Abstract

Two tridentate imine–oxime–amine ligands have been synthesized and their corresponding copper(II) complexes have been isolated. These copper(II) complexes are readily oxidized both chemically and electrochemically to give relatively stable copper(III) complexes. In the pH range 1.5–3.0 the electron transfer process is electrochemically reversible with $\Delta E_p = 60$ mV and $i_{pa}/i_{pc} \sim 1$. Plots of $E_{1/2}$ versus pH are linear with a slope $= -60$ indicating the involvement of one proton in the electron transfer process. Aqueous solutions of copper(III) complexes have high molar absorption at λ_{max} with $\varepsilon > 10^4$ M^{-1} cm^{-1}. Solid samples of the complexes are diamagnetic consistent with a d^8 square planar geometry. It seems that only imine–oxime nitrogens are coordinated to copper(II) with the NH_2 group being free as indicated by i.r. spectra. Substitution of a $-CH_3$ group on the carbon atom adjacent to the oxime group by the more electron donating group $-CH(CH_3)_2$ lowers electrode potential by more than 90 mV. This is consistent with an earlier observation that electron-donating substituents on the carbon atom adjacent to the oxime group lower the potential of Cu^{III}/Cu^{II} couples and stabilize the higher oxidation state.

Keywords: Imine–oxime–amine ligands; Diamagnetic copper(III); Proton-dependent electrochemically reversible $E_{1/2}$

1. Introduction

It is now very well established that the trivalent oxidation state copper is stabilized by several ligands [1,2]. The resolved X-ray structures of copper(III) complexes with various ligands as well as the diamagnetism of most of the others are consistent with prevalence of a square planar structure [3–10]. Few other reports have shown that other structures, square pyramidal and octahedral geometries are also possible [11,12]. The trivalent oxidation state of copper was found to be easily generated in aqueous solution by chemical oxidation of Cu^{II}(HDMG) (H_2DMG = dimethyglyoxime) [13]. We have previously reported the isolation and characterization of copper(III) complexes with tetradentate imine–oxime ligands [14]. These complexes are diamagnetic and hence are believed to be square planar. It was noticed that in coordinating solvents, these complexes undergo a colour change. It is believed that this may arise from weak axial coordination by a solvent molecule(s) forming either a five- or a six-coordinate species. The two tridentate imine–oxime–amine ligands of type (HL^n) and their corresponding copper(II) complexes have been synthesized

doi:10.1016/j.poly.2006.04.019

Copper(II) complexes were formed in the mole ratio 1:2 metal:ligand. The availability of six donating atoms around the copper ion may thus facilitate the formation of an octahedral complex. If this complex is oxidizable and also retains its structure it may lead to the formation of an octahedral copper(III) complex. Octahedral copper(III) complexes have been reported [15,16].

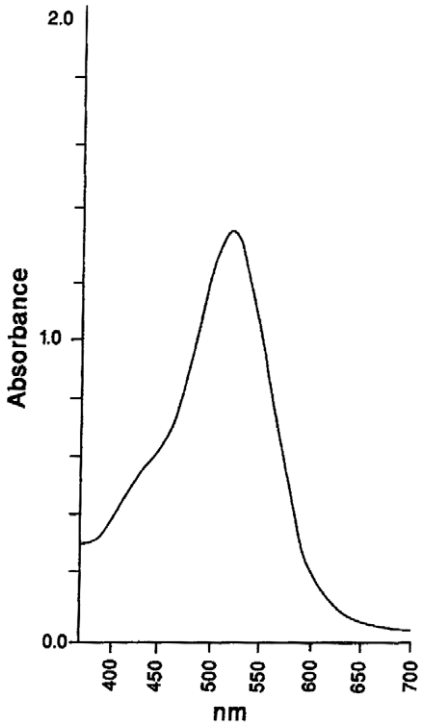
2. Experimental

2,3-Butanedione monoxime, 1,3-diaminopropane (pn), 4-methylpentan-2-one, ethyl acetate, copper(II) acetate, methanol, and ethanol were used as received. The keto-oxime 4-methyl-3-oximinopentan-2-one was prepared according to the literature method [17]. Buffer solutions were prepared from solutions with known concentrations. In the low pH range HCl/KCl solutions were used. Buffer solutions in the high pH range were prepared from CH_3CO_2H/NaOH solutions. Ionic strength was maintained at 0.10 M with $NaNO_3$.

The tridentate ligands, HL^1 and HL^2, were prepared following the same procedure. The keto-oxime was dissolved in ethyl acetate and was added drop wise to a stirred solution of (pn) dissolved in ethyl acetate at ~25 °C. The reaction mixture was kept overnight. The precipitate that was formed was filtered and washed with cold ethyl acetate and dried over P_2O_5. The diamine concentration was always greater than that of the keto-oxime (1.5:1 mol ratio) to avoid the formation of the tetradentate ligands. The copper(II) complexes, with the ligands HL^1 and HL^2, were prepared by refluxing the ligand with copper(II) acetate in a 2:1 mol ratio in methanol for 2 h. The complexes were precipitated by addition of solid $NaClO_4$. The products were recrystallized from methanol. Elemental analysis was performed at UMIST, Manchester (UK). Copper(III) solutions were generated by chemical oxidation of a buffered solution (pH ~ 4.0) of copper(II) complex using PbO_2.

Cyclic voltammetry of the complexes was measured with an Oxford Electrodes potentiostat and were recorded on an Allen X-Y recorder. The voltammograms were generated using a three-electrode system consisting of a carbon paste working electrode, a Pt wire auxiliary electrode and a saturated calomel reference electrode. Typically, votammograms were recorded at scan rates of 100 mV s^{-1} with a complex concentration of 5×10^{-4} M. Magnetic susceptibility was measured using a Johnson Matthy susceptibility balance at room temperature. A Nicolet 510P-FTIR spectrometer was used to record the i.r. spectra. Electronic spectra were recorded on a Lambda 25 UV–Vis spectrophotometer.

Copper(III) complexes with both ligands were readily formed in aqueous acidic solutions by chemical oxidation by PbO_2 to give intensely deep red coloured solutions. The visible absorption spectrum of the oxidized complex $[Cu^{III}(L_1)_2]^+$ is shown in Fig. 1. Solid copper(III) complexes were isolated by filtration after addition of solid $NaClO_4$ and cooling. The isolated complexes were dried over P_2O_5.



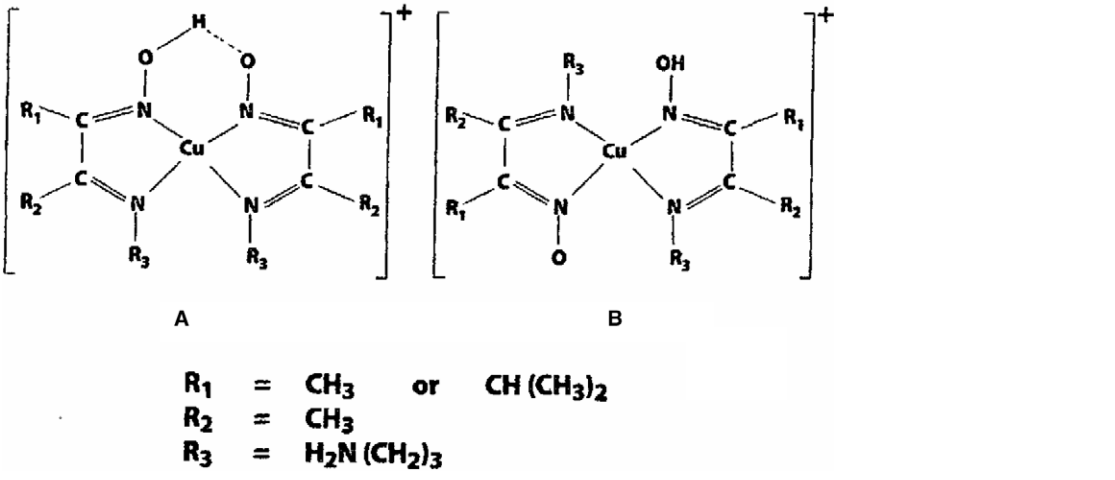


Fig. 1. Visible absorption spectrum of $[Cu^{III}(L^1)_2]^+$ in aqueous solution. $[Cu^{III}(L^1)_2^+] = 1.0 \times 10^{-4}$ M at pH 4.6.

3. Results and discussion

Elemental analysis of the two copper complexes are consistent with the formulations $[Cu^{II}(HL^1)(L^1)]ClO_4$. and $[Cu^{II}(HL^2)(L^2)]ClO_4.CH_3OH$ for the two complexes with the ligands HL^1 and HL^2, respectively. *Anal.* Calc. for $CuC_{14}H_{29}N_6O_6Cl$: C, 35.3; H, 6.1; N, 17.6. Found: C, 35.0; H, 5.6; N, 17.2% and Calc. for $CuC_{18}H_{41}N_6O_7Cl$: C, 40.4; H, 7.3; N, 14.9. Found: C, 40.7; H, 6.0; N, 14.9%. The inclusion of methanol in the crystal of a copper(II) imine–oxime complex has been observed before [18]. The copper(II) complexes with ligands HL^1 and HL^2 have m.p. of 173 and 195 °C, respectively. These values are lower by more than 30 °C than the m.p. of the corresponding tetradentate ligands. Copper(II) complexes with these tridentate ligands may lead to the formation of complexes in which the two nitrogen atoms of the oxime groups are *cis* or *trans* (A and B, respectively). Structure (B) seems to be favored as the i.r. spectra of the complexes displayed sharp bands at 3337 cm^{-1}. This is indicative of the absence of hydrogen-bonding between oxime oxygen atoms. The i.r. spectra of complexes with both ligands showed the presence of an NH_2 group confirming the addition of only one keto-oxime ligand to 1,3-diaminopropane (pn). The two copper(III) complexes show high molar absorption (ε_{max}) of 1.36×10^4 and 1.48 M^{-1} cm^{-1} at 518 nm, respectively. The band maxima positions are identical to those of the

tetradentate ligands [14]. It was observed that copper(III) complexes of the tridentate ligands are slightly less stable than the tetradentate ligands in aqueous acidic solutions. The high ε_{max} may be attributed to ligand to metal charge transitions (LMCT) by analogy to other complexes that display similar high absorption in this region. The visible spectra of the two copper(III) has a shoulder at ~440 nm. The isolated copper(III) complexes are diamagnetic; and this is consistent with a d^8 square planar structure. Aqueous acidic solutions of these complexes are very rapidly reduced by SO_3^{2-}, $S_2O_3^{2-}$, I^- and 1,2- and 1,4-dihydroxybenzene to give the initial copper(II) complexes.

donor ability and steric effects of substituents [10,14,19–21]. We have previously shown that substituents on the carbon atom adjacent to oxime group affect the magnitude of the electrode potential [14]. The electrode potentials of copper(III) complexes of tetradentate imine–oxime ligands are lowered on substituting $-CH_3$ by $-CH(CH_3)_2$. In the complexes considered here the same affect is observed. The electrode potential of the Cu^{III}/Cu^{II} couple with the ligand HL^2 having $-CH(CH_3)_2$ replacing $-CH_3$ in HL^1 is lowered by 90 mV. The lowering of $E_{1/2}$ is reflected in the greater stability of $[Cu^{III}(L^2)_2]^+$ relative to $[Cu^{III}(L^1)_2]^+$. The standard electrode potential, $E^0_{1/2}$, for the two complexes were calculated from Eq. (2) as 1.17 and 1.08 V (n.h.e.) for Cu^{III}/Cu^{II}

Cyclic voltammetry has established further evidence for the stabilization of the +3 oxidation state of copper by tridentate imine–oxime ligands. The voltammograms of the complexes $[Cu^{II}(L^1)(HL^1)]^+$ and $[Cu^{II}(L^2)(HL^2)]^+$ are electrochemically reversible at low pH values as shown in Fig. 2A. The anodic peak, E_{pa}, and the cathodic peak, E_{ca}, separation, $\Delta E_p = 60$ mV and $i_{pa}/i_{ca} \sim 1$ at pH 2.40. However, as the pH increases the electron process becomes less reversible and ΔE_p progressively increases (Fig. 2(B)). The electrode potential $E_{1/2}$ ($E_{1/2} = 0.5(E_{pa} + E_{pc})$) decreases with increasing pH. Plots of $E_{1/2}$ versus pH are linear for both complexes with slopes -60 ± 2 mV as shown in Fig. 3. This is consistent with the involvement of one proton in the electrochemical process. The electrode reaction for the copper(III) complexes can be described by Eq. (1)

$$[Cu^{III}(L^n)_2]^+ + H^+ + e \leftrightarrow [Cu^{III}(HL^n)(L^n)]^+ \quad (n = 1 \text{ or } 2) \tag{1}$$

The variation of the electrode potential with pH is given by Eq. (2)

$$E_{1/2} = E^0_{1/2} - 0.059\ \text{pH} \tag{2}$$

It has previously been reported that electrode potentials of copper(III) complexes are affected by both the electron couples with the ligands HL^1 and HL^2, respectively. These values are only slightly higher than values reported for $E^0_{1/2}$ for the tetradentate ligands synthesized using two equivalents of the same keto-oximes [14].

Previously it has been shown that the reaction designated in Eq. (1) may be separated into electron-transfer and proton-transfer processes as in Eqs. (3) and (4) [14,22]:

$$[Cu^{III}(L^n)_2]^+ + e \leftrightarrow [Cu^{II}(L^n)_2] \tag{3}$$

$$[Cu^{II}(L^n)_2] + H^+ \leftrightarrow [Cu^{II}(HL^n)(L^n)]^+ \tag{4}$$

The formal free energy change ΔG^0_T corresponding to Eq. (1) is given by

$$\Delta G^0_T = -nFE^0_T \tag{5}$$

A similar relation exit for Eq. (3) in which the free energy change and the formal electrode potential are represented by $(\Delta G^0_T)_{el}$ and $(E^0_T)_{el}$, respectively. The free energy associated with the proton transfer process (Eq. (4)) is given by Eq. (6), where K is the dissociation constant of $[Cu^{II}(HL^n)(L^n)]^+$ (K is the inverse of the dissociation constant of Eq. (4))

$$(\Delta G^0_T)_{pr} = RT \ln K \tag{6}$$

The relation for the free energy balance is given in Eq. (7) and this can be combined with Eqs. (5) and (6) to give Eq. (8):

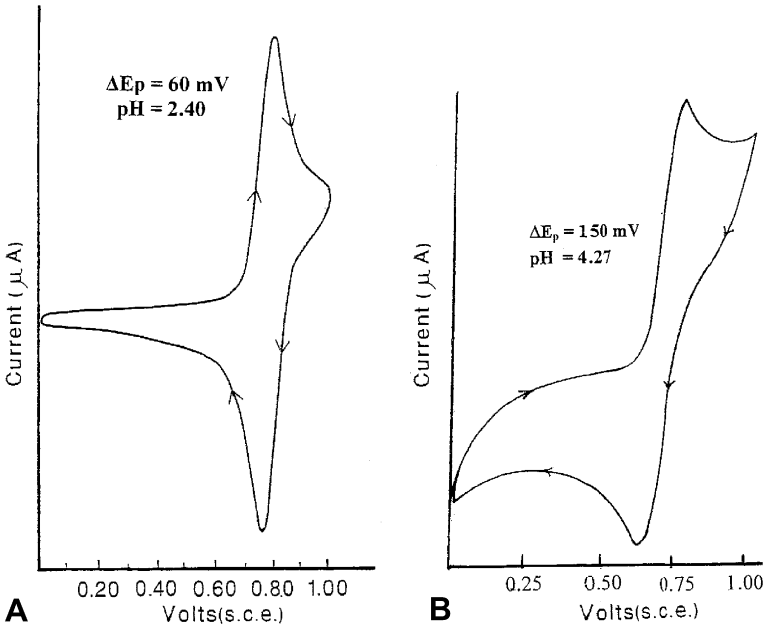

Fig. 2. Cyclic voltammogram of $[Cu^{II}(HL^1)(L^1)]^+$ in aqueous acidic solution at a carbon paste electrode. $[Cu^{II}(HL^1)(L^1)^+] = 5.0 \times 10^{-4}$ M, (A) pH 2.40, (B) pH 4.27, $I = 0.10$ M ($NaNO_3$) at a scan rate = 100 mV s^{-1}.

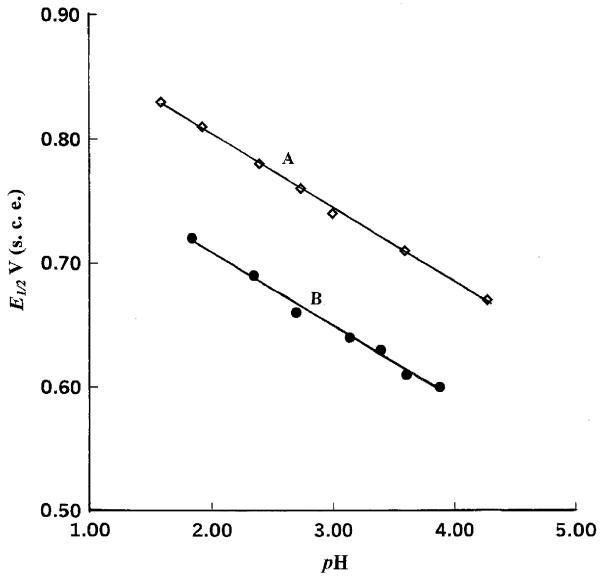

Fig. 3. Plot of $E_{1/2}$ vs. pH for $[Cu^{II}(HL^1)(L^1)]^+$ (A), and $[Cu^{II}(HL^2)(L^2)]^+$ (B).

$$\Delta G^0_T = \left(\Delta G^0_T\right)_{el} + \left(G^0_T\right)_{pr} \quad (7)$$

$$E^0_{1/2} = \left(E^0_{1/2}\right)_{el} + (0.059/n)pK \quad (8)$$

The pK_a value for the complex $[Cu^{II}(HL^1)(L^1)]^+$ has been determined by spectrophotometric titration as 11.2 and the value of pK_a for $[Cu^{II}(HL^2)(L^2)]^+$ is taken as 11.5 equal to that of the tetradentate ligand [14]. Using these values of pK_a and the standard $E^0_{1/2}$ in Eq. (8), the values of $(E^0_{1/2})_{el}$ are calculated as 0.51 and 0.39 V for Cu^{III}/Cu^{II} couples with HL^1 and HL^2 ligands, respectively. These values are very close to the values calculated for Cu^{III}/Cu^{II} couples with tetradentate ligands.

The two tridentate ligands coordinated to Cu^{III} seem to function only as bidentate ligands, with the amine group being free, and seem to form a square planar geometry as indicated by the diamagnetism of the Cu^{III} complexes. The formation of an octahedral complex Cu^{III} with either ligand would have resulted in the complexes being paramagnetic. It thus seems that with this type of ligands a square planar geometry is preferred. It has now been shown that the +3 oxidation state of copper(II) is stabilized by bidentate *vic*-dioximes as well as tridentate imine–oxime–amine and tetradentate imine–oxime ligands.

Abstract

The chelation of 3-hydroxy-, 5-hydroxy- and 5,7-dihydroxychromone with Al^{3+} was studied spectrophotometrically. Both the molar ratio method and method of continuous variation (Job's method) were used to determine the composition of the complexes. In all cases, complex formation involved 1:1 aluminum ion to hydroxychromone ratios. For the 5-hydroxy and 5,7-dihydroxy derivatives, this composition agrees with that for the corresponding hydroxyflavone. However, 3-hydroxyflavone (flavonol) forms a 2:1 complex with Al^{3+} in methanol in contrast to the results for 3-hydroxychromone in this study. The importance of the cinnamoyl mesomeric form for stabilizing the complex between flavonol and Al^{3+} is invoked to explain this discrepancy.

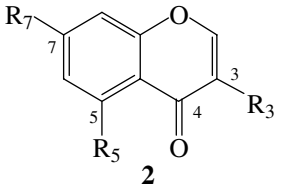
1. Introduction

Flavonoids (specifically hydroxyflavonoids) have been extensively studied in recent years because of their antioxidant properties [1–9]. These studies have included reports of the effect of metal chelation on antioxidant activity [10–13] and determining binding strengths with metals ions [10,14–33]. For the hydroxyflavones (**1**), metal chelation occurs at the 3-hydroxy-4-keto binding site [17,27,34–40], 4-keto-5-hydroxy binding site [27,41] or, if present, at vicinal dihydroxy sites of the B ring [27,38,39] although it has also been postulated that the 1-ether-2′-hydroxy groups can bind Co^{2+} in morin (**1d**) [42,43].

1



1a: R_3 = OH; $R_5 = R_7 = R_{2'} = R_{4'}$ = H: flavonol
1b: R_5 = OH; $R_3 = R_7 = R_{2'} = R_{4'}$ = H: 5-hydroxyflavone
1c: $R_5 = R_7$ = OH; $R_3 = R_{2'} = R_{4'}$ = H: 5,7-dihydroxyflavone
1d: $R_3 = R_5 = R_7 = R_{2'} = R_{4'}$ = OH: morin

Removal of the B ring from flavones gives the chromone (**2**) class of molecules. We became interested in these molecules to investigate the molecular properties important in protecting wood against fungal decay knowing that hydroxyflavones such as morin inhibit wood decaying fungi [44]. The postulate that a Fenton-type process is in

2c: $R_5 = R_7$ = OH; R_3 = H;
5,7-dihydroxychromone

In this paper, we report the results of complexation studies of chromone derivatives **2a**, **2b** and **2c** with Al^{3+} in methanol using the spectrophotometric method employed for the corresponding studies with hydroxyflavones [32,37–41]. The results obtained will be compared with those for the hydroxyflavones (**1a**–**c**) to determine the importance of the B ring on metal chelation at either the 3-hydroxy-4-keto or 4-keto-5-hydroxy binding site.

2. Experimental

Infrared spectra were obtained on a Midac FT-IR. NMR spectra were recorded using a Bruker AMX-300 spectrometer operating at 300 MHz.

2.1. Synthesis of hydroxychromones (*2a*–*c*)

Chromones (**2a**–**c**) were synthesized according to the literature procedures [54–56]. Melting points, infrared spectra and ^1H NMR spectra for compounds synthesized all agreed with those reported in the literature [57,58].

2.2. Spectroscopic studies

Spectroscopic studies were carried out on a Varian 50 Bio UV–Vis spectrometer at room temperature (21.5 ± 0.5 °C). A 1-cm pathlength quartz cell was used for all measurements. Two methods were used to study the binding of hydroxychromones with Al^{3+} in methanol solution. These are the molar ratio method and the method of continuous variation (Job's method [59]) as described by Cornard and co-workers [37]. In the former method, the molar ratio of $AlCl_3$/hydroxychromone (with constant hydroxychromone concentration) is varied between 0 and 3.0 and the UV–Vis spectrum is obtained at each ratio. A plot of absorbance at maximum wavelengths for complex and uncomplexed hydroxychromone versus molar ratio allows for the determination of the ratio of Al^{3+}/hydroxychromone in the complex. In Job's method, the mole fraction of hydroxychromone in a mixture with Al^{3+}, where the total concentration of Al^{3+} and hydroxychromone is held constant, is varied between 0 and 1 and the UV–Vis spectrum at each $\chi_{hydroxychromone}$ is obtained. A plot of λ_{max} (complex) (corrected for uncomplexed Al^{3+} and/or hydroxychromone) versus $\chi_{hydroxychromone}$ gives a maximum at the mole fraction of hydroxychromone in the complex. In both methods, the absorbance measurement was made 1 h after solution preparation to allow for complete complex formation. Each spectroscopic study was repeated twice.

3. Results and discussion

Fig. 1 shows the change in UV–Vis spectra (methanol solvent) as the ratio of Al^{3+}/5-hydroxychromone was varied. A similar behavior was observed for all hydroxychromone/$AlCl_3$ mixtures studied. The spectroscopic results for the chromones and their complexes with Al^{3+} are compiled in Table 1. The unsubstituted chromone was also studied as a possible ligand for Al^{3+}. At all ratios of Al^{3+}/chromone studied, the UV–Vis spectrum remained unchanged from that of the pure chromone, indicating no complex formation as anticipated.

Plotting the absorbances at the λ_{max} for the hydroxychromone and complex versus metal/ligand ratio results in a graph as shown in Fig. 2 for Al^{3+} with 3-hydroxychromone. The intercept of the lines drawn through the rising points and those on the plateau allows for a determination of the ratio in the complex. For 3-hydroxychromone with Al^{3+}, a 1:1 complex is formed. The method of continuous variation (Job's method) results in a graph such as is depicted in Fig. 3. This graph confirms the 1:1 nature of the complex for Al^{3+} with **2a**. Table 1 contains the ratio of Al^{3+}:hydroxychromone from the method of continuous variation and molar ratio experiments and the results for the corresponding hydroxyflavones.

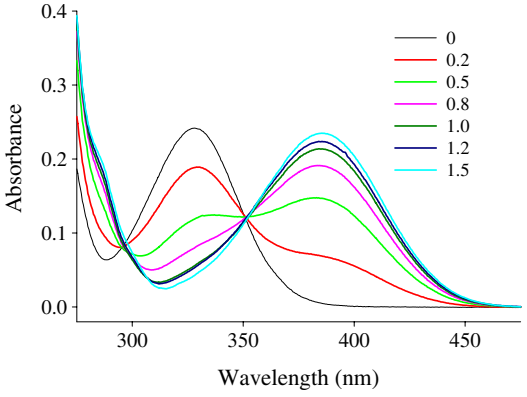

Fig. 1. UV–Vis spectra of 5-hydroxychromone (**2b**) and Al^{3+} in methanol at various ratios of Al^{3+}:**2b**.

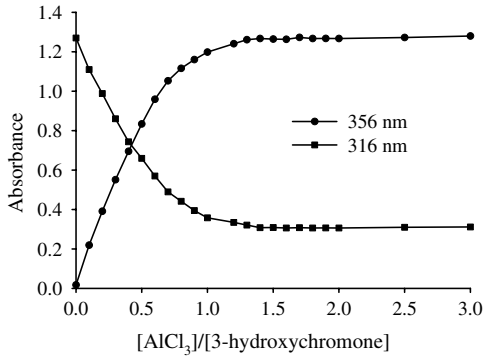

Fig. 2. Plot of absorbance at 356 and 316 nm vs. ratio of Al^{3+}:**2a** in methanol.

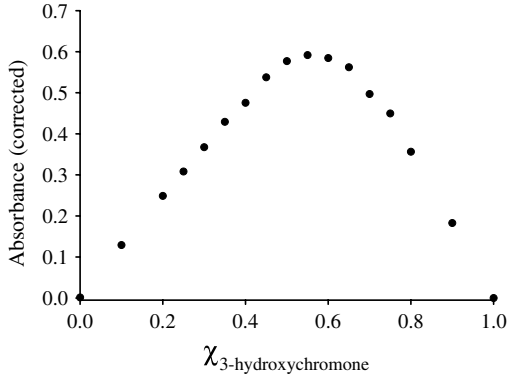

Fig. 3. Job's plot at 356 nm for mixtures of Al^{3+} and **2a** in methanol.

To verify the methods employed in this study, the spectroscopic experiments for the binding of hydroxyflavones with Al^{3+} in methanol were repeated. The results obtained matched those for **1a** and **1b** [37,41], but there is a discrepancy in the literature concerning the ratio of Al^{3+}:5,7-dihydroxyflavone (**1c**) with one group reporting a 1:1 ratio [31] while another a 1:2 ratio [30]. The present work clearly indicates a 1:1 ratio as expected from the behavior of **1b** with Al^{3+}.

The similarity of the results for the binding of **2b** and **2c** with Al^{3+} with those for the corresponding hydroxyflavones (**1b** and **1c**) suggests that the phenyl substituent has little effect when chelation occurs at the 4-keto-5-hydroxy site. On the other hand, the phenyl substituent has a significant effect on complexation when metal coordination occurs at the 3-hydroxy-4-keto site. Indeed, in the case of **1a** there are 2 flavonols bound to each Al^{3+}, whereas for **2a** only a single 3-hydroxychromone binds per metal. This insinuates that the metal complex is much more stable when the phenyl group is attached at the 2 position of the A ring.

This behavior can be readily explained by referring to the theoretical calculations performed on the complexes of **1a** and **1b** with Al^{3+} by Cornard and co-workers [37,41]. These calculations suggest that the metal complex is stabilized by the generation of negative charge on the 4-keto oxygen atom and that this can be done by invoking a number of mesomeric forms. The two most important ones are the pyronium and cinnamoyl forms (Fig. 4).

Obviously, in the case of the chromones the cinnamoyl form is not available. Therefore, the much greater binding of **1a** with Al^{3+} compared with **2a** can be rationalized by the fact that the cinnamoyl form contributes significantly to the stability of the complex when Al^{3+} is bound at the 3-hydroxy-4-keto position of **1a**. On the other hand, the similarity in the bonding strengths of **1b** and **2b** with Al^{3+} suggests that the cinnamoyl form is not an important contributor to the stability of the complex when complexation occurs at the 4-keto-5-hydroxy binding site.

It is interesting to note that the cinnamoyl form may be important in another property of hydroxyflavones. In unpublished work from this laboratory, the crystal structures of both **2a** and **2b** have been determined. While **2b** has an intramolecular hydrogen bond similar to what is observed for **1b** [60], **2a** does not show any indication of intramolecular hydrogen bonding in stark contrast to **1a** [61]. Thus, the cinnamoyl form is likely important in promoting intramolecular hydrogen bonding between the 3-hydroxy and 4-keto groups. The variation in dihedral angle observed between the B and C rings versus the

intramolecular hydrogen bond formation in various 3-hydroxyflavone derivatives supports this hypothesis [61].

It is the goal of this research to correlate the ability of hydroxyflavone, hydroxychromone and other molecules to protect wood against fungal decay with their propensity for chelating metal centers [53,62,63]. Once accomplished, this allows for the rational design of molecules able to prevent the fungal destruction of woody materials for economical and environmentally-benign non-metallic preservatives.

4. Conclusions

The chelation of 3-hydroxychromone, 5-hydroxychromone and 5,7-dihydroxychromone with Al^{3+} was studied spectrophotometrically in methanol. All three molecules form 1:1 complexes with this metal ion. The results for the latter two molecules are in agreement with those for the corresponding hydroxyflavone. However, significant differences exist in the strength of the binding between the 3-hydroxy derivatives. In contrast to the present work, 3-hydroxyflavone forms a 2:1 complex with Al^{3+}. This reflects the importance of the cinnamoyl mesomeric form in the stabilization of the 3-hydroxyflavone complex.

Abstract

Two novel polynuclear complexes with methanoate anions and 3-hydroxypyridine ligands $[Cu(\mu\text{-}HCO_2)_2(3\text{-}pyOH)]_n$ (**1**) and $[Cu_2(\mu\text{-}HCO_2)_2(\mu\text{-}3\text{-}pyOH)_2(3\text{-}pyOH)_2(HCO_2)_2]_n$ (**2**), respectively, were synthesized and characterized. The central copper atom in **1** is surrounded by four methanoates and a 3-pyOH molecule, forming a square-pyramidal CuO_3NO chromophore. All the methanoates are bidentate and serve as bridges between the adjacent copper ions via *syn-anti* and *anti–anti* coordination. The basal square coordination axes are formed by *O*(*syn*), *N*(3-pyOH) (1.974(2), 2.016(2) Å) and *O*(*anti*), *O*(*anti*) (1.945(2), 1.960(2) Å), while the third *O*(*anti*) (2.247(2) Å) is on the top of the pyramid. A ferromagnetic transition with an exchange constant $2J/k_B = 9.2\ cm^{-1}$ is found for **1** below 20 K. This interaction probably takes place through two *syn-anti* methanoates extended in a chain through the 2D structure. On the other hand, two monoatomic Cu–O–Cu intra-dinuclear asymmetric (1.986(2), 2.415(2) Å) bridges of two methanoates in $[Cu_2(HCO_2)_4(3\text{-}pyOH)_4]$ (**2**) are present. An elongated distorted octahedral coordination sphere around each copper(II) atom is completed by an additional monodentate terminal methanoate (1.975(2) Å), two *N*-coordinated 3-pyOH (2.005(2), 2.002(2) Å) and the third weakly *O*-coordinated 3-pyOH (2.732(2) Å). Although a shorter Cu···Cu distance is noticed in **2** than in **1** (4.690(1) Å **1**, 3.442(1) Å **2**), much weaker ferromagnetism is found in **2**.

1. Introduction

Copper carboxylates are well known to form a variety of structures even with ligands of the same homologous series. Our recent investigations include efforts to find new synthetic routes for the preparation of copper carboxylates with additional *N*-donor ligands. A choice of ligands with a hydrogen-bonding functionality could lead to the formation of useful inorganic materials with desired physical properties. Some of them may serve also as bioinorganic models, since coordination compounds of the first-row transition metals are known to participate in multiple biological processes involving acid–base and redox reactions. In this sense, complexes of hydroxypyridine are of considerable interest [1,2]. However, only a few coordination compounds of copper(II) carboxylates with 3-hydroxypyridine (3-pyOH) have been structurally characterized so far. A two-dimensional network, linked by inter-molecular hydrogen bonds between trifluoroacetate and 3-pyOH ligands, is present in $[Cu(O_2CCF_3)_2(3\text{-}pyOH)_2(THF)_2]$ [2]. A similar 2D network is also reported for $[Cu(O_2CCF_3)_2(3\text{-}pyOH)_2]_n$ [3], however, 3-pyOH ligands serve as bridges (N, O) and intra-molecular H-bonding is present.

Replacement of the carboxylate ligand reveals structurally significantly different compounds. Due to tetradentate bridging oxalates, a 1D zig-zag chain structure of *cis*-$[Cu(\mu\text{-ox})(3\text{-pyOH})_2]_n$ [4] is formed. On the other hand, acetates coordinate bidentately, as in dinuclear *paddle-wheel* $[Cu_2(O_2CCH_3)_4(3\text{-pyOH})_2]$ [5] or in mononuclear $[Cu(O_2CCH_3)_2(3\text{-pyOH})_2]_n$ [6]. Only one example of 3-pyO, the deprotonated form of 3-pyOH, was found in the literature, in $\{[Cu(\mu\text{-3-pyO})(3\text{-pyO})(3\text{-pyOH})(H_2O)]\cdot 2H_2O\}_n$ [1]. For some of these complexes ferromagnetic or antiferromagnetic properties were reported, either through the carboxylate group or 3-pyO(H).

In this work, we present two novel coordination compounds with methanoate and 3-pyOH ligands. The methanoates show rather rare coordination modes in both cases, playing a distinguishing role in the magnetic properties of both complexes.

2. Experimental

2.1. Synthesis

Chemicals were readily available from commercial sources and were used as received without further purification.

$[Cu(\mu\text{-}HCO_2)_2(3\text{-pyOH})]_n$ (**1**). A mixture of $[Cu_2(OH)_2CO_3]$ (0.33 g, 1.5 mmol) and 3-pyOH (0.57 g, 6.0 mmol) in 30 mL CH_3OH and 3 mL HCOOH was refluxed in air for 1 h. A small amount of a solid residue was filtered off and the resulting solution was left at 279 K for 72 h. Light blue crystals of **1** were filtered off and dried in a desiccator over KOH for 24 h. Yield 57%. *Anal.* Calc. for $C_7H_7CuNO_5$: C, 33.8; H, 2.84; N, 5.63; Cu, 25.6. Found: C, 33.7; H, 3.02; N, 5.25; Cu, 26.1%. IR ($\bar{\nu}$/cm^{-1}): 1630 s $\nu_{as}(CO_2)$, 1580sh, 1564s $\nu_{as}(CO_2)$ + ν(ring), 1482 m ν(ring), 1369s $\nu_s(CO_2)$, 1344 s, 1297 s ν(C–O). UV/Vis (λ_{max}/nm): 225, 285, 610. EPR (295 K) g 2.150.

$[Cu_2(\mu\text{-}HCO_2)_2(\mu\text{-3-pyOH})_2(3\text{-pyOH})_2(HCO_2)_2]_n$ (**2**). The synthetic path for the dark blue compound **2** was the same as for **1**: $[Cu_2(OH)_2CO_3]$ (0.25 g, 1.1 mmol), 3-pyOH (1.1 g, 12 mmol), absolute C_2H_5OH (30 mL), HCOOH (2 mL). Yield 67%. *Anal.* Calc. for $C_{24}H_{24}Cu_2N_4O_{12}$: C, 41.9; H, 3.52; N, 8.15; Cu, 18.5. Found: C, 42.3; H, 3.79; N, 7.94; Cu, 18.3%. IR ($\bar{\nu}$/cm^{-1}): 1600 s $\nu_{as}(CO_2)$, 1557 m ν(ring), 1452 m ν(ring), 1370 m $\nu_s(CO_2)$, 1333 s, 1285 s ν(C–O). UV/Vis (λ_{max}/nm): 225, 285, 615. EPR (295 K) $g_\perp$ 2.100, $g_\parallel$ 2.257.

The single crystals of **1** and **2**, suitable for X-ray analysis, were obtained by a similar procedure, but at a lower concentration of the starting compounds.

2.2. X-ray structure analysis

Details of the crystal data, data collection and refinement parameters for **1** and **2** are listed in Table 1, and selected distances and angles in Table 2. The diffraction data were collected on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation. The data were processed using DENZO [7]. The structures were solved by direct methods using SIR97 [8] and refined using XTAL3.6 [9] by a full-matrix least-squares procedure based on F. All of the non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms for both structures were located using difference Fourier maps. They were refined together with their isotropic displacement parameters for **1**. The H-atoms parameters of **2** were not refined.

