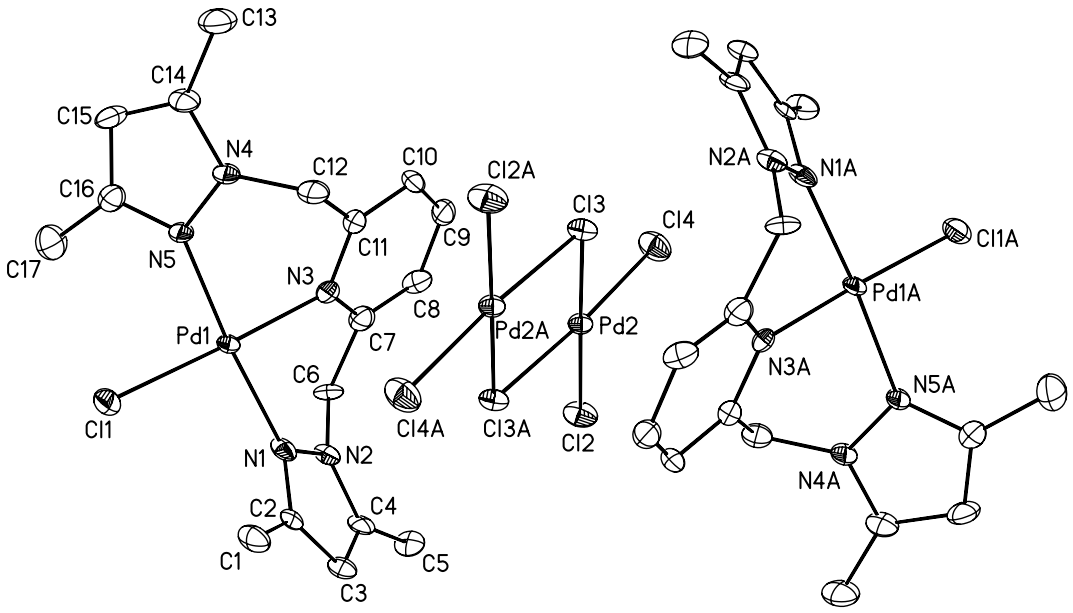

Fig. 4. Molecular structure of compound **11** shown with 50% probability ellipsoids. The hydrogen atoms are omitted for clarity.

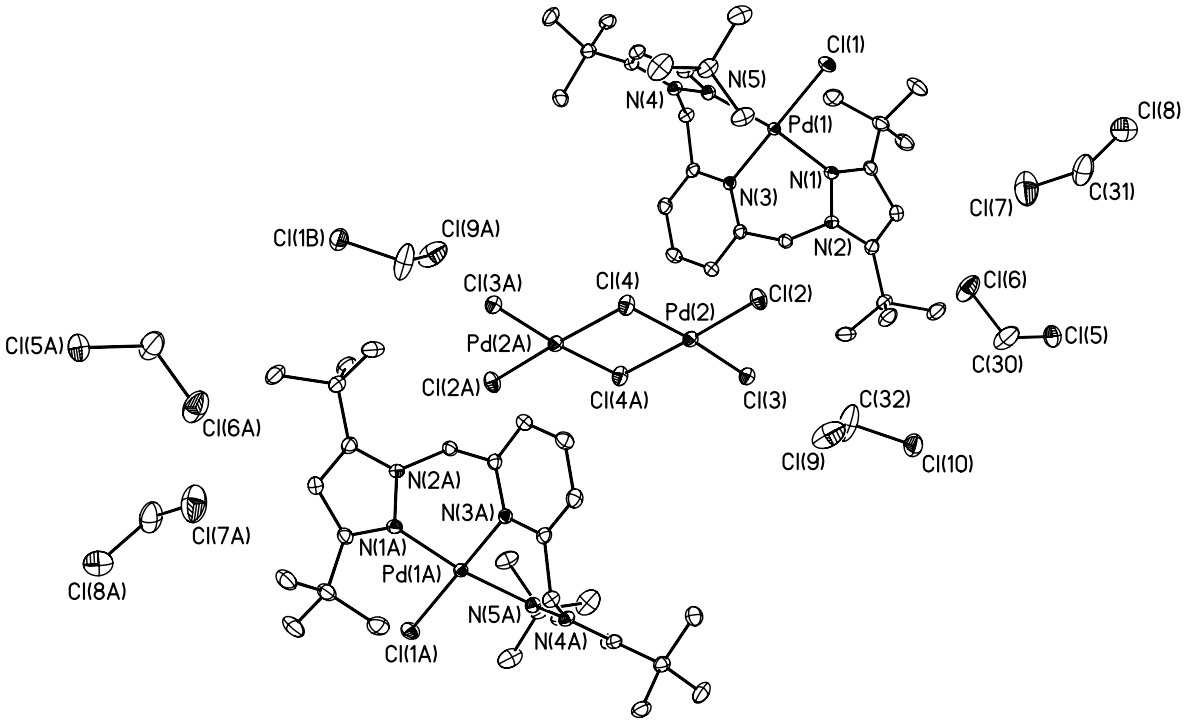

Fig. 5. Solid state structure of solvated complex **12** shown with 50% probability ellipsoids. The hydrogen atoms are omitted for clarity.

hand, the Pd–N(py) distance in **6** is substantially longer than those in **5**, **11** and **12**, and that is attributed to the high *trans* influence of the methyl group as compared to the chloro ligand. A shorter Pd–N(py) bond length 2.128(2) Å for **6** and 2.031(4) Å for **5**. A shorter Pd–$N_{(py)}$ bond length of 2.036(3) Å has been recently reported for the chloro complex, [Pd(ĈN̂C)Cl]BF_4 compared to 2.116(3) Å of the methyl analogue, [Pd(ĈN̂C)Me]BF_4 [20]. The average bond length of Pd–$N_{(py)}$ of 2.028(2) Å and Pd–C of 2.044(1) Å of **6** are significantly shorter than those reported for the carbene methylene bridged cationic Pd complex [Pd(ĈN̂C)Me]BF_4 of 2.0154(9) and 2.044(1) Å respectively [20]. The Pd–Cl bond distances of 2.3125(5) Å (**3**), 2.2803(13) Å (**5**), 2.2838(18) Å (**11**) and 2.2872(6) Å (**12**) in the mononuclear complexes agree well with the average bond distances of 2.33(5) Å determined by averaging 2055 Pd–Cl bonds in 1268 relevant complexes reported to the CSD [19]. Interestingly, the average Pd–$N_{(pz)}$ bond distances of 2.026(3) Å (**3**) and 2.029(2) Å (**12**) and Pd–Cl bond distances of 2.3125(5) Å (**3**) and

2.2872(6) Å (**12**) are statistically similar even though the Pd metal in **12** is more electrophilic and is expected to have shorter bond distances. Surprisingly, the longer $Pd–N_{(pz)}$ distance of 2.012(5) Å is observed for **11** than for **12** (2.028(2) Å) that contains a bulkier tridentate ligand.

4. Conclusions

The potentially tridentate bis(pyrazolylmethyl)pyridine compounds form monometallic palladium complexes with one uncoordinated pyrazolyl unit when complexed with either $[PdCl_2(NCMe)_2]$ or [Pd(COD)MeCl]. Coordination of the dangling pyrazolyl unit upon chloride abstraction in an attempt to generate catalysts for ethylene oligomerization or polymerization results in the formation of inactive cationic tridentate species. The same palladium complexes however, do form catalysts that catalyze the oligomerization and polymerization of the more reactive phenylacetylene producing a mixture of oligomers and low molecular weight polyphenylacetylene. Competitive coordination of phenylacetylene and the second pyrazolyl unit to the Pd metal centre appears to control the catalysis process. The polydentate ligands were also characterized with the use of the ligand solid angles.

this work were obtained by anodic oxidation of the metals in ethanol in the presence of LiCl as a conductive additive according to [8]. Rhenium oxide was prepared by direct oxidation of a powder of rhenium metal in a flow of dry oxygen gas at 460–480 °C. The resulting bright yellow crystals were collected under dry oxygen and sealed and stored in evacuated glass ampoules. IR spectra were registered for nujol mulls on a Perkin–Elmer Spectrum 100 instrument. ^{1}H and ^{13}C NMR spectra were registered for $CHCl_3$ solutions on a Bruker 400 MHz instrument at 300 K. Microanalysis studies of all samples have been carried out at the laboratory of Organic Analysis of the Moscow State Academy of Fine Chemical Technology using a Heraeus CHN-O-RAPID instrument (standard deviations: C ±0.3%, H ±0.1%).

2.1. $Nb_4O_2(OEt)_{14}(ReO_4)_2$ (1)

$Nb_2(OEt)_{10}$ (0.4398 g) was dissolved in 5 ml toluene. Rhenium (VII) oxide (0.5063 g) was added to the obtained solution, which immediately changed color from light yellowish to light brown. The mixture was stirred until complete dissolution of Re_2O_7 for 20–30 min at room temperature. The obtained solution was quickly warmed to 60 °C and subjected to a short reflux. The solution turned reddish brown and the formation of colorless crystals could be observed. The reaction vessel was cooled to room temperature and left for crystallization overnight. The mother liquor was then removed by decantation and the practically colorless crystals were dried in vacuum. Yield: 0.8296 g (83%). *Anal.* Calc. for $H_{70}C_{28}O_{24}Nb_4Re_2$: C, 19.81; H, 4.30. Found: C, 21.91; H, 4.59%. IR, ν/cm^{-1}: 1277 s br, 1099 m, 1068 m, 1020 sh, 932 st, 892 sh, 878 m, 814 st, 536 m br, 478 sm br. ^{1}H NMR, δ, ppm (interpretation): 4.93 poorly resolved quadruplet (2H, CH_2, OEt-group in *trans*-position to the μ-O-ligand), 4.69 poorly resolved quadruplet (4H, CH_2, OEt-group in *trans*-position to the μ-OEt-ligand), 4.64 well resolved quadruplet (2H, CH_2, OEt-group in *trans*-position to the μ-OEt-ligand, $J = 5.6$ Hz), 4.55 poorly resolved quadruplet (2H, CH_2, OEt-group in *trans*-position to the μ-OEt-ligand), 4.43 poorly resolved quadruplet (4H, CH_2, μ-OEt-ligand), 1.38 poorly resolved triplet (9H, CH_3), 1.29 poorly resolved triplet (6H, CH_3), 1.22 poorly resolved triplet (3H, CH_3), 1.20 poorly resolved triplet (3H, CH_3). MS, *m*/*z* (%), interpretation: 271(100), $Nb(OEt)_4^+$, 265 (67.3), $ReO(OEt)(OH)^+$, 229 (43.4), $Nb(OEt)_2(OH)(OCH_3)^+$, 169 (17.7), $NbO(OEt)(OH)^+$. In an analogous synthesis the crystallization was also carried out at −15 °C yielding the product **1a**.

2.2. $Ta_4O_2(OEt)_{14}(ReO_4)_2$ (2)

A procedure analogous to that for compound **1** was applied, using $Ta_2(OEt)_{10}$ (1.7483 g) and Re_2O_7 (0.5292 g). Yield: 2.0302 g (86%). *Anal.* Calc. for $H_{70}C_{28}O_{24}Ta_4Re_2$: C, 16.28; H, 3.58. Found: C, 17.82; H, 3.74%. IR, ν/cm^{-1}: 1304 sm, 1108 m br, 1076 m, 1018 sm br, 936 m, 892 sh, 876 m, 810 st br, 668 sm, 527 m br, 479 sm br. ^{1}H NMR, δ, ppm (interpretation): 4.83 (2H, CH_2, OEt-group), 4.68 (2H, CH_2, OEt-group), 4.61 (4H, CH_2, OEt-group), 4.58 (4H, CH_2, OEt-group), 4.32 (2H, CH_2, OEt-group), 1.38 and 1.25 (21H in total, CH_3), all signals were poorly resolved. ^{13}C NMR, δ, ppm (interpretation): 72.94, 71.19 higher intensity, 70.89, 70.57, 70.25, 69.90, 69.41 (*C*H_2, OEt-group), 19.05, 18.94, 18.70, 18.55, 18.45, 18.05, 17.80 (*C*H_3, OEt-group). MS, *m*/*z* (%), interpretation: 361 (100), $Ta(OEt)_4^+$, 265 (64.7), $ReO(OEt)(OH)^+$, 219 (16.2), ReO_2^+. In an analogous synthesis the crystallization was also carried out at −15 °C yielding the product **2a**.

2.3. Crystallography

The data collection has been carried out at room temperature using a Bruker SMART CCD 1 K diffractometer at the Department of Chemistry, SLU and at $T = 100$ K using an Excalibur with sapphire-3 CCD detector (Oxford Diffraction Ltd.) at the Department of Structural Chemistry, Stockholm University (Mo Kα radiation, graphite-monochromator) for the experimental details see Table 1. The structures were solved by direct methods. Metal atom coordinates were located in the initial solution and all the other non-hydrogen atoms in the subsequent difference Fourier syntheses. All non-hydrogen atoms were refined by full-matrix techniques, first in isotropic and then in anisotropic approximation. The coordinates of the hydrogen atoms were calculated geometrically and introduced in the final refinement in isotropic approximation using a riding model. All calculations were performed using SHELXTL-NT program package [9] on a personal computer.

3. Results and discussion

The molecular structures of $Nb_4O_2(OEt)_{14}(ReO_4)_2$ (**1**) and $Ta_4O_2(OEt)_{14}(ReO_4)_2$ (**2** and **2a**) are very close to each other (see Fig. 1, Tables 1 and 2). Each of them contains a practically rectangular M(V)$_4$ core, where M(V) = Nb or Ta. Each M(V) atom is octahedrally coordinated. The octahedra along one pair of the edges in the rectangle share an edge, a pair of OEt-ligands. The thus defined pairs of octahedra are connected to each other via almost ideally linear oxo-bridges, defined by O(9) atoms (Ta(1A)–O(9)–Ta(2) 175.7(9)° and Ta(1A)–O(9)–Ta(2) 178.2(6)° in **2** and **2a**, respectively). The perrhenate ligands are attached to the rectangle in a centrosymmetric manner, i.e. to the Ta atoms defining one of its diagonals. The coordination of each of these atoms is completed by two terminal alkoxide ligands. The other two tantalum atoms bear three terminal alkoxide ligands each.

Both alkoxide and oxo-ligands are efficient π-donors, which leads to the increase of the bond order in the terminal M=O and M–O(R) fragments and asymmetric bonding for the bridging ligands. The normal bond length for

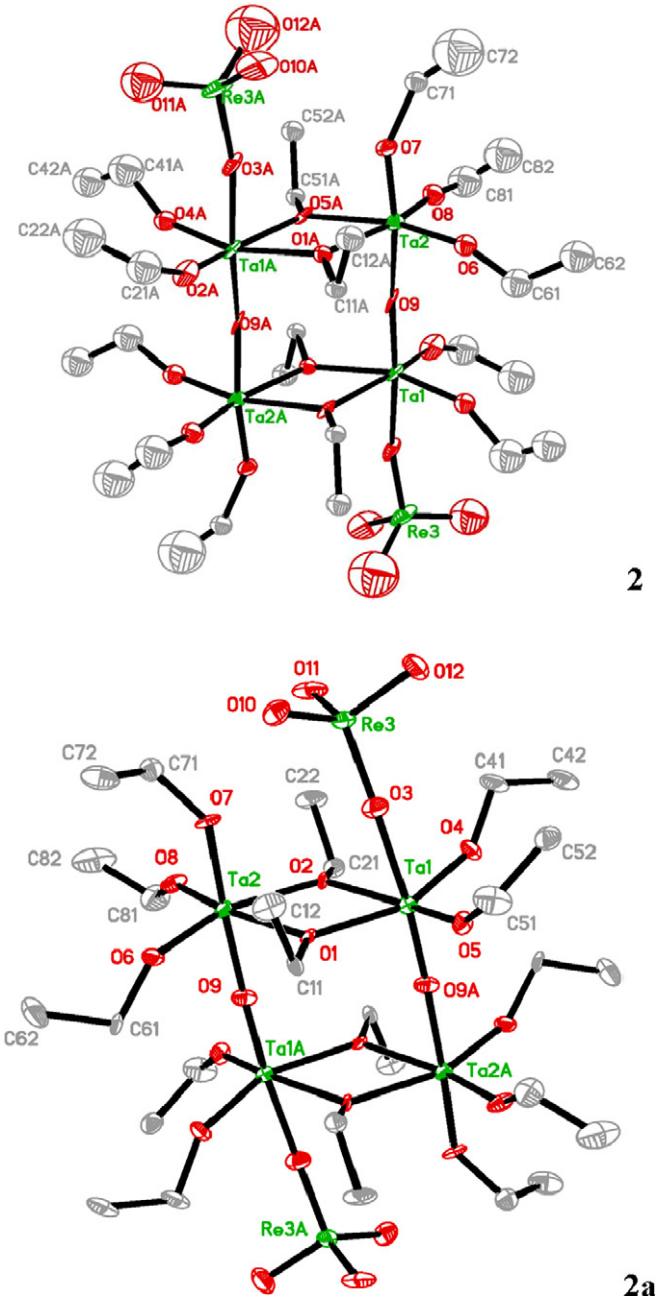

Fig. 1. Molecular structures of the **2** and **2a** samples of $Ta_4O_2(OEt)_{14}(ReO_4)_2$. The thermal ellipsoids are provided with 10% probability.

ordinary metal–oxygen bonds can be estimated from the sum of the covalent radii for the corresponding atoms, $r_c(O) = 0.66$ Å; $r_c(Re) = 1.37$ Å; $r_c(Ta) = 1.43$ Å; $r_c(Nb) = 1.43$ Å. This gives $r_c(M) + r_c(O)$ of 2.03–2.09 Å for Re, Nb and Ta. The analysis of the bond lengths (see Table 2) indicates double bonding for all the Re=O fragments with a slightly longer Re–μ-O(3) bond (1.738(18) and 1.753(9) Å in **2** and **2a**, respectively) compared to truly terminal Re–O bonds (1.55(6)–1.66(8) Å in **2** and 1.677(11)–1.695(11) Å in **2a**). The Ta–O and Nb–O bonds opposite the M(V)–O-Re bridges are in their turn considerably elongated (2.237(13), 2.118(18) and 2.175(9) Å in **1**, **2** and **2a**, respectively). The

bonds of the M(V) atoms to the μ-O(9) oxo-bridging atoms are also asymmetric. The part M(1)–μ-O(9), situated in a *trans*-position to the elongated bond of the perrhenate ligand, is considerably shorter than the other part of the bridge M(2)–μ-O(9) (1.858(17) and 1.833(9) Å compared to 1.967(17) and 2.038(9) Å, respectively). Generally the bond lengths distribution can be rationalized with respect to the multiplicity of the M–O bonds (decreasing π-contribution) in the series:

$$r(\text{Re–O})\text{term} < r(\text{Re–O})\mu < r(\text{Ta–OR})\text{term} < r(\text{Ta–O})\mu < r(\text{Ta–OR})\mu < r(\text{Ta–O–Re})\mu$$

It is interesting to compare the bonding parameters in the structures of the ethoxide derivatives with those in the structures of their methoxide analogs (see Table 3). It can clearly be seen that the lengths of all M–O bonds in the structures of $M^V_4O_2(OMe)_{14}(ReO_4)_2$ are noticeably shorter than those in the structures of $M^V_4O_2(OEt)_{14}(ReO_4)_2$. The reason for this difference lies most probably in the much higher density of packing in the structures of the methoxides, resulting in closer intermolecular contacts and contraction of the M–O distances.

The density of packing also constitutes a major difference between the structure of the forms of $Ta_4O_2(OEt)_{14}(ReO_4)_2$ isolated at different temperatures (compounds **2** and **2a**). In this latter case the bond lengths appear very similar and the strong decrease in the cell volume results from the general contraction in the M–O–C and O–C–C bond angles. The packing conserves the same motive and the low-temperature structure (isolated from the sample

[b] Literature data [8].

crystallized at −15 °C and where the data collection has been carried out at −120 °C) cannot be, in direct crystallographic meaning, considered as a different modification. It should be noted, however, that when the crystals isolated at −15 °C are transferred to room temperature for selection of a crystal for X-ray study, they "explode" under the paraffin oil. This indicates high steric tension and occurs most probably because these crystals have a complex domain structure. The quick warming up of the domains situated closer to the surface leads evidently to their quicker expansion than those inside the volume of the crystal, which makes them shrink on the contact surface and leave the crystal with a convection stream. We have noticed this phenomenon in a number of cases, where a strong dependence of the cell volume on temperature was observed, both in the presence and in the absence of true phase transitions.

Compounds **1** and **2** are soluble in hydrocarbon solvents at room temperature (about 5 wt%) and according to the NMR spectra appear to conserve their molecular geometry in solution. Both ^1H and ^{13}C spectra show the presence of the different structural functions for the ethoxide ligands present in molecules of **1** and **2**. The well-resolved ^{13}C spectrum in the methyl carbon region displays a separate signal for each alkoxide group. Their solutions are stable in time: the spectra remain unchanged and no coloration and/or precipitation can be observed for the solutions in either hexane or toluene at this concentration. This makes them attractive precursors for the deposition of rhenium oxide catalysts on different substrates using sol–gel technology.

It should be mentioned that the oxoalkoxides $M^V_4O_2(OEt)_{14}(ReO_4)_2$ are the only family of alkoxide perrhenates that can be isolated for the ethoxide derivatives. No non-oxo alkoxide perrhenate species could be isolated in this case in contrast to the methoxides, where the non-oxo $M^V_2(OMe)_8(ReO_4)_2$ complexes were formed at low temperatures. This difference is caused evidently by easier oxidation of ethanol resulting in release of water and formation of oxospecies. Crystallization of $M^V_4O_2(OEt)_{14}(ReO_4)_2$ occurs even on cooling the reaction mixture, but the gentle warming described in the provided experimental procedures offers higher yields of them.

4. Conclusions

Reproducibly soluble and solution stable oxo-alkoxo-perrhenate derivatives of niobium and tantalum, $M^V_4O_2(OEt)_{14}(ReO_4)_2$, can be obtained in high yields by the interaction of $M^V(OEt)_5$ with rhenium heptoxide. The isolation of crystals of these compounds has to be carried out at room temperature because of the strong temperature dependence of the unit cell volume, making crystals isolated in the cold transform into a powder on heating to room temperature.

Acknowledgments

The authors express their gratitude to Lars Eriksson, Department of Structural Chemistry, Stockholm University for the assistance with data collection on compound **2a** and to the Swedish Research Council, the Royal Swedish Academy of Sciences (KVA) and Russian Foundation

for Basic Research (RFBR Project No. 06-03-32444) for financial support.

Appendix A. Supplementary material

CCDC 617392, 617393 and 617394 contain the supplementary crystallographic data for **1**, **2** and **2a**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit @ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.09.088.

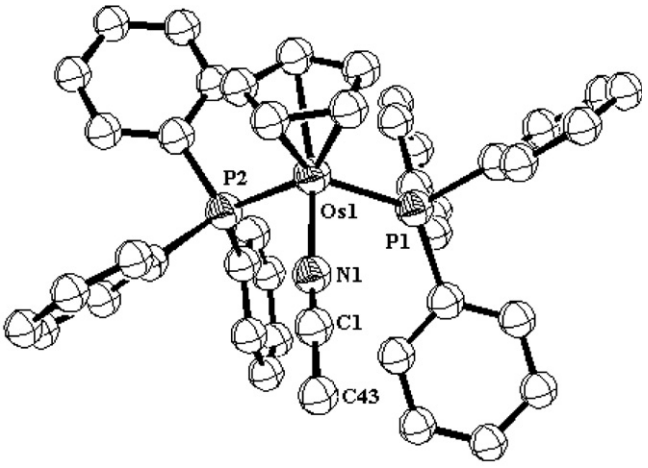
resonances of the methylene protons of the [S_2CNEt_2] ligand of complex **3** appear as two sets of quartets at 4.03 and 3.72 ppm. A triplet at 1.27 ppm, assignable to the methyl protons of the [S_2CNEt_2] ligand, was also observed. Protons corresponding to the cyclopentadienyl ligand also appear at 4.74 ppm while the PPh_3 peaks are observed as a bunch in the aromatic region. The IR spectrum taken in KBr showed a strong peak at 1491 cm^{-1}, unambiguously assignable to the ν_{CN} vibration of [S_2CNEt_2] [7]. We also observed bands at 2277 cm^{-1} and 1084 cm^{-1} assignable to ν_{CN} of coordinated CH_3CN and ν_{BF} of BF_4^-. We have employed this synthetic strategy hoping that the *in situ* generated complex [$CpOs(PPh_3)_2(CH_3CN)$]BF_4 (**2 · BF$_4$**) would easily give **3** or the chelate complex [$CpOs(PPh_3)_2(\kappa^2\text{-}S_2CNEt_2)$]. Unfortunately, we never obtain the latter compound, and to our surprise attempts to separate **2 · BF$_4$** and **3** proved to be futile owing to the similar solubility of these two complexes.

Then, we attempted to synthesize **3** from [$CpOs(PPh_3)_2(CH_3CN)$]BF_4 (**2 · BF$_4$**) and $Na \cdot S_2CNEt_2$ in refluxing methanol (Scheme 1). The formation of **3** may be gauged by the appearance of white precipitate after about one hour of refluxing. But to our surprise, a ^1H NMR spectrum taken in $CDCl_3$ of this crude product still showed the presence of **2 · BF$_4$**. Fortunately, after many attempts, we were able to get single crystals from this crude product by slow diffusion of hexane into an acetone solution of this mixture; very pale yellow crystals were obtained after one week leaving an oily blackish-yellow residue on the wall of the crystallization tube and the ^1H NMR spectrum revealed that this is a decomposed material. The ^1H NMR, $^{13}P\{^1H\}$ NMR, IR, elemental analysis as well as the X-ray crystallographic analysis of these crystals has revealed that this compound is the starting [$CpOs(PPh_3)_2(CH_3CN)$]BF_4 (**2 · BF$_4$**). However, as no report of the structural data of this compound is available in the literature, we have reported this structure here. The ORTEP diagram is shown in Fig. 1. For the final attempt, we tried the reaction starting from a new complex [$CpOs(PPh_3)_2(DMSO)$]BF_4 (**4 · BF$_4$**), however this compound does not seem to undergo the anticipated substitution reaction in the present experimental conditions. The complex [$CpOs(PPh_3)_2(DMSO)$]BF_4 (**4 · BF$_4$**) was prepared by the reaction of [$CpOs(PPh_3)_2Br$] with an excess of DMSO in methanol. The compound is isolated as a very pale yellow hydroscopic powder. It was characterized with the help of IR, ^1H and $^{13}P\{^1H\}$ spectroscopy. The IR spectrum showed a band at 1023 cm^{-1}, assignable to S-bound DMSO [8].



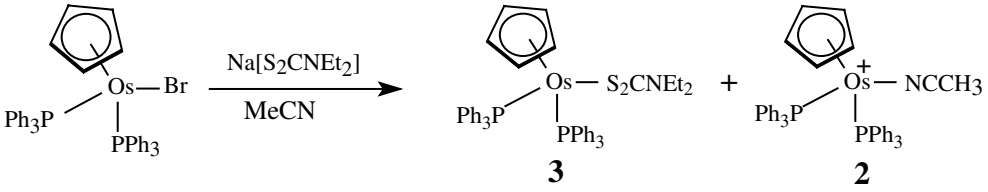


Fig. 1. Molecular structure of [$CpOs(PPh_3)_2(MeCN)$]BF_4 (**2 · BF$_4$**) with BF_4^- and all the hydrogens atoms omitted for clarity.

The ^1H NMR spectrum showed a resonance of the methyl group of the coordinated DMSO at 3.53 and 3.43 ppm. The $^{13}P\{^1H\}$ NMR showed a singlet at −2.67 ppm, suggesting a similar environment of both P atoms of the PPh_3 ligands. Thus, all our attempts to isolate the pure [$CpOs(PPh_3)_2(\kappa^1\text{-}S_2CNEt_2)$] (**3**) were unsuccessful.

In the complex [$CpOs(PPh_3)_2(CH_3CN)$]BF_4 (**2 · BF$_4$**), the osmium(II) centre adopts a pseudo-octahedral coordination geometry with an almost linear Os1–N1–C1 (171.16°) moiety occupying one site. The bond lengths N1–C1 (1.132(6) Å) and C1–C43 (1.455(8) Å) are in very close agreement with those reported for [$CpRu(CH_3CN)_3$]BF_4 where $N\text{–}C_{av} = 1.131$ Å and $C\text{–}C_{av} = 1.445$ Å [9]. The other coordination sites are occupied by a pentahapto-bound cyclopentadienyl ligand and two triphenylphosphines. The Os–P1 and Os–P2 bond lengths [2.328 Å and 2.343 Å respectively] are comparable with those found in [$CpOs(=C=C=CPh_2)(PPh_3)_2$][$PF_6$] [10] and [$CpOs(PPh_3)_2(OSO_2CF_3)$] [11].

We have extended our work to a closely related system, the reaction of [$CpRu(PPh_3)_2Cl$] or [$CpRu(PPh_3)_2(CH_3CN)$]BF_4 with $Na.S_2CNEt_2$ leads to the formation of an orange colored complex that is soluble in almost all common solvents, even in hexane. The IR spectrum showed a strong ν_{CN} peak at 1483 cm^{-1}. The ^1H NMR spectrum showed the resonance of the cyclopentadienyl ligand at 6.22 ppm, a bunch of peaks corresponding to methylene proton in the range of 3.76–4.42 ppm and a triplet at 1.28 ppm. Thus, IR and ^1H NMR data clearly suggested the formation of the expected well-known bidentate

Scheme 1.

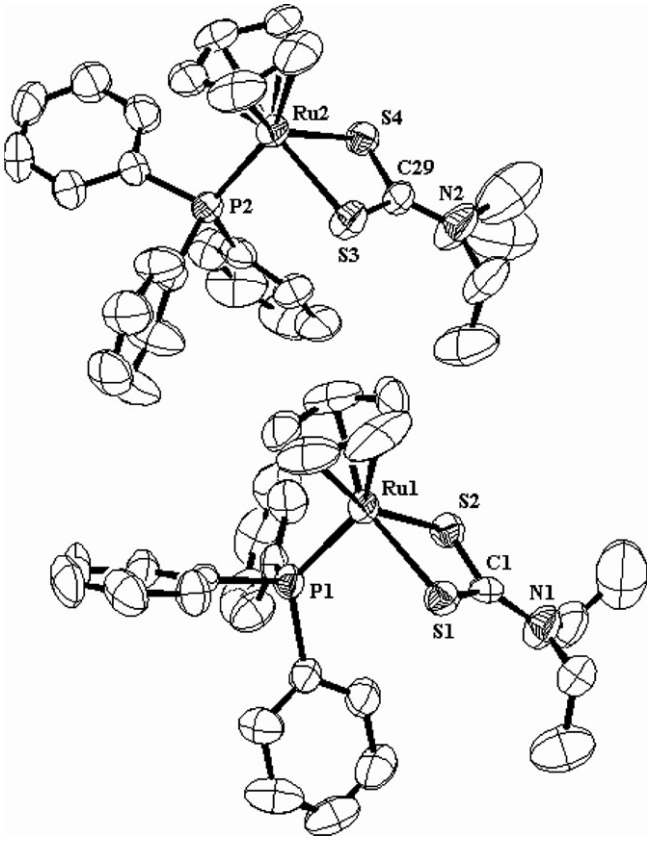

Fig. 2. Molecular structure of $[CpRu(PPh_3)_2(\kappa^2\text{-}S_2CNEt_2)]$ (**5**) with all the hydrogen omitted for clarity.

diethylthiocarbamato complex $[CpRu(PPh_3)(\kappa^2\text{-}S_2CNEt_2)]$ (**5**), the X-ray crystal structure determination also confirmed these spectroscopic evidences and has revealed that the compound contain two independent, discrete molecules (Fig. 2). The molecules are structurally identical except in the orientation of the ethyl group of the $[S_2CNEt_2]$ ligand. The metrical bonding parameters are comparable to those found in the analogous complexes $[CpRu(PPh_3)(S_2CNMe_2)]$ [12] and $[CpRu(PPh_3)(S_2CNPr_2)]$ [13].

3. Experimental

All solvents were dried and purified by standard procedures. ^1H and $^{13}P\{^1H\}$ NMR spectra were recorded on a Bruker 300 MHz spectrometer using Me_4Si and H_2PO_4 (85%) respectively as internal standards. IR spectra were recorded using a Nicolet Impact Spectrophotometer. $Na \cdot S_2CNEt_2 \cdot 3H_2O$ was obtained from a commercial source and was used as received. $[CpOs(PPh_3)_2Br]$ [14], $[CpOs(PPh_3)_2(MeCN)]BF_4$ (**2 · BF$_4$**) [6], $[CpRu(PPh_3)_2X]$, (X = Cl, MeCN) [15] were prepared according to literature procedures.

3.1. Synthesis of $[CpOs(PPh_3)_2(\kappa^1\text{-}S_2CNEt_2)]$ (3)

A mixture of $[CpOs(PPh_3)_2(MeCN)]BF_4$ (**2 · BF$_4$**) (0.05 g, 0.055 mmol) and $Na \cdot S_2CNEt_2 \cdot 3H_2O$ (0.013 g, 0.055 mmol) in 10 mL methanol was refluxed for 10 h, whereby the color of the solution changed to bright yellow with some whitish materials settling down at the bottom of the flask. The solvent was removed *in vacuo* and the residue was extracted with CH_2Cl_2 and filtered through a short silica gel column. Subsequent concentration and addition of excess hexane yielded a pale yellow powder containing a mixture of **3** and **2 · BF$_4$**. Yield: 0.038 g. ^1H NMR ($CDCl_3$, δ): 7.67–7.20 (m, 30H, Ph), 4.74 (s, 5H, Cp), 4.03 (qr, 2H, 7 Hz, CH_2), 3.72 (qr, 2H, 7 Hz, CH_2), 1.27 (t, 6H, CH_3). $^{13}P\{^1H\}$ NMR}: −1.53 (s). IR (KBr, cm^{-1}): 1491 (w), 1433 (ms), 1084 (ν_{BF}, s), 1055 (s), 750 (m), 697 (s).

3.2. Synthesis of $[CpOs(PPh_3)_2(DMSO)]BF_4$ (4 · BF$_4$)

A mixture of $[CpOs(PPh_3)_2Br]$ (0.1 g, 0.117 mmol) and dimethylsulfoxide (1 mL, 0.055 mmol) in methanol (30 mL) was refluxed for 3 h, whereby the color of the solution changed to very pale transparent yellow. The solvent was removed in vacuo and the residue was extracted with CH_2Cl_2 and loaded onto a short alumina column. The compound was eluted with methanol. Concentration of this methanol solution and addition of diethylether with vigorous shaking gave the very pale yellow solid of **4 · BF$_4$**. ^1H NMR ($CDCl_3$, δ): 7.49–7.14 (m, 30H, Ph), 5.47 (s, 5H, Cp), 3.53 (s, 3H, CH_3), 3.43 (s, 3H, CH_3). $^{13}P\{^1H\}$ NMR}: −2.67 (s). IR (KBr, cm^{-1}):1023 (ν_{SO}), 1089 (ν_{BF}).

3.3. Synthesis of $[CpRu(PPh_3)_2(\kappa^2\text{-}S_2CNEt_2)]$ (5)

A mixture of $[CpRu(PPh_3)_2(MeCN)]BF_4$ (0.05 g, 0.061 mmol) or $[CpRu(PPh_3)_2Cl]$ (0.044 g, 0.061 mmol) and $Na \cdot S_2CNEt_2 \cdot 3H_2O$ (0.014 g, 0.061 mmol) in methanol (10 mL) was refluxed for 8 h, then the solvent was removed *in vacuo* and the residue was extracted with CH_2Cl_2 and filtered through a short silica gel column. CH_2Cl_2 was removed *in vacuo* and the residue was extracted with hexane, which on standing overnight yielded orange crystals of **5**. Yield: 0.040 g, 59%. ^1H NMR ($CDCl_3$, δ): 7.67–7.31 (m, 30H, Ph), 6.22 (s, 5H, Cp), 4.53–3.42 (m, 12H, CH_2), 1.24 (t, 3H, 7.3 Hz, CH_3).$^{13}P\{^1H\}$ NMR}: 19.6 (s). IR (KBr, cm^{-1}): 1483 (ν_{CN}, s), 1457 (w), 1429(s), 1271 (s), 1214(w), 1141(m), 1089 (s), 748 (m), 696(s).

4. X-ray data collection and solution

Suitable single crystals for X-ray analysis of complex **2 · BF$_4$** were grown by slow diffusion of hexane into a concentrated acetone solution and **5** were grown by slow evaporation of a hexane/dichloromethane solution (1:2 v/v). A summary of the single-crystal X-ray structure analyses are shown in Table 1, and selected bond lengths and bond angles are presented in Tables 2 and 3 respectively. The X-ray intensity data were measured on a Bruker SMART APEX CCD area detector system equipped with a graphite monochromator and a Mo Kα fine-focus sealed tube

($\lambda = 0.71073$ Å) operated at 1600 W power (50 kV, 32 mA). The detector was placed at a distance of 5.8 cm from the crystal. A total of 1850 frames were collected with a scan width of 0.3° in ω and the frames were integrated with the Bruker SAINT software package using a narrow-frame integration algorithm. Data were corrected for absorption effects using the multiscan technique (SADABS) [16]. The structures were solved and refined using the Bruker SHELXTL (Version 6.1) software package [17].

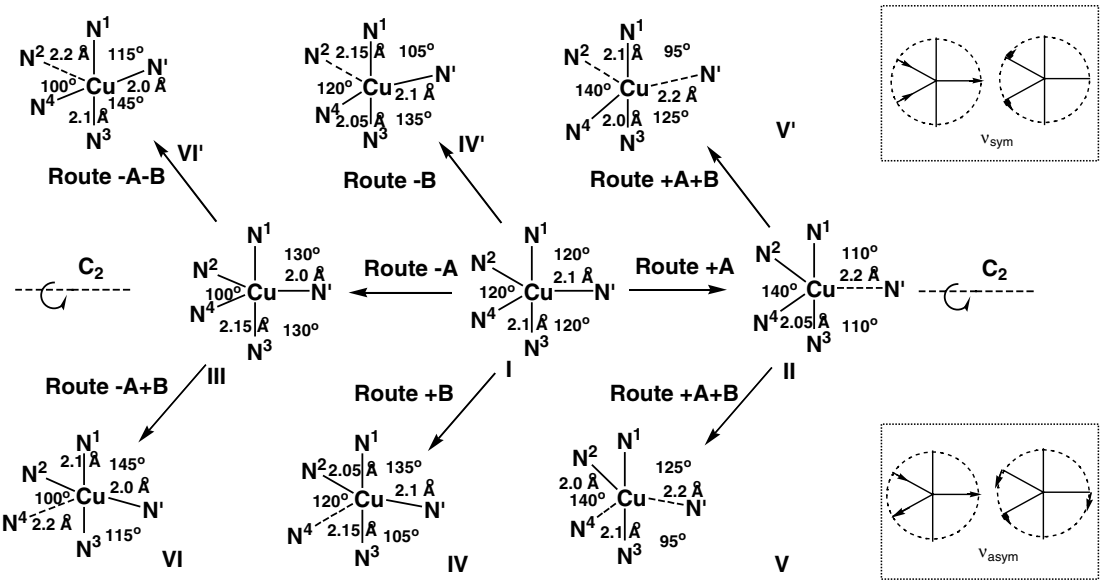

Fig. 1. The forms of distortion of the RTB CuN_4N' chromophore involving the $\pm A$, $\pm B$ and $\pm A$ $\pm B$ routes.

by soft modes of vibration of the more regular stereochemistries. Hence, the concept of a structural pathway [3–5], Fig. 1, for [Cu(chelate)$_2$X][Y] type complexes has been developed.

In 1984, Addison, Reedijk and co-workers introduced a very useful parameter, τ, which provides a measure of the degree of square-based pyramidal (SBP) versus trigonal bipyramidal (TBP) geometry adopted by five-coordinate Cu(II) complexes [6]. This parameter provides a convenient tool for comparing structures of similar five-coordinate Cu(II) complexes. The parameter τ is defined as $(\beta - \alpha)/60$, where β and α are the largest coordination angles, and its value varies from 0 (in regular SBP) to 1 (in regular TBP). The molecular structures of five-coordinate copper(II) complexes range extensively from regular trigonal bipyramidal (RTBP, D_{3h}) to regular square based pyramidal (RSBP, C_{4v}) with most complexes falling between these two stereochemistries [7], somewhere along the classical Berry pathway [6,8]. This feature can be useful in probing the relationships between structural correlations and the respective structural pathway involving vibronic type coupling.

In the majority of [Cu(chelate)$_2$X][Y] complexes the differences in stereochemistry may be associated with the differences in the ligands present i.e. chelate = 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen) and di-2-pyridylamine (dpyam) and X = Cl^-, Br^-, I^- or H_2O, respectively. A number of structural pathways of various copper(II) five-coordinate series, [Cu(bipy)$_2$X][Y] and [Cu(phen)$_2$X][Y] have now been reported in the literature [3,9]. These systems represent various types of structural pathways and such structural correlations have been found to be consistent with spectroscopic data involving EPR and electronic reflectance spectra. However, structural studies and structural correlations involving five-coordinate complexes containing the more flexible dpyam ligand and a pseudohalide, such as NCO^- have not been reported to date in the literature. Moreover, the square pyramidal geometry in new dpyam complexes is inherently different than previously reported five-coordinate square pyramidal geometries involving copper(II) and other chelate ligands [3,9]. The axial position of the square pyramid in this complex series is the occupied by dpyam nitrogen which is different from those of the bipy and phen series to which the halide or H_2O is occupied. Hence, it is of interest to look at potential structural correlations and investigate the existence of a potential structural pathway for the series of five-coordinate copper(II) complexes of the type, [Cu(dpyam)$_2$(NCO)][Y].

2. Experimental

2.1. General

The ligand, di-2-pyridylamine and all reagents are commercial grade materials and were used without further purification. IR spectra were recorded on a Perkin–Elmer Spectrum One FT-IR spectrophotometer as KBr disc in the 450–4000 cm^{-1} spectral range. Solid-state (diffuse reflectance) electronic spectra were measured as polycrystalline samples on a Perkin–Elmer Lambda 2S spectrometer, over the range 8000–18 000 cm^{-1}. X-band electron paramagnetic resonance (EPR) measurements were performed at room temperature on a JEOL RE2X spectrometer, using DPPH ($g = 2.0036$) as a standard. Higher EPR frequencies were employed in experiments conducted at 77 K: K-band (~27 GHz), V-band (~54 GHz) and W-band (~100 GHz). In this case a transmission single-pass home-made spectrometer based on a superconducting magnet was used [10]. Elemental analyses (C, H, N) were determined on a Perkin–Elmer PE2400 CHNS/O.

[Cu(dpyam)$_2$(NCO)](Br) (**1**): A warm solution of di-2-pyridylamine (0.171 g, 1.0 mmol) in methanol (15 cm^3) was added to a hot aqueous solution (15 cm^3) of $CuBr_2$ (0.071 g, 0.5 mmol). Solid KNCO (0.162 g, 2.0 mmol) was then added to the reaction mixture. The solution was allowed to evaporate at room temperature in air. Dark green needle-like crystals of **1** deposited after three days. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 95%. *Anal*. Calc. for $C_{21}H_{18}N_7CuOBr$: C, 47.78; H, 3.44; N, 18.57. Found: C, 47.84; H, 3.35; N, 18.70%.

[Cu(dpyam)$_2$(NCO)](CF$_3$SO$_3$) (**2**): A warm solution of di-2-pyridylamine (0.171 g, 1.0 mmol) in methanol (15 cm^3) was added to a hot aqueous solution (15 cm^3) of $Cu(CF_3SO_3)_2$ (0.181 g, 0.5 mmol). An aqueous solution (20 cm^3) of KNCO (0.162 g, 2.0 mmol) was then added. The green solution was slowly evaporated at room temperature. After several days, dark green needle-like crystals of **2** formed. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 60%. *Anal*. Calc. for $C_{22}H_{18}N_7CuO_4F_3S$: C, 44.26; H, 3.03; N, 16.42. Found: C, 43.98; H, 2.98; N, 16.29%.

[Cu(dpyam)$_2$(NCO)](BF$_4$) · dpyam (**3**): A warm solution of di-2-pyridylamine (0.171 g, 1.0 mmol) in methanol (15 cm^3) was added to a hot aqueous solution (15 cm^3) of $Cu(BF_4)_2 \cdot nH_2O$ (0.118 g, 0.5 mmol). An aqueous solution (10 cm^3) of KNCO (0.081 g, 1.0 mmol) was then added to the reaction mixture. The green solution was slowly evaporated at room temperature. Green needle-like crystals of **3** deposited after several days. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 75%. *Anal*. Calc. for $C_{31}H_{27}N_{10}CuOBF_4$: C, 52.74; H, 3.85; N, 19.84. Found: C, 53.08; H, 4.00; N, 19.67%.

[Cu(dpyam)$_2$(NCO)](Cl) · 4H$_2$O (**4**): A warm solution of di-2-pyridylamine (0.171 g, 1.0 mmol) in methanol (15 cm^3) was added to a boiling aqueous solution (15 cm^3) of $CuCl_2 \cdot 2H_2O$ (0.085 g, 0.5 mmol). KNCO (0.041 g, 0.5 mmol) was then added to the reaction mixture. The green solution was slowly evaporated at room temperature. After two weeks, green needle-like crystals of **4** formed. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 78%. *Anal*. Calc. for $C_{21}H_{26}N_7CuO_5Cl$: C, 45.41; H, 4.71; N, 17.65. Found: C, 45.28; H, 4.57; N, 17.67%.

[Cu(dpyam)$_2$(NCO)](NO$_3$) (**5**): A warm solution of di-2-pyridylamine (0.171 g, 1.00 mmol) in methanol (15 cm^3) was added to a hot aqueous solution (10 cm^3) of $Cu(NO_3)_2 \cdot 3H_2O$ (0.121 g, 0.5 mmol). Solid KNCO (0.081 g, 1.0 mmol) was then added. The green solution was slowly evaporated at room temperature. After several days dark green-like rod-shaped crystals of **5** formed. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 88%. *Anal*. Calc. for $C_{21}H_{18}N_8CuO_4$: C, 52.80; H, 3.32; N, 20.05. Found: C, 52.56; H, 3.24; N, 20.17%.

[Cu(dpyam)$_2$(NCO)](PF$_6$) (**6**): A warm solution of di-2-pyridylamine (0.17 g, 1.00 mmol) in methanol (15 cm^3) was added to a hot aqueous solution (10 cm^3) containing $Cu(CH_3COO)_2 \cdot nH_2O$ (0.091 g, 0.5 mmol) and KNCO (0.081 g, 1.0 mmol). An aqueous solution (15 cm^3) of KPF_6 (0.184 g, 1.0 mmol) was then added. The green solution was slowly evaporated at room temperature. After several days, green rod-shaped crystals of **6** formed. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 90%. *Anal*. Calc. for $C_{21}H_{18}N_7CuOPF_6$: C, 45.83; H, 2.88; N, 15.59. Found: C, 45.65; H, 2.77; N, 15.46%.

[Cu(dpyam)$_2$(NCO)](ClO$_4$) (**7**): A warm solution of di-2-pyridylamine (0.171 g, 1.0 mmol) in methanol (15 cm^3) was added to a hot aqueous solution (10 cm^3) of $Cu(ClO_4)_2 \cdot nH_2O$ (0.185 g, 0.5 mmol). An aqueous solution (15 cm^3) of KNCO (0.081 g, 1.0 mmol) was then added. The dark green solution was slowly evaporated at room temperature. After a week, dark green needle-like crystals of **7** formed. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 75%. *Anal*. Calc. for $C_{21}H_{18}N_7CuO_5Cl$: C, 49.41; H, 3.11; N, 16.80. Found: C, 49.58; H, 2.99; N, 16.68%. *Caution*: perchlorates are explosive!

[Cu(dpyam)$_2$(NCO)](BPh$_4$) (**8**): A warm solution of di-2-pyridylamine (0.171 g, 1.0 mmol) in methanol (15 cm^3) was added to a hot aqueous solution (10 cm^3) of $Cu(CH_3COO)_2 \cdot nH_2O$ (0.091 g, 0.5 mmol). Solid KNCO (0.081 g, 1.00 mmol) and solid of $NaBPh_4$ (0.342 g, 1.0 mmol) were then added to the reaction mixture. The green solution was slowly evaporated at room temperature. After two weeks, green rod-shaped crystals of **8** formed. The crystals were filtered off, washed with mother liquor and air-dried. Yield: ca. 80%. *Anal*. Calc. for $C_{45}H_{38}N_7CuOB$: C, 70.45; H, 4.99; N, 12.78. Found: C, 70.47; H, 5.00; N, 13.01%.

2.2. Crystallography

The X-ray single-crystal data of complexes **1**–**3** and **5**–**8** were collected at 293 K on a 4 K Bruker SMART CCD area-detector diffractometer rotating anode, graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) using the SMART program [11]. Data reduction and cell refinements were performed using the program SAINT [12]. An empirical absorption correction was applied using the SADABS [13] program, which resulted in transmission coefficients ranging from 0.854 to 1.000 for **1**, 0.402 to 1.000 for **2**, 0.774 to 1.000 for **3**, 0.811 to 1.000 for **5**, 0.890 to 1.000 for **6**, 0.834 to 1.000 for **7** and 0.898 to 1.000 for **8**. The unit-cell parameters of complex **4** were determined and the intensity data collected on an Enraf-Nonius MACH3 diffractometer with Mo Kα radiation ($\lambda = 0.70183$ Å) at 298 K. An absorption correction was performed using the ψ-scan program, which resulted in transmission coefficients ranging from 0.904 to 1.000.

All eight structures were solved by direct methods and refined by full-matrix least-squares method on $(F_{obs})^2$ with

anisotropic thermal parameters for all nonhydrogen atoms using the SHELXTL-PC V 6.12 [14] software package. All hydrogen atoms in **1**–**8** were located by difference synthesis and refined isotropically, except the hydrogen atoms of the water molecules in **4**, which we were unable to locate and not fix. The molecular graphics were created using SHELXTL-PC. The O atom in isocyanato group of **2** and **3** showed disorder; the occupancies of the disordered positions were initially refined and later fixed at 0.5 and 0.5 for **2** and 0.7 and 0.3 for **3**. The F and O atoms of the trifluoromethanesulfonate group of **2** showed disorder; the occupancies of the disordered positions were initially refined and later fixed at 0.5 and 0.5, respectively. The F atoms of the tetrafluoroborate group of **3** and hexafluorophosphate group of **6** also showed disorder. They were divided into two sets with occupancies of 0.5 and 0.5. The O atoms of the perchlorate group of **7** showed disorder; the occupancies of the disordered positions were initially refined and later fixed at 0.5 and 0.5, respectively. The crystal and refinement details for complexes **1**–**8** are listed in Table 1. Selected bond lengths and bond angles are given in Table 2. Fig. 2 shows a representative molecular structure for the $[Cu(dpyam)_2(NCO)]^+$ cation, the atomic numbering scheme and the angle notation used.

3. Results and discussion

3.1. Crystal structures

The asymmetric unit of complexes **1**–**8** involves a $[Cu(dpyam)_2(NCO)]^+$ cation and Br^-, $CF_3SO_3^-$, $BF_4^-\cdot$ dpyam, $Cl^-\cdot 4H_2O$, NO_3^-, PF_6^-, ClO_4^- and BPh_4^- anions, respectively in the lattice. In addition, **3** and **4** involve one dpyam molecule and four water molecules in the unit cell, respectively. None of the anions or water molecules is close enough (<3.0 Å) to be considered even weakly semi-coordinated to the copper(II) cation [15]. The structure of the cations all involve a five-coordinate CuN_4N' chromophore, with a square pyramidal stereochemistry having a trigonal bipyramidal distorted square based pyramidal stereochemistry (TBDSBP) in **1**–**5**, an intermediate five-coordinate stereochemistry for **6** and **7**, and a square based pyramidal distortion (SBPDTB) for **8**. All eight complexes are further examples of distortion isomers of the $[Cu(dpyam)_2(NCO)]^+$ cation, whose stereochemistries are related by the structural pathways of Fig. 1. No attempt will be made to describe the individual structures of complexes **1**–**8**, Table 2, but scatter-plot analysis will be used to compare their structures with that of $[Cu(dpyam)_2(NCO)](SO_4)_{0.5}\cdot dpyam\cdot 0.5H_2O$ (**9**) the only other complex of known crystal structure [16]. Table 2 summarises the selected bond lengths and angles of all eight complexes, sequenced in order of their τ values, where $\tau = (\alpha_8 - \alpha_1)/60$ [6], and Table S1 summarises the maximum, minimum, difference (Δ) and average bond length and bond angle values for the series of nine $[Cu(dpyam)_2(NCO)][Y]$ complexes. Table S3 gives the sums of the in-plane bond angles, and bond distances, Cu–N(2), Cu–N(4) and Cu–N′, respectively.

3.2. The $[Cu(dpyam)_2(NCO)][Y]$ data

The structures of the nine five-coordinate CuN_4N' chromophores vary from TBP to near SBP, reflected in a range of τ values of 0.76–0.09, $\Delta\tau = 0.67$. This is a substantial variation in τ, the largest seen to date for the cation distortion isomers of the $[Cu(dpyam)_2X][Y]$ series of complexes [17]. None of the complexes has a near RTB (regular trigonal bipyramidal) stereochemistry or lies on a twofold axis of symmetry. Six complexes (**1**–**5** and **9**) have τ values in the more limited range of 0.09 to 0.31 and their stereochemistries are best described as TBDSBP. Complexes **6** and **7** have τ values of 0.53 and 0.54 and their stereochemistries are best described as intermediate five coordinate. Complex **8** has a τ value of 0.76 and its stereochemistry is best described as SBPDTB.

