$$g_y = g_e - 2\lambda[4\kappa_y^2/\Delta_y(^3A_g \rightarrow {}^3B_{2g})] \quad (9)$$

$$\chi_{TIP} = N_A\mu_0\mu_B^2(2/3)[4\kappa_x^2/\Delta_x(^3A_g \rightarrow {}^3B_{3g}) + 4\kappa_y^2/\Delta_y(^3A_g \rightarrow {}^3B_{2g}) + 4\kappa_z^2/\Delta_z(^3A_g \rightarrow {}^3B_{1g})] \quad (10)$$

These spin-Hamiltonian parameters are frequently understood as internal characteristics of the complex under study (molecular constants) and fixed by fitting the experimental data (magnetic susceptibility, magnetization, heat capacity, INS, ESR, MCD and FAR-IR spectra). However, all of them originate in the electronic structure of the complex and they can be reconstructed with the help of the more principal electronic-structure parameters [2]: the Racah parameters B and C (electron repulsion), the crystal-field strengths Dq, Ds, ... (or more exactly the crystal-field poles for each ligand F_2(L) and F_4(L)), the spin–orbit coupling constant ξ, and the orbital reduction factors κ (which could be anisotropic, κ_z, κ_x). With a tetragonal compression (negative structural tetragonality), the ground state is the Γ_5-multiplet, and D is negative. On tetragonal elongation (positive structural tetragonality) the ground state is Γ_4-multiplet, and D is positive. Such a general forecast, however, is tuned by the orbital reduction factors κ_z and κ_x.

Three publications preceded the present communication [3–5] where the axial zero-field parameter D (subtracted from the susceptibility and magnetization data sets) has been correlated with the structural anisotropy parameter D_{str} that characterizes the degree of the tetragonality. The complexes involved in such a correlation were either homoleptic (imidazole and its derivative, {NiN_6}-chromophore), N-donor only of the [Ni(base)$_4$(NCS)$_2$] type (possessing the {$NiN_4N'_2$}-chromophore), or heteroleptic complexes of the type [Ni(base)$_2$(carboxylate)$_2$(H_2O)$_2$] having the {$NiN_2O_2O'_2$}-chromophore. We prepared and structurally characterized some more members of the above series with the {NiO_4N_2}, and {NiN_4O_2} chromophores, respectively (three complexes). Five complexes were subjected to magnetochemical studies and involved in the above mentioned correlation.

Because the present paper is, in fact, a continuation of our previous work on heteroleptic Ni(II) complexes [5], we have kept numbering of the previously characterized complexes as follows: [Ni(*Meiz*)$_2$(HCOO)$_2$(H_2O)$_2$] (**1**), [Ni(*Me*$_2$*iz*)$_2$(HCOO)$_2$(H_2O)$_2$] (**2**), [Ni(*iqu*)$_2$(CH_3COO)$_2$(H_2O)$_2$] (**3**), [Ni(*fupy*)$_2$(CH_3COO)$_2$(H_2O)$_2$] (**4**). The new complexes under study are: [Ni(*bzfupy*)$_2$(*ac*)$_2$(H_2O)$_2$] (**5**), [Ni(*Me*$_2$*fupy*)$_2$(H_2O)$_4$](*ac*)$_2$ (**6**), [Ni(*Me*$_2$*iz*)$_4$(H_2O)$_2$]$Cl_2 \cdot 3H_2O$ (**7**), [Ni(*pz*)$_4$(*ac*)$_2$] (**8**) and [Ni(L^{NN})$_2$(H_2O)$_2$] (**9**).

2. Experimental

2.1. Synthesis

The starting materials (1,2-dimethylimidazole, $NiCl_2 \cdot 6H_2O$ and CH_3COOK) were purchased from commercial sources and were used as received. The syntheses of 2,3-dimethylfuro[3,2-*c*]pyridine (abbr. *Me*$_2$*fupy*) and benzo[4,5]furo[3,2-*c*]pyridine (abbr. *bzfupy*) have been conducted in accordance with published recipes [6–9].

Nickel(II) acetate was synthesized by adding potassium acetate to a nickel(II) chloride ethanol solution. Elemental analysis (C, H, N) was performed on an elemental analyzer Eager 300 (Carlo Erba). The nickel content was determined chelatometrically using murexide as indicator.

The two complexes [Ni(*bzfupy*)$_2$(*ac*)$_2$(H_2O)$_2$] (**5**) and [Ni(*Me*$_2$*fupy*)$_2$(H_2O)$_4$](*ac*)$_2$ (**6**) were prepared from nickel acetate. Into the solution of nickel acetate a stoichiometric amount of ligand was added and stirred for half hour. After 2 days the solid complexes were collected. Single crystals were grown from the ethanol solution. The complex [Ni(*Me*$_2$*iz*)$_4$(H_2O)$_2$]$Cl_2 \cdot 3H_2O$ (**7**) was prepared by reacting nickel(II) chloride with a four-fold excess of 1,2-dimethylimidazole in warm ethanol over a 4 h reflux. The single crystals of (**7**) were obtained by slow evaporation at room temperature. Syntheses of compounds **8** and **9** are described elsewhere [11,12].

Anal. Calc. for (**5**) $C_{26}H_{24}N_2NiO_8$: C, 56.66; H, 4.39; N, 5.08. Found: C, 56.09; H, 4.52; N, 5.04%. Calc. for (**6**) $C_{22}H_{32}N_2NiO_{10}$: C, 48.65; H, 5.94; N, 5.16. Found: C, 48.30; H, 6.17; N, 5.47%. Calc. for (**7**) $C_{20}H_{42}Cl_2N_8NiO_5$: C, 39.76; H, 7.01; N, 18.55. Found: C, 40.0; H, 7.05; N, 18.5%.

2.2. Physical measurements

Single-crystal X-ray diffraction experiments for all complexes have been performed using an Xcalibur CCD apparatus (Oxford Diffraction). Data reduction and empirical absorption correction were performed by SHELXS-97.

Electronic spectra were measured using the DRIFT method on a Magna FTIR 750 spectrometer (Nicolet) in the region 5000–11 000 cm^{-1} and in Nujol mull on a Specord 200 (Analytical Jena) in the range 50 000–10 000 cm^{-1}.

Magnetic susceptibility and magnetization measurements were done using a SQUID magnetometer (Quantum Design) between 2 and 300 K at $B = 0.1$ T. The magnetization data until $B = 5.5$ T were taken at $T = 2.0$ and 4.6 K, respectively. Raw susceptibility data were corrected for underlying diamagnetism using a set of Pascal constants [10]. The effective magnetic moment has been calculated as usual: $\mu_{eff}/\mu_B = 798(\chi' T)^{1/2}$ when SI units are employed.

3. Results and discussion

3.1. Molecular and crystal structure

Crystal data for compounds **5** through to **7** are collected in Table 1. The molecular structure is viewed in Fig. 1.

The structure of complex **5** consist of [Ni(*bzfupy*)$_2$(*ac*)$_2$(H_2O)$_2$] monomeric units in which the central Ni(II) atom has a distorted octahedral configuration. The coordination around the Ni(II) atom is defined by two aqua ligands (w), two acetate ligands (a) and two neutral benzo[4,5]furo[3,2-*c*]pyridine (b). The Ni–O(a) distances are 2.060(2) Å, the Ni–O(w) distances are 2.073(2) Å and the Ni–N(b) dis-

Table 2
Selected bond lengths (Å)[a]

Contact	5	6	7
Ni1–N1	2.128	2.168	2.100
Ni1–N2	2.128	2.168	2.065
Ni1–N3			2.077
Ni1–N4			2.063
Ni1–O1	2.073[w]	2.194[w]	2.095[w]
Ni1–O2	2.073[w]	2.194[w]	2.106[w]
Ni1–O3	2.060	2.048[w]	
Ni1–O4	2.060	2.048[w]	

[a] w, the aqua ligand.

tances are 2.128(2) Å (see Table 2). Two oxygen atoms from water molecules and two oxygen atoms from acetate groups form the equatorial plane and two nitrogen atoms from benzo[4,5]furo[3,2-*c*]pyridine are situated in the axial sites.

The molecular structure of complex **6** consists of discrete $[Ni(Me_2fupy)_2(H_2O)_4]^{2+}$ monomeric units with the Ni(II) atom in a distorted octahedral configuration defined by four equatorial aqua (w) ligands and two axial 2,3-dimethylfuro[3,2-*c*]pyridine (b) ligands. The Ni–O(w) distances are 2.194 and 2.048 Å and the Ni–N(b) distances are 2.168(2) Å. Such a geometry predisposes that the usual assumption $|D| > 3E$ is no longer valid for this $\{Ni(O_2O'_2)_{eq}N_2\}$ chromophore.

The $[Ni(Me_2iz)_4(H_2O)_2]^{2+}$ monomeric units represent the structure of compound **7**. The central Ni(II) atom possesses a distorted octahedral configuration formed by two aqua ligands and four neutral 1,2-dimethylimidazole (b) ligands. The distances inside the chromophore are Ni–O(w) 2.095 and 2.106 Å, Ni–N(b) 2.100, 2.065, 2.077 and 2.063 Å, respectively.

For compounds **8** and **9**, whose structures have been published elsewhere, we refer to the original sources [11,12].

The intermolecular O–H···O hydrogen bonds for **5** [H···O = 1.834 and 1.934 Å, and O–H···O = 165 and 163°] are formed through aqua-ligand OH groups to uncoordinated acetate-ligand O-atoms from a neighboring molecule, and they are situated in the equatorial plane. In the crystal structure of this complex, the secondary N-atoms are not involved in the hydrogen bonds; consequently only a two-dimensional network is formed (Fig. 2).

The registered intermolecular contacts for **6** are O–H···O [H···O = 1.683, 1.821, 1.918 and 2.184 Å, O–H···O = 161°, 166°, 171° and 176°]. They are formed by aqua-ligand OH groups to the O atom from an uncoordinated acetate molecule in the equatorial plane. Thus, these hydrogen bonds form a two-dimensional network because the N-atoms are not involved in the hydrogen bonds.

For complex **7** the O–H···O hydrogen bonds [H···O = 2.688, 2.767 and 2.784 Å, Cl···O = 3.146, 3.125, 3.096, 3.142 and 3.110 Å, O–H···O = 161°, 171° and 167° and O–H···Cl = 162°, 170°, 174°, 160° and 167°] are formed through coordinated water OH groups to crystal-water

molecules and one of these three hydrogen bonds is formed between two crystal–water molecules. These hydrogen bonds form a two-dimensional network.

3.2. Electron spectra

The electron spectra of the studied complexes show three principal d–d bands ($^3T_{2g} \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$, characteristic for the octahedral geometry) in the region 9400–10893 cm^{-1}, 15300–16681 cm^{-1} and 26000–27004 cm^{-1}, which are split due to the symmetry lowering of the crystal field (Table 3). The splitting is evidenced as an arm and is well visible for the second principal transition; this refers to the transition $^3A_{2g} \leftarrow {}^3B_{1g}$ within the point-group D_{4h}. A weak feature with a maximum at ~13600 cm^{-1} can be assigned to the spin-forbidden transition ($^1A_{1g} \leftarrow {}^3B_{1g}$) arising from the ^1D term.

3.3. Magnetic data

Magnetic data for the complexes under study are shown in Fig. 3. This figure displays the temperature dependence of the effective magnetic moment and the field dependence of the molar magnetization at two temperatures. The effective magnetic moment keeps an almost constant value except at very low temperatures when its decrease reflects a zero-field splitting. The ZFS is also responsible for deviation of the magnetization from the Brillouin-function behaviour.

The experimental data were fit using the spin-Hamiltonian

$$\widehat{H} = \widehat{H}^{\mathrm{zfs}} + \widehat{H}^{\mathrm{Z}} \tag{11}$$

where the first contribution is the zero-field splitting term

$$\widehat{H}^{\mathrm{zfs}} = \hbar^{-2}D(\widehat{S}_z^2 - \widehat{S}^2/3) + \hbar^{-2}E(\widehat{S}_x^2 - \widehat{S}_y^2) \tag{12}$$

describing the axial and rhombic magnetic anisotropy. The Zeeman term entering the spin-Hamiltonian is expressed through the grids of polar angles ϑ_k and φ_l as

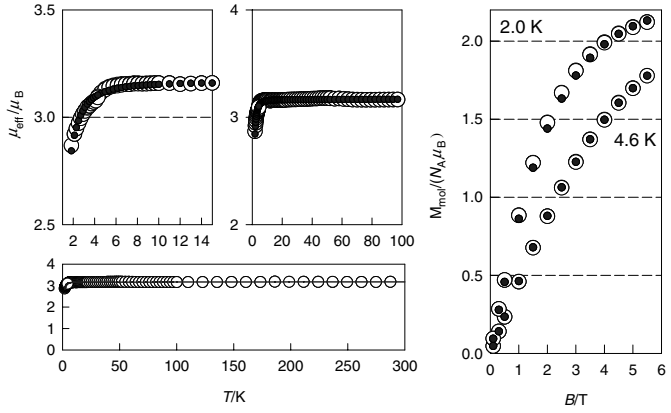
$$\widehat{H}^{\mathrm{Z}}(\vartheta_k, \varphi_l) = \mu_{\mathrm{B}} B_m \hbar^{-1}(g_x \sin\vartheta_k \cos\varphi_l \widehat{S}_x + g_y \sin\vartheta_k \times \cos\varphi_l \widehat{S}_y + g_z \cos\vartheta_k \widehat{S}_z) \tag{13}$$

In order to reduce the free parameters, the zero-field splitting parameters were restricted according to the constraints offered by the spin-Hamiltonian formalism

$$D = (\lambda/2)[g_z - (g_x + g_y)/2] \tag{14}$$

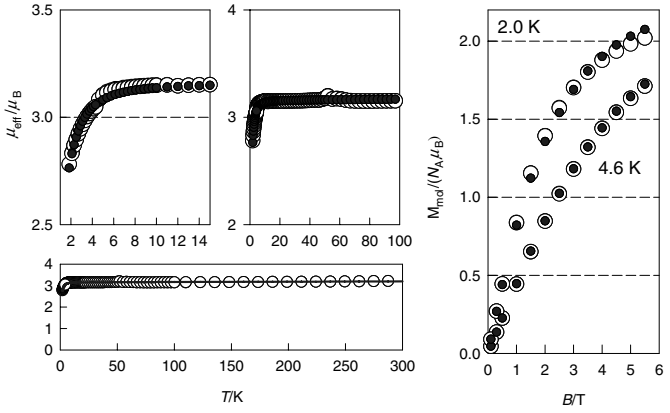
$$E = (\lambda/4)(g_x - g_y) \tag{15}$$

Two experimental data-sets (M versus T at 0.1 T, and M versus B at 2.0 and 4.6 K) have been treated simultaneously. The average magnetization data have been calculated as a correct powder average using a random spherical distribution of the magnetic-field vector [13]



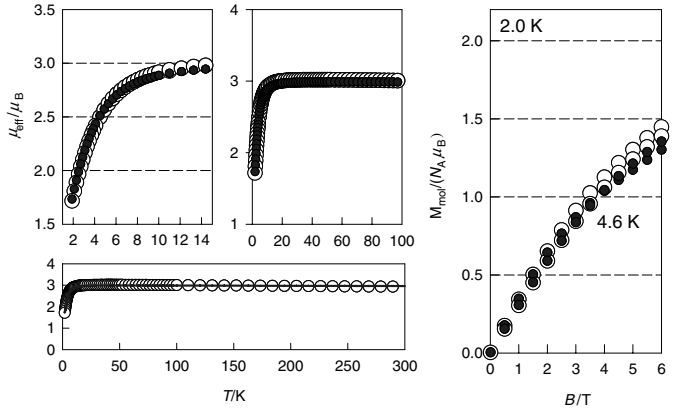
$$M_{\mathrm{av}} = \frac{1}{4\pi}\int_0^{\pi}\int_0^{2\pi} M(\vartheta,\varphi)\sin\vartheta\,\mathrm{d}\vartheta\,\mathrm{d}\varphi \tag{16}$$

The free parameters to be optimized are g_x, g_y, g_z and α_{TIP} (temperature-independent paramagnetism).

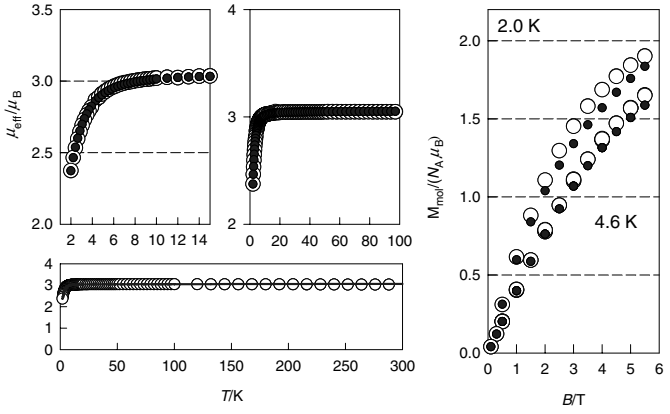


The calculated magnetic parameters are listed in Table 4. The acquired data for compounds **5**–**9** show that the D-parameters adopt values between −3 and +11 cm^{-1}. Enhancement of the magnetic anisotropy in these complexes is caused by the different crystal-field strengths in the axial and equatorial positions.

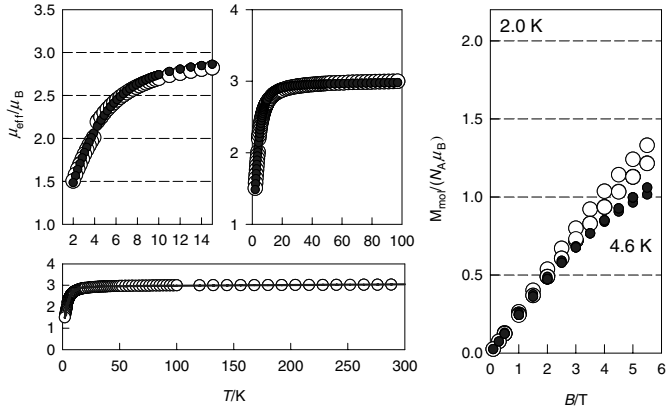
We also tested the hypothesis about the sign reversal for the D-parameter, since it is problematic to fix the sign of the D-parameter from powder data alone when $|D|$ is small. The sign reversal always led to a worse fit of magnetic data with an enlarged R-factor. Some other techniques could also be applied in detecting the zero-field splitting (e.g., high-field/high-frequency ESR, frequency-domain spectroscopy) but these are less common and hardly accessible for routine usage [1]. Nevertheless, a simultaneous utilization of the susceptibility and magnetization data-sets helps substantially in a reliable determination of the sign of the D-parameter.



The fitting procedure results in appreciable values of the axial zero-field splitting parameter D. These magnetic data



$[Ni(bzfupy)_2(ac)_2(H_2O)_2]$, **5**



$[Ni(Me_2fupy)_2(H_2O)_4](ac)_2$, **6**

were used in correlation with the structural D-values subtracted from the X-ray structure data. The latter parameter, in the case of the heteroleptic complexes, is defined as

$$D_{\mathrm{str}} = \Delta_z - (\Delta_y + \Delta_x)/2 \tag{17}$$

where $\Delta_a = (d_a - \bar{d}_i)$ for $a = x, y, z$ is a shift relative to the mean distance $\bar{d}_i$ for a given bond (i = N, O). For the N- and O-donor ligands these values have been taken from complexes containing the $[Ni(NH_3)_6]^{2+}$ and $[Ni(H_2O)_6]^{2+}$ units, respectively; $\bar{d}(\mathrm{Ni–N}) = 2.145$ Å and $\bar{d}(\mathrm{Ni–O}) = 2.055$ Å [14]. As seen from Fig. 4, the correlation of the magnetic D_{mag} values versus the relative structural tetragonality parameters D_{str} is fairly good. However, three notes need to be added: (i) the magnetic as well as structural data bring evidence also for the rhombic anisotropy, which has not been included into the correlation; (ii) the correlation

curve cannot be linear, since the compressed bipyramid cannot be extrapolated to zero metal–ligand distances; (iii) the magnetic parameters (D, E) are influenced by the orbital reduction factors via Eqs. (5) and (6). The last aspect manifests itself in the complex [Ni(imidazole)$_4$](acetate)$_2$: the structural distortion is extremely positive (strongly elongated bipyramid) whereas the axial zero-field splitting parameter, that measures the magnetic anisotropy, is extremely negative, $D/hc = -23\ cm^{-1}$ [15]. This apparent contradiction can be understood by inspecting Eq. (1): the orbital reduction factor for very long axial Ni···O contacts approaches a value of $\kappa_z = 1.0$ whereas that for the equatorial Ni–N bonds adopts normal values of $\kappa_x = 0.7$; this causes the sign reversal of the D-parameter.

It is recapitulated that in the solid state, the magnetic anisotropy for homoleptic Ni(II) complexes adopts small values: $D/hc = -3.5$ to $+2.0\ cm^{-1}$ for [Ni(*iz*)$_6$](*car*)$_2$ type complexes [3] (*car* – carboxylate). In heteroleptic, but "effective octahedral" complexes of the [Ni(*N*-base)$_4$(NCS)$_2$]·*n*H$_2$O type the registered magnetic anisotropy is not enhanced significantly: $D/hc = -3$ to $-1.5\ cm^{-1}$ [4]. On passing to the heteroleptic complexes of the [Ni(*N*-base)$_2$(H$_2$O)$_2$(*car*)$_2$] type the magnetic anisotropy is enhanced substantially: $D/hc = -8$ to $-5\ cm^{-1}$ [5]. Two complexes of the present study (**5** and **6**) span this interval, which is typical for the {NiO$_2$O$_2$N$_2$} chromophore. The remaining complexes (**7**, **8** and **9**) possessing the {NiN$_4$O$_2$} chromophore adopt positive values of $D/hc = +4$ to $+11\ cm^{-1}$.

conditions and we separated complexes of Ca(II), Cd(II) and Mn(II) with the 5-(4-pyridyl)tetrazolato (4-PTZ) anion as ligand [21]. Newly, other Mn(II)-5-pyridyl-tetrazolato (PTZ) complexes were obtained under similar experimental conditions [22].

We now report four new M(II) (M = Cu, Co) complexes obtained by the 1,3-dipolar addition reaction of cyano pyrazine with azide in aqueous solution and analyse their solid state structures using the concept of three-dimensional nets [23].

2. Experimental

2.1. Materials and instrumentation

Infrared spectra were recorded on a Bruker IFS-125 model FT-IR spectrophotometer as KBr pellets [24]. C, H, N analyses were carried out using a Perkin–Elmer analyzer [25], Cu were analysed by a Perkin–Elmer Analyst 300, AAS atomic absorption spectrometer. Raman spectra were recorded on a Bruker IFS 6/s FT-Raman spectrometer with Nd:CYAG laser wavelength (1064 nm) as the light source [26]. Thermogravimetry, TG and differential thermogravimetry, DTG were carried out on a shimadzu DT-50. The measurements were performed by using a dynamic nitrogen atmosphere with a flow rate of 20 ml/min. The heating rate was kept at 10 °C min^{-1} and the sample sizes ranged in mass from 1.45 to 1.66 mg contained in a platinum crucible. Al_2O_3 was used as a reference material. Pyrazine carbonitrile has been purchased from Aldrich Company and other chemicals were of analytical grade quality and used without further purification.

Caution: Metal azide and metal tetrazolate complexes are potentially explosive. Only a small amount of material should be prepared and should be handled with caution.

2.2. Synthesis of copper complexes *1*, *2a*, and *3*

To an ethanolic solution of $Cu(NO_3)_2 \cdot 3H_2O$ (0.48 g, 2 mmol) in 15 cm^3, a (0.42 gm, 4 mmol) of pyrazinecarbonitrile, in 10 cm^3 ethanol were added. Further, (0.65 g, 10 mmol) NaN_3 aqueous solution was added dropwise with continuous stirring. The clear blue solution was allowed to stand at room temperature for a couple of days. Deep blue crystals of (**1**) $[Cu(pyztz)_2(H_2O)]$, green crystals of (**2a**), $[Cu(pyztz)_2(H_2O)_2]$ and blue crystals of (**3**) $[Cu(pyztz)_2(H_2O)_2](H_2O)$ were formed. The three complexes were separated under microscope after filtration, dried in air. The product yielding about ~10% of complex **1**, 20% of complex **2**, and 60% of complex **3**. *Anal.* Calc. for **1**: C, 31.95; H, 2.14; N, 44.72; Cu, 16.91. Found: C, 32.21; H, 2.52; N, 44.85; Cu, 17.23%. *Anal.* Calc. for **2**: C, 30.49; H, 2.55; N, 42.68; Cu, 16.13. Found: C, 30.34; H, 2.34; N, 42.19; Cu, 16.37%. *Anal.* Calc. for **3**: C, 29.16; H, 2.93; N, 40.80; Cu, 15.43. Found: C, 29.06; H, 2.21; N, 40.63; Cu, 15.69%.

2.3. Synthesis of cobalt complex *2b*

To a methanolic solution of $CoCl_2 \cdot 6H_2O$ (0.476 g, 2 mmol) in 15 cm^3, (0.42 gm, 4 mmol) of pyrazinecarbonitrile, in 10 cm^3 methanol was added. Further, (0.65 g, 10 mmol) NaN_3 aqueous solution were added dropwise with continuous stirring. The clear yellow solution was allowed to stand in a refrigerator at around +4 °C for a couple of days. Orange crystals of (**2b**) $[Co(pyztz)_2(H_2O)_2]$ suitable for X-ray measurements were collected by filtration, dried in air. The product yields about ~50%. *Anal.* Calc. for **2b**: C, 30.86; H, 2.59; N, 43.19; Co, 22.08. Found: C, 30.95; H, 2.53; N, 43.35; Co, 22.13%.

2.4. X-ray crystallography

Single crystal X-ray data of **1**, **2a**, and **3** were measured at 100(2) K on a modified STOE four circle diffractometer, of **2b** were collected on a Bruker-AXS SMART APEX CCD diffractometer, using graphite crystal-monochromatized Mo Kα radiation ($\lambda = 0.7107$ Å). The intensities were corrected for Lorentz-polarisation effects and for absorption. Crystallographic data and processing parameters are given in Table 1. The structures were solved by direct methods and subsequent Fourier analyses. The programs DIFABS [27a], SADABS [27b] and SHELXTL/PC program package [28] were used for computations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated. Anisotropic displacement parameters were applied to non-hydrogen atoms in full-matrix least-squares refinements based on F^2. All hydrogen atoms were located from difference Fourier maps assigned with isotropic displacement factors and included in the final refinement cycles as follows: (a) pyrazine hydrogen atoms bonded to carbon by geometrical restraints using the HFIX utility of SHELXTL/PC package; (b) water hydrogen atoms by use of O–H distance restraints. Split occupancy of 0.5 was applied to the disordered lattice water molecule O(2) of **3**. Selected bond distances and bond angles are given in Tables 2–5, for complexes **1**, **2a**, **2b** and **3**, respectively.

2.5. Network analysis

Abbreviations for 3D nets have been taken from M. O'Keeffe and O.M. Yaghi, Reticular Chemistry Structure Resource, 2005, Arizona State University, Tempe, http://okeeffe-ws1.la.asu.edu/rcsr/home.htm where crystallographic coordinates and other useful details for 3D-nets can be obtained. Another source is the EPINET project (http://epinet.anu.edu.au).

3. Results and discussion

In the attempt to prepare $[M(pyrazinecarbonitrile)_2(N_3)_2]_n$, the [2+3] cycloaddition reaction of pyrazinecarbonitrile and sodium azide occurred in the presence of M^{2+} as

Lewis acid catalyst. This gave deep blue crystals of $[Cu(pyztz)_2(H_2O)]$ (**1**), green crystals of $[Cu(pyztz)_2(H_2O_2)]$ (**2a**), orange crystals of $[Co(pyztz)_2(H_2O)_2]$ (**2b**) and blue crystals of $[Cu(pyztz)_2(H_2O)_2](H_2O)$ (**3**).

It is well-known that the tetrazole ring formation via the [2+3] cycloaddition of 4-cyanopyridine and azide takes place under hydrothermal conditions so it is notable that the tetrazole rings were formed at room temperature. The cycloaddition reaction was probably accelerated by the presence of the M(II) salt as a Lewis acid catalyst.

3.1. Structures

A perspective view with atom labelling scheme of complex **1** is given in Fig. 1, selected bond parameters are summarized in Table 2. The copper(II) ions are penta-coordinated by nitrogen atoms N(1), N(3) N(11) and N(13) of two chelating pyztz ligands, which adopt the basal sites, and oxygen atom O(1) of an aqua ligand at apical site. The CuN_4O coordination polyhedron may be described as a slightly distorted tetragonal pyramid ($\tau = 0.04$) [29]. The Cu–N_{pyz} bonds [2.048(4) and 2.052(4) Å] are a little bit longer than the Cu–N_{tet} bonds [1.975(4) and 1.967(3) Å], whereas the Cu(1)–O(1) bond is 2.219(4) Å. Cu(1) is located 0.186 Å above the basal N_4 plane. The chelating N–Cu–N bond angles are 81.1(2)° and 81.5(2)°, the other N–Cu–N bond angles are 97.7(2)°

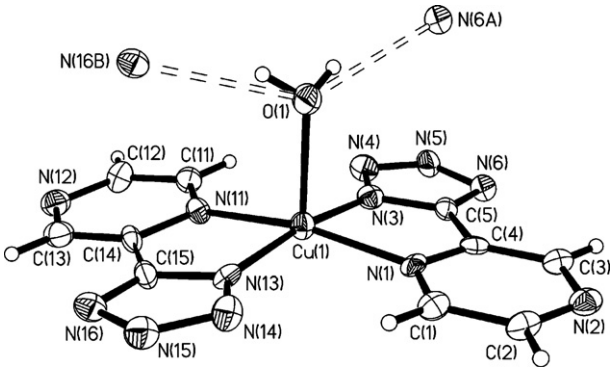

Fig. 1. Perspective view of $[Cu(pyztz)_2(H_2O)]$ (**1**).

and 97.8(2)°, whereas the N–Cu–O bond angles are in the range from 93.3(2)° to 96.22(14)°. The tetrazolato-rings of the pyztz ligands are twisted by 3.2° and 4.2° from their sixmembered pyrazine-rings. The mean planes of the two pyztz ligands have an acute angle of 14.1°. A packing view of **1** is given in Fig. 2. The isolated polyhedra of **1** have a Cu···Cu separation of 6.861(3) Å, and are connected via hydrogen bonds of type O–H···N from O(1) to N(16) $[-x, -y, 1-z]$ and N(6) $[1-x, 1-y, -z]$ to form a 1-D system extented along $[1, 1, -1]$ with O···N separations of 2.841(5) and 2.920(5) Å, respectively. Within these chains adjacent polyhedra are arranged head to tail in order to allow π–π-stacking interactions between neighbouring chelating pyztz ligands.

The molecular structure of **2a**, Fig. 3, has a centrosymmetric configuration, in which the octahedral Cu(II) ion is coordinated by four equatorial nitrogen atoms from two pyztz ligands and axial oxygen atoms of coordinated water molecules. As in **1**, each pyztz ligand chelates to Cu through one tetrazolato-nitrogen atom N1-site of the tetrazolato-ring and through the pyrazine nitrogen atom. The tetrazolato-ring is twisted by 5.1° from the sixmembered ring. Selected bond parameters are listed in Table 3. The

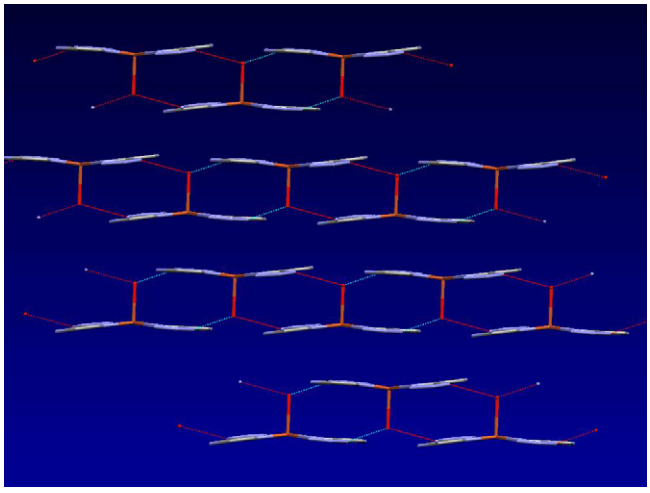

Fig. 2. Packing plot of $[Cu(pyztz)_2(H_2O)]$ (**1**). Broken lines indicate hydrogen bonds.

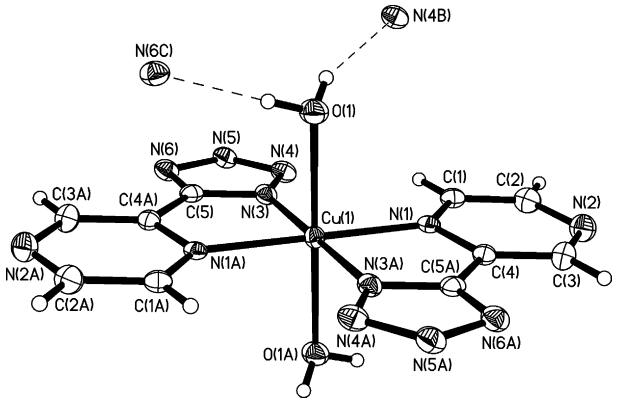

Fig. 3. Perspective view of $[Cu(pyztz)_2(H_2O)_2]$ (**2a**).

distorted CuN_4O_2 octahedron has Cu–N_{pyz} and Cu–N_{tet} bond lengths of 2.078(2) and 1.996(2) Å, respectively, and a Cu–O bond distance of 2.316(2) Å. The water molecule forms hydrogen bonds of type O–H···N from O(1) to N(4) $[1-x, 1-y, -z]$ and N(6) $[-1/2+x,\ 1/2-y,\ -1/2+z]$ with O···N separations of 2.936(4) and 2.816(3) Å, respectively, where two N atoms of the tetrazolato rings in position 1 and 2 act as hydrogen bond acceptors to form cyclic tetrameric subunits. The shortest Cu···Cu separation between Cu(II) polyhedra is 6.294(2) Å, the basal CuN_4 planes form acute angles of 21.6°. Compound **2b** as shown in Fig. 4 is isostructural and selected bond parameters are listed in Table 4. The hydrogen bonding system in **2** differs from that observed in the structure of corresponding $[Mn(2\text{-}PTZ)_2(H_2O)_2]$ complex, (2-PTZ = 5-(2-pyridyl)-tetrazolate anion) [22]. In this latter Mn complex eight intermolecular O–H···N(tetrazole) hydrogen bonds link each Mn complex to four other Mn complexes. In contrast to compounds **2a** and **2b** nitrogen atoms of the 2-PTZ moiety act as acceptors which correspond to N(5) and N(6) atoms of the present tetrazole ligands see Ref [22, Fig. 1b].

A perspective view of compound **3** is given in Fig. 5, selected bond parameters are summarized in Table 5. Although **3** has a similar centrosymmetric configuration as **2a**, in which the octahedral Cu(II) ion is also coordinated by four equatorial nitrogen atoms from two pyztz ligands and axial oxygen atoms of coordinated water molecules, the bond parameters within the CuN_4O_2 coordination polyhedron differ significantly. The Cu–N_{pyz} and Cu–N_{tet} bond lengths are shortened to 2.044(3) and 1.989(3) Å, respectively, whereas the axial Cu–O bond distance is elongated to 2.416(3) Å. The aqua ligands form hydrogen bonds of type O–H···N from O(1) to N(6) $[1-x, 1-y, 1-z]$ and N(5) $[1/2+x, -1/2+y, z]$ to form a supramolecular network, with O···N separations of 2.913(4) and 2.831(3) Å, respectively. In addition, the disordered lattice water molecule with split occupancy 0.5 and related by a diad, form hydrogen bonds of type O–H···O to apical O(1) atoms of adjacent Cu(II) polyhedra. The O···O separations are 2.790(13) and 2.928(13) Å. As a consequence of this additional lattice water molecule the packing of **3** is quite different compared to **2a**. The monomeric polyhedra have a V-type arrangement with acute angles of basal CuN_4 planes of 49.8°. The shortest metal–metal distance is 7.334(2) Å.

Bond lengths and bond angles of the five-membered tetrazolate rings in complexes **1**–**3** are very similar and agree

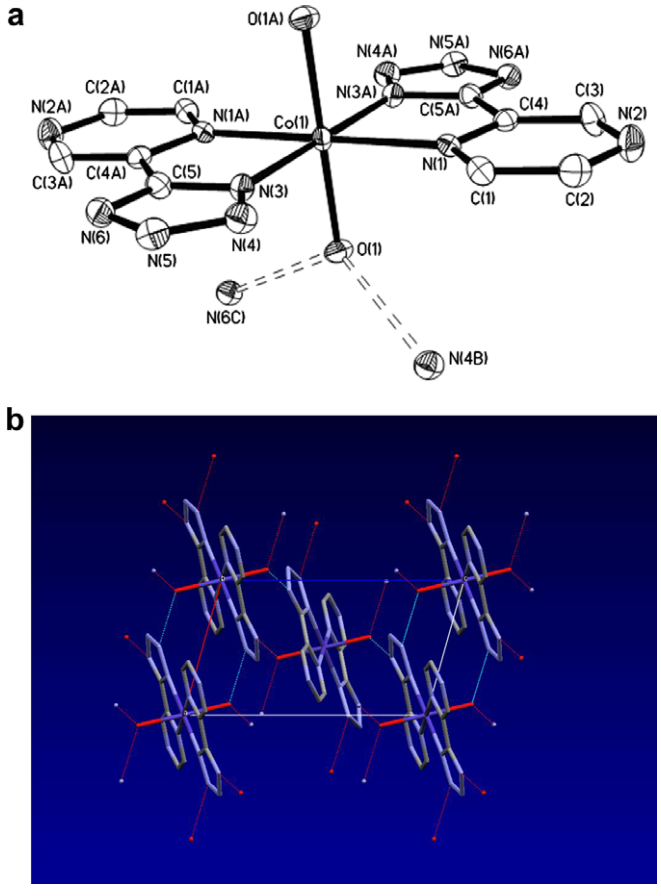

Fig. 4. (a) Perspective view of $[Co(pyztz)_2(H_2O)_2]$ (**2b**). (b) Packing plot of $[Co(pyztz)_2(H_2O)_2]$ (**2b**).

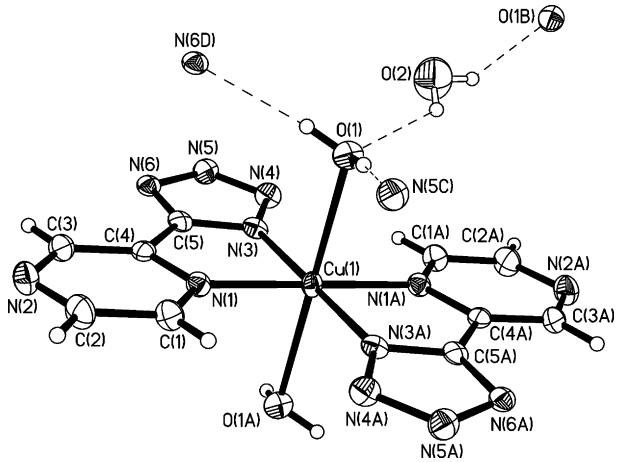

Fig. 5. Perspective view of $[Cu(pyztz)_2(H_2O)_2]\cdot(H_2O)$ (**3**).

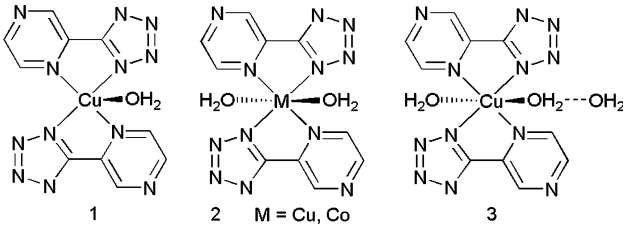
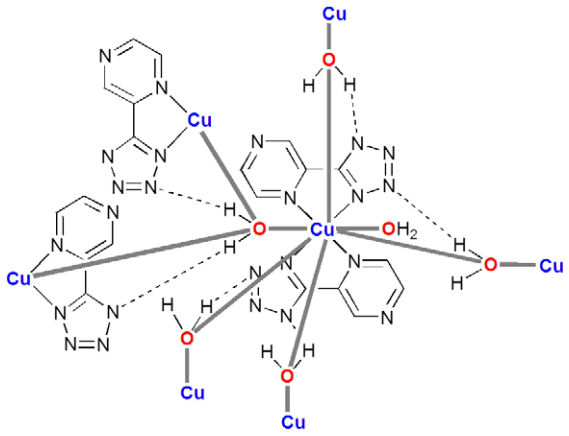
well with values reported in a series of bis-tetrazolate-dianions [30]. The N2–N3 bond opposite to C in position 5 is significantly shorter [1.298(5)–1.325(5) Å] than other interatomic distances within the heterocycle despite of the aromatic nature of the five-membered ring. In case of 5-phenyl tetrazolate anion (5-PhTZ) the deprotonation had also led to a noticeable elongation of the N2–N3 bond from 1.247 to 1.307(3) Å, in excellent agreement with *ab initio* calculations [31].



It is interesting to note that in case of the present complexes **1**–**3**, only one (in case of **1**) and two (in case of **2a,b** and **3**) out of four uncoordinated nitrogen donor atoms per pyztz molecule act as hydrogen bond acceptors. In case of previous reported complexes with 5-(4-pyridyl)tetrazolato ligands (4-PTZ) [21] all nitrogen donors are involved in hydrogen bonds. In fact, compound **1** can be described as hydrogen bond mismatched as it has nine possible hydrogen bond acceptors but only two hydrogens can act as classical donors. In **2**, this ratio is 10:4 and in **3** 11:6. Consequently, the most complex hydrogen bond pattern is found in **3**. This fact and the higher nitrogen content compared to the 4-PTZ ligand may also explain the thermal instability of the present compounds.

3.2. Network analysis



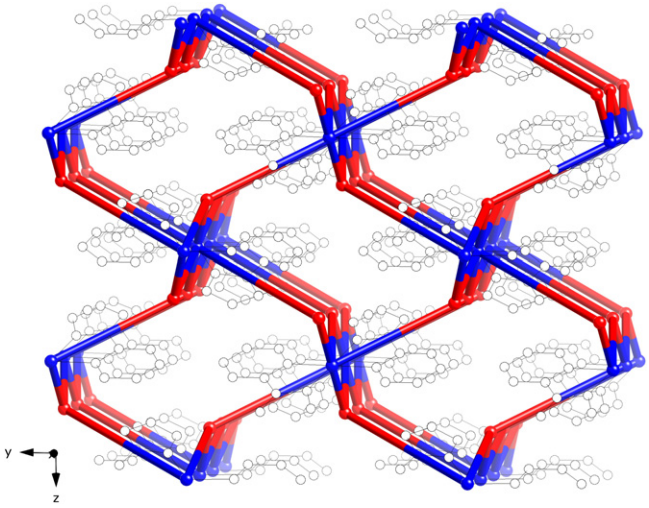
The analysis of network patterns as an aid in the understanding of crystal structures was advocated already in the mid 1950:ies by UK crystallographer Alexander Wells, [32] and recently network analysis of 3D-coordination polymers and Metal–Organic Frameworks have become increasingly important [23,33]. However, as was shown already by Wells, this analysis is relevant also for hydrogen bonded systems [24].

It should be emphasised that all structures do not form 3D-networks, even if hydrogen bonding is considered, so for example is compound **1** clearly well described as the packing of 1D hydrogen bonded chains. Compound **2** on the other hand is clearly hydrogen bonded in all three dimensions, and these bonds are few (compared to the total number of atoms in the molecule) and well defined, thus this structure is probably well described as a 3D-network Scheme 1.

Indeed, when we assign nodes and links in **2** according to Scheme 2 we get a three- and six-connected network, see Fig. 6. Close inspection of this net (visually and by calculating vertex symbols [34]) shows that the net topology is

Scheme 1.

Scheme 2.



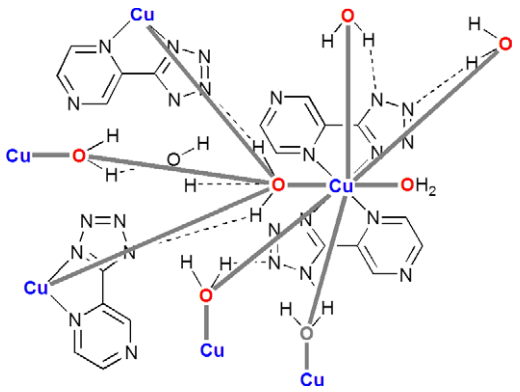


Fig. 6. The three- and six-connected network in **2**, the net topology is a **rtl** or rutile net, the most common of all three- and six-connected nets.

a **rtl**- or rutile net, the most common of all three- and six-connected nets Scheme 3.

The situation in **3** is slightly more complicated as we have introduced more possible hydrogen bond acceptor and donor sites. It appears, however, that this structure can be described by the **fsh**-net, see Fig. 7.

Scheme 3.

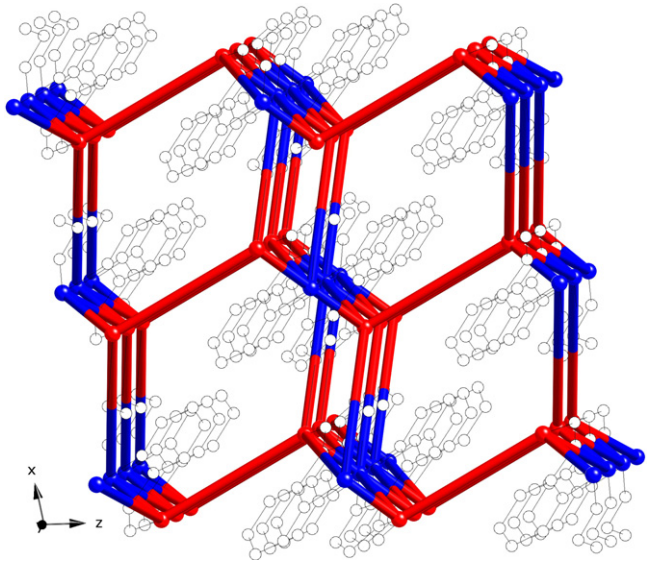

Fig. 7. The four- and six-connected network in **3** has the **fsh** topology.

Note that both nets are somewhat distorted from the ideal nets, but they still have the same topology as the ideal nets as they can be transformed into each other without breaking any bonds.

3.3. Thermal analysis

Thermal decomposition analysis of the given tetrazolate complexes was performed under quite sensitive conditions; very small samples were taken (1.4–1.6 mg.) due to the high explosion properties of such compounds. The only published thermal analysis data for pyridine tetrazolate complexes were performed and tentatively assigned till 250 °C [21]. The DTA and DSC measurements of these complexes failed as the samples were exploding even at low temperatures and lower masses less than 2.0 mg. It also gave some vapors which affects the sensor of the DSC instrument. The stages of decomposition, temperature range, decomposition product losses as well as the found and calculated weight loss% of the complexes are given in Table 6. The TG and DTG curves of complexes **1**, **2a**, **2b** and **3**, Fig. 8, show the decomposition steps.

The first step, almost in all complexes, represents the loss of water content, hydrated and coordinated water molecules in the temperature range 103–280 °C. Although the tetrazolate group is a sensitive exploding group in the complexes, it decomposes slowly over a wide range of temperature, perhaps overlapping with the loss of water molecules or decomposition of the subsequently formed cyano-pyrazine group. Decomposition and liberation of an azido group was found in the temperature range 154–355 °C. The third and fourth steps were generally the decomposition of the cyano-pyrazine group, liberating the pyrazine moiety and leaving the cyano group on the metal atom which was further oxidized to give the final residue as a metal oxide.

3.4. Spectra

In the high energy region the room temperature IR spectra of the crystalline complexes **1**, **2a**, **2b** and **3** exhibit strong broad bands around 3000–3550 cm^{-1} corresponding to the coordinated water molecules to the Cu(II) ro Co(II) ions in the three complexes. Extensive hydrogen bonding of

the types O–H···O and N–H···O are indicated by the presence of broad medium strong bands centered around 2400–2600 cm^{-1}. The absence of any bands in the 2200–1750 cm^{-1} region confirms ring formation to the tetrazolate ligand by the 1,3-dipolar reaction of the azide group with the nitrile group on the pyrazine ring. Neither vibrations associated with νCN of the 2-cyanopyrazine (expected week to medium band centered around 2240 cm^{-1}) nor strong bands associated with $\nu_{as}N_3$ in the 2150–2000 cm^{-1} region are present [35]. The vibration frequencies of the coordinated pyrazine tetrazolato ligands could be tentatively assigned in agreement with recently reported metal pyridine tetrazolate [21,22]. In the far region few bands around 296 cm^{-1} could tentatively be

assigned as a M–L vibration. The Raman spectra show some anti-Stokes peaks around −126 m, −137 m and −292 m, cm^{-1} for complexes **1**, **2a** and **3** respectively. Results are summarized in Table 7.

The electronic spectrum of complex **1** exhibits the d–d transitions as a relatively strong broad absorption band around 15000 cm^{-1} suggesting five-coordination geometry around the central copper ion, along with a shoulder on the high frequency side at 24300 cm^{-1} which could be attributed to the LMCT from the pyrazine tetrazolate ligands to the central copper ion [36]. The spectra of penta-amin copper(II) complexes with square pyramidal geometry have been found to exhibit an intense absorption band in the 17000–15000 cm^{-1} range [37]. The complexes **2a** and **3** show the LMCT absorption bands around 26000 cm^{-1} but the d–d transition bands are shifted to higher energy. It is found at 15600 cm^{-1} for complex **2a** and at 16500 cm^{-1} for complex **3**. The cobalt(II) complex **2b** shows the LMCT absorption bands around 26595 cm^{-1} while the d–d transition bands are shifted to higher energy. It is found as a broad band around 20160 cm^{-1}. These shifts could be interpreted as the effect of an increased cf-splitting due to the existence of a sixth ligand and is consistent with the 6-fold coordination field for the copper complexes [38] and the cobalt complex [39].

4. Conclusions

The preparation of 5-(pyridyl)tetrazole M(II) complexes from azide ions and 4-cyanopyridine were achieved under exceptionally mild conditions. The compounds prepared form a series of pseudo-polymorphs with different numbers of water molecules present, going from a system with a massive over-representation of hydrogen bond acceptors through a more balanced system as more water molecules are added. It was shown that the structures showing extended hydrogen bonds in three-dimensions could readily be analysed using the concept of 3D-nets.

5. Supplementary material

CCDC 278952, 278953, 622096 and 278954 contain the supplementary crystallographic data for **1**, **2a**, **2b** and **3**, respectively. These data can be obtained free of charge via http://www.ccdc.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

influence of different factors, such as pH, temperature, solvent, catalyst and the steric effects of the substrate, on this hydrolytic reaction were shown to be necessary.

In recent years, the steric influence of the palladium(II) catalyst on the rate of hydrolytic cleavage of the amide bond in histidine- and methionine-containing peptides has been the subject of very broad investigations [3,5,6,8]. It was found that in the reaction between MeCOHis-Gly and different *cis*-$[Pd(L)(H_2O)_2]^{2+}$ complexes (L is ethylenediamine, en; 1,2-propylenediamine, 1,2-pn; *N*-methylethylenediamine, Meen; isobutylenediamine, ibn; or *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, Me_4en, acting as a bidentate ligand) in the pH range 2.0–2.5 and at 60 °C, the rate of the regioselective cleavage of the amide bond involving the carboxylic group of histidine decreases as the steric bulk of the palladium(II) complex increases (en > 1,2-pn > Meen > ibn > Me_4en) [5]. The observed rates of hydrolytic reaction were investigated in terms of steric hindrance of the chelating diamine on the palladium(II) complexes and the results showed that with increasing number of methyl groups at the nitrogen or carbon atom of the chelated diamine ligand, the number of hydrolyzed His-Gly peptide bonds in MeCOHis-Gly decreased. For example, the reaction between *cis*-$[Pd(en)(H_2O)_2]^{2+}$ and this peptide after 48 h at 60 °C was two times faster in comparison with *cis*-$[Pd(Me_4en)(H_2O)_2]^{2+}$, and one and a half times faster in relation to *cis*-$[Pd(ibn)(H_2O)_2]^{2+}$. The results for MeCO-His-Gly peptide are not in accordance with those obtained for MeCOMet-Gly peptide and palladium(II) complexes containing different chelated diamine ligands (en, 1,2-pn, ibn, 1,2-dach, Meen and Me_4en) [8]. The rate of the hydrolysis of the Met-Gly amide bond was approximately the same and the amount of the hydrolyzed MeCOMet-Gly peptide was between 80% and 88% after 4 h. This was explained by the existence of the same catalytically active form in the reaction of *cis*-$[Pd(L)(H_2O)_2]^{2+}$ complexes with MeCOMet-Gly peptide complex obtained by the replacement of the chelated diamine ligand from the initially formed binuclear palladium(II)–peptide complex. Giving importance to recent results with sterically crowded *cis*-$[Pd(L)(H_2O)_2]^{2+}$ complexes and histidine- and methionine-containing peptides and the different effects of these complexes on the rate of hydrolytic cleavage of the amide bonds in these peptides, it seemed reasonable to further investigate the reactions of these peptides with new *cis*-$[Pd(L)(H_2O)_2]^{2+}$ type complexes. The main aim of these investigations was to design a new palladium(II) complex capable of the regioselective cleavage of the amide bond in peptides containing both methionine and histidine amino acids in the side chains.

In the present study, *cis*-$[Pd(dpa)Cl_2]$ and *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ complexes (dpa is 2,2′-dipyridylamine) were synthesized and employed to investigate their reactions with the dipeptides Met-Gly and His-Gly, and also the reactions of the *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ complex with the *N*-acetylated derivatives of these peptides, MeCOMet-Gly and MeCOHis-Gly. ^{1}H NMR study of the regioselective hydrolytic cleavage of the amide bond in only the MeCOMet-Gly peptide and the absence of this hydrolytic reaction with the other investigated peptides are promising and may help in the development of new palladium(II) complexes as artificial metallopeptidases.

2. Experimental

2.1. Reagents

Distilled water was demineralized and purified to a resistance greater than 10 MΩ cm^{-1}. The compounds D_2O, DNO_3, NaOD, $(CD_3)_2SO$, 2,2′-dipyridylamine (dpa), K_2PdCl_4 were obtained from the Aldrich Chemical Co. All common chemicals were of reagent grade. The dipeptides methionylglycine (Met-Gly) and histidylglycine (His-Gly) were obtained from the Sigma Chemical Co. The terminal amino group in the peptides was acetylated by standard methods [9].

2.2. Synthesis of cis-dichloro(2,2′-dipyridylamine)palladium(II), cis-[Pd(dpa)Cl$_2$]

The *cis*-$[Pd(dpa)Cl_2]$ complex was prepared by a modification of a method described in the literature [10]. K_2PdCl_4 (0.2000 g, 0.61×10^{-4} mol) was dissolved in 25 cm^3 of water, and to this solution an equivalent amount of 2,2′-dipyridylamine (0.1049 g; 0.61×10^{-4} mol) was added. The pH of the solution was adjusted to ca. 3 by the addition of 1 M HCl, which was followed by refluxing for 5 h. If the pH was carefully controlled, a clear color change from brown to yellow was observed during this time. The obtained yellow solution was left overnight at room temperature. The crystals of *cis*-$[Pd(dpa)Cl_2]$ were removed by filtration, washed with a small amount of water, and air dried. Yield 0.1922 g (90%). *Anal.* Calc. for *cis*-$[Pd(dpa)Cl_2] \equiv C_{10}H_9Cl_2N_3Pd$ (FW = 348.52): C, 34.46; H, 2.60; N, 12.06%. Found: C, 34.35; H, 2.70; N, 12.02%. ^{1}H NMR ($(CD_3)_2SO$, 200 MHz); δ 7.15 (t, H5); δ 7.27 (d, H3); δ 7.96 (t, H4); δ 8.58 (dd, H6); δ 11.12 (s, H–N); ^{13}C NMR ($(CD_3)_2SO$, 200 MHz); δ 114.09 (C4); δ 119.01 (C5); δ 141.33 (C3); δ 149.44 (C6); δ 150.83 (C2).

2.3. Synthesis of cis-diaqua(2,2′-dipyridylamine)palladium(II), cis-[Pd(dpa)(H$_2$O)$_2$]$^{2+}$

Because all the solutions were made in D_2O, all the aqua ligands actually were D_2O. However, for simplicity and consistency with our previous publications, we show the D_2O ligands as H_2O. The *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ was prepared from the corresponding chloro complex in the same manner as described in the literature for the preparation of similar Pd(II) aqua complexes [11,12]. The *cis*-$[Pd(dpa)Cl_2]$ complex was treated in D_2O solution with the appropriate amount of $AgNO_3$. The Pd(II) complex and $AgNO_3$ were mixed in a molar ratio of 1:1.95. The mixture was stirred at room temperature in the dark for up to 24 h. The precip-

itated AgCl was removed and the filtrate containing *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ was stored in a refrigerator until used for reaction with the dipeptides.

2.4. Synthesis of bis(2,2′-dipyridylamine)palladium(II) dichloride tetrahydrate, $[Pd(dpa)_2]Cl_2 \cdot 4H_2O$

The schematic presentation of the reaction for the synthesis of the *cis*-$[Pd(dpa)_2]Cl_2 \cdot 4H_2O$ complex is given in Fig. 1. The dipeptide Met-Gly (0.0300 g, 1.45×10^{-4} mol) was dissolved in 4 $cm^3$of water and solid *cis*-$[Pd(dpa)Cl_2]$ (0.0507 g, 1.45×10^{-4} mol) was added to this solution. The pH of the solution was adjusted to ca. 2.4 by the addition of 1 M HCl and then mixture was stirred at 60 °C for 4 h. The precipitate of the unreacted *cis*-$[Pd(dpa)Cl_2]$ was removed, and the filtrate was left in a refrigerator for several days. The light yellow crystals of $[Pd(dpa)_2]Cl_2 \cdot 4H_2O$ were removed by filtration, washed with a small amount of ethanol, and air-dried. Yield 0.0343 g (40%). *Anal.* Calc. for $[Pd(dpa)_2]Cl_2 \cdot 4H_2O = C_{20}H_{26}Cl_2N_6O_4Pd$ (FW = 591.77): C, 40.59; H, 4.43; N, 14.20%. Found: C, 40.06; H, 4.54; N, 14.12%. Spectral characterization: ^{1}H NMR (D_2O, 200 MHz); δ 7.13 (t, H5), δ 7.46 (d, H3); δ 7.61 (d, H4), δ 8.05 (m, H6); ^{13}C NMR (D_2O, 200 MHz); δ 119.41 (C4); δ 125.10 (C5); δ 146.59 (C3); δ 153.48 (C6); δ 155.58 (C2).

2.5. Measurements

All pH measurements were made at 25 °C. The pH meter (Iskra MA 5704) was calibrated with Fischer certified buffer solutions of pH 4.00. The results were not cor-

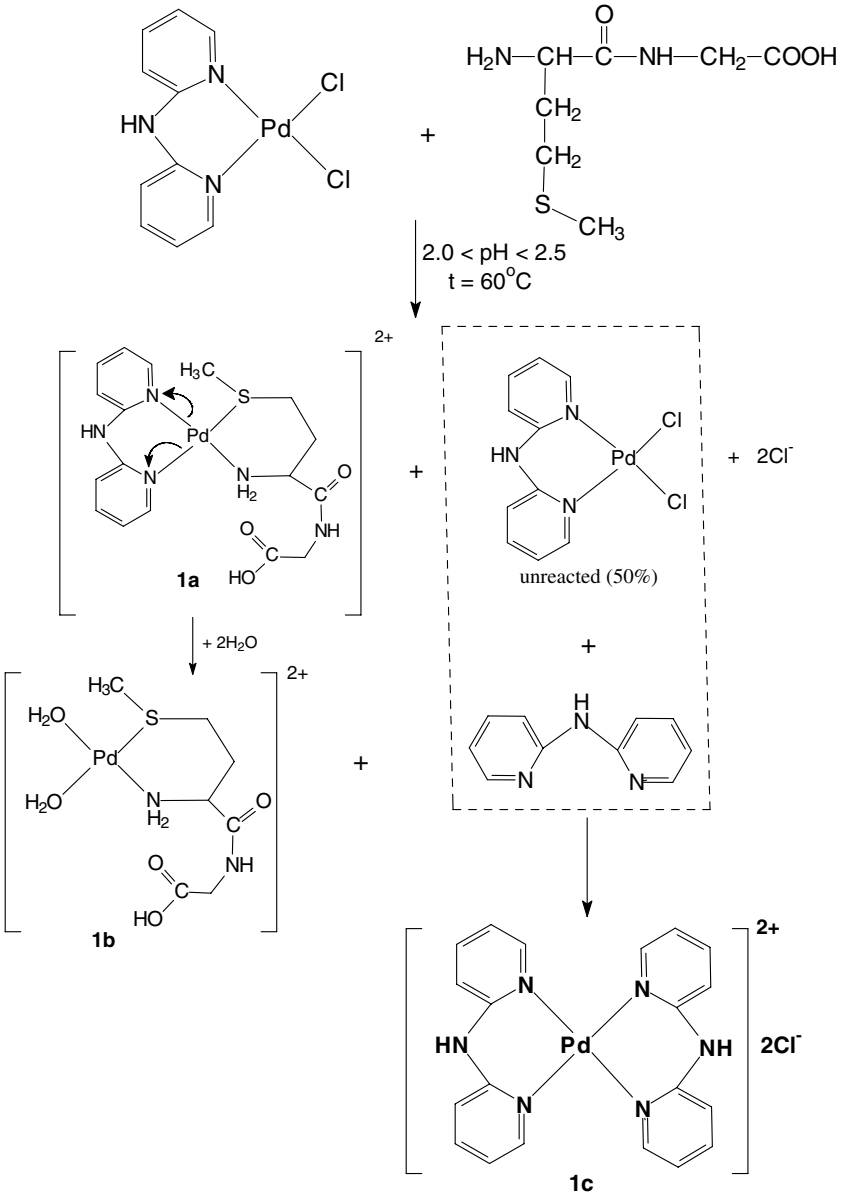

Fig. 1. The reaction scheme between *cis*-$[Pd(dpa)Cl_2]$ and the Met-Gly peptide in the pH range $2.0 < pH < 2.5$ and at 60 °C with the $[Pd(dpa)_2]Cl_2 \cdot 4H_2O$ complex as the final product.

rected for the deuterium isotope effect. The ^{1}H NMR spectra of D_2O solutions containing TSP (3-trimethylsilylpropane-1-sulfonate) as the internal reference were recorded with a Varian Gemini 200 spectrometer. Elemental microanalyses for carbon, hydrogen, and nitrogen were done at the Faculty of Chemistry, University of Belgrade.

2.6. Crystal structure determination of the $[Pd(dpa)_2]Cl_2 \cdot 4H_2O$ complex

The crystal data of the $[Pd(dpa)_2]Cl_2 \cdot 4H_2O$ complex, and the parameters of data collection are summarized in Table 1. The intensity data were measured on a light yellow, plate-like crystal of dimensions $0.25 \times 0.15 \times 0.05$ mm with a KM4CCD kappa-geometry diffractometer [13] using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at ambient temperature, up to the θ value of 25°. The structure was solved by direct methods using SHELXS-86 [14] and refined by least-squares techniques with SHELXL-97 [15]. The intensity data were corrected for Lp effects as well as for absorption. Anisotropic thermal parameters were employed for the non-hydrogen atoms. The hydrogen atoms connected to carbon atoms were placed at the calculated positions while those attached to the water oxygen atoms and the nitrogen atom were located on the subsequent difference Fourier maps. The O–H and N–H bond lengths were standardized to values of 0.85 and 0.90 Å, respectively. All hydrogen atoms were allowed to ride on the atoms to which they were attached and their isotropic displacement parameters were given values 30% higher than the isotropic equivalent for the atom to which the H-atom was bonded. A Siemens Stereochemical Workstation was used to prepare the drawings [16].

3. Results and discussion

^{1}H NMR spectroscopy was applied to study the reactions of the palladium(II) complexes, *cis*-[Pd(dpa)Cl$_2$] and *cis*-[Pd(dpa)(H$_2$O)$_2$]$^{2+}$ (dpa is a bidentate 2,2′-dipyridylamine) with the dipeptides methionylglycine (Met-Gly) and histidylglycine (His-Gly), and the reactions of *cis*-[Pd(dpa)(H$_2$O)$_2$]$^{2+}$ with the *N*-acetylated derivatives of these dipeptides, MeCOMet-Gly and MeCOHis-Gly. All reactions were carried out with equimolar amounts of the palladium(II) complex and the peptide in the pH range 2.0–2.5 and at two different temperatures, 25 and 60 °C. As was shown in previous studies [1–3,17], acidic solutions are needed to suppress the formation of hydroxo-bridged oligomeric palladium(II) complexes, which are catalytically inactive.

3.1. Reactions of the cis-$[Pd(dpa)Cl_2]$ and cis-$[Pd(dpa)(H_2O)_2]^{2+}$ complexes with Met-Gly and His-Gly

In the reactions between *cis*-[Pd(dpa)Cl$_2$] and *cis*-[Pd(dpa)(H$_2$O)$_2$]$^{2+}$ and the peptides Met-Gly or His-Gly, no hydrolysis of the peptide bond was observed in the pH range 2.0–2.5, neither at 25 °C, nor at 60 °C. The signal at 3.80 ppm for the methylene protons of the free glycine did not appear in the ^{1}H NMR spectrum even after the reaction mixture had been kept at 60 °C for 7 days. Upon addition of glycine to the reaction mixture, its resonance at the above mentioned chemical shift appeared immediately. The reaction scheme between *cis*-[Pd(dpa)Cl$_2$] and Met-Gly is given in Fig. 1. A similar reaction pathway can be presumed for the reaction of *cis*-[Pd(dpa)(H$_2$O)$_2$]$^{2+}$ with this peptide, or any of these two palladium(II) complexes with the His-Gly peptide. As can be seen from Fig. 1, one of the final products in these reactions is the square-planar $[Pd(dpa)_2]^{2+}$ complex (**1c**). The preparation of this complex starting from *cis*-[Pd(dpa)Cl$_2$] and the Met-Gly peptide has been described in the experimental part of this paper and the crystal structure of $[Pd(dpa)_2]Cl_2 \cdot 4H_2O$ was confirmed by X-ray diffraction. The absence of hydrolysis of the peptide bond in the reactions between the Pd(II) complexes and Met-Gly, or His-Gly peptides is in accordance with previous results obtained for the Pd(II) complexes and Met-X or His-X peptides (X is an aliphatic amino acid) containing a non-acetylated N-terminal amino group [7]. The final product in these reactions was an extremely stable palladium(II)–peptide complex in which the Pd(II) ion is bound through the sulfur donor atom of methionine, or the N3 imidazole nitrogen atom of histidine, and the nitrogen atom of the N-terminal amino group [18]. This mode of coordination holds the Pd(II) complex away from the downstream peptide bond and prevents its cleavage. It is well established that for the cleavage of the peptide bond involving the carboxylic group of histidine, or methionine, in the His-X and Met-X peptides, it is always necessary to protect their N-terminus amino group [1–3,7].

When an equimolar amount of *cis*-[Pd(dpa)Cl_2] was incubated with Met-Gly at $2.0 < pH < 2.5$ and at 60 °C, the intermediate palladium(II)–peptide complex **1a** was formed (Fig. 1). In this complex, the peptide is bidentate coordinated to the Pd(II) ion via the methionine sulfur atom and the N-terminal amino group. In the reaction with His-Gly, the bidentate coordination of this peptide occurs through the N3 imidazole nitrogen atom and the N-terminal amino group. The coordination of the Pd(II) ion to the methionine sulfur atom can easily be detected in the ^{1}H NMR spectrum. The signal at 2.14 ppm for the CH_3–S protons of the free Met-Gly was decreased, while the signal at 2.54 ppm, corresponding to these protons of the peptide bound to Pd(II) ion through the sulfur atom, appeared in the spectrum. The amount of the palladium(II)–peptide complex **1a** formed in this reaction was calculated by integration of these two signals. This reaction was rather slow, what is opposed to previous results and the well established high affinity of Pt(II) and Pd(II) ions for sulfur-containing ligands [19,20]. The inhibition of this reaction is additionally supported by the steric hindrance between the dpa ligand and the entering Met-Gly peptide in the square-planar [Pd(dpa)(Met-Gly-*S*,*N*)]$^{2+}$ complex **1a**. Approximately 50% of the *cis*-[Pd(dpa)Cl_2] complex had reacted after 2 h at 60 °C. When this reaction was carried out at 25 °C, less than 50% of the complex had reacted after more than 12 h. The next step after the formation of the complex **1a** is the release of the dpa ligand from palladium(II) and its displacement by water molecules, whereby complex **1b** is formed (Fig. 1). The conversion of **1a** into **1b** was very fast and owing to the overlap of the signals corresponding to the protons in free dpa and in the palladium(II)–peptide complex **1a**, multiplet in the region 7.00–8.50 ppm, the displacement of the dpa ligand by water molecules could not be followed by ^{1}H NMR spectroscopy. The fast release of the dpa ligand is also supported by the acidic medium and by the *trans* effect of the coordinated sulfur atom [21]. The liberated dpa ligand further reacts with unreacted *cis*-[Pd(dpa)Cl_2] complex producing the [Pd(dpa)$_2$]$Cl_2 \cdot 4H_2O$ complex **1c**, as one of the final products of the investigated reaction. The latter complex was also obtained in a separate experiment starting from *cis*-[Pd(dpa)Cl_2] and the dpa ligand. The reaction of *cis*-[Pd(dpa)Cl_2] complex with His-Gly was three times slower than that with the Met-Gly peptide, finally resulting in a very small yield of the [Pd(dpa)$_2$]$Cl_2 \cdot 4H_2O$ complex.

3.2. Description of the crystal structure of [Pd(dpa)$_2$]$Cl_2 \cdot 4H_2O$

The title compound consists of a square-planar-coordinated [Pd(dpa)$_2$]$^{2+}$ cation, chloride anions and water molecules (Fig. 2). It represents one of the five Pd(dpa) complexes hitherto investigated by X-ray diffraction [22–24]. The asymmetric unit contains half of the Pd(dpa)$_2$ cation located on an inversion center, two independent Cl^- counterions and two independent solvent water molecules. The Pd(II) ion is four coordinated and bonded in a bidentate fashion to two pyridine rings of the two dpa ligands (Fig. 2). The values of bond lengths and angles, describing the geometry of the complex are presented in Table 2. The distances between the metal center and the N-donor atoms (2.017(3) and 2.024(3) Å) correspond to the mean value of 2.017(4) Å calculated for the variously substituted Pd(dpa) units [23,25–30] (28 observations in the CSD [31]), and the dpa ligand bite angle is 86.16(12)°, rather small in relation to the Pd(II) center, smaller than in the other four Pd(dpa) complexes investigated by X-ray diffraction [22–24], where this value is in the range 87.8–91.8°. The two pyridine rings of the dpa moiety are twisted with respect to each other with a dihedral angle of 42.8(1)°. Again this angle is much larger than the values found in the CSD for Pd(dpa) complexes, which range from 16.2° to 31.3°. There seems to be an inverse relationship between the dpa ligand bite angle and the degree of mutual bending of the pyridine rings of the

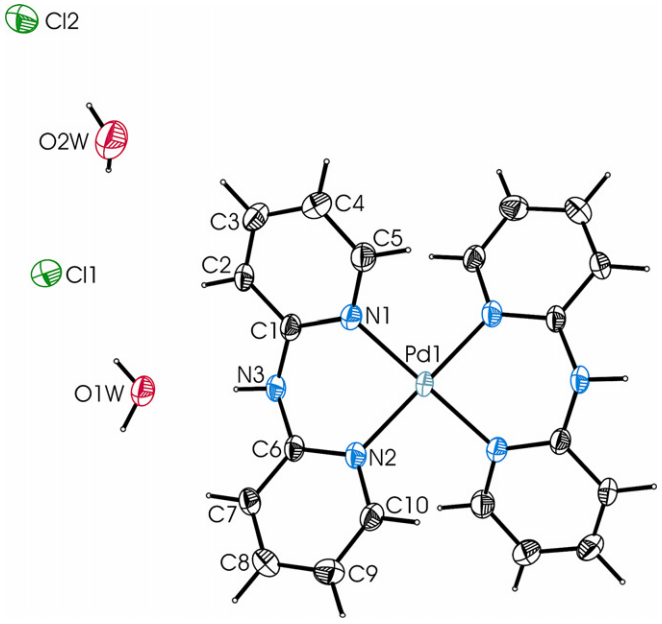

Fig. 2. View of the complex cation with accompanying chloride counterions and water molecules. Displacement ellipsoids for non-H atoms are shown at the 40% probability level. Only symmetry independent atoms are labeled. Generation of the second half of the complex cation requires the symmetry operation $-x, -y, 1-z$.

Table 2
Selected bond distances (Å) and angles (°)

Bond distance (Å)		Bond angle (°)	
Pd(1)–N(2)	2.017(3)	N(2)[a]–Pd(1)–N(1)	93.84(12)
Pd(1)–N(1)	2.024(3)	N(2)–Pd(1)–N(1)	86.16(12)

		C(1)–N(3)–C(6)	123.4(3)

[a] Atom was generated by inversion.

dpa. The chelate six-membered ring adopts a boat conformation with Pd1 and N3 in the flagpole positions, pointing in the same direction, although the deviation of N3 from the plane of the chelate is smaller than that of Pd1 (0.374(4) versus 0.842(4) Å, respectively). Two chloride anions (Cl2 and its translational equivalent along b) are located above and below the PdN_4 plane but the value of the Pd···Cl^- distance (3.879(2) Å) excludes any bonded interaction.

The solvent water molecules act as double donors to the chloride atoms and either do not accept hydrogen bonds (O2w) or act as single acceptor (O1w) from N–H group of the ligand. Each chloride anion accepts four hydrogen bonds from four neighboring water molecules, with an average O(H)···Cl distance of 3.203(30) Å. The water molecules and the chloride ions form hydrogen bonded tapes oriented along the *c* axis and consisting of $R_4^2(8)$ synthons, as shown in Fig. 3. A search of the CSD [31] affords 534 structures with the water–chloride $R_4^2(8)$ motif, nevertheless, this type of water–chloride cluster seems to have been overlooked in studies on halide ion hydration [32,33]. The hydrogen bond parameters are listed in Table 3. Uninterrupted tapes formed by $R_4^2(8)$ synthons connected in a spiro fashion bind together the columns of Pd(II) cations complexed by the organic ligand. Within the columns, weak off-face stacking interactions between one of the pyridine rings (N2, C6, C7, C8, C9 and C10) and its symmetry equivalent ($-1/2 - x$, $1/2 - y$, $1 - z$) are observed with the distance between the centroids equal to 4.135(3) Å (Fig. 4).

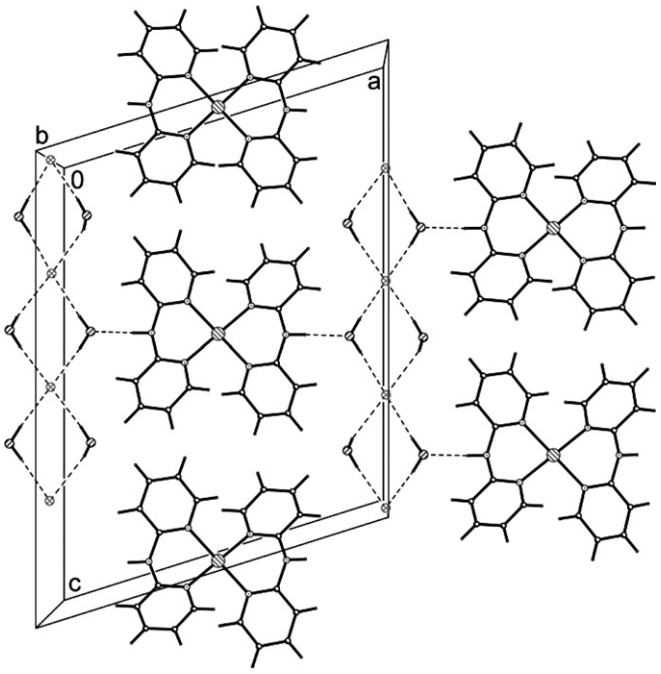

Fig. 3. Supramolecular $R_4^2(8)$ motifs consisting of hydrogen bonded chloride anions and water molecules join together into tapes in a spiro mode. The tapes bind to the metal–organic regions via water molecules acting as acceptors of protons from the N–H groups of the ligand.

3.3. Reactions of *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ with MeCOMet-Gly and MeCOHis-Gly

The reactions between *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ and the *N*-acetylated dipeptides, MeCOMet-Gly and MeCOHis-Gly, were carried out at $2.0 < pH < 2.5$ and at two different temperature, 25 and 60 °C. The schematic presentations of the investigated reactions are given in Fig. 5. In the reaction between this Pd(II) complex and the MeCOMet-Gly peptide, regioselective cleavage of the amide bond involving the carboxylic group of methionine was observed. This hydrolytic reaction can be followed successfully using ^1H NMR spectroscopy. The mixing of the palladium(II) complex with an equimolar amount of MeCOMet-Gly resulted in the spontaneous coordination of the palladium(II) com-

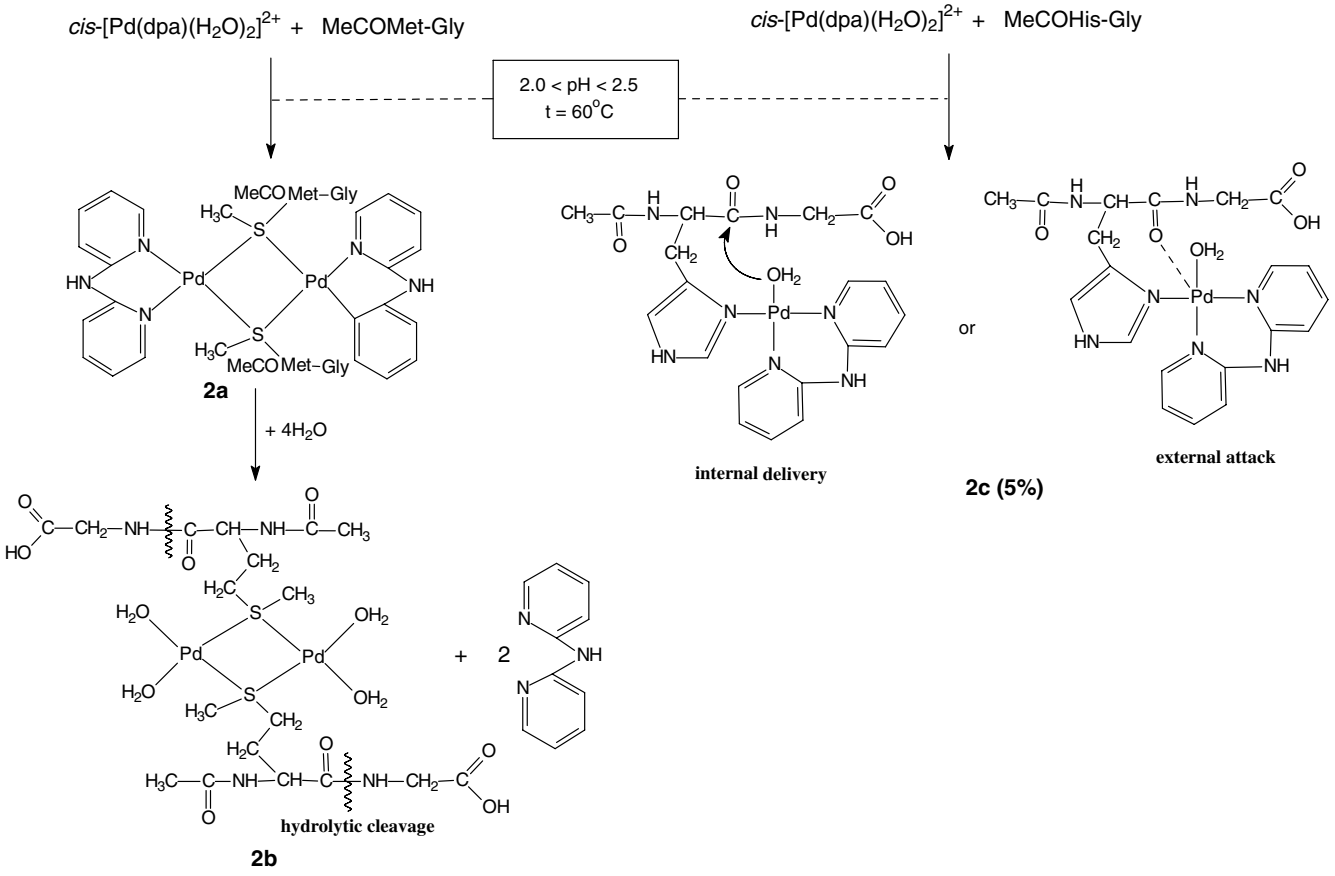

Fig. 5. Different pathways of the hydrolytic reactions between *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ and the *N*-acetylated dipeptides, MeCOMet-Gly and MeCOHis-Gly, in the pH range $2.0 < pH < 2.5$ and at 60 °C. The regioselective cleavage of the amide bond in the peptide containing a methionine residue.

plex to the sulfur atom of the methionine residue. The binding of palladium(II) to the methionine side chain is very fast and can be easily detected in the ^1H NMR spectrum, as was already explained for the reaction of the Pd(II) complexes with the Met-Gly peptide. The resonance at 3.94 ppm corresponding to the glycine protons of the non-hydrolyzed MeCOMet-Gly decreased while that at 3.60 ppm for free glycine increased. Upon addition of glycine to the reaction mixture, its resonance was enhanced. The amounts of the non-hydrolyzed peptide and the hydrolysis products were determined from the known initial concentration of MeCOMet-Gly and from the integrated resonance of the free glycine. Some of the liberated glycine reacts with the catalyst to form a small amount of the *cis*-$[Pd(dpa)(Gly\text{-}N,O)]^+$ complex, which is easily detected by ^1H NMR spectroscopy by the resonance at 3.52 ppm. Indeed, the same complex is formed upon the mixing of equimolar amounts of *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ and glycine. The catalytic ability of the *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ complex in the investigated reaction was determined by measuring the amount of the hydrolyzed MeCOMet-Gly with time under the same experimental conditions. The concentrations of the free and the hydrolyzed MeCOMet-Gly were determined every 30 min and the reaction was followed for 72 h. It was found that 25% of the MeCOMet-Gly had hydrolyzed at 60 °C after 2 h, and 90% when the reaction was carried out for 72 h. When the reaction was performed at 25 °C, only 40% of the MeCOMet-Gly had hydrolyzed after 10 days of reaction.

The hydrolytic reactions of methionine-containing peptides with palladium(II) complexes have been studied in great detail by Milović and Kostić [7]. From the NMR spectra, it was concluded that different promoters produce different hydrolytically active palladium(II)–peptide complexes. When the promoter was $[PdCl_4]^{2-}$, the active form is a mononuclear palladium(II)–peptide complex, whereas with $[Pd(H_2O)_4]^{2+}$ as promoter, a binuclear complex was formed, with the two sulfur atoms of the two methionine side chains as bridges and water molecules in unspecified terminal positions. It was shown that this binuclear complex was more efficient than the corresponding mononuclear complex in promoting the hydrolysis of the scissile amide bond. Additionally, it was found that with methionine-containing peptides and *cis*-$[Pd(en)(H_2O)_2]^{2+}$ (en is ethylenediamine), *cis*-$[Pd(Me_4en)(H_2O)_2]^{2+}$ (Me_4en is *N*,*N*,*N*′,*N*′-tetramethylethylenediamine), and *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ (py is pyridine) complexes, the nitrogen coordinated ligands were replaced with water molecules, and presumably the same active complex was formed as from $[Pd(H_2O)_4]^{2+}$ [34]. These results are in agreement with results recently obtained in the reactions of MeCOMet-Gly with the series palladium(II) complexes of the type *cis*-

$[Pd(L)(H_2O)_2]^{2+}$ (L is 1,2-propylenediamine, isobutylenediamine, 1,2-diaminocyclohexane, *N*-methylethylenediamine) [8]. As is shown in Fig. 5, from the intermediate binuclear palladium(II)–peptide complex **2a**, the a bidentate dpa ligand had been displaced by water molecules, forming the catalytically active palladium(II)–peptide complex **2b**. The replacement of the chelated dpa ligand by water molecules is very fast and this reaction is additionally supported by the *trans*-effect of the bridged sulfur atom of the methionine side chain and the acidic medium. The binuclear complex **2b** was also observed by Chen et al. in the reaction of *cis*-$[Pd(en)(H_2O)_2]^{2+}$ and *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ with MeCOMet-Gly [34]. As all the aqua ligands in complex **2b** are in the *cis* position to the substrate, anyone of them can be delivered to the scissile peptide bond.

In the reaction between *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ and MeCOHis-Gly at $2.0 < pH < 2.5$ and at 60 °C, cleavage the amide bond of neither His-Gly nor MeCO–His was observed. The intensities of the resonances at 3.94 ppm for the glycine protons and 2.00 ppm for the methyl protons of free MeCOHis-Gly remained unchanged under these experimental conditions even when the reaction was prolonged to 7 days. During this time, the resonances at 3.60 ppm for free glycine and 2.08 ppm for the methyl protons of acetic acid, both possible hydrolytic products if cleavage of the amide bonds occurs, did not appear in the ^1H NMR spectrum. The schematic presentation of this reaction is given in Fig. 5. MeCOHis-Gly was used as a model peptide for the study of the mechanism of the regioselective cleavage of the amide bond catalyzed by *cis*-$[Pd(L)(H_2O)_2]^{2+}$ type complexes (L is a bidentate diamine ligand) [1–3,5,7,35]. It was shown that in the reaction between this peptide and *cis*-$[Pd(en)(H_2O)_2]^{2+}$ complexes at $pH < 3$, five palladium(II)–peptide products were formed [1]. These complexes were distinguished on the basis of the chemical shifts of two imidazole protons, H-2 and H-5. Experiments with MeCOHis-Gly selectively methylated at the N-1 or N-3 atom of imidazole and *cis*-$[Pd(en)(H_2O)_2]^{2+}$ showed that only the palladium(II) complex with monodentate coordination to the N-3 atom of imidazole can affect the cleavage of the amide bond involving the carboxylic group of histidine; none of the four other modes of coordination is effective [2]. These findings were explained in terms of two possible limiting mechanisms, external and internal, for the hydrolytic cleavage of the peptide bond promoted by palladium(II) [1–3]. As can be seen from Fig. 5, both of these mechanisms presented for the palladium(II)–peptide complex **2c** require the close approach of the pendant catalyst to the adjacent peptide bond, and in both cases the steric bulk of the palladium(II) complex hinders this crucial interaction. The *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ complex is sterically very demanding because the two bulky pyridine rings in the dpa ligand, contain a large π-electron density and are close to the palladium(II) center and thus hinder its approach to the MeCOHis-Gly. It has been shown that in the reaction with this peptide in the pH range 2.0–2.5 and at 60 °C only 5% of the *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ had reacted after 7 days of reaction. The very slow reaction of this complex with the MeCOHis-Gly peptide can be attributed to the large steric hindrance between the dpa ligand of the palladium(II) complex and the entering imidazole ring of the histidine side chain, finally resulting in the total inhibition of the investigated hydrolytic reaction.

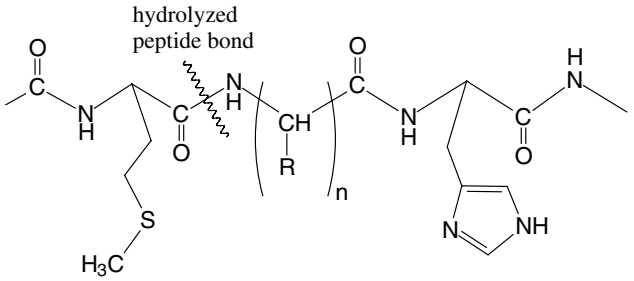

Fig. 6. Schematic presentation of the possible regioselective cleavage of the amide bond involving the carboxylic group of methionine in the proposed polypeptide containing both methionine and histidine residues promoted by the *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ complex.

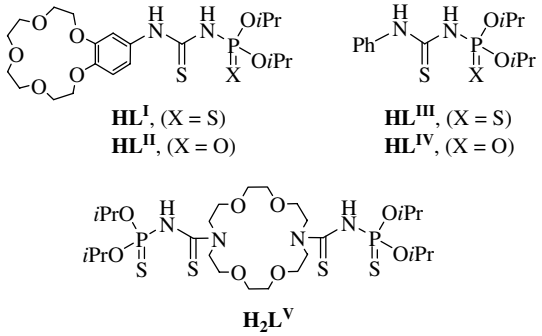
4. Conclusions and prospects

Summing up, the sole product of the reaction between *cis*-$[Pd(dpa)Cl_2]$ or *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ and the peptides Met-Gly or His-Gly is the square-planar $[Pd(dpa)_2]^{2+}$ complex, indicating that no hydrolysis of the peptide bond occurs in the pH range 2.0–2.5, neither at 25 °C nor at 60 °C. On the other hand, the reaction of the *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ complex with the MeCOHis-Gly or MeCOMet-Gly peptides under the same experimental conditions is remarkably selective in the cleavage of the amide bond involving the carboxylic group of methionine. The schematic representation of the regioselective hydrolytic cleavage of the amide bond in the theoretically proposed polypeptide containing both methionine and histidine residues is given in Fig. 6. The modes of coordination of *cis*-$[Pd(dpa)Cl_2]$ in the reactions with the non-acetylated Met-Gly and His-Gly peptides and the total steric inhibition of the hydrolytic reaction of MeCOHis-Gly peptide with the *cis*-$[Pd(dpa)(H_2O)_2]^{2+}$ complex can be attributed to the steric bulk of the palladium(II) complex. This finding should be taken into consideration in designing new palladium(II) complexes for the regioselective cleavage of peptides and proteins. Studies aimed at investigating these new possible synthetic metalpeptidases are in progress.

5. Supplementary material



CCDC 622748 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 1.

$[K(Me_2CO)PhC(S)NP(S)(OiPr)_2]$ [10], $[K(MeOH)PhC(O)NP(S)Ph_2]$ [11] also have polymeric structures in the crystal form. A similar situation is observed for salts of imidodiphosphinate ligands $R_2P(X)NHP(Y)R'_2$ [12,13].

The monomeric structure is characteristic for complexes of alkali salts of *N*-phosphorylamides and thioamides with crown-ether molecules $[M(crown)PhC(Y)NP(X)(OiPr)_2]$, (X, Y = O, S; $M = Na^+$, K^+; crown = 18-crown-6, dibenzo-18-crown-6, 1,10-diaza-18-crown-6). Depending on the nature of the atoms X and Y, the ligand anion in a crystal may have monodentate or bidentate coordination with the cation being situated in a cavity of the macrocycle [6].

It was established that sodium salts of crown-containing thioureas $\mathbf{HL^{I,II}}$ quantitatively precipitate from 96% aqueous ethanol medium and are insoluble in the majority of organic solvents, which allows the separation of Na^+ and K^+ cations. For the other synthesized compounds a similar effect is not displayed.

2. Experimental

2.1. Physical measurements

Infrared spectra (Nujol) were recorded with a Specord M-80 spectrometer in the range 400–3600 cm^{-1}. NMR spectra were obtained on a Varian Unity-300 NMR spectrometer at 25 °C. ^1H and $^{31}P\{^1H\}$ spectra were recorded at 299.948 and 75.429 MHz, respectively. Chemical shifts are reported with reference to $SiMe_4$ (^1H) and H_3PO_4 ($^{31}P\{^1H\}$). Electron ionization high resolution mass spectra of the salts $[\mathbf{NaL^{I,II}}]$ were measured on a TRACE MS Finnigan MAT instrument. The ionization energy was 70 eV. The substance was injected directly into the ion source at 150 °C. Heating was carried out in a programmed mode from 35 to 200 °C at a rate of 35 °C/min. Electrospray ionization mass spectra of the salts $[\mathbf{NaL^{I–IV}}]$, $[\mathbf{KL^{I–IV}}]$, $[\mathbf{Na_2L^{V}}]$, $[\mathbf{K_2L^{V}}]$ were measured with a Thermo Finnigan LCQ mass spectrometer on a 10^{-6} M solution in a $CHCl_3/CH_3OH$ mixture (1:1 v/v). The speed of sample submission was 3 μL/min. The ionization energy was 4.1 kV. The capillary temperature was 210 °C. Electrospray ionization mass spectra of the salts $[\mathbf{LiL^{I,III,IV}}]$, $[\mathbf{BaL_2^{I,III,IV}}]$, $[\mathbf{Li_2L^{V}}]$, $[\mathbf{BaL^{V}}]$ were measured with a Finnigan-Mat TCQ 700 mass spectrometer on a 10^{-6} M solution in CH_3OH. The speed of sample submission was 2 μL/min. The ionization energy was 4.5 kV. The capillary temperature was 200 °C. Elemental analyses were performed with a Perkin–Elmer 2400 CHN microanalyzer. Flame atomic absorption and emission spectrophotometry measurements were performed on a Hitachi Z-6100 Polarized Zeeman Atomic Absorption Spectrophotometer (Hitachi, Japan). An acetylene-air flame and standard 10 cm burner were used for the analyte atomization. For sodium determination a hollow cathode lamp (MITORIKA Co., Japan) was operated at 10 mA; 589.0 nm was selected as the analytical line. Potassium was detected in the emission mode of the spectrophotometer at 766.5 nm. Slit widths were 0.4 and 1.3 nm, respectively. Background correction was used for potassium determination. A stock solution of potassium was prepared from highly pure solid KCl. Working standard solutions were freshly prepared by diluting appropriate aliquots of the stock solution in high-purity water. Quantification of potassium was made from a linear calibration curve.

2.2. Experiment I

Sodium hydroxide was used for the preparation of a Na^+ cation solution. To a solution of $\mathbf{HL^{I}}$ (104.4 mg, 0.2 mmol) in 96% aqueous ethanol (3 mL) a solution of NaOH (8 mg, 0.2 mmol) in 96% aqueous ethanol (3 mL) was added. The initial concentration of Na^+ cations was 33.33 mmol/L (766.67 mg/L). Formation of a white deposit was observed. The solution settled within 15 min. Then 3 mL of solution was taken, the solvent was evaporated and the solid residue was dissolved in the same volume of deionized water. Then the concentration of Na^+ cations was determined. The concentration of Na^+ cations was at the level of the limit of detection of the device, ~0.00044 mmol/L (~0.01 mg/L).

2.3. Experiment II

Sodium and potassium hydroxides were used for preparation of a Na^+ and K^+ cation mixture solution. To a solution of $\mathbf{HL^{I}}$ (104.4 mg, 0.2 mmol) in 96% aqueous ethanol (3 mL) a solution of NaOH (4.0 mg, 0.1 mmol) and KOH (5.6 mg, 0.1 mmol) in 96% aqueous ethanol (3 mL) was added. The initial concentration of Na^+ and K^+ cations was 16.66 mmol/L (383.33 and 650.00 mg/L, respectively). Formation of a white deposit was observed. The solution settled within 15 min. Then 3 mL of solution was taken, the solvent was evaporated and the solid residue was dissolved in the same volume of deionized water. Then the concentration of Na^+ cations was determined. The concentration of Na^+ cations was at the level of the limit of detection of the device, ~0.00044 mmol/L (~0.01 mg/L). For definition of the concentration of K^+ cations 1 mL of a solution was taken and deionized water (249 mL) was added. The concentration of K^+ cations was 16.62 mmol/L (648.05 mg/L).

2.4. Synthesis of HL^{I-IV} (general procedure)

A solution of amine (5.2 mmol) in anhydrous CH_2Cl_2 (15 mL) was treated under vigorous stirring with a solution of $(i\text{PrO})_2\text{P(X)NCS}$ (X = O, S) (5.2 mmol) in anhydrous CH_2Cl_2 (15 mL). The mixture was stirred for an additional 30 min to complete the reaction. The solvent was removed in vacuo, and the product was purified by crystallization from a methylene chloride/*n*-hexane mixture (1:5 v/v).

HL^{I} was prepared using 4′-aminobenzo-15-crown-5 and $(i\text{PrO})_2\text{P(S)NCS}$. M.p. 94 °C. ^{1}H NMR ($CDCl_3$): $\delta = 1.36$ (d, $^3J_{H,H} = 6.2$ Hz, 12H, CH_3), 3.64–4.62 (m, 16H, CH_2), 4.84 (d. sept, $^3J_{POCH} = 10.6$ Hz, $^3J_{H,H} = 6.2$ Hz, 2H, OCH), 6.80–6.83 (m, 1H, H^3, C_6H_3), 6.86–6.60 (m, 1H, H^2, C_6H_3), 7.04 [d, $^2J_{PNH} = 6.1$ Hz, 1H, NHP(S)], 7.23 (s, 1H, H^1, C_6H_3), 9.59 (s, 1H, NH) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = 52.8$ ppm. IR: $\tilde{\nu} = 640$ (P═S), 980 (POC), 1140 (COC), 1520, 1556 (S═C–N), 3220, 3280 (NH) cm^{-1}. *Anal.* Calc. for $C_{21}H_{35}N_2O_7PS_2$ (522.16): C, 48.26; H, 6.75; N, 5.36. Found: C, 48.28; H, 6.76; N, 5.34%.

HL^{II} was prepared using 4′-aminobenzo-15-crown-5 and $(i\text{PrO})_2\text{P(O)NCS}$. Yield: 1.394 g (53%). M.p. 120 °C. ^{1}H NMR ($CDCl_3$): $\delta = 1.38$ (d, $^3J_{H,H} = 6.0$ Hz, 6H, CH_3), 1.39 (d, $^3J_{H,H} = 6.1$ Hz, 6H, CH_3), 3.68–4.22 (m, 16H, CH_2), 4.73 (d. sept, $^3J_{POCH} = 7.1$ Hz, $^3J_{H,H} = 6.3$ Hz, 2H, OCH), 6.81 [s, 1H, NHP(O)], 6.82–6.85 (m, 1H, H^3, C_6H_3), 7.01–7.04 (m, 1H, H^2, C_6H_3), 7.32 (s, 1H, H^1, C_6H_3), 10.66 (s, 1H, NH) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = -5.8$ ppm. IR: $\tilde{\nu} = 1000$ (POC), 1140 (COC), 1216 (P═O), 1516, 1564 (S═C–N), 3136, 3280 (NH) cm^{-1}. *Anal.* Calc. for $C_{21}H_{35}N_2O_8PS$ (506.19): C, 49.79; H, 6.96; N, 5.53. Found: C, 49.81; H, 6.95; N, 5.56%.

HL^{III} was prepared using aniline and $(i\text{PrO})_2\text{P(S)NCS}$. M.p. 86 °C (85 °C, Ref. [14]). ^{1}H NMR ($CDCl_3$): $\delta = 1.29$ (d, $^3J_{H,H} = 5.9$ Hz, 6H, CH_3), 1.30 (d, $^3J_{H,H} = 6.2$ Hz, 6H, CH_3), 4.78 (d. sept, $^3J_{POCH} = 10.4$ Hz, $^3J_{H,H} = 6.2$ Hz, 2H, OCH), 7.03 [s, 1H, NHP(S)], 7.14–7.17 (m, 1H, *p*-H, C_6H_5), 7.28–7.31 (m, 2H, *m*-H, C_6H_5), 7.43–7.47 (m, 2H, *o*-H, C_6H_5), 9.57 (s, 1H, NH) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = 55.1$ ppm. IR: $\tilde{\nu} = 636$ (P═S), 1000 (POC), 1536 (S═C–N), 3063, 3200 (NH) cm^{-1}.

HL^{IV} was prepared using aniline and $(i\text{PrO})_2\text{P(O)NCS}$. M.p. 125 °C (124–125 °C, Ref. [15]) ^{1}H NMR ($CDCl_3$): $\delta = 1.39$ (d, $^3J_{H,H} = 6.0$ Hz, 6H, CH_3), 1.40 (d, $^3J_{H,H} = 6.1$ Hz, 6H, CH_3), 4.75 (d. sept, $^3J_{POCH} = 7.3$ Hz, $^3J_{H,H} = 6.2$ Hz, 2H, OCH), 6.94 [d, $^2J_{PNH} = 6.1$ Hz, 1H, NHP(O)], 7.21–7.24 (m, 1H, *p*-H, C_6H_5), 7.37–7.41 (m, 2H, *m*-H, C_6H_5), 7.58–7.61 (m, 2H, *o*-H, C_6H_5), 10.78 (s, 1H, NH) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = -5.3$ ppm. IR: $\tilde{\nu} = 1012$ (POC), 1216, 1244 (P═O), 1508 (S═C–N), 3136, 3304 (NH) cm^{-1}.

2.5. Synthesis of H_2L^V

This was prepared similarly to compounds **HL^{I-IV}** using 1,10-diaza-18-crown-6 and a double amount of $(i\text{PrO})_2$P(S)NCS. M.p. 128 °C (129–132 °C, Ref. [16]). ^{1}H NMR ($CDCl_3$): $\delta = 1.32$ (d, $^3J_{H,H} = 5.9$ Hz, 24H, CH_3), 3.48–4.28 (m, 24H, CH_2), 4.91 (d. sept, $^3J_{POCH} = 10.8$ Hz, $^3J_{H,H} = 6.0$ Hz, 4H, OCH), 8.83 [d, $^2J_{PNH} = 8.1$ Hz, 2H, NHP(S)] ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = 60.6$ ppm. IR: $\tilde{\nu} = 616$ (P═S), 976 (POC), 1100 (COC), 1520 (S═C–N), 3152 (NH) cm^{-1}.

2.6. Alkali and barium(II) salts of thioureas HL^{I-IV} and H_2L^V

The salts were obtained by a common technique. A suspension of **HL^{I-IV}** (1.2 mmol) in aqueous ethanol (15 mL) was mixed with an ethanol solution (15 mL) of lithium, sodium, potassium hydroxide [1.3 or 2.6 mmol (8% surplus)] or barium hydroxide [0.65 or 1.3 mmol (8% surplus)]. The mixture was stirred at room temperature for a further 1 h. The solvent was then removed in vacuo. A colorless precipitate was recrystallized from an ethanol/*n*-hexane mixture. Compounds [**ML**], [**BaL$_2$**], [**M$_2$L^V**] and [**BaL^V**] were obtained as white powders.

2.6.1. $[LiL^I]$

Yield: 0.393 g (62%). M.p. 87 °C. ^{1}H NMR (D_2O): $\delta = 1.30$ (d, $^3J_{H,H} = 6.1$ Hz, 12H, CH_3), 3.68–4.26 (m, 16H, CH_2), 4.73 (m, 2H, OCH), 6.92–7.02 (m, 2H, H^2+H^3, C_6H_3), 7.18 (s, 1H, H^1, C_6H_3) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 64.4$ ppm. IR: $\tilde{\nu} = 616$ (P═S), 1004 (POC), 1120 (COC), 1523 (SCN), 3218 (NH) cm^{-1}. ES-MS (positive ion): *m*/*z* (%) = 529.1 (100) $[LiL+H]^+$, 566.9 (33.9) $[LiL+CH_3OH+Li]^+$, 1081.2 (18.4) $[Li_2L_2+H_2O+Li]^+$, 1609.3 (2.9) $[Li_3L_3+H_2O+Li]^+$. *Anal.* Calc. for $C_{21}H_{34}LiN_2O_7PS_2$ (628.17): C, 47.72; H, 6.48; N, 5.30. Found: C, 47.75; H, 6.50; N, 5.28%.

2.6.2. $[NaL^I]$

Yield: 0.640 g (98%). M.p. 197 °C. ^{1}H NMR (D_2O): $\delta = 1.26$ (d, $^3J_{H,H} = 6.1$ Hz, 12H, CH_3), 3.64–4.18 (m, 16H, CH_2), 4.75 (m, 2H, OCH), 6.87–6.90 (m, 1H, H^2, C_6H_3), 6.93–6.96 (m, 1H, H^3, C_6H_3), 7.13 (s, 1H, H^1, C_6H_3) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 65.9$ ppm. IR: $\tilde{\nu} = 610$ (P═S), 1002 (POC), 1133 (COC), 1532 (SCN), 3190 (NH) cm^{-1}. EI-HRMS: *m*/*z* = 463.17945 (exact mass = 463.17936) $[NaL-NaNCS]^+$, 488.17939 (exact mass = 488.17461) $[NaL-NaSH]^+$. ES-MS (positive ion): *m*/*z* (%) = 545.0 (100) $[NaL+H]^+$, 566.9 (5.0) $[NaL+Na]^+$, 1128.9 (5.6) $[Na_2L_2+H_2O+Na]^+$. ES-MS (negative ion): *m*/*z* (%) = 521.0 (41.9) $[L]^-$, 1065.0 (100) $[NaL+L]^-$, 1608.7 (4.4) $[Na_2L_2+L]^-$. *Anal.* Calc. for $C_{21}H_{34}N_2NaO_7PS_2$ (544.14): C, 46.31; H, 6.29; N, 5.14. Found: C, 46.33; H, 6.27; N, 5.15%.

2.6.3. $[KL^I]$

Yield: 0.349 g (52%). M.p. 181 °C. ^{1}H NMR (D_2O): $\delta = 1.24$ (d, $^3J_{H,H} = 6.3$ Hz, 6H, CH_3), 1.25 (d, $^3J_{H,H} = 6.1$ Hz, 6H, CH_3), 3.62–4.24 (m, 16H, CH_2), 4.82 (m, 2H, OCH), 6.86–6.89 (m, 1H, H^2, C_6H_3),

6.91–6.94 (m, 1H, H^3, C_6H_3), 7.13 (s, 1H, H^1, C_6H_3) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 64.7$ ppm. IR: $\tilde{\nu} = 608$ (P═S), 1016 (POC), 1128 (COC), 1512 (SCN), 3232 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 561.0 (100) $[KL+H]^+$, 679.7 (4.9) $[KL+CHCl_3+K]^+$, 1139.9 (44.4) $[K_2L_2+H_2O+H]^+$, 1683.6 (0.9) $[K_3L_3+H]^+$. ES-MS (negative ion): m/z (%) = 521.0 (76.3) $[L]^-$, 1080.8 (11.9) $[KL+L]^-$, 1099.9 (100) $[KL+H_2O+L]^-$, 1659.7 (6.3) $[K_2L_2+H_2O+L]^-$. *Anal.* Calc. for $C_{21}H_{34}KN_2O_7PS_2$ (560.12): C, 44.98; H, 6.11; N, 5.00. Found: C, 44.95; H, 6.13; N, 5.02%.

2.6.4. [BaL^I_2]

Yield: 0.404 g (57%). M.p. 190 °C. ^1H NMR (D_2O): $\delta = 1.31$ (d, $^3J_{H,H} = 6.2$ Hz, 12H, CH_3), 3.68–4.32 (m, 16H, CH_2), 6.41–6.43 (m, 1H, H^2, C_6H_3), 6.56 (s, 1H, H^1, C_6H_3), 6.89–6.92 (m, 1H, H^3, C_6H_3) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 64.5$ ppm. IR: $\tilde{\nu} = 604$ (P═S), 1024 (POC), 1160 (COC), 1533 (SCN), 3384 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 545.1 (100) $[NaL+H]^+$, 586.9 (45.5) $[HL+2CH_3OH+H]^+$, 595.1 (86.9) $[NaL+CH_3OH+H_2O+H]^+$, 717.9 (34.5) $[BaL+2CH_3OH]^+$, 1837.0 (6.2) $[Ba_2L_3]^+$. *Anal.* Calc. for $C_{42}H_{68}BaN_4O_{14}P_2S_4$ (1180.21): C, 42.73; H, 5.81; N, 4.75. Found: C, 42.75; H, 5.78; N, 4.77%.

2.6.5. [NaL^{II}]

Yield: 0.596 g (94%). M.p. 183 °C. ^1H NMR (D_2O): $\delta = 1.26$ (d, $^3J_{H,H} = 6.0$ Hz, 6H, CH_3), 1.27 (d, $^3J_{H,H} = 6.2$ Hz, 6H, CH_3), 3.62–4.20 (m, 16H, CH_2), 4.57 (m, 2H, OCH), 6.93 (s, 2H, H^2+H^3, C_6H_3), 7.12 (s, 1H, H^1, C_6H_3) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 8.0$ ppm. IR: $\tilde{\nu} = 1020$ (POC), 1216 (P═O), 1132 (COC), 1528 (SCN), 3208 (NH) cm^{-1}. EI-HRMS: $m/z = 447.20059$ (exact mass = 447.20220) $[NaL-NaNCS]^+$, 472.19688 (exact mass = 472.19745) $[NaL-NaSH]^+$. ES-MS (positive ion): m/z (%) = 529.0 (100) $[NaL+H]^+$, 550.9 (21.9) $[NaL+Na]^+$, 1096.9 (8.1) $[Na_2L_2+H_2O+Na]^+$, 1624.9 (0.9) $[Na_3L_3+H_2O+Na]^+$. ES-MS (negative ion): m/z (%) = 505.1 (7.5) $[L]^-$, 1033.1 (100) $[NaL+L]^-$, 1561.1 (10.6) $[Na_2L_2+L]^-$. *Anal.* Calc. for $C_{21}H_{34}N_2NaO_8PS$ (528.17): C, 47.72; H, 6.48; N, 5.30. Found: C, 47.70; H, 6.45; N, 5.32%.

2.6.6. [KL^{II}]

Yield: 0.291 g (43%). M.p. 186 °C. ^1H NMR (D_2O): $\delta = 1.28$ (d, $^3J_{H,H} = 6.1$ Hz, 6H, CH_3), 1.29 (d, $^3J_{H,H} = 6.1$ Hz, 6H, CH_3), 3.60–4.26 (m, 16H, CH_2), 4.58 (d. sept, $^3J_{POCH} \approx {}^3J_{H,H} \approx 6.3$ Hz, 2H, OCH), 6.94 (s, 2H, H^2+H^3, C_6H_3), 7.15 (s, 1H, H^1, C_6H_3) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 8.1$ ppm. IR: $\tilde{\nu} = 1024$ (POC), 1196 (P═O),1128 (COC), 1520 (SCN), 3232 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 545.0 (100) $[KL+H]^+$, 1107.9 (38.9) $[K_2L_2+H_2O+H]^+$, 1635.6 (1.3) $[K_3L_3+H]^+$. ES-MS (negative ion): m/z (%) = 504.5 (21.3) $[L]^-$, 1067.9 (100) $[KL+H_2O+L]^-$, 1595.9 (18.1) $[K_2L_2+L]^-$, 1612.4 (21.9) $[K_2L_2+H_2O+L]^-$. *Anal.* Calc. for $C_{21}H_{34}KN_2O_8PS$ (544.14): C, 46.31; H, 6.29; N, 5.14. Found: C, 46.33; H, 6.27; N, 5.15%.

2.6.7. [LiL^{III}]

Yield: 0.276 g (68%). M.p. 58 °C. ^1H NMR (D_2O): $\delta = 1.31$ (d, $^3J_{H,H} = 6.0$ Hz, 12H, CH_3), 6.58–7.52 (m, 5H, *o*-H+*m*-H+*p*-H, C_6H_5) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 68.4$ ppm. IR: $\tilde{\nu} = 618$ (P═S), 993 (POC), 1536 (SCN), 3328 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 339.0 (16.8) $[LiL+H]^+$, 694.9 (100) $[Li_2L_2+H_2O+H]^+$, 683.1 (38.4) $[Li_2L_2+Li]^+$, 1037.0 (29.7) $[Li_3L_3+Na]^+$, 1359.2 (8.3) $[Li_4L_4+Li]^+$, 1375.1 (4.6) $[Li_4L_4+Na]^+$. *Anal.* Calc. for $C_{13}H_{20}LiN_2O_2PS_2$ (338.09): C, 46.15; H, 5.96; N, 8.28. Found: C, 46.18; H, 5.99; N, 8.24%.

2.6.8. [NaL^{III}]

Yield: 0.353 g (83%). M.p. 108 °C. ^1H NMR (D_2O): $\delta = 1.32$ (d, $^3J_{H,H} = 6.0$ Hz, 12H, CH_3), 4.77 (d. sept, $^3J_{POCH} \approx {}^3J_{H,H} \approx 6.3$ Hz, 2H, OCH), 7.15–7.18 (m, 1H, *p*-H, C_6H_5), 7.35–7.39 (m, 2H, *m*-H, C_6H_5), 7.43–7.47 (m, 2H, *o*-H, C_6H_5) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 64.3$ ppm. IR: $\tilde{\nu} = 612$ (P═S), 1012 (POC), 1516 (SCN), 3336 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 354.9 (38.4) $[NaL+H]^+$, 725.9 (100) $[Na_2L_2+H_2O+H]^+$, 1084.6 (51.6) $[Na_3L_3+Na]^+$, 1100.6 (30.3) $[Na_3L_3+2H_2O+H]^+$, 1438.6 (18.8) $[Na_4L_4+Na]^+$, 1454.5 (15.1) $[Na_4L_4+2H_2O+H]^+$, 1792.4 (11.3) $[Na_5L_5+Na]^+$. ES-MS (negative ion): m/z (%) = 330.8 (17.5) $[L]^-$, 684.7 (100) $[NaL+L]^-$, 1038.5 (29.7) $[Na_2L_2+L]^-$, 1392.2 (5.9) $[Na_3L_3+L]^-$, 1746.1 (1.3) $[Na_4L_4+L]^-$. *Anal.* Calc. for $C_{13}H_{20}N_2NaO_2PS_2$ (354.06): C, 44.06; H, 5.69; N, 7.90. Found: C, 44.08; H, 5.70; N, 7.88%.

2.6.9. [KL^{III}]

Yield: 0.329 g (74%). M.p. 119 °C. ^1H NMR (D_2O): $\delta = 1.30$ (d, $^3J_{H,H} = 6.1$ Hz, 12H, CH_3), 4.77 (m, 2H, OCH), 7.13–7.17 (m, 1H, *p*-H, C_6H_5), 7.34–7.38 (m, 2H, *m*-H, C_6H_5), 7.40–7.44 (m, 2H, *o*-H, C_6H_5) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 64.5$ ppm. IR: $\tilde{\nu} = 616$ (P═S), 1004 (POC), 1544 (SCN), 3256 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 408.9 (18.1) $[KL+K]^+$, 759.9 (100) $[K_2L_2+H_2O+H]^+$, 778.7 (55.9) $[K_2L_2+K]^+$, 1132.5 (35.3) $[K_3L_3+Na]^+$, 1150.5 (33.8) $[K_3L_3+K]^+$, 1502.1 (10.6) $[K_4L_4+Na]^+$, 1521.3 (13.8) $[K_4L_4+K]^+$, 1877.1 (19.4) $[K_5L_5+K]^+$. ES-MS (negative ion): m/z (%) = 330.9 (29.7) $[L]^-$, 700.7 (100) $[KL+L]^-$, 1070.2 (12.8) $[K_2L_2+L]^-$, 1441.2 (2.8) $[K_3L_3+L]^-$, 1809.9 (1.6) $[K_4L_4+L]^-$. *Anal.* Calc. for $C_{13}H_{20}KN_2O_2PS_2$ (370.03): C, 42.14; H, 5.44; N, 7.56. Found: C, 42.12; H, 5.45; N, 7.60%.

2.6.10. [BaL^{III}_2]

Yield: 0.389 g (81%). M.p. 143 °C. ^1H NMR (D_2O): $\delta = 1.31$ (d, $^3J_{H,H} = 6.2$ Hz, 12H, CH_3), 4.75 (m, 2H, OCH), 7.14–7.18 (m, 1H, *p*-H, C_6H_5), 7.35–7.39 (m, 2H, *m*-H, C_6H_5), 7.42–7.46 (m, 2H, *o*-H, C_6H_5) ppm. $^{31}P\{^1H\}$

NMR (D_2O): $\delta = 64.4$ ppm. IR: $\tilde{\nu} = 615$ (P═S), 1013 (POC), 1540 (SCN), 3320 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 334.0 (60.1) $[HL+H]^+$, 470.1 (45.0) $[BaL]^+$, 802.9 (100) $[BaL_2+H]^+$, 1272.3 (14.3) $[Ba_2L_3]^+$. *Anal.* Calc. for $C_{26}H_{40}BaN_4O_4P_2S_4$ (800.05): C, 39.03; H, 5.04; N, 7.00. Found: C, 39.00; H, 5.07; N, 7.02%.

2.6.11. [LiL^{IV}]

Yield: 0.228 g (59%). M.p. 44 °C. ^1H NMR (D_2O): δ = 1.30 (d, $^3J_{H,H} = 6.1$ Hz, 12H, CH_3), 4.62 (m, 2H, OCH), 6.59–7.55 (m, 5H, *o*-H+*m*-H+*p*-H, C_6H_5) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 12.1$ ppm. IR: $\tilde{\nu} = 1012$ (POC), 1208 (P═O), 1542 (SCN), 3218 (NH) cm^{-1}. ES-MS (positive ion): m/z (%) = 323.0 (11.5) $[LiL+H]^+$, 663.0 (100) $[Li_2L_2+H_2O+H]^+$, 1003.1 (52.9) $[Li_3L_3+2H_2O+H]^+$, 1307.3 (6.3) $[Li_4L_4+H_2O+H]^+$. *Anal.* Calc. for $C_{13}H_{20}LiN_2O_3PS$ (322.11): C, 48.45; H, 6.25; N, 8.69. Found: C, 48.44; H, 6.27; N, 8.72%.

2.6.12. [NaL^{IV}]

Yield: 0.239 g (59%). M.p. 181 °C. ^1H NMR (D_2O): $\delta = 1.30$ (d, $^3J_{H,H} = 6.3$ Hz, 6H, CH_3), 1.31 (d, $^3J_{H,H}$ = 5.9 Hz, 6H, CH_3), 4.61 (d. sept, $^3J_{POCH} \approx {}^3J_{H,H} \approx 6.2$ Hz, 2H, OCH), 7.13–7.17 (m, 1H, *p*-H, C_6H_5), 7.36–7.40 (m, 2H, *m*-H, C_6H_5), 7.42–7.46 (m, 2H, *o*-H, C_6H_5) ppm. $^{31}P\{^1H\}$ NMR (D_2O): $\delta = 8.1$ ppm. IR: $\tilde{\nu} = 1028$ (POC), 1176 (P═O), 1532 (SCN), 3224 (NH) cm^{-1}. 2.6.18. [BaL^V]

Yield: 0.967 g (92%). M.p. 185 °C. ^1H NMR (D_2O): $\delta = 1.33$ (d, $^3J_{H,H} = 6.2$ Hz, 12H, CH_3), 1.34 (d, $^3J_{H,H}$ = 6.2 Hz, 12H, CH_3), 3.68–4.22 (m, 24H, CH_2), 4.74 (m, 4H,

OCH) ppm. $^{31}P\{^{1}H\}$ NMR (D_2O): $\delta = 62.2$ ppm. IR: $\tilde{\nu} = 612$ (P=S), 996 (POC), 1154 (COC), 1564 (SCN) cm^{-1}. ES-MS (positive ion): m/z (%) = 504.3 (33.1) $[H_2L-(iPrO)_2P(S)NCS+H]^+$, 640.5 (57.2) $[BaL-(iPrO)_2P(S)NCS]^+$, 879.9 (100) $[BaL+H]^+$, 903.3 (14.5) $[BaL+Na]^+$. *Anal.* Calc. for $C_{26}H_{52}BaN_4O_8P_2S_4$ (876.12): C, 35.64; H, 5.98; N, 6.39. Found: C, 35.66; H, 5.97; N, 6.41%.

2.7. Crystal structure determination and refinement

The X-ray diffraction data for the crystals of **[K(Me$_2$CO)L^{III}]** and **HL^{III}** were collected on a CAD4 Enraf-Nonius automatic diffractometer using graphite monochromated Mo Kα (0.71073 Å) and Cu Kα (1.54184 Å) radiation. The crystal data, data collection and the refinement are given in Table 1. The stability of the crystals and the experimental conditions were checked every 2 h using three control reflections, while the orientation was monitored every 200 reflections by centering two standards. No significant decay was observed. An empirical absorption correction based on ψ-scans was applied. The structures were solved by a direct method using the SIR [17] program and refined by full matrix least-squares using SHELXS-97 [18] program. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated and refined as riding atoms. All calculations were performed on PC using the WinGX [19] program. Cell parameters, data collection and data reduction were performed on an Alpha Station 200 computer using the MolEN [20] program. All figures were made using the program PLATON [21].

3. Results and discussion

3.1. Synthesis

Thioureas **HL$^{I–IV}$** and **H$_2$L^{V}** were synthesized by treatment of 4′-aminobenzo-15-crown-5, aniline, or 1,10-diaza-18-crown-6 with isothiocyanates of diisopropylthiophosphoric and diisopropylphosphoric acids, respectively. The structures of the obtained compounds were confirmed by IR, ^{1}H, and ^{31}P NMR spectroscopy.

Salts of thioureas **HL$^{I–IV}$** and **H$_2$L^{V}** of the formulae **[LiL^{I,III,IV}]**, **[NaL$^{I–IV}$]**, **[KL$^{I–IV}$]**, **[Ba(L^{I,III,IV})$_2$]**, **[M$_2$L^{V}]**, and **[BaL^{V}]** have been obtained by treatment with the hydroxide of the corresponding metal ($M = Li^+$, Na^+, K^+) in 96% aqueous ethanol medium. All salts are solid and stable in air.

Interaction of **HL^{I}** with NaOH in 96% aqueous ethanol medium results in a plentiful precipitate of white color. The same process is observed for thiourea **HL^{II}** but it takes nearly for 15 min under similar conditions. The precipitates are insoluble in the majority of organic solvents (alcohol, acetone, acetonitrile, methylene chloride, benzene, toluene, tetrahydrofuran, dioxane) and slightly soluble in water, dimethylsulfoxide and dimethylformamide. According to the microanalysis they have the composition **[NaL^{I,II}]**.

This phenomenon has induced us to investigate the structures and properties of the proximate analogues of **[NaL^{I,II}]**. Salts of the formulae **[ML$^{I–IV}$]**, **[Ba(L^{I,III,IV})$_2$]**, **[M$_2$L^{V}]**, and **[BaL^{V}]** ($M = Li^+$, Na^+, K^+) were isolated and characterized for the first time. It was established that for none of them was a reduction in solubility observed. On the contrary, there is an expected increase in solubility of the obtained salts in polar organic solvents.

Crystals of the solvate **[K(Me$_2$CO)L^{III}]** were obtained by recrystallization from an acetone/*n*-hexane mixture of **[KL^{III}]**. The structure was investigated by X-ray analysis.

The structures of the obtained compounds were proven by IR, ^{1}H, and ^{31}P NMR spectroscopy, ES-MS experiments (electrospray method) and the composition was confirmed by microanalysis.

3.2. IR and NMR spectroscopy

The IR spectra of **HL$^{I–IV}$** contain two absorption bands for the NH groups in the ranges: 3200–3304 (narrow band) and 3063–3220 (wide intensive band) cm^{-1}. There is only one absorption band for the NH group at 3152 cm^{-1} in the spectrum of **H$_2$L^{V}**.

The P=S group absorption bands for **HL^{I,III}** and **H$_2$L^{V}** are observed in the characteristic area: 616–640 m^{-1} [6,22]. The IR spectra of **HL^{II,IV}** contain strong bands at 1216–

1244 m^{-1} due to the P=O group. Besides very strong absorption bands for the POC group in the region 976–1000 cm^{-1}, there are bands of the COC groups at 1100–1140 m^{-1} in the IR spectra of $\mathbf{HL^{I,II}}$ and $\mathbf{H_2L^V}$, containing crown-ether fragments. Presence of a wide absorption band of the POC fragment in $\mathbf{HL^{III,IV}}$ in the area 1000–1012 cm^{-1} also unequivocally confirms the substituted phosphoric fragment.

The phosphorus atoms of $\mathbf{HL^{I–IV}}$ and $\mathbf{H_2L^V}$ ligands appear as singlet signals at 52.8–60.6 (X = S) and −5.2 to −5.8 (X = O) ppm in the $^{31}P\{^1H\}$ NMR spectra. The observed chemical shift ranges are typical for neutral N-thiophosphorylated and N-phosphorylated thioureas respectively [6,14,23].

Consideration of the ^1H NMR spectra of $\mathbf{HL^{I–IV}}$ and $\mathbf{H_2L^V}$ allows a structure of the obtained compounds to be established definitively and to confirm the fact of interaction of the isothiocyanate with the NH_2 or NH groups of the corresponding amines. In the ^1H NMR spectra of $\mathbf{HL^{I,II}}$ and $\mathbf{H_2L^V}$, containing crown-ether cycles, the signals for the CH_2 protons are at 3.48–4.62 ppm. Integrated intensities of these signals correspond to 16 protons for thioureas $\mathbf{HL^{I,II}}$ and to 24 protons for the thiourea $\mathbf{H_2L^V}$.

The IR spectra of $[\mathbf{ML^{I–IV}}]$ and $[\mathbf{BaL_2}]$ contain the unique absorption band of ArNH groups at 3190–3384 cm^{-1}, whereas no NH group bands are observed for $[\mathbf{M_2L^V}]$ and $[\mathbf{BaL^V}]$. In the spectra of all obtained salts there are intense absorption bands of the conjugated SCN group in the area 1490–1564 cm^{-1} [6]. The absorption bands of the P=S and P=O groups in the IR spectra of the salts are at 604–618 and 1156–1216 cm^{-1}, respectively. They are shifted to low frequencies relative to the band of the parent ligands.

The $^{31}P\{^1H\}$ NMR signals of the obtained salts appear at $\delta = 62.1–68.4$ (X = S) and 8.0–12.1 (X = O) ppm, respectively, with a downfield shift relative to that of the free ligands.

The ^1H NMR spectroscopy unequivocally testifies to the preservation of the ligand structure on deprotonation. In all cases there is a single set of signals for the ligand protons. The integrated intensities of the signals correspond to the offered structure. The signals for the ArNH group protons are absent in the ^1H NMR spectra because of an exchange with the solvent (D_2O).

In the ^1H NMR spectra of the thiourea salts containing crown-ether cycles, the signals for the CH_2 protons are at 3.58–4.32 ppm. Integrated intensities of these signals correspond to the proposed structures.

3.3. EI and ES mass spectrometry

The electron impact mass-spectra (EI-MS) of $[\mathbf{NaL^{I,II}}]$ does not contain the molecular ion peaks, which are unstable under the measurement conditions and undergo rearrangement with exhaust fragments [NaSCN] and [NaSH]. The composition of the formed crown-containing amidophosphates [4′-benzo-15-crown-5]NHP(X)(O*i*Pr)$_2$ and carbodiimides [4′-benzo-15-crown-5]N=C=NP(X)(O*i*Pr)$_2$ is confirmed by high resolution EI-MS.

The ES-MS (electrospray method) of the positive and negative ion area shows propensity of the obtained salts to form dimers and polynuclei associations.

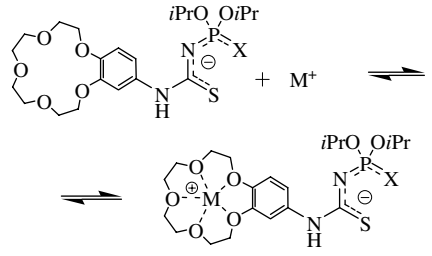
In the ES-MS of $[\mathbf{ML^{III,IV}}]$ the peaks of dimers $[M_2L_2+H_2O+H]^+$ ($M = Li^+$; Na^+; K^+) have maximal intensity. In the salts of $[\mathbf{Ba(L^{III,IV})_2}]$ the peaks with a relative intensity of 100% are fixed for molecular ions of the composition $[BaL_2+H]^+$. The mass spectra also contain peaks of pentanuclei cations of the following composition: $[Na_5L_5+Na]^+$ for $[\mathbf{NaL^{III}}]$, $[K_5L_5+K]^+$ for $[\mathbf{KL^{III}}]$ and $[K_5L_5+2CH_3CN+H]^+$ for $[\mathbf{KL^{IV}}]$. There is a $[Ba_2L_3]^+$ peak in the mass spectrum of $[\mathbf{BaL_2^{III–IV}}]$ with a relative intensity of 14%. Positive ions with a greater weight in the ES-MS of $[\mathbf{BaL_2^{III–IV}}]$ under the measurement conditions were not observed.

ES-MS experiments on $[\mathbf{NaL^{III,IV}}]$ and $[\mathbf{KL^{III}}]$ show peaks for the negative ions. Besides the peaks of $[L]^-$, peaks of the composition $[ML+L]^-$ are fixed with a relative intensity of 100%. There are also peaks of oligomeric composition: $[M_2L_2+L]^-$ (12.9–41.3%), $[M_3L_3+L]^-$ (2.8–19.4%) and $[M_4L_4+L]^-$ (1.3–1.9%).

In the mass spectra of $[\mathbf{ML^{I,II}}]$ salts, in the area of positive ions, the most intense peak belongs to the cation of the composition $[ML+H]^+$. ES-MS of $[\mathbf{LiL^I}]$, $[\mathbf{NaL^{II}}]$ and $[\mathbf{KL^{I,II}}]$ also contain ions of monomer, dimer, and trimer composition, whereas the mass spectrum of $[\mathbf{NaL^I}]$, with the exception of a peak of the composition $[Na_2L_2+H_2O+Na]^+$, does not have peaks of heavier ions. In the mass spectrum of $[\mathbf{Ba(L^I)_2}]$ the peak with the greatest intensity belongs to the cation of composition $[NaL+H]^+$, that, apparently, can indicate the propensity of $\mathbf{HL^I}$ to form the most stable compounds with the sodium cation rather than with the barium one.

In the area of negative ions of $[\mathbf{NaL^{I,II}}]$ and $[\mathbf{KL^{I,II}}]$, besides the peaks of $[L]^-$, the peaks of ions $[NaL+L]^-$ for $[\mathbf{NaL^{I,II}}]$ and $[KL+H_2O+L]^-$ for $[\mathbf{KL^{I,II}}]$, with relative intensity 100%, are observed. Ions of dinuclear composition are also fixed in the ES-MS spectra of these compounds.

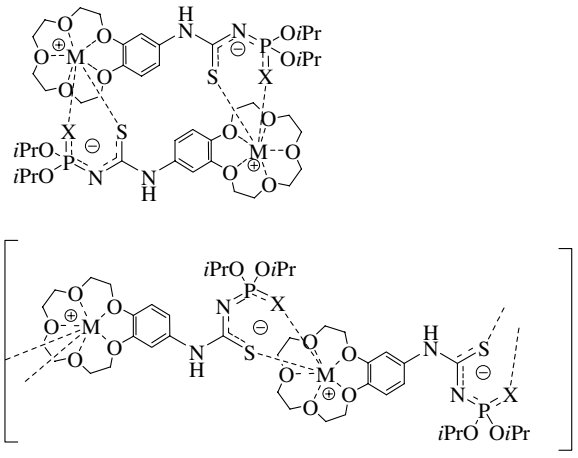
The ES-MS spectra of $[\mathbf{M_2L^V}]$ show peaks for cations of dimer composition $[M_2L_4+M]^+$ ($M = Li^+$, Na^+, K^+). In the area of negative ions of $[\mathbf{Na_2L^V}]$ and $[\mathbf{K_2L^V}]$ there are also intensive peaks for the anion $[\mathbf{H_2L^V}–(i\mathrm{PrO})_2\mathrm{P(S)}\text{-}\mathrm{NCS}–\mathrm{H}]^-$ (9.4–58.1%). Mass spectra of $[\mathbf{Na_2L^V}]$ and $[\mathbf{K_2L^V}]$ contain the peaks of composition $[HL]^-$ and $[M_2L–M]^-$, which have maximal intensity.



3.4. Flame atomic absorption and emission spectrophotometry research of Na^+ and K^+ cation separation using thiourea HL^I

As it has been noted above, interaction of $\mathbf{HL^I}$ with NaOH in 96% aqueous ethanol medium results in precipitation of $[\mathbf{NaL^I}]$. It was interesting to estimate the degree of Na^+ cation precipitation and also to try and separate Na^+

and K^+ cations from an equimolar solution of NaOH and KOH. For the definition of Na^+ and K^+ concentration, the methods of flame atomic absorption spectrophotometry and flame atomic emission spectrophotometry, respectively, have been used.



Our research has shown that precipitation of the salt [$\mathbf{NaL^I}$] results in a fall of concentration of Na^+ cations in solution from 766.67 mg/L to the limit of detection of the device: 0.01 mg/L. It was also established that addition of $\mathbf{HL^I}$ to the equal amount solution of Na^+ and K^+ cations leads to precipitation of Na^+ up to the limit of detection of the device while the concentration of K^+ cations remains constant within the limits of experimental error.

We suppose that the effect of solubility reduction, observable for the salts [$\mathbf{NaL^{I,II}}$], can be connected with a distinction in character of the intermolecular association of these compounds in the solid state. The intramolecular interaction of pendant arms with a cation in the macrocyclic cavity is complicated for compounds $\mathbf{HL^{I,II}}$ in comparison with the crown-ethers, modified by flexible exocyclic groups [1]. We assume that the [$\mathbf{ML^{I,II}}$] salt formation in solution leads to zwitter-ionic molecules (Scheme 2), displaying an expressed propensity for self-association.

Scheme 2.

These zwitter-ions can exist in a crystal phase in the form of ''head-to-tail'' type dimers or polymeric chains (Scheme 3). The presence of the Ar–NH–C moiety in a molecule will allow the realization both of types of interaction. Joint participation of a macrocycle and exocyclic group in complexation in such associates leads to 3D cavity formation, that in turn causes an increase of efficiency and selectivity of the interaction with cations of alkali metals.

Scheme 3.

However, it does not explain the remarkable selectivity toward the sodium cation, found in the case of $\mathbf{HL^{I,II}}$. In our opinion, the observed effect can appear by changing the intermolecular assembly type in the case of [$\mathbf{NaL^{I,II}}$], e.g. formation of a dimer instead of a polymeric structure in the other cases. These changes are caused by the affinity of the Na^+ cation to the cavity of 15-crown-5 and the lower coordination number of Na^+ in comparison with the K^+ cation. Cation desolvatation followed by precipitation of the associates from ethanol medium makes this process irreversible.

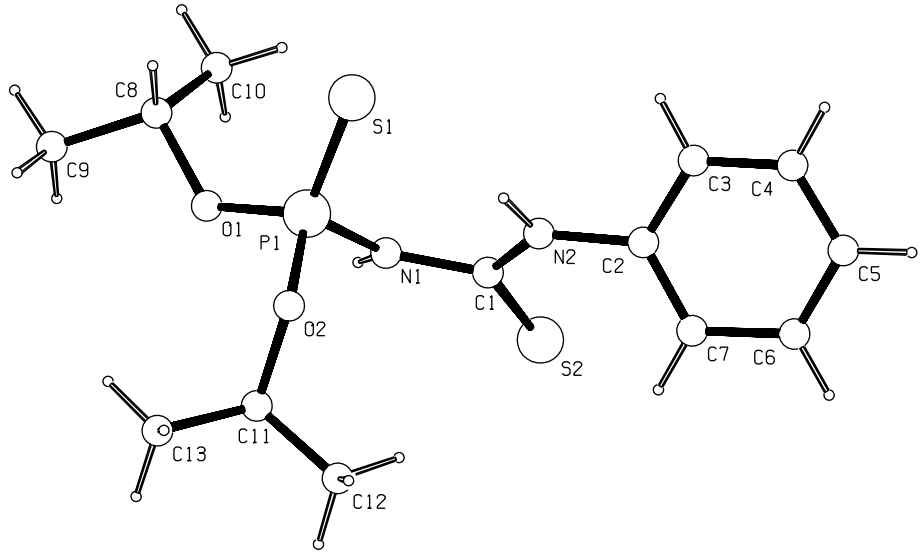


Fig. 1. Molecular structure of $\mathbf{HL^{III}}$.

Additional effective stabilization of di- or polymeric structures can be provided by solid state intermolecular interactions, e.g. intermolecular H-bonding [5]. ArNH-groups could form H-bonds with the sulfur atom of the CS-group – similar to that, found in the crystal of [**K(Me$_2$CO)L^{III}**] (see below) – with oxygen (from the (thio)phosphoryl group or crown-ether moiety), P═S sulfur or P–N nitrogen donor atoms of the neighbor [**ML**] molecule. Obviously, the stabilizing effect of intermolecular hydrogen bonding will strongly differ for different types of the intermolecular assembly. For confirmation of the stated assumptions we are going to carry out additional research, using X-ray diffraction methods and multinuclear NMR spectroscopy in the solid state.

3.5. Crystal structure of *HL^{III}* and *[K(Me$_2$CO)L^{III}]*

Unfortunately, we could not get suitable crystals for structure determination for the salts with crown-containing thioureas. It has induced us to investigate the structure of **HL^{III}** (Fig. 1) and its potassium salt of composition [**K(Me$_2$CO)L^{III}**] (Fig. 2). X-ray data are in Tables 1 and 2.

In a solvate crystal of [**K(Me$_2$CO)L^{III}**] the anion of $[L^{III}]^-$ interacts with the K^+ cation through the sulfur atoms of C═S and P═S groups and an oxygen atom from one *i*PrO group. The coordination number of potassium is supplemented up to six due to interaction with oxygen atoms of two molecules of acetone and a sulfur atom of a P═S group of the neighboring ligand. The coordination environment of potassium can be described as a distorted trigonal prism, on one side of which there are three sulfur atoms, S1, S2, and S2_a, and on the other – oxygen atoms, O1, O40, O40_b (Scheme 4).

Molecules in the crystal form chains due to μ^2-bonds, with participation of POCH oxygen and thiophosphoryl sulfur atoms of the ligands and oxygen atoms of acetone molecules. The chains are parallel to the *oa* plane. The association is similar to the solvate [K(Me$_2$CO)PhC(S)NP(S)(O*i*Pr)$_2$] [10], but in the latter case the ligand forms μ^2-bonds with participation of both sulfur atoms.

Scheme 4.

The negative charge delocalization in the anion $[L^{III}]^-$ results in a characteristic change of bond length in the SCNPS fragment (Table 2) [6]. Bonds C–S and P–S elongate, whereas the C–N and P–N bonds shorten in comparison with a molecule of the neutral ligand $\mathbf{HL^{III}}$. Predictably, the bond N2–C1 increases in length with a reduction of the participation in conjugation of the lone-pair of electrons of N2. In both cases, in a molecule of the ligand it is possible to evolve a planar fragment S2C1N1(N2)P1.

A distinction in the nature of the intermolecular interactions in crystals of $\mathbf{HL^{III}}$ and $[\mathbf{K(Me_2CO)L^{III}}]$ results in the essential distinction of the conformations of the ligand molecules (Table 2). The molecule of $\mathbf{HL^{III}}$ in the crystal has a *syn*-orientation of the bonds C1–S2 and C3–N2 and an *anti*-orientation of the C1–S2 and N1–P1 bonds. The bonds C1–S2 and P1–S1 are in an *anti*-orientation. Such arrangement, apparently, is caused by formation of intramolecular hydrogen bridges N(2)H···S(1) and intermolecular bonds N(1)H···S(2)_a. Parameters for intermolecular hydrogen bonds: N(2)–H(2)···S(1) *d*[N(2)–H(2)] 0.8600, *d*[H(2)···S(1)] 2.47, *d*[N(2)···S(4)] 3.259(4) Å, ∠N(2)H(2)S(4) 152.00°. Parameters for intramolecular hydrogen bonds: N(1)–H(1)···S(2)′ $(2-x, -y, -z)$; *d*[N(1)–H(1)] 0.86, *d*[H(1)···S(2)] 2.60, *d*[N(1)···S(2)]

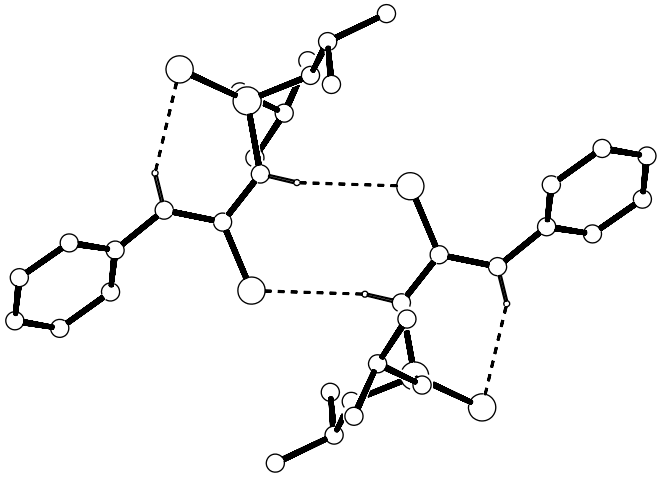

Fig. 3. View of intra- and intermolecular hydrogen bonds NH···S in the crystal of $\mathbf{HL^{III}}$.

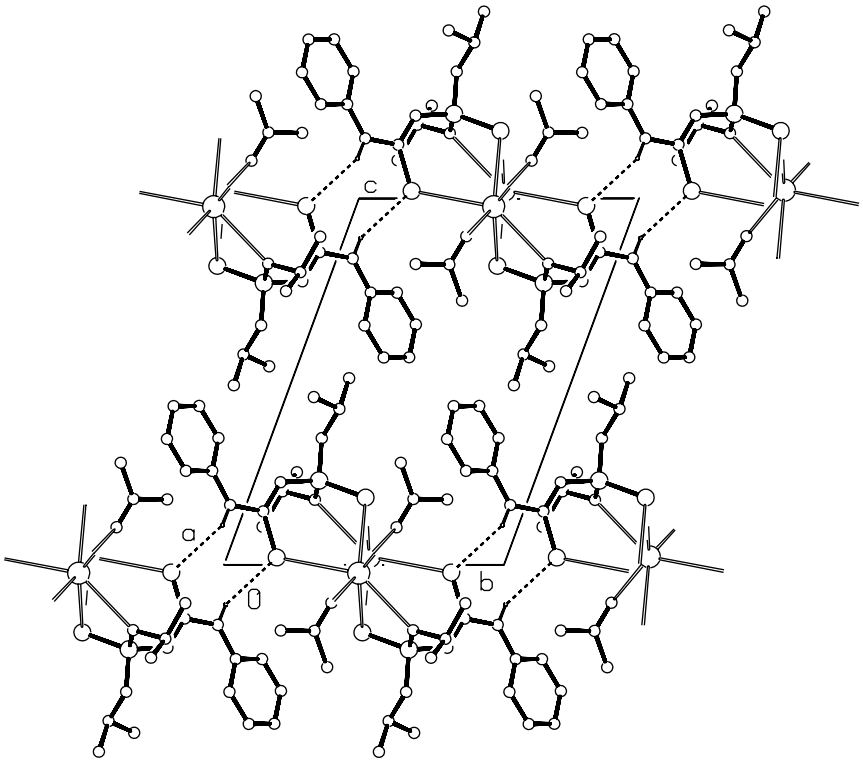

Fig. 4. Structure of molecular layers in a crystal of $[\mathbf{K(Me_2CO)L^{III}}]$.

3.383(3) Å, ∠N(1)H(1)S(2) 151°. As a result of the intermolecular interactions, a centrosymmetric dimer is formed (Fig. 3).

Interaction with the potassium cation results in *gosh*-orientations of the bonds C1–S2 and P1–S1 in the crystal of [**K(Me$_2$CO)L^{III}**]. The geometry of the anion [L^{III}]$^-$ in the crystal is characterized by an *anti*-orientation of the bonds C1–S2 and C3–N2 and a *syn*-orientation of the C1–S2 and N1–P1 bonds.

There are short contacts N(2)H···S(2)_a between molecules of the next polymeric chain in the crystal of [**K(Me$_2$CO)L^{III}**]. The chains, bound by hydrogen bonds, form layers which are parallel to the plane *oab* (Fig. 4). Parameters for intermolecular hydrogen bonds: N(2)–H(2)···S(4)′ (−*x*, −*y*, 2 − *z*) *d*[N(2)–H(2)] 0.9177, *d*[H(2)···S(4)′] 2.7390, *d*[N(2)···S(4)′] 3.597(3) Å, ∠N(2)H(2)S(4)′ 156.04°.

4. Conclusion

The combination of a crown-ether and a negative charged chelating group in a ligand molecule can have unusual consequences. To date we have failed to find another example of alkali ion sedimentation by crown-containing *N*-(thiophosphoryl)thioureas. However we believe that further investigation of the obtained effect would be interesting for the development of new principles of division and concentration of metal ions based on supramolecular interactions of ionic macromolecules.

Well known ways of crown-ether modification are based on intramolecular interactions of additional fragments with a cation in the macrocycle cavity [1], or using additional fragments to form heteronuclei complexes [2,24–26]. However, association in one molecule crown-ether and chelating groups, unable to interact intramolecularly, may be very useful to bind cations of a given type. In this case the effect of recognition can be achieved in two stages: due to selective cation–ligand interaction, and due to interaction of organic molecules after inclusion of the cation in the cavity of the macrocycle.

studied on the human erythrocyte membrane, which suggested the structural perturbations induced by titanium citrate to human erythrocytes can be extended to the other cells, affecting their functions [21]. Moreover, like some other soluble titanium compounds, titanium citrate exerts effects on the growth of plants [22]. In the form of Ti(III) citrate, it has been used extensively to probe redox reactions involving enzyme catalytic functions [23]. In most of the above cases, the titanium citrate complexes are prepared in situ without rigorous characterization. The compositions, spectroscopic and structural properties of titanium citrate require further attention.

Several important Ti(IV) citrate complexes have been structurally characterized recently. This includes several mononuclear titanium complexes, such as $[Ti(H_2cit)_3]^{2-}$ [24], $[Ti(H_2cit)(Hcit)_2]^{4-}$ [25], $[Ti(Hcit)H(cit)_2]^{6-}$ [26] and $[Ti(cit)_3]^{8-}$ [27] having only citrate ligands with different counterions, an oxo titanium complex with a Ti_8O_{10} structural core [28], two tetranuclear [29] and one dinuclear [30] complex of peroxo citrato titanates(IV). Very recently, a trivalent species $[Ti(H_2cit)_2(Hcit)]^{3-}$ has also been reported [31]. The characterization of these complexes represents important progress towards the structural features of the coordination chemistry of Ti(IV) with citrate. However, there has been no systematical study on the different charges of titanium citrate anions from 2 to 8, in which the citrate binds to the titanium(IV) ion via α-alkoxy and α-carboxy groups in 1:3 Ti:citrate ratio. Moreover, the relationship between the isolated solid complexes and the titanium citrate solutions remains unknown. In this paper, the interaction of Ti(IV) with citrate has been investigated in aqueous solution in detail, including the speciation of the soluble titanium citrate complexes and their related pH-dependent transformations, which contain different counterions at different pH values. At the same time, the ^{13}C NMR studies of a titanium citrate solution in a 1:3 mole ratio were also carried out in the pH ranges 2.0–9.0 for comparison.

2. Experimental

Infrared spectra were recorded as Nujol mulls between KBr plates using a Nicolet 360 FT-IR spectrometer. The pH value was measured by the potentiometric method with a digital pH meter. Elemental analyses were performed using an EA 1110 elemental analyzer. ^1H NMR and ^{13}C NMR spectra were recorded on a Varian UNITY 500 NMR spectrometer using DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as an internal reference.

2.1. Preparation of $Na_3[Ti(H_2cit)_2(Hcit)]\cdot 9H_2O$ (1) [31], $K_4[Ti(H_2cit)(Hcit)_2]\cdot 4H_2O$ (2) and $K_5[Ti(Hcit)_3]\cdot 4H_2O$ (3)

A typical procedure was used for the preparation of complex **1**. A quantity of citric acid monohydrate (6.30 g, 30 mmol) was placed in a flask and dissolved in 10 mL of water. Subsequently, titanium tetrachloride (1.90 g, 10 mmol) was added slowly under continuous stirring. Aqueous sodium hydroxide (1.0 M) was then added slowly to adjust the pH value to 3.0. The mixture was filtered. Cold ethanol was added to the clear solution, and the resulting solution was placed in a refrigerator at 4 °C. A week later, colorless crystalline material was deposited. The product was isolated by filtration and dried at room temperature. Yield of complex **1**: 4.3 g (50%). C and H elemental *Anal*. Calc. for $C_{18}H_{35}O_{30}Na_3Ti$: C, 25.5; H, 4.2. Found: C, 25.5; H, 3.9%. IR ν_{as}(COOH) 1704_{vs}; $\nu_{as}(CO_2)$ 1624_{vs}, 1557_{vs}; $\nu_s(CO_2)$ 1425_m, 1325_s; ν_s(Ti–O) 671_s, 641_s, 552_m. ^1H NMR δ_H (500 MHz, D_2O) ppm, 2.708 (d, J 14.0 Hz, CH_2), 2.930 (d, J 14.5 Hz, CH_2); ^{13}C NMR δ_C (D_2O) ppm, 186.1 $(CO_2)_\alpha$; 174.8 $(CO_2)_\beta$; 88.7 (=CO); 43.8 (CH_2).

The above procedure for **1** was utilized except the pH value of the mixture was adjusted to 4.0 or 6.0 with aqueous potassium hydroxide (1.0 M), affording the colorless crystals of **2** and **3**. Yield of complex **2**: 4.2 g (50%). C and H elemental *Anal*. Calc. for $C_{18}H_{23}O_{25}K_4Ti$: C, 25.6; H, 3.0. Found: C, 25.5; H, 3.2%. ν_{as}(COOH) 1725_m, 1709_m, 1700_m; $\nu_{as}(CO_2)$ 1648_{vs}, 1627_{vs}, 1526_w; $\nu_s(CO_2)$ 1441_m, 1347_s, 1311_s; ν_s(Ti–O) 662_m, 646_s, 537_m. ^1H NMR δ_H (500 MHz, D_2O) ppm, 2.713 (d, J 14.0 Hz, CH_2), 2.937 (d, J 14.0 Hz, CH_2); ^{13}C NMR δ_C (D_2O) ppm, 189.0 $(CO_2)_\alpha$; 177.5 $(CO_2)_\beta$; 91.6 (=CO); 46.6 (CH_2). Yield of complex **3**: 3.5 g (40%). C and H elemental *Anal*. Calc. for $C_{18}H_{23}O_{25}K_5Ti$: C, 24.5; H, 2.6. Found: C, 24.3; H, 2.8%. IR (KBr, cm^{-1}): ν_{as}(COOH) 1709_m; $\nu_{as}(CO_2)$ 1629_{vs}; $\nu_s(CO_2)$ 1428_w, 1372_m, 1320_m; ν_s(Ti–O) 649_m, 636_s, 543_m. ^1H NMR δ_H (500 MHz, D_2O) ppm, 2.703 (d, J 14.5 Hz, CH_2), 2.926 (d, J 14.0 Hz, CH_2); ^{13}C NMR δ_C (D_2O) ppm, 189.8 $(CO_2)_\alpha$; 180.2 $(CO_2)_\beta$; 92.1 (=CO); 47.6 (CH_2).

2.2. Preparation of $Na_7[Ti(cit)H(cit)(cit)]\cdot 18H_2O$ (4)

A quantity of citric acid monohydrate (6.30 g, 30 mmol) was placed in a flask and dissolved in 10 mL of water. Subsequently, titanium *n*-butoxide (3.40 g, 10 mmol) was added slowly under continuous stirring. The resulting reaction mixture was taken to dryness at 70 °C in a rotary evaporator. The residue was redissolved in 3 mL of water, and the pH value of the solution was raised to 6.5 with 1.0 M sodium hydroxide. The mixture was filtered. Cold ethanol was added to the solution, and the resulting solution was placed in a refrigerator at 4 °C. A week later, colorless crystalline material was deposited. The product was isolated by filtration and dried at room temperature. Yield: 4.4 g (40%). C and H elemental *Anal*. Calc. for $C_{18}H_{49}O_{39}Na_7Ti$: C, 19.7; H, 4.5. Found: C, 19.9; H, 4.3%. IR (KBr, cm^{-1}): ν(COO···H···OOC) 1632_m; $\nu_{as}(CO_2)$ 1578_{vs}; $\nu_s(CO_2)$ 1403_m, 1351_m; ν_s(Ti–O) 647_m, 553_m. ^1H NMR δ_H (500 MHz, D_2O) ppm, 2.723 (d, J 14.5 Hz, CH_2), 2.956 (d, J 14.5 Hz, CH_2); ^{13}C NMR δ_C (D_2O) ppm, 190.0 $(CO_2)_\alpha$; 189.9, 180.4 $(CO_2)_\beta$; 92.3 (=CO); 47.8 (CH_2).

2.3. Interconversion of $K_4[Ti(H_2cit)(Hcit)_2]\cdot 4H_2O$ (2) to $K_5[Ti(Hcit)_3]\cdot 4H_2O$ (3)

$K_4[Ti(H_2cit)(Hcit)_2]\cdot 4H_2O$ (**2**) (1.69 g, 20 mmol) was dissolved in 5 mL of water at 45 °C. The pH value of the solution was adjusted to ~6.0 with an aqueous solution of 1 M potassium hydroxide under continuous stirring. Cold ethanol was added to the solution, and the resulting solution was placed in a refrigerator at 4 °C. A week later, colorless crystalline material was deposited. The product was isolated by filtration and dried at room temperature. Yield: 0.79 g (45%). In a similar procedure, complex **3** was converted to complex **2** in 60% yield. Positive identification of the crystalline material as complexes **2** and **3** came from the IR spectra and the X-ray unit cell determinations.

2.4. Preparations of the solutions a–e (Ti:H_4cit = 1:3) and NMR studies

Citric acid monohydrate (6.30 g, 30 mmol) was placed in a flask and dissolved in 40 mL of water. Titanium *n*-butoxide (3.40 g, 10 mmol) was added slowly under continuous stirring. All of the free solvent was removed on a rotary evaporator, leaving a fine white powder. Distilled water (40 mL) was added, and the mixture was dissolve at 70 °C. Further reduction on the rotary evaporator removed the solvent from the residual before the solution was diluted to 40 mL with water. The resulting solution was divided into five parts (a–e). The pH value of each solution was adjusted to 2.0, 3.5, 5.0, 7.0 and 9.0 with 1.0 M sodium hydroxide. The volume was maintained at 8 mL after evaporation, resulting in approximately a 0.25 M solution based on Ti. The ^{13}C NMR spectra of the solution were recorded in D_2O after 1 h.

2.5. X-ray data collection, structure solution and refinement

Crystals of **1** and **3** were measured on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated Mo Kα radiation at 296 K. Crystals of **2** and **4** were measured on a Bruker Smart Apex CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 296 K. The data were corrected for Lorentz and polarization effects. An absorption correction was applied using the SADABS program [32]. The structures were primarily solved by direct methods, SHELXS-97 [33], and refined by full-matrix least-squares procedures with anisotropic thermal parameters for all of the non-hydrogen atoms. All calculations were performed on a microcomputer using SHELXL-97 [34]. Hydrogen atoms, except those of O4 and O14 of complex **4** and the disordered water molecules of the four complexes, were calculated geometrically and refined riding on their parent atoms as usual. A summary of the crystallographic data for **1**–**4** is given in Table 1. Selected bond distances and angles of the four complexes are listed in Table 2.

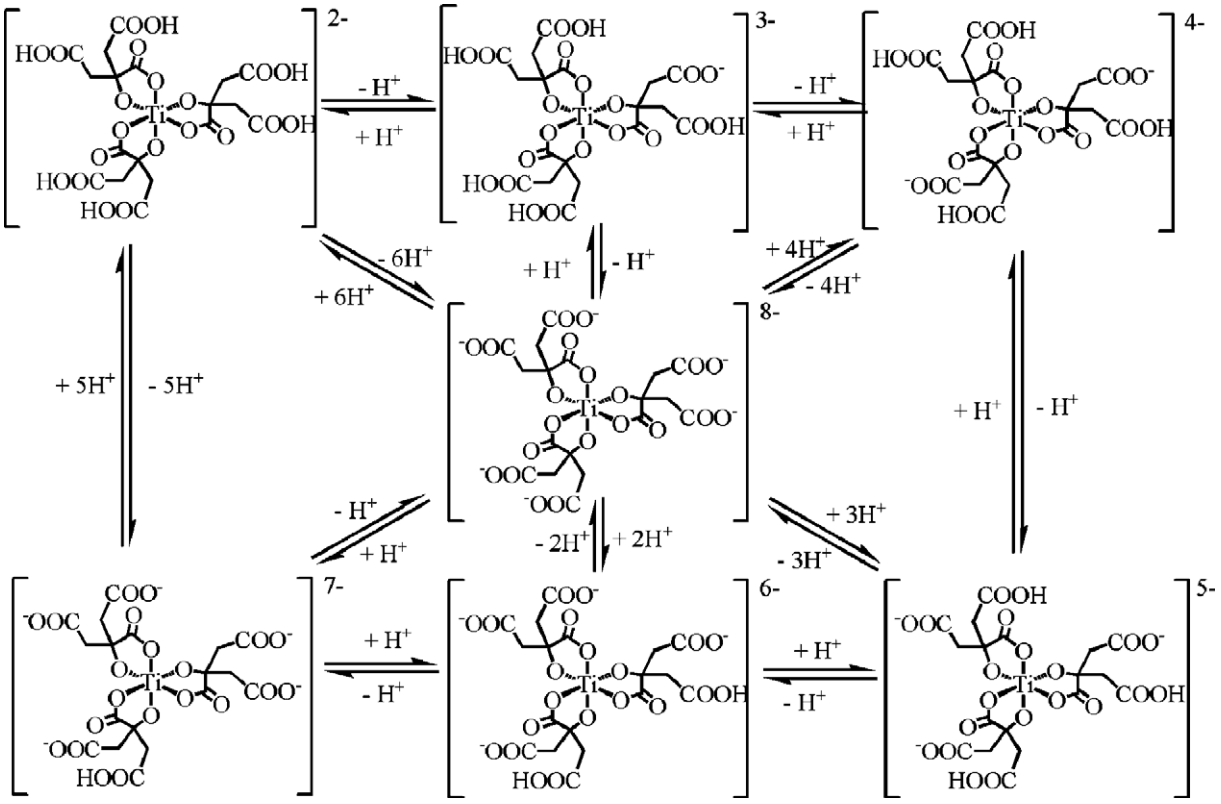
3. Results and discussion

3.1. Syntheses and interconversions

Syntheses of complexes **1**–**4** were expediently carried out in aqueous solutions under slightly different conditions. In these reactions, the products do not mainly depend on the ligand-to-metal ratio. Control of the high ratio of titanium(IV) ion and citric acid in the synthetic procedures will drive the reaction completely and lead to the isolation of titanium(IV) citrate complexes in high yield. In the preparation of complex **4**, in order to acquire a good crystal for X-ray structure determination, we choose titanium *n*-butoxide as the titanium source. The procedures for the syntheses of titanium(IV) citrate complexes illustrate the sensitivity of the reactions toward pH and counterions in aqueous solutions containing titanium(IV) ion and citric acid. When the pH is lower than 4.0, solutions containing titanium(IV) ion, sodium ion and citric acid only deposited complex **1**; in contrast, control of pH values in the range of 4.5–6.0, 6.5 and 7.0 results in the formation of $Na_6[Ti(Hcit)H(cit)_2]\cdot 16H_2O$, $Na_7[TiH(cit)_3]\cdot 18H_2O$ and $Na_8[Ti(cit)_3]\cdot 17H_2O$, respectively. When pH is higher than 7.0, no titanium(IV) citrate complexes were isolated from the above solutions. In addition, attempts to isolate the complexes formulated as $Na_2[Ti(H_2cit)_3]\cdot nH_2O$, $Na_4[Ti(H_2cit)(Hcit)_2]\cdot nH_2O$ and $Na_5[Ti(Hcit)_3]\cdot nH_2O$ from the solutions containing titanium(IV) ion, sodium ion and citric acid proved unsuccessful. However, when solutions contain titanium(IV) ion, potassium ion and citric acid, only the complexes formulated as $K_2[Ti(H_2cit)_3]\cdot 4H_2O$, $K_4[Ti(H_2cit)(Hcit)_2]\cdot 4H_2O$ and $K_5[Ti(Hcit)_3]\cdot 4H_2O$ are isolated at the pH values of 2.0, 4.0 and 6.0, respectively. Similarly, no titanium(IV) citrate complex is isolated from solutions containing titanium(IV) ion, potassium ion and citric acid, when the pH is higher than 7.0. These results suggested that the pH values of the solutions containing titanium(IV) and citrate have important effect on the precipitation of titanium citrate complexes.



The pH-dependent transformations were carried out between complexes **2** and **3**. The simple dissolution of complex **2** in water and the adjustment of the pH to a final value of ~6.0, with aqueous potassium hydroxide, led to the isolation of complex **3** upon addition of ethanol at 4 °C. Conversely, when complex **3** was dissolved in water and the pH was adjusted to a final value of ~4.0 with aqueous hydrochloric acid, complex **2** could be isolated upon the addition of ethanol at 4 °C. In view of the acid–base reactivity observed between the two mononuclear complexes and a similar result in previously reported literature [24], similar behaviors were envisioned to exist between the two titanium citrate anions which had been synthesized, isolated and characterized crystallographically in the past [24–27]. Based on the interconversions described and all of the seven well characterized titanium species between the charges of 2 and 8, Scheme 1 shows the pH-dependent interconversions of the titanium citrate anions reported.

All the complexes are soluble in water, especially in hot water, and slightly soluble in organic solvents such as ethanol and acetone.

3.2. Description of the crystal structures

The crystal structures of the titanium(IV) citrate complexes **1**–**4** were determined and the ORTEP diagram of complex **3** is given in Fig. 1. The ORTEP diagrams of the other three complexes are given in Figs. S1–S3, respectively.

The titanium atom in all of the complexes is six-coordinated in an octahedral environment by α-alkoxy and α-carboxy groups from three citrate ligands. This geometry is similar to those found in the previously reported titanium citrate complexes [24–27]. But it is different from those of seven-coordinated peroxo titanium(IV) citrate complexes, such as $(NH_4)_8[Ti(O_2)(cit)]_4\cdot 8H_2O$ [29a], $Ba_2(NH_4)_2[Ti_4(O_2)_4(Hcit)_2(cit)_2]\cdot 10H_2O$ [29b] and $(NH_4)_4[Ti(O_2)(cit)]_2\cdot 2H_2O$ [30]. The coordination mode of the titanium atom also argues against the previous models inferred from spectroscopic data, in which the titanium atom is coordinated by α-alkoxy and β-carboxy groups of three citrates

Scheme 1. Transformations of titanium citrate anions in the Ti–citrate–H_2O system.

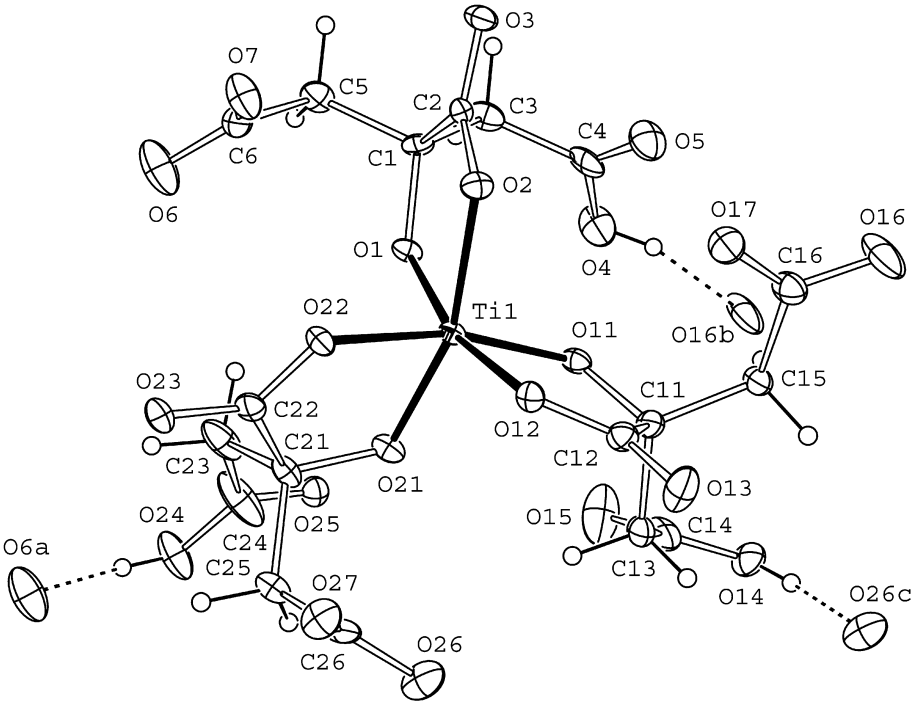


Fig. 1. ORTEP plot of the anion structure of $K_5[Ti(Hcit)_3]\cdot 4H_2O$ (**3**) at the 30% probability level.

[13a,13b], or by three α-alkoxy groups, one α-carboxy group and two β-carboxylic groups [13d]. Bidentate coordination of the citrate ligand through its α-alkoxy group and α-carboxy group with the titanium atom is independent with the pH variations in the pH range 1.0–7.0. Generally, the citrate anion uses its α-hydroxy or α-alkoxy, α- and β-carboxy groups to interact with the metal atom, such as in the complexes $(NH_4)_3[Ga(Hcit)_2]\cdot 4H_2O$ [35],

Table 3
Comparison of the average Ti–O bond distances (Å) in the titanium(IV) citrate complexes

Complex	Anion	Ti–$O_{\alpha\text{-alkoxy}}$	Ti–$O_{\alpha\text{-carboxy}}$	Reference
$K_2[Mg(H_2O)_6][Ti(H_2cit)_3]\cdot 6H_2O$	−2	1.865(1)	2.045(1)	[24]

$Na_3(NH_4)_3[Ti(Hcit)_2(cit)]\cdot 9H_2O$	−6	1.868(3)	2.049(4)	[26]
$Na_6[Ti(Hcit)_2(cit)]\cdot 16H_2O$	−6	1.867(2)	2.052(2)	[26]
$Ba_3(NH_4)_7[Ti(Hcit)_3(cit)_3Ti]\cdot 15H_2O$	−6.5	1.871(2)	2.026(2)	[25]
$Na_7[TiH(cit)_3]\cdot 18H_2O$ (**4**)	−7	1.855(2)	2.024(2)	this work
$Na_8[Ti(cit)_3]\cdot 17H_2O$	−8	1.850(2)	2.054(2)	[27]

$(NH_4)_4[M(Hcit)_2]\cdot xH_2O$ [M = Mn(II), Co(II), $x = 0$; M! = Ni(II), $x = 2$] [36] and $(NH_4)_5[M(cit)_2]\cdot 2H_2O$ (M = Mn(III), Fe and Al) [36,37]. A comparable result could be found in vanadate(V) citrate complexes, such as $K_2[V_2O_4(H_2cit)_2]\cdot 4H_2O$, $(NH_4)_2[V_2O_4(H_2cit)_2]\cdot 2H_2O$ [38], $Na_2K_2[V_2O_4(Hcit)_2]\cdot 9H_2O$, $K_4[V_2O_4(Hcit)_2]\cdot 4H_2O$ [39], $(NH_4)_4[V_2O_4(Hcit)_2]\cdot 4H_2O$, $K_2(NH_4)_4[V_2O_4(cit)_2]\cdot 6H_2O$ and $(NH_4)_6[V_2O_4(cit)_2]\cdot 6H_2O$ [40].

The uncoordinated protonated β-carboxylic groups are strongly hydrogen-bonded to the deprotonated β-carboxylate groups of an adjacent molecule, resulting in the polymeric anionic structures of complexes **1**–**4**. The anionic structures of the four titanium citrate complexes through hydrogen-bonding interactions are shown in Figs. S4–S7, respectively. The important hydrogen-bonding interactions of the four complexes are listed in Table 2. Specifically, two of the bound citrate ligands share a hydrogen with their neighbors in complex **4** [O4···O4(a) = 2.416(5), O14···O14(b) = 2.423(5) Å], thus affording the −7 dinuclear citrate ion $[TiH(cit)_3]^{7-}$, which is similar to the centrosymmetric dimer formed through the linear hydrogen bonding of a β-carboxylic acid to a β-carboxy group in the complexes $Ba_3(NH_4)_7[Ti(Hcit)_3(cit)_3Ti]\cdot 15H_2O$ [$O6\cdots O6^i = 2.478(2)$ Å] [25], $Na_6[Ti(Hcit)_2(cit)]\cdot 16H_2O$ [$O7\cdots O7^i = 2.467(2)$ Å; $O17\cdots O17^i = 2.455(2)$ Å] and $Na_3(NH_4)_3[Ti(Hcit)H(cit)_2]\cdot 16H_2O$ [$O7\cdots O7^i = 2.474(2)$ Å; $O17\cdots O17^i = 2.446(2)$ Å] [26]. The hydrogen bond in **4** should be extraordinary strong in view of its intermolecular mode with the consideration of the intramolecular hydrogen bonding distance [O···O = 2.636(7) Å] in salicylic acid [41], and the ordinary OH bond of 0.96 Å.

Comparisons of Ti–O distances for titanium(IV) citrate complexes are given in Table 3. The average Ti–$O_{\alpha\text{-alkoxy}}$ bond distances [1.856(4), 1.856(4), 1.868(3) and 1.871(2) Å for **1**–**4**] are similar to those found in related titanium citrate complexes, or the titanium lactate complex $(NH_4)_2[Ti(lact)_3]$ [1.848(5) Å] [42] (H_2lact = lactic acid). The average Ti–$O_{\alpha\text{-carboxy}}$ distances [2.052(4), 2.037(3), 2.052(4) and 2.024(2) Å for **1**, **2**, **3** and **4**] are normal, the distances also being similar to the reported titanium(IV) complexes. It appears that similar angles are observed in **1**, **2**, **3** and **4** and a number of $Ti^{IV}O_6$-core containing complexes. It is noted that the trends in bond distances of the Ti–O bonds are complicated, which is probably related to the different counterions in the titanium citrate complexes.

3.3. Solution NMR spectroscopy of complexes 1–4

The solution ^{13}C NMR spectra of complexes **1**–**4** were measured in D_2O and the results are listed in Table 4. Owing to obvious dissociation on dissolving in H_2O (D_2O), the solution ^{13}C NMR spectra of **1**–**4** showed some peaks of the free citrate. The observed two sets of resonances were attributed to the free and bound citrate in the titanium citrate complexes. The free citrate could serve as an indicator in the spectra for coordination. There exists an equilibrium between tricitrato titanate(IV) and free citrate ligand. Additional species of titanium citrate are not observed in the ^{13}C NMR spectra.

Fig. 2 illustrates the ^{13}C NMR spectrum of **1**, and the ^{13}C NMR spectra of **3** and **4** are shown in Fig. S8. The results display that the dissociation of the titanium citrate complexes in H_2O (D_2O) changes with the pH value. Specifically, the intensities of free citrate resonances increase with the rise of pH value, while those of peaks belonging to the coordinated titanium citrate complex decrease gradually. Given the similar ^{13}C NMR spectra of **1**–**4**, herein, only the ^{13}C NMR spectrum of complex **1** is discussed. Compared with the corresponding free ligand dissociated from complex **1** [178.2 $(CO_2)_{\alpha\text{-carboxy}}$, 174.8 $(CO_2)_{\beta\text{-carboxy}}$, 74.0 $(C\text{–}O)_{\alpha\text{-hydroxy}}$, 43.8 $(CH_2)_{methylene}$], complex **1** shows large lower field shifts of α-alkoxy and α-carboxy carbons ^{13}C resonances ($\Delta\delta \sim 14.7$ and 7.9 ppm) via coordination.

Table 4
Relevant ^{13}C NMR data, δ/ppm of $Na_3[Ti(H_2cit)_2(Hcit)]\cdot 9H_2O$ (**1**), $K_4[Ti(H_2cit)(Hcit)_2]\cdot 4H_2O$ (**2**), $K_5[Ti(Hcit)_3]\cdot 4H_2O$ (**3**) and $Na_7[TiH(cit)_3]\cdot 18H_2O$ (**4**)

Compound	CH_2	=C–O	$(CO_2)_\alpha$	$(CO_2)_\beta$	C–OH	$(CO_2)_{\alpha\text{-free}}$
1	43.8	88.7	186.1	174.8	74.0	178.2
2	46.6	91.6	189.0	177.5	77.0	181.9
3	47.6	92.1	189.8	180.2	77.4	183.3
4	47.8	92.3	190.0	180.4	77.9	183.7

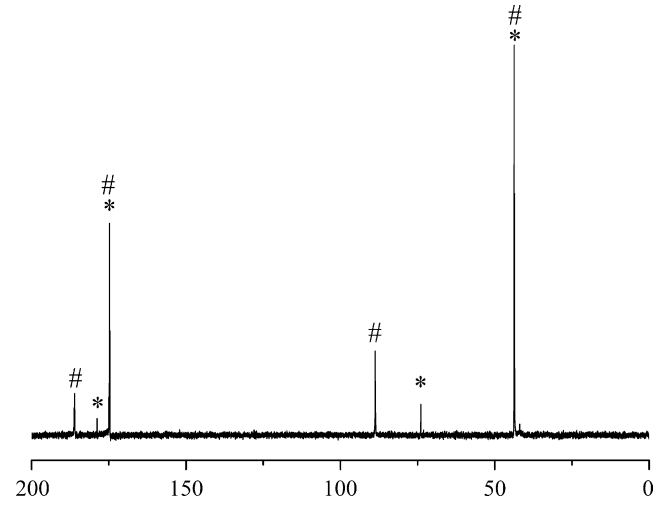

Fig. 2. ^{13}C NMR spectrum of $Na_3[Ti(H_2cit)_2(Hcit)]\cdot 9H_2O$ (**1**) in D_2O. Labels: free citrate (∗); coordinated titanium citrate complex (#).

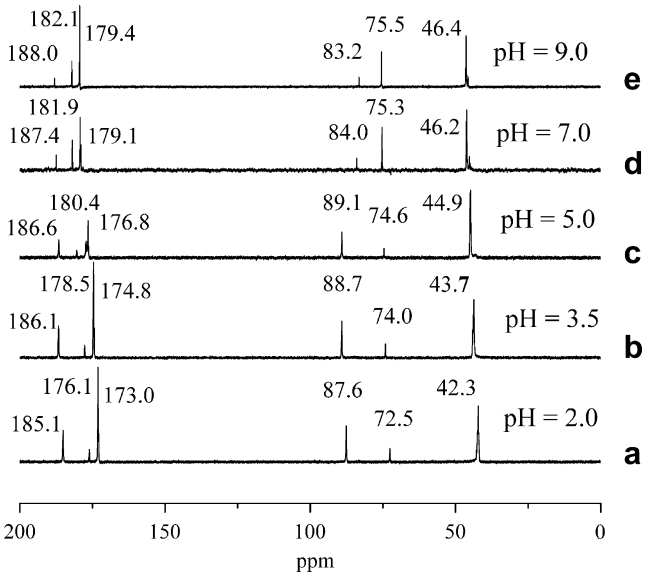

Fig. 3. ^{13}C NMR spectra for the solutions (a–e) with the molar ratio Ti/H_4cit = 1:3 at various pH values.

This indicates that the α-hydroxy and α-carboxylic acid groups in citric acid are fully deprotonated and coordinate to the titanium atom simultaneously. The observation is in agreement with the conclusion derived from the X-ray crystal structure. The ^1H NMR spectrum of complex **1** shows two groups of sharp AB quartets for methylene protons, which also corroborates with the dissociation of the titanium(IV) citrate complex in aqueous solution.

It is worth noting that the previous report showed an undissociated ^{13}C NMR spectrum of complex $Na_6[Ti(Hcit)_2(cit)]\cdot 16H_2O$ [26], in which only one set of resonances were observed. Two peaks in the highfield region were assigned to methylene (47.6 ppm) and α-alkoxy (77.3 ppm) carbon atoms of the bound citrate, while the other two peaks in the downfield region were assigned to the α-carboxy (183.2 ppm) and β-carboxy (180.3 ppm) carbons of the bound citrate. In consideration of the corresponding ^{13}C NMR signals of the bound and dissociated citrate ligands in **3** and **4** at high pH values, it is suggested that full dissociation was observed for the complex of $Na_6[Ti(Hcit)_2(cit)]\cdot 16H_2O$.

3.4. ^{13}C NMR spectroscopy studies of 1:3 Ti:citrate solution

Fig. 3 shows the ^{13}C NMR spectra of 1:3 Ti:citrate solutions of a–e in the region 0–200 ppm, which demonstrates the coordination of the citrate ligand with Ti(IV) ion is consistent with those isolated at the corresponding pH values lower than 7.0. For example, the ^{13}C NMR spectrum of the 1:3 Ti:citrate solution at a pH value of 3.5 reveals two sets of ^{13}C resonances, which is very similar to the ^{13}C NMR spectrum of complex **1** isolated in the pH range 2.0–4.0. The peaks at 186.1, 174.8, 88.7 and 43.7 ppm were assigned to the resonances of α-carboxy, β-carboxy, α-alkoxy and methylene carbons for the coordinated citrate ligands, respectively, and the peaks at 178.5, 174.8, 74.0 and 43.7 ppm were attributed to those of the free citrate ligands. It is noted that the intensities of the free citrate resonances increased with pH, whereas the intensities of those peaks belonging to the coordinated titanium citrate complexes decreased gradually. One of the most striking results is that the ^{13}C NMR spectrum of the 1:3 Ti:citrate solution at a pH value of 7.0 is different from that of the titanium citrate complex $Na_8[Ti(cit)_3]\cdot 17H_2O$ isolated at the corresponding pH value [27], which is attributed to the free citrate ligand. Despite there being two sets of ^{13}C NMR peaks, the peaks at 181.9, 179.1, 75.3 and 46.2 ppm were assigned to the carbons resonances of free citrate, while the peaks at 187.4 and 84.0 ppm were likely attributed to the α-carboxy and α-alkoxy of the bound citrate ligand, respectively. However, the downshift of 8.7 ppm for the α-alkoxy group was less than those in the related titanium citrate complexes. There was not a consistency between the ^{13}C NMR spectra of the 1:3 Ti:citrate solution recorded at pH < 7.0 and those at pH $\geqslant 7.0$. It is probable that the coordinated modes of the citrate ligand with the Ti(IV) ion change when the pH value is higher than 7.0.

4. Biological relevance

Titanium is an essential component of prosthetics used in surgical rectification of human skeletal aberrations or dental fillings [30]. Simultaneously, a series of complexes containing titanium have been used in cancer treatment [43]. Therefore, titanium in one form or another may come in contact with biological fluids such as citric acid. Consequently, it elicits interactions from biological fluids (such as citrate). In so doing, the solubility and bioavailability of the titanium in the relevant fluids are essential for developing these requisite chemistries. The aqueous chemistry of the binary titanium–citrate system shown here has revealed a number of discrete species, all of them reflecting the

solubilization of titanium in the presence of physiological substrate citric acid. Furthermore, in view of the pH-dependent transformations of the titanium citrate complexes in aqueous solutions, it would be reasonable to envision that a pH-dependent chemistry on titanium species with physiological ligands (such as citrate) promotes formation of soluble bioavailable species, which are capable of eliciting interactions from extracellular and intracellular targets. To this end, variable biochemical processes could be influenced. The clearly defined chemical properties of the four mononuclear titanium citrate species reported here constitute a distinct case of species likely to participate in the aqueous speciation of titanium(IV) in the citrate.

The previous works reported titanium citrate can deliver titanium to serum protein transferring in the physiological pH value [16,18,20]. However, titanium nitrilotriacetate does not deliver Ti(IV) to apoprotein. This fact is ascribed to the higher stability of titanium(IV) nitrilotriacetate compared to titanium(IV) citrate [20]. The ^{13}C NMR spectra of the four titanium citrates isolated here and the 1:3 Ti:citrate solutions at different pH suggested the stability of titanium(IV) citrate complexes in aqueous solution decrease with the increase pH value, regardless of the existence of titanium citrate species in solution. In neutral solution, the titanium citrate complex decomposes completely. It probably demonstrates that titanium citrate, as the titanium source, may react easily with apotransferrin in physiological pH value. The structural and spectroscopic characterization of the titanium citrate complexes and the solution behavior of the titanium citrate binary system in different pH values offer a new perspective in pursuit of probing other systems encompassing physiological ligands and metal ions.

5. Conclusions

In summary, the isolated titanium(IV)–citrate complexes $Na_3[Ti(H_2cit)_2(Hcit)]\cdot 9H_2O$ (**1**), $K_4[Ti(H_2cit)(Hcit)_2]\cdot 4H_2O$ (**2**) $K_5[Ti(Hcit)_3]\cdot 4H_2O$ (**3**) and $Na_7[TiH(cit)_3]\cdot 18H_2O$ (**4**) show a similar tricitrato titanium core in different protonated forms, which is not much influenced by the pH values and couterions in the complexes. The aqueous solution ^{13}C NMR spectra of 1:3 Ti:citrate demonstrated the coordination of citrate ligand with Ti(IV) ion is consistent with the titanium citrate complexes isolated when the pH value is lower than 7.0. The dissociation of the citrate ligand increases with the rise in pH values, while the ratios of the bound citrate complexes decrease gradually. The synthetic efforts targeting Ti(IV)–citrate complexes from aqueous solutions have contributed to delineating the nature of a number of such species arising in the course of pH-dependent reactions.

which are normally stable planar chelates, $[M(L)_2]X_2$ [8]. Recently, dach and daco have been alkylated with ethylene sulfide to give a derivative with pendant arms, and then coordinated to the metal [9]. However, the related cyclic diamines have not been studied extensively for mixed chelate complex systems.

In this work, we have obtained new mixed complexes with the medach ligand and some kinds of β-diketonates (dike), Ni(medach)(dike)X, and have determined their crystal structures and the equilibrium constants between a square-planar structure and an octahedral one with coordinated strong donor solvent molecules [10].

2. Experimental

2.1. Materials and instrumentation

Nickel(II) nitrate hexahydrate, nickel(II) sulfate hexahydrate, *N*-methyl-1,4-diazacycloheptane (medach), acetylacetone (Hacac), benzoylacetone (Hbzac), dibenzoylmethane (Hdibm), anhydrous sodium carbonate, sodium tetraphenylborate and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine were purchased from Wako Chemical Co. Ltd. and used without further purification. As the solvents used for spectral measurements 1,2-dichloroethane (DCE), dimethylsulfoxide (DMSO), acetone (ACO) and nitromethane (NM) were used without further purification, all of the solvents were of guaranteed grade for spectral measurements.

Elemental analyses were performed on a Perkin–Elmer 2400 II CHN analyzer. Infrared spectra (400–4000 cm^{-1}) were measured with a Perkin–Elmer FT-IR SPECTRUM 2000 using KBr disks. Electronic spectra of the complexes in solution were observed with Shimadzu UV-3100PC UV–VIS Scanning Spectrophotometer using 10 mm quartz cells and concentrations between 1.0×10^{-3} and 5.0×10^{-3} mol dm^{-3}, except where mentioned differently in the text. Magnetic susceptibility measurements were performed by the Faraday method with a Shimadzu Torsion Magnetometer MB-100 at room temperature. Electric conductances of the solutions were measured with a Conductivity Outfit Model AOC-10 (Denki-Kagaku-Keiki Co. Ltd.) at 25 ± 0.2 °C.

2.2. Syntheses of chelates

2.2.1. Chelates of the nitrate, [Ni(medach)(dike)NO_3]

To an ethanol solution of $Ni(NO_3)_2 \cdot 6H_2O$ (5 mmol in 30 cm^3 of ethanol), a mixture of the appropriate β-diketone (5 mmol) and anhydrous sodium carbonate (2.5 mmol) was added. The ligand, medach (5 mmol in 10 cm^3 of ethanol) was added dropwise to the metal-solution with vigorous stirring. After the reaction was complete, the green solution was filtered and concentrated using a rotary evaporator. The crude crystals obtained were recrystallized from DCE to yield bluish-green crystals. Yield: 70–85%.

Ni(medach)(bzac)NO_3 (**1a**). *Anal*. Calc. for $C_{16}H_{23}N_3O_5Ni$: C, 48.52; H, 5.85; N, 10.61. Found: C, 48.54; H, 5.88; N, 10.62%. μ_{eff}: 3.12 B.M.

Ni(medach)(dibm)NO_3 (**2a**). *Anal*. Calc. for $C_{21}H_{25}N_3O_5Ni$: C, 54.92; H, 5.46; N, 9.14. Found: C, 55.06; H, 5.50; N, 9.17%. μ_{eff}: 3.02 B.M.

2.2.2. Chelates of the tetraphenylborate, [Ni(medach)(dike)]BPh_4

The crude nitrate compounds (1 mmol) were dissolved in DCE, and sodium tetraphenylborate (1.5 mmol) was added with stirring and then filtered. During the procedure, the color of the solution changed from green to reddish-orange. The crude crystals obtained were recrystallized from DCE to yield orange crystals. They were all diamagnetic. Yield: 70–85%.

Ni(medach)(bzac)BPh_4 (**1b**). *Anal*. Calc. for $C_{40}H_{43}N_2O_2BNi$: C, 72.14; H, 6.63; N, 4.33. Found: C, 73.54; H, 6.63; N, 4.29%.

Ni(medach)(dibm)BPh_4 (**2b**). *Anal*. Calc. for $C_{45}H_{45}N_2O_2Ni$: C, 75.51; H, 6.55; N, 3.96. Found: C, 75.55; H, 6.34; N, 3.92%.

2.2.3. Chelates of the ternary bis-diketonate, [Ni(medach)$(dike)_2$]

$NiSO_4 \cdot 6H_2O$ was dissolved in a small amount of water and a chloroform solution containing an equimolar amount of medach and two molar amounts of Hdike was added to it in a separatory funnel. Then sodium carbonate was added to the mixture with shaking. After standing for a minute, the chloroform layer was separated from the aqueous solution and evaporated. The crude crystals obtained were recrystallized from DCE to yield bluish-green crystals. Yield: 70–85%.

Ni(medach)$(bzac)_2$ (**1c**). *Anal*. Calc. for $C_{26}H_{32}N_2O_4Ni$: C, 63.03; H, 6.51; N, 5.66. Found: C, 62.68; H, 6.66; N, 5.63%. μ_{eff} for **1c** · DCE: 2.66 B.M.

Ni(medach)$(dibm)_2$ (**2c**). *Anal*. Calc. for $C_{36}H_{36}N_2O_4Ni$: C, 69.81; H, 5.86; N, 4.52. Found: C, 69.72; H, 5.89; N, 4.39%. μ_{eff}: 3.20 B.M.

2.3. Equilibrium constants

The equilibrium constants (log β) defined by Eq. (1) have been determined by a spectrophotometric method (calculation by a least-square method using the data sets from the electronic spectra at constant temperature, 25 ± 0.2 °C). All spectral data, as a function of the total concentrations of the reactants, were computer-fitted to the appropriate equation, depending on the model to be tested. As a result, the equilibrium constants for each species (log β) and the molar extinction coefficients (ε_{calc}) for each species in the solution were calculated. The number of points used for the calculation of equilibrium constants was 12 from each data set, which were picked up at every 10 nm wavelength in the range of 530–420 nm.

$$[Ni(diam)(dike)]^+ + 2S \xrightarrow{\beta} [Ni(diam)(dike)S_2]^+$$
$$\beta = [Ni(diam)(dike)S_2]^+ / [Ni(diam)(dike)]^+[S]^2 \quad (1)$$

The solvent ligand (S = DMSO) was added to a DCE solution of the respective complex, [Ni(diam)(dike)]BPh_4.

2.4. X-ray crystallography

The measurements for complex **3a** were made on a DIP2030K automated diffractometer with graphite-monochromatic Mo Kα radiation ($\lambda = 0.71073$ Å) at 298 K. The measurements for complexes **1a**, **2a**, **1b**, **3b**, and **2c** were made on a MXC03K automated diffractometer with graphite-monochromatic Mo Kα radiation ($\lambda = 0.71073$ Å) at 298 K. The unit cell parameters were determined by the least square method using 22 well-centered reflections for all the complexes. The reflections were corrected for Lorentz and Polarization effects but not for absorption. Every structure was solved by the direct method SIR92 [11], and was refined by full matrix least-square techniques SHELXS-97 [12]. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters. Crystallographic data and refinement parameters are detailed in Table 1.

3. Results and discussion

3.1. Synthesis and structure of the complexes, Ni(medach)(dike)X

We obtained eight mixed ligand complexes of the general formula Ni(medach)(dike)X (X = NO_3^-, BPh_4^- or dike), which are classified into three types: i.e., type **a** = nitrate complexes, type **b** = tetraphenylborate complexes and type **c** = ternary bis-diketonate complexes, and the numbers of the complexes, **1**, **2** and **3**, mean benzoylacetonate, dibenzoylmethanate and acetylacetonate, respectively. Magnetic data of these complexes at room temperature are listed in the experimental section, which show the tetraphenylborate complexes are diamagnetic, and the nitrate and bis-dike complexes have values of nearly 3.0 B.M. These data mean that: (a) the Ni(II) coordination geometry in the tetraphenylborate complexes is square-planar with a N2O2 donor set (type **b**), and (b) those of the nitrate complexes (type **a**) and the ternary bis-dike complexes (type **c**) are octahedral with a N2O4 donor set.

Among these complexes we obtained six good single crystals for X-ray diffraction analysis, complexes **1a**, **2a**, **3a**, **1b**, **3b** and **2c**, whose crystal structures have been determined. For two acac-complexes, **3a** and **3c**, which were previously reported [10], the structures are clarified in this work. The ORTEP plots of complexes **1a**, **1b** and **2c** as examples are depicted in Figs. 1–3, with the atom numbering scheme. Selected bond distances and angles are given in Table 2.

3.1.1. Structure of [Ni(medach)(bzac)NO_3] (*1a*, type *a*)

Complex **1a** crystallizes in the monoclinic space group $P2_1/c$. The nickel atom is coordinated to give an octahedral geometry with two N atoms of the bidentate medach ligand, two O atoms of the bidentate bzac ligand and

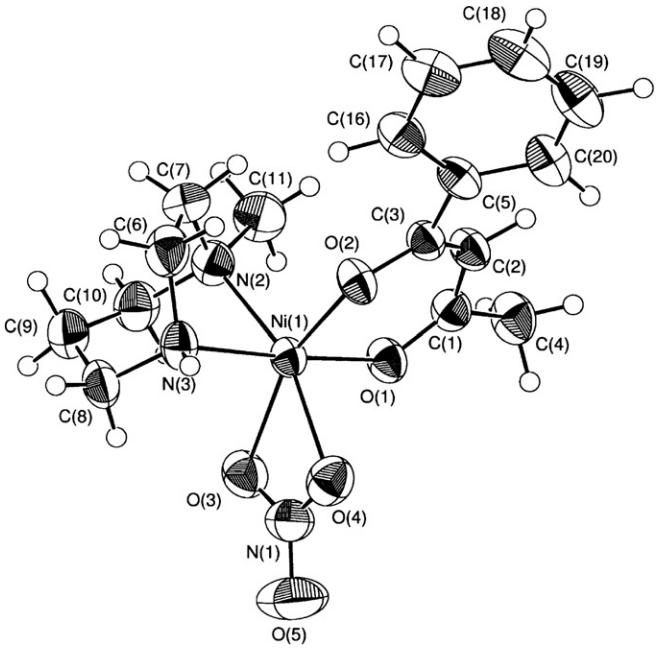

Fig. 1. ORTEP diagram of the complex [Ni(medach)(bzac)NO_3] (**1a**). Thermal ellipsoids are at 50% probability.

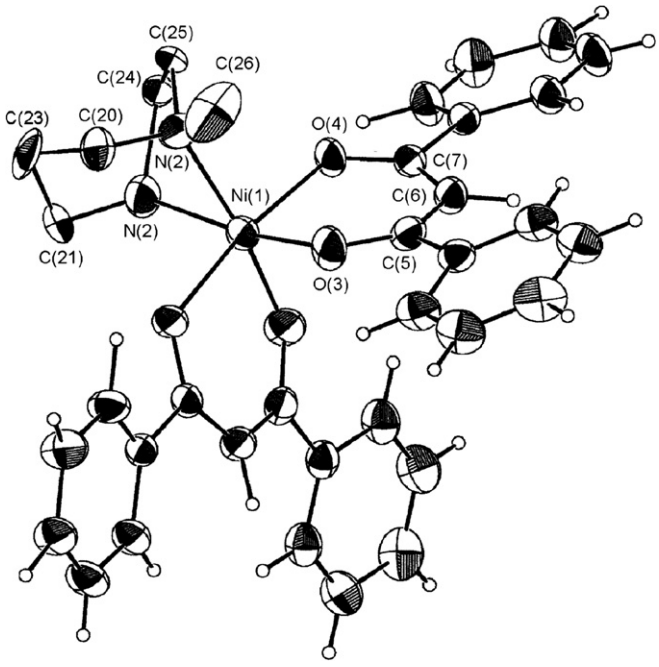

Fig. 3. ORTEP diagram of the complex [Ni(medach)$(dibm)_2$] (**2c**). Thermal ellipsoids are at 50% probability.

two O atoms of the bidentate NO_3 ligand as shown in Fig. 1. The angles O(1)–Ni(1)–N(3), O(2)–Ni(1)–O(3), O(4)–Ni(1)–N(2), O(1)–Ni(1)–O(2), O(3)–Ni(1)–O(4), and N(3)–Ni(1)–N(2) are 173.97°, 158.68°, 160.11°, 91.00°, 59.92° and 76.60°, respectively. The bite angle of the NO_3 ligand to the metal center is too narrow and the bond lengths of Ni(1)–O(3) 2.167 Å and Ni(1)–O(4) 2.173 Å are rather longer than those of the Ni–O(bzac) (Ni(1)–O(1) = 2.009, Ni(1)–O(2) = 2.003 Å). The structural strain of the ligand NO_3 affects the easy dissociation of the NO_3 ligand from the coordination sphere in acceptor or strong donor solvents. Another structural interest is that the axial bonds Ni(1)–O(2) and Ni(1)–O(3) are repelled by the cyclic medach ligand, which means that the angle O(2)–Ni(1)–O(3) 158.68° is smaller than the other equatorial *trans*-bonds. This interligand repulsion between medach and the axial donor atoms (NO_3) may reflect the another reason for the weakened coordination ability of the NO_3 ligand. The structures of **2a** and **3a** show also similar structural properties as explained in this case of **1a**.

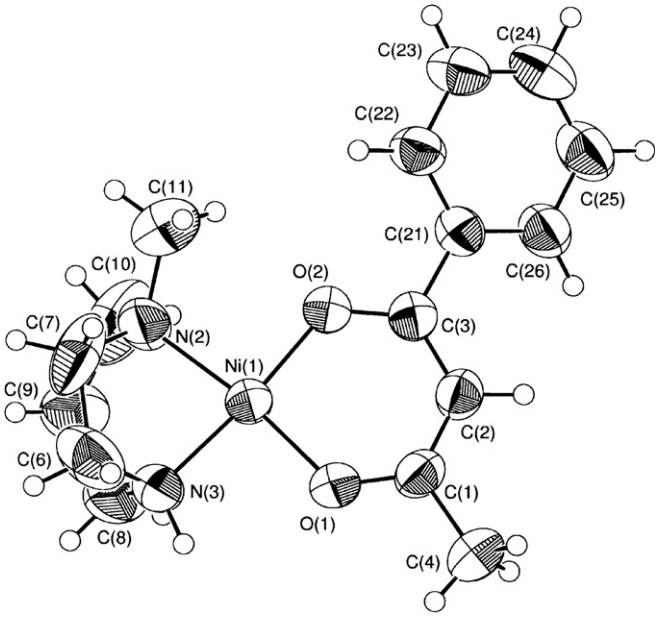

Fig. 2. ORTEP diagram of the complex $[Ni(medach)(bzac)]^+$ (**1b**). Thermal ellipsoids are at 50% probability.

3.1.2. Structure of [Ni(medach)(bzac)]BPh_4 (*1b*, type *b*)

Complex **1b** crystallizes in the monoclinic space group $P2_1/c$. As shown in Fig. 2, the nickel atom is coordinated with medach and bzac to give a square-planar geometry and the uncoordinating anion BPh_4^-. The N2O2 donor set from medach and bzac and the central Ni atom are located on the same plane. If we compare these metal–ligand bond distances and their bite angles with those of

Table 2
Selected bond lengths (Å) and angles (°) for complexes **1a**, **1b** and **2c**

	1a	**1b**		**2c**
Ni(1)–O(1)	2.009(3)	1.819(3)	Ni(1)–O(3)	2.01(14)
Ni(1)–O(2)	2.003(3)	1.831(3)	Ni(1)–O(4)	2.05(14)
Ni(1)–N(2)	2.093(4)	1.936(4)	Ni(1)–N(2)	2.14(14)
Ni(1)–N(3)	2.093(3)	1.887(4)		
Ni(1)–O(3)	2.167(3)			
Ni(1)–O(4)	2.173(3)			
O(1)–Ni(1)–O(2)	91.00(11)	95.80(14)	O(3)–Ni(1)–O(4)	88.(6)
N(2)–Ni(1)–N(3)	76.60(14)	81.3(2)	N(2)–Ni(1)–N′(2)	76.(5)

the corresponding octahedral nitrate complex **1a**, this planar complex has shorter bond lengths Ni–O(bzac) 1.819 and 1.831 Å and Ni–N(medach) 1.936 and 1.887 Å and wider bite angles O(1)–Ni(1)–O(2) 95.80 and N(2)–Ni(1)–N(3) 81.3° than those of the octahedral complex. In this planar complex, the tertiary N-donor of medach coordinates more weakly to the metal center than the secondary N–M bond. The chelate angle of medach in this square-planar mixed complex is almost the same as the angle in the bis-dach square-planar homoleptic complex, $[Ni(dach)_2]Cl_2 \cdot 2H_2O$ 82.2° [13]. It means that the chelate angle of the cyclic dach ligand was determined by the rigid conformation of the ligand and the same metal-ligand bond length. The crystal structure of **3b** show also same geometry as **1b**.

3.1.3. Structure of $[Ni(medach)(dibm)_2]$ (**2c**, type ***c***)

Complex **2c** crystallizes in the monoclinic space group $C2/c$. As shown in Fig. 3, the nickel atom is coordinated to give an octahedral geometry with two N atoms of the bidentate medach ligand and four O-donor atoms from two bidentate dibm ligands, forming the non-charged complex. The medach ligand in the structure is disordered and the structural data is not so well refined. The characteristic properties of this type of complex in the solid state shows the plasticity of the non-charged weak intermolecular interaction in the case of ternary bis-hexafluoroacetylacetonate (hfac), $[M(tmen)(hfac)_2]$ [14]. Due to the very weak intermolecular interaction in this crystal, the diamine (medach) moiety of the complex can easily move position at the temperature for this X-ray crystal determination. Therefore, we could not determine the position of medach ligand with certain accuracy. For the complex **1c**, a good single crystal for X-ray analysis could not be obtained.

3.2. Solvatochromic behavior with the structure change of the complexes in solution

3.2.1. Electric conductivity data of the chelates in various solvents

Table 3 gives the electrical conductivity data at room temperature for the complexes in some organic solvents with different donor numbers (DN) and acceptor numbers (AN) [15]. The standard values of 1:1 electrolytes in the respective solvents are shown in the same table [16]. It can be seen from the table that the ionization of NO_3^- from the complexes in NM is about 10%, which indicates partial dissociation into the NO_3^- anion and the cationic planar complex, $[Ni(medach)(dike)]^+$. In DCE or ACO, the nitrate complexes show almost non-electrolytic behavior, which means that the species in solution is the same as that of the solid state. On the other hand, in a very strong donor solvent like DMSO, the conductivity data show that the nitrate complexes are almost 1:1 electrolytes. Consequently the nitrate complexes are strongly influenced by the respective (donor and acceptor) properties of the solvents for coordination and dissociation of the NO_3^- ion. These data support the following section on spectral chromotropic behaviors (Scheme 1).

Table 3
Molar conductivity ($ohm^{-1}\,cm^2\,mol^{-1}$ at 25 ± 0.2 °C)

	DCE	NM	DMSO	ACO
Ni(medach)(bzac)NO_3 (**1a**)	0.13	7.65	23.43	2.13
Ni(medach)(dibm)NO_3 (**2a**)	0.07	7.55	22.91	1.54

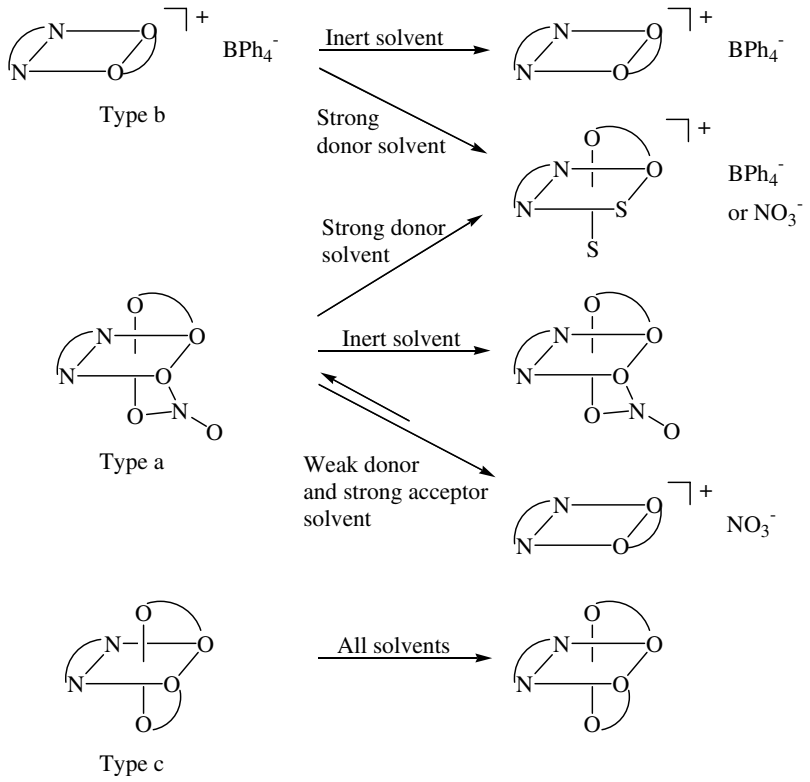
3.2.2. The nitrate complexes $[Ni(medach)(dike)NO_3]$ (type ***a***)

Fig. 4 shows the typical electronic absorption spectra of the nitrate complex **1a** in various organic solvents. These spectra were measured at room temperature in DCE, NM, ACO and DMSO. In Table 4, all of the spectral data for the complexes in these solvents are summarized.

The spectra in DCE and ACO have nearly the same pattern, showing two bands corresponding to the similar spectral pattern of octahedral complexes (Eq. (2)). The anomaly of the spectra is their intensity, which means that the intensity of the first band, at ca. $10 \times 10^3\ cm^{-1}$, is nearly half of that of the second band, $16.5 \times 10^3\ cm^{-1}$. It is probably due to the existence of the bidentate nitrate ion, i.e., the deformation from a regular octahedral structure and the smaller four membered chelate ring of the NO_3 ligand. On the other hand, in the case of DMSO although the spectra also show octahedral bands, the spectral profile is different from that in DCE, especially the intensity profile is drastically changed. The electric conductivity data mentioned above also support that the complexes in DCE or ACO are non-charged octahedral with the coordination of NO_3, while those in DMSO are 1:1 electrolytes and octahedral with the coordination of the solvent molecules (Eq. (3)). In NM, with intermediate acceptor and poor donor properties, the nitrate ion is partially dissociated from the octahedral complex and gives square-planar spectra (Eq. (4)), which shows a new solvatochromism.



$$[Ni(medach)(dike)(NO_3)] \rightarrow [Ni(medach)(dike)(NO_3)] \quad (2)$$

$$[Ni(medach)(dike)(NO_3)] + 2DMSO \rightarrow [Ni(medach)(dike)(DMSO)_2]^+ + NO_3^- \quad (3)$$

$$[Ni(medach)(dike)(NO_3)] \rightarrow [Ni(medach)(dike)]^+ + NO_3^- \quad (4)$$

3.2.3. The tetraphenylborate complexes $[Ni(medach)(dike)]BPh_4$ (type ***b***)

Fig. 5 shows the typical electronic absorption spectra of the tetraphenylborate complex **1b** in various organic solvents. These spectra were measured at room temperature in DCE, NM, ACO and DMSO. In Table 4, all of the

Scheme 1. Solid structure and solvatochromic behaviors of the complexes in solution.

spectral data for the complexes in these solvents are summarized. In non-coordinated solvents like DCE or NM, the spectra are similar to those of the square-planar species reported earlier [17]. Also in an intermediate coordinating solvent like ACO, they are dissolved as predominantly square-planar species. This is critically different from similar complexes with linear chain diamines, such as tmen, in which the complexes exist as an equilibrium mixture of the square-planar and octahedral species (Eq. (5)). This is a characteristic property of the cyclic diamine. In a strong donor solvent like DMSO, the spectra indicate that the only species in solution is octahedral (Eq. (6)).

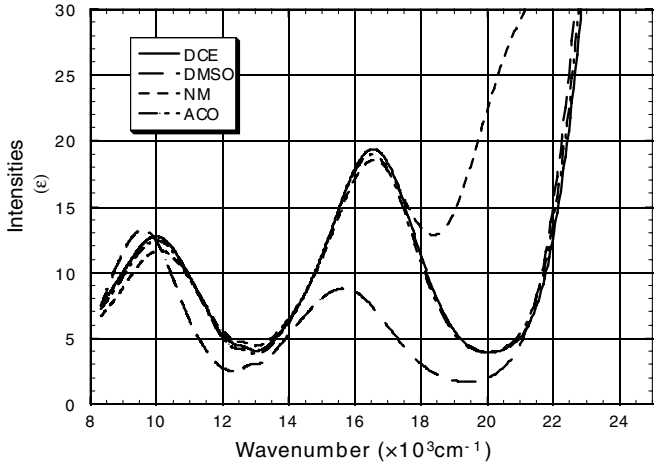


Fig. 4. UV–Vis absorption spectra of [Ni(medach)(bzac)NO_3] (**1a**).

$$2[Ni(medach)(dike)]BPh_4 + 2S \rightarrow [Ni(medach)(dike)(S)_2]^+ + [Ni(medach)(dike)]^+ + 2BPh_4^- \quad (5)$$

$$[Ni(medach)(dike)]BPh_4 + 2DMSO \rightarrow [Ni(medach)(dike)(DMSO)_2]^+ + 2BPh_4^- \quad (6)$$

3.2.4. The ternary bis-diketonato complexes, *[Ni(medach)(dike)$_2$] (type **c**)*

In any kind of solvent, these ternary bis-dike complexes do not show any solvatochromism, which means the spectra in all of the solvents used are similar and any solvent coordination could not be observed.

It is noteworthy that the chelates are very soluble in various organic solvents with high concentrations, which means that there are weak intermolecular interactions in the crystal. As already known for the structure of Ni(acac)$_2$, the chelate is rather insoluble in organic solvents and it is not mononuclear but the trinuclear [Ni_3(acac)$_6$] [18], in which each nickel(II) center is octahedral (other kinds of diketonate chelates also show similar structures). The homoleptic trinuclear, [Ni_3(dike)$_6$] is dissociated into the heteroleptic mononuclear, [Ni(medach)(dike)$_2$], by the addition of the diamine (medach) (Eq. (7)).

$$[Ni_3(dike)_6] + 3medach \rightarrow 3[Ni(medach)(dike)_2] \quad (7)$$

The resultant mononuclear mixed chelates, with very bulky substituent groups on each diamine and diketonate, show very high solubility in various organic solvents, which

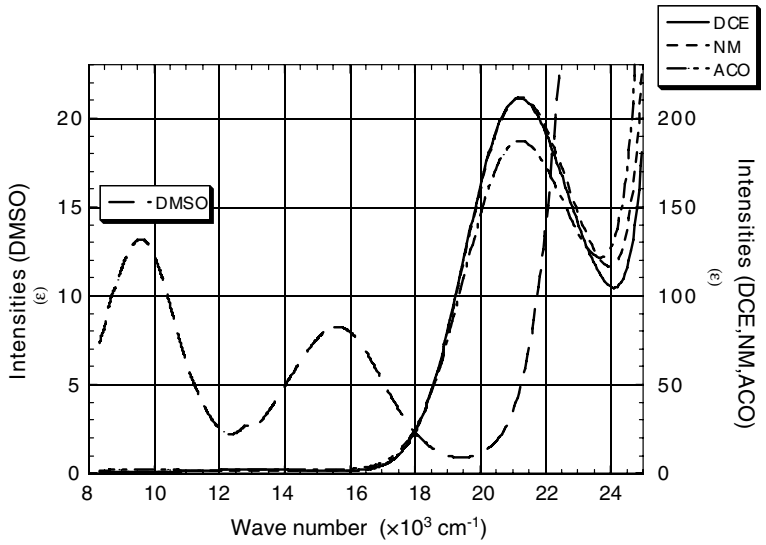

Fig. 5. UV–Vis absorption spectra of [Ni(medach)(bzac)]BPh_4 (**1b**). The left axis is for DMSO solution and the right axis is for DCE, NM and ACO solutions.

means the mixed chelates have hydrophobic properties and weak intermolecular interactions.

3.3. Equilibrium constants

Fig. 6 shows an example of the spectra obtained in the course of the titration procedure of [Ni(medach)(bzac)]-BPh_4 in DCE solution. The absorption maximum of the square-planar species decreases on addition of donor solvent, DMSO, and the absorption band of the octahedral species in the region between 570 and 600 nm increases. A titration procedure can be used to evaluate formation constants. Equilibrium constants ($\log\beta$) according to the reaction are given in Table 5.

The d–d band positions and the corresponding molar absorption coefficients are shifted by a change in the substituents at the diamine ligand. On the other hand, an increase in equilibrium constants of these complexes can be seen with increasing electron-withdrawing and decreasing electron-releasing effects of the substituent group on the β-diketonate ligand; dibm > bzac > acac.

The medach complexes prefer the square-planar geometry to the octahedral geometry. The steric hindrance to axial coordination at the N-donor atoms appears to be much smaller for tmen complexes than the corresponding medach complexes.

4. Conclusion

We have obtained six new mixed chelate complexes with the ligand bzac or dibm as a β-diketonate, medach and three kinds of monoanion, nitrate, tetraphenylborate or

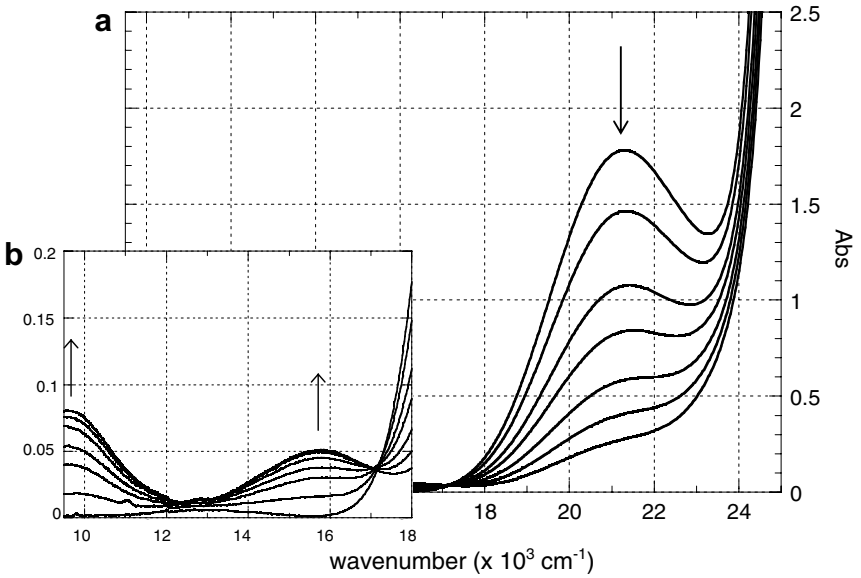

Fig. 6. Spectral changes of [Ni(medach)(bzac)]BPh_4 (**1b**) with the addition of DMSO ligand: (a) square-planar spectral decrease and (b) octahedral spectral increase. The initial concentration of the complex in DCE solution was 8.0×10^{-3} mol dm^{-3} (initial amount of solution: 20 ml) and the light path was 1 cm. The solution was titrated with DMSO–DCE solution (8.0×10^{-1} mol dm^{-3}). Ratios of DMSO/complex are 0, 0.25, 0.50, 0.70, 1.00, 1.35 and 1.85 ((a) spectral curves from top to bottom; (b) those from bottom to top, respectively).

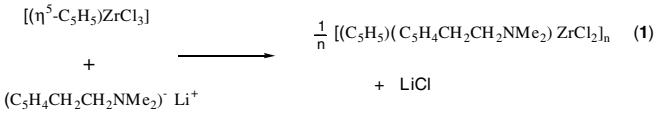
Table 5
Stability constants (log β) (mol^{-1} dm^3)

dike	[Ni(medach)(dike)]BPh_4	[Ni(tmen)(dike)]BPh_4
acac	2.32 ± 0.01	4.50 ± 0.01
bzac	3.04 ± 0.01	5.20 ± 0.02
dibm	3.13 ± 0.02	5.31 ± 0.01

one more β-diketonate, and have determined their crystal structures. These complexes are classified as three categories, type **a** (octahedral with a bidentate nitrate coordination), type **b** (square-planar with tetraphenylborate as a counter anion) and type **c** (octahedral with two β-diketonate ligands). Type **a** complexes show solvatochromic behavior due to the change of acceptor property of the solvents. Type **b** complexes show another type of solvatochromism due to the change of donor properties of the solvents. Type **c** complexes are inert stable octahedral complexes without any chromotropic behavior in various solvents. The medach ligand in the mixed chelate [Ni(dike)(medach)]$^+$ has a much stronger influence on the axial coordination of the donor solvents, which means that the series of the medach mixed ligand system exist as the more stable square-planar structure in comparison to the complexes of the linear *N*-alkylated diamines, such as the tmen analogue.

Acknowledgements

Prof. Hiroshi Miyamae of Josai University in Tokyo is acknowledged for his advice on crystal structure determination. The authors are grateful to Prof. Frank S. Howell of Sophia University in Tokyo for his scientific discussion and also for revising the English of this manuscript.



Appendix A. Supplementary material

CCDC 208117, 212342, 207923, 212341, 208119, and 208118 contain the supplementary crystallographic data for **1a**, **2a**, **3a**, **1b**, **3b**, and **2c**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.11.003.

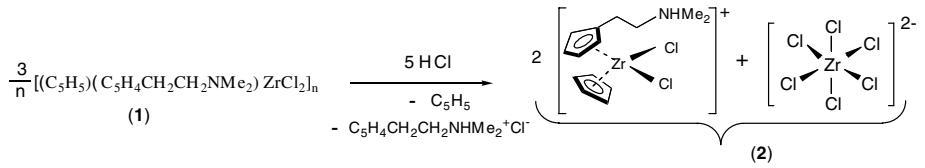
Scheme 1.

The polymerization reaction of monomeric **1** is relatively slow. The deposition of polymeric **1** from a dilute solution takes place after several hours at ambient temperature. Unlike $[Cp_2ZrCl_2]$, **1** is extremely sensitive towards moisture. In contact with atmospheric air **1** turns to a brown slurry in about 10 s.

The examination of a solution of **1** in C_5D_5N by ^1H and ^{13}C NMR indicates some amount (≈20%) of $CpZrCl_3$. The ^1H NMR spectrum displays in the range 3.5–0 ppm strong singlets at 2.54 ppm (broad) and 2.32 ppm, together with three singlets of medium intensity (2.83, 2.51 and 2.18 ppm) and some weak signals. The solution indicates only a very small amount of THF. It seems rather difficult to distinguish between the presence or lack of $Me_2N \rightarrow Zr$ coordination because this solution displays signals which can be attributed to either NMe_2 groups which coordinate to the zirconium centre or to NMe_2 groups which do not coordinate. For compounds which indicate $N \rightarrow Zr$ coordination in the solid state, the NMe_2 resonances are observed near 2.6 ppm, e.g. for $[(C_5H_4CH_2CH_2NMe_2)TiCl_3]$ $\delta(NCH_3) = 2.69$ ppm [3], for $[(C_5H_4CH_2CH_2NMe_2)ZrCl_3 \cdot THF]$ $\delta(NCH_3) = 2.60$ ppm [4] and for $[Cp(C_5H_4CH_2CH_2NMe_2)TiCl_2]$ $\delta(NCH_3) = 2.71$ ppm [8] (no structural data available). For $[(C_5H_4CH_2CH_2NMe_2)Ti(NMe_2)_3]$ without $NMe_2 \rightarrow Ti$ coordination $\delta(NCH_3) = 2.15$ ppm [4] and for $(C_5H_4CH_2CH_2NMe_2)Tl$ $\delta(NCH_3) = 2.21$ ppm [10]. Weak signals in the ^1H NMR spectrum of **1** can be probably be attributed to the $-CH_2CH_2NHMe_2^+$ group, but surely not to $C_5H_4CH_2CH_2NMe_2$. The ^{13}C NMR spectrum of **1** displays sharp singlets in the range for C_5H_5 rings, but the resonances of $CH_2CH_2N(CH_3)_2$ are in the form of broad multiplets which suggests a dynamic equilibrium of oligomeric species in solution.



Compound **1** reacts with a methanolic HCl solution (Scheme 2). We have used a solution of monomeric or/and oligomeric **1** in THF for this purpose. Under the applied conditions (1.35 equivalents of HCl) we have isolated pale yellow-green crystals of $[(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4CH_2CH_2NHMe_2)ZrCl_2]_2[ZrCl_6]$ (**2**). Recrystallization from CH_3CN solution yields crystals of X-ray quality with the minor formation of a deep green insoluble species. The formation of compound **2** indicates that HCl in polar solvents is able to split off not only $C_5H_4CH_2CH_2NMe_2$ but also the C_5H_5 ligand from $CpZrCl_3$, with the formation of the $[ZrCl_6]^{2-}$ anion. The formation of $C_5H_5CH_2CH_2N^iPr_2 \cdot HCl$ on hydrolysis of polymeric $[(C_5H_4CH_2CH_2N^iPr_2)_2ZrCl_2]_n$ was reported previously [5]. A protonolysis of one Cp group from Cp_2ZrCl_2 was found to be rapid in aqueous KNO_3 solution [11]. Similarly, the splitting of only one Cp group and the formation of tri- or dinuclear OH bridged zirconium complexes were reported in the reaction of Cp_2ZrCl_2 with sodium benzoate in H_2O solution [12], in the reaction of Cp_2ZrCl_2 with nitric acid in $CHCl_3$ solution [13] and in the reaction of Cp_2ZrCl_2 with a THF solution of AgX ($X = CF_3SO_3^-$ or ClO_4^-) followed by subsequent treatment of the reaction solution with water [14].

^1H and ^{13}C NMR spectra of **2** are in agreement with the X-ray structure of this compound. The NMR signals were assigned to **2** according to the literature data for $[(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4CH_2CH_2NMe_2)TiCl_2 \cdot HCl]$ [4].

2.2. X-ray crystallographic studies and discussion

The molecular structure of $[(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4CH_2CH_2NHMe_2)ZrCl_2]_2[ZrCl_6]$ (**2**) is shown in Fig. 1. Compound **2** crystallizes in the monoclinic space group $P2_1/n$. Its cation is essentially a zirconium chloride sandwich complex which is protonated on the nitrogen atom and occupies a general position in the crystal. The Zirconium Zr2 atom from the $ZrCl_6^{2-}$ anion sits on the symmetry centre at the Wyckoff position *d*. The ions are kept together by additional hydrogen bonds of the $^+N\text{–}H\cdots Cl^-$ type which are both charge-assisted and bifurcated (one donor and two acceptors) at the same time – see Fig. 2.

The surroundings of the Zr1 atom display a distorted pseudotetrahedral geometry. Distances Zr1–Cl1 243.13(12) pm and Zr1–Cl2 244.49(13) pm are typical for pseudotetrahedrally coordinated Zr (IV). For Cp_2ZrCl_2 the related distances are 244.4 and 245.0 pm, and the angle Cl1–Zr1–Cl2 of 95.98(5)° for **2** is similar to the corresponding angle in Cp_2ZrCl_2 (97.04°) [15–17]. The distances to the Cp-plane rings Zr1–Cp^N(C6–C10) of 221.08 pm and Zr1–Cp(C1–C5) of 220.30 pm are similar and in the same range as in Cp_2ZrCl_2 (219.5 and 219.2 pm) [15–17]. Thus, the tethered $CH_2CH_2NHMe_2$ group exerts only minor impact on the geometry of the related zirconocene dichloride skeleton.

Scheme 2.

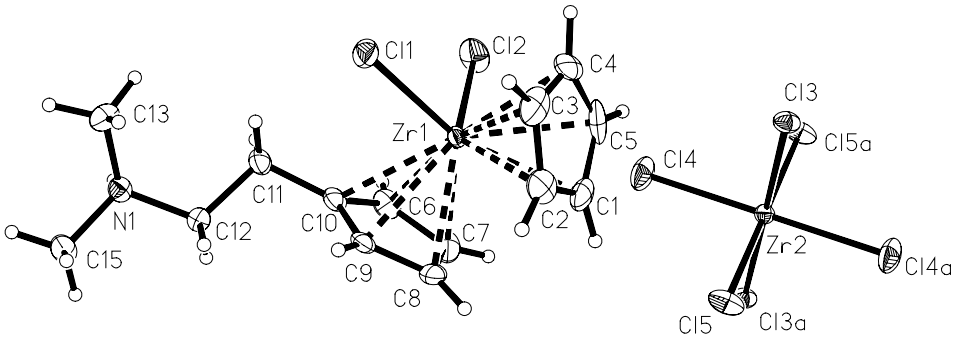


Fig. 1. Molecular structure of $\{2[Cp(Me_2NHC_2H_4C_5H_4)ZrCl_2]^+, ZrCl_6^{2-}\}$, **1**. One cation and one anion are shown. Displacement ellipsoids 50%, symmetry code *a*: $-x+1, -y, -z+2$.

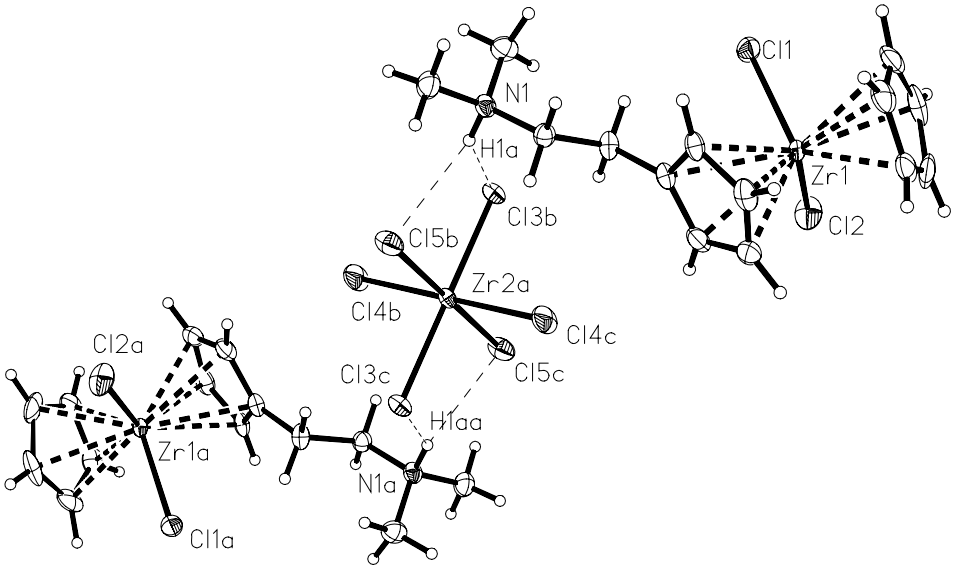

Fig. 2. Hydrogen bonds in the system. N1–H1a 93.0 pm, H1a–Cl3 259.8 pm, H1a–Cl5 259.5 pm, N1–H1a–Cl3 139.97°, N1–H1a–Cl5 135.48°, displacement ellipsoids 50%.

3. Experimental

All manipulations were performed in flame-dried Schlenk type glassware on a vacuum line. THF and toluene were dried over Na/benzophenone and distilled under nitrogen. Pentane was dried over Na/benzophenone/diglyme and distilled under nitrogen. Acetonitrile was distilled under nitrogen over CaH_2 and renewed over P_4O_{10}. ^1H and ^{13}C NMR spectra were recorded on a Varian 500 MHz spectrometer at ambient temperature. $[(\eta^5\text{-}C_5H_5)ZrCl_3]$ [18] and $C_5H_5CH_2CH_2NMe_2$ [19] were prepared by reported methods.

3.1. Synthesis of $(C_5H_4CH_2CH_2NMe_2)Li$

A solution of $C_5H_4CH_2CH_2NMe_2$ (0.48 g, 3.5 mmol) in THF (15 ml) was treated with 1.6 M hexane solution of BuLi (2.2 ml, 3.5 mmol) at 0 °C. The mixture was allowed to warm to room temperature.

3.2. Synthesis of $[(C_5H_5)(C_5H_4CH_2CH_2NMe_2)ZrCl_2]_n$ (*1*)

A solution of $(C_5H_4CH_2CH_2NMe_2)Li$ in THF (3.5 mmol in ≈17.5 ml) was added at −40 °C to solution of $[CpZrCl_3 \cdot DME]$ (1.23 g, 3.5 mmol) in THF (50 ml). The mixture was allowed to warm to room temperature and stirred for 1 day. The colour of the solution turned yellow, then orange and finally brown. After 10 h a brown precipitate was deposited, then filtrated and the solution was evaporated under vacuum (0.001 Torr) for 6 h, yield 0.609 g (48%).

1 ^1H NMR (500 MHz, C_5D_5N, ambient temp.) δ, ppm: several signals were observed in the range 2.1–3.5: 2.83, 2.54 (broad or overlapped), 2.51, 2.32, 2.18; 6.49 (m*, 2.8 Hz, C_5H_4); 6.53 (m*, 2.8 Hz, C_5H_4); 6.58 (s, C_5H_5 of **1**); 6.62 (s, C_5H_5 of $CpZrCl_3$); The weak signals (not listed) might be attributed to the $-CH_2CH_2NHMe_2^+$ group. $^{13}C\{^1H\}$ NMR (89.9 MHz, C_5D_5N, ambient temp.) δ,

ppm: 25.5–28.0 (3 b. m., CpCH_2); 43.0–44.8 (4 b. m., NH(CH_3)$_2$); 57.8–59.8 (3 b. m., NCH_2); 114.32 (s, C_5H_4); 116.34 (s, C_5H_4); 117.20 (s, C_5H_5 of **1**); 118.08 (s, C_5H_5 of $CpZrCl_3$).

We observed several additional weak signals in the range 109.2–120.2 ppm (m* – AA′XX′ pattern, pseudotriplet 2.8 Hz).

We were not able to perform elemental analysis on **1** because of its extreme sensitivity towards atmospheric moisture.

$C_5H_4CH_2CH_2NMe_2$ ^{1}H NMR (500 MHz, C_5D_5N, ambient temp.) δ, ppm: 2.20, s, (CH_3)$_2$N; 2.22, s, (CH_3)$_2$N; 2.44, m; 2.51, m; 2.59, m; 2.93, s; 5.90–6.57 (multiplets).

3.3. Synthesis of $[(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4CH_2CH_2NHMe_2)\text{-}ZrCl_2]_2[ZrCl_6]$ (2)

The solution of monomeric or/and oligomeric **1** was prepared according to 3.1 and 3.2 using 0.267 g (1.95 mmol) $C_5H_4CH_2CH_2NMe_2$, 1.2 ml of 1.6 M BuLi solution in hexane (1.95 mmol) and 0.688 g (1.95 mmol) [$CpZrCl_3 \cdot$ DME]. The final solution of **1** was stirred for 2 h at ambient temperature and 15 ml of 0.18 M HCl solution in methanol (2.7 mmol) were dropped in. The brown colour turned rapidly to pale yellow-green. After ca. 1 h the solution was concentrated under vacuum and kept for four days at about +4 °C. 0.419 g of pale yellow-green solid deposited. The precipitate was dissolved in acetonitrile, filtered and the solution was partially evaporated under vacuum and kept at +4 °C. The pale yellow-green crystals of **2** deposited together with a small amount of a deep green oily contamination, insoluble in CH_3CN.

2 ^{1}H NMR (500 MHz, CD_3CN, ambient temp.) δ, ppm: 2.774 {d, 4.9 Hz, (CH_3)$_2$NH}; 3.13 (m, CpCH_2); 3.23 (m, NCH_2); 6.38 (m*, C_5H_4); 6.51 (m*, C_5H_4); 6.56 (s, C_5H_5); ^{13}C{^{1}H} NMR (89.9 MHz, CD_3CN, ambient temp.) δ, ppm: 25.57 CpCH_2; 35.25 weak signal (?); 43.31 NH(CH_3)$_2$; 57.76 NCH_2; 114.52 C_5H_4; 117.37 C_5H_4; 118.30 C_5H_5; 129.94 C_5H_4(*ypso*) (m* – AA′XX′ pattern, pseudotriplet 3.0 Hz).

Elemental analysis (**2**): C, 32.8; H, 3.99, $C_{28}H_{40}Cl_{10}N_2Zr_3$ calc. C, 32.56; H, 3.90%.

3.4. X-ray diffraction structural studies

The structure has been solved by direct methods and refined with the SHELX-97 software package. All non-hydrogen atoms have been refined in anisotropic approximation. H atoms attached to C atoms were positioned geometrically and refined as riding, with methyl C–H = 0.98 Å, methylene C–H 0.99 Å, aromatic C–H = 0.95 Å and $U_{iso}(H) = 1.2\ U_{eq}(C)$ in all cases. The maximum differential electron-density peak is located 0.63 Å from the Zr1 atom and the deepest hole 1.39 Å from the same atom.

ligands to give a deformed octahedral surrounding. In addition to the structural, electrochemical and spectral study, the interaction of the complexes with the circular and linear forms of p-Bluescript DNA has been reported. The three tested complexes reduce the fluorescence intensity of both circular and linear DNA, but the nature of these interactions remains unknown.

Aoki et al. prepared and studied the zinc supramolecular complex $[(Zn_3L)_4(ttc)_4](NO_3)_{12} \cdot 22H_2O$ (L = 1,3,5-tris-(1,4,7,10-tetraazacyclododecan-1-ylmethyl)benzene), where the ttc anion links three Zn-cyclen moieties through Zn–S coordination bonds [19]. The complex forms a twisted cub-octahedral exterior in which various hydrophobic guest molecules, such as adamantine, can be encapsulated. In another work of this group, zinc supramolecules have been reported with other spacers connecting the cyclene derivatives [20]. In the presented X-ray structure of $[(Zn_3L_1)_3(ttc)_3](NO_3)_9 \cdot 21.5H_2O$, ($L_1$ = tris-cyclen), there are two kinds of ttc bonding i.e. by S atoms only and a tris bidentate chelating mode. In work published by our group we prepared and solved the molecular structure of the complex [Zn(bapen)(ttcH)] · EtOH (bapen = *N*,*N*′-bis(3-amino propyl)ethylenediamine) [21]. The compound is mononuclear only and the zinc atom is coordinated by four N atoms of bapen and by the chelating S, N set of the ttcH dianion.

Many other complexes containing trithiocyanurate anions have been prepared and structurally studied. These complexes can be mononuclear as well as polynuclear, with a chelating S, N donor set or bound by S or N atoms only [22–27]. In our previous works we prepared and structurally characterized a series of nickel(II) and iron(II) complexes containing the trithiocyanurate anion and nitrogen-donor ligands [28–30].

Herein, we present the results of the synthesis and characterization of a series of mixed-ligand complexes involving trithiocyanuric acid and nitrogen-donor ligands of the following composition: [Zn(pmdien)(ttcH)] (**1**), [Zn(taa)-(ttcH)] · H_2O (**2**), $[Fe(nphen)_2(ttcH)] \cdot H_2O$ (**3**), $[Fe(dmbpy)_3](ttcH_2)_2 \cdot 4H_2O$ (**4**), $[Mn(phen)_2(ttcH)] \cdot H_2O$ (**5**), Mn(bpy)(ttcH) · H_2O (**6**), [Ni(taa)(ttcH)] · H_2O (**7**) and $[Ni(phen)_3](ttcH) \cdot 5H_2O$ (**8**), where pmdien = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine, $ttcH_3$ = trithiocyanuric acid, taa = tris(2-aminoethyl)amine, nphen = 5-nitro-1,10-phenanthroline, dmbpy = 4,4′-dimethyl-2,2′-bipyridine, phen = 1,10-phenanthroline and bpy = 2,2′-bipyridine. Compounds **3**, [30] **7** [31] and **8** [32] were prepared before by our group and in that work they were tested for biological activity. According to what we know, manganese complexes with a combination of N ligands and the trithiocyanurate anion are reported for the first time. We were also interested in finding out if the newly prepared complexes show any biological activity. In vitro cytotoxic activity of the complexes against G-361 (human malignant melanoma), HOS (human osteogenic sarcoma), K-562 (human chronic myelogenous leukaemia) and MCF-7 (human breast adenocarcinoma) cancer cell lines was determined. Antimicrobial activity was tested on *Escherichia coli* 3954, 3988, 4225, *Pseudomonas aeruginosa* 3955, *Staphylococcus aureus* 3953, 4223 and *Enterococcus faecalis* 4224.

2. Experimental

2.1. Materials and methods

The chemicals and solvents were purchased from Aldrich Co. and Lachema Co. and were used without further purification. The complexes $[Fe(nphen)_2(ttcH)] \cdot H_2O$ (**3**), [Ni(taa)(ttcH)] · H_2O (**7**) and $[Ni(phen)_3](ttcH) \cdot 5H_2O$ (**8**) were prepared according to the literature methods [30–32].

The C, H, N, S analyses were carried out on an EA 1108 instrument (FISONS). IR spectra (400–4000 cm^{-1}) were recorded on a Perkin–Elmer Spectrum One FT-IR spectrometer using KBr pellets. The absorption spectra in MeCN and the diffuse-reflectance spectra in nujol (11 000–40 000 cm^{-1}) were obtained on a Lambda 35 UV/Vis spectrometer (Perkin–Elmer). Magnetochemical data were obtained by the Faraday method at 293 K using a Sartorius M-25D electrobalance. $Hg[Co(SCN)_4]$ was used as a calibrant. The correction for diamagnetism was calculated using Pascal's constants. The transmission Mössbauer spectrum was recorded using a Mössbauer spectrometer in constant acceleration mode with a $^{57}Co(Rh)$ source. Isomer shift parameters are related to metallic iron (with a calibration temperature of 300 K).

2.2. Preparation of the complexes

2.2.1. [Zn(pmdien)(ttcH)] (1)

N,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (pmdien) (0.2 ml, 1 mmol) was added to an aqueous solution (70 ml) of $Zn(NO_3)_2 \cdot 6H_2O$ (0.3 g, 1 mmol). The mixture was stirred at room temperature for 30 min. A solution of $ttcNa_3 \cdot 9H_2O$ (0.14 g, 0.33 mmol) in water (5 ml) was added in the form of drops. The formation of a white precipitate was observed. The pH of the solution was adjusted to 8 by addition of aqueous NaOH and the rest of the precipitate was removed by filtration. After a week light yellow crystals were separated by filtration, washed with water and dried under an infrared lamp at 40 °C. Yield: 72%. *Anal.* Calc.: C, 34.8; H, 5.8; N, 20.3; S, 23.2. Found: C, 34.8; H, 6.0; N, 20.5; S, 23.7%. IR (cm^{-1}): 456w, 488m, 750w, 776m, 798m, 857s, 906w, 933m, 984m, 1022m, 1043w, 1120w, 1175m, 1215s, 1243m, 1264w, 1432vs, 1631m, 2897w, 2970w, 3436s.

2.2.2. [Zn(taa)(ttcH)] · H_2O (2)

Tris(2-aminoethyl)amine (taa) (0.15 ml, 1 mmol) was added to an EtOH solution (80 ml) of zinc(II) acetate dihydrate (0.22 g, 1 mmol). The mixture was stirred at room temperature for 30 min. A solution of $ttcNa_3 \cdot 9H_2O$ (0.14 g, 0.33 mmol) in water (5 ml) was added in the form of drops. The white precipitate that formed was dissolved

by addition of aqueous NaOH (resulting pH 11). Light yellow crystals suitable for X-ray analysis were obtained after a week. They were filtered, washed with a small amount of EtOH and dried in air. Yield: 67%. *Anal.* Calc.: C, 26.7; H, 5.2; N, 24.2; S, 23.8. Found: C, 26.9; H, 4.9; N, 24.1; S, 23.0%. IR (cm^{-1}): 422w, 469m, 545w, 632w, 650m, 742m, 781w, 858s, 872s, 978s, 994w, 1072s, 1124m, 1194vs, 1248m, 1283w, 1329s, 1360w, 1435vs, 1489vs, 1576m, 2852w, 2932w, 3297m, 3411m.

2.2.3. $[Fe(dmbpy)_3](ttcH_2)_2 \cdot 4H_2O$ (**4**)

4,4′-Dimethyl-2,2′-bipyridine (dmbpy) (0.36 g, 2 mmol) in EtOH (50 ml) was added with stirring to an aqueous solution (50 ml) of $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ (0.39 g, 1 mmol). The mixture was heated at 60 °C for 45 min. After cooling, a small amount of precipitate was filtered off. Then, $ttcNa_3 \cdot 9H_2O$ (0.4 g, 1 mmol) in water (10 ml) was added dropwise to the solution. A dark red substance, which appeared during addition of the solution of $ttcNa_3$, was filtered off, washed with EtOH and dried under an infrared lamp at 40 °C. Yield: 54%. *Anal.* Calc.: C, 48.8; H, 4.7; N, 16.3; S, 18.6. Found: C, 49.1; H, 4.5; N, 15.9; S, 17.8%. IR (cm^{-1}): 455s, 482m, 530m, 622w, 719w, 824m, 873s, 1038w, 1129vs, 1228vs, 1339m, 1480vs, 1521vs, 1618s, 2888w, 3068m, 3417s. UV–Vis (MeCN/cm^{-1}) ($\varepsilon \times 10^{-4}$/$dm^3\ mol^{-1}\ cm^{-1}$): 18900(1.8), 25200(1.5), 36800(10.3). $\mu_{eff} = 2.44$ BM.

Mössbauer spectrum (300 K): doublet I with isomer shift (i.s.) $= 0.29 \pm 0.01$ mm s^{-1}, quadrupole splitting (q.s.) $= 0.29 \pm 0.01$ mm s^{-1}, half-width of the spectral line (Γ) $= 0.30 \pm 0.01$ mm s^{-1} and relative spectrum area (A) = 61.5%; doublet II with i.s. $= 0.35 \pm 0.01$ mm s^{-1}, q.s. $= 0.81 \pm 0.01$ mm s^{-1}, $\Gamma = 0.43 \pm 0.01$ mm s^{-1}, $A =$ 38.5%.

2.2.4. $[Mn(phen)_2(ttcH)] \cdot H_2O$ (**5**)

1,10-Phenanthroline (phen) (0.4 g, 2 mmol) was added to a water solution (80 ml) of manganese(II) acetate tetrahydrate (0.25 g, 1 mmol). Then $ttcNa_3 \cdot 9H_2O$ (0.4 g, 1 mmol) in water (10 ml) was added in drops to the solution. The yellow precipitate which appeared immediately was filtered off, washed several times with water and EtOH and dried under an infrared lamp at 40 °C. Yield: 76%. *Anal.* Calc.: C, 53.3; H, 3.2; N, 16.1; S, 15.8. Found: C, 53.1; H, 3.0; N, 15.7; S, 15.6%. IR (cm^{-1}): 421w, 639m, 725s, 845s, 865s, 1101m, 1129m, 1206s, 1342s, 1424vs, 1460s, 1516m, 1589w, 1622m, 3429s. UV–Vis (cm^{-1}): 25150, 26200, 29400. $\mu_{eff} = 6.20$ BM.

2.2.5. $Mn(bpy)(ttcH) \cdot H_2O$ (**6**)

A preparation similar to that for the synthesis of (**5**) was applied, only 2,2′-bipyridine (bpy) (0.32 g, 2 mmol) was used instead of 1,10-phenanthroline. The substance is also yellow. Yield: 66%. *Anal.* Calc.: C, 38.6; H, 2.7; N, 17.3; S, 23.8. Found: C, 38.4; H, 2.8; N, 16.9; S, 22.9%. IR (cm^{-1}): 411w, 627m, 649m, 736m, 763s, 873s, 1016m, 1042w, 1059w, 1153 m, 1224s, 1315w, 1439vs, 1473s, 1574w, 1595s, 3090w, 3413s. UV–Vis (cm^{-1}): 25450, 27400, 28900, 36360. $\mu_{eff} = 5.90$ BM.

2.3. X-ray crystallography

X-ray data of (**2**) were collected on a Siemens SMART CCD diffractometer with Mo Kα radiation ($\lambda =$ 0.71073 Å, graphite monochromator). The crystal was cooled to 173(2) K by a flow of nitrogen gas using the LT-2A device. A full sphere of reciprocal space was scanned by 0.3 steps in ω with a crystal-to-detector distance of 3.97 cm. A preliminary orientation matrix was obtained from the first frames using SMART [33]. The collected frames were integrated using the preliminary orientation matrix which was updated every 100 frames. Final cell parameters were obtained by refinement of the positions of reflections with $I > 10\sigma(I)$ after integration of all the frames using the SAINT software [33]. The data were empirically corrected for absorption and other effects using the SADABS program [34]. The structures were solved by direct methods and refined by full-matrix least squares on all $|F^2|$ data using SHELXTL software [35].

The largest peak and hole on the final difference map were 0.427 and −0.251 e $Å^{-3}$. Important crystallographic parameters are as follows: $C_9H_{21}N_7OS_3Zn$, wavelength 0.71073 Å, monoclinic, space group $P2_1/c$, $a =$ 11.8044(3) Å, $b = 12.7373(4)$ Å, $c = 10.7776(3)$ Å, $\beta =$ 95.051(1)°, volume 1614.19(8) $Å^3$, $Z = 4$, density (calc.) 1.666 Mg/m^3, absorption coefficient 1.919 mm^{-1}, $F(000) = 840$, crystal size $0.31 \times 0.19 \times 0.11$ mm, index ranges $-18 \leqslant h \leqslant 17$, $-19 \leqslant k \leqslant 18$, $-16 \leqslant l \leqslant 16$, reflections collected/independent 29364/5883 ($R_{int} = 0.0213$), refinement method full-matrix least-squares on F^2, data/restraints/parameters 5883/0/224, goodness-of-fit on $F^2 = 1.024$, final R_1 (2σ data) = 0.0207, $wR_2 = 0.0550$, final R_1 (all data) = 0.0250, $wR_2 = 0.0571$.

2.4. Biological activity testing

K-562, MCF7, G-361 and HOS were used for a cytotoxicity determination of the complexes by a calcein AM assay. The tumor cells were maintained in 75 ml plastic tissue culture flasks (TPP) and grown on Dulbecco's modified Eagle's cell culture medium (DMEM) containing 1 g l^{-1} glucose, 4 mM glutamine, 100 IU ml^{-1} penicillin, 100 μg ml^{-1} streptomycin, 10% foetal bovine serum and 3.7 g l^{-1} sodium bicarbonate. The cell suspension of approximate density 1.25×10^{-5} cells/ml was redistributed into 96-well microtitre plates (Nunc, 80 μl per well). After preincubation (12 h at 37 °C, 5% CO_2), the test compounds, in sixfold dilutions, were added (20 μl per well). Incubation of the cells with the tested compounds (in the 0.2–100 μM range) lasted for 72 h at 37 °C in 5% CO_2 atmosphere, 100% humidity. At the end of this period, the cells were incubated for 1 h with calcein AM and the fluorescence of the live cells was measured at 485 nm/538 nm (ex/em) with a Fluoroscan Ascent (Labsystems,

Finland). IC_{50} values, the drug concentrations lethal to 50% of the tumor cells, were estimated.

The antimicrobial activities of $ttcNa_3$ and its metal complexes were estimated by MIC ($\mu g\ ml^{-1}$). The bacteria were inoculated into 5 ml of a liquid medium (Mueller-Hinton broth), and cultured for 2 h at 37 °C, then diluted with distilled water in a 1:10 ratio. The cultured fluids were adjusted to the cell concentration of 100 μl and used for inoculation in the MIC test. The test ligand and complexes were dissolved in water. Solutions with concentrations 100 $\mu g\ ml^{-1}$ for $ttcNa_3$ and 357 $\mu g\ ml^{-1}$ for the complexes were prepared. Each 1 ml of culture medium containing various concentrations of the test materials was inoculated with 0.1 ml of the microorganism suspension prepared above. Bacteria were cultured for 18 h at 37 °C, then the growth of microorganisms was observed. When no growth of microorganisms was observed in the medium containing the lowest concentration of the test materials, the MIC of the test material was defined at this point of dilution. All compounds were tested three times and results are given as an average of the three independent experiments.

3. Results and discussion

New Zn(II), Fe(II) and Mn(II) complexes were prepared by the reaction of metal salts with the appropriate amines or imines followed by addition of the sodium salt of trithiocyanuric acid in aqueous or ethanol media. Their composition was proved by elemental analysis and they were characterized by spectroscopic methods and magnetochemical measurements. The results of elemental analysis together with results of physical techniques are given in Section 2. Moreover, our findings dealing with the composition of the complexes were confirmed by complete X-ray analysis of complexes **1**, **2** and **4**. In this work we present the X-ray structure of **2** only, whereas structures of complexes **1** and **4** will be published elsewhere. Briefly, the zinc atom in complex **1** is in a deformed trigonal bipyramidal arrangement formed by three N atoms of pmdien and the N,S donor set of the $ttcH^{2-}$ anion. The structure is similar to that of [Ni(pmdien)(ttcH)], which we reported earlier [29]. The iron atom in **4** is in a deformed octahedral arrangement of three N–N ligands (dmbpy), whereas the $ttcH_2^-$ anions and water molecules are outside the coordination sphere.

3.1. Spectral and magnetochemical study

The vibrational frequencies with their relative intensities are given in the experimental part. In our previous work we used density-functional theory calculations for the geometry optimization and IR frequencies calculations of differently protonated forms of $ttcH_3$ [30]. On the base of DFT calculations, we can assign bands which are connected with the ν(C–N) and ν(C–S) vibrations of the 2,4,6-trimercapto-1,3,5-triazine ring. These are observed in the IR spectra of the complexes in the 1515–1576 and 1175–1264 cm^{-1}, and 845–873 and 411–422 cm^{-1} regions, respectively. The bands observed in the 3068–3436 cm^{-1} region can be attributed to ν(C–H) and ν(N–H) vibrations [36]. In the spectra of complexes **1**, **2** and **4** the bands in the region 2852–2970 cm^{-1} can be connected with $\nu_s(CH_2)$ and $\nu_{as}(CH_2)$ vibrations. IR spectra of complexes **4**–**6**, with coordinated aromatic heterocycles (bpy, phen), contain several bands in the regions 700–900 and 1400–1600 cm^{-1} which are attributed to the ν(C–C) and ν(C–N) ring modes and the ring deformation vibrations, respectively. Most of the peaks of the free ligands are shifted to higher frequencies upon coordination.

There are three bands in the electronic absorption spectrum of **4**. The weak bands at 18 900 and 25 200 cm^{-1} can be attributed to d–d and metal to ligand charge transfer (MLCT) transitions, respectively [37]. The third strong absorption band observed at 36 800 cm^{-1} is probably due to a CT or π–π* transition associated with the ligands. In the spectra of the Mn(II) complexes **5** and **6** we can observe bands expected for octahedral high spin species at 25 150, 26 200 and 29 400 cm^{-1} for **5**, and 25 450, 27 400 and 28 900 cm^{-1} for **6**. These bands can be attributed to the d–d transitions. Very intensive bands in the UV range are probably due to CT or π–π* transitions.

The magnetic moment value for **4** ($\mu_{eff} = 2.44$ BM) is higher than that expected for a low spin deformed octahedral Fe(II) complex. A similar value of magnetic moment ($\mu_{eff} = 2.38$ BM) was calculated for $[Fe(phen)_2(NCS)_2]$ [38]. The authors explained a higher value of magnetic moment by residual paramagnetism due to polymorphism of the complex. Another explanation of a high magnetic moment value is deformation of the octahedral iron environment caused by the presence of methyl groups and the influence of water in the crystal lattice. This suggestion seems to be in agreement with the results of Mössbauer spectroscopy. The room temperature Mössbauer spectrum of **4** is composed of two doublets with the values of isomer shift (0.29 and 0.35 mm s^{-1}) typical for octahedral low-spin iron(II) complexes [39,40]. The doublet I with relative spectrum area $A = 61.5\%$ has a lower value of the quadrupole splitting parameter (q.s. = 0.29 mm s^{-1}) than the doublet II ($A = 38.5\%$, q.s. = 0.81 mm s^{-1}). The two different values of quadrupole splitting show that there are two octahedrally coordinated iron centers with lower and higher distortion from ideal octahedral arrangement found in the polycrystalline material. In our previous work, similar spectra with two doublets were also obtained and interpreted as a result of distortion of the octahedral arrangement of the central atoms in iron(II) complexes [30].

The manganese complexes **5** and **6** have magnetic moments 6.20 and 5.90 μ_{eff}/BM, respectively. These values are very close to the spin only value (5.93 μ_{eff}/BM) expected for five unpaired electrons of high spin deformed octahedrally coordinated manganese(II) atoms. From the composition of **6** we can propose a polymeric structure for the complex, where ttcH can form a bridge between the central atoms.