2.3. Physical measurements

The magnetic susceptibility data of powdered polycrystalline samples were measured with a Quantum Design SQUID magnetometer, equipped with a 5 T magnet. The molar magnetic susceptibility χ_M was investigated in the temperature interval between 300 and 2 K in a magnetic field strength $H = 50$ Oe. The data were corrected for the experimentally determined contribution of the sample holder. Corrections for the diamagnetic response of the compounds, due to closed atomic shells as estimated from the Pascal's constants, were applied [10].

Metal analysis was carried out electrogravimetrically with Pt electrodes. *C,H,N* analysis was performed with a Perkin–Elmer, Elemental Analyzer 2400 CHN. Infrared spectra were measured on mineral oil mulls, using a Perkin–Elmer FT-IR 1720X spectrometer. Electronic spectra were recorded as nujol mulls with a Perkin–Elmer UV/Vis/NIR spectrometer Lambda 19. EPR spectra of the powdered samples were recorded by a Bruker ESP-300

spectrometer, operating at X-band at room temperature and at 100 K. The values of parameters g were calculated directly from the signal positions in the spectra.

3. Results and discussion

The crystal structure analysis of $[Cu(\mu\text{-}HCO_2)_2(3\text{-}pyOH)]_n$ (**1**) (*katena-bis-(μ-methanoato-O,O′)-(3-hydroxypyridine-N)copper(II)*) reveals a polynuclear structure of Cu and 3-hydroxypyridine (3-pyOH) moieties (Cu–N 2.016(2) Å) bridged by four methanoates (Fig. 1). Due to the symmetry relations, only two different methanoates are in the structure. One coordinates *syn-anti* (Cu–O21′ 1.974(2), Cu–O22 1.960(2), Cu···Cu (4.690(1) Å), while the other *anti-anti* (Cu–O11 1.945(2), Cu–O12′ 2.247(2), Cu···Cu 5.935(1) Å). The coordination sphere around the copper(II) atom is square-pyramidal with N–Cu–O21′ and O11–Cu–O22 coordination axes and O12′ on the top of the pyramid. The methanoate bridges enable a layered structure, while 3-pyOH is involved only in an inter-layer H-bonding network (O41(H41)···O12 2.692(2) Å).

Two copper(II) atoms in the dinuclear central core of $[Cu_2(\mu\text{-}HCO_2)_2(\mu\text{-}3\text{-}pyOH)_2(3\text{-}pyOH)_2(HCO_2)_2]_n$ (**2**) (*katena-bis-(μ-3-hydroxypyridine-O,N)-bis-(μ-methanoato-O)-(methanoato-O)-(3-hydroxypyridine-N)dicopper(II)*) are connected by two monoatomic non-symmetric methanoate bridges (Cu–O41 1.986(2), Cu′–O41 2.415(2) Å, Cu–O41–Cu′ 102.50(4)°; Fig. 2). Two additional monodentate methanoates (Cu–O31 1.975(2) Å) are on the terminal positions of the dinuclear unit, *trans* to the closer bridging methanoate oxygen atom (O41). Two 3-pyOH ligands are coordinated *trans* on each copper atom, and thus are perpendicular to the copper–methanoate plane (Cu–N1 2.005(2), Cu–N2 2.002(2) Å) and complete the dinuclear unit. The so far described coordination sphere of **2** is very similar to that reported for $[\{Cu(tzq)_2(HCO_2)\}_2((\mu\text{-}HCO_2)_2]\cdot 4H_2O$ (tzq = [1,2,3]triazolo[1,5-a]quinoline) [13]. A shorter intra-dinuclear Cu···Cu distance in the tzq complex (3.339(2) Å) than in **2** (3.442(1) Å) is likely to be due to a stronger π···π interaction (tzq complex: $12\pi e^-$/ligand;

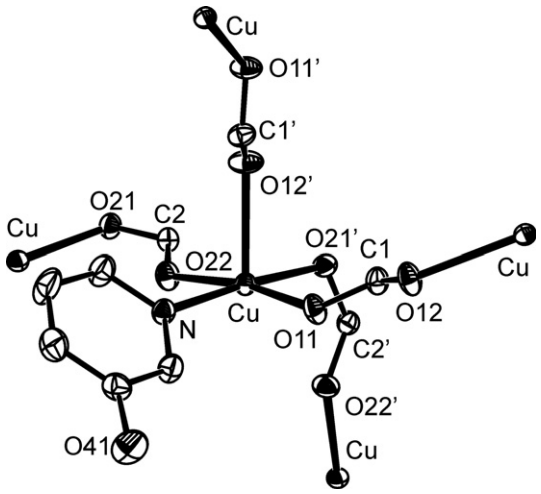

Fig. 1. Two types of four methanoate bridges among the Cu-3-pyOH moieties in the polymeric structure of **1** [11,12] (Cu···Cu: *syn–anti* 4.690(1) Å, *anti–anti* 5.935(1) Å). All H-atoms are omitted for clarity.

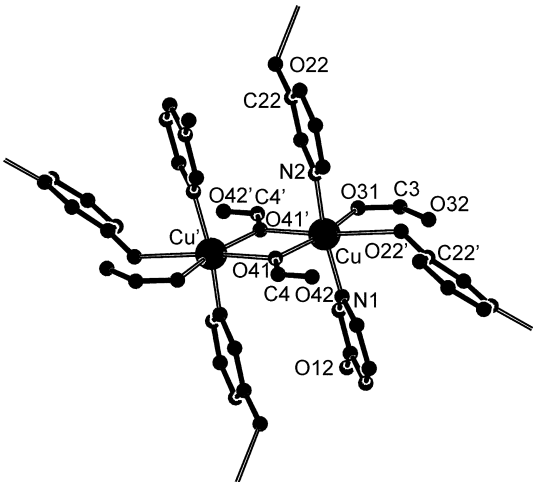

Fig. 2. A dinuclear unit in the structure of **2** bridged by 3-pyOH molecules, forming a 2D network (Cu···Cu′ 3.442(1) Å) [11,12]. All H-atoms are omitted for clarity.

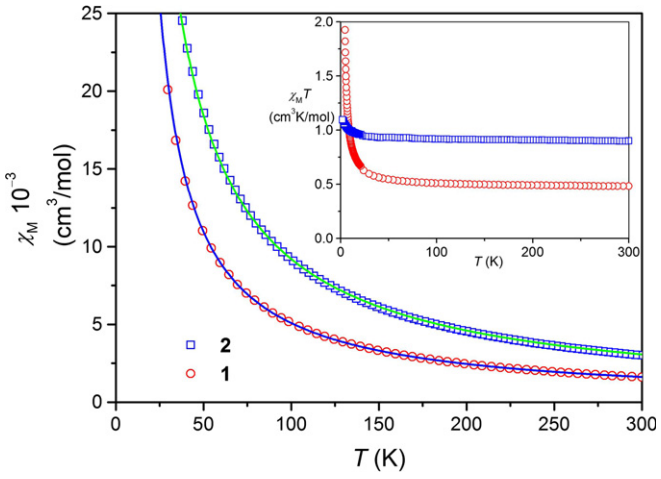

Fig. 3. The magnetic properties χ_M and $\chi_M T$ (inset) of the title compounds, measured in 50 kOe. The full lines in the graph χ_M correspond to the Curie–Weiss law.

2: 6πe⁻/ligand). The dinuclear units in the tzq complex are inter-molecularly H-bonded by water molecules, while in **2**, they are connected by 3-pyOH molecules. Two 3-pyOH molecules, strongly bonded inside one dimer in **2**, are thus additionally semi-coordinated to the apical position of the adjacent dimers (Cu–O22′ 2.732(2) Å) forming inter-dinuclear bridges. The hydroxo oxygen atom O22′ coordinates *trans* to the more distant bridging methanoate atom O41′, completing the elongated Jahn–Teller axis (Fig. 2, Table 2). This inter-dinuclear bridge is additionally strengthened by a strong H-bond between the hydroxo group and the non-coordinated terminal methanoato oxygen atom (O22′(H22′)···O32 2.540(2) Å). Such a poly-dinuclear structure shows a 2D network, H-bonded between adjacent layers via non-coordinated oxygen atoms of the bridging methanoates, and those 3-pyOH hydroxo groups not involved in the semi-coordination (O12(H12)···O42 2.695(2) Å). Additional stabilization inside the dinuclear units is found in π–π stacking (cg···cg 3.878(2) Å, mean interplanar separation 3.537, 3.506 Å) of the 3-pyOH rings.

The molar magnetic susceptibility χ_M of compounds **1** and **2**, increases with decreasing temperature, while the product $\chi_M \cdot T$ is approximately constant in the temperature interval from 300 K to 50 K, indicating a paramagnetic behaviour (Fig. 3) [14]. High temperature susceptibility data χ_M (above 50 K) were fitted with the Curie–Weiss law: $\chi_M = C/(T-\theta)$. The Curie constant C and the Weiss constant θ are 0.47, 0.92 cm^3 K/mol and 6.6, 0 K for **1** and **2**, respectively. Below 50 K, $\chi_M T$ remains almost constant for **2**, and only a very weak ferromagnetic interaction is noticed (inset in Fig. 3). On the contrary, $\chi_M T$ for **1** significantly increases below 20 K, and the magnetic susceptibility $\chi_M(M/H)_{H\to 0} = 14$ cm^3/mol (2 K) is much higher than expected for non-interacting $S = 1/2$ spins of Cu^{II}. In a small magnetic field strength H, the magnetization M_M of **1** linearly increases, however at 1 kOe the $\mu_a(H)$ dependence becomes non-linear and M_M saturates at $H \sim 20$ kOe (Fig. 4). The magnetization saturation is 1.07 μ_B per Cu^{II} atom, showing that all Cu^{II} atoms in the sample contribute to specific magnetic properties of the sample. No hysteresis loop for the $\mu_a(H)$ dependence was detected. Due to a large increase of χ_M below 20 K, $\theta = 6.6$ K, and an "S" shaped curve $\mu_a(H)$ at 2 K with an absence of hysteresis, a soft ferromagnetic behaviour at low temperature for **1** is clearly noticed.

Magnetic interactions among non-diluted copper(II) atoms have been described frequently, however mostly for dicopper tetracarboxylates with a strong antiferromagnetic interaction. In those *paddle-wheel* structures, the carboxylates coordinate bidentately in a *syn–syn* mode. The coordination sphere is square-pyramidal with the magnetic Cu^{II} orbital $d_{x^2-y^2}$ oriented towards four bridging carboxylates and the non-magnetic d_{z^2} towards the apical ligand [15–17]. This agrees with the magnetic interaction between

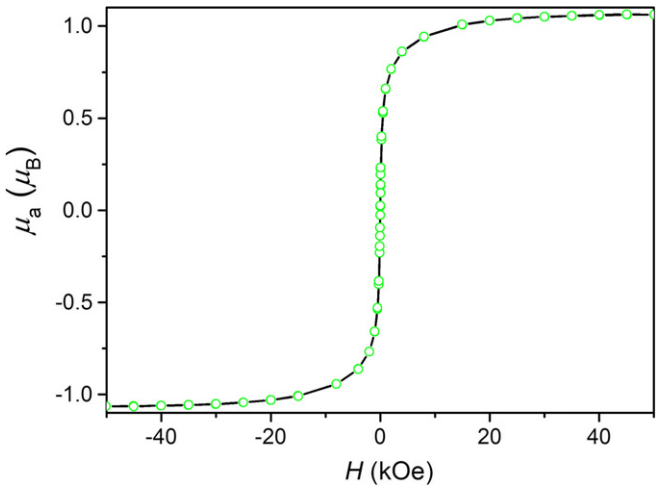

Fig. 4. The magnetization $\mu_a(H)$ for Cu^{II} (S = 1/2) species in **1**, calculated per 1 copper atom and measured at 2 K.

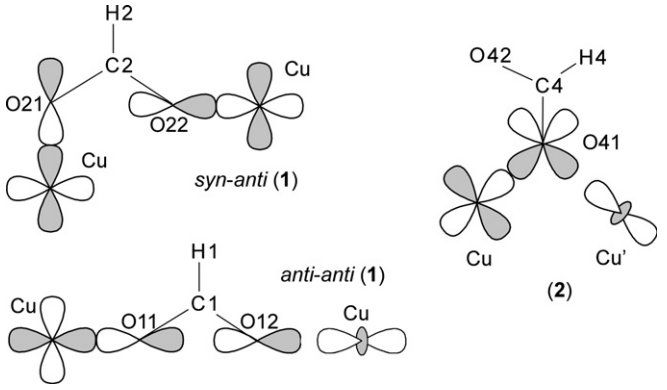

two $S = 1/2$ spins of two Cu^{II} always found only inside the dinuclear unit. Although such dinuclear moieties are often connected by various types of bridges, no inter-dinuclear interactions via $S = 1/2$ were confirmed, but sometimes suggested via $S = 1$ joint dinuclear spins ($2 \times Cu^{II}$) [18,19]. Some evidence for these interactions may be found in the EPR spectra. If less than four carboxylates bridge two Cu^{II} atoms, a significant reduction of the magnetic interaction is observed [17,20–22], despite the magnetic $d_{x^2-y^2}$ orbitals involved on both sides of the bridge. Theoretically, for the *syn-anti* carboxylate bridged models [17], a weak ferromagnetic interaction was calculated, while a weak antiferromagnetic for the *syn–syn* bridge and a moderate antiferromagnetic for the *anti–anti* models. The reported complexes with the less common *syn–anti* bridging mode show ferromagnetic or antiferromagnetic properties, with small magnitudes of their exchange coupling constants J [23–29]. Generally, the exchange interaction is a combination of two components, negative antiferromagnetic and positive ferromagnetic ($J = J_{AF} + J_F$) [30]. The J_{AF} magnitude is proportional to the square of the overlap integral between the magnetic orbitals centred on the adjacent metal atoms, while for the J_F, it is governed by the overlap density between the magnetic orbitals [31]. Polyatomic extended ligands thus reduce the ferromagnetic contribution. The unfavourable overlap of the *syn–anti* oriented ligand orbitals [23] and non-planarity of the bridging network significantly reduce especially the antiferromagnetic part, to the extent that the ferromagnetic one becomes predominant [27,32].

Such an explanation fits both the herein analyzed compounds **1** and **2**. In **1**, the *anti–anti* methanoates (Cu–O11–C1–O12–Cu) connect the non-magnetic d_{z^2} with the magnetic $d_{x^2-y^2}$ Cu^{II} orbitals, while the *syn–anti* type (Cu–O21–C2–O22–Cu) enables the ferromagnetic interaction, since it connects the $d_{x^2-y^2}$ magnetic orbitals only (Scheme 1). This interaction between the magnetic orbitals is not limited to two Cu atoms, but is extended in a chain, due to two *syn–anti* bridges from a *cis* position of each Cu atom to two adjacent Cu atoms (Fig. 1). The *syn–anti* connected Cu atoms are pushed out of the O–C–O bridge plane by 0.105(1) and 0.398(1) Å, respectively, thus the Cu–O21–C2–O22–Cu skeleton deviates from planarity, in accordance with an absence of an antiferromagnetic interaction in **1**. A weak interaction between the nearest Cu^{II} neighbours can be treated as a small perturbation added to the Zeeman term: $\widehat{H} = -z2J\widehat{S}_1 \cdot \widehat{S}_2$, where z is the number of nearest neighbours and $2J$ is the interaction parameter between them [33,34]. Due to the two magnetically interacting nearest neighbours ($z = 2$) found in the structure of **1**, $2J/k_B = 9.2\ cm^{-1}$ can be calculated (Eq. (1))

$$2J = \frac{3k_B\theta}{zS(S+1)} \tag{1}$$

In the structure of **2**, the monoatomic methanoate and the 3-pyOH molecule bridges are present, however they all connect the magnetic $d_{x^2-y^2}$ (Cu–O41(equatorial) 1.986(1) Å) and the non-magnetic d_{z^2} Cu^{II} orbitals (Cu′-O41(axial) 2.415 (1) Å) (Scheme 1). Therefore, they do not enable a magnetic interaction of the same magnitude as found in **1** despite the shorter Cu···Cu distance (4.690(1) Å **1**, 3.442(1) Å **2**). Actually, the inset in Fig. 3 shows a very weak ferromagnetism for **2**, and the interaction more likely takes place through the methanoates than 3-pyOH due to a shorter length of such bridges. This weak interaction may be possible by some admixture of d_{z^2} character with the $d_{x^2-y^2}$ type of Cu(II) orbital, where the unpaired electron lies primarily. A significant octahedral distortion of the copper coordination sphere in **2** (see Table 2) strongly supports such a theory. A very weak ferromagnetism in **2** and a weak antiferromagnetism in the related $[\{Cu(tzq)_2(HCO_2)\}_2(\mu\text{-}HCO_2)_2] \cdot 4H_2O$ [13] may be correlated with different distances and almost the same angle in their monoatomic Cu–O–Cu bridges (tzq: 1.950(4), 2.331(4) Å, 102.2(2)°; **2**: 1.986(1), 2.415(1) Å, 102.5(2)°). Longer distances in **2** reduce the magnetic orbital overlap, and thus the antiferromagnetic contribution to the extent that ferromagnetism predominates. A numerical analysis to predict the antiferromagnetic or the ferromagnetic properties of dicopper complexes with two monoatomic chlorine bridges has been introduced [22,29]. The higher value ϕ/R (angle Cu–Cl–Cu = ϕ, Cu–Cl axial distance = R) suggests antiferromagnetism, while lower value ferromagnetism. The ϕ/R values 42.4 (**2**) and 43.8 (tzq) °/Å thus fit with the measured magnetic properties of **2** and the tzq complex.

The EPR spectrum of **1** (298 K) shows one signal ($g = 2.150(3)$), revealing pseudo isotropic symmetry of the complex and the presence of an isolated paramagnet with $S = 1/2$. Similar was observed for another Cu ferromagnetic complex with a *syn–anti* carboxylate bridge [27]. On the other hand, two axial symmetry signals ($g_\parallel = 2.257(3)$, $g_\perp = 2.100(3)$) are found in the spectrum of **2**. Significantly longer Cu–L distances for the z-axis oriented ligands in **2** than in **1** are thus in agreement with the EPR spectra. The

Scheme 1. A relative orientation of the magnetic $d_{x^2-y^2}$ and non-magnetic d_{z^2} Cu^{II} orbitals and their interactions through the methanoate bridges in **1** and **2**. Every d_{z^2} orbital is shifted away from the ligand bonding p orbital to stress a longer Cu–O distance in the axial direction.

spectra of both compounds do not change by decrease of temperature to 100 K, and they are consistent with the magnetic susceptibility analysis. A full correlation was not done, due to unavailability of the EPR experiment below 100 K. On the other hand, some comparison was done for the structurally related $[Cu_2(\mu\text{-}HCO_2)_2(\mu\text{-}3\text{-}pyOH)_2(3\text{-}pyOH)_2(HCO_2)_2]_n$ (**2**) and $[\{Cu(tzq)_2(HCO_2)\}_2(\mu\text{-}HCO_2)_2]\cdot 4H_2O$ [13]. Different spectra were recorded at room temperature, only two signals ($H_{\|}$ and $H_{\perp}$) are found for **2**, while the $\Delta M_s \pm 2$ resonance and four $\Delta M_s \pm 1$ signals are reported for the tzq complex. These differences are related to the observations described by the magnetic susceptibility analysis.

4. Concluding remarks

The coordination compound $[Cu(\mu\text{-}HCO_2)_2(3\text{-}pyOH)]_n$ (**1**) shows triatomic methanoate bridges of *anti–anti* and *syn–anti* mode. On the other hand, $[Cu_2(\mu\text{-}HCO_2)_2(\mu\text{-}3\text{-}pyOH)_2(3\text{-}pyOH)_2(HCO_2)_2]_n$ (**2**) reveals only monoatomic methanoate coordination, either to one Cu atom or bridging inside the dinuclear moiety. Additionally, one half of the 3-pyOH molecules also serve as bridges, connecting the adjacent dinuclear units in **2** in a poly-dinuclear network. A ferromagnetic interaction is found in both complexes, however, this is significantly important only for **1** ($2J = 9.2\ cm^{-1}$). This interaction takes place via the *syn–anti* methanoates, due to the magnetic Cu(II) $d_{x^2-y^2}$ orbitals on both sides of the bridge. In all the other bridging cases in **1** and **2**, the non-magnetic d_{z^2} orbital is always involved. Such a ferromagnetic interaction in **1** is also in agreement with a medium sized length of the triatomic O–C–O *syn–anti* bridge and non-planarity of its Cu–O–C–O–Cu skeleton.

Abstract

The preparation and characterization by spectroscopic and electrochemical techniques of new dinuclear complexes of the type $[(tpm)(bpy)Ru^{II}(L)Ru^{II/III}(NH_3)_5]^{4+/5+}$ (bpy = 2,2′-bipyridine), tpm = tris(1-pyrazolyl)methane, L = pz (pyrazine), 4,4′-bpy (4,4′-bipyridine), BPE (*trans*-1,2-bis(4-pyridyl)ethylene) and PCA (= 4-pyridinecarboxaldehyde azine), are described in this work. The analysis of the visible spectral data for the metal-to-metal charge transfer (MMCT) bands in the corresponding mixed-valent species $[Ru_b^{II}, Ru_a^{III}]$ (Ru_b = Ru bonded to bpy; Ru_a = Ru bonded to NH_3) allows the determination of the reorganization energies λ and electronic coupling elements H_{AB} for the intramolecular electron transfers $Ru_b^{II} \rightarrow Ru_a^{III}$ mediated by L. An increased transmission of the metal-to-metal electronic interaction is disclosed for this series, when comparing the distance dependence of H_{AB} to that of the analogous series with trpy (2,2′:6′,2″-terpyridine) acting as a spectator ligand instead of tpm.

Keywords: Mixed valence; Scorpionate ligands; Ruthenium dinuclear complexes; Electronic interaction; Intervalence transitions

1. Introduction

The distance dependence of intramolecular electron transfer parameters in mixed-valence complexes is an important issue in connection to artificial photosynthesis [1]. The magnitude and the mechanism of the donor–acceptor electronic interactions can be tuned by changing the bridge and/or the co-ligands [2].

We have recently described the syntheses and spectroscopic, electrochemical and photophysical properties of mononuclear complexes of the type $[Ru(bpy)(L)(tpm)]^{2+}$, with bpy = 2,2′-bipyridine, tpm = tris(1-pyrazolyl)methane, L = pz (pyrazine), 4,4′-bpy (4,4′-bipyridine) and BPE (*trans*-1,2-bis(4-pyridyl)ethylene) [3]. These species have now been used as building blocks for new unsymmetric ruthenium complexes of formulae $[(tpm)(bpy)Ru^{II}(L)Ru^{II}(NH_3)_5]^{4+}$, with L = pz (**1**), 4,4′-bpy (**2**), BPE (**3**) and PCA (**8**), and $[(tpm)(bpy)Ru^{II}(L)Ru^{III}(NH_3)_5]^{5+}$, with L = pz (**4**), 4,4′-bpy (**5**), BPE (**6**) and PCA (**9**), on which a few preliminary results were reported [3]. The additional bridging ligand PCA (4-pyridinecarboxaldehyde azine) has also been included for comparison purposes [4]. Besides, the new mononuclear complex $[Ru(bpy)(PCA)(tpm)]^{2+}$ (**7**), has been synthesized and characterized. The main objective in this work is the determination of the influence of metal–metal distance on the reorganization energies and electronic coupling elements for the L-mediated intramolecular electron transfers in the mixed-valent species $[Ru_b^{II}, Ru_a^{III}]$ (where Ru_b = Ru bonded to bpy; Ru_a = Ru bonded to NH_3).

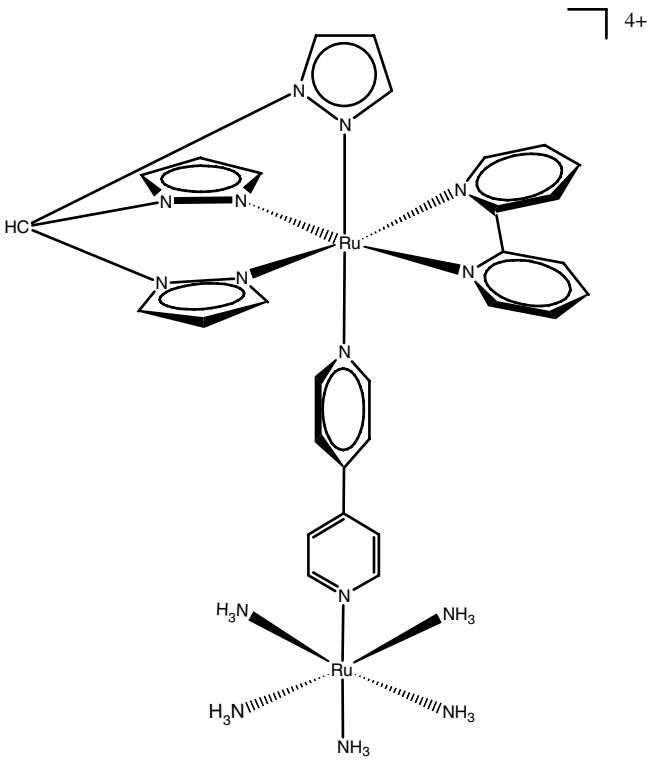
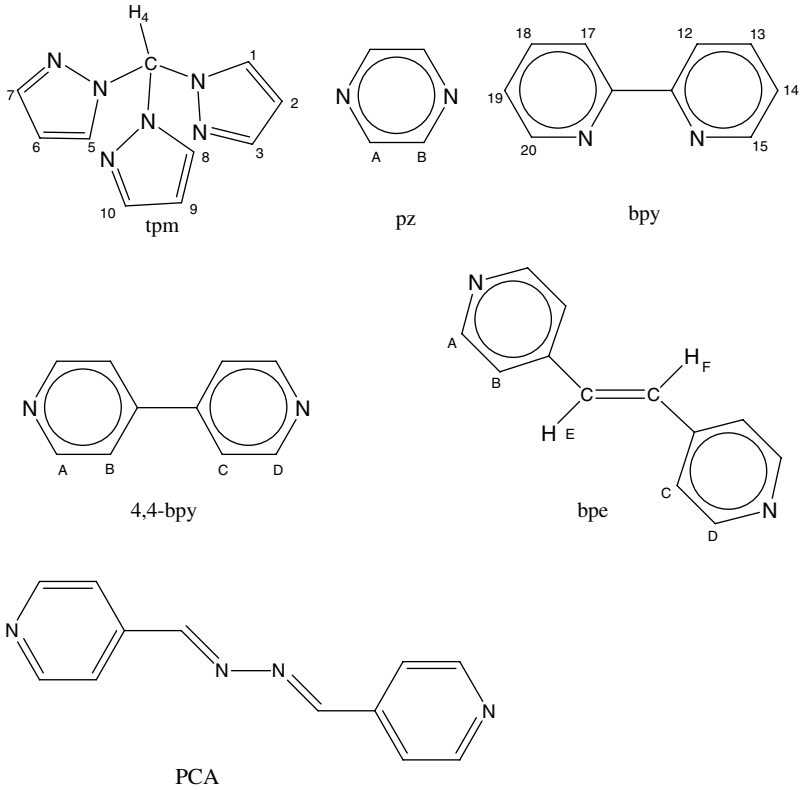
In a previous work [5], we have studied the series $[(trpy)(bpy)Ru^{II}(L)Ru^{II/III}(NH_3)_5]^{4+/5+}$, with, trpy = 2,2′:6′, 2″-terpyridine, L = pz, 4,4′-bpy and BPE. In this work, we report the syntheses and characterization by spectroscopic and electrochemical techniques of the analogous tpm complexes, in order to establish the degree of influence of ligand electronic properties and geometry when going from a meridional (trpy) to a facial (tpm) coordination. Scheme 1 shows the structures of the ligands used in this work and Scheme 2 shows the structure of complex **2** as a representative example.



2. Experimental

2.1. Preparations



All synthetic manipulations were routinely performed under a nitrogen atmosphere using Schlenk tubes and vacuum line techniques. Electrochemical experiments were performed in the dark under a N_2 or Ar atmosphere with degassed solvents.

2.2. Syntheses

Complexes of formulae $[(tpm)(bpy)Ru^{II}(L)Ru^{II}(NH_3)_5](PF_6)_4$ (with L = pz (**1**), 4,4′-bpy (**2**), BPE (**3**) and PCA (**8**)) have been prepared by the following technique: 0.2 g of $[Ru(tpm)(bpy)(L)](PF_6)_2$, prepared as in Ref. [3], or by refluxing for 2 h $[Ru(tpm)(bpy)(H_2O)](PF_6)_2$ with an excess of L in MeOH, were mixed with an equimolar amount of $[Ru(NH_3)_5(H_2O)](PF_6)_2$, obtained as in Ref. [5], in 10 mL of acetone, under Ar in the dark and using

Scheme 2. Structure of complex **2**.

Scheme 1. Structure of the ligands.

Schlenk techniques. After stirring the mixture for 4 h at room temperature, the desired complexes were precipitated with 50 mL of ether, filtered, washed with ether and dried under vacuo over P_4O_{10}. Purification was achieved by chromatography in Sephadex LH-20. Yields were between 70% and 80%. Elution of the dinuclear species were performed with CH_3CN. After rotoevaporating to complete dryness, samples were re-precipitated from acetone/ether.

2.2.1. [(tpm)(bpy)Ru(pz)Ru(NH_3)$_5$](PF_6)$_4$·0.5(CH_3)$_2$CO (1)

Anal. Calc. for $C_{25.5}H_{40}F_{24}N_{15}O_{0.5}P_4Ru_2$ (1346.7): C, 22.7; H, 3.0; N, 15.6. Found: C, 22.5; H 2.9; N 15.7%.

2.2.2. [(tpm)(bpy)Ru(4,4′-bpy)Ru(NH_3)$_5$](PF_6)$_4$·(CH_3)$_2$CO (2)

Anal. Calc. for $C_{33}H_{47}F_{24}N_{15}OP_4Ru_2$ (1451.8): C, 27.3; H, 3.3; N 14.5. Found: C, 27.3; H 3.1; N 14.9%. ^{1}H NMR (500 MHz, CD_3CN, 25 °C): δ, 6.31 (dd, 1, $J_{9-10} = 3.0$ Hz, $J_{9-8} = 2.2$ Hz, H_9), 6.59 (d, 1, $J_{9-10} = 2.2$ Hz, H_{10}), 6.78 (dd, 1, $J_{2-1} = 2.1$ Hz, $J_{2-3} = 3.0$ Hz H_2), 7.50 (d, 2, $J_{C-D} = 6.8$ Hz, H_C), 7.54 (o, 2, H_B), 7.55 (o, 2, H_A), 7.57 (dd, 2, $J_{13-14} = 8.8$ Hz, $J_{15-14} = 6.0$ Hz, H_{14}), 7.95 (d, 2, $J_{3-2} = 2.1$ Hz, H_3), 8.23 (dd, 2, $J_{12-14} = 8.8$ Hz, $J_{12-13} = 8.1$ Hz, H_{13}), 8.38 (d, 1, $J_{8-9} = 3.0$ Hz H_8), 8.51 (d, 2, $J_{D-C} = 6.8$ Hz, H_D), 8.57 (d, 2, $J_{1-2} = 3.0$ Hz, H_1), 8.67 (d, 2, $J_{15-14} = 6.0$ Hz, H_{15}), 8.79 (d, 2, $J_{12-13} = 8.1$ Hz, H_{12}), 9.06 (s, 1, H_4) ppm. ^{13}C NMR (500 MHz CD_3CN, 25 °C): δ, 75.9 (C_4), 108.7 (C_9), 110 (C_2), 120.7 (C_B) 121.4 (C_C), 125.1 (C_{12}), 126.5 (C_{14}), 135.6 (C_8), 135.9 (C_1), 137.8 (C_{13}), 144.1 (C_{10}), 147.4 (C_3, C_D), 152.8 (C_{15}), 154.1 (C_A) ppm.

2.2.3. [(tpm)(bpy)Ru(BPE)Ru(NH_3)$_5$](PF_6)$_4$·(CH_3)$_2$CO (3)

Anal. Calc. for $C_{35}H_{49}F_{24}N_{15}OP_4Ru_2$ (1477.9): C, 28.5; H, 3.3; N 14.2. Found: C, 28.6; H 3.1; N, 15.0%. ^{1}H NMR (500 MHz, CD_3CN, 25 °C): δ, 6.30 (dd, 1, $J_{9-8} = 2.8$ Hz, $J_{9-10} = 2.0$ Hz H_9), 6.58 (dd, 1, $J_{9-10} = 2.0$ Hz, $J_{10-8} = 2.8$ Hz H_{10}), 6.77 (dd, 2, $J_{2-3} = 2.0$ Hz $J_{2-1} = 2.6$ Hz H_2), 7.27 (d, 2, $J_{B-A} = 6.75$Hz H_B), 7.35(d overlapped, 1, H_E), 7.39 (d overlapped, 1, H_F), 7.43 (d, 2, $J_{B-A} = 6.75$ Hz H_A), 7.47 (d, 2, $J_{C-D} = 6.0$ Hz, H_C), 7.54 (dd, 2, $J_{14-15} = 5.7$ Hz, $J_{14-13} = 7.8$ Hz, H_{14}), 7.96 (d, 2, $J_{2-3} = 2.0$ Hz H_3), 8.21 (dd, 2, $J_{14-13} = 7.8$ Hz, $J_{12-13} = 8.2$ Hz, H_{13}), 8.37 (t, 1, $J_{9-8} = 2.8$ Hz, H_8), 8.55 (d 2.6 Hz, 2, H_1), 8.59 (d, 2, $J_{C-D} = 6.0$ Hz, H_D), 8.65 (d, 2, $J_{14-15} = 5.7$ Hz, H_{15}), 8.76 (d, 2, $J_{12-13} = 8.2$ Hz H_{12}), 9.02 (s, 1, H_4) ppm. ^{13}C NMR (500 MHz, CD_3CN, 25 °C): δ, 76.0 (C_4), 108.7 (C_9), 110.0 (C_2), 122.1 (C_B), 125 (C_{12}), 126.4 (C_{14}), 128.0 (C_{12}), 128.7 ($C_{E,F}$), 135.7 (C_8), 135.8 (C_1), 138 (C_{13}), 143.8 (C_{10}), 147.3 (C_3), 150.7 (C_D), 152.9 (C_{15}), 153.3 (C_A) ppm.

The mixed-valent species [(tpm)(bpy)Ru^{II}(L)Ru^{III}-(NH_3)$_5$]$^{5+}$ (L = pz (**4**), 4,4′-bpy (**5**), and BPE (**6**)) were generated *in situ* by adding Br_2 vapour to an acetonitrile solution of (**1**), (**2**) and (**3**), respectively, or by bulk electrolysis at 0.5–0.8 V in CH_3CN, 0.1 M TBAH.

2.2.4. [(tpm)(bpy)Ru(PCA)](PF_6)$_2$·4H_2O (7)

Anal. Calc. for $C_{32}H_{36}F_{12}N_{12}O_4P_2Ru$ (1043.7): C, 36.8; H, 3.5; N 16.1. Found: C, 36.9; H, 3.0; N 15.4%.

The corresponding dinuclear complexes [(tpm)(bpy)-Ru^{II}(PCA)Ru^{II}(NH_3)$_5$]$^{4+}$ (**8**) and [(tpm)(bpy)Ru^{II}(PCA)-Ru^{III}(NH_3)$_5$]$^{5+}$ (**9**) were obtained and characterized in solution by procedures similar to those already described for the other complexes.

2.3. Equipments and techniques

All used chemicals were reagent grade. CH_3CN was freshly distilled for electrochemical measurements. UV–Vis spectra were recorded with Shimadzu UV-160A and Cary 50 spectrophotometers. IR spectra were performed on a Perkin–Elmer 983G spectrophotometer. Cyclic voltammetry experiments were carried out in CH_3CN, using a BAS Epsilon EC equipment, with Ag/AgCl (3 M KCl) as reference electrode, vitreous C as working electrode, Pt wire as auxiliary electrode and 0.1 M TBAH [tetrakis-(*n*-butyl)ammonium hexafluorophosphate] as supporting electrolyte. A special OTTLE cell designed by BAS was used for the spectroelectrochemical measurements. All NMR data were recorded in CD_3CN with a Bruker 500 MHz spectrometer. 2D COSY, 2D HSQC and 2D NOESY (mixing time 500 ms) experiments were collected in routine conditions. Chemical Analyses were carried out at INQUIMAE, UBA, Argentina, with an estimated error of ±0.5%.

3. Results and discussion

3.1. Synthesis and IR spectra

All dinuclear complexes of the type [(tpm)(bpy)Ru(L)-$Ru(NH_3)_5$](PF_6)$_4$ (with L = pz, 4,4′-bpy, BPE and PCA) were prepared by mixing stoichiometric amounts of [Ru(tpm)(L)(bpy)](PF_6)$_2$ and [$Ru(NH_3)_5(H_2O)$](PF_6)$_2$ in acetone under Ar for 2 h, with subsequent purification by standard chromatographic techniques, as described in the experimental section. The mixed-valent species were synthesized *in situ* by adding excess of bromine to CH_3CN solutions of the reduced complexes, since the redox potential of the Br_2/Br_2^- couple is higher than that of the Ru_b^{III}, Ru_a^{II} couple but lower than that of the Ru_a^{III}/Ru_b^{II} couple (vide infra) [6].