Relative to a RTB stereochemistry, the out-of-plane distances, Table 2, show only small differences, Table S1, with ΔCu–N(1) = 0.030 Å and ΔCu–N(3) = 0.044 Å. The largest variations in bond lengths are present in the equatorial bond distances Cu–N(4), Cu–N′ and Cu–N(2), respectively. The Cu–N(4) distances show the largest variation ranging from 2.089(1) to 2.283(3) Å, with $\Delta = 0.194$ Å and with an average value = 2.182(3) Å. The Cu–N(2) distances vary from 2.014(10) to 2.074(2) Å, with $\Delta = 0.060$ Å and with a mean value = 2.044(2) Å. The Cu–N′ distances range from 1.903(3) to 1.984(1) Å, with $\Delta = 0.081$ Å and with an average value = 1.947(1) Å. The average of the in-plane Cu–N(2,4,N′) distances, 2.057(2) Å, is greater than the average of the axial Cu–N(1,3) distances, 2.015(1) Å, by 0.042 Å, consistent with a TB stereochemistry and slightly lesser than the difference of 0.1 Å normally observed [18]. The out-of-plane bond angles, Table 2, show only small differences, Table S1, with $\Delta\alpha_{4-7}$ and $\Delta\alpha_{8-10}$ ranging from 3.6° to 6.5° and 6.2–15.4°, respectively. The α_1 in-plane angles show the largest variation ranging from 124.7(2)° to 167.1(1)°, with $\Delta = 42.4°$ and with a mean value = 151.8(1)°. The α_2 angles show the smallest variation ranging from 98.8(2)° to 119.4(1)°, with $\Delta = 20.6°$ and average = 108.4(1)°. The α_3 angles vary from 93.7(1)° to 115.9(1)°, with $\Delta = 22.6°$ and with an average value = 99.3(1)°. From Table 2 it is noticeable that within the range of τ values of 0.76–0.09, there is slight gap of 0.22 in τ value between the value of 0.54 for **7** to the next value of 0.76 for **8**. This gap corresponds with a change in the ratio of the α_9 and α_{10} angles, for τ values >0.54, $\alpha_9 > \alpha_{10}$, but for τ values <0.54, $\alpha_9 < \alpha_{10}$. These relatives have been used to suggest a structural pathway from a regular trigonal bipyramidal to a distorted square-based pyramidal stereochemistry and suggest that, **1**–**9** form a point in a more extensive structural pathway for the CuN_4N' chromophore.

3.3. Scatter-plot analysis for the [Cu(dpyam)$_2$(NCO)][Y] series of complexes

This section presents the data for the [Cu(dpyam)$_2$-(NCO)][Y] series of complexes, Table 2, using scatter-plot analysis. The scatter plots (Fig. 3) discussed are as follows: (a) τ versus Cu–N(4), (b) α_3 versus α_1, (c) α_3 versus Cu–N′ and (d) Cu–N(2) versus Cu–N(4). An overview of the range of stereochemistries is provided by the plot of τ versus Cu–N(4). However, as τ involves two simultaneous angle changes, it will not be used further. A number of suggested extreme data points, Table S2, are included in the plots, with the geometry of the extreme seesaw stereochemistry illustrated in Fig. S1. The nine data points in Fig. 3(a) vary from trigonal bipyramidal, TB, to near regular square-based pyramidal, RSBP, with the τ values decreasing from 0.76 to 0.09, respectively as the Cu–N(4) distances increase from 2.089(1) to 2.283(3) Å. The data points show a broad *inverse* trend, and clearly do not cluster around the RTB geometrical point. This plot provides an overview of the observed stereochemistries of the [Cu(dpyam)$_2$(NCO)][Y] series of complexes. There is one data point, **1**, at near SBP with $\tau = 0.09$, but there are no data points at RTB ($\tau = 1.0$). Five of the nine data points have τ values in the range 0.23–0.31 with stereochemistries best described as TBDSBP. Two data points **6** and **7** lie on the main correlation trend-line containing the RTB and RSBP data points. Two data points, **4** and **8** lie on a parallel correlation, with the remaining one data point, **9** lying nearby. Data points **1** and **2** lie off the RTB → RSBP trendline, due to their slightly long Cu–N(4) bond distances, which are ≈0.1 Å greater than expected [16].

The data points in Fig. 3(b) show the α_3 values decreasing from 115.9(1)° to 94.1(2)° as the α_1 values concomitantly increase from 124.7(2)° to 167.1(1)°. All eight data points have α_1 values >120° and α_3 values <120°, Table 2. Eight data points are found in the $-A + B$ section of the graph. The exception is data point, **1**, which lies close to the RSBP reference point. It is noticeable that within the α_1 and α_3 data set, point **1** has greater α_1 and α_3 values compared to those of a RSBP stereochemistry. There is no data points, which lies on the RTB → RSBP ($-A + B$) distortion pathway. Four data points, **2**, **3**, **4** and **9**, and the SBP data point, show an *inverse* trend, with each of these data points having α_2 105 ± 2°. The remaining data points, **8**, **7** and **5**, lie on two possible parallel correlations (---) displaying α_2 values of 120 ± 2°, 115 ± 2° and 110 ± 1°, respectively. This series of three possible parallel correlations have the same gradients. The data points show a SBP distortion, but only the correlation containing the data points corresponding to an α_2 value of 105° can end up at RSBP. For each parallel correlation, the α_2 values remain constant, therefore $\Delta\alpha_1\uparrow \approx \Delta\alpha_3\downarrow$ as $\alpha_1 + \alpha_2 + \alpha_3 = 360°$, Table S3, and possibly suggesting the occurrence of preferred or magic angles [19]. The % $-A$ and % $+B$ distortion values calculated from the in-plane α_1 and α_3 bond angle data of Fig. 3(b) are given in Table 3.

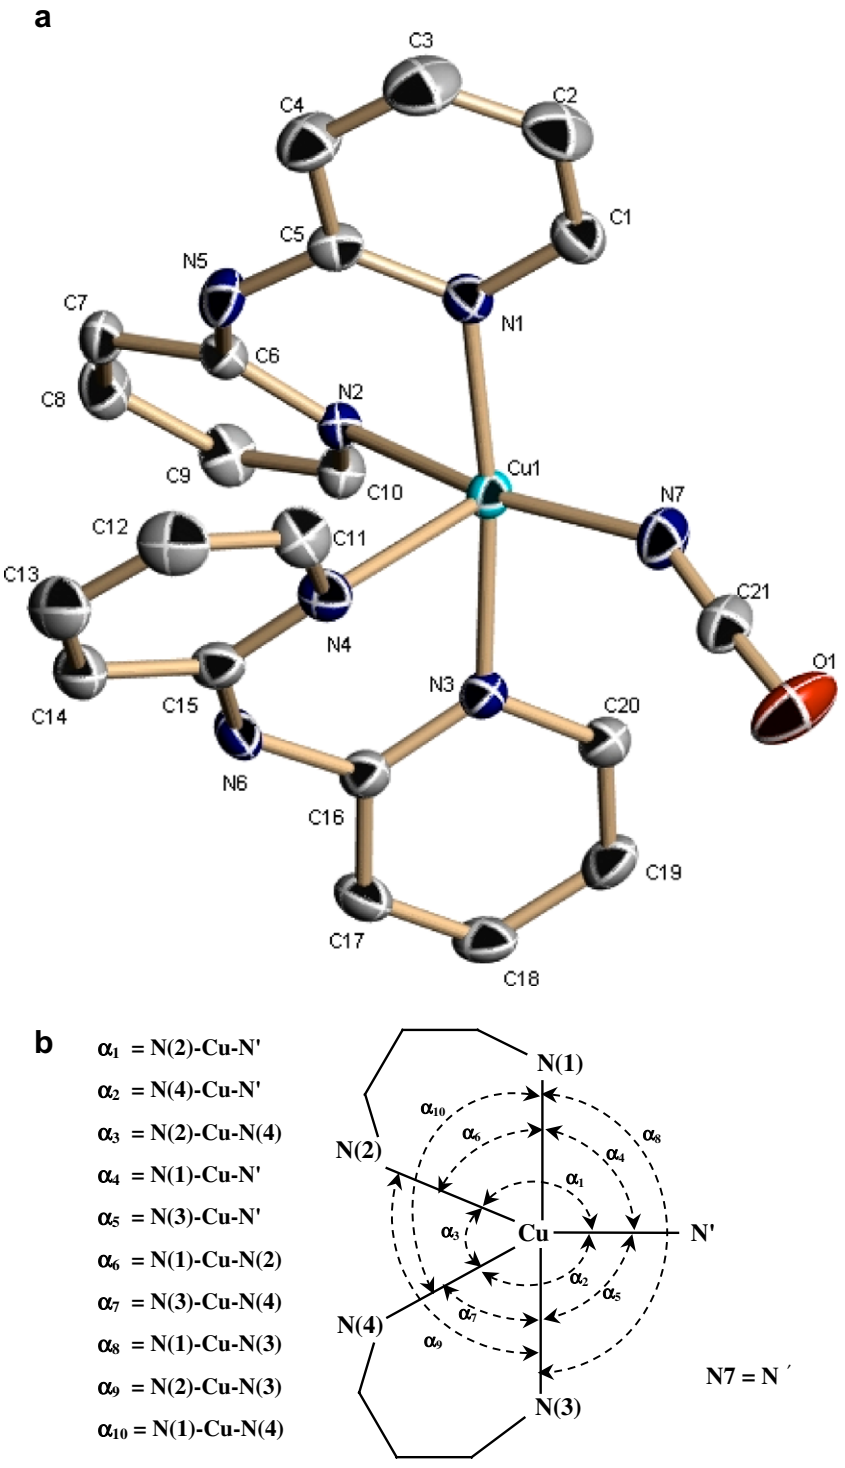

Fig. 2. (a) The molecular structure of the $[Cu(dpyam)_2(NCO)]^+$ cation of complex **1**, (b) the atom numbering scheme and α_n notation for the CuN_4N' chromophore.

The nine data points in Fig. 3(c) show the α_3 values decreasing from 115.9(1)° to 94.1(2)°, $\Delta\alpha_3 = 21.8°$ as the Cu–N′ distances decrease from 1.984(1) to 1.903(13) Å, ΔCu–N′ = 0.081Å. All data points have α_3 values <120° and Cu–N′ distances <2.092 Å, suggesting $-A$ route distortion. Data point, **8** lies well off the $-A \rightarrow$ RTB $\rightarrow +A$ pathway, with Cu–N′ distances significantly shorter, ≈0.08 Å, than predicted from its corresponding α_3 values, while data points **1**–**7** also seem to have slightly shorter Cu–N′ distances, ≈0.05 Å, than expected from their corresponding α_3 values. There are no data points connecting the RTB data point to the extreme 'see saw' data point (the $-A$ route distortion, SSDTB in Fig. S1) There are two possible higher parallel trend lines involving one data point **8**, and two data

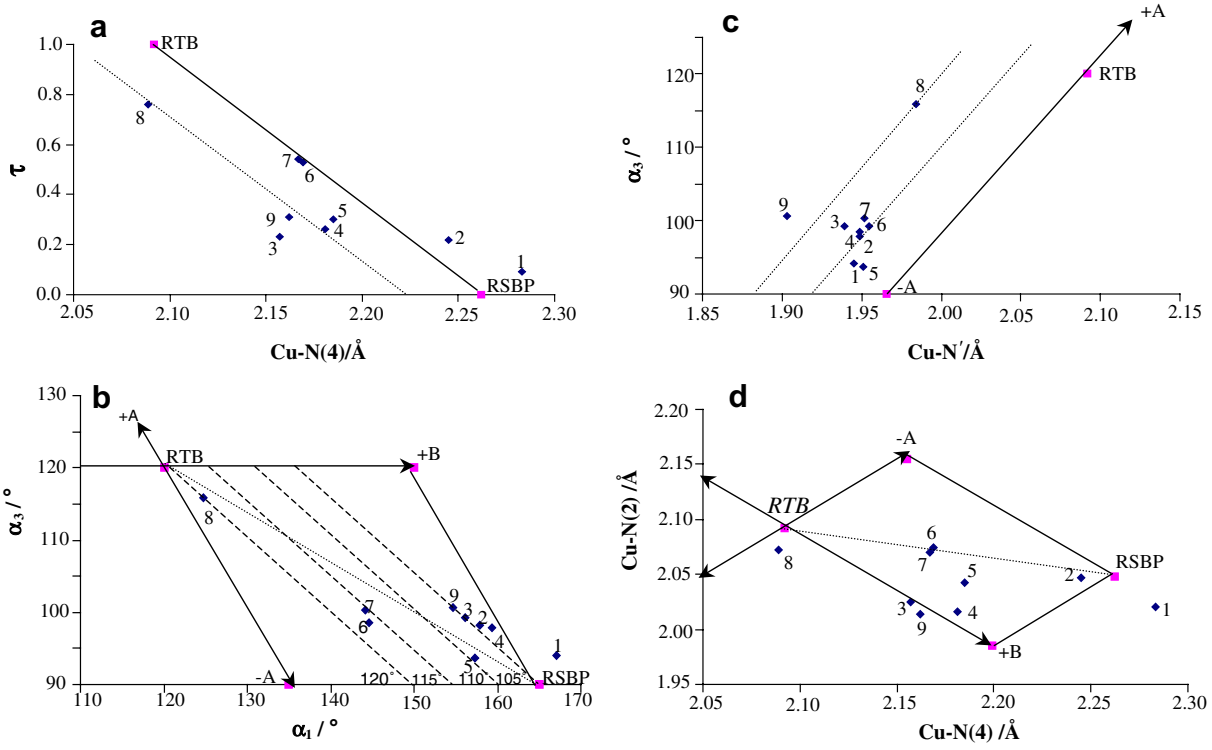

Fig. 3. Standard scatter plots for the [Cu(dpyam)(NCO)][Y] complexes.

points, **2** and **6** with **1**, **3**, **4**, **5** and **7** lying close by. These linear correlations do not have enough data points to be convincing. However, it is significant that the three correlations involve approximately equal separations between the lines of either ≈11° in the α_3 values or of ≈0.040 Å in the Cu–N′ distances. If the data of Fig. 3(c) are related to those of Fig. 1, then both the α_3 angles and the Cu–N′ distances correspond to a pure $-A$ route distortion of the RTB stereochemistry. In practice, the α_1 and α_2 angles are not even approximately equal, varying from $\Delta(\alpha_1 - \alpha_2) = 5.3$–$68.3°$, Table 2. The extreme $-A$ route distortion is clearly five-coordinate, with three short bonds,

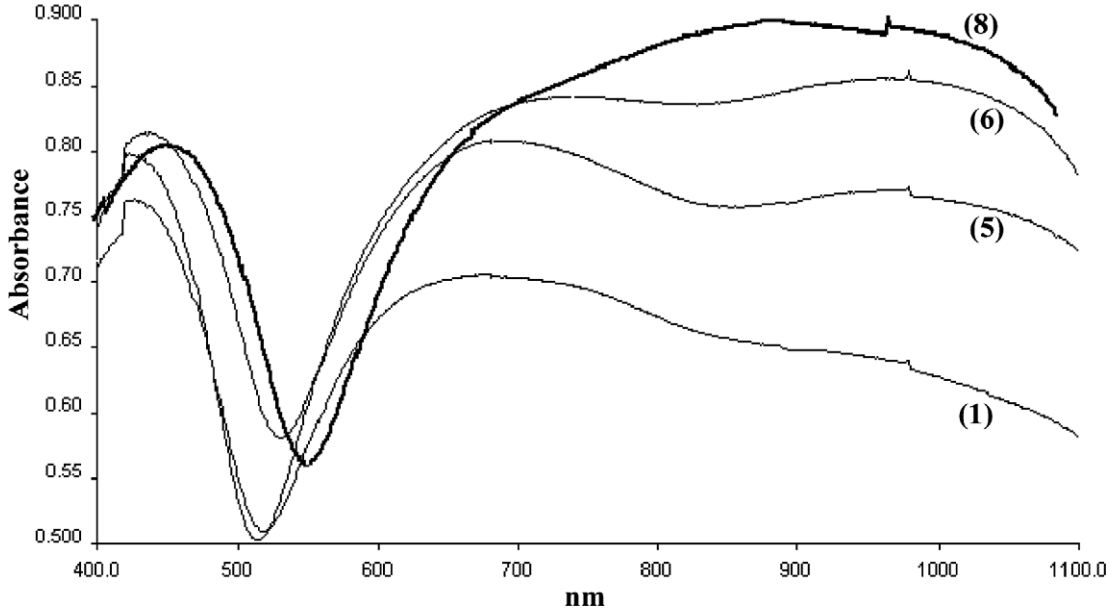

Fig. 4. Electronic reflectance spectra of representative $[Cu(dpyam)_2(NCO)][Y]$ complexes with different τ values: $\tau = 0.09$ for (**1**), 0.30 for (**5**), 0.53 for (**6**) and 0.76 for (**8**).

Table 3
The % $-A$ and % $+B$ route distortion values of the complexes calculated using the in-plane angle data of Fig. 3(b)

	Complex							
	1	**2**	**3**	**4**	**5**	**9**	**6**	**7**	**8**
% $-A$		82.0	77.3	81.2	97.9	71.7	80.0	73.2	15.3
% $+B$		94.4	85.8	89.6	80.7	83.0	46.1	47.2	8.8

Cu–N(1) = Cu–N(3) ≈ 2.0 Å, Cu–N′ ≈ 1.95 Å, and two longer bonds, Cu–N(2) = Cu–N(4) ≈ 2.15 Å, with in-plane angles of $\alpha_1 = \alpha_2 = 135°$ and $\alpha_3 = 90°$.

The data points in Fig. 3(d) show the Cu–N(2) distances decreasing from 2.074(2) to 2.014(10) Å, while the Cu–N(4) distances increase from 2.089(1) to 2.283(3) Å. Five data points, **2**, **4**–**7** are observed in the $-A + B$ quadrant of the graph, with points **1**, **3**, **8** and **9** lying outside this quadrant. There are no data points on the RTB $\rightarrow \pm A$ trendline, but there is one data point, **3** which lies directly on the RTB $\rightarrow +$ B route pathway. There are two data points **6** and **7** which also lie precisely on the RTB $\rightarrow$ RSBP ($-A + B$) pathway, with data point **2**, lying close by. Table 4 shows the % $-A$ and % $+B$ distortion values of the complexes calculated using the in-plane Cu–N(2) and Cu–N(4) distance data. The values are closely comparable to those in Table 3 using the corresponding in-plane bond angle data. In general, Tables 3 and 4 show a large % $-A$ and a large % $+B$ distortion. Data point **8** is exceptional because it shows a few % $-A$ and % $+B$ distortion values.

3.4. General conclusions and comparison of the [Cu(dpyam)$_2$(NCO)][Y] series with other [Cu(chelate)$_2$(X)][Y] series of complexes

The information obtained from the scatter-plot analysis of this series of nine [Cu(dpyam)$_2$(NCO)][Y] complexes can be summarised as follows:

(1) The distribution of the data points is not random, with respect to the RTB and RSBP data points. They involve a significant spread of 42° and 0.19 Å, Table S1.
(2) The τ plot is consistent with a SBP distortion of the RTB CuN_4N' chromophore, but with neither the RTB or RSBP structures present. Data point, **1**, has extreme to near RSBP geometry with a τ value of 0.09. Five complexes have τ values in the range of 0.23–0.31. Data points, **6** and **7**, have an intermediate τ values of 0.53 and 0.54, respectively. Data point, **8**, has an exceptional τ value of 0.76, which equates with an unusual SBPDTB stereochemistry for a [Cu(dpyam)$_2$(NCO)][Y] complex.
(3) The plot of α_3 versus α_1 shows data points lying on parallel correlations, with fixed α_2 values of $120 \pm 5°$, 10° or 15°, suggesting the existence of preferred or magic angles, consistent with $\alpha_1 + \alpha_2 + \alpha_3 = 360°$, Table S3.
(4) The ±A and ±B axes of Fig. 1 can be superimposed on the plots. All data points lie in the $-A + B$ section of the graphs except data point **1** which lies close to the RSBP stereochemistry. Tables 3 and 4 show the % $-A$ and % $+B$ distortion values of the complexes calculated from the in-plane angle and distance data and show large % values of both $-A$ and $+B$ distortion.
(5) The five-coordinate structures of the dpyam series are comparable to the five-coordinate copper(II) complexes [Cu(chelate)$_2$(X)][Y] when chelate = bipy and phen and X = Cl^-, Br^-, I^- and H_2O. Those of the bipy and phen families also show distortions ranging from RTB to RSBP, but differ in two aspects. First, almost all the τ values in the corresponding bipy and phen complexes range between intermediate to near RTB, [Cu(phen)$_2$Cl][Y] [9a] (0.56–0.81), [Cu(phen)$_2$Br][Y] [9b] (0.72–0.95), [Cu(phen)$_2$I][Y] [9b] (0.84–1.06), [Cu(bipy)$_2$Cl][Y] [3,9d] (0.53–1.00), [Cu(bipy)$_2$Br][Y] [9b,9d] (0.49–0.91), [Cu(bipy)$_2$I][Y] [9b] (0.80–0.90) and [Cu(chelate)$_2$(OH$_2$)][Y]$_2$ [9c] (0.53–0.89), which differ significantly from the dpyam series of complexes where most τ values = 0.09–0.54 due to the more flexible dpyam ligand. Secondly, the distortion structural pathway in the dpyam series involves a $-A + B$ route (Fig. 1), which is different from that of the higher symmetry with twofold axis of [Cu(chelate)$_2$(OH$_2$)][Y]$_2$ series which involves, a unique ±A route.

The stereochemistries of the [Cu(chelate)$_2$(OH$_2$)][Y]$_2$ complexes differ from that of the dpyam complexes in having a crystallographic twofold axis of symmetry and hence are best described as having a pure $\pm A$ route distortion, which involves the pure ν_{sym}^{str} and ν_{sym}^{bend} modes of vibration. The [Cu(dpyam)$_2$(NCO)][Y] complexes in contrast, with their slight contraction along the Cu–N′ distance (opposite α_3), their non-equivalence of the α_1 and α_2 angles without a

Table 4
The % $-A$ and % $+B$ route distortion values of the complexes calculated using the in-plane distance data of Fig. 3(d)

	Complex							
	1	**2**	**3**	**4**	**5**	**9**	**6**	**7**	**8**
% $-A$		82.5		7.9	28.6		46.0	38.1	
% $+B$		91.8	60.9	76.8	66.5	69.3	45.9	44.0	8.4

twofold axis of symmetry are considered to involve a $-A + B$ route distortion with the obvious domination of $+B$ over $-A$, involving all the four modes of vibration ν_{sym}^{str}, ν_{sym}^{bend}, ν_{asym}^{str} and ν_{asym}^{bend}, namely the molecular structure **VI** of Fig. 1. Alternatively, the precise coordination geometry displayed may be interpreted [9b] as an effect of vibronic coupling of a linear combination of the nuclear modes of vibrations ν_{sym}, a symmetric C_2 mode, and ν_{asym}, an asymmetric non-C_2 mode, of the CuN_4N' chromophore.

3.5. IR, electronic properties and EPR of the [Cu(dpyam)$_2$(NCO)][Y] complexes

The infrared spectra display a strong band at 2214 and 2180 cm^{-1} for **1**, 2214 cm^{-1} for **2**, 2209 cm^{-1} for **3**, 2220 cm^{-1} for **4**, 2219 and 2202 cm^{-1} for **5**, 2222 cm^{-1} for **6**, 2214 cm^{-1} for **7** and 2218 cm^{-1} for **8**, which can be assigned to the ν_{asym}(NCO) absorption band. The spectrum of **2** also displays a broad and intense band at approximately 1280–1040 cm^{-1}, consistent with the characteristic peak $\nu_4(SO_3)$ of $CF_3SO_3^-$ anion. The spectrum of **3** displays a broad and intense band at approximately 1074–1014 cm^{-1}, consistent with the characteristic peak of BF_4^- anion. The spectrum of **5** displays an intense band at approximately 1384 and 1307 cm^{-1}, consistent with the characteristic peak of ν_{as}(NO) and ν_s(NO) of NO_3^- anion. The spectrum of **6** displays a broad and intense band at approximately 845–837 cm^{-1}, consistent with the characteristic peak of PF_6^- anion. The spectrum of **7** displays a broad and intense band at approximately 1166–1076 cm^{-1}, consistent with the characteristic peak of ClO_4^- anion.

The polycrystalline electronic reflectance spectra of complexes **1**, **5**, **6** and **8** are represented in Fig. 4. For **8** a single d → d transition occurs at 11 420 cm^{-1} (876 nm), with some evidence of an unresolved high-energy shoulder at 12 880 cm^{-1} (776 nm), consistent with near TB stereochemistry ($\tau = 0.76$). The one-electron ground-state configuration is $d_{z^2} > d_{xy} \approx d_{x^2-y^2} > d_{xz} \approx d_{yz}$. The principal absorption may be assigned as a $d_{x^2-y^2} \rightarrow d_{z^2}$ transition, with the low-energy assigned as a $d_{xz} \approx d_{yz} \rightarrow d_{z^2}$ transition. The electronic spectrum of **8** is comparable to those of complexes with similar Cu(II) environment [Cu(phen)$_2$Cl][Y], Y = $BF_4 \cdot 0.5H_2O$, PF_6 and ClO_4 [9a], [Cu(phen)$_2$Br][Y], Y = Br · H_2O, ClO_4 and PF_6 [9b]. The spectra of **6** and **7**, $\tau = 0.53$ and 0.54, respectively, both having an intermediate stereochemistry between RTB and RSBP, involve two clearly resolved peaks at 10 330 cm^{-1} (968 nm) and 13 870 cm^{-1} (721 nm) for **6** and 10 350 (966 nm) and 13 800 cm^{-1} (725 nm) for **7**, with the lower-energy peak showing a slightly greater intensity, consistent with the intermediate five-coordinate geometry. The one-electron ground-state configuration is $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{xz} \approx d_{yz}$. The transitions may be assigned as the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition for the low-energy peak and the $d_{xz} \approx d_{yz} \rightarrow d_{x^2-y^2}$ transition for the high-energy peak. The electronic spectra of **6** and **7** are comparable to those of complex with similar environment [Cu(phen)$_2$Cl][CF_3SO_3] · H_2O [9a]. Complexes **1**–**5**, $\tau = 0.09$–0.31, which have a TBDSBP stereochemistry, involve high-energy, high-intensity peak at 14 510 cm^{-1} (689 nm), 14 420 cm^{-1} (694 nm), 14 240 cm^{-1} (702 nm), 14 200 cm^{-1} (704 nm) and 13 930 cm^{-1} (718 nm), respectively, with low-energy, low-intensity shoulder at 10 150 cm^{-1} (985 nm), 10 180 cm^{-1} (982 nm), 10 220 cm^{-1} (978 nm), 10 350 cm^{-1} (966 nm) and 10 270 cm^{-1} (974 nm), respectively. The one-electron ground state configuration is $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{xz} \approx d_{yz}$. The transitions may be assigned as the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition for the low-energy shoulder and the $d_{xz} \approx d_{yz} \rightarrow d_{x^2-y^2}$ transition for the high-energy peak. The electronic spectra of **1**–**5** are comparable to those of complexes with similar environment [Cu(phen)$_2$Cl][BPh_4] [9a] and [Cu(phen)$_2$Br][BPh_4] [9b].

The corresponding spectro-structural correlation plots (Fig. S2) reveal that ΔE values increase with increasing τ values for the low-energy peak and the reverse result has been found for the higher-energy peaks. It is evident from Fig. S3, that the basal angles themselves correlate very well with the ΔE values. This plot clearly indicates that a linear correlation between τ and the ΔE values exists in the set of **1**–**8** where α and β have been defined consistently.

The polycrystalline X-band EPR spectrum at room temperature of complexes **1**–**8** is isotropic (Table 5), yielding no information in relation to the electronic ground state. Low-temperature (77 K) EPR spectra were performed at higher frequencies (K-band and V-band) than X-band, both on polycrystalline samples, and DMSO solutions, in

Temperature: 77 K; magnetic field sweep rate: 2 mT/s; magnetic field modulation: frequency 40 kHz, amplitude 1 mT.

order to increase the *g*-value resolution, and possibly also resolve hyperfine structure. Indeed, Q-band (34 GHz) spectra of frozen DMSO solutions showed nicely resolved parallel and perpendicular g components, with a hyperfine structure due to the nuclear $I = 3/2$ spin characteristic for Cu^{2+} observed on top of the parallel component (not shown), this was expected to study the correlation between the five-coordinate geometries and the hyperfine splitting ($A_\parallel$ values). However, an analysis of the solution spectra revealed that the complexes under study are decomposed, or otherwise altered in these conditions. These studies were consequently abandoned. Instead, EPR on polycrystalline samples at K-band (27 GHz) and V-band (54 GHz) was successful in fully resolving *g*-values. Fig. 5 shows spectra of **4** and **8** at both frequencies, accompanied by powder simulations using *g*-values as in Table 5. Table 5 also presents *g*-values for the remaining complexes under study. The EPR spectra of complexes **1**–**7** are in rhombic type [4,7] and three *g*-factors are obtained as in Table 5, with the lowest *g*-values > 2.0 which is consistent with the $d_{x^2-y^2}$ ground state, while the EPR spectrum of complex **8** is axial with $g_\perp = 2.185$ and $g_\parallel = 2.005$, consistent with a d_{z^2} ground state for the approximately trigonal bipyramidal stereochemistry of the CuN_4N' chromophore present, $g_\perp \gg g_\parallel > 2.0$.

4. Conclusions

The present report describes the preparation, crystal structure determination, spectroscopic properties and structural pathway of the five-coordinate copper(II) complexes with pseudohalide ligand, NCO^-. The structure of the $[Cu(dpyam)_2(NCO)]^+$ cations all involve a five-coordinate CuN_4N' chromophore with TBDSBP in **1**–**5** and **9** ($\tau = 0.09$–0.31, respectively). Complexes **6** and **7** exhibit an intermediate five-coordinate, slightly distorted toward TBP ($\tau = 0.53$ and 0.54, respectively). The complex **8** shows SBPDTB with a τ value of 0.76. The detailed structure of a five-coordinate copper(II) complex is dependent upon the type of counter anion in the lattice, due to the 'Plasticity Effect', showing how the same complex in different crystal modifications, can have slightly different structures. In the present work the 'Plasticity Effect' has been considerably extended by reference to cation distortion isomers, in which the structures of a given cation is modified in the presence of different counter anions. The relatively small structural

differences produced have been correlated to suggest the existence of a continuous 'Structural Pathway', connecting the extreme structures, with the individual structures linked by a soft mode of vibration. All data points are found in the $-A + B$ section of the graph, except a data point **1**, which is closed to RSBP. It is noticeable that the α_1 and α_3 of **1** are greater than the usual values of α_1 and α_3 usually found for RSBP complexes, leading to this deviation. Moreover, this structure is the most extreme RSBP known of five-coordinate with dpyam ligand.

In our investigations on organophosphonates [28–31], we were interested in a polymerizable phosphorus based system with alkene/alkyne substituents at two ends that would ultimately lead to polymer-terminated phosphonic acids as the end products. For this purpose, we realized that the easily synthesized and inexpensive precursor *cis*-$[ClP(\mu\text{-}N\text{-}t\text{-}Bu)]_2$ (**1**) with two reactive P–Cl ends is an attractive precursor. In this paper, we report that the products of *cis*-**1** with various propargylic alcohols undergo facile rearrangement to lead to bis-allenes incorporated into a cyclic $[NP]_2$ skeleton. We also describe the first examples of the *cis*- and the *trans*-allenic cyclophosph(V)azane [or bis-(allenyl)phosphoramidates] isomers bearing the same substituents that are characterized by X-ray crystallography. The resulting compounds, we believe, are useful precursors for polymerization reactions. In order to probe this reaction further, the reaction of **1** with the Baylis–Hillman alcohol $PhCH(OH)C(CO_2Me)=CH_2$ [32] is also examined and the results are compared with those utilizing propargylic alcohols.

2. Experimental

Chemicals were procured from Aldrich or local manufacturers; they were purified when required according to standard procedures [33]. All reactions, unless stated otherwise, were performed in a dry nitrogen atmosphere. ^1H, ^{13}C and $^{31}P\{H\}$ NMR spectra were recorded using a 200 or a 400 MHz spectrometer in $CDCl_3$ (unless stated otherwise) with shifts referenced to $SiMe_4$ ($\delta = 0$) or 85% H_3PO_4 ($\delta = 0$). Infrared spectra were recorded on a JASCO FT/IR 5300 FT-IR spectrometer. Melting points were determined by using a local hot-stage melting point apparatus and are uncorrected. Microanalyses were performed using a Thermo Finnigan EA1112 analyzer.

The precursor $[ClP(\mu\text{-}N\text{-}t\text{-}Bu)]_2$ (**1**) was prepared using a literature procedure [34].

2.1. Synthesis of allenylphosphoramidates $[RR'C{=}C{=}CHP(O)(\mu\text{-}N\text{-}t\text{-}Bu)]_2$ (9–11)

2.1.1. General procedure

To a solution of **1** (2.04 g, 7.4 mmol) in dry THF (30 mL) was added triethylamine (1.49 g, 14.8 mmol) at 0 °C, the mixture stirred for 5 min and then the required substituted propargyl alcohol $HC{\equiv}CCR'R''(OH)$ (14.8 mmol) was added at 0 °C. The reaction mixture was stirred for 3 h at room temperature and the formed triethylamine hydrochloride was filtered off. The filtrate was heated under reflux for 15–18 h and the solvent removed *in vacuo*. Compound **9** was purified by crystallization from THF. The geometrical isomers of **10** or **11** were separated using column chromatography (15% ethyl acetate in hexane).

2.1.2. *cis*-$[H_2C{=}C{=}CHP(O)(\mu\text{-}N\text{-}t\text{-}Bu)]_2$ (9)

Yield: 1.76 g (75%). Mp: 159–161 °C. IR (KBr, cm^{-1}): 3059, 2971, 1962, 1937, 1464, 1370, 1256, 1086. ^1H NMR (400 MHz, $CDCl_3$): δ 1.48 (s, 18H, *t*-Bu–*H*), 5.09–5.14 (m, 4H, C=CH_2), 5.45–5.50 (m, 2H, PC*H*). ^{13}C NMR (50 MHz, $CDCl_3$): δ 30.9 (s, $C(CH_3)_3$), 55.5 (s, $C(CH_3)_3$), 76.8 (d, $^3J \sim 8.5$ Hz, C=*C*H_2), 85.0 (dd, $^1J(P\text{–}C) \sim 161.9$ Hz, $^3J(P\text{–}C) = 6.1$ Hz P*C*), 215.9 (s, PC=*C*). ^{31}P NMR (160 MHz, $CDCl_3$): δ 2.5. *Anal.* Calc. for $C_{14}H_{24}N_2O_2P_2$: C, 53.5; H, 7.7; N, 8.9. Found: C, 53.7; H, 7.7; N, 8.9. X-ray structural analysis was performed for this sample.

Analogous reaction of **1** with the alcohols $HC{\equiv}CCH(Me)(OH)$ and $HC{\equiv}CC(Ph)(Me)(OH)$ also gave essentially a single product ascribable to the *cis*-isomer

in each case [δ(P) 3.1 and 2.4 respectively] but we did not make attempts to isolate them.

*2.1.3. cis-[Me_2C=C=CHP(O)(μ-N-t-Bu)]$_2$ (**10a**)*

Yield: 1.65 g (60%). Mp: 160–164 °C. IR (KBr, cm^{-1}): 2971, 1960, 1750, 1373, 1260, 1225, 1088. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.43 and 1.44 (2s, 18H, *t*-Bu–*H*), 1.78 (m, 12H, C=C(CH_3)$_2$), 5.25 (br m, 2H, PC*H*). ^{13}C NMR (50 MHz, $CDCl_3$): δ 18.8 (s, C=C(*C*H$_3$)$_2$), 31.1 (s, NC(*C*H$_3$)$_3$), 55.2 (s, N*C*(CH$_3$)$_3$), 83.5 (dd, ^1J(P–C) $\sim$ 163.8 Hz, ^3J(P–C) = 7.3 Hz P*C*), 97.8 (dd $\rightarrow$ t, $^{3,5}J \sim 8.5$ Hz, C=*C*Me$_2$), 211.8 (s, PC=*C*). ^{31}P NMR (160 MHz, $CDCl_3$): δ 4.9. *Anal.* Calc. for $C_{18}H_{32}N_2O_2P_2$: C, 58.4; H, 8.7; N, 7.6. Found: C, 58.4; H, 8.7; N, 7.6. X-ray structural analysis was performed for this sample.

*2.1.4. trans-[Me_2C=C=CHP(O)(μ-N-t-Bu)]$_2$ (**10b**)*

Yield: 0.41 g (15%). Mp: 212–216 °C. IR (KBr, cm^{-1}): 2971, 1958, 1474, 1354, 1262, 1082, 912. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.39, 1.41 and 1.44 (3s, 18H, *t*-Bu–*H*), 1.77–1.80 (m, 12H, C=C(CH_3)$_2$), 5.46 (br, 2H, PC*H*). ^{13}C NMR (50 MHz, $CDCl_3$): δ 18.8 (s, C=C(*C*H$_3$)$_3$), 30.9 and 32.0 (2s in 2:1 ratio, NC(*C*H$_3$)$_3$), 54.8 (s, N*C*(CH$_3$)$_3$), 85.5 (d, ^1J(P–C) = 156.5 Hz, P*C*), 98.0 (s, C=*C*Me$_2$), 212.5 (s, PC=*C*). ^{31}P NMR (160 MHz, $CDCl_3$): δ 9.2. *Anal.* Calc. for $C_{18}H_{32}N_2O_2P_2$: C, 58.4; H, 8.7; N, 7.6. Found: C, 58.3; H, 8.7; N, 7.8. X-ray structural analysis was performed for this sample.

*2.1.5. cis-[(Me)(Et)C=C=CHP(O)(μ-N-t -Bu)]$_2$ (**11a**)*

Yield: 1.17 g (40%). Mp: 148–152 °C. IR (KBr, cm^{-1}): 2967, 1958, 1458, 1368, 1260, 1225. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.07 (t, 6H, ^3J(H–H) $\sim$ 7.3 Hz, CH$_2$CH_3) 1.45 (s, 18H, *t*-Bu–*H*), 1.76–1.79 (m, 6H, C=CH_3), 2.08 (br m, 4H, CH_2CH$_3$), 5.29 (br, 2H, PC*H*). ^{13}C NMR (50 MHz, $CDCl_3$): δ 12.0 (s, CH$_2$*C*H$_3$), 17.3 (s, *C*H$_2$CH$_3$), 26.4 (s, C=*C*H$_3$), 31.1 (s, NC(*C*H$_3$)$_3$), 55.2 (s, N*C*(CH$_3$)$_3$), 85.2 (dd, ^1J(P–C) $\sim$ 162.6 Hz, ^3J(P–C) = 7.3 Hz, P*C*), 104.1 (d, $J \sim 8.5$ Hz, C=*C*(Me)(Et)), 211.8 (s, PC=*C*). ^{31}P NMR (160 MHz, $CDCl_3$): δ 4.6. *Anal.* Calc. for $C_{20}H_{36}N_2O_2P_2$: C, 60.3; H, 9.1; N, 7.0. Found: C, 60.3; H, 9.1; N, 7.2.

*2.1.6. trans-[(Me)(Et)C=C=CHP(O)(μ-N-t-Bu)]$_2$ (**11b**)*

This was crystallized from dichloromethane. Yield: 0.44 g (15%). Mp: 198–200 °C. IR (KBr, cm^{-1}): 2969, 1950, 1456, 1368, 1262, 1235. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.09 (t, 6H, ^3J(H–H) $\sim$ 7.3 Hz, CH$_2$CH_3) 1.43 (s, 18H, *t*-Bu–*H*), 1.80 (s, 6H, C=CH_3), 2.12 (br m, 4H, CH_2CH$_3$), 5.58 (br, 2H, PC*H*). ^{13}C NMR (50 MHz, $CDCl_3$): δ 12.1 (s, CH$_2$*C*H$_3$), 17.2 (s, *C*H$_2$CH$_3$), 26.4 (s, C=*C*H$_3$), 30.9 (br s, NC(*C*H$_3$)$_3$), 53.4 and 54.7 (2s, N*C*(CH$_3$)$_3$), 87.1 (d, ^1J(P–C) = 157.7 Hz, P*C*), 104.1 (s, C=*C*(Me)(Et)), 212.1 (s, PC=*C*). ^{31}P NMR (160 MHz, $CDCl_3$): δ 9.0. *Anal.* Calc. for $C_{20}H_{36}N_2O_2P_2$: C, 60.3; H, 9.1; N, 7.0. Found: C, 60.3; H, 9.2; N, 7.0.

2.1.7. [((Ph)HC=C(CO_2Me)-CH_2)(O)P-μ-N-t-Bu]$_2$ · H_2O (13 · H_2O)

This compound was prepared by treating **1** (2.20 g, 8 mmol) in dry THF (30 mL) with the Baylis–Hillman alcohol PhCH(OH)C(CO_2Me)=CH_2 (3.08 g, 16 mmol) in the presence of Et_3N (1.70 g, 16.8 mmol) at 0 °C. The reaction mixture was stirred for 5 h at room temperature and the formed triethylamine hydrochloride was filtered off. The solvent was removed *in vacuo* and the reaction mixture heated at 150 °C for 20 min to afford **13** in quantitative yields [^{31}P NMR]; it was purified by passing through a short silica-gel column (eluent: hexane–ethyl acetate). Crystallization (dichloromethane + hexane) in open air led to **13** · H_2O. Yield: 4.70 g (quantitative). Mp: 117–119 °C. IR (KBr, cm^{-1}): 2973, 1701, 1451, 1372, 1267, 1065. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.29, 1.30 (2s, 18H, *t*-Bu–*H*), 3.64 (d, 4H, ^2J(P–H) = 18.0 Hz, PCH_2), 3.85, 3.86 (2s, 6H, 2OCH_3), 7.36–7.80 (m, 12H, 2C=C*H* + Ar–*H*). This sample showed a peak at $\delta \sim 1.67$ (close to water of $CDCl_3$) in addition to the other peaks. ^{13}C NMR (100 MHz, $CDCl_3$): 30.8, 30.8$_8$ and 30.9$_2$ (3s, NC(*C*H$_3$)$_3$), 32.8 (dd, ^1J(P–C) = 108.4 Hz, ^3J(P–C) = 6.6 Hz, P*C*), 52.4 (s, COO*C*H$_3$), 56.1 (s, N*C*(CH$_3$)$_3$), 124.8 (d, ^2J(P–C) = 11.6 Hz, PC*C*), 128.7, 129.1, 129.6, 134.8 (Ar*C*), 141.3 (d, ^3J(P–C) = 12.1 Hz, C=*C*(Ph)), 168.2 (s, *C*OOCH$_3$). ^{31}P NMR (160 MHz, $CDCl_3$): δ 20.8. *Anal.* Calc. for $C_{30}H_{42}N_2O_7P_2$: C, 59.6; H, 7.0; N, 4.6. Found: C, 59.6; H, 7.0; N, 4.6. X-ray structural analysis was performed on this sample.

2.2. X-ray crystallography

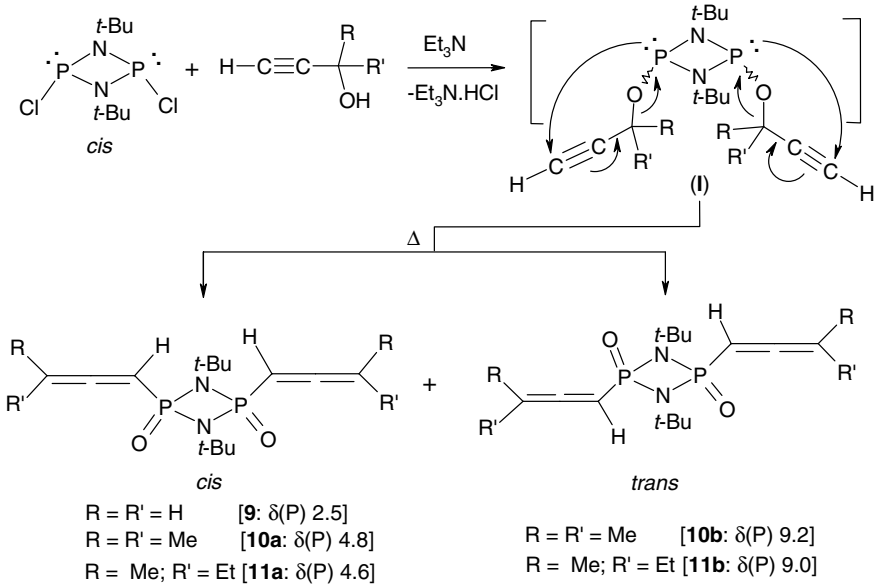
Single crystal X-ray data were collected on an Enraf-Nonius MACH3 or on a Bruker AXS-SMART diffractometer, using Mo Kα ($\lambda = 0.71073$ Å) radiation. The structures were solved by direct methods and refined by full-matrix least squares method using standard procedures [35]. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were fixed by geometry using a riding model except for the solvent molecules. The terminal carbon atoms of the *t*-butyl groups showed higher thermals than the N–C carbon in these systems. Crystallographic data as .CIF files are deposited (CCDC Nos. 618526–618529).

2.2.1. Crystal data

Compound **9**: $C_{14}H_{24}N_2O_2P_2$, $M = 314.29$, orthorhombic, space group *Pnca*, $a = 11.556(2)$, $b = 17.406(4)$, $c = 18.298(4)$ Å, $V = 3680.5(13)$ Å^3, $Z = 8$, $\mu = 0.239$ mm^{-1}, data/restraints/parameters: 3240/0/203, R indices ($I > 2\sigma(I)$): $R_1 = 0.0493$, wR_2 (all data) = 0.1528.

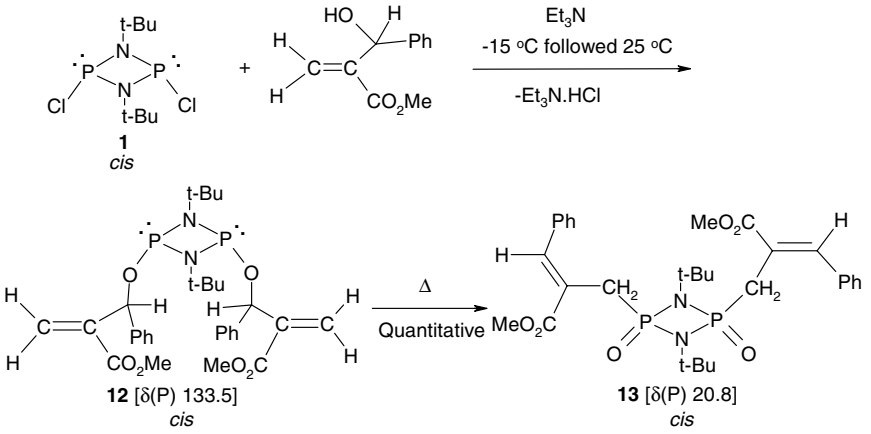
Compound **10a**: $C_{18}H_{32}N_2O_2P_2$, $M =$ 370.40, monoclinic, space group $P2_1/c$, $a = 10.1983(13)$, $b = 10.8569(14)$, $c = 21.244(3)$ Å, $\beta = 100.984(2)$, $V = 2309.1(5)$ Å^3, $Z = 4$, $\mu = 0.199$ mm^{-1}, data/restraints/parameters: 4058/0/227, R indices ($I > 2\sigma(I)$): $R_1 = 0.0618$, wR_2 (all data) = 0.2020.

Compound **10b**: $C_{18}H_{32}N_2O_2P_2$, $M = 370.40$, triclinic, space group $P\bar{1}$, $a = 7.5400(15)$, $b = 8.9400(18)$, $c = 9.4900(19)$ Å, $\alpha = 62.84(3)°$, $\beta = 74.57(3)°$, $\gamma = 89.33(3)°$, $V = 544.1(3)$ Å^3, $Z = 1$, $\mu = 0.212$ mm^{-1}, data/restraints/parameters: 1922/0/114, R indices ($I > 2\sigma(I)$): $R_1 = 0.0652$, wR_2 (all data) = 0.1922.



Compound **13** · H_2O: $C_{30}H_{42}N_2O_7P_2$, $M = 604.60$, triclinic, space group $P\bar{1}$, $a = 8.786(2)$, $b = 12.570(3)$, $c = 15.540(3)$ Å, $\alpha = 95.41(3)°$, $\beta = 97.33(3)°$, $\gamma = 107.32(3)°$, $V = 1609.1(6)$ Å^3, $Z = 2$, $\mu = 0.181$ mm^{-1}, data/restraints/parameters: 5667/3/403, R indices ($I > 2\sigma(I)$): $R_1 = 0.0591$, wR_2 (all data) = 0.1630.

3. Results and discussion

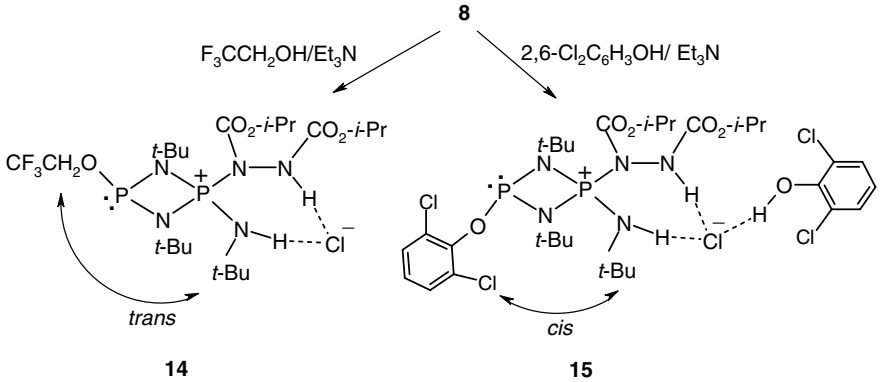


3.1. Synthesis, spectra and mode of formation

Compounds **9**, **10a**,**b** and **11a**,**b** are synthesized by treating *cis*-[ClP(μ-*N*-*t*-Bu)]$_2$ (**1**) with the corresponding propargylic alcohol in the presence of triethylamine as shown in Scheme 1. The initially formed (alkoxy)cyclodi*phosph(III)*azanes **I** undergo thermal rearrangement to give rise to the (allenyl)cyclodi*phosph(V)*azane products. The reaction using the unsubstituted propargylic alcohol HC≡CCH$_2$OH gives essentially the *cis*-isomer **9** and only traces of the *trans*-isomer. In contrast, substituted propargyl alcohols HC≡CC(Me)(R)OH (R = Me, Et) afforded both *cis*- and *trans*-isomeric products **10a**,**b** and**11a**,**b** in decent yields. These two isomers are readily distinguishable by their ^{31}P NMR chemical shifts with the *trans*-isomer appearing downfield by ~4.5 ppm. Although this feature is similar to that of P(III) derivatives ($\Delta\delta \sim 52$ ppm) [16], the $\Delta\delta$ values between the two isomers are smaller for **10a**,**b** and **11a**,**b**. The ^{13}C NMR spectra show a characteristic doublet ($^1J = 156$–164 Hz) for the P–C carbon at δ 84–87. The signal for the *trans*-isomer appears at lower field with a lower ^1J(P–C) value compared to the *cis*-isomer. The IR stretch for the allenic moiety appears at 1950–1960 cm^{-1} with that for the *trans*-isomer appearing at slightly lower wave number.

Since the starting material **1** has a *cis*-disposition of the two P–Cl groups, one may expect the reaction to lead to only *cis*-isomer of the P(III) alkoxide **I** as long as the phosphazane ring remains intact during the reaction. Although, as briefly pointed out in the Introduction, this may not be the case when lithium or sodium alkoxides/aryloxides are used, it is more likely when alcohol/triethylamine system is used [5]. If only *cis*-P(III) alkoxide is formed, it may be expected that rearrangement to the allenyl phosphoramidates **9**–**11** leads only to the corresponding *cis*-isomer. We made an attempt to identify the P(III) intermediate **I** in the case of **10a**,**b** by performing the reaction at −15 °C (ca. ~1 h) in THF and recording the ^{31}P NMR spectrum immediately (<1 h). However, the reaction mixture showed essentially the P(V) products **10a**,**b**, indicating that the rearrangement is very facile under these conditions. Even the partially rearranged products with P(III)–*N*–P(V) system were not observed. The *cis*-compound **10a** was stable up to 180 °C/2 h and no perceptible conversion to the *trans*-form was noticed [^{31}P NMR]. Also, the *trans*-P(V) compound **10b** did not appear to convert to the *cis*-form upon heating. Thus, once formed, **10a** and **10b** do not isomerize. We also tried to see if use of the lithium salt of the corresponding propargyl alcohol could increase the yield of the *trans*-isomer **10b**. Although the reaction mixture showed more of the *trans*-product, there were many other peaks that hampered a complete analysis. Preliminary theoretical calculations (using coordinates from X-ray structure and optimizing the geometry) done at B3LYP/6-31G** level suggest that the *cis*-isomer **10a** is

Scheme 1.



Scheme 2.

marginally more stable than the *trans*-isomer **10b** by ~6.5 kJmol^{-1} in the gas phase.

Since it is known that allyloxy products of P(III) derivatives also can rearrange to their respective P(V) phosphonates [28,36], we wanted to check the feasibility of identifying the intermediates in these cases for comparison. Thus we treated the Baylis–Hillman alcohol (a substituted allyl alcohol) $PhCH(OH)C(CO_2Me)=CH_2$ with $[ClP(\mu\text{-}N\text{-}t\text{-}Bu)]_2$ (**1**) (Scheme 2). In this case, we could observe mainly the *cis*-alkoxy P(III) product **12** *prior to rearrangement* by ^{31}P NMR [δ(P) 133.5]. The assignment of a *cis*-structure to **12** is based upon comparison of its δ(P) value with those available in the literature for other compounds [5,16]. The same mixture after a day at 25 °C showed a complete absence of **12** and the peak corresponding to **13** started developing [δ(P) 20.8]. Upon heating the original reaction mixture at 150 °C for 20 min, only the *cis*-isomer **13** is formed quantitatively. Interestingly, in the initial reaction mixture, there is a P(V) product exhibiting two close peaks at δ(P) 24.3 and 24.4 ascribable to the *trans*-isomer of **13** (further isomerism is possible at the site of the C=C bond which may be the reason for two peaks with close δ(P) values). Another peak at $\delta \sim 101.6$ is unassigned. None of these intermediates is seen after heating the original reaction mixture at 150 °C.