3.2. X-ray structure of [Zn(taa)(ttcH)] · H_2O (2)

The molecular structure of [Zn(taa)(ttcH)] · H_2O (**2**) is depicted in Fig. 1, while selected bond lengths and angles are listed in Table 1. The crystal structure is stabilized by hydrogen bonds (see Table 2, Fig. 2). The molecular structure of **2** consists of an electroneutral zinc complex and one crystal water molecule, which is hydrogen-bonded to the hydrogen atom of $ttcH^{2-}$. The central zinc atom is coordinated by four N atoms of taa and one N atom of the trithiocyanurate(2^-) dianion. The coordination polyhedron around the zinc atom is deformed trigonal-bipyramid with terminal nitrogen atoms N3A, N3B and N3C of taa in the basal plane while the central (tertiary) nitrogen atom N1 of taa and N2 atom of $ttcH^{2-}$ are coordinated in apical positions. The axial Zn–N1 bond length (2.3490(8) Å) is significantly longer than the equatorial Zn–N bond lengths, which are in the range 2.0618(9)–2.0887(9) Å. The Zn–N2 bond length of 2.1272(8) Å is longer than that found in Ni–N(trithiocyanurate) of [Ni(taa)(ttcH)] (2.040(2) Å),

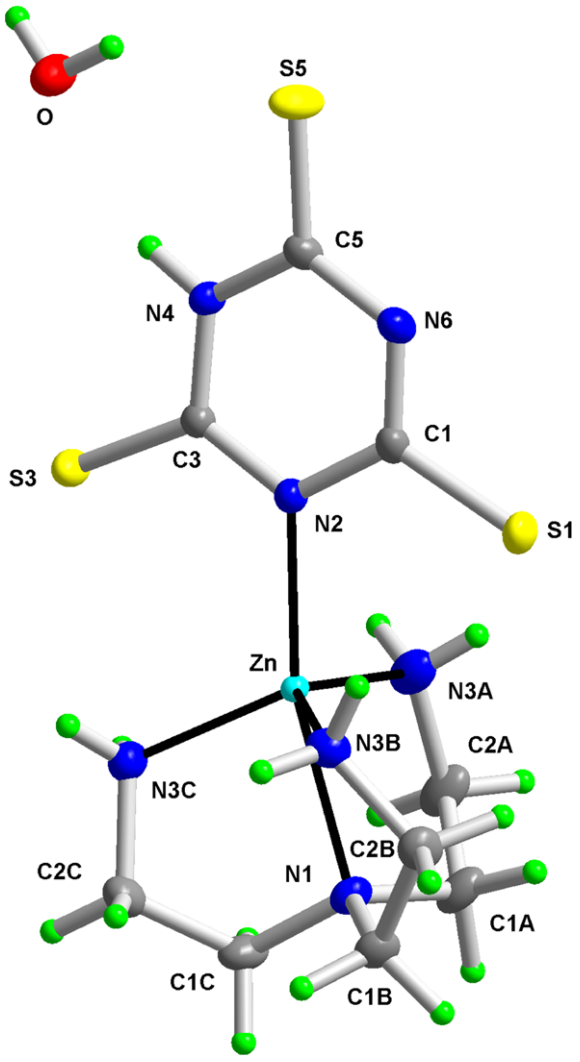

Fig. 1. The molecular structure of **2** with the numbering scheme and atomic displacement ellipsoids drawn at the 50% probability level.

Symmetry transformations used to generate equivalent atoms: (i) $-x$, $-y+1$, $-z$, (ii) x, $-y+1/2$, $z-1/2$, (iii) $-x$, $y-1/2$, $-z+1/2$, (iv) x, $-y+1/2$, $z+1/2$, (v) $-x+1$, $y-1/2$, $-z+1/2$, (vi) $-x$, $-y$, $-z$.

whereas other Ni–N(taa) distances are within the range of 2.063(3)–2.109(3) Å, comparable with those found in **2** [31]. In [Zn(bapen)(ttcH)] · EtOH (bapen = *N*,*N*′-bis-(3-aminopropyl)ethylenediamine), where $ttcH^{2-}$ is coordinated in a chelating fashion through N and S atoms, the Zn–N(trithiocyanurate) (2.3132(18) Å) distance is significantly longer in comparison with the Zn–N2 distance in **2** [21].

When we compare the known structures of zinc complexes with the taa ligand [Zn(taa)(H_2O)](ClO_4)$_2$, [Zn(taa)(MeOH)](ClO_4)(BPh_4) and [Zn(taa)(NCS)](SCN) with **2**, we can observe that the equatorial Zn–N bond lengths are very similar, whereas there are big differences in Zn–N(axial) bonds [41–43]. The axial bond lengths are 2.193(4), 2.16(1) and 2.292(4) Å, for the above mentioned complexes, while in **2** the distance is longer (2.3490(8) Å). In comparison with Zn–N(thiocyanate), the distance (2.073(5) Å) in [Zn(taa)(NCS)](SCN) is shorter than that found in **2**, Zn–N(trithiocyanurate) (2.1272(8) Å). We can also mention big differences in the equatorial N–Zn–N angles. In the three complexes mentioned above the

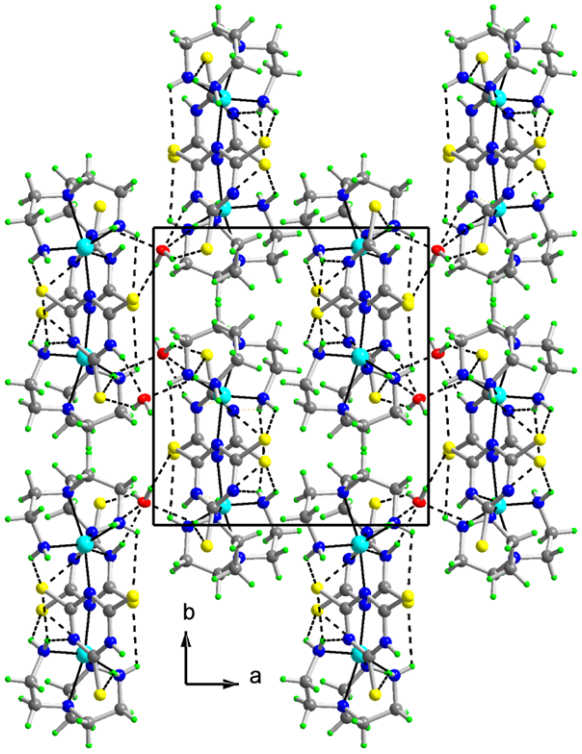

Fig. 2. Hydrogen bonding pattern in projection along the *c*-axis. Hydrogen bonds are shown as broken lines. For geometrical details see Table 2.

equatorial angles are all within an average of 118°, whilst in **2** the angles are in the range 107.82(4)–130.52(4)°.

3.3. In vitro cytotoxicity and antimicrobial activities

The cytotoxic activity of the complexes **1**–**8** and the sodium salt of trithiocyanuric acid ($ttcNa_3$) were studied on G-361, HOS, K-562 and MCF7 cancer cell lines. The results of the study are listed in Table 3. It can be clearly seen that zinc (**1**, **2**) and nickel (**7**, **8**) complexes as well as $ttcNa_3$ show no activity against K-562 and MCF7 in the concentration range used. On the other hand, very promising results were achieved for iron (**3**, **4**) and manganese (**5**, **6**) compounds. The four compounds show activity on K-562 and MCF7 cell lines. Based on average IC_{50} values, in the two cell lines compounds **3** and **5** are the most active ones and the results are comparable or mostly better than those obtained for cisplatin and oxaliplatin. Compound **4** is less active and **6** shows very low activity. The very low activity of **6** can be caused by the possible polymeric structure of the compound. The most active compounds i.e. **3** and **5** were selected for testing on G-361 and HOS cancer cell lines. The compounds are very efficient in inhibiting these cell line growths. They are comparable in activity with cisplatin and are two to four times more effective than oxaliplatin.

A combination of imines and the trithiocyanurate anion is not sufficient in bringing about cytotoxicity. It is seen when complexes **4** and **8** are compared. It can be clearly seen that the metal ion has a big influence on cytotoxicity of the complexes. Zinc and nickel compounds with amines or imines are inactive, whereas those containing iron or manganese ions show cytotoxicity. It seems that it is also important whether the trithiocyanurate anion is coordinated to the central atom or not. It can be demonstrated

Table 3
In vitro cytotoxicity of the complexes

	K-562	MCF7	G361	HOS
(**1**) [Zn(pmdien)(ttcH)]	>25	>25		
(**2**) $[Zn(taa)(ttcH)] \cdot H_2O$	>100	>100		
(**3**) $[Fe(nphen)_2(ttcH)] \cdot H_2O$	5.1	3.9	3.4	3.0
(**4**) $[Fe(dmbpy)_3](ttcH_2)_2 \cdot 4H_2O$	9.8	22.7		
(**5**) $[Mn(phen)_2(ttcH)] \cdot H_2O$	2.7	6.0	3.8	1.6
(**6**) $Mn(bpy)(ttcH) \cdot H_2O$	65.6	45.3		
(**7**) $[Ni(taa)(ttcH)] \cdot H_2O$	>25	>25		
(**8**) $[Ni(phen)_3](ttcH) \cdot 5H_2O$	>25	>25		
$ttcNa_3 \cdot 9H_2O$	>100	>100		
Oxaliplatin	8.8	18.2	7.1	6.8
Cisplatin	4.7	10.9	2.9	3.0

The results are given as IC_{50} values for the compounds (μM) assessed by calcein AM assay of surviving tumor cells. The tumor cell lines (K-562, MCF7, G361, HOS) were treated with a solution of the tested compound in the 0.2–25 μM (**1**, **7**, **8**) and 0.2–100 μM range (for the other compounds) for 72 h at 37 °C, 5% CO_2.

Table 4
Antimicrobial activities of the complexes evaluated by MIC (μg ml^{-1})[a]

	3953[b]	4223[b]	4224[b]	4225[b]	3988[b]	3954[b]	3955[b]
(**1**) [Zn(pmdien)(ttcH)]	>357	>357	>357	>357	>357	>357	>357
(**2**) $[Zn(taa)(ttcH)] \cdot H_2O$	>357	>357	>357	>357	>357	>357	>357
(**3**) $[Fe(nphen)_2(ttcH)] \cdot H_2O$	44.6	44.6	>357	>357	>357	>357	>357
(**4**) $[Fe(dmbpy)_3](ttcH_2)_2 \cdot 4H_2O$	89.3	89.3	>357	89.3	89.3	89.3	89.3
(**5**) $[Mn(phen)_2(ttcH)] \cdot H_2O$	>357	>357	>357	44.6	44.6	89.3	178.5
(**6**) $Mn(bpy)(ttcH) \cdot H_2O$	357	357	>357	357	357	357	357
(**7**) $[Ni(taa)(ttcH)] \cdot H_2O$	>357	>357	>357	>357	>357	>357	>357
(**8**) $[Ni(phen)_3](ttcH) \cdot 5H_2O$	178.5	178.5	>357	357	357	>357	>357
$ttcNa_3 \cdot 9H_2O$	>100	>100	>100	>100	>100	>100	>100

[a] The final concentration was 357 μg ml^{-1} for the complexes and 100 μg ml^{-1} for $ttcNa_3 \cdot 9H_2O$.
[b] The antimicrobial activities were evaluated against *Staphylococcus aureus* 3953, 4223, *Enterococcus faecalis* 4224, *Escherichia coli* 4225, 3988, 3954, *Pseudomonas aeruginosa* 3955.

on complexes **3** and **4**. Complex **3**, where the ttcH anion is coordinated, shows better activity.

The results of antimicrobial activities of $ttcNa_3$ and the complexes, estimated by MIC ($\mu g\ ml^{-1}$), are listed in Table 4. The free salt $ttcNa_3$ and complexes **1**, **2**, **6** and **7** did not inhibit the growth of the test organisms. Compound **3** showed selective and effective antimicrobial activities against Gram-positive bacteria (*S. aureus*); **4** exhibited effective activities against all tested bacteria, except for *E. faecalis*. Complex **5** showed effective activities against *Escherichia coli* and modest activity against *P. aeruginosa*, whereas **8** exhibited modest activities against *S. aureus*. It seems that compounds containing imines are active with the exception of **6**, where a polymeric structure is suggested.

4. Supplementary material

CCDC 610058 contains the supplementary crystallographic data for **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

clear need to synthesize and investigate novel species of this type. What is more, the *fac*-$Re(CO)_3^+$ complexes can be used as diagnostic and therapeutic radiopharmaceuticals. It has resulted in an added increase in the interest of these compounds [13,14].

Here, we present the synthesis, spectroscopic characterization, crystal, molecular and electronic structure of the *fac*-[$Re(CO)_3$(dppt)Cl] tricarbonyl. 5,6-Diphenyl-3-(2-pyridyl)-1,2,4-triazine (dppt) is a bipy-like ligand, but very little is currently know about the binding of this ligand to the rhenium center.

The molecular orbital diagram of the examined complex has been calculated with density functional theory (DFT) calculations, and additional information about binding has been obtained by NBO analysis. Density functional theory (DFT) is commonly used to examine the electronic structure of transition metal complexes. It meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [16]. The spin-allowed singlet–singlet electronic transitions of *fac*-[$Re(CO)_3$(dppt)Cl] have been calculated with the time-dependent DFT method (TDDFT method), and a good assignment with the experimental spectrum has been observed.

1. Experimental

1.1. General procedure

All synthetic manipulations were performed under argon atmosphere. The solvents were dried before use, using the appropriate drying reagents. $Re(CO)_5Cl$ and 5,6-diphenyl-3-(2-pyridyl)-1,2,4-triazine were purchased from Aldrich, and they were used as received.

IR spectrum was recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectrum was measured on a spectrophotometer Lab Alliance UV–VIS 8500 in the range 900–200 nm in dichloromethane solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

1.2. Preparation of [$Re(CO)_3$(dppt)Cl]

$Re(CO)_5Cl$ (0.2 g, 0.55 mmol) and dppt (0.18 g, 0.58 mmol) in toluene (50 cm^3) were refluxed for 6 h. After cooling of the reaction mixture to room temperature and slow evaporation of the solvent under reduced pressure, an orange solid was precipitated. The product was further purified by re-crystallization from acetone/hexane. X-ray quality crystals of *fac*-[$Re(CO)_3$(dppt)Cl] were obtained by re-crystallization from a hexane/dichloromethane mixture (Yield 90%).

IR (KBr, cm^{-1}): $\nu_{CO} = 2021$, 1930 and 1891; 1566(w), ν_{CN} and $\nu_{C=C} = 1608$, 1597, 1578 and 1517.

Anal Calc. for $C_{23}H_{14}N_4O_3ClRe$: C, 44.84; H, 2.29; N, 9.09. Found: C, 44.70; H, 2.20; N, 9.20%.

1.3. Crystal structure determination and refinement

A orange crystal of [$Re(CO)_3$(dppt)Cl] was mounted on a KM-4-CCD automatic diffractometer equipped with a CCD detector, and used for data collection. X-ray intensity data were collected with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at a temperature of 293.0(2) K. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and empirical absorption correction using spherical harmonics implemented in SCALE3 ABSPACK scaling algorithm [17] were applied. The structure was solved by means of the Patterson method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix, least-squares technique. The hydrogen atoms of the phenyl rings were treated as "riding" on their parent carbon atoms [d(C–H) = 0.96 Å] and assigned isotropic temperature factors equal to 1.2 times the value of the equivalent temperature factor of the parent carbon atom. SHELXS97 [18], SHELXL97 [19] and SHELXTL [20] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

Maximum and minimum transmission	0.510 and 0.841
Data/restraints/parameters	6405/0/289
Goodness-of-fit on F^2	1.160
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0412$,
	$wR_2 = 0.0959$
R indices (all data)	$R_1 = 0.0706$,
	$wR_2 = 0.1161$
Largest difference in peak and hole (e Å^{-3})	1.835 and −1.660

1.4. Computational details

The GAUSSIAN03 program [21] was used in the calculations. The geometry optimization was carried out with the DFT method with the use of the B3LYP functional [22,23]. The electronic spectrum was calculated with the TDDFT method [24]. The calculations were performed by using the ECP basis set on the rhenium atom, the standard 6-31+G** basis for chlorine, oxygen and nitrogen, 6-31+G* for carbon and 6-31G basis for hydrogen atoms. The Xe core electrons of Re were replaced by an effective core potential and the DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [25] was used for the valence electrons. An additional *d* function with exponent $\alpha = 0.3811$ and *f* function with exponent $\alpha = 2.033$ on the rhenium atom were added. Natural bond orbital (NBO) calculations were performed with the NBO code [26] included in GAUSSIAN03.

2. Results and discussion

2.1. Preparation and infrared data

The $[Re(CO)_3(dppt)Cl]$ complex was prepared by refluxing the compound $[Re(CO)_5Cl]$ with a small excess of 5,6-diphenyl-3-(2-pyridyl)-1,2,4-triazine (dppt) in toluene. The complex was isolated as an air-stable, microcrystalline solid, soluble in common organic solvents. The infrared spectrum of the complex displays three bands in the carbonyl stretching region: a sharp intense band at 2021 cm^{-1} and two lower-energy bands closely spaced (1930 and 1891 cm^{-1}), typical of Re(I) diimine tricarbonyl complexes [27].

The characteristic bands of the C=C and C=N stretching modes are observed in the range 1616–1510 cm^{-1} [28].

2.2. Crystal structure

The crystallographic data for the title complex are given in Table 1. A perspective drawing of the structure of the complex with the atomic numbering is shown in Fig. 1. The phenyl rings show symptoms of disorder. Detailed examination of difference Fourier maps electron density did not show any abnormal peaks or holes around the disordered atoms, thus it could be supposed that the disorder is dynamic in character. The coordination geometry at the Re atom is a distorted octahedron with the three carbonyl

Table 2
The experimental and optimized bond lengths (Å) and angles (°) for $[Re(CO)_3(dppt)Cl]$

	Bond lengths			Bond angles	
	Experimental	Optimized		Experimental	Optimized
Re(1)–C(1)	1.917(8)	1.934	C(1)–Re(1)–C(2)	91.0(4)	90.60

			O(2)–C(2)–Re(1)	177.6(8)	178.19
			O(3)–C(3)–Re(1)	175.7(7)	179.52

ligands arranged in a *facial* fashion. The deviation of the rhenium coordination sphere from an ideal octahedron is ascribed to the small bite angle of the five membered chelate ring. Selected bond lengths and angles of $[Re(CO)_3(dppt)Cl]$ are given in Table 2. The Re–C and Re–N bond distances are about the same as those reported for other diimine systems $[Re(CO)_3(diimine)L]$ [15]. A noticeable difference between Re–N(pyridine) and Re–N triazine bond lengths indicates the different donor strength of the two nitrogens donors. The triazine ring favours π-back donation from the rhenium ion to the carbonyl in the *trans* position. Hence, Re–C(1) is shorter in comparison to Re–C(2). In the structure no intermolecular short contacts, which can be considered as classical hydrogen bonds or stacking interactions, were found.

2.3. Optimised geometry

The geometry of $[Re(CO)_3(dppt)Cl]$ was optimised in a singlet state by the DFT method with the B3LYP functional. The optimised geometric parameters are gathered in Table 2. Generally, the calculated bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data.

2.4. Electronic structure and NBO analysis

The $[Re(CO)_3(dppt)Cl]$ complex is a closed-shell structure. Its molecular orbital diagram with several highest HOMO and lowest LUMO contours is presented in Fig. 2. The HOMO–LUMO gap equals 2.67 eV. The low-

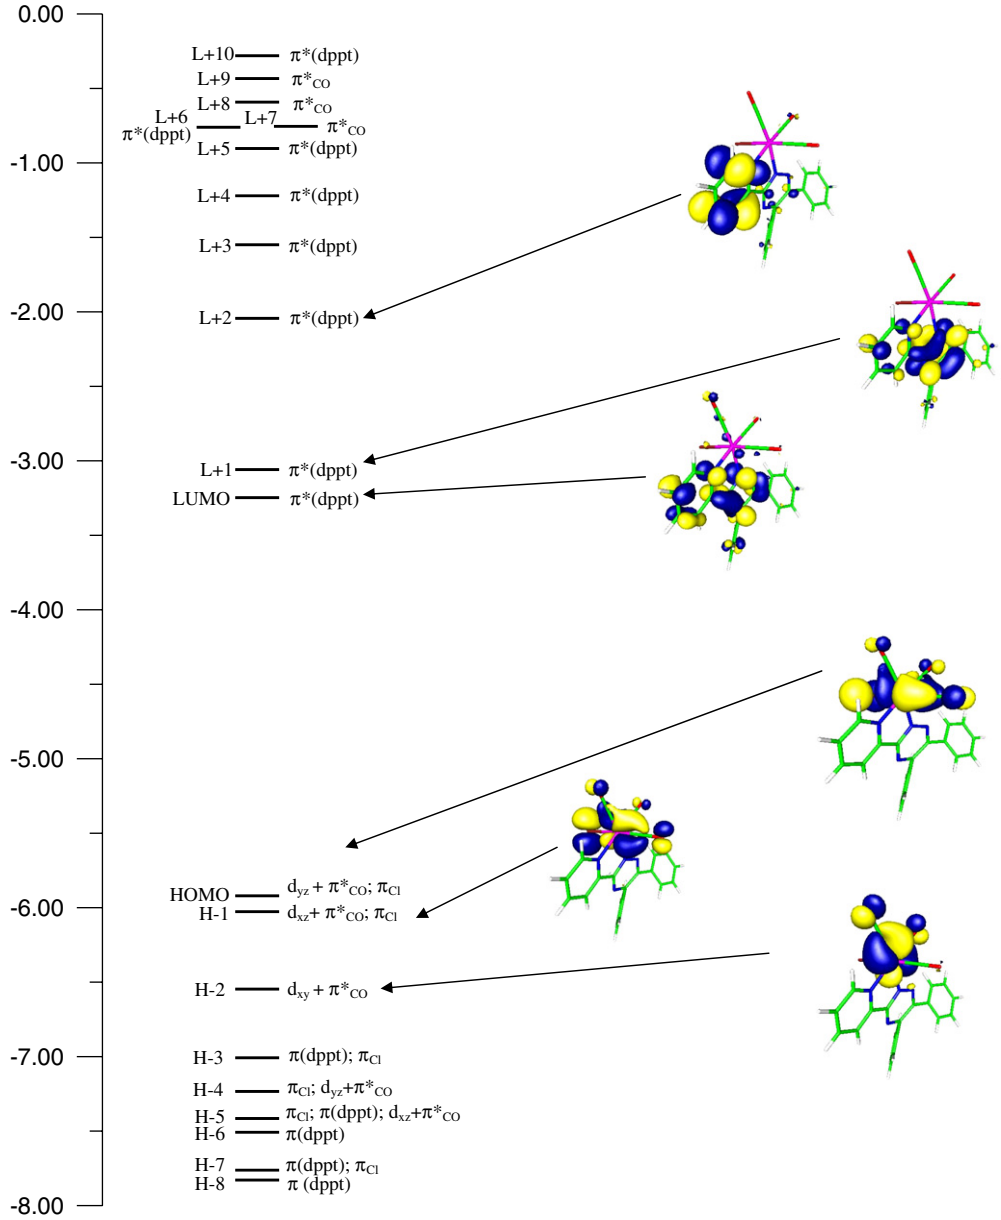

Fig. 2. The energy (eV), character and some contours of the unoccupied molecular orbitals of $[Re(CO)_3(dppt)Cl]$.

lying virtual orbitals correspond to π^*_{dppt} and π^*_{CO}, and energy of the π^*_{dppt} is lower than π^*_{CO} orbitals. The HOMO, HOMO − 1 and HOMO − 2 orbitals are predominantly of d_{Re} orbital character, corresponding to the $(5d_{xy})^2$ $(5d_{\pi})^4$ occupation.

Table 3 presents the occupancies and hybridization of the calculated Re–C and C–O natural bond orbitals (NBOs).

Each natural bond orbital (NBO) σ_{AB} can be written in terms of two directed valence hybrids (HHOs) h_A i h_B on atoms A and B

$$\sigma_{AB} = c_A h_A + c_B h_B$$

where c_A i c_B are polarization coefficients. Each valence bonding NBO must in turn be paired with a corresponding valence *anti*-bonding NBO

$$\sigma^*_{AB} = c_B h_A - c_A h_B$$

to complete the span of the valence space. The Lewis-type (donor) NBOs are thereby complemented by the non-Lewis-type (acceptor) NBOs that are formally empty in an idealized Lewis picture. The interactions between 'filled' Lewis-type NBOs and 'empty' non-Lewis NBOs lead to loss of occupancy from the localized NBOs of the idealized Lewis structure into the empty non-Lewis orbitals, and they are referred to as 'delocalization' corrections to the zeroth-order natural Lewis structure [29].

For each carbonyl group of the $[Re(CO)_3(dppt)Cl]$ complex, three natural bond orbitals were detected for the C–O bond, and one orbital for the Re–C bond. All the Re–C bond orbitals are polarized towards the carbon atom, and the C–O bond orbitals are polarized towards the oxygen end. Each oxygen atom of the carbonyl ligand possesses one lone pair (LP) orbital. The occupancies of the *anti*-bonding NBOs are given in round brackets.

The resonance structure $M-\overset{+}{C}\equiv O:$, which presents the best bonding between the CO ligands and the Re ion in $[Re(CO)_3(dppt)Cl]$, is consistent with the values of the calculated atomic charges. The atomic charges from the Natural Population Analysis (NPA) for $[Re(CO)_3(dppt)Cl]$ are shown in Table 4. The calculated charge on the rhenium atom of $[Re(CO)_3(dppt)Cl]$ is lower than the formal charge +1. The carbon atoms of the carbonyl ligands are positive, whereas the oxygen atoms are negatively charged.

Table 3
The occupancies and hybridization of the calculated Re–C and C–O natural bond orbitals (NBOs) for $[Re(CO)_3(dppt)Cl]$

BD	Occupancy	Hybridization of NBO
Re(1)–C(1)	1.966 (0.299)	$0.563(sd^{2.23})_{Re} + 0.827(sp^{0.55})_C$

2.5. Electronic spectrum

The experimental (measured in dichloromethane solution) and calculated electronic spectra of $[Re(CO)_3(dppt)Cl]$ are presented in Fig. 3. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}. In the Fig. 3, the low-energy calculated bands of $[Re(CO)_3(dppt)Cl]$ seems to be somewhat shifted in relation to the longest wavelength experimental band. However, the comparison of the energies in eV for these transitions indicates a satisfactory agreement between the

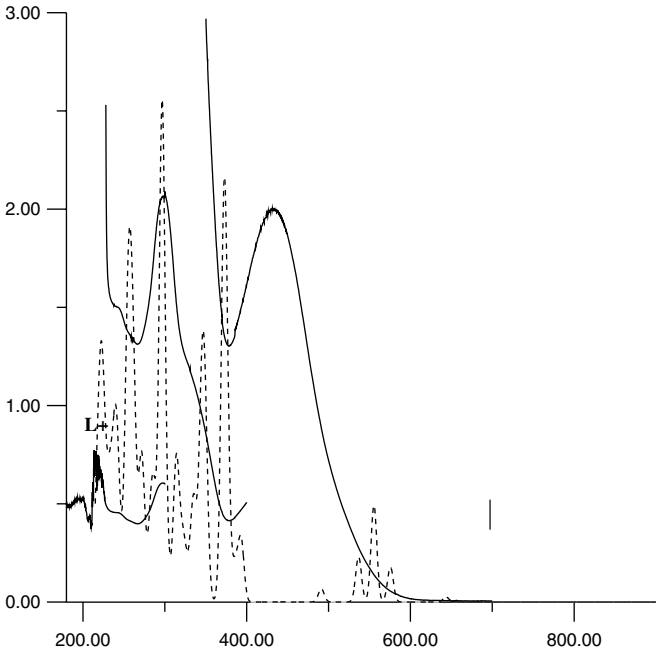

Fig. 3. The experimental (——) and calculated (----) electronic absorption spectra of $[Re(CO)_3(dppt)Cl]$.

experimental and calculated spectra. The spin-allowed singlet–singlet electronic transitions calculated with the TDDFT method for $[Re(CO)_3(dppt)Cl]$ are gathered in Table 5. For the high energy part of the spectrum (below 250 nm), only transitions with oscillator strengths larger than 0.015 are listed in Table 5.

The assignment of the calculated transitions to the experimental bands is based on the criterion of the energy and oscillator strength of the calculated transitions. In the description of the electronic transitions only the main components of the molecular orbital are taken into consideration.

The title complex contains a reducing metal center and an acceptor ligand with low-energy π^* orbitals. Similar to other Re(I) carbonyl-diimine complexes, the UV–Vis spectrum of $[Re(CO)_3(dppt)Cl]$ exhibits a broad low-energy

absorption band attributed to *MLCT* transitions from the rhenium center to the π-antibonding orbitals of the chelating ligand. The Re → π^*_{dppt} absorption appears at 449.4 nm, and is clearly red shifted in comparison with Re → π^*_{bipy} (370 nm) for [Re(CO)$_3$(bipy)Cl]. The dppt ligand leads to a slight decrease in the HOMO–LUMO energy gap, giving slightly lower energy MLCT transitions.

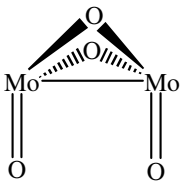
The experimental absorption bands at 331, 300 and 242 nm result from *Metal–Ligand Charge Transfer* (occurring from the rhenium ion to the π-antibonding orbitals of the N–N ligand or π-antibonding orbitals of the carbonyl group) and *Ligand–Ligand Charge Transfer* transitions. However, the main contribution in these bands can be assigned to the *LLCT* excitations. The oscillator strengths of the *LLCT* transitions are considerable larger than those of *MLCT* transitions.

The intra- and interligand transitions are assigned to the highest energy absorption band at 216 nm.

3. Conclusions

The [Re(CO)$_3$(dppt)Cl] complex has been prepared and structurally as well as spectroscopically characterized. X-ray and IR studies confirm a *facial* geometry of the carbonyl ligands in [Re(CO)$_3$(dppt)Cl]. The molecular orbital diagram of the tricarbonyl has been calculated with the density functional theory (DFT) method. The HOMO, HOMO − 1 and HOMO − 2 orbitals are predominantly of d_{Re} orbital character corresponding to the $(5d_{xy})^2$ $(5d_\pi)^4$ occupation. The low-lying virtual orbitals correspond to π^*_{dppt} and π^*_{CO}. Additional information about binding in [Re(CO)$_3$(dppt)Cl] was obtained by NBO analysis. The resonance structure $\bar{M}-\overset{+}{C}\equiv O:$, represents the best bonding between the CO ligands and the Re ion in [Re(CO)$_3$(dppt)Cl]. The spin-allowed electronic transitions of *fac*-Re(CO)$_3$(dppt)Cl have been calculated with the time-dependent DFT method (TDDFT method), and a good agreement between calculated and experimental spectra is observed.

4. Supplementary material



CCDC 623685 contains the supplementary crystallographic data for $C_{23}H_{14}N_4O_3ClRe$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgement

The GAUSSIAN03 calculations were carried out in the Wrocław Centre for Networking and Supercomputing, WCSS, Wrocław, Poland.

Scheme 1.

$[n\text{-}Bu_4N]_2[Re_2Cl_8]$ provide a tetramolybdenum cluster consisting of $[Mo_2^{V,V}]$ and $[Mo_2^{V,VI}]$ cores linked through a μ_3-O bridge. X-ray structure of $[Mo_2O_2Cl_2(\mu_2\text{-}O)_2(HprNP)_2]$ (HprNP = 2-(2-pyrrolyl)-1,8-naphthyridine) is also discussed.

2. Results and discussion

Quadruply bonded $[Mo^{II}{\equiv}Mo^{II}]$ complexes undergo aerial oxidation in the presence of π-acid ligands to yield dinuclear polyoxomolybdates. Compounds with neutral and anionic bidentate ligands such as 2,2′-dipyridyls [8], 2-pyridyl(diisopropylphosphino)methane [9a] and 2-mercapto pyrimidines [9b] have been structurally characterized. Our recent interest lies in the 1,8-naphthyridine (NP) based ligands pyNP and HprNP [11]. The reaction of $[Mo_2(OAc)_2(CH_3CN)_6][BF_4]_2$ with HprNP in acetonitrile gave a red solid which was dissolved in dichloromethane and layered with hexane in air yielding red crystals of $[Mo_2O_2Cl_2(\mu_2\text{-}O)_2(HprNP)_2]$ (**1**) at the interface. The IR spectrum of **1** exhibit bands at 968 cm^{-1} assigned to Mo=O and at 724 cm^{-1} assigned to Mo–O_μ stretching vibrations [12].

The X-ray study of **1** reveals the molecular structure to be $[Mo_2O_2Cl_2(\mu_2\text{-}O)_2(HprNP)_2]$. The ORTEP diagram of **1** is shown in Fig. 1 and the structural parameters are given in Table 1. The molecular structure of **1** consists of the $[Mo_2O_2(\mu_2\text{-}O)_2]$ core with the *cisoid* Mo=O bonds [13]. The Mo–Mo bond distance of 2.5707(5) Å is indicative of a Mo–Mo single bond resulting from a d^1–d^1 (Mo^V–Mo^V) interaction [8,14]. The distorted octahedral environment around each Mo atom is completed by one chloride, and one HprNP ligand chelating the metal center through the naphthyridine unit. The N–H hydrogens of the pyrrolyl appendages are engaged in hydrogen bonding interaction with the bridging oxygen atoms (N3···O1 = 2.954(4) Å, angle N3–H3–O1 = 155.9(1)°; N6···O2 = 2.874(4) Å, angle N6–H6–O2 = 177.6(1)°). The two Cl atoms are *trans* to the Mo–Mo single bond with the Mo–Cl distances 2.431(1), 2.448(1) Å and Cl1–Mo1–Mo2–Cl2 dihedral angle 157.9(1)°. The Mo(μ-O)$_2$Mo ring is buckled with the distance between the mid-points of the non-intersecting O···O and Mo···Mo vectors of 0.465 Å. The Mo–O_μ–Mo angles are 82.70(12)° and 83.16(12)° and the O_μ–Mo–O_μ angles are 90.32(13)° and 90.70(13)° reflecting the remarkable symmetry of the bridge. There is a slight twist in the central $[Mo_2O_2]$ core with the O=Mo–Mo=O torsional angle of 8.7(2)°. The Mo–O(bridging) distances are in the range 1.915(3)–1.961(3) Å and the Mo–O(terminal) distances are 1.674(3), 1.680(3) Å. The strong interaction of the Mo atoms with the terminal oxo ligands is demonstrated in an enounced *trans* influence with the Mo–N distances (2.198(4), 2.185(4) Å) *cis* to the Mo=O functionality being shorter than the *trans* Mo–N distances (2.503(4), 2.451(4) Å).

The *cis*-$[Mo_2(OAc)_2(pyNP)_2][BF_4]_2$ exhibits an irreversible metal-based oxidation at +0.86 V. The quadruply bonded $[Re_2Cl_8]^{2-}$ was employed as oxidizing agent ($E_{1/2}$(red) = 1.31 V) yielding the tetranuclear molybdenum cluster $[Mo_4Cl_5O_8(pyNP)_2]$ (**2**). As the reaction was carried out in strict anaerobic condition, the source of oxygens in **2** is possibly the inadvertent water molecules. The use of moist $[n\text{-}Bu_4N]Cl$ failed to yield **2** in any discernable amount implying the essential role of $[Re_2Cl_8]^{2-}$ in the oxi-

dation process. The vibrational spectrum is consistent with that of an oxomolybdate. The band at 970 cm^{-1} is assigned to Mo=O stretching vibrations [8]. The EPR spectrum reveals a single electron species with $g = 1.94$ (Fig. 2).

Compound **2** was characterized by X-ray study. The molecular formula of the tetrameric compound may be envisioned as $[Mo_2Cl_3O_2(\mu_2\text{-}O)(\eta^3\text{-}pyNP)][\mu_3\text{-}O][Mo_2Cl_2O_2(\mu_2\text{-}O)_2(\eta^2\text{-}pyNP)]$, the fusion of two oxo-bridged Mo_2 cores bridged through μ_3-oxo linkage. The Mo3 and Mo4 form an ESBO unit involving the $[Mo_2O_2(\mu_2\text{-}O)_2Cl_2]$ core. The Mo_2O_2 four-member ring is puckered and the terminal oxo groups are located in a *cis* arrangement similar to that observed in compound **1**. The distance between the mid points of the non-intersecting O···O and Mo···Mo vectors of 0.431 Å. The eclipsed oxygen atoms form O5–Mo3–Mo4–O8 dihedral angle of 3.1(2)°. The Mo–O (bridged and terminal) distances are typical of those found in other oxomolybdates [13]. The Mo–O_μ–Mo angles are 83.67(17)° and 82.82(17)° and the Oμ–Mo–Oμ angles are 90.5(2)° and 91.8(2)° indicating the remarkable symmetry of the bridge (Table 2). The Cl5–Mo4–Mo3–Cl4 dihedral angle is 10.1(1)° and the Mo–Cl distances are 2.413(2) and 2.441(2) Å. The pyNP ligand caps one end of this Mo_2 core in bypridyl chelating fashion with N4–Mo4–N5 angle 70.1(2)°.

Interestingly, the Mo3 is penta coordinated. Apart from one terminal, two bridging oxo ligands and one chloride, Mo3 is further coordinated to an oxo ligand. The latter oxo ligand, in turn, bridges another Mo_2 unit (Fig. 3). The torsional angle Mo3–O4–Mo2–Mo1 is 173.7(5)°, indicative of almost the planar triply bridging mode of oxygen atom connecting the two Mo_2 cores. The Mo1 and Mo2 form an ESBO structure with both the atoms have in common a μ_3-oxo, μ_2-oxo, one terminal oxo and a chloride ligand. The pyNP ligand bridges the dimetal unit via N–C–N mode and at the same time the pyridyl N-atom binds Mo2 with N3–Mo2–N2 angle of 70.3(2)°. The Mo1 has an additional chloride ligand. The Mo=O distances are 1.666(5) and 1.673(5) Å. The Mo1–O4 and Mo2–O4

Scheme 2.

distances (1.958(5), 1.983(4) Å) are longer in comparison to the doubly bridged Mo–O distances (Mo1–O2 1.942(5) Å, Mo2–O2 1.925(5) Å). The Mo–O_μ–Mo angles are 82.64(17)°, 84.55(18)° and the O_μ–Mo–O_μ angles are 95.08(19)° and 95.30(18)°, once again indicating the remarkable bridge symmetry. The two terminal oxygen atoms are eclipsed with dihedral angle 2.3(2)°. The extent of deviation of the Mo(μ-O)$_2$Mo ring from planarity is significantly less with the distance between the mid-points of the non-intersecting O···O and Mo–Mo being 0.201 Å. Both the molybdenum atoms have terminal chlorine atom with Cl1–Mo1–Mo2–Cl3 torsional angle of 5.1(1)°.

The Mo–Mo distances in compound **2** needs special mention. The Mo1–Mo2 distance of 2.6015(9) Å is longer than the Mo3–Mo4 distance (2.5685(10) Å) despite one pyNP bridging the Mo1–Mo2 whereas the second pyNP chelates the Mo4. It should be noted that pyNP is known to bridge dimetal unit of metal-metal bond order ranging from zero to four and does not influence the metal-metal distance considerably [15]. The electron counting suggests the compound **2** to be a $[Mo_4]^{21+}$ species, a d^3 electron system. The EPR study, however, reveals that compound **2** has one unpaired electron. It is postulated that Mo3–Mo4 utilizes the two d-electrons to form a σ bond of formal bond order 1.0, and the Mo1–Mo2 involves in a 2c–1e bond of formal bond order 0.5 [16].

Dimerization of two Mo_2 cores to a tetranuclear structure has been reported in the literature [5a,17]. The resulted oxochloromolybdates usually are symmetric and posses a combination of oxo and alkoxo bridges [3b]. One such example is shown in Scheme 2a. In compound **2**, however, two Mo_2 units are coupled through one μ_3-oxo link leading to an asymmetric structure (Scheme 2b). Formation of more extended structure is precluded by the pyNP ligand capping the ends of the oligomer.

3. Conclusion

Here we describe the synthesis of polyoxomolybdates incorporating 1,8-napthyridine based ligands. Aerial oxidation of the quadruply bonded $Mo_2(OAc)_4$ in presence of organic ligand and in dichloromethane provides oxochloromolybdates containing the well-characterized $[Mo_2O_2Cl_2(\mu_2\text{-}O)_2]$ core. An alternative route to access high-oxidation state oxomolybdates is to employ suitable oxidizing agent. The quadruply bonded $[Re_2Cl_8]^{2-}$ oxidizes the $Mo_2(OAc)_4$ to oxochlorodimolybdates those subsequently dimerizes to give the tetrameric $[Mo_4Cl_5O_8(pyNP)_2]$. It is our expectation that the *in situ* oxidation of the $[Mo^{II}{\equiv}Mo^{II}]$ core in the presence of suitable peripheral ligands would provide access to polyoxomolybdates of unprecedented topologies.

4. Experimental

4.1. Materials and physical characterizations

The ligands pyNP and HprNP were prepared by the Friedlander condensation of 2-aminonicotinaldehyde with corresponding acyl derivatives [11]. Compounds *cis*-$[Mo_2(pyNP)_2(OAc)_2][BF_4]_2$ and $[n\text{-}Bu_4N]_2[Re_2Cl_8]$ were synthesized according to the literature procedures [10,18]. Infrared spectra were recorded in the range 4000–400 cm^{-1} on a Vertex 70 Bruker spectrophotometer on KBr pellets. EPR spectra were recorded on a Bruker EMX X-band spectrometer. Elemental analyses were performed on a Thermoquest EA1110 CHNS/O analyzer.

4.2. Synthesis

Synthesis of $[Mo_2O_2Cl_2(\mu_2\text{-}O)_2(HprNP)_2]$ (***1***). A sample of $[Mo_2(OAc)_2(CH_3CN)_6][BF_4]_2$ (70.7 mg, 0.097 mmol) dissolved in 20 mL of CH_3CN was treated with HprNP (44 mg, 0.224 mmol), which led to a color change from light pink to dark red. After 8 h stirring at room temperature, red precipitation occurred. The filtrate was discarded; the precipitate was washed with benzene (2 × 10 mL) and isolated. Crystallization was tried in open air by dissolving the precipitate in dichloromethane and layering with hexane in air. Red crystals appeared at the junction of two solvents. Yield: 55 mg (79%). IR (KBr) data (cm^{-1}): ν(Mo=O): 970 cm^{-1}, ν(Mo–O_μ): 724 cm^{-1}. *Anal.* Calc.

for $C_{24}H_{18}N_6Cl_2O_4Mo_2$: C, 40.19; H, 2.53; N, 11.72. Found: C, 40.35; H, 2.71; N, 11.54%.

Synthesis of [*Mo$_4$O$_8$Cl$_5$(pyNP)$_2$*] (**2**). To an acetonitrile solution (20 mL) of *cis*-$[Mo_2(pyNP)_2(OAc)_2][BF_4]_2$ (55 mg, 0.061 mmol) was added $[n\text{-}Bu_4N]_2[Re_2Cl_8]$ (77 mg, 0.068 mmol). The solution was stirred at room temperature for 8 h to give a bright red solution. Stirring was stopped at this point, concentrated, and layered with 15 mL of dichloromethane. The solution was left undisturbed at room temperature, when red-orange single crystals of the title compound appeared at the interface of two solvents within a day in quantitative yield. The crystals were isolated, washed with diethyl ether and dried under vacuum. Yield: 50 mg (74%). IR (KBr) data (cm^{-1}): *ν*(Mo=O): 968 cm^{-1}, *ν*(Mo–O$_μ$): 724 cm^{-1}. *Anal.* Calc. for $C_{26}H_{18}N_6Cl_5O_8Mo_4$: C, 28.30; H, 1.64; N, 7.62. Found: C, 28.45; H, 1.87; N, 7.45%.

4.3. X-ray data collection and refinement

Single-crystal X-ray studies were performed on a CCD Bruker SMART APEX diffractometer equipped with an Oxford Instruments low-temperature attachment. Data were collected at 100(2) K using graphite-monochromated Mo Kα radiation ($\lambda_\alpha = 0.71073$ Å). The frames were integrated in the Bruker SAINT software package, and data were corrected for Lorentz and polarization effects, and an absorption correction was applied. Structures were solved and refined with SHELX suite of programs. Pertinent crystallographic data are provided in Table 3. Hydrogen atoms of the ligands, unless mentioned otherwise, were included in the final stages of the refinement and were refined with a typical riding model. ORTEP-III was used to produce the diagrams. SQUEEZE option was applied for both the compounds to remove severely disordered solvent molecules that could not be modeled. For compound **2**, one of the CH_2Cl_2 was found to be disordered and modeled satisfactorily. All non-H atoms of the CH_2Cl_2 solvates were refined isotropically except C11S and C12S. Hydrogen atoms are not included for solvent molecules. The anisotropic refinement of N4 atom resulted in non-positive definite displacement parameter, and was refined isotropically.

These 1D zincophosphates are synthesized in aqueous medium at various temperatures (from room temperature to 180 °C) using different amines as a template. At the present time their mechanism of formation is not well established.

This paper reports the synthesis and the crystal structure determination of a new 1D zincophosphate $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$ obtained under hydrothermal conditions using 2-aminomethyl(1-ethyl)pyrrolidine as an organic template.

2. Experimental

2.1. Hydrothermal synthesis

A mixture of 1.18 g (12 mmol) phosphoric acid (Fluka 85 wt% H_3PO_4), 0.51 g (4 mmol) AMEP (Acros), and 0.16 g (2 mmol) zinc oxide (Prolabo) was stirred in 20 mL water (pH ≈ 2) for 20 min. The mixture was then transferred to a Teflon-lined stainless-steel autoclave and kept at 130 °C under autogenous pressure for five days. After cooling to room temperature, transparent prismatic crystals with suitable dimensions for crystallographic study were collected. The crystals were washed several times with distilled water and dried in the open air. They are stable for months under normal conditions of temperature and humidity. Schematically the reaction can be written as follows:

$$ZnO + 3H_3PO_4 + C_7H_{15}N_2 \rightarrow [Zn(H_2PO_4)_2(HPO_4)] \times [C_7N_2H_{17}] + H_2O.$$

2.2. Investigation techniques

The title compound has been studied by various physico-chemical methods: X-ray diffraction, solid state NMR spectroscopy combined with ab initio calculations, infrared spectroscopy and thermal analysis.

2.2.1. X-ray diffraction

The intensity data collection was performed using a MACH3 Enraf Nonius diffractometer. The experimental conditions of data collection, the strategy followed for the structure determination and the final results are given in Table 1. The structure was solved by the SIR 92 [12] program and refined by full-matrix least-squares techniques based on F, using SHELXL 97 [13]. The structure factors were obtained after Lorentz polarization corrections. Analytical empirical absorption corrections were made [14]. The positions of the heavier atoms, including the Zn atom, were located by the direct method. The remaining atoms were found in a series of alternating difference Fourier maps and least-square refinements. The positions of the hydrogen atoms of this hybrid compound were located directly from the difference Fourier maps. The drawings were made with DIAMOND [15].

Weighting scheme	σ
Refined parameters	249
Residual Fourier density (Å^3 < ρ < 1.34 Å^3): −0.88	$R = 0.048$; $R_w = 0.1304$
Drawings made with DIAMOND	[37]
Goodness-of-fit on F^2	1.081
Largest shift/error	0.000

2.2.2. NMR spectroscopy

All NMR spectra were recorded on a Bruker DSX-300 spectrometer operating at 75.49 MHz for ^{13}C and 121.51 MHz for ^{31}P with a classical 4 mm probehead allowing spinning rates up to 10 kHz. ^{13}C chemical shifts are given relative to tetramethylsilane and ^{31}P ones relative to 85 % H_3PO_4 (external references, precision 0.5 ppm). The phosphorus spectrum was recorded both under classical MAS conditions with high power proton decoupling and

by use of cross-polarization from protons while the carbon one was obtained by use of cross-polarization (contact time 5 ms) and MAS. In all cases it was checked that there was a sufficient delay between the scans allowing a full relaxation of the nuclei. When cross-polarization was used, typically the delay between two consecutive scans was 1 s, while it was 30 s for the classical ^{31}P NMR spectrum.

2.2.3. Ab initio calculations

DFT calculations (at the B3LYP/6-31+G* level) were made to allow the attribution of the ^{31}P and ^{13}C NMR signals to the various crystallographically inequivalent atoms. For phosphorus, the chemical shifts were determined by taking the coordinates of the PO_4 tetrahedra found by X-ray diffraction and calculation of the chemical shifts with the GIAO method. For carbon, the positions of the hydrogen atoms were first optimized at the same level of theory, the carbon and nitrogen atoms being frozen. All calculations were made with the GAUSSIAN 98 software.

2.2.4. Thermal behavior

Thermal analysis was performed using the "multimodule 92 Setaram" analyzer operating from room temperature up to 873 K at an average heating rate of 5 K min^{-1} in a flowing drying argon atmosphere.

2.2.5. IR spectroscopy

Spectra were recorded in the range 4000–400 cm^{-1} with a "Perkin-Elmer FTIR" spectrophotometer 1000 using a sample dispersed in a spectroscopically pure KBr pellet.

3. Results and discussion

3.1. Structure description

Final atomic coordinates and thermal parameters for ZnP-AMEP are given in Table 2. The entities of the main geometrical features are reported in Table 3. All atoms are at general positions. An ORTEP drawing of the asymmetric unit of the compound templated by organic cations is shown in Fig. 1.

The asymmetric unit of ZnP-AMEP contains 25 non-hydrogen atoms. There are one Zn and three crystallographically distinct P atoms present in the asymmetric unit. The Zn atom is tetrahedrally coordinated by four oxygen atom neighbours, with average Zn–O bond lengths of 1.929 Å. The average O–Zn–O bond angle has the expected tetrahedral angle of 109.4°. The Zn atom is connected to four phosphorus atoms through Zn–O–P linkages with an average bond angle of 140.1°. Among the three crytallographically independent phosphorus atoms, P(1) and P(2) are connected to two different Zn atoms via two P–O–Zn linkages. P(1) possesses two terminal P–OH bonds while P(2) has one P–OH and one P–O bond. P(3) exhibits an isolated (H_2PO_4) tetrahedra.

The marginally longer P═O are mainly due to the presence of a large number of hydrogen bond interactions in this compound. As expected, (ZnO)─P═O angles (average 113.7°) as well as the (ZnO)–P–(OZn) angles (average 113.9°) are significantly bigger than O–P–O angles with an OH group involved therein (107.6°). O–P–O angles with two OH residues are again significantly smaller (106.1°).

$U_{eq.} = \frac{1}{3}\sum_i\sum_j U_{ij}a_i^*a_j^*(a_i.a_j)$.
Esd are given in parentheses.

The ZnP-AMEP is constructed by the vertex linking of ZnO_4, $PO_3(OH)$ and $PO_2(OH)_2$ tetrahedral units. The connectivity between these tetrahedral units gives rise to one-dimensional chains built from ($Zn_2P_2O_{12}$) four-membered rings sharing their tetrahedral ZnO_4, propagated along $[1\bar{1}0]$ with a general formula of $[Zn(H_2PO_4)(HPO_4)]_n^-$ (Fig. 2). Not only are the individual chain units held together by hydrogen bond interactions and form a sheet-like architecture organization centered by $z = 1/2$ planes, but they are also held with pure phosphate $(H_2PO_4)_n^{n-}$ chains extending along [100] direction at $y = 1/2$ to form finally a 3D anionic network (Fig. 3). To the best of our knowledge, compound ZnP-AMEP represents the first organic templated metallophosphate in which the four-membered rings interact with chains of dihydrogenophosphate. Among the five P–OH entities, two participate in an intra-chain phosphate H bond and three form inter-chain links. This arrangement yields cavities and apertures, wherein the amine molecules reside, this latter has a constraint configuration, confirmed by the short distance (about 6.884 Å) between the sheets of $[Zn(H_2PO_4)(HPO_4)]_n^-$ and chains of $(H_2PO_4)_n^{n-}$. The cavities formed by such interactions (Fig. 4) closely resemble those

in the organic channel structures formed through non-covalent interactions [16].

Assuming the usual valence of Zn, P and O atoms to be +2, +5 and −2, respectively, the framework of $Zn(PO_4)_3$ would result in the highly charged framework of −7. The double protonated AMEP would account for +2. The excess negative charge of −5 then needs to be balanced. Bond valence sum values [17] indicate that P(1)–O(1), P(1)–O(2), P(2)–O(6), P(3)–O(9) and P(3)–O(10) with distances of 1.570(2), 1.549(3), 1.585(3), 1.567(2) and 1.566(3) Å are P–OH units. This assignment is also in agreement with the proton positions observed near the oxygen atoms in the difference Fourier map. The presence of –OH groups in the structure gives rise to an interrupted framework material.

As can be seen, corner-shared chains are indeed rare. The chain of ZnP-AMEP has architectures comparable to similar structures reported in the literature. In the one-dimensional $[Zn_8(HPO_4)_8(H_2PO_4)_8]_8(C_2H_8N)\cdot 4H_2O$ [18] and $RbZn(HPO_4)(H_2PO_4)\cdot H_2O$ [19] , the four-membered rings, forming the corner-shared chains, are made from linkages involving ZnO_4, HPO_4 and H_2PO_4 units. The presence of H_2PO_4 units indicates that the chains can undergo further condensation, giving rise to products with higher dimensional architectures, by deprotonation of terminal –OH groups. This suggestion is validated by the

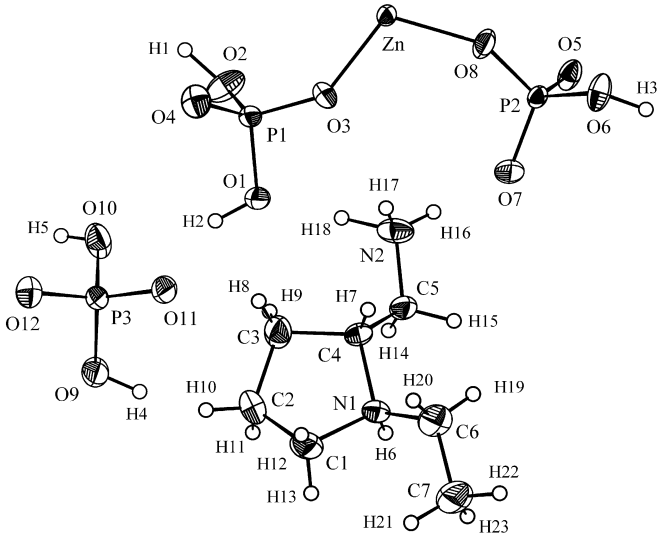

Fig. 1. Asymmetric unit of $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$. Thermal ellipsoids are shown at 50% probability.

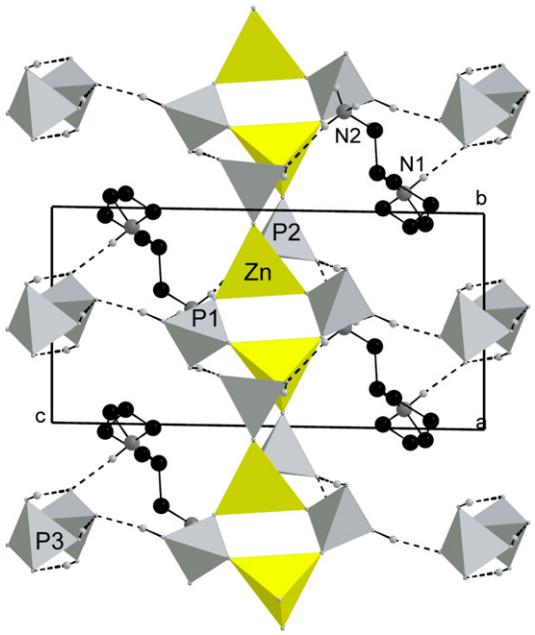

Fig. 3. Projection along the **a** axis of the atomic arrangement in $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$ showing pure $(H_2PO_4)_n^{n-}$ phosphate chains extending along the [1 0 0] direction at $y = 1/2$.

synthesis of a two-dimensional layer Zn phosphate from the same reaction mixture as employed for the preparation of the one-dimensional chain [20]. The structure of ZnP-AMEP, on the other hand, is closely related to that of $[Zn(HPO_4)_2](C_6H_{14}N_2)$ [21], where the corner-sharing four-membered rings are made only from ZnO_4 and $PO_3(OH)$ tetrahedra. Isolation of an organic templated metallophosphate with a corner-shared chain architecture is important because in one of the mechanisms proposed for the formation of open-framework phosphates the corner-shared chain structure is considered to be the primary building unit [22,23]. A possible reason that such lower dimensional structures are seldom found under conventional hydrothermal conditions may be because they undergo easy transformations to layer and three-dimensional structures.

3.2. NMR spectroscopy and ab initio calculations

The ^{31}P CP-MAS NMR spectrum of ZnP-AMEP is shown in Fig. 5. Three different phosphorus atoms can be seen. As the three signals are enhanced by cross-polarization, it can also be concluded that the three phosphorus atoms are linked to protons, probably via P–O–H bonds. All these features are in full agreement with the X-ray structure. Ab initio calculations can allow the attribution of the three signals to the three crystallographically inequivalent P atoms in the structure. For this purpose, the absolute chemical shifts of the three phosphorus were

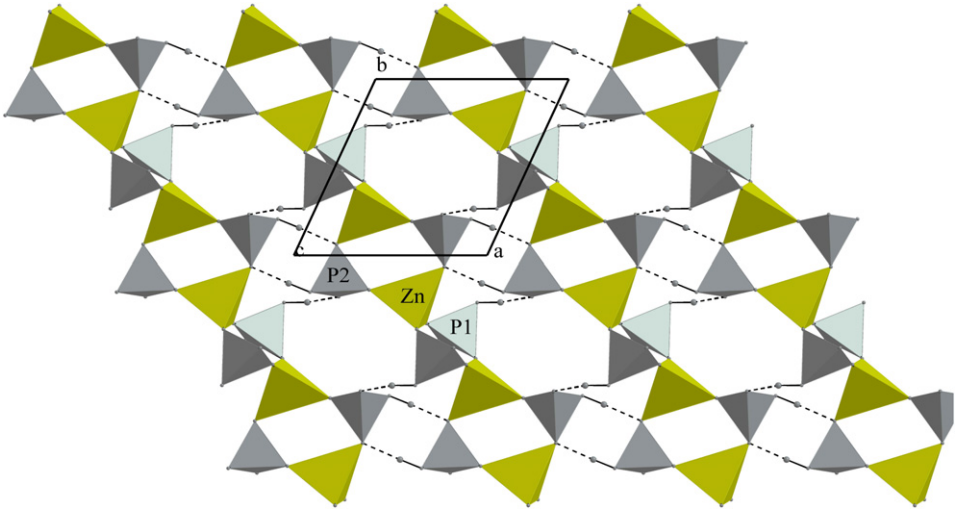

Fig. 2. The atomic arrangement of chains $[Zn(H_2PO_4)(HPO_4)]_n^-$ viewed down the **c** direction.

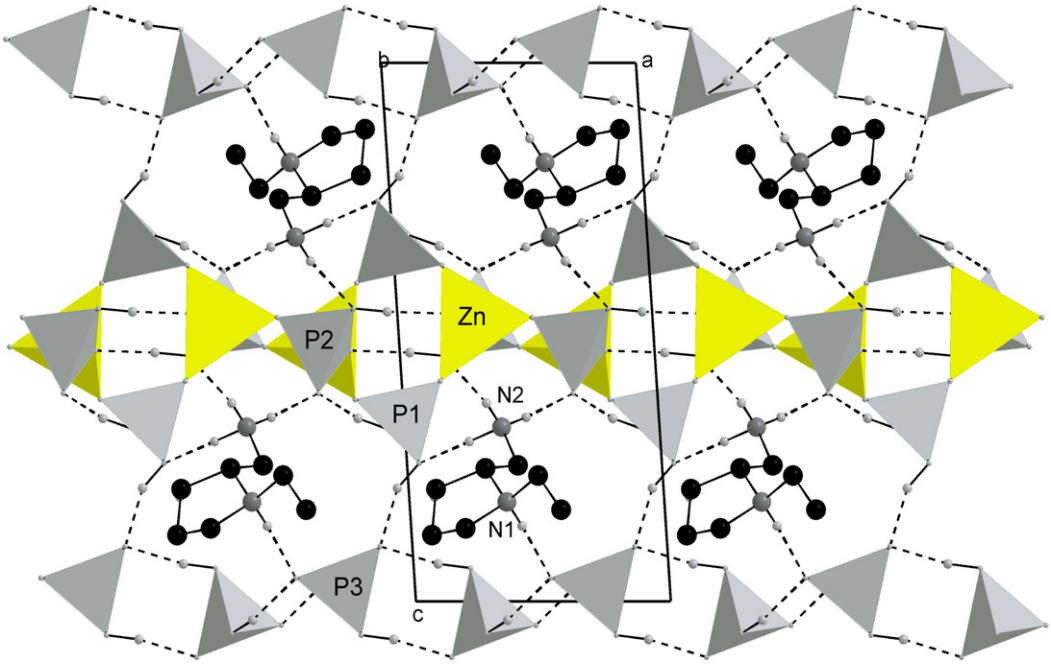

Fig. 4. Structure of $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$ along the **b** axis showing the position of the amine. Dotted lines represent the various hydrogen bond interactions.

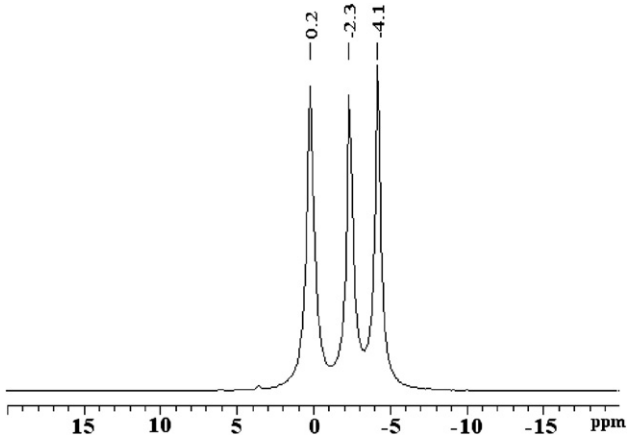

Fig. 5. ^{31}P MAS NMR spectrum of $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$.

calculated by using the B3LYP/6-31+G* method. The absolute chemical shifts vary in the order P(1) = 362.4 > P(2) = 361.3 > P(3) = 359.5. The same order was also found with other methods and basis sets. As the experimental chemical shifts correspond to the difference between the reference chemical shift and the absolute chemical shift, the experimental chemical shifts should vary in the order P(3) > P(2) > P(1). We can then propose the following attribution:

$P(1)\delta = -4.1$ ppm; $P(2)\delta = -2.3$ ppm; $P(3)\delta = 0.2$ ppm.

These chemical shift values agree well with those of monophosphates (between −10 and +5 ppm), depending on the compound [24–30] (see Table 4).

Table 4
Hydrogen bonds for $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$ (Å and °)

D–H···A	*d*(D–H)	*d*(H···A)	D(D···A)	∠(DHA)
O(2)–H(1)···O(7)	1.03	1.53	2.540(4)	167
O(1)–H(2)···O(11)	0.92	1.69	2.549(3)	155
O(6)–H(3)···O(5)	0.96	1.69	2.646(4)	176
O(9)–H(4)···O(11)	0.93	1.72	2.640(4)	171
O(10)–H(5)···O(12)	0.82	1.84	2.645(4)	167
N(1)–H(6)···O(12)	0.89	1.83	2.714(3)	176
N(2)–H(16)···O(7)	0.94	1.80	2.738(4)	175
N(2)–H(17)···O(6)	0.86	2.02	2.878(4)	170
N(2)–H(18)···O(1)	1.17	1.80	2.965(4)	179

The ^{13}C CP-MAS NMR spectrum is shown in Fig. 6. It displays seven well-resolved signals which can be attributed to the seven crystallographically inequivalent carbon atoms in the structure. Note that NMR shows that there is only one organic molecule in the asymmetric unit. As for phosphorus, it is possible to attribute the different signals to the various carbon atoms of the structure. For this purpose, the coordinates of C and N atoms of the AMEP molecule were taken from the X-ray structure. The protons were optimized at the B3LYP/6-31+G* level and the chemical shifts were determined. The values were then subtracted from that of C in tetramethyl silane optimized at the same level of theory. The results are depicted in Table 5. There is a relatively good agreement between experimental and theory. More interestingly, the AMEP molecule was also fully optimized and the chemical shifts calculated. The values are also listed in Table 5. The discrepancies between the two sets of theoretical values are a good indication of

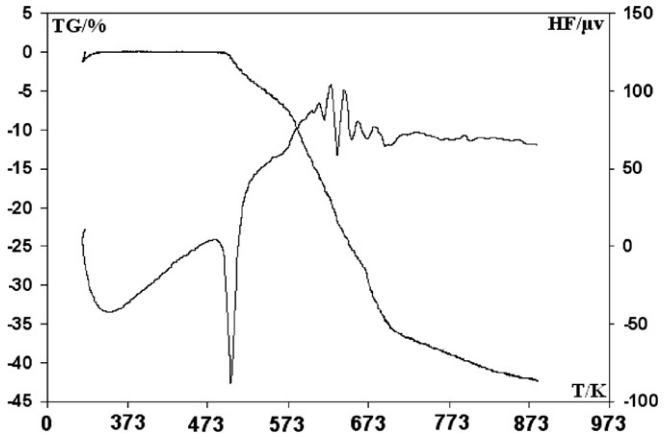

Fig. 7. DTA and TGA curves of $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$ at the rising temperature.

Table 5
Experimental and theoretical ^{13}C chemical shifts for the AMEP molecule

Carbon	δ experimental (ppm)	δ theory H optimized (ppm)	δ theory fully optimized (ppm)
C1	54.2	57.3	59.3
C2	22.4	23.7	26.1
C3	26.4	26.1	29.4
C4	64.7	65.9	66.8
C5	38.9	42.0	48.3
C6	51.5	56.0	58.7
C7	11.4	13.5	14.4

where constraints are located. The most important constraint is located on C5, the carbon atom linked to the NH_3^+ group. This is probably related to a special position of that chain in the structure. More surprisingly, other constraints exist also on C″, C2 and (less) C1 carbon atoms. These data are in full agreement with the structure as depicted in Fig. 1: the C2 and C3 carbon atoms are located near the $P(3)O_4$ tetrahedra.

3.3. Thermal analysis

Two curves corresponding to differential and thermogravimetric analyses (DTA/TG) under argon flow are given in Fig. 7. The DTA curve shows that the zinc phosphate ZnP-AEMP undertakes at 502 K an endothermic peak which corresponds to the removal of two water molecules arising from the irreversible dehydroxylation reactions due to the presence of terminal P–OH groups and deprotonation of the amine cations, (weight loss calculated 7.43%, experimental 7.41%), according to the following reaction:

$$[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2] \longrightarrow ZnH_3P_3O_{10} + C_7N_2H_{15} + 2H_2O$$

The simultaneous departure of two water molecules proves the presence of two phosphate chains $[(H_2PO_4)_n^-$, $Zn(H_2PO_4)(HPO_4)_n^-]$ in the compound, which confirms the X-ray diffraction result. Indeed, the removal of two dehydroxylation water molecules of the hydrogenmonophosphates occurs usually at two different temperatures [31] according to the following reactions:

$$2H_3PO_4 \xrightarrow{\approx 473\ K} H_4P_2O_7 + \overset{\uparrow}{H_2O}$$

$$H_4P_2O_7 \xrightarrow{\approx 573\ K} 2HPO_3 + \overset{\uparrow}{H_2O}$$

The weight loss, between 575 K and 694 K, corresponds to the degradation of the template molecule (organic entities), giving the zinc triphosphate $ZnH_3P_3O_{10}$ as the decomposition product. The observed weight loss (26.21%) agrees well with the calculated value (26.65%).

Between 694 K and 873 K, the weight loss corresponds to the condensation of the P–OH groups in $ZnH_3P_3O_{10}$. A grey solid is finally obtained containing probably a carbon residue. This latter can be eliminated by calcination of the sample at 1100 K in air. However, the presence of $ZnH_3P_3O_{10}$ was confirmed by the IR spectrum of the final product. This latter compound exhibits broad bands between 3600 and 3000 cm^{-1} corresponding to the P–OH groups [32]. The stretching vibrations of the PO_2 central groups are observed between 1300 and 1100 cm^{-1}, while those between 1200 and 950 correspond to the stretching vibrations of the PO_3 terminal groups [33,34] and those ranging from 975 to 650 cm^{-1} correspond to the stretching POP modes [35].

3.4. IR spectroscopy

IR spectroscopy is one of the major physical methods for the investigation of molecular structures. Thus, we have studied the IR spectrum of crystalline zinc phosphate, $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$, which is shown in Fig. 8. To assign the IR peaks to vibrational modes, we examined the modes and frequencies observed in similar compounds [32].

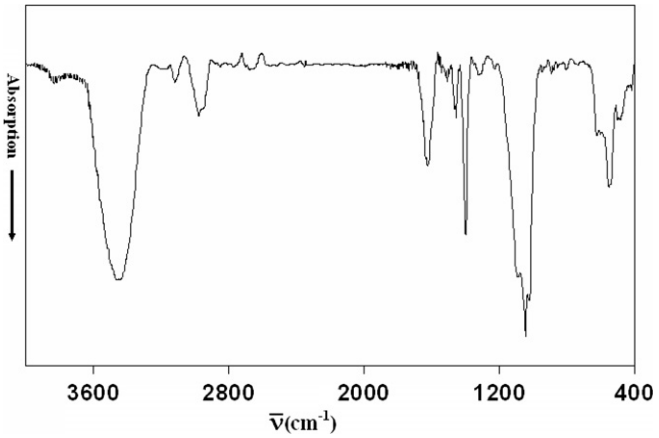

Fig. 8. IR absorption spectrum of $[Zn(H_2PO_4)_2(HPO_4)][C_7H_{17}N_2]$.

- The high-frequency region, between 3400 and 2300 cm^{-1}, is related to the valence vibrations of C–H, N–H and O–H groups interconnected by a system of hydrogen bonds in the crystal [33].
- The vibrations between 1650 and 1200 cm^{-1} are assigned to bending modes (δNH_3^+, δCH_2) [34–37].
- The various vibration bands between 1200 and 400 cm^{-1} are characteristic of monophosphate and correspond to valence and bending modes [38].
- Frequencies in the range 1200–800 cm^{-1} are attributed to the two stretching modes v_s and v_{as} (respectively symmetric and asymmetric) of the PO_4 group [39,40].
- The observed bands between 650 and 400 cm^{-1} can be attributed to the two bending modes δ_s and δ_{as} of the PO_4 group [41–44].

4. Conclusion

A new organic templated metallophosphate, $[Zn(H_2PO_4)_2HPO_4)][C_7H_{17}N_2]$, has been synthesized hydrothermally using 2-aminomethyl,1-ethylpyrrolidine as structure-directing agent. Our investigation shows that it is possible to form 3D open-framework materials containing removable organic templates which might have many potential applications. Further studies are necessary to understand the role of minor compositional changes in yielding different 3D open-framework structures.

Appendix A. Supplementary material

CCDC 622547 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.11.052.

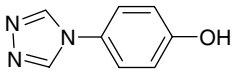
2. Results and discussion

We have found that the reaction of copper(II) chloride with 4-(4-hydroxyphenyl)-1,2,4-triazole (*L*, $C_8H_7N_3O$, Scheme 1) in EtOH solution with a Cu:*L* molar ratio of 5:1 leads to formation of two crystalline complexes $[Cu_6(\mu_6\text{-Cl})(\mu_3\text{-OH})_2(\mu\text{-}L)_6Cl_9(H_2O)_3]\cdot 3H_2O$ (**1**) and $[Cu(\mu\text{-L})(\mu\text{-OH})(H_2O)_2]Cl$ (**2**). Complex **1** is the main product of the reaction:



$$6Cu^{2+} + 6L + 12Cl^- + 8H_2O \rightarrow [Cu_6(\mu_6\text{-Cl})(\mu_3\text{-OH})_2(\mu\text{-}L)_6Cl_9(H_2O)_3]\cdot 3H_2O + 2HCl$$

Despite a 1:1 metal-to-ligand stoichiometry in **1** the five times excess of $CuCl_2$ is strongly recommended to avoid precipitating the low soluble ligand.

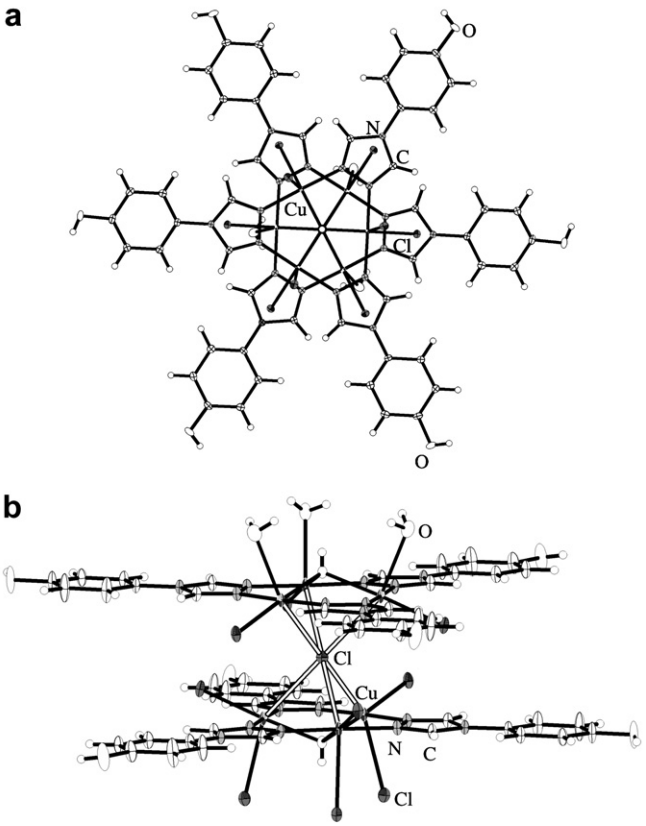
We found conditions when complex **1** can be prepared pure in high yield, and investigated its magnetic properties. Complex **1** is stable in the ambient air and is readily soluble in water and water–organic mixtures, but poorly soluble in organic solvents (ethanol, MeCN, 2-propanol, $CHCl_3$) and their mixtures. Unfortunately, our attempts to prepare a phase of the individual compound **2** failed.

2.1. Crystal structures

In both compounds the *L* molecules are coordinated to copper ions by N^1 and N^2 atoms in a bidentate-bridging manner. However, the structures of **1** and **2** are different due to the difference in the coordination mode of the hydroxo-group and the role of chloride anion. In compound **1** there are three types of bridging ligands. Three bidentate-bridging 4-(4-hydroxyphenyl)-1,2,4-triazole molecules are coordinated to three copper ions to form Cu_3L_3 triangle. The OH-group caps the Cu_3 triangle, and finally two $Cu_3L_3(OH)$ triangles are joined to one another in quite an unusual way, by the μ_6-Cl ligand (Fig. 1) to form a hexanuclear complex. The distance between Cu_3 planes is 4.21 Å. The coordination polyhedron of the μ_6-Cl ion is trigonal antiprism. The resulting complex molecule lies on the fixed point of the $\bar{3}$ axis of the $R\bar{3}$ space group. Each copper ion has two coordination positions, equatorial and apical, available for terminal ligands. All six equatorial positions are occupied by chloride ions, whereas the apical ones are statistically occupied by three water molecules and three chloride ions. The statistical distribution of H_2O and Cl over the six apical positions is imposed by relatively high crystallographic symmetry. It only became possible to distinguish the positions of Cl ($Cu–Cl_{apical}$, 2.7774(19) Å) and H_2O ($Cu–O_{apical}$, 2.466(7) Å) and to locate H atoms at O of the H_2O molecules due to the low temperature at the diffraction measurements. Thus, the coordination sphere of Cu^{2+} consists of $2N + \mu_3\text{-O(H)} + Cl + \mu_6\text{-Cl} + (Cl \text{ or } H_2O)$. The coordination polyhedron of the copper ion is a distorted octahedron elongated towards μ_6-Cl and $(Cl/H_2O)_{apical}$ positions (Fig. 1).

L

Scheme 1.



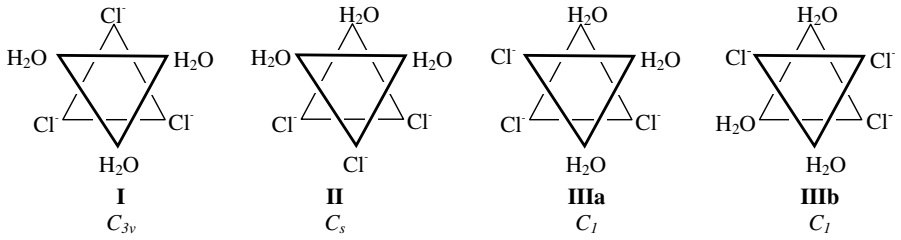


Fig. 1. Molecule of **1**, view along the $\bar{3}$ axis (a) and side-view (b). Main bond distances (Å): Cu ⋯ Cu (within Cu_3), 3.3651(4), Cu–N, 1.9662(17), 1.9632(17), $Cu–\mu_3$-O(H), 2.0681(10), $Cu–\mu_6$-Cl, 2.8397(3), $Cu–Cl_{eq}$, 2.2692(6), $Cu–Cl_{apical}$, 2.7774(19), $Cu–(H_2O)_{apical}$, 2.466(7).

According to the statistical distribution of H_2O and Cl^- over six apical positions, four geometrical and optical isomers of molecule **1** (Scheme 2, view along $\bar{3}$ axis.) may theoretically coexist, but cannot be recognized in the crystal by using X-ray diffraction data.

The most symmetrical isomer, **I**, is shown in Fig. 1, where all "upper" apical positions are occupied by three water molecules and the "lower" ones by chloride ions. It is achiral because of C_{3v} point symmetry. Two isomers with lower symmetry correspond to the combination of $2H_2O + Cl^-$ on one Cu_3 triangle and $H_2O + 2Cl^-$ on the other. One of them, **II**, possesses a mirror plane and therefore is achiral too, while the last, **III**, is asymmetrical and exists as the pair of chiral forms, **IIIa** and **IIIb**. However, the nature of the 6Cu–Cl bonding is unclear, we could even expect free rotation of one $Cu_3L_3(OH)$ triangle with respect to the other. The free rotation might occur, for example, in solution, if the molecule **1** does not dissociate. In this case only two isomers, **I** and **II**, would exist. The existence of an eclipsed conformation in this case might also be possible.

Scheme 2.

The main bond distances are given in Fig. 1 caption. The μ_6-Cl-ligand is equidistant from six copper ions. Relatively large Cu–(μ_6-Cl) distances of 2.8397(3) Å indicate that the two Cu_3 units are weakly joined together. According to the Cambridge Structural Database (release 5.27) [16] the only one copper(II) complex containing μ_6-Cl is known, $[Cu_6(\mu_6\text{-Cl})(\mu_3\text{-OMe})_2(\mu\text{-pz})_9]$ (**3**; pz – pyrazolate anion) [17]. In **3**, in contrast to **1**, two Cu_3 triangles are joined not only by a chloride anion but also by three pyrazolate ligands; all are coordinated to Cu in a bidentate-bridging mode. The resulting coordination environment of the μ_6-Cl^- is trigonal prism, in contrast to trigonal antiprism in **1**. The presence of additional bridging pyrazolate ligands resulted in a shortening of the Cu–Cl bonds to 2.6032(13)–2.623(2) Å. In **3** the chloride ion is "caged" into the molecule while in **1** it binds two parts of the molecule together. Note that in all possible isomers of **1** two Cu_3 triangles are not equivalent but all six (μ_6-Cl)–Cu bonds are of the same length. We carefully checked the residual density around the chloride ion and its a.d.p. ellipsoid shape, and came to the conclusion that it is definitely ordered. It could be an argument *pro* covalent and not electrostatic Cu–Cl bonding.

In the crystal packing, the molecules of **1** are involved in extended network of intermolecular hydrogen bonds between terminal OH-groups of the 4-(4-hydroxyphenyl)-1,2,4-triazole ligand, apical water molecules coordinated to copper and disordered solvent water molecules.

In compound **2** the hydroxo groups together with *L* join copper ions into infinite cationic $\{[Cu(\mu\text{-}L)(\mu\text{-}OH)(H_2O)_2]^+\}_\infty$ polymeric chains (Fig. 2) running along the *b* axis. The chloride anion is in the outer sphere. The coordination environment of Cu^{2+} ions is accomplished by two water molecules and consists of 2N + 2μ-O(H) + 2 elongated $O(H_2)$, thus the coordination polyhedron of the copper ion is a distorted octahedron, as in **1**. There is weak hydrogen bonding between the chloride counter anion and the hydroxo group of *L*, Cl ⋯ O(H), 3.01 Å.

There are about 20 compounds containing the fragment [Cu(μ-*L′*)(μ-OH)], where *L′* is a substituted N-containing heterocycle, coordinated through the N–N bond in a bidentate bridging manner similarly to **2**. All but three of them are molecular, while three chain structures achieve a polymeric motif through neither NO_3 group [18], coordinated to the copper ion, nor through the oxygen atom of an OH-group, being additionally coordinated to one more copper ion [19,20] with an elongated contact Cu–O of about 2.7–2.8 Å. However, most similar to **2**, the compounds contain a cyclic tetranuclear anion $\{Cu_4(\mu\text{-}OH)_2Cl_4(\mu\text{-}pz)_4\}^{2-}$ (**4** [21]) and an octanuclear molecule $\{Cu(\mu\text{-}OH)(\mu\text{-}Me_2pz)\}_8$ (**5** [22,23]). The copper ions in **4**, **5** and **2** are joined through two bridging ligands, N-containing heterocycle and OH-groups, resulting in cyclic species in **4**, **5** and polymeric chains in **2**. The Cu ⋯ Cu distances in **2** are longer by ~0.1 Å and can be compared only with those in the Cu–O(H) ⋯ Cu fragment in **4**, where one of the copper ions weakly coordinates the OH group (Table 1). However, a rather long Cu ⋯ Cu distance leads to Cu–O(H) and Cu–N bonds also becoming longer. Besides, the coordination environment of the copper ions, being distorted octahedral in **2**, also differs from that in **4** and **5**. In **4** there is no additional coordination to the copper ion, the coordination polyhedra of all copper ions are distorted tetrahedra, while in **5** there are copper ions in tetrahedral and in trigonal prismatic environments.

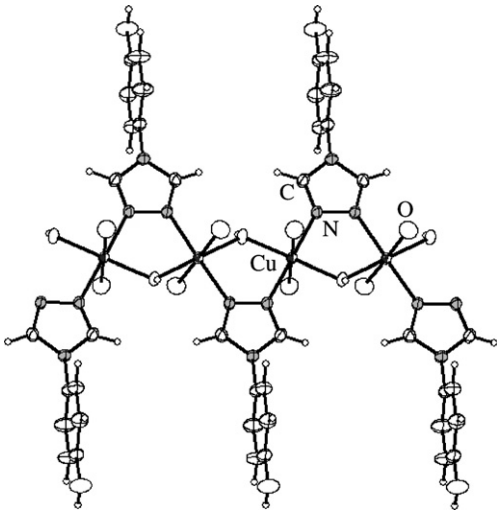

Fig. 2. Fragment of the cationic polymeric chain $\{[Cu(\mu\text{-}L)(\mu\text{-}OH)(H_2O)_2]^+\}_\infty$ in **2**. Main bond distances (Å): Cu ⋯ Cu, 3.3852(3) (*b*/2), Cu–N, 2.0100(17), Cu–μ-O(H), 1.9474(10).

The experimental powder diffraction pattern of **1** (Fig. 3) is in good agreement with that calculated for compound **1**. Some differences between intensity profiles may be accounted for by the texture of the sample.

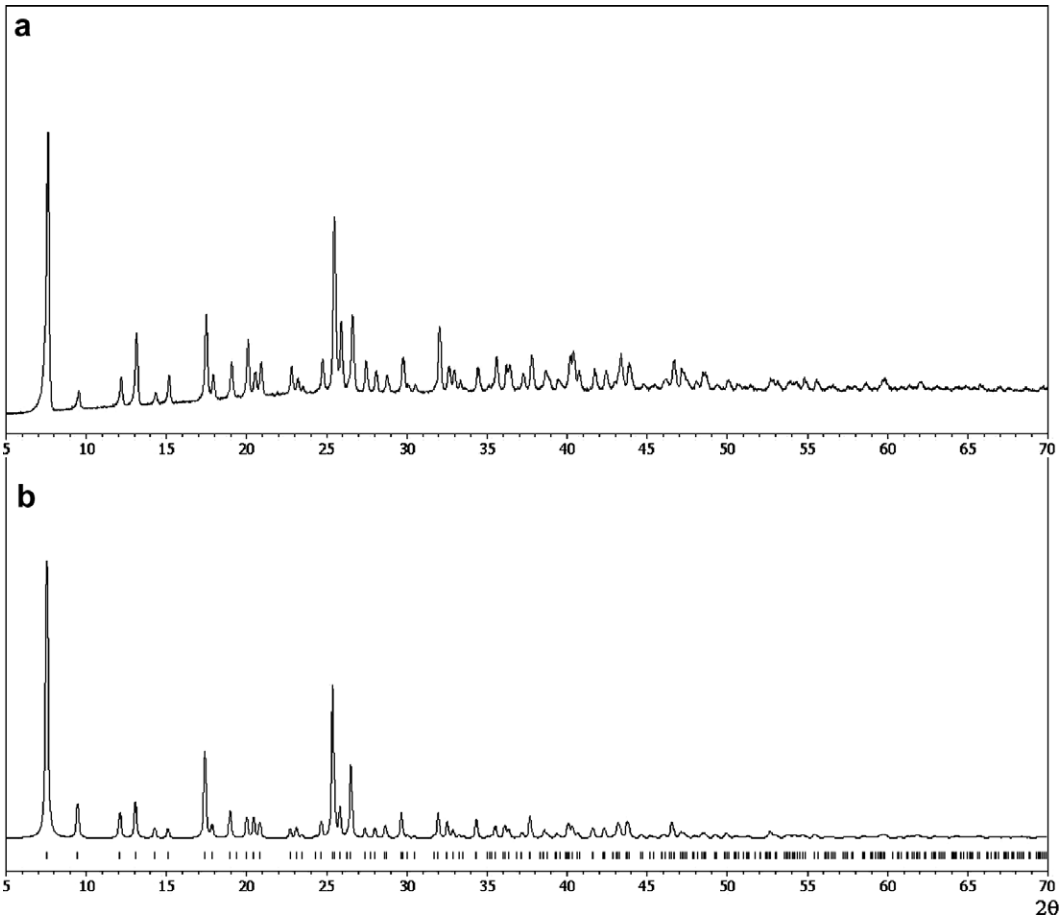

Fig. 3. Observed (a) and calculated (b) X-ray powder diffraction patterns of **1**.

The presence of peaks referring to any additional phase (e.g. phase **2**) is not observed. This fact clearly indicates that the bulk product synthesized corresponds to phase **1** only.

2.2. Magnetic properties

The dependence of the magnetic moment (μ_{eff}) on temperature of **1** is shown in Fig. 4. On decreasing the temperature from 300 K, the μ_{eff} value decreases continuously down to a plateau near 80 K. Further decrease of the temperature causes a decrease of μ_{eff} to 1.75 β at 2 K. Such a behavior points to mainly antiferromagnetic exchange interactions in complex **1**. The structural data shown in Fig. 1 were used to choose a theoretical model for a description of the dependence observed. Thus, we chose the most adequate model for the description of the magnetic properties, consisting of two triangles joined by a μ_6-Cl ion. We considered the model of the exchange cluster consisting of two weakly interacting triangles. The model is valid because the distances between copper(II) ions of different triangles bonded through μ_6-Cl ion are 5.73 Å and are much larger than the distances between copper(II) ions within the same triangle. The model assumes that the value of the exchange interaction parameter J between Cu(II) ions inside triangles is much larger than that of both inter-cluster exchange interactions for the same molecule and other molecules (zJ').

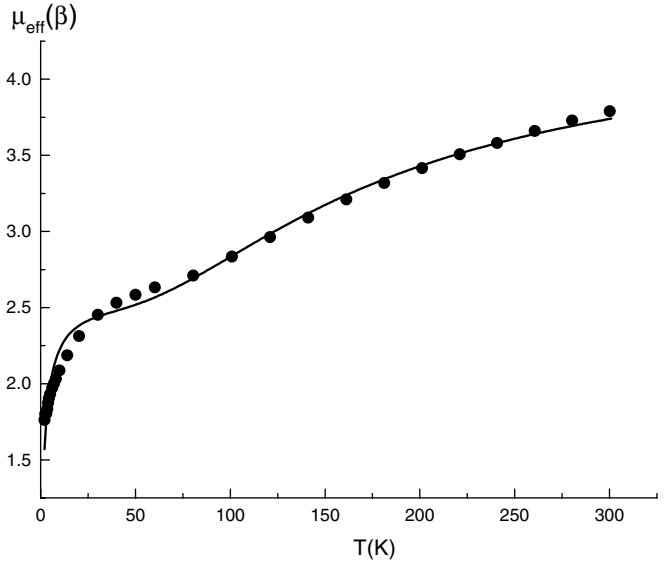

Fig. 4. The dependence of the magnetic moment (μ_{eff}) on the temperature for **1**.

The theoretical analysis of the magnetic behavior was carried out in cluster approximation with the isotropic spin-Hamiltonian ($\widehat{H} = -2J\sum_i \widehat{S}_i \cdot \widehat{S}_j$) [25]. As the result of optimization the following parameters for the theoretic curve (solid line in Fig. 4) were found: $g_{Cu} = 2.10(5)$, $J = -51.4(3)$ cm^{-1}, $zJ' = -2.3(2)$ cm^{-1}.

A comparison of magnetic properties of complexes **1** and **3** shows that the values of the exchange interaction parameters between Cu(II) ions inside copper triangles for these complexes are comparable ($-51.4(3)$ cm^{-1} in complex **1** (this paper) and $-66.4(1)$ cm^{-1} in complex **3** [17]). However, inter-cluster exchange interactions differ considerably: $zJ' = -2.3(2)$ cm^{-1} (**1**) and $J_2 = -17.1(1)$ cm^{-1} (**3**). This is expected to be due to structural reasons. The Cu_3 units in complex **3** are bonded more strongly than in complex **1** due to the three bridging pyrazolates between them. In **1** only the μ_6-Cl ion bridges similar Cu_3 units.

3. Conclusions

Thus, the reaction between copper(II) chloride and 4-(4-hydroxyphenyl)-1,2,4-triazole leads to the formation of two crystalline complexes, hexanuclear **1** and polymeric **2**. The 1,2,4-triazole ring coordinates in a bidentate-bridging mode. One of complexes, **1**, with an unusual molecular structure is obtained as the bulk product. Two Cu_3 triangles appear to be joined together by six unsupported Cu–Cl bonds of length 2.8397(3) . We think that this crystal structure could be of importance for structural chemistry because it elucidates some aspects of weak chemical bonding between metal and ligand atoms. Traditional structural chemistry treats long interatomic contacts as a sort of non-bonding interaction (specific, electrostatic, *etc.*). In our opinion, we found an example of bonding that lies somewhere between a "normal" covalent bond and specific non-valent bonding. The argument for some covalent nature to this bonding is that the chloride ion symmetrically binds non-equivalent Cu_3 units. The argument for the specific non-bonding nature is that the magnetic exchange between those units is quite small. However, the nature of this bonding is still open. We hope that quantum chemical calculations that we plan in the future will help.

4. Experimental

4.1. General

For the synthesis, we used $CuCl_2 \cdot 3H_2O$ of "p" grade and 4-(4-hydroxyphenyl)-1,2,4-triazole was prepared by the procedure in [24], $T_{m.p.} = 288$–290 °C ($T_{m.p.} = 285$–286 °C [24]).

4.2. Synthesis of $[Cu_6(\mu_6\text{-}Cl)(\mu_3\text{-}OH)_2(\mu\text{-}L)_6Cl_9(H_2O)_3] \cdot 3H_2O$ (1)

A hot solution of L (1 mmol) in 20 ml of ethanol was slowly added with stirring to a hot solution of $CuCl_2 \cdot 2H_2O$ (5 mmol) in 5 ml of water. A green precipitate was formed after a short time (*ca.* 1 min). After stirring for 30 min the precipitate was filtered off, washed with

small amount of ethanol and dried in ambient air. Yield 85%.

Anal. Calcd for $C_{48}H_{56}N_{18}Cl_{10}O_{14}Cu_6$: C, 31.2; H, 3.1; N, 13.7; Cu, 20.7. Found: C, 31.2; H, 3.0; N, 13.3; Cu, 20.6.

Green crystals of **1** suitable for X-ray analysis were obtained by slow evaporation of an ethanol solution of the compound over two weeks.

With a greater excess of copper chloride against *L*, both green crystals of **1** and blue crystals of the complex **2** suitable for X-ray analysis were formed from a solution after leaving in air for two weeks. Unfortunately, we did not succeed in isolating the individual phase of compound **2** without impurities of compound **1**.

4.3. Physical measurements

The copper content was determined by complexonometric titration, the samples being decomposed in a 1:1 mixture of concentrated H_2SO_4 and $HClO_4$. The CHN analyses were performed with a Carlo-Erba analyzer using standard procedures.

4.4. Magnetic measurements

Magnetic susceptibility measurements of polycrystalline samples of the complex were performed on a SQUID magnetometer MPMS-5s (Quantum Design) over the temperature range 2–300 K. The magnitudes of the magnetic field were 5 kOe. Dependence between magnetic susceptibility and intensity of the magnetic field was not found. The effective magnetic moment μ_{eff} was calculated by the formula $\mu_{\text{eff}} = \left(\frac{3k}{N\beta 2}\cdot \chi T\right)^{1/2} \approx (8\chi T)^{1/2}$, where χ is the paramagnetic susceptibility corrected for diamagnetism and is equal to $-870\times10^{-6}\,\text{cm}^3/\text{mol}$, N is Avogadro's number, k is the Boltzsmann constant and β is Bohr's magneton.

4.5. X-ray crystallographic study

Crystallographic data and details of single-crystal diffraction experiments are given in Table 2. X-ray intensity data were collected on a Bruker X8Apex CCD diffractometer at 90 K (**1**) and room temperature (**2**) using standard techniques (ω- and ϕ-scans of narrow frames) and corrected for absorption effects [26]. The structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL program set (version 6.22) [27]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms at OH-groups and H_2O molecules were refined without geometrical constraints and with thermal parameters related to those of the oxygen atoms. Hydrogen atoms at carbon atoms were refined in calculated positions. In structure **2** the hydrogen atoms of the water molecule coordinated to copper were not located. The solvent water molecule in **1** appeared to be statistically disordered over two symmetrically related positions and refined with s.o.f. = 0.5.

X-ray powder diffraction analysis was performed with a Philips PW1700 automatic diffractometer in Bragg-Brentano geometry with Si as an external standard. Ni-filtered Cu Kα radiation was used. The diffraction pattern was scanned with a step of 0.02° 2θ and in the angular range from 5° to 70° 2θ at room temperature. The PowderCell program set [28] was used to calculate the powder pattern from the single crystal data.

grade and were used as received without further purification.

2.1.1. X-ray crystallography

X-ray crystallographic data were collected using a Bruker SMART APEX-CCD diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å). The intensity data were corrected for Lorentz and polarization effects and empirical absorption corrections were applied using the SAINT program [20,21]. All the structures were solved by direct methods using SHELXS-97 [22]. Non-hydrogen atoms located from the difference Fourier maps were refined anisotropically by full-matrix least-squares on F^2, using SHELXL-97 [22]. The hydrogen atoms were included in the calculated positions and refined isotropically using a riding model.

2.1.2. Thermal measurements

Thermogravimetry was studied by a computer controlled METTLER TOLEDO STAR^e system of module TGA/SDTA851^e under a static nitrogen atmosphere using a platinum pan at a heating rate of 10 °C min^{-1} in the temperature range 25–700 °C. The instrument was calibrated using a RTypSDTA sensor. The onset temperature obtained from the DTG curve was used to evaluate the onset decomposition temperature of the samples.

2.2. Syntheses

2.2.1. N-(2-Pyridylethyl)pyridine-2-carbaldimine (*L*)

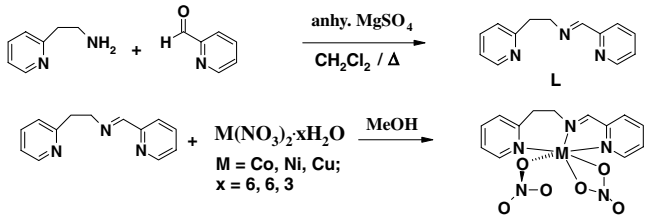
To 2.5 g of anhydrous $MgSO_4$ suspended in 20 mL of CH_2Cl_2, 565 mg (4.62 mmol) of 2-pyridine-2-ylethanamine was added followed by 500 mg (4.62 mmol) of pyridine-2-carbaldehyde. The reaction mixture was refluxed for 1.5 h until a yellowish color appeared and then it was stirred at ambient temperature for another 3 h. The solution was filtered, washed with 2×5 mL portions of CH_2Cl_2, and the volatile components in the combined solution were removed by evaporation in vacuum. The crude product was obtained as a yellowish oil, which was pure enough as inferred from the ^{1}H NMR spectrum, and was used without further purification. Yield: 970 mg (100%). ^{1}H NMR (δ (*J*, Hz), $CDCl_3$): 3.22 (2H, t, 7.2), 4.08 (2H, t, 7.2), 7.08 (1H, t, 6), 7.16 (1H, d, 7.6), 7.26 (1H, t, 6), 7.54 (1H, t, 7.6), 7.69 (1H, t, 7.6), 7.93 (1H, d, 8), 8.31 (1H, s), 8.52 (1H, d, 4.4) and 8.59 (1H, d, 4.4). IR (neat, cm^{-1}): 1648 (C=N_{im}), 1590 (C=N_{py}).

2.2.2. [Co*L*(NO_3)$_2$] (*1*)

To 180 mg (0.85 mmol) of **L** dissolved in 25 mL of methanol, was added 247 mg (0.85 mmol) of $Co(NO_3)_2 \cdot 6H_2O$ dissolved in 20 mL methanol with stirring. After stirring for 4 h, the reaction mixture was left to crystallize. Orange block-like crystals deposited, were collected and washed with ice-cold methanol. Yield: 0.26 g (77%). IR (KBr, cm^{-1}): 1653 (C=N_{im}), 1610 (C=N_{py}). *Anal.* Calc for $C_{13}H_{13}N_5O_6Co$: C, 39.57; H, 3.30; N, 17.76. Found: C, 39.25; H, 3.21; N, 16.50%.

2.2.3. [Ni*L*(NO_3)$_2$] (*2*)

To 180 mg (0.85 mmol) of **L** dissolved in 25 mL of methanol, was added to 250 mg (0.85 mmol) of $Ni(NO_3)_2 \cdot 6H_2O$ dissolved in 20 mL of methanol with stirring, and the stirring was continued overnight. The reaction mixture was kept undisturbed and pale green-colored block-like crystals obtained after few days were collected after washing with ice-cold methanol. Yield: 0.25 g (74%). IR (KBr, cm^{-1}): 1650 (C=N_{im}), 1600 (C=N_{py}). *Anal.* Calc for $C_{13}H_{13}N_5O_6Ni$: C, 39.59; H, 3.30; N, 17.77. Found: C, 39.35; H, 3.19; N, 17.14%.



2.2.4. [Cu*L*(NO_3)$_2$] (*3*)

To 180 mg (0.85 mmol) of **L**, dissolved in 25 mL of methanol was added 205 mg (0.85 mmol) of $Cu(NO_3)_2 \cdot 3H_2O$. The reaction mixture was stirred at room temperature overnight and the blue precipitate that deposited was filtered and washed thoroughly with methanol. Dark blue crystals were obtained by slow evaporation of acetonitrile solution. Yield: 0.33 g (97%). IR (KBr, cm^{-1}): 1653 (C=N_{im}), 1602 (C=N_{py}). *Anal.* Calc for $C_{13}H_{13}N_5O_6Cu$: C, 39.11; H, 3.26; N, 17.55. Found: C, 39.18; H, 3.21; N, 17.50%.

3. Results and discussion

3.1. Syntheses

Ligand **L** was synthesized (Scheme 1) in quantitative yield, by refluxing equimolar quantities of pyridine-2-carbaldehyde and 2-aminoethylpyridine in dichloromethane using anhydrous $MgSO_4$ as a Lewis acid as well as a drying agent to absorb the water formed as a product of the condensation. The yellow-oily product obtained after removal of hydrated $MgSO_4$ and other volatile components, does not require further purification and loses its identity on standing, as ascertained from its ^{1}H NMR spectrum. Therefore, freshly prepared **L** was used for the synthesis of the complexes. This method of synthesis is advantageous over the reported procedure, having a shorter reaction time [23]. Complexes of the molecular formula [M**L**(NO_3)$_2$], M = Co(II), Ni(II), and Cu(II) were synthesized in methanol using equimolar quantities each of **L** and the corresponding metal nitrate.

Scheme 1. Synthesis of **L** and complexes.

3.2. Optical properties

UV–Vis spectra of **1**, **2**, and **3** exhibit d–d transitions in acetonitrile solution. The curves were fitted to a Gaussian to obtain λ_{max} and the corresponding molar extinction coefficient values. In complex **1**, two higher energy transitions were observed at 417 nm and as a shoulder at 342 nm with ε values 121 and 200 $M^{-1}\,cm^{-1}$ respectively. Complex **2** shows three transitions at 888, 745, and 590 nm, having the respective molar extinction coefficient values 110, 20, and 46 $M^{-1}\,cm^{-1}$. In the case of **3**, two transitions were observable with λ_{max} at 675 and at 383 nm with ε values 55 and 34 $M^{-1}\,cm^{-1}$ [24,25].

3.3. Magnetism and EPR spectra

The room temperature magnetic moments of **1**, **2**, and **3** are in agreement with the presence of 3 (high-spin Co(II)), 2 and 1 unpaired electrons respectively. The effective magnetic moment, μ_{eff} and molar susceptibility, χ_M of the complexes were determined using a least-square fitting method and are listed in Table 1. In all three cases $\mu_{eff} > \mu_{so}$ is consistent with more than a half-filled configuration for the metal ions. Since $\mu_{S+L} > \mu_{eff} > \mu_{so}$, there is the existence of spin–orbit coupling in the three complexes [26–28]. The X-band (9.44 GHz) EPR pattern of **1** indicates that the complex is high spin in nature.

Table 1
Molar susceptibility and effective magnetic moment

	1	2	3
$\chi_M \times 10^3$ (emu mol^{-1})	6.475	6.372	1.600
μ_{eff} (BM)	3.928	3.897	1.952

The powder EPR spectrum recorded at room temperature exhibits a well-defined $S = 3/2$ $M_s = |\pm 1/2\rangle$ signal indicating a system having modest spin–orbit coupling and a high degree of rhombic distortion of the axial zero-field splitting, with $g_{(x,y)} = 4.25$, $g_z = 2.08$ as well as a signal corresponding to $g_{eff} \sim 10.9$. At 77 K in the X-band (9.12 GHz), the powder EPR spectrum of **1** shows an eight line hyperfine splitting of $g_z(^{59}Co, I = 7/2)$ with $A_z = 91.7 \times 10^{-4}\ cm^{-1}$, whereas in acetonitrile solution an isotropic spectrum with $g_0 = 2.01$ is observed [6–10]. The X-band (9.12 GHz) powder EPR spectrum of **2** at 77 K shows a single-quantum line within the scan range 2000–4000 G having $g_z = 2.16$, $g_x = 2.06$, $g_y = 1.99$ and $g_{ave} = 2.07$, while the acetonitrile solution at 77 K exhibit an isotropic spectrum with $g_0 = 2.01$ [11–13]. The acetonitrile solution as well as polycrystalline sample of **3** at 77 K, exhibits an axial spectrum having $g_\parallel$ and $g_\perp$ values 2.21 and 2.07 respectively and does not show hyperfine splitting. The trend $g_\parallel > g_\perp > 2$, is in agreement with the unpaired electron being in the $d_{x^2-y^2}$ orbital [8–10,14,15].

3.4. Molecular structures

The molecular structures of all three complexes were determined by X-ray crystallography. The crystallographic data and refinement parameters are summarized in Table 2 and selected bond parameters are listed in Table 3. All three complexes are isomorphous and crystallized in the space group *Cc*. In each case, the bivalent metal ion is coordinated by the three nitrogen atoms of the tridentate **L** with two pyridine-N occupying *trans* positions. **L** binds to the metal ions by a near-planar five-membered and a puckered six-membered chelate ring. Of the two nitrate ions, one binds in a bidentate fashion and the other in a monodentate

				N1–M–N3	169.4(3)	172.9(4)	174.3(3)

fashion, giving an overall pseudo-octahedral geometry for the metal center. Therefore, the basal plane contains the three nitrogen (N1, N2, and N3) atoms of **L** and an oxygen (O1) of the bidentate nitrate, the apical positions being occupied by oxygen atoms (O2, O4) from each of the two nitrate ions. In **3**, a long axial Cu1···O4 contact of 2.54(2) Å is present. A perspective view of **1** is shown in Fig. 1. The N1–Co1–N2 angle of the five-membered chelate ring is 73.9(2)°, while N2–Co1–N3 of the six-membered ring is 95.7(3)°. These angles deviate significantly from the ideal value of 90° due to the sizes of the five-membered planar and the six-membered non-planar chelate rings. Average Co1–N lengths are shorter by 0.055(8) Å than that of the Co1–O distances of the bidentate NO_3^-. The bidentate NO_3^- has a shorter contact with Co1 than when it coordinates with one oxygen atom. The chelate bite angle of NO_3^- in **1** is 56.6(3)°. The O1–Co1–N2 angle, 140.7(3)°, deviates considerably from linearity by 39.3° due to the smaller chelate bite of the nitrate group and

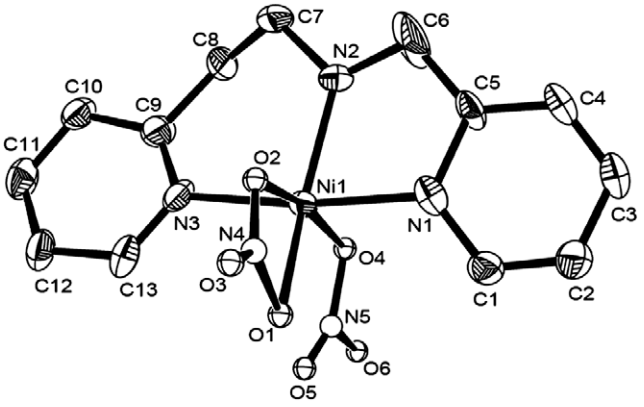

Fig. 2. ORTEP diagram of **2** (30% probability, hydrogens are omitted for clarity).

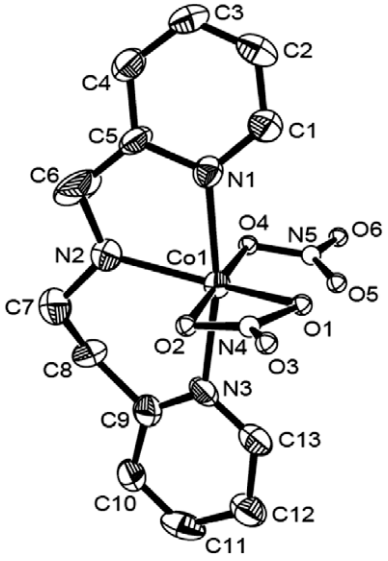

Fig. 1. ORTEP diagram of **1** (30% probability, hydrogens are omitted for clarity).

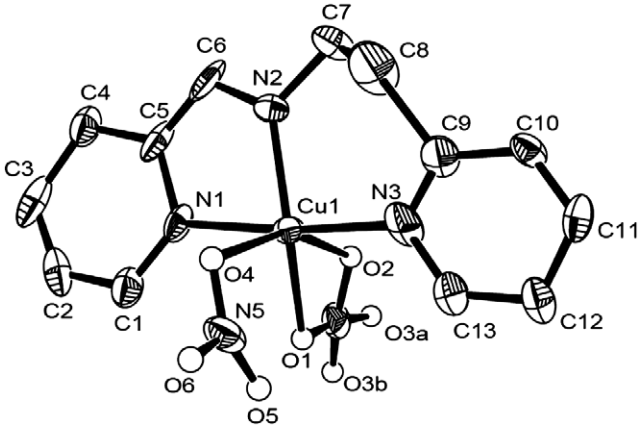

Fig. 3. ORTEP diagram of **3** (30% probability, hydrogens are omitted for clarity). O3a and O3b are disordered entities.

non-bonded O1···O5 interaction of 2.73(2) Å. A perspective views of **2** and **3** are shown in Figs. 2 and 3. Oxygen atoms of the monodentate NO_3^- in **2** are disordered and a reasonable disorder pattern could not be fixed. O3 oxygen atom of the bidentate NO_3^- in **3** is disordered and therefore refined with variable site occupancy factors (O3a, 0.37754; O3b, 0.62246). A non-bonded O1···O5 interaction is present at 2.98(2) Å in **2** and at 3.03 (2) Å in **3**.

On comparison, M–N_{im} and M–N_{py} bond lengths follow the order, Co > Ni > Cu, consistent with the trend in the relative size of the bivalent ions. The six-membered chelate ring has a twisted conformation, N3–M–N2–C7, C9–N3–M–N2, M–N2–C7–C8, and N2–C7–C8–C9 torsional angles respectively lie in the range 0–2°, 10–14°, −(25–36°), and 61–70°. This clearly indicates that C8 and C9 atoms deviate from the plane formed by N3–M–N2–C7 atoms. Twisting about C8 and C9 is more severe in **3** than in **1** and **2**. However, the five-membered chelate ring is closer to planarity as shown by the torsional angles Cu1–N2–C6–C5, N2–C6–C5–N1, and C6–C5–N1–Cu1 respectively being 11.6, −5.2°, and −2.5°. The values of these angles in order in **1** and **2** are 18.5°, −17.0°, 9.3° and 19.6°, −15.9°, 7.4°, respectively suggesting that the deviation is marginal.

3.5. Thermogravimetric (TG) analysis

TG and DTG curves, shown in Fig. 4, (all the temperatures noted in this section are onset mid-point temperatures) of **1** and **2** shows weight loss in two distinct steps: in the first step, loss of the ligand **L** (found 52.9%, 52.7%; *ca.* 53.6%, 53.5%) occurs at 276 and 273 °C respectively and in the second step, loss of two moles of NO_2 and half mole of O_2 gas are at 570 and 482 °C. Whereas, in **3** the loss (84.3%) of ligand **L**, two moles of NO_2 and one mole of O_2 (*ca.* 84.2%) all occur in a single step at 266 °C. This indicates the thermal stability order Co(II) > Ni(II) > Cu(II). The identities of the final residuals were not analyzed.

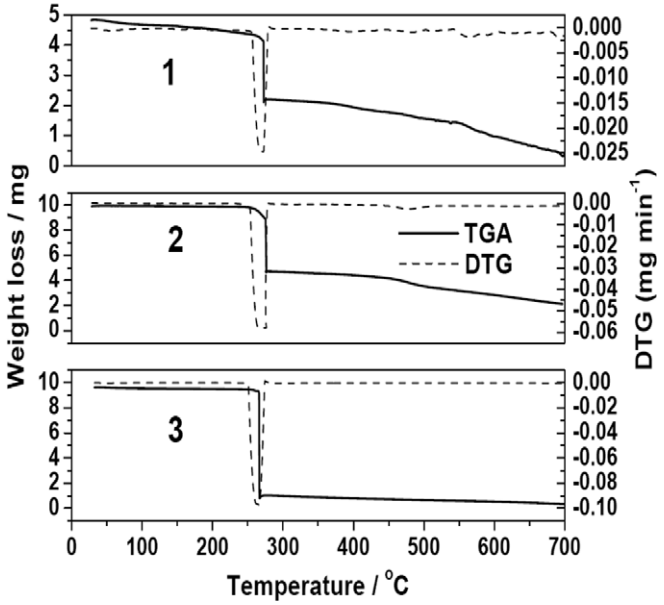

Fig. 4. TG/DTG curve of the complexes **1**, **2**, and **3**.

4. Conclusion

A triad of complexes of the type $[ML(NO_3)_2]$ (M = Co(II), Ni(II), Cu(II)), based on a tridentate N_3–donor ligand, were isolated and characterized using spectral, thermal, and single crystal X-ray studies. Cobalt, nickel, and copper complexes have pseudo-octahedral geometry with a N_3O_3 chromophore. All the complexes exhibit d–d transitions in the visible region. The high-spin Co(II) complex shows modest spin–orbit coupling and a high degree of rhombic distortion of the axial zero-field splitting. The thermal stability order is **1** > **2** > **3**, showing a reverse Irving-Williams trend.

Acknowledgements

We are grateful to the Department of Science and Technology (DST) New Delhi for a financial grant (SR/S1/IC-01/2002) and for establishing the single crystal X-ray diffractometer facility under the FIST scheme. The authors are thankful to Babulal Das for X-ray data, CIF IIT Guwahati for NMR spectrum and SAIF IIT Madras for EPR spectra and VSM data.

When entering the body, hydroxamic acid derivatives of peptides as potential drugs may interact with other metal ions, beside the one in the target enzyme, thus the knowledge of their metal ion binding strengths is of particular importance. Furthermore, information about this interaction with metals may aid the design of new chelators specific for a certain metal ion (thus for a given class of enzyme).

Despite the above challenges, only very few papers have been published concerning metal ion peptide hydroxamate interactions in the past two decades. Chang and co-workers studied the Ni^{2+}, Cu^{2+}, Zn^{2+}, UO_2^{2+} and Pb^{2+} complexes of Z-AlaGlyNHOH (Z = benzyloxycarbonyl) and found only the coordination of the hydroxamate group in the complexes [6]. Brown and Mageswaran investigated the Fe^{3+} and Ni^{2+} binding capabilities of GlyGlyNHOH and GlyGlyGlyNHOH [7]. The results obtained at a high excess of ligands indicated again exclusive [O,O] coordination with both metal ions. In a study by Farkas and Kiss the Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} and Fe^{3+} complexes of ProLeuNHOH and ProLeuGlyNHOH were investigated [8]. While the formation of complexes with moderate stability was found with Co^{2+} and Zn^{2+} in the pH range 6.0–8.5 without the deprotonation of the peptide amides, [NH_2, N_{amid}, $N_{hydrox.}$] coordination of the ligands was suggested above pH 6.0 with Cu^{2+} and Ni^{2+}.

Due to the very limited data and the contradictory results in this field, a systematic investigation was undertaken. In the present paper, we report a detailed solution equilibrium study using combined pH-potentiometric and spectroscopic (UV–Vis, EPR, CD, ^{1}H NMR) methods on the interaction of iron(III), aluminium(III), nickel(II), copper(II) and zinc(II) with simple primary peptide hydroxamic acids, L-Ala-L-AlaNHOH (L^3) or L-Ala-L-SerNHOH (L^4) (Scheme 1). The biological significance of Fe(III), Cu(II) and Zn(II) as constituent of various metalloenzymes is beyond doubt. Ni(II) in ureases and the toxicity of Al(III) make these metal ions also of interest. Since the terminal amino group in oligopeptides has an important role as an anchor in the enhancement of the deprotonation and coordination of the peptide amide group to soft or borderline metal ions [9], for comparative purposes, the Z-protected models, Z-L-Ala-L-AlaNHOH (L^1) and Z-L-Ala-L-Ser-NHOH (L^2) (Scheme 1) were also involved in the work.

R_1	R_2	R_3	Ligand	Abbreviation
$PhCH_2OCO$	CH_3	CH_3	Z-AlaAlaNHOH	L^1
$PhCH_2OCO$	CH_3	CH_2OH	Z-AlaSerNHOH	L^2
H	CH_3	CH_3	AlaAlaNHOH	L^3
H	CH_3	CH_2OH	AlaSerNHOH	L^4

Scheme 1.

2. Experimental

2.1. Materials and stock solutions

Methanol was purified and dried by standard methods [10]. Z-L-Ala-L-Ala-OMe and Z-L-Ala-L-Ser-OMe were purchased from Bachem, hydroxylamine hydrochloride from Fluka, palladium/carbon (10%) from Merck. All chemicals were of the highest purity commercially available and were used without further purification.

The metal ion stock solutions were prepared from $CuCl_2 \cdot 2H_2O$, $NiCl_2 \cdot 5H_2O$, $AlCl_3 \cdot 6H_2O$, $FeCl_3 \cdot 6H_2O$ (Reanal, Hungary) using doubly deionised and ultrafiltered water obtained from a Milli-Q RG (Millipore) water purification system. In the latter two cases the stock solutions also contained hydrochloric acid (~0.1 M). ZnO (Reanal) was dissolved in diluted HCl. The metal ion concentrations were checked gravimetrically via precipitation of the quinolin-8-olate salts; [Fe^{3+}] was determined by a complexometric titration. The acid content of the Al(III) and Fe(III) stock solutions was measured by Gran's method [11]. The purity and the exact concentration of the ligand stock solutions were also determined by Gran's method [11].

2.2. Syntheses of the ligands

2.2.1. Z-L-Ala-L-AlaNHOH (L^1)

To a chilled (0 °C) and stirred solution of $NH_2OH \cdot HCl$ (290 mg, 4.17 mmol) in dry methanol (4 mL), 29%(m/m) NaOMe solution in methanol (1.33 mL, 7.09 mmol) was added under nitrogen. To this mixture, containing solid NaCl, a solution of Z-L-Ala-L-Ala-OMe (1.157 g, 3.75 mmol) in dry methanol (4.5 mL) was added and the mixture was stirred at 0 °C for 5 h. Upon adding water (8 mL) and 1 M HCl (10 ml) to the reaction mixture, a clear solution was obtained which was allowed to stay at 4 °C overnight. The white crystals that separated were filtered off and recrystallised from water/methanol (6/4) affording 577 mg (48%) pure, protected hydroxamic acid. ^{1}H NMR (360 MHz, D_2O/DMSO-d_6 (6/1)) δ: 7.42 (5H, m, C_6H_5); 5.12 (2H, s, $C_6H_5CH_2$); 4.22 (1H, q, CH); 4.10 (1H, q, CH); 1.35 (3H, d, CH_3); 1.32 (3H, d, CH_3). ESI MS, *m/z* (%): 332.133 (100) $[M+Na]^+$ (calc. for $C_{14}H_{19}N_3O_5Na$, 332.122), 641.267 (29) $[2M+Na]^+$.

2.2.2. Z-L-Ala-L-SerNHOH (L^2)

The same procedure was applied using $NH_2OH \cdot HCl$ (472 mg, 6.79 mmol) in methanol (7 mL), 29%(m/m) NaOMe solution in methanol (2.19 mL, 11.5 mmol) and Z-L-Ala-L-Ser-OMe (2.00 g, 6.17 mmol) in methanol (10 mL). Upon adding water (9 mL) and 1 M HCl

(11 ml) to the mixture, a clear solution was obtained. The volume was reduced to half by evaporation and allowed to stay at 4 °C overnight. White crystals were filtered off and recrystallised from water/methanol (6/4) affording 836 mg (42%) pure, protected hydroxamic acid. ^{1}H NMR (360 MHz, D_2O/DMSO-d_6 (6/1)) δ: 7.42 (5H, m, C_6H_5); 5.13 (2H, s, $C_6H_5CH_2$); 4.34 (1H, t, CH); 4.16 (1H, q, CH); 3.79 (2H, d, CH_2); 1.35 (3H, d, CH_3). ESI MS, m/z (%): 348.134 $[M+Na]^+$ (calc. for $C_{14}H_{19}N_3O_6Na$, 348.117), 673.266 (27) $[2M+Na]^+$.

2.2.3. L-Ala-L-AlaNHOH · HCl (*L*^{3} · *HCl*)

Z-L-Ala-L-AlaNHOH (550 mg, 1.78 mmol) was dissolved in a mixture of dry methanol (20 mL) and methanolic HCl solution (1.06 M, 2 mL). Palladium/carbon (10%(m/m), 180 mg) was added and the mixture was hydrogenated for 5 h. The catalyst was removed by filtration and the solution was evaporated to dryness. The fine white, slightly hygroscopic solid was dried in a vacuum at 40 °C. Yield: 335 mg (89%). ^{1}H NMR (360 MHz, D_2O) δ:4.26 (1H, q, CH); 4.08 (1H, q, CH); 1.53 (3H, d, CH_3); 1.39 (3H, d, CH_3). ESI MS, *m/z* (%): 143.094 (99) $[M-NHOH+H]^+$, 176.118 (100) $[M+H]^+$ (calc. for $C_6H_{14}N_3O_3$, 176.103), 198.101 (12) $[M+Na]^+$.

2.2.4. L-Ala-L-SerNHOH · HCl (*L*^{4} · *HCl*)

Z-L-Ala-L-SerNHOH (500 mg, 1.54 mmol) was hydrogenated using the same procedure and conditions as for the AlaAla ligand. Yield: 328 mg (94%). ^{1}H NMR (360 MHz, D_2O) δ:4.40 (1H, t, CH); 4.14 (1H, q, CH); 3.83 (2H, d, CH_2); 1.55 (3H, d, CH_3). ESI MS, m/z (%): 120.075 (40) $[M-COCH(Me)NH_2+H]^+$, 131.090 (61) $[M-CONHOH+H]^+$, 159.086 (100) $[M-NHOH+H]^+$, 192.109 (83) $[M+H]^+$ (calc. for $C_6H_{14}N_3O_4$, 192.098), 214.098 (5) $[M+Na]^+$, 383.199 (19) $[2M+H]^+$.

2.3. Potentiometric and spectroscopic studies

PH-potentiometric and spectrophotometric measurements were carried out at an ionic strength of 0.2 M (KCl) and at 25.0 ± 0.1 °C. Carbonate-free KOH solutions of known concentrations (ca. 0.2 M) were used as titrant. HCl stock solutions were prepared from cc. HCl (both the acid and base were Merck products) and their concentrations were determined by potentiometric titrations. A Radiometer pHM 84 instrument equipped with a Metrohm combined electrode (type 6.0234.100) and Metrohm 715 Dosimat burette were used for the pH-metric measurements. The electrode system was calibrated according to Irving et al. [12], the pH-metric readings could therefore be converted into hydrogen ion concentration. The water ionization constant, pK_w, is 13.76 ± 0.01 under the conditions employed. The titrations were performed in the pH range 2.0–11.0, or until precipitation occurred. The initial volume of the samples was 5.00 mL. The ligand concentrations were varied in the range 0.002–0.004 M and the metal ion to ligand ratios in the range 1:1–1:5. For copper(II) 1.2–1.5:1 metal ion to ligand ratios were also studied. Typically, four or five ratios were measured in each system. The reproducibility of the titration points included in the evaluation was within 0.005 pH unit. Titration points with a waiting time of 10 min or more were omitted from the calculations. About 200 titration points were used for each system. The accepted fitting of the titration curves was always less than 0.006 mL. The samples were in all cases completely deoxygenated by bubbling purified argon for ca. 20 min before the measurements.

An HP 8453 or Perkin–Elmer Lambda 25 spectrophotometer was used to record the UV–Vis spectra over the range 250–900 nm for copper(II), iron(III) and nickel(II) containing systems. The path length was 1 cm. Measurements for the iron(III) containing samples were carried out preparing individual samples in which the 0.2 M KCl was partially or completely replaced by HCl. pH values, varying in the range ca. 0.7–1.6, were calculated from the HCl content. The metal ion concentrations were in the range 0.0004–0.0008 M and the metal ion to ligand ratios were in the range 1:3–1:5. Spectrophotometric titrations were also performed with samples containing Fe(III), Cu(II) or Ni(II) in 0.0004–0.004 M concentrations at metal to ligand ratios ranging from 1.5:1 to 1:5. Spectrophotometric results were utilized to calculate the stability constants for the Fe(III) complexes formed below pH 2.0. Above pH 2.0 potentiometric data were used to find the stoichiometry of the species and calculate their concentration stability constants. The calculations were performed by the PSEQUAD computer program [13] using the literature data ($\log\beta$) for the iron(III) [14] or aluminium(III) [15] hydrolytic species (the Davies equation was used to take the different ionic strengths into account).

^{1}H NMR spectra were recorded on a Bruker AM360 FT NMR instrument at 25 °C. Chemical shifts are reported in ppm (δ_H) from sodium 3-(trimethylsilyl)-propionate (TSP) as internal reference. NMR titrations were carried out in D_2O (99.8%) at $c_{ligand} = 0.025$ M in order to determine the protonation microscopic constants of L-Ala-L-AlaNHOH or L-Ala-L-SerNHOH using the p*D* dependence of the chemical shifts of the CH, CH_2 or CH_3 nuclei. The pH was set up with NaOD or DCl in D_2O. The micro constants were calculated with the aid of PSEQUAD [13] and a MATLAB program [16].

CD spectra of the Cu(II) – L-Ala-L-AlaNHOH or L-Ala-L-SerNHOH systems were taken at different pH values by a JASCO J-810 spectropolarimeter using 1 cm cells in the 300–800 nm range. The temperature was 23 °C. The metal ion to ligand ratios varied in the range 1.5:1–1:2 and c_{ligand} was 0.003 M. The pH was changed by adding small portions of either 0.2 M KOH or HCl solutions to the samples. CD spectra are reported as the difference in molar absorptivity ($\Delta\varepsilon = \varepsilon_l - \varepsilon_r$).

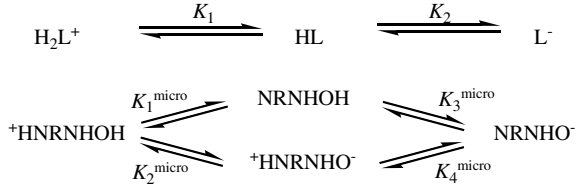
Electrospray ionisation time-of-flight mass spectrometric (ESI-TOF MS) analysis of the ligands was carried out on a Bruker BIOTOF II ESI-TOF instrument using 0.004 M concentration.

Frozen solution EPR spectra in aqueous samples of the copper systems were recorded on a Bruker ER 200D spectrometer equipped with a 3220 data system at 150 K using $^{63}Cu(NO_3)_2$ stock solution. The operating frequency was ~ 9.4 GHz (X-band). The samples for low-temperature measurements contained a few drops of ethylene glycol to ensure good glass formation. The metal ion to ligand ratios varied in the range 1.5:1–1:5 and $c_{Cu(II)}$ was 0.005 M.

3. Results and discussion

3.1. Protonation equilibria of the ligands

The Z-protected ligands L^1 and L^2 can release one proton each, while the fully protonated peptide hydroxamic acids L^3 or L^4 have two deprotonation processes in the measurable pH range. The calculated dissociation constants are listed in Table 1. Taking the different experimental conditions into account the dissociation constants of L^1 and L^2 relating to the hydroxamic group are in reasonable agreement with reported data for Z-AlaGlyNHOH (8.32) [6].



Comparison of the corresponding pK values of L^3 or L^4 with those of H-GlyGlyNHOH (7.52; 8.40) [7] and H-ProLeuNHOH (8.17; 9.11) [8] indicates that the values for L^3 and L^4 fit well in the acidity order of dipeptide hydroxamic acids with increasing electron donating substituents. The values also indicate that the two dissociation processes overlap each other considerably. Therefore, the microscopic protonation processes were also explored from the ^{1}H NMR titration of L^3 and L^4. Chemical shifts of the NMR active nuclei of L^4 in the function of pD are presented in the supplementary material (S1). Calculated values together with the notation of the deprotonation micro processes are summarised in Table 1 (as an example, the distribution of the micro species as a function of pH for L^4 is shown in S2). The data in Table 1 reveal that the $^+NH_3$ groups of L^3 or L^4 are more acidic than the CONHOH functions. This is in accordance with earlier results on α-alanine hydroxamic acid [17]. The overlap between the two dissociation micro processes (see S2) is slightly more considerable for L^4 than L^3: the first proton dissociates to an extent of ca. 78% (L^3: 87) from the $^+NH_3$ group and ca. 22% (L^3: 13) from the CONHOH group.

3.2. Metal complexes of the peptide hydroxamic acids L^3 and L^4

The shape of the corresponding titration curves with L^3 and L^4 is very similar, therefore the curves registered in the Fe(III)-, Al(III)-, Ni(II)-, Cu(II)- and Zn(II)-L^3 systems at 1:2 metal to ligand ratio are only depicted in Fig. 1. As it is seen the complex formation is already significant below pH 2.0 with Fe^{3+}, it starts at 2.5 with Al^{3+}, at 3.0 with Cu^{2+} and at 5.0–5.5 with Zn^{2+} or Ni^{2+}. The best models obtained after the evaluation of the titration curves together with the composition and stability constants of the complexes are summarised in Table 2. All the results on the M^{n+}-L^3 and -L^4 systems indicate that the hydroxyl group of the serine moiety in L^4 has no role in metal binding in the pH range studied.

With iron(III) the complexation starts below pH 2.0 (Fig. 1), therefore this process was also studied quantitatively by UV–Vis. As an example, the absorption spectra of the Fe^{3+}–L^3 system are shown in Fig. 2. It can be seen in Fig. 2 that in the pH range 0.8–1.7 increase of the absorption at $\lambda_{max.} = 494$ nm occurs without any shift. This indicates the formation of a single complexed species. The value of $\lambda_{max.}$ is consistent with the formation of a monohydroxamate complex [18] therefore its composition is most likely to be $[FeHL]^{3+}$. Upon increasing the pH, a continuous shift of the absorption spectra and increase in ε values show unambiguously the formation of bis ($\lambda_{max.} \sim 470$ nm; $\varepsilon \sim 1800\ M^{-1}\ cm^{-1}$) and tris ($\lambda_{max} \sim 425$ nm; $\varepsilon \sim 2500\ M^{-1}\ cm^{-1}$) [18] chelated hydroxamate complexes.

Table 1
Dissociation macro constants (pK_i) and micro constants (pK_i^{micro}) of the ligands at 25.0 °C and at $I = 0.20$ mol/dm^3(KCl)

	L^1	L^2	L^3	L^4
pK_1	8.91(1)	8.69(1)	7.66(1)	7.63(1)
pK_2			8.88(1)	8.73(1)

Standard deviations (3σ values) are in parentheses.
[a] Determined from spectrophotometric titration.

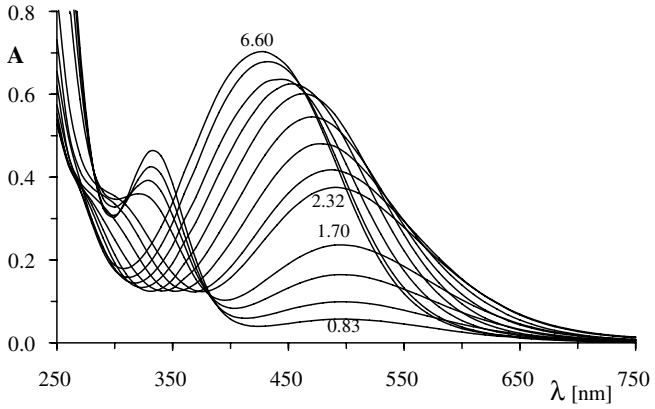

Fig. 2. Representative UV–Vis spectra recorded in the Fe^{3+}– L^3 system at a 1:5 metal to ligand ratio, $c_{Fe(III)} = 0.0003$ mol dm^{-3}, $I = 0.2$ mol dm^{-3} and $t = 25.0$ °C. Numbers indicate selected pH values.

Evaluation of the absorption spectra allowed the calculation of the stability constants of all these major species; the values appear in Table 2. With the fixed constant for $[FeHL]^{3+}$ from spectrophotometry the calculation of the full speciation was possible by treating the pH-potentiometric data. The good agreement between the corresponding values of the major complexes (Table 2) obtained from

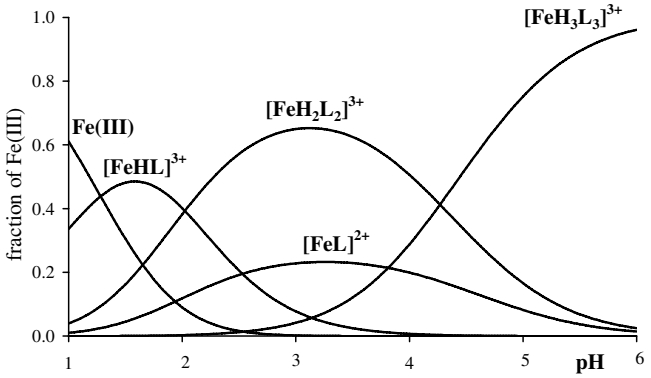

Fig. 3. Concentration distribution curves of the complexes formed in the Fe(III)–L^3 system at a 1:5 metal to ligand ratio, $c_{Fe(III)} = 0.0008$ mol dm^{-3}, $I = 0.2$ mol dm^{-3} and $t = 25.0$ °C.

different techniques also supports the correctness of the model. Representative concentration distribution curves are depicted for the Fe^{3+}– L^3 system in Fig. 3. Above pH 6.0 hydrolysis became significant yielding very slow processes, therefore no attempt was made to evaluate these parts of the titration curves.

In the aluminium(III) containing systems the titration curves can be fitted best with the assumption of mono and binary complexes with a different degree of protonation (Table 2). $[AlHL]^{3+}$ may contain one hydroxamate chelate while the amino group is protonated. Upon increasing the pH, $[AlL]^{2+}$, $[AlHL_2]^{2+}$ and $[AlL_2]^{+}$ are formed. Comparison of the pK values of $[AlHL]^{3+}$ or $[AlHL_2]^{2+}$ (Table 3, rows 8 and 9) with pK_4^{micro} of the free ligands (Table 1), referring to the deprotonation microscopic process of the ammonium group and also with the first hydrolytic constant of Al(III) ($\log\beta_{1-10} = -5.52$) [15], indicates

Table 3
Derived equilibrium constants calculated from the data presented in Tables 2 and 4[a]

Derived equilibrium constant	L^1	L^2	L^3	L^4
$\log K_2$[b]	8.67	8.52	16.38	16.19
$\log K_3$[c]	6.83	6.79	14.61	14.50
$\log(K_1/K_2)$	1.51	1.43	1.24	1.20
$\log(K_2/K_3)$	1.84	1.73	1.77	1.69
$\log K_{FeHL} - pK_4^{micro}$			9.71	9.35
$\log K_{FeH_2L_2} - 2pK_4^{micro}$			18.18	17.50
$\log K_{FeH_3L_3} - 3pK_4^{micro}$			24.88	23.96
pK_{AlL} (L^1, L^2); pK_{AlHL} (L^3, L^4)	5.2	4.66	5.15	4.75

pK_{ZnL}			8.22	7.88

[a] For Fe(III) species the data obtained from spectrophotometry were used.
[b] Refers to the following equilibria: $FeL + L \rightleftharpoons FeL_2$ (L^1, L^2) or $FeHL + HL \rightleftharpoons FeH_2L_2$ (L^3, L^4).
[c] Refers to the following equilibria: $FeL_2 + L \rightleftharpoons FeL_3$($L^1$, L^2) or $FeH_2L_2 + HL \rightleftharpoons FeH_3L_3$ (L^3, L^4).

that in $[AlHL]^{3+}$ or $[AlHL_2]^{2+}$ deprotonation of the water molecule in the coordination sphere of the metal ion takes place. The formation of mixed hydroxo complexes is further supported by the fact that the formation of tris chelated species cannot be detected and that precipitation occurs above pH 5 even at a 1:5 metal to ligand ratio. Furthermore, it should also be mentioned that pH-potentiometry is not able to distinguish between $[AlH_{-1}L]_n$ type complexes, therefore the formation of oligomeric or polymeric species cannot be ruled out either.

With nickel(II) the complex formation started at pH ~ 5.0 (Fig. 1), above pH 7.0 it became slow and the almost colourless samples turned yellow during the titration. The colour change strongly suggests the formation of square planar complexes [19], yielding a single absorption band ($\lambda_{max.} \sim 450$ nm, $\varepsilon \sim 200\ M^{-1}\ cm^{-1}$) in the visible spectra over the pH range 7–11. Similarly to earlier findings on the ProLeuNHOH system [8], a maximum consumption of four equivalents of base was found in mostly overlapping processes at a 1:1 ratio. Taking into consideration these findings it is reasonable to assume that the two "extra" equivalents of base consumption (promoted by the metal ion) is due to the deprotonation and coordination of the peptide amide and that of the water molecule in the coordination sphere yielding $[NiH_{-2}L]^-$ (more precisely $[NiH_{-1}L(OH)]^-$). Although these processes overlap considerably, the stability constant for $[NiH_{-1}L]$ with [NH_2, N_{amid}, $N_{hydrox.}$] coordination could also be calculated. The model yielding the best fit together with the stability constants is presented in Table 2. As an illustration, the concentration distribution curves obtained in the Ni^{2+}–L^3 system at a 1:1 ratio are shown in Fig. 4.

A strong interaction was also found with copper(II): both L^3 and L^4 were able to keep in solution even 50% Cu^{2+} excess up to pH 11. Depending upon the metal ion to ligand ratio the samples became light green in the pH range 3.5–5.0 and grey to violet above pH 5.0. UV–Vis spectra showed above pH 3.2 a C.T. band at $\lambda \sim 325$ nm, which is characteristic for Cu^{2+}-hydroxamate [O,O] coordination [20]. EPR spectra also indicated clearly the presence of monomeric species with [O,O] coordination up to pH 4.5, but above that a decrease in intensity showed the formation of complexes with higher nuclearity as well (for EPR spectra recorded at a 1:1.1 metal to ligand ratio in the Cu(II)–L^3 system see S3). CD spectra recorded at different metal ion to ligand ratios (Figs. 5 and 6) exhibited two sets of bands in the 300–450 nm region. The series with $\lambda_{max.} \sim 330$ nm may belong to Cu^{2+}-hydroxamate-O^- charge transfer, while the series with $\lambda_{max.} \sim 400$ nm is characteristic for Cu^{2+}-hydroxamate-N^- charge transfer [20]. This is further supported by the CD spectra of the Cu^{2+}-AlaAlaN(Me)OH system (not shown), where only one set of bands with $\lambda_{max.} \sim 350$ nm is observed, which must be characteristic for Cu^{2+}-hydroxamate-O^- charge transfer since hydroxamate-N^- coordination for the secondary hydroxamic acid ligand is not possible [21]. Analysis of the CD spectra in Figs. 5 and 6 indicates therefore that with L^3 (and L^4 too) Cu^{2+}-hydroxamate-O^- interaction takes place up to pH 8 while at more basic conditions the coordination of hydroxamate-N^- is detectable.

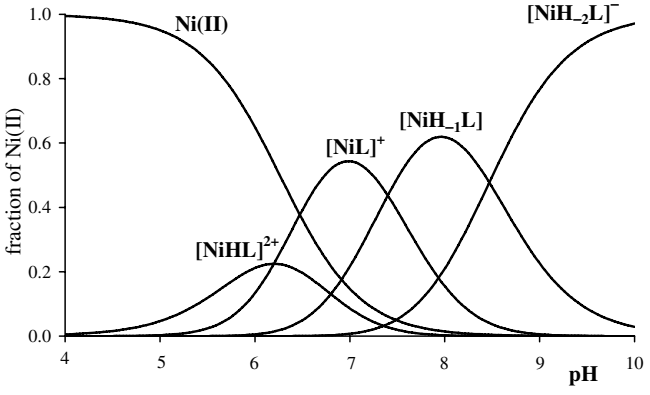

Fig. 4. Concentration distribution curves of the complexes formed in the Ni(II)–L^3 system at a 1:1 metal to ligand ratio, $c_{Ni(II)} = 0.004$ mol dm^{-3}, $I = 0.2$ mol dm^{-3} and $t = 25.0$ °C.

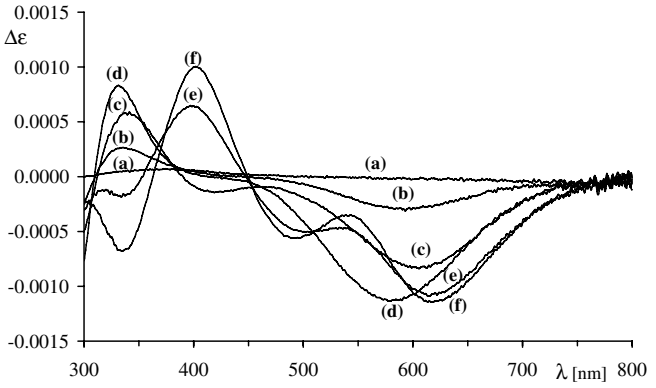

Fig. 5. CD spectra of the Cu(II)–L^3 system at a 1:2 metal to ligand ratio, $c_{Cu(II)} = 0.0015$ mol dm^{-3}, $I = 0.2$ mol dm^{-3} and $t = 25$ °C. The pH values are as follows: 4.33 (a), 4.95 (b), 6.09 (c), 7.93 (d), 10.08 (e), 11.01 (f).

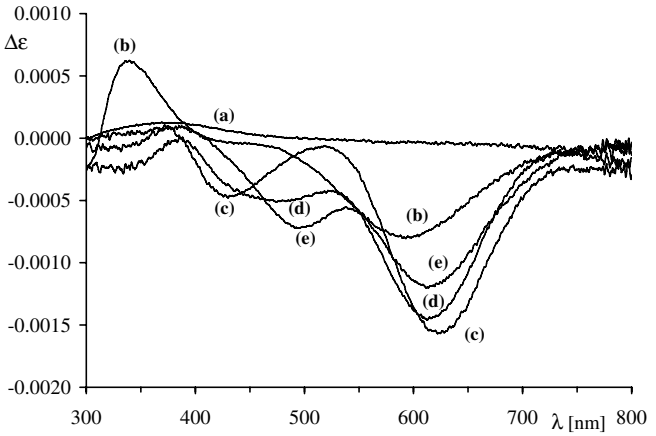

Fig. 6. CD spectra of the Cu(II)–L^3 system at a 1.5:1 metal to ligand ratio, $c_{Cu(II)} = 0.0045$ mol dm^{-3}, $I = 0.2$ mol dm^{-3} and $t = 25$ °C. The pH values are as follows: 4.15 (a), 4.81 (b), 7.00 (c), 9.94 (d), 11.01 (e).

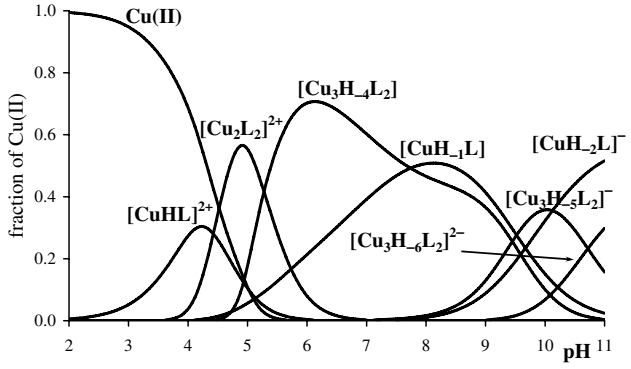

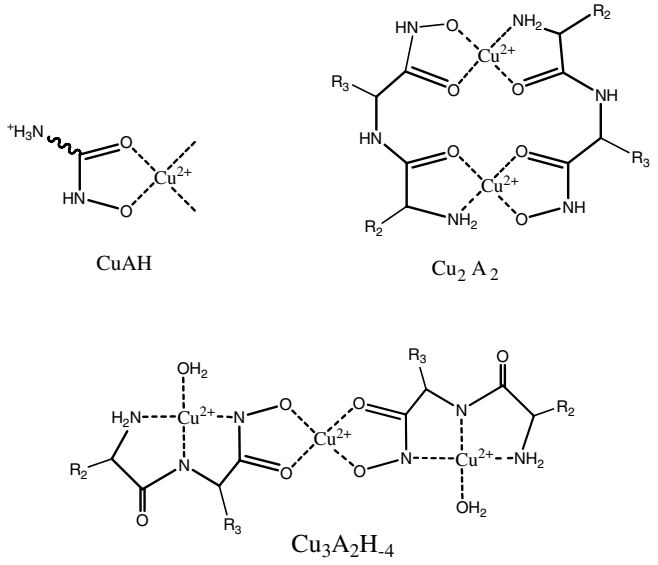

Fig. 7. Concentration distribution curves of the complexes formed in the Cu(II)–L^3 system at a 1:1 metal to ligand ratio, $c_{Cu(II)} = 0.004$ mol dm^{-3}, $I = 0.2$ mol dm^{-3} and $t = 25.0$ °C.

Scheme 2.

Taking into consideration the general spectroscopic information, the best model suitable to fit the potentiometric data is shown in Table 2 while the concentration distribution curves are depicted in Fig. 7. The complexation starts with the formation of $[CuHL]^{2+}$. In this species the ligand coordinates via the [O,O] hydroxamate chelate while the amino group is protonated (Scheme 2). This binding mode is supported by the corresponding VIS and EPR parameters ($CuHL^3$: $\lambda_{max.} \sim 755$ nm, $\varepsilon \sim 15$ M^{-1} cm^{-1}, $g_{\|} = 2.346$, $A_{\|} = 157 \times 10^{-4}$ cm^{-1}; $CuHL^4$: $\lambda_{max.} \sim 760$ nm, $\varepsilon \sim 19$ M^{-1} cm^{-1}, $g_{\|} = 2.338$, $A_{\|} = 160 \times 10^{-4}$ cm^{-1}) which are comparable with those for the mono chelated Cu(II)-hydroxamate species (acetohydroxamate: $g_{\|} = 2.340$, $A_{\|} = 170 \times 10^{-4}$ cm^{-1}, 2,3-diamino-*N*-hydroxypropanamide: $\lambda_{max.} \sim 760$ nm, $g_{\|} = 2.314$, $A_{\|} = 162 \times 10^{-4}$ cm^{-1}) [22,23]. Deprotonation of $[CuHL]^{2+}$ causes considerable change in the spectral parameters and a strong decrease in the intensity of the EPR spectra indicating rearrangement of the binding mode and partial formation of oligonuclear species too. VIS data ($\lambda_{max.} \sim 585$ nm, $\varepsilon \sim 30$–85 M^{-1} cm^{-1}) in the pH range ~4.4–5.0 support the involvement of nitrogen donor(s) in the coordination. Although the pH-metric data could be fitted best with $[Cu_2L_2]^{2+}$ in this range the presence of $[CuL]^{+}$ in the form of different binding isomers cannot be ruled out either. Above pH 6, where the samples still showed decreased EPR activity, a new broad signal with low intensity could be detected which exhibited a continuous shift indicating two EPR active species with very similar structure. VIS spectra ($\lambda_{max.} \sim 585$–575 nm, $\varepsilon \sim 110$ M^{-1} cm^{-1}) in the pH range 4.5–8.5 are supportive for an average of almost 3N coordination [19]. Taking into account these spectral features with the finding that ligands L^3 and L^4 are capable of accommodating up to 50% excess of Cu^{2+}, the potentiometric data could be rationalised with the assumption of trinuclear $[Cu_3H_xL_2]^{x+4}$ type ($x = -4$ to -6) complexes with the parallel presence of monomeric species $[CuH_{-1}L]$ and $[CuH_{-2}L]^{-}$ (Table 2). $[Cu_3H_{-4}L_2]$ most probably consists of two $[CuH_{-1}L]$ units with [NH_2, N_{amide}, $N_{hydrox.}$] coordination of the ligand. Since these units still have uncoordinated hydroxamic chelating groups they may bind a third metal ion with further loss of two protons (Scheme 2). Above pH 8.0 further deprotonation results in the formation of $[Cu_3H_{-5}L_2]^{-}$ and $[Cu_3H_{-6}L_2]^{2-}$. High pK values for $[Cu_3H_{-4}L_2]$ or $[Cu_3H_{-5}L_2]^{-}$ (Table 3, rows 10-11) are consistent with the proton loss from the coordinated water molecules. In the absence of an excess of Cu^{2+} the formation of the EPR silent trinuclear species is slightly less favoured. The base consumption processes above pH 6 can be fitted best with the assumption of $[CuH_{-1}L]$ and $[CuH_{-2}L]^{-}$, beside the trinuclear complexes. The spectral parameters for $[CuH_{-1}L]$ ($\lambda_{max.} \sim 565$ nm, $\varepsilon \sim 130$ M^{-1}cm^{-1}, $g_{\|} = 2.21$, $A_{\|} = 193 \times 10^{-4}$ cm^{-1}) unambiguously supports [NH_2, N_{amide}, $N_{hydrox.}$] coordination, which was found with ProLeuNHOH ($\lambda_{max.} \sim 562$ nm, $g_{\|} = 2.217$, $A_{\|} = 191.3 \times 10^{-4}$ cm^{-1}) [8]. Further deprotonation takes place at the coordinated water molecule as indicated by $pK_{CuH_{-1}L}$ values (Table 3; ProLeuNHOH: 9.92) [8].

For the zinc(II) systems the best models including the refined stability data are presented in Table 2. In order to gain information about the solution structure of the complexes, ^{1}H NMR titrations were also carried out both with L^3 and L^4 at a 1:1 ratio, resulting in identical results. Comparison of the pD dependence of the chemical shifts (δ_H) for the CH, CH_2 or CH_3 protons in the Zn(II)–L^4 system with those of the free ligand (Fig. 8) indicates that at pH = 5.5 where $[ZnHL]^{2+}$ is formed both of the signals belonging to CH(Ala) or CH(Ser) exhibit a shift in the presence of the metal ion. This supports that the ligands are capable of coordinating to Zn(II) either via the hydroxamate group while the amino group is protonated or via the [NH_2, CO] chelating set with the protonated hydroxamic function. Despite the fact that linkage isomers can be formed, attempts to evaluate the potentiometric data of samples having an excess of metal ion always failed. Upon increasing the pH parallel with the formation of

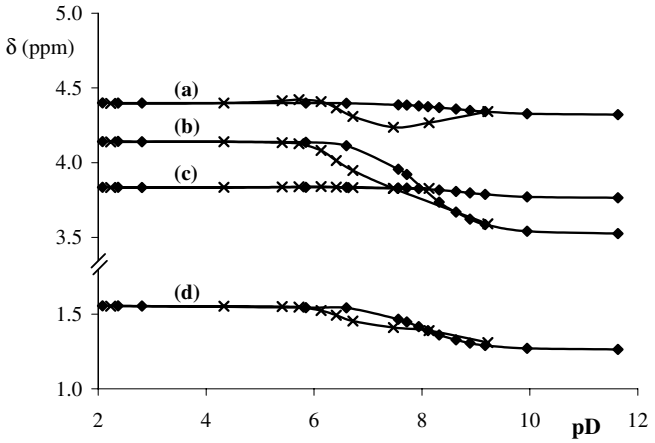

Fig. 8. The pD dependence of the chemical shifts (δ_H) of the CH (a, b), CH_2 (c) and CH_3 (d) protons of the ligand L^4 in the absence (◆) and in the presence of Zn(II) (×) at a 1:1 metal to ligand ratio, $c_{Zn(II)} = 0.02$ mol dm^{-3}, $I = 0.2$ mol dm^{-3} and $t = 25$ °C.

$[ZnHL_2]^+$ mixed hydroxo complexes with a 1:1 stoichiometry, [ZnL] and $[ZnH_{-1}L]^-$, are formed. (Although in the model presented in Table 2, [ZnL] can be replaced by $[Zn_2L_2]$, assumption of the former complex resulted in a slightly better fit and assumption of the parallel formation of them resulted in the rejection of the dimeric species.) The values of pK_{ZnHL} or pK_{ZnL} (Table 3, last two rows) together with the NMR information support hydrolysis and the lack of deprotonation and coordination of the peptide group in these complexes.

3.3. Metal complexes of the Z protected peptide hydroxamic acids L^1 and L^2

The role of the terminal amino group of oligopeptides or aminohydroxamic acids in metal ion binding is well known [9]. The amino group as an anchor facilitates the deprotonation and coordination of the peptide group in oligopeptides or rearrangement from hydroxamate [O,O] binding to N donors in aminohydroxamates yielding stable complexes with soft or borderline metal ions [9].

In order to study the effect of the terminal group on metal ion binding for peptide hydroxamic acids the Z-protected (Z = benzyloxycarbonyl) ligands, L^1 and L^2 were also involved in the work. Similarly to the L^3 and L^4 systems no effect of the hydroxyl group of the serine moiety with any of the metal ions was found.

Depending upon the ligand excess in all systems, precipitation occurred. The useful pH range at a 1:3 metal to ligand ratio was limited to pH = 0.8–4.4 (Fe^{3+}), 2.5–4.7 (Al^{3+}), 5.0–7.0 (Ni^{2+}) and 4.8–7.5 (Zn^{2+}). In the Cu^{2+} containing samples precipitation occurred at a pH as low as 3.6, therefore stability constants could not be determined. However, EPR analysis of the solutions containing the green solid showed the presence of CuL_2 with 2 × [O,O] coordination of the ligand. Stoichiometry and values of the stability constants regarding the other systems are summarised in Table 4.

Table 4
Stability constants ($\log\beta_{pqr}$) for the Fe(III), Al(III), Ni(II) and Zn(II) complexes formed with the Z-protected peptide hydroxamic acids at 25.0 °C and at $I = 0.20$ mol/dm^3(KCl)

Metal ion	Complex	p	q	r	$\log\beta_{pqr}$	
					L^1	L^2
Fe(III)	$[FeL]^{2+}$	1	0	1	10.18(1)[a]	9.95(1)[a]
	$[FeH_{-1}L]^+$	1	−1	1	7.18(2)	7.18(3)
	$[FeL_2]^+$	1	0	2	18.53(9)	19.23(7)
					18.85(2)[a]	18.47(1)[a]
	$[FeL_3]$	1	0	3	25.8(1)	26.6(1)
					25.68(3)[a]	25.26(3)[a]

	$[ZnH_{-1}L]$	1	−1	1	−3.19(3)	−3.09(3)

Standard deviations (3σ values) are in parentheses.
[a] Determined from spectrophotometric titration.

Similarly to L^3 and L^4, with Fe^{3+} complex formation starts well below pH ~ 2.0, therefore spectrophotometric titrations were also carried out. The absorption spectra (not shown) are very similar to those recorded in the presence of L^3 or L^4, indicating unambiguously the formation of 1:1, 1:2 and 1:3 complexes at a 1:5 metal ion to ligand ratio. In the pH range 0.7–1.8 evaluation of the spectra made it possible to calculate the stability constant for the $[FeL]^{2+}$ complexes having one hydroxamate chelate. Keeping this value fixed, computation of the potentiometric data resulted in the model and constants which are presented in Table 4. Upon increasing the pH, 1:2 and 1:3 complexes are present and the formation of $[FeH_{-1}L]^+$, a mixed hydroxo species, can also be detected. At a 1:5 metal ion to ligand ratio the stability constants of the major complexes can be calculated from spectrophotometry too (Table 4). As it is seen in Table 4 the agreement between the corresponding values using different methods is reasonable while the uncertainties of the stability constants from pH-potentiometry are larger than those obtained from spectrophotometry. This difference indicates that at a 1:5 metal ion to ligand ratio (spectrophotometric results) the hydrolysis of Fe^{3+} is no longer significant, whilst at the conditions that the potentiometry was carried out (1:1–1:5 ratios), this process takes place parallel with the coordination of the ligand(s). Therefore, the latter model and values reflect better (although with higher uncertainty) the situation present at a lower excess of ligand.

In order to compare directly the Fe(III) binding strengths of L^3 and L^4 with that of L^1 and L^2, the stepwise formation constants of the iron complexes of L^3 and L^4 corrected by the corresponding protonation microscopic constant (the latter being characteristic for the deprotonation of the non-coordinated ammonium group of the ligand)

($\log K_{FeH_nL_n} - n \times pK_4^{micro}$ values ($n = 1$–3) in Table 3) are calculated. Comparison of them with the corresponding $\log K_{FeL_n}$ values ($n = 1$–3) of L^1 and L^2 (Tables 3 and 4) indicates that the Z protected ligands (L^1 and L^2) form slightly more stable chelates with the metal ion. Comparison of the $\log(K_1/K_2)$ values (Table 3) shows that the preference for the formation of the bis complex is smaller in the case of L^1 or L^2 than L^3 or L^4, most probably due to steric hindrance. However, the corresponding $\log(K_2/K_3)$ values reveal that the preference for the coordination of the third ligand is almost the same in all systems. This suggests that the steric reasons are significantly compensated by charge neutralisation for L^1 and L^2.

With the other metal ions, the formation of 1:1 complexes with different protonation degrees can be detected. In [ML] the ligands L^1 and L^2 most probably coordinate via [O,O] hydroxamate chelation. Upon increasing the pH, the formation of sparingly soluble complexes becomes significant as a consequence of the large Z group and/or hydrolysis of the metal ions. With the "nitrogenophilic" Ni(II) the absence of the amino group decreases dramatically the metal ion binding capabilities of L^1 and L^2 because the rearrangement of the initial [O,O] chelate to the strong [NH_2, N_{amide}, $N_{hydrox.}$] coordination is not possible.

4. Conclusion

Primary dipeptide hydroxamic acids, L^3 and L^4, were found to form stable complexes with hard metal ions, Fe^{3+} and Al^{3+}, at acidic conditions with the exclusive involvement of [O,O] hydroxamate chelates. Due to the stronger interaction with Fe^{3+}, unlike with Al^{3+}, the formation of 1:3 complexes can also be detected in the pH range 4.0–6.5. At physiological conditions, however, with both metals hydrolysis becomes significant. NMR information proved that with Zn^{2+} L^3 and L^4 act as ambidentate ligands, but neither the [O,O] nor the [NH_2, CO] chelates are stable enough to enhance the deprotonation and coordination of the peptide amide group upon increasing the pH. Ni^{2+} and Cu^{2+} form stable complexes with L^3 and L^4 involving the [NH_2, N_{amide}, $N_{hydrox.}$] chelating set after rearrangement of the initial [O,O] or [NH_2, CO] chelation. With Cu^{2+}, the formation of trinuclear species is also significant.

Blocking the terminal amino group in L^1 and L^2 has no major influence on the binding of hard metal ions. The presence of the bulky and hydrophobic Z group, however, results in complexes with less solubility. Furthermore, the effect of charge compensation and therefore enhanced tris complex formation was found with Fe^{3+} compared to the L^3 and L^4 systems. The lack of the NH_2 group as an anchor makes L^1 and L^2 very weak ligands for Ni^{2+} and results in the formation of [O,O] chelated species having partly low solubility with Cu^{2+} and Zn^{2+}.

Acknowledgments

We thank Dr. Katalin Osz for her help in calculating the microscopic protonation constants of the ligands. This work was supported by the Hungarian Scientific Research Fund (OTKA T 046366). P.B. gratefully acknowledges the Hungarian Academy of Sciences for a János Bolyai Research Fellowship.

formation of a multisilver complex. For instance, dinuclear (2:2) macrocycles are the most frequently encountered structural motifs for silver(I) salts with oxo-anions when long-chained flexible diphosphanes are used, whereby the rigid bis(diphenylphosphano)acetylene (dppa) selectively forms cationic disilver complexes with triply-bridging diphosphane units [6]. In this context, previous related work from our laboratory has also revealed the variety of structural motifs observed within a series of thione/phosphane ligated derivatives of Ag(I) halides or Ag(I) nitrate to be dependent on the choice of the bidentate phosphane ligand [7].

In the quest for new materials with specialized catalytic properties, investigations are directed at present towards the development of new fine-tuned ligands for catalytic systems with suitable activity and selectivity. For example, the use of sterically demanding diphosphanes as ligands in transition metal catalysed synthesis of chiral organic compounds is becoming a very intense area of study [8]. The P–M–P bite angle has been established to be an important parameter related to the properties of the catalysts. Concerning the later bite angle effect, considerable progress has been made since the development of new diphos ligands based on xanthene-type backbones [9]. In the course of our systematic structural studies on mixed-ligand coordination compounds of group 11 metals, we recently reported on the coordination capability of two sterically demanding and configurationally inflexible diphosphanes, namely 4,5-bis(diphenylphosphano)-9,9-dimethylxanthene (xantphos), the parent member of the extended xantphos ligand family, and 1,2-bis(diphenylphosphano)benzene (dppbz) towards copper(I) halides in the presence of heterocyclic thiones as co-ligands [10]. As these two diphosphanes, based on rigid aromatic backbones, produced different products to those of their extensively studied flexible counterparts, we decided to extend our studies to the analogous silver(I) halide complexes, starting in the present paper with the structural characterization of some derivatives of silver(I) bromide. In addition, these comparative studies could provide useful information regarding the dimerization frequently observed within this class of complexes.

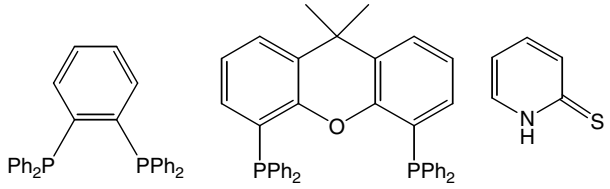
2. Experimental

2.1. Materials and instruments

Commercially available silver bromide, 1,2-bis(diphenylphosphano)benzene (dppbz), 4,5-bis(diphenylphosphano)-9,9-dimethyl-xanthene (xantphos) were used as received while pyridine-2-thione (py2SH) was recrystallized from hot ethanol prior to use (Scheme 1). All the solvents were purified by their respective suitable methods and allowed to stand over molecular sieves. Infra-red spectra in the region of 4000–250 cm^{-1} were obtained in KBr discs with a Perkin-Elmer FT-IR Spectrum 1 spectrophotometer, while a Perkin-Elmer-Hitachi 200 spectrophotometer was used to obtain the electronic absorption spectra. ^1H NMR spectra were recorded on a Brucker AM 300 spectrometer at 25 °C with chemical shifts given in ppm referenced to internal TMS. Melting points were measured in open tubes with a STUART scientific instrument and are uncorrected. Molar conductivities, magnetic susceptibility measurements and elemental analyses for carbon, nitrogen and hydrogen were performed as described previously [11]. Thermogravimetric analyses were performed on a SETSYS-1200 machine with a DTG facility in dry nitrogen atmosphere. Sample sizes were in the range 8–10 mg and open Pt crucibles were used. The heating rate was 10°/min.

2.2. X-ray crystallographic study

Single crystals of **1** and **2** suitable for X-ray crystallographic study were grown by slow concentration over several days at ambient temperature of their acetone and acetonitrile mother liquid, respectively, whereas compound **4** was obtained from an ethanolic solution. X-ray diffraction data were collected on an Enraf-Nonius Kappa CCD area-detector diffractometer.



The programs DENZO [12] and COLLECT [13] were used in data collection and cell refinement. Details of crystal and structure refinement are shown in Table 1. The structures were solved using the program SIR 97 [14] and refined with the program SHELX-97 [15]. Molecular plots were obtained with the program ORTEP-3 [16].

2.3. Synthesis of compounds *1* and *2*

The homoleptic complexes were prepared according to the following general procedure. A suspension of silver bromide (47 mg, 0.25 mmol) and 0.25 mmol of the appropriate diphosphane (111.6 mg for dppbz or 144.7 mg for xantphos) in 60 cm^3 acetone or acetonitrile was refluxed for 2 h. The resulting mixture was filtered off and the clear solution was kept at room temperature. Slow evaporation of the solvent at room temperature gave the microcrystalline solid, which was filtered off and dried in vacuo.

2.4. [Ag(μ-Br)(dppbz)]$_2$ (*1*)

2.5. [AgBr(xantphos)] · CH_3CN (2)

Colourless crystals. Yield: 186 mg (92%), m.p. 338 °C; *Anal*. Calc. for $C_{41}H_{35}AgBrNOP_2$: C, 60.99; H, 4.37; N, 1.73. Found: C, 60.62; H, 4.23; N, 1.57%. IR (cm^{-1}): 3437m, 3049w, 2975w, 1480m, 1435s, 1405vs, 1238s, 1097m, 1027m, 789s, 746vs, 695vs, 509vs, 457s; UV–Vis (λ_{max}, $\log\varepsilon$): ($CHCl_3$); 253 (3.76). ^{1}H NMR ($CDCl_3$, δ ppm): 7.58 (d, 1H, $H^3_{xantphos}$), 7.30 (m, 8H, PC_6H_5), 7.20 (m, 12H, PC_6H_5), 7.06 (dd, 1H, $H^3_{xantphos}$), 6.58 (d, 1H, $H^1_{xantphos}$), 1.67 (s, 6H, $H_3C_{xantphos}$).

2.6. Synthesis of compounds 3 and 4

The heteroleptic complexes were prepared according to the following general procedure. A suspension of silver bromide (47 mg, 0.25 mmol) and 0.25 mmol of the appropriate diphosphane (111.6 mg for dppbz or 144.7 mg for xantphos) in 40 cm^3 ethanol was refluxed for 2 h until a

white precipitation formed. A solution of pyridine-2-thione (28 mg, 0.25 mmol) in ethanol was treated with a small quantity of pyridine and was then added dropwise to the hot suspension and the reaction mixture was refluxed for an additional 2 h. The resulting solution was filtered off and the clear yellow solution was kept at room temperature. Slow evaporation of the solvent at room temperature gave the microcrystalline solid, which was filtered off and dried in vacuo.

3. Results and discussion

3.1. Preparative considerations

The reaction between equimolar quantities of silver(I) bromide and 1,2-bis(diphenylphosphano)benzene (dppbz) or 4,5-bis(diphenyl-phosphano)-9,9-dimethyl-xanthene (xantphos) in dry acetone or acetonitrile afforded microcrystalline solids which, on elemental analysis, were found to be of the composition [AgBr(diphos)] (compounds **1** and **2**, respectively). It should be pointed out that both diphosphanes showed a strong preference for chelation at a single metal centre in their reactions with copper(I) halides [10], despite of the marked difference in their natural bite angles. This coordination behaviour undoubtedly demonstrates their strong chelating power but should be also ascribed, to a significant degree, to the extraordinary versatility of a d^{10} metal ion and therefore chelation was expected to be preferred over bridging also in the case of silver(I). On the other hand, there is a well known tendency for copper(I) and to a lesser extent for silver(I) to achieve the common four-coordination forming dinuclear species involving halide ligands in a μ_2-X bridging mode. Thus, according to our previous experience, particularly with dppbz, compounds **1** and **2** were expected to be halide-bridged dimers of type $[Ag(\mu_2\text{-}Br)(diphos)]_2$. X-ray crystal structure determinations showed, however, that this is the case only for the dppbz derivative, whereas compound **2** is a three-coordinated monomer.

Following the one-pot two-step synthetic procedure that has proven to produce mixed-ligand copper(I) and silver(I) complexes virtually for any heterocyclic thione, we next attempted the preparation of heteroleptic complexes of the type [AgBr(diphos)(thione)]. In particular, we prepared suspensions of compounds **1** and **2** in dry acetonitrile and treated these with an equimolar quantity of a methanolic solution of the appropriate thione. Heating of the mixture at reflux for several hours did not caused, as expected, the disappearance of the white precipitate, indicating the presence of unreacted starting material. Indeed, the white amorphous solid isolated by filtration could be identified as compounds **1** and **2**, respectively. On the other hand, the composition of the microcrystalline solid that was obtained on evaporation of the yellow solution at ambient temperature changed over time as a function of the evaporation state, indicating the presence of a product mixture. Surprisingly, only in the case of py2SH did the reaction proceed towards the expected products, employing an ethanol/pyridine mixture as solvent, which may seem quite unusual and was initially used to possibly favour deprotonation of the thione, thus to increase its coordination capability. It should be, however, anticipated that both [AgBr(dppbz)(py2SH)] (**3**) and [AgBr(xantphos)(py2SH)] (**4**) still contain the thione unit in its neutral (protonated) form.

All the prepared complexes are microcrystalline solids, slightly soluble in acetonitrile and only marginally soluble in chloroform and acetone. They are stable to air and moisture and can be manipulated in air without appreciable decomposition. Their solutions in acetonitrile exhibit no conductivity. Room temperature magnetic measurements confirm the expected diamagnetic nature of the compounds.

3.2. Spectroscopic characterization

The solid state FT-IR spectra of the four compounds, recorded in the range 4000–250 cm^{-1}, show all the expected strong phosphane bands, which remain practically unshifted upon coordination. Moreover the spectra of the mixed-ligand complexes **3** and **4** contain the four characteristic "thioamide bands" required by the presence of the heterocyclic thioamide, with shifts suggestive of its coordination mode. "Thioamide(IV)", for instance, which appears at 742 cm^{-1} in the spectrum of the "free" pyridine-2-thione and mainly involves contribution from the ν(C=S) vibration, undergoes a significant downward shift

(by more than 30 cm^{-1}) upon coordination, indicating M–S bond formation. The thione form of the coordinated heterocyclic thioamide is further established by the presence of the NH stretching vibration at 3159 and 3149 cm^{-1} for **3** and **4**, respectively, in combination with the lack of an S–H stretching band around 2560 cm^{-1}.

The room temperature ^1H NMR spectra of the complexes, recorded in deuterated chloroform, are dominated by the presence of complex multiplets in the 7.20–7.40 ppm region due to phenyl/phenylene resonances, as well as, in the case of compounds **3** and **4**, signals attributable to the aromatic protons of the pyridine-2-thione unit. Upon coordination, the multiplets assigned to the PPh_2 groups of the phosphane ligands undergo splitting due to a small upfield shift of the *ortho*-positioned protons, whereas the signals of the corresponding backbone protons remain practically unshifted.

The electronic absorption spectra of compounds **1** and **2** in chloroform solutions appear to be mainly of intraligand character, consisting of three or one intense sharp band respectively (see Section 2). These bands can be attributed to intraligand $\pi^* \leftarrow \pi$ transitions on the phenyl group of the phosphane ligands, since the uncoordinated 1,2-bis(diphenylphosphano)benzene and 4,5-bis(diphenylphosphano)-9,9-dimethyl-xanthene reveal three or one strong absorptions respectively at 245, 273 and 299 nm or 264 nm, all of them undergoing small shifts upon coordination to Ag(I). The spectra of complexes **3** and **4** show an additional lower energy band that lies in the region where the free thione absorbs, expressing a small red shift as a consequence of the coordination to Ag(I) and should be, therefore, considered as a thione-originating intraligand transition which possesses some MLCT character [17].

3.3. Thermal decomposition

The thermal behaviour of the new compounds was investigated using simultaneous differential thermoanalysis (DTA) and thermogravimetry (TG) in a nitrogen atmosphere. TG and DTA data curves for compounds [AgBr(xantphos)] (**2**) and [AgBr(xantphos)(py2SH)] (**4**) are given in Fig. 1.

Complexes **1** and **2** decompose in one single stage that starts at 330 or 390 °C, respectively and extends over a temperature range of 100 °C. The observed mass loss notified by the TG curve fits in each case perfectly as the loss of the diphosphane, whereby the corresponding DTA curve shows a strong endothermic effect. Complexes **3** and **4** show the typical decomposition pattern observed for the analogous copper(I) halide compounds [10a,10c], generally consisting of two main stages, the low temperature initial stage, observed in the TG curve in the 240–280 °C range, being connected with two endothermic events in the DTA curve and involving overall weight loss indicative of gradual thermal breakdown of the pyridine-2-thione ligand. A very strong endothermic event appears at about 380 °C, which does not affect the consistency of the compounds,

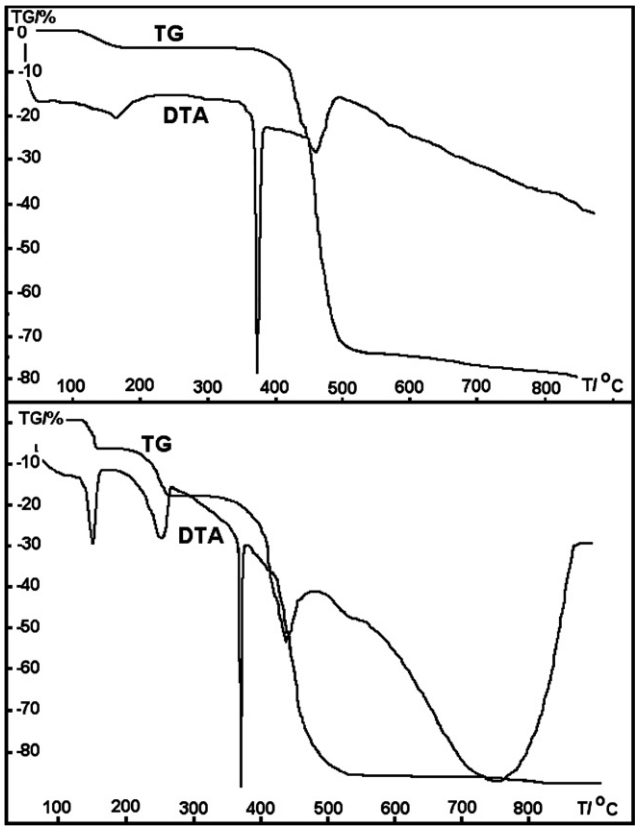

Fig. 1. TG and DTA curves for [AgBr(xantphos)] (**2**) and [AgBr(xantphos)(py2SH)] (**4**).

in any form. In the case of compounds **2** and **4** solvent retention occurs at the temperature 170 °C, indicated by a weak endothermic effect. For all the compounds further heating causes gradual sublimation of the residual AgBr which is almost completely removed at 980 °C.

3.4. Crystal structures

The X-ray crystal structures of $[Ag(\mu_2\text{-}Br)(dppbz)]_2$ (**1**), [AgBr(xantphos)] (**2**) and [AgBr(xantphos)(py2SH)] (**4**) (details of crystal and structure refinement are shown in Table 1) corroborate the spectroscopic results discussed above. Note that many heavy transition metal complexes with xantphos or dppbz have been described in the literature, but no Ag^I complexes are known to be structurally characterized by X-ray crystallography.

Colorless crystals of **1** suitable for X-ray crystallography were grown from its acetone mother liquid by slow evaporation at ambient temperature. The complex crystallizes in the triclinic space group $P\bar{1}$ with two formula units in the unit cell. The asymmetric unit consists of two half-molecules as well as one acetone molecule, which will not be further discussed as there is no evidence of any specific interaction involving this latter solvent molecule. Respective bond lengths and angles within the two half-molecules are slightly different, thus two different centrosymmetric molecules (A and B) result by suitable symmetry transformations.

Fig. 2 depicts a perspective of one of these molecules showing the atom numbering. Bond lengths and angles around the Ag^{I} centre are listed in Table 2.

The crystal structure contains a center of symmetry and features a dinuclear unit in which the two silver(I) centers are joined by two bromine bridges to form a "diamond-shaped" Ag_2Br_2 core with Ag–Br–Ag and Br–Ag–Br bond angles that clearly deviate from the ideal values for symmetric dimers (70.5° and 109.5°) but are very close to the ideal geometry for $Y_2MX_2MY_2$ dimers according to theoretically proposed criteria [18]. The Ag···Ag separation of 3.4985(3) Å is slightly longer than the sum of the van der Waals radii [19], thus excluding any possible metal–metal attractive interaction. It should be noted that, unlike the remarkable non-planarity within the Cu_2Br_2 moiety of the recently reported $[Cu(\mu_2\text{-Br})(dppbz)]_2$ [10b], complex **1** displays a strictly planar central core commonly adopted by halide-bridged dimeric complexes. Another noticeable difference between the two structures arises from the P–M–P intraligand angles, the acute P(1)–Ag(1)–P(2) bite-angle of 79.596(19)° in the present structure being clearly smaller than the corresponding P–Cu–P angles found in the above mentioned copper counterpart, which certainly can be ascribed to the different M–P bond lengths.

As expected, the carbon atoms of the phenylene backbone and the two adjacent phosphorus atoms are nearly coplanar, but the AgPCCP five-membered ring adopts an envelope conformation with the metal atom displaced out of the plane containing the four diphos ligand atoms by 1.2773(15) Å. The two phenyl rings on each phosphorus atom are nearly perpendicular to each other. However, the C(7)–C(12) and C(19)–C(24) phenyl rings have their planes in an almost parallel arrangement as a consequence of a 3.6400(14) Å π-stacking interaction between them. Within the Ag_2Br_2 backbone there are two different Ag–Br bond distances that are somewhat shorter than those found in other tetracoordinate silver(I) phosphane complexes, e.g. in $[Ag(\mu_2\text{-Br})(pymtH)]_2$ [20]. Finally, the two Ag–P distances of 2.5142(6) Å and 2.5260(6) Å are within the limits of the value range expected for tetrahedrally coordinated Ag^{I}.

Symmetry transformations used to generate equivalent atoms: # $-x+1$, $-y+1$, $-z+1$.

Structure refinement for compound **2** was performed in both $P2_1$ and $P2_1/m$ monoclinic space groups and the higher symmetry space group $P2_1/m$ was adopted. However, disorder involving the Br atom position (split over two sites), a poorly defined solvent molecule (occupying

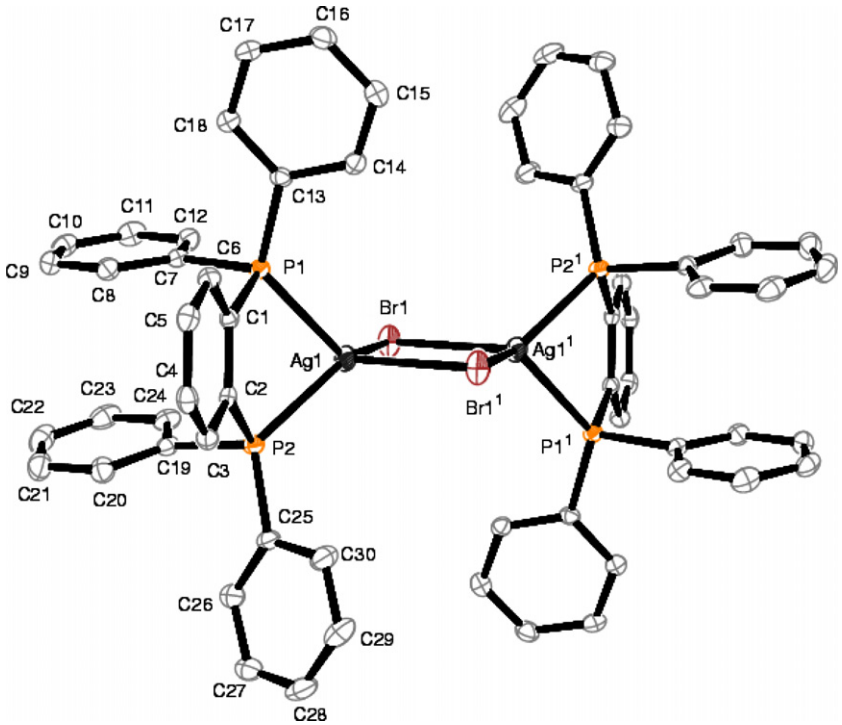

Fig. 2. Molecular structure of complex **1** with atom labels. Displacement ellipsoids are shown at the 50% probability level.

17% of the crystal volume, 18 electrons removed by PLATON [21] and some residual electron density spread along the 2-fold axis led to a structure less well defined than **1** or **4**. Fig. 3 depicts a perspective of the molecule showing the atom labelling scheme. Selected bond lengths and angles are listed in Table 3.

Contrary to the above discussed structure of the silver/dppbz complex, the xantphos derivative is a monomer, the inability for dimerization caused most probably by the marked steric demands of the bulky diphos ligand, expressed by its wide P–Ag–P bite angle versus the corresponding acute bite angle in the structure of **1**. Thus, the silver(I) metal exhibits a distorted trigonal coordination environment surrounded by two phosphorus atoms of the chelating xantphos as well as one bromine atom, with quite small angular deviations from the ideal trigonal value of 120° being mainly directed by the diphosphine bite angle. The crystal structure possess a symmetry plane defined by the C(1), C(8), C(9), O(1), Ag(1) and Br(1a) atoms, which require the P_2AgBr central core to be strictly planar. The smallest angle within this core corresponds to the P(1)–Ag(1)–P(1)# angle, whose value of 109.38(7)° is very close to the ligands calculated "natural" bite angle of 111° [21], indicating the extraordinary versatility of the closed shell central metal ion. Nevertheless, some adjustment on the part of the diphos ligand seems to be unavoidable in order to act as a chelate, which is expressed by the folding of the xanthene unit along its symmetry axis. In fact, the dihedral angle between the planes of the two benzenoid rings form a dihedral angle of 150.3(2)° whereas a value of 156.58° was found for the "free" xanthene molecule [21].

Compound **4** crystallizes in the monoclinic space group $P2_1/n$ with four formula units in the unit cell. Fig. 4 depicts a perspective of the molecule showing the atom numbering.

Table 3
Selected bond lengths (Å) and angles (°) for **2**

Ag(1)–P(1)	2.4478(14)	P(1)–C(6)	1.829(6)
		P(1)–C(10)	1.831(6)
Ag(1)–Br(1a)	2.658(7)		
P(1)–Ag(1)–P(1)#	109.38(7)	C(16)–P(1)–C(6)	104.3(3)
P(1)–Ag(1)–Br(1a)	125.31(4)	C(6)–P(1)–C(10)	103.1(2)
		P(1)–C(6)–C(5)	123.2(4)
Ag(1)–P(1)–C(16)	111.62(19)	P(1)–C(6)–C(7)	118.8(4)

Symmetry transformation used to generate equivalent atoms: $x, -y+0.5, z$.

Bond lengths and angles around the Ag^I are listed in Table 4. Two P donors, one S donor of the heterocyclic thione and the bromine atom form a fairly regular tetrahedron, where the angles around the silver atom vary from 103.300(18)° for S(1)–Ag(1)–Br(1) to 117.13(3)° for P(2)–Ag(1)–S(1). Interestingly, upon chelation the xantphos ligand exactly retains its "natural" bite angle [21].

The geometrical characteristics of the structure under investigation generally refer to those of other silver(I) complexes tetrahedrally coordinated by phosphine and thione ligands. Thus, the two Ag–P distances vary little [Ag(1)–P(1) = 2.4843(5) and Ag(1)–P(2) = 2.4994(5) Å] and lie at the upper limit of values found for a number of complexes containing tetracoordinated silver atoms bonded to two phosphorus atoms [7b]. The Ag–S bond distance of 2.5395(5) Å, coincident with the sum of the corresponding atomic radii, is typical for this bonding arrangement. Finally, hydrogen bonds of type N–H···Br and O–H···Br (from the ethanol molecule) are observed, as well as a weak intramolecular π–π stacking interaction between the C(33) and C(38) phenyl ring of the xantphos unit and the heterocyclic thione ring.

4. Conclusion

The aim of this work was the study of the coordination capability of the diphos ligands 1,2-bis(diphenylphosphano)benzene (dppbz) and 4,5-bis(diphenylphosphano)-9,9-dimethylxanthene (xantphos) toward silver(I) bromide. We have found that, despite the quite different geometrical characteristics of the two diphosphanes, xantphos providing a much larger bite angle than the acute bite angle of dppbz, chelation was observed as the only coordination mode for both diphos ligands. Compounds of the same composition [AgX(diphos)], but of different geometry and nuclearity were formed, namely a halide bridged dimer with tetrahedrally coordinated Ag^I centers for dppbz and monomeric trigonal in the case of xantphos. Both complexes proved to be good precursors for the preparation of mixed ligand monomeric complexes which contain, besides the chelating diphos unit, a heterocyclic thioamide bonded to the metal via the thione-S atom. According to the overall geometries of the structures presented, the xantphos ligand applied can be considered as best tailored for chelation of silver(I) centres.

5. Supplementary material

CCDC 612754, 612755 and 612756 contain the supplementary crystallographic data for **1**, **2** and **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

We thank the EPSRC X-ray crystallography service at the University of Southampton for collecting the X-ray data.

supramolecules *via* intermolecular interactions such as hydrogen bonding, electrostatic and aromatic–aromatic π–π stacking interactions often takes place. Organic counter-cations formed as a result of protonation of pyridine N atom act as templating agents leading to quite unusual crystal structures. The nature of the halogenorhodate(III) or halogenoruthenate(III) species formed is dependent on the size of the counter cation, and the concentration of the halide ion in solution used in the syntheses. In the present paper two new inorganic anions of the type $[(MCl_3M_1Cl_3)^{2-}]_n$, M = Rh, Ru, M_1 = Na, K, have been obtained. Their X-ray structures and IR spectra are presented and discussed.

2. Experimental

2.1. General conditions

Rhodium chloride(III) hydrate, ruthenium chloride(III) hydrate were obtained from Aldrich Chemical Company, 2-amino-6-methylpyridine from Fluka AG.

Infrared spectra were recorded in KBr pellets, as well as in nujol and fluorolube mulls using a Bruker IFS 66/S instrument in the 50–4000 cm^{-1} range.

2.2. Synthesis

All reagents and solvents (except for 2-amino-6-methylpyridine) from commercial sources were used without further purification. 2-Amino-6-methylpyridine was recrystallized from CH_2Cl_2 by addition of petroleum ether.

The complex salt sodium bis(2-amino-6-methyl-pyridinium) heksachlororhodium(III), $Na(C_6H_9N_2)_2[RhCl_6]$ (**1**) is prepared as follow: boiling of hydrochloric acid solution (1 ml of concentrated (36%) HCl and 5 ml of water) of 2-amino-6-methyl-pyridine (0.10814 g, 1 mmol), NaCl (0.02338 g, 0.4 mmol) and rhodium(III) chloride (0.05265 g, 0.2 mmol) (within 10–15 min) gives dark red, clear solution. Slow evaporation (several days) gives red crystals of products **1** adequate for X-ray analysis.

Anal. Calc. for $C_{12}H_{18}N_4NaRhCl_6$: C, 25.88; H, 3.26; N, 10.06; Cl, 38.20. Found: C, 26.01; H, 2.91; N, 10.05; Cl, 38.05%. Selected IR data (KBr pellet, cm^{-1}: 3405vs, 3319vs, 3306shs, 3270 s, 3214vs, 3133vs, 3087s, 3018m, 2992m, 1677shm, 1658vs, 1637s, 1624s, 1550w, 1471w, 1437vw, 1400w, 1377w, 1309w, 1214vw, 1177w, 993w, 948vw, 794m, 715vw, 521w, 454w, 416w. FIR: 319vs, 309shvs, 233w, 176w, 162w, 136vw, 95m.

Potassium bis(2-amino-6-methyl-pyridinium) heksachlororuthenium(III), $K(C_6H_9N_2)_2[RuCl_6]$ (**2**) is prepared in the analogous way as **1** using 2-amino-6-methyl-pyridine (0.10814 g, 1 mmol), KCl (0.02982 g, 0.4 mmol) and ruthenium(III) chloride (0.05229 g, 0.2 mmol).

Anal. Calc. for $C_{12}H_{18}N_4KRuCl_6$: C, 25.31; H, 3.19; N, 9.85; Cl, 36.88. Found: C, 25.74; H, 2.86; N, 9.98; Cl, 37.23%. Selected IR data (KBr pellet, cm^{-1}: 3415vs, 3330vs, 3268s, 3214vs, 3138vs, 3106shs, 3084shs, 2989s, 2921s, 1666shvs, 1658vs, 1635vs, 1621shs, 1554w, 1471w, 1398m, 1377m, 1310m, 1223w, 1177m, 1045w, 993w, 949w, 788vs, 714m, 585w, 562w, 467m, 450m, 417w. FIR: 325vs, 315shvs, 269m, 109bm

2.3. X-ray crystallographic study

X-ray data for both crystals were collected at low temperature using an Oxford Cryosystem device on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo Kα radiation. The crystals were positioned at 65 mm from the CCD camera. 612 frames were measured at 0.75° intervals with a counting time of 20 s. Accurate cell parameters were determined and refined by least-squares fit of 1150 and 1700 the strongest reflections for **1** and **2**, respectively. The data were corrected for Lorentz and polarization effects. Analytical absorption corrections were applied. Data reduction and analysis were carried out with the Oxford Diffraction (Poland) Sp. z o.o. programs. Both structures were solved by direct methods (program SHELXS97 [25]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL97 [26] programs. Non-hydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms were included from geometry of molecules and $\Delta\rho$ maps and were refined as riding groups. Crystal data are given in Table 1, together with the refinement details.

3. Results and discussion

3.1. Crystal structures

Both compounds are isostructural and crystallize in the triclinic space group $P\bar{1}$ – therefore molecular structure with crystallographic numbering and hydrogen bond system (Fig. 1), molecular packing diagram (Fig. 2) as well as perspective view of the layered packing in crystal (Fig. 3) are given for compound **1**. The structure determination shows $[MCl_6]^{3-}$ (M = Rh, Ru), M_1^+ (M_1 = Na, K) and $C_6H_9N_2^+$ ions to be present in the crystal in 1:1:2 ratio.

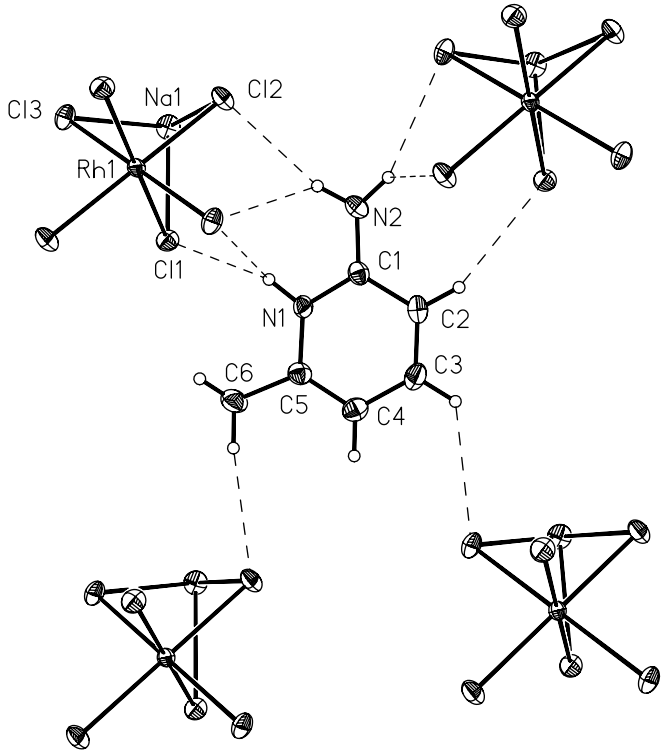

Fig. 1. Molecular structure with crystallographic numbering and hydrogen bond system in **1**.

3.1.1. $NaRhCl_6(2NH_2\text{-}6CH_3\text{-}pyH)_2$ (**1**)

The structure of **1** consists of discrete 2-amino-6-methylpyridinium cations and 1D polymeric $[(RhCl_3NaCl_3)^{2-}]_n$ anions. Both the Rh and Na atoms are situated in symmetry centres with the octahedral environment, and are placed on a line parallel to the [1 0 0] direction (Rh–Na–Rh angle equals 180.0°). Coordination number for both Na and Rh equals 6. The octahedral Rh(III) and Na(I) centers are achieved by means of six bridging chloride atoms. The existence of the triple chloride bridges M–Cl–M_1 makes the polymeric anion more rigid (the same situation occurs in **2**). The resulting infinite linear chain has composition $[(RhCl_3NaCl_3)^{2-}]_n$. $RhCl_6$ and $NaCl_6$ octahedra are sharing only of pair of opposite faces (each octahedron with Rh ion in its center is linked to the two neighboring octahedra with sodium cations in their centers). Similar linking of octahedra have been found in $BaNiO_3$, $CsNiCl_3$ or ZrI_3 [27].

The hexachlororhodate(III) anions exhibit an almost regular octahedral geometry (Table 2), with deviations of the Cl–Rh–Cl angles from the ideal values less than 2.6°. The Rh–Cl bond lengths in $C_{12}H_{18}Cl_6N_4NaRh$ (**1**) in the range 2.3417(12)–2.3545(13) (Table 2) are typical for $[RhCl_6]^{3-}$ anionic octahedra and can be compared with that of 2.302(4)–2.364(4) Å in $K_3RhCl_6 \cdot H_2O$ [28], 2.3415(6)–2.3524(6) Å in $[H_3N(CH_2)_6NH_3]_2[H_9O_4][RhCl_6]Cl_2$ [14],

Symmetry transformations used to generate equivalent atoms: #1 $-x, -y, -z$; #2 $x-1, y, z$; #3 $-x+1, -y, -z$; #4 $x+1, y, z$; #5 $x, y+1, z$; #6 $-x, -y+1, -z$; #7 $x, y+1, z+1$; #8 $x, y, z+1$.

The Rh–Na distance is equal half of the ***a*** lattice vector, ie. 3.47 Å and the Rh–Na–Rh units are linear as in $[KAuCl_4(C_{10}H_8N_2)]_n$ ($C_{10}H_8N_2$ = 4,4′-bipyridine) [29] for which Au···K separation is 3.6805 (10) Å. This distance is significantly longer than for Rh–Na (**1**) and Ru–K (**2**) polymers in which Rh–Na and Ru–K are connected via three chlorine bridges.

The inorganic chains are cross-linked by 2-amino-6-methyl-pyridinium cations through bifurcated N–H···Cl hydrogen bonds (Fig. 1) with the N–H···Cl lengths in the range 3.25–3.57 Å (Table 3), indicating rather weak interactions. Both amine hydrogen atoms and protonated pyridine hydrogen take part in the hydrogen bond formation.

There are also some C–H···Cl short contacts (Table 3) which complete the net of hydrogen bonds.

Pyridinium cations are oriented perpendicularly to the anionic polymeric chains and form stacks parallel to [1 0 0] direction. The neighbouring cation molecules are related by centers of symmetry. Alternate perpendicular distances between the aromatic rings are 3.35 and 3.40 Å. These similar distances are typical for π–π stacking interactions. Values of the off set calculated for neighbour aromatic rings equal 0.46 and 1.44 Å show that the column has a *zig-zag* structure. As a result of these interaction cationic column and anionic polymeric chain are packed in a crystal forming a layered structure. The organic cationic layers are separated by anionic inorganic chains (Fig. 3).

The C–N–C angles of pyridine are very sensitive to protonation [30,31]. A pyridinium cation always possesses an expanded angle of C–N–C in comparison with its parent pyridine. The angle of C(1)–N(1)–C(5) [124.2(4)°] in **1** is consistent with the type of pyridinium cation.

In both compounds the N(2)–C(1) bond is slightly but significantly shorter than the N(1)–C(5) bond, which is consistent with the iminium tautomer. Moreover, the existence of the iminium tautomer is supported by the fact that the C(1)–C(2) and C(3)–C(4) bonds are longer than the C(2)–C(3) and C(4)–C(5) bonds [21,22,32–34].

3.1.2. K $RuCl_6(2NH_2\text{-}6CH_3\text{-}pyH)_2$ (2)

The structure of **2** consists of discrete 2-amino-6-methyl-pyridinium cations and 1D polymeric $[(RuCl_3KCl_3)^{2-}]_n$ anions. The asymmetric unit consists of a single $RuCl_3$ moiety, 2-amino-6-methyl-pyridinium cation, and potassium cation. This compound is a 1D coordination polymer isostructural to **1**, with relatively short Ru–K distance of 3.753 Å (half of ***a*** lattice vector). As for **1**, the infinite chains of composition $[(RuCl_3KCl_3)^{2-}]_n$ are linked together *via* hydrogen bonds with 2-amino-6-methyl-pyridinium cations in a way shown in Fig. 1. The hydrogen bonds are rather weak with the N–H···Cl bond lengths in the range 3.20–3.51 Å (Table 3). These interactions are completed by the C–H···Cl contacts as in **1**.

The cation molecules form columns packed in the crystal in a similar fashion as in **1** (Figs. 2 and 3). They involve the π–π stacking interactions. Distances between the aromatic rings are equal 3.35 and 3.48 Å whereas values of the off set are 1.33 and 1.84 Å, respectively. The latter value suggests a smaller overlap between aromatic rings in this cationic column in comparison to **1**.

3.2. IR spectroscopic investigations

The IR spectra of both **1** and **2** in 4000–400 cm^{-1} show bands characteristic for protonated 2-amino-6-methyl-pyridine. Strong bands are observed between 3500 and 2700 cm^{-1} due to the NH_2, NH^+ and CH_3, CH stretching modes, while ring vibrations and NH_2, NH^+ bending and rocking modes occur in the 1670–1600 and 800–600 cm^{-1} regions.

The conclusion derived from X-ray studies concerning symmetry of $[MX_6]^{3-}$ anions in **1** and **2** is confirmed by the FIR spectra where a strong band at ca. 320 cm^{-1} with a shoulder at ca. 310 cm^{-1} due to the M–Cl (M = Rh, Ru) asymmetric stretching mode (ν_3 (F_{1u})) occurs. Fig. 4 compares the FIR spectra obtained for **1** and **2** with that for $K_3RhCl_6 \cdot H_2O$ obtained according to [11] in which the symmetry of $RhCl_6$ octahedron is lower.

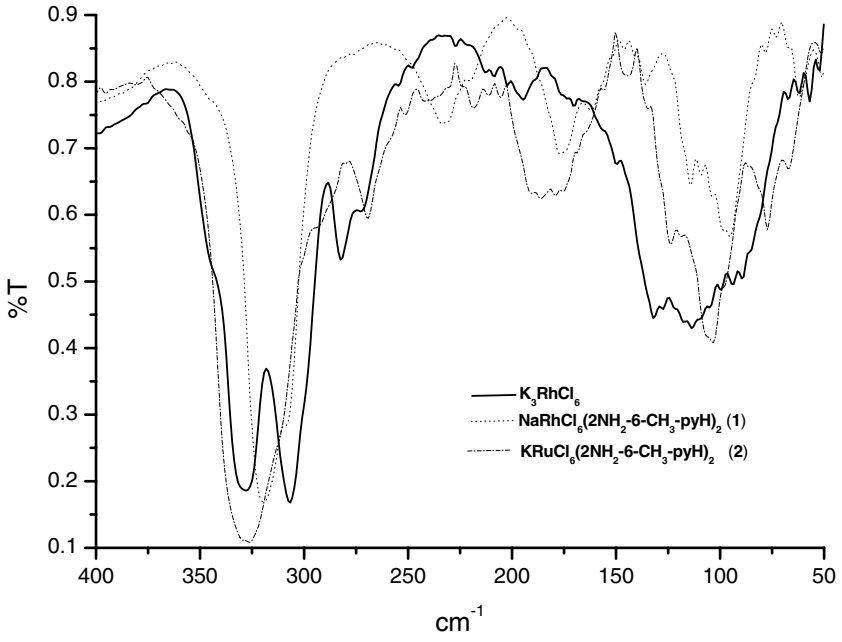

Fig. 4. FIR spectra for **1** and **2**. For comparison the FIR spectrum of K_3RhCl_6 is also given.

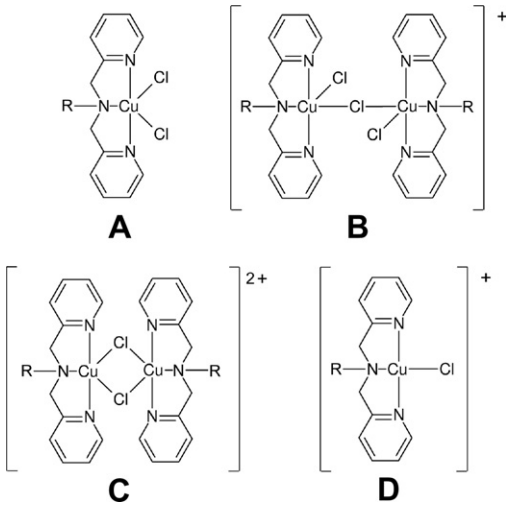
4. Conclusion



The main feature of the atomic arrangement of both **1** and **2** is the existence of a new kind of 1D linear coordination anionic polymers of the type $-Cl_3MCl_3M_1Cl_3-$ ($M = Rh$ and $M_1 = Na$ or $M = Ru$ and $M_1 = K$). Metal atoms (Rh, Na or Ru, K) in polymeric anions are in octahedral environment. In these polymers all M and M_1 atoms are bonded *via* chloride bridges and M and M_1 atoms are placed in the inversion centers. This is clearly seen in FIR spectra of **1** and **2** where only one strong band (with a shoulder on it) at *ca.* 320 cm^{-1} occurs due to the ν_3 (F_{1u}) mode. Additionally, the existence of chloride bridges makes the polymeric anions more rigid. The polymeric chains are interconnected through hydrogen bonds established between the NH^+ and NH_2 groups of the 2-amino-6-methyl-pyridinium cations as well as *via* C–H···Cl short contacts. All organic cations form columns involving the π–π stacking interactions, and the columns are parallel to the infinite, $[(MCl_3M_1Cl_3)^{2-}]_n$ chains. In the crystal packing columns of organic cations form layers, separated by the layers of inorganic polymeric anions. According to our knowledge these are the first examples of polymeric $[(MCl_3M_1Cl_3)^{2-}]_n$ anions for Rh and Ru.

5. Supplementary material

CCDC 615815 and 615816 contain the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.11.040.

Scheme 1. Structural arrangements observed (**A**–**C**) and postulated (**D**) [14] for copper(II) complexes of the N_3-tridentate ligands bpa (R = H), mebpa (R = CH_3) and phbpa (R = C_6H_5).

non-coordinating phenyl substituent in phbpa, coordination oligomerisation to give, for example, the dimeric species $[Cu_2Cl_2(phbpa)_2]^{2+}$ (structure **C** in Scheme 1) seems more likely for this latter complex. We report here structural characterisation of the dinuclear cation type **C**, together with its bpa and mebpa analogues. For phbpa, cation **C** is observed in the solid state in combination with the dinuclear cation **B**, suggesting that an equilibrium exists between the two in solution. In the presence of the coordinating acetate anion, a further variation of the cation type **B** is observed, namely $[CuCl_2(phbpa)_2(CH_3CO_2)]^+$, in which one terminal chloride is replaced by acetate.

2. Experimental

2.1. Synthesis

bis(2-Pyridylmethyl)amine (bpa) was purchased from Aldrich. Mebpa · $2HClO_4$ [15] and phbpa [16] were prepared as described previously. Perchlorate salts of metal complexes are potentially explosive and should be handled with caution in small quantities.

2.1.1. *[$CuCl_2$(phbpa)] (**1**)*

$CuCl_2 \cdot 2H_2O$ (0.1865 g, 1.09 mmol) in 3 ml methanol was added to phbpa (0.3004 g, 1.09 mmol) in 6 ml methanol. After three days, the initial turquoise precipitate redissolved and grass-green rods of **1** were deposited. Yield: 76%.

2.1.2. *[Cu_2Cl_3(phbpa)$_2$]$_2$[Cu_2Cl_2(phbpa)](ClO_4)$_4$ · $2CH_3OH$ (**2a**)*

$CuCl_2 \cdot 2H_2O$ (0.0535 g, 0.31 mmol) in 1 ml methanol and $NaClO_4 \cdot H_2O$ (0.0882 g, 0.62 mmol) in 0.75 ml methanol were added to phbpa (0.0774 g, 0.28 mmol) in 2 ml methanol. After 5–10 min, small dark green crystals of **2a** were deposited. Yield: 63%.

2.1.3. *[Cu_2Cl_3(phbpa)$_2$]$_2$[Cu_2Cl_2(phbpa)](PF_6)$_4$ · $2CH_3OH$ (**2b**)*

Method 1. $CuCl_2 \cdot 2H_2O$ (0.0532 g, 0.31 mmol) in 1 ml methanol and NH_4PF_6 (0.1019 g, 0.63 mmol) in 0.25 ml methanol were added to phbpa (0.0856 g, 0.31 mmol) in 2.25 ml methanol. After 5–10 min, dark green needles of **2b** were deposited. Yield: 81%.

Method 2. NH_4PF_6 (0.0735 g, 0.45 mmol) in 0.5 ml methanol was added to **1** (0.0925 g, 0.23 mmol) in 4 ml hot methanol. After 5–10 min, dark green crystals of **2b** precipitated. Yield: 41%.

2.1.4. *[Cu_2Cl_3(phbpa)$_2$](PF_6) · 0.5CH_3OH (**3**)*

Turquoise crystals of **3** deposited from the filtrate of **2b** (both Method 1 and Method 2 above) in days to weeks. The single crystal used to confirm the structure of **3** was taken from the filtrate of Method 2.

2.1.5. *[Cu_2Cl_2(bpa)$_2$(CH_3OH)$_2$](ClO_4)$_2$ (**4**)*

This complex was isolated as a minor crystalline by-product in an attempt to prepare a more complicated copper complex of an amine-functionalized bpa molecule. Either contaminant bpa was present in the reaction mixture, or it was produced by *N*-dealkylation. We have not optimized this synthesis.

2.1.6. *[Cu_2Cl_2(mebpa)$_2$](ClO_4)$_2$ (**5**)*

Mebpa · $2HClO_4$ (0.0941 g, 0.23 mmol) in 5 ml hot dry methanol was added to $CuCl_2$ (0.0307 g, 0.23 mmol) in 6 ml dry methanol. Dark blue crystals of **5** precipitated at low temperature (−20 °C). Further (polycrystalline) product was obtained by evaporation of the solvent. Total yield: 43%.

2.1.7. *[Cu_2Cl_3(phbpa)$_2$ · 0.5(CH_3OH)]$_{0.85}$ [Cu_2Cl_2(CH_3CO_2)(phbpa)$_2$]$_{0.15}$(PF_6) (**6**) and [Cu_2Cl_2(CH_3CO_2)(phbpa)$_2$](PF_6) · 1.5CH_3OH (**7**)*

Crystals of **6** and **7** were obtained from the same synthesis batch: $Cu(CH_3CO_2)_2 \cdot H_2O$ (0.0131 g, 0.0656 mmol) in 0.75 ml hot methanol, NH_4Cl (0.0035 g, 0.0654 mmol) and NH_4PF_6 (0.0107 g, 0.0656 mmol) were added to phbpa (0.0181 g, 0.0657 mmol) in 0.75 ml methanol. Medium blue crystals precipitated at low temperature (−20°C). The two types of crystals could be distinguished by their habits: crystals of **6** were plates, while those of **7** were blocks.

2.2. Single-crystal X-ray diffraction

X-ray diffraction data were collected at 180(2) K using a Bruker-Nonius X8APEX-II diffractometer (Mo Kα radiation). Selected crystallographic data are summarised in Table 1. The structures were solved by direct methods and refined against F^2 using SHELXTL [17]. H atoms bound to C and N atoms were placed geometrically and refined using a riding model. The H atom of the coordinated methanol molecule in **4** was also placed geometrically and refined in

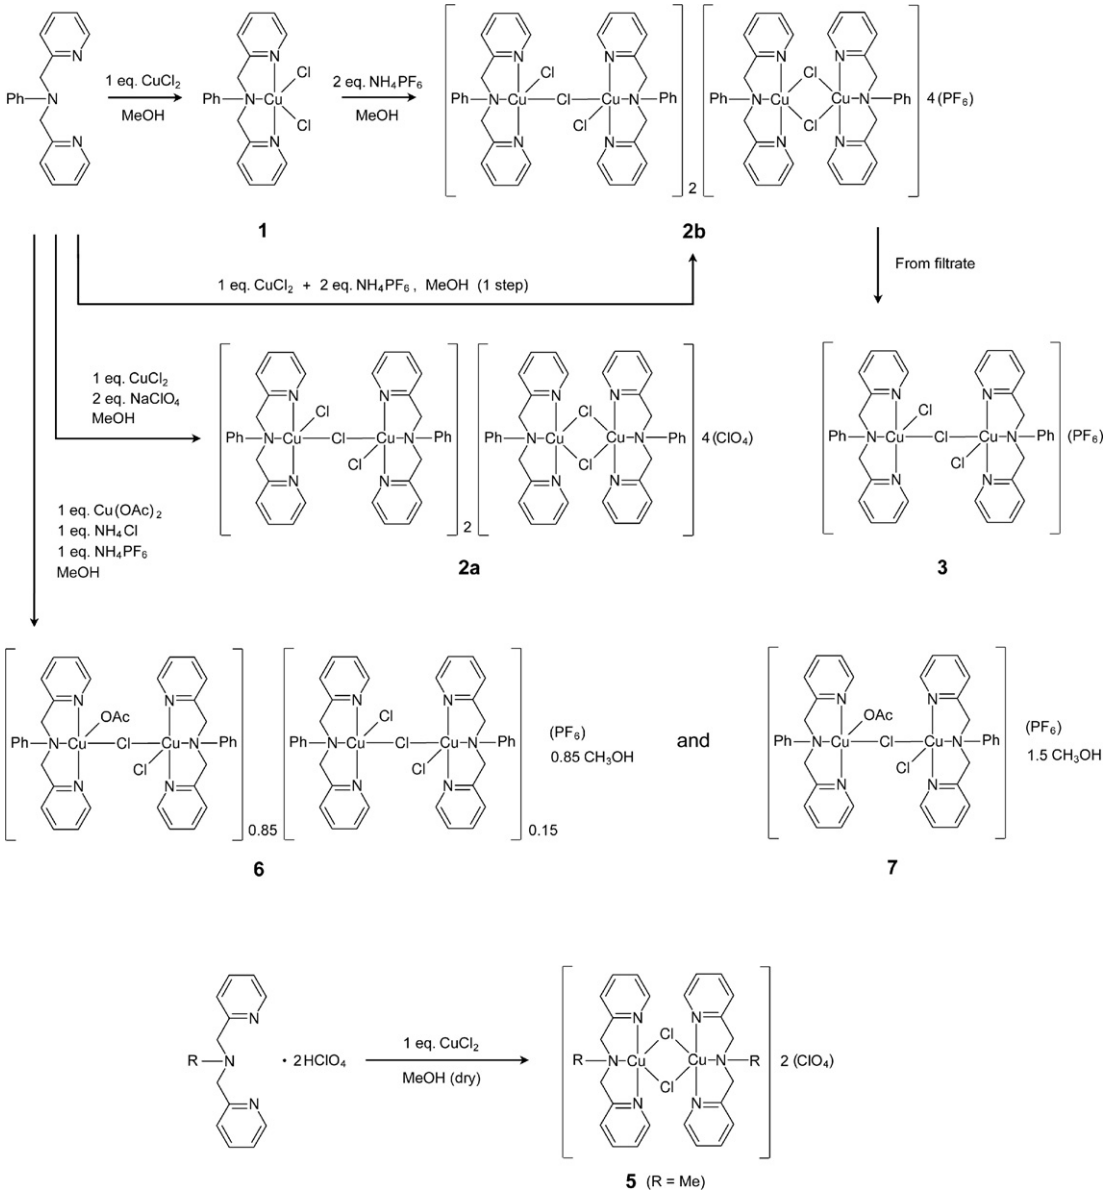
[a] All data (including Friedel opposites) treated as independent.

the same way. The H atoms of the solvent methanol molecules in **2a**, **2b**, **6** and **7** were placed so as to form a reasonable hydrogen-bond network, at a distance of 0.84 Å along the vectors from the O atom to which they are bound to the nearest H-bond acceptor. They were then allowed to ride on the parent O atom during subsequent refinement.

Refinements of structures **2a**, **2b**, **4** and **5** were straightforward, but structures **6** and **7** presented some difficulties. For **6**, refinement of the complex as $[Cu_2Cl_3(phbpa)_2]$, with the terminal chloride Cl(1) having full site occupancy resulted in an equivalent isotropic displacement parameter (U_{eq}) of 0.0573(3) Å^2 for Cl(1), somewhat larger than 0.0458(2) Å^2 for the other terminal chloride Cl(3). In addition, peaks in the residual electron density of ca. 1 e Å^{-3} were observed in positions close to Cl(1), suggestive of an acetate anion coordinated to Cu(1). Inclusion of this group and refinement of site occupancies (constrained to sum to unity) gave 0.84(1) for Cl(1) and 0.16(1) for the acetate anion. These values were subsequently constrained to be 0.85 and 0.15, respectively. With the chloride/acetate disorder modelled, U_{eq} for Cl(1) refined to 0.0440(3) Å^2 and the highest remaining peak in the residual electron density was 0.70 e Å^{-3}, lying in the vicinity of the PF_6^- anion. Disorder of the substituents bound to Cu(1) has some consequences for the methanol solvent molecule: the intermolecular contact distances suggest that it can only be present when Cl(1) is present. The O atom of this methanol molecule lies on a centre of inversion half-way between two Cl(1) atoms. Thus, there is only one methanol molecule per two $[Cu_2Cl_3(phbpa)_2]$ complexes, and the empirical formula is therefore best written $[Cu_2Cl_3(phbpa)_2 \cdot 0.5(CH_3OH)]_{0.85}$-$[Cu_2Cl_2(CH_3CO_2)(phbpa)_2]_{0.15}(PF_6)$. The X-ray analysis does not distinguish between two discrete crystal domains, i.e. $[Cu_2Cl_3(phbpa)_2 \cdot 0.5(CH_3OH)](PF_6)$ and $[Cu_2Cl_2$-$(CH_3CO_2)(phbpa)_2](PF_6)$, or disorder that is randomly distributed.



All crystals examined for **7** were twinned by 2-fold rotation about c^*. On account of the β angle that differs only minimally from 90°, the diffraction patterns from the two domains exhibit partial overlap. The measured diffraction pattern was indexed (using the program CELL_NOW [18]) on the basis of two domains, each accounting for ca. 8500 unique discrete reflections, with 14815 unique reflections considered to be overlapped. The frames were integrated using SAINT-PLUS [19] and scaled using TWINABS [19]. The structure was solved with data taken from the major domain (including overlapped reflections), then refined against the two-component data via the HKLF 5 format in SHELXL [17].

3. Results and discussion

3.1. Syntheses

The syntheses and products are summarised in Scheme 2. Mixtures of copper(II) chloride and phbpa crystallize from methanol as the neutral mononuclear complex $[CuCl_2$-(phbpa)] (**1**), identical to that reported previously

[14]. If perchlorate or hexafluorophosphate anions are present in solution, however, crystallisation of chloro-bridged dinuclear cationic species is favoured, presumably driven at least in part by formation of an ionic lattice. Formation of the dichloro-bridged cation **C** or the monochloro-bridged cation **B** is dependent to some degree on the nature of the group R bound to the amine-N atom. For phbpa ($R = C_6H_5$), the dichloro-bridged cation **C** is observed in the double salts, $[Cu_2Cl_3(phbpa)_2]_2[Cu_2Cl_2(phbpa)](ClO_4)_4 \cdot 2CH_3OH$ (**2a**) and $[Cu_2Cl_3(phbpa)_2]_2[Cu_2Cl_2(phbpa)](PF_6)_4 \cdot 2CH_3OH$ (**2b**), in both cases with the monochloro-bridged cation **B** also present in the crystal. The previously characterised **B** salt $[Cu_2Cl_3(phbpa)_2](PF_6) \cdot 0.5CH_3OH$ (**3**) [14] can be isolated by fractional crystallisation after filtration of **2b** from the mother liquor, suggesting that the formation of cation **B** in preference to **C** is favoured by increasing the relative chloride concentration. Conversely, a larger counteranion excess pushes the equilibrium back towards the formation of **C**. Cation **C** also appears to be favoured for both bpa and mebpa, isolated here as the perchlorate salts $[Cu_2Cl_2(bpa)_2(MeOH)_2](ClO_4)_2$ (**4**) and $[Cu_2Cl_2(mebpa)_2](ClO_4)_2$ (**5**). Cation **B** has not been isolated to date for bpa or mebpa. When the coordinating acetate anion is present in the reaction mixture for phbpa, an additional equilibrium exists between cation **B** and the dinuclear cation in which one terminal chloride is replaced by an acetate anion. Two types of crystal have been isolated: **6** exhibits partial replacement of chloride by acetate and **7** exhibits complete replacement.

Scheme 2. Summary of the synthesis conditions and reaction products.

3.2. Crystal structures

The crystal structures of **1** and **3** have been reported previously [14].

3.2.1. Crystal structures of *2a* and *2b*

The structures of the perchlorate salt **2a** and the hexafluorophosphate salt **2b** are essentially identical. The dichloro-bridged cation **C** (Fig. 1) is situated on a centre of inversion, while the monochloro-bridged cation **B** (Fig. 1) lies on a general position. Details of the coordination geometry around the Cu atoms are given in Table 2. The square-pyramidal geometry around Cu is closely comparable in cations **B** and **C** in each of the structures. The τ parameters [20] for each Cu atom (Table 3) indicate that the type **C** cations deviate slightly further from ideal square-pyramidal geometry towards trigonal-bipyramidal geometry, compared to the type **B** cations. The Cu–N and Cu–Cl distances in the basal plane of the square pyramid show no significant differences between the two structures. The axial Cu–Cl distances are elongated in all cases compared to those in the basal plane. These distances are significantly longer in the **B** cations than in the **C** cations. A small concomitant decrease is observed in the Cu–N distance to the amine-N atom in each **B** cation. In the **C** cation of both **2a** and **2b**, the phenyl substituents lie close to co-planar with the Cu_2Cl_2 unit and the shortest contacts to the backside of the Cu square pyramids are made by H atoms in the *ortho*-positions of the phenyl rings. Thus, the phenyl groups partially block any further coordination to Cu(1), and the shortest contacts to Cu(1) are ca. 4 Å, made by an O atom of one (disordered) perchlorate anion in **2a** (ca. 3.9 Å), and by an F atom of one hexafluorophosphate anion in **2b** (ca. 4.07 Å). In the **B** cation of both structures, the Cu_2Cl_3 unit is close to planar, with the terminal Cl atoms lying in an *anti* conformation (the angle between the two terminal Cu–Cl bonds is ca. 180° in projection). One phenyl substituent [C(49)–C(54)] lies close to the plane of the Cu_2Cl_3 unit, again partially blocking any further coordination to Cu(3). The other phenyl substituent [C(31)–C(36)] is twisted from this plane. The principal difference between **2a** and **2b** lies in the magnitude of this twist: the dihedral angle between the least-squares plane through C(31)–C(36) and that defined by the five atoms of the Cu_2Cl_3 unit is 82.0(2) and 50.0(3)° in **2a** and **2b**, respectively. The twist appears to be driven by accommodation of the perchlorate or hexafluorophosphate anions in the vicinity of the phenyl ring. However, peaks in the residual electron density of **2b** suggest a minor rotational disorder component for C(31)–C(36) (which was not modelled), corresponding closely to the ring orientation observed in **2a**.

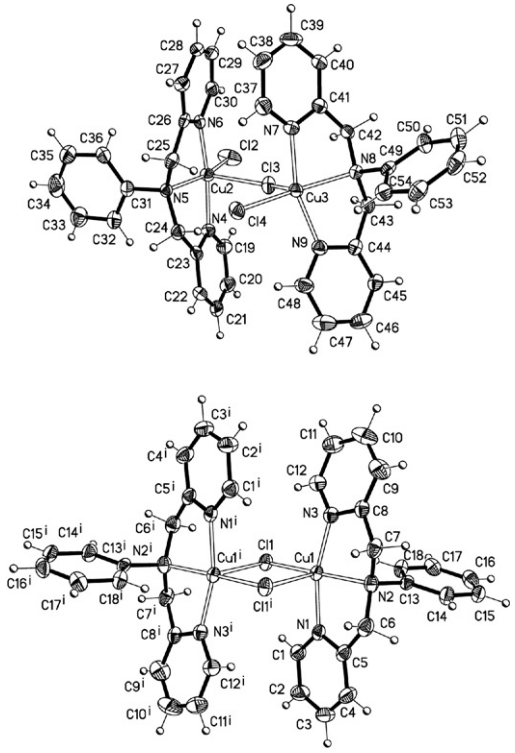


Fig. 1. Type **B** cation (top) and type **C** cation (bottom) in the structure of **2a**, showing displacement ellipsoids at 50% probability for non-H atoms and the atom-labelling scheme. The superscript (i) in the lower figure refers to atoms generated by the symmetry operator $-x, 2-y, -z$. The structure of **2b** is comparable.

3.2.2. Crystal structures of *4* and *5*

In both **4** and **5** (Fig. 2), the dichloro-bridged dinuclear cation (type **C**) lies on a centre of inversion. Details of the coordination geometry around Cu are given in Table 4. The τ parameters (Table 3) indicate that the distortion towards trigonal-bipyramidal geometry is comparable to that of the type **C** cations in **2a** and **2b**, and the Cu–Cl and Cu–N distances in the basal plane are also closely comparable. There are, however, distinct differences in the axial coordination sites. In **4**, the site to the backside of the Cu_2Cl_2 unit is occupied by a methanol molecule, coordinated to Cu with a Cu–O distance of 2.5712(17) Å. The axial Cu–Cl(bridging) distance *trans* to this is 3.1288(7) Å, the longest seen in this series of complexes. The coordination of MeOH to Cu in this complex is facilitated by two features: the N–H group of the bpa ligand provides no steric hindrance to coordination, and furthermore provides an N–H···O hydrogen bond to the perchlorate anion, that is adopted in preference to coordination of ClO_4^- to Cu. The OH group of the coordinated methanol molecule also forms a hydrogen bond to the same O atom of the perchlorate anion, giving rise to a complementary cyclic arrangement of contacts (Fig. 3a). In **5**, the perchlorate anion (modelled as disordered over two closely comparable orientations) is coordinated directly to the Cu atom, with a Cu–O distance of ca. 2.8 Å. This longer Cu–O coordination distance compared to **4**, is coupled with a shorter Cu–Cl(bridging) dis-

tance of 2.8283(4) Å in the axial site *trans* to O. The methyl substituent of mebpa provides no steric hindrance to coordination of the perchlorate anion, but the absence of the N–H donor in **5** evidently renders this a more stable outcome than incorporation of a MeOH molecule in the sixth coordination site, as seen in **4**.

Table 3

[a] Based on the position of Cl(1).
[b] Based on the position of O(1A).

3.2.3. Crystal structures of **6** and **7**

Details of the coordination geometry around Cu for **6** and **7** are given in Table 5. There are two symmetry-independent molecules in **7**, and the conformation of each is closely comparable to that in **6** (Fig. 4). In all cases, the planes of the phenyl substituents remain aligned with the Cu–N(amine) bonds so that the H atoms in the *ortho*-positions of the phenyl rings partially block further coordination to the Cu atoms. In **7**, one terminal Cl atom is replaced by an acetate anion, displaying an asymmetric μ_2 binding mode in which one O atom lies in a position directly comparable to that adopted by Cl in **2a** and **2b** (Cu–O = 1.927(9) and 1.964(9) Å), and the other O atom forms a significantly longer Cu–O contact (2.774(10) and 2.897(10) Å) towards the backside of the Cu–Cl–Cu bridge. The plane of the acetate anion lies close to that

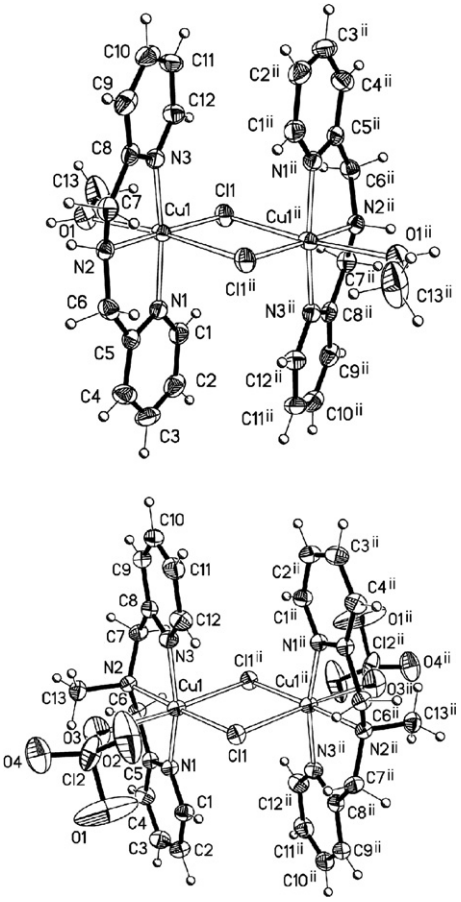

Fig. 2. Type **C** cation in the structure of **4** (top) and **5** (bottom) showing displacement ellipsoids at 50% probability for non-H atoms. The superscript (ii) refers to atoms generated by the symmetry operator $1-x, 1-y, 1-z$.

Superscript (ii) indicates atoms related by the symmetry operator $1-x$, $1-y$, $1-z$.

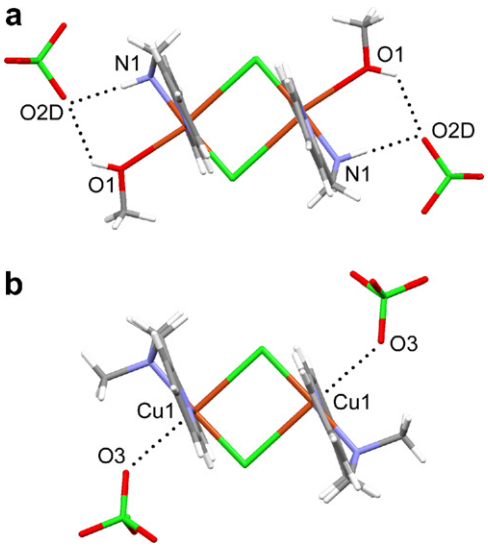

Fig. 3. Location of the perchlorate anions (a) in **4** and (b) in **5**. In **4**, the perchlorate anion accepts hydrogen bonds from the N–H group of bpa and also from a coordinated methanol molecule. In **5**, no comparable hydrogen bond can be formed from mebpa, and the perchlorate anion coordinates directly to Cu.

of the phenyl substituent of the phbpa ligand, and the latter O atom forms a relatively short contact to the *ortho* H atom (C14–H14···O2 = 2.36/2.45 Å), with a linear geometry suggestive of a C–H···O hydrogen bond. This contact may provide a further stabilizing contribution for complexation of the acetate anion. The τ parameters in **7** (Table 3; defined using the O atom of the acetate moiety that forms the shortest Cu–O bond) are comparable to those in **2a** and **2b**, and suggest that there is a slightly greater distortion towards trigonal-bipyramidal geometry for the Cu atoms bearing an acetate anion than for those bearing chloride. In **6**, there appears to be only partial replacement of the terminal chloride by an acetate anion (ca. 15%), and the structure is modelled as disordered. The Cu–O distances in this case are 1.846(16) and 2.932(13) Å. The plane of the acetate anion in **6** forms a dihedral angle of ca. 39° with respect to the plane of the phenyl group in the phbpa moiety [C(13)–C(18)], forming a considerably longer and more bent C–H···O contact compared to that in **7** (C(14)–H(14)···O(2A) = 2.60 Å). Aside from the inclusion or partial inclusion of the acetate anion, a major distinction exists from the planar Cu_2Cl_3 units in the type **B** cations of **2a** and **2b**: the two [(phbpa)Cu(Cl/OAc)] units of the cation in **6** and **7** are rotated with respect to each other so that the terminal Cu–Cl/O bonds form an angle of ca. 110° in projection (torsion angle Cl–Cu···Cu–Cl = 112.7(3)° in **6**, Cl–Cu···Cu–O = 108.6(5)° and 108.0(5)° in **7**). The Cu–Cl–Cu bridge is also marginally closer to linear compared to that in **2a** and **2b**.

on two parameters: (a) Cu–N(azide)–Cu angle and (b) Cu–N(azide) bond distance. For example, if the aforesaid angle falls within the range of 96–104° the interaction is ferromagnetic, otherwise it is antiferromagnetic. This is almost in line with Thompson's prediction on the basis of the extrapolation of the magneto-structural correlation found for the μ-1,1 azido complexes [1c]. However, the magnetic character for the end-on azido bridges can be predestined only in the basal-basal linkage. When azido groups bridge Cu(II) centers in a basal-apical fashion, the structural parameters described above do not explain the observed magnetic phenomenon. For asymmetric (basal-apical) end-on azido bridged complexes magnetic interaction is inefficient to exhibit strong ferromagnetic interaction [8]. Various factors like strict and accidental orthogonality of magnetic orbitals [4], spin polarization [4], delocalization of unpaired electrons [4], charge transfer [9], including mean out-of plane deviation of the azido group and hydrogen bonding path way [1c,1g,1h,10a,8a] are found to have considerable influence in determining the characteristic of the magnetic coupling between paramagnetic centers. However, recently the literature has been enriched with asymmetric end-on azido bridged complexes showing antiferromagnetic interactions [10]. It is noteworthy that the copper(II) centers of these dimers are mostly penta-coordinated, whereas dimers with hexa-coordinated copper(II) centers are still very rare [1a,10a,10e].

In earlier attempts, we have succeeded in isolating rare variety of asymmetric μ_2-1,1-azido copper(II) dimers [10c,10d] using (NNO) donor tridentate Schiff bases as co-ligand. The magnetic property of these complexes and other similar μ_2-1,1-azido copper(II) complexes were established by full-structure based DFT calculations [10c]. Further exploration of copper(II) azido systems based on tridentate Schiff base (NNN) donor ligand allowed us to structurally and magnetically characterize a new antiferromagnetic Cu(II) azido system. Here, we report investigation on the synthesis, crystal structure and magnetic properties of a rare asymmetric end-on azido bridged dimer of copper(II) having octahedral coordination environment. The present work constitutes a part of our continuing study on metal-azido complexes of tridentate Schiff base ligands based on diamines.

2. Experimental

2.1. General

All chemicals and solvents used during the synthesis were of AR grade and used as received. Elemental analyses (CHN) were performed using a Perkin Elmer 240 elemental analyzer. IR spectra were recorded on a Nicolate Magna IR 750 Series II FT-IR spectrophotometer. Magnetic measurements were carried out with Quantum Design's SQUID MPMS XL magnetometer. The instruments used for other measurements were reported earlier [11].

2.2. Preparation of $[Cu_2(L)_2(N_3)_2(NO_3)_2]$ (1)

To prepare the complex (**1**), the methanolic solution of 1,3-propanediamine (1 mmol, 0.74 g) was added to a clear solution of $Cu(NO_3)_2 \cdot 3H_2O$ (1 mmol, 0.241 g) dissolved in 25 ml methanol, which immediately produced an intense blue colored solution. This solution was then heated to boil and then a methanolic solution of pyridine-2-aldehyde (1 mmol, 0.107 g) was added with the help of a dropping funnel in 2 h in refluxing condition. After the completion of the addition of pyridine-2-aldehyde the reflux was continued for another 45 min. On cooling the mixture a small amount of green solid was precipitated. The green mass was then filtered out and an excess amount of sodium azide (2 mmol, 0.130 g) dissolved in a minimum volume of water was added to the filtrate. On slow evaporation of the resulting bluish-green solution the light green flaky crystals of (**1**) were separated out in two days. The crystals were filtered out, washed with methanol and dried in air (yield ca. 90%). *Anal.* Calc. for $C_{18}H_{26}N_{14}Cu_2O_6$: C, 32.7; H, 3.9; N, 29.7. Found: C, 32.2; H, 3.8; N, 29.8. IR (KBr): ν_{as} (N_3), 2041 cm^{-1}; ν (NO_3), 1383 cm^{-1}; $\delta(N_3)$, 648 cm^{-1}; ν(C=N), 1597 cm^{-1}. $\lambda_{max} = 285.4$ nm, 383.9 nm and 615.9 nm.

2.3. X-ray crystallography

2.3.1. Crystal data

$C_9H_{13}N_7CuO_3$, $M = 330.8$, triclinic, space group $P\bar{1}$, $a = 7.8396(8)$, $b = 8.6615(9)$, $c = 10.7240(11)$ Å, $\alpha = 69.693(2)$, $\beta = 70.630(2)$, $\gamma = 85.376(3)^\circ$, $V = 643.78(11)$ $Å^3$, $Z = 2$, $R_{int} = 0.18$, $D_{calc} = 1.707$ g cm^{-3} $F_{000} = 338$, $\mu = 1.717$ mm^{-1}, green flaky crystal, dimensions = $0.10 \times 0.40 \times 0.60$ mm, $T = 293$ K.

2.3.2. X-ray single crystal structure determination of (1)

The crystals of the complex were extremely flaky and fragile. A reasonably suitable single crystal was selected and the X-ray diffraction data were collected on a Bruker-Nonius MACH3 diffractometer at room temperature using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å); the intensity data were rather weak possibly owing to the poor quality of the crystals. Of the 2251 reflections that were collected, 2122 ($R_{int} = 0.18$) were unique. The data were corrected for Lorentz, polarization and absorption effects. The structure was solved by direct methods using the program SHELXS-97 [12] and refined on $|F^2|$ by the least-squares method using anisotropic thermal parameters for the non-hydrogen atoms [12]. The final cycle of full-matrix least-squares refinement converged to the unweighted and weighted agreement factors of 0.116 and 0.287, respectively. The hydrogen atoms were placed in idealized geometrical positions and included in the structure factor calculations by being made to 'ride' on the atoms to which they were bonded [12]. Neutral atom scattering factors were taken from Cromer and Weber [13], and anomalous dispersion effects were included in F_{calc} [14].

3. Results and discussion

3.1. Description of structure of the complex (1)

The structure determination reveals that the azido complex consists of a neutral dinuclear entity. It results from the pairing of two mononuclear units related by a crystallographic center of inversion (Fig. 1). Here, two centrosymmetrically related copper(II) centers are bridged by azide ions in an asymmetric end-on fashion leading to a relatively large Cu–Cu distance of 3.317(2) Å. Within this dimeric unit, each of the two octahedrally distorted copper(II) centers is coordinated by four nitrogen atoms: N1, N2, N3 of the tridentate Schiff base ligand, and an end nitrogen atom of the bridging azide ion. This comprises the puckered basal plane. A second nitrogen, N4′ (symmetry = $2-x,-y,-z$) from the centrosymmetrically related bridging azide coordinates axially at a distance of 2.548(13) Å. The sixth coordination site is occupied by the oxygen atom O2 of the nitrate anion through a distal coordination of 2.852(18) Å. The four basal donors N1, N2, N3 and N4 deviate from the least-squares mean plane through them by −0.217(10), 0.263(11), −0.285(12) and 0.321(13) Å, respectively. The copper atom is pulled out of this plane by 0.126(2) Å towards the apical donor atom N4′. The Cu–O2 and Cu–N4′ distances from the basal plane are 2.641(18) and 2.658(13) Å, respectively. The five membered chelate ring Cu–N1–C5–C6–N2 is essentially planar with deviations from planarity lying between −0.032(13) Å for C5 and 0.018(13) Å for C6. The six membered chelate ring Cu–C7–C8–C9–N3–N2 has a chair conformation with the puckering parameters $q_2 = 0.189(12)$, $q_3 = -0.507(13)$, $Q = 0.541(14)$, $\varphi_2 = 15.4(40)^\circ$ and $\theta = 159.5(11)^\circ$ [15].

The bridging Cu_2N_2 network, Cu–N4–Cu′–N4′, is exactly planar as dictated by symmetry. Due to the formation of the basal apical μ_2-1,1-N_3 bridging, the Cu–N bond lengths, Cu–N4 and Cu–N4′, are significantly different ($\Delta d = 0.621$ Å) for the complex. The bridging N_3 anions are quasi-linear; the N4–N5–N6 angle is 173.9(14)°. The crystal structure exhibits the hydrogen bonding pattern

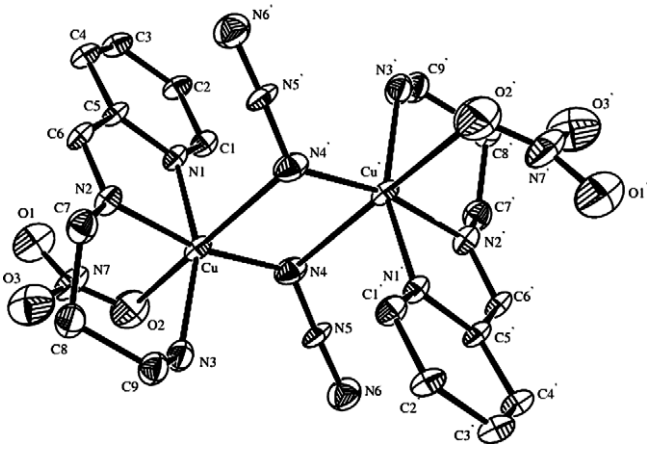

Fig. 1. ORTEP diagram of complex (**1**) showing atom numbering scheme. Symmetry code for the dash marked atoms is $2-x, -y, -z$.

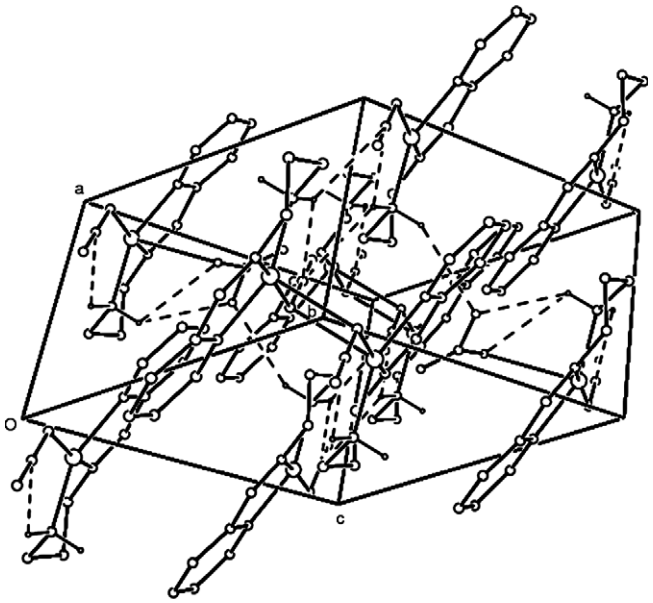

Fig. 2. Diagram showing crystal packing of complex (**1**). The dotted lines denote the intermolecular H-bonding as discussed in the text.

illustrated in Fig. 2; the geometrical details are given in Table 1. The two amino hydrogen atoms, H3A and H3B, are available for hydrogen bond formation, and both of them take part in trifurcated hydrogen bonds with the nitrate oxygen atoms O2 and O3, and the three azide nitrogen atoms N4, N5 and N6 acting as acceptors (Table 2).

3.2. Magnetic properties of $[Cu_2(L)_2(N_3)_2(NO_3)_2]$ (1)

The temperature dependence of the molar magnetic susceptibility, χ_M, for complex (**1**) was measured in 5–300 K temperature range under magnetic field of 1 kOe and is shown in Fig. 3. The $\chi_M T$ value of 0.82 $cm^3\ mol^{-1}$ K at 300 K for complex (**1**) is almost equal to the value expected for two isolated magnetically uncoupled copper(II) ion ($\chi_M T = 0.83\ cm^3\ mol^{-1}$ K for $g = 2.11$). Upon cooling the $\chi_M T$ value for copper(II) ions of complex (**1**) remains almost the same until ca. 60 K and then decreases rapidly

Symmetry codes: (i) $-x+1, -y, -z+1$; (ii) $-x+1, -y, -z$.

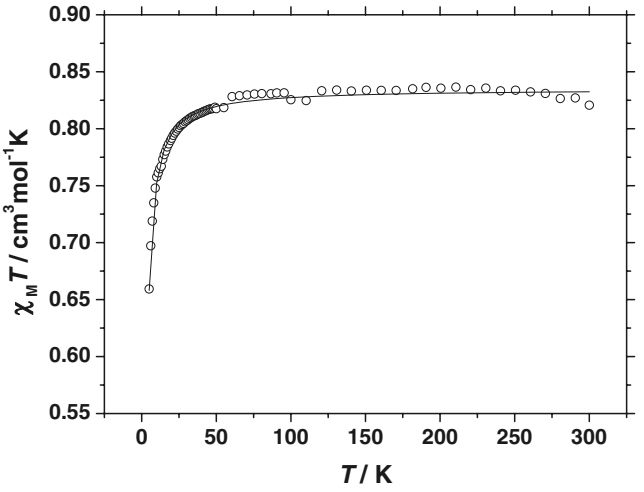

Fig. 3. $\chi_M T$ vs. T (○) plot for complex (**1**). Solid lines represent the best fit of the data with the model described in the text.

to reach a minimum of 0.66 $cm^3\ mol^{-1}$ K at ca. 5 K. The fitting of $1/\chi_M$ versus T with the Curie–Weiss equation yields $C = 0.83$ emu mol^{-1} K and $\theta = -1.29$ K for compound (**1**), which clearly indicates that magnetic interaction between copper(II) ions is antiferromagnetic.

To estimate the magnitude of the antiferromagnetic coupling the magnetic susceptibility data were fitted to the modified Bleaney–Bowers equation for two interacting copper(II) ions ($S = 1/2$) with the Hamiltonian in the form $H = -J\hat{S}_1\hat{S}_2$. The susceptibility equation for such a dimeric system can be written as follows [4a]:

$$\chi = \frac{2Ng^2\beta^2}{kT}[3 + \exp(-J/kT)]^{-1}(1-\rho) + \frac{Ng^2\beta^2}{2kT}\rho \qquad (1)$$

where N, g, β and ρ parameters in the equation bear their usual meaning.

The best fitted parameters obtained were $J = -1.27(1)$ cm^{-1}, $g = 2.11(1)$ and $\rho = 0.0005$. Though it is well established that end-on double azido bridged copper(II) dimers are usually ferromagnetic, the present study clearly indicates that the coupling between two copper(II) ions in this complex is antiferromagnetic.

Generally, the double end-on azido bridging ligands are considered to be capable of inducing a ferromagnetic coupling in copper(II) complexes whereas the double end-toend azido bridging ligands for the antiferromagnetic interactions. However, for asymmetric complexes, experimental results show that there are end-on and end-to-end complexes with the opposite behavior showing antiferromagnetic and ferromagnetic coupling, respectively. In this case it is the Cu–N(azide) distances that are more important than the N(azide)–Cu–N(azide) angles concerning the magnetic interaction. Notably it has been proposed on the basis of DFT study of double end-on azido bridged copper(II) complexes with basal-basal linkage, N(azide)–Cu–N(azide) angles play an important role as regards the nature of the interaction [7]. Recently Triki et al. have reported the DFT calculations of asymmetric end-on azido copper(II) complexes to address this apparently paradoxical nature of magnetic interaction [16]. They have shown for asymmetric end-on azido bridged copper(II) dimers having basal-apical linkage, the magnetic interaction is antiferromagnetic with the Cu–N(azide) distance 2.1–2.8 Å. In complex (**1**) the Cu′–N4 (or Cu–N4′) distances were equal to 2.548(13) Å. This is even significantly longer than the cutoff distance (2.05 Å) for the interaction being ferromagnetic as proposed by Ruiz et al. [7].

Structural and magnetic parameters of the similar other μ_2-1,1 azido bridged octahedral copper(II) complexes are given in Table 3. Even a cursory look at the Table 3 it will be apparent that the J value for complex $[Cu_2(\mu\text{-}N_3)_2(4\text{-Etpy})_4(\mu\text{-}NO_3)_2]$ and $[Cu_2(\mu\text{-}N_3)_2(3\text{-ampy})_4(\mu\text{-}NO_3)_2]\cdot$

$[Cu(L)(N_3)(NO_3)]_2$ (**1**)	3.317	1.927 2.548	94.7	−2.46	this work

4-Etpy = 4-ethylpyridine; 3-ampy = 3-aminopyridine; L1 = *N*,*N*-bis-(2-methylpyridyl) (3,5-dimethyl-2-hydroxybenzyl)-amine; terpy = terpyridine.

EtOH is positive and significantly larger than the other complexes. It is noteworthy that in both these complexes μ_2-1,1 azido ligands connect two copper sites through basal-basal linkage, hence, they show fairly strong ferromagnetic interaction. But for the rest of the complexes including the complex (**1**), which have bridging azido ligands that connect copper sites in basal-apical fashion, magnetic interaction is found to be antiferromagnetic.

4. Conclusion

In summary, we have been succeeded in synthesizing rather a rare variety of azido dimer consisting of octahedral copper(II) sites. In complex (**1**) azido ligands bridged Cu and Cu′ via asymmetric basal-apical linkages. The magnetic interaction in this complex is antiferromagnetic as expected for such type of copper(II) complexes with relatively longer Cu–N(azide) distances.

5. Supplementary material

CCDC 617630 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

The work was financially supported by the CSIR, New Delhi, by a Grant (01/(1972)/05/EMR II) to S.K. We are grateful to CDRI, Lucknow for elemental analyses (on a chargeable basis).

15-dibenzo-1,4-dioxa-8,12-diazacyclopentadeca-5,14-diene (L) under focused microwave conditions and by conventional thermal reactions either in refluxing ethanol or heating in the solid state. To the best of our knowledge, this is the first example of utilization microwave irradiation to form an alkali metal complex of a macrocyclic compound as well as of sodium macrocyclic complexation in a solid-state reaction. A wide range of coordination compounds, mostly of transition metal ions, have been synthesized by microwave-assisted reactions in solution [10], but among them there are only a few examples of those derived from macrocyclic ligands [11]. In our recent study, we investigated the interactions of a heteromacrocycle L with a series of sodium salts NaX (X = picrate, ClO_4, BF_4, PF_6, SCN, and BPh_4) in methanol and acetonitrile solution [12,13]. Although the hole size of the 15-membered macrocycle would be suitable for complexation of a sodium ion [14], it was shown that in these reactions the sodium complexes were not formed but instead the protonated ligand salts containing the protonated macrocyclic ligand as the cation and the anion from the sodium salt as its counterion were obtained. Crystal structure analyses of these compounds have shown a different mode of ligand protonation and a hydrogen bond network which stabilizes the binding site of the proton. As a continuation of this work herein we report the formation of the sodium complex obtained by the interaction of L with an organophosphorus sodium salt.

2. Experimental

2.1. Materials and instrumentation

5,6,14,15-Dibenzo-1,4-dioxa-8,12-diazacyclopentadeca-5,14-diene (L) was used directly as supplied (Aldrich). The sodium salt of monoethyl [4-α-(benzeneazoanilino)-*N*-benzyl]phosphonic acid ($NaEP \cdot 1.5H_2O$) was prepared and purified as described earlier [15]. Solvents used (AR grade) were purified and dried by standard procedures. Microwave experiments were performed in a microwave oven in an open porcelain vessel at 700 W. The melting point was determined on a hot stage microscope and is uncorrected. FTIR spectra were recorded on an ABB Bomen MB102 spectrometer using KBr pellets. ESI mass measurements were performed on a Finnigan LCQ DECA instrument (ThermoFinnigan, Palo Alto, Ca, USA) operating in the positive ion mode. The compounds were dissolved in methanol (10^{-6} M solutions) and directly injected by a syringe pump at a flow of 5 μL min^{-1}. LDI mass spectra were performed on a Voyager-DE PRO instrument (Applied Biosystems, Foster City, CA, USA) and a Finnigan FT/MS 2001 DD instrument (Finnigan, Madison, Wisconsin, USA), operating in the linear positive ion mode. The one- and two-dimensional ^1H and ^{13}C NMR spectra (in $CDCl_3$), including ^1H, ^{13}C APT, ^1H–^1H COSY, ^1H–^{13}C COSY, HMQC, and HMBC experiments, were recorded with a Bruker XWIN-600 Fourier-transform spectrometer at ambient temperature. The ^1H and ^{13}C chemical shifts (δ) were referred to $SiMe_4$. All two-dimensional experiments were performed by standard pulse sequences, using Bruker XWIN-NMR software Version 3.5. Elemental analyses (CHN) were performed on a Perkin–Elmer Analyser PE 2400 Series 2. The thermogravimetric analyses (TG) were carried out on a Cahn RG electromicrobalance in an air atmosphere at a heating rate of 4 °C min^{-1} up to 850 °C. Differential thermal analyses (DTA) were performed with a Netzsch 406 differential thermal analyzer, applying a heating rate of 5 °C min^{-1} in static air atmosphere. The reference substance was pure alumina.

2.2. Preparations of the complex $[Na(L)(\mu\text{-}EP) \cdot H_2O]_2$

2.2.1. Focused solid-state microwave irradiation

Equimolar amounts of 5,6,14,15-dibenzo-1,4-dioxa-8,12-diazacyclopentadeca-5,14-diene (L) (0.152 g, 0.49 mmol) and the hydrated sodium salt of ethyl [4-α-(benzeneazoanilino)-*N*-benzyl]phosphonic acid ($NaEP \cdot 1.5H_2O$) (0.218 g, 0.49 mmol) in a porcelain mortar were ground together until a fine homogenous powder was obtained. This mixture was then irradiated for 12 min (6 × 2) using a 700 W microwave. After the reaction was completed, the liquefied product was allowed to cool down, washed with diethyl ether and dried *in vacuum* for 24 h giving an orange glassy solid. Yield: 0.337 g, 92%, mp 96–98 °C. *Anal*. Calc. for $C_{40}H_{47}N_5O_5PNa$ (M/2 = 747.79): C, 64.24; H, 6.34; N, 9.37; H_2O, 2.41. Found: C, 64.03; H, 6.10; N, 9.09; H_2O, 2.11%. Selected IR data (KBr, cm^{-1}) 3360 m vbr [ν(NH), ν(OH)], 3060–2825 [ν(aliphCH), ν(ArCH)], 1602 vs, 1512 s [δ(NH),ν(C=C)], 1240 s br, 1220 sh, 1196 sh [$\nu_{as}(PO_2^-)$, ν_{as}(ArCOC), ν(CNC)], 1075 s, 1047 s [$\nu_s(PO_2^-)$, ν(POC)], 941 s [ω, τ, $\rho(CH_2)$, ν(aliphCC)], 795 m, 753 vs, 732 m [δ(NH), δ(ArCH) out-of-plane]. ^1H NMR (600 MHz, $CDCl_3$, δ ppm) L: 1.70 (2H, m, CH_2–CH_2–CH_2), 2.58 (4H, t, J_{HH} = 5.3 Hz, NH–CH_2–CH_2), 2.70 (2H, br s, NH), 3.70 (4H, s, Ar-CH_2–NH), 4.34 (4H, s, O–CH_2), 6.87 (2H, d, J_{HH} = 8.2 Hz, Ar*H*-a), 6.93 (2H, t, J_{HH} = 7.4 Hz, Ar*H*-c), 7.20 (2H, dd, J_{HH} = 7.3; 1,5 Hz, Ar*H*-d), 7.31 (2H, dt, J_{HH} = 8.0; 1.5 Hz, Ar*H*-b), EP: 1.10 (3H, t, J_{HH} = 7.0 Hz, CH_3), 3.76 (2H, m, $POCH_2$), 4.59 (1H, d br, J_{PH} = 23 Hz, PCH), 5.65 (3H, s br, NH, H_2O), 6.55 (2H, d, J_{HH} = 8.1 Hz, H-8,12), 7.15 (1H, t, J_{HH} = 6.8 Hz, H-4), 7.22 (2H, $J_{HH} \sim 7$ Hz, H-3,5), 7.34 (1H, t, J_{HH} = 7.4 Hz, H-16), 7.42 (2H, d, J_{HH} = 7.6 Hz, H-2,6), 7.43 (2H, t, J_{HH} = 7.6 Hz, H-15,17), 7.70 (2H, d, J_{HH} = 7.7 Hz, H-9,11), 7.77 (2H, t, J_{HH} = 8.1 Hz, H-14,18). ^{13}C NMR (150.90 MHz, $CDCl_3$, δ ppm) L: 25.83 (CH_2–*C*H_2–CH_2), 48.50 (NH–*C*H_2–CH_2), 49.58 (Ar-*C*H_2–NH), 65.14 (O–*C*H_2), 109.86 (Ar*C*-a), 120.33 (Ar*C*-c), 127.80 (Ar*C*–CH_2–NH), 129.25 (Ar*C*-b), 131.45 (Ar*C*-d), 156.39 (Ar*C*–O–CH_2), EP: 16.35 ($^3J_{POCC}$ = 6.1 Hz, *C*H_3), 56.38 ($^1J_{PC}$ = 135.1 Hz, P*C*H), 60.74 ($^2J_{POC}$ = 5.6 Hz, P–O*C*H_2), 112.55 (C-8,12), 121.65 (C-14,18), 124.50 (C-9,11), 125.76 (C-4), 127.26

NaEP: MS (+LDI) *m/z* 1275 ($[(NaEP)_3+Na]^+$, 12%), 858 ($[(NaEP)_2+Na]^+$, 10%), 441 ($[NaEP+Na]^+$, 100%). TG data (temperature range, °C) 40–110 (dehydration), 200–860 (degradation processes). DTA data (exothermic peaks, °C) 310 and 575.