IR spectra (as KBr pelletes) of **1**, **2**, and **3** show characteristic ligand vibrations between 1600 and 600 cm^{-1}. The typical ammonia symmetric deformation frequencies $\delta_{sym}(NH_3)$ appear in these complexes at 1287, 1286 and 1286 cm^{-1}, respectively, indicating oxidation

states (II) for all ruthenium atoms bonded to amines (= Ru_a) [5].

3.2. NMR spectra

Fig. 1 shows the ^1H NMR spectrum of $[(tpm)(bpy)Ru^{II}(BPE)Ru^{II}(NH_3)_5]^{4+}$ in CD_3CN at 500 MHz, as a representative example. NMR chemical shifts are closely related to those reported [3] for the mononuclear species of the type $[Ru(tpm)(L)(bpy)]^{2+}$, confirming the molecular symmetry of the complexes and the relative position of each coordinating position of all N-containing ligands around the first Ru center. The effect of the additional $Ru(NH_3)_5$ moiety has minor effects on chemical shift values. All NMR data have been confirmed and fully assigned by using 2D COSY, HSQC and NOESY experiments.

3.3. Redox properties

The electrochemical measurements in CH_3CN (0.1 M TBAH) for complexes **1**, **2** and **3** show in the oxidative range of potentials two reversible redox waves that can be assigned to the couples Ru_b^{III}/Ru_b^{II} ($E_{1/2} = 1.30$, 1.21 and 1.19 V, versus SCE, for the species bridged by pz, 4,4′-bpy and BPE, respectively) and Ru_a^{III}/Ru_a^{II} ($E_{1/2} =$ 0.46, 0.35 and 0.35 V, versus SCE, for the same species, respectively). The redox potentials for the Ru_b^{III}/Ru_b^{II} couples decrease in the order pz > 4,4′-bpy > BPE, evidencing the decreasing order of π-backbonding effects from Ru_b to the L ligands, as demonstrated before for the corresponding mononuclear precursors $[Ru(tpm)(L)(bpy)]^{2+}$ ($E_{1/2} =$ 1.20, 1.15 and 1.10 V, versus SCE, for L = pz, 4,4′-bpy and BPE, respectively) [3]. The higher values obtained here for the dinuclear species can be attributed to their higher charges. On the other hand, the values of the redox potentials for the Ru_a^{III}/Ru_a^{II} couples are consistent with those already obtained in the analogous $[(trpy)(bpy)Ru^{II}(L)Ru^{II/III}(NH_3)_5]^{4+/5+}$ series ($E_{1/2} = 0.66$, 0.39 and 0.31 V, versus SCE, for L = pz, 4,4′-bpy and BPE, respectively) [5]. When comparing these values to those of the mononuclear complexes $[Ru(NH_3)_5(L)]^{2+}$, a small increase in $E_{1/2}$ is observed when pz is the bridging ligand, but almost no changes are detected when BPE is the bridging ligand [5]. Complex **8** (with PCA as a bridging ligand) exhibits values of $E_{1/2}$ at 1.21 and 0.41 V, versus SCE, for the Ru_b^{III}/Ru_b^{II} and Ru_a^{III}/Ru_a^{II} couples, respectively, indicating electronic π-backbonding effects intermediate between those of pz and 4,4′-bpy. Fig. 2 shows the CV of complex **8**, as a representative example of this series.

3.4. UV–Vis spectra

Fig. 3 shows the UV–Vis spectrum of complex **3** in CH_3CN, as a representative example.

Table 1 shows the UV–Vis absorption spectral data of complexes **1**, **2**, **3** and **8** in CH_3CN. The bands observed between 200 and 300 nm can be assigned to intraligand $\pi \rightarrow \pi^*$ absorptions [3,5]. The bands at $\lambda_{max} = 397$, 416, 420 and 444 nm (corresponding to L = pz, 4,4′-bpy, BPE and PCA, respectively) are readily assigned to MLCT (metal-to-ligand charge transfer) transitions $d_\pi(Ru_b) \rightarrow \pi^*(bpy)$ of lowest energy, since these values are similar to those obtained for the mononuclear species $[Ru(tpm)(L)(bpy)]^{2+}$ ($\lambda_{max} = 392$, 395, 410 and 430 nm, corresponding to L = pz, 4,4′-bpy, BPE and PCA, respectively) [3]. The bands at $\lambda_{max} = 510$, 514, 523 and 545 nm (for L = pz, 4,4′-bpy, BPE and PCA, respectively), which disappear upon addition of Br_2 vapour, can be assigned to MLCT transitions d_π (Ru_a) → $\pi^*(L)$. These latter bands, as the former ones, are shifted to lower energies than the corresponding ones in $[Ru(NH_3)_5L]^{2+}$ complexes ($\lambda_{max} = 455$, 470, 500 and 536 nm for pz, 4,4′-bpy, BPE and PCA, respectively) [4,7], indicating a considerable decrease in the energies of the d–π^* excited states when connecting a second metallic center to the free N of the bridging ligand.

In the mixed-valent species **4**, **5**, **6** and **9**, the lowest energy bands of **1**, **2**, **3** and **8** disappear completely and new bands appear at 790, 680, 674 and 630 nm (values determined by gaussian deconvolution) for L = pz, 4,4′-bpy, BPE and PCA, respectively, due to MMCT

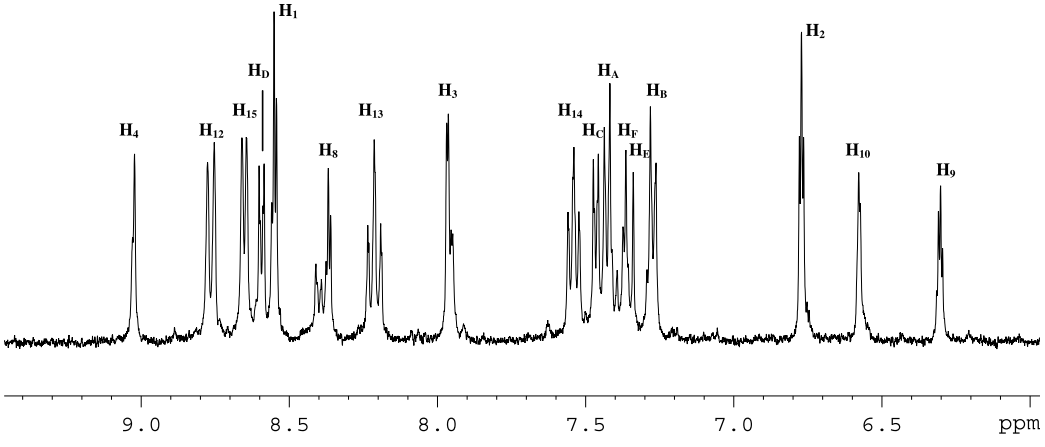


Fig. 1. ^1H NMR spectrum of $[(tpm)(bpy)Ru^{II}(BPE)Ru^{II}(NH_3)_5]^{4+}$, in CD_3CN, at 500 MHz.

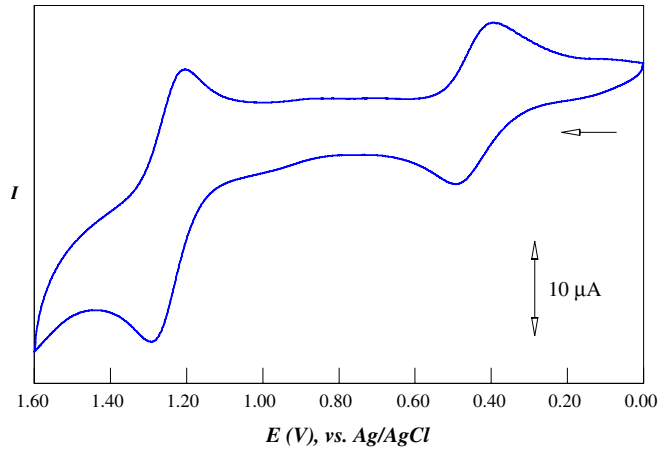

Fig. 2. Cyclic voltammogram of $[(tpm)(bpy)Ru^{II}(PCA)Ru^{II}(NH_3)_5]^{4+}$, in CH_3CN, 0.1 M TBAH, $v = 100$ mV s^{-1}.

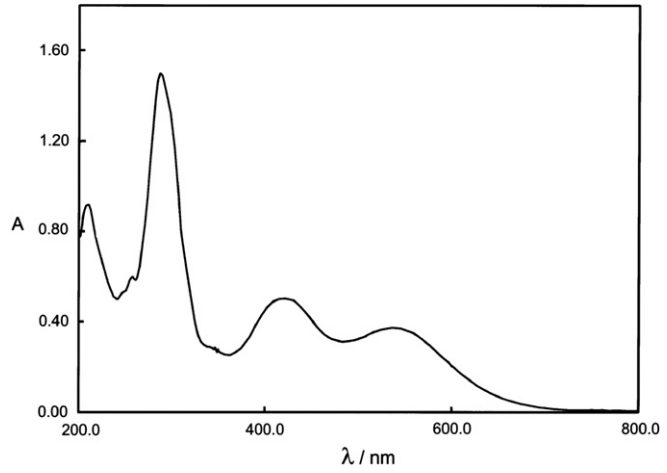

Fig. 3. UV–Vis spectra of $[(tpm)(bpy)Ru^{II}(BPE)Ru^{II}(NH_3)_5]^{4+}$, in CH_3CN, at room temperature ($C = 2.8 \times 10^{-5}$ M).

Table 1

pz	**1**	510 (14.0), 397 (10.6), 338 (sh), 284 (31.1), 224 (18.9)
4,4′-bpy	**2**	508 (17.8), 416 (15.0), 337 (sh), 286 (33.6), 245 (30.4)
BPE	**3**	534 (13.3), 420 (17.9), 343 (sh), 288 (53.2), 209 (32.5)
PCA[a]	**8**	545 (10.1), 444 (10.4), 330 (sh), 285 (36.0), 256 (23.0)

[a] Values of ε_{max} are estimated by comparison with the UV bands of the mononuclear species **7**.

(metal-to-metal charge transfer) transitions $[Ru_b^{II} \rightarrow Ru_a^{III}]$. As a representative example, Fig. 4 shows the spectrum of **6** obtained after adding Br_2 vapour to a concentrated solution of **3** in CH_3CN. This assignment is confirmed by the detection of MMCT bands in similar ranges of the related complexes $[(trpy)(bpy)Ru^{II}(L)Ru^{III}(NH_3)_5]^{5+}$ and $\{(bpy)_2Ru^{II}[(L)Ru^{III}(NH_3)_5]_2\}^{8+}$, with L = CN^-, pz, 4-CNpy, 4,4′-bpy and BPE [5,8]. Controlled potential electrolyses at 0.5–0.8 V for the three complexes showed identical

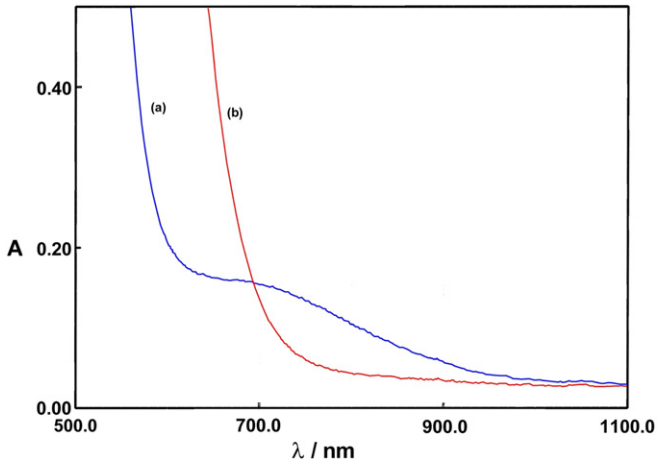

Fig. 4. UV–Vis spectra of: (a), $[(tpm)(bpy)Ru^{II}(BPE)Ru^{III}(NH_3)_5]^{5+}$ and (b), $[(tpm)(bpy)Ru^{II}(BPE)Ru^{II}(NH_3)_5]^{4+}$, in CH_3CN, at room temperature ($C = 2.8 \times 10^{-4}$ M). (a) was obtained from (b) by oxidation with bromine vapour.

results, as shown in Fig. 5, where the spectra of complexes **2** and **5** (the latter one obtained by electrolysis of **2**) are compared. These oxidation processes are reversible in a longer time-scale (*ca.* 1 h).

3.5. Intramolecular electron transfer parameters

Using the Marcus–Hush formalism [9,10] and the experimental spectral data of the MMCT bands in the mixed-valent species, the reorganization energy (λ) for the intramolecular electron transfer through the bridging ligand L and the electronic coupling element between both metal centers (H_{AB}) can be calculated as follows:

$$\lambda = E_{op} - \Delta G^0 - \Delta E_{ex} \quad (1)$$

$$H_{AB} = \frac{2.06 \times 10^{-2}}{r}(\varepsilon_{max} \cdot \Delta\tilde{\nu}_{1/2} \cdot \tilde{\nu}_{max})^{1/2} \quad (2)$$

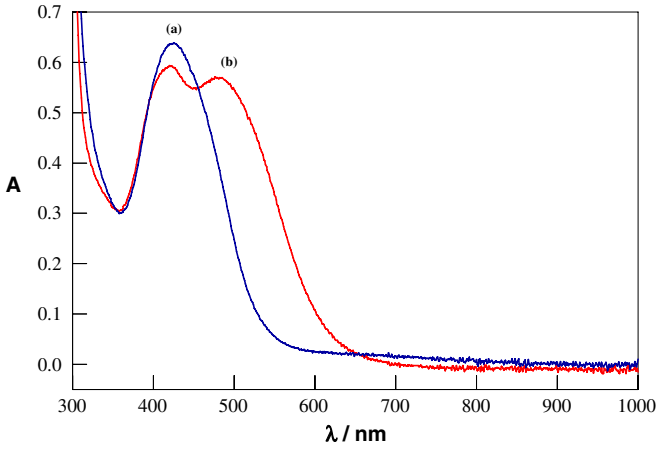

Fig. 5. UV–Vis spectra of: (a), $[(tpm)(bpy)Ru^{II}(4,4'\text{-}bpy)Ru^{III}(NH_3)_5]^{5+}$ and (b), $[(tpm)(bpy)Ru^{II}(4,4'\text{-}bpy)Ru^{II}(NH_3)_5]^{4+}$, in CH_3CN, 0.1 M TBAH, at room temperature ($C = 3.8 \times 10^{-5}$ M). (a) was obtained from (b) by electrolysis at $V = 0.5$ V.

where E_{op} is the energy of the absorption maximum (in eV), ΔG° is the free energy difference between both redox sites (approximated as the difference in the redox potentials $\Delta E_{1/2}$) and ΔE_{exc} is an excited-state energy difference, estimated as 0.25 eV [8]. ε_{max} is the absorption coefficient of the MMCT band, $\tilde{\nu}_{max}$ is the energy maximum of the same band (in cm^{-1}), $\Delta\tilde{\nu}_{1/2}$ is the bandwidth at half-height, and r is the metal–metal distance in Å [10].

Table 2 shows the obtained values for these parameters in the series of mixed-valent complexes **4**, **5**, **6** and **9**.

For all these mixed-valent species, the values of $H_{AB} \ll \lambda$; therefore, they can be classified as belonging to Class II according to Robin and Day nomenclature [10]. The reorganization energy λ increases with r in going from pz to PCA, as predicted by Marcus theory [11]. Moreover, this increment is reflected in the increasing values of E_{op} with r, as recently reported in unsymmetric mixed-valent Co^{III}–Fe^{II} complexes [12]. For L = pz and 4,4′-bpy, the reverse intramolecular electron transfers $Ru_a^{II} \rightarrow Ru_b^{III}$ are predicted to be in the Marcus inverted region, since $\lambda < -\Delta G^{\circ}$, while for L = BPE, the analogous charge recombination falls almost in the barrierless region ($\lambda \cong -\Delta G^{\circ}$). This trend is similar to that found for the corresponding species with trpy [5]. In the case of L = PCA, this charge recombination falls in the normal region, since $\lambda > -\Delta G^{\circ}$.

The electronic coupling H_{AB} decreases with increasing metal-to-metal distance, as expected from Marcus theory [11], but the obtained values are higher than those found in the trpy complexes by an average factor of *ca.* 1.3 [5]; for example, the value of H_{AB} is 750 cm^{-1} for $[(tpm)(bpy)Ru^{II}(L)Ru^{III}(NH_3)_5]^{5+}$ and 614 cm^{-1} for $[(trpy)(bpy)Ru^{II}(L)Ru^{III}(NH_3)_5]^{5+}$, pointing to a stronger electronic communication in the tpm series. Moreover, as shown in Fig. 6, the distance dependence is less steeper: a value of $\beta = 0.3$ $Å^{-1}$ is obtained (where β is the slope of $2\ln H_{AB}$ versus r), when considering the four ligands, which is 25% lower than the value determined for the series of the trpy complexes ($\beta = 0.4$ $Å^{-1}$) [5].

As stated before [13], the value of β determines the attenuation with distance of the electronic overlap between both metallic centers with the bridging ligand. Pure σ-connectors, such as polyprolines acting as bridges in ruthenium amines [14], have a slope $\beta = 0.6$ $Å^{-1}$. Pure π-connectors, such as polyenes acting as bridges in ruthenium amines [15], have a slope $\beta = 0.2$ $Å^{-1}$. Since the value of β obtained in this work is much closer to that of the pure π-connectors, we deduce that the facial geometry and poor π-acceptor character of tpm induce a better transmission of the metal-to-metal electronic interaction in these complexes. Connecting at least three metal centers may eventually lead to a molecular-wire behaviour [16].

Table 2
Intramolecular electron transfer parameters in the series of mixed-valent complexes of the type $[(tpm)(bpy)Ru^{II}(L)Ru^{III}(NH_3)_5]^{5+}$

L	Complex	r (Å)	E_{op} (eV)	ΔG° (eV)	λ (eV)	H_{AB} (cm^{-1})
pz	**4**	7.0	1.62	0.84	0.53	750
4,4′-bpy	**5**	11.3	1.82	0.86	0.71	350
BPE	**6**	13.8	1.84	0.84	0.75	320
PCA	**9**	14.9	1.97	0.80	0.92	200

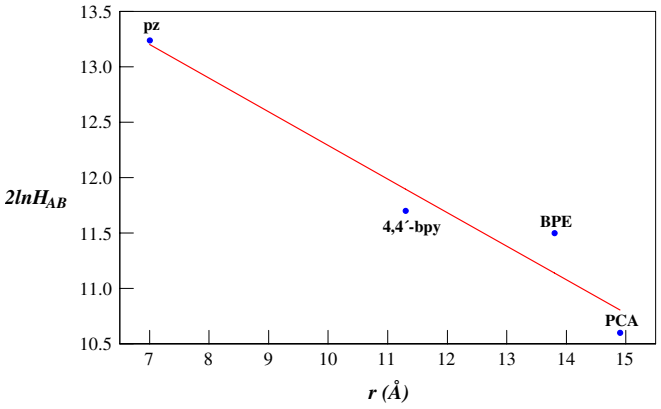

Fig. 6. Plot of $2\ln H_{AB}$ vs. r for the four mixed-valent species $[(tpm)(bpy)Ru^{II}(L)Ru^{III}(NH_3)_5]^{5+}$, in CH_3CN (L = pz, 4,4′-bpy, BPE and PCA).

4. Conclusions

We conclude that the distance dependence of the reorganization energies and the electronic coupling elements in the new mixed-valent unsymmetric complexes prepared and characterized in this work point to a stronger electronic communication between both metallic centers than in the analogous complexes with trpy. Moreover, an increased transmission of the electronic interaction is induced in these complexes by using tpm instead of trpy as a spectator ligand.

Abstract

To investigate the interactions between hydrogen bond donor and acceptor giving rise to three dimensional networks, compounds $[Ni(H_2O)_6](ClO_4)_2 \cdot 2\{(CH_2)_6N_4\} \cdot 2H_2O$ (**1**), $[Ni(H_2O)_6]Cl_2 \cdot 2\{(CH_2)_6N_4\} \cdot 4H_2O$ (**2**) and $[Cd(H_2O)_4\{(CH_2)_6N_4\}_2](ClO_4)_2 \cdot 2H_2O$ (**3**) (where $(CH_2)_6N_4$ = hexamethylenetetramine) have been prepared and their crystal structures were investigated. In all three complexes, the metal coordination is octahedral. The hexamine molecules are complexed in the cadmium compound, **3** but are free in the nickel salts, **1** and **2**. The supramolecular structures of **1** and **2** show $R_4^4(16)$ motif linking the cationic moieties with hexamine which are in turn interwoven with anionic moieties via water molecules. In contrast the supramolecular structure of **3** shows $R_2^2(12)$ motif.

1. Introduction

Understanding of charge assisted non-covalent interactions such as hydrogen bonding, π–π stacking, dipole–dipole, hydrophobic interactions, etc., collectively constitute a promising field of persistent research interest [1]. The weak intermolecular interactions between molecular building units enforce a self-assembling process to generate molecular networks of different dimensionality with specific architectural and functional behaviors [2]. Experimental generation of supramolecular aggregates based on H-bonding could be achieved via versatile donor–acceptor interactions among the metal coordinated N, O rich ligands and even with free partners (solvents, organic molecules) in the lattice [3]. Increasing the number of components, polar bridging groups with variable spacer and counter-ions definitely play a crucial role in deciding whether 1-D molecular chains are interlocked to form 2-D networks which in turn could be cross linked into 3-D networks. Therefore, the intricate association of molecular synthons through weak forces results in novel multidimensional structures [4]. Molecular assemblies possessing translational symmetry of one or several assembling units could be modeled by interplay of H-bonding and other weak forces depending upon the chemical environment. This implies the necessity of rational designing strategy known as crystal engineering [5], yet to be explored at its best, to obtain desired architecture. Higher stability, better dimensionality and complementary combination of donors and acceptors in H-bonding could be superiorly utilized in crystal engineering over the other intermolecular forces [6]. Transition metal ions can be incorporated into H-bonding networks by employing bi-functional ligands that contain

doi:10.1016/j.poly.2006.07.019

unaffected H-bonding functionalities in addition to chelating centres [7].

To substantiate these assumptions, we were encouraged to examine the interactive details in the crystal structures of two Ni(II) complexes and of a Cd(II) complex derived from hexamethylenetetramine, respective metal salts and water molecules. Herein, some striking observations have been accessed in the context of H-donor acidity, H-acceptor basicity, steric/electronic demands of counter-ions, conformational constraints of hexamine to inspire high nuclearity and metal contrast.

2. Experimental

2.1. Starting materials

$NiCl_2 \cdot 6H_2O$ and hexamine were purchased from spectrochem, India and used as received. $Ni(ClO_4)_2 \cdot 6H_2O$ and $Cd(ClO_4)_2 \cdot 2H_2O$ salts were prepared in our laboratory. *Caution:* Perchlorate salts are hazardous and may explode.

2.2. Synthesis of complexes

2.2.1. $[Ni(H_2O)_6](ClO_4)_2 \cdot 2\{(CH_2)_6N_4\} \cdot 2H_2O$ (**1**)

$Ni(ClO_4)_2 \cdot 6H_2O$ (0.165 g, 0.45 mmol) dissolved in minimum volume of water was added to an aqueous solution of hexamine (0.126 g, 0.90 mmol). On slow evaporation at room temperature single crystals appeared. Yield: 298 mg (79%). *Anal.* Calc. for $C_{12}H_{40}Cl_2N_8NiO_{16}$: C, 21.12; H, 5.86; N, 16.42. Found: C, 21.06; H, 5.83; N, 16.40%. IR (ν/cm^{-1}): 3495, 3417 (ν_{O-H}), 2984, 2889 (ν_{C-H}), 1662 (δ_{O-H}), 1089, 622 (ν_{ClO_4}).

2.2.2. $[Ni(H_2O)_6]Cl_2 \cdot 2\{(CH_2)_6N_4\} \cdot 4H_2O$ (**2**)

This complex was prepared by a similar procedure taking $NiCl_2 \cdot 6H_2O$ (0.107 g, 0.45 mmol) and hexamine (0.126 g, 0.90 mmol). Yield: 226 mg (82%). *Anal.* Calc. for $C_{12}H_{44}Cl_2N_8NiO_{10}$: C,24.40; H, 7.45; N, 18.97. Found: C, 24.37; H, 7.41; N, 18.92%. IR (ν/cm^{-1}): 3397 (ν_{O-H}), 2980, 2885 (ν_{C-H}), 1663 (δ_{O-H}).

2.2.3. $[Cd(H_2O)_4\{(CH_2)_6N_4\}_2](ClO_4)_2 \cdot 2H_2O$ (**3**)

This complex was prepared by a similar procedure taking $Cd(ClO_4)_2 \cdot 2H_2O$ (0.174 g, 0.5 mmol) and hexamine (0.140 g, 1.0 mmol) Yield: 297 mg (85%). *Anal.* Calc. for $C_{12}H_{36}CdCl_2N_8O_{14}$: C, 20.57; H, 5.14; N, 17.43. Found: C, 20.53; H, 5.09; N, 17.41%. IR (ν/cm^{-1}): 3435, 3413 (ν_{O-H}), 2982, 2885 (ν_{C-H}), 1633 (δ_{O-H}), 1096, 626 (ν_{ClO_4}).

2.3. Physical measurements

IR (KBr disc), Perkin–Elmer RXI FT-IR spectrometer and Nicolet Magna IR 750 Series II. A Perkin–Elmer 2400 Series II elemental analyzer was used for microanalysis (C, H, N). Thermal analysis (TG-DTA) were carried out on a Metler Toledo TGA/SDTA 851 thermal analyzer in a dynamic atmosphere of dinitrogen (flow rate: 30 cm^3 min^{-1}). The sample was heated in an alumina crucible at a rate of 5 °C min^{-1}.

2.4. Crystal structure determination

Single crystal X-ray diffraction data were collected on a Bruker AXS single crystal X-ray diffractometer using SMART APEX CCD detector. The X-ray generator was operated at 50 kV and 35 mA using Mo Kα radiation. Data were collected with a ω scan width of 0.3°. A total of 606 frames per sets were collected in three different settings of φ (0°, 90° and 180°) keeping the sample to detector distance of 6.03 cm and the 2θ value fixed at −25°. The data were reduced by SAINT-PLUS [8] and an empirical absorption correction was applied using the package SADABS [8]. All the structures were solved using SIR92 [9] and refined using SHELXL-97 [10]. Molecular and packing diagrams were generated by ORTEP-32 [11] and CAMERON [12] present in the WinGx (Version 1.64.03b) [13] program suite. The geometric calculations were done by PARST-95 [14] and PLATON [15]. In compound **1** the perchlorate ion is disordered. Details of crystallographic data and refinements of three complexes are summarized in Table 1 while selected bond lengths and bond angles are presented in Table 2. A list of H-bonds in the three complexes is given in Tables 3a–3c.

3. Results and discussion

The ions and ligands were chosen in such a way so as to generate a H-bonded supramolecular frameworks. The neutral ligand, hexamine was chosen along with perchlorate and chloride ions as hydrogen bond acceptor. The Ni(II) compounds, **1** and **2** were prepared by using the counterions perchlorate and chloride, respectively, whereas compound **3** was prepared by replacing the nickel salt with cadmium perchlorate.

3.1. Description of the structures of *1* and *2*

In complex **1** the crystallographic asymmetric unit, as illustrated in the ORTEP (Fig. 1a) of the molecule, consists of one half of the aquated cation, one perchlorate anion, one neutral hexamine molecule and one crystallized water molecule. The remaining portion of the cationic complex is generated via a centre of inversion (at 0.5, 0.5, 0) giving a distorted octahedral nickel centre. The Ni–O bond lengths vary in the range 2.03–2.06 Å and are more or less comparable to those of the similar compounds reported in the literature [16].

A supramolecular structure generated via hydrogen bonding patterns between the $[Ni(H_2O)_6]^{2+}$ and hexamine moities, and those between $[Ni(H_2O)_6]^{2+}$ and perchlorate ions are illustrated separately in Figs. 1b and 1c, respectively. The supramolecular structure can be described in terms of the following subunits: a $[Ni(H_2O)_6]^{2+}$ cationic 2-D assembly incorporating neutral hexamine molecules

and cation···anion interaction through hydrophilic porous channels together with the solvent molecules. The cationic structure is mainly dominated by three different types of hydrogen bonds. Of them, two interactions viz. [O(3W)–H(1W3)···N(4)] and [O(2W)–H(1W2)···N(2)] together constitute a 16-membered hydrogen bonded rings [graph set $R_4^4(16)$] [17]. These rings are repeated in the lattice by translation along the y-axis. The x-direction is characterized by the formation of a similar 16-membered rings [graph set $R_4^4(16)$] [17] comprised of the interactions [O(1W)–H(1W1)···N(1)] and [O(3W)–H(1W3)···N(4)] (Fig. 1b). Consequently, a 2-D network results via the interplay of [O(2W)–H(1W2)···N(2)] and [O(1W)–H(1W1)···N(1)] interactions within the 2D framework and the two sets of rings are interwoven utilizing the common [O(3W)–H(1W3)···N(4)] bonding. Therefore the 2-D network can be envisaged as having been generated by the O–H···N interactions involving two co-facial N atoms [N(1), N(2)] of hexamine and coordinated water molecules [O(1W), O(2W)]. The structural intricacy has been further enhanced by the active participation of O–H donor functionality of the uncoordinated lattice water. The H(1W4) atom of the uncoordinated water molecule O(4W) is engaged in a moderately strong H-bonding with the remaining nitrogen atom N(3) of the hexamine species [O(4W)–H(1W4)···N(3)], thereby defining the z-axis with the formation of a 16-membered H-bonded ring [O(3W)–H(1W3)···N(4)……N(3)···H(1W4)–O(4W)……] (Fig. 1b). Another type of intermolecular interaction has been noticed between the hydrogen H(2W4) of O(4W) and O(3A) of the counterion perchlorate [O(4W)–H(2W4)···O(3A)] (Fig. 1c). In conjunction with this interaction, an additional one existing between H(2W1) of coordinated oxygen O(1W) and O(1) of the anionic moiety results in the formation of a 20-membered ring [graph set $R_6^6(20)$]

[17] (Fig. 1c) which serves as a linker between the graph sets propagating along the *x*- and *z*-directions.

In complex **2** the crystallographic asymmetric unit, as illustrated in the ORTEP (Fig. 2a) of the molecule, consists of one half of hexaaua Ni(II), one chloride anion, one uncoordinated neutral hexamine moiety and two molecules of water of crystallization. The remainder of the cation is generated by transformation through the inversion centre at 0, 0, 0 (the nickel atom location; site occupancy 0.5). The coordination geometry of nickel is distorted octahedral with Ni–O distances ranging from 2.02–2.05 Å [16].

Hydrogen bonding patterns between $[Ni(H_2O)_6]^{2+}$ and hexamine moieties, and those between $[Ni(H_2O)_6]^{2+}$ and chloride ions are shown in Figs. 2b and 2c, respectively. A 16-membered ring $[R_4^4(16)]$ [17] (Fig. 2b) formed by cations and hexamine moieties via the H-bonding interactions [O(3W)–H(2W3)···N(2) and O(1W)–H(1W1)···N(3)] propagates along the *z*-axis. A similar 16-membered ring formed by the interactions of N(3) and N(4) with hydrogens of the coordinated water molecules O(1W) and O(2W) [O(1W)–H(1W1)···N(3) and O(2W)–H(2W2)··· N(4)] is translated along the *y*-axis. The two sets of rings share the H-bonding

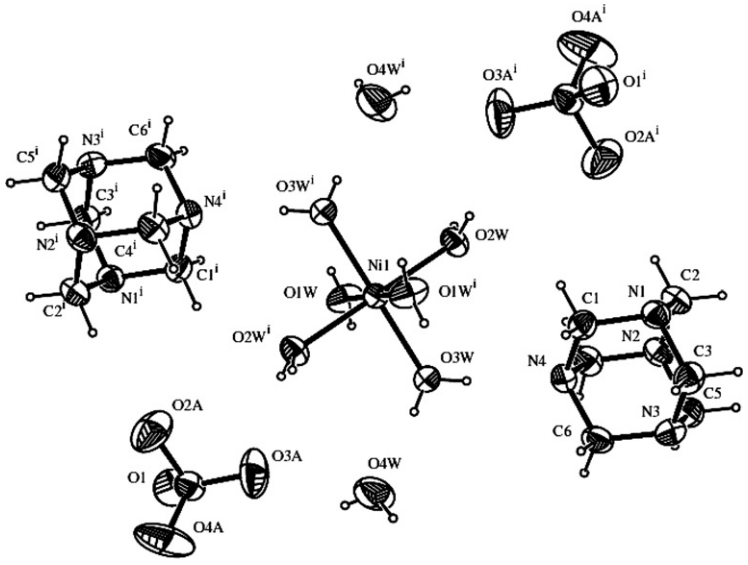

Fig. 1a. ORTEP-3 plot of the structure of $[Ni(H_2O)_6](ClO_4)_2 \cdot 2C_6H_{12}N_4 \cdot 2H_2O$. Atoms having superscripted labels are those generated by the centre of inversion at the Ni centre.

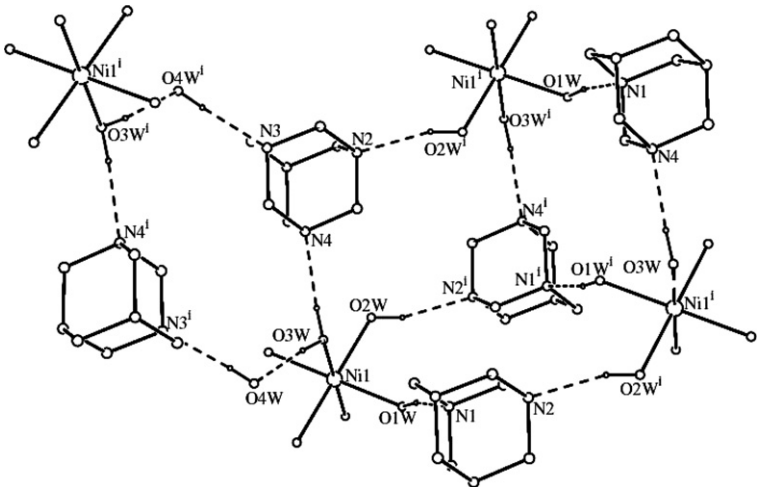

Fig. 1b. Hydrogen bonding patterns between the $[Ni(H_2O)_6]^{2+}$, the hexamine moieties and the included water molecule in the crystal structure of $[Ni(H_2O)_6](ClO_4)_2 \cdot 2C_6H_{12}N_4 \cdot 2H_2O$.

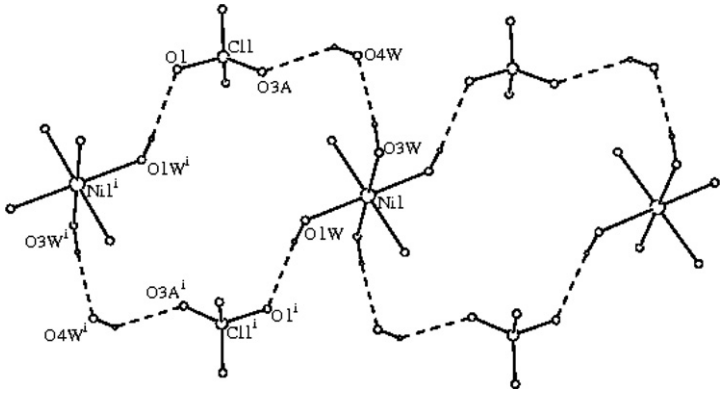

Fig. 1c. Hydrogen bonding patterns between the $[Ni(H_2O)_6]^{2+}$, the perchlorate ions and the included water molecule in the crystal structure of $[Ni(H_2O)_6](ClO_4)_2 \cdot 2C_6H_{12}N_4 \cdot 2H_2O$.