As regards *cis–trans*-isomerism in other types of cyclodiphosph(V)azanes, X-ray structures of *cis*- and *trans*-$[RNHP(S)NR]_2$ are reported but both the isomers with the same R group are not seen [21]. In these cases, the reaction chemistry is different and the compounds were obtained by sulfur-oxidation of the respective aminocyclodiphosph(III)azanes. In the reaction of compound **8** with 2,2,2-trifluoroethanol and 2,6-dichlorophenol in the presence of Et_3N, we have previously reported that the P(III)–*N*–P(V) products obtained have different stereochemistry [20,37]. While the former gave *trans*-product **14**, the latter afforded the *cis*-product **15**. This feature reveals that the incoming nucleophile also has a role to play in determining the geometry of the final products. The reactive site in these cases is the same P(III)–Cl bond in **8** which is *cis* to the P=N(*t*-Bu) group at the other phosphorus. Based on these observations and the fact that we did not observe the isomerization of pure *cis* (**10a**) or *trans* (**10b**) allenyl compounds, we think that the formation of *cis*- and *trans*-isomeric pairs **10a**,**b** and **11a**,**b** takes place via thermal rearrangement of *cis*- and *trans*-P(III) alkoxy products of type **I**. In the formation of **13** that contains sterically more demanding substituents, however, it is possible that the rearranged P(V) *trans*-product/s [δ(P) 24.3, 24.4] isomerize to the *cis*-form [δ(P) 20.8]. This proposition needs further confirmation since there is also a possibility of monomer (phosphazene)-dimer (diphosphazane) equilibrium in these systems [38]:

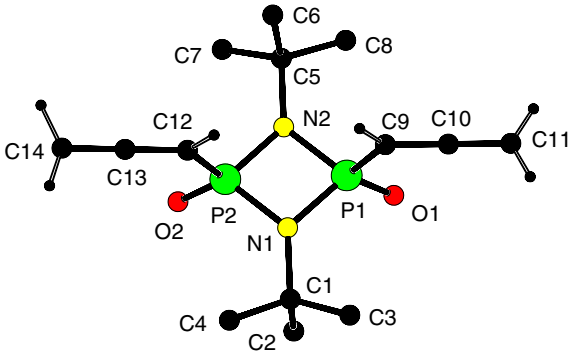


Fig. 1. Molecular structure of **9**.

3.2. X-ray structures of *9*, *10a,b* and *13* · H_2O

The molecular structures of **9**, **10a** and **10b** are shown in Figs. 1 and 2. Selected geometrical parameters are given in Table 1. Since phosphorus atoms are chemically equivalent, the endocyclic P–N distances to a particular phosphorus atom are nearly equal. These P–N distances [1.660–1.680 Å] are clearly shorter than those found for several other cyclodiphosph(III)azanes (1.71–1.74 Å) [39] or the apical P–N bonds in pentacoordinate phosphoranes [40]. Although the allenic C=C bonds in **9** appear to be slightly shorter than those found in **10a**,**b**, the variations are within the three times the esd's and hence a definite conclusion cannot be given. The P–C bond distance in all the three compounds is in the expected range [41]. The ring nitrogen atoms are essentially planar with the sum of the bond angles at nitrogen in the range 356–360°. This feature is unlike that in the P(III) compound $Et_2C[CH_2OP(\mu\text{-}N\text{-}t\text{-}Bu)_2PNH\text{-}t\text{-}Bu]_2$ wherein the ring nitrogen atoms are non-planar [$\sum N = 347–348°$] [39]. The $[NP]_2$ rings in all the three compounds are essentially planar with the maximum deviation of 0.02 Å found for **10a**.

The *cis*-stereochemistry in **13** · H_2O is also clearly revealed by X-ray crystallography (Fig. 3). The P–N distances are similar to those observed in **9** and **10a**,**b**, but the P–C bonds (mean 1.815 Å) are slightly longer. The $[NP]_2$ ring is slightly distorted with the mean deviation of the fitted atoms from the mean plane of the ring being ~0.03 Å. The ring nitrogen atoms are more pyramidal [$\sum N(1) = 358.3°$; $\sum N(2) = 352.2°$] than those in **9** and **10a**,**b**. The solvate water molecule is hydrogen bonded to the phosphoryl oxygen atoms, but since this was not the

interest in the present study, we have not probed this aspect further.[1]

4. Summary and outlook

What we have shown here is that both the *cis*- and *trans*-forms of allenylphosphoramidates based on a cyclodiphosph(V)azane skeleton can be readily obtained by treating the well-known precursor $[ClP(\mu\text{-}N\text{-}t\text{-}Bu)]_2$ (**1**) with substituted propagylic alcohols in the presence of triethylamine. Although the precursor **1** has a *cis*-geometry, both the *cis* and *trans* rearranged products are obtained in many cases. X-ray structural characterization for both the isomers from a single system has been achieved for the first time. These compounds, by means of the allenyl residues at two ends, have the potential to be used for further reactions including polymerization. The derivative **13** could also be a good substrate for the Horner–Wadsworth–Emmons reaction [36].

second- and third-order nonlinear optical properties in solution, high thermal stability, mesogenic behavior, Langmuir–Blodgett film formation, semiconducting properties, etc. [28–33].

There are three principal synthetic strategies for preparing unsymmetrical phthalocyanines made up of two different phthalonitrile units in 3:1 ratio: the statistical condensation route, the polymer support route and the subphthalocyanine route [34–37]. The most common method is the statistical condensation of two differently substituted dinitriles or diiminoisoindolines followed by chromatographic separation of the resulting mixture [38–40].

In contrast to their tetra-crowned analogs, unsymmetrical crown-ether phthalocyanine derivatives have been the subject of only few studies [41–45]. Mono-functional phthalocyanines with only one reactive functional group such as one nitro, sulfo, amino, hydroxyl or carboxyl group is important intermediate for the synthesis of many new mononuclear, binuclear and polynuclear phthalocyanines [46–48].

The electrochemistry of these complexes has attracted increasing attention to settle their usage in various areas such as photosensitization, gas sensor, catalysis, photovoltaic cell, and electrochromic display. These fundamental usages of the complexes are arisen from their superior electron transfer capacities [1,49–55]. The electron transfer abilities of phthalocyanines depend on the kind and the number of the substituents and are due to the interaction between the phthalocyanine ring and the metal center which is influenced by the conjugated π-electron current of the phthalocyanine ring. Determination of electron transfer properties of a compound is a primary activity for the technological application of the materials. An electrochemical reaction involves not only electron charge transfer, but also involves various processes such as adsorption of electroactive species on the electrode, aggregation of the species, and the contribution of coupled chemical reactions. Especially particular electrochemical processes are accurately required in the development of functional materials [56–58].

In the present paper, the preparation, characterization and spectral properties of unsymmetrical metallophthalocyanines with three crown-ether units and one nitro side group are described. Electrochemical analysis of CuPc was also carried out by cyclic voltammetry techniques and differential pulse voltammetry.

2. Experimental

IR spectra were recorded on a Perkin Elmer Spectrum One FT-IR (ATR sampling accessory) spectrophotometer, electronic spectra on a Unicam UV2 spectrophotometer. ^{1}H NMR spectra were recorded on a Bruker 250 MHz spectrometer using TMS as internal reference. Mass spectra were performed on Ultima Fourier transform and Varian 711 mass spectrometer. All reagents and solvents were dried and purified as described by Perrin and Armarego [59]. The homogeneity of the products was tested in each step by TLC. 4-Nitrophthalonitrile (**1**) [60] and 1-{[(benzo-15-crown-5)-4′-yl]oxy}phthalonitrile (**2**) [27] were synthesized according to published methods, by a multistep reaction sequence.

All electrochemical techniques were carried out with a Princeton Applied Research Model Versastat II potentiostat/galvanostat controlled by an external PC utilizing a three-electrode configuration at 25 °C. The working electrode was a Pt plate with an area of 0.10 cm^2. The surface of the working electrode was polished with a H_2O suspension of Al_2O_3 before each run. The last polishing was done with a particle size of 50 nm. A Pt wire served as the counter electrode. A saturated calomel electrode (SCE) was employed as the reference electrode and separated from the bulk of the solution by a double bridge containing saturated KCl adjacent to SCE and solvent and carrier adjacent to the solution. Ferrocene/ferrocenium internal reference electrode was used and all potential were given with respect to Fc/Fc^+ couple. Electrochemical grade tetrabutylammoniumperchlorate (*TBAP*) in extra pure *DCM* was employed as the supporting electrolyte at a concentration of 0.1 mol dm^{-3}. High purity N_2 was used for deaeration and to maintain a nitrogen blanket for at least 15 min prior to each run. For CPC studies, a Pt gauze working electrode (10.5 cm^2 surface areas) and a Pt wire counter electrode separated with a double bridge were used.

2.1. 2-Nitro-9,16,23-tri{[(benzo-15-crown-5)-4′-yl]oxy}-phthalocyaninatozinc(II) (3)

A mixture of 0.084 g of **1** (0.48 mmol), 0.59 g of **2** (1.44 mmol), 0.09 g of anhydrous $Zn(CH_3COO)_2$ (0.48 mmol), and 1.5 ml of anhydrous DMF was mixed in a glass tube which was sealed under nitrogen and heated and stirred at 145 °C for 18 h. The dark green mixture was cooled to room temperature and diluted with methanol until the crude product precipitated. The precipitate was filtered off and washed several times with hot ethanol and methanol to remove the by products. The resulting dark colored residue was purified by column chromatography on alumina with $CHCl_3$ as an eluent to give the first fraction of symmetrical crown-ether substituted phthalocyanine and the second fraction consisting largely of **3**. The crude unsymmetrical product was further purified by column chromatography on alumina with $CHCl_3$/MeOH (6:1) as an eluent to give pure product. Yield: 0.10 g, 15%. *Anal.* Calc. for $C_{74}H_{69}N_9O_{20}Zn$: C, 60.47; H, 4.73; N, 8.58. Found: C, 60.21; H, 4.69; N, 8.45%; m.p. > 200 °C. IR, ν (cm^{-1}): 2952–2868 (CH aliph.), 1598, 1505, 1334, 1255–1217(Ar–O–C), 1119–1081(C–O–C), 988, 934, 848 cm^{-1}; ^{1}H NMR ($CDCl_3$): δ: 7.71–7.67 (m, 3H, Ar–H), 7.53–7.49 (m, 9H, Ar–H), 6.82–6.38 (m, 9H, Ar–H), 4.26–3.75 (m, 48H, O–CH_2); UV–Vis λ_{max} (nm) (log ε) in $CHCl_3$: 377 (4.59), 675 (4.87), 696 (4.82).

2.2. 2-Nitro-9,16,23-tri{[(benzo-15-crown-5)-4′-yl]oxy}-phthalocyaninatocupper(II) (4)

A mixture of 0.112 g of **1** (0.64 mmol), 0.79 g of **2** (1.92 mmol), 0.104 g of anhydrous $CuCl_2$ (0.64 mmol), and 2 ml of anhydrous DMF was mixed in a glass tube which was sealed under nitrogen and heated and stirred at 150 °C for 24 h. The dark green mixture was cooled to room temperature and then methanol was added in order to precipitate the product. The residue was filtered off and then washed several times with hot ethanol. The green precipitate was chromatographed on alumina, fist using $CHCl_3$ as eluent to yield the symmetrical phthalocyanine and the desired product was finally collected by elution with $CHCl_3/CH_3OH$ (6:1). Yield: 0.20 g, 22%. *Anal.* Calc. for $C_{74}H_{69}N_9O_{20}Cu$: C, 60.55; H, 4.74; N, 8.59. Found: C, 60.32; H, 4.67; N, 8.28%; m.p. > 200 °C. IR, ν (cm^{-1}): 2926–2862 (CH aliph.), 1725, 1599, 1504, 1454, 1258–1217 (Ar–O–C), 1117–1070 (C–O–C), 986, 939, 826 cm^{-1}; MS(FAB) m/z: 1467 $[M]^+$; UV–Vis λ_{max} (nm) ($\log\varepsilon$) in $CHCl_3$: 338 (4.81), 627 (4.82), 679 (4.83).

2.3. 2-Nitro-9,16,23-tri{[(benzo-15-crown-5)-4′-yl]oxy}-phthalocyaninatocobalt(II) (5)

A mixture of 0.084 g of **1** (0.48 mmol), 0.59 g of **2** (1.44 mmol), 0.066 g of anhydrous $CoCl_2$ (0.48 mmol), and 2 ml of anhydrous DMF was heated and stirred at 140 °C in a sealed glass tube for 32 h under nitrogen. After cooling to room temperature, blue–green suspension was treated with H_2O: methanol (1:1) and centrifuged. The precipitate was washed several times with methanol and dried. The product was isolated on alumina column first with $CHCl_3$ and then with $CHCl_3/CH_3OH$ (6:1) as eluent. Yield: 0.07 g, 10%. *Anal.* Calc. for $C_{74}H_{69}N_9O_{20}Co$: C, 60.74; H, 4.75; N, 8.61. Found: C, 60.43; H, 4.71; N, 8.46%; m.p. > 200 °C. IR, ν (cm^{-1}): 2936–2865 (CH aliph.), 1722, 1597, 1502, 1451, 1267–1218 (Ar–O–C), 1120–1095 (C–O–C), 985, 935, 824 cm^{-1}; MS(FAB) m/z: 1463 $[M]^+$; UV–Vis λ_{max} (nm) ($\log\varepsilon$) in $CHCl_3$: 338 (4.62), 630 (4.26), 678 (4.87).

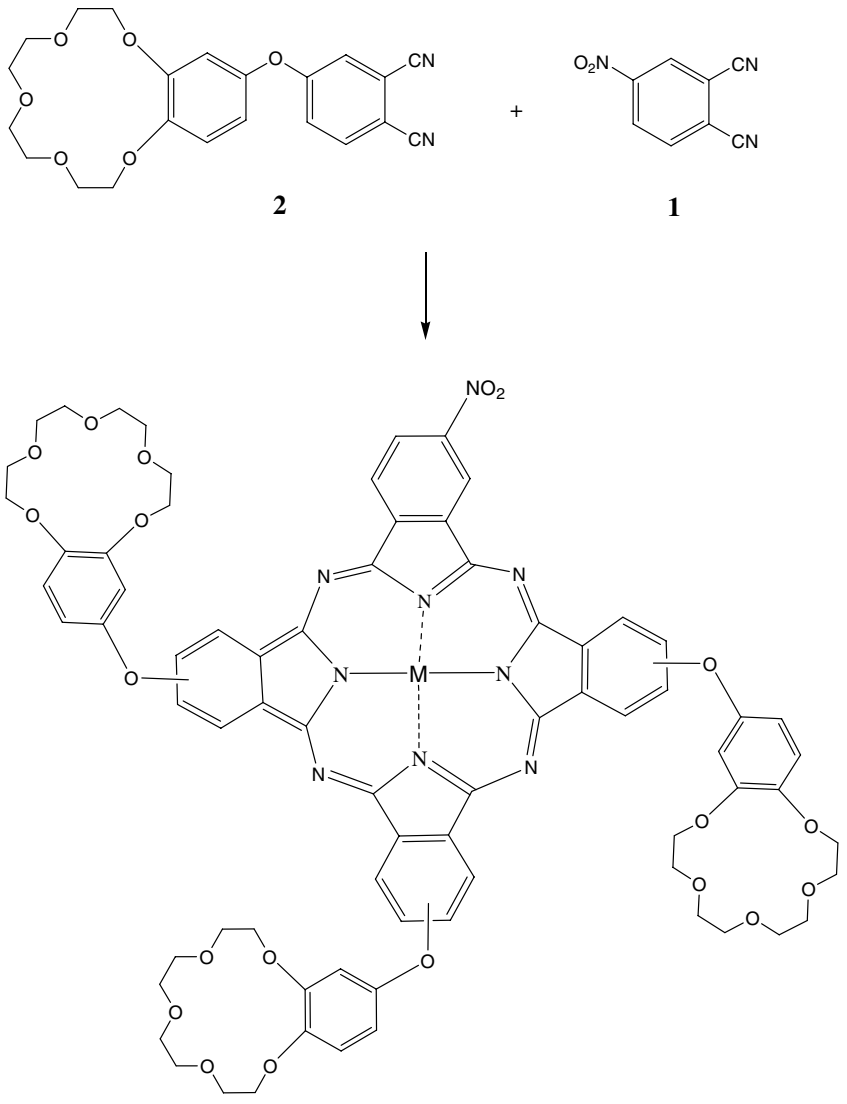
2.4. 2-Nitro-9,16,23-tri{[(benzo-15-crown-5)-4′-yl]oxy}-phthalocyaninatonickel(II) (6)

A mixture of 0.084 g of **1** (0.48 mmol), 0.59 g of **2** (1.44 mmol), 0.061 g of anhydrous $NiCl_2$ (0.48 mmol), and 1.5 ml of anhydrous DMF was mixed in a glass tube which was sealed under nitrogen and heated and stirred at 155 °C for 30 h. The dark green mixture was cooled to room temperature and diluted with methanol until the crude product precipitated. The precipitate was filtered off and washed several times with hot ethanol and methanol to remove unreacted materials. The green product was isolated on alumina column first with $CHCl_3$ and then with $CHCl_3$/MeOH (6:1) as eluent. Yield: 0.04 g, 6%. *Anal.* Calc. for $C_{74}H_{69}N_9O_{20}Ni$: C, 60.75; H, 4.75; N, 8.62. Found: C, 60.39; H, 4.61; N, 8.32%; m.p. > 200 °C. IR, ν (cm^{-1}): 2918–2849 (CH aliph.), 1733, 1599, 1505, 1454, 1258–1218 (Ar–O–C), 1121–1085 (C–O–C), 988, 937, 827 cm^{-1}; ^1H NMR ($CDCl_3$): δ: 7.68–7.64 (m, 3H, Ar–H), 7.51–7.45 (m, 9H, Ar–H), 6.79–6.35 (m, 9H, Ar–H), 4.25–3.73 (m, 48H, O–CH_2); UV–Vis λ_{max} (nm) ($\log\varepsilon$) in $CHCl_3$: 338 (4.56), 624 (4.22), 675 (4.92).

3. Results and discussion

3.1. Synthesis and characterization

Scheme 1 shows the synthesis of the target unsymmetrical phthalocyanines **3**–**6**. The study was based on mixed-condensations involving a 4-nitrophthalonitrile (**1**) and 1-{[(benzo-15-crown-5)-4′-yl]-oxy} phthalonitrile (**2**). Compound **2** was obtained by the base-catalyzed nucleophilic aromatic nitro displacement of 4-nitrophthalonitrile with 4′-hydroxybenzo-15-crown-5 [27]. The reaction was carried out in a single step synthesis by using the K_2CO_3 as the nitro-displacing base at 30 °C in dry DMF under N_2 atmosphere.



Statistical considerations predict that two phthalonitriles A and B, if of the same reactivity, when reacted together in the ratio 3:1 will give a mixture of the symmetric Pc (AAAA), and the desired 3:1 Pc (AAAB) and other cross-condensation products [34,61].

In this work, the phthalocyanines were synthesized by co-cyclotetramerization of three equivalents of **2** and one equivalent of **1** in the presence of the anhydrous metal salts $Zn(CH_3COO)_2$, $CuCl_2$, $CoCl_2$, or $NiCl_2$ in anhydrous DMF. Different molar ratios were used in order to increase the yield of the aimed unsymmetrically substituted phthalocyanines **3**–**6**. However, a 3:1 ratio of the two precursors was found to be the most suitable for dinitriles **1** and **2**.

In work-up procedure after tetramerization reaction between **1** and **2**, the crude products were chromatographed over alumina using $CHCl_3$ as eluent. In all cases the first fraction proved to be the totally symmetrical crown-ether substituted phthalocyanines identified TLC by comparison with authentic samples [27]. The second fraction still contained traces of the symmetrical phthalocyanine together with the products **3**–**6**. This mixture was re-chromatographed using $CHCl_3/CH_3OH$ (6:1) as eluent. The first fraction in this second separation process was still the symmetrical phthalocyanine derivative and it was discarded. The subsequent fraction was identified as the required 3:1 phthalocyanine derivative in **3**–**6**.

The novel compounds were characterized by IR, NMR, Mass, and UV–Vis spectral data together with elemental analysis. Spectral investigations and the results are in accord with the proposed structures.

In the IR spectrum of **3**–**6** the vibrations of the crown ether moieties kept their places, but as expected, the C≡N stretching vibrations of the starting materials **1** and **2** disappeared after phthalocyanine formation. This

	3	4	5	6
M	Zn^{2+}	Cu^{2+}	Co^{2+}	Ni^{2+}

Scheme 1. Synthesis of the unsymmetrical phthalocyanines **3**–**6**.

spectrum exhibits characteristic frequencies at around 2952–2868 (C–H), 1255–1217 (Ar–O–C) and 1119–1081 (C–O–C) cm^{-1}. In the ^1H NMR spectrum of **3**, the aromatic protons of the phthalocyanine core appear at around 7.71–7.49 ppm while those of crown ether moiety appear at 6.82–6.38 ppm. The ether protons of the crown ether group are observed between 4.26 and 3.75 ppm. The IR spectra of **3**–**6** and ^1H NMR spectra of **3** and **6** are very similar.

In addition, the assignment of the product to a 3:1 combination of the reactant was made on the basis of elemental analysis and mass spectral data results confirming the proposed structures. The molecular ion peaks at 1467 and 1463 were obtained by FAB-MS for **4** and **5**.

The electronic spectra of all phthalocyanine derivatives exhibit two main bands a Soret or B band (π–π^*) between 300 and 400 nm and another around 600–700 nm denoted the Q band (π–π^*). The symmetric phthalocyanines with four benzo-15-crown-5 units through oxy-bridges have similar electronic spectra with intense single band for both the Q and B band. In contrast, the electronic spectra on unsymmetrical phthalocyanines **3**–**6**, with three crown ether units and nitro group, clearly show a splitting of the Q band (Fig. 1) [44,46,62–64]. The electronic absorption spectra of **3**–**6** exhibit a split Q band at 675 and 696; 627 and 679; 630 and 678; and 624 and 675 nm, respectively. These differences are consequence of unsymmetry in these molecules which can be described by Gauterman's four-orbital model for the optical spectra of porphyrins and porphyrazines [65].

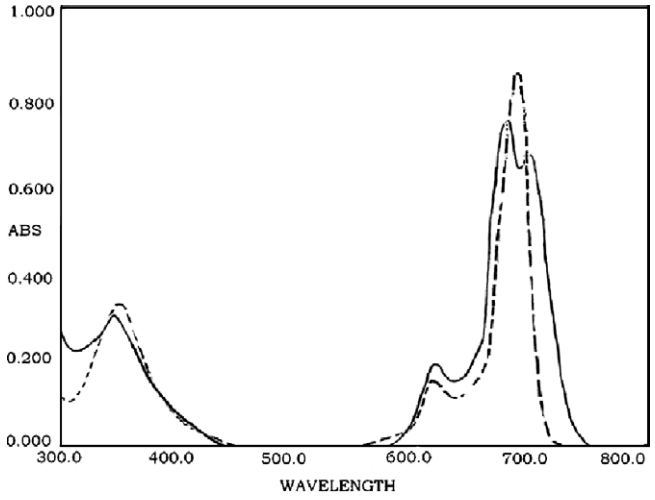


Fig. 1. UV–Vis spectra of symmetrically substituted zinc phthalocyanine with four benzo-15-crown-5 (– – – –) and, the unsymmetrical zinc phthalocyanine **3** (—-) in chloroform solution.

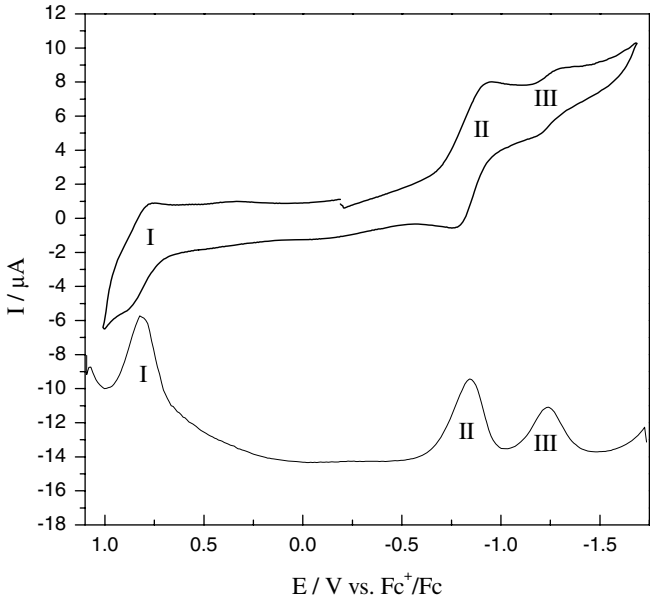

Fig. 2. Cyclic and differential pulse voltammograms of 5.0×10^{-4} mol dm^{-3} of **4** in 0.1 mol dm^{-3} TBAP/DCM electrolyte system at 0.100 mV s^{-1} scan rate.

3.2. Electrochemical measurements

Electrochemical properties of **4** were studied by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) at different scan rates. The CVs of the complex shown in Fig. 1 display two reduction processes at −0.857 and −1.245 V during the cathodic scan and one oxidation process at 0.815 V during the anodic scan vs. Fc/Fc^+ at 0.100 Vs^{-1} scan rate with in the available potential range of TBAP/DCM solvent system. DPVs support the redox processes recorded with CV. The reduction and oxidation behavior of metallophthalocyanine derivatives is due to the interaction between the phthalocyanine ring and the central metal ions. If the transition metal ion concerned has no accessible d orbital levels lying within the $1a_{1u}$ (HOMO)-$1e_g$ (LUMO) gap of a phthalocyanine species, then its redox chemistry will appear very like that of redox inactive metallophthalocyanines. The copper group behaves in this fashion, with the Cu(II) central ion being unchanged as the CuPc unit is either oxidized or reduced [1,56–58]. These studies clearly point out that all of these processes could be ascribed to the phthalocyanine ring electron transfer reactions. According to these studies the redox processes of **4** recorded in this study are as shown in the following equation:

$$[\mathrm{Cu(II)Pc}(-1)]^{+} \underset{0.815\ \mathrm{V}}{\overset{e^-}{\Longleftrightarrow}} [\mathrm{Cu(II)Pc}(-2)] \underset{-0.857\ \mathrm{V}}{\overset{e^-}{\Longleftrightarrow}} [\mathrm{Cu(II)Pc}(-3)]^{1-} \underset{-1.245\ \mathrm{V}}{\overset{e^-}{\Longleftrightarrow}} [\mathrm{Cu(II)Pc}(-4)]^{2-} \quad (1)$$

The voltammogram of **4** carrying three benzo-15-crown-5 units and one nitro is compared with the voltammogram of ZnPc carrying four benzo-15-crown-5 units, studied in our previous study [27]. The results clearly show that substitution of the electron withdrawing nitro group instead of one of the four benzo-15-crown-5 units shifts the electrochemical processes approximately 200 mV to the positive potentials. All redox couples labeled as I, II, and III in Fig. 2 show quasi-reversible peak character which have ΔE_p of 96, 115, and 90 mV at 0.100 Vs^{-1} scan rate and increases with increasing scan rates. Constant values of $I_p/v^{1/2}$ suggest diffusion-controlled electron transfer mechanism for all redox processes. The ratios of I_{pc}/I_{pa} for all processes are approximately unity and do not considerably vary with the scan rates, supporting diffusion-controlled mass transfer mechanism of the complex. The peak-to-peak separation of the processes II and III (388 mV) is generally common for metallophthalocyanines containing electrochemically inactive metal center. The difference between the average value of the half-wave potentials of the first reduction (−0.857 V) and first oxidation (0.815 V) gives the measure of gap (1.672 V) between the HOMO and LUMO for the complex, characterizing the phthalocyanines carrying electrochemically inactive metal center [1,27,40,56–58,66–68]. In conclusion, cyclic voltammetric and differential pulse measurements showed that **4** give three ligand-centered redox processes indicating quasi-reversible peak behaviors. Peak-to-peak separation and HOMO–LUMO gap of the complex are in harmony with the common phthalocyanine complexes.

3

Probably the bidentate nature of the three ligands in systems **1**–**3** and the bigger bite in the case of **1** than diphenylphosphinomethane (dppm) are responsible for the enhanced stability. The good reactivity in the case of **1** and **3** originates from the formation of four membered chelate rings

(1)

The results of these investigations are given in this paper.

2. Experimental

The C and H analyses were carried out with a Perkin–Elmer elemental analyzer 240 C. The ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra were recorded on a Bruker Spectrospin DPX-300 NMR spectrometer at 300.13 and 75.47 MHz, respectively. ^{13}C CPMAS spectra were recorded on a Bruker DSX-300 NMR spectrometer at 75.47 MHz. A flame atomic absorption spectrometer (FAAS) of the Perkin–Elmer Instruments, Shelton, USA, model Analyst 100 equipped with an air–acetylene flame was used for Pd determination.

2.1. Synthesis of aminopropyl silica gel (APSG)

Silica gel was boiled with 5 N HCl for 8 h, filtered, washed with water until free from acid, dried at 110 °C for 12 h and degassed with nitrogen at 100 °C under *vacuo*. The resulting activated silica gel (10.0 g) was mixed with (3-aminopropyl)triethoxysilane (20.0 cm^3) in 150 ml of dry *p*-xylene under dry dinitrogen atmosphere. The mixture was refluxed for 72 h, after which the resulting aminopropyl silica gel (APSG) was filtered. It was washed successively with *p*-xylene (4×50 cm^3), ethanol (4×50 cm^3) and acetone (3×50 cm^3). The APSG was dried in *vacuo* at 80–100 °C and stored under inert conditions. N, 4.42%. IR (KBr cm^{-1}) 3463 (NH stretching), 1644 (CH_2), 1588 (NH bending); ^{13}C CP-MAS NMR (δ, ppm): 10.2 (Si–CH_2), 25.1 (CH_2), 47.5 (N–CH_2).

2.2. Deactivation of unreacted silanol groups of silica gel

Aminopropyl silica gel (APSG) (1.0 g) was mixed with dichlorodimethylsilane (2 cm^3) in dry diethylether (20 cm^3) and the mixture was stirred under an inert atmosphere for 1 h. Deactivated APSG was filtered, washed with degassed (with N_2) ether (5×10 cm^3), dried in *vacuo* and stored under inert conditions.

2.3. Reaction of deactivated APSG with PPh_2Cl

A mixture of deactivated APSG (1.0 g) and chlorodiphenylphosphine (1.64 cm^3) was refluxed in dry benzene under nitrogen atmosphere in presence of triethylamine (0.06 cm^3) for 48 h. Silica gel functionalized with Ph_2PNPPh_2 groups (PNPSG) was filtered, washed successively with ethanol (5×30 cm^3) and acetone (5×30 cm^3), dried under *vacuo* and stored in an inert atmosphere. Analysis: C, 9.85, H, 1.74, N, 1.27%. IR (KBr, cm^{-1}): 1437 and 1484 (CH_2), 2900–3075 (CH aromatic). ^{13}C CP-MAS NMR, δ (ppm): 10.2 (Si–CH_2), 25.1(CH_2), 47.5 (N–CH_2) 132.7 (Ar–C, PPh_2).

2.4. Synthesis of *1*

One gram of PNPSG was mixed with $PdCl_2$ (0.52 g), dissolved in acetone (30 cm^3) and the mixture was refluxed for 48 h under nitrogen atmosphere to give red-brown PNPSG complexed with Pd(II). It was filtered, washed with degassed acetone (3×10 cm^3) and dried under vacuum. PNPSG loaded with Pd(II) was treated with hydrazine hydrate (1.5 g), then dissolved in ethanol (30 cm^3) at 30 °C under nitrogen atmosphere. The resulting product (PNPSG loaded with Pd(0)), reddish in colour, was filtered and washed with degassed (with nitrogen) ethanol (4×30 cm^{-3}) and diethylether (2×30 cm^{-3}), and dried under *vacuo*. It was stored under an inert atmosphere. To determine the Pd content of PNPSG loaded with Pd(0) (**1**), it was treated successively with 20 cm^3 mixture of concentrated HNO_3 and HCl (1:3) and $HClO_4$ (10 cm^3), and filtered. The filtrate was diluted to 50 cm^3 with distilled water and subjected to FAAS determination using a precalibrated instrument. Pd content = 141 μmol g^{-1}.

2.5. Synthesis of **2**

Deactivated APSG (2.0 g) was mixed with 2-(1,1-diphenylphosphino)-1-phenyl-1-ethanone (1.18 g, 3.9 mmol) in dry ethanol (30 cm^3) and the mixture was stirred under nitrogen atmosphere for 48 h. The modified silica gel was filtered, washed successively with degassed (with nitrogen) ethanol (5×30 cm^3) followed by acetone (5×30 cm^3), dried under vacuum and stored in an inert atmosphere. Analysis: C, 9.70; H, 1.79; N, 1.72%. IR (KBr, cm^{-1}): 1460 (deformation mode of CH_2 of the *n*-propyl chain), 1546–1639 (skeleton vibrations of the ring), 1845 (C=N stretching) 2784–2933 cm^{-1} (CH_2 stretching), 3023–3128 (CH stretching of the aromatic ring). ^{13}C CP-MAS NMR (δ, ppm): 9.8 (Si–CH_2), 22.0 (CH_2), 42.5 (N–CH_2), 127.8 (Ar–C), 160.0 (C=N).

The silica gel loaded with 2-(1,1-diphenylphosphino)-1-phenyl-1-ethanone (1.0 g) was mixed with $PdCl_2$ (0.30 g, 1.69 mmol) dissolved in acetone (30 cm^3) and the mixture was refluxed for 48 h under nitrogen atmosphere to give red-brown Pd(II) immobilized silica gel. It was filtered, washed with degassed acetone (3×10 cm^3) and dried under vacuum. Pd(II) immobilized gel was treated with hydrazine hydrate (1.5 g) dissolved in ethanol (30 cm^3) at 30 °C under nitrogen atmosphere. The resulting red-brown Pd(0) immobilized gel (**2**) was filtered and washed with degassed (with nitrogen) ethanol (4×30 cm^3) and diethylether (2×30 cm^3), and dried under *vacuo*. It was stored under an inert atmosphere. ^{13}C CP MAS (δ, ppm) 18.3 (Si–CH_2), 28.5 (CH_2), 39.3 (N–CH_2), 126.4 (Ar–C). The Pd content loaded on **2** was determined by FAAS, as described in the case of **1**. Pd content = 156 μmol g^{-1}.

2.6. Synthesis of 2-diphenylphosphinopyridine immobilized silica gel and **3**

2-Diphenylphosphinopyridine (2.75 g, 10.45 mmol) was reacted with *n*-BuLi–LiDMAE (DMAE = dimethylaminoethoxide) under nitrogen atmosphere. (3-Chloropropyl)triethoxysilane (2.07 g, 10.45 mmol) was added dropwise to the mixture at −78 °C and the mixture was allowed to come to room temperature overnight. The THF was evaporated on a rotary evaporator and deoxygenated dichloromethane (30 cm^3) was added to extract the compound. The dichloromethane layer was filtered through celite and evaporated on a rotary evaporator to get 2-(1,1-diphenylphosphino)-6-[3-(1,1,1-triethoxysilyl)propyl]pyridine as a colourless oil to which activated silica gel (2.0 g) in dry *p*-xylene was added, and the mixture was refluxed under nitrogen atmosphere for 48 h. The modified silca gel was filtered, washed successively with ethanol (5×30 cm^3) and acetone (5×30 cm^3), dried under vacuum and stored in an inert atmosphere. Analysis: C, 9.66; H, 2.80; N, 1.76%. IR (KBr, cm^{-1}): 3000–3220 (CH stretching of the aromatic ring), 2850–2950 (aliphatic CH stretching), 1510–1646 (skeleton vibrations involving C–C stretching within the ring), 1420, 1485 (deformation of CH_2 of the *n*-Pr chain), 695–803 (out of plane pyridine ring bending), 1150 (P–C_6H_5 stretching vibrations).

To cap unreacted –SiOH groups, ligand anchored silica gel (1.0 g), was mixed with dichlorodimethylsilane (2 cm^3) in dry diethylether (20 cm^3), and the mixture was stirred under an inert atmosphere for 1 h. The resulting products were filtered, washed with degassed (with nitrogen) diethylether (5×10 cm^3), dried in *vacuo* and stored under inert conditions.

One gram of the ligand anchored silica gel, after capping, was mixed with $PdCl_2$ (0.30 g, 1.69 mmol), dissolved in acetone (30 cm^3) and the mixture was refluxed for 48 h under nitrogen atmosphere to give red-brown Pd(II) immobilized gel. It was filtered, washed with degassed acetone (3×10 cm^3) and dried under vacuum. Pd(II) immobilized gel was treated with hydrazine hydrate (1.5 g) dissolved in ethanol (30 cm^3) at 30 °C under nitrogen atmosphere. The resulting Pd(0) immobilized gel (**3**), red brown in colour, was filtered and washed with degassed (with nitrogen) ethanol (4×30 cm^3) and diethylether (2×30 cm^3) and dried under *vacuo*. It was stored under an inert atmosphere. ^{13}C CP-MAS NMR (δ, ppm) 10.1 (Si–CH_2) 26.0 (CH_2), 64.4 (N–CH_2), 120.0 (phenyl carbon), 132.0 (pyridine carbon). The Pd content loaded on **3** was determined by FAAS, as described in the case of **1**. Pd content = 132 μmol g^{-1}.

2.7. Synthesis of (*E*)-3-(4-chlorophenyl)acrylic acid (**4**)

A mixture of acrylic acid (0.20 g, 2.75 mmol), *p*-chloroiodobenzene (0.70 g, 2.50 mmol), tri(*n*-butyl)amine (1.0 g, 5.5 mmol), *p*-xylene (2.0 cm^{-3}) and each of the catalysts **1**–**3** (37.5 mg) was stirred under nitrogen atmosphere in an oil bath at 110 °C for 8 h. The reaction was monitored by TLC. After completion of the reaction, the mixture was cooled to room temperature. The catalyst was filtered and washed with chloroform (3×10 cm^3) followed by acetone (3×10 cm^3) to remove the reagents from it, dried in *vacuo* and stored under inert conditions for re-use. The filtrate was mixed with $NaHCO_3$ (0.50 g) and water (30 cm^3). The mixture was stirred for 1 h at room temperature. The aqueous phase was separated and acidified with 5 N HCl. After cooling to 0 °C, the solid precipitate was filtered, washed with water and air dried to give (*E*)-3-(4-chlorophenyl)acrylic acid. Mp 250–251 °C; *Anal*. Calc. for $C_9H_7ClO_2$: C, 59.17, H, 3.83. Found: C, 59.12, H, 3.82%. ^1H NMR (DMSO-d_6, 25 °C): δ (vs TMS): 6.52–6.58 (d, IH, CH–COOH), 7.46–7.49 (d, 2H, Ar–H *o* to Cl), 7.55–7.60 (d, 1H, CH Ar–CH), 7.71–7.74 (d, 2H, Ar–H *m* to Cl); ^{13}C {^1H} NMR (DMSO-d_6, 25 °C): δ (vs TMS) 120.1 (CH–COOH), 128.1 (Ar–C *m* to Cl), 130.87 (Ar–C *o* to Cl), 133.2 (Ar–C *p* to Cl), 134.7 (Ar–C–Cl), 142.5 (Ar–CH), 167.4 (C=O).

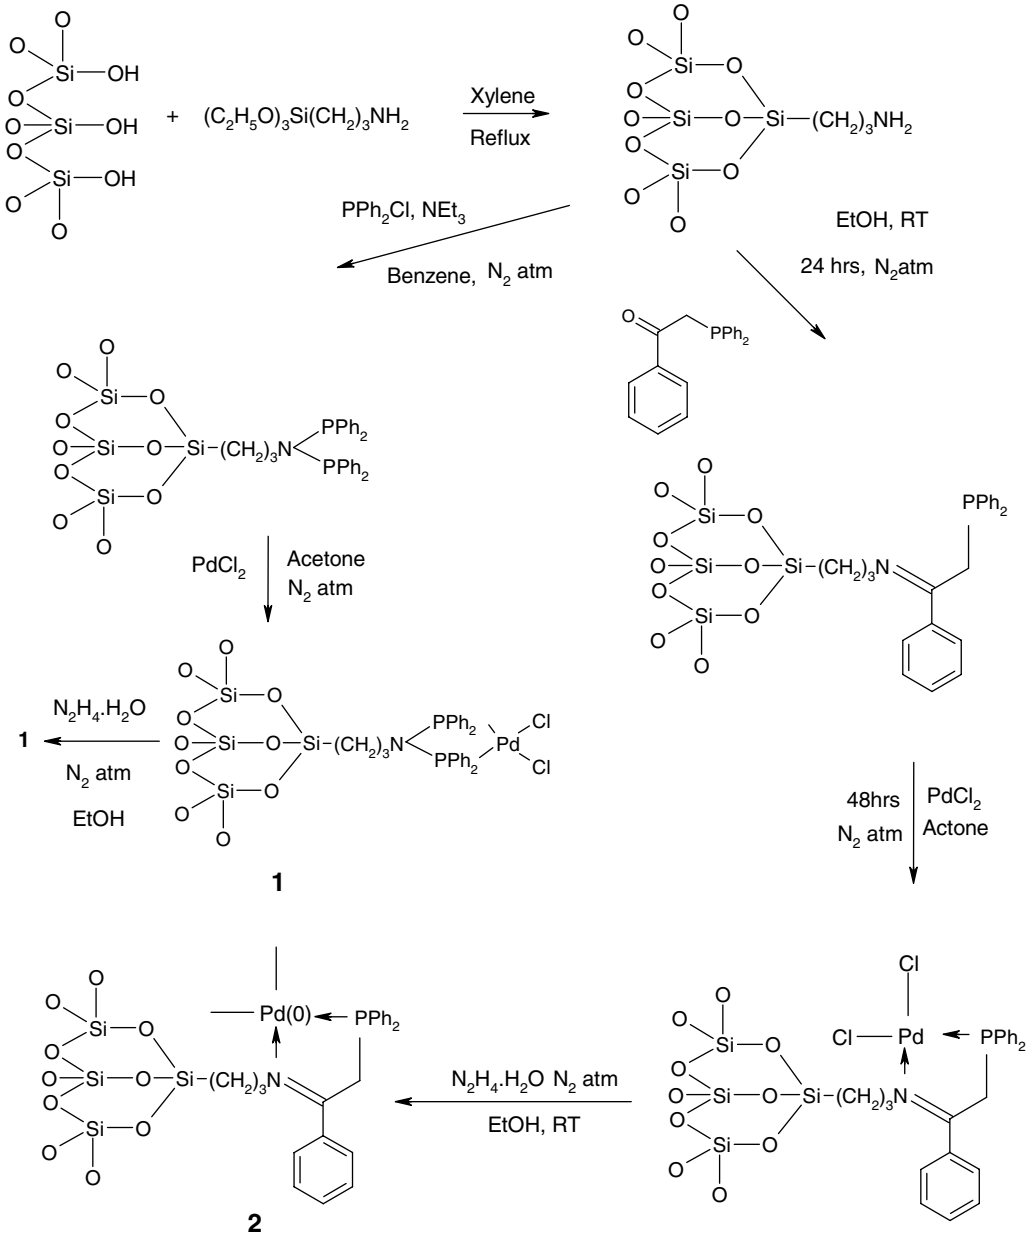
2.8. Synthesis of (*E*)-3-(4-nitrophenyl)acrylic acid (**5**)

A mixture of acrylic acid (0.20 g, 2.75 mmol), *p*-iodonitrobenzene (0.62 g, 2.50 mmol)/*p*-bromonitrobenzene

(0.50 g 2.5 mmol) (10 mol% of PPh_3 was also added in the case of *p*-bromonitrobenzene) and tri-(*n*-butyl)amine (1.0 g, 5.5 mmol) in *p*-xylene (2.0 cm^3) was made. After adding one of the catalysts **1**–**3** (37.5 mg), the mixture was stirred under nitrogen atmosphere in an oil bath at 110 °C (140 °C for *p*-bromonitrobenzene) for 8 h. The reaction was monitored with TLC. After completion of the reaction, the mixture was cooled to room temperature. The catalyst was filtered and washed with chloroform (3×10 cm^3) followed by acetone (3×10 cm^3) to remove the reagents from it, dried in *vacuo* and stored under inert conditions for re-use. The filtrate was mixed with $NaHCO_3$ (0.50 g) and water (30 cm^3). The mixture was stirred for 1 h at room temperature. The aqueous phase was separated and acidified with 5 N HCl. After cooling to 0 °C, the solid precipitate was filtered, washed with water and air dried to give (*E*)-3-(4-nitrophenyl)acrylic acid. Mp 286–287 °C; *Anal*. Calc. for $C_9H_7NO_4$: C, 55.95; H, 3.62. Found: C, 55.89; H, 3.61%. ^1H NMR (DMSO-d_6, 25 °C): δ (vs TMS) 6.71–6.76 (d, 1H, CH–COOH), 7.66–7.71 (d, 1H, CH Ar–CH), 7.95–7.98 (d, 2H, Ar–H *o* to NO_2), 8.21–8.24 (d, 2H, Ar–H *m* to NO_2); ^{13}C NMR (DMSO-d_6, 25 °C): δ (vs TMS) 123.6 (CH), 123.9 (Ar–CH, *o* to NO_2), 130.3 (Ar–CH, *m* to NO_2) 140.7 (Ar–CH *p* to NO_2), 141.3 (Ar–CH), 147.9 (Ar–C–NO_2), 167.0 (C=O).

2.9. Synthesis of (*E*)-1-(4-chlorophenyl)-2-phenylethene (**6**)

A mixture of styrene (0.28 g, 2.75 mmol), *p*-chloroiodobenzene (0.70 g, 2.5 mmol), *n*-Bu_3N (0.54 g, 3.0 mmol) made in *p*-xylene (2.0 cm^3) and Pd(0) catalyst **1**–**3** (37.5 mg) was stirred under nitrogen atmosphere in an oil bath at 110 °C for 8 h. Thereafter the mixture was cooled to room temperature and stirred with chloroform (40 cm^3). The catalyst was filtered, washed with chloroform (3×10 cm^3) followed by acetone (3×10 cm^3), dried in *vacuo* and stored under inert atmosphere for re-use. The filtrate was washed with 5 N HCl (2×15 cm^3), water (2×20 cm^3), brine (2×10 cm^3), and then dried over Na_2SO_4. The crude product obtained after the evaporation of the solvent on a rotary evaporator of this filtrate was purified through a silica gel column using hexane–ethylacetate mixture (9:1). The solid product thus obtained was recrystallized from ethanol to get pure (*E*)-1-(4-chlorophenyl)-2-phenylethene. Mp 129 °C; *Anal*. Calc. for $C_{14}H_{11}Cl$: C, 78.32; H, 5.12. Found: C, 78.12; H, 5.10%. ^1H NMR ($CDCl_3$, 25 °C): δ (vs TMS): 7.06 (s, 2H, CH=CH), 7.25–7.51 (m, 9H, Ar–H); ^{13}C NMR ($CDCl_3$, 25 °C): δ (vs TMS) 126.5 (Ar–CH), 127.3 (Ar–C *o* to CH=CH), 127.6 (Cl–Ar–CH), 127.8 (Ar–C *p* to CH=CH), 128.7 (Ar–C *m* to CH=CH), (Ar–C *m* to Cl), 129.2 (Ar–C *o* to Cl), 133.1 (Ar–C–Cl), 135.8 (Ar–C *p* to Cl), 136.9 (Ar–C–CH=CH).

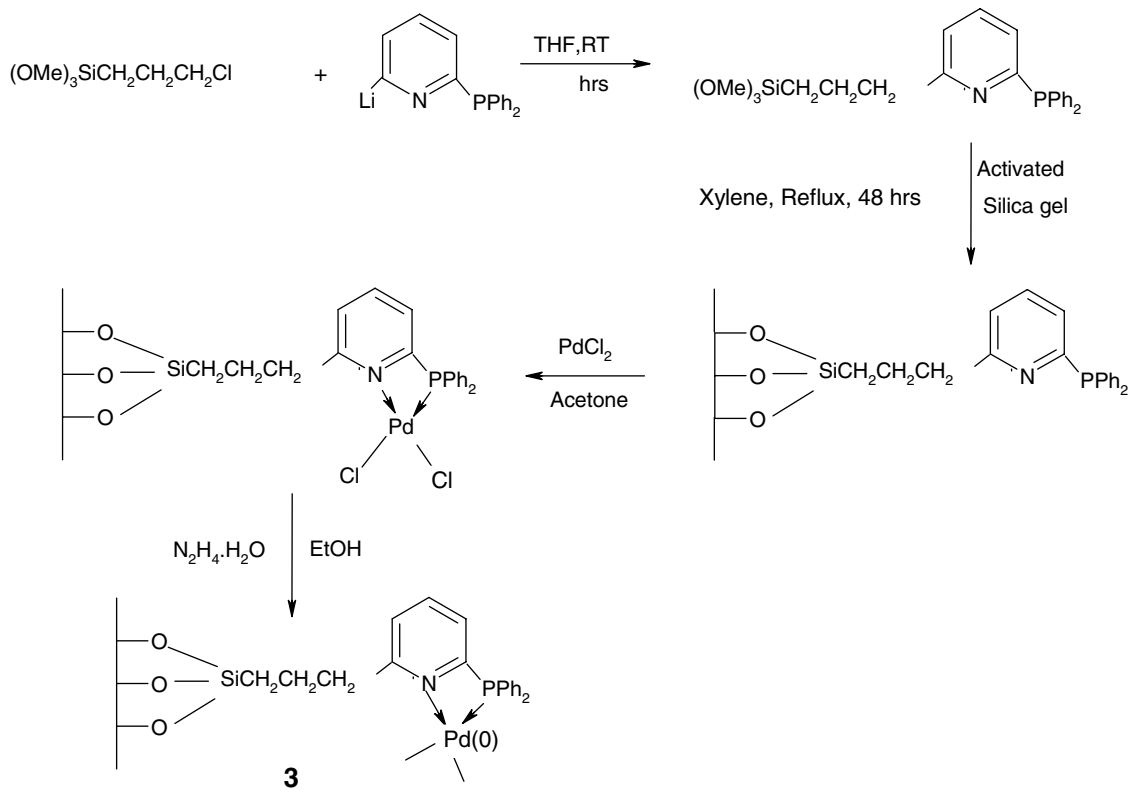


2.10. Synthesis of (*E*)-1-(4-nitrophenyl)-2-phenylethene (**7**)

A mixture of styrene (0.28 g, 2.75 mmol), *p*-iodonitrobenzene (0.62 g, 2.5 mmol)/*p*-bromonitrobenzene (0.50 g, 2.5 mmol) (10 mol% of PPh_3 was added additionally in the case of *p*-bromonitrobenzene), *n*-Bu_3N (0.54 g, 3.0 mmol), *p*-xylene (2.0 cm^3) and catalyst **1**–**3** (37.5 mg) was stirred under nitrogen atmosphere in an oil bath at 110 °C (140 °C for bromonitrobenzene) for 8 h, after which the mixture was cooled to room temperature and treated with chloroform (40 cm^3). The catalyst was filtered, washed with chloroform (3×10 cm^3) followed by acetone (3×10 cm^3), dried in *vacuo* and stored under inert atmosphere for re-use. The filtrate was washed with 5 N HCl (2×15 cm^3), water (2×20 cm^3), brine (2×10 cm^3) and dried over Na_2SO_4. The crude product obtained after the evaporation of the solvent of the filtrate on a rotary evaporator was purified through a silica gel column using hexane–ethylacetate mixture (9:1). The solid product obtained was recrystallized from ethanol to give pure (*E*)-1-(4-nitrophenyl)-2-phenylethene. Mp 157 °C; *Anal*. Calc. for $C_{14}H_{11}NO_2$: C, 74.66; H, 4.88. Found: C, 74.52; H, 4.79%. ^1H NMR ($CDCl_3$, 25 °C): δ (vs TMS) 7.12 (s, 2H Ar–CH), 7.32–7.57 (m, 9H, Ar–H); ^{13}C NMR ($CDCl_3$, 25 °C): δ (vs TMS) 124.1 (Ar–C *o* to NO_2), 126.2 (Ar–CH), 127.0 (O_2N–Ar–CH, Ar–C *o* to CH=CH), 127.8 (Ar–C *p* to CH=CH), 128.8 (Ar–C *m* to CH=CH), 133.3 (Ar–C *m* to NO_2), 136.1 (Ar–CH=), 143.8 (Ar–C *p* to NO_2), 146 (Ar–C–NO_2).

3. Results and discussion

The catalysts **1** and **2** were designed by the sequence of reactions given in Scheme 1 and **3** by those in Scheme 2. We have phosphinated the NH_2 group after anchoring it on silica gel, as doing it earlier resulted in two main side reactions occurring [27]. First the phosphine moieties of the linkers can be quaternized by ethyl groups from the ethoxysilyl functions. Second, the bisphosphinoamine group can rearrange to the corresponding phosphinimine unit that is subsequently hydrolyzed, resulting in the amine and tetraphenyldiphosphine oxide. The catalysts **1** and **2** were stored under a nitrogen atmosphere because due to the presence of Pd(0) their susceptibility to aerial oxidation is very likely. The catalysts do not show any visual sign of decomposition even after six months if stored under nitrogen. The yields of the C–C coupling reactions (Eq. (1)) were also found to be unchanged when aged catalysts were used. For all the catalysts **1**–**3** the anchoring of the ligands/complexes is authenticated by ^{13}C solid state NMR spectra. The ^{13}C CP-MAS NMR spectra of the three catalysts and their intermediates do not indicate the significant presence of unreacted ethoxy groups under the present reaction conditions, which are more drastic [28]. All the catalysts **1**–**3** have been found to be efficient at catalyzing the C–C coupling reaction shown in Eq. (1), and are recyclable. The products **4**–**7** formed by reaction of Eq. (1) have been authenticated by solution ^1H and ^{13}C NMR spectra, elemental analyses and IR spectra.

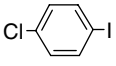


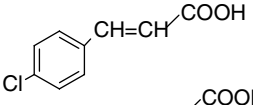
The formation of the *trans* isomer is supported by $^3J(H–H) = 16$ Hz; for a *cis* isomer these coupling constants

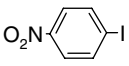
Scheme 1.