2.2.2. Conventional solid-state thermal method

A homogenous mixture of equimolar amounts of L and NaEP · 1.5H_2O was heated at 190 °C for 6 h giving the liquefied product. The heating was continued for 1 h and the solid obtained after cooling, besides the sodium complex (ca. 70%), contained side products, which could not be completely separated and successfully identified. Heating at lower temperatures or prolonged heating did not give better results. On the other hand, heating over 200 °C initiated a degradation processes of the complex, which was supported by the thermal analyses.

The progress of complex formation in both solid-state reactions was monitored by IR and ^{1}H NMR spectroscopy and the optimal reaction conditions for both methods are reported.

2.2.3. Conventional thermal method in solution

A mixture of L (0.110 g, 0.35 mmol) and NaEP · 1.5H_2O, (0.158 g, 0.40 mmol) in dry EtOH (20 cm^3) was refluxed for 5–6 h with continuous stirring to give a clear solution, which was filtered after cooling and set aside for evaporation. The sodium complex was obtained as a syrup after all the solvent was driven off, and solidified as an orange glassy product on standing under *vacuum* for 24 h. Yield: 0.222 g, 85%; mp 96–98 °C. In reactions carried out in methanol and acetonitrile solutions, the free macrocyclic compound gradually precipitated on cooling and the sodium complex was not isolated.

3. Results and discussion

3.1. Synthesis and properties

The coordination number of the sodium(I) ion varies from five to seven and coordinative forces of macrocyclic ligands play an important role in forming stable metal complexes. It was shown that the type, number, and arrangement of the donor atoms in a macrocyclic cavity have great influence on the cation binding selectivity. An investigation of the interaction of a 15-membered macrocycle containing an O_2N_2-donor set (L) with a number of sodium salts in solution shows that the affinity of this macrocycle for a proton is much larger than for the sodium ion [12,13]. A strong solvation capability of the sodium ion as well as the presence of only two oxygen and two nitrogen donor atoms are in favor of proton binding. The choice of anion in a salt-ligand system along with the choice of solvent (methanol or acetonitrile) is important for the resulting inter- or intra-ligand protonation and hence the different hydrogen bonding networks in various types of protonated macrocyclic salts. The formation of the sodium ethyl benzeneazophosphonate complex of L, containing only four donor atoms, enables additional interactions with the anion phosphonate oxygen atoms. The very low melting point of the complex (96–98 °C), with respect to the high melting point of the free sodium salt (above 220 °C) [15], indicates that the charge of the sodium ion in the complex is extremely delocalized. Some degree of charge transfer between the sodium ion and anion can take place, increasing the stability of the complex. It may be presumed that the sodium ion is bonded to both oxygen and nitrogen donor atoms of the macrocycle and to the two oxygen atoms of the two different molecules of the phosphonic ester, as shown in Fig. 1. The two other oxygen atoms of each molecule of ester are bonded to a second sodium ion and thus form a dinuclear phosphonate-bridged complex in which the sodium ions are hexacoordinated. The same dimeric bridged structure was detected for the corresponding sodium benzeneazophosphonate complex of a 14-membered macrocycle with four oxygen donors, dibenzo-14-crown-4 [16]. The crystal structure determination of this complex, $[Na(DB14C4)(\mu\text{-}EP)]_2$, has shown stronger interactions between the sodium ion and the phosphonate oxygens than with the oxygens in the crown ring. As we could not grow crystals for X-ray analysis, the sodium phosphonate complex of L was identified and characterized on the basis of elemental and thermal (TG and DTA) analyses, and from infrared, ^{1}H and ^{13}C NMR and mass (LDI and ESI) spectroscopic studies.

A comparative study between microwave and conventional heating in ethanol did not reveal significant differences in yields (ca. 7%), while the complexation time was much shorter in the reaction run under microwave irradiation (12 min) compared to that with classical heating (5–7 h). Conventional solid-state heating gave the sodium complex with some impurities (ca. 30%) which could not be successfully separated and identified. It is worth noting that reactions of L with NaEP in methanol and acetonitrile solutions failed to produce either the protonated ligand salt or the sodium complex. It may be presumed that solvent media effects primary arise from the difference in the ion and ligand solvation and the alkali salt solubilization. In addition, it is interesting to note that the solid-state complexation of L also occurred very slowly on irradiation by ultraviolet light in the sun. The reaction was monitored by infrared spectroscopy.

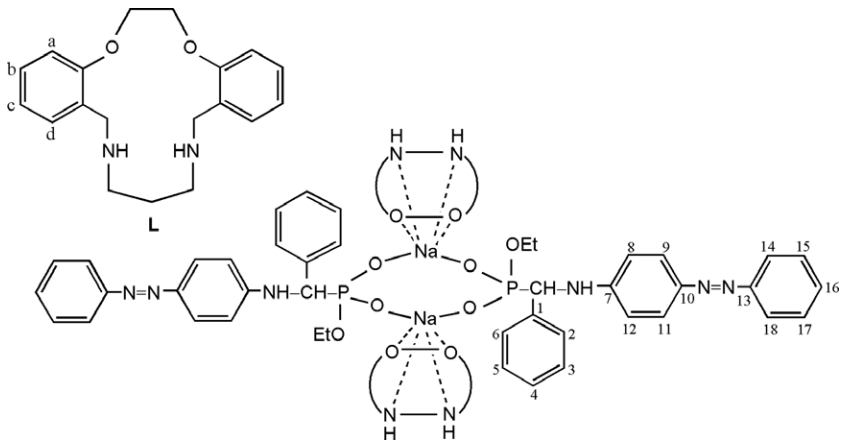

Fig. 1. Schematic molecular structure of the sodium complex.

3.2. Spectroscopic study

The IR spectrum of the complex is very complicated with significant overlapping of absorption bands. However, it is distinctively different from the spectrum of the physical mixture of the sodium salt and the free ligand (Fig. 2), and shows the absence of the uncomplexed constituents [17,18]. Upon complexation the most significant changes may be noticed in the ligand absorptions associated with various stretching and deformation modes of the NH vibrations in the 3400–1500 and 790–730 cm^{-1} regions, as well as within the 2800–2600 cm^{-1} region, where in the free L a series of sharp bands of strong to medium intensity appear, assigned to the perturbed symmetrical stretching vibrations of α-methylene C–H bonds oriented trans to the lone pair of electrons on the nitrogen atoms (Bohlmann bands) [12,19]. These bands are missing in the sodium complex. In addition, marked changes could be observed between 1250 and 1190 cm^{-1} where the stretching ArC–O–C and C–N–C vibrations occur, superimposed on the phosphonate $\nu_{as}(PO_2^-)$ absorption, as well as between 1000 and 900 cm^{-1} where deformation modes of the methylene vibrations are expected to occur [8,13,20]. A very broad absorption around 3360 cm^{-1}, arising from a ν(OH) vibration overlapped with that of a ν(NH) absorption, indicates metal bonding with the macrocyclic amino nitrogens and no interaction with the water oxygens. A broad dehydration step over the range 40–110 °C in the TG curve of the complex supports that the water molecules are lattice-held in this compound. Generally, water in the complex is considered to be metal coordinated if relatively sharp absorption bands appear over 3400 cm^{-1}, especially above 3500 cm^{-1} [21]. The phosphonate bands are broad and complex in structure, confirming bonding of the sodium ion to the phosphonate oxygens.

The ^1H and ^{13}C NMR spectral pattern of the aromatic region of the sodium complex is in general similar to those obtained for the free macrocycle and ethyl benzeneazophosphonate salt [8,22]. As expected, pronounced differences could be observed in the ^1H NMR spectra for the NH protons as well as the methylene macrocyclic and the phosphonate PCH and $POCH_2$ resonances. While the NH absorption broadens and moves to lower field, the methylene protons are shifted upfield by 12–36 Hz with respect to the free macrocycle. These differences may be

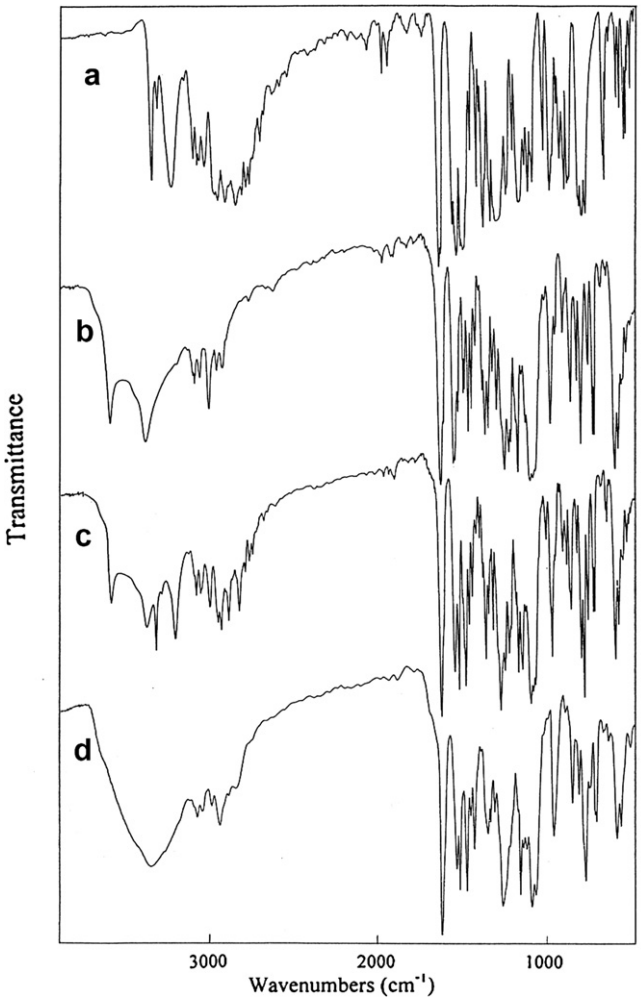

Fig. 2. Infrared spectra of (a) L; (b) $NaEP \cdot 1.5H_2O$; (c) 1:1 mixture of L and $NaEP \cdot 1.5H_2O$; (d) $[Na(L)(\mu\text{-}EP) \cdot H_2O]_2$.

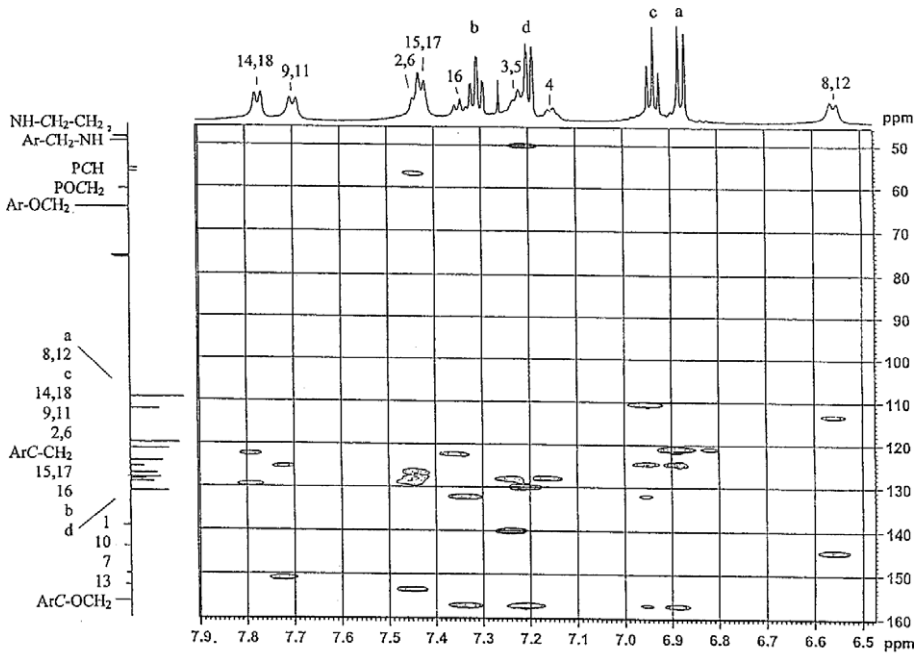

Fig. 3. A part of the long-range ^{1}H–^{13}C HMBC spectrum of the sodium complex.

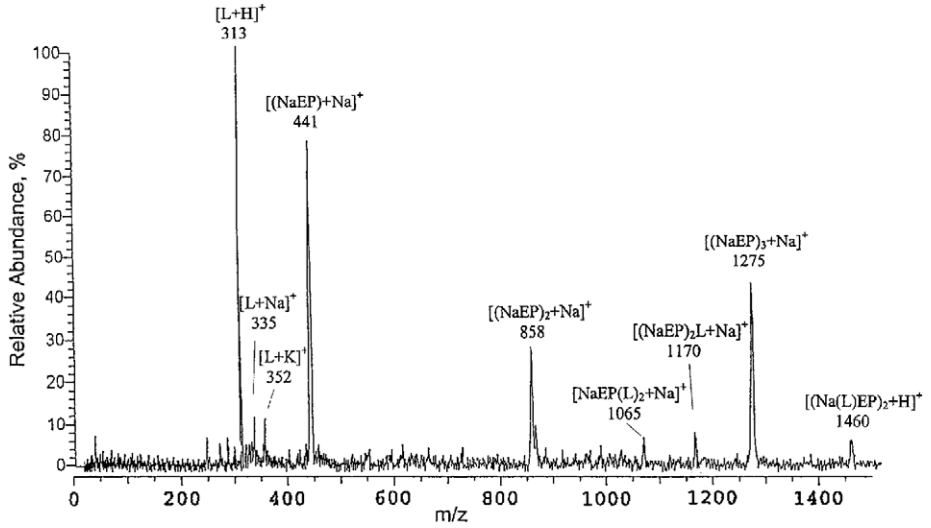

Fig. 4. Positive-ion LDI spectrum of the sodium complex.

explained by the proximity of the macrocycle molecule to the aromatic rings of the phosphonate anion in spite of the complexation with the alkali cation, which in itself would induce a downfield shift due to the increased electronegativity of the donor atoms. In the case of the phosphonate anion, there is an upfield shift for PCH as well as a downfield shift of about 36 Hz ppm for the P–OCH_2 protons. Small changes could also be observed for the corresponding carbon resonances. Various 2D homo- and heteronuclear correlated experiments enabled a complete ^{1}H and ^{13}C signal assignment (Fig. 3).

The MS properties of the sodium complex have been studied by spectrometric measurements carried out under positive-ion ESI and LDI conditions. Both spectra show the base peak at *m*/*z* 313, corresponding to the protonated ligand ion $[LH]^{+}$. While in the ESI spectrum this ion is the only intense fragment ion (the relative abundances of all other fragment ions are very small), the fragmentation pattern is more extensive in the LDI spectra giving relevant structural information about this compound (Fig. 4). The protonated molecular ion, $[(Na(L)EP)_2+H]^{+}$ at *m*/*z* 1460, and the structure-specific fragment ions formed by

decomposition of the complex by the loss of one macrocycle ligand molecule, $[(NaEP)_2L+Na]^+$ at m/z 1170, as well by the loss of one ethyl benzeneazoanilinophosphonate moiety, $[Na(L)_2EP+Na]^+$ at m/z 1065, support the existence of the sodium complex as a dimeric species. Their relative abundance is about 6%. More abundant ions are those containing NaEP molecules $[(NaEP)_3+Na]^+$, $[(NaEP)_2+Na]^+$, and $[(NaEP)+Na]^+$ at m/z 1275 (43%), m/z 858 (29%), and m/z 441 (58%), respectively, indicating strong bonding between the sodium ion and the phosphonate anion. This fact is in accordance with structural data obtained for the sodium benzeneazophosphonate complex of the oxa-macrocycle dibenzo-14-crown-4 [16]. These ions are also dominant in the LDI spectrum of free NaEP.

4. Conclusion

In summary, the first example of supported microwave-assisted synthesis of an alkali complex derived from a heteromacrocyclic compound is described. This simple work-up, eco-friendly solvent free reaction resulted in the formation of a sodium benezeneazophosphonate complex with a 15-membered macrocycle containing an O_2N_2-donor set in a shorter reaction time, with high purity and excellent yield, compared to conventional thermal reactions carried out either in refluxing ethanol or by heating in the solid state.

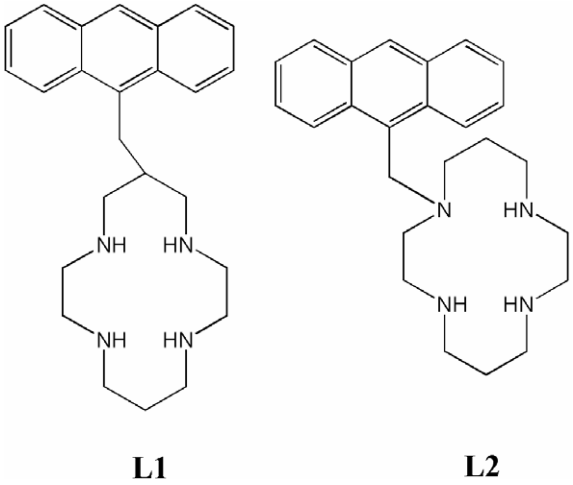

Fig. 1. Structures of the **L1** and **L2** ligands.

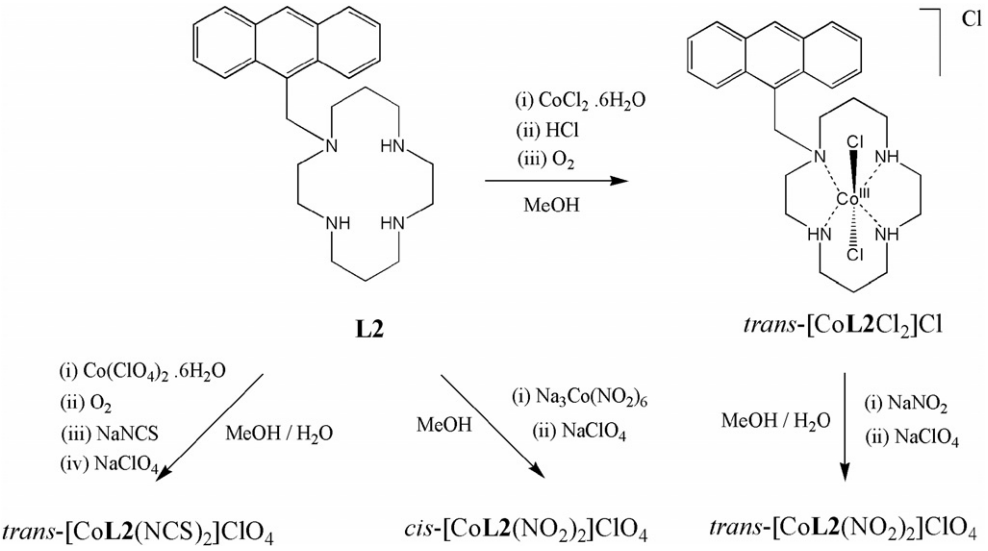

With a view to further developing these ideas, and to better understand the photochemistry of donor–acceptor complexes containing cobalt(III) as the acceptor group, we have prepared a series of cobalt(III) complexes of 1-(anthracen-9-ylmethyl)-1,4,8,11-tetraazacyclotetradecane (hereafter **L2)** in which anthracene (the donor) is appended to a nitrogen atom of the cyclam macrocycle (Fig. 1). The complexes are of the type *trans*-$[Co\mathbf{L2}X_2]^+$ in which $X = Cl^-$, NCS^-, and NO_2^-. These anionic ligands were chosen to cover a broad range of the spectrochemical series and it is these ligands that may be lost following a photo-induced process, with the cobalt atom remaining bound to the cyclam macrocycle. Investigation of complexes of **L2** will also allow comparison of the photochemical properties of these N-appended complexes with those of their C-appended analogues derived from **L1**. In this paper we describe the synthesis and structural characterisation of a series of complexes derived from **L2**. The preparation and structure of the complex *cis*-$[Co\mathbf{L2}(NO_2)_2]^+$, which contains one N-bonded and one O-bonded nitrite ligand is also described.

2. Results and discussion

2.1. Synthesis

The synthesis of **L2** was accomplished by the N-alkylation of cyclam with 9-chloromethyl-anthracene following the method described by Fabrizzi et al. [7]. The synthetic route to the series of complexes *trans*-$[Co\mathbf{L2}X_2]^+$ ($X = Cl^-$, NCS^- and NO_2^-) is summarised in Scheme 1.

The complex *trans*-$[Co\mathbf{L2}Cl_2]^+$ was prepared by the addition of cobalt(II) chloride to **L2** in methanol. Subsequent addition of hydrochloric acid and aerial oxidation led to formation of the *trans*-dichloro cobalt(III) complex which was isolated as its green chloride salt. The complex *trans*-$[Co\mathbf{L2}(NCS)_2]^+$ was prepared by first adding cobalt(II) perchlorate hexahydrate to **L2** in methanol. The resultant complex (presumably with water as the axial ligands) was oxidised to cobalt(III) in air and then an excess of sodium thiocyanate was added. The further addition of excess sodium perchlorate led to the isolation of the complex as its red/brown perchlorate salt. The complex *trans*-$[Co\mathbf{L2}(NO_2)_2]^+$ was prepared via in situ generation of *trans*-$[Co\mathbf{L2}Cl_2]^+$ followed by exchange of the chloride ions with nitrite following the addition of an excess of sodium nitrite. The complex was isolated as its orange perchlorate salt following the addition of $NaClO_4$. The complexes were characterised by elemental analysis, ^1H NMR, ESI-MS and single crystal X-ray diffraction. ESI-MS of each of the complexes discussed in this work clearly displayed M^+ as the most abundant peak with $[M-HX]^+$ and $[M-2(HX)]^+$ peaks ($X = Cl^-$, NCS^- and NO_2^-) also clearly distinguishable. The bridging methylene protons in these complexes

Scheme 1. Reaction scheme for the synthesis of the series of cations *trans*-$[Co\mathbf{L2}X_2]^+$ ($X = Cl^-$, NCS^- and NO_2^-) and the *cis*-$[Co\mathbf{L2}(NO_2)_2]^+$ cation.

were inequivalent and appeared in each case as a single AB quartet [11], within the chemical shift range δ 4.8–6.0 ppm. The presence of a single AB quartet was used to confirm the isomeric purity of the complex.

We were also motivated to explore the synthesis of *trans*-[Co**L2**$(NO_2)_2]^+$ by reaction between **L2** and $Na_3[Co(NO_2)_6]$ rather than by the method described above. In this case the macrocycle **L2** was stirred with $Na_3Co(NO_2)_6$ in a MeOH/H_2O solution for 1 h. Following work up, a red-orange solid was obtained. The ^{1}H NMR spectrum of this material was complex and different from that of *trans*-[Co**L2**$(NO_2)_2]^+$. As indicated above, peaks in the ^{1}H NMR spectrum arising from the bridging methylene protons provide a guide to the isomeric purity of complexes derived from **L2**. The presence in the ^{1}H NMR spectrum of this product of three sets of AB quartets [11] indicated that a mixture of three isomers had resulted from the reaction of **L2** with $Na_3[Co(NO_2)_6]$. The spectrum contained a set of doublets centred at δ 5.2 ppm and the isomer associated with these peaks made up about 70% of the reaction product. Subsequent dissolution of this crude product in chloroform (as the nitrite salt) and slow recrystallisation by diffusion of diethyl ether vapour permitted the isolation of the major product in pure form. ESI-MS and elemental analysis indicated the formation of [Co**L2**$(NO_2)_2]NO_2$. Crystallographic analysis of the perchlorate salt of this complex indicated formation of the *cis*-isomer. The formation of the *cis*-isomer may reflect the kinetic inertness of the cobalt centre which was in a +3 oxidation state before inclusion in the macrocycle. Complexes of the *trans*-[Co**L2**$X_2]^+$ series were formed by reaction with cobalt in its more labile +2 oxidation state, thereby allowing the complex to rearrange to its perhaps more thermodynamically favourable *trans* configuration before being locked in by aerial oxidation to Co(III).

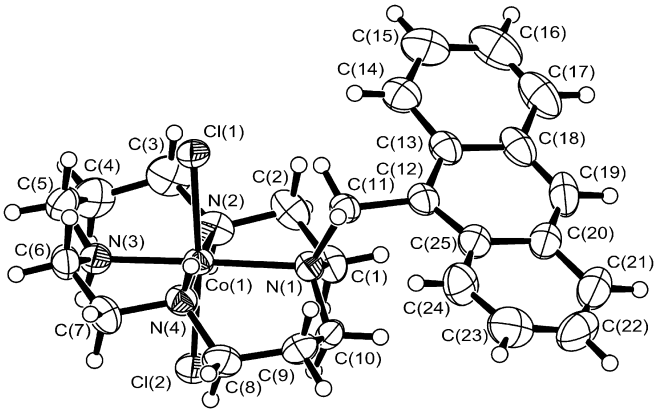

Fig. 2. Crystal structure obtained for the *trans*-[Co**L2**$Cl_2]^+$ cation. Ellipsoids are represented at the 50% probability level.

2.2. Crystal structures

According to Tobe the most thermodynamically favorable configuration of a metal cyclam complex is one where the metal adopts a "*trans(III)*" configuration i.e. two protons on adjacent amines, separated by a C_3 link, point upwards while the other two amine protons are directed downwards [12]. This arrangement is favoured due to a relief of strain in the macrocyclic ring. Accordingly it is reasonable to expect that the complexes, [Co**L2**$Cl_2]^+$, [Co**L2**$(NCS)_2]^+$ and [Co**L2**$(NO_2)_2]^+$ would adopt such a configuration.

The structure of the *trans*-[Co**L2**$Cl_2]^+$ complex is presented in Fig. 2. The metal centre adopts an octahedral geometry with the two *trans* chloro ligands Cl(1) and Cl(2) at distances of 2.25(1) and 2.27(1) Å, respectively, from the cobalt centre. The Cl(1)–Co–Cl(2) bond angle is 173.95(5)°. The macrocycle adopts Tobe's *trans*-(III) configuration. All Co–N bond lengths are typical for cobalt(III)-cyclam complexes (ca. 1.97 Å, Table 1). The N(1)–Co bond is an exception, a longer bond length of 2.123(3) Å perhaps a consequence of the relative steric bulk of the tertiary amino group [13]. All other C–N and non-aromatic C–C bond lengths are typical, as are all bond angles and torsional angles based on a staggered arrangement of the macrocycle about the metal. The relative orientations of the chromophore and macrocycle are presented in Fig. 3a and b. The dihedral angle between the mean planes of the anthracene and the four coordinating nitrogen atoms is 29.75(6)° and the metal is separated by 5.78 Å from the centroid of the anthracene moiety. A slight buckling is observed at one end of the anthracene which may be a result of steric interactions between the chromophore and cyclam ring. Apart from minor distortions associated with this buckling all other C–C bond lengths and

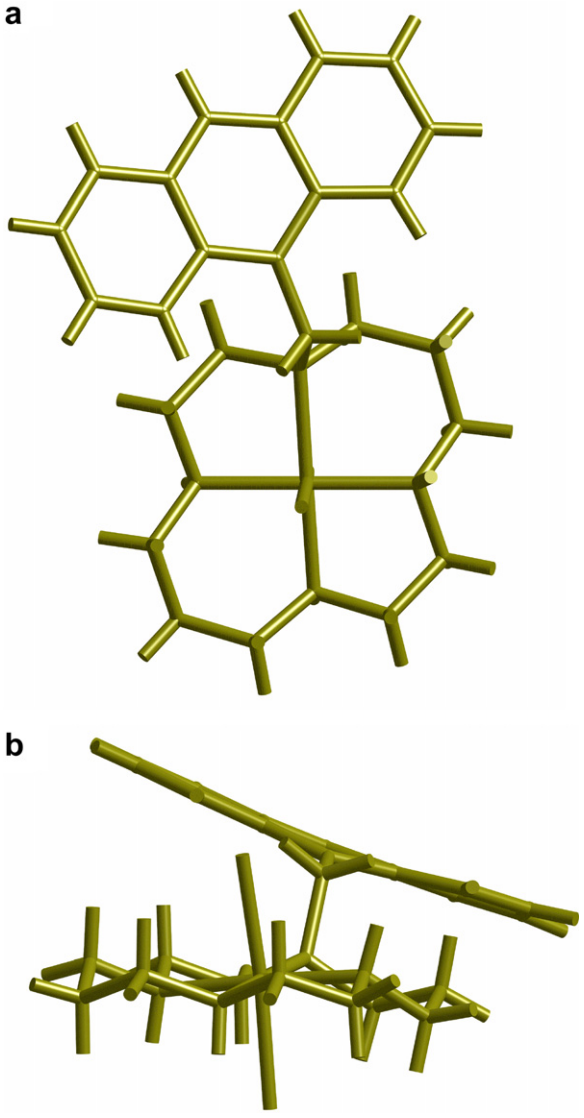

Fig. 3. A view of the *trans*-[Co**L2**Cl_2]$^+$ cation (a) normal to the approximate plane of the macrocycle, (b) parallel to the approximate plane of the macrocycle.

angles are typical for anthracene. While the solid state structure is not necessarily representative of the conformation of the complex in solution, the aforementioned steric interactions with the cyclam may significantly restrict the rotation of the chromophore about the N(1)–C(11) and C(11)–C(12) bonds.

The structure of the thiocyanato complex is presented in Fig. 4 and reveals both axial ligands to be N-bound like the arrangement in the *trans*-[Co(cyc)$(NCS)_2$]$^+$ complex in which the anthracene moiety is absent [14]. The cobalt centre is octahedral with the two nitrogen atoms of the thiocyanato ligands lying at distances of 1.873(5) and 1.897(6) Å from the metal centre (Table 1). The other Co–N bond lengths are in the typical range expected for cobalt(III)-cyclam complexes (ca. 1.97 Å, Table 1) with the exception of the Co–N(1) bond (2.067(5) Å) reflecting the relative steric bulk of the tertiary amino group [13]. A bend is observed at atom N(5) (Co–N(5)–C(26) = 162.8(5)°). As

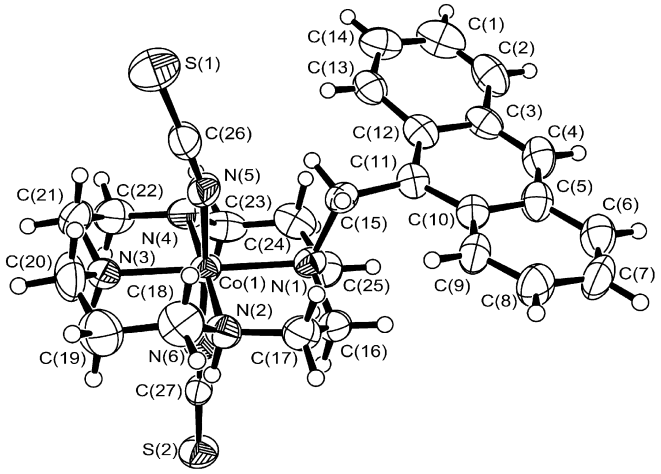

Fig. 4. Crystal structure obtained for the *trans*-[Co**L2**$(NCS)_2$]$^+$ cation. Ellipsoids represented at the 50% probability level.

with the dichloro analogue of the complex, a *trans*-(III) configuration is adopted with the appended chromophore situated well away from the macrocycle. The complex adopts a different conformation to that of the *trans*-[Co**L2**Cl_2]$^+$ complex in which the anthracene moiety is tilted towards a five-membered chelate ring formed by the metal, two amines and a 2-C link of the macrocycle (Fig. 3a). In the *trans*-[Co**L2**$(NCS)_2$]$^+$ complex, the anthracene is tilted towards a six-membered chelate ring. The dihedral angle between the mean planes of the anthracene and the four coordinating nitrogen atoms is 10.6(2)°, and there is a 5.75 Å separation between the cobalt centre and the centroid of the anthracene group. All C–C and C–N bond lengths and bond angles of the macrocycle are unexceptional. Observed torsion angles are as expected based on a staggered arrangement of the macrocycle about the metal centre. Buckling at both ends of the chromophore occurs, which is likely to be a consequence of steric interactions involving the anthracene and cyclam ring. Apart from minor distortions associated with this buckling, all anthracene C–C bond lengths and angles are normal. Like the *trans*-[Co**L2**Cl_2]$^+$ complex, the above-mentioned steric interactions with the cyclam ring are likely to restrict the rotation of the chromophore both in the plane and perpendicular to the plane of the macrocycle.

The structure of the *trans*-[Co**L2**$(NO_2)_2$]$^+$ complex is displayed in Fig. 5 and reveals, quite remarkably, that one of the nitrite ligands is O-bound and the other is N-bound. The metal adopts an octahedral geometry, with the nitro and nitrito donor atoms at distances of 1.93(1) Å and 1.94(1) Å, respectively, from the metal centre. All other Co–N bond lengths are typical for cobalt(III)-cyclam complexes (ca. 1.97 Å, Table 1), the Co–N(1) and Co–N(4) bonds slightly elongated at 2.10(1) and 2.012(9) Å, respectively. All bond lengths, bond angles and torsion angles in the macrocycle are as expected. The N-bound nitro ligand appears to be stabilised by a hydrogen bonding interaction between one of its oxygens and an amine hydrogen of the macrocycle with an O(2)···H–N(2)

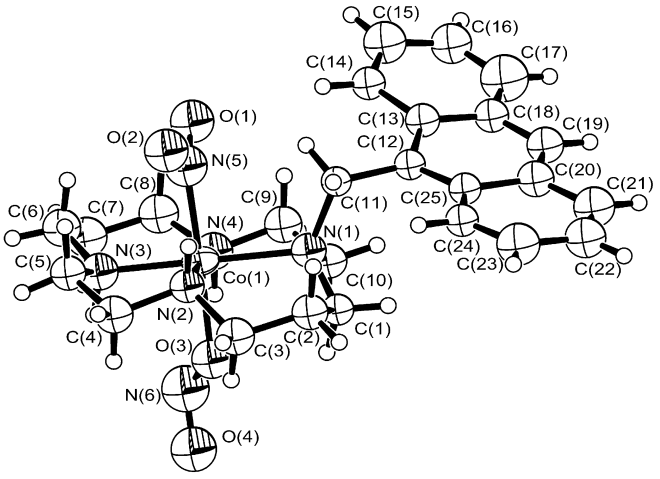

Fig. 5. Crystal structure obtained for the *trans*-[Co**L2**$(NO_2)_2$]$^+$ cation. Ellipsoids represented at the 50% probability level.

separation of 2.72(1) Å. Like the *trans*-[Co**L2**Cl_2]$^+$ complex, the anthracene is situated over a five-membered chelate ring of the macrocycle. The dihedral angle between the mean planes of the anthracene and the four coordinating nitrogen atoms is 26.9(2)° and the metal is separated by 5.73 Å from the centroid of the anthracene moiety. Like the *trans*-[Co**L2**$(NCS)_2$]$^+$ complex, a buckling is observed at both ends of the chromophore. Apart from minor distortions associated with this buckling, all C–C bond lengths and angles are as expected for anthracene.

The structure of the *cis*-[Co**L2**$(NO_2)_2$]$^+$ complex is represented in Fig. 6. The macrocycle wraps itself around the metal centre leaving the two monodentate ligands in a *cis* configuration. This is a remarkable arrangement for a cyclic quadridentate ligand and to the best of our knowledge, the first reported involving cyclam in a *cis*-arrangement about a cobalt centre with two monodentate ligands. Two diagonally opposite amine hydrogen atoms are directed downwards from the plane of the macrocycle while the chromophore and the remaining amine hydrogen are directed upwards i.e. a *cis*-*(V)* configuration according to Tobe's classification [12]. Like the analogous *trans*-[Co**L2**$(NO_2)_2$]$^+$ complex, the structure reveals both a nitro and nitrito ligand in the one complex. The coordination geometry about the cobalt centre is octahedral, the nitro and nitrito donor atoms being at distances of 1.936(2) and 1.915(2) Å, respectively, from the metal centre. All other Co–N bond lengths are slightly longer when compared with the other complexes of the series (Table 1) with the exception of the Co–N(3) bond. All C–N and non-aromatic C–C bond lengths and bond angles are typical as are all torsion angles based on a staggered arrangement of the macrocycle about the metal centre. The structure reveals the anthracene to be situated well away from the macrocycle as one may expect given the steric crowding about the cobalt. The mean plane of the chromophore forms a dihedral angle of 13.95(5)° with the plane formed by nitrogen donor atoms N(1), N(2), N(3) and N(5). The cobalt is a separated by 5.86 Å from the centroid of the anthracene group. Buckling is evident at one end of the chromophore, which is likely to be due to a steric interaction between the anthracene and cyclam ring. Like the complexes of the *trans*-[Co**L2**X_2]$^+$ series, these interactions may well restrict the rotation of the chromophore about both the N(1)–C(11) and C(11)–C(12) bonds. Apart from minor distortions associated with buckling of the chromophore, all aromatic C–C bond lengths and angles are as expected for anthracene.

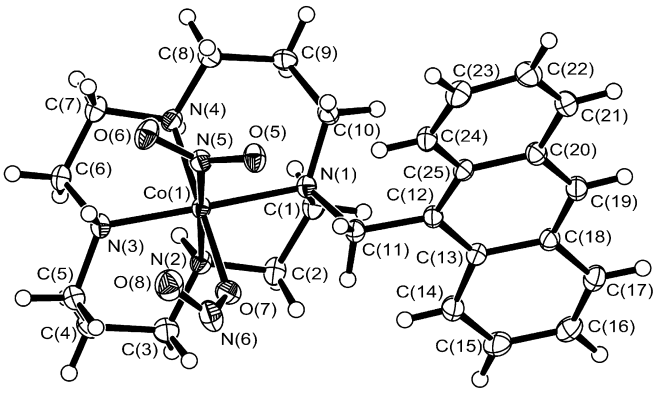

Fig. 6. Solid state structure of the *cis*-[Co**L2**$(NO_2)_2$]$^+$ cation. Thermal ellipsoids represented at the 50% probability level.

3. Conclusion

In this work we have demonstrated the coordinating ability of the ligand **L2** by preparing a series of cobalt(III) complexes of the form [Co**L2**X_2]$^+$. In the 'simple' complex *trans*-[Co(cyc)$(NO_2)_2$]$^+$ both nitro ligands are N-bound [15], so we were somewhat surprised to observe linkage isomerism in the solid state for both the *cis*- and *trans*-isomers of [Co**L2**$(NO_2)_2$]$^+$. There are several examples of mononuclear complexes containing both a nitro and nitrito ligand in the one molecule for complexes of Ni(II) [16–19], Fe(III) [20], Ru(III) [21] and Cu(II) [22], although to our knowledge the complexes *cis*-[Co**L2**$(NO_2)_2$]$^+$ and *trans*-[Co**L2**$(NO_2)_2$]$^+$ are the first examples reported for cobalt(III). The formation of the *cis*- rather than the *trans*-isomer of [Co**L2**$(NO_2)_2$]$^+$ appears to be determined by the oxidation state of the cobalt salt used in the synthesis, with the kinetically inert cobalt(III) favouring the formation of the *cis*-isomer. The photochemistry of these cobalt(III) complexes will be reported in more detail elsewhere [23], however it is worth noting here that the two isomers display marked differences in ground state and excited state behaviour. The *trans*-isomer of [Co**L2**$(NO_2)_2$]$^+$ is labile to ligand exchange in the ground state while, in contrast, the *cis*-isomer is ground state inert but undergoes ligand exchange reactions upon photoexcitation making it a potentially useful photoactivated ligand release system.

4. Experimental

4.1. Instrumentation

ESI-MS experiments were performed using an ion trap (Finnigan Mat) LC-Q spectrometer on dilute solutions of the complexes in methanol. ^{1}H NMR spectra were measured in *d*-chloroform, d_3-acetonitrile and d_4-methanol on a Unity Plus 400 spectrometer. Chemical shifts (δ, positive downfield) are given in ppm (solvent reference) and *J* values in Hz. Aromatic hydrogens are labelled according to IUPAC conventions for anthracene (see supplementary information). Absorption spectra were collected using a Varian Cary 50 Bio ultraviolet–visible spectrophotometer in methanol at 1.0 mM. Elemental analyses were performed by the Microanalytical Laboratory, Department of Chemistry, University of Otago, Dunedin, New Zealand.

4.2. Synthesis

Caution: perchlorate salts of metal complexes with organic ligands are potentially explosive. No problems were encountered with the complexes described below, however, as a precaution, perchlorate salts should never be heated as solids or be handled with metal spatulas.

Reactions were performed in air using as received solvents and AR reagents. Cyclam [24] and 9-chloromethyl-anthracene [25] were prepared by published procedures. 1-(Anthracen-9-ylmethyl)-1,4,8,11-tetraazacyclotetradecane (**L2)** was prepared by the method described by Fabrizzi et al. [7].

4.3. trans-[CoL2Cl$_2$]Cl trans-[1-(anthracen-9-ylmethyl)-1,4,8,11-tetraazacyclotetradecane] dichloro cobalt(III) chloride

A solution of cobalt(II) chloride hexahydrate (0.12 g, 0.52 mmol) in MeOH (15 mL) was added to a solution of **L2** (0.20 g, 0.52 mmol) in MeOH (15 mL). Conc. HCl (1 mL) was added immediately to the brown solution and the mixture was refluxed for 5 min. The solvent and acid were then removed by passage of a stream of air across the mixture. The residue was then stirred with MeOH (15 mL) to yield a green solution and some insoluble material. The mixture was filtered and the filtrate concentrated to 2 mL whereupon a green solid formed. This was collected and recrystallised by infusion of diethyl ether vapour into a concentrated solution of the complex in MeOH to yield small olive green crystals (0.12 g, 0.22 mmol, 42%), m.p. 227–230 °C, ESI-MS data: M^+ *m/z* 519, 521. *Anal.* Calc. for $C_{25}H_{34}N_4Cl_3Co$: C, 54.02; H, 6.17; N, 10.08, Cl, 19.13. Found: C, 53.84; H, 6.29; N, 9.78; Cl, 19.11%. Visible λ_{max}: 618 nm, ε_{max}: 48 L mol^{-1} cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.68 (d, *J* 8.8, 1H, Ar-8); 8.61 (br, 1H, Ar-1); 8.53 (s, 1H, Ar-10); 8.35 (br, 1H, NH); 8.04 (d, *J* 8.3, 2H, Ar-4,5); 7.44–7.63 (m, 4H, Ar-2,3,6,7); 5.96 (br, 1H, NH); 5.93 (d, *J* 15.6, 1H, Ar-CH_2-); 5.62 (d, *J* 15.6, 1H, Ar-CH_2-); 4.0–1.0 (many complex multiplets, ~20H, cyclam -CH_2-).

4.4. trans-[CoL2(NCS)$_2$]ClO$_4$ · CH$_3$CN trans-[1-(anthracen-9-ylmethyl)-1,4,8,11-tetraazacyclotetradecane] bis(thiocyanato-N) cobalt(III) perchlorate-CH$_3$CN

A solution of cobalt(II) perchlorate hexahydrate (0.19 g, 0.52 mmol) in MeOH (15 mL) was added to a solution of **L2** (0.20 g, 0.52 mmol) in MeOH (15 mL). Air was bubbled through the brown solution for 4 h and NaNCS (0.13 g, 1.6 mmol) in MeOH (10 mL) was added. The intensely coloured red-brown solution was refluxed for 1 h, then cooled and sodium perchlorate (0.36 g, 2.6 mmol) in H_2O (2 mL) added. The solution was filtered and slowly concentrated to 2 mL by passing a gentle stream of air across the solution whereupon a red-brown solid formed. The solid was collected and recrystallised by the infusion of diethyl ether vapour into a concentrated solution of the complex in acetonitrile yielding intensely coloured red/brown plates (75 mg, 0.11 mmol, 22%), m.p. 205–207 °C, ESI-MS data: M^+*m/z* 565. *Anal.* Calc. for $C_{27}H_{34}N_6O_4S_2ClCo \cdot CH_3CN$: C, 49.33; H, 5.28; N, 13.88; S, 9.08. Found: C, 49.66; H, 5.33; N, 14.19; S, 9.13%. ^{1}H NMR (400 MHz, CD_3CN): δ 8.68 (s, 1H, Ar-10); 8.30 (br, 2H, Ar-1,8); 8.13 (d, *J* 8.4, 2H, Ar-4,5); 7.54–7.63 (m, 4H, Ar-2,3,6,7); 6.37 (br, 1H, NH); 5.60 (br, 1H, NH); 5.23 (br, 1H, NH); 5.11 (d, *J* 15.6, 1H, Ar-CH_2-); 4.89 (d, *J* 15.6, 1H, Ar-CH_2-); 3.8–1.0 (many complex multiplets, ~20H, cyclam -CH_2-).

4.5. trans-[CoL2(NO$_2$)$_2$]ClO$_4$ trans-[1-(anthracen-9-ylmethyl)-1,4,8,11-tetraazacyclotetradecane] (nitrite-N) (nitrito-O) cobalt(III) perchlorate

A solution of cobalt(II) chloride hexahydrate (0.12 g, 0.52 mmol) in MeOH (15 mL) was added to a solution of **L2** (0.20 g, 0.52 mmol) in MeOH (15 mL). Conc. HCl (1 mL) was added immediately to the brown solution and the mixture was refluxed for 5 min. The solvent and acid were then removed by passage of a stream of air across the mixture. The residue was then stirred with MeOH (15 mL) to yield a green solution and some insoluble material. The mixture was filtered and to the filtrate was added $NaNO_2$ (0.11 g, 1.6 mmol) in H_2O (2 mL). The resulting orange/red solution was heated at reflux for 1 h, then cooled and sodium perchlorate (0.36 g, 2.6 mmol) in H_2O (2 mL) was added. The solution was filtered and slowly concentrated to 2 mL by passing a stream of air across the solution whereupon an orange solid formed. This was collected and recrystallised by infusion of diethyl ether vapour into a concentrated solution of the complex in acetonitrile to yield an orange microcrystalline solid (0.11 g, 0.18 mmol, 35%), m.p. 125 °C (dec.), ESI-MS data: M^+ *m/z* 541. *Anal.* Calc. for $C_{25}H_{34}N_6O_8ClCo$: C, 46.85; H, 5.35; N, 13.11; Cl, 5.53. Found: C, 46.85; H, 5.50; N, 13.00; Cl, 5.23%.

^{1}H NMR (400 MHz, CD_3CN): δ 8.68 (s, 1H, Ar-10); 8.21 (br, 2H, Ar-1,8); 8.12 (d, J 8.4, 2H, Ar-4,5); 7.53–7.63 (m, 4H, Ar-2,3,6,7); 6.43 (br, 1H, NH); 5.29 (br, 1H, NH); 5.07 (d, J 15.1, 1H, Ar-CH_2-); 4.88 (d, J 15.1, 1H, Ar-CH_2-); 4.77 (br, 1H, NH); 4.0–1.0 (many complex multiplets, ~20H, cyclam -CH_2-).

4.6. *cis-[CoL2(NO$_2$)$_2$]NO$_2$ cis-[1-(anthracen-9-ylmethyl)-1,4,8,11-tetraazacyclotetradecane] (nitrite-N)-(nitrito-O)-cobalt(III) nitrite*

A solution of trisodium hexanitrocobaltate(III) (0.33 g, 0.57 mmol) in 80:20 MeOH:H_2O (ca. 15 mL) was added to a solution of **L2** (0.20 g, 0.52 mmol) in MeOH (ca. 15 mL) and the pale brown suspension which resulted was stirred at room temperature for 1 h. The resulting blood red solution was filtered and the filtrate taken to dryness under a stream of N_2. The residue was then stirred with chloroform (ca. 15 mL) to yield a red solution and some orange insoluble material (ca. 50 mg). The solid was removed by filtration and the filtrate stirred with the slow addition of diethyl ether (ca. 100 mL) whereupon a red solid formed. This was collected and recrystallised by infusion of diethyl ether vapour into a concentrated solution of the complex in chloroform yielding irregularly-shaped ruby red crystals (54 mg, 0.092 mmol, 18%), m.p. 175 °C (dec.), ESI-MS data: M^+ m/z 541. *Anal*. Calc. for $C_{25}H_{34}N_7O_6Co$: C, 51.11; H, 5.83; N, 16.69. Found: C, 51.28; H, 5.81; N, 16.61%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.98 (d, J 9.0, 1 H, Ar-8); 8.46 (s, 1H, Ar-10); 7.93 (m, 3H, Ar-1,4,5); 7.65 (br, 1H, NH); 7.35–7.55 (m, 4H, Ar-2,3,6,7); 7.22 (br, 1H, NH); 6.54 (br, 1H, NH); 5.31 (d, J 15.4, 1H, Ar-CH_2-); 5.13 (d, J 15.4, 1H, Ar-CH_2-); 3.6–1.0 (many complex multiplets, ~20H, cyclam -CH_2-). The ^{1}H NMR spectrum was recorded with the addition of two drops of d_6-DMSO to the $CDCl_3$ solution to aid dissolution of the compound.

4.7. Crystallography

The following is a short summary of the details of the crystal used in each of the structure determinations including the methods employed in their structure determinations. Details of data collection and refinement are summarised in Table 2. Full details, including all bond lengths, angles and atomic coordinates are recorded in cif files on the CCDC database. Structures were refined using a full matrix least squares procedure based on F^2 with all data being used in the refinement. All structures were solved and refined using SHELX-97 [26].

4.8. *trans-[CoL2Cl$_2$]Cl*

Crystals suitable for X-ray crystallography were grown by slow evaporation from a dilute solution of the complex in methanol to produce green rectangular prisms. Data were collected from a single crystal of approximate dimensions $0.27 \times 0.17 \times 0.14$ mm on an Enraf-Nonius CAD4 single crystal X-ray diffractometer using the ω:2θ scan technique.

[a] Includes one CH_3CN solvent molecule.

4.9. trans-[CoL2(NCS)$_2$]ClO$_4$ · CH$_3$CN

Crystals suitable for X-ray crystallography were grown by slow evaporation from a dilute solution of the complex in an acetonitrile/water mix to produce dark red/brown rectangular plates. Data were collected from a single crystal of approximate dimensions $0.46 \times 0.19 \times 0.04$ mm on an Enraf-Nonius CAD4 single crystal X-ray diffractometer using the ω:2θ scan technique.

4.10. trans-[CoL2(NO$_2$)$_2$]ClO$_4$

Crystals suitable for X-ray crystallography were grown by H_2O diffusion into a concentrated solution of the complex in acetonitrile to produce irregularly shaped orange/red crystals. Data were collected from a crystal of approximate dimensions $0.25 \times 0.12 \times 0.10$ mm on a Bruker CCD area detector, single crystal X-ray diffractometer. Inspection of the diffraction pattern revealed that the crystal was in fact a multiple crystal. A number of crystals were investigated but all showed significant twinning. Using the program RLATT [27] it was possible to identify reflections belonging to a single crystal. These reflections were indexed in order to obtain a unit cell and an orientation matrix. Since this crystal represented only a small portion of the multiple crystal, the data are very weak and there are very few reflections at high angles. Given the paucity of data only the cobalt and chlorine atoms were refined anisotropically. Despite the difficulties associated with the crystal, the non-hydrogen atoms are clearly defined and the connectivity is beyond doubt.

4.11. cis-[CoL2(NO$_2$)$_2$]ClO$_4$

Crystals suitable for X-ray crystallography were grown from a solution of the perchlorate salt of *cis*-[CoL2(NO$_2$)$_2$]NO$_2$. This was prepared by dissolving *cis*-[CoL2(NO$_2$)$_2$]NO$_2$ (ca. 10 mg) in methanol (ca. 2 mL) and adding $NaClO_4$ (ca. 5 equiv.) in water (0.5 mL) producing an immediate red precipitate. Crystals suitable for X-ray crystallography were grown by diethyl ether diffusion into a dilute solution of the complex in acetonitrile to produce rod-shaped ruby red crystals. Data were collected from a crystal of approximate dimensions $0.17 \times 0.17 \times 0.45$ mm on a Bruker CCD area detector single crystal X-ray diffractometer. The crystal was covered in oil and placed in a stream of cooled nitrogen during the data collection.

as supplied. All the chemicals used were of AR grade. Solvents used in this study were purified following the standard procedures.

2.2. Analysis

Elemental analyses (C, H, N) were performed on a model 2400 Perkin–Elmer elemental analyzer. The vanadium content of each of the complexes was determined volumetrically [13] using decinormal $KMnO_4$ solution as an oxidizing agent in the presence of sulfurous acid. A 100 mg sample of the compound was placed in a silica crucible, decomposed by gentle heating and then adding 1–2 ml of concentrated HNO_3, 2–3 times. An orangish mass (V_2O_5) was obtained after decomposition and complete drying. It was dissolved in the minimum amount of dilute H_2SO_4, and the solution so obtained was diluted with distilled water to 100 ml in a measuring flask. The amount of vanadium in the sample solution was calculated using the standard [13] relationship given below.

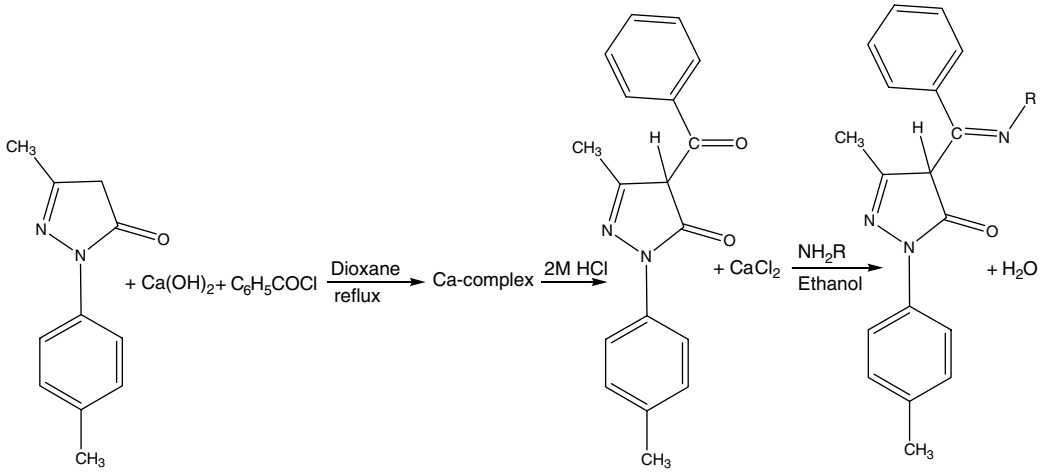
One milliliter of 0.1 N $KMnO_4 = 0.005094$ g vanadium.

2.3. Physical measurements

Infrared (IR) spectra were recorded on a Nicolett-400D spectrometer as KBr pellets. NMR spectra were recorded on a model DPX 200 Bruker FT NMR instrument. The electronic spectra were recorded on a model UV160A Shimadzu spectrophotometer. Specific conductivity of the complexes was measured on a model 305 Systronic conductivity bridge. Magnetic moments were measured on a model 7304 Lake Shore Cryotronics vibrating sample magnetometer.

2.4. Synthesis of ligands

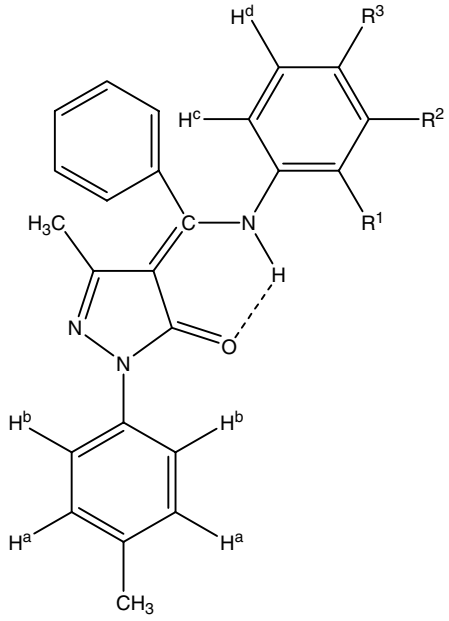
The synthesis of ligand is summarized in Scheme 1. However detail procedure is given in the following pages.



2.4.1. Preparation of 4-benzoyl-3-methyl-1-(4′-methylphenyl)-2-pyrazolin-5-one

3-Methyl-1-(4′-methylphenyl)-2-pyrazolin-5-one (20.1 g, 0.1 mol) was dissolved in hot dioxane (80 cm^3) in a flask equipped with a stirrer, separating funnel and reflux condenser. Calcium hydroxide (14.81 g, 0.2 mol) was added to this solution, followed by benzoyl chloride (18.01 g, 0.1 mol) added dropwise with precaution, as this reaction was exothermic. During this addition the whole mass was converted into a thick paste. After the complete addition, the reaction mixture was refluxed for half an hour and then it was poured into dilute hydrochloric acid (200 cm^3, 2 M). The coloured crystals thus obtained were separated by filtration and recrystallized from an acidified methanol-water mixture ($HCl:MeOH:H_2O = 1:80:19$). Yield 67%. *Anal.* Calc. for $C_{18}H_{15}N_2O_2$: C, 74.21; H, 5.19; N, 9.63. Found: C, 73.43; H, 5.01; N, 9.97%.

2.4.2. General method for the preparation of the ligands



5-methyl-4-(phenyl-phenylamino-methylene)-2-*p*-tolyl-2,4-dihydro-pyrazol-3-one (HL^1)
5-methyl-4-(phenyl-*o*-tolylamino-methylene)-2-*p*-tolyl-2,4-dihydro-pyrazol-3-one (HL^2)
5-methyl-4-(phenyl-*m*-tolylamino-methylene)-2-*p*-tolyl-2,4-dihydro-pyrazol-3-one (HL^3)
5-methyl-4-(phenyl-*p*-tolylamino-methylene)-2-*p*-tolyl-2,4-dihydro-pyrazol-3-one (HL^4)
5-methyl-4-[(2-chloro-pheynylamino)-phenyl-methylene]-2-*p*-tolyl-2,4-dihydro-pyrazol-3-one (HL^5)
5-methyl-4-[(3-chloro-pheynylamino)-phenyl-methylene]-2-*p*-tolyl-2,4-dihydro-pyrazol-3-one (HL^6)
5-methyl-4-[(4-chloro-pheynylamino)-phenyl-methylene]-2-*p*-tolyl-2,4-dihydro-pyrazol-3-one (HL^7)

The compound 4-benzoyl-3-methyl-1-(4′-methylphenyl)-2-pyrazolin-5-one (2.91 g, 0.01 mol) was dissolved in ethanol (20 cm^3) and the appropriate amine (0.01 mol, aniline for HL^1, *ortho*-, *meta*- and *para*-toludine for HL^2–HL^4, respectively, and *ortho*-, *meta*- and *para*-chloroaniline for

Scheme 1.

HL^5–HL^7, respectively) was added to this solution. The reaction mixture was refluxed for 2 h. During the reflux a microcrystalline compound was separated, which was isolated by filtration, washed with ethanol and dried in air. Suitable crystals for single crystal X-ray study were grown from acetonitrile (Fig. 1).

HL^1: $R^1 = H^c$, $R^2 = H^d$, $R^3 = H$

HL^2: $R^1 = CH_3$, $R^2 = H$, $R^3 = H$ HL^5: $R^1 = Cl$, $R^2 = H$, $R^3 = H$

HL^3: $R^1 = H$, $R^2 = CH_3$, $R^3 = H$ HL^6: $R^1 = H$, $R^2 = Cl$, $R^3 = H$

HL^4: $R^1 = H^c$, $R^2 = H^d$, $R^3 = CH_3$ HL^7: $R^1 = H^c$, $R^2 = H^d$, $R^3 = Cl$

Fig. 1. Structural drawing of the ligands with the labeling of the protons.

2.4.3. General method for the preparation of the OV(IV) complexes $[OV(L)_2(H_2O)]$ ($L = L^1$, L^2, L^3, L^4, L^5, L^6 and L^7)

The appropriate ligand (0.01 mol) dissolved in hot DMF (20 cm^3) was added dropwise into an aqueous solution (20 cm^3) of Vanadyl sulfate pentahydrate (0.01 mol, 2.53 g) with stirring. After the complete addition, 2.0 g of sodium acetate was added to the solution and the reaction mixture was refluxed for 2 h. The solution thus obtained was concentrated to half of its original volume by evaporation using a hot plate and allowed to cool to room temperature. During this period, a light greenish microcrystalline solid was separated, which was isolated by filtration, washed with hot water followed by ethanol and dried in air. Yield 50–60%.

2.4.4. X-ray crystallography data collection and processing

Crystallographic data for five of the ligands are summarized in Table 1. The data collections were carried out on a Bruker Mart Apex CCD diffractometer using graphite monochromated Mo Kα ($\lambda = 71\,073$ Å) radiation at 293 K. An absorption correction based on SADABS [14] was also applied. The structures were solved by direct methods (SHELXTL) and refined by least squares methods with atomic anisotropic thermal parameters for all non-hydrogen atoms [15,16]. All hydrogen atoms were either generated geometrically or obtained from the Fourier difference map, and were assigned fixed isotropic thermal parameters in the structure factor calculations. Conformational and H-bonding analysis was performed using PLATON [17].

3. Results and discussion

3.1. Characterization of the ligands

All seven ligands, HL^1–HL^7, gave satisfactory elemental analysis (Table 2). The molecular structures of these ligands are such that they can exist in three tautomeric forms as shown in Fig. 2. Detailed solution and solid-state studies of these ligands were carried out to establish their geometry. The IR spectra of these ligands exhibit two characteristic bands in the ranges 3220–3245 and 1610–1630 cm^{-1}, which can either be assigned to $\nu_{(O-H)}$ and $\nu_{(C=N)}$ respectively for the tautomeric imine-ol form (Fig. 2, II) or $\nu_{(N-H)}$ and $\nu_{(C=O)}$ respectively for the amine-one form (Fig. 2, III) of the ligand. We assigned these two peaks to $\nu_{(N-H)}$ and $\nu_{(C=O)}$, respectively for the later form based on the information obtained from crystallographic studies (discussed later).

The ^1H NMR spectra of all the ligands were recorded in $CDCl_3$ at room temperature and the data are presented in Table 3. The signals due to methyl protons appeared as singlets in the range δ 1.56–2.42 ppm. In some cases signals of CH_3 groups are overlapped and all of these signals are so closely spaced that it is difficult to assign each signal to a particular methyl group unambiguously [18]. Moreover, such assignment will not contribute to establish the geometry of the ligands, therefore, no attempt has been made for such assignment. In the aromatic region, a few doublets and in few cases some overlapping doublets/multiplets are observed in the range δ 6.49–7.92 ppm. These doublets/multiplets are due to aryl protons of three benzene rings. Another singlet corresponding to one proton for all compounds is observed in the range δ 12.83–12.99. This signal disappeared when a D_2O exchange experiment was carried out. It can be assigned either to OH or NH, in either case it is strongly deshielded because of hydrogen bonding with the other atom (N/O). It may be noted that the integration of this signal perfectly matches with one proton and there is no other fragment(s) of this signal, which suggests that only one tautomeric form of the ligands exist in solution under the experimental conditions. We have not done any temperature dependent experiments. Comparing with the solid state study, we prefer to assign this signal to NH, however, assignment of this peak to OH cannot be ruled out provided solid state structural evidence is not considered [18].

Table 2
Melting point, elemental analysis (C, H and N)[a] and yield of the ligands

Ligand	Melting point (°C)	% C	% H	% N	Yield (%)
HL^1	154	78.89 (78.44)	5.63 (5.76)	11.01 (11.44)	67

3.2. Molecular structures of the ligands

The molecular structures of five ligands (HL^1–HL^5) were determined from single crystal X-ray studies. ORTEP diagrams of compounds HL^1 to HL^5 with the atom numbering schemes are shown in Fig. 3. Important bond lengths and angles for all the compounds are listed in Table 4. The ligand HL^1 crystallizes in the $P\bar{2}1/n$ space group

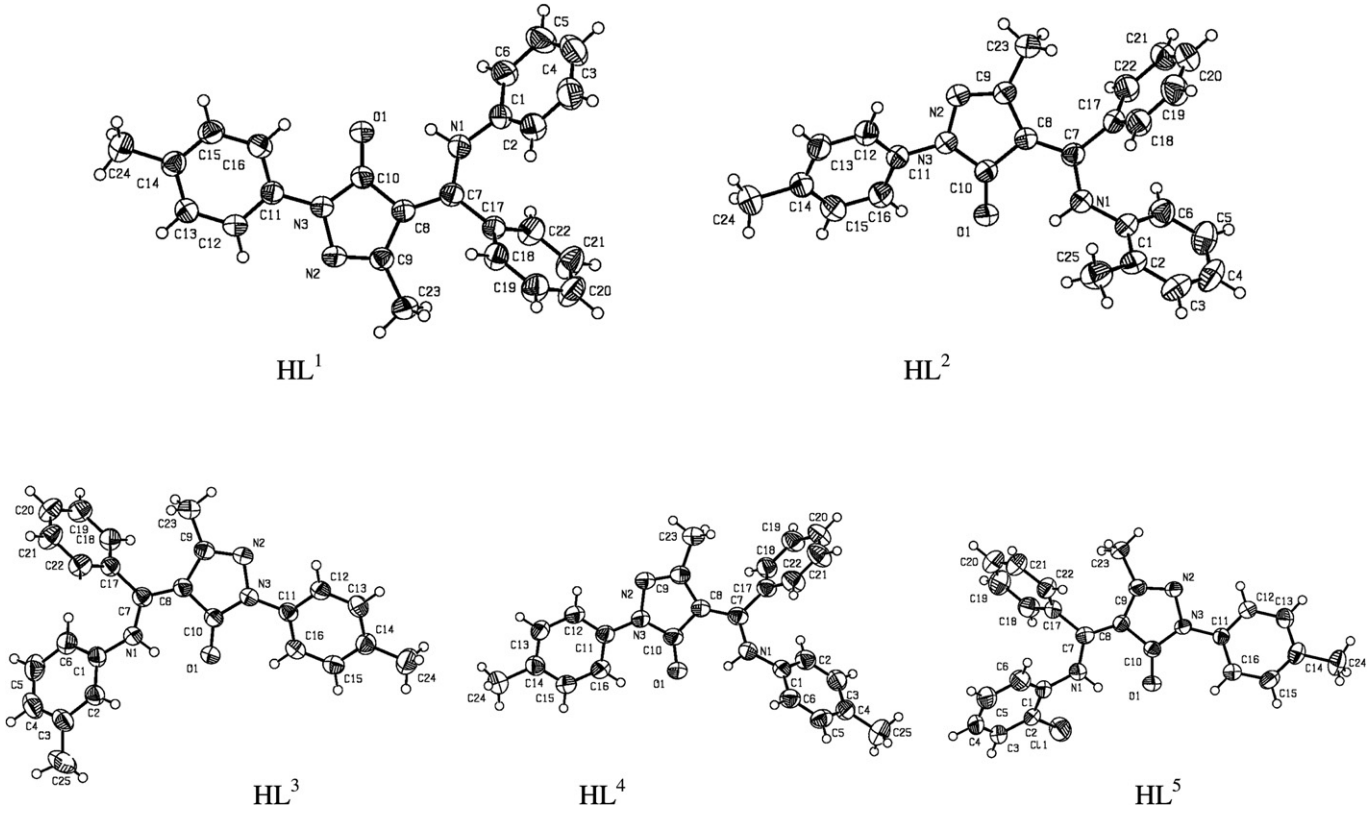

Fig. 3. ORTEP diagram of ligands $HL^{1\text{-}5}$.

with two molecules in the asymmetric unit. The packing diagram of this compound is depicted in Fig. 4.

Existence of acyl pyrazolone derivatives in different tautomeric forms (Fig. 2) in solid state is well known phenomenon and thus many studies have been made to establish the geometry of these derivatives including ours [18–22]. The single crystal X-ray diffraction study on this compound clearly indicates that the present compound exists in amine-one form without any ambiguity. Structural data shows that the C(10)–O(1) distances in the pyrazole moiety of these compounds are in the range 1.240–1.249 Å, which are significantly shorter than the distance found for >C–OH in some pyrazolone derivatives, 1.341, 1.346 Å [23] and 1.331 Å [24]; but well in the range of >C=O distances found similar compounds and 1.254 Å [25]. Significantly longer C(7)–N(1) distances of the imine moiety 1.334–1.343 Å, compared to the C=N in pyrazolone compound, 1.298 Å [26] and 1.292 Å [25], and comparable to >C–N (1.339 Å) distance observed in similar compounds [27], further supports the amine-one from in the present case. The C=O and C–N distances observed in this compound is comparable and well within the range reported by Allen et al. [28] in compilation of CSD data base, which summarizes many bond distances for various types of bonds including required one. The N–H proton is strongly hydrogen bonded with the O(1) atom, the N(1)···O(1) distances are in the range 2.667–2.713 Å and <N(1)–H(1)···O(1) are in the range 135.84–144.28° (Table 5). In addition to the above observations, the location of the hydrogen atom attached to the N1 atom from the difference Fourier map and the geometry around the atom C8 carbon shows the total values of the angle involving the C8 carbon (C(7)–C(8)–C(9) = 132.3–132.9°, C(7)–C(8)–C(10) = 121.9–122.4°, C(9)–C(8)–C(10) = 104.7–105.3° are in the range 358.9–360.6°, which is very close to 360°, expected from the coplanar C(7), C(8), C(9) and C(10) atoms and thus rules out the possibility of imine-ol form with the attachment of hydrogen with C(8). Thus it is clear from the X-ray studies establishing the amine-one form in the present compounds in accordance with the series of similar compounds reported by us recently [18–20].

3.3. Ab initio calculations for HL^1

The full geometry optimization of HL^1 has been carried out in Cartesian coordinates by quasi-Newton–Raphson gradient method using the restricted Hartree–Fock (RHF) approximation with help of Gamess program package [29]. Symmetry restrictions were not applied. The standard basis set of Gauss functions 6-31G [30,31] was used. The choice of basis set was optimal taking into account the computational time required and a reasonable accuracy of the results. The energy corresponds to the minima obtained is −1158.8256151 hartrees. The obtained minimum (Fig. 5) is true minima because it is identical with the crystal structure of the molecule. The same is also confirmed from the conformational analysis. The present compound contains too many hetero atoms. Thus it is interesting to know that out of these which one are the coordinating atoms. The lowdin atomic charges on N1 and O1 are −0.270560, −0.477742, respectively, whereas the lowdin atomic charges on N2 and N3 are −0.141167,

−0.149783, respectively. Thus due to highest electron density available on atoms N1 and O1, these are the atoms which undergo coordination with the metal ions [20].

3.4. Characterization of the metal complexes

OV(IV) complexes of all the seven ligands have been synthesized by the reaction of $VOSO_4 \cdot 5H_2O$ and the respective ligands in water–DMF (1:1) under reflux conditions in the presence of sodium acetate according to following equation:

$$VOSO_4 \cdot 5H_2O + HL^{1\text{–}7} \rightarrow [OV(L^{1\text{–}7})_2(H_2O)] + H_2SO_4$$

where L = deprotonated HL^1, HL^2, HL^3, HL^4, HL^5, HL^6 and HL^7.

The resulting compounds are non-hygroscopic and air-stable solids. The C, H, N and metal percentage along with their conductivity and magnetic moment data of these complexes are presented in Table 6. The analytical data supports the above said molecular composition for these complexes. The observed molar conductance (Table 6) in 10^{-3} M DMF solution of these complexes are consistent with non-electrolytic nature of the complexes. Such a non-zero molar conductance value for each of the complex in the present study is most probably due to the strong donor capacity of DMF, which may lead to the displacement of anionic ligand and change of electrolyte [32] type. The oxovanadium(IV) is a $S = 1/2$ system. The magnetically dilute oxovanadium(IV) complexes usually exhibit magnetic moments to their spin-only value of 1.73 BM. At room temperature, the observed value of the magnetic moments for the present complexes, are in the range 1.63–1.93 BM, as expected for a simple $S = 1/2$ paramagnets with a d_{xy} based ground state [33]. These data suggest that the complexes under this investigation are mononuclear [33]. The IR spectra of the metal complexes exhibit no band for $\nu_{(N\text{–}H)}$ (3228 cm^{-1}) of the ligands, indicating deprotonation of the N–H group in metal complexes. Most of the oxovanadiun(IV) complexes exhibit a strong band near 1000 cm^{-1}, which has been assigned to the $\nu_{(V=O)}$ [34]. In the present work, the $\nu_{(V=O)}$ is found at 900–930 cm^{-1} which suggests the absence of a —V=O—V=O— chain structure [35,36]. To confirm the presence of weakly coordinating H_2O molecules in the complex we carried out thermogravimetric analyses of all the complexes. This study shows loss of weight corresponding to one water molecule in the temperature range 130–170 °C, indicating that the water molecule in these complexes is weakly coordinated to the metal ion. The presence of a H_2O molecule in the complexes is also indicated by IR spectra, which show a broad band centered around 3400 cm^{-1} and two sharp bands at 710 and 420 cm^{-1}, the later two can be assigned to the wagging and rocking modes of vibration of the water molecule, respectively [37]. On the basis of all these data, the molecular geometry assigned to the metal complexes is shown in Fig. 6. Attempts have been made to grow X-ray quality single crystals of these complexes, however, this has been unsuccessful so far.

Table 6
Elemental analysis (M, C, H and N)[a], molar conductance and magnetic moment data of the OV(IV) complexes

Complex	% M	% C	% H	% N	Λ_M[b]	$\mu_{eff.}$ (BM)

[b] Ohm^{-1} cm^2 mol^{-1} in DMF.

3.5. Electronic spectra of the metal complexes

The electronic spectra of all the complexes were recorded in DMF and the data are presented in Table 7. Complexes of oxovanadium(IV) usually show coordination numbers five and six giving tetragonal pyramidal and distorted octahedral structures respectively [38,39]. Because of the presence of a strong axial field, the energy levels associated with these two structures do not differ considerably [40]. Therefore, the same scheme can be used for the interpretation of the spectra of both types of the complexes. The electronic spectra of all complexes show three bands in the region 12 000–26 000 cm^{-1}. These bands may be assigned to three transitions as shown in Table 7, following the "Clustered level" Scheme [41,42]. In addition, all the complexes show a band at ~31 000 cm^{-1}, which may be due to the first spin forbidden charge transfer transition [43]. To support the above assignments, the following study was made for all the complexes. Each complex was dissolved in 2:1:1 ether:toluene:ethanol mixture and allowed to stand

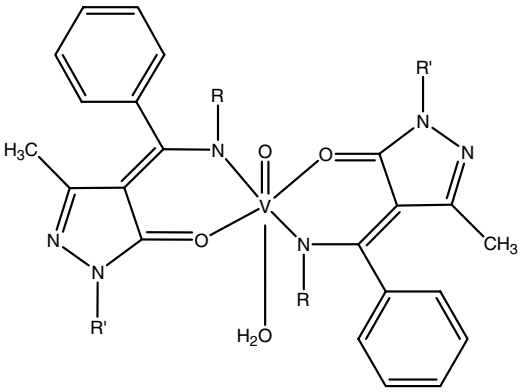

Fig. 6. Structural drawing of the OV(II) complexes.

[a] Pyridine spectra.
[b] Oxidation spectra.

to bring the oxidation of OV(IV) to OV(V) [43,44]. The colour of each complex in solution changes rapidly from green to brown. This suggests the change of oxidation state of OV(IV). The solution spectra of the above solutions showed the absence of bands in the region 12000–26000 cm^{-1}. However, only one band ~31000 cm^{-1} appeared in the solution spectra of the all the complexes. The d–d bands are expected to disappear for the OV(V) complexes and therefore, the observed band may be due to charge-transfer process [45]. The vanadyl complexes can usually accept a sixth ligand to vanadium in the axial position trans to the oxygen atom. When this happens, the d-d transition bands will be solvent-dependent. The pyridine spectra of the complexes are very similar to each other and also to those of their electronic spectra. Clearly, there is no significant shift of absorption bands in strong donating solvent, suggesting that it is unlikely that there is any strong interaction between vanadium and the donating molecule. This suggests that, there is no pyridine coordination and no change of the stereochemistry of these complexes in a donor solvent [46,47]. This also confirms the tetragonally distorted octahedral structure for these complexes.

4. Supplementary material

CCDC 617622, 617623, 617624, 617625, and 617626 contain the supplementary crystallographic data for the ligands (HL^1–HL^5). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

1,10-phenanthroline-5,6-dione [11], (IP) and (PIP) [12], $[Co(en)_2phen]Br_3$ [13] *cis*-$[Co(en)_2Cl_2]Cl \cdot 3H_2O$ [14] and $[Co(en)_2L]Br_3$ were prepared by the procedures given below. The structures of the complexes and ligands are shown in Fig. 1. All the experiments involving the interaction of the complexes with DNA were carried out in a buffer (5 mM Tris–HCl, 50 mM NaCl, pH 7.2). A solution of CTDNA in the buffer gave a ratio of UV absorbance at 260 and 280 nm of about 1.90, indicating that the DNA was sufficiently free of protein [15]. The DNA concentration per nucleotide was determined by absorption spectroscopy using the molar absorption coefficient (6600 M^{-1} Cm^{-1}) at 260 nm [16].

2.2. Synthesis of complexes

2.2.1. *[Co(en)$_2$PIP]Br$_3$*

A mixture of *cis*-$[Co(en)_2Cl_2]Cl$ (1.43 g) and phenylimidazo[4,5-f][1,10]-phenanthroline (1 g) was dissolved in EtOH (6 ml), and NaBr (3.0 g) in H_2O (5 ml) was added. The resulting mixture was heated on a water bath until a dark yellow solution was formed. This was then cooled in ice and the thick crystalline precipitate of $[Co(en)_2PIP]^{3+}$ was collected and recrystallized from water (30 ml). The yield by this method was about 80%. (Elemental *Anal.* Calc. for $C_{23}N_8H_{28}Br_3Co$: C, 38.2; H, 3.96; N, 15.7. Found: C, 37.12; H, 3.2; N 14.6%.) IR stretching frequencies: (C=C); 1458, (C=N); 1508, (Co–N (en)); 779, (Co–N(ligand)); 625.5 cm^{-1}.

2.2.2. *[Co(en)$_2$IP]Br$_3$*

The complex $[Co(en)_2IP]^{3+}$ was prepared according to the procedure described above from a mixture of *cis*-$[Co(en)_2Cl_2]Cl$ (1.43 g) and IP (1 g). (Yield: 88%). (Elemental *Anal.* Calc. for $C_{23}N_8H_{28}Br_3Co$: C, 32.08; H, 3.80; N, 17.6. Found: C, 32.28; H, 3.2; N, 16.6%.). IR stretching frequencies: (C=C); 1398, (C=N); 1558, (Co–N (en)); 614, (Co–N(ligand)); 573 cm^{-1}.

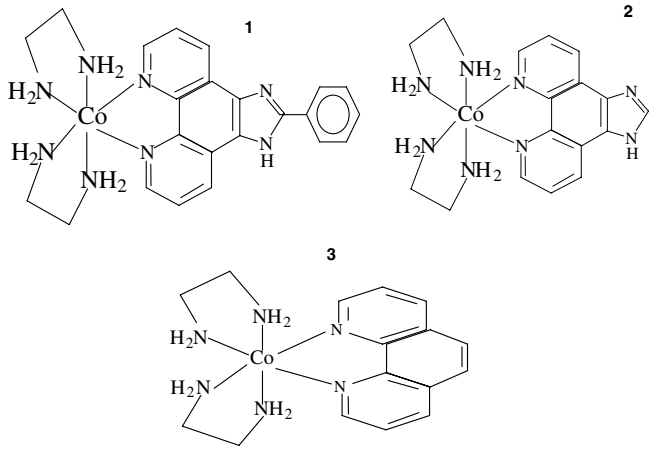

Fig. 1. Chemical structures of the complexes.

2.3. Physical measurements

UV–Vis spectra were recorded with an Elico Bio-spectrophotometer, model BL198. IR spectra were recorded in KBr discs on a Perkin-Elmer FT-IR-1605 spectrometer. ^1H NMR spectra were measured on a Varian XL-300 MHz spectrometer with D_2O as the solvent at room temperature and using tetramethylsilane (TMS) as the internal standard. Magnetic susceptibility measurements for solid samples of the complexes were carried out using a Faraday bakany model. Hg $[Co(CNS)_4]$ was employed as the magnetic susceptibility standard. Microanalyses (C, H and N) were carried out on a Perkin-Elmer 240 elemental analyzer. For the absorption spectra an equal amount of DNA was added to both the complex solution and reference solution to eliminate the absorbance of DNA itself.

Viscosity experiments were carried out using an Ostwald viscometer maintained at a constant temperature of 30.0 ± 0.1 °C in a thermostatic waterbath. Calf thymus DNA samples of approximately 200 bp of average length were prepared by sonicating in order to minimize complexities arising from DNA flexibility [17]. Data were presented as $(\eta/\eta_0)^{1/3}$ versus the concentration of the Co(III) complexes, where η is the viscosity of DNA in the presence of the complex, η_0 is the viscosity of DNA alone. Viscosity values were calculated from the observed flow time of DNA-containing solutions ($t > 100$ s) corrected for the flow time of buffer alone $(t_0)\eta = t - t_0/t_0$, where t is the observed flow time of DNA and t_0 is the flow time of buffer [18]. The DNA melting experiments were carried out by controlling the temperature of the sample cell with a Shimadzu circulating bath while monitoring the absorbance at 260 nm.

For the gel electrophoresis experiments, super coiled pBR 322 DNA (100 μM) was treated with the Co(III) complexes in 50 mM Tris–HCl, 18 mM NaCl buffer, pH 7.2, and the solutions were incubated for 1 h in the dark, then irradiated at room temperature with a UV lamp (302 nm, at 10 W). The samples were analyzed by electrophoresis for 2.5 h at 40 V on a 0.8% agarose gel in tris–acetic acid EDTA buffer; pH 7.2 The gel was stained with 1 μg/ml ethidium bromide and then photographed under UV light.

2.4. Spectroscopic characterization

The IR spectral data for the two complexes were determined, and the complexes clearly exhibit bands at 1450 and 1560–1590 cm^{-1}, corresponding to C=C and C=N of the ring, respectively. Bands at around 626 and 579 cm^{-1} correspond to Co–N(en) and Co–N of L = PIP and IP. NH_2 (en) bending was observed at around 1650 cm^{-1}. The UV–Vis emission maxima were observed at 317, 492 and 347, 437 nm and fluorescence peaks at 408 and 407 for the $[Co(en)_2IP]^{3+}$ and $[Co(en)_2PIP]^{3+}$ complexes, respectively. These bands are due to a MLCT [19]. The electronic environments of the many aromatic hydrogen atoms (PIP and IP) are similar and hence the ^1H NMR spectra appear

in a narrow chemical shift range. In fact the aromatic regions of the spectra of these complexes are complicated due to the overlapping of several signals, which have precluded the identification of individual resonances. In the ^{1}H NMR spectra of the cobalt(III) complexes the peaks due to various H-atoms of PIP and IP were shifted downfield compared to the free ligands, suggesting complexation. As expected the signals for PIP and IP appeared in the range between 7.5 and 9.2 ppm, in agreement with an earlier report [19]. CH_2 groups of the ethylenediamine gave peaks at 2.72 (4H,en-CH_2).

3. Results and discussion

3.1. Absorption spectral studies

The application of electronic absorption spectroscopy is one of the most useful techniques for DNA binding studies [20]. Complex binding with DNA through intercalation usually results in hypochromism and bathochromism, due to the intercalative mode involving a strong stacking interaction between an aromatic chromophore and the base pairs of DNA. The extent of the hypochromism commonly parallels the intercalative binding strength. The absorption spectra of the complexes $[Co(en)_2PIP]^{3+}$ and $[Co(en)_2IP]^{3+}$, in the absence and presence of CT-DNA, are given in Figs. 2 and 3. As the concentration of DNA is increased, it results in hypochromism and a moderate bathochromic shift in the UV spectra of both $[Co(en)_2PIP]^{3+}$ and $[Co(en)_2IP]^{3+}$. According to the data presented in Figs. 2 and 3 it seems that the change in absorption spectra of the two complexes upon addition of DNA follows: $[Co(en)_2PIP]^{3+} > [Co(en)_2IP]^{3+}$. These spectral data may suggest a mode of binding that involves a stacking interaction between the complex and the base pairs of DNA. To compare quantitatively the binding strength of the two complexes, the intrinsic binding constants K of the two complexes with CTDNA were determined according to the following equation [21] through a plot of [DNA]/$(\sum b - \sum f)$ versus [DNA]

$$[\mathrm{DNA}]\Big/\Big(\sum a - \sum f\Big) = [\mathrm{DNA}]\Big/\Big(\sum b - \sum f\Big) + 1\Big/\Big(K\Big(\sum b - \sum f\Big)\Big),$$

where [DNA] is the concentration of DNA in base pairs, the apparent absorption coefficients $\sum a$, $\sum f$ and $\sum b$ correspond to A_{obsd}/[Co], the extinction coefficient for the free cobalt complex and the extinction coefficient for the free cobalt complex in the fully bound form, respectively. In plots of DNA]/$(\sum b - \sum f)$ versus [DNA], K is given by the ratio of the slope to the intercept. Intrinsic binding constants K of $[Co(en)_2PIP]^{3+}$ and $[Co(en)_2IP]^{3+}$ were obtained, the values being $5.34 \pm 0.2 \times 10^4$ and $4.575 \pm 0.3 \times 10^4$ M^{-1}. The binding constants indicate that $[Co(en)_2PIP]^{3+}$ binds more strongly than $[Co(en)_2IP]^{3+}$. This result is expected since PIP possesses a greater planar area and extended π system than that of IP, which would lead to PIP penetrating deeper and stacking more strongly. Hypochromism was indeed observed in the complexes, the order being $[Co(en)_2PIP]^{3+} > [Co(en)_2PIP]^{3+} > [Co(en)_2phen]^{3+}$.

3.2. Fluorescence studies

The complexes $[Co(en)_2PIP]^{3+}$ and $[Co(en)_2IP]^{3+}$ can emit luminescence in Tris buffer (pH 7.0) at ambient temperature with λ maxima at 408 and 407 nm, respectively. Binding of both complexes to DNA was found to increase the fluorescence intensity. The emission spectra of both complexes in the absence and presence of CT DNA are

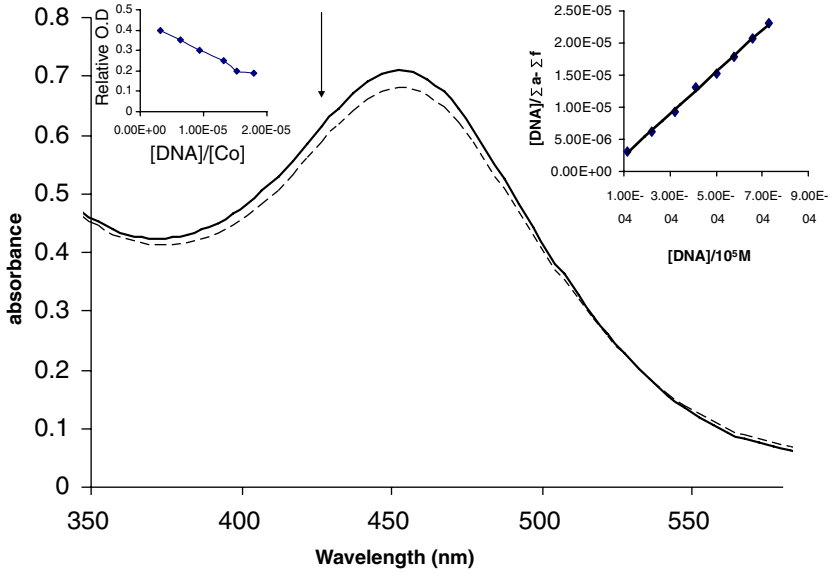

Fig. 2. Absorption spectra of $[Co(en)_2PIP]^{3+}$ (——) in the absence and presence (------) of CT DNA in Tris–HCl buffer; the absorbance changes upon increasing CT DNA concentrations. (10 μl, 20 μl, 30 μl, 40 μl ----- of DNA addition), [Co] = 10 μM, [DNA] = 0–126 μM. The arrow shows the intensity change with increasing DNA concentration. Insert: plots of [DNA]/$(\sum a - \sum f)$ vs. [DNA] for the titration of DNA with the Co(III) complex.

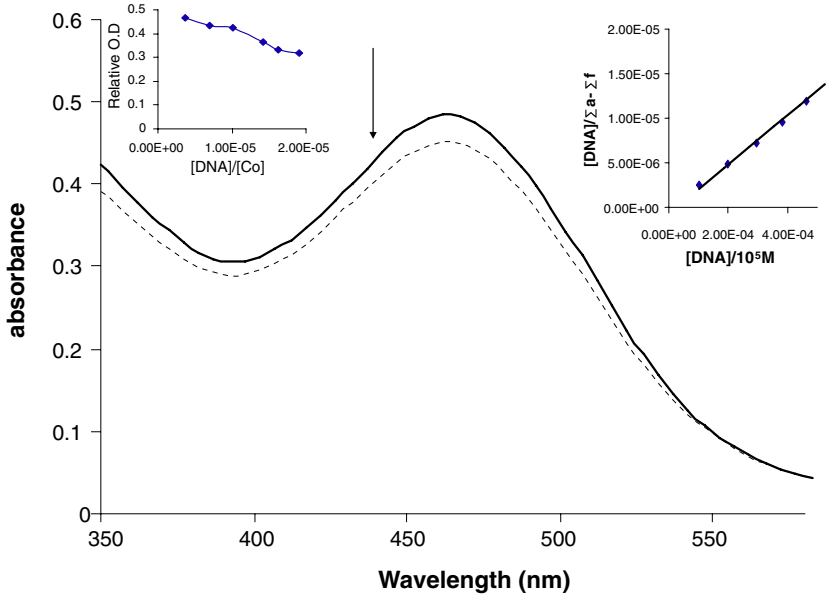

Fig. 3. Absorption spectra of $[Co(en)_2IP]^{3+}$ in the absence (——) and presence (------) of DNA in Tris–HCl buffer. The absorbance changes upon increasing the CT DNA concentration (10 μl, 20 μl, 30 μl, 40 μl ------ of DNA addition), [Co] = 10 μM, [DNA] = 0–126 μM. The arrow shows the intensity change upon increasing the DNA concentration. Insert: plots of $[DNA]/(\sum a - \sum f)$ vs. [DNA] for the titration of DNA with the Co(III) complex.

shown in Figs. 4 and 5. The plots of the relative intensity versus the ratio of [DNA]/[Co] are also indicated in Figs. 4 and 5. Upon addition of CT DNA, the emission intensity increases steadily. The emission intensity difference between absence of CT DNA and presence of CT DNA is greater for the PIP complex than the IP complex, as shown in Figs. 4 and 5. The extent of enhancement increases on going from $[Co(en)_2IP]^{3+}$ to $[Co(en)_2PIP]^{3+}$, which is consistent with the above absorption spectral results. The order of increase in emission intensity of complexes is $[Co(en)_2PIP]^{3+} > [Co(en)_2IP]^{3+} > [Co(en)_2phen]^{3+}$.

This observation is further supported by the emission quenching experiments using $[Fe(CN)_6]^{4-}$ as a quencher. The method essentially consists of titrating a given amount of DNA and DNA binding-metal complexes with an increasing concentration of $[Fe(CN)_6]^{4-}$, and measuring

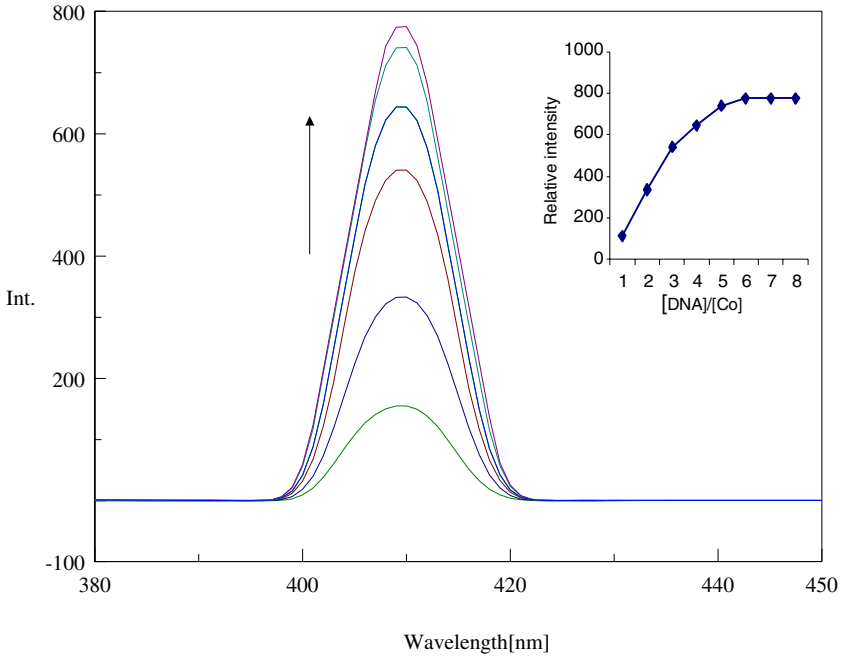

Fig. 4. Emission spectra of complex of $[Co(en)_2PIP]^{3+}$ in aqueous buffer (Tris 5 mM, pH 7.2) at 298 K in the presence of CT DNA, [Co] = 20 μM, [DNA]/[Co] 0, 5, 50, λ_{ex} = 320 nm. The arrow shows the intensity change upon increasing the DNA concentration. Inset: plots of relative integrated emission intensity vs. [DNA]/[Co].

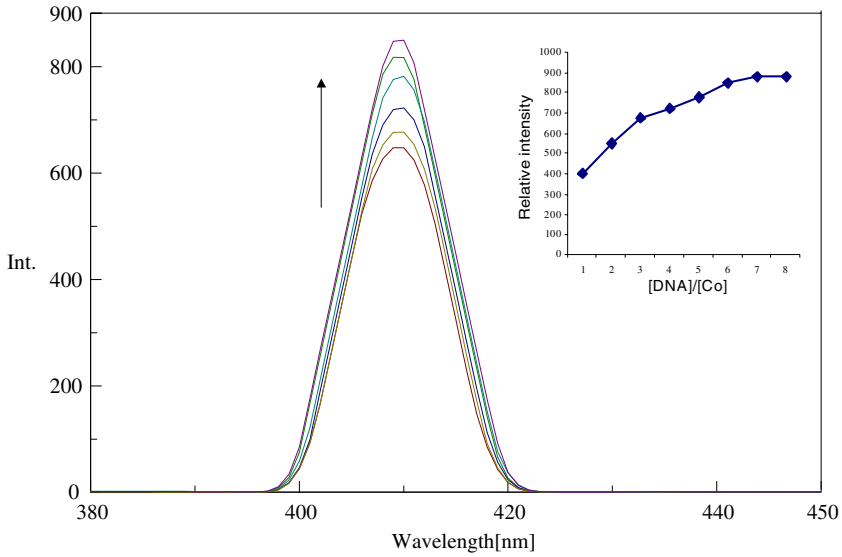

Fig. 5. Emission spectra of complex of $[Co(en)_2IP]^{3+}$ in aqueous buffer (Tris 5 mM, pH 7.2) at 298 K in the presence of CT DNA, [Co] = 20 μM, [DNA]/[Co] 0, 5, 50, λ_{ex} = 320 nm. The arrow shows the intensity change upon increasing the DNA concentration. Insert: plots of relative integrated emission intensity vs. [DNA]/[Co].

the change in fluorescence intensity. The ion $[Fe(CN)_6]^{4-}$ has been shown to be able to distinguish differentially bound cobalt(III) complexes. Positively charged free complex ions would be readily quenched by$[Fe(CN)_6]^{4-}$, whereas a DNA bound complex is protected from the quencher because the highly negatively charged $[Fe(CN)_6]^{4-}$ would be repelled by the negatively charged DNA phosphate backbone, hindering quenching of the bound complex. The ferrocyanide quenching curves for $[Co(en)_2PIP]^{3+}$ and $[Co(en)_2IP]^{3+}$ in the presence and absence of CTDNA are shown in Fig. 6. Obviously the complex $[Co(en)_2PIP]^{3+}$ inserts into DNA much deeper than the complex $[Co(en)_2IP]^{3+}$ Fig. 7.

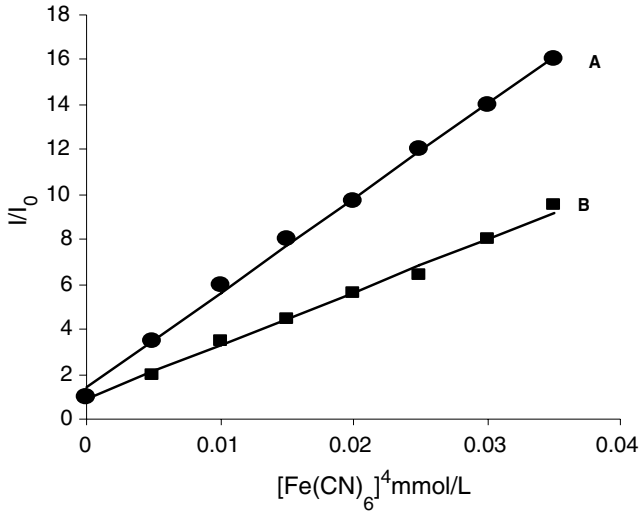

Fig. 6. Emission quenching curves of (A) $[Co(en)_2IP]^{3+}$ (●) and (B) $[Co(en)_2PIP]^{3+}$ (■) in presence of DNA ([Co] = 2 μmol/cm^{-3}, [DNA]/[Co] = 40).

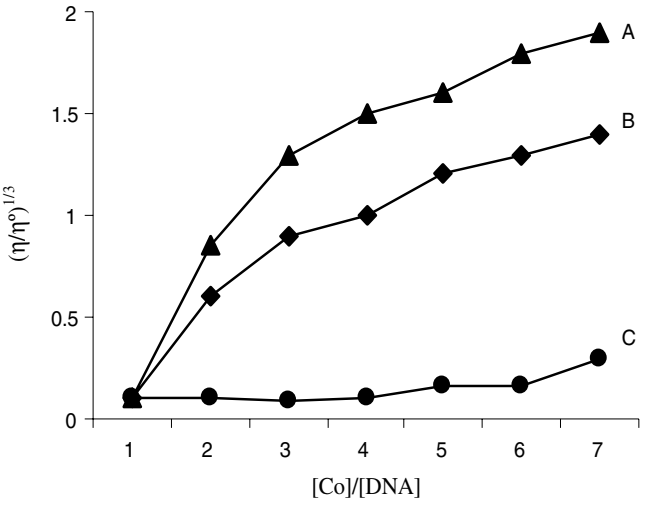

Fig. 7. Effect of increasing the amount of $[Co(en)_2PIP]^{3+}$ (A), $[Co(en)_2IP]^{3+}$ (B) and $[Co(en)_2phen]^{3+}$ (C) on the relative viscosities of CT DNA at 25 ± 0.1 °C.

3.3. Viscosity studies

The mode of the two complexes binding to DNA was explained by viscosity measurements. Optical photo physical probes are necessary, but do not give sufficient clues to support a binding model. Hydrodynamic measurements that are sensitive to length change (i.e. viscosity and sedimentation) are regarded as the least ambiguous [18]. For complexes **2** and **1**, the viscosity of DNA increases greatly with increasing concentration of complex, which is similar to that of the proven intercalator EtBr [22]. Both complexes change the relative viscosity of DNA in a manner consistent with binding by the intercalation mode shown in Fig. 4. This result also parallels the pronounced hypochromism

and spectral red shift and emission enhancement of both complexes, and is comparable with the proven classical intercalator EtBr. The viscosity of DNA increases with the increase of concentration of EtBr. So these two complexes increase the DNA helix length. On the basis of the viscosity results, the complexes bind with DNA through the intercalation mode. The order of increase in viscosity of the complexes follows the order: $[Co(en)_2PIP]^{3+} > [Co(en)_2IP]^{3+} > [Co(en)_2phen]^{3+}$.

3.4. DNA melting studies

Another strong evidence for the binding of the $[Co(en)_2PIP]^{3+}$, $[Co(en)_2IP]^{3+}$ and $[Co(en)_2phen]^{3+}$ complexes to the double helix of DNA is melting temperature T_m. The binding of small molecules into the double helix is known to increase the helix melting temperature. The helix melting temperature is the temperature at which the double helix is denatured into single-stranded DNA. The extinction coefficient of DNA bases at 260 nm in the double-helical form is much less than in the single stranded form. Hence melting of the helix leads to an increase in the absorption at this wavelength. Thus the transition temperature from helix to coil can be determined by monitoring the absorbance of the DNA base at 260 nm as a function of temperature. The melting curves of CT DNA in the absence and presence of $[Co(en)_2PIP]^{3+}$, $[Co(en)_2IP]^{3+}$ and $[Co(en)_2phen]^{3+}$ are presented in Fig. 8. The increase in the melting temperature values of IP and PIP complexes are comparable to the value observed with the classical intercalator EtBr. The values are presented in Table 1. It is clear from these figures that the complexes $[Co(en)_2PIP]^{3+}$ and $[Co(en)_2IP]^{3+}$ are intercalators because the relative absorbance is high compared to that of the pure DNA sample. The increase in absorbance of the complexes follows the order $[Co(en)_2PIP]^{3+} > [Co(en)_2IP]^{3+} > [Co(en)_2phen]^{3+}$.

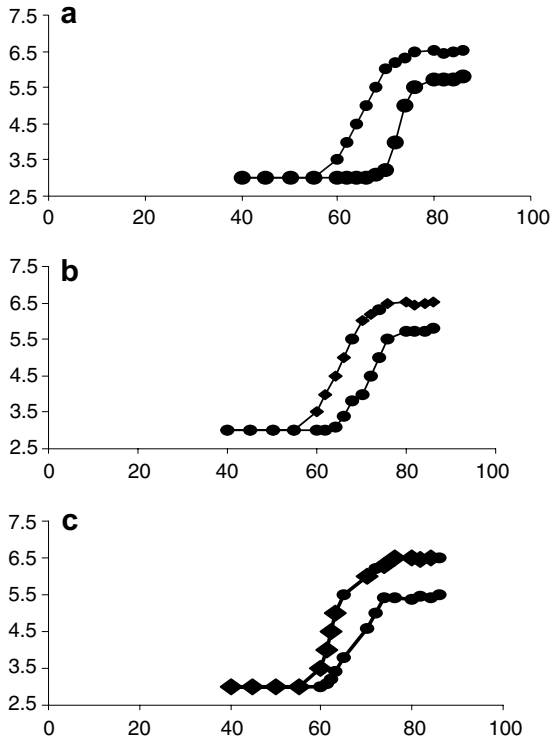

Fig. 8. Thermal melting curves of calf thymus DNA and DNA + Co(III) complexes $[Co(en)_2PIP]^{3+}$ (A), $[Co(en)_2IP]^{3+}$ (B) and $[Co(en)_2phen]^{3+}$ (C).

Table 1
Results of absorption titration and thermal melting experiments

Compound	T_M (°C)
CT DNA	60
$[Co(en)_2phen]^{3+}$	62
$[Co(en)_2IP]^{3+}$	64
$[Co(en)_2PIP]^{3+}$	68

3.5. Photoactivated cleavage of pBR 322 DNA by the Co(III) complexes

There has been considerable interest in DNA endonucleolytic cleavage reactions that are activated by metal ions [23,24]. The delivery of high concentrations of metal ion to the helix, locally generating oxygen or hydroxide radicals, leads to an efficient DNA cleavage reaction. DNA cleavage is monitored by the relation of supercoiled circular pBR 322 (form I) to the nicked circular (form II) and linear (form III) forms. When circular plasimd DNA is subjected to electrophoresis, relatively fast migration will be observed for the supercoiled form (form I). If scission occurs on one strand (nicking), the supercoils will relax to generate a slower-moving open circular form (form II) [25]. If both strands are cleaved, a linear form (form III) will be generated that migrates between forms I and II. Fig. 8 shows the gel electrophoretic separations of plasmid pBR 322 DNA after incubation with Co(III) complexes and irradiation at 302 nm. Fig. 9 reveals the conversion of forms I and II after 60 min irradiation in the presence of varying concentrations of $[Co(en)_2PIP]^{3+}$, $[Co(en)_2IP]^{3+}$ and $[Co(en)_2phen]^{3+}$. It was observed that by increasing the concentration of $[Co(en)_2PIP]^{3+}$, $[Co(en)_2IP]^{3+}$ and $[Co(en)_2phen]^{3+}$ form (I) diminishes gradually. The same has been observed with increasing irradiation time. This is the result of single strand cleavage of pBR322 DNA. It can also be seen in Fig. 8 that neither irradiation of DNA at 302 nm without Co(III) nor incubation with Co(III) without light yields significant strand scission. It is most likely that the reduction of Co(III) is the important step leading to DNA cleavage. Further studies are required to find out the path of the reaction mechanism.

4. Conclusions

The binding behavior of complexes $[Co(en)_2phen]^{3+}$, $[Co(en)_2IP]^{3+}$ and $[Co(en)_2PIP]^{3+}$ with DNA were characterized by absorption titration, fluorescence quenching and viscosity measurements. The results show that the binding

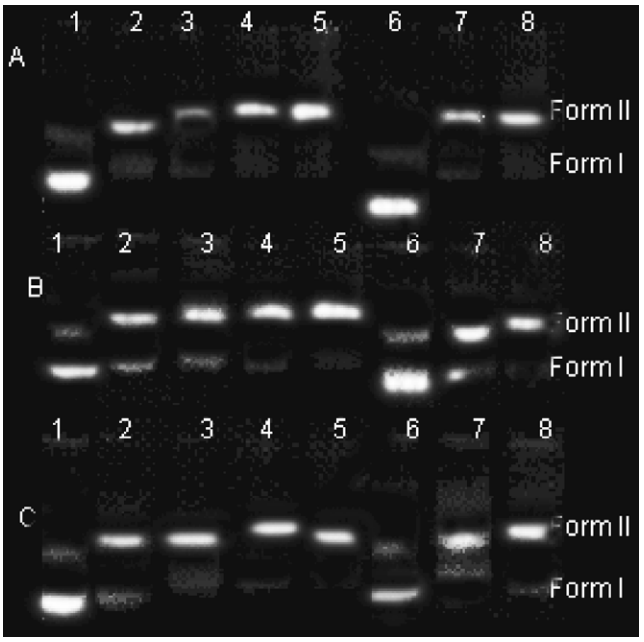

Fig. 9. Photoactivated cleavage of pBR 322 DNA, Lane 1 control plasmid DNA (untreated pBR 322), lanes 2–5 addition of complex 5 μl, 10 μl, 20 μl, 30 μl, and 6th lane +5 μm at 0 time, lanes 7 and 8 +5 μM complex upon irradiation ($\lambda_{irrd} = 302$ nm) at 5 min and 10 min. Complex (A) $[Co(en)_2phen]^{3+}$, (B) $[Co(en)_2IP]^{3+}$ and (C) $[Co(en)_2PIP]^{3+}$.

constants followed the order: $[Co(en)_2PIP]^{3+} > [Co(en)_2PIP]^{3+} > [Co(en)_2phen]^{3+}$, indicating that the PIP ligand, with its large planar surface, is a better intercalating ligand than IP and phen, which interact by electrostatic interactions only.

Cl^-, N_3^-, NCS^-). In this study, it was observed that the ligand field strengths and redox potentials for the axial ligands reflect the normal spectrochemical series. To date, however, only a few cobalt(III) tetraaza macrocyclic complexes have been isolated and structurally characterized by X-ray crystallography [15–20]. For example, the cyclam and modified cyclam cobalt(III) complexes *trans*-$[Co(cyclam)Cl_2]\,Cl \cdot 4H_2O \cdot 0.47HCl$ [17] and $[Co(H_2ddta)Cl_2](ClO_4)_3 \cdot 2H_2O$ [18] exhibit a low-spin octahedral geometry with four secondary amines of the macrocycle and two axial chloride ligands. However, the coordination environment of $[Co(ddta)](ClO_4)_3$ [18] shows a distorted octahedron with four secondary amines and two pendant amines at the axial positions, in which the maxima in the electronic spectrum is shifted towards higher energy and the redox couple is shifted to a more negative value as compared to $[Co(H_2ddta)Cl_2](ClO_4)_3 \cdot 2H_2O$.

In this paper, we report the synthesis and characterization of $[Co(L)(int)_2]Cl \cdot 3H_2O$ (**1**), $[Co(L)(NCS)_2]NCS \cdot H_2O$ (**2**), $[Co(L)(NCO)_2]NCO \cdot H_2O$ (**3**) (L = 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1.18}$,$0^{7.12}$]docosane, int = isonicotinate). To evaluate the effect of the axial groups, we have investigated the X-ray crystal structures, spectroscopic and electrochemical properties of these complexes.

2. Experimental

2.1. Materials and physical methods

All chemicals used in syntheses were of reagent grade and were used without further purification. The macrocycle 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1.18}$,$0^{7.12}$]-docosane (L) and $[Co(L)Cl_2]Cl \cdot 4H_2O$ were prepared according to the literature methods [20,21]. Infrared spectra were recorded as KBr pellets on a Perkin–Elmer Paragon 1000 FT-IR spectrometer. Solution electronic spectra were obtained on a Jasco Uvidec 610 spectrophotometer. Solid-state spectra were measured by the diffuse reflectance method on a Shimadzu UV2401 PC/DRS spectrophotometer. Elemental analyses (C, H, N) were performed on a Perkin–Elmer CHN-2400 analyzer. Electrochemical measurements were accomplished with a three-electrode potentiostat BAS-100BW system. A hanging mercury dropping electrode was used as the working electrode. The counter electrode was a coiled Pt wire and a Ag/AgCl electrode was used as a reference electrode. Cyclic voltammetric data were obtained in DMSO solution with 0.10 M Et_4NClO_4 (TEAP) as the supporting electrolyte at 20.0 ± 0.1 °C. The solution was degassed with high purity N_2 prior to carrying out the electrochemical measurements.

2.2. Syntheses of $[Co(L)(int)_2]Cl \cdot 3H_2O$ (1)

To a methanol solution (20 ml) of $[Co(L)Cl_2]Cl \cdot 4H_2O$ (287 mg, 0.5 mmol) was added sodium isonicotinate (145 mg, 1.0 mmol). The mixture was heated to reflux for 1 h and then the color of the solution changed from green to red. The solution was filtered and left at room temperature until red crystals formed. The product was recrystallized from a hot water/acetonitrile (1:1 v/v, 10 ml) mixture. Yield: 73%. *Anal.* Calc. for $C_{32}H_{54}ClCoN_6O_7$: C, 52.71; H, 7.46; N, 11.53. Found: C, 52.63; H, 7.54; N, 11.61%. IR (KBr, cm^{-1}): 3397(s), 3134(m), 3058(m), 2942(m), 2864(m), 1606(s), 1553(s), 1508(w), 1448(w), 1433(w), 1404(m), 1390(m), 1352(s), 1315(m), 1285(w), 1224(w), 1133(m), 1116(m), 1105(m), 1055(m), 1012(m), 998(w), 911(w), 850(w), 846(w), 763(m), 709(m), 695(s), 615(w), 556(w).

2.3. Syntheses of $[Co(L)(NCS)_2]NCS \cdot H_2O$ (2)

This compound was synthesized as red crystals in a reaction similar to that of **1**, except for the use of excess KNCS instead of sodium isonicotinate. The product was recrystallized from a hot water/acetonitrile (1:1 v/v, 10 ml) mixture. Yield: 78%. *Anal.* Calc. for $C_{23}H_{42}CoN_7OS_3$: C, 47.00; H, 7.20; N, 16.68. Found: C, 47.12; H, 7.28; N, 16.56%. IR (KBr, cm^{-1}): 3421(w), 3176(s), 2948(m), 2116(s), 2062(s), 1621(w), 1448(m), 1427(m), 1388(w), 1363(w), 1341(w), 1304(m), 1279(w), 1219(w), 1172(w), 1155(w), 1093(s), 1070(m), 1048(m), 1011(m), 975(m), 906(m), 850(w), 840(w), 798(w), 664(w), 611(w), 555(w).

2.4. Syntheses of $[Co(L)(NCO)_2]NCO \cdot H_2O$ (3)

The red complex was prepared by a method similar to that for **1**, except that excess NaNCO was used instead of sodium isonicotinate. The solid was recrystallized from a hot water/acetonitrile (1:1 v/v, 10 ml) mixture, but unfortunately crystals suitable for X-ray analysis were not obtained. Yield: 67%. *Anal.* Calc. for $C_{23}H_{42}CoN_7O_4$: C, 51.20; H, 7.85; N, 18.17. Found: C, 51.31; H, 7.74; N, 18.06%. IR (KBr, cm^{-1}): 3422(m), 3204(m), 2940(m), 2264(s), 2162(w), 1623(m), 1449(m), 1434(m), 1391(w), 1368(w), 1338(m), 1308(w), 1226(w), 1176(w), 1097(s), 1073(m), 1051(w), 1013(w), 976(m), 909(m), 852(w), 792(w), 662(w), 606(w), 556(w).

2.5. X-ray crystal structure analysis

Intensity data for compounds **1** and **2** were measured on a Bruker SMART 1000 CCD diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Accurate cell parameters and an orientation matrix were determined by the least-squares fit of 25 reflections. The intensity data were collected by the ω–2θ technique and corrected for Lorentz and polarization effects. An empirical absorption correction was applied with the SADABS program [22]. The structure was solved by direct methods [23] and the least-squares refinement of the structure was performed by the SHELXL-97 program [24]. For **1**, all atoms except all hydrogen atoms and Ow(3) were refined anisotropically.

Hydrogen atoms were placed in calculated positions, allowing them to ride on their parent C atoms with $U_{iso}(H) = 1.2U_{eq}$(C or N). The hydrogen atoms of Ow(3) were not found. For **2**, the hydrogen atoms of Ow(1) were not found. Crystal parameters and details of the data collections and refinement are summarized in Table 1.

3. Results and discussion

3.1. Crystal structures

An ORTEP drawing of $[Co(L)(int)_2]Cl \cdot 3H_2O$ (**1**) with the atomic numbering scheme is shown in Fig. 1 and selected bond lengths and angles are listed in Table 2. The ligand skeleton of the present compound takes the *trans*-III(*R*,*R*,*S*,*S*) configuration with two chair six-membered and two gauche five-membered chelate rings. The structure of **1** shows that the cobalt(III) ion is coordinated by the secondary amines of the macrocycle and that the axial positions are bonded by the two carboxylate oxygen atoms of the isonicotinate ligands, which is a distorted octahedral environment. The average Co–N (secondary amine) distance of 1.990(2) Å is similar to that found in *cis*-$[Co(cyclam)(en)]Cl_3 \cdot 3H_2O$ [1.996(2) Å] [16] and $[Co(L)Cl_2]Cl \cdot 4H_2O$ [1.999(2) Å] [20]. The N–Co–N angles

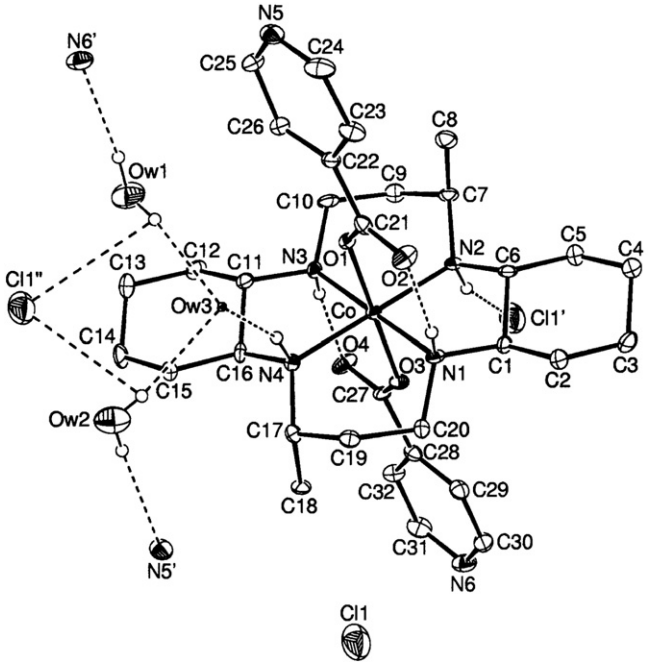

Fig. 1. An ORTEP diagram of $[Co(L)(int)_2]Cl \cdot 3H_2O$ (**1**) with the atom-numbering scheme (30% probability ellipsoids shown). The hydrogen bonds are indicated by dotted lines. The hydrogen atoms except for water molecules are omitted for clarity.

O(4)–C(27)–C(28)	118.1(4)		

of the six-membered chelate rings are larger than those of the five-membered chelate rings. The dihedral angle (α) between the plane of the carboxylate group and CoN_4 plane is 86.7(4)°. The axial Co–O bonds are not perfectly perpendicular to the CoN_4 plane with the O–Co–N angles ranging from 85.4(2)° to 94.7(2)°. Interestingly, the secondary amines of the macrocycle are hydrogen bonded to the uncoordinated carboxylate oxygen atoms of the isonicotinate [$N(1)\cdots O(2)^{ii}$ 2.717(6) Å, 154.9°; $N(3)\cdots O(4)^{ii}$ 2.726(6) Å, 156.1°; symmetry code: ii: x, y, z], chloride anion [$N(2)\cdots Cl(1)^{iii}$ 3.197(4) Å, 161.9°; symmetry code: iii: x, y, $z+1$] and the water molecule [$N(4)\cdots Ow(3)^{ii}$ 3.256(4) Å, 161.5°]. Furthermore, the water molecules found in the lattice also form hydrogen bonds with the nitrogen atoms of the isonicotinate [$Ow(1)\cdots N(6)^{iv}$ 3.042(7) Å, 151(5)°; $Ow(2)\cdots N(5)^{v}$ 3.066(7) Å, 160(5)°; symmetry codes: iv: $x+1$, $y+1$, $z-1$; v: x, $y-1$, z], with the chloride anion [$Ow(1)\cdots Cl(1)^{i}$ 3.028(6) Å; $Ow(2)\cdots Cl(1)^{i}$ 3.153(6) Å] and with other water inclusions [$Ow(1)\cdots Ow(3)^{ii}$ 3.228(6) Å, 166(4)°; $Ow(2)\cdots Ow(3)^{ii}$ 3.016(6) Å, 172(6)°; $Ow(3)\cdots Ow(2)^{ii}$ 3.016(6) Å; $Ow(3)\cdots Ow(1)^{ii}$ 3.228(6) Å].

An ORTEP drawing of $[Co(L)(NCS)_2]NCS \cdot H_2O$ (**2**) with the atomic numbering scheme is shown in Fig. 2 and selected bond lengths and angles are listed in Table 3. The structure of **2** consists of a $[Co(L)(NCS)_2]^+$ cation, one NCS^- anion and a water molecule. The crystal structure of **2** confirms a six-coordinated octahedral geometry with bonds from the cobalt(III) ion to the secondary amines of the macrocycle and to the two axial thiocyanate ligands. The average Co–N (secondary amines) distance of 1.999(3) Å is significantly longer than the average axial Co–N (thiocyanate) distance [1.886(4) Å], which is similar to that observed for complex **1**. The Co–N (thiocyanate) linkages are bent slightly off perpendicular to the CoN_4 plane by 0.3–2.9°. The two Co–N–C and N–C–S angles coordinated to the thiocynate ligands are 171.4(5)–171.6(5)° and 175.1(10)–177.1(6)°, respectively.

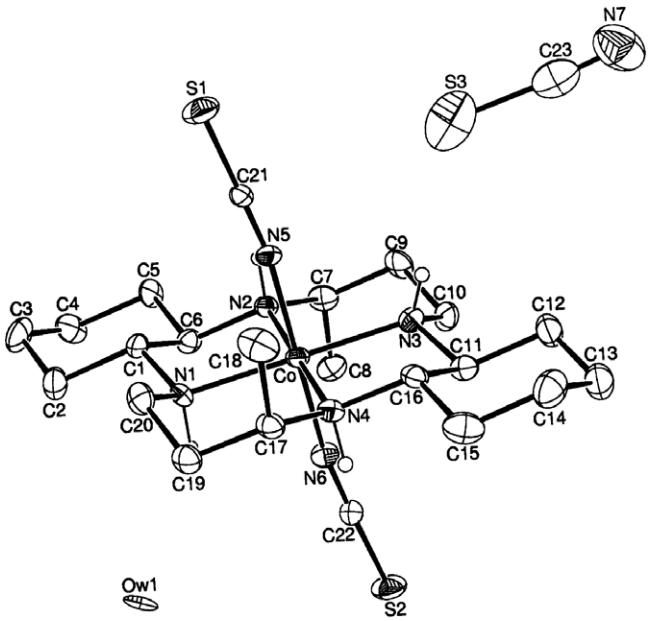

Fig. 2. An ORTEP diagram of $[Co(L)(NCS)_2]NCS \cdot H_2O$ (**2**) with the atom-numbering scheme (30% probability ellipsoids shown). The hydrogen atoms are omitted for clarity.

3.2. Characterization of the complexes

The infrared spectra of these complexes show bands at 3200–3212 cm^{-1}, which are assigned to ν(NH) of the coordinated secondary amines of the macrocycle. That the spectrum of **1** contains two strong ν(COO) bands at 1606 and 1553 cm^{-1} is consistent with the coordinated isonicotinate ligand. Two strong bands at 2116 and 2062 cm^{-1} in **2** are assigned to ν(NCS) stretching of the lattice and coordinated thiocyanate ligands, which are in agreement with

the crystal structure of **2**. For **3** the IR data are in accordance with a N-bonded isocyanato structure, as a strong band at 2264 cm^{-1} is characteristic of Co–N bonding [25]. The spectroscopic data of the complexes are listed in Table 4. The electronic spectra of these complexes in DMSO and in the solid state show bands in the regions 258–264 and 543–583 nm and are attributed to intraligand charge transfer ($n \rightarrow \pi^*$) and d–d transition ($^1A_{1g} \rightarrow {}^1T_{2g}$), respectively, in a low spin d^6 octahedral symmetry [26]. However, the wavelength of the d–d bands of the complexes **1**–**3** is somewhat shorter than that of $[Co(L)Cl_2]\cdot 4H_2O$ [20] in spite of the similar average Co–N(secondary amines) bond distance. Furthermore, the wavelengths of the d–d bands of the complexes increase toward higher energies in the order **1** < **2** < **3**, which is reasonably explained by the spectrochemical series. It was previously observed for cobalt(III) complexes with a tetraaza macrocycle containing various axial ligands that the spectra are affected by the type of the axial ligand [15].

Cyclic voltammetric data for the cobalt(III) complexes in 0.10 M TEAP–DMSO solution are given in Table 5 along with the other macrocyclic cobalt(III) complexes. A typical cyclic voltammogram of **1** is shown in Fig. 3. The complexes exhibit a one-electron wave corresponding to the Co(III)/Co(II) process. It is of interest to compare the redox potentials for the $[Co(L)X_2]^+$ complexes with axial ligands. The reduction potentials for these complexes are considerably more negative than that of *trans*-$[Co(L)Cl_2]Cl\cdot 4H_2O$ [20], indicating that these complexes make reduction more difficult. The reduction potentials of these complexes decrease with the axial ligands in the order **3** > **2** > **1**. That is, the type of axial ligand significantly affects the electrochemical properties of the Co(III) complexes. The above results, together with the crystal structures and spectroscopic data, clearly show that the axial groups of the Co(III) complexes are coordinated to the metal(III) ion.

been rarely reported [9]. Our group is interested in the supramolecular coordination chemistry of lanthanide ions with amide-based open-chain crown ethers that have strong coordination capability to the lanthanide ions and terminal group effects [10]. So we have designed a series of multi-functional amide-based open-chain crown ethers having the ability to coordinate lanthanide ions and thus enhance luminescence of lanthanide complexes by providing chromophores suitable for energy transfer, i.e., aryl substitutes.

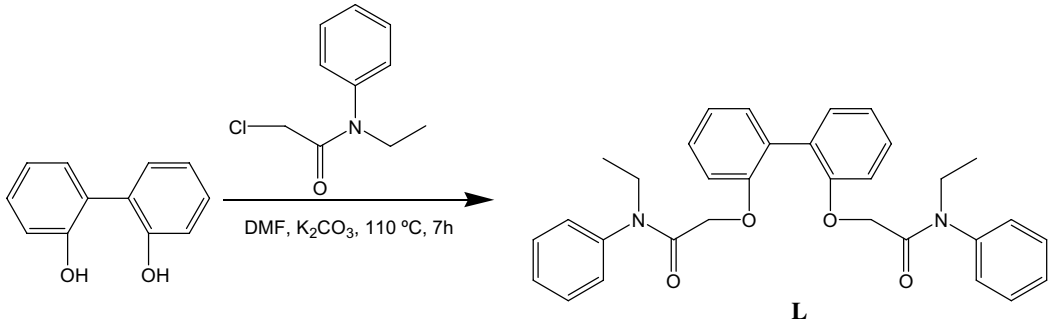
In this work, we introduced biphenyl groups as the basic molecular frame and obtained a new open-chain crown ether ligand, *N*-phenyl-2-{2′-[(phenyl-ethyl-carbamoyl)-methoxy]-biphenyl-2-yloxy}-*N*-ethyl-acetamide (**L**), and reported the synthesis, luminescent properties of lanthanide complexes with the new ligand and the supramolecular structures of $La(pic)_3L$ and $2[La(NO_3)_3L(H_2O)]\cdot H_2O\cdot 0.5C_2H_5OH$. The results indicate that under excitation, the Eu(III) picrate complex had strong characteristic luminescence whereas the terbium picrate complex showed no luminescence. The lowest triplet state energy level of the ligand in the picrate complex which was calculated from the phosphorescence spectrum of the Gd(III) picrate complex at 77 K, and indicates that the triplet state energy level of the ligand matches better to the resonance level of Eu(III) than Tb(III) ion. The Eu(III) nitrate complex exhibited quite weak characteristic emissions. The $La(Pic)_3L$ crystal structure shows that the La(III) ion could be effectively encapsulated and protected by the coordinated ligand. Furthermore, the $La(Pic)_3L$ complex units are linked by the significant intermolecular π–π interactions between coordinate picrates to form a one-dimensional (1-D) supramolecular zigzag chain. The $2[La(NO_3)_3L(H_2O)]\cdot H_2O\cdot 0.5C_2H_5OH$ crystal structure shows that **L** gives two different arrangements around La(III) ions, and induces axial chirality directed by metal ions in the self-assembly process. Each La(III) ion is coordinated with four oxygen atoms from the ligand **L**, six oxygen atoms from three bidentate nitrate groups and one coordinate water molecule. Furthermore, the $[La(NO_3)_3L(H_2O)]$ complex units are linked by the intermolecular hydrogen bonds and π–π interaction to form a three-dimensional (3-D) netlike supramolecule.

2. Experimental

2.1. Materials

Lanthanide picrate [11] and *N*-ethyl-*N*-phenylchloroacetamide [12] were prepared according to the literature methods. All commercially available chemicals were of A.R. grade and were used without further purification.

2.2. Methods



The metal ions were determined by EDTA titration using xylenal orange as indicator. C, H and N were determined using an Elementar Vario EL. Conductivity measurements were carried out with a DDS-307 type conductivity bridge using 10^{-3} mol dm^{-3} solutions at 25 °C. IR spectra were recorded on Nicolet FT-170SX instrument using KBr discs in the 400–4000 cm^{-1} region, ^{1}H NMR spectra were measured on a Varian Mercury plus 300 M spectrometer in $CDCl_3$ solution with TMS as internal standard. Fluorescence and phosphorescence measurements were made on a Hitachi F-4500 spectrophotometer. Mass spectra were obtained on a VG-ZAB-HS mass spectrometer.

2.3. Synthesis of the ligand

The synthetic route for the ligand is shown in Scheme 1. Anhydrous K_2CO_3 (5.6 g, 41 mmol) was added into the 15 mL DMF solution of 2,2′-dihydroxybiphenyl (1.86 g, 10 mmol) at 100 °C. After 1 h, a solution of *N*-ethyl-*N*-phenylchloroacetamide (5.92 g, 30 mmol) in 10 mL DMF was added dropwise to the mixture and maintained at 110 °C for 7 h. When cool, distilled water (60 ml) was added and the turbid solution was extracted with chloroform (3×40 mL). The combined organic phases were washed with water and dried with anhydrous Na_2SO_4. The solvent was removed and the residue was chromatographed to afford the ligand **L**; yield: 85%.

2.4. Synthesis of the lanthanide picrate complexes

To a solution of 0.2 mmol lanthanide picrate in 5 ml of ethanol was added dropwise the solution of 0.2 mmol **L** in

Scheme 1. The synthetic route for the ligand **L**.

10 ml of ethanol. The mixture was stirred at room temperature for 5 h. The precipitated solid complex was filtered, washed with ethanol and dried in vacuum over P_2O_5 for 48 h. All the complexes were obtained as yellow powders in a yield of 80–85%. Slowly evaporating a solution of the lanthanum complex in $CHCl_3/CH_3CH_2OH$ at room temperature, resulted in the formation of block crystals after 2 weeks.

2.5. Synthesis of the lanthanide nitrate complex

To a solution of 0.2 mmol lanthanide lanthanide nitrate in 5 ml of ethanol was added dropwise the solution of 0.2 mmol **L** in 10 ml of ethanol. The mixture was stirred at room temperature for 10 h and a clear solution obtained. The clear solution of lanthanum nitrate complex was filtered and left to crystallise. After about a month, a colorless crystal formed from the solution. After solvent evaporation from the solution of europium nitrate complex in vacuum, a white precipitate obtained, washed with little ethanol and dried in vacuum over P_2O_5 for 72 h.

2.6. Crystal structure determination

X-ray diffraction data of $La(pic)_3L$ and $2[La(NO_3)_3L(H_2O)]\cdot H_2O\cdot 0.5C_2H_5OH$ were collected on a Bruker Smart-1000 CCD area detector diffractometer, using graphite-monochromatized Mo Kα ($\lambda = 0.71073$ Å) at 298(2) K. The structures were solved by direct method and refined by full matrix least-squares techniques on F^2 with all non-hydrogen atoms treated anisotropically. All calculations were performed with the program package SHELXTL. The hydrogen atoms were assigned with common isotropic displacement factors and included in the final refinement by using geometrical restrains.

3. Results and discussion

3.1. Properties of the complexes

Analytical data for the complexes, listed in Table 1, indicate that the seven complexes of rare earth picrates and europium nitrate conform to a 1:1 metal-to-ligand stoichiometry $Ln(pic)_3L$ and $Eu(NO_3)_3L$. All the picrate complexes are soluble in DMF, DMSO, acetonitrile, acetone and $CHCl_3$, but slightly soluble in ethanol. The molar conductances of the picrate complexes in acetone and $Eu(NO_3)_3L$ in DMF (see Table 1) indicate that all the picrate complexes and $Eu(NO_3)_3L$ act as non-electrolytes [13], implying that all the picrate groups and nitrate groups are in the coordination sphere.

3.2. Crystal structure of $La(Pic)_3L$

A summary of crystallographic data and details of the structure refinements are listed in Table 2. The selected bond lengths and bond angles are given in Table 3.

The single-crystal X-ray analysis of the complex $La(Pic)_3L$ reveals that the La(III) ion is coordinated with 10 oxygen donor atoms, six of which belong to three bidentate picrate groups and the remaining four to the tetradentate ligand **L** (Fig. 1). The coordination polyhedron around La(III) ion is a distorted bicapped square antiprism (Fig. 2). The two phenyl rings about the central bond in the molecule have a drastic twisting, with the dihedral angle between them being 62.49°. The La—O (C=O) distances (mean 2.461 Å) are significantly shorter than the La–O (C–O–C) distances (mean 2.701 Å). This suggests that the La—O (C=O) bond is stronger than the La–O (C–O–C) bond.

In the complex, the requirement of high coordination number of the lanthanide ion is satisfied by the tetradentate ligand and three bidentate picrate groups. Due to the space obstacle of coordinated picrates, no coordinated solvent molecules exist in the complex, which can efficiently quench lanthanide luminescence, this is important in the design of supramolecular photonic devices.

Interestingly, the complex has significant intermolecular π–π interaction [14] between two picrates of one complex molecule and equivalent picrates of the adjacent molecules with the dihedral angles between them being 0° and 0°, and the distances between their centroids being 3.774, 4.019 Å, respectively, thus, producing a one-dimensional (1-D) supramolecular zigzag chain (Fig. 3).

3.3. Crystal structure of $2[La(NO_3)_3L(H_2O)]\cdot H_2O\cdot 0.5C_2H_5OH$

A summary of crystallographic data and details of the structure refinements are listed in Table 2. The selected bond lengths and bond angles are given in Table 4.

The $2[La(NO_3)_3L(H_2O)] \cdot H_2O \cdot 0.5C_2H_5OH$ crystal structure reveals that there are two independent molecules in the unit cell. Each La(III) ion is coordinated with 11 oxygen donor atoms. Six of them belong to three bidentate nitrate groups, one of them belongs to one coordinate water molecule, and the remaining four are from the tetradentate ligand **L** (Fig. 4). Upon coordination, **L** gives two different arrangements (A and B) around La(III) ions in the unit cell. In structure A, the two phenyl rings about the central bond in the molecule have a drastic twisting, with the dihedral angle between them being 56.75°. Again, the La(1)—O (C=O) distances (mean 2.512 Å) are shorter than the La–O (C–O–C) distances (mean 2.764 Å), suggesting that La—O (C=O) bond is stronger than the La–O (C–O–C) bond. The same situation occurs in structure B, where the dihedral angle between the two phenyl rings in the molecule is 58.61°, the average distance between La(2) atom and oxygen atoms (C=O) is 2.525 Å and the average distance between La(2) and oxygen atoms (C–O–C) is 2.781 Å. It is interesting that the free ligand is achiral, but upon metal coordination, it induces axial chirality. As shown in Fig. 4, the ligand exhibits (*S*) configuration in structure A and (*R*) configuration in structure B in the unit cell, which is contributed to the metal-directed self-assembly process of the ligands with the metal ions [15].

In structure A, atom O(14) acts as hydrogen bond donor to form O–H···O with the oxygen atom O(12) of the adjacent equivalent molecule [O(12)···H(68), 2.268 Å and O(14)–H(68)···O(12), 144.34°], thus, generating a one-dimensional (1-D) supramolecular zigzag chain along the b axis as shown in Fig. 5a.

In structure B, atom C(51) acts as hydrogen bond donor to form C–H···O with the oxygen atom O(22) of the adjacent equivalent molecule [O(22)···H(51), 2.604 Å and C(51)–H(51)···O(22), 134.33°] [16], thus, generating a dimer as shown in Fig. 5(b); furthermore, the dimeric blocks are linked by the intermolecular hydrogen bond O(28)–H(70)···O(26) [O(26)···H(70), 2.222 Å and O(28)–H(70)···O(26), 150.84°] to form a two-dimensional (2-D) supramolecular layer with hydrogen bonded channels as shown in Fig. 5c and d.

In addition, intermolecular π–π interaction [14] between one phenyl ring of one ligand frame from one chain and another phenyl ring of the adjacent ligand frame from the adjacent layer with the dihedral angle between them being 6.01° and the distance between their centroids being

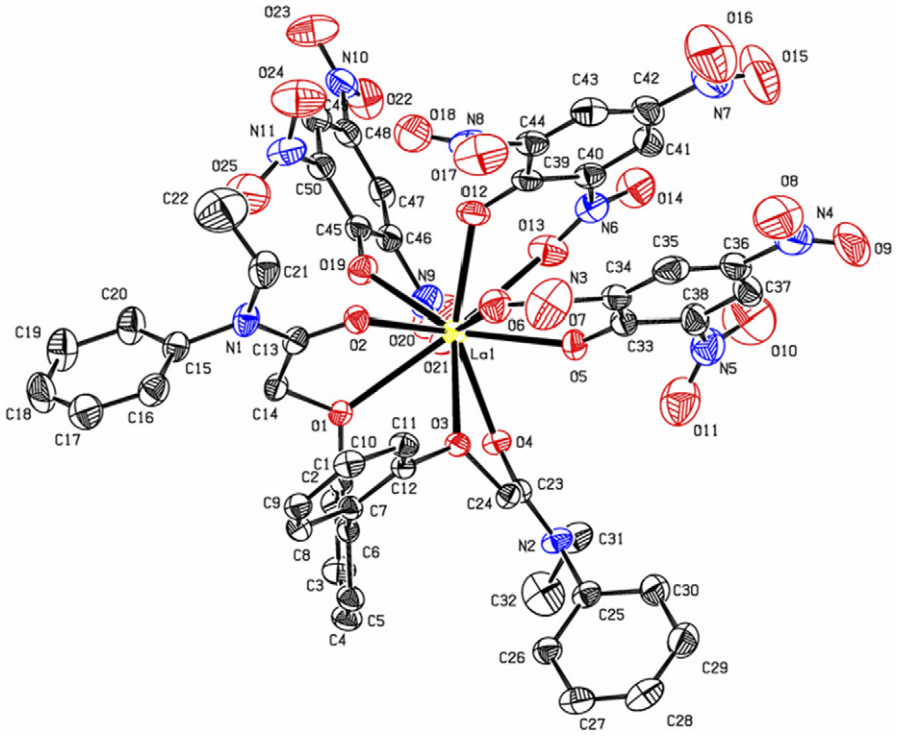

Fig. 1. ORTEP diagram (30% probability ellipsoids) showing the coordination sphere of [La(pic)$_3$L]. Hydrogen atoms are omitted for clarity.

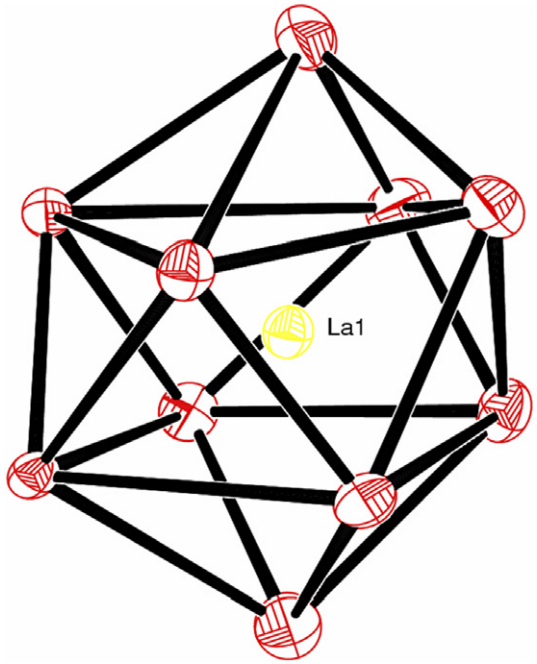

Fig. 2. Coordination polyhedron of La(III) ion in La(pic)$_3$L.

4.058 Å, further produce a three-dimensional (3-D) netlike supramolecule as shown in Fig. 6.

3.4. IR spectra

The main infrared bands of the ligand and their complexes are presented in Tables 5 and 6. The "free" ligand **L** exhibits two absorption bands at 1676 and 1126 cm^{-1} which are assigned to ν(C=O) and ν(C–O–C), respectively.

In picrate complexes, the ν(C=O) and ν(C–O–C) of the free ligand shift by ca. 57 and 46 cm^{-1} towards lower wave numbers, thus indicating that the C=O and ether O-atoms take part in coordination to the metal ions.

The OH out-of-plane bending vibration of the free Hpic at 1151 cm^{-1} disappears in the spectra of the complexes indicating that the H atom of the OH group is replaced by Ln(III) ions. The vibration ν(C–O) at 1265 cm^{-1} is shifted towards higher frequency by ca. 10 cm^{-1} in the complexes. This is due to the following two effects. First, the hydrogen atom of the OH group is replaced by Ln(III), increasing the π-bond character in the C–O bond. Secondly, coordination of the oxygen atom of **L** to Ln(III) causes the π-character to be weakened [10b]. The free Hpic has $\nu_{as}(NO_2)$ and $\nu_s(NO_2)$ at 1555 and 1342 cm^{-1}, respectively, which splits into two bands at 1584, 1545 cm^{-1} and 1352, 1331 cm^{-1} in the complexes. This indicates that some of the O-atoms in the nitro group of Pic$^-$ take part in coordination [17]. On the basis of the similarity of their IR spectra, it may be assumed that the picrate complexes have the similar structures.

In the europium nitrate complex, the ν(C=O) and ν(C–O–C) of the free ligand shift by ca. 50 and 54 cm^{-1} towards lower wave numbers, thus indicating that all the C=O and ether O atoms take part in coordination to the metal ion. The absorption bands assigned to the coordinated nitrate groups (C_{2v}) are observed at about 1495 cm^{-1} (ν_1), 1308 cm^{-1} (ν_4), 1030 cm^{-1} (ν_2) and 815 cm^{-1}(ν_3) [18] for the nitrate complex. In addition, the separation of the

O(4)–La(1)–O(2)	60.9(2)	O(18)–La(2)–O(16)	61.5(2)

two strongest frequencies $|\nu_1-\nu_4|$ is approximately 187 cm^{-1}, clearly establishing that the NO_3^- groups in the solid complex coordinate to the rare earth ion as bidentate ligands [19]. Also no bands at 1380, 820 and 720 cm^{-1} in the spectrum of complex indicates that free nitrate groups (D_{3h}) are absent, in agreement with the result of the conductivity experiment.

3.5. ^1H NMR spectra and mass spectra

L: ^1H NMR ($CDCl_3$): δ 7.34–7.18(m, 10H, ArH and $C_{12}H_8$–), 7.07(q, $J = 7.8$ Hz, 4H, ArH), 6.96(t, $J = 7.5$ Hz, 2H, ArH), 6.73(d, $J = 7.8$ Hz, 2H, ArH), 4.21(s, 4H, –O–CH_2–CO–), 3.71(q, $J = 7.2$ Hz, 4H, –N–CH_2–), 1.08(t, $J = 7.2$ Hz, 6H, –CH_3).

$[La(pic)_3\cdot L]$: ^1H NMR ($CDCl_3$): δ8.94(s, 6H, pic-), 7.39–7.07(m, 18H, ArH and $C_{12}H_8$–), 4.45(d, $J = 14.7$ Hz, 2H, –O–CH_2–CO–), 4.09(d, $J = 14.7$ Hz, 2H, –O–CH_2–CO–), 3.51(q, $J = 6.9$ Hz, 4H, –N–CH_2–), 0.91(t, $J = 6.9$ Hz, 6H, –CH_3).

$[Y(pic)_3\cdot L]$: ^1H NMR ($CDCl_3$): δ8.84(s, 6H, pic-), 7.42–7.19(m, 18H, ArH and $C_{12}H_8$–), 4.80(d, $J = 15.3$ Hz, 2H, –O–CH_2–CO–), 4.11(d, $J = 15.3$ Hz, 2H, –O–CH_2–CO–), 3.51(q, $J = 6.9$ Hz, 4H, –N–CH_2–), 0.91(t, $J = 6.9$ Hz, 6H, –CH_3).

The ^1H NMR spectra of the "free" ligand **L**, the diamagnetic Ln(III) picrate complexes $La(Pic)_3L$ and $Y(Pic)_3L$ were measured in $CDCl_3$. The spectrum of **L** exhibits a multiplet at ca. 7.26 ppm, a quadruplet at 7.07 ppm ($J = 7.8$ Hz), a triplet at 6.96 ppm ($J = 7.5$ Hz) and a doublet at 6.73 ppm ($J = 7.8$ Hz) assigned to $C_{12}H_8$– and –C_6H_5 protons, a singlet at 4.21 ppm, a quadruplet at 3.71 ppm ($J = 7.2$ Hz), and a triplet at 1.08 ppm ($J = 7.2$ Hz) assigned to –O–CH_2–CO– protons, –N–CH_2– protons, –CH_3 protons, respectively.

Upon coordination, the proton signal of –O–CH_2–CO– in the lanthanum and yttrium complexes split into two doublets at 4.45 ppm ($J = 14.7$ Hz), 4.09 ppm ($J = 14.7$ Hz) and 4.80 ppm ($J = 15.3$ Hz), 4.11 ppm ($J = 15.3$ Hz), respectively. The signal of –N–CH_2– and –CH_3 are shifted to higher field by 0.20 and 0.17 ppm, respectively. The reason is not clear.

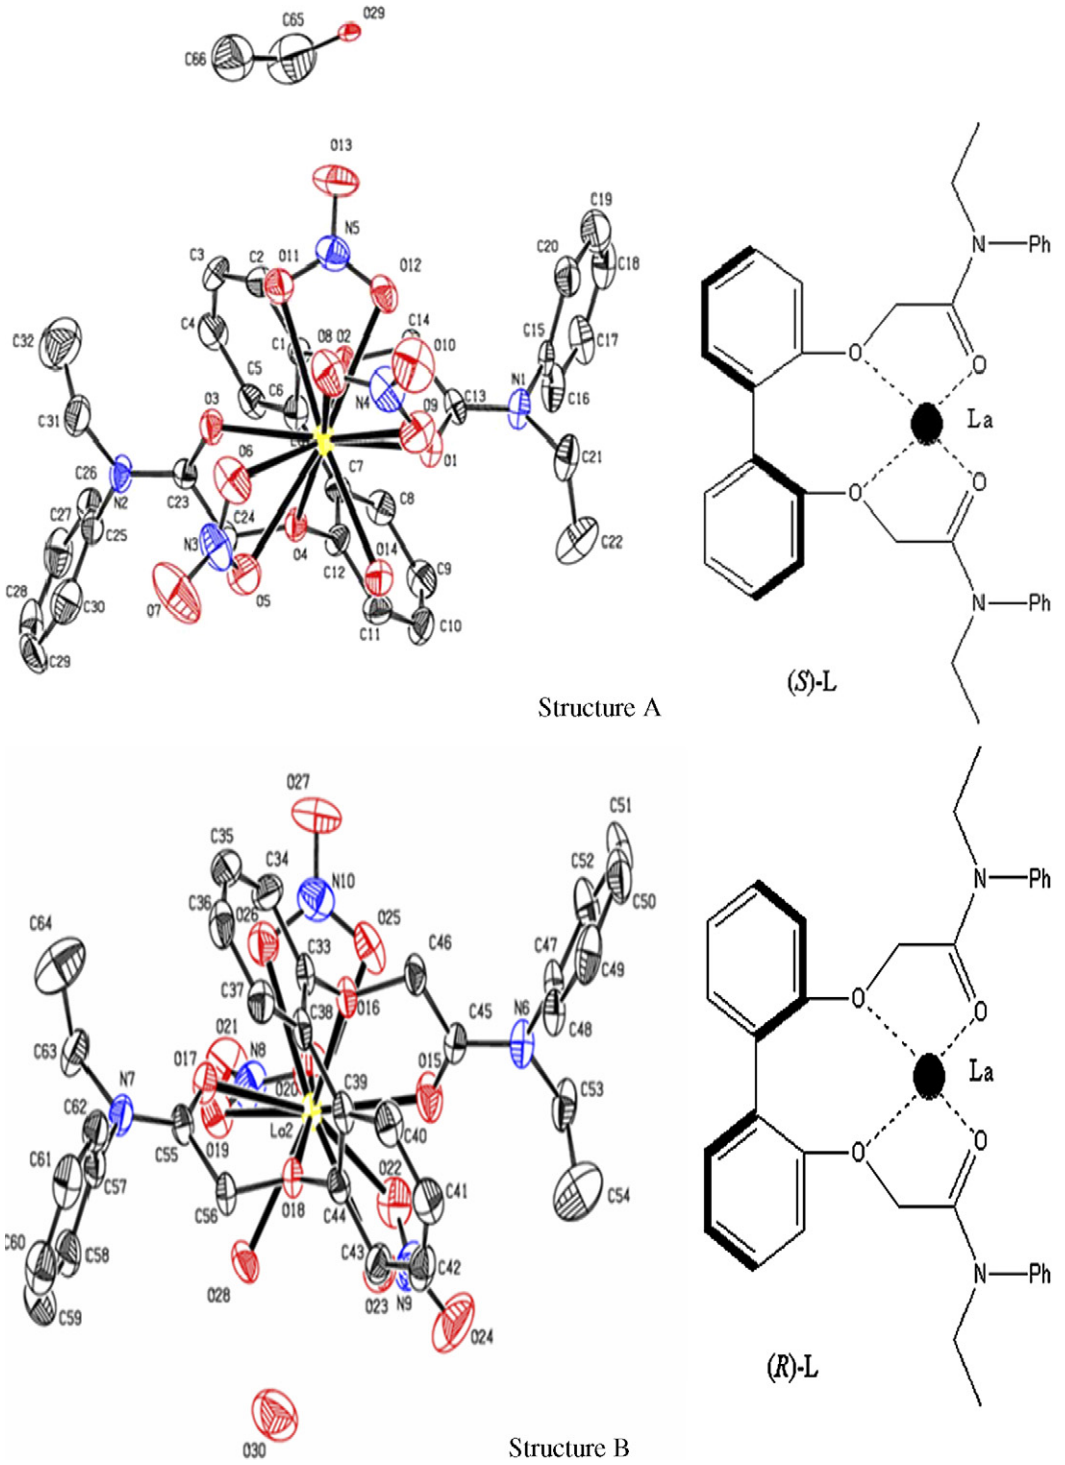

Fig. 4. ORTEP diagram (30% probability ellipsoids) showing the coordination sphere of $[La(NO_3)_3L(H_2O)]$ and coordination modes of L in the nitrate complex.

The proton signal of the OH group in free HPic disappears in the complexes, indicating that the H atom of the OH group is replaced by Ln(III). The benzene ring protons of the free HPic exhibit a singlet at 9.12 ppm. Upon coordination, the signal moves to higher field. Only one singlet is observed for the benzene ring protons of the three coordination picrate groups, indicating fast exchange among the groups in solution [20].

The mass spectrum of **L**shows a molecular ion at $m/z = 509$ (M + H), confirming the molecular formula of **L** as $C_{32}H_{32}N_2O_4$. Above the mass of $C_{12}H_8$ ($m/z = 152$) are observed three major fragment ions at $m/z = 360$ (M−[–CO–$NC_6H_5(C_2H_5)$]), 330 (M−[–O–CH_2–CO–$NC_6H_5(C_2H_5)$]), and 181 (M−[O–CO–$NC_6H_5(C_2H_5)$]–[–O–CH_2–CO–$NC_6H_5(C_2H_5)$]).

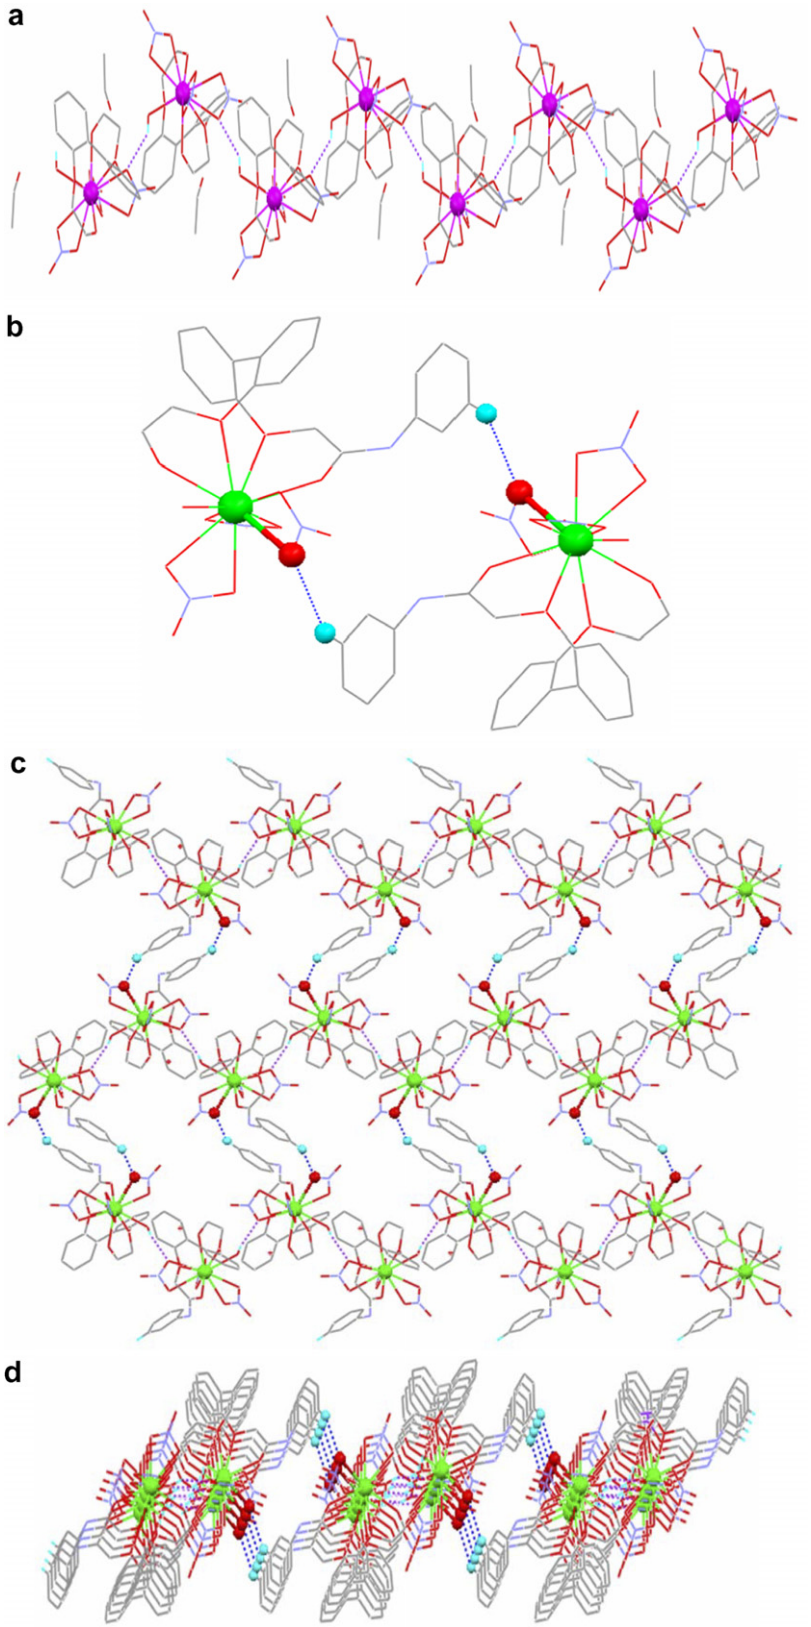

Fig. 5. Hydrogen bonding architecture in lanthanum nitrate complex: (a) 1-D zigzag chain of structure A generated by intermolecular O(14)–H(68) ⋯ O(12) hydrogen bonds [symmetry code is $-x$, $-1/2 + y$, $1/2 - z$; and the hydrogen bonds are indicated by the purple dashed lines]; (b) the dimer of structure B generated by intermolecular C(51)–H(51)⋯O(22) hydrogen bonds [symmetry code is $1 - x$, $2 - y$,$1 - z$; and the hydrogen bonds are indicated by the blue dashed lines]; (c) 2-D layer of structure B generated by intermolecular O(28)–H(70)⋯O(26) hydrogen bonds [symmetry code is $1 - x$, $1/2 + y$, $1/2 - z$; and the hydrogen bonds are indicated by the purple dashed lines] and C(51)–H(51)⋯O(22) hydrogen bonds (the hydrogen bonds are indicated by the blue dashed lines); (d) 2-D layer of structure B viewed down the crystallographic *b*-axis showing the hydrogen bonded channels. Some atoms of the ligand are omitted for clarity.

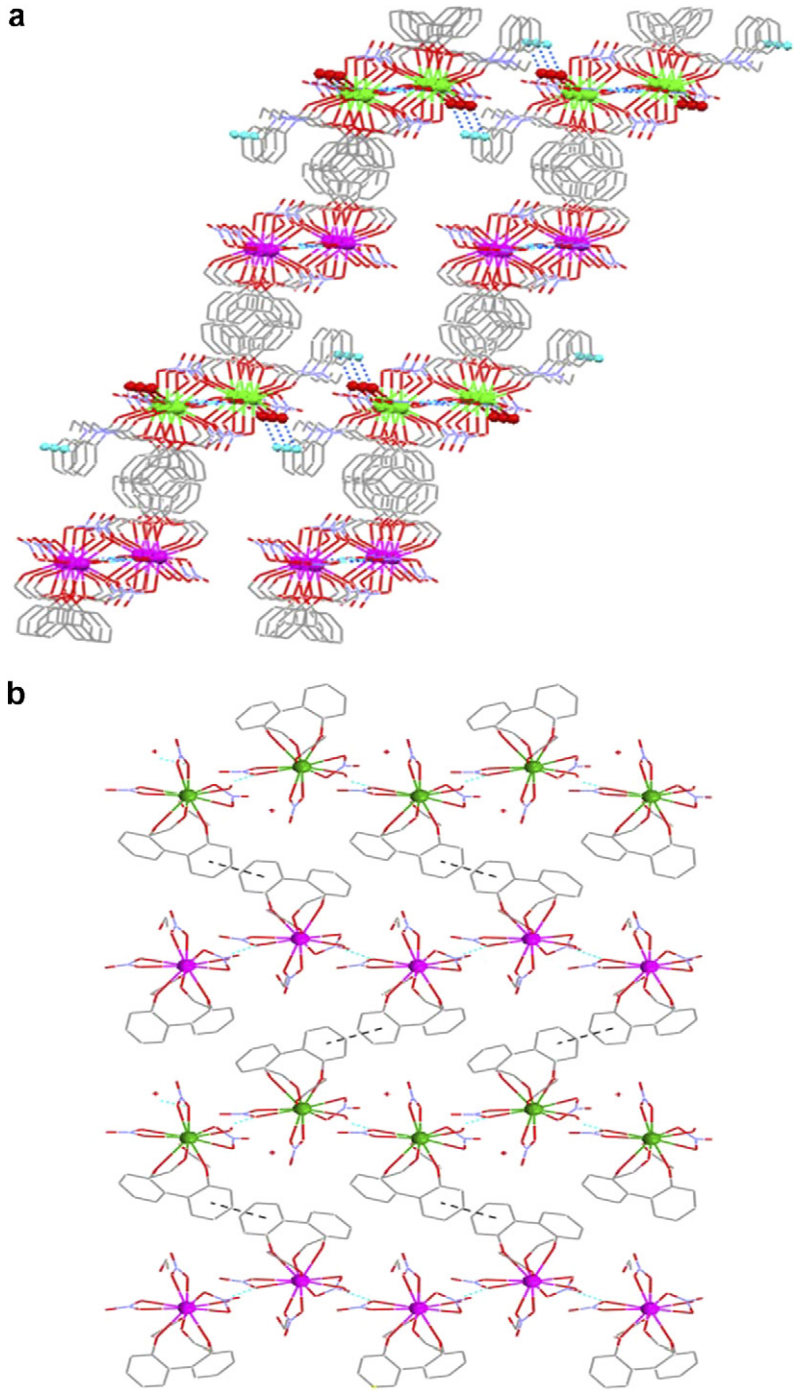

Fig. 6. The intermolecular π–π stacking interactions between the chains and the layers in lanthanum nitrate complex: (a) viewing of the packing diagram of networks along the *b*-axis; (b) packing diagram of the chains and the layers along *a*-axis. Some atoms of the ligand are omitted for clarity.

3.6. Electronic spectra

The electronic spectra in the visible region of the Ln(III) complexes exhibit alternations in intensity and shifts in position of the absorption bands relative to the corresponding Ln(III) aquo ions. The shift has been attributed by Jorgensen to the effect on the crystal field of interelectronic repulsion between the 4f electrons, and is related to the covalent character of the metal–ligand bond, assessed by Sinha's parameter (δ), the nephelauxetic ration (β) and the bonding parameter ($b^{1/2}$) [21]. Absorption spectrum of the Nd(III) complex was recorded in chloroform solution at room temperature and the covalent parameters were calculated (Table 7). The values of β, which are less than unity, and positive values of δ and $b^{1/2}$ support the existence of partial covalent bonding between metal and ligand [22].

3.7. Fluorescence studies

Monitored by the emission band at 600 nm, the europium picrate complex exhibits broad excitation bands around 450 nm. The luminescence emission spectra of the europium picrate complex in solid state (the excitation and emission slit widths were 1.0 nm, Fig. 7) and in solution (the excitation and emission slit widths were 5.0 nm, Fig. 8) were recorded at room temperature. The luminescence characteristics of the europium picrate complex in solid state and in $CHCl_3$, acetone, acetonitrile, and DMF solutions (concentration: 1.0×10^{-3} mol L^{-1}) are listed in Table 8. It can be seen that the europium picrate complex shows strong emission when excited with 451 nm in the solid state. The highest intensity ratio value $\eta(^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1)$ is 7.7, indicative of the Eu(III) ion not lying in a centro-symmetric coordination site [23]. It could also be seen that in DMF solution, the luminescence of europium was quenched which is ascribed to the decomposition of the europium picrate complex in this solvent. In the other three solvents, the europium picrate complex has the similar excitation and emission wavelengths.

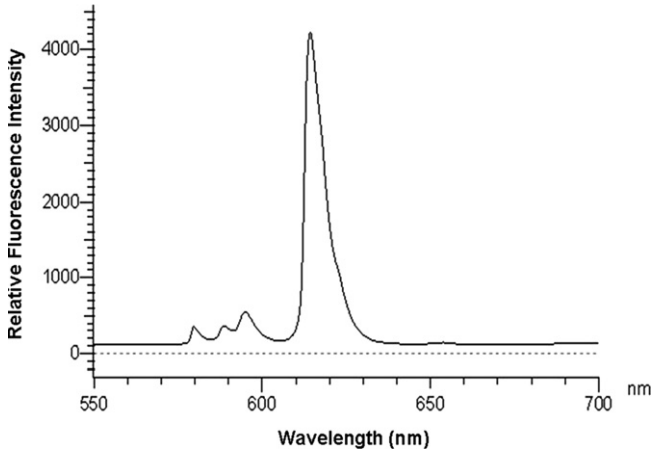

Fig. 7. The emission spectrum of the europium picrate complex in solid state.

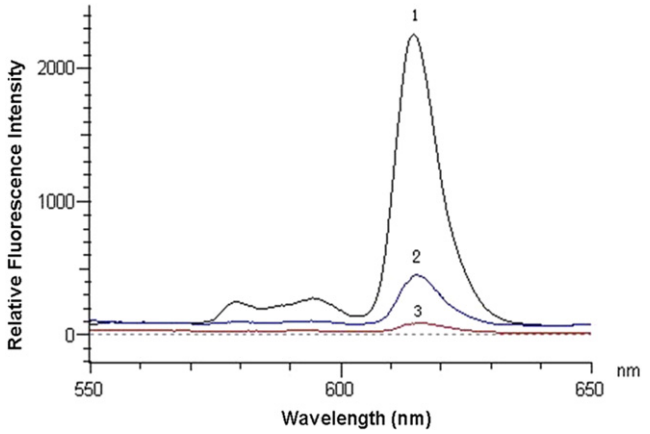

Fig. 8. The emission spectrum of the europium picrate complex in different solutions at room temperature: (1) in $CHCl_3$, (2) in acetone, and (3) in acetonitrile solution.

In $CHCl_3$ solution, the europium picrate complex has the strongest luminescence, followed by acetone and then acetonitrile. This is due to the coordinating effects of the solvents, namely solvate effect [24] where vibrational quenching of the complex excited state may occur through high energy oscillators on the solvent molecule.

The fluorescence quantum yield **Φ** of the europium picrate complex in $CHCl_3$ (concentration: 1.0×10^{-5} mol L^{-1}) was found to be 5.81×10^{-3} with quinine sulfate as Ref. [25].

Table 8
Fluorescence data for the europium picrate complex

Complex	Solvent	λ_{ex} (nm)	λ_{em} (nm)	RFI	assignment

			615	92	$^5D_0 \rightarrow {}^7F_2$
	DMF				

The characteristic luminescence of the terbium picrate complex was not observed, either in solid state or in solutions. The reason is probably that the energy gap between the triplet state levels of the ligand in picrate complex and the lowest resonance level of the europium favor the energy transfer process for europium. In order to acquire the triplet excited state T_1 of the ligand **L** in the picrate complex, the phosphorescence spectrum of the Gd(III) picrate complex was measured at 77 K in a chloroform–methanol–ethanol mixture (v:v:v, 1:5:5). The triplet state energy levels T_1 of the ligand **L** in picrate complex, which was calculated from the shortest wavelength phosphorescence band [26] of the Gd(III) picrate complex, is 21186 cm^{-1}. This energy level is above the lowest excited resonance level $^5D_0$ of Eu(III) (17300 cm^{-1}) and $^5D_4$ (20500 cm^{-1}) of Tb(III). Thus the absorbed energy could be transferred from ligand to the Eu(III) or Tb(III) ions. The triplet state energy level T_1 of this ligand **L** in picrate complex matches better to the lowest resonance level of Eu(III) ($\Delta v = 3886\ cm^{-1}$) than Tb(III) ($\Delta v = 686\ cm^{-1}$) ion, because such small $\Delta v(T_1 - {}^5D_4)$ could result in a back-energy transfer process from the excited resonance level $^5D_4$ of Tb(III) to the triplet state energy level T_1 of this ligand **L** and quench the luminescence of the Tb(III) picrate complex [27].

In contrast with the strong emission of the europium picrate complex, the europium nitrate complex exhibited weak characteristic emission (the excitation and emission slit widths were 2.5 nm, Fig. 9). The phosphorescence spectrum of the Gd(III) nitrate complex was measured at 77 K in a methanol–ethanol mixture (v:v, 1:1), the triplet state energy levels T_1 of the ligand **L** in the nitrate complex, which was calculated from the shortest wavelength phosphorescence band [26] of the Gd(III) nitrate complex, is 22075 cm^{-1}. The results indicate that the counter anions of complexes hardly influence the triplet state energy level T_1 of this ligand **L**, but notably affect the fluorescence properties of the europium complexes.

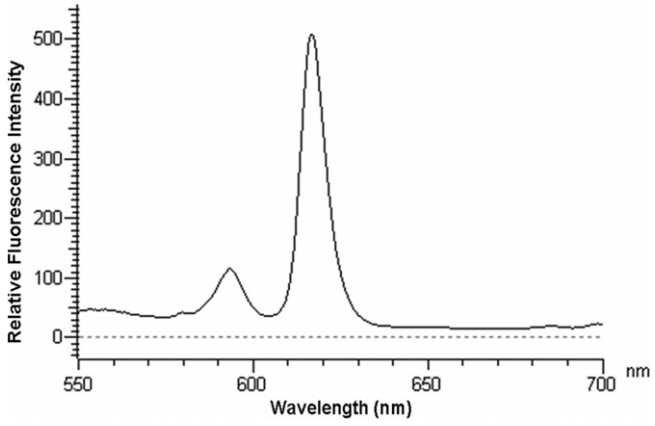

Fig. 9. The emission spectrum of the europium nitrate complex in solid state.

We deduce that this is due to the following three effects. First, the coordinated picrates participate in the energy absorption and transfer process for the Eu(III) ion, make the three-component complex system an optimal state for the luminescence of europium, accordingly enhancing the relative fluorescence intensity of the europium picrate complex. Secondly, the intermolecular π–π stacks between picrates favor to the energy transfer for europium. However, the coordinated nitrates do not play these roles like picrates in the europium complex. Thirdly, the non-radiative deactivation of the europium emitting state could quench the luminescence of the Eu(III) nitrate complex [27].

4. Conclusion

In this paper, we reported the preparation, luminescent properties of *N*-phenyl-2-{2′-[(phenyl-ethyl-carbamoyl)-methoxy]-biphenyl-2-yloxy}-*N*-ethyl-acetamide (**L**) lanthanide complexes and the supramolecular structures of $[La(pic)_3L]$ and $2[La(NO_3)_3L(H_2O)] \cdot H_2O \cdot 0.5C_2H_5OH$ which are the assemblies of the complex units via the intermolecular hydrogen bonds and π–π stacking interactions. The free ligand is achiral, but it induces axial chirality in the lanthanum nitrate complex, which is directed by the metal ions in the assembly process of the organic ligands with the metal ions. The europium picrate complex exhibited strong characteristic fluorescence whereas the terbium picrate complex showed no luminescence. The lowest triplet state energy level of the ligand in the picrate complex matches better to the resonance level of Eu(III) than Tb(III) ion. The Eu(III) nitrate complex exhibited quite weak characteristic fluorescence. So we can see that the counter anion of complexes is very essential in determining the fluorescent properties of the rare earth complexes. Further studies on the ligand and their complexes are in proceeding.

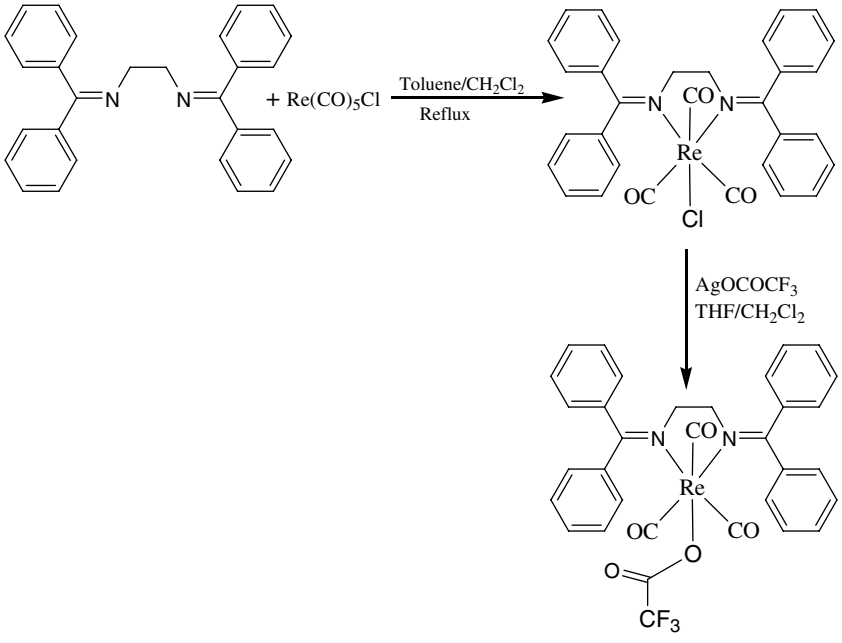
2. Results and discussion

2.1. Chloro- and trifluoroacetato tricarbonylrhenium(I) complexes



2.1.1. Synthesis and spectroscopic characterization

The new *fac*-[$Re(CO)_3(bz_2en)X$] (X = Cl and $OCOCF_3$), complexes were obtained via substitution reactions, as o utlined in Scheme 1. In the first step (a), the chloride carbonyl, **1**, was prepared in good yield by refluxing equivalent amounts of Re(I) pentacarbonyl chloride and bz_2en in a mixture of toluene/dichloromethane following a previously established method [13]. The trifluoroacetato complex was synthesized by allowing the halide carbonyl, **1**, to react with 1 equiv. of $AgOCOCF_3$ in CH_2Cl_2 in the dark, overnight. After cooling, the AgCl that formed during the reaction was removed by filtration. The partial removal of the solvent and addition of *n*-hexane resulted in the formation of the corresponding complex **2** in good yield.

The new complexes are stable in the solid state and in solution at room temperature, and were characterized by the usual spectroscopic techniques. The IR spectra for complexes exhibit three absorption bands in the carbonyl stretching region, as a sharp intense band at 2017, and two closely spaced bands at 1910 and 1878 cm^{-1} for **1** and about 2024 and 1920 cm^{-1} for **2**, typical of the *fac*-Re(I) α-diimine tricarbonyl complexes [14,15]. The nature of the axial ligand influences to some extent the position and the shape of the absorption bands in the IR spectra. The π-donor character of the Cl ligand and the oxygen atom in the trifluoroacetate group increase the Re → CO back-bonding, which decreases the energy of υ(CO) [15].

The ^1H NMR spectra and peak assignments are presented in the experimental section. For complex **1**, the signal due to the methylene protons of the ethylenediamine chelate appear at 3.72–377 and 4.19–4.24 ppm as two sets of multiplets, and for **2**, at 3.79–3.84 and 3.95–4.00 ppm, respectively. The signal due to the aromatic protons appears at about 7.25–7.62 and 7.22–7.55 ppm for **1** and **2**, respectively. In keeping with the *fac* arrangement of the CO ligands, the $^{13}C\{^1H\}$ NMR spectra show two low-field signals assignable to the CO groups, at about 192.88, 193.93 and 192.46, 197.69 ppm for axial and equatorial carbonyl groups for **1**, and **2**, respectively.

The UV–Vis spectral data of complexes **1** and **2** are presented in Table 1. The absorption spectra of complexes **1** and **2** are dominated in the UV region by ligand-centered π → π* transitions which are qualitatively similar to [$Re(CO)_3$(2-PC)Cl], in which 2-PC is *n*-(2-pyridinylmethylene)cyclohexylamine [16]. The shorter wavelength bands include certainly an intraligand (IL) transition of the

Scheme 1.

Table 1
UV–Vis spectral data of complexes **1** and **2**.

Compound	Concentration (M)	Solvent	UV–Vis λ_{max} (nm) [ε] (M^{-1} cm^{-1})
1	6.25×10^{-5}	CH_2Cl_2	249 [59168], 320 [18727]
2	3.12×10^{-5}	CH_2Cl_2	250 [25488], 323 [8544]

diimine, which absorbs as a free ligand in the same spectral region. The spectral positions of the IL bands are significantly red-shifted in comparison to the free ligand, due to the coordination of the heavy metal core.

The electrochemical behaviour of complexes **1** and **2** was examined by means of cyclic voltammetry (CV) in CH_2Cl_2 (Fig. 1). The ligand bz_2en is electroinactive in the working potential region. Anodic scans reveal a single reversible oxidation at about 1.44 and 1.51 V versus Ag/AgCl for complexes **1** and **2**, respectively. This is assigned to the Re(II)/Re(I) redox couple, which is similar to the anodic peak potential reported for the complexes *fac*-[$Re(CO)_3$(2-PC)Cl] and *fac*-[$Re(CO)_3$(2,2N)Br] [16,17], except that the latter complexes show irreversible behaviour. It is clear from the oxidation potential that complex **2** is more resistant to oxidation than the complex **1** owing to the greater electron-withdrawing property of the trifluoroacetate group. Complexes **1** and **2** show quasireversible redox couples with $E_{1/2}$ values of 1.35 and 1.45 V, respectively. In the cyclic voltammetry, peak-to-peak separations (ΔE_p) of 170 and 100 mV were observed at a scan rate (υ) of 100 mV/s for complexes **1** and **2**, respectively.

2.1.2. X-ray structural study of complexes *1* and *2*

The molecular structure of **1** is shown in Fig. 2, and selected bond lengths and angles are listed in Table 2. The rhenium center is in a distorted octahedral geometry defined by two donors derived from the bz_2en ligand, three carbonyls and one chlorine ligand. The axially disposed chlorine and carbonyl ligands are disordered over two positions and were refined with 53.7% and 46.3% site-occupancy factors. The lengths of the Re–C bond *trans* to the nitrogen atoms range from 1.911(4) to 1.916(4) Å. In the major component of the disorder, due to the π-donor character of the chlorine ligand, the length of the axial Re–C bond is slightly shorter than the values of the equatorial Re–C bonds (see Table 2). The lengths of the two Re–N bonds formed with the bz_2en ligand are equal (2.217(3) Å), and are in the range reported for the *fac*-$Re(CO)_3$(3,2N)Br complex, where 3,2N is the 3,3′-trimethylene-2,2-biquinoline ligand [17]. The X-ray analysis established that the bz_2en ligand in **1** is bound to the rhenium center in a bidentate chelating fashion, leading to five-membered ReN_2C_2 chelate ring with a N(1)–Re(1)–N(2) bite angle of 78.0(1)°. In spite of the sp^2 hybridization of the donor nitrogen atoms of the bz_2en ligand, the ReN_2C_2 five-membered chelate ring is significantly puckered and the mean deviation of the atoms from the least-squares plane is 0.22 Å. The strain in the chelate ring is also reflected in the deviation from the 120° angle about the chelating nitrogen atoms: Re(1)–N(1)–C(1) and Re(1)–N(2)–C(4) angles are 130.8(3) and 129.9(3)°, respectively. The steric requirements of this bidentate ligand cause distortion of the octahedral coordination sphere, which is clearly reflected in the values of the equatorial C(5)–Re(1)–N(1) and C(6)–Re(1)–N(2) bond angles. As can be seen in Table 2, these equatorial bond angles are far from the ideal octahedral value of 90°. In the crystal, the molecules of **1** are linked by C–H ⋯ O hydrogen bonds (Table 3) into infinite chains.

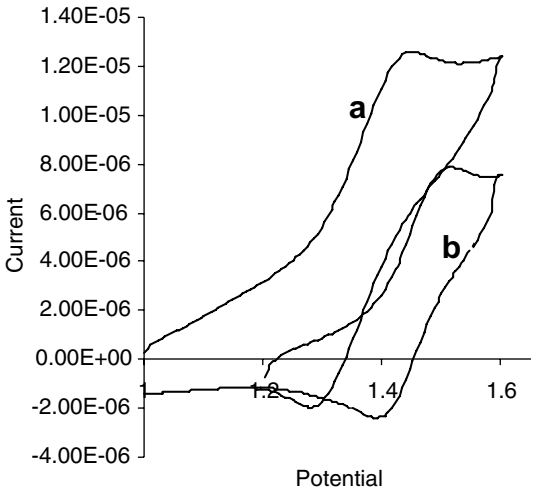


Fig. 1. Cyclic voltammograms of **1** (a) and **2** (b) in CH_2Cl_2 at 293 K (scan rate, 100 mV/s, $C = 2.5 \times 10^{-4}$ M): (a) [$Re(bz_2en)(CO)_3Cl$] (**1**) and (b) [$Re(bz_2en)(CO)_3OCOCF_3$] (**2**).

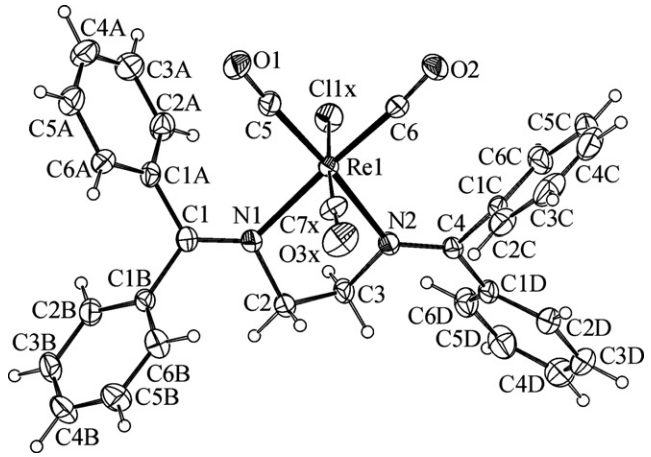

Fig. 2. ORTEP drawing for complex **1**. Non-hydrogen atoms are shown as 30% probability ellipsoids. Only the major component of the disordered axially disposed CO and Cl ligands is shown.

The molecular structure of **2**, established by single-crystal X-ray diffraction, is shown in Fig. 3. The relevant geometric parameters are collected in Table 2. The X-ray data obtained for **2** reveal that there are two structurally similar but symmetry independent molecules (unprimed and primed) in the unit cell. In each molecule, the rhenium center is located in a distorted octahedral coordination environment, with the equatorial plane consisting of two nitrogen atoms of the bidentate bz_2en ligand and two CO ligands, and one CO and the oxygen atom of the trifluoroacetate in the axial positions. The structural similarity between **1** and **2** is reflected in the practically unaltered N–Re–N bite angles (77.5(3)° for the unprimed and 78.1(2)° for the primed molecule) and Re–N distances (Table 2). In a manner similar to **1**, the five-membered ReN_2C_2 chelate rings are significantly puckered and the

mean deviation of the atoms from the least-squares plane is 0.21 Å in both molecules. Owing to the π-donor character of the oxygen atom of the $OCOCF_3$ group, the CO ligand *trans* to the O atom forms shorter Re–C bonds (1.867(9) Å in the unprimed and 1.892(9) Å in the primed molecule) than the other two CO ligands *trans* to the N atoms of the bz_2en ligand (see Table 2). The CF_3 group has high thermal motion consistent with some unresolved rotational disorder, as is often found in other trifluoroacetate compounds [18–20]. In addition, there are some weak C–H ⋯ O interactions (Table 3) in the crystal.

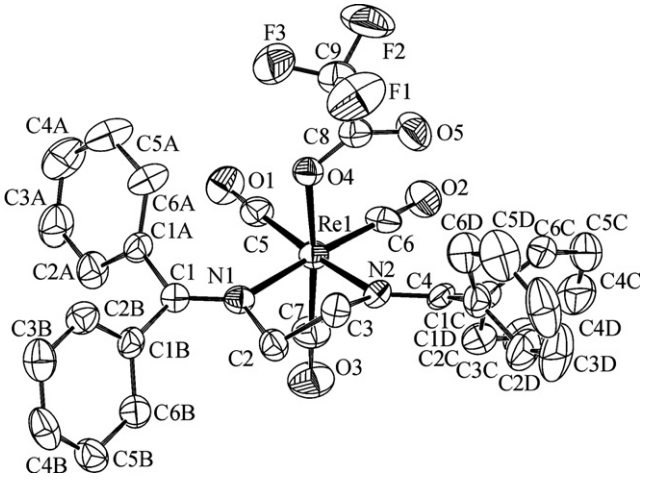

Fig. 3. ORTEP drawing for complex **2**, showing one of the two chemically similar but symmetry independent molecules. Non-hydrogen atoms are shown as 30% probability ellipsoids. Hydrogen atoms have been omitted for clarity.

3. Conclusion

The *fac*-[Re(bz_2en)$(CO)_3X$] (X = Cl and $OCOCF_3$) rhenium(I) complexes have been prepared and characterized by IR, UV–Vis, ^1H, ^{13}C NMR, electrochemical and X-ray diffraction techniques. Variations in the electronic properties related to the rhenium (I), carbonyl and X ligands – such as electronic transition, CO stretching and some crystallographic parameters of the complexes – were interpreted on the basis of the σ- and π-donor character of the X ligand. It is clear from the data that by varying the nature of the X ligand attached to rhenium, the electronic properties of the *fac*-[Re(bz_2en)$(CO)_3X$] complexes could be ''tuned''.

4. Experimental

4.1. Starting materials

All reagents were used as received from Fluka and Merck without further purification. Solvents used for the reactions were purified by literature methods [21]. The ligand *N*,*N*-bis(benzophenone)-1,2-diiminoethane (bz_2en) was synthesized and purified as reported [22].

4.2. Synthesis

4.2.1. [Re(bz_2en)$(CO)_3Cl$] (**1**)

A mixture of $Re(CO)_5Cl$ (181 mg, 0.5 mmol) and bz_2en (118 mg, 0.5 mmol) in 20 ml CH_2Cl_2 and 30 ml of toluene was heated at reflux for 2 h to give a bright yellow solution. The solvent was removed under vacuum and the crude

material recrystallized from CH_2Cl_2/hexane to give $Re(bz_2en)(CO)_3Cl$ as a pure bright yellow powder.

Anal. Calc. for $C_{31}H_{24}ClN_2O_3Re$: C, 53.64; H, 3.48; N, 4.04. Found: C, 53.67; H, 3.50; N, 4.05%.

IR (KBr, cm^{-1}): υ_{max} 3050 (CH); 2017, 1910 and 1878 (CO); 1592 (C=N).

^1H NMR ($CDCl_3$, δ_{ppm}): 3.72–3.76 (m, 2H, $-CH_2-$); 4.20–4.24 (m, 2H, $-CH_2-$); 7.25–7.29 (m, 4H, aromatic hydrogens); 7.39–7.47 (m, 12H, aromatic hydrogens); 7.61–7.62 (m, 4H, aromatic hydrogens).

$^{13}C\{^1H\}$ NMR ($CDCl_3$, δ_{ppm}): 61.25 ($-CH_2-$); 128.27, 128.53, 128.79, 129.47, 130.63, 130.79, 137.55, and 141.93 (aromatic carbons); 183.17 (iminic carbon); 192.88 (CO); 193.93 (2CO).

UV–Vis: λ_{max}, ε (nm, $M^{-1}\,cm^{-1}$): 249 (59 168); 320 (18 727).

4.2.2. $[Re(bz_2en)(CO)_3OCOCF_3]$ (2)

A solution of $AgOCOCF_3$ (55 mg, 0.25 mmol) in 5 ml of THF was added to a solution of $[Re(bz_2en)(CO)_3Cl]$ (166 mg, 0.24 mmol) in 50 ml of CH_2Cl_2 and immediately gave a cloudy yellow mixture. After stirring for 2 h, the precipitate was removed by filtration and the crude material recrystallized from CH_2Cl_2/hexane to give $[Re(bz_2en)(CO)_3OCOCF_3]$ as a pure pale-yellow powder.

Anal. Calc. for $C_{33}H_{27}F_3N_2O_5Re$: C, 51.16; H, 3.51; N, 3.62. Found: C, 51.20; H, 3.50; N, 3.64%.

IR (KBr, cm^{-1}): υ_{max} 3060 (CH); 2024, 1920 (CO); 1592 (C=N).

^1H NMR ($CDCl_3$, δ_{ppm}): 3.79–3.84 (m, 2H, $-CH_2-$); 3.95–4.00 (m, 2H, $-CH_2-$); 7.22–7.24 (m, 4H, aromatic hydrogens); 7.41–7.47 (m, 12H, aromatic hydrogens); 7.51–7.55 (m, 4H, aromatic hydrogens).

$^{13}C\{^1H\}$ NMR ($CDCl_3$, δ_{ppm}): 61.29 ($-CH_2-$); 114.95, 117.26, 128.35, 128.54, 128.86, 128.90, 129.26, 129.37, 130.99, 160.82, 161.10 (aromatic carbons); 184.36 (iminic carbon); 192.46 (CO); 197.69 (2CO).

UV–Vis: λ_{max}, ε (nm, $M^{-1}\,cm^{-1}$): 250 (25 488); 323 (8544).

4.3. Physical measurements

4.3.1. Spectroscopic experiments

NMR spectra were obtained on a Brucker Avance DRX500 (500 MHz) spectrometer. The chemical shifts (δ) are reported in part per million (ppm) relative to an internal standard of Me_4Si. The UV–Vis spectra were recorded on a Shimadzu UV-160 spectrophotometer with quartz cells (1 cm path length). Elemental analyses were performed using a Heraeus elemental analyzer. IR spectra were determined as KBr pellets on a Nicolet Impact 400D spectrophotometer. Electrochemical data were obtained by cyclic voltammetry (CV) with a three-electrode cell containing an Ag/AgCl reference electrode, a Pt wire counter electrode and a Pt working electrode. A Metrohm multipurpose instrument model 757 was used. CV measurements were performed in CH_2Cl_2 with 25 mM of Bu_4NClO_4 (TBAP) as a supporting electrolyte. In all electrochemical experiments, the solutions were purged with Ar gas for at least 5 min.

4.3.2. X-ray crystallography

Suitable single crystals of $[Re(bz_2en)(CO)_3Cl]$ (**1**) and $[Re(bz_2en)(CO)_3OCOCF_3)]$ (**2**) were obtained by diffusion of *n*-hexane vapour into a CH_2Cl_2 solution at −18 °C. Crystal data and refinement parameters for complexes **1** and **2** are summarized in Table 4. Intensity data for complexes **1** and **2** were collected on a Rigaku R-AXIS RAPID image plate diffractometer (λ(Mo Kα radiation) = 0.71070 Å) at 295 ± 2 K. Several scans in the ϕ and ω direction were made to increase the number of redundant reflections, which were averaged over the refinement cycles. The structures were solved by a direct method (SIR92) [23] and refined by full-matrix least-squares (SHELXL-97) [24]. All calculations were carried out using the WINGX package of crystallographic programs [25]. All non-hydrogen atoms were refined anisotropically in the F^2 mode. The water molecule in **2** is disordered and the refined site-occupancy factors of the disordered parts (O1wx/O1wy and associated H atoms) are 0.52(5) and 0.48(5). The water H atoms were found in a difference Fourier map and refined with O–H distances restrained to 0.85(1), $H\cdots H$ distance restrained to 1.37(2) and $U_{iso}(H) = 0.08\ ^2$. Other hydrogen atomic positions were

to the selectivity process that is taking place during the crystallization procedure, which results in an exclusive admission of only M(II) ions at the hydrated site [4]. So far the only two complexes that do not conform to the above generalizations are the seven-coordinated $[Cd(1,3\text{-pdta})(H_2O)]^{2-}$ complex, crystallized with the hexaaquamagnesium counter ion in space group *Pbcn* [4], and the eight-coordinated homometallic $[Ca(H_2O)_3Ca(1,3\text{-pdta})(H_2O)]$ complex [3], both reported by us previously. In this paper, we shall illustrate, that depending on the reaction conditions, the Mn(II) ion forms either six- or seven-coordinated complexes with 1,3-pdta ligand by crystallizing with the hexaaquamagnesium counter ion in either *Pnna* or *Pbcn* space groups, respectively. Moreover, by presenting the crystal structure of mixed crystals of the composition $[Mg(H_2O)_6][Mg_{0.5}Mn_{0.5}(1,3\text{-pdta})]\cdot 2H_2O$, we shall demonstrate that the octahedral metal(II) complexes with 1,3-pdta ligand not only form isostructural crystals but also possess the ability to form solid solutions. So far in the heterobimetallic $M[M'(1,3\text{-pdta})]\cdot 8H_2O$ complexes each of the two different metallic ions occupied one of the two types of coordination sites. In this respect, the reported structure of the mixed crystal is unique and can give rise to a new class of materials. A useful by-product of this study is the precise low-temperature crystal structure of the $[Mg(H_2O)_6][Cd(1,3\text{-pdta})(H_2O)]\cdot 2H_2O$ complex, previously investigated at room temperature [4] but now determined at 130 K to allow a direct comparison with the analogous Mn(II) complex and to establish the type of disorder present in its crystal lattice.

2. Experimental

2.1. Compounds preparation

All commercially obtained reagent-grade chemicals were used without further purification. Preparation of barium (1,3-propanediaminetetraacetato)barium(II) dihydrate, $Ba[Ba(1,3\text{-pdta})]\cdot 2H_2O$, has been reported elsewhere [1,8]. The $[Mg(H_2O)_6][Mg_{0.5}Mn_{0.5}(1,3\text{-pdta})]\cdot 2H_2O$ (**1**) and $[Mg(H_2O)_6][Mn(1,3\text{-pdta})(H_2O)]\cdot 2H_2O$ (**2**) complexes have been prepared according to the method described in the literature for preparation of a series of $[M(H_2O)_6][M'(1,3\text{-pdta})]\cdot 2H_2O$ type complexes (M = Co(II), Mg(II), Zn(II); M′ = Co(II), Cu(II), Ni(II), Mg(II), Zn(II)) [1–5].

2.1.1. Preparation of hexaaquamagnesium (1,3-propanediaminetetraacetato)manganese(II)-magnesium(II) dihydrate, $[Mg(H_2O)_6][Mg_{0.5}Mn_{0.5}(1,3\text{-pdta})]\cdot 2H_2O$ (*1*)

$MnSO_4\cdot H_2O$ (0.85 g; 0.005 mol) was dissolved in 25 cm^3 of distilled water at 60 °C. To this solution, solid $Ba[Ba(1,3\text{-pdta})]\cdot 2H_2O$ (6.13 g; 0.01 mol) was added and the reaction mixture was heated at 60 °C with stirring for 20 min. Then, $MgSO_4\cdot 6H_2O$ (3.43 g; 0.015 mol) was added and stirring with heating at 60 °C was continued for next 20 min. The precipitated barium sulphate was filtered out. To the obtained filtrate 5–6 cm^3 of ethanol was added and the solution was left to stand in a refrigerator overnight. The obtained crystals of $[Mg(H_2O)_6][Mg_{0.5}Mn_{0.5}(1,3\text{-pdta})]\cdot 2H_2O$ are colourless in solution, but out of solution they have slightly light-green colour. These crystals were collected, washed with ethanol, and air-dried. The yield was 3.57 g (70%). *Anal.* Calc. for $[Mg(H_2O)_6][Mg_{0.5}Mn_{0.5}(1,3\text{- pdta})]\cdot 2H_2O$, $C_{11}H_{30}Mg_{1.50}Mn_{0.50}N_2O_{16}$ (FW = 510.29): C, 25.89; H, 5.92; N, 5.49. Found: C, 26.00; H, 6.19; N, 5.48%.

2.1.2. Preparation of hexaaquamagnesium aqua(1,3-propanediaminetetraacetato)manganese(II) dihydrate, $[Mg(H_2O)_6][Mn(1,3\text{-pdta})(H_2O)]\cdot 2H_2O$ (*2*)

$MnSO_4\cdot H_2O$ (1.69 g; 0.01 mol) was dissolved in 25 cm^3 of distilled water at 60 °C. To this solution, solid $Ba[Ba(1,3\text{-pdta})]\cdot 2H_2O$ (6.13 g; 0.01 mol) was added and the reaction mixture was heated at 60 °C with stirring for 20 min. The precipitated barium sulphate was filtered out and to the obtained filtrate the solid $MgSO_4\cdot 6H_2O$ (2.28 g; 0.01 mol) was added and stirring with heating at

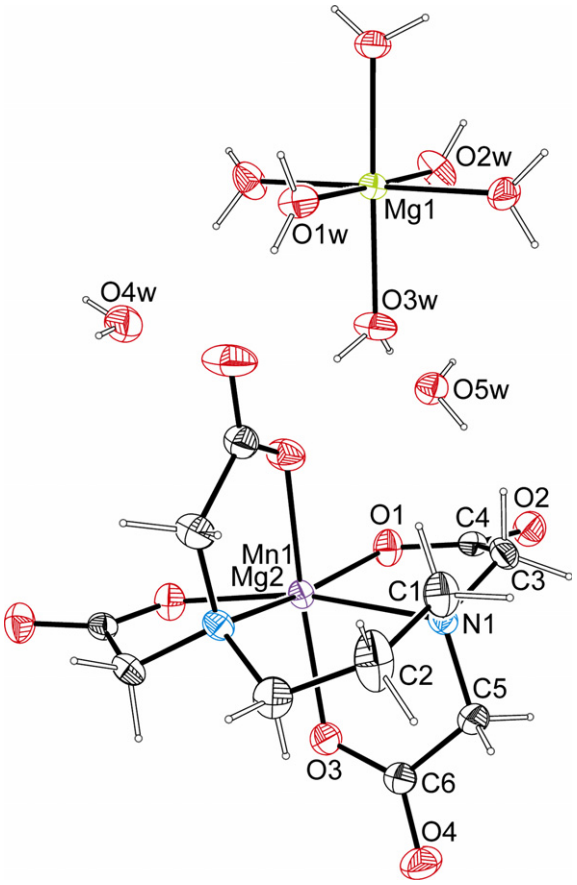

Fig. 1. Perspective drawings of the structural units constituting the crystals of **1**. All molecules occupy twofold symmetry sites. Thermal ellipsoids which are drawn at 40% probability illustrate the displacements of atoms at 295 K. In the anionic complex of **1** both Mn^{II} and Mg^{II} cations occupy the same site, with s.o.f. 0.25.

60 °C was continued for next 20 min. The precipitated barium sulphate was again filtered out. To the obtained filtrate 5–6 cm^3 of ethanol was added and the solution was left to stand in a refrigerator overnight. The light-pink crystals of $[Mg(H_2O)_6][Mn(1,3\text{-pdta})(H_2O)]\cdot 2H_2O$ complex were collected, washed with ethanol, and air-dried. The yield was 3.93 g (75%). The complex was recrystallized from a water solution left to stand in a desiccator over methanol for several days. The recrystallized product was checked by elemental microanalyses and IR spectroscopy, and the obtained results were equal to those for the precipitates obtained before recrystallization. *Anal.* Calc. for $[Mg(H_2O)_6][Mn(1,3\text{-pdta})(H_2O)]\cdot 2H_2O$, $C_{11}H_{32}MgMnN_2O_{17}$ (FW = 543.64): C, 24.30; H, 5.93; N, 5.15. Found: C, 24.24; H, 6.13; N, 5.10%.

2.2. Elemental microanalyses

Elemental microanalyses for carbon, hydrogen, and nitrogen were done by the Faculty of Chemistry, University of Belgrade, Serbia.

2.3. Crystallographic data collection and refinement of the structures

The crystal data of the solid solution of the composition $[Mg(H_2O)_6][Mg_{0.5}Mn_{0.5}(1,3\text{-pdta})]\cdot 2H_2O$ (**1**), $[Mg(H_2O)_6][Mn(1,3\text{-pdta})(H_2O)]\cdot 2H_2O$ (**2**) and $[Mg(H_2O)_6][Cd(1,3\text{-pdta})(H_2O)]\cdot 2H_2O$ (**3**), and the parameters of data collection are summarized in Table 1. The intensity data were measured with a KM4CCD kappa-geometry diffractometer [9] using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 295(2) K for the crystals of **1**, and at 130 K for the crystals of **2** and **3**. The structures were solved by direct methods using SHELXS-97 [10] and refined by least-squares techniques with SHELXL-97 [11]. The intensity data were corrected for Lp effects as well as for absorption. Anisotropic thermal parameters were employed for the non-hydrogen atoms. Hydrogen atoms connected to carbon atoms have been placed at calculated positions, while those attached to the water oxygen atoms have been located on subsequent difference Fourier maps. Although refined at the earlier stages of structure determination, the hydroxyl hydrogens were eventually fixed at a distance of 0.85 Å from their respective oxygen atoms because some of the bond lengths and angles involving these hydrogens as well as their displacement parameters refined to unreasonable values. All hydrogen atoms were allowed to ride on the atoms to which they were attached and their isotropic displacement parameters were given values 20% higher than the isotropic equivalent for the atom to which the H-atom was bonded. Since in the crystals of **1** both the Mn and Mg atoms share the same occupation site 4d [7], the same *x*, *y*, *z* parameters and the same anisotropic displacement parameters were used for both atoms. The occupancy factor refined to 0.25 for both Mn and Mg atoms. In the crystal structures of **2** and **3**, carbon atom C2, as well as hydrogen atoms attached to C1 are disordered and were refined with occupation number 0.5. A Siemens Stereochemical Workstation was used to prepare drawings [12].

[c] The mean deviation from octahedral angles.

which the chelated metal atom site M′ is in 50% occupied by Mn(II) and in 50% by Mg(II) cations. The crystal is isostructural with those of metal(II)-1,3-pdta complexes, namely $[M(H_2O)_6][Cu(1,3\text{-pdta})]\cdot 2H_2O$ (M = Mg(II) [1] or Mn(II) [6]), $[Mg(H_2O)_6][M'(1,3\text{-pdta})]\cdot 2H_2O$ (M′ = Co(II)) [2], Ni(II) [5], Zn(II) [4] and homobimetallic $[Mg(H_2O)_6][Mg(1,3\text{-pdta})]\cdot 2H_2O$ [3], $[Zn(H_2O)_6][Zn(1,3\text{-pdta})]\cdot 2H_2O$ [4] and $[Co(H_2O)_6][Co(1,3\text{-pdta})]\cdot 2H_2O$ [2]. Metal–ligand bond lengths and angles observed in the investigated structure are compared in Table 3 with the corresponding values reported previously for the series of 1,3-pdta structures containing different metal(II) ions.

The structural units consist of a mixture of $[Mn(1,3\text{-pdta})]^{2-}$ and $[Mg(1,3\text{-pdta})]^{2-}$octahedra sharing the same site, and $[Mg(H_2O)_6]^{2+}$ octahedra, as well as two water solvent molecules. All these constituents of the crystal lattice occupy special position sites of twofold symmetry. The twofold axis of the chelated complex anion passes through the M′ metal (which is either Mn(II) or Mg(II)) and C2 atom and bisects the N1–M(II)–N1[a] bond angle ([a] stands for the symmetry operation x, $-0.5-y$, $0.5-z$) making the two glycinate rings of the R type as well as the two glycinate rings of the G type identical.[1] The six-membered (T) ring adopts a symmetrical *twist-boat* conformation with the average torsion angle moduli of 44.7°. The R rings are almost flat, while the G-rings are much more puckered and are halfway between an *envelope* and *twist* conformations. As can be seen from Table 3, the M′–O bond distances are greater in the flat R rings than in the puckered G rings, the difference being 0.095 Å, and the M′–N bonds are by 0.153 Å longer than the average M′–O bond. Examination of the bond angles shows that the reported $[Mg(H_2O)_6][Mg_{0.5}Mn_{0.5}(1,3\text{-pdta})]\cdot 2H_2O$ complex is the most, while the $[Mg(H_2O)_6][Ni(1,3\text{-pdta})]\cdot 2H_2O$ complex is the least distorted from octahedral geometry (compare av. ΔO_h parameters listed in Table 3). The severe distortion from octahedral geometry of Mn(II) and Mg(II) complexes is not unexpected owing to the electronic configuration of the two ions ($3d^0$ and $3d^5$, respectively) and connected with it the lack of crystal field stabilization energy (CFSE) contribution [15].

In the crystal structure of **1**, as in other crystals belonging to the isomorphic series [1–6], the complex cations and anions alternate throughout the entire lattice. This is best viewed along the [0 0 1] direction, as illustrated in Fig. 2. Both "hydrated" and "chelated" complex ions are situated on the twofold axis parallel to *a*-direction. Apart from the electrostatic interactions, the $[M'(1,3\text{-pdta})]^{2-}$ and $[M(H_2O)_6]^{2+}$ octahedra are hydrogen bonded to form a puckered layer parallel to (0 0 1) lattice plane in which the metal aqua ions act solely as donors to carboxylate oxygens [O2, O3 and O4] acting as acceptors. The solvent

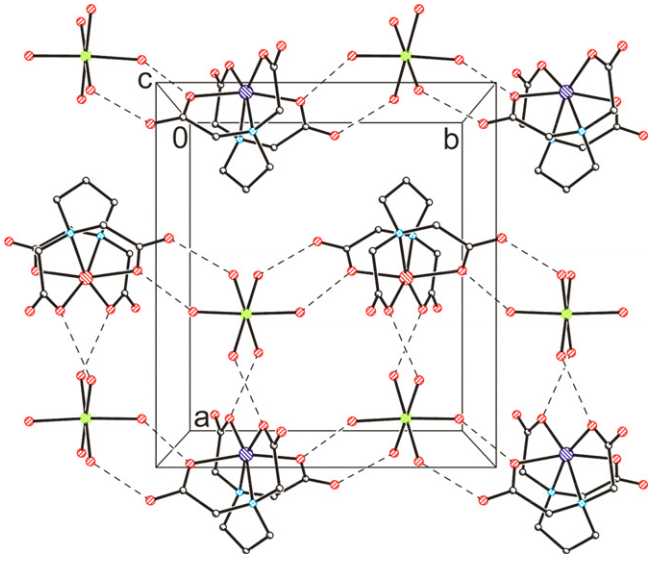

Fig. 2. View of the (0 0 1) layer in the crystal structure of **1**. The layer contains alternating complex cations and anions. The subsequent layers are separated by uncoordinated water molecules.

[1] The convention for describing the various chelate rings formed by edta-type ligands is credited to Weakliem and Hoard [13]. According to the authors, G rings are those whose mean planes are more nearly parallel to the N–M–N plane and R rings are those rings whose mean planes are more nearly perpendicular to the N–M–N plane.

water molecules [O4W and O5W], situated in between the (0 0 1) layers, act as double donors and double acceptors and help to join the neighboring layers. The crystal structure is additionally stabilized by C=O dipolar interactions around the symmetry center at 1/2 1/2 1/2. No carboxylate bridges, commonly present in the crystal structures of $[M(edta\text{-}type)]^{2-}$ and $[M(1,3\text{-}pdta)]^{-}$ complexes [14] are observed.

3.2. Description of the isomorphic crystal structures of $[Mg(H_2O)_6][Mn(1,3\text{-}pdta)(H_2O)]\cdot 2H_2O$ (2) and $[Mg(H_2O)_6][Cd(1,3\text{-}pdta)(H_2O)]\cdot 2H_2O$ (3) at 130 K

An ORTEP drawing of the $[Mg(H_2O)_6][Mn(1,3\text{-}pdta)(H_2O)]\cdot 2H_2O$ (**2**) complex, is depicted in Fig. 3, where the numbering scheme adopted for the respective atoms is also given. As **2** and **3** form isostructural crystals, drawing of the units that constitute complex **3** has not been provided. Metal–ligand bond lengths and valence angles around metal ions are compared in Table 4.

The structural units of **2** and **3** consist of $[Mg(H_2O)_6]^{2+}$ cations, situated at the inversion centers, and either $[Mn(1,3\text{-}pdta)(H_2O)]^{2-}$ or $[Cd(1,3\text{-}pdta)(H_2O)]^{2-}$ complex anions situated on twofold axes of symmetry, and two symmetry related water solvent molecules. The highest symmetry (C_2) axis of both complex anions passes through the metal center and coordinated water molecule O1W making the two out-of-plane glycinate rings (R rings), as well as the two in-plane glycinate rings (G rings), identical. The central carbon atom (C2) of the six-membered 1,3-propanediamine ring and hydrogen atoms attached to C1 are statistically distributed about the twofold symmetry axis. Both transition metals display the sevenfold coordination: with the hexadentate 1,3-pdta ligand and one water molecule O1W, the coordination polyhedron being a C_2 hybrid of the monocapped trigonal prism (CTP) and the pentagonal bipyramid (PB). That the geometry is better described as PB is seen by a detailed examination of Table 4 and Fig. 3. Among in-plane *cis* bond angles, O1–M(II)–O1W (M(II) stands for either Mn(II) or Cd(II)) is the closest to the value of 72° expected for ideal PB structure, while the largest deviation is observed for diamine bite angles (N1–M(II)–N1′) which adopt the values in the range 88.71(19)–90.47(15)°. Conformations of the chelate rings are found to be *envelope* for the glycinates and almost ideal *sofa* (*half boat*) for the six-membered diamine ring in both **2** and **3**, with the out of plane atom C2 disordered over two equally occupied alternative positions. Compared to octahedral complex **1**, the R-rings in **2** and **3** are significantly more puckered. Combined with this is the reverse relationship between M(II)–O_R and M(II)–O_G bond distances: while in octahedral complex **1** the M(II)–O_G bond lengths are significantly shorter than the M(II)–O_R distances, the reverse holds in PB complexes. Hence, we may conclude that a change in coordination number from 6 to 7 mostly affects the conformations of the R- and T-rings, and bond lengths, and angles in the girdle plane. The variation in M(II)–O bond lengths in PB complexes **2** and **3** (0.069 and 0.125 Å, for M(II)–O_G and M(II)–O_R, respectively) corresponds somewhat to the difference in the ionic radii of Cd(II) and Mn(II) ions (0.120 Å) [16] but for M(II)–N bonds the variation is much smaller (0.011 Å) indicating

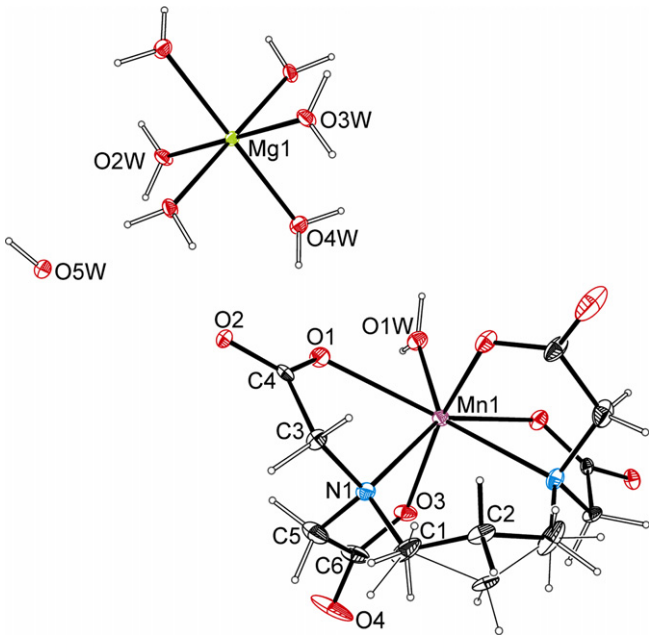

Fig. 3. Perspective drawing of the structural units constituting the crystal of **2.** The symmetry independent parts of the complexed cation and anion are marked by labeled atoms. Thermal ellipsoids which are drawn at 40% probability illustrate the displacements of atoms at 130 K. Within the complex anion, carbon atom C2, as well as hydrogen atoms attached to C1 are statistically distributed over two sites related by a twofold axis. The alternative position is shown by thin lines.

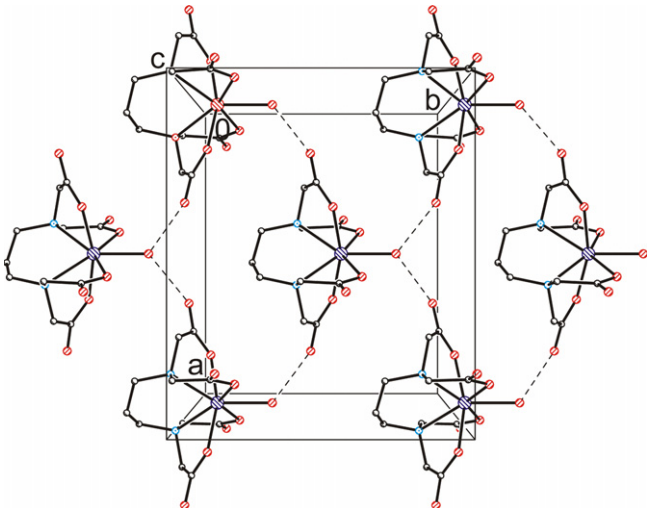

Fig. 4. View of the polar anionic (0 0 1) layer in the crystal structure of **2**. The subsequent anionic layers, separated by the hydrated magnesium cations, are arranged antiparallel.

a marked preference of Cd(II) cation for nitrogen donor atoms.

In the isostructural crystals of **2** and **3**, the complex anions, situated on a twofold *y*-axis, are arranged in (0 0 1) layers (Fig. 4). Within each layer the coordinated water molecules all point in the same direction, demonstrating its polarity. By acting as double hydrogen bond donors these water molecules join together the complex anions within the layer. Anionic layers are loosely packed, thus allowing for static disorder within the 1,3-propanediamine ring (*vide supra*). The type of disorder has been unequivocally established by comparing the previously reported room temperature X-ray results for **3** [4] with those at 130 K, presented in this paper, since lowering the temperature had no effect on the observed disorder. The neighboring anionic layers are arranged antiparallel and are separated by hydrated magnesium cations and solvent water molecules. Apart from electrostatic interactions, the cationic and anionic layers are joined together *via* water/carboxylate type of hydrogen bonds.

4. Conclusions

Isolation and X-ray elucidation of two distictly different Mn(II) complexes with 1,3-pdta ligand confirm our previous observations that 1,3-pdta ligand prefers hexadentate coordination. For metal ions with ionic radii exceeding 0.9 Å, the seven-coordinated hexadentate complex is to be expected. So far we have demonstrated that this is indeed the case for metal ions with d^0 [3], d^5 [this work] and d^{10}[4] configuration, as these ions provide no crystal field stabilization energy (CFSE), so the CFSE confers no advantage on any complex geometry [15]. The Mn(II) cation of the ionic radii 0.97 Å represents most probably the borderline case and, because of its electronic configuration (d^5), is particularly well suited to form complexes with variable geometries. Moreover, the described here solid solution of the composition $Mn_{0.5}Mg_{1.5}$ may be considered as resulting from isomorphic replacement of the Mg(II) ions occupying the "chelate" site by Mn(II) cations. In order to achieve this, the Mn(II) cations, which in general prefer to form seven-coordinated complex anions with 1,3-pdta ligand, readily adjust to the geometrical requirements of the six-coordinate 1,3-pdta complex, however, at the expense of the increased strain of the Mn(II) complex anion. From our previous investigations it follows that metals that can occupy both the "hydrated" and "chelated" site and hence might be expected to form solid solutions of the type described here, are Co(II), Zn(II) and Mg(II). To the best of our knowledge, no solid solution formation in 1,3-pdta complexes have been reported so far.

The chemical shift scale of ^{113}Cd covers about 900 ppm and shows a great sensitivity to the environment of Cd, even for complexes with closely related structures. Environments in which ^{113}Cd is completely ligated by oxygen usually give rise to resonances between −100 and +150 ppm. Coordination to nitrogen usually results in a downfield shift with resonances between +200 and +380 ppm, whereas bonding to sulfur causes a further downfield shift to between +350 and +800 ppm [10]. However, within these regions there are relatively few useful correlations with coordination numbers, and so structural predictions from solution chemical shift data are difficult to make. There is the added difficulty that ^{113}Cd chemical shifts in solution are affected by changes in pH and concentration, and there may also be large anion dependences. Further, cadmium complexes in solution are often labile and the chemical exchange behavior of ligands can severely handicap spectral interpretation [9,12–14].

Complexes of heterocyclic ligands such as imidazolidine-2-thione (Imt) and its derivatives with metal ions are of interest in bioinorganic chemistry because of the search for simple model compounds for metal-proteins [5–7]. In view of this, Cu(I), Au(I), Ag(I), Cd(II), Hg(II) and Pd(II) complexes with these ligands have been widely investigated in recent years [15–20]. These penta-atomic ligands exist in the N=C–SH and N–C=S forms, exhibiting a thiol $\Longleftrightarrow$ thione equilibrium [7,21]. However, it has been established that the thione form dominates in the solid state [7]. We have studied extensively the interaction of metal ions with imidazolidine-2-thione (Imt) and its derivatives [19,20,22].

In this paper, we report the solid state, solution NMR as well as X-ray structure studies of $Cd(thione)_2Cl_2$ complexes. Their antimicrobial activities are compared with the corresponding $Zn(thione)_2Cl_2$ complexes (see Scheme 1).

2. Experimental

2.1. Chemicals

$CdCl_2$, acetone, acetonitrile and DMSO-d_6 were obtained from Fluka Chemical Co. All the thiones were synthesized according to the procedure described earlier [23].

2.2. Preparation of the complexes

$CdCl_2$ (10 mmol) was dissolved in a minimum amount of water and the ligands (20 mmol) were dissolved in minimum amount of MeOH. In the case of poorly soluble ligands, acetonitrile was added to achieve complete solubility. Both solutions were mixed and stirred for about 30 min. The precipitates were collected and dried under vacuum. Yields of 55–65% were obtained.

The elemental analyses of all the complexes are given in Table 1.

2.3. Spectroscopic measurements

The measurements of solid-state IR and solution NMR were recorded as described in the literature [10a]. The chemical shifts of the ligands along with the corresponding complexes are given in Table 2.

2.4. Solid-state NMR

Natural abundance ^{113}Cd and ^{13}C solid-state NMR spectra were obtained on a JEOL LAMBDA 500 spectrometer operating at 110.85 MHz and 125.65 MHz, respectively, corresponding to a magnetic field of 11.74 T, at an ambient temperature of 25 °C. Samples were packed into 6 mm zirconia rotors. Cross-polarization and high power decoupling were employed. A pulse delay of 7.0 s and a contact time of 5.0 ms were used for cadmium and carbon observations in the CP MAS experiments. The magic angle spinning rates were from 3000 Hz to 5000 Hz. The cadmium chemical shifts were referenced using the secondary reference $Cd(NO_3)_2 \cdot 4H_2O$, by settings the peak to −100 ppm relative to 0.1 M $Cd(ClO_4)_2$ solution. The same $Cd(NO_3)_2 \cdot 4H_2O$ sample was used to set up the Hartmann–Hahn condition for the CPMAS experiments. ^{13}C chemical shifts were referenced to TMS by setting the high frequency isotropic peak of solid adamantine to 38.56 ppm. The isotropic peaks were differentiated from the spinning side-bands by recording the spectra at two different spinning speeds. ^{113}Cd CPMAS spectra for $Cd(EtImt)_2Cl_2$ and $Cd(N,N'DiMeImt)_2Cl_2$ complexes are shown in Figs. 1 and 2, respectively, and the isotropic peaks are indicated by an asterix. The ^{113}Cd and ^{13}C spectra containing spinning side-band manifolds were analyzed using a program based on Maricq and Waugh [24] and developed by Durham University, UK and run on a Unix platform. The calculated ^{113}Cd shielding tensors are shown in Table 3 and the chemical shifts of the thione complexes are given in Table 4.

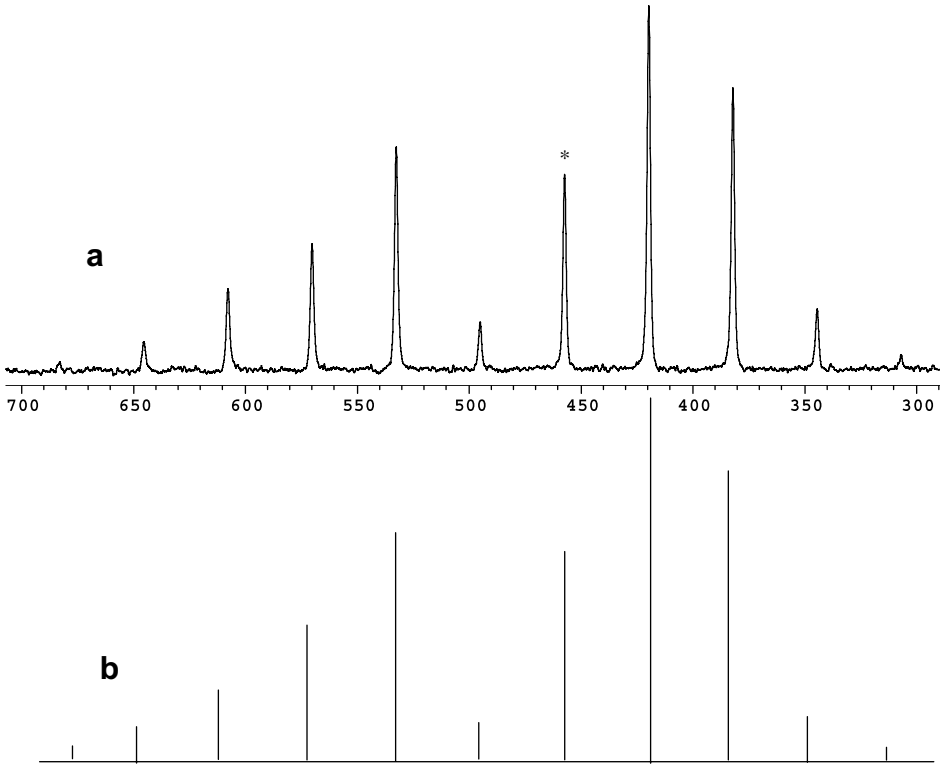

Fig. 1. ^{113}Cd CP MAS spectrum of $Cd(EtImt)_2Cl_2$. (a) Observed (1000 scans) and (b) calculated. * denotes the isotropic peak.

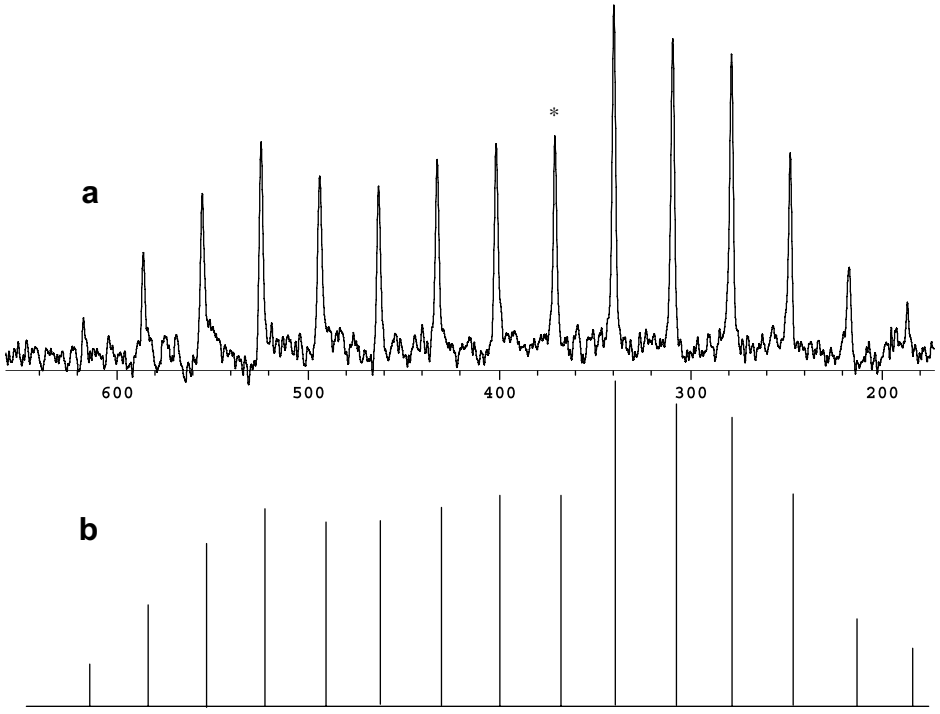

Fig. 2. ^{113}Cd CPMAS spectrum of $Cd(N,N'Me_2Imt)_2Cl_2$. (a) Observed (2000 scans) and (b) calculated. * indicates the isotropic peak.

2.5. Antimicrobial activity

Antimicrobial activity was measured as described in the literature [25]. The data for heterotrotropic plate counts (HPC), *Pseudomonas aeruginosa* (*P. aeruginosa*), Fecal Streptococcus (FS) and *Escherichia coli* (*E. coli*) are given in Table 5.

2.6. X-ray data collection and structure determination

Crystals were mounted on glass fibers. Diffraction data were recorded on a Bruker-Axs Smart Apex system equipped with graphite-monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). The data were collected using SMART [27]. The data integration was performed using SAINT [28]. An empirical absorption correction was carried out using SADABS [29]. The structure was solved with the direct methods and refined by full-matrix least-square methods based on F^2, using the structure determination and graphics package SHELXTL [30] based on SHELX-97 [31]. Hydrogen atoms were included at calculated positions using a riding model. An sp^2 hybridization was assumed for the nitrogen atoms of the NH groups. Crystallographic data are given in Table 6. Selected bond lengths and angles are given in Table 7. Complete bond lengths and bond angles, anisotropic thermal parameters and calculated hydrogen coordinates are deposited as Supplementary materials. The ORTEP atomic labelling schemes are given in Figs. 3 and 4.

3. Results and discussion

3.1. Solution NMR studies

$CdCl_2$ reacts with Imt and its derivatives in a 1:2 ratio, forming tetrahedral complexes of the general formula CdL_2Cl_2, except for the Diaz ligand. As demonstrated by the ^{13}C NMR (Table 2), the C-2 resonance is shifted by

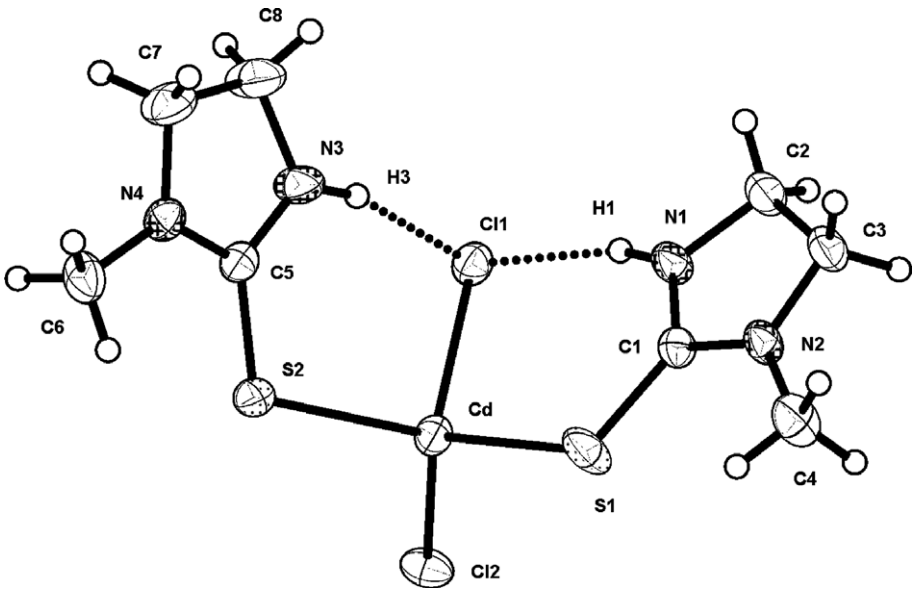

Fig. 3. Molecular structure of $(NMeImt)_2CdCl_2$ (**1**) showing the atomic labelling scheme.

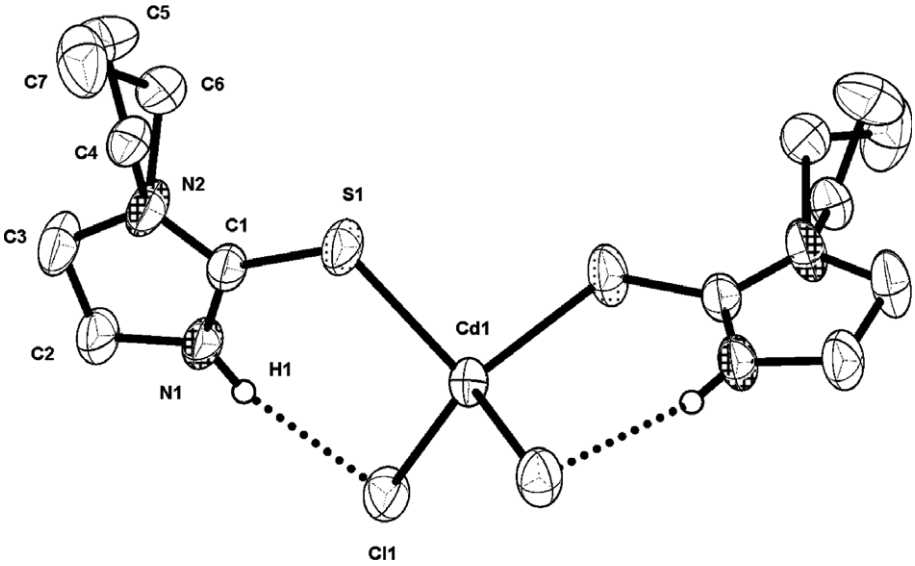

Fig. 4. Molecular structure of $(NEtImt)_2CdCl_2$ (**2**) showing the atomic labelling scheme. Most hydrogen atoms have been omitted for clarity.

2–3 ppm upfield upon complexation. However, similar complexations with HgL_2Cl_2 have shown shifts of more than 5 ppm for the C-2 resonances. All other resonances of the ligands remain unshifted, indicating the thione (>C=S) group of the ligand binding to the $CdCl_2$. Recently, we have reported the complexation of thiourea (TU) with MCl_2 where (M = Zn, Cd and Hg) forming $M(TU)_2Cl_2$ type complexes. The ^{13}C NMR chemical shifts between free and bound TU also show a similar trend, indicating Hg(II) > Cd(II) > Zn(II) [10a]. Lopez-Torres et al. [32] have studied the complexation of benzilbisthiosemicarbazone with Zn(II), Cd(II) and Hg(II) nitrate complexes. They found a similar bonding nature of these metal ions to the thione ligands, where the metal is bonded to the thione group of the ligand along with other binding sites, forming octahedral complexes. Their thione carbon is shifted the highest for the Hg(II) complex. However, selenourea (SeU) complexes with MCl_2 where (M = Zn, Cd and Hg), forming $M(SeU)_2Cl_2$ type complexes, show that the ^{77}Se NMR chemical shift difference between the free and bound SeU in $Cd(SeU)_2Cl_2$ is higher compared to $Zn(SeU)_2Cl_2$ and $Hg(SeU)_2Cl_2$ [10a]. The ^{77}Se NMR nucleus in $Cd(SeU)_2Cl_2$ is deshielded by 87 ppm on coordination relative to the free ligand. In comparison, the analogous Zn(II) and Hg(II) complexes, show deshielding by 33 and 50 ppm, respectively, indicating that the orbital overlap of Se with the second row transition metal is better than that with either the first or third-row metals.

3.2. Solid NMR studies

The cadmium chemical shift tensors, anisotropies and asymmetry factors for the complexes studied are shown in Table 3. Environments in which ^{113}Cd is completely ligated by oxygen usually give rise to resonances between −100 and +150 ppm, coordination to nitrogen results in a high-frequency shift to between +200 and +380 ppm, and bonding to sulfur causes a further high-frequency shift to between +350 and +800 ppm [9]. Among the chalcogens, sulfur is known to be the most deshielding [9].

The ^{113}Cd isotropic shift range observed in the complexes under investigation is +370 to +600 ppm. The cadmium chemical shift anisotropy in half of the complexes studied is negative while that for the other half of complexes are positive. This arises due to apparent swapping of σ_{11} and σ_{33} components in the different complexes. Hence proper care needs to be exercised when comparing individual tensor values. The least shielded tensor element can be aligned nearly orthogonal to the planes containing S ligands, as S would deshield Cd by removing electrons from filled shells in Cd via orbital mixing with outer metal orbitals and ligand orbitals of the appropriate symmetry. The asymmetry factor, η, for the complexes, falls in the full range of 0.0–0.99, indicating that the point symmetry occupied by cadmium in these complexes is very different from one another. This is further supported by the chemical shift anisotropy values showing a wide range. $CdCl_2$(N-Et Diaz)$_2$ and $CdCl_2$(OH Diaz)$_2$ complexes showed two sets of Cd resonances, indicating perhaps the presence of two crystallographically different Cd environments in the unit cell.

The ^{13}C isotropic chemical shifts are given in Table 4. We are able to see two carbon environments for all complexes, except for the Imt, NEtImt, N,N′Me$_2$Imt and N-Et Diaz complexes. Our X-ray study (vide infra) of (NMeImt)$_2CdCl_2$ confirms the presence of two slightly different environments for the two thione ligands, whereas the (NEtImt)$_2CdCl_2$ complex shows a twofold symmetry and hence only one type of thione ligand. However, only two complexes showed two different environments in the Cd spectra. So it may be concluded that most of the complexes studied show two non-equivalent ligands per molecule or two crystallographically inequivalent molecules per unit cell. This can only be resolved by X-ray studies. The thione carbons in the complexes are shielded by about 5 to 9 ppm compared to the free ligands [23] in the solid state.

3.3. Molecular structures of (NMeImt)$_2CdCl_2$ (1) and (NEtImt)$_2CdCl_2$ (2)

In both compounds, the metal ion is bound to the S atoms of two imidazolidine thione ligand molecules, in addition to two chloride ions. The four coordinate complexes have a distorted tetrahedral geometry. The bond angles are in the range 100.77(2)–117.18(3)° and 102.48(5)–111.91(5)° for **1** and **2**, respectively. In compound **1**, the average Cd–S and Cd–Cl bond lengths are 2.5387(7) Å and 2.4999(7) Å, respectively. A pronounced variation of the metal–ligand bond distances is observed in this compound, primarily for Cd–Cl and relatively to a less extent for Cd–S bond distances. In compound **2**, the molecule is located on a twofold rotation axis and due to symmetry considerations the sole bond distances are Cd1–S1: 2.5399(8) Å and Cd1–Cl1: 2.4284(8) Å. The ethyl group was found to be disordered on two positions with 0.5 occupancy each. The observed bond distances of the coordination sphere in the two compounds are in the same range as those found in the complexes $Cd(Imt)_2Cl_2$ [33] and $Cd(thiou)_2Cl_2$ [34]. In compounds **1** and **2**, the ligand molecules have their SCN_2 moieties essentially planar and have similar bond distances. For instance the corresponding bond distances in compound **2** are S1–C1: 1.702(2) Å, N1–C1: 1.312(4) Å and N2–C1: 1.309(3) Å. The bond lengths reported for the free imidazolinethione molecule are d(S–C) = 1.688(3) Å, d(C–N) = 1.330(3) Å and 1.329(4) Å [35]. Intramolecular and intermolecular hydrogen bonding interactions take place in the two compounds between the N-bonded hydrogen atoms and the chloride ions. These are believed to be the main factor at the origin of the distortion of these compounds. The significantly longer bond distance Cd–Cl1: 2.5497(7) Å compared with Cd–Cl2: 2.4501(6) Å in **1** is probably due to the stronger hydrogen bonding interactions of the Cl1 ion, engaged in intramolecular hydrogen bonding with H1 and H3

(Cl1···H1: 2.388 Å and Cl1···H3: 2.379 Å), while the Cl2 ion is involved in relatively weaker intermolecular hydrogen bonding interactions.

3.4. Bioactivity studies

The results of the bioactivity studies are given in Table 5. The Imt free ligand shows significant antimicrobial activity compared to Diaz and Diap. After complexation with Zn(II), the antimicrobial activity is increased [36]. The comparison between the activity of Imt and $Zn(Imt)_2Cl_2$, shows that HPC increased from 650 to 950, *P. aeruginosa* from 250 to 550, FS from 300 to 700, *E. coli* from 250 to 550. However, if we compare Diap and its $CdCl_2$ complex, it is observed that all antimicrobial activities are reduced, indicating the effect of the Cd^{2+} ion. On the other hand, the Zn^{2+} complex of Diap shows no significant effect. These results are important because no bioactivities for any thione ligands are reported in the literature. Since thione and thiol are in equilibrium, the data can be related to thiol containing complexes [25,26].

4. Conclusion

In this study, we have shown that a series of thiones react with $CdCl_2$ to form complexes of the type CdL_2Cl_2, in which the ligands exist in the thione form both in solution as well as in the solid state. The X-ray structures of $(NMeImt)_2CdCl_2$ (**1**) and $(NEtImt)_2CdCl_2$ (**2**) revealed distorted tetrahedral geometries for both complexes. The antimicrobial activity studies show that Imt has the highest activity compared to its six- and seven-membered ring counterparts and their Zn(II) complexes. However, the $Cd(Diap)_2Cl_2$ complex shows significant biological activity.

attracted considerable interest [7]. Although the mechanism of catalysis depends on the nature of the substrate, the oxidant and experimental conditions, it has been shown [8] that metal ions act as catalysts by one of these different paths such as the formation of complexes with reactants or oxidation of the substrate itself or through the formation of free radicals. Ruthenium(III) catalysis in redox reactions involves several complexes, different oxidation states of ruthenium, etc. The uncatalysed reaction of oxidation of L-leucine by DPA has been studied [9]. We have observed that ruthenium(III) catalyzes the oxidation of L-leucine by DPA in alkaline medium in micro amounts. In order to understand the active species of oxidant and catalyst, and to propose the appropriate mechanism, the title reaction has been investigated in detail. An understanding of the mechanism allows the chemistry to be interpreted, understood and predicted.

2. Experimental

2.1. Materials and reagents

All chemicals used were of reagent grade and double distilled water was used throughout the work. A solution of L-leucine (Sisco – Chem Ltd.) was prepared by dissolving an appropriate amount of recrystallised sample in double distilled water. The required concentration of L-leucine was used from its aqueous stock solution. A stock solution of Ru(III) was prepared by dissolving $RuCl_3$ (S.D. Fine Chemicals) in 0.20 mol dm^{-3} HCl. The concentration was determined [10] by EDTA titration. KNO_3 and KOH (BDH) were used to maintain the ionic strength and alkalinity of the reaction, respectively. An aqueous solution of $AgNO_3$ was used to study the product effect, Ag(I). A stock standard solution of IO_4^- was prepared by dissolving a known weight of KIO_4 (Riedel-de Haen) in hot water and used after keeping for 24 h. Its concentration was ascertained iodometrically [11] at neutral pH maintained using phosphate buffer. KNO_3 and KOH were used to maintain ionic strength and alkalinity of the reaction, respectively. Aqueous solution of $AgNO_3$ was used to study the product effect, Ag(I). The pH of the medium in the solution was measured using a [ELICO (LI613)] pH meter.

2.2. Preparation of DPA

DPA was prepared by oxidizing Ag(I) in the presence of KIO_4 as described elsewhere [12]: the mixture of 28 g of KOH and 23 g of KIO_3 in 100 cm^3 of water along with 8.5 g $AgNO_3$ was heated just to boiling and 20 g of $K_2S_2O_8$ was added in several lots with stirring, the mixture was then allowed to cool. It was filtered through a medium porosity fritted glass filter and 40 g of NaOH was added slowly to the filtrate, whereupon a voluminous orange precipitate agglomerated. The precipitate was filtered as above and washed three to four times with cold water. The pure crystals were dissolved in 50 cm^3 water and warmed to 80 °C with constant stirring, thereby some solid dissolved to give a red solution. The resulting solution was filtered when it was hot, and on cooling at room temperature orange crystals separated out and were recrystallised from water.

The complex was characterized from its UV spectrum, exhibiting three peaks at 216, 255 and 362 nm. These spectral features were identical to those reported earlier for DPA [12]. The magnetic moment study revealed that the complex is diamagnetic. The compound prepared was analysed [13] for silver and periodate by acidifying a solution of the material with HCl, recovering and weighing the AgCl for Ag and titrating the iodine liberated when excess KI was added to the filtrate for IO_4^-. The aqueous solution of DPA was used for the required [DPA] in the reaction mixture. During the kinetics a constant concentration, viz. 1×10^{-4} mol dm^{-3} of KIO_4, was used throughout the study unless otherwise stated. The possibility of oxidation of L-leucine by periodate was tested and found that there was no significant interference due to KIO_4 under the experimental conditions. The effect of dissolved oxygen on the rate of reaction was checked by preparing the reaction mixture and following the reaction in an atmosphere of nitrogen. No significant difference between the results obtained under nitrogen and in the presence of air was observed.

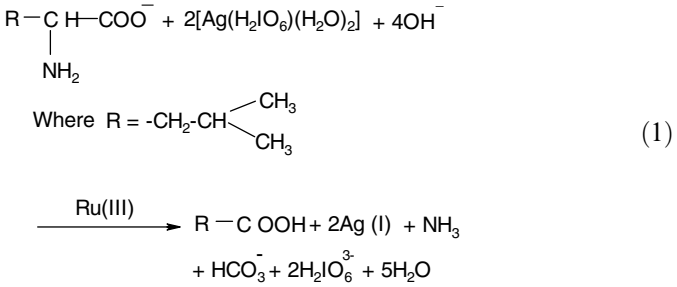
2.3. Kinetic measurements

The kinetic measurements were performed on a Varian CARY 50 Bio UV–Vis spectrophotometer. The kinetics were followed under pseudo-first-order conditions where [L-leu] > [DPA] at 25 ± 0.1 °C, unless specified. The reaction was initiated by mixing DPA with the L-leucine solution which also contained the required concentration of KNO_3, KOH, catalyst Ru(III) and KIO_4. The progress of the reaction was followed spectrophotometrically at 360 nm by monitoring the decrease in absorbance due to DPA with the molar absorbance index, 'ε' being 13 900 ± 100 dm^3 mol^{-1} cm^{-1}. It was verified that there was negligible interference from other species present in the reaction mixture at this wavelength.

The pseudo-first-order rate constants, 'k_C', were determined from the log(absorbance) versus time plots. The plots were linear up to 85% completion of the reaction under the range of [OH^-] used. The orders for various species were determined from the slopes of plots of $\log k_C$ versus respective concentration of species, except for [DPA] in which non-variation of 'k_C' was observed as expected for the reaction conditions. During the kinetic tests, a constant concentration (viz. 1.0×10^{-4} mol dm^{-3}) of KIO_4 was used throughout the study unless otherwise stated. Since periodate is present in excess with DPA, the possibility of oxidation of L-leucine by periodate in alkaline medium at 25 °C was tested. The progress of the reaction was followed iodometrically. However, it was found that there was no

significant reaction under the experimental conditions employed compared to the DPA oxidation of L-leucine. The total periodate concentration was calculated by considering the periodate present in the DPA solution and that was additionally added.

In view of the modest concentration of alkali used in the reaction medium, attention was also directed to the effect of the reaction vessel surface on the kinetics. Use of polythene/acrylic wares and quartz or polyacrylate cells gave the same results, indicating that the surface does not have any significant effect on the reaction rates.



In view of the ubiquitous contamination of carbonate in the basic medium, the effect of carbonate was also studied. Added carbonate had no effect on the reaction rates, however, fresh solutions were nevertheless used for carrying out each kinetic run.

Regression analysis of experimental data to obtain the regression coefficient r and the standard deviation S, of points from the regression line, was performed with the Microsoft office Excel-2003 program.

3. Results and discussion

3.1. Stoichiometry and product analysis

Different sets of reaction mixtures containing varying ratios of DPA to L-leucine in the presence of a constant amount of OH^-, KNO_3 and catalyst, were kept for 3 h in a closed vessel under nitrogen atmosphere. The remaining concentration of DPA was estimated by spectrophotometrically at 360 nm. The results indicate that two moles of DPA consumed one mole of L-leucine, 2:1 stoichiometry, for both catalysts as given in the following equation:

(1)

The main oxidation products were identified as pentanoic acid by a spot test [14], ammonia by Nessler's reagent and the CO_2 was qualitatively detected by bubbling nitrogen gas through the acidified reaction mixture and passing the liberated gas through a tube containing limewater. The nature of the carboxylic acid was confirmed by its IR spectrum, which showed a carbonyl(C=O) stretch at 1708 cm^{-1} and a signal at 3042 cm^{-1} due to the O–H stretching of the acid. The formation of free Ag+ in the solution was detected by adding KCl solution to the reaction mixture, which produced white turbidity due to formation of AgCl. It was observed that pentanoic acid does not undergo further oxidation under the present kinetic conditions. The products obtained are similar to those obtained for the uncatalysed reaction.

3.2. Reaction orders

As the diperiodatoargentate(III) oxidation of L-leucine in alkaline medium proceeds at a measurable rate in the absence of Ru(III), the catalysed reaction is understood to occur in parallel paths with contributions from both the catalysed and uncatalysed paths. Thus, the total rate constant (k_T) is equal to the sum of the rate constants of the catalysed (k_C) and uncatalysed (k_U) reactions, so $k_C = k_T - k_U$. Hence, the reaction orders have been determined from the slopes of $\log k_C$ versus log(concentration) plots by varying the concentrations of L-leucine, IO_4^-, OH^- and catalyst Ru(III), in turn, while keeping the others constant. The DPA concentration was varied in the range of 1.0×10^{-5}–1.0×10^{-4} mol dm^{-3} and the linearity of the plots of log(absorbance) versus time up to 85% completion of the reaction indicates a reaction order of unity in [DPA]. This is also confirmed by varying of [DPA], which did not result in any change in the pseudo-first-order rate constant, k_C (Table 1; Ru(III)). The L-leucine concentration was varied in the range 5.0×10^{-5}–5.0×10^{-4} mol dm^{-3} at 25 °C while keeping other reactant concentrations and conditions constant. The k_C values increased with the increase in concentration of L-leucine, indicating an apparent less than unit order dependence on [L-leu] (Table 1). The effect of alkali on the reaction has been studied in the range of 0.04–0.40 mol dm^{-3} at constant concentrations of L-leucine, DPA, catalyst and a constant ionic strength of 0.60 mol dm^{-3}. The rate constants increased with increasing [alkali] and the order was found to be less than unity (Table 1).

3.3. Effect of [periodate]

Periodate concentration was varied from 8.0×10^{-5} to 8.0×10^{-4} at constant [DPA], [L-leu], [catalyst] and ionic strength. It was observed that the rate constants decreased by increasing $[IO_4^-]$ (Table 1).

3.4. Effect of added products

Initially added products, Ag(I) and pentanoic acid do not affect the rate of reaction.

3.5. Effect of ionic strength (I) and dielectric constant of the medium (D)

The addition of KNO_3, to increase the ionic strength of the reaction, increased the rate of reaction at constant [DPA], [L-leu], $[OH^-]$, $[IO_4^-]$ and [Ru(III)]; the plot of $\log k_C$ versus $\sqrt{I}$ was found to be linear with a negative slope (Fig. 1).

The dielectric constant of the medium, 'D' was varied by varying the t-butyl alcohol and water percentage. The

decrease in dielectric constant of the reaction medium increases the rate and the plot of $\log k_C$ versus $1/D$ was linear with a negative slope (Fig. 1).

3.6. Effect of temperature

The influence of temperature on the rate of reaction was studied at 25, 30, 35 and 40 °C. The rate constants (k) of the slow step of Scheme 1 were obtained from the slopes, as were the intercepts of the plots of [Ru(III)]/k_C versus 1/[L-leu], [Ru(III)]/k_C versus 1/[OH] and [Ru(III)]/k_C versus [$H_3IO_6^{2-}$] at four different temperatures. The values are given in Table 2. The activation parameters for the rate determining step were obtained by the least square method of the plot of $\log k$ versus $1/T$ and the results are presented in Table 2.

3.7. Test for free radicals (polymerization study)

The intervention of free radicals was examined as follows, the reaction mixture, to which a known quantity of acrylonitrile scavenger had been added initially, was kept in an inert atmosphere for 1hr. Upon diluting the reaction mixture with methanol, a precipitate resulted, suggesting there is participation of free radicals in the reaction.

3.8. Effect of [Ru(III)]

The [Ru(III)] concentrations were varied from 1.0×10^{-6} to 1.0×10^{-5} mol dm^{-3}, at a constant concentration of diperiodatoargentate(III), L-leucine, alkali and ionic strength. The order in [Ru(III)] was found to be unity from the linearity of the plots of $\log k_C$ versus log[Ru(III)].

3.9. Catalytic activity

It has been pointed out by Moelwyn-Hughes [15] that in the presence of the catalyst, the uncatalysed and catalysed reactions proceed simultaneously, so that

[DPA] = 3.0×10^{-5}; [L-leu] = 2.0×10^{-4}; [OH$^-$] = 0.20; [Ru(III)] = 5.0×10^{-6} mol dm^{-3}; [IO_4] = 1.0×10^{-4} mol dm^{-3}.

$$k_T = k_U - K_C[\text{catalyst}]^x \quad (2)$$

Here, k_T is the observed pseudo-first-order rate constant in the presence Ru(III) catalyst, k_U the pseudo-first-order rate constant for the uncatalysed reaction, K_C the catalytic constant and 'x' the order of the reaction with respect to [Ru(III)]

$$K_C = \frac{k_T - k_U}{[\text{catalyst}]^x} = \frac{k_C}{[\text{catalyst}]^x} \quad (\text{where, } k_T - k_U = k_C) \quad (3)$$

In the present investigations, x values for the standard run were found to be unity for Ru(III). Then the value of K_C was calculated using Eq. (3). The values of K_C were evaluated for the Ru(III) catalyst at different temperatures and found to vary with temperature. Further, plots of log K_C versus $1/T$ were linear and the values of the energy of activation and other activation parameters with reference to the catalyst were computed. These results are summarized in Table 3. The value of K_C for Ru(III) is 3.6×10^2 at 298 K.

In the later period of the 20th century, the kinetics of oxidation of various organic and inorganic substrates were

[DPA] = 3.0×10^{-5}; [L-leu] = 2.0×10^{-4}; [OH$^-$] = 0.20; [IO_4] = 1.0×10^{-4}; $I = 0.60$; [Ru(III)] = 5.0×10^{-6} mol dm^{-3}.

studied by Ag(III) species, which may be due to its strong versatile nature of a two electron oxidant. Among the various species of Ag(III), $Ag(OH)_4^-$, diperiodatoargentate(III) and ethylenebis (biguanide) (EBS) silver(III) were of maximum attention to the researchers due to their relative stability [16]. The stability of $Ag(OH)_4^-$ is very sensitive towards traces of dissolved oxygen and other impurities in the reaction medium whereupon it had not drawn much attention. However, the other two forms of Ag(III) [5,6,17] are considerably stable; DPA is used in highly alkaline medium and EBS is used in highly acidic medium.