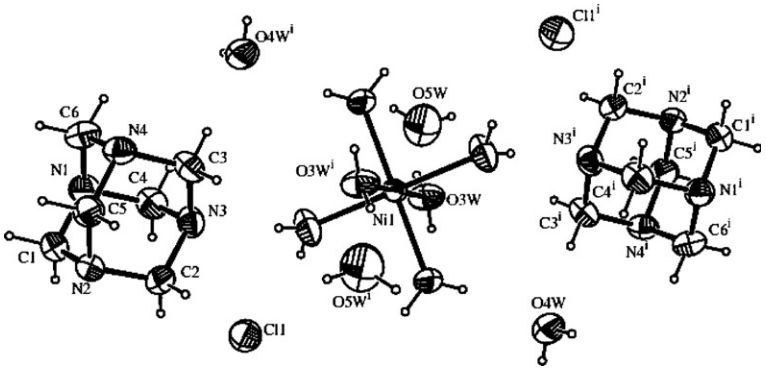

Fig. 2a. ORTEP-3 plot of the structure of $[Ni(H_2O)_6]Cl_2 \cdot 2C_6H_{12}N_4 \cdot 4H_2O$. Atoms having superscripted labels are those generated by the centre of inversion at the Ni centre.

link [O(1W)–H(1W1)···N(3)], thereby forming a 2-D network of graph sets. The remaining nitrogen atom N(1) of the hexamine moiety forms a strong H-bonding interaction with one of the hydrogen atom H(2W4) of the uncoordinated water molecule O(4W) along the *x*-direction, leading to the formation of a 20-membered ring [O(1W)–H(1W1)···N(3)……N(1)···H(2W4)–O(4W) ···H(1W3)–O(3W)……] $[R_6^6(20)]$ [17] (Fig. 2c). The chloride ion H-bonded with the uncoordinated water molecules gives rise to a number of anionic ring systems (Fig. 2c). One of the hydrogen atoms H(2W5) of the uncoordinated water molecule O(5W) connects the chloride ion and forms a 16-membered ring

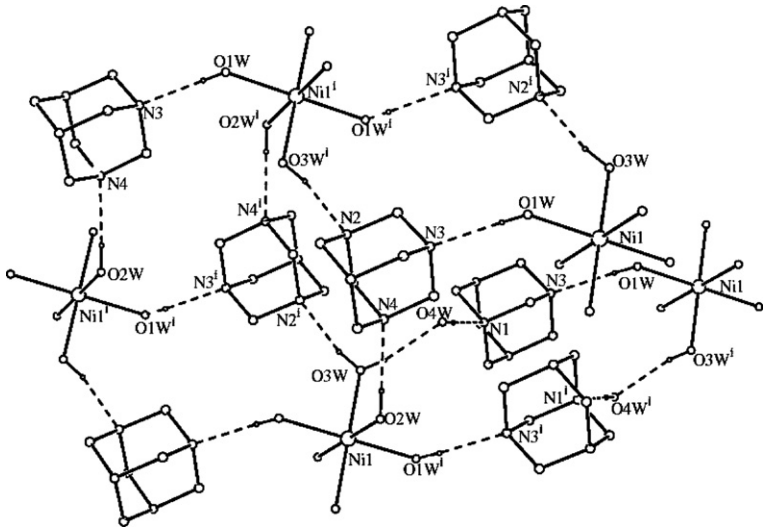

Fig. 2b. Hydrogen bonding patterns between the $[Ni(H_2O)_6]^{2+}$, the hexamine moieties and one of the included water molecules, O4W, in the crystal structure of $[Ni(H_2O)_6]Cl_2 \cdot 2C_6H_{12}N_4 \cdot 4H_2O$.

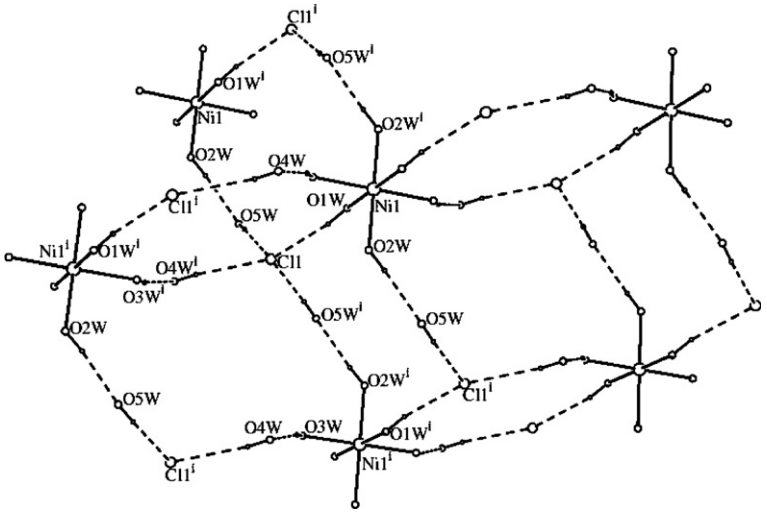

Fig. 2c. Hydrogen bonding patterns between the $[Ni(H_2O)_6]^{2+}$ and chloride ions and the included water molecules, O4W and O5W, in the crystal structure of $[Ni(H_2O)_6]Cl_2 \cdot 2C_6H_{12}N_4 \cdot 4H_2O$.

[O(1W)–H(2W1)···Cl1···H(2W5)–O(5W)···H(1W2)–O(2W) .....] propagating along the *z*-direction. The remaining hydrogen atom H(2W5) of O(5W) forms a similar ring system [O(2W)–H(1W2)···O(5W)–H(1W5)··· Cl1···H(2W1)–O(1W).....] $[R_6^4(16)]$ [17] propagating along the *x*-direction (Fig. 2c). One of the remaining hydrogen atoms H(1W4) of O(4W) connects the ring systems propagating along the *x*-direction with the system [O(3W)–H(1W3)···O(4W)–H(1W4)···Cl1···H(1W5)–O(5W)···H(1W2)–O(2W).....] $[R_8^6(20)]$ [17]. Interweaving of these anionic and cationic frameworks results in the formation of a three-dimensional network.

3.2. Effects of counterions in **1** and **2**

In both the structures **1** and **2** the counterions ClO_4^- and Cl^-, respectively, are uncoordinated. The significant differences, in, electronegativity of H-bond acceptor centres and polarizability arising from their differing sizes, affects the number and modes of H-bonds associated with them. In addition to the smaller size of counterion Cl^-, the extent of solvation is higher in **2** compared to that in **1** [four water of crystallization per metal centres in **2** versus two molecules in **1**], thereby dictating different H-bonding patterns in the complexes involving uncoordinated water molecules. In **1**, ClO_4^- is engaged in only one H-bonding interaction with the water oxygen O(4W) whereas for the chloride ion there are three interactions with the uncoordinated water oxygens in complex **2**, once with O(4W) and twice with O(5W). Thus, the weak interactions involving the ClO_4^- ion is only two, whereas there are four such interactions involving the Cl^- ion, thereby attesting to the better polarizability towards H-bond formation of the latter.

3.3. Description of structure of **3**

In compound **3**, the crystallographic asymmetric unit, as illustrated in the ORTEP-3 plot (Fig. 3a) of the molecule, consists of one half of a cation coordinated to two water molecules and one hexamine ligand, one perchlorate anion, and one uncoordinated water molecule. The remaining half of the cation complex is generated by the centre of inversion at the cadmium atom (located at 1, 0, 0), giving a distorted octahedral geometry around Cd^{2+}. The symmetry related second hexamine moiety, the perchlorate anion and the water molecule completes the molecular view.

The cations are linked through two principle hydrogen bonds between O(1W)–H(1W1) and N(4) and O(2W)–H(2W2) and N(3) involving the coordinated hexamine and water molecules of two adjacent moieties (Fig. 3b). The former H-bonding interactions lead to the formation of 12-membered rings [graph set $R_2^2(12)$] [17] which propagate through the lattice, translated along the *x*-direction. The latter interaction similarly gives rise to a 12-membered H-bonded ring defining the *z*-direction. As a consequence of the interaction of these two graph sets a third graph set is generated [O(1W)–H(1W1)……N(4)……N(3)……H(2W2)–O(2W)……]. Again a H-bond [O(3W)–H(1W3)···N(2)] between one of the uncoordinated water molecules and a glide related hexamine nitrogen interlink the graph sets giving rise to 3-D network. No significant graph set is formed by the perchlorate ion. It is engaged

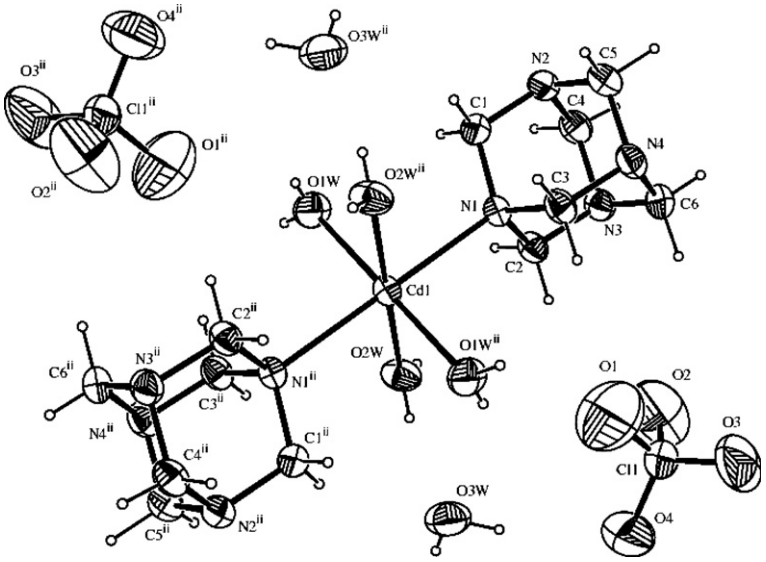

Fig. 3a. ORTEP-3 plot of the structure of $[Cd(H_2O)_4(C_6H_{12}N_4)_2](ClO_4)_2 \cdot 2H_2O$. Atoms having superscripted labels are those generated by the centre of inversion at the Cd centre.

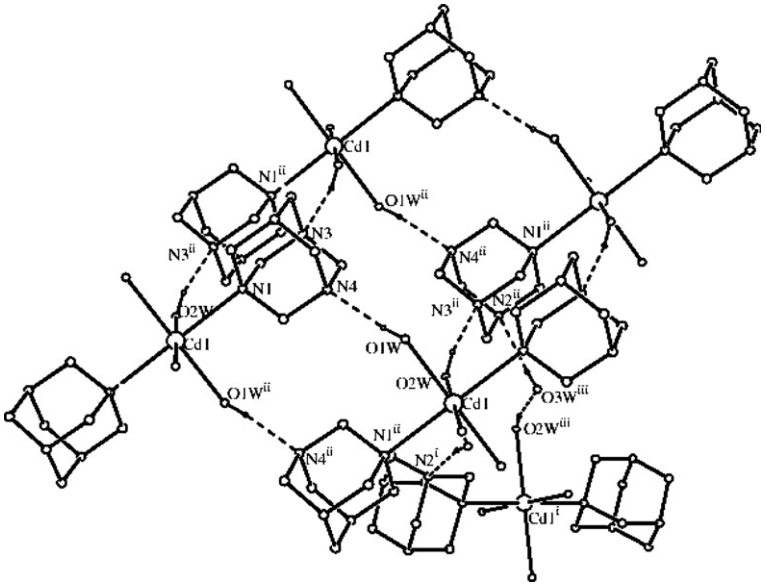

Fig. 3b. Hydrogen bonding patterns between hexamine and water molecules in the crystal structure of $[Cd(H_2O)_4(C_6H_{12}N_4)_2](ClO_4)_2 \cdot 2H_2O$ (**3**).

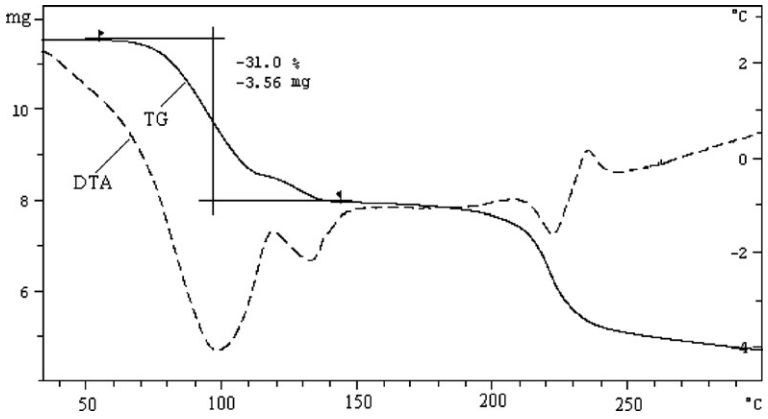

Fig. 4. TG-DTA curve of complex **2** (sample mass: 11.5 mg).

in simple H-bonding with the coordinated water molecule O(1W) and the uncoordinated water molecule O(3W), this pattern is extended throughout the crystal lattice.

Complex **3** has simpler H-bonding pattern compared to the other two structures due to the following reasons: (a) decrease in H-bond receptors of coordinated hexamine, (b) coordination induces decrease in the basicity of N-centres, and (c) induced stereochemical rigidity of methylene spacer due to chelation imposed decrease in rotational freedom.

3.4. Effect of metal ions on the structures

The structures of **1** and **3**, both containing perchlorate as counter ion, show an interesting difference. The two hexamine molecules are coordinated to Cd(II) in **3** to form octahedral $[Cd(H_2O)_4\{(CH_2)_6N_4\}_2]^{2+}$ species whereas in **1**, they remain uncoordinated resulting in hexaaqua nickel complex, $[Ni(H_2O)_6]^{2+}$. Hexamine molecules remain uncoordinated in the other nickle salt, **2** also. Ni(II) being a transition element, prefers strong field ligands to be coordinated to gain crystal field stabilization energy. Thus, its primary coordination sphere consists of six small water molecules leaving the two bulky hexamine molecules containing weakly coordinating tertiary amine nitrogen outside the coordination sphere. On the other hand, Cd(II) being larger and softer metal ion with no crystal field stabilization energy accommodates the two hexamine molecules into its coordination sphere. Therefore, for this kind of structures although the multi-point hydrogen bonding is a very important set of interaction, it is not the only one dominant set. The stability of structure as a whole governs the set of coordinating molecules, crystal packing and molecular stoichiometry. A similar conclusion has also been drawn for the hydrogen bonded sandwich structure for a range of aquated metal complexes with 18-crown-6 [18].

3.5. Thermogravimetry

The TGA trace of **1** shows that it starts to lose water molecules at 60 °C and becomes completely deaquated at 130 °C in two steps. The weight loss in the first step is 15.5% and in the second is 6.1%. The total weight loss corresponds to the loss of eight H_2O molecules per formula unit. The compound starts decomposing at 200 °C. The TGA trace of **2** also shows that the deaquation occurs in two overlapping steps in the temperature range 60–140 °C. A total weight loss of ca. 31.1%, corresponding to the loss of ten H_2O molecules per formula unit (Fig. 4). On further heating, the compound starts to decompose at 220 °C. The deaquation of **3** in the temperatrure range 60–145 °C is also a two-step process as that of **1** and **2**. The first loss of 12.5% and the second loss of 2.6% suggest that all the six H_2O molecules per formula unit are lost. The anhydrous species thus produced for all three compounds do not reabsorb any water molecule from the humid atmosphere suggesting that the framework integrity breaks down once the water molecule are lost.

4. Conclusion

The compounds studied, namely $[Ni(H_2O)_6](ClO_4)_2 \cdot 2C_6H_{12}N_4 \cdot 2H_2O$ (**1**), $[Ni(H_2O)_6]Cl_2 \cdot 2C_6H_{12}N_4 \cdot 4H_2O$ (**2**) and $[Cd(H_2O)_4(C_6H_{12}N_4)_2](ClO_4)_2 \cdot 2H_2O$ (**3**) exhibit 3-D H-bonding networks in the solid state. In the cases of the two Ni(II) compounds, the uncoordinated neutral hexamine and anionic counterparts behave as H-bond receptors in contrast to water molecules acting both as donors and acceptors. Similar donor–acceptor modes are witnessed in the cadmium complex also. Variation of counter-anions in **1** (ClO_4^-) and **2** (Cl^-) does not alter the potential to form rings, but does influence the pattern of interaction between the moieties to form networks. The impact of counter-anions in controlling the overall molecular assembly through H-bonding with $[Ni(H_2O)_6]^{2+}$ motif in **1** and **2** is worth mentioning. Interestingly, compound **2** is stabilized with four molecules of water of crystallization per metal centre unlike **1**, which enjoys lower degree of hydration with only two water molecules per metal centre, attributable to counter-anion change. Replacement of Ni^{2+} by Cd^{2+} in **3** has been attended with a notable change in the coordination sphere resulting in a different H-bonding pattern with fewer acceptor N atoms available for H-bond formation.

Abstract

The reactions of $NiX_2 \cdot 6H_2O$ ($X = Cl^-$, ClO_4^-, NO_3^-) with a new macrocyclic Schiff base ligand (**L** = 8,9,18,19-tetrahydro-7*H*,17*H*-dibenzo[*f*,*o*][1,5,9,13]dioxadiaza cyclohexadecine-8,18-diol), potentially hexadentate containing two alcoholic pendant arms, have been investigated by template condensation of 2-[3-(2-formylphenoxy)-2-hydroxypropoxy]benzaldehyde and 1,3-diamino-2-propanol. The isolation of a selection of 1:1 (metal:ligand) complexes of nickel(II) has been carried out and IR and UV–Vis spectroscopy, conductance measurements and X-ray determination have been employed to probe the nature of the respective complexes in both solid and solution states. The UV–Vis spectra and X-ray determination indicate that the complexes are of the type [NiLX]X, with a distorted octahedral ligand field. However, the perchlorate complex of Ni(II) is of the $[NiL(solv)]^{2+}$ form in solution. In all complexes, the potentially hexadentate ligand behaves as a pentadentate ligand.

1. Introduction

In order to improve the understanding of the coordination geometry, electrochemical and magnetic behavior of nickel, many complexes of nickel with different macrocycles have been studied [1–3]. Macrocyclic ligands containing a heteroatom are important complexing agents for cations, anions and molecules [4–8]. The coordination chemistry of macrocyclic ligands is a fascinating area of intense study for inorganic chemists [9–14]. The aspect of interest in macrocyclic ligands is raised from features such as the nature, number and arrangement of ligand donors, as well as ligand conjugation, substitution and flexibility, which produce different types of macrocyclic molecules suitable for specific uses [15]. In general, a pendant arm enhances the binding strength of the macrocycle toward cations, by cooperative ring-side arm interaction, in comparison with the macrocycle analogues without pendant arms [16–20]. Therefore, the synthesis of pendant arm macrocycles has attracted considerable attention because of their unique coordination and structural properties [21–25] and their roles in bioinorganic chemistry as models of biomolecules and in modern chemical techniques such as magnetic resonance imaging [26–30]. Previously, we have reported the synthesis and structures of some nickel(II) complexes of one alcohol pendant arm macrocyclic Schiff base ligand [1 + 1] with a N_2O_3 donor set [21,22].

We report here the synthesis, structure and spectral properties of some Ni(II) complexes of a two alcohol pendant arms macrocyclic Schiff base, potentially a

hexadentate ligand [1 + 1] with 16-members and mixed N_2O_4 donors, containing different counter ions.

2. Experimental

2.1. Materials

Solvents were dried and purified before being used according to published procedures [31]. Other reagents were purchased from Merck or Fluka and were used without further purification. Caution: Although no problems were encountered during this work with the perchlorate salt, it should be regarded as potentially explosive.

2.2. Physical measurements

CHN analyses were carried out using a Heraeus, CHN-O-RAPID elemental analyzer. The UV–Vis measurements were carried out in DMF solution using a Shimadzu 1650PC UV–Vis spectrophotometer. Infrared spectra were obtained on a Bomem, FT-IR MB-100 instrument as KBr pellets. Mass spectrum was recorded on a Finnigan mass spectrometer. Conductance measurements were performed using a Metrohm 712 conductometer.

2.3. X-ray crystallography

Single crystals of the $[NiLCl]Cl \cdot 0.75H_2O$ complex were obtained from acetonitrile solution by slow evaporation. The crystal was not of ideal quality, although it was the very best available. The structure was solved by direct methods and refined by full matrix least squares using SHELXL-97 [32,33]. SHELX operations were automated using ORTEX, which was also used to obtain the drawings [34]. Data were corrected for Lorentz and polarization effects but not for absorption. Hydrogen atoms were included in calculated positions with thermal parameters 30% larger than the atom to which they were attached. The non-hydrogen atoms were refined anisotropically. All calculations were performed on a Pentium PC.

The data was collected on a Marresearch image plate using monochromatized Mo Kα radiation (0.71069 Å) at 298 K: Molecular formula $C_{20}H_{21}NiCl_2N_2O_{4.75}$, M 495, triclinic, space group $P\bar{1}$, $a = 8.114(4)$ Å, $b = 13.482(9)$ Å, $c = 20.271(10)$ Å, $\alpha = 94.56(2)°$, $\beta = 90.96(2)°$, $\gamma = 100.58(2)°$, $V = 2172(2)$ Å^3, $Z = 4$, $D_{calc} = 1.514$ Mg/m^3, absorption coefficient $\mu = 1.172$ mm^{-1}, crystal dimensions: $0.48 \times 0.42 \times 0.31$ (mm), $F(000)$: 1020, θ range for data collection: 5.65–20.30 (°), index ranges: $-7 \leqslant h \leqslant 7$, $-12 \leqslant k \leqslant 13$, $-19 \leqslant l \leqslant 19$, reflections collected/unique: 7345/3616, significant unique reflections: 3289 with $I > 2\sigma(I)$, refinement method: full-matrix least-squares on F^2, data/parameters/restraints: 3616/540/0, goodness-of-fit on F^2: 1.022, final R indices $[I > 2\sigma(I)]$: $R_1 = 0.0517$, $wR_2 = 0.1287$, R indices (all data): $R_1 = 0.0564$, $wR_2 = 0.1321$, weighting scheme: $w = 1/[(\sigma F_o)^2 + (0.0419^*P)^2 + 5.3765^*P]$ where $P = (F_o^2 + 2F_c^2)/3$, largest difference peak and hole (e/Å^3): 0.528 and −0.372.

$R_1 = [\Sigma||F_o| - |F_c||]/\Sigma|F_o|$ (based on F),

$wR_2 = \left[[\Sigma_w(|F_o^2 - F_c^2|)2]/[\Sigma_w(F_o^2)^2]\right]^{1/2}$ (based on F^2).

2.4. Syntheses

2.4.1. 2-[3-(2-Formylphenoxy)-2-hydroxypropoxy] benzaldehyde (*1*)

Compound **1** was prepared in a way similar to the reported method [21,35] using salicylaldehyde and 1,3-dichloro-2-propanol.

2.4.2. Macrocycle (*L*)

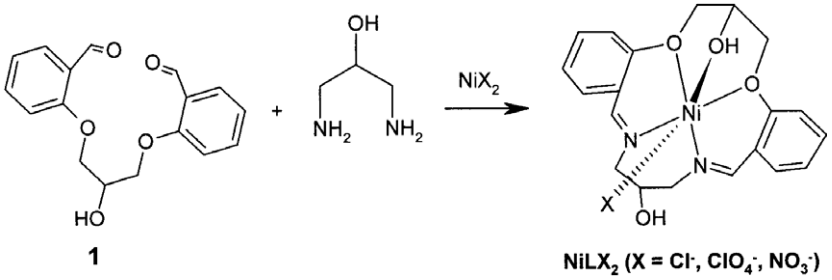
1,3-Diamino-2-propanol (0.0905 g, 1 mmol) in methanol (20 mL) was added to a solution of **1** (0.3002 g, 1 mmol) in warm methanol (50 mL). The reaction mixture was then refluxed for 3 h. The mixture was cooled to room temperature and the solvent removed under reduced pressure until a solid product was formed that was washed with cold methanol. Yield (72.5%), Mp 90–92 °C. Selected FT-IR data, ν (cm^{-1}): 3377b, 3072w, 2888w, 1637s (C=N), 1595m, 1486s, 1242s, 1107m, 1034m, 754s. *Anal.* Calc. for $C_{20}H_{22}N_2O_4 \cdot 2H_2O$: C, 61.5; H, 6.7; N, 7.2. Found: C, 61.6; H, 6.1; N, 7.0%. Mass spectral parent ion; m/z 354.

2.4.3. Nickel complexes

A 1-butanol solution (120 mL) of 1,3-diamino-2-propanol (0.3694 g, 4 mmol) was added slowly with stirring to a 200 mL hot 1-butanol solution of **1** (1.206 g, 4 mmol) and $NiX_2 \cdot 6H_2O$ (4 mmol). The solution was refluxed for 2 h and then filtered. The volume of the resulting solution was reduced using a rotary evaporator. The resultant product was recrystallized and dried in a vacuum desiccator over P_4O_{10}.

$NiLCl_2$: Blue crystals were recrystallized from acetonitrile. Yield: 0.9 g (55.8%). Mp > 230°C (dec). Selected FT-IR data, ν (cm^{-1}): 3456w, 3361w, 3252w, 3029w, 2927w, 1637s (C=N), 1603m, 1492m, 1432m, 1283w, 1220s, 1128m, 985s, 804m, 771m, 627w, 584w, 534w, 472w. *Anal.* Calc. for $C_{20}H_{21}NiCl_2N_2O_{4.75}$: C, 48.5; H, 4.2; N, 5.6. Found: C, 49.0; H, 4.7; N, 4.8%. $\Lambda_m = 94$ cm^2 Ω^{-1} mol^{-1} in DMF. Electronic spectrum in DMF (λ, nm) (ε, M^{-1} cm^{-1}): 620(16.9), 798(shoulder) (2.4), 1075(8.1).

$NiL(ClO_4)_2$: Blue-green crystals were recrystallized from acetonitrile/methanol (1:1 v/v). Yield: 0.5 g (25%). Mp > 215°C (dec). Selected FT-IR data, ν (cm^{-1}): 3386b, 3078w, 2937w, 1639 s (C=N), 1604s, 1491m, 1446m, 1285w, 1216s, 1144s, 1113, 1088, 1019w, 988m, 796w, 766m, 630s, 475w. *Anal.* Calc. for $C_{20}H_{22}Cl_2NiN_2O_{12} \cdot 0.33CH_3OH$: C, 39.25; H, 3.62; N, 4.58. Found: C, 39.22; H, 3.78; N, 4.50%. $\Lambda_m = 125$ cm^2 Ω^{-1} mol^{-1} in DMF. Electronic spectrum in DMF (λ, nm) (ε, M^{-1} cm^{-1}): 613(5.9), 1089(5.7).



NiL(NO$_3$)$_2$: Blue crystals were recrystallized from acetonitrile. Yield: 0.79 g (41.5%). Mp > 235 °C (dec). Selected FT-IR data, ν (cm^{-1}): 3433w, 3068w, 2955w, 1637s (C=N), 1605m, 1483m, 1421s, 1384s, 1313s, 1223s, 1120w, 984m, 814m, 770m, 529w, 476w. *Anal.* Calc. for $C_{20}H_{22}NiN_4O_{10}\cdot 0.5H_2O$: C, 43.99; H, 4.2; N, 10.3. Found: C, 44.00; H, 4.3; N, 10.0%. $\Lambda_m = 86\ cm^2\ \Omega^{-1}\ mol^{-1}$ in DMF. Electronic spectrum in DMF (λ, nm) (ε, $M^{-1}\ cm^{-1}$): 598(10.8), 773(shoulder) (5), 1046(8.5).

3. Results and discussion

3.1. Syntheses and characterization

Since macrocycle **L** is not soluble in methanol, ethanol and 1-butanol, the complexes were prepared by template cyclocondensation reactions in the presence of $NiX_2\cdot 6H_2O$ ($X = Cl^-$, ClO_4^-, NO_3^-) salts and yielded solids according to Scheme 1, which were characterized by IR, elemental analysis, UV–Vis and conductance measurements.

The molar conductivity data for ca. 10^{-3} M of $NiLCl_2$ and $NiL(NO_3)_2$ in DMF solutions at room temperature are in accordance with those expected for a 1:1 electrolyte, while the measured value for $NiL(ClO_4)_2$ under the same conditions is as expected for a 2:1 electrolyte [36]. These observations imply that at least one of the anions in $NiLCl_2$ and $NiL(NO_3)_2$ is coordinated to the Ni atom, while the perchlorate anions in $NiL(ClO_4)_2$ solution does not participate in coordination. The IR spectra of all the complexes confirm the presence of imine bonds and each complex exhibits the ν(C=N) mode at ca. 1637 cm^{-1}, while no band attributable to a C=O stretching vibration is detected related to aldehyde which indicates that condensation and cyclization has occurred. The stretching mode of O–H in the $NiLCl_2$ complex (3456, 3361 and 3252 cm^{-1}) is split and shifted compared to that of the free macrocycle (3377 cm^{-1}) which may indicate the existence of three kinds of hydroxyl groups, two groups are alcohol pendant arms, one is coordinated to the Ni atom, and third one corresponds to lattice water as is found from the crystal structure of the $NiLCl_2$ complex, but the stretching mode of O–H in the case of the $NiL(NO_3)_2$ and $NiL(ClO_4)_2$ complexes is only shifted. The vibration band at 1242 cm^{-1}, assigned to ν(C–O–C) in the free ligand, was shifted toward lower frequency by ca. 26 cm^{-1}, indicating the complexation of the ether oxygen atoms to the nickel ion. The C=C vibration band of the aromatic ring at 1595 cm^{-1} of the free ligand was shifted towards higher frequency by ca. 10 cm^{-1} in the complex due to hindrance to the ring breathing vibration. The vibration bands of the ClO_4^- and NO_3^- groups provide some useful structural information [37]. The IR spectrum for the nitrate complex shows bands at ca. 1421 cm^{-1} (ν_5) and 1313 cm^{-1} (ν_1), suggesting the presence of a coordinated nitrate group, and a band at ca. 1384 cm^{-1} is attributable to ionic NO_3^-. The separation $\nu_5 - \nu_1$ can be used as a near criterion to distinguish between the degree of covalence of the nitrate coordination. The magnitude of this value (110 cm^{-1}) is indicative of a unidentate interaction. The perchlorate bands were assigned according to Refs. [21,24,25,38,39]. The IR spectrum of the perchlorate complex exhibits bands assignable to the asymmetric Cl–O stretching mode (ν_3) around 1100 cm^{-1} and the asymmetric Cl–O bending mode (ν_4) at 630 cm^{-1}. The higher energy band shows three well-resolved maxima of the perchlorate at 1144, 1113 and 1088 cm^{-1}. This may reflect different environments in this complex arising from crystal packing or hydrogen bonding and or lowering of the symmetry of the perchlorate group owing to coordination to nickel. It must be pointed out that the $\nu(C–O–C)_{ether}$ band also falls in this region. Thus it is not possible to precisely define the coordination mode of ClO_4^- [21,24,39]. The UV–Vis spectra of the nickel complexes in DMF solutions show two absorption bands in the regions of 1046–1100 and 598–620 nm. These absorption bands may be assigned to the $^3A_{2g} \rightarrow {}^3T_{2g}$ (F) (ν_1) and $^3A_{2g} \rightarrow {}^3T_{1g}$ (F) (ν_2) transitions, respectively, and reflect Ni(II) d^8 ions in an octahedral geometrical environment [21,24]. One absorption band near 800 nm is also present and is probably due to the spin forbidden transition $^3A_{2g} \rightarrow {}^1E_g$ observed in $NiLCl_2$ and $NiL(NO_3)_2$ complexes [21,40]. According to the molar conductivity data, the perchlorate ions do not participate in coordination in a $NiL(ClO_4)_2$ solution in DMF, but its UV–Vis spectrum shows Ni(II) has an octahedral geometry environment so that one can assume the participation of one solvent molecule in the sixth coordination position of Ni(II) due to the high donor capacity of DMF. The absorption bands for the complexes increase toward higher energies in the order

1 **NiLX$_2$ (X = Cl$^-$, ClO$_4^-$, NO$_3^-$)**

Scheme 1.

DMF < Cl^- < NO_3^-, indicating that the presence of these coordinated axial ligands affects the ligand field strength of the complexes. The 10 Dq values of $[NiL(DMF)]^{2+}$, $[NiLCl]^+$ and $[NiL(NO_3)]^+$ are 9182.7, 9302.3 and 9560 cm^{-1}, respectively. The observed disagreement in the order of DMF and Cl^- may arise from DMF-macrocycle steric effects.

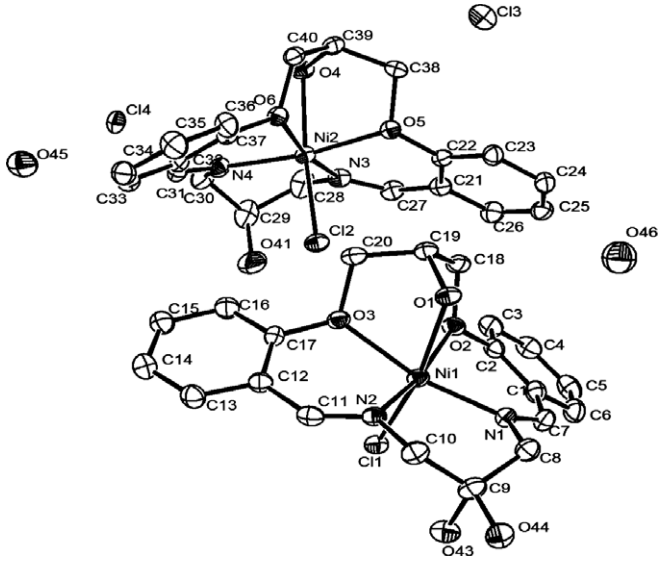


Fig. 1. ORTEP representation of the asymmetric unit for $NiLCl_2$. Hydrogen atoms are omitted for clarity.

In all the complexes, the ligand **L** behaves as pentadentate as a similar macrocycle with one alcohol pendant arm [21,22]. It seems that the second alcohol pendant arm cannot participate in coordination because of the rigidity of **L** in the region of the imine nitrogen bonds.

Table 1
Selected some bond lengths (Å) and bond angles (°) for $NiLCl_2$

Bond lengths			
Ni(1)–N(1)	1.994(5)	Ni(2)–N(3)	1.990(5)

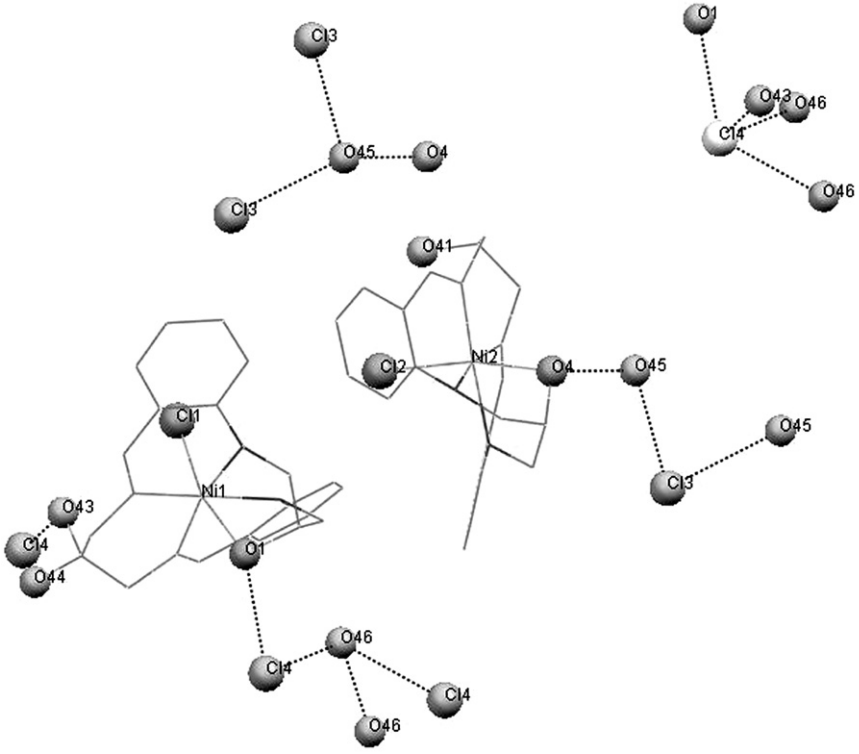

Fig. 2. H-Bonds in the asymmetric unit.

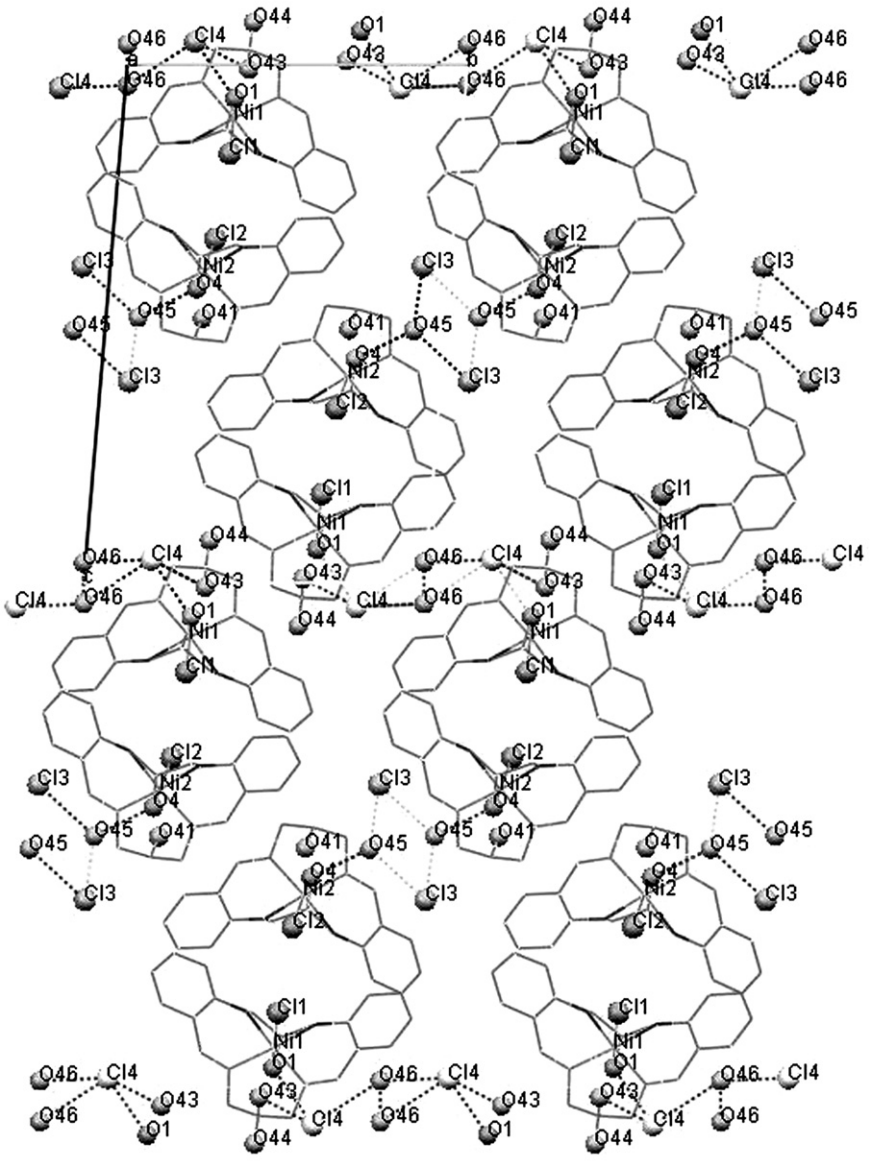

Fig. 3. H-Bonds and crystal packing along the *a*-axis.