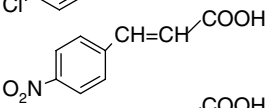
have values less than 10 Hz. With up to 15–16 re-uses of the catalysts **1**–**3**, the yields of the products do not change significantly as they are within ±3–5%. Thereafter, some small lowering in yields was noticed. They can be used up to 30-times with a reduction in yield of the order of 10–15%. In Table 1 the yields of the products obtained at optimum reaction temperatures are compared. The values of the yields are with respect to aryl halides. In the case of bromo derivatives, the yields are bit lower as expected due to some difficulty of the insertion of Pd into the C–Br bond. Only the *trans* isomer was obtained in all reactions of the type represented by Eq. (1). It appears that the C–C coupling reaction involves the processes given in Scheme 3 and due to steric reasons the organic residues go *trans* to each other.

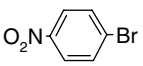
In the synthesis of **4**–**7**, on lowering the reaction temperatures (oil bath) by 10 °C, a yield decrease of ~7–8% was observed, whereas on raising the temperature of the oil bath by 20 °C above the optimum value the yield does not change. For the catalytic synthesis of **4**–**7** addition of *n*-Bu_3N is essential. It was found to be better than Et_3N as with the later the yields are reduced by half. The effect of the amount of catalysts **1**–**3** on the formation of **4**–**7** was studied. It was found that 37.5 mg of **1**–**3** is sufficient for catalytic formation of **4**–**7** from reactants having concentration levels up to 200 mmol. The yield is reduced by 10–15% if only 20 mg of catalysts **1**–**3** is added. The yields with catalyst **3** are greater than those obtained with **2**. In the case of catalyst **2**, the ring formed with Pd is five membered

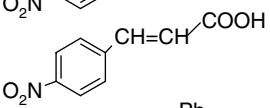


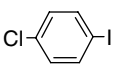


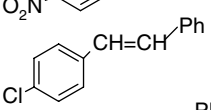


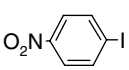


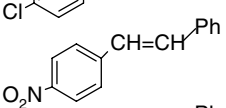


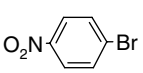


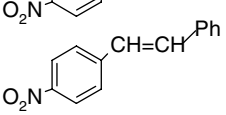


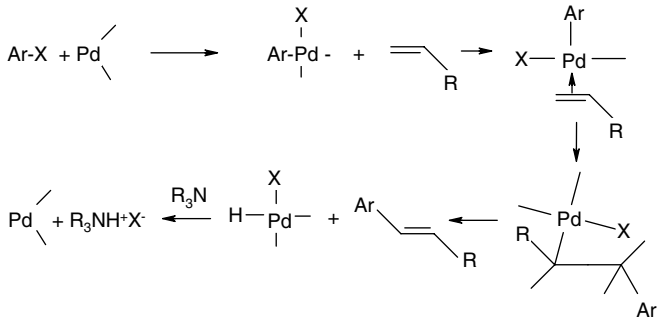












Scheme 2.

while with catalyst **3** four membered ring formation takes place with the metal centre. As the four membered chelate is strained, the ring opening is easier as compared to the five membered chelate. Due to this, the activity of **3** is found to be better than that of catalyst **2**. In the case of **1**, the chelate ring formed is four membered but both donor sites are phosphorus atoms and consequently the stability of the chelate formed with Pd appears to be greater than that of the (P,N) ligand present in catalyst **3**.

The Heck reaction and the form of the palladium catalyst catalyzing it has been a subject of debate in the recent

Table 1
Yields and temperature for the reaction between aryl halides and alkenes (Eq. (1))

Ar–X	Y	Temperature (°C) Catalyst 1/2/3	Product	Yield (%) Catalyst 1/2/3
	COOH	110		79/74/86
	COOH	110		76/82/89
	COOH	140		71/72/76
	Ph	110		83/80/90
	Ph	110		84/78/92
	Ph	140		74/75/79

Scheme 3.

past. De Vries et al. have reported [29,30] that ligand-free $Pd(OAc)_2$ can be used as a catalyst in the Heck reaction of aryl bromides as long as the amount of catalyst is kept between 0.01 and 0.1 mol%. At higher concentrations Pd black forms and the reaction stops. The formation of nanoparticles of palladium has been suggested as a pathway [31] when some palladium complexes of Schiff bases were used as catalyst for the Heck reaction. This reaction has also been demonstrated to be taking place via nanoparticles of palladium in ionic liquids [32]. However, importance of the ligands on the silica surface in retaining palladium catalyzing Heck reactions has not been denied [33]. With our catalysts **1**–**3**, it has been observed that their colour (close to dark red) does not change, even after recycling them. Therefore, it appears that the Pd-complexes in them most probably remain tethered molecular species and stay as such after the catalytic cycle.

4. Conclusion

The catalytic systems **1**–**3** have been designed and found to be suitable for selective Heck reactions as only the *trans* product is obtained in good yield. It appears that the Pd-complexes in them most probably remain tethered molecular species and stay as such after the catalytic cycle.

extension of this work has been conducted by conveniently linking the hydroxy group of **1** to desired ligands such as pyridine. The pyridyl-functionalized ADT-bridged diiron complex [{(μ-SCH_2)$_2$N(CH_2CH_2OOCPy)}Fe_2(CO)$_6$] (**2**) is a potential building block for construction of a photoactive catalyst such as [2Fe2S]–[Ru] catalyst-photosensitizer system for light-driven H_2-production [24–26].

2. Experimental

2.1. Reagents and instruments

All reactions and operations related to organometallic complexes were carried out under a dry, oxygen-free dinitrogen atmosphere with standard Schlenk techniques. All solvents were dried and distilled prior to use according to the standard methods. Isonicotinyl chloride hydrochloride was purchased from Alfa Aesar and $LiEt_3BH$ from Aldrich. Commercially available chemicals, paraformaldehyde, ethanol amine and [$Fe(CO)_5$] were used as received. Complex (μ-SH)$_2$$Fe_2$($CO$)$_6$ was prepared according to the literature procedure [27].

Infrared spectra were recorded on a JASCO FT/IR 430 spectrophotometer. NMR Spectra were collected on a Varian INOVA 400NMR spectrometer. Mass spectra were recorded by electro-spray ionization (ESI) on an HP1100 MSD instrument. Elemental analyses were performed on a THERMOQUEST-FLASH EA 1112 elemental analyzer.

2.2. Synthesis of [{(μ-SCH_2)$_2$N(CH_2CH_2OH)}Fe_2(CO)$_6$] (**1**)

Paraformaldehyde (1.79 g, 0.06 mol) was added to a solution of ethanol amine (1.75 g, 0.03 mol) in THF (25 mL). The reaction mixture was stirred at room temperature for 6 h, and then (μ-HS)$_2$$Fe_2$($CO$)$_6$, prepared in situ from (μ-S_2)Fe_2(CO)$_6$ (1.0 g, 3 mmol) according to the literature [16], was added. The solvent was removed after 1 h. The crude product, a dark red solid, was purified by column chromatography on silica gel using CH_2Cl_2 as eluent. The solvent was completely removed by rotary evaporation to give red solid **1** (0.31 g, 25%). Recrystallization in CH_2Cl_2/hexane afforded crystals of **1** suitable for X-ray crystallography study. *Anal.* Calc. for $C_{10}H_9Fe_2NO_7S_2$ (431.0): C, 27.87; H, 2.10; N, 3.25. Found: C, 28.12; H, 2.17; N, 3.68%. IR (CH_2Cl_2): *ν*CO 2073 (s), 2034 (s), 1999 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.60 (s, 4H), 3.52 (s, 2H), 2.87 (s, 2H). MS: *m*/*z* 429 [$M-H^+$]$^-$.

2.3. Synthesis of [{(μ-SCH_2)$_2$N(CH_2CH_2OOCPy)}Fe_2(CO)$_6$] (**2**)

Triethylamine (2 mL) was added to a solution of isonicotinyl chloride hydrochloride (0.47 g, 2.65 mmol) in CH_3CN (20 mL) and the mixture was stirred for several minutes. A solution of **1** (0.88 mg, 2.04 mmol) in CH_3CN (40 mL) was then added dropwise at room temperature over 2 h. After the mixture was stirred for 24 h the solvent was removed under vacuum. Pure complex **2** (0.72 g, 66%) was obtained following the same procedure as that for **1**. *Anal.* Calc. for $C_{16}H_{12}Fe_2N_2O_8S_2$ (536.1): C, 35.85; H, 2.26; N, 5.23. Found: C, 35.74; H, 2.33; N, 5.52%. IR (CH_2Cl_2): *ν*CO 2074 (s), 2034 (s), 1999 (s), 1728 (m) cm^{-1}. ^1H NMR (acetone-d_6): δ 9.30 (s, 2H), 7.99 (s, 2H), 4.31 (m, 2H), 3.90 (s, 4H), 3.30 (m, 2H). MS: *m*/*z* 558 [$M+Na$]$^+$.

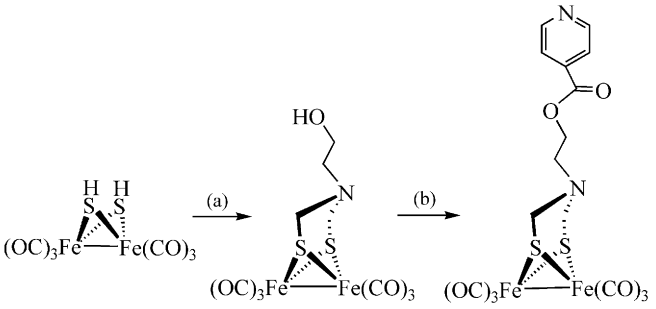
2.4. Crystal structure determination of complexes *1* and *2*

Single crystal X-ray diffraction measurements were made on a Smart APEX II diffractometer using graphite monochromated Mo Kα radiation (λ = 0.71073 Å). Complete crystal data and parameters for data collection and refinement are listed in Table 1. Data processing was accomplished with the SAINT processing program [28]. Intensity data were corrected for absorption with empirical methods. The structures were solved by direct methods and refined by matrix least-squares methods on F_o^2 by using the SHELXTL crystallographic software package [29]. All hydrogen atoms, except the hydrogen of the OH group in complex **1**, were located by difference maps and their positions were refined isotropically. All non-hydrogen atoms were refined anisotropically.

2.5. Electrochemistry

Acetonitrile (Aldrich, spectroscopy grade) used for performance of electrochemistry was dried with molecular sieve (4 Å) and then freshly distilled from CaH_2 under N_2. A solution of 0.05 M [^{n}Bu$_4$N]PF_6 (Fluka, electrochemical grade) in CH_3CN was used as electrolyte. Electrochemical measurements were recorded using a BAS-100W electrochemical potentiostat. The electrolyte solution was degased by bubbling with dry argon for 10 min before measurement. Cyclic voltammograms were obtained in a three-electrode cell under argon. The working electrode was a glassy carbon disc (diameter 3 mm) successively polished with 3 and 1 μm diamond pastes and sonicated in ion-free water for 10 min. The reference electrode was a non-aqueous Ag/Ag^+ electrode (1.0 mM $AgNO_3$ in CH_3CN) and the auxiliary electrode was a platinum wire.

Table 1
Crystallographic data and refinement parameters for complexes **1** and **2**



Complex	**1**	**2**

Largest difference in peak and hole (e Å^{-3})	0.522 and −0.471	0.412 and −0.365

3. Results and discussion

3.1. Synthesis and spectroscopic characterization of complexes *1* and *2*

Complex **1** was successfully obtained by the reaction of freshly prepared $[(\mu\text{-HS})_2Fe_2(CO)_6]$ [27] with *N*-(2-hydroxyethyl)-2-aza-1,3-propanediol, produced in situ by condensation of formaldehyde and ethanol amine in THF. The complex (Fig. 1b), designed as a model of the H_2O-coordinate H_{ox} state of the H-cluster, could not be formed via intramolecular CO-displacement by the OH group of **1** in the presence of CO-removing reagent Me_3NO and/or under irradiation of an ultraviolet lamp. The reaction of complex **1** and isonicotinyl chloride hydrochloride in the presence of excess Et_3N in CH_3CN afforded pyridyl-functionalized diiron complex **2** in a good yield (Scheme 1).

Complexes **1** and **2** were characterized by MS, IR, ^{1}H NMR spectra and elemental analysis. The results of elemental analyses for **1** and **2** are in good agreement with the supposed compositions. The mass spectra show the parent ion peaks at m/z 429 $[M-H]^-$ for **1**, measured by an API-ES negative mode, and at m/z 558 $[M+Na]^+$ for **2** by an API-ES positive mode. Complexes **1** and **2** in CH_2Cl_2 each display three strong νCO bands in the region of 1990–2080 cm^{-1} in IR spectra. The wavenumbers of the νCO bands for complexes **1** and **2** are almost identical. The characteristic frequency for the OH group at 3483 cm^{-1} for **1** and a strong band of the acyl group at 1728 cm^{-1} for **2** were also observed.

Scheme 1. (a) $(CH_2O)_n/H_2NCH_2CH_2OH$, THF; (b) $PyCOCl \cdot HCl$, NEt_3, CH_3CN.

3.2. Molecular structures and intermolecular contacts in the crystals of complexes *1* and *2*

The crystallographic structures of **1** and **2** are given as SHELXL-97 diagrams in Fig. 2. Selected bond lengths and angles are listed in Table 2. Crystallographic studies show the structural resemblance of the framework of **1** and **2** to previously reported 2Fe2S models [5–8]. The central structure of the [2Fe2S] core is in a butterfly conformation and each Fe atom is coordinated with a pseudo-square-pyramidal geometry. The Fe–Fe distances, 2.501 for **1** and 2.503 Å for **2**, are somewhat shorter than that in the structures of Fe-only hydrogenases (ca. 2.6 Å) [3,4], and in good agreement with the Fe–Fe bonds (2.49–2.51 Å) found for other all-CO diiron azadithiolates [19–22]. The bridged-N atoms of **1** and **2** deviate upwards from the plane defined by the C(7), C(8) and C(9) atoms. The sums of the C–N–C angles around N are 352.9° for **1** and 350.9° for **2**. Both hydroxy and pyridyl groups in the crystals of complexes **1** and **2** are in the vertical position.

A packing diagram of molecules in the crystals of complex **1** along the *b*-axis is given in Fig. 3. Hydrogen atoms were generated with isotropic thermal parameters in idealized positions, riding on their carrier atoms, except for the hydrogen atoms of the hydroxyl group, which were located on two different positions from the difference Fourier map and then idealized. As shown in the packing diagram (Fig. 3b), extended networks are constructed by intermolecular H-bonds. In the crystals of complex **1**, in addition to the H-bonds among OH groups, the hydrogen atom of the OH group also form H-bonds with the oxygen atom of the CO ligand, presumably due to the vibration of the OH group. The distances and angles of the two kinds of H-bonds in the crystals of complex **1** are given in Table 3.

A packing diagram of molecules in the crystals of complex **2** along the *a*-axis is given in Fig. 4a. A simplified view of the coupled molecules is given in Fig. 4b to clearly show the assembly geometry and the intermolecular S···O interactions in the crystals of complex **2**. A particularly attractive aspect is the well-arranged centrally symmetric coupling of the molecules, resulting from close S···O intermolecular contacts (3.244 Å) and the π–π stacking of the pyridyl rings (the distance of two adjacent pyridyl rings 2.692 Å). The intermolecular S···O distance in the crystals of complex **2** is slightly shorter than the sum of van der Waals radii but apparently shorter than the observed average value (3.45 Å) of S···O intermolecular contacts reported by Rowland and Taylor [30]. The relative angles

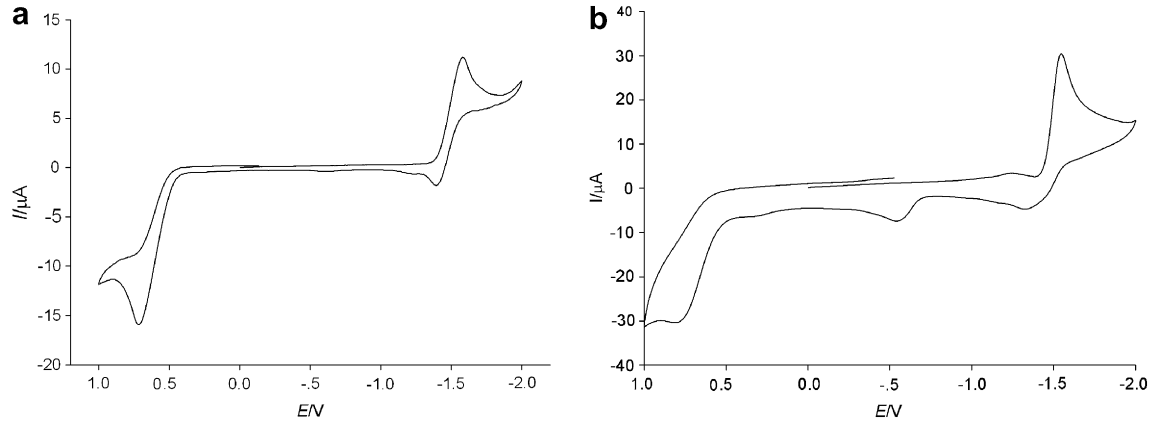

Fig. 5. Cyclic voltammograms of **1** (a) and **2** (b), 1.0 mmol in 0.05 M [^{n}Bu$_4$N]PF$_6$/CH$_3$CN at a scan rate of 100 mV s^{-1}. Potentials are vs. Fc/Fc$^+$.

Table 4
Electrochemical data of complexes **1** and **2**[a]

Complex	E^{ox}_{pirr} (V) Fe(I)Fe(I)/Fe(II)Fe(I)	E_{pc}, E_{pa} (V) Fe(I)Fe(I)/Fe(0)Fe(I)
1	+0.59	−1.66, −1.45
2	+0.61	−1.65, −1.47

[a] All potentials are vs. Fc/Fc^+.

interactions with the S···O non-bonded distances (2.03–3.00 Å) significantly shorter than the sum of the corresponding van der Waals radii (3.25 Å) [33]. To the best of our knowledge, so far there is no report on the intermolecular non-bonded S···O interaction for organometallic complexes. The intermolecular contact between the bridging-sulfur and the oxygen atom of the electro-attracting PyC═O moiety gives a further proof for the nucleophilicity of the bridging-sulfur atoms in the 2Fe2S model complexes, which may play a role of in-site base in the process of enzymetic H_2-evolution [34].

3.3. Cycle voltammograms of model complexes *1* and *2*

Electrochemistry of model complexes **1** and **2** were studied to evaluate their redox properties. The cyclic voltammograms of **1** and **2** were recorded in CH_3CN with 0.05 M *n*-Bu_4NPF_6 as electrolyte (Fig. 5). The electrochemical data are given in Table 4. Complexes **1** and **2** each display an irreversible oxidation peak and an irreversible reduction peak. The oxidation peaks, at +0.59 V versus Fc/Fc^+ for **1** and +0.61 V for **2**, are ascribed to the $Fe(I)Fe(I) \rightarrow Fe(II)Fe(I) + e^-$ process and the reduction peaks, at −1.66 V for **1** and −1.65 V for **2**, are assigned to the one-electron process of $Fe(I)Fe(I) + e^- \rightarrow Fe(0)Fe(I)$, as described for other analogous all-CO diiron complexes reported previously [35]. The redox potentials of diiron complexes are hardly influenced by changing the functional group on the N-bonded ethylene chain. The peak of the second reduction process does not observed within the solvent window.

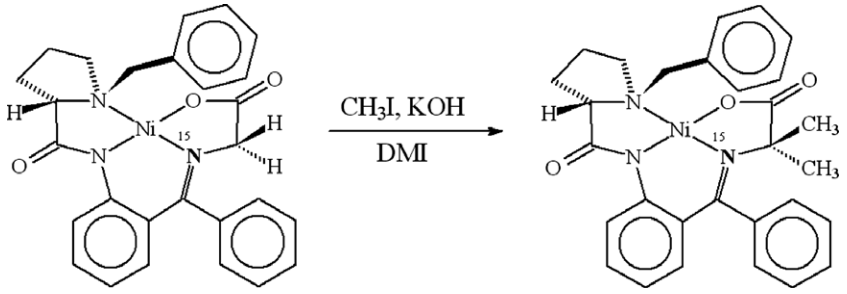
[11] for positron emission tomography (PET) visualization of cancer cells and in vivo metabolism of 3,4-dioxyphenylalanine (DOPA).

Recently, several stereoselective analogous synthons carrying substituents on the benzyl group were developed [12]. Electronic and steric effects influencing the stereochemistry of alkylation of the synthons were thoroughly investigated by a number of physical–chemical approaches. The conformations of the complexes in solutions were disclosed by NMR [7,13].

A number of X-ray structures of related complexes were published, including pairs of diastereomers with opposite configurations of the α-carbon of the amino acid fragments [14] (for overview, see [13c]). The distribution of the electron density in a single crystal of a glycine synthon was studied by X-ray diffraction by Kožíšek et al. [15]. Ab initio quantum-chemical modelling and topological analysis of electron density were also performed for this molecule [13c,15]. A similar but more acidic Ni(II) complex of the Schiff base of (*S*)-*N*-(2-benzoyl-4-chlorophenyl)-1-benzylpyrrolidine-2-carboxamide and glycine was studied by NMR only [13b]. In spite of their synthetic application as intermediates in the synthesis of α-[^{11}C]methyl amino acids, single crystals of complexes with a quaternary α-carbon of the amino acid fragment have never been studied by X-ray diffraction, neither has complete assignment of their ^{1}H and ^{13}C NMR spectra been done. Here we present X-ray structure determinations for both the Ni(II) complex of the Schiff base of (*S*)-*N*-(2-benzoyl-4-chlorophenyl)-1-benzylpyrrolidine-2-carboxamide and glycine (**1**) and the hemihydrate of the Ni(II) complex of the Schiff base of (*S*)-*N*-(2-benzoylphenyl)-1-benzylpyrrolidine-2-carboxamide and 2-aminoisobutiric acid (**2**), and the full assignment of ^{1}H and ^{13}C NMR spectra of the later structure. These structures are also model compounds for the study of long-range ^{13}C–^{15}N and ^{13}C–^{13}C spin–spin interactions in NMR spectra [13c,16] and circular dichroism [7,17] (see Scheme 1).

1 **2**



Scheme 1.

2. Experimental

Complex **1** was prepared according to Popkov et al. [13b]. The synthesis of ^{15}N-labelled complex **2**, (^{15}N)Me$_2$GK, was as follows (see also Reaction scheme). To a solution of the Ni(II) complex of the Schiff base of (*S*)-*N*-(2-benzoylphenyl)-1-benzylpyrrolidine-2-carboxamide and (^{15}N)glycine ((^{15}N)GK) (20 mg, 0.04 mmol), cf. Jirman et al. [16], in 1,3-dimethylimidazolidin-2-one (DMI, 1 ml) under an atmosphere of Ar at 20 °C, an excess of KOH and CH_3I (12.6 μl, 0.2 mmol) were added and the reaction mixture was stirred for 30 min. The reaction mixture was poured into 10% aqueous citric acid (30 ml), stirred and the resulting red suspension was filtered off and dried in air. The filter was dried and extracted with chloroform. The extract was evaporated in vacuo. (^{15}N)Me$_2$GK was purified by preparative TLC using silica gel (Merck 60H) eluted with CH_2Cl_2. The obtained complex was then purified by chromatography on Sephadex LH-20 with toluene:MeOH = 2:1 as red crystals. Yield: 15 mg (71% related to (^{15}N)GK), m.p. 212–217 °C (from acetone). Calculated mass for $C_{29}H_{29}N_2{}^{15}NO_3Ni$: $[M^+] = 526.1533$. High resolution FAB MS found $[M^+] = 526.1539$.

NMR spectroscopy: Bruker AMX 360, 23 °C, hexamethyldisiloxane ($\delta(^1H) = 0.05$ ppm) was used as an internal standard. Assigned ^{1}H NMR and ^{13}C NMR spectra for (^{15}N)Me$_2$GK are presented in Table 1.

X-ray analysis: Siemens SMART 1K CCD area detector diffractometer equipped with LT-2 low temperature device, using graphite-monochromated Mo Kα characteristic radiation ($\lambda = 0.71073$ Å). Data were collected at 173 K, with a crystal-to-detector distance 3.97 cm, ω-scans covering whole sphere of reciprocal space with

Reaction scheme.

steps of 0.3° [18a]. Data were corrected for absorption effects [18b]. The structures were solved by direct methods [18c] and refined by least-squares method on F^2 with H-atoms constrained to ideal geometries and riding on their respective pivot atoms [18c]. Graphics were produced by DIAMOND [18d].

Crystal data for complex **1**: $C_{27}H_{24}ClN_3NiO_3$, M_r 532.65, triangular red plate, crystal size (mm) = 0.60 × 0.60 × 0.30, monoclinic, space group $P2_1$, $a = 11.4695(1)$ Å, $b = 7.6323(1)$ Å, $c = 13.7066(2)$ Å, $\beta = 98.077(1)°$, $V = 1187.95(3)$ Å^3, $Z = 2$, $D_{calc} = 1.489$ g cm^{-3}, $\mu_{Mo} = 0.965$ mm^{-1}, $\theta_{max} = 32.78°$, $T_{min} = 0.6143$, $T_{max} = 0.7490$. 20736 measured, 8228 independent ($R_{int} = 0.0206$) and 8026 observed ($I > 2\sigma_I$) reflections, 340 parameters, $R_1 = 0.0265$ for observed and $wR(F^2) = 0.0714$ for all reflections, $S = 1.016$, $\Delta\rho_{max} = 0.483$, $\Delta\rho_{min} = -0.286$ e Å^{-3}.

Crystal data for complex **2**: $C_{29}H_{29}N_3NiO_3 \cdot 0.5H_2O$, M_r 535.27, red block crystal, size (mm) = 1.00 × 0.70 × 0.50, trigonal, space group $P3_121$, $a = 14.2295(1)$ Å, $b = 14.2295(1)$ Å, $c = 21.5928(1)$ Å in hexagonal cell, $V = 3786.33(4)$ Å^3, $Z = 6$, $D_{calc} = 1.408$ g cm^{-3}, $\mu_{Mo} = 0.807$ mm^{-1}, $\theta_{max} = 27.12°$, $T_{min} = 0.3113$, $T_{max} = 0.6683$. 45414 measured, 5579 independent ($R_{int} = 0.0728$) and 4778 observed ($I > 2\sigma_I$) reflections, 365 parameters, $R_1 = 0.0343$ for observed and $wR(F^2) = 0.0840$ for all reflections, $S = 0.978$, $\Delta\rho_{max} = 0.278$, $\Delta\rho_{min} = -0.296$ e Å^{-3}.

3. Results and discussion

Crystals of the Ni(II) complex of the Schiff base of (*S*)-*N*-(2-benzoyl-4-chlorophenyl)-1-benzylpyrrolidine-2-carboxamide and glycine (**1**) [GKCl], suitable for X-ray analysis, were obtained by slow evaporation of an acetone solution. Crystals of the Ni(II) complex of the Schiff base of (*S*)-*N*-(2-benzoylphenyl)-1-benzylpyrrolidine-2-carboxamide and 2-aminoisobutiric acid (**2**) [Me_2GK] were grown by the same method. The numbering schemes for complexes **1** and **2** are shown in Figs. 1 and 2, respectively. X-ray structure analysis established unambiguously the absolute structure with Flack parameters [19] being −0.002(5) and −0.031(12), using 3738 and 2452 Friedel pairs for complexes **1** and **2**, respectively. Both complexes show nickel in a square-planar coordination geometry with small pyramidal distortions. In Table 2 we present a selection of bond distances, as well as some stereochemical data. We define the three chelate rings of complexes **1** and **2** as follows: the five-membered ring A is defined by atoms Ni/O2/C20/C19/N3, the six-membered ring B is defined by atoms Ni/N2/C6/C11/C12/N3 and the five-membered ring C is defined by atoms Ni/N1/C4/C5/N2. The conformations of these rings are indicated in Table 2 and they differ substantially between both complexes; while Me_2GK complex **2** adopts an asymmetric λ-envelope/asymmetric δ-boat/asymmetric λ-envelope conformation for rings A/B/C/, respectively,

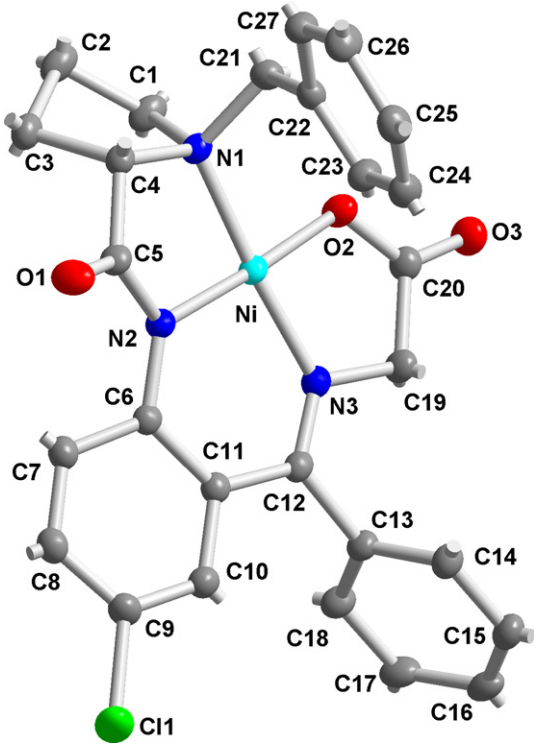

Fig. 1. The numbering scheme of **1** with atomic displacement ellipsoids drawn at the 50% probability level. H atoms are omitted for clarity and indicated by partial bonds only.

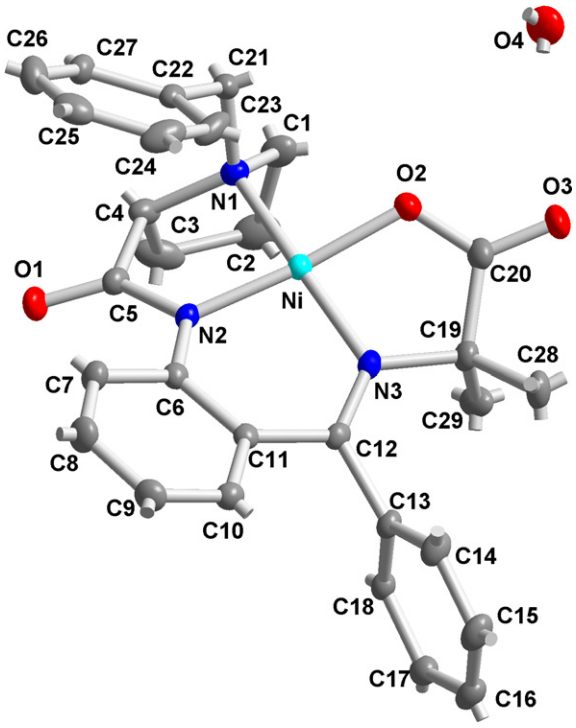

Fig. 2. The numbering scheme of **2** with atomic displacement ellipsoids drawn at the 30% probability level. H atoms are omitted for clarity and indicated by partial bonds only.

			asym. δ-env.	asym. λ-env.

[a] The deviations are considered positive when the atom is on the same side as the benzyl group atoms (C21 to C27).

the complex GKCl (**1**) adopts an asymmetric δ-envelope/λ-skew boat/asymmetric δ-envelope conformation (for nomenclature see [20]). Thus complex **2** has a similar conformation to the [Ni((*S*)-BBP-L-Ser)] and [Ni((*S*)-BBP-L-aaIm)] complexes reported by Pessoa et al. [17], while complex GKCl (**1**) has a conformation somewhat similar to [Ni((*S*)-BBP-Gly)], reported by the same authors, but published earlier by us [13c,15].

We observed a π-charge delocalization, similar to the recently described structure of the Ni complex of the Schiff base of (*S*)-*N*-(2-benzoylphenyl)-1-benzylpyrrolidine-2-carboxamide and (*S*)-2-amino-3-(1-naphthyl)propanoic acid [7], in the proximity of the N2 atom due to the free π-orbital of this nitrogen atom. The bonds {complex **1**: N2–C6 1.3968(16) Å, N2–C5 1.3910(15) Å; complex **2**: N2–C6 1.398(3) Å, N2–C5 1.371(3) Å} are shorter than the published [21] average value for the N–C(sp^2) bond {$d_{C-N} \approx 1.47(1)$ Å}. We also found a small deviation of the C5–O1 bond {complex **1**: 1.2299(15) Å, complex **2**: 1.230(3) Å} from the published [9] value of $d_{C=O} \approx 1.21(1)$ Å for ketones. The situation is less clear at the N3 atom {complex **1**: N3–C12 1.3059(16) Å, N3–C19 1.4838(16) Å; complex **2**: N3–C12 1.300(3) Å, N3–C19 1.509(3) Å}. These values are in good accordance with the average values for 17 similar structures [1f,14, Refs. [17,19,20,22–24] in 13c,22], namely 1.40(3) Å for N2–C6, 1.37(2) Å for N2–C5, 1.231(9) Å for C5–O1, 1.301(13) for N3–C12 and 1.48(2) Å for N3–C19.

The hydrogen bond schemes of the two complexes are different: complex GKCl (**1**) forms a chain along the *c*-axis (Fig. 3) via weak hydrogen bonds of C–H···O type (for details see Table 3), while the Me_2GK complex **2** forms dimers of molecules, mediated by a water molecule located at the crystallographic twofold axis, see Fig. 4.

In order to assign the ^{1}H NMR and ^{13}C NMR spectra, cross-peaks in 2D NOESY spectra due to a through-space interaction mechanism were obtained for neighbouring protons and, thus, such cross-peaks were found in analogous positions as those observed in the H,H-COSY spectrum based on coupling constants. Conformationally, the most important cross-peaks in the 2D NOESY spectra were found for pairs of resonances at δ 7.00/1.78,

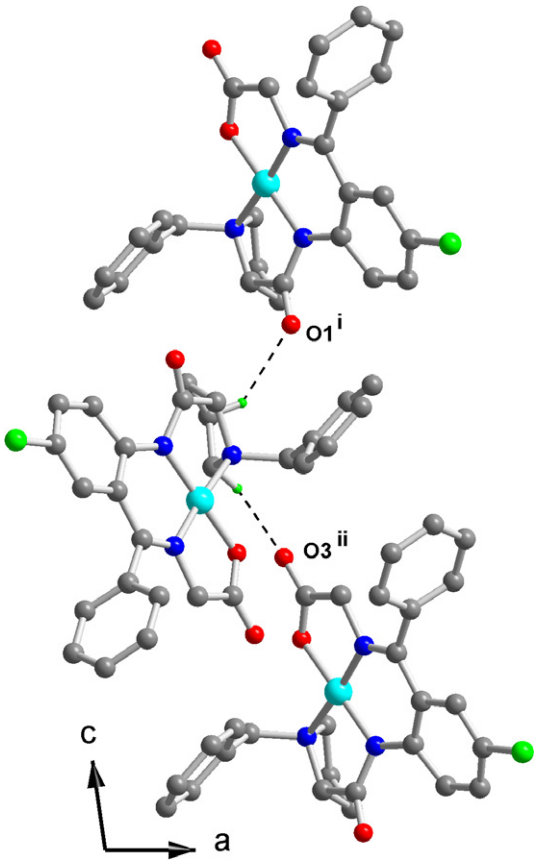

Fig. 3. The hydrogen-bonding pattern in the crystal lattice of **1**. Only H atoms taking part in the presented bonds are shown. For symmetry codes see Table 3. Chains of molecules parallel to c-axis are formed.

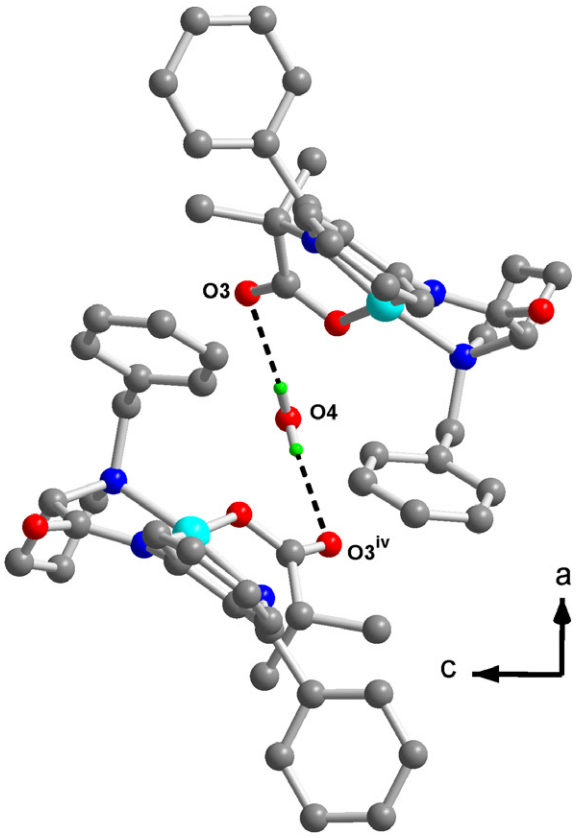

Fig. 4. The hydrogen-bonding pattern in the crystal lattice of **2**. Only H atoms taking part in the presented bonds are shown. Dimers of molecules are formed. Symmetry code: (iv) $-x, -x+y, 1/3-z$.

Table 3
Hydrogen-bonding geometry (Å, °) for GKCl complex (**1**) and Me_2GK complex (**2**)

D–H···A	D–H	H···A	D···A	D–H···A
Complex ***1***				
C2–H2A···O1^{i}	0.99	2.55	3.2946(17)	131.9
C7–H7···O1	0.95	2.25	2.7089(16)	108.5
C21–H21B···O2	0.99	2.38	2.9247(16)	113.8
C1–H1B···O3^{ii}	0.99	2.51	3.4824(19)	167.8
Complex ***2***				
O4–H4A···O3	0.79(4)	2.16(4)	2.942(3)	167(4)
C1–H1B···O2	0.99	2.32	2.893(4)	116.2
C7–H7···O1	0.95	2.27	2.807(3)	115.2
C21–H21B···O3^{iii}	0.99	2.58	3.506(4)	155.9
C28–H28B···O3	0.98	2.40	2.819(4)	105.0

Symmetry codes: (i) $2-x, 1/2+y, 2-z$; (ii) $2-x, 1/2+y, 1-z$; (iii) $-1-x+y, 1-x, z-1/3$.

7.28/1.08, 6.71/7.28, 4.46/3.46 and 8.08/3.46 ppm, corresponding to space proximity of protons H14/H28, H18/H29 (the assignment of these two pairs may be mutually interchanged since an absolute assignment is not clear), H10/H18, H4/H21 and H4/H23,27. From these experimental results it follows that the conformation of the Ni complex in solution should be the same as that in the solid state. Similarity of conformations in $CDCl_3$ solution and in the solid state was previously proved for a similar complex derived from glycine [13a,13b], in the case of the complex derived from (*S*)-2-amino-3-(1-naphthyl)propanoic acid, conformations in $CDCl_3$ solution and in the solid state are significantly different [7].

In complex **2**, the repulsion between the benzyl group and an equatorial methyl group affects the conformation of the benzyl group, distribution of π-electron density in this group and distortion of the internal coordination sphere. In strong contrast to the complex (^{15}N)GK [16] derived from non-substituted (^{15}N)glycine, long range through-space spin–spin interactions are not observed in ^{13}C and ^{15}N NMR spectra of complex **2** (Table 1). A longer distance from the benzyl group to the amino acid and the benzophenone fragments of the molecule is probably responsible for this absence of spin–spin interactions. In (^{15}N)GK, a partial positive charge of the nickel atom leads to polarisation of π-electron density of the benzyl group towards the nickel atom [15]. In several similar complexes, MP2 modelling followed by a topological analysis revealed the formation of weak covalent bonds between carbon atoms in the benzyl group and carbons in the benzophenone fragment or oxygen atoms of the carboxy residue [A. Popkov, M. Breza, unpublished results]. Both polarisation and the weak bond formation could be involved in long range through-space spin–spin interactions. In the complex **2**, these two factors do not play their role due to

a more distant position of the benzyl group compared to complex (^{15}N)GK.

Preparation of a labelled analogue of complex **1** from (^{15}N)glycine is underway.

Appendix A. Supplementary material

CCDC 294429 and 294430 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.09.103.

Scheme 1.

–CH_2COOMe arm was observed; however, weak intermolecular O···H bonds lead to a dimeric arrangement.

2. Experimental

2.1. Materials and physical measurements

All reagents and solvents were commercially obtained, and used without further purification. The ACDA [25,26], ACDASA [6], and ACDASAMe [24] were synthesized by methods in the literature. Infrared spectra were recorded in the range 4000–200 cm^{-1} on a Bruker Vector 22 spectrometer as CsI powder. The ^1H (300 MHz) and ^{13}C (75 MHz) NMR spectra were recorded in DMSO and $CDCl_3$/DMSO (2:1) mixture on a Jeol Eclipse+ 300 spectrometer at room temperature using TMS as reference or solvent signal. EI-mass spectra were performed on a JEOL JMS-AX505HA instrument. UV–Vis spectra were determined in $CHCl_3$ solutions (240–800 nm) on a Spectronic Genesys 5 spectrophotometer using a quartz crystal cell equipped with a Teflon cap. Elemental analyses were obtained from Galbraith Laboratories (Knoxville, TN).

2.2. Ni(ACDASAMe)$_2$ (1)

$NiCl_2 \cdot 6H_2O$ (0.237 g, 1 mmol) was dissolved in ethanol and added to an ethanolic solution of ACDASAMe (0.462 g, 2 mmol). The mixture was stirred for 45 min and the compound that precipitated out as green needles was filtered off and washed with ethanol several times. Yield 0.38 g (73.3%), m.p. 226–227 °C. *Anal.* Calc. for $C_{18}H_{24}N_2NiO_4S_4$: C, 41.63; H, 4.66; N, 5.39. Found: C, 41.37; H, 4.58; N, 5.34%. IR (CsI power) cm^{-1}, 3281s ν(N–H), 1588m ν(N–H) + ν(C=C), 950m and 905m ν_{as}(CSS), 469w and 498w ν(M–N), 320m ν(M–S), 256w δ(N–M–S). EI–MS: m/z 518 (M^+). ^1H NMR in DMSO (assignments according to X-ray atom-labeling), δ: 1.83 (m, 2H, CH_2(6)), 2.50 (m, 7H, CH_2(5 and 7) + DMSO), 3.64 (s, 3H, O–CH_3(9)), 3.99 (s, 2H, S–CH_2(2)–), 7.87 (bs, NH(free)). ^{13}C NMR in DMSO (assignments according to X-ray atom-labeling), δ: 21.7 (C(6)), 31.7 and 34.04 (C(5 and 7)), 37.85 (C(2)), 52.27 (C(9)), 123.08 (C(3)), 154.01 (C(8)), 169.01 (C(4)), 175.18 (C(1)).

2.3. Co(ACDASAMe)$_2$ (2)

ACDASAMe (0.462 g, 2 mmol) was dissolved in ethanol and added to a solution of $CoCl_2 \cdot 6H_2O$ (0.238 g, 1 mmol) in ethanol. The mixture was stirred for 45 min and the brown precipitate was filtered off and washed with ethanol several times. Yield 0.43 g (82.8%), m.p. 191–192 °C. *Anal.* Calc. for $C_{18}H_{24}CoN_2O_4S_4$: C, 41.61; H, 4.66; N, 5.39. Found: C, 41.23; H, 4.55; N, 5.33%. IR (CsI power) cm^{-1}, 3256s ν(N–H), 1592m ν(N–H) + ν(C=C), 943m and 908m ν_{as}(CSS), 460w and 497w ν(M–N), 375w ν(M–S). EI-MS: m/z 518 (M^+).

2.4. X-ray analysis

Suitable crystals for X-ray analysis of Ni(ACDASAMe)$_2$ were obtained from a mixture of CH_2Cl_2 and hexane. The data collection was performed on a Siemens P4/PC diffractometer at room temperature, with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Crystal data: $C_{18}H_{24}N_2NiO_4S_4$, $M = 519.34$, Crystal size $0.52 \times 0.16 \times 0.06$ mm, Monoclinic, $a = 8.808(2)$ Å, $b = 20.393(7)$ Å, $c = 12.476(2)$ Å, $\beta = 92.97°$, $V = 2237.9\ (10)$ Å^3, Density (calculated) 1.541 Mg/m^3, $T = 293(2)$ K, space group $P2_1/n$ (No. 14), $Z = 4$, μ (Mo Kα) = 1.267 mm^{-1}, 4213 reflections collected, 3943 unique ($R_{int} = 0.0565$) which were used in all calculations. Maximum and minimum transmission 0.870 and 0.777, final R values: $R_1 = 0.0531$, $wR_2 = 0.0968$, $R_1 = 0.1110$, $wR_2 = 0.1182$ (all data) ($R_1 = \sum\|F_o|-|F_c\|/\sum|F_o|$, $wR^2 = [\sum w(F_o^2 - F_c^2)^2/\sum w(F_o^2)^2]^{1/2}$), goodness-of-fit 1.030. The structure was solved by direct methods using SHELXS-90 [27] and refined by full-matrix least-squares on F^2 using SHELXL-97 [28]. The hydrogen atoms of the amino moiety were located from the difference map and their positional parameters refined.

3. Results and discussion

The metal complexes were readily obtained by mixing equimolar amounts of metal chloride with the free ligands in ethanol. They exhibit varying degrees of solubility in common organic solvents such as CH_2Cl_2, $CHCl_3$, EtOH, DMSO, ethyl acetate, etc.

The IR spectra of the complexes exhibit characteristic bands that emulate the features observed for the (N,S) coordination mode on diorganosilicon(IV) and indium(III) compounds with an S-alkyl substituted ACDA type ligand [29,30]. The ν(N–H) bands (3281, 1588 and 3256 and 1592) are shifted to higher frequencies in relation to the free ligand (3320 and 1615 cm^{-1}). This is indicative of the deprotonation of NH_2 group on M–NH coordination. In addition, the presence of two signals at 940 and 910 cm^{-1} (ν_{as}(CSS)) provides evidence for the M–S coordination through one sulfur atom. These observations have been further supported by the appearance of new bands at low frequencies, which can be assigned to ν(M–N) and ν(M–S) modes.

In the ^1H NMR spectrum, the lack of the signal at 11 ppm (which corresponds to the proton of the amino group involved in the N–H···S bond in the free ligand

[24]) indicates the removal of that proton on complexation. This is confirmed by a downfield shift of the remaining NH signal at 7.87 (at 6.0 ppm for the free ligand) suggesting an M–N coordination. In addition, the upfield shift of the S–CH_2(2)– proton signals supports the involvement of the sulfur atom on coordination. Similar patterns were also observed in the analogous organosilicon(IV) and indium(III) complexes reported by Sharma [29] and Singh [30] respectively, for which they also suggested a bidentate coordination of the ACDA type ligands through the nitrogen and sulfur atoms.

The UV–Vis spectra of **1** and **2** in $CHCl_3$ solution were obtained, the high intensity bands below 380 nm are probably of ligand origin assignable to intraligand n–π/π–π* transitions. The absorptions observed at 380 and 440 for **1**, and at 397 nm for **2** may be interpreted as ligand to metal charge transfer bands [31]. The lowest energy absorption at 612 for **1** has an intensity consistent with the spin allowed d–d transition $^1A_{1g} \rightarrow {}^1A_{2g}$, as expected for a square planar d^8 species [31]. The second ligand field band ($^1A_{1g} \rightarrow {}^1B_{1g}$), expected to appear at higher energy, may be assigned to the shoulder at 480 nm. Similar spectrum patterns are commonly observed for analogous square-planar Ni(II) complexes with N_2S_2 coordination sphere [15,34]. For cobalt(II) complex **2**, the absorptions associated with the d–d transitions are masked by the tail of the more intense ligand to metal charge transfer bands. The mass spectra show low-intensity signals for the corresponding molecular ions, but rather intense signals for the ligand and fragments containing metal, all exhibiting the expected isotopic distribution patterns.

3.1. Description of the Ni(ACDASAMe)$_2$ (1) structure

Selected bond distances and angles are given in Table 1. Fig. 1 shows a thermal ellipsoid plot of the molecular structure of the Ni(ACDASAMe)$_2$ (**1**) along with the atom-labeling.

The structure consists of independent neutral Ni(ACDASAMe)$_2$ molecules with the nickel(II) exhibiting a slightly distorted square planar coordination. The metal center is coordinated by two ligands through the nitrogen and sulfur atoms showing a *cis* configuration. Both chelate rings are planar (the mean deviations from plane are 0.0174 and 0.0401 Å) with an angle of 8.4° between them. Therefore nickel(II) geometry deviates somewhat from the perfect square planar (mean deviation of 0.0731 Å). A comparable tetrahedrally distorted square planar structure was found in the nickel(II) complex of methyl-2-(β-salicylaldimino-2-hydroxypropyl)cyclopent-1-ene-1-dithiocarboxylate, $(NiHL^3) \cdot H_2O$ [22]. The *trans* N1–Ni–S3 and N2–Ni–S1 angles are 173.7(2) and 174.6(2)°, while the values for the endocyclic N–Ni–S angles are 95.2(2) and 95.0(2)° and the exocyclic N–Ni–S angles are 88.0(2) and 82.3(1)°. This contrast to the corresponding N–Ni–S angles of 180° observed in the *trans*-nickel(II) complex with the S-methyl substituted ACDA-type ligand (ACDE, methyl 2-amino-1-cyclopentenedithiocarboxylic acid) [15].

Table 1
Selected bond distances (Å) and angles (°) for Ni(ACDASAMe)$_2$

Interatomic distances (Å)		Bond angles (°)	
Ni–N(1)	1.875(5)	N(1)–Ni–N(2)	88.0(2)
Ni–N(2)	1.878(5)	N(1)–Ni–S(1)	95.2(2)
Ni–S(1)	2.175(2)	N(2)–Ni–S(1)	174.6(2)
Ni–S(3)	2.176(2)	N(1)–Ni–S(3)	173.7(2)
S(1)–C(8)	1.725(6)	N(2)–Ni–S(3)	95.0(2)
S(2)–C(8)	1.770(6)	S(1)–Ni–S(3)	82.3(1)
S(3)–C(17)	1.714(6)	C(8)–S(1)–Ni	111.7(2)
S(4)–C(17)	1.772(6)	C(8)–S(2)–C(2)	105.3(3)
N(1)–C(4)	1.297(7)	C(17)–S(3)–Ni	112.0(2)
N(2)–C(13)	1.303(8)	C(4)–N(1)–Ni	133.8(4)
C(3)–C(8)	1.364(8)	C(13)–N(2)–Ni	133.5(4)
C(3)–C(7)	1.515(8)	C(8)–C(3)–C(4)	124.5(5)
C(3)–C(4)	1.431(8)	C(3)–C(8)–S(1)	127.1(4)
C(5)–C(6)	1.528(9)	C(3)–C(8)–S(2)	114.8(4)
C(4)–C(5)	1.519(8)	C(17)–C(12)–C(13)	125.8(5)
C(12)–C(13)	1.422(8)	C(17)–C(12)–C(16)	126.1(5)
C(6)–C(7)	1.528(9)	C(12)–C(17)–S(3)	126.2(5)
C(12)–C(17)	1.306(8)	S(3)–C(17)–S(4)	118.1(4)
C(12)–C(16)	1.528(8)		
C(13)–C(14)	1.503(8)		

In comparison with the free ligand a shortening of the N1–C4, C3–C8 bonds distances, and a lengthening of C3–C4, C8–S1 bond lengths within the six-membered chelate ring are observed. This and the angles at C8, which are closer to those of the ideal sp^2 hybridization, are in accordance with a significant electronic delocalization in the chelate rings. The Ni–S and Ni–N bond lengths (av. 2.175 and av. 1.876 Å) are comparable to those observed in the above mentioned *trans*-nickel(II) complex, Ni(ACDE)$_2$ [15].

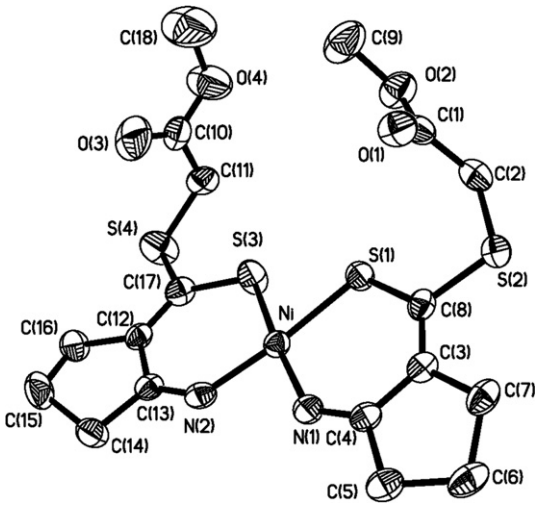

Fig. 1. ORTEP plot of the molecular structure of the Ni(ACDASAMe)$_2$ (**1**) along with the atom-labeling.

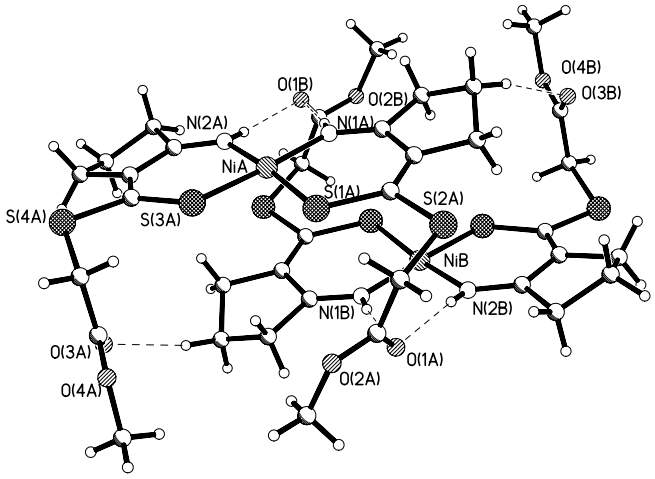

Fig. 2. Dimeric association through hydrogen bonds between two adjacent Ni(ACDASAMe)$_2$ molecules.