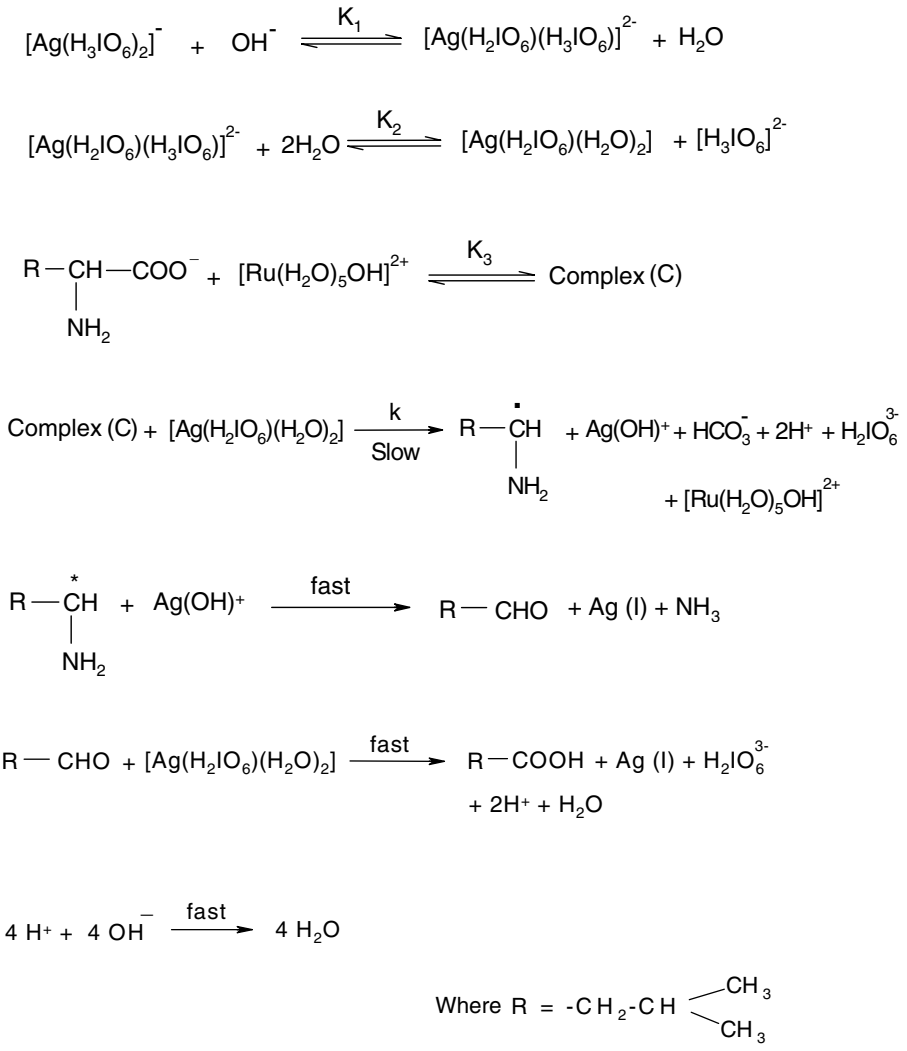
The literature survey [12] reveals that the water soluble diperiodatoargentate(III) (DPA) has a formula $[Ag(IO_6)_2]^{7-}$ with the dsp^2 configuration of a square planar structure, similar to the diperiodatocopper(III) complex with two bidentate ligands, periodate, which forms a planar molecule. When the same molecule is used in alkaline medium, it is unlikely to exist as $[Ag(IO_6)_2]^{7-}$ as periodate is known to be in various protonated forms [18] depending on the pH of the solution, as given in the following multiple equilibria (4)–(6):

$$H_5IO_6 \rightleftharpoons H_4IO_6^- + H^+ \quad (4)$$

$$H_4IO_6^- \rightleftharpoons H_3IO_6^{2-} + H^+ \quad (5)$$

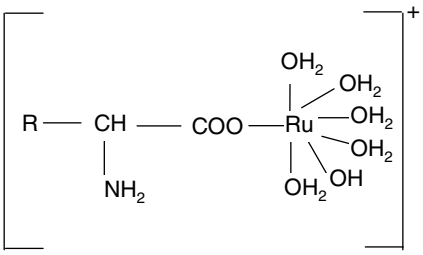
$$H_3IO_6^{2-} \rightleftharpoons H_2IO_6^{3-} + H^+ \quad (6)$$

Periodic acid exists as H_5IO_6 in acid medium and as $H_4IO_6^-$ at pH 7. Thus, under the present alkaline conditions, the main species are expected to be $H_3IO_6^{2-}$ and $H_2IO_6^{3-}$. At higher concentrations, periodate also tends to dimerise [3b]. However, formation of this species is negligible under the conditions employed for this kinetic study. On the contrary, the authors [5] in recent past studies have proposed DPA as $[Ag(HL)_2]^{x-}$ in which 'L' is a periodate with an uncertain number of protons and 'HL' is a protonated periodate of an uncertain number of protons. This can be ruled out by considering the alternative form [18] of IO_4^- at pH > 7, which is in the form $H_3IO_6^{2-}$ or $H_2IO_6^{3-}$. Hence, DPA could be $[Ag(H_3IO_6)_2]^-$ or $[Ag(H_2IO_6)_2]^{3-}$ in alkaline medium. Therefore, under the present conditions, diperiodatoargentate(III), may be



depicted as $[Ag(H_3IO_6)_2]^-$. A similar speciation of periodate in alkali was proposed [19] for diperiodatonickelate(IV).

It is interesting to identify the probable ruthenium(III) chloride species in alkaline media. The added chloride had no effect on the rate of reaction. Electronic spectral studies [20] have confirmed that ruthenium chloride exists in the hydrated form as $[Ru(H_2O)_5OH]^{2+}$. In the present study (at pH 13.3), it is quite probable that for $[Ru(III)(OH)_x]^{3-x}$, the x value would always be less than six because there are no definite reports of any hexahydroxy ruthenium species. The remainder of the coordination sphere would be filled by water molecules. Hence, under the conditions employed, e.g. $[OH^-] \gg [Ru(III)]$, ruthenium(III) is mostly present as the monomerichydroxylated species, $[Ru(H_2O)_5OH]^{2+}$ [21].



Since, the reaction was enhanced by $[OH^-]$, added periodate retarded the rate and there was first order dependency in [DPA] and catalyst, Ru(III), and fractional order in [L-leu] and $[OH^-]$, Scheme 1 has been proposed by considering L-leu as the anionic form of L-leu in alkaline medium, which also explains all other experimental observations.

In the prior equilibrium step 1, $[OH^-]$ deprotonates the DPA to give a deprotonated diperiodatoargentate(III); in the second step displacement of a periodate ligand takes place to give free periodate, which is evidenced by the decrease in rate with increase in [periodate] (Table 1). It may be expected that lower Ag(III) periodate species such as monoperiodatoargentate(III) (MPA) is a more important active species in the reaction than the DPA. The inverse fractional order in $[H_3IO_6]^{2-}$ might also be due to this reason. In the pre-rate determining stage, the hydroxylated species of Ru(III) combines with a molecule of anionic form of L-leu to give an intermediate complex, which further reacts with one mole of MPA in a rate determining step to give a free radical derived from L-leucine, with regeneration of the ruthenium(III) catalyst. This free radical from L-leucine further reacts with another molecule of MPA species in a fast step to give the products as given in Scheme 1.

The probable structure of complex (C) is given below:

Scheme 1. Detailed scheme for the Ru(III) catalysed oxidation of L-leucine by alkaline diperiodatoargentate(III).

Spectroscopic evidence for complex formation between the catalyst and substrate was obtained from UV–Vis spectra of L-leucine (2.0×10^{-4}), Ru(III) (5.0×10^{-6}, $[OH^-] = 0.2$ mol dm^{-3}) and a mixture of both. A hypsochromic shift of about 4 nm from 511 nm to 507 nm in the spectra of Ru(III) was observed. However, the Michaelis–Menton plot proved the complex formation between the catalyst and the reductant, which explains less than unit order in [L-leu]. Such a complex between a substrate and a catalyst has been observed in other studies. The rate law (8) for Scheme 1 could be derived as

$$\text{Rate} = \frac{-\mathrm{d}[\text{DPA}]}{\mathrm{d}t} = \frac{kK_1K_2K_3[\text{Ag(III)}][\text{L-leu}][OH^-][\text{Ru(III)}]}{[H_3IO_6^{2-}] + K_1[OH^-][H_3IO_6^{2-}] + K_1K_2[OH^-] + K_1K_2K_3[OH^-][\text{L-leu}] + K_3[H_3IO_6^{2-}][\text{L-leu}] + K_1K_3[\text{L-leu}][OH^-][H_3IO_6^{2-}]} \quad (7)$$

The terms $K_3[H_3IO_6^{2-}][\text{L-leu}]$ and $K_1K_3[\text{L-leu}][OH^-][H_3IO_6^{2-}]$ of the denominator of Eq. (7) can be neglected in the view of the low concentrations of L-leucine and periodate used in this study. Therefore, Eq. (7) becomes

$$\frac{\text{Rate}}{[\text{DPA}]} = k_C = k_T - k_U = \frac{kK_1K_2K_3[\text{L-leu}][OH^-][\text{Ru(III)}]}{[H_3IO_6^{2-}] + K_1[OH^-][H_3IO_6^{2-}] + K_1K_2[OH^-] + K_1K_2K_3[OH^-][\text{L-leu}]} \quad (8)$$

Eq. (8) can be rearranged into Eq. (9), which is suitable for verification

$$\frac{[\text{Ru(III)}]}{k_C} = \frac{[H_3IO_6^{2-}]}{kK_1K_2K_3[\text{L-leu}][OH^-]} + \frac{[H_3IO_6^{2-}]}{kK_2K_3[\text{L-leu}]} + \frac{1}{kK_3[\text{L-leu}]} + \frac{1}{k} \quad (9)$$

According to Eq. (9), plots of $[\text{Ru(III)}]/k_C$ versus $[H_3IO_6]^{2-}$, $\text{Ru(III)}]/k_C$ versus $1/[OH^-]$ and $[\text{Ru(III)}]/k_C$ versus $1/[\text{L-leu}]$ should be linear (Fig. 2). From the intercepts and slopes of such plots, the reaction constants K_1, K_2, K_3 and k were calculated as (0.25 ± 0.01) dm^3 mol^{-1}, $(1.61 \pm 0.06) \times 10^{-3}$ mol dm^{-3}, $(3.64 \pm 0.14) \times 10^4$ dm^3 mol^{-1} and $(1.0 \pm 0.03) \times 10^3$ dm^3 mol^{-1} s^{-1}, respectively. These constants were used to calculate the rate constants and were compared with the experimental k_C values, and were found to be in reasonable agreement with each other (Table 1), which fortifies Scheme 1. The equilibrium constant K_1 is far greater than K_2 which may be attributed to the greater tendency of DPA to undergo deprotonation compared to the formation of hydrolysed species in alkaline medium.

The thermodynamic quantities for the different equilibrium steps in Scheme 1 can be evaluated as follows. The L-leucine and hydroxide ion concentrations (Table 1) were varied at different temperatures. The plots of $[\text{Ru(III)}]/k_C$ versus $1/[\text{L-leu}]$ ($r \geqslant 0.9992$, $S \leqslant 0.00131$), $[\text{Ru(III)}]/k_C$ versus $[H_3IO_6^{2-}]$ ($r \geqslant 0.9991$, $S \leqslant 0.00132$), $[\text{Ru(III)}]/k_C$ versus $1/[OH^-]$ ($r \geqslant 0.9994$, $S \leqslant 0.00087$) should be linear as shown in Fig. 2. From the slopes and intercepts, the values of K_1 are calculated at different temperatures. A van't Hoff's plot was made for the variation of K_1 with temperature [i.e., $\log K_1$ versus $1/T$ ($r \geqslant 0.9992$, $S \leqslant 0.1104$)] and the values of the enthalpy of reaction ΔH, entropy of reaction ΔS and free energy of reaction ΔG, were calculated. These values are also given in Table 2. A comparison of the latter values with those obtained for the slow step of the reaction shows that these values mainly refer to the rate limiting step, supporting the fact that the reaction before the rate determining step is fairly slow and involves a high activation energy [22]. In the same manner, K_2 and K_3 values were calculated at different temperatures and the corresponding values of thermodynamic quantities are given in Table 2.

The decrease in the rate with increasing ionic strength is in favour of a reaction between opposite charged species of reactants, as presented in Scheme 1 of the proposed mechanism. The effect of solvent on the reaction rate is described in detail in the literature [23]. For the limiting case of a zero angle approach between two dipoles or anion–dipole system, Amis [23] has shown that a plot of $\log k_C$ versus $1/D$ gives a straight line with a negative slope for a reaction between a negative ion and a dipole or two dipoles, and with a positive slope for positive ion and dipole interaction. In the present study, the plot observed had a negative slope, which is in the right direction as shown in Scheme 1.

The negative value of $\Delta S^{\#}$ suggests that the intermediate complex is more ordered than the reactants [24]. The

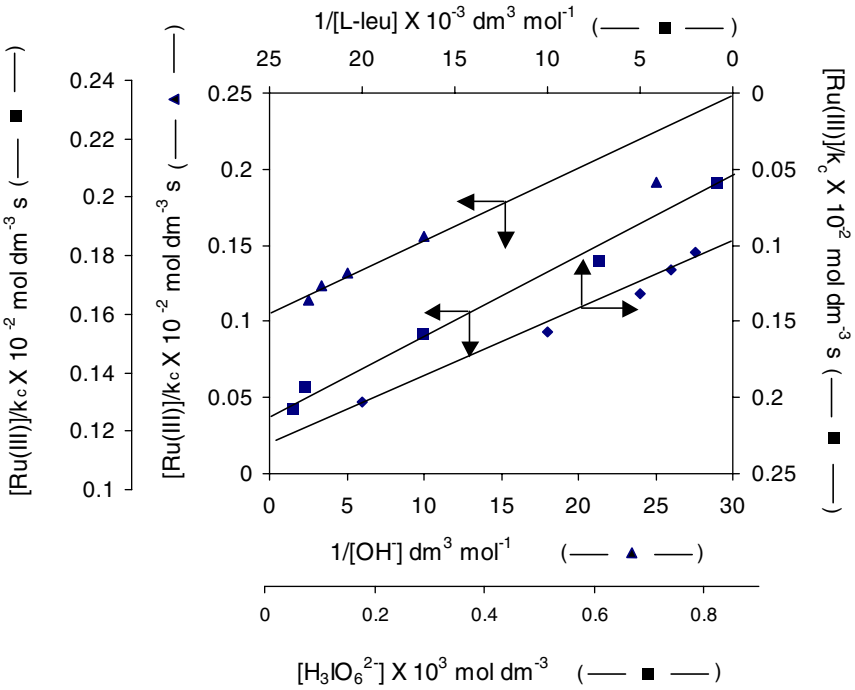


Fig. 2. Verification of rate law (9) of Ru(III) catalysed oxidation of L-leucine by diperiodatoargentate(III) at 25 °C.

observed modest enthalpy of activation and a higher rate constant for the slow step indicates that the oxidation presumably occurs via an inner-sphere mechanism. This conclusion is supported by earlier observations [25]. The activation parameters evaluated for the catalysed and uncatalysed reaction explain the catalytic effect on the reaction. The catalyst Ru(III) form the complex (C) with the substrate, which enhances the reducing property of the substrate than that without the Ru(III) catalyst. Further, the Ru(III) catalyst modifies the reaction path by lowering the energy of activation.

4. Conclusion

The Ru(III) catalysed oxidation of L-leucine by diperiodatoargentate(III) was studied. Oxidation products were identified. Among the various species of Ag(III) in alkaline medium, in earlier reports diperiodatoargentate(III) was the active species, whereas monoperiodatoargentate(III) is considered to be the active species for the title reaction. The active species of Ru(III) was found to be $[Ru(H_2O)_5OH]^{2+}$. Activation parameters were evaluated for both catalysed and uncatalysed reactions. Catalytic constants and the activation parameters with reference to the catalyst were also computed.

2. Experimental

2.1. Materials and measurements

Benzhydrazide, 2-acetylpyridine, copper(II) perchlorate hexahydrate (Fluka), sodium thiocyanate and sodium azide (Aldrich) were used as received. The solvents used were of reagent grade.

Elemental analyses were carried out using a Perkin–Elmer 2400 II elemental analyser. The infrared spectra were recorded on a Perkin–Elmer RX 1 FT-IR spectrophotometer with a KBr disc. The electronic spectra were recorded, in acetonitrile, on a Perkin–Elmer Lambda 40 (UV–Vis) spectrophotometer. Magnetic susceptibility measurements for the complexes **1** and **2** were carried out with a Quantum Design MPMS-5S SQUID magnetometer under an applied magnetic field of 5000 Oe. The temperature dependence of the molar magnetic susceptibility, χ_M, for the complexes **1** and **2** was measured on polycrystalline samples in the temperature range 2–300 K. Diamagnetic corrections were estimated from Pascal tables and magnetic data were corrected for diamagnetic contributions of the sample holder.

2.2. Synthesis of ligand and metal complexes

2.2.1. $[C_6H_5C(O)NHN{=}C(CH_3)C_5H_4N]$ (**LH**)

The ligand **LH** was prepared by the condensation of benzhydrazide (1.36 g, 10 mmol) with 2-acetylpyridine (1.12 ml, 10 mmol) in methanol (50 ml) according to the procedure reported elsewhere [9]. The resulting light yellow liquid was used without further purification.

Caution! Perchlorate salts are potentially explosive and should be used in small quantity and with much care.

2.2.2. $[Cu_2(L)_2(\mu_{1,1}\text{-}N_3)_2]$ (**1**)

To a methanolic solution (20 ml) of copper perchlorate hexahydrate (0.370 g, 1 mmol), the solution of the hydrazone ligand (**LH**) (1 mmol) was added, followed by the addition, with constant stirring, of a solution of sodium azide (0.065 g, 1 mmol) in minimum volume of water–methanol mixture. The final solution was kept at refrigerator temperature yielding dark green, hexagonal crystals suitable for X-ray diffraction after 6 days. Crystals were isolated by filtration and were air-dried. Yield – 61%. *Anal.* Calc. for $C_{14}H_{12}N_6OCu$: C, 48.86; H, 3.52; N, 24.42. Found: C, 48.61; H, 3.32; N, 24.09%.

2.2.3. $[Cu(L)(\mu_{1,3}\text{-}NCS)]_n$ (**2**)

The complex **2** was synthesised in a similar manner as described for **1**, except that sodium thiocyanate was used instead of sodium azide. Dark green, hexagonal crystals suitable for X-ray diffraction were obtained after 7 days. Crystals were collected by filtration and were air-dried. Yield – 53%. *Anal.* Calc. for $C_{15}H_{12}N_4OSCu$: C, 50.01; H, 3.36; N, 15.56. Found: C, 49.00; H, 3.32; N, 14.94%.

2.3. X-ray crystallography

The determination of the unit cell and the data collection for dark green coloured crystals of **1** and **2** was performed on a Bruker-Nonius X8 Apex2 Diffractometer. All data were collected with Mo Kα radiation ($\lambda = 0.71073$ Å). The structures of all the complexes were determined by direct method procedures in SHELXS [10a], and refined by full-matrix least-squares methods in SHELXL [10b]. Carbon-bonded hydrogen atoms were included in idealised positions and set to ride on the parent atoms. The crystallographic data and the refinement results are listed in Table 1.

3. Results and discussion

3.1. Description of the crystal structures

3.1.1. $[Cu(L)_2(\mu_{1,1}\text{-}N_3)_2]$ (**1**)

An ORTEP diagram of **1** with atom numbering scheme is given in Fig. 1. Bond dimensions about the copper atom in **1**, together with those **2**, are in Table 2; dimensions in the main chains of the **L** ligand and in the bridging ligands in both the complexes **1** and **2** are collated in Table 3. The structural study reveals that **1** is a semi-bridging centrosymmetric dimer. The azide ion bridges in an asymmetric (basal-apical) fashion so the bridging Cu–N bond lengths are significantly different ($\Delta d = 0.566$ Å). The copper centres are five-coordinate, bonded to three coordinating

atoms [N_2O] from the ligand **L** and nitrogen atoms from two bridging azide anions. Both azides bridge in an *end-on* fashion and this leads to a relatively small Cu–Cu (3.205 Å) separation.

The di-$\mu_{1,1}$-azido bridging nitrogen atom is in a planar Cu_2N_2 ring about a crystallographic inversion centre. The azide ions are nearly linear with N–N–N angle of 176.3(11)°. The geometry of the Cu(II) centres is close to square pyramidal with $\tau = 0.268$, [$\tau = |\beta - \alpha|/60°$, where

E.s.ds are in parentheses.

β and α are the two largest angles around the central atom; $\tau = 0$ and 1 for the perfect square pyramidal and trigonal bipyramidal geometries, respectively] [11]. The square base is formed by pyridyl and imine nitrogen atoms, a benzoyl oxygen atom and the closer of bridging azido nitrogen atoms. The nitrogen atom from the semi-bridging azide group with the longer Cu–N distance is at the apex. The distortion in the geometry is evident from the variation of the basal angles (Table 2) from equivalent *cis* and *trans* values.

3.1.2. [Cu(L)($\mu_{1,3}$-NCS)]$_n$ (2)

An ORTEP representation of **2** with the atom numbering scheme is shown in Fig. 2 and relevant bond dimensions are included in Tables 2 and 3. The structure is made up of infinite chains, in which Cu(II) centres are connected by single *end-to-end* thiocyanate bridges. The copper(II) pentacoordination sphere comprises the N_2O donor atoms from the tridentate deprotonated hydrazone ligand **L**, and a nitrogen and a sulfur atom from two molecules of bridging thiocyanate ligands. The geometry around the copper centre can be described as square pyramidal with $\tau = 0.0135$. The basal plane is formed by the N_2O donor atoms of **L** and the nitrogen atom of a thiocyanate ligand. The sulfur atom from the other thiocyanate ligand is at the apex. The apical Cu–S bond distance is significantly longer [2.7110(1) Å] than the basal bond distances [1.924(4)–2.020(5) Å], even when taking into account the larger covalent radius of sulfur . The bond dimensions around the Cu(II) ion are comparable to those in similar systems [7]. The thiocyanate ligand is almost linear at C1. The intrachain copper–copper separation is

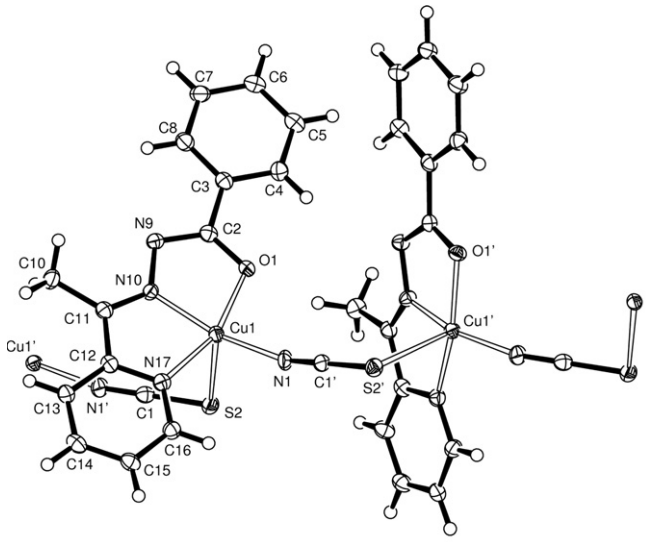

Fig. 2. View of two units in a chain of **2**, with atom labels. Displacement ellipsoids are shown at 50% probability level.

5.806 Å which is comparable to previously reported singly thiocyanate bridged copper complexes [12].

The crystal packing of the complex indicates that adjacent chains have pairwise π–π interactions, by overlap of phenyl with pyridine rings, with four adjacent chains (Fig. 3), thus connecting the chains in a three-dimensional network.

3.2. Infrared spectra

The infrared spectra of the complexes **1** and **2** display absorption bands at *ca.* 1563 cm^{-1} which can be assigned to the C=N stretching frequency of the coordinated ligand **L** [13]. In the spectra of complexes **1** and **2**, strong, well-resolved sharp bands at 2086 and 2028 cm^{-1} are assigned to $\nu_{N=N}$ of the azide (N_3) group and $\nu_{C=N}$ of the NCS group respectively. The ligand coordination to the metal centre is substantiated by two bands appearing for each complex, at 422, 312 (**1**) and 424, 315 (**2**) cm^{-1} attributable to ν_{Cu-N} and ν_{Cu-O} respectively.

3.3. Electronic spectra

The electronic spectral data for the complexes in acetonitrile are in good agreement with their geometries. The UV absorption bands exhibit a charge transfer transition (CT) in the range 350–420 nm for Cu(II) complexes and may be assigned to the ligand-to-metal charge transfer transition for each of the compounds **1** and **2**. The spectra of complexes **1** and **2** each display a broad band at 623 and 635 nm respectively, consistent with the expected five-coordinate geometry.

3.4. Magnetic studies

The temperature dependence of $\chi_M T$ for **1** is depicted in Fig. 4. The curve of $\chi_M T = f(T)$ is almost constant above 60 K with a value near 0.825 cm^3 K mol^{-1}, in good agreement with the expected value for two Cu(II) ions. Below 60 K, $\chi_M T$ slightly increases as T decreases to reach 0.875 cm^3 K mol^{-1} at 4 K. According to the dimeric structure of the complex, the $\chi_M T$ curve has been fitted using a classical Bleaney and Bowers law, using the phenomenological Hamiltonian $\mathbf{H} = -J\mathbf{S}_A\cdot\mathbf{S}_B$. The resulting law has the following form:

$$\chi_M T = \frac{2Ng^2\beta^2}{k[3 + \exp(-J/kT)]}$$

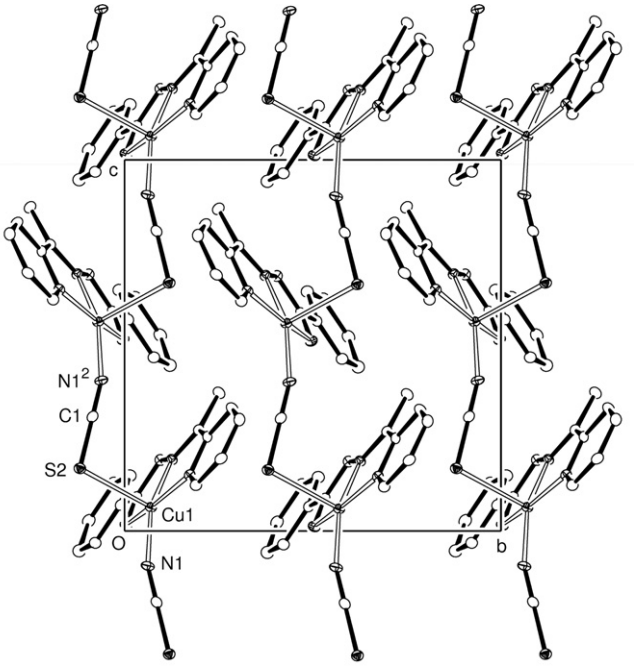

Fig. 3. Crystal packing showing the parallel chains of **2**, and the alignment of overlapping phenyl and pyridine rings.

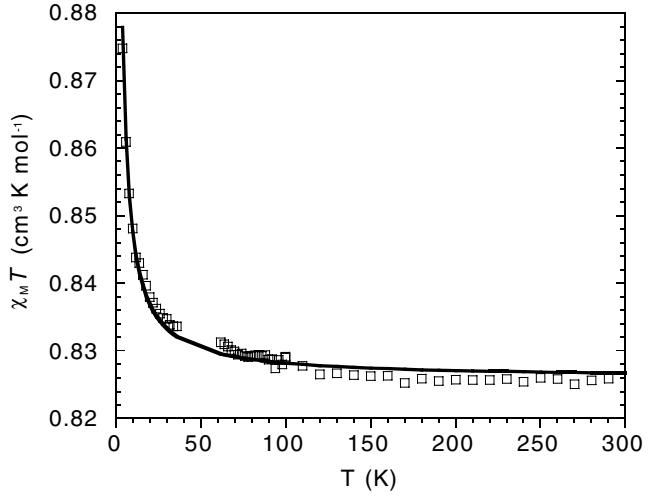

Fig. 4. Experimental (□) and calculated (—) temperature dependence of $\chi_M T$ for **1**.

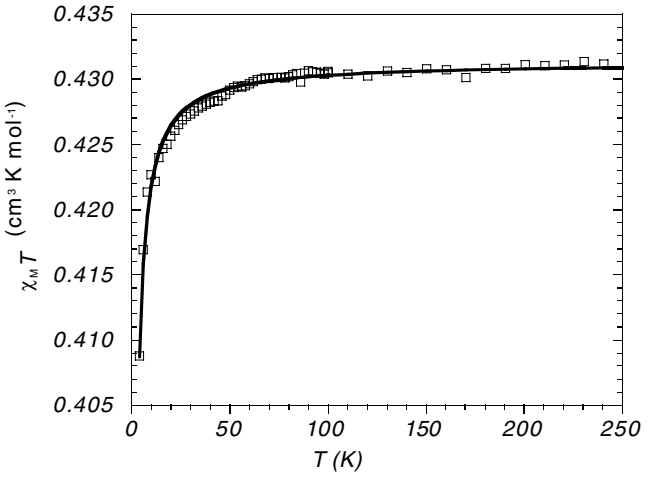

Fig. 5. Experimental (□) and calculated (—) temperature dependence of $\chi_M T$ for **2**.

The best fit was obtained with a Lande factor, g of 2.1, isotropic interaction parameter $J = +0.75\ \text{cm}^{-1}$. The two copper atoms of the dinuclear unit are linked by two azido bridging ligands in an *end-on* fashion. The copper atoms have a square pyramidal geometry and the bridging nitrogen atom of each azido ligand is in a basal position of one copper and the apical position of the second copper.

The temperature dependence of $\chi_M T$ for **2** is shown in Fig. 5. Due to the chain structure of the complexes, the model of equally spaced copper(II) ions has been used. The spin Hamiltonian in zero-field is $H = -J\sum_{i=1}^{n-1} S_{A_i} \cdot S_{A_{i+1}}$ where the summation runs over the n sites of the chain. When n tends to infinity, there is no analytical method to determine the magnetic susceptibility. However, the results can be fitted using the numerical expression for $J < 0$ [14]

$$\chi_M T = \frac{Ng^2\beta^2}{k} \frac{0.25 + 0.074975x + 0.075235x^2}{1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3}$$

with $x = -J/kT$.

For **2**, the best fit was obtained with a Lande factor, g of 2.14 and isotropic interaction parameter $J = -0.23\ \text{cm}^{-1}$. The sulfur atom of the thiocyanate bridge occupies the apical position of the copper cation.

The weak coupling for both the complexes may be explained as follows: the magnetic orbital describing the unpaired electron on a copper(II) ion in square pyramid is of the $d_{x^2-y^2}$ type (the x and y axes being defined by the short basal bonds). The overlap between the magnetic orbitals of two neighbouring coppers is thus very small, and the isotropic interaction parameter (roughly proportional to the square of this overlap) is expected to be small.

4. Conclusion

A double *end-on* azido bridged dinuclear copper(II) hydrazone complex, and a 1D chain copper(II) polymer of the same hydrazone ligand (**L**) with single *end-to-end* thiocyanate bridges have been isolated. Electronic spectra of the complexes support their geometries as established from X-ray analysis. Magnetic studies indicate a weak ferromagnetic interaction operates between the two metal centres in the doubly azido bridged complex **1**, whereas complex **2** exhibits weak antiferromagnetic interactions.

5. Supplementary material

CCDC 615282 and 615283 contain the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

L is hexadentate [10], tridentate [11], bidentate [12] or monodentate [13], respectively. These cationic species show a large variety of SC behaviors, depending on the non-coordinated counter anions and solvent of crystallization. The other family includes neutral compounds $[Fe(L)_y(A)_2]$ where $y = 1$ or 2 when L is tetradentate [14] or bidentate [15], respectively. The monodentate ligands A are most often NCS^- or $NCSe^-$ anions because halides or pseudohalides like N_3^- or NCO^- yield HS compounds (low ligand-field) while LS complexes can be obtained with CN^- (strong ligand field). To our knowledge, very few SC complexes have been prepared with tetradentate ligands [14,16] and an unique example of dissymmetrical ligand is depicted for an Fe^{II} complex [17]. The synthesis of new SC compounds is of utmost importance in this research area, particularly when the synthesis is performed in a controlled manner with the aim of obtaining compounds exhibiting a predictable SC behavior.

In the present contribution, we report an original synthetic route for the synthesis of new SC materials. We first synthesized new Fe^{II} complexes from symmetrical tetradentate Schiff base ligands: $[FeL^A(NCS)_2]$ (**1**) (L^A stands for *N*,*N*′-bis(1-pyridin-2-ylethylidene)-2,2-dimethylpropane-1,3-diamine), and $[FeL^{Bx}(NCS)_2]$ (**2**–**4**) (L^{Bx} stands for *N*,*N*′-bis[(2-R-1*H*-imidazol-4-yl)methylene]-2,2-dimethylpropane-1,3-diamine, with: R = H for L^{B1} in **2**, R = Me for L^{B2} in **3**, and R = Ph for L^{B3} in **4** (Fig. 1)). Complexes **1**–**4** remaining in the same spin-state over the 80–400 K range, dissymmetrical tetradentate Schiff bases L^{Cx} containing both pyridine and imidazole rings (Fig. 1) were then prepared as their $[FeL^{Cx}(NCS)_2]$ complexes, **5**–**10** (L^{Cx} stands for *N*-[(2-R_2-1*H*-imidazol-4-yl)methylene]-*N*′-(1-pyridin-2-ylethylidene)-2,2-R_1-propane-1,3-diamine, with: R_1 = H in **5**–**7**, and Me in **8**–**10**; R_2 = H for L^{C1} in **5** and **8**, R_2 = Me for L^{C2} in **6** and **9**, and R_2 = Ph for L^{C3} in **7** and **10**). Together with the single-crystal X-ray structures of **7** and **9**, variable-temperature magnetic susceptibility and Mössbauer studies of **5**–**10**, showed that it is possible to tune the spin-crossover properties in the $[FeL^{Cx}(NCS)_2]$ series by changing the 2-imidazole and/or C2-propylene substituent of L^{Cx}.

2. Experimental

2.1. Materials

All reagents and solvents were commercially available (Aldrich, Wako) and were used without further purification.

2.2. Syntheses

2.2.1. Ligands

The ligands were characterized by ^1H and in some cases by ^{13}C NMR in $CDCl_3$ (δ, ppm; s, singlet; d, doublet; t, triplet; dt = doublet of triplets; m, multiplet; b, broad).

2.2.1.1. Symmetrical ligands L^A and L^{Bx}. 2,2-Dimethyl-1,3-diaminopropane (0.102 g, 10^{-3} mol) and 2-acetyl-pyridine (0.242 g, 2×10^{-3} mol) for L^A, imidazole-4-carboxaldehyde (0.192 g, 2×10^{-3} mol) for L^{B1}, 2-methylimidazole-4-carboxaldehyde (0.220 g, 2×10^{-3} mol) for L^{B2}, 2-phenylimidazole-4-carboxaldehyde (0.344 g, 2×10^{-3} mol) for L^{B3}, were stirred for 2 h in 20 mL of methanol at room temperature. Slow evaporation of the solvent yielded brown-yellow oils (yield: 0.280 g (90%); 0.210 g (80%); 0.243 g (85%); 0.330 (80%) for L^A, L^{B1}, L^{B2}, and L^{B3},

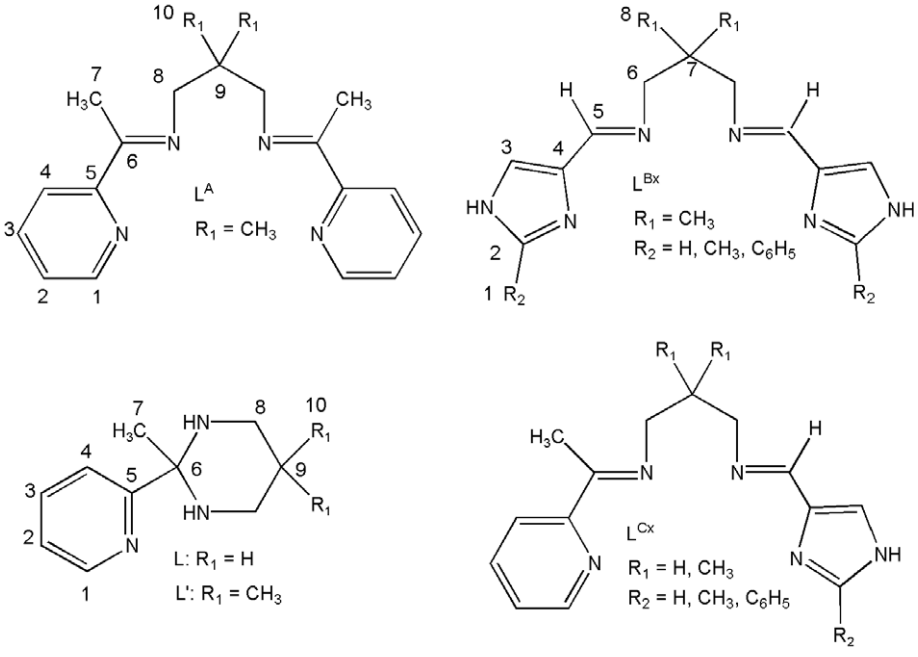

Fig. 1. Schematic representation of ligands L^A, L^{Bx}, L^{Cx} and of the half units L and L′ (R_1 = H, Me; R_2 = H, Me, Ph).

respectively). ^{1}H (250 MHz): L^{B1}, δ 7.91 (s, H5, 2H), δ 7.67–7.65 (sb, H1 and H3, 4H), δ 3.59 (s, H6, 4H), δ 1.06 (s, H8, 6H); L^{B2}, δ 7.98 (s, H5, 2H), δ 7.40 (s, H3, 2H), δ 3.37 (s, H6, 4H), δ 2.40 (s, H1, 6H), δ 0.93 (s, H8, 6H); L^{B3}, δ 7.97 (s, H5, 2H), δ 7.900–7.30 (m, H1, 10H), δ 7.69 (s, H3,2H), 3.42 (s, H6, 4H), δ 1.06 (s, H8, 6H). ^{1}H NMR spectra of L^A could not be assigned due to the presence of a mixture including the aminal resulting from single condensation followed by cyclization, and the Schiff base resulting from the usual bis-condensation [18]. Nevertheless, complexation with $Fe(NCS)_2 \cdot x$solvent led to quantitative formation of the desired symmetrical complex.

2.2.1.2. Synthesis of the half-units L and L′. 2-Acetyl-pyridine (0.121 g, 10^{-3} mol) was added to a solution of 1,3-diaminopropane (0.074 g, 10^{-3} mol) for L or of 2,2-dimethyl-1,3-diaminopropane (0.102 g, 10^{-3} mol) for L′ in 10 mL of CH_2Cl_2. The resulting pale yellow solution was stirred for 30 min and kept undisturbed at room temperature until complete evaporation of the solvent (yield: 0.17 g, 85% for L; 0.15 g, 83% for L′). Colorless crystals and an oil were obtained for L and L′, respectively. Both ligands were characterized by elemental analyses, IR (L), and 2D ^{1}H–^{13}C NMR. Ligand L: *Anal.* Calc. for $C_{10}H_{15}N_3$ (177 g mol^{-1}): C, 67.76; H, 8.53; N, 23.71. Found: C, 66.63; H, 8.25; N, 23.90%. IR (cm^{-1}): 1589, 1558, 1463, 1429, 786. ^{1}H NMR (400 MHz): δ 8.59 (d, H1, $J = 5.5$ Hz, 1H), δ 7.10 (t, H2, $J = 5$ Hz, 1H), δ 7.73 (t, H3, $J = 1.5$ Hz, 1H), δ 7.76 (d, H4, $J = 6$ Hz, 1H), δ 1.35 (s, H7, 3H), δ 2.62 and 2.93 (s, H8, 2H + 2H), δ 1.63 (m, H9, 2H). ^{13}C {^{1}H}NMR (100.6 MHz): δ 164.3 (C5), δ 158.2 (C1), δ 137.2 (C3), δ 121.3 (C2), δ 121.2 (C4), δ 71.7 (C6), δ 41.8 (C8), δ 27.0 (C9). Ligand L′. *Anal.* Calc. for $C_{12}H_{19}N_3$ (205 g mol^{-1}): C, 70.20; H, 9.33; N, 20.47. Found: C, 69.23; H, 9.26; N, 20.54%. ^{1}H (400 MHz): δ 8.61 (d, H1, $J = 5.5$ Hz, 1H), δ 7.77 (d, H4, $J = 7$ Hz, 1H), δ 7.71 (td, H3, $J = 2$ Hz and $J = 7$ Hz, 1H), δ 7.19 (td, H2, $J = 5.5$ Hz and $J = 2$ Hz, 1H), δ 1.41 (s, H7, 3H), δ 2.38 and 2.99 (s, H8, 2H + 2H), δ 0.69 and 1.14 (s, H10, 6H). ^{13}C {^{1}H} NMR (100.6 MHz):δ 164.1 (C5), δ 149.4 (C1), δ 137.1 (C3), δ 122.2 (C2), δ 122.0 (C4), δ 71.3 (C6), δ 53.7 (C8), δ 28.7 (C9), δ 23.3 and 23.88 (C10).

2.2.2. Complexes

All complexation reactions and sample preparations for physical measurements were carried out in a purified nitrogen atmosphere within a glovebox (Vacuum Atmospheres H.E.43.2) equipped with a dry train (Jahan EVAC 7).

2.2.2.1. $Fe(NCS)_2 \cdot xMeOH$. $Fe(ClO_4)_2 \cdot xH_2O$ (10^{-3} mol) was reacted with potassium thiocyanate (0.195 g, 2×10^{-3} mol) in 10 mL of MeOH following a procedure adapted from the preparation of $Fe(py)_4(NCS)_2$ [19]. After removal of potassium perchlorate through filtration, the freshly prepared $Fe(NCS)_2 \cdot x$MeOH was used immediately for the preparation of complexes **1**–**10**.

Caution: Although no such behavior was observed during the present work, perchlorate salts are potentially explosive and should be handled in small quantities and with much care.

*2.2.2.2. General procedure (**1**–**4**).* To a methanolic solution (10^{-3} mol in 10 mL) of the ligand was added slowly a methanolic solution (10^{-3} mol in 10 mL) of $[Fe(NCS)_2] \cdot x$MeOH. The solution immediately changed from pale yellow to dark blue (**1**) or orange–yellow (**2**–**4**) and was left under stirring for 30 min.

$[FeL^A(NCS)_2]$ (**1**): Slow crystallization (over 1 month) yielded dark blue crystals suitable for X-ray analysis. Yield: 0.34 g, 68%. *Anal.* Calc. for $FeC_{21}H_{24}N_6S_2$ (480.4 g mol^{-1}): C, 52.50; H, 5.04; N, 17.49; S, 13.35; Fe, 11.62. Found: C, 52.25; H, 5.05; N, 17.27; S, 13.29; Fe, 11.57%. IR (cm^{-1}): 2110–2090 (NCS); 1600 (imine).

$[FeL^{B1}(NCS)_2]$ (**2**): Orange crystals suitable for X-ray analysis were obtained after addition of Et_2O to the methanolic solution of **2**. Yield: 0.32 g, 75%. *Anal.* Calc. for $FeC_{15}H_{18}N_8S_2$ (430.3 g mol^{-1}): C, 41.87; H, 4.22; N, 26.04; S, 14.90; Fe, 12.98. Found: C, 41.78; H, 3.91; N, 25.88; S, 14.65; Fe, 12.89%. IR (cm^{-1}): 2110–2090 (NCS); 1603 (imine).

$[FeL^{B2}(NCS)_2]$ (**3**): Slow crystallization (over one week) yielded orange crystals suitable for X-ray analysis. Yield: 0.32 g, 70%. *Anal.* Calc. for $FeC_{17}H_{22}N_8S_2$ (458.4 g mol^{-1}): C, 44.55; H, 4.84; N, 24.45; S, 14.00; Fe, 12.20. Found: C, 44.47; H, 4.55; N, 24.44; S, 13.93; Fe, 11.61. IR (cm^{-1}): 2110–2090 (NCS); 1611 (imine).

$[FeL^{B3}(NCS)_2]$ (**4**): Yellow microcrystalline powder. Yield: 0.38 g, 65%. *Anal.* Calc./found for $FeC_{27}H_{27}N_8S_2$ (583.5 g mol^{-1}): C, 55.67; H, 4.50; N, 19.24; S, 11.00; Fe, 9.58. Found: C, 55.60; H, 4.27; N, 19.05; S, 10.29; Fe, 9.20%. IR (cm^{-1}): 2110–2090 (NCS); 1603 (imine).

*2.2.2.3. General procedure (**5**–**10**).* To a pale yellow solution (10^{-3} mol, 10 mL methanol) of the aminal L (**5**–**7**) or L′ (**8**–**10**) the freshly prepared $Fe(NCS)_2$ solution (10^{-3} mol, 10 mL methanol) was slowly added. The color of the reaction mixture immediately turned to dark blue and was stirred for 5 min. The appropriate 2R-imidazole-4-carboxaldehyde (10^{-3} mol, 10 mL methanol) was then added (imidazole-4-carboxaldehyde for **5** and **8**, 2-methylimidazole-4-carboxaldehyde for **6** and **9**, and 2-phenylimidazole-4-carboxaldehyde for **7** and **10**). No further color change was observed; the solution was stirred for 30 more minutes and then left undisturbed until a microcrystalline powder or crystals quantitatively formed.

$[FeL^{C1}(NCS)_2]$ (**5**): Dark blue powder. Yield: 0.32 g, 75%. *Anal.* Calc. for $FeC_{16}H_{17}N_7S_2$ (427.3 g mol^{-1}): C, 44.97; H, 4.01; N, 22.94; S, 15.01; Fe, 13.07. Found: C, 45.15; H, 4.00; N, 22.85; S, 14.67; Fe, 12.72%. IR (cm^{-1}): 2112–2060 (NCS); 1620 (imine).

$[FeL^{C2}(NCS)_2]$ (**6**): Dark blue powder. Yield: 0.32 g, 73%. *Anal.* Calc. for $FeC_{17}H_{19}N_7S_2$ (441.4 g mol^{-1}): C, 46.26; H, 4.34; N, 22.22; S, 14.53; Fe, 12.65. Found: C,

46.33; H, 4.49; N, 20.32; S, 14.39; Fe, 12.50%. IR (cm^{-1}): 2060 (NCS); 1638 (imine).

[$FeL^{C3}(NCS)_2$] (**7**): Dark blue single crystals. Yield: 0.30 g, 60%. *Anal*. Calc. for $FeC_{22}H_{21}N_7S_2$ (503.4 g mol^{-1}): C, 52.49; H, 4.21; N, 19.48; S, 12.74; Fe, 11.09. Found: C, 52.19; H, 3.84; N, 19.09; S, 12.70; Fe, 10.90%. IR (cm^{-1}): 2068 (NCS); 1641 (imine).

[$FeL^{C4}(NCS)_2$] (**8**): Dark blue powder. Yield: m = 0.32 g, 72%. *Anal*. Calc. for $FeC_{18}H_{21}N_7S_2$ (455.4 g mol^{-1}): C, 47.48; H, 4.65; N, 21.53; S, 14.08; Fe, 12.26. Found: C, 47.82; H, 4.47; N, 20.74; S, 13.81; Fe, 11.80%. IR (cm^{-1}): 2108–2058 (NCS); 1618 (imine).

[$FeL^{C5}(NCS)_2]\cdot H_2O$ (**9**): Dark blue single crystals. Yield: 0.35 g, 72%. *Anal*. Calc. for $FeC_{19}H_{23}N_7S_2\cdot H_2O$ (487.4 g mol^{-1}): C, 46.82; H, 5.17; N, 20.12; S, 13.16; Fe, 11.46. Found: C, 47.10; H, 4.52; N, 20.29; S, 12.73; Fe, 11.30%. IR (cm^{-1}): 2058 (NCS); 1634 (imine).

[$FeL^{C6}(NCS)_2$] (**10**): Dark blue microcrystals. Yield: 0.35 g, 66%. *Anal*. Calc. for $FeC_{24}H_{25}N_7S_2$ (531.5 g mol^{-1}): C, 54.24; H, 4.74; N, 18.45; S, 12.06; Fe, 10.51. Found: C, 54.04; H, 4.31; N, 18.16; S, 11.64; Fe, 10.51, 10.37%. IR (cm^{-1}): 2072 (NCS); 1643 (imine).

2.3. Physical measurements

Elemental analyses were carried out on a Perkin–Elmer 2400 series II device (C, H, N) at the Microanalytical Laboratory of the Laboratoire de Chimie de Coordination in Toulouse, and on a Maxim Thermoelectron device (S, Fe) at the Service Central de Microanalyses du CNRS in Vernaison, France. 1D ^1H and 1D ^{13}C NMR spectra were performed on an AC 250 FT spectrometer (Bruker) and 2D $^1H^{13}C$ spectra on an AMX 400 spectrometer (Bruker). Chemical shifts are given in ppm versus TMS (^1H and ^{13}C) using $CDCl_3$ as solvent. IR spectra were measured in the 400–4000 cm^{-1} range on a 9800 FTIR spectrometer (Perkin–Elmer). Samples were run as KBr pellets. Mössbauer spectra were recorded on a constant-acceleration conventional spectrometer with a 50 mCi source of ^{57}Co (Rh matrix). The absorber was a powdered sample enclosed in a 20 mm diameter cylindrical plastic sample holder, the size of which has been determined to optimize the absorption. Spectra were obtained in the 80–400 K range using a MD306 Oxford cryostat (4–293 K) or an home-made vacuum oven (300–500 K), the thermal scanning being monitored by an Oxford ITC4 servo control device (±0.1 K accuracy). A least square computer program [20] was used to fit the Mössbauer parameters and to determine their standard deviations of statistical origin (given in parentheses). Isomer shift values (δ) are relative to iron foil at 293 K. Variable temperature magnetic susceptibility data were collected on powdered samples on a MPMS-55 Quantum Design SQUID magnetometer or a Faraday type susceptometer under applied magnetic fields lower than 0.1 T. Diamagnetic corrections were applied by using Pascal's constants.

2.4. Crystallographic data collection and structure determination for *1*, *2*, *3*, *7* and *9*

The X-ray data for compounds **1**, **2**, **7** and **9** were collected on a Stoe Imaging Plate Diffractometer System (IPDS) equipped with an Oxford Cryosystems cooler device using a graphite monochromator ($\lambda = 0.71073$ Å). Data were collected [21] using φ rotation movement with the crystal-to-detector distance equal to 70 mm ($\varphi = 0.0$-270°, $\Delta\varphi = 1.5°$ for **1**, $\varphi = 0.0$–200°, $\Delta\varphi = 1.5°$ for **2** and **9** and $\varphi = 0.0$–250°, $\Delta\varphi = 1.4°$ for **7**). Diffraction data for **3** were collected using an Oxford-Diffraction XCALIBUR CCD diffractometer equipped with a graphite-monochromated Mo Kα radiation source. The crystal was placed 50 mm from the CCD detector. More than the hemisphere of reciprocal space was covered by combination of four sets of exposures; each set had a different φ-angle (0°, 90°, 180°, 270°) and each exposure of 20 s covered 0.75° in ω. Coverage of the unique set is 99.5% complete up to $2\theta = 63.22°$. The unit cell determination and data integration were carried out using the CrysAlis package of Oxford Diffraction [22]. All structures were solved by direct methods using SHELXS-97 [23] and refined by full-matrix least-squares on F_o^2 with SHELXL-97 [24] with anisotropic displacement parameters for non-hydrogen atoms. The hydrogen atoms were placed in calculated positions (C–H 0.96 Å) and they were included in the refinement in the riding-model approximation with $U_{iso} = 1.1$ U (atom of attachment). Positional parameters of the H(water) atoms in compound **9** were obtained from difference Fourier syntheses and verified by the geometric parameters of the corresponding hydrogen bonds. Scattering factors were taken from the standard compilation [25]. The molecular plots were obtained by using the ZORTEP program [26]. Numerical absorption corrections [27] were applied for **3**, while for compounds **1**, **2**, **7** and **9** the absorption corrections were introduced by semi-empirical methods based on equivalent reflections, using the program MULTISCAN [28]. The final full-matrix least-squares refinement, minimizing $\left[\sum w\left(|F_o^2| - |F_c^2|\right)^2\right]^2$, converged at the values of R and wR listed in Table 1, together with the main crystallographic parameters. The relatively high R-factors for complex **7** are due to the low quality of the crystals: among several sets of diffraction data obtained from different crystals which all diffracted poorly, the best one was used to solve this structure.

3. Results

3.1. Syntheses

While the reaction of 2 equiv of 2R-imidazole-4-carboxaldehyde with 1 equiv of 2,2-dimethyl-1,3-diaminopropane yielded pure samples of the corresponding acyclic tetradentate bis-Schiff bases L^{Bx}, the corresponding condensation reaction carried out with 2-acetyl-pyridine yielded a mixture including the cyclic aminal L′ resulting from single

condensation, and the Schiff base resulting from the usual bis-condensation. This lower reactivity of ketone compared to aldehyde carbonyl function is well documented [29] but has been scarcely exploited to prepare so-called 'half-unit' synthons through 1:1 condensation with the aim to generate dissymmetrical ligands through opening of the aminal ring and condensation of the amine function with a different carbonyl [30]. One of the reasons is the occurrence of redistribution reactions that yield mixtures of the respective symmetrical bis-Schiff bases corresponding to each carbonyl synthon, including or not a small percentage of the targeted dissymmetrical bis-Schiff base. Using a metal ion in order to favor the acyclic Schiff base versus the cyclic aminal intermediate through complexation, and to subsequently favor formation of the tetracoordinated dissymmetric bis-Schiff base has occasionally allowed avoiding redistribution reactions, and has thus allowed preparing dissymmetric bis-Schiff base cleanly and quantitatively in a very few cases [31].

Based on these results, we explored the 1:1 condensation reactions between 2-acetyl-pyridine and 1,3-diaminopropane or 2,2-dimethyl-1,3-diaminopropane. These reactions yielded the isolated aminal type ligands L: 2-(2-methylhexahydro-2-pyrimidinyl)pyridine and L′: 2-(2-methyl-5-dimethylhexahydro-2-pyrimidinyl)pyridine, respectively (first reaction sketched in Fig. 2).

The NMR spectra clearly showed that, in the case of L and L′, in the absence of metal ion the acyclic single condensation intermediate is not stable and the equilibrium is totally shifted toward the cyclic aminal form. Addition of 2R-imidazole-4-carboxaldehyde to L (L′) yielded mixtures of the respective symmetrical bis-Schiff bases and possibly a small amount of the targeted dissymmetrical bis-Schiff base, as suggested by the NMR spectra that showed a large number of intricated absorption resonances.

Clean and quantitative syntheses of the dissymmetrical ligands L^{Cx} could only be performed in the presence of $Fe(NCS)_2\cdot x$MeOH yielding their $[FeL^{Cx}(NCS)_2]$ (x = 1–6) complexes (Fig. 2). These results suggest that the metal ion displaces totally the equilibrium from the cyclic aminal toward the acyclic Schiff base intermediate through complexation as sketched in the second reaction of Fig. 2. The presence of the pyridine aromatic ring conjugated with Fe^{II} results in a strong MLCT band [32] responsible for the intense blue color of compounds **5**–**10** which are crystals (**7**, **9**), microcrystals (**10**), or more or less microcrystalline powders (**5**, **6**, **8**). The homogeneity (in color and texture) of all samples has been checked by microscopy. Moreover, Mössbauer spectroscopy has confirmed the presence of both HS and LS spin isomers in temperature dependent ratios for all compounds in this series, except for **6** which is 100% HS (see Mössbauer section and Table SM.2). Compounds **5**–**10** are oxidized in aerobic solutions. However, in the solid state, they are reasonably stable in aerobic conditions provided the samples are not exposed to moisture and/or heat. The absence of oxidation for all samples of compounds **1**–**10** in the solid state has been checked by

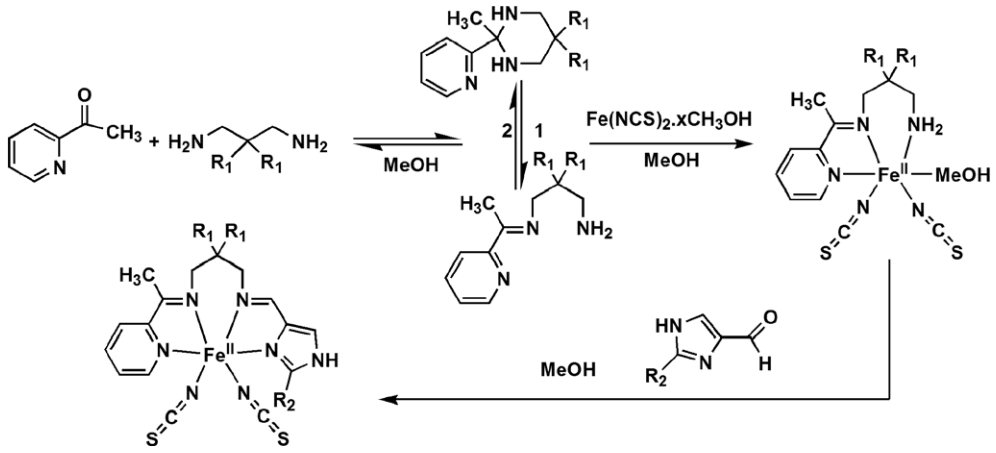

Fig. 2. Synthetic pathway for the family of complexes $[FeL^{Cx}(NCS)_2]$ based on the dissymmetrical tetradentate Schiff base ligands L^{Cx} (R_1 = H, Me; R_2 = H, Me, Ph).

EPR spectroscopy. Formation of the intermediate complexes $FeL(NCS)_2(MeOH)$ and $FeL'(NCS)_2(MeOH)$ sketched in Fig. 2 as resulting from addition of the ferrous salt to L (L′) is assessed on the basis of the color change observed upon addition of $Fe(NCS)_2 \cdot x$MeOH and on the rationale that complexation with the acyclic Schiff base intermediate is more likely due to the entropy gain upon conversion of the bidentate cyclic aminal into the tridentate Schiff base. However, these dark blue intermediate complexes are very soluble and we have not attempted to isolate them.

3.2. Description of the structures

ORTEP plots of complexes **1**, **3**, and **9** are shown in Figs. 3–5, respectively. Selected inter-atomic distances and angles for complexes **1**, **2**, **3**, **7** and **9** are collated in Table 2.

The overall molecular structure of the five complexes is similar: the distorted octahedral $[FeN_6]$ coordination environment includes four nitrogen atoms belonging to the tetradentate Schiff base ligand (L^A (**1**), L^{Bx} (**2** and **3**), and L^{Cx} (**7** and **9**)) in the equatorial positions, while the apical positions are occupied by nitrogen atoms from two NCS^- ligands. Within the estimated standard deviations, the iron atom is in the mean plane of the four equatorial nitrogen donors. However, the tetradentate Schiff base ligands, as a whole, exhibit more or less significant deviations from planarity. This can be due to the steric constraints imposed by the pyridine and/or imidazole moieties upon coordination to the metal center, and results in tilts of the aromatic rings from the mean plane of the tetradentate ligand. The larger tilt is observed for the py–py dihedral angle of **1** (32.6°), and the smaller one for the py–imidazole dihedral angle of **9** (4.8°). The Fe–N bond distances are characteristic of the spin-state of Fe^{II}: the average 1.949 Å value for **1** (293 K) is in good agreement with those observed for similar LS iron(II) complexes, while the average Fe–N bond distances of 2.185 Å (**2**, 200 K), 2.189 Å (**3**, 180 K), 2.196 Å (**7**, 180 K) and 2.150 Å (**9**, 293 K) indicate that the Fe^{II} center is in the HS state at the temperatures of the X-ray data collections for the four remaining compounds that have been structurally characterized [4,18]. In average, in the HS structures the N–Fe–N angles depart more from those expected for a regular octahedron (Table 2). It may thus be concluded that, except for the metric differences resulting from the difference in Fe^{II} spin-state, the complexes based on the L^A, L^{Bx} and L^{Cx} ligands have similar molecular structures.

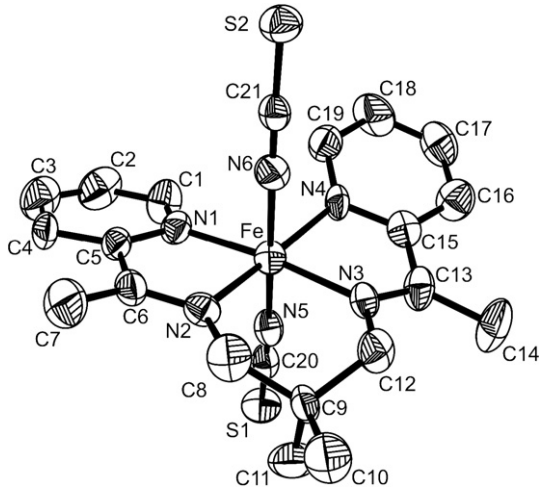

Fig. 3. ORTEP plot of complex **1** at the 40% probability level. H-atoms have been omitted for clarity.

On the other hand, these compounds provide a diversity of crystal packing modes, with a large variety of network topologies and these peculiarities deserve detailed consideration.

The crystal packing of **1** results from an extended 3D network of C–H···S contacts. A fragment of the crystal structure showing five H-bonded molecules is displayed in Fig. 6. The C···S distances between C–H···S bonded molecules are in the 3.59–3.69 Å range, in keeping with previous reports [18,33]. In addition, π–π stacking interactions involving the pyridine rings of molecules related by a crystallographic inversion center participate in the crystal

packing, as evidenced by the short interplanar (3.64 and 3.93 Å) and centroid to centroid (3.88 and 4.47 Å) distances between interacting pyridine rings.

The asymmetrical unit of **2** contains two crystallographically independent $[FeL^{B1}(NCS)_2]$ complex molecules denoted A and B (Fig. 7). Molecules A and B are linked

into a 3D supramolecular network via NH···S and NH···N hydrogen bonds, responsible for the crystal packing. A view of this supramolecular network showing four H-bonded molecules is displayed in Fig. 7, along with the hydrogen-bonding parameters. The four non-coordinated nitrogen atoms of molecules A and B act as proton donors, thus fulfilling all H-bonds opportunities in the crystal. The complex molecules inside each [A, B] pair are linked through N8B–H···N5A and N8A–H···S2B hydrogen bonds. It is noteworthy, that one of these hydrogen bonds involves as acceptor the nitrogen atom N7A coordinated to FeA, while the other one involves as acceptor the non-coordinated atom S2B. Further association of the complex molecules results from the N7B–H···S2A short contact which leads to the formation of tetra-molecular centrosymmetrical aggregates and finally to a 3D network through the N7A–H···S1B′ hydrogen bond (Fig. 7).

The crystal packing of **3** results from an extended 3D network of intermolecular interactions. Each $[FeL^{B2}(NCS)_2]$ complex molecule is involved in NH···S hydrogen bonds with its three nearest neighbors. A view of the supramolecular network showing four H-bonded molecules is displayed in Fig. 8, along with the hydrogen-bonding parameters, illustrating how this 3D supramolecular network is generated by two short intermolecular contacts involving the two non-coordinated imidazole nitrogen atoms and both sulfur atoms of the coordinated NCS^- anions. As for compound **2**, all H-bond opportunities are realized.

The molecular structure and crystal packing of **7** are shown in Fig. 9. The latter consists of alternate two-dimensional layers oriented along an *ac* crystallographic plane. Each layer is built from infinite chains connected through short intermolecular contacts (3.797(6) Å) between the S1 and S2 atoms related by translation along *a*. Two types of interactions are responsible for the association of the neutral $[FeL^{C3}(NCS)_2]$ molecules into a chainlike structure:

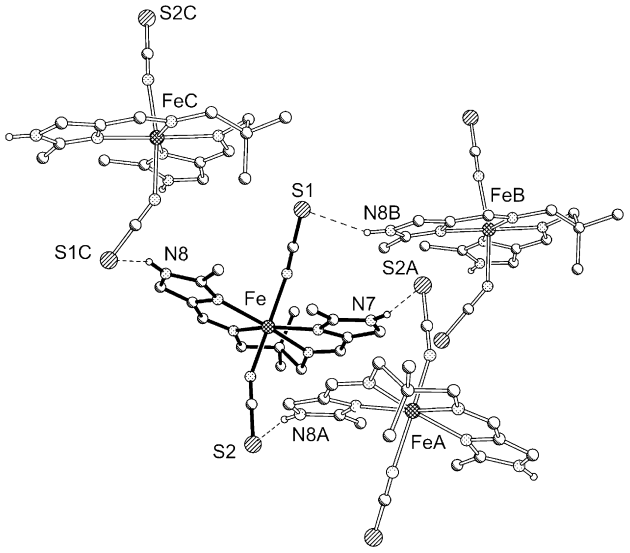

Fig. 8. Intermolecular interactions responsible for the supramolecular structure of $[FeL^{B2}(NCS)_2]$ (**3**). Metric parameters (d, Å; ∠, °): N7···S2′, 3.320(1); H···S2′, 2.457; ∠N7–H···S2′, 146.7°; N8···S1″, 3.340(1); H···S1″, 2.569; ∠N8–H···S1″, 166.7°; symmetry codes: (′) $1-x$, $1-y$, $2-z$; (″) $1.5-x$, $0.5+y$, $1.5-z$.

(i) the N7–H···S2′ (x, $0.5-y$, $-0.5+z$) hydrogen bond (N7···S2′, 3.37(2) Å; H···S2′, 2.52 Å; ∠N7–H···S2′, 170.3°); (ii) the π-stacking interaction between the pyridine and imidazole rings of adjacent molecules (centroid to centroid distances of 3.87 Å).

A view of the crystal packing of complex **9** is shown in Fig. 10. The supramolecular network is built from aggregates of complex molecules connected via two intermolecular H-bonds through the solvated water molecules. The water molecule acts as proton acceptor towards the non-coordinated imidazole nitrogen atom (N7···O1w, 2.83(2) Å; H···O1w, 1.97 Å; ∠N7–H···O1w, 173.8°). The water molecule also acts as proton donor towards the sulfur atom S2 of the symmetry related ($0.5-x$, $y-0.5$, $z-0.5$) complex molecule (O1w···S2′, 3.59(2) Å; H···S2′,

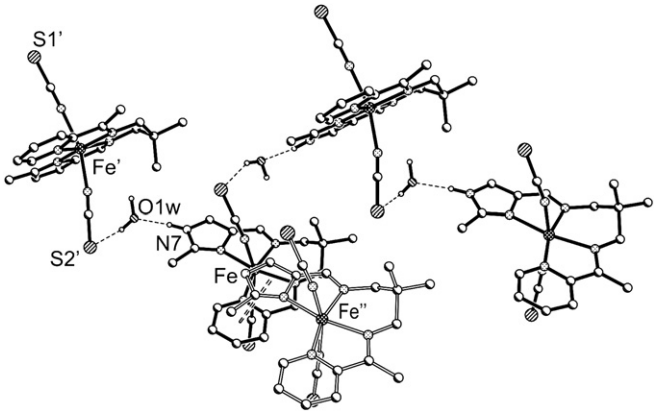

Fig. 10. View of the crystal packing of $FeL^{C5}(NCS)2] \cdot H_2O$ (**9**). Centroid to centroid distances between overlapping rings are materialized by broken double lines.

2.74 Å; ∠O1w–H···S2′, 152.8°). The chains of H-bonded molecules extend into a 3D network through π-stacking interactions between pyridine and imidazole rings belonging to adjacent chains, as evidenced by their centroid to centroid distances of 3.77 Å (Fig. 10). The dihedral angles between π-stacked rings equals 5.3°.

3.3. Magnetic studies

The thermal variation of the magnetic susceptibility χ_M has been explored for complexes **1**–**10** and the $\chi_M T$ data for selected temperatures (T) are collated in Table SM.1. The complete sets of $\chi_M T$ versus T data are shown in Figs. 11 and 12 (**1**–**4**) (**5**–**10**). The $\chi_M T$ product for **1** remains lower than 0.12 $cm^3\ mol^{-1}$ K between 110 and 400 K, indicating that the iron(II) center in this material is LS over the whole temperature range. The $\chi_M T$ product for the $[FeL^{Bx}(NCS)_2]$ complexes **2**–**4** is comprised between 4.12 and 3.70 $cm^3\ mol^{-1}$ K in the 80–300 K temperature range, indicating that the iron(II) center in this series of materials is HS over the whole temperature range. These data agree with the structural studies of complexes **1**–**3** that indicate Fe–N bond lengths characteristic of the LS (**1**, 293 K)

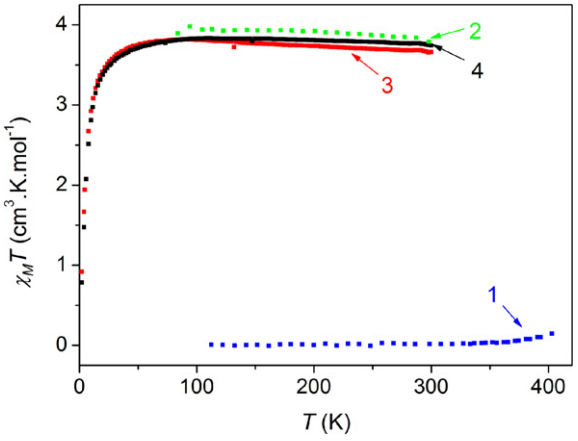

Fig. 11. Thermal variation of the $\chi_M T$ product for $[FeL^{A}(NCS)_2]$ (**1**), and the $[FeL^{Bx}(NCS)_2]$ complexes **2**–**4**.

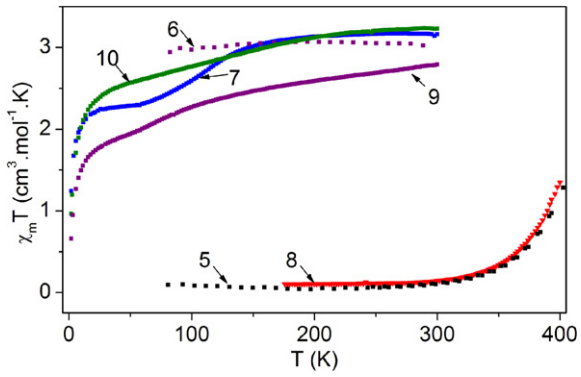

Fig. 12. Thermal variation of the $\chi_M T$ product for the $[FeL^{Cx}(NCS)_2]$ complexes **5**–**10**.

and HS (**2**, 200 K; **3**, 180 K) states, respectively. However, the $\chi_M T$ product at room temperature for **2**–**4**, as well as that for **7** and **10** that will be discussed next, is higher than the spin-only value of ~3 $cm^3\ mol^{-1}$ K expected for $S = 2$ ($g = 2$), as often observed for HS Fe^{II} compounds. The presence of small amounts of HS Fe^{III} (possibly resulting from oxidation of the prepared Fe^{II} materials) being discarded by their Mössbauer spectra (see following subsection), these high $\chi_M T$ values are attributed to operation of spin-orbit coupling (SOC). The $^5T_2$ ground state is split by SOC yielding levels separated by energies on the order of kT (thermally populated in the high temperature range) which results in slightly temperature dependent $\chi_M T$ values above ca. 60 K [34].

With the exception of compound **6**, and at variance with the two previous series, the $\chi_M T$ product for the $[FeL^{Cx}(NCS)_2]$ complexes **5**–**10** is not constant over the explored temperature range (Fig. 12). The $\chi_M T$ product for complexes **7** and **10** (R_2(imidazole) = Ph) is practically constant from 300 to 160 K and characteristic of a large predominance of HS Fe^{II}. Then it decreases between 150 and 50 K: for **7**, $\chi_M T$ decreases from 3.03 to 2.25 $cm^3\ mol^{-1}$ K, indicating a partial HS → LS transition centered around 100 K of ca. 20% Fe^{II} centers. The transition is much more gradual for **10** (Table SM.1). The thermal variation of the $\chi_M T$ product for complex **9** (R_1 = Me, R_2(imidazole) = Me) showing a very gradual and partial SC between 250 and 50 K (ca. 25%) is similar to that described above for **7** and **10** (R_2(imidazole) = Ph). All three compounds exhibit a sharp $\chi_M T$ decrease below 30 K resulting from zero field splitting (ZFS) of HS Fe^{II}. The $\chi_M T$ product for complex **6** (R_1 = H, R_2(imidazole) = Me) is practically constant over the 80–300 K temperature range indicating the absence of SC for Fe^{II} in this material above 80 K.

On the other hand, the magnetic behavior of complexes **5** and **8** (R_2(imidazole) = H) is strikingly different: their $\chi_M T$ product, practically constant and lower than 0.10 (**5**) and 0.13 (**8**) $cm^3\ mol^{-1}$ K from 80 to 300 K, is characteristic of LS Fe^{II}. Then, above 330 K, $\chi_M T$ increases up to 1.29 and 1.37 $cm^3\ mol^{-1}$ K at 400 K for **5** and **8**, respectively, indicating a LS → HS transition centered above

400 K (ca. 30% Fe^{II} centers are involved between 330 and 400 K).

3.4. Mössbauer spectroscopy

Mössbauer spectra have been recorded at selected temperatures in the 20–400 K range for complexes **1**–**10**. Values of the Mössbauer parameters (isomer shift, δ, quadrupole splitting, ΔE_Q, and line width, Γ) resulting from fitting the 80 and 293 K spectra are collated in Table SM.2. The isomer shift values slightly decrease with increasing temperature, indicating operation of second-order Doppler effect [35].

3.4.1. $[FeL^{A}(NCS)_2]$ and $[FeL^{Bx}(NCS)_2]$ complexes

As expected from the structural and magnetic data, the Mössbauer spectrum of **1** at 293 K consists of a unique doublet characteristic of LS Fe^{II} (δ, 0.328(2) mm s^{-1}; ΔE_Q, 0.865(3) mm s^{-1}). In agreement with the structural and magnetic data, Mössbauer spectra of complexes **3** and **4**, recorded between 80 and 293 K, show a unique quadrupole split doublet characteristic of HS Fe^{II} (Table SM.2). At variance with those of **3** and **4**, the Mössbauer spectra of **2** evidence two HS doublets in agreement with the presence of two distinct Fe^{II} sites, Fe^{II}(A) and Fe^{II}(B), in the crystal structure. These doublets present similar isomer shifts (~1.15 mm s^{-1} at 80 K, Table SM.2) as expected for identical N_6 donor sets around the Fe^{II}(A) and Fe^{II}(B) sites and quite different ΔE_Q values (~1.51 and ~2.58 mm s^{-1} at 80 K for Fe^{II}(A) and Fe^{II}(B), respectively), in agreement with different low symmetry environments [36]. The differences in Fe–N bond lengths and N–Fe–N angles associated to the different hydrogen contacts lead to significant differences in symmetry of the ligand environment for the Fe^{II} centers of molecules A and B, see Section 3.2.

3.4.2. $[FeL^{Cx}(NCS)_2]$ complexes

The Mössbauer spectra of complexes **6**–**10** confirm the spin-states deduced from the magnetic data for these materials; however, due to poor counting statistics, the high temperature spectra (350–400 K) of complexes **5** and **8** could not be fitted. As an example, in the following we describe the behavior of complex **7**, $[FeL^{C3}(NCS)_2]$, for which representative Mössbauer spectra recorded in the cooling mode are shown in Fig. 13. These spectra, measured in the 20–293 K range, confirm the partial SC deduced from the magnetic measurements.

The relative area of the HS doublet ($\delta = 1.113(2)$ and $\Delta E_Q = 2.563(4)$ mm s^{-1} at 80 K) slightly decreases from 80% at 293 K to 60% at 20 K, confirming the gradual and incomplete character of the SC in this material. The Mössbauer parameters of the LS doublet ($\delta = 0.439(3)$ and $\Delta E_Q = 0.732(5)$ mm s^{-1} at 80 K) are in agreement with previously reported values [4,18,35].

Comparison of Table SM.1 and Figs. 11 and 12 on the one hand to Table SM.2 and Fig. 13 on the other hand illustrates how important it is to use a local probe like Mössbauer spectroscopy in addition to bulk susceptibility measurements in order to assess the presence or absence of SC, and the relative percentages of spin isomers. Among compounds **6**–**10** for example, **7** shows the second highest $\chi_M T$ product in the high temperature range, suggesting the absence of LS fraction at high temperature. However, Mössbauer spectroscopy evidences a partial SC with ~20% of residual LS fraction at 293 K, the second highest among materials **6**–**10**. On the other hand, **6** shows the lowest $\chi_M T$ product at room temperature while Mössbauer spectroscopy evidences the absence of LS fraction at 293 K.

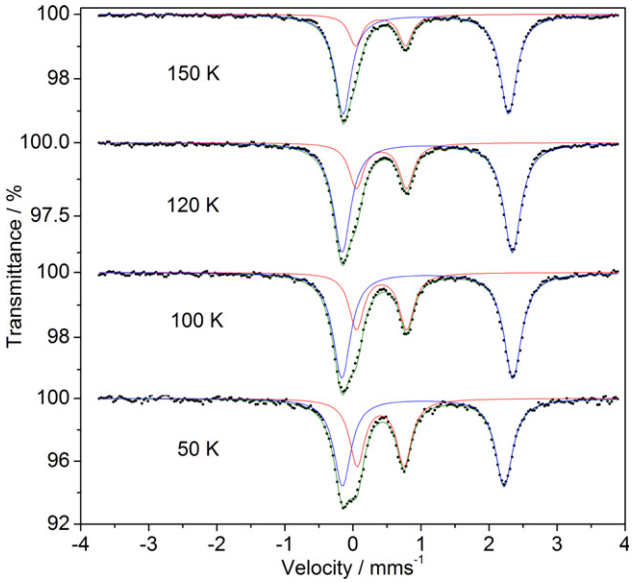

Fig. 13. Selected Mössbauer spectra of $[FeL^{C3}(NCS)_2]$ (**7**).

3.5. IR spectroscopy

The IR study has been focussed on the NCS stretching absorptions (2000–2100 cm^{-1} range) which constitute a good sensor for the *cis* or *trans* conformation of coordinated thiocyanate anions. Usually, *trans* isomers give a single absorption whereas *cis* isomers are characterized by a splitting of the ν_{CN} absorption [15b,37]. However, this criterion must be considered with much caution because the splitting of this band is very sensitive to slight deformations of the coordination sphere (in particular the N–M–N angle between the two thiocyanate ligands coordinated to the metal center). The structural study of complex **3** has evidenced a distorted octahedral geometry around Fe^{II} with a *trans* conformation of the thiocyanate ligands. Two well distinct ν_{CN} absorption bands were observed in the IR spectra at 2093 and 2065 cm^{-1} in compliance with the strong deviation from an ideal *trans* conformation evidenced by the 158.8° (C17–N8–Fe) and 137.5° (C16–N7–Fe) angles. The same conclusion can be drawn from the IR spectra of complexes **2** and **4**, as well as for complexes **5**–**10** ($[FeL^{Cx}(NCS)_2]$ series). The larger splitting (64 cm^{-1})

observed for **4** suggests a larger deformation of the ligand environment symmetry around Fe^{II}, in agreement with the large quadrupole splitting evidenced by Mössbauer spectroscopy. The third band (low intensity) observed for **2** can be explained by the presence of two types of NCS ligands, depending on the atom through which they participate into hydrogen bonds (NH···SCN or NH···NCS that leads to two Fe^{II} sites distinguishable crystallographically and by Mössbauer spectroscopy, see the corresponding subsections above). In line with our previous report on parent iron(II) compounds with related dissymmetric Schiff bases [32], the $\nu_{C=N}$(imine) absorptions observed for compounds **1**–**10** do not seem to depend on the spin-state of iron(II). This is possibly because they are no longer pure $\nu_{C=N}$ (imine) stretches, but correspond to the simultaneous involvement of $\nu_{C=N}$(imine), $\nu_{C=N}$(py) and $\nu_{C=N}$(imidazole) vibrators.

4. Discussion

Tetradentate ligands including exclusively nitrogen donors have been scarcely used in association with coordinating pseudohalide anions to prepare Fe^{II} SC complexes with a N_6 ligand environment. The first examples were reported by Toftlund et al. [14a]. and included tripodal ligands of the tris-pyridylamine (tpa) type associated with two *cis*-coordinated pseudohalide anions: varying the tpa substituents or the pseudohalide yielded different SC behaviors or mixtures of spin isomers. A related type of Fe^{II} SC material, also including a tripodal N_4 ligand (dppa) and two *cis*-coordinated NCS^-, was reported later by Matouzenko et al. [14c]. Finally, Toftlund et al. [14b] also reported a series of Fe^{II} compounds including acyclic Schiff bases resulting from condensation of R-pyridinecarboxaldehydes (R = H, Me) or acetylpyridine with ethylenediamine or propylenediamine (bpn ligand type) associated with two pseudohalide anions: again, depending on the ligand substituents and alkyl bridge, they observed different magnetic behaviors. While the *cis*-coordination mode of NCS anions was imposed by the tpa or the dppa topology, no such constraint was imposed by the bpn ligands; however the NCS anions were also *cis*-coordinated in the bpn series of Fe^{II} compounds [14b]. The diversity of reported SC behaviors in contrast to the scarcity of SC materials built from tetradentate ligands including exclusively nitrogen donors associated with coordinating pseudohalide anions led us to explore the use of such ligand environments with the aim to tune the SC behavior through minute changes in the ligand. An additional incentive to this study was the possibility to benefit from the versatile arrangement of the two pseudohalide ligands: indeed, while the pseudohalide anions are *cis*-coordinated in many SC materials [1,38], a recent work has evidenced that the *trans*-NCS isomer of a Fe^{II} compound including a bidentate triaryltriazole ligand exhibits SC while its *cis*-NCS counterpart is a HS material [15b].

In this study, the 2:1 condensation of acetylpyridine and 2,2-dimethyl-1,3-diaminopropane followed by reaction with ferrous thiocyanate yielded $[FeL^A(NCS)_2]$ (**1**) where the tetradentate ligand is the symmetrical bis-schiff base including two N(pyridine) and two N(imine) donors. This new ferrous material, although based on a tetradentate ligand closely related to bptn [14b] (bptn results from the 2:1 condensation of pyridine carboxaldehyde with 1,3-diaminopropane), is significantly different from $[Fe(bptn)(NCS)_2]$: while the NCS ligands are *cis* in the latter, they are *trans* in compound **1**, and while $[Fe(bptn)(NCS)_2]$ is a SC material, **1** is LS in the 80–400 K temperature range. The differences between **1** and $[Fe(bptn)(NCS)_2]$ are the substituents (Me, H, respectively) on the central carbon atom of the alkyl chain, the substituents (Me, H, respectively) on the imine carbon atoms, and the *trans* versus *cis* arrangement of the NCS ligands. The possible respective roles of these three factors in the difference of electronic behavior between the two materials cannot be untangled yet: it is one of the aims of [32], this report, and a paper in preparation, [40], to independently assess the role of each of these factors.

Condensation of 2R-imidazole-4-carboxaldehyde with the same diamine in the 2:1 ratio followed by reaction with ferrous thiocyanate was expected to yield ferrous complexes with symmetrical tetradentate ligands similar to that in **1**, but better suited to stabilize HS Fe^{II} or to yield Fe^{II} SC materials, depending on the decrease in ligand field on going from L^A to L^{Bx}, and on the *cis* or *trans* arrangement of the thiocyanates ligands. Indeed, compounds **2**–**4** include the expected symmetrical tetradentate ligands L^{Bx} and two *trans*-coordinated thiocyanates. As shown by the results described in the previous section, the ligand field generated by the L^{Bx} ligands associated with two *trans*-NCS stabilizes the HS Fe^{II} state, regardless of the imidazole substituent R_2 (H, Me, Ph). This is in line with the significant difference between L^A and L^{Bx} that results from the replacement of two pyridyl (strong ligand field N donor) by two imidazolyl rings (weaker ligand field N donor).

Considering that the NCS^- ligands are *trans*-coordinated in compounds **1**–**4**, regardless of the tetradentate ligand (L^A or L^{Bx}), it was anticipated that combination of pyridyl and imidazolyl rings to yield a dissymmetrical L^{Cx} bis-Schiff base chelated to Fe^{II} would not affect the *trans*-coordination mode of the NCS^- anions. Then, the only difference in ligand field would result from the change in the tetradentate ligand. Indeed, the results described in the previous section confirm that the NCS^- ligands are *trans*-coordinated in compounds **5**–**10**, allowing us to consider the differences between the tetradentate ligands L^A, L^{Bx} and L^{Cx} as the sole origin of the different electronic behaviors among all materials reported in this study.

Then, comparison of the electronic behavior of **1**–**4** on the one hand to that of **5**–**10** on the other hand evidences that combination of pyridyl and imidazolyl rings to yield a dissymmetrical tetradentate L^{Cx} ligand has indeed

allowed to bring the ligand field from the high (**1**) and low-field (**2**–**4**) ranges to the intermediate SC ligand field range (**5**–**10**).

Within the series, the differences originate from: (i) the substituents on the central carbon atom of the alkyl chain ($R_1 = H$ (**5**–**7**), Me (**8**–**10**)), and (ii) the 2-substituent on the imidazolyl ring ($R_2 = H$ (**5**, **8**), Me (**6**, **9**), Ph (**7**, **10**)). The most important difference in the SC properties within this series is the SC temperature $T_{1/2}$: it is higher than 400 K for **5** and **8**, while it is around 100 K for the remaining compounds. In other words, substitution of the phenyl or methyl group by an hydrogen atom at the C2 imidazolyl shifts the transition temperature $T_{1/2}$ by ~300 K towards higher temperatures.

This result evidences that a prominent electronic effect is exerted by R_2 but not R_1: in other words, the tuning of the ligand field is essentially obtained through modifications of the heterocyclic aromatic rings of the tetradentate ligand. In this report we concentrate on the imidazolyl ring; the effect of pyridyl ring substituents has been described in a previous report [32]. Considering that the ligand fields exerted by L^{C1} (**5**) and L^{C4} (**8**) ($R_2 = H$) are weaker (higher $T_{1/2}$) than those exerted by the remaining L^{Cx} ligands ($R_2 =$ Me or Ph), it may be suggested that the steric effect of the R_2 substituent overpasses its inductive (+I, Me) or mesomeric (+M, Ph) effect. As estimated through roughly approximated $T_{1/2}$ values, the role of R_1 in tuning the ligand field is much more limited. However, although subtle, the trend is the same within the three pairs (**5**, **8**), (**6**, **9**) and (**7**, **10**): the lower $T_{1/2}$ is associated with $R_1 = H$ (**5**–**7**). This seems to indicate that the inductive effect of R_1 (Me for **8**–**10**) slightly lowers the ligand field with regard to its counterpart (**5**–**7**) in each pair. This trend is further substanciated by the results described in [32].

For clarity, only intramolecular effects have been taken into account in the above considerations: this is of course a first approximation because intermolecular effects may also indirectly but significantly contribute to the ligand field onto the Fe^{II} center [39].

Acknowledgements

Financial support by the French Ministry for Education, Research, and Technology, through a doctoral grant to N.B., and by the CNRS-DFG collaborative programme, through a postdoctoral grant to S.S. are gratefully acknowledged.

Appendix A. Supplementary material

CCDC 613879, 613880, 613881, 613882 and 613883 contain the supplementary crystallographic data for **1**, **2**, **3**, **7** and **9**. These data can be obtained free of charge via htpp://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +(44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.12.017.

[40] N. Bréfuel, S. Shova, C. Duhayon, J.-P. Tuchagues, in preparation.

Compound **2** has been reported previously by Sievers and Morris [12–14]. It is usually described as a green crystalline material [12,14,15], but is evidently dichroic and the crystals also can appear as maroon-colored.

The infrared spectrum of $Cr(hfac)_3$ matches that reported previously [13]. The spectrum of $Cr(hfac)_2(thf)_2$ is very similar to that of $Cr(hfac)_3$ except that it exhibits additional bands at 1029, 916, 872, and 467 cm^{-1} due to the thf ligands.

2.2. Crystal structures of $Cr(hfac)_2(thf)_2$ and $Cr(hfac)_3$

Compound **1** crystallizes in the tetragonal space group $P4_2/mnm$, with two molecules per unit cell. The crystal data are summarized in Table 1, selected distances and angles are given in Table 2, and the molecular geometry of **1** is shown in Fig. 1. The chromium center, which resides on a site of *mmm* symmetry, is trans octahedral, with the two bidentate hfac ligands in the equatorial plane and the two thf molecules in the axial positions. The Cr–O(hfac) distance of 1.936(3) Å is slightly shorter than the two Cr–O distances of 1.984(3) and 1.979(3) Å present in the square-planar acetylacetonate complex $Cr(acac)_2$ [16]. The 92.7° O–Cr–O bite angle of $Cr(hfac)_2(thf)_2$, on the other hand, is greater than the corresponding 90.3(1)° bite angle of $Cr(acac)_2$ [16]. The Cr–O(thf) distance in **1** of 2.019(6) Å is only slightly longer than the Cr–O(hfac) distances. A large tetragonal distortion is not expected in this complex because no Jahn–Teller effect is operative: the axial ligands are chemically different from the equatorial ligands, and, perforce, the electronic symmetry is already broken.

The structure of $Cr(hfac)_2(thf)_2$ is very similar to those of several reported $Mn(hfac)_2L_2$ compounds, the principal difference being that the M–O(hfac) distances are about 0.15–0.2 Å shorter in **1**, as expected for high-spin Cr(II) and Mn(II) species. For example, the Mn–O(hfac) lengths are 2.120(3)–2.145(4) Å in $Mn(hfac)_2(proxyl)_2$ (proxyl = 2,2,5,5-tetramethylpyrrolidinyl-1-oxy) [17], 2.120(4)–2.160(3) Å in $Mn(hfac)_2(tempo)_2$ (tempo = 2,2,6,6-tetramethylpiperidinyl-1-oxy) [17], 2.169(3)–2.212(3) Å in $Mn(hfac)_2(Him)_2$ (Him = imidazole) [18], and 2.171(2)–2.143(3) Å in $Mn(hfac)_2(NOPy)_2$ (NOPy = 4-(*N*-oxy-*N*-*tert*-butylamino)pyridine) [19].

Crystals of the chromium(III) complex **2**, grown by sublimation, conform to the trigonal space group $P\bar{3}c1$ with six molecules per unit cell, but are twinned by merohedry. Because the volumes of the two twin individuals were very nearly equal (volume fractions of 0.547 and 0.453), the diffraction pattern conforms very closely to that expected for hexagonal symmetry under the space group $P6_3/mcm$. Interestingly, the X-ray diffraction pattern of **2** has previously been indexed to the space group $P6_3/mmc$ but with different cell axes ($a = 21.2$ and $c = 12.4$ Å vs. our finding of $a = 18.1$ and $c = 12.1$ Å) [20]. The different apparent space group and cell dimensions probably are consequences

Table 1
Crystallographic data for $Cr(hfac)_2(thf)_2$ and $Cr(hfac)_3$

	$CrC_{18}H_{18}F_{12}O_6$	$CrC_{15}H_3F_{18}O_6$

[a] Primed atoms are related to the unprimed atoms by the transformation $(-x, -y, -z)$, doubly primed atoms by $(-x, -y, z)$, and triply primed atoms by $(x, y, -z)$.

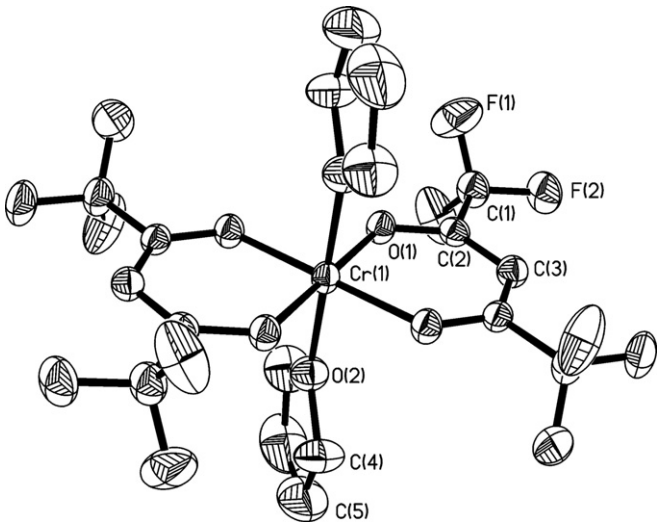

Fig. 1. X-ray crystal structure of $Cr(hfac)_2(thf)_2$ (**1**). The 30% probability density surfaces are shown. Hydrogen atoms have been removed for clarity.

of polymorphism. That polymorphism is likely is shown by the fact that crystals of $Cr(hfac)_3$ are not isomorphous with those of $Fe(hfac)_3$ [21] and $Mn(hfac)_3$ [22]. The latter two complexes crystallize in the monoclinic crystal system, space group $P2_1/c$.

The crystal data for **2** are summarized in Table 1 and the structure is shown in Fig. 2. There are two independent chromium centers in the asymmetric unit, one residing on a site of $\bar{3}$ symmetry and the other on a site of 3 symmetry. We will present the results for the latter molecule, which had the smaller atomic displacement parameters. $Cr(hfac)_3$ is, as expected, an octahedral complex with three equivalent hfac ligands. The two Cr–O distances of 1.943(5) and 1.955(5) Å are very similar to the 1.936(3) Å Cr–O(hfac) distance in the chromium(II) complex **1**; the bite angles of the hfac ligands in **2** are 90.8(2)° (Table 3).

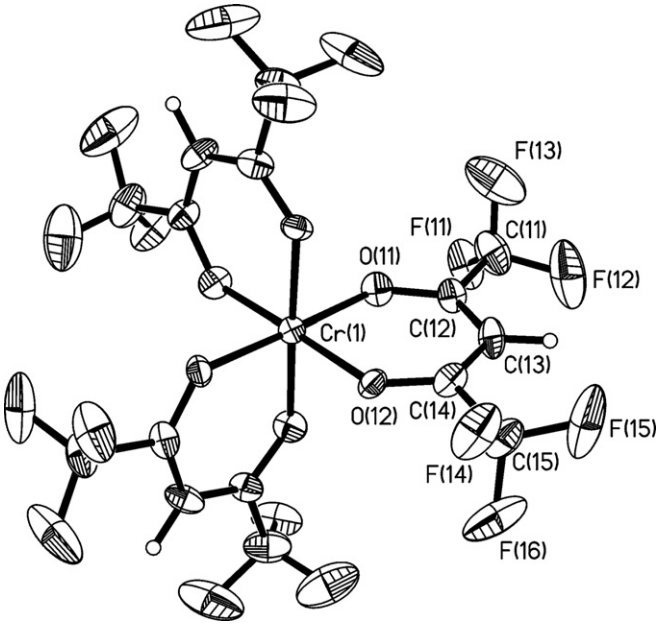

Fig. 2. X-ray crystal structure of $Cr(hfac)_3$ (**2**). The 30% probability density surfaces are shown, except for the hydrogen atoms, which are represented by arbitrarily-sized spheres.

Table 3
Selected bond distances (Å) and bond angles (°) for $Cr(hfac)_3$[a]

[a] Primed atoms are related to the unprimed atoms by the transformation $(-x+y+1, -x+1, z)$, and doubly primed atoms by $(-y+1, x-y, z)$.

The structure of **2** deduced crystallographically is very similar to that determined previously by electron diffraction. In the gas phase, $Cr(hfac)_3$ adopts a slightly distorted octahedral structure with a Cr–O distance of 1.957(8) Å and an O–Cr–O angle of 87.0° [23]. In the analogous chromium(III) acetylacetonate compound $Cr(acac)_3$ [24], the Cr–O distances lie between 1.942(7) and 1.959(7) Å, and the average bite angle is 91.1°.

The structure is also similar to that of tris(β-diketonate) complexes of other first-row metals. The structure of $Fe(hfac)_3$ exhibits Fe–O lengths of 1.969–2.021(10) Å, and O–Fe–O angles of 86.5–87.6(4)° [21]. In the acetylacetonate derivative $Fe(acac)_3$, the Fe–O distances lie between 1.986 and 2.004(6) Å and the O–Fe–O angles are 86.7–87.3(3)° [25].

Unlike $Cr(hfac)_3$, the manganese complex $Mn(hfac)_3$ is a tetragonally-elongated octahedron owing to a Jahn–Teller effect [22]. The long Mn–O distances are 2.141(3) and 2.147(3) Å whereas the short Mn–O distances are between 1.906(2) and 1.937(3) Å. The average O–Mn–O bite angle is 88.8°. At least two polymorphs of the acetylacetonate analog $Mn(acac)_3$ are known: one in which the molecules are axially compressed [26], and one in which they are axially elongated [27].

3. Experimental

All synthetic procedures were carried out in vacuum or under argon. Tetrahydrofuran, toluene, diethyl ether, and pentane were distilled from sodium/benzophenone. Sodium hydride (Aldrich) was used without further purification. Hexafluoroacetylacetone (Oakwood) was degassed by a freeze-pump-thaw method. The starting materials $CrCl_2(thf)$ [28] and $Cr[N(SiMe_3)_2]_2(thf)_2$ [29] were prepared as previously described. The IR spectra were recorded as Nujol mulls between KBr plates on a Nicolet Impact 410 FTIR instrument. Elemental analyses were performed by the University of Illinois Microanalytical Laboratory. The crystallographic data were collected by the George L. Clark X-ray Laboratory at the University of Illinois. Magnetic moments were determined by the Evans method [30].

3.1. Sodium hexafluoroacetylacetonate

A 60% (w/w) suspension of sodium hydride in mineral oil (5.51 g, 0.138 mol) was washed with toluene (60 mL), and the resulting solid was suspended in tetrahydrofuran (50 mL). To this suspension was added hexafluoroacetylacetone (8.00 mL, 0.0565 mol), and the reaction mixture was stirred at room temperature for 40 min. The yellow-brown solution was filtered, and the solid residue was washed with additional tetrahydrofuran (22 mL). The filtrate and the washings were combined and taken to dryness under vacuum. The yellow-white solid was washed with pentane (100 mL) and dried under vacuum to afford a white solid. Yield: 12.0 g (84%). *Anal.* Calc. for $Na(hfac) \cdot 0.33thf$: C, 29.9; H, 1.46. Found: C, 29.8; H, 1.50%. IR (cm^{-1}): 1672

m, 1556 m, 1533 m, 1514 m, 1488 m, 1318 w, 1261 s, 1202 s, 1144, s, 1079 w, 1046 w, 893 w, 800 m, 795 m, 767 w, 740 w, 665 m, 580 m, 525 w.

3.2. Bis(hexafluoroacetylacetonato)bis(tetrahydrofuran) chromium(II)

To a solution of $CrCl_2$(thf) (2.18 g, 11.2 mmol) in tetrahydrofuran (30 mL) was added a solution of Na(hfac) · 0.33thf (5.55 g, 21.8 mmol) in tetrahydrofuran (30 mL). The initially pale blue solution changed to dark brown. The reaction mixture was stirred overnight at room temperature. The solvent was removed under vacuum, and the resulting residue was extracted with diethyl ether (150 mL). The extract was filtered, and the filtrate was cooled to −20 °C to afford dark brown crystals. Yield: 1.67 g (24%). M.p.: 117–118 °C. *Anal.* Calc. for $CrC_{18}H_{18}F_{12}O_6$: C, 35.4; H, 2.97; Cr, 8.52. Found: C, 35.3; H, 3.60; Cr, 8.46%. IR (cm^{-1}): 1641 m, 1615 m, 1564 w, 1511 w, 1442 s, 1366 w, 1348 w, 1255 s, 1225 s, 1173 s, 1136 s, 1029 m, 916 m, 872 m, 810 m, 742 m, 688 m, 613 w, 580 m, 534 w, 478 sh, 467 m. μ_{eff} (thf): 4.6 μ_B.

3.3. Tris(hexafluoroacetylacetonato)chromium(III)

To a solution of $Cr[N(SiMe_3)_2]_2(thf)_2$ (2.19 g, 4.23 mmol) in diethyl ether (120 mL) at −78 °C was added hexafluoroacetylacetone (1.2 mL, 8.48 mmol) dropwise over 10 min. The initially blue-grey solution turned red-brown. The solution was warmed to room temperature, filtered, concentrated to ~40 mL, and cooled to −20 °C. The resulting red needles were isolated; an additional crop of crystals could be obtained by concentrating and cooling the supernatant. Yield: 0.51 g (26%). M.p.: 92–93 °C. The identity of the product was determined by IR and crystallography. IR (cm^{-1}): 3156 w, 1635 m, 1614 m, 1567 w, 1541 w, 1442 s, 1376 w, 1365 w, 1259 s, 1224 s, 1164 s, 1148 s, 1108 m, 916 w, 872 w, 814 m, 748 m, 678 m, 598 m, 534 w.

3.4. Crystallographic studies [31]

Single crystals of $Cr(hfac)_2(thf)_2$, (**1**), grown from diethyl ether, were mounted on glass fibers with Paratone-N oil (Exxon) and immediately cooled to −75 °C in a cold nitrogen gas stream on the diffractometer. (Single crystals of $Cr(hfac)_3$, (**2**), grown by sublimation in vacuum, were treated similarly. Subsequent comments in parentheses will refer to this compound.) Standard peak search and indexing procedures, followed by least squares refinement, yielded the cell dimensions given in Table 1. The measured intensities were reduced to structure factor amplitudes and their esd's by correction for background and Lorentz and polarization effects. Systematic absences for $0kl$ ($k + l \neq 2n$) were consistent with space groups $P4_2/mnm$, $P4_2nm$, and $P\bar{4}n2$; the centrosymmetric space group $P4_2/mnm$ was chosen and was eventually proven correct upon successful refinement of the proposed model. Systematically absent reflections were deleted and symmetry-equivalent reflections were averaged to yield the data set used to solve the structure. (For **2**, systematic absences for $h\bar{h}0l$ ($l \neq 2n$) were consistent with the trigonal groups $P3c1$ and $P\bar{3}c1$, and the hexagonal groups $P6_3cm$, $P\bar{6}c2$, and $P6_3/mcm$. The diffraction pattern conformed closely to the Laue group $6/mmm$, but no satisfactory solution could be found in any of the hexagonal space groups. Eventually, a satisfactory solution was found in the space group $P\bar{3}c1$.)

The structure of **1** was solved by direct methods, and positions for all the non-hydrogen atoms were deduced from an E-map (SHELXTL). (For **2**, Patterson methods led to a refinable model consisting of two independent chromium atoms. Subsequent least squares refinement and difference Fourier calculations revealed the positions of many of the remaining non-hydrogen atoms. Some of the expected non-hydrogen atoms, however, did not surface in the difference maps, and suitable atoms were added, with bond distance restraints, to complete the molecules.)

The analytical approximations to the scattering factors were used, and all structure factors were corrected for both real and imaginary components of anomalous dispersion. All 832 (2022) unique data were used in the least squares refinement. The quantity minimized by the least squares program was $\sum w(F_o^2 - F_c^2)^2$, where $w = [(\sigma(F_o^2))^2 + (0.0852P)^2 + 0.6505P]^{-1}$ and $P = (F_o^2 + 2F_c^2)/3$. (For **2**, $w = [(\sigma(F_o^2))^2 + (0.0749P)^2]^{-1}$.)

(For **2**, despite the fact that all of the non-hydrogen atoms had been located, wR_2 remained above 0.65 and the "most disagreeable reflections" list was composed entirely of reflections for which $|F_c/F_c(\max)| < 0.03$ and $F_o^2 \gg F_c^2$. This result suggested that the crystal was twinned by merohedry. An investigation of possible twin laws eventually revealed one that led to a substantial reduction in the weighted residual. The twin law relates hkl to $hk\bar{l}$, which corresponds to reflection through the **a*****b*** plane. The intensities were calculated from the expression $F_c^2 = vF_c(hkl)^2 + (1 - v)F_c(hk\bar{l})^2$, where v is the volume fraction of one of the twin individuals. The volume fraction of the major twin individual refined to 0.547(3). At this point, all restraints on atom positions were lifted).

In the final cycle of least squares, independent anisotropic displacement factors were refined for the non-hydrogen atoms. Hydrogen atoms were readily apparent among the largest peaks in the difference maps, and their locations were refined independently. (For **2**, hydrogen atoms were readily apparent among the largest peaks in the difference maps, but they tended to refine to give unreasonable distances, so they were fixed in "idealized" positions with C–H = 0.95 Å.) The isotropic displacement parameters for the hydrogen atoms were set equal to 1.2 times U_{eq} for the attached carbon atom. Although corrections for crystal decay were unnecessary, an empirical absorption correction was applied (SADABS), the maximum and minimum transmission factors being 0.970 and 0.931 (0.998 and 0.937). Successful convergence was indicated by the maximum shift/error of 0.002 (0.001) for the last cycle.

Final refinement parameters are given in Table 1. The largest peak in the final Fourier difference map (0.35 e $Å^{-3}$) was located 0.97 Å from Cr1. (For **2**, the largest peak in the final Fourier difference map (0.39 e $Å^{-3}$) was located 2.1 Å from O21, F23, and C22.) A final analysis of variance between observed and calculated structure factors showed no apparent errors.

Acknowledgements

We thank Rosann Bish for carrying out some of the early stages of the synthetic work, and Dr. Scott Wilson and Ms. Teresa Prussak-Wieckowska for collecting the crystallographic data. We thank the Department of Energy (Grant DEFG02-91-ER45439) for support of this work.

Appendix A. Supplementary material

CCDC 626676 and 626677 contain the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.12.007.

Preface to the proceedings of ICMM 2006

This special issue of Polyhedron is devoted to the proceedings of the 10th International Conference on Molecule-based Magnets, continuing a tradition that has been in place for some time. Hopefully the papers contained in this issue will provide a snapshot of the conference for those in the molecular magnetism community, and also be a stimulating and useful introduction to this exciting area of research to the broader readership.

The 10th ICMM took place from August 13 to 17, 2006 in Victoria, British Columbia, marking the first time this international meeting has been hosted in Canada. 274 delegates from 22 countries gathered in Victoria, and fortunately the weather cooperated, providing a most pleasant setting. Scientifically, the meeting commenced with a new 'keynote' lecture in Olivier Kahn's name, created by the 2006 ICMM Organizing Committee as tribute to a true pioneer and leader in molecular magnetism. Dante Gatteschi, the inaugural ICMM Kahn lecturer, provided an entertaining and outstanding opening to the conference.

The scientific content of the meeting was rich and intense: 65 invited and contributed talks and 235 poster presentations made for a jam-packed program, which also included a wonderful experimental demonstration session on the magic of molecular magnets organized by Michel Verdaguer and Bob Thompson. The program was loosely organized into contemporary themes in molecule-based magnetism. Sunday provided a glimpse of current advances in the magnetism of organic radical-based materials. Monday focused on multifunctional materials, highlighted by an opening plenary lecture by Philipp Gütlich (Mainz) on spin crossover. Tuesday dealt with coordination complexes and materials and was commenced by a plenary lecture on spin glasses by Art Epstein (Ohio State). The plenary given by Juan Novoa (Barcelona) on intermolecular magnetic interactions, marked the beginning of Wednesday's session on physical and computational approaches to understanding molecule-based magnetic materials. Finally, Chris Murray (IBM) introduced the world of magnetic nanoparticles to open Thursday's session on nanomagnetism. It was particularly telling that one of the more difficult tasks facing the organizing committee in assembling the program was deciding where to place many of the presentations, which clearly fell under two or more of these themes. This is a tribute to the truly cross-disciplinary nature of the field.

Organizing a meeting of this size and scope is a hugely time-consuming and, at times, stressful activity. But it is also immensely rewarding too, and it is with pleasure that I have the opportunity to acknowledge the many people who helped make this conference a huge success. First and foremost, I offer my deep gratitude to the members of the ICMM 2006 organizing committee: Natia Frank (University of Victoria), Danny Leznoff (Simon Fraser University), Bob Thompson (University of British Columbia) and Laurie Thompson (Memorial University of Newfoundland). You were a delight to work with and deserve a large portion of the credit for the success of this meeting. I also offer sincere thanks to the student volunteers, essentially the members of my research group as well as Dr. Frank's, for all their hard work behind (and in front of) the scenes. The staff at the Victoria Conference Center also deserves our thanks for their outstanding service in helping the meeting run seamlessly. The efforts of George Christou and Sondra Hayes in assembling this special issue certainly deserve to be recognized. Finally, I wish to acknowledge the sponsors whose contributions made the conference possible. Thanks to Elsevier, the University of Victoria, the American Chemical Society-Petroleum Research Fund, Quantum Design, IQuantum Corporation, Bruker Canada, Rigaku, and the Inorganic and Organic Divisions of the Canadian Society for Chemistry.

Looking forward to an outstanding 11th ICMM in 2008 in Florence!

temperature interval between the two-steps [7]. This was also the case in one of the two-step μ-bipyrimidine compound, [Fe(NCS)(bt)]$_2$(μ-bpym) [3]. In contrast, as part of a wide study using different types of bridges [1], some of the present authors have recently described the first 'ordered' [HS–LS] dinuclear molecule containing two bis-bidentate dipyridylamine bridging groups linked, in each ligand, by a pyridyl donor [8]. The term 'ordered', in the present context, means that the dinuclear molecules have a HS Fe(II) end and a LS Fe(II) end when structurally characterised at the [HS–LS] plateau temperature. This is different to the alternative possibility for such an 'intermediate' spin state that contain 50% HS–HS and 50% LS–LS molecules in the crystal lattice, a situation found by Kaizaki et al. in a pyrazolate-bridged complex, [Fe(NCBH$_3$)(4-Ph-py)]$_2$(μ-bpypz)$_2$ [9].

Other key features of interest in solid state dinuclear, and higher nuclearity cluster, SCO systems include their thermal hysteresis (memory/cooperativity) properties, in comparison to related mononuclear Fe(II) compounds [1], and their photomagnetic (LIESST; light induced excited spin state trapping [10]) properties, the latter being investigated, in our case, in collaboration with Letard [11], and, from the Mössbauer spectroscopic perspective, with Gütlich and coworkers [12].

The work reported here focuses on one aspect of covalent bridging in dinuclear Fe(II) crossover compounds. It was aimed at probing the effect upon spin-crossover that the rigidity, ligand field strength and superexchange-coupling properties of two very closely related covalent, bridging ligands produces, in otherwise similar pairs of molecules. The bridges, {N–N}-azolates, are contained in 3,5-bis(2-pyridyl)pyrazolate (bpypz$^-$), used recently, as indicated above, by Kaizaki and coworkers [5,9] and in the triazolate analogue, 3,5-bis(2-pyridyl)-1,2,4-triazolate (bpytz$^-$) (Fig. 1). While 1,2,4(R)-triazole bridging has been incorporated in dinuclear [6,13] and 1D chain iron(II) SCO materials [14,15], the anionic triazolates (trz$^-$) have only been incorporated, along with triazoles, into 1D chain [Fe(Htrz)$_2$(trz)](BF$_4$) species ($T_{1/2} \sim 360$ K, $\Delta T = 60$ K), this occurring [16] as far back as 1977 [14–16]. The general coordinating properties of triazolates, particularly towards 2nd and 3rd row d-block ions, have been reviewed by Haasnoot and reference to the work of his Leiden coworkers is included [16]. A tetranuclear [Cu(I)$_4$(bpytz)$_4$] cluster, and extended [Cu(I)(bpytz)]$_n$ networks have recently been reported [17], in which the bpytz$^-$ ligand bridges adjacent metal centres, and we have recently obtained related Fe$_5$- and Fe$_7$-bpytz clusters as an offshoot of the present work [18].

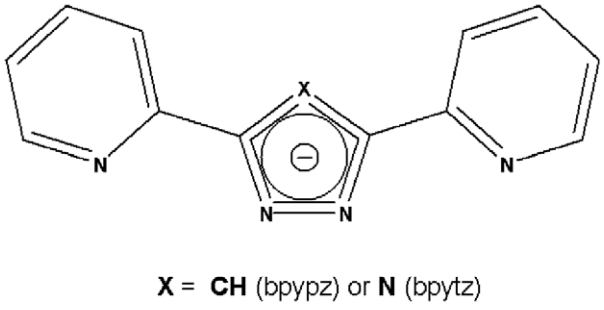

Fig. 1. The *bis*-bidentate bridging ligands 3,5-bis(2-pyridyl)pyrazolate (bpypz$^-$) and 3,5-bis(2-pyridyl)-1,2,4-triazolate (bpytz$^-$).

The present complexes have the general formula [Fe(NCX)(py)]$_2$(μ-L)$_2$. They contain the axial N-donor ligand NCX$^-$, where X = S, Se or BH$_3$, the coplanar equatorial bridging ligand L$^-$ = bpypz$^-$ or bpytz$^-$, and a pyridine (py) in the *trans* axial position. The structural, magnetic and Mössbauer spectral properties are described for representative examples of [Fe(NCS)(py)]$_2$(μ-bpypz)$_2$ (**1**), [Fe(NCSe)(py)]$_2$(μ-bpypz)$_2$ (**2**), [Fe(NCS)(py)]$_2$-(μ-bpytz)$_2$ (**3**), [Fe(NCSe)(py)]$_2$(μ-bpytz)$_2$ (**4**), [Fe(NCBH$_3$)(py)]$_2$(μ-bpytz)$_2$ (**5**). Complex **1** has previously been reported by Kaizaki et al. [5]. We have determined its crystal structure and show that the SCO behaviour previously reported is not exhibited by the crystal phase, but only by precipitated samples.

2. Experimental

Methanol was dried over magnesium turnings while pyridine was used without further purification. Solvents were deoxygenated before use. Iron(II) complexes were synthesised using Schlenk conditions under a nitrogen atmosphere with ~10 mg of ascorbic acid being added to each reaction to prevent oxidation to iron(III). The ligands 3,5-bis(2-pyridyl)pyrazole (Hbpypz) and 3,5-bis(2-pyridyl)-1,2,4-triazole (Hbpytz) were prepared using literature methods [19,20] as were [Fe(NCS)$_2$(py)$_4$] [21] and [Fe(NCS)(py)]$_2$](μ-bpypz)$_2$ (**1**) [5]. Microanalytical data on repeat samples of 'precipitated' **1** [5] were typically as follows: *Anal.* Calc. for $C_{38}H_{28}Fe_2N_{12}S_2$: C, 55.09; H, 3.41; N, 20.29%. *Anal.* Calc. for $C_{38}H_{28}Fe_2N_{12}S_2 \cdot H_2O$: C, 53.91; H, 3.57; N, 19.85; S, 7.58. Found: C, 54.37; H, 3.51; N, 19.54; S, 7.21%. Crystals of **1** were grown as described below. Microanalyses were performed by the Campbell Microanalysis Laboratory, Chemistry Department, University of Otago, Dunedin, New Zealand. Infrared spectra were obtained on a Bruker Opus/IR IFS 55 spectrometer in the range of 4000–400 cm^{-1}. Samples were prepared as a KBr discs (16 scans, resolution ±4 cm^{-1}).

2.1. Syntheses of [(n-Bu$_4$)N](bpypz) and [(n-Bu)$_4$N](bpytz) [5]

Hbpypz and Hbpytz were converted to their respective tetra-*n*-butylammonium salts by dissolving the ligand (3.54×10^{-4} mol) in ~15 ml of methanol followed by the addition of 1 M tetra-*n*-butylammonium hydroxide (0.36 ml). After a period of 15 min, the mixture was condensed to an oily residue in vacuo. The residue was then washed and condensed, repeatedly, with 3 × 20 ml portions of methanol and dried under high vacuum, forming a white to off-white crystalline solid.

2.2. Synthesis of [Fe(NCSe)(py)]$_2$(μ-bpypz)$_2$ (**2**)

$Fe(ClO_4)_2 \cdot 6H_2O$ (0.085 g, 3.3×10^{-4} mol) was dissolved in methanol (5 ml) and, to this solution, was added KNCSe (0.095 g, 6.6×10^{-4} mol). The resulting solution turned a pink colour and $KClO_4$ was deposited. This mixture was filtered and pyridine (5 ml) was added to the clear filtrate, resulting in the precipitation of a yellow solid, $[Fe(NCSe)_2(py)_4]$. To this suspension a solution of [(*n*-Bu$_4$)N](bpypz) (0.153 g, 3.3×10^{-4} mol) in pyridine (5 ml) was added dropwise over a period of 20 min resulting in the initial yellow solid dissolving. The solution was stirred for a further 2 h, with precipitation of a yellow solid observed, which was collected and washed, successively, with methanol and diethyl ether and allowed to dry. Yield: 0.078 g, 51%. *Anal.* Calc. for $C_{38}H_{28}Fe_2N_{12}Se_2$: C, 49.48; H, 3.06; N, 18.22. Found: C, 49.88; H, 3.20; N, 17.72%. IR (KBr disc) cm^{-1}: 2080 *ν*(C≡N).

2.3. Synthesis of [Fe(NCS)(py)]$_2$(μ-bpytz)$_2$ (**3**)

A solution of [(*n*-Bu)$_4$N](bpytz) (0.153 g, 3.3×10^{-4} mol) in pyridine (5 ml) was added dropwise to a stirred methanolic solution of $[Fe(NCS)_2(py)_4]$ (0.161 g, 3.3×10^{-4} mol). The reaction mixture turned a yellow colour with a yellow precipitate being formed. After 2 h, the mixture was filtered to yield a yellow microcrystalline product which was successively washed with methanol and diethyl ether and allowed to dry. Yield: 0.090 g, 66%. *Anal.* Calc. for $C_{36}H_{26}Fe_2N_{14}S_2$: C, 52.06; H, 3.16; N, 23.61. Found: C, 51.47; H, 3.28; N, 22.86%. IR (KBr) cm^{-1}: 2075 *ν*(C≡N).

2.4. Synthesis of [Fe(NCSe)(py)]$_2$(μ-bpytz)$_2$ (**4**)

The same method as for compound **2** was employed. $Fe(ClO_4)_2 \cdot 6H_2O$ (0.085 g, 3.3×10^{-4} mol) was dissolved in methanol (5 ml) to which KNCSe (0.095 g, 6.6×10^{-4} mol) was added. To the resulting clear filtrate was added a pyridine solution of [N(*n*-Bu)$_4$](bpytz) (0.153 g, 3.3×10^{-4} mol), dropwise. This resulted in the formation of a yellow precipitate, which was collected and treated as previously described. Yield: 0.060 g, 39%. *Anal.* Calc. for $C_{36}H_{26}Fe_2N_{14}Se_2$: C, 46.78; H, 2.84; N, 21.22. Found: C, 46.80; H, 2.99; N, 20.60%. IR (KBr) cm^{-1}: 2084 *ν*(C≡N).

2.5. Synthesis of [Fe(NCBH$_3$)(py)]$_2$(μ-bpytz)$_2$ (**5**)

A similar method was again employed, as for compound **2**, but using $Fe(SO_4) \cdot 7H_2O$ (0.092 g, 3.3×10^{-4} mol) and $Na(NCBH_3)$ (0.042 g, 6.8×10^{-4} mol). The methanolic solution (5 ml) of $Fe(SO_4) \cdot 7H_2O$ turned a purple colour upon mixing with $Na(NCBH_3)$ and a precipitate of Na_2SO_4 formed and was removed by filtration. To this clear, methanolic solution, a larger than normal volume of pyridine (15 ml) was added such that the initial yellow precipitate of $[Fe(NCBH_3)_2(py)_4]$ dissolved. To this solution was added, slowly, a solution of [(*n*-Bu)$_4$N](bpytz) (0.153 g, 3.3×10^{-4} mol) in pyridine (5 ml), with the reaction solution turning an orange colour. After 2 h of stirring, and with no precipitation observed, stirring was stopped. The reaction solution was allowed to slowly evaporate by $\sim^2/_3$ of its volume, under a stream of nitrogen, for three days. Fine orange needles of **5** were formed. Yield: 0.055 g, 42%. *Anal.* Calc. for $C_{36}H_{32}B_2Fe_2N_{14}$: C, 54.45; H, 4.06; N, 24.70. Found: C, 55.05; H, 4.47; N, 23.42%. IR (KBr) cm^{-1}: 2356 *ν*(B-H), 2188 *ν*(C≡N).

Single X-ray quality crystals of complexes **1** and **3** grown by slow diffusion methods in H-tubes. One arm of the H-tube contained a solution of NH_4SCN and $Fe(ClO_4)_2 \cdot 6H_2O$, in methanol, and a small amount of ascorbic acid. The other arm contained a solution of [(*n*-Bu)$_4$N](bpypz) (or [(*n*-Bu)$_4$N](bpytz) dissolved in pyridine). Both arms were filled halfway and then layered with a methanol-pyridine (50:50) solution. Crystals formed over 2 weeks.

2.6. Magnetic measurements

Variable temperature DC magnetic susceptibilities of powder samples (~20 mg) were measured on a Quantum Design MPMS 5 SQUID magnetometer with an operating field of 1 Tesla, over a temperature range of 2–300 K. Representative samples were checked for lack of crystallite torquing by dispersal of the powder in a Vaseline mull, and none was present. This is a feature, that can lead to anomalous μ_{eff} ($\chi_M T$) values, and is sometimes observed at low temperatures in orbitally degenerate ($^5T_{2g}$) HS Fe(II) octahedral compounds [22].

2.7. Mössbauer spectral measurements

The spectra were measured using a conventional constant acceleration drive with a symmetrical saw-tooth waveform. The source of ^{57}Co in rhodium was maintained at room temperature. Fresh crystalline samples were loaded into a piston type Perspex holder. The holder was placed in a cold-finger type cryostat in good thermal contact with a reservoir containing liquid nitrogen. The spectra were fitted to Lorentzian lines, with the matching lines of a doublet constrained to have the same intensity and line width. Isomer shifts were calibrated against the spectrum of α-iron.

2.8. X-ray diffraction measurements

Single crystals of **1** and **3** were quench cooled to 123(2) K and mounted on a Bruker Apex-II diffractometer employing graphite monochromated Mo-Kα radiation generated from a fine-focus sealed tube. Cell constants were obtained from a least squares refinement against 4622 reflections located between 0.82 and 56.56° 2*θ*. Data were collected at 123(2) K with scans to 56.46° 2*θ*. Subsequent computations were carried out with the WinGX [23] graphical user interface. An empirical absorption correction determined with SADABS [24] was applied to the data. The structures of **1** and **3** were solved in the space group $P2_1/n$ (#14), by

direct methods, with SHELXS-97 [25], and extended and refined with SHELXL-97 [25]. The non-hydrogen atoms in the asymmetric unit were modelled with anisotropic displacement parameters. A riding atom model with group displacement parameters was used for the hydrogen atoms. Crystallographic data are given in Table 1. The structure of **1** was also solved at the temperatures 200(2) K and 90(2) K, the latter by both rapid and slow cooling, to try and obtain the cell volumes and Fe – N distances and angles in the perceived HS–HS and LS–LS regimes, respectively, as judged by the spin transition observed in a bulk sample at 125 K (Fig. 5) and in earlier work [5]. The crystal data, at these temperatures, are given in Table 1 and the bond distances and angles are essentially the same as those given in Table 2. The change in cell volume from 1784.26(19) Å^3 at 90 K, to 1807.9(3) Å^3 at 200 K, is due to normal thermal expansion.

Table 2
Comparisons of bond lengths (Å) and angles (°) for complexes **1** and **3** at 123 K (HS–HS forms)

Bond(s)	**1**	**3**
Lengths (Å)

Powder X-ray diffraction patterns were obtained by Mr. R. Mackie (School of Physics, Monash University) using a Cu lamp with $\lambda = 1.5405$ Å.

3. Results and discussion

3.1. Syntheses and characterisation

The $[Fe(NCX)(py)]_2(\mu\text{-bpypz})_2$ complexes, **1** (X = S) and **2** (X = Se), were prepared by the route of Kaizaki et al. [5] in which the precursor complexes $[Fe(NCX)_2(py)_4]$ were reacted with $[(n\text{-Bu})_4N](bpypz)$. The new triazolate-bridged analogues $[Fe(NCX)(py)]_2(\mu\text{-bpytz})_2$, **3** (X = S), **4** (X = Se) and **5** (X = BH_3) were likewise made from $[Fe(NCX)_2(py)_4]$, prepared in situ, by reaction with $[(n\text{-Bu})_4N](bpytz)$. Single X-ray quality crystals of **1** and **3** were grown by H-tube methods also. The IR spectra of all the complexes show the presence of a strong C≡N (NCX) stretching band in the range 2075–2188 cm^{-1}. An additional strong band at 2356 cm^{-1} for complex **5** belongs to the ν(B–H) vibration of the cyanoborohydride ligand. The microanalysis data of each complex indicated that the constituent ligands and Fe were present in a ratio of 1:1:1:1. While our early microanalytical results on precipitated samples of **1** were consistent with a monohydrate being formed, and the reported data could likewise be so fitted [5]. Crystal structure analysis did not indicate the presence of water.

3.2. Crystal and molecular structures of *1* and *3*

The structure of $[Fe(NCS)(py)]_2(\mu\text{-bpypz})_2$ (**1**), first synthesised by Kaizaki et al. [5], was solved here, first to confirm the magnetic spin transition reported [5], and also for comparison to the triazolate-bridged analogue, $[Fe(NCS)(py)]_2(\mu\text{-bpytz})_2$ (**3**). The structures and numbering schemes for **1** and **3** are given in Fig. 2. Selected bond lengths and angles are given in Table 2, which were measured at 123 K, a temperature close to the $T_{1/2}$ value. In these isostructural compounds, the two pyrazolate (**1**) or triazolate (**3**) groups bridge Fe(1) and Fe(1′) equatorially to form a rigid, co-planar 6-membered {Fe–N–N–Fe–N–N} ring. The nitrogens of the equatorial pyridyl arms and of the *bis*-azolate core, together with the axial pyridine (py) nitrogen and the NCS^- nitrogen, form the distorted octahedral FeN_6 coordination environments within the centrosymmetric structure. The same coordination sphere about the iron(II) centres, and the same bridge geometry, was observed for the analogous structure of $[Fe(NCBH_3)(py)]_2(\mu\text{-bpypz})_2$ reported by Kaizaki and co-workers [5]. The Fe–N distances in the HS–HS forms of **1** and **3**, given in Table 2, are 2.1–2.2 Å, typical of HS iron(II) and similar to those in the HS–HS form of the $NCBH_3$– derivative [5]. There are some interesting angular distortions, the apical N(1)–Fe(1)–N(2), for example, being 166.2° **1**, 165.3° **3** and Fe(1)–N(1)–C(1) being 173.5° **1**, 169.3° **3**. The outer N(3)–Fe(1)–N(5) angle, 116.1° **1**, 121.6° **3** is more obtuse than the inner N(4)–Fe(1)–N(6) ring angle, 94.2° **1**, 91.2° **3**, as expected. The Fe(1)..Fe(1′) separations are 4.23 Å **1** and 4.34 Å **3**.

From an inter-molecular perspective, there is no solvent molecule present in either crystal lattice and no hydrogen bonding occurs between dinuclear molecules. There are π–π interactions present between dinuclear units in the lattice with the π densities of the pyridyl arm of $bpytz^-$ (or $bpypz^-$) interacting with the azolate ring on the neighbouring dimer, in a slipped π-stacking manner, at a distance of 3.366 Å **1**, 3.353 Å **3**, as shown in Fig. 3 for compound **3**. The π-interactions in the crystal lattice have directed the orientation of the dinuclear molecules into near-perpendicular layers of chains that are connected by the π–π overlap, as shown in Fig. 4. These π interactions and packing orientations are very similar to those observed previously in the complex $[Fe(NCBH_3)(py)]_2(\mu\text{-bpypz})_2$ [5], and also include the bpytz py..py edge-to-edge π–π stacking noted in that case. The intra-dinuclear and inter-dinuclear structural features are very similar for **1** and **3**.

The structure of **1** was also solved at 200 K and 90 K to obtain metrical details on what were expected to be dinuclear Fe(II) molecules existing in the HS–HS and LS–LS spin states (Fig. 5 and Ref. [5]). Surprisingly, the HS–HS

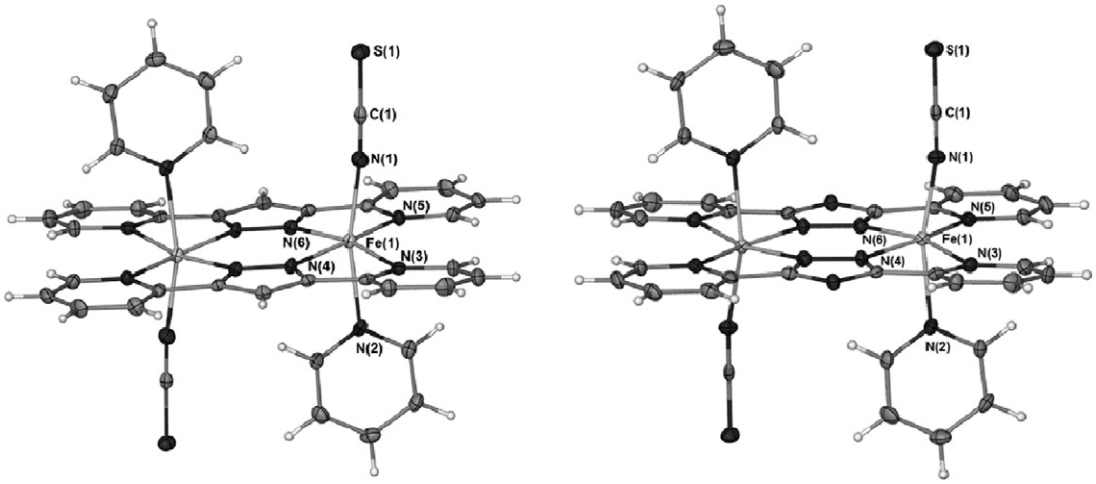

Fig. 2. ORTEP representations (50% probability) of $[Fe(NCS)(py)]_2(\mu\text{-bpypz})_2$ (**1**), left, and $[Fe(NCS)(py)]_2(\mu\text{-bpytz})_2$ (**3**), right, both at 123 K.

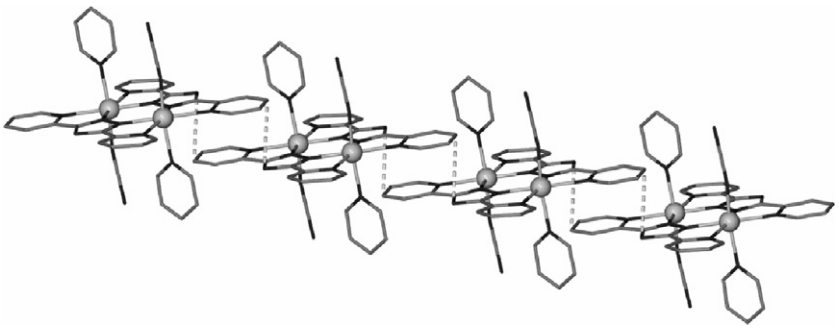

Fig. 3. Stick representation of the inter-ligand π-stacking (dotted lines) in the chains of dinuclear molecules in the μ-bpytz complex, **3**, at 123 K.

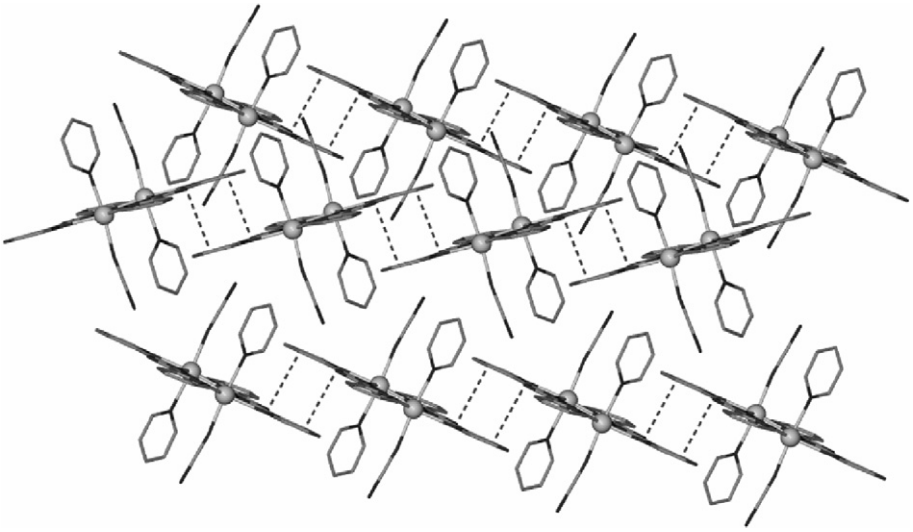

Fig. 4. Stick representation of the inter-dinuclear layer structure of **3**, at 123 K.

form persisted at all temperatures, as did the yellow colour of the crystal, typical of the HS–HS state. We comment further on the crystal and bulk forms of **1** below.

3.3. Magnetic susceptibilities and Mössbauer spectra

The μ_{eff} (per Fe(II)) versus temperature plot for a bulk, powder sample of $[Fe(NCS)(py)]_2(\mu\text{-bpypz})_2$ (**1**), shown in Fig. 5, revealed an abrupt single step spin transition, from HS–HS to LS–LS states, with a $T_{1/2}$ value of 127 K, the same temperature as that reported for this compound by Kaizaki et al. [5]. There was no thermal hysteresis at $T_{1/2}$. The bulk sample of **1** used for the magnetic measurement had a powder X-ray diffraction pattern in which the major crystalline phase appeared to be consistent with that calculated from the crystal structure (*vide infra*).

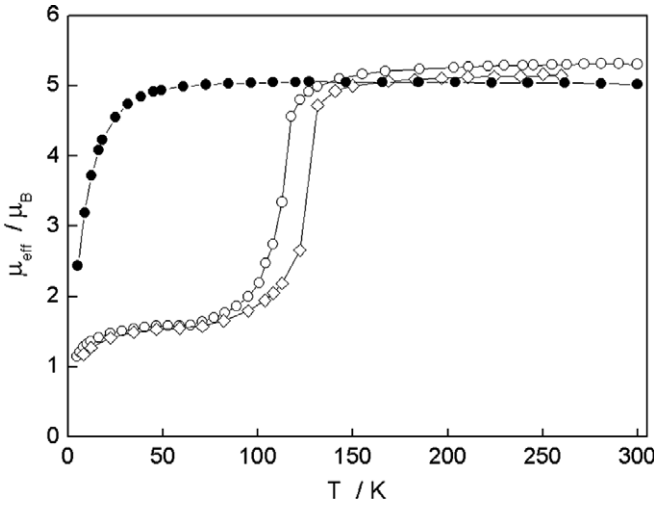

Fig. 5. Plots of magnetic moment, per Fe(II), vs. temperature, for $[Fe(NCX)(py)]_2(\mu\text{-bpypz})_2$, X = S (**1**) and Se (**2**). ● is the sample of identical crystals of **1**; ◇ is the bulk, precipitated powder of **1**; ○ is the bulk powder of **2**. The solid lines join the points.

It can be seen in Fig. 5 that, over the temperature range 300–150 K, the μ_{eff} values plateau at 5.1 μ_B, typical of HS–HS values, and then decrease abruptly to reach a LS–LS plateau value of 1.5 μ_B, a little higher than that reported earlier [5], and somewhat higher than expected for second-order Zeeman effects in t_{2g}^6 Fe(II) centres. Below ~25 K, a small decrease in μ_{eff} is due to a combination of zero-field splitting of remnant Fe(II) $^5T_{2g}$ single-ion states, combined with very weak antiferromagnetic coupling, the latter facilitated by the pyrazolate bridges. The lack of any discernable decrease in μ_{eff}, with decreasing temperature, in the HS–HS region, 150–300 K, supports the antiferromagnetic coupling being very weak. Such decreases were more pronounced in the bipyrimidine bridged SCO compounds of Real et al. [2,3] for which J values of $\sim -4\ cm^{-1}$ were observed.

The crystallography results on **1**, obtained at three temperatures, prompted us to measure the magnetism on single crystals obtained from the same H-tube as the crystallography sample. In contrast to the SCO plot of the precipitated sample, the crystals remain HS–HS over the whole temperature range, with μ_{eff} values constant at 5.0 μ_B (Fig. 5), a decrease towards 2.4 μ_B occurring below ~40 K being due to weak coupling and zero-field splitting effects that are also noted, below, for **3**. The powder XRD data on samples of **1** that display the spin transition at 127 K, described above, suggest that the bulk precipitated powder of **1** is composed, either in part or in its entirety, of a second form, such as a polymorph or solvate.

The new member of the bpypz-bridged family, $[Fe(NCSe)(py)]_2$ μ-$(bpypz)_2$ (**2**), displays an abrupt HS–HS ↔ LS–LS spin transition, without thermal hysteresis, with a $T_{1/2}$ of 109 K.[1] The μ_{eff} values for freshly made, repeat samples are 5.3 μ_B between 300–150 K and they rapidly

[1] Kaizaki et al. have recently observed the same magnetism for crystals of **2** and have solved the structure at 90 K (LS–LS) and at 200 K (HS–HS) [27].

decrease to the LS–LS plateau value of ~1.5 μ_B, per Fe(II) (Fig. 5). For bulk precipitated samples, the $T_{1/2}$ values for the NCSe- and NCS-bpypz compounds appear to be in reverse order to what is commonly expected from the stronger ligand-field strength of $NCSe^-$. Since all other intra-dinuclear constituents of the bpypz compounds are common, we were puzzled by the position of $T_{1/2}$. However, the lack of SCO in crystals of **1**, now of known structure, puts the NCS^- and $NCSe^-$ data in correct order. The Mössbauer spectrum of **2**, at 295 K, shows a single, asymmetric quadrupole doublet due to HS Fe(II) in the HS–HS dinuclear molecules, with parameter values that are typical [5] of this kind of structure; $\delta = 1.00(1)$ mm s^{-1}, $\Delta E_Q = 1.99(1)$ mm s^{-1}. At 79 K, there is a very broad, unusual lineshape that could be fitted to a sum of three static lines, but with line widths (FWHM) of over 1 mm s^{-1}, much bigger than the normal linewidths of 0.3 mm^{-1} found at 295 K (Fig. 6). The three doublets have the following similar sized isomer shifts, probably indicative of one spin state undergoing relaxation effects; (i) $\delta = 0.58(2)$ mm s^{-1}, $\Delta E_Q = 3.71(12)$ mm s^{-1}, area % = 30(11); (ii) $\delta = 0.54(2)$ mm s^{-1}, $\Delta E_Q = 1.15(40)$ mm s^{-1}, area % = 49(33); and (iii) $\delta = 0.49(3)$ mm s^{-1}, $\Delta E_Q = 0.33(12)$ mm s^{-1}, area % = 21(30). Further work is needed to understand the relaxation mechanism. The $NCBH_3^-$ member of the bpypz family had a $T_{1/2}$ of 205 K observed by Kaizaki et al., a position expected from its higher ligand-field strength compared to NCS^- and $NCSe^-$ [5]. Its reported Mössbauer parameters were similar to those of **2** at 295 K, but quite different at 79 K.

In the triazolate-bridged family, prepared here for the first time, a sample of $[Fe(NCS)(py)]_2(\mu\text{-bpytz})_2$ (**3**), that had been checked by powder XRD to be the same as the crystal structure sample, was found to display HS–HS magnetic moment behaviour over the whole temperature range. In Fig. 7, the magnetic moments, μ_{eff}, remain constant at 5.2 μ_B between 300 K and 50 K, as expected for octahedral Fe(II) centres that are showing extremely weak antiferromagnetic coupling across the two, coplanar triazolate bridges. The moments decrease rapidly below 50 K to reach 2.7 μ_B at 2 K. Fitting of these data to a $S = 2$ dimer ($-2J\mathbf{S}_1 \cdot \mathbf{S}_2$) model, assuming zero field splitting (D) to be negligible, gave a best-fit g value of 2.16 and J value of -0.80 cm^{-1}. J values for triazole bridging ligands are known to be small and negative (weakly antiferromagnetic) and those for triazolate bridging are essentially unknown but expected to be even weaker [13,16]. The $NCSe^-$ analogue, **4**, likewise remains HS–HS at all temperatures and shows (Supplementary material) similar magnetism to **3** with best-fit parameters $g = 2.11$ and $J = -0.83$ cm^{-1}.

Only with the stronger field $NCBH_3^-$ ligand in the *trans*-apical positions, does the bpytz family display spin-crossover. Thus, the magnetic moment plot for **5**, in Fig. 8, shows a full spin transition, of the two-step kind, in which the step from the HS–HS state (μ_{eff}, per Fe, $= 5.0$ μ_B), occurring between 210 K and 180 K ($T_1 = 194$ K) is a little more gradual than is the step to the LS–LS state ($\mu_{eff} = 1.8$ μ_B), occurring between 160 K and 120 K ($T_2 =$ 151 K). The plateau of the intermediate "HS–LS" state, with $\mu_{eff} = 3.8$ μ_B, extends over the range 163–188 K. A repeat sample of **5** showed the same two-step transition but with a higher value of μ_{eff} below the transition, the powder XRD patterns of the samples being identical except for the repeat sample lines being a little broader and indicative of a less crystalline sample. Comparison of the powder diffraction pattern and the derived cell constants to those calculated for $[Fe(NCBH_3)(py)]_2(\mu\text{-bpypz})_2$ [5], showed that the two cells were essentially the same. Unfortunately, in the absence of a crystal structure for **5**, it is not possible to unambiguously identify the intermediate spin state, in the plateau region, as a 50:50 HS–HS:LS–LS mixture of dinuclear molecules, as in $[Fe(NCBH_3)(4\text{-Ph-py})]_2(\mu\text{-bpypz})_2$ [3,9], that displayed a rather similar plot to Fig. 6, or as a HS–LS state. Examples of the latter kind have recently been discovered [3,7,8,26].

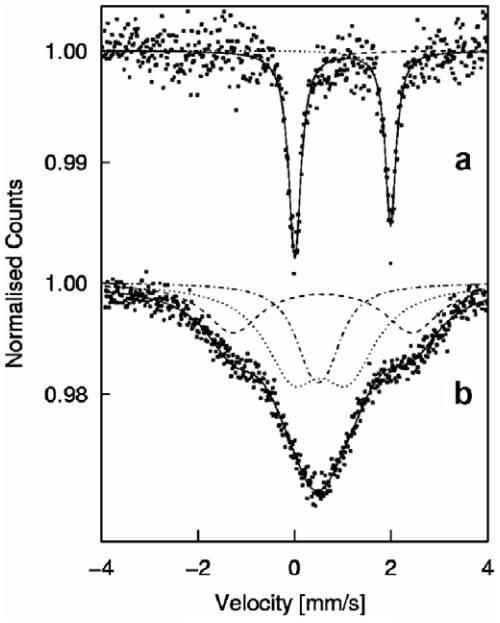

Fig. 6. Mössbauer spectra of compound **2** at (a) 295 K, (b) 79 K, showing the component lines (dots and dashes) used to fit the lineshapes.

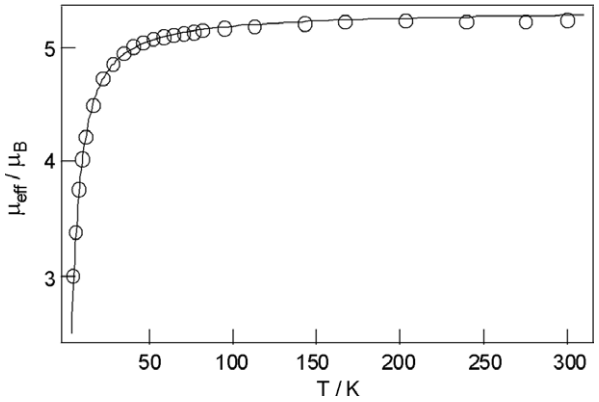

Fig. 7. Plot of magnetic moment, per Fe(II), vs. temperature, for $[Fe(NCS)(py)]_2(\mu\text{-bpytz})_2$ (**3**). The solid line is the best fit to a $S = 2$ dimer model using the g and J parameters given in the text.

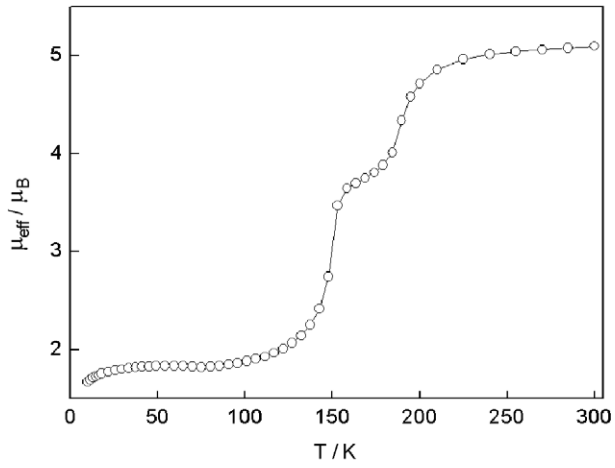

Fig. 8. Plot of the two-step SCO in $[Fe(NCBH_3)(py)]_2(\mu\text{-bpytz})_2$ (**5**).

The variable temperature Mössbauer spectra of **5** are shown in Fig. 9 and the fitted parameters are; (a) 295 K; $\delta = 0.99(1)$ mm s^{-1}, $\Delta E_Q = 1.20(1)$ mm s^{-1}, area % = 100, due to the HS–HS state; (b) 123 K; $\delta = 1.18(2)$ mm s^{-1}, $\Delta E_Q = 2.63(4)$ mm s^{-1}, area % = 9; $\delta = 0.49(1)$ mm s^{-1}, $\Delta E_Q = 0.76(4)$ mm s^{-1}, area % = 51(10); $\delta = 0.51(1)$ mm s^{-1}, $\Delta E_Q = 10.25(3)$ mm s^{-1}, area % = 40; (c) 82 K; $\delta = 1.10(1)$ mm s^{-1}, $\Delta E_Q = 3.07(1)$ mm s^{-1}, area % = 10(1), due to a minor HS species, and $\delta = 0.60(1)$ mm s^{-1}, $\Delta E_Q = 0.55(1)$ mm s^{-1}, area % = 90(1) due to the dominant LS–LS species. The spectra at 295 K and 82 K are as anticipated and like the $[Fe(NCBH_3)(py)]_2(\mu\text{-bpypz})_2$ analogue [5], except for the HS quadrupole splitting at 82 K being much larger than it is at 295 K. In the intermediate region of 123 K, a broad lineshape, quite unlike the spectrum of $[Fe(NCBH_3)(py)]_2(\mu\text{-bpypz})_2$, is observed with a minor

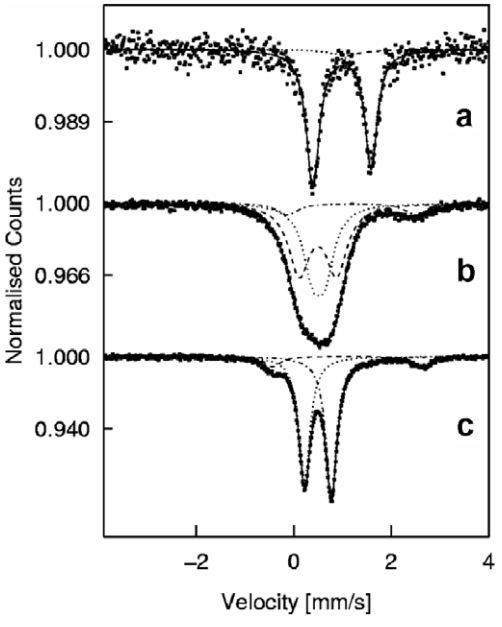

Fig. 9. Mössbauer spectra of compound **5** at (a) 295 K, (b) 123 K, and (c) 82 K, showing the component lines (dots and dashes) used to fit the lineshapes.

HS doublet having splitting of an intermediate magnitude. Inclusion of a third LS-like doublet, with area similar to that of the main LS doublet, was able to reproduce the unusual shape very well. The Mössbauer results suggest two non-identical Fe(II) sites are present with half going LS between 295 K and 82 K, while the other half show dramatic changes in their spectrum that is influenced by the original half. Dynamic processes could also be important. Clearly, when considered with the magnetic data, the spin transition in this bpytz-$NCBH_3$ material, **5**, is different in detail than it is in the corresponding bpypz-$NCBH_3$ species.

3.4. Conclusions

The spin states and spin transitions in structurally similar di-μ-pyrazolate and di-μ-triazolate iron(II) compounds have been probed by means of crystal structures, magnetic susceptibilities and Mössbauer spectral data. New and unexpected observations have emerged in comparison to Kaizaki's earlier, related work [5]. Neither of the examples for which the structures have been solved, $[Fe(NCS)(py)]_2(\mu\text{-bpypz})_2$ (**1**), and $[Fe(NCS)(py)]_2(\mu\text{-bpytz})_2$ (**3**), display a spin crossover transition in their crystalline phases, the compounds remaining HS–HS. The ligand fields provided by the bpypz pyrazolate-nitrogen donor atoms is therefore broadly similar to that of the triazolate-nitrogen donors. Possible reasons have been given to explain a HS–HS to LS–LS transition observed in precipitated samples of **1**. Comparison of the NCSe pair, **2** and **4**, show that $bpypz^-$ provides a stronger ligand field than $bpytz^-$. Only in one di-μ-triazolate example, $[Fe(NCBH_3)(py)]_2(\mu\text{-bpytz})_2$ (**5**), was a spin transition observed in the form of a well resolved 2-step HS–HS to LS–LS crossover, the $NCBH_3^-$ ligand providing a sufficiently strong ligand field contribution in that case. When compared to the di-μ-pyrazolate, $[Fe(NCBH_3)(py)]_2(\mu\text{-bpypz})_2$ [5], with an one-step transition at 205 K, the relative ligand fields are, again, marginally stronger for the pyrazolate bridge. Mössbauer data for **2** and **5** are intriguing and different to those of the pyrazolate analogue.

The synergy between antiferromagnetic coupling across the di-μ-azolate bridges and the spin crossover on each Fe(II) in the dinuclear moieties examined here is probably negligible in view of the very weak spin coupling in comparison, for example, to the well studied bipyrimidine-bridged iron(II) family. The similar crystal packing and intermolecular π-stacking interactions found in **1** and **3** suggest that intermolecular effects play little part in inducing SCO behaviour. The lack of strong cooperativity in **2** and **5**, reflected in a lack of thermal hysteresis, support this conclusion. However, in other dinuclear systems, with different and more flexible bridging ligands, and which display significant molecule–molecule interactions, via enclathrated solvate molecules and/or π–π interactions, the situation is different and observations such as two-step spin transitions have recently been made, as mentioned above [3,8].

Scheme 1. Synthesis of metal oxamato complexes [5].

was measured by single-crystal rotation in three planes which are perpendicular to each other. Spectra were recorded in 5° intervals. The spectra simulations were performed using the program package SIMFONIA [6].

Quantum chemical calculations were performed with the program package TURBOMOLE [7,8] using methods of density functional theory applying the B3-LYP hybrid functional [9] with def2-TZVP [10] basis sets for all atom types. The two $[^nBu_4N]^+$ counter ions were neglected and the charge of the dianion was compensated by the conductor-like screening model (COSMO) [11], as in previous treatments [12]. This leads to negative energies for all occupied orbitals. All calculations were done with default settings for convergence criteria and with default parameters for the COSMO model. Analysis of the spin density, i.e., the difference of densities of alpha and beta electrons, was done for the optimized geometry.

3. Results and discussion

3.1. EPR spectroscopic investigations

$[^nBu_4N]_2[Cu(dana)]$ **2** was investigated by EPR in single-crystals and powder samples diamagnetically diluted by the corresponding Ni(II) complex **3** as well as in liquid solution using chloroform as solvent. Compound **3** crystallizes monoclinic, space group C2/c, with four molecules in the unit cell [5]. The molecules of the unit cell are magnetically equivalent, therefore, in the single-crystal spectra only one site will be observed. A representative single-crystal EPR spectrum is shown in Fig. 1, together with its simulation. It consists of a quartet ($I(^{63,65}Cu) = 3/2$) of quintets ($I(^{14}N) = 1$) for B_0 field orientations for which both N donor atoms are magnetically equivalent.

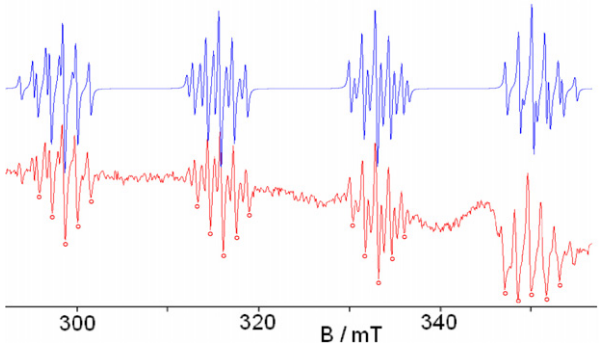

Fig. 1. Simulated (upper graph) and experimental EPR spectrum (lower graph) of single-crystal (0.5% **2** in the crystal lattice of **3**). The peaks resulting from the hyperfine coupling with the isotope ^{63}Cu are marked with circles.

Since the experimental linewidth is small ($\Delta B_{pp} \approx 0.5$–0.6 mT) the individual ^{63}Cu and ^{65}Cu signals which are different in intensity because of their different natural abundances (^{63}Cu (69%), ^{65}Cu (31%), $g_N(^{63}Cu) = 1.4804$, $g_N(^{65}Cu) = 1.5860$) can be observed. For B_0 orientations in the molecular x, y-plane the spectra become more complicated since due to the small $^{63,65}Cu$ hyperfine coupling the ^{14}N quintets overlap each other. In addition, for arbitrary B_0 orientations the nitrogen donor atoms are not magnetically equivalent resulting in more or less resolved triplets of triplets for the ^{14}N hyperfine patterns.

The EPR spectra were analyzed using the following spin-Hamiltonian

$$H_{sp} = \mu_B B_0 \cdot g \cdot S + S \cdot A^{Cu} \cdot I^{Cu} + \sum_{i=1}^{2} S \cdot A^{N_i} \cdot I^{N_i}$$

where all symbols have their usual meaning. The directions of the principal axes within the molecular frame of **2** is shown in Fig. 2. The principal values of g, A^{Cu}, and A^N are given in Table 1, where $g_x = g_y = g_\perp$, $g_z = g_\parallel$, $A_x = A_y = A_\perp$, and $A_z = A_\parallel$ is assumed.

The principal axes of g and A^{Cu} coincide with their maximum components located perpendicular to the molecular plane. The maximum components of the ^{14}N hyperfine tensors, however, were found to lie parallel to the Cu–N bond vectors. Thus, in the parallel part ($B_0 \| z$) of the powder EPR

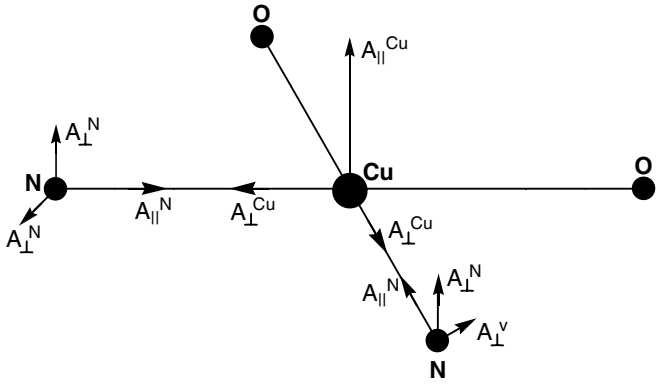

Fig. 2. Principal axis system in **2**.

Table 1
Principal values of g, A^{Cu} and A^N for **2**

g		A^{Cu} ($\times 10^{-4}$ cm^{-1})		A^N ($\times 10^{-4}$ cm^{-1})	
$g_\perp$	2.046 ± 0.003	$A_\perp^{Cu}$	33.4 ± 1.5	$A_\perp^N$	18.7 ± 0.5
$g_\parallel$	2.187 ± 0.002	$A_\parallel^{Cu}$	214.9 ± 1.0	$A_\perp^N$	13.3 ± 0.5
g_{av} [a]	2.093 ± 0.003	A_{av}^{Cu} [a]	91.4 ± 1.5		
g_{iso} [b]	2.094 ± 0.003	A_{iso}^{Cu} [b]	95.6 ± 1.0	A_{iso}^N [b]	15.0 ± 0.5

[a] $g_{av} = (2\,g_\perp + g_\parallel)/3$; $A_{av}^{Cu} = (2A_\perp^{Cu} + A_\parallel^{Cu})/3$.
[b] Liquid solution data.

spectrum the observed ^{14}N hyperfine coupling corresponds to $A_{\perp}^{N}$.

The spin densities in the s and p orbitals (d orbitals for copper) are proportional to the isotropic (A_{iso}) and the dipolar ($A_{dip} = A_{iso} - A_{\perp}$) hyperfine coupling constants, respectively. The procedure for calculating spin densities from experimentally obtained hyperfine coupling constants is given by Morton and Preston [13]. Following this model provided in the literature, the spin densities on the N and Cu atoms were estimated to $(15 \pm 2)\%$ and $(58 \pm 3)\%$, respectively. Thus most of the spin density $(88 \pm 7)\%$ is localized on the N–Cu–N part of the molecule. In the EPR experiment it was not possible to observe ^{17}O hyperfine structure satellites due to the low natural abundance of the ^{17}O isotope (^{17}O, $I = 5/2$, natural abundance 0.04%). To verify the experimentally determined spin density distribution quantum chemical calculations were employed.

3.2. Quantum chemical calculations

For the Ni compound, **3**, a diamagnetic state was found. The spin density, ρ_s, for **2** is plotted in Fig. 3; iso-density surfaces are shown for ρ_s=0.1(0.01) electrons/Bohr^3. One observes a clear localization of the spin-density at the Cu atom and at the N and O atoms. The unpaired electrons occupy the d-orbital pointing to the surrounding N and C atoms and p orbitals of the latter pointing to the central Cu atom.

A Mulliken population analysis was carried out for the spin density in order to quantify the relative distribution of unpaired electrons. Due to the high localization of the spin density this procedure is expected to yield very reliable values. One obtains values of 55.4% at Cu, 14.9% per N, 6.5% per (Cu-bonding) O atom and below 1% for all other atoms, which is in excellent agreement with the values calculated from the experimental data presented above.

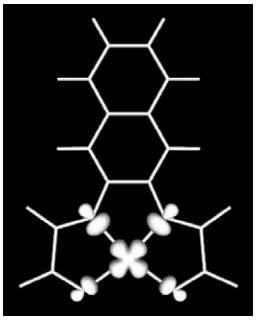

Fig. 3. Spin density of **2**. Iso-surfaces are drawn at 0.01 electrons/Bohr^3.

4. Conclusion

The spin density distribution around the Cu(II) centre in a *N*,*N*′-bis(oxamato) type complex was experimentally determined using EPR spectroscopy in the X-band. The Cu–N bond was found to accommodate a higher spin density compared to the Cu–O bond indicating that the Cu–N bond is more covalent than the Cu–O bond. Quantum chemical calculations using density functional theory provide a spin density distribution very similar to that estimated from the experiment.

N,*N*′-bis(oxamato) type complexes were already used for the synthesis of magnetic molecules whereby the free carbonyl groups coordinate further transition metals (see e.g., [1,2]). In such multimetallic complexes the oxamato-bridge was found to mediate an antiferromagnetic superexchange interaction. The results of this work indicate that the superexchange interaction takes place mainly over the N atoms of the oxamato-bridge.

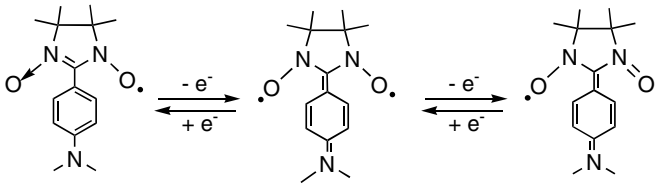
describe the synthesis, electronic structure, and hole-transporting property of a nitronyl nitroxide derivative combined with a trialylamine moiety, *N*,*N*-bis(4-methoxyphenyl)-*N*-{4-(1-oxyl-3-oxide-4,4,5,5-tetramethylimidazolin-2-yl)-phenyl}phenylamine (**1**). The redox and hole-transporting property of the control compound, 2-(4-methoxyphenyl)-1-oxyl-3-oxide-4,4,5,5-tetramethylimidazolin-2-yl (**2**), is also described (see Chart 1).



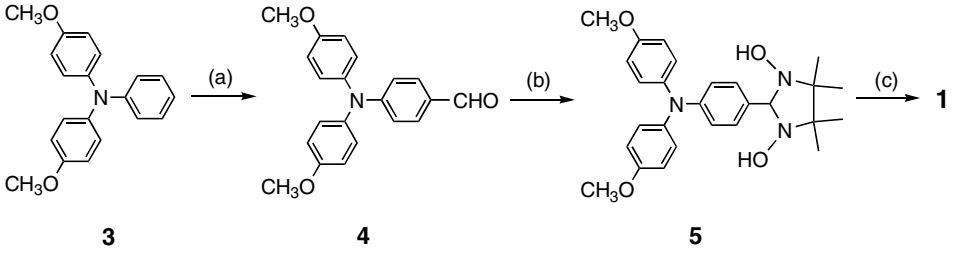


Chart 2.

2. Results and discussion

The synthetic route of the nitronyl nitroxide radical **1** is shown in Scheme 1. The radical **1** was prepared from the corresponding formyl derivative **4** via the Ullman procedure [9]. Bis(4-methoxyphenyl)-4-formylphenylamine **4** was obtained by the Vilsmeier–Haack reaction [10]. 2,3-Bis(hydroxyamino)-2,3-dimethyl-*n*-butane was reacted with **4** to yield the hydroxyamine derivative **5** as the precursor of **1**. Chemical oxidation of **5** with sodium periodate afforded the nitronyl nitroxide **1**. The nitronyl nitroxide bearing the 4-methoxyphenyl moiety, **2**, was also prepared according to the literature [9,11]. The ESR spectrum of **1** in the THF solution gave a five-line signal at $g = 2.006$ with $a_N = 0.78$ mT as the hyperfine coupling constant, which was assigned as a nitronyl nitroxide radical. This hyperfine coupling constant is comparable to 0.75 mT of *N*,*N*-bis[4-(1-oxyl-3-oxide-4,4,5,5-tetramethylimidazolin-2-yl)phenyl]-4-methoxyphenylamine [8a] as a triarylamine-combined nitronyl nitroxide.

Cyclic voltammograms of **1** and **2** are shown in Fig. 1. Two reversible redox couples were observed for **1**, and clearly separated at $E_{1/2} = 0.23$ and 0.49 V with an irreversible reduction wave at −1.2 V. The first reversible redox couple could be attributed to the one-electron oxidation from the triarylamine-moiety to yield the corresponding cationic radical with the quinoid structure, because the oxidation potential of the control triarylamine derivative, *N*,*N*-bis(4-methoxyphenyl)phenylamine **3**, appeared at 0.16 V. The second reversible oxidation of **1** was assigned to the oxidation of the nitronyl nitroxide moiety to afford the corresponding dication, represented in Chart 2. Fig. 2 also shows the reversible redox wave (oxidation potential at $E_{1/2} = 0.33$ V) of **2**, which was slightly lower than the second oxidation potential of **1**. This lower oxidation potential of **2** indicated the electron-donating effect of the methoxy group; on the other hand, the second oxidation of **1** appeared at a higher potential because of the Coulombic interaction between the aminium cation and the nitroxide in $\mathbf{1}^+$. This result also supported the first oxidation of **1** that was ascribed to the oxidation of the triarylamine moiety.

Fig. 2 depicts the UV–Vis absorption spectra during the electrochemical oxidation of **1** in a dichloromethane solution under the potentials up to 0.8 V. The strong absorption bands at 350 nm (π–π*) and 650 nm (n–π*) due to the nitronyl nitroxide moiety [9] gradually disappeared

Scheme 1. Synthesis of **1**. (a) $POCl_3$, DMF, (b) 2,3-bis(hydroxyamino)-2,3-dimethylbutane monosulfate, K_2CO_3, CH_2Cl_2, (c) $NaIO_4$ aq, K_2CO_3, CH_2Cl_2.

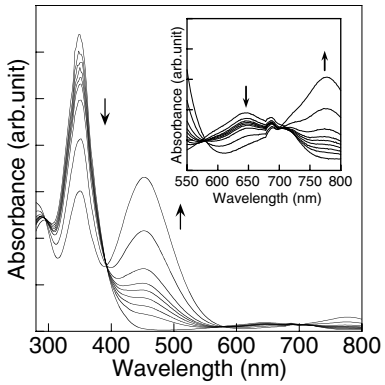

Fig. 2. UV–Vis absorption spectra during electrochemical oxidation of **1** in CH_2Cl_2 with 0.1 M $(n\text{-}C_4H_9)_4NBF_4$ at room temperature (inset: enlarged spectra from 550 to 800 nm).

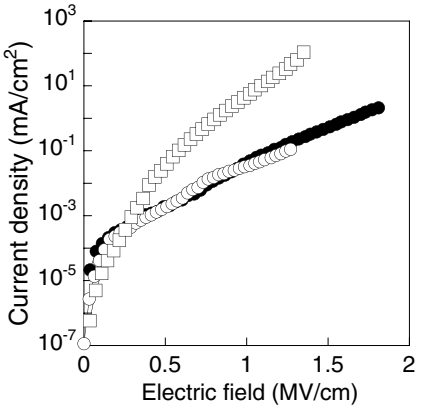

Fig. 3. Current density–electric field characteristics for single-layer devices of **1** (closed circle), **2** (open circle), and TPD (open square) in the device configuration of ITO/hole-transporting molecule:polycarbonate (150 nm)/Al.

during the first oxidation. In contrast, new absorption bands at 780 nm ascribed to the aminium cation moiety and at 450 nm due to the quinoid structure appeared with isosbestic points at 296 and 392 nm. These indicated no subsequent reaction was involved during the one electron oxidation process, which is consistent with the reversible redox couples of **1** observed during the cyclic voltammetry.

A single-layer hole-only device configurated with indium–tin oxide (ITO)/**1**:polycarbonate (150 nm)/Al(150 nm) was fabricated. Compound **1** was dissolved in the THF solution of polycarbonate at a 16 μmol/10 mg ratio, and the resultant solution was spin-coated onto a precleaned ITO substrate. After removal of the solvent under vacuum, aluminum was vapor deposited onto the top of the organic layer as the cathode. Single-layer devices consisting of the polycarbonate layer containing *N*,*N*′-diphenyl-*N*,*N*′-bis(3-methylphenyl)-4,4′-diamine (TPD) or 4-methoxyphenyl nitronyl nitroxide (**2**) were also fabricated as the control.

Current density–electric field plots of the device are shown in Fig. 3. The maximum current density of the **1** device was 0.19 mA/cm^2 at 1.28 MV/cm, which was comparable to that for **2** (0.11 mA/cm^2 at 1.27 MV/cm). The ionization potential of **1** measured by photoelectron spectroscopy was −5.38 eV, which agreed with that of TPD (−5.4 eV) [12]. The hole-injection barrier between the ITO anode (work function = −4.8 eV) and **1** was estimated to be 0.6 eV, which was comparable to that (∼0.6 eV) on the ITO/TPD interface. Therefore, the lower values of the current density for **1** or **2** suggest that the net currents in the radical-containing devices may be dominated by the hole-drift mobility [13] in the radical molecule layer as well as the high hole-injection barrier for the interface between the ITO and the radical layer. The hole-transporting process possibly involves the second redox process due to the localized nitronyl nitroxide moiety or an energetic disorder effect [14] induced by the dipole interaction; These might generate a hole-trapping site, resulting in the lower current density.

Our results concluded that the nitronyl nitroxide combined with the triarylamine moiety possesses a hole-transporting property, which is applicable to a hole-transporting layer. However, the hole-drift mobility would be lower than those of the simple triarylamine derivatives. The drift mobility measurements and further studies to examine the more efficient hole-transporting property by synthesizing other triarylamine-combined nitroxide radical molecules are now underway.

3. Experimental

3.1. *N,N-Bis(4-methoxyphenyl)-4-foymylphenylamine (**4**)*

Compound **4** was synthesized by the Vilsmeier formylation [10]. Phosphoric chloride (10.0 g, 65.2 mmol) was added dropwise into 5.67 ml of DMF at 0 °C under nitrogen, and stirred for 1 h. To the solution was added *N*,*N*-bis(4-methoxyphenyl)-*N*-phenylamine (**3**) (5.00 g, 16.4 mmol) in 20 ml DMF, and the reaction mixture was stirred for 18 h at 100 °C. After cooling to room temperature, the reaction mixture was treated with an aqueous NaCl solution, extracted with CH_2Cl_2, and dried over $MgSO_4$. The solvent was removed under reduced pressure, and the residue was purified by chromatography on silica with the eluent of hexane/dichloromethane (1/4). Recrystallization from ether/hexane afforded greenish-yellow needles. Yield 67%; ^{1}H NMR ($CDCl_3$, 500 MHz) $\delta = 9.75$ (s, 1H), 7.63 (d, $J = 8.8$ Hz, 2H), 7.13 (d, $J = 8.8$ Hz, 4H), 6.89 (d, $J = 9.0$ Hz, 4H), 6.84 (d, $J = 8.8$ Hz, 2H), 3.81 (s, 6H); ^{13}C NMR ($CDCl_3$) $\delta = 190.3$, 157.3, 154.1, 138.8, 131.4, 128.0, 127.8, 116.7, 115.0, 55.5; MS *m*/*z* 333 (M^+). *Anal*. Calc. for $C_{21}H_{19}NO_3$: C, 75.7; H, 5.7; N, 4.2. Found: C, 75.4; H, 5.6; N, 4.1%; mp 102 °C.

3.2. *N,N-Bis(4-methoxyphenyl)-4-(1,3-dihydroxy-4,4,5,5-tetramethylimidazolidin-2-yl)phenylamine (**5**)*

2,3-Bis(hydroxyamino)-2,3-dimethylbutane sulfate (2.95 g, 12.0 mmol) and K_2CO_3 (16.5 g, 120 mmol) were added to 40 ml of ethanol, and stirred for 30 min under nitrogen.

Compound **4** (2.00 g, 6.01 mmol) was added to the reaction mixture and stirred for 48 h at 65 °C. The reaction mixture was concentrated, and the resulting precipitate was filtered and washed with cold methanol and CH_2Cl_2 to give **5** as a white powder (1.73 g). Yield 63%; ^{1}H NMR ($CDCl_3$, 500 MHz) $\delta = 7.27$–7.26 (m, 4H), 7.05–7.03 (m, 4H), 6.91 (d, $J = 8.5$ Hz, 2H), 6.81–6.80 (m, 4H), 4.64 (s, 1H), 3.79 (s, 6H), 1.09 (s, 12H); ^{13}C NMR ($CDCl_3$) $\delta = 155.7$, 148.7, 141.1, 132.2, 129.2, 126.4, 120.6, 114.6, 90.3, 66.9, 55.5, 24.2, 17.0; MS *m*/*z* 461 (M^+).

3.3. N,N-Bis(4-methoxyphenyl)-4-(1-oxyl-3-oxide-4,4,5,5-tetramethylimidazolin-2-yl)phenylamine (*1*)

To the solution of **4** (0.150 g, 0.325 mmol) in CH_2Cl_2 (160 ml) was added a solution of K_2CO_3 (0.454 g, 3.29 mmol) in 5.0 ml of water, and stirred for 5 min under nitrogen. A solution of $NaIO_4$ (83.4 mg, 0.390 mmol) in 5 ml of water was added to the reaction mixture and stirred for 2 h. The reaction mixture was washed with water, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by flash-chromatography on triethylamine-mediated silica gel (hexane/ethylacetate = 3/2) to afford a purple powder (71.8 mg, 0.156 mmol): Yield 48%; FAB MS *m*/*z* 460 (M^+); ESR (in THF): $g = 2.006$, five lines, $|a_N| = 0.78$ mT. *Anal.* Calc. for $C_{27}H_{30}N_3O_4$: C, 70.4; H, 6.6; N, 9.1. Found: C, 70.3; H, 6.8; N, 9.1%.

3.4. Other materials

The other materials, *N*,*N*-bis(4-methoxyphenyl)phenylamine (**3**) [7a], 2,3-bis(hydroxyamino)-2,3-dimethylbutane monosulfate [15], and 2-(4-methoxyphenyl)-4,4,5,5-tetramethylimidazolin-1-oxyl-3-oxide (**2**) [9,11] were prepared according to the literature.

3.5. Measurements

^{1}H and ^{13}C NMR spectra were recorded using a JEOL-Lambda 500 spectrometer. Mass and FAB-Mass spectra were obtained using a Shimadzu GC–MS 17A and a JEOL JMS-SX102A, respectively. UV–Vis spectra were measured with a JASCO V-550. Cyclic voltammetric measurements were carried out with a BAS 100B/W electrochemical analyzer (Bioanalytical Systems, Inc.). The working electrode, the counter electrode, and the reference electrode were a platinum disk, a platinum wire, and a saturated Ag/AgCl, respectively. All cyclic voltammograms were rescaled by the formal redox potential of the ferrocene/ferrocenium couple. ESR spectra were recorded on a JEOL LES-TE200 ESR spectrometer with 100 kHz field modulation. Thin films of the polymers were prepared by spin-coating of a THF solution (1 ml) with radical/polycarbonate = 16 μmol/10 mg on an ITO-glass substrate. The organic solution was filtered through a PTFE filter (pore size ∅ 0.2 μm) before the spin-coating. Thickness of the organic layer was measured with a Dektak surface profilometer. Current–voltage characteristics were measured using a Keithley2400 Source Meter.

common feature for these molecular solids is the system having a quarter-filled π-band, namely, there exists one electron or hole per two molecules.

TCNQ radical (TCNQ = 7,7,8,8-tetracyanoquinodimethanide) possesses a series of variable valences (for example, 0, −0.5 and −1) due to the fine tunable degree of charge transfer and the columnar stack in a donor–acceptor compound, and thus it is possible to obtain the molecular magnets with quasi-1D structure and mixed-valence feature. In this paper, we report the syntheses, crystal structures, IR spectroscopic and magnetic properties of two mixed-valence magnets, $[CNQl]_2[TCNQ]_3$ (**1**) and $[CNPy]_2[TCNQ]_3$ (**2**), where $CNQl^+$ = 1-(4′-cyanobenzyl)quinolinium and $CNPy^+$ = 1-(4′-cyanobenzyl)pyridinium, respectively.

2. Experiments

2.1. Chemicals and reagents

All chemicals and solvents were reagent grade, and were used without further purification. 4-Cyanobenzyl chlorine is the product of Synica Chemicals. 1-(4′-Cyanobenzyl)quinolinium chloride (abbr. as [CNQl]Cl) and 1-(4′-cyanobenzyl)pyridinium chloride (abbr. as [CNPy]Cl) were synthesized following the published procedure [12].

2.2. Physical measurements

Elemental analyses were performed with a Perkin–Elmer 240 analytical instrument. IR spectra were recorded on a Fourier Transform Infrared Spectrometer (170SX) (KBr pellet). Magnetic susceptibility data of **1** and **2** on polycrystalline sample were collected over the temperature range of 2–300 K using a Quantum Design MPMS-5S superconducting quantum interference device (SQUID) magnetometer, and the diamagnetic corrections were made using Pascal's constants ($\chi_0 = 3.3$ emu mol^{-1} for **1** and 2.8 emu mol^{-1} for **2**) [13]. X-band EPR spectra of **1** and **2** were recorded on a Bruker 2000-D-SRC spectrometer on polycrystalline material at room temperature and the microwave frequency is near to 9.7 GHz.

2.3. Syntheses of $[CNQl]_2[TCNQ]_3$ (1) and $[CNPy]_2[TCNQ]_3$ (2)

A modified procedure, described in Ref. [14], was utilized to prepare **1** and **2**. Li(TCNQ) [15] (213 mg, 1.0 mmol) and [CNQl]Cl (283 mg, 1.0 mmol) (1:1 molar ratio) were mixed in water (40 mL) at room temperature, in heterogeneous phase, and stirred for ∼2 h. The black precipitate formed was filtered off, washed with H_2O. The crude product was dissolved in MeOH (∼15 mL) giving a clear solution. The violet-red crystals, which are suitable for X-ray analysis, were obtained after most solvent was evaporated. The crystals of **1** were collected by filtration, washed with Et_2O, and dried in air. Yield: ∼50%. *Anal.* Calc. for $C_{35}H_{19}N_8$: C, 76.2; H, 3.47; N, 20.3. Found: C, 76.0; H, 3.76; N, 20.2%. IR spectra (cm^{-1}): 2227(m) 2199 (m), 2181 (vs), 2174 (vs) and 2156 (sh).

Compound **2** was prepared as that described in **1**, starting from Li(TCNQ) and [CNPy]Cl in water. The yield of final product of crystals is about 52%. *Anal.* Calc. for $C_{31}H_{17}N_8$: C, 74.2; H, 3.42; N, 22.3. Found: C, 73.8; H, 3.68; N, 22.0%. IR spectra (cm^{-1}): 2233 (m), 2185 (vs), 2179 (sh), 2156 (vs).

2.4. X-ray crystallography

Diffraction data of **1** and **2** were collected at 293 K on a Bruker SMART APEX CCD-based diffractometer with graphite-monochromatic Mo Kα radiation. The structures were solved by direct method and refined on F^2 by full-matrix least-squares method using the SHELXTL-PC program package [16]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in their calculated positions and refined following the riding model. Crystal data for **1**: $C_{35}H_{19}N_8$, $M = 551.58$, monoclinic, space group $P2(1)/c$, $a = 16.083(3)$ Å, $b = 10.8627(17)$ Å, $c = 17.099(3)$ Å, $\beta = 114.327(3)°$, $V = 2722.0(7)$ Å [3], $Z = 4$, $D_{calc} = 1.346$ g cm^{-3}, $\mu = 0.084$ mm^{-1}, final R, $R_w = 0.0521$, 0.1327. 3856 observed reflections [$I > 2\sigma(I)$] out of 4781 unique ($R_{int} = 0.0534$), GOF = 0.913. Crystal data for **2**: $C_{31}H_{17}N_8$, $M = 501.53$, triclinic, space group $P-1$, $a = 7.314(2)$ Å, $b = 7.659(3)$ Å, $c = 25.131(8)$ Å, $\alpha = 89.900(5)°$, $\beta = 89.450(5)°$, $\gamma = 64.846(5)°$, $V = 1274.2$ (7) Å [3], $Z = 2$, $D_{calc} = 1.307$ g cm^{-3}, $\mu = 0.082$ mm^{-1}, final R, $R_w = 0.0734$, 0.2064. 3556 observed reflections [$I > 2\sigma(I)$] out of 4393 unique ($R_{int} = 0.0511$), GOF = 1.089.

2.5. Details of DFT calculation

The whole non-modelized molecular structure of the real compounds were taken directly from the X-ray crystallography, and the unrestricted density functional theory (DFT) calculations with UB3LYP functional and the 3-21G* basis set are performed using the GAUSSIAN 98 program [17] on the SGI 3800 workstation.

3. Results and discussion

3.1. Descriptions of crystal structures

$[CNQl]_2[TCNQ]_3$ (**1**). Compound **1** crystallizes in a monoclinic system with space group $P2(1)/c$, and an asymmetric unit contains one and half TCNQ entries together with one $[CNQl]^+$ cation (Fig. 1a). For the sake of simple description, two crystallographic independent TCNQ molecules are represented as TCNQ (A) and TCNQ (B). The TCNQ (B) unit containing N(5) atom possesses a inversion centre, while the TCNQ (A) unit containing N(1) atom does not possess any symmetry. The mean molecular planes defined by the corresponding quinodimethane groups between TCNQ (A) and TCNQ (B) make 0.9°

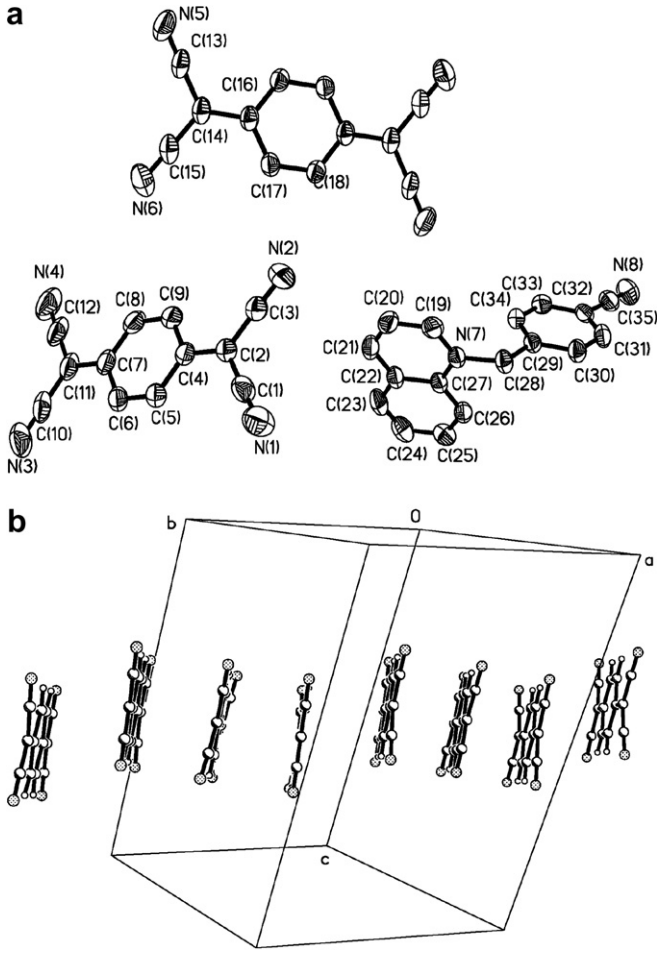

Fig. 1. (a) ORTEP view of **1** at 50% possibility ellipsoids; (b) packing structure of anions showing a triad column in **1**.

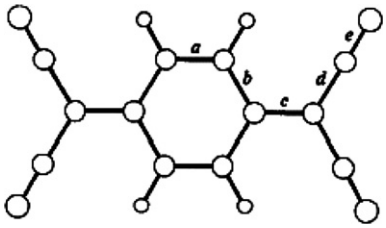

dihedral angle, indicating they are almost parallel to each other. The averaged lengths of chemically similar bonds in TCNQ (A) and TCNQ (B) units, summarized in Table 1, are somewhat different from each other, which are approximately close to $TCNQ^{-1}$ and $TCNQ^{0}$ entries, respectively [18]. Two TCNQ (A) and one TCNQ (B) molecules stack into a triad, and the triads further develop into a column in a pattern …ABA…ABA… along *b*-axis (Fig. 1b). In a TCNQ column, the mean inter-planar separations within three different overlap pairs are 3.207 Å for AA, 3.311 Å for AB and 3.184 Å for BA pairs, respectively.

For the cation, the bond lengths and molecular conformation are in fare agreement with those in $[NO_2Ql]$-$[Ni(mnt)_2]$ [19], and the dihedral angles between aromatic rings and the reference plane, C(28)/C(29)/N(7), are 10.6° for benzene, 73.8° for quinoline, respectively. There exist only van de Waals interactions between the neighboring anions and cations.

[CNPy]$_2$[TCNQ]$_3$ (**2**). Compound **2** crystallizes in a triclinic system with space group $P\bar{1}$, and the asymmetric unit contains one and half TCNQ moieties together with one $CNPy^{+}$ moiety (cf. Fig. 2a). Similar to **1**, one of two crystallographic inequivalence TCNQ molecules possesses an inversion centre (which contains N(5) atom and is labeled as TCNQ (B)), and another does not possess any symmetry (which contains N(1) atom and is labeled as TCNQ (A)). The averaged lengths of chemically similar bonds in TCNQ (A) and TCNQ (B) units are listed in Table 1. It is worthy noting that it is difficult to assign the valence for two crystallographic independent TCNQ species from the metric bond parameters (the averaged bond lengths such as *a*, *b*, *c*, *d* and *e*; cf. Table 1), which is obviously different from that in **1**. Another difference in the aspect of structural feature is the relative arrangement between TCNQ (A) and TCNQ (B) molecules. As shown in Fig. 2b, the mean molecular planes through the corresponding quinodimethane groups in A and B units make a dihedral angle of 68.2°, and TCNQ (A) and TCNQ (B) species form two types of TCNQ columns, respectively.

Table 1
Averaged bond lengths (Å) of the TCNQ molecules in **1** and **2**

The labeling system is illustrated below

	a	*b*	*c*	*d*	*e*
TCNQ in **1** (part A)	1.353	1.412	1.404	1.414	1.140
TCNQ in **1** (part B)	1.344	1.425	1.383	1.421	1.140
TCNQ in **2** (part A)	1.355	1.421	1.405	1.418	1.141
TCNQ in **2** (part B)	1.347	1.418	1.398	1.412	1.142
$TCNQ^{0}$ [18c]	1.346	1.448	1.374	1.440	1.138
$TCNQ^{-1/3}$ [1]	1.350	1.435	1.393	1.430	1.140
$TCNQ^{-1/2}$ [18b]	1.355	1.433	1.396	1.424	1.145
$TCNQ^{-1}$ [18a]	1.362	1.424	1.413	1.417	1.149

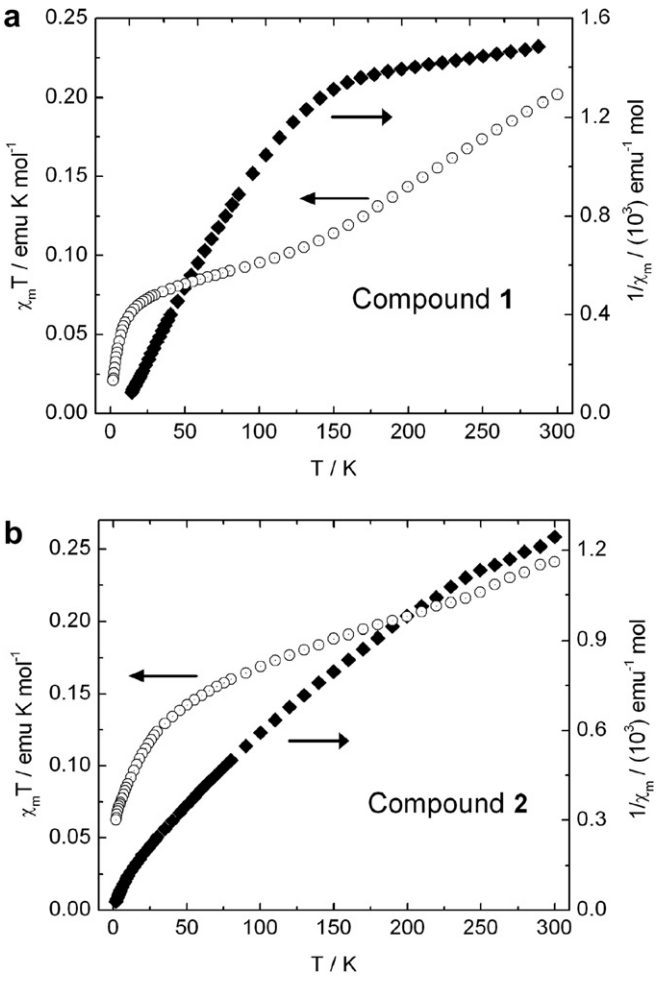

Fig. 3. Temperature dependences of magnetic susceptibility in the forms of $1/\chi_m - T$ and $\chi_m T - T$ for **1** and **2**.

Two different distances between mean-molecular planes are 3.121 and 3.338 Å in TCNQ (A)-type versus 3.771 and 3.771 Å in TCNQ (B)-type columns. Separated by the cations, no short atomic contact is observed between the neighboring TCNQ columns. In $CNPy^+$ moiety, the dihedral angles between aromatic rings and the reference plane, C(24)/C(25)/N(7), are 77.9° for benzene, 129.3° for pyridine, respectively. And there are only weak van de Waals forces between neighboring $CNPy^+$ and TCNQ species.

3.2. Magnetic susceptibilities and EPR spectra

The temperature dependences of magnetic susceptibility are shown as the plots of $1/\chi_m - T$ and $\chi_m T - T$ for **1** and **2** in Fig. 3. To some extent, the magnetic behaviors of both **1** and **2** are similar to each other, and exhibit below features: (1) the $\chi_m T$ values at room temperature are much smaller than expected spin-only values, and upon cooling the $\chi_m T$ values decrease slowly in high temperature range while drop quickly in lower temperature, (2) there is no linear relationship between $1/\chi_m$ and T. These characteristics indicate that there exist strong antiferromagnetic (AFM) coupling interactions within a magnetic TCNQ column and a temperature dependent magnetic coupling behavior. Obviously, the magnetic coupling interaction is stronger in the low temperature range than that in the high temperature range. It is understandable that the temperature dependent magnetic coupling behavior in **1** and **2**. For the planar molecule with extended electric structure, such as TCNQ and M(dithiolene)$_2$ species, spin polarization plays an important role in the intermolecular magnetic coupling interactions, and relatively small adjustments of the intermolecular arrangement (for example, a switch to an eclipsed rather than staggered arrangement) can easily change the magnetic coupling feature. Moreover, a variety of molecular arrangement can be easily reached with temperature change in such molecular crystals, since there are only weak intermolecular interactions. Therefore, the magnetic coupling nature is sensitive to the external perturbations (for example, temperature variation or pressure change) [20,21].

Fig. 4 depicts EPR spectra of **1** and **2** with polycrystalline samples at room temperature. Compound **1** exhibits only one resonance signal even though there exist two types of TCNQ species in solids. The typical radical EPR signal exhibits an isotropic feature without any sizable hyperfine structure observed. The resonance magnetic field, H_r, centered at 3481 Gs with a typical half-width at half-height of

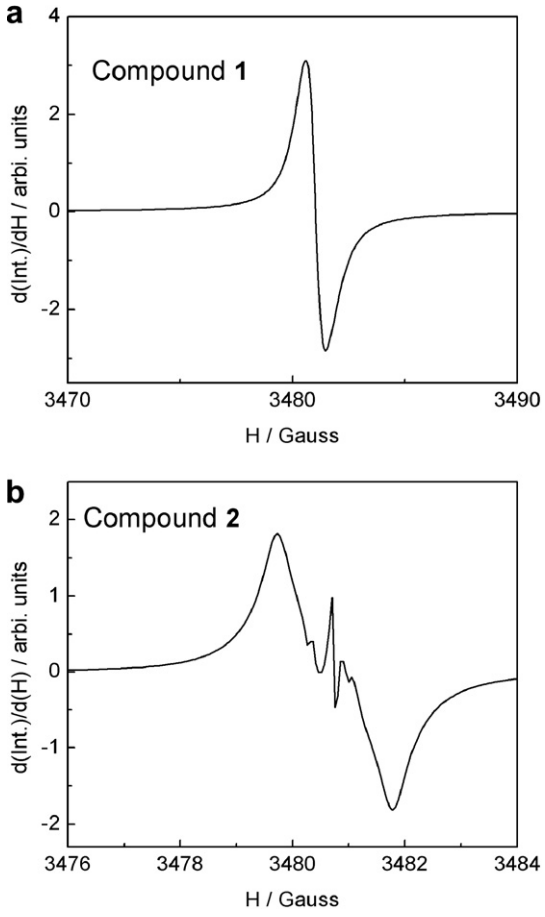

Fig. 4. EPR spectra of **1** and **2** at room temperature.

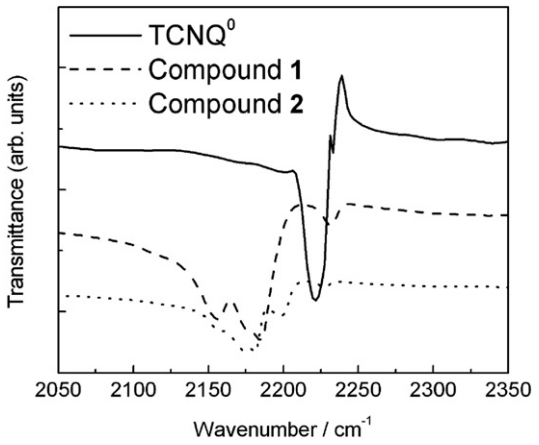

Fig. 5. IR spectra for **1**, **2** and neutral TCNQ in the range of 2050–2350 cm^{-1} at room temperature, and spectra 1 and neutral TCNQ were shifted arbitrarily to transmittance values in order to clarify the figure.

~2 Gs, so the *g*-factors of 2.0066 was obtained. In spectra of **2**, two sets of radical signals are observed. For one set, the resonance field centered at $H_r = 3480$ Gs with a half-width at half-height of ~3 Gs and the corresponding $g = 2.0062$, showing an isotropic characteristic. The other signal exhibits clearly fivefolds hyperfine structure that might arise from the interactions between spins of electron and four equivalent hydrogen atomic nuclear ($I_H = 1/2$) in a quinodimethane group, and the corresponding *g* and *A* values are estimated as 2.0067 and 0.25 Gs, respectively.

3.3. IR spectra and DFT calculations for spin and charge density distribution

For TCNQ species, the geometry varies with the electron population of the MO's, as expected. Thus it is possible to obtain an estimate of the molecular charge from the experimental geometry and IR spectra data. Actually, the relationship between geometric parameters in TCNQ species, IR spectra (especially the intense vibration band *v*(CN) which displays in general no overlap with other vibration models) [22] and the degree of charge transfer has been investigated so far. However, in most cases the different analysis approaches do not consist with each other [18a,18b,18c,18d,22,23]. Fig. 5 shows IR spectra of **1** and **2** which indicate the presence of two types of TCNQ species (*v*(CN) for the neutral TCNQ molecule is usually higher than 2200 cm^{-1}), and one of them seems corresponding to $TCNQ^0$ species. This observation is approximately agreement with the bonding length analyses for **1**, but not for **2** (Ref. Table 1). The reason to cause such a puzzle may arise from that each method is approximate and ignores some other effects, such as the influence of molecular packing on intermolecular geometry [22,23b].

In order to understand the charge distribution of TCNQ species in both **1** and **2**, the DFT calculation for the valence assignment in a $[(TCNQ)_3]^{2-}$ unit was performed at UB3LYP/3-21G* level (one $[(TCNQ)_3]^{2-}$ unit includes two TCNQ (A) moieties and one TCNQ (B) moiety). The calculation results disclosed that two crystallographic independent TCNQ molecules have significantly different charges in **1**. The total charge is −0.8264 for TCNQ (A), −0.8257 for symmetry generated TCNQ (A), and −0.3479 for TCNQ (B) units, that is, the negative charge is mainly localized on TCNQ (A) molecule. For **2**, the total charge is −0.6565 for TCNQ (A), −0.6228 for the symmetry generated TCNQ (A), and −0.7208 for TCNQ (B) units, meaning the negative charges are almost distributed averagely on TCNQ (A) and TCNQ (B) molecules. The above results consist approximately with EPR results of **1** and **2**.

4. Conclusion and remarks

In summary, we have investigated the crystal structural, magnetic property characterizations and theoretic analyses for two radical compounds based on the $[(TCNQ)_3]^{2-}$ unit. In crystals of both **1** and **2**, an asymmetric unit in a cell includes two crystallographic independent TCNQ species (labeled as unit A and B). The unit A and B form a stack in the pattern …ABA…ABA… in **1**, while two types of homogeneous columns (…AA… and …BB…) in **2**, respectively. Temperature dependences of magnetic

susceptibility revealed the magnetic features of strong AFM coupling interaction within a TCNQ stack and temperature dependent magnetic coupling behavior. The IR spectra clearly show the existence of a mixed-valence state in both **1** and **2**, namely, the crystallographic inequivalent TCNQ (A) and TCNQ (B) units possess different negative charge and the values based on the analyses of IR spectra and bond lengths are approximately in agreement with each other for **1** but not for **2**. EPR spectra exhibit two different resonance signals in **2**, however, only one resonance signal in **1** even though **1** and **2** have the same stoichiometry $[cation]_2[TCNQ]_3$. Further, DFT calculation for charge distribution performed in each crystallographic independent TCNQ species disclosed the TCNQ (A) and TCNQ (B) units may be assigned to $TCNQ^{-1}$ and $TCNQ^{0}$ in **1**, and $TCNQ^{-\delta}$ (where partial charge $\delta = 0.62$–0.72) in **2**.

magnetic building block, $[Ni(mnt)_2]^-$ monoanion, whose syntheses, crystal structures and magnetic susceptibilities are described.

2. Experiment

Disodium maleonitriledithiolate (abbr. as Na_2mnt) were prepared according to the published procedure [9]. [Diprotonated benzene-1,4-diamine][$Ni(mnt)_2$]$_2$ (**1**) and [diprotonated 1,4-diazabicyclo[2.2.2]octane][$Ni(mnt)_2$]$_2 \cdot 3MeCN$ (**2**) were synthesized using a similar procedure described in the literature [8]. *Anal*. Calc. for $C_{11}H_5N_5NiS_4$ (**1**): C, 33.5; N, 17.8; H, 1.28. Found: C, 33.2; N, 17.7; H, 1.47%. *Anal*. Calc. for $C_{28}H_{23}N_{13}Ni_2S_8$ (**2**): C, 36.7; N, 19.9; H, 2.53%. Found: C, 36.2; N, 19.3; H, 2.81%.

The MeCN solution of **1** or **2** was put in a refrigerator at about 0 °C for 24 h, and the block-shaped crystals were obtained which were suitable for X-ray structural analysis and other measurements.

2.1. X-ray crystallography

The diffraction data were collected at 293 K for **1** and 253 K for **2** with graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å) on a Rigaku Raxis-Rapid diffractometer. Structures were solved by direct methods using the SHELXL-97 software package [10]. The non-H atoms were refined anisotropically using the full-matrix least-squares method on F^2. All H atoms were placed at calculated positions and refined riding on the parent atoms. The crystallographic details about data collection and structure refinement are summarized in Table 1.

2.2. Magnetic susceptibility measurements

Temperature dependent magnetic susceptibilities on polycrystalline samples of **1** and **2** were measured between 2 and 350 K using a Quantum Design MPMS XL superconducting quantum interference device (SQUID) magnetometer.

3. Results and discussion

3.1. Descriptions of crystal structures

*Crystal structure of **1***: An asymmetric unit of **1** consists of one $[Ni(mnt)_2]^-$ anion and a half cation (diprotonated benzene-1,4-diamine), and the centre of benzene ring coincides with an inversion centre, as shown in Fig. 1a. The anion $[Ni(mnt)_2]^-$ possesses an approximately planar geometry. The Ni–S lengths range from 2.1448(8) to 2.1524(8) Å and two S–Ni–S angles in the chelate rings are 92.75(3)° and 92.67(3)°, respectively. These values are in fare agreement with those reported $[Ni(mnt)_2]^-$ compounds [1e,6]. As shown in Fig. 1d, the anions form a π-stacked layer, which is approximately parallel to the *ab*-plane. Two overlap fashions between neighboring anions along the direction of a stack were depicted in Fig. 1b and c. Face-to-face overlap involves anionic pairs containing Ni(1) and Ni(1)^{i} (symmetric code i $= -x+1, -y, -z+1$), in which the distances [Ni(1)...Ni(1)^{i}, 3.717 Å, Ni(1)...S(2)^{i}, 3.887 Å, Ni(1)...S(4)^{i}, 3.872 Å, S(2)...S(3)^{i}, 3.669 Å, and S(1)...S(4)^{i}, 3.698 Å] are comparable to the distance (3.532 Å) between the corresponding mean-molecular-planes (which is defined by the core NiS_4). Longitudinal and transverse offset involve anionic pairs containing Ni(1) and Ni(1)^{ii} (symmetric code ii $= -x+1, -y+1, -z+1$), in which the distances [Ni(1)...Ni(1)^{ii}, 5.829 Å, S(3)...S(4)^{ii}, 4.122 Å, of Ni(1)...S(3)^{ii}, 4.715 Å] are much longer than that of the corresponding mean-molecular-planes (3.685 Å). The interstack Ni...Ni, Ni...S and S...S distances (the shortest distances are 6.331 Å for Ni...Ni, 4.706 Å for Ni...S, and 3.705 Å for S...S) are slight greater than the intrastack distances.

There exist the H-bonding interactions between anions and cations as illustrated in Fig. 2, and geometric parameters, listed in Table 2, are comparable with the values in the literature [1e,11–14]. The adjacent anionic sheets are held together by cations through H-bonding interactions to develop into a 3D network.

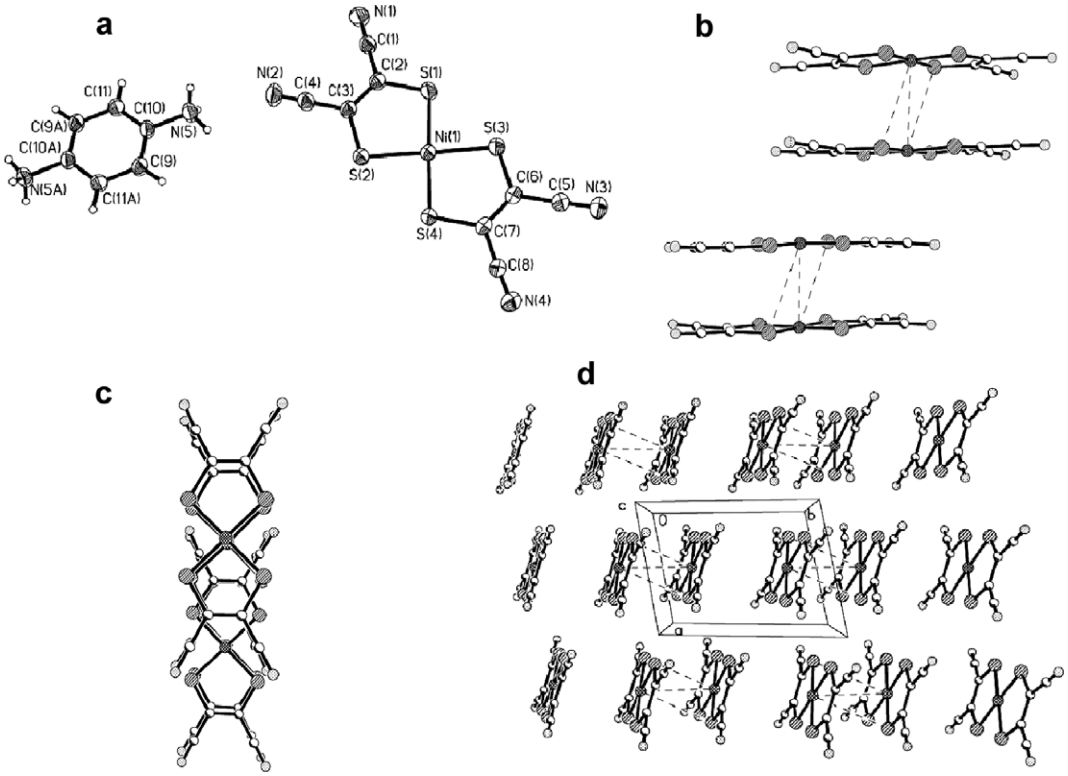

Fig. 1. (a) ORTEP draw (50% probability thermal ellipsoids) of **1**, showing non-hydrogen atomic numbering; (b) side view; (c) top view of anionic stack; (d) anionic layer projected on *ab*-plane.

Crystal structure of **2**: Compound **2** crystallizes in a triclinic system with space group $P\bar{1}$, and an asymmetric unit contains two anions, one cation together with three molecules of solvent MeCN. For a cation, diprotonated 1,4-diazabicyclo[2.2.2]octane, the bond lengths and angles are in good agreement with those reported in the literature [8]. The molecular structures of two crystallographic inequivalent anions rather resemble to **1**, and the Ni–S lengths are in the range 2.1436(11)–2.1472(13) Å and two S–Ni–S angles in the chelate rings are 92.72(4)° and 92.95(4)° in the anion containing Ni(1) [and the corresponding values Ni–S lengths: 2.1450(11)–2.1539(11) Å; S–Ni–S angles in the chelate rings: 92.52(5)° and 92.69(4)° in the anion containing Ni(2)].

As shown in Fig. 3, two adjacent anions stack into a dimer [denoted as Ni(1)Ni(2)], in which the shorter intermolecular separations are 3.802 Å for Ni(1)...Ni(2)^{i}, 3.794 Å for Ni(1)...S(4)^{i} and 3.800 Å for S(1)...S(4)^{i} and 3.807 Å for S(2)...S(3)^{i} (symmetric code i = x, y, $-1+z$). The dimers form a columnar stack in a fashion of

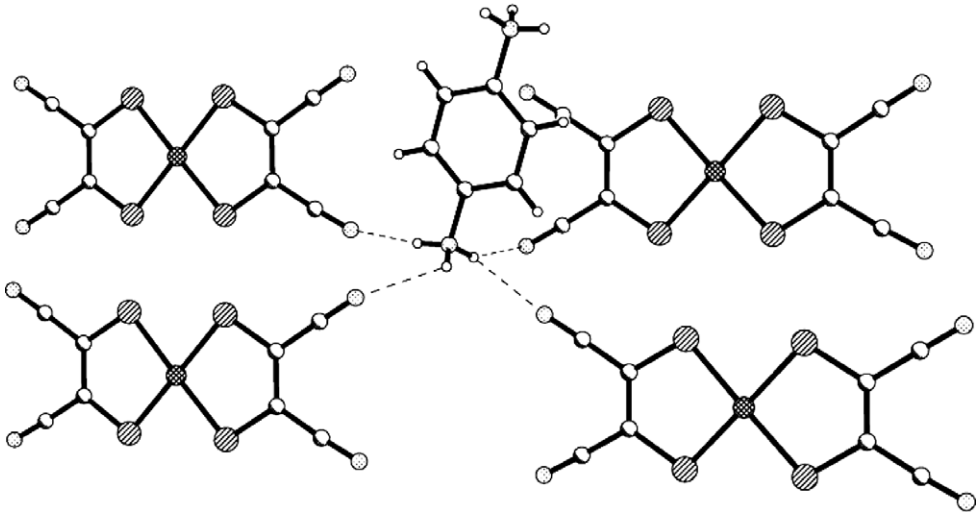

Fig. 2. H-bonding interactions between cation and anions in **1**.

Table 2
Geometric parameters of hydrogen bonds in **1** and **2** (Å and °)

D–H...A	*d*(D–H)	D(H...A)	*d*(D...A)	∠(DHA)

N(5)–H(5B)...N(3)#2	0.89	2.42	2.954(3)	118.6
N(5)–H(5C)...N(3)#3	0.89	2.32	3.117(3)	149.9
N(5)–H(5C)...N(1)#4	0.89	2.55	2.980(3)	110.6
Symmetric codes: #1 = $-x+2, -y, -z+1$; #2 = $-x+1, -y, -z+1$; #3 = $-x+2, -y, -z$; #4 = $-x+1, -y, -z$				
2				
N(9)–H(9A)...N(1)#1	0.91	2.20	2.931(5)	137.0
N(9)–H(9A)...N(7)#2	0.91	2.45	3.122(4)	130.9
N(10)–H(10A)...N(2)#3	0.91	2.30	3.022(4)	136.7
N(10)–H(10A)...N(13)#3	0.91	2.42	3.116(7)	133.8
Symmetric codes: #1 = $-x, -y-2, -z+1$; #2 = $x+1, y, z$; #3 = $x, y, z-2$				

$\cdots$Ni(2)Ni(1)$\cdots$Ni(1)Ni(2)$\cdots$Ni(2)Ni(1)$\cdots$, and the shorter intermolecular separations are 3.705 Å for Ni(1)...S(2)^{j} and 3.794 Å for Ni(2)...S(6)^{k} Å (symmetric codes: j = $-x, -2-y, 2-z$; k = $-1-x, -3-y, -z$) between the inter-dimers. Further, the anionic stacks arrange into a sheet which is approximately parallel to the crystallographic *ab*-plane. The H-bonding interactions are also observed between cations and anions, as well between cations and solvent molecules (cf. Fig. 4), and their geometric parameters are summarized in Table 2.

In the field of utilizing the crystal-oriented syntheses via non-covalent interactions to generate functional materials, it is important to understand the self-assembly feature of functional molecular building blocks. In our studies, we noted that the countercation, benzylpyridinium derivatives, induces the magnetic molecular building block, $[Ni(mnt)_2]^-$ ion, to form separated stacking columns of cations and anions [6], while the countercation with H-bonding donor nature makes $[Ni(mnt)_2]^-$ ions easily to construct a 2D anionic layer structure [8,14].

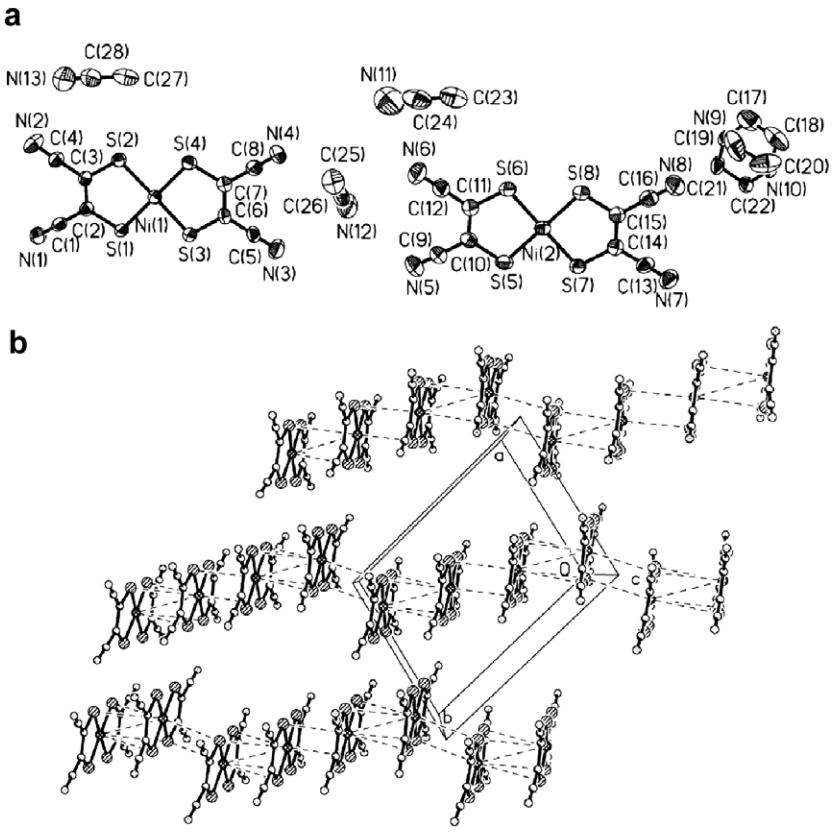

Fig. 3. (a) ORTEP draws of **2** at 50% probability thermal ellipsoids, showing non-hydrogen atomic numbering (H-atoms omitted for clarity). (b) An anionic sheet projected on *ab*-plane.

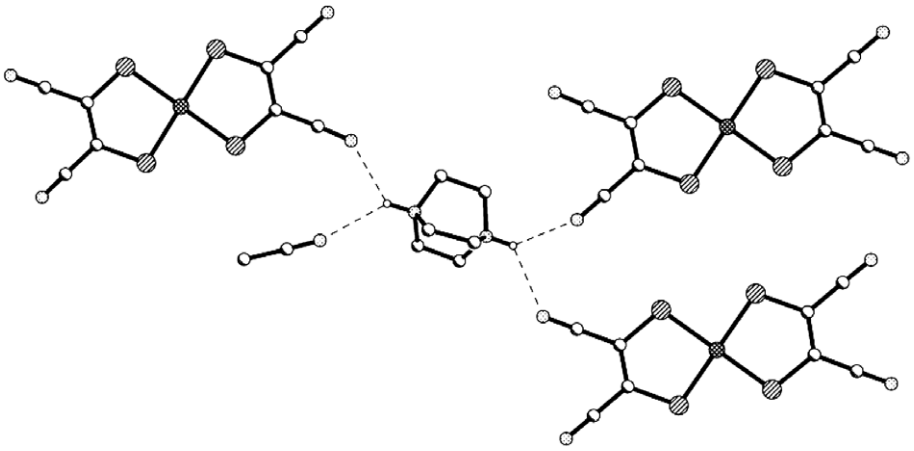

Fig. 4. H-bonding interactions between anions and cation and between solvent molecule MeCN and cation in **2**.

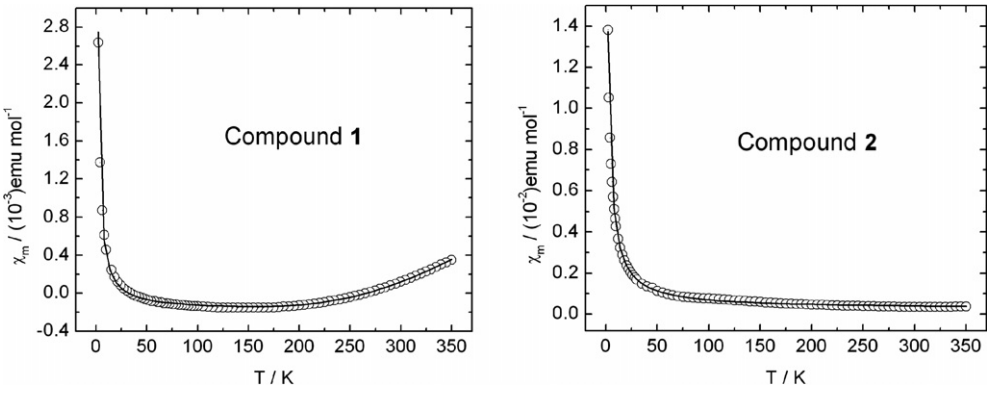

Fig. 5. Temperature dependences of the magnetic susceptibility of **1** and **2**, and the open circles and solid lines are experimental data and fits, respectively (see text).

3.2. Magnetic susceptibilities

Fig. 5 shows the temperature dependences of magnetic susceptibility for **1** and **2**. Compound **1** exhibits an activated magnetic behavior in the high-temperature range together with a Curie tail at the lower temperature range due to magnetic impurities. From the viewpoint of crystal structure, it is possible for **1** to exhibit the magnetic behavior of a spin dimer with $S = 1/2$, however, the temperature dependences of magnetic susceptibility does not follow the Bleaney–Bowers. While Eq. (1) [15] for a dimerized Hubbard spin chain system can be used to fit the magnetic susceptibility data,

$$\chi_m = \frac{\alpha}{T^{\gamma}} \cdot \exp(-\Delta/k_B T) + \frac{C}{T} + \chi_0 \quad (1)$$

where α is a constant corresponding to the dispersion of excitation energy, Δ/k_B is the magnitude of the spin gap, and γ is a constant. The term C/T represents the contributions of the magnetic impurity, χ_0 is the contributions from core diamagnetism and possibly Van Vleck paramagnetism, and other symbols have their usual meanings. The best fits magnetic susceptibility data to Eq. (1) yielded the parameters: $\alpha = 1.76(5)$, $\gamma = 0.65(3)$, $\Delta/k_B = 1504$ (50) K, $C = 5.85(4) \times 10^{-3}$ emu K mol^{-1}, $\chi_0 = -1.8(2) \times 10^{-4}$ emu mol^{-1}. For **2**, the magnetic behavior follows the Curie–Weiss law,

$$\chi_m = \frac{C}{T - \theta} + \chi_0 \quad (2)$$

and fitting the temperature dependence of magnetic susceptibility to Eq. (2) gave the reasonable parameters $C = 4.53(2) \times 10^{-2}$ emu K mol^{-1}, and $\chi_0 = -2.5(1) \times 10^{-4}$ emu mol^{-1}. The smaller Curie constant indicates that the weak paramagnetic interactions maybe originate from the magnetic impurity (lattice defect), and hence the inherent magnetic behaviors of **2** should be diamagnetic due to existence of very strong antiferromagnetic coupling interactions within the eclipsed $[Ni(mnt)_2]^-$ dimers.

4. Conclusions

Summarily, the crystal structures and magnetic properties were presented for two new H-bonding molecular magnets based on molecular building block $[Ni(mnt)_2]^-$. In crystals of both **1** and **2**, the common feature of the crystal

structure is that $[Ni(mnt)_2]^-$ monoanions form π-stacked sheet and the neighboring sheets are held together via H-bonding interactions between anions and cations. The magnetic behavior of **1** deviates from the model of spin dimer with $S = 1/2$ but follows a dimerized Hubbard spin chain model even though its crystal structure reveals the dimer feature. The strongly antiferromagnetic exchange interactions between the nearest spins in **2** make this compound to be nearly diamagnetic. It is very interesting and significant to understand how the geometric nature of a countercation to influence the stacking pattern of $[Ni(mnt)_2]^-$ anions, and how the stacking pattern of $[Ni(mnt)_2]^-$ anions influence on the magnetic coupling feature between anions. To gain more insight into such questions, further experimental and theoretic investigations are in progress [16].

2. Experimental

The precursor **SB** [17] prepared from diphenylamine and acridone in three steps [8] was oxidized with *m*-chloroperbenzoic acid (mCPBA) (Scheme 2). To a solution of **SB** (301 mg; 0.87 mmol) in $CHCl_3$ (20 mL) was added a solution of mCPBA (512 mg; 3.0 mmol) in $CHCl_3$ (30 mL) at 0 °C with stirring, and the combined solution was stirred further at 0 °C for 12 h. The color turned dark red. The mixture was passed through a short column (basic alumina) with CH_2Cl_2 as an eluent. A red fraction was collected and concentrated under reduced pressure. The mixture was purified again by HPLC (Japan Analytical Industry 1H + 1H GPC columns; eluted with $CHCl_3$; a flow rate: 3.5 mL min^{-1}). The elution was monitored at UV 254 nm absorption. A red fraction of the retention time of 65 min contained **SBDO** and that of 68 min contained **SBO**, which were assigned by means of ESR and other spectroscopic methods. The yields were 15 mg (0.040 mmol; 5%) and 118 mg (0.33 mmol; 38%) for **SBDO** and **SBO**, respectively. **SBO** · ($CHCl_3$): m.p. 35–36 °C ($CHCl_3$ liberation). *Anal.* Calc. for $C_{26}H_{18}Cl_3N_2O$: C, 64.95; H, 3.77; N, 5.83. Found: C, 65.86; H, 3.90; N, 5.91%. ESI-TOF MS *m*/*z* 384 ($M + Na^+$). IR (KBr disc) 746, 1335, 1373, 1485, 1518, 1608, 3352 cm^{-1}. ESR (9.7 GHz, benzene, room temperature) $g = 2.0082$, $a_N = 8.80$ G, $a_H = 2.35$, 0.72 G. Recrystallization of **SBO** from CH_2Cl_2, $CHCl_3$, CH_3OH, CH_3CN, and C_6H_5Cl gave solvated molecular complexes, **SBO** · (CH_2Cl_2)$_2$, **SBO** · $CHCl_3$, **SBO** · CH_3CN, **SBO** · C_6H_5Cl, and **SBO** · CH_3OH, respectively. **SBDO**: m.p. 226–227 °C (dec). *Anal.* Calc. for $C_{25}H_{16}N_2O_2$: C, 79.77; H, 4.28; N, 7.44. Found: C, 78.06; H, 5.08; N, 7.57%. ESI-TOF MS *m*/*z* 399 ($M + Na^+$). IR (KBr disc) 754, 1373, 1435, 1485, 1610, 1637 cm^{-1}. ESR (9.7 GHz, benzene, room temperature) a broad singlet at $g = 2.008$ with a peak-to-peak line width of ca. 16 G.

Scheme 2. Preparation of **SBO** and **SBDO**.

Diffraction data of single crystals of **SBDO** and solvated **SBO** were collected on a Rigaku R-axis RAPID diffractometer with graphite monochromated Mo Kα or Cu Kα radiation. The structures were directly solved and the parameters were refined in the CrystalStructure program package (version 3.5.1, Rigaku/MSC, The Woodlands, TX 77381, USA (2003)). Numerical absorption correction was used. All of the hydrogen atoms were experimentally found. Selected crystallographic parameters of **SBO** · (CH_2Cl_2)$_2$, **SBO** · CH_3CN and **SBDO** are listed in Table 1. The crystal structures of **SBO** · $CHCl_3$, **SBO** · C_6H_5Cl, and **SBO** · CH_3OH were preliminarily solved.

Magnetic susceptibilities of polycrystalline specimens of **SBDO** and solvated **SBO** were measured on a Quantum Design MPMS SQUID magnetometer equipped with a 7 T coil in a temperature range of 1.8–300 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder measured separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constant.

An ESR spectra were recorded on a Bruker ESP300E X-band (9.7 GHz) spectrometer equipped with an Oxford cryostat for low-temperature measurements. Saturation effects were carefully removed from the spectra by lowering the microwave power. Solid solutions in poly(butyl methacrylate) was obtained from mixing substrate and polymer (the substrate concentration was 10^{-3} to 10^{-5} w/w%) in dichloromethane followed by casting as film on a glass plate. Simulated spectra for the frozen and liquid solutions were calculated in the WinEPR Simfonia program (version 1.25, Bruker Biospin, Rheinstetten, Germany (1996)).

[a] $R = \sum ||F_o| - |F_c|| / \sum |F_o|$.

[b] $wR = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$.

Molecular orbital calculations were performed on the GAUSSIAN 03 program (Revision C.02, Gaussian Inc., Pittsburgh, PA 15106, USA (2003)). We applied unrestricted density functional (DFT) UB3LYP methods with the Becke exchange functional [18] and the Lee–Yang–Parr correlation functional [19]. The 6-31G** basis set was chosen. The convergence criterion for the energy was set at 10^{-9} a.u. The structural parameters were given from the crystallographic analysis.

3. Results and discussion

Oxidation of **SB** with *m*-chloroperbenzoic acid gave **SBDO** together with a monoradical, **SBO**. Both crystalline radicals are stable in air at room temperature, but **SBDO** in a solution phase was gradually decomposed under ambient conditions. Fig. 1a shows the observed and simulated X-band ESR spectra for **SBO**. The observed coupling pattern is typical of 9,10-dihydroacridin-10-oxyls [14–16]. The hyperfine coupling constants due to the *o*- and *p*-H atoms are close to each other, and those of *m*-H atoms are much smaller than those of *o*- and *p*-H atoms, where *o*-, *m*-, and *p*-positions are defined with respect to the nitroxide group. The simulated curve reproduced well the experimental one with the optimized parameters: $a_{o\text{-H}} = a_{p\text{-H}} = 2.35$ G and $a_{m\text{-H}} = 0.72$ G together with $a_{\text{N}} = 8.80$ G. On the other hand, **SBDO** showed a broad and distorted single signal even in a sufficiently deairated and dilute solution (Fig. 1b). This broadening is owing to intramolecular dipole–dipole and exchange interactions among the unpaired electrons. The presence of monoradical impurities was suggested with the hyperfine structures superposed, indicating that a small portion of **SBDO** is decomposed during these measurements in solutions.

The molecular structures of **SBO** and **SBDO** were unequivocally determined by means of X-ray crystallographic analysis. We found molecular complexes, **SBO** · $(CH_2Cl_2)_2$, **SBO** · $CHCl_3$, **SBO** · CH_3CN, **SBO** · C_6H_5Cl,

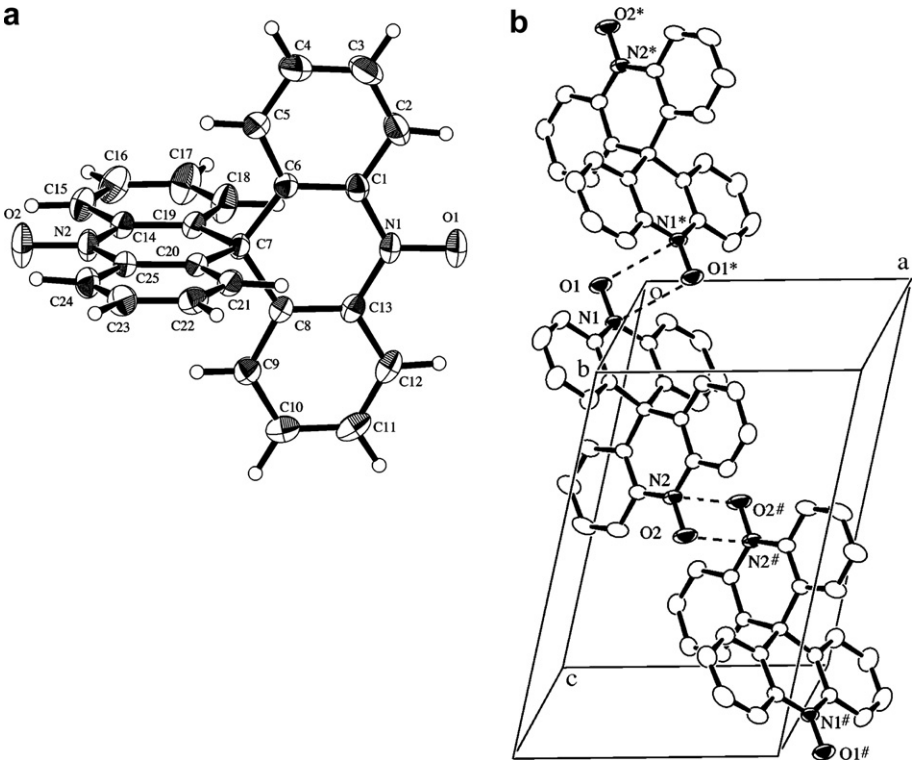
and **SBO** · CH_3OH (Fig. 2 for **SBO** · $(CH_2Cl_2)_2$ and **SBO** · CH_3CN). The solvent molecules are located in a hydrophobic cavity surrounded by the walls of the acridine skeleton. The rigid molecular structure of **SBO** is suitable to form nearly rectangular cavities in the crystal. It has been proved that the a methoxy-derivative of **SB** (abbreviated as **MSB**) can work as a host for conventional organic solvent molecules, affording **MSB** · $(CH_2Cl_2)_2$, **MSB** · $(CHCl_3)_2$, and **MSB** · $CH_2Cl_2 \cdot C_6H_6$ for example [8]. The methoxy group in **MSB** and the oxyl group in **SBO** seem responsible for expansion of the cavity sizes. In the case of **SBO** · $(CH_2Cl_2)_2$, **SBO** · $CHCl_3$, **SBO** · CH_3CN, and **SBO** · C_6H_5Cl, hydrogen-bonding interaction is found between the nitroxide oxygen and amine hydrogen atoms in the crystal packing, while the methanol oxygen atom in **SBO** · CH_3OH interacts with amine hydrogen atoms instead. The nitroxide group in **SBO** has a quite usual geometry as indicated by very planar configuration around the nitrogen atom and the bond lengths of N–O ranges in 1.288(2)–1.292(3) Å being typical of 9,10-dihydroacridin-10-oxyls [14–16].

The crystal structure of **SBDO** was determined, where no solvent molecule was incorporated. Ortep drawing and crystal packing diagram are depicted in Fig. 3a and b. The N–O bond distances are 1.290(1) and 1.283(2) Å, which are also typical of 9,10-dihydroacridin-10-oxyls [14–16]. The intermolecular N–O · · · N–O contacts are found in both sides of the nitroxide groups (Fig. 3b). There is a crystallographical inversion center between two nitroxide groups in neighboring molecules, and two N–O groups form a head-to-tail rectangle. The geometries around N1–O1 · · · $N1^*$–$O1^*$ and around N2–O2 · · · $N2^{\#}$–$O2^{\#}$ are similar to each other. The interatomic distances are 3.176(2) and 3.184(2) Å for O1 · · · $N1^*$ and O2 · · · $N2^{\#}$, respectively, which are only 4% longer than the sum of Van der Waals radii [20]. Recently, very close intermolecular contacts of nitroxide groups are reported to show a practically diamagnetic nature [21,22]. The present compound would exhibit relatively strong antiferromagnetic coupling in an intermolecular manner. Furthermore, this proximity leads to closer packing in the crystal, and purges a guest molecule to give the unsolvated crystal.

We measured the magnetic susceptibility of a randomly oriented polycrystalline sample of **SBDO** to clarify magnetic exchange interaction operative in the crystal. Fig. 4 shows the temperature dependence of the molar magnetic susceptibility χ_{mol} and the product $\chi_{mol}T$ for **SBDO**. The $\chi_{mol}T$ value decreased on lowering temperature, indicating the presence of dominant antiferromagnetic coupling. A step-like behavior was found at 0.1 $cm^3\,K\,mol^{-1}$ due to the almost magnetically isolated monoradical species. The $\chi_{mol}T$ decreased again on further cooling. To estimate the magnitude of magnetic interaction, we applied a singlet–triplet model [23], where the spin-Hamiltonian is defined as $H = -2JS_1 \cdot S_2$. The presence of $S = 1/2$ paramagnetic impurity due to partial decomposition was taken into



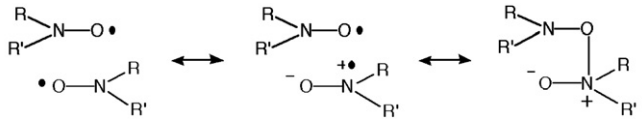


Fig. 3. (a) Ortep drawing of **SBDO** with the thermal ellipsoids at the 30% probability level for non-hydrogen atoms. (b) Molecular arrangement in the crystal of **SBDO**. Three molecules are drawn in a linear array along the $a + b + c$ diagonal direction. Hydrogen atoms are omitted for clarity. Relatively short distances are indicated with dotted lines. Symmetry operation codes for ∗and # are $(-x, -y, -z)$ and $(-x + 1, -y + 1, -z + 1)$, respectively.

consideration, and the molar fraction of the doublet was defined as α. In addition, inter-monomer interaction is included as a Weiss mean field parameter (θ), and Eq. (1) was derived accordingly. We obtained the following optimized parameters: $J/k_B = -70.2(7)$ K, and $\alpha = 0.316(9)$, and $\theta = -2.6(3)$ with $g = 2$ (fixed). The calculated curve well reproduced the experimental data (the solid lines in Fig. 4)

$$\chi_{mol} = (1-\alpha)\frac{Ng^2\mu_B^2}{k_B T}\frac{2}{3+\exp(2J/k_B T)} + \alpha\frac{Ng^2\mu_B^2}{4k_B(T-\theta)} \quad (1)$$

The bulk specimen included a somewhat large quantity of monoradical impurities, which might be decomposed products during the sample preparation. The X-ray diffraction study demonstrated the satisfactory determination of the crystal structure because of the process of manual selection of a well-shaped crystal. Thus, portions of single crystals were sufficiently pure whilst the remainder was not. We found difficulty in preparation of a highly pure bulk specimen, as clarified by the purification and magnetic measurements of **SBDO** several times.

A question arises here: to which the singlet-triplet model should be assigned, a **SBDO** molecule or N–O ··· N-O contacts? In other words, is the ground state of a **SBDO** molecule triplet or singlet? Possible intramolecular magnetic interaction would be clarified by means of a solid solution ESR study and suggested by theoretical calculation (see below). From the results of the X-ray crystallographic analysis of **SBDO**, it is most likely that the observed antiferromagnetic interaction would be ascribed mainly to intermolecular interaction due to a SOMO–SOMO overlap at relatively close contacts. This interaction can be depicted as the following canonical structures; that is, antiferromagnetic coupling appears as a contribution of a very weak covalent bond. There are two independent intermolecular N–O ··· N–O contacts, but both situations are fortunately quite similar to each other. Thus, the coupling constant obtained here implies the average of the two intermolecular interactions.

We attempted ESR measurements of **SBDO** under diluted conditions. Fig. 5a shows the X-band ESR spectrum of **SBDO** solved in a poly(butyl methacrylate) matrix at 20 K. This figure shows a clear fine structure, but additional signals were superposed. Possible origins of the additional signals are hyperfine interaction due to the nitrogen atoms [24] and aggregation of **SBDO** molecules leading to superposition of triplet signals. We supposed that the most outer lines at 3259 and 3437 G were assigned to the **SBDO** $H//z$ signals. The point dipole approximation, $|D'| = |D|/g\mu_B = |-3g\mu_B/2r^3|$, from the zero-field splitting parameter $|D'|$ of 89 G gave a dipole–dipole distance of 6.8 Å. This value is somewhat smaller than the actual distance of

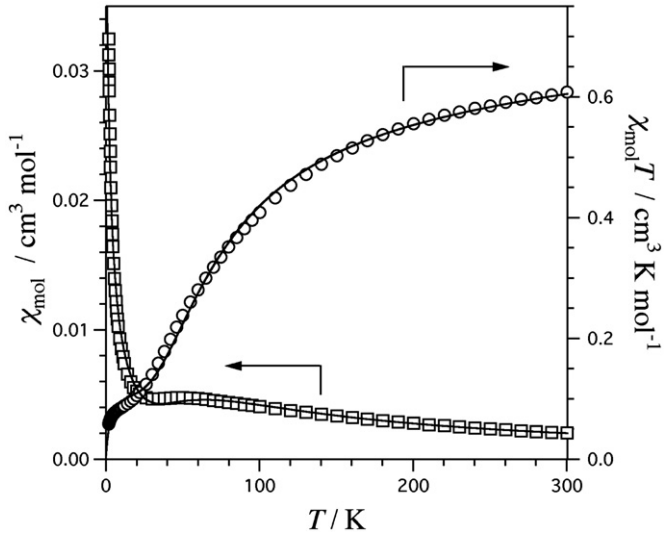

Fig. 4. Temperature dependence of χ_{mol} (squares) and $\chi_{mol}T$ (circles) for **SBDO** measured at 5000 Oe. Solid lines represent a theoretical fit. See the text for the equation and parameters.

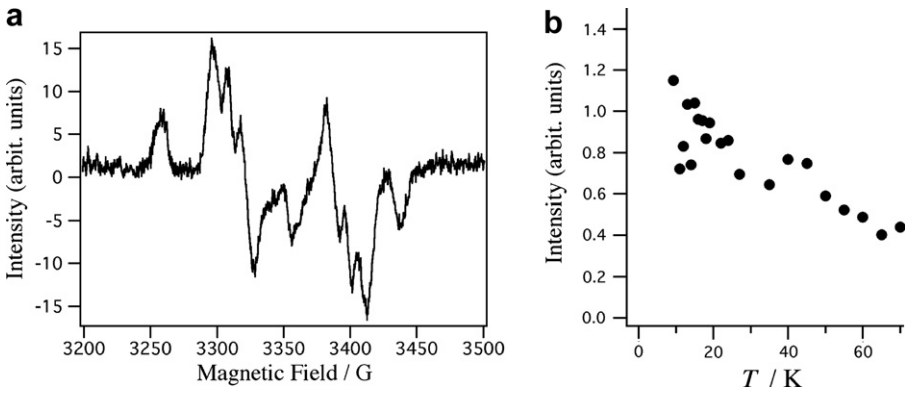

Fig. 5. (a) X-band ESR spectrum of **SBDO** measured in poly(butyl methacrylate) at 20 K. (b) Temperature dependence of the signal intensity of the average of the most outer signals at 3259 and 3437 G.

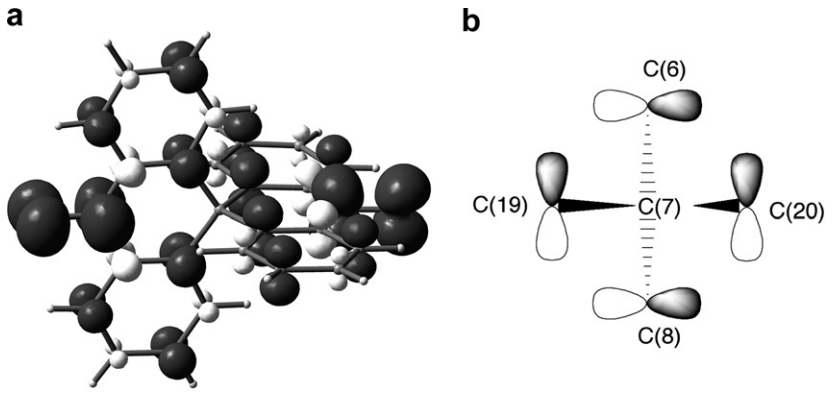

Fig. 6. (a) Spin density distribution at the triplet state of **SBDO** calculated on the UB3LYP/6-31G** level (dark gray: positive spin density; light gray: negative spin density). The geometry was given from the X-ray crystallographic analysis. (b) Orthogonal arrangement between two SOMOs. See Fig. 3 for the atomic numbering.

7.8 Å defined between the centers of the N–O bonds. The calculated distance is rationally acceptable because the spins are delocalized onto the adjacent phenyl rings to approach effectively each other. Another parameter $|E'|$ was 6.7 G, which could not be precisely determined because of the additional lines.

The temperature dependence of the peak heights of the $H//z$ signals approximately obeyed the Curie law (Fig. 5b); the ESR signal intensity increased on lowering temperature. This finding is in sharp contrast to those of the magnetic susceptibility of the bulk **SBDO** solid. The ground spin multiplicity of a free **SBDO** molecule is suggested to be triplet. However, it is not completely eliminated that the singlet and triplet states would be almost degenerate.

We performed theoretical calculation of **SBDO** based on the unrestricted density functional theory (UB3LYP/6-31G**). The distribution of the spin density (2e in total) is drawn in Fig. 6a, which clearly represents the SOMOs carrying a π-character. The alternative spin density throughout the conjugation system is illustrated. We also confirmed orthogonality of the two SOMOs (Fig. 6b), and accordingly ferromagnetic coupling is strongly suggested from this geometry. In this calculation, the SCF energies for the triplet and singlet states were −1221.97118170 and −1221.97110516 a.u., respectively. The calculation indicates that the triplet state is more stable than the singlet state by the energy difference of 7.65×10^{-5} a.u. The energy gap between the $S = 1$ and $S = 0$ states corresponds to $2J_{\text{intra}}$, and accordingly the calculated J_{intra} value was estimated to be 3.83×10^{-5} a.u. $= 1.01 \times 10^{2}$ J mol^{-1}, which is converted to 12 K or 8.4 cm^{-1}.

To evaluate the solid solution data by modeling a free single molecule, the molecular geometry was fully optimized in the calculation of UB3LYP/6-31G** for **SBDO**. We obtained results similar to those of the geometry fixed; the triplet state (−1222.16232761 a.u.) is more stable than the singlet state (−1222.16224543 a.u.) by the energy difference of 8.22×10^{-5} a.u., which gives the calculated J_{intra} value of 13 K. The SOMO lobes and spin density maps were practically identical to those of the single point calculation of the molecular structure determined in the crystal. Thus, the intramolecular ferromagnetic coupling is expected from the DFT calculation. Furthermore, the intramolecular interaction ($J_{\text{intra}}/k_{\text{B}} = 12$–$13$ K) was calculated to be much smaller than the intermolecular antiferromagnetic interaction ($|J_{\text{inter}}/k_{\text{B}}| = 70$ K), and the experimental results on the **SBDO** solid can reasonably be interpreted by the fact that the former is buried by the latter.

It should be noted that **SBDO** has a significant π-spin polarization whilst the dinuclear nickel(II) complex [{Ni(hfac)$_2$}$_2$(py$_4$C)] (**4** in Scheme 1) has a σ-spin superexchange mechanism [12], where Hhfac stands for 1,1,1,5,5,5-hexafluoropentane-2,4-dione. In the case of σ-spin systems, the magnitude of the exchange coupling decays with an increase of the distance between two spins. Actually, the $J_{\text{Ni–Ni}}$ of [{Ni(hfac)$_2$}$_2$(py$_4$C)] was very small (+0.57 K), being consistent with the long distance through the Ni–N–C–C–C–N–Ni skeleton [12]. The calculation on **SBDO** indicates that J_{intra} (12–13 K) is much larger than that of [{Ni(hfac)$_2$}$_2$(py$_4$C)], because the π-spin is ready to be delocalized onto the aromatic rings especially to the *o*- and *p*-positions, and the four carbon atoms surrounding the spiro center possess considerable coefficients of SOMOs. Therefore, the organic free radical systems may have the advantage for development of ground high-spin molecules.

4. Summary

We successfully synthesized and characterized 9,9′(10*H*,10′*H*)-spirobiacridine-10,10′-dioxyl (**SBDO**) as a quite unique molecule symbolized by a point group D_{2d}. Magnetic measurements on the polycrystalline sample of **SBDO** revealed the presence of antiferromagnetic interaction, which can be ascribed mainly to intermolecular interaction due to close contacts between two nitroxide groups. The ESR experiments and DFT calculation indicated the

ground triplet state of **SBDO**. There have been numerous reports on the magnetic properties tunable by mans of supramolecular techniques [25–30]. Possible host-guest molecular complexes from **SBDO** may clarify the intrinsic ground state of **SBDO**, owing to the separation of the radical center and accordingly the absence of intermolecular interactions. To stabilize the nitroxide groups under ambient conditions, introduction of alkoxyl groups to the acridine phenyl rings is now underway.

5. Supporting materials

CCDC 617554, 617555, and 617556 contain the supplementary crystallographic data for the compounds **SBO** · $(CH_2Cl_2)_2$, **SBO** · CH_3CN, and **SBDO**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

with the zero-dimensional $FeCl_4^-$ anion a field-induced-superconductivity with π–d interaction was evidenced which is believed to mediate through S···Cl between donor and anion [4,5]. We have been interested in exploring the intermediate dimensionality (1D) by developing methods of obtaining uniform one-dimensional anion with $(C_2O_4)^{2-}$ and Cl^- as charge balancing units with TTF, BEDT-TTF and BEDT-TSF donors, because it is possible to introduce the magnetic interaction by the oxalate bridges between moment-carriers as well as π–d interaction through S···Cl contacts [4] and thus, to produce dual-function molecular materials. This effort resulted in the isolation of charge-transfer salts containing the one-dimensional $[Fe^{III}(C_2O_4)Cl_2^-]_n$ and long range antiferromagnetic ordering at 20 K was observed for the charge-transfer wide-gap semiconductor $TTF[Fe^{III}(C_2O_4)Cl_2]$ and displaying weak-ferromagnetism [6]. In addition, the first weak-ferromagnetic organic conductor κ-$BETS_2[Fe^{III}$-$(C_2O_4)Cl_2]$ was obtained and it has a weakly temperature-dependent metallic conductivity to 4.2 K, [7] and magnetic ordering at 4.5 K. Here, we present a summary of the structural, optical, electrical and magnetic properties of the two above-mentioned charge-transfer salts.

2. Experimental

Charge-transfer complexes of TTF and BETS with the one-dimensional polymeric $[Fe(C_2O_4)Cl_2^-]_n$ anions were obtained by diffusion and electrocrystallization method, respectively. Black small shiny crystals of $TTF[Fe(C_2O_4)Cl_2]$ were obtained by diffusing an acetone solution of $TTF_3[BF_4]_2$ into one of $Me_4NFe(C_2O_4)Cl_2$. Black plate crystals of κ-$BETS_2[Fe(C_2O_4)Cl_2]$ were obtained by electrocrystallization of BETS in the presence of either Me_4N-$Fe(C_2O_4)Cl_2$ or $[Me_4N]_3Fe(C_2O_4)_3$ from C_6H_5Cl and C_2H_5OH. The composition of the crystal was determined on Electron Probe Microanalyzer. Polarized IR reflective spectra, using a Bio-rad FTS6000/UMA500 spectrometer and a gold mirror as reference, were used to identify the different phases.

Single crystal X-ray diffraction data for $TTF[Fe(C_2O_4)Cl_2]$ and κ-$BETS_2[Fe(C_2O_4)Cl_2]$ were collected on a Rigaku AFC7R fine-focus system at room-temperature. The overlap-integrals obtained by extended-Hückel were used to calculate the electronic band-structure by tight-binding method. The conductivity was measured by two-probe or four-probe methods using 20 μm gold wire electrodes attached to the single crystals with gold paste. The magnetic properties were measured by use of a Quantum Design MPMS 7XL system. The magneto-resistance measurements were performed on a PPMS-9 system.

3. Results and discussion

The crystallographic data of the two compounds are listed in Table 1.

Goodness-of-fit (GOF)	1.132	0.984

For $TTF[Fe(C_2O_4)Cl_2]$, the asymmetric unit contains one TTF and one $[Fe^{III}(C_2O_4)Cl_2^-]$. All the atoms of the TTF cation were found to be coplanar and bond-valence correlation gives it a formal charge of +1. Therefore, it is a half filled system with a spin (1/2) per unit. The structure consists of parallel stacks of donor cations, TTF and $[Fe(C_2O_4)Cl_2^-]_n$ anionic chains along the a-axis (Fig. 1). TTF-pair was formed within the donor stack with short S···S contacts. There are several short contacts between donor and anions as S···Cl, which may be responsible for the π–d interactions in the crystal.

In κ-$BETS_2[Fe(C_2O_4)Cl_2]$ (Fig. 2), the donor molecules stack in two-dimensional κ-phase (Fig. 3) which is slightly different to that of the reported κ-$BETS_2FeCl_4$ and κ-$(BEDT\text{-}TTF)_2Cu[N(CN)_2]_2$. There are Se···Se contacts within the dimers and Se···S, S···S between dimers in one layer where the chain anion fits in the channel between the two donor layers. The formal charge of the donor is assigned by bond-valence correlation to $BETS^{+0.5}$ in κ-$BETS_2$-$[Fe(C_2O_4)Cl_2]$.

The counter-anion of complexes in the one-dimensional chain anion $[Fe(C_2O_4)Cl_2^-]_n$ where the valence of the iron is assigned to Fe^{3+}. Fe(III) is coordinated by oxalate anion in *cis*-position and two terminal chlorine atoms to complete the octahedra. The Fe–O and Fe–Cl bonds lengths in these crystals are listed in Table 2, and lie in the range of those

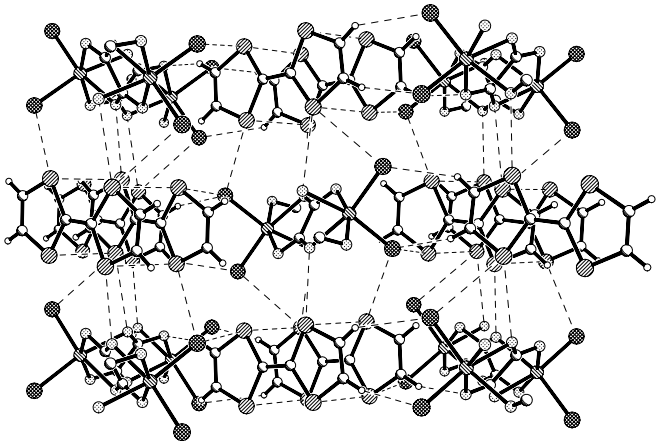

Fig. 1. View of the packing of $TTF[Fe(C_2O_4)Cl_2]$ along a-axis.

reported for Fe–O(oxalate), Fe–Cl bond lengths in charge-transfer complexes and show it can be fit to the different donor arrangements from a one-dimensional column to two-dimensional layer due to its flexibility.

Depending on the formal charge and arrangement of the donor, band structure calculations predict that $TTF[Fe(C_2O_4)Cl_2]$ should be a poor conductor while κ-$BETS_2[Fe(C_2O_4)Cl_2]$ a good conductor.

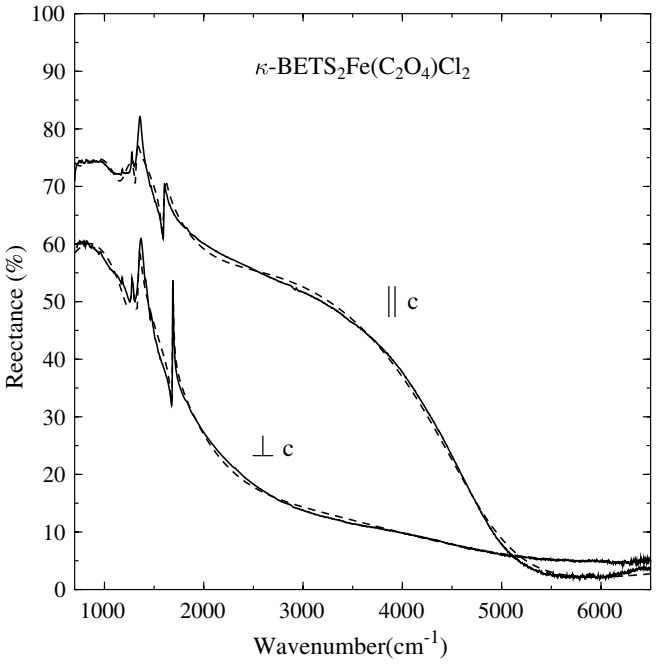

Fig. 4. Polarized IR reflectivity measured at room temperature for κ-$BETS_2[Fe(C_2O_4)Cl_2]$. The dashed lines show the Drude–Lorentz fits.

The IR reflectivity of κ-$BETS_2[Fe(C_2O_4)Cl_2]$ is consistent with those of a conductor (Fig. 4), its band structure and Fermi surface (Fig. 5) [8]. The conductivity was measured on single crystals using 20 μm gold wires attached by gold paste. $TTF[Fe(C_2O_4)Cl_2]$ is a wide-band gap semiconductor with $\sigma_{300\,K} = 10^{-7}$ S cm^{-1} by two-probe methods. κ-$BETS_2[Fe(C_2O_4)Cl_2]$ is a conductor with $\sigma_{300\,K} = 10^2$ S cm^{-1} and retains this state of metallicity down to 2 K. These are in good agreement with the calculated band structures [6,7].

The magnetic properties of the charge-transfer complexes were measured using a Quantum Design MPMS 7XL SQUID. The feature of the temperature dependence of the susceptibility is a broad hump around 50 K that is due to the existence of the one-dimensional antiferromagnetism of the $[Fe(C_2O_4)Cl_2^-]_n$ chain while the most prominent feature is the irreversible ZFC/FC susceptibility below 20 K for $TTF[Fe(C_2O_4)Cl_2]$ (Fig. 6) and 4.5 K for κ-$BETS_2[Fe(C_2O_4)Cl_2]$. The high temperature data above 25 K were fitted to the model of a one-dimensional antiferromagnetic $S = 5/2$ chain and a contribution from Curie impurity as well as a dimer $S = 1/2$ for $TTF[Fe(C_2O_4)Cl_2]$ or a temperature independent term for κ-$BETS_2[Fe(C_2O_4)Cl_2]$. The long-range magnetic ordering can only be ascribed to the presence of π–d interaction between donors and anions because theoretically no long-range ordering is possible at such a high temperature for a 1D-magnetic system. The isothermal magnetization measurement shows a linear dependence above 10 K, a 150 Oe coercive field was observed at 2 K. The magnetization at 70 kOe is lower than that expected if all the moments were aligned parallel. κ-$BETS_2[Fe(C_2O_4)Cl_2]$ is the first organic conductor displaying weak-ferromagnetism deriving from the two-sublattices while κ-$BEDT_2$-

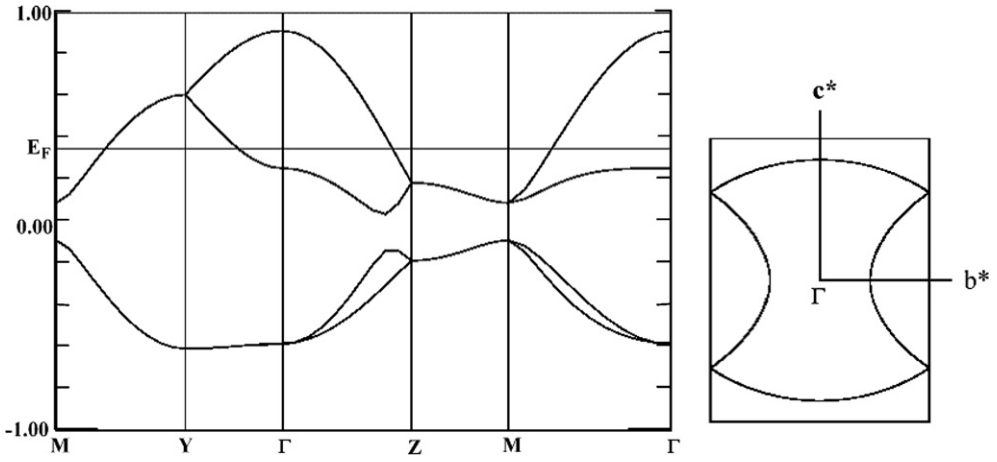

Fig. 5. Band structure and Fermi surface of κ-$BETS_2[Fe(C_2O_4)Cl_2]$.