3.2. X-ray structure of $NiLCl_2$

The asymmetric unit of the crystal is illustrated in Fig. 1, and selected bond distances and bond angles are listed in Table 1. There are two $[NiLCl]^+$ cations and two Cl^- counter ions per asymmetric unit. Each asymmetric unit has two water molecules (O45 and O46) of crystallization, one of which has half site occupancy. This gives a molecular formula of $[NiLCl]Cl \cdot 0.75H_2O$. The two molecules in the asymmetric unit are almost identical and they are almost coincident. There is also disorder in the position of one of the uncoordinated hydroxyl oxygens in one of the molecules over two positions (O43, O44) with occupancy ratios of 0.7 and 0.3. In both molecules it is clear that one of the hydroxyls (O1 in one molecule and O4 in the other) is coordinated to Ni while the other (O43–O44 and O41) is not, and that one Cl (Cl1 and Cl2) is coordinated to Ni and the other (Cl3 and Cl4) is not. The Ni atoms in the molecules are hexacoordinated with a distorted octahedral geometry. One Cl^- ion and one of the hydroxyl pendants on the etheric backbone occupy the apical positions and two imine nitrogen atoms and two ether oxygen atoms of the macrocycle occupy basal positions of the octahedron. The Ni–Cl bond lengths [2.327(2) and 2.3448(19) Å] are almost comparable to those of reported Ni–Cl complexes with an octahedral geometry [41,42]. The Ni–N bond distances [1.994(5), 2.008(5), 1.990(5) and 2.021(6) Å] and Ni–O bond distances [2.139(4), 2.069(4), 2.091(4), 2.118(4), 2.073(4) and 2.069(4) Å] are comparable to the corresponding values [2.007(4), and 2.008(4) Å] for Ni–N and [2.119(4), 2.080(3) and 2.085(3) Å] for Ni–O in our previous work on a N_2O_3 macrocyclic ligand [21]. The

conformation of the macrocycle is such that the two phenyl rings are tilted to the same side. Figs. 2 and 3 show the H-bonds in the asymmetric unit and crystal packing along *a*-axis respectively. O1 and O43 in one of the molecules are H-bonded to their corresponding adjacent uncoordinated Cl4s, while in the other molecule only the coordinated hydroxyl group, O4, is H-bonded to its corresponding adjacent water molecule O45. Both uncoordinated Cls are H-bonded to water molecules. However the water molecules are involved in H-bonding which is 3D in nature and thus not easy to describe in any simple way. The H-bond distances involved in the asymmetric unit are O45···O4 2.594, O45···Cl3 3.099 and O46···O46 2.596, O46···Cl4 3.093 Å. The Cl2···O41 and Cl1···O43 distances are 3.295(7) and 3.537(7) Å respectively.

4. Conclusion

The UV–Vis spectra, conductivity measurements and X-ray determination indicate that the complexes are of the type [NiLX]X with a distorted octahedral ligand field. However, the perchlorate complex of Ni(II) has the $[NiL(solv)]^{2+}$ form in solution. In all the complexes, the ligand **L**, potentially hexadentate, bearing two pendant alcohol arms, behaves as a pentadentate ligand.

Synthesis and characterization of silver(III) complexes with tetradentate and tridentate ligands with imine-oxime groups

Mohamed A. Eltayeb, Yousif Sulfab *

Department of Chemistry and Earth Sciences, College of Arts and Sciences, Qatar University, P.O. Box 2713, Doha, Qatar

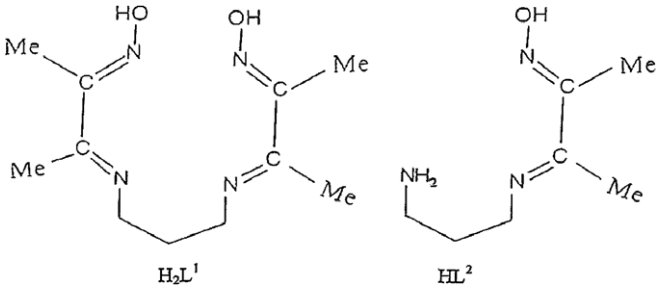
Available online 4 August 2006

Abstract



The trivalent oxidation state of silver is stabilized by tetradentate imine-oxime and tridentate imine-oxime-amine ligands. Silver(I), in the presence of these ligands, is readily oxidized by PbO_2 in acidic solutions or by $S_2O_8^{2-}$ to the corresponding silver(III) complexes. The isolated complexes were characterized by elemental analysis, IR, UV–Vis spectra, magnetic susceptibility, TG and cyclic voltammetry. The complexes are diamagnetic, consistent with the formation of spin-paired d^8 square planar or tetragonal structures. The complexes have a high molar absorption in the UV–Vis region with $\varepsilon > 10^4\ M^{-1}\ cm^{-1}$, that may be attributed to ligand to metal charge transfer (MLCT). The complexes seem to be stable in the solid state when kept dry and away from light. The complexes decompose very slowly in aqueous solutions. The rate of decomposition is accelerated by both acids and bases. The decomposition involves oxidation of the ligands by Ag^{III}.

Keywords: Diamagnetic silver(III) complexes; Imine-oxime ligands; Ligand to metal charge transfer; Irreversible cyclic voltammograms

1. Introduction

Trivalent silver is often proposed as a transient species in silver catalyzed peroxydisulfate oxidations [1]. Complexes of Ag^{III} are considered to be unstable, rare and much more restricted than those of Ag^{II} [2]. However, several compounds and complexes of Ag^{III} have been isolated and are well characterized. These include the mixed-valent oxides AgO and Ag_3O_4 as well as the stoichiometric Ag_2O_3 [3,4]. Other complexes include diamagnetic four-coordinate and paramagnetic six-coordinate fluoro-complexes, diperiodato, ditellurato, dithioccarbamate, porphyrins, tetrazamacrocycles, biguanides, phosphines, arsines, *vic*-dioximes, polypeptides, hydroxide and aminoethylpyridine complexes [5–19]. Silver(III) complexes with biguanides, corroles and carboporphrins have been isolated and their structures resolved by X-ray crystallography [20–22].

Imine-oxime, pyridine-oxime and *vic*-dioxime ligands have been shown to be good ligands for the stabilization of uncommon high oxidation states of transition metals [23–28]. The ability of imine-oxime and *vic*-dioxime ligands to stabilize Cu^{III}, Ni^{III} and Ni^{IV} has been attributed to the oxime π-donor character as well as the negative charge on the oximato oxygen.

We have previously shown that *vic*-dioximes and tetradentate imine-oxime ligands such as H_2L^1 stabilize Cu^{III}. The tridentate imine-oxime-amine ligand, HL^2, has been synthesized and was shown to stabilize the +3 oxidation

doi:10.1016/j.poly.2006.07.026

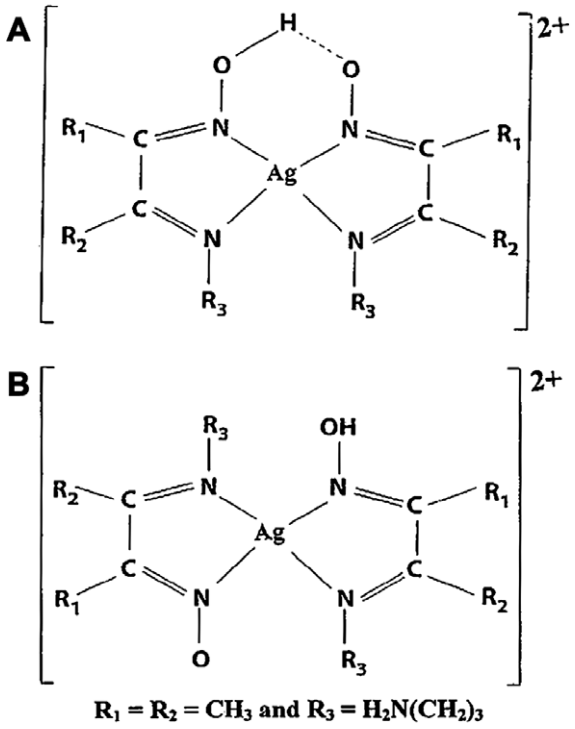
state of copper [29]. It seems that ligands, such as periodate, tellurate, biuret, *vic*-dioximes and tetraazamacrocyclic ligands, which are capable of stabilizing Cu^{III} stabilize Ag^{III} as well. In this work, we report the synthesis, isolation and characterization of new Ag^{III} complexes using the ligands H_2L^1, HL^2.

2. Experimental

2-Oximinobutan-3-one (Sigma), 1,3-diaminopropane (Aldrich) and ethyl acetate (Aldrich) were used as received. All other organic solvents used were of reagent grade and were used as received. Tetrabutylammonium hexafluorophosphate, $(n\text{-Bu})_4NPF_6$(Fluka), was used as a supporting electrolyte.

The ligand H_2L^1 was synthesized as reported previously [23b,24]. The ligand HL^2 was prepared by adding 2-oximinobutan-3-one (2.02 g, 20 mmol) dropwise to a stirred solution of 1,3-diaminopropane (1.85 g, 25 mmol) at room temperature. Both reactants were dissolved in methyl acetate. The reaction product was collected the next day and was washed with cold ethyl ether and dried over P_4O_{10}. The Ag^I-imine-oxime complexes were formed in situ by mixing $AgNO_3$ solution with an aqueous suspension of the ligand of choice with metal:ligand mole ratios 1:1.1 for H_2L^1 and 1:2.2 HL^2 in water at room temperature. Typically 0.85 g of $AgNO_3$ was used with the appropriate amount of the ligand. The mixtures were stirred until pale yellow solutions were formed. To the stirred solution of the Ag^I complex with the ligand H_2L^1, 2.0 g of PbO_2 was added and the solution acidified with drops of glacial acetic acid. The intensely orange-red solution that was formed was filtered and the complex formed was precipitated by the addition of NH_4PF_6 solution. The precipitate was filtered, washed with diethyl ether and dried over P_4O_{10}. The Ag^I complex with the ligand HL^2 was oxidized by either PbO_2 or $S_2O_8^{2-}$. The Ag^{III} complex was also precipitated by addition of NH_4PF_6. The IR spectra of the metal complexes were measured as KBr pellets using a Nicolet 510P-FT-IR spectrometer. The electronic spectra were recorded on a Lambda 25 UV–Vis spectrophotometer. Magnetic susceptibilities were measured at room temperature (~25 °C) by the Gouy method using a Sherwood Instruments magnetic susceptibility balance. Cyclic voltammograms were generated using an EG&G Princeton Applied Research Instruments Model 394 Electrochemical Trace analyzer. A three electrode system consisting of a Pt working electrode, an auxiliary platinum electrode and Ag/Ag^+ (0.10 M $AgNO_3$) reference electrode for a non-aqueous medium was used. Elemental analyses were performed at the UMIST (UK) and at Ain Shams University (Egypt).

A Perkin–Elmer TG A7 unit was used to record TG and DTG curves in a static N_2 atmosphere at a heating rate of 10 °C/min in the 30–900 °C range using platinum crucibles. The conductivity of the complexes was measured at 25 °C in water because the complexes are very unstable in non-aqueous solvents.



3. Results and discussion

The elemental analyses are consistent with the formation $[Ag^{III}HL^1](PF_6)_2 \cdot 4H_2O$ and $[Ag^{III}(HL^2)(L^2)](PF_6)_2 \cdot 3H_2O$. Elemental analyses for the complexes with the ligands H_2L^1 and HL^2 are: *Anal.* Calc.: C, 18.6; H, 3.8; N, 7.5. Found: C, 18.6; H, 3.6; N, 7.6% and *Anal.* Calc.: C, 22.0; H, 3.9; N, 11.0. Found: C, 21.8; H, 4.6; N, 9.9%, respectively. The thermal analysis curve for the complex with the ligand H_2L^1 showed that decomposition takes place in four stages in the 30–480 °C temperature range. The first endothermic stage corresponds to the dehydration process. The TG and DTG curves of the complex with the tetradentate ligand show a weight loss of 10.0%, which is in good agreement with the formula $[Ag^{III}HL^1](PF_6)_2 \cdot 4H_2O$. The weight loss of all four water molecules, calculated as 10.2%, occurs between 100 and 185 °C. The thermal decomposition of the complex with the ligand HL^2 proceeds in five stages. The first stage corresponds to the loss of three water molecules. The observed weight loss of 7.5% is in fairly good agreement with the loss of three water molecules (calc. 7.05%) from the formula $[Ag^{III}(HL^2)(L^2)](PF_6)_2 \cdot 3H_2O$. It seems that the ligands lose only one proton when coordinated to Ag^{III} unlike the case of Cu^{III} complexes with these same ligands where both protons are lost [23b,24]. The conductivity of the complexes $[Ag^{III}HL^1](PF_6)_2 \cdot 4H_2O$ and $[Ag^{III}(HL^2)(L^2)](PF_6)_2 \cdot 3H_2O$ was determined as 183 and 212 Ω^{-1} cm^2 mol^{-1}, respectively. This is consistent with the loss of only one proton and the formation of 1:2 electrolytes. The difference in the number of protons in the Cu^{III} and Ag^{III} complexes probably points the difference in the sizes of the +3 oxidation state of these metal ions, with the former being more polarizing than the latter due to its smaller size. The electronic spectrum of each complex is markedly affected by the nature of the solvent. This is indicative of the formation axial bonds. It also indicates that in the complex $[Ag^{III}(HL^2)(L^2)](PF_6)_2 \cdot 3H_2O$ the tridentate ligand is functioning only as a bidentate ligand. All the isolated complexes are diamagnetic, consistent with the formation of a low spin d^8 square planar or tetragonal structure with water molecules occupying axial positions.

The IR spectra of the two ligands showed the disappearance of the carbonyl band of the 2-oximinobutan-3-one and the appearance of sharp C=N bands. In the ligand HL^2 two bands appeared around 3256 cm^{-1} which are assigned to NH_2, confirming the 1:1 condensation between 1.3-diaminopropane and 2-oximinobutan-3-one. The C=N bands of the ligands are shifted to lower frequencies in the Ag^{III} complexes indicating bonding to the metal.

The UV–Vis absorption spectrum of the complex $[Ag^{III}HL^1]^{2+}$ is shown in Fig. 1. The complex $[Ag^{III}(HL^2)(L^2)]^{2+}$ showed a similar spectrum with slight variation in peak positions. A similar behavior was shown by the closely related Ag^{III}-dioximate complexes [16]. The high absorption in the visible region may be assigned to ligand to metal charge transfer (LMCT) by analogy to other

related complexes. Other Ag^{III}–N_4 ligand systems also exhibit similar LMCT bands in the visible region [21,22]. The positions of the UV bands in these complexes are very close to those of the free ligands and may be assigned to $\pi \rightarrow \pi^*$ transitions. The molar absorption of the complexes with the ligands H_2L^1 and HL^2 were measured at λ_{max} 486 nm as 1.76×10^4 and 1.12×10^4 M^{-1} cm^{-1}, respectively. Both complexes decompose slowly in aqueous solutions and the rate of decomposition is accelerated by both acid and base. A similar behavior was observed for the Cu^{III} complexes with the same ligands [23,24]. The complexes show marked color changes on dissolution of the complexes in coordinating solvents such as Me_2CO, Me_2SO and MeCN. This, most likely, is due to axial coordination to the four-coordinate Ag^{III} complex. Reported X-ray crystal structures have shown axial coordination by H_2O, NO_3^- as well as SO_4^{2-} [20]. Silver(III)-imine-oxime complexes decompose much more readily in non-aqueous solvents than in water. The d–d transition bands in these and other Ag^{III} complexes are not observed because they fall in the same spectral region as the charge-transfer bands.

The Ag^{III} complex with the ligand HL^2 may assume either structure A or B. However, all attempts to form crystals were unsuccessful because the complex decomposes slowly. Indeed both complexes decompose in the solid state if they are not kept dry and away from light.

The cyclic voltammograms of the complexes, shown in Figs. 2 and 3, indicate that the electron transfer processes are electrochemically irreversible and these generally involve a two-electron process [19]. This is not unexpected

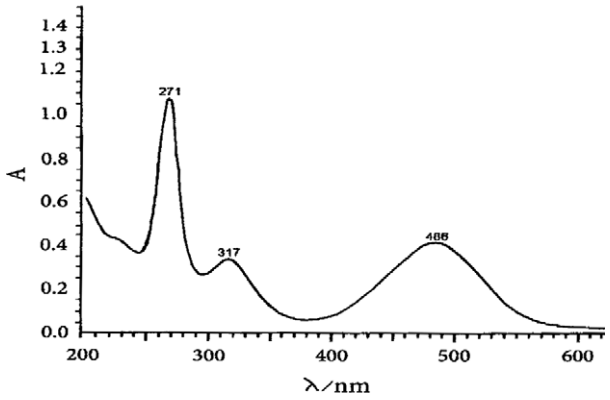


Fig. 1. UV–Vis absorption spectrum of $[Ag^{III}HL^1]^{2+}$ in aqueous solution at pH 4.60.

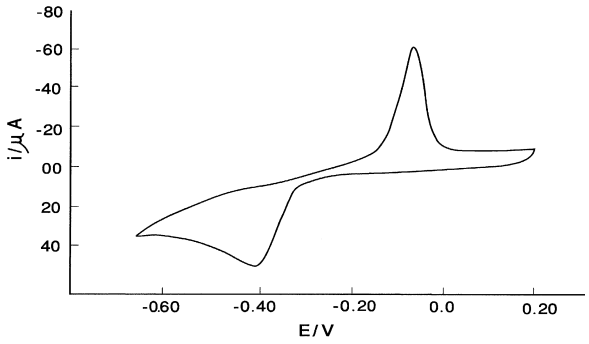

Fig. 2. Cyclic voltammogram of $[Ag^{III}HL^1]^{2+}$ in acetonitrile at $I = 0.10$ M $(n\text{-}Bu)_4NPF_6$ against Ag/Ag^+ (0.10 M $AgNO_3$) reference electrode for non-aqueous solvents.

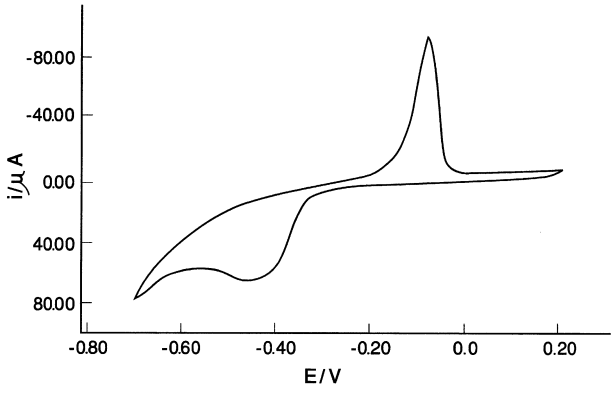

Fig. 3. Cyclic voltammogram of $[Ag^{III}HL^2]^{2+}$ in acetonitrile at $I = 0.10$ M $(n\text{-}Bu)_4NPF_6$ against Ag/Ag^+ (0.10 M $AgNO_3$) reference electrode for non-aqueous solvents.

as the conversion of $Ag^{III} \rightarrow Ag^{I}$ would be accompanied by structural changes. Electrochemically reversible cyclic voltammograms are only observed for $Ag^{III} \rightarrow Ag^{II}$ processes, where the electron transfer step is accompanied by only small structural changes [30]. Fig. 2 shows a cyclic voltammogram of the Ag^{III} complex with the ligand H_2L^1. The anodic, E_{pa}, and the cathodic, E_{pc}, potentials appear at −90 and −410 mV, respectively. The anodic and cathodic

potentials for the Ag^{III} complex with the ligand HL^2, shown in Fig. 3, appear at −83 and −440 mV, respectively, at a scan rate of 100 mV/s. Electrochemical irreversibility remained even at a scan rate of 20 mV/s. The i_a/i_c ratio is <1, thus confirming the irreversibility of the electron transfer. The peaks separations, ΔE_p, of 320 and 357 mV of the complexes with the tetradentate and tridentate ligands, respectively, are much higher than the 28 mV expected for a reversible two-electron transfer process. It may thus be concluded that tetradentate imine-oxime ligands stabilize higher oxidation states better than tridentate imine-oxime-amine ligands.

Abstract

The reaction of $TiCl_4$ with pyridine- and pyrimidine-thiol has been investigated. Reaction of $TiCl_4$ with 3 equiv. of 2-mercaptopyridine and 3 equiv. of *tert*-butylpyridine in toluene at room temperature resulted in the formation of the tris(pyridine-2-thiolate) complex $[TiCl(SC_5H_4N)_3]$ (**1**). The related reaction between $TiCl_4$ with 3 equiv. of 2-mercaptopyrimidine and 3 equiv. of *tert*-butylpyridine in toluene at room temperature resulted in the isolation of the complex $[TiCl(SC_4H_3N_2)_3]$ (**2**). Compound **2** has been characterised by X-ray crystallography. Low pressure CVD of **1** and **2** produced brown/gold films of TiS_2/TiO_2 on glass substrates at 550 and 600 °C.

1. Introduction

Early transition metal thiolate complexes represent a class of compound that have only been studied to a limited extent until recently [1]. Early routes to titanium thiolates involved the reaction of thiols with $[Ti(NR_2)_4]$ (R = Me or Et) resulting in the formation of complexes of the type $[Ti(SR')_4(HSR')_x(NHR_2)_y]$ (where $(x + y)$ varied from 0.8 to 1.33) [2]. We have recently shown that the reaction of $[Ti(NEt_2)_4]$ with C_6F_5SH and $PhCH_2SH$, resulted in the formation of ionic complexes of the type $[Et_2NH_2][Ti(SC_6F_5)_4(NEt_2)]$ and $[Et_2NH_2][Ti_2(\mu\text{-}SCH_2Ph)_3(SCH_2Ph)_6]$, respectively [3,4]. Similarly, reaction of $[Ti(NMe_2)_4]$ with CF_3CH_2SH afforded the salt $[Me_2NH_2]_2[Ti(SCH_2CF_3)_6]$ [5]. In contrast, addition of an excess of ^{t}BuSH to $[Ti(NEt_2)_4]$ resulted in the neutral complexes $[Ti(S^tBu)_4]$ and $[Ti(S^tBu)_3(NEt_2)]$ [6]. Titanium thiolates have also been prepared by reaction of an alkali metal thiolate with $TiCl_4$. For example, the titanium(III) thiolate $[Li(OEt_2)_3][Ti(S\text{–}2,4,6\text{–}^iPr_3C_6H_2)_4]$ was formed from the reaction of the lithiated thiol with $TiCl_3$ [7]. The homoleptic titanium thiolate $[Ti(S\text{-}2,3,5,6\text{-}Me_4C_6H)_4]$ resulted from reaction of $TiCl_4$ with 4 equiv. of $K[S\text{-}2,3,5,6\text{-}Me_4C_6H]$ [8]. The salt $[Et_4N]_2[Ti(SPh)_6]$ was isolated from $TiCl_4$, NaSPh and Et_4NBr [9]. In general, the isolation and purification of products from the reaction of $TiCl_4$ with alkali metal thiolates is difficult due to the strong interaction of titanium cations with halide ions. In order to avoid the purification problems associated with the route *via* alkali metal thiolates, trimethylsilylsulfides (Me_3SiSR) have also been used [10].

Early transition metal thiolates are of interest as potential precursors to transition metal disulfides, which in turn show a wide range of interesting characteristics from high temperature lubricating properties due to their layered structures to a variety of electronic properties (TiS_2 and MoS_2 are semiconductors; TaS_2 and NbS_2 are superconductors) [11–14]. However, most research has focussed on the use of TiS_2 as the cathode material in lithium rechargeable batteries [15,16]. TiS_2 has one of the highest

doi:10.1016/j.poly.2006.07.017

intercalation energies when lithium diffuses into the van der Waal's gap between sulfur layers. TiS_2 is used as the cathode for lithium microbatteries, where formation of Li_xTiS_2 occurs on the discharge process. The surface area and morphology of the TiS_2 material is important as a large surface area, with the crystallographic *c*-axis of the TiS_2 parallel to the substrate, gives the highest lithium diffusion, which relates directly to the current density produced by the battery. In addition, a large surface area such as a thin film could improve intercalation rates.

In this paper the synthesis and structures of the pyridine- and pyrimidine-thiolate titanium(IV) complexes, $[TiCl(SC_5H_4N)_3]$ (**1**) and $[TiCl(SC_4H_3N_2)_3]$ (**2**) are reported. The pyridine- and pyrimidine-thiolate ligands were chosen in an attempt to stabilise neutral titanium(IV) thiolate complexes. The thermal decomposition of **1** and **2** has also been studied.

2. Experimental

2.1. General procedure

All manipulations were carried out under a dry, oxygen-free dinitrogen atmosphere using either standard Schlenk techniques or in a MBraun Unilab glove box. Dichloromethane was distilled from CaH_2 prior to use, toluene dried using sodium and hexanes were dried using sodium/benzophenone. All other reagents were procured commercially from Aldrich. Microanalytical data were obtained at University College London (UCL).

NMR spectra were recorded on a Bruker AMX400 spectrometer at UCL, referenced to CD_2Cl_2, which was dried and degassed over molecular sieves prior to use; ^1H and ^{13}C chemical shifts are reported relative to $SiMe_4$ (δ 0.00). Thermal gravimetric analysis (TGA) was performed under a dinitrogen atmosphere with a heating rate of 10 °C min^{-1} and obtained from the Thermal Methods Laboratory at Birkbeck College London. Raman spectra were acquired on a Renishaw Raman System 1000 using a helium–neon laser of wavelength 632.8 nm. The Raman system was calibrated against the emission lines of neon. EDAX was obtained on a JOEL 25 and SEM was obtained on a Hitachi S570 instrument using the KEVEX system. X-ray powder diffraction patterns were measured on a Siemens D5000 diffractometer using monochromated Cu $K\alpha_1$ radiation ($\lambda = 1.5406$ Å). The diffractometer used glancing incident radiation (1.5°). Samples were indexed using unit cell and compared to database standards. X-ray photoelectron spectra were recorded using a VG ESCALAB 220i XL instrument using focused (300 μm spot) monochromatic Al Kα radiation at a pass energy of 20 eV. Scans were acquired with steps of 50 meV. A flood gun was used to control charging and the binding energies were referenced to an adventitious C 1s peak at 284.8 eV. Depth profile measurements were obtained by using argon beam sputtering. Film solubility was assessed by immersing a 2 cm × 7 mm strip, cut from the substrate, into solvent (water, dichloromethane, ether, toluene, acetone and concentrated nitric and hydrochloric acids). Hardness scratch tests were conducted using a brass stylus and a stainless steel scalpel.

2.2. Preparation of compound *1*

2-Mercaptopyridine (0.35 g, 3.15 mmol) was added to a solution of $TiCl_4$ (1.05 cm^3 of 1 M solution in toluene, 1.05 mmol) in toluene (30 ml) with stirring. 4-*tert*-Butylpyridine (0.47 ml, 3.15 mmol) was added causing an immediate colour change from yellow to deep purple. Stirring was continued for 3 h and a dark purple precipitate had formed. The solution was removed by filtration and the solid was washed with 2×5 cm^3 of hexanes and dried *in vacuo*. Dark purple needle-like crystals (0.36 g, 84%) were formed over a week from diffusion of a concentrated dichloromethane solution with an overlayer of hexane at room temperature. ^1H NMR (CD_2Cl_2) δ 7.1 (1H, m, *m*, C_5H_4NS), 7.2 (1H, m, *p*, C_5H_4NS), 7.4 (1H, m, *m*, C_5H_4NS), 7.6 (1H, m, *o*, C_5H_4NS). $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ 118.4 (*m*, C_5H_4NS), 128.5 (*p*, C_5H_4NS), 129.3 (*o*, C_5H_4NS), 179.3 (*o*, C_5H_4NS). *Anal.* Calc. for $C_{15}H_{12}ClN_3S_3Ti$: C, 43.5; H, 2.9; N, 10.2. Found: C, 43.7; H, 2.7; N, 10.7%. Melting point: 70 °C.

2.3. Preparation of compound *2*

2-Mercaptopyrimidine (0.35 g, 3.15 mmol) was added to a solution of $TiCl_4$ (1.05 cm^3 of 1 M solution in toluene, 1.05 mmol) in toluene (30 ml) with stirring. 4-*tert*-Butylpyridine (0.47 ml, 3.15 mmol) was added causing an immediate colour change to deep red. Stirring was continued for 3 h and a dark red precipitate had formed. The solution was removed by filtration and the solid was washed with 2×5 cm^3 of hexanes and dried *in vacuo*. Dark red needle-like crystals (0.37 g, 86%) were formed over a week from a concentrated dichloromethane solution at room temperature. ^1H NMR (CD_2Cl_2) δ 1.4 (18H, s, $(CH_3)_3CC_5H_4NH$), 6.9 (1H, m, *p*-$C_4H_3N_2S$), 7.1 (2H, m, *m*-$C_4H_3N_2S$), 7.9 (4H, m, *m*-$(CH_3)_3CC_5H_4NH$), 8.7 (4H, m, *o*-$(CH_3)_3CC_5H_4NH$), 9.7 (2H, s, $(CH_3)_3CC_5H_4NH$). $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ 30.2 ($(CH_3)_3CC_5H_4NH$), 36.9 ($(CH_3)_3CC_5H_4NH$), 124.5(*m*-$(CH_3)_3CC_5H_4NH$), 125.6 (*p*-$C_4H_3N_2S$), 128.5 (*m*-$C_4H_3N_2S$), 129.3 (*i*-$C_4H_3N_2S$), 140.7 (*o*-$(CH_3)_3CC_5H_4NH$) 151.4 (*p*-$(CH_3)_3CC_5H_4NH$). *Anal.* Calc. for $C_{30}H_{37}Cl_3N_8S_3Ti$: C, 47.4; H, 4.9; N, 14.7. Found: C, 47.7; H, 5.1; N, 14.1%. Melting point: 147 °C.

2.4. Low pressure CVD experiments

The experimental apparatus was the same as that described previously although quantities of precursor and size of substrates were different as described below [20]. The same procedure was carried out for all compounds (**1**, **2**) shown here for **2**. A sample of compound **2** (0.3 g) was loaded into the end of a glass ampoule (40 cm

length × 16 mm diameter) in the glovebox. Glass substrates (10 cm × 7 mm – uncoated microscope slide) were placed carefully inside the ampoule. The ampoule was then placed in a furnace such that 30 cm was inside the furnace and the end containing the sample protruded by 4 cm. The ampoule was heated to a temperature of 500 and 600 °C under dynamic vacuum (3.0 kPa), except for the section of the tube containing the sample. The ampoule was slowly drawn into the furnace over a period of a few minutes until **2** started to melt. Once the compound had decomposed the furnace was allowed to cool to room temperature. Brown/gold films were deposited on the glass substrates. The films were analyzed by EDAX/SEM, powder X-ray diffraction, Raman and X-ray photoelectron spectroscopy.

2.5. Crystal structures determination and refinement

Crystals of **2** were isolated from dichloromethane at room temperature. A single crystal was mounted on a glass fibre and all geometric and intensity data were taken from this sample on a Bruker SMART APEX CCD diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 150 ± 2 K. Data reduction and integration was carried out with SAINT+ and absorption corrections applied using the programme SADABS. The structure was solved by direct methods and developed using alternating cycles of least-squares refinement and difference-Fourier synthesis. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and their thermal parameters linked to those of the atoms to which they were attached (riding model). Structure solution and refinement used the SHELXTL Plus v6.10 program package [17]. See Table 1 for selected crystal data.

3. Results and discussion

Reaction of $TiCl_4$ and 3 equiv. of both HSC_5H_4N and 4-*tert*-butyl pyridine resulted in the isolation, after work up, of $[TiCl(SC_5H_4N)_3]$ (**1**). A dark purple precipitate of **1** formed in an 84% yield. Dark purple needle-like crystals of **1** suitable for X-ray analysis were formed by the diffusion of hexane into a concentrated dichloromethane solution at room temperature. Analytical and spectroscopic data for **1** were consistent with the formation of the tris(pyridine-thiolate) complex $[TiCl(SC_5H_4N)_3]$ (**1**) (Eq. (1)). The room temperature ^{1}H NMR spectrum of **1** in CD_2Cl_2 shows one set of resonances for the three thiolate ligand. These results are consistent with compound **1** being fluxional on the NMR time scale. Compound **1** has been prepared (in lower yield) and structurally characterised previously from the reaction of $TiCl_4$ and $Me_3SiSC_5H_4N$ [10]. Compound **1** has a distorted seven-coordinate pentagonal bipyramidal geometry at the titanium centre (Eq. (1)). The melting point of **1** was 70 °C which is sufficiently low to suggest that vaporisation and subsequent film growth could be possible by CVD.

(2)

2

The reaction of $TiCl_4$ with 3 equiv. of both $HSC_4H_3N_2$ and 4-*tert*-butyl pyridine was carried out in toluene at room temperature with the formation of a dark red precipitate. After work up of the reaction, red needle-like crystals were isolated, which were shown by a single crystal structure determination to consist of the pyrimidine-thiolate $[TiCl(SC_4H_3N_2)_3]$ (**2**) (Eq. (2)). The structure of compound **2** was determined by X-ray crystallography, the results are shown in Fig. 1; selected bond lengths and angles are shown in Table 2. Compound **2** crystallises into the monoclinic, $P2_1/n$ space group. The geometry adopted by titanium is a distorted seven-coordinate pentagonal bipyramidal with the Cl atom in an axial position, as for

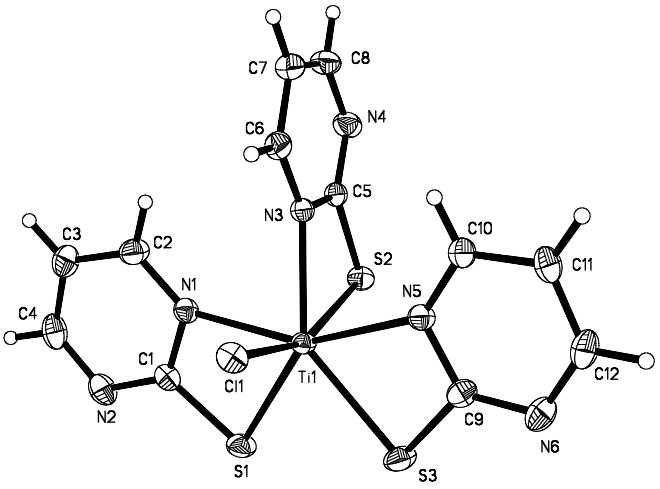

Fig. 1. X-ray structure of compound **2**.

compound **1**. The ligands are orientated such that the three S atoms are in all-*cis* positions on one triangular face of the pentagonal bipyramid. The Ti–S bond lengths are in the range 2.4361(11)–2.4548(11) Å and are comparable to those in **1** (2.4257(18)–2.4528(17) Å). A similar seven-coordinate structure incorporating dithiocarbamate ligands, namely $[TiCl(S_2CNMe_2)_3]$, where the chlorine atom adopts an axial position has previously been reported [18]. The Ti–S bond lengths in **1** and **2** are comparable to those reported for $[TiCl(S_2CNMe_2)_3]$ (2.473(3)–2.577(3) Å) and other titanium thiolate complexes [3–6,8–10,18]. The Ti–Cl bond length for compound **2** (2.2940(11) Å) is similar to that found in compound **1** and reported for $[TiCl(S_2CNMe_2)_3]$ (2.305(3) Å) [18]. The S–C bond lengths (1.733(4)–1.740(4) Å) are comparable to those in the dithiocarbamate $[TiCl(S_2CNMe_2)_3]$ (av. 1.715(10) Å) but shorter than other reported S–C(sp^2) bond lengths, for example the S–C bond lengths in $[Li(OEt_2)_3][Ti(S\text{-}2,4,6\text{-}^iPr_3C_6H_2)_4]$ were in the range 1.798(4)–1.806(5) Å [7]. The Ti–N bond lengths (2.182(3)–2.219(3) Å) in **2** are longer than that observed for a covalent Ti–N bond (e.g. 1.856(5) Å in $[Ti(NEt_2)(S^tBu)_3]$) but shorter than in titanium pyridine complexes such as $[Ti(N^tBu)Cl(N_3)(py)_2]_2$ (av. Ti–N 2.241(5) Å) [6,19]. The shorter Ti–N and S–C bond lengths suggest that there is some contribution from canonical form b, shown in Fig. 2, as was also observed for **1**. The spectroscopic and analytical data for **2** showed the presence of the side product $[^tBuC_5H_4NH]Cl$.