In our compound, the most remarkable feature is the *cis* arrangement of the ACDASAMe ligands. The two –CH_2COOMe moieties lie down the coordination plane in a nearly perpendicular fashion (75.2 and 89.5°). Although the potential oxygen donor atom from the –CH_2COOMe arms is available for coordination, no metal interaction is observed. This confirms the observed inherent reluctance on the part of nickel(II) to adopt pentacoordination in the presence of a hard donor atom to occupy the axial position as in $(NiHL^3)\cdot H_2O$ [22,32] where the dangling free pyrazolyl arm exhibits no metal interaction. In our compound, the –C=O group of one of the hanging moieties establishes two hydrogen bonds with the *cis* NH groups of a neighboring molecule. The –C=O group of the remaining arm forms a hydrogen bridge with the C6 atom from the same neighboring molecule. These hydrogen bridges between the two adjacent molecules lead to a dimeric assemblage (see Fig. 2). The O···N distances O(1A)···N(1,2B) = av. 3.19 Å and O(3A)···C(6) = 3.428(2) Å are in the expected range for weak hydrogen bonds [33]. Probably, these hydrogen bonds are responsible of the observed *cis* configuration since they avoid a *trans* ligand arrange similar to that found in the related nickel(II) complex, Ni(ACDE)$_2$ [15]. A comparable *cis*-array was observed in the analogous palladium(II) and platinum(II) complexes of ACDE, where a water molecule hydrogen bonded to both amine protons prevents the claimed favored *trans* configuration observed with nickel(II) [15].

In addition to these intermolecular interactions, there are short S–O distances, which hold the crystal packing.

4. Conclusion

The most remarkable feature is the dimeric assemblage of the Nickel(II) complex, which results from the hydrogen bonds between the dangling –CH_2COOMe arms and the *cis* NH groups and the C6 of the main building of two adjacent molecules. This fact might be the origin of the *cis* configuration of the ACDASAMe ligands on interacting with nickel(II) that avoid the expected ligands *trans* isomerism.

5. Supplementary material

CCDC 286991 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 2. Preparation of **1** at varied pH.

was stirred and heated in a grease free Schlenk for 1 day at 65 °C.

After 1 day, the reaction mixture was filtered and transferred to a beaker for further crystallization. The clear reaction mixture yielded white crystals suitable for X-ray diffraction. Yield = 42% (based on $InCl_3$), Mp >250 °C, the sample shows an evolution of a gas in the interval 100–105 °C (H_2O). The sample did not melt at 250 °C. IR (KBr pellets, υ cm^{-1}); 3413.0 (s), 1067 (m), 1613 (s), 1578 (m), 1383 (m), 784.37 (m), 738.61 (m), 709.0 (m), 568.26 (m).

5. Preparation of 3

An aqueous solution of DMSO (dimethyl sulfoxide) (5 ml) pyrazine (0.04 g, 0.50 mmol), indium(III) chloride tetrahydrate (0.22 g, 0.75 mmol) were stirred at room temperature in an open beaker for 24 h. The solution was filtered to remove any insoluble material. After storage at room temperature for 1 day suitable white crystalline material was obtained. Yield = 49%, based on $InCl_3$, Mp = 137–138 °C. IR (KBr pellets, υ cm^{-1}); 3569.3 (w), 3036.1 (m), 2999.5 (m), 2932.6 (m), 2918.8 (m), 1409.2 (s), 1316.6 (m), 1296.3 (s), 1036.0 (s), 988.15 (s), 951.08 (m).

6. Results and discussion

The reaction of aqueous ethanol or methanol solutions of $InCl_3 \cdot 4H_2O$ with pyrazine ($C_4H_4N_2$) or pyrazine, 2-carboxylic acid (pyz-ca) (1:1.5) at 70 °C for 24 h, is a moderate yielding facile reaction affording $[InCl_3(pyz)]_n$ compound **1**, and $[InCl_3(OH)_2(pyz\text{-}ca)]_n$ compound **2** (Scheme 1). Compound **1** crystallizes as a one-dimensional polymeric material and compound (2) a one-dimensional zigzag framework. Pyrazine and pyz-ca were selected as spacer molecules as are crystalline bidentate molecules, which have good solubility in readily available 'green' solvents such as ethanol and water. Derivatives of the pyrazine molecule, such as pyrazine, 2-carboxylic acid are useful as they promote hydrogen bonding that is often crucial for framework growth.

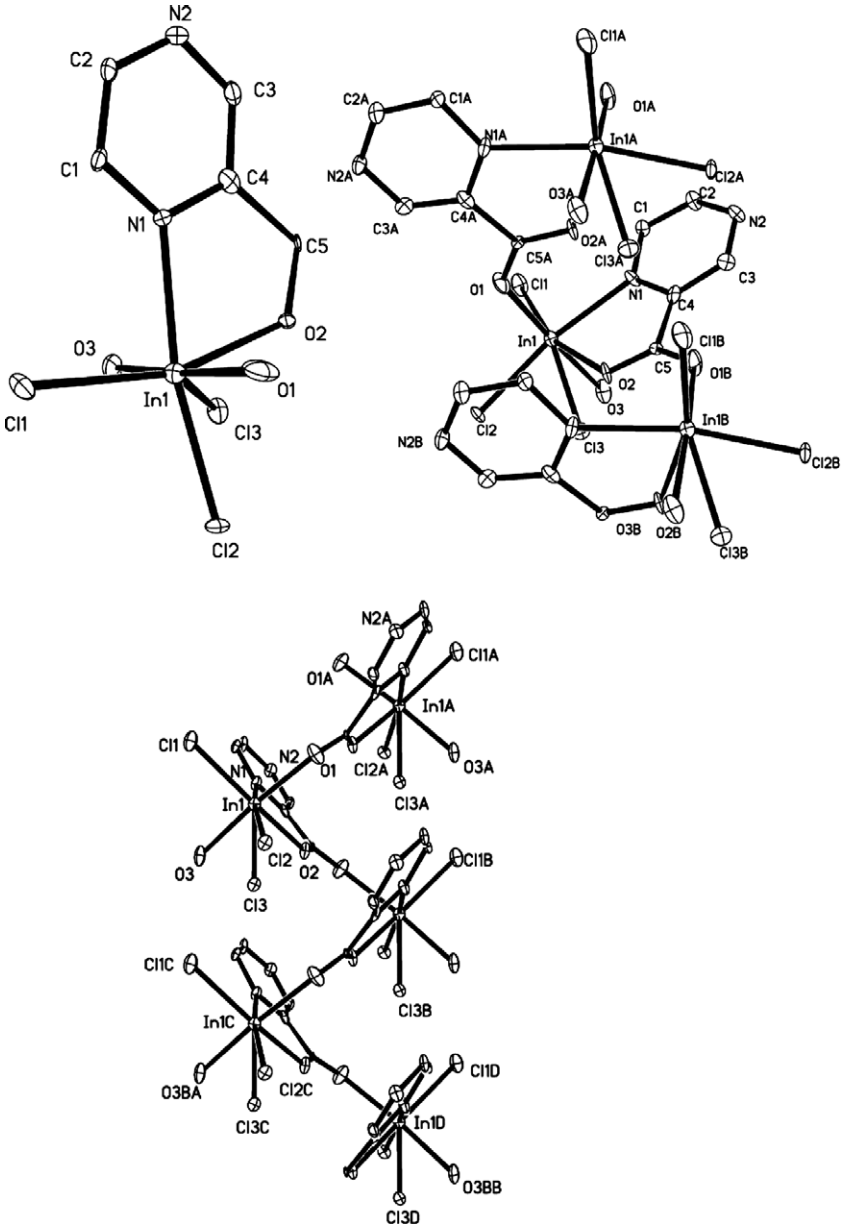

Fig. 3. ORTEP of compound **2**, thermal ellipsoids at 30% probability, hydrogen atoms are removed for clarity.

The solid-state structure of **1** was determined using X-ray crystallography[1] (Fig. 2), and revealed a six-coordinated indium center and a polymeric structure interlinked through pyrazine molecules. Crystal data for compounds **1**–**3** is given in Table 1.

Compound **1** crystallizes in the tetragonal space group, *P*4(2)/*mnm*. The asymmetric unit consists of one indium center, two halves of bridging pyrazine molecules and two terminal chloride ions. One of the bridging pyrazine molecules is disordered over 2 by symmetry equivalent positions. Because of the disorder associated with this pyrazine, the structure was refined with no hydrogen on the carbon atom, C(2). The geometry of both orientations is shown in Fig. 2. The In(III) center is coordinated to three chlorine atoms and three nitrogen atoms. The coordination geometry can be described as a slightly distorted octahedron. Selected bond lengths and angles are given in Table 2.

The In–Cl distances are within the expected range, however the In–N distance of 2.372 Å is shorter than the distances of 2.528–2.540 Å that are found in compound **A** (Fig. 1) [8a]. This shortening of the bond is presumably

[1] Crystal data were collected with a Bruker SMART 1000 diffractometer using graphite monochromated molybdenum radiation ($\lambda = 0.7107$ Å). The data were corrected for absorption. Structures were solved by direct methods using the SHELXS-97 program and refined via full-matrix least squares: (a) G.M. Sheldrick, SHELXS-97, Program for the solution of crystal structures; University of Göttingen, Germany, 1997; (b) G.M. Sheldrick, SHELXL-97, Program for the refinement of crystal structures.

due to packing arrangement of the octahedral geometry. The rectangular distance between the chains is 6.997 by 7.503 Å, which is comparable to a distance of 7.8 Å along the pyrazine linker axis of compound **A** [8a] (Fig. 1).

Previous research [12] has described how pH plays an important role in the assembly process; therefore, the synthesis of **1** was performed under various pH conditions.

Experimental results revealed that an acidic medium is required for the preparation of **1**. Under basic conditions compound **1** could not be isolated, furthermore if the reaction were performed in the presence of a base such as pyridine (Scheme 2, reaction (i)), or triethylamine the products isolated were the adduct, $InCl_3(py)_3$ or $NEt_3{}^+Cl^-$.

The original crystalline material that the X-ray data were collected on was obtained from a reaction mixture of indium(III) chloride and indium(III) nitrate, however further experimental work has shown that compound **1** can also be isolated directly from the reaction of indium(III) chloride with pyrazine under similar reaction conditions.

In a similar manner as was used to prepare compound **1**, compound **2** was isolated as X-ray quality single colorless crystals from methanol. The solid-state structure and key bond lengths and angles are depicted in Fig. 3. Each indium center is coordinated to three chlorides, one nitrogen atom from the pyrazine spacer and three oxygen atoms.

Presumably, the oxygen (OH) coordinated to the indium center arises from the aqueous reaction medium and reaction work-up and aids in the formation of a framework structure through hydrogen bonding.

A seven-coordinated indium atom affords distorted pentagonal bypyramidal geometry. The high coordination number at the indium center is not a new phenomenon and has been previously observed in an indium three-dimensional oxalate polymer [13]. Each indium center is linked by a bridged oxygen atom resulting in an infinite 'zigzag' polymeric structure. The approximate distance between the zigzag chains is 6.029 Å (i.e. from Cl1a–Cl1b, or O3–O3ba). The average In–O distance is 2.171 Å (see Table 3 for pertinent bond lengths and angles) which is comparable to 2.154 Å as observed in similar indium–carboxylate systems [14].

The infra-red spectra of **2** reveals a broad peak centered at 3413 cm^{-1} attributed to the symmetric and asymmetric stretch of the hydroxyl group. At 1067 cm^{-1} the bending mode of μ-OH is observed and at 1613 (s), 1578, 1478 and 1383 cm^{-1} frequencies that correspond to υ asym, υ sym (CO_2H) [14].

In the course of preparing compounds **1** and **2** various solvent systems were investigated. $[InCl_3(dmso_2)(pyz)]_2$, compound **3** (Fig. 4) was isolated from the reaction of $InCl_3 \cdot 4H_2O$ with pyrazine in DMSO (dimethylsulfoxide).

The isolation of compound **3** reveals that in order to obtain a polymeric framework, coordinating solvents must be avoided to prevent blocking potential coordination sites at the metal center. Compound **3** is a dimeric In(III) complex that has a slightly distorted octahedral geometry around both indiums that are linked by a molecule of pyrazine. Each indium center also has two molecules of DMSO coordinated. No noteworthy discrepancies in bond lengths or angles are observed.

Table 3
Selected bond lengths (Å) and angles (°) of compound **2**

In(1)–O(1)	2.186(10)
In(1)–O(2)	2.159(8)

N(1)–In(1)–Cl(1)	89.9(3)

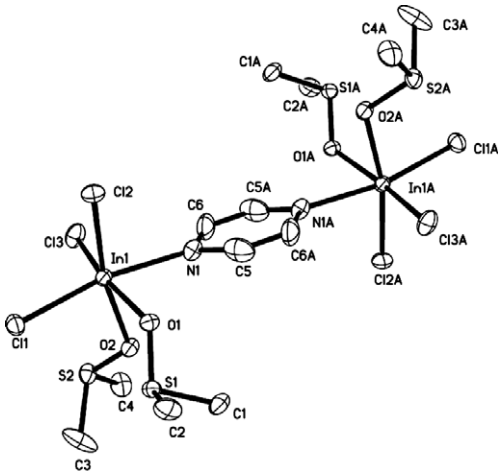

Fig. 4. ORTEP of compound **3**, thermal ellipsoids are at 30% probability, hydrogen atoms are removed for clarity.

Compounds **1**–**3** are insoluble in non-polar solvents, but readily soluble in polar solvents. Compounds **1** and **2** have high thermal stability and show no visible decomposition at temperatures of >250 °C. Compound **3** has a lower melting point of 137–138 °C as anticipated given the DMSO coordination.

Preliminary experiments to exchange the indium atoms with inorganic ions in compounds **1** and **2** have to date been unsuccessful but will be pursued in forthcoming work.

7. Conclusions

The resultant structures **1**–**3** provide an interesting comparison of how changing the functionality of the spacer and the reaction conditions can direct the framework motif. These results will be used in future work to develop the syntheses of a variety of structural frameworks for new chemical systems and will study the application potential of these systems.

8. Supplementary materials

CCDC 610418, 610417 and 610416 contain the supplementary crystallographic data for **1**, **2** and **3**. These data can be obtained free of charge via htpp://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; or e-mail: deposit@ccdc.cam.ac.uk.

2. Experimental

2.1. Material and instrumentation

Infrared spectra were recorded on Nicolet AVATAR 360 FT-IR instrument as KBr plates. Elemental analysis (C, H, N) were performed with Element Analysis system EA 1112 CE Instruments by the Korea Basic Science Institute. $[Fe^{III}(\mathbf{L})_2](ClO_4)$ was prepared according to the literature [5]. All other materials were used as received without further purification.

2.2. Synthesis of $[(Fe^{II}(\mathbf{L})_2)(Mn^{III}(salen))(ClO_4)\cdot 2CH_3CN\cdot CH_3OH]$ ($\mathbf{1}\cdot 2CH_3CN\cdot CH_3OH$)

Method A. A mixture of a solution of $[Fe^{III}(\mathbf{L})_2](ClO_4)$ (0.134 g, 0.2 mmol) in CH_3CN (15 mL) and a solution of $[Mn(salen)(H_2O)](ClO_4)$ (0.088 g, 0.2 mmol) in CH_3OH (10 mL) was refluxed overnight. After cooling at ambient temperature, small amount of precipitate was removed by filtration. Resultant dark brown solution was left without any disturbance. The golden flat crystals were separated. (0.082 g, 46.8%). *Anal.* Calc. for $C_{28}H_{28}B_2ClFeMnN_{20}O_4$ (vacuum-dried powder): C, 38.37; H, 3.22; N, 31.96. Found: C, 37.99; H, 3.58; N, 32.05%. IR (KBr, cm^{-1}): 2512 (w, ν(BH)), 1147, 1095(s, $\nu(ClO_4)$).

Method B. A mixture of $[Fe^{III}(\mathbf{L})_2](ClO_4)$ (0.033 g, 0.05 mmol) and hydroquinone (0.011 g 0.1 mmol) in CH_3CN (5 mL) was mixed up with a solution of $[Mn(salen)(H_2O)](ClO_4)$ (0.022 g, 0.05 mmol) in CH_3OH (5 mL). Resultant dark brown solution was left without any disturbance. The golden flat crystals were separated.

2.3. Crystal structure and determination

The diffraction data for **1** were collected on a Nonius Kappa-CCD diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) at 150(1) K. The CCD data were integrated and scaled using the DENZO-SMN software package [6]. The structures were solved by SIR-92 and refined by using SHELXTL/PC V6.12 [7]. There exist two molecules of CH_3CN and one molecule of CH_3OH. But CH_3OH was grossly disordered and was inhibiting the refinement. Therefore, CH_3OH contribution was removed using SQUEEZE (PLATON) [8]. All hydrogen atoms were located in the calculated positions on riding model. Crystallographical data and refinement details for **1** are listed in Table 1.

2.4. X-ray absorption spectroscopy

Fe K-edge X-ray absorption spectra were recorded in the Electrochemistry beam line (BL7C1) of Pohang Accelerater Laboratory (PAL) with a ring current of 120–170 mA at 2.5 GeV. A Si(1 1 1) monochromator crystal was used with detuning to 85% in intensity to eliminate high-order harmonics. The data were collected in transmission mode with the nitrogen (85%) and argon (15%) gas-filled ionization chambers as detectors. Energy calibration was carried out for all measurements using Fe foil placed in front of the third ion chamber, assigning the first inflection point to 7112 eV.

3. Results and discussion

The reaction of $[Fe^{III}(\mathbf{L})_2](ClO_4)$ with $[Mn(salen)](ClO_4)$ afforded a 1D coordination polymer of $[(Fe^{II}(\mathbf{L})_2)(Mn^{III}(salen))(ClO_4)\cdot 2CH_3CN\cdot CH_3OH]$ ($\mathbf{1}\cdot 2CH_3CN\cdot CH_3OH$) as golden plate crystals. During the reaction, $[Fe^{III}(\mathbf{L})_2]^+$ is reduced to ferrous species of $[Fe^{II}(\mathbf{L})_2]$, due to the strong reducing ability of the borate ligand [9a]. Hydroquinone facilitated the reduction of $[Fe^{III}(\mathbf{L})_2]^+$. It implies that $[Fe^{III}(\mathbf{L})_2](ClO_4)$ should be considered as a good metalloligand which can introduce the spin crossover candidate [9,10]. ($Fe^{II}N_6$) of $[Fe^{II}(\mathbf{L})_2]$ into multidimensional coordination polymers. Although a neutral $[Fe^{II}(\mathbf{L})_2]$ [9a] has been already known, insolubility of this prohibits its participating in further extended architecture. Meanwhile, $[Fe^{III}(\mathbf{L})_2](ClO_4)$ has the advantage of good solubility in CH_3CN and CH_3NO_3. Single crystal X-ray analysis of $\mathbf{1}\cdot 2CH_3CN\cdot CH_3OH$ reveals that among six N_{exo} atoms of $[Fe^{II}(\mathbf{L})_2]$ moiety, only two ones with an inversion symmetry relation on iron centre take part in coordinating the axial sites of $[Mn(salen)]^+$ in a zigzag manner (Fig. 1). This is because the steric bulkiness of $[Mn(salen)]^+$ moiety prohibits all N_{exo} atoms from coordinating to Mn sites. In comparison, in the case of a small well-directed paddle wheel type $[Rh_2(OAc)_4]$, all the free N_{exo} atoms are bound to the axial sites of rhodium moieties. At last unusual neutral 3D 4^66^9 ferrous framework is fabricated, showing incomplete spin transition [5]. The

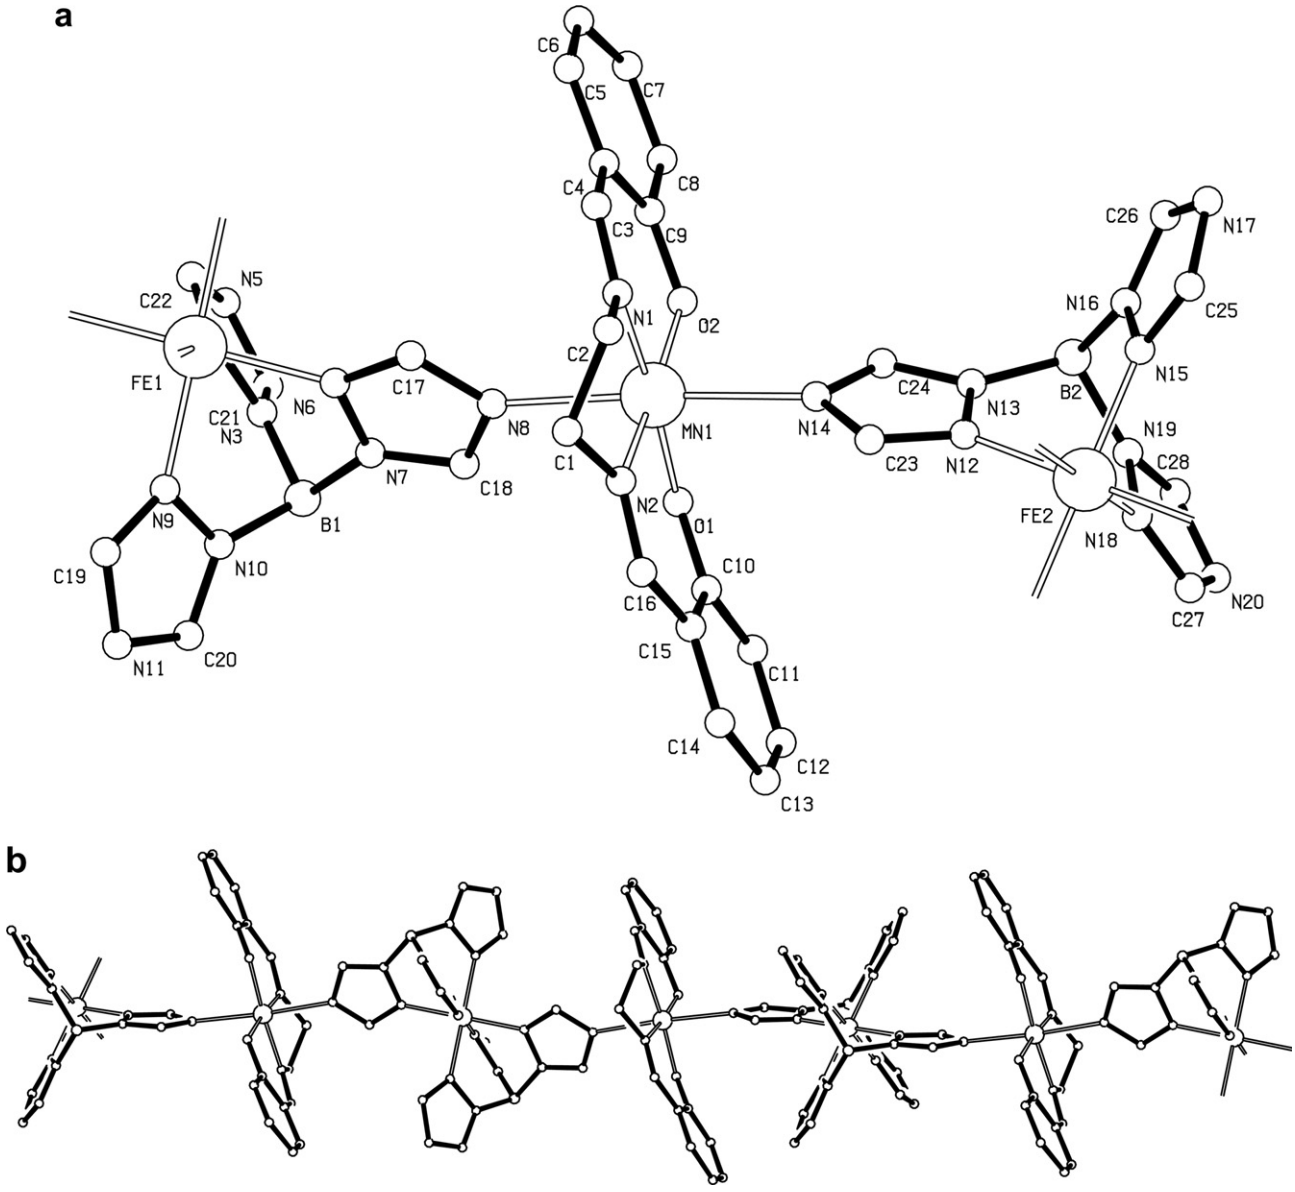

Fig. 1. Asymmetric unit (a) of $\mathbf{1} \cdot 2CH_3CN \cdot CH_3OH$ and 1D infinite chain (b) incorporated with ferrous complex of $[Fe^{II}(\mathbf{L})_2]$. Hydrogen atoms, CH_3CN and CH_3OH were omitted for clarity.

Fe-N bond lengths (1.965(3)–2.018(3) Å) are similar with those of a low spin ferrous complex of $[Fe^{II}(\mathbf{L})_2]$ (avg. 1.99 Å) [9a]. This indicates that the low spin ferrous complex is predominant species at 150 K, comparing with a high spin ferrous complex of $[Fe^{II}(Tp^{3,5\text{-}Me2})_2]$ (2.172 Å) [11] where $Tp^{3,5\text{-}Me2}$ stands for hydrotris(3,5-dimethylpyrazolyl)borate according to the crystallographic evidence. The coordination sphere of Mn^{III} centre comprises N_2O_2 binding system from salen ligand and two N_{exo} atoms of $[Fe^{II}(\mathbf{L})_2]$ moieties with the distances of 2.323(2) and 2.304(2) Å. The angle (176.35(1)°) of N(8)–Mn–N(12) is nearly linear. Consequently, 1D infinite coordination polymer results with Fe^{II}–Mn^{III} set repeating. Selected bond lengths and angles are listed in Table 2. TGA indicate that $\mathbf{1} \cdot 2CH_3CN \cdot CH_3OH$ begins losing CH_3OH and CH_3CN below 26 °C and is completely desolvated above 230°, which related to one CH_3OH and two CH_3CN. Abrupt weight loss at 270 °C is due to the decomposition of **L** and salen. $\mathbf{1} \cdot 2CH_3CN \cdot CH_3OH$ is so efflorescent as to make it difficult to interpret the magnetic property on the ground that XRPD pattern of $\mathbf{1} \cdot 2CH_3CN \cdot CH_3OH$

Table 2
Selected bond lengths (Å) and angles (°) for $\mathbf{1} \cdot 2CH_3CN \cdot CH_3OH$

Fe(1)–N(4)	1.999(3)	Fe(1)–N(6)	1.991(2)
Fe(1)–N(9)	2.018(3)	Fe(2)–N(12)	1.984(2)
Fe(2)–N(15)	1.972(3)	Fe(2)–N(18)	1.965(3)
Mn(1)–N(8)	2.304(2)	Mn(1)–N(14)	2.323(2)
N(4)–Fe(1)–N(6)	86.77(1)	N(4)–Fe(1)–N(9)	90.97(1)

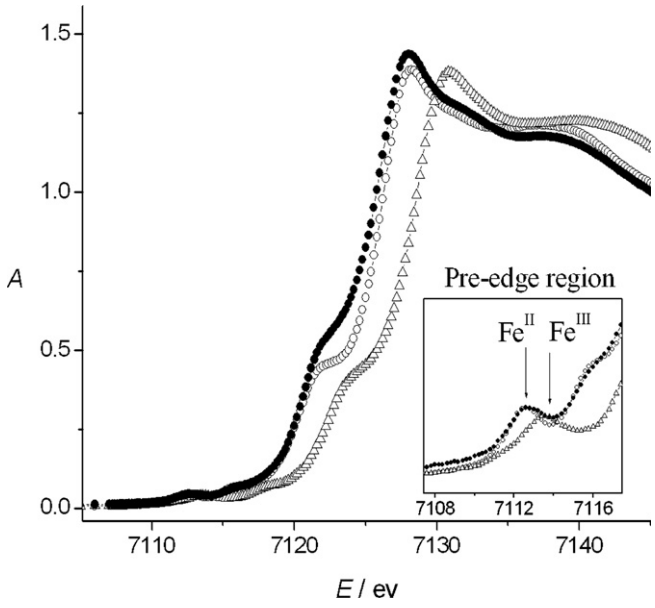

Fig. 2. Fe K-edge XANES spectra of **1** (●), $[Fe^{II}(\mathbf{L})_2]$ (○) and $[Fe^{III}(\mathbf{L})_2](ClO_4)$ (△). The inset shows expanded view of 1s → 3d transition in pre-edge region.

indicates that its 1D framework collapses out of the mother liquor at ambient temperature.

Therefore, we examined the Fe K-edge X-ray absorption structure (XAS) of **1** (vacuum-dried sample), $[Fe^{II}(\mathbf{L})_2]$ and $[Fe^{III}(\mathbf{L})_2](ClO_4)$ for a comparative study at ambient temperature to investigate the oxidation state of the iron centre of **1** (Fig. 2). The features of pre-edge absorption peaks corresponding to 1s → 3d transition in the XAS spectra can inform of the useful structure parameters such as the oxidation state of the chemical species, site symmetry, and covalent bond strength [12,13]. Absorption pattern of **1** in the 1s → 3d pre-edge region (Fig. 2, inset) coincides nearly with that of the low-spin ferrous complex of $[Fe^{II}(\mathbf{L})_2]$ but is far different from that of ferric complex ($[Fe^{III}(\mathbf{L})_2](ClO_4)$). In addition of lower energy absorption of **1** than the ferric $[Fe^{III}(\mathbf{L})_2](ClO_4)$, single 1s → 3d pre-edge absorption peak (7112.6 eV) of **1** is indicative of the low spin ferrous complex like $[Fe^{II}(\mathbf{L})_2]$ (7112.6 eV) because this is able to be assigned as the allowed electric quadrupole transition from $^1A_{1g}$ ground state with an electronic hole configuration of $(e_g)^4$ to ^2E_g excited state with $(e_g)^3$ as a pre-edge feature of a low spin ferrous complex [12].

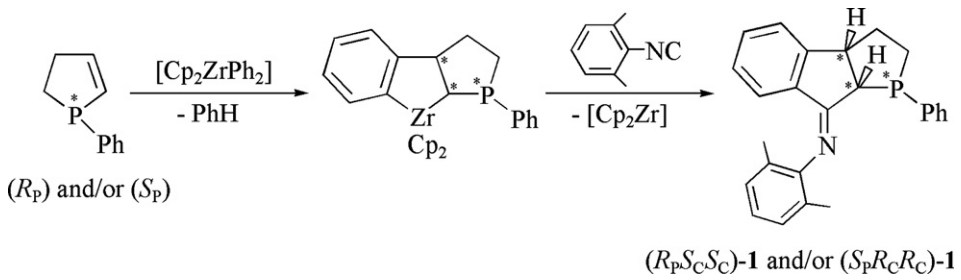

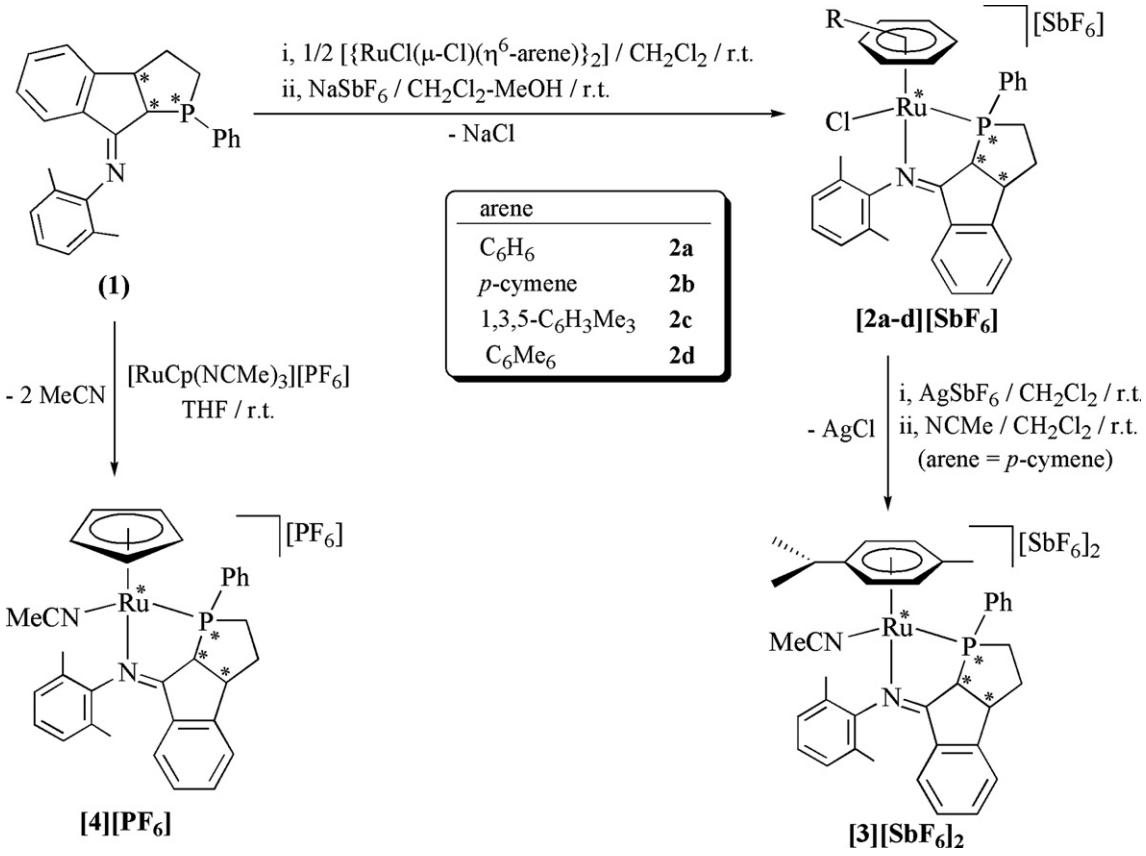

Chart 1. Synthesis of the tricyclic β-iminophosphine ligand **1**.

Scheme 1. Synthesis of half-sandwich ruthenium(II) derivatives containing ligand **1**.

2. Results and discussion

2.1. Synthesis and characterization of the half-sandwich ruthenium(II) compounds [2a–d][SbF6], [3][SbF6]2 and [4][PF6]

The treatment of a dichloromethane solution of dimers $[\{RuCl(\mu\text{-}Cl)(\eta^6\text{-arene})\}_2]$ (arene = C_6H_6, *p*-cymene, 1,3,5-$C_6H_3Me_3$, C_6Me_6) [7] with a twofold excess of ligand **1**[1] leads to the selective formation of the cationic derivatives $[RuCl(\eta^6\text{-arene})(\kappa^2\text{-}P,N\text{-}\mathbf{1})][Cl]$ (**[2a–d][Cl]**), which have been isolated as the corresponding hexafluoroantimonate salts **[2a–d][SbF6]** in 65–88% yield *via* classical Cl^-/SbF_6^- exchange using a methanolic solution of $NaSbF_6$ (Scheme 1). Compounds **[2a–d][SbF6]** have been characterized by means of elemental analyses, conductance measurements, and IR and NMR (^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$) spectroscopies, all the data being fully consistent with the proposed structure (details are given in Section 4). Remarkably, the chelation of ligand **1**, which implies the generation of a new stereogenic centre on the ruthenium atom, takes place with complete diastereoselectivity as clearly assessed by the appearance of only one set of signals in their NMR spectra. In particular, the $^{31}P\{^1H\}$ NMR spectra display an unique singlet signal at δ 71.1 (**[2a][SbF6]**), 71.4 (**[2b][SbF6]**), 73.0 (**[2c][SbF6]**) and 69.0 (**[2d][SbF6]**) ppm. The coordination of the imine function

[1] Used as the racemic $R_PS_CS_C/S_PR_CR_C$ mixture.

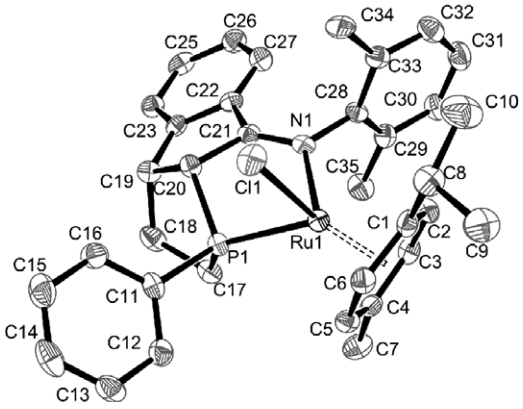

Fig. 1. CAMERON-type view of the structure of cation **[2b]**$^{+}$ showing the crystallographic labelling scheme. Hexafluoroantimonate anion and hydrogen atoms have been omitted for clarity. Thermal ellipsoids are drawn at the 30% probability level. Selected bond distances (Å) and angles (°): Ru–C* = 1.7299(13); Ru–Cl(1) = 2.4090(10); Ru–P(1) = 2.3181(9); Ru–N(1) = 2.145(3); P(1)–C(20) = 1.815(4); C(20)–C(21) = 1.510(5); C(21)–N(1) = 1.293(4); C*–Ru–N(1) = 130.99(9); C*–Ru–Cl(1) = 125.14 (6); C*–Ru–P(1) = 134.68(6); N(1)–Ru–Cl(1) = 88.59(8); N(1)–Ru–P(1) = 78.07(8); P(1)–Ru–Cl(1) = 81.82(4); Ru–P(1)–C(20) = 101.71(12); P(1)–C(20)–C(21) = 104.8(2); C(20)–C(21)–N(1) = 120.3(3); C(21)–N(1)–Ru = 121.3(2). C* = centroid of the *p*-cymene ring (C(1), C(2), C(3), C(4), C(5) and C(6)).

to ruthenium is evidenced by the $^{13}C\{^{1}H\}$ NMR spectra which show a downfield shift of the iminic carbon with respect to the free ligand ($\delta = 190.0$ (**[2a][SbF$_6$]**), 189.8 (**[2b][SbF$_6$]**), 190.0 (**[2c][SbF$_6$]**) and 189.1 (**[2d][SbF$_6$]**) versus 175.0 (**1**) ppm [3b]). Furthermore, the ν(C=N) stretching frequencies (1603 (**[2a][SbF$_6$]**), 1595 (**[2b][SbF$_6$]**), 1580 (**[2c][SbF$_6$]**), 1576 (**[2d][SbF$_6$]**) cm^{-1}) are also in accordance with a metal-bonded imine function [8].

The structure of the cymene compound **[2b][SbF$_6$]** has been unequivocally confirmed by means of an X-ray diffraction study. A drawing of the molecular structure is depicted in Fig. 1; selected bond distances and angles are listed in the caption. Cation **[2b]**$^{+}$ exhibits a classical pseudooctahedral three-legged piano-stool geometry, the coordination sphere around the ruthenium consisting of the *p*-cymene ring, one chloride, and the PhP and imine groups of the bidentate ligand. The distance of the carbon–nitrogen double bond (C(21)–N(1) = 1.293(4) Å) is in the expected range for a coordinated imine function and comparable to that observed in the palladium compound [PdCl$_2$(κ^2-*P*,*N*-**1**)] (C–N = 1.311(12) Å), previously reported by us [5]. The molecule drawn in Fig. 1 shows an $S_{Ru}R_PR_{C(20)}R_{C(19)}$ configuration.[2] As expected, the enantiomer $R_{Ru}S_PS_{C(20)}S_{C(19)}$, not represented here, is also present in the crystal lattice. The preferential formation of the $S_{Ru}R_PR_CR_C/R_{Ru}S_PS_CS_C$ diastereomer versus the $R_{Ru}R_PR_CR_C/S_{Ru}S_PS_CS_C$ one[3] seems to be sterically controlled, the former diastereomer leading to a less congestion between the *p*-cymene ligand substituents and the sterically demanding *P*-phenyl and *N*-mesityl groups. Moreover, in the $S_{Ru}R_PR_CR_C/R_{Ru}S_PS_CS_C$ diastereomer the chloride ligand points in the same direction as the hydrogen atoms C(19)–H and C(20)–H thus minimizing its interaction with the bidentate iminophosphine ligand.

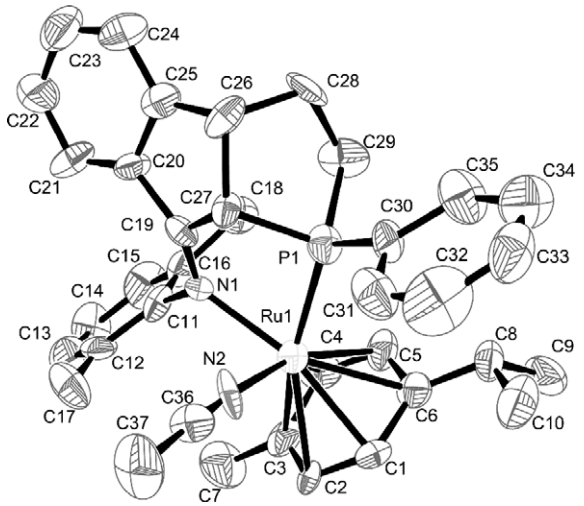
Starting from the *p*-cymene compound **[2b][SbF$_6$]**, the dicationic species [Ru(η^6-*p*-cymene)(NCMe)(κ^2-*P*,*N*-**1**)]-[SbF$_6$]$_2$ (**[3][SbF$_6$]$_2$**) could also be prepared in high yield (71%) through the initial Ag(I)-promoted chloride ligand abstraction and subsequent addition of an excess of acetonitrile (Scheme 1). Compound **[3][SbF$_6$]$_2$** presents spectroscopic data very similar to those of its parent monocationic precursor **[2b][SbF$_6$]**, the most remarkable differences consisting in the appearance of a new resonance at 1.64 ppm in the ^{1}H NMR spectrum, and two singlets at 5.0 and 127.7 ppm in the $^{13}C\{^{1}H\}$ NMR spectrum, attributable to the coordinated acetonitrile molecule. The presence of the acetonitrile ligand is also evidenced in the IR spectrum which exhibits a characteristic C=N absorption at 2242 cm^{-1} [9]. Once again, as inferred by the spectroscopic data (see details in Section 4), the formation of **[3][SbF$_6$]$_2$** takes place with total diastereoselectivity, its stereochemistry being unambiguously determined by a single crystal X-ray diffraction study. As shown in Fig. 2, dication **[3]**$^{2+}$ adopts the expected three-legged piano stool geometry around the ruthenium atom, with values of the interligand angles P(1)–Ru–N(1), P(1)–Ru–N(2), N(1)–Ru–N(2), and those between the centroid of the arene ring C* and the legs in the expected range for this type of complexes. The diastereomer obtained presents a $S_{Ru}S_PS_{C(27)}S_{C(26)}/R_{Ru}R_PR_{C(27)}R_{C(26)}$ configuration[4] (only the former enantiomer is drawn in Fig. 2). The substitution of the chloride ligand by an acetonitrile molecule does not affect significantly the structure of the ruthenacycle, the bond distances within the cyclic skeleton remaining almost unchanged when compared to those shown by **[2b]**$^{+}$ (*ca.* ± 0.04 Å).

As depicted in Scheme 1, the related solvento complex [Ru(η^5-C$_5$H$_5$)(NCMe)(κ^2-*P*,*N*-**1**)][PF$_6$] (**[4][PF$_6$]**) was synthesized (75% yield) by displacement of two labile acetonitrile ligands in the cationic cyclopentadienyl-Ru(II) precursor [Ru(η^5-C$_5$H$_5$)(NCMe)$_3$][PF$_6$] [10]. The most characteristic spectroscopic features of compound **[4][PF$_6$]** are: (i) in the $^{31}P\{^{1}H\}$ NMR spectrum, a sole singlet at 80.3 ppm evidencing the formation of a unique diastereomer, (ii) in the ^{1}H NMR spectrum, two singlets at 1.72 and 4.43 ppm attributable to the coordinated acetonitrile and the η^5-Cp ligand, respectively, and (iii) in the

[2] The priority order to determinate the ruthenium configuration is as follows: η^6-arene > Cl > P > N. Note that, although the spatial disposition remains unchanged, the preference orders for the phosphorus atom change after coordination on the metal inverting the *R*/*S* assignment.

[3] Other diastereoisomers resulting from the epimerization of one of the three stereogenic centres of the ligand **1** are not probable due to its high rigidity.

[4] The priority order to determinate the ruthenium configuration is as follows: η^6-arene > P > N(2) of acetonitrile > N(1) of imine.



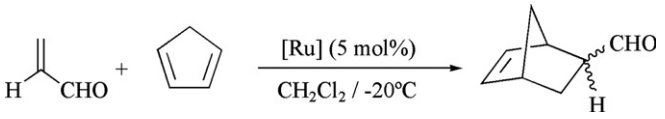


Fig. 2. CAMERON-type view of the structure of dication **[3]**$^{2+}$ showing the crystallographic labelling scheme. Hexafluoroantimonate anions and hydrogen atoms have been omitted for clarity. Thermal ellipsoids are drawn at the 30% probability level. Selected bond distances (Å) and angles (°): Ru–C* = 1.739(4); Ru–N(1) = 2.114(8); Ru–N(2) = 2.058(10); Ru–P(1) = 2.319(3); P(1)–C(27) = 1.822(9); C(27)–C(19) = 1.513(13); C(19)–N(1) = 1.264(12); N(2)–C(36) = 1.131(12); C(36)–C(37) = 1.445(14); C*–Ru–N(1) = 133.7(3); C*–Ru–N(2) = 125.4(3); C*–Ru–P(1) = 130.55(17); N(1)–Ru–N(2) = 84.3(3); N(1)–Ru–P(1) = 77.4(2); N(2)–Ru–P(1) = 88.5(3); Ru–P(1)–C(27) = 100.3(3); P(1)–C(27)–C(19) = 103.5(6); C(27)–C(19)–N(1) = 120.7(10); C(19)–N(1)–Ru = 121.9(7); Ru–N(2)–C(36) = 173.6(10); N(2)–C(36)–C(37) = 175.3(13). C* = centroid of the *p*-cymene ring (C(1), C(2), C(3), C(4), C(5) and C(6)).

$^{13}C\{^{1}H\}$ NMR spectrum, a doublet resonance at 187.2 ppm corresponding to the iminic carbon, and two singlets at 3.9 and 127.0 ppm assignable to the coordinated acetonitrile ligand. Unfortunately, all attempts to obtain crystals suitable for X-ray analysis failed, and therefore the configuration of the diastereomer formed could not be determined.

At this point it should be noted that, apart from the widely studied phosphine-oxazoline containing compounds [11], species $[RuCl(\eta^5\text{-}C_9H_7)\{\kappa^2\text{-}P,N\text{-}2\text{-}Ph_2PC_6H_4C(H)=NBu^t\}]$ (C_9H_7 = indenyl) [12], $[Ru(\eta^5\text{-}C_5Me_5)\{\kappa^3\text{-}P,N,N\text{-}2\text{-}Ph_2PC_6H_4C(H)N(CH_2)_2N=C(H)\text{-}2\text{-}C_6H_4PPh_2\}]_2[ZnCl_4]$ and $[\{Ru(\eta^5\text{-}C_5Me_5)(NCMe)\}_2\{\kappa^4\text{-}P,N,N,P\text{-}2\text{-}Ph_2PC_6H_4C(H)=N(CH_2)_2N=C(H)\text{-}2\text{-}C_6H_4PPh_2\}][ZnCl_4]$ [13] are, as far as we are aware, the only precedents of half-sandwich Ru(II) derivatives containing coordinated iminophosphine ligands reported in the literature [14].

2.2. Catalytic Diels–Alder reactions

Owing to their inherent Lewis-acidity, organometallic ruthenium cations are able to promote Diels–Alder cycloaddition processes [15]. In particular, during the last decade, dicationic (η^6-arene)-ruthenium(II) compounds [11e,16] and monocationic (η^5-cyclopentadienyl)-ruthenium(II) derivatives [17] containing optically active bidentate ligands have proven to be an appealing alternative to the classical Al-, B- or lanthanide-based Lewis-acid catalysts for asymmetric Diels–Alder reactions due to their increased resistance to hydrolysis. With these precedents in mind, we have prepared the optically pure compounds **[2a–d][SbF$_6$]**, **[3][SbF$_6$]$_2$** and **[4][PF$_6$]** starting from the non-racemic iminophosphine ligand ($R_PS_CS_C$)-**1** and we have explored their catalytic performances in the Diels–Alder cycloaddition between acrolein and cyclopentadiene (Scheme 2).

Scheme 2. Diels–Alder reaction of acrolein with cyclopentadiene catalyzed by ruthenium.

Table 1
Diels–Alder reaction of acrolein with cyclopentadiene[a]

Catalyst	Time (h)	Yield[b] (%)	*endo*:*exo*[b]
[2a][SbF$_6$]	20	92	68:32
[2b][SbF$_6$]	20	99	74:26
[2c][SbF$_6$]	20	90	71:29
[2d][SbF$_6$]	20	87	69:31
[3][SbF$_6$]$_2$	20	89	73:27

[a] All reactions were carried out in CH_2Cl_2 at −20 °C using 1.5 mmol of acrolein, 9 mmol of CpH and 5 mol% of ruthenium.
[b] GC determined using *cis*-decaline as internal standard.

We note that starting from the arene–ruthenium(II) precursors **[2a–d][SbF$_6$]**, the catalytically active species, *i.e.* the dications $[Ru(\eta^6\text{-arene})(\kappa^2\text{-}P,N\text{-}\mathbf{1})]^{2+}$, were generated *in situ* upon treatment of **[2a–d][SbF$_6$]** with one equivalent of $AgSbF_6$, while the solvento compounds $[Ru(\eta^6\text{-}p\text{-cymene})(NCMe)(\kappa^2\text{-}P,N\text{-}\mathbf{1})][SbF_6]_2$ (**[3][SbF$_6$]$_2$**) and $[Ru(\eta^5\text{-}C_5H_5)(NCMe)(\kappa^2\text{-}P,N\text{-}\mathbf{1})][PF_6]$ (**[4][PF$_6$]**) were used directly in the catalytic experiments (see details in Section 4). The results obtained are summarized in Table 1.

As shown in Table 1, the use of the arene–ruthenium(II) catalysts **[2a–d][SbF$_6$]** and **[3][SbF$_6$]$_2$** leads to the almost quantitative formation of the expected bicyclo[2.2.1]hept-5-ene-2-carboxaldehyde after 20 h, albeit with moderate diastereoselectivity and with a total lack of enantioselectivity. On the other hand, the cyclopentadienyl compound **[4][PF$_6$]** did not afford the expected cycloadduct, the cyclopentadiene dimer being the only product detected by GC.

3. Conclusion

In this work, we have evidenced the ability of the iminophosphine **1** to chelate half-sandwich ruthenium(II) fragments. In particular, the arene–ruthenium(II) compounds $[RuCl(\eta^6\text{-arene})(\kappa^2\text{-}P,N\text{-}\mathbf{1})][SbF_6]$ (arene = C_6H_6, *p*-cymene, 1,3,5-$C_6H_3Me_3$, C_6Me_6) and $[Ru(NCMe)(\eta^6\text{-}p\text{-cymene})(\kappa^2\text{-}P,N\text{-}\mathbf{1})][SbF_6]_2$, and the cyclopentadienyl derivative $[Ru(NCMe)(\eta^6\text{-}C_5H_5)(\kappa^2\text{-}P,N\text{-}\mathbf{1})][PF_6]$ have been prepared in excellent yields. Remarkably, the chelate

coordination of **1** to ruthenium takes place in all cases with complete diastereoselectivity due probably to the high rigidity and steric requirement of this ligand. Unfortunately, their use in catalytic asymmetric Diels–Alder reactions only affords disappointing diastereo- and enantioselectivities.

4. Experimental

4.1. General information

The manipulations were performed under an atmosphere of dry nitrogen using vacuum-line and standard Schlenk techniques. Solvents were dried by standard methods and distilled under nitrogen before use. All reagents were obtained from commercial suppliers with the exception of ligand **1** [3,4], and derivatives $[\{RuCl(\mu\text{-}Cl)(\eta^6\text{-arene})\}_2]$ (arene = C_6H_6 [18], *p*-cymene [19], 1,3,5-$C_6H_3Me_3$ [18], C_6Me_6 [19]) and $[Ru(\eta^5\text{-}C_5H_5)(NCMe)_3][PF_6]$ [20] which were prepared by following the methods reported in the literature. Infrared spectra were recorded on a Perkin–Elmer 1720-XFT spectrometer. The conductivities were measured at room temperature, in *ca.* 10^{-3} mol dm^{-3} acetone solutions, with a Jenway PCM3 conductimeter. The C, H, and N analyses were carried out with a Perkin-Elmer 2400 microanalyzer. GC measurements were made on a Hewlett–Packard HP6890 equipment using a Supelco Gama-Dex™ 225 (30 m, 250 μm) column. NMR spectra were recorded on a Bruker DPX-300 instrument at 300 MHz (^{1}H), 121.5 MHz (^{31}P) or 75.4 MHz (^{13}C) using $SiMe_4$ or 85% H_3PO_4 as standards. DEPT experiments have been carried out for all the compounds reported.

4.2. Synthesis of compounds *[RuCl(η⁶-arene)(κ²-P,N-**1**)][SbF₆]* (*arene* = C_6H_6 (***[2a][SbF₆]***), *p*-cymene (***[2b][SbF₆]***), 1,3,5-$C_6H_3Me_3$ (***[2c][SbF₆]***), C_6Me_6 (***[2d][SbF₆]***))

A solution of the corresponding dimeric precursor $[\{RuCl(\mu\text{-}Cl)(\eta^6\text{-arene})\}_2]$ (0.2 mmol) in 15 mL of dichloromethane was treated, at room temperature, with ligand **1** (0.150 g, 0.406 mmol) for 1 h. A solution of $NaSbF_6$ (1.035 g, 4 mmol) in methanol (10 mL) was then added and the resulting solution stirred at room temperature for 6 h. The solvents were then removed under vacuum, the crude product extracted with dichloromethane (*ca.* 20 mL), the extract filtered over Kieselguhr, the filtrate evaporated to dryness, and the resulting orange oily residue washed with diethyl ether (3 × 10 mL) and dried in vacuum. **([2a][SbF₆])**: Yield: 65% (0.213 g); *Anal.* Calc. for $RuC_{31}H_{30}F_6ClNPSb$ (819.82 g mol^{-1}): C, 45.42; H, 3.69; N, 1.71. 4.5. General procedure for the catalytic Diels–Alder reaction promoted by [2a–d][SbF₆]

A Schlenk tube was charged, under N_2 atmosphere, with the corresponding ruthenium(II) salt (0.075 mmol) and $AgSbF_6$ (0.051 g, 0.15 mmol). Dichloromethane (5 mL) was added and the mixture stirred at room temperature for 30 min, followed by filtration over Kieselguhr to remove the precipitated AgCl. The filtrate was evaporated to dryness, dissolved in 2 mL of CH_2Cl_2 and transferred, under N_2 atmosphere, into a jacketed Schlenk tube refrigerated by a closed ^{i}PrOH circuit kept at −20 °C with a cryostat. Freshly distilled acrolein (0.1 mL, 1.5 mmol), 2,6-lutidine (4 μL, 0.0375 mmol) and *cis*-decaline (0.231 mL, 1.5 mmol) were added. The resulting yellow solution was equilibrated at −20 °C for 30 min before addition of freshly distilled cyclopentadiene (0.6 mL, 9 mmol). The course of the reaction, *i.e.* conversion, *endo:exo* ratio and *ee* excess, was monitored by GC [Supelco Gama-Dex™ 225 (30 m, 250 μm) column; helium 4 mL/min, 60 °C, 10 °C/min to 200 °C: 5.53 min (*cis*-decaline), 5.88 and 6.00 min (*exo* cycloadducts), 6.60 and 6.66 min (*endo* cycloadducts)].