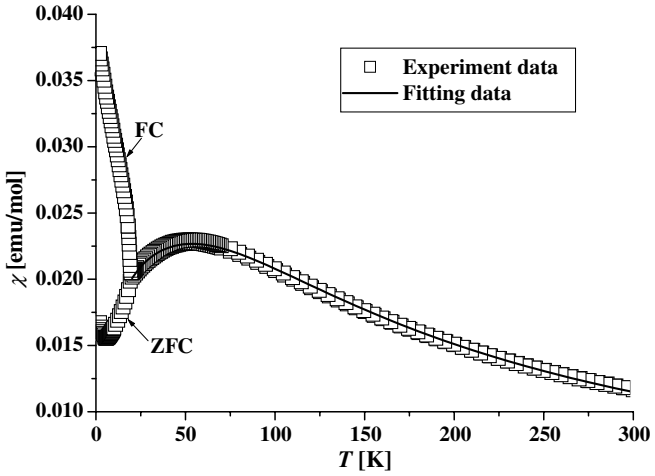

Fig. 6. ZFC and FC-M/H curves in 100 Oe for $TTF[Fe(C_2O_4)Cl_2]$. The black squares are experimental data and the solid line is the calculated susceptibility.

$[Cu\text{-}(N(CN)_2)Cl]$ also exhibits weak-ferromagnetism that, in contrast, is derived from only the π-electrons.

The magneto-resistance measurement of the weak-ferromagnetic organic conductor κ-$BETS_2[Fe(C_2O_4)Cl_2]$ was performed with current flow along the *c*-axis in field of 90 kOe at 2 K. The anisotropic magneto-resistance was observed by rotating the crystal around the *b*-axis. A minimum is observed when the magnetic field is perpendicular to the conduction plane while a maximum value for field parallel to conduction plane. It is different to those of κ-$BETS_2FeBr_4$ and λ-$BETS_2Fe_xGa_{1-x}Cl_4$ where minima were observed when the magnetic fields were parallel to the conduction plane and also where field-induced superconductivity was first observed [9].

4. Conclusion

We have succeeded in preparing the charge-transfer complex containing the magnetic chain anion $[Fe(C_2O_4)Cl_2^-]_n$ [6,7] and have characterized some complexes by single-crystal x-ray, SQUID magnetometry, optical reflectivity and transport measurements as well as calculating their band-structures. The magnetic properties range from paramagnetic, antiferromagnetic to weak-ferromagnetic and conductivity from insulator-like 10^{-7} to 10^2 S/cm. The observation of weak-ferromagnetism suggests the presence of π–d interaction, and proves $[Fe(C_2O_4)Cl_2^-]_n$ is a good anion for dual-function molecular crystals. The search and characterization on new charge-transfer complexes containing the magnetic chain $[Fe(C_2O_4)Cl_2^-]_n$ are in progress.

5. Supplementary material

CCDC 265713 and 280931 contain the supplementary crystallographic data for $TTF[Fe(C_2O_4)Cl_2]$ and κ-$BETS_2[Fe(C_2O_4)Cl_2]$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

applications. This ligand has been known in organic chemistry for a long time [17], but its uses to date in coordination chemistry have been limited [18]. We used this ligand in the preparation of a new compound: $[Mn_6O_2(O_2CPh)_8L_3]$ (**1**), with an unprecedented hexanuclear Mn_6 topology and structure. The synthesis, structure, and magnetic properties of complex **1** are as follows.

2. Experimental

2.1. Synthesis

All solvents and reagents where used as received, no purification was necessary. All reactions were performed under aerobic conditions. $[Mn_3O(O_2CPh)(py)_2(H_2O)]$ [19] was prepared as described in the literature. The ligand of HL was prepared via a Claisen condensation reaction similar to that previously reported for a similar ligand [17].

2.1.1. $[Mn_6O_2(O_2CPh)_8L_3]$ (**1**)

$[Mn_3O(O_2CPh)_6(py)_2(H_2O)]$ (0.498 g 0.460 mmol) was dissolved in 30.0 ml CH_2Cl_2 and the solid HL (0.169 g, 0.751 mmol) was added. A yellow-brown solution was obtained after stirring for 10 min. The solution was filtered to eliminate any remaining solid and the filtrate was layered with two volumes of a 1:1 hexane/Et_2O solvent to slowly give well-formed brown crystals. The sample for crystallography was maintained in contact with mother liquor to avoid solvent loss and it was identified as $\mathbf{1}\cdot 2CH_2Cl_2$. Yield 40% (based on Mn). *Anal.* Calc. For $[Mn_6O_2(O_2CPh)_8L_3]$ (**1**): C, 59.31; H, 3.75; N, 2.05. Found: C, 59.24; H, 3.99; N, 2.05%. IR data (KBr disk, cm^{-1}): 3062 (w), 2922 (w), 1604 (s), 1561 (s),1499 (s), 1445 (s), 1398 (vs), 1291 (m), 1174 (w), 1068 (w), 1044 (w), 1025 (w), 942 (w), 839 (w), 770 (w), 716 (s), 676 (m), 632 (m), 589 (w), 513 (w).

2.2. X-ray crystallography

Data collation parameters are listed in Table 1. Diffraction measurement for $\mathbf{1}\cdot 2CH_2Cl_2$ was carried out using a Bruker–Nonius Kappa CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.7107$ Å). Cell parameters were retrieved and refined using DENZO-SMN [20] software on all reflections. Data reduction was performed with the DENZO-SMN software. Structure analysis was made by using SHELXTL program on a personal computer. The structure of $\mathbf{1}\cdot 2CH_2Cl_2$ was solved using the SHELXS-86 [21] program and refined using SHELXL-97 [22] program by full-matrix least-squares on F^2 values. All non-hydrogen atoms were refined anisotropically, whereas the hydrogen atoms were placed in ideal, calculated positions, with isotropic thermal parameters riding on their respective carbon atoms. The asymmetric unit of complex $\mathbf{1}\cdot 2CH_2Cl_2$ consists of a Mn_6 molecule and two CH_2Cl_2 molecules. The phenyl rings of one diketonate and one benzoate are disorder as is one pyridine ring of diketonate.

[b] $wR = [\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]]^{1/2}$.

2.3. Physical measurements

Infrared spectra were recorded in the solid state (KBr pellets) on a Nicolet Magna 550 FTIR spectrometer in the 400–4000 cm^{-1} range. ^1H NMR and ^{13}C NMR spectra were measured in d_6-acetone solution on a Bruker AMX-400 (400 MHz) spectrometer with tetramethylsilane (TMS) as the internal standard. The EI-Mass spectrum was recorded on a Bruker APEX II. The melting point was measured using a capillary melting point apparatus. Elemental analyses have been carried out by using an Elementar vario EL III analyzer. Variable temperature dc and ac magnetic susceptibility measurements were collected on a microcrystalline sample, restrained in eicosane to prevent torquing, on a Quantum Design MPMS-XL SQUID magnetometer equipped with a 7.0 T magnet and operating in the range of 1.8–300.0 K. Diamagnetic corrections were estimated from Pascal's constants [23] and subtracted from the experimental susceptibility data to obtain the molar paramagnetic susceptibility of the compound.

3. Results and discussion

3.1. Synthesis

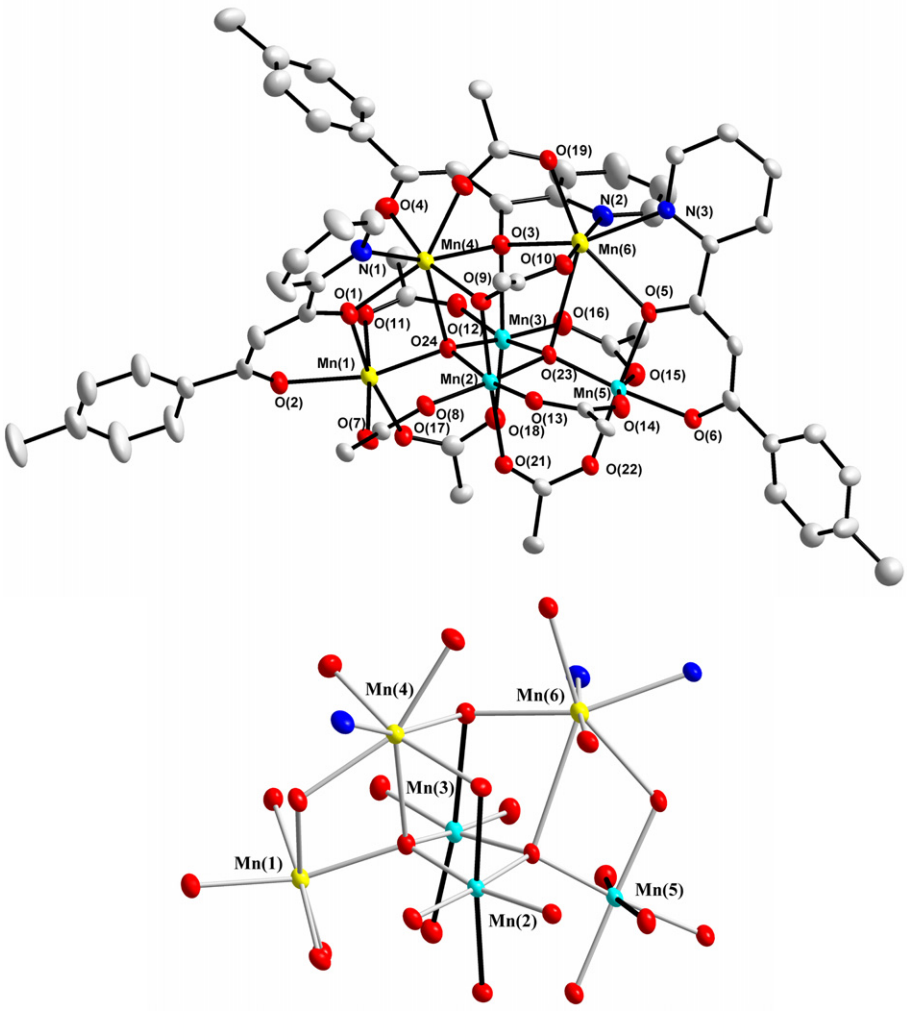
Complex **1** is prepared from a reaction employing the benzoate $Mn^{II}Mn_2^{III}$ complex of $[Mn_3O(O_2CPh)(py)_2(H_2O)]$. Reaction of this complex with ~1.5 equiv. of HL in CH_2Cl_2 followed by filtration and layering the resulting solution with hexane/ether, affords crystalline $[Mn_6O_2(O_2CPh)_8L_3]$ in 40% yield, after one week. The use of more than 2 or less than 1.5 equiv. of HL reduced the yield of the final product. Charge considerations and the inspection of metric parameters indicate that complex **1** is a mixed-valence $Mn_3^{II}Mn_3^{III}$ with a trapped-valence situation (vide infra). The reaction involves reduction state of Mn center

from an average oxidation state of +2.67 in the $Mn^{II}Mn_2^{III}$ starting complex to +2.5 in the $Mn_3^{II}Mn_3^{III}$ product. For **1**, clearly, the overall conversion of $[Mn_3O(O_2CPh)_6(py)_2(H_2O)]$ into the product must involve a complicated mechanism involving the reduction of Mn_3O, fragmentation, and recombination steps.

3.2. Description of structure

Complex $\mathbf{1}\cdot 2CH_2Cl_2$ crystallizes in the monoclinic space group $P2_1/n$. The ORTEP representation of **1** is shown in Fig. 1 and selected interatomic distances and angles are listed in Table 2. The structure of **1** reveals a $[Mn_3^{II}Mn_3^{III}(\mu_4\text{-}O)_2]^{11+}$ core which comprises a central, distorted cubane-like $[Mn_2^{II}Mn_2^{III}O_2(OR)(O_2CR)]$, and either side of which is attached one Mn^{III} [Mn(5)] and one Mn^{II} [Mn(1)] ions by two $\mu_4\text{-}O^{2-}$ ions. The peripheral ligations are provided by eight $PhCO_2^-$ groups and three diketonate ligands. Seven of the eight $PhCO_2^-$ groups are bridging two Mn ions and are in their familiar *syn,syn*-$\eta^1{:}\eta^1{:}\mu_2$ binding mode. The final $PhCO_2^-$ group is in the fairly rare $\eta^1{:}\eta^2{:}\mu_3$ mode, O(10) terminal to Mn(6) and O(9) bridging Mn(4) and Mn(2). The three diketonate groups are categorized into two groups: (i) two diketonate groups behave as $\eta^1{:}\eta^2{:}\eta^1{:}\mu_2$ ligands, where each ligand chelates one metal ion through its nitrogen atom [N(1) and N(3)] and connects this metal ion with a second one through a bridging O atom [O(1) and O(5)] and a terminal O atom [O(2) and O(6)]; and (ii) one diketonate group chelates as a $\eta^1{:}\eta^3{:}\eta^1{:}\mu_3$ bridging type; the coordination of this ligand is similar to (i) by connecting to the metal ion terminally though the N(2) and O(4) atoms, but bridging three Mn ions by O(3) (Scheme 1).

For complex **1**, Mn(1), Mn(2), Mn(3) and Mn(5) are six-coordinate with slightly distorted octahedral geometry, while Mn(4) and Mn(6) are seven-coordinate with distorted pentagonal bipyramidal geometry. In addition, although there is a weak interaction in Mn(6)–O(23) at a distance of 2.870(5), it was considered as the seventh coordination position around Mn(6). Charge considerations require a $3Mn^{II}$, $3Mn^{III}$ oxidation state description, and Mn(1), Mn(4) and Mn(6) are assigned as the Mn^{II} ions on the basis



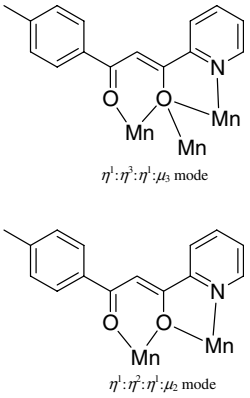


Fig. 1. Crystallographic structure (top) and JT axes orientation (highlight bond) in core structure (bottom) of $[Mn_6O_2(O_2CPh)_8L_3]\cdot 2CH_2Cl_2$ (**1**). Thermal ellipsoids at the 30% probability level. The H atoms and solvated molecules have been omitted for clarity.

Table 3
Bond valence sums of Mn atoms in complex **1**

	Complex **1**					
	Mn(1)	Mn(2)	Mn(3)	Mn(4)	Mn(5)	Mn(6)
Mn(II)	2.174	3.403	3.449	2.039	3.450	1.828
Mn(III)	2.005	3.138	3.180	1.880	3.181	1.686
Mn(IV)	1.967	3.079	3.121	1.845	3.121	1.654

of: (i) the longer average bond lengths compared with those of the other Mn ions. (ii) the clear presence of the Jahn–Teller (JT) axial elongation at Mn(2), Mn(3) and Mn(5), as expected for a high-spin d^4 ion in a near-octahedral geometry; and (iii) bond valence sum calculation (BVS) calculations [24], which give values (Table 3) in good agreement with the above assignments.

3.3. Direct current magnetic susceptibilities and magnetization

Solid-state, variable-temperature magnetic susceptibility measurements were performed on microcrystalline sample of complex **1**, all suspended in eicosane to prevent torquing. The dc magnetic susceptibility data were collected in the 2.0–300 K range in a 1.0 kG magnetic field. In Fig. 2, for complex **1**, the value of $\chi_M T$ gradually decreases from 16.93 emu mol^{-1} K at 300 K to 12.59 emu mol^{-1} K at 30 K. Below this temperature, $\chi_M T$ decreases more rapidly to 5.96 emu mol^{-1} K at 2.0 K. The value of $\chi_M T$ at 300 K is lower than that expected for a cluster of 3 Mn^{II} and 3 Mn^{III} noninteracting ions (22.12 emu mol^{-1} K for $g = 2$), suggesting that antiferromagnetic couplings dominate the overall intramolecular exchange interactions within the complex. The rapid decrease observed for the $\chi_M T$ value for temperatures below 30 K are most likely because of ZFS effects and perhaps weak intermolecular interactions. Because of the topological complexity of the molecule, it is not possible to determine the individual pairwise Mn exchange interactions using the Kambe method [25].

To determine the spin of the ground state, magnetization (M) measurements were performed in the 2.0–4.0 K

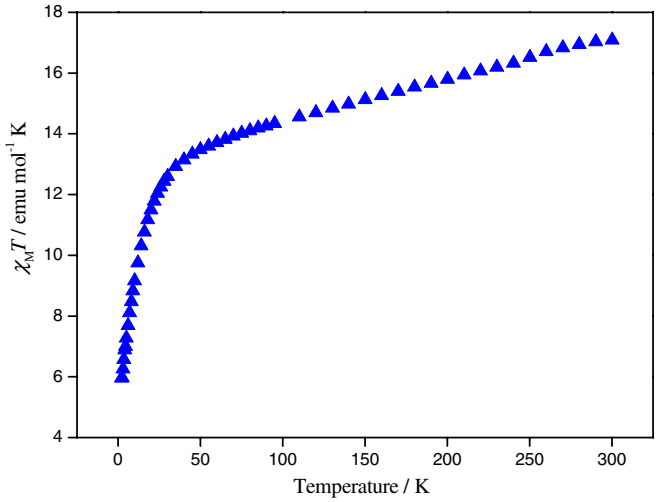

Fig. 2. Plot of $\chi_M T$ vs. temperature for a microcrystalline sample of complex **1**.

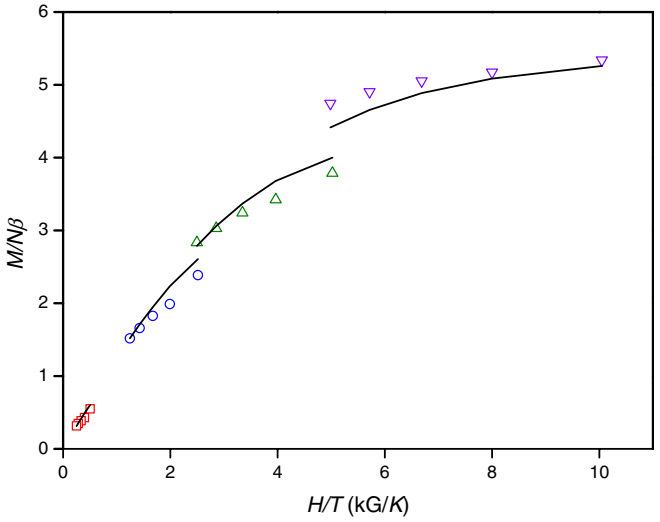

Fig. 3. The reduced magnetization of **1** plotted as $M/N\beta$ vs. H/T at 1 (□), 5 (○), 10 (△), and 20 (▽) kG in eicosane.

temperature range and the 1.0–20 kG dc magnetic field range. The data of complex **1** is plotted as the reduced magnetization ($M/N\beta$) versus H/T in Fig. 3, where N is Avogadro's number, β is Bohr magneton, and H is the applied magnetic field. For a system occupying only the ground state and experiencing no ZFS, the various isofield lines would be superimposed and $M/(N\beta)$ would saturate at a value of gS. The nonsuperposition of the isofield lines in Fig. 3 is indicative of the presence of a significant ZFS. The data were fit using the ANISOFIT [26], which assumes only the spin ground state of the molecule is significantly populated. The best fit for complex **1** was $S = 7/2$, $g = 1.90$, $D = -0.46\ \text{cm}^{-1}$ and $E = -0.003\ \text{cm}^{-1}$ (where D is the axial ZFS parameter and E is the rhombic ZFS parameter).

3.4. Alternating current magnetic susceptibilities

The measurements of the ac magnetic susceptibility were performed on vacuum-dried, microcrystalline sample of complex **1** in the temperature range 1.8–10 K in a zero dc field and a 3.5 G ac field oscillating at frequencies in the 250–1500 Hz range. The results representative of complex **1** are shown in Fig. 4. If the magnetization vector can relax fast enough to keep up with the oscillating field, then there is no imaginary (out-of-phase) susceptibility signal (χ''_M), and the real (in-phase) susceptibility (χ'_M) is equal to the dc susceptibility. However, if the barrier of magnetization relaxation is significant compared to thermal energy (kT), then there is a nonzero χ''_M signal and the in-phase signal decreases. In addition, the χ''_M signal will be frequency-dependent. Such frequency-dependent χ''_M signals are a characteristic signature of the superparamagnetic-like properties of a SMM (but by themselves do not prove the presence of a SMM). The sloping $\chi'_M T$ versus T plot is strongly indicative of a population of low-lying excited states as occupation of only the ground state would give an essentially temperature-independent value. Extrapolation of the plot of $\chi'_M T$ vs. T to 0 K gives a value of ca. 5.2 emu K mol^{-1}, indicative of an $S = 7/2$ ground state and these results are consistent with the fitting of magnetization data. At lower temperatures, the in-phase signal decreases and a frequency-dependent χ''_M signal appears,

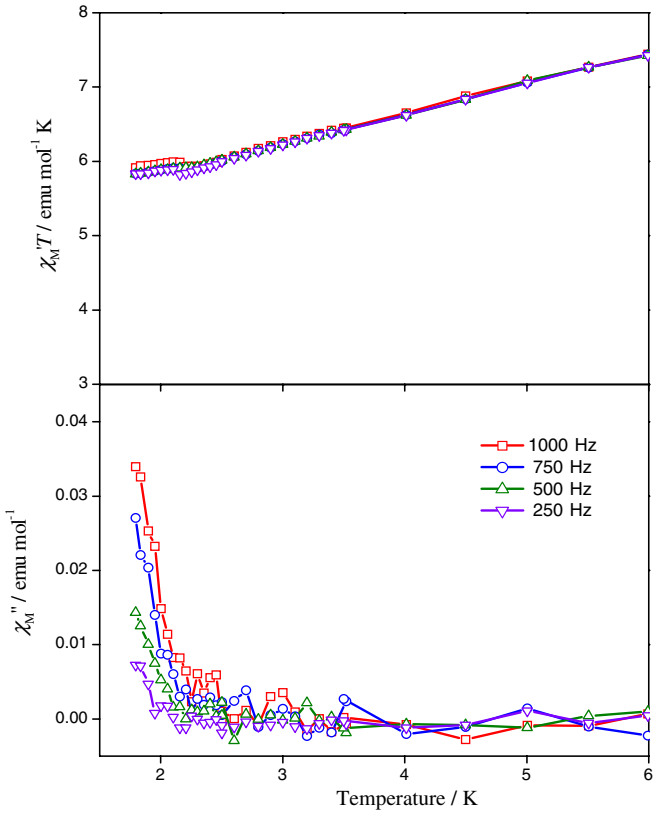

Fig. 4. Plot of $\chi'_M T$ (top) and χ''_M (bottom) vs. temperature for a powder sample of complex **1** in a 3.5 G ac field.

suggestive of the slow relaxation of a single-molecule magnet. However, the peak maxima clearly lie at temperatures below 1.8 K, the operating limit of our instrument. The data thus suggest that complex **1** may exhibit the slow magnetization relaxation of SMMs.

4. Conclusion

The pyridine containing β-diketone of 1-(2-pyridly)-3-(p-tolyl)propane-1,3-dione (HL) has proven to be a bridging ligand and allowed the synthesis a new manganese complex. The reaction of HL with $[Mn_3O(O_2CPh)_6(H_2O)(py)_2]$ yield a hexanuclear of $[Mn_6O_2(O_2CPh)_{10}L_3]$, complex **1**, which represents a new structural topology of $[Mn^{II}_3Mn^{II}_3(\mu_4\text{-}O)_2]^{11+}$ in Mn chemistry. Complex **1** has a ground state spin value of $S = 7/2$, together with a significant magnetoanisotropy as gauged by the D value of $-0.46\ cm^{-1}$, and it shows superparamagnetic behavior in ac susceptibility measurement at low temperature.

Acknowledgements

The magnetic measurements were obtained from SQUID (MPMS XL-7) in NSYSU and we thank the National Science Council of Taiwan (NSC-94-2113-M-006-011) for financial support.

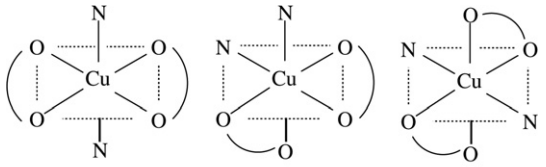

Chart 1. Coordination geometry of a six-coordinated copper ion in polynuclear complexes.

1–**7**, respectively. These polymeric complexes are characterized to be one-dimensional polynuclear compounds and their magnetic properties are investigated on a SQUID magnetometer.

2. Results and discussion

2.1. Preparation and characterization

The products of reaction of [Cu(hfac)$_2$] with diazaaromatic rings are listed in Table 1. All of the products were characterized by means of spectroscopic methods, and the elemental analysis satisfied the 1/1 molar ratio of the Cu/L contents. Molecular structures with the atomic numbering and polymeric molecular arrangement in the crystals of (a) **1**, (b) **2**, (c) **3**, (d) **4**, (e) **5**, (f) **6**, and (g) **7** are shown in Figs. 1 and 2. Selected crystallographic data of the complexes are listed in Table 1 and the Cu–X (X = O, N) bond lengths in Table 2.

2.2. Crystal structures of ax-N_2 Oh type

Complexes **1**, **2**, **4**, **5**, and **6** are polynuclear and the geometry about the copper ion is approximately an Oh structure. The axial positions of the copper ion are occupied by nitrogen atoms of two diazaaromatic rings, and the four equatorial positions are occupied by oxygen atoms from the bidentate hfac ligands (Fig. 1). The coordination geometry of the copper ion belongs to the ax-N_2 Oh type.

Complex **1**. The Cu(1)–N(1) bond (2.543(3) Å) is longer than that of [{Cu(hfac)$_2$(μ-pyz)}$_n$] (2.529(9) Å) [1]. Furthermore, the Cu(1)–N(1)–C(2) bond angle (130.7(2)) is larger than that of Cu(1)–N(1)–C(1) (111.9(2)). Similar bond angles are observed in [{Cu(hfac)$_2$}$_3$(μ-2,3,5-pyz)$_2$] (2,3,5-pyz = 2,3,5-trimethylpyrazine) [2b]. Thus, the neighboring methyl group of the nitrogen atom hinders the approach of the copper ion to the nitrogen atom.

Complex **2**. The Cu(1)–N(1) bond (2.606(2) Å) is longer than the Cu(1)–N(2′) bond (2.408(2) Å). The longer Cu–N bond arises from the steric hindrance of neighboring methyl groups of the 1-nitrogen atom. On the other hand, the 2,6-pyz molecules in **2** are arranged in a head-to-tail fashion. This fashion may result from a mutual repulsion between the hfac ligands coordinated to Cu(1) and the neighboring methyl groups of the 1-nitrogen atom.

Although 2,3,5- and 2,6-pyz molecules have a sterically crowded 2,6-dimethylpyridine-type nitrogen atom [10], the former gave trinuclear complex [{Cu(hfac)$_2$}$_3$(μ-2,3,5-pyz)$_2$] [2b], but the latter gave polynuclear **2**. In [{Cu(hfac)$_2$}$_3$(μ-2,3,5-pyz)$_2$], the geometry about Cu(2) is approximately a trigonal bipyramid with the nitrogen atom N(2) from 2,3,5-pyz molecule at the equatorial position. The Cu(2)–N(2) bond length is 2.030(9) Å. Generally, the coordinating ability of the ligand is affected by steric factors in addition to the electronic effect [11]. In this case, the coordinating ability of the 1-nitrogen atom in 2,6-pyz seems to be weaker than that of the 4-nitrogen atom in 2,3,5-pyz.

Complex **4**. The Cu(2)–N(2) and Cu(2)–N(3) bonds (2.615(7) and 2.657(8) Å, respectively) are somewhat longer than those of [{Cu(hfac)$_2$(μ-pyz)}$_n$] and **1** (Table 2). In addition, the bond angles Cu–N–C are not equal. For example, the Cu(1)–N(1)–C(1) and Cu(1)–N(1)–C(8) bond angles are 116.5(5) and 127.5(5)°, respectively. The *peri*-hydrogen atoms attached to the qxln ring hinder the approach of the chelated copper ion (Fig. 1(d)) [10].

Complex **5**. To our knowledge, the Cu(1)–N(1) bond (2.856(4) Å) is one of the longest Cu–N bonds of [{Cu(hfac)$_2$(μ-L)}$_n$] ever reported [1–7]. On the other hand, Cu(1)–O(1) and Cu(1)–O(2) bonds (1.915(3) and 1.923(3) Å, respectively) are notably shorter than those of [{Cu(hfac)$_2$(μ-L)}$_n$] (Table 2). The bond angles O(1)–Cu(1)–N(1) and O(2)–Cu(1)–N(1) are equal (90.0°), and Cu(1)–N(1)–C(1) and Cu(1)–N(1)–C(1′) are also equal (122.1(2)). Thus the coordination geometry of the copper ion belongs to the extremely elongated ax-N_2 Oh type. It should be noted that the Cu–N distance of 2.856(4) Å is shorter by ca. 0.1 Å than the sum of the van der Waals radii of Cu (1.40 Å) and N (1.55 Å) [12]. Although the Cu–N bond is quite long in **5**, the interaction between the Cu and N atoms seems to be attracting, from the nitrogen atoms located just above the copper center despite of the steric hindrance. The bonding character is also supported by the spectroscopic methods (see the UV–Vis study section).

The steric hindrance of the *peri*-hydrogen atoms attached to the phenazine ring is much larger than that of quinoxaline, which is unhindered on one side of the nitrogen atom described above. Similar steric hindrance of *peri*-hydrogen atoms is observed in the [Cu(acac)$_2$]–acridine complex (Hacac = pentane-2,4-dione) in the ESR measurements [10].

Complex **6**. The Cu(1)–N(2′) bond (2.628(4) Å) is considerably longer than that of **1** (2.543(3) Å), while Cu(1)–N(1) bond (2.505(3) Å) is somewhat shorter. The coordination geometry of Cu(1) belongs to the ax-N_2 Oh type owing to the steric reason. Its structure is rather different from those of [{Cu(hfac)$_2$(μ-pym)}$_n$] (pym = pyrimidine) and [{Cu(hfac)$_2$(μ-4-pym)}$_n$], which have the ax–eq-N_2 Oh structure [5,7].

2.3. Crystal structures of ax-N_2 and trans–eq-N_2 Oh type

Complex **3**. The geometry about Cu(1), Cu(2) and Cu(3) forms approximately an Oh structure. The coordination

[a] $R = \sum\|F_o| - |F_c\|/\sum|F_o|$ (unit weights).

[b] $R_w = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$.

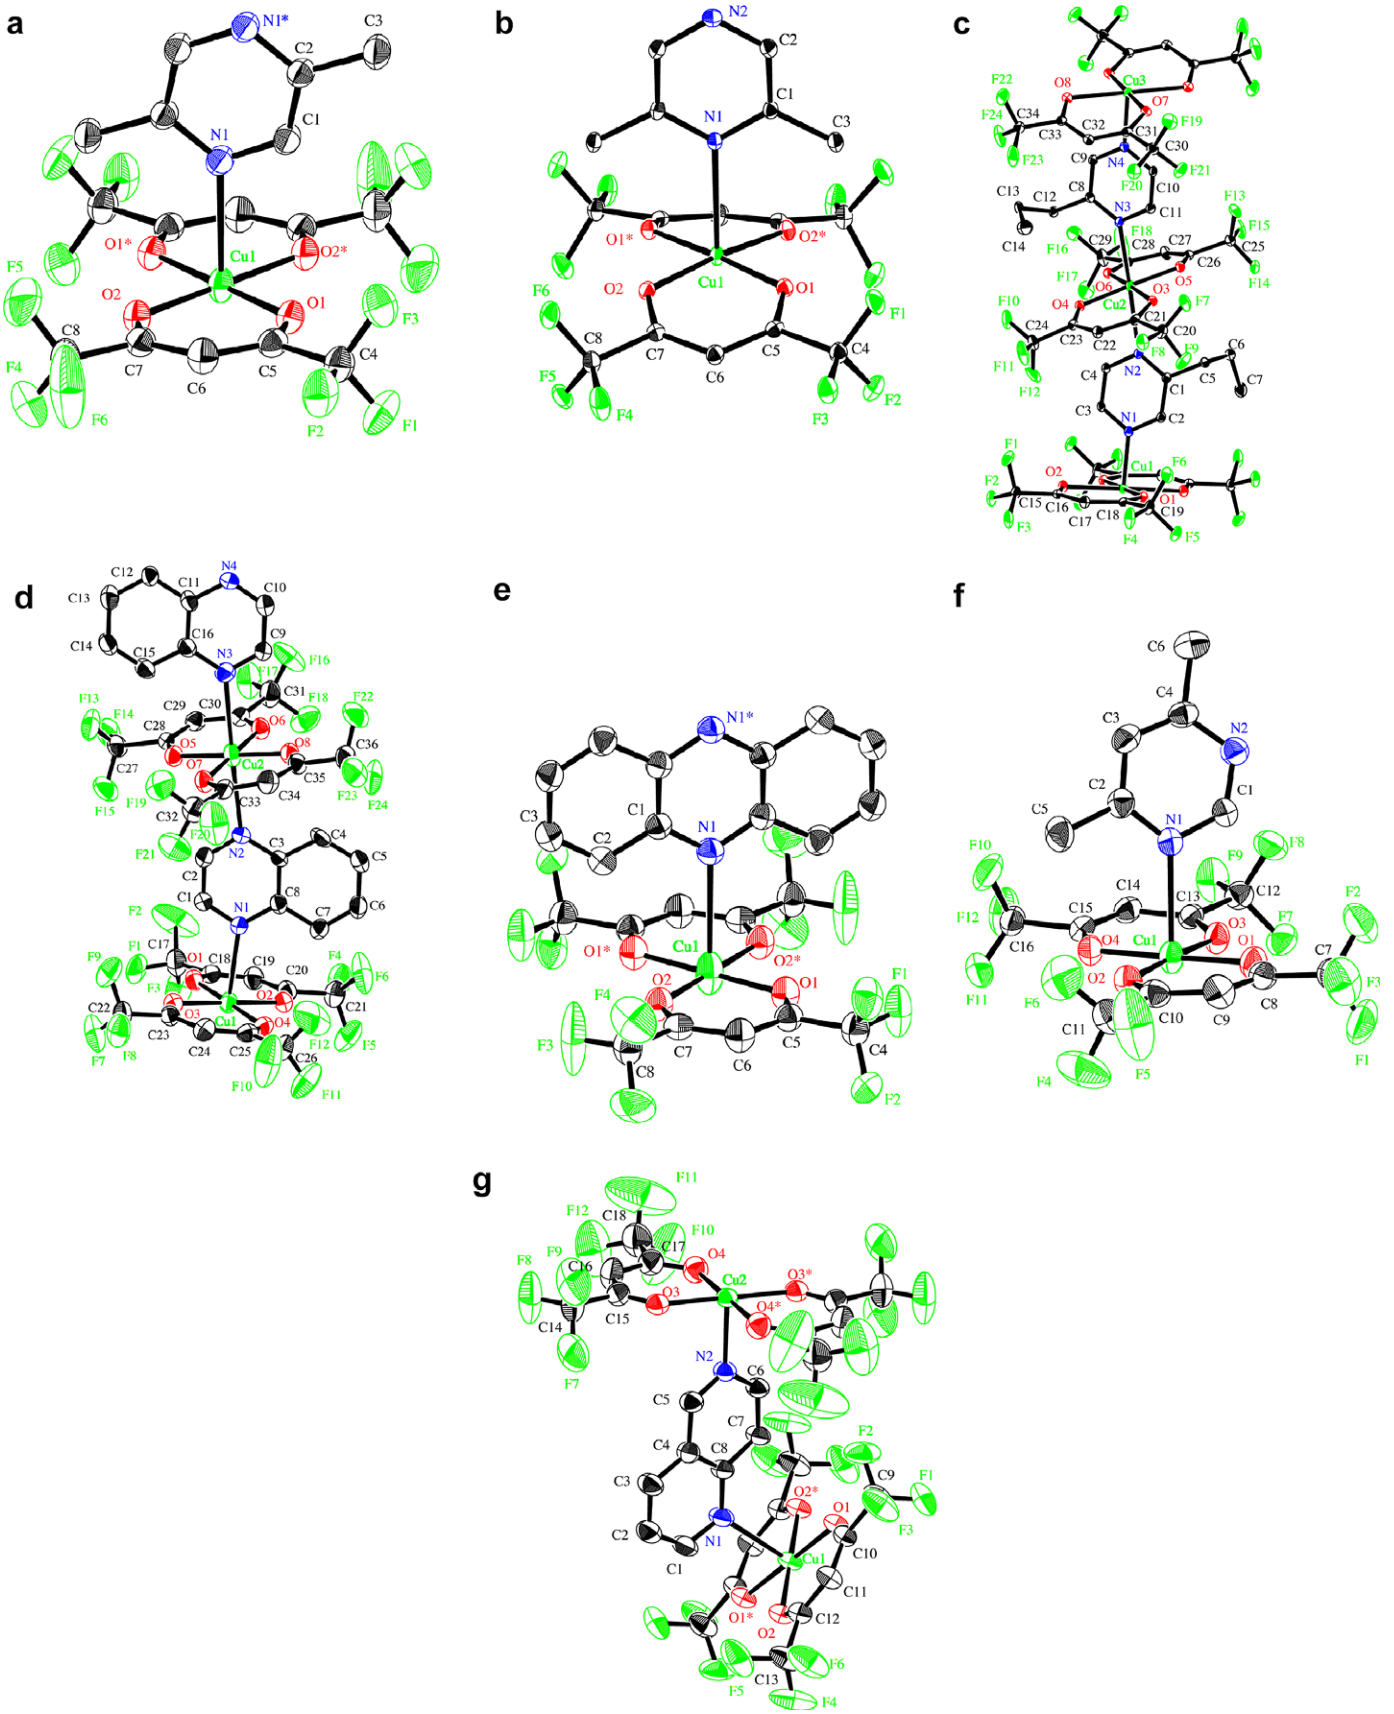

Fig. 1. ORTEP drawings of (a) **1**, (b) **2**, (c) **3**, (d) **4**, (e) **5**, (f) **6**, and (g) **7**. Thermal ellipsoids are drawn at the 30% probability level for (a) and (d)–(g) and the 50% probability level for (b) and (c). Hydrogen atoms are omitted for the sake of clarity.

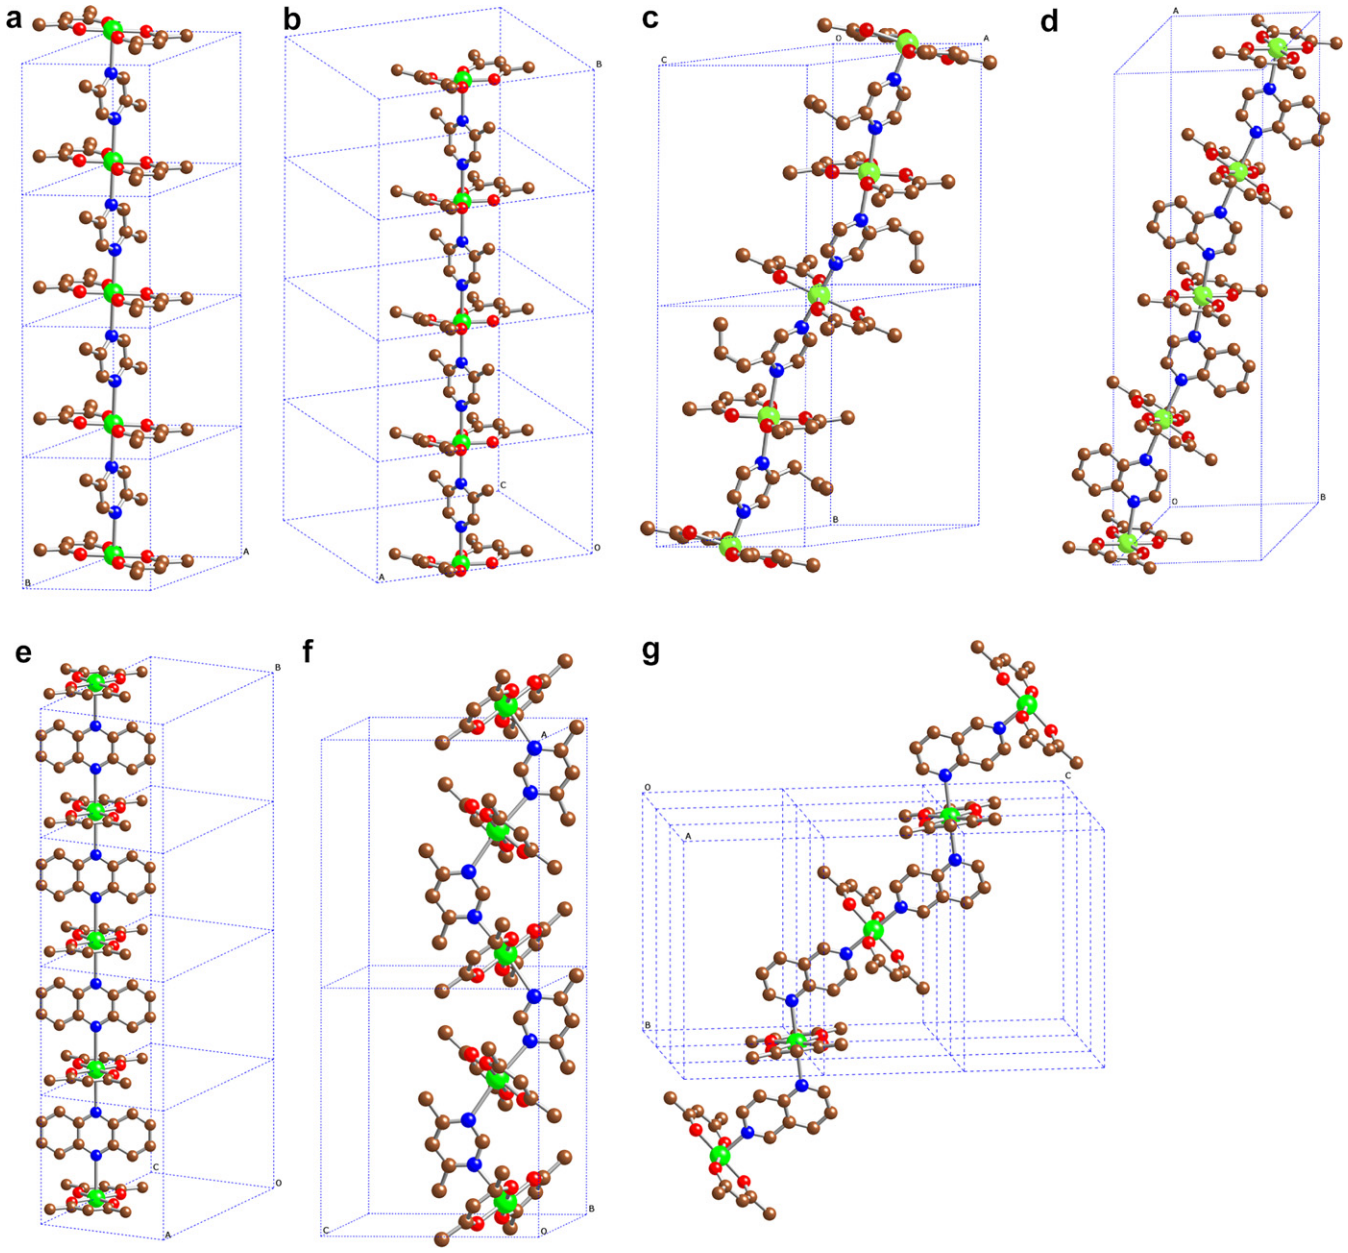

Fig. 2. Polymeric molecular arrangement in the crystals of (a) **1**, (b) **2**, (c) **3**, (d) **4**, (e) **5**, (f) **6**, and (g) **7**. Hydrogen and fluorine atoms are omitted for the sake of clarity.

geometry of Cu(1) and Cu(3) belongs to the *trans*–eq-N_2 Oh type, while that of Cu(2) to the ax-N_2 Oh type (Fig. 1(c)). The equatorial positions of Cu(1) and Cu(3) are occupied by the 4-nitrogen atoms of two prpyz molecules. On the other hand, the 1-nitrogen atoms occupy the two axial positions of Cu(2).

Complex **7**. The coordination type of Cu(1) and Cu(2) is classified into the ax-N_2 and *trans*–eq-N_2 Oh types, respectively. The equatorial positions of Cu(2) are occupied by 6-nitrogen atoms of two 1,6-nprn molecules. The Cu(1)–N(1) and Cu(2)–N(2) bonds (2.444(3) and 2.080(3) Å, respectively) are similar to, or slightly longer than, those of $[\{Cu(hfac)_2(\mu\text{-qzln})\}_n]$ (qzln = quinazoline) (2.439(3) and 2.043(3) Å, in a low-temperature phase) [7].

2.4. Structures of one-dimensional chains

As Fig. 2 shows, all of the present compounds possess the one-dimensional structures consisting of alternating $Cu(hfac)_2$ portions and diazaaromatic bridging ligands (μ-Ls). In the μ-pyrazine series, **2** and **5** show an exactly straight chain structure owing to the symmetry of μ-Ls, while **1** shows a very slight zigzag chain. Complexes **3** and **4** construct a somewhat slant chain against the crystallographic axis (Fig. 2). The linear chain structure of **5** (Fig. 2(e)) is similar to that of $[\{Cu(hfac)_2(\mu\text{-pyz})\}_n]$ [1]. Complex **2** exhibits a head-to-tail arrangements of μ-Ls. On the other hand, complex **3** is a one-dimensional zigzag chain, which has the ax-N_2 and *trans*–eq-N_2 Oh structures.

Table 2
Cu–X (X = O, N) bond lengths (Å) for complexes **1**–**7**

Complex																
1	Cu(1)–O(1)	1.954(2)	Cu(1)–O(2)	1.942(2)					Cu(1)–N(1)	2.543(3)						
2	Cu(1)–O(1)	1.9633(14)	Cu(1)–O(2)	1.9591(12)					Cu(1)–N(1)	2.606(2)	Cu(1)–N(2′)	2.408(2)				
3	Cu(1)–O(1)	1.964(2)	Cu(1)–O(2)	2.2873(18)					Cu(1)–N(1)	2.035(2)

5	Cu(1)–O(1)	1.915(3)	Cu(1)–O(2)	1.923(3)					Cu(1)–N(1)	2.856(4)						
6	Cu(1)–O(1)	1.940(3)	Cu(1)–O(2)	1.953(3)	Cu(1)–O(3)	1.950(3)	Cu(1)–O(4)	1.936(3)	Cu(1)–N(1)	2.505(3)	Cu(1)–N(2′)	2.628(3)				
7	Cu(1)–O(1)	1.972(2)	Cu(1)–O(2)	1.955(3)					Cu(1)–N(1)	2.444(3)						
					Cu(2)–O(3)	1.977(3)	Cu(2)–O(4)	2.288(5)			Cu(2)–N(2)	2.080(3)				

The prpyz molecules are arranged in a head-to-head fashion.

Complexes **6** and **7** exhibit essentially a zigzag chain structure. The one-dimensional chain of **6** (Fig. 2(f)) is rather different from those of $[\{Cu(hfac)_2(\mu\text{-}L)\}_n]$ (L = pym, 4-pym, 5-pym, and qzln) [4,7]. The structural differences among them arise from their Oh structures; **6** has the ax-N_2 Oh structure whereas the pym, 4-pym, 5-pym, and qzln derivatives have the ax–eq-N_2 Oh one, which leads to different magnetic coupling across the μ-Ls (see below). The chain structure of **7** is arranged in a head-to-head fashion (Fig. 2(g)), and is similar to that of $[\{Cu(hfac)_2(\mu\text{-qzln})\}_n]$ [3,7].

2.5. Infrared study

In infrared spectral analysis, the *ν*(C–O) band and the ring deformation band are very useful for prediction of the presence of different hfac ligands, namely different coordination geometry around the copper ion [1,2,9,13]. The spectra of complexes **1**, **2**, **4**–**6** have a single band in the region 1639–1641 cm^{-1}, which is assigned to the vibration of the hfac ligands in the basal plane around the ax-N_2 Oh structures. For complex **3** and **7**, split *ν*(C–O) bands were observed at 1653 and 1641 cm^{-1} for **3**, and 1656 and 1643 cm^{-1} for **7**, respectively (see Section 4). The higher *ν*(C–O) values are assigned to the carbonyl groups in the hfac ligands of *trans*–eq-N_2 Oh copper ion. Similarly split *ν*(C–O) bands were observed at 1654 and 1642 cm^{-1} for $[\{Cu(hfac)_2\}_3(\mu\text{-5-pym})_2]$, which are assigned to the vibration of the hfac ligands around the six-coordinated Cu(1) classified as the *trans*–eq-N_2 Oh type and around the five-coordinated Cu(2), respectively [2].

In the *trans*–eq-N_2 Oh type, the higher *ν*(C–O) band is ascribed to the longer axial Cu–O bond in chelated hfac ligands [2,9]. Actually, the Cu(1)–O(2) and Cu(3)–O(8) bonds (2.287(2) and 2.284(2) Å, respectively) for **3**, and the Cu(2)–O(4) bond (2.288(5) Å) for **7**, are considerably longer than those of the equatorial Cu–O bonds in the complexes.

In addition, the splitting of the ring deformation band of chelated hfac ligand was observed at 681 and 669 cm^{-1} for **3**. The former is assigned to the hfac ligands in the ax-N_2 Oh copper ion, and the latter to those in the *trans*–eq-N_2 Oh copper ion. Similarly the spectrum of **7** showed two ring deformation bands at 680 and 670 cm^{-1}. The lower deformation band is also ascribed to the longer axial Cu–O bond. Thus, the analysis of a pair of the *ν*(C–O) and ring deformation bands is predictable for the presence of the ax-N_2 and *trans*–eq-N_2 Oh types.

2.6. UV–Vis study

For the purpose of assignment of the structures, UV–Vis spectroscopy is very effectively utilized [9]. The diffuse reflectance spectra of the polynuclear complexes **1**, **4** and **6** resemble each other, showing broad maxima at 686,

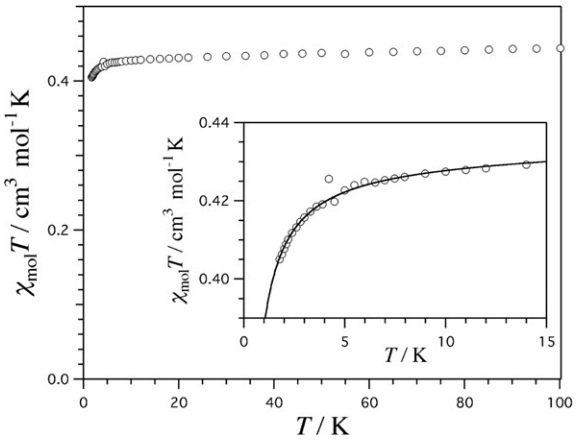

Fig. 3. Temperature dependence of the product $\chi_{mol}T$ for **3**. Inset shows a magnification of a low-temperature region. The solid line represents the theoretical fit. See the text for the equation and optimized parameters.

690 and 694 nm, respectively. On the other hand, the absorption maximum of **5** is observed at 666 nm, which is shifted to lower wavelength than those of them. This may arise from the extremely elongated ax-N_2 Oh structure. One may wonder how can we characterize chemical bonds rather than van der Waals contacts, because the Cu–N distances were sometimes very long. Definite evidence is provided from such UV–Vis absorption measurements. An apparent color of anhydrous [Cu(hfac)$_2$] having a square-planar four-coordinated structure is purple [14], whereas those of [Cu(hfac)$_2$L$_2$] having Oh structures with two N-donor ligands at the axial positions are usually green. All of the present compounds are green. Similarity of the spectra suggests that these complexes have a similar coordination geometry, which is classified as the ax-N_2 Oh structure.

2.7. Magnetic study

The present complexes possess distant axial bonds, which may bring about very weak magnetic channels between the copper(II) spins. Fig. 3 shows the $\chi_{mol}T$ versus T plot for **3**. The magnetic properties in all of the present compounds were found to be almost ideal paramagnetic, and very small antiferromagnetic coupling was observed in some case. Among the pyrazine-bridged series, **3** has the largest interaction, as indicated by the most significant decrease of $\chi_{mol}T$ value on cooling. The other complexes showed practically flat $\chi_{mol}T - T$ profiles (i.e., obeyed the Curie law) after removing the contribution of the temperature independent paramagnetism.

We determine the exchange parameters in **1**–**7** from fitting to a model, where the parameter J is defined with the Heisenberg spin Hamiltonian, $H = -2J\sum S_i \cdot S_j$. Assuming that the chain is equally spaced, we adopted the Bonner–Fisher model [15] to the antiferromagnetic infinite chain structure. Though there are two crystallographically independent Cu—Cu relations in **3** and **4**, they were actually quite similar to each other and this assumption is acceptable. The best fit parameters were: $J/k_B = -0.086(3)$ K and $g = 2.14(7)$ for **3**, and the calculated curve reproduced well the experimental data (Fig. 3, inset). Similar analysis on the plots for other complexes gave the corresponding J and g values, as listed in Table 3.

Table 3
Magnetic coupling parameters (J) and g values for complexes **1**–**7**

Complex	J/k_B	g
1	−0.034(8)	2.2(1)
2	−0.018(2)	2.34(8)
3	−0.086(3)	2.14(7)
4	−0.043(8)	2.1(1)
5	−0.031(6)	2.1(1)
6	−0.10(1)	2.3(2)
7	−0.003(5)	2.1(1)

The simplest pyrazine bridged compound [{Cu(hfac)$_2$-(μ-pyz)}$_n$] with the Cu–N(axial) bond of 2.529(9) Å [1] has been reported to show antiferromagnetic coupling with $\theta = -0.54 \pm 0.5$ K [16] or −0.06 K [5]. We can point out the relationship between the Cu–N distance and exchange coupling. The dibenzo derivative possessed somewhat longer Cu–N(axial) bonds (2.856(4) Å in **5**) due to the steric effect and exhibited smaller magnetic interaction. On the other hand, **3** involves much shorter Cu–N bonds (2.033(2) and 2.035(2) Å), and accordingly **3** showed the largest exchange interaction.

We have already reported several pyrimidine-bridged [Cu(hfac)$_2$] complexes, and many of them showed ferromagnetic couplings [3,6]. We should not overestimate spin-polarization effects [17] onto the heteroaromatic rings, because quite a few compounds containing pyrimidine-bridging ligands did not show ferromagnetic coupling [18]. 4,6-Dimethylpyrimidine in **6** is coordinated to the copper(II) ions at the axial positions on both sides (i.e., ax-N_2 Oh) and transmit no significant exchange interaction, being consistent with our formalism [6,19]. The pyrimidine bridge usually works as a ferromagnetic coupler with an ax–eq-N_2 Oh structure [6,19]. In this sense, **3** raise a question of interest. One nitrogen atom is coordinated to a copper ion at an axial position, and at the same time the other coordinated at an equatorial site, but **3** exhibited antiferromagnetic coupling. This finding may be interpreted partly in terms of spin-polarization on the diazaaromatic rings.

3. Summary

Seven polynuclear complexes of [Cu(hfac)$_2$] with diazaaromatic rings have been prepared and fully characterized. These complexes consist of a one-dimensional chain structure, and the copper centers are six-coordinated. Their magnetic properties were found to be paramagnetic or very weakly antiferromagnetic, which can be ascribed to the somewhat long Cu–N distances due to the steric effect from the bridging ligands. Various diazaaromatic rings play a

role of bridging ligands in spite of sterically bulky substituents (benzo, 2-methyl-, 2-propyl, etc.), which may allow us to develop polynuclear magnetic chains using these bridging ligands with other transition metal ions as a paramagnetic center. More significant magnetic interactions would be available when suitable paramagnetic metal ions are involved, especially metal ions having dπ or dσ(z^2) spins.

4. Experimental

4.1. Materials

Bis(1,1,1,5,5,5-hexafluoropentane-2,4-dionato)copper(II) was purchased from Aldrich Chemical Co. and purified by the reported method [14]. 2,5- and 2,6-Dimethylpyrazines, propylpyrazine, quinoxaline, phenazine, 4,6-dimethylpyrimidine and 1,6-naphthyridine were used without further purification.

[{Cu(hfac)$_2$(μ-2,5-pyz)}$_n$] (**1**). The complex [Cu(hfac)$_2$] (67 mg, 0.14 mmol) was dissolved in a mixture of light petroleum (13 cm^3) and acetone (2 cm^3) with an equimolar quantity of 2,5-dimethylpyrazine (15.2 mg, 0.14 mmol). The solution was refluxed for 1 h. After standing for a few days, light green crystals were formed. They were filtered, washed with a small amount of chilled light petroleum and dried *in vacuo* (51.6 mg, 63% yield). *Anal.* Found: C, 32.55; H, 1.58; N, 4.74%. $C_{16}H_{10}N_2O_4F_{12}Cu$ requires C, 32.81; H, 1.72; N, 4.78%. IR (KBr disk) ν(C–O) 1640, ring def. 681, $\delta_s CF_3$ 597 cm^{-1}.

[{Cu(hfac)$_2$(μ-2,6-pyz)}$_n$] (**2**). This complex was prepared by a similar method to that described above. *Anal.* Found: C, 32.82; H, 1.49; N, 4.76%. $C_{16}H_{10}N_2O_4F_{12}Cu$ requires C, 32.81; H, 1.72; N, 4.78%. IR (KBr disk) ν(C–O) 1639, ring def. 682, $\delta_s CF_3$ 597 cm^{-1}.

[{Cu(hfac)$_2$(μ-prpyz)}$_n$] (**3**). The complex [Cu(hfac)$_2$] (156 mg, 0.327 mmol) was dissolved in pentane with an equimolar quantity of propylpyrazine (40 mg, 0.327 mmol). The solution was refluxed for 1 h. After standing for a few days, light green crystals were formed. They were filtered, washed with a small amount of chilled pentane and dried *in vacuo* (128 mg, 65% yield). *Anal.* Found: C, 33.82; H, 2.24; N, 4.53%. $C_{17}H_{12}N_2O_4F_{12}Cu$ requires C, 34.04; H, 2.02; N, 4.67%. IR (KBr disk) ν(C–O) 1653 and 1641, ring def. 681 and 669, $\delta_s CF_3$ 598 cm^{-1}.

[{Cu(hfac)$_2$(μ-qxln)}$_n$] (**4**) and [{Cu(hfac)$_2$(μ-pnzn)}$_n$] (**5**). These complexes were prepared by a similar method to that described for complex **1**. *Anal.* Found for **4**: C, 35.48; H, 1.21; N, 4.52%. $C_{18}H_8N_2O_4F_{12}Cu$ requires C, 35.57; H, 1.33; N, 4.61%. IR (KBr disk) 1641 ν(C–O), 680 ring def., 596 $\delta_s CF_3$ cm^{-1}. *Anal.* Found for **5**: C, 40.17; H, 1.53; N, 4.26%. $C_{22}H_{10}N_2O_4F_{12}Cu$ requires C, 40.17; H, 1.35; N, 4.25%. IR (KBr disk) ν(C–O) 1639, ring def. 681, $\delta_s CF_3$ 598 cm^{-1}.

[{Cu(hfac)$_2$(μ-4,6-pym)}$_n$] (**6**). The complex [Cu(hfac)$_2$] (45 mg, 0.094 mmol) was dissolved in a mixture of light petroleum (13 cm^3) and acetone (2 cm^3) with an excess of 4,6-dimethylpyrimidine (19.5 mg, 0.18 mmol). The solution was refluxed for 1 h. After standing for a few days, light green needles were formed. They were filtered, washed with a small amount of chilled light petroleum and dried *in vacuo* (26 mg, 47% yield). *Anal.* Found: C, 33.09; H, 1.65; N, 4.93%. $C_{16}H_{10}N_2O_4F_{12}Cu$ requires C, 32.81; H, 1.72; N, 4.78%. IR (KBr disk) ν(C–O) 1641, ring def. 680, $\delta_s CF_3$ 596 cm^{-1}.

[{Cu(hfac)$_2$(μ-1,6-nprn)}$_n$] (**7**). This complex was prepared by a similar method to that described for complex **1**. *Anal.* Found: C, 35.47; H, 1.13; N, 4.66%. $C_{18}H_8N_2O_4F_{12}Cu$ requires C, 35.57; H, 1.33; N, 4.61%. IR (KBr disk) ν(C–O) 1656 and 1643, ring def. 680 and 670, $\delta_s CF_3$ 595 cm^{-1}.

The diffuse reflectance spectra were recorded on a Jasco Ubest V560 spectrophotometer, and IR on a Nicolet 5ZDX Fourier-transform spectrophotometer.

4.2. X-ray crystallographic analysis

X-ray diffraction data of **1**–**7** were collected on a Rigaku R-axis RAPID diffractometer with graphite monochromated Cu Kα ($\lambda = 1.5418$ Å) or Mo Kα ($\lambda = 0.71069$ Å). The structures were directly solved by a heavy-atom Patterson method and expanded using Fourier techniques in the CrystalStructure program package [20]. Numerical absorption correction was used. The parameters of all of the hydrogen atoms were refined as "riding". The thermal displacement parameters of non-hydrogen atoms were refined anisotropically. Full-matrix least-squares methods were applied using all of the unique reflection data. The thermal ellipsoids of these fluorine atoms are somewhat elongated along the motional track. A disorder model was applied for trifluoromethyl groups showing conformational isomerism, but somewhat large thermal displacement parameters of fluorine atoms still remained. Selected crystallographic data are summarized in Table 1.

4.3. Magnetic measurements

Magnetic properties of polycrystalline specimens of **1**–**7** were measured on a Quantum Design MPMS SQUID magnetometer equipped with a 7 T coil in a temperature range 1.8–300 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder measured separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constants.

5. Supplementary material

CCDC 617325, 617326, 617327, 617328, 617329, 617330 and 617331 contain the supplementary crystallographic data for **1**, **2**, **3**, **4**, **5**, **6** and **7**. These data can be obtained free of charge via htpp://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK;

fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

the ratio between the number of molecules in high spin state and the total number of molecules.

For a thermal transition the warming/cooling modes are to be distinguished and there are two different types of FORC experiments, according to the sense of the thermal variations. The measurements start at a sufficiently high/low temperature, such that the high/low temperature (HS/LS) domain structure is saturated. Then temperature is lowered/raised until a given temperature T_b/T_b^*, the reversal temperature, and afterwards raised/lowered, in the warming/cooling mode, respectively, as illustrated in Fig. 1. During the second step of the process, n_{HS}/n_{HS}^* is measured as a function of the actual temperature, T_a/T_a^*. The experiment is repeated for several values of T_b/T_b^*, and the set of $n_{HS}(T_a,T_b)/n_{HS}^*(T_a^*,T_b^*)$ values forms the FORC data.

The FORC distribution is defined as the second mixed derivative of these curves:

$$\rho(T_a,T_b) = -\frac{\partial^2 n_{HS}(T_a,T_b)}{\partial T_a \partial T_b}$$

In the case of non-interacting domains, the FORC distribution $\rho(T_a,T_b)$ is equivalent to the Preisach distribution, e.g. $P(T_{down},T_{up})$ in the warming mode and $P(T_{up},T_{down})$ in the cooling mode. In such a case, the FORC distributions obtained in the cooling and warming modes are expected to be the same, in the limit of inherent experimental errors [4].

Diluted systems are of higher interest for investigating the nature and range of interactions. In the mean-field description, the "effective" interaction in the diluted system is proportional to the number of spin-crossover neighbours, i.e., to the composition parameter x and qualitatively explains why the hysteresis loop collapses bellow a threshold value $x = 0.40$ in the isostructural systems $[Fe_xM_{1-x}(btr)_2(NCS)_2]\cdot H_2O$ where the dilution metal M was Co or Ni [6,7].

In the case of pure and diluted spin transition materials $[Fe_xZn_{1-x}(btr)_2(NCS)_2]\cdot H_2O$, we calculated distributions of internal stresses and domain size, increasing with dilution $(1-x)$. The FORC analysis shows, for increasing dilution parameter an increasing width of the bias distribution, a decreasing width of the coercivity distribution, as well as an increasing correlation between the bias and coercivity distribution. The large variation of the mean transition temperature upon the effect of dilution can be explained by the large ionic radius of the Zn(II) ion, which roughly matches the Fe(II) ion radius in the high spin state.

The representative major thermal hysteresis loops of some Ni diluted compounds are reported in Fig. 2. In Fig. 3, we present the spin state phase diagram for all the three dilutions. A threshold dilution value, which is the limit of the Fe concentration that implies the presence of a hysteresis can be established for every impurity, varying from 0.3 in the case of Zn to about 0.5 for Ni. The large variation of the threshold value, as of the mean transition temperature upon the effect of dilution can be explained by different ionic radius of the impurities. Following the steric arguments used in [6,7], the presence of molecular units with a large radius stabilizes the high spin state of the spin-crossover units, i.e. lowers the equilibrium temperature.

In this paper, we shall present a throughout experimental investigation using the FORC diagram for different dilution metals (Zn, Co and Ni).

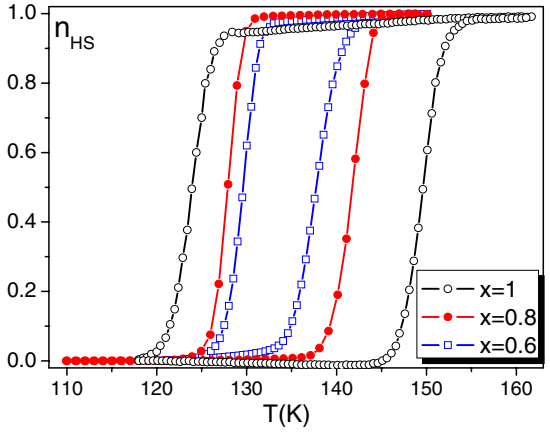

Fig. 2. Thermal hysteresis of $[Fe_xNi_{1-x}(btr)_2(NCS)_2]\cdot H_2O$ for different concentrations.

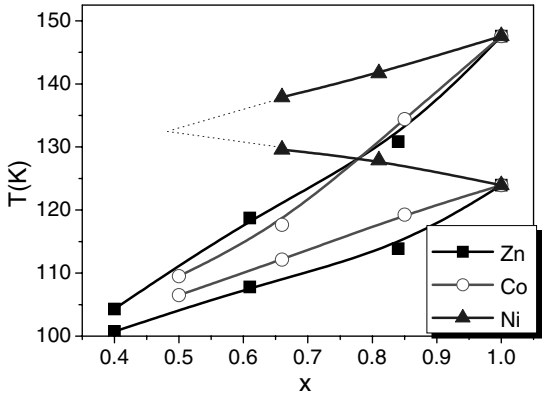

Fig. 3. The dilution phase diagrams of Fe $x = 1$, Zn ($x = 0.8$, 0.6 and 0.4) Co ($x = 0.8$, 0.6 and 0.5) and Ni ($x = 0.8$ and 0.6) taking the switching temperatures corresponding to $n_{HS} = 0.5$.

2. Metal dilution effect investigation with FORC method

We now proceed to a general discussion of the properties induced by dilution of the spin transition complex $[Fe(btr)_2(NCS)_2]\cdot H_2O$ according to the nature of the different diluents: Zn, Co, Ni.

A crucial point is the steric effect induced by the substitution of transition metal in the spin crossover molecular unit. To a first approach, the change in the metal–ligand distance will merely follow the change in the ionic radius, which can be derived from the data listed in Table 1.

Therefore, it can be expected [7] that Ni-dilution will not induce sizeable steric effects, because the Ni(II) radius almost equals the average value of the low-spin and high-spin Fe(II). Consequently, the equilibrium temperature, that is the central temperature of the thermal hysteresis loop is not expect to depend on the dilution factor. On the contrary, Zn-dilution, and to a lesser extent, Co-dilution will induce an increase in the lattice parameter, which favors the Fe(II) high spin state, and finally induce a shift of the thermal hysteresis loop towards the low temperatures.

In our experiments, we used small crystals, in shape of rectangular pellets, slightly coloured (from white to yellow) at room temperature and turning to dark purple at low temperature. We have used magnetization measurements, made with a SQUID magnetometer (MPMS5 Quantum Design) in the RSO (Reciprocating sample option – a more sensitive head) mode. In Fig. 4, we present the experimental FORCs and FORC diagrams of $[Fe_{0.6}Co_{0.4}(btr)_2(NCS)_2]\cdot H_2O$ and $[Fe_{0.6}Ni_{0.4}(btr)_2(NCS)_2]\cdot H_2O$ samples (about 5 mg), derived from the magnetization measurements. Temperature was scanned every 0.5 K for both T_a and T_b and the applied field was 1000Oe. The high spin fraction was derived from the susceptibility value, considering the, respectively, paramagnetic and diamagnetic characters of the high spin and low spin states.

For an easier comparison, we plotted all diagrams on the same graph, in (T_a,T_b) plane (see Fig. 5). It is worth noting that the centres of the FORC distributions are situated along a straight line, which of course is consistent with the phase diagram already shown in Fig. 3. In order to facilitate the discussion of the results in physical terms, we have chosen the $b=(T_a+T_b)/2$, $c=(T_a-T_b)/2$ axes (Fig. 6) which roughly correspond to the energy gap Δ and intra-domain interaction J. The corresponding axes for magnetic systems would be the bias (interactions between domains) and coercivity, respectively.

Table 1
Selected values of ionic radius of divalent 3d transition metals in octahedral symmetry (after [6])

Metal	r (pm)
Zn(II)	96
Fe^{HS}(II)	92
Co(II)	88.5
Ni(II)	83
Fe^{LS}(II)	75

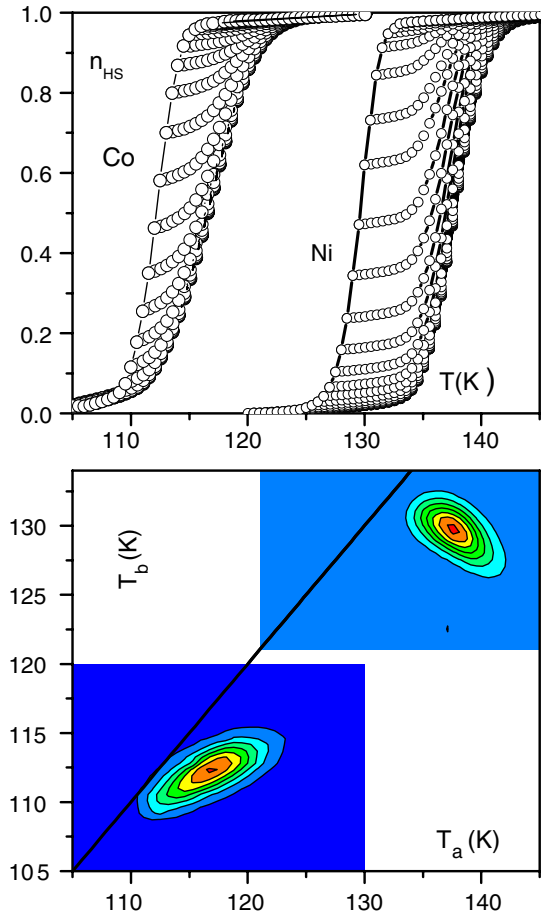

Fig. 4. FORCs and diagram of $[Fe_{0.6}Co_{0.4}(btr)_2(NCS)_2]\cdot H_2O$ and $[Fe_{0.6}Ni_{0.4}(btr)_2(NCS)_2]\cdot H_2O$.

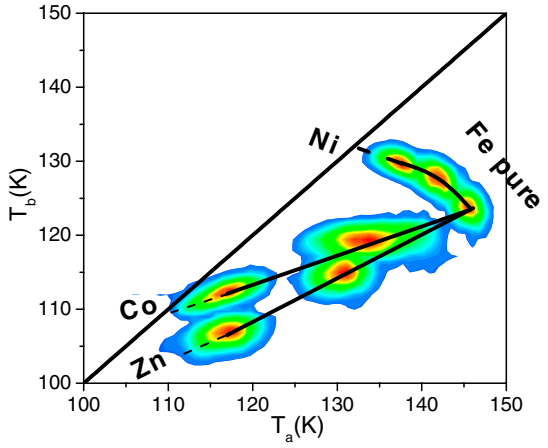

Fig. 5. FORC diagrams of all diluted system in (T_a, T_b) plane.

We also performed the statistical analysis after the procedure described in [4], and we collected in Table 2 the main parameters obtained by this analysis. Following this procedure, we were able to obtain the average values of bias ($\bar{b}$) and coercivity ($\bar{c}$), the dispersion of distributions,

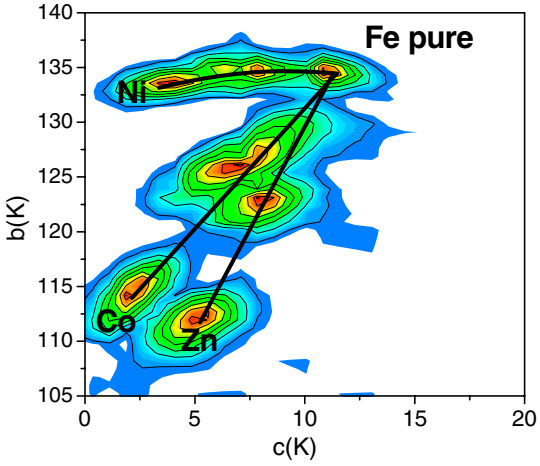

Fig. 6. The diagrams of all diluted systems, in $(b - c)$ plan.

Table 2
The statistical data of (b, c) distributions of diluted $[Fe(btr)_2(NCS)_2] \cdot H_2O$

x		$\bar{c}$ (K)	$\bar{b}$ (K)	σ_c (K)	σ_b (K)	r
Zn	0.61	5.05	111.58	1.28	1.65	0.52
	0.84	7.74	122.61	1.47	1.71	0.25
Co	0.66	1.79	114.4	1.96	1.98	0.76
	0.85	7.47	126.7	2.5	2.57	0.69
Ni	0.66	4.05	133.50	1.77	1.36	0.48
	0.81	7.03	134.61	1.58	1.03	0.11
Fe	pure	10.81	134.56	1.24	1.03	−0.26

σ_b, σ_c, respectively and the factor r which represents the degree of correlation between the joint distributions.

The comparison between the different systems is now made with the help of correlation plots between the bias and coercivity parameters, reported in Figs. 7 and 8. Such plots eliminate the uncertainties or errors which might affect the compositional parameters, and lead to the following observations:

(i) a quasi-linear correlation exists between the $\bar{b}$ and $\bar{c}$ values, for each type of dilution metal, see Fig. 7. This is consistent with the simple idea that both parameters depend linearly on the composition parameter. The plot of course agrees with the phase diagram shown in Fig. 3 since it originates from the same experimental data.

(ii) a similar correlation is suggested between the dispersion width parameters, σ_b and σ_c, with however a larger scatter. This observation supports the idea that the spreading of parameters are also linear functions of the composition parameter.

(iii) the Ni-system, the equilibrium temperature of which little depends on composition, is then expected to exhibit an almost constant dispersion in the bias parameter; this is consistent with Fig. 8.

(iv) the Co-system exhibits very large dispersion width parameters, which have already been assigned to an exceptionally large spreading in composition. The slope of the correlation straight line in Fig. 8 however, is smaller than that of the Zn-system. This can be related to the lesser sensitivity of the equilibrium temperature upon dilution, already illustrated by the phase diagram shown in Fig. 3.

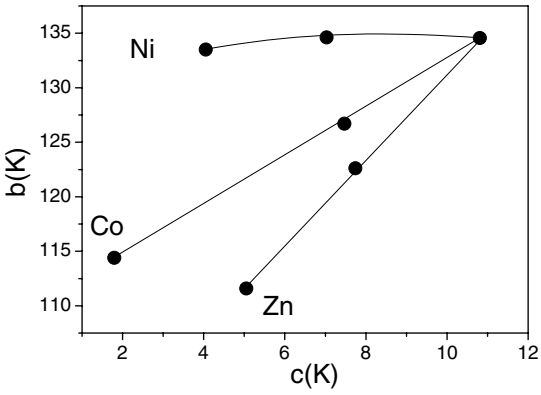

Fig. 7. The average values of the FORC distributions represented in $c - b$ plan.

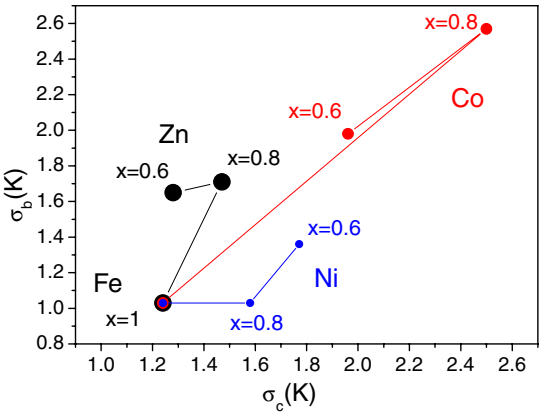

Fig. 8. The coercivity – bias dispersions representation for studied samples.

3. On the squareness of the thermal hysteresis loop

It is known that the ratio between the remanent and saturation magnetization in a magnetic material is an indicator of the importance of the reversible processes. Unfortunately, it is not possible to define a similar parameter in spin transition due to the fact that there is no way to establish in an accurate manner where the origin lies inside the hysteresis loop. We propose here to use the ratio coercivity dispersion/hysteresis width as a general and non-arbitrary procedure to evaluate the reversible component. This statement can be justified by the following observation: when the reversible component is large, the high spin fraction measured on a FORC, will increase right after the returning point thus contributing to a large distribution. If the reversible component is negligible, the variation of the n_{HS} on a FORC will take place in a very small region inside the hysteresis loop, even if the width of the hysteresis is

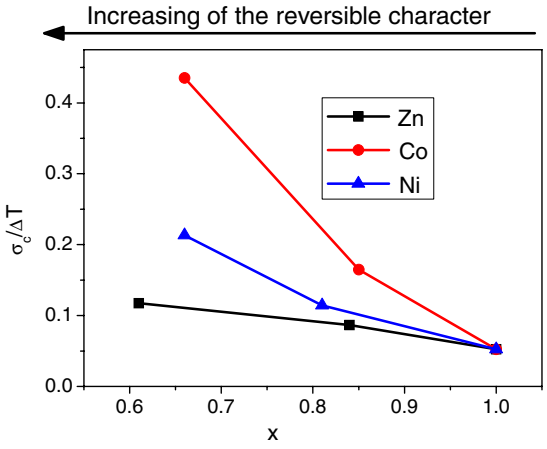

Fig. 9. The plot of relative coercivity dispersion vs. composition parameter of diluted system.

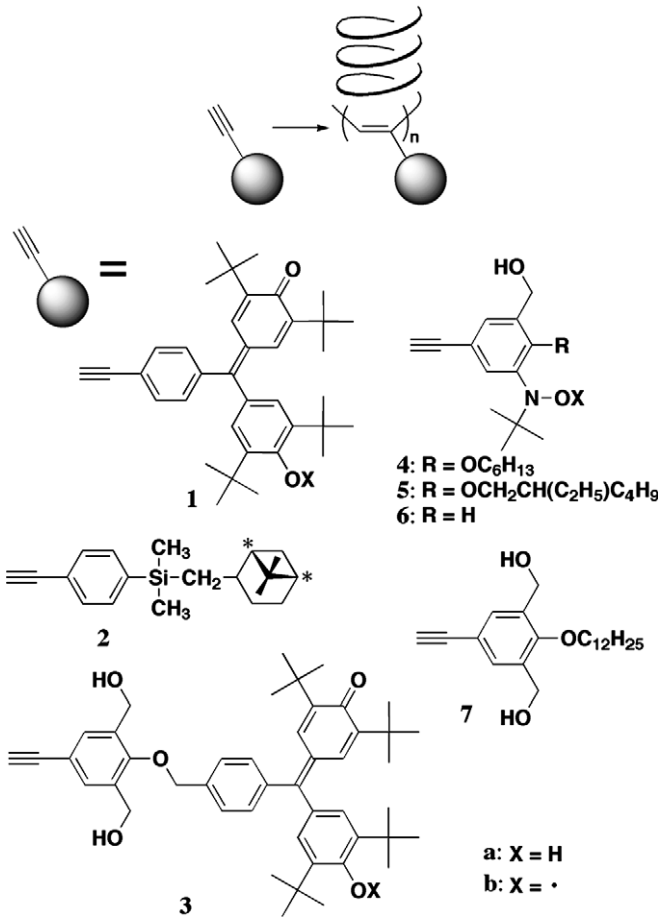
quite big (Fig. 4). The plot of the new parameter values is shown in Fig. 9.

4. Conclusions



Experimental data on the system under study are consistent with the very simple picture of independent like-spin domains characterized by their equilibrium temperature and internal interaction parameter. In the diluted system, a narrow distribution of composition can explain the observed correlation between equilibrium temperatures and internal interaction parameters.

Scheme 1.

(**1a**) and a chiral acetylene monomer **2** using $[Rh(nbd)Cl]_2$ catalyst [14]. The second is the addition of chiral regents leading to interaction or reaction with achiral polymers, which induces a chiral bias between right-handed and left-handed helical conformations. There are no reports about chiral polyradicals using this method, because it is difficult to design polymers which require the ability to form both stable radicals and one-handed helix. The third is the helix-sense-selective polymerization using chiral catalysts or chiral initiators. The helix-sense-selective polymerization is a possible method of obtaining various one-handed helical polymers since the process demands no chiral moiety in the monomer. This fact will give increased flexibility to monomer design, besides obvious economic implications due to using only a catalytic amount of chiral compounds that are often expensive. We have already succeeded in synthesizing optically active helical poly(**1a**) [12,13], poly(**3a**), poly(**4a**), poly(**5a**) and poly(**6a**-*co*-**7**) [15] bearing stable radical precursor by the helix-sense-selective polymerization of the corresponding achiral phenylacetylenes, using the rhodium complex catalyst, in the presence of chiral 1-phenylethylamine. The helical chirality of the polymers was kinetically stabilized by intramolecular hydrogen bonds among hydroxyl groups in the polymer for poly(**3a**), poly(**4a**), poly(**5a**) and poly(**6a**-*co*-**7**), and by the achiral side group's own bulkiness for poly(**1a**) although the obtained polymers possess no chiral moieties except for helicity.

It is well known that poly(phenyleneethynylene)s are obtained from substituted phenylacetylenes by condensation polymerization besides poly(phenylacetylene)s [1,16,17]. In particular, some poly(1,3-phenyleneethynylene)s can form helical foldamer conformation depending on their side groups and/or solvent [18–20], while poly(aryleneethynylene)s have been investigated as a backbone structure of polyradical for magnetic materials [21–28]. Although some poly(1,3-phenyleneethynylene)s bearing stable radicals were also synthesized [29–32], there are no report about optically active helical poly(1,3-phenyleneethynylene)-based polyradicals. In this study, we first synthesized an optically active poly(1,3-phenyleneethynylene) poly(**8b**-*alt*-**9**) bearing galvinoxyl units, which are known as a stable radical, and dimethyl(10-(1*S*)-pinanyl)silyl groups via synthesis of the hydrogalvinoxyl precursor polymer poly(**8a**-*alt*-**9**) by condensation polymerization of (3,5-dihalogenophenyl)hydrogalvinoxyl $\mathbf{8}_{I}\mathbf{a}$ (or $\mathbf{8}_{Br}\mathbf{a}$) and 1,3-diethynylbenzene monomer bearing dimethyl(10-(1*S*)-pinanyl)silyl groups $\mathbf{9}_{H}$ (or $\mathbf{9}_{Hip}$) using $Pd(PPh_3)_4$ catalyst (Scheme 2). The natural optical activity, magnetic optical

Scheme 2.

activity and magnetic interaction of the polymers were discussed in terms of the circular dichroism (CD) spectra, the magneto-circular dichroism (MCD) spectra and SQUID measurements, respectively.

The monomer $\mathbf{8}_{I}\mathbf{a}$ and $\mathbf{8}_{Br}\mathbf{a}$ were synthesized via treatment of 3,5-diiodophenyllithium and 3,5-dibromophenyllithium with 4,4′-diacetoxy-3,3′,5,5′-tetra-*tert*-butylbenzophenone, respectively, followed by elimination of the protecting acetyl groups. 3,5-Dibromophenyllithium was also treated with chlorodimethyl(10-(1*S*)-pinanyl)silane to give 3,5-dibromo-1-(dimethyl(10-(1*S*)-pinanyl)silyl)benzene. The monomer $\mathbf{9}_{Hip}$ was obtained by cross-coupling reaction of 3,5-dibromo-1-(dimethyl(10-(1*S*)-pinanyl)silyl)benzene with twice amount of 2-methyl-3-butyn-2-ol in the presence of a palladium complex catalyst. The monomer $\mathbf{9}_{Hip}$ was converted to the monomer $\mathbf{9}_{H}$ by the elimination reaction of the terminal acetylene-protecting groups.

The polymerization of the monomers was carried out in the presence of $Pd(PPh_3)_4$ catalyst. A yellow solid polymer poly(**8a**-*alt*-**9**) was obtained by precipitation from the polymerization mixtures into methanol. The polymerization data for these resultant polymers are summarized in Table 1. The molecular weight of the polymer was improved by using $\mathbf{8}_{I}\mathbf{a}$ instead of $\mathbf{8}_{Br}\mathbf{a}$. The monomer $\mathbf{8}_{I}\mathbf{a}$ was polymerizable with $\mathbf{9}_{H}$ at lower temperature, i.e. room temperature, in comparison with $\mathbf{8}_{Br}\mathbf{a}$. However, the polymerization of $\mathbf{9}_{Hip}$ with $\mathbf{8}_{I}\mathbf{a}$ required the higher temperature, although this process was expected to circumvent an oxidative coupling side reaction to produce diyne linkage due to combining the deprotection of the ethynyl group and the cross-coupling to the aromatic halide. The polymer was soluble in chloroform, tetrahydrofuran, ethyl acetate, benzene and toluene, but insoluble in acetone, diethyl ether, DMSO, DMF, alcohols and aliphatic hydrocarbons. It was confirmed by IR and ^{1}H NMR spectra of the polymers that polymerization proceeded by cross-coupling reaction between a terminal acetylene and halogeno group of monomers, i.e., the reduction of the peaks assignable to the ethynyl group of $\mathbf{9}_{H}$ at 3302 cm^{-1} ($\nu_{\equiv C-H}$) in IR and δ 3.09 ppm (s, 2H, ≡C–H) in ^{1}H NMR, and the reduction of the peak assignable to the aromatic proton of $\mathbf{8}_{I}\mathbf{a}$ at δ 8.10 ppm (t, 1H, ArH) in ^{1}H NMR. The alternate structure of **8a** and **9** in the polymer was confirmed by ^{1}H NMR; ^{1}H NMR ($CDCl_3$, 270 MHz, ppm) δ 0.29 (s, 3H, $SiCH_3$), 0.30 (s, 3H, $SiCH_3$), 0.65–0.88 (m, 2H, CH or CH_2 in pinanyl), 0.76 (s, 3H, *gem*-CH_3 in pinanyl), 1.13 (s, 3H, *gem*-CH_3 in pinanyl), 1.2–1.3 (m, 1H, CH or CH_2 in pinanyl), 1.25 (s, 9H, *tert*-butyl), 1.28 (s, 9H, *tert*-butyl), 1.34 (d, 1H, $J = 9.9$ Hz, CH or CH_2 in pinanyl), 1.42 (s, 18H, *tert*-butyl), 1.5–1.7 (m, 4H, CH or CH_2 in pinanyl), 1.81 (m, 1H, CH or CH_2 in pinanyl), 1.98 (m, 1H, CH or CH_2 in pinanyl), 2.11 (m, 1H, CH or CH_2 in pinanyl), 5.54 (s, 1H, OH), 7.04 (br, 3H, ArH in **8a**), 7.23 (br, 1H, ArH in **8a**), 7.41 (d, 2H, $J = 1.1$ Hz, ArH in **8a**), 7.60 (d, 2H, $J = 1.1$ Hz, ArH in **9**), 7.63 (t, 1H, $J = 1.1$ Hz, ArH in **9**), 7.78 (t, 1H, $J = 1.1$ Hz, ArH in **8a**).

The polyradical poly(**8b**-*alt*-**9**) was obtained by oxidizing the polymer poly(**8a**-*alt*-**9**) by treatment of the polymer solution in degassed chloroform with fresh PbO_2. The spin concentration of polyradicals were determined by doubly integrating the ESR signal in comparison with that of 2,2,6,6-tetramethyl-1-piperidinyloxyl (TEMPO) solution as a standard. The polyradicals were appropriately stable for maintaining the initial spin concentration under the ESR and SQUID measurement conditions. The ESR spectrum of poly(**8b**-*alt*-**9**) showed a unimodal broad signal at $g = 2.0046$ indicating the formation of the phenoxyl radical, where disappearance of hyperfine structure is attributable to the intramolecular aggregation of radical units along the main chain (Fig. 1).

The CD spectra of poly(**8a**-*alt*-**9**) and poly(**8b**-*alt*-**9**) were measured in various solution. In the CD spectrum of poly(**8a**-*alt*-**9**) taken in ethyl acetate solution, clear Cotton effects were observed in the absorption region of the

[e] Based on the phenyleneethynylene unit, and estimated from M_w.

backbone and hydrogalvinoxyl chromophore, indicating an excess of one-handed helical foldamer conformation (Fig. 2). However, the formation of poly(**8b**-*alt*-**9**) unfortunately became insoluble in ethyl acetate. On the other hand, Cotton effects were hardly observed in chloroform, THF and benzene solution for both poly(**8a**-*alt*-**9**) and poly(**8b**-*alt*-**9**). But the CD signals appeared in CD spectra of the polymer and polyradical by addition of methanol to the chloroform solution, accompanying bathochromic shift of absorption maxima of galvinoxyl chromophore and hypochromic effect of absorption around 300 nm (Fig. 3).

MCD spectra of poly(**8a**-*alt*-**9**) in chloroform are shown in Fig. 4. There, positive and negative Faraday effects are observed for poly(**8a**-*alt*-**9**) in the absorption region of the backbone chromophore (300–350 nm) and of the hydrogalvinoxyl chromophore (420 nm) corresponding to the negative and positive magnetic fields, respectively. On the other hand, the MCD spectrum of poly(**8a**-*alt*-**9**) in ethyl acetate solution shows the Faraday effects overlapping with Cotton effects in the absorption region of the backbone chromophore and of the hydrogalvinoxyl chromophore, and the differential spectrum ($[\theta]_M - [\theta]$) are in agreement with the MCD spectrum of poly(**8a**-*alt*-**9**) in chloroform (Fig. 2). This fact suggests that Faraday effects of poly(**8a**-*alt*-**9**) were independent of the conformation of poly(**8a**-*alt*-**9**). MCD spectra of poly(**8b**-*alt*-**9**) in chloroform are also shown in Fig. 5. The MCD signals, which are mirror images of each other depending on the direction of the magnetic field, appear in the absorption region of the backbone chromophore (300–350 nm) and of the galvinoxyl-radical chromophore (470 nm), although the Cotton effects in the CD spectrum were hardly observed in chloroform.

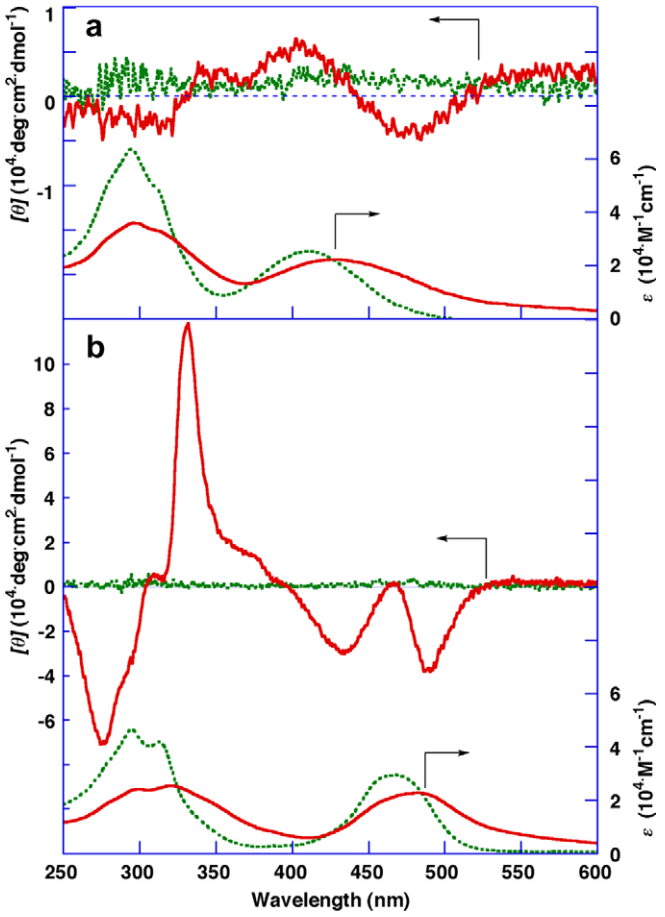

Fig. 3. CD and UV–Vis absorption spectra of (a) poly(**8a**-*alt*-**9**) and (b) poly(**8b**-*alt*-**9**) at 20 °C in chloroform (dashed line) and chloroform/methanol (1/1 (v/v)) (solid line).

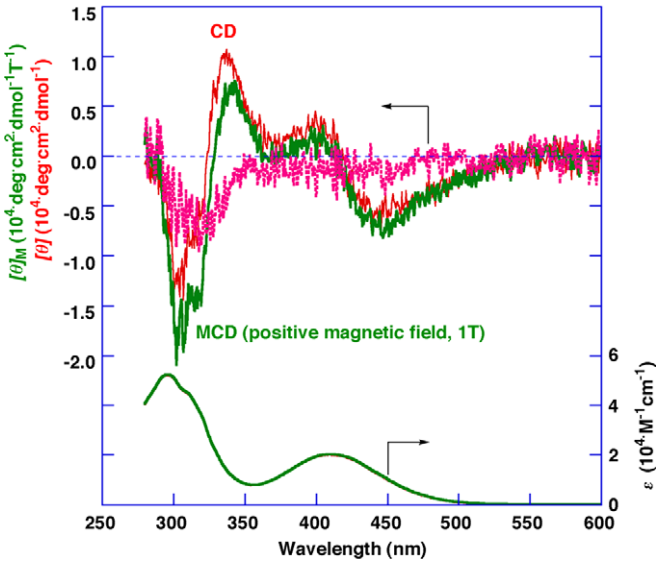

Fig. 2. CD ($[\theta]$), MCD ($[\theta]_M$) and UV–Vis absorption spectra of poly(**8a**-*alt*-**9**) at 20 °C in ethyl acetate. Dashed line: differential spectrum ($[\theta]_M - [\theta]$).

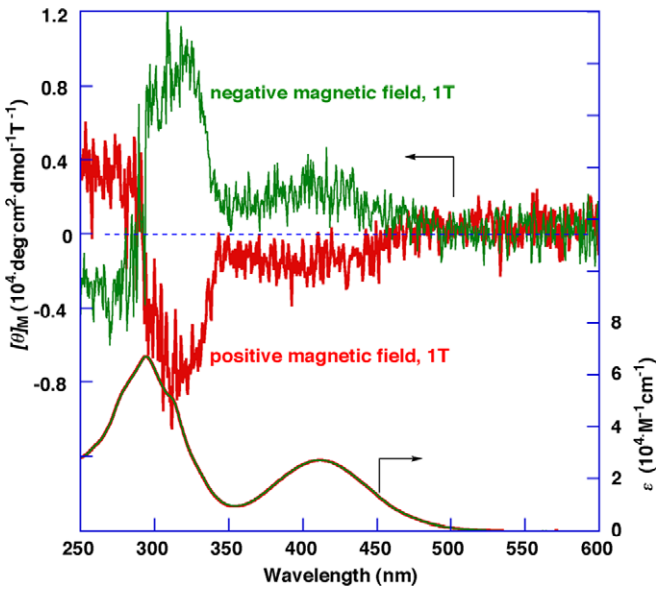

Fig. 4. MCD and UV–Vis absorption spectra of poly(**8a**-*alt*-**9**) at 20 °C in chloroform.

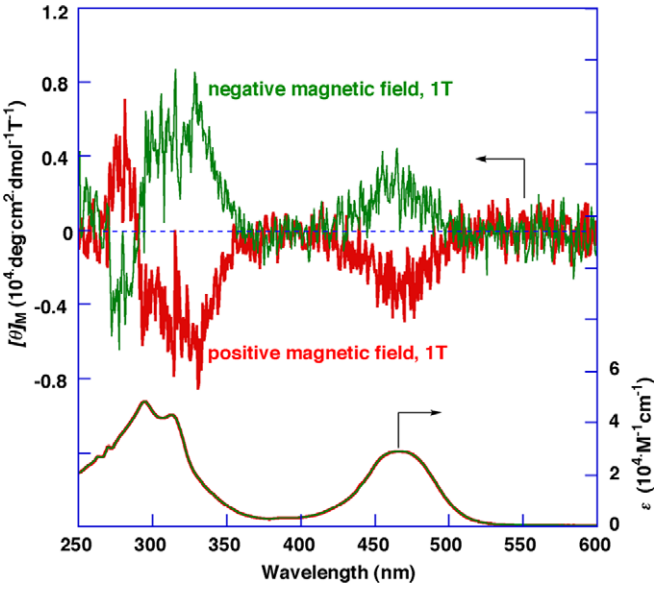

Fig. 5. MCD and UV–Vis absorption spectra of poly(**8b**-*alt*-**9**) at 20 °C in chloroform.

The static magnetic susceptibility (2–300 K at 0.5 T) of poly(**8b**-*alt*-**9**) was measured using a SQUID magnetometer. The powder sample was prepared by evaporating solvent from the chloroform solution of poly(**8b**-*alt*-**9**) and by drying in vacuum. Downward deviation of the χT value of poly(**8b**-*alt*-**9**) at lower temperatures indicated the antiferromagnetic interaction (Weiss const. = −0.7 K, spin conc. = 0.8 spin/unit).

In summary, we have first succeeded in the synthesis of an optically active poly(1,3-phenyleneethynylene)-based polyradical bearing galvinoxyl units, poly(**8b**-*alt*-**9**). The interchain magnetic interaction of helical polyradicals may be modified by the sense of helicity. That is, a one-handed helical polyradical has only interaction between chains of same helical sense, while a racemic helical polyradical has two types of interchain interaction, i.e., interactions between chains of same helical sense and between chains of opposite helical sense. Additionally, magneto-chiral dichroism (MChD) effect is expected in chiral magnetic materials [33–36]. The magnetic and magneto-optical properties of the optically active helical polyradicals will be discussed in more detail in a subsequent paper.

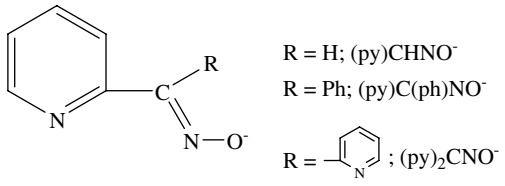

Fig. 1. Formulae and abbreviations of the 2-pyridyloximate(-1) ligands used in this work. The neutral ligands are abbreviated as (py)C(R)NOH.

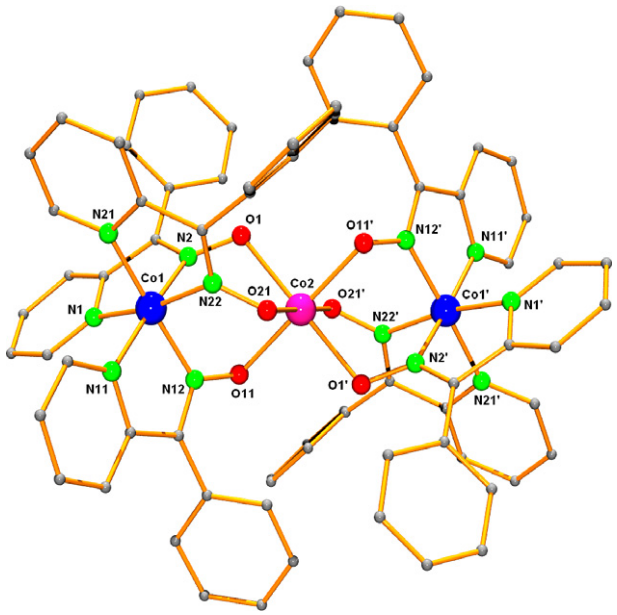

Fig. 2. Molecular structure of the cation $[Co_3^{III,II,III}\{(py)C(ph)NO\}_6]^{2+}$ present in **1** · 6MeCN. Primes are used for the symmetry-related ($-x$, $-y$, $-z$) atoms.

$(py)C(ph)NO^-$ ligands. The six sites on each of the distorted octahedral low-spin, terminal Co^{III} ions are occupied by the nitrogen atoms that belong to the "chelating" part of three $(py)C(ph)NO^-$ ligands, with the three oximate N atoms in the *fac* configuration. Complex **1** can also be obtained by the 2:1 reaction between *mer*-$[Co^{III}\{(py)C(ph)NO\}_3]$ [4] and $Co(PF_6)_2 \cdot 6H_2O$ in MeCN ("metal complexes as ligands" strategy), see Eq. (1). Magnetically, complex **1**

$$2[Co^{III}\{(py)C(ph)NO\}_3] + Co^{II}(PF_6)_2 \cdot 6H_2O \xrightarrow[T]{MeCN} \underset{\mathbf{1}}{[Co_3\{(py)C(ph)NO\}_6](PF_6)_2} + 6H_2O \quad (1)$$

behaves as a monomeric octahedral, high-spin Co(II) complex ($\mu_{eff} = 5.01$ BM per trimer at 22 °C). The Co/(py)CHNOH chemistry [4] is very similar to the Co/(py)C(ph)NOH chemistry.

In order to investigate to what extent the presence of a donor atom on the substituent R of the oxime group of 2-pyridyl oximes might affect the identity of isolated Co products, we studied the Co/$(py)_2$CNOH chemistry. Aerobic reaction of $Co(O_2CMe)_2 \cdot 4H_2O$ with $(py)_2$CNOH, in the presence of $NaClO_4$(1:1:1 reaction ratio), in MeOH/H_2O (5:1, v/v) led to the red cluster $[Co_2^{II}Co_2^{III}(OH)_2(O_2CMe)_2\{(py)_2CNO\}_4(MeOH)_2](ClO_4)_2$ (**2**) in very good yield (>65%), see Eq. (2). The tetranuclear, mixed-valent cation of **2** · 4MeOH · 3.08H_2O (Fig. 3)[2]

$$4Co(O_2CMe)_2 \cdot 4H_2O + 4(py)_2CNOH + O_2 + 2NaClO_4 + 2MeOH \xrightarrow[25\,^\circ C]{MeOH/H_2O} \underset{\mathbf{2}}{[Co_2^{II}Co_2^{III}(OH)_2(O_2CMe)_2\{(py)_2CNO\}_4(MeOH)_2](ClO_4)_2} + 2NaO_2CMe + 4MeCO_2H + H_2O_2 + 14H_2O \quad (2)$$

has the four metal ions in a rectangular arrangement. Based on Co-donor atom bond lengths, Co(1) and its symmetry-related Co(1′) are assigned as the Co^{III} ions. The cobalt centers are bridged along each short edge of the rectangle [Co(1)···Co(2) = 3.213(1) Å] by one hydroxide [O(21), O(21′)], one syn,syn $\eta^1{:}\eta^1{:}\mu_2$-$MeCO_2^-$ group and one oximate group. The bridging along each long side [Co(1)···Co(2′) = 4.441(1) Å] occurs through one oximate group only. Short edge $(py)_2CNO^-$ ligands adopt the $\eta^1{:}\eta^1{:}\eta^1{:}\mu_2$ coordination mode, while long edge $(py)_2CNO^-$ ions function as $\eta^1{:}\eta^1{:}\eta^1{:}\eta^1{:}\mu_2$ ligands. Complex **2** has a novel inverse 12-metallacrown-4 structural motif [5]. Since the paramagnetic, high-spin d^7 Co^{II} ions alternate with the diamagnetic Co^{III} ones in the ring of **2**, superexchange between the former is negligible. The observed decrease of $\chi_M T$ as T is lowered (Fig. S1) can be attributed to the spitting of the $^4T_{1g}$ ground state by low symmetry ligand fields and spin–orbit coupling [6].

Use of 2-pyridyloximate(-1) ligands in nickel(II) chemistry gives different clusters, as expected. The synthetic investigation of the Ni^{II}/(py)CHNOH/OH^- reaction systems in H_2O, H_2O/MeOH or H_2O/MeCN in the presence of coun-

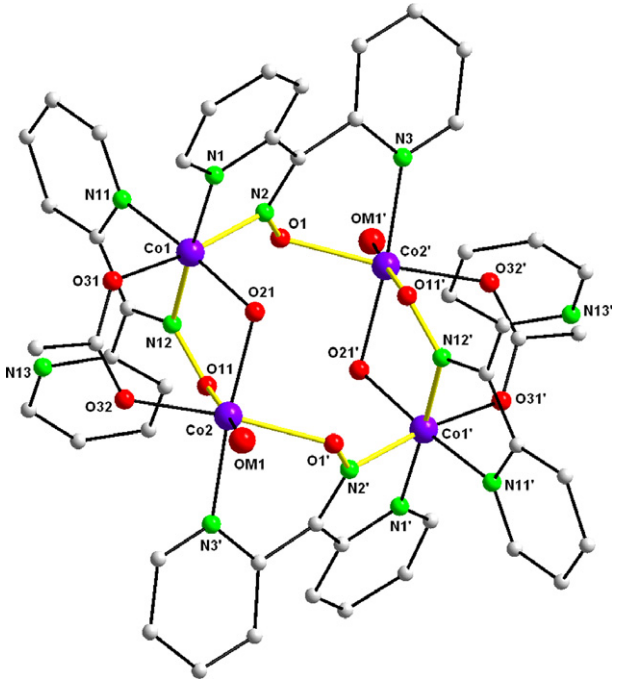

Fig. 3. The molecular structure of the $Co_2^{II}Co_2^{III}$ cation present in complex **2** · 4MeOH · 3.08H_2O. Primed and unprimed atoms are related by the crystallographic inversion center.

terions has led to a variety of salts possessing the thermodynamically stable enneanuclear cation $[Ni_9(\mu_3\text{-}OH)_2(\mu_2\text{-}OH)_2\{\mu_3\text{-}(py)CHNO\}_4\{\mu_2\text{-}(py)CHNO\}_6(\mu_2\text{-}OH_2)_2(H_2O)_6]^{4+}$ ($\mathbf{3}^{4+}$) [7,8]. The preparation of the representative salt **3** $\{N(CN)_2\}_3(ClO_4)$ is summarized in Eq. (3). The cation (Fig. 4)[2] can be described as consisting of two

$$9Ni(ClO_4)_2\cdot 6H_2O + 10(py)CHNOH + 3NaN(CN)_2 + 14NaOH \xrightarrow[\text{“pH”}=7]{H_2O\text{–}MeCN} \underset{\mathbf{3}\{N(CN)_2\}_3(ClO_4)}{[Ni_9(OH)_4\{(py)CHNO\}_{10}(H_2O)_8]\{N(CN)_2\}_3(ClO_4)} + 17NaClO_4 + 56H_2O \quad (3)$$

$[Ni_4(\mu_2\text{-}OH)_2\{\mu_2\text{-}(py)CHNO\}_5(\mu_2\text{-}OH_2)(H_2O)_3]^+$ subunits linked to the central Ni(1) ion through four oximate oxygens and two *trans* disposed bridging OH^- groups; as a result of this association, one OH^- group of each subunit becomes μ_3, and two oximate oxygens of each subunit become μ_2. Six of the $(py)CHNO^-$ ions behave as $\eta^1\text{:}\eta^1\text{:}\eta^1\text{:}\mu_2$ ligands and the remaining four as $\eta^1\text{:}\eta^1\text{:}\eta^2\text{:}\mu_3$ ligands. All the salts of $\mathbf{3}^{4+}$ exhibit a very similar magnetic behaviour. The $\chi_M T$ vs. T plot for the representative cluster $\mathbf{3}(ClO_4)_4\cdot 7.85H_2O\cdot 1.4MeOH$ (2–300 K, 0.1 T), shown in Fig. 5, is indicative of strong antiferromagnetic coupling.

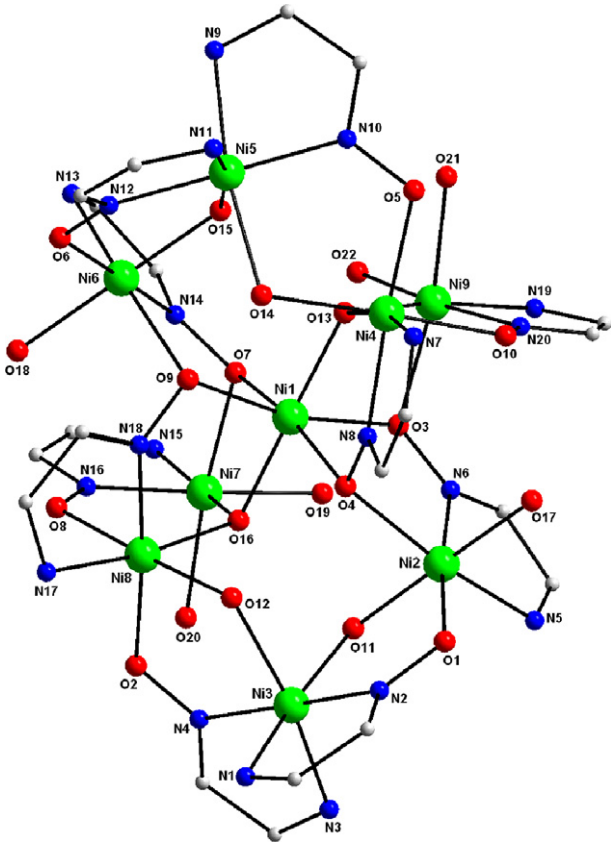

Fig. 4. A plot of the enneanuclear cation present in $\mathbf{3}\{N(CN)_2\}_3(ClO_4)\cdot 11.11H_2O$. Most carbon atoms of the 10 $(py)CHNO^-$ ligands have been omitted. Atoms O(13), O(16) belong to the $\mu_3\text{-}OH^-$ ligands, while atoms O(11) and O(15) to the $\mu_2\text{-}OH^-$ ligands. The $\mu_2\text{-}H_2O$ oxygen atoms are O(12) and O(14), while O(17)–O(22) are the oxygen atoms of the terminal aqua ligands. The rest oxygen atoms belong to the $(py)CHNO^-$ ligands.

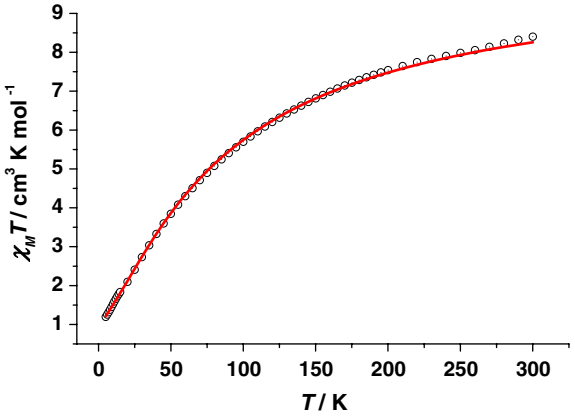

Fig. 5. Plot of the $\chi_M T$ product vs. T for an analytically pure sample of complex $\mathbf{3}(ClO_4)_4\cdot 7.85H_2O\cdot 1.4MeOH$ [6,7]. The solid line is the fit of the data to the appropriate 3-J model (see text).

Magnetization experiments at 2 K (Fig. S2) up to a field of 5 T show a saturation value equivalent to two electrons, indicating an $S_T = 1$ ground state. The susceptibility data were fit to a 3-J model. Best-fit parameters, obtained by means of the program CLUMAG [9], are $J_1 = -16.4\ cm^{-1}$, $J_2 = -8.7\ cm^{-1}$, $J_3 = -27.1\ cm^{-1}$ and $g = 2.079$. The J_1 coupling constant is assigned to Ni···Ni interactions involving a diatomic oximate group and a single O atom that belongs to a $\mu_3\text{-}OH^-$, a $\mu_2\text{-}OH^-$ or to a μ_3-oximate group. The J_2 coupling constant is assigned to Ni···Ni interactions involving two single oxygen atoms, one from a μ_3-oximate group and the second from a $\mu_3\text{-}OH^-$ group, while the J_3 coupling constant is assigned to Ni···Ni interactions through a diatomic oximate group.

Reaction of $Ni(O_2CMe)_2\cdot 4H_2O$ with one equivalent of (py)C(ph)NOH in MeOH and layering of Et_2O onto the resulting red solution gave violet crystals of $[Ni_4(O_2CMe)_4\{(py)C(ph)NO\}_4(MeOH)_2]$ (**4**), see Eq. (4); the yield was 65%.

$$4Ni(O_2CMe)_2\cdot 4H_2O + 4(py)C(ph)NOH + 2MeOH \xrightarrow{MeOH} \underset{\mathbf{4}}{[Ni_4(O_2CMe)_4\{(py)C(ph)NO\}_4(MeOH)_2]} + 4MeCO_2H + 16H_2O \quad (4)$$

The crystal structure of $\mathbf{4}\cdot 2MeOH$[2] reveals the presence of tetranuclear molecules (Fig. 6). The core consists of a tetrahedron of Ni^{II} ions to form a distorted $[Ni_4(NO)_4]^{4+}$ 'cube' (the term '*cubane*' is avoided since it implies the existence of only monoatomic bridges between the metal ions) comprising single (O) and double (N–O) atom edges. Each molecule is held together by two syn,syn $\eta^1\text{:}\eta^1\text{:}\mu_2\text{-}MeCO_2^-$ groups and four $\eta^1\text{:}\eta^1\text{:}\eta^2\text{:}\mu_3$ $(py)C(ph)NO^-$ ligands; the remaining two acetates are monodentate, while one terminal MeOH molecule completes octahedral coordination at Ni(2) and Ni(2′). The terminal acetates can easily be replaced by other monoanionic monodentate ligands providing a family of structurally similar $[Ni_4(O_2CMe)_2X_2\{(py)C(ph)NO\}_4(ROH)_2]$ clusters (X = Cl, Br, NCS, $N(CN)_2^-$, …; R = Me, Et, ^{n}Pr, …). Preliminary variable-

temperature magnetic susceptibility data (Fig. 7) are indicative of antiferromagnetic coupling within the cluster with a resultant $S_T = 0$ ground state.[3]

In conclusion, the present work emphasizes the ability of 2-pyridyloximate ligands to form interesting structural types in 3d-metal cluster chemistry. The great structural diversity of the complexes described stems in part from the ability of the (py)C(R)NO$^-$ ligands to exhibit a variety of distinct coordination modes. Results at the time of writing show that employment of β-diketonates or sulfates in the (py)C(R)NO$^-$ cobalt and nickel chemistry give an extraordinary structural flexibility in the resulting ligand "blends". Reactions are also in progress for the substitution of the hydroxo bridges that are present in **2** and salts of $\mathbf{3}^{4+}$ by end-on azido ligands, in an effort to specifically introduce ferromagnetic components in the superexchange scheme of these clusters.

[3] Details will be provided in the full paper.

in 1992 [8]. Here, iron nitrate is dissolved in H_2O and the pH of the solution raised to approximately 3.5 through the addition of pyridine. Addition of the polydentate 'H_3metheidi' (*N*-(1-Hydroxymethylethyl)iminodiacetic acid; {$N(CH_2CO_2H)_2(CH(CH_3)CH_2OH)$}) pro-ligand then crystallizes the product within 1 day in yields up to a maximum of approximately 40%. The structure of this complex is related to the $Mg(OH)_2$ brucite lattice.

We recently discovered [9] that the simple dissolution of Fe(III) halides in pyridine leads to the formation of all-ferric pieces of molecular magnetite of formula Hpy-$[Fe_{17}(O)_{16}(OH)_{12}(py)_{12}X_4]X_4$ (X = halide). Here we report an extension of this study by showing that the pyridine – that acts simultaneously as solvent, base and capping ligand – can be replaced with *'similar'* liquid bases such as isoquinoline, 3,5-lutidine, β-picoline, etc. to form analogous heptadecametallic iron clusters of general formula $HL_x[Fe_{17}(O)_{16}(OH)_{12}(L)_{12}Br_4]Br_{3+x}$ (L = isoquinoline, 3,5-lutidine, β-picoline; $x = 0, 1$).

The synthesis is simple – dissolution of anhydrous $FeBr_3$ in L with stirring leads to a dark red solution which, after approximately one hour, is then filtered and allowed to evaporate. Dark red crystals $[Fe_{17}O_{16}(OH)_{12}(\beta\text{-pic})_{12}Br_4]Br_3$ (**1**); Hisoq$[Fe_{17}O_{16}(OH)_{12}(iso\text{-quin})_{12}Br_4]Br_4$ (**2**) and Hlut$[Fe_{17}O_{16}(OH)_{12}(3,5\text{-lut})_{12}Br_4]Br_4$ (**3**) form within 3 days. Their yields can be improved by adding a co-solvent of crystallization such as MeCN, THF or acetone. **1-3** crystallize in the monoclinic space group $P21/c$; the triclinic space group $P\bar{1}$; and the tetragonal space group $I41/a$, respectively. The three complexes (Fig. 1) contain a central tetrahedral Fe(III) ion linked via μ_4-oxo bridges to 12 outer octahedral Fe(III) ions – forming a truncated tetrahedron (Fig. 2). These ions are linked to each other via a combination of μ_3- and μ_4-oxides, and μ_2-hydroxide ligands. The hexagonal faces of the truncated tetrahedron are capped by four further Fe(III) ions each linked via three μ_3-oxo ligands. The inner Fe(III) ion and the four outer Fe(III) ions sit in the tetrahedral sites of the 'lattice' with the others occupying the octahedral sites. The four bromide ions cap the outer tetrahedral Fe(III) ions with the L molecules capping the octahedral Fe(III) ions. The Fe–O–Fe bridges fall into two clear categories (Table 1): those that connect the tetrahedral Fe(III) ions to the octahedral Fe(III) ions are all characterized by angles in the range ~121–127°, whilst those that bridge solely between octahedral Fe(III) ions are characterized by angles in the range ~93–100°. The oxidation states of both Fe and O centres were confirmed by bond length and charge balance considerations, and bond valence sum (BVS) calculations. An inspection of the cores of **1**–**3** reveal that they are fragments of the iron and oxygen positions defined by the magnetite lattice, however their all-ferric nature is in contrast to the situation in magnetite where half the octahedral sites in the lattice are occupied by Fe(II) ions.

Variable temperature magnetic susceptibility data were collected on complex **1** in the temperature range 300–2 K in an applied field of 900 G. The room temperature

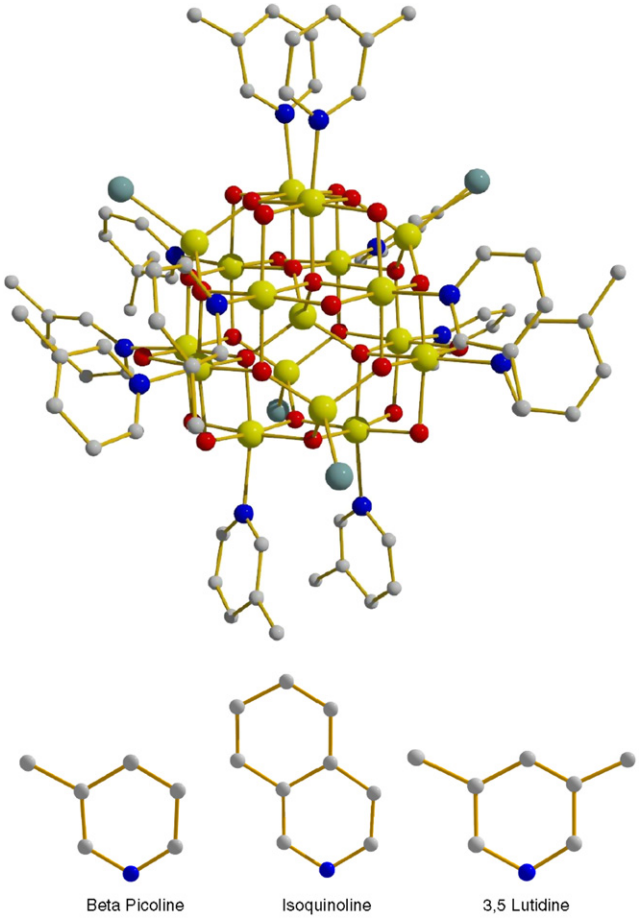

Fig. 1. The molecular structure of complex **1**; colour scheme, Fe = yellow, O = red, N = blue; Br = green, C = grey (top). Structures of β-picoline, isoquinoline and 3,5-lutidine (bottom). (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

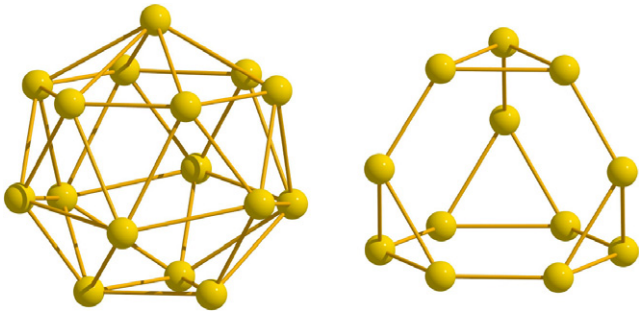

Fig. 2. The metallic core common to complexes **1**–**3**; the central unit is a hexagonal antiprism capped on the upper face by a single Fe ion, and on the lower face by three Fe ions. The truncated tetrahedron formed by the octahedral Fe ions (right). The central tetrahedral Fe ion has been excluded for clarity.

$\chi_M T$ value of approximately 125 cm^3 K mol^{-1} rises constantly as temperature is decreased to a maximum value of approximately 165 cm^3 K mol^{-1} at 75 K, before decreasing to a value of approximately 145 cm^3 K mol^{-1} at 2 K. The spin only ($g = 2$) value for a $[Fe^{III}_{17}]$ unit is approximately 74 cm^3 K mol^{-1}. This behaviour is indicative of

Table 1
Fe–O–Fe angle (°) ranges for complexes **1**–**3**

Complex	Fe–μ_4O–Fe	Fe–μ_3O–Fe	Fe–μ_2OH–Fe
1	93.6–123.3	93.0–127.4	97.4–99.1
2	93.6–123.4	93.8–126.4	93.6–98.7
3	94.0–122.1	93.4–127.3	97.3–100.0

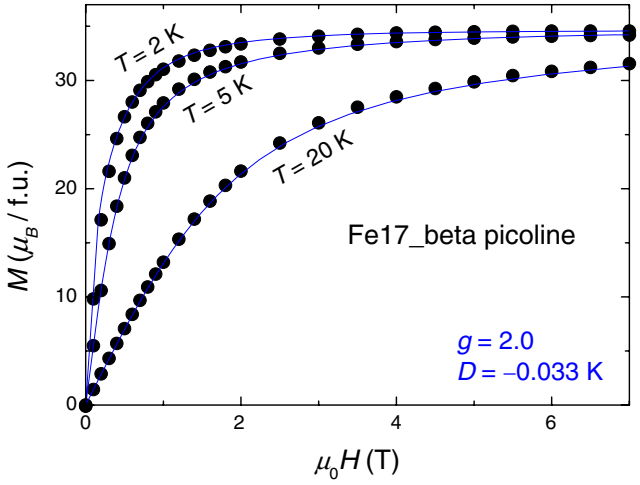

Fig. 3. Isothermal molecular magnetization for complex **1** collected at $T = 2$, 5 and 20 K. The solid lines are a fit of the data – see text for details.

dominant antiferromagnetic exchange between the metal centres with the low temperature maximum indicating an $S \approx 35/2 \pm 1$ spin ground state. The low temperature decrease is likely due to antiferromagnetic inter-molecular interactions. Field-dependencies of the molar magnetization $M(H)$ (Fig. 3) were collected for **1** at $T = 2$, 5 and 20 K. If we consider the single-spin Hamiltonian

$$H = DS_z^2 + g\mu_B \vec{H} \cdot \vec{S},$$

the magnetization in the whole field-range can be fitted with net molecular spin $S = 35/2$, $D = -0.033$ K and $g = 2.00(3)$. This is consistent with the parameters obtained for the analogous pyridine based complex Hpy $[Fe_{17}O_{16}(OH)_{12}(py)_{12}Br_4]Br_4$ (**4**) (Table 2) [10]. The ground state can be rationalized by assuming an antiferromagnetic interaction between the tetrahedral and octahedral Fe(III) sites – consistent with the two distinct categories of Fe–O–Fe bridging angles present in the complex.

In conclusion, simply dissolving $FeBr_3$ in pyridine produces a heptadecametallic cluster that is an all-ferric piece of molecular magnetite. A family of analogous compounds can be made by simply changing the base – that also acts as the solvent and terminal capping ligand. This is therefore a new, simple and extremely attractive methodology for the synthesis of molecular magnetic oxides. Antiferromagnetic exchange between the octahedral and tetrahedral Fe(III) ions, as governed by the Fe–O–Fe bridging angles, leads to the stabilization of an $S = 35/2$ spin ground state.

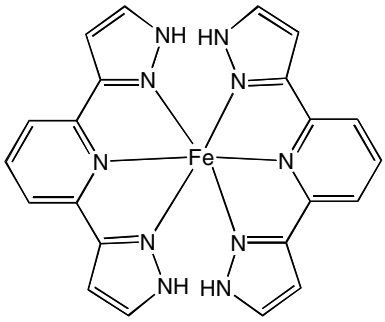

Table 2
Comparison of the magnetic properties of complexes **1** and **4**

Complex	Space group	S	g	D/K
1	$P21/c$	35/2	2.00(3)	−0.033
4a	R-3	35/2	2.06(3)	−0.023
4b	Pa-3	35/2	2.06(3)	−0.023

Details of complex **4** can be found in Ref. 10.

Scheme 1.

of the magnetic orbitals and to larger metal to metal distances. Most of these compounds show Tc's below 3 K, with few exceptions reaching up to 6 K.

The use of "electroactive" cations, instead of the electronically "innocent" ones in the formation of such anionic networks has been one of the most successful approaches to multifunctional materials, where unprecedented multifunctional magnets have been obtained, such as ferromagnetic molecular metals [13,14], chemically-built magnetic multilayers [15], photoactive magnets [16], or chiral magnets [7,8,17]. Most of these examples are built from the hexagonal 2D honeycomb $[M^{II}M^{III}(ox)_3]^-$ networks. The 3D analogs have been much less explored on this regard, probably due to the more synthetically strict conditions needed. Spin crossover complexes [18] and other cations with interesting photophysical properties [19] have been embedded into these 3D systems, but including diamagnetic alkali metals in the network, preventing the appearance of magnetic ordering.

We have been investigating for several years the possibility to use Fe^{II} complexes as templates for oxalate-based magnets. Until now, all our attempts yielded the highly insoluble salts $[A^I][Fe(L)_3][M^{III}(ox)_3]\cdot xH_2O$ (A = Li, Na, K, NH_4^+) [20]. These compounds exhibit indeed spin crossover behavior, but no magnetic ordering is observed, since the paramagnetic centers are isolated from one another in the structure. Here we report how the complex $[Fe(bpp)_2]^{2+}$ (Scheme 1); bpp = 2,6(bis(pyrazol-3-yl)pyridine) that exhibits spin crossover behavior in other simple salts [21] including the LIEST effect [22], is able to be used as cationic guest for bimetallic oxalate-based 3D magnets.

2. Experimental

2.1. Synthesis

All reagents were commercially available and used without further purification The precursor $Ag_3Cr(ox)_3\cdot 3H_2O$ was prepared by metathesis in water from $K_3Cr(ox)_3\cdot 3H_2O\cdot Ag_3Cr(ox)_3\cdot 3H_2O$ (0.098 g, 0.142 mmol) was suspended in 7.5 mL methanol, and then a solution of $MnCl_2\cdot 4H_2O$ (0.042 g, 0.213 mmol) in 7.5 mL methanol was added dropwise. The white AgCl precipitate formed was filtered, and the green solution was added to a red solution of $Fe(ClO_4)_2\cdot H_2O$ (0.090 g, 0.355 mmol) and bpp (0.149 g, 0.71 mmol) in 15 mL of hot MeOH. This solution was refluxed for 2 h. The yellowish precipitate formed was hot filtered, and washed with methanol and acetone. This powder was dissolved in DMF and crystals of $[Fe(bpp)_2][MnCr(ox)_3]_2\cdot bpp\cdot CH_3OH$ (1) were grown from layering this solution with acetone. Yield: 30%. IR (cm^{-1}): 3427, w; 3124, w; 2929, w; 1654, s; 1652, s; 1628, m; 1629, m; 1462, m; 1384, m; 1277, m; 906, w; 811, w; 669, s; 541, m; 478, m; 414, m. $Mn_2N_{15}O_{25}Cr_2FeC_{46}H_{31}$, $M_w = 1463.59$. Elemental *Anal.* Calc.: C, 37.75; H, 2.13; N 14.36. Found: C, 37.12; H, 2.45; N, 15.20%. Desolvation of the sample was carried out by heating the crystals in air at 125 °C for 6 h.

2.2. Structural characterization

A reddish prismatic single crystal of **1** was fixed on a glass fiber and mounted on a Kappa CCD diffractometer equipped with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Cell refinements and data reduction were performed at 150 K using the DENZO and SCALEPACK programs [23]. The structure was solved by direct methods using the SIR97 program [24] and refined on F^2 with the SHELXL-97 program [25]. All atoms belonging to the anionic network were located by successive Fourier transform routines, and refined anisotropically. The cations and solvent molecules, occupying the wholes left in the structure, could no be located due to the presence of severe crystallographic disorder. Two crystallographic independent positions for the Fe centers were found, with partial occupancy. Only the first coordination sphere of N atoms could be located. No good model for these complexes and solvent molecules, including the interstitial bpp moiety could be found due to heavy disorder. Crystal, data collection, and refinement parameters are summarized in Table 1.

Table 1
Crystallographic data and refinement parameters for $[Fe(bpp)_2][MnCr(ox)_3]_2\cdot bpp\cdot CH_3OH$ (**1**)

2.3. Magnetic characterization

Bulk magnetization measurements were carried out on grained polycrystalline samples with a Quantum Design magnetometer with an applied field of 1000 G (0.1 T) in the temperature range 2–300 K, with cooling and warming cycles. AC data was collected in the 2–10 K range with an alternating field of 3.95 G (3.95×10^{-4} T) with frequencies between 1 and 1000 Hz. Hysteresis loops at 2 K were collected between 5 and −5 T. Data were corrected for diamagnetic contributions calculated using the Pascal constants.

2.4. Mössbauer spectroscopy

Mössbauer spectra were collected at different temperatures in transmission mode using a conventional constant-acceleration spectrometer and a 25 mCi ^{57}Co source in a Rh matrix. The velocity scale was calibrated using α-Fe foil. Isomer shifts (IS, Table 2) are given relative to metallic α-Fe at room temperature. Low-temperature spectra were collected using a JANIS bath cryostat. The spectra were fitted to Lorentzian lines using a non-linear least-squares method [26]. The relative areas and widths of both peaks in a quadrupole doublet were kept equal during refinement.

3. Results and discussion

3.1. Synthesis and structure

The insertion of the spin crossover cation $[Fe(bpp)_2]^{2+}$ as guest into oxalate-based bimetallic networks had to start by overcoming the precipitation of the kinetic product $[A^{I}][Fe(bpp)_2][M^{III}(ox)_3] \cdot xH_2O$. This was done following the procedure used in the preparation of other oxalate bimetallic complexes avoiding the presence of any other cations in solution but the transition metal themselves. However, when a solution of $Mn_3[Cr(ox)_3]_2$ is treated with any salt of $[Fe(bpp)_2]^{2+}$, again, an undesired precipitate is obtained. This material could not be structurally characterized. The 2:2:1 ratio found for Fe:Cr:Mn by analysis and the paramagnetic behavior suggest that maybe it is formed by oxalate-bridged trimers [2]. If the same reaction is carried out under reflux conditions for several hours this initial precipitate slowly redisolves to yield a second product, where no traces of this first compound can be found. The main component of this precipitate can be isolated by layering a DMF solution with acetone, to yield a crop of single crystals of $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ (**1**).

The structure of **1** is built from an anionic 3D polymeric oxalate-bridged bimetallic structure. As in the well-known chiral 3D networks, this anionic structure is formed by bischelating oxalate ligands that connect each divalent metal to three trivalent metals, and vice versa, building ten-membered rings in a (10, 3) topology (Fig. 1). The big difference with the reported chiral 3D networks is that, in this case, the compound is achiral. Actually, it belongs to the centrosymmetric monoclinic $P2_1/n$ space group, with metal centers of both chiralities present. This is somehow surprising because it was discussed in the past that only homochiral networks would be able to adopt such a 3D structure.

In this case, Mn(II) and Cr(III) occupy crystallographically different positions, since they are non-equivalent, and can be clearly distinguished attending to the M–O distances. The metal position with longer distances is assigned to Mn^{II}–O (2.05(3)–2.28(3) Å), and the other to Cr^{III}–O (1.94(3)–2.04(3) Å). There are two crystallographically independent Mn and Cr positions in the asymmetric unit, each one belonging to a different chirality, that are bridged together through heterochiral connections. Thus, if we con-

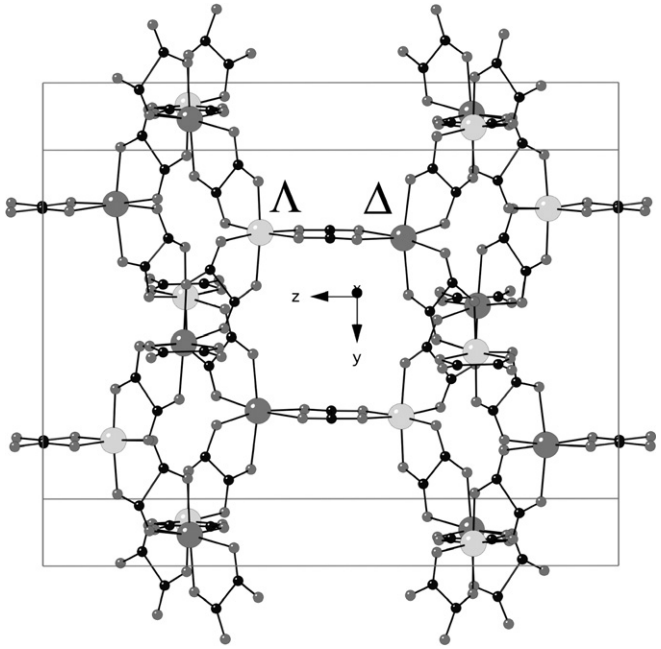

Fig. 1. Two 10-membered rings in the structure of $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ (**1**) of opposite chirality, connected along the c direction.

sider the rings perpendicular to the *a* and *b* axis, these are formed by five adjacent units of one chirality and opposite to that of the other five. The projections of this achiral 3D structure on the *ac* and *bc* planes are almost identical to those of the well-known chiral 3D analogs (Fig. 2), where all three projections (*ab*, *bc*, and *ac*) are identical. On the contrary, the projection on the *ab* plane for compound **1** now shows an eclipsed disposition of the rings (Fig. 3). This can be understood as a relative movement of the rings on this plane to allow for the heterochiral junctions between homochiral rings.

The electron density inside this 3D network could not be assigned to a good chemical model, due to the presence of important crystallographic disorder. One reason for this, when compared with the chiral 3D analogs, is the much higher present of interstitial solvent molecules, since only one Fe complex is present per MnCr pair, and therefore no extra anions are needed as in those. The cationic complexes occupy analogous positions in the crystal structure, but now with half occupancy, since this positions are shared with disordered solvent and free bpp moieties. With the data obtained, only the position for the Fe atoms, including the first coordination sphere of six N atoms could be located.

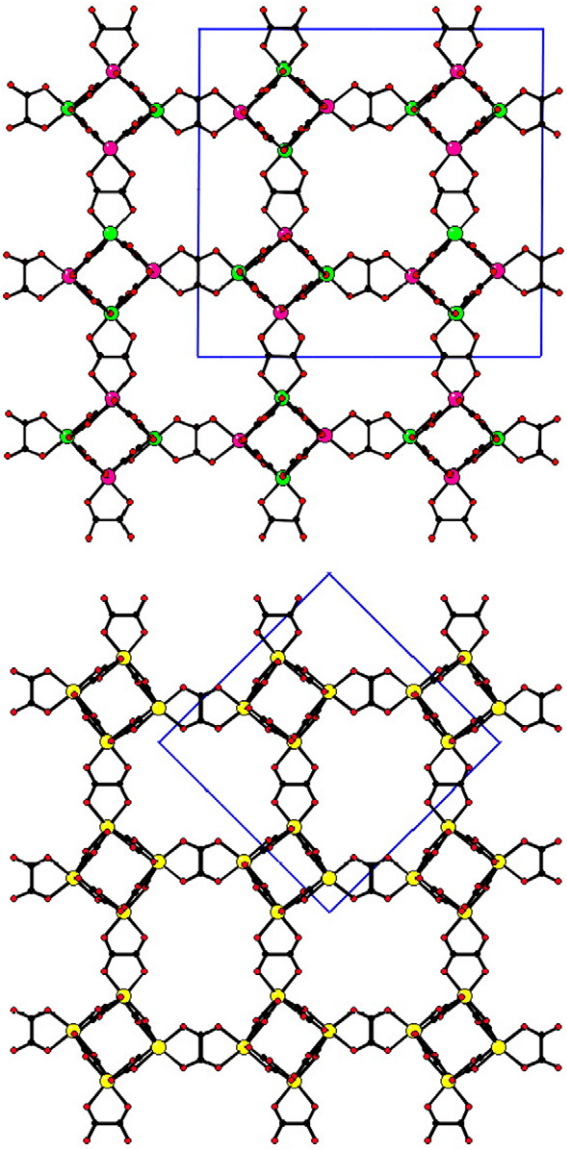

Fig. 2. Projections of the crystal structure of $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ (top) and $[Ru(bpy)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ [7] (bottom) on the *bc* plane.

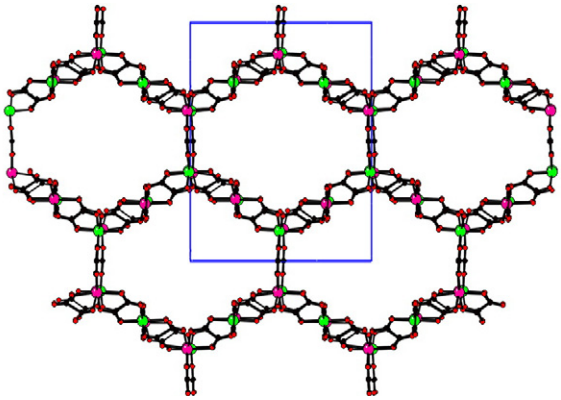

Fig. 3. Projections of the crystal structure of $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ on the *ab* plane.

3.2. Magnetic properties

With exception of the achiral nature of this network, the connectivity between the metals is identical to that of the chiral 3D bimetallic magnets described before and thus, the magnetic properties were expected to be analogous, with the addition of the magnetic behavior of the embedded Fe^{II} complexes. The thermal dependence of the $\chi_m T$ product (Fig. 4) shows a small but continuous decrease when cooling down the sample. Since the interactions

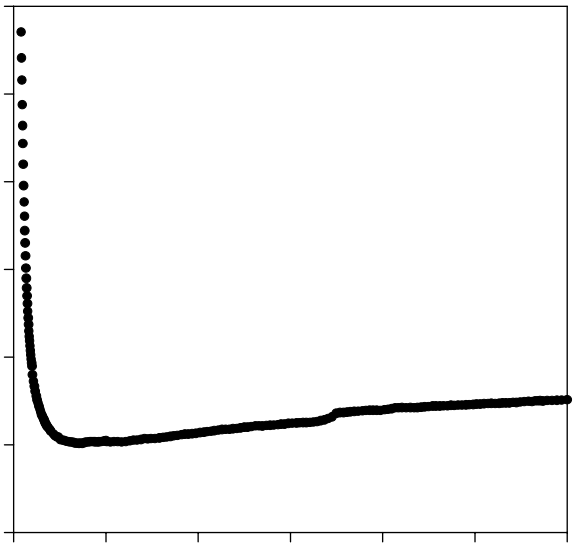

Fig. 4. Thermal dependence of the χT product for $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$.

between Mn^{II} and Cr^{III} centers promoted by the oxalate bridge are expected to be ferromagnetic, this behavior suggests a slow and non-cooperative spin transition for the Fe centers, between high spin (HS) and low spin (LS) configurations. The high temperature regime can be fitted to a Curie Weiss law with a Curie constant of 15.49 emu K mol^{-1}, in perfect agreement with the spin only expected value for a magnetically diluted sample. At 300 K the $\chi_m T$ *is* 15.05 emu K mol^{-1}. This suggests that around 15% of the Fe centers are LS at this temperature. The $\chi_m T$ product reaches a minimum at 35 K (14.03 emu K mol^{-1}) and starts to increase rapidly, due to the ferromagnetic interaction in the network, and suggesting the presence of magnetic ordering at very low temperatures.

AC susceptibility magnetic data (Fig. 5) confirm the onset of ferromagnetic ordering below 3.0 K, with an appearance of a frequency independent out-of-phase signal, accompanying a maximum in the in-phase signal. This temperature is in good agreement with that found for other 3D $[MnCr(ox)_3]^-$ networks, where ferromagnetic ordering is achieved up to 3.9 K [7]. The appearance of ferromagnetic ordering was also confirmed by zero field cooled and field cooled DC measurements at very low applied magnetic fields that deviate from one another at this very same temperature.

The field dependence of the magnetization in the ordered state at 2 K (Fig. 6) shows a very fast increase at low fields and then tends to saturation, although it is not reached even at 5 T, with a value of 15.06μ_B. This is very close to the 16μ_B expected for ferromagnetic alignment of the Mn and Cr centers in the network, and confirms that the magnetic ordering is indeed of ferromagnetic nature. No clear contribution of the Fe centers is found, what suggests that at this temperature most of the Fe centers will be in their LS configuration.

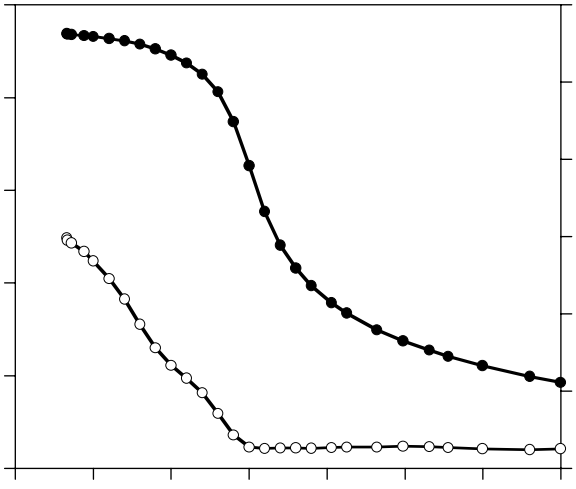

Fig. 5. Thermal dependence of the AC in-phase (χ', full circles) and out-of-phase (χ'', empty circles) magnetic susceptibilities for $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ at 333 Hz.

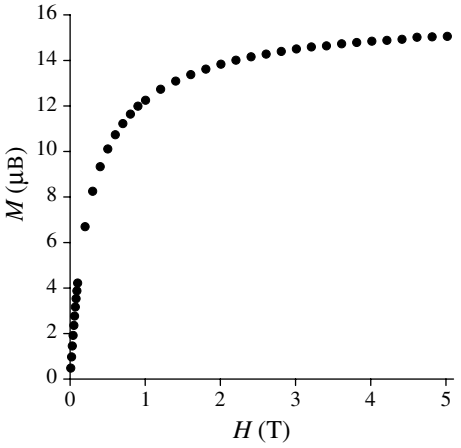

Fig. 6. Field dependence of the magnetization at 2 K for $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ at 333 Hz.

Since desolvation usually affects the spin crossover behavior, we also performed DC magnetic measurements on desolvated samples. We found that the behavior is essentially identical, while the $\chi_m T$ product is slightly lower, indicating that desolvation increases the population of LS Fe^{II}, but it does not affect qualitatively the thermal magnetic behavior of the sample.

3.3. Mössbauer spectroscopy

All the Mössbauer spectra (Fig. 7) may be fitted with two quadrupole doublets. The estimated parameters (Table 2) for the doublet with the largest quadrupole splitting, QS, are typical of HS Fe^{II} with $S = 2$ [27]. The significantly lower QS and IS as well as the temperature independent

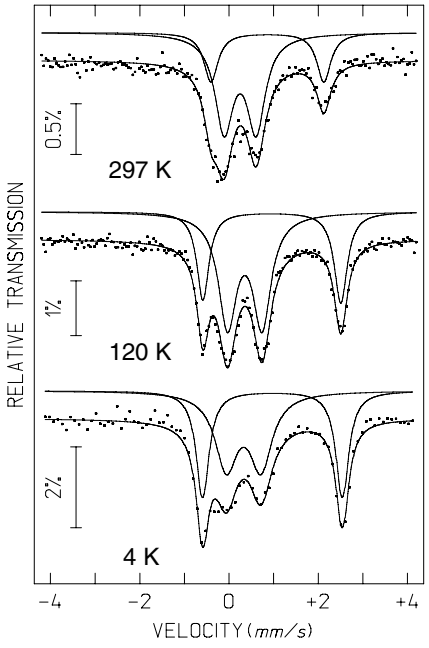

Fig. 7. Mössbauer spectra for $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ at different temperatures.

QS of the other doublet are consistent with LS Fe^{II}, $S = 0$. After heat treatment, QS and the peak widths estimated for HS Fe^{II} change significantly (Table 2). Furthermore estimated relative areas indicate a stabilization of the LS relative to the HS state after desolvation.

If the recoil-free fractions of both HS and LS Fe^{II} are similar in the measured temperature range a much unexpected conclusion is derived: the fraction of Fe^{II} in the HS state significantly decreases with increasing temperature for both untreated and heat-treated samples. As far as we know, such a result has never been reported. A more detailed investigation is however necessary as the observed difference in the temperature dependencies of the HS and LS Fe^{II} relative areas may be due to much stronger chemical bonds established by HS Fe^{II} than by LS Fe^{II}. This would imply a stronger decrease with increasing temperature of the recoilless factor of the LS Fe^{II} as compared to HS Fe^{II}.

4. Conclusions

We have shown how it is possible to obtain molecule-based magnets based on bimetallic oxalate complexes using as template the spin crossover complex $[Fe(bpp)_2]^{2+}$. The compound $[Fe(bpp)_2][MnCr(ox)_3]_2 \cdot bpp \cdot CH_3OH$ shows ferromagnetic ordering below 3.0 K. From the structural point of view, this is the first achiral polymorph to the well-known chiral 3D cubic structure $[Z(L)_3][ClO_4]$-$[MnCr(ox)_3]$ ($Z = Ru$, Fe; $L = 2,2'$-dipyridyl). It was discussed in the past that the extra perchlorate anions were needed to obtain this type of salts. Now we have also demonstrated that this is not true, and these magnets can also be obtained by substitution of half of the cations by solvent molecules. This lower occupancy of cations and anions inside the anionic network could be responsible for losing the enantiopure character of these systems.

The $[Fe(bpp)_2]^{2+}$ units embedded in this oxalate network are not showing a clear spin transition. Apparently, LS and HS centers co-exist at all temperatures. Magnetic measurements suggest that there is a small decrease in the HS population when the temperature is decreased, that would be responsible for the lowering of the magnetic moment. On the other hand, Mössbauer spectra do not support this hypothesis. They suggest quite the opposite, if recoil-free fractions of LS and HS Fe^{II} are assumed to be similar. At this moment there is no satisfactory explanation for these apparently contradictory data. In any case, although magnetic ordering is achieved, the lack of cooperative spin transition in this compound precludes the study of possible synergy between both processes. Other spin crossover complexes, able to better fill the holes in such structural motif would probably be better candidates in the search for such a material.

SMM not simply because of its ease of synthesis and stability in solution but because it displays beautiful hysteresis loops in single crystal *M versus H* studies that possess well defined steps at regular intervals of field indicative of magnetic quantum tunneling [8].

We therefore decided to attempt to make further derivatives of complex **1**, and herein report the syntheses, structures and initial magnetic properties of four such molecules. The complexes $[Mn_9O_7(O_2CMe)_{11}(tmp)(py)_3(H_2O)_2]$ (**2**); $[Mn_9O_7(O_2CMe)_{11}(Hpeol)(py)_3(H_2O)_2]$ (**3**); $[Mn_9O_7(O_2CPh)_{11}(Hpeol)(py)_3(H_2O)_2]$ (**4**); and $[Mn_9O_7(O_2CCMe_3)_{11}(Hpeol)(py)_3(H_2O)_2]$ (**5**) (H_3tmp = 1,1,1-tris(hydroxymethyl)propane; H_4peol = pentaerythritol) are all made in an identical manner, *via* the reaction of the appropriate $[Mn_3O(O_2CR)_6L_3]^{0/+}$ triangle with the appropriate tripodal alcohol in MeCN. All five crystallize in the monoclinic space group $P2(1)/n$.

The metallic skeletons of **2**–**5** (Fig. 1) comprise a series of ten-edge-sharing triangles that describes part of an idealized icosahedron in which three of the twelve vertices are missing. The $[Mn^{IV}_3Mn^{III}_4Mn^{II}_2O_7]^{14+}$ central core can be described as either a series of vertex- and edge-sharing $[Mn_3O]$ units, or perhaps most easily as a $[Mn^{III}_4Mn^{II}_2O_6]^{4+}$ ring on which is sitting a smaller $[Mn^{IV}_3O]^{10+}$ ring. The upper $[Mn_3O]^{10+}$ ring consists only of Mn(IV) ions and is capped on one side by the sole tripodal ligand each O-arm of which acts as a μ-bridge, and on the other side by a μ_3-oxide. The $[Mn^{IV}_3O]^{10+}$ unit is connected to the $[Mn^{III}_4Mn^{II}_2O]^{4+}$ ring *via* six μ_3-oxides within the six-membered wheel and three carboxylates which bridge in their familiar *syn*, *syn*, μ-mode. The remaining carboxylates in the structure bridge between the Mn ions in the $[Mn^{III}_4Mn^{II}_2O_6]^{4+}$ ring in the same manner. The remaining coordination sites are occupied by two water molecules and three pyridines. All the Mn ions are in distorted octahedral geometries, with their oxidation states assigned using charge balance considerations, bond lengths and bond valence sum (BVS) calculations. The Jahn–Teller elongations of the Mn(III) ions all lie approximately perpendicular to the plane of the $[Mn^{III}_4Mn^{II}_2O_6]^{4+}$ ring.

Variable temperature magnetic susceptibility data were collected on **2**–**5** in the temperature range 300–1.8 K in an applied field of 1 kG. For each complex the observed behavior is similar [9]. The room temperature value of $\chi_M T$ of approximately 18 cm^3 K mol^{-1} remains constant until around 200 K where it begins to increase to a maximum value of approximately 37 cm^3 K mol^{-1}at 20 K, before dropping sharply below this temperature. The spin only (g = 2) value for a $[Mn^{IV}_3Mn^{III}_4Mn^{II}_2]$ unit is approximately 30 cm^3K mol^{-1}.The maximum in $\chi_M T$ is indicative of a $S = 17/2 \pm 1$ spin ground state, with the low temperature decrease assigned to zero-field splitting, Zeeman effects and/or intermolecular antiferromagnetic interactions. Magnetization data collected in the ranges 10–70 kG and 1.8–4.0 K for **5** are plotted as reduced magnetization ($M/N\mu_B$) *versus* H/T in Fig. 2. For a complex entirely populating the ground state and experiencing no zero-field splitting, the observed isofield lines should

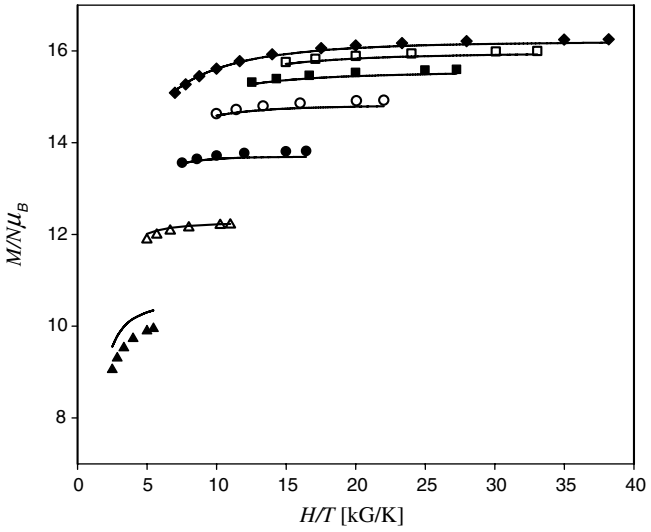

Fig. 2. Plot of reduced magnetization *vs.* H/T for **5**. The solid lines are the fit of the data. See text for details.

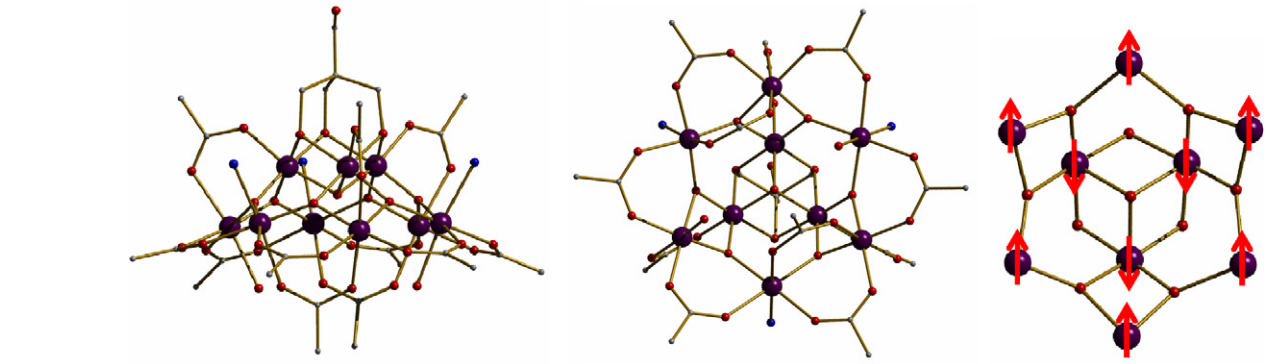

Fig. 1. The molecular structure of complex **5**, viewed parallel (left) and perpendicular (middle) to the $[Mn^{III}_4Mn^{II}_2O_6]^{4+}$ ring; the Me groups of the O_2CCMe_3 ligands and the C atoms of the pyridines have been removed for clarity. The metal–oxygen core common to complexes **1**–**5**, showing the proposed spin topology (right). Colour code: Mn, purple; O, red; N, blue; C, grey. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

superimpose and saturate at a value ($M/N\mu_B$) equal to gS. This is clearly not the case and is suggestive of appreciable ZFS. The data were fitted by a matrix-diagonalization method to a model that assumes only the ground state is populated, includes axial zero-field splitting ($D\hat{S}_z^2$), and carries out a full powder average [10]. The best fit gave $S = 17/2$, $g = 1.98$ and $D = -0.27\ cm^{-1}$. The ground state can be rationalized by assuming an antiferromagnetic interaction between the ferromagnetically coupled Mn(IV) ions in the $[Mn_3^{IV}O]^{10+}$ ring and the Mn(III/II) ions in the $[Mn_4^{III}Mn_2^{II}O_6]^{4+}$ ring (Fig. 1).

The in-phase ($\chi'_M T$) and out-of-phase (χ''_M) ac susceptibility signals for **5** are shown in Fig. 3. The in-phase signal shows a plateau above *ca.* 5 K indicative of an isolated spin ground state. Extrapolation of this slope to 0 K gives a value of $\sim 37\ cm^3\ K\ mol^{-1}$ suggesting a spin ground state of $S = 17/2 \pm 1$ in agreement with the dc data. There is a frequency-dependent decrease in the $\chi'_M T$ signal and a frequency-dependent out-of-phase signal at $T < 5$ K. The peak at 1000 Hz occurs at approximately 3.5 K. Both are strong indicators of SMM behavior. The S and D values obtained suggest an upper limit to the potential energy barrier (U) to magnetization reversal ($U = (S^2 - 1/4)|D|$) of ~28 K. This was confirmed by single crystal hysteresis loop and relaxation measurements performed using a micro-SQUID setup [11]. Studies of the magnetization performed at very low temperature and high fields show that all complexes behave as SMMs with long relaxation times. Fig. 4 presents typical magnetization (M) *versus* applied DC field measurements for **5**. Hysteresis loops are observed, whose coercivity is strongly temperature and sweep-rate dependent, increasing with decreasing temperature and increasing field sweep rate, as expected for the superparamagnetic-like behavior of a SMM. The hysteresis

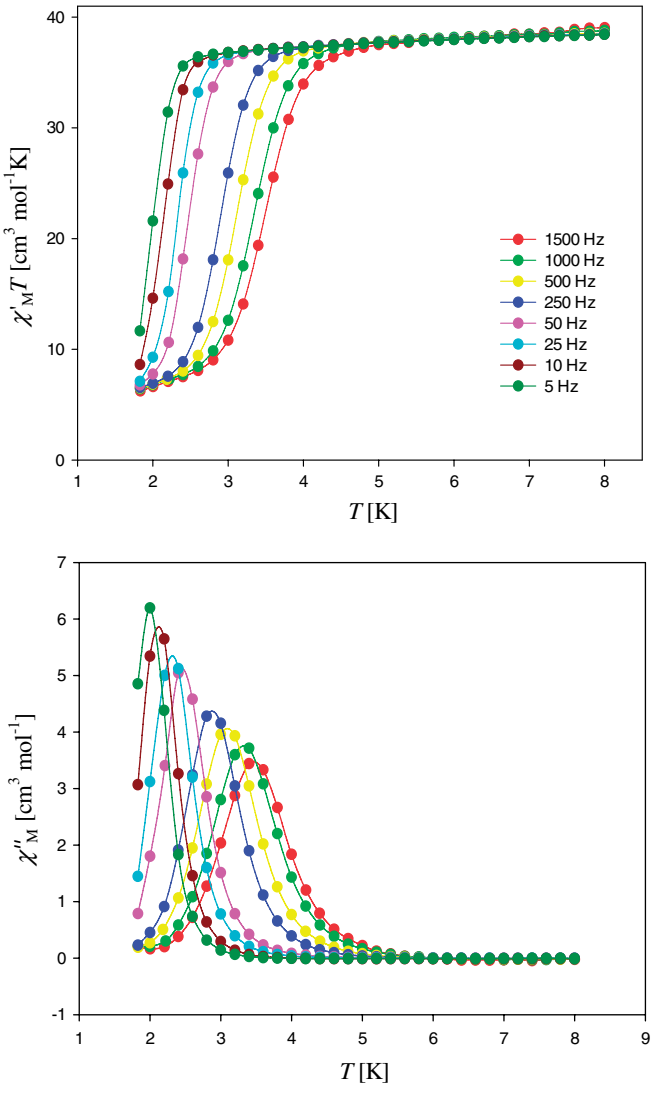

Fig. 3. Plots of the in-phase (χ'_M)) signal as ($\chi'_M T$) and out-of-phase (χ''_M) signal in ac susceptibility studies *vs.* temperature for **5** in a 3.5 G field oscillating at the indicated frequencies.

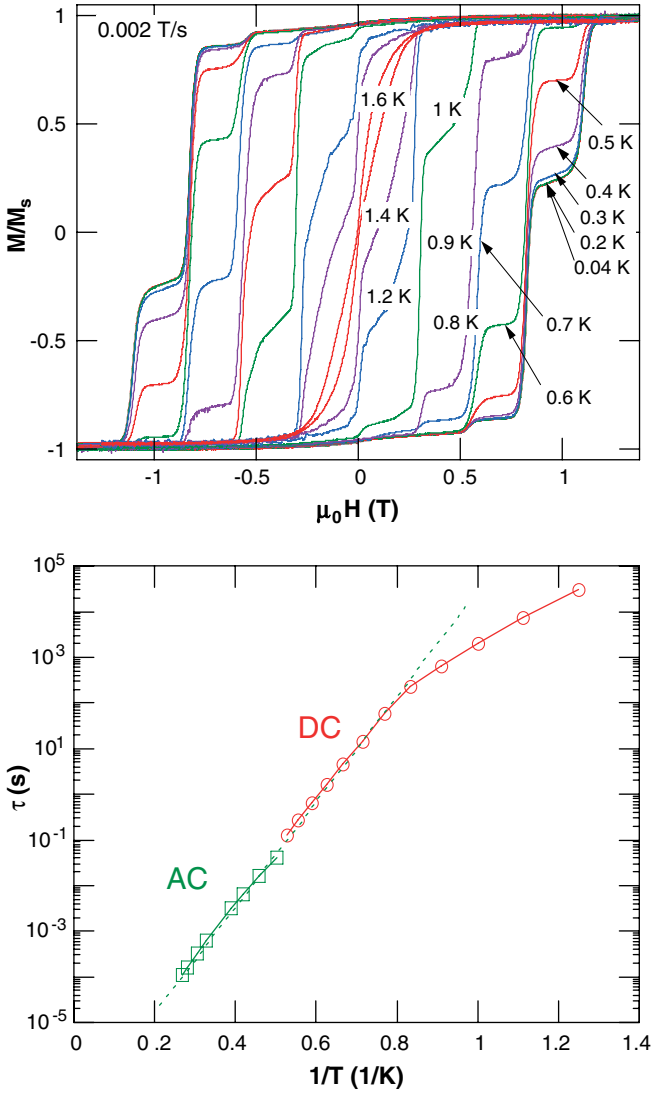

Fig. 4. Single crystal magnetisation (M) *vs.* field (H) hysteresis loops for complex **5** (top) at the indicated field sweep rates and temperatures; the magnetisation is normalised to its saturation value (M_S). Arrhenius plot for **5**; the dashed line is the fit of the thermally-activated region to the Arrhenius equation.

loops show the step-like features indicative of quantum tunneling of magnetization. Relaxation data determined from a combination of single crystal dc relaxation decay measurements and ac measurements on a powdered sample allow the construction of a τ *versus* $1/T$ plot based on the Arrhenius relationship $\tau = \tau_0 \exp(U_{\text{eff}}/kT)$ (Fig. 4). The slope of the thermally-activated region yields an effective energy barrier for the reorientation of the magnetization of 26.5 K with $\tau_0 = 9.6 \times 10^{-8}$ s.

In conclusion, we have successfully made four new analogues of the Mn_9 SMM. These are made *via* analogous reactions choosing the appropriate Mn triangle and the appropriate tripodal ligand in MeCN. Their structures and magnetic properties are similar to the original complex **1** [8]. All display $S = 17/2$ spin ground states and are new examples of high-spin half-integer Mn SMMs. The Mn_9 family have much in common with the prototype Mn SMM $[Mn_{12}O_{12}(O_2CR)_{16}\ (H_2O)_4]^{n-}$ $(n = 1,2)$ family and can be considered their 'baby brothers': not only do they look similar, but in each case the central ferromagnetically coupled Mn(IV) ions couple antiferromagnetically with the surrounding wheel of Mn(III/II) ions, and both have an interchangeable organic 'coat'.

Supplementary material

CCDC 189138 contains the supplementary crystallographic data for **1**–**5**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

We chose to synthesize and examine compounds based on copper chloride and phenazine for comparison to the known copper chloride compounds of pyrazine [17] and quinoxaline [18]. Here we report the synthesis and structural analysis of phenazinodichlorocopper(II) [Cu(phz)Cl_2] (**1**) bis(phenazinium) tetrachlorocuprate(II) monohydrate $(phzH)_2$ [$CuCl_4$] · H_2O (**2**) and di[aquaphenazinodichlorocopper(II)] [Cu(phz)(H_2O)Cl_2]$_2$ (**3**) as well as the magnetic properties of compounds **1** and **2**.

2. Experimental

Reagents were purchased from Aldrich or Aesar Chemical Company and used without further purification. Infrared spectra were recorded on a Paragon 500 Spectrophotometer as KBr pellets and referenced to polystyrene.

2.1. Cu(phz)Cl_2 (**1**)

A solution of $CuCl_2$ (anhydrous) (1.34 g, 0.01 moles) dissolved in 40 mL of methanol was added to a stirred solution of phenazine (1.80 g, 0.01 moles) dissolved in 200 mL of methanol. The resulting solution was covered with Parafilm, with a few small holes punched in it, and placed in a fume hood to evaporate. Red crystals grew after several weeks and were recovered by vacuum filtration, 1.66 g (52%). IR data (KBr) ν 1523m, 1473m, 1434m, 1354m, 1151m, 1125s, 839m, 738s, 601m cm^{-1}.

2.2. $(phzH)_2CuCl_4 \cdot H_2O$ (**2**)

Anhydrous $CuCl_2$ (1.34 g, 0.01 moles) was dissolved in 30 mL concentrated HCl and subsequently diluted with 10 mL of water. Phenazine (1.80 g, 0.01 moles) was dissolved in 85 mL concentrated HCl and subsequently diluted with 115 mL of water. The dark green $CuCl_2$ solution was added slowly to the phenazine solution. The beaker was placed in the fume hood for slow evaporation. After several weeks, orange needles of **2** formed and were isolated by vacuum filtration to give 3.31 g (58%) IR data (KBr) ν 3400br m, 2637br m, 1617m, 1518m, 1422s, 1351m, 1129s, 825s, 764s, 753s, 737s, 594s cm^{-1}.

2.3. Cu(phz)$Cl_2 \cdot H_2O$ (**3**)

A phenazine solution (0.097 M) was prepared by mixing 2.18 g phenazine with 125 mL 95% ethanol. A $CuCl_2 \cdot 2H_2O$ (0.1 M) solution was then prepared by mixing 8.5 g $CuCl_2 \cdot 2H_2O$ into 500 mL 95% ethanol. The product was formed via a slow diffusion method in which one container filled with the phenazine solution and one container filled with the copper chloride solution were placed inside a 1 L beaker. The beaker was slowly filled

with 95% ethanol until the tops of both smaller containers were submerged. This was covered and allowed to sit for several months. Both dark red rods (compound **1**) and yellow/green plates (compound **3**) formed on the sides of the beakers. Small quantities of **3** were manually separated from **1** under a stereomicroscope. No yield was recorded. IR data (KBr) ν 3436br m, 1630br m, 1524m, 1474m, 1434m, 1354m, 1125m, 738s, 601m cm^{-1}.

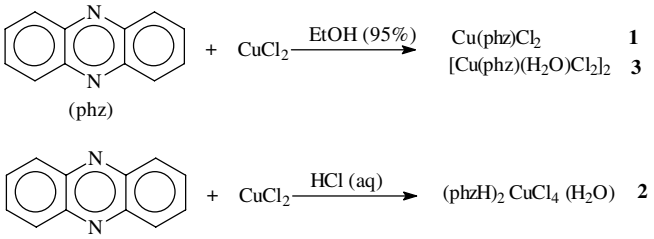
2.4. X-ray data collection and refinement

Crystals of $Cu(phz)Cl_2$ (**1**) (red), $(phzH)_2CuCl_4 \cdot H_2O$ (**2**) (orange) and $[Cu(phz)Cl_2 \cdot H_2O]_2$ (**3**) (green) resulting from slow evaporation or slow diffusion (see above) were analyzed by single crystal X-ray diffraction. Crystal data and experimental details are reported in Table 1. Selected bond lengths and angles are listed in Table 2.

2.5. Magnetic data collection

Magnetic studies were performed at Clark University on a Quantum Designs MPMS-XL SQUID magnetometer. External field dependent magnetic measurements at 1.8 K were also measured on all three compounds in fields up to 5 T. Compounds **1** and **2** were studied in fields up to 30 T at the National High Magnetic Field Laboratory in Tallahassee, FL. Temperature dependent magnetic susceptibility data were collected in the range 1.8–325 K for compounds **1** and **2**. Corrections were made for diamagnetic contributions (DIA) of the samples according to Pascal's constants and for temperature independent paramagnetism (TIP). Compound **3** was also measured, but the data were not reproducible due to an apparent irreversible, temperature-dependent phase change. Limited amounts of material prevented repeated attempts.

In the discussion below, all data have been interpreted in terms of the single J form of the Heisenberg Hamiltonian



$$H = J\Sigma S_i \cdot S_{I+1}$$

where a positive value of J corresponds to antiferromagnetic interactions.

3. Results and discussion

Reaction of one equivalent of copper (II) chloride with one equivalent of phenazine in 95% ethanol gave red crystals of $Cu(phz)Cl_2$ (**1**) and green crystals of $[Cu(phz)Cl_2 \cdot H_2O]_2$ (**3**) (see Scheme 1). In methanol solution, only red crystals of $Cu(phz)Cl_2$ (**1**) were obtained. $(phzH)_2CuCl_4 \cdot H_2O$ (**2**) was obtained from a 1:1 solution of copper (II) chloride and phenazine in diluted HCl solution (see Scheme 1).

Crystals of $Cu(phz)Cl_2$ (**1**) and $(phzH)_2CuCl_4 \cdot H_2O$ (**2**) suitable for X-ray analysis were obtained through slow evaporation, while single crystals of $Cu(phz)Cl_2 \cdot H_2O$ (**3**) were collected from a slow inter-diffusion of 95% ethanol solutions of Cu(II) chloride dihydrate and phenazine. $Cu(phz)Cl_2$ (**1**) crystallizes in the orthorhombic space

Scheme 1.

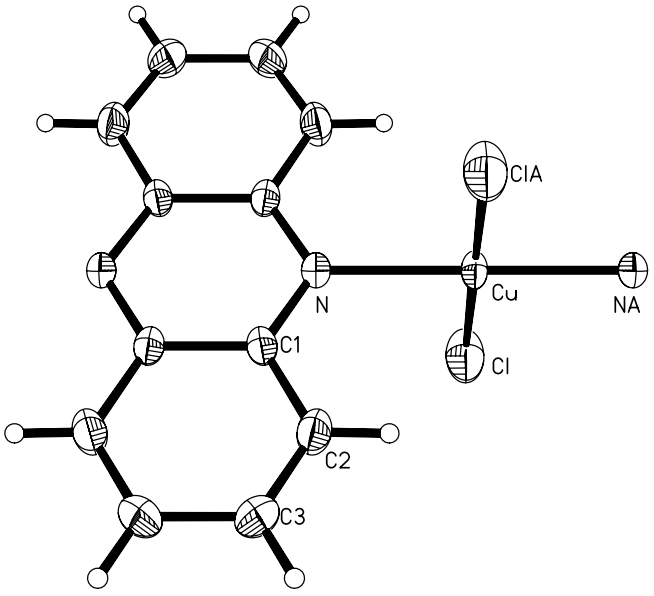


Fig. 1. The molecular structure of $Cu(phz)Cl_2$ (**1**) showing 50% probability thermal ellipsoids. Only the asymmetric unit and the copper coordination sphere have been labeled.

group Pbam (see Fig. 1). The Cu(II) is located in the unit cell at (0,0,0.5) on a two-fold axis and a mirror plane. The local coordination about the Cu ion is square planar with two coordinated phenazine rings and two coordinated chloride ions. The bond angles about the Cu-ion are 90°. The Cu–N bond to the phenazine is 2.067(4) Å which is comparable to the same bond in $Cu(phz)_2Br_2$ and is intermediate in length compared to Cu(I)–N bonds in other phenazine complexes (range 1.977 Å–2.124 Å) [19]. The bond lengths and angles within the phenazine ring are in general unremarkable and compare well with those of phenazine itself [20]. The phenazine ring is planar (mean deviation = 0.0024 Å) and is nearly perpendicular to the Cu coordination plane ($\angle = 89.3°$).

The phenazine ligands link the copper(II) ions into chains parallel to the *c*-axis wherein successive Cu ions are separated by 6.935(1) Å (Fig. 2). Those chains are further linked into sheets along the *b*-axis through π-stacking of the phenazine rings (Fig. 3). The distance between the planes of the phenazine rings is 3.597(1) Å, while the slip angle is 10.6(2)°.

$(phzH)_2CuCl_4 \cdot H_2O$ (**2**) crystallizes in the triclinic space group $P\bar{1}$. The local Cu coordination sphere is a distorted tetrahedron with a mean trans angle of 131.6(1)° (Fig. 4) [21]. The phenazinium ions do not coordinate to the Cu ions through the unprotonated nitrogen atoms as has been observed for some pyrimidine compounds [22]. The Cu–Cl bond lengths range from 2.209(1) Å to 2.286(1) Å. The bond lengths of C(2)–N(1) and C(14)–N(1) are identical to the centro-symmetric structure of the phenazinium

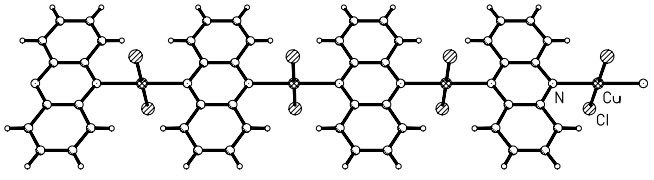

Fig. 2. Detail of the packing diagram for $Cu(phz)Cl_2$ (**1**) showing the chain through the Cu(II) atoms parallel to the *c*-axis.

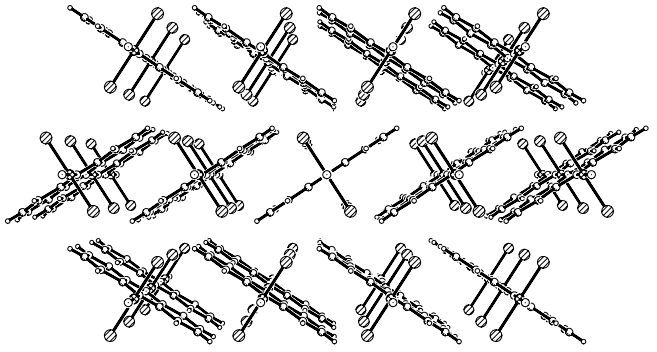

Fig. 3. Packing diagram for $Cu(phz)Cl_2$ (**1**) showing π-stacking of the Cu(phz) chains.

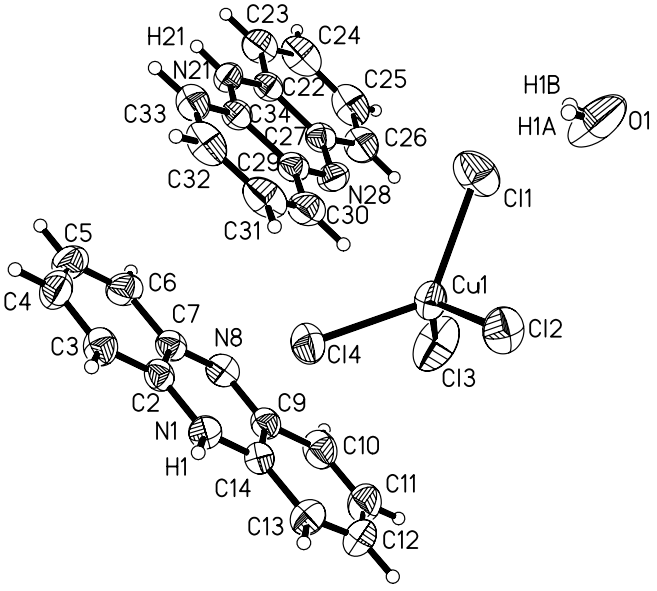

Fig. 4. The molecular unit for $(phzH)_2CuCl_4 \cdot H_2O$ (**2**) showing 50% probability thermal ellipsoids. Only H atoms in refined positions have been labeled.

ligand in (phzH)[Ni(dmit)$_2$]$_3$ [23]; however, the symmetry of the phenazinium ion is reduced in compound **2** as the C(9)–N(8) bond becomes the shortest bond in the central phenazine ring. The N21-containing phenazinium ring exhibits four identical C–N bonds of 1.340(6) Å. Both phenazinium rings are nearly planar with mean deviations of 0.0091 Å (N11) and 0.0426 Å (N21).

Chloride···chloride contacts link the Cu ions into chains parallel to the *a*-axis with successive Cl ions separated by 3.621(1) Å wherein the connection Cu1–Cl1···Cl4A–Cl1A is nearly planar (torsion ∠ = 14.4°) (Fig. 5). Consecutive copper ions are separated by a distance of 7.6934(12) Å. These chains are isolated in the lattice by the phenazinium ions (Fig. 6). The chains are hydrogen bonded to each other by the lattice H_2O molecules to make a ladder motif, but the Cl···Cl distances are too large to support significant magnetic interactions (Fig. 7) (Cl···Cl distance = 4.781 Å; Cu–Cu distance = 7.525 Å). The phenazinium ions in the lattice are nearly coplanar (angle between mean planes = 3.7°) with an interplanar distance of 3.328(1) Å. The phenazinium ions exhibit π-stacking as the C(4) and N(21) ring centroids are separated by a distance of 3.411 Å with alternating slip angles of 12.7° and 9.2°, respectively.

[Cu(phz)Cl$_2$ · H$_2$O]$_2$ (**3**) also crystallizes in the triclinic space group $P\bar{1}$ as a centrosymmetric dimer with the copper ions bridged by chloride ions (Cu–Cu1A = 3.546 Å, see Fig. 8). The Cu ion bonds to the nitrogen in the phenazine ligand with a Cu–N bond length of 2.049(13) Å which is intermediate in length compared to Cu(I)–N bonds in related phenazine complexes [19].

The Cu is bonded to three different Cl atoms (Cl1, Cl2, Cl2A) and a water molecule with bond lengths Cu–Cl = 2.2454(15) Å, 2.2760(14) Å, and 2.5951(13) Å, respectively, and Cu–O = 2.055(3) Å. All bonds, but one, within the central phenazine ring are longer compared to those in phenazine [20]. Using the Continues Symmetry Measure approach [24], the local coordination sphere about the copper is somewhat closer to a square pyramidal configuration with a symmetry factor of 2.183 compared to the 2.601 symmetry factor for a trigonal bipyramid (lower symmetry factors indicate closer agreement with the idealized geometry) [25].

The Cu dimers are linked into layers via hydrogen bonding (see Fig. 9). The dimers are linked into structural ladders due to H-bonding between the coordinated water molecule and the uncoordinated nitrogen on the phenazine ring of the next dimer parallel to the A-face diagonal

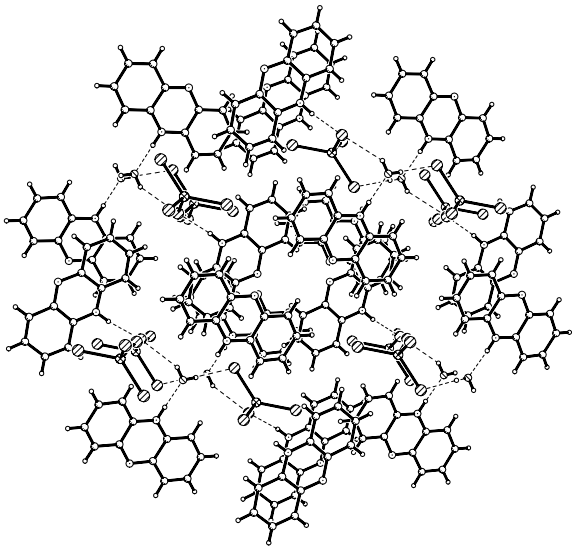

Fig. 6. The packing diagram for (phzH)$_2$CuCl$_4$ · H$_2$O (**2**) showing the alternation of the phenazinium ions through the crystal. Dotted lines represent hydrogen bonds.

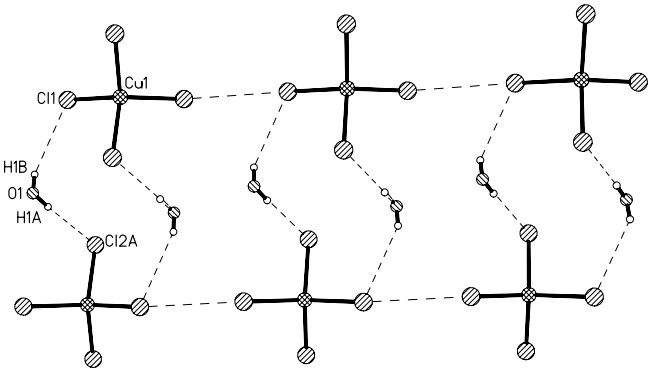

Fig. 7. Detail of chain interactions via hydrogen bonding to the water molecules in the lattice of **2** viewed parallel to the A-face diagonal (the *a*-axis is horizontal) Dotted lines represent hydrogen bonds and close Cl···Cl contacts.

[O1–H1B = 0.75(4) Å, H1B–N = 2.25(4) Å, O1–N = 2.980(5) Å, O–H–N ∠ = 162(5)°]. The ladders are then linked into layers parallel to the *a*-axis via H-bonds between the water molecules and an adjacent Cl1 atom [O1–H1A = 0.77(4) Å, H1A–Cl1 = 2.40(4) Å, O1–Cl1 = 3.136(4) Å, O–H–Cl ∠ = 161(5)°]. π-Stacking between the phenazine ligands also contributes to the layer organization. The distance between adjacent phenazine rings is 3.413(3) Å with a slip angle of 23.9(2)° between the

centroid of the terminal ring and the centroid of the central ring of the successive phenazine. As seen in Fig. 10, the layers are offset parallel to the *a*-axis to minimize the free volume of the crystal.

Infrared data for compounds **1**–**3** are summarized in Table 3. The IR spectrum of the phenazine ligand shows characteristic bands at 1513, 1430, 1359, 1146, 1108, 819, and 742 cm^{-1} which are assigned as previously reported [26]. The expected coordination shifts are observed in **1**–**3** and additional bands are observed in **2** and **3** as a result of the loss of the center of symmetry in the phenazine.

The magnetic susceptibility as a function of temperature between 1.8 K and 325 K of **1** is shown in Fig. 11. The data is characterized by a rounded maximum near 21 K and a local minimum at 6.2 K. This behavior is characteristic of a low-dimensional Heisenberg antiferromagnet with a small paramagnetic contribution that dominates at the lowest temperatures. Considering the linear chain structure of **1**, the data was compared to the theoretical prediction for a $S = 1/2$ Heisenberg antiferromagnetic with a paramagnetic impurity. Three parameters (C, J, and the fraction of paramagnetic impurity) were allowed to the vary and a best fit obtained with values of $C = 0.401(2)$ emu/K-mol, $J/k = 33.8(2)$ K and a paramagnetic impurity fraction of 1.00(5)%. This fit is represented as the solid line in Fig. 11 and is an excellent representation of the data over the entire temperature range.

The molar magnetization of **1** was studied at 1.9 K in fields up to 30 T at the National High Magnetic Field Laboratory. The results are presented in Fig. 12 as the ratio of $M(H/H_{SAT})/M_{SAT}$ versus $H/(H_{SAT})$, where the saturation moment has been calculated from the formula $M_{SAT} = N_A\, g\mu_B/2$ and the value of g (2.07) was obtained from the Curie constant of 0.401(2) emu/K-mol obtained from the fit to the susceptibility data.

The saturation field H_{SAT} was obtained from the molecular-field expression $2H_{SAT} = zk_BJ/(g\mu_B)$ where z is the number of nearest neighbors, using the value of g and J from the susceptibility fit. From these values, $H_{SAT} = 49$ T. As seen in Fig. 12, the magnetization data show the characteristic upward curvature with field, due to the field-induced quenching of the quantum fluctuations in this type of magnetic system.

For this set of experimental data, the ratio of temperature to exchange strength ($T/J = 1.9$ K/33.8 K) equals 0.056. For comparison purposes, the predicted behavior of a $S = 1/2$ Heisenberg antiferromagnetic chain at relative temperatures of 0.05 and 0.10 are shown as well. These two predicted sets only differ by a few percent as the saturation field is approached. The predictions exactly represent the experimental data over the field range measured, confirming both the magnetic one-dimensionality of **1** and the values of C and J obtained from the susceptibility study.

The magnetic susceptibility of **2** as a function of temperature between 1.8 K and 325 K is shown in Fig. 13. The data is also characterized with a rounded maximum, but at a lower temperature, near 5.3 K. This behavior is qualitatively similar to that of **1** and has likewise been compared to the theoretical prediction for an $S = 1/2$ Heisenberg antiferromagnetic chain. Although no low-temperature Curie-like tail is obvious in the data, the best fit was obtained with values of $C = 0.46(1)$ emu/K-mol, $J/k = 8.6(2)$ K and a paramagnetic impurity fraction of 1.23(5) %. This fit is represented as the solid line in Fig. 13 and is an excellent representation of the data over the entire temperature range. The field-dependent magnetization of **2** was measured at 1.8 K in fields up to 5 T. The magnetization is linear up to 1.2 T and shows upward curvature

at larger fields. Based on the molecular field prediction for saturation field described above, it is anticipated that the moments will reach saturation at a field near 12.5 T.

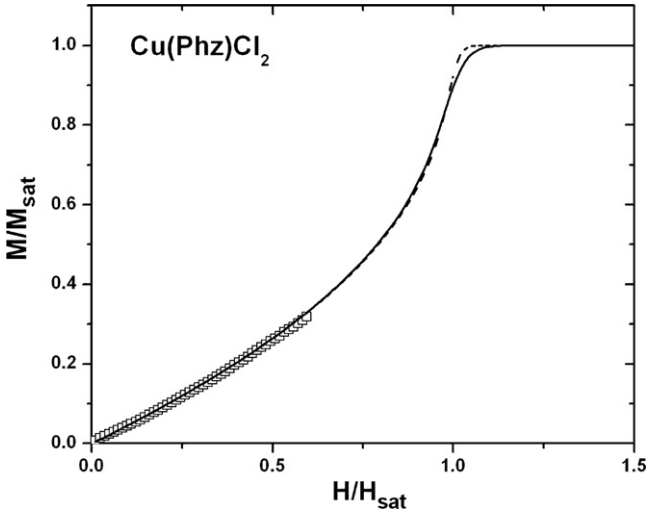

Fig. 12. A plot of moment/saturation moment vs field/saturation field for compound **1**. The squares represent data taken up to 30 T. The dashed and solid lines represent *T*/*J* predictions for 0.05 and 0.1, respectively.

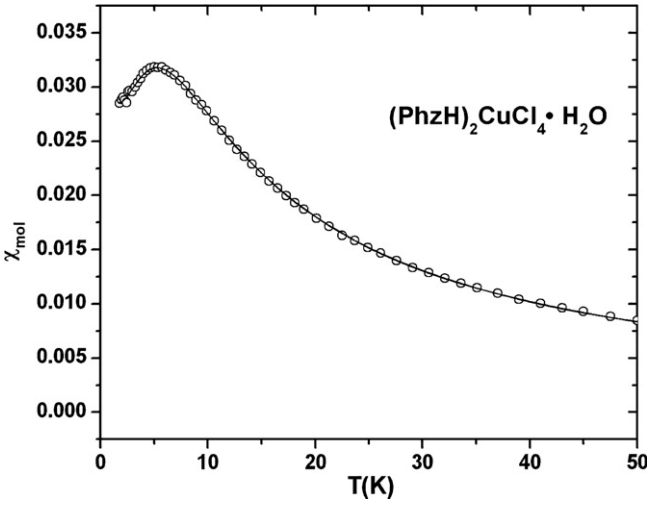

Fig. 13. A plot of χ_{mol} vs temperature for compound **2**. The solid line shows the best fit to the Heisenberg linear chain model.

Attempts to collect magnetic data for **3** were unsuccessful. The sample changed color from green to brown while in the cryostat; different protocols of cooling/heating and application of fields yielded varying and non-reproducible results.

4. Discussion

Compound **3** was a by-product of the synthesis of **1**. During the slow diffusion process in 95% ethanol, both compounds **1** and **3** were produced. Compound **3** was manually isolated from compound **1** under a stereomicroscope. Attempts to prepare compound **3** from aqueous solutions were unsuccessful, most likely due to the insolubility of phenazine in water. We were able to prepare **1** as the sole product**,** however, using absolute methanol as the solvent. The reaction of phenazine and $CuCl_2$ in a concentrated aqueous solution of HCl gave only **2**.

4.1. Structure analysis

The structure of the coordination sphere around the Cu(II) in compound **1** is surprising since it exhibits an idealized square planar geometry with all of the angles 90.00°. The phenazine ligand is also planar (mean deviation = 0.0024 Å) and is nearly perpendicular to the Cu coordination plane ($\angle = 89.3°$). The $\pi - \pi$ stacking of the phenazine rings structurally links the phenazine-bridged chains together along the *b*-axis, but the magnetic interactions are expected to be significantly weaker as evidenced by the excellent fit to the Heisenberg antiferromagnetic chain model, instead of a 2-D model.

In contrast, compound **2**, $(phzH)_2CuCl_4 \cdot H_2O$, contains tetrachlorocuprate(II) anions and discrete phenaznium ions. It is not surprising that this salt forms a magnetic linear chain; such motifs have been observed previously with tetrachlorocuprate systems [27]. As expected, the phenazinium ions are nearly planar and provide the steric bulk and hydrogen bonding which stabilizes the lattice and isolates the chains magnetically. The phenazinium ions are closer together in the lattice than they are in compound **1**, but the π-stacking interactions are still relatively weak.

The dimer, **3**, is unique. No structures for such dimers are reported for any five-coordinate transition metal complexes with water, halides and a coordinated nitrogen, although several related structures with six-coordinate geometries (with the coordinated nitrogen as part of a chelating ligand) have been reported [28]. The coordination sites occupied by the water molecules prevent chain formation as seen in **1** and allow for the structural and magnetic dimer. The symmetry about the inversion center is convenient for the π–π stacking of the phenazine rings and the hydrogen bonding. This allows for the structural layer and ladder motifs to be present within the crystal. The ladder and layer structure might prove to provide interesting magnetic data for this crystal; however, thus far the data has been irreproducible and preliminary results suggest that the coordinated water molecules are easily lost.

4.2. Magnetic data

Pyrazine and substituted pyrazines are well known to provide a superexchange pathway in the range $5 < J < 25$ [1,6–8] while the double halide exchange for chlorides is generally small even though it can be as high as 27 K [29,30]. It is clear from Figs. 11 and 13 that the temperature-dependant magnetic susceptibility data fit very well to a Heisenberg antiferromagnetic linear chain model [31]. Fits to other models (dimers, layers, ...) were also attempted, but the results were clearly poorer.

We have previously reported other S = 1/2 Heisenberg antiferromagnetic linear chains as well with pyrazine, substituted pyrazines, and pyrazine-based ligands such as quinoxaline [32]. The magnetic exchange strengths for these systems differ greatly even though the main superexchange pathway is via a six-membered diazine ring in all cases (see Table 4). The linear chain coordination polymer $Cu(pz)(NO_3)_2$ was originally reported by Santoro et al. [2] and its magnetism studied by Hatfield and coworkers [3] who reported moderate Heisenberg-type exchange ($J/k_B = 10.6$ K).

It appears that as additional rings are added onto the pyrazine ring itself the strength of the exchange increases. The coordination spheres of the compounds are different with the pyrazine and quinoxaline linear chains being nitrate compounds as opposed to chlorides as is the case for **1**. However, the corresponding copper halide compounds of pyrazine [33] and quinoxaline [13] are not linear chains, but rather a layer and a ladder, respectively, and therefore not suitable for direct comparison. Attempts to synthesize $Cu(phz)(NO_3)_2$ have been unsuccessful to date, limiting the usefulness of direct comparison of the magnetic exchange values.

Compound **1**, $Cu(phz)Cl_2$, fits to this linear magnetic chain model ($R^2 = 0.99965$) far better than any other model. This compound has a very strong exchange strength ($|J|/k_B = 33.84(9)$) through the copper, as compared to the other diazine chains [7]. This comparatively strong exchange strength is most likely due to its extremely symmetrical crystallographic structure (Fig. 2).

Compound **2**, $(phzH)_2CuCl_4 \cdot H_2O$, fits almost perfectly to an spin S = 1/2 linear magnetic chain ($R^2 = 0.99973$), even though structurally it is different from compound **1** and the other two diazine-bridged linear chains. $(phzH)_2CuCl_4 \cdot H_2O$ contains its major linear magnetic interactions

Table 4
Comparison of exchange constants

Compound	J/k_B
$Cu(pz)(NO_3)_2$	10.6(2) [8]
$Cu(qnx)(NO_3)_2$	12.82(1) [32]
$Cu(phz)Cl_2$ (**1**)	33.84(9)
$(Phz)_2CuCl_4 \cdot H_2O$ (**2**)	8.59(3)

through the Cl···Cl contacts between adjacent $CuCl_4^{2-}$ groups (Fig. 5). The contact parameters are: $d_{Cl\cdots Cl} = 3.61(1)$ Å, $\angle_{Cu1-Cl1\cdots Cl4A} = 157.78(5)°$, $\angle_{Cu1-Cl4\cdots Cl1B} = 151.56(5)°$, $\tau_{Cu1-Cl1\cdots Cl4A-Cl1A} = 14.4(2)°$. Cu-X···X angles approaching 180° and Cu–X···X–Cu torsion angles near 0° or 180° are correlated with stronger double halide exchange [21] and support the observed exchange strength through the chain of $|J|/k_B = 8.59(3)$ K.

Magnetization as a function of field was also collected for **1** and **2**. Both compounds show the characteristic upward curvature of low-dimensional antiferromagnetic materials (see Fig. 12). Compound **1** was fit to the results of a Quantum Monte Carlo simulation of a 1D chain for a variety of *T*/*J* ratios [34]. Our experimental *T*/*J* ratio was 0.056 and the predictions for ratios of both 0.05 and 0.1 are plotted in Fig. 12. Both values fit the experimental data within the error limit supporting the one-dimensional magnetic nature of the sample.

5. Conclusions

The ability of diazines to provide an effective super exchange pathway has been further demonstrated in the linear chain coordination polymer **1**. The effect of the size and shape of organic cations on the packing of CuX_4^{2-} is shown through the production of the packed linear magnetic system seen in **2**. Regrettably, the instability of **3** prevented the collection of reproducible magnetic data and analysis of the exchange through the bihalide bridge. Further work is in progress on both systems varying the substituents on the phenazine ring and the ancillary ligands on the copper(II).

Scheme 1.

Scheme 2.

calculation than the previous semi-empirical ones showed the basic picture of the characteristics of the MOs near HOMO–LUMO region is essentially unchanged. More importantly, the calculations predicted that the two-electron oxidation leads to a significantly shortened Pc–Pc distance, which has a effect to strengthen the ligand-field potential under which the lanthanide ion is placed.

2. Theoretical calculation

We have employed model complexes $[Pc_2Y]^-$ and $[Pc_2Y]^+$ with D_{4d} symmetry in which two Pc ligands are in skewed positions made by rotating one Pc by 45° around C_4 axis from an eclipsed position. Y was used in the place of Ln, because the ionic radius of Y^{3+} is among those of trivalent lanthanide ions (more specifically, very close to Ho^{3+}).[1] An X-ray crystal analysis by Koike et al. has shown that the geometric structure of $[Pc_2Ln]^-$ smoothly changes with the atomic number of Ln, and only the size of the lanthanide (and yttrium) ion governs the overall geometric structure of the complexes [4].

The B3LYP theory [5] was employed for obtaining fully optimized molecular structures of both anionic and cationic Pc double-decker complexes. For Y atom, we used the LANL2DZ basis set of valence double-zeta quality [6,7], in which inner core electrons are replaced by an effective core potential (ECP). The triple-zeta type 6-311G(d) basis set, which includes d-type polarization function, was used for H, C and N atoms. Since each Pc ligand in the double-decker complex significantly distorted from planarity, inclusion of the d-polarization function is mandatory in obtaining accurate optimized geometry.

The calculations were carried out using the programs GAMESS [8] on a Pentium-D personal computer and GAUSSIAN-98 [9] on a NEC SX-5 vector supercomputer at Global Scientific Information and Computing Center at Tokyo Institute of Technology, Japan.

3. Results and discussion

Fig. 1 shows energy diagrams of Kohn–Sham orbitals near HOMO–LUMO region obtained for $[Pc_2Y]^-$ and $[Pc_2Y]^+$. The symmetric characters of HOMO, next-HOMO, LUMO, next-LUMO of $[Pc_2Y]^-$ are a_2, b_1, e_3 and e_1, respectively. This is exactly the same as that obtained with the semi-empirical calculations previously reported [3]. In a pictorial view in which two Pc ligands (belonging to D_{4h} point group) make a Pc dimer in face-to-face configuration (D_{4d} point group), the a_2 HOMO and b_1 next-HOMO are obtained by antibonding and bonding linear combination of a_{2u} HOMOs of the two Pc monomers. In the cationic complex $[Pc_2Y]^+$, two electrons are removed from the a_2 orbital (Fig. 1, right), which is now LUMO, and the b_1 orbital becomes HOMO accordingly.

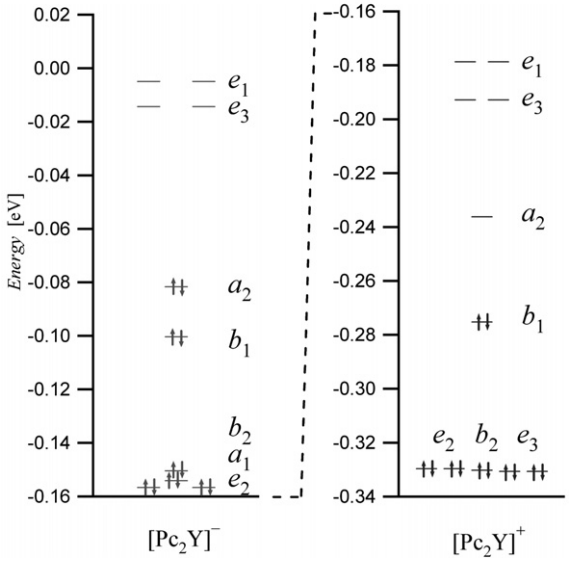

Fig. 1. Energy diagram of Kohn–Sham orbitals of $[Pc_2Y]^-$ and $[Pc_2Y]^+$.

[1] Ionic radius of Ho^{3+} and Y^{3+} are 1.155 Å and 1.159 Å, respectively.

Iso-contour surface of the a_2 HOMO and b_1 next-HOMO of $[Pc_2Y]^-$ are shown in Fig. 2. Inspection of the figure clearly shows the bonding character of the b_1 orbital: the 2p orbitals on the two facing C_α atoms (Fig. 3) on opposite Pc ligands make a bonding linear combination. In contrast, the a_2 HOMO orbital shows anti-bonding linear combination at the same positions. It should be noted that no contribution from Y atom is involved. The ''bond order'' between the C_α atoms in facing Pc ligands has a crucial rule for determining the inter-planar distance since these positions gives the only atom-to-atom contacts (about 3.3 Å) between the two ligands.

Table 1 summarizes theoretical predictions of geometrical changes caused by two-electron oxidation of $[Pc_2Y]^-$. The closest interplanar C_α–C_α distance is predicted to be shortened upon oxidation by ca. 0.10 Å, which is a significant amount. This is a direct effect of the removal of the two electrons in the anti-bonding a_2 HOMO. Since the ''bridges'' connecting two Pc ligands are shortened, the ''Pc–Pc distance'', which can be defined as the distance between the centers of the two Pc ligands, is accordingly decreased by the same degree (bottom, Table 1). The $(N_\alpha)_4$–$(N_\alpha)_4$ distance, which directly affects the LF potential to the lanthanide ion, is shortened by 0.08 Å.

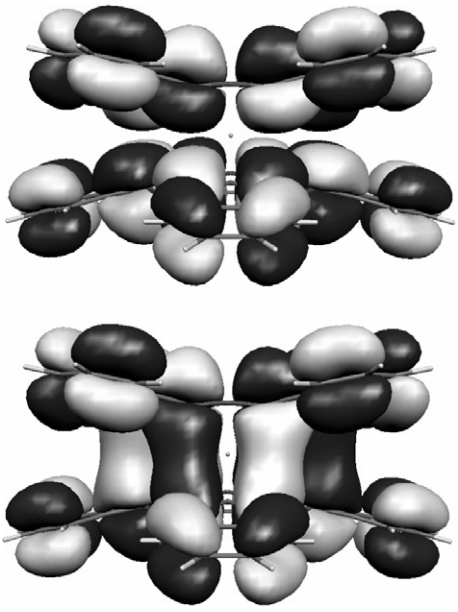

Fig. 2. Iso-contour surface of a_2 HOMO (top) and b_1 next-HOMO (bottom) of $[Pc_2Y]^-$.

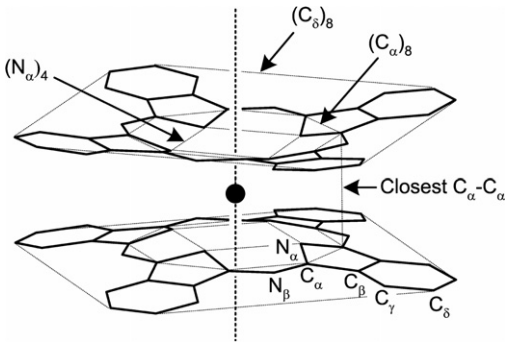

Fig. 3. Planes made by four inner nitrogen atoms, ''$(N_\alpha)_4$'', eight inner carbon atoms, ''$(C_\alpha)_8$'', and eight most-outer carbon C_δ atoms, ''$(C_\delta)_8$''.

Table 1
Closest C_α–C_α and several interplanar distances (Å) of $[Pc_2Y]^-$ and $[Pc_2Y]^+$

	$[Pc_2Y]^-$	$[Pc_2Y]^+$	Difference
Closest C_α–C_α	3.38	3.28	−0.10
$(N_\alpha)_4$–$(N_\alpha)_4$[a]	2.87	2.79	−0.08
$(C_\alpha)_8$–$(C_\alpha)_8$[b]	3.38	3.28	−0.10
$(C_\delta)_8$–$(C_\delta)_8$[c]	5.18	5.15	−0.03
Pc-Pc (C, N)[d]	4.08	4.00	−0.08

[a,b,c] The planes are defined in Fig. 3.
[d] Distance between averaged z coordinates over all C and N atoms in each Pc.

Table 2
Bond lengths and related distances (Å) and angles of $[Pc_2Y]^-$ and $[Pc_2Y]^+$

	$[Pc_2Y]^-$	$[Pc_2Y]^+$	Difference
C_α–N_α	1.368	1.368	0.000
C_α–N_β	1.328	1.328	0.000
C_α–C_β	1.464	1.470	0.006
C_β–C_β	1.404	1.401	−0.003
C_β–C_γ	1.393	1.388	−0.005
C_γ–C_δ	1.392	1.398	0.006
C_δ–C_δ	1.406	1.400	0.006
C_γ–H	1.084	1.084	0.000
C_δ–H	1.086	1.085	−0.001
N_α–Y	2.469	2.440	−0.029
Side of $(N_\alpha)_4$ square	2.840	2.830	−0.010
$\angle(C_\alpha)_8$–(C_α–N_α–C_α)	18.41°	17.73°	−0.68°

Table 2 shows changes of C–C, C–N and C–H bond lengths upon two-electron oxidation. Changes in bond lengths within Pc ligand are not significant compared to the interplanar distances. No bond-length in a Pc ligand is predicted to change by more than 0.006 Å. These results clearly illustrate the effect of the two-electron oxidation to the geometry change of $[Pc_2Ln]^-$: the Pc–Pc distance is significantly shortened while structures of the Pc ligands are essentially unchanged.

The N_α–Y bond length is shortened on the oxidation by ca. 0.03 Å. This is consistent with the decrease of $(N_\alpha)_4$–$(N_\alpha)_4$ length. The side length of the $(N_\alpha)_4$ square is also shortened, as the angle formed by $(N_\alpha)_4$ and C_α–N_α–C_α planes is decreased while keeping N_α–C_α length.

4. Conclusion and perspective

The DFT theoretical calculations predicted that two-electron oxidation of the $[Pc_2Ln]^-$ complexes shortens the interplanar C_α–C_α distance by about 0.1 Å and $(N_\alpha)_4$–$(N_\alpha)_4$ distance by 0.08 Å. This suggests that the ligand field applied to the lanthanide ion is significantly strengthened in the cationic $[Pc_2Ln]^+$ complex. These results gives us expectation that the single-lanthanide-ionic SMM $[Pc_2Tb]^-$ may acquire much larger ligand field splitting, and

accordingly diminished transition rate between "spin-up" and "spin-down" states. We indeed are now undertaking an experimental study, in the light of these interesting results of the theoretical study, towards controlling of dynamic magnetisms of the lanthanide SMMs by ligand oxidation. We have succeeded in establishing preparation methods for two complexes with different oxidation condition in the ligand system, $[(Pc^*)_2Ln]^-N(C_4H_9)_4^+$ and $[(Pc^*)_2Ln]^+(SbCl_6)^-$, where Pc^* is octaethoxyl-Pc. In preliminary AC magnetic susceptibility measurements, we found that the cationic $[(Pc^*)_2Tb]^+$ shows SMM behavior at considerably higher temperature range than the corresponding anionic complex. For example, the χ'' peak for 10^3 Hz AC field was observed at 52 K for the cationic complex which is 12 K higher than the anionic complex. We will report elsewhere the experimental study on the effect of the ligand oxidation to the static and dynamic magnetism of Pc–Tb and Pc–Dy type SMMs.

super paramagnetic particles. At even lower temperatures the thermal energy cannot overcome the anisotropy energy and the system is said to be in the blocked state

$$E_A = KV \sin^2 \theta. \quad (1)$$

Magnetic properties of nanoparticles dispersed in a non-magnetic matrix have been studied previously. For example, studies of Co [11] and MFe_2O_4 (M = Mn and Co) nanocrystals [12] have shown that interactions are concentration dependent, consistent with dipole–dipole interactions. Several models have been put forth to explain the dependence of the energy barrier on interparticle interactions [9,13]. However, to our knowledge, there has been no study of the interactions in dispersions consisting of mixtures of two types of nanoparticles with distinct superparamagnetic properties.

In this contribution, we study the magnetic behaviour of mixtures of superparamagnetic nanoparticles in the bulk. We take advantage of the synthetic control afforded by the choice of the chemical composition [14] and the size distribution [15] to compare dispersions containing nanoparticles with distinct superparamagnetic properties, but very similar sizes and distributions. The results of this study will be contrasted with those of the study of similar nanoparticles encased within a metal oxide matrix [1].

2. Experimental

2.1. Synthesis of metal oxide nanoparticles

We used previously published methods for the preparation of the metal ferrite nanocrystals [15]. The synthesis of these nanocrystals has been described elsewhere [1].

2.2. Transmission electron microscopy

The nanocrystals were imaged in bright field mode using a FEI Tecnai 20 transmission electron microscope, operating at 200 kV. Nanoparticles were dissolved in hexane, and a drop of the solution was allowed to evaporate on a carbon-coated copper grid.

2.3. SQUID magnetometry

Cobalt ferrite nanoparticles (3.21 mg) were weighed in a polycarbonate capsule. Maghemite nanoparticles (0.67 mg) were added to this capsule. A few drops (~3–4) of hexane were added to the nanocrystals resulting in a solution. A few drops (~1–2) of anhydrous ethanol were added to the solution and a precipitate formed. A strong magnet was placed at the bottom of the capsule and the solvent was decanted. The capsule was then dried for 30 min in a furnace at 100 °C. The capsule was then sealed with Kapton tape and inserted in a diamagnetic plastic straw. This gave a sample consisting of 82.7% (w/w) $CoFe_2O_4$. Samples with 62.5%, 50.5%, 32.9% and 15.8% (w/w) $CoFe_2O_4$ were prepared in a similar fashion. The samples consisting of either of the pure nanoparticles were weighed directly in gelatin capsules.

SQUID magnetometry measurements were carried out using a commercial SQUID magnetometer (Quantum Design MPMS XL-7S). Zero-field cooled (ZFC) and field cooled (FC) measurements were carried out by cooling the samples from 400 to 1.8 K in the absence (ZFC) or presence (FC, $H = 100$ Oe) of an applied magnetic field. A field of 100 Oe was then applied, and the magnetization of the sample measured upon warming from 1.8 to 400 K. Magnetization as a function of field measurements was also carried out.

2.4. Mössbauer spectroscopy

^{57}Fe Mössbauer effect spectra in zero applied magnetic field were measured using a Web Research spectrometer operating in transmission mode. The ^{57}Co in Rh source was mounted on a velocity transducer driven in a constant acceleration mode, using a triangular waveform. Detection of the γ-rays was done using a Reuters–Stoke proportional counter. Spectra were calibrated against a 25 μm Fe foil spectrum obtained at room temperature. The samples were prepared by spreading nanoparticles on Parafilm, and sealed with Kapton tape. Samples were cooled in a Janis Research SHI-850 variable temperature closed cycle refrigerator. WMOSS (v. 2.5) Mössbauer spectral analysis software was used for data analysis and fitting.[1]

3. Results

3.1. Transmission electron microscopy

The nanoparticles were imaged using bright field TEM. The nanoparticles appear spherical, and have narrow size distributions (Figs. 1 and 2). The $CoFe_2O_4$ nanoparticles were found to have an average diameter of 5.1 nm with a standard deviation of 0.7 nm, while the γ-Fe_2O_3 nanocrystals have an average size of 5.0 ± 0.6 nm. The nanoparticles were not agglomerated. In particular, no direct contact between nanoparticles is observed, and we believe this is due to the presence of the oleic acid surfactant at the surface of the nanoparticles. Direct magnetic exchange between nanoparticles is prevented, and the magnetic particles will be coupled primarily via dipole–dipole interactions.

3.2. ^{57}Fe Mössbauer effect spectroscopy

The analysis of low-temperature ^{57}Fe Mössbauer spectra is a useful tool for the differentiation of magnetite (Fe_3O_4) from maghemite (γ-Fe_2O_3) both of which can be formed in this general synthesis [15–17]. These materials

are not easily distinguished using diffraction techniques due to their similar lattice parameters and structures [18,19].

The 4.2 K spectrum of the iron oxide nanoparticles used in this study is presented in Fig. 3. The spectrum consists of six lines and the highest velocity line is clearly asymmetric. The spectrum is consistent with being composed of two sextets. The sextet with the smaller isomer shift is responsible for 35.4% of the observed signal. The individual components and the fit line of the two sextets are also shown in Fig. 3. The parameters corresponding to the fit are presented in Table 1.

The values for the isomer shifts suggest that both observed sextets originate from high spin iron(III) [20]. This result also excludes the possibility of the sample consisting of Fe_3O_4, which contains both Fe^{3+} and Fe^{2+} in octahedral sites, which exchange faster than the ^{57}Fe Mössbauer measurement timescale. Consideration of published values [21] indicates that these data are consistent with the assignment of the nanocrystals as maghemite. The structure of maghemite is closely related to that of magnetite (and cobalt ferrite), but contains vacancies on the cation sublattice. As such, γ-Fe_2O_3 may be viewed as $[Fe]^{tet}[Fe_{5/3}\square_{1/3}]^{oct}O_4$, with octahedral (B) and tetrahedral (A) iron sites wherein $\square$ represents a vacant site [19]. The two observed isomer shifts are hence associated with the A and B sites and the assignment given in Table 1 follows the literature assignment.

The 4.2 K spectrum of the $CoFe_2O_4$ nanoparticles is presented in Fig. 4. The spectrum is qualitatively similar

to the maghemite spectrum and could be fit to two sextets. The relative areas and values of the isomer shifts and hyperfine fields are presented in Table 1.

The two sextets arise from the presence of ferric ions in tetrahedral (A) and octahedral (B) sites in the spinel structure of $CoFe_2O_4$. The degree of inversion x, which represents the fraction of M^{2+} cations in octahedral sites, can be determined from the Mössbauer spectra using

$$\frac{I_A}{I_B} = \frac{f_A}{f_B}\frac{x}{2-x} \tag{2}$$

in which I_A and I_B are the relative intensities due to subspectra due to iron in sites A and B, and f_A/f_B is the recoil-free fraction of ^{57}Fe nuclei in octahedral and tetrahedral sites. We assume the value of f_A/f_B at 4.2 is the same as the fraction estimated at 0 K, at which temperature it is equal to 1 [22]. From the values presented in Table 1 and Eq. (2), we find that our nanoparticles have the inverse spinel structural formula, with a cation distribution of $[Fe]^{tet}[CoFe]^{oct}O_4$.

3.3. SQUID magnetometry

A sample of γ-Fe_2O_3 nanocrystals was cooled in the absence of an applied field and the magnetization measured upon warming in an applied field of 100 Oe. The resultant ZFC measurement is shown in Fig. 5. At low temperature the magnetization is small and increases with increasing temperature. The magnetization reaches a maximum at 22 K. Increasing the temperature results in a loss of magnetization of the sample.

The result can be understood in terms of the forces which act upon the magnetization vector of the individual nanoparticles. When the sample is cooled in the absence of a magnetic field (ZFC) the magnetization vector of each nanoparticle will align with the easy axis of the crystal. Since the nanoparticles are randomly oriented, this results in a random orientation of magnetization vectors, and the observed small magnetization of the sample. As the temperature is increased in the presence of an applied magnetic field, magnetization vectors will align with the poling field, resulting in an increase in magnetization. As temperature is increased, the poling effect of the applied field will be overcome by thermal energy, and the magnetization vectors will start to fluctuate, which will result in a loss in magnetization. The overall effect is a rise and subsequent decay of the magnetization. The blocking temperature is identified as the maximum in the magnetization curve which we observe at 22 K for γ-Fe_2O_3 samples nanocrystals.

A similar experiment was conducted with $CoFe_2O_4$ nanocrystals and the result is shown in Fig. 5. The qualitative features are as was observed for the γ-Fe_2O_3 nanocrystals. The magnetization was minimal at low temperature, reached a maximum, and then decreased as the temperature was increased. The observed blocking temperature for the $CoFe_2O_4$ nanocrystals was 150 K.

The higher blocking temperature observed in cobalt ferrite is consistent with the relative anisotropy constant for the two materials. The anisotropy constant for cobalt ferrite is higher than that of maghemite (18×10^5 vs. 0.47×10^5 erg/cm^3, respectively) [12,23]. In particles of similar volume, this is the dominant contribution which results in a significantly higher anisotropy energy barrier, according to Eq. (1). This barrier is in effect the barrier to changing the orientation of the magnetization vector in the absence of an applied field. When an external field is present the barrier to aligning with that field is reduced. As the temperature is increased, the higher thermal energy results in a greater number of magnetization vectors being able to overcome the barrier. The result is that a greater number of magnetization vectors align with the field, and as such the observed magnetization increases until the blocking temperature is reached [7]. The blocking temperature is hence related to the anisotropy barrier.

The magnetization of the nanocrystals was also measured following cooling of the samples under an applied filed (FC) of 100 Oe. Samples of maghemite nanocrystals had a high magnetization at low temperature which decreased slightly with increasing temperature until the temperature approaches the vicinity of the blocking temperature. Upon farther warming, the magnetization continues to decrease, albeit with a more pronounced temperature dependence. This is the expected behaviour.

When the sample is cooled in the presence of an applied field (FC), the magnetization vectors will be predominantly aligned with the poling field. At low temperature, a high magnetization will be measured. As the temperature is increased the thermal energy overcomes the alignment forces resulting in a decrease in the magnetization which becomes more pronounced above the blocking temperature.

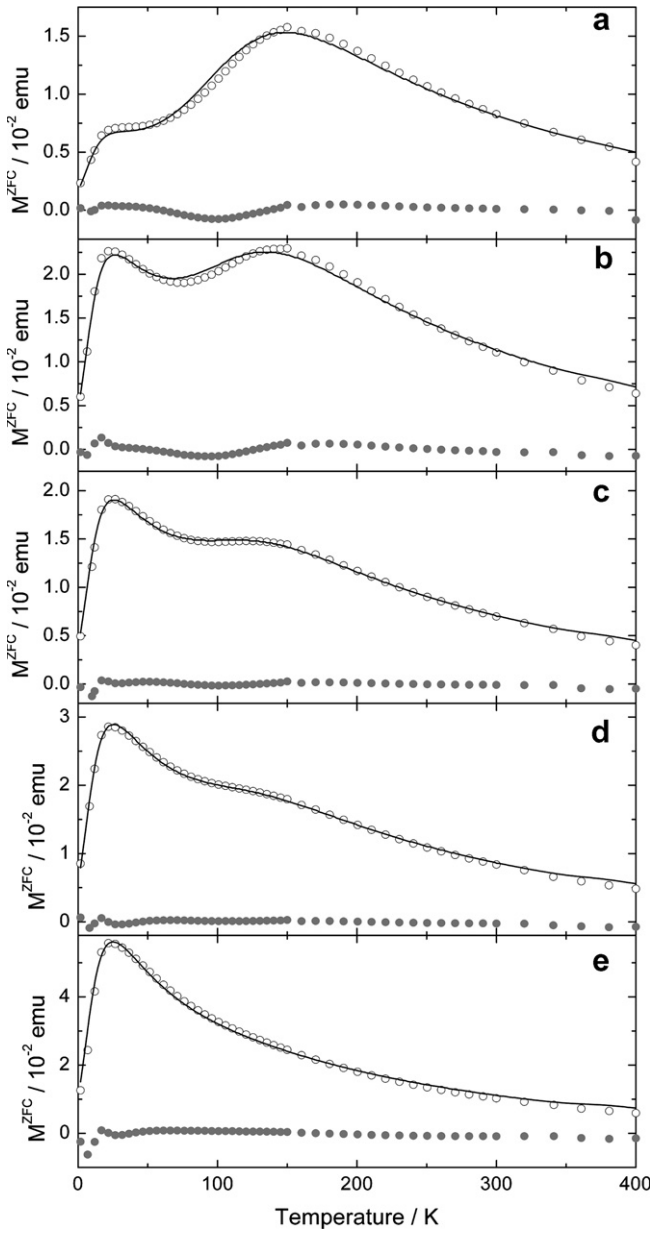

Fig. 6. Experimental (○○○) and fit (—, see text) magnetization curves for zero field cooled mixtures of $CoFe_2O_4$ and γ-Fe_2O_3 nanoparticles consisting of 83 (a), 65 (b), 51 (c), 33 (d), and 16 (e) percent weight $CoFe_2O_4$ measured in a 100 Oe field . Fit residuals are also shown (●●●).

A similar result was obtained for the FC magnetization measurements for cobalt ferrite nanocrystals. A high magnetization is observed at low temperature. As the temperature is increased the magnetization decreases. The loss of magnetization with temperature change increases beyond the blocking temperature of cobalt ferrite at 150 K.

ZFC magnetization measurements were also obtained for mixtures of the $CoFe_2O_4$ and γ-Fe_2O_3 nanoparticles. In Fig. 6a the magnetization curve for a 83% (w/w) $CoFe_2O_4$ nanoparticle mixture is shown. At low temperature, the magnetization is low. As the temperature is raised, the magnetization increases, and then levels off in the region of 20 K. Further increase in temperature results in a further increase in magnetization and a maximum in the magnetization in the region of 150 K. Further increase in the temperature results in a decrease in the observed magnetization.

This behaviour is as anticipated for a non-interacting mixture of two types of nanoparticles. In the zero field cooled experiment the magnetization vectors are aligned with the easy axis of the individual nanocrystals. As the temperature is increased the magnetization vectors of the γ-Fe_2O_3 nanoparticles become free to move and align with the poling field. This results in the initial rise in magnetization which forms a plateau in the region of 20 K. As the temperature is further increased the magnetization of the sample increases as the effect of the poling field overcomes the alignment of the $CoFe_2O_4$ nanoparticles magnetization vector with respect with their easy axis. The magnetization reaches a maximum at 150 K corresponding to the maximal alignment of the $CoFe_2O_4$ nanoparticles.

If there is no interaction between nanoparticles then we may expect that the observed magnetization as a function of temperature, $M^{ZFC}_{total}(T)$, would simply be a weighted average of the magnetization curves (Eq. (3)) of the constituent nanoparticles, $M^{ZFC}_{\gamma\text{-}Fe_2O_3}(T)$ and $M^{ZFC}_{CoFe_2O_4}(T)$, which could be parametrically fit using Eqs (4) and (5):

$$M^{ZFC}_{total}(T) = m_{CoFe_2O_4} \cdot M^{ZFC}_{CoFe_2O_4}(T) + m_{\gamma\text{-}Fe_2O_3} \cdot M^{ZFC}_{\gamma\text{-}Fe_2O_3}(T), \tag{3}$$

$$M^{ZFC}_{CoFe_2O_4}(T) = \frac{a + bT + cT^2 + dT^3 + eT^4}{1 + fT + gT^2 + hT^3 + iT^4 + jT^5}, \tag{4}$$

$$M^{ZFC}_{\gamma\text{-}Fe_2O_3}(T) = \frac{a' + b'T + c'T^2 + d'T^3 + e'T^4 + f'T^5}{1 + g'T + h'T^2 + i'T^3 + j'T^4 + k'T^5}. \tag{5}$$

In these equations, the magnetization is in emu g^{-1}. The best fits are shown as solid lines in Fig. 5.[2]

Using Eqs. (4) and (5), the ZFC magnetization of the cobalt ferrite and maghemite nanoparticle mixture was

[2] See Supplementary Information for parameter values.

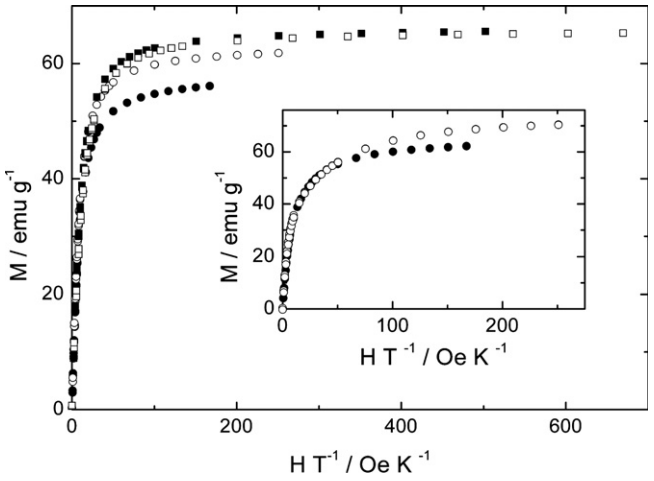

Fig. 7. Magnetization of γ-Fe_2O_3 nanoparticles as a function of field measured at various temperatures above the T_B: 300 (●), 200 (○), 100 (■) and 75 (□) K. The inset figure provides the data for $CoFe_2O_4$ nanoparticles.

fit. The weighting of the contribution from each curve was varied to provide the best fit shown as the solid line in Fig. 6a according to Eq. (3). Using Eq. (3) the mass fraction was determined to be 85%.

Similar results were obtained for each of the nanoparticle mixtures studied. In all cases, two maxima are observed, corresponding to maghemite, at lower temperature, and cobalt ferrite at higher temperature, nanoparticles going through a blocked-superparamagnetic transition. As the amount of cobalt ferrite is decreased in the mixture, the amplitude of the second maximum (cobalt ferrite) decreases with respect to the first (maghemite). The fits obtained from Eqs. (3)–(5) are the solid lines shown in Fig. 6.

Magnetization vs. field measurements were carried out on the γ-Fe_2O_3 nanoparticles at 300 K, in a field of up to 50 kOe. The magnetization increases with applied field and approaches saturation. Upon decreasing the field no hysteresis was observed. The result is shown in Fig. 7 and is as expected for a superparamagnetic sample.

Similar data were obtained at other temperatures above the blocking temperature, and for the cobalt ferrite nanoparticles, also above their blocking temperature. In each case the same behaviour was observed. These results are summarised in Fig. 7. Magnetization versus field curves were also obtained for the nanoparticle mixtures studied here. The results were qualitatively similar.

4. Discussion

The nanoparticles used in this study were prepared by the general method of solvothermal decomposition of metalorganic precursor in the presence of surfactants in a high boiling point solvent. The specific synthesis used here was that of Sun and coworkers who reported the preparation of 6 nm nanoparticles of Fe_3O_4 under these conditions [15]. In our hands the result was the formation of 5 nm nanoparticles of maghemite. This result is not unexpected as previous workers had shown using a similar thermolysis method that the material obtained in the synthesis changed from magnetite to maghemite when the size of the nanoparticle was reduced from 9 to 5 nm [16].

The nanoparticle mixtures were all prepared by forming a solution of both nanoparticles then precipitating the mixture of nanoparticles from this solution. The separation was aided by a strong magnet. The magnet was sufficiently strong that it appeared that all the precipitated material was retained in the capsule as the liquid phase was decanted. Given this observation we do not believe that the reprecipitation altered the size distribution of the sample. Similarly there was no indication that the coprecipitated sample was not intimately mixed and in the discussion of the magnetism we assume intimate mixing was obtained by this procedure.

The magnetization of an ideal superparamagnetic particle with magnetic moment μ_P is described by the Langevin function given as Eq. (6). Acceptable fits were obtained for each of the magnetization versus field measurements indicating that the sample behaved as a superparamagnet. Since the Langevin function depends only on the experimental variable H/T magnetization measurements at various temperatures are expected to scale with H/T [7]. This is clearly not the case, as can be seen in Fig. 7

$$M^{\mathrm{LAN}}(H,T) = M_S\left\{\coth\left(\frac{\mu_P H}{k_B T}\right) - \frac{k_B T}{\mu_P H}\right\}. \quad (6)$$

That the magnetization at various temperatures does not scale as indicates that the system is not a simple superparamagnet. The difference is presumably indicative of a temperature dependent change in the individual magnetic moments, μ_P which comprise the superparamagnet. This behaviour would not be possible if the magnetic moments which form the ensemble were the moments of individual nanoparticles (and hence constant) but are indicative of a cluster contributing the magnetic moment. If the cluster size or internal coupling were a function of temperature then the lack of scaling with H/T would be explained.

Evidence for the cluster interpretation arises from the fits of individual magnetization vs. field measurements. For example magnetization vs. field measurements at 300 K for each of the pure nanoparticles were fit to a Langevin function with additional first and second order terms in the susceptibility [8], in which $M(H,T) = M^{\mathrm{LAN}}(H,T) + \chi^{(1)}H + \chi^{(2)}H^2$. The curves and accompanying best fits are presented in Fig. 8. The magnetic moments μ_P extrapolated from the fits are $3565 \pm 25\ \mu_B$ and $4200 \pm 100\ \mu_B$ for the γ-Fe_2O_3 and $CoFe_2O_4$ nanoparticles, respectively. Fits to the simple Langevin function gave qualitatively similar results but the corrections provided a better fit.

The measured values of μ_P can be compared with calculated values based on the particle size. The expected magnetic moment for a nanoparticle is given by $\mu_P = M_S \rho V$

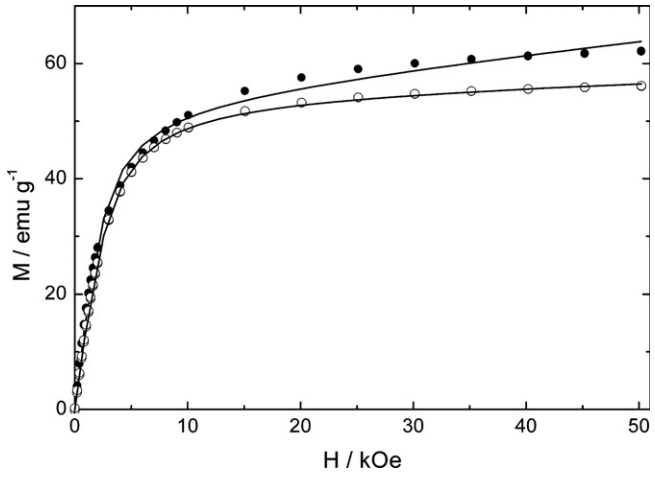

Fig. 8. Magnetization as a function of field measured at 300 K for $CoFe_2O_4$ (●●●) and γ-Fe_2O_3 (○○○) nanoparticles. Lines are best fits obtained using a Langevin with first and second order susceptibility terms model (see text).

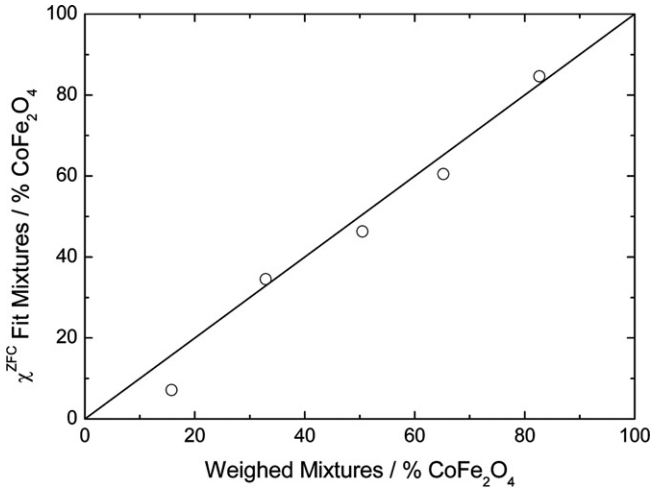

Fig. 9. Comparison between the composition of the samples from weighing and from fitting the ZFC measurements using the Eqs. (3)–(5) described in the text. The solid line represents the identity relationship.

wherein M_S is the saturation magnetization, ρ is the density and V is the volume of the nanoparticle. Using the average sizes determined from the TEM measurements and typical values for M_S and ρ($M_S \sim 80$ and ~ 75 emu g^{-1} and $\rho \sim 4.86$ and 5.3 g cm^{-3} for maghemite and cobalt ferrite, respectively) [24,25], one expects μ_P values of $\sim$2750 and $\sim 3000\mu_B$ for the maghemite and cobalt ferrite nanoparticles. These estimations are in fact upper limits, as it is common for the saturation magnetization of nanoparticles to be below the bulk values used above (see Fig. 8). This is usually attributable to the presence of a magnetically disordered layer at the surface of the nanoparticle [26]. Both of the calculated values of μ_P exceed the measured values substantially.

We believe that these higher than expected magnetic moments are attributable to the presence of clusters of a few correlated nanoparticles, similar to magnetic domains, in which the nanoparticles are coupled in an overall enhanced magnetization state. The mechanism responsible for these clusters is likely to be the same as in two-dimensional assemblies [4,5]. Such nanoparticulate clusters have also been proposed by Zhang in dispersions of $CoFe_2O_4$ nanoparticles [12].

Similar measurement were conducted with the mixtures of nanoparticles. The results are qualitatively similar to the pure nanoparticles. The overall magnetic moments which formed the superparamagnet were larger than the calculated moments of the individual nanoparticles indicating cluster behaviour. The apparent size of the clusters in the mixed nanoparticles was slightly increased over the weighted size from the pure nanoparticles, but it was not clear that this effect was significant.

The ZFC magnetization measurements of the nanoparticle mixtures were fit using Eqs. (3)–(5). The resulting mixtures deduced from this fit can be compared to the measured composition (Fig. 9). In general, this phenomenological model describes fairly well the samples.

This would suggest that the blocking of one species of nanoparticles is not affected by the presence of the other species. If significant magnetic pinning occurred, deviations form the identity relationship would be expected when comparing the measured compositions to the fit compositions. The fact that the behaviour of the mixture is adequately modeled as an algebraic sum of the behaviours of the individual components shows that interactions are not affecting (in any significant way anyways) the relaxation behaviour of the nanoparticles.

We can contrast this behaviour with the magnetic behaviour of $\sim$1:1 mixtures of these nanocrystals, in matrices which we described elsewhere [1]. In that study the nanoparticles were encapsulated in thin films of amorphous aluminium oxide and amorphous titanium dioxide. The results are presented in Fig. 10 for comparison with

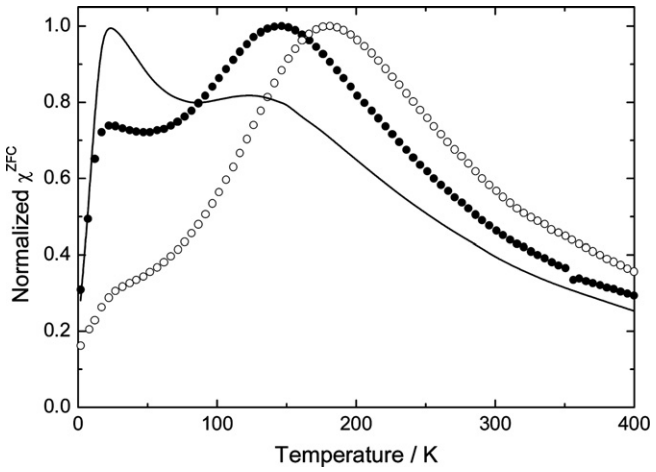

Fig. 10. Experimental magnetization curves for zero field cooled samples consisting of $\sim$1:1 mixtures of γ-Fe_2O_3 and $CoFe_2O_4$ nanoparticles encapsulated in amorphous aluminum oxide (●●●) and amorphous titanium oxide (○○○) (see Ref. [1]). The solid line represents the calculated ZFC curve expected for a 1:1 mixture.

Fig. 6c. The matrix encapsulated sample appears to have a much larger fraction of material behave as if it is blocked at a higher blocking temperature. We tentatively suggested that in a large number of clusters the $CoFe_2O_4$, with a higher T_B, is magnetically pinning the γ-Fe_2O_3 nanoparticles, which then mimic the temperature dependence of the $CoFe_2O_4$ nanoparticles [1].

While this behaviour was observed in clusters encapsulated within the thin films, it is clear that this mechanism is not the prevailing factor in the bulk mixtures presented here. This new result indicates that the behaviour of the encapsulated material may be mediated by the encapsulating material. Support for this interpretation comes from consideration of the difference of the behaviour of the mixture encapsulated in different matrix materials (Fig. 10). In these two samples the deviation from the expected (non-interacting) behaviour is quite different. This is consistent with direct involvement of the matrix material in the behaviour of the magnetization near the blocking temperature.

5. Conclusions

We have studied the magnetic properties of mixtures of $CoFe_2O_4$ and γ-Fe_2O_3 nanoparticles with similar size distributions, but distinct superparamagnetic properties. We find that the zero field cooled magnetization curves can be appropriately modeled as the algebraic sum of the two superparamagnetic contributions. However, magnetization vs. field measurements suggest that the samples do not exhibit ideal superparamagnetism. We find evidence for the presence of magnetic clusters consisting of a few nanoparticles magnetically coupled. In the bulk, the interactions within these clusters must be weak enough as to not influence the relaxation dynamics of ensembles of mixed nanoparticles with distinct superparamagnetic properties. This suggests that the role of the metal oxide matrix in previously studied nanocomposite thin films [1] may go beyond that of an innocent host, and will be addressed in future studies.

2. Experimental

Non-saturated horse spleen ferritin containing 2200 iron atoms was obtained from Sigma–Aldrich and was exhaustively dialyzed against water using a Spectra/Por Float-A-Lyzer with a molecular weight cut-off (MWCO) of 300 000 Da prior use. EA/SME mixtures in a 1:4 ratio were dissolved in $CHCl_3$ as spreading solution. An appropriate amount of this solution was carefully spread onto an aqueous subphase with 0.01 mg/mL of ferritin at pH 5.7 and 21 °C, and the spreading solvent was allowed to evaporate for 10 min prior to compression. The monolayer was compressed up to a surface pressure of 30 mN/m for transfer. Multilayer LB films were assembled to the substrates by the vertical lifting method. The equipment used for the measurements presented in this communication is described in a previous publication [6].

3. Results and discussion

A commercially available ferritin containing 2200 iron atoms has been used for all the experiments. In our previous work we extended the method developed by Britt et al. to prepare Langmuir monolayers of ferritin at the water–air interface [7] for preparing LB films of four ferritin derivatives with a variable iron content [6]. This method is based on the adsorption of ferritin dissolved in the aqueous subphase, which is negatively charged at the pH of the water subphase (5.5), onto a positively charged monolayer. Britt et al. showed that a higher amount of ferritin is adsorbed using eicosylamine as a cationic surfactant instead of the DODA/SME mixed monolayer [7]. In view of those results we have tried to prepare LB films of ferritin using EA as a cationic surfactant with the aim of increasing the amount of ferritin incorporated within the films. Since transfer onto solid substrates was not possible using pure eicosylamine monolayers, we tried several EA/SME mixtures (EA/SME ratio of 1/1, 1/2 and 1/4). A successful deposition of the monolayers onto solid substrates by the vertical lifting method was achieved for the 1/4 mixture at constant surface pressure of 30 mN/m. Transfer ratios close to unity were obtained giving rise to Y-type and optically defect-free multilayer LB films.

Before the transfer process, the surface pressure–area (π–A) isotherms were recorded. Fig. 1 shows the isotherms corresponding to the mixed EA/SME films fabricated on a subphase in the absence (dashed line) and presence of ferritin (solid line). The area is expressed per surfactant molecule. The presence of ferritin causes an area expansion at low surface pressure, although such a expansion does not correspond to the ferritin area ($d = 120$ Å, $A_{\text{ferritin}} \approx 11\,300$ Å^2/molecule) and thus, it is thought that ferritin molecules are located under the lipid matrix as observed for the DODA/SME mixed monolayer [6].

The mixed monolayers in both the absence and presence of ferritin in the subphase were observed directly by BAM at the air–water interface to obtain information about the morphological properties of the different films. BAM images of the 1/4 EA/SME mixture on pure water, obtained at different surface pressures are shown in Fig. 2a. Thus at a low surface pressure (π) of 0.1 mN/m, a coexistence of gas and liquid expanded phases is observed. Under further compression, when the surface pressure abruptly increases, i.e. around 1 mN/m, a homogeneous monolayer is observed. Further increases of the surface pressure lead to an increase of the reflectivity over the entire surface and to the onset of small brighter points which could correspond to collapse. In the case of the mixed monolayer at the air–water interface with ferritin in the subphase, the morphological characteristics of the film (Fig. 2b) change drastically with respect to the same system in absence of ferritin. At the beginning of the compression process, small irregular domains with higher reflectivity are observed. Under compression, these domains tend to fuse but zones of lower reflectivity remain for all the surface pressures. Reflectivity of these two regions increases continuously under compression. These differences with respect to those recorded without ferritin in the subphase are indicative of the presence of the protein at the interface, probably attached under the lipid matrix. Although these molecules of protein do not seem to form a full monolayer under the mixed film, an increase of the homogeneity is observed with respect to the DODA/SME monolayer [6]. Ellipsometric angle measurements in the zones of different brightness of the mixed monolayer are in progress in order to study the distribution of the protein under the lipid matrix.

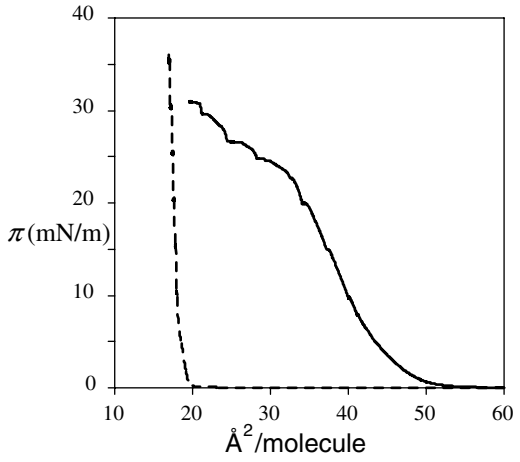

Fig. 1. π–A isotherms of different monolayers prepared at the air–water interface: EA/SME = 1:4 in absence of ferritin (dashed line) and in presence of ferritin, $[\text{ferritin}]_{\text{subphase}} = 0.01$ mg/ml (solid line).

The infrared spectrum of the transferred film (29 monolayers deposited on CaF_2) is shown in Fig. 3. It presents besides the bands at 2916, 2849 and 1456 cm^{-1}, assigned to the CH_2 stretching or scissoring vibrations of EA and SME alkyl chains, and the band at 1738 cm^{-1}, assigned to C=O vibration of SME, two strong bands associated with ferritin at 1653 and 1541 cm^{-1}. These two bands are assigned to the N–H and C=O structural units of the

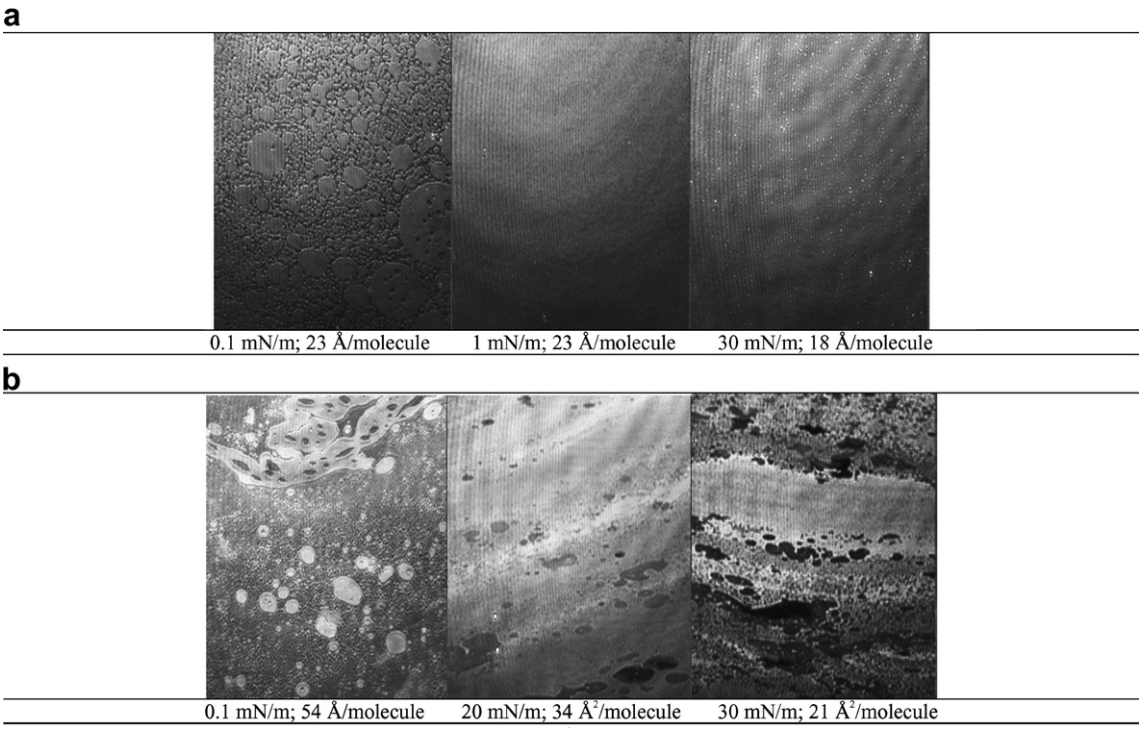

Fig. 2. BAM images of a mixed monolayer of EA/SME = 1:4 on pure water (a) and on a subphase containing ferritin ([ferritin] = 0.01 mg/ml) (b) at several surface pressures. The brightness of each image has been scaled to improve contrast. Width: 430 μm.

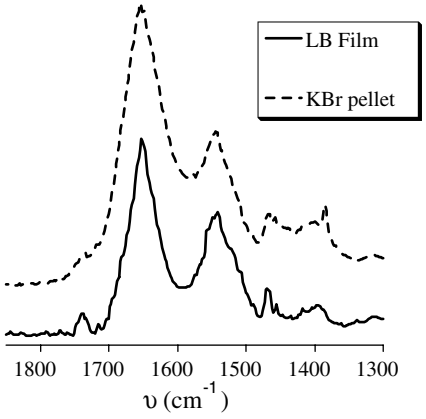

Fig. 3. Infrared spectra of ferritin in KBr pellet and of a LB film of ferritin of 29 monolayers on a CaF_2 substrate.

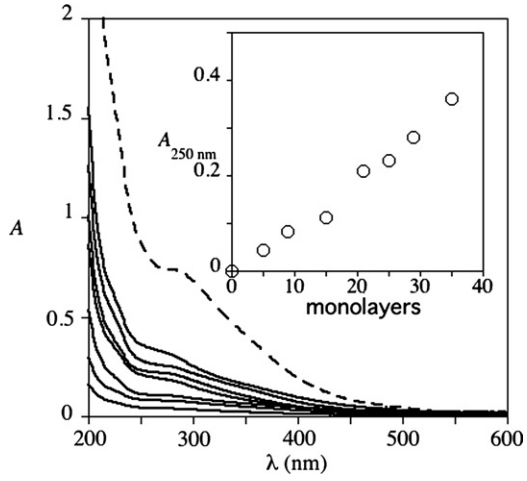

Fig. 4. UV–Vis spectra of LB films of ferritin with 5, 9, 15, 21, 25, 29 and 35 monolayers on a quartz substrate and of a solution of ferritin (dashed line). Inset: Absorbance values at 250 nm of these LB films vs. the number of monolayers.

protein together with the superposition of the –OH bending absorption on the band at 1653 cm^{-1} [8].

The UV–Vis absorption spectra of a LB film of ferritin on quartz substrates shows the typical broad absorption centered below 500 nm of the ferritin iron-core with a shoulder around 280 nm, characteristic of the apoferritin shell (Fig. 4). A linear dependence is found between the absorbance at a given wavelength and the number of monolayers. This indicates that the Langmuir film is transferred in a regular manner after each dipping cycle. Assuming that ferritin molecules are isotropically distributed within the LB films, it is possible to estimate the number of molecules trapped within the LB films. From the absorbance values at 250 nm, a surface concentration of $6.0 \pm 0.5 \times 10^{-13}$ mol/cm^2 per monolayer is calculated for the LB films with 25, 29 and 35 monolayers. This value is higher than that calculated for DODA/SME 1/6 LB films (4×10^{-13} mol/cm^2) [6]. Therefore, these data indicate that the use of a EA/SME mixed monolayer produces an increase of the adsorbed ferritin within the LB films with respect to the DODA/SME mixed monolayer. On the other hand, a mean area per ferritin molecule of 28000 ± 2000 $Å^2$ can be calculated from the inverse of the concentration per

monolayer. This value is higher than the area of the ferritin molecule ($d = 120$ Å, $A_{\text{ferritin}} \approx 11\,300$ Å^2). This indicates that a complete monolayer of ferritin has not been achieved. More measurements with other techniques such as TEM or AFM are in progress to study the arrangement of ferritin molecules in these LB films.

The iron oxohydride core of ferritin is antiferromagnetic below 140 K but possesses a net magnetic moment arising from uncompensated iron spins largely at the surface of the core. It has been shown that ferritin behaves as a superparamagnet above 20 K [9–11]. The magnetic properties of a LB film of ferritin with 260 monolayers deposited onto a diamagnetic mylar substrate were measured. Temperature dependence of the susceptibility of this LB film is very similar to powder measurements (Fig. 5a). The zero-field-cool (ZFC) curve presents a maximum of the susceptibility around 11 K and ZFC and field-cool (FC) curves are superimposed above 20 K (Fig. 5b). This proves clearly that ferritin molecules are present within the LB films. A marked hysteresis loop of magnetisation is obtained with a coercive field of 2400 G (Fig. 6). The shape of the hysteresis loop of magnetisation is again very similar to that of powder measurements. This is an expected result since the magnetic properties of this molecule have a molecular origin and the magnetic isolation provided by the diamagnetic apoferritin shell prevents any magnetic interaction between ferritin molecules.

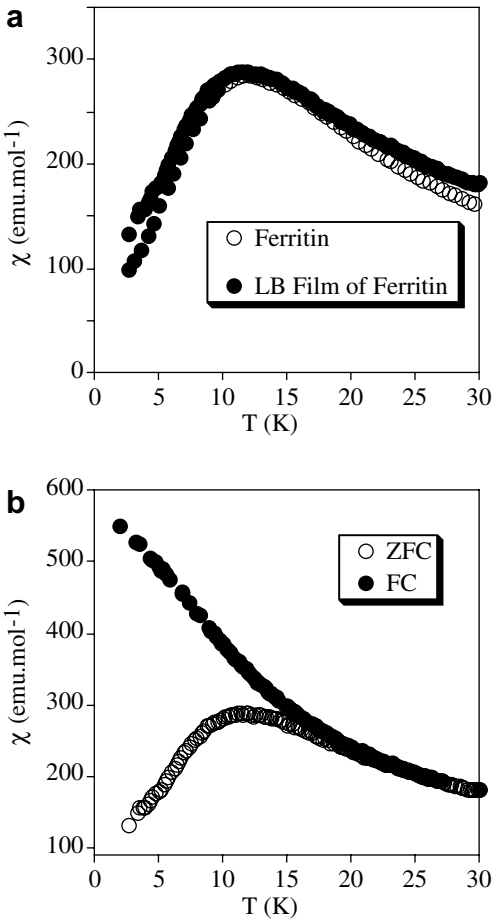

Fig. 5. (a) Thermal dependence of the ZFC susceptibility with an applied field of 50 G of the evaporated sample of ferritin (empty circles) and the LB film of ferritin (full circles) with 260 monolayers deposited on a mylar substrate. (b) Thermal dependence of the ZFC (empty circles) and FC susceptibility (full circles) with an applied field of 50 G of the LB film of ferritin with 260 monolayers deposited on a mylar substrate. The molar susceptibility of the LB film is obtained by normalization to that of the evaporated sample.

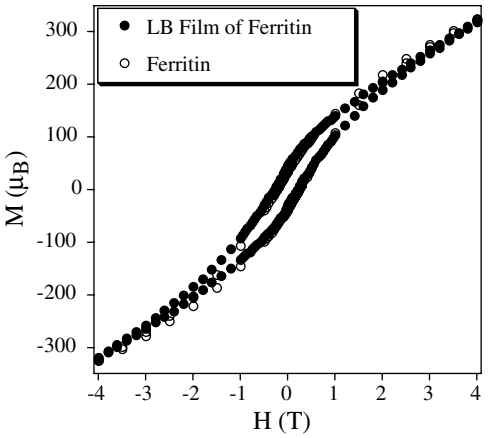

Fig. 6. Hysteresis loop of magnetisation of the evaporated sample of ferritin and the LB film of ferritin with 260 monolayers deposited on a mylar substrate at 2 K. The magnetisation of the LB film was normalized to that of the evaporated sample.