In order to study the decomposition pathway of compounds **1** and **2** thermal analyses were carried out. The TGA (thermal gravimetric analysis) of **1** (10 °C/min from 20 to 500 °C) shows a weight loss of 91%. The decomposition of **1** does not occur in clean, discrete stages but is continuous from the onset at *ca.* 150 °C throughout the temperature range studied. The mass loss of 91% is significantly higher than the calculated mass loss of 73% for **1** to form TiS_2. It is worth noting that TGA at atmospheric pressure only gives an indication of the potential of the precursors to form bulk titanium sulfide. Any sublimation of the precursor, a desirable characteristic for low pressure chemical vapour deposition (LPCVD) studies, would register as a further mass loss, as observed in the TGA of **1**. The DSC of **1** shows a sharp endotherm at 70 °C which corresponds to the melting point. The decomposition of **1** begins at a higher temperature than the melting point suggesting that transport of the intact molecule to the substrate could be successfully achieved. This would suggest that compound **1** would be a good CVD precursor. The TGA for **2** shows that the onset of decomposition is *ca.* 200 °C and continues over the entire temperature range up to 500 °C. As with compound **1** there are no discrete steps observed in the TGA, suggesting that the decomposition will not proceed cleanly. The measured mass loss of 57% is less than the required mass loss to produce TiS_2 (73%). This behaviour indicates an incomplete decomposition to TiS_2 up to 500 °C, although it is possible that the required weight loss could be attained at higher temperatures (the TGA set-up allows analysis only to 500 °C). The DSC of **2** shows a sharp endotherm at 147 °C signifying the melting point. This is significantly higher than the pyridine analogue, compound **1**.

LPCVD of **1** and **2** were investigated, the details of which are described in Section 2 [20]. The films produced

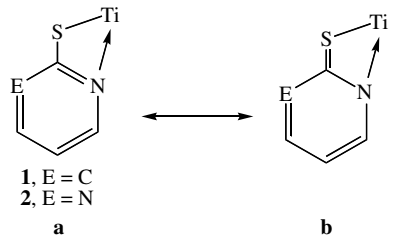

Fig. 2. Resonance forms of the mercapto-pyridine and -pyrimidine ligand.

were analyzed by EDAX/SEM, XPS, powder XRD and Raman spectroscopy. The films produced from **1** and **2** under LPCVD conditions were adhesive to the substrate in that they passed the Scotch Tape Test but were easily scratched by a brass or stainless steel stylus. Chemically, the films showed no reactivity to common organic solvents. Concentrated nitric acid digested a film within 30 s of immersion, whereas concentrated hydrochloric acid dissolved the film over 2 h. Brown/gold reflective films were deposited from compound **1** at 500 and 600 °C, 0.03 mm Hg. All the films deposited from **1** were sulfur deficient by EDAX with a titanium to sulfur ratio of 1:1.6 at 600 °C and 1:1 at 500 °C. No chlorine contamination was found by EDAX. The Ti:S ratios could indicate the formation of Ti_2S_3 and TiS (at 600 and 500 °C, respectively) or alternatively could be due to partial oxidation of the films with the formation of a mixture of TiS_2 and TiO_2. However, the XPS of the film deposited at 600 °C from **1** does not show the presence of TiO_2 in the Ti 2p spectrum [21]. The peaks at 456.8 and 462.4 eV correspond to Ti $2p_{3/2}$ and Ti $2p_{1/2}$, respectively, which match well with those previously reported for TiS_2 (Ti $2p_{3/2}$, 456.2 eV; Ti $2p_{1/2}$, 462.2 eV) [21]. The S 2p peaks in the XPS confirm that TiS_2 has been formed, with peaks observed at 161.6 and 163.4 eV (corresponding to S $2p_{3/2}$ and $2p_{1/2}$, respectively). Furthermore, the XPS shows that only one sulfur environment is present within the film and that this corresponds to sulfur in TiS_2. No chlorine contamination was observed in the XPS.

Further evidence for the formation of TiS_2 films from **1** were provided by Raman spectroscopy and powder XRD. The Raman patterns for the films deposited from **1** show the characteristic TiS_2 peak at 332 cm^{-1} and do not show the presence of TiO_2 peaks suggesting that the sulfur deficiency is not due to surface oxidation. Glancing angle XRD for the film deposited at 600 °C from **1** shows peaks which correspond well with the literature values for TiS_2. In contrast to the Raman patterns which did not show the presence of TiO_2, the glancing angle XRD for the film deposited from **1** at 500 °C shows peaks corresponding to TiS_2 and TiO_2 (anatase). The XRD suggests some preferential orientation. The SEM image for the film deposited at 600 °C shows a series of hexagonal platelets in a perpendicular orientation to the substrate (Fig. 3a). The platelets measure *ca.* 1.5 μm in diameter. The perpendicular orientation of this film would be particularly favoured for use in battery applications as intercalation is maximised, where films are perpendicular to the substrate. In addition, the platelets are indicative of film formation *via* an island growth type mechanism. The SEM image for the film deposited at 500 °C also shows platelets in a perpendicular orientation to the substrate which are *ca.* 3.7 μm in diameter (Fig. 3b). Small clusters are also observed on the surface of the substrate, which are 0.7 μm in diameter. This could explain the inconsistent XRD and Raman results for films deposited at 500 °C, in that there is a deposit of TiO_2 (clusters) on the surface, with TiS_2 platelets above. The Raman pattern does not show TiO_2, as this is a surface sensitive technique (with a penetration depth of *ca.* 600 nm), whereas XRD penetrates further. The EDAX results are also in agreement with these observations as EDAX measures a large area and penetrates into the film and therefore the titanium to sulfur ratio of 1:1 is explained by the mixed TiS_2/TiO_2 film. Therefore, the presence of TiO_2 is not a consequence of surface oxidation as TiO_2 peaks would be observed in the Raman pattern, instead it was formed at the time of deposition and could be due to reaction with the uncoated glass substrate. TiS_2 films were produced from **1** at 600 °C although some slight deviations were noted from this composition by EDAX, where breakthrough to the underlying glass was observed.

The films deposited from **2** had a titanium to sulfur ratio of 1:1.5 by EDAX showing them to be sulfur deficient which may be due to oxidation of the films. The XPS for Ti 2p gave a binding energy of 458.5 and 464.2 eV for Ti $2p_{3/2}$ and $2p_{1/2}$, respectively, which match well with those previously reported for TiS_2 [21]. The spectrum was particularly clean with no titanium peaks due to TiO_2 observed.

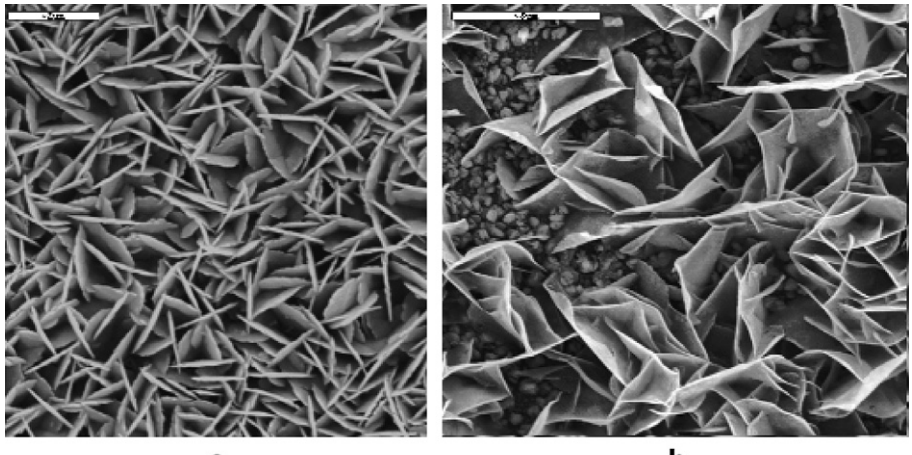

Fig. 3. SEM image for a film deposited by LPCVD from compound **1** at: (a) 600 °C and (b) 500 °C.

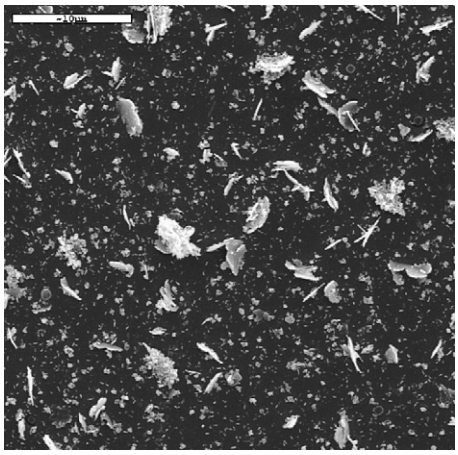

Fig. 4. SEM image for a film deposited by LPCVD from compound **2** at 600 °C.

The S 2p peaks in the XPS show one sulfur environment, which corresponds with that in TiS_2. The peaks at 161.7 and 163.2 eV can be attributed to S $2p_{3/2}$ and $2p_{1/2}$, respectively, the values matching well with those previously reported [21]. Chlorine contamination (*ca.* 4%) was found in the films by XPS. In addition, both carbon and nitrogen contamination was observed in the films suggesting that the decomposition mechanism of **2** is not particularly clean. These results are consistent with the TGA observed for **2**. The Raman pattern for the film deposited from **2** showed the presence of the TiS_2 peak at 329 cm^{-1} with a shoulder at 373 cm^{-1}. The XRD for these films showed them to be amorphous to X-rays. This is in contrast with films deposited from the pyridine analogue **1** which were crystalline even at 500 °C.

The SEM image for the films deposited from **2** shows hexagonal platelets in a perpendicular orientation to the substrate's surface (Fig. 4). This corresponds with the morphology of films grown from the pyridine analogue **1**. However, the image of the film produced from **2** shows that the platelets are much more dispersed than in the films deposited from **1**. The SEM image of the film grown from **2** shows small clusters (0.6 μm in diameter) and needle-like features (0.6 μm in length) between the platelets. This suggests that the growth rate of the films from **2** are significantly slower than from **1**. This supports the TGA data, where **2** decomposed further than **1** at the same temperature.

4. Conclusions

The titanium thiolate complexes, $[TiCl(SC_5H_3N)_3]$ and $[TiCl(SC_4H_3N_2)_3]$ have been synthesized and characterised. X-ray crystallography showed that $[TiCl(SC_4H_3N_2)_3]$ is monomeric with seven-coordinate titanium atoms. Low pressure CVD indicate that $[TiCl(SC_5H_3N)_3]$ is an effective titanium sulfide precursor resulting in TiS_2 films at 600 °C or TiS_2/TiO_2 films at 500 °C. In contrast, $[TiCl(SC_4H_3N_2)_3]$ was shown to be unsuitable as a precursor since amorphous TiS_2 films contaminated with C, N and Cl were obtained.

Abstract

This paper describes the synthesis of the first Ni(II) complexes with pyridoxal semicarbazone (PLSC), viz. $Ni(PLSC)Cl_2 \cdot 3.5H_2O$ (**1**), $[Ni(PLSC)(H_2O)_3](NO_3)_2$ (**2**), $Ni(PLSC)(NCS)_2 \cdot 4H_2O$ (**3**), $[Ni(PLSC\text{-}2H)NH_3] \cdot 1.5H_2O$ (**4**), as well as two new complexes with pyridoxal thiosemicarbazone (PLTSC), $[Ni(PLTSC\text{-}H)py]NO_3$ (**5**) and [Ni(PLTSC-H)NCS] (**6**). Complexes **1**–**3** are paramagnetic and have most probably an octahedral structure, for complex **2** this was proved by X-ray diffraction analysis. In contrast, complexes **4**–**6** are diamagnetic and have a square-planar structure, and in the case of complex **5** this was also confirmed by X-ray structural analysis. In all cases the Schiff bases are coordinated as tridentate ligands with an ONX (X = O, PLSC; X = S, PLTSC) set of donor atoms. With the complexes involving the neutral form of PLSC and the monoanionic form of PLTSC, the PL moiety is in the form of a zwitterion. In addition to the above-mentioned techniques, all the complexes were characterized by measuring their molar conductivities, UV–Vis and partial IR spectra.

1. Introduction

For some time, semi- and thiosemicarbazones have been a subject of interest to researchers of different profiles. In view of the fact that these compounds form with many metals complexes of diverse chemical, physical and structural characteristics, they are of special interest to coordination chemists [1–3]. In addition, many of these compounds as well as their metal complexes, especially those with thiosemicarbazones, have shown a wide spectrum of biological activity, so that they have also become a subject of intense research for pharmacologists [4].

One of the newer semicarbazone ligands, which is the subject of our research, is pyridoxal semicarbazone (PLSC), whose only complexes reported up to now are those with Cu(II), Fe(III) and Pt(IV) [5–8]. In contrast to PLSC, a number of pyridoxal thiosemicarbazone (PLTSC) complexes, involving not only transition metals (among them Ni(II) too) but also some non-transition metals, have been described [9].

doi:10.1016/j.poly.2006.07.031

As a continuation of our study of the complexing properties of PLSC, we describe here the synthesis and some physico-chemical and structural characteristics of its first complexes with Ni(II), as well as two new Ni(II) complexes with PLTSC.

2. Experimental

All chemicals used for the synthesis and measurements were commercial products, except for the ligands, which were prepared according to the previously described procedures [6].

Elemental (C, H, N) analysis of air-dried samples was carried out by standard micromethods in the Center for Instrumental Analysis, Faculty of Chemistry, Belgrade.

2.1. Syntheses of complexes

2.1.1. Ni(PLSC)$X_2 \cdot nH_2O$ (**1–3**); (X = Cl, n = 3.5 (**1**); X = NO_3, n = 3 (**2**), X = NCS, n = 4 (**3**))

To a warm suspension of 0.26 g (1.0 mmol) of PLSC $\cdot$ $2H_2O$ in 10 cm^3 of EtOH 1.2 mmol of solid $NiX_2 \cdot 6H_2O$ (X = Cl, NO_3) was added and the content heated until the reactants were completely dissolved. In the case of the reaction with $Ni(NCS)_2 \cdot 2H_2O$ use was made of aqueous solutions of the reactants. The green solutions were left to evaporate at room temperature. The crystals were filtered and washed with EtOH. Yield: 50–70%.

2.1.2. [Ni(PLSC-2H)NH_3] $\cdot$ 1.5H_2O (**4**)

To a warm suspension of 0.26 g (1 mmol) of PLSC $\cdot$ $2H_2O$ in 10 cm^3 of EtOH, a warm EtOH (5 cm^3) solution of 0.35 g (1.2 mmol) of $Ni(NO_3)_2 \cdot 6H_2O$ was added, and the content heated to complete dissolution of the ligand. To the green solution NH_3(aq.) (1 cm^3) was added and the content heated for 2–3 min, whereby the solution became red. After 10 h the orange microcrystalline precipitate was filtered and washed with EtOH. Yield: 0.28 g (86%).

2.1.3. [Ni(PLTSC-H)py]NO_3 (**5**)

A mixture of 0.15 g (0.5 mmol) of PLTSC $\cdot$ $3H_2O$ and 0.17 g (0.6 mmol) of $Ni(NO_3)_2 \cdot 6H_2O$ was dissolved by heating in MeOH (10 cm^3), and pyridine (0.5 cm^3) was added to the solution. The red solution was left at room temperature for 24 h. The obtained red monocrystals were filtered and washed with MeOH. Yield: 0.10 g (44%).

2.1.4. [Ni(PLTSC-H)NCS] (**6**)

A warm solution of 0.12 g (0.6 mmol) of $Ni(NCS)_2 \cdot 2H_2O$ in H_2O (5 cm^3) was mixed with a warm solution of 0.15 g (0.5 mmol) of PLTSC $\cdot$ $3H_2O$ in DMF (2 cm^3) and heated mildly for 2–3 min. The complex started to crystallize immediately from the warm solution. After 10 h brown crystals were filtered and washed with H_2O and EtOH. Yield: 0.10 g (55%).

Data of microanalysis and measurements of magnetic susceptibility, molar conductivity, along with the description of colors and geometry of all the complexes, are given in Table 1.

2.2. Physical methods

Magnetic susceptibilities were measured at room temperature using a magnetic susceptibility balance MSB-MKL (Sherwood Scientific Ltd. Cambridge, England).

Molar conductivities of the freshly prepared 1×10^{-3} M aqueous or methanolic solutions were measured on a Jenway 4010 conductivity meter.

IR spectra (KBr disk) were recorded on a Thermo Nicolet (NEXUS 670 FT-IR) instrument.

Electronic spectra were recorded on a Secomam (Anthelie 2, Advanced, for the range 200–900 nm) and on a Thermo Nicolet instrument (NEXUS 670 FT-IR, for the range 900–1400 nm) in (2–4) $\times 10^{-4}$ mol dm^{-3} MeOH and DMF solutions of the complexes.

2.3. Crystal structure determination

Single crystals of the title compounds **2** (green) and **5** (dark red) were selected and glued on glass threads. Diffraction data were collected on a Bruker PLATFORM three-circle goniometer equipped with SMART 1K CCD detector for **2** and on a Nonius Kappa CCD diffractometer for **5**. The crystal to detector distances were 5.4 and

3.0 cm for **2** and **5**, respectively. Graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) was employed in both measurements. Frame widths of 0.3° and 2° in ω, with 10 and 200 s were used to acquire each frame for **2** and **5**, respectively. More than hemispheres of three-dimensional data were collected in both measurements. The data were reduced using the Bruker program SAINT for **2** and Nonius program COLLECT for **5**. A semiempirical absorption-correction based upon the intensities of equivalent reflections was applied, and the data were corrected for Lorentz polarization and background effects. Scattering curves for neutral atoms, together with anomalous-dispersion corrections, were taken from the International Tables for X-ray Crystallography [10]. The structures were solved by direct methods [11], and the figures were drawn using ORTEP [12]. Refinements were based on F^2 values and done by full-matrix least-squares [13] with all non-H atoms anisotropic. The positions of hydrogen atoms were found from the inspection of the difference Fourier maps. The final refinement included atomic positions and displacement parameters for all atoms. The non-H atoms were refined anisotropically, while all H sites were refined with isotropic displacement parameters. The crystal data and refinement parameters for the title compounds are listed in Table 2.

3. Results and discussion

3.1. Syntheses, physico-chemical characteristics and geometric structures of the complexes

Reactions of warm EtOH or H_2O solutions of PLSC and $NiX_2 \cdot nH_2O$ (X = Cl, NO_3, NCS) in a mole ratio of 1:1 yielded the paramagnetic green monoligand complexes of the general formula $Ni(PLSC)X_2 \cdot nH_2O$ (**1**, **2**, **3**) (Table 1). In the presence of NH_3(aq.) and pyridine (py), $Ni(NO_3)_2 \cdot 6H_2O$ forms with PLSC and PLTSC, respective diamagnetic complexes $[Ni(PLSC\text{-}2H)NH_3] \cdot 1.5H_2O$ (**4**), and [Ni(PLTSC-H)py]NO_3 (**5**). The other, also diamagnetic, complex with PLTSC, viz. [Ni(PLTSC-H)NCS] (**6**) was obtained in the reaction of an H_2O solution of $Ni(NCS)_2$ and DMF solution of PLTSC. The isolated complexes are crystalline substances that are stable in air. With the exception of $[Ni(PLSC\text{-}2H)NH_3] \cdot 1.5H_2O$, which is slightly soluble only in DMF, the other PLSC complexes, in addition to being soluble in DMF, are also soluble in H_2O, but are somewhat less soluble in MeOH and EtOH. The PLTSC complexes are soluble in DMF but dissolve poorly in H_2O and alcohols.

Some physical characteristics of the complexes that are relevant to their geometric structures are presented in

Table 1. First of all, the X-ray analysis of $[Ni(PLSC)(H_2O)_3](NO_3)_2$ (**2**) (vide infra) showed that it has an octahedral structure, formed by the tridentate ONO coordination of the PLSC ligand and three H_2O molecules. The Ni(II) complexes are of the characteristic green color and have the expected μ_{eff} values (Table 1). Based on this, the same geometric configuration could also be ascribed to the other two paramagnetic PLSC complexes **1** and **3**, this configuration being the most frequently observed for paramagnetic Ni(II) complexes [14]. Therefore, apart from the PLSC ligand, H_2O molecules or acid residues must participate in coordination. In the case of the $Ni(PLSC)(NCS)_2 \cdot 4H_2O$ complex, the coordination of the NSC group is also supported by the position of the ν(CN) band in the IR spectrum, which appears as a doublet at 2091 and 2104 cm^{-1}, i.e. in the region of a coordinated NCS-group [15], bonded through the nitrogen atom, as is usual with Ni(II) as a representative of medium-hard acids. The weak ν(CS) and δ(NCS) bands, appearing at lower energies, cannot be located as they are masked by the bands of the organic ligand. On the basis of the IR spectrum of complex **1**, it can be supposed that Cl^- does not participate in coordination. This assumption is based on the absence of the ν(Ni–Cl) band. The conclusion is also supported by the great similarity of the IR spectra of the octahedral $[Ni(PLSC)(H_2O)_3](NO_3)_2$ complex and the Cl-containing complex in the range below 350 cm^{-1}, i.e. at the wavelengths where one could expect the ν(Ni–Cl) bands [15,16].

Molar conductivities (λ_M) of H_2O solutions of the paramagnetic PLSC complexes (Table 1) indicate the presence of a 2:1 type of electrolyte [17]. The same also holds for the MeOH solutions of the Cl- and NO_3-containing complexes. In contrast to them, the λ_M values of MeOH solutions of the NCS complex correspond to a 1:1 type of electrolyte [17], which suggests partial replacement of the coordinated NCS group with solvent molecules. However, for the same complex in acetone solution $\lambda_M = 32\ \Omega^{-1}\ cm^2\ mol^{-1}$ was obtained, which is significantly lower than the usual value for a 1:1 electrolyte ($\lambda_M = 100$–$140\ \Omega^{-1}\ cm^2\ mol^{-1}$) [17], suggesting the coordination of both NCS groups is preserved in solution.

Concerning the exact formulas of the octahedral complexes **1** and **3**, it can be supposed that the structure of complex **1** is similar to that of complex **2**, which is also supported by the similarity of the values of their molar conductivities (electrolyte type 2:1). Hence, the probable formula involves a complex cation of the type $[Ni(PLSC)(H_2O)_3]^{2+}$. However, for complex **3**, for which a coordination of two NCS groups and one water molecule in crystal is supposed, the molar conductivity data indicate that the NCS-group coordination depends on the nature of the solvent: in the least polar solvent, acetone, both groups remain coordinated, in MeOH only one is coordinated, whereas in H_2O both are dissociated. Hence, this complex and complexes **1** and **2** in aqueous solution have the same complex cation, i.e. $[Ni(PLSC)(H_2O)_3]^{2+}$.

The diamagnetism and color of complex **4** and of two new PLTSC complexes **5** and **6** suggest their structure is square-planar [14]. In the case of **5**, this was proved by X-ray analysis (vide infra). In contrast to the other compounds, the PLSC complex **4** contains the ligand in a dianionic form, arising from the deprotonation of not only the enol-form of the semicarbazide moiety but also of the zwitter ion of the PL residue, which also explains its non-electrolytic nature. Both PLTSC complexes contain the ligand in its monoanionic form, resulting from the deprotonation of the thiol form of the thiosemicarbazide moiety. As is the case with the other complexes containing this ligand [9], both PLTSC complexes involve the ONS set of donor atoms; the fourth coordination site being occupied by a py or NCS group. The ν(CN) band of the coordinated NCS group is observed at 2113 cm^{-1}. The molar conductivity of this complex in DMF (Table 1) suggests partial replacement of the NCS group with solvent molecules.

In the example of the reactions of $Ni(NCS)_2$ with these two ligands it can be concluded that the TSC residue is a stronger acid than the SC residue, i.e. that PLTSC is more readily deprotonated than PLSC. The same conclusion can be made on the basis of the reaction of PLTSC with $Ni(NO_3)_2$ too, keeping in mind the fact that in this reaction Ferrari et al. [18] obtained a complex involving the monoanionic form of the ligand of the composition $Ni(PLTSC\text{-}H)NO_3 \cdot 2H_2O$. It should be noted that these authors also described the compound $Ni(PLTSC\text{-}2H) \cdot 2H_2O$, obtained from the reaction of PLTSC with $Ni(OAc)_2$.

3.2. Electronic spectra

Table 3 summarizes the electronic spectral data for the investigated complexes in two solvents, recorded in the range of 220–1200 nm (MeOH) and 270–1200 nm (DMF). As can be seen, the spectra display several electronic transitions. The strong peak at the blue end of the spectra of the complexes in MeOH (at about 240 nm) can be ascribed to $\pi \rightarrow \pi^*$ pyridine ring absorptions [19], which are, due to an increased conjugation in the complexes, shifted by about 10–20 nm to higher wavelengths compared to those of the ligands alone [20]. Other spectral characteristics are mainly influenced by the coordinated ligand and its deprotonation and only slightly by solvent effects.

The paramagnetic semicarbazone complexes are characterized by two main bands at about 300 and 400 nm (Fig. 1). Obviously, the bands are complex, each being composed of at least two close bands. The band at 300 nm comprises transitions $\pi \rightarrow \pi^*$ imine and $n \rightarrow \pi^*$ of both the imine and pyridine ring, which are also present in this range in the spectra of the ligand alone [21]. The other band (~400 nm) may be due mainly to LMCT transitions. In this spectral range, one would expect LM N → Ni and SCN → Ni charge transfers, but the band for Cl → Ni is usually observed at somewhat higher energies (around 330 nm) [22]. In addition, low intensity d–d

bands (ν_3) should also be present in this range, but they are masked by the stronger CT absorptions.

Because of their low spectral intensities and the low solubilities of the complexes, the data on d–d transitions are difficult to assign unambiguously. However, having in mind the crystal structure of **2** and the paramagnetic characteristics of the complexes, their light yellow-greenish color of solutions and molar conductivity data, it is reasonable to presume a pseudo-octahedral configuration. Since the PLSC ligand in the crystal occupies three coordination sites in the equatorial plane, the other three sites in the meridional plane are occupied either by three water molecules (**1**, **2**) or, probably, two NCS^- and one water molecule (**3**). In solutions, partial replacement of the anion (NCS^-) with solvent molecules occurs, which was confirmed by the conductivity measurements (see above). However, the recorded spectra of all three complexes in d–d range are similar thus suggesting a presumption of a similar geometry of these compounds in solution.

A comparison of the spectral data in the two solvents suggests a red shift of the CT bands in the more polar solvent (DMF), arising as a consequence of a positive solvatochromic effect.

The diamagnetic non-electrolyic complex **4**, which is square-planar in the crystal, has probably the same configuration in solution. This assumption is supported by the

lack of bands in the visible region. In fact, a d–d band (456 nm, $\varepsilon = 2400\ M\ cm^{-1}$) appears in MeOH as a shoulder of a stronger CT band, but in DMF these bands overlap. The very poor solubility of this complex in both solvents may be the reason for an apparent absence of weak bands in the region of 900–1000 nm.

The thiosemicarbazone complexes have very broad and unresolved bands in the range 300–350 nm, which are of similar origin to those in the semicarbazone complexes. The other complex band at about 400 nm resulted from

the overlapping absorptions of two transitions: LMCT (S → Ni) and the second n → π* of the deprotonated ligand [22]. The data obtained for d–d transitions, with the exception of the band at about 470–490 nm which appears as a shoulder of the stronger CT band, are ambiguous because of the mentioned low solubility and resultant low absorption intensity. However, on the basis of their diamagnetism, orange-to-red color in solutions and very weak bands (shoulders) in the range of 700–900 nm, a distorted square-planar configuration can be suggested. Furthermore, the existence of a mixture of these and pseudo-tetrahedral complexes cannot be completely excluded, especially in DMF solutions, as was observed in some previous cases [23].

3.3. Crystal structure of $[Ni(PLSC)(H_2O)_3](NO_3)_2$ (2)

The crystal lattice of compound **2** consists of discrete complex cations $[Ni(PLSC)(H_2O)_3]^{2+}$ and $(NO_3)^-$, bound together by hydrogen bonds. The coordination environment around the central ion is a distorted octahedron. In the equatorial position of the complex cation, the tridentate (ONO) neutral pyridoxal semicarbazone (PLSC) chelates the nickel atom, which is additionally surrounded by three water molecules in the meridional position (Fig. 2). The apical positions of the octahedron are occupied by two water oxygens at the distances Ni–Ow1 2.093(2) Å and Ni–Ow2 2.115(2) Å (Table 4). The Ni–O(2) (phenolic) bond of 1.983(2) Å is significantly shorter than Ni–O1 (2.068 Å) and Ni–Ow3 (2.054 Å), probably because of the presence of a negative charge on the phenolic deprotonated oxygen (the pyridoxal ring adopts the role of a zwitter ion). The zwitter ion form, i.e. pyridine nitrogen protonation is suggested by the angle of ~124° for C6–N4–C8 [9]. The octahedral bond angles Ow1–Ni–Ow2 (173.8°) and Ow3–Ni–N3 (176.2°) are close to each other and slightly different from the theoretical value of 180°, while the bond angle O1–Ni–O2 (168.7°) is significantly smaller due to the chelation ring strain. The whole ligand molecule deviates considerably from planarity. The

Equivalent positions: (1) x, y, z; (2) $-x+1, -y, -z+1$; (3) $x+2, -y+1/2, +z+1/2$; (4) $-x-1, +y-1/2, -z+1/2$

dihedral angles between the mean planes of the pyridoxal moiety (A) and six- (B) and five-membered (C) chelate rings are A–B 12.3°, A–C 15.2° and B–C 3.5°. The basal plane of the coordination polyhedron is slightly tetrahedrally deformed, with a maximum distance from the least squares plane of 0.039(1) Å for N3. The nickel atom is displaced towards the apical Ow2 atom by 0.0208(3) Å. Bond distances and bond angles in PLSC are in good agreement with the corresponding values found in the structure of dibromo(pyridoxal semicarbazone-$\kappa^3N^1,O^3,O^{3'}$)copper(II) [5]. The geometry of the NO_3 groups do not deviate from the usual literature values. Possible hydrogen bonds are listed in Table 5. The packing (Fig. 3) of this compound is determined by a large network of hydrogen bonds, a few of which are bifurcated among the complex molecules, the nitrate ions and water molecules.

3.4. Crystal structure of [Ni(PLTSC-H)py]NO_3 (5)

Experimental details of the crystal structure of complex **5** are presented in Table 2. The asymmetric unit consists of the well-separated complex cation $[Ni(PLTSC\text{-}H)py]^+$ and the NO_3^- anion. The monodeprotonated PLTSC is coordinated to the Ni atom through the phenolic oxygen O2, imine nitrogen N3, and thiolato sulfur of the Schiff base. The pyridine nitrogen N completes the coordination plane (Fig. 4). Because of the different character of the atoms forming the environment around the Ni(II) ion, the coordination square is distorted, as is confirmed by the given interatomic distance values and bond angles (Table 4). The coordination plane is slightly tetrahedrally deformed with a maximum distance of 0.076(2) Å for O2. The Ni atom is displaced by −0.0173(3) Å from the least squares plane. The same square-planar arrangement around Ni(II) ion with very similar Ni-donor bond distances and angles can be found in the structure of the amine (salicylidenethiosemicarbazonato(2^-)) nickel(II) [24]. Bond distances and angles in the chelate ligand of complex **5** are in good agreement with those found for the free pyridoxal thiosemicarbazone molecule [18]. An exception is the C1–N2–N3 angle of the thiosemicarbazide fragment (112.5°), which is in **5** significantly smaller than 120°, due to deprotonated nitrogen N2. The whole chelate ligand is close to coplanarity. If the skeletal atoms are considered, the largest deviation from the least-squares plane is 0.116(3) Å for C4 atom. At the same time, the atoms C7, C5 and Ni deviate from this plane by 0.252(4), −0.287(4) and −0.0572(3) Å, respectively. The dihedral angles between the pyridoxal

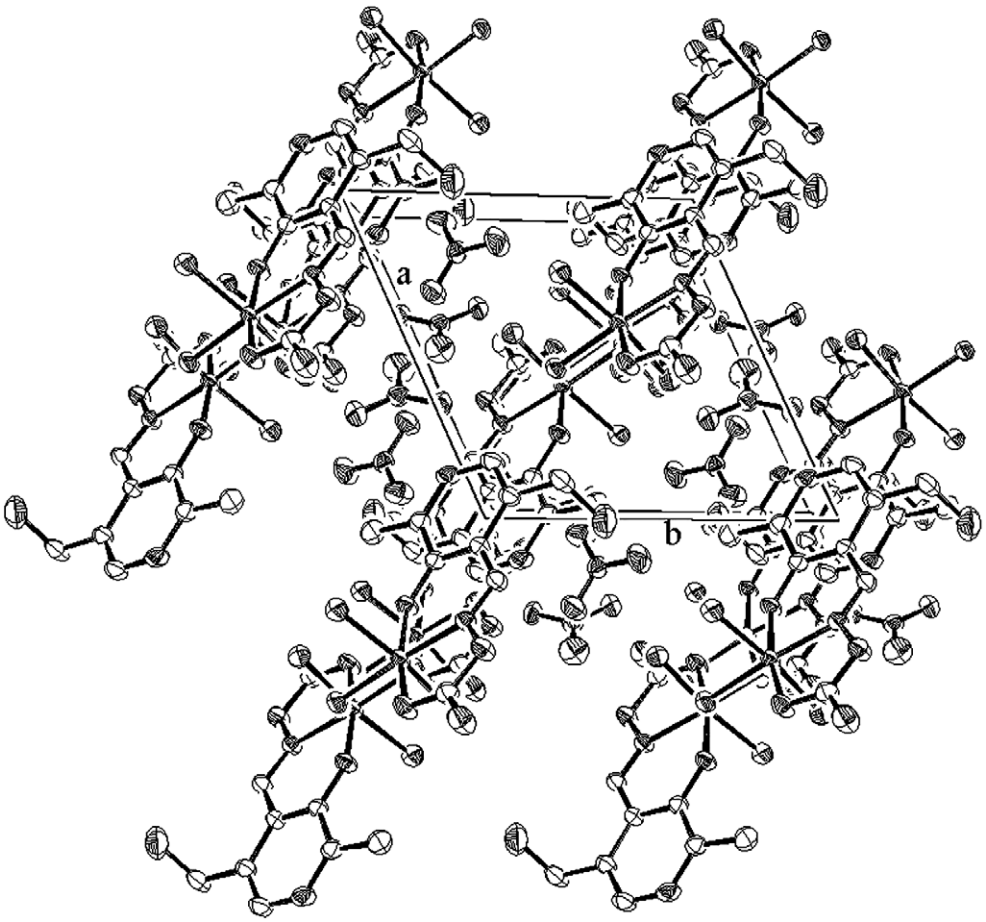

Fig. 3. The crystal structure of $[Ni(PLSC)(H_2O)_3](NO_3)_2$ viewed along the *c*-axis.

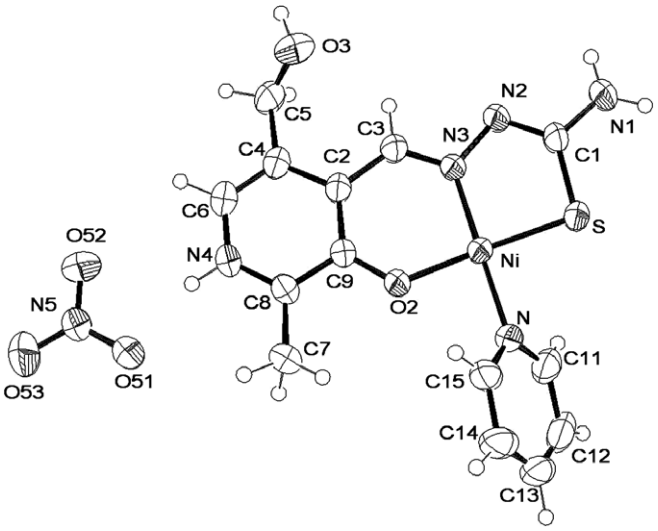

Fig. 4. ORTEP view of [Ni(PLTSC-H)py]NO_3.

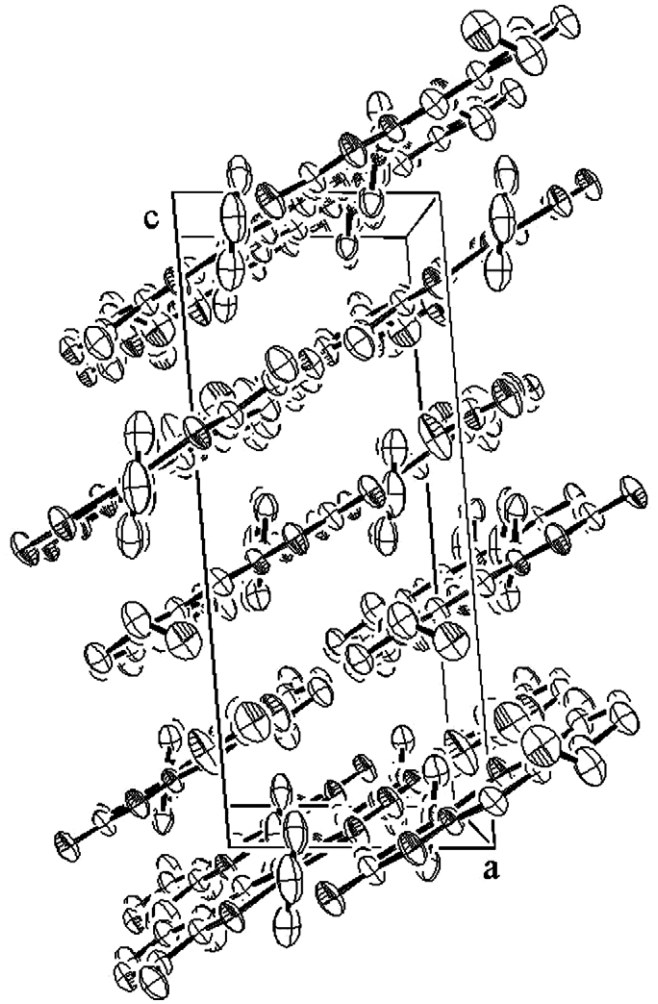

Fig. 5. The crystal structure of [Ni(PLTSC-H)py]NO_3 viewed along the *b*-axis.

moiety (A) and the six- (B) and five-membered (C) chelate rings are A–B 4.71(7)°, A–C 6.63(7)° and B–C 2.85(4)°. The pyridine nitrogen deviates from the ligand best plane by −0.224(2) Å. The dihedral angle between the pyridine and the chelate ligand best plane is about 52°. The angle of ∼124° for C6–N4–C8 suggests the protonation of the nitrogen from the PL moiety [9]. The nitrate group is strictly planar, and the NO_3 plane lies close to the ligand best plane, with a dihedral angle of 3.9(1)°. The packing (Fig. 5) is determined by an extended network of hydrogen bonding, as can bee seen from Table 5.

4. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as CCDC 603421 for [Ni(PLSC)-$(H_2O)_3$]$(NO_3)_2$ and CCDC 603420 for [Ni(PLTSC-H)py]-NO_3. Copies of the available material can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033 or e-mail: deposit@ccdc.cam.ac.uk).

Abstract

The complexation of uranium(VI) with the amino acids L-glycine and L-cysteine has been investigated by time-resolved laser-induced fluorescence spectroscopy (TRLFS) and UV–Vis spectroscopy at a low pH range. The identified 1:1 and 1:2 uranyl-L-glycine complexes fluoresce and have similar absorbance properties. In contrast to the glycine system, uranyl forms two different non-fluorescent 1:1 complexes with L-cysteine, showing individual absorbance properties under the given experimental conditions. The corresponding complex formation constants were calculated using the spectroscopic data.

1. Introduction

For determination of uranium speciation in biosystems such as plants and bacteria, the investigation of the complexation behavior of uranium(VI) with biologically important organic ligands of relevant functionalities, like amino acids, is necessary. L-Glycine and L-cysteine (Fig. 1) are non-essential proteinogenic amino acids. Both amino acids have a carboxylic group and cysteine additionally has a sulfuryl functionality in the side chain of the molecule, which can bind heavy metals. Next to L-glutamic acid, L-glycine and L-cysteine are the ground elements of phytochelatines. These appear to be the primary metal-binding polypeptides of plants.

Some studies about uranium complexation by L-glycine [1–8] and L-cysteine [9–12] have been published. Generally a 1:1 and a 1:2 complex were found in the case of glycine using potentiometric titration, calorimetric investigations, spectrophotometric measurements or polarography. Treatment of the experimental data of Ramanujam et al. [1] and Bismondo et al. [2] has shown that glycine acts as unidentate ligand through the carboxylate group, while the amino moiety is not involved in the metal coordination. Contrary to this Lagrange et al. [3,4] and Cerfola et al. [5] favored the formation of a chelate complex between the uranyl cation and the amino acid. IR spectroscopic measurements carried out by Lagrange suggest the dissociation of a proton from the $-NH_3^+$ during the interaction with UO_2^{2+}. Szabo and Grenthe [6] could demonstrate the formation of uranyl glycine complexes in the form of a ''zwitterion'' without deprotonation at low pH and of a chelate with deprotonation at higher pH values. Alcock et al. [8] characterized a tetrakis(glycine)dioxo-uranium(VI) nitrate complex using absorption, luminescence and X-ray structural methods. All glycine ligands are in the zwitterionic form and act as O-donors in the triclinic structure with hexagonal bipyramidal coordination about the uranium atom. They observed both monodentate and bidentate coordination of the uranyl ion to the carboxyl group.

Iftekhar and Dubey [10] and Raghavan and Santappa [11,12] investigated the complex formation of U(VI) with L-cysteine using potentiometry. They found a 1:1 uranyl-cysteine species ML. The α-amino moiety and the carboxylic

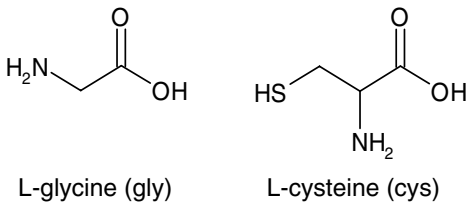

Fig. 1. Structure of the investigated amino acids.

group are coordinated to the uranyl cation. Iftekhar postulated further a stabilization of the complex by the S atom.

UV–Vis absorption and time-resolved laser-induced fluorescence spectroscopy are important experimental techniques for the investigation of uranium(VI) complexation behavior with a variety of ligands in aqueous systems. Detailed background information about uranyl ion absorption and uranyl ion emission spectroscopy is given in [13,14]. The aim of this work was to determine the absorption and fluorescence emission properties of uranium(VI) complexes with L-glycine and L-cysteine at low pH values. Further, the complex formation constants of the formed uranyl complexes were calculated based on the measured spectroscopic data.

2. Experimental

2.1. Solutions and reagents

A stock solution of uranium(VI) perchlorate (10^{-2} M) was prepared from sodium diuranate as described in [15] and analyzed using ICP-MS. Ligand stock solutions of L-glycine and L-cysteine (Merck) were prepared freshly for each experiment. The complex formation experiments were performed at pH 2, 3 and 4. The pH value of each reference and complex solution was adjusted with $HClO_4$ or NaOH. The possible influence of U(VI) hydrolytic species at pH 4 was considered in the analysis of the spectroscopic data.

2.2. TRLFS measurements

Laser pulses at 266 nm with an average pulse energy of 250 μJ (Nd:YAG laser system, Spectron Laser systems, SL 401-20, Rugby) were used for the excitation of the uranyl fluorescence (22 ± 1 °C). The emitted fluorescence light from the initial and complex solutions was focused into a fiber optic, deconvolved by an Acton Research 500 nm spectrograph (model 1236, provided by EG&G). The resulting spectra were measured in time-resolved mode using a digital delay generator (EG&G, model 9650) and a gated diode array (EG&G, model 1471A) of the same company. The TRLFS spectra from 407.3 to 634.8 nm were recorded by averaging 100 laser pulses using a gate time of 2 μs. Each sample was measured three times on every delay time. All functions of the laser spectrometer were computer controlled. A more detailed description of the equipment is given elsewhere [16].

The TRLFS experiments were carried out at constant uranium concentration of 5×10^{-5} M. The concentration of amino acids varied between 0 and 4×10^{-1} M. The measurements were performed at an ionic strength of 0.1 and 0.5 M ($NaClO_4$).

2.3. UV–Vis measurements

The absorption spectroscopy measurements were performed using a CARY5G UV–Vis–NIR Spectrometer (Varian Co.) at room temperature (22 ± 1 °C). The spectra were recorded between 200 and 600 nm. For the determination of the uranyl absorption signals, the spectra were background corrected and analyzed in the wavelength range from 360 to 480 nm.

The uranium concentration was always constant at 1×10^{-3} M. The concentration of amino acids varied between 0 and 3×10^{-1} M. All absorption spectra were measured at an ionic strength of $I = 0.5$ M ($NaClO_4$).

3. Results and discussion

3.1. TRLFS-measurements

Fig. 2 shows examples of the measured TRLFS spectra of uranium(VI) as a function of the total ligand concentration in the glycine (A) and cysteine (B) system.

The fluorescence emission spectra of the U(VI) glycine complex solutions showed an increase in the fluorescence intensity and a significant bathochromic shift of the emission maxima with increasing ligand concentration. Contrary to that, the U(VI)/cysteine system is characterized by a decrease of the fluorescence intensity without a shift of the emission bands in comparison to the uranyl test solution without cysteine at low pH values. This we found already at minor ligand excess. The fluorescence signal was completely quenched at an excess of ligand greater than 100.

The time dependency of the fluorescence signal represents the sum of the fluorescence intensities of all species in the solution with

$$E(t) = \sum E_i \cdot e^{-\frac{t}{\tau_i}} \quad (1)$$

where E is the total fluorescence intensity at time t, E_i the fluorescence intensity of the species i at $t = 0$ and τ_i the corresponding fluorescence lifetime.

The time-resolved fluorescence spectra of uranyl glycine complex solutions at ionic strengths of 0.1 M and 0.5 M showed a bi-exponential fluorescence decay in each case about the investigated pH range (Fig. 3(C)). That means two species are the main components in each complex solution. The averaged lifetimes are $\tau_1 = 1800 \pm 100$ ns and $\tau_2 = 3200 \pm 270$ ns for an ionic strength of 0.1 M and $\tau_1 = 1880 \pm 140$ ns and $\tau_2 = 3500 \pm 470$ ns for an ionic strength of 0.5 M, up to U(VI)/glycine concentration ratios of 1:1000. The shorter lifetime is typical for the free uranyl

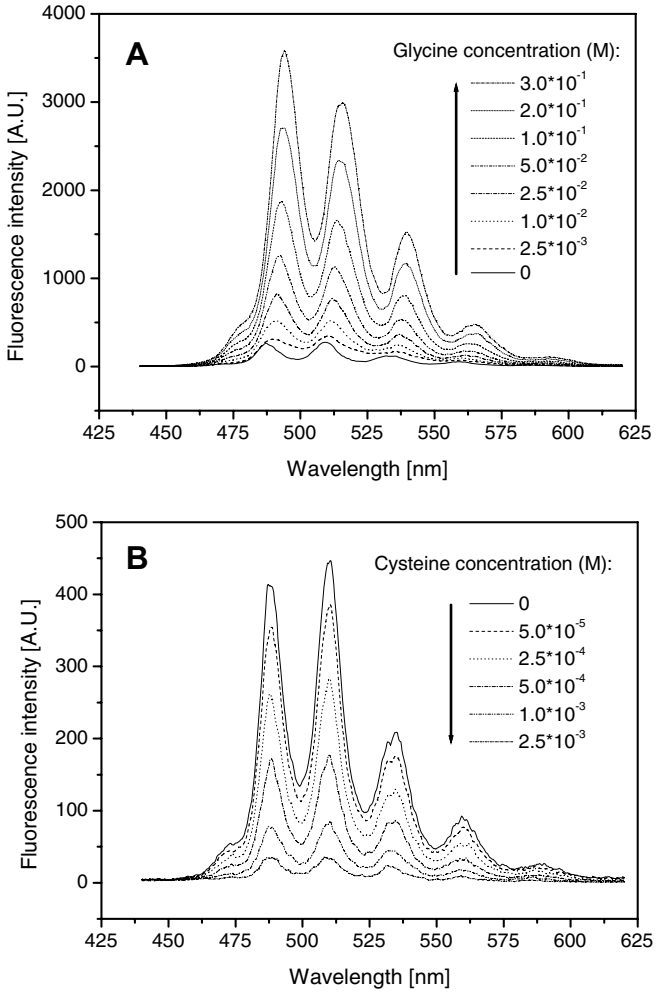

Fig. 2. Fluorescence emission spectra of uranium(VI) as a function of the ligand concentration: (A) glycine at pH 4 and $I = 0.5$ M, (B) cysteine at pH 3 and $I = 0.1$ M.

ion [17]. The marginal longer lifetime can be assigned to a first uranyl glycine complex.

At higher glycine excess ([U]:[glycine] < 1:1000) and pH 3 and 4 we found, additional to the first uranyl complex

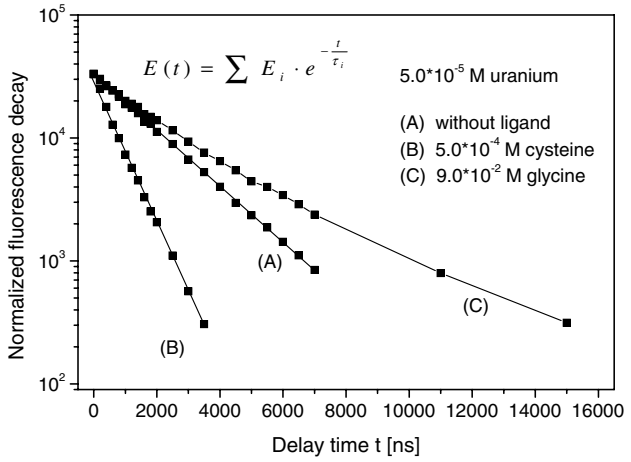

Fig. 3. Exponential fluorescence decay of uranium at pH 3 and $I = 0.1$ M: (A) monoexponential with $\tau_{UO_2^{2+}}$, (B) monoexponential with $\tau_{UO_2^{2+}\text{quenched}}$ and (C) bi-exponential with $\tau_{UO_2HGly^{2+}}$ and $\tau_{UO_2(Hgly)_2^{2+}}$.

species with τ_2, a further uranyl complex species which has an average lifetime of $\tau_3 = 690 \pm 240$ ns at an ionic strength of 0.1 M and $\tau_3 = 690 \pm 190$ ns at an ionic strength of 0.5 M. It is shorter than the lifetime of the free uranyl ion and the first uranyl glycine species.

We used the factor analysis program SPECFIT [18] for the analysis of the mixed spectra and their decomposition into single spectra of the different species. The program performs a global analysis of equilibrium and kinetic systems with singular value decomposition and non-linear regression modelling by the Levenberg–Marquardt method. The spectra of the uranium test solution without ligand and all complex solutions, the known total concentration of uranium and ligand, the pH value of each sample and the protonation constants for glycine were the input parameters for the spectra analysis and data fitting. The spectra were evaluated for each pH value separately. Besides the decomposition of the mixed spectra into single components, we determined the stoichiometry (x, y, z) of the formed uranyl complexes and the corresponding stability constants with this program (Eq. (2)).

The complex formation reaction of UO_2^{2+} with glycine can be written in general as

$$x UO_2^{2+} + y H^+ + z Gly^- \overset{\beta_{xyz}}{\rightleftarrows} \{(UO_2)_x H_y Gly_z\}^{(2x+y-z)+} \quad (2)$$

with $\beta_{xyz} = \frac{[(UO_2)_x H_y Gly_z^{(2x+y-z)+}]}{[UO_2^{2+}]^x [H^+]^y [Gly^-]^z}$.

The obtained stability constants of each uranyl glycine complex at each selected pH value were averaged over the whole investigated pH range.

The results of the factor analysis program demonstrated that the first formed uranyl glycine species is of the type MHL (fluorescence lifetime τ_2). The second uranyl glycine complex has a metal:proton:ligand ratio of 1:2:2 and is of the type $M(HL)_2$. The resulting stability constants are assigned to be $\log\beta_{111} = 10.84 \pm 0.10$ and $\log\beta_{122} = 21.19 \pm 0.13$ at an ionic strength of 0.1 M. In analogy to the analysis of the measurements at $I = 0.1$ M, the complex formation constants at an ionic strength of 0.5 M are calculated to be $\log\beta_{111} = 10.79 \pm 0.22$ and $\log\beta_{122} = 20.93 \pm 0.14$ (Table 1). For the direct reaction of UO_2^{2+} with the zwitterionic form $HGly^{+/-}$, the stability constants are $\log K_{111} = 1.26 \pm 0.11$ and $\log K_{122} = 2.03 \pm 0.14$ at an ionic strength of 0.1 M as an example. They are comparable with the values obtained by Bismondo [2] and Ramanujam [3] under slightly different experimental conditions (ionic strength, temperature).

The mathematical deconvolution of a mixed spectrum using the molar single spectra of the UO_2HGly^{2+} and $UO_2(HGly)_2^{2+}$ species obtained by the factor analysis procedure is shown in Fig. 4. The molar fluorescence yield of the uranyl complex species is clearly higher than the molar fluorescence yield of the free uranyl ion. The main emission bands of the 1:1:1 and 1:2:2 uranyl glycine complexes show a bathochromic shift of about 4 and 7 nm, respectively, in comparison to the bands of the free uranyl cation (Table 2).

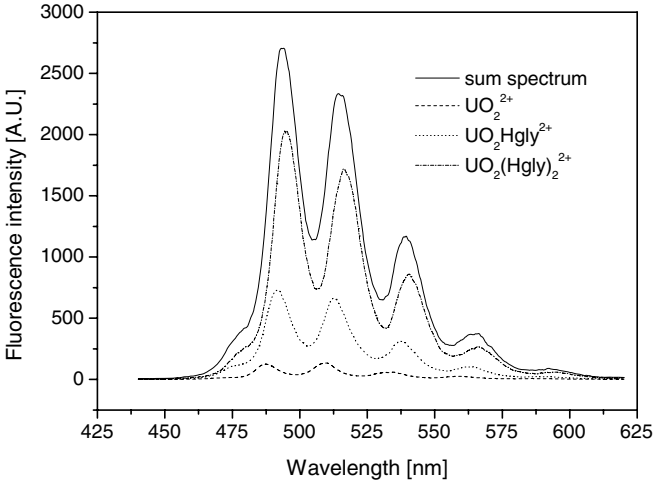

Fig. 4. Result of the peak deconvolution of the fluorescence spectrum of a solution containing 5×10^{-5} M uranium(VI) and 2×10^{-1} M glycine at pH 4 and $I = 0.5$ M.

The analysis of the time-resolved fluorescence measurements of the U(VI)/cysteine system showed a decrease of the fluorescence intensity with increasing cysteine concentration without a shift of the main emission bands. The fluorescence decay was monoexponential in all samples (Figs. 3(B) and 5).

This behavior is typical for static fluorescence quenching due to the complex formation and decrease of the free uranyl ion concentration. We therefore conclude that only the free uranyl ion is present in the complex solutions as fluorescent species and the formed uranyl cysteine complex(es) shows or show no fluorescence properties. The significant decreasing lifetime with increasing ligand concentration (Fig. 5) indicates additionally a dynamic quenching. The cause of the dynamic quenching in the presence of cysteine has not been clarified up to now. Fluorescence investigations with organic ligands which have such a quenching effect are little known. The process of dynamic quenching can be described quantitatively by a Stern–Volmer plot [20]. The averaged quenching constant for the cysteine system in the pH range from 2 to 4 was calculated to be $K_Q = 3840 \pm 40\ M^{-1}$, based on the obtained fluorescence lifetime values of free uranyl without and with ligand. Using the corresponding quenching constant and experimental lifetime data of each complex solution it was possible to calculate the fluorescence intensity of UO_2^{2+} if no dynamic quenching takes place. The corrected fluorescence spectra of each complex solution and corresponding fluorescence intensity of the free uranyl cation were used for the calculation of the realistic uranyl concentration in all complex solutions and the complex formation constants in the U(VI)/cysteine system with the factor analysis program SPECFIT.

In analogy to glycine, the reaction of UO_2^{2+} with cysteine can be formulated in the following equation:

$$x\mathrm{UO_2}^{2+} + y\mathrm{H}^+ + z\mathrm{Cys}^{2-} \overset{\beta_{xyz}}{\rightleftarrows} \{(\mathrm{UO_2})_x\mathrm{H}_y\mathrm{Cys}_z\}^{(2x+y-2z)+} \quad (3)$$

with $\beta_{xyz} = \frac{[(\mathrm{UO_2})_x\mathrm{H}_y\mathrm{Cys}_z^{(2x+y-2z)+}]}{[\mathrm{UO_2}^{2+}]^x[\mathrm{H}^+]^y[\mathrm{Cys}^{2-}]^z}$.

Using SPECFIT we could determine one uranyl cysteine species with a metal:proton:ligand ratio of 1:2:1 under the given experimental conditions. The formation constant was calculated to be $\log\beta_{121} = 20.05 \pm 0.14$ (Table 1). Due to

the existence of two functional protons in the uranyl cysteine complex species, a binding of the uranyl cation only on the deprotonated carboxyl group is very probably. The SH− and NH_3+ functionalities do not seem to be involved in the metal coordination by deprotonation and chelate formation.

3.2. UV–Vis measurements

Fig. 6 depicts a summary of the measured UV–Vis absorption spectra of uranium(VI) with glycine in comparison to cysteine as a ligand at different pH values. The detected significant increase in the absorption and a bathochromic shift of the absorption maxima compared to the free uranyl cation indicate complex formation between the uranyl cation and the amino acid glycine at pH 3 (Fig. 6(A)) as an example. The same results were obtained for the U(VI)/glycine system at pH 2 and 4. Contrary to this, the U(VI)/cysteine system is characterized by a change in the absorption behavior in the investigated pH range from 2 to 4. Additional to an increase of absorption with increasing cysteine concentration in the whole investigated pH range, a bathochromic shift at pH 2 and 3 (Fig. 6(B1)) and an increasing hypsochromic shift of the main absorption bands at pH 4 (Fig. 6(B2)) were detected. Therefore we can assume that species with different metal–proton–ligand ratio and/or different structure (binding of metal) are formed.

The measured UV–Vis absorptions of each test and complex solution can be described with the Lambert–Beer's law and is the summary of the absorption of each species in the solution. It is given by

$$A(\lambda) = \sum \varepsilon_{i,\lambda} \cdot c_i \tag{4}$$

where A is the absorption of light by the solution at wavelength λ, $\varepsilon_{i,\lambda}$ the molar absorption coefficient of the species i at the wavelength λ and c_i the concentration of the species i in the solution at a thickness of the cuvette of 1 cm. In analogy to the analysis of the fluorescence spectra, the mixed UV–Vis spectra of both U(VI) amino acid systems were decomposed in the single components and the metal:proton:ligand ratio in the formed complex species with corresponding constants were estimated using the factor analysis program SPECFIT. The molar ($c_i = 1$ M) absorption spectra of each species (uranyl and complex species) obtained from the factor analysis procedure are the basis for the determination of the wavelengths of the main absorption bands and the molar extinction coefficients $\varepsilon_{i,\lambda}$. From this information we could determine two different uranyl glycine species of the type MHL and $M(HL)_2$ with complex formation constants of $\log\beta_{111} = 10.74 \pm 0.08$ and $\log\beta_{122} = 20.91 \pm 0.10$. They are in good agreement with the corresponding data obtained by our fluorescence measurements (Table 1). The absorption properties of the uranyl glycine species in the UV range are very similar. The absorption wavelengths and the molar extinction coefficients of both uranyl glycine species differ only slightly and are summarized in Table 3.

The UV–Vis spectra of the U(VI) cysteine system were evaluated in the same way. Here we obtained, additional to the 1:2:1 species, a 1:1:1 species in the pH range from 3 to 4. This species has the same metal to ligand ratio, but lower proton number. It is generally accepted in the literature that deprotonation can occur simultaneously from SH and NH_3^+ groups. In combination with the large hypsochromic shift of the absorption bands of the system at pH 4 we assume that next to the deprotonated carboxyl group, the $-S^-$ or the $-NH_2$ group is already involved in the

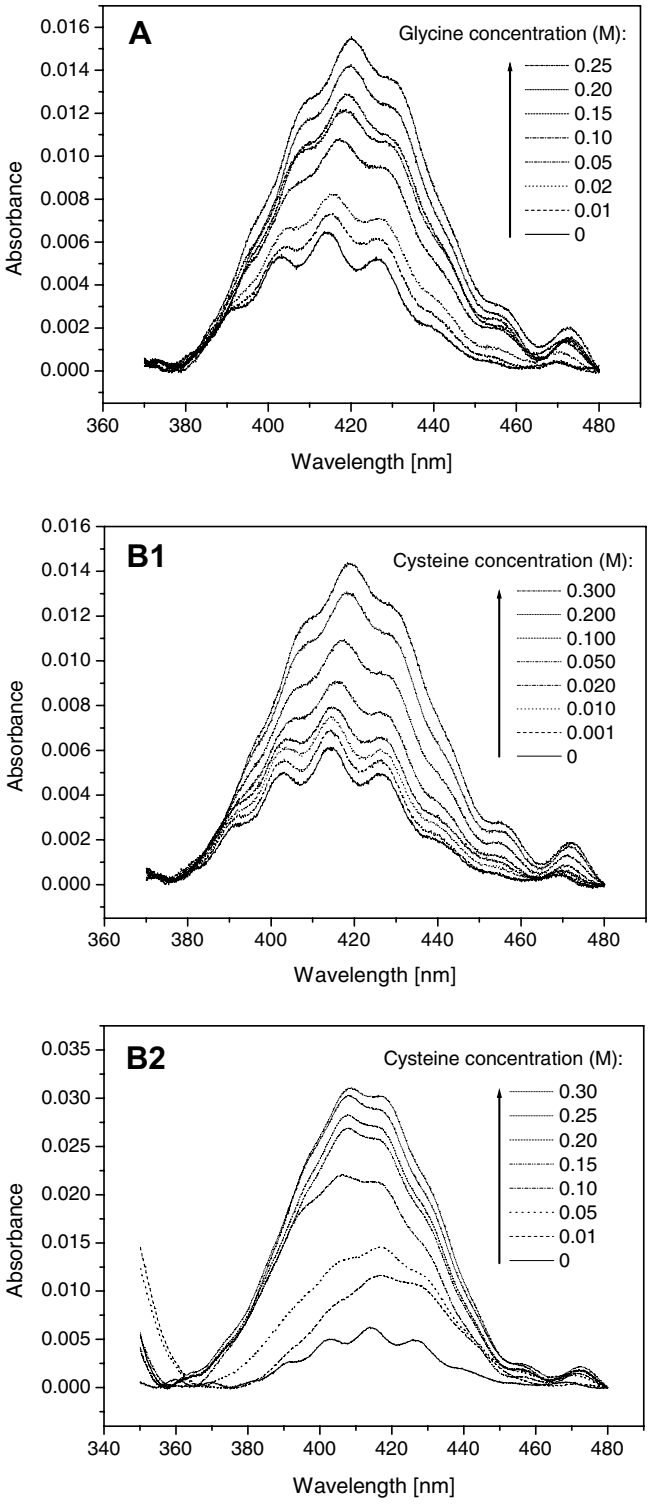

Fig. 6. Summary of UV–Vis spectra at 1×10^{-3} M uranium(VI) and $I = 0.5$ M ($NaClO_4$) as a function of the ligand concentration: (A) glycine system at pH 3, (B1) cysteine system at pH 2 and (B2) cysteine system at pH 4.

coordination of the uranyl cation. It could not be clarified by the applied methods which group is preferred for the metal coordination. The formation constants are $\log \beta_{121} = 19.28 \pm 0.04$ and $\log \beta_{111} = 15.28 \pm 0.04$ (Table 1). The value of $\log \beta_{111}$ is in the range of complex formation constants for the corresponding simple protonated 1:1 complexes with Ni^{2+} and Zn^{2+} at $I = 0.2$ M [21]. Fig. 7 shows examples for the spectra deconvolution of mixed spectra

Table 3
Main absorption bands and calculated molar extinction coefficients (in parenthesis) of the uranium species in the uranium(VI)/amino acid system in the pH range from 2 to 4

Species	Absorption bands (nm) (ε (L mol^{-1} cm^{-1}))

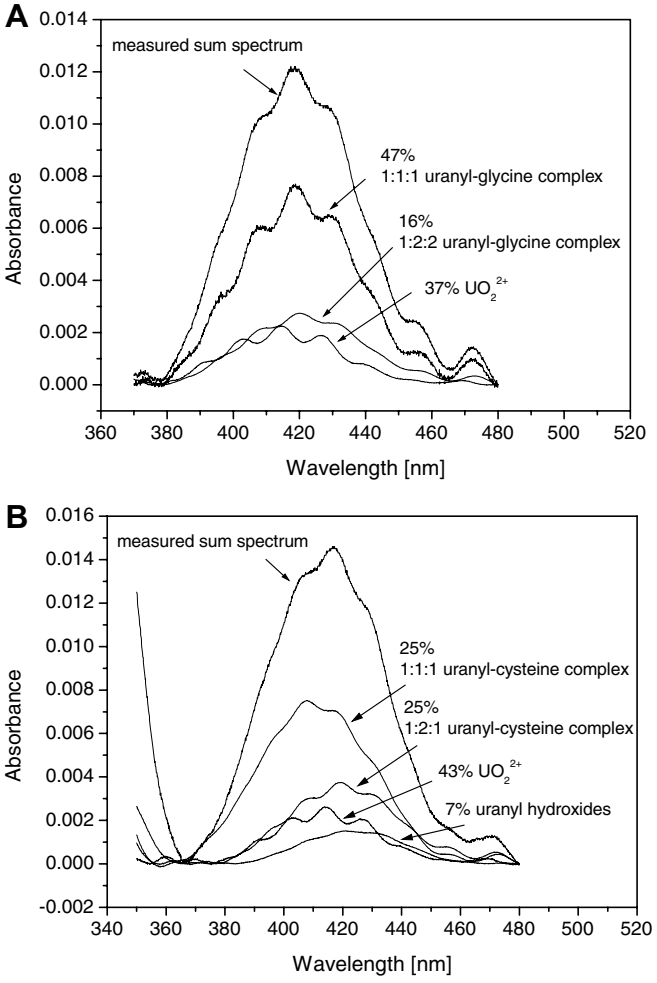

Fig. 7. Results of the peak deconvolution of the UV–Vis spectra of solutions containing 1×10^{-3} M uranium(VI) and (A) 1×10^{-1} M glycine at pH 3 and (B) 5×10^{-2} M cysteine at pH 4.

in the U(VI)/glycine and U(VI)/cysteine system using molar absorption spectra of several species. The deconvolution of the UV–Vis spectrum of a selected uranyl cysteine complex solution at pH 4 (Fig. 7(B)) demonstrates that a small quantity of uranyl hydroxides are formed at the uranium concentration 10^{-3} M and relatively high uranyl ligand concentration ratio (low excess of ligand) during the reaction of U(VI) and the amino acid.

4. Conclusion

U(VI) complexes with different amino acids can be formed on cell surfaces e.g., in biological systems like plants, algae and bacteria over a wide pH range. Time-resolved laser-induced fluorescence spectroscopy and UV–Vis spectroscopy were used to investigate the complex behavior of U(VI) with the amino acids L-glycine and L-cysteine in aqueous solution. Spectroscopic properties of the formed uranyl complexes were determined in comparison to the free uranyl cation. We found several protonated uranyl amino acids complexes with metal: ligand ratios of 1:1 (glycine and cysteine system) and 1:2 complexes (glycine system) at low pH values. The results showed a change of the complexation behavior of amino acids towards the uranyl cation and the spectroscopic properties of the system dependent on the presence of the functional groups ($-COOH/-COO^-$, $-SH/-S^-$, NH_2/NH_3^+). At relative high uranium concentration a 1:1 species in the U(VI)/cysteine system with a metal coordination through the deprotonated carboxyl group and –S or $-NH_2$ group was detected. This species has other absorption properties than the 1:1 species where the metal is bound only to the carboxyl group. TRLFS was applied at lower biological more relevant uranium concentration.

An important aspect is that in contrast to the uranyl glycine complexes the U(VI) complexes with cysteine do not fluoresce. The identification of uranyl cysteine species in biological systems seems to be not possible by TRLFS at room temperature.

Acknowledgment

The authors thank Tabea Birk for the samples preparation.

Abstract

The reaction between $BaI_2 \cdot 2H_2O$ and NaHFIP [HFIP = $OCH(CF_3)_2$] in a 1:1 stoichiometry gave the heterometallic compound $NaBaI_2(HFIP)(H_2O)(THF)_{0.5}$ (**1**). Attempts to recrystallize **1** in the presence of N- or O-donor ligands lead to redistribution reactions. Barium iodide adducts such as $BaI_2(DME)_3$ (**2**), *trans*-BaI_2(DME)(triglyme) (**3**) and *cis*-BaI_2(DME)(tetraglyme) (**4**) were isolated with DME as solvent. A similar behavior was observed for the reaction between $BaI_2 \cdot 2H_2O$ and NaTFA (TFA = O_2CCF_3) in a 1:1 stoichiometry in THF, and [Ba(tetraglyme)$_2$]$I_2 \cdot C_7H_8$ (**6**) was isolated in the presence of excess tetraglyme. All compounds have been characterized by elemental analysis, IR and ^{1}H NMR as well as single crystal X-ray studies for **3**, **4** and **6**. Compounds **3** and **4** are covalent adducts with eight- and nine-coordinate barium, respectively. Compound **6** is an ionic compound where two tetraglyme ligands wrap the 10-coordinate barium cation in a helical fashion. The presence of DME actually allows the coordination number of barium in the mixed-ligand adducts **3** and **4** to be tuned. The average Ba–O bond lengths (2.80 for **3** to 2.87 Å for **6**) reflect the coordination number of the metal. The same observation is valid for the average Ba–I bond distance, 3.442 for **3** vs. 3.536 Å for **4**.

1. Introduction

Barium derivatives with fluorinated ligands such as trifluoroacetate (TFA = $CF_3CO_2^-$) [1] have attracted attention due to their use for the elaboration of high T_c superconductors coatings by metal organic deposition (MOD). Their preferential decomposition into barium fluoride represents a means to avoid the formation of the highly stable barium carbonate, which is detrimental for the superconducting properties [2]. However, formation of corrosive hydrofluoric acid during decomposition is a drawback [3]. Barium iodide, along with yttrium and copper(I) iodides, has been used in all iodide routes to high T_c superconductors [4]. The lower stability of BaI_2 with respect to $BaCO_3$ (decomposition 660 vs. 1100 °C) and lower volatility of CuI in comparison to $Cu(TFA)_2$ could be more favorable than the TFA-MOD approach for $YBa_2Cu_3O_{7-x}$ films. However, barium iodide is a rather inert cluster due to its three-dimensional network structure [5] and its chemistry remains poorly known. Homoleptic barium derivatives supported by trifluoroacetate [6], trifluoromethane sulfonate [7] or fluoroisopropoxide ligands [8] are known but no heteroleptic barium iodide derivatives with these ligands have been reported, despite the fact that such compounds could reduce the hazard of hydrofluoric acid and provide better solubility than BaI_2 in organic media. The stability of heteroleptic alkaline earth metal derivatives depends on a delicate balance of steric effects,

doi:10.1016/j.poly.2006.08.007

metal size, ligand basicity and solubility equilibria [9]. A challenge for their isolation is the Schlenk-type equilibrium leading to rearrangement of heteroleptic species into their homoleptic counterparts [10]. To our knowledge, only five heteroleptic barium iodides stabilized by bulky anionic ligands, namely $\{[C_5(SiMe_3)_3H_2]BaI(THF)_2,\ 1/2C_7H_8\}_\infty$ [9], $Ba_2(\mu\text{-}I)_2(OC_6H_2Bu^t{}_2\text{-}2,6\text{-}Me\text{-}4)_2(THF)_6, (THF)_2$ [11], $Li_4BaI(\mu_4\text{-}OH)(\mu_3\text{-}OBu^t)_4(THF)_4$ [12], $[Ba\{\eta^2\text{-}(2,6\text{-}Pr^i{}_2\text{-}C_6H_3)NC(Bu^t)CH_2C(Bu^t)N(2,6\text{-}Pr^i{}_2C_6H_3)\}(\mu\text{-}I)]_2$ and $(\eta^5\text{-}L)_4Ba_4(\mu\text{-}I)_2(\mu\text{-}\eta^2{:}\eta^5\text{-}L)_2$ ($L = Bu^tNC(Me)(CHC(Me)NBu^t)$) [13], have been fully characterized.

We wish to present here our results on our attempts to isolate and characterize heteroleptic barium iodide derivatives with hexafluoroisopropoxide or trifluoroacetate ligands. The polar media needed for their crystallization afforded barium iodide complexes, namely $BaI_2(DME)_3$ (**2**), *trans*-BaI_2(DME)(triglyme) (**3**), *cis*-BaI_2(DME)(tetraglyme) (**4**) and $[Ba(tetraglyme)_2]I_2 \cdot C_7H_8$ (**6**), which were characterized by elemental analysis, IR and ^1H NMR spectroscopy as well as single crystal X-ray analysis for **3**, **4** and **6**.

2. Experimental

All reactions were carried out under argon using Schlenk tubes and vacuum line techniques. $BaI_2 \cdot 2H_2O$ and BaI_2 (Aldrich) were used as received. Solvents were purified by standard methods, hexafluoroisopropanol, trifluoroacetic acid and glymes $MeO(CH_2CH_2O)_xMe$ ($x = 1, 3, 4$) were stored over molecular sieves. ^1H NMR spectra were registered on a Bruker AC-300 spectrometer. FT-IR spectra were recorded as Nujol mulls on a Perkin–Elmer Paragon 500 spectrometer. Analytical data were obtained from the Service Central d'Analyses du CNRS.

2.1. Synthesis of $NaBaI_2(HFIP)(H_2O)(THF)_{0.5}$ (1)

Freshly prepared sodium hexafluoroisopropoxide (NaHFIP) [Na (0.084 g, 3.65 mmol) and $HOCH(CF_3)_2$ (0.4 ml, 3.70 mmol) in 10 ml THF] was added to a suspension of $BaI_2 \cdot 2H_2O$ (1.56 g, 3.65 mmol) in THF (10 ml). No sodium iodide or other derivative could be crystallized out and the solution was evaporated to dryness after 4 h to give **1** as a light yellow solid, 2.40 g (99%). *Anal.* Calc. for $C_5H_7F_6O_{2.5}NaBaI_2$: C, 9.30; H, 1.09, Na, 3.62. Found: C, 8.84; H, 1.09, Na, 3.50%. IR (Nujol, cm^{-1}): 3478, 3420 br (ν_{OH}), 1622 m, 1608 m (δ_{OH}), 1277 s, 1228 s, 1179 s, 1136 s, 1085 s (ν_{C-F}, ν_{C-O}), 1039 m, 891 m, 848 m, 801 m, 733 m, 680 m, 560 m; 514 m (ν_{Ba-I}), 442 m. ^1H NMR ($CDCl_3$, ppm): 4.58 [br, 1H, $CH(CF_3)_2$], 3.73 [m, 2H, α-H (THF)], 1.86 [m, 2H, β-H (THF)].