4.6. General procedure for the catalytic Diels–Alder reaction promoted by [3][SbF₆]₂ and [4][PF₆]

A jacketed Schlenk tube refrigerated by a closed ^{i}PrOH circuit kept at −20 °C with a cryostat was charged, under N_2 atmosphere, with the corresponding ruthenium(II) complex (0.075 mmol) and 2 mL of CH_2Cl_2. Freshly distilled acrolein (0.1 mL, 1.5 mmol), 2,6-lutidine (4 μL, 0.0375 mmol) and *cis*-decaline (0.231 mL, 1.5 mmol) were added. The resulting yellow solution was equilibrated at −20 °C for 30 min before addition of freshly distilled cyclopentadiene (0.6 mL, 9 mmol).

4.7. X-ray crystal structure determination of compounds [2b][SbF₆] and [3][SbF₆]₂

Single-crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of diethylether into a

In this paper, we report four new silver(I) complexes based on PyBIm, namely, $[Ag(PyBIm)\cdot H_2O]\cdot NO_3$ (**1**), $[Ag(PyBIm)\cdot H_2O]\cdot ClO_4$ (**2**), $[Ag_2(PyBIm)_2]\cdot(SiF_6)\cdot 2H_2O$ (**3**) and $[Ag(PyBIm)\cdot(HBDC)]$ (**4**). The Ag(I) atoms are three coordinated in complexes **1** and **2** but two and four coordinated in **3** and **4**, respectively. All the silver(I) atoms of the complexes are bridged by PyBIm via N_{Py} and N_{BIm} into "zigzag" chains. The counter ions have a great effect on the hydrogen bonding systems and coordination spheres, leading to great differences in the crystal packing. Through the hydrogen bonding interactions, the structures of **1**–**3** display a double-layer, a three-dimensional framework and a novel double-chain, respectively. As for complex **4**, the bridging $HBDC^-$ anions connect the $[Ag(PyBIm)]_\infty$ zigzag chain into a two-dimensional coordinate sheet. The counter ions effects and hydrogen-bonding interactions on the polymeric structures represent a new contribution to this active area of study.

2. Experimental

2.1. Materials and methods

The ligand 2-(4-pyridyl)benzimidazole (PyBIm) was synthesized according to the procedure reported by Fieselman [6]. Other reagents and solvents employed were commercially available and used as received without further purification. Elemental analyses were carried out on an EA1110 CHNS-0 CE element analyzer and the IR spectra (KBr pellets) were recorded at a Nicolet Magna 750 FT-IR spectrometer in the range 400-4000 cm^{-1}. Thermogravimetric analyses (TGA) were performed with a Netzsch STA-499C thermoanalyzer under N_2 (30–800 °C range) at a heating rate of 10 °C/min. X-ray powder diffractions (XRPD) were performed on a Bruker D8 Advanced diffractometer with Cu Kα radiation ($\lambda = 1.5418$ Å) at room temperature.

Safety notes. Caution! Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of material should be prepared, and it should be handled with great care.

*Synthesis of $[Ag(PyBIm)\cdot H_2O]\cdot NO_3$ (**1**).* An acetonitrile (5 mL) solution of $AgNO_3$ (0.085 g, 0.50 mmol) was slowly diffused into an ethanol (5 mL) solution of PyBIm (0.097 g, 0.50 mmol). Colorless crystals formed in about two weeks (80% yield) *Anal.* Calc. for $C_{12}H_{11}AgN_4O_4$: C, 37.62; H, 2.89; N, 14.62. Found: C, 37.15; H, 3.12; N, 14.13%. IR (KBr pellet, cm^{-1}): 3434s, 1613s, 1559w, 1537w, 1495m, 1480w, 1443, 1414, 1385s, 1357s, 1229m, 1072m, 1041m, 1017w, 838m, 821m, 782s, 700m, 556m, 502w.

*Synthesis of $[Ag(PyBIm)\cdot H_2O]\cdot ClO_4$ (**2**).* An ethanol solution (5 mL) of $AgClO_4$ (0.06 g, 0.30 mmol) was slowly diffused into an ethanol solution of PyBIm (0.06 g, 0.30 mmol). Colorless crystals formed in about three weeks (75% yield). *Anal.* Calc. for $C_{12}H_{11}AgClN_3O_5$: C, 34.27; H, 2.64; N, 9.99. Found: C, 34.15; H, 3.12; N, 10.13%. IR (KBr pellet, cm^{-1}): 3496s, 1612s, 1537w, 1494m, 1481w, 1436s, 1319m, 1285w, 1226m, 1120vs, 1085vs, 969w, 932w, 838m, 816m, 775s, 744w, 672w, 624s, 557w, 500w.

*Synthesis of $[Ag_2(PyBIm)_2]\cdot(SiF_6)\cdot 2H_2O$ (**3**).* A solution of Ag_2SiF_6 (0.22 g, 0.61 mmol), PyBIm (0.24 g, 1.22 mmol), NaF (0.025 g, 0.61 mmol) and H_2O (15 ml) was stirred under ambient conditions, then sealed in a Teflon-lined stainless steel vessel, heated at 150 °C for 5 days and cooled to room temperature. The resulting product was recovered by filtration, washed with distilled water and dried in air (65% yield). *Anal.* Calc. for $C_{24}H_{22}Ag_2F_6N_6O_2Si$: C, 36.75; H, 2.83; N, 10.72. Found: C, 36.54; H, 3.09; N, 10.79%. IR (KBr pellet, cm^{-1}): 3445s, 1614s, 1560w, 1541m, 1496w, 1481w, 1439s, 1384w, 1319m, 1287w, 1227m, 1118s, 1084s, 1065s, 1022s, 839m, 818m, 775s, 745s, 558m, 500w, 473m.

*Synthesis of $[Ag(PyBIm)(HBDC)]$ (**4**).* A solution of Ag_2O (0.069 g, 0.30 mmol), PyBIm (0.24 g, 1.22 mmol), H_2BDC (0.101 g, 0.61 mmol) and H_2O (15 ml) was stirred under ambient conditions, then sealed in a Teflon-lined stainless steel vessel, heated at 150 °C for 5 days and cooled to room temperature. The resulting product was recovered by filtration, washed with distilled water and dried in air (60% yield). *Anal.* Calc. for $C_{20}H_{14}AgN_3O_4$: C, 51.31; H, 3.01; N, 8.97. Found: C, 51.52; H, 3.26; N, 9.06%. IR (KBr pellet, cm^{-1}): 3433s, 1416s, 1566m, 1778w, 1438m, 1384s, 1319m, 1283w, 1228w, 1095w, 1069m, 936m, 839m, 751s, 687m, 539w, 507w.

2.2. X-ray crystallography

Suitable single crystals of **1**–**4** were carefully selected under an optical microscope and glued to thin glass fibers. The diffraction data were collected on a Siemens Smart CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 293 K. An empirical absorption correction was applied using the SADABS program [7]. The structures were solved by direct methods and refined by full-matrix least-squares methods on F^2 by using the SHELXTL-97 program package [8]. Attempts to locate the hydrogen atoms of water in complex **3** failed; the other hydrogen atoms on carbon and nitrogen atoms were generated geometrically. The crystallography details for the structure determination of complexes **1**–**4** are presented in Table 1. Selected bond lengths and bond angles are listed in Table 2.

2.3. Result and discussion

2.3.1. Syntheses and general characterization

Complex **1** can also be obtained by hydrothermal methods, but the crystals obtained were not suitable for X-ray diffraction. As for complex **2**, it can be obtained by hydrothermal methods (the reaction temperature might be better less than 120 °C for security considerations) with the

production of crystals of excellent quality that are suitable for X-ray diffraction, but for safety considerations, this is not worthy of recommendation. As for complexes **3** and **4**, attempts to get crystals under solution conditions failed. The purities of the four complexes were also identified by XRPD (see supporting information).

The $HBDC^-$ anions bridge the $[Ag_2(PyBIm)_2]_\infty$ chain into a two-dimensional sheet in complex **4**, the protonated carboxylate groups greatly contribute to the crystal packing. Attempts to get a crystal bridged by BDC^{2-} rather than $HBDC^-$ anions failed, the products are only amorphous, and could not be identified easily.

The TGA diagrams show complexes **1**–**3** have similar thermal stabilities and behaviors in the range of 50–220 °C. Complex **1** exhibits loss of one lattice water between 65 and 216 °C (4.91% weight loss observed; 4.70% calculated), complex **2** exhibits loss of the water molecules between 48 and 147 °C (4.05% weight loss observed; 4.28% calculated), while complex **3** exhibits loss of two water molecules between 66 and 195 °C (4.53% weight loss observed; 4.60% calculated). Complex **4** does not show any weight loss up to 262 °C, this is consistent with no lattice or coordinated water in the complex (see supporting information).

2.3.2. Crystal structures

Complex **1** crystallizes in the orthorhombic *Aba*2 space group, the absolute structure was determined from the Flack parameter, refined to be 0.01(3), indicating the complex is of correct absolute structure. X-ray structure analysis reveals that **1** is a one-dimensional zigzag chain based on the $[Ag(PyBIm) \cdot H_2O]$ unit (Fig. 1). The silver(I) atom is three coordinated, by one aqua ligand (Ag1–O1w 2.596(3) Å) and two PyBIm ligands via N_{Py} and N_{BIm} nitrogen donor atoms (Ag1–N1 2.222(3), Ag1–N2 2.172(2) Å), exhibiting

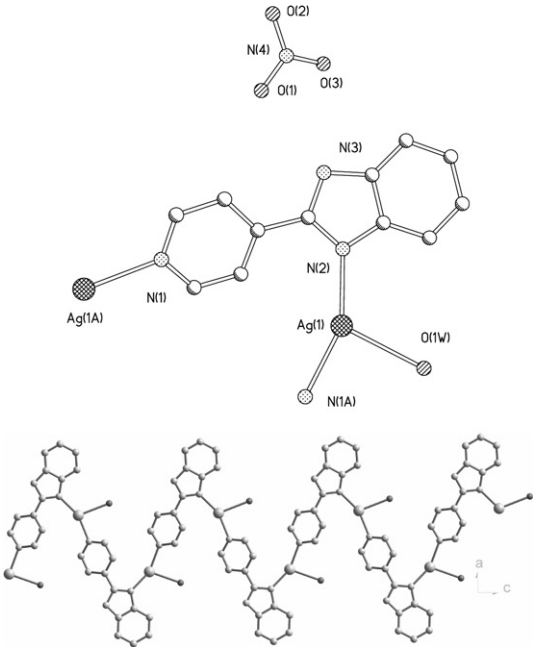

Fig. 1. (Top) Perspective view of the coordination environment of the Ag(I) atom in complex **1**. (Bottom) A view of the "zigzag" chain of $[Ag_2(PyBIm)_2(H_2O)_2]$.

a distorted "T" shaped coordination (N1–Ag1–O1w 89.2(1)°, N2–Ag1–N1 151.3(1)°, N2–Ag1–O1w 114.5(1)°).

The benzimidazolyl rings are almost coplanar in the "zigzag" chain, and the pyridyl ring deviates from the benzimidazolyl ring of the same PyBIm ligand with a dihedral angle of 26.7°. The Ag(I) atoms are bridged by the PyBIm ligands with a separation of 7.111 Å. Strong hydrogen-bonding interactions between the N–H group of benzimidazolyl, lattice water and nitrate (N3···O1 2.901(4) Å, O1w···O1 2.969(4) Å, O1w···O2 2.850(5) Å) as well as π–π (3.36 Å) interactions connect the one-dimensional chains into a two-dimensional double-layer, and the double-layers are further connected into a three-dimensional framework through inter-molecular interactions (Fig. 2), the π–π interactions of the adjacent double-layer are rather weak, as the overlap of the aromatic rings can be neglected (more than 4.5 Å).

In the two-dimensional double-layer, interestingly, the one-dimensional "zigzag" chains are connected by the nitrate groups to the adjacent chains from the other layer

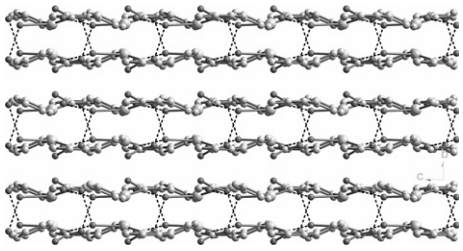

Fig. 2. Perspective view of the 3-D framework of stacked double layer sheets for complex **1**.

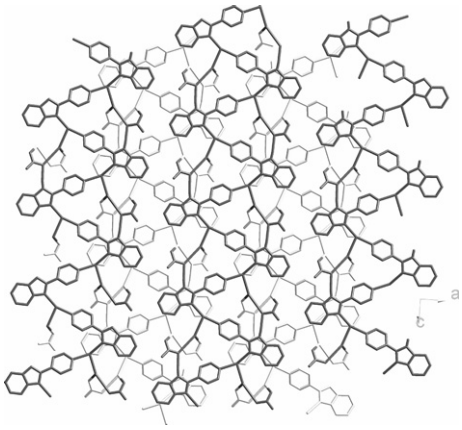

Fig. 3. The hydrogen-bonding interactions connecting the one-dimensional "zigzag" chain into a double-layer in complex **2**.

through hydrogen-bonding as well as strong π–π interactions (3.36 Å) (Fig. 3). This two-dimensional double-layer is not like the common reported ones [9]. In complex **1**, the one-dimensional "zigzag" chains are not directly connected into a two-dimensional sheet, but indirectly. To the best of our knowledge, this phenomenon has not been reported before.

With regard to the influence of the N–H group of the PyBIm ligand, this structure is greatly different from the reported complex $[Ag(2,4\text{-bpy})] \cdot NO_3$ [3a], where the counter ion is weakly coordinated with the silver atom and leads to a two-dimensional sheet without hydrogen-bonding interactions. Although the coordination sphere is similar to that of $[Ag_2(PyBIm)_2(H_2O)_2]SO_4 \cdot H_2O$ [3c], due to the anion effect, great differences occur in the crystal packing.

Complex **2** crystallizes in the orthorhombic *Pbcn* space group, the single-crystal X-ray structure analysis reveals that **2** has the similar one-dimensional zigzag chain based on $[Ag(PyBIm) \cdot H_2O]$ units, as in complex **1**. Similar to complex **1**, the silver(I) atom is also three coordinated by one aqua ligand (Ag1–O1w 2.482(2) Å) and two PyBIm

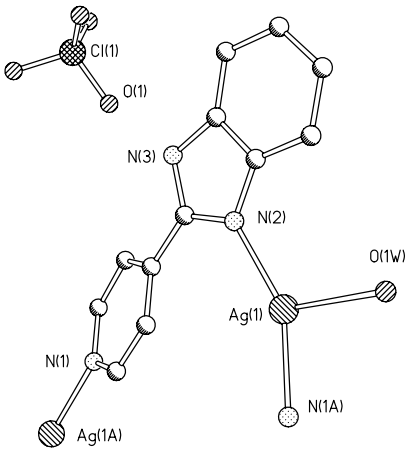

Fig. 4. Perspective view of the coordination environment of the Ag(I) atom in complex **2**.

ligands via N_{Py} and N_{BIm} nitrogen donor atoms (Ag1–N1 2.198(2), Ag1–N2 2.152(2) Å), exhibiting a distorted "T" shaped coordination geometry (N1–Ag1–O1w 90.2(8)°, N2–Ag1–N1 153.4(8)°, N2–Ag1–O1w 112.6(8)°) (Fig. 4).

The benzimidazolyl rings are almost coplanar in the "zigzag" chain, and the pyridyl ring deviates from the benzimidazolyl ring of the same PyBIm ligand with a dihedral angle of 28.8°. The silver atoms are bridged by the PyBIm ligands with a separation of 7.225 Å. Strong hydrogen-bonding interactions involving the N–H group of benzimidazolyl, lattice water and perchlorate (N3···O1 2.881(3) Å, N3···O2 2.945(3) Å, O1w···O2 2.947(3) Å, O1w···O3 2.880(4) Å), as well as π–π interactions (3.35 Å) connect the one-dimensional chains into a three-dimensional framework. Similar to that of complex **1**, the "zigzag" chains in complex **2** are connected by ClO_4^- alternatively with the adjacent layer.

In this three-dimensional framework, for the ordered arrangement of the "zigzag" chains, a one-dimensional channel with a window of 7.7 Å × 10.9 Å is formed, and these channels are filled by ClO_4^- groups and lattice water as guest molecules [10] (see supporting information).

Despite the ClO_4^- also acting as a counter ion in the complex $[Ag(2,4\text{-bpy})]\cdot ClO_4$ [3a], ligand unsupported weak metal–metal interactions occur, whereas this phenomenon does not exist in complex **2**. The abundant hydrogen-bonding interactions in complex **2** lead to a crystal packing that is greatly different from that of $[Ag(2,4\text{-bpy})]\cdot ClO_4$.

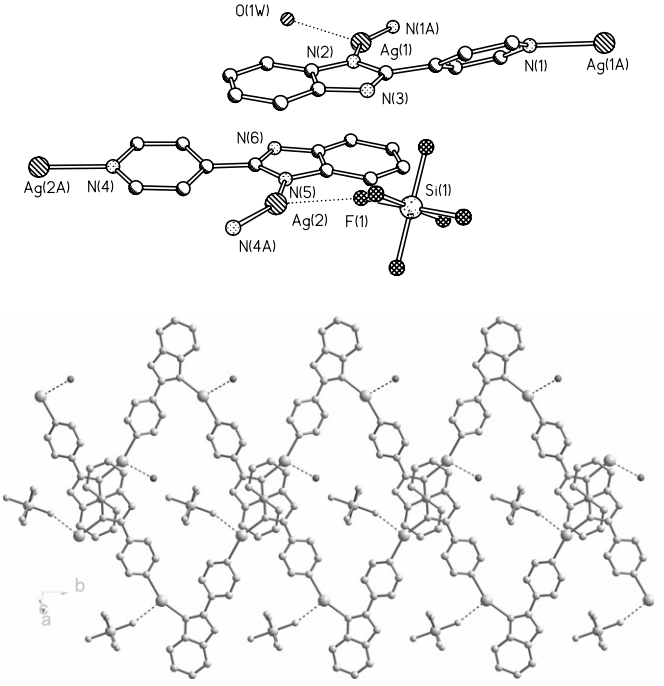

Fig. 5. (Top) Perspective view of coordination sphere of the Ag(I) atoms for complex **3**. (Bottom) Perspective view of the double chain for complex **3**.

Complex **3** consists of a one-dimensional double-chain (Fig. 5), each unit has two distinct silver atoms in the complex. Both of them are two coordinated and bridged by the PyBIm ligands via N_{Py} and N_{BIm} (Ag1–N1 2.178(4), Ag1–N2 2.135(4), Ag2–N4 2.193(4), Ag2–N5 2.155(3) Å) into two "zigzag" chains with adjacent intra-chain Ag···Ag separations of 7.443 and 7.542 Å. The N_{Py}–Ag–N_{BIm} bond angles are slightly larger than those of complexes **1** and **2** (N1–Ag1–N2 157.8(2), N4–Ag1–N5 155.8(2)°), indicating stronger covalent interactions among the silver(I) and nitrogen atoms. The two distinct "zigzag" chains are connected by hydrogen-bonding (O1w···F3 3.019 Å) as well as π–π interactions (3.35–3.40 Å) into a double-chain, unlike the common reported molecular ladder or molecular railroad [11], the double-chain in complex **3** is not jointed by coordination bonds. Besides, O1w and F1 of $[SiF_6]^{2-}$ are also weakly coordinated to the silver(I) atoms with a distance of about 2.610 and 2.605 Å (Ag1···O1w 2.610, Ag2···F1 2.605 Å), respectively. The Ag···F (2.605 Å) distance is much shorter than other silver(I) complexes with the $[SiF_6]^{2-}$ groups acting only as a counter ion (2.702 Å) [12], but longer than the bonded Ag–F distance in the BF_4^- system (2.34–2.53 Å) [13]. The interaction between O1w and Ag1 is comparable to that found in silver(I) carboxylate and oxalate complexes (2.23–2.52 and 2.17–2.61 Å), respectively [14], whilst it is greatly shorter than the sum of van der Waals radii (3.24 Å) of the Ag(I) ion and oxygen atom [15]. The hydrogen-bonding interactions between O1w and F3 (O1w···F3 3.019 Å) also bring the double-chains into a two-dimensional sheet (see supporting information), and these sheets are further aggregated into a three-dimensional framework through strong π–π interactions, with the lattice water and SiF_6^{2-} groups acting as guest molecules [10]. Interestingly, the SiF_6^{2-} groups are connected by the lattice water molecules (O2w) through hydrogen-bonding (O2w···F3 2.708, O2w···F5 2.894 Å) interactions into a one-dimensional chain in the channel (see supporting information).

The single crystal X-ray analysis reveals that complex **4** is attributed with a two-dimensional network. Unlike the former complexes, the silver(I) atom is four coordinated (Ag1–N1 2.195(2) Å, Ag1–N2 2.188(2) Å, Ag1–O1 2.571(2) Å, Ag1–O3 2.597(2) Å), exhibiting a distorted tetrahedral coordination sphere (N2–Ag1–N1 149.8(6)°, N2–Ag1–O1 113.1(6)°, N1–Ag1–O1 91.1(6)°, N2–Ag1–O3 89.4(6)°, N1–Ag1–O3 115.3(6)°, O1–Ag1–O3 74.6(5)°) (Fig. 6). The silver(I) atom deviates from the basic plane formed by N2, N1a and O3a less than 0.0991 Å. The Ag–O bond lengths (2.571(2) and 2.597(2) Å, respectively) are slightly shorter than that in complex **3** (Ag1–O1w 2.610 Å), which is in the normal range for Ag–O bond distances for silver carboxylate and oxalate complexes [14]. The O2 atom of the 1,3-BDC ligand is protoned, C13–O2 (1.297(3) Å) is longer than C13–O1 (1.223(3) Å), and forms hydrogen-bonding interactions with the O3 atom (O2···O3 2.450(2) Å) of the adjacent $HBDC^-$ ligand. The silver(I) atoms are bridged by PyBIm into the similar "zigzag"

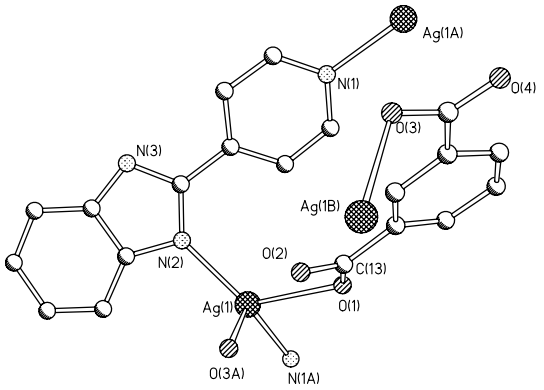

Fig. 6. Perspective view of coordination sphere of the Ag(I) atoms for complex **4**.

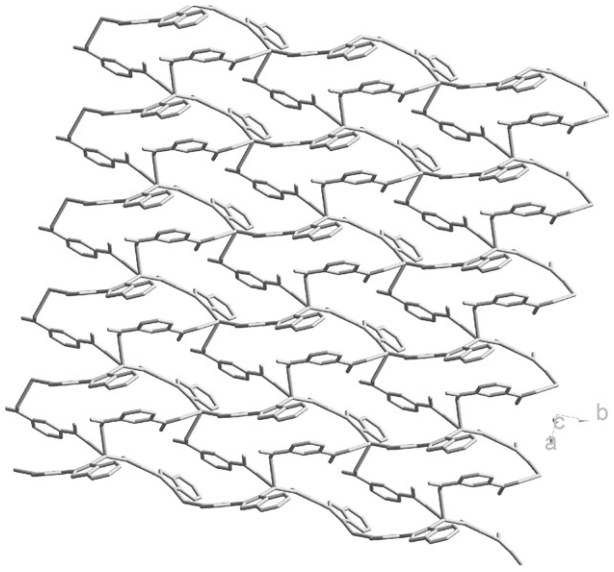

Fig. 7. Bridging HBDC ligands connecting the "zigzag" chain of $[Ag_2(PyBIm)_2(H_2O)_2]^{2+}$ into two-dimensional undulating sheets for complex **4**.

$[Ag(PyBIm)]_\infty$ chain as complexes **1**–**3**, and the chains are further connected by the bridging $HBDC^-$ ligand into a two-dimensional sheet (Fig. 7). The hydrogen-bonding (O2···O3 2.450(2) Å) as well as π–π interactions aggregate the undulating sheets into a three-dimensional framework.

The coordination mode of the HBD^- ligand is greatly different from the reported silver(I) complexes based on benzenecarboxylate derivatives, where the adoption of a bidentate mode for the carboxylate group is very common, leading to weak ligand unsupported Ag···Ag interactions [16]. In complex **4**, either the carboxylate or carboxylic group demonstrates a unidentate bonding fashion.

3. Anion exchange properties of complexes 2 and 3

The ClO_4^- anion does not coordinate to silver(I) in complex **2**, while the F^- of SiF_6^{2-} weakly coordinates to the Ag(I) atom in complex **3**, both anions are only loosely bound to the framework through the hydrogen bonds. To investigate whether these loosely bound ClO_4^- and SiF_6^{2-} anions can be exchanged by other anions, anion exchange reactions were carried out for complexes **2** and **3**. Well-ground powers of complexes **2** and **3** (50 mg) were suspended in aqueous solution (10 ml) of $NaBF_4$ and Na_2SO_4 (1 g), respectively. These mixtures were stirred for one day at room temperature, then filtered, washed with water and dried under vacuum to give a white powder. This procedure was repeated at least three times. The element analyses reveal nearly 100% exchange for both complexes **2** and **3**, the exchanged products gave sharp XPRD patterns, which are similar to that of complexes **2** and **3**, respectively. Indicating the crystal structures have been maintained in both complexes (see supporting information). This phenomenon is similar to the anion properties of cage-like frameworks and cation-layered architectures [17].

4. Conclusions

The PyBIm ligand acts as a bridging ligand rather than a terminal one [18] in the four silver(I) complexes, and bridges the Ag(I) atoms into similar "zigzag" chains, in which the coordination number of the silver(I) atom varies from two to four. Due to the influence of anion symmetry [4b], a great difference in crystal packing is demonstrated. For instance, NO_3^- (D_{3h}) forms hydrogen-bonding interactions greatly different from that of ClO_4^- (D_{4h}) and SiF_6 (D_{6h}), resulting in a double-layer, a three-dimensional framework and a novel double-chain structure, respectively. The $HBDC^-$ anions act not only as counter ions but also as bridging ligands, leading to the formation of a two-dimensional coordinate sheet. Although the N–H groups of the PyBIm ligands do not coordinate to silver(I) atoms, they form strong hydrogen-bonding interactions with the lattice water and anionic counter ions, leading to a great influence on the crystal packing.

Scheme 1.

solved. On the other hand, modifying the reaction conditions, is possible to obtain new zwitterionic inner sphere Zn(II) complexes with polymethylene-bisadenines: $[H\text{-}(Ade)_2C_3(ZnCl_3)]$ (**6**), $[H\text{-}(Ade)_2C_4(ZnCl_3)]\cdot 1.5H_2O$ (**7**) and $[H\text{-}(Ade)_2C_4(ZnCl_3)_2]\cdot 3H_2O$ (**8**). We report here the results of single crystal X-ray diffraction studies on **5**, **5a** and **6** as well as the characterization of **7** and **8** by spectroscopic measurements.

2. Experimental

2.1. Analysis and physical measurements

Elemental analyses were carried out using Carlo-Erba models 1106 and 1108 and Thermo Finnigan Flash 1112 microanalysers. Infrared spectra (KBr pellets) were recorded on a Bruker IFS 66. ^{1}H NMR spectra were obtained with a Bruker AMX 300 spectrometer. Proton chemical shifts in dimethylsulfoxide solution (DMSO-d_6) were referenced to DMSO-d_6 itself [^{1}H NMR, δ(DMSO) = 2.50]. Due to the low solubility of these products the ^{13}C NMR spectra were not clear and do not give useful information. All organic and inorganic (Sigma and Aldrich) reagents were used without further purification.

2.2. Crystallographic studies

Prismatic crystals were selected and mounted on an Enraf-Nonius CAD4 diffractometer. Intensities were collected with graphite monochromatized Mo K_α radiation using $\omega/2\theta$ scan-technique. Three reflections were measured every 2 h as orientation and intensity control, significant intensity decay was not observed. Lorentz-polarization and absorption corrections were made. The structures were solved by Direct methods using SHELXS computer program [4] and refined by full-matrix least-squares method with SHELX97 [5]. Selected crystallographic data are presented in Table 1.

$\{[(H\text{-}Ade)_2C_4][Cd_2Cl_6(H_2O)_2]\cdot 2H_2O\}_n$ (**5**): All non-water hydrogen atoms were computed and refined using a riding model with an isotropic temperature coefficient equals to 1.2 times of equivalent value of carbon or nitrogen atom linked to H.

$\{[(H\text{-}Ade\mathit{N}^3)\text{-}(CH_2)_4\text{-}(H\text{-}Ade\mathit{N}^9)]_2][Cd_3Cl_{10})\cdot 2H_2O\}_n$ (**5a**): 18 H atoms were located from a difference synthesis and refined with an overall isotropic temperature factor and 2 H atoms were computed and refined with an overall isotropic temperature factor using a riding model.

$[H\text{-}(Ade)_2C_3(ZnCl_3)]$ (**6**): All H atoms were computed and refined, using a riding model with an isotropic temperature factor.

2.3. Synthesis of the ligands

2.3.1. Syntheses of $N^9,N^{9'}$-polymethylene-bisadenines (Ade_2C_x) ($x = 3,4$)

The preparation of the ligands was carried out by a method previously described in the literature [1]: a suspension of 2.5 g of adenine and 1 g of NaH (55% dispersion in mineral oil) in 75 ml of dry DMF was stirred at room temperature under Ar atmosphere for 1 h, and then, 0.5 equivalent of the corresponding α,ω-dibromoalkane was added. The resulting suspension was stirred for 2 days, filtered and washed with water and acetone (overall yield 20–30%). The product was purified in boiling water.

2.3.2. $N^9,N^{9'}$-trimethylene-bisadenine (Ade_2C_3) (**1**)

Anal. Calc. for $C_{13}H_{14}N_{10}$: C, 50.3; H, 4.5; N, 45.1. Found: C, 50.4; H, 4.5; N, 45.1%. 2.4. Preparation of the complexes

As published previously [1,2], ^{1}H NMR spectra of the complexes are very similar to the ligands. Major chemical shift differences are caused by protonation, for this reason the complexes were not characterized by NMR.

2.4.1. Outer sphere complexes: general method [1,2]

To a stirred solution of 2 mmol of the corresponding ligand in 20 ml of HCl 2 M at 50 °C, 2.5 mmol MCl_2 were added, stirred for 30 min and allowed to stay at room temperature. Firstly, a white precipitate of the corresponding complex was formed, filtered and air dried. Suitable crystals for X-ray were obtained, from the resulting solution, after several days.

2.4.1.1. $[(H\text{-}Ade)_2C_3][ZnCl_4] \cdot H_2O$ (**3**) [2]. *Anal.*

Calc. for $C_{13}H_{18}Cl_4N_{10}OZn$: C, 29.0; H, 3.4; N, 26.0. Found: C, 28.9; H, 3.3; N, 26.0%. Selected IR bands (cm^{-1}): 1694vs, 1683vs, 1614s, 1518s, 1441sh, 1416s, 1342m, 1227s, 1062m, 953m, 855m, 820m, 785m, 740w, 726m, 695m, 682m, 643m, 599m, 534m.

2.4.1.2. $[(H\text{-}Ade)_2C_3]_2[Cd_2Cl_8(H_2O)_2] \cdot 4H_2O$ (**4**) [1]. *Anal.*

Calc. for $C_{13}H_{22}CdCl_4N_{10}O_3$: C, 25.1; H, 3.5; N, 22.5. Found: C, 25.0; H, 3.4; N, 22.3%. Selected IR bands (cm^{-1}): 3360s, 3327s, 3275s, 1708vs, 1668s, 1603vs, 1578s, 1488m, 1455m, 1418s, 1358s, 1331m, 1303s, 1259m, 1241m, 1214s, 1192m, 1083w, 1008w, 955w, 802m, 779m, 718m, 642m, 561m.

2.4.1.3. $\{[(H\text{-}Ade)_2C_4][Cd_2Cl_6(H_2O)_2] \cdot 2H_2O\}_n$ (**5**).

The general method only yields microcrystalline samples. Suitable crystals for X-ray were obtained after several weeks in modified conditions: 0.5 mmol of the ligand were stirred with 2.5 mmol of $CdCl_2$ in 20 mL of HCl 0.1 M at

50 °C for 30 min and then allowed to stand at room temperature Yield 60%. *Anal.* Calc. for $C_{14}H_{24}Cd_2Cl_6N_{10}O_3$: C, 20.6; H, 3.0; N, 17.1. Found: C, 20.7; H, 3.0; N, 16.8%. Selected IR bands (cm^{-1}): 3338s, 1693vs, 1635s, 1601s, 1519s, 1438m, 1414s, 1348m, 1321m, 1211s, 933w, 887w, 717s, 670s, 561m, 529m.

2.4.2. Inner sphere complexes

To a stirred solution of 0.5 mmol of the ligand in 20 mL of HCl 0.1 M at 50 °C, 2.5 mmol of $ZnCl_2 \cdot 2H_2O$ were added, stirred 30 min and allowed to stay at room temperature. The resulting precipitate was filtered and air dried.

*2.4.2.1. [H-(Ade)$_2$C$_3$(ZnCl$_3$)] (**6**).* Yield 50%. Crystals suitable for X-ray appeared from filtering waters. *Anal.* Calc. for $C_{13}H_{15}Cl_3N_{10}Zn$: C, 32.3; H, 3.1; N, 29.0. Found: C, 32.5; H, 3.1; N, 28.8%. 3. Results and discussion

Compounds **5**, **5a** and **6** have been characterized by X-ray diffraction and **7**, **8** by comparison of spectroscopic data (IR spectra) with other unequivocally described complexes.

3.1. Cd(II) complexes

Complex $\{[(H\text{-}Ade)_2C_4][Cd_2Cl_6(H_2O)_2] \cdot 2H_2O\}_n$ (**5**) constitutes the first crystal structure isolated with the ligand Ade_2C_4 (Fig. 1).

Its structural analysis reveals the presence of both protonated adenine rings with an anti disposition [dihedral angle N(9)–C(10)–C(10′)–N(9′) = 180°]. The bisadenine molecules are connected among them by two hydrogen bonds N(6)···N(7) producing chains of molecules along the *c*-axis. The structure presents a polymeric chain formed by the union of $[Cd_2Cl_6(H_2O)_2]^{2-}$ units along the *a*-axis. The Cd(II) displays a distorted octahedral geometry with

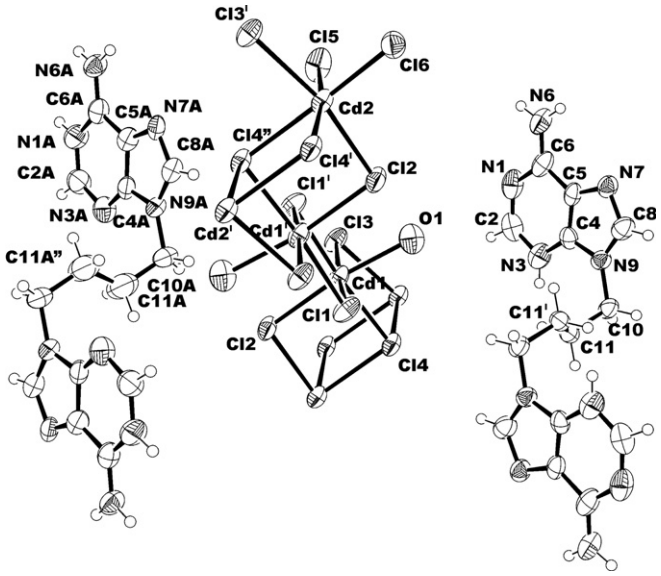

Fig. 1. ORTEP representation of $\{[(H\text{-}Ade)_2C_4][Cd_2Cl_6(H_2O)_2] \cdot 2H_2O\}_n$ (**5**) polymeric structure. Displacement ellipsoids are drawn at the 50% probability level and H atoms are drawn as circles of arbitrary radii.

bridging chlorine atoms. Similar $[Cd_2Cl_8(H_2O)_2]^{4-}$ units were described for the Cd(II) Ade_2C_3 outer sphere complex [1]. The organic and inorganic chains are linked by hydrogen bonds (Fig. 2).

A surprising result related to the reaction between Ade_2C_4 and $CdCl_2$ in acidic media was the isolation – only once – of a single crystal of an inner sphere complex of Cd(II) with an unexpected N^9,$N^{3'}$-tetramethylene-bisadenine: $\{[(H\text{-}Ade N^3)\text{-}(CH_2)_4\text{-}(H\text{-}Ade N^9)]_2][Cd_3Cl_{10}) \cdot 2H_2O\}_n$ **5a** which was suitable for X-ray diffraction analysis (Fig. 3). This complex present an asymmetric and intriguing diprotonated N^9,$N^{3'}$-tetramethylene-bisadenine. Although the details of their formation are not known, several experiences to investigate how the asymmetric ligand is

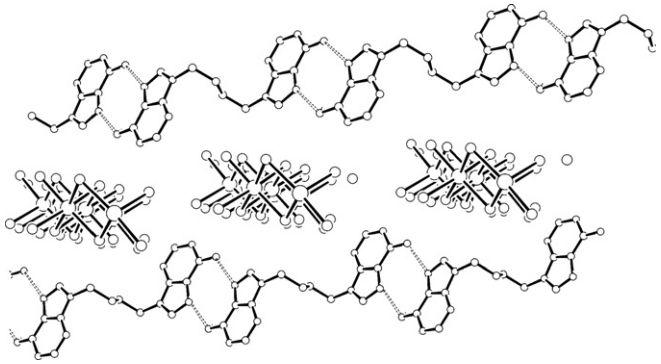

Fig. 2. Crystal structure of 3D network of $\{[(H\text{-}Ade)_2C_4][Cd_2Cl_6(H_2O)_2] \cdot 2H_2O\}_n$ (**5**). A layer: Adenine – Cd(II) polyanion: [N(1A)·Cl(3) = 3.20 Å, N(6A)·Cl(5) = 3.27 Å]; Adenine – Adenine: [N(7)·N(6′) = 2.86 Å]. B layer: Adenine – Adenine: [N(6)·N(7) = 2.98 Å]; Adenine – H_2O: [N(1)···O(4) = 2.84 Å]; H_2O – Cd(II) polyanion: [Cl(6)···O(1) = 3.16 Å, Cl(2)···O(2) = 3.22 Å, Cl(5)···O(4) = 3.21 Å]; H_2O – H_2O: [O(1)···O(2) = 2.78 Å, O(2)···O(4) = 2.84 Å, O3···O(4) = 2.23 Å].

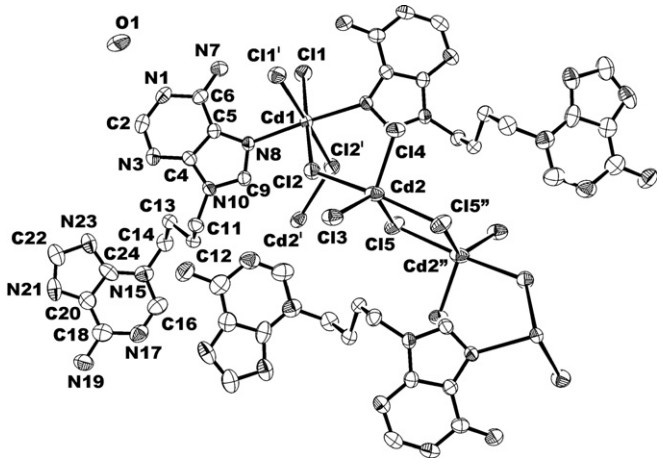

Fig. 3. ORTEP representation of $\{[(\text{H-Ade}N^3)\text{-}(CH_2)_4\text{-}(\text{H-Ade}N^9)]_2\}\text{-}(Cd_3Cl_{10})\cdot 2H_2O\}_n$ (**5a**). Displacement ellipsoids are drawn at the 50% probability level and H atoms are drawn as circles of arbitrary radii.

formed have been undertaken. Additional proofs are under study.

The metal ion forms a polymeric anionic structure with two different types of Cd(II) environments: (i) Cd(II) coordinated directly to two N^9-adenine moieties with an octahedral coordination; (ii) dimeric $[Cd_2Cl_8]^{4-}$ units bridging two octahedral Cd-Adenine moieties (Fig. 4).

The behaviour of the two adenine rings is completely different. The adenine linked through N(9) is protonated at N(1) and coordinated through N(7) to a Cd(II) ion [N(7)···Cd(1) = 2.38 Å]. The adenine linked by N(3) is protonated at N(7) and does not interact with any metal ion. Fig. 5 show the main intermolecular interactions observed.

In order to understand this surprising result, a study of ^{1}H NMR spectra of crude reaction material, obtained in the synthesis of the ligand, show the presence of a minority secondary product, which we have assigned to $N^9,N^{3'}$-trimethylene-bisadenine by comparison of literature data (Fig. 6) [6,7]. In our hands, the best results have been

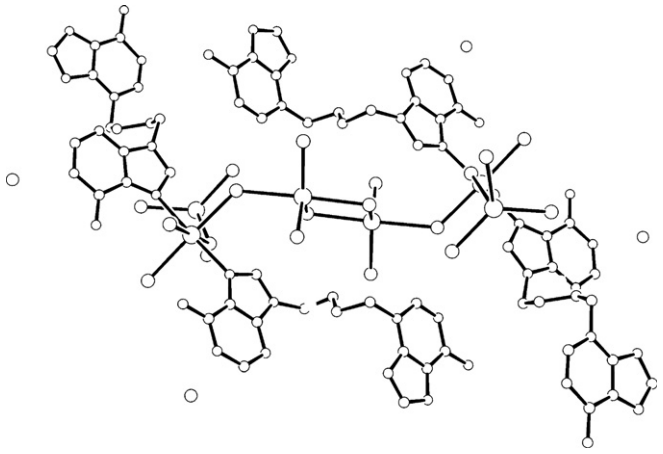

Fig. 4. Polymeric structure of $\{[(\text{H-Ade}N^3)\text{-}(CH_2)_4\text{-}(\text{H-Ade}N^9)]_2\}\text{-}(Cd_3Cl_{10})\cdot 2H_2O\}_n$ (**5a**).

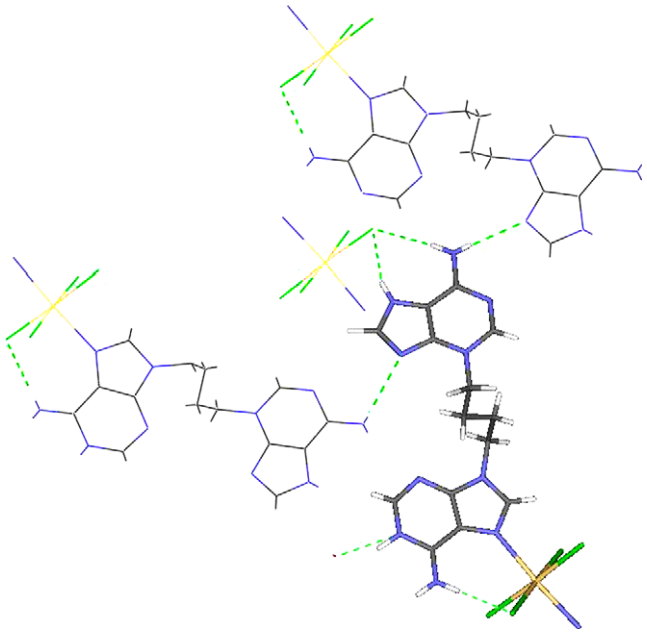

Fig. 5. $\{[(\text{H-Ade}N^3)\text{-}(CH_2)_4\text{-}(\text{H-Ade}N^9)]_2](Cd_3Cl_{10})\cdot 2H_2O\}_n$ (**5a**) additional interactions: [N(19)···N(23) = 3.06 Å]; [N(19)···Cl(1) = 3.3 Å y N(21)···Cl(1) = 3.23 Å]. [N(7)···Cd(1) = 2.38 Å]; [N(1)···O(10) = 2.65 Å]; [N(6)··· Cl(4) = 3.14 Å, N(6)···Cl(1) = 3.27 Å].

obtained with Ade_2C_3 ligand because its higher solubility, although the isolated single crystal was obtained for Ade_2C_4. Thus, a tentative assignation of ^{1}H NMR (DMSO-d^6) would be $\delta = 8.37$ s [1H, H(2′ or 8′) (N^3-Ade)], 8.20 s [1H, H(2) (N^9-Ade)], 8.12 s [1H, H(8) (N^9-Ade)], 7.76 s [1H, H(2′ or 8′) (N^3-Ade)], 7.90 bs [2H, $NH_{2'}$, (N^3-Ade)], 7.21 s [2H, NH_2, (N^9-Ade)], 4.40 t [2H, H(10′), CH_2-(N^3-Ade)], 4.17 t [2H, H(10), CH_2-(N^9-Ade)], 2.39 t [2H, H(11), –CH_2–]. In the literature we can find examples of N^3 substitution of adenines but the experimental conditions (acidic or neutral pH) are very different to those described in this paper [8–10]. In order to optimize the preparation of this new ligand we have modified reaction conditions (use of DMF or anhydrous DMF; addition of drops of water to the reaction mixture; temperature: from r.t. to 100 °C; reaction times from 24 h. to 48 h; different bases: NaOH, K_2CO_3 anhydrous, NaH… or even without base) but, in our hands it has been extremely difficult to obtain a pure sample of this product.

3.2. Zn(II) complexes

Complex $[\text{H-}(Ade)_2C_3(ZnCl_3)]$ (**6**) represents the first inner sphere complex with a $N^9,N^{9'}$-bisadenine. The structure shows a zwitterionic form with one ring protonated at N(1) while the other ring is coordinated to a $ZnCl_3$ moiety, as in other complexes with alkyl-adenines [11,12] (Fig. 7).

Intramolecular hydrogen bonds stabilize the coordination through N(7). Additional intermolecular interactions are present forming dimeric units (see Fig. 8). The two

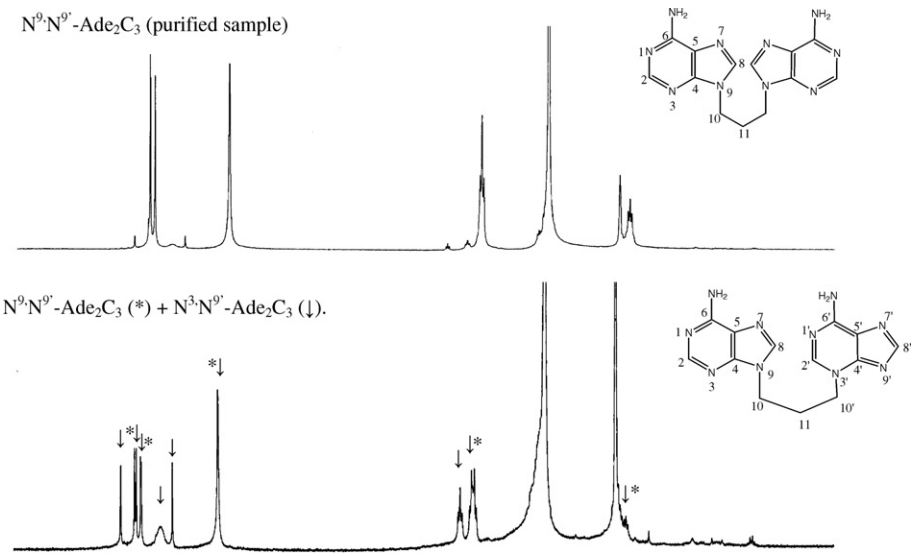

Fig. 6. ^{1}H NMR spectra of N^{9},$N^{9'}$-trimethylene-bisadenine and a sample of reaction crude (best conditions to obtain ^{9},$N^{3'}$-trimethylene-bisadenine: 80 °C, NaH in anhydrous DMF and 48 h).

adenine rings for each molecule present a *s-cis* disposition which allows a *stacking* interaction between the imidazolic rings [average distance 3.39(3) Å], similar to that found in the neutral form [1].

3.3. IR spectra

Although NMR spectroscopy was not useful to characterize the structure of the complexes, the IR data results were very conclusive. The IR spectra of the outer sphere complexes are very similar to the corresponding hydrochlorides. The bands related to δ(NH) are shifted to higher frequencies and the peak at ca. 1328 cm^{-1} assigned to $\nu(C_5–N_7–C_8)$ remains practically unchanged [1,2]. Table 2 shows tentative assignments for the neutral and protonated ligands. Thus, in the infrared spectrum of the zwitterionic inner sphere complex **6**, four bands are exhibited between 1710 and 1570 cm^{-1} (see Fig. 9) which correspond to δ(NH): 1708 and 1668 cm^{-1}, $\delta(NH) + \nu(C_5–C_6)$: 1603 cm^{-1} and $\nu(C_5–N_7–C_8)$: 1578 cm^{-1}. Similar pattern band distribution for [H-(Ade)$_2$C$_4$ZnCl$_3$] (**7**) is indicative of an asymmetric structure and coordination type. The other

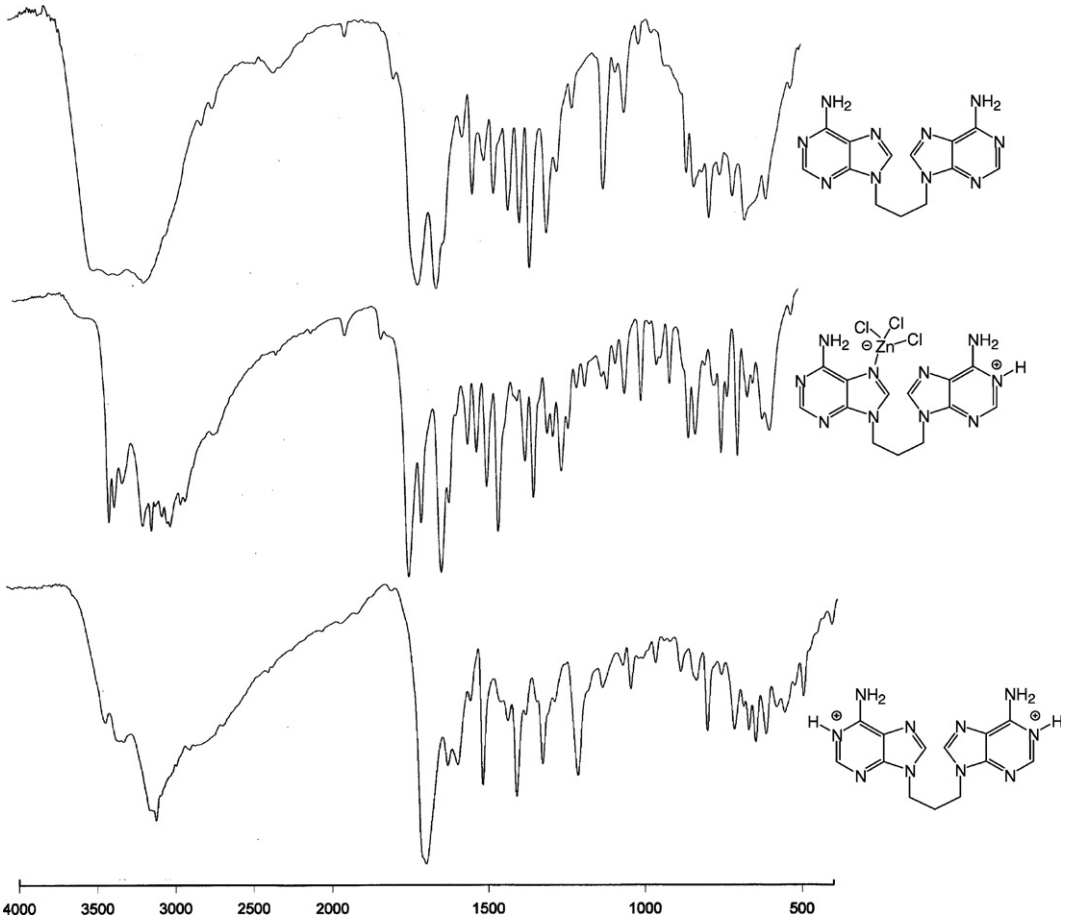
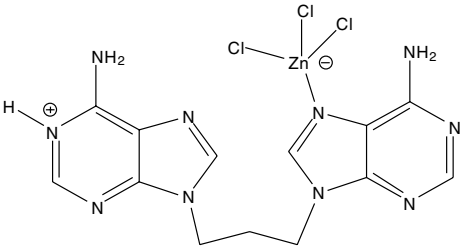
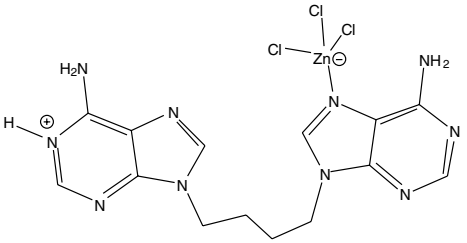
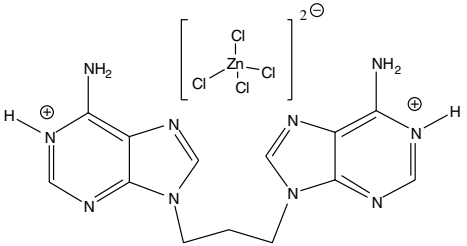
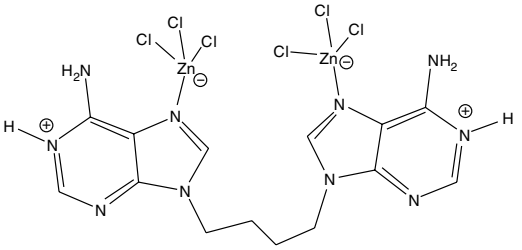
[a] Values of **1** and **1a** are equivalent to those previously reported [1,2].
[b] Compound **5** presents a similar IR spectrum to that of **2a**.