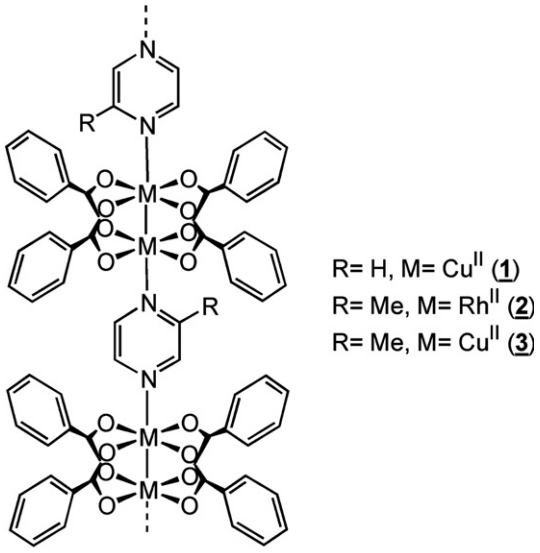
4. Conclusions



In this communication we have reported the preparation of Langmuir monolayers and LB films of ferritin using a mixed matrix containing EA and SME. These LB films show magnetic memory. The main interest of the LB method is that it permits the preparation of thin films with magnetic memory in a more controlled manner than with other techniques. In this work we have optimized the conditions to obtain LB films of ferritin with a more homogeneous distribution of ferritin, as shown by preliminary BAM measurements at the water–air interface, and with a higher density of the protein, as deduced from UV–Vis data. This may be useful for magnetic recording applications. The next step will be the use of other ferritin derivatives in which the antiferromagnetic iron oxohydride core of natural ferritin has been replaced by other nanoparticles of magnets with higher T_c (metal nanoparticles).

Scheme 1.

2. Experimental

Single-crystal hosts **1** and **2** were synthesized as described elsewhere [8,9]. Using the same synthetic procedure performed in **1** and **2**, blue plate crystals of $[Cu_2(bza)_4(2\text{-mpyz})]_n$ (**3**) were obtained by the careful vapor diffusion of 2-methylpyrazine into the methanol solution of copper(II) benzoate in 60% yield. Experimental procedures were performed under strict exclusion of oxygen and water vapor. Careful treatment, especially for NO gas, was taken because of its high degree of reactivity with oxygen.

2.1. Physical measurements

The NO gas used during the physical measurements had a purity of >99.9%. The NO adsorption isotherms for all adsorbents were measured by a volumetric method at 195 K on a Quantachrome Autosorb-1MP instrument (the pressure for the data collections ranged from 0.3 to 800 Torr for all adsorbents). Magnetic susceptibilities of the included NO molecules were measured on a Quantum Design SQUID magnetometer MPMS-XL with an applied magnetic field of 1 T. The crystals were sealed in glass tubes with pressurized NO gas (2.0 MPa for **1**, 2.6 MPa for **2**, and 2.5 MPa for **3**) at 195 K, which can separate from the condensed excess NO at low temperatures. Measurement of the pure NO was performed by using a sample tube containing solid NO, which corresponds to an inner pressure of 7.5 MPa at 298 K. Susceptibility was corrected by the trace background values of the cell and each empty crystal. Calculation of the molar magnetization and susceptibility of the included NO was based on a mass of 1.83 for **1**, 1.00 for **2**, and 1.14 for **3** per M_2 unit, which were estimated by theoretical Bohr magneton numbers applied for the observed maximum values at around 200 K.

3. Results and discussion

3.1. Gas adsorption properties

The NO adsorption isotherm curves of **1**, **2**, and **3** at 195 K are shown in Fig. 1. The sorption curves show a slight curve in **1** and a linear increase to 800 Torr in **2** and **3**; all curves smoothly return reversibly to the starting point without hysteresis. The isotherm curves reach 0.61 for **1**, 0.30 for **2**, and 0.23 for **3** per M_2 unit at 800 Torr. **1** adsorbed more NO molecules than did **2** and **3**. We have reported that, under a saturated inclusion state, the host possesses a one-dimensional channel even if the channel surface is modified by the substituents on the pyrazine linker, such as methyl and ethyl groups, and strong contacts are found between the guests and the substituents on the channel surface [9,25]. Therefore, the observed difference in the NO adsorption property is probably influenced by

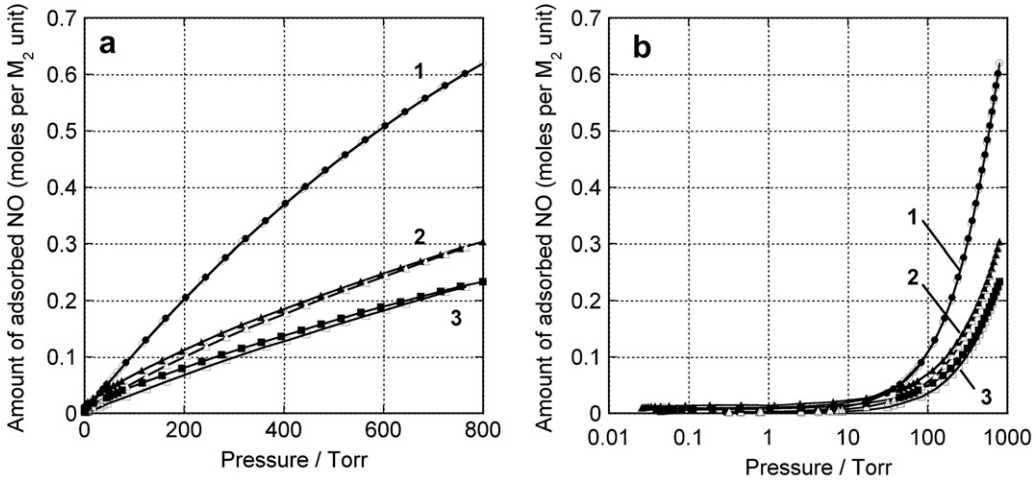

Fig. 1. NO sorption isotherm curves for **1**, **2**, and **3** at 195 K: adsorption process (open point), desorption process (solid point). (a) Linear plot, (b) log plot.

the interference of the channel surface to the adsorbed gas. Cu complex **3** adsorbed a slightly lesser amount of NO molecules than did Rh complex **2**. The difference between the metals might be linked to the flexibility of the host lattice, which is important for the transfer of guests in the process of adsorption, especially for our single-crystal adsorbents, as was described in previous studies [7–19].

We have determined the adsorption properties by sorption isotherm measurement: 2.5(CO_2) for **1** at 195 K [8], 2.4(O_2) for **1** at 77 K [19], 2(CH_4) at 153 K, and 3(N_2O) at 195 K for $[Rh_2(bza)_4(pyz)]_n$ [15,16] per M_2 unit. As compared with these adsorption properties, the amount of NO adsorbed was considerably lower despite its simple molecular structure. This low amount of adsorption might be related to both the shape and dipole moment of the NO molecule within the hydrophobic space, which is reflected in the guest packing, inter-guest interaction, and host–guest interaction.

3.2. Magnetic properties of NO molecule in channel crystals

DC magnetic measurements were conducted on single crystals of **1**, **2**, and **3** under pressurized NO conditions in the temperature range of 2–250 K at an applied field of 1 T. The maximum values of apparent μ_{eff} were obtained based on the compositions estimated from gas adsorption measurements at 195 K at 800 Torr (3.19 μ_B at 212 K for **1**, 3.35 μ_B at 194 K for **2**, and 4.09 μ_B at 174 K for **3**). These apparent μ_{eff} values were extremely high in comparison with the theoretical effective Bohr magneton number of 1.836 for gaseous NO at 293 K [26] because the actual adsorption amounts may increase under the high pressure for the SQUID measurements. The assumption that the observed maximum μ_{eff} values at around 200 K can meet the theoretical value of 1.836 μ_B gave the adsorption amounts of 1.83, 1.00, and 1.14 for **1**, **2**, and **3**, respectively per M_2 unit. The roughly estimated numbers of adsorbed NO molecules for **1**, **2**, and **3** increased 3, 3.3, and 5 times as much as those estimated from the NO adsorption measurements, respectively. The pressure effect on the increase of adsorption amounts was observed more notably in **2** and **3**. Compound **1** adsorbed the NO molecules effectively in comparison with compounds **2** and **3**. This order of the estimated adsorption amounts is in good agreement with that observed in the gas adsorption measurements. A significant increase in the adsorption amount was found in **1**, which is probably influenced by the gas adsorption characteristics of the crystal host with the different bridging ligands of pyz (**1**) and 2-mpyz (**2**, **3**). Fig. 2 shows the converted μ_{eff} versus T plots for **1**, **2**, and **3** with the bulk NO data measured by SQUID methods. With a decrease in temperature, the μ_{eff} value gradually increases and reaches a maximum at around 200 K for **1** and **2**, and at around 175 K for **3**. Below this temperature, the μ_{eff} value decreases rapidly to 0.60 μ_B at 108 K, 0.28 μ_B at 114 K, and 0.60 μ_B at 45 K, for **1**, **2**, and **3**, respectively. With a decrease in temperature, the μ_{eff} value for **1** continuously decreases to reach a minimum of 0.49 μ_B at 30 K. The μ_{eff} values for **1**, **2**, and **3** then increase from their respective minimum values to reach small peaks of 0.55 μ_B at 14 K for **1**, 0.92 μ_B at 8.6 K for **2**, and 0.70 μ_B at 16 K for **3** and finally decrease to 2.0 K (0.34, 0.66, and 0.52 μ_B for **1**, **2**, and **3**, respectively). The increases of μ_{eff} in the high-temperature regions were probably caused by the adsorption of NO into the host as the temperature decreased. The slight difference in magnetic behavior below 110 K between compound **1** and compounds **2** and **3** would be caused by a difference in the guest array because of the substituents on the host lattice of **2** and **3**. These magnetic behaviors of the NO-inclusion crystals are completely different from those of bulk NO. In bulk NO, the spin–orbital contributions of the NO molecule cause the effective magnetic moment to deviate from the Curie law as temperature decreases, and the generation of dimerized NO in solid phase results in very feeble magnetization due to its diamagnetic nature [23,26–28]. In the case of included NO molecules in micropores, two different magnetic properties have been reported. One property is that the dimerized NO molecules generated in the activated carbon fiber exhibit a diamagnetic nature [24]. The other property is that the NO molecules adsorbed on the surface of the silica and alumina gel show magnetization without deviation from the Curie law due to the uncoupling of the spin–orbital interactions [29,30].

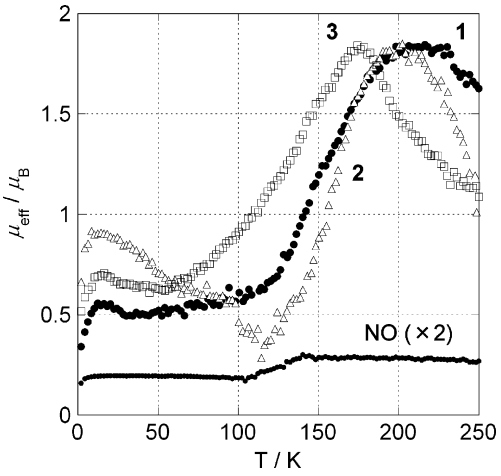

Fig. 2. Temperature dependence of the effective magnetic moment for included NO in **1**, **2**, and **3** at 1 T. Calculation for molar magnetization was based on the mass of NO molecules corrected by the theoretical value and the measured value. The magnetic data of the pure NO was measured by the SQUID method; its intensity was multiplied by 2.

The rapid decrease of μ_{eff} observed in **1**, **2**, and **3** is understood by the antiferromagnetic interaction between the included NO molecules, which is similar to that reported in the oxygen-included crystals of $\mathbf{2}\cdot 3(O_2)$ [9]. We have found one-dimensional arrays of the included oxygen molecules with short inter-guest contacts in both **1** and **2** [9,19]. As shown in Fig. 3, because each chain is separated from the nearest chains with a minimum inter-guest distance of 6.7 Å, the contacts within the channel will mostly contribute to the antiferromagnetic interactions. Based on the reported results, the abrupt decrease of μ_{eff}

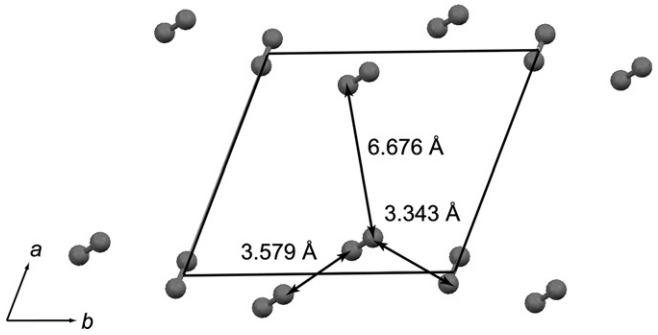

Fig. 3. Ball-and-stick representation of one-dimensional arrays of the included O_2 in the channels of crystal **1** at 90 K (reported in Ref. [19]).

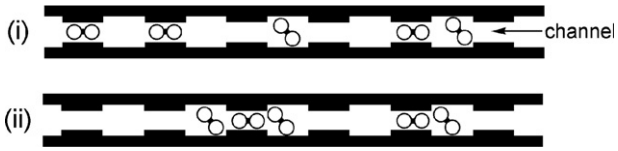

Fig. 4. Schematic views of molecular distributions within the channels under an unsaturated adsorption state: (i) isolated guest molecules; (ii) the aggregated structure.

observed in the included NO molecules indicates that the adsorbed NO molecules generate densely packed structures with short contacts along the channel, which effectively mediate the magnetic interactions.

It was reported that liquid NO exhibits ca. 0.05 μ_B at around 100 K because of a 97% association to N_2O_2 [27,28]. At 90 K, values of μ_{eff} larger than 0.05 μ_B for bulk NO are found with 0.58, 0.58, and 0.83 μ_B for **1**, **2**, and **3**, respectively, which indicate that diamagnetic dimers are not generated in the channels. This is different from that observed in bulk NO. In spite of the relatively strong antiferromagnetic interaction, the μ_{eff} curves showed a gradual decrease for **1** and an increase for **2** and **3**. Because the adsorption amounts of NO are low as compared to the expected value of 3 molecules per dinuclear M_2 unit for the saturated structure, there are two possible methods of distribution of the adsorbed NO in the channels, which could be related to the appearance of magnetic behavior. The first possible method is that the molecules that are located close to each other contribute to antiferromagnetic interactions. The second possible method is that the isolated molecules that are generated by the unsaturated state result in residual paramagnetic contributions (Fig. 4). The observed magnetic behavior of adsorbed NO within the channels of **1**–**3** exhibited antiferromagnetic interaction without residual paramagnetic contributions. This fact confirms that the narrow channels of **1**–**3** include NO molecules with the suppression of N_2O_2 formation and assist in forming NO molecular aggregation even under unsaturated conditions.

4. Conclusion

We have described the NO adsorption properties of a series of single-crystal adsorbents, **1**, **2**, and **3**, and the magnetic properties of the included NO molecules. More NO molecules were adsorbed in compound **1** having no substituent on the host lattice than in compounds **2** and **3** with substituents. Thus, the property of NO gas adsorption probably depends on differences in channel space. The included NO molecules exhibited antiferromagnetic interaction between neighboring guests, which is different from the bulk NO phase. The magnetic behavior of the included NO molecules suggests that the adsorbed NO molecules exist in the monomer NO state without dimerization to N_2O_2, and generate the aggregation fragment of a 1D array within the channel, instead of an isolated array.

Calc. for $C_{60}H_{78}N_8O_{33}Mn_5$: C, 42.04; H, 4.59; N, 6.54. Found: C, 41.92; H, 4.46; N, 6.45%. IR (KBr disk): $\nu = 1625.9$, 1591.2 cm^{-1}.

2.3. Synthesis of $[Co_4^{II}Co_2^{III}(fsaea)_2(OMe)_4(NO_3)_2(OAc)_2(MeOH)_2]$ ($[Co_4^{II}Co_2^{III}]$)

To a solution of 3-formylsalicylic acid (498 mg, 3.0 mmol), triethylamine (1212 mg, 12.0 mmol) and 2-ethanolamine (183 mg, 3.0 mmol) in methanol (100 ml) was added a $Mn(OAc)_2 \cdot 4H_2O$ (1471 mg, 6.0 mmol), and the mixture was stirred for several minutes. The resulting solution was diffused with diethyl ether to give brown solid. The brown solid was dissolved in methanol (100 ml), and $Co(NO_3)_2 \cdot 6H_2O$ (1746 mg, 6.0 mmol) was added to the solution. The resulting solution was allowed to stand for several days to give red lozenge crystals of $[Co_4^{II}Co_2^{III}]$. *Anal*. Calc. for $C_{30}H_{42}N_4O_{24}Co_6$: C, 30.12; H, 3.54; N, 4.68; Mn, 0.00, Co, 29.56. Found: C, 30.32; H, 3.56; N, 4.71; Mn, 1.13; Co, 28.72%. IR (KBr disk): $\nu = 1651.0$, 1598.9, 1384.8 cm^{-1}.

2.4. X-ray crystallography

A brown lozenge crystal ($0.30 \times 0.18 \times 0.07$ mm^3) of $[Mn_3^{II}Mn_2^{III}]$, and a red lozenge crystal ($0.17 \times 0.16 \times 0.06$ mm^3) of $[Co_4^{II}Co_2^{III}]$ were mounted with epoxy resin on the tip of a glass fiber. Diffraction data were collected at −70 °C on a Bruker SMART APEX diffractometer fitted with a CCD type area detector, and a full sphere of data were collected using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). At the end of data collection, the first 50 frames of data were recollected to establish that the crystal had not deteriorated during the data collection. The data frames were integrated using SAINT and were merged to give a unique data set for structure determination. Total reflections collected were 7939 and 25 546 for $[Mn_3^{II}Mn_2^{III}]$ and $[Co_4^{II}Co_2^{III}]$, respectively, of which independent reflections were 6665 ($R_{int} = 0.0597$) and 9326 ($R_{int} = 0.0487$). The structures were solved by direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELXTL 5.1 package (Bruker Analytical X-ray Systems). Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atoms.

Crystal data for $[\{Mn^{II}Mn^{III}(fsatren)\}_2Mn^{II}(H_2O)_4] \cdot 2MeOH \cdot 3H_2O$ ($[Mn_3^{II}Mn_2^{III}]$): $C_{32}H_{32}N_4O_{15}Mn_{2.5}$, F.W. = 849.97; brown lozenge, triclinic, space group $P\bar{1}$, $a = 12.345(2)$ Å, $b = 13.142(2)$ Å, $c = 13.862(3)$ Å, $\alpha = 77.451(4)°$, $\beta = 82.671(4)°$, $\gamma = 65.767(4)°$, $V = 2000.0(6)$ $Å^3$, $Z = 2$, $D_{calc} = 1.411$ Mg m^{-3}, μ(Mo Kα) = 0.850 mm^{-1}, $R_1 = 0.0808$, $wR_2 = 0.2269$ ($I > 2\sigma(I)$).

Crystal data for $[Co_4^{II}Co_2^{III}(fsaea)_2(OMe)_4(NO_3)_2(OAc)_2(MeOH)_2]$ ($[Co_4^{II}Co_2^{III}]$): $C_{30}H_{42}N_4O_{24}Co_6$, F.W. = 1196.26; red lozenge, orthorhombic, space group $P2_12_12_1$, $a = 15.097(3)$ Å, $b = 16.137(3)$ Å, $c = 17.164(3)$ Å, $V = 4181.7(13)$ $Å^3$, $Z = 4$, $D_{calc} = 1.900$ Mg m^{-3}, μ(Mo Kα) = 2.419 mm^{-1}, $R_1 = 0.0696$, $wR_2 = 0.1711$ ($I > 2\sigma(I)$).

3. Result and discussion

3.1. Crystal structures

An ORTEP drawing of $[Mn_3^{II}Mn_2^{III}]$ is shown in Fig. 1. X-ray structure analyses for $[Mn_3^{II}Mn_2^{III}]$ reveals that a $[Mn^{II}(H_2O)_4]$ unit bridges two $[Mn^{II}Mn^{III}(fsatren)]^-$ units to form a linear pentanuclear manganese core. In the $[Mn^{II}Mn^{III}(fsatren)]^-$ unit, a Mn(II) ion has seven-coordinated geometry (monocapped trigonal prism environment)

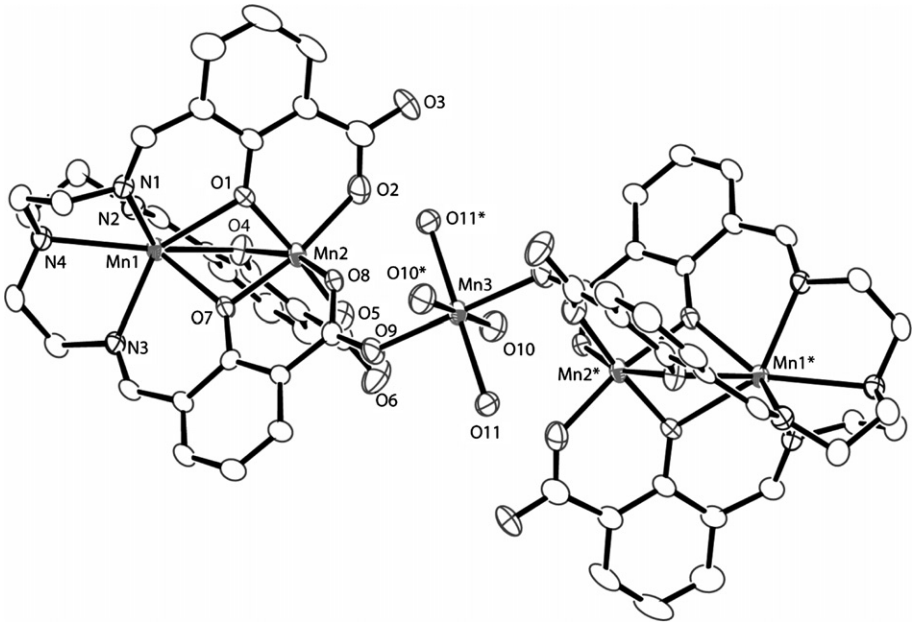

Fig. 1. ORTEP drawing of $[\{Mn^{II}Mn^{III}(fsatren)\}_2Mn^{II}(H_2O)_4] \cdot 2MeOH \cdot 3H_2O$ ($[Mn_3^{II}Mn_2^{III}]$).

and locates at an N_4O_3 site of fsatren^{3-} ligand, whereas a Mn(III) ion has a distorted octahedral environment and locates an O_6 site of fsatren^{3-} ligand. The terminal carboxyl group of $[Mn^{II}Mn^{III}(fsatren)]^-$ unit connects to additional Mn(II) ion with *syn–anti* manner bridge to form a linear pentanuclear manganese core. Coordination bond lengths about Mn1, Mn2 and Mn3 are in the range of 2.245(6)–2.561(7), 1.861(7)–2.059(6) and 2.130(7)–2.220(7) Å, respectively. On the bases of bond valence sum calculations and coordination bond lengths, Mn1 and Mn3 ions are Mn^{II} ions, and Mn2 ions are Mn^{III} ions. Interatomic Mn1···Mn2 and Mn2···Mn3 separations are 3.144(2) and 5.237(2) Å, respectively. The bridging angles of Mn1–O1–Mn2, Mn1–O4–Mn2, and Mn1–O7–Mn2 are 90.9(3)°, 95.2(3)°, and 94.1(3)°, respectively.

An ORTEP drawing for $[Co_4^{II}Co_2^{III}]$ with atom numbering scheme is shown in Fig. 2. The structure of $[Co_4^{II}Co_2^{III}]$ is composed of a face shared incomplete tetra cubane core with four cobalt(II) ions (Co2, Co3, Co5, Co6) and two cobalt(III) ions (Co1, Co4) bridged by μ_3-MeO^-, phenoxo, alkoxo and carboxyl groups. Co1 and Co4 ions have an octahedral coordination geometry and locate at an N_1O_2 site of fsaea^{3-} ligand. Co2 and Co5 ions have an octahedral coordination and locate at an O_2 site of fsaea^{3-} ligand. Co3 and Co6 ions have a distorted octahedral geometry and are coordinated by the oxygen atom of carboxyl group of fsaea^{3-} ligand. Coordination bond lengths are in the range of 1.881(6)–1.942(5), 2.022(5)–2.136(5), 2.009(5)–2.228(6), 1.863(7)–1.950(5), 2.032(5)–2.116(5), 1.995(5)–2.179(6) Å for Co1–Co6, respectively. The assignment of oxidation number was confirmed by the bond distances.

3.2. Magnetic property

Magnetic susceptibilities for $[Mn_3^{II}Mn_2^{III}]$ and $[Co_4^{II}Co_2^{III}]$ were measured in the temperature range of 1.8–300 K. $\chi_m T$ versus T and M versus H plots are given in Figs. 3 and 4, respectively. In the case of $[Mn_3^{II}Mn_2^{III}]$, the $\chi_m T$ value at 300 K is 17.809 emu mol^{-1} K, which is smaller than the expected spin-only value for uncorrelated three Mn(II) ions and two Mn(III) ions (19.125 emu mol^{-1} K, $g = 2$). The $\chi_m T$ value gradually decreased as the temperature was lowered, and reached the value of 6.655 emu mol^{-1} K, which suggests that $[Mn_3^{II}Mn_2^{III}]$ has spin ground states $S = 7/2$ ($g_{ave} = 1.84$). The Curie–Weiss plot gave a negative Weiss constant ($C = 18.939$ emu mol^{-1} K, $\theta = -15.284$ K), which suggested antiferromagnetic interaction between the Mn ions. A magnetization measurement performed at 1.8 K yielded a value of 8.73 $N\beta$ at 5 T, which is still unsaturated. This magnetization behavior suggests the existence of near excited state above a ground spin state $S = 7/2$. In the case of $[Co_4^{II}Co_2^{III}]$, the $\chi_m T$ value at 300 K is 11.978 emu mol^{-1} K, which is larger than the value expected for uncorrelated four Co(II) ions (7.5 emu mol^{-1} K, $g = 2$). As the

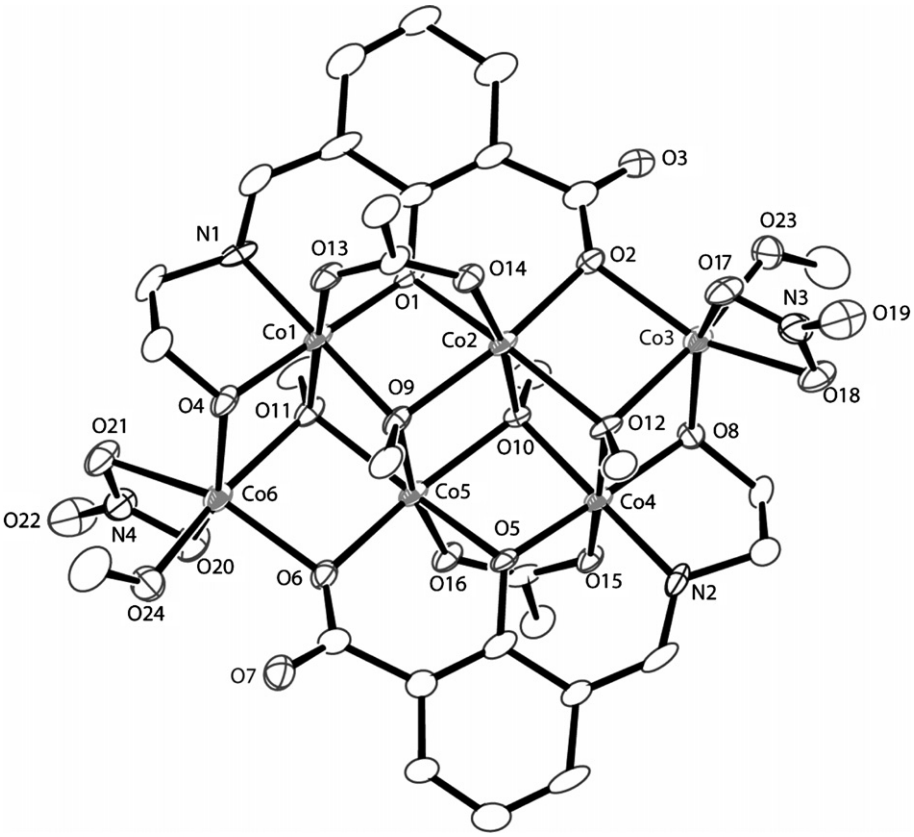

Fig. 2. ORTEP drawing of $[Co_4^{II}Co_2^{III}(fsaea)_2(OMe)_4(NO_3)_2(OAc)_2(MeOH)_2]$ ($[Co_4^{II}Co_2^{III}]$).

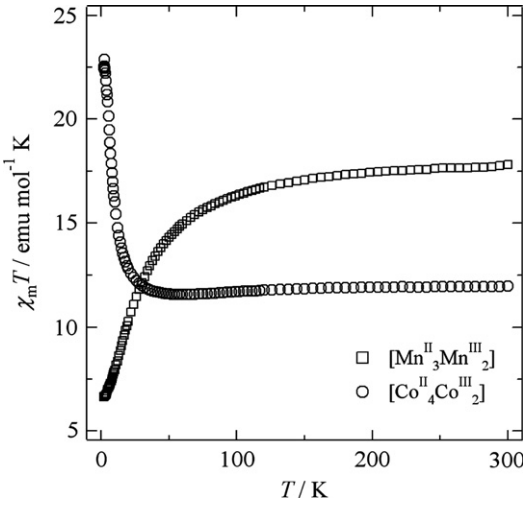

Fig. 3. Plots of $\chi_m T$ vs. T for $[Mn^{II}_3Mn^{III}_2]$ (□), and $[Co^{II}_4Co^{III}_2]$ (○).

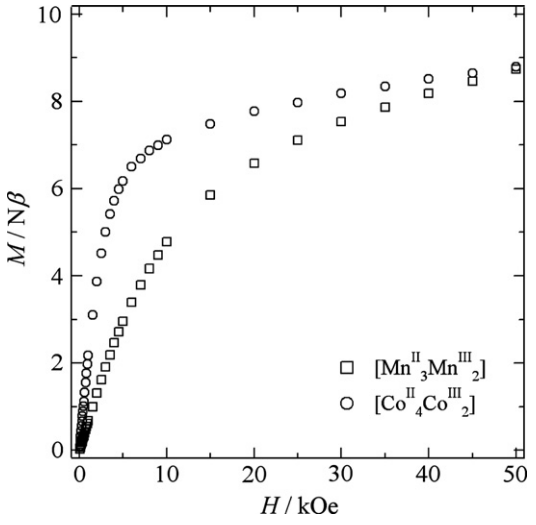

Fig. 4. Plots of M vs. H for $[Mn^{II}_3Mn^{III}_2]$ (□), and $[Co^{II}_4Co^{III}_2]$ (○).

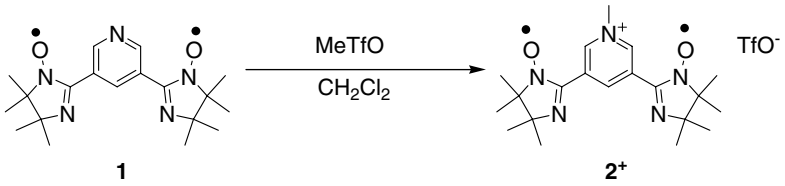
temperature decreased, the $\chi_m T$ value slightly decreased, reaching a minimum value of 11.573 emu mol^{-1} K at 58 K followed by steep increase to 22.877 emu mol^{-1} K at 2.2 K. This magnetic behavior is indicative of ferromagnetic interactions between the Co(II) ions, giving rise to an $S = 6$ ground state. A magnetization measurement performed at 1.8 K yielded a value of 8.80 $N\beta$ at 5 T, which is still unsaturated. The observed magnetization is smaller than the value expected for $S = 6$ ground spin state. This deviation will be brought about by T term contribution of high-spin Co(II). The ferromagnetic behavior can be understood by the accidental orthogonality of magnetic orbitals of Co(II) ions derived from a face shared incomplete tetra cubane core. It is noted that out-of-phase signals in ac magnetic susceptibility measurements were not observed.

4. Conclusion

Mixed-valence pentanuclear manganese complex, $[\{Mn^{II}Mn^{III}(fsatren)\}_2Mn^{II}(H_2O)_4]\cdot n(sol)$, and hexanuclear cobalt complex, $[Co^{II}_4Co^{III}_2(fsaea)_2(OMe)_4(NO_3)_2(OAc)_2(MeOH)_2]$, with Schiff-base ligand derived from 3-formylsalicylic acid have been synthesized. $[Mn^{II}_3Mn^{III}_2]$ complex has a linear pentanuclear core bridged by phenoxo and carboxyl groups, whereas $[Co^{II}_4Co^{III}_2]$ complex has a face shared incomplete tetra cubane core bridged by μ_3-MeO$^-$, phenoxo, alkoxo and carboxyl groups. $[Mn^{II}_3Mn^{III}_2]$ complex shows an antiferromagnetic interaction between the Mn(II) ions, while $[Co^{II}_4Co^{III}_2]$ complex shows a ferromagnetic interaction between Co(II) ions.

5. Supplementary material



CCDC 617363 and 617364 contain the supplementary crystallographic data for $[Mn^{II}_3Mn^{III}_2]$ and $[Co^{II}_4Co^{III}_2]$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 1. Synthesis of $\mathbf{2}^+ \cdot TfO^-$.

magnetically diluted system in an organic polymer matrix, in which intermolecular exchange interactions are suppressed. The intramolecular ferromagnetic interaction of **1** has been found to be $2J/k_B = 7.0$ K [6]. In this communication, we report ionization of **1**, which gives a cationic biradical, 3,5-bis(1-oxyl-4,4,5,5-tetramethylimidazoline-2-yl)-1-methylpyridinium ($\mathbf{2}^+$) as a trifluoromethanesulfonate salt $\mathbf{2}^+ \cdot TfO^-$ (Scheme 1).

It has been well established that alternant hydrocarbon molecules with two unpaired electrons delocalized in the π-conjugation of *m*-phenylene linkage have a ferromagnetic exchange interaction, giving the energy preference for a triplet ($S = 1$) state [7,8]. Various *m*-phenylene derivatives of nitronylnitroxide and iminonitroxide biradicals have been synthesized and their magnetic properties have been reported [3,9]. Heterocyclic analogues of stable *m*-phenylene biradicals have been found as well in neutral 2,6-pyridine-substituted biradicals [10]. Examples of low-spin species with the *m*-phenylene linkage, however, have been found in heteroatom-substituted oligoradicals [11,12]. An ionic charge in π-conjugated systems is known to affect the high-spin preference [13]. It is shown that a neutral pyridine ring is a ferromagnetic coupling unit, while cationic pyridinium gives both ferromagnetic and antiferromagnetic couplings, depending on substitution at 2,4-, 2,6-, or 3,5-positions [14]. Thus, the preference for a high-spin ground state is not guaranteed for the heteroatom-substituted, charged system of $\mathbf{2}^+$. The ground-state spin multiplicity of $\mathbf{2}^+$ in the salt $\mathbf{2}^+ \cdot TfO^-$ is examined from magnetic susceptibility measurements in both a magnetically diluted system and a neat crystalline solid state. The magnetic susceptibility of the neat crystalline solids of $\mathbf{2}^+ \cdot TfO^-$ is analyzed on the basis of the X-ray crystal structure, supporting the results of the magnetically diluted system.

2. Experimental

2.1. Synthesis

The salt of the biradical cation $\mathbf{2}^+$ was prepared by *N*-alkylation of the neutral precursor **1** with methyl trifluoromethanesulfonate (MeTfO). To MeTfO (0.072 g, 0.439 mmol) in 5 mL of dichloromethane was added the biradical **1** (0.103 g, 0.288 mmol). The solution was stirred at 0 °C for 20 min. Removal of the solvent in vacuo and recrystallization from dichloromethane/hexane gave red needle crystals of the triflate $\mathbf{2}^+ \cdot TfO^-$ (0.102 g, 68%). Elemental analysis (C, H, N) *Anal.* Calc. for $C_{21}H_{30}F_3N_5O_5S$: C: 48.36; H: 5.80; N: 13.43. Found: C: 48.08; H: 5.82; N: 13.40%.

2.2. Crystal structure analysis

Single-crystal X-ray diffraction data of the salt $\mathbf{2}^+ \cdot TfO^-$ were collected on a Rigaku Mercury CCD diffractometer with graphite monochromated Mo Kα radiation at 143 K. The crystal structure was solved by using direct methods in a program package CrystalStructure [15]. Anisotropic thermal parameters analysis was applied for nonhydrogen atoms. Hydrogen atoms with isotropic thermal parameters were refined as riding models.

2.3. Magnetic susceptibility measurements

Magnetic susceptibility was measured on a Quantum Design SQUID magnetometer MPMS-XL under the static magnetic field of 0.1 T in the temperature range down to 1.9 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constants. A polyvinylchloride (PVC) film of the salt was prepared by slow evaporation of dichloromethane solution of PVC and $\mathbf{2}^+ \cdot TfO^-$ (12 wt%), which was used as magnetically diluted samples.

3. Results and discussion

3.1. Crystal structure

The crystallographic data for the salt biradical $\mathbf{2}^+ \cdot TfO^-$ are summarized in Table 1. The unit cell contains two crystallographically independent molecules, $\mathbf{2A}^+ \cdot TfO^-$ and $\mathbf{2B}^+ \cdot TfO^-$.[1] ORTEP drawings of the molecule $\mathbf{2A}^+ \cdot TfO^-$ and $\mathbf{2B}^+ \cdot TfO^-$ are depicted in Fig. 1. The ONCN groups of the iminonitroxide and the pyridinium ring have small dihedral angles (22.11(8)° and 16.23(9)° in $\mathbf{2A}^+$, 5.4(1)° and 24.96(9)° in $\mathbf{2B}^+$) as compared with those of *m*-phenylene bis(iminonitroxide) biradical [9e] and a 2,6-substituted pyridine analogue [10g] of iminonitroxide. The cation molecules $\mathbf{2}^+$ are arranged in a chain structure along the *a*-axis,[1] as shown in Fig. 2. Within

[1] Indexing of observed reflections failed when a lattice of higher symmetry was assumed with one molecule of $\mathbf{2}^+ \cdot TfO^-$ in an asymmetric unit.

the chain, intermolecular short distances close to the Van der Waals contact [16] are found around the nitroxide oxygen atoms with large spin density. Around the O2 atom of $\mathbf{2}A^{+}$, we find (i) O2–N10 = 3.341(3) Å, (ii) O2–O7 = 3.299(3) Å, and (iii) O2–C34 = 3.597(4) Å, while the oxygen atom O6 of $\mathbf{2}B^{+}$ has contacts (iv) O6–O1 = 3.328(3) Å, (v) O6–N2 = 3.575(3) Å, (vi) O6–N3 = 3.051(3) Å, and (vii) O6–C6 = 3.053(3) Å, as depicted in Fig. 3. These contacts are expected to contribute to intermolecular exchange interactions.

3.2. Magnetic susceptibility

The intramolecular exchange interaction in the cation $\mathbf{2}^{+}$ was examined by paramagnetic susceptibility χ_p for the sample of the triflate salt $\mathbf{2}^{+}\cdot TfO^{-}$ dispersed in a polyvinylchloride (PVC) film, in which intermolecular magnetic interactions were suppressed. The χ_pT value of the magnetically diluted system increases as the temperature is lowered, as shown in Fig. 4. This indicates the occurrence of ferromagnetic exchange interaction within the molecule. The temperature dependence of χ_pT is analyzed with the Bleany–Bowers model [17]

$$\chi_p = \frac{2\alpha N_A g^2 \mu_B}{3k_B(T-\theta)} \frac{3}{3+\exp(-2J_F/k_BT)} \quad (1)$$

where the parameter J_F represents the intramolecular ferromagnetic exchange interaction and α denotes the purity of the paramagnetic entity. The mean field θ represents residue of intermolecular exchange interactions due to incomplete dispersion of the molecules in the film, as found in other nitroxide compounds in polymer matrices [18]. The g-factor was fixed as $g = 2.006$ in Eq. (1), which was observed in an ESR spectrum in a dichloromethane solution. The other symbols have their usual meanings. The observed temperature dependence of χ_pT was reproduced by Eq. (1) with the intramolecular exchange interaction of $2J_F/k_B = 7.5 \pm 0.1$ K, the intermolecular mean field of $\theta = -0.50 \pm 0.01$ K, and the purity of $\alpha = 0.880$. The reduced purity is attributed to decomposition during the preparation of the PVC film. It is concluded from the results of magnetic susceptibility for the magnetically diluted system that the ground state of the cation biradical $\mathbf{2}^{+}$ is triplet ($S = 1$).

The temperature dependence of χ_pT measured for neat polycrystalline solid samples of $\mathbf{2}^{+}\cdot TfO^{-}$ is depicted in Fig. 4. With decreasing temperature the χ_pT value increased to reach the maximum of 0.787 emu K mol^{-1} at 17 K. Below this temperature, the χ_pT value decreased down to 0.387 emu K mol^{-1} at the base temperature of 1.9 K. The increase in χ_pT shows that the dominating exchange interaction in the crystalline solid of $\mathbf{2}^{+}\cdot TfO^{-}$ is ferromagnetic, which is assigned to the intramolecular exchange interaction J_F. The decrease in χ_pT below 17 K indicates that additional weak antiferromagnetic interactions are operative between the molecules. The exchange interactions J_F and J_{AF} were estimated by using an antiferromagnetic chain model of arbitrary spin S [19][2]

$$\chi_p = f[2N_A g^2 \mu_B^2/(3k_BT)][(1+u)/(1-u)] \quad (2a)$$

$$u = \coth[2J_{AF}S(S+1)/(k_BT)] - k_BT/[2J_{AF}S(S+1)] \quad (2b)$$

$$f = 3/[3+\exp(-2J_F/k_BT)] \quad (2c)$$

The temperature-dependent population f of the triplet state in the cation molecule $\mathbf{2}^{+}$ is approximated by the simple Boltzmann distribution in Eq. (2c). The observed tempera-

[2] The magnitude alternation of J_{AF} along the chain is neglected.

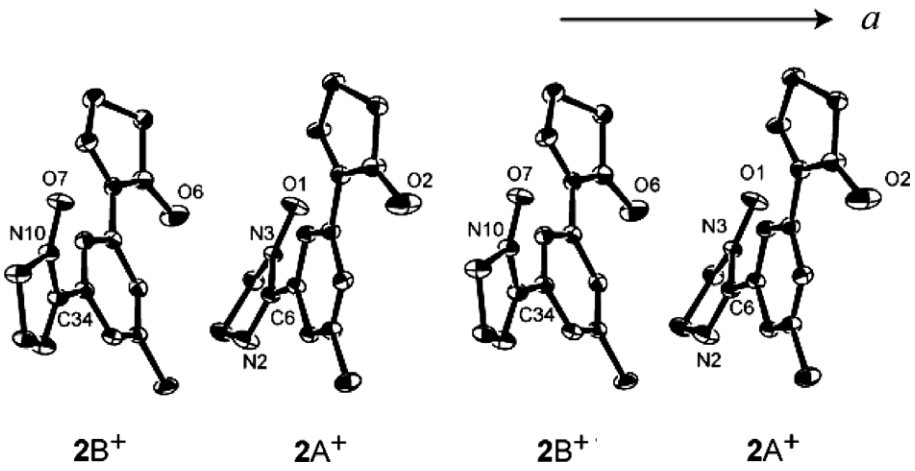

Fig. 2. Molecular chain of the cationic biradical $\mathbf{2}^+$ along the *a*-axis. The methyl groups of the iminonitroxide and the hydrogen atoms are omitted for clarity.

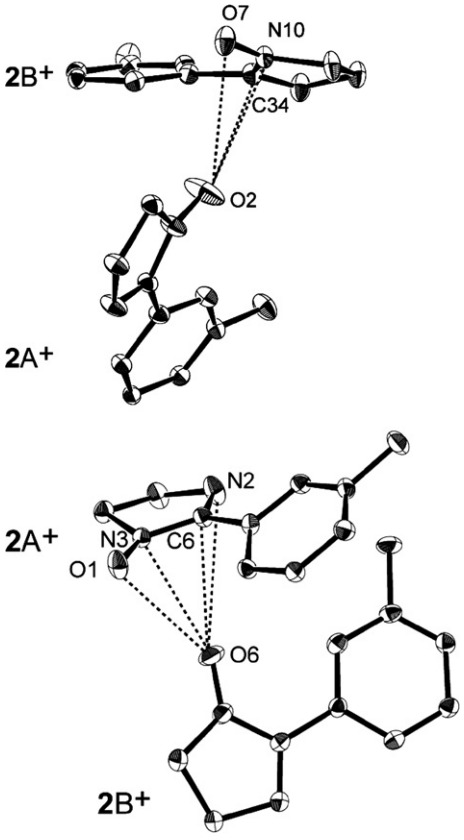

Fig. 3. Intermolecular short contacts of $\mathbf{2}^+ \cdot \mathrm{TfO}^-$ contributing to the intermolecular exchange interactions.

ture dependence of $\chi_p T$ was reproduced by Eq. (2) ($S = 1$) with the intramolecular exchange interaction of $2J_F/k_B = 10.0 \pm 0.1$ K and the intermolecular exchange interaction of $2J_{AF}/k_B = -1.00 \pm 0.01$ K. In the fitting, the *g*-factor was fixed as $g = 2.006$. Fixing the intramolecular ferromagnetic interaction of $2J_F/k_B = 7.5$ K as estimated from the magnetically diluted samples has given a poor fit to the observed temperature dependence of $\chi_p T$. The slightly enhanced interaction of $2J_F/k_B = 10.0$ K suggests a change in the dihedral angles of $\mathbf{2}^+$ in the polymer matrix.

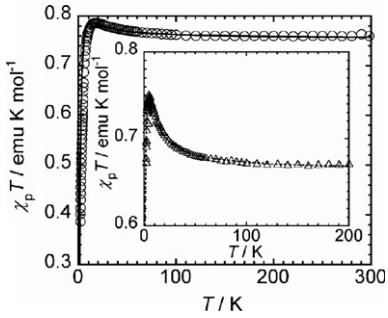

Fig. 4. Temperature dependence of paramagnetic susceptibility χ_p of $\mathbf{2}^+ \cdot \mathrm{TfO}^-$ measured on a SQUID magnetometer with $B = 0.1$ T in the $\chi_p T$ vs. T plots. The solid line denotes the calculated values from Eq. (2). In the inset are shown the $\chi_p T$ values of $\mathbf{2}^+ \cdot \mathrm{TfO}^-$ diluted in the PVC film with $B = 0.1$ T. The dashed line represents the calculated values from Eq. (1).

The magnitude of the intramolecular ferromagnetic exchange interaction in the pyridinium cation $\mathbf{2}^+$, $2J_F/k_B = 7.5 \sim 10$ K, is almost the same as that of the neutral pyridine analogue **1**, $2J_F/k_B = 7$ K [6]. Similar conservation of the intramolecular exchange interactions on *N*-alkylation of the pyridine ring as found in the iminonitroxide biradicals **1** and $\mathbf{2}^+$ has been found in nitronylnitroxide biradicals [20]. Meanwhile, the intramolecular ferromagnetic exchange interaction J_F of $\mathbf{2}^+$ is smaller than that of *m*-phenylene analogues of iminonitroxide [9e]. The heteroatom substitution in the π-conjugated exchange coupler seemingly influences the magnitude of the intramolecular exchange interaction, while we are not allowed to make straightforward comparison of the J values between the related derivatives with differing dihedral angles between the nitroxide and the aryl rings [6,9e,20].

4. Conclusion

The cation biradical of iminonitroxide $\mathbf{2}^+ \cdot \mathrm{TfO}^-$ has been synthesized and isolated in the crystalline solid state. The ground-state spin multiplicity of $\mathbf{2}^+$ has been found to be triplet with the singlet–triplet energy gap of $2J/k_B = 7.5$ K from the magnetic susceptibility of the

magnetically diluted system dispersed in the polymer film. There is little influence of the *N*-methylation for the 3,5-pyridine-substituted iminonitroxide biradicals on the intramolecular exchange interaction. The cation $\mathbf{2}^{+}$ is a building block molecule for ionic crystalline materials, which is stable and, at the same time, carries a ground-state $S = 1$ spin composed of two nitronylnitroxide radical fragments [21]. The ground-state triplet biradical $\mathbf{2}^{+}$ serves as a building block for molecule-based magnets of $S > 1/2$ based on intermolecular noncovalent bonding.

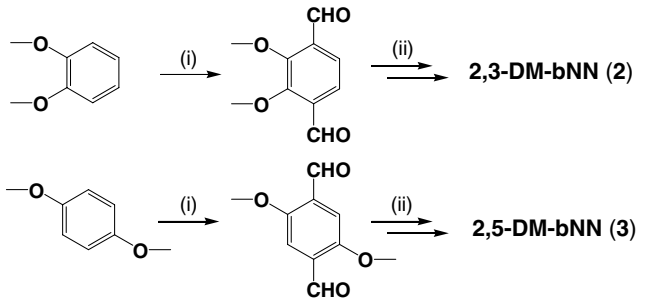
[21] A dihydrophenazine radical cation substituted with a nitronyl nitroxide group has been synthesized and the triplet ground state has been found: S. Hiraoka, T. Okamoto, M. Kozaki, D. Shiomi, K. Sato, T. Takui, K. Okada, J. Am. Chem. Soc. 126 (2004) 58.



Scheme 1. Biradicals **bNN** (**1**), **2,3-DM-bNN** (**2**) and **2,5-DM-bNN** (**3**).

π-conjugation of *p*-phenylene is discussed from both experiment and DFT molecular orbital calculations. A stable nitronyl nitroxide derivative of *p*-phenylene, **bNN** (**1**, Scheme 1), has an intramolecular antiferromagnetic exchange interaction of $2J/k_B = -104\ \mathrm{K} \sim -106\ \mathrm{K}$ from magnetic susceptibility measurements [9]. In order to clarify effects of torsion angles between the phenyl and the imidazole rings of nitronyl nitroxide, we have designed and synthesized two biradicals **2,3-DM-bNN** (**2**) and **2,5-DM-bNN** (**3**) (Scheme 1). Large torsion angles are expected for **2** and **3** owing to the bulky substituents of the methoxy groups. The intramolecular exchange interactions in **1**, **2**, and **3** are discussed based on magnetic susceptibility, X-ray crystal structures, and DFT molecular orbital calculations. The potentiality of the ground-state singlet biradicals as building blocks for novel exchange-coupled spin systems is discussed.

2. Experimental

2.1. Synthesis

The biradicals **2** and **3** were synthesized from commercial veratrole and 1,4-dimethoxybenzene, respectively, by following the route shown in Scheme 2. The generation of nitronyl nitroxide radicals (Step ii) was carried out by following the conventional method [10]. Elemental analysis (C, H, N) of **2** and **3**. *Anal.* Calc. for $C_{22}H_{32}N_4O_6$: C, 58.91; H, 7.19; N, 12.49. Found for **2**: C, 59.01; H, 7.20; N, 12.45%. Found for **3**: C, 58.98; H, 7.23; N, 12.44%. Single crystals of **2** and **3** suitable for X-ray crystallography experiments were obtained by recrystallization from a mixture of dichloromethane and hexane.

Scheme 2. Synthetic route for **2** and **3**. Reagents: (i) *n*-butyllithium in diethylether; (ii) 2,3-bis(hydroxylamino)-2,3-dimethylbutane in benzene and $NaIO_4$ in CH_2Cl_2/H_2O.

2.2. Crystal structure analysis

Single-crystal diffraction data of **2** and **3** were collected on a Rigaku Mercury CCD diffractometer with graphite monochromated Mo Kα radiation. The crystal structure was solved by using direct methods in a program package *CrystalStructure* [11]. Anisotropic thermal factors were applied for non-hydrogen atoms. Hydrogen atoms with isotropic thermal factors were refined as riding models.

2.3. Magnetic susceptibility measurements

Magnetic susceptibility was measured on a Quantum Design SQUID magnetometer MPMS-XL under the static magnetic field of 0.1 T in the temperature range down to 1.9 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constants.

2.4. DFT molecular orbital calculations

The total electronic energy was calculated for the biradicals **1**, **2**, and **3** by the use of the unrestricted density functional theory (DFT) at UB3LYP/6-31+G(d,p) level with a program package GAUSSIAN98 [12]. The molecular geometries of the biradicals, **1** [9], **2** and **3**, was taken from the X-ray crystal structures.

3. Results and discussion

3.1. Crystal structure

The crystallographic data of **2** and **3** are listed in Table 1. The molecular structures are shown in Fig. 1. A half of the molecule of **3** is crystallographically independent. The common atom numbering was, however, given to **2** and **3** in order to facilitate comparison of the molecular structures. The torsion angles between the phenyl ring and the ONCNO group of nitronyl nitroxide are 66.7° (C2–C1–C7–N2) and 63.8° (C5–C4–C14–N4) for **2** and 70.4° for **3**. The torsion angles of **2** and **3** are much larger than those of **1** (28.5°) [9]. The methoxy groups induce the large dihedral angles, which is likely to weaken the intramolecular exchange interaction through the π-conjugation in **2** and **3** as compared with that in **1**.

No intermolecular short distances close to the van der Waals contact were found around the N–O groups with a large spin density, which would contribute to possible intermolecular exchange interactions.

[b] $R_{w2} = \left[\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2\right]^{0.5}$.

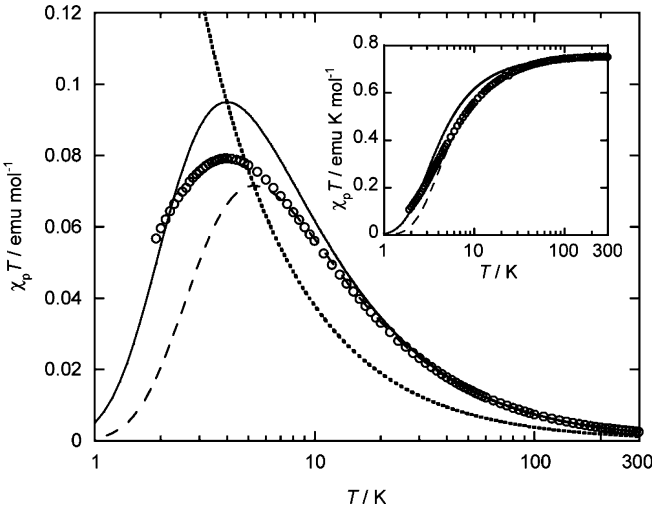

Fig. 2. Temperature dependence of paramagnetic susceptibility χ_p of **2,3-DM-bNN** (**2**) measured for the neat polycrystals. The inset shows the temperature dependence of the product χ_pT. The solid and dashed lines represent the calculation of Eq. (1) with $2J/k_B = -6.4$ K and -8.5 K, respectively. The dotted line shows the trajectory of (T_{max}, χ_{max}) in Eq. (4).

3.2. Magnetic susceptibility

The paramagnetic susceptibility χ_p measured for neat polycrystalline samples of **2** is depicted in Fig. 2. The χ_pT value of 0.75 emu K mol^{-1} at 300 K is consistent with 2 mol of $S = 1/2$ spins with the g-factor of 2.007, which has been determined from an observed ESR spectrum in a solution. The high-temperature limit of χ_pT indicates that the purity is satisfactory.

The magnitude of the intramolecular exchange interaction $2J$ in **2** is estimated using the Bleany–Bowers model [13]

$$\chi_p = \frac{2N_A g^2 \mu_B^2}{k_B T} \times \frac{1}{3 + \exp(-2J/k_B T)} \quad (1)$$

Numerical differentiation of χ_p in Eq. (1) with respect to T gives the temperature T_{max} where χ_p has a maximum

$$T_{max} = 1.247|J|/k_B \quad (2)$$

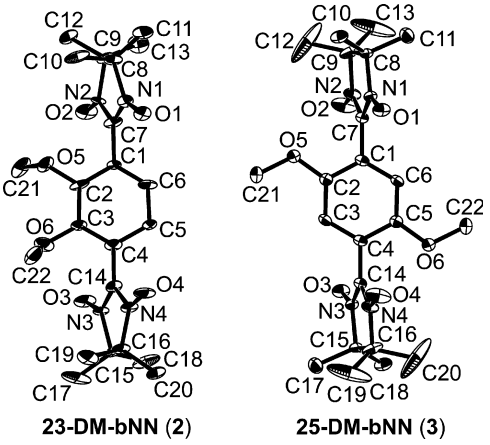

Fig. 1. ORTEP views of **2** and **3** at the 50% probability level. The hydrogen atoms are omitted for the sake of clarity.

as a function of $|J|$. The maximum value of χ_p at T_{max} is given as

$$\chi_{max} = 0.07547g^2/(|J|/k_B) \quad (3)$$

From Eqs. (2) and (3), the trajectory, the locus, of a point (T_{max}, χ_{max}) for the maximum in χ_p is given by

$$\chi_{max} = 0.09413g^2/T_{max} = 0.3792/T_{max} \quad (g = 2.007) \quad (4)$$

The observed maximum in χ_p for **2** is inconsistent with the trajectory Eq. (4), as shown in Fig. 2. The discrepancy is not attributed to impurity of paramagnetic molecules with only one unpaired electron or diamagnetic molecules, since the purity of the polycrystalline sample of **2** has been found to be satisfactory. The biradical **2** has no short contacts giving possible intermolecular exchange interactions,[1] as described above. The dashed line in Fig. 2 shows the best-fit curve calculated with Eq. (1), in which the larger weight is applied for the observed χ_p value at the higher temperature. This gives an estimate for the upper limit of $2|J|$, $2J/k_B = -8.5$ K. A lower limit of $2|J|$ acquired from Eq. (2) is $2J/k_B = -6.4$ K. The estimate of the intramolecular exchange interaction $2J/k_B$ of **2** ranges from -6.4 to -8.5 K.

In the high-temperature range from 300 K down to 10 K, the χ_pT value of **3** is consistent with that of **2** (Fig. 3). This indicates that the magnitude of the intramolecular interaction of **3** is in the same order as that of **2**. The fit with the larger weight at higher temperatures gives an estimate for the upper limit of $2|J|$, $2J/k_B = -8.2$ K for **3**, being comparable to $2J/k_B = -8.5$ K for **2**. The exchange interaction of $2J/k_B = -8.2$ K should give a maximum in χ_p at $T = 6.6$ K. The observed χ_p value of **3** exhibits no maximum in the temperature range examined. A trace of

[1] Trials with a modified Bleany–Bowers model with a mean field θ did not improve the fitting.

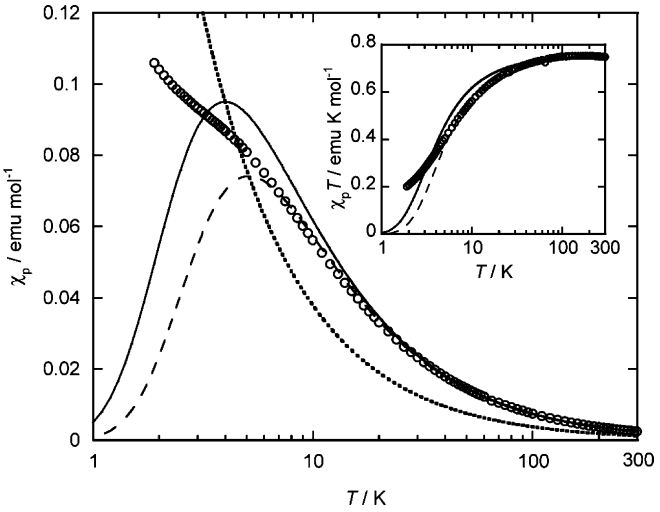

Fig. 3. Temperature dependence of paramagnetic susceptibility χ_p of **2,5-DM-bNN** (**3**) measured for the neat polycrystals. The inset shows the temperature dependence of the product χ_pT. The solid and dashed lines represent the calculation of Eq. (1) with $2J/k_B = -6.4$ K and -8.2 K, respectively. The dotted line shows the trajectory of (T_{max}, χ_{max}) in Eq. (4).

maximum in χ_p is found at $T_{max'} = 4.0$ K, where the second derivative $\partial^2\chi_p/\partial T^2$ is zero, which gives a lower limit of the intramolecular exchange interaction $2J/k_B = -6.4$ K. Thus, the exchange interaction $2J/k_B$ of **3** ranges from -6.4 to -8.3 K.

The growth of χ_p for **3** below 3.5 K is not attributed to any paramagnetic impurity or lattice defects, since the purity is almost 100%, as estimated from the observed χ_pT at 300 K. The growth of χ_p suggests that the magnitude $|J|$ in **3** is reduced at lower temperatures, $2J/k_B \ll -6.4$ K. The temperature-dependent $|J|$ value results from a possible change in the dihedral angle between the phenyl ring and the ONCNO group of nitronyl nitroxide at low temperatures. Similarly, the poor fit for **2** is attributed to the temperature-dependent $|J|$ value as well.

3.3. DFT molecular orbital calculations

It has been established that an energy E_{BS} of a broken-symmetry (BS) state described with an unsymmetrical spin and spatial functions affords a satisfactory estimate for the lowest singlet state [14]. The intramolecular exchange interaction J of a biradical is related to the energy gap between the lowest singlet and the lowest triplet states, $E_{BS} - E_T$, as estimated from DFT-based molecular orbital calculations. The exchange parameter J_{DFT} is expressed as [15]

$$J\mathrm{DFT} = \frac{(E_{BS} - E_T)}{\langle S^2\rangle_T - \langle S^2\rangle_{BS}} \quad (5)$$

where $\langle S^2\rangle$ denotes the spin expectation value for the triplet (T) or the BS singlet state, minimizing spin contamination effects in J_{DFT}. The $2J_{DFT}$ value was calculated for the parent compound **1** with varying torsion angles with increments of 15°, which are compared with those calculated for **2**, and **3**, as listed in Table 2. Although the calculated

Table 2
Torsion angles and intramolecular exchange interactions $2J$

Compound	Torsion angle	$2J_{calc}$[a]	$2J$ (exp.)[b]
1a[c]	15	−421.2	
1[d]	28.5	−306.2	−104 ∼ −106
1b[c]	30	−290.8	
1c[c]	45	−135.8	
1d[c]	60	−33.2	
1e[c]	75	−3.2	
2[d]	63.8 and 66.7	−17.8	−6.4 ∼ −8.5
3[d]	70.4	−8.6	−6.4 ∼ −8.2

[a] Calculated with Eq. (5).
[b] Experimentally estimated from the analysis of magnetic susceptibility.
[c] Molecular geometries are based on the X-ray crystal structure of **1**. Only the torsion angles are altered from those of **1**.
[d] Molecular geometries are taken from the X-ray crystal structure.

$2J_{DFT}$ values are overestimated as compared to the experimental values,[2] the tendency of the $2J$ values *versus* torsion angles is in good agreement with experiment.

4. Conclusion

The new *p*-phenylene-bis(nitronyl nitroxide) biradicals **2** and **3** have been designed and synthesized. The methoxy groups have given rise to the larger torsion angles in **2** and **3** as compared with that in **1**. The large torsion angles should suppress π-conjugation in the *p*-phenylene, providing the smaller intramolecular antiferromagnetic interactions. It is suggested that one of the two biradicals, **2,5-DM-bNN** (**3**), has the temperature-dependent exchange interaction.

In our previous studies, it has been found from theoretical calculations that a one-dimensional alternating chain composed of ground-state singlet biradicals and monoradicals has three kinds of ground states: Two are ferrimagnetic and the other is non-magnetic (spin-less) [16]. The theory indicates that subtle modification of the intra- and intermolecular interactions results in possible switching between the ferrimagnetic high-spin and non-magnetic states [16]. The ground-state singlet biradicals **2** and **3** are potentially suitable building blocks for the theoretical model in which the magnitude of the intramolecular exchange interaction is comparable to those of intermolecular exchange interactions and susceptible to crystal lattice environment.

2. Experimental

2.1. Measurements

The ^{1}H NMR spectra were measured with a JEOL JNM-EX400 spectrometer (400 MHz). Tetramethylsilan was used as an internal standard for chemical shifts. The IR spectra were measured with a JASCO FT/IR-230 spectrometer. Size exclusion chromatography (SEC) was measured with a TOSOH HLC-8020 chromatograph. THF was used as an eluant and the temperature was kept at 40 °C. The ESR spectra were measured with a JEOL JES-RE1X spectrometer (X-band). Mn^{2+} was used as a standard for the g value. The spin concentration of polyradical was determined by using a solution of 1,3,5-triphenylverdazyl in dichloromethane prepared in known concentration. The temperature dependence of the ESR signal intensity was measured in the region of 123–333 K. The magnetization was measured with a Quantum Design MPMS-7T SQUID magnetometer. The external magnetic field dependence of the magnetization was measured in the region of 0–6 T at the constant temperature. The temperature dependence of the magnetic susceptibility was measured in the region of 2–300 K at the constant external magnetic field of 0.5 T. The diamagnetic contribution from a sample holder, poly(vinyl chloride) (PVC) and poly (methyl methacrylate) (PMMA) was previously measured and corrected. The diamagnetic contribution of the paramagnetic sample was estimated with the Pascal's constants and corrected.

2.2. Synthesis of precursors

Precursors **4**, **5**, **9**, and **10** were prepared by the Suzuki-Miyaura coupling and the Pd-catalyzed amination according to Scheme 1. The procedures were similar for preparing precursor polymers **11** and **12** as mentioned below.

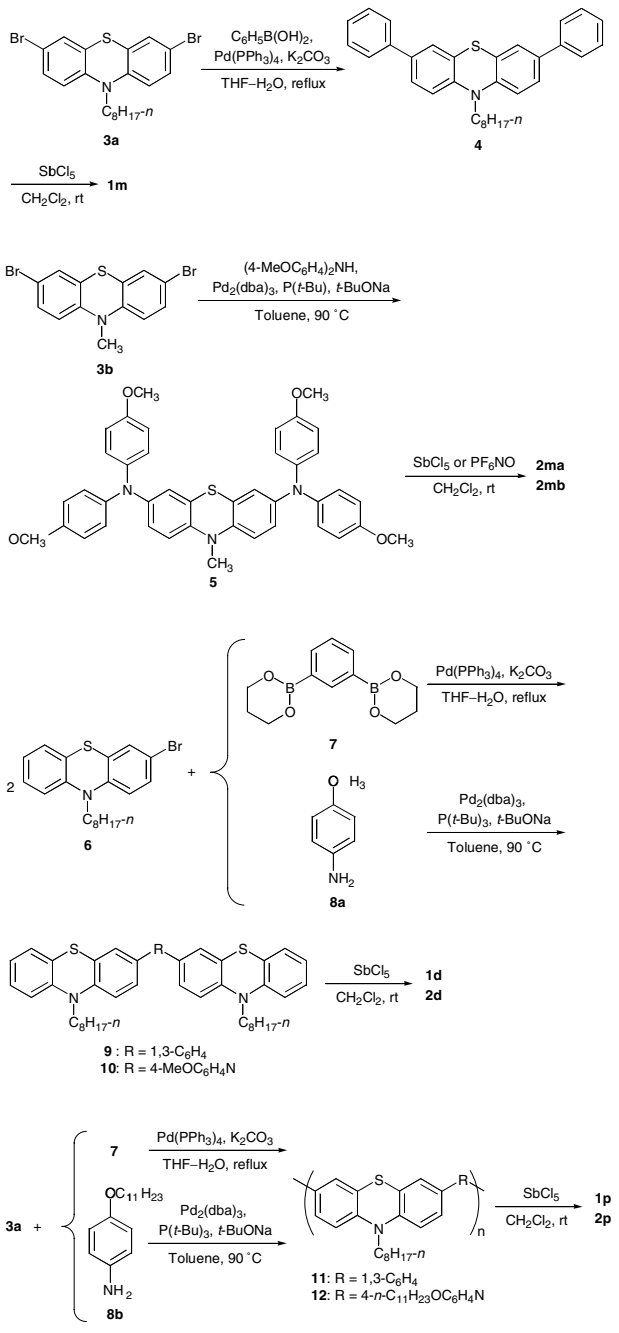
2.2.1. Precursor *4*

Yield: 48.3%. Yellow oil. ^{1}H NMR (acetone-d_6) δ 0.85 (t, $J = 7.1$ Hz, 3H), 1.21–1.41 (m, 8H), 1.51 (q, $J = 7.6$ Hz, 2H), 1.86 (q,$J = 7.1$ Hz, 2H), 4.02 (t, $J = 7.1$ Hz, 2H), 7.12 (d, $J = 8.5$ Hz, 2H), 7.32 (tt, $J = 7.3$, 1.2 Hz, 2H), 7.42–7.47 (m, 6H), 7.50 (dd, $J = 8.5$, 2.2 Hz, 2H), 7.63 (dd, $J = 7.3$, 1.2 Hz, 4H).

2.2.2. Precursor *5*

Yield: 58.0%. Yellowish green prisms. ^{1}H NMR (DMSO-d_6) δ 3.21 (s, 3H), 3.71 (s, 12H), 6.60 (d, $J =$ 2.4 Hz, 2H), 6.73 (dd, $J = 8.8$, 2.4 Hz, 2H), 6.75–6.92 (m, 18H).

2.2.3. Precursor *9*



Yield: 34.1%. Yellow oil. ^{1}H NMR (chloroform-d) δ 0.87 (t, $J = 6.8$ Hz, 6H), 1.05–1.51 (m, 20H), 1.84 (q, $J = 6.3$ Hz, 4H), 3.87 (t, $J = 7.1$ Hz, 4H), 6.80–7.02 (m, 6H), 7.08–7.22 (m, 4H), 7.36–7.52 (m, 8H).

2.2.4. Precursor *10*

Yield: 71.0%. Yellowish green oil. ^{1}H NMR (DMSO-d_6) δ 0.83 (t, $J = 6.6$ Hz, 6H), 1.11–1.31 (m, 16H), 1.37 (q, $J = 6.8$ Hz, 4H), 1.66 (q, $J = 6.8$ Hz, 4H), 3.73 (s, 3H), 3.80 (t, $J = 6.8$ Hz, 4H), 6.66 (d, $J = 2.4$ Hz, 2H), (dd, $J = 8.7$, 2.4 Hz, 2H), 6.84–7.01 (m, 10H), 7.09 (d, $J = 7.6$ Hz, 2H), 7.19 (t, $J = 8.3$ Hz, 2H). *Anal.* Calc. for $C_{47}H_{55}N_3OS_2$: C, 76.07; H, 7.47; N, 5.66. Found: C, 76.29; H, 7.67; N, 5.86%.

2.2.5. Precursor *11*

To a solution of **3a** (0.469 g, 1.00 mmol) and **7** (0.246 g, 1.00 mmol) in THF (10 mL) were added a 2M-potassium carbonate aqueous solution (2 mL), tetra-*n*-butylammonium bromide (0.870 g, 2.67 mmol) and $Pd(PPh_3)_4$ (69 mg, 0.06 mmol) and the heterogeneous mixture was refluxed for 24 h under nitrogen. The organic layer was separated and washed with a 5%-sodium cyanide aqueous

Scheme 1. Synthetic route.

solution (3 mL) and brine. After evaporating, the residue was reprecipitated from THF-methanol (7–70 mL) to give **11** in 87.7% yield (0.338 g) as yellow powder. *Anal.* Calcd. for $(C_{26}H_{27}NS)_n$: C, 80.99; H, 7.06; N, 3.63. Found: C, 80.72; H, 7.12; N, 3.54%. The ^{1}H NMR and SEC measurements could not be performed because of the insolubility.

2.2.6. Precursor *12*

To a solution of **3a** (0.704 g, 1.50 mmol) and 4-*n*-undecyloxyaniline (**8b**) (0.395 g, 1.50 mmol) in toluene (15 mL) were added sodium *t*-butoxide (0.432 g, 4.50 mmol), tri-*t*-butylphosphine (36 mg, 0.18 mmol) and $Pd_2(dba)_3$ (82 mg, 0.09 mmol) and the mixture was heated at 90 °C for 12 h under nitrogen. After filtering, the filtrate was washed with a 5%-sodium cyanide aqueous solution (4.4 mL) and brine and dried with anhydrous magnesium sulfate. After evaporating, the residue was reprecipitated from dichloromethane-hexane (5–50 mL) to give **12** in 88.0% yield (0.753 g) as brownish yellow powder. ^{1}H NMR (chloroform-*d*) δ 0.68–0.98 (br s, 6H), 1.09–1.99 (m, 30H), 3.50–4.08 (m, 4H), 6.48–7.18 (m, 10H). *Anal.* Calc. for $(C_{37}H_{50}N_2OS)_n$: C, 77.85; H, 8.83; N, 4.91. Found: C, 65.43; H, 7.18; N, 3.92%. $M_n = 5790$, $M_w = 9640$ (polystyrene standard).

2.3. Formation of cation radicals

To a solution of precursor in dichloromethane was added antimony(V) chloride or nitrosonium hexafluorophosphate. The mixture was stirred for 20 min at room temperature and poured into excess hexane. The precipitate was corrected and recrystallized or reprecipitated.

1m. Recrystallization from dichloromethane-benzene. Yield: 17.4%. Dark green prisms. M.p. 144–145 °C. *Anal.* Calc. for $C_{32}H_{33}Cl_6NSSb$: C, 48.15; H, 4.17; N, 1.75. Found: C, 48.21; H, 4.27; N, 1.64%.

2ma. Reprecipitation from dichloromethane-ether (1:10). Yield: 91.7%. Dark bluish green powder. M.p. 159–160 °C. *Anal.* Calc. for $C_{41}H_{37}Cl_5N_3O_4SSb$: C, 50.93; H, 3.86; N, 4.35. Found: C, 50.22; H, 3.84; N, 4.44%.

2mb. Reprecipitation from THF-ether (1:10). Yield: 58.6%. Dark bluish green powder. M.p. 155–156 °C. *Anal.* Calc. for $C_{41}H_{37}F_6N_3O_4PS$: C, 60.59; H, 4.59; N, 5.17. Found: C, 58.51; H, 4.33; N, 5.76%.

1d. Yield: 22.7%. Reprecipitation from dichloromethane-hexane (1:5). Dark green powder. M.p. 135–136 °C. *Anal.* Calc. for $C_{46}H_{52}Cl_{12}N_2S_2Sb_2$: C, 40.45; H, 3.84; N, 2.05. Found: C, 42.67; H, 4.12; N, 2.08%.

2d. Reprecipitation from dichloromethane-ether (1:10). Yield: 37.7%. Dark bluish green powder. M.p. 129–130 °C. *Anal.* Calc. for $C_{47}H_{55}Cl_{10}N_3OS_2Sb_2$: C, 42.12; H, 4.14; N, 3.14. Found: C, 42.19; H, 4.25; N, 3.38%.

1p. Reprecipitation from dichloromethane-ethyl acetate (1:10). Yield: 85.4%. Dark green powder. *Anal.* Calc. for $(C_{26}H_{27}Cl_6NSSb)_n$: C, 43.37; H, 3.78; N, 1.95. Found: C, 43.17; H, 3.93; N, 1.81%.

2p. Reprecipitation from dichloromethane-ether (1:10). Yield: 79.7%. Dark bluish green powder. *Anal.* Calc. for $(C_{37}H_{50}Cl_5N_2OSSb)_n$: C, 51.09; H, 5.79; N, 3.22. Found: C, 50.88; H, 5.63; N, 3.01%.

3. Results and discussion

3.1. ESR measurement of monomers

The ESR spectra of monomers were measured in dichloromethane (Fig. 1, upper). The spectrum was observed at $g = 2.0055$ for **1m** and 2.0035 for **2ma**. For both **1m** and **2ma**, the signal shape was not a simple triplet line as often observed in the N-centred radicals or cation radicals. The spectrum was then analyzed by the computer-simulation

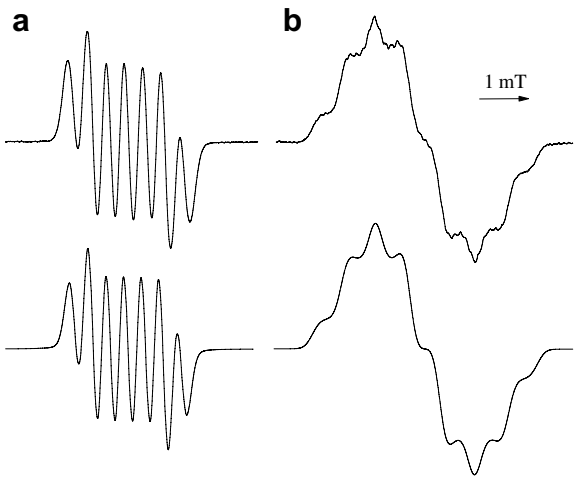


Fig. 1. ESR spectra of (a) **1m** and (b) **2ma** in dichloromethane at room temperature. The upper and bottom spectra are the observed and simulated spectra, respectively.

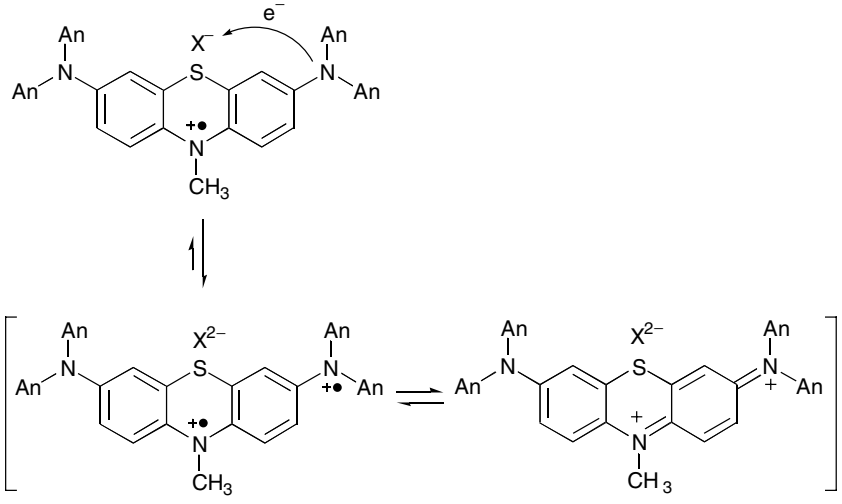
and the hyperfine coupling (hfc) constants were determined: $a_N = 0.730$ and $a_H = 0.108$ (2H), 0.079 (2H), 0.036 (2H) and 0.362 (2H) mT for **1m** and $a_N = 0.659$ (1N) and 0.234 (2N) and $a_H = 0.118$ (2H), 0.088 (2H), 0.042 (2H) and 0.611 (3H) mT for **2ma**. The simulated spectra reproduced with these hfc constants were in excellent agreement with the observed spectra (Fig. 1, bottom). For **1m**, the delocalization of the spin to two phenyl groups could not be confirmed from this ESR spectrum. Whereas, for **2ma**, the a_N value due to diarylamine nitrogen nuclei suggested the delocalization of the spin to the diarylamine moieties. But, the spin concentration of **2ma** was determined by ESR to be 0.15 spins per molecule, which was unexpectedly low. This would be probably due to another electron transfer shown in Scheme 2. In **2ma**, the electron transfer occurs from not only the phenothiazine moiety but also the diarylamine moiety, resulting in forming dication diradical. Because dication diradical is a singlet specie as shown in the equilibrium with dication, the formation of dication diradical reduces the spin concentration. To improve the spin concentration, the anion part was changed from $SbCl_5$ to PF_6, that is, **2mb** was synthesized (Scheme 1), but the spin concentration was 0.10 spins per molecule, which was similar for **2ma**.



3.2. ESR and magnetization measurements of dimers

The ESR spectra of dimers were measured in dichloromethane and in polymer matrix (Fig. 2). The spectrum was observed in dichloromethane at $g = 2.0051$ for **1d** and 2.0035 for **2d**. For **1d**, the signal shape was a quintet line. Whereas, for **2d**, the signal shape was a singlet line. To confirm the intramolecular spin interaction, the ESR spectra in diluted polymer matrix were measured at 77 K. For **1d** in PMMA matrix, the $\Delta M_S = \pm 2$ transition was observed at ca. 162 mT, indicating of existing the intramolecular spin interaction. The magnetization measurement of **1d** in PMMA matrix was also carried out by a SQUID magnetometer. The external magnetic field dependence of the magnetization is shown in Fig. 3. The experimental data at 2, 4, and 6 K are in accordance with the $S = 1$ line given by the Brillouin function, indicating that **1d** was in the $S = 1$ spin state. This shows that 1,3-phenylene gives the intramolecular ferromagnetic spin interaction as well as polycarbenes and poly(triarylmethine radical)s.

For **2d**, the $\Delta M_S = \pm 2$ transition was not observed in the ESR spectra in PVC matrix. The spin concentration of **2d** was then determined to be 0.34 spins per molecule. Because there are two phenotiazine moieties in **2d**, the percentage of the spin generation was 17%, which was similar for **2ma**. Due to this low spin concentration, **2d** could not be in the triplet state.

3.3. ESR and magnetization measurements of polymers

Because **1p** was insoluble, the ESR spectrum was measured in solid state (Fig. 4a). The spectrum was a singlet

Scheme 2. Potential another electron transfer in **2ma** and **2mb**.

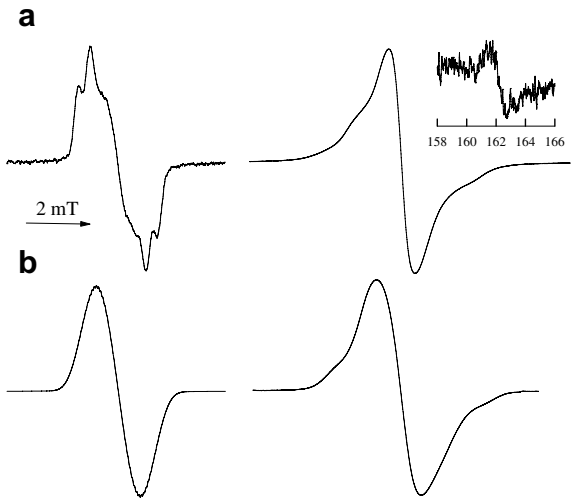


Fig. 2. ESR spectra of (a) **1d** and (b) **2d** at room temperature. The left and right spectra are observed in dichloromethane and in diluted polymer matrix (PMMA for **1d** and PVC for **2d**), respectively. The $\Delta M_S = \pm 2$ transition was observed at ca. 162 mT at 77 K in PMMA matrix in Fig. 2(a).

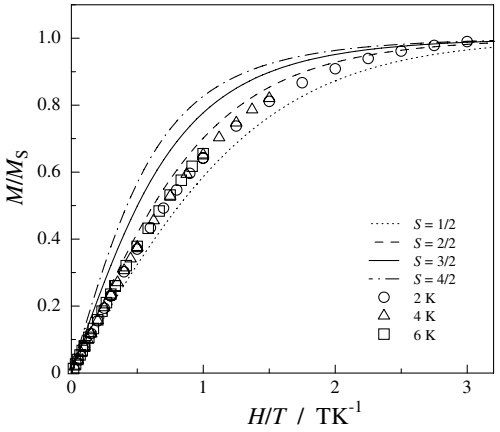

Fig. 3. External magnetic field dependence of the magnetization of **1d** in PMMA matrix (4.7 wt% content). The points are the experimental data at 2, 4, and 6 K. The lines are the theoretical lines for $S = 1/2$, 2/2, 3/2, and 4/2 given by the Brillouin function.

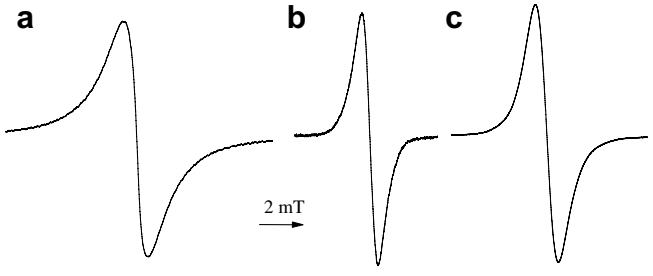

Fig. 4. ESR spectra of **1p** and **2p** at room temperature. (a) **1p** in solid state. (b) **2p** in dichloromethane. (c) **2p** in PVC matrix.

line, indicating that the spin concentration is high. The spin concentration was estimated from the magnetic susceptibility measured by SQUID (Fig. 5). The $\chi_{mol}T$ value is 0.290

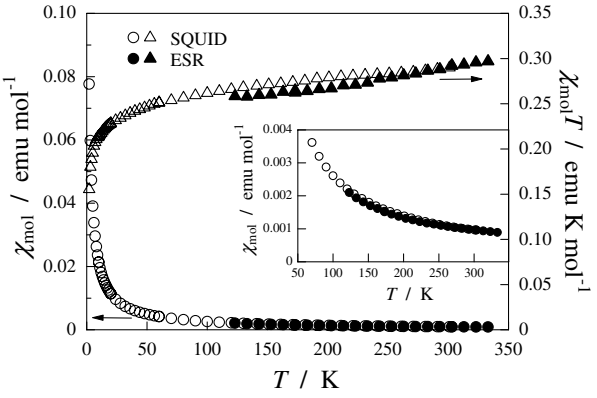

Fig. 5. Temperature dependence of the magnetic susceptibility and the ESR signal intensity of **1p** (bulk solid). The external magnetic field was 0.5 T in the SQUID measurement.

at 300 K, which corresponds to the spin concentration of 0.77 spins per repeating unit. The $\chi_{mol}T$ value already decreases near room temperature region as the temperature decreases. This was also confirmed by ESR [11]. The temperature dependence of the ESR signal intensity is in good accordance with the data obtained by SQUID. The decrease of the $\chi_{mol}T$ value indicates the antiferromagnetic interaction. Because dimer **1d** was in the $S = 1$ spin state (Fig. 3), the intramolecular spin interaction in **1p** was ferromagnetic. Therefore, the antiferromagnetic interaction was due to the intermolecular spin interaction.

The ESR spectra of **2p** were measured in dichloromethane and in PVC matrix (Fig. 2). The spectrum in dichloromethane was observed at $g = 2.0046$ and the signal shape was a singlet line. The spin concentration was determined by ESR to be 0.16 spins per repeating unit. Although the formation percentage of complexes between the phenothiazine moieties in **12** and $SbCl_5$ were estimated to be near 100% from the result of the elemental analysis, the spin concentration was low as well as **2ma** and **2d**. In the ESR

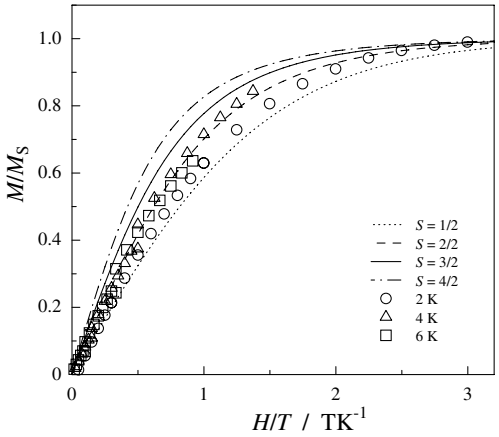

Fig. 6. External magnetic field dependence of the magnetization of **2p** in PVC matrix (4.6 wt% content). The points are the experimental data at 2, 4, and 6 K. The lines are the theoretical lines for $S = 1/2$, 2/2, 3/2, and 4/2 given by the Brillouin function.

spectrum in PVC matrix at 77 K, no $\Delta M_S = \pm 2$ transition was observed, which would be due to the low spin concentration. But, in the magnetization measurement in PVC matrix (Fig. 6), the external magnetic field dependence of the magnetization showed that **2p** was in the $S = 1$ state. In taking into account that the degree of polymerization of **12** was ca. 10 and the spin concentration of **2p** was 0.16 spins per repeating unit, there were two spins per molecule in **2p**. There would be the ferromagnetic interaction between those two spins in the low temperature region.

4. Summary

Two types of organic open-shell polymer containing phenothiazine cation radicals as spin resources were synthesized. The one is the 1,3-phenylene-linked polymer **1p**, and the other is the arylamine nitrogen-linked polymer **2p**. Precursor polymers were prepared by the Suzuki-Miyaura coupling and the Pd-catalyzed amination. The formation of complexes between the phenothiazine moieties in precursor polymers and antimony(V) chloride gave stable open-shell polymers. The magnetic behavior of **1p** was intramolecularly ferromagnetic, but intermolecularly antiferromagnetic. Whereas, **2p** was in the $S = 1$ spin state in spite of low spin concentration of 0.16 spins per repeating unit.

Acknowledgement

We thank the Materials Design and Characterization Laboratory, Institute for Solid State Physics, The University of Tokyo for using a SQUID magnetometer.

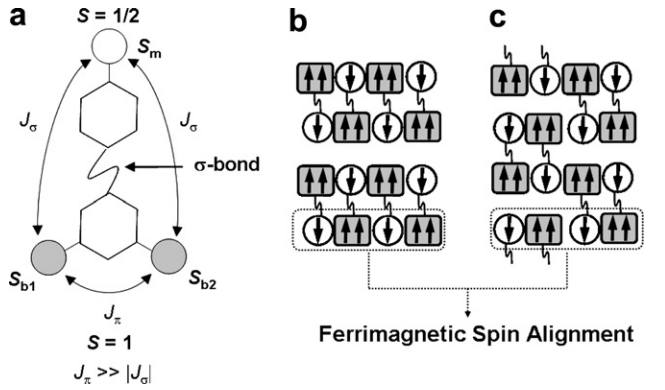

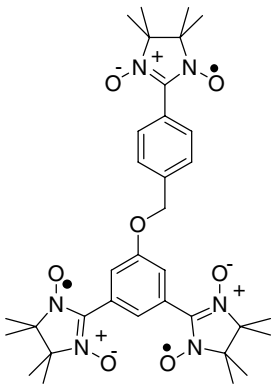

Fig. 1. (a) Triradical consisting of weakly coupled monoradical and biradical moieties. In the three-centered exchange-coupled system, J_σ show the weak exchange interaction through the σ-bonds, while J_π denotes the ferromagnetic exchange interaction through the π-conjugation in the *m*-phenylene-based biradical moiety. (b,c) Head-to-tail packings of triradical molecules leading to the ferrimagnetic spin alignment.

ferrimagnetic spin alignment in a head-to-tail molecular packing of the triradical molecules, as depicted in Fig. 1(b) and (c).

The alternating aggregation of the heterospin entities is achieved by tuning the molecular geometry of the building-block molecules, leading to the close packing of approximately isosceles triangular molecules in a head-to-tail fashion. As building blocks for the head-to-tail packing of the approximately isosceles triangular molecules, we have designed triradicals based on a 1,3,5-triyl benzene framework of 3,5-substituted phenyl benzoate [3]. A close packing of the isosceles triangular molecules has been found to lead to the alternating aggregation of the two kinds of open-shell entities [3]. In the present study, we have designed another type of approximately isosceles triangular molecules; benzyl-phenyl ether derivative of nitronyl nitroxide ***p*-trisNN** (**1**) (Scheme 1). The ether group is expected to truncate the exchange interactions through the π-conjugation. The synthesis of **1** has been reported [4]. Magnetic susceptibility of **1** has been measured for magnetically diluted systems of organic polymer films [4], in which intermolecular exchange interactions are suppressed. From the susceptibility of the isolated molecules, it has been found that the magnitude of $|J_\sigma|$ is much weaker than that of J_π by two orders of magnitude; $J_\pi/k_B = 16.8$ K, $J_\sigma/k_B = -0.27$ K for **1** [4]. Thus, the condition Eq. (2) is fulfilled in **1**, indicating its potential as a building block for single-component ferrimagnetics. In this communication, we report magnetic properties of **1** in the neat crystalline solid state in relation to its crystal structure.

***p*-trisNN (1)**

Scheme 1. Triradical *p*-**trisNN** (**1**).

2. Experimental

2.1. Crystal structure analysis

Single-crystal X-ray diffraction data of **1** were collected on a Rigaku Mercury CCD diffractometer with graphite-monochromated Mo Kα radiation. The crystal structure was solved by using direct methods in a program package CrystalStructure.[1] From powder X-ray diffraction experiments, we have confirmed that the crystal structure of the polycrystalline samples used in magnetic susceptibility measurements is the same as that determined in the single crystal X-ray experiments.

2.2. Magnetic susceptibility measurements

Magnetic susceptibility was measured on a Quantum Design SQUID magnetometer MPMS-XL under the static magnetic field of 0.1 T in the temperature range down to 1.9 K.

3. Results and discussion

3.1. Crystal structure

The crystallographic data of *p*-**trisNN** (**1**) are listed in Table 1. The molecular structure with the atom numbering scheme is given in Fig. 2. The molecules of **1** are arranged in a head-to-tail manner along the *a* axis, as depicted in Fig. 3(a). Intermolecular close contacts shorter than the van der Waals one [5] are found only in pairs of inversion-related nearest-neighboring molecules. Thus, the molecular chain along the *a* axis is regarded as an assemblage of exchange-coupled six $S = 1/2$ spins in the pairs, or dimers, of the triradicals. One of the contacts within the dimer is found between the nitronyl nitroxide group (NN1) of the biradical moiety and the group NN2 of the neighboring inversion-related molecule. The NN1–NN2 contact, termed "Contact A", contains interatomic short distances of O5–C7′ = 3.088(5) Å and O5–C3′ = 3.198 (5) Å, as shown in Fig. 3(b). Another contact occurs between the biradical moiety (NN1) and the phenyl ring (Ph2) with a short distance of O3–C23′ = 3.373(4) Å, as designated "Contact B" in Fig. 3(b). Intermolecular

T (K)	143

[a] $R = \sum ||F_o| - |F_c|| / \sum |F_o|$.

[b] $R_{w2} = \left[\sum w(F_o^2 - F_c^2)^2 \Big/ \sum w(F_o^2)^2\right]^{\frac{1}{2}}$, $w = 1/[0.0142F_o^2 + 1.0000\sigma^2(F_o^2)]/(4F_o^2)$.

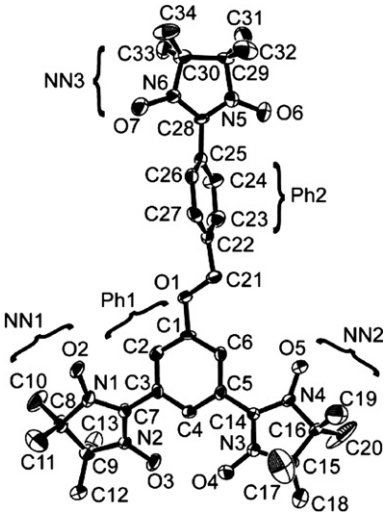

Fig. 2. ORTEP view of **1** at the 50% probability level. The hydrogen atoms are omitted for the sake of clarity.

exchange interactions are expected at Contact A and Contact B, which are designated J_A and J_B, respectively. The possible intermolecular interactions J_A and J_B, together with the intramolecular interactions J_π and J_σ, afford a six-spin cluster in the dimer, as illustrated in Fig. 3(c).

3.2. Magnetic susceptibility

The paramagnetic susceptibility χ_p measured for neat polycrystalline solid samples of ***p*-trisNN (1)** is depicted in Fig. 4 in the χ_pT versus T plots. On lowering the temperature the χ_pT value increases from the high-temperature limit for three moles of $S = 1/2$ spins, indicating the occurrence of a dominating ferromagnetic interaction. It should be noted that the observed χ_pT value is larger than 1.38 emu K mol^{-1}

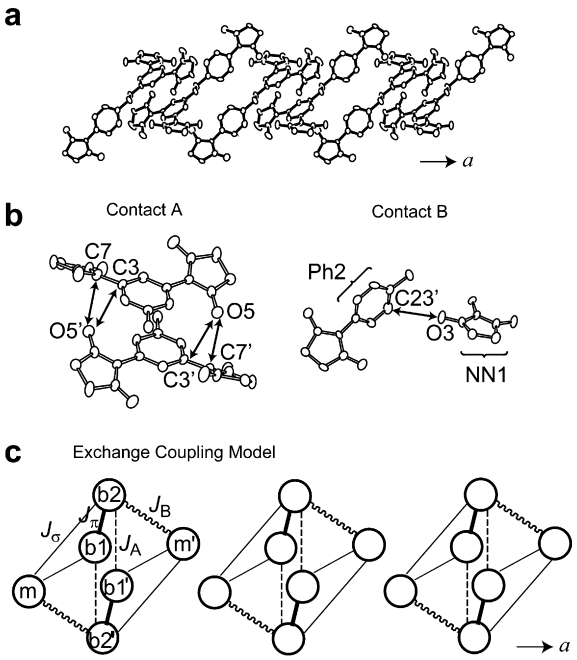

Fig. 3. (a) Molecular packing of ***p*-trisNN (1)** in the head-to-tail alignment along the a-axis. (b) Two types of intermolecular short contacts A, B in the dimer of **1**. (c) Exchange coupling model for the molecular assembly of **1**. The thick and thin solid lines represent the intramolecular exchange interactions J_π and J_σ, respectively. The dashed and wavy lines denote the intermolecular exchange interactions J_A and J_B at the contacts A and B, respectively.

at low temperature, which is expected for a noninteracting pair of $S = 1/2$ and $S = 1$ spins. This indicates that the ferromagnetic interaction is operative between the biradical moieties in the dimer that is ascribed to J_A at Contact A. The χ_pT value has a maximum at 12 K, indicating an antiferromagnetic intermolecular interaction between the monoradical moiety and the ferromagnetically-coupled four $S = 1/2$ spins of the biradical moieties in the dimer, that is J_B of Contact B. The temperature dependence of χ_pT was analyzed with the six-spin cluster model

$$\begin{aligned} H = &-2J_\pi(\mathbf{S}_{b1}\cdot\mathbf{S}_{b2} + \mathbf{S}_{b1'}\cdot\mathbf{S}_{b2'}) \\ &- 2J_\sigma(\mathbf{S}_{b1}\cdot\mathbf{S}_{m} + \mathbf{S}_{b2}\cdot\mathbf{S}_{m} + \mathbf{S}_{b1'}\cdot\mathbf{S}_{m'} + \mathbf{S}_{b2'}\cdot\mathbf{S}_{m'}) \\ &- 2J_A(\mathbf{S}_{b1}\cdot\mathbf{S}_{b2'} + \mathbf{S}_{b2}\cdot\mathbf{S}_{b1'}) - 2J_B(\mathbf{S}_{m}\cdot\mathbf{S}_{b2'} + \mathbf{S}_{b2}\cdot\mathbf{S}_{m'}) \end{aligned} \quad (3)$$

which has been suggested from the X-ray crystal structure analysis [6], as depicted in Fig. 3(c). Numerical diagonalization was applied to Eq. (3), giving energy eigenvalues E_i and spin eigenvalues S_i for the ith eigenstate from which the temperature dependence of χ_pT was calculated as

$$\chi = \frac{N_A g^2 \mu_B^2}{6k_B T} \cdot \frac{\sum_i [S_i(S_i+1)(2S_i+1)\exp(-E_i/k_B T)]}{\sum_i [(2S_i+1)\exp(-E_i/k_B T)]} \quad (4)$$

The intramolecular interactions of $J_\pi/k_B = 16.8$ K and $J_\sigma/k_B = -0.27$ K as obtained from the diluted organic polymer film [4] were assumed to remain unchanged in the crystal in order to avoid overparameterization. The

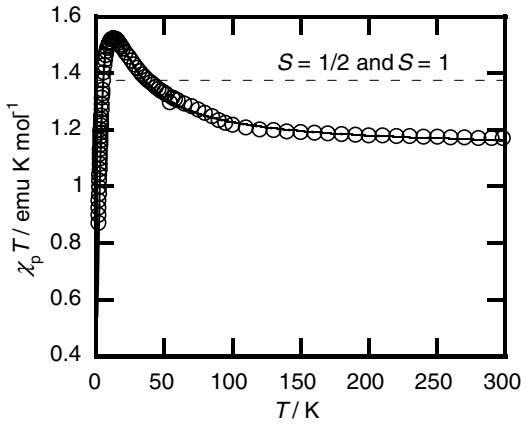

Fig. 4. Temperature dependence of paramagnetic susceptibility χ_p of ***p*-trisNN** (**1**) in the $\chi_p T$ versus T plots. The solid line denotes the calculated values from the six-spin cluster model (Eqs. (3) and (4)). The horizontal dotted lines show the Curie law for a noninteracting pair of $S = 1/2$ and $S = 1$.

g-factor of $g = 2.006$ as observed from the solution ESR spectra of **1** was fixed as well. The independent adjustable parameters J_A and J_B were optimized to be $J_A/k_B = 13 \pm 2$ K, $J_B/k_B = -3.0 \pm 0.4$ K.

An intermolecular short contact between the central carbon atom of nitronyl nitroxide, which is usually negatively spin-polarized, and the nitroxide oxygen with a positive spin density, such as C7 and O5 of contact A in **1**, is expected to give rise to an intermolecular ferromagnetic interaction as found in other nitronyl nitroxide crystals [7]. This is consistent with the positive parameter of $J_A/k_B = 13$ K for **1**.

4. Conclusion

The triradical derivative of nitronyl nitroxide, ***p*-trisNN** (**1**), has been synthesized as a building block molecule for single-component organic molecule-based ferrimagnetics. The crystal structure and the magnetic properties in the solid state have been examined. The alternating arrangement of the $S = 1$ and the $S = 1/2$ moieties has been accomplished by uniting the two open-shell entities in the approximately isosceles triangular geometry. Another triradical derivative (**2**) of benzyl-phenyl ether with the approximately isosceles triangular geometry has been synthesized.[2] The molecular packing of **2** is quite similar to that of **1**, indicating the efficiency of the close packing of isosceles triangular molecules leading to the alternating aggregation of the two kinds of molecular entities. The triradical **1**, however, has been found to possess the intermolecular ferromagnetic interaction which is not suitable for ferrimagnetic spin alignment. The head-to-tail molecular packing of the biradical–monoradical composite molecules is not necessarily compatible with interatomic contacts between the radical fragments leading to intermolecular antiferromagnetic exchange interactions. Further elaborate control for molecular arrangement is necessary for the full control of intermolecular exchange interactions suitable for ferrimagnetic spin alignment.

[2] The monoradical moiety of the isomer **2** is substituted with *m*-benzyl. The magnetic susceptibility of **2** was analyzed with the same model as **1** (Eqs. (3) and (4)) based on the similarity of the crystal structure. The exchange interactions derived from the analysis are $J_\pi/k_B = 16.0$ K, $J_\sigma/k_B = -0.14$ K, $J_A/k_B = 1.5$ K, and $J_B/k_B = -5.2$ K.

ion. Taking the total S value in the hexacoordinate cobalt (II) complex into account, a pyridine ligand having five diazo moieties, **cD5py**, in addition to **D1py**[1] was prepared. The pyridine ligand, **cD5py**, was expected to produce the high-spin carbene, **cC5py**, with $S = 10/2$ after irradiation.

In this work, the magnetic property of 1:2 mixture of Co(*p*-tolsal)$_2$ and cyclic pentadiazo-pyridine ligands, **cD5py**, in dilute frozen solution after irradiation was investigated by SQUID magneto/susceptometry.

2. Experimental

2.1. General

Infrared spectra were recorded on a JASCO 420 FT-IR spectrometer. ^{1}H NMR spectra were measured on a Varian UNITY-400 using $CDCl_3$ as solvent and referenced to TMS. Visible spectra were recorded on a JASCO V570 spectrometer and an NACC cryo-system LTS-22X was attached for the low temperature measurements. The solution samples were placed in separable quartz cells (path length; 1 mm) under helium atmosphere. Photolyses of diazo samples were performed by argon ion laser (514 nm, 200 mW, Omnichrome 543–200 M). Melting points were obtained with a MEL-TEMP heating block and are uncorrected.

2.2. X-ray crystal and molecular structure analyses

Crystallographic data and experimental details for **cD5py** are summarized in Table 1. The selected suitable single crystals were glued on a glass fiber by epoxy resin. All the X-ray data were collected on a Rigaku Raxis-Rapid diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71069$ Å). Reflections were collected at 123 ± 1 K. The structures were solved by direct methods (SIR92) [6]. The refinements were converged using the full-matrix least-squares method of the Crystal Structure software package [7] to give a space group as $P\bar{1}$ (no. 2). All non-hydrogen atoms were refined anisotropically.

Table 1
Crystallographic data of **cD5py**

[1] The work using **D1py** in a similar heterospin system will be reported elsewhere.

Hydrogen atoms were found by standard method or from differential electron map and refined isotropically.

2.3. Measurements and analyses of magnetic properties

Ac and dc magnetic susceptibility data were obtained on Quantum Design MPMS2 (0–±10 kOe) and MPMS-5S (0–±50 kOe) SQUID magneto/susceptometers, respectively. Irradiation by the light from an argon ion laser (514 nm, 200 mW, Omnichrome 543–200 M) through a flexible optical fiber (Newport F-MBD; 3 m of length, 1.0 mm of core size, and 1.4 mm of diameter) which passes through the inside of a sample folder for SQUID was performed inside a sample room of SQUID at 7 K. One end of the optical fiber was fixed at 40 mm above the sample cell (capsule) and the other end was attached to a coupler (Body; Newport M-F-916T and lens; M-10X) for the lasers. The bottom part of the capsule (6 mm × 10 mm) without a cap was used as a sample cell. Fifty microlitres of the sample solution (5 mM) in MTHF was placed in the cell held by a straw.

2.4. Materials

2-Methyltetrahydrofuran (MTHF) and ether were distilled from sodium benzophenone ketyl. The cobalt complex, Co(*p*-tolsal)$_2$, was prepared by the procedure reported previously.

cD5py Calix[4]arene derivative which was reported by Rajca [8], was used as the starting compound. A cyclic pentaketone–pyridine derivative, **cO5py**, was prepared by a procedure similar to that for the linear polyketone–pyridine compounds.[1] **cO5py** was converted to the corresponding diazo derivative **cD5py** quantitatively by using a standard procedure reported previously [4]. **cD5py** was crystallized from CH_2Cl_2 at 4 °C and obtained as red needles. Mp: 102 °C (decomp.). IR (KBr disc) ν 2043 cm^{-1}, UV–Vis (CH_2Cl_2, ε) 504 nm (535); ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.51(dd, $J = 1.7$, 4.7 Hz, 2H), 7.13 (d, $J = 1.7$ Hz, 6H), 7.07 (dd, $J = 1.7$, 4.7 Hz, 2H), 6.99 (d,$J = 1.7$ Hz, 2H), 6.95 (s, 4H).

3. Results and discussion

3.1. X-ray molecular structure analysis of *cD5py*

ORTEP drawing of the molecular structure for **cD5py** is shown in Fig. 1. The geometry of the cyclic framework of **cD5py** is similar to that for the calix[4]arene derivatives, in which the phenyl ring directs alternately. The bond angles of the carbon of the diazo moiety inside the ring structure are in the range of 125–129°, which is consistent with that of 127° for the out side the ring structure and for **D1py**, indicating that the carbon of the diazo moieties undergoes no strain caused by the cyclic structure. The dihedral angles between the phenyl rings are in the range of 63–73°. Those values are slightly larger than those (ca. 45°) for linear diphenyldiazo derivatives. The selected bond angles and dihedral angles are given in Table 2.

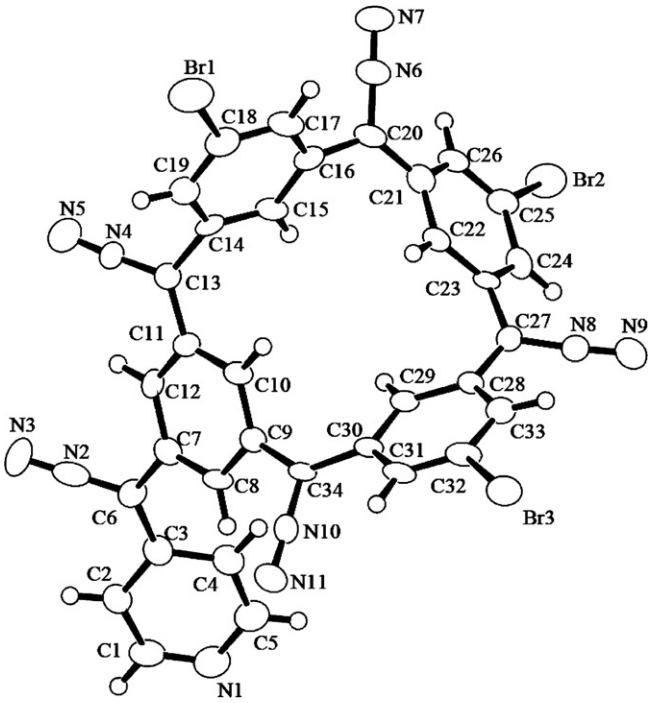

Fig. 1. ORTEP drawing of the molecular structures for **cD5py** showing 50% probabilities ellipsoids, including CH_2Cl_2 are omitted for clarity.

Table 2
Selected bond angles (°), and dihedral angles (°) of **cD5py**

Bond angles (°)		Dihedral angles (°)	
C(11)C(13)C(14)	125.62	C(22)C(24)C(26)–C(15)C(17)C(19)	71.270

C(3)C(6)C(7)	127.26	C(8)C(10)C(12)–N(1)C(2)C(4)	46.617

3.2. Visible spectra of *cD5py* and Co(*p*-tolsal)$_2$-(*cD5py*)$_2$ complex

To confirm the generation of carbene after irradiation and the formation of a six-coordinate structure for **cD5py** and Co(*p*-tolsal)$_2$-(**cD5py**)$_2$ complex, respectively, Visible spectra before and after irradiation were measured at 12 K. The solutions (5 mM) of **cD5py** and Co(*p*-tolsal)$_2$-(**cD5py**)$_2$ complex in MTHF were used as the samples. In the Visible spectrum of **cD5py** at 12 K, the characteristic absorption at 504 nm due to n–π^* transition of the diazo moiety decreased on photolysis ($\lambda = 514$ nm) and a new broad absorption with shoulders in a range of 450–400 nm due to the carbenes appeared. The visible spectrum for a 1:2 mixture of Co(*p*-tolsal)$_2$ and **cD5py** in MTHF at 12 K showed the absorption (shoulder) at ca. 520 nm which is characteristic the d–d transition for an octahedral structure. However, the absorption was overlapped with those

for the diazo moieties with relatively large intensity ($\varepsilon \sim 530$) and could not be clearly assigned as that due to an octahedral structure. A new broad absorption at 650 nm appeared on photolysis at 12 K (Fig. S1), suggesting that **cC5py** coordinates with the cobalt ion. The new absorption disappeared after annealing at 90 K.

3.3. Magnetic properties

3.3.1. *cD5py* in frozen solution after irradiation

In order to determine the ground-state spin multiplicity, S, for **cC5py**, the field dependence of the magnetization after irradiation of **cD5py** was investigated. The solution (4 mM, 50 μl) of **cD5py** in MTHF was used as a sample and the magnetization measurement was carried out under the frozen solution condition. Magnetization data (M_a and M_b; M_a and M_b are magnetization after and before irradiation, respectively,) were collected at 2 and 5 K in the field range of 0–50 kOe. The field dependence of M/M_s; $M = M_a - M_b$ and M_s is a saturation magnetization, for **cC5py** is shown in Fig. 2 together with a theoretical curve with $S = 10/2$. All experimental data at 2 and 5 K traced on the theoretical curve with $S = 10/2$, indicate that five carbene centers generated by photolysis of the diazo units in **cD5py** interact ferromagnetically through the *m*-phenylene ring to produce a high-spin carbene, **cC5py**, with $S = 10/2$.

3.3.2. Co(*p*-tolsal)$_2$-(*cD5py*)$_2$ complex in frozen solution after irradiation

The solution (4 mM, 50 μl) of the 1:2 mixture of Co(*p*-tolsal)$_2$ and **cD5py** in MTHF, was employed as a sample. The ac and dc magnetic susceptibilities of the frozen solution samples were measured before and after irradiation. Photolysis of the sample was performed in SQUID apparatus through an optical fiber and followed by magnetization (M_{mol}) measurements at 5 kOe at 5 K. The magnetization was plotted as the function of the irradiation time (Fig. 3). When the irradiation started, the M_{mol} values gradually developed and leveled off after ca. 1 h. The increase in the M_{mol} values on photolysis results from the generation of carbene.

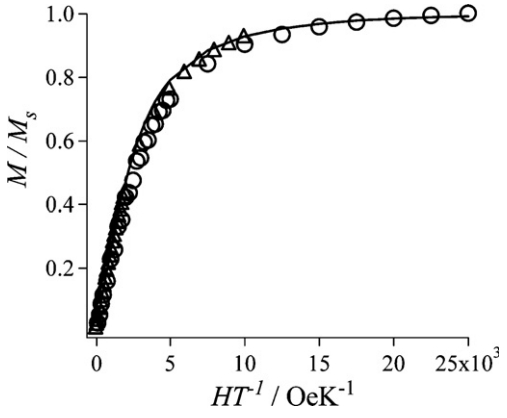

Fig. 2. The plot of M/M_s vs H/T at 2.0 (○) and 5 (△) K for **cC5py** in MTHF frozen solution. The solid curve is theoretical one with $S = 10/2$.

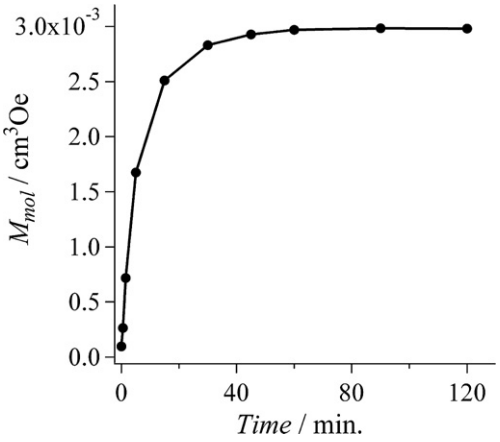

Fig. 3. The plot of M vs. *irradiation time* at 5 kOe at 5 K for the solution sample of 1:2 mixture of Co(*p*-tolsal)$_2$ and **cD5py**.

3.3.2.1. AC magnetic susceptibility measurements. Ac magnetic susceptibility measurements with a 5 Oe ac field oscillating at 997, 499, 99.9, 10, and 1 Hz, for the 1:2 mixture of Co(*p*-tolsal)$_2$ and **cD5py** after irradiation were carried out. The in-phase and out-of phase components (χ' and χ'' signals, respectively) with frequency dependence were observed. The plots of $\chi'T$ versus T and χ'' versus T are shown in Fig. 4a and b, respectively.

In the plot of $\chi'T$ versus T, the in-phase $\chi'T$ value is 37.2 cm^3 K mol^{-1} at 10 K and remains essentially constant on cooling down to 5–7 K. The value (37.2) at 10 K is obviously larger than 31.6 cm^3 K mol^{-1} calculated by a spin-only equation with the isolated carbenes and the cobalt(II) ion (15×2 for carbene and $\chi'T = 1.6$, which is the value before irradiation, for the Co(II) ion), indicating that the carbenes generated by photolysis interact with the cobalt(II) ion ferromagnetically to form a species with $S = 21/2$. Below 5 K, the $\chi'T$ values decreased and the χ'' signals increased depending on the frequency. The peak-top temperature of χ'' signals at each frequency shifted to lower temperature as the frequency increased; 6.3 and 4.1 K at 997 and 1 Hz, respectively. The observation of both signals, χ' and χ'', and their frequency dependence strongly suggest that the 1:2 complex, Co(*p*-tolsal)$_2$-(**cD5py**)$_2$, has slow magnetic relaxation. Since at the peak-top temperature for the χ'' signal, the relaxation rate ($1/\tau$) is equal to the angular frequency ω ($=2\pi\nu$, where ν is the ac field oscillation frequency), the ac data were used for the Arrhenius plot of $\ln(1/\tau)$ versus $1/T$, based on the Arrhenius relationship of equation; $(1/\tau) = (1/\tau_0)\exp(-U_{eff}/k_BT)$, where U_{eff} is the effective activation barrier for the reversal of the magnetism, τ_0 is the pre-exponential factor, and k_B is the Boltzmann constant. The values of U_{eff}/k_B and τ_0 for Co(*p*-tolsal)$_2$-(**cC5py**)$_2$ are 72 K and 2.0×10^{-9} s^{-1}, respectively (see Fig. 4c).

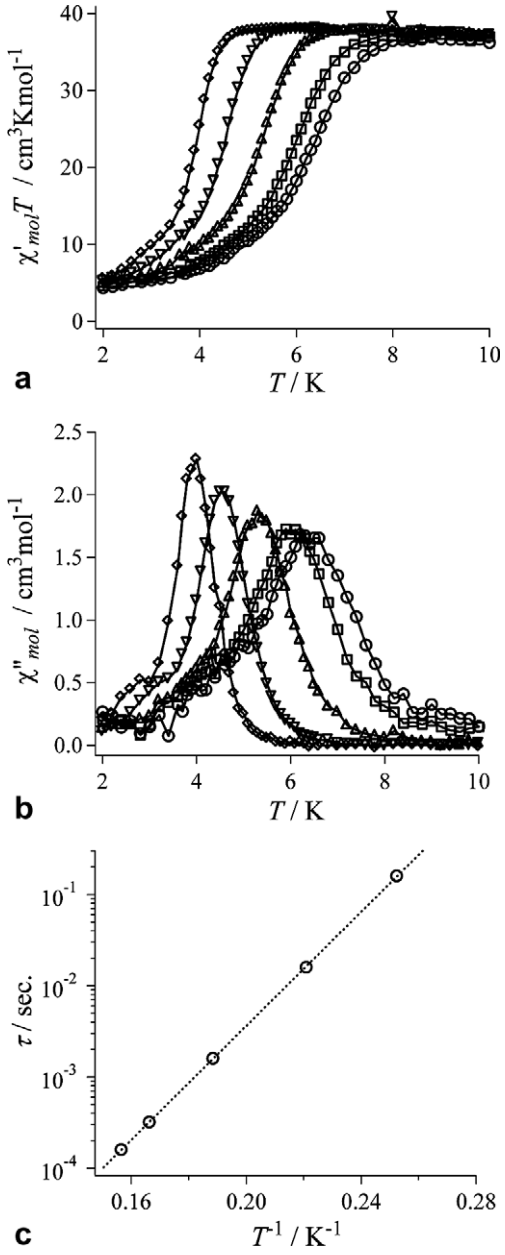

Fig. 4. Plots of (a) $\chi'T$ vs. T and (b) χ'' vs. T after irradiation of the 1:2 mixture of Co(p-tolsal)$_2$ and **cD5Py** in frozen MTHF solution with a 5 Oe ac field oscillating at 997 (○), 499 (□), 99.9 (△), 10 (▽), and 1 (◇) Hz. The solid lines are visual guides; (c) Arrhenius plot.

As observed in Fig. 4b, the signals due to χ'' in the low temperature region at each frequency showed a weak peak (or shoulder), indicating the presence of minor component(s) under the experimental conditions.

*3.3.2.2. Relaxation process of Co(p-tolsal)$_2$-(**cC5py**)$_2$.* In order to investigate the relaxation process due to the cobalt complex in a frozen solution, the ac magnetic susceptibility measurements in more detail were carried out. The ac magnetic susceptibility data after irradiation of the 1:2 mixture, Co(p-tolsal)$_2$-(**cD5py**)$_2$, in frozen MTHF solution were collected by holding the temperature constant and varying the frequency of the ac field (5 Oe) from 997 to 1 Hz. The measurements at two temperatures, 5.5, and 6.0 K, were performed. The plots of χ' versus χ'' (Cole–Cole diagram) at 5.5, and 6.0 K are shown in Fig. 5.

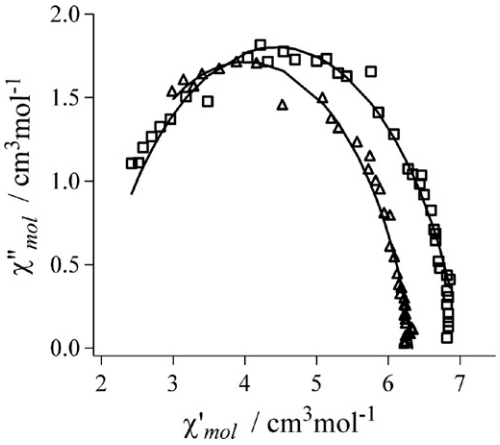

Fig. 5. Plot of χ' vs. χ'' (Cole–Cole plot) at 5.5 (□), and 6.0 (△) K for Co(p-tolsal)$_2$-(**cC5py**)$_2$. Solid lines are a least-square fitting of the data to the distribution of a single relaxation process.

The Cole–Cole plots [9] at 5.5 and 6.0 K, which are nearly symmetric with $\alpha = 0.19$ and 0.23, respectively, also supported that a single relaxation process is present in the Co(p-tolsal)$_2$-(**cC5py**)$_2$. The obtained α value is relatively large, which suggests that there is a distribution in the single relaxation process. This distribution is mainly due to the frozen solution condition used for the formation of SMM. Similar distribution in the relaxation was observed in [CoX$_2$(**4NOpy**)$_4$]; X = NCO and NCS, reported previously [5] and it was elucidated as the distribution in the environment of the metal ion. The distribution in the environment of the cobalt ion–carbene system is more likely in a frozen solution condition than in the microcrystalline state. In a frozen solution, for example, the complex might have various dihedral angles between the N_2O_2 plane for the p-tolsal ligand and the pyridine plane, which leads to the distribution of the zero-field splitting parameters, D and E. The distribution of D and E leads to the distribution in the effective activation barrier, U_{eff}, and in the dc magnetization decay due to a quantum tunneling, respectively. All relaxation fitting parameters obtained from the χ' versus frequency at 5.5 and 6.0 K, are listed in Table 3 and the curves obtained from the least-square fittings of the χ' versus χ'' data are shown as solid lines in Fig. 5.

Table 3
All relaxation fitting parameters obtained from the least-square fitting of the χ' vs. frequency data at 5.5 and 6.0 K for Co(p-tolsal)$_2$-(**cC5py**)$_2$ to a distribution of the single relaxation process

T (K)	χ_0	χ_∞	α
5.5	1.85	7.02	0.23
6.0	1.70	6.33	0.19

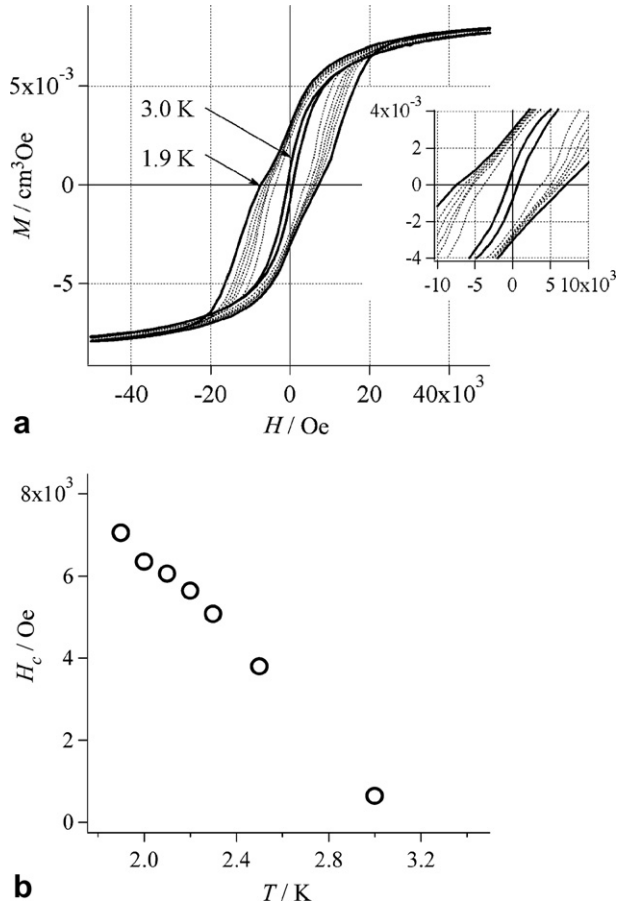

Fig. 6. (a) M vs. H plot at various temperatures below 3.0 K after irradiation of a 1:2 mixture of Co(p-tolsal)$_2$ and **cD5py** in frozen MTHF solution with a sweeping rate of 0.35 kOe/s. The inset shows the magnification of the low field region in M vs. H plot. (b) H_c vs. T plot.

3.3.2.3. Hysteresis loop below 3.0 K. The dc magnetization for the 1:2 complex, Co(p-tolsal)$_2$-(**cC5py**)$_2$, was measured in the range −50 to 50 kOe with a field-sweeping rate of 0.35 kOe/s at seven temperatures in the range 1.9–3.0 K. The cobalt complex showed hysteresis with respect to the applied field below ca. 3.0 K. The hysteresis loops in the temperature range 1.9–3.0 K are shown in Fig. 6a. Coercive force (H_c) and remnant magnetization (M_r) depend on the temperature. On cooling from 3.0 K, both values gradually increased until 1.9 K which is an accessible temperature for our apparatus (Fig. 6b). This temperature dependence of H_c and M_r values is one characteristic of SMM. The values of H_c and M_r at 1.9 K are 7.1 kOe and 3.0×10^4 cm^3 Oe mol^{-1}, respectively.

The strong frequency dependences of the χ'_{mol} and χ''_{mol} signals and the physically reasonable values of τ_0 suggest that these Co(II) complexes in frozen solution function as an SMM rather than a spin glass. The value of $\Delta T_f/T_f(0)\Delta(\log w)$ supports the formation of an SMM, where ΔT_f is the shift of the peak-temperature in χ'_{mol}, $\log w$ is the logarithm of the applied frequency, and $T_f(0)$ is the position of the peak at zero frequency, obtained by the χ'_{mol} versus T plots. The values are 0.21 for Co(p-tolsal)$_2$-(**cC5py**)$_2$. According to Mydosh's work [10], those values are in the region $\Delta T_f/T_f(0)\Delta(\log w) > 0.2$, for an SMM.

4. Conclusion

A cyclic pentadiazo-pyridine derivative, **cD5py**, was prepared as a precursor of a pyridine ligand with $S = 10/2$ for a monometallic SMM in a heterospin system. It was confirmed by the field dependence of magnetization that **cD5py** was photolyzed to form **cC5py** with $S = 10/2$ in frozen solution. The magnetic properties of the 1:2 mixture of Co(p-tolsal)$_2$ and **cC5py** in MTHF frozen solution were investigated by SQUID magneto/susceptometry. Ac and dc magnetic susceptibility experiments indicated that the 1:2 complex, Co(p-tolsal)$_2$-**(cC5py)**$_2$, with $S = 21/2$ formed in frozen solution functions as a monometallic SMM with $U_{eff} = 72$ K and $H_c = 7.1$ kOe at 1.9 K. Similar magnetic behaviors were also observed in the 1:2 complexes using linear polycarbene–pyridine with $S = 2/2$, 4/2, and 6/2 under frozen solution condition.[1]

This time, a cyclic pentadiazo-pyridine derivative **cD5py** was designed and prepared for an SMM in the heterospin system. The framework of **cD5py** still has three positions at which the pyridine units for binding the metal ion can be introduced. Therefore, the use of this framework will be expected as the ligand of an anisotropic metal ion for a higher dimensional spin network. Research work along this line is in progress.

2. Experimental

2.1. $[Cu(HF_2)(pyz)_2]BF_4$ (1)

The synthesis of **1** has been described previously [5].

2.2. $Cu(ReO_4)_2(H_2O)_2(pyz)$ (2)

Originally, crystals of **2** were obtained as a byproduct in the attempted synthesis of $[Cu(HF_2)(pyz)_2]ReO_4$. Copper(II) chloride dihydrate (341 mg, 2 mmol, Aldrich) was dissolved in 10 ml water. A slurry of silver(I) perrhenate (1432 mg, 4 mmol, Aldrich) in 10 ml water was added. The precipitate of silver chloride was removed from the copper(II) perrhenate solution by filtration. Ammonium hydrogen difluoride (114 mg, 2 mmol, Aldrich) and pyrazine (160 mg, 4 mmol, Aldrich) were placed in a Teflon beaker and dissolved in 20 ml water. The previously prepared copper(II) perrhenate solution was added. After most of the water had slowly evaporated, blue crystals of **2** were found among some unidentified green powder.

In order to prepare **2** in high purity, the following procedure was used. Perrhenic acid solution (70%, 1435 mg, 4 mmol, Aldrich) was added to copper(II) hydroxide (195 mg, 2 mmol, Aldrich) in 10 ml water. When this had dissolved, a 10 ml aqueous solution of pyrazine (144 mg, 2 mmol, Aldrich) was added. The blue crystals of **2**, which began forming after 10 min, were collected by filtration after 2 days. *Anal.* Calc. for $C_4H_8N_2O_{10}CuRe_2$: C. 7.06; H, 1.19; N, 4.12. Found: C, 7.09; H, 1.32; N, 3.98%. IR (cm^{-1}): 3181br, 3135w, 3094m, 3046m, 3009w, 1436s, 1160m, 1126m, 1119w, 1097w, 1074m, 973m, 916sh, 891vs, 836s.

2.3. X-ray data collection and refinement for 2

The crystal structure of **2** was determined by X-ray diffraction using a Siemens SMART single crystal diffractometer equipped with a CCD-based area detector and a sealed-tube Mo Kα source (graphite monochromator). The detector frames were integrated by use of the program SAINT [6] and the intensities corrected for absorption by Gaussian integration based on the measured crystal shape using the program XPREP of SAINT. Other systematic variations were corrected by the analysis of replicate reflections using the program SADABS [7]. The structures were solved by use of direct methods, while full-matrix least-squares refinement on F^2 (including all data) was performed, both using the program package SHELXTL [8]. The electron density difference map shows a large residual peak and hole of 2.96 and −1.15 $e^-/Å^3$, respectively, located 0.86 and 0.66 Å from the Re and Cu atoms. A summary of the crystallographic data is given in Table 1, selected bond lengths and angles are given in Tables 2 and 3. The atomic numbering scheme is illustrated in Fig. 2. Further details of each structure are available in the CIF files also deposited as Electronic supplementary information.

at 125 Hz. Powder samples with masses of 144 and 200 mg, for **1** and **2**, respectively, were mounted in Delrin® holders and attached to the end of the sample rod. All measurements consisted of zero-field cooling to the lowest temperature and data collected upon warming.

3. Results and discussion

3.1. Crystal structure of $[Cu(HF_2)(pyz)_2]BF_4$ (*1*)

While details of the structure for **1** are given elsewhere [5] we will summarize those results here. At 295 K $[Cu(HF_2)(pyz)_2]BF_4$ crystallizes in the tetragonal space group *P*4/*nbm* with the lattice parameters $a = b = 9.6901(4)$ and $c = 6.6193(4)$ Å. Each Cu^{2+} ion is coordinated to four different pyrazine ligands in the equatorial plane and two F atoms from bifluoride anions along the *c*-direction (Fig. 1). The fourfold rotation symmetry of the Cu site induces counter-rotating pyrazine rings with a twist angle of 59.4(2)° with-respect-to the *ab*-plane. The hydrogen atom of the HF_2^- molecule is symmetrically positioned between the fluorine atoms at a distance of 1.102(4) Å. A 3D coordination polymer results where BF_4^- counterions occupy the interiors of each "cube". The structure of **1** is similar to $[Cu(NO_3)(pyz)_2]PF_6$ where bridging NO_3^- ions link the square layers into a 3D network [9].

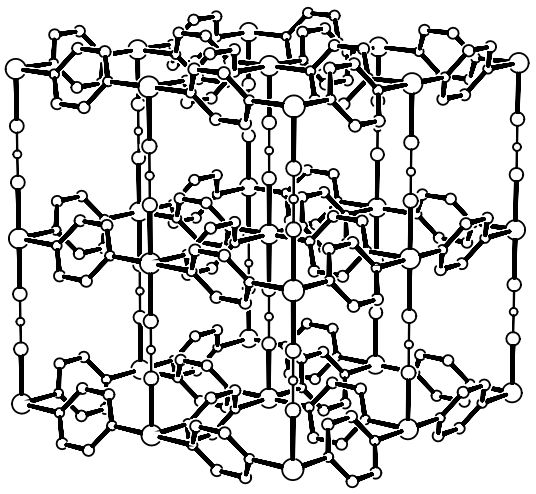

Fig. 1. Crystal structure of **1** showing the μ-bridging HF_2^- and pyrazine linkages. Pyrazine H-atoms and BF_4^- counterions have been omitted for clarity.

3.2. Crystal structure of $Cu(ReO_4)_2(H_2O)_2(pyz)$ (*2*)

Selected bond lengths and angles for **2** are presented in Table 1. As shown in Fig. 2, each Cu^{2+} ion is octahedrally coordinated to two H_2O [Cu–O(4) = 1.963(5) Å], two pyrazine [Cu–N(1) = 2.024(5) Å], and two ReO_4^- [Cu–O(1) = 2.417(6) Å]. Ligands of the same type adopt *trans*-configurations. The geometry of the CuO_4N_2 octahedron deviates slightly from ideal O_h symmetry with largest distortion being the O(1)–Cu–O(4) bond angle that is 92.0(2)°. The ReO_4^- anion adopts a fairly regular tetrahedral geometry with Re–O(1), Re–O(2), and Re–O(4) bond lengths of 1.727(5), 1.724(4), and 1.698(6) Å, respectively. Because the slightly shorter Re–O(3) bond is not affected by additional interactions such as hydrogen bonds, the electron density distribution is more concentrated between those atoms and less withdrawn from the bonding region thus creating a slightly shorter bond. Corresponding bond angles within the perrhenate anion are 108.2(2) [O(2)–Re–O(3)], 109.3(3) [O(1)–Re–O(3)], and 111.1(2)° [O(1)–Re–O(2)]. All bond lengths and angles observed for the pyrazine ligand agree with those previously reported including those found in **1** [2,3,5,9]. Cu(pyzc)(H_2O)(ReO_4)(pyzc = pyrazine-carboxylate) also contains a perrhenate anion however it acts as a bidentate bridge between two different Cu(II) ions [10].

The extended structure of **2** is that of a 1D coordination polymer as shown in Fig. 3. Each octahedron is linked to neighboring octahedra via pyrazine bridges to form linear chains. Pyrazine ligands are uniformly rotated 52.6(3)° out of the equatorial plane defined by Cu, N(1), and O(4). This twist angle is comparable to the 51° observed in the room temperature structure of $Cu(NO_3)_2(pyz)$ [2b]. An extensive hydrogen bonded 3D network (Fig. 3) results

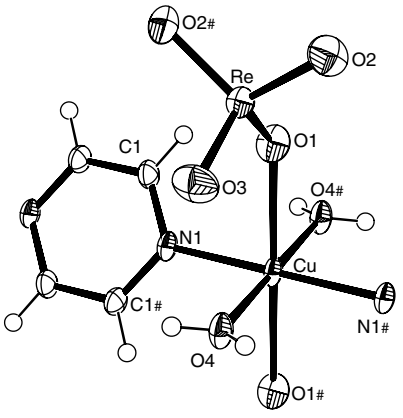

Fig. 2. ORTEP drawing and atom labeling scheme for **2**. Thermal ellipsoids are drawn at the 50% probability level.

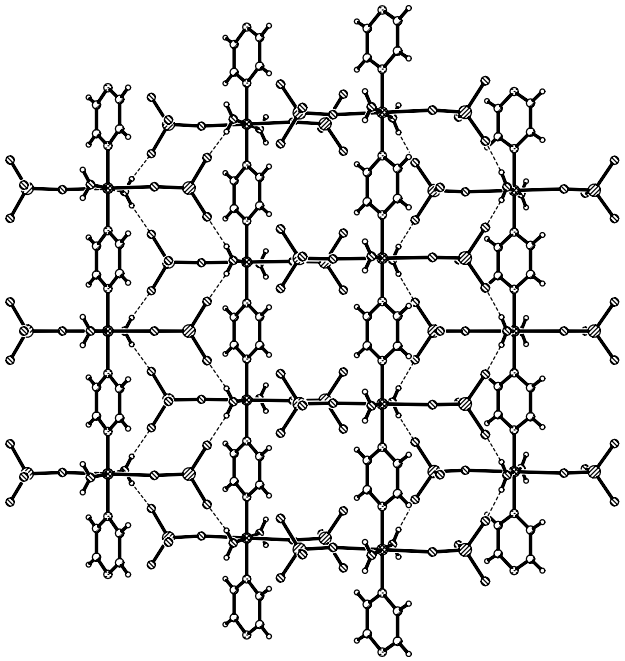

Fig. 3. Chain packing diagram for **2**. Dashed lines delineate hydrogen bonds.

from O(4)–H(2)···O(2) interactions that have an H···O distance of 1.89 Å and a bond angle of 172.5°. Both O(2) and O(2′) participate in hydrogen bonding while O(1) is directly coordinated to the Cu center. The structure of **2** complements that of $Cu(NO_3)_2(pyz)$ in that analogous 1D linear chains are also observed, however **2** features an extensive hydrogen bond network. An X-ray powder diffraction pattern for **2** was also obtained at 295 K and a comparison between the experimental and calculated pattern based on the single crystal structural parameters is shown in Fig. 4.

3.3. Magnetic properties

The temperature-dependence of the real component of the ac susceptibility, χ', for both **1** and **2** are shown in Fig. 5. Each compound shows a broad maximum due to short-range magnetic ordering albeit at somewhat different

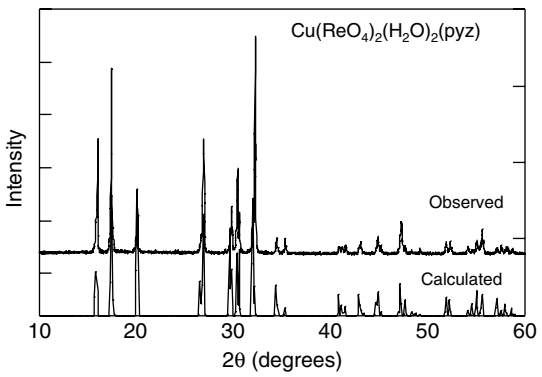

Fig. 4. Comparison of the observed (top) and calculated (bottom) X-ray powder patterns for **2** at 295 K.

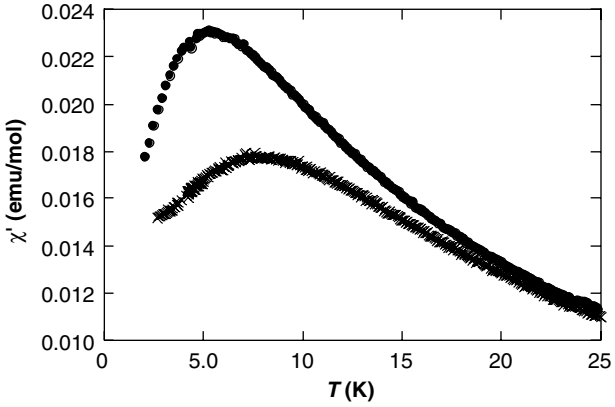

Fig. 5. Temperature-dependence of the real component of the ac susceptibility for **1** (●) and **2** (×) measured between 2 and 25 K.

temperatures; $\chi(T_{max}) = 5.5$ K for **1** and $\chi(T_{max}) = 7.8$ K for **2**. The higher value of $\chi(T_{max})$ for **2** indicates a stronger Cu–pyz–Cu magnetic interaction even though there are twice as many nearest neighbors linked via pyz bridges in **1** than **2**. Below the maximum, the magnetic susceptibility decreases smoothly with no indication for the transition to long-range ordering (LRO) above 2 K. There is no imaginary χ'' component, suggesting a simple collinear antiferromagnetic structure for both **1** and **2**. SQUID magnetic measurements have been reported for **1** [5] and are being conducted on **2**. The full temperature range is needed to fit the data to the appropriate model in order to determine J.

In a previous work [5], **1** was shown by muon-spin relaxation measurements to undergo LRO below $T_N = 1.54(1)$ K. Similar detailed studies are in progress to identify T_N for **2** which we believe may order at a higher temperature due to extensive interchain hydrogen bonding.

The observed antiferromagnetic interactions can be explained in terms of the orientation of the Cu $d_{x^2-y^2}$ magnetic orbital with-respect-to the pyrazine lone-pair orbitals. In the case of **1**, the magnetic orbital lies in the 2D $[Cu(pyz)_2]^{2+}$ plane which places the non-magnetic d_{z^2} orbital along the direction of the bifluoride bridge. For compound **2**, two lobes of the $d_{x^2-y^2}$ magnetic orbital overlap with the nitrogen lone-pair orbitals of the pyrazine ring while the other two lobes overlap lone-pair orbitals of coordinated H_2O ligands. This suggests that there could be an important interchain exchange pathway mediated by the O–H···O–Re hydrogen bonds. Further studies on **2** are in progress to establish the significance of these hydrogen bond interactions.

evaporated. The residue was recrystallized with filtration from ethylacetate (80 ml). The resulting rust colored platelets were filtered off, washed with cold ethylacetate, and dried in air. Yield 2.48 g (49%), mp 193–195 °C. IR: $\tilde{\nu}_{max} = 547$, 564, 690, 900, 998, 1133, 1149, 1226, 1375, 1402, 1466, 1761, 2877, 2992 cm^{-1}. Elemental *Anal.* Calc. for $C_7H_{12}N_2O_3$: C, 48.8; H, 7.0; N, 16.3. Found: C, 50.6; H, 7.1; N, 15.8%.

2.1.2. 1,3-Dihydroxy-4,4,5,5-tetramethylimidazolidin-2-one (*3*)

An orange solution of **2** (100 mg, 0.29 mmol) in MeOH (or EtOH) (5 ml) was kept at room temperature for a week. After a week, the solution almost completely decolorized. The solution was evaporated till dry and recrystallized from a mixture of MeOH with toluene. The colorless needles were filtered off. Yield 60 mg (59%). Mp 212–215 °C. IR: $\tilde{\nu}_{max} = 678$, 750, 846, 932, 967, 995, 1052, 1091, 1161, 1213, 1249, 1286, 1362, 1391, 1461, 1692, 2986, 3226 cm^{-1}. Elemental *Anal.* Calc. for $C_7H_{14}N_2O_3 \cdot 0.5H_2O$: C, 45.9; H, 8.3; N, 15.3. Found: C, 45.8; H, 8.3; N, 15.2%.

2.1.3. 2-Methylpropane-2-aminium 3-oxyl-4,4,5,5-tetramethyl-2-oxoimidazolidin-1-olate ((NH_3Bu^t)**1**)

2.1.3.1. Method 1. A suspension of **2** (50 mg, 0.29 mmol) in a mixture of NH_2Bu^t ("Aldrich") (2 ml) and MeOH (2 ml) was kept in a closed vessel at ~5 °C for a week. The resulting blue solution was cooled to −15 °C and stored for another 12 h. The bluish violet thin needles were filtered off and dried in a flow of argon. Yield 20 mg (28%).

2.1.3.2. Method 2. A suspension of **2** (100 mg, 0.58 mmol) in NH_2Bu^t (3 ml) was kept in a closed vessel at ~5 °C for a week. Crystals **2** gradually vanished, and thin violet needle crystals, like "absorbent cotton", filled the bulk of solution. The crystals were quickly transferred to a filter, washed with dry hexane, and dried under argon. Yield 30 mg (42%). When exposed to air, (NH_3Bu^t)**1** crystals transformed into **2** after an hour. When stored under argon, they are stable within a few days. Elemental *Anal.* Calc. for $C_{11}H_{24}N_3O_3$: C, 53.6; H, 9.8; N, 17.1. Found: C, 52.6; H, 9.5; N, 16.7%.

2.1.4. Di-(tert-butylaminopotassium) 3-oxyl-4,4,5,5-tetramethyl-2-oxoimidazolidin-1-olate [$K(NH_2Bu^t)_2$]*1*

Solid KOH (17 mg, 0.30 mmol) was added to a solution of **2** (50 mg, 0.29 mmol) in anhydrous MeOH (5 ml). The reaction mixture was stirred for 10 min, which resulted in a deep blue solution. NH_2Bu^t (50 μl) and toluene (5 ml) were added to the solution, and the mixture was kept for a week in a flask closed with an adapter with $CaCl_2$ at ~5 °C. The resulting navy blue crystals were filtered off and dried on a filter under argon. Yield 20 mg (47%). Elemental *Anal.* Calc. for $C_{15}H_{34}KN_4O_3$: C, 50.4; H, 9.6; N, 15.7. Found: C, 49.2; H, 9.5; N, 15.1%.

2.2. X-ray crystallography and magnetic measurements

Single crystal diffraction data for the compounds were collected on a SMART APEX CCD (Bruker AXS) automatic diffractometer (Mo Kα, $\lambda = 0.71073$ Å, room temperature); an absorption correction was applied using the Bruker SADABS program, version 2.10. The structures were solved by direct methods and refined by the full-matrix least-squares method in an anisotropic approximation for non-hydrogen atoms. The H atoms were located on difference electron density maps and refined together with non-hydrogen atoms in an isotropic approximation. The methyl H atoms were refined as a rigid group with isotropic thermal parameters. All structure solution and refinement calculations were carried out with SHELX-97 and Bruker SHELXTL Version 6.14 program packages.

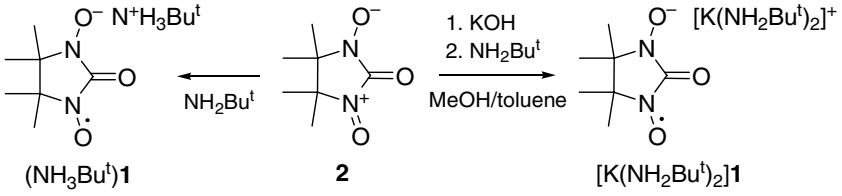
The magnetochemical experiment was run on an MPMS-5S ("Quantum Design") SQUID magnetometer at temperatures from 2 K to 300 K in a homogeneous external magnetic field of up to 5 kOe. The paramagnetic components of magnetic susceptibility χ were determined with allowance for the diamagnetic term estimated from Pascal's constants. The effective magnetic moment was calculated by the formula $\mu_{eff} = [(3k/N_A\beta^2)\chi T]^{1/2} \approx (8\chi T)^{1/2}$, where k is Boltzmann's constant, N_A is the Avogadro number, and β is the Bohr magneton.

3. Results and discussion

3.1. Synthesis

To have compound **1** stabilized we attempted to use NH_4^+ or its alkyl derivatives for the cation. The initial orange color of the ethanolic solution of zwitterion **2** gradually changed to blue color due to the formation of the ammonium salt (NR_4)**1** after an ethanolic solution of NH_3, NH_2Bu^n, or $NH(Pr^i)_2$ had been added and the reaction mixture had been stored for a month. Similar changes followed after storage of solutions of **2** in pure NH_2Bu^n or $NH(Pr^i)_2$. Evaporation of the resulting solutions, however,

restored the initial color of **2**, and the solid contained the starting compound **2** as the major product. After recrystallization from an ethyl acetate–hexane mixture, the yield of **2** was 80–85%.



Treatment of **2** with an amine containing a branched hydrocarbon substituent (NH_2Bu^t) and further storage of the reaction mixture in a closed vessel at ~5 °C proved successful. After the reaction mixture had been stored for a week, it was permeated with thin needle crystals of (NH_3Bu^t)**1** throughout (Scheme 2). An X-ray diffraction study of this compound could not be performed because of extremely small crystals of (NH_3Bu^t)**1** and low stability of the salt in air (in contact with air, (NH_3Bu^t)**1** completely converted into the starting compound **2** after an hour). If, however, solid KOH and NH_2Bu^t were added to a solution of **2** in absolute MeOH and the reaction mixture was diluted with toluene, further slow evaporation in dry atmosphere yielded $[K(NH_2Bu^t)_2]$**1** as large navy blue prisms. $[K(NH_2Bu^t)_2]$**1** crystals proved kinetically much more stable than (NH_3Bu^t)**1**. When stored in air, they are slowly covered with an orange film, but are quite stable in an argon atmosphere. It is worth to note, that syntheses of (NH_3Bu^t)**1** and $[K(NH_2Bu^t)_2]$**1** are reproducible but at the moment it is difficult to indicate the possible reducing agent in both cases.

Storage of a MeOH solution of **2** (or of an EtOH suspension of **2**) for a week in the absence of bases led to reduction of **2** to 1,3-dihydroxy-4,4,5,5-tetramethylimidazolidin-2-one (**3**) obtained as colorless needles of a semihydrate $\mathbf{3}\cdot 0.5H_2O$; these crystals, like $[K(NH_2Bu^t)_2]$**1**, are suitable for an X-ray study.

3.2. Structural data

Before discussing the structure of $[K(NH_2Bu^t)_2]$**1** and $\mathbf{3}\cdot 0.5H_2O$, let us recall the structure of compound **2** investigated earlier [2]. Molecule **2** has a twofold symmetry axis through the C7–O3 atoms and the middle of the C1–C4 bond (Fig. 1a). If the methyl substituents are removed from molecule **2**, then all other atoms lie in virtually the same plane. The N–O bond length (1.246 Å) is intermediate between the single and double bond lengths; the C–O bond length (1.204 Å) compares closely with the same bond length in carbonyls [4], and the N1–C7 and N2–C7 distances are equal to 1.368 Å. In the O1–N1–C7(O3)–N2–O2 fragment, high degree of conjugation between atoms is suggested by their coplanarity and interatomic distances, which are markedly smaller than those for single bonds. The torsion angle C1–C4–N1–N2 is 7.4° (Fig. 1a). After sequential reduction of **2** to **1** and then to **3**, this angle opens considerably (to 16.3 and 25.2° (26.0)°, respectively), the symmetry of the O1–N1–C7(O3)–N2–O2 fragment is broken, and the bond lengths in this fragment increase. The general tendencies of variation for parameters are presented in Fig. 1, and it is useful to consider them before discussing the structure of $[K(NH_2Bu^t)_2]$**1** and $\mathbf{3}\cdot 0.5H_2O$.

In the structure of $[K(NH_2Bu^t)_2]$**1**, the five-membered heterocycle is non-planar (Fig. 2a); the deviations of the

Scheme 2.

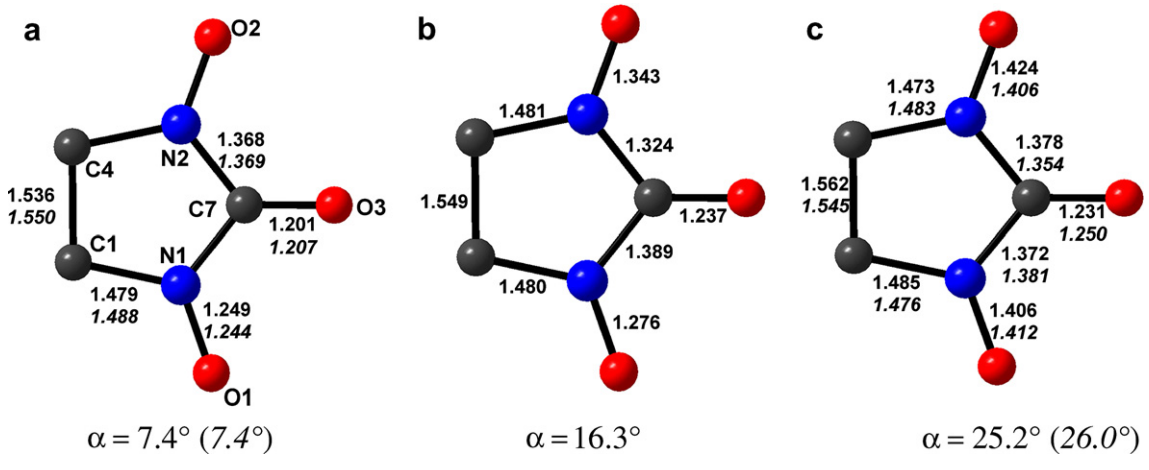


Fig. 1. Atomic numbering scheme (a) and changes in the bond lengths and in the α torsion angle C1–C4–N1–N2 on passing from **2** (a) to **1** (b) and **3** (c) (italicized values are the bond lengths and angles in crystallographically independent molecules).

C1 and C4 atoms from the plane of the CN_2 fragment is, on the average, 0.21 Å, which is much larger than in **2**. The O1A atom of the nitroxyl group lies in the plane of the N1A–C7A–N2A fragment, and the O2A atom of the deprotonated hydroxyl group departs to a distance of 0.150 Å from this plane. Since the N1A–O1A distance (1.276(3) Å) is typical for nitronylnitroxides and the O1A–N1A–C7A–N2A atomic group lies in one plane, the N1A–O1A fragment is reasonably considered to be an >NO nitroxyl group. The N2A–O2A bond length is much larger (1.343(3) Å), which may be attributed to the predominant localization of the negative charge on this group (>N–O$^-$). The C=O distance (1.237(3) Å) is larger than the same distance in **2**, while the N1A–C7A and N2A–C7A distances differ from each other (1.389(3) and 1.324(3) Å).

In solid $[K(NH_2Bu^t)_2]$**1**, the K^+ ions together with H_2NBu^t molecules form centrosymmetric binuclear fragments (Fig. 2b) with K···K distances of 5.029(1) Å and K–N distances of 3.209(3)–3.286(2) Å. This is a unique structure. The Cambridge Crystallographic Database has

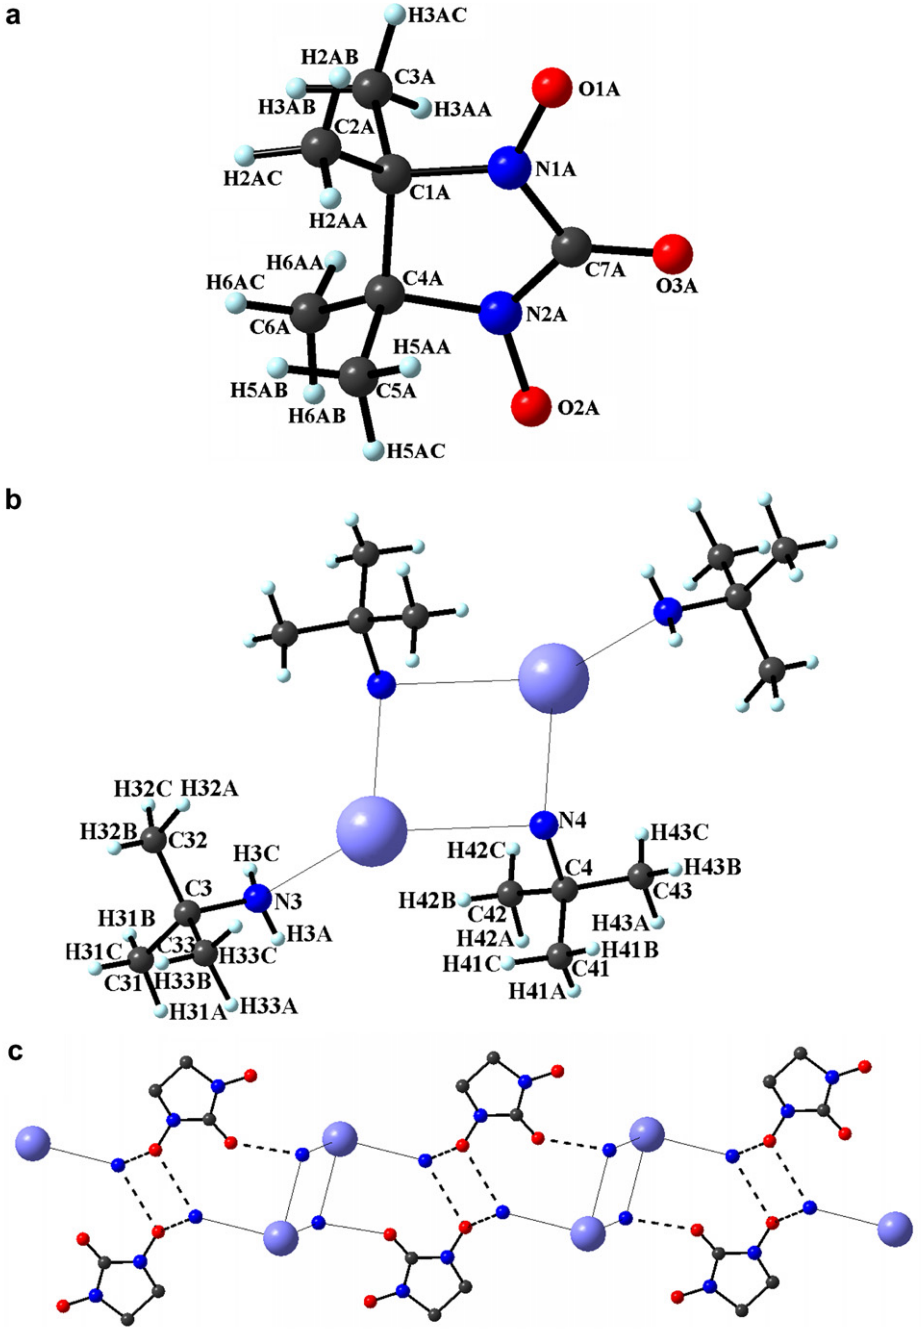

Fig. 2. Structure of anion **1** (a); $\{K_2(NH_2Bu^t)_4\}$ binuclear fragment (b); chain formation in the structure of $[K(NH_2Bu^t)_2]$**1** (c; CH_3 and $(CH_3)_3C$ groups discarded for clarity).

no examples of a binuclear structure of this kind with alkali metal ions surrounded by amine molecules [5]. In the structure, these dimers are hydrogen-bonded with anions, forming infinite chains (Fig. 2c).

According to X-ray diffraction data, in the two crystallographically independent molecules of hydroxyamine derivative **3** (Fig. 3a), the imidazolidine ring is non-planar. The deviations of the C1 and C4 atoms to opposite sides from the plane of the N2C7N1 fragment are, on the average, 0.33 and 0.36 Å. This plane is also flanked by the O1 and O2 atoms of hydroxyl groups, deviating by ~0.66 Å from the plane. The N–O distances vary from 1.406 to 1.424 Å, this variation being typical for the N–O single bond in hydroxyamines [4]. The C7–O3 (1.250(6) and 1.231(6) Å) and N1–C7 and N2–C7 distances (1.354(6)–1.381(6) Å) are virtually the same as in **1**. In solid $\mathbf{3}\cdot 0.5H_2I$, the molecules are bonded by strong H bonds into a framework (Fig. 3b).

Thus structure investigation of $[K(NH_2Bu^t)_2]\mathbf{1}$ and $\mathbf{3}\cdot 0.5H_2O$ and comparison of the resulting data with the structural parameters of **2** have made it possible to trace structure dynamics in the O1–N1–C7(O3)–N2–O2 unit after sequential reduction of zwitterion **2** to the corresponding radical anion **1** and further to dihydroxy derivative **3**.

3.3. Magnetic properties

Magnetic measurements for $(NH_3Bu^t)\mathbf{1}$ showed that the effective magnetic moment $\mu_{eff} \sim 1.73$ B.M. is constant

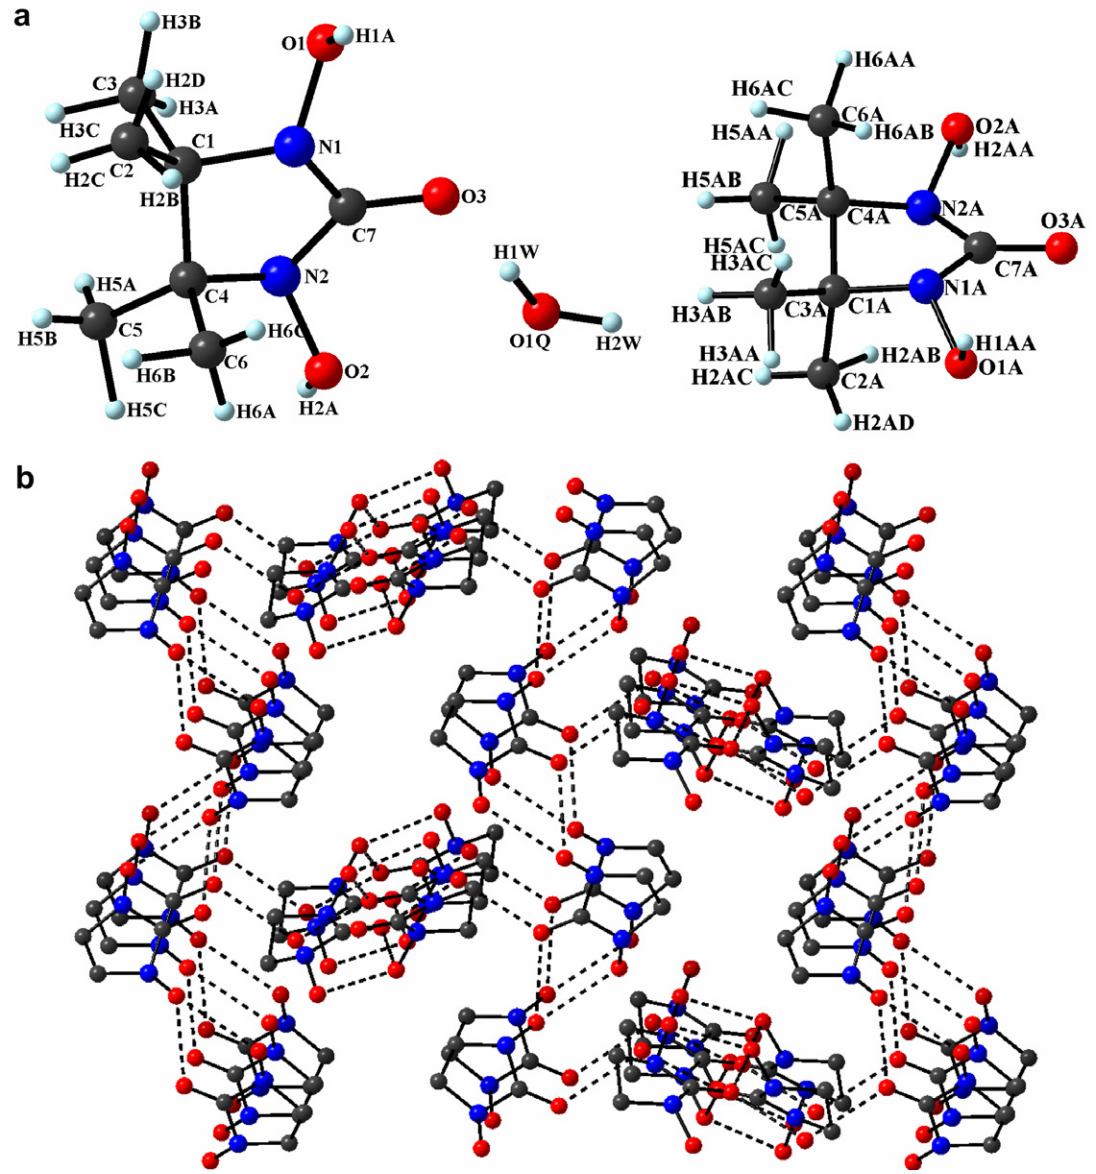

Fig. 3. Structure of crystallographically independent molecules **3** (a) and their packing (b) in the structure of $\mathbf{3}\cdot 0.5H_2I$.

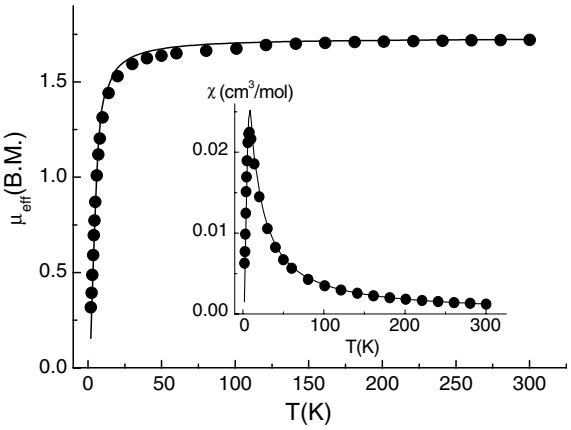

Fig. 4. Temperature dependences of effective magnetic moment and magnetic susceptibility (insert) for $[K(NH_2Bu^t)_2]$**1**.

within the whole temperature range of measurements, indicating that there are very weak exchange interactions between the odd electrons of the paramagnetic anions in solid (NH_3Bu^t)**1**. In polycrystalline $[K(NH_2Bu^t)_2]$**1** (Fig. 4), however, the effective magnetic moment decreases with temperature; the dependence of magnetic susceptibility $\chi(T)$ (insert) has a maximum, which points to dominant antiferromagnetic interactions between the odd electrons of the paramagnetic centers at low temperatures.

As shown by X-ray data, the structure of this complex consists of alternate chains (Fig. 2c) in which the dimers formed by the nitroxyl groups of two radicals bridged by two nitrogen atoms alternate with $[K_2(NH_2Bu^t)_4]^{2+}$ dimer fragments (Fig. 2b). Simulation of experimental data indicated that the most realistic model is the one with isolated dimers weakly interacting with one another via $[K_2(NH_2Bu^t)_4]^{2+}$ fragments. Optimization gave the following parameters of the Bleaney–Bowers equation for dimers with $S = 1/2$ [6]: $g = 2.01$, $-2J = 8.7\ cm^{-1}$. The theoretical curves are shown by solid lines in Fig. 4.

Thus synthetic procedures for **1** and **3** have been developed. In future, these compounds will be introduced in complexation processes with transition metal ions.

4. Supplementary material

CCDC 616899 and 616900 contain the supplementary crystallographic data for $[K(NH_2Bu^t)_2]$**1** and $\mathbf{3}\cdot 0.5H_2O$. These data can be obtained free of charge via htpp://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

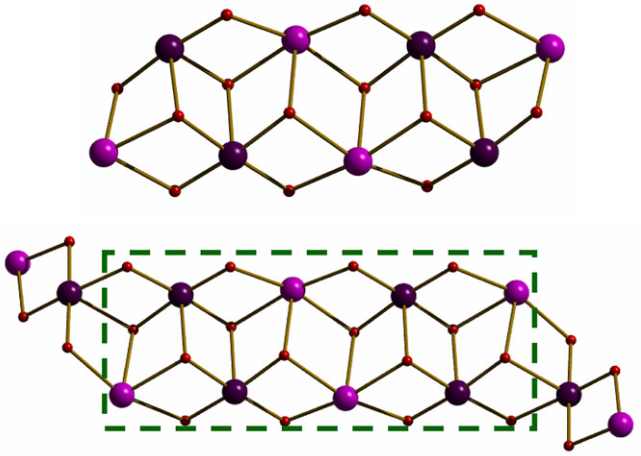

Fig. 2. The Mn–O cores of **1** (top) and **2** (bottom). Colour code: Mn(III), purple; Mn(II), pink; O, red. The $[Mn_4^{III}Mn_4^{II}(\mu_3\text{-}OR)_6(\mu_2\text{-}OR)_8]^{6+}$ unit common to both is highlighted in green. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

The core of complex **2** $[Mn_{12}(Hthme)_8(thme)_2(py)_2Br_8]$ is remarkably similar (Figs. 1 and 2). The molecule, made from the reaction of $MnBr_2 \cdot 4H_2O$, H_3thme and H_3tea (triethanolamine) in MeCN/py, consists of a non-planar $[Mn_6^{III}Mn_6^{II}(\mu_2\text{-}OR)_{14}(\mu_3\text{-}OR)_8]^{8+}$ unit, with a trapped-valent core that can be described as consisting of eight edge-sharing $[Mn_3O]$ triangles, or four edge-sharing $[Mn_4O_2]$ butterfly ('planar diamond') units. The 10 central metals this describes are planar with the two outermost (pentagonal bipyramidal) Mn(II) ions above and below that plane, respectively.

The six Mn(III) display Jahn–Teller elongations, all of which are approximately co-parallel at an angle of ~70° with respect to Mn_{10} plane. The two fully deprotonated $thme^{3-}$, ligands are located directly above and below the Mn_{10} plane bridging in a $\eta^3{:}\eta^3{:}\eta^2{:}\mu_5$-fashion to five metal centres that describe three edge-sharing triangles. The other eight tripodal ligands are doubly deprotonated ($Hthme^{2-}$) and coordinate in two different ways: two in a $\eta^3{:}\eta^3{:}\eta^1{:}\mu_5$-fashion linking five metals into three edge-sharing triangles; and six in a $\eta^1{:}\eta^2{:}\eta^2{:}\mu_3$-fashion linking three metals in a near-linear array. Four of the eight bromides are coordinated terminally to the Mn(II) ions in the central Mn_{10} plane, with the remaining four bonded to the peripheral five coordinate Mn(II) ions. The coordination sphere of these ions is completed by two terminal pyridines.

The two complexes are clearly related with the $[Mn_4^{III}Mn_4^{II}(\mu_3\text{-}OR)_6(\mu_2\text{-}OR)_8]^{6+}$ unit present in **1** being replicated exactly in the central section of complex **2** (Fig. 2). The *planar diamond* $[Mn_2^{III}Mn_2^{II}(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_4]$ moiety seen twice in both complex **1** and complex **2** is well known and has been reported previously in the tetranuclear complexes $[Mn_2^{III}Mn_2^{II}(hmp)_6(NO_3)_2(MeCN)_2]^{2+}$ (**3**), $[Mn_2^{III}Mn_2^{II}(hmp)_6(NO_3)_4]$ (**4**), $[Mn_2^{III}Mn_2^{II}(hmp)_4(acac)_2(MeO)_2]^{2+}$ (**5**), $[Mn_2^{III}Mn_2^{II}(O_2CMe)_2(pdmH)_6]^{2+}$ (**6**), $[Mn_2^{III}Mn_2^{II}Br_2(hmp)_6(H_2O)_2]^{2+}$ (**7**), $[Mn_2^{III}Mn_2^{II}(O_2CMe)_2(teaH)_2(teaH_2)_2(H_2O)_2]^{2+}$ (**8**), $[Mn_2^{III}Mn_2^{II}(O_2CPh)_2(teaH)_2(teaH_2)_2(H_2O)_2]^{2+}$ (**9**), and $[Mn_2^{III}Mn_2^{II}(O_2\,CEt)_2(teaH)_2(teaH_2)_2(H_2\,O)_2]^{2+}$ (**10**) (where hmpH = 2-hydroxymethylpyridine; $pdmH_2$ = pyridine-2,6-dimethanol; $teaH_3$ = triethanolamine) [3–6]. Three '*reverse*' rhomboidal clusters with $[Mn_2^{II}Mn_3^{III}(OR)_6]$ cores in which the metal ions have *swapped* places, i.e. the Mn(III) ions are the 'wing-tips' and the Mn(II) ions are the 'body-ions', have also been reported: $[Mn_2^{III}Mn_2^{II}(O_2CPh)_4(teaH)_2(acac)_2]$ (**11**); $[Mn_2^{III}Mn_2^{II}(teaH)_2(acac)_4(MeOH)_2](ClO_4)_2$ (**12**); $[Mn_2^{III}Mn_2^{II}(bheapH)_2(acac)_4(MeOH)_2](ClO_4)_2$ (**13**) ($bheapH_3$ = 1-[*N*,*N*-bis(2-hydroxyethyl)amino]-2-propanol) [7]. This 'reversed' $[Mn_2^{II}Mn_2^{III}]$ distribution is also found in the hexanuclear cluster $[Mn_2^{III}Mn_4^{II}(teaH)_2(teaH_2)_2(O_2CCH\text{-}Ph_2)_8]$ (**14**) [8].

Both structures are also related to the octa- and dodecanuclear Mn rods $[Mn_8O_4(O_2CCMe)_{10}(py)_2]$ (**15**) and $[Mn_{12}O_4(OH)_2(PhCOO)_{12}(thme)_4(py)_2]$ (**16**) we previously described [2], but here the cores contain bridging O^{2-} ions, and are in different oxidation levels, consisting of a homovalent $[Mn_8^{III}(\mu_3\text{-}O)_4(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_4]^{10+}$ unit and a $[Mn_{10}^{III}Mn_2^{II}O_4(OH)_2]^{24+}$ unit, respectively.

Solid-state dc magnetic susceptibility (χ_M) measurements were performed on polycrystalline samples of **1** and **2** in a 0.1 T applied dc magnetic field in the 5.00–300 K temperature range. The results are plotted as $\chi_M T$ versus T in Fig. 3. For **1**, the room temperature $\chi_M T$ value

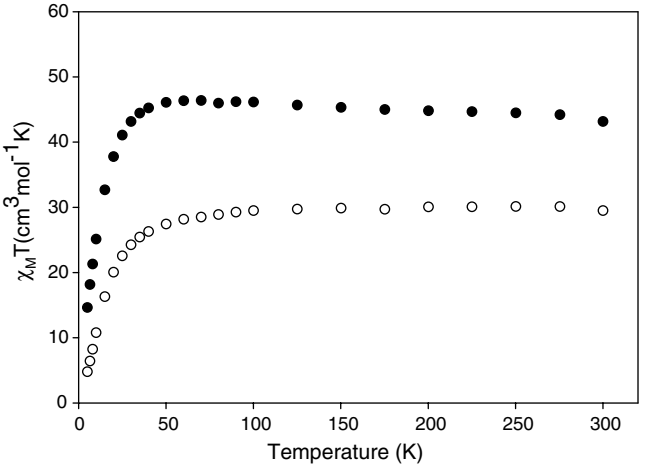

Fig. 3. Plot of $\chi_M T$ versus T for **1** (○) and **2** (●) in an applied field of 0.1 T and the temperature range 300–5 K.

of approximately 29 cm^3 K mol^{-1} (0.1 T) is slightly lower than that expected for a complex comprising four Mn(III) and four Mn(II) ions (29.5 cm^3 K mol^{-1} with $g = 2$). The value of $\chi_M T$ remains almost constant as the temperature is decreased until *ca.* 50 K where it then decreases rapidly to a value of approximately 2 cm^3 K mol^{-1} at 5.0 K. For **2** the behaviour is rather similar: the room temperature $\chi_M T$ value of approximately 43 cm^3 K mol^{-1} (spin only = ~46 cm^3 K mol^{-1}) remains essentially unchanged until *ca.* 50 K where it drops rapidly to a value of 14.6 cm^3 K mol^{-1} at 5 K. This is indicative of dominant (weak) antiferromagnetic exchange between the metal centres with the low temperature values suggesting small spin ground states for both complexes.

In-phase ac susceptibility measurements performed in the temperature range 1.8–10 K support the above assignments: extrapolation of the $\chi'_M T$ signal from values above ~3 K (to avoid decreases due to such effects as intermolecular interactions at lower temperatures) to 0 K gives values of 1 ± 1 cm^3 K mol^{-1} for both. In each case the slope of the $\chi'_M T$ versus T plot decreases rapidly with decreasing temperature revealing the presence of several spin-states of larger S values lying very close to the ground-state. This is to be expected for molecules containing multiple Mn(II) ions that are known to promote weak exchange interactions – the result of which is likely to be a large number of S states with comparable energies to the ground state. This behaviour is consistent with other Mn(III)–Mn(II) systems [3–8].

An attempt to rationalize the $S = 0$ or $S = 1$ ground-states of **1** and **2** (although clearly very difficult) can be made on the basis of the well-known magnetic behaviour of complexes **3**–**13**. The planar diamond $[Mn^{III}_2Mn^{II}_4(OR)_6]$ unit present in complexes **3**–**10** in which the Mn(III) ions occupy the central body positions gives rise to ferromagnetic exchange and $S = 9$ spin ground states. The $[Mn^{II}_2Mn^{III}_2(OR)_6]$ unit in **11**–**13** in which the Mn ions have 'swapped' positions is characterized by antiferromagnetic exchange and results in small ($S = 0$ or 1) spin ground states. The calculated exchange interactions for all are given in Table 1. The majority of the Mn(III)–Mn(III) and Mn(III)–Mn(II) interactions appear to be ferromagnetic (with only J_{wb} in **12** and **13** antiferromagnetic) – but in all cases the interactions are very weak. Both **1** and **2** are linked at their centres by two Mn(II) ions *via* two μ_3-OR bridges. Previous experimental evidence suggests that this interaction is likely to be weak and antiferromagnetic [9–12]. DFT calculations on Mn(II)–O–Mn(II) dimers also suggest an antiferromagnetic interaction with a strong dependence of the strength of coupling as function of the Mn–O–Mn angle. Below angles of ~98° the interaction is weak and antiferromagnetic but becoming increasingly strong and antiferromagnetic for angles in the 98–110° range [13,14]. The Mn(II)–O–Mn(II) angle is 100.3(1)° in **1** and 99.9(1)° in **2** and thus we might expect a reasonably 'strong' antiferromagnetic exchange for both. If we assume that each 'isolated' $[Mn^{III}_2Mn^{II}_2]$ diamond on either side of this central Mn(II)–Mn(II) unit remains ferromagnetically coupled then we can imagine that for complex **1** the two 'halves' of the molecules are "spin-up" and "spin-down" respectively, leading to an $S = 0$ ground state. For **2** we can then simply assume that the two remaining Mn(III)–Mn(II) *dimers* (Mn–O–Mn = ~103–104°) at each end of the same $[Mn_8]$ core 'cancel each other out' either *via* a local antiferromagnetic interaction or one *ferromagnetic dimer* being "spin-up" and the other "spin-down".

All previously characterized Mn rod-like complexes were obtained from reactions involving the oxo-centred metal triangles $[Mn_3O(O_2CR)_6L_3]^{0/+}$. The present work shows that structurally similar complexes but with different levels of oxidation can be made from simple Mn(II) salts like $MnBr_2 \cdot 4H_2O$. Although both complexes **1** and **2** possesses $S = 0$ or $S = 1$ ground states, the magnitude of the exchange interactions present in these types of species suggest that only a very small change in the magnitude of one J-value (e.g. that between the two central Mn(II) ions) could have a pronounced effect on the nature of the ground state. Of course it remains extremely difficult to predict the magnitude and sign of such interactions in complicated molecules, but by synthesizing families of related

Table 1

compounds and studying their magnetic properties we can build up some understanding of the correlation between structural and magnetic data which may help us design complexes with predictable, sought-after properties. We hope that chemical/electrochemical oxidation of some of the Mn(II) ions in both **1** and **2** will allow us to further this idea.

1. Supplementary material

CCDC 280380 contains the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

example), a current will be induced which will travel in phase with the field. If, on the other hand, the charged particles are bound within regions of the material, the electric field component will cause them to move until opposing forces balance the electric force [20,21]. The fundamental difference between microwave heating and conventional heating is that heating under microwave irradiation occurs in an *in–out* fashion, i.e. from the solution to the tube/flask, while with conventional heating energy is transferred *out–in*, i.e. from the flask to the solution. This effect results in superheating phenomena under microwave irradiation. Water, for example, reaches 105 °C before boiling, and acetonitrile makes it to 120–38 °C above its normal boiling point.

In spite of the range of applications and advantages of this heating method, reactions involving liquid phase inorganic syntheses have not yet received great attention. In the area of polymetallic cluster compounds this is hugely surprising since the major problems are often associated with yield and reproducibility. This tends to be especially true as the nuclearity of the product increases and is clearly a stumbling block if detailed physical characterisation is to follow. Coordination chemists attempting to make large polymetallic clusters of paramagnetic transition metals rarely perform syntheses in conditions other than ambient temperature and pressure. The reason is simple – it is not necessary, since the overwhelming majority of polynuclear complexes have been made via simple bench-top methods [22–27]. Only when making complexes of inert ions such as Cr^{3+} have alternative techniques been pursued [28]. Indeed the use of solvothermal synthesis has only recently become 'standard practice' for metal clusters of, for example, Fe, Ni and Mn. Given our recent success in the solvothermal synthesis of large metal clusters [29] we decided to examine whether microwave heating could be used for a similar purpose. In our experience, microwave heating not only provides an alternative synthetic tool, but may help improve the yield and reproducibility of large polymetallic complexes. Moreover, it may lead to novel products, by permitting access to alternative kinetic pathways and stabilizing different energy minima in a reaction system than the conventional methods of heating. This is especially possible when it effects exceptionally rapid heating of the reaction components [30]. Irrespective of the nature of the product, the reduction of reaction times through microwave heating permit a larger number of reaction conditions to be explored more quickly, making exploratory synthetic programs more efficient.

2. Manganese clusters

The first inorganic cluster complex synthesized using microwave heating was $[Mn^{III}_6O_2(sao)_6(O_2CH)_2(CH_3OH)_4]$ (**1**), formed from the reaction of $Mn(ClO_4)_2 \cdot 6H_2O$ with $saoH_2$ (salicylaldoxime) in the presence of NaOMe in MeOH [31]. The reaction mixture was simply placed in a sealed glass tube in the cavity of a microwave reactor and heated at 110 °C under 100 psi pressure for a total of 5 min, with the power of the microwave irradiation kept constant at 200 W. The complex formed immediately upon cooling and after 24 h the yield was approximately 80%. Initially the sample was heated for 10 min but we later found that reducing this to 5 min had no adverse effects on the yield of the product. Complex **1** can be made by repeating the reaction under ambient conditions but crystalline material does not appear immediately – indeed the maximum yield of ~30% is only achieved after a 60 min reaction and a 5 day crystallization period. The complex crystallizes in the triclinic space group $P\bar{1}$ with the molecule lying on an inversion centre. The core of the complex (Fig. 1) contains a non-planar $[Mn^{III}_6(\mu_3\text{-}O^{2-})_2(\mu_3\text{-}O^{1-})_2]^{12+}$ unit of two off-set, stacked $[Mn^{III}_3(\mu_3\text{-}O^{2-})]^{7+}$ triangles linked by two central oximato oxygens. The remaining sao^{2-} ligands bridge in a $\eta^1{:}\eta^1{:}\eta^1{:}\mu$-fashion along the edges of the $[Mn^{III}_3(\mu_3\text{-}O^{2-})]^{7+}$ triangles, with the coordination geometry of the metal ions completed by a combination of terminal methanol and μ-formate groups – the latter derived from the high temperature/pressure assisted oxidation of the solvent. All six Mn ions are in the 3+ oxidation state, as confirmed by a combination of bond length and charge balance considerations and bond valence sum (BVS) calculations. Four are six coordinate and in distorted octahedral geometries displaying the expected Jahn–Teller elongations (Fig. 1), while two are five-coordinate and square-pyramidal. The four Jahn–Teller axes and the apical bond of the five coordinate Mn ions are approximately co-parallel, all perpendicular to the $[Mn_3]$ planes [31].

Magnetization data (Fig. 2), collected in the 1–70 kG and 1.8–6.0 K ranges, were fitted by a matrix-diagonalisation method to a model that assumes only the ground state is populated, includes axial zero-field splitting ($D\hat{S}^2_z$), and carries out a full powder average – the corresponding Hamiltonian is given in the following equation:

$$H = D\hat{S}^2_z + g\mu_B\mu_0\hat{S}\cdot H \quad (1)$$

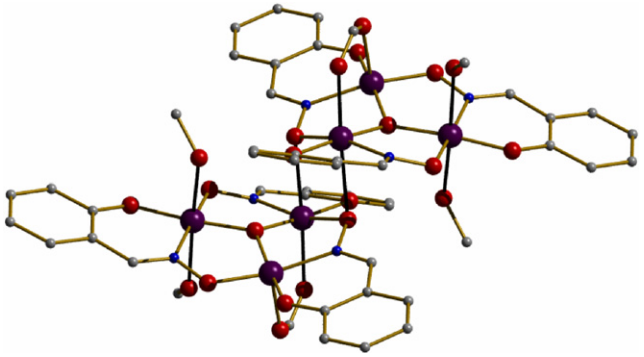

Fig. 1. The molecular structure of complex **1**. The dark bonds highlight the Jahn–Teller axes. Colour code: Mn = purple; O = red; N = blue; C = grey. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

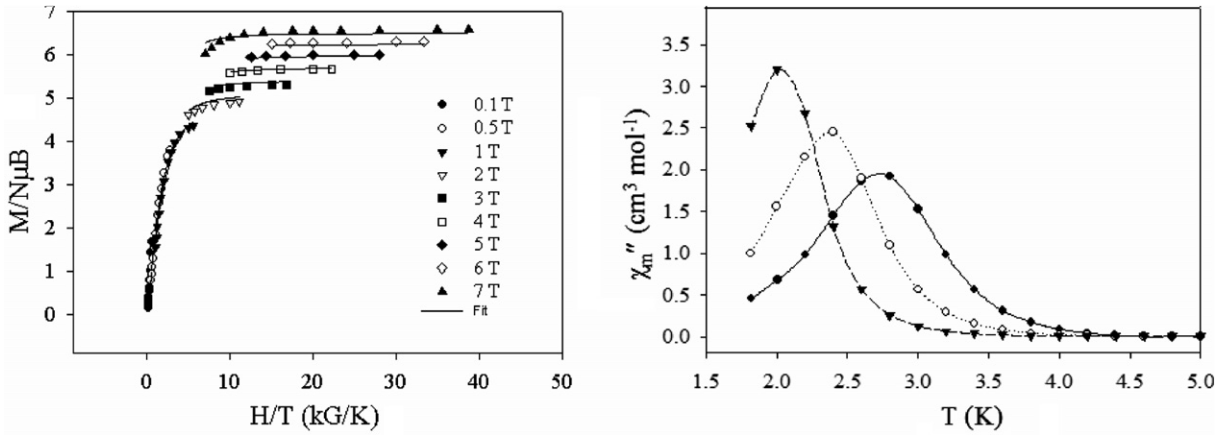

Fig. 2. Plot of reduced magnetization vs. H/T for **1**, the solid lines are the fit of the data (left). Out-of-phase (χ''_M) ac susceptibility measurements for **1** in the temperature range 1.8–5 K and frequencies 50 (▼), 250 (○), 1000 (●) Hz (right).

The best fit parameters were $S = 4$, $g = 1.99(3)$ and $D = -1.39\ \text{cm}^{-1}$. This D value in the largest ever reported for any $[\text{Mn}_x]$ $(x > 3)$ polynuclear complex and is likely the consequence of the parallel alignment of the JT axes of the Mn^{III} ions. Frequency-dependent out-of-phase ac susceptibility signals are observed at $T \leqslant 4$ K. Single-molecule magnetism behaviour was confirmed by the presence of temperature and sweep rate dependent hysteresis loops in single crystal M versus H studies (Fig. 3) performed on an array of micro-SQUIDs [32]. The loops and are not smooth, showing a large step at zero field indicative of quantum tunnelling of the magnetization (QTM). Relaxation data (Fig. 4) determined from a combination of single crystal dc relaxation decay measurements and ac measurements on a powdered sample allow the construction of a τ versus $1/T$ plot based on the Arrhenius relationship of the following equation:

$$\tau = \tau_0 \exp(U_{\text{eff}}/kT), \tag{2}$$

where U_{eff} is the effective relaxation barrier, τ is the relaxation time, and k is the Boltzmann constant. The slope of the thermally activated region yielded an effective energy barrier for the reorientation of the magnetization of $U_{\text{eff}} \approx 28$ K and $\tau_0 = 2 \times 10^{-8}$ s. Below 0.8 K the relaxation rate flattens out suggesting relaxation via ground state quantum tunneling.

The same complex can also be isolated from the reaction of $\text{Mn}(\text{O}_2\text{CH})_2 \cdot 4\text{H}_2\text{O}$ with saoH_2, NaOMe in alcohol, i.e. replacement of $\text{Mn}(\text{ClO}_4)_2 \cdot 4\text{H}_2\text{O}$ with $\text{Mn}(\text{O}_2\text{CH})_2 \cdot 4\text{H}_2\text{O}$ in an otherwise identical reaction. Alternatively **1** can also be made by replacing the NaOMe with TBAMnO_4. By then simply using a different carboxylate a whole family of compounds of general formula $[\text{Mn}^{\text{III}}_6\text{O}_2(\text{sao})_6(\text{O}_2\text{CR})_2(\text{CH}_3\text{OH})_4]$ (R = Me (**2**), Et (**3**), Ph (**4**)) can be isolated. Each displays similar magnetic properties to **1** [33]. Repeating these reactions but in pyridine rather than alcohol results in the formation of the triangular complexes $[\text{Mn}_3\text{O}(\text{sao})_3(\text{O}_2\text{CR})(\text{H}_2\text{O})(\text{py})_3]$ (R = Me (**5**), Ph (**6**), Fig. 5). These have very similar structures to the well-known 'basic carboxylates' of general formula $[\text{Mn}_3\text{O}(\text{O}_2\text{CR})_6\text{L}_3]^{n+}$ (L = py, MeCN, etc.; $n = 0, 1$) and can be regarded as the triangular building blocks of complexes **1**–**4** [33], i.e. **1** contains two such Mn_3 units bridged together via two μ-oximato oxygens. Both **5** and **6** can in fact be isolated under a range of conditions (ambient and solvothermal) but we initially isolated them from

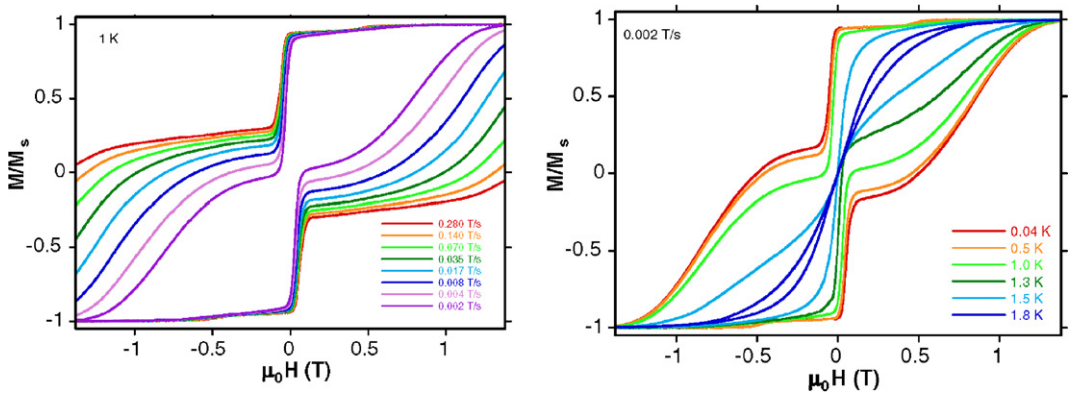

Fig. 3. M vs. H hysteresis loops for a single crystal of **1**. The loops are shown at different field sweep rates (left) and temperatures (right); M is normalized to its saturation value.

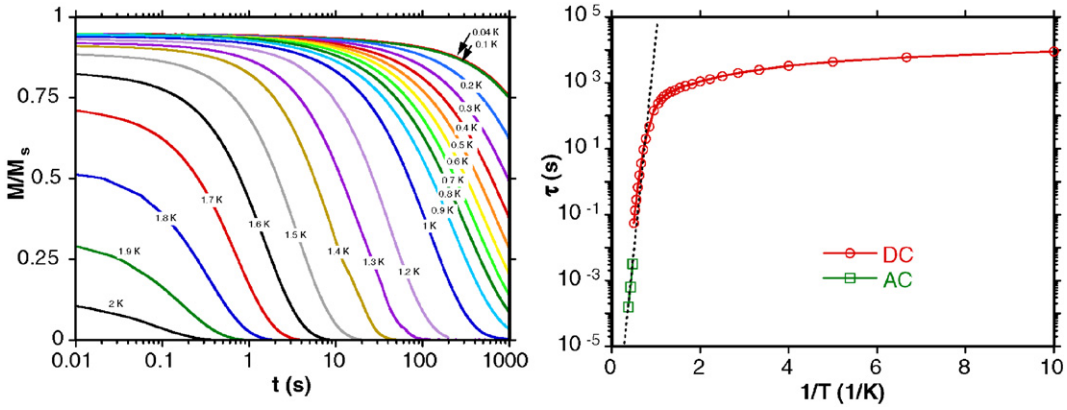

Fig. 4. Single-crystal relaxation data for **1**, plotted as M/M_S vs. time (left). Arrhenius plot using ac and dc data. The dashed line is the fit of the thermally activated region to Eq. (2).

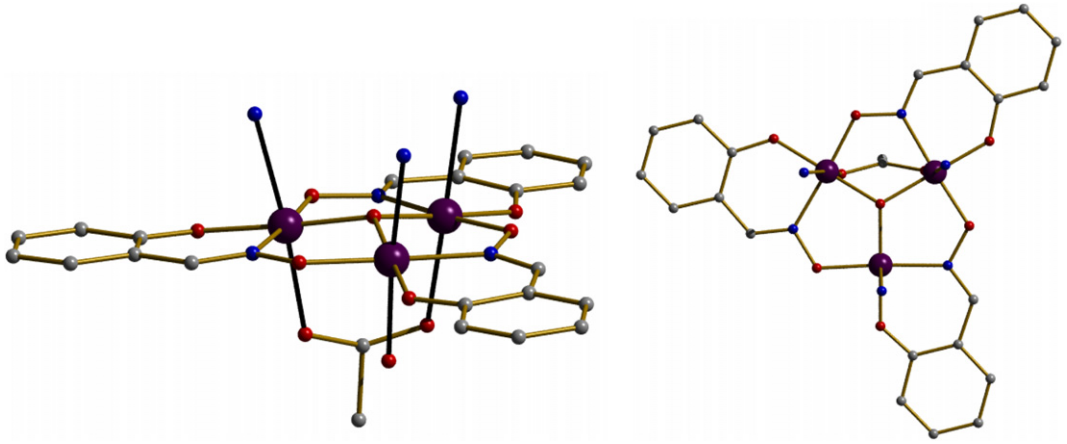

Fig. 5. The molecular structure of complex **5**. The carbon atoms of the pyridine molecules have been omitted for clarity. The solid black lines describe the three Jahn–Teller axes. Colour scheme as for Fig. 1. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the microwave ($T = 110$ °C; 10 min, 120 psi) and indeed this remains the fastest and most efficient method of synthesis. The structures (Fig. 5) consist of an oxo-centered triangular arrangement of three Mn^{III} ions with each edge bridged by one sao^{2-} ligand. The remaining axial sites on the Mn ions are filled by a combination of terminal pyridine and water molecules and one μ-carboxylate. Magnetic studies reveal that both species display dominant antiferromagnetic exchange interactions between the metal centres with ground states $S = 2 \pm 1$ for **5** and $S = 3 \pm 1$ for **6** [33]. The susceptibility data for **5** were fit to the theoretical expression for an isosceles triangle yielding $J_1 = -6.3$ cm^{-1}, $J_2 = +11.9$ cm^{-1}, but we were unable to fit the data for **6**. In-phase (χ'_M) ac susceptibility measurements taken below 10 K are suggestive the presence of low lying excited states with larger S values for both complexes. Such low-lying excited states are a common feature in many Mn clusters that exhibit relatively weak exchange interactions. The population of excited states even at very low temperatures is difficult to avoid and this clearly complicates the analysis of the data. Frequency-dependent out-of-phase (χ''_M) ac susceptibility signals are seen for complex **6** below approximately 3 K (but no peaks are observed) suggestive of the onset of slow magnetization relaxation. Single crystal hysteresis loop and relaxation measurements are currently underway to see if complex **6** behaves as an SMM.

3. Iron clusters

Heating a mixture of $Fe(O_2CMe)_2$, $saoH_2$ and pyridine at 120 °C, 130 psi and 200 W for a total of 5 min produces the complex $[Fe^{III}_8O_4(sao)_8(py)_4]$ [34] (**7**, Fig. 6), which forms immediately inside the microwave tube in ~70% yield. Complex **2** cannot be made under ambient reaction conditions, nor by refluxing a pyridine solution of $Fe(O_2CMe)_2$ and $saoH_2$. The use of various $Fe^{II/III}$ salts, different solvents or combinations of solvents, and different reaction times did not reproduce **2**. Microcrystalline material displaying a similar IR spectrum to complex **2** can be isolated under solvothermal reaction conditions (sealed Teflon container; 120 °C) using pyridine as solvent but

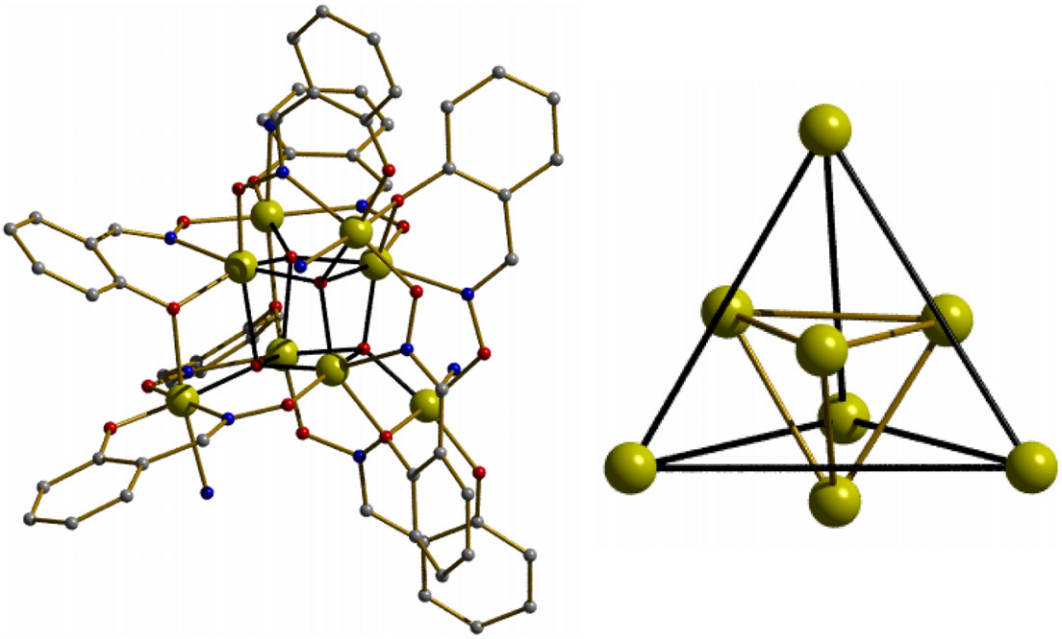

Fig. 6. The molecular structure of complex **7** (left) and its metallic skeleton, showing the tetrahedron inside a tetrahedron (right). The pyridine molecules have been removed for clarity. Colour code: Fe = yellow; O = red; N = blue; C = gold. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

requires a minimum heating/cooling period of 24 h and forms in yields of less than ~10%; this equates to an approximately sevenfold decrease in comparison to the microwave reaction, and suggests the rapid heating and pressure rate employed in the microwave cavity (the reaction reached its maximum temperature/pressure in less than 30 s) plays an important synthetic role.

The complex crystallizes in the tetragonal space group $I4_1/a$. The core of the complex (Fig. 6) contains a central $[Fe^{III}_4O_4]^{4+}$ cubane with each of the four (distorted) tetrahedral μ_4-O^{2-} ions further bridged to a peripheral Fe^{III} ion. The peripheral metal ions themselves form a tetrahedron, encapsulating the cubane such that each face of the tetrahedron is capped. The eight sao^{2-} ligands bridge in two ways: four in a η^2:η^1:η^1:μ_3-fashion along one complete edge of the tetrahedron with the phenolate oxygen atom bridging one Fe ion of the cube and one Fe ion of the tetrahedron; and four in a η^1:η^1:η^1:μ-fashion along half an edge, between an Fe ion in the tetrahedron and a face-capping Fe ion of the central cube. The observed η^2:η^1:η^1:μ_3-coordination mode is unique amongst the structurally characterized metal complexes containing the sao^{2-} ligand [35–37]. A μ_3-behaviour has been observed in sao^{2-} complexes but with the oximate oxygen providing the bridge between metal ions. The coordination sphere of each of the four Fe ions in the outer tetrahedron is completed by a terminal pyridine molecule. Within the $[Fe_4O_4]^{4+}$ cubane there are two small (~96°) and one large Fe–O–Fe (106°) angles suggesting a rather 'twisted' metal cubane. The $[Fe_8O_4]^{4+}$ core is uncommon, observed only in one other complex: $[Fe_8O_4(pz)_{12}Cl_4]$ (pz = pyrazolate anion) reported in 1999 [38] and the central $Fe^{III}_4O_4$ cubane is an extremely rare unit at this oxidation level. Some Fe/O cubanes with Fe^{II} or mixed $Fe^{II/III}$ cores are known, but there are only two $Fe^{III}_4O_4$ cubane units (both inside larger clusters) in the literature [38,39]. Complex **7** has a $S = 0$ ground state, probably due to antiferromagnetic exchange between the peripheral Fe^{III} ions in the tetrahedron and the central Fe^{III} ions in the cubane, mediated by the μ_4-bridging O^{2-} ions that display Fe–O-Fe angles in the range 102.9(1)–124.8(1)°.

4. Nickel and cobalt clusters

The reaction between $Ni(O_2CMe)_2 \cdot 4H_2O$ and one equivalent of NaN_3 in pyridine/MeOH under microwave irradiation ($T = 120$ °C; power = 250 W; pressure = 130 psi) for 4 min produces $[Ni_3(N_3)_3(O_2CMe)_3(py)_5]$ (**8**) in yields of ~55%. The analogous procedure using $Co(O_2CMe)_2 \cdot 4H_2O$ gives pink crystals of $[Co_3(N_3)_3(O_2CMe)_3(py)_5]$ (**9**) in ~40% yield [40]. Neither complex could be produced under ambient reaction conditions despite the use of various solvents and starting materials. The lower yield for **9** can be attributed to the formation of $[Co^{III}(N_3)_3(py)_3]$ which crystallizes upon prolonged standing [41]. Complex **8** crystallizes in the monoclinic space group $P2_1/n$ (Fig. 7). The core of the molecule contains a isosceles triangle of three Ni^{II} ions with Ni···Ni distances of ~3.1 and 3.8 Å. The 'apical' Ni ion is connected to the two basal nickel ions via two end-on, μ-N_3^- ions, two *syn*, *syn*, η^1:η^1:μ-acetates and one end-on μ_3-N_3^- ligand. The basal nickel ions are further bridged by one *syn*, *syn*, η^1:η^1:μ-acetate. The metal coordination environments are completed by five pyridine molecules. All three nickel ions

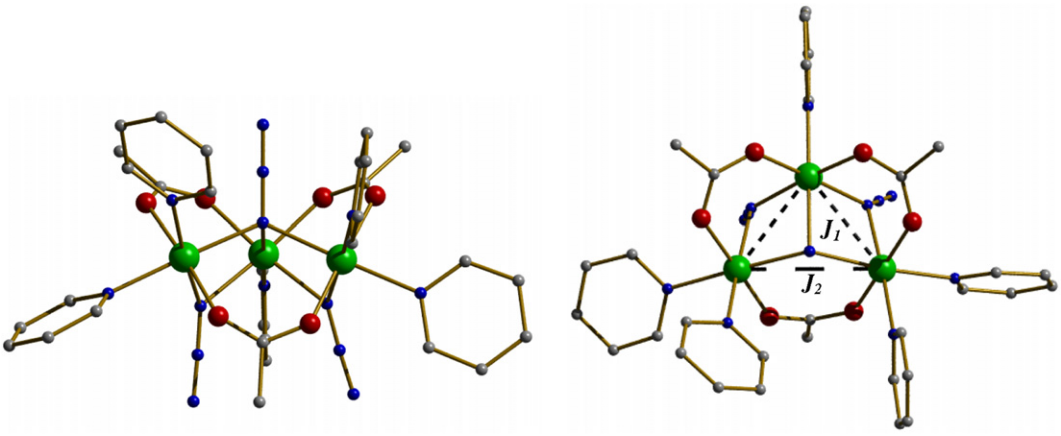

Fig. 7. The molecular structure of complex **3** viewed parallel (left) and perpendicular (right) to the Ni_3 plane. Colour code: Ni = green, O = red, N = blue, C = grey. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

are six-coordinate in slightly distorted octahedral geometry. Complex **9** crystallizes in the monoclinic space group $P2_1/n$ and its structure is analogous to that of **8**, with all three Co ions in the 2+ oxidation state. Both complexes can be considered as M^{II} analogues of the well-known "*M^{III} basic-carboxylates*" of general formula $[M_3O(O_2CR)_6(L)_3]^{n+}$ (M = V, Cr, Mn, Fe, Co; L = py, H_2O, MeCN; $n = 0$, 1) whose structures consist of oxo-centered metal triangles. Here, the compensation of charge is achieved by replacing (a) the central μ_3-O^{2-} ion with a central μ_3-N_3^- ion, and (b) three of the six bridging carboxylates with a combination of two μ-N_3^- ions and two additional terminal pyridines.

Complex **8** has an $S = 3$ ground state as a result of ferromagnetic exchange between the apical and basal Ni ions (Fig. 7). The best-fit parameters obtained by means of the program MAGPACK and employing the spin Hamiltonian $\hat{H} = -2J_1(\hat{S}_1 \cdot \hat{S}_2 + \hat{S}_1 \cdot \hat{S}_3) - 2J_2(\hat{S}_2 \cdot \hat{S}_3)$ were $J_1 = +15.7$ cm^{-1}, $J_2 = -1.2$ cm^{-1} and $g = 2.16$ [40]. Magnetization data collected in the ranges 10–50 kG and 2.0–7.0 K gave best fit parameters of $S = 3$, $g = 2.18$ and $D = +0.67$ cm^{-1}. The exchange in complex **9** is also ferromagnetic. Magnetization data collected in the ranges 10–50 kG and 2.0–7.0 K reveal that saturation is almost reached with a value of $M/N\beta \approx 8.4$ corresponding to an effective $S' = 3/2$ with a large anisotropic g'-value [40].

5. Conclusions

The important chemical message from this preliminary work is that microwave irradiation presents a powerful tool toward the preparation of new polymetallic cluster compounds. It may lead to novel products by permitting access to alternative kinetic pathways and stabilizing different energy minima in a reaction system compared to conventional methods of heating. Here we have shown this to be valid with the synthesis of a host of new metal clusters – many of which have shown interesting magnetic properties. It has also provided a means of improving the yields of known complexes in faster times, and indeed may even be considered a "*green*" approach to the synthesis of polynuclear complexes, since in general, it employs minimal solvent and minimizes energy and heat loss via the *direct* heating of the sample. This all suggests that the future potential of microwave-assisted synthesis to be truly enormous.

Acknowledgements

The work described has been done in collaboration with a number of groups. In particular, the authors thank Prof. George Christou (University of Florida), Dr. Wolfgang Wernsdorfer (Laboratoire Louis Néel), Dr. Mark Murrie (University of Glasgow) and Prof. Spyros Perlepes (University of Patras). Funding for the research was given by The Leverhulme Trust and EPSRC (UK).

predilection for antiparallel spin alignments in these molecules. Second, there are complications that usually arise when a transmission of such intermolecular ferromagnetic interactions, along two or three dimensions of the solid and over a long range, is desired. And third, it is impossible to predict the ultimate structure of even the simplest crystalline solids from a knowledge of their chemical composition [9].

In order to minimize these inconveniences, crystal engineering tools are needed. Crystal engineering is the design, construction and study of crystal structures from molecular components built with predesigned intermolecular interactions [10]. Besides π-stacking between verdazyl radicals, that has allowed the transmission of very strong magnetic exchange interactions [11], hydrogen bonds (H-bonds) have been mostly studied because their directional and often predictive nature may allow controlling long-range supramolecular order in solid state [12]. H-bonds are formed by strong donor–acceptor functionalities (OH, NH_2, CO_2H, $CONH_2$) and with weak donors (C≡C–H, C_6H_5, C=C–H, $C(sp^3)$–H) and acceptors (CN, NO_2, halogen, π). In such a context, Veciana and co-workers [13] proposed the idea to use these H-bonds to control the self-assembly of open-shell building-blocks which were used also successfully by Sugawara and co-workers [14]. Such a study was initiated by studying the family of aromatic nitronyl nitroxide derivatives with one or two hydroxylic groups on the aromatic ring as functional groups, susceptible to form hydrogen bond interactions. Success of this approach was reflected in two different organic ferromagnets based on molecules **17** [15] and **18** [16] that are substituted with one and two hydroxylic groups, and which orders at 0.45 and 0.50 K, respectively (Chart 2). Furthermore, additional examples belonging to this family substituted with one or several H-bond donors such as phenol [17], boronic acid [18], imidazole [19], benzimidazole [20], triazole [21], uracil [22], pyrazole [23], phenyl acetylene [24] and benzoic acid [25] have provided an interesting assortment of magnetic behaviours.

In addition to the hydroxylic groups, carboxylic groups are also important for crystal engineering because they also form strong and directional O–H···O hydrogen bonds. H-bonded patterns in carboxylic derivatives in solid state have been described in detail by Leiserowitz [26]. The most frequent and dominant H-bonded motif is the syn–syn centrosymmetric dimer. However, other patterns in the form of infinite non-cyclic H-bonded catemer motifs and more rare cyclic trimeric and tetrameric motifs can also been found [27,28].

Given this background, our group has initiated a new experimental approach based on the synthesis and study of organic/molecular magnetic materials based on the supramolecular arrangement of polychlorotriphenylmethyl

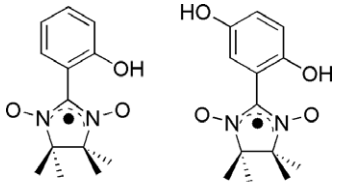

Chart 2.

(PTM) radicals functionalized with carboxylic groups in the *para*- and *meta*-positions of the aromatic rings with respect of the central methyl carbon (Chart 3). The interest for these molecules is multiple according to magnetic, geometrical and structural considerations. First, they exhibit a high thermal and chemical stability thanks to the presence of six bulky chlorine atoms that are shielding the central carbon atom, where the most part of the spin density is localized. Second, from a structural point of view, the rigidity and bulkiness of this family of open-shell molecules [29] was expected not only to prevent close packing and to form robust networks [30], but also to minimize undesired through space magnetic interactions in the solid state. Moreover, for example, PTMTC radical can be considered as an expanded versions of the trimesic acid molecule [31], where the benzene-1,3,5-triyl units has been replaced by an sp^2 hybridized carbon atom decorated with three 4-substituted 2,3,5,6-tetrachlorophenyl rings. Therefore, according to its related trigonal symmetry and functionality and to the molecule rigidity, PTMTC radical was expected to yield a purely organic magnetic open-framework, a goal within the sole crystal engineering field [32]. The last relevant facet of these molecules is related to the possibility to functionalize these radicals with carboxylic acid groups. As has been stated above, among the numerous functional groups used to build self-assembled networks, carboxylic acid groups combine the capability to form strong and directional H-bonds with their ability to promote magnetic interactions between radical species [25]. These functional groups are also particularly appealing in order to use in a further step: PTM radicals as ligands to access to porous and magnetic metal-organic coordination polymers [33], following a strategy combining the so-called ''reticular synthesis'' [34] together with the well-known ''metal-radical approach'' [35].

When we decided to start this work, only three examples of carboxylic substituted PTM radicals were described in the literature [36], and only two of them were characterized magnetically [36b,36c]. They were obtained in low overall yields following multistep synthetic methodologies, and none of them was characterized by X-ray diffraction. As a consequence, the work undertaken was also particularly challenging related to the synthetic and crystal engineering fields.

Here, an overview of the work that has been developed over the last six years in our group on this research line is presented. From the seminal work on the monocarboxylic PTM (Section 2), of great help to determine both the ability of these molecules to form intermolecular H-bonds and the nature of the intermolecular interactions mediated through the resulting supramolecular motifs, we will move to the self-assembly of PTM radicals functionalized with two and three carboxylic groups (Section 3). In both cases, the self-assembly of the paramagnetic units yield robust and porous magnetic organic/molecular structures, associating in some cases magnetic ordering to the latest remarkable characteristics. The last part of the review will present the latest results obtained with the idea to increase both the structural and magnetic dimensionality in purely organic PTM-based materials using a PTM radical functionalized by six carboxylic groups (Section 4). New trends and challenges for this research line, concerning the design and synthesis of new PTM radicals, as well as the obtaining of PTM based sensors or multifunctional materials will be presented in the concluding section (Section 5).

2. The simplest model: self-assembly of monocarboxylic PTMMC radical

The first stage of our study was focused to investigate the capacity of carboxylic acid functions of PTM radicals for the formation of intermolecular H-bonds. Although the ability of carboxylic groups to form H-bonds was widely reported [26,27,31], the neighbouring chlorine atoms located at the aromatic rings of these radicals should cause a high sterical impediment that could frustrate the formation of any direct H-bonds between carboxylic groups. To answer this question, we selected the monocarboxylic PTMMC radical previously synthesized by Ballester et al. in 1982 [36a]. The synthesis, crystallization and structural and magnetic characterization of this simple radical with only one carboxylic moiety would certainly help us to identify the formation of H-bonds as well as the nature and the strength of the expected magnetic exchange interactions mediated through these supramolecular interactions.

PTMMC was obtained following the synthetic procedure that is presented in Scheme 1 [36]. Briefly, this

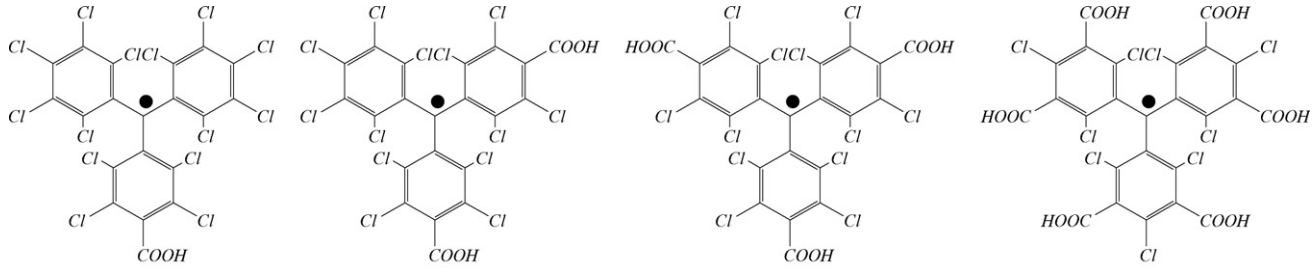

Chart 3.

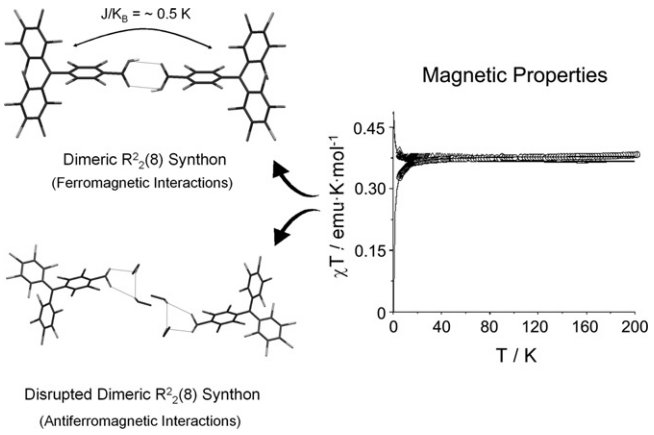
synthesis involves five crucial points: (i) the formation of the triphenyl methane skeleton (molecule **24**), *via* a Grignard reaction followed by the reduction of the triphenylcarbinol derivative **23** obtained after this reaction; (ii) the chlorination of the methyl group, which is accompanied by the chlorination of the central carbon atom (molecule **25**), that makes necessary an additional step for removing this chlorine; (iii) the chlorination of the three phenyl rings, to obtain the perchlorinated skeleton (molecule **27**); (iv) the conversion of the trichloromethyl group into carboxylic acid (molecule **28**); and finally, (v) the oxidation step to form the PTMMC radical.

The crystallization of this radical was performed by diffusion of hexane into a methylene chloride solution of PTMMC [25e]. This procedure yielded an α-phase of the radical, in which the PTMMC radicals are associated into H-bonded centrosymmetric $[R_2^2(8)]$ dimeric synthons defined by O···O distances of 2.676 Å and O–H···O angles of 144° (Fig. 1) [37,38]. In this synthon, both carboxylate groups of PTMMC are twisted by 88° with respect to the phenyl plane to which they are bonded. We believe that this characteristic is mostly due to the previously predicted steric hindrance from the neighbouring chlorine atoms to the carboxylic groups. Crystal packing of these dimers is then governed by interdimer Cl···Cl short contacts that yield to the formations of tapes running in a plane, while additional Cl···Cl contacts are responsible of the 3-D close packing. A detailed revision of all supramolecular contacts is given in Table 1 (see also Fig. 2a for atom labelling).

Taking into account the basic H-bonded dimeric organization of PTMMC radicals found in α-phase, and that the shortest distance between the central methyl carbons that



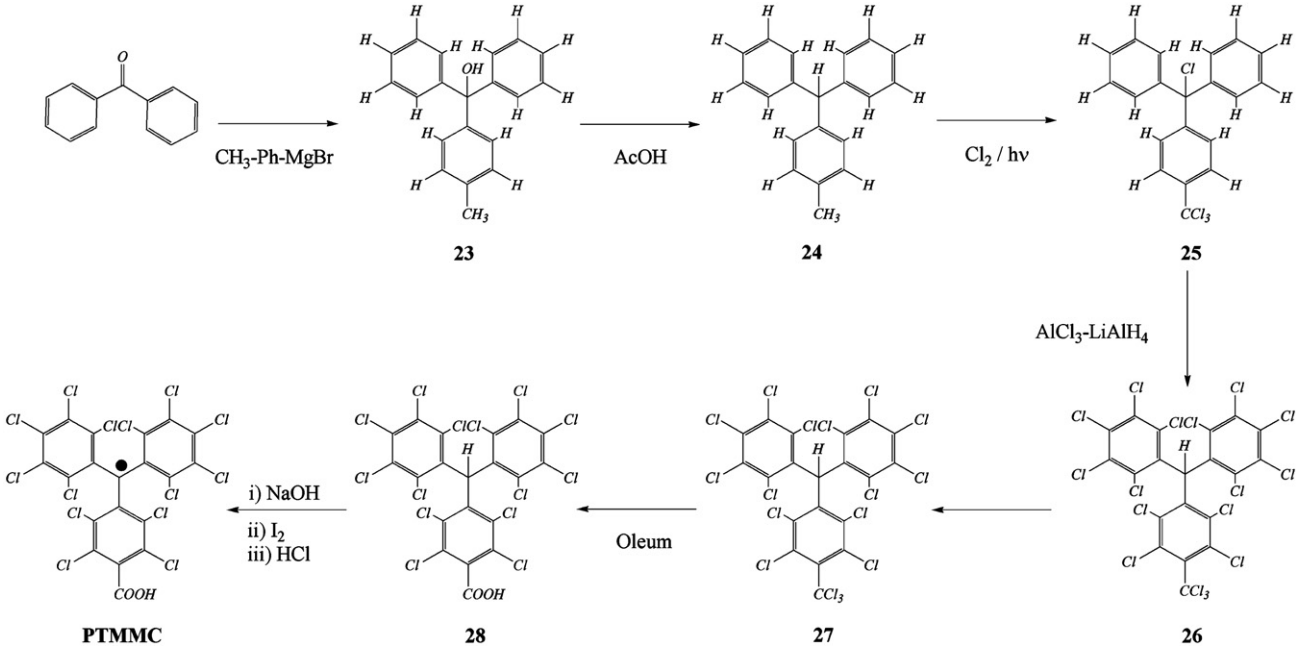


Fig. 1. Temperature dependences of the magnetic susceptibility, χ, of polycrystalline samples of α (Δ) and β (○) phases of radical PTMMC which are plotted as $\chi \cdot T$ vs. T. Solid lines are the best fit of the experimental data. $[R_2^2(8)]$ H-bonded dimers in α phase of PTMMC (top) yield weak ferromagnetic interactions while disruption of this synthon by ethanol molecules in β phase of PTMMC (bottom) is traduced by the onset of weak antiferromagnetic interactions at low temperatures.

bear most of the spin density is just found within these dimers at a length of 15.36 Å, the analysis of the magnetic properties provided the ideal scenario to study the transmission of magnetic exchange interactions between H-bonded PTM radicals. SQUID measurements revealed a paramagnetic behaviour in the 6–200 K temperature range, and the onset of weak ferromagnetic interactions below 6 K (Fig. 1). To confirm this behaviour, ESR measurements were performed on an oriented single crystal of the α phase and revealed the same trend. Hence, weak dominant ferromagnetic interactions are present in this phase.

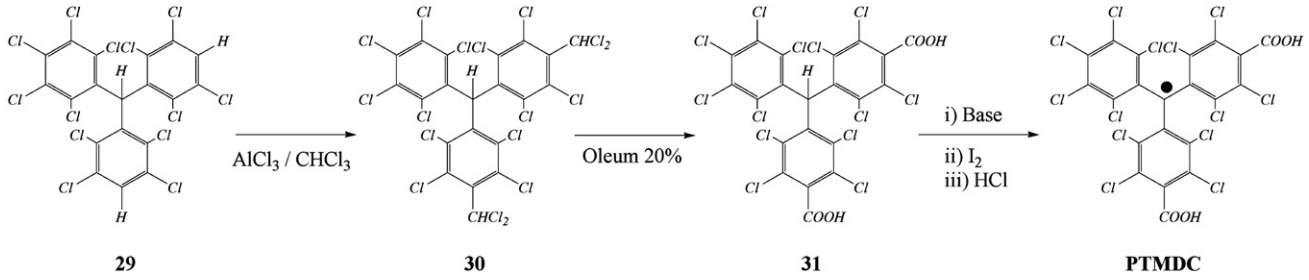
[a] Abbreviations o (*ortho*), m (*meta*) and p (*para*) positions of the phenyl rings with respect to the central carbon of carboxylic substituted PTM radicals.

The H-bonded dimers could be responsible for the appearance of the ferromagnetic interaction within the dimers. As only Cl···Cl contacts are present between the dimers and the distances between them are quite large, it is possible that the dimers behave as magnetically independent species. Therefore, the Bleaney-Bowers equation was used to fit the magnetic data and gave the following exchange coupling constant, $J/k_B = 0.5 \pm 0.1$ K. This value was later confirmed by fitting single crystal ESR data which gave a similar value, $J/k_B = 1.6 \pm 0.2$ K.

Beside the formation of direct intermolecular H-bonds, a second interesting feature on the crystallization of carboxylic-based PTM radicals was discovered when PTMMC radical was crystallized by slow evaporation of a radical solution in ethanol. From this crystallization, a second β-phase was obtained: the $[R_2^2(8)]$ synthons observed in the α-phase are disrupted by ethanol molecules. Indeed, change in the solvent nature and the possibility offered by ethanol to form H-bonds with carboxylic groups conduces to the disruption of any direct H-bond between PTMMC radicals (Fig. 1). Similar to the first phase, the packing of the PTM units is assumed *via* additional Cl···Cl short contacts that lead to a close packed structure (Table 1 and Fig. 2b).

From a magnetic point of view, the frustration of direct H-bonds between PTMMC radicals allowed us to further investigate the transmission of the magnetic interactions between these radicals. In principle, if H-bonded synthons are mostly responsible for the ferromagnetic interaction measured in α phase, this interaction should not be present in the β-phase. Magnetic measurement on this sample showed a paramagnetic behaviour down to low temperature, where a decrease of the $\chi \cdot T$ value is observed (Fig. 1). This behaviour was fitted to the Curie-Weiss law yielding a Weiss constant of $\theta = -0.80$ K, indicating the presence of dominant antiferromagnetic interactions. Cl···Cl contacts may be responsible for this weak antiferromagnetic interactions, as seen in other chlorinated triphenylmethyl radical derivatives [39]. Hence, the comparison of the solid-state magnetic data of both phases clearly concludes that the propagation of ferromagnetic interactions mostly occurs through the pathways defined by the intermolecular H-bonds between the carboxylic functions of PTM radicals.

(a) α phase of PTMMC, (b) β phase of PTMMC, (c) PTMDC (POROF-1), (d) PTMTC (POROF-2), (e) [PTMHC · $(Et_2O)_3$], and (f) [PTMHC · $(THF)_6$]. Thermal ellipsoids are set at 30% of probability and solvates solvent molecules have been omitted for clarity.



3. Extending the H-bonded dimensionality: self-assembly of di- (PTMDC) and tricarboxylic (PTMTC) radicals

The ability of PTMMC radicals to interact ferromagnetically through H-bonds prompted us to go a step further building extended purely organic/molecular structures, in which the transmission of ferromagnetic interactions could be propagated along the three dimensions and, therefore, induce a long-range magnetic ordering. The natural and rational step to extend the H-bonds in these radicals is the addition of more carboxylic functions to the skeleton of the PTM radicals. Thus, in a first approach, we designed two PTM radicals with two (PTMDC) and three (PTMTC) carboxylic functions to the *para*-positions of the aromatic rings with respect of the central carbon atom (Chart 3). From a structural point of view, both PTMDC and PTMTC radicals can be considered expanded versions of isophtalic and trimesic acids, respectively, where the benzene-1,3-diyl or the benzene-1,3,5-triyl unit has been replaced by an sp^2 hybridized carbon atom decorated with three perchlorophenyl rings substituted with carboxylic groups. And since isophtalic and trimesic acid molecules have been successfully used as building-blocks to create a wide diversity of extended H-bonded organic structures, a similar behaviour could be expected for both radicals [31,40]. Furthermore, the related trigonal symmetries and functionalities of both organic radicals also provides a typical template for getting cavities or channels, which envisions the synthesis of a series of purely organic/molecular magnetic structures with additional porosity characteristics.

A previous synthesis of the PTMDC radical together with preliminary magnetic characterizations was reported in 1994 by Domingo et al. Nevertheless, the overall yield of this multistep synthesis was rather low (12%) and magnetic characterizations, even if showing the onset of weak ferromagnetic interactions at low temperature, were performed on an amorphous sample of the radical [36b].

PTMDC was prepared following a new three-step procedure, starting from compound **29** (Scheme 2). Dichloromethyl groups were introduced by reacting **29** with chloroform following a Friedel–Crafts reaction, using $AlCl_3$ as catalyst (78%), and were subsequently converted to carboxylic groups by a hydrolysis–oxidation reaction using oleum 20% (31%). Finally, the subsequent treatment of the hydrocarbon precursor **31** with excess of NaOH, I_2, and HCl allowed the recovering radical (90%) [41]. Despite the low yield observed for the second step, this straightforward synthetic approach gave a higher overall yield than the synthesis previously reported for the molecule (21%).

With the experience acquired with the crystallization processes of PTMMC radical and in order to avoid any disruption of the expected H-bonded network, the crystallization of PTMDC was carried out without using solvent highly susceptible to generate H-bonds, such as alcohols. Thus, by reproducing the same crystallization conditions

Scheme 2. Synthesis of PTMDC.

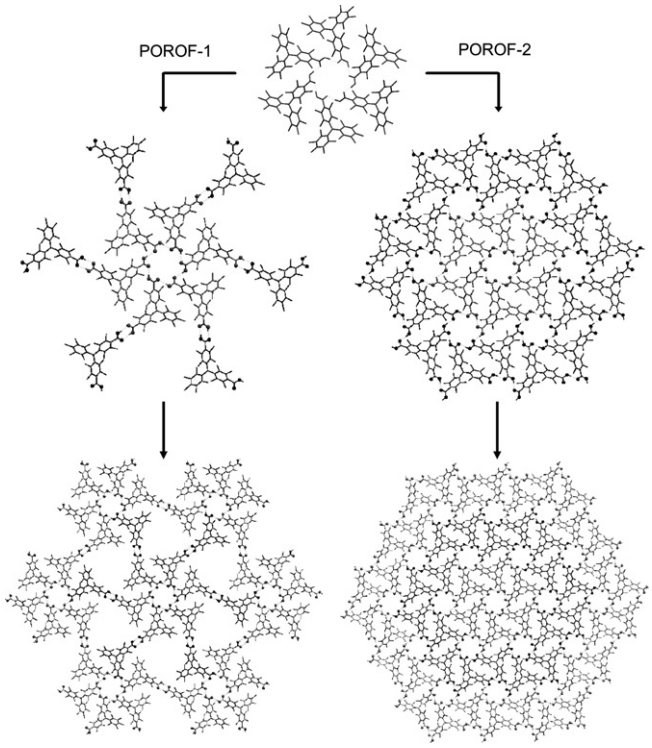


Fig. 3. Crystal structures of POROF-1 and POROF-2. Repetitive $[R_6^6(24)]$ hexamers (center) are connected through $[R_2^2(8)]$ synthon in POROF-1 (left) while this unique motif is responsible of the formation of 2-D porous H-bonded layers in POROF-2.

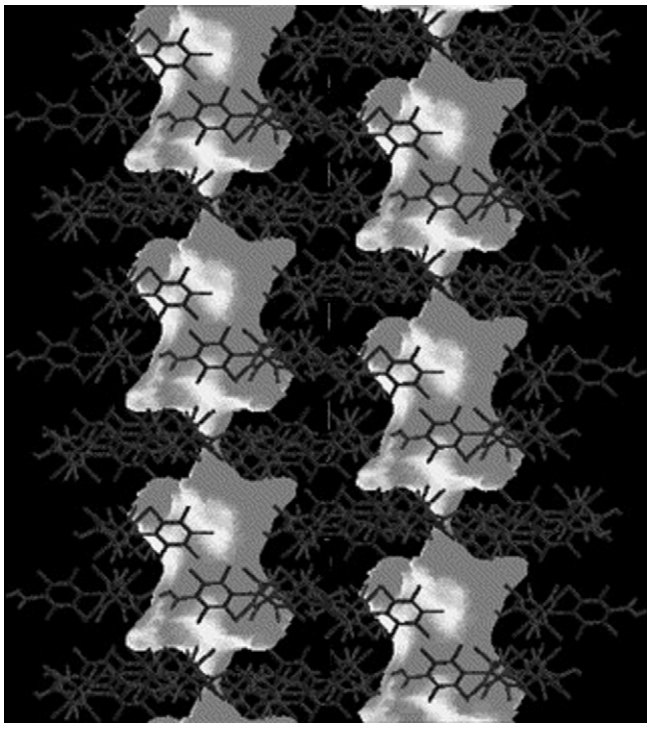

Fig. 4. Space-filling view along the *b* axis of the large nanocontainers formed along the 1-D channels in POROF-1.

that yielded the α-phase of PTMMC, a robust porous extended H-bonded network (POROF-1, where POROF refers to as Pure Organic Radical Open-Framework), that combines the presence of highly non-polar nanocontainers connected by polar narrow windows, was obtained. Thus in the solid state, the intermolecular H-bonded connections between PTMDC radicals create a primary structure consisting of 2-D H-bonded sheets, where each molecule of PTMDC adopts two H-bonded motifs, the expected dimeric $[R_2^2(8)]$ and the unusual hexameric $[R_6^6(24)]$ motifs (Fig. 3)[1] [28]. The first $[R_2^2(8)]$ synthon is almost identical to that observed in the α-phase of PTMMC with O···O distances of 2.677 Å and O–H···O angles of 164°. On the other hand, the new centrosymmetric cyclic $[R_6^6(24)]$ motif is formed by six mutually H-bonded carboxylic groups of PTMDC radicals with O···O distances of 2.692 and O–H···O angles of 169°. Precisely, this hexameric $[R_6^6(24)]$ motif is the repetitive unit in POROF-1, which involves the participation of one of two carboxylic groups of PTMDC radical. The second carboxylic group of each PTMDC radical forms the dimeric motif, which acts as a connecting element. Indeed, the formation of the dimer permits to connect each hexamer with six more identical units in an hexagonal topology, extending the infinitely H-bonded net along the two dimensions (Fig. 3).

These 2-D layers pack together in a shifted manner through several weak Cl···Cl contacts (Table 1 and Fig. 2c), leading an organic/molecular open-framework structure with 1-D channels formed by narrowed polar windows and larger hydrophobic cavities, where a sphere 10 Å in diameter can fit inside them (Fig. 4). The smaller

[1] Cyclic hydrogen bonded supramolecular motifs, as well as polymeric hydrogen bonded catemers, are particularly rare. See Ref. [27].

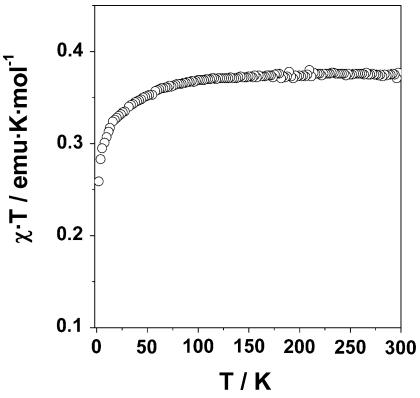

Fig. 5. Temperature-dependence of the magnetic susceptibility of POROF-1.

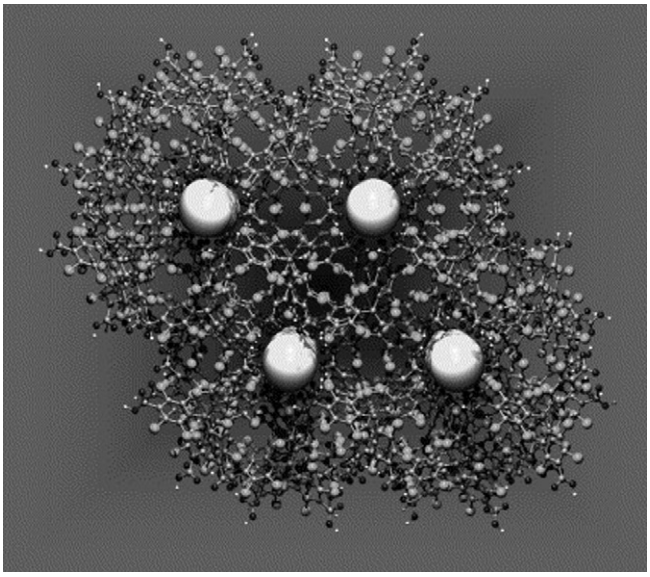
windows with a highly hydrophilic environment, due to the presence of the carboxylic groups at the inner walls, have a diameter of 5 Å, considering van der Waals radius. The combination of supercages and windows gives way to solvent-accessible voids in the crystal structure that amount up to 31% (5031 $Å^3$ per unit cell) of the total volume (16158 $Å^3$). Furthermore, the fact that POROF-1 is composed of radical tectons leads a magnetic character to this open-framework structure, which exhibits weak antiferromagnetic interactions between radical units at low temperatures (Fig. 5).

The new synthetic approach developed to synthesize PTMDC also allowed the access to the PTM radical with three carboxylic groups at the *para*-positions of phenyl rings. The PTMTC radical was prepared following a similar three-step procedure, starting from compound **32** (Scheme 3), and with a remarkable high overall yield (74%).

The crystallization of this radical was again carried out by diffusing a layer of hexane into a dichloromethane solution of PTMTC. The crystal packing of PTMTC molecules forms a robust porous extended H-bonded 2-D network (POROF-2), which combines the presence of highly polar tubular channels and very interesting magnetic properties, such as long-range magnetic ordering at low temperatures [42]. As shown in Fig. 3, the repetitive unit is the identical cyclic $[R_6^6(24)]$ motif identical to those found in POROF-1, and herein formed by six mutually H-bonded molecules of PTMTC with O···O distances of 2.657 Å and O–H···O angles of 169°. Since every radical unit contains three carboxylic groups, each PTMTC molecule participates in the construction of three identical hexameric units that propagates along a plane (Fig. 3). Remarkable is the fact that the stacking of layers through Cl···Cl contacts (Table 1 and Fig. 2d) occurs in an eclipsed fashion generating a 3-D structure that exhibits regular tubular channels, where a sphere of 5.2 Å in diameter can fit inside them (Fig. 6), without significant constrictions in contrast with POROF-1. In addition, such channels are surrounded by a second set of small pores with a diameter of 3.3 Å. The combination of both originates solvent-accessible voids in the crystal structure that amount up to 15% (450 $Å^3$ per unit cell) of the total volume. Interestingly, the location of carboxylic groups at the inner walls of the largest channels furnishes them with a highly polar and hydrophilic environment. This fact may stand for the lack of guest solvent non-polar molecules within the channels when crystallized from dichloromethane and hexane.

Variable temperature magnetic susceptibility data for a crystalline sample of POROF-2 revealed a paramagnetic behaviour from 300 to 5 K, where the $\chi \cdot T$ value increases on cooling down to 2 K according with the presence of



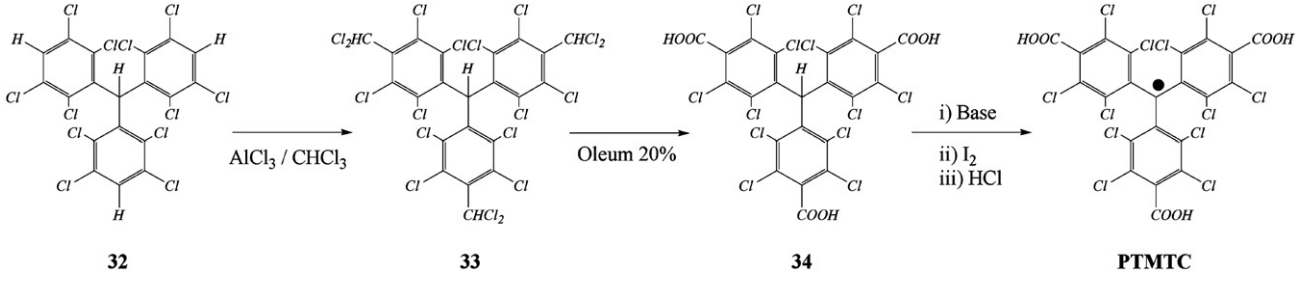


Fig. 6. View of the channel-like system of POROF-2 filled with ideal spheres with 5.2-Å diameter.

Scheme 3. Synthesis of PTMTC.

weak ferromagnetic interactions (Fig. 7). This behaviour was fitted to the Curie–Weiss law with a Weiss constant of $\theta = +0.2$ K. To investigate the existence of a long-range magnetic ordering at very low temperatures, variable temperature magnetic susceptibility experiments down to 70 mK were performed in a dilution cryostat. A considerable increase of the $\chi \cdot T$ value up to a maximum peak around 110 mK was observed on cooling down below 2 K, which reveals the transition to a ferromagnetic ordered state at very low temperatures. The intensity of the peak decreases whereas its maximum shifts slightly to higher temperatures on increasing the external applied magnetic field. For instance, for an applied magnetic field of 20 Oe a value of 2.2 emu K mol^{-1} was obtained, whereas for an external field of 50 Oe the value is reduced to 1.4 emu K mol^{-1}. This behaviour originates in the saturation of magnetization for fields of few hundred Oe. Magnetization curves were measured above and below the critical temperature and are illustrated in Fig. 7b. At 1.35 K, POROF-2 remains in the paramagnetic region, and therefore, the magnetization curve has a slight gradient. On the contrary, the curve at 80 mK, even if it is very close to the critical temperature, traces a hysteretic loop characteristic of a soft ferromagnet. The magnetization is almost saturated at about 400 Oe, and though the coercive force is of the order of 50 Oe (see inset of Fig. 7b) the remanent magnetization at zero field is of about 35% of the saturation value.

4. A highly carboxylic building-block: self-assembly of hexacarboxylic PTMHC radical

As a natural evolution due to the interest rose up by the work performed on the previous carboxylic substituted radicals, we decided to increase again the number of carboxylic acid functions and prepare a PTM radical with six carboxylic groups in *meta*-positions, studying its supramolecular organization and magnetic properties. In addition to the synthetic challenge that implies the synthesis and characterization of this novel radical [43,44], changes in both the number (six) and location (*meta*-positions) of the carboxylic groups along the PTM moiety was expected to afford new 3-D assemblies, as recently demonstrated in the case of triphenylmethane-based polyphenols [45]. In addition, the presence of six carboxylic groups in PTMHC was also expected to enhance the number of magnetic exchanges pathways between PTM radicals by endorsing the H-bonded network.

PTMHC was prepared following an adaptation of the synthetic methodology used to obtain PTMDC and PTMTC radicals (Scheme 4). While the initial part of this synthetic route was identical, the increase of the number of carboxylic groups in **37** compared to the corresponding di and tri-acid molecules **31** and **34** makes impossible the direct formation of the radical starting from this molecule [46]. To overcome this inconvenience, the hexa-acid **37** was first converted into the corresponding hexa-ester **38**, and then oxidized to give the hexa-ester radical **39**. Methyl groups were finally easily removed to obtain PTMHC with a good overall yield (30%).

The same principles applied for the crystallization of the previous radicals were considered for the crystallization of PTMHC. Multiple attempts of crystallization were performed and different crystallization techniques used in order to disfavour the formation of H-bonds between PTMHC and solvent molecules and, therefore, create a fully 3-D H-bonded organic/molecular material. Thus far, however, all these tries have failed, mainly because of the lack of solubility of the highly polar radical PTMHC in non-oxygenated solvents. Also, other common techniques such as gas phase neutralization, and based on a diffusion of HCl vapours into a saturated solution of the PTMHC hexacarboxylate, did not afford any satisfactory result.

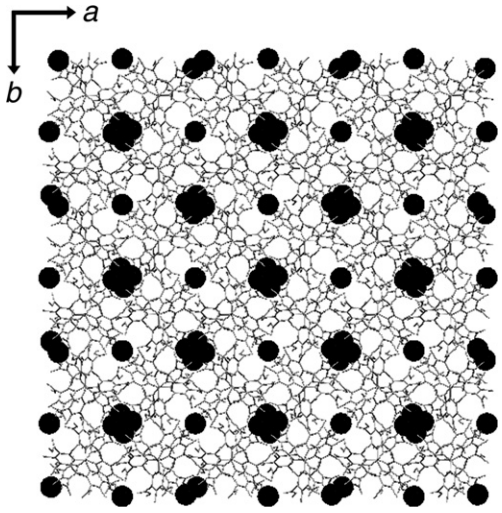
An alternative method for crystallizing highly carboxylic substituted molecules was reported by Darlow in 1961

Scheme 4. Synthesis of PTMHC.

[43a]. By recrystallizing benzene hexacarboxylic acid in concentrated nitric acid, a solvent free structure of this compound was obtained. Following this methodology, we tried the crystallization of the non-radical **37** as a first approach [47]. As expected, the use of this method afforded an organic solid with a formula of $[\mathbf{37}\cdot(H_2O)_{1.5}]$ that shows a fully 3-D H-bonded structure with 1-D channels. Noteworthy is the fact that this H-bonded network is partially disrupted by water molecules, but this disruption is not enough to prevent the formation of a 3-D H-bonded structure. In the structure, the solvent molecules are located in the 1-D channels as isolated water molecules or water tetrahedrons (Fig. 8). Overall, this structure possesses an accessible volume near 8.5% when the water molecules are omitted, that corresponds to a solvent accessible volume of 568.1 $Å^3$ versus the volume of the total unit cell (6564.0 $Å^3$).

If successful with PTMHC, a similar crystallization could lead us to the obtaining of a pure organic/molecular porous material with a 3-D H-bonded structure similar to the water solvate of **37**, with foreseeable magnetic properties. However, and in spite of the fact that the fully chlorinated PTM radical was already shown to be stable in hot concentrated nitric acid during several days [48], PTMHC was oxidized with nitric acid to give the corresponding diamagnetic fuchsone **40**, probably because of the good solubility of this compound in nitric acid at high temperatures which contrasts with the low solubility of the fully chlorinated PTM radical (Scheme 5).

Besides the failures of previous crystallizations, a partial success was later on obtained when a mixture of diethyl ether and *n*-hexane was used. Although diethyl ether molecules can form H-bonds with carboxylic acid groups, the crystallization of PTMHC using these solvents yields an organic/molecular $[\mathrm{PTMHC}\cdot(Et_2O)_3]$ solid with an H-bonded structure that is only partially disrupted by solvent molecules (Table 1 and Fig. 2e). Thus, the primary structure is formed by the H-bonded connections of PTMHC radicals into 2-D H-bonded corrugated layers. As shown in Fig. 9, the repeating unit consists of an unusual



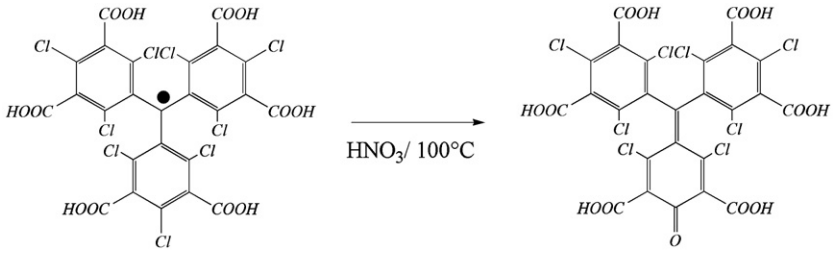


Fig. 8. Crystal structure of $[\mathbf{37}\cdot(H_2O)_{1.5}]$. Packing of molecules of **37** creates a 3-D H-bonded structure that reveals the presence of polar channels in which water molecules are localized. Water molecules are represented as spheres for clarity.

PTMHC 40

Scheme 5. Oxidation of PTMHC to the corresponding fuchsone.

$[R_6^6(48)]$ H-bonded motif formed by six PTMHC molecules (Fig. 9a). In this motif, each radical is H-bonded to two neighbouring radicals through one carboxylic group with O···O distances of 2.696 Å and O–H···O angles of 164°. It is important to note the similarities of these H-bonds with the ones found in POROF-2. The remaining carboxylic group localized in the same phenyl ring is also involved in one H-bond with a diethyl ether molecule. Since every radical unit contains six carboxylic groups (three are involved in H-bonds with PTMHC molecules and three in H-bonds with solvent molecules) each radical molecule participates in the construction of three identical hexameric units, resulting in open polar windows that propagate along the H-bonded layers (Fig. 9b). Three diethyl ether molecules are localized on each side of each polar window contributing to isolate one layer from the two neighbouring ones (the shortest radical-radical interlayer distance is 6.892 Å). Interdigitation of diethyl ether molecules belonging to neighbouring layers avoids then the formation of a fully 3-D H-bonded structure, leading to a ABC arrangement of these layers (Fig. 9c).

The disruption of the direct H-bonds between PTMHC radicals was further confirmed when PTMHC was crystallized from a mixture of THF and *n*-hexane. The higher ability of THF molecules to form H-bonds [27,49] in comparison with diethyl ether yielded a new phase $[PTMHC \cdot (THF)_6]$, in which no direct intermolecular H-bonds between PTMHC radicals can be found (Table 1 and Fig. 2f). Indeed, this crystal shows the particularity that all six carboxylic acid groups of PTMHC radicals are involved in the formation of H-bonds with one THF (Fig. 10a). Consequently, the resulting "supramolecular radical–THF clusters" $[PTMHC \cdot (THF)_6]$, avoid any direct H-bonds between radical molecules pushing them far away. The shortest distance between radical centers, 7.514 Å, is observed in supramolecular columns running along the *c* axis (Fig. 10b). Close packing of supramolecular radical-THF clusters takes place through several weak H-bonds between neighbouring THF molecules leading to a PTMHC-templated honeycomb-like arrangement of the solvent molecules (Fig. 10c).

Variable temperature magnetic susceptibility data for as-synthesized crystalline sample of $[PTMHC \cdot (Et_2O)_3]$ showed a very similar magnetic behaviour than POROF-2 (Fig. 11). At high temperatures (between 20 and 300 K), this compound behaves as a pure paramagnet. However, below 20 K, the $\chi \cdot T$ value smoothly increases upon decreasing temperature to reach a value of 0.395 emu K mol^{-1}at 1.8 K. This result is again in agreement with the presence of very weak intermolecular ferromagnetic interactions between H-bonded radical molecules and, presumably, to the presence of a long-range magnetic ordering at very low temperatures. On the contrary, and also as expected, $[PTMHC \cdot (THF)_6]$ behaves as a paramagnet with only very weak intermolecular antiferromagnetic interactions (through space) at very low temperatures, in agreement with the lack of direct H-bonds between PTMHC radicals in that solvate (Fig. 11).

5. Self-assembly of carboxylic substituted PTM radicals: concluding remarks, new trends and challenges

In this short review, we have demonstrated that polychlorinated triphenylmethyl radicals, properly functionalized with one or more carboxylic functions, are excellent organic building-blocks for the preparation of purely organic/molecular magnetic molecular materials. While the self-assembly of PTMMC yield to the formation of supramolecular dimers and to the onset of weak ferromagnetic interactions between the radical units, increase in the number of carboxylic acid functions in PTMDC and PTMTC has allowed the access to the first examples of purely organic-radical open-frameworks, POROF-1 and POROF-2, that are associating astonishing structural characteristics together with relevant magnetic properties, such as long-range magnetic ordering. Indeed, POROF-1, built by self-assembly of PTMDC molecules, is a paramagnetic material that presents a high porosity, with highly non-polar nanocontainers connected through polar narrow windows. High porosity is also observed in the case of POROF-2, in which the 2-D self-assembly of PTMTC molecules and the packing of the resulting H-bonded layers yield a hydrophilic porous architecture. However, compared to POROF-1, this supramolecular nanoporous purely organic "zeolite-like" material exhibits a long-range ferromagnetic ordering that behaves as a soft-magnet.

Two are the most important features to explain the results obtained for POROFs materials. First, the

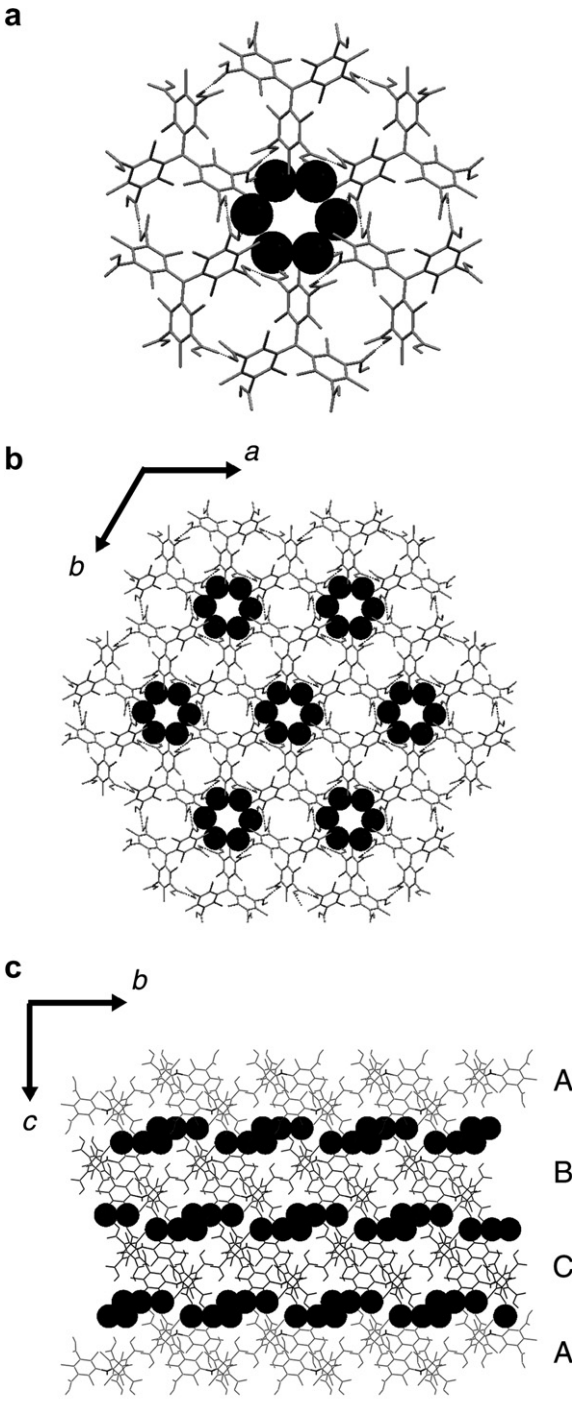

Fig. 9. Crystal structure of [PTMHC · $(Et_2O)_3$]. (a) $R_6^6(48)$ hexamer and (b) extended hydrogen-bonded corrugated layer. (c) ABC arrangement of the layers that are isolated one from each other by solvent molecules. Et_2O molecules are represented as spheres for clarity.

carboxylic groups on these radicals have been shown as good superexchange pathways for attaining magnetic couplings. And second, the geometry and the rigidity of the molecules that together with the paramagnetic character of carboxylic substituted PTM radicals offer magnetic and porous materials with a purely organic nature.

Attempts to take advantage of these characteristics to build a 3-D H-bonded porous and magnetic structure using PTMHC have given interesting results: even if, mainly for solubility problems, the access to a PTM-based 3-D H-bonded structure is still not achieved, the presence of ferromagnetic interactions in the diethyl ether solvate of this radical together with the structural analogy between its structure and the one of POROF-2 are particularly promising. Moreover, two points are particularly relevant for magnetic considerations: (i) increase in the number of carboxylic groups is traduced by the lack of Cl···Cl contacts in the solid state, contacts that are usually responsible for antiferromagnetic interactions in this type of radicals [39]; and (ii) change in the carboxylic groups relative position compared to PTMMC and PTMTC (*meta versus para*) does not modify the nature of the intermolecular magnetic interactions, that are still ferromagnetic. Thus, attempts to crystallize PTMHC are still under progress, but the last point and the possibility to access to new POROFs or new metal-organic materials [33], only changing the relative positions of carboxylic groups, make particularly attractive the synthesis of molecules **41**, **42** and **43** (Chart 4). The later compound, with its distorted tetrahedral geometry, appears also to be a good candidate and a good alternative to PTMHC in order to access to 3-D H-bonded porous and magnetic PTM based materials.

The remarkable properties and characteristics of POROF materials could also be exploited to address several challenging aspects for both crystal engineering and molecular magnetism fields [50]. The synergism of magnetic properties and porous materials together with the molecular characteristics purely organic materials opens a new route to the development of Purely Organic Multifunctional Molecular Materials. For instance, along with the possibility to act as zeolite-like materials, POROFs materials offer excellent conditions to encapsulate different functional systems with conducting, optical, chiral and NLO properties... using, for instance, functional molecules as templates during the crystallization of the radicals [51]. In consequence, the resulting material would combine the magnetic properties of the framework and the inherent properties and applications of the encapsulated functional molecules.

Another field of research for which this type of materials could be particularly interesting is their use as purely organic sensors. For instance, and since the magnetic properties are close dependant to the presence of intermolecular H-bonds between PTM units into the crystal structure, insertion of polar molecules in the solvent-free polar channels of POROF-2 could be expect to yield to weak structural changes (because of the numerous chlorine–chlorine contacts present in the material) and to strong changes in the magnetic properties, by disruption of the H-bonded two dimensional network. In a second time, removal of the solvent molecules only heating the solvated material could be expect to give back the starting

POROF-2 material with soft-magnet properties, opening the line towards purely organic magnetic solvent sensors [33c,52].

Actually, work on these two challenging research lines is underway in our laboratory. Further experimentations aimed not only at the generation of new magnetic and porous molecular materials using PTMDC, PTMTC or PTMHC radicals but also at the obtaining of new organic building-blocks by the chemical modification of the polychlorotriphenylmethyl skeleton, such as molecules **41**–**43**, are also in progress. Thus, the use of these radicals as building-blocks is expected to allow the design of novel architectures with interesting porosity characteristics, magnetic properties and surprising topologies. In conclusion, such new radical units, along with PTMDC, PTMTC and PTMHC radicals, are expected to increase the new family of magnetic purely organic/molecular (POROF) radical open-frameworks.

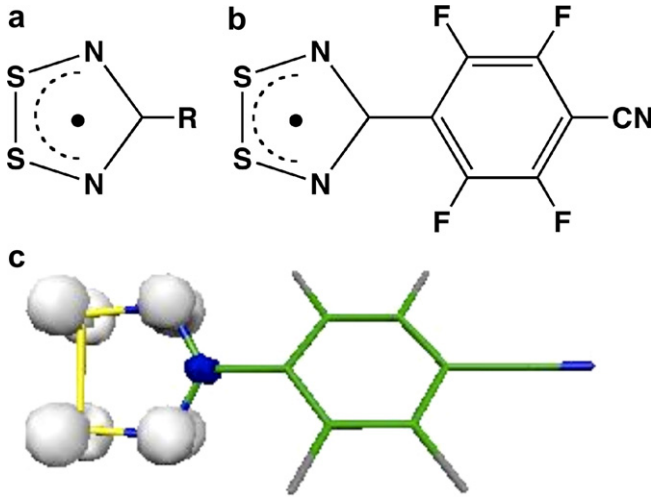

Fig. 1. (a) General formulae of heterocyclic 1,2,3,5-dithiadiazolyl radical (in short, R-CNSSN·). (b) Chemical formulae of cyano-perfluoraryl-dithiadiazolyl, NC-C_6F_4-CNSSN·. (c) Spin density of a NC-C_6F_4-CNSSN· radical at B3LYP/6-31+G(d) level of theory (isodensity surface 0.01 a.u.).

In the α-phase, the interactions are thought to be weaker, leading to a sharp maximum in χ at 10 K indicative of *bulk* antiferromagnetic order. In the β-phase, a broad maximum in χ is observed around 60 K, indicative of short-range ordering, followed by a transition to a canted antiferromagnetic state (critical temperature 36 K). In this first work, we will just focus on the magnetic properties of the α phase (also identified in the literature as α-YOMXUT [9]), given the complexities that it presents. A study of the β phase will form the basis of a future report. In α-YOMXUT, the radicals pack to form chains, which are linked via CN···S interactions, and further connected into planes via additional N···S and S···S interactions (Fig. 2a). These layers stack in a regular ···*AAA*··· disposition (Fig. 2b). However, the experimental magnetic susceptibility curve could not be fitted by any simple magnetic model. Our study will show that this fact is due to the presence of strong ferro and antiferromagnetic interactions whose interplay results in a complex 3D magnetic topology.

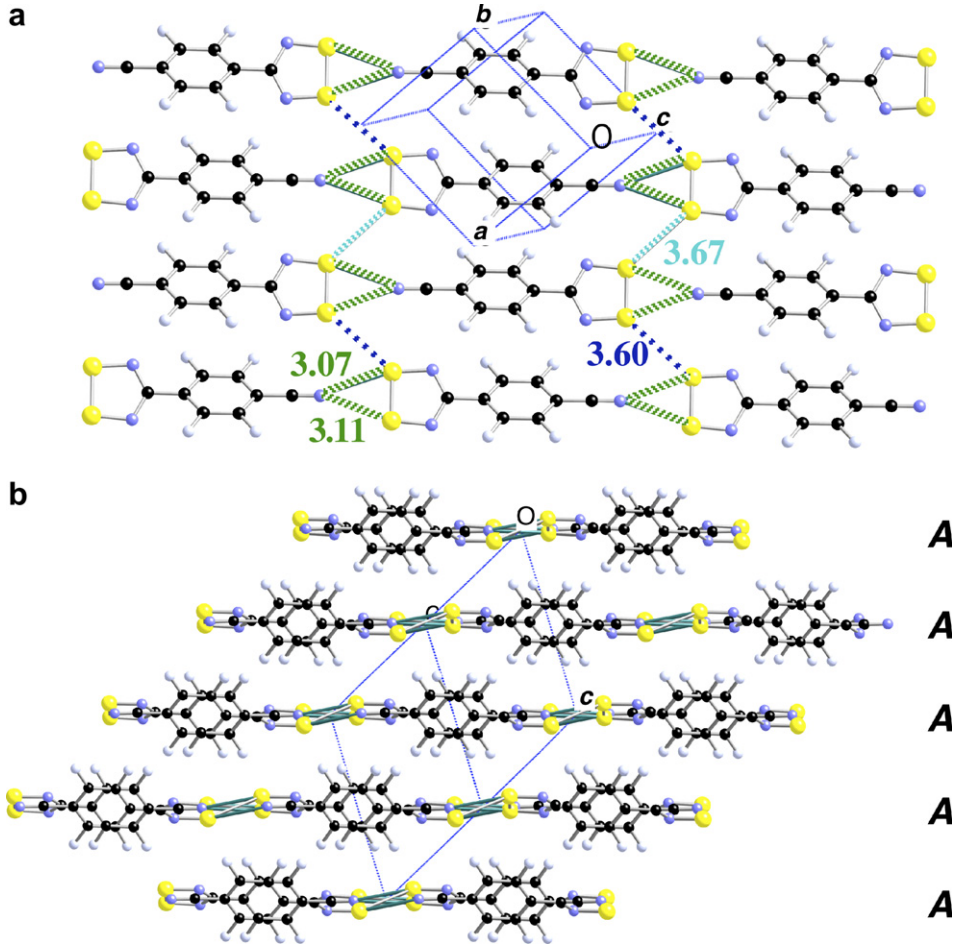

Fig. 2. (a) Crystal packing analyzed in terms of shortest intermolecular distances between NC-C_6F_4-CNSSN· radicals, which form chains in terms of N···S contacts at 3.07 and 3.11 Å that interact with nearby antiparallel chains by means of S···S contacts at 3.60 and 3.67 Å (resulting into *A* sheets). (b) General ···*AAA*··· disposition.

2. Methodology

The theoretical study of the magnetism of α-YOMXUT will be performed applying our first-principles *bottom-up* methodological approach [10], which consists in the sequential application of the following four steps:

(1) Analysis of the crystal structure in order to find all unique A–B radical–radical pairs that might be responsible for the microscopic magnetic interactions.
(2) Computation of the microscopic J_{AB} radical–radical magnetic interactions for all pairs.
(3) Definition of the magnetic topology of the crystal and corresponding minimal magnetic model using the non-negligible J_{AB} values.
(4) Calculation of the macroscopic magnetic properties of the crystal.

In the first step, one selects all unique radical–radical pair candidates (identified as *di*) capable of presenting non-negligible magnetic interaction (identified as $J_{AB}(di)$ and computed in the second step). In practical terms, such selection is done by identifying each unique radical and then choosing all radical–radical pairs whose distance is smaller than a selected cutoff value (that includes all first-nearest neighbors and the closest second-nearest neighbors). Because of the exponential dependence on the distance of the magnetic interactions [11], this was considered to be a safe procedure for selecting all magnetically relevant pairs of radicals. Notice that this procedure is totally unbiased since it does not make any a priori assumptions on the nature or size of the $J_{AB}(di)$ magnetic interactions.

The $J_{AB}(di)$ parameters computed in the second step are defined in terms of the following general Heisenberg Hamiltonian:

$$\widehat{H} = -2\sum J_{AB}\widehat{S}_A \cdot \widehat{S}_B \quad (1)$$

As the *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radicals are doublets, the $J_{AB}(di)$ values can be obtained from the following expression:

$$J_{AB} = E^S_{BS} - E^T \quad (2)$$

where E^T is the energy of the triplet state in the radical–radical pair and E^S_{BS} is the energy of the open-shell singlet state within the broken symmetry approach [12]. Notice that Eq. (2) is obtained after accounting for the zero overlap of the SOMO orbitals of the interacting radicals ($S_{ab} = 0$), that is, by strict application of the broken-symmetry equation for the Heisenberg Hamiltonian (1), whose general expression is:

$$J_{AB} = \frac{E^S_{BS} - E^T}{1 + S^2_{ab}} \quad (3)$$

The values of E^T and E^S_{BS} are computed using the UB3LYP functional [13] and the 6-31+G(d) basis set [14]. These computations were done using the appropriate options in GAUSSIAN-98 [15] to obtain J_{AB} values with an accuracy of $|0.02|$ cm^{-1}. Those *di* pairs whose absolute $J_{AB}(di)$ value is smaller than $|0.05|$ cm^{-1} were discarded (we have previously observed that smaller J_{AB} values are not relevant in the following steps of the first-principles *bottom-up* procedure).

The network of non-negligible $J_{AB}(di)$ magnetic interactions among the radicals define the *magnetic topology* of the crystal. Obviously, such magnetic topology extends over the whole crystal and is infinite. However, for our procedure, we need to find a finite subset of the crystal (the so-called *minimal magnetic model space*) that describes the magnetic interactions of the whole crystal in a balanced way, and whose repetition along the (a,b,c) crystallographic directions regenerates the magnetic topology of the infinite crystal. Then, using the complete set of spin functions of this finite subset, one computes the matrix representation of the Heisenberg Hamiltonian (1). Such matrix representation is diagonalized to obtain the full spectrum of energies. These energies are then used in the appropriate statistical mechanics expressions to obtain the macroscopic magnetic properties in a rigorous way. We stress that the entire procedure is completely unbiased and allows us to connect, in a rational way, the macroscopic magnetic properties with their microscopic $J_{AB}(di)$ origin. As the sign and size of the microscopic $J_{AB}(di)$ parameters depend on the geometry of the radical–radical pairs, the first-principles *bottom-up* procedure is an interesting tool towards a rational design of new materials that could present improved magnetic properties.

3. Results and discussion

The 160 K X-ray structure of the α-phase crystal of the NC-C_6F_4-CNSSN$^{\bullet}$ radical belongs to the triclinic space group $P\bar{1}$, with two radicals per unit cell ($Z = 2$; $a = 7.574$ Å, $b = 8.065$ Å, $c = 9.509$ Å, $\alpha = 65.73°$, $\beta = 69.17°$, $\gamma = 67.52°$ [3]). The crystal packing presents a chain motif with the radicals in a head-to-tail arrangement, in which the shortest S···NC interactions are found at 3.07 and 3.11 Å (see Fig. 2a). Adjacent chains are arranged antiparallel to each other and form planes through S···N and S···S interactions. These planes stack in an $\cdots AAA\cdots$ disposition (see Fig. 2b). The shortest S···S contacts are found at 3.60 and 3.67 Å. The shortness of the in-plane CN···S interactions might indicate a chain-like magnetic topology with one dominant exchange interaction in the crystal.

We now present the results obtained in each step of the first-principles bottom-up theoretical study of the α-YOMXUT crystal.

Step 1: Selection of all unique radical–radical pairs present in the crystal. Theoretical B3LYP/6-31+G(d) calculation on the *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radical indicates that most of the spin density is located on the CNSSN five-membered ring of the radical (see Fig. 1c for 0.01 a.u. isodensity surface). Thus, the CNSSN group is the spin-carrier group of the *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radical. Therefore, it seems appropriate

to select the candidate *di* radical–radical pairs on the basis of the distance between the CNSSN spin-carrier groups, for these pairs that are not symmetry equivalent within the crystal.

In terms of the shortest NSSNC···CNSSN distances, we selected all first nearest-neighbors (cutoff distance of 13 Å) and only the closest next (second) nearest-neighbors. In practice, 16 crystallographically different radical–radical pairs (*d*1–*d*16) were selected in the α-YOMXUT crystal (Fig. 3 shows their geometrical positions within the crystal, while Table 1 collects the value of the NSSNC···CNSSN distances). The geometry of each *di* dimer is fully documented in the supplementary material (Figs. S1–S16, using two different views, depending on whether the dithiadiazolyl ring is parallel or perpendicular to the plane of the figure). Except for the *d*10 and *d*13 pairs, which are second nearest neighbors, all other pairs are first nearest neighbors. Among them, six pairs sit on the same *A* plane (*d*3, *d*4, *d*7–*d*9 and *d*16), and the remaining 10 pairs (*d*1, *d*2, *d*5, *d*6, *d*10–*d*15) are located in adjacent *A*···*A* planes.

Step 2: Evaluation of the microscopic J(di) magnetic interactions. The computed *J*(*di*) values are collected in Table 1. Only six interactions (*d*1–*d*4, *d*7 and *d*8, see Fig. 4 for geometry and also Fig. 3 for their position within the crystal) are non-negligible with two of them (*d*2 and *d*8 with values +10.91 and −10.25 cm^{-1}) much stronger than the remaining four (with values −1.44, +1.02, +0.67, and +0.29 cm^{-1}). It is clear form Table 1 and Fig. 4 that

Table 1
Unrestricted DFT broken symmetry UB3LYP/6-31+G(d) results for the dimeric interaction of all 16 candidates (*d*1–*d*16) listed as NSSNC···CNSSN distance increases for α-YOMXUT crystal

Candidate *di*	Distance (NSSNC···CNSSN) (Å)	$J_{AB}(di)$ (cm^{-1})
*d*1	4.789	+1.02
*d*2	4.990	+10.91
*d*3	6.534	+0.29
*d*4	6.588	+0.67
*d*5	7.574	<|0.05|
*d*6	8.065	<|0.05|
*d*7	8.285	−1.44
*d*8	8.454	−10.25
*d*9	8.700	<|0.05|
*d*10	9.509	<|0.05|
*d*11	9.614	<|0.05|
*d*12	9.785	<|0.05|
*d*13	9.792	<|0.05|
*d*14	9.827	<|0.05|
*d*15	10.482	<|0.05|
*d*16	12.053	<|0.05|

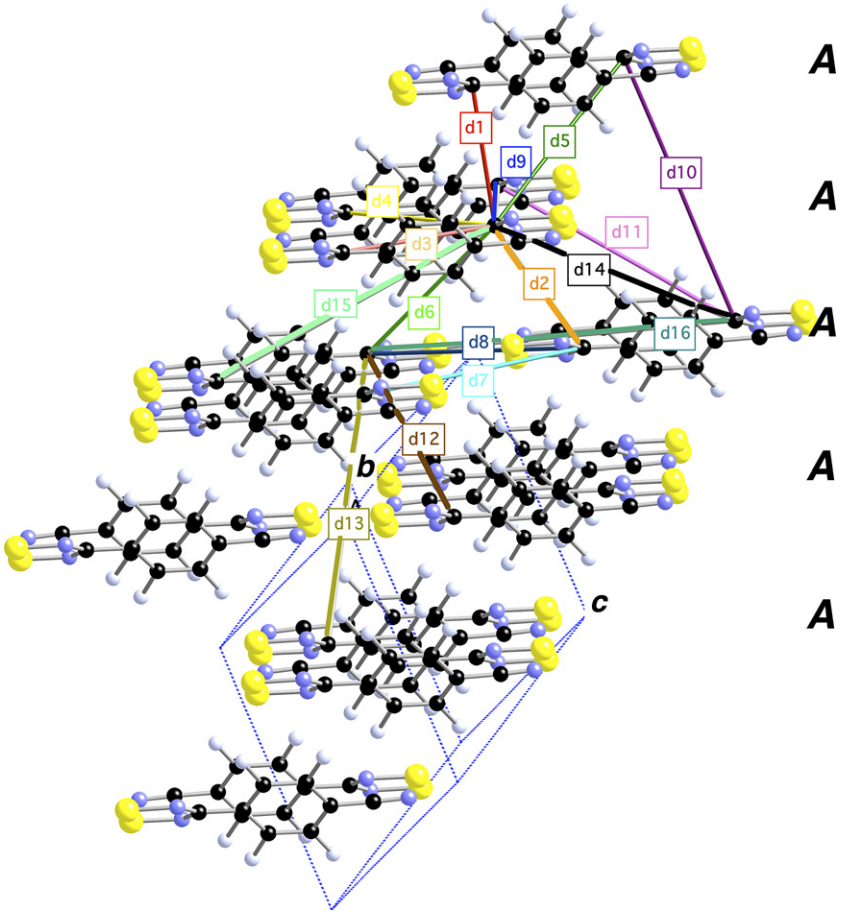

Fig. 3. Representation of all unique *di* pairs of radicals selected in order to compute the corresponding $J_{AB}(di)$ pair interaction.

the $J(di)$ values are sensitive not only to the distance but also to the relative orientation of the *p*-NC-C_6F_4-CNSSN$^{\cdot}$ radicals within the pairs. Among these six non-negligible magnetic interactions, there are some ferromagnetic (FM: $d1$, $d2$, $d3$, $d4$) and some antiferromagnetic (AFM: $d7$, $d8$) interactions. Notably the head-to-tail $d16$ pair, which exhibits the shortest CN···S intermolecular contacts (Fig. 2a), is numerically negligible and consequently cannot contribute to the macroscopic magnetism of α-YOMXUT, i.e. the likely structure-directing influence of this interaction does not influence the magnetic behavior.

Step 3: Definition of the magnetic topology and minimal magnetic model space of the crystal. The magnetic topology is defined in terms of the radicals that are magnetically connected (that is, showing non-negligible magnetic interactions). Fig. 5 shows a diagrammatic representation of Fig. 3, where each radical is replaced by the C-atom of the CNSSN group (the lines represent the non-negligible $J(di)$ magnetic interactions; to improve its clarity, a change in the orientation of the crystallographic axes was done compared to previous figures). The magnetic topology of the α-YOMXUT crystal is clearly three-dimensional (3D) but very complex. The dominant interactions (the ferromagnetic $J(d2) = +10.91\ \mathrm{cm}^{-1}$ and antiferromagnetic $J(d8) = -10.25\ \mathrm{cm}^{-1}$) form alternating FM–AFM zigzag chains, which are connected along the *bc*-plane by adjacent

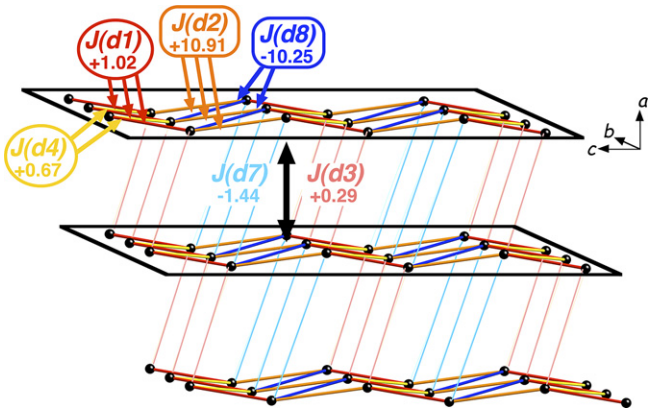

Fig. 5. Magnetic topology of α-YOMXUT crystal. The numerical values of the non-negligible $J_{AB}(di)$ magnetic pair interactions are also given (in cm^{-1}).

alternating FM–FM zigzag chains resulting from the interplay of weaker $J(d1)$ and $J(d4)$ pairs (their values being $+1.02$ and $+0.67\ \mathrm{cm}^{-1}$, respectively). Adjacent *bc*-planes are connected by means of antiferromagnetic ($J(d7) = -1.44\ \mathrm{cm}^{-1}$) and ferromagnetic ($J(d3) = +0.29\ \mathrm{cm}^{-1}$) interactions. This 3D magnetic topology is consistent with the *bulk* antiferromagnetic behavior experimentally reported for α-YOMXUT.

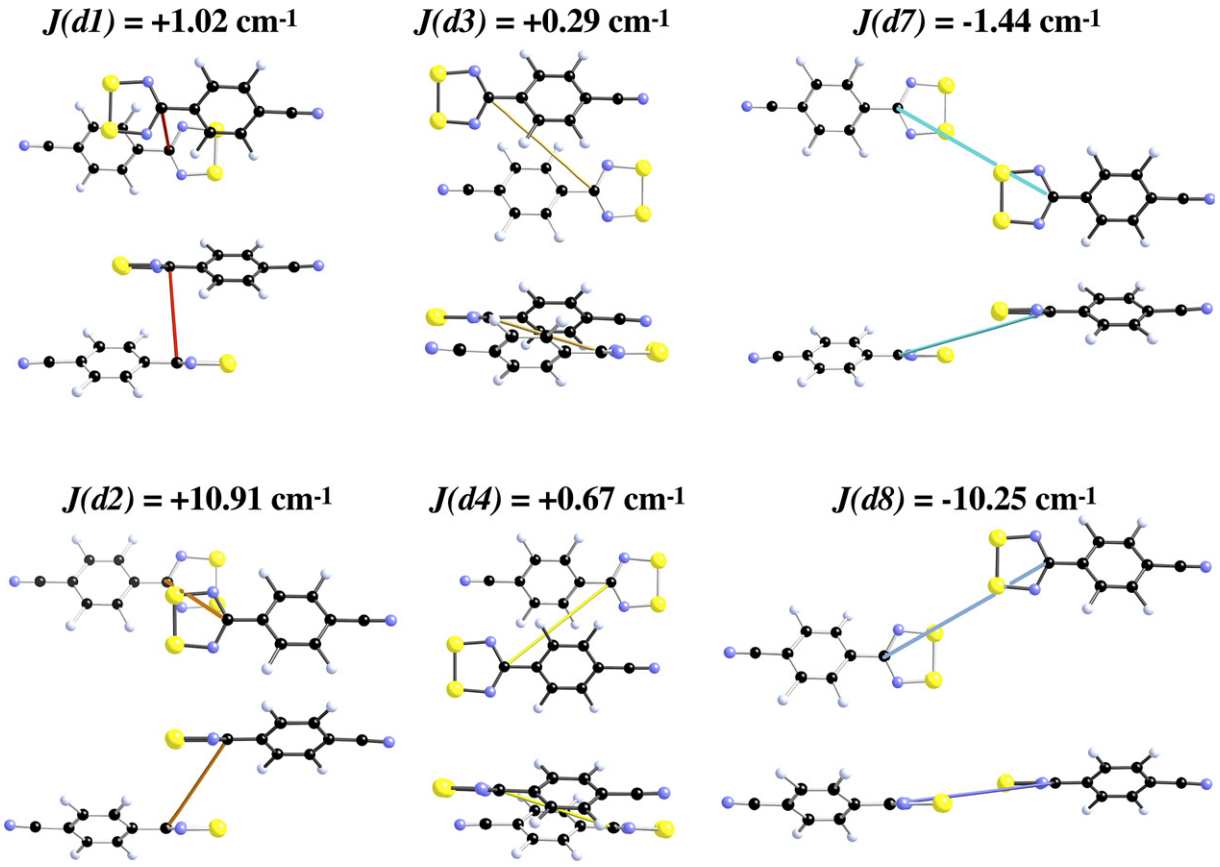

Fig. 4. Pairs of radicals with non-negligible $J_{AB}(di)$ magnetic interaction (see Table 1 for numerical values). For each pair of radicals, the upper and lower views correspond to displaying the dithiadiazolyl rings parallel and perpendicular to the plane of the figure, respectively.

The smallest finite space that can describe the complexities of the previous 3D magnetic topology (the so-called minimal magnetic model space) is the eight-radical model shown in Fig. 6a (we will refer later on to it as the 3d8s model). Fig. 6a also indicates how by extension along the crystallographic axes of this 3d8s minimal model one can generate the infinite crystal.

Step 4: Calculation of the magnetic susceptibility $\chi(T)$. The calculation of the macroscopic magnetic properties of the crystal, such as magnetic susceptibility $\chi(T)$, is carried out using the energy levels obtained from the diagonalization of the matrix representation of the following Heisenberg Hamiltonian:

$$\widehat{H} = -\sum_{A,B} J_{AB}\left(2\widehat{S}_A \cdot \widehat{S}_B + \frac{1}{2}\widehat{I}_{AB}\right) \quad (4)$$

This Hamiltonian provides a spectrum of energies equivalent to that provided by the Heisenberg Hamiltonian of Eq. (1), except for a shift in all energy values; the corresponding energy differences being thus the same. We used Eq. (4) because it is computationally more efficient for our suit of programs. One must be aware of the fact that the matrix representation increases with the number N of doublet radicals as $N!/(N/2)!(N/2)!$. In α-YOMXUT, we have studied the magnetic susceptibility $\chi(T)$ using magnetic models ranging from 8 to 16 radicals (see Fig. 6), with matrix representations of dimensions 70×70 and $12\,870 \times 12\,870$, respectively. The larger models were used to study the convergence of the computed $\chi(T)$ curves when the minimal model space was extended along the crystallographic axes.

The magnetic susceptibility curve for α-YOMXUT was computed from room temperature to nearly 0 K (Fig. 6b and c shows the $\chi T(T)$ and $\chi(T)$ curves, respectively). There is good agreement between the computed and experimental curves, except for some small oscillations found in the experimental data, which have been attributed to the quality of the data acquisition. The computed curves using the 3d8s minimal magnetic model and its extension along (a, b, c)-axes (Fig. 6b and c), are almost identical. Notice that no scaling factor was required to mimic the experimental curves. This possibly could be attributed to the fact that the crystal structure used in our calculations (determined at 160 K, instead of at room temperature [16]) properly reflects the magnetic behavior at lower temperatures. Notice also that the computed $\chi T(T)$ curve shows a

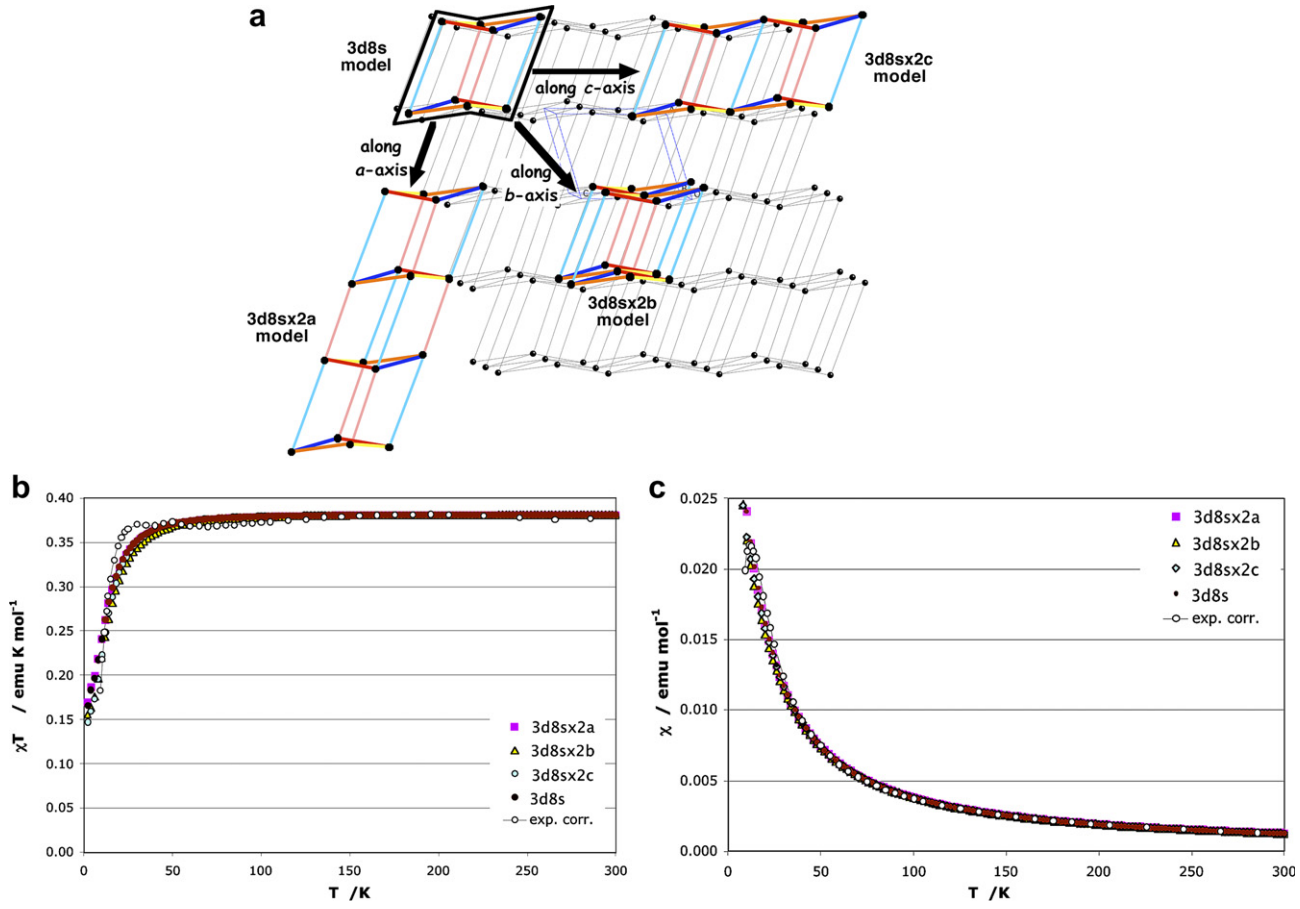

Fig. 6. (a) Representation of the 3d8s (three-dimensional eight-site) minimal magnetic model, and its corresponding extended models along the a, b, c crystallographic axes (3d8sx2a, 3d8sx2b, 3d8sx2c, respectively). (b) Computed and experimental $\chi T(T)$ curves for the α-YOMXUT crystal, obtained using the 3d8s minimal magnetic model and the 3d8sx2a, 3d8sx2b, 3d8sx2c models. (c) Computed and experimental $\chi(T)$ curves for the α-YOMXUT crystal using the same models than in (b).

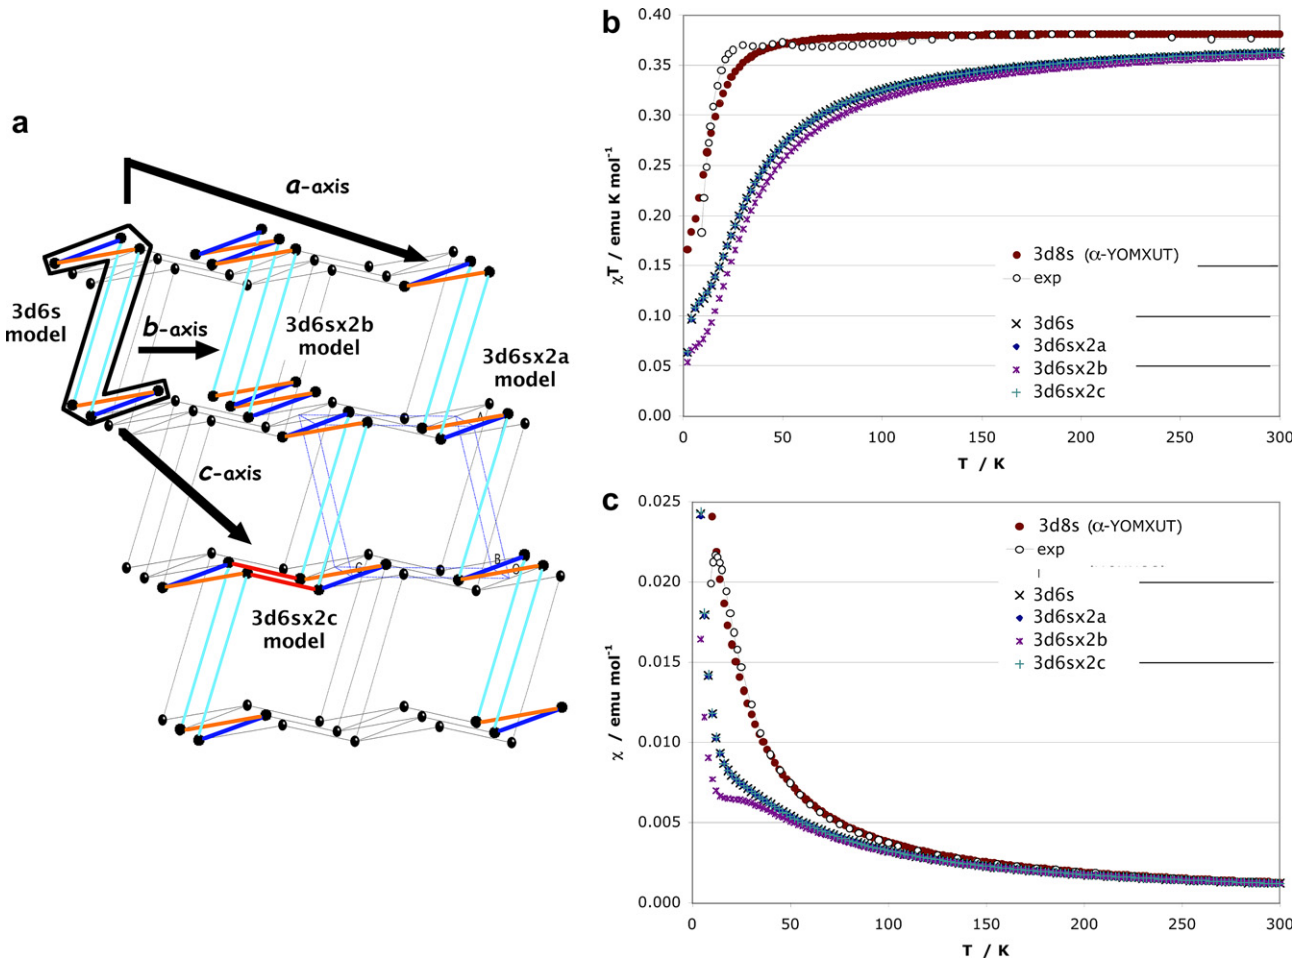

Fig. 7. (a) Representation of the 3d6s (three-dimensional six-site) minimal magnetic model, obtained when α-YOMXUT is truncated to only its five-membered ring, showing also its extended models along the *a*, *b*, *c* crystallographic axes (3d6sx2a, 3d6sx2b, 3d6sx2c, respectively). (b) Computed and experimental $\chi T(T)$ curves using the 3d6s, 3d6sx2a, 3d6sx2b, and 3d6sx2c minimal magnetic models. (c) Computed and experimental $\chi(T)$ curves using the same models than in (b). The curves obtained using the 3d8s model in Fig. 6 are also shown, to allow comparison.

dominating antiferromagnetic behavior, despite the fact that the two dominant $J(di)$ are of similar magnitude but opposite sign. This indicates the key influence of the magnetic topology on the macroscopic magnetic behavior, a fact that cannot be qualitatively evaluated just by looking at the size and sign of the microscopic interactions alone.

At this point, we have completed the first-principles *bottom-up* theoretical description of the α-YOMXUT crystal. The good agreement between the model and the experimental data indicates that the calculated values not only reproduce the experimental results but also provide an unbiased and rigorous microscopic explanation of the origin of the macroscopic behavior. Therefore, we could have ended here our study. However, we decided to pursue carrying out two additional and complementary studies, described in the following two paragraphs.

Our results have shown that the dominant part of the 3D magnetic topology is the alternating FM–AFM zigzag chains that is formed by the propagation of the $J(d2)$ ($+10.91\ cm^{-1}$) and $J(d8)$ ($-10.25\ cm^{-1}$) radical–radical pairs through the structure.[1] In order to test the effect of the smaller exchange interactions, we attempted to model the magnetism based only upon an isolated alternating chain model, excluding the weaker exchange terms. Detailed calculations using a number of alternating chain models (see Fig. S17) indicate that such models cannot reproduce the magnetic properties of α-YOMXUT crystal; the results strongly depend on the number of radicals in the

[1] An infinite alternating chain model would have the same number of FM $J(d2)$ and AFM $J(d8)$ interactions. However, there are two possibilities to build up a finite alternating chain model with an even number of magnetic dithiadiazolyl radical sites to allow both antiferromagnetic and ferromagnetic states depending on the ratio between $J(d2)$ and $J(d8)$ interactions. For instance, the smallest model one can think of is a 4-radical alternating chain model whose $J(d2)$:$J(d8)$ ratio will be either 1:2 or 2:1. We have named AF_F_AF (F_AF_F) the first (second) series of calculations since the number of $J(d8)$ AFM interactions overcomes the number of $J(d2)$ FM interactions (and otherwise). In theory, whenever the model has a large enough number of radical sites, both series will eventually converge.

model space and the ratio between the $J(d2)$ and $J(d8)$ interactions. Thus, we discard a simple chain model to describe the magnetism of this crystal.

Our second test was addressed at evaluating the validity of the common belief that macroscopic magnetic properties can be rationalized only by examining the spin-carrier part of a given radical (in this case, the CNSSN five-membered ring, see Fig. 1c). We thus performed additional calculations for the six non-negligible radical–radical pairs using HCNSSN$^{\bullet}$ radicals instead of *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radicals. In these calculations, each heterocyclic HCNSSN ring adopted the same spatial conformation as in *p*-NC-C_6F_4-CNSSN, just replacing the fluorinated rings by hydrogen atoms. The re-calculated $J(di)$ values (see Table 2) indicate that $J(d1)$, $J(d3)$ and $J(d4)$ are now one order of magnitude smaller than the values obtained with the full-sized *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radicals. The two dominant interactions $J(d2)$ and $J(d8)$ maintain their dominant character, because their shortest contacts are not affected by the absence of the six-membered ring. Even so, the value of $J(d2)$ changes remarkably. Overall, the magnetic topology (Fig. 7) is still 3D, but some significant changes take place. As a consequence, the minimal magnetic model required to compute the magnetic susceptibility is different than the 3d8s model: it is a three-dimensional 6-radical model, referred as the 3d6s model. Not surprisingly, the shape of the $\chi(T)$ and $\chi T(T)$ curves computed using the 3d6s model and the extended models along the crystallographic axis do not agree neither with the experimental magnetic susceptibility curve nor with that computed values using the minimal 3d8s model. Thus, the *p*-NC-C_6F_4-substituent plays an important role in determining the magnetic properties of α-YOMXUT.

Table 2
Study of the effect that the dithiadiazolyl cycle has on the magnetically non-negligible $d1$–$d4$ and $d7$–$d8$ pair interactions using HCNSSN models at the UDFT broken symmetry UB3LYP/6-31+G(d) level. Candidates $d1$–$d4$ and $d7$–$d8$ are listed as (C···C) distance increases

Candidate *di*	Distance (C···C) (Å)	J_{AB} (cm^{-1})
*d*1	4.789	+0.13
*d*2	4.990	+17.65
*d*3	6.534	<|0.05|
*d*4	6.588	<|0.05|
*d*7	8.285	−1.62
*d*8	8.454	−10.04

Finally, we can try to get a deeper insight over the size and sign of the $J(d2)$ and $J(d8)$ through-space magnetic interactions. It has been speculated that $J(d2)$ is a FM interaction due to the almost orthogonality of the SOMO orbitals [17]. UB3LYP/6-31+G(d) calculations show that the SOMO of the *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radical (see Fig. 8) is a π^* orbital localized on the heterocyclic ring in agreement with previous results [18]. However, looking at Fig. 8, the SOMO orthogonality argument does not appear satisfactory. The McConnell-I mechanism [19] also fails to rationalize the sign of the magnetic interaction of *d*2 and *d*8 pairs of *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radicals only in terms of spin densities. According to the common use of the

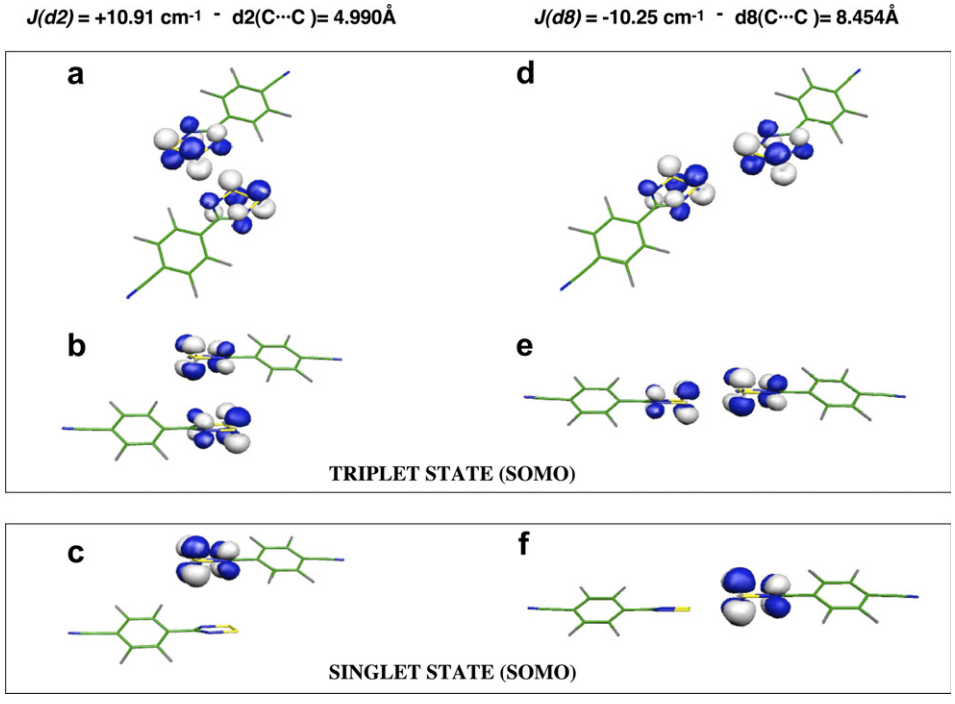

Fig. 8. (a and b) Two different views of the SOMO orbital for the triplet state of the *d*2 pair of NC-C_6F_4-CNNSS radicals ($d2$(C···C) = 4.990 Å, see Fig. 4 for radicals geometry, with $J(d2) = +10.91$ cm^{-1}) for α-YOMXUT at B3LYP/6-31+G(d) level. (c) SOMO orbital for the open-shell singlet state of the *d*2 pair. (d and e) Two different views of the SOMO orbital for the triplet state of the *d*8 pair of NC-C_6F_4-CNNSS radicals ($d8$(C···C) = 8.454 Å, see Fig. 4 for radicals geometry, with $J(d8) = -10.25$ cm^{-1}) for α-YOMXUT. (f) SOMO orbital for the open-shell singlet state of the *d*8 pair.

McConnell-I model, the shortest contacts for *d*2 overlap regions of positive π-spin density of the five-membered rings (see S and N atoms of the two radicals in Fig. 4), and therefore should be antiferromagnetic (whereas it is calculated to be ferromagnetic).

4. Conclusions

A first principles *bottom-up* theoretical study of the magnetism of α-YOMXUT indicates the existence of six non-negligible radical–radical interactions: two interactions of opposite sign (+10.91 and $-10.25\ cm^{-1}$) being one order of magnitude larger than the rest ($\leqslant|1.44|\ cm^{-1}$). The magnetic topology of the crystal has a complex 3D shape, and cannot be inferred from direct observation of the crystal structure. The dominant interactions (+10.91 and $-10.25\ cm^{-1}$) form alternating FM–AFM zigzag chains, which are connected along the *bc*-plane by adjacent FM–FM zigzag chains (+1.02 and $+0.67\ cm^{-1}$). Adjacent *bc*-planes are in turn connected by means of AFM ($-1.44\ cm^{-1}$) and FM ($+0.29\ cm^{-1}$) interactions. The overall antiferromagnetic shape of the experimental magnetic susceptibility is fully reproduced. It is also found that a simple alternating chain motif (in terms of dominating +10.91 and $-10.25\ cm^{-1}$ interactions) does not reproduce the experimental magnetic susceptibility curve. No scaling factor was needed to mimic the experimental curve. When the study was done using only the five-membered HCNSSN ring of the *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radical, the experimental magnetic susceptibility curve was also not properly reproduced.

The sign and magnitude of the *J*(*di*) values has no simple interpretation neither in terms of orthogonality of the SOMOs nor in terms of the standard use of McConnell-I model. The size of the *J*(*di*) values are found to depend on the distance and relative orientation of the *p*-NC-C_6F_4-CNSSN$^{\bullet}$ radicals within each pair.

methanol. 4-Acetamidobenzaldehyde (**pAcB**, Avocado Research Chemicals, 0.326 g, 2.00 mmol) was added and the mixture stirred under nitrogen for 2 days at room temperature. The resulting white precipitate was filtered, washed with water, and dried under vacuum for several hours to give 0.123 g (21%) of a white solid, m.p. 205–208 °C. ^{1}H NMR (DMSO-d_6): δ 1.04 (s, 6H), 1.06 (s, 6H), 2.03 (s, 3H), 4.45 (s, 1H), 7.38 (d, $J = 8.6$ Hz, 2H), 7.49 (d, $J = 8.6$ Hz, 2H), 7.69 (s, 2H), 9.88 (s, 1H).

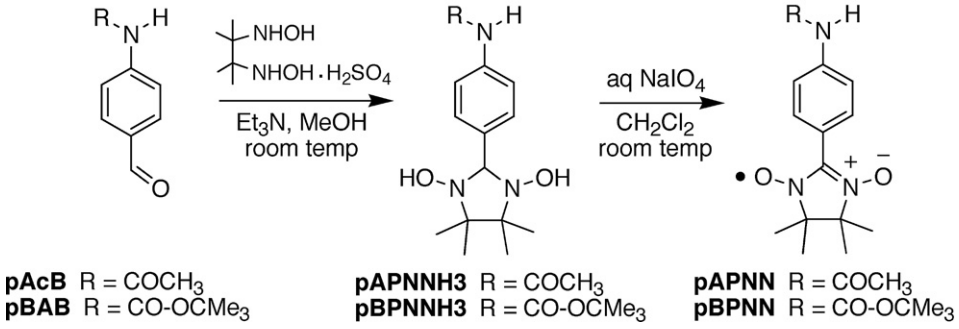
2.2. 2-(para-Acetamidophenyl)-4,4,5,5-tetramethyl-4,5-dihydro-1H-imidazole-3-oxide-1-oxyl (*pAPNN*)

pAPNNH3 (0.4247 g, 1.448 mmol) in 40 mL of dichloromethane under nitrogen was treated with 33 mL of 0.2 M aq $NaIO_4$ added slowly by syringe, and the reaction mixture stirred for 30 min. The layers were separated and the aqueous layer extracted with 15 mL of dichloromethane. The combined organic layers were washed with 2×15 mL of saturated aq NH_4Cl and dried over anhydrous $MgSO_4$. The solution was filtered and dried under vacuum to yield a blue solid that was recrystallized from dichloromethane:ether to yield 0.345 g (82%) of blue-black solid, m.p. 204–205 °C; *Anal*. Calc. for $C_{15}H_{20}N_3O_3$ requires: C, 62.05; H, 6.94; N, 14.47. Found: C, 61.90; H, 6.91; N, 14.45%. FTIR (KBr, cm^{-1}): 3341, 2992, 1707. ESR (9.65164 GHz, toluene, room temperature): $g = 2.00682$, a(N) = 7.49 gauss (2N).

2.3. 2-para-(tert-Butyloxycarbonyl)aminobenzaldehyde (*pBAB*)

para-Aminobenzyl alcohol (Lancaster Synthesis, 1.0 g, 8.12 mmol) was acetylated to the corresponding "boc" derivative using a literature method [7] to give *para*-(*tert*-butyloxycarbonyl)aminobenzyl alcohol (m.p. 74–76 °C), which was oxidized by stirring at room temperature with solid MnO_2 (10 g, 115 mmol) in 50 mL of dichloromethane for 1 day. Filtration of the reaction and removal of the solvent gave crude product, which was air dried to give 0.569 g (59%) of **pBAB**, a cream-colored solid, m.p. 140–142 °C (lit m.p. 138 °C [7b]). This material was sufficiently pure to use in the next step. ^{1}H NMR (DMSO-d_6): δ 1.49 (s, 9H), 7.67 (d, 2H, $J = 8.0$ Hz), 7.80 (d, 2H, $J = 8.0$ Hz), 9.83 (s, 1H), 9.89 (s, 1H).

2.4. 2-(para-(tert-Butyloxylcarbonyl)aminophenyl)-1,3-dihydroxy-4,4,5,5-tetramethylimidazolidine (*pBPNNH3*)



2,3-Bis(hydroxylamino)-2,3-dimethylbutane monosulfate [6] (0.462 g, 1.87 mmol) and 0.3 mL of triethylamine were stirred for 10 min at room temperature in 15 mL of methanol. **pBAB** (0.4145 g, 1.873 mmol) was added and the mixture stirred under nitrogen for 2 days at room temperature. The resultant white precipitate was filtered, washed with cold methanol, and dried under vacuum to give 0.131 g (20%) of white solid, m.p. 180–182 °C, pure enough to use in the next synthetic step. ^{1}H NMR (DMSO-d_6): δ 1.03 (s, 6H), 1.05 (s, 6H), 1.47(s, 9H), 4.43 (s, 1H), 7.32 (d, J 8.6 Hz, 2H), 7.36 (d, J 8.6 Hz, 2H), 7.69 (s, 2H), 9.26 (s, 1H).

2.5. 2-(para-(tert-Butyloxylcarbonyl)aminophenyl)-4,4,5,5-tetramethyl-4,5-dihydro-1H-imidazole-3-oxide-1-oxyl (*pBPNN*)

pBPNNH3 (0.2127 g, 0.605 mmol) was dissolved in 20 mL of dichloromethane under nitrogen and treated with 13.8 mL of 0.2 M $NaIO_4$ added slowly by syringe, and the reaction mixture stirred for 30 min. The layers were separated and the aqueous layer extracted with 10 mL of dichloromethane. The combined organic layers were washed with 2×10 mL of saturated aq NH_4Cl and dried over anhydrous $MgSO_4$. The solution was filtered and the solvent removed under vacuum to yield a blue solid that was recrystallized from dichloromethane:ether to yield. 0.148 g (70 %) of blue-black solid, m.p. 215–218 °C, *Anal*. Calc. for $C_{18}H_{26}N_3O_4$ requires: C, 62.05; H, 7.52; N, 12.06. Found: C, 62.03; H, 7.55; N, 12.04%. FTIR (KBr, cm^{-1}): 3340, 2980, 1728, 1604. ESR (9.65027 GHz, toluene, room temperature): $g = 2.00683$, a(N) = 7.47 gauss (2N).

3. Synthesis and characterization

pAPNN and **pBPNN** were made from the aldehydes shown in Scheme 1. **pAcB** and **pBAB** were each made by functionalizing the $-NH_2$ group of the appropriate aminobenzyl alcohol and oxidizing the alcohol to the corresponding aldehydes. These were then condensed with 2,3-bis(hydroxylamino)-2,3-dimethylbutane monosulfate,

Scheme 1. Synthesis of amide functionalized radicals **pAPNN** and **pBPNN**.

and oxidation to the final NN product. Both the NNs were stable solids at room temperature that were readily characterized by solution ESR, FTIR in KBr matrix, and MS or elemental microanalysis.

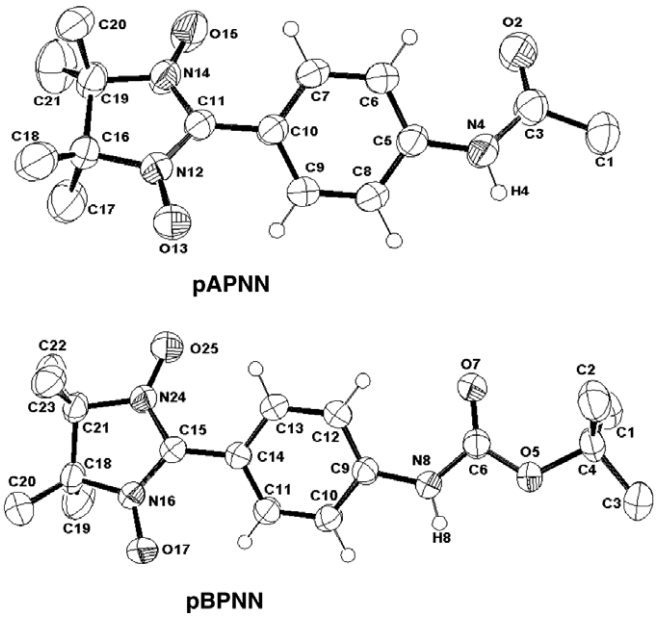


Fig. 1. ORTEP representations of **pAPNN** and **pBPNN**; ellipsoids for non-hydrogen atoms shown at 50% probability limits. Methyl hydrogen atoms omitted for ease of viewing.

4. Crystallography

Diffraction grade single crystals of **pAPNN** and **pBPNN**, were obtained by precipitation from dichloromethane/ether and analyzed [8]. Fig. 1 shows ORTEP style representations of **pAPNN** and **pBPNN**. Structural and crystallographic details are summarized in Tables 1 and 2.

5. Magnetic studies

Measurements for **pAPNN** and **pBPNN** were carried out over 1.8–300 K using a Quantum Design SQUID MPMS5 magnetometer for polycrystalline samples placed in gelatin capsules and held in place with a small plug of cotton. Magnetic susceptibilities were corrected for temperature independent magnetic contributions. Fig. 2 summarizes the results.

6. Results and discussion

The crystallography of **pAPNN** shows antiparallel oriented pairs of molecules held together by amide NH to nitroxide ON hydrogen bonds. For every molecule, only one nitroxide unit, N(12)–O(13), participates in hydrogen bonding, acting as an acceptor to an amide N(4)–H(4) group on another radical, as shown in Fig. 3. The other nitroxide, N(14)–O(15) is stacked almost antiparallel to the N(14′)–O(15′) group in another hydrogen bonded pair, with distance r[N(14)···O(15′)] = 3.931(2) Å (Table 2). The

hydrogen bonds and the stacks are the major contacts involving nitronylnitroxide NO groups, and so are likely candidates to provide intermolecular exchange pathways between molecules by spin polarization.

The magnetic susceptibility data for **pAPNN** show a strong low temperature downturn indicating antiferromagnetic (AFM) exchange. Magnetization versus field measurements at 1.8 K (not shown) gave near linear increase from 0 to 50,000 Oe, also consistent with AFM exchange. The near perfect antiparallel alignment of N–O groups in the antiparallel stacks shown in Scheme 2 and Fig. 3 ($\angle$N(14)–O(15)···N(14′) = 91.5°) is ideal [9] to provide antiferromagnetic (AFM) exchange interactions consistent with the observed loss of susceptibility. A nonlinear least squares fit using an equilibrium singlet-triplet (Bleaney–Bowers [10]) model with a mean field term gives an excellent fit to the data as shown in Fig. 2 with $g = 1.998 \pm 0.003$, $2J/k = (-)4.99 \pm 0.02$ K $\theta = (-)0.86 \pm 0.12$ K; uncertainties are statistical 95% confidence limits.

In principle, combination of the hydrogen bonds and nitroxide stacks (involving both NO groups of the nitronylnitroxides) could create chains of **pAPNN** molecules in the lattice. However, a 1D Heisenberg AFM chain model [11] fit to the susceptibility gave poor results. The spin density on the amide NH of **pAPNN** will be quite small [12], so exchange through the hydrogen bond is likely to very weak if present at all. Assuming that there are no gross low temperature crystal lattice changes in **pAPNN**, its AFM exchange appears to be *primarily* due to spin pairing between the close contact N(14)–O(15) nitroxide groups.

pBPNN, unlike **pAPNN**, lacks close direct intermolecular contacts between nitronylnitroxide NO units. There is limited classical hydrogen bonding, despite the presence of the carbamate type HN–CO–O–*t*Bu groups. There is some hydrogen bonding from the nitronylnitroxide O(17) to carbamate H(8′)–N(8)′ unit, but that interaction appears to be assisted by close NO to aryl HC contacts of (N(16))–O(17)···H(10′)–C(10′) – see Fig. 4 and Table 2. There are also some dipolar contacts from the nitronylnitroxide O(25) atoms to nearby aryl C(12′)–H(12′) and C(13′)–H(13′) groups. The NO to aryl HC contacts are possible sources of spin polarized exchange, but are somewhat ambiguous to interpret in magnetostructural terms, because the NO group seems near-equally likely to interact with C–H groups that are both *ortho* and *meta* to a nitronylnitroxide. The signs of the spin density on H(12) and H(13) are expected to be different, so the exchange effects of both interacting with one NO are unlikely to reinforce one another.

The lack of close intermolecular contacts between sites of large spin density is consistent with the essentially isolated paramagnetic behavior shown by the $1/\chi(T)$ (Curie–Weiss) and $\chi T(T)$ plots for **pBPNN** in Fig. 2. The $1/\chi(T)$ linear fit for the data where $T > 100$ K yields a Curie constant of 0.375 ± 0.008 emu K/Oe mol, in excellent agreement with the value expected for $S = 1/2$ spin carriers. The small downturn in the $\chi T(T)$ plot indicates only quite weak AFM interactions that are very difficult to attribute to specific close contacts among any of the intermolecular contacts in **pBPNN**.

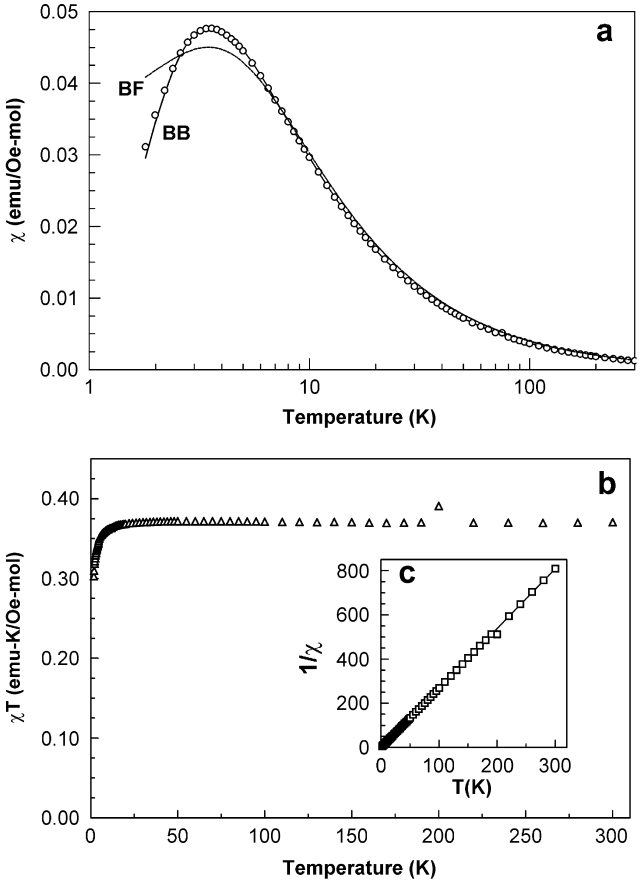

Fig. 2. Magnetic measurements for **pAPNN** (chart a) and **pBPNN** (charts b and c). All data in these charts obtained at 1000 Oe. BF, best fit to Bonner–Fisher 1D AFM chain model; BB, best fit to Bleaney–Bowers spin pairing model with mean field correction. See the text for details. Solid line in chart c is a linear fit to the data for $T > 100$ K.

Scheme 2. Simplified representation of NO/ON stacking in **pAPNN**.

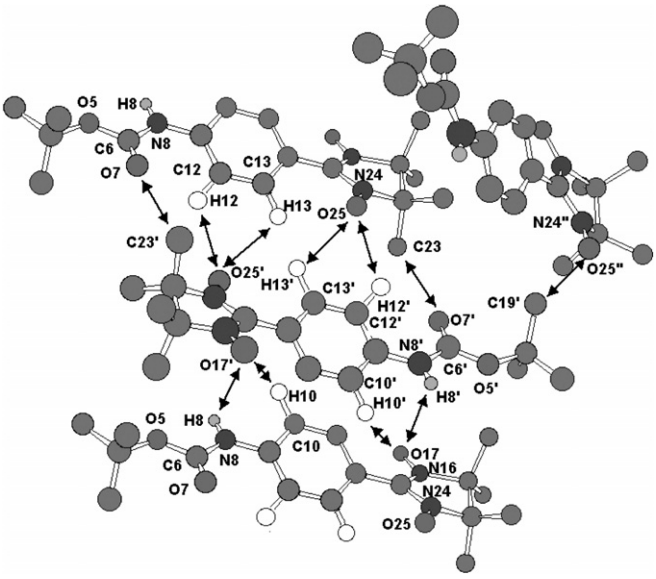

Fig. 4. Selected crystallographic close contacts in **pBPNN**. Numbering derived from Fig. 1. See also Table 2.

7. Conclusions

The amido-substituted radicals **pAPNN** and **pBPNN** differ primarily in that the amido derivative forms pairs due to directional, classic hydrogen bonds between the amide NH and one NO of nitronylnitroxide group, while the boc-derivatized system forms pairs due to a variety of intermolecular contacts in which hydrogen bonds do not necessarily dominate. Spin pairing in **pAPNN** occurs due to a moderately close nitroxide–nitroxide contact. This contact between large spin density sites dominates the magnetic behavior of the amide derivative, although other contact may contribute to a lesser extent to the overall magnetic behavior. By comparison, **pBPNN** shows nearly isolated paramagnetic behavior, with very limited exchange between molecules in the lattice.

The results demonstrate a weakness of the strategy of using hydrogen bonds to bring organic radicals into close proximity in an effort to promote strong exchange interactions: even when the hydrogen bonding is successful, one needs more interactions between sites of significant spin density to promote exchange beyond simple spin pairing

behavior. Further work is ongoing to deprotect the $-NH_2$ groups in these systems and to change from *para* to *meta* connectivity, to try to alter and extend the dimensionality of their exchange interactions in the solid state, by allowing more possibilities for hydrogen bonding.

Scheme 1. Structural formulas.

ethereal solution (25 mL) containing 2-bromopyridine (507 mg; 3.21 mmol) was added a hexane solution (1.57 mol/L) of *n*-butyl lithium (2.1 mL; 3.3 mmol) dropwise at −78 °C under nitrogen atmosphere. The mixture was stirred at −78 °C for 0.5 h. After an ether solution (25 mL) containing *p*-nitrosoanisole (440 mg; 3.21 mmol) was added to the above mixture from a dropping funnel at −78 °C, the mixture was stirred at −78 °C for further 3 h. The reaction mixture was quenched by aqueous $NaHCO_3$ at room temperature, and the organic layer was washed with aqueous $NaHCO_3$ three times. After the mixture was dried over anhydrous $MgSO_4$, the ether solution was filtered and concentrated under reduced pressure. A main product was purified by passing through a short column (silica gel) with ether as an eluent. Recrystallization from ether gave 189 mg of a colorless solid of **1** (0.874 mmol; 27%). M.p. 95–97 °C. ^{1}H NMR (270 MHz, $CDCl_3$) δ 3.81, 6.67, 6.68, 6.89, 7.21, 7.44, 8.13. The OH proton signal was missing. ^{13}C NMR (68 MHz, $CDCl_3$) δ 55.6, 113.7, 114.6, 123.7, 124.6, 127.8, 137.9, 147.5, 157.2, 160.2. MS (EI, 70 eV) *m*/*z* 216.1 (M^+), 199.1, 184.0. IR (KBr disc) 766, 1250, 1431, 1500, 1604, 2656, 3059 cm^{-1}.

2.2. Preparation of 2,6-bis(N-t-butylhydroxylamino)-pyridine (2)

To the ethereal solution (50 mL) containing 2,6-dibromopyridine (1.19 mg; 5.02 mmol) and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (2.56 g; 22.0 mmol) was added a pentane solution (1.56 mol/L) of *t*-butyl lithium (14 mL; 22 mmol) at −78 °C under nitrogen atmosphere. The mixture was stirred at −30 °C for 0.5 h, and then cooled again to −78 °C. After an ether solution (30 mL) containing 2-methyl-2-nitrosopropane (1.05 g; 12.1 mmol) was added to the above mixture from a dropping funnel, the mixture was stirred at −78 °C for further 5 h. Aqueous work up was done in a manner similar to that of **1**. Recrystallization from ether/hexane gave 0.531 g of a colorless solid of **2** (2.10 mmol; 42%). M.p. 132–134 °C. ^{1}H NMR (270 MHz, $CDCl_3$) δ 1.27, 6.60, 6.89, 7.55. The OH proton signal was missing. ^{13}C NMR (68 MHz, $CDCl_3$) δ 26.6, 619.9, 112.3, 138.0, 159.3. MS (EI, 70 eV) *m*/*z* 253.1 (M^+), 197.1, 141.0. IR (KBr disc) 822, 1203, 1362, 1439, 1576, 2972, 3211 cm^{-1}.

2.3. ESR spectroscopy

ESR spectra were recorded on a Bruker ESP300E X-band (9.7 GHz) spectrometer. The samples of **1** and **2** were oxidized with Ag_2O in toluene at room temperature for 1 h, and the solid was filtered off. After the sample solution was thoroughly purged with nitrogen, the ESR spectra were recorded immediately. Simulated spectra were calculated in the WinEPR Simfonia program (version 1.25, Bruker Biospin, Rheinstetten, Germany (1996)).

2.4. X-ray crystal structure analysis

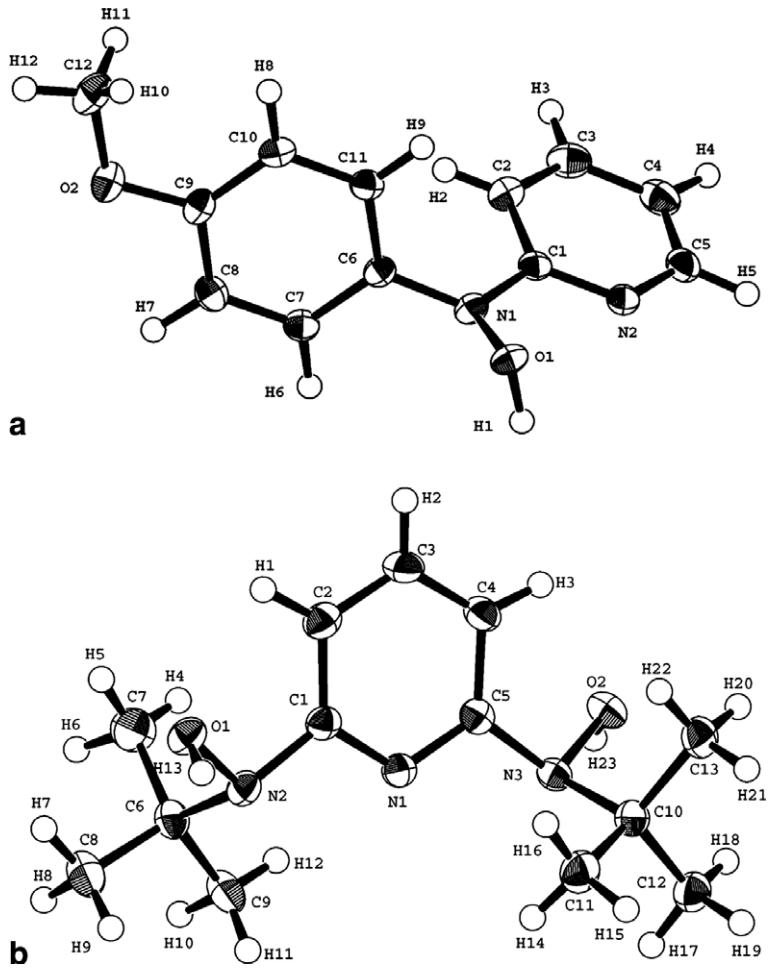
X-ray diffraction data of single crystals of **1** and **2** were collected on a Rigaku R-axis RAPID diffractometer with graphite monochromated Mo Kα ($\lambda = 0.71069$ Å) radiation at 90 K. The structures were directly solved and the parameters were refined in the CRYSTALSTRUCTURE program package (version 3.5.1, Rigaku/MSC, The Woodlands, TX 77381, USA (2003)). Numerical absorption correction was used. All of the hydrogen atoms were found experimentally. Thermal displacement parameters were refined anisotropically for non-hydrogen atoms and those of hydrogen atoms were treated isotropically. Selected crystallographic data: **1**: $C_{12}H_{12}N_2O_2$, triclinic, $P\bar{1}$, $a = 9.426(2)$ Å, $b = 9.774(3)$ Å, $c = 12.836(4)$ Å, $\alpha = 105.26(3)°$, $\beta = 106.32(2)°$, $\gamma = 91.72(3)°$, $V = 1088.0(6)$ Å^3, $Z = 4$, $d_{calc} = 1.320$ g cm^{-3}, μ(Mo Kα) = 0.092 mm^{-1}, $R(F)(I > 2\sigma(I)) = 0.0393$, and $R_w(F^2)$ (all data) = 0.0503 for 4961 unique reflections. **2**: $C_{13}H_{23}N_3O_2$, monoclinic, $P2_1/c$, $a = 12.41(1)$ Å, $b = 16.828(13)$ Å, $c = 14.131(12)$ Å, $\beta = 92.52(7)°$, $V = 2947(4)$ Å^3, $Z = 8$, $d_{calc} = 1.142$ g cm^{-3}, μ(Mo Kα) = 0.078 mm^{-1}, $R(F)(I > 2\sigma(I)) = 0.0651$, and $R_w(F^2)$ (all data) = 0.0893 for 6493 unique reflections.

2.5. Molecular orbital calculation

Molecular orbital calculations were performed on the GAUSSIAN03 program (Revision C.02, Gaussian Inc., Pittsburgh, PA 15106, USA (2003)). We applied unrestricted density functional (DFT) UB3LYP methods with the Becke exchange functional [11] and the Lee–Yang–Parr correlation functional [12]. The 6-31G** basis set was chosen. The convergence criterion for the energy was set at 10^{-9} a.u.

3. Results and discussion

We have successfully prepared two precursors for paramagnetic chelating ligands, **1** and **2**. They were characterized by means of spectroscopic methods. The X-ray crystallographic analysis revealed the molecular structures as shown in Fig. 1. All of the hydrogen atoms were found



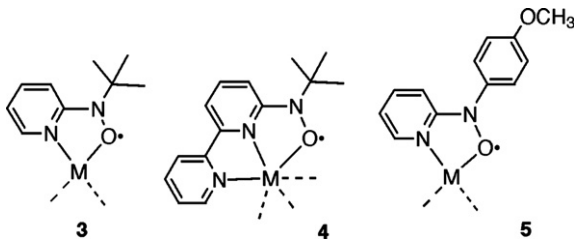


Fig. 1. Ortep drawings of (a) **1** and (b) **2** with the thermal ellipsoids at the 50% probability level for non-hydrogen atoms.

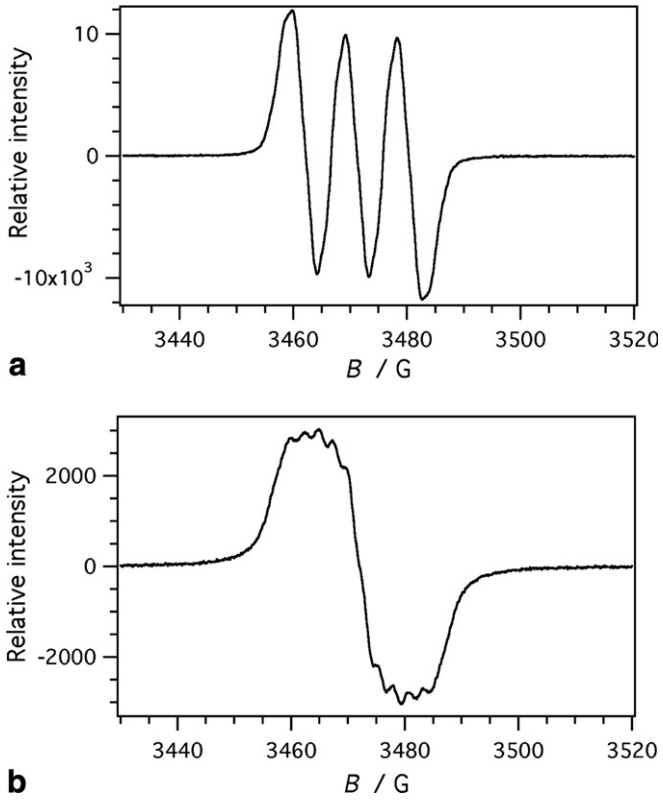
experimentally. As for **2**, there are two crystallographically independent molecules in a unit cell, one of which is shown in Fig. 1(b). The N–O bond distances are 1.420(1) Å for **1** and 1.450(2), 1.449(2), 1.446(2), and 1.450(2) Å for **2**. The latter values are comparable to those of typical *N*-*t*-butyl-*N*-phenylhydroxylamines [13]. The former value is slightly shorter than those of **2**, being compatible with the fact that a slight decrease of electron density at the hydroxylamino nitrogen atom due to the π-conjugation from two aromatic rings. The hydroxylamino nitrogen atom in **1** shows a less pyramidalized geometry than those of **2**.

The successful isolation of **1** is regarded as a rare case, since *N*,*N*-diarylhydroxylamines cannot be isolated in general because of facile autoxidation [14]. The 2-pyridyl group has an intrinsic electron-deficient nature, and may slow down the autoxidation of the hydroxylamino group. After the purification of **1**, the oxidation with silver(I) oxide gave a radical (**1r**) showing an ESR signal at $g = 2.0057$ with $a_N = 9.15$ G (toluene at room temperature), being typical of diaryl nitroxides (Fig. 2a). We have already prepared transition-metal complexes containing *t*-butyl 2-pyridyl nitroxides (**3** and **4**; M = Cu^{II}, Ni^{II}) [7,8]. The *t*-butyl group is useful for kinetically stabilizing nitroxide radicals but, at the same time, has a fatal disadvantage for intermolecular interaction; that is, intermolecular van der Waals contacts keep the spin centers apart from each other owing to the steric bulkiness. When we use the *p*-anisyl group as a stabilizing substituent and the resultant radical (**1r**) is coordinated to a paramagnetic metal ion giving **5**, possible intermolecular interaction would be larger than those of the complexes such as **3** and **4**. It is well known that the *p*-anisyl group has a satisfactorily stabilizing effect on nitroxide radicals [6,15].

Oxidation of **2** gave an unstable radical (**2r**). In sharp contrast to the case of **1r**, the X-band ESR spectrum of **2r** showed an unresolved single line at $g = 2.0060$ even in a dilute and deaerated toluene solution (Fig. 2b). This



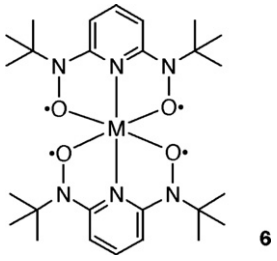


Fig. 2. X-band ESR spectra of **1r** and **2r** in toluene at room temperature.

broadening is due to intramolecular dipole–dipole and exchange interactions among the unpaired electrons and also probably to overlap of different signals and hyperfine structures of conformational isomers like 1,3-phenylene bisnitroxide biradicals [16]. We are now attempting complexation without purification of the corresponding radical (**2r**) to give **6**.

6

Although we could not isolate **2r** so far, we performed theoretical calculation of **2r** based on the unrestricted density functional theory (UB3LYP/6-31G**) with the molecular geometry fully optimized on the same level. The distribution of the spin density (2e in total) is drawn in Fig. 3, which clearly represents the SOMOs carrying a π-character. The alternating spin density on the pyridine ring is illustrated. The SCF energies for the triplet and singlet states were −822.617945729 and −822.616950231 a.u., respectively. The calculation indicates that the triplet state

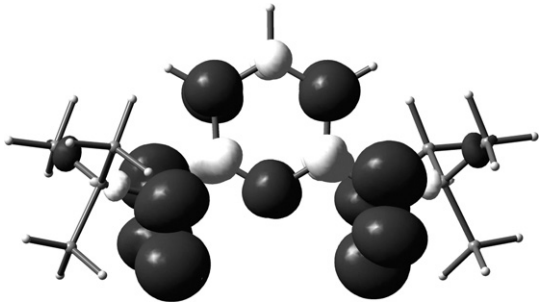

Fig. 3. Spin density distribution at the triplet state of **2r** calculated on the UB3LYP/6-31G**//UB3LYP/6-31G** level (dark gray: positive spin density; light gray: negative spin density).

is more stable than the singlet state by the energy difference of 9.95×10^{-4} a.u., which is converted to 2.61 kJ mol^{-1} or 314 K. This finding is compatible with the fact that 1,3-phenylene bridges work as a ferromagnetic exchange coupler [17], as expected from the spin polarization scheme [18]. Furthermore, the spin polarization mechanism is also applicable to the azabenzene systems. Several magnetic studies involving pyridyl-substituted radical compounds provided ample discussion [19]. Transition-metal complexes containing **2r** would be of great interest for development of ferromagnetic hybrid solids.

4. Conclusion

We successfully synthesized and characterized two precursors for paramagnetic chelating ligands, *N*-*p*-anisyl-*N*-2-pyridylhydroxylamine and 2,6-bis(*N*-*t*-butylhydroxylamino)pyridine. After the purification of the hydroxylamines, oxidation with silver(I) oxide gave radicals showing typical nitroxide ESR signals. Theoretical DFT calculation indicated that the bisnitroxide radical, pyridine-2,6-diyl bis(*t*-butyl nitroxide), had a triplet ground state. Although these radicals are unisolable under ambient conditions, complexation with transition-metal ions would stabilize the radicals [20]. We are now attempting preparation of transition-metal complexes containing **1r** and **2r** by means of in situ trapping of the fragile radicals.

5. Supplementary materials

CCDC 617091 and 617092 contain the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit @ccdc.cam.ac.uk.

Scheme 1. Structural formulas.

$[\{Cu(emg)(Hemg)(ROH)\}_2\{Dy(hfac)_2(ROH)\}_2]$ (R = Me, Et; abbreviated as $[Dy_2Cu_2]$-R hereafter) as Dy analogs of $[Gd_2Cu_2]$. We found that $[Dy_2Cu_2]$-Me and $[Gd_2Cu_2]$ were completely isomorphous to each other. The corresponding polymer $[\{Cu(dmg)(Hdmg)\}_2\{Dy(hfac)_2(CH_3OH)\}_2]_n \cdot 2(MeOH)$ ($[Dy_2Cu_2]_n$) could also be prepared as fine polycrystalline solids, which is isomorphous to the known polymer, $[Gd_2Cu_2]_n$.

2. Experimental

After deprotonation of $[Cu(Hemg)_2]$ in basic media, the resultant anionic oxygen atoms were planned to be trapped with dysprosium(III) hexafluoroacetylacetonate $[Dy(hfac)_3]$ [19]. Practically the same procedure as the preparation of $[Gd_2Cu_2]$ by use of $[Dy(hfac)_3]$ in place of $[Gd(hfac)_3]$ gave $[\{Cu(emg)(Hemg)(ROH)\}_2\{Dy(hfac)_2(ROH)\}_2]$ ($[Dy_2Cu_2]$-Me and $[Dy_2Cu_2]$-Et) in 16% and 26% yields, respectively. Methanol and ethanol molecules from the reaction solvents were incorporated as an O-donor. Polymeric form $[\{Cu(dmg)(Hdmg)\}_2\{Dy(hfac)_2(CH_3OH)\}_2]_n$ was obtained from the reaction of $[Cu(Hdmg)_2]$ and $[Dy(hfac)_3]$ in methanol in 25% yield.

X-ray diffraction data of single crystals of $[Dy_2Cu_2]$-Me and $[Dy_2Cu_2]$-Et were collected on a Rigaku R-axis RAPID diffractometer with graphite monochromated Mo Kα ($\lambda = 0.71069$ Å) radiation at 90 K. The structures were directly solved and the parameters were refined in the CrystalStructure program package (version 3.5.1, Rigaku/MSC, The Woodlands, TX 77381, USA, 2003). Numerical absorption correction was used. All of the hydrogen atoms were located at the calculated position. Thermal displacement parameters were refined anisotropically for non-hydrogen atoms. Owing to the small size of the crystal of $[Dy_2Cu_2]_n$, only the cell parameters of $[Dy_2Cu_2]_n$ were determined. Selected crystallographic parameters are summarized in Table 1.

Magnetic susceptibilities of polycrystalline samples were measured on a Quantum Design MPMS SQUID magnetometer at an applied magnetic field of 500 Oe over a temperature range 1.8–100 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constant. Ac magnetic susceptibilities of polycrystalline samples were measured on a Quantum Design PPMS ac/dc magnetometer down to 1.8 K. Low-temperature magnetizations were measured by using a conventional inductive probe in pulsed magnetic fields, and the temperature was obtained as low as 0.5 K [20].

3. Results and discussion

3.1. Crystal structure analysis

Fig. 1a shows the molecular structure of $[Dy_2Cu_2]$-Me, which is isomorphous to $[Gd_2Cu_2]$ [18], as supported by

the cell parameters (Table 1). The Gd ions are octacoordinate and a methanol molecule is coordinated in place of an hfac ligand. A lost anion charge is compensated with an oximate oxygen atom (O3). A half of molecule is crystallographically independent and related with the other half by inversion symmetry. The Cu1 ion is coordinated with an additional methanol molecule (C22O10) as a cap. The Dy1–Dy1*, Dy1–Cu1, and Dy1*–Cu separations are 3.919(1), 3.918(2), and 4.730(2) Å, respectively, within a molecule. Though we can expect *cis–trans* isomerism in the [Cu(Hemg)(emg)] moiety, we actually observed solely the *trans*-isomer in the crystal. The ethyl groups in [Cu(Hemg)(emg)] are bent in the same direction with respect to the copper basal plane, and accordingly this steric hindrance disable to dimerize [Cu(Hemg)(emg)] like the starting material [Cu(Hdmg)$_2$] [21]. Instead, a methanol ligand from the solvent occupies the axial position.

Although the space group of [Dy$_2$Cu$_2$]-Et ($P\bar{1}$) (Fig. 1b) is different from that of [Dy$_2$Cu$_2$]-Me ($C2/c$) and accordingly the crystal packing motif is quite different, the core structure of [Dy$_2$Cu$_2$]-Et was practically the same as that of [Dy$_2$Cu$_2$]-Me (Fig. 1c). There are two independent molecules in a unit cell, each of which has an inversion center. The Dy1–Dy1*, Dy1–Cu1, and Dy1*–Cu separations are 3.9549(6), 3.988(1), and 4.699(1) Å, respectively, in a molecule (Fig. 1b) and 3.9380(5), 3.959(1), and 4.724(1) Å, respectively, in the other molecule (not shown). In sharp contrast to the case of [Dy$_2$Cu$_2$]-Me, we observed solely the *cis*-isomer of the [Cu(Hemg)(emg)] moiety in [Dy$_2$Cu$_2$]-Et.

The crystal structure of [Dy$_2$Cu$_2$]$_n$ could not be determined so far, owing to the small size of the crystals, but the cell parameter strongly suggests that [Dy$_2$Cu$_2$]$_n$ and [Gd$_2$Cu$_2$]$_n$ are isomorphous (Table 1). The polymeric complex [Dy$_2$Cu$_2$]$_n$ can be regarded as a polymer form of [Dy$_2$Cu$_2$]-R, just like the Gd version ([Gd$_2$Cu$_2$]$_n$ and [Gd$_2$Cu$_2$]) previously characterized [18]. As the polymer [Gd$_2$Cu$_2$]$_n$–monomer [Gd$_2$Cu$_2$] system shows [18], the polymerization linkage consists of a copper(II)–O (axial) bond formation as a local [Cu(dmg)$_2$]$_2$ dimerization in the absence of alcohol molecules at the axial position of the copper(II) ion. Thus, the proposed structure of [Dy$_2$Cu$_2$]$_n$ is shown below. It should be noted that ferromagnetic coupling takes place between the copper(II) spins within the dimers [18,21].

[Dy$_2$Cu$_2$]$_n$

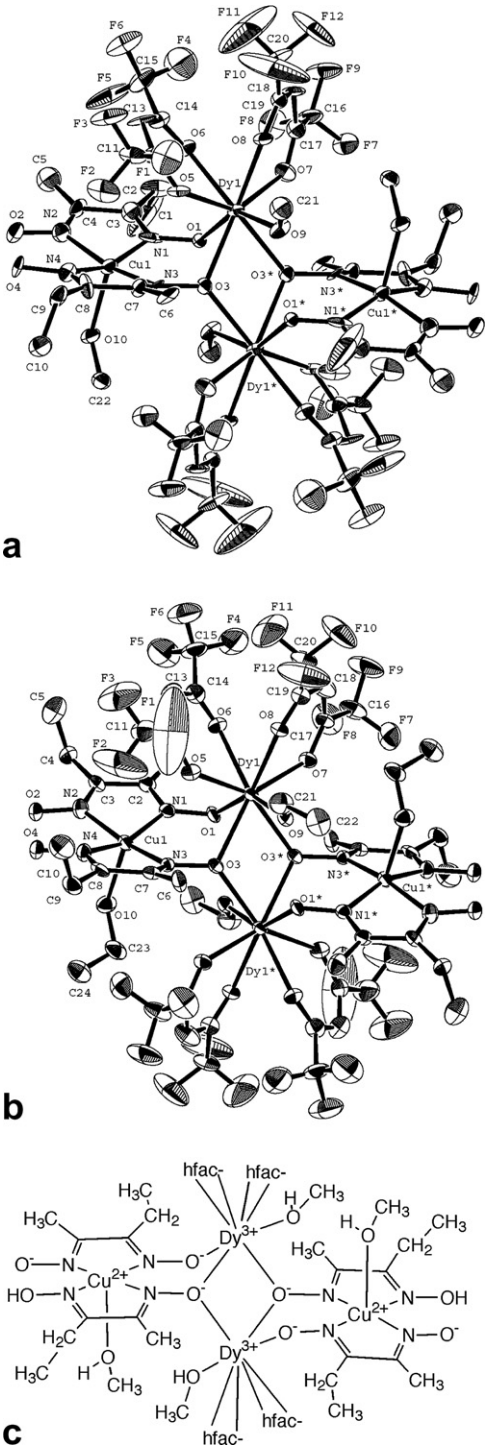

Fig. 1. Ortep drawings of [{Cu(emg)(Hemg)(ROH)}$_2${Dy(hfac)$_2$(ROH)}$_2$] ((a) [Dy$_2$Cu$_2$]-Me for R = Me; (b) [Dy$_2$Cu$_2$]-Et for R = Et) with the thermal ellipsoids at the 50% probability level. Hydrogen atoms are omitted. One of the two crystallographically independent molecules is shown for [Dy$_2$Cu$_2$]-Et. (c) Structural formula of [Dy$_2$Cu$_2$]-Me.

3.2. Magnetic properties

The dc magnetic properties of [Dy$_2$Cu$_2$]-Me were investigated down to 1.8 K (Fig. 2a). The theoretical high-temperature limit of the $\chi_{mol}T$ value should be

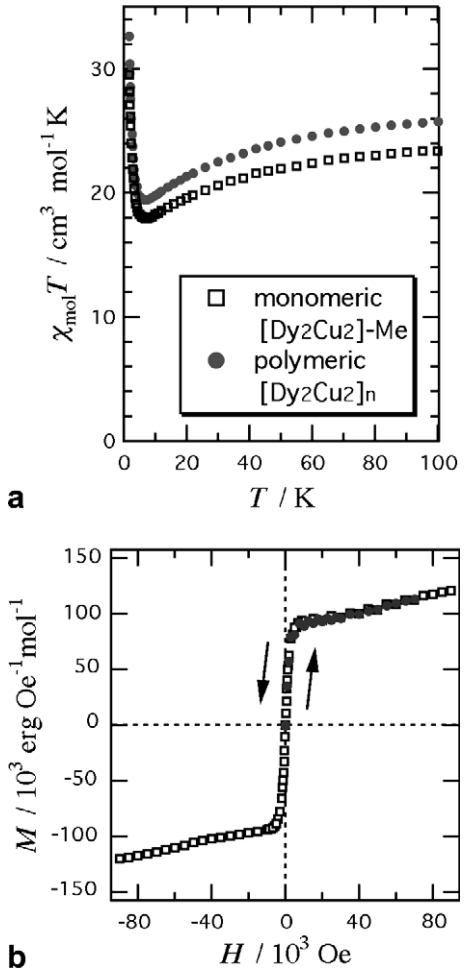

Fig. 2. (a) Temperature dependence of the $\chi_{mol}T$ products for randomly oriented polycrystalline samples of $[Dy_2Cu_2]$-Me and $[Dy_2Cu_2]_n$ measured at 500 Oe. The samples were fixed with a small amount of mineral oil. (b) Magnetization curves for polycrystalline samples of $[Dy_2Cu_2]$-Me (squares) and $[Dy_2Cu_2]_n$ (dark circles) measured at 1.8 K. The field scan rate was 65 Oe s^{-1}.

28.8 cm^3 K mol^{-1} for a Dy_2Cu_2 unit with $J_{Dy} = 15/2$, $g_J = 4/3$, and $S_{Cu} = 1/2$, $g_{Cu} = 2.0$. As Fig. 2a shows, the experimental $\chi_{mol}T$ value (23.4 cm^3 K mol^{-1}) at 100 K are compatible with the calculated one, and the Dy_2Cu_2 spin quantity was verified. Upon cooling, the $\chi_{mol}T$ value once decreased and turned to increase like the $[Gd_2Cu_2]$ case [18]. The decrease of the $\chi_{mol}T$ is presumably caused by the strong anisotropy of Dy ions and the sizable energy gap (see below) between the ground ferrimagnetic state and the excited ferromagnetic state. The sharp increase in lower temperature is due to the evolution of the large ferrimagnetic moment: $\sim 18\mu_B$/$[Dy_2Cu_2]$. The antiferromagnetic coupling between Dy and Cu ions is confirmed by the high-field magnetization measurements shown below. The magnetic couplings between Dy and Cu ions are dominant compared to those between Dy ions, and therefore the present tetranuclear clusters can be regarded as antiferromagnetically correlated four-centered macrocycles, leading to the Dy magnetic moments aligned parallel as schematized like [Cu(↓)Dy(↑)Cu(↓)Dy(↑)].

There have been several reports on the ferromagnetic coupling between Ln^{III} ($4f^n$; $n \geqslant 7$) and Cu^{II} ions so far [22–27], but it has also been pointed out that the coupling is susceptible to the geometry, especially, to the bent structure of the Ln–O–N–Cu bridge [16,28,29]. In the present complex, the torsion angles of Ln–O–N–Cu are considerably large (−60.3(6), 55.1(5), −95.1(4)° in $[Gd_2Cu_2]$ [18]; −58.6(15), 57.0(13), and −94.5(13) in $[Dy_2Cu_2]$-Me). In all cases of our study, the twisted Ln–O–N–Cu bridges play the role of an antiferromagnetic coupler between Ln^{III} and Cu^{II}.

Kahn and co-workers proposed that the ferromagnetic couplings between Ln^{III} and Cu^{II} ions can be explained as follows [27]: when the number of 4f electrons is more than seven, the orbital and spin momenta of Ln^{III} are parallel, and the ferromagnetic spin coupling gives rise to an overall ferromagnetic interaction. In our case, $[Gd_2Cu_2]$ involves the accidentally antiferromagnetic spin coupling between Gd^{III} and Cu^{II} [18], and therefore, in the isomorphous Dy^{III} ($4f^9$) analogue, the spin coupling of Dy^{III} and Cu^{II} is also antiferromagnetic, leading to the overall antiferromagnetic interaction. We have already reported that the pentanuclear $[Gd_4Cu]$ rectangle showed antiferromagnetic coupling between Gd^{III} and Cu^{II} [16,17], and recently we found that the isomorphous $[Tb_4Cu]$ and $[Dy_4Cu]$ rectangles also exhibited antiferromagnetic couplings between Ln^{III} and Cu^{II} [30]. Thus, the Ln^{III}–Cu^{II} interactions have the same sign as that of Gd^{III}–Cu^{II} for the heavier Ln^{III} ions than Gd^{III}, especially for Tb^{III} and Dy^{III}.

We found a stepwise saturation behavior in the M–H curve for $[Dy_2Cu_2]$-Me (Fig. 2b), supporting the ground ferrimagnetic state. The magnetization showed a plateau in 1–4 T and increased again with an increase of the applied field. A plot of dM/dH versus H shows a broad peak around 5 T. The theoretical saturation value should be 1.22×10^5 erg Oe^{-1} mol^{-1} and the experimental value was 1.20×10^5 erg Oe^{-1} mol^{-1} at 9 T. The plateau is located at ca. 1.00×10^5 erg Oe^{-1} mol^{-1}. Therefore, the step is assigned to be a 4-μ_B jump due to the reorientation of two copper(II) spins. The energy-level cross between the ferrimagnetic [Cu(↓)Dy(↑)Cu(↓)Dy(↑)] and the ferromagnetic [Cu(↑)Dy(↑)Cu(↑)Dy(↑)] states occurs here with an aid of the Zeeman energy. The zero field splitting between these two states is evaluated to be 27 K. It is much higher than that observed in the previous $[Dy_2Cu]$ complex [5]. It should be noticed that the ferromagnetic [Cu(↑)Dy(↑)-Cu(↑)Dy(↑)] state is not the first excited state and other states such as [Cu(↑)Dy(↑)Cu(↑)Dy(↓)] are located in between these two states. It means that the energy barrier is much smaller than 27 K.

We performed the χ_{mol}–T and M–H measurements on $[Dy_2Cu_2]_n$ under the same conditions, and clarified that $[Dy_2Cu_2]_n$ exhibited behavior quite similar to that of $[Dy_2Cu_2]$-Me. A $\chi_{mol}T$ minimum around 7 K and an

upsurge on further cooling were found in the $\chi_{mol}T$ versus T plot (Fig. 2a; dark circles). The M–H curve of $[Dy_2Cu_2]_n$ measured at 1.8 K (Fig. 2b; dark circles) was practically identical with that of $[Dy_2Cu_2]$-Me. These findings indicate that the polymer form can be described as an only slightly perturbed system from the monomeric one; i.e., the polymerization linkage Cu–N–O–Cu transmits very small magnetic interaction.

The magnetization jump around 5 T was reproduced in the low-temperature magnetization curve at 0.5 K by means of a pulsed-field technique (Fig. 3a). The jump becomes sharper in lower temperatures because of the suppression of thermal excitations. The magnetization also exhibits a relatively narrow hysteresis within ±0.4 T (Fig. 3b). At beginning, the ferrimagnetic moments of clusters take both parallel and anti-parallel directions to the external magnetic field. The latter group should show the reversal to the parallel at level crossing points. The crossing fields are located in the low field region because the Zeeman energy difference between the ground [Cu(↓)Dy(↑)-Cu(↓)Dy(↑)] state and the excited state [Cu(↑)Dy(↑)-Cu(↑)Dy(↓)] or [Cu(↓)Dy(↑)Cu(↓)Dy(↓)] are large. It is the similar situation as we discussed in the $[Dy_2Cu]$ SMM (see Fig. 3(c) in Ref. [5]). In a small field region, the dM/dH versus H plot (Fig. 3b) clarifies mainly three fine magnetization jumps. Usually this behavior is related with quantum tunneling of magnetization, which is characteristic of a SMM. In the adiabatic limit, the peak positions should be independent of a sweeping rate; however, the small dependence was found here. The reason might be the non-adiabatic feature for the very fast sweeping rate or the mixture of the residual thermal relaxation. The further investigation is needed with a single crystal or oriented crystals to clarify this point.

It is also found that hysteresis curves are asymmetric; in the negative field each step was shifted with respective to the positive one, indicating the presence of a dipolar-coupling bias that affects the field at which magnetization tunneling takes place.

We measured the ac magnetic susceptibility of $[Dy_2Cu_2]$-Me (Fig. 4a). With an increase of frequency, a χ'_{ac} decrease and a concomitant χ''_{ac} increase were clearly observed. We confirmed that the magnetization relaxation became relatively slow, compared with the timescale of these

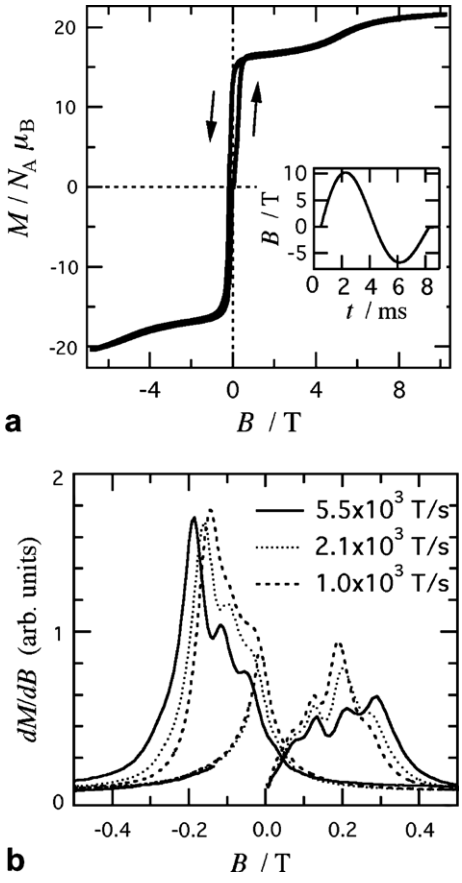

Fig. 3. (a) Magnetization curve of $[Dy_2Cu_2]_n$ measured at 0.5 K. Inset: a field-sweep sequence as a function of time. (b) Differential magnetization curves as a function of a field sweeping rate at 0.5 K.

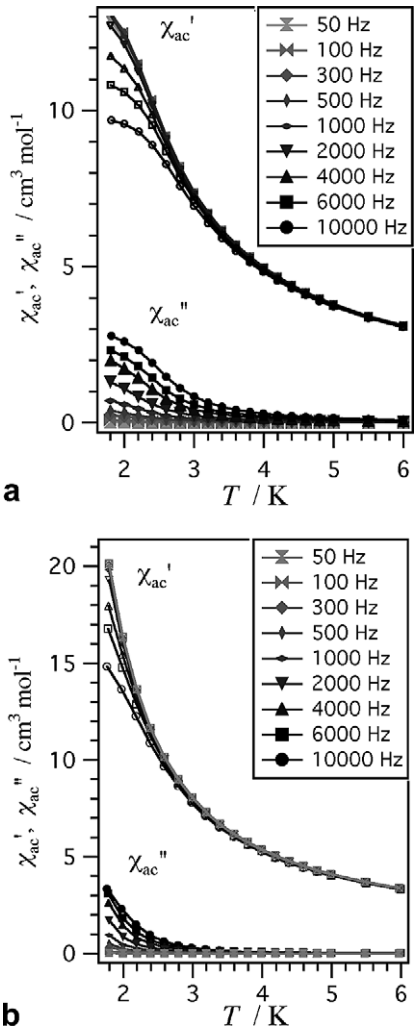

Fig. 4. Ac magnetic susceptibilities (χ'_{ac} and χ''_{ac} for in-phase and out-of-phase parts, respectively) for (a) $[Dy_2Cu_2]$-Me and (b) $[Dy_2Cu_2]_n$ as a function of temperature and frequency. The amplitude of the applied ac magnetic field was 5 Oe.

experiments. However, the χ''_{ac} peak could not be observed above 1.8 K in our apparatus and the activation energy of the magnetization reorientation could not be estimated. We assume that the blocking temperature would be lower than 1.8 K, because no hysteresis was observed in the *M–H* curve measured with a relatively slow field-sweep rate (65 Oe s^{-1}) (Fig. 2b).

Under the same conditions, we measured the ac magnetic susceptibility of $[Dy_2Cu_2]_n$ (Fig. 4b). Similarly, we could observe a χ''_{ac} increase with an increase of frequency. The increase of χ''_{ac} is smaller than that of $[Dy_2Cu_2]$-Me, suggesting that the reorientation rate of $[Dy_2Cu_2]_n$ is faster than that of $[Dy_2Cu_2]$-Me. The polymeric form gives rise to disadvantage in SMM characteristics, which may be caused by acceleration of relaxation due to the presence of spins nearby. On the other hand, Miyasaka and co-workers have reported that the energy barrier for magnetization reorientation of the single-chain magnet (SCM) was larger than that of the precursory SMM for the $[Mn_2Ni]$ and $[Mn_2Fe]$ systems [31]. Here we point out that the present system contains the $S = 1/2$ spins, which may work as the nucleation center of the propagating correlated reversal in SCM. The ESR measurement may be useful to clarify this issue, which shows the collective mode in $[Mn_2Ni]$ system [32].

4. Conclusion

We prepared tetranuclear heterometallic cycles $[Dy_2Cu_2]$-Me and $[Dy_2Cu_2]$-Et, and their polymeric form $[Dy_2Cu_2]_n$. They have isostructures of $[Gd_2Cu_2]$ and $[Gd_2Cu_2]_n$, respectively, which have been fully characterized previously [18]. We clarified that the $[Dy_2Cu_2]$ motif possessed antiferromagnetic coupling between Dy and Cu ions, leading to the ferrimagnetic ground state. Ac magnetic susceptibility measurements of $[Dy_2Cu_2]$-Me and $[Dy_2Cu_2]_n$ exhibited the χ''_{ac} increase with an increase of frequency, indicating the slow magnetization reorientation. Actually, hysteresis curves accompanied by magnetization jumps could be observed at 0.5 K for $[Dy_2Cu_2]_n$ by means of a pulsed-field technique. Their magnetic properties and quantum tunneling mechanism on the single-molecule and single-chain levels are of great interest. Our study demonstrates that the 4f–3d heterometallic approach is a very promising pathway to SMMs and SCMs. Studies on terbium(III) analogs, $[Tb_2Cu_2]$ and $[Tb_2Cu_2]_n$, are currently underway.

5. Supplementary material

CCDC 616904 and 616905 contain the supplementary crystallographic data for $[Dy_2Cu_2]$-Me and $[Dy_2Cu_2]$-Et. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 1. The ditopic nature of ligand L.

supramolecular polymetallic cluster structures [6]. We report here a new tetrameric copper complex of one such ligand, 3{5}-(pyrid-2-yl)-5{3}-*tert*-butylpyrazole ('L', Scheme 1), namely $[Cu_4(\mu_3\text{-}OH)_4(L)_4](ClO_4)_4 \cdot xCH_2Cl_2$ ($\mathbf{1} \cdot xCH_2Cl_2$). The only metal complexes of this ligand to have been reported previously are platinum metal compounds, designed for catalysis [7] or electroluminescence [8] applications, and a pair of isostructural metal carboxylate coordination networks [9].

2. Experimental

5{3}-*tert*-Butyl-3{5}-(pyrid-2-yl)-1*H*-pyrazole (L) was synthesized using a previously reported procedure [10]. Metal salts were obtained commercially while all solvents were used without further purification. *Caution*: Although no difficulties were experienced in handling $\mathbf{1} \cdot xCH_2Cl_2$, metal-organic perchlorates are potentially explosive and should be handled carefully in small quantities.

2.1. Synthesis

$Cu(ClO_4)_2 \cdot 6H_2O$ (400 mg, 1.08 mmol) and 5-*tert*-butyl-3-(pyrid-2-yl)-1*H*-pyrazole (L) (220 mg, 1.08 mmol) were added to 1 equiv. of solid NaOH (86 mg, 1.08 mmol) in 30 cm^3 MeOH and stirred for 24 h. On filtration the green slightly cloudy solution was left to evaporate to dryness. On redissolution in CH_2Cl_2 followed by slow Et_2O diffusion, aqua blue block-like crystals of $\mathbf{1} \cdot xCH_2Cl_2$ were obtained in 20% yield (346 mg). Drying *in vacuo* led to crystal decomposition, affording a material containing 1 mole equiv. of solvent by microanalysis and by NMR. *Anal.* Calc. for $C_{48}H_{60}N_{12}O_{20}Cl_4Cu_4 \cdot CH_2Cl_2$: C, 36.55; H, 4.13; N, 10.44. Found: C, 36.85; H, 4.10; N, 10.55%. Field desorption mass spectrum: *m/z* 627 $[^{63}Cu_4L_4(^{35}ClO_4)_2]^{2+}$, 663 $[^{63}CuL_3\text{–}H]^+$, 527 $[^{63}Cu_4L_4\text{–}2H]^{2+}$, 495 $[^{63}Cu_3L_4\text{–}2H]^{2+}$, 464 $[^{63}Cu_2L_4\text{–}2H]^{2+}$. Selected IR (Nujol): 3485(b), 3236(b), 3131(m), 2725(m), 2670(m), 1619(m), 1574(m), 1561(m), 1303(m), 1269(m), 1218(w), 1204(w), 1141(m), 1113(m), 1041(m), 1000(w), 983(w), 925(w), 828(w), 787(w), 776(w), 722(m) cm^{-1}. ^1H NMR (CD_3NO_2, 298 K): δ, ppm 2.09 (s, 36H, $C(CH_3)_2$), 5.6 (2H, CH_2Cl_2), 13.8 (4H, Py H^4), 25.9 (4H, N*H*), 39.2, 40.2, 43.6 (all 4H, Py H^3 and H^5, and Pz H^4), 119.5 (4H, Py H^6).

2.2. X-ray crystallographic studies

All diffraction measurements were carried out on a Bruker-Nonius Apex X8 diffractometer utilizing a FR591 5 kW X-ray generator, Mo Kα rotating anode X-ray source ($\lambda = 0.71073$) and an Apex II detector. Temperature control was achieved using Oxford Cryosystems 600 and Oxford Helix cryostats to obtain temperatures of 150 and 30 K, respectively. The asymmetric unit of $\mathbf{1} \cdot xCH_2Cl_2$ at 150 and 30 K contains one $[Cu_4(\mu_3\text{-}OH)_4(L)_4](ClO_4)_4$ formula unit, lying on a general position, and four or five partial dichloromethane molecules with occupancies of 0.5 or less. Both structures were solved using direct methods (SHELXS86 [11]) while each of the early refinement models were obtained by least-squares refinement on F^2 (SHELX97 [12]). Figures were produced using XSEED [13], which incorporates POVRAY [14]. Experimental data for the two structure determinations are summarized in Table 1.

The structure of $\mathbf{1} \cdot xCH_2Cl_2$ at 150 K exhibited extensive disorder which was modeled as follows. Three of the four ClO_4^- anions in the asymmetric unit were modeled over two sites in a 50:50 occupancy (labeled A and B). The restraints Cl–O = 1.45(2) and O···O = 2.38(4) Å were applied to these disordered groups. Two of the *tert*-butyl groups of the L ligands were also disordered over two sites and again a 50:50 occupancy proved a suitable model for such disorder. The restraints C–C = 1.55(2) and

1,3-C···C = 2.55(4) Å were used for these moieties. Five partial CH_2Cl_2 solvent molecules also occupy the asymmetric unit, two that are half-occupied and three with occupancies of 0.25. The C–Cl bond lengths in these moieties were all restrained to 1.75(2) Å. All wholly occupied non-H atoms, plus Cl atoms with occupancy $\geqslant 0.5$, were refined anisotropically. No H atoms could be found in the difference map, so these were placed in calculated positions and refined using a riding model.

The structure at 30 K exhibits less disorder than at 150 K. Just two ClO_4^- anions and one *t*-Bu group are now disordered, while five partial CH_2Cl_2 solvent molecules were also located, showing somewhat different positions and occupancies from those at 150 K. The disordered *tert*-butyl group was modeled over two sites using a 50:50 occupancy model. One of the disordered ClO_4^- anions was modeled over two orientations, sharing a common Cl atom, with a 50:50 occupancy, while the second disordered anion was refined over three sites with a 40:30:30 occupancy distribution. The same restraints used at 150 K were applied to all these disordered groups, while other details of the 30 K refinement were also the same as at the higher temperature.

2.3. Other measurements

Elemental analysis was carried out at the University of Leeds School of Chemistry microanalytical service. Infra red spectrum collected as a Nujol mull pressed between NaCl plates in a 600–4000 cm^{-1} frequency range using an Avatar 360 spectrophotometer. Magnetic susceptibility measurements were obtained using a Quantum Design SQUID magnetometer in an applied field of 1000 G. Diamagnetic corrections were estimated from Pascal's constants [15]. Paramagnetic ^1H NMR was carried out using a Bruker ARX 250 MHz instrument, operating at 250.13 MHz. X-band EPR spectra were obtained with a Bruker EMX spectrometer fitted with an ER4119HS resonator and ER4131VT cryostat.

3. Results

Reaction of L [10] with stoichiometric amounts of $Cu(ClO_4)_2 \cdot 6H_2O$ and NaOH in MeOH yielded a blue solution, which was evaporated to dryness. Re-dissolution of the solid residue in the minimum volume of CH_2Cl_2, and slow diffusion of Et_2O vapour into the filtered solution, gives rise to the tetrameric cubane $[Cu_4(\mu_3\text{-}OH)_4(L)_4](ClO_4)_4 \cdot xCH_2Cl_2$ (**1** · xCH_2Cl_2) in 20% recrystallised yield. The crystallographic studies described below implied that x varies between 1.75 and 1.9 in the crystalline material. However, the crystals decompose upon drying *in vacuo*, the resultant powder analysing as the mono-dichloromethane solvate (*i.e.* $x = 1$). The presence of CH_2Cl_2 in the dried material was confirmed by ^1H NMR spectroscopy in CD_3NO_2, which showed a clear singlet peak at 5.6 ppm. Six other contact-shifted peaks of approximately equal integral, and one peak in the diamagnetic region integrating to 9H with respect to the others, were also present in the spectrum. This is the number expected for a single metal-bound L environment, if the pyrazole N–H group is included. The X-band EPR spectrum of solid **1** · xCH_2Cl_2 at 100 K consisted of a single isotropic signal centred at $g = 2.08$, with no detectable half-field resonance.

The room temperature $\chi_m T$ value of 1.66 $cm^3\,mol^{-1}$ K for **1** · xCH_2Cl_2 is that expected from four non-interacting copper(II) centres with a reasonable g value of 2.1–2.2. This value stays essentially constant upon cooling to 100 K, but decreases gradually on further cooling to 1.35 $cm^3\,mol^{-1}$ K at 30 K (Fig. 1). Below this temperature $\chi_m T$ plateaus again at this value, before finally decreasing slightly again below 15 K. The data above 30 K could be well reproduced by treating the cubane core as a pair of non-interacting dimers, through the Bleaney Bowers equation [15] (Fig. 2, $J' = 0$). This afforded the parameters $J = -5.2(1)\ cm^{-1}$ and $g = 2.14(1)$ for the Hamiltonian $H = -2J(S_1 \cdot S_2)$, with a correlation coefficient of 0.980.

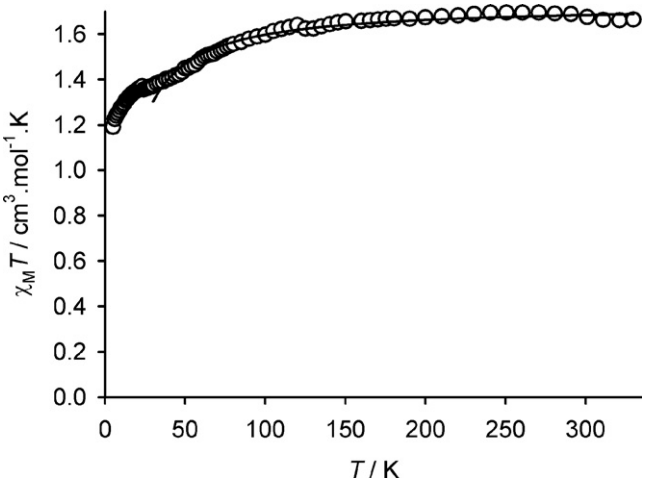

Fig. 1. Observed magnetic susceptibility data (circles) from **1** in the 4–300 K temperature range in a field of 1000 G, and the fit of the data above 30 K to the Bleaney Bowers equation for two dicopper(II) dimers. See text for fitting parameters.

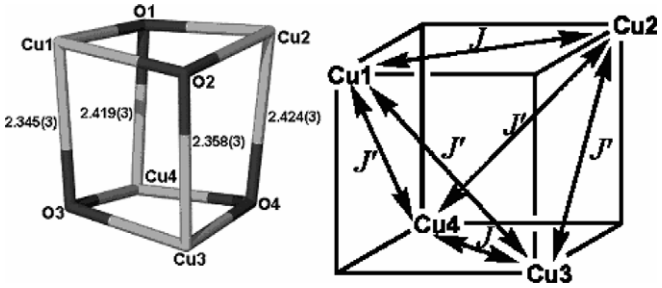

Fig. 2. (left) Cu–O distances (Å) observed in **1** at 150 K illustrating the axial elongation of the distorted cubane along the *z*-axis. Other relevant metric parameters in the cluster core are given in Table 1. (right) Schematic of model used to fit magnetic susceptibility data obtained from **1**.

This approach was necessary because J and J' correlated strongly when refined simultaneously (using the equation in [16]), and is reasonable because the crystal structure of the compound implies that $J \gg J'$ (see below). A paramagnetic impurity term in the fitting equation refined to zero, while no TIP contribution was included. Data below 30 K could not be modeled using the Bleaney Bowers equation, or any other Hamiltonian consistent with the crystal structure, since they all predict an $S = 0$ magnetic ground state for the complex and a steady decrease in $\chi_m T$ towards zero below 30 K, contrary to the observation. Incorporation of a mean field correction into our equations, to model intermolecular interactions [15], was similarly unsuccessful at treating the low-temperature data.

The crystal structure of $\mathbf{1} \cdot x\mathrm{CH_2Cl_2}$ was determined at both 150 K and 30 K, in order to investigate any structural basis for the anomalous low-temperature magnetic behaviour of the compound. It was necessary to use different crystals for these two analyses, which proved to have slightly different solvent contents ($x = 1.75$ at 150 K, $x = 1.90$ at 30 K). The crystals are isostructural at the two temperatures, in the orthorhombic space group

Atom O19 is part of a perchlorate anion that is disordered over two sites at 150 K and three sites at 30 K, labeled A, B and C. Symmetry code: (i) $1/2 + x$, $3/2 - y$, z.

Pna2_1, although some of the anion and *tert*-butyl group disorder that is present at 150 K has become frozen out at 30 K. A decay in crystal quality as the temperature was lowered means that the 30 K structure is less precise than the 150 K one, despite the reduced disorder present. All the metric parameters quoted in the following paragraph are from the 150 K structure.

The asymmetric unit contains one tetrameric complex and four perchlorate anions, all lying on general positions, and a disordered region containing four or five partial dichloromethane environments. Three of the four copper ions in the cubane complex, Cu1–Cu3, are five-coordinate with one long apical Cu···OH^- bond of 2.328(5)–2.424(3) Å (Table 2 and Fig. 3). The τ parameters for these three copper ions range from 0.11 to 0.26, confirming that their coordination geometry is best described as square pyramidal [17]. The other copper ion, Cu4, is six-coordinate with long axial bonds to one OH^- ligand [2.419(3) Å], and a disordered perchlorate ion [Cu···O = 2.5–2.6 Å] (Table 2). The disposition of elongated Cu···O bonds within the $[Cu_4(OH)_4]^{4+}$ cubane core results in a tetragonal elongation, with two short intermetallic distances of Cu1···Cu2 = 2.9853(9) and Cu3···Cu4 = 2.9489(8) Å spanning opposite faces of the cube. The other four Cu···Cu distances within the cluster core range between 3.2838(9) and 3.3153(9) Å (Fig. 2). Hence, the cubane is best considered as an approximately S_4-symmetric, loosely-associated dimer of $[Cu_2(OH)_2]^{2+}$ dimers. The four basal, apical Cu–O···Cu pathways linking the dimers within the cubane should contribute negligibly to superexchange in the compound, since the apical Cu–O bonds do not overlap with the copper $d_{x^2y^2}$ magnetic orbitals [16,18].

Comparison of the crystal structures at 30 K and 150 K shows that there is a small contraction of the distance between the pair of dimers in the cluster. Two of the apical Cu···O bonds linking the dimers, Cu1···O3 and Cu3···O2, are shorter at 30 K by 0.029(7) Å and 0.030(6) Å, respectively. This leads to a decrease in the four long Cu···Cu distances in the cubane, which are all 0.0257(17)–0.0337(17) Å shorter at 30 K than at 150 K (Table 2). This small perturbation should have no bearing on the magnetochemistry of the compound, since superexchange between the dimers is expected to be very weak [16,18]. Importantly, the Cu–O bonds and Cu–O–Cu angles linking Cu1 and Cu2, and Cu3 and Cu4, are all indistinguishable at the two temperatures, as are the distances between these two pairs of strongly linked copper ions. Hence, the small structural changes in the cubane core observed upon cooling to 30 K cannot be used to rationalise the low-temperature magnetic behaviour of $\mathbf{1} \cdot x CH_2Cl_2$.

Detailed consideration of hydrogen bonding in the compound is hampered by disorder in three of the ClO_4^- anions at 150 K, and in two of them at 30 K. However, it is clear that each of the anions in the structure accepts

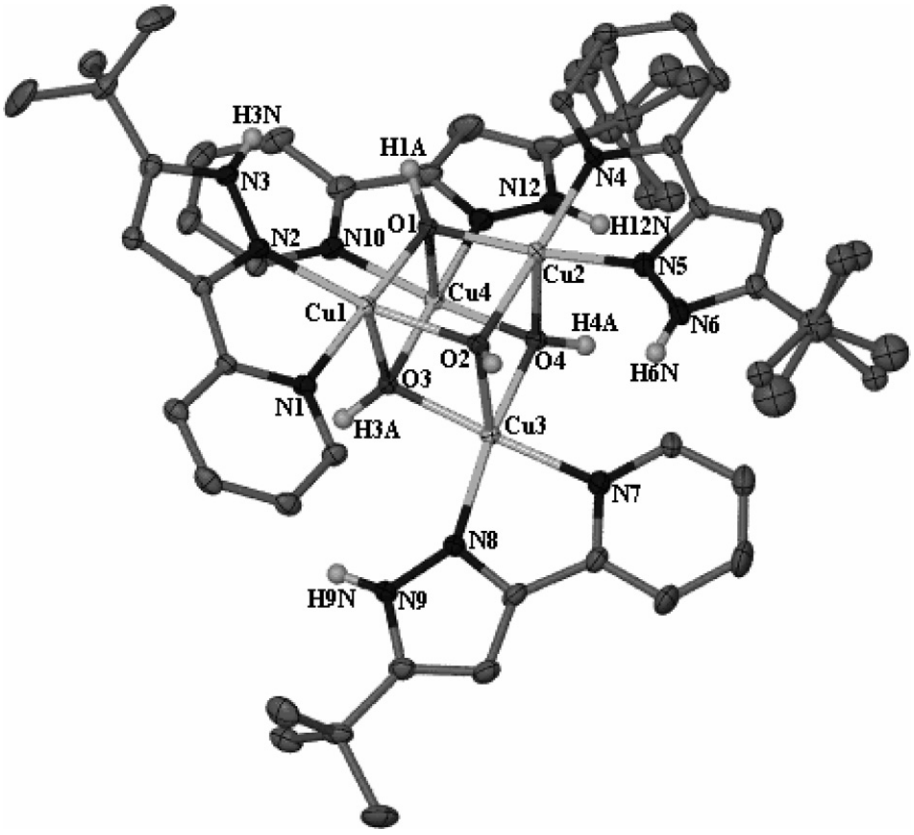

Fig. 3. ORTEP representation of the $[Cu_4(\mu_3\text{-}OH)_4(L)_4]^{4+}$ cations in **1** at 150 K. Thermal ellipsoids are at a 30% probability level and the peripheral H atoms and ClO_4^- counter anions have been omitted for clarity.

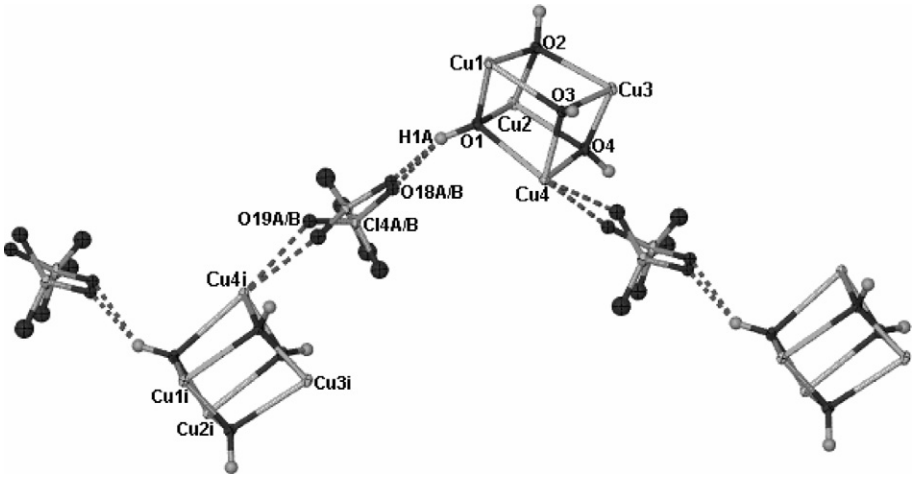

Fig. 4. ORTEP representation at 20% thermal ellipsoids illustrating the intermolecular bonding linking the $[Cu_4(\mu_3\text{-}OH)_4(L)_4]^{4+}$ moieties *via* H-bonding of the disordered O18A/B oxygen donor atom (of the Cl4A/B perchlorate anion) and the axial Cu–O interaction between $Cu4^i$ and O19A/B of the same counter anion.

hydrogen bonds from one OH^- group and from the N–H group of one L ligand, thus occupying alternate corners of the cubane molecule. Importantly, one of the disordered anions also forms the aforementioned weak axial contact, through O19, to Cu4 in a neighbouring molecule related by $-1/2 + x$, $3/2 - y$, z. This bridging interaction associates the cubanes into 1-D chains that zig-zag along the crystallographic *a* direction, that are linked through alternating X–H···O (X = N or O) and Cu···O interactions (Fig. 4). We tentatively attribute the anomalous magnetic behaviour of $\mathbf{1} \cdot x CH_2Cl_2$ below 30 K to weak intermolecular ferromagnetic superexchange mediated by the bridging perchlorate anions.

4. Discussion

Complex $\mathbf{1} \cdot x CH_2Cl_2$ represents only the sixth tetranuclear cupric cluster to exhibit the $[Cu_4(\mu_3\text{-}OH)_4]^{4+}$ distorted cubane core, five of which (including $\mathbf{1} \cdot x CH_2Cl_2$) have been studied magnetically [19–23]. Table 3 contains the structural and magnetic data reported from four previously reported $[Cu_4(\mu_3\text{-}OH)_4(L)_4]^{4+}$ clusters along with data collated in this work. Three of the other complexes have the same approximate S_4 core symmetry found in $\mathbf{1} \cdot x CH_2Cl_2$, and their magnetic susceptibility data were therefore also best fitted using the Bleaney-Bowers dinuclear model. Hatfield and Hodgson's magnetostructural correlation for $[Cu_2(OH)_2]^{2+}$ dimers [24] predict weak ferromagnetic exchange in **3** and strong antiferromagnetic exchange in **5**, due to their Cu–(μ_3-OH)–Cu angles averaging 96.5° and 101.5°, respectively (Table 3). These prediction were proven correct, since these compounds show $J = +12$ and $-207.0\ cm^{-1}$ respectively. Likewise the average Cu–(μ_3-OH)–Cu angle of 98.8° in **4** would impose weaker antiferromagnetic exchange, as proven by the magnetic exchange value of $J = -41.0\ cm^{-1}$. Magnetic susceptibility measurements on **2** were consistent with antiferromagnetic exchange, but no fitting of these data was attempted. Compound $\mathbf{1} \cdot x CH_2Cl_2$ shows comparable Cu···Cu and Cu–O distances with respect to the five previously reported $[Cu_4(\mu_3\text{-}OH)_4(L)_4](X)_4$ systems. Interestingly, the averaged Cu–(μ_3-OH)–Cu angles within each dinuclear unit in **1** at 150 and 30 K range from 96.7° to 99.8°, which lie in the ferromagnetic and antiferromagnetic regions of Hatfield and Hodgson's correlation, respectively. The structure of **1** is therefore in close proximity to the singlet/triplet ground state interface for each strongly coupled dicopper unit, and a very small *J* value would be predicted, as observed.

Table 3
Intradimer structural and magnetic data for $[Cu_4(\mu_3\text{-}OH)_4(L)_4]^{4+}$ cubane clusters[a]

	Cu–O (Å)	Cu···Cu (Å)	Cu–(OH)–Cu (°)	$J\ (cm^{-1})$	Reference

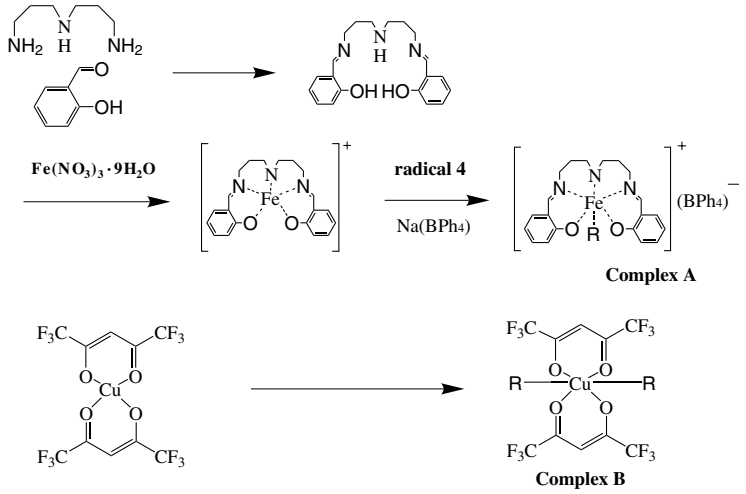
acetate = 10:1). Recrystallization from ethanol gave **3** as red powders. Mp 205–208 °C. *Anal.* Calc. for $C_{32}H_{28}N_3O$: C, 81.67; H, 6.00; N, 8.83. Found: C, 81.69; H, 5.93; N, 8.93%.



Compound **4** was purified by silica gel column chromatography using mix solvent (dichloroethane:ethyl acetate = 9:1). Recrystallization from toluene gave **4** as blue powders. Mp 224–228 °C. *Anal.* Calc. for $C_{32}H_{28}N_3O_2$: C, 78.99; H, 5.80; N, 8.64%. Found: C, 79.09; H, 5.81; N, 8.39%.

2.2. Synthesis of metal complexes *A* and *B*

Complexes **A** and **B** were synthesized according to Scheme 2. The complex **A** was synthesized according to the similar procedures reported previously [14].

A mixture of 3,3-diaminodipropylamine and salicylaldehyde in methanol solution was stirred for 2 h at room temperature. The solution was fell in drops $Fe(NO_3)_3 \cdot 9H_2O$ methanol solution. To the solution was added a solution of the radical **4**, and the mixture was stirred for 1 h at room temperature. Then, to the solution was added a methanol solution of sodium tetraphenylborate, and stirred for 1 h. The dark purple crystals were collected by filtration and, recrystallized from acetone-ethanol solution, gave the complex A, $[Fe(III)(L)(4)] \cdot (BPh_4)$. ($LH_2$ = *N*,*N*′-bis(1-hydroxy-2-benzyliden)-1,7-diamino-4-azaheptane). *Anal.* Calc. for $C_{76}H_{71}$- $BFeN_6O_4$: C, 76.13; H, 5.97; N, 7.01. Found: C, 76.65; H, 5.49; N, 5.86%.

A solution of $[Cu(hfac)_2 \cdot xH_2O]$ in heptane was concentrated about by distillation. To this solution was added a solution of **4** in toluene. The crystal was collected by filtration, recrystallized from ethanol gave the complex **B**, $Cu(II)(hfac)_2(\mathbf{4})_2$. In the complex using 4-pyridinyl substituted π-radicals as a ligand, it was found by X-ray crystallographic analysis that the complex was contained toluene as crystal solvent. The complex B be expected to contain toluene. *Anal.* Calc. for $C_{76}H_{62}CuF_{12}N_6O_8$: C, 63.46; H, 4.49; N, 5.35. Found: C, 63.86; H, 4.43; N, 5.25%.

Scheme 2. Synthesis of complexes **A** and **B**.

2.3. Measurements

Electro chemical behaviors of **3** and **4** were studied in acetonitrile solution by CV method using a Hokuto Denko HSV-100. The measurements were made with a standard three-electrode configuration: a glassy carbon disk electrode served as the working electrode, a Pt wire and Ag/Ag+ were used as the counter electrode and the reference electrode, respectively. 0.1 M of $(t\text{-Bu})_4NBF_6$ was used as the electrolyte. Ferrocene was used as internal standard.

UV–Vis absorption spectra were obtained with a Hitachi U-3000. Magnetic susceptibility measurements were carried out using a powder samples of **3**, **4**, complexes **A** and **B** on a Quantum Design MPMS2 SQUID magnetometer. Conventional ESR spectra were observed with a JEOL TE300 X-band ESR spectrometer. The ab initio molecular orbital calculations were carried out based on the density functional theory (DFT) using Gaussian 98 [15]. In the ab initio calculations, the STO 6-31G basis sets and UHF Becke 3LYP (UBecke 3LYP) hybrid method were employed. The photo-excited states were investigated by the TRESR measurements. The detail of our experimental setup of the TRESR apparatus was described in our previous paper [3]. The temperature in the ESR and TRESR measurements was controlled using an Oxford ESR 910 cold He gas flow system.

3. Results and discussion

The UV–Vis spectra of the radicals **1**, **3** and **4** are shown in Fig. 2. Peaks of 350–400 nm are assigned to π–π transition of the anthracene moiety. The peak of the radical **3** is red-shifted by about 10 nm relative to **1**. The result shows that energy gap between HOMO and LUMO of the radical **3** decreases by the attachment of the 3-pyridinyl group. Broad peak of 400–500 nm is arising from the $n\pi^*$ transition of the iminonitroxide radical. From this experiment, a laser light of $\lambda = 355$ nm is used for the excitation in the TRESR experiment.

Oxidation potentials of **1**, **3** and **4** are listed in Table 1. First and second oxidation potentials of **3** are larger than the corresponding ones of **1**, showing stabilization both of HOMO and SOMO of **3**.

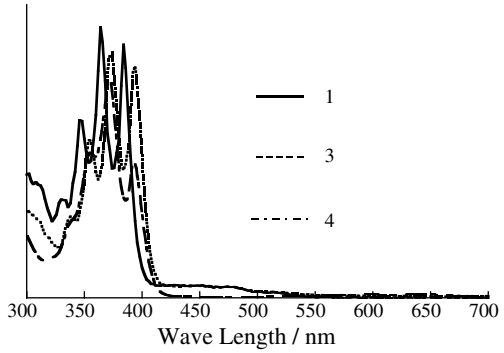


Fig. 2. UV–Vis spectra of **1**, **3** and **4**.

Table 1
Oxidation potentials of **1**, **3** and **4** in acetonitrile

	First oxidation potential (V)	Second oxidation potential (V)
1	0.79	0.91
3	0.81	1.04
Difference	0.02	0.13
4	0.36	0.94

Ferrocene was used as internal standard.

In the ground states, the magnetic properties of the radicals were examined by the susceptibility measurements.

Figs. 3 and 4 are the temperature dependences of $\chi_{mol}T$ for **3** and **4** in the range of 1.7–300 K respectively. Solid lines in these figures are calculated using the Curie–Weiss law. From these fitting, the Weiss constant θ of **3** and **4** were determined to be −1.5 to −0.7 K, respectively, showing inter-molecular interactions of **3** and **4** are weak antiferromagnetic in the ground states. In order to clarify the photo-excited states of the radicals **3** and **4**, TRESR experiments were carried out.

Fig. 6 shows TRESR spectra and spectral simulation [16] of **3** and **4**, respectively. Their TRESR spectra were observed at 30 K in a glass matrix (isopentane:diethylether = 2:3). From the spectral simulation, spin Hamiltonian parameters of **3** were determined to be $S = 3/2$, $g = 2.0043$, $D = 0.0238\ cm^{-1}$ and $E = 0.0004\ cm^{-1}$. For **4**, $S = 3/2$, $g = 2.0045$, $D = 0.0235\ cm^{-1}$ and $E = 0.0004\ cm^{-1}$ were obtained. D of **3** is larger than that of **1** by about 2%. The small difference means that the unpaired electron is almost localized within the phenylanthracene

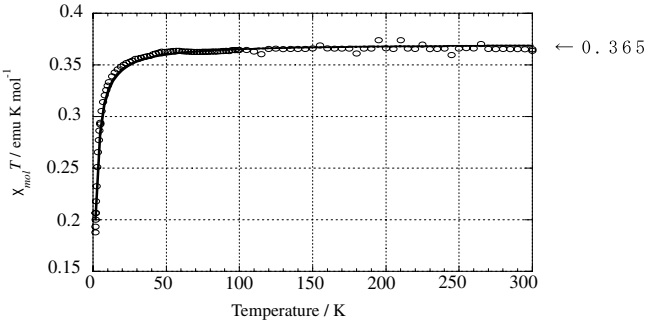

Fig. 3. Temperature dependence of $\chi_{mol}T$ plots for **3**; solid line corresponds to calculation using the Curie–Weiss law.

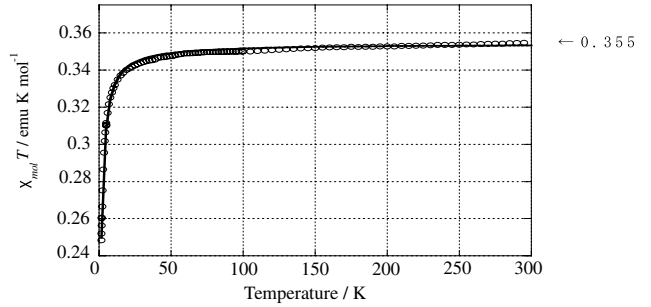

Fig. 4. Temperature dependence of $\chi_{mol}T$ plots for **4**; solid line corresponds to calculation using the Curie–Weiss law.

and the radical moieties and the delocalization toward the 3-pyridinyl group is a little. This result is also supported by the molecular orbital calculation (Fig. 5). Interestingly, spectral intensity of **3** is stronger than that of **1**. The spectral intensity of **4** is also stronger than that of **2** (TRESR signal of **2** was not clearly observed because of the weak intensity). The result shows that the attachment of the 3-pyridinyl group makes the intersystem crossing toward the quartet high-spin state more efficient. TRESR experiments revealed both radicals have the quartet ($S = 3/2$) high-spin photo-excited states.

Therefore, we can conclude that 3-pyridinyl substituted radicals **3** and **4** are used for the candidates of ligands to study the exchange interaction between the photo-excited high-spin state of π-radical and the paramagnetic centers of metal ions.

We have succeeded to synthesize complex **A** and **B**, when we used **4** as the ligand. Unfortunately, the crystals with a suitable size for a X-ray crystallographic analysis were not obtained at the moment.

The temperature dependences of $\chi_{mol}T$ for the complexes **A** and **B** in the range of 1.7–300 K are shown in Figs. 7 and 8, respectively. Solid lines in Figs. 7 and 8 are calculated using the Bleaney–Bowers model

$$\chi T = \frac{Ng^2\beta^2}{k}\frac{1}{3+\exp(-2J/kT)} \tag{1}$$

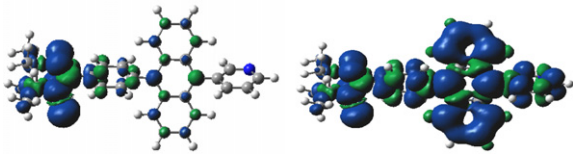

Fig. 5. Spin density of **3** by the molecular orbital calculation (left: ground state, right: excited state).

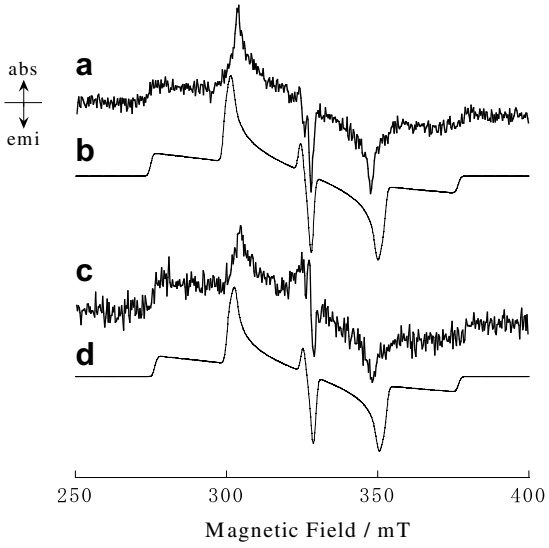

Fig. 6. TRESR spectra and simulations of **3** and **4** (a) spectrum of **3**, (b) simulation of **3**, (c) spectrum of **4**, and (d) simulation of **4**.

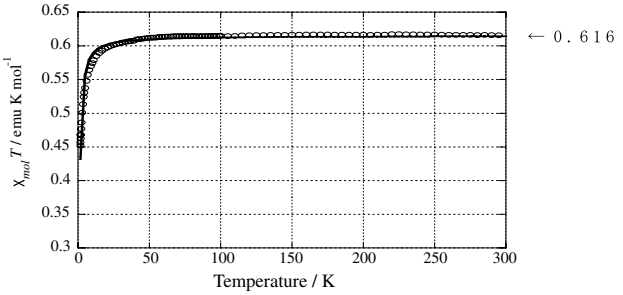

Fig. 7. Temperature dependence of $\chi_{mol}T$ plots for complex **A**; solid line corresponds to calculation using the Bleaney–Bowers model.

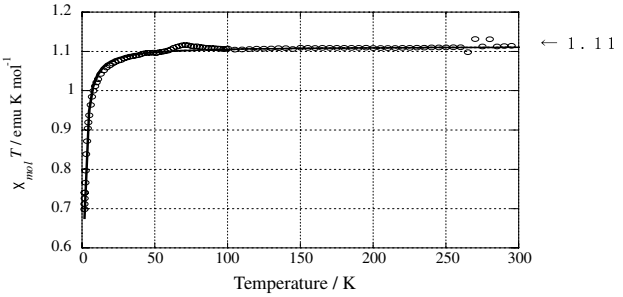

Fig. 8. Temperature dependence of $\chi_{mol}T$ plots for complex **B** (+toluene); solid line corresponds to calculation using three spin cluster model.

and three spin cluster model of S_1–S_M–S_2 ($S_1 = S_M = S_2 = 1/2$).

$$\chi T = \frac{Ng^2\beta^2}{4k}\frac{1+\exp(2J/kT)+10\exp(3J/kT)}{1+\exp(2J/kT)+2\exp(3J/kT)} \tag{2}$$

Here, N is the number of two spin dimmers or three spin clusters.

From the analysis, exchange interaction between the metal ion and the organic ligand of the complexes **A** and **B** were determined to be −0.86 and −1.0 K, respectively, showing weak exchange interactions between them in the ground states. These fitting are not enough accurate because the magnitudes of J values are very small. This is due to a little delocalizaton of the unpaired electron toward the 3-pyridinyl group in their electronic ground states of **4**. In the photo-excited quartet state, the unpaired electrons are expected to be more delocalized to the 3-pyridinyl group as with π-radical **3**. Therefore, the larger exchange interactions and photo-induced spin alignment are predicted between the paramagnetic centers of the metal ions and the photo-excited quartet states of the π-radicals, **3** and **4**. The TRESR experiments are going in progress to clarify the spin alignment in the photo-excited states of the metal complexes.

4. Conclusions

The pyridinyl substituted π-radicals **3** and **4** have the photo-excited quartet states. Their signal intensity of the quartet states become stronger than that of their parent radicals. We have succeeded to synthesize complexes **A**

and **B** using **4** as a ligand. Their magnetic properties were clarified and the exchange interactions between the metal ions and radicals are weak in the ground states.

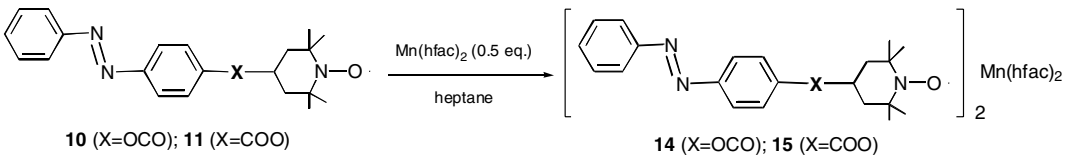
Scheme 2.

4-carboxyazobenzene (**4**) and 4-hydroxy-TEMPO (**7**) by the similar condensation reaction in 66% yield.

2.2. Photo-responsive properties of azobenzene derivatives *8–11*



Irradiation of the azobenzene with 4-dimethylamino-substituent (**8**) with an UV light in dichloromethane solution showed an apparent change of its absorption spectrum, suggesting occurrence of the photo-isomerization in the solution but the corresponding *cis*-isomer could not be isolated probably because of unstable nature of the isomer in the solid-state. Similarly, any attempt was failed to isolate the *cis*-isomer of 4-nitroazobenzene derivative (**9**) under the various conditions examined.

Table 1
Magnetic data of azobenzene derivatives **8–13**

Compound	Magnetic interaction	C (emu K mol^{-1})	θ (K)	J (K)
8	antiferromagnetic[a]	0.36	−12.3	
9	ferromagnetic[a]	0.32	0.26	
10	antiferromagnetic[a]	0.37	−3.2	
11	antiferromagnetic[b]			−47.6
12	ferromagnetic[a]	0.38	0.32	
13	ferromagnetic[a]	0.38	0.11	

[a] CW model.
[b] ST model.

On the other hand, the photo-isomerizations of the unsubstituted derivatives with no substituent at 4-position (**10** and **11**) was found to proceed smoothly and the

Scheme 3.

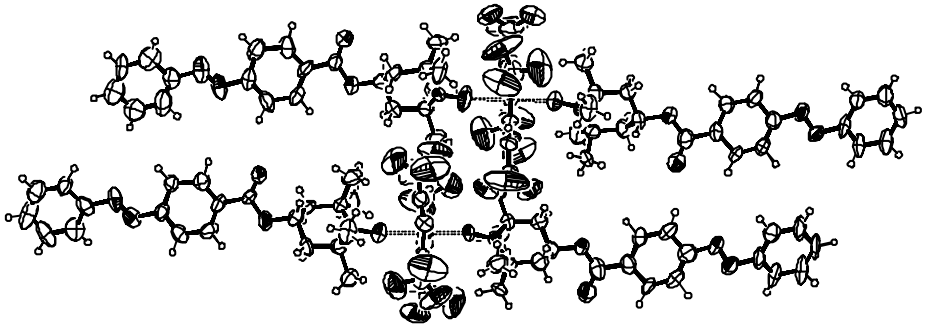


Fig. 1. Crystal structure of complex **15**.

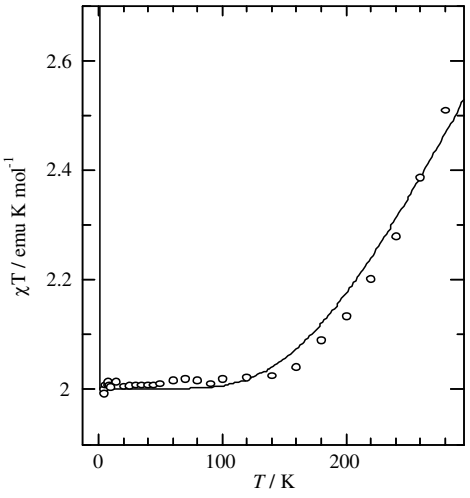

Fig. 2. Temperature dependence of χ_T-values of complex **15**. The theoretical data are shown in a solid line.

corresponding *cis*-isomers (**12** and **13**) could be isolated as relatively stable solid materials.

Thus, irradiation of the *trans*-isomer of an oxocarbonyl-TEMPO-substituent (**10**) with the light of 365 nm in benzene solution showed such an absorption change that a maximum at around 324 nm shifted gradually to a newly developed absorption at around 438 nm with an isosbestic point at 385 nm, while the reverse change was found to occur by irradiation of the latter solution with a fluorescent lamp and hence a reversible system could be constructed in this case (Scheme 2). Moreover, the *cis*-isomer **12** could fortunately be isolated as a relatively stable solid and was found to be durable without appreciable change when kept in the dark and stored in a refrigerator. Similar change was also observed for the isomer **11** to give the corresponding *cis*-isomer **13** as a relatively stable solid material.

2.3. Magnetic properties of azobenzene derivatives 8–13

The magnetic data were obtained by using SQUID susceptometer between the temperature range from 2 K to 300 K and the data for the azobenzenes **8**–**13** are summarized in Table 1. Thus, intermolecular magnetic interactions being based on Curie-Weiss (CW) law were observed in the *trans*-isomers **8** and **9** with relatively large antiferromagnetic interaction in 4-dimethyamino-substituted compound **8** and weak ferromagnetic one in 4-nitro derivative **9**, respectively. While weak antiferromagnetic interaction of CW behavior was apparent in the ester isomer **10**, fairly large exchange interaction ($J = -47.6$ K) of singlet–triplet (ST) model was revealed between the spins in the other ester isomer **11**. Regarding the magnetic properties of the corresponding *cis*-isomers **12** and **13**, both showed weak ferromagnetic interactions of CW behavior and thus, apparent change of intermolecular magnetic interactions could apparently be discerned between both of the photo-isomer couples (**10/12** and **11/13**).

2.4. Preparation and properties of Mn(hfac)$_2$ complexes formed from 10 or 11

When an ester isomer **10** was reacted with 0.5 equiv. of Mn(hfac)$_2$ in heated heptane solution [5], the corresponding Mn(hfac)$_2$ complex **14** was found to form in moderate yields (51%) (Scheme 3). [1]Similarly, a Mn(hfac)$_2$ complex **15** could be prepared from another ester isomer **11** (37%)

[1] Crystal data for **14**: $C_{54}H_{54}N_6O_{10}F_{12}Mn$, $F_W = 1229.97$, monoclinic ($P2_1/n$), $a = 21.7990(6)$ Å, $b = 15.0275(9)$ Å, $c = 35.6207(7)$ Å, $\beta = 96.400(5)°$, $V = 11596.1(6)$ Å^3, $T = 293$ K, $Z = 8$, $D_{calc} = 1.409$ mg cm^{-3}, $R = 0.1046$, $R_W = 0.1049$ [8481 observed reflections and 1603 parameters, $I > 3\sigma(I)$].

and the structure was substantiated by a X-ray analysis obtained by a single crystal of the complex (Fig. 1).

As illustrated in Fig. 1, there are two crystallographically independent complexes in the crystal of the manganese complex **15** and the *trans*-conformation of the azobenzene units are apparently seen for both of them. All of the interatomic distances between the manganese atom and the oxygen atoms of the aminoxyls fall approximately into *ca.* 2.1–2.2 Å [6], suggesting the formation of six-coordinate sphere around the metal centers with oxygen atoms from aminoxyls in *trans* apical fashion.

The magnetic data of the complex **15** are shown in Fig. 2 together with the fitting data as a solid line. The Curie constant at lower temperature region is estimated to be 2.01 emu K mol^{-1} and the gradual increase of the χ_T-values is observed along with the increase of temperatures. Preliminary fitting data shown in Fig. 2 are obtained by using an equation with three spin system of $S = 1/2$, 5/2 and 1/2 [7] and the exchange interaction between the correlating spins is estimated from the data to be $J = -133$ K.

Quite similar magnetic behavior was also observed in the spins of another complex **14** and slightly larger exchange interaction ($J = -147$ K) is suggested in the spins of this complex than that of the complex **15**.

We next tried to isomerize the complexes **14** or **15** photo-chemically under the similar condition with the parent radicals **10** and **11** but the complexes were found to be reluctant to the photo-isomerization and any effort to isolate the corresponding *cis*-isomers has so far been unsuccessful. Nevertheless, we are still making efforts to the possibility under different conditions.

In summary, we have prepared several azobenzene derivatives with a TEMPO radical (**8**–**11**) and explored their photo-responsive as well as magnetic properties. Among them, the *cis*-isomers of unsubstituted derivatives at 4-position and with a TEMPO group at 4′-position (**12** and **13**) could successfully be isolated as relatively stable solid materials showing apparent changes of intermolecular magnetic interactions between the photo-isomer couples. A couple of $Mn(hfac)_2$ complexes derived from isomeric TEMPO-substituted esters (**14** and **15**) were prepared and the magnetic properties of the complexes were investigated but the photo-isomerization but the isolation of the corresponding *cis*-isomers has so far been remained without success.

Found: C, 59.95; H, 3.97; N, 28.99%. ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C): δ 10.16 (s, 1H, CHO), 8.57 (dd, $J = 0.7$, 2.6 Hz, 2H, Pyz), 8.27 (s, 2H, Py), 7.81 (dd, $J = 0.7$, 1.6 Hz, 2H, Pyz), 6.54 (dd, $J = 1.6$, 2.6 Hz, 2H, Pyz).

2.1.3. 2,6-Di(pyrazol-1-yl)-4-(4,4,5,5-tetramethyl-1-oxido-3-ylooxy-4,5-dihydro-3H-imidazol-2′-yl)pyridine (dppNN)

N,*N*′-dihydroxy-2,3-diamino-2,3-dimethylbutane (150 mg, 1.04 mmol) in benzene (6 ml) was added to **3** (750 mg, 1.02 mmol) in benzene (7 ml) and stirred for 2 weeks to obtain white precipitate. The resulting white solid was filtered and dissolved with chloroform (10 ml) and then sodium periodate (215 mg, 1.00 mmol) in water (5 ml) was added. After stirring for 30 min, deep blue solution was obtained and the mixture was washed with water and extracted with dichloromethane. The crude product was purified by silica-gel column chromatography using ethylacetate/dichloromethane (3/1, v/v) as an eluent to yield 90 mg of dppNN (0.25 mmol, 42%). *Anal*. Calc. for $C_{18}H_{20}N_7O_2$: C, 59.01; H, 5.50; N, 26.76. Found: C, 59.21; H, 5.51; N, 26.96%.

2.1.4. [Fe(dppNN$_2$)$_2$](BF$_4$)$_2$ · (CH$_3$COCH$_3$) (*1*)

A solution of $Fe(BF_4)_2 \cdot 6H_2O$ (25 mg, 0.16 mmol) in degassed acetone (5 ml) was added to the blue solution of dppNN (35 mg, 0.06 mmol) in acetone (5 ml) and stirred for 30 min to obtain dark red solution. Diffusion of diethylether to the resulting solution gave dark red crystals of **1**. *Anal*. Calc. for $C_{62}H_{50}B_2F_8Fe_5N_{10} \cdot 4H_2O$: C, 51.00; H, 4.00; N, 9.59. Found: C, 51.18; H, 3.91; N, 9.50%.

2.2. X-ray crystallography

A crystal of **1** was mounted on a glass capillary, and data were collected at −70 °C (Bruker SMART APEX diffractometer coupled with a CCD area detector with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation). The structure was solved by a direct method and expanded by using Fourier techniques using SHELXTL program. Crystal data of **1** at −73 °C: $C_{39}H_{37}B_2F_8FeN_{14}O_5$, $M = 1011.30$, monoclinic space group $P2_1$, $a = 8.387(2)$, $b = 23.039(4)$, $c = 12.215(2)$ Å, $\beta = 96.587(3)°$, $V = 2346.4(7)$ Å^3, $Z = 2$. A total of 10 549 were collected ($3° < 2\theta < 47°$) of which 5439 unique reflections (R(int) = 0.0379) were measured. Residual R and wR were 0.0739 and 0.1941, respectively, from the refinement on F^2 with $I > 2\sigma(I)$. Empirical absorption corrections by SADABS (G.M. Sheldrick, 1994) were carried out. In the structure analyses, non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atoms.

2.3. Magnetic measurements

DC magnetic susceptibility data of **1** were collected by using a Quantum Design MPMS-XL SQUID magnetometer at temperatures ranging from 5 to 340 K. For the LIESST experiment, Xe lamp was used as light source and 500–600 nm light was isolated by using colour filter and was guided via an optical fiber into the SQUID magnetometer. Irradiation was performed inside the SQUID sample room at 5 K.

3. Results and discussion

3.1. Syntheses of dppNN and [Fe(dppNN)$_2$](BF$_4$)$_2$ · (CH$_3$COCH$_3$) (*1*)

A tridentate ligand of dppNN was synthesized from ethyl 2,6-di(pyrazol-1-yl)isonicotinate[7] by three-step reactions. In

the first step, the carboxyethyl group was reduced by sodium borohydrate affording a hydroxymethyl group, and the hydroxymethyl group was oxidized to a formyl group by the Swern oxidation in the second step. A reaction of formyl compound with *N*,*N*′-dihydroxy-2,3-diamino-2,3-dimethylbutane followed by an oxidation with sodium periodate yielded the ligand dppNN in a moderate yield. An Iron(II) complex of $[Fe(dppNN)_2](BF_4)_2 \cdot (CH_3COCH_3)$ (**1**) was obtained by a reaction of dppNN with $Fe(BF_4)_2 \cdot 6H_2O$. All compounds were characterized by elemental analyses.

3.2. Description of crystal structure: *1*

X-ray crystal structure analysis for **1** was performed at 200 K, and ORTEP diagram of the complex molecule was depicted in Fig. 1. **1** crystallized in monoclinic space group $P2_1$, and the asymmetric unit is composed of one complex cation, two tetrafluoroborate anions, and one acetone molecule. A central iron(II) ion is coordinated by six nitrogen atoms from two tridentate dppNN giving distorted octahedral coordination geometry. Coordination bond lengths of Fe–N1 and Fe–N8 (N1 and N8 are pyridyl nitrogen atoms) are 1.889(6) Å and 1.903(6) Å, respectively, which are shorter than the coordination bond lengths of Fe^{II} ion with pyrazole nitrogen atoms (Fe–N2, N4, N9 and N11: 1.958(6)–1.983(7) Å). The average coordination bond length of 1.948 Å and bite angles (N1–Fe–N2, –N5, N8–Fe–N9, –N12) of 79.7(3)–80.4(3) are typical values for low spin iron(II) ions in the series of this tridentate ligand [9]. Interatomic distances of N–O groups in nitronyl nitroxides are in the range of 1.26(1)–1.28(1) Å for N6–O1, N7–O2, N13–O3 and N14–O4, respectively, which are characteristic of radical centers. It should be mentioned that no significant intermolecular contact between the NO groups of dppNN (>4 Å) was observed and cations are magnetically isolated.

3.3. Magnetic susceptibility measurements of *1*

Magnetic susceptibility measurements for **1** was done in the temperature range of 5–340 K and a $\chi_m T$–T plot was shown in Fig. 2. The $\chi_m T$ values below 130 K are almost constant (0.83 emu mol^{-1} K), which corresponds to the uncorrelated two radical spins. It is pointed out that coordination bond lengths at 200 K are typical values for low-spin iron(II) ions, which magnetically isolate two radicals in the molecule. Sudden decrease of the $\chi_m T$ values below 30 K is due to weak intermolecular antiferromagnetic interactions between dppNN radicals. As the temperature was increased up to 340 K, gradual increase of $\chi_m T$ values was observed and this increase was recovered in the cooling process, suggesting this phenomenon being a reversible thermal spin-crossover phenomenon. A $\chi_m T$ value of 1.21 emu mol^{-1} K at 340 K corresponds to 14% of the central iron(II) ion being in the high spin state. The sum of Curie constants for isolated iron(II) ion and two radicals is 3.75 emu mol^{-1} K, and the critical temperature of the spin transition is higher than 340 K. When the sample was irradiated with 500–600 nm light at 5 K, the $\chi_m T$ values of **1** abruptly increased, suggesting that the metastable HS state was trapped. The $\chi_m T$ values of the light irradiated sample (metastable high-spin state) increased as the temperature was increased, reaching a maximum value of 1.27 emu mol^{-1} K at 26 K. The $\chi_m T$ value is smaller than the value

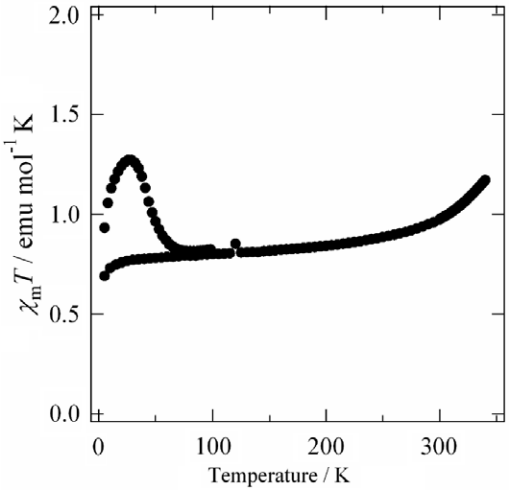

Fig. 2. $\chi_m T$–T plot for **1**.

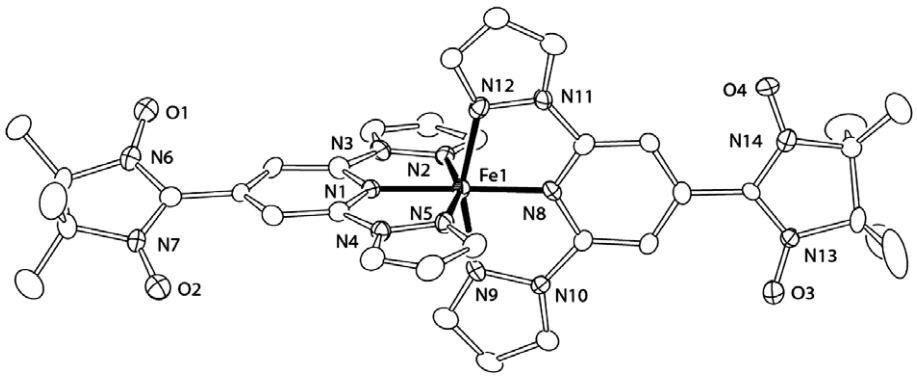

Fig. 1. ORTEP diagram of **1**. Selected interatomic distances (Å) for **1**: Fe1–N1 1.889(6), Fe1–N2 1.974(6), Fe1–N5 1.958(6), Fe1–N8 1.903(6), Fe1–N9 1.983(7), Fe–N12 1.982(8), O1–N6 1.28(1), O2–N7 1.27(1), O3–N13 1.26(1), O4–N14 1.27(1).

(3.75 emu mol^{-1} K) expected for the isolated iron(II) ion and two radicals, and this might be due to the incomplete spin conversion or antiferromagnetic interactions between high spin iron(II) ion and organic radicals. Further increase of temperature resulted in sudden decrease of $\chi_m T$ values, which indicates the occurrence of complete relaxation from the metastable HS state to the LS state.

4. Conclusion

We prepared a novel iron(II) complex with nitronyl nitroxide radicals, and its structure and magnetic property were studied. Magnetic susceptibility measurement suggests central iron(II) ion show the thermal spin transition with a critical temperature higher than 340 K, and LIESST phenomenon was confirmed by light irradiation at 5 K.

2. Experimental

2.1. Syntheses

All reagents were purchased and used without further purification. Schiff base ligands of $H_2$5-Br-sae, $H_2$3-OMe-sap, $H_2$5-Br-sap, and H_2sap were prepared by condensation reactions of corresponding salicylaldehyde with aminoethyl alcohol or aminopropyl alcohol.

*[$Mn^{III}Cu^{II}$(**5**-Br-sap)$_2$Cl(EtOH)] (**1**)*: 5-Br-salicylaldehyde (201 mg, 1.0 mmol), 3-aminopropanol (75 mg, 1.0 mmol) and triethylamine (202 mg, 2.0 mmol) were dissolved in ethanol (20 ml), forming yellow solution. $MnCl_2 \cdot 4H_2O$ (198 mg, 1.0 mmol) in ethanol (10 ml) was added to the yellow solution to obtain dark brown solution, and $CuCl_2 \cdot 2H_2O$ (56 mg, 0.33 mmol) in ethanol (10 ml) was added. The reaction mixture was allowed to stand for overnight to give dark brown crystals of **1**. *Anal.* Calc. for $C_{22}H_{26}N_2Br_2Cl_1Cu_1Mn_1O_5 \cdot C_2H_5OH \cdot H_2O$: C, 37.13; H, 4.41; N, 3.61; Cu, 8.92; Mn, 7.71. Found: C, 37.03; H, 4.22; N, 3.46; Cu, 8.33; Mn, 7.47%.

*[$Mn^{III}Cu^{II}$(5-Cl-sap)$_2$Cl(MeOH)] (**2**)*: Dark brown crystals of **2** were obtained in the same manner as **1** using 5-Cl-salicylaldehyde as a starting material. *Anal.* Calc. for $C_{21}H_{24}N_2Cl_3Cu_1Mn_1O_5 \cdot H_2O$: C, 40.21; H, 4.17; N, 4.46; Cu, 10.43; Mn, 9.02. Found: C, 40.19; H, 3.56; N, 4.47; Cu, 10.29; Mn, 9.21%.

[$Mn^{III}_2Cu^{II}_2$(5-Br-sap)$_4$(H_2O)$_2$](ClO_4)$_2$ (**3**(ClO_4)$_2$): 5-Br-salicylaldehyde (201 mg, 1.0 mmol), 3-aminopropanol (75 mg, 1.0 mmol) and triethylamine (202 mg, 2.0 mmol) were dissolved in acetonitrile (10 ml), forming yellow solution. $Mn(ClO_4)_2 \cdot 6H_2O$ (288 mg, 1.0 mmol) in acetonitrile (10 ml) was added to the yellow solution to give dark brown solution and $Cu(ClO_4)_2 \cdot 6H_2O$ (124 mg, 0.33 mmol) in acetonitrile (10 ml) was added. The reaction mixture was allowed to stand for 3 days to obtain dark brown crystals of **3**$(ClO_4)_2$. *Anal.* Calc. for $C_{40}H_{44}N_4Br_4Cl_2Cu_2Mn_2O_{18} \cdot CH_3CN$: C, 32.81; H, 3.08; N, 4.56; Cu, 8.92; Mn, 7.71. Found: C, 32.61; H, 2.85; N, 4.26; Cu, 7.65; Mn, 7.68.

[$Mn^{III}Cu^{II}_3$(5-Br-sae)$_4$(H_2O)$_2$](PF_6)·2Et_2O (**4**(PF_6) · 2Et_2O): 5-Br-salicylaldehyde (201 mg, 1.0 mmol), 2-aminoethanol (61 mg, 1.0 mmol) and triethylamine (202 mg, 2.0 mmol) were dissolved in methanol (20 ml), forming yellow solution. $MnCl_2 \cdot 4H_2O$ (198 mg, 1.0 mmol) in methanol (10 ml) was added to the yellow solution to give dark brown solution and $CuCl_2 \cdot 2H_2O$ (56 mg, 0.33 mmol) in methanol (10 ml) was added. After stirring for 30 min, $AgPF_6$ was added to the reaction mixture and AgCl was removed by suction. After standing for overnight, resulting precipitate was filtered off and dissolved in acetonitrile. The slow diffusion of diethylether to the acetonitrile solution gave green crystals of **4**$(PF_6) \cdot 2Et_2O$. *Anal.* Calc. for $C_{36}H_{36}N_4Br_4Cu_3F_6Mn_1O_{10}P_1$: C, 31.00; H, 2.60; N, 4.02; Cu, 13.67; Mn, 3.94. Found: C, 31.35; H, 2.55; N, 3.95; Cu, 13.99; Mn, 3.73%.

*[$Mn^{III}_2Mn^{II}_2Cu^{II}_4$(3-OMe-sap)$_4$($\mu_4$-O)$_2$($\mu_2$-OMe)$_2Cl_2$]$Cl_2$ · 2MeOH (**5**Cl_2 · 2MeOH)*: *o*-vaniline (152 mg, 1.0 mmol), 3-amino-1-propanol (75 mg, 1.0 mmol) and triethylamine (202 mg, 2.0 mmol) were dissolved in methanol (20 ml), forming yellow solution. $MnCl_2 \cdot 4H_2O$ (198 mg, 1.0 mmol) in methanol (10 ml) was added to the yellow solution to give dark brown solution, and $CuCl_2 \cdot 2H_2O$ (114 mg, 0.67 mmol) in methanol (10 ml) was added. The reaction mixture was allowed to stand for a week to obtain dark green crystals of **5**$Cl_2 \cdot 2$MeOH. *Anal.* Calc. for $C_{46}H_{58}N_4Cl_4Cu_4Mn_4O_{16} \cdot 2H_2O$: C, 35.08; H, 3.97; N, 3.56; Cu, 16.14; Mn, 13.95. Found: C, 35.20; H, 4.15; N, 3.29; Cu, 16.18; Mn, 13.95%.

[$Mn^{III}_2Ni^{II}_2$(sap)$_2$(sal)$_2$(μ_3-OMe)$_2$(OAc)$_2$] (**6**): Salicylaldehyde (= Hsal, 122 mg, 1.0 mmol), 3-amino-1-propanol (75 mg, 1.0 mmol) and triethylamine (202 mg, 2.0 mmol) were dissolved in methanol (20 ml), forming yellow solution. $Mn(CH_3COO)_2 \cdot 4H_2O$ (246 mg, 1.0 mmol) in methanol (10 ml) was added to the yellow solution to obtain dark brown solution. To the dark brown solution, green mixture of Hsal (122 mg, 1.0 mmol), triethylamine (202 mg, 2.0 mmol), and $Ni(CH_3COO)_2 \cdot 4H_2O$ (248 mg, 1.0 mmol) in methanol (30 ml) was added. The reaction mixture was allowed to stand for one night to give dark green crystals of **6**. *Anal.* Calc. for $C_{40}H_{44}N_2Mn_2Ni_2O_{14} \cdot H_2O$: C, 47.00; H, 4.53; N, 2.74; Mn, 10.75; Ni, 11.48. Found: C, 47.17; H, 4.67; N, 2.67; Mn, 10.69; Ni, 11.88%.

[$Mn^{III}_2Ni^{II}_2$(sap)$_2$(sal)$_2$(μ_3-OMe)$_2$(NO_3)$_2$(MeOH)$_2$] (**7**): Dark green crystals of **7** were obtained in the same manner as **6** using $Mn(NO_3)_2 \cdot 6H_2O$ and $Ni(NO_3)_2 \cdot 6H_2O$ as metal sources. *Anal.* Calc. for $C_{38}H_{46}N_4Mn_2Ni_2O_{19}$: C, 41.87; H, 4.49; N, 5.14; Mn, 10.06; Ni, 10.75. Found: C, 41.96; H, 4.25; N, 5.05; Mn, 9.66; Ni, 10.78%.

2.2. X-ray crystallography

All crystals were mounted on a glass capillary, and data were collected at −70 °C (Bruker SMART APEX diffractometer coupled with a CCD area detector with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation), respectively. Structures were solved by direct methods and expanded by using Fourier techniques using SHELXTL program. Crystal data for the complexes were summarized in Table 1. Empirical absorption corrections by SADABS (G.M. Sheldrick, 1994) were carried out. In the structure analyses, non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atoms.

2.3. Physical measurements

DC magnetic susceptibility data were collected by using a Quantum Design MPMS-XL SQUID magnetometer at temperatures ranging from 1.8 to 300 K.

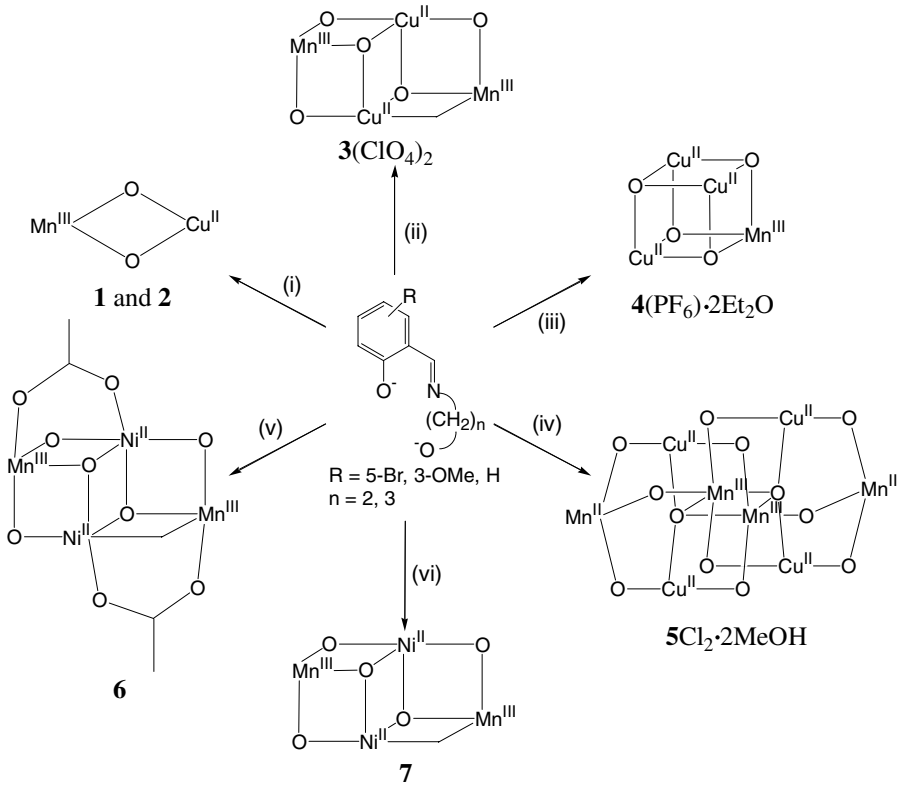
3. Results and discussion

3.1. Syntheses of Mn–Cu and Mn–Ni hetero-metal clusters

The Mn–Cu and Mn–Ni hetero-metal clusters, **1**–**7**, were synthesized by simple reactions of multidentate schiff base ligands ($H_2$5-Br-sae, $H_2$3-OMe-sap, $H_2$5-Br-sap, and H_2sap) (Scheme 1), with metal sources and suitable co-ligands (Scheme 2). All reactions possessed good selectivity for the target compounds, and the selectivity can be achieved by optimization of reaction conditions. The dinuclear complex of **1** and **2** were synthesized by the reaction of tridentate Schiff base ligand (5-Br-sap^{2-}) and metal chlorides with a reaction ratio of 3:3:1. The similar reaction in acetonitrile using metal perchlorate gave a tetranuclear complex of **3**$(ClO_4)_2$. The tetranuclear complex of **4**$(PF_6) \cdot 2Et_2O$ was obtained by using metal chloride and 5-Br-sae^{2-} followed by removing chloride ions with $AgPF_6$. On the other hand, octanuclear complex of **5**$Cl_2 \cdot 2MeOH$ was synthesized by employing a quadridentate Schiff base ligand of 3-OMe-sap^{2-}. $Mn^{III}_2Ni^{II}_2$ tetranuclear clusters of **6** and **7** were obtained by the reactions of tridentate Schiff base ligand (sap^{2-}), bidentate co-ligand (sal^{1-}), and metal sources, where **6** and **7** were obtained as acetate and nitrate salts.



Scheme 1.

3.2. Descriptions of crystal structures

3.2.1. [$Mn^{III}Cu^{II}$(5-Br-sap)$_2$Cl(EtOH)] (**1**) and [$Mn^{III}Cu^{II}$(5-Cl-sap)$_2$Cl(MeOH)] (**2**)

An ORTEP diagram of a Mn–Cu dinuclear complex of **1** is shown in Fig. 1. **1** crystallizes in monoclinic space group $P2_1/c$ with the molecule lying on the crystallographic centre of inversion. The Crystal structure of **1** is isostructural with the previously reported dinuclear complex of [$Mn^{III}Cu^{II}$(5-Br-sap)$_2$Cl(MeOH)] [13], and **1** has a dinu-

(i) $MnCl_24H_2O$, $1/3CuCl_24H_2O$, MeOH, (ii) (1) $MnCl_24H_2O$, $1/3CuCl_24H_2O$, MeOH (2) $AgPF_6$, MeCN, (iii) $Mn(ClO_4)_26H_2O$, $1/3Cu(ClO_4)_26H_2O$, MeCN, (iv) $MnCl_24H_2O$, $2/3CuCl_24H_2O$, MeOH, (v) $Mn(OAc)_24H_2O$, $Ni(OAc)_24H_2O$, sal^{1-}, MeOH, (vi) $Mn(NO_3)_26H_2O$, $Ni(NO_3)_26H_2O$, sal^{1-}, MeOH.

clear structure composed of a Mn^{III} and Cu^{II} core doubly bridged by two alkoxo groups. The dc magnetic susceptibility data and bond valence sum (BVS) considerations (3.05 and 2.02 for Mn^{III} and Cu^{II} ions, respectively) support that **1** is not a 1:1 mixture but a mixed metal system. The dinuclear unit has a crystallographic inversion, and the Mn^{III} and Cu^{II} ion sites are, therefore, positionally disordered. The coordination geometry about Mn^{III} and Cu^{II} ions are presumed to be octahedral and square planar geometry, respectively. Equatorial coordination sites of the Mn^{III} ion are occupied by three oxygen atoms and one nitrogen atom from the tridentate Schiff base ligand, and the axial sites of Mn^{III} ion are occupied by an oxygen atom of coordinating ethanol molecule and a chloride ion. Coordination bond lengths in the equatorial plane are in the range of 1.871(6)–1.959(7) Å, while the axial coordination bonds showed significant elongation (2.477(11) and 2.694(5) Å) which is due to the Jahn–Teller distortion. The coordination bond lengths for Cu^{II} ions are the same as those for the corresponding coordination bonds of Mn^{III} ion due to the crystallographic inversion centre. The Cu^{II} and Mn^{III} ions are bridged by alkoxo groups with bridging angles of 102.0(2)°. The crystallographic data and the molecular structure of **2** were similar to those of **1** except for the coordinating solvent molecule and substituent group on the ligand (Fig. 2). The coordination bond lengths for the equatorial coordination sites of Mn^{III} and Cu^{II} ions are 1.871(6)–1.959(7) Å, and the Jahn–Teller axis of Mn^{III} ion involves an oxygen atom of methanol and a chloride ion with inter-atomic distances of 2.573(7) and 2.662(3) Å, respectively. BVS calculations gave values of 3.00 and 1.99 for Mn^{III} and Cu^{II} ions, respectively. The bridging angle between Mn^{III} and Cu^{II} ions (Mn1–O2–Cu1) are 101.84(15)°.

3.2.2. $[Mn^{III}_2Cu^{II}_2(5\text{-}Br\text{-}sap)_4(H_2O)_2](ClO_4)_2$ (**3**$(ClO_4)_2$)

The tetranuclear complex of **3**$(ClO_4)_2$ crystallizes in triclinic space group $P2_1/c$ and crystallographic inversion centre exists in the middle of the complex cation. The tetranuclear core consists of an incomplete face-sharing double cube composed of two Mn^{III} and two Cu^{II} ions (Fig. 3). Assignments of metal ions were confirmed by the BVS calculations (3.22 and 2.09 for Mn^{III} and Cu^{II} ions, respectively) and the short coordination bond lengths for Mn^{III} ions. The Mn^{III} and Ni^{II} ions are doubly bridged to form a dinuclear unit by two oxygen atoms (O2 and O4), and the symmetrically related dinuclear cores are linked by two phenoxo (O1 and O1$^{\#}$) and two alkoxo groups (O4 and O4$^{\#}$) in μ_2 and μ_3 fashions, respectively. The Mn^{III} ions have N_1O_5 chromophore in which equatorial sites and one of the axial sites are occupied by four oxygen atoms and one nitrogen atom from the Schiff base ligands and remaining axial sites are coordinated by a water molecule, leading to the distorted octahedral coordination geometry. The coordination bond lengths about Mn^{III} ions are in the range of 1.851(4)–2.008(5) Å for the equatorial sites (Mn1–N2, O2, O3, O4), and 2.312(5) and 2.329(4) Å for the axial sites (Mn1–O5, Mn1–O1$^{\#}$). The coordination

Symmetry operation #: $-x$, y, $-z+1/2$.

geometry of Cu^{II} ions is square pyramidal, and equatorial positions are occupied by three oxygen atoms (O1, O2, O4) and one nitrogen atom (N1) with coordination bond lengths of 1.896(4)–2.004(4) Å. The apical position of the Cu^{II} ions is weakly coordinated by oxygen atom ($O4^{\#}$) of μ_3-alkoxo group and the bond length of Cu1–$O4^{\#}$ is 2.585(4) Å. The bridging angles between Cu^{II} and Mn^{III} ions are 96.17(16)–105.33(17)°, while Cu1–O4-$Cu1^{\#}$ is 96.94(16)°.

3.2.3. $[Mn^{III}Cu^{II}_3(5\text{-}Br\text{-}sae)_4(H_2O)_2](PF_6)\cdot 2Et_2O$ ($\mathbf{4}(PF_6)\cdot 2Et_2O$)

The ORTEP drawing of **4** is shown in Fig. 4. The crystal of $\mathbf{4}(PF_6)\cdot 2Et_2O$ has monoclinic space group $P2/c$ and the unit cell contains two complex cations, two counter anions, and four diethylether molecules. The complex cation is composed of a tetranuclear cubic core, in which four metal ions are bridged by four μ_3-alkoxo groups from the Schiff base ligands. The cubic core contains two crystallographically independent metal ions with square pyramidal or distorted octahedral coordination geometries, and the two sets of metal ions are related by the crystallographic two-fold axis passing through the centre of the complex cation. The valence sum considerations, elemental analysis, and dc magnetic susceptibilities measurement suggested that the complex cation is constructed by three Cu^{II} ions and one Mn^{III} ion. Consequently, the five-coordinated metal ions are assigned to Cu^{II} ions, while symmetrically related two six-coordinated metal ions can be considered to be positionally disordered Mn^{III} and Cu^{II} ions, respectively. The equatorial coordination bond lengths of the square pyramidal Cu^{II} coordination sites are in the range of 1.898(5)–1.953(5) Å, and the apical position is coordinated by an alkoxo group of the Schiff base ligand with coordination bond length of 2.511(5) Å. The positionally disordered Mn^{III} and Cu^{II} ions have distorted octahedral geometry with elongated axis along O4–Mn1–O5, and the coordination bond lengths with axial atoms are 2.319(5) and 2.534(5) Å for Mn1–O5 and Mn1–O4, respectively. Bridging angles of metal ions with alkoxo groups are in the range of 89.93(16)–109.7(2)°.

3.2.4. $[Mn^{III}_2Mn^{II}_2Cu^{II}_4(3\text{-}OMe\text{-}sap)_4(\mu_4\text{-}O)_2(\mu_2\text{-}OMe)_2Cl_2]Cl_2 \cdot MeOH$ ($\mathbf{5}Cl_2 \cdot 2MeOH$)

$\mathbf{5}Cl_2 \cdot 2MeOH$ crystallizes in monoclinic space group $P2_1/n$ and complex cation situated on the crystallographic inversion centre (Fig. 5). **5** has hexanuclear Mn^{III}_2 Cu^{II}_4 core bridged by μ_4-oxo and μ_2-alkoxo groups, and peripheral Mn^{II} ions are attached to the Cu^{II} and Mn^{III} ions in the core by μ_2-phenoxo- and μ_2-methoxo-bridges, respectively. In **5**, Schiff bases act as quadridentate ligands to construct octanuclear core. The metal assignment and their oxidation states were confirmed by considering coordination bond lengths, existence of Jahn–Teller elongation, and BVS calculations (3.11, 2.06, 1.82 and 1.98 for Mn1, Mn2, Cu1 and Cu2 ions, respectively). Mn^{III} ions have a five-coordinated square pyramidal coordination geometry. The equatorial coordination sites of Mn^{III} ions are occupied by four oxygen atoms (O2, O5, O7, and O8) from two Schiff base ligands, one μ_4-oxo and μ_2-alkoxo groups, respectively, and $O7^{\#}$ ion coordinates from the apical position. The coordination geometries of four-coordinated Cu^{II} ions are square planar with N_1O_3 chromophore and coordination bond lengths are in the range of 1.932(3)–2.036(2) and 1.911(2)–1.959(2) Å for Cu1 and Cu2 ions, respectively. Mn^{II} ions have octahedral coordination geometry, where two Schiff base ligands coordinate to the Mn^{II} ions with phenoxy and methoxy groups acting as bidentate ligands. The remaining coordination sites are occupied by μ_2-alkoxo and chloride ions. The coordination bond lengths of Mn^{II} ions are in the range of 2.119(3)–2.4335(12) Å, which are apparently longer than those of Mn^{III} ions.

3.2.5. $[Mn^{III}_2Ni^{II}_2(sap)_2(sal)_2(\mu_3\text{-}OMe)_2(OAc)_2]$ (**6**) and $[Mn^{III}_2Ni^{II}_2(sap)_2(sal)_2(\mu_3\text{-}OMe)_2(NO_3)_2(MeOH)_2]$ (**7**)

The ORTEP diagrams of tetranuclear complexes **6** and **7** are shown in Figs. 6 and 7. Both complexes crystallized in triclinic space group $P\bar{1}$. The complex **6** has an incomplete face-sharing double cubane core composed of two Mn^{III} and two Ni^{II} ions (Fig. 6). The metal ions were assigned by BVS calculations and observations of Jahn–Teller elongations for the Mn^{III} ions. BVS calculations gave the values of 3.18 and 2.12 for Mn^{III} and Ni^{II} ions, respectively. The Mn^{III} ions are coordinated by tridentate Schiff base ligands forming mononuclear units, while Ni^{II} ion constructs mononuclear unit with bidentate co-ligands (sal^{1-}). These mononuclear units are linked to form a planar Mn^{III}–Ni^{II} dinuclear unit by μ_2-alkoxo and μ_3-methoxo groups, where additional acetate ion bridged the Mn^{III} and Ni^{II} ions from the axial direction supporting dinuclear core. The crystallographically related two dinuclear units are bridged by μ_2-phenoxo and μ_3-methoxo groups to form the tetranuclear core. The equatorial sites of six-coordinated Mn^{III} ions are occupied by N1, O1, O2, O7 atoms with bond lengths of 1.865(2)–2.021(3) Å, and the axial coordination bond lengths are 2.340(2) and 2.198(2) Å, which are significantly elongated due to Jahn–Teller distortions. The Ni^{II} ions

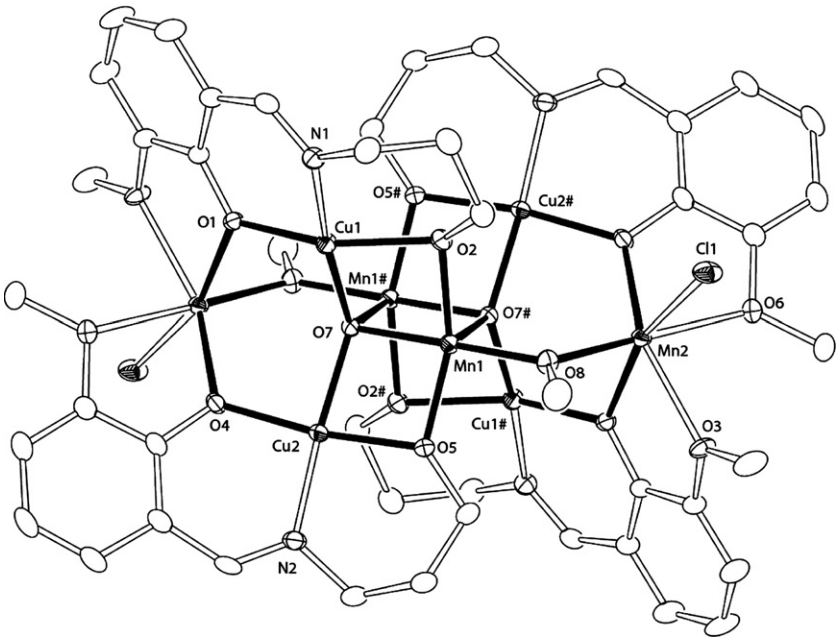

Fig. 5. ORTEP drawing of $\mathbf{5}Cl_2 \cdot 2MeOH$. Symmetry operation #: $-x+2$, $-y+1$, $-z$.

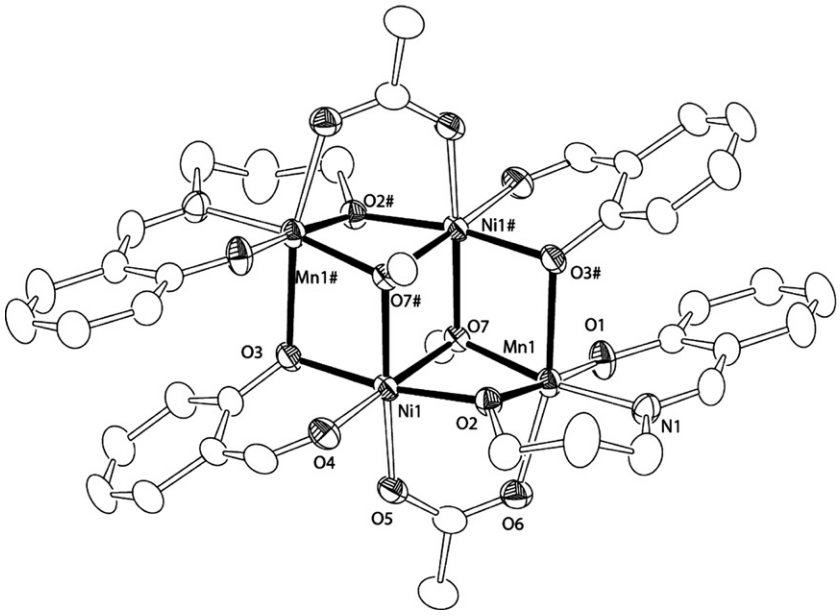

Fig. 6. ORTEP drawing of **6**. Selected bond lengths (Å) and angles (°); Mn(1)–O(1) 1.865(2), Mn(1)–O(2) 1.873(2), Mn(1)–O(7) 1.966(2), Mn(1)–N(1) 2.021(3), Mn(1)–O(6) 2.198(2), Mn(1)–O(3)# 2.340(2), Mn(1)–Ni(1) 2.9614(7), Ni(1)–O(3) 2.006(2), Ni(1)–O(2) 2.027(2), Ni(1)–O(5) 2.032(2), Ni(1)–O(4) 2.044(2), Ni(1)–O(7) 2.0766(19), Ni(1)–O(7)# 2.094(2), Mn(1)–O(2)–Ni(1) 98.74(9), Ni(1)–O(3)–Mn(1)# 94.19(8), Mn(1)–O(7)–Ni(1) 94.16(8), Mn(1)–O(7)–Ni(1)# 103.61(8), Ni(1)–O(7)–Ni(1)# 98.19(8). Symmetry operation #: $-x+1$, $-y+1$, $-z+1$.

with six-coordinated octahedral geometry have coordination bond lengths of 2.027(2)–2.094(2) Å, which are longer than those of Mn^{III} ions. **7** has a similar structural feature as **6** except for the bridging structure between Mn^{III} and Ni^{II} ions (Fig. 7). In the case of **6**, Mn^{III} and Ni^{II} ions in the dinuclear unit were bridged by μ_2-alkoxo, μ_3-methoxo, and μ_2-acetato groups, while in **7** bridging μ_2-acetato groups were replaced with methanol molecules and nitrate ions. It is noted that those different bridging structures lead to the significant difference in the magnetic interactions between Mn^{III} and Ni^{II} ions. The equatorial coordination bond lengths of Mn^{III} ions are in the range of 1.855(4)–

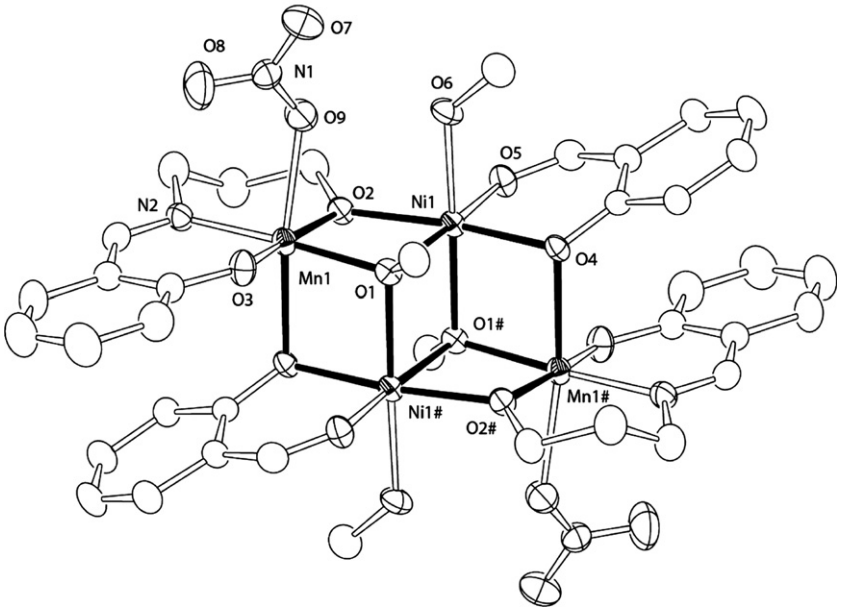

Fig. 7. ORTEP drawing of **7**. Selected bond lengths (Å) and angles (°); Mn(1)–O(3) 1.855(4), Mn(1)–O(2) 1.886(3), Mn(1)–O(1) 1.971(3), Mn(1)–N(2) 2.000(4), Mn(1)–O(4)#1 2.251(3), Mn(1)–O(9) 2.283(4), Ni(1)–O(4) 1.998(3), Ni(1)–O(2) 2.030(3), Ni(1)–O(5) 2.034(4), Ni(1)–O(1) 2.087(3), Ni(1)–O(6) 2.096(4), Ni(1)–O(1)#1 2.109(3), Ni(1)–Mn(1) 3.0758(11), Mn(1)–O(1)–Ni(1) 98.51(14), Mn(1)–O(1)–Ni(1)# 99.95(14), Ni(1)–O(1)–Ni(1)# 97.85(14), Ni(1)–O(4)–Mn(1)# 94.54(13), Mn(1)–O(2)–Ni(1) 103.45(15). Symmetry operation #: $-x$, $-y+2$, $-z+2$.

2.000(4) Å, and the axial coordination bond lengths are 2.251(3) and 2.283(4) Å. The Ni^{II} ions have an O_6 chromophore with bond lengths of 1.998(3)–2.109(4) Å. BVS calculations for Mn^{III} and Ni^{II} ions yielded the values of 3.19 and 2.05, which support the assignment of metal ions. The bridging angles between Ni^{II} and Mn^{III} ions for **6** and **7** are in the range of 94.19(8)–103.61(8)° and 94.54(13)–103.45(15)°, while the crystallographically related two Ni^{II} ions are bridged with the angles of 98.19(8)° and 97.35(14)° for **6** and **7** respectively.

3.3. Magnetic properties of the complexes 1–7

3.3.1. Magnetic properties of 1 and 2

The dc magnetic susceptibility measurements for **1** and **2** were performed in the temperature range of 1.8–300 K (Fig. 8). The $\chi_m T$–T curves for **1** and **2** were very similar to that for the previously reported dinuclear complex of $[Mn^{III}Cu^{II}(5\text{-Br-sap})_2Cl(MeOH)]$ [13], which was proven to be an SMM with $S = 5/2$ and $D = -1.86\ cm^{-1}$. The $\chi_m T$ values at 300 K are 3.91 emu mol^{-1} K and 3.85 emu mol^{-1} K for **1** and **2**, respectively, which is larger than the value (3.375 emu mol^{-1} K with $g = 2$) expected for the uncorrelated Mn^{III} and Cu^{II} ions. The $\chi_m T$ values gradually increased as decreasing the temperature, reaching the plateau values of 4.23 emu mol^{-1} K and 4.03 emu mol^{-1} K for **1** (100 K) and **2** (150 K), respectively. The temperature dependences of $\chi_m T$ values suggested the occurrence of ferromagnetic interactions between Mn^{III} and Cu^{II} ions to give $S = 5/2$ spin ground states in **1** and **2**. The smaller $\chi_m T$ values in the plateau compared with the theoretical value (4.20 emu mol^{-1} K) for the $S = 5/2$ state are due to smaller g value of Mn^{III} ions than 2.0. The sudden decrease of $\chi_m T$ values at lower temperature region is due to intermolecular antiferromagnetic interactions and/or zero-field splitting. The magnetic susceptibility data were analyzed using spin Hamiltonian of $H = -2J_{MnCu}S_{Mn} \cdot S_{Cu}$. The least squares calculations using the data above 24 K (**1**) and 50 K (**2**) gave the best fit parameters of $J_{MnCu} = +64\ cm^{-1}$, $g_{Mn} = 1.93$, $g_{Cu} = 2.10$ for **1**, and $J_{MnCu} = +85\ cm^{-1}$, $g_{Mn} = 1.90$, $g_{Cu} = 2.08$, $\theta = -1.96\ cm^{-1}$ for **2**, where θ is intermolecular magnetic interaction. The preliminary ac magnetic susceptibility measurements for **1** and **2** showed the frequency dependent out-of-phase ac susceptibilities (Figs. S1 and S2), suggesting both complexes being SMMs.

3.3.2. Magnetic properties of $3(ClO_4)_2$, $4(PF_6) \cdot 2Et_2O$, and $5Cl_2 \cdot 2MeOH$

The dc magnetic susceptibility measurements were carried out in the temperature range of 1.8–300 K and the results were depicted in Fig. 9. In $\mathbf{3}(ClO_4)_2$, the $\chi_m T$ value at 300 K is 6.80 emu mol^{-1} K, which is a good agreement with the spin only value for magnetically isolated two Mn^{III} and two Cu^{II} ions (6.75 emu mol^{-1} K, $g = 2$). Upon decreasing the temperature, the $\chi_m T$ value showed gradual increase down to 150 K, followed by the decrease at lower temperature, and this suggested that the ferromagnetic interactions are operative in high temperature region, followed by antiferromagnetic interactions leading to $S = 0$ spin ground state. Analyses of the susceptibility data for $\mathbf{3}(ClO_4)_2$ were carried out by using simple butterfly model, however, curve fitting was inferior, which might be due to the simplified model, and further analysis of the magnetic data has not been done yet. In the $\chi_m T$ versus T plot for $\mathbf{4}(PF_6) \cdot 2Et_2O$, $\chi_m T$ values shows steady decrease upon temperature was lowered, which suggests overall antiferromagnetic couplings among metal ions. The $\chi_m T$ value at 300 K is 3.38 emu mol^{-1} K, which is smaller than the Curie constant (4.13 emu mol^{-1} K) for uncorrelated one Mn^{III} and three Cu^{II} ions. The $\chi_m T$ value reached the minimum value of 0.5 emu mol^{-1} K at 1.8 K. The data was analyzed by using spin Hamiltonian of $H = -2J_{CuCu}(S_{Cu1} \cdot S_{Cu2} + S_{Cu2} \cdot S_{Cu3} + S_{Cu1} \cdot S_{Cu3}) - 2J_{CuMn}S_{Mn1} \cdot (S_{Cu1} + S_{Cu2} + S_{Cu3})$. The least squares calculation gave the best fit parameters of $J_{CuCu} = -12.4\ cm^{-1}$, $J_{MnCu} = -18.0\ cm^{-1}$, $g_{Mn} = 1.98$, and $g_{Cu} = 2.19$, with a spin ground state of $S = 1/2$. The $\chi_m T$ value at 300 K for $\mathbf{5}Cl_2 \cdot 2MeOH$ is 12.38 emu mol^{-1} K and showed constant decrease as temperature was lowered, reaching the value of 2.35 emu mol^{-1} K at

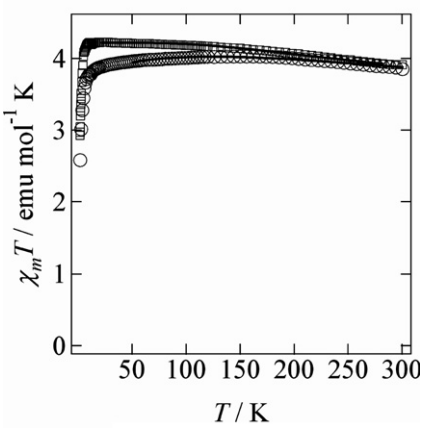

Fig. 8. $\chi_m T$ vs. T plots for **1** (□) and **2** (○).

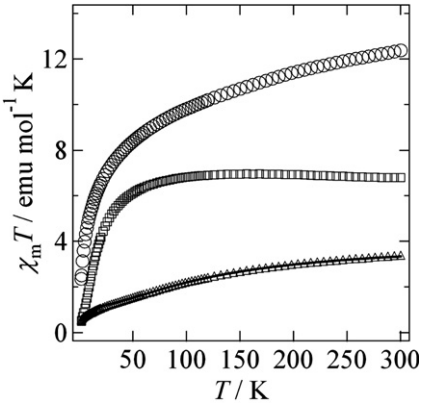

Fig. 9. $\chi_m T$ vs. T plots for $\mathbf{3}(ClO_4)_2$ (□), $\mathbf{4}(PF_6) \cdot 2Et_2O$ (△) and $\mathbf{5}Cl_2 \cdot 2MeOH$ (○).

1.8 K. The theoretical value expected for magnetically isolated four Cu^{II} and two Mn^{III} and Mn^{II} ions is 16.25 emu mol^{-1} K and the smaller value might be due to relatively strong antiferromagnetic interactions. The $\chi_m T$–T plot for **5**$Cl_2 \cdot 2MeOH$ indicated that overall antiferromagnetic interactions are dominant in whole temperature range and further analysis of magnetic data has not been carried out due to complicated magnetic interactions among the metal ions.

3.3.3. Magnetic properties of 6 and 7

DC magnetic susceptibility measurements were performed on **6** and **7** in the temperature range of 1.8–300 K. $\chi_m T$ versus temperature plots for complex **6** and **7** are shown in Fig. 10. In **6**, the $\chi_m T$ value at 300 K is 8.07 emu mol^{-1} K, which is close to the value (8.00 emu mol^{-1} K, $g = 2$) expected for the isolated two Mn^{III} and two Ni^{II} ions. Upon cooling the temperature, the $\chi_m T$ value gradually decreased and reached to 1.97 emu mol^{-1} K at 1.8 K, and this suggested the occurrence of antiferromagnetic interactions among metal centres. The temperature dependence of magnetic data above 20 K was analyzed by using simplified symmetrical butterfly model with spin Hamiltonian of $H = -2J_{MnNi}(S_T^2 - S_A^2 - S_B^2) - 2J_{NiNi}(S_A^2 - S_{Cul}^2 - S_{Cul}^2)$, where $S_A = S_{Ni1} + S_{Ni1\#}$, $S_B = S_{Mn1} + S_{Mn1\#}$, $S_T = S_A + S_B$. The least squares calculation gave the fit parameters of $J_{MnNi} = -1.80$ cm^{-1}, $J_{NiNi} = -3.41$ cm^{-1}, where g_{Ni} and g_{Mn} are fixed to be 2.2 and 1.9, and the spin ground state can be considered to be an $S = 2$. The $\chi_m T$ value at 1.8 K was smaller than the Curie constant (3.00 emu mol^{-1} K, $g = 2$) for an $S = 2$ state, which is due to zero-field splitting and/or intermolecular antiferromagnetic interactions. In complex **7**, the $\chi_m T$ value is 8.93 emu mol^{-1} K at 300 K, which is slightly larger than the spin only value of 8.00 emu mol^{-1} K expected for a complex consisting of two Mn^{III} and two Ni^{II} noninteracting ions. As lowering the temperature, $\chi_m T$ values gradually increased, reaching a maximum value of 17.65 emu mol^{-1} K at 5.00 K, followed by decrease down to 14.83 emu mol^{-1} K at 1.8 K. Based on temperature dependent susceptibility data ferromagnetic interactions were operative between the Mn^{III} and Ni^{II} ions, which is in contrast to **6**. The magnetic data for **7** was fitted by using the data above 20 K and the best fit parameters of $J_{MnNi} = +3.62$ cm^{-1}, $J_{NiNi} = -7.81$ cm^{-1}, $g_{Ni} = 2.2$ (fixed), and $g_{Mn} = 1.9$ (fixed) were obtained. The spin ground state was considered to be $S = 5$. The difference in the magnetic properties between **6** and **7** is originating from the bridging structures of the Mn^{III} and Ni^{II} ions. In **6**, the magnetic paths between Mn^{III} and Ni^{II} ions are through μ_2-alkoxo, μ_3-methoxo and μ_2-acetato bridges, among which antiferromagnetic pathways through acetate bridges might be predominant, leading to the lower spin ground state of $S = 2$. On the other hands, complex **7** has high spin ground state originating from ferromagnetic interactions through μ_2-alkoxo, μ_3-methoxo groups, which might be due to the accidental orthogonality of the magnetic orbitals.

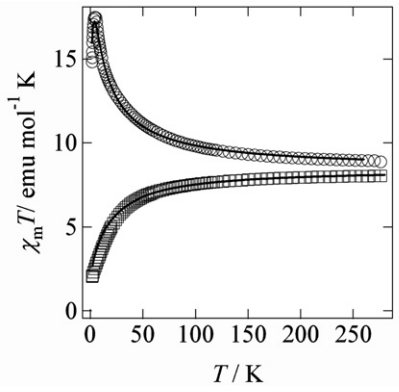

Fig. 10. $\chi_m T$ vs. T plots for **6** (□) and **7** (○).

4. Conclusion

A versatile synthetic method for multi-nuclear hetero-metal clusters has been developed, and a series of Mn–Cu clusters with the core structures of $[Mn^{III}Cu^{II}]$, $[Mn^{III}_2Cu^{II}_2]$, $[Mn^{III}Cu^{II}_3]$, and $[Mn^{III}_2Mn^{II}Cu^{II}_4]$, as well as Mn–Ni clusters with $[Mn^{III}_2Ni^{II}_2]$ cores were synthesized. This strategy might be applicable to prepare various 3d–3d and 3d–4f hetero-metal clusters by changing reaction conditions and slight modifications of bridging ligands. Further studies to obtain larger clusters are in progress.

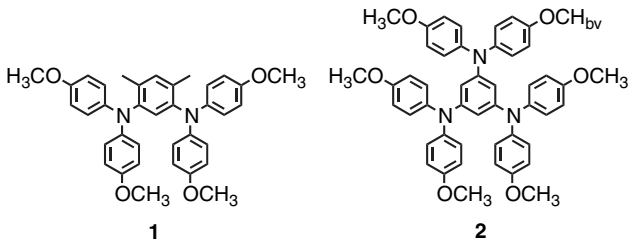

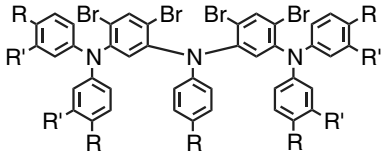

Fig. 1. Structures of *N*,*N*,*N*′,*N*′-tetrakis(4-anisyl)-4,6-dimethyl-1,3-phenylene-diamine (**1**) and *N*,*N*,*N*′,*N*′,*N*″,*N*″-hexakis(4-anisyl)-1,3,5-phenylene-triamine (**2**).

nutation (ESTN) method was applied to the di- and trication, unequivocally identifying the spin multiplicities in their triplet and quartet ground state, respectively. In the designed molecules, four or six methoxy groups, i.e., strong electrodonating groups, are introduced to stabilize the di- or tricationic states, respectively. We have examined the relationship for a number of 1,3-bis(diarylamino)benzenes as exemplified by **1**, establishing the molecular design rules to obtain diamine-based stable triplet dications in the ground state. Thus, an elaborate molecular design for tricationic entities has been challenging issues for us. Although we reported that a two-dimensionally extended triamine gives the corresponding stable trication in solution at low temperature [2b], as one-dimensionally extended triamines, 3,3′-bis(diarylamino)triphenylamines emerge, which allow us to modify molecular structures more easily in terms of synthetic chemistry. Recently, Ito et al. have reported a highly brominated derivative **3** (Fig. 2), which gives the corresponding stable dication upon two electrons oxidation [2h]. However, they failed to detect the corresponding trication with polybromo substitutions. Their results encouraged us to design and synthesize compound **4**, which has five electrodonating methyl groups at the peripheral rings and four bromo groups at the central rings. Compound **4** is expected to yield more thermodynamically stable mono- and oligo-cations than those of **3** [2j]. The CV measurements of **4** showed the generation of both stable dication $\mathbf{4}^{++}$ and moderately stable trication $\mathbf{4}^{+++}$ at ambient temperature. The electron transfer stopped-flow (ETSF) method allowed us to study the spectroscopic properties of the mono-, di- and tricationic states of **4**. These results are the first report on detection of a one-dimensional oligoarylamine-based tricationic state. The enhancement of the thermodynamic and kinetic stability

3: R=Br, R'=H

5: R=R'=CH_3

Fig. 2. Structures of 3,3′-bis(diarylamino)triphenylamines (**3**–**5**).

for oligo-cations of **4** is ascribed to the steric as well as electronic effects of the electrodonating methyl groups, which raise the HOMO energy level. The ESR study of the dication $\mathbf{4}^{++}$ showed that the ground state is spin-triplet. The trication $\mathbf{4}^{+++}$ was not stable enough in a time scale for the conventional ESR sampling, indicating that chemical modification was not successful enough to stabilize the tricationic states in solution.

In this study, we have redesigned and synthesized a new alkylated triamine **5** with nine methyl groups at the peripheral aromatic rings, which is expected to give thermodynamically more stable oligocationic states. The stabilities of the corresponding oligo-cationic states have been examined by using the cyclic voltammetry and ETSF method. The electronic states of the oligocationic states have been identified by cw-ESR measurements in rigid glass at low temperature.

2. Results and discussion

2.1. Synthesis of 2,2′,4,4′-tetrabromo-4″-methyl-5,5′-bis(di(3,4-dimethylphenyl)amino)-triphenylamine (5)

As shown in Fig. 3, compound **5** was synthesized and isolated as colorless powder by the similar method reported by Ito et al. [2h]. Benzyltrimethylammonium tribromide (BTMA · Br_3), a mild bromination reagent, has successfully been employed for the regioselective bromination at all *para*-positions of 3,3'-bis(diarylamino)triphenylamines [2h,2k]. As all *para*-positions of the peripheral rings are protected by methyl groups for **7**, only the *para*-positions of the central rings would be brominated. All new compounds were fully characterized by spectroscopic methods. Data only for **5** and **7** are given below. Compound **7**: ^{1}H NMR($CDCl_3$): δ 2.13 (s, 12H), 2.18 (s, 12H), 2.24 (s, 3H), 6.51 (dd, 4H, $J = 8.0$, 1.6 Hz), 6.56 (dd, 4H, $J = 8.0$, 1.6 Hz), 6.75–6.78 (m, 6H), 6.89–7.00 (m, 10H). Compound **5**: In spite of repeated recrystallization, compound **5** exhibited a complicated ^{1}H NMR spectrum probably due to the restricted rotation of the nitrogen–aromatic ring bonds. HRMS: Calc.: 1017.0503 for $C_{51}H_{47}N_3Br_4$. Obsd.: 1017.0498.

2.2. Cyclic voltammetry measurements

For compound **5**, cyclic voltammetry in *n*-butyronitrile at ambient temperature revealed two chemically reversible one-electron transfers, indicating the corresponding stable mono- and dications in solution. However, upon further oxidation, an irreversible oxidation wave was observed, indicating the possible generation of the unstable trication. ($E_1^0 = 0.545$V, $E_2^0 = 0.702$V, $E_3^{ox} = 1.129$V, versus F_c/F_c^+) (Fig. 4). Comparing the first redox potential of **5** and **4** ($E_1^0 = 0.605$V versus F_c/F_c^+) [2k], **5** can be oxidized more easily, suggesting the elevated HOMO level due to polyalkylation. AM1 calculation also indicated that the HOMO energy level of **5** is higher than that of **4**.

2.3. Electron transfer stopped-flow (ETSF) method

The detail of the ETSF method was described previously [4,5]. The ETSF measurements were carried out in dehydrated acetonitrile (AN) as solvent at ambient temperature. In this study, tris(2,4-dibromophenyl)amine cation radical ($TDBPA^{+\cdot}$)[1] was employed. Compound **5**, upon mixing with 1 equiv. of $TDBPA^{+\cdot}$, exhibited a broad absorption peak at 766 nm, and no decrease in the peak intensity was observed over 1 min, indicating the generation of the stable monocation from **5** (Figs. 5 and 6). The molar absorptivity (ε) of $\mathbf{5}^{+\cdot}$ was determined to be $1.21 \times 10^4\ M^{-1}\ cm^{-1}$ at 766 nm. The ε value of $\mathbf{5}^{+\cdot}$ is smaller than that of $\mathbf{4}^{+\cdot}$ ($\varepsilon = 2.06 \times 10^4\ M^{-1}\ cm^{-1}$), indicating presumably a nonplanar structure for $\mathbf{5}^{+\cdot}$.

Upon mixing with 2 equiv. of $TDBPA^{+\cdot}$, **5** exhibited an absorption peak of the dication $\mathbf{5}^{++}$ at 765 nm. The ε value for $\mathbf{5}^{++}$ was $2.13 \times 10^4\ M^{-1}\ cm^{-1}$ at 765 nm. No decrease in the peak intensity was observed over 1 min, indicating also the stable dication from **5** (Figs. 5 and 6).

On the other hand, upon mixing with 3 equiv. of $TDBPA^{+\cdot}$, **5** exhibited an absorption peak of the trication $\mathbf{5}^{+++}$ at 763 nm ($\varepsilon = 3.18 \times 10^4\ M^{-1}\ cm^{-1}$). Similar to **4**, the ratio of ε for the monocation:dication:trication of **5** was nearly 1:2:3, as expected. Surprisingly, the peak of $\mathbf{5}^{+++}$ completely disappeared in less than 0.2 s, indicating very unstable nature of the trication. As previously reported, $\mathbf{4}^{+++}$ showed the stable trication under the similar condition. The observations suggest that the introduction of extra methyl groups into the *meta*-positions of the peripheral rings results in an unexpectedly large destabilizing effect on the tricationic states. Based on the results of CV, ETSF and ESR measurements of **4** [2k] and the molecular design rules for the stable diamine based dication diradicals, we carefully designed **5**, expecting the trication $\mathbf{5}^{+++}$ to be thermodynamically more stable than $\mathbf{4}^{+++}$. We have claimed that the molecular design guidelines for

[1] TDBPA was synthesized by WAKO Pure Chemicals Ltd. after receiving our special order. See also Ref. [5].

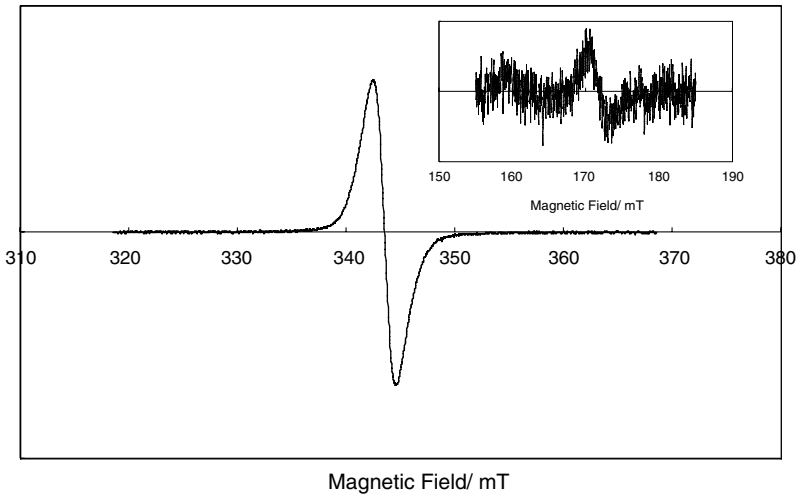

Fig. 7. ESR spectrum observed at 6 K for compound **5** after the oxidation by 3 equiv. of $SbCl_5$, in the allowed ESR transition region (Inset: in the $\Delta M_s = \pm 2$ region). The microwave frequency used was 9.48078 GHz.

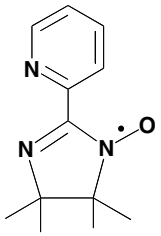
the stable monoamine-based cation radicals cannot naively be applied to that for the stable diamine-based dication diradicals. These results suggest that the more sophisticated molecular design rules are required for stabilizing triamine-based trication triradicals. At the present stage, molecular structures of the decomposed products are not identified. Recently, we have found that the ground-state triplet dication $\mathbf{1}^{++}$ slowly decomposes via π-conjugation cleavage [6], suggesting that a similar reaction may have occurred for $\mathbf{5}^{+++}$. Analysis of the decomposed products of $\mathbf{5}^{+++}$ is now in progress.

2.4. ESR measurements

In order to examine the electronic structures of the oligo-cationic states, cw-ESR measurements of chemically oxidized **5** were carried out at liquid-helium temperature. Upon addition of 3 equiv. of $SbCl_5$ into a CH_2Cl_2 solution of **5**, the color of the solution immediately turned blue, indicating the generation of oxidized species. The cw-ESR spectrum observed at 6 K for the oxidized species in the rigid glass is shown in Fig. 7. There appeared a broad line in the allowed ESR transition region. In addition, a weak forbidden transition was observed in the $\Delta M_s = \pm 2$ region, clearly indicating the presence of spin-triplet or quartet species in the ground state (Fig. 7). No signal was observed in the $\Delta M_s = \pm 3$ region. On the other hand, upon addition of a large excess amount of $SbCl_5$, the color of solution containing **5** similarly turned blue immediately, but followed by rapid discoloration to be brown in a few seconds, suggesting the occurrence of rapid decomposition reaction of $\mathbf{5}^{+++}$.

3. Conclusions



A polyalkylated 3,3′-bis(diarylamino)triphenylamine, (**5**), has been designed and successfully synthesized. Cyclic voltammetry and ETSF measurements have revealed that **5** gives very stable mono- and dicationic states at ambient temperature. However, the corresponding tricationic state was unstable with the lifetime of 0.2 s despite our elaborative molecular design. Conventional continuous-wave ESR study of the chemically oxidized **5** showed that the dication $\mathbf{5}^{++}$ is spin-triplet in the ground state. But the tricationic $\mathbf{5}^{+++}$ may not be stable enough in a time scale for the conventional ESR sampling. Pulse-ESR-based electron nutation spectroscopy at low temperature is applicable to the oxidized states of **5** generated upon addition of 3 equiv. of $SbCl_5$ into a CH_2Cl_2 solution of **5**. Differentiation between the triplet and quartet species is underway by invoking the pulsed-ESR spectroscopy.

IM-2py

Scheme 1.

to the intraligand IM2py-IM2py magnetic interaction [18]. More definite magnetic information will be afforded from mono (IM2py) complexes without intraligand IM2py–IM2py magnetic interaction. Moreover, IM2py Co(II) complexes are more appropriate to study the magnetic interaction than the NIT2py complexes, because there is a definite antiferromagnetic or ferromagentic interaction of the SOMO π^* with t_{2g} or e_g orbital arising from the orbital overlap or orthogonality, respectively, as found for the Ni(II) and Cr(III) complexes [4–8,12–15].

In this paper, we report a new series of [Co(β-diketonate)$_2$(IM-2py)] with four kinds of β-diketonates; 4,4,4-trifluoro-R-1,3-butanedionates (Rtfc) as shown in Scheme 2, in order to examine the optical and magnetic properties through the substituents effect on the d orbital splitting which are expected from the difference between the electron withdrawing CF_3 and the other substituent groups.

2. Experimental

2.1. Materials

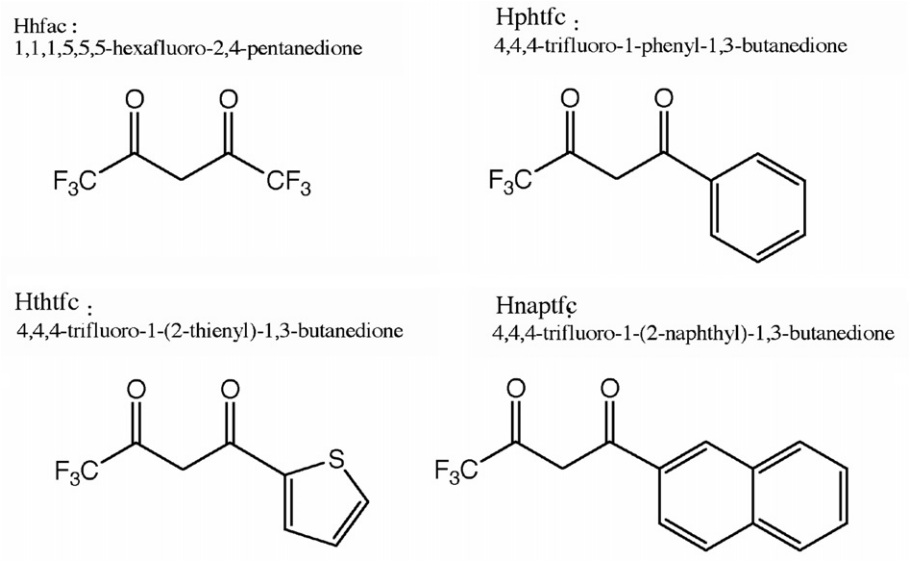
The three 4,4,4-trifluoro-R-1,3-butandiones(HRtfc) of four β-diketones, 4,4,4-trifluoro-1-(trifluoromethyl)-1,3-butanedione(hexafluoroacetylacetone = Hhfac), 4,4,4-trifluoro-1-phenyl-1,3-butanedione(Hphtfc) and 4,4,4-trifluoro-1-(2-naphtyl)-1,3-butanedione(Hnaptfc), were purchased, respectively, from Dojindo Molecular Technologies Inc. and the 4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione(Hthtfc) from Aldrich.

They were used without further purifications.

2.2. Preparation of IM2py

This was prepared by the literature method [1].

2.3. Preparation of complexes



2.3.1. [Co(β-diketonate)$_2$(H$_2$O)$_2$]

The starting complexes [Co(β-diketonate)$_2$(H$_2$O)$_2$] were prepared according to the literature method [2] for the hfac complex by mixing an aqueous solution of $Co(CH_3COO)_2 \cdot 4H_2O$ with twice equimolar amounts of 4,4,4-trifluoro-R-1,3-butandione. The precipitate was filtered, washed with cold water, and dried under vacuum.

2.3.2. [Co(β-diketonate)$_2$(IM2py)]

[Co(β-diketonate)$_2$(H$_2$O)$_2$] (0.10 mmol) was dissolved in hot dry *n*-heptane (50 ml). To this solution was added IM2py (0.10 mmol). After the mixed solution was stirred for 10 min, the precipitate obtained was filtered. Yields were about 60%. The elemental analysis for [Co(hfac)$_2$-(IM2py)] (**1**), [Co(phtfc)$_2$(IM2py)] (**2**), [Co(thtfc)$_2$(IM2py)] (**3**), and [Co(naptfc)$_2$(IM2py)] (**4**) gave the satisfactory results as shown in Table 1.

The identifications for the powdery samples have been confirmed by powder X-ray diffraction patterns (XRD) which were in good agreement with the simulated pattern reproduced from the F_c values of the calculated crystal structures.

Scheme 2.

2.3.3. X-ray crystallography

The crystals suitable for the X-ray analysis were obtained from *n*-heptane solution by a diffused vapor method using ethyl ether.

The X-ray intensities of complex [Co(phtfc)$_2$(IM2py)] (**2**) were measured on a Rigaku automated four-circle diffractometer AFC-5R [graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), ω–2θ scan, $2\theta_{max} = 60°$], and those complexes **3** and **4** on a Rigaku Mercury CCD [graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), $2\theta_{max} = 55°$]. The structures were solved by Rigaku Crystal Structure 3.7.0 [23] and refined on F^2 by full-matrix least squares using SHELXL 97 [24].

The *R* value for the complex **4** is rather large probably owing to a small size of the crystal employed. However, the goodness-of-fit number is not so large as compared with the other complexes as shown in Table 1.

2.3.4. Physical measurements

The magnetic susceptibility data were collected with a SQUID magnetometer on a QUANTUM design model MPMS. Data were corrected for magnetization of the sample holder and for the diamagnetic contributions, which were estimated from Pascal's constants. UV–Vis spectra were measured on a Perkin–Elmer Lambda 19 spectrophotometer. Magnetic circular dichroism (MCD) spectra in CH_3CN were obtained in a magnetic field of 1.5 T ($1\ T = 1.0 \times 10^4$ Gauss) with a Jasco J-720W spectropolarimeter at room temperature. Resonance Raman spectra were measured in solid states on a Jasco NR 1800 spectrophotometer at room temperature using Ar laser lines (514.5 nm), the He–Ne laser line (632.8 nm), and dye laser lines (R6G, 580 nm; DCM, 690, 705 nm) as excitation sources. The Si–O (silicone) stretching at 518 cm^{-1} was used as internal standard.

3. Results and discussion

3.1. Molecular structures

The crystallographic data of the complexes **2**–**4** are given in Table 2.

The ORTEP view of complex [Co(phtfc)$_2$(IM2py)] (**2**) is shown in Fig. 1 and Fig. S1.

The complex has two didentate phtfc other than one chelated IM2py coordinated via the pyridyl and the imidazol nitrogen atoms to a Co(II) center, and forming the six-coordinate octahedron. It is noted that the oxygen atoms close to the trifluoromethyl group in the phtfc ligands are placed at the mutual *trans* position. The other complexes **3** and **4** also take the same *trans*(CF_3) geometrical structure (Figs. S2 and S3). In other words, only the *trans*(CF_3)-isomer among three possible isomeric structures is stereospecifically formed for this kind of complexes. The Co–O bond lengths (2.017(5)–2.089(5) Å) range within those of the hfac Co(II) complex with monodentate NIT radical [20]. There is no systematic tendency in Co–O bond lengths with respect to the substituent positions of the Rftc ligands. The Co–N(py) bond lengths (2.118(8)–2.146(5) Å) are longer than the Co–N(IM) bond lengths (2.082(7)–2.115(8) Å), while this difference is reverse to the case of [MCl_2(IM2py)$_2$](M^{II} = Mn, Co, Ni, Zn); M–N(py) bond lengths are shorter than M–N(IM) ones [18]. Each bond length of Co–N(py) and Co–N(IM) is shorter than those in [$CoCl_2$(IM2py)$_2$]. The averaged N–O bond lengths of IM2py are 1.270(9)–1.252(10) Å, 1.267(8)–1.255(8) Å and 1.281(10)–1.275(8) Å, respectively, in complexes **2**, **3**, and **4**, which are comparable to the reported ones (1.265–1.271 Å) for the IM2py complexes [12,14]. Therefore this

fact supports the existence of the imino niroxide radical in these complexes. The bite angles for the IM2py chelate are 77.3(3)–76.2(3)°, 77.1(2)–76.5(2)°, and 76.0(2)–76.4(2)° for the complexes **2**, **3**, and **4**, which are somewhat larger than that for $[CoCl_2(IM2py)_2]$ [18]. The chelate rings of the IM2py are almost planar, since the averaged dihedral angles between the plane Co–N(py)–N(IM) and the plane N(IM)–C(IM)–C(py)–N(py) are 2.93°, 1.70°, 4.44° for the **2**–**4** complexes, respectively.

3.2. The UV–Vis spectra and magnetic circular dichroism

NIR–UV–Vis spectra of complexes (**1**)–(**4**) in CH_2Cl_2 at room temperature are shown in Fig. 2.

The broad absorption band with similar intensities ($\log\varepsilon \approx 1$) around 9700 cm^{-1} is assigned to the first spin allowed d–d $^4T_1 \rightarrow {}^4T_2$ transition. For the hfac complex (**1**), the d–d band is observed at the lower frequency side than those of the other complexes (**2**)–(**4**). Two intense broad bands are located around 16 500 cm^{-1} and 20 000 cm^{-1} for complexes **2**, **3**, and **4**. For complex **1**, a shoulder and a broad band are observed at 17 500 cm^{-1} and 24 000 cm^{-1}, respectively. The MCD spectra show the similar behavior to the UV–Vis spectra as in Fig. 2. The weak positive MCD band around 17 000 cm^{-1} appears for the phtfc **2** and thtfc **3** complexes, whereas the hfac **1** complex gives a blue-shifted weak positive band with a higher frequency negative component. At the higher frequency side around 20 000–24 000 cm^{-1}, the strong positive MCD band with the lower frequency shoulder is observed for all the complexes, but the difference in peak position between the complex **1** and the Rtfc complexes **2**–**3** is about 2800 cm^{-1}, which is much larger than that (500 cm^{-1}) of the lower frequency one around 17 000 cm^{-1}. Such a similarity in MCD pattern suggests that two absorption bands of the Rtfc complexes (**2**)–(**4**) at 17 000 and 20 000 cm^{-1} arise from the same origins for those of the hfac complex **1** at 17 500 cm^{-1} and 24 000 cm^{-1} , respectively, as inferred from the following resonance Raman spectroscopy.

For $[Co(phtfc)_2(IM2py)]$ (**2**), the resonance Raman spectra gave significant intensity enhancement or the excitation profiles under the visible band around 17 000 cm^{-1}, especially for the Raman peaks due to the stretching vibrations of the O–N–C moiety of the IM2py ligand around 1520, 1468, and those due to the stretching of Co–N(imino) and Co–N(pyridyl) around 443 and 255 cm^{-1} as shown in Fig. 3, as compared from the previous results for the

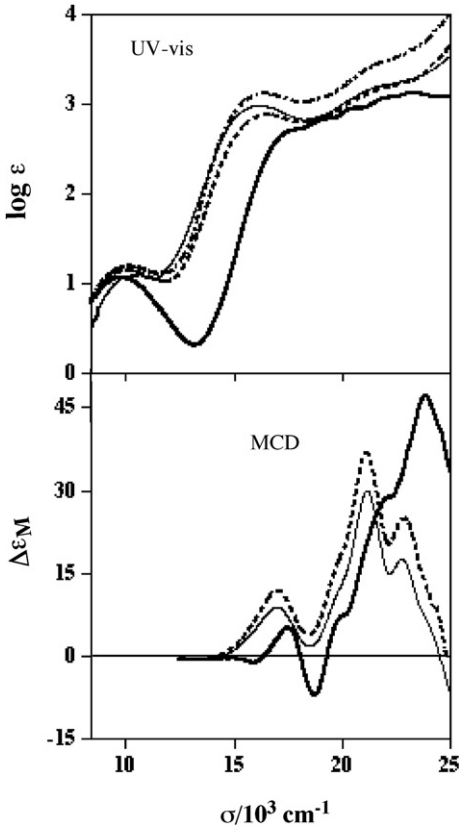

Fig. 2. UV–Vis spectra in CH_2Cl_2 (top) and MCD in CH_3CN (bottom) of $[Co(hfac)_2(IM2py)]$ (—), $[Co(phtfc)_2(IM2py)]$ (—), $[Co(thtfac)_2(IM2py)]$ (----), $[Co(naptfc)_2(IM2py)]$ (—·—).

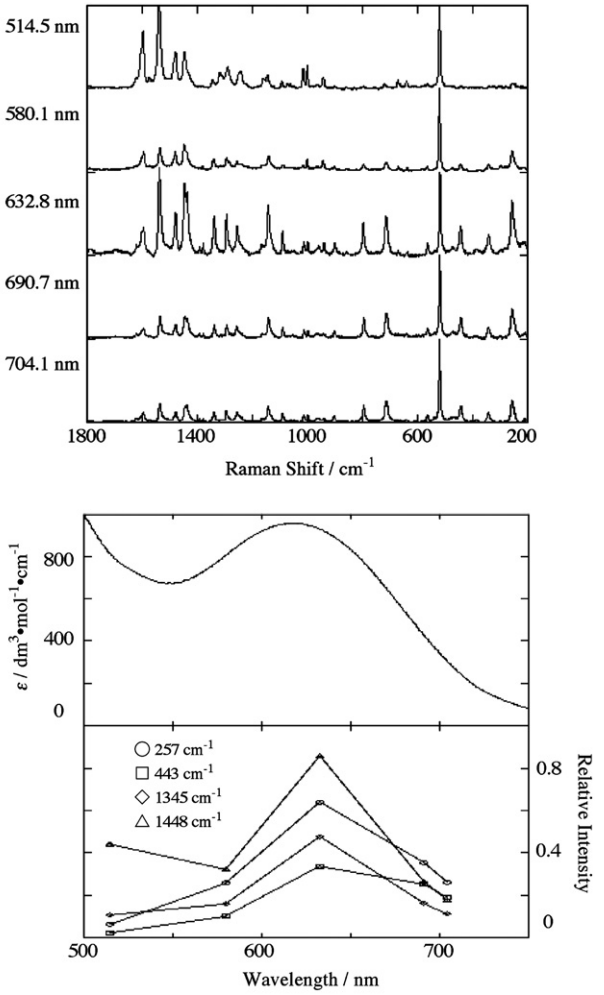

Fig. 3. (Top) Resonance Raman spectra with variation of the excitation lights (bottom) and excitation profile of $[Co(phtfc)_2(IM2py)]$.

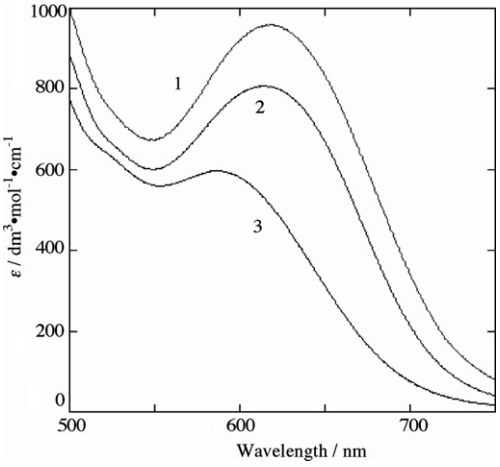
Ni(II) and Cr(III) complexes [10–13]. The same behavior for the resonance Raman spectra were observed for the other three complexes **1**, **3**, **4** (Figs. S4–S9). Therefore, the visible band near 17000 cm^{-1} may be assigned to the charge transfer(CT) transition. This CT band is probably due to the metal-to-ligand SOMOπ^*(MLCT) as similarly observed for Ni(II) and Cr(III) complexes [10–13]. For complex **2**, the visible absorption band in dichloromethane or benzene is shifted to longer wavelength side in acetonitrile as shown in Fig. 4. All the complexes have a blue-shifted absorption band with increasing the polarity of the solvents (Figs. S10–S12). These assignments to the MLCT are supported by the similarity of MCD patterns as mentioned above.

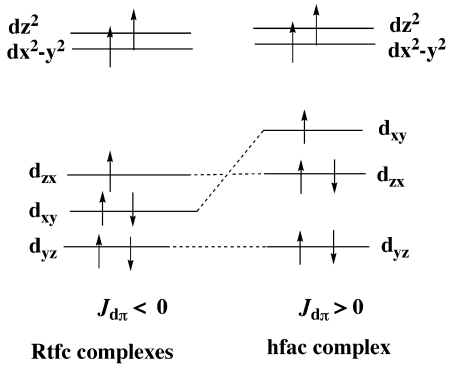
3.2.1. Substituents effect on the electronic spectra

The higher energy shifts of the MLCT bands from the Rtfc to the hfac complexes would be elucidated as follows. In the triplet–triplet $t_{2g} \rightarrow \pi^*$ and $e_g \rightarrow \pi^*$ MLCT for octahedral IM2py high spin Co(II) complexes, the transition energy is estimated to be $30(\chi(\mathrm{Co}) - \chi(\mathrm{IM})) + 2D$ for $E(t_{2g} \rightarrow \pi^*)$ with the triplet d^6 excited CT state and $30(\chi(\mathrm{Co}) - \chi(\mathrm{IM})) - \Delta + 2D$ for $E(e_g \rightarrow \pi^*)$, where χ(Co) and χ(IM) refer to the optical electronegativity for Co(II) and the IM2py ligand, respectively and Δ and D are the ligand field splitting and the spin-pairing energy, respectively [25]. The energy difference between two MLCT, $\Delta E = E(e_g \rightarrow \pi^*) - E(t_{2g} \rightarrow \pi^*) = -\Delta$ should be negative. Therefore, the lower energy MLCT component around 17000 cm^{-1} is due to the $e_g \rightarrow$ SOMO MLCT, in accordance with our previous assignment to the d_σ–SOMO transition for the *cis*-[$CoCl_2(IM2py)_2$] [18]. The higher energy shift of the $e_g \rightarrow$ SOMO MLCT for the hfac complex may result from the difference in the ligand field splitting: Δ(hfac) < Δ(Rtfc) being suggested from the lower energy shift of the $^4T_1$–$^4T_2$ d–d band for the hfac complex (Fig. 2). The higher frequency band near 20000 and 24000 cm^{-1} for the Rtfc and hfac complexes, respectively, could be due to the t_{2g}–SOMO MLCT. This assignment is supported by the intensity difference; the $d_{zx}(t_{2g})$–SOMO MLCT intensity with large orbital overlap being stronger than the d_{z^2} (e_g)–SOMOπ^* MLCT one with small overlap. The much higher frequency shift of the $d_{zx}(t_{2g})$–SOMO MLCT for the hfac complex may arise from the spin-pairing energy expense associated with the d_{zx}–SOMO transition from $(d_{yz})^2(d_{zx})^2(d_{xy})^+(d_{z^2})^+(d_{x^2-y^2})^+(\mathrm{SOMO})^-$ to $(d_{yz})^2(d_{zx})^-(d_{xy})^+(d_{z^2})^+(d_{x^2-y^2})^+(\mathrm{SOMO})^2$ or $(d_{xy})^2(d_{zx})^2$-$(d_{yz})^+(d_{z^2})^+(d_{x^2-y^2})^+(\mathrm{SOMO})^-$ to $(d_{xy})^2(d_{zx})^-(d_{yz})^+$ $(d_{z^2})^+$-$(d_{x^2-y^2})^+(\mathrm{SOMO})^2$ for the hfac complex as compared with that from $(d_{yz})^2(d_{xy})^2(d_{zx})^+(d_{z^2})^+(d_{x^2-y^2})^+(\mathrm{SOMO})^-$ to $(d_{yz})^2(d_{xy})^2(d_{z^2})^+(d_{x^2-y^2})^+(\mathrm{SOMO})^2$ as a result of the inversion of the d_{zx} and d_{xy} energy levels (Scheme 3) where the d_{zx}, d_{xy} and d_{yz} are defined according to the Cartesian coordinate in Scheme 4. This inversion of the d orbital orderings is consistent with that inferred from the magnetic properties (vide infra).

3.3. Magnetic properties

The temperature dependences of the $\chi_M \cdot T$ (χ_M = molar magnetic susceptibilities) of [Co(β-diketonato)$_2$(IM2py)] are shown in Fig. 5. The values of $\chi_M \cdot T$ (3.22 for **1**; 3.60 for **2**; 3.49 for **3**; 3.37 $cm^3 \cdot mol^{-1} \cdot K$ for **4**) at 300 K indicate the existence of a high-spin cobalt(II) ion ($S = 3/2$)





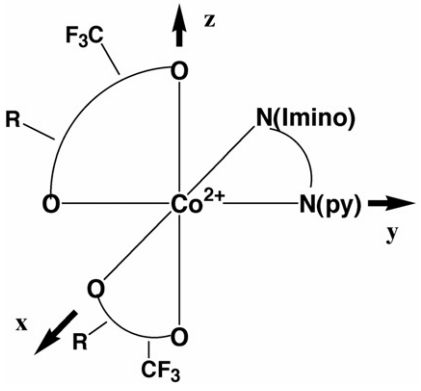


Fig. 4. Solvent dependent UV–Vis spectra of [Co(phtfc)$_2$(IM2py)]: (1) CH_2Cl_2; (2) C_6H_6; (3) CH_3CN.

Scheme 3.

Scheme 4.

and an unpaired electron ($S = 1/2$) of IM2py. The magnetic exchange coupling constants J between cobalt(II) and IM2py were estimated by fitting the magnetic susceptibilities using a two-spin system, as employed for a dinuclear Cu(II)–Co(II) complex [26], including the Weiss constant θ. This model gives the spin-Hamiltonian in Eq. (1) and the molar magnetic susceptibility in Eq. (2) as follows:

$$\hat{H} = -2JS_{Co}S_{rad} \tag{1}$$

$$\chi_M = \frac{N\beta^2}{k(T-\theta)}\left\{\frac{10g_2^2 + 2g_1^2\exp(-4J/kT)}{5 + 3\exp(-4J/kT)}\right\} \tag{2}$$

where $g_1 = (5g_{Co} - g_{IMpy})/4$ and $g_2 = (3g_{Co} + g_{IM2py})/4$ (g_{Co} and g_{IM2py} are g value of cobalt(II) and IM2py, respectively). The $\chi_M \cdot T$ curve is almost flat at high temperature. It follows that only one populated level is the ground $S = 2$ level of the complex even at room temperature. It is not easy to analyze the magnetic data, since the ground state of the octahedral cobalt(II) is $^4T_{1g}$ with large anisotropy components. Large depopulation of the lower energy levels or Kramers doublets in the ground state of cobalt(II) makes it difficult to assess the magnetic behavior at low temperature before complete occupation of the lowest level. Therefore, the magnetic exchange coupling constants J between a cobalt(II) and IM2py were estimated between 30 and 300 K, by fitting Eq. (2) (Figs. S13–S16). In Table 3, the best fit results of the coupling constants J, g and θ values are summarized. The g_{Co} values from 2.40 to 2.60 are close to those for the dichloro bis(IM2py) Co(II) complex [18].

It is noted that J values vary with the substituents in the β-diketonate coligand. The hfac complex (**1**) exhibits the fairly large positive J value or ferromagnetic interaction, whereas there are found smaller J values, or weaker antiferromagnetic or ferromagnetic interactions for complexes **2**, **3**, and **4**. Such magnetic behavior is accounted for on the basis of the d orbital energy splitting as previously discussed for the bis(IM2py) Co(II) complexes [18].

3.3.1. The substituent effect on magnetic interactions

The above-mentioned difference in the magnetic properties is considered to be associated with the d orbital splitting: suggesting the substituents effect on going from **1** to **2**, **3**, **4** complexes. The difference in magnetic properties originates from two interactive modes between the magnetic d orbitals of Co(II) and IM2py SOMO; $J_{d\pi}$ and $J_{d\sigma}$ with the $d_\pi(t_{2g})$ and $d_\sigma(e_g)$ orbitals, respectively. The total coupling constant $J(J_{obs})$ is represented as follows:

$$J_{obs} = J_{d\sigma} + J_{d\pi} \tag{3}$$

Since the d_σ orbitals of cobalt(II) ion is orthogonal to the SOMO as found from the X-ray analysis (vide supra), the magnetic interaction of IM2py with the d_σ could be ferromagnetic ($J_{d\sigma} > 0$) [5,12,14]. On the other hand, the interactions of the d_π orbital with the SOMO depend on the splitting patterns of the d_π orbitals. That is, the overlap and orthogolality between the magnetic d_π orbital and the SOMO result in antiferromagnetic ($J_{d\pi} < 0$) [6,12,14] and ferromagnetic interaction ($J_{d\pi} > 0$), respectively. Therefore, it is considered that the substituents effect of the β-diketonate on the magnetic properties originates from the different splitting pattern in d_π orbitals. As assumed from the MLCT band shifts in the previous section, the highest occupied magnetic d_π orbital of the hfac complex **1** is d_{xy}, which is orthogonal with the SOMO (Scheme 3). In this case, both the contributions to the magnetic interaction from the d_σ and d_π are ferromagnetic, so that there may be a fairly large ferromagnetic interaction, $J_{obs} = J_{d\sigma}(F) + J_{d\pi}(F)$. This is the finding just as for the hfac complex **1**. For the complexes **2**, **3** and **4**, on the other hand, the magnetic d_π orbital is d_{zx}, which overlaps with the SOMO. Thus, the total magnetic interaction or $J_{obs} = J_{d\sigma}(F) + J_{d\pi}(ANT)$ would become smaller.This case accords with a weak antiferromagnetic or weak ferromagnetic interaction as observed for complexes **2**, **3**, **4**. It is likely that the inversion of the energy level ordering results from the difference in the electronic properties between the

Table 3
Magnetic data

Complexes	J/cm^{-1}	θ/K	g_{Co}	g_{rad}	χ^2
[Co(hfac)$_2$(IM2py)] (**1**)	21.0 ± 1.10		2.45 ± 0.01	2.0	1.57×10^{-5}
[Co(phtfc)$_2$(IM2py)] (**2**)	−0.81 ± 0.11	−2.93 ± 0.17	2.60 ± 0.01	2.0	1.79×10^{-3}
[Co(thtfc)$_2$(IM2py)] (**3**)	4.47 ± 1.01	−7.89 ± 0.29	2.78 ± 0.05	2.0	1.48×10^{-3}
[Co(naptfc)$_2$(IM2py)] (**4**)	3.14 ± 0.53	−3.90 ± 0.12	2.70 ± 0.03	2.0	1.17×10^{-3}

electron withdrawing CF_3 and the electron donating R groups as examined by the AOM consideration as follows.

The d_π orbital energies are given by the AOM parameters as follows.

$$\varepsilon(d_{xy}) = 2_\pi(O(R))$$
$$\varepsilon(d_{zx}) = e_\pi(N(IM)) + e_\pi(O(CF_3))$$
$$\varepsilon(d_{yz}) = e_\pi(N(py)) + e_\pi(O(CF_3))$$

where the AOM parameters $e_\pi(O(R))$, $e_\pi(O(CF_3))$, $e_\pi(N(IM))$ and $e_\pi(N(py))$ represent the interaction energy between the π orbital of the donor ligand atoms and the dπ orbital orthogonal to the β-diketonate chelate planes: O(R) and $O(CF_3)$ for the oxygen in the O–C–R and O–C–CF_3 of Rtfc, respectively, and N(IM) and N(py) for the nitrogen in the imino radical and the pyridyl group of IM2py, respectively. Assuming the transferability of the AOM parameters among the four complexes, only the d_{xy} orbital energy varies with the substitutents of the Rtfc ligands. The inequality $e_\pi(O(CF_3)) > e_\pi(O(R))$ is required in terms of $\varepsilon(d_{xy}) > \varepsilon(d_{zx})$ for the hfac complex and $\varepsilon(d_{xy}) < \varepsilon(d_{zx})$ for the other Rtfc complexes (Scheme 3). The relation $e_\pi(O(CF_3)) > e_\pi(O(R))$ may reflect the destabilization of the d orbitals by the CF_3 group as inferred from the charge transfer spectra of the β-diketonato Cr(III) complexes [27]. Therefore, the examination in terms of the AOM parametrization supports the inversion of the d orbital energy orderings or the substituents effect on the magnetic properties as well as the MLCT band shifts.

4. Conclusion

The difference in the MLCT band shifts and magnetic interactions among the bis(β-diketonato or Rtfc) IM2py Co(II) complexes can be elucidated on the basis of the d_π orbital energy orderings supported by the AOM parametrization and the ligand field splitting or the spin-paring energy. Thus the present results suggest possibility to regulate magneto-optical properties by changing the electronic properties of the substituents in the β-diketonate coligand.

2. Experimental

2.1. General method

Chemicals were used as received without further purification. Melting points were measured on a Yanako MP-J3 apparatus and are uncorrected. ^{1}H NMR spectra were recorded on JEOL JNM-LA300 (300 MHz) or -LA400 (400 MHz). The chemical shifts were described as values in parts per million relative to tetramethylsilane. MS-spectra were obtained using a JEOL JMS-700T mass spectrometer. ESR spectra were recorded on a JEOL JFS-FE2XG. X-ray data were collected with Rigaku/MSC Mercury CCD system using graphite monochrometer Mo Kα radiation. The magnetic susceptibility measurements were conducted on a Quantum Design SQUID magnetometer MPMS-XL.

2.2. Synthesis of *3H*, *4*, *5*, and the reaction of *3H* with copper acetate in methanolic ammonia solution

2.2.1. Synthesis of 1,3-dihydroxy-4,6-bis(1,3-dihydroxy-4,4,5,5-teramethylimidazolidine-2-yl)benzene (*4*)

A suspension of 4,6-dihydroxyisophthalaldehyde (3.04 g, 24.3 mmol), dry potassium carbonate (8.42 g, 60.9 mmol), and 2,3-dihyroxylamino-2,3-dimethylbutane-H_2SO_4 salt (18.0 g, 73.1 mmol) in dry methanol (300 ml) was refluxed for 24 h under an inert atmosphere. The solvent was partially evaporated under reduced pressure. Then, water (300 ml) was added to the stirred reaction mixture, to give precipitates. The precipitates were filtered and dried over P_2O_5 under reduced pressure, to give almost pure **4** as a pale yellow powder (8.81 g, 20.7 mmol, 85% yield). Compound **4**: HRMS (FAB) *m*/*z* Calc. for $C_{20}H_{34}N_4O_6$: 426.2478; found: 427.2568 (M+H); ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.06 (s, 12H), 1.07 (s, 12H), 4.51 (s, 2H), 5.98 (s, 1H), 6.92 (s, 1H), 8.07 (s, 4H), 11.34 (s, 2H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 17.21, 24.49, 65.87, 88.55, 102.62, 112.66, 132.82, 158.24.

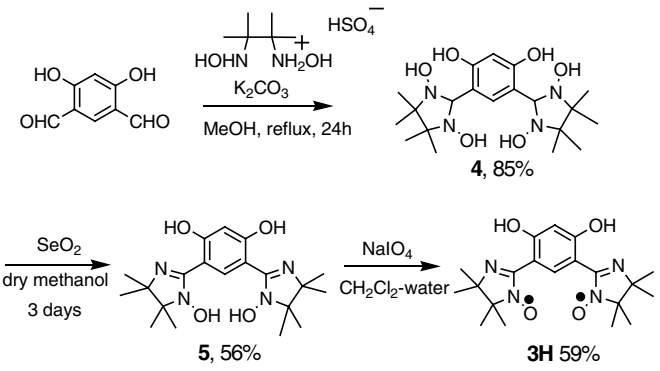
2.2.2. Synthesis 1,3-dihydroxy-4,6-bis(1-hydroxy-4,4,5,5-tetramethylimidazoline-2-yl)benzene (*5*)

A suspension of **4** (2.01 g, 4.72 mmol) and a catalytic amount of selenium dioxide (0.205 g, 1.84 mmol) was stirred at room temperature for 3 days, to give a yellow-colored solution containing a small amount of insoluble materials. The reaction mixture was filtered and concentrated in vacuo. The crude product was purified by a silica gel column eluted with ethyl acetate:methanol = 4:1 (R_f = 0.48) to give a yellowish powder (1.04 g, 2.65 mmol, 56% yield). Recrystallization from ethyl acetate containing a small amount of methanol gave **5** as orange plates (43%). Compound **5**: HRMS (FAB) *m*/*z* Calc. for $C_{20}H_{30}N_4O_4$: 390.2267; found 391.2347 (M+H); ^{1}H NMR (300 MHz, DMSO-d_6) 1.24 (s, 12H), 1.25 (s, 12H), 5.90 (s, 1H), 7.44 (s, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 19.19, 23.30, 62.27, 71.05, 103.64, 107.87, 131.92, 152.14, 168.19.