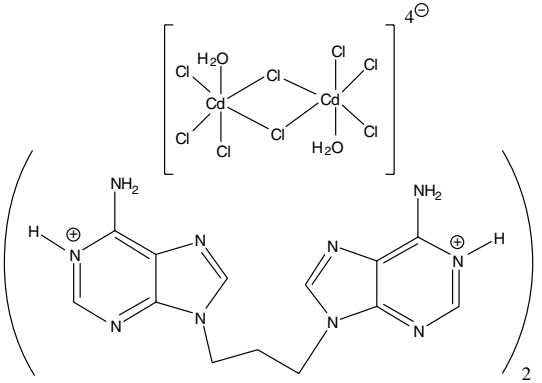












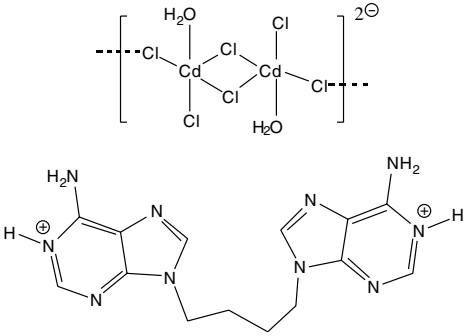


Fig. 9. Comparison of the IR spectra of Ade_2C_3 (**1**), [H-$(Ade)_2C_3(ZnCl_3)$] (**6**) and $Ade_2C_3 \cdot 2HCl$ (**1a**).

inner sphere [$(H\text{-}Ade)_2C_4(ZnCl_3)_2$] (**8**) complex present two broad bands in the same area which can be attributed to the presence of a more symmetric structure equivalent to that found in $N^6,N^{6'}$-[$(H\text{-}Ade)_2C_3(ZnCl_3)_2$] previously described [3].

4. Conclusions

The general behaviour of (tri and tetramethylene)-bisadenines with Zn(II) and Cd(II) in acidic media is shown in Table 3.

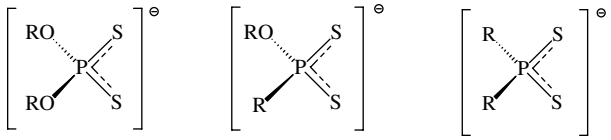
Table 3
Proposed structures for the isolated complexes

Experimental conditions		Ade_2C_3	Ade_2C_4
Zn	HCl 0.1 M	$[H\text{-}(Ade)_2C_3(ZnCl_3)]$ (**6**) 	$[H\text{-}(Ade)_2C_4(ZnCl_3)] \cdot 1.5H_2O$ (**7**) 
	HCl $\geqslant$ 1 M	$[(H\text{-}Ade)_2C_3][ZnCl_4] \cdot H_2O$ (**3**) 	$[(H\text{-}Ade)_2C_4(ZnCl_3)_2 \cdot 3H_2O$ (**8**) 
Cd	HCl 0.1 M	$[(H\text{- }Ade)_2C_3]_2[Cd_2Cl_8(H_2O)_2] \cdot 4H_2O$ (**4**) 	$\{[(H\text{- }Ade)_2C_4][Cd_2Cl_6(H_2O)_2] \cdot 2H_2O\}_n$ (**5**) 
	HCl $\geqslant$ 1 M		

These results show:

(i) In our hands, Cd(II) ion only yields outer sphere complexes with N^9,$N^{9'}$-polymethylene-bisadenines in acidic media. Two different anionic species are obtained. The dimeric $[Cd_2Cl_8(H_2O)_2]^{4-}$ with Ade_2C_3 previously described [1] and the polymeric chain based on $[Cd_2Cl_6(H_2O)_2]^{2-}$ units present in the new Ade_2C_4 Cd(II) complex obtained.
(ii) In strong acidic media Ade_2C_3 reactions with Zn(II) only yield outer sphere complexes while Ade_2C_4 yield a bis-zwitterionic inner sphere complex similar to N^6,$N^{6'}$-Ade_2C_3 Zn(II) complex.
(iii) By a modification of the reaction conditions (HCl 0.1 M) is possible to isolate equivalent inner sphere complexes for both ligands: $[H\text{-}(Ade)_2C_x(ZnCl_3)]$ ($x = 3$, 4).

5. Supplementary material



CCDC numbers 612160 , 612161 and 612162 contain the supplementary crystallographic data for **5**, **5a** and **6**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

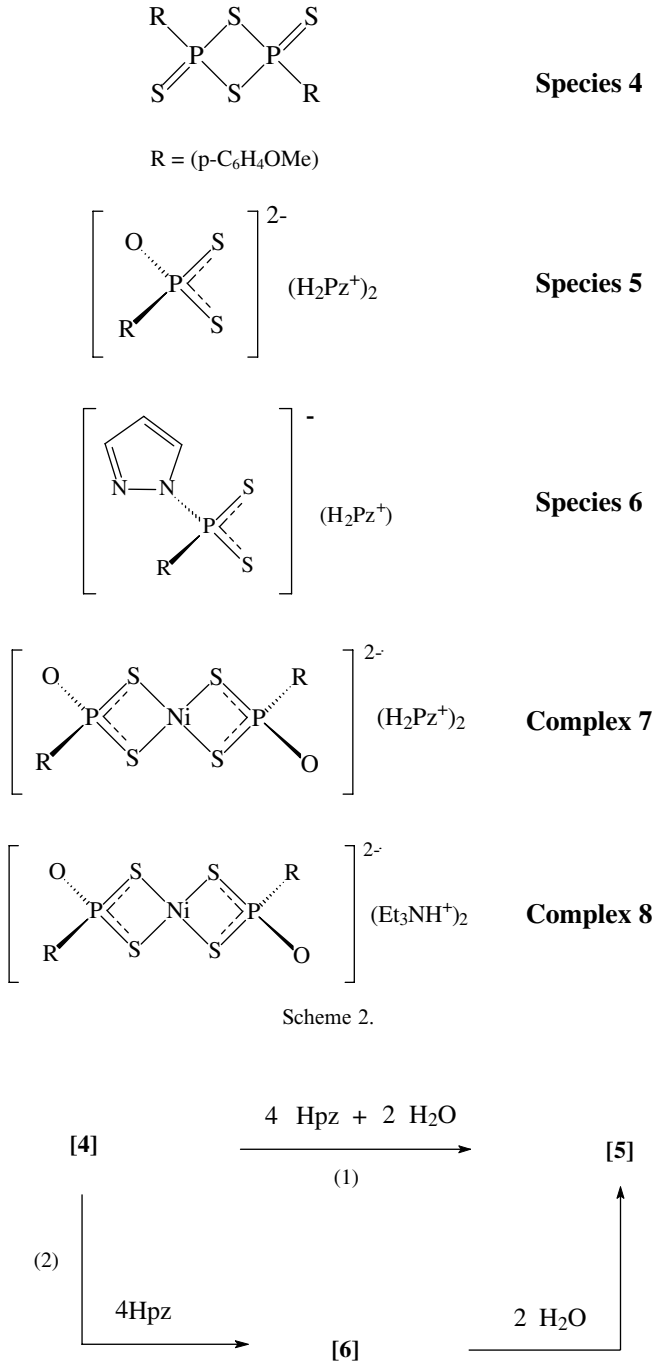
Scheme 1.



2. Results and discussion

2.1. Synthesis, characterization and solution properties of species 5 and 6

When a suspension of the Lawesson's dimer $[S_2P(p\text{-}C_6H_4OMe)]_2$ (**4**, Scheme 2) in toluene was treated under nitrogen with a large excess of pyrazole (Hpz), a white precipitate formed (**5**, Scheme 3, pathway 1), which, on the basis of elemental analysis, IR and multinuclear spectroscopy, was formulated as an adduct between pyrazole and dithiophosphonic acid (H_2L), with $H_2L \cdot 2Hpz$ formula. Nevertheless, the presence of multiple bonding sites for the acidic proton [the N site(s) on the pz moiety and the S or O sites on the dithiophosphonate ligand] cannot rule out the presence of different tautomers, such as a bispyrazolium salt, $L(H_2pz)_2$, or even a species where the hydrogen atoms are extensively shared between the above quoted N, O and S acceptors.[1]

Species **5** was found to transform from a white solid into a dense liquid if left in air. Why this occurs it is not clear. X-ray powder diffraction (XRPD) indicated the solid to be highly crystalline; yet, as observed by performing a profile fitting of time-dependent XRPD traces, the decomposition has a $t_{1/2}$ value just above 4 h (Fig. 1). GC–MS measurements of the evolved gas fraction did not support any conclusive information, thus leaving the question still open. The XRPD crystalline trace (collected in conventional Bragg–Brentano mode in the air) is nevertheless too complex for an ab initio structural analysis; *inter alia*, this agrees with the presence of two formula units in the asymmetric unit of the crystals, as evidenced by solid state ^{31}P NMR (vide infra). The IR spectrum of solid **5**, recorded in nujol mull, shows a broad absorption at 1869 cm^{-1}, which is likely due to strong hydrogen bonds of the P–O–H–N kind, involving the dithiophosphonic acid and the heteroaromatic ring.

The ^{31}P NMR spectrum of **5** in acetone-d_6 shows one singlet centred at 78.6 ppm (see Table 1). This value shows an upfield shift of about 30 ppm compared to that found earlier for dithiophosphonate ligands [15,16], suggesting the presence of a relatively highly charged (dianionic) form of L for **5**, thus supporting, at least in solution, the formulation of **5** as a bispyrazolium salt, $L(H_2pz)_2$. On lowering the temperature down to 183 K, the ^{31}P NMR spectrum shows only one broader peak at 86.2 ppm, indicating that the system is in the fast exchange regime at room temperature (RT) and that the exchange rate decreases only slightly at low temperature. Unfortunately, the corresponding low temperature ^1H NMR spectrum cannot be employed to follow in detail this process, due to the complexity of the signals in the aromatic region. At room temperature, the ^1H NMR spectrum of **5** (in acetone-d_6) shows two multiplets at 7.9 and 7.1 ppm due to the protons of the aryl group, one singlet centred at 3.8 ppm for the OMe residue and

[1] For the sake of completeness, it must be said that even a formulation of the $[(MeO)C_6H_4\text{–}PS_2\text{–}O\text{–}PS_2\text{–}C_6H_4(OMe)](Hpz)_2(H_2pz)_2$ kind cannot be excluded (*Anal.* Calc.: C, 44.95; H, 4.64; N, 16.13), being it consistent even with the ^{31}P CPMAS NMR evidences.

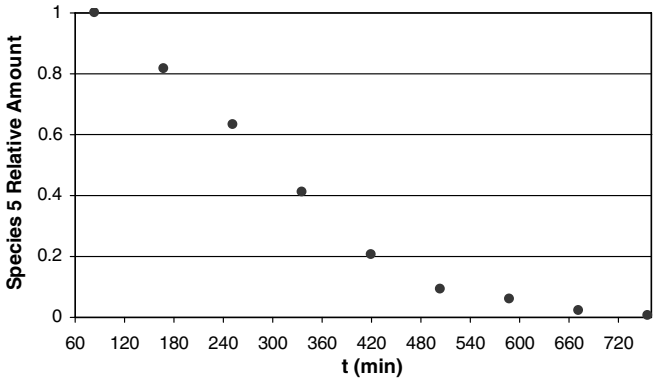

Fig. 1. Time dependence of the solid to liquid decomposition of the (polycrystalline) species **5** if left in air at RT, as followed by the disappearance of the pertinent peaks in the powder diffraction traces.

[c] Spectra recorded in methanol.

two signals at 7.7 and 6.3 ppm, assigned to the protons of the pyrazole moiety. The assignment of the signal at 10.3 ppm to acidic (N–H) protons [17] was confirmed by its disappearance after isotopic exchange with D_2O.

The formulation of **5** was also confirmed by the ^{13}C NMR spectrum (recorded at RT in acetone) which shows, beside the phenyl C-atoms signals, only two resonances for the heterocycle at 105.0 and 133.6 ppm, attributed to C(4) and C(3)/C(5), respectively. This excludes any possibility of a P–N bound species.

On the basis of these spectral observations, intermolecular hydrogen bonds between the adducts can be ruled out in solution and, taking into account the elemental analysis, the presence of two molecules of pyrazole *per* molecule of dithiophosphonic acid is implicit.

The fact that no pyrazolium *N*-pyrazolyl-4-methoxyphenyl-phosphonamidodithiolate was obtained when pyrazole alone was reacted with the Lawesson's reagent is here attributed to the specific electron properties of this heterocycle. Indeed, pyrazole can be considered a "hybrid" molecule, the lone pair on N(2) making it nucleophilic, while its aromatic nature transforming it into a good leaving-group.

In order to investigate the role played by Hpz in the reaction with **4**, a new synthesis was carried out in anhydrous conditions. It is well known that aliphatic amines readily react with the Lawesson's dimer forming a stable P–N bond [18]. Accordingly, when a solventless reaction between the Lawesson's reagent and an excess of pyrazole was carried out at 343 K and under nitrogen atmosphere, a new derivative, **6**, could be isolated. Species **6** was formulated as a 4-methoxy-phenylphosphonoaminodithiolate pyrazolium salt (Scheme 2), on the basis of multinuclear NMR spectroscopy. The RT ^{31}P NMR spectrum of **6** recorded in acetone-d_6 shows a sharp signal centred at 72.8 ppm in agreement with the presence of a phosphorus atom directly bound to a nitrogen one [18,19]. In the presence of water, or moisture, compound **6** hydrolyzes very quickly and species **5** is immediately formed, as confirmed by the ^{31}P NMR spectrum of **6**, recorded (in acetone-d_6) after addition of few drops of water and under nitrogen: the latter spectrum shows, beside the signal due to the N-bound P atom, a new peak centred at 78.1 ppm, i.e. that of the phosphorous atom of the P–O bound species **5**. After 30 min, only the signal centred at 78.1 ppm can be observed. This spectroscopic evidence suggests that the first step of the reaction between **4** and pyrazole is the ring opening reaction by nucleophilic attack of the heterocycle to the Lawesson's reagent with the formation of **6**. In the presence of water, the labile species **6** hydrolyzes quickly, forming the more stable derivative **5** (see Scheme 3, pathway 2). The proposed chemical nature of **6** was also confirmed by ^{31}P solid state NMR spectroscopy, as described below.

2.2. Solid state NMR characterization of species 5 and 6

In the absence of samples suitable for conventional X-ray diffraction studies, species **5** and **6** were analysed by solid state NMR spectroscopy, in order to gain some structural information. The ^{31}P CPMAS spectrum of **5** (Fig. 2a, Table 1) shows two distinct peaks at 97.3 ppm and 94.5 ppm, with a downfield shift of about 20 ppm with respect to the single resonance observed in the NMR spectrum in solution (78.6 ppm in acetone). This different chemical shift between the spectra in the solid state and in solution may depend on packing effects, likely the presence of intermolecular hydrogen bonds between the dithiophosphonic acid and the pyrazole.

The chemical shifts of the peaks in the solid state are in agreement with previous studies [19] which report P–O signals resonating in the range 95–110 ppm. The splitting of the ^{31}P signal into two peaks is confirmed by the ^{13}C CPMAS spectrum (Fig. 2b), in which the isolated signals of the O-methyl (at about 55 ppm) and the P-*ipso* (about 160 ppm) carbon nuclei are split into two peaks each. Unfortunately, the extreme peak overlapping in the aromatic region does not allow to unambiguously assign the pyrazole signals. However, it is well known that, in the solid state, pyrazole gives three distinct peaks at

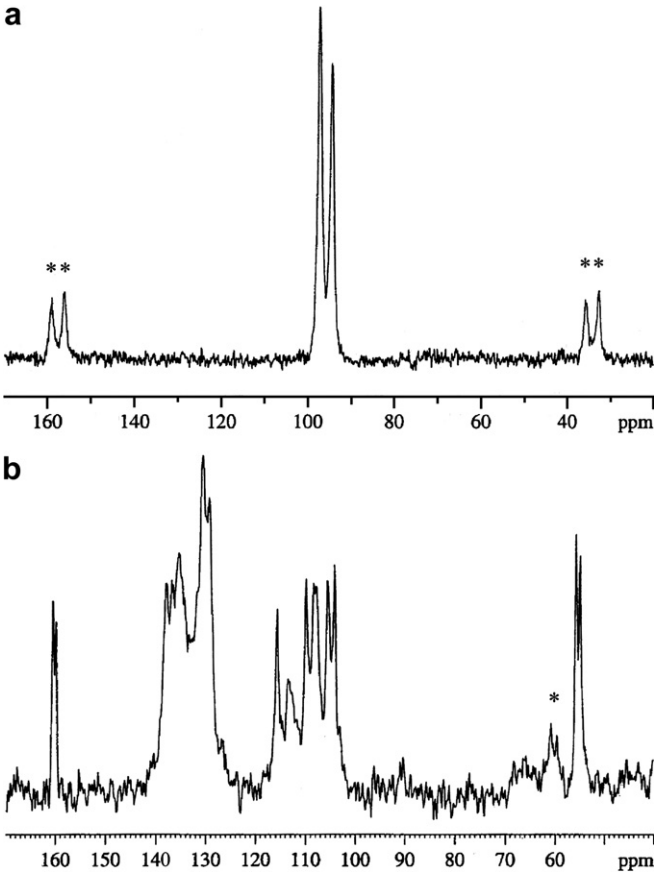

Fig. 2. Solid state NMR spectra of **5**: (a) ^{13}C CPMAS, Number of scans (NS) = 820. (b) ^{31}P CPMAS, NS = 20. Asterisks indicate spinning sidebands.

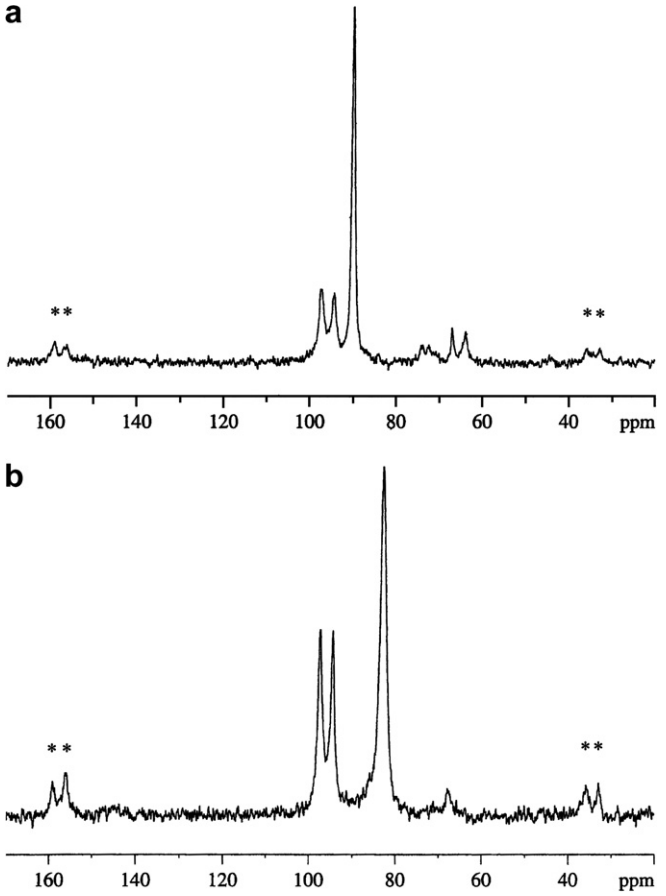

Fig. 3. ^{31}P SPE experiment with recycle delay of 5 s for (a) **5** quenched, Number of scans (NS) = 164, (b) **6***, NS = 48. Asterisks indicate spinning sidebands.

138.7 ppm (C3), 107.0 ppm (C4) and 128.8 ppm (C5) ppm [20]. The clear absence of peaks in the 128 ppm region in the spectrum of **5** seems to indicate that no ''free'' pyrazole is present in species **5**, thus suggesting, in agreement with the above IR results, the presence of a network of hydrogen bonds in the solid.

The presence of split ^{31}P and ^{13}C peaks may suggest either the occurrence of two different phosphorous chemical environments coexisting in a single crystalline phase, or the co-presence of different crystalline forms within the sample. On the basis of the relative intensities of the two peaks (approximately 1:1) the first hypothesis seems more likely. The existence of two crystalline forms in the sample is ruled out by a further experiment in which **5** is obtained by rapidly quenching the reaction mixture down to 273 K before filtering. The ^{31}P CPMAS spectrum recorded on this product was identical to that of species **5**, whereas the ^{31}P SPE spectrum registered with a short recycle delay shows an additional peak at 89.9 ppm (Fig. 3a). The SPE experiment is known to enhance the resonance of those nuclei with a short relaxation time, T_{1P}, i.e. phosphorous nuclei possessing distinct dynamics from those responsible for the peaks in the CPMAS spectrum (in the present case, the two peaks at 97.3 ppm and 94.5 ppm). We suggest that the new peak at 89.9 ppm may belong to an amorphous phase, the formation of which is favoured upon fast cooling and, as expected, is absent in the ^{31}P SPE spectrum of **5** obtained upon slow crystallization. Besides, the presence of the two peaks at 97 and 94 ppm with similar relative intensity, supports the exclusion of the concomitant existence of two crystalline phases.

With the purpose of characterizing the P–N bound species by solid state NMR, **6** was recrystallized using anhydrous toluene, thus changing the consistency of the sample from a sticky material to a solid suitable to be packed in the NMR rotor, **6***. The ^{31}P CPMAS spectrum (not reported) shows two peaks centred at 97.2 ppm and 94.4 ppm, assigned to **5**, which is quickly formed by hydrolysis of **6**. However, an additional peak at 82.2 ppm was found in the ^{31}P SPE spectrum (Fig. 3b), which, on the basis of its chemical shift value [19], is assigned to a phosphorous nucleus of the P–N bound species **6**, thus corroborating the existence of an intermediate P–N species.

2.3. Synthesis and spectroscopic characterization of species 7 and 8

Although both derivatives **5** and **6** can be considered flexible multitopic ligands, the low stability of **6** pushed

us to investigate the coordination properties of species **5** only.

When a suspension of **5** in acetonitrile was treated with $Ni(ClO_4)_2 \cdot 6H_2O$, a violet compound formed, which, on the basis of elemental analysis and spectroscopic data, was formulated as $[NiL_2](H_2Pz)_2$ (**7**). The IR spectrum of **7** (nujol mull) shows one broad band at 1870 cm^{-1}, due to the presence of strong hydrogen bonds of the P–O–H–N kind (as substantiated by the complete structure determination, vide infra).

The RT ^{31}P NMR spectrum of **7** in solution presents one broad peak centred at about 85 ppm, while, on lowering the temperature at 183 K, two sharp peaks at 82.0 and 80.4 ppm appear, suggesting that at low temperatures a slow exchange regime is reached. This fluxional property of **7** may be assigned to the interconversion of the *cis* and *trans* isomers [15].

The RT ^1H NMR spectrum of **7** shows two multiplets centred at 8.1 and 7.1 ppm (phenyl protons), a singlet at 3.9 ppm (methoxo protons) and one broad peak at 4.2 ppm, attributed to an acidic proton. At RT, the protons of pyrazole are undetectable, probably because their signals are so broad to be hidden in the baseline, suggesting an intermediate exchange rate for pyrazole. At 163 K, the ^1H NMR spectrum of **7** shows new signals: one triplet centred at 6.5 ppm, and one doublet at 8.1 ppm, assignable to the protons of the heteroaromatic ring. This indicates that the fluxional process involving pyrazole is substantially slowed down at 163 K. A fundamental role in lowering the rate of the fluxional process may be played by the possibility of formation of strong hydrogen bonds (of P–O–H–N type) even in solution. This was indeed confirmed by the fact that, at RT, after addition of few drops of deuterium oxide, the pyrazole signals do appeared. Apparently, the presence of ^2H versus ^1H nuclei slows down the fluxional process, as does lowering the temperature. Similar isotopic effects have been recently reviewed [21].

On the other hand, when the reaction between **5** and $Ni(ClO_4)_2 \cdot 6H_2O$ was carried out in the presence of triethylamine, a brown precipitate formed, which, on the basis of elemental analysis, IR and ^1H NMR spectroscopy, was formulated as $[NiL_2](Et_3NH)_2$ (**8**), as confirmed by the single crystal X-ray diffraction characterization described below. Species **8** can also be obtained starting from **7** in the presence of triethylamine, showing the stronger basicity of the tertiary amines versus pyrazole.

The RT ^{31}P NMR spectrum of **8** in methanol-d_4 shows one singlet centred at 69.4 ppm while, lowering the temperature at 173 K, two sharp peaks at 73.7 and 72.2 ppm appear. Analogously to what observed for **7**, a slow exchange regime is reached at 173 K, which allows to detect the interconversion process between the *cis* and *trans* isomers.

The RT ^1H NMR spectrum of **8** registered in acetone-d_6 shows two multiplets centred at 8.3 and at 6.7 ppm (aromatic protons), one singlet at 3.8 ppm (methoxo group), and two multiplets centred at 3.2 and 1.3 ppm, due to the triethylamonium ion. On lowering the temperature down to 173 K, these spectral features do not change.

The ^{31}P CPMAS spectra for both nickel complexes **7** and **8** show single peaks at 77.3 ppm and 59.7 ppm, respectively. This large chemical shift difference can be in principle attributed to two distinct, but possibly convergent, effects: the strength of the P–O–H–N interactions, and the electronic reorganization within the RPS_2O fragments, with different hybridization and double bond character of the P=O bond. These subtle effects will be further considered when discussing the X-ray diffraction results (vide infra). The finding of an individual peak for both complexes indicates that only one phosphorus environment is present in the structure, and that the complex must lie about a crystallographic symmetry element. This also suggests that both species crystallize in a unique isomeric form, also in agreement with the crystallographic features which identify the *trans* isomer.

2.4. Crystal and molecular structure of species 7 and 8

Both complexes **7** and **8** crystallize in the triclinic space group $P\bar{1}$. The asymmetric unit of the former species comprises half a Ni(II) ion, lying about a crystallographic inversion centre, one phosphodithiolate ligand (L) and one pyrazole moiety. Whether the latter is a true neutral Hpz molecule, a pyrazolium cation (H_2pz^+) or an intermediate form is not relevant, since an extended network of hydrogen-bonds shows that the acidic hydrogen atoms are shared, in the solid, in the different D–H···A wells.

Also in species **8**, a centrosymmetric $[NiL_2]^{2-}$ complex is present, hydrogen-bonded to one triethylammonium cation on each side. As can be appreciated in Figs. 4 and 5, in both **7** and **8**, the metal centre is tetracoordinated in square planar geometry by four sulfur atoms belonging to two distinct L ligands. Thus, in both compounds, the L moiety acts as a S,S′-chelating ligand, promoting comparable Ni–S bonds of about 2.22 Å and similar S–Ni–S angles of about 88° and 92° (Table 2). Within both $[NiL_2]^{2-}$ complexes, the 4-methoxyphenyl and oxo substituents on each phosphorous atom adopt a *trans* disposition with respect to the mean plane individuated by the NiS_2P_2 moiety, in agreement with the ^{31}P CPMAS NMR observations of a unique isomer and magnetically equivalent P nuclei.

In **7**, the pyrazole ligand is not coordinated to the metal centre. Nevertheless, both nitrogen atoms are involved in hydrogen bond interactions of about 2.65 Å with the oxo substituents of L ligands belonging to two distinct, adjacent $[NiL_2]^{2-}$ complexes (Fig. 6). The presence of such a hydrogen bond implies a slight (yet statistically significant) lengthening of the P–O bond distance, being 1.538(2) Å in complex **7** versus 1.502(2) Å in **8**. It is worth noting that even in species **8** the oxo substituent is involved in a hydrogen bond interaction of about 2.7 Å with the nitrogen atom of an adjacent triethylammonium cation. The different number (and type) of P=O–H–N bonds in **7** and **8** (Table 1) thus affects the local electronic distribution at the P=O

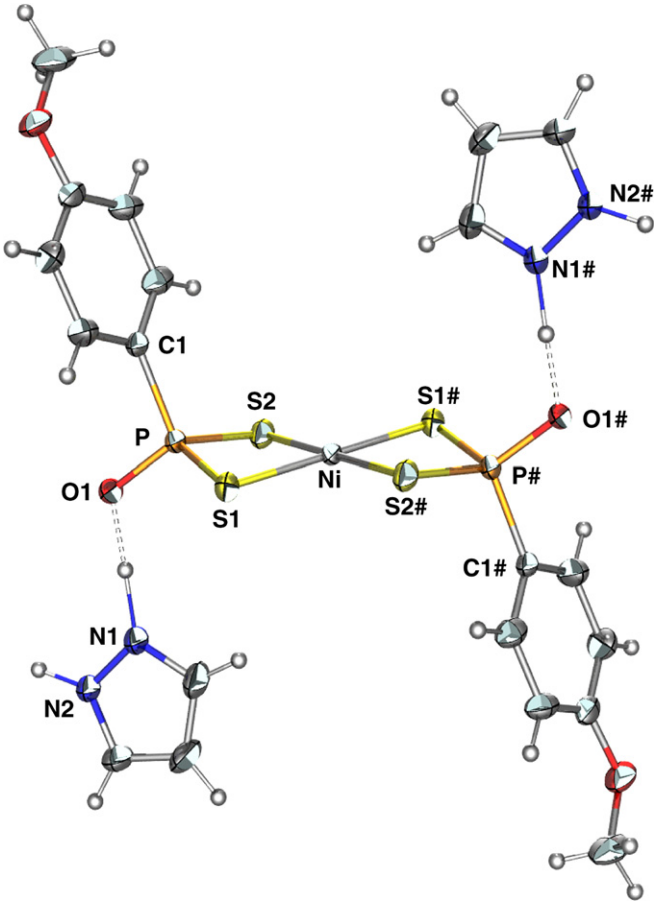

Fig. 4. ORTEP representation (30% probability level) of the molecular structure in complex **7**. fragment; this is also counterbalanced by the slight lengthening (ca. 0.01 Å, i.e. 10σ) of the P–S bonds; these subtle effects may be likely considered responsible for the downfield shift of the ^{31}P peak in the CPMAS spectrum of **7** (with respect to that of **8**), as mentioned above.

As appreciable in Fig. 6, and thanks to the ditopic nature of the pyrazolium cations, the intermolecular interactions present in **7** generate monodimensional chains running in the [1 0 1] direction. At variance, no extended network can exist in **8** and centrosymmetric molecules surrounded each by two triethylammonium cations are present.

3. Experimental

3.1. Materials and methods

Pyrazole (HPz), Lawesson's reagent and salts were used as supplied (Aldrich Chemical Co.). Solvents were dried and distilled by standard methods. All preparations and manipulations were carried out under dinitrogen atmosphere using conventional Schlenk techniques. *Caution:* Perchlorate salts in the presence of transition metal ions

and organic material are potentially explosive and should be handled with care!

Infrared spectra were recorded on a Shimadzu Prestige-21 instrument. Elemental analyses were carried out on a Perkin–Elmer CHN Analyzer 2400 series II.

NMR spectra were recorded using a Bruker ADVANCE 400 spectrometer, employing for solid state experiments a 4 mm double bearing MAS probe. The standard ^{1}H, ^{13}C and ^{31}P spectra in solution were carried out in acetone (methanol for **8**) at room temperature. For the solid samples ^{31}P cross-polarization magic-angle spinning (CPMAS) spectra were recorded using a recycle time of 4 s, contact times of 1 ms and spinning rates of 10 kHz. ^{31}P single pulse excitation (SPE) experiments with high power proton decoupling were recorded with recycle times of 5 s. The CPMAS experiment select the most hindered carbons, those in the crystalline phase, whereas the SPE experiment acquired with a recycle delay of 5 s selects more mobile carbons (5 s is not enough for complete relaxation of rigid carbons). The ^{31}P spectra were referenced with respect to 85% aqueous H_3PO_4 by setting the ^{31}P NMR peak of poly crystalline ammonium dihydrogenphosphate to +2.5 ppm. The ^{13}C CPMAS spectra were recorded using a recycle time of 5 s, contact times of 1 ms, spinning rates of 7 kHz. Both ^{31}P and ^{13}C solid-state NMR spectra were recorded at room temperature and were transformed using a line broadening of 20 Hz. The number of scans (NS) are indicated in the figure captions.

3.2. Synthesis of species 5–8

3.2.1. Synthesis of 5

To a suspension of the Lawesson's reagent $[S_2P(\mu\text{-}C_6H_4\text{-}OMe)]_2$ (0.404 g; 1.0 mmol) in wet toluene (15 ml), pyrazole was added (0.680 g; 10.0 mmol). The reaction mixture was kept under stirring for 4 h at 333 K, then the white compound was filtered off, washed with toluene and dried under vacuum. IR (nujol): strong and broad absorption band at 1869 cm^{-1} assigned to hydrogen bonds of either the N–H···O, or, for the formulation reported in footnote 1, the N–H···N type [22,23]. *Anal.* Calc. for $C_{13}H_{17}N_4O_2PS_2$ (356.4 g mol^{-1}): C, 43.81; H, 4.81; N, 15.72. Found: C, 44.12; H, 4.67; N, 15.76%. δ_H (400 MHz; CD_3COCD_3; Me_4Si) 9.3 (1H, b s, N–H/O–H), 7.99 (2H, m, Ph), 7.76 (4H, s, $C(3,5)_{pz}$-H), 7.05 (2H, m, Ph), 6.33 (2H, s, $C(4)_{pz}$-H), 3.88 (3H, s, OCH_3) – δ_C (100 MHz; CD_3COCD_3; Me_4Si) 162.7 (Ph), 133.6 ($C_{pz}(3,5)$), 132.7 (Ph), 113.8 (Ph), 105.0 [$C_{pz}(4)$], 55.4 (OCH_3) – δ_P (162 MHz; CD_3COCD_3; H_3PO_4) 78.6 (s) – δ_P (162 MHz; solid state): 97.3 (s), 94.5 (s).

3.2.2. Synthesis of 6

The Lawesson's reagent (0.404 g; 1.0 mmol) and pyrazole (0.680 g; 1.0 mmol) were heated at 75 °C in a sealed flask under nitrogen atmosphere and under stirring for 4 h. The mixture was then allowed to cool and solidify giving a white compound. The residue was then washed many times with anhydrous toluene in order to eliminate excess of pyrazole and to solidify the sample. δ_P (162 MHz; CD_3COCD_3; H_3PO_4) 72.8 (s) – δ_P (162 MHz; solid state): 82.3 (s).

3.2.3. Synthesis of 7

To a solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.150 g; 4.2×10^{-1} mmol) in acetonitrile (4 ml), at room temperature and under inert atmosphere, species **5** (0.300 g; 8.4×10^{-1} mmol) was added in one portion. The reaction mixture was kept under stirring for 2 h, then filtered off, washed with acetonitrile and dried under vacuum (yield: 80.2%). IR (nujol): absorption at 1870 cm^{-1}. *Anal.* Calc. for $C_{20}H_{24}N_4O_4S_4P_2Ni$ (633.3 g mol^{-1}): C, 37.93; H, 3.82; N, 8.85. Found: C, 37.82; H, 3.73; N, 8.64%. δ_H (400 MHz; CD_3COCD_3; Me_4Si) 8.12 (2H, m, Ph), 7.12 (2H, m, Ph), 4.19 (1H, b s, N–H/O–H), 3.92 (3H, s, OCH_3) – δ_P (162 MHz; CD_3COCD_3; H_3PO_4) 85 (b s) – δ_P (162 MHz; solid state): 77.3 (s). Crystals suitable for

an X-ray structure determination were obtained by slow diffusion of dichloromethane into an acetone solution of **7**.

3.2.4. Synthesis of 8

To a stirred solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.150 g; 4.2×10^{-1} mmol) in acetonitrile (4 ml) at room temperature and under inert atmosphere, **5** (300 g; 8.4×10^{-1} mmol) was added in one portion. After a couple of minutes, Et_3N (0.800 ml) was added dropwise. The brown solid formed was stirred under dinitrogen atmosphere for 2 h, then filtered out, washed with acetonitrile and acetone and dried under vacuum (yield: 84.3%). *Anal.* Calc. for $C_{26}H_{44}N_2O_4S_4P_2Ni$ (699.5 g mol^{-1}): C, 44.63; H, 6.58; N, 4.00. Found: C, 44.82; H, 6.66; N, 4.07%. δ_H (400 MHz; CD_3COCD_3; Me_4Si) 8.24 (2H, m, Ph), 6.98 (2H, m, Ph), 4.83 (1H, b s, N–H/O–H), 3.87 (3H, s, OCH_3), 3.28 (12 H, q, CH_2), 1.35 (18 H, t, CH_3) – δ_P (162 MHz; CD_3COCD_3; H_3PO_4) 69.4 (b s) – δ_P (162 MHz; solid state): 59.7 (s). Crystals suitable for an X-ray structure determination were obtained by slow diffusion of diethyl ether into a methanol solution of **8**.

3.3. X-ray crystallography

Species **7** and **8** crystallize as violet and brown single crystals suitable for X-ray diffraction. Crystals of approximate $0.20 \times 0.14 \times 0.06$ and $0.30 \times 0.20 \times 0.05$ mm dimensions (for **7** and **8**, respectively) were glued on the tip of a glass fibre and mounted on top of a goniometer head. The data were collected using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) on Bruker AXS SMART (**7**) or Enraf Nonius CAD-4 (**8**) automated diffractometers. In the first case, the unit cell was determined by acquiring 60 frames (44 reflections) at different ω and ϕ goniometer angles. In the latter, the unit cell was determined on the basis of the setting angles of 25 intense, randomly distributed, reflections with θ in the 9–12° range. A total of 9989 and 3254 reflections, in the $2.3° < \theta < 30.0°$ and $3.0° < \theta < 25.0°$ range (for **7** and **8**, respectively), were collected in the ω-scan mode [SMART: $\Delta\omega = 0.3°$; CAD-4: $\Delta\omega = 0.8 + (0.35\tan\theta)$]. Generator settings: 45 kV, 40 mA (SMART); 50 kV, 30 mA (CAD-4). The data were corrected for Lorenz-polarization and for absorption effects [24,25]. The structure solutions and refinements were performed by direct methods (SIR-97) [26] and full-matrix least-squares procedures on F^2 (SHELX-97) [27], respectively, as implemented in the WinGX suite of programs. All non-hydrogen atoms were treated anisotropically. Hydrogen atoms were made riding on the pertinent parent atoms with an isotropic thermal displacement parameter arbitrarily chosen as 1.2 times that of the parent atom itself. In the case of complex **7** both hydrogen atoms involved in the P–O–H–N hydrogen bond interactions were arbitrarily assigned to the nitrogen atoms. Further details of the crystal structure analyses can be found in Table 3.

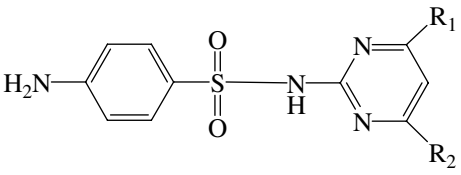
4. Conclusions

The syntheses and spectroscopic characterization of the new, S-donor 4-methoxophenyldithiophosphonate ligand (L) have been described. Its coordination properties have been investigated towards the Ni(II) metal centre, and the structural characterization of two salts, containing the centrosymmetric *trans*-$[NiL_2]^{2-}$ anion, has been performed. The extensive solution and solid state multinuclear characterization has allowed to determine the nature of labile intermediates, which could neither be isolated as single crystals nor as *air stable* polycrystalline materials.

Work is in progress, aiming at obtaining distinct thiophosphonate salts of higher stability to be used in the

formation of new metal complexes, by employing differently substituted pyrazoles, and new characterization techniques, such as ab initio X-ray powder diffraction methods [28].

Acknowledgments



This work was supported by the Ministero dell'Università e della Ricerca (MIUR). We deeply thank Prof. N. Masciocchi, University of Insubria, for helpful discussions.

Appendix A. Supplementary material

Crystallographic data (excluding structure factors) for the two crystal phases have been deposited with the Cambridge Crystallographic Data Centre. CCDC 606670 and 606671 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.09.077.

Sulfadiazine (sdr) when R_1 and R_2 are hydrogen (H)
Sulfamerazine (smr) when R_1 is H and R_2 is methyl group (CH_3)
Sulfamethazine (smz) when R_1 and R_2 are methyl group (CH_3)

The diversity of the coordination numbers for the mercury complexes can be found in the literature. In mono-organomercury(II) compounds, the primary bonds leave the Hg atom with enough residual acidity for it to be able to reach a coordination number of six when the donor atoms forming the secondary bonds are small. There are only a small number of Hg complexes with coordination number two [15]. However, Hg(II), has an extremely high affinity for thiol-containing compounds, and forms 1:2 metal: ligand linear complexes with them [16].

In this context, we will discuss the syntheses, spectroscopic characterization and X-ray crystal structure determination of the Hg complexes of sulfa drugs sulfamerazine sulfadiazine and sulfamethazine.

2. Experimental

2.1. General procedures

Analar grade chemicals (SIGMA and BDH) were used as received. CHN microanalysis was carried out using a Perkin–Elmer 2400 CHN elemental analyzer. The IR spectra were recorded on a Nicolet 510 FTIR spectrometer, each compound was pressed into a KBr disk that was prepared in a sample holder by compressing a powdered sample with a 20-fold excess of dry KBr. NMR spectra were recorded on a Bruker Avance AMX-400 spectrometer. ^{1}H and ^{13}C NMR spectra were obtained from a solution of the compounds in d_6-DMSO. The chemical shifts are expressed in ppm relative to internal TMS.

2.2. X-ray crystallography

The crystallographic measurements for the complexes were made at 150 K on a Bruker Nonius Kappa CCD area detector using graphite monochromatised Mo Kα radiation, $\lambda = 0.71073$ Å. The structures were solved by direct methods (SHELXS-97) [17] and refined on F^2 by full-matrix least squares (SHELXL-97) [18] using all unique data and parameters. The absorption correction was made by multi-scan method [19]. The hydrogen atoms on the amino groups of sulfa drugs in the complexes were located from the difference Fourier maps and refined freely.

2.2.1. Preparation of the complex $[Hg(sdz)_2(DMF)_2]$ (1)

Sodium salt of sulfadiazine (0.545 g, 2 mmol) was dissolved in hot methanol and to this, a methanolic solution of $(CH_3COO)_2Hg$ (0.319 g, 1 mmol) was added with constant stirring. A white precipitate was formed and stirring continued for 6 h. It was filtered and dried over silica gel in a dessicator. The precipitate was dissolved in DMF and a few drops of ammonia was added and stirred for 30 min. The solution was filtered and left to crystallize. A few days later, white block crystals were obtained. The compound is soluble in DMF and DMSO but insoluble in water, alcohol and acetonitrile. Anal. Found: C, 36.89, H, 3.85; N, 16.53%. Calc. for $C_{26}H_{32}HgN_{10}O_6S_2$: C, 36.94; H, 3.82; N, 16.57%. IR: (KBr disc): cm^{-1}, 3467(s), 3365(s), 3048(m), 2930, 1655(s), 1614(vs), 1588(vs), 1557(vs), 1506(vs), 1440(sh), 1414(vs), 1342(s), 1291(vs), 1184(w), 1127(sh), 1086(s), 994(w), 958(w), 907(s), 820, 682(s), 651(w), 574(vs), 547(vs), 518(vw), 457(vw), 416(w); ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.50 [2H, d, $J = 4.9$, C(12/14)], 7.78 [2H, d, $J = 8.5$, C(16/20)], 6.98 [1H, t, $J = 4.8$, C(13)], 6.56 [2H, d, $J = 8.6$, C(17/19)], 5.92 [2H, s, (–NH_2)]. ^{13}C NMR (100.6 MHz, DMSO-d_6): δ 162.7 [C(12/14)], 158.8 [C(11)], 153.0 [C18], 130.6 [C(16/20)], 126.1 [C(15)], 114.7 [C(13)], 112.4 [C(17/19)].

2.2.2. Preparation of the complex $[Hg(smr)_2]$ (2)

As with the previous experiment, but sulfamerazine (0.530 g, 2 mmol) was used instead of sodium sulfadiazine. The compound is soluble in DMF and DMSO but insoluble in water, alcohol and acetonitrile. Anal. Found: C, 36.59, H, 3.02; N, 15.57%. Calc. for $C_{22}H_{22}HgN_8O_4S_2$: C, 36.34; H, 3.05; N, 15.41%. IR: (KBr disc): cm^{-1}, 3436(s), 3317(s), 3228(m), 1632(vs), 1598(vs), 1571(vs), 1501(vs), 1465(sh), 1435(vs), 1392(vs), 1371(s), 1332(m), 1310(sh), 1281(vs), 1259(m), 1189(m), 1135(sh), 1093(s), 1010(w), 971(w), 945(w), 917(s), 869(w), 823, 792(s), 769(vw), 716(vw), 689(s), 635(w), 582 (vs) and 546; ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.37 [1H, d, $J = 5.1$, C(14)], 7.84 [2H, d, $J = 8.5$, C(16, 20)], 6.92 [2H, d, $J = 5.1$, C(17, 19)], 6.63 [1H, d $J = 8.8$, C(13)], 5.97 [2H, s, (–NH_2)], 2.39 [3H, s, (CH_3)]. ^{13}C NMR (100.6, DMSO-d_6): δ 168.4 [C(11)], 161.4 [C(12)], 158.3 [C(14)], 152.9 [C(18)], 130.8 [C(15)], 126.2 [C(16/20)], 114.1 [C(17/19)], 112.2 [C(13)], 23.6 [CH_3].

2.2.3. Preparation of the complex $[Hg(smz)_2(DMF)_2]$ (3)

With the same procedure in experiment 2.2.1 except the sodium salt of sulfamethazine (0.601 g, 2 mmol) was used instead of sodium sulfadiazine. The compound is soluble in DMF and DMSO but insoluble in water, alcohol and acetonitrile. Anal. Found: C, 39.72, H, 4.58; N, 15.51%. Calc. for $C_{30}H_{40}HgN_{10}O_6S_2$: C, 39.97; H, 4.47; N, 15.54%. IR: (KBr disc): cm^{-1}, 3457(s), 3360(s), 3247(m), 2919, 1660(vs), 1599(vs), 1577(vs), 1547(vs), 1506, 1429(sh), 1393(vs), 1373(s), 1332(m), 1292(vs), 1258(m), 1194 (w), 1137(sh), 1086(s), 994(w), 965, 897(w), 820, 779(vw), 682(s), 635(w), 589(vs), 549(vs). ^{1}H NMR (400 MHz, DMSO-d_6): δ 7.80 [2H, d, $J = 8.6$ Hz, C(16/20)], 6.57 [2H, d, $J = 8.7$, C(17/19)], 6.69 [1H, s, C(13)], 5.90 [2H, s, (–NH_2)], 2.51 [6H, s, CH_3]. ^{13}C NMR

(DMSO-d_6): δ 167.9 [C(11)], 159.6 [C(12/14)], 152.8 [C(18)], 131.0 [C(15)], 126.3 [C(16/20)], 113.1 [C(17/C19)], 112.0 [C(13)], 23.5 [CH_3].

3. IR spectra

The infrared spectra of the complexes taken in the region 4000–400 cm^{-1} were compared with those of the free ligands. The bands that appear between 3500 and 3400 cm^{-1} due to asym(NH_2) and sym(NH_2) vibrations of the amino (–NH_2) group [13–20] are modified with respect to those of the free respective ligands. These modifications are most probably due to the hydrogen bonding between complexes involving the NH_2 and SO_2 groups.

The peak for the sulfonamidic (N–H) group in the free ligands at around 3125 cm^{-1}, are not present in the spectra of the complexes, confirming the deprotonation of the –SO_2NH– moiety. The scissoring vibrations for the amino (–NH_2) groups appear in the range of 1614–1662 cm^{-1} and peaks due to phenyl ring appear at around 1547 and 1600 cm^{-1}. The peaks around 1325 and 1331 cm^{-1} are assigned to $\nu_{as}(SO_2)$, and those at 1155–1157 cm^{-1} to $\nu_{sy}(SO_2)$, show significant changes upon complexation. The first one splits into two peaks at 1291–1386 cm^{-1} and the second appears at around 1131–1194 cm^{-1} in the complexes.

The 945–965 cm^{-1} bands in the ligands are assigned to ν(S–N) [20] and are at higher frequencies (958–1046 cm^{-1}) in all cases, as a consequence of coordination to the metal. This shift to higher frequencies is in accordance with the shortening of the S–N bond lengths, which have been observed in the crystal structures of complexes (see Table 1).

4. ^{1}H NMR and ^{13}C NMR spectra

Due to these compounds being insoluble in less polar solvents, ^{1}H and ^{13}C NMR spectra were obtained from a solution of the complex in d^6-DMSO. The chemical shifts are expressed in ppm relative to internal TMS. The NMR data is presented in Tables 2–4. The data shows that while the ligands are present in the complex, they only display very small shifts in comparison to the free ligands. The most notable feature is the sulfonamidic proton and correspondingly the relatively large shift of the carbon signal (C11) next to the amide. Whether or not the structure of the complex is retained in solution, or if it exists as solvated cation and ligand anion can not be determined from these spectra.

5. Crystal structure of the complexes 1, 2 and 3

Single crystals suitable for X-ray determination were obtained for the complexes by the slow evaporation of a DMF solution of the complex, in the presence of NH_3. The crystal data and refinement details for the complexes are listed in Table 5.

The crystal structures of the complexes [Hg(sdz)$_2$(DMF)$_2$] (**1**), [Hg(smr)$_2$] (**2**) and [Hg(smz)$_2$(DMF)$_2$] (**3**) are shown in Figs. 1,3, and 5, respectively together with the crystallographic atom numbering scheme used. The selected bond lengths and angles are collected together in Table 6.

The complexes [Hg(sdz)$_2$(DMF)$_2$] (**1**) and [Hg(smz)$_2$(DMF)$_2$] (**3**) have a '2+6' geometry with the Hg atom lying on the two-fold axis. Both molecules contain two short Hg–N(11) amide distances (2.047(3)–2.050(3) Å) as well

Table 1

as six other longer Hg–O/N interactions. These interactions derive from the additional co-ordination of one sulfoxide and one pyrimidine donor of each sulfa drug ligand, as well as two molecules of DMF co-ordinated to each metal. The three donor atoms from each sulfa ligand (N(11), N(13) and O(12)) and the Hg atom all lie within a plane. While at first it might appear that the six donors from the two sulfa ligands might define a distorted hexagonal planar array, the two planes defined by the ligands and the central mercury atom are slightly offset. The DMF molecules are coordinated to the Hg atom and may almost be considered as axial donors to the six equatorial donors of the sulfa ligands.

By contrast, the $[Hg(smr)_2]$ complex **2** has a '2+4' coordination geometry with two molecules of sulfamerazine coordinated with short Hg–N distances through the sulfonamidic nitrogen atoms. Due to the steric constraints of the ligand, the other donors (N(13) and O(12)) are in close

proximity to the sulfonamidic donor. The closeness of these donors leads to open spaces about the metal centre and an irregular co-ordination sphere. However, the open spaces about the metal centre are apparently not sufficiently large to fit two extra solvent molecule donors. While the comparative steric congestion of the metal centre, as compared to the sulfadiazine complex, might explain the lack of co-ordinated solvent molecules, there is no obvious reason why this molecule would be any more congested than the sulfamethazine complex (with an additional methyl substituent), whose crystal structure also has two co-ordinated solvent molecules. Ultimately, these crystal structures may be determined by crystal packing forces and the observed structures only offer suggestions of their structure in solution. In solution, the structure of **2** may be identical to that of **1** and **3**.

In complexes **1** and **3**, the long Hg–O(1) distances from the DMF donors (2.713(3) Å for **1** and 2.727(2) Å for **3** are slightly shorter than the corresponding bond Hg–O(1) in $[Hg(sdz)_2(DMSO)_2]$ (2.769(7) Å) [11]. The short Hg–N(11) bond distances of 2.047(3) Å for **1**, 2.017(4) Å for **2** and 2.050(3) Å for **3** are also comparable with those of $[Hg(smpz)_2]$ (2.071(4) Å) [13], $[Hg(sdz)_2(DMSO)_2]$ (2.087(4) Å) [11], $[Hg(mq)_2]$ (2.041(6) and 2.031(6) Å) [21] and $[Hg(bpy)_2(NO_2psgly\text{-}N,O)]0.5H_2O$ (2.14(2) Å) [22] (where smpz, sdzH, mq and NO_2psgly are sulfamethoxypiridazine, sulfadiazine, 4-methyl-2(1*H*)-quinoline and *N*-2-nitrophenylsulfonylglycine, respectively).

The C(18)–N(14) bond distances of 1.384(6) Å in **1**, 1.369(7) Å in **2** and 1.375(4) Å in **3** are in good agreement with the corresponding bond in the pure ligands [23]. It is also comparable with the corresponding bond found in the mercury–sulfadiazinato complex $[Hg(sdz)_2(DMSO)_2]$ [11] [1.383(14) Å]. Typically if the terminal amino group is co-ordinated, N–C bond lengths of about 1.413(9)Å are expected [13].

Interestingly, the geometry about the Hg atom in complexes **1** and **3** results in a mutually square planar arrangement of the sulfonamidic and solvent molecules donors. This arrangement is fairly regular showing only minor variations from ideal geometry of the mutually *cis* 90° and *trans* 180° angles. This is evident from the values of *trans* angles for N(11′)–Hg(1)–N(11) (179.4(2)°) and O(1′)–Hg(1)–O(1) (162.7(2)°) for **1** and 180.0° for **3**. The *cis* angles vary from 88.0(1) to 92.1(2)° in the complex **1** and 85.2(2)–94.8(2)° in the complex **3**. Complex **2** lies on a two-fold axis in which the sulfamerazinato ligands are bonded to the Hg-atom through the sulfonamidic nitrogen [N(11)] atom with a N(11)–Hg–N(11′) angle of 171.5(2)° indicating the 'linearity' of the complex.