2.2.3. Synthesis of 1,3-dihydroxy-4,6-bis(4,4,5,5-tetramethylimidazoline-1-oxyl-2-yl)benzene (*3H*)

To a stirred nitrogen-bubbled heterogeneous solution of water (10 ml) and methylene chloride (15 ml) containing **5** (517 mg, 1.32 mmol) was added sodium periodate (561 mg, 2.62 mmol) slowly at 0 °C. The mixture was further stirred at 0 °C for 20 min. The water-layer was removed and the organic layer was washed with water and dried over sodium sulfate under nitrogen. The organic layer was concentrated in vacuo. The resulting solid was recrystallized from ether–hexane in a glove box freezer (−30 °C) to give diradical **3H** (304 mg, 0.779 mmol, 59% yield) as red blocks. Compound **3H**: MS (FAB) *m*/*z* 390 (M+2H); IR (cm^{-1}, KBr) 2986, 2974, 1638, 1605, 1533, 1377, 1331, 1257, 1211, 1180, 1159; *Anal.* Calc. for

$C_{20}H_{28}N_4O_4$: C, 61.84; H, 7.27; N, 14.42. Found: C, 61.91; H, 7.34; N, 14.19%.



2.2.4. Reaction of *3H* with copper acetate in methanol containing aqueous ammonia

To a solution of copper acetate (64.3 mg, 0.165 mmol) in methanol (6 ml) and aqueous ammonia (25%, 0.2 ml) was slowly added a solution of **3H** (29.0 mg, 0.160 mmol) in methylene chloride (2 ml) in a glove box. Fine precipitates soon appeared and were filtered using a membrane filter with a porous size of 0.2 μm. The collected precipitates were well washed by methanol and methylene chloride to give a blue-green powder (39 mg, 54%). The powder was hardly soluble in various organic solvents. Elementary analysis of the obtained powder: *Anal.* Calc. for $C_{20}H_{26}CuN_4O_4$: C, 53.38; H, 5.82; N, 12.45. Found: C, 53.87; H, 6.11; N, 11.95%; IR (cm^{-1}, KBr) 2980, 2933, 1582, 1516, 1466, 1448, 1433, 1416, 1390, 1369, 1329, 1296, 1265, 1217, 1148, 820, 644.

3. Results and discussion

3.1. Synthesis and structure of *3H*

The synthesis of **3H** is outlined in Scheme 1. 1,3-Dihydroxy-4,6-bis(1,3-dihydroxy-4,4,5,5-tetramethylimidazolidine-2-yl)benzene (**4**) was prepared by the condensation of 4,6-dihydroxylisophthaldehyde with 2,3-dihyroxylamino-2,3-dimethylbutane-H_2SO_4 salt in 85% yield. The conversion of **4** to **5** was conducted by the selenium dioxide oxidation method developed by Ulrich and Ziessel [8]. Oxidation of **5** to **3H** was conducted using periodate oxidation under an inert atmosphere. Diradical **3H** was somewhat unstable in solution even under an inert atmosphere and gradually (with a time scale of days) decomposed into unidentified products. However, this slow decomposition would not be important when one applies **3H** to rapid reactions such as metal complexation at low temperature. Compound **3H** was fairly stable in a solid state. Recrystallization from a mixture of ether–hexane in a freezer of a glove box gave dark-green crystals suitable for X-ray structure analysis.

Scheme 1.

Table 1
Crystallographic data of **3H**

Formula	$C_{20}H_{28}N_4O_4$
Formula weight	388.36
Crystal system	monoclinic
Space group	$P2_1/c$ (#14)
a (Å)	10.6195(11)
b (Å)	11.0214(9)
c (Å)	18.422(2)
α (°)	90.00
β (°)	105.959(4)
γ (°)	90.00
V (Å^3)	2073.1(3)
Z	4
Crystal size (mm)	$0.30 \times 0.20 \times 0.20$
T (K)	173
D_{calc} (g cm^{-3})	1.401
$F(000)$	832.00
μ (Mo Kα) (cm^{-1})	0.88
Unique reflections	4473
Observation	3432 ($I > 2\sigma(I)$)
R_1 [$I > 2\sigma(I)$][a]	0.044
R_w[b]	0.045
Goodness-of-fit	0.91
Largest shift	0.00

[a] $R_1 = \sum ||F_o| - |F_c|| / \sum |F_o|$.
[b] $R_w = [w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$.

The crystallographic data for **3H** are shown in Table 1. The molecular structure is shown in Fig. 1a. Intramolecular hydrogen bonds between the phenolic hydrogen atoms (H1, H2) and the nitrogen atoms (N1, N2) in the imidazoline rings were clearly seen; the hydrogen atoms H1 and H2 are observed atoms and were refined isotropically with the bond length of H1–N1 = 1.83 Å, H2–N2 = 1.75 Å. As a result, the dihedral angle between the benzene ring and the plane defined by N1–C7–N3 (or N2–C8–N4) is as small as 8.7° (or 4.9°).

Relatively short intermolecular contacts were observed (Fig. 1b). The two benzene rings were aligned almost parallel in anti direction and form a dimer structure with the distance of C2–C6* = C6–C2* = 3.23 Å, which is considerably shorter than the sum (3.54 Å) of the van der Waals radii of aromatic carbon atoms (1.77 Å) [9]. These intermolecular contacts between chemically equivalent carbon atoms should cause an antiferromagnetic interaction between these diradicals. Fig. 1c shows a schematic model (four-spin model) of magnetic interaction based on the X-ray structure considering these intermolecular contacts, where the imino nitroxide radical ($S = 1/2$) is shown as a circle. The model will be discussed in the next section.

3.2. EPR study of *3H*

Fig. 2a shows the EPR spectrum of **3H** measured at 123 K in frozen butyronitrile. High purity of this diradical species is apparent from the spectrum, although a small amount of mono-radical impurities can be observed in the center magnetic field. The spectrum was simulated by using

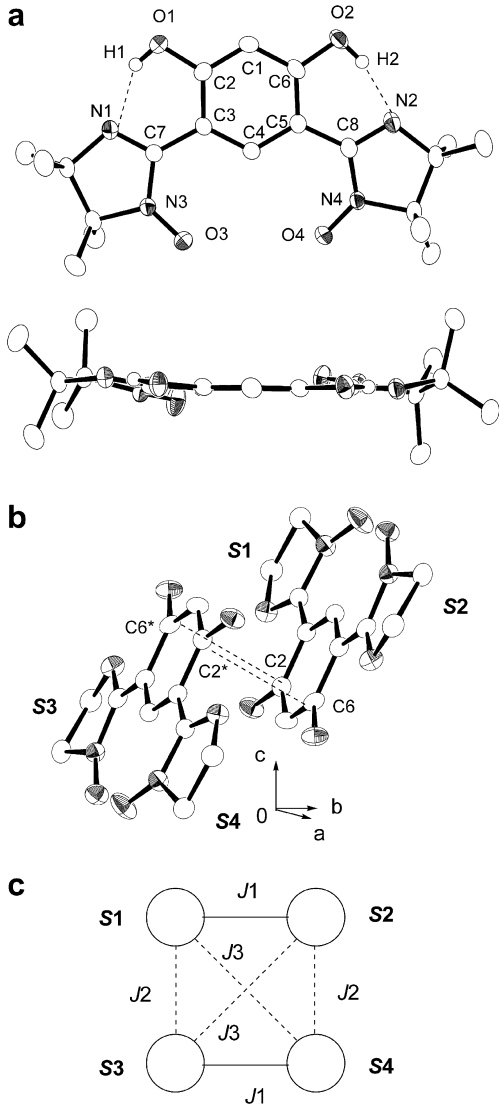


Fig. 1. Molecular structure (a), an intermolecular contact (b), and schematic model (c) for the magnetic interaction of **3H**.

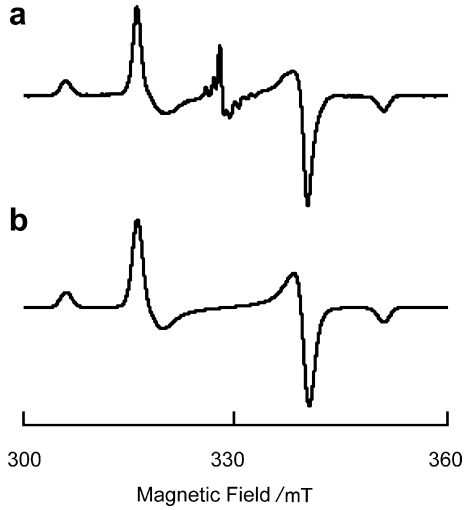

Fig. 2. EPR spectrum of **3H** in butyronitrile at 123 K (a) and a simulated spectrum with the parameters of $D/hc = 0.0211\ \mathrm{cm}^{-1}$ and $E/hc = 0\ \mathrm{cm}^{-1}$ (b).

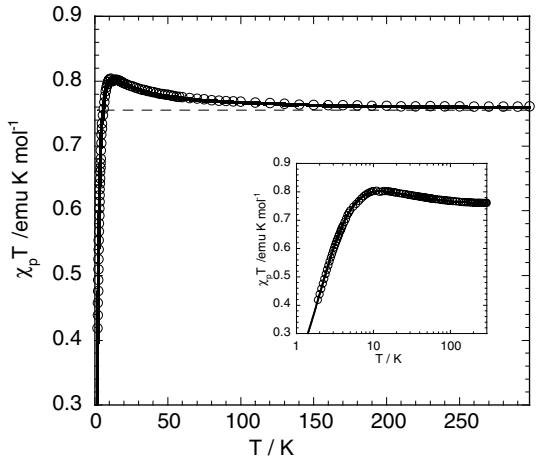

Fig. 3. Magnetic susceptibility of **3H** under magnetic field of 1000 Oe in the $\chi_p T$–T plots; the broken line shows the $\chi_p T$ value corresponding to 2 mol of $S = 1/2$ spins ($\chi_p T = 0.755$ with $g = 2.006$). The solid line shows the simulation curve based on the four spin model with $J_1/k_B = +5.0$ K, $J_2/k_B = J_3/k_B = -0.9$ K. The inset shows the plots in the logarithmic scale of temperature.

the parameters of $D/hc = 0.0211\ \mathrm{cm}^{-1}$ and $E/hc = 0\ \mathrm{cm}^{-1}$ (Fig. 2b). A weak forbidden signal due to $|\Delta m_S| = 2$ was observed in a $g = 4$ region. Linear relationship was observed between the signal intensity of $|\Delta m_S| = 2$ and the reciprocal of temperature, indicating a triplet ground state as expected from the structure of the *m*-phenylene linkage of bis(imino nitroxides) [10]. The singlet–triplet energy gap ($2J$) was estimated from the measurement of magnetic susceptibility of **3H**.

3.3. Magnetic properties of *3H*

Fig. 3 shows the temperature dependence of $\chi_p T$ for **3H**. The $\chi_p T$ value at room temperature was 0.761 emu K mol^{-1}, that is close to 2 mol of $S = 1/2$ spins ($\chi_p T = 0.755$ emu K mol^{-1} with $g = 2.006$ shown as a broken line in Fig. 3). The $\chi_p T$ value increases gradually as temperature decreases (298–10 K) and sharply decreases in lower temperatures. These observations indicate that there are at least two magnetic interactions, which have opposite signs of J, J_1 (ferromagnetic) and J_2 (antiferromagnetic). As shown in the previous section, the intramolecular magnetic interaction through the *m*-phenylene spacer should be responsible to the ferromagnetic interaction J_1. The short contacts between the dimer observed in the crystal structure may cause an intermolecular antiferromagnetic interaction. Another antiferromagnetic interaction may be operative as shown in the diagram of Fig. 1c. We analyzed the temperature dependence of the magnetic susceptibility of **3H** using the four-spin model (Fig. 1c). The spin Hamiltonian of this model is shown in Eq. (1)

$$H = -2J_1(\mathbf{S}_1 \cdot \mathbf{S}_2 + \mathbf{S}_3 \cdot \mathbf{S}_4) - 2J_2(\mathbf{S}_1 \cdot \mathbf{S}_3 + \mathbf{S}_2 \cdot \mathbf{S}_4) - 2J_3(\mathbf{S}_1 \cdot \mathbf{S}_4 + \mathbf{S}_2 \cdot \mathbf{S}_3) \quad (1)$$

One quintet, three triplets, and two singlets are possible for the four-spin model. The energies for these spin-states are given by the following Eqs. (2)–(7):

$$E(S_1 = 2) = -J_1 - J_2 - J_3 \quad (2)$$

$$E(S_2 = 1) = J_1 + J_2 - J_3 \quad (3)$$

$$E(S_3 = 1) = J_1 - J_2 + J_3 \quad (4)$$

$$E(S_4 = 1) = -J_1 + J_2 + J_3 \quad (5)$$

$$E(S_5 = 0) = J_1 + J_2 + J_3 - 2\sqrt{J_1^2 + J_2^2 - J_2J_3 + J_3^2 - J_1(J_2 + J_3)} \quad (6)$$

$$E(S_6 = 0) = J_1 + J_2 + J_3 + 2\sqrt{J_1^2 + J_2^2 - J_2J_3 + J_3^2 - J_1(J_2 + J_3)} \quad (7)$$

The thermal equilibrium between these spin states gives the temperature dependence of magnetic susceptibility as

$$\chi_p = \frac{N_A g^2 \mu_B^2}{3k_B T} \frac{\sum_i S_i(S_i+1)(2S_i+1)\exp(-E(S_i)/k_B T)}{\sum_i (2S_i+1)\exp(-E(S_i)/k_B T)} \quad (8)$$

To avoid over-parameterization, we assumed $J_2 = J_3$. Then, the estimated value is regarded as an average of two magnetic interactions. The observed $\chi_p T$ values are well reproduced using Eq. (8) with $J_1/k_B = +5.0$ K and $J_2/k_B = J_3/k_B = -0.9$ K (solid line in Fig. 3).

3.4. Characterization of a Cu-complex of *3H*

The complex obtained from the reaction of **3H** with copper acetate in methanol containing aqueous ammonia was hardly soluble in various organic solvents. Further purification could not be possible. However, the elementary analysis of this powder showed reasonable values within ±0.5% as a formula of **3 · Cu**. The Cu-complex was stable at room temperature. Because of lack of the structure information for this complex, quantitative argument is not possible. We describe here qualitative characterization including magnetic properties of the obtained powder.

The UV–Vis reflection spectra for solid samples of the obtained Cu-complex **3 · Cu** (Fig. 4a), diradical **3H** (Fig. 4b), Cu-complex **2** (Fig. 4c), and copper(II) acetate (Fig. 4d). A broad absorption extending to 900 nm was observed for **3 · Cu**. The spectrum is similar to that of **2**. The diradical **3H** does not have absorption longer than 700 nm. The longer absorption is obviously due to the Cu(II) species. Furthermore, complex **3 · Cu** showed a very broad EPR spectrum in the region 0–800 mT with the bandwidth of ca. 200 mT at half height. Complex **2** also showed a similar broad EPR signal but with a little narrower bandwidth (ca. 140 mT). The broad signals indicate strong magnetic interactions between the Cu(II) and the radical spins [11].

Fig. 5 shows the $\chi_p T$–T plots for **3 · Cu**. The molecular formula in a magnetic repeating unit was tentatively assumed to be $C_{20}H_{26}CuN_4O_4$ (**3 · Cu**) for the χ_p calculation. One magnetic repeating unit involves 2 mol of imino nitroxide spins and 1 mol of Cu(II) spin. The observed $\chi_p T$ value at room temperature was 1.32 emu K mol^{-1}, which is higher than the value (1.23 emu K mol^{-1}) of magnetically independent 2 mol radical ($S = 1/2$ with a typical value of $g = 2.007$) spins and a one Cu(II) ($S = 1/2$ with a typical value of $g = 2.2$) spin. Decreasing the temperature (298–55 K) increased the $\chi_p T$ values (1.32–1.50 K), indicating the presence of a ferromagnetic interaction between the radical spin and the Cu(II) spin. Further cooling decreased the $\chi_p T$, suggesting a weaker antiferromagnetic interaction. The ferromagnetic interaction observed at high temperature region well accords with our expectation.

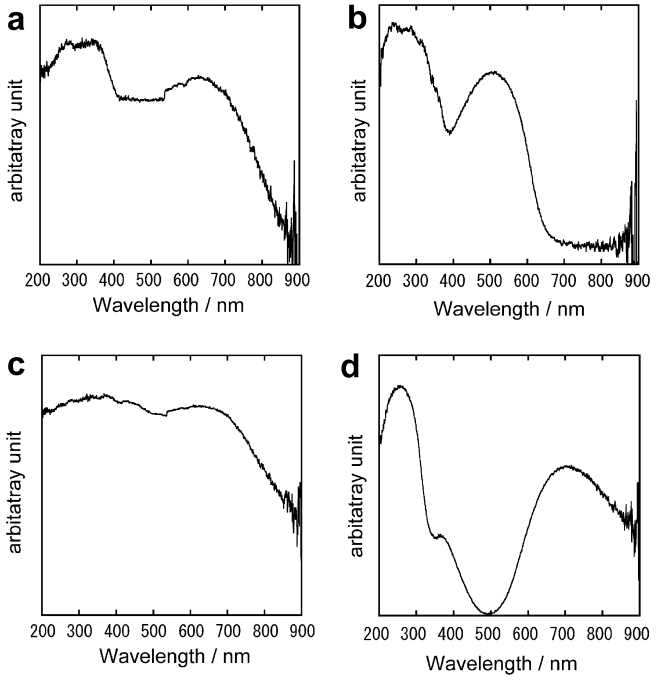

Fig. 4. UV–Vis reflection spectra of Cu-complex **3 · Cu** (a), **3H** (b), **2** (c), and copper acetate (d).

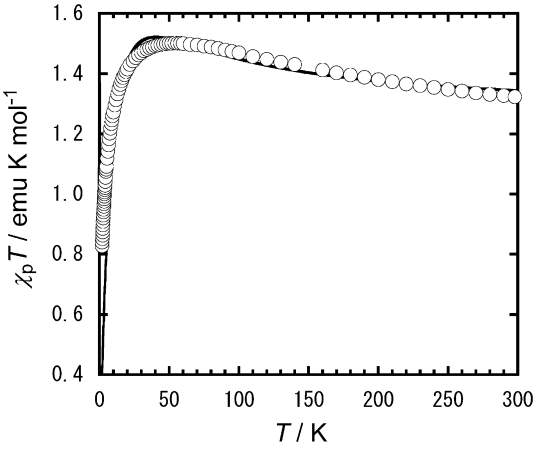

Fig. 5. The $\chi_p T$–T plots of the copper complex of **3H**; the solid line is a simulation line with $J/k_B = +40$ K and $\theta = -8$ K.

Assuming that the ferromagnetic interaction between Cu(II) spin and the radical spins observed at higher temperatures is much stronger than the magnetic interactions through the *m*-phenylene moiety, we may apply the following three-spin model:

$$H = -2J(\mathbf{S}_{IN1} \cdot \mathbf{S}_{Cu} + \mathbf{S}_{Cu} \cdot \mathbf{S}_{IN2}) \quad (9)$$

where the three $S = 1/2$ operators, $\mathbf{S}_{IN1}$, $\mathbf{S}_{IN2}$ on the imino nitroxide moieties and $\mathbf{S}_{Cu}$ on the Cu(II) ion, were coupled by the exchange interaction J. The possible difference in the exchange interactions, J(IN1–Cu) $\neq J$(IN2–Cu), was disregarded. The parameter J in Eq. (9) is regarded as an averaged one. The trimer model affords one quartet ($S = 3/2$) and two doublet ($S = 1/2$) states. The energies of these states are given by

$$E(S_1 = 3/2) = 0 \quad (10)$$

$$E(S_2 = 1/2) = J \quad (11)$$

$$E(S_3 = 1/2) = 3J \quad (12)$$

The thermal equilibrium between these states gives the temperature dependence of susceptibility as

$$\chi_p = \frac{N_A g^2 \mu_B^2}{3k_B(T-\theta)} \frac{15 + \frac{3}{2}e^{-J/kT} + \frac{3}{2}e^{-3J/kT}}{4 + 2e^{-J/kT} + 2e^{-3J/kT}} \quad (13)$$

where θ represents the intermolecular interaction in the mean-field approximation. The observed temperature dependence of $\chi_p T$ was reproduced by Eq. (13) with the parameters $J/k_B = +49$ K and $\theta = -8$ K, as depicted by the solid line in Fig. 5.

The obtained J value is considerably smaller than the value of ferromagnetic interaction ($J/k_B = +250$ K) observed for Cu-complex **2** [7a]. Several explanations are possible; (1) a part of imino nitroxide may not survive under the complexation conditions, so that tight ferromagnetic interaction between imino nitroxide and Cu(II) may be partly lost, (2) only a part of Cu(II) may form the complex. Although these unfavorable reactions should be minor paths judging from the $\chi_p T$ value at room temperature and the elementary analysis, the occurrence of these reactions may seriously affect the overall magnetic behavior of **3 · Cu**.

Appendix A. Supplementary material

CCDC 617391 contains the supplementary crystallographic data for **3H**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.09.058.

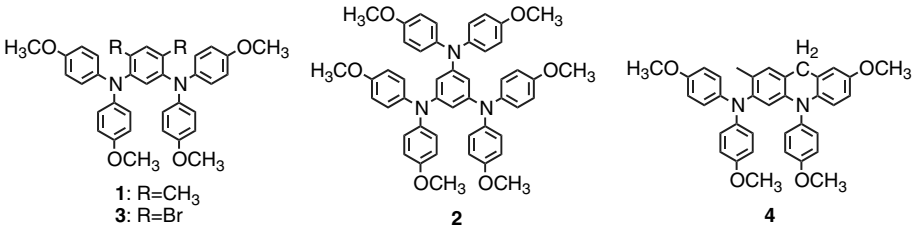

Fig. 1. Structures of compounds **1**–**4**.

states [2k,4]. However, the stabilization mechanism is still not clear. We assumed that the decomposed product was compound **4**, which was generated by intramolecular hydrogen abstraction. Until now, there was no direct evidence for the generation of **4**. Although a number of experimental and theoretical studies have been performed about reaction mechanisms of mono cation radicals [5], triplet dication diradicals have very rarely been dealt with. In this study, we report the generation and decomposition of $\mathbf{1}^{++}$ in preparative scale, and the identification of the structures for the decomposed products.

2. Results and discussion

The diamine **1** was synthesized by the methods reported before [2b]. Compound **3** was synthesized by bromination of *N*,*N*,*N*′,*N*′-tetra(*p*-anisyl)-1,3-phenylenediamine. The synthetic detail of **3** will be reported elsewhere [3]. Fig. 2 shows the NMR spectra of **1** and the corresponding decomposition products. The compound **1** exhibits absorption peaks of the methyl and methoxy groups at 1.97 ppm and 3.75 ppm, respectively (Fig. 2a). The generation of the mono cationic state was conducted as shown below. To the solution of **1** (0.127 g, 0.23 mmol) in dichloromethane (10 ml), 1.5 equiv. of $SbCl_5$ (44.3 μl, 0.35 mmol) in dichloromethane (10 ml) were slowly dropped at 15 °C under nitrogen atmosphere. Upon the addition of $SbCl_5$, the color of the solution immediately turned to blue, indicating the generation of radical species. The solution was stirred for 3 days until no change in solution color was observed. The obtained solution was mixed with aqueous ascorbic acid solution, extracted with chloroform, dried over sodium sulfate, and evaporated under reduced pressure to give pale yellow oil. The NMR spectrum of the product showed approximately quantitative recovery of **1**.

The generation of the dicationic state was conducted similarly. The solution of **1** (0.127 g, 0.23 mmol) in dichloromethane (10 ml) was mixed with 3 equiv. of $SbCl_5$ (87.4 μl, 0.69 mmol) in dichloromethane (10 ml), and allowed to stand for 3 days under the same condition described for the monocation. The color of the solution gradually changed from blue to bluish-purple. The

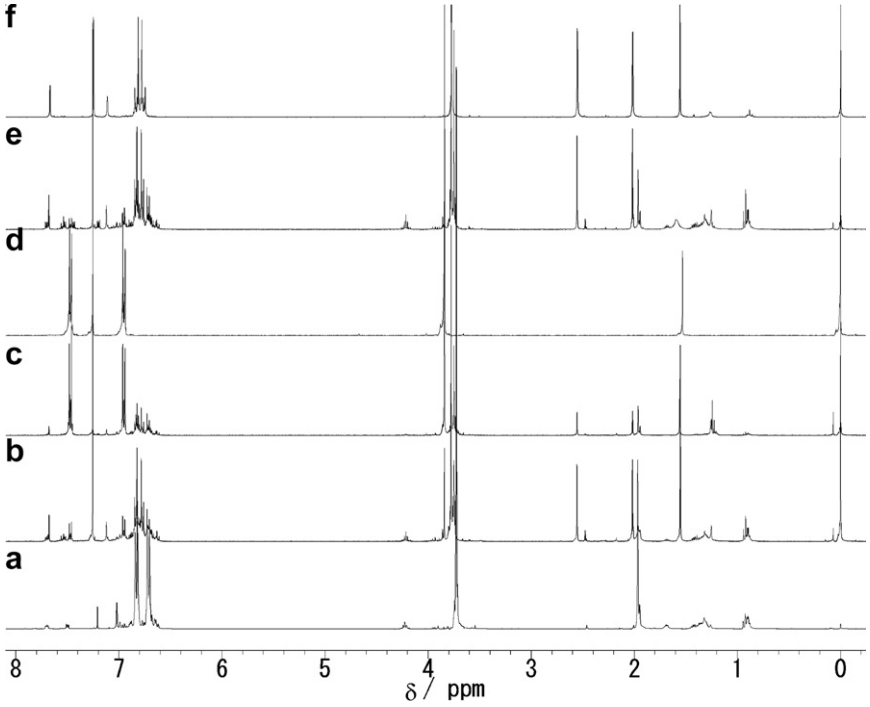

Fig. 2. NMR spectra of **1** and its decomposition products (see the text for details).

obtained solution was treated similarly to give brown oil. As the NMR spectrum of the oil was too complex to identify, short silica gel column chromatography (eluted with chloroform) was conducted to remove minor products with high polarity to give pale yellow oil (0.060 g). The NMR spectrum of the crude product is shown in Fig. 2b. The absorption peaks derived from **1** disappeared almost entirely. Two singlet peaks were observed at 2.0 and 2.5 ppm. Several peaks were observed in the region from 3.6 to 4.0 ppm. Complicated absorption pattern was observed in the aromatic region. The crude oil was recrystallized from ethanol to give pale yellow crystals. The NMR (Fig. 2c) and mass ($m/z = 214.2$) spectra of the main product are consistent with those of commercially available 4,4′-dimethoxybiphenyl (**5**) (Fig. 2d). The absorption peaks derived from anisole (methoxybenzene) were not observed. On the other hand, the filtrate was evaporated and dried in vacuo. The NMR spectrum of the filtrate is shown in Fig. 2e. Some characteristic peaks are completely consistent with that of authentic *N*,*N*-bis(4-methoxyphenyl)-5-nitro-2,4-xylidine (**6**) prepared by us (Fig. 2f) [2b]. UV–Vis MS measurements also supported the formation of **6** ($\lambda_{max} = 284$ nm in $CHCl_3$, $m/z = 378.2$). These results show that the dication $\mathbf{1}^{++}$ decomposed via cleavages of pi-system (Fig. 3). No evidence of the formation of **4** was observed. The other components have not been characterized. The mono- and dicationic states of **3** were generated in the same manner to **1**, and **3** was quantitatively recovered upon reduction by ascorbic acid, indicating surprisingly stable dicationic state on the day time scale. Previously, we examined the stability and absorption spectrum of $\mathbf{1}^{++}$ by ETSF methods [2j]. Dication diradical $\mathbf{1}^{++}$, which was chemically generated by mixing with two equivalents of tris(2,4-dibromophenyl)amine cation radical, gradually decomposed over 10 s. During the process, compound **6** was not observed, showing the generation of **6** after mixing with aqueous ascorbic acid. On the other hand, formation of **5** in the decomposition process was not clear due to the overlapping with other absorption peaks at the shorter wavelength region around 250 nm. Summarizing the experimental results described above, a

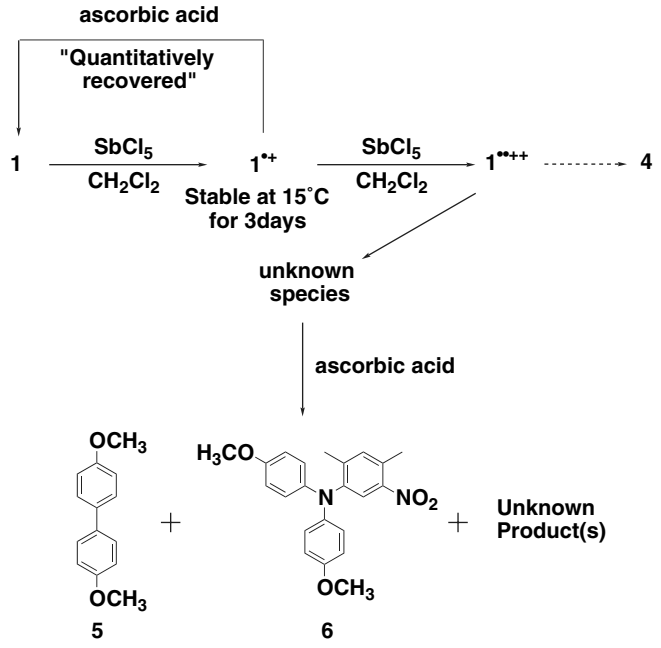

Fig. 3. Decomposition routes of the mono- and dication of **1**.

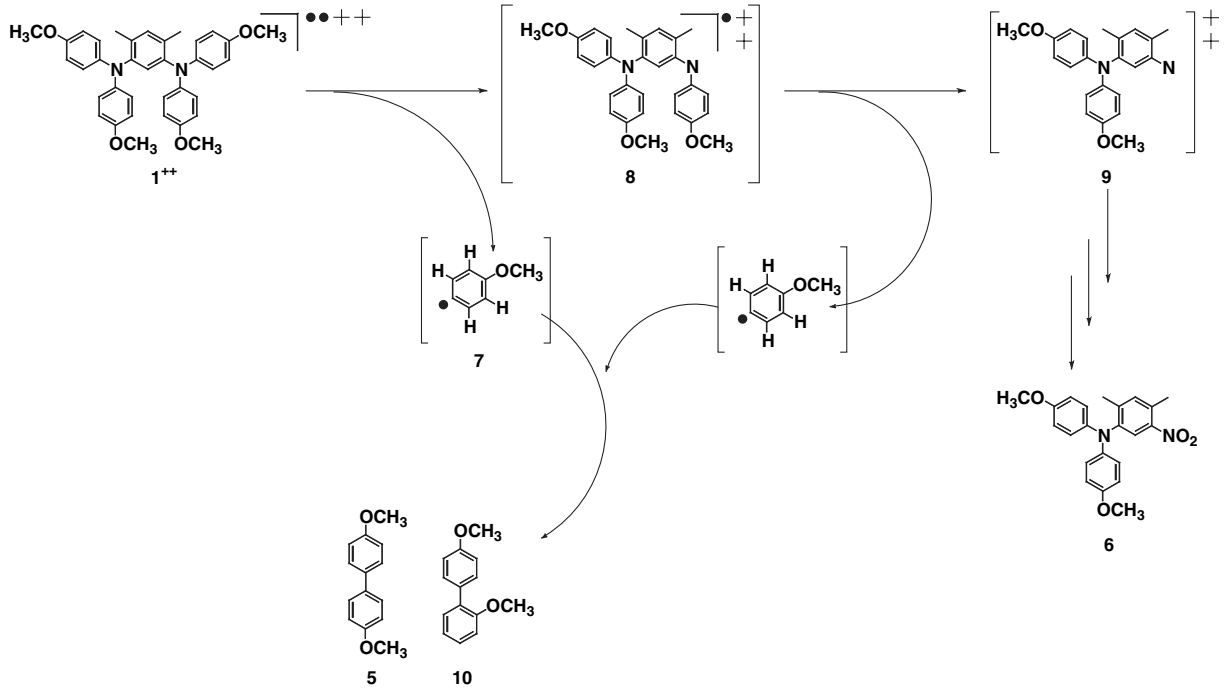

Fig. 4. Proposed decomposition routes of $\mathbf{1}^{++}$.

proposed decomposition route is shown in Fig. 4. Dication diradical $\mathbf{1}^{++}$ decomposes via the cleavage of one nitrogen-aryl bond to give anisyl radical (**7**) and a dication monoradical (**8**). Then **8** decomposes to give one more **7** and a dication (**9**), which was not observed by conventional experimental techniques and suggested to be short-lived. Dimerization of compounds **7** gives **5** via *p–p* coupling reaction. Meanwhile, 2, 4′-dimethoxybiphenyl (**10**), which was not detected in this study, could be formed via *o–p* coupling reaction. In order to examine whether **5** was formed before the addition of ascorbic acid, decomposition of $\mathbf{1}^{++}$ in the presence of radical trapping reagents is underway. Dication **9**, which is tentatively considered to be the precursor of **6**, would be reduced with ascorbic acid and may finally be converted to stable **6** via several steps. At present, the origin of two oxygen atoms in **6** is not clear. Spectroscopic detection of **9** is now in progress

It is widely known that triphenylamine gives the corresponding mono cation radical upon one electron oxidation, which immediately dimerize to give tetraphenylbenzidine [6]. On the other hand, triarylamines with substituents on the *para* positions give very stable mono cation radicals due to the thermodynamic and kinetic stabilization [6]. Based on the knowledge, molecular designs of the oligotriarylamine precursors have been carried out. In other words, the substituents were introduced to avoid rapid follow-up dimerization reactions. We have carefully designed **1** with electrodonating methoxy and methyl groups so that the corresponding mono- and dicationic states could be stabilized. Although $\mathbf{1}^{++}$ is effectively blocked by the substituents from external reagents, it may not be enough for thermodynamic stabilization, leading to the decomposition via the cleavages of the pi-conjugation. In this light, it is crucial to develop a new strategy to stabilize the oligocationic states. To elucidate the role of bromo groups, MO-based theoretical considerations are also underway.

3. Conclusions

In order to clarify the decomposition reaction of ground-state triplet dication diradicals, compound **1** was oxidized with $SbCl_5$ in preparative scale. The mono cation $\mathbf{1}^{+}$ was quantitatively recovered whereas the dication $\mathbf{1}^{++}$ gradually decomposed to give **5** and **6** as the main products, which are considered to be generated via the cleavage of the pi-conjugation. On the other hand, **3** with bromo groups gave extremely stable dication, indicating effectiveness of the bromo groups for the stabilization of the oligoarylamine-based cationic states. Based on the knowledge, studies on brominated 3,3′-bis(diarylamino)triphenylamine trication triradicals in the ground-state quartet are in progress.

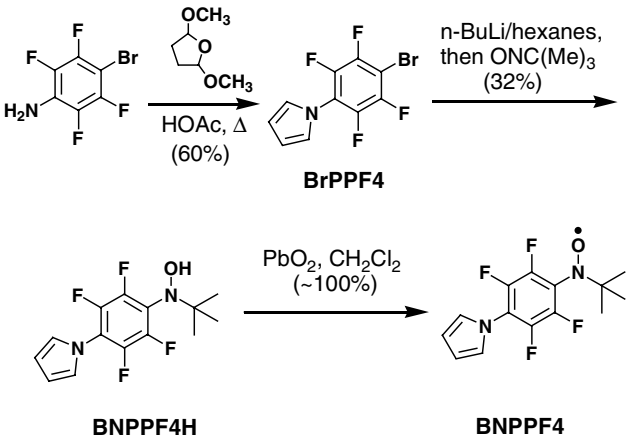
by adaptation of the procedure of Nakazaki et al. [3] to give a white solid in 60% yield. Mp: 42–47 °C. ^{1}H NMR ($CDCl_3$): δ 6.42 (t, 2H, $J = 2.0$ Hz), 6.93 (t, 2H, $J = 2.0$ Hz).

2.2. 1-(4-[N-tert-Butylhydroxylamino]-2,3,5,6-tetrafluorophenyl)pyrrole (*BNPPF4H*)

A solution of 2.0 M of *n*-BuLi in hexanes (1.37 mL, 2.8 mmol) was slowly added to a solution of **BrPPF4** (0.75 g, 2.5 mmol) in 10 mL of anhydrous THF at −78 °C under nitrogen. After 1 h, a solution of 2-methyl-2-nitrosopropane [4] (0.25 g, 2.8 mmol) in 10 mL of anhydrous THF was added dropwise to the reaction mixture. The reaction was allowed to warm to room temperature while stirring overnight, then was quenched by addition of saturated aqueous ammonium chloride. The layers were separated, and the organic layer was washed with water. The combined aqueous layers were extracted with ether, and the combined organic layers dried over anhydrous magnesium sulfate. The organic solution was reduced in volume *in vacuo*, then the residue was filtered to collect part of the product as white powder; that filtrate was then rotary evaporated and was subjected to column chromatography (silica, dichloromethane) to give additional product (total yield of **BNPPF4H** 0.24 g, 32%). Mp: 128–130 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 6.93 (m, 2H, $J = 4$ Hz), 6.40 (m, 2H, $J = 4.4$ Hz), 5.43 (s, 1H); 1.26 (s, 9H).

2.3. 1-(4-[N-tert-Butylaminoxyl]-2,3,5,6-tetrafluorophenyl)pyrrole (*BNPPF4*)



Solid PbO_2 (0.20 g, 0.84 mmol) was added to a solution of **BNPPF4H** (0.103 g, 0.34 mmol) in dichloromethane. The reaction was monitored by TLC and was complete after 1.5 h. The reaction was filtered and evaporated, and the resulting red oil recrystallized from hexanes to give red crystalline product (0.10 g, 100%). Mp: 62–65 °C. *Anal.* Calc. for $C_{14}H_{13}F_4N_2O$: C, 55.82; H, 4.35; N, 9.30. Found: C, 55.94; H, 4.51; N, 9.21%. ESR (9.59 GHz, toluene, 230 K): $g = 2.00780$, $a_N = 12.14$ G.

2.4. Magnetic measurements

Measurements for **BNPPF4** were carried out over 1.8–300 K using a Quantum Design SQUID MPMS5 magnetometer for polycrystalline samples placed in gelatin capsules and held in place with a small plug of cotton. Magnetic susceptibilities were corrected for temperature independent magnetic contributions.

3. Synthesis and characterization

The synthesis of **BNPPF4** is shown in Scheme 1. The radical is red solid that appears to be indefinitely stable under ambient conditions. Its electron spin resonance

Scheme 1. Synthesis of **BNPPF4**.

(ESR) spectrum showed a 1:1:1 hyperfine coupled (hfc) triplet with $a(N) = 12.1 \pm 0.2$ G, somewhat larger than the 11.72 ± 0.02 G nitrogen hfc found [5] for closely related **BNPP** (uncertainties are 95% confidence limits). Steric repulsion between the **BNPPF4** *tert*-butylnitroxide group and its *ortho* C–F units presumably disfavors a conformation where the nitroxide is coplanar or nearly coplanar with the *ortho*-fluorinated arene. The crystallography of **BNPPF4** supports this, as described below.

The limited data available from ESR and NMR studies of aryl-fluorinated, alkyl-arylnitroxides show $a(N) \sim 11$–13 G, and $a(F) \sim 0.6$–1.2 G, with $a(N)$ much affected by steric hindrance (size of the alkyl group on the nitroxide) that interacts with the *ortho* fluorine atoms [2b,2c]. This effect on conformation could lead to unusual delocalization behavior of the radical spin. Torssell and co-workers concluded [2b] that all of the fluorine atoms in 1-(*N*-*tert*-butylnitroxyl)pentafluorobenzene (**PhF5NIT**) surprisingly had the same spin polarization, contrary to the usual expectation of alternant spin density sites. They attributed this to sensitivity of nitroxide delocalization to steric induced twisting of the nitroxide, leading to σ-framework polarization rather than π-spin polarized delocalization. We have not yet obtained $a(F)$ for **BNPPF4** (Torssell and coworkers used perdeuterated *tert*-butyl groups to do this

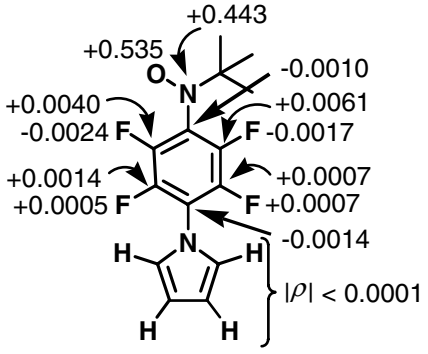


Fig. 1. UB3LYP/EPR-II computed Mulliken spin densities (ρ) for **BNPPF4**, using the geometry of Form A in Fig. 2.

for **PhF5NIT**), but have computed [6] spin densities for **BNPPF4** using the UB3LYP/EPR-II method with Gaussian 03 (Fig. 1). The nonalternant spin polarization found on the aryl carbons is not in accord with a typical π-polarization mechanism, but we did not find the fluorines all to have the same spin polarization sign, unlike the case reported for **PhF5NIT**. Further studies will be needed to determine the hfc of the fluorine atoms in **BNPPF4** and allow further comparisons to the computational results and to **PhF5NIT**.

4. Crystallography

Diffraction grade single crystals of **BNPPF4** were obtained by precipitation from hexanes and analyzed [7]. Fig. 2 shows an ORTEP style representation of the two forms present in the lattice, which have small differences in the nitroxide and pyrrole dihedral torsions relative to the tetrafluoroaryl ring. Structural and crystallographic details are summarized in Tables 1 and 2 for the analysis at room temperature. Analysis of a crystal at 105 K showed little structural change relative to the room temperature structure.

5. Magnetic studies

Fig. 3 shows temperature dependent magnetic susceptibilities and magnetization versus field data for **BNPPF4**. The Curie–Weiss plot shows strong deviation from linearity below about 10 K due to onset of antiferromagnetic (AFM) exchange interactions. A linear fit to the data for $1/\chi(T > 50\ \mathrm{K})$ yielded a Curie constant of 0.362 emu/Oe mol, in good agreement with the expected value for $S = 1/2$ spin carriers; the Weiss constant = (−)1.2 K. The AFM exchange is further shown by the strong downturn in the $\chi(T)$ data below about 7 K. The magnetization plot has inverted curvature consistent with significant AFM exchange, to the point that $M(H)$ does not nearly approach the expected saturation value for $S = 1/2$ at fields up to 50 000 Oe.

[a] See Fig. 2 for atom numbering.

of both forms A and B, consistent with the nitrogen ESR hfc being larger than that for **BNPP** in solution. This implies that the degree of nitroxide spin delocalization onto the aryl ring is small, as mentioned above, and confirmed by the computational investigation.

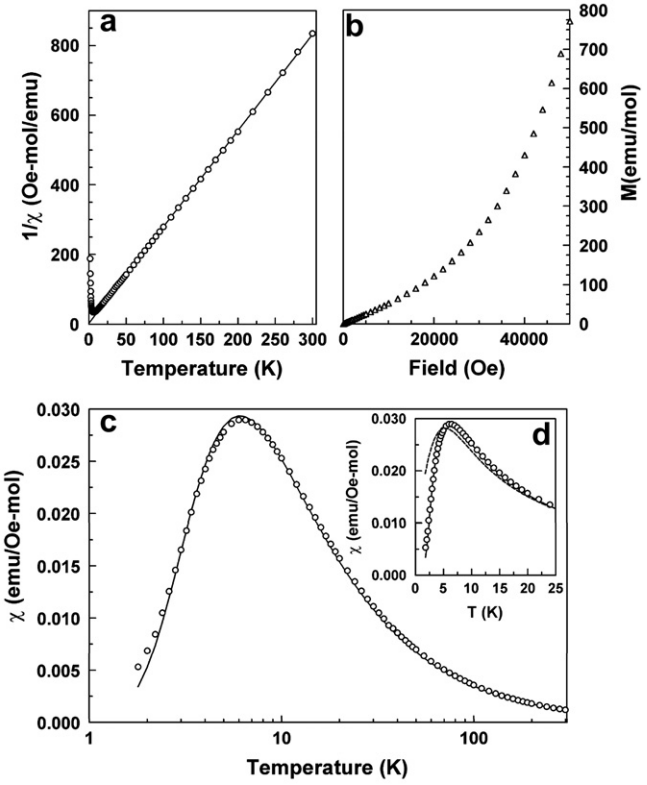

Fig. 3. Magnetic data for **BNPPF4**: (a) Curie–Weiss plot obtained at 1000 Oe, showing a linear fit to the data for $T > 50$ K, (b) magnetization vs. field (M vs. H) plot obtained at 1.8 K, (c) $\chi T(T)$ plot obtained at 1000 Oe, showing spin-pairing fit, (d) expansion of plot (c), comparing a spin-pairing fit (solid black line) to 1D Heisenberg AFM chain fit (gray broken line).

The magnetic exchange behavior of **BNPPF4** was unexpected relative to the room temperature crystal structure. The $\chi(T)$ data show loss of about 90% of paramagnetic susceptibility upon cooling from 8 K to 2 K, suggestive of spin-pairing behavior. An antiferromagnetically coupled singlet–triplet equilibrium model using spin Hamiltonian equation (1) and the Bleaney–Bowers [8] susceptibility equation (2) was applied to the $\chi(T)$ data with inclusion of a mean-field correction θ. For Eq. (2), the constants N, β, and k are Avogadro's number, the Bohr magneton, and the Boltzmann constant, per the usual practice:

$$\hat{H} = -2J\hat{S}_A\hat{S}_B \tag{1}$$

$$\chi = \frac{2Ng^2\beta^2}{k(T-\theta)} \cdot \frac{e^{2J/kT}}{1+3e^{2J/kT}} \tag{2}$$

The fit showed good agreement over the full temperature range studied (Fig. 2c), with $2J/k = (-)8.7 \pm 0.2$ K and $\theta = (-)0.2 \pm 0.2$ K, and $g = 2.017 \pm 0.014$: the uncertainties are 95% confidence limits. However, the only crystallographic dyad motifs are those shown in Fig. 4 relating two molecules of Form A, and two of Form B, both by the symmetry operation $(1/2 - x, y, -1 - z)$. The dyads are head-to-tail π-stacks with the electron poor fluorinated aryl rings interacting with the pyrrole rings. This arrangement

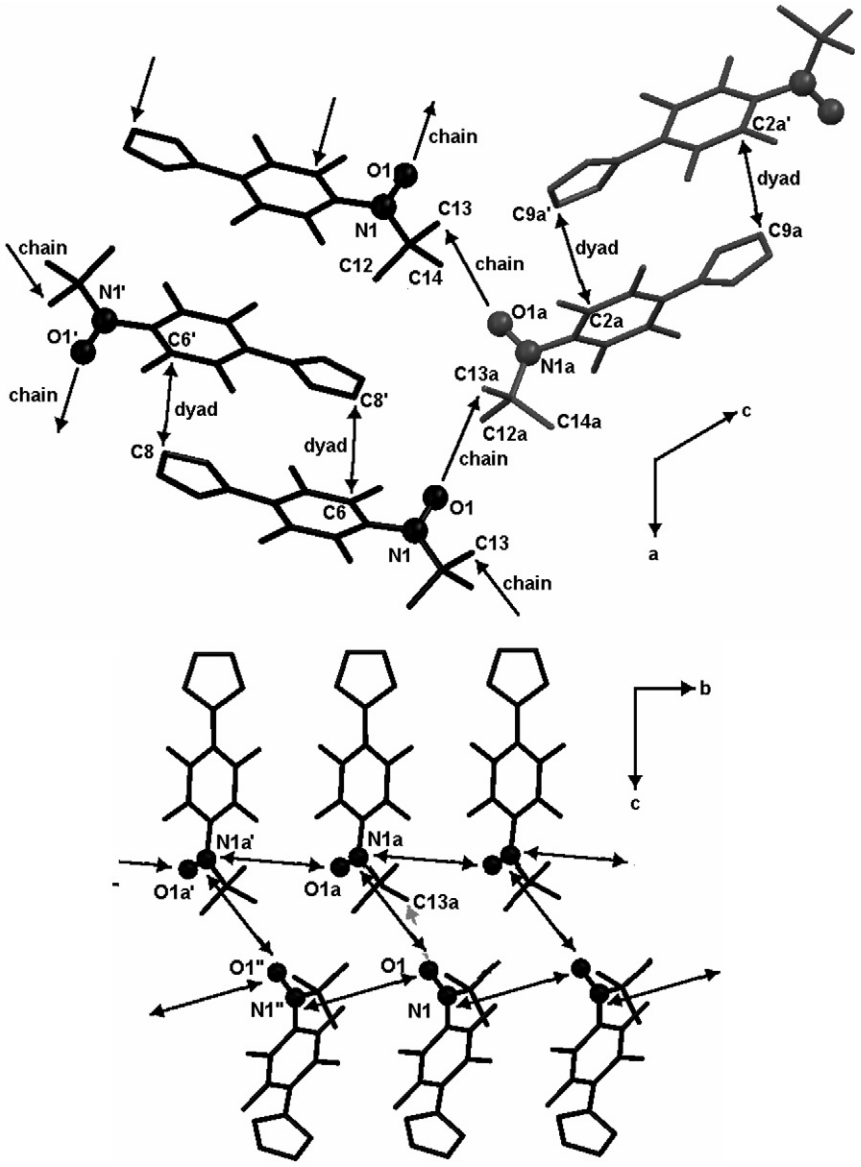

Fig. 4. Crystallographic close contacts in **BNPPF4**. Labeling follows Fig. 2.

brings the large spin density NO sites into contact with pyrrole groups that have virtually no spin density. There are no nitroxide NO–NO contacts at all at distances less than 5.40-5.5 Å. Thus, a simple spin-pairing mechanism between large spin density sites is not easily related to the crystalline packing in **BNPPF4**.

The crystallography suggests the possibility of 1D chain behavior, due to the chains of nitroxide to *tert*-butyl close contacts along the *a*-axis, and of nitroxide to nitroxide contacts along the *b*-axis (Table 2, Fig. 4). Although the *tert*-butyl groups have little unpaired spin density, there might be enough to induce some intermolecular exchange, given the interaction with the large spin density on the nitroxyl oxygen. As mentioned above, the chains of nitroxide NO–NO contacts have large, 5.5 Å distances between large spin density sites, but still should allow for some exchange between nitroxides.

Despite the presence of multiple 1D crystallographic motifs, a 1D AFM Heisenberg chain (Bonner–Fisher) [9] model fit to the $\chi(T)$ data shows poor agreement, even when a mean-field term is included. The nonlinear least squares best fit to this model, shown in Fig. 2d, gives $J/k = (-)3.4 \pm 1.3$ K, and $\theta = (-)0.8 \pm 1.9$ K, with $g = 2.022 \pm 0.014$, and deviates strongly from the data in the lower temperature range.

A tentative explanation for apparent spin-pairing exchange behavior in a nominally chain-like crystal lattice would be if **BNPPF4** undergoes a spin Peierls transition [10] at or somewhat above 8 K from 1D chain to a dimeric or strongly alternating AFM chain behavior. Decreasing temperature could distort the crystal packing in a manner to bring molecules closer together at low temperatures, and favor spin-pairing behavior. No significant change in the crystallography of **BNPPF4** was found down to

105 K, so any spin Peierls transition would have to occur well below this temperature.

Of course, the various close contacts involving C–F bonds may induce unexpected exchange behavior in **BNPPF4**, since that the scarce data to date concerning aryl C–F bond experimental spin polarization and spin density distributions appear to be in some ways anomalous, and sensitive to local environment. Overall, the magnetostructural behavior of **BNPPF4** is not straightforward to interpret, making it a rather interesting though simple molecule.

7. Conclusions

Radical **BNPPF4** is apparently the first heavily ring-fluorinated aryl *tert*-butyl nitroxide to be made by a preparative scale synthetic route, and to be subjected to magnetostructural analysis. Its crystallization behavior is reasonably consistent with interaction between attractive dipoles (nitroxide–HC interactions, fluoroarene–pyrrole π-stack interactions), but its magnetic behavior is not straightforward by comparison to obvious intermolecular close contacts. Neither intramolecular spin density distributions nor their related intermolecular exchange interactions in fluoroarene-substituted *tert*-butylnitroxides have been much explored to date. Further investigation seems warranted for this and related variants to get a better idea of the effect of aryl group fluorination upon organic magnetism of *tert*-butylnitroxides and related systems.

compound (H_5PTCE, Fig. 1a), whose properties we report here for the first time. Phenyltricyanoethylene reacts with $V(CO)_6$ to yield a material that is magnetically ordered below 215 K. We also report the re-examination of the reaction of $V(CO)_6$ with pentafluorophenyltricyanoethylene (F_5PTCE, Fig. 1b) that, with improved synthesis and handling, gives a material that is attracted to a permanent magnet at room temperature and orders at the highest temperature we have seen for an acceptor other than TCNE, 307 K [8]. On a mass percent basis, this compound has the lowest fraction of transition metal for a material ordered at room temperature (8.6 mass% based on the empirical formula V[acceptor]$_2$).

2. Experimental

2.1. General considerations

Preparations of air sensitive compounds were carried out in a nitrogen-filled Vacuum Atmospheres glovebox. Vanadium hexacarbonyl was made from $[V(CO)_6]^-$-$[(Et)_4N]^+$ according to the literature procedure [10]. Malononitrile, *N*-chlorosuccinimide and piperidine were purchased from Aldrich. Pentafluorobenzaldehyde was purchased from Acros and sublimed prior to use. Reagents were used as received except as noted below. Dichloromethane was distilled from P_2O_5 and degassed with glovebox nitrogen prior to use. Acetonitrile was distilled from P_2O_5 followed by distillation from CaH_2 under argon prior to use. F_5PTCE was synthesized based loosely on the literature procedure and described below [11]. Purity was established by ^{1}H and ^{19}F NMR and by infrared spectroscopy. Elemental analyses were performed by Desert Analytics, Tucson, AZ.

2.2. Magnetic measurements

All magnetic measurements were performed on a 7 T Quantum Design MPMS SQUID magnetometer. Measurements of magnetization as a function of temperature were performed from 5 to 310 or 315 K as indicated. Powder samples were cooled in 100 G applied field and measured upon warming in 5 G applied field. Measurements of magnetization as a function of applied magnetic field were performed at 5 K. The amplitude of the oscillating magnetic field used for ac susceptibility measurements was 3.5 Oe with zero dc bias field and at frequencies of 1, 10 and 100 Hz. Diamagnetic corrections were not applied to the *M* versus *T* or *M* versus *H* data.

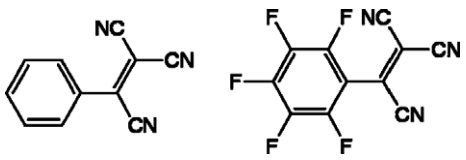

Fig. 1. Structure of (a) phenyltricyanoethylene (H_5PTCE), (b) pentafluorophenyltricyanoethylene (F_5PTCE).

2.3. Electrochemistry measurements

The cyclic voltammogram was recorded using a CH Instruments model 600A potentiostat. Measurements were performed on ~5 mM solutions in CH_3CN/0.1 M [*n*-Bu_4N]-[PF_6] and taken between the potential range of 0 and −400 mV at a scan rate of 100 mV/s using a polished carbon electrode with Ag/AgCl as the reference. Solution resistance was compensated 95% using positive feedback IR compensation for all measurements.

2.4. Powder diffraction measurements

Samples were sealed in 1.0 mm diameter glass capillaries (Blake Industries, Scotch Plains, NJ) inside the glovebox and data were collected in transmission mode on an R-Axis Rapid diffractometer using copper radiation, a graphite-monochromator and a 0.5 mm incident beam collimator.

2.5. Synthesis

2.5.1. 2-(Pentafluorophenyl)-1,1-dicyanoethylene

In a 200 mL beaker, pentafluorobenzaldehyde (6.30 g, 32.1 mmol) and malononitrile (2.15 g, 32.6 mmol) were stirred together and dissolved in 80 mL of 100% ethanol. While stirring, two drops of piperidine were added. The solution was allowed to stir overnight. Afterwards, the solution was diluted with 80 mL of dichloromethane, washed with water (4 × 80 mL), dried with anhydrous sodium sulfate and the solvent removed in vacuo to afford light yellow crystals. Yield: 4.07 g (51.8%). IR (KBr): ν(CN), 2243 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.75 (s, 1H) ppm versus TMS. ^{19}F NMR (376 MHz, $CDCl_3$) δ −132.7 (m, 2F), −143.7 (m, 1F), −158.6 (m, 2F) ppm versus Freon 11 (external standard).

2.5.2. 2-(Pentafluorophenyl)-1,1,2-tricyanoethane

In a 1 L beaker, 2-(pentafluorophenyl)-1,1-dicyanoethylene (3.50 g, 14.3 mmol) was dissolved in 250 mL of 100% ethanol. Separately, potassium cyanide (1.93 g, 29.6 mmol) was dissolved in 150 mL of water and cooled in an ice bath. In quick succession, the cold potassium cyanide solution was added to the ethanol solution followed by 500 mL of ice cold water. After stirring for 45 min, 4 mL of conc. HCl was added to yield a white precipitate. After stirring the solution for another 15 min, the stirbar was removed and the beaker was transferred to the refrigerator overnight to allow the solid to settle. The white crystals were filtered, rinsed thoroughly with water and dried by suction. Yield: 2.68 g (69%). IR (KBr): ν(CN), 2267 cm^{-1} and 2265 cm^{-1} (shoulder). ^{1}H NMR (400 MHz, $CDCl_3$) δ 4.85 (d, 1H), 4.45 (d, 1H) ppm versus TMS. ^{19}F NMR (376 MHz, $CDCl_3$) δ −138.6 (m, 2F),

−145.4 (m, 1F), −156.9 (m, 2F) ppm versus Freon 11 (external standard).

2.5.3. 2-(Pentafluorophenyl)-1,1,2-tricyanoethylene (F_5PTCE)

In a 100 mL round bottom flask equipped with a magnetic stirbar, 2-(pentafluorophenyl)-1,1,2-tricyanoethane (500 mg, 1.84 mmol) was dissolved in ~25 mL of diethyl ether and cooled to 0 °C. *N*-Chlorosuccinimide (260 mg, 1.94 mmol) was then added with rapid stirring. Over the course of 20 min, ~45 mL of ice cold water was also added with vigorous stirring. The mixture was transferred to a separatory funnel; the organic layer was washed with ice cold water (3 × 30 mL) and dried with anhydrous sodium sulfate. Removal of the ether in vacuo left behind a light pink solid which was purified by silica gel column chromatography with dichloromethane as the mobile phase. Yield: 293 mg (59%). IR (KBr): ν(CN), 2248 cm^{-1} and 2238 cm^{-1}. ^{19}F NMR (376 MHz, $CDCl_3$) δ −132.9 (m, 2F), −140.6 (m, 1F), −156.3 (m, 2F) ppm versus Freon 11 (external standard).

2.5.4. Phenyltricyanoethylene (H_5PTCE)

H_5PTCE was prepared by a similar procedure, using benzaldehyde as the starting material. IR (KBr): ν(CN), 2235 cm^{-1}, 2233 cm^{-1} (shoulder). ^1H NMR (400 MHz, $CDCl_3$) δ 8.01 (m, 2H), 7.73 (m, 1H), 7.63 (m, 2H) ppm versus TMS.

2.5.5. $V[F_5PTCE]_2$

Under a nitrogen atmosphere, vanadium hexacarbonyl (21.1 mg, 0.0930 mmol) dissolved in dichloromethane (2 mL) was added dropwise to a solution containing F_5PTCE (77.1 mg, 0.286 mmol) in dichloromethane (2 mL) while stirring. After 15 min, the black precipitate, which adheres to the magnetic stirbar, was collected on a medium frit, rinsed with dichloromethane (3 × 2 mL) and dried in vacuo for 1 h. Yield: 51 mg (93%). IR (KBr): ν(CN), 2140 cm^{-1} and 2101 cm^{-1}. *Anal.* Calc. for $C_{22}F_{10}N_6V \cdot 1/20CH_2Cl_2$: C, 44.63; H, 0.02; N, 14.06. Found: C, 44.69; H, <0.1; N, 13.87%.

2.5.6. $V[H_5PTCE]_2$

$V[H_5PTCE]_2$ was prepared by a similar procedure, using 24.4 mg of $V(CO)_6$ and 54.0 mg of H_5PTCE as the starting materials. Yield: 33 mg (55%). IR (KBr): ν(CN), 2210 cm^{-1} and 2129 cm^{-1}. *Anal.* Calc. for $C_{22}H_{10}N_6V \cdot 3/8CH_2Cl_2$: C, 60.93; H, 2.46; N, 19.05. Found: C, 60.93; H, 2.31; N, 19.14%.

3. Results and discussion

3.1. Synthesis of the coordination polymers

The reaction of either H_5PTCE or F_5PTCE with $V(CO)_6$ in dichloromethane in an inert atmosphere glovebox yields a black air-sensitive solid; in the latter case, the product sticks to the stirbar because it is ordered at room temperature. Based on elemental analyses, the formulas for these compounds are $C_{22}H_{10}N_6V \cdot 3/8CH_2Cl_2$ and $C_{22}F_{10}N_6V \cdot 1/20CH_2Cl_2$, respectively, indicating two acceptors for each vanadium ion. The 2:1 acceptor/V^{2+} ratio has also been established by multiple preparations with different ratios of reactants which yield inferior products (based on lower T_cs) at less than 2:1 and materials with similar T_cs at 2.5:1 and 3:1. Both compounds have been found by powder diffraction to be amorphous, like all of the other examples in this family. The structures are assumed to be a disordered coordination polymer networks of V^{2+} cations bridged through the three nitrile nitrogen atoms by H_5PTCE or F_5PTCE radical anions. In the IR, shifts in the CN stretch to lower wavenumbers in the coordination polymers relative to the free ligands are consistent with reduction of the acceptor to the radical anionic state. H_5PTCE and F_5PTCE have $E_{red} = -0.44$ V and −0.19 V versus Ag/AgCl, respectively. For comparison, the E_{red} for TCNE = +0.25 V.

3.2. Magnetic properties

The magnetic properties of $V[H_5PTCE]_2$ have been determined by SQUID magnetometry on a freshly prepared sample. Magnetization as a function of temperature measured on warming in 5 G applied field (Fig. 2) shows a slow decrease up to about 170 K, followed by a steeper drop, finally going to zero at about 215 K. $V[H_5PTCE]_2$ is a soft ferrimagnet as indicated by the near zero coercivity and a saturation magnetization that is consistent with one unpaired electron per formula unit as would be expected (vide infra, Fig. 3). It is essentially saturated in a field of 100 G. The frequency-independent ac susceptibility (Fig. 4) confirms the onset of order below about 215 K. The corresponding perfluorinated compound, $V[F_5PTCE]_2$ exhibits similar behavior showing a slow decrease in magnetization up to about 250 K, followed by a steeper drop, finally going to zero at 307 K (Fig. 5). This compound is also a soft ferrimagnet (Fig. 6) and shows frequency-independent ac susceptibility with a T_c of 298 K (Fig. 7). The saturation magnetization is slightly below that

expected for three unpaired electrons on V(II) antiferromagnetically coupled to one unpaired electron on each of two radical anions (5585 emu G/mol, assuming $g = 2.0$). This might reflect some formation of $[TCNE]_2^{2-}$, a diamagnetic structure we have observed in crystal structures of model compounds [12].

The T_cs of both compounds decay over time when the compounds are stored at room temperature, even when under vacuum (Figs. 2 and 5), which provides insight into the slight variability of the T_c from sample to sample. More thorough removal of solvent, more careful handling of these air-sensitive materials and the ability to take magnetic measurements immediately after preparation is credited with the increased T_c for $V[F_5PTCE]_2$ when compared to the previous publication [8]. In a representative experiment, T_c decreased from 305 K to ~295 K after 3 days, but with no significant change in the sharpness of the transition. Even after three months, the sample retains a T_c of ~271 K. The reason for this has not yet been established, but could be the result of a reaction between V^{2+} and carbon–chlorine bonds in the residual solvent, even in the solid state. The causes of variations in T_c have recently been addressed in a publication [2].

4. Conclusions

The phenyltricyanoethylene skeleton clearly supports magnetic order at relatively high temperatures. However, the reasons for the difference in T_c with different acceptors need to be established. One set of experiments that could explore this question is the preparation and reaction of the various mono- and di-fluorine substituted phenyltricyanoethylene derivatives, which we are currently pursuing.

Acknowledgments

We acknowledge the Donors of the Petroleum Research Fund administered by the American Chemical Society for support of this work and the National Science Foundation

and the Virginia Tech ASPIRES program for partially funding the purchase of the SQUID magnetometer. We also thank Professor Ray Butcher for help with powder diffraction.

and structure will lead to a high-spin cluster and even more difficult to then synthesize such a species [4]. Moreover, it is also important in this area of chemistry to not only make new examples of high-spin molecules and single-molecule magnets (SMMs), but also to build up families of related compounds so that structure–property relations can be investigated. Towards this end, two successful but opposite strategies have been employed. The first is the use of rigid bridging ligands that impose structural restrictions on the geometry of the resultant cluster [5], and the second is the use of flexible ligands that impose little or no restrictions [6].

In the majority of polynuclear metal complexes, exchange interactions are mainly propagated by bridging OH^-, OR^-, O^{2-}, or RCO_2^- groups (or a combination of these), ligands which usually lead to antiferromagnetic coupling. One approach for increasing the ground state S is the replacement of some or all of these bridges with groups that promote ferromagnetic coupling. One of the best examples of the latter is the azide (N_3^-) group bridging metal ions in the 1,1-fashion (end-on); in this case the exchange coupling is ferromagnetic for a wide range of M–N–M angles [7]. We also have a continuing interest in the usefulness of flexible pyridine-based alkoxide ligands (Fig. 1) in Mn cluster chemistry, and have noticed that the anion of 2-(hydroxymethyl)pyridine (hmp^-) is a versatile N,O-chelating and bridging ligand whose alkoxide arm often supports ferromagnetic coupling between the metal atoms it bridges [8].

In this paper, we describe two mixed-valence Mn_{10} clusters of formula $[Mn^{II}_4Mn^{III}_6O_4(N_3)_4(hmp)_{12}](X)_2$ [$X = N_3^-$ (**1**), ClO_4^- (**2**)] obtained by using a combination of N_3^- and hmp^- groups in certain Mn reactions. They possess very aesthetically pleasing structures of high (T) symmetry, and are completely ferromagnetically coupled with a resulting $S = 22$ ground state, one of the highest yet reported [9]. In addition, the Mn_{10} cation is the first example of μ_3-1,1,1 azido ligands bridging *exclusively* Mn^{3+} ions, and thus presages a potentially rich new area of Mn^{III} clusters with high spin values.

A reaction mixture of $Mn(NO_3)_2$, hmpH, Et_3N and NaN_3 in a 1:1:1:1: ratio in MeCN/MeOH (20:1, v/v) gave a dark brown solution from which was subsequently isolated dark-brown hexagonal crystals of $[Mn_{10}O_4(N_3)_4(hmp)_{12}](N_3)_2$ (**1**) in 20% yield. The use instead of $Mn(ClO_4)_2$ gave the isostructural $[Mn_{10}O_4(N_3)_4(hmp)_{12}](ClO_4)_2 \cdot MeCN$ (**2** · MeCN) in a much higher yield of 75%. The latter reaction but using only MeOH as reaction solvent gave known $[Mn^{II}_2Mn^{III}_2(N_3)_2(hmp)_6]_n(ClO_4)_{2n}$ (**3**), which is a one-dimensional chain [8c].

The cation $[Mn_{10}O_4(N_3)_4(hmp)_{12}]^{2+}$ (Fig. 2) consists of ten Mn ions with a tetra-face-capped octahedral topology (Fig. 3). The central octahedron comprises six Mn^{3+} ions, and the eight faces are bridged by four μ_3-N_3^- ions and four μ_4-O^{2-} ions, with the latter also bridging to four external Mn^{2+} ions that thus cap four non-adjacent faces of the octahedron (Fig. 1). The μ_3-N_3^- ions bind in an η^1:η^1:η^1 (end-on) fashion. The Mn^{II}/Mn^{III} and O oxidation states were assigned using a combination of charge balance, bond length considerations, bond valence sum (BVS) calculations [10], and the presence of the JT distortions expected for octahedral Mn^{3+}. All Mn^{3+} ions (Mn2 and its symmetry related partners) are six-coordinate with near-octahedral geometry and thus display a Jahn–Teller (JT) distortion, which takes the form of an axial elongation of the two *trans* Mn–N_{azide} bonds (2.412(3) Å). The four Mn^{2+} ions (Mn1 and its symmetry related partners) are seven-coordinate with distorted face-capped octahedral geometry, the capping atom being the oxide atom O1 (Mn^{2+}–O^{2-} = 2.304(4) Å). The peripheral ligation about the $[Mn_{10}(\mu_4\text{-}O)_4(\mu_3\text{-}N_3)_4]^{14+}$ core is provided by the twelve hmp^- groups. Three of the latter bind terminally through their N atom to each of the exterior Mn^{2+} ions, with their alkoxide arms bridging this Mn^{2+} ion to a Mn^{3+} ion (Mn2)

(For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

(Fig. 1). There are only weak intermolecular interactions, which involve the hmp phenyl groups.

Complexes **1** and **2** join only a handful of previous mixed-valent Mn_{10} clusters [11], and are the first at the $4Mn^{2+}$, $6Mn^{3+}$ level. The $[Mn_{10}(\mu_4\text{-}O)_4(\mu_3\text{-}N_3)_4]^{14+}$ core has T_d symmetry, but inclusion of the hmp groups removes the σ_d planes and S_4 axes, and the complete $[Mn_4^{II}Mn_6^{III}O_4(N_3)_4(hmp)_{12}]^{2+}$ cation consequently has rare

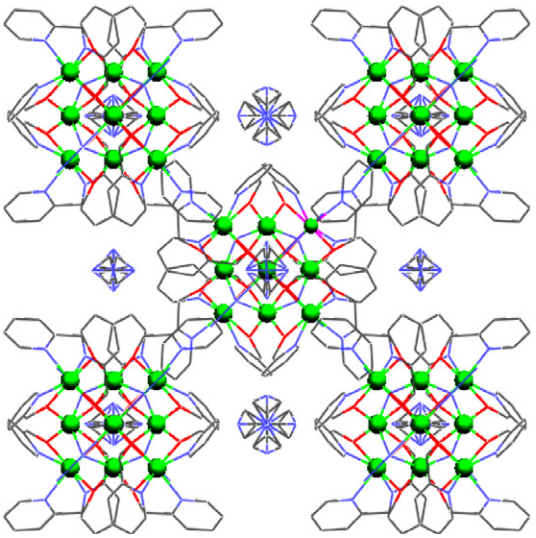

Fig. 4. Packing diagram of **1** along the *a*-axis. N_3^- counter ions are located in the middle of each neighboring Mn_{10} molecules.

T point group symmetry, which is crystallographically imposed; point group T is the rotational sub-group of T_d. This aesthetically pleasing symmetry extends to the packing of the molecules in the crystal, as shown in Fig. 4.

The magnetic behavior of the two complexes is similar. As a result of the high-yield of complex **2** (compared to that of **1**), magnetic data are presented only for the former cluster. Solid-state DC magnetic susceptibility (χ_M) data for complex **2** · MeCN were collected in the temperature range 5.0–300 K in an applied field of 1 kG (0.1 T). The $\chi_M T$ value steadily increases from 53.78 $cm^3\ mol^{-1}$ K at 300 K to a maximum of 231.56 $cm^3\ mol^{-1}$ K at 10 K, before dropping to 220.23 $cm^3\ mol^{-1}$ K at 5.0 K (Fig. 5).

The spin-only ($g = 2$) value for a non-interacting $[Mn_4^{II}Mn_6^{III}]$ unit is 35.5 $cm^3\ mol^{-1}$ K. This indicates ferromagnetic exchange interactions within **2** and the 10 K data strongly suggest a very large ground-state spin (S) value, with the sharp decrease at the lowest temperatures assigned to Zeeman effects, zero-field splitting and/or weak intermo-

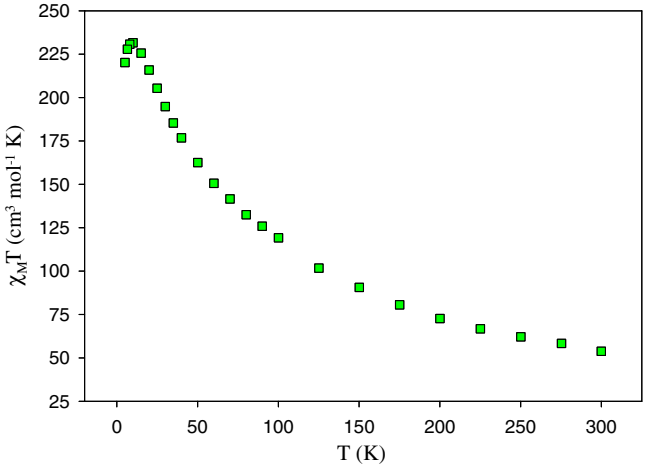

Fig. 5. $\chi_M T$ vs. T plot for complex **2** · MeCN in a 1 kG field.

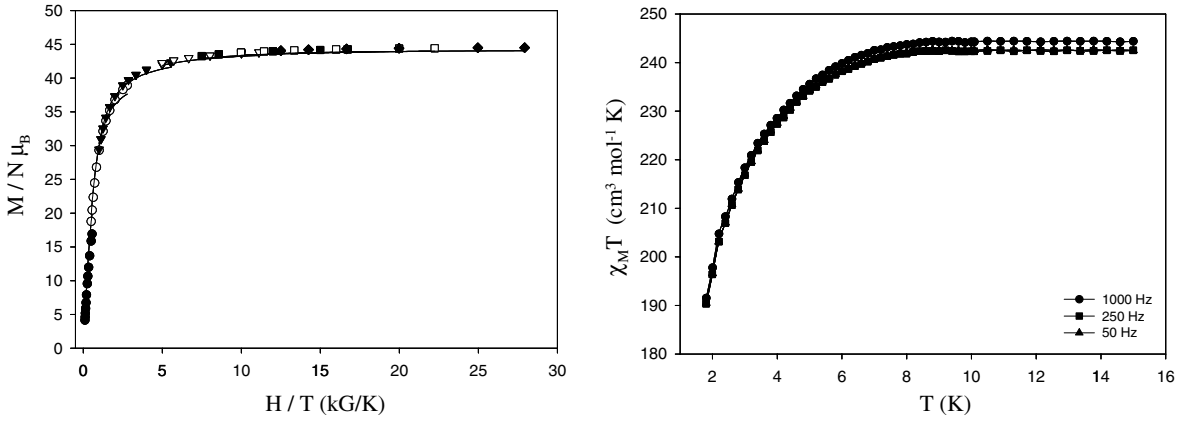

Fig. 6. Plot of reduced magnetization ($M/N\mu_B$) vs. H/T for **2** · MeCN in the temperature range 1.8–10 K and in fields of 0.1 T (●), 0.5 T (○), 1.0 T (▼), 2.0 T (▽), 3.0 T (■), 4.0 T (□), 5.0 T (◆). The solid lines are fits of the data (left). In-phase ac susceptibility ($\chi'_M T$) measurements of complex **2** · MeCN measured below 15.0 K at the indicated frequencies (right).

lecular interactions. The 10 K value is consistent with an $S = 22$ ground state, the maximum possible, and a g value slightly less than 2.0, as expected for a Mn^{II}/Mn^{III} complex; the spin-only ($g = 2$) value for an $S = 22$ state is 253 $cm^3\ mol^{-1}\ K$.

In order to confirm the ground state of **2** · MeCN, magnetization (M) data were collected in the 0.1–5 T and 1.8–10.0 K ranges, and these are plotted as $M/N\mu_B$ versus H/T in Fig. 6. The various isofield lines are virtually superimposed, indicating essentially no zero-field splitting (ZFS) within the ground state, and the saturation value of $M/N\mu_B \approx 44$ is consistent with $S = 22$. The data were fit by matrix-diagonalization to a model that assumes only the ground state is populated, includes axial zero-field splitting ($D\hat{S}_z^2$) and the Zeeman interaction, and carries out a full powder average. The best fit (solid lines in Fig. 4) gave $S = 22$, $g = 2.00(1)$ and $D = -0.011(1)\ cm^{-1}$, confirming a very high-spin ground state with little or no magnetic anisotropy. The $S = 22$ ground state was further supported by alternating current (ac) susceptibility experiments, in which a weak field of 3.5 G oscillating at a particular frequency (ν) was applied to the sample. Ac susceptibility studies use no dc field and thus are an excellent complementary tool for determining S by avoiding potential complications from a large dc field. The in-phase susceptibility (χ'_M) for **2** · MeCN is shown as $\chi'_M T$ versus T in Fig. 6, and $\chi'_M T$ can be seen to be temperature-independent at ~244 $cm^3\ mol^{-1}\ K$ from 15 K down to ~8 K, and this temperature-independent value is consistent with $S = 22$ and $g \sim 1.96$, in satisfying agreement with the dc magnetization fits. The temperature-independent $\chi'_M T$ also indicates no population of excited states in this temperature range. At lower temperatures, $\chi'_M T$ decreases slightly, which we assign to weak intermolecular interactions, both dipolar and superexchange in nature.

There is no out-of-phase (χ''_M) ac susceptibility signal down to 1.8 K, which indicates an insignificant barrier (versus kT) to magnetization relaxation. To explore whether slow relaxation might become apparent at even lower temperatures, magnetization vs dc field scans were performed on a single crystal of **2** · MeCN down to 0.04 K. No hysteresis was observed. The combined results indicate an isotropic crystal and fast magnetization relaxation even at 0.04 K, which are consistent with $D \sim 0$.

In summary, the combination of azide and hmp^- ligands in Mn cluster chemistry has yielded an unusual cation that has both a very high $S = 22$ ground state value and high (T) symmetry. Such a high S value is extremely rare, very similar in magnitude to the $S = 23$ for an Fe_{14} cluster, the largest S in Fe chemistry [1g].

mode has the potential to significantly increase the flexibility of design in materials using the DTDA radical (see Scheme 1).

2. Experimental

2.1. General considerations

2,5-Diformylfuran [41], prepared from D-fructose, was used as the starting material for 4-(2′-cyanofuryl-5′)-1,2,3,5-dithiadiazolyl (**1**) [31], following literature procedure. The bis(hexafluoroacetylacetonato) metal starting materials were prepared as dihydrates $M(hfac)_2 \cdot 2H_2O$, according to literature procedure [42], and converted to bis(tetrahydrofuran) adducts $M(hfac)_2 \cdot 2THF$ prior to use; absence of a hydrate O–H stretch at ca. 3400 cm^{-1} in the IR (KBr). THF was dried over Na/benzophenone and distilled under Ar(g). All coordination reactions were performed under Ar(g) atmosphere using standard Schlenk techniques. Infrared spectra were collected using a Nicolet 4700-FTIR spectrometer. Elemental analyses were performed by MHW Labs, Phoenix, AZ, USA. Mass spectra were recorded by Dr. R. Smith at the WATSPEC Facility at the University of Waterloo, Waterloo, Ont., Canada, using a JEOL HX110 double focusing instrument.

2.2. Preparation of Mn complex *2*

Dry THF (45 mL) was added to a solid mixture of **1** (352.2 mg, 1.79 mmol) and $Mn(hfac)_2 \cdot 2THF$ (1.1358 g, 1.85 mmol) and the resulting solution was heated at 60 °C, stirring, for 3.5 h (note that dry 1,2-dichloroethane can be substituted for THF). The solution was allowed to cool to RT whereupon a black precipitate formed. This was recovered by filtration and determined to be uncomplexed **1** (216.1 mg, 1.101 mmol). The solvent was removed *in vacuo* from the remaining filtrate affording a gray-green powder (960.1 mg). This was sublimed under dynamic vacuum (10^{-2} Torr) using a three-stage gradient tube furnace (125, 70, 40 °C) in order to separate complex **2** from the unreacted yellow $Mn(hfac)_2 \cdot 2THF$ and further unreacted **1** starting materials. The recovered complex **2** was then purified by a second sublimation generating dark red block-like crystals. Yield: 133.9 mg (0.2013 mmol, 11.24%). IR (KBr): 3174(w), 3141(w), 2262(m), 1647(s), 1615(w), 1599(w), 1584(w), 1557(m), 1530(m), 1500(s), 1486(s), 1401(w), 1388(w), 1350(m), 1256(s), 1219(s) 1206(s), 1146(s), 1096(w), 1024(m), 986(w), 969(w), 943(w), 860(w), 814(w), 799(s), 780(w), 742(w), 696(w) 665(s), 585(m), 527(w), 517(w) cm^{-1}. Elemental *Anal.* Calc. for $C_{16}H_4N_3O_5S_2F_{12}Co$: C, 28.70; H, 0.60; N, 6.28. Found: C, 29.25; H, 0.66; N, 5.96%.

2.4. Preparation of Ni complex *4*

Complex **4** was prepared in the same manner as complex **2**, using $Ni(hfac)_2 \cdot 2THF$ as the starting material. Red-brown block-like crystals of **4** were recovered from sublimation. Yield: 12.3%. IR(KBr): 3166(w), 3142(w),

2279(s), 1647(s), 1593(w), 1577(w), 1555(w), 1526(m), 1508(m), 1485(m), 1401(m), 1389(m), 1350(m), 1256(s), 1220(m), 1206(m), 1147(s), 1103(w), 1025(m), 988(w), 972(m), 948(w), 862(w), 813(m), 796(m), 777(m), 743(w), 696(w), 675(m), 591(m), 530(w), 517(w) cm^{-1}. Mass spec. (C.I. using NH_3; r.t. = 0.70 min; parent ion assigned as $M = NCC_4H_2OCN_2S_2Ni(O_2C_5F_6)_2$; *m/e*): 788.1 ($[M–NiO_2C–NH_4]^+$, 100%, isotope pattern for 2 Ni), 686.1 ($[M–NH_4]^+$, 54.69%, isotope pattern for 1 Ni), 507.1 ($[Ni(O_2C_5F_6)_2–NH_3–NH_4]^+$, 75.49%, isotope pattern for 1 Ni), 196.0 ($[NCC_4H_2OCN_2S_2]^+$, 57.81%), 136.1 ($[NCC_4H_2OCN–NH_4]^+$, 19.38%). Elemental *Anal.* Calc. for $C_{16}H_4N_3O_5S_2F_{12}Ni$: C, 28.72; H, 0.60; N, 6.28. Found: C, 29.00; H, 0.50; N, 6.38%.

2.5. Crystallographic details

Crystals of $[Mn(C_5HF_6O_2)_2(\mu\text{-}C_6H_2N_3O_1S_2)]$ (**2**) arrived at U.W.O. from the University of Guelph. The red plate was mounted on a goniometer head. Data were collected at low temperature (−173 °C) on a Nonius Kappa-CCD area detector diffractometer with COLLECT [43]. The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using HKL2000 DENZO-SMN [44]. The absorption correction was applied using HKL2000 DENZO-SMN (SCALEPACK). The reflection data were consistent with a triclinic space group: $P\bar{1}$. The SHELXTL/PC V6.14 for Windows NT suite of programs [45] was used to solve the structure by direct methods. The complex consisted of a linear chain of $Mn(hfac)_2$ units bridged by the ligand. Most of the atoms were well ordered, however, one of the perfluoro butyl groups showed some disorder. The disorder was modeled as a staggered configuration with the occupancies set at 0.71 and 0.29. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. The largest residue electron density peak (0.368 e/Å^3) was associated with one of the sulfur atoms. Full-matrix least squares refinement on F^2 gave $R_1 = 5.96$ for 2σ data and $wR_2 = 16.20$ for all data (goodness-of-fit = 1.049).

Crystals of $[Co(C_5HF_6O_2)_2(\mu\text{-}C_6H_2N_3O_1S_2)]$ (**3**) arrived at U.W.O. from the University of Guelph. The red shoebox was mounted on a goniometer head. Data were collected at low temperature (−173 °C) on a Nonius Kappa-CCD area detector diffractometer with COLLECT [43]. The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using HKL2000 DENZO-SMN [44]. The absorption correction was applied using HKL2000 DENZO-SMN (SCALEPACK). The reflection data were consistent with a triclinic space group: $P\bar{1}$. The SHELXTL/PC V6.14 for Windows NT suite of programs [45] was used to solve the structure by direct methods. The complex consisted of a linear chain of $Co(hfac)_2$ units bridged by the ligand. The molecule was very well ordered. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. The largest residue electron density peak (0.446 e/Å^3) was associated with one of the trifluoro moieties. Full-matrix least squares refinement on F^2 gave $R_1 = 4.27$ for 2σ data and $wR_2 = 10.01$ for all data (goodness-of-fit = 1.012).

Crystals of $[Ni(C_5HF_6O_2)_2(\mu\text{-}C_6H_2N_3O_1S_2)]$ (**4**) arrived at U.W.O. from the University of Guelph. The dark, red block was mounted on a goniometer head. Data were collected at low temperature (−173 °C) on a Nonius Kappa-CCD area detector diffractometer with COLLECT [43]. The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using HKL2000 DENZO-SMN [44]. The absorption correction was applied using HKL2000 DENZO-SMN (SCALEPACK). The reflection data were consistent with a triclinic space group: $P\bar{1}$. The SHELXTL/PC V6.14 for Windows NT suite of programs [45] was used to solve the structure by direct methods. The complex consisted of a linear chain of $Ni(hfac)_2$ units bridged by the ligand. The molecules were well ordered. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. The largest residue electron density peak (0.531 e/Å^3) was associated with the furan ring. Full-matrix least squares refinement on F^2 gave $R_1 = 5.47$ for 2σ data and $wR_2 = 12.69$ for all data (goodness-of-fit = 1.089).

3. Results

The single crystal X-ray structural determinations of complexes **2**–**4** reveal identical chain-like complexes in the solid state. These chains are characterized by three important interactions. The $M(hfac)_2$ unit bridges two ligands (**1**) via coordination with one nitrogen atom of the DTDA ring

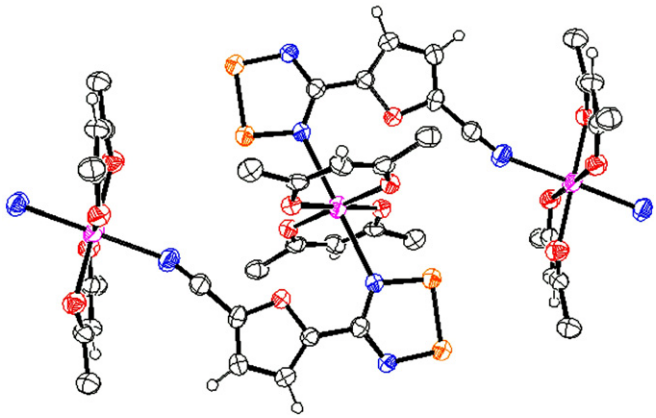

Fig. 1. Single crystal X-ray structure of Mn complex **2** showing the monodentate N-coordination of the two DTDA rings to a Mn(II) ion. Color scheme: C, H: black; O: red; N: blue; S: orange; Mn: magenta. F atoms omitted for clarity. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

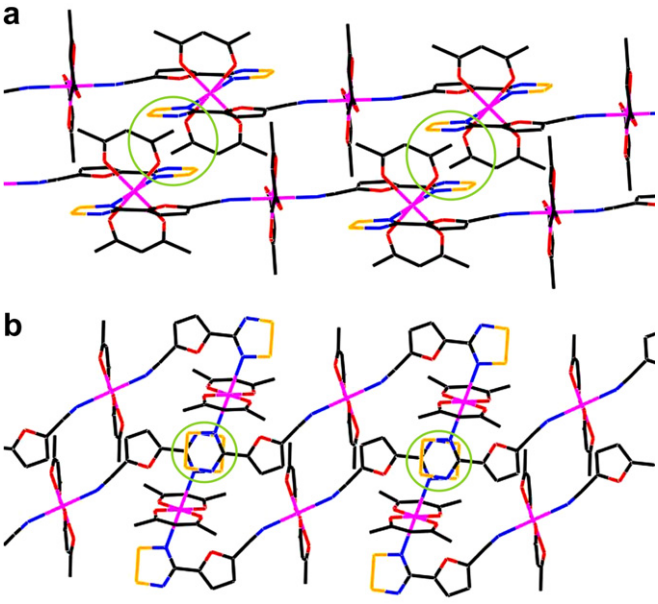

Fig. 2. Single crystal X-ray structure of Mn complex **2** showing: (a) side view of DTDA dimers (green circles) and (b) top view of DTDA dimers (green circles). H and F atoms omitted for clarity. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

of each. The hexafluoroacetylacetonato-ligands are in the equatorial plane while the nitrogen atoms of the DTDA rings are in the axial positions of a pseudo-octahedral coordination sphere about the metal center (Fig. 1). A second bridging interaction of the $M(hfac)_2$ unit with one nitrogen atom of the pendant nitrile group of each of two ligands (**1**) is also present. Again the hfac-ligands are in the equatorial plane while the nitrile groups complete the pseudo-octahedral coordination sphere at the axial positions. The third important interaction is the interchain dimerization of the ligands through a cofacial interaction of the DTDA rings. This dimerization is highlighted by circles in Fig. 2.

Table 1 provides a summary of the important crystallographic features of all three complexes. The only notable differences in structure are the changes in M–N bond lengths about the metal sites depending on the nature of the metal ion. In all important respects, the three complexes are crystallographically equivalent. The DTDA nitrogen to metal bond distances are of particular interest. They range from 2.459(5) to 2.309(5) Å, depending on the nature of the metal ion. These are longer than the $M–N_{(DTDA)}$ contacts for the chelated Mn(II)–, Co(II)– and Ni(II)– $(hfac)_2$ complexes with 4-(2′-pyridyl)-1,2,3,5-dithiadiazolyl, which range from 2.288(6) to 2.082(15) Å [39,40,46]. Nevertheless, they are reasonable metal to nitrogen bond distances. It is tempting to suggest that there is some contribution from the furyl oxygen atom, given that it is oriented toward the metal center. It should be noted, however, that the furyl oxygen to metal distances range from 3.160(4) to 3.285(4) Å and are, therefore, significantly longer than would normally be assigned as a bond.

The intermolecular sulfur to sulfur atom contacts are longer than ca. 3.1 Å, the typical distance for most known DTDA dimers in the solid state [31]. Nevertheless, the DTDA rings are dimerized in the solid state through what has been referred to as a *trans*-cofacial interaction [30,47] that suffices to render the DTDA dimer unit diamagnetic. In order to confirm that there is no significant contribution from the DTDA units to the magnetic properties of these materials, the magnetic susceptibility measurements for complex **2** (Fig. 3) were obtained by DC-SQUID. These indicate a room temperature $\chi_{para}T$ value of ca. 4.7 emu K mol^{-1} that decreases only slightly with decreasing temperature until ca. 20 K. This is consistent with isolated Mn(II) ions ($S = 5/2$). The decrease in $\chi_{para}T$ below 20 K suggests the onset of weak intermolecular

Table 1
Selected crystallographic information for complexes **2**–**4**

	Complex **2** (Mn)	Complex **3** (Co)	Complex **4** (Ni)

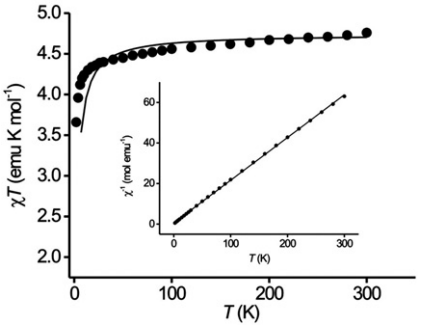

Fig. 3. Magnetic susceptibility measurements of **2** as a microcrystalline solid (●) performed using DC-SQUID at a field of 100 Oe. Diamagnetic contributions subtracted using Pascal's constants. Curie–Wiess fit (−) of $1/\chi$ as a function of temperature; $C = 4.74 \pm 0.01$ emu K mol^{-1}, $\theta = -2.4 \pm 0.4$ K.

antiferromagnetic exchange interactions, possibly between manganese centers mediated through the dimerized DTDA ligands. A Curie–Wiess fit was optimized for a plot of $1/\chi$ as a function of temperature (Fig. 3, inset) generating a Curie constant C of 4.74 ± 0.01 emu K mol^{-1} and a Wiess constant θ of -2.4 ± 0.4 K. These fitting parameters were then used to generate a $\chi_{para}T$ curve as a function of temperature, shown as a solid line in Fig. 3. Clearly, the data is adequately fit using a Curie–Wiess function, supporting the hypothesis that the dimerized DTDA moieties do not contribute to the magnetic properties of these complexes in the solid state to any significant degree.

4. Discussion

In order to ascertain at which point in the preparatory procedure the chain-like complexes identified in the crystal structures of **2**–**4** are, in fact, formed, we have monitored the C ≡ N stretch in the IR absorption spectrum. In the free ligand **1**, the CN stretch occurs at 2234 cm^{-1}. In the Mn, Co and Ni complexes, the absorption occurs at 2261, 2271 and 2279 cm^{-1}, respectively. Using the Mn complex **2** as a representative case, the IR spectrum of the grayish powder recovered after removal of the solvent reveals a new CN stretch at 2254 cm^{-1} in addition to the absorption at 2234 cm^{-1} for the free ligand **1**, in a roughly 1:10 ratio with respect to peak area. This stretch is neither free ligand nor the chain-like complex. Our hypothesis is that it is representative of some intermediate coordination mode that is formed in solution, perhaps involving only one nitrile group coordinated to a Mn(hfac)$_2$ unit. Only after sublimation of this gray solid (under dynamic vacuum) did the IR spectrum of the recovered dark red crystals show evidence of the chain-like complex. In light of this discovery, we have attempted the synthesis of **2** by grinding the solid starting materials, under inert atmosphere, to homogeneity with a mortar and pestle and submitting this mixture to sublimation under dynamic vacuum at the same conditions. The result was quantitative recovery of the free ligand **1** and the unreacted Mn(hfac)$_2 \cdot$ 2THF starting materials from different zones of the three-stage sublimation tube furnace. The procedure was repeated using static vacuum at the same temperature, and again only starting materials were recovered. Thus, it appears that formation of an intermediate *in solvo* is a necessary step in the preparatory procedure, perhaps to generate monomeric units from which the chain is ultimately comprised. It is worth noting that, once formed in the crystalline state, these chain-like structures can be re-sublimed and recovered quantitatively. This supports the idea that the structure may be comprised of preformed, volatile monomeric or oligomeric units. Further evidence is provided by the mass spectra of the complexes wherein m/e values consistent with fragmentation of oligomeric units are detected.

The relatively low yield of **2**–**4** is likely a reflection of the equilibrium between free starting materials and some initial coordination complex in solution. For this reason, we attempted the synthesis in THF, 1,2-dichoroethane, dichloromethane and acetonitrile. The highest yields were obtained from sublimation of the gray product formed in THF, but reasonable quantities were also obtained from dichloroethane. No product was obtained from dichloromethane or acetonitrile, probably owing to the insolubility of the starting materials at achievable temperatures in the former and competing nitrile moieties of the solvent in the latter. It should be noted, however, that the red crystalline product, once formed, is sparingly soluble in warm dichloromethane or dichloroethane such that it will slightly colour the solvent. IR spectra of very dilute warm solutions in either solvent (1.0 mm CaF_2 cell) show a CN stretch at 2262 cm^{-1} for **2**, indicating that the coordination of the nitrile moieties to the metal remains intact. Furthermore, when **2** is heated vigourously into a large volume of dichloroethane, red crystals form upon cooling, again suggesting that once the oligomeric units are formed, the chain-like complexes can be reformed nearly quantitatively.

Although we have successfully obtained IR spectra in very dilute warm solutions, the relatively low solubility of these complexes has inhibited other solution state analyses. We have attempted to collect solution magnetometry data in toluene and dichloroethane by Evans' NMR method, but the achievable concentration is too low to have a measurable impact on the shifting of the solvent signal, even at higher temperatures (ca. 60 °C). We have also attempted to collect solution EPR data of the Mn(II) complex at room temperature and at higher temperatures (ca. 60 °C) but have been unable to resolve a signal. The concentration of the complex is likely too low to observed the manganese-centered unpaired electrons, however, it is not unreasonable to expect to observe the ligand-centered unpaired electrons at very low concentration. There are three possible explanations for the lack of signal, then. The first is that the dimers persist in solution. We feel this is unlikely given that the intermolecular interaction between DTDA rings is generally considered to be weak and therefore there should be at least a monomer–dimer equilibrium. The second explanation is that coordination of Mn(II) to the DTDA

affects the relaxation properties of the ligand centered spin such that the intensity of the absorption is lowered and the solution's concentration is too low for the signal to be observed. The third possible explanation is that solution state oligomeric units have integer ground state S values and sufficient zero-field splitting that they are EPR silent (e.g., for one Mn(II) coordinated to one DTDA, $S = 2$ for AFM coupling). In any case, we are unable to make any comment regarding spin distribution or the magnetic nature of these complexes in solution.

5. Conclusions

Ligand **1** reacts with $M(hfac)_2 \cdot 2THF$ (M = Mn, Co, Ni) generating chain-like complexes **2**–**4** in the solid state. Although the yields of purified material are relatively low (ca. 10%), the syntheses are reproducible and complexes of all three metal ions have the same crystalline motif. The most interesting feature of these complexes is the unprecedented monodentate N-coordination of the DTDA moiety to the metal ion. This new coordination mode has the potential to significantly increase the design flexibility of materials incorporating DTDA-based radicals as spin-bearing ligands.

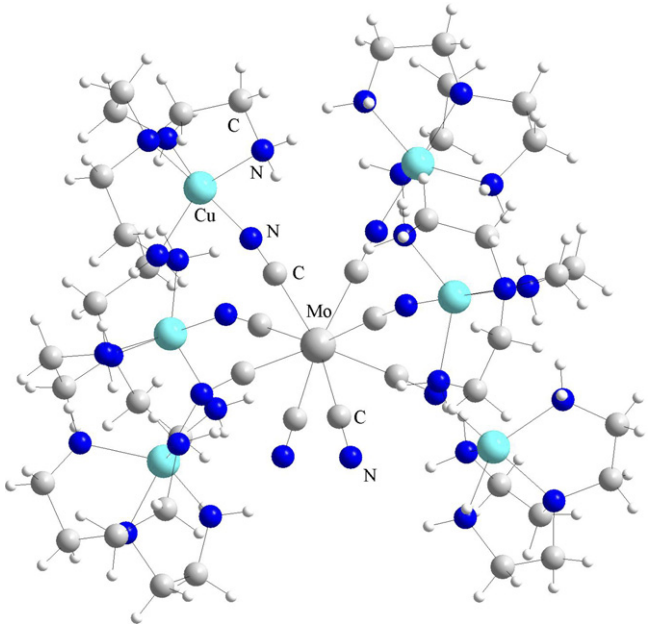
reversible magnetic switching. Then Kawamoto et al. [27] calculated the band structure of Co–Fe cyanide using full-potential linearized augmented planewave method (FLAPW). Their calculated results indicated that the interaction between the d electrons of the Co^{III} ion and surrounding crystal field might conduce metal–metal charge transfer. Further Kawamoto et al. [27,28] performed ab initio quantum chemical cluster computations and concluded that the existence of vacancies for absent Fe^{II} ions is essential for the bidirectional photoinduced magnetic phase transition in Co–Fe Prussian blue analogues. In the meantime, their studies [29] showed that the light excitation could induce the local structures of the crystal to be changed forward and backward. All the theoretical works mentioned obviously indicate that it is necessary to exist a meta-stable intermediate structure in the photoinduced magnetization process. As a matter of fact, both experimentally and theoretically there is yet a lack of explicit detailed evidence of the meta-stable intermediate structure in the reversible photoinduced magnetization.

The photoinduced high-spin molecule, $[Mo^{IV}(CN)_2(CN\text{-}CuL)_6]^{8+}$ with perchlorate was synthesized and structurally characterized in 2004 [14], where the terminal ligand L is tris(3-aminoehtylamine). Its geometry structure is depicted in Fig. 1. It should be said that this experimentally isolated molecule is of great advantage to theoretical study on the meta-stable intermediate structure, thereby opens the door of the theoretical study on photoinduced magnetization in chemical detail. The experimentally measured $\chi_M T$ value for the molecule is a constant (2.5 cm^3 K mol^{-1} down to 20 K), which indicates that each $[Mo^{IV}(CN)_2(CN\text{-}CuL)_6]^{8+}$ cation is constituted with a diamagnetic Mo^{IV} surrounded by six $S = 1/2$ paramagnetic Cu^{II} cations in the ground state. Thus the magnetic property of the ground state molecule behaves like a system with six isolated spin 1/2 ions. Once irradiated with blue light (406–415 nm) at 10 K for 10 h, the magnetic behaviors changed drastically, with the $\chi_M T$ value of 4.8 cm^3 K mol^{-1}, which reveals a high-spin ferromagnetic molecule with total spin $S = 3$. Experimentally it is also shown that when turning off the light and heating up the system to 300 K, the change process of the magnetic properties is totally reversible. Herrera et al. [14] attributed the change of magnetic properties to MMCT between the Mo^{IV} and one Cu^{II} cations induced by the light irradiation, thus yielding the $Mo^{V}Cu^{I}Cu^{II}_5$ electronic configuration, which implies ferromagnetic interaction between the $S = 1/2$ Mo^{V} ion and five $S = 1/2$ Cu^{II} ions. After 1 h at room temperature, the $\chi_M T$ values measured in the cooling process indicate the compound almost completely relaxed back to the initial state. Herrera et al. ascribed the high relaxation temperature to the photoinduced metastable state related to significant change of the coordination sphere around the Cu^{I} ion. Thus the structure and the properties of the metastable state are the most important thing to explain the micromechanism of the reversible photoinduced magnetization. Unfortunately, there is no direct experimental verity of the metastable structure till now. In this communication, we shall focus on calculations of the structure and magnetic properties of the possible metastable state to understand micromechanism of the photoinduced magnetization phenomenon of $[Mo^{IV}(CN)_2(CN\text{-}CuL)_6]^{8+}$. Both density functional theory and ab initio multireference configuration interaction [30,31] methods are used in geometry optimization and exchange coupling constant calculations.



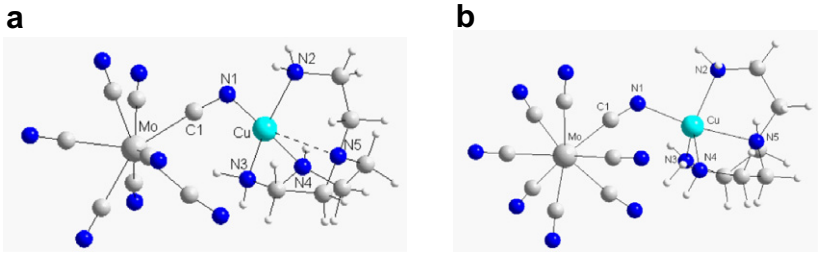


Fig. 1. X-ray crystal structure of the $[Mo^{IV}(CN)_2(CN\text{-}CuL)_6]^{8+}$ cation [14].

As shown in the previous theoretical studies [27,28], the local structure or composition around transition metal cations might be changed with the light irradiation. For the $[Mo^{IV}(CN)_2(CN\text{-}CuL)_6]^{8+}$ cation, the change might occur around the Mo^{IV} and Cu^{II} ions. Except for outer anions, each $[Mo^{IV}(CN)_2(CN\text{-}CuL)_6]^{8+}$ entity has 191 atoms, it is too large to directly calculate the geometry structure optimization and the magnetic properties for the whole cation. Considering the six $(Cu–L)^{2+}$ parts have nearly same geometry structures, it is a reasonable choice to reserve only one and omit all the other five $(Cu–L)^{2+}$ groups, then the left calculated model is the $[Mo(CN)_8CuL]^{2-}$ anion. After the MMCT from the Mo^{IV} to a Cu^{II} with light irradiation, there exist one $[Mo^{V}(CN)_8Cu^{I}L]^{2-}$ (abbreviated to Mo^{V}-Cu^{I}) and five $[Mo^{V}(CN)_8Cu^{II}L]^{-}$ (abbreviated to Mo^{V}-Cu^{II}) fragments in the photoinduced molecule at the same time. The Fig. 2 displays the optimized local geometry structures and selected bond distances of these two fragments by using density functional theory with ADF software package [32].

Comparing the bond distances calculated in Fig. 2, the distance of Cu–N5 is 2.24 Å in the fragment **B**, but 2.71 Å in the fragment **A**, lengthened by 0.47 Å, which likely further leads the Cu–N5 bond to be broken. The change for all the other bond distances is so few as to be

A $[Mo^{V}(CN)_8Cu^{I}L]^{2-}$

Cu–N1	2.04Å	Cu–N2	2.24Å
Cu–N3	2.13Å	Cu–N4	2.28Å
Cu–N5	2.71Å		
Mo–C1	2.20Å	C1–N1	1.18Å

B $[Mo^{V}(CN)_8Cu^{II}L]^{-}$

Cu–N1	2.02Å	Cu–N2	2.16Å
Cu–N3	2.13Å	Cu–N4	2.17Å
Cu–N5	2.24Å		
Mo–C1	2.19Å	C1–N1	1.18Å

Fig. 2. Optimized geometry structures and selected bond distances for the fragments **A** $[Mo^{V}(CN)_8Cu^{I}L]^{2-}$ (a) and **B** $[Mo^{V}(CN)_8Cu^{II}L]^{-}$ (b).

negligible effect on the coordination properties of the Cu and Mo atoms. It seems that the light irradiation induces the reducing of one copper cation from Cu^{II} to Cu^{I}, and simultaneously the change of its coordination environment from five- to four-coordination. The tetrahedral Cu^{I} ion coordinated by four nitrogen atoms holds the one electron originating from the Mo^{IV} ion and this electron does not be relaxed back spontaneously to the Mo^{IV} ion. The other five Cu^{II} cations have little structure changes and are still coordinated by five nitrogen atoms in an ordinary trigonal-bipyramid manner. It is interesting to note that the two optimized local geometry structures mentioned above consist well with the previous proposal experimentally on the local reorganization of the coordination sphere around Cu^{I} [14].

Because the Cu^{I} ion is a diamagnetic center, the magnetic behavior of the photoinduced molecule is determined by the magnetic coupling interactions between the paramagnetic Mo^{V} ion and five Cu^{II} ions. Following the above modelling, we calculated the magnetic coupling properties of the $Mo^{V}Cu^{II}$ fragment by using the density functional theory combined with broken symmetry approach (DFT-BS) [33] and the ab initio complete active space self-consistent-field (CASSCF) [34,35], as well as multireference configuration interaction (MRCI) methods [30,31], respectively. In general, the magnetic coupling between two magnetic centers is usually described in term Heisenberg spin Hamiltonian:

$$H = -JS_A \cdot S_B, \tag{1}$$

where S_A and S_B are electron spin operators at the magnetic centers A and B, respectively; J stands for the spin coupling constant, which magnitude and sign character the magnetic exchange interaction in the magnetic molecule. A positive J predicts the ferromagnetic interaction between the magnetic centers A and B.

In the calculations with DFT-BS method [36], spin Hamiltonian (1) is relative to the calculated energy difference $E_{HS} - E_{BS}$:

$$\frac{1}{2}S_{max}J_{AB} = E_{BS} - E_{HS}, \tag{2}$$

where S_{max} is the highest spin multiplet of the $Mo^{V}Cu^{II}$ fragment studied; E_{BS} and E_{HS} are the energy expecting value of the broken symmetry state (BS) and the energy eigenvalue of the highest spin state (HS), respectively. The calculated J value is 89.7 cm^{-1} when using the general gradient approximation (Becke and Perdew exchange correlation functional [37–39]). The calculated positive J value indicates that the magnetic interaction is ferromagnetic between the Mo^{V} and Cu^{II} cations. As reported in the literature [40], the DFT-BS approach can give a reasonable evaluation of the magnetic exchange interaction qualitatively for large binuclear transition metal systems. Meanwhile, the CASSCF and MRCI methods, under the active space and active electrons referring to CAS(2,2), are further used to calculate the exchange coupling constant in the fragment $[Mo^{V}(CN)_8Cu^{II}L]^{-}$. The calculated J values are 6.2 and 7.4 cm^{-1} at CASSCF and MRCI levels of theory, respectively. Due to existing such five magnetic interactions between the Mo^{V} and Cu^{II} cations for the whole cation studied, we can conclude that the photoinduced metastable state of the $[Mo^{V}(CN)_2(CN\text{-}Cu^{I}L)(CN\text{-}Cu^{II}L)_5]^{8+}$ cation is a high-spin molecule with strong ferromagnetic properties. It is evident that the DFT-BS calculated J value, 89.7 cm^{-1}, is closer to the experimental evaluation ($J > 100$ cm^{-1}) [14] than that of CASSCF (6.2 cm^{-1}) and MRCI (7.4 cm^{-1}). Herein, the calculated results from the different methods reproduce well the high-spin magnetic properties of the photoinduced intermediate, though there is discrepancy of the magnitude of the calculated J values for the different methods.

Spin density distribution can experimentally be observed by the neutron scattering experiment, and gives valuable information for the magnetic exchange mechanism. For further confirming the spin density distribution of Mo^{V}, Cu^{I} and Cu^{II} ions in the fragments **A** and **B**, the Mulliken spin populations are calculated using DFT method. Because the spin population of the copper cation tends to

delocalize unduly in the DFT calculations, the population analyses based on the CASSCF method are also carried out for the purpose of comparison. Calculated spin populations of the metal ions and the bridge ligand atom C1, N1 are listed in Table 1, where all the other nonmetal atoms are not shown for simplify.

From Table 1, the calculated spin populations on the Mo^{V}, Cu^{I} and Cu^{II} cations are approximately in accord with the electronic configuration of $Mo^{V}Cu^{I}$ and $Mo^{V}Cu^{II}$. In the DFT calculations, for the fragment $Mo^{V}Cu^{I}$, the spin population value 0.035 on the Cu^{I} ion indicates that it is a diamagnetic ion and no magnetic coupling with the Mo^{V} center might occur. The results of CASSCF calculations for the Cu^{I} ion confirm its diamagnetic character. On the contrary, for the fragment $Mo^{V}Cu^{II}$, the spin population values on the Mo^{V} and Cu^{II} ions are as large as 0.877 and 0.410, respectively. While in the CASSCF calculations the spin population values on the Mo^{V} and Cu^{II} ions for the fragment $Mo^{V}Cu^{II}$ are 0.940 and 0.888, respectively. The latter is close to one formal unpaired electron on the Mo^{V} and Cu^{II} ions, respectively. It is evident that both the Mo^{V} and Cu^{II} ions for the fragment $Mo^{V}Cu^{II}$ are the paramagnetic ions. Combined with the calculated exchange coupling constant *J*, it could conclude that the Mo^{V} ion interacts with the Cu^{II} ion by means of ferromagnetic coupling through the superexchange pathway of the cyano ligand. Just this magnetic coupling determines the magnetic properties of the whole system.

In summary, there are two key reasons of photoinduced magnetization. The first one is changes of bonding and the structure with light induced, which could produce a metastable state. And this metastable state could not be relaxed back to initial state fast and spontaneously. The second one is that the part or whole structure of the metastable state has appropriate magnetic properties. In our calculations, the local geometry structure of the possible metastable state for the $[Mo^{IV}(CN)_2(CN\text{-}CuL)_6]^{8+}$ cation is optimized with the DFT method. The calculation results indicate that the trigonal-bipyramid coordination environment surrounding one Cu^{II} ion has been changed to the tetrahedral coordination around the Cu^{I} ion after the light irradiation. The magnetic properties calculated by using different levels of theory reveal the high-spin ground state, which are also consistent with the experimental results. The spin population analyses confirm the validity of the calculated models. These calculations will help to understand photoinduced magnetization phenomenon and provide a clue for the synthesization of new reversible photoinduced magnetic compounds.

Table 1
Spin populations on the Mo, Cu ions for $[Mo^{V}(CN)_8Cu^{I}L]^{2-}$ and $[Mo^{V}(CN)_8Cu^{II}L]^{-}$ fragments

Atom	DFT-BS		CASSCF	
	$Mo^{V}Cu^{I}$	$Mo^{V}Cu^{II}$	$Mo^{V}Cu^{I}$	$Mo^{V}Cu^{II}$
Mo	0.907	0.877	0.949	0.940
Cu	0.035	0.410	0.001	0.888
C1	0.048	0.009	−0.002	0.007
N1	−0.041	0.085	0.008	0.042

2. Experimental

2.1. Measurements

The ^{1}H NMR spectra were measured with a JEOL JNM-EX400 spectrometer (400 MHz). Tetramethylsilan was used as an internal standard for chemical shifts. The IR spectra were measured with a JASCO FT/IR-230 spectrometer. Size exclusion chromatography (SEC) was measured with a TOSOH HLC-8020 chromatograph. THF was used as an eluant and the temperature was kept at 40 °C. The ESR spectra were measured with a JEOL JES-RE1X spectrometer (X-band). Mn^{2+} was used as a standard for the *g* value. The spin concentration of polyradical was determined by using a solution of 1,3,5-triphenylverdazyl in dichloromethane prepared in known concentration. The magnetization was measured with a Quantum Design MPMS-7T SQUID magnetometer. The external magnetic field dependence of the magnetization was measured in the region of 0–6 T at the constant temperature. The temperature dependence of the magnetic susceptibility was measured in the region of 2–300 K at the constant external magnetic field of 0.5 T. The diamagnetic contribution from a sample holder and poly(vinyl chloride) (PVC) was previously measured and corrected. The diamagnetic contribution of the paramagnetic sample was estimated with the Pascal's constants and corrected.

2.2. Suzuki–Miyaura coupling between dibromo- and diboron monomers

To a solution of dibromo- (1.50 mmol) and diboron monomes (1.50 mmol) in THF (15 mL) were added a 2 M-pottasium carbonate aqueous solution (3 mL), TBA Br (1.29 g, 4.00 mmol) and $Pd(PPh_3)_4$ (0.104 g, 0.09 mmol) and the heterogeneous mixture was refluxed for 24 h under nitrogen. The organic layer was separated, washed with a 5%-sodium cyanide aqueous solution (4.5 mL) and brine and dried with anhydrous magnesium sulfate. After evaporating, the residue was reprecipitated from THF–methanol (7 mL–70 mL) to give polymers **6** or **10**.

*Polymer **6***. Yield: 85.6%. ^{1}H NMR (chloroform-*d*): 0.87 (t, $J = 6.8$ Hz, 3H), 1.15–1.43 (m, 10H), 1.50 (s, 9H), 1.60–1.76 (m, 2H), 2.62–2.77 (m, 2H), 7.28–7.41 (m, 6H), 7.50–7.63 (m, 5H).

*Polymer **10***. Yield: 50.3%. ^{1}H NMR (chloroform-*d*): 1.41 (s, 9H), 1.49 (s, 9H), 3.70 (s, 1H), 6.91 (br s, 2H), 7.14 (br s, 1H), 7.24–7.37 (m, 4H), 7.50–7.61 (m, 4H).

2.3. BOC deprotection

To a solution of **6** or **10** (0.480 mmol) in dichloromethane (8 mL) was added trifluoroacetic acid (2.75 g, 24.1 mmol). The mixture was stirred for 1h at room temperature and poured into water (30 mL). The organic layer was separated, washed with 1 N-sodium hydroxide aqueous solution and brine and dried with anhydrous magnesium sulfate. After evaporating, the residue was reprecipitated from dichloromethane–hexane (5 mL–50 mL) or THF–hexane (5 mL–50 mL) to give polymers **7** or **11**, respectively.

Polymer 7. Yield: 60.4%. ^{1}H NMR (chloroform-*d*): 0.88 (t, $J = 6.6$ Hz, 3H), 1.10–1.49 (m, 10H), 1.56–1.83 (m, 2H), 2.50–2.82 (m, 2H), 5.89 (br s, 1H), 7.09–7.24 (m, 4H), 7.30–7.44 (m, 2H), 7.49–7.74 (m, 5H). *Anal*. Calc. for $(C_{26}H_{29}N)_n$: C, 87.84; H, 8.22; N, 3.94. Found: C, 83.73; H, 8.17; N, 3.62%.

*Polymer **11***. Yield: 66.0%. ^{1}H NMR (chloroform-*d*): 1.43 (s, 9H), 5.87 (br s, 1H), 6.84–6.92 (m, 2H), 7.06–7.23 (m, 5H), 7.47–7.60 (m, 4H). *Anal*. Calc. for $(C_{22}H_{22}N_2)_n$: C, 84.04; H, 7.05; N, 8.91. Found: C, 78.80; H, 6.73; N, 8.05%.

2.4. Oxidation of the precursor polymer

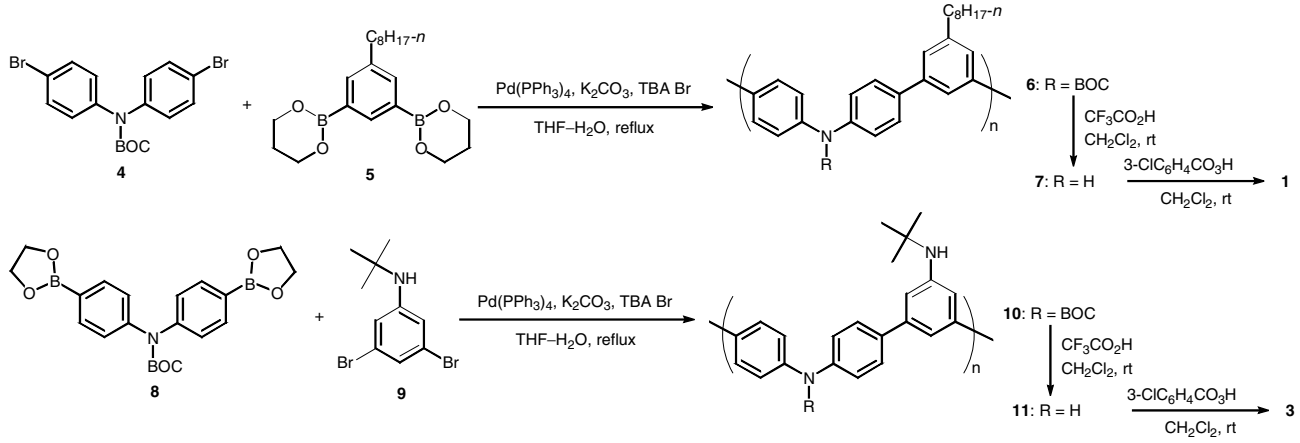
To a solution of **7** (70 mg) in dichloromethane (4 mL) was added 3-chloroperoxybenzoic acid (80 mg) and the mixture was stirred for 20 min at room temperature. After a 10%-sodium carbonate aqueous solution (5 mL) was added, the organic layer was separated, washed with brine and dried with anhydrous magnesium sulfate. After evaporating, the residue was reprecipitated from dichlorometh-

ane–methanol (3 mL–30 mL) to give **1** as brownish red powder in 26.0% yield (19 mg). The spin concentration determined by ESR was 0.57 spins per repeating unit.

To a solution of **11** (72 mg) in dichloromethane (10 mL) was added 3-chloroperoxybenzoic acid (178 mg) and the mixture was stirred for 20 min at room temperature. After a 10%-sodium carbonate aqueous solution (5 mL) was added, the organic layer was separated, washed with brine and dried with anhydrous magnesium sulfate. After filtering, the filtrate was directly used in the ESR measurement and in the preparation of the poly(vinyl chloride) (PVC) matrix sample. The spin concentration determined by ESR was 0.93 spins per repeating unit.

3. Results and discussion

3.1. Synthesis



Polyradicals **1** and **3** were synthesized according to Scheme 1. The precursor polymers were prepared by the Miyaura–Suzuki coupling between dibromo- and diboron monomers and the following BOC deprotection. In the Suzuki–Miyaura coupling, the amino group of diphenylamine moiety was protected by the *t*-butoxycarbonyl (BOC) group to make the coupling proceed efficiently. The yields of **6** and **10** were 86 and 50%, respectively. The BOC deprotection was carried out by using trifluoroacetic acid. The deprotection proceeded completely, which was confirmed by the disappearance of the carbonyl group of BOC in the IR spectra. The yields of **7** and **11** were 60 and 66%, respectively. The molecular weights of **7** and **11** were determined by SEC. The number-averaged molecular weight (M_n) was 3010 for **7** and 1570 for **11**. From these values, the degree of polymerization (n) was estimated to be 6.6 for **7** and 5.0 for **11**. The degree of polymerization was also estimated from the result of the elemental analysis. The found elemental analysis values of **7** were C = 83.73, H = 8.17 and N, 3.62%. When it is assumed that the end groups of **7** are Br and $B(OH)_2$, the calculated elemental analysis values are C = 83.65, H = 7.91 and N = 3.75% for $n = 7$ and C = 84.15, H = 7.94 and N = 3.77% for $n = 8$. These values are in good agreement with the found values. Similarly, the degree of polymerization of **11** was estimated to be 5–6 (Found: C = 78.80; H = 6.73; N = 8.05%. Calc.: C = 77.86, H = 6.65 and N = 8.25% for $n = 5$ and C = 78.83, H = 6.72 and N = 8.36% for $n = 6$). From these results, the degree of polymerization was ca. 7 for **7** and ca. 5 for **11**.

The oxidation of precursor polymers was carried out by using 3-chloroperoxybenzoic acid. Radical **1** was very stable both in solution and in solid state in the atmosphere. The spin concentration was determined by ESR to be 0.57 spins per repeating unit. Whereas, **3** was stable in solution, but decomposed when the solvent was removed. Therefore, as soon as the oxidation was carried out, the dichloromethane solution was used in the ESR measurement and in the preparation of the PVC matrix sample. The spin concentration determined by ESR was 0.93 spins per repeating unit. Because there is two spin generation sites per repeating unit in **11**, the spin concentration per spin generation site was 0.47.

3.2. ESR spectra of polyradicals

The ESR spectra of polyradical **1** were measured in dichloromethane, in PVC matrix and in powder solid state at room temperature (Fig. 1a). The spectrum in dichloromethane was observed at $g = 2.0060$, which is typical for nitroxides. The signal was split five lines, showing that the spin concentration is low because the spectrum of a polyradical is a singlet line in the case of the high spin concentration. The spectrum in PVC matrix was neither a singlet line. The shape was similar for the anisotropic spectrum of mononitroxides [8]. These ESR spectra suggests that there is no intramolecular spin interaction, but the $\Delta M_S = \pm 2$ transition was observed in the $g = 4$ region at 103 K.

The ESR spectra of **3** were measured in dichloromethane and in PVC matrix (Fig. 1b). The spectrum in dichloromethane was observed at $g = 2.0058$. The shape was a

Scheme 1. Synthetic route of **1** and **3**.

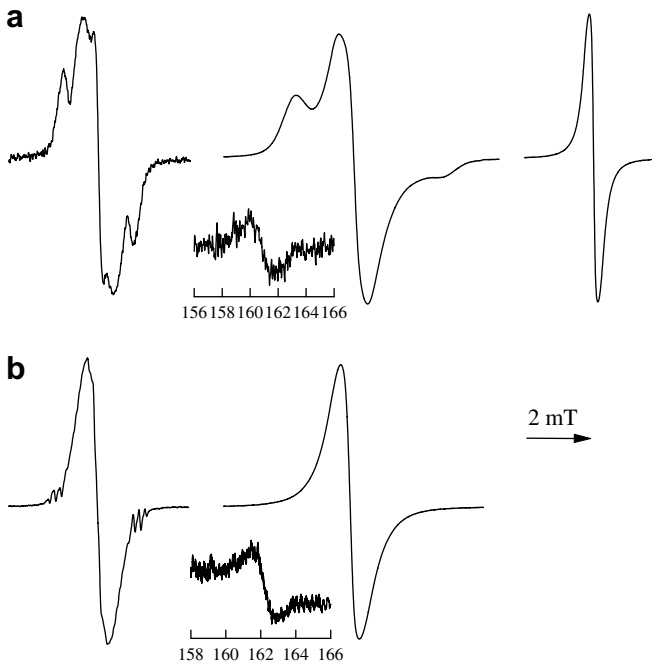


Fig. 1. ESR spectra of (a) **1** and (b) **3** at room temperature. The spectra were measured in dichloromethane (left), PVC matrix (center) and powder solid state (right, only **1**). The spin concentration was 0.57 for **1** and 0.93 spins per repeating unit for **3**. The $\Delta M_S = \pm 2$ transition was observed in the $g = 4$ region in PVC matrix at 103 K for **1** and at 77 K for **3**.

singlet line with small finely splitting lines at the foot. Although the spin concentration of **3** was low, the exchanging narrowing would occur because the distance between spins is close. The spectrum in PVC matrix was also a singlet line. At 77 K, the $\Delta M_S = \pm 2$ transition was observed in the $g = 4$ region as well as **1**. This indicates that there is the intramolecular spin interaction.

3.3. Magnetization measurement

The magnetization of polyradicals **1** and **3** was measured by a SQUID magnetometer. To investigate the intramolecular spin interaction, the external magnetic field dependence of the magnetization of polyradicals in diluted PVC matrix was measured (Fig. 2). The experimental data at 2, 4 and 8 K for **1** were in accordance with the $S = 2/2$ theoretical line given by the Brillouin function, indicating that **1** was in the $S = 2/2$ spin state. From the degree of polymerization of ca. 7 and the spin concentration of 0.57 spins per repeating unit, there were of ca. 4 spins (ca. 7×0.57) per molecule, that is, 2 spins out of 4 spins were aligned in **1**. Whereas, for **3**, the experimental data at 2, 4 and 6 K were in accordance with the $S = 3/2$ theoretical line, indicating that **3** was in the $S = 3/2$ spin state. From the degree of polymerization of ca. 5 and the spin concentration of 0.93 spins per repeating unit, there were ca. 5 spins (ca. 5×0.93) per molecule, that is, 3 spins out of 5 spins were aligned in **3**. The spin sate of **2** was 3/2 and 3 spins out of 8 spins were aligned because there were 8 spins per molecule from the degree of polymerization of

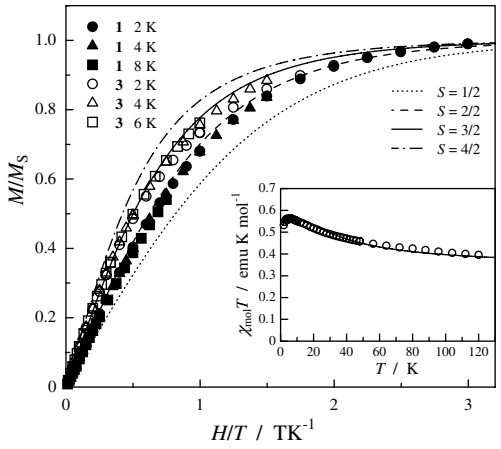

Fig. 2. External magnetic field dependence of the magnetization of **1** and **3** in PVC matrix. The spin concentration was 0.57 for **1** and 0.93 spins per repeating unit for **3**. The points are the experimental data at the constant temperature. The lines are the theoretical lines for $S = 1/2$, 2/2, 3/2 and 4/2 given by the Brillouin function. Inset: the temperature dependence of the magnetic susceptibility of **3** in PVC matrix. The line is the least-square fit with Eq. (2).

ca. 11 and the spin concentration of 0.71 spins per repeating unit [7]. Therefore, the intramolecular spin interaction in **3** occurs more efficiently than in **2**.

To examine the intramolecular spin interaction in **1**–**3**, the S values were numerically calculated. The spin concentration of polyradical can be expressed as 4/7 (=0.57) for **1**, 8/11 (=0.73) for **2** and 5/10 (=0.50) for **3** based on the degree of polymerization and the spin concentration. Because there are 4 spins (and 3 spin defects) on 7 repeating units in **1**, the number of spin arrangement patterns is calculated to be 35 (=7!/4!3!). Similarly, the numbers of spin arrangement patterns in **2** and **3** are calculated to be 165 (=11!/8!3!) [7] and 252 (=10!/5!5!), respectively. Some spin arrangement patterns in **1** are shown in Table 2. When it is assumed that the intramolecular spin interaction between two neighboring spins is ferromagnetic and the spin defect intercepts the spin interaction, which are expressed as $J_0 > 0$ and $J_1 = 0$ in Fig. 3, respectively, there are one $S = 1/2$ and one $S = 3/2$ states in entry 2 in Table 1. In this way, when the number of the spin states in all entries are counted, the total number and the percentage in each spin state are 38% and 49% for $S = 1/2$, 22% and 28% for $S = 2/2$, 18% and 18% for $S = 3/2$ and 4% and 5% for $S = 4/2$ as shown in Tables 1 and 2. Because many spin states are intermingled in open-shell polymers, except for

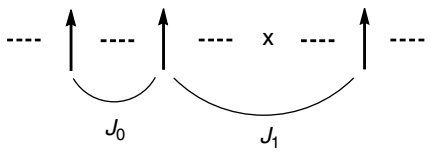

Fig. 3. Intramolecular exchange interaction J_0 and J_1. The subscript denotes the number of spin defects between spins. ↑ and × denote the spin and the spin defect, respectively.

Table 1
Spin arrangement pattern for 4 spins on 7 repeating units

Entry	Spin arrangement pattern[a]	Exchange interaction[b]	Number of the spin states			
			1/2	2/2	3/2	4/2
1	↑↑↑↑×××	$J_0 > 0, J_1 = 0$	0	0	0	1
		$J_0 > 0, J_1 > 0$	0	0	0	1
2	↑↑↑×↑××	$J_0 > 0, J_1 = 0$	1	0	1	0
		$J_0 > 0, J_1 > 0$	0	0	0	1
⋮	⋮	⋮			⋮	
35	↑×↑×↑×↑	$J_0 > 0, J_1 = 0$	4	0	0	0
		$J_0 > 0, J_1 > 0$	0	0	0	1
	Total number	$J_0 > 0, J_1 = 0$	38	22	18	4
		$J_0 > 0, J_1 > 0$	12	10	12	18

[a] ↑ and × denote the spin and the spin defect, respectively.
[b] J_0 and J_1 are defined in Fig. 3.

the cases of the spin generation percentage near 100%, the external magnetic field dependence of the magnetization is expressed as follows:

$$\frac{M}{M_S} = p_{1/2}B_{1/2} + p_{2/2}B_{2/2} + \cdots + p_{n/2}B_{n/2} = \sum p_S B_S, \qquad (1)$$

where p_S is the percentage of the spin state S in the spin states intermingling and B_S is the Brillouin function for the spin state S. The external magnetic field dependence of the magnetization calculated with Eq. (1) is shown as open circles ($J_0 > 0$ and $J_1 = 0$) in Fig. 4. The curve drawn by open circles in Fig. 4a corresponds to the line given by the Brillouin function for $S = 0.86$, that is, the calculated S value for **1** was 0.86. This is in good agreement with the experimental value. Similarly, the percentages of the spin states intermingling in **2** and **3** are calculated as shown in Table 2 and the calculated S value for **2** was 1.23 as shown in Fig. 4b, which is also in good agreement with the experimental value. But, for **3**, the calculated S value was 0.80, which is much lower than the experimental value. Then, the S value in the case of $J_0 > 0$ and $J_1 > 0$ was calculated. The result is shown as open triangles in Fig. 4c. From the curve drawn by open triangles, the calculated S value was 1.21, which is in good agreement with the experimental value. The calculated S values in the case of $J_0 > 0$ and $J_1 > 0$ for **1** and **2** were 1.27 and 2.56, respectively, which are

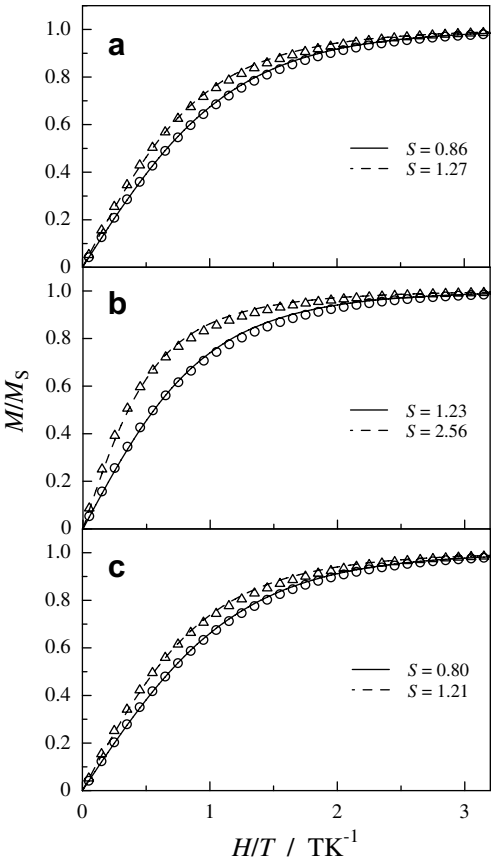

Fig. 4. External magnetic field dependence of the calculated normalized magnetization for (a) **1**, (b) **2** and (c) **3**. The points are the calculated normalized magnetization: open circle, $J_0 > 0$ and $J_1 = 0$; open triangle, $J_0 > 0$ and $J_1 > 0$. The lines are the theoretical lines given by the Brillouin function.

larger than the experimental values. These results indicate that the spin defect intercepts the intramolecular spin interaction in **1** and **2**, but there is the spin interaction across the spin defect in **3**.

The inset in Fig. 2 is the temperature dependence of the magnetic susceptibility of **3** in PVC matrix. The $\chi_{mol}T$ value increases as the temperature decreases. The behavior was analyzed by using Eq. (2) which is often used as the doublet–quartet model for analyzing the intramolecular spin interaction in triangle triradicals [9,10]:

Table 2
Percentage of the spin state in polyradical

Polyradical[a]	Exchange interaction[b]	Percentage of the spin state in polyradical (%)							
		1/2	2/2	3/2	4/2	5/2	6/2	7/2	8/2
1	$J_0 > 0, J_1 = 0$	49	28	18	5				
(4/7)	$J_0 > 0, J_1 > 0$	23	19	23	35				
2	$J_0 > 0, J_1 = 0$	29	25	18	13	7	5	2	1
(8/11)	$J_0 > 0, J_1 > 0$	8	8	8	8	8	8	8	44
3	$J_0 > 0, J_1 = 0$	55	27	13	4	1			
(5/10)	$J_0 > 0, J_1 > 0$	28	22	21	16	13			

[a] The number in parenthesis is the spin concentration.
[b] J_0 and J_1 are defined in Fig. 3.

$$\chi_{\mathrm{mol}}T = f\frac{2Ng^2\mu_{\mathrm{B}}^2}{4k_{\mathrm{B}}}\frac{1+5\exp(3J/k_{\mathrm{B}}T)}{1+\exp(3J/k_{\mathrm{B}}T)}\frac{T}{T-\theta}. \quad (2)$$

The least-square fit gave $J/k_{\mathrm{B}} = +17.7$ K. This value is larger than that of **2** ($J/k_{\mathrm{B}} = +4.2$ K) [7]. This is due to that the distance between spins is closer in **3** than in **2**.

4. Summary

Stable 1,3-phenylene linked polyradicals **1** and **3** were synthesized. Compound **1** was stable both in solution and in solid state, whereas **3** was stable only in diluted solution or PVC matrix. The comparison of the experimental S values with the values numerically calculated based on the degree of polymerization and the spin concentration showed that there is the intramolecular spin interaction across the spin defect in **3**.

Generally speaking, an $\widehat{O}_x^y$ Stevens operator utilizes xth order spin operators to create energy biases having y-fold rotational symmetry as the applied magnetic field rotates about the quantization (z)-axis. Here, a zero-fold pattern indicates contributions to the zfs. As one moves to the right along the terms in Eq. (1), ignoring the Zeeman interaction for the moment, contributions to the energies diminish, making it more difficult to detect the presence of higher order terms in experiment. The sum as a whole then parameterizes the spin–orbit coupling in a SMM.

Out of necessity, the giant spin model ignores the fact that large numbers of exchange-coupled ions contribute to the magnetism in a SMM, and the parameters associated with the Stevens operators have little physical significance. In reality, each of these linked ions has its own spin–orbit parameterization. We set out to explore the relationships between the local and molecular anisotropies and also to address whether higher order terms in the giant spin Hamiltonian could arise from a simple isotropic Heisenberg exchange interaction.

One interesting compound, $[Ni(hmp)(dmb)Cl]_4$ and referred to as Ni_4 hereafter, falls into a regime where it may be studied numerically as either a giant spin or as four spins coupled through Heisenberg exchange [3]. The magnetic core is composed of four $S = 1$, Ni^{2+} ions, which couple ferromagnetically to form a spin $S = 4$ ground state. Hilbert spaces span 9 and 81 dimensions for the giant spin and exchange models, respectively. High frequency EPR experiments have determined giant spin parameters up to fourth order with non-zero D, B_4^0 and B_4^4 [3,4]. Thermodynamic measurements have also determined a value for the exchange coupling constant J [5,6]. Additionally, single-ion anisotropy parameters and alignments with respect to crystallographic axes have been found through synthesis and experiment on an isostructural form, $[Zn_{3.91}Ni_{0.09}(hmp)_4(dmb)_4Cl_4]$ or NiZn for short [7]. These studies found non-zero d and e values for the single ions. With this significant base of experimental data one may begin to piece together an exchange coupled Hamiltonian with a general expectation as to what parameters should fit the model.

$$\widehat{H} = \sum_{i=1}^{4}\left[d\widehat{O}_2^0(i) + e\widehat{O}_2^2(i) + g\mu_B\vec{B}\cdot\widehat{S}_i\right] + \sum_{i=1}^{4}\sum_{j>i} J\widehat{S}_i\cdot\widehat{S}_j \tag{2}$$

A four-ion Hamiltonian is written in Eq. (2), where $\widehat{O}_2^0(i)$ and $\widehat{O}_2^2(i)$ represent Stevens operators for the ith particle, scaled by d and e. Lower case indicates parameters for the four-ion model to prevent confusion with the giant spin Hamiltonian. The Hamiltonian matrices for the individual ions have dimensions 3×3. Consequently, the second order Stevens operators completely account for the local anisotropy. The four ions are each coupled to the others netting six interactions with identical J values. A more precise model would include two values of J, due to the axial distortion of the cubic core of the molecule (having S_4 symmetry). However, the use of a single J value does not have any significant effect on the analysis below, where the discussion is of a more qualitative nature. In addition, fits to magnetic susceptibility data using a two-J model suggest that the values are quite similar [6].

The four-ion model is evaluated in two ways. The first part involves the zfs, i.e. the energy differences between adjacent m_s states at $B = 0$. The second part involves fitting oscillations of the ground state splitting as a function of the applied field orientation within the hard plane. The latter provides the most straightforward measurement of the off-diagonal (transverse) anisotropy parameters via an EPR experiment [8]. We then compare the data generated via the four-ion model with those from the giant spin Hamiltonian. In looking at the ground state multiplet for the four-ion Hamiltonian, one would expect to find d to be the primary contributor to the zfs, and e to dictate the behavior when the field is in the hard plane. This is indeed the case. However, as we shall see, J does play an important role for both regimes. Furthermore, due to its S_4 symmetry, the molecular E parameter is necessarily zero. It is, therefore, interesting to see how e influences the transverse anisotropy in the giant spin Hamiltonian, and what role (if any) J plays in the correspondence between the anisotropy parameters in the two models.

2. Data and discussion

Fig. 1 compares the zfs for both the giant spin and four-ion models. Black data points in Fig. 1a represent the lowest nine zero field energies for the four-ion model with their shape indicating the spin projection within the $S = 4$ state,

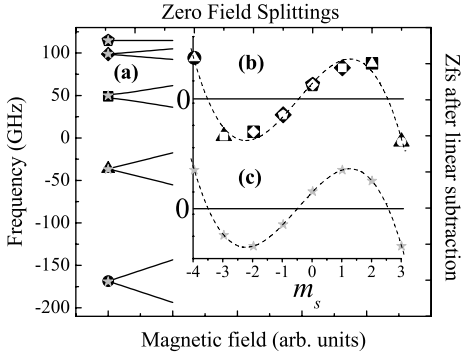

Fig. 1. (a) The lowest nine energy levels (black shapes) are plotted for the four-ion model with the full set of corresponding energies from the giant spin model (grey stars), superimposed with lines proceeding to higher field representing the Zeeman splitting brought on by a longitudinal field. (b) The energy differences between consecutive projections, m_s (horizontal axis), are plotted for the four-ion model after subtraction of the linear dependence. This is necessary to graphically represent the differences between the two models. A cubic polynomial fit to the eight data points is included to provide a guide to the eye. (c) The energy differences between consecutive m_s states are plotted for the giant spin model after subtraction of the linear dependence. In (c), the data points all fall onto the fit whereas, in (b), points fall away from the fit indicating a subtle difference between the two models.

where projections of equal magnitude are essentially degenerate. Lines emerging to the right of the data points indicate the energy splitting arising from an applied longitudinal field. The grey stars are the energies calculated from the giant spin model using parameters which are published elsewhere [3,4]. At first glance this comparison shows that one may indeed model zero field data using a four-ion model, i.e. there is no visible difference between the two sets of data points.

A subtle contrast appears only upon closer inspection of the differences between the zfs energies predicted in either model. As previously discussed, the dominant second order axial anisotropy results in a linear dependence of the zfs on m_s, where m_s represents the lower of the values for the two levels in question, i.e. the zfs are numbered from -4 to $+3$ (see Fig. 1b). Plotting the eight zfs versus m_s (not shown) reveals a slight deviation from linearity [5]. This shift is small enough that, in order to make comparison between models graphically, the linear component must be subtracted. This allows emphasis to be placed on the curvature (non-linearity, or higher-order zfs) with the results shown in Fig. 1b for the four-ion model, and Fig. 1c for the giant spin model. Cubic polynomial fits overlay the two sets of data points. The discrepancy between the two models reveals itself as points in Fig. 1b that fall away from the cubic fit. In other words, higher order polynomial components are required to fit the data points for the four-ion model.

The analysis to this point reveals several very important results. The cubic behavior seen in Fig. 1c is a direct consequence of $\widehat{O}_4^0$, and the cubic term in the polynomial fit provides a direct measure of the B_4^0 parameter in the giant spin model. However, when one applies the four-ion model to the same data set, higher-order corrections to the cubic behavior automatically appear. The experimental accuracy of the data is insufficient to determine which model is correct. However, one can directly compare the two models. In doing so, it seems that one must include terms of order higher than four in the giant spin model in order to force it into agreement with the four-ion model. Indeed, there is no physical reason for truncating the giant spin Hamiltonian (Eq. (1)) at fourth order, whereas local anisotropy terms in Eq. (2) of order higher than two are completely unphysical. In this sense, although both approaches already involve approximation, Eq. (2) is somehow complete, whereas Eq. (1) is further approximated by limiting it to 4th order.

Nevertheless, there is a more important conclusion that can be drawn from comparison between the two models. Namely, that the non-linearities in Fig. 1b depend explicitly on the isotropic Heisenberg interaction parameter J. This dependence is discussed at greater length in a separate paper [5]. For infinite coupling, the curvature goes to zero. In other words, one necessarily requires a finite J to account for the cubic behavior observed in the experimental data and, therefore, the B_4^0 term deduced on the basis of the giant spin model. Thus, a combination of d and J is required to account for the non-linear dependence of the zfs on m_s in the four-ion model. What is more, the resultant non-linearities produce fourth and higher-order terms in the giant spin model. The effect of a finite J is to generate mixing between spin multiplets with different S quantum numbers. This mixing leads to a breakdown of the giant spin approximation.

Fig. 2 illustrates the oscillation of the ground state splitting as a transverse field sweeps through 360° within the hard plane. Here, the ground state splitting indicates the energy difference between the two lowest levels at 5 T. In the main part of the figure, eigenvalues are plotted as a function of magnetic field for two orientations, with arrows indicating the maximum (grey) and minimum (black) magnitudes of the splitting. An oscillation in the splitting occurs when operators, $\widehat{O}_x^{2n}$ with $n > 0$, appear in either Hamiltonian. Tracing this magnitude over 360° yields a four-fold oscillatory pattern shown in the lower left inset, which represents both the giant spin and four ion models, i.e. they are indistinguishable on this scale. Here the four-ion model replicates the effect of the B_4^4 term in the giant spin model. Precisely as noted above for the zfs above, a combination of both the exchange interaction parameter J, and the e term in Eq. (2) is required to produce the desired result; the magnitude of the oscillation scales inversely with J. Although each of the ions has an e term, the molecular S_4 symmetry guarantees cancellation of the second order (two-fold) behavior plotted in the upper right inset for comparison. Were one to break the S_4 symmetry of the Ni_4 molecule, such an angle dependence would naturally arise, even for infinite J. In the strictly S_4 case, no oscillation (transverse anisotropy) is observed for infinite

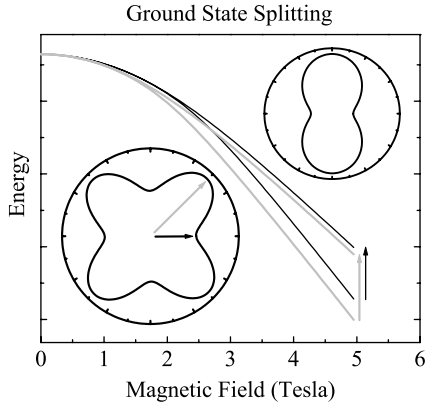

Fig. 2. The ground state energy splitting is plotted for increasing values of transverse magnetic field for two angles within the hard plane. The grey traces indicate field orientations which yield maximum splitting, while the black traces show minimal splitting. The arrows indicate the energy differences (ground state splitting) which are plotted as insets in the lower-left and upper-right portions of the figure for a full rotation of a 5 T field within the hard plane. The combination of an e term and the exchange parameter J in the four-ion model replicates the effect of a B_4^4 term in the giant spin model. By contrast, a similar plot for a single particle with an e term (or an E term for a giant spin) is plotted in the upper right inset.

J. For a finite J, the effect of the second order e term shows up again at higher orders in the giant spin model.

3. Conclusion

Heisenberg exchange coupling does indeed introduce apparent effects attributed to higher-order anisotropic interactions in the giant spin Hamiltonian. Non-linear zfs attributed to the B_4^0 term in the giant spin model appears to result from the interaction between energy levels belonging to higher-lying spin multiplets [5]. A similar behavior was recently noted in an Fe_4 complex [9]. Although the mapping is not exact, the similarity is striking. The difference between models indicates a shift in an EPR peak of close to 0.03 T, which in many cases is difficult to measure because of peak broadening brought on by D- and g-strain within a typical crystal. As the giant spin model is an expansion of terms that leads into higher orders, it seems reasonable that the models should come into better agreement as more terms such as B_6^0 and B_8^0 are added into the giant spin parameterization. But that discussion diverts from the main point. The apparent B_4^0 and B_4^4 terms measured under the giant spin Hamiltonian are actually artifacts of exchange, which in turn convolutes the physical meaning of a giant spin Hamiltonian. The series of terms no longer parameterizes spin–orbit coupling but instead measures a combination of interactions, which are impossible to extract from the model. While the giant spin model will work in the simulation of experimental data, it does not do an ideal job of explaining the physical processes within a SMM. The above calculations were made using the Hamiltonian parameters, $d = -141.8$ GHz, $e = -35.6$ GHz, $J = -178$ GHz, $g = 2.25$, including a dipolar interaction as well as a 15° tilt of the Ni ion easy axes away from the molecular easy axes [5,7].

chain taken from experimental structure. The theoretical methodology was developed in our recent works [5a,6], the new results proving its reliability in tackling the realistic description of real chemical systems and physical problems.

2. Experimental

All chemicals and solvents were used as received and no purification was needed. The complex $[Fe(bpca)_2][Er(NO_3)_3(H_2O)_4]\cdot NO_3\cdot H_2O$ (**1**) was obtained by adding a solution of $Er(NO_3)_3\cdot 6H_2O$ (0.05 mmol) in methanol (2 mL) to an equimolar solution of $[Fe(bpca)_2]NO_3$ (synthesized as described elsewhere [7]) in nitromethane (2 mL). After 30 min stirring at room temperature, the solution was left undisturbed. Well formed orange crystals resulted in several days (yield 83%). Crystals were used for X-ray and magnetic measurements. *Anal*. Calc. for $C_{24}H_{18}ErFeN_{10}O_{21}$ (**1**): C, 28.67; N, 13.93; H, 1.80. Found: C, 28.54; N, 13.71, H, 2.20%.

The diffraction data were collected on SMART-1000/CCDD (Bruker AXS) area detector using the standard procedure (Mo Kα radiation). The data integration and reduction were undertaken with SAINT and XPREP [8]. The intensity data were empirically corrected for absorption using the program SADABS [9]. The structures were solved by direct methods and refined using least-squares methods on F^2 with SHELXL-97 [10]. Non-hydrogen atoms were modeled with anisotropic displacement parameters, and hydrogen atoms were placed by difference Fourier syntheses and refined isotropically. $\lambda(\text{Mo K}\alpha) = 0.71073$ Å, $T = 100$ K, orange blocks, formula $C_{24}H_{16.33}ErFeN_{10}O_{21}$, MW = 1003.91, $0.80\times0.65\times0.60$ mm, triclinic, $P\bar{1}$, $a = 13.4837(15)$ Å, $b = 19.766(3)$ Å, $c = 20.801(2)$ Å, $\alpha = 85.321(4)°$, $\beta = 85.321(4)°$, $\gamma = 85.321(4)°$, $Z = 6$, $V = 5182.0(11)$ Å^3, $R_1 = 0.0411$, $wR_2 = 0.0979$, GOF = 1.012.

Magnetic measurements for **1** were carried out on a Quantum Design SQUID MPMS 5S magnetometer on polycrystalline samples. The dc measurements were made using an external magnetic field of 1000 Oe over a temperature range of 1.8–300 K and ac measurements using a 3 Oe magnetic field oscillating at 10–1400 Hz. Diamagnetic corrections were estimated from Pascal constants.

3. Results and discussion

The network of compound **1** contains the $[Fe(bpca)_2]^+$ distinct cations and 1-D assembled $[Er(NO_3)_3(H_2O)_4]$ neutral units, the d and f nodes being weakly connected by hydrogen bonding. The non-coordinated nitrate ions play a role in the hydrogen bond bridging of neighbor lanthanide complex units. The $[Fe(bpca)_2]^+$ cation is a compressed octadedron (see Fig. 1), made of tris-dentate mononegative ligands $bpca^-$ and Fe(III). As expected for a system consisting in floppy components (lanthanide coordination spheres and the intermolecular connections), the crystal structure show disordering promoted by the hydrogen bond dynamics.

The disorder brings slight differences between the lanthanide molecular moieties (belonging to three species in the crystal). These are, however, roughly similar, differing in rather small tilts of the chelate NO_3^- groups. A description that match the common features of $[Er(NO_3)_3(H_2O)_4]$ units is the 10 vertex topology established by the three NO_3^- chelates and the four monodentate H_2O ligands. In each case, two NO_3^- groups are coordinated symmetrically, with Er–O bond lengths in the 2.30–2.58 Å range, while another group coordinates asymmetrically, with one bond elongated at 3.2–3.6 Å. The four water ligands are situated approximately in the same plane, in a sequence of *cis* mutual positions. The average planes of $\{(H_2O)_4Er\}$ and $\{Er(NO_3)_3\}$ molecular halves are mutually perpendicular. It is worth noting the dipolar structure of the neutral $[Er(NO_3)_3(H_2O)_4]$ complexes, with the negative ligands placed in one hemisphere. The $\{(H_2O)_4Er\}$ molecular half shows, in counterpart, positive polarization and outer protons as vectors for hydrogen bonding. The dipolar nature and hydrogen bonding capabilities are the factors determining the 1-D assembling of the lanthanide units. The

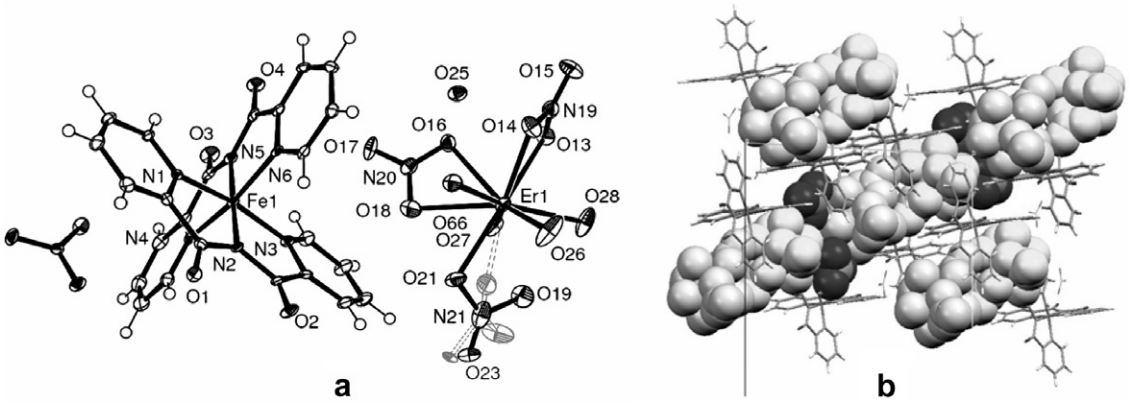

Fig. 1. (a) ORTEP view of complex $[Fe(bpca)_2][Er(NO_3)_3(H_2O)_4]\cdot NO_3\cdot H_2O$ (**1**) with 50% thermal probability ellipsoids and selected atom labeling scheme. (b) Packing diagram of the crystal structure **1**, showing the chain arrangement of the lanthanide units (light grey spheres) including the non-coordinated NO_3^- groups (dark grey spheres), while the $[Fe(bpca)_2]^+$ complexes are drawn with sticks.

qualitatively estimated electric dipole orientations of individual complexes are tilted with respect of the chain averaged direction. The symmetry along the chain involves inversion operations. Therefore the crystal is, as sum, non-polar. At the point where the inversion of sequences occurs, the lattice NO_3^- groups are intervening to establish hydrogen bond bridges with ligands from $\{(H_2O)_4Er\}$ molecular sides of neighbour units. The described features can be visualized in Fig. 2.

The magnetic properties of the complex **1** were studied using a polycrystalline sample in the 1.8–300 K temperature range. The χT product (Fig. 3) at room temperature is 12.03 $cm^3 \cdot K/mol$, in line with an effective $^4I_{15/2}$ ground state on Er(III) plus the uncoupled $S = 1/2$ Fe(III) center. Treated with a simplistic Curie–Weiss linearization, $\chi^{-1} = (T - \theta)/C$, the parameters are $C = 12.23\ cm^3 \cdot K/mol$ and $\theta = -9.75$ K. The C value is close to the paramagnetic summation equated using the ideal values $g_J = 1.2$, $J = 15/2$ for Er(III) component and $g_S = 2$, $S = 1/2$ for Fe(III). The θ parameter is similar with the values reported in comparable cases [11]. However, this cannot be assigned, as attempted in the above cited work, to some antiferromagnetic coupling, the Er(III) single ion anisotropy being likely the origin of the χT function of temperature. The χT increasing from 6.02 $cm^3 \cdot K/mol$ at 1.8 K occurs on a large temperature domain, a fact that implies statistics over energy gaps larger that those conceivable to d–f or f–f exchange coupling. The magnetization versus field measurements shows the highest value of the magnetization at about 5.62 μ_B at 50 kOe at 1.8 K. The magnetization curve does not correspond to a regular Langevin pattern, but is in line with an effective moment lower than the maximal one, as suggested also by the χT value at the lowest temperature.

Zero field cooled and field cooled (ZFC-FC) dependences were recorded on the polycrystalline sample and no difference was observed between the two curves down to 1.8 K. The temperature dependence of the ac magnetic susceptibilities of the polycrystalline sample of **1** measured in zero magnetic field is shown in Fig. 4a. In a field oscillating at 1400 Hz, the complex shows no out-of-phase component of ac magnetic susceptibility χ'' above 1.8 K, while the in-phase component χ' decreases monotonically with the increasing of the temperature. This behavior suggests that

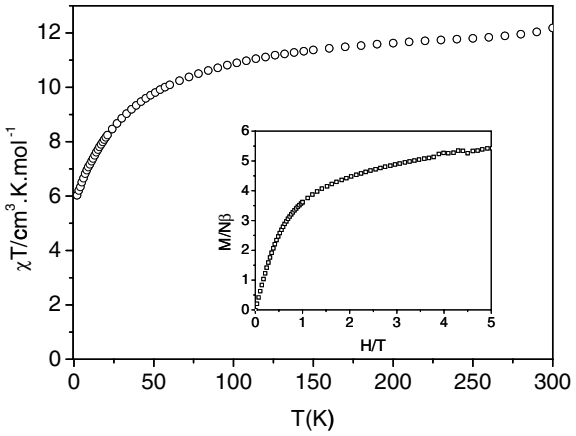

Fig. 3. Temperature dependence of the χT product for **1**. Inset the magnetization vs. field (1.8 K).

the magnetic moments follow the ac magnetic field. In the presence of a static magnetic field (Fig. 4b) the complex shows a significant decrease in χ' from the corresponding zero dc field values and, for χ'', peaks depending on the ac frequency, suggesting a lag in the response of the magnetic moment to the ac magnetic field.

The ac susceptibility for **1** was measured down to 1.8 K and in the frequency range 10–1400 Hz (Fig. 4c and d). Such behavior is similar to the other several systems containing lanthanide ions [12] and this procedure avoids fast tunneling regime of the Kramer type systems at zero static field. The explanation for the origin of dc field-induced relaxation as the lifting of the Kramer degeneracy by magnetic field is valid merely for "isolated ion-like" systems [13]. Even having a presumable small role in the χT function, the long range couplings, dipolar, or even exchange mediated through hydrogen bonds, can play decisively in assisting the dynamic magnetic behavior. Considering the Er···Er separation in the chain, around 7.7 Å, one may estimate, with dipolar formulas, energies in a 0.26 cm^{-1} range, suggesting that such effects can intervene in the intricate phenomena related with the magnetization relaxation.

An interesting view to the magnetic anisotropy was added with the help of the ab initio calculations. As described elsewhere [5a,6], the calculation of lanthanide systems is a non-routine task, for which we developed spe-

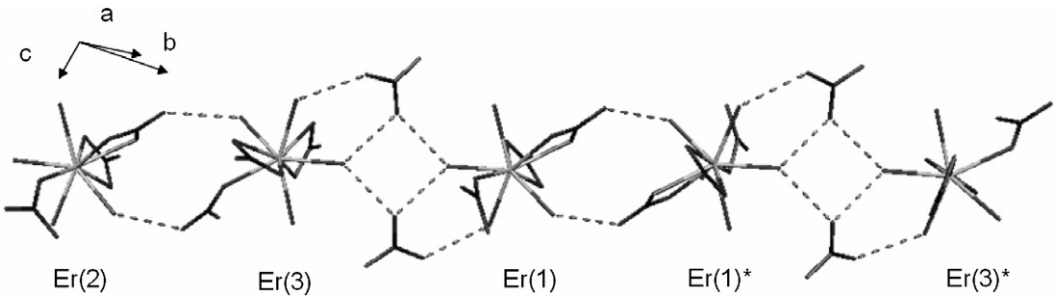

Fig. 2. The hydrogen-bonded chain structure formed by $[Er(NO_3)_3(H_2O)_4]$ units. Selected lengths: Er(1)–Er(3) 8.419 Å, Er(3)–Er(2) 7.732 Å. The symmetry operation for the (*) atoms: $-x$, $-y$, $-z$.

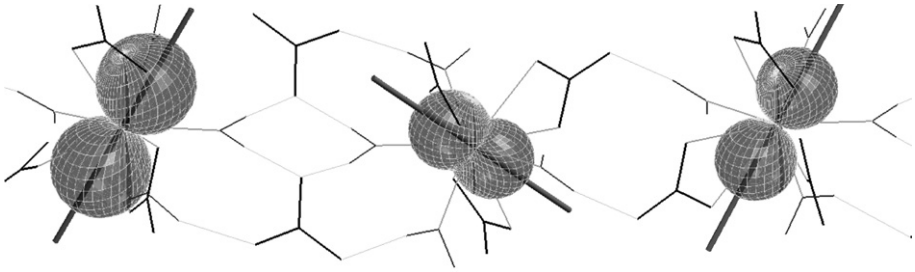

Fig. 5. The magnetization tensors for the groundstates of the $[Er(NO_3)_3(H_2O)_4]$ units, obtained via CASSCF+SO ab initio calculations including subsequently the modeling of magnetic field effects. The axes drawn with the origin in each center correspond to a -10 μ_B to $+10$ μ_B scale. Note the tilt of the easy magnetization axis resulted on centers related by inversion operations (the two nodes from the right side sequence).

cial procedures. The calculations were performed with the GAMESS program [14], the further handling using original codes. The calculation were performed on three individual $[Er(NO_3)_3(H_2O)_4]$ complex units as depicted in Fig. 5. The position of hydrogen atoms was fixed with the help of geometry optimization considered for a $\{[Lu(NO_3)_3(H_2O)_4]_5(NO_3)_4\}^{(-4)}$ sequence (similar to those depicted in Fig. 2), where Lu(III) was used as surrogate to avoid at this step the open shell intricacies. The next calculations consisted in CASSCF(11,7) procedures (i.e. 11 electrons in 7 orbitals) corresponding to the f^{11} configuration of the Er(III) in the $[Er(NO_3)_3(H_2O)_4]$ complexes. A state-averaging regime (on 13 levels) was employed, accounting in balanced manner for the ^4I multiplet.[3] Afterwards, the spin orbit (SO) calculations were done, incorporating as result all the ^4I_J sets with J between 15/2 and 9/2 (totally, 52 microstates). The CASSCF calculations accounted well for the ligand field regime, yielding a total gap about 400 cm^{-1}on the ^4I term, with SO ignored. The subsequent SO computation yielded for the groundstate sequence a series of 16 states grouped in doubly degenerate pairs, whose full gap falls in the 300 cm^{-1} range. The spacing between successive sublevels are in the 20–60 cm^{-1} range. This interplay between ligand field and spin orbit effects is somewhat similar to the ZFS effect, but in a more complex fashion. The doubly degenerate companions formally correspond to $\pm J_z$ pairs, but one may take the precaution to consider that, in principle, the J_z labels may loose their effective quantum number qualities, due to the imbrications with the ligand field part.

The full output from CASSCF+SO calculations afforded the supplementary information needed to build the

[3] The SBKJC effective potential and basis set were used on the Er atom and 6-31G* basis sets for O, N, and H atoms.

orbital part of the Zeeman Hamiltonian, aside to the obvious spin type Zeeman part. Taking this advent and having all the necessary ingredients, we modeled the further splitting in magnetic field with a separate original code. Performing the corresponding derivatives with the field, the magnetization tensors became available. The computed polar diagrams for the ground state magnetization of the selected centers are depicted in Fig. 5.

The maximal extension along the easy magnetization axis is at one center about 7 μ_B (left side in Fig. 5). This would correspond to a certain reduction of the $g_z J_z \mu_B$ amount taken with respect of the ideal $J_z = \pm 15/2$ projections. The other centers show advanced reduction, about 5 μ_B in the magnitude of magnetic anisotropy. Keeping a semi-quantitative use of ab initio results, one may suggest a rather significant dependence of magnetic properties as function of slight geometry changes. The noticed reduction can be assimilated to a non-monotonous J_z type ordering or a J_z projection-admixed nature of levels, once the J_z labels cease to be rigorous quantum numbers. A certain reduction of effective magnetization of the ground state (as compared to the ideal maximal 15/2 component), while, in counterpart, the next levels bear higher moments, would be in line with the observed χT increase with T, as such sequences are progressively populated. The intermediate effective J_z is also in line with lower plateau trend in magnetization taken at small temperatures. Though too complex yet for the full understanding, the magnetic properties due to intrinsic anisotropy and complicate dependence on ligand field can be gradually decrypted, taking different structural case studies and complementing them with theoretical insight, as we attempted here. The ab initio approach, reliable for accounting the main ligand field and spin orbit mechanisms, at least qualitatively, helps encompassing parametric uncertainties and algebraic complications that affect traditional ligand field model approaches on lanthanide systems. The investigation of lanthanide complexes with different symmetries and ligand fields can provide rationalization for the dynamical magnetism of lanthanide complexes. Further systems and structural correlations in this line are in the progress and our current focus.

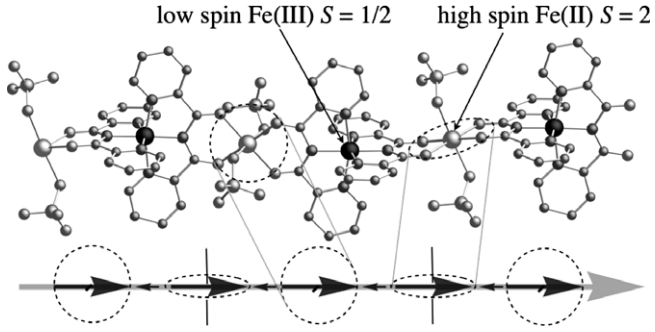

Fig. 1. Crystal structure and spin arrangement of **1**.

the formula of $\mathbf{1}\cdot 3CH_3NO_2$.[1] Each chain is directing along crystallographic a–c vector, and cylindrical pores are formed along this axis surrounded by four chains (Fig. 2a). The crystal of **1** contains three molecules CH_3NO_2 molecules per a Fe(II)–Fe(III) unit as crystallization solvent which occupy the pores. These CH_3NO_2 molecules can be released gradually at room temperature and the crystal breaks into fragments. Thermogravimetry analysis for the fresh crystals of **1** was carried out to show 19% decrease of weight at 30 °C, which corresponds to the loss of three CH_3NO_2 molecules from the solvated crystal (17.5%) (Fig. 2b). Here after, we called the crystal which contains three CH_3NO_2 molecules as solvated sample ($\mathbf{1}\cdot 3CH_3NO_2$), and the crystal which released all CH_3NO_2 molecules as dried sample (**1**).

Although the completely dried sample does not maintain its quality for the single crystal X-ray diffraction, a partially dried crystal of **1** keeps enough quality for single crystal X-ray analysis. To investigate the structure of dried sample, we first revealed the X-ray structure for partially dried single crystal of **1**. A freshly prepared single crystal was covered with grease and dried under vacuum for 1 h. The partially dried **1** has the similar structure with the solvated crystals, however, the space group was changed from $P2_1/n$ to $C2/c$, with the formula changing to $\mathbf{1}\cdot 2.5CH_3NO_2$.[2] The unit cell volume is decreased (from 3966 Å^3 to 3910 Å^3) along with the decrease of the number of CH_3NO_2 (from 3 to 2.5). Intra and inter-chain Fe–Fe distances are maintained during the changing of the volume.

To confirm the structure of the completely dried sample, an X-ray powder diffraction (XRD) analysis was carried out

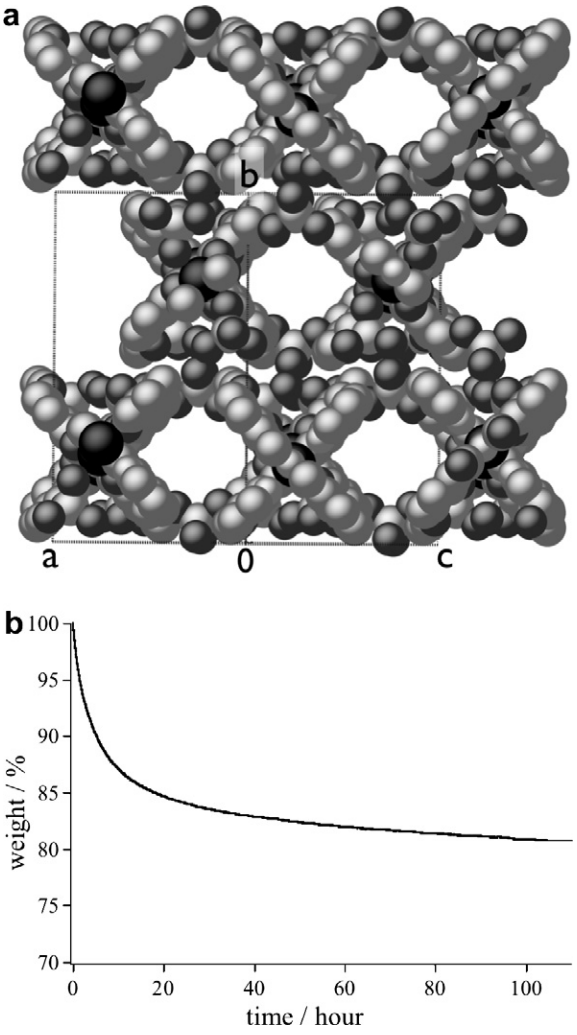

Fig. 2. (a) The packing diagram of **1** viewed from the chain direction. (b) Plot of weight vs. time at 30 °C for fresh prepared solvated sample.

on the powdered **1** of which crystals were mashed under N_2 and dried for 1 h, and compared with the simulated XRD pattern on the basis of the crystal data for the partially dried single crystal with the $C2/c$ space group mentioned above (Fig. 3a upper and Fig. 3b). Compound **1** keeps its crystal character under a completely dried condition and does not change to the amorphous phase. Both the diffraction pattern for the completely dried sample and the simulation pattern for the partially dried crystal are very similar to each other and a slight difference was found from the simulation pattern of solvated $\mathbf{1}\cdot 3CH_3NO_2$ crystallized in $P2_1/n$ (Fig. 3a lower). A Rietvelt analysis, based on the parameter of partially dried single crystal structural data with $C2/c$, resulted to give a smaller unit cell volume of 3815 Å^3 for the former, which is consistent with the complete loss of solvent molecules [7].[3]

[1] Crystallographic data for the fresh prepared solvated **1**: Dark red bar, fomula $C_{27}H_{16}Cl_3\,Fe_2N_9O_{22}$, MW = 1036.54, 0.5 mm × 0.2 mm × 0.1 mm, monoclinic, space group $P2_1/n$, $a = 13.818(9)$ Å, $b = 18.549(1)$ Å, $c = 15.474(1)$ Å, $\beta = 90.268(4)°$, $V = 3966.1(5)$ Å^3, $T = 293(2)$ K, $Z = 4$, $D_{calc} = 1.736$ g/cm^3, 22978 reflections were observed, of which 6231 were independent, $R_1 = 0.0681$ ($I > 2\sigma(I)$) and $wR_2 = 0.1769$ (all data) for 508 parameters, GOF = 0.913.

[2] Crystallographic data for the partially dried **1**: Dark red bar, formula $C_{26.5}H_{16}Cl_3Fe_2N_{8.5}O_{21}$, MW = 1007.54, 0.5 mm × 0.2 mm × 0.1 mm, monoclinic, space group $C2/c$, $a = 13.795(1)$ Å, $b = 18.509(2)$ Å, $c = 15.316(2)$ Å, $\beta = 90.317(4)°$, $V = 3910.6(7)$ Å^3, $T = 293(2)$ K, $Z = 4$, $D_{calc} = 1.711$ g/cm^3, 11161 reflections were observed, of which 3054 were independent, $R_1 = 0.0681$ ($I > 2\sigma(I)$) and $wR_2 = 0.1839$ (all data) for 257 parameters, GOF = 1.099.

[3] Cell parameters from Rietvelt analysis: dried: $C2/c$, $a = 13.748(4)$ Å, $b = 18.528(3)$ Å, $c = 14.992(4)$ Å, $\beta = 92.27(2)°$, $V = 3815(2)$ Å^3. Solvated: $P2_1/n$, $a = 13.884(3)$ Å, $b = 18.651(4)$ Å, $c = 15.600(3)$ Å, $\beta = 90.36(1)°$, $V = 4039(2)$ Å^3.

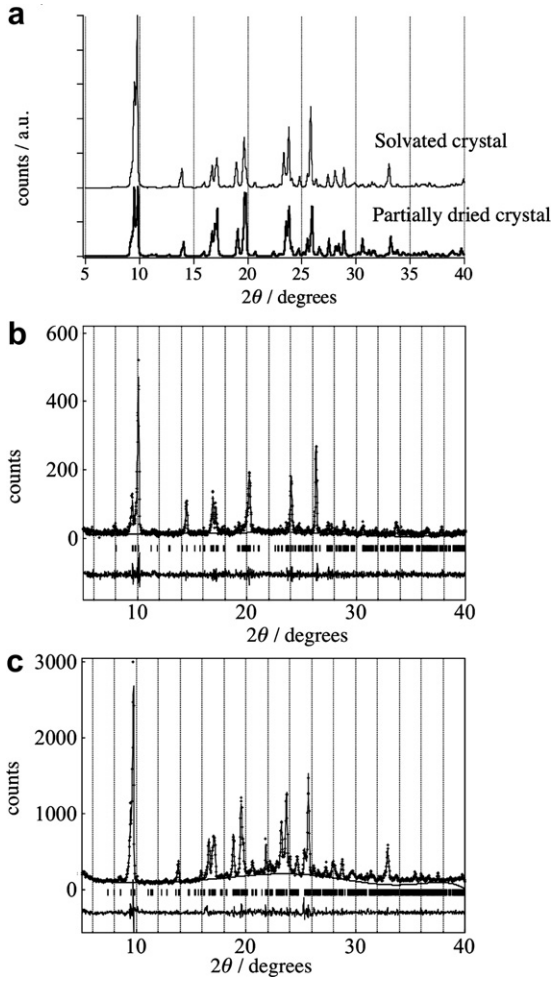

Fig. 3. X-ray powder diffraction patterns. (a) Simulated patterns based on the single crystal diffraction data of the freshly prepared sample (solvated sample; upper) and partially dried sample (lower). (b) Comparison between the observed and calculated patterns of dried sample. From top to bottom: dotted line, observed intensity; solid line, calculated intensity; vertical short lines, position of reflections; solid line, difference between observed and calculated intensity. (c) Comparison between the observed and calculated patterns of solvated **1**. From top to bottom: dotted line, observed intensity; solid line, calculated intensity; vertical short lines, position of reflections; solid line, difference between observed and calculated intensity.

Interestingly, dried sample reabsorbs CH_3NO_2 and reproduce the similar condition of the initial solvated sample. The 20 mg of completely dried sample was added about 0.1 ml of CH_3NO_2 and kept for 2 h, then XRD measurement is carried out (Fig. 3c). The XRD pattern is different from dried one, and very similar to the simulation XRD pattern obtained from structural data of the initial single crystal. The Rietvelt analysis shows the reversion of unit cell volume 4039 Å^3 which indicates that dried crystal reabsorb CH_3NO_2 molecules and return to the solvated condition.

The crystal of **1** can release or reabsorb $MeNO_2$ molecules reversibly like "sponges", possessing the chain structure of **1**.

Magnetic properties of the freshly prepared solvated sample ($\mathbf{1}\cdot 3CH_3NO_2$) and dried sample (**1**) are shown in Fig. 4. The solvated sample was dried under N_2 for 48 h to give the dried sample. DC magnetic susceptibilities for both samples at room temperature are equal to 4.40 cm^3 K mol^{-1} which is corresponding to the expected spin-only value of 4.275 cm^3 K mol^{-1} for a high-spin Fe(II) ($S = 2$) and a low-spin Fe(III) ($S = 1/2$). The χT value remains constant down to about 20 K for both solvated and dried samples. Under 20 K, the χT value of dried sample rapidly increased to a maximum value of 58.7 cm^3 K mol^{-1} around 3 K. On the other hand, the χT value of solvated sample starts increasing at lower temperature (13 K) and does not show a peak down to 1.8 K (Fig. 4a). Fig. 4b shows the frequency dependence of the out-of-phase AC magnetic susceptibility (χ'') of the solvated and dried samples. The temperature, at which χ'' has the maximum value, corresponds to blocking temperature (T_B) for each frequency. With the crystal condition changed from the solvated to the dried, the peak top for each frequency shifts toward higher temperature. The increase of T_B is 21% for the dried sample compared with the solvated sample. By analyzing T_B versus $\ln(2\pi f)$ using Arrhenius equation, $1/T_B = -(k_B/\Delta)\{\ln(2\pi f) + \ln\tau_0\}$, the values of Δ/k_B were estimated as 21.9(3) K for solvated condition, 26.0(9) K for dried condition, respectively. Similar to the change of T_B, Δ/k_B increases when the crystal state changes from the solvated condition to the dried condition. At some fixed temperatures, semicircle Cole–Cole diagrams were obtained with small α values both for the solvated and dried samples (0.24 and 0.14, respectively), as expected for a Debye model with a single relaxation time [8].

This changing of magnetic properties is reversible. Fig. 5 shows the reversible changing of Arrhenius plot of **1**. The Δ/k_B value obtained for each condition remains almost unchanged for three drying and CH_3NO_2 addition cycles. This result is consistent with the reversible changing of the crystal structure.

We can point out the possible structural distortion of Fe(II)–Fe(III) chain which is increasing when changing from the solvated to the dried. Since the easy-axis of this SCM arises from the strict orthogonal arrangement of each easy-plane of Fe(II) ion along chain, slight deviation of the easy-plane from the ideal position might strongly affects the magnetic property of the whole chain.[4] Moreover, neighboring Fe(II)–Fe(III) ions present a moderate antiferromagnetic interaction through a long Fe(II)–Fe(III) distance (longer than 5 Å), and during the condition changing,

[4] Partially dried single crystal of **1** shows slightly different magnetization behavior from that of the freshly prepared single crystal of **1**. The latter only shows a very weak magnetization when the external magnetic filed was applied perpendicular to the chain, whereas, the former shows a considerable magnetization even in a weak magnetic field perpendicular to the chain. This indicates that a slight structural distortion occurs on the alignment of the magnetic easy-plane along the chain axis during the process of the solvent removal.

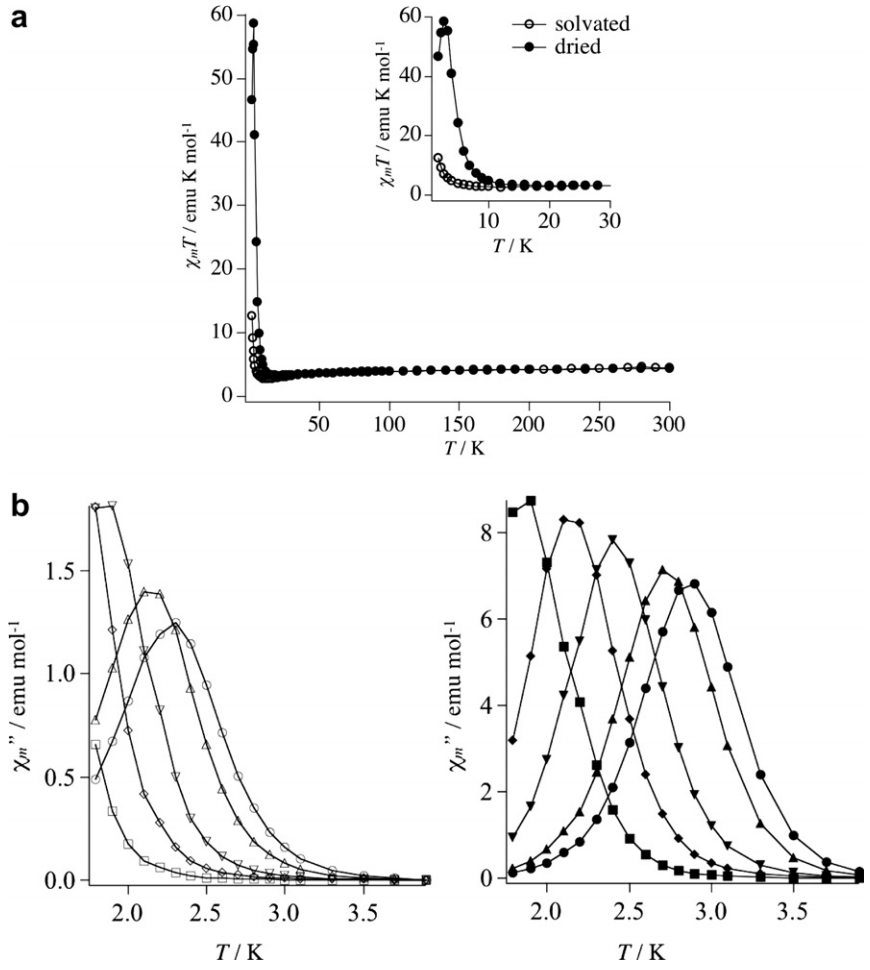

Fig. 4. (a) Plot of χT vs. T under 0.01 T for solvated and dried samples. Solid lines are guides. (b) Plot of χ'' vs. T under zero dc field for the solvated (left) and the dried (right) samples (○, ●: 1000 Hz, △, ▲: 500 Hz, ▽, ▼: 100 Hz, ◇, ◆: 25 Hz, and □, ■: 5 Hz, respectively). Solid lines are guides.

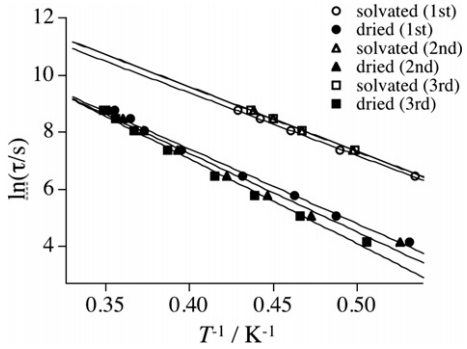

Fig. 5. The reversible changing of Arrhenius plot for the sample under dried/moistened cycles with CH_3NO_2. Open and closed makers represent the solvated and dry conditions, respectively.

it may be shortened with the decreasing of cell parameters to enhance the magnetic interaction. To reveal the small structural changes, more detailed XRD analyses for both samples should be needed. The high-field magnetization study for the dried sample will give the information both for intra-chain magnetic interaction J and magnetic anisotropy of Fe(II) ion D, and detailed studies for these phenomena are now ongoing.

In summary, the crystal of **1** can release and reabsorb CH_3NO_2 molecules reversibly like "sponges" maintaining the structure of the Fe(II)–Fe(III) chain, and simultaneously, its magnetic properties changes significantly. Compound **1** is the first nano-magnet, which shows the solvent induced reversible change of magnetic properties.

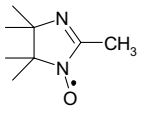
1. Introduction



Reactions of polynuclear pivalates of paramagnetic metal ions with nitroxides are capable of triggering self-assembly of highly dimensional magnetic heterospin structures [1]. High solubility of the polynuclear pivalate in low-polar organic solvents is an important factor that favors effective interaction of this compound with organic paramagnets. The symmetric structure of the nitronyl nitroxide molecule, in turn, favors bridging coordination of the latter (formation of polymer structures), although co-existence of bulky substituents "on the periphery" of the polynuclear molecule and in the structure of the organic paramagnet does not always favor spatial complementarity of reactant molecules [2].

$[Co_6(O)_2Piv_{10}Thf_3H_2O]$

NIT-Me

Im-Me

Recently, it was demonstrated that the $[Mn_6(O)_2Piv_{10}Thf_4]$ hexanuclear matrix (Piv is trimethylacetate and Thf is tetrahydrofuran) shows high efficiency in reactions with nitronyl nitroxides containing alkyl or heterocyclic substituents in the side chain, leading to heterospin compounds [1–3], including compounds capable of cooperative magnetic ordering. Therefore, it was interesting to investigate $[Co_6(O)_2Piv_{10}Thf_3H_2O]$, whose molecular structure is similar to that of the hexanuclear Mn pivalate. For the starting nitronyl nitroxide we chose 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazole-3-oxide-1-oxyl (NIT-Me), which does not create steric hindrances to highly dimensional structures formed in the reaction with the hexanuclear Mn pivalate [1–3]. All this gave us reason to hope that the reaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]$ with NIT-Me would also provide a convenient route to new heterospin systems with a $\{Co_6(O)_2Piv_{10}\}$ cluster nucleus and coordinated NIT-Me molecules. As in the case of $[Mn_6(O)_2Piv_{10}Thf_4]$, the interaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]$ with NIT-Me was expected to lead to substitution of the monodentate Thf molecules and probably to replacement of the water molecule by nitroxide. Our study, however, revealed that the reaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]$ with NIT-Me and/or 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazole-1-oxyl (Im-Me) occurs with simultaneous transformation of both the polymetallic nucleus and nitroxides. This conclusion was made from X-ray crystallographic analysis of the reaction products isolated as single crystals. This paper describes the procedures that gave single crystal products of the interaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]$ with NIT-Me and/or Im-Me and reports structural data for the complex products.

2. Experimental

2.1. Synthesis

All solvents were commercially available and used as received. 2,4,4,5,5-Pentamethyl-4,5-dihydro-1*H*-imidazole-3-oxide-1-oxyl (NIT-Me) and 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazole-1-oxyl (Im-Me) nitroxides were prepared according to the literature [4–6]. To synthesize $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ according to the known procedure [7] for the starting compound we used the $[Co(OH)_x(OOCCMe_3)_{2-x}]_n$ polymer obtained by the known procedure [8], as well as purified [9] Thf, which was then intentionally kept exposed to light and air for a month in order to generate organic peroxides for mild oxidation of Co^{II} into Co^{III} (Thf was not used in syntheses of heterospin complexes with nitroxides).

2.1.1. $[Co_9Piv_{12}(OH)_2L^1_2]\cdot n0.5C_7H_{16}$ $(n = 0.5, 1, 2)$

NIT-Me (0.06 g, 0.35 mmol) dissolved in a mixture of heptane (1 ml) and CH_2Cl_2 (1 ml) was added at room temperature to a solution of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ (0.15 g, 0.089 mmol) in a mixture of heptane (2 ml) and CH_2Cl_2 (1 ml). The resulting reaction mixture was passed through a paper filter, and heptane (5 ml) was then added through the filter. After 24 h, fine dark red crystals of the complex formed in the filtrate, and after another six or seven days the crystals were filtered off and washed with MeCN. The crystal surface generally contained a minor blue gel impurity, which was separated mechanically. The yield of $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 0.5C_7H_{16}$ was 0.006 g (2–3%). *Anal.* Calc. for $Co_{18}C_{159}H_{288}N_8O_{68}$: C, 43.8; H, 6.5; N, 2.5. Found: C, 42.7; H, 6.9; N, 2.5%. Single crystals of the same complex more highly saturated with heptane solvate molecules ($[Co_9Piv_{12}(OH)_2L^1_2]\cdot C_7H_{16}$ and $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 2C_7H_{16}$) are formed when synthesis is carried out in heptane (without a CH_2Cl_2 addition). Since the starting polynuclear Co compound has better solubility in a heptane/CH_2Cl_2 mixture than in pure heptane, more heptane is needed for the same initial amounts of reagents. A typical procedure for the preparation of $[Co_9Piv_{12}(OH)_2L^1_2]\cdot C_7H_{16}$ and $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 2C_7H_{16}$ is given below. To a solution of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ (0.15 g, 0.089 mmol) in heptane (5 ml) was added NIT-Me (0.06 g, 0.35 mmol) in heptane (10 ml). The resulting dark claret red solution was filtered through a paper filter, and another portion of heptane (5 ml) was then added to the reaction mixture through this filter. The reaction mixture was kept for three or four days in an open flask. The solvent gradually evaporated, and a thin layer of blue gel settled at the bottom of the flask. Fine dark red crystals of $[Co_9Piv_{12}(OH)_2L^1_2]\cdot C_7H_{16}$ and $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 2C_7H_{16}$ suitable for an X-ray analysis formed under the gel layer; they were filtered off together with gel and then separated from gel mechanically. The total mass of the crystals was up to 5–6 mg. A similar process of crystal growth from gel is described elsewhere [10].

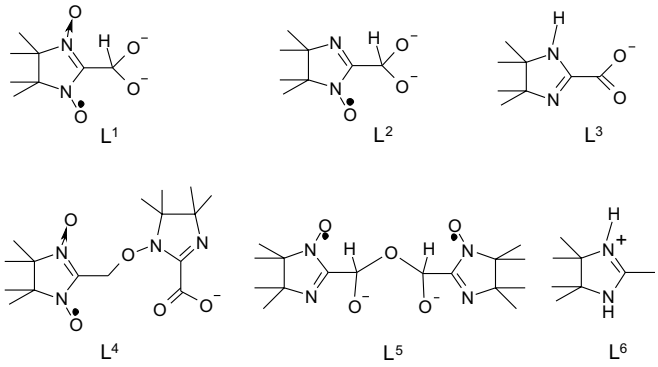
2.1.2. $[Co_8Piv_8(OH)_6(HPiv)_4(H_2O)_2L^4_2]$

A solution of iminonitroxide Im-Me (0.018 g, 0.12 mmol) in heptane (3 ml) and a solution of nitronylnitroxide NIT-Me (0.02 g, 0.12 mmol) in heptane (3–4 ml) were added to the solution of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ (0.1 g, 0.059 mmol) in heptane (3 ml). The resulting claret red mixture was filtered, and the filtrate was diluted with heptane (5–6 ml) and kept in an open flask at room temperature. Dark red crystals formed in three or four days; after another three or four days they were filtered off, washed with cooled heptane, and separated mechanically from the minor gel impurity. The mass of the crystals formed was up to 0.007 g. *Anal.* Calc. for $Co_8C_{92}H_{174}N_8O_{42}$: H, 6.9; N, 4.4. Found: H, 6.8; N, 4.3%.

2.1.3. $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$, $[Co_6Piv_8(HPiv)_2L^5_2]\cdot nC_6H_6$ $(n = 0, 1)$, $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_7H_{16}$, and $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$

Im-Me (0.038 g, 0.238 mmol) in hexane (or heptane) (2–3 ml) was added to the solution of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ (0.1 g, 0.059 mmol) in hexane (or heptane) (2 ml) and CH_2Cl_2 (1 ml). The resulting brown solution was filtered and another (8 ml) portion of hexane was added through the same filter. After two or three days, dark green crystals formed in the solution; they were separated by decanting and recrystallized from CH_3CN. $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$ crystals suitable for an X-ray analysis formed. Yield 0.018 g (10%). *Anal.* Calc. for $Co_6C_{63}H_{122}N_2O_{28}$: C, 44.3; H, 7.2; N, 1.6. Found: C, 44.4; H, 7.2; N, 1.7%. Storage of the mother solution obtained by decanting for another two days led to red crystals of $[Co_6Piv_8(HPiv)_2L^5_2]$. *Anal.* Calc. for $Co_6C_{82}H_{144}N_8O_{30}$: C, 47.5; H, 7.0; N, 5.4. Found: C, 48.0; H, 7.6; N, 5.1%. In some experiments, brown crystals of $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_7H_{16}$ were isolated in small amounts along with the crystals of the given complex. *Anal.* Calc. for $Co_{16}C_{201}H_{358}N_{16}O_{72}$: C, 47.4; H, 7.1; N, 4.4. Found: C, 47.1; H, 7.2; N, 4.2%. Also, thin pale green platelets with a composition $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$ (XRD data) were occasionally found among the crystalline products. The total mass of the crystals isolated in different experiments was up to 5 mg. For an X-ray investigation, the single crystals of the compounds were selected mechanically. When benzene was used as a solvent, only $[Co_6Piv_8(HPiv)_2L^5_2]\cdot C_6H_6$ solvate crystals formed in very small amounts; their structure and composition were determined by X-ray diffraction analysis. Further analysis for $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$ and $[Co_6Piv_8(HPiv)_2L^5_2]\cdot C_6H_6$ was not possible because of the low yields of these compounds.

2.2. X-ray crystallography and magnetic measurements



For all compounds, data were collected on a Smart Apex diffractometer (λMo Kα, graphite monochromator). The structures were solved by direct methods and refined by full-matrix least-squares (SHELX97 program complex). Some of the hydrogen atoms were localized in a difference electron density map; the remaining hydrogen atoms were placed geometrically and refined as a rigid group. Crystal data for the complexes and selected bond lengths and angles in the structures are listed in Tables 1 and 2.

Magnetic measurements for the polycrystalline samples were carried out on an MPMS-5 s Quantum Design SQUID magnetometer in the temperature range from 2 to 300 K and in magnetic fields of up to 4.5 O. The paramagnetic components of magnetic susceptibility χ were determined with allowance for the diamagnetic contribution estimated from Pascal's constants. The effective magnetic moment was calculated by the formula $\mu_{\text{eff}} = (\frac{3k}{N_A\beta^2}\cdot\chi T)^{1/2} \approx (8\chi T)^{1/2}$, where N_A is the Avogadro number, β is the Bohr magneton, and k is Boltzmann's constant.

3. Results and discussion

3.1. Synthesis of compounds

Investigation of the products of interaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ with NIT-Me and/or Im-Me showed that the ensuing redox processes transform both the $\{Co_6(O)_2Piv_{10}\}$ polymetallic matrix and the starting nitroxide. In nitroxide molecules, the methyl substituent in the 2nd position of the 2-imidazoline ring is oxidized, leading to complexes with ligands L^1-L^5 shown below.

Special attention should be paid to the spin-labeled anions L^1, L^2, L^4, and L^5 fixed in the polynuclear matrix. Simple salts and organic derivatives of these anions are unknown, and it is now difficult to suggest pure organic approaches to their synthesis. The starting nitroxide molecule is transformed on the coordinating polymetallic matrix; for L^4 and L^5, this transformation is a variety of template synthesis. In this case, the polymetallic matrix serves for fixation and kinetic stabilization of the resulting organic substrate molecules.

Oxidation of NIT-Me and/or Im-Me is accompanied by reduction of Co^{III} to Co^{II} and transformation of the polymetallic matrix. It seems that Co^{III} plays an important role

in these processes. It is not ruled out that the presence of Co^{III} is just responsible for the oxidation of the organic substrate. This is supported by the fact that oxidation of an organic substrate was not previously recorded in reactions of NIT-R (including NIT-Me) with $[Mn^{III}_2Mn^{II}_4(O)_2Piv_{10}Thf_4]$. The $[Mn^{III}_2Mn^{II}_4(O)_2Piv_{10}Thf_4]$ polymetallic nucleus always remained unchanged [1–3].

The reactions leading to L^1–L^6 are essentially multistep transformations accompanied not only by the rearrangement of the starting hexanuclear framework, but also, in many cases, by a change in the nuclearity of the polymetallic fragment. Therefore at the initial stage, it was difficult to suggest a reasonable scheme for the transformation of nitroxide molecules, especially because these processes can form by-products. Moreover, investigation was complicated by the fact that the starting components and reaction products have high solubility in organic solvents [10] so that single crystals had to be grown from small volumes of rather concentrated solutions. Fast removal of the minor residue of the solvent from the reaction system had to be avoided because it ended in the formation of a lacquer film. Growth of single crystals of the complexes was also hindered by the fact that concentration of the reaction mixture led to the formation of an amorphous gel. Moreover, some compounds ($[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$ and $[Co_6Piv_8(HPiv)_2L^5_2]\cdot C_6H_6$) could only be obtained as unit crystals. Further analysis, therefore, was not possible because of the small yields of these compounds; according to Christou [11], this is a frequent occurrence in studies on compounds of this type. Nevertheless, structural analysis of all isolated single crystals convinced us that interaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ with NIT-Me and/or Im-Me leads to simultaneous transformation of both the polymetallic nucleus and the nitroxides.

All synthetic procedures given in Section 2 are well reproducible, despite the low yields of the products. The compounds were obtained as single crystals mostly suitable for an X-ray crystal structure analysis. The quality of the crystals was higher if they were separated as early as possible after they appeared in solution. Naturally, the product yield was extremely low in this situation. Numerous attempts were made to raise the yield. As mentioned above, these complexes, which are well soluble in organic solvents, had to be grown from very small volumes of solutions. Attempts to raise the yield led to the formation of large amounts of increasingly small crystals of the complex, from which we had to separate larger crystals for X-ray analysis. Moreover, when the volume of the solution became very small, dark blue gel formed at the bottom of the flask. The gel not only covered the single crystals and retarded their growth, but also provoked complex formation in the form of numerous fine crystals. The composition of the gel was not determined because it quickly dried into finely disperse powder after the mother solution was separated. No compounds other than the complexes described in the present work and amorphous gel have been recorded.

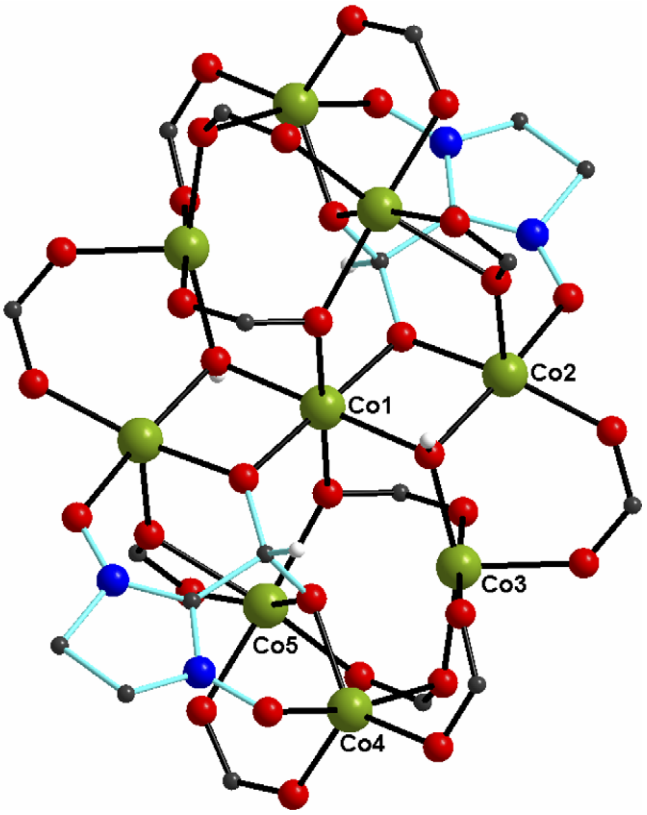

Fig. 1. Nonanuclear molecule $Co_9Piv_{12}(OH)_2L^1_2$. The $(CH_3)_3C$ groups of pivalates and the CH_3 groups of the 2-imidazoline cycles are omitted for clarity. (Co: green ball; O: red ball; N: navy ball; C: small black ball; H: small white ball. Blue bonds highlight the atom connectivity in L^1).

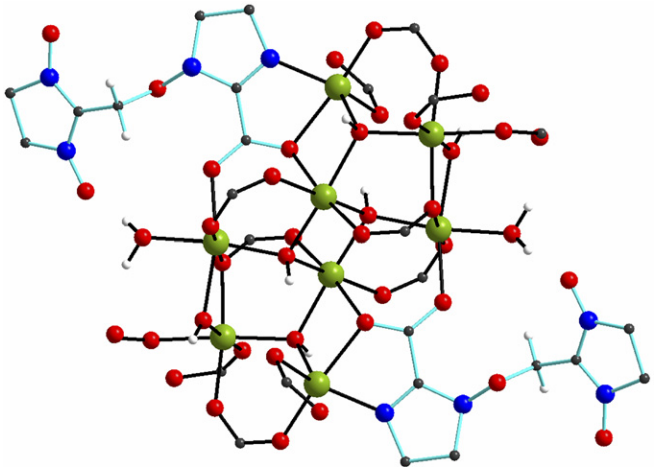
3.2. Structural data

Interaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ with thoroughly purified NIT-Me always led to the formation of $[Co_9Piv_{12}(OH)_2L^1_2]\cdot nC_7H_{16}$ crystals, where $n = 0.5$, 1, or 2. The number of solvate molecules in $[Co_9Piv_{12}(OH)_2L^1_2]\cdot nC_7H_{16}$ depends on synthetic conditions, although the $[Co_9Piv_{12}(OH)_2L^1_2]$ hexanuclear molecules proper (Fig. 1) are identical in all solvates. The $Co_9Piv_{12}(OH)_2L^1_2$ molecule is centrosymmetric relative to the Co1 atom. The polyhedron is a distorted octahedron for Co1 and Co5, square pyramid for Co2, and elongated distorted trigonal bipyramid for Co3 and Co4. The O atom of the OH group links three Co atoms (Co1, Co2, and Co3; d_{Co-O} 2.040(5), 1.991(5), and 2.048(5) Å). The sum of the CoOCo angles in this unit is ~315°, indicating that the bridging O atom of the OH group lies inside the Co1Co2Co3H pyramid.

In the NO groups of L^1, the distances are virtually identical: 1.289(4) and 1.292(4) Å. In the $C2—C\begin{smallmatrix}H\\<\\O\end{smallmatrix}$ fragment, where C2 is the C atom in the 2nd position of the imidazoline ring, the C–O bond lengths are 1.361(4) and 1.406(5) Å. The C2–C–O angles are 111.1(3) and 111.3(3)°. These parameters confirm that the structure has a methanediolate substituent in the 2nd position of the imidazoline ring. As



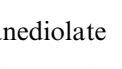


Fig. 2. Octanuclear molecule $[Co_8Piv_8(OH)_6(HPiv)_4(H_2O)_2L^4_2]$. The $(CH_3)_3C$ groups of pivalates and the CH_3 groups of the 2-imidazoline cycles are omitted for clarity. (Co: green ball; O: red ball; N: navy ball; C: small black ball; H: white ball. Blue bonds highlight the atom connectivity in L^4).

shown in Fig. 1, all four O atoms of the bridging L^1 ligand are coordinated to the Co1, Co2, Co4, and Co5 atoms. In this case, L^1 is a hexadentate ligand because one of the O atoms of the deprotonated methanediolate fragment is a bridge between Co1 and Co2 (d_{Co-O} 1.994(2) and 2.001(3) Å), and another O atom links Co4 and Co5 (d_{Co-O} = 1.999(2) and 2.043(3) Å). The NO groups are coordinated by the Co4 and Co2 atoms (d_{Co-O} = 2.085(3) and 2.117(3), respectively), forming two six-membered metallocycles involving the Co2 and Co4 atoms.

The reaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ with a specially prepared mixture of NIT-Me and Im-Me led to crystals of the octanuclear $[Co_8Piv_8(OH)_6(HPiv)_4(H_2O)_2L^4_2]$ complex containing a spin-labeled anion L^4 (the product of complex transformation of NIT-Me and Im-Me on the polynuclear matrix). The $[Co_8Piv_8(OH)_6(HPiv)_4(H_2O)_2L^4_2]$ molecule is centrosymmetric (Fig. 2). All Co atoms bonded to only O atoms have a distorted octahedral environment. Two Co atoms bonded to the imine N atom of the imidazoline ring are surrounded by a distorted trigonal bipyramid. The Co–O and Co–N distances are in the range 2.003(7)–2.231(11) Å.

All atoms of the conjugated O˙–N–C=N → O nitronyl nitroxide fragment of the coordinated L^4 ligand lie in one plane, which is typical for nitronyl nitroxides. The distances in the NO groups are 1.266(11) and 1.312(12) Å. In the alkoxy imine fragment between the nitronyl nitroxide fragment and the coordinated 2-carboxy derivative of 2-imidazoline, the N–O bond length is much larger, 1.423(8) Å. In contrast to the atoms of the above-discussed methanediolate fragment L^1, in the  fragment (CO_2 is a carboxylate fragment and C2 is the C atom in the 2nd position of the coordinated imidazoline ring) all atoms lie in one plane. In the carboxylate fragment of L^4 (1.251(11) and 1.262(10) Å), the C–O distances are much shorter than the C–O distances in the methanediolate fragment L^1 (1.361(4) and 1.406(5) Å). The coordinated L^4 molecules generally perform the bridging tridentate function. One of the O atoms, together with the imine N atom of the 2-imidazoline heterocycle, forms a five-membered chelate ring. In the $[Co_8Piv_8(OH)_6(HPiv)_4(H_2O)_2L^4_2]$ molecule, the central $\{Co_4O_2\}$ fragment (Fig. 3a) is identical in structure to the same fragment analyzed in detail by Winpenny [10], who constructed integral topology of polynuclear frameworks for the cobalt-pivalate system.

Investigation of the single crystals resulting from the reaction of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ with Im-Me revealed the following. The reaction primarily formed dark green crystals of $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$. In this compound, the $[Co_6(O)_4Piv_9(H_2O)_2]^-$ anion has exactly the same structure as in the previously described compound $[(C_4H_9)_4N][Co_6(O)_4Piv_9(H_2O)_2]$ [10], also dark green in color. This anion has a $[Co^{III}_4O_4]$ heterocubane fragment bonded to two terminal Co^{II} ions [10] in the $\{Co_6O_4\}$ hexanuclear unit (Fig. 3b). The role of the cation is performed by L^6, which is protonated 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazole (Fig. 3c).

The L^6 cation is not likely to be the product of Im-Me transformation; rather, this is a minor admixture of 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazole, which was present from the start. This is indicated by well-known data of classical studies [5,6], stating that Im-Me is very difficult to be isolated as an individual compound. Moreover, because of its ion associate nature and hence low solubility in organic solvents, $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$ is always the first compound to be isolated as a solid after consolidation of the solutions of $[Co_6(O)_2Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ and Im-Me. After $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$ crystals have been separated, new crystals of this

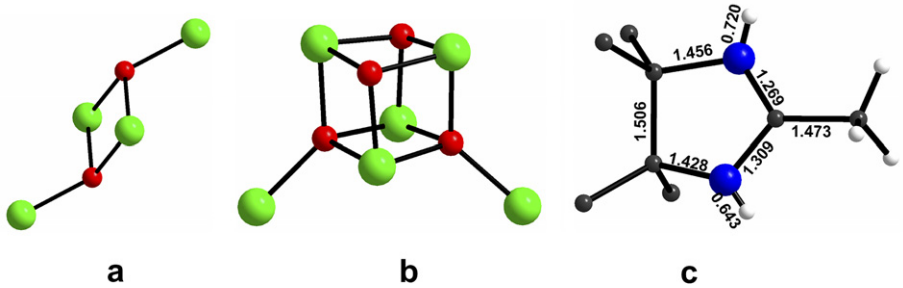

Fig. 3. Fragments of $[Co_8Piv_8(OH)_6(HPiv)_4(H_2O)_2L^4_2]$ and $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$: $\{Co_4O_2\}$ (a); $\{Co_6O_4\}$ (b), and L^6 cation (c).

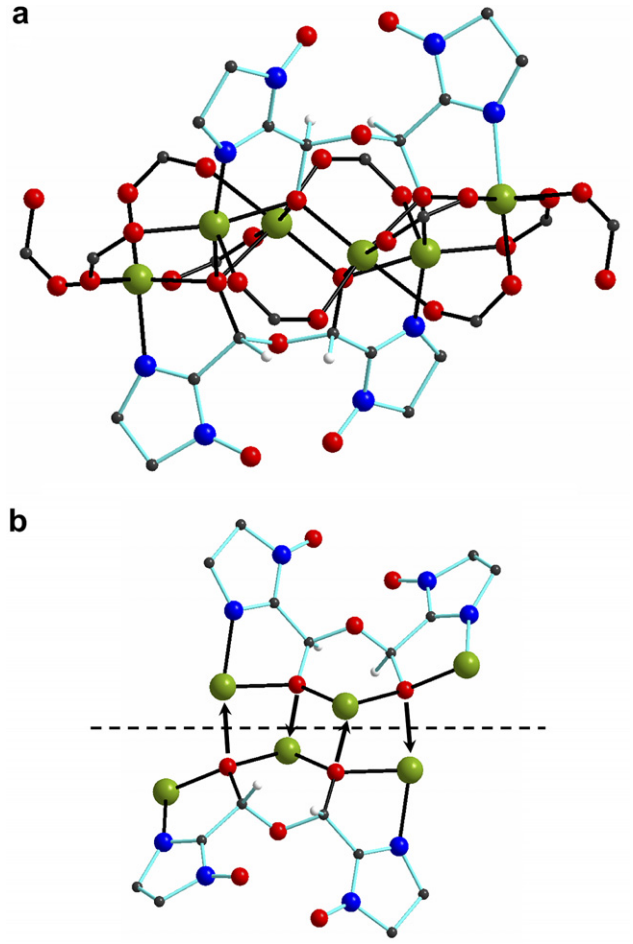

Fig. 4. Hexanuclear molecule $[Co_6Piv_8(HPiv)_2L^5_2]$ (a). Fragment of the molecule containing L^5s and Co atoms (b). The $(CH_3)_3C$ groups of pivalates and the CH_3 groups of the 2-imidazoline cycles are omitted for clarity. (Co: green ball; O: red ball; N: navy ball; C: small black ball; H: white ball. Blue bonds highlight the atom connectivity in L^5).

compound are no longer formed in the mother solution even when stored for arbitrarily prolonged periods of time.

After $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$ crystals have been separated, further storage of the mother solution leads to crystallization of $[Co_6Piv_8(HPiv)_2L^5_2]$ (sometimes with a minor admixture of $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_7H_{16}$ crystals and, more rarely, with a still smaller admixture of $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$ crystals). Structure analysis indicated that these are structurally related compounds that form a single group of reaction products.

Fig. 4a shows the structure of the centrosymmetric hexanuclear molecule of $[Co_6Piv_8(HPiv)_2L^5_2]$. The structure is quite simple – it does not contain any bridging OH groups, and all cobalt atoms are bonded to the L^5 paramagnetic ligand, which is the major distinction of the compound. L^5 is formally the product of condensation of two imino nitroxides with a methanediolate substituent in the 2nd position of the imidazoline ring. It is certainly formed on the polynuclear matrix because pure organic approaches to synthesis of such compounds are unknown. In Fig. 4b, all Piv and HPiv are discarded, and the remaining fragment is conventionally halved by a dashed line; it can be seen that each L^5 forms three metallocycles with three Co atoms of the isolated half. Furthermore, each of the oxygen donor bridging atoms is coordinated to the Co atom from the other half of the polynuclear fragment (these bonds are indicated by alternant arrows). As a result, L^5 serves as a bridging octadentate ligand because each of the bridging O atoms is coordinated to three different Co atoms. Also note that the geometrical characteristics of the complex molecule in the structure of the $[Co_6Piv_8(HPiv)_2L^5_2]\cdot C_6H_6$ solvate obtained from benzene are nearly identical to those in $[Co_6Piv_8(HPiv)_2L^5_2]$.

Let us consider the structure of the $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ polynuclear molecule (Fig. 5a) in the isolated $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$ solvate. Like $[Co_6Piv_8(HPiv)_2L^5_2]$, this molecule does not contain any bridging OH groups, and all cobalt atoms are bonded to L^2 and/or L^3, which together with Piv serve as bridges in the Co_{10} metal core. If the monodentate HPiv and bridging Piv ligands are removed (Fig. 5b), one can see that each bridging L^3 ligand is bonded to three Co atoms. With one of them L^3 forms a chelate ring. Each L^2 ligand is bonded to five Co atoms enclosed in a dashed ellipse in Fig. 5b. With two of these Co atoms L^2 forms chelate cycles.

All atoms of L^3 depicted in Fig. 5b lie in the same plane. The C–O bond lengths are 1.18(2) and 1.29(2) Å. This shows that L^3 is the 2-carboxy derivative of 4,5-dihydro-1*H*-imidazole. In the L^2 methanediolate fragment, the C–O bond lengths are much larger (1.35(1) and 1.39(1) Å), and the O atoms of the C2—C(H)(O)O fragment, where C2 is a C atom in the 2nd position of the imidazoline ring, are not coplanar with the C2 and C atoms of this fragment.

From synthetic viewpoint, it is important that the L^2 ligands fixed in the structure of $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ are precursors of L^5 found in the structure of $[Co_6Piv_8(HPiv)_2L^5_2]$. L^5 is formally the product of condensation of two L^2. It is not surprising, therefore, that we succeeded in isolating only unit crystals of $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$. It is not ruled out that the decanuclear $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ is constantly transformed into the hexanuclear $[Co_6Piv_8(HPiv)_2L^5_2]$, which is much easier to crystallize. Apart from being itself isolated as a solid, the $[Co_6Piv_8(HPiv)_2L^5_2]$ product brings out of solution some part of $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ (see Section 2) in the form of a pair cluster of mixed nuclearity $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_7H_{16}$. The structure of the latter does not require special discussion because the structure of separate components of the $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ pair cluster coincides with the structure of $[Co_6Piv_8(HPiv)_2L^5_2]$ and $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ examined in a separate study. Therefore, Fig. 6 shows only a fragment of the packing

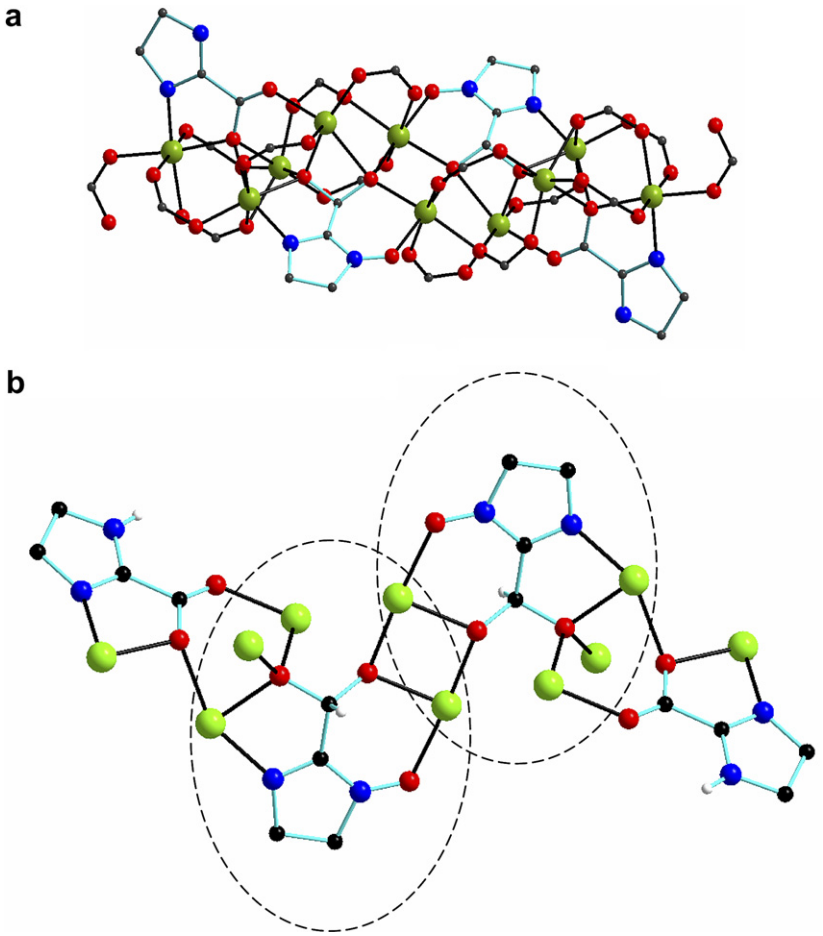

Fig. 5. Decanuclear molecule $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ (a). Fragment of the molecule containing L^2s, L^3s, and Co atoms (b). The $(CH_3)_3C$ groups of pivalates and the CH_3 groups of the 2-imidazoline cycles are omitted for clarity. (Co: green ball; O: red ball; N: navy ball; C: small black ball; H: white ball. Blue bonds highlight the atom connectivity in L^2 and L^3).

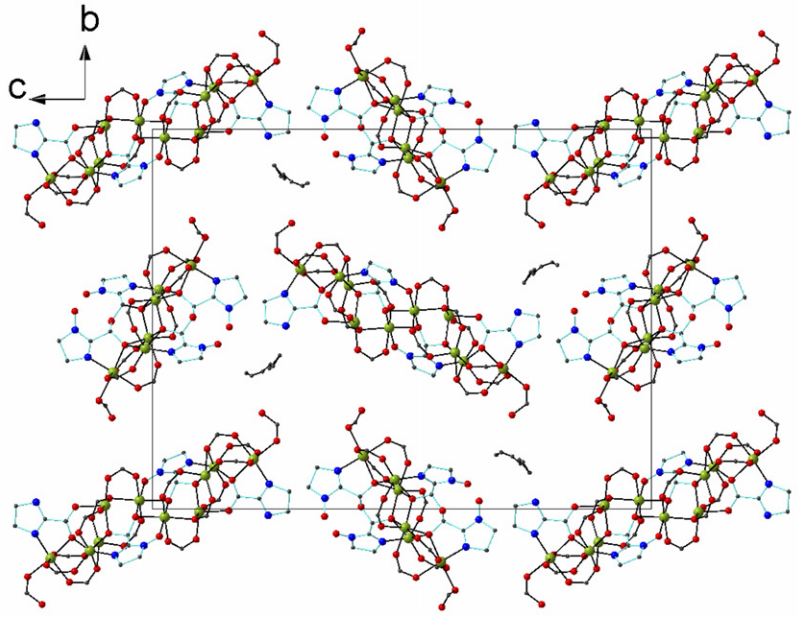

Fig. 6. Packing of clusters in $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2] \cdot C_7H_{16}$.

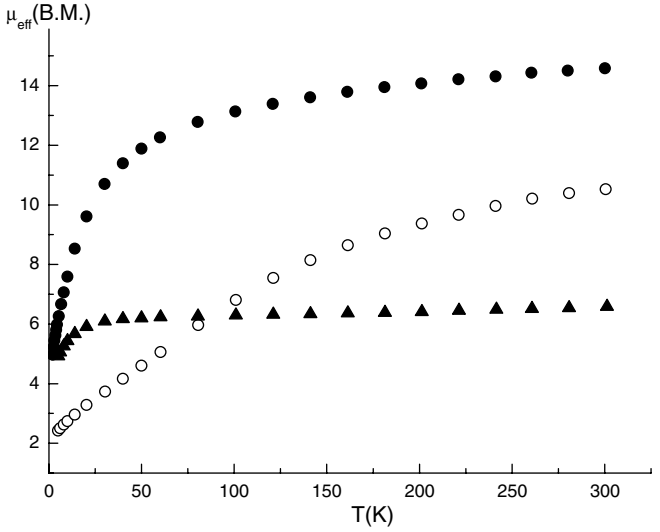

Fig. 7. Temperature dependences of μ_{eff} for $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 0.5C_7H_{16}$ (●), $[Co_6Piv_8(HPiv)_2L^5_2]$ (○), and $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$ (▲).

of the $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]$ pair cluster.

Magnetic measurements did not reveal any specific effects for the compounds under study. No dependence of magnetic susceptibility on the magnetic field has been found over the whole range of measurements (2–300 K). Fig. 7 shows the experimental dependences $\mu_{eff}(T)$ for $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 0.5C_7H_{16}$, $[Co_6Piv_8(HPiv)_2L^5_2]$, and $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2$ HPiv. All of them belong to the same type of dependence. At reduced temperatures, μ_{eff} decreases, suggesting that antiferromagnetic exchange interactions dominate inside the polynuclear clusters. At 300 K, μ_{eff} is 14.6, 10.5, and 6.6 B.M. for $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 0.5C_7H_{16}$, $[Co_6Piv_8(HPiv)_2L^5_2]$, and $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$, respectively. For the first two complexes, these values correspond to the effective magnetic moments for the sum of contributions from nine and six Co(II) atoms, respectively. In view of the difficulty of theoretical analysis of magnetic properties for Co^{II} compounds, one can only state that the high-temperature asymptotics of μ_{eff} lie in the range of expected values for all compounds under study. For $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2$ HPiv, μ_{eff} is much smaller than for other complexes because of all compounds we studied this is the only compound containing Co^{III} ions. As is known [10], the diamagnetic Co^{III} ions form a cubane fragment $[Co^{III}_4O_4]$ (Fig. 3b). Therefore, the contribution to magnetic susceptibility of $L^6[Co_6(O)_4Piv_9(H_2O)_2]\cdot 2HPiv$ is made by only two of the remaining terminal Co^{II} ions.

Thus our study gave a new group of heterospin complexes based on polynuclear cobalt pivalates with nitroxides $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 0.5C_7H_{16}$, $[Co_9Piv_{12}(OH)_2L^1_2]\cdot C_7H_{16}$, $[Co_9Piv_{12}(OH)_2L^1_2]\cdot 2C_7H_{16}$, $[Co_8Piv_8(OH)_6(HPiv)_4(H_2O)_2L^4_2]$, $[Co_6Piv_8(HPiv)_2L^5_2]$, $[Co_6Piv_8(HPiv)_2L^5_2]\cdot C_6H_6$, $[Co_6Piv_8(HPiv)_2L^5_2][Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_7H_{16}$, $[Co_{10}Piv_{14}(HPiv)_2L^2_2L^3_2]\cdot C_6H_{14}$, where L^1– L^5 are modified molecules of the starting 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazole-(3-oxide)-1-oxyl. It has been found that the reaction of $[Co_6(O)_2\text{-}Piv_{10}Thf_3H_2O]\cdot 1.5Thf$ with NIT-Me and/or Im-Me occurs with simultaneous transformation of both the starting polynuclear fragment and the starting nitroxide (nitroxides). The possibility of this transformation should be taken into account in design of heterospin systems based on polynuclear metal-containing matrices and nitroxides.

total spin value of 3d-metal clusters [7–9]. We herein report examples of this approach.

2. Experimental

2.1. General and physical measurements

All manipulations were performed under aerobic conditions using materials (reagent grade) and solvents as received. Microanalyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Laboratory using an EA 1108 Carlo Erba analyser. IR spectra (4000–500 cm^{-1}) were recorded on Perkin–Elmer 16 PC and Nicolet 520 FTIR spectrometers with samples prepared as KBr pellets. Magnetic susceptibility measurements under magnetic fields of approximately 0.1 T in the range 2–300 K and magnetisation measurements (only for complexes **2** and **4**) in the field range of 1–5 T were performed with a Quantum Design MPMS-XL SQUID magnetometer at the Magnetochemistry Service of the University of Barcelona. All measurements were performed on polycrystalline samples. Pascal's constants were used to estimate the diamagnetic corrections which were subtracted from the experimental susceptibilities to give the corrected molar magnetic susceptibilities.

2.2. Compound preparation

2.2.1. $[Co_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]\cdot 14.6H_2O$ ($\mathbf{1}\cdot 14.6H_2O$)

MeCN (45 mL) was added to a mixture of $Co(O_2CMe)_2\cdot 4H_2O$ (0.27 g, 1.08 mmol) and $(py)_2CO$ (0.10 g, 0.54 mmol). The solids dissolved on stirring under reflux for 2 h to give a pale purple solution, which was allowed to stand undisturbed at room temperature overnight. Well-formed, X-ray quality crystals of $\mathbf{1}\cdot 14.6H_2O$ appeared slowly. The purple crystals were collected by filtration, washed with a little cold EtOH, and dried in air. Yield: 30%. *Anal.* Calc. for $C_{60}H_{87.2}Co_9N_8O_{40.6}$: C, 34.31; H, 4.18; N, 5.33; Co, 25.25. Found: C, 34.42; H, 4.13; N, 5.51; Co, 25.74%. IR (KBr, cm^{-1}): 3589s, 3434s, 2927w, 1675s, 1584s, 1476m, 1431s, 1352w, 1293w, 1232m, 1155w, 1123m, 1097m, 1031s, 976m, 890w, 805m, 784m, 754m, 690m, 675m, 646m, 621m, 542w, 485w, 445w, 416w.

2.2.2. $[Co_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]\cdot 4DMF\cdot 2.5H_2O$ ($\mathbf{2}\cdot 4DMF\cdot 2.5H_2O$)

DMF (25 mL) was added to a mixture of $Co(O_2CMe)_2\cdot 4H_2O$ (0.17 g, 0.60 mmol), $(py)_2CO$ (0.06 g, 0.32 mmol) and NaN_3 (0.02 g, 0.30 mmol). The solids dissolved on stirring under heating to give a dark blue solution, which was allowed to stand undisturbed at room temperature for 3 days. Well-formed, X-ray quality pink-red crystals of $\mathbf{2}\cdot 4DMF\cdot 2.5H_2O$ appeared, which were isolated by filtration, washed with DMF and Et_2O, and dried in air. Yield: 60%. *Anal.* Calc. for $C_{72}H_{89}Co_9N_{18}O_{30.5}$: C, 38.87; H, 4.03; N, 11.33. Found: C, 38.24; H, 4.05; N, 11.65%. IR (KBr, cm^{-1}): 3446m, 3070w, 3025w, 2928w, 2802w, 2504w, 2073s, 1669s, 1583s, 1475m, 1430s, 1346w, 1294w, 1254w, 1229m, 1155w, 1119m, 1092m, 1057s, 1041s, 1020m, 973m, 962m, 890w, 806m, 780m, 757m, 686m, 664m, 617w, 529w, 475w, 442w, 421w.

2.2.3. $[Ni_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]\cdot 19H_2O$ ($\mathbf{3}\cdot 19H_2O$)

DMF (25 mL) was added to a mixture of $Ni(O_2CMe)_2\cdot 4H_2O$ (0.15 g, 0.60 mmol) and $(py)_2CO$ (0.06 g, 0.32 mmol). The solids dissolved on stirring under heating to give a green solution, which was allowed to stand undisturbed at room temperature for 4 days. Well-formed, X-ray quality green crystals of $\mathbf{3}\cdot 19H_2O$ appeared, which were isolated by filtration, washed with DMF and Et_2O, and dried in air. Yield: 60%. *Anal.* Calc. for $C_{60}H_{96}Ni_9N_8O_{45}$: C, 33.09; H, 4.44; N, 5.15. Found: C, 33.41; H, 4.48; N, 5.03%. IR (KBr, cm^{-1}): 3591s, 3441s, 2930w, 1678s, 1588s, 1477m, 1431s, 1353w, 1293w, 1232m, 1157w, 1125m, 1098m, 1030s, 975m, 891w, 807m, 782m, 756m, 691m, 676m, 648m, 620m, 540w, 484w, 445w, 416w.

2.2.4. $[Ni_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]\cdot 4DMF\cdot 4.5H_2O$ ($\mathbf{4}\cdot 4DMF\cdot 4.5H_2O$)

Method A. DMF (25 mL) was added to a mixture of $Ni(O_2CMe)_2\cdot 4H_2O$ (0.15 g, 0.6 mmol), $(py)_2CO$ (0.06 g, 0.32 mmol) and NaN_3 (0.02 g, 0.30 mmol). The solids dissolved on stirring under heating to give a green solution, which was allowed to stand undisturbed at room temperature for 7 days. Well-formed, X-ray quality green crystals of $\mathbf{4}\cdot 4DMF\cdot 4.5H_2O$ appeared, which were isolated by filtration, washed with DMF and Et_2O, and dried in air. Yield: 60%. *Anal.* Calc. for $C_{72}H_{93}Ni_9N_{18}O_{32.5}$: C, 38.28; H, 4.15; N, 11.16. Found: C, 38.50; H, 4.19; N, 11.25%. IR (KBr, cm^{-1}): 3436s, 3070w, 2929w, 2085s, 1652s, 1587s, 1477m, 1431s, 1348w, 1293w, 1232m, 1156w, 1123m, 1099m, 1039s, 976m, 891w, 807m, 782m, 757m, 691m, 675m, 648m, 620w, 537w, 486w, 445w, 420w.

Method B. DMF (15 mL) and MeOH (10 mL) were added to a mixture of $\mathbf{3}\cdot 19H_2O$ (0.15 g, 0.6 mmol) and NaN_3 (0.08 g, 1.20 mmol). The solids dissolved on stirring under heating to give a green solution, which was allowed to stand undisturbed at room temperature for 5 days. Well-formed, X-ray quality green crystals of $\mathbf{4}\cdot 4DMF\cdot 4.5H_2O$ appeared, which were isolated by filtration, washed with DMF and Et_2O, and dried in air. Yield: 80%. IR data and elemental analyses (C, H, N) were similar to the data obtained for the product prepared by Method A.

2.3. Single-crystal X-ray crystallography

Crystals of $\mathbf{2}\cdot 4DMF\cdot 2.5H_2O$, $\mathbf{3}\cdot 19H_2O$ and $\mathbf{4}\cdot 4DMF\cdot 4.5H_2O$ were mounted in air, while crystals of $\mathbf{1}\cdot 14.6H_2O$ were mounted in capillary. Diffraction measurements for $\mathbf{1}\cdot 14.6H_2O$ were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo

Table 1
Brief crystallographic data for complexes $\mathbf{1}\cdot 14.6H_2O$, $\mathbf{2}\cdot 4DMF\cdot 2.5H_2O$, $\mathbf{3}\cdot 19H_2O$ and $\mathbf{4}\cdot 4DMF\cdot 4.5H_2O$

radiation. Analyses on $\mathbf{2}\cdot 4DMF\cdot 2.5H_2O$, $\mathbf{3}\cdot 19H_2O$ and $\mathbf{4}\cdot 4DMF\cdot 4.5H_2O$ were carried out with a MAR345 diffractometer with an image plate detector; intensities were collected with graphite-monochromated Mo radiation. Crystal data and parameters for data collection and processing are reported in Table 1.

The structures were solved by direct methods (SHELXS-86, SHELXS-97) and refined by full-matrix least squares techniques on F^2 (SHELXL-97). For the four structures, almost all non-hydrogen atoms were refined using anisotropic thermal parameters. Almost all hydrogen atoms were introduced at calculated positions as riding on their respective bonded atoms.

3. Results and discussion

The reaction of an excess of $Co(O_2CMe)_2\cdot 4H_2O$ with di-2-pyridyl ketone, $(py)_2CO$ (Fig. 1), in MeCN under reflux for 2 h gave the enneanuclear cluster $[Co_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**1**), see Eq. (1). The complex contains the doubly deprotonated form, $(py)_2CO_2^{2-}$, of the *gem*-diol form of di-2-pyridyl ketone, $(py)_2C(OH)_2$ (Fig. 1) [10]; this is a consequence of the excess of acetates in the reaction mixture. The structure of $\mathbf{1}\cdot 14.6H_2O$ consists of

$(py)_2CO$ $(py)_2C(OH)_2$

Fig. 1. Structural formulae and abbreviations of di-2-pyridyl ketone (left) and its *gem*-diol form (right). The ligand $(py)_2C(OH)_2$ does not exist as a free species, but only in the presence of metal ions.

enneanuclear molecules (Fig. 2, top). The complex has a crystallographic twofold axis passing through Co(1) and bisecting the angles around this metal ion, i.e. O(1)–Co(1)–O(1), O(2)–Co(1)–O(2), O(3)–Co(1)–O(3) and O(4)–Co(1)–O(4),

$$9Co(O_2CMe)_2\cdot 4H_2O + 4(py)_2CO \xrightarrow[T]{MeCN} \underset{\mathbf{1}}{[Co_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]} + 10MeCO_2H + 30H_2O \quad (1)$$

which is the shared apex of two square pyramids. The most characteristic feature of the structure is the coordination number 8 for Co(1), which is extremely rare in cobalt(II) chemistry. The dianion $(py)_2CO_2^{2-}$ bridges five metal ions (Fig. 3) with the simultaneous formation of three chelate rings per ligand (coordination mode $\eta^1{:}\eta^3{:}\eta^3{:}\eta^1{:}\mu_5$). Each of the two hydroxides bridges four metal ions and all $MeCO_2^-$ groups are in the familiar *syn*,*syn*-$\eta^1{:}\eta^1{:}\mu_2$ mode. The complex has an overall antiferromagnetic behaviour; the antiferromagnetic interactions are due to the $\eta^4{:}\mu_4$ OH^- ligands [11]. It is self-evident that we could not predict the structure of **1**; clearly it was obtained by serendipity [12].

At this point we started thinking in a more rational way. We decided to perform the same reaction that leads to **1**, but in the presence of N_3^- ions. The choice of the latter was based on established magnetostructural correlations which had shown that the end-on N_3^- ligand is an effective ferromagnetic coupler [13]. We hoped that the end-on azido ligands would be incorporated into the enneanuclear skeleton, instead of the hydroxo ligands which mediate a strong antiferromagnetic interaction. This substitution would lead to an increase of the total spin in the ground state.

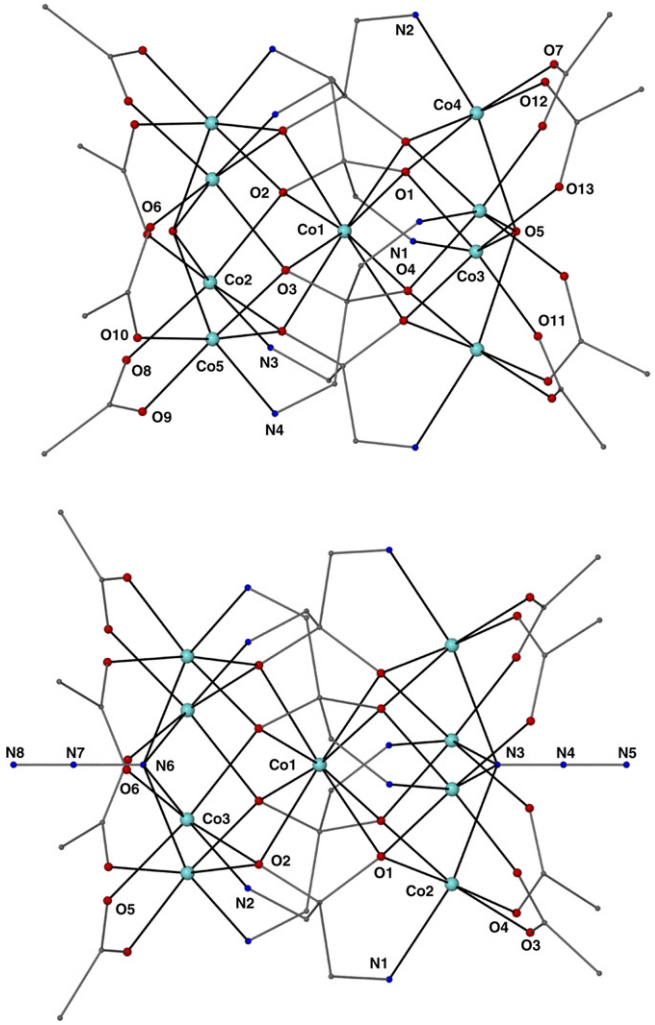

Fig. 2. Partially labeled plots of $[Co_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**1**, top) and $[Co_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**2**, bottom). All H atoms and most C atoms of the $(py)_2CO_2^{2-}$ ligands have been omitted for clarity.

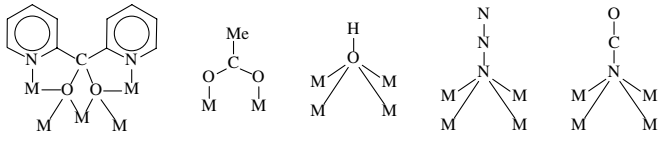

Fig. 3. The crystallographically established coordination modes of the ligands present in the complexes discussed in this work.

This has, indeed, turned out to be the case. The reaction represented by Eq. (2) in hot DMF (to keep the produced NaO_2CMe soluble) gave a dark blue solution from which the enneanuclear cage $[Co_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**2**) was isolated in 60% yield. Complex **2** · 4DMF · 2.5H_2O (Fig. 2, bottom) bears striking structural similarity

$$9Co(O_2CMe)_2\cdot 4H_2O + 4(py)_2CO + 2NaN_3 \xrightarrow{DMF} \underset{\mathbf{2}}{[Co_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]} + 8MeCO_2H + 2NaO_2CMe + 32H_2O \quad (2)$$

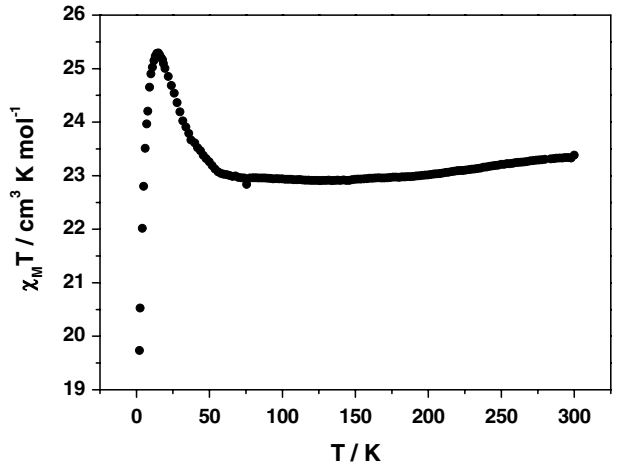

Fig. 4. Plot of the $\chi_M T$ vs. T product for **2**.

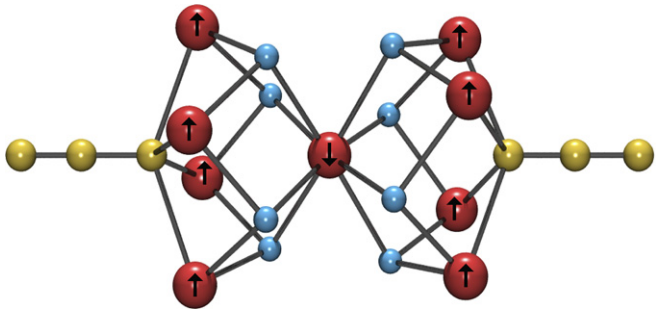

Fig. 5. The ferrimagnetic "structure" of complex **2**.

with the hydroxo cluster, the only difference being the presence of the novel quadruply bridging end-on azido ligands (η^4:μ_4, Fig. 3) instead of the quadruply bridging hydroxo ligands. The complex has a crystallographic fourfold axis passing through Co(1) and the azido nitrogen atoms N(3), N(4), N(5), N(6), N(7) and N(8), thus bisecting the angles around this metal ion, i.e O(1)–Co(1)–O(1′) [1.5 − x, 1.5 − y, z] and O(2)–Co(1)–O(2′) [1.5 − x, 1.5 − y, z].

The weak minimum in the $\chi_M T$ vs. T plot at 116 K for **2** (Fig. 4) is the ferrimagnetic signature of the antiferromagnetic coupling between the central Co^{II} ion and the two ferromagnetically-coupled squares in the bases of the cage (Fig. 5). The ferromagnetic coupling in the square bases of the double square pyramid is mediated by the end-on μ_4-N_3^- ligands [7].

A similar reaction performed by using NaOCN instead of NaN_3 yielded the cyanate analogue of **2** containing novel μ_4 end-on (through the single N atom) OCN^- ligands (Fig. 3).[1]

Using procedures similar to those described in Eqs. (1) and (2), the nickel(II) analogues of **1** and **2**, i.e. complexes $[Ni_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**3**) and $[Ni_9(N_3)_2$-

[1] Details will be given in another paper.

$(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**4**), respectively, were prepared in very good yields and structurally characterized. Their molecular structures (Figs. 6 and 7) are very similar to those of the analogous Co_9^{II}/OH^- and Co_9^{II}/N_3^- clusters. Complex **4** can also be prepared by the reaction of the pre-formed hydroxo cluster **3** with a slight excess of N_3^- ions in DMF–MeOH (2:1 v/v) in ~80% yield.

$$[Ni_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4] + 2NaN_3 \underset{\mathbf{3}}{} \xrightarrow{\text{DMF–MeOH}} [Ni_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4] + 2NaOH \quad (3)$$
$$\mathbf{4}$$

Variable temperature (300–2.0 K) dc magnetic susceptibility data for **3** (Fig. 8) indicate a dominant antiferromagnetic superexchange pattern. Full analysis of the data [8] shows that the antiferromagnetic behaviour is due to the OH^- bridges and that the ground-state total spin is 1.

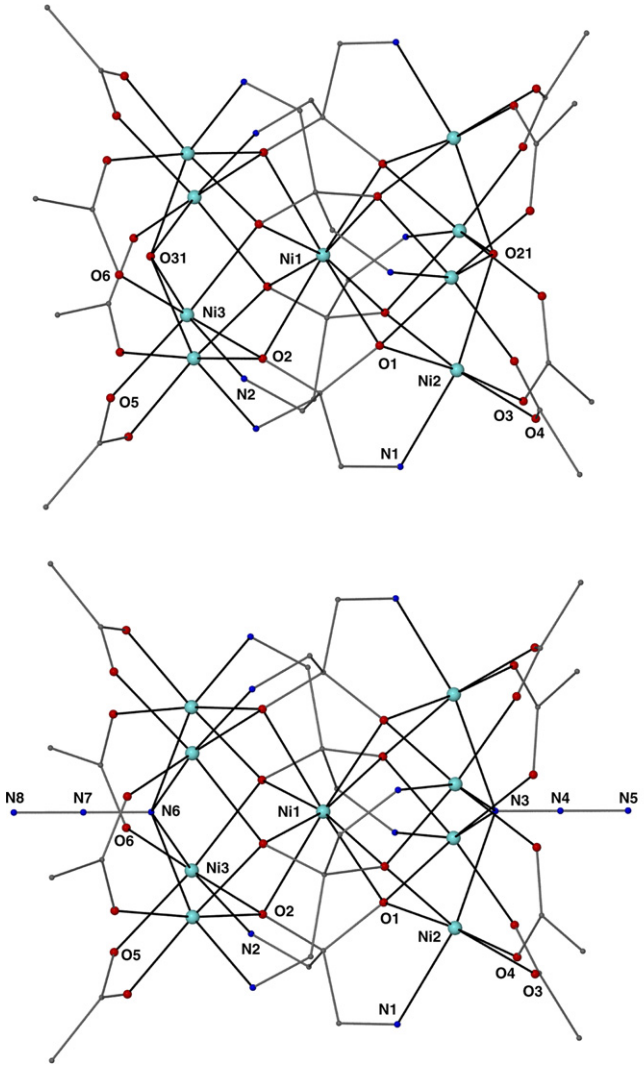

Fig. 6. Partially labeled plots of $[Ni_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**3**, top) and $[Ni_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**4**, bottom). Both complexes have a fourfold axis. All H atoms and most C atoms of the $(py)_2CO_2^{2-}$ ligands have been omitted for clarity.

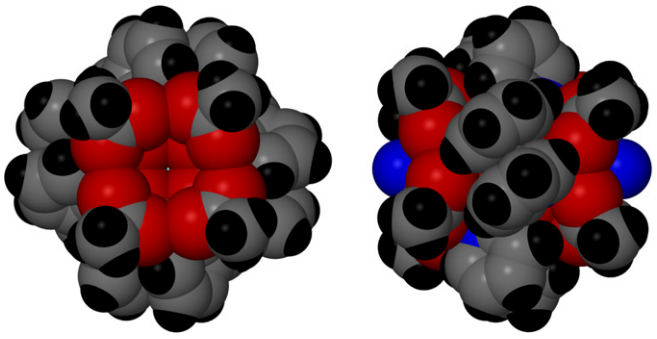

Fig. 7. Space filling models of $[Ni_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**4**); a view perpendicular to the base of the double square pyramid showing the N_3^--trapping cavity (left) and a view showing the azides within the cavities (right).

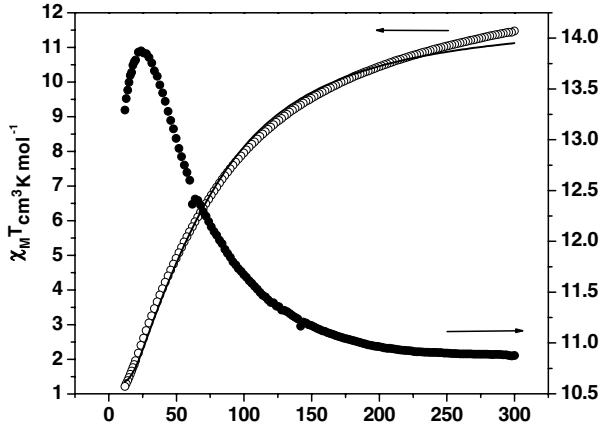

Fig. 8. Plots of the $\chi_M T$ vs. T products for **3** (left y axis, open circles) and **4** (right y axis, solid circles). The solid line is fit of the data to the appropriate 3-**J** model [8].

The dc $\chi_M T$ product of **4** increases from the 300 K value of 10.87 cm^3 mol^{-1} K to a maximum of 13.88 cm^3 mol^{-1} K at 24 K, and then decreases continuously down to 2.0 K (Fig. 8). This behaviour is compatible with moderate ferromagnetic coupling. Full analysis of the data shows that the ferromagnetic behaviour is due to the end-on azido bridges and that the ground-state total spin of the cluster is probably 9 (Fig. 9).

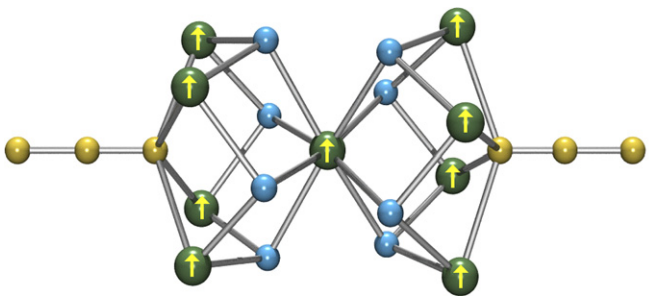

Fig. 9. The ferromagnetic "structure" of complex **4**.

The pivalate analogues of **1**–**4** have also been prepared.[1] These clusters have very similar molecular structures and magnetic properties with their corresponding acetate clusters. Similar chemistry occurs also with iron(II). Reactions of the initially isolated OH^--bridged cluster $[Fe_9(OH)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ with N_3^- and OCN^- ions in refluxing MeCN under an inert atmosphere yielded complexes $[Fe_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ and $[Fe_9(NCO)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$, respectively, that contain quadruply bridging pseudohalogeno ligands. Not only the N_3^-- and OCN^--bridged clusters are ferromagnetic in nature, but these also display SMM behaviour [9].

4. Conclusions and perspectives

In summary, the end-on azido (and probably N-cyanato ligands) are good substitutes for hydroxo bridges in 3d-metal clusters to increase the *S* value of the ground state. The described N_3^- or OCN^- for OH^- substitution has the potential for wide application in the area of high-spin molecules. Often this approach involves ''true'' reactivity chemistry on pre-isolated clusters. Results at the time of writing reveal that application of the described strategy in at least 10 different hydroxo and alkoxo clusters leads to the retainment of the core and the introduction of specific ferromagnetic components in the superexchange scheme.

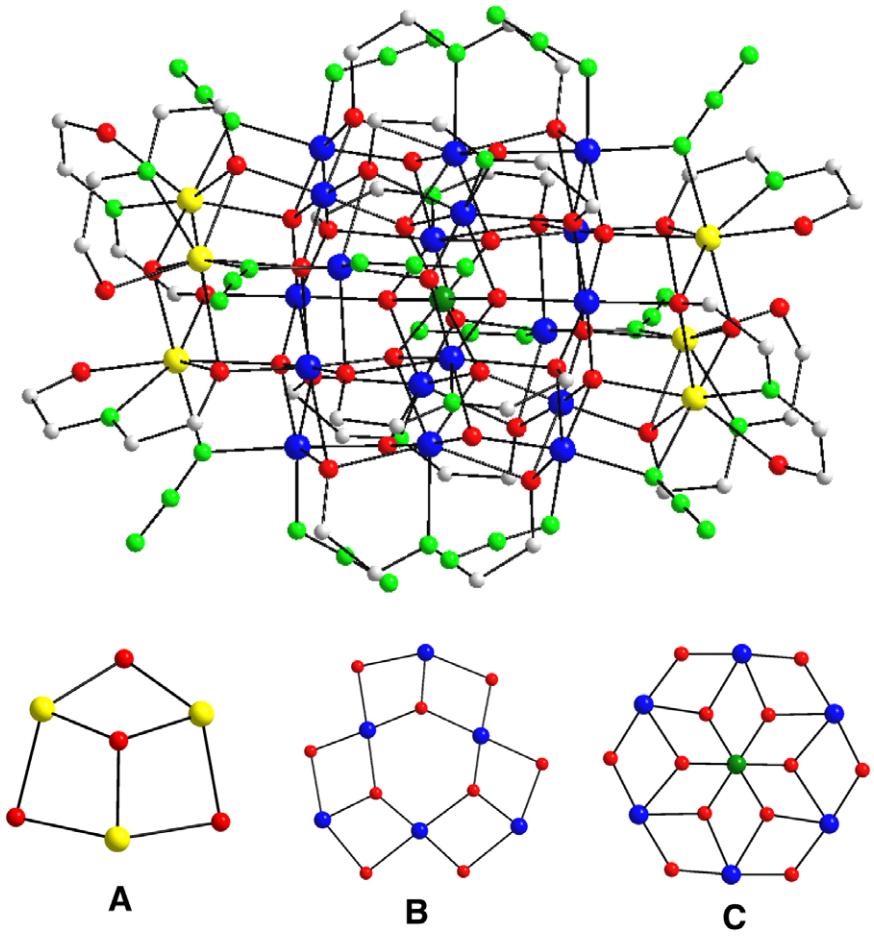

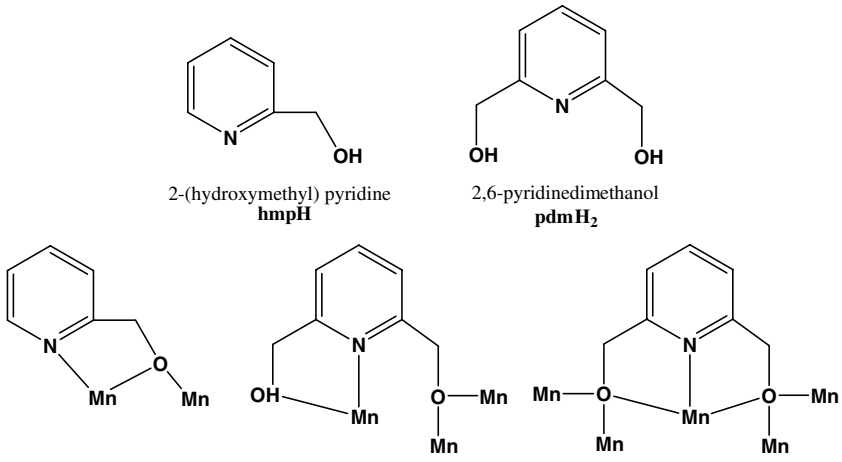

Fig. 1. Structure of the cation of **1** (top) and the three types of constituent layers of its core (bottom). Color code: Mn^{II} yellow, Mn^{III} blue, Mn^{IV} olive, O red, N green, C gray. H atoms have been omitted for clarity. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

An alternative approach to new high-spin molecules pertinent to the present report is to start with a preformed, high-spin molecule and then perturb it in some way, without major structural change, in order to modify the constituent exchange parameters and possibly alter the ground state (hopefully to a larger value rather than a smaller one). While this is often stated in the literature as an objective, it has yet to be realized. In the present work, we show that it is indeed possible to significantly modify the ground state spin of a complicated, already high-spin molecule without significant core structural change by controlled ligand substitution within the peripheral ligation about the magnetic core. Specifically, we show that ligand-induced tweaking of a SMM with $S = 51/2$ causes the ground state to increase to $S = 61/2$ without unduly affecting the anisotropy. As a result, the product is a new SMM.