When bonded to mercury the ligand acts as a tridentate donor, albeit with two very long and one short interaction. Never the less, the 'tridentate' coordination mode of this ligand is particularly rare. Typically, ligands such as pyridyl sulfonamides form complexes where the ligand is monodentate or bidentate. Typical examples are of bidentate co-ordination where the nitrogen of the heterocycle

and the sulfonamidic nitrogen co-ordinate [24,25] or bidentate co-ordination of nitrogen of the heterocycle and the oxygen of the sulfoxide group co-ordinate [24–26].

The packing of these complexes in the solid state is strongly influenced by the extensive hydrogen bonding between (i) the amino ($-NH_2$) group of one complex unit and the sulfonyl oxygen [N(14)–H(14A) ⋯ O(12) (of other complex unit): 2.346(2) Å with an angle of 157.75(3)°] and (ii) hydrogen bonding between the amino ($-NH_2$) group of one complex unit and the pyrimido nitrogen atoms of the next unit, [N(14)–H(14B) ⋯ N(13) (other complex unit) = 2.452(1) Å with an angle of 136.74(3)°]. The packing diagram of the complex $[Hg(sdz)_2(DMF)_2]$ (**1**) is shown in Fig. 2 and dimensions of the hydrogen bonding is listed in Table 7.

In the packing diagram of the complex **2** the amino group, sulfonyl oxygen and pyrimido nitrogen atoms are hydrogen bonded which is shown in Fig. 4 by dashed lines. Necessarily, the lack of DMF within the lattice leads to a different overall arrangement of hydrogen bonds, though the hydrogen bonding occurs between the same donors and acceptors See Fig. 5. However, on close inspection of the hydrogen binding network in **3**, (Fig. 6), it can be seen that now, the pyrimidine does not participate in hydrogen bonding and now both hydrogens of the amino group are hydrogen bonding to the sulfonyl oxygen of two different ligands. This change in hydrogen bonding is due, in some part, to the additional methyl group on the ligand which will sterically hinder the pyrimidine group.

O(80)–Ti(3)–O(90)	101.21(6)	102.23(1)	102.88(2)

The solid-state structure is comprised of three face sharing distorted Ti(IV) octahedra, with the trimetallic core forming an isosceles triangle with an average non-bonding Ti–Ti distance of 3.641 Å. Two of the metal centres, Ti(1) and Ti(3), are joined in a six-membered ring consisting of the two titanium centres and the two oximate N–O groups {N(1)–O(1) and N(2)–O(3)}. The coordination spheres of Ti(1) and Ti(3) are completed by the phenolic oxygen atoms of the salicylaldoxime ligands, two terminal isopropoxides and a bridging isopropoxide. The third titanium, Ti(2), sits above this six-membered ring and is linked to it by two bridging isopropoxides and two bridging oximate {O(1) and O(3)} oxygen atoms. In total the core, made up of the metal centres, consists of one six-membered ring, two five-membered rings and two Ti_2O_2 four-membered rings. The terminal isopropoxides have Ti–O bond lengths varying between 1.782(1) and 1.820(1) Å, consistent with literature precedent [10–14]. The interactions between the bridging isopropoxides and the two metal centres it bridges differ significantly in nature; for example O(70) binds to Ti(2) and Ti(3) with distances of 1.977(1) Å [Ti(2)–O(70)] and 2.106(1) Å [Ti(3)–O(70)] respectively. These bond lengths are, however, within the expected range for bridging isopropoxides [11,14–17]. The oximato N–O groups bond to all titanium centres, with the nitrogen atom bonding to one titanium and the oxygen atoms bridging the other two; for example N(2) is bonded to Ti(3) and its related oxygen O(3) bridges between Ti(1) and Ti(2). This

structure is the first characterised example of N–O triply bridging coordination known for a titanium oximate. However, it is observed for oximates of other metals for example Ag/Ni [18], Cu/La [19], Fe[20] and V [21]. The Ti–N bond lengths are 2.232(1) Å [Ti(1)–N(1)] and 2.236(1) Å [Ti(3)–N(2)] respectively, which are consistent with the literature [22,23]. The oximate oxygen atoms bridge two titanium centres and, as seen for the bridging alkoxides, these are asymmetric in nature. The bond lengths between the salicylaldoxime phenoxy groups and titanium are 1.891(1) Å [Ti(1)–O(2)] and 1.899(1) Å [Ti(3)–O(4)], which are typical of Ti–O bond lengths in non-bridging phenoxides [24–26], Ti(2) can be considered as part of a 'trapped' $Ti(O^iPr)_4$ molecule, dissociation of which would not lead to any gross structural changes in the remainder of the complex.

The ^1H NMR ($C_6D_5CD_3$) spectrum of $Ti_3(\mathbf{1})_2(O^iPr)_8$ consists of four isopropyl septets of equal intensity (4.63, 4.95, 5.02 and 5.14 ppm). From NOESY and COSY measurements it is possible to assign the resonances at 4.63 and 5.14 ppm to the two sets of terminal isopropoxides adorning Ti(1) and Ti(3) (the A and D sets of protons, Fig. 4). The resonances at 4.95 and 5.02 ppm correspond to either the terminal isopropoxides bound to Ti(2) or the bridging isopropoxide moieties (the B and C sets of protons). Variable temperature ^1H NMR spectroscopic studies (Fig. 4) have shown that dissociation is not observed when heated to 80 °C in deuterated toluene with the only visible dynamic process being exchange between the B and C sets of protons as the temperature is raised. Coalescence begins at 50 °C while at 80 °C the signal begins to sharpen. On cooling, the room temperature spectrum is again observed. ^{13}C NMR spectroscopy also confirms that the solid-state structure is maintained in solution, with four distinct peaks for the separate isopropoxide methine environments. Presumably, the resistance to dissociation is related to the fact that the presence of the $Ti(O^iPr)_4$ group allows the titanium centres to retain their preferred pseudo-octahedral coordination geometry.

Having established the synthetic protocol, attention turned to ligands $\mathbf{2}H_2$ and $\mathbf{3}H_2$ which reacted with $Ti(O^iPr)_4$ to form complexes $Ti_3(\mathbf{2})_2(O^iPr)_8$ and $Ti_3(\mathbf{3})_2(O^iPr)_8$ respectively. Structures were identified from X-ray diffraction and that for $Ti_3(\mathbf{3})_2(O^iPr)_8$ is given in Fig. 5.

Complexes $Ti_3(\mathbf{2})_2(O^iPr)_8$ and $Ti_3(\mathbf{3})_2(O^iPr)_8$ are structurally analogous to complex $Ti_3(\mathbf{1})_2(O^iPr)_8$, as exemplified by the bond lengths (Å) and angles (°) (see Table 1). A very subtle difference between $Ti_3(\mathbf{2})_2(O^iPr)_8$/$Ti_3(\mathbf{3})_2(O^iPr)_8$ and $Ti_3(\mathbf{1})_2(O^iPr)_8$ is that the phenolic-titanium bond is slightly longer for the complexes containing the electron

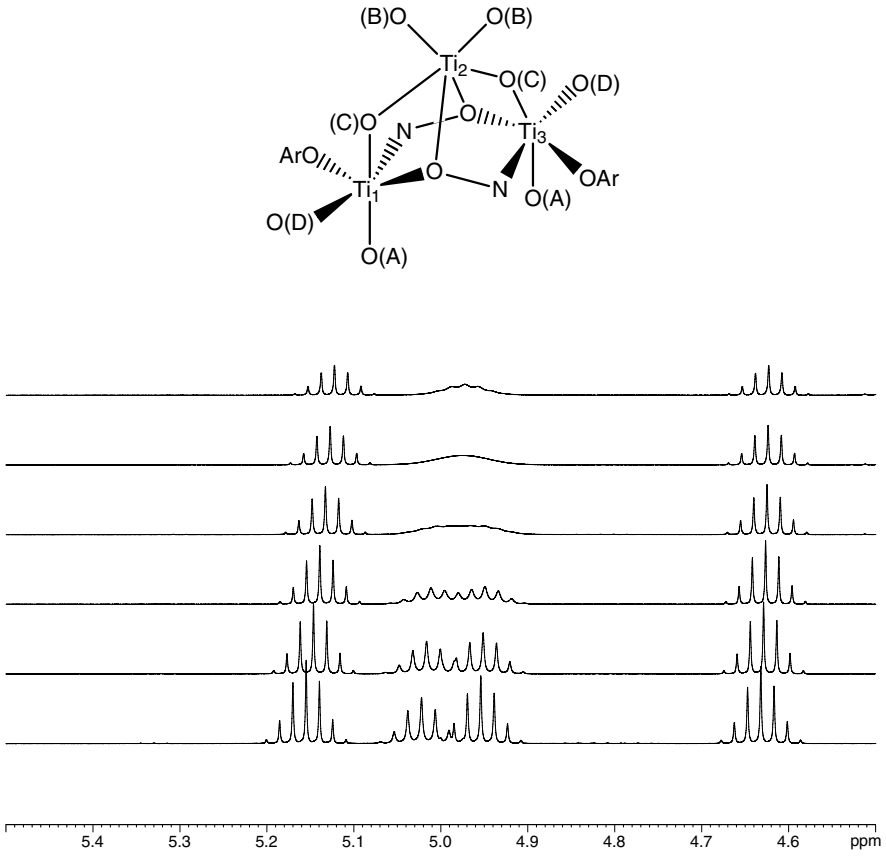

Fig. 4. Top: Representation of the structure of $Ti_3(\mathbf{1})_2(O^iPr)_8$ showing the isopropoxide groups under discussion in the text. Bottom: Variable temperature ^1H NMR spectroscopic studies of $Ti_3(\mathbf{1})_2(O^iPr)_8$, using $C_6D_5CD_3$ as the solvent. The bottom spectrum was acquired at 30 °C going up in 10 °C steps until 80 °C.

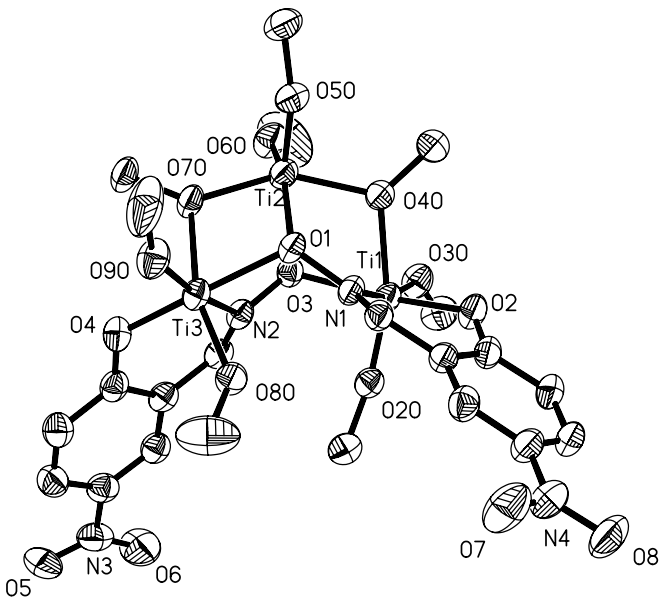

Fig. 5. Molecular structure of complex $Ti_3(\mathbf{3})_2(O^iPr)_8$. Ellipsoids are shown at the 50% probability level. Hydrogen atoms and the isopropoxide methyl groups have been omitted for clarity. The same numbering scheme was applied to complex $Ti_3(\mathbf{2})_2(O^iPr)_8$.

withdrawing groups. Variable temperature ^1H NMR spectroscopy for $Ti_3(\mathbf{3})_2(O^iPr)_8$ yielded similar spectra as shown for $Ti_3(\mathbf{1})_2(O^iPr)_8$ and are given as Supporting information.

As an extension of our studies we endeavoured to examine the reactivity of ligands in which the oxime group is the only potentially anionic group. Thus, 2 equiv. of ligand **4**H were reacted with 1 equiv. of $Ti(O^iPr)_4$. The crystal structure of complex $Ti_2(\mathbf{4})_4(O^iPr)_4$ is given in Fig. 6, pertinent bond lengths and angles are summarised in Table 2.

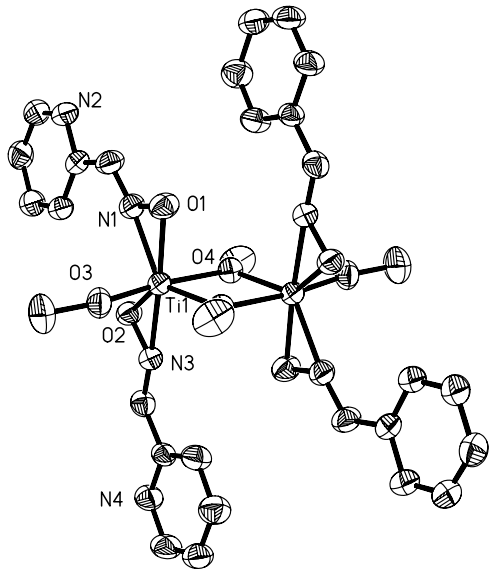

Fig. 6. Molecular structure of complex $Ti_2(\mathbf{4})_4(O^iPr)_4$. Ellipsoids are shown at the 50% probability level, the hydrogen atoms and the isopropoxide methyl groups have been omitted for clarity.

O(2)–Ti(1)–O(3)	93.45(9)
N(1)–Ti(1)–N(3)	131.37(9)
N(1)–Ti(1)–O(2)	92.97(9)
O(3)–Ti(1)–O(1)	94.79(9)
O(3)–Ti(1)–O(4)	173.77(9)

The complex consists of two titanium centres, which are bridged by two isopropoxide ligands. In addition each of the metal centres is ligated by two oximate groups and a terminal isopropoxide ligand completes the coordination sphere of each titanium centre. The oximes are non-bridging and bond to titanium through their oxygen and nitrogen atoms, the pyridyl nitrogen takes no part in bonding. For titanium this bonding mode has only been observed by Thewalt et al. [9]. However, this mode has been observed for other metal oximate complexes; for example Cu [27], Mo [28], Os[29] and Ru [30]. As expected the Ti–oximate bond lengths are shorter than those observed in complexes $Ti_3(\mathbf{1})_2(O^iPr)_8$, $Ti_3(\mathbf{2})_2(O^iPr)_8$ and $Ti_3(\mathbf{3})_2(O^iPr)_8$ due to the non-bridging nature of the oximato group. The ^1H NMR spectrum at 298 K of $Ti_2(\mathbf{4})_4(O\ ^iPr)_4$ only contains one isopropoxide resonance indicating exchange on the NMR time-scale. Upon cooling to 243 K two separate isopropoxide resonances are observed, in agreement with the solid-state structure.

3. Conclusions

In conclusion four new crystal structures of titanium oximes have been determined, which are the first salicylaldoximate complexes of titanium to be crystallographically characterised. These cluster complexes with multiple titanium centres have been shown to be stable at elevated temperatures. In addition these complexes exhibit a triply bridging mode for the oximate ligand, which has not been previously reported for titanium.

4. Experimental

4.1. General

For the preparation and characterisation of complexes, all reactions and manipulations were performed under an inert atmosphere of argon using standard Schlenk or glove-box techniques and all solvents were freshly distilled

over suitable drying agents and degassed prior to use. All ligands were purchased from Aldrich or synthesised using standard literature procedures and recrystallised in petroleum ether prior to use [31]. Ti(O^{i}Pr)$_4$ was purchased from Aldrich and purified by vacuum distillation prior to use. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker Avance 400 or 300 MHz spectrometer, referenced to residual solvent peaks, variable temperature NMR studies were performed in deuterated toluene. Coupling constants are given in Hertz. Elemental analysis was performed by Mr. A.K. Carver at the Department of Chemistry, University of Bath. Crystallographic data were collected on a Nonius KappaCCD area detector diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å), and all structures were solved by direct methods and refined on all F^2 data using the SHELXL-97 suite of programs [32]. Hydrogen atoms were uniformly included at idealised positions and refined using the riding model. Absorption corrections were applied on merit. See Table 3 for full crystallographic parameters. Complexes Ti$_3$(**1**)$_2$(O^{i}Pr)$_8$ and Ti$_3$(**2**)$_2$(O^{i}Pr)$_8$ have disordered isopropoxide moieties, the carbon atoms of which were modelled over two sites in a 1:1 ratio. The yields quoted are for the first crop of crystals and due to their high solubility in common organic solvents the yields are relatively low. These could be improved by concentrating the filtrate to obtain more material.

4.2. Preparation of *Ti$_3$(**1**)$_2$(O^{i}Pr)$_8$*

A solution of salicylaldoxime (1.37 g, 10 mmol) was prepared in dry toluene (10 ml) under an inert atmosphere. To this Ti(O^{i}Pr)$_4$ (4.5 ml, 15 mmol) was added to give an orange solution. This solution was vigorously stirred for one hour and heated to reflux. The solvent was removed *in vacuo* to give an orange solid product. This product was suspended in hexane and toluene added until dissolution occurred on warming. Standing at room temperature yielded a crop of orange blocks. Yield = 2.12 g (46%), melting point = 147–150 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C) 0.71 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 0.81 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 1.15 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.21 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.23 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.23 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.21 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 1.34 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 4.39 (sept, $J = 6$ Hz, 2H, CH (A or D)), 4.73 (sept, $J = 6$ Hz, 2H, CH (B or C)), 4.80 (sept, $J = 6$ Hz, 2H, CH (B or C)), 4.93 (sept, $J = 6$ Hz, 2H, CH (A or D)), 6.68 (m, 4H, Ar–H), 7.09 (m, 2H, Ar–H), 7.18 (m, 2H, Ar–H), 7.96 (s, 2H, imine CH). ^{13}C{^{1}H} NMR, $CDCl_3$: 24.6, 24.9, 25.7, 25.7, 26.0, 26.0, 26.6, 26.7 (CH_3), 75.6, 77.6, 78.7, 79.1 ($CH(CH_3)_2$), 114.3, 118.3, 120.7, 130.8, 132.1 (Ar), 151.2 (NCH), 162.6 (Ar–O). Elemental *Anal.* Calc. for $C_{38}H_{66}N_2O_{12}Ti_3$: C, 51.5; H, 7.50; N, 3.16. Found: C, 50.6; H, 7.27; N, 2.91%.

4.3. Preparation of *Ti$_3$(**2**)$_2$(O^{i}Pr)$_8$*

An analogous procedure to that of Ti$_3$(**1**)$_2$(O^{i}Pr)$_8$ was followed. Ti(O^{i}Pr)$_4$ (0.9 ml, 3 mmol), **2**H$_2$ (0.41 g, 2 mmol). Yield = 0.84 g (84%), melting point = 136–139 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C) 0.73 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 0.84 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 1.10 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.20 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.23 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.24 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.31 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 1.35 (d ,$J = 6$ Hz, 6H, CH_3 (A or D)), 4.39 (sept, $J = 6$ Hz, 2H, CH (A or D)), 4.66–4.83 (2 overlaying septets, 4H, CH (B or C)), 4.94 (sept, $J = 6$ Hz, 2H, CH (A or D)), 6.97 (d, $J = 2.5$ Hz,

4.4. Preparation of $Ti_3(\mathbf{3})_2(O^iPr)_8$

An analogous procedure to that of $Ti_3(\mathbf{1})_2(O^iPr)_8$ was followed. $Ti(O^iPr)_4$ (0.9 ml, 3 mmol), $\mathbf{3}H_2$ (0.41 g, 2 mmol). Yield = 0.63 g (65%), melting point = 211–214 °C (dec.). ^1H NMR (400 MHz, $CDCl_3$, 25 °C) 0.71 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 0.87 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 1.11 (d, $J = 6$ Hz, 6H, CH_3 (B or C)), 1.21–1.26 (m, 18H, CH_3 (B or C)), 1.32 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 1.36 (d, $J = 6$ Hz, 6H, CH_3 (A or D)), 4.42 (sept, $J = 6$ Hz, 2H, CH (A or D)), 4.70 (sept, $J = 6$ Hz, 2H, CH (B or C)), 4.77 (sept, $J = 6$ Hz, 2H, CH (B or C)), 4.95 (sept, $J = 6$ Hz, 2H, CH (A or D)), 6.74 (d, $J = 10$ Hz, 2H, Ar–H), 8.00 (s, 2H, imine CH), 8.05–8.10 (m, 4H, Ar–H). $^{13}C\{^1H\}$ NMR $CDCl_3$: 24.5, 24.9, 25.6, 25.7, 25.8, 25.9, 26.6, 26.7 (CH_3), 76.1, 80.0, 80.3, 80.6 ($CH(CH_3)_2$), 119.7, 120.0, 127.7, 128.3, 139.1 (Ar), 150.6 (NCH), 168.5 (Ar–O). Elemental *Anal.* Calc. for $C_{38}H_{64}N_4O_{16}Ti_3$: C, 46.7; H, 6.61; N, 5.74. Found: C, 47.2; H, 6.54; N, 5.66%.

4.5. Preparation of $Ti_2(\mathbf{4})_4(O^iPr)_4$

A solution of *syn*-pyridine-2-aldoxime (1.22 g, 10 mmol) was prepared in dry acetonitrile (10 ml) under an inert atmosphere. To this $Ti(O^iPr)_4$ (1.5 ml, 5 mmol) was added to give a bright orange suspension. This suspension was vigorously stirred at reflux for one hour to give a yellow solution. On cooling this solution yielded a crop of colourless blocks. Yield = 0.90 g (44%), melting point = 132–135 °C. ^1H NMR (400 MHz, $CDCl_3$, 25 °C) 1.17 (br, 24H, CH_3), 4.52 (br, 4H, CH), 7.19–7.32 (m, 4H, Ar–H), 7.63–7.83 (m, 8H, Ar–H), 8.30–8.53 (m, 8H, Ar–H and NCH). $^{13}C\{^1H\}$ NMR $CDCl_3$: 25.9 (CH_3), 77.6 ($CH(CH_3)_2$), 121.4, 122.1, 124.2, 136.9, (Ar), 149.8 (NCH). Elemental *Anal.* Calc. for $C_{36}H_{48}N_8O_8Ti_2$: C, 53.0; H, 5.93; N, 13.72. Found: C, 52.2; H, 5.90; N, 13.60%.

2. Experimental

2.1. General procedures

All reactions and manipulations were carried out using standard Schlenk techniques under an atmosphere of pure nitrogen. Solvents were purified, dried and distilled under a nitrogen atmosphere prior to use. Reactions were monitored by TLC. Chromatographic separations and purification were performed on 200-300 mesh silica gel column. The $Co_2(CO)_8$ was purchased from Aldrich. Published procedures or extensions thereof were used to synthesize initial intermediates $FcC(CH_3)_2Fc'$–C≡CH and FcC≡CH [22–24].

IR spectra were recorded on a Nicolet FT-IR spectrometer, KBr disk. Elemental analyses were carried out on a Elementar var III-type analyzer. ^1H and ^{13}C NMR spectra in $CDCl_3$ were recorded on Inova-500 MHz spectrometer. The mass spectra were determined by using Polaris Q MS, Autospec Ultima-TOF and JMS-T100LC instruments. Melting points were determined by using XT-4 melting point apparatus.

2.2. Synthesis of ligand $FcC(CH_3)_2Fc'$–C≡C–C≡C–Ph ($\mathbf{L}_1$)

$FcC(CH_3)_2Fc'$–C≡CH (80 mg, 0.17 mmol), Ph–C≡CH (40 mg, 0.40 mmol) and CuCl (9 mg, 0.09 mmol) were dissolved in 8 ml pyridine. The mixture solution was stirred for 3 h in air at 60 °C. The solvent was removed under reduced pressure. The resulting mixture was washed with saturated NH_4Cl solution and extracted with CH_2Cl_2. The organic phase was incorporated and then dried using the dehydrated $MgSO_4$ and filtrated. The filtrate was concentrated and the residue was subjected to chromatographic separation on the neutral alumina column (2.0 × 30 cm). Elution with a mixture of hexane–benzene (2:1, v/v) afforded a yellow band. The yellow crystal of ligand $\mathbf{L}_1$ was obtained by recrystallizing from hexane–benzene. Yield: 61% (56 mg, 0.10 mmol). m.p. 158–161 °C. *Anal.* Calc. for $C_{33}H_{28}Fe_2$: C, 73.91; H, 5.26. Found: C, 73.67; H, 5.14%. IR (KBr disk) 3089 [Cp, ν_{C-H}]; 2976, 2930, 2863 [$C(CH_3)_2$, ν_{C-H}]; 2208, 2141 [C≡C, $\nu_{C\equiv C}$]; 1588, 1491, 1440 [C_6H_5, $\nu_{C=C}$]; 1105, 999 [Cp, γ_{C-H}]; 818 [Cp, δ_{C-H}]; 755, 688 [C_6H_5, γ_{C-H}] cm^{-1}. ^1H NMR ($CDCl_3$, δ): 7.3–7.5 (m, 5H, C_6H_5), 4.0–4.4 (m, 17H, Cp), 1.5 [s, 6H, $C(CH_3)_2$]. ^{13}C NMR ($CDCl_3$, δ): 132.3, 128.8, 128.4, 122.2 (C_6H_5); 118.6, 102.8, 70.7, 70.2, 68.3, 67.3 (Cp); 82.5, 78.7, 74.8, 71.0 (–C≡C–C≡C–); 33.2, 30.2 [$C(CH_3)_2$]. MS (EI): 536 (M^+).

2.3. Synthesis of ligand Fc–C≡C–C≡C–Ph ($\mathbf{L}_2$)

Fc–C≡CH (100 mg, 0.50 mmol), Ph–C≡CH (50 mg, 1.00 mmol) and CuCl (12 mg, 0.12 mmol) were dissolved in 20 ml pyridine. The mixture solution was stirred for 3 h in air at 60 °C. The solvent was removed under reduced pressure. The resulting mixture was washed with saturated NH_4Cl solution and extracted with CH_2Cl_2.The organic phase was incorporated and then dried using the dehydrated $MgSO_4$ and filtrated. The filtrate was concentrated and the residue was subjected to chromatographic separation on the neutral alumina column (2.0 × 30 cm). Elution with a mixture of hexane–benzene (3:1, v/v) afforded a yellow band. The yellow crystal of ligand $\mathbf{L}_2$ was obtained by recrystallizing from hexane. Yield: 47% (73 mg, 0.24 mmol). m.p. 114–115 °C. *Anal.* Calc. for $C_{20}H_{14}Fe$: C, 77.45; H, 4.55. Found: C, 77.60; H, 4.70%. IR (KBr disk) 3083 [Cp, ν_{C-H}]; 2218, 2145 [C≡C, $\nu_{C\equiv C}$]; 1593, 1490, 1441 [C_6H_5, $\nu_{C=C}$]; 1104, 1001 [Cp, γ_{C-H}]; 817 [Cp, δ_{C-H}]; 755, 688 [C_6H_5, γ_{C-H}] cm^{-1}. ^1H NMR ($CDCl_3$, δ): 7.3–7.5 (m, 5H, C_6H_5), 4.3, 4.6 (2s, 9H, Cp). ^{13}C NMR ($CDCl_3$, δ): 132.3, 128.8, 128.4, 122.2 (C_6H_5); 82.1, 78.9, 74.7, 72.3 (–C≡C–C≡C–); 70.3, 70.1, 69.6, 63.2 (Cp). MS (EI): 310 (M^+).

2.4. Synthesis of complex $[FcC(CH_3)_2Fc'$–C≡C–C≡C–Ph$][Co_2(CO)_6]$ (**1**)

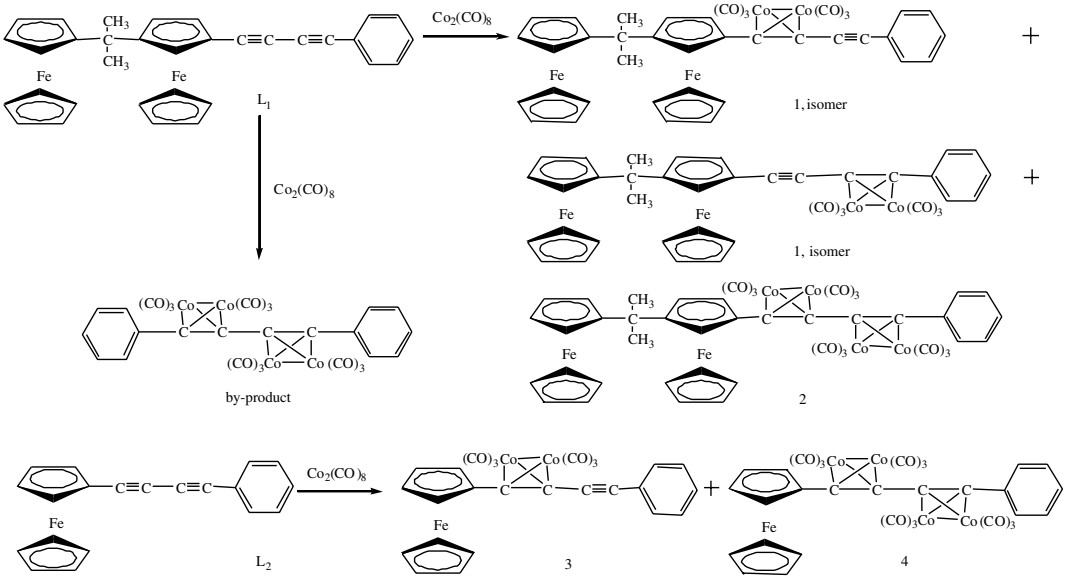
A benzene solution of $Co_2(CO)_8$ (45 mg, 0.13 mmol) and ligand $\mathbf{L}_1$ (70 mg, 0.13 mmol) was stirred for 12 h at room temperature. The solvent of the resulting mixture was removed in vacuum. The residue was dissolved in a minimal amount of benzene and subjected to chromatographic separation on a silica gel column (2.0 × 40 cm). Elution with hexane–benzene (5:1,v/v) afforded four bands, respectively. The first band is red by-product [Ph–C≡C–C≡C–Ph][$Co_2(CO)_6$]$_2$ (14 mg); the second band is the brown-green complex **2** (15 mg); the third and fourth bands are coordinated isomers [$FcC(CH_3)_2Fc'$–C≡C–C_2–Ph]-[$Co_2(CO)_6$] [brown-green oil, Yield: 28% (30 mg, 0.04 mmol); *Anal.* Calc. for $C_{39}H_{28}O_6Co_2Fe_2$: C, 56.97; H, 3.43. Found: C, 57.69; H, 3.74%. IR (KBr disk) ν (CO) 2089s, 2056vs, 2025vs cm^{-1}; $\nu_{C\equiv C}$ 2172w cm^{-1}]. and [$FcC(CH_3)_2Fc'$–C_2–C≡C–Ph][$Co_2(CO)_6$] [brown-green solid, m.p. 124 °C (dec.), Yield: 19% (20 mg, 0.03 mmol). *Anal.* Calc. for $C_{39}H_{28}O_6Co_2Fe_2$: C, 56.97; H, 3.43. Found: C, 57.46; H, 3.75%. IR (KBr disk) ν (CO) 2090s, 2054 vs, 2026vs cm^{-1}; $\nu_{C\equiv C}$ 2172w cm^{-1}]. The isomer [$FcC(CH_3)_2Fc'$–C_2–C≡C–Ph][$Co_2(CO)_6$] of complex **1**: ^1H NMR ($CDCl_3$, δ): 7.3–7.7 (m, 5H, C_6H_5), 3.9–4.5 (m, 17H, Cp), 1.5 [s, 6H, $C(CH_3)_2$]. ^{13}C NMR ($CDCl_3$, δ): 198.7 (CO); 129.2, 128.9, 113.6 (C_6H_5); 100.8, 91.1 (–C≡C–C≡C–); 65.8-72.3 (Cp); 30.3 [$C(CH_3)_2$]. MS (FAB): 822 (M^+).

2.5. Synthesis of complex $[FcC(CH_3)_2Fc'$–C≡C–C≡C–Ph$][Co_2(CO)_6]_2$ (**2**)

A benzene solution of $Co_2(CO)_8$ (77 mg, 0.22 mmol) and ligand $\mathbf{L}_1$ (60 mg, 0.11 mmol) was stirred for 12 h at room temperature. The solvent of the resulting mixture

was removed in vacuum. The residue was dissolved in a minimal amount of benzene and subjected to chromatographic separation on a silica gel column (2.0 × 40 cm). Elution with hexane–benzene (5:1,v/v) afforded a brown-green band (**2**). The crystal of **2** was obtained by recrystallizing from hexane at −20 °C. Yield: 24% (29 mg, 0.03 mmol) m.p. 105 °C (dec.). *Anal.* Calc. for $C_{45}H_{28}O_{12}Co_4Fe_2$: C, 48.78; H, 2.55. Found: C, 48.31; H, 2.64%. IR (KBr disk) *v*(CO) 2097s, 2077vs, 2054s, 2036vs, 2019vs cm^{-1}. ^1H NMR ($CDCl_3$, δ): 7.3–7.5 (m, 5H, C_6H_5), 4.0–4.3 (m, 17H, Cp), 1.6 [s, 6H, $C(CH_3)_2$]. ^{13}C NMR ($CDCl_3$, δ): 198.8 (CO); 129.3, 128.7, 127.8 (C_6H_5); 65.8–72.3 (Cp); 30.5, 29.5 [$C(CH_3)_2$]. MS (FAB): 1108 (M^+).

2.6. Synthesis of complex [Fc–C≡C–C≡C–Ph]-[$Co_2(CO)_6$] (3)



A benzene solution of $Co_2(CO)_8$ (55 mg, 0.16 mmol) and ligand $\mathbf{L}_2$ (50 mg, 0.16 mmol) was stirred for 3 h at room temperature. The solvent of the resulting mixture was removed in vacuum. The residue was dissolved in a minimal amount of benzene and subjected to chromatographic separation on a silica gel column (2.0 × 40 cm). Elution with hexane–benzene (15:1, v/v) afforded a brown-green band (**3**). The complex **3**: Yield: 22% (21 mg, 0.04 mmol). m.p. 83–85 °C. *Anal.* Calc. for $C_{26}H_{14}O_6Co_2Fe$: C, 52.39; H, 2.37. Found: C, 52.46; H, 2.44%. IR (KBr disk) *v* (CO) 2094s, 2058vs, 2038vs, 2011vs cm^{-1}. ^1H NMR ($CDCl_3$, δ): 7.3–7.6 (m, 5H, C_6H_5), 4.3–4.5 (m, 9H, Cp). ^{13}C NMR ($CDCl_3$, δ): 198.7 (CO), 131.4, 128.5 (C_6H_5), 70.1, 69.8, 69.3 (Cp). MS (CSI): 596 (M^+).

2.7. Synthesis of complex [Fc–C≡C–C≡C–Ph]-[$Co_2(CO)_6$]$_2$ (4)

A benzene solution of $Co_2(CO)_8$ (220 mg, 0.64 mmol) and ligand $\mathbf{L}_2$ (100 mg, 0.32 mmol) was stirred for 21 h at room temperature. The solvent of the resulting mixture was removed in vacuum. The residue was dissolved in a minimal amount of benzene and subjected to chromatographic separation on a silica gel column (2.0 × 40 cm). Elution with hexane–benzene (10:1, v/v) afforded a brown-green band (**4**). The crystal of **4** was obtained by recrystallizing from hexane at −20 °C. The complex **4**: Yield: 78% (220 mg, 0.25 mmol). m.p. 135–138 °C. *Anal.* Calc. for $C_{32}H_{14}O_{12}Co_4Fe$: C, 43.58; H, 1.60. Found: C, 43.91; H, 1.68%. IR (KBr disk) *v* (CO) 2075s, 2053vs, 2023vs, 2010s, 2002s cm^{-1}. ^1H NMR ($CDCl_3$, δ): 7.3–7.5 (m, 5H, C_6H_5), 4.3–4.5 (m, 9H, Cp).^{13}C NMR ($CDCl_3$, δ): 199.1 (CO), 138.4, 129.3, 128.6, 128.3 (C_6H_5), 88.3 (–C≡C–C≡C–), 71.1, 69.6, 68.7 (Cp). MS (FAB): 882 (M^+).

2.8. X-ray crystallography of compounds L_1, L_2, 2 and 4

The crystals of $\mathbf{L}_1$, $\mathbf{L}_2$, **2** and **4** were mounted on a glass fiber, respectively. All measurements were made on the Bruker SMART APEX CCD diffractometers with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. All data were collected at 20 °C using the φ and ω scan techniques. All structures were solved by direct methods and expanded using Fourier technique [25]. An absorption correction based on the SADABS was applied [26]. All non-hydrogen atoms were refined by the full matrix least-squares on F^2. Hydrogen atoms were located and refined by geometry method. The cell refinement, data collection and reduction were done by Bruker SMART and SAINT [27].

The structure solution and refinement were performed by SHELXSL97 [28].

3. Results and discussion

3.1. Synthesis and characterization of compounds L_1, L_2, 1, 2, 3 and 4

The reactions carried out in this work are summarized in Scheme 1. A new ligand $FcC(CH_3)_2Fc'$–C≡C–C≡C–Ph ($\mathbf{L_1}$) was synthesized by the cross coupling reaction of $FcC(CH_3)_2Fc'$–C≡CH and Ph–C≡CH in the presence of catalyst CuCl, and ligand Fc–C≡C–C≡C–Ph ($\mathbf{L_2}$) was obtained by the similar route. Complexes $[FcC(CH_3)_2Fc'–C≡C–C≡C–Ph][Co_2(CO)_6]$ (**1**) and $[Fc–C≡C–C≡C–Ph][Co_2(CO)_6]$ (**3**) were achieved by the reactions of $\mathbf{L_1}$ and $\mathbf{L_2}$ with equal $Co_2(CO)_8$ under mild condition, respectively, and complexes $[FcC(CH_3)_2Fc'–C≡C–C≡C–Ph][Co_2(CO)_6]_2$ (**2**) and $[Fc–C≡C–C≡C–Ph]$- $[Co_2(CO)_6]_2$ (**4**) were provided by the reactions of $\mathbf{L_1}$ and $\mathbf{L_2}$ with excess $Co_2(CO)_8$, respectively. By-product $[Ph–C≡C–C≡C–Ph][Co_2(CO)_6]_2$ is probably produced by the self-coupling of the fragment –C≡C–Ph of ligand $FcC(CH_3)_2Fc'$–C≡C–C≡C–Ph and the reaction with $Co_2(CO)_8$. The coordinated isomers of complex **1**, $[FcC(CH_3)_2Fc'–C≡C–C_2–Ph][Co_2(CO)_6]$ and $[FcC(CH_3)_2Fc'–C_2–C≡C–Ph][Co_2(CO)_6]$ have successfully been separated by the column chromatography technique.

Ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ are yellow and air-stable crystal compound which is soluble in both non-polar solvents such as hexane, petroleum ether, benzene and polar solvents such as diethylether and chloroform. Complexes **2** and **4** are brown-green and air-stable crystal compound which their solubility is similar to ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ and complexes **1** and **3** are also brown-green but air-sensitive. By-product $[Ph–C≡C–C≡C–Ph][Co_2(CO)_6]_2$ is red air-stable crystal compound and the coordinated isomers $[FcC(CH_3)_2Fc'–C≡C–C_2–Ph][Co_2(CO)_6]$ and $[FcC(CH_3)_2Fc'–C_2–C≡C–Ph][Co_2(CO)_6]$ are oil compound, which their solubility is also similar to ligand $\mathbf{L_1}$.

The FTIR spectra in the region 2097–2002 cm^{-1} confirm that there is the coordinated $Co_2(CO)_6$ species and ^1H and ^{13}C NMR reflect that there are Fc, Ph, C≡C, $C(CH_3)_2$ and CO groups in complexes **1**, **2**, **3** and **4**. The structure and composing of compounds $\mathbf{L_1}$, $\mathbf{L_2}$, **1**, **2**, **3** and **4** are further proved by the data of their elemental analysis and MS. The molecular structures of compounds $\mathbf{L_1}$, $\mathbf{L_2}$, **2** and **4** were determined by X-ray crystallography.

3.2. Molecular structures of compounds L_1, L_2, 2 and 4

The molecular structures of compounds $\mathbf{L_1}$, $\mathbf{L_2}$, **2** and **4** were determined by X-ray single crystal analysis. Crystal data and relevant structural parameters are enumerated in Table 1.The structures with the atom numbering scheme are shown in Figs. 1–4, respectively, and the selected bond lengths and angles for $\mathbf{L_1}$, $\mathbf{L_2}$, **2** and **4** are listed in Table 2.

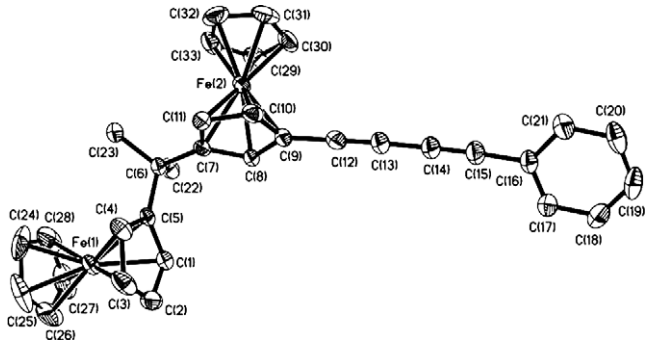

Fig. 1. Molecular structure of ligand L_1.

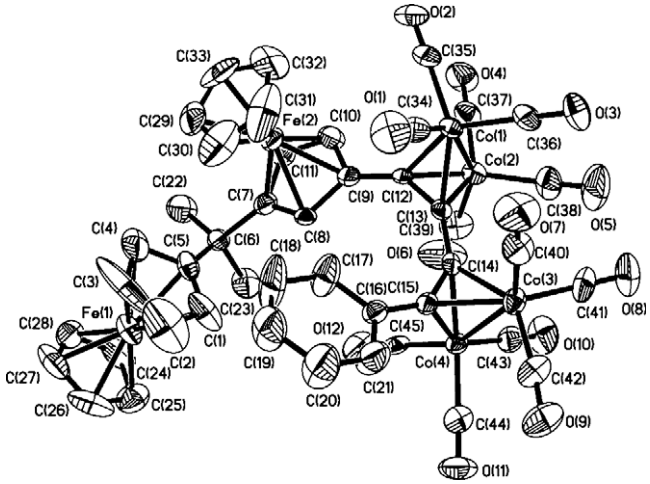

Fig. 2. Molecular structure of complex **2**.

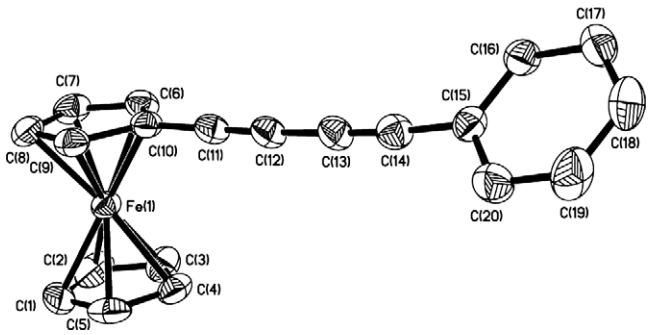

Fig. 3. Molecular structure of ligand L_2.

The molecule of ligand $\mathbf{L_1}$ contains a butadiynyl chain, of which terminals are phenyl and bisferrocenylpropane groups, respectively (see Fig. 1). The bond distances C(12)–C(13) (1.193 Å) and C(14)–C(15) (1.200 Å) show there are carbon–carbon triple bonds in $\mathbf{L_1}$. The shorter C(9)–C(12) (1.436 Å), C(13)–C(14) (1.370 Å) and C(15)–C(16) (1.432 Å) bond distances are the results of electron delocalization of the C_4 diyne chain, phenyl unit and cyclopentadiene ring. The data of the bond angles [C(9)–C(12)–C(13), 174.6°; C(12)–C(13)–C(14), 177.6°; C(13)–C(14)–C(15), 178.0°; C(14)–C(15)–C(16), 177.0°] demonstrate

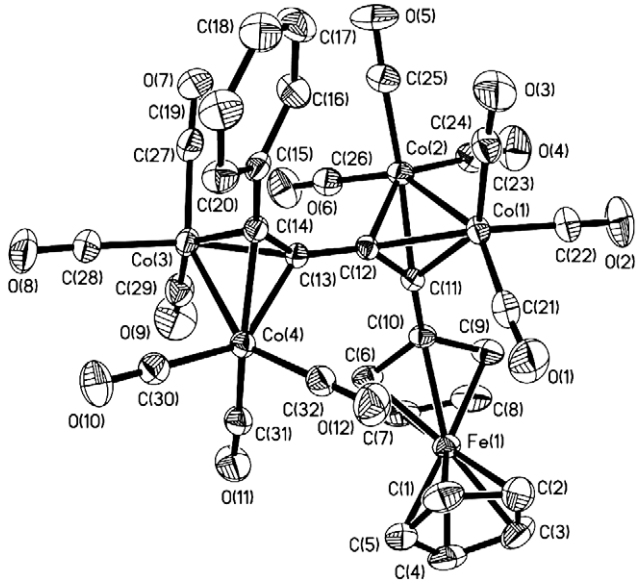

Fig. 4. Molecular structure of complex **4**.

the carbon chain C(9) C(12) C(13) C(14) C(15) C(16) is nearly linear structure. The bond angle C(22)–C(6)–C(23) (108.5°) is close to 109° and other bond angles [C(5)–C(6)–C(7), 105.3°; C(5)–C(6)–C(22), 110.8°; C(5)–C(6)–C(23), 111.0°; C(7)–C(6)–C(22), 111.4°; C(7)–C(6)–C(23), 110.0°] clearly deviate from 109° around the sp^3-hybridized C(6) in $\mathbf{L}_1$ because of the influence of large bulk of ferrocenyl moieties.

In complex **2** the bond angle data [C(9)–C(12)–C(13), 143.4°; C(12)–C(13)–C(14), 145.8°; C(13)–C(14)–C(15), 142.9°; C(14)–C(15)–C(16), 141.4°] and the torsion angle [C(12)–C(13)–C(14)–C(15), −39°] demonstrate the construction of $\mathbf{L}_1$ is altered from the linear to nonlinear structure while $\mathbf{L}_1$ was coordinated to $Co_2(CO)_6$ units. It is noteworthy that $Co_2(CO)_6$ units are coordinated to the alkyne bond in a *cis* configuration and two terminal groups (phenyl and bisferrocenylpropane) are also in a *cis* position (see Fig. 2). Because of a large substituted group bisferrocenylpropane, the molecular structure of **2** is quite different from **4**.

In $\mathbf{L}_1$ the distance of Fe atom to the plane of cyclopentadiene ring [Fe_1 to plane (1) C(1)C(2)C(3)C(4)C(5), 1.65 Å; Fe_1 to plane (2) C(24)C(25)C(26)C(27)C(28), 1.65 Å; Fe_2 to plane (3) C(7)C(8)C(9)C(10)C(11), 1.64 Å; Fe_2 to plane (4) C(29)C(30)C(31)C(32)C(33), 1.66 Å] is nearly equal. The dihedral angles between plane (1) C(1)C(2)C(3)C(4)C(5) and plane (2) C(24)C(25)C(26)C(27)C(28) (3.59°) and between plane (3) C(7)C(8)C(9)C(10)C(11) and plane (4) C(29)C(30)C(31)C(32)C(33) (3.57°) in $\mathbf{L}_1$ reveal that two Cp planes in Fc or Fc′ deviate from parallel because of different substituted Cp ring and steric interaction. It is interesting to note that the dihedral angle between plane (2) and plane (3) is nearly perpendicular(88.98°) as a result of the steric influence. In **2** the distance of Fe atom to the plane

of cyclopentadiene ring [Fe(1) to plane(1), 3.32 Å; Fe(1) to plane (2), 6.86 Å; Fe (2) to plane (3), 0.65Å; Fe (2) to plane (4), 2.57Å] is quite different from $\mathbf{L}_1$ because of the coordination effect of Co_2 core with diyne. The dihedral angles between plane (1) and plane (2) (5.27°) and between plane (3) and plane (4) (2.12°) demonstrate that two Cp planes in **2** also deviate from parallel like $\mathbf{L}_1$ but the dihedral angle between plane (2) and plane (3) alters from 88.98° to 67.11° as a result of the diyne coordinated to Co_2 core.

The molecule of ligand $\mathbf{L}_2$ also contains a butadiynyl chain but its terminals are phenyl and ferrocenyl group, respectively (see Fig. 3). The relevant bond distances in $\mathbf{L}_2$ are similar to $\mathbf{L}_1$, which also reveal the electron delocalization among C_4 diyne chain, phenyl and cyclopentadiene ring. The data of bond angles (see Table 2) demonstrate the carbon chain C(10) C(11) C(12) C(13) C(14) C(15) of $\mathbf{L}_2$ is nearly linear structure.

The –C≡C–C≡C– acetylenic linkage in complex **4** is nonlinear, which is proved by the bond angles [C(10)–C(11)–C(12), 147.4°; C(11)–C(12)–C(13), 145.8°; C(12)–C(13)–C(14), 143.5°; C(13)–C(14)–C(15), 141.9°] and the torsion angle [C(11)–C(12)–C(13)–C(14), 159.3°], contrasting sharply with the linear –C≡C–C≡C– carbon chain of $\mathbf{L}_2$. In **4** the two C_2Co_2 units are coordinated to the C_4 diyne chain in a *trans* configuration. The outer C atoms of the diyne chain, C(11) and C(14), carry ferrocenyl and phenyl substituents also orientated *trans* to each other (see Fig. 4). The molecular structure of $\mathbf{L}_2$ and **4** are similar to compounds Fc–C≡C–C≡C–Fc and Fc–C≡C–C≡C–Fc $[Co_2(CO)_6]_2$, respectively [11,29,30].

In $\mathbf{L}_2$ the distance of Fe atom to the plane of cyclopentadiene ring [Fe to plane (1) C(1)C(2)C(3)C(4)C(5), 1.65 Å; Fe to plane (2) C(6)C(7)C(8)C(9)C(10), 1.64 Å] is similar to that in$\mathbf{L}_1$. The dihedral angle (0.26°) between plane (1) and plane (2) shows that two Cp planes are nearly parallel. The dihedral angle between plane (2) and the plane of phenyl ring is 40.98°. Although the distance of Fe atom to the plane of cyclopentadiene ring in **4** is similar to that in $\mathbf{L}_2$, the dihedral angle of **4** is quite different from that of $\mathbf{L}_2$. In **4** the dihedral angle between plane (1) and plane (2) (4.94°) shows that two Cp planes in Fc′ deviate from parallel and the dihedral angle between plane (2) and the plane of phenyl ring (53.02°) become larger because of the steric influences as a result of the diyne coordinated to Co_2 core.

4. Conclusion

Two butadiynyl ligands $FcC(CH_3)_2Fc'$–C≡C–C≡C–Ph ($\mathbf{L}_1$) and Fc–C≡C–C≡C–Ph ($\mathbf{L}_2$) have been synthesized by the cross coupling reaction of terminal alkynes and four corresponding complexes $[FcC(CH_3)_2Fc'–C≡C–C≡C–Ph][Co_2(CO)_6]_n$ [(**1**): $n = 1$; (**2**): $n = 2$] and [Fc–C≡C–C≡C–Ph][$Co_2(CO)_6$]$_n$ [(**3**): $n = 4$ 1; (**4**): $n = 2$] have successfully been obtained by the reaction of ligands $\mathbf{L}_1$ and $\mathbf{L}_2$ with $Co_2(CO)_8$, respectively. The composition and structure of compounds $\mathbf{L}_1$, $\mathbf{L}_2$, **1**, **2**, **3** and **4** have been characterized by elemental analysis, FTIR, ^1H and ^{13}C NMR and MS. The crystal structures of compounds $\mathbf{L}_1$, $\mathbf{L}_2$, **2** and **4** have been determined by X-ray single crystal diffraction. The syntheses and structures of compounds $\mathbf{L}_1$, **1**, **2**, **3** and **4** and the structure of ligand $\mathbf{L}_2$ are firstly reported. The molecular structure data show the butadiynyl groups of ligands $\mathbf{L}_1$ and $\mathbf{L}_2$ are nearly linear structure and the coordinated butadiynyl groups in the complexes **2** and **4** have deviated from linear structure of ligands $\mathbf{L}_1$ and $\mathbf{L}_2$.

Intermolecular interactions analysis in crystalline systems is very important in this field of chemical research. These interactions are responsible for crystal packing, and their understanding could lead to the comprehension of collective properties, providing the design of new structures with specific physical and chemical properties [3]. In crystal engineering, oxocarbon ions have been currently employed as building blocks [3–5], due to the simplicity of these cyclic species. In particular, squarate ion ($C_4O_4^{2-}$) exhibits very unusual electronic and vibrational properties, as can be seen in several investigations in literature [6]. This species presents D_{4h} symmetry and high degree of electronic delocalization, which are very interesting characteristics discussed in many structural [4,7] and spectroscopic investigations [8]. In addition, squarate ion shows both terminal and bridging coordination modes, such as 1,2-bidentate chelating [9] or 1,2-bis(monodentate) [10] and 1,3-bis(monodentate) [11] bridging and even using all four oxygen atoms [2c]. The 1,3-bis(monodentate) bridging coordination mode is very interesting to generate one dimensional (1D) polymeric structures [12,13] and the dimensionality can be expanded to 2D or 3D arrays using multidentate spacer ligands [14]. In this sense, pyridyl-donor ligands, like 1,3-bis(4-pyridyl)propane (BPP), show up as good candidates to generate 2D and 3D network designs [15].

BPP is a very flexible versatile bifunctional ligand [16] due to its aliphatic chain [–$(CH_2)_3$–] between two pyridyl rings. It presents different conformations and consequently different topologies in polymeric structures can be reached by using this ligand [17]. Several determined crystal structures of transition metal and BPP indicate the formation of polymeric structures with 1D, 2D and 3D network designs [18]. This nitrogen ligand can assume different conformations (TT, TG, GG and GG′) that display quite different N–N distances [17,18]. Comparing some crystal structures involving BPP as ligand, Carlucci et al. [19] defined a range of N–N distance in each type of conformation. For instance, for TT this range is 9.1–10.1 Å, for TG is 8.6–9.2 Å, for GG only three examples [20] are found in the literature with distances between 3.9 and 5.3 Å and in GG′ the range is 6.7–8.6 Å.