2.2. Synthesis of $BaI_2(DME)_3$ (2)

Dissolution of 0.5 g of **1** in DME and THF (10 ml each) at 70 °C, followed by filtration and crystallization gave **2** (0.22 g, 45%). *Anal.* Calc. for $C_{12}H_{30}O_6BaI_2$: C, 21.78, H, 4.53. Found: C, 20.87, H, 4.32%. IR (Nujol, cm^{-1}): 1282 m, 1243 m, 1191 m, 1115 s, 1064 s, 1024 m, 892 w, 855 s (ν_{C-O}), 722 w, 686 w, 569 m (ν_{Ba-I}), 429m (ν_{Ba-O}). ^1H NMR ($CDCl_3$, ppm): 3.41 [s, 18H, Me], 3.56 [s, 12H, OCH_2]. Monoclinic $P2_1/n$, $a = 8.668(2)$, $b = 9.886(1)$, $c = 13.651(3)$ Å, $\beta = 104.58(1)°$, $V = 1132.2(4)$ Å^3. Due to the poor quality of the crystals, the data could not be refined.

$BaI_2(DME)_3$ was also isolated along with sodium iodide adducts $[Na_2(H_2O)_2(PMDTA)_2]I_2$ and $Na_2I_2(PMDTA)_2$ at −20 ° C from the reaction between $BaI_2 \cdot 2H_2O$ (1.015 g, 2.73 mmol) in DME (7 ml) with $NaOCH(CF_3)_2$ (2.34 mmol) in 7 ml of THF in the presence of *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDTA) (0.7 ml, 3.35 mmol).

2.3. Synthesis of $BaI_2(DME)(triglyme)$ (3) and $BaI_2(DME)(tetraglyme)$ (4)

Triglyme (0.48 g, 2.69 mmol) was added to a DME (20 ml) solution of **1** (0.711 g, 1.58 mmol). After stirring for 6 h and filtration, **3** crystallized (0.3 g, 42%). FT-IR (Nujol, cm^{-1}): 1346 m, 1297 m, 1243 m, 1199 m (ν_{C-C}), 1085 s, 1062 s, 1016 m, 942 m, 858 m (ν_{C-O}), 720 m, 522 m (ν_{Ba-I}); ^1H NMR ($CDCl_3$, ppm): 3.40 [s, 6H, Me (DME)], 3.42 [s, 6H, Me (triglyme)], 3.54 [s, 4H, CH_2 (DME)], 3.61 [m, 4H, CH_2 (triglyme)], 3.7 [m, 8H, CH_2 (triglyme)].

Using the same procedure, **4** was obtained by reacting **1** (0.65 g, 1.44 mmol) and tetraglyme (0.48 g, 2.17 mmol) in DME (20 ml) (0.26 g, 40%). *Anal.* Calc. for $C_{14}H_{32}O_7BaI_2$: C, 23.89; H, 4.55. Found: C, 24.41; H, 4.78%. FT-IR (Nujol, cm^{-1}): 1458 s, 1376 m, 1351 m, 1283 m, 1249 m, 1200 m (ν_{C-C}), 1092 s, 1023 m, 945 m, 848 m (ν_{C-O}), 797 m, 719 w, 679 w, 527 w (ν_{Ba-I}). ^1H NMR ($CDCl_3$, ppm): 3.57 [s, 6H, Me (DME)], 3.58 [s, 6H, Me (tetraglyme)], 3.59 [s, 4H, CH_2 (DME)], 3.65 [m, 4H, CH_2 (tetraglyme)], 3.66 [m, 12H, CH_2 (tetraglyme)].

Compounds **3** and **4** were isolated in better yields at −20 °C from reactions in DME between BaI_2 (0.341 g, 0.87 mmol) and triglyme (15 ml) (0.4 g, 70%) or BaI_2 (0.35 g, 0.90 mmol) and tetraglyme (15 ml) (0.47 g, 75%), respectively.

2.4. Synthesis of $NaBaI_2(TFA)(THF)(H_2O)_{0.5}$ (5)

A freshly prepared solution of NaTFA [Na (0.076 g, 3.33 mmol) and TFAH (0.26 ml, 3.40 mmol) in 10 ml THF was added to a suspension of $BaI_2 \cdot 2H_2O$ (1.30 g, 3.33 mmol) in 10 ml of THF. The resulting solution was stirred for 5 h and since no solid could be precipitated out, evaporated to dryness giving a yellow solid **5** (2.0 g, 98%). *Anal.* Calc. for $C_6H_9F_3O_{3.5}NaBaI_2$: C, 11.88; H, 1.48, Na 3.78. Found: C, 12.4; H, 1.42, Na, 3.62%. FT-IR (Nujol, cm^{-1}): 3430 br (ν_{O-H}), 1677br ($\nu_{as}CO_2$), 1461 s, 1376 s, 1297 m, 1258 m, 1204 w, 1150 m (ν_{C-F}, ν_{C-O}), 1081 w, 1027 w, 964 w, 885 w, 850 w, 802 w, 724 s, 548 m.

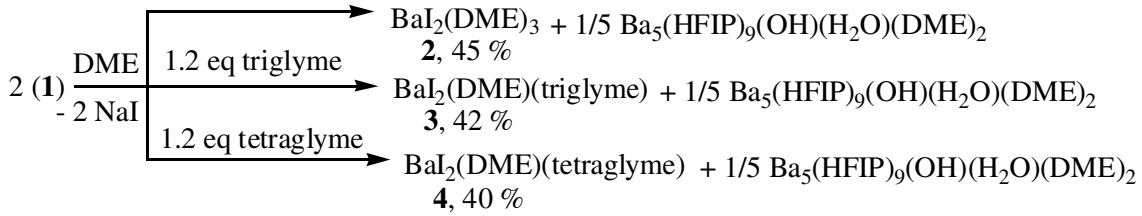
2.5. Synthesis of $[Ba(tetraglyme)_2]I_2 \cdot C_7H_8$ (6)



Tetraglyme (0.48 g, 2.16 mmol) was added to a solution of **5** (0.57 g, 1.44 mmol) in THF (8 ml) and toluene (7 ml). After stirring for 6 h, sodium iodide was filtered out. The filtrate afforded colorless crystals of **6**, 0.98 g (47%). After drying under *vacuo*, these lost half of their toluene molecules. *Anal.* Calc. for $C_{23.5}H_{48}O_{10}BaI_2$: C, 32.0; H, 5.44. Found: C, 32.08; H, 5.59%. 2.6. X-ray structure determination of trans-$BaI_2(DME)(triglyme)$ (3), cis-$BaI_2(DME)(tetraglyme)$ (4) and $[Ba(tetraglyme)_2]I_2 \cdot C_7H_8$ (6)

Suitable crystals of **3**, **4** and **6** were obtained at room temperature from the reaction media. Data were collected at 150 K on a Nonius Kappa CCD diffractometer using the COLLECT software [14]. Reduction of the data was carried out with DENZO [15]. Frame scaling and unit-cell parameters refinement were made through SCALEPACK [15]. Absorption corrections were achieved with DIFABS [16]. The structures were solved by direct methods with SIR92 [17] and successive difference Fourier map analyses. Refinement on F^2 was carried out with CRYSTALS [18]. The hydrogen atoms were placed geometrically and included in the refinement using soft restraints on bond lengths and angles to regularize their geometry (C–H in the range 0.93–0.98 Å and O–H = 0.82 Å) and isotropic atomic displacement parameters (U(H) 1.2–1.5 times $U_{eq.}$ of the adjacent atom). Eight independent moieties were found in the asymmetric unit of compound **6**, generating thus a large number of data to refine. The maximum electron density peak was found at 0.851 Å from I(3). Crystallographic data and structure refinement are listed in Table 1.

3. Results and discussion

The reaction between $BaI_2 \cdot 2H_2O$ and sodium hexafluoroisopropoxide (NaHFIP) (1:1 stoichiometry) in THF gave a solution from which no sodium iodide could be precipitated out. Evaporation to dryness gave a compound having a formula $NaBaI_2(HFIP)(H_2O)(THF)_{0.5}$ (**1**) according to elemental analysis. Compound **1** is insoluble in non-polar media suggesting the formation of a polynuclear species, but soluble in THF and DME. However, these polar solvents favor redistribution reactions and formation of homoleptic species (Scheme 1). $BaI_2(DME)_3$ (**2**) crystallizes out as the first Ba species from DME solutions after elimination of sodium iodide due to its low solubility. Attempts to stabilize **1** by using other polyethers such as triglyme or tetraglyme in DME lead also to simple barium iodide adducts namely $BaI_2(DME)(triglyme)$ (**3**) and BaI_2-$(DME)(tetraglyme)$ (**4**). The elemental analysis and FT-IR spectra of the second barium compound isolated from all these media corresponds to that of $Ba_5(HFIP)_9(OH)(H_2O)(DME)_2$ (by comparison with the product of a 1:2 reaction of $BaI_2 \cdot 2H_2O$ with NaHFIP in DME and also with an authentic sample derived from $Ba_5(\mu_5\text{-}OH)$-$(\mu_3\text{-}HFIP)_4(\mu\text{-}HFIP)_4(HFIP)(THF)_4(H_2O) \cdot THF$ [8]). The use of non-polar solvents such as toluene was precluded by the insolubility of **1** even in the presence of an excess of glymes and by refluxing for several hours.

Scheme 1. Redistribution reactions of **1**.

N-donor ligands were also evaluated for stabilization of **1**. The reaction between $BaI_2 \cdot 2H_2O$ and $NaOCH(CF_3)_2$ (1:1 solution) in THF/DME in the presence of 1.5 equiv of *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDTA) afforded crystals of $BaI_2(DME)_3$ and of PMDTA adducts of sodium iodide $[Na_2(H_2O)_2(PMDTA)_2]I_2$ and Na_2I_2-$(PMDTA)_2$ [19]. These reactions indicate that BaI_2 adducts are more stable with O-donors, even only bidentate, than with even polydentate N-donors. **3** and **4** were also obtained, in better yields, directly from BaI_2.

The reaction between $BaI_2 \cdot 2H_2O$ (or BaI_2) and sodium trifluoroacetate (NaTFA) (1:1 stoichiometry) in THF afforded the heterometallic Na–Ba derivative **5**. Attempts to crystallize **5** from THF/toluene at room temperature gave $BaI_2 \cdot 2H_2O$ (43%). Attempts to stabilize **5** by excess tetraglyme resulted in crystallization of $[Ba(tetraglyme)_2]I_2 \cdot C_7H_8$ (**6**) (Eq. (1)):

$$BaI_2 \cdot 2H_2O + NaTFA \xrightarrow{THF,5\ h} \mathbf{5} \xrightarrow{1.5\ \text{equiv tetraglyme THF+toluene}} \underset{\mathbf{6},\ 47\%}{1/2\,[Ba(\text{tetraglyme})_2]\,I_2 \cdot C_7H_8} + 1/2m[Ba(TFA)_2]_m \quad (1)$$

Similar to lanthanide chemistry, formation of 'ate' complexes with alkali metals are not unusual for alkaline earth metal compounds and numerous examples of alkali-alkaline earth metal 'ate' complexes such as $LiBa(\eta^5\text{-}C_5Me_5)_2$-$[CH(SiMe_3)_2](THF)_2$, $LiBa(\eta^5\text{-}C_5Me_5)_2[N(SiMe_3)_2](THF)_2$, [20], $LiM(OSO_2R)_2[CH(SiMe_3)_2](THF)$ (M = Ca, Sr, Ba; R = C_6H_4Me-4, $C_6H_2Me_3$-2,4,6 and $C_6H_4Bu^t$-4) and $KM[CH(SiMe_3)_2]_3(THF)_3$ (M = Ca, Sr, Ba) [21] are known. The reactions between $BaI_2 \cdot 2H_2O$ and NaHFIP or NaTFA here are particularly reminiscent of that between $Ba(\eta^5\text{-}C_5Me_5)_2(THF)_2$ and $LiCH(SiMe_3)_2$ in which the formed $LiBa(\eta^5\text{-}C_5Me_5)_2[CH(SiMe_3)_2](THF)_2$, insoluble in toluene, regenerates the metallocene and alkyl anion in THF [20]. It can, however, be noted that the only other known heteroleptic alkali metal-barium iodide cluster, $Li_4BaI(\mu_4\text{-}OH)(\mu_3\text{-}OBu^t)_4(THF)_4$ [12], is stable in solution because of its hydroxo-bridged pentanuclear structure and stabilizing effect of bulky *tert*-butoxide groups.

3.1. Spectroscopic characterization

The FT-IR spectrum of **1** exhibits strong absorptions at 1278, 1239, 1215 and 1174 cm^{-1} for ν(C–F) and ν(C–O), vibrations respectively. The νBa–O frequency appears as a medium intensity band at 519 cm^{-1}. The heterometallic TFA derivative $NaBaI_2(TFA)(THF)(H_2O)_{0.5}$ (**5**) shows absorptions due to ν(O–H), ν_{as}(C=O) and ν(C–F) at 3432, 1656 and 1206–1083 cm^{-1}, respectively. Three characteristic strong absorptions for the TFA ligands are also found at 850, 800 and 728 cm^{-1}. The presence of DME, triglyme or tetraglyme is confirmed by their characteristic absorptions bands in the IR spectra of **2**, **3**, **4** and **6**. The solubility of **1** in $CDCl_3$ allowed characterization by ^1H NMR. Its spectrum displays a broad peak at 4.58 ppm for the CH proton of $OCH(CF_3)_2$ and multiplets at 3.72 and 1.86 ppm for the THF ligands. ^1H NMR spectra of the adducts $BaI_2(DME)_3$ (**2**), *trans*-BaI_2(DME)(triglyme) (**3**), *cis*-BaI_2(DME)(tetraglyme) (**4**) and $[Ba(tetraglyme)_2]$-$I_2 \cdot C_7H_8$ (**6**) are in agreement with those of coordinated polyethers. For example, two singlets in a 3:2 ratio are observed for **2** at 3.41 and 3.56 ppm for the Me and OCH_2– groups of DME, respectively.

Although structural prediction of **1** and **5** on the basis of elemental analysis and limited spectroscopic data would be highly speculative, the structures of these two compounds may well be related to either solvated ion-pairs, Na^+-$[BaI_2(X)]^-$ (X = $(CF_3)_2CHO^-$, $CF_3CO_2^-$), or bridged bimetallic compounds, as reported for $[Yb\{N(SiMe_3)_2\}$-$\{\mu\text{-}N(SiMe_3)_2\}_2Na]$ [22]. The secondary Ba–F bonds are likely to complete the coordination sphere of barium as observed for other barium compounds with fluorinated ligands [8,23].

3.2. X-ray structures of trans-BaI_2(DME)(triglyme) (3), cis-BaI_2(DME)(tetraglyme) (4) and $[Ba(tetraglyme)_2]I_2 \cdot C_7H_8$ (6)

All Ba iodide adducts with bidentate and/or polydendate glymes are monomeric. Selected bond lengths and angles are collected in Tables 2–4. The eight-coordinate Ba atom in *trans*-BaI_2(triglyme)(DME) (**3**) (Fig. 1) has a distorted hexagonal bipyramidal geometry. The six oxygens of the DME and triglyme ligands form a distorted hexagonal plane with the DME ligand being slightly tilted with respect to the equatorial plane. The angle between the DME and triglyme molecular planes is 39.6(2)°. The two iodide are in *trans* positions, the value of the I(1)–Ba–I(2) angle being 164.4(1)°. The Ba–I(1) and Ba–I(2) bond distances, 3.434(1) and 3.449(1) Å, respectively, are longer than those in other covalent monomeric barium iodide adducts such as $BaI_2(THF)_5$ (3.379 Å av.) for instance

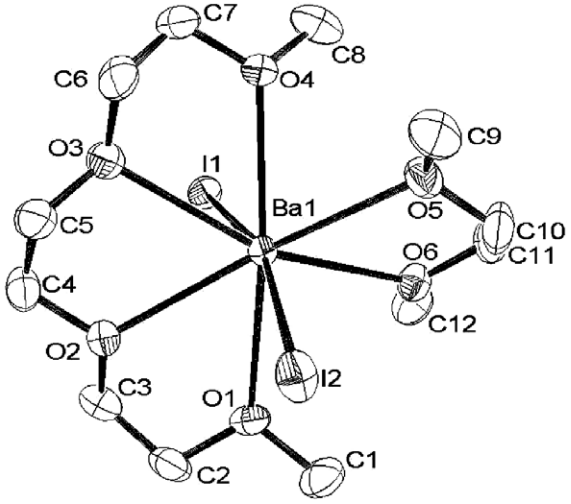

Fig. 1. Molecular structure of *trans*-BaI_2(DME)(triglyme) (**3**) (thermal ellipsoids at 50% probability). H atoms have been omitted for clarity.

[24] due to the higher coordination number of barium (eight in **3** vs. seven in $BaI_2(THF)_5$). They are the shortest among the structures reported here. The structure of **3** can be related to the recently reported samarium(II) compound *trans*-SmI_2(triglyme)(DME), which crystallises as two independent molecules (enantiomers) per asymmetric unit [25].

Assignment of the chiral space group $P2_1$ for **3** was unequivocal. The chirality in **3** stems from the presence of DME and triglyme ligands, which form odd numbers of five-membered rings upon coordination to the barium atom, the three rings of triglyme exhibiting alternate patterns of δ and λ chiral conformations. Another element of chirality in **3** is the orientation of the terminal methyl groups in the triglyme ligand; one methyl group is located below the triglyme plane while the other one is situated above it. However, a value of 0.57(4) for the Flack parameter suggests that there is substantial racemic twinning with

micro-domains of each enantiomer present in the same crystal.

Replacement of triglyme with tetraglyme gives a nine-coordinate barium atom in *cis*-BaI_2(tetraglyme)(DME) (**4**) (Fig. 2). As expected, the more bulky ligand causes DME and tetraglyme molecular planes to be inclined by 73.99(9)°. In contrast to **3**, the iodide ligands are in *cis* positions with a I–Ba–I angle of 118.22(5)°. The Ba–I bond distances [3.538(6) and 3.534(6) Å] are on average 0.095 Å longer than those in **3**, due to the higher coordination number as well as to the repulsion between the iodides in *cis*-positions [26]. The Ba–O(DME) bond lengths (2.81 Å av.) are shorter than the Ba–O(tetraglyme) ones (2.84 Å av.). It is quite surprising that both iodides occupy *cis* positions. In general, molecular alkaline earth metal halide complexes with coordination numbers equal or larger than six, preferentially exhibit a *trans* orientation of halide ligands [27,28]. Compound **4**, with SrI_2(diglyme)$_2$ [26], is the only example of a molecular alkaline earth metal iodide where the iodides are *cis*. For further comparison, both *cis*-SmI_2(diglyme)$_2$ and *trans*-SmI_2(diglyme)$_2$ have actually been isolated from the same solution [29]. It is worth mentioning that in the gas phase, BaI_2 is bent with an angle between 102° and 105° [30].

In contrast to **3** and **4** which are covalent, compound **6** is ionic with two iodide anions (Ba···I distance of 6.40 Å av.) and a $[Ba(tetraglyme)_2]^{2+}$ cation whose structure is shown in Fig. 3. The barium ion is coordinated by ten oxygen atoms of two tetraglyme ligands, the five oxygen atoms of each tetraglyme ligands lying approximately in a plane. The planes of the two tetraglymes are inclined to each other by 86.32(6)°. The Ba–O(tetraglyme) bond lengths (2.87 Å av.) in **6** are longer than the Ba–O(tetraglyme) ones (2.84 Å av.) in **4** due to the higher coordination number and the ionic character [27]. A similar helical wrapping of metals by tetraglyme has been reported for $[Sm(tetraglyme)_2]^{2+}$ [25] and $[Cs(tetraglyme)_2]^{+}$ [31]. Compound **6** is the first example of discrete ionic species of the heavier alkaline earth metal halide adducts with polyethers.

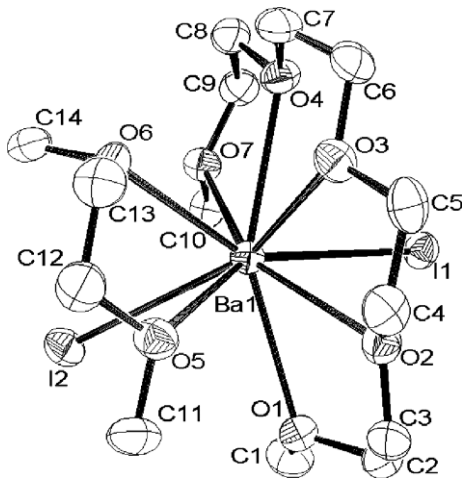

Fig. 2. Molecular structure of *cis*-BaI_2(DME)(tetraglyme) (**4**) (thermal ellipsoids at 50% probability). H atoms have been omitted for clarity.

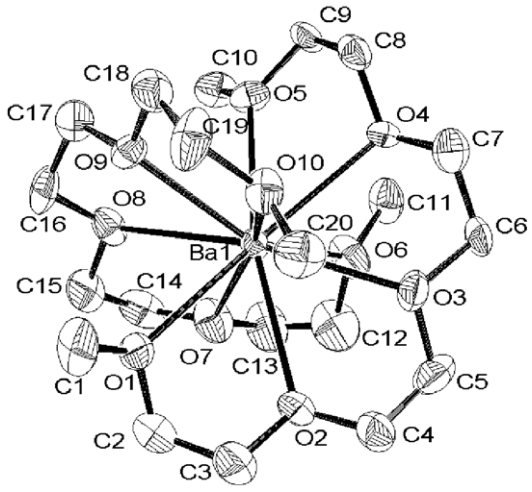

Fig. 3. Molecular structure of $[Ba(tetraglyme)_2]^{2+}$ of **6** (thermal ellipsoids at 50% probability). H atoms have been omitted for clarity.

The same heteroleptic Na–Ba species **1** and **5** were obtained using either $BaI_2 \cdot 2H_2O$ or BaI_2 as starting material, although the hydrate was more reactive. The presence of water ligands in the formula of **1** and **5** might be favored by the high Lewis acidity generated by the fluorinated ligands but does not preclude the presence of water ligands. The new barium iodide adducts **2**, **3**, **4** and **6** derived from **1** and **5** with bidentate and/or polydentate ethers, either covalent or ionic, are monomeric, mainly because of the absence of water in their coordination sphere. Indeed, it has been shown by Fromm et al. [32,33] that the number of water molecules in the coordination sphere of alkaline earth metal iodides directs their dimensionality by H-bonding, iodides acting as acceptors. BaI_2(triglyme)$_2$(H_2O), $[M(diglyme)_2(H_2O)_x]I_2$, ($M = Ca$, $x = 2$; $M = Ba$, $x = 3$) and $[Ca(triglyme)(H_2O)_4]I_2$, obtained from MI_2 and glymes containing 1% water, are thus 0D-, 1D-, 2D- and 3D-polymers, respectively [32,33].

4. Conclusions

Our attempts to isolate heteroleptic barium iodide derivatives with hexafluoroisopropoxide or trifluoroacetate ligands resulted into redistribution reactions where the use of DME and/or other polyethers such as triglyme or tetraglyme led to crystallization of simple barium iodide adducts with polyethers. Heteroleptic barium derivatives with sterically less demanding ligands have been shown to rearrange into their homoleptic counterparts via a Schlenk-type equilibrium [9,10]. Crystallization of barium iodide adducts with bidentate and/or polydentate ethers as either covalent or ionic compounds depends on the nature of the solvent(s). The use of DME as a solvent affords molecular adducts since the DME ligand allows the coordination number of the metal in the mixed-ligand adducts **3** and **4**

to be tuned. The absence of DME in the reaction medium and/or a large excess of tetraglyme favors the formation of the ionic species **6** in comparison to **4**.

Abstract

A novel *tert*-butylcalix[4]arene bridged bis double-decker lutetium(III) phthalocyanine (Lu_2Pc_4) (**5**) has been synthesized by the reaction of dimeric lutetium(III) phthalocyanine (**4**) with two equiv. of dilithium octakis hexylthiophthalocyanine in amyl alcohol. The phthalonitrile derivative **1** was obtained through the displacement reaction of 4-nitrophthalonitrile with 1,3-dimethoxy-4-*tert*-butylcalix[4]arene and was converted to the isoindoline derivative **2** by bubbling ammonia gas in dry MeOH. Compound **4** was prepared from **2**, 4,5-bis(hexylthio)-1,2-diiminoisoindoline (**3**), and lutetium acetate in dry DMF. The new compounds and phthalocyanines were characterized by elemental analysis, IR, UV–Vis, ^{1}H NMR, ESR and MALDI-TOF MS spectra. The electrochemical properties of **4** and **5** have been examined by cyclic voltammetry, and compared. Distinctive differences between the voltammetric behaviour of **4** and **5** were detected. These differences were compatible with the structures of the compounds. A detailed study of the effect of temperature on the d.c. conductivity and impedance spectra (40–10^5 Hz) of spin coated films of **4** and **5** at temperatures between 290 K and 420 K was carried out. By analyzing the d.c. electrical behaviour of the **5** film, it was found that the experimental data are described by a thermally activated conductivity dependence on temperature with an activation energy of 0.77 eV. The a.c. results give a power law behaviour, $\sigma_{a.c.} = A(T)\omega^s$, in which the frequency exponent s decreases with temperature. The sensing behaviour of the film for the online detection of volatile organic solvent vapors was investigated by utilizing an AT-cut quartz crystal resonator. It was observed that the adsorption of the target molecules on the coating surface cause a reversible negative frequency shift of the resonator. Thus, a variety of solvent vapors can be detected by using the **5** film as sensitive coating, with sensitivity in the ppm and response times in the order of several seconds depending on the dipole moment of the organic solvent.

Keywords: Phthalocyanine; Calix[4]arene; Double decker; Cyclic voltammetry; Gas sensing

1. Introduction

Phthalocyanines (Pcs) exhibit a number of unique properties that make them of great interest in different scientific and technological areas. Some technological applications of these macrocycles, such as electrophotography, photovoltaic and solar cells, semiconductive devices, rectifying devices, molecular electronics, electrochromic display devices, low-dimensional conductors, gas sensors, liquid crystals, non-linear optics, optical disks, photosensitizers in photodynamic cancer therapy and electrocatalytic agents, have been intensively investigated [1]. Among the classical Pcs, unsymmetrical ones are important for the development of new methods of synthesis. Although the synthesis of symmetrical tetra- or octa-substituted Pcs by cyclotetramerization of a suitable phthalonitrile as a single precursor can be accepted as a relatively straightforward method,

unsymmetrical Pcs containing different substituents on the benzo groups are difficult to obtain [2].

Our previous papers have described a series of symmetric and unsymmetric Pcs carrying various substituents. An essential shortcoming of the Pcs remains in their low solubility and spectroscopic measurement in organic solvents which hinders their application in solution. The introduction of different central metal ions or benzenoid rings turned out to be a powerful means of modifying the chemical and physical properties of Pcs [3,4]. Our group has been actively engaged in the synthesis of phthalocyanines with macrocyclic, acyclic or heterocyclic substituents, the immediate consequences of which are enhanced solubility and additional donor sites for alkali and/or transition metal ions [5–15]. Rare-earth diphthalocyanines, especially the lutetium derivatives, have become objects of intense investigations. The interest for this kind of compounds is actually increasing because of their electrochromic properties [16–29] and unusual conductivity [30–34]. Substituents on the periphery of a macrocycle ring like a Pc are known to affect its physicochemical properties. Many relationships between the chemical structure and properties like photoconductivity [35], electrocrystallization [36] and redox potentials [37] have been established. Chemical groups linked to the peripheral benzene rings not only modify the electronic properties of the phthalocyanines, but also those of the materials obtained from these molecular units [38,39]. The aim of the synthesis and study of substituted diphthalocyanines is the possibility to design molecules with two different phthalocyanine rings. These asymmetric dimeric compounds are interesting for different reasons. The delocalization of the electrons and the polarizability will be different from what is generally observed for the symmetrical diphthalocyanines, inducing perhaps unusual electrical or optical properties. The unsymmetrical derivatives, bearing hydrophilic and lipophilic groups, respectively, on each of the two units, are important for the preparation of oriented phases, using the Langmuir–Blodgett technique for example. Sandwich-type phthalocyaninato metal complexes, in which the large conjugated π systems are held in close proximity by metal ions, have found widespread applications in materials science [40]. The lutetium complex $LuPc_2$, for example, is an intrinsic molecular semiconductor with a conductivity of $5\times 10^{-5}\ \Omega^{-1}\ cm^{-1}$ in thin films [41] and shows promising electrochromic [42] and gas sensing properties [43]. As the bulk characteristics of a molecular material are largely related to the properties of individual molecules, various modifications have been made on these sandwich compounds with the goal of improving their performance as advanced materials [29–34].

There is an increasing demand for the detection of volatile organic solvents in the field of environmental analysis, industrial process control and work-place monitoring. A number of materials, e.g., Pc [44,45], PVC blended lipid membrane [46], ω functionalized alkanethiols [47], substituted azacyclophanes [48] and tetradentate dithioglyoximes [49] have been used as sensitive coatings for the recognition of organic solvent molecules. It is well established that a quartz crystal resonator (QCR) also known as a quartz crystal microbalance becomes a highly sensitive gas sensor when coated with the appropriate materials [50]. The application of the QCR in gas sensors is based on interactions between the surface of a quartz crystal coated with a thin layer of sensitive material and the target molecules. These interactions result in detectable changes in the fundamental resonant frequency (Δf) of the resonator. When a small mass (Δm) is deposited or sorbed into a coating layer on the surface of the QCR, it induces a decrease in the resonant frequency, which is a function of (Δm). According to Sauerbrey [51], the deposition of a homogeneous coating promotes a shift of the natural resonant frequency of the crystal, which, for assumed negligible mass increase and rigid layer behaviour, is described by the following linear relationship:

$$\Delta f = \frac{f_0}{A\rho_q h_q}\Delta m, \tag{1}$$

where f_0 is the fundamental resonant frequency of the quartz crystal, ρ_q is the density of the quartz crystal, h_q is thickness of the quartz and A is the surface area of the electrode.

We have previously synthesized a triazine carrying three phthalocyaninato zinc (II) macrocycles through amino groups [52] and a new type of sandwich dilutetium tetraphthalocyanine for the first time which exhibit variable range hopping conductivity as inorganic semiconductors and also have observed an electrochromic effect from cyclic voltammetry (CV) measurements [29].We have also reported on the synthesis and characterization of novel s-triazines bearing three oxygen-linked metallophthalocyanines and lutetium bisphthalocyanine sandwich complexes [53,54]. Synthesis, characterization, conduction and gas sensing properties of novel multinuclear metallophthalocyanines with alkylthio substituents were also reported in the literature [44].

In the present work, a novel *tert*-butylcalix[4]arene bridged bis double-decker lutetium(III) phthalocyanine (Lu_2Pc_4) (**5**) has been prepared by the reaction of compounds **3** and **4** in amyl alcohol in the presence of lithium metal at reflux temperature, and characterized. Also, the electrochemical properties of *tert*-butylcalix[4]arene bridged **4** and **5** in solution were investigated by cyclic voltammetry. In addition, the electrical (a.c. and d.c.) and gas sensing properties of **4** and **5** are discussed.

2. Experimental

2.1. Synthesis and characterization

All reagents and solvents obtained from commercial suppliers were of reagent-grade quality. The solvents were stored over molecular sieves (4 Å). 4-Nitrophthalonitrile [55] and 4,5-bis(hexylthio)-1,2-diimino-isoindoline (**3**) [56]

were prepared by the literature methods. Column chromatography was used for purification of the complexes.

Routine IR were recorded on a Mattison 1000 FTIR spectrometer using KBr pellets, electronic spectra were measured in $CHCl_3$ with a UNICAM UV 500 UV–Vis spectrometer. Elemental analysis was performed by the LECO CHNS 932 in the Instrumental Analysis Laboratory of TUBITAK Ankara Research Center. ^1H NMR spectra were recorded on a Bruker Avance DPX-400 spectrometer. The ESR spectra were carried out using a Varian E-L 9″ X-band ESR spectrometer operating at 9.5 GHz and equipped with a TE104 rectangular double cavity.

2.1.1. Preparation of 1,3-bis(3,4-dicyanophenoxy)-4-tert-butylcalix[4]arene (1)

1,3-Dimethoxy-4-*tert*-butylcalix[4]arene (1.9 g, 2.8 m mol) and 4-nitrophthalonitrile (0.972 g, 5.6 mmol) were added successively with stirring to dry DMSO (60 ml). After they were dissolved, anhydrous K_2CO_3 (1.16 g, 8.4 mmol) was added and the reaction mixture was stirred at 85 °C for 76 h. Reaction was monitored by TLC. Then, the reaction mixture was poured into 200 ml of cold water, acetic acid (2 ml) was added and it was stirred for 15 min. The precipitate was filtered off, flushed several times with cold water until the filtrate was neutral, and then dried in air at 70 °C. This compound was readily soluble in the majority of organic solvents such as ethanol, methanol, chloroform, THF, acetone, diethyl ether, DMF and DMSO. Yield: 2.26 g (87%), m.p. 165–168 °C; ^1H NMR ($CDCl_3$): δ, ppm 7.78–6.31 (m, 14H, arom.), 3.73–3.23 (m, 6H, OCH_3), 2.66 (s, 8H, Ar-CH_2), 1.63–1.12 (m, 36H, *t*-BuCH_3). IR (KBr): ν, cm^{-1} 3046, 2959–2869 (CH aliph.), 2822, 2357, 2323, 2229 (C≡N), 1734, 1596 (Ar C=C), 1476, 1359, 1290, 1245 (Ar–O–Ar), 1193, 1117, 1017, 949, 873, 834, 523. *Anal.* Calc. for $C_{62}H_{64}N_4O_4$ (928): C, 80.17; H, 6.89; N, 6.03. Found: C, 79.93; H, 6.68; N, 5.96%.

2.1.2. Preparation of 1,3-bis(3,4-tetra iminoisoindoline)-4-tert-butylcalix[4]arene (2)

To a solution of compound **1** (0.568 g, 0.612 mmol) in dry methanol (100 ml) under argon, sodium methoxide (0.017 g, 0.314 mmol) in dry methanol (5 ml) was added. Anhydrous ammonia was bubbled through the mixture for 6 h at reflux temperature, after which time the reaction was complete (TLC). The NH_3 inlet was stopped, the volume of the solution was reduced to 10 ml in vacuo and 40 ml of diethyl ether was added to the residue. After filtration, the filtrate was evaporated to dryness to give a pale yellow product. Yield: 0.551 g (93.5%). This product is soluble in diethyl ether, chloroform, acetone and DMF, m.p. 183–186 °C; ^1H NMR ($CDCl_3$): δ, ppm 7.27–6.20 (m, 14H, arom.), 3.64 (s, 6H, NH), 3.44–3.13 (m, 6H, OCH_3), 2.54 (s, 8H, Ar-CH_2), 1.58–1.23 (m, 36H, *t*-BuCH_3). IR (KBr): ν, cm^{-1} 3362 (NH), 3192 (NH), 3046 (CH arom.), 2958–2868 (CH aliph.), 2821, 2736, 2359, 1729, 1663 (NH bending), 1606 (Ar C=C), 1546, 1473, 1359, 1287, 1240 (Ar–O–Ar), 1199, 1117, 1019, 935, 872, 832, 793, 756, 713, 637, 522. *Anal.* Calc. for $C_{62}H_{70}N_6O_4$ (962): C, 77.33; H, 7.27; N, 8.73. Found: C, 76.94; H, 7.19; N, 8.35%.

2.1.3. Synthesis of 1,3-bis[2-oxa-9,10,16,17,23,24-hexa(hexylthio) phthalocyaninato lutetium(III) acetate]-4-tert-butylcalix[4]arene [$(LuOAc)_2(Pc)_2$] (4)

A mixture of compound **2** (0.162 g, 0.17 mmol), compound **3** (0.385 g, 1.02 mmol) and lutetium acetate (0.120 g, 0.34 mmol) was refluxed in dry DMF (2 ml) under argon for 24 h. The mixture was cooled, the dark green mixture was diluted with EtOH (20 ml) and the crude product precipitated. This was filtered off and washed several times with ethanol to remove unreacted organic materials. The precipitate was then heated at 80 °C with DMSO (3 × 15 ml) and at 60 °C with MeOH (3 × 15 ml) and filtered off. The dark green product was washed with acetone and EtOH and it was dried in vacuo. Then, the crude product was dissolved in ethyl acetate (40 ml), the solution was filtered and the filtrate was evaporated to a smaller volume (ca. 10 ml). Reprecipitation from the solution with ethanol, washing successively with water and with ethanol prior to drying in vacuo gave a dark green powder. Finally, pure **4** was obtained by chromatography with silica gel using $CHCl_3$ as eluent This compound is soluble in DCM, $CHCl_3$, CCl_4, THF, ethyl acetate, diethyl ether and DMF. Yield: 0.108 g, 18%, m.p. >300 °C. UV–Vis λ_{max} ($CHCl_3$, 14.99 μM) ($\log \varepsilon/dm^3\,mol^{-1}\,cm^{-1}$): 364 (5.187), 640 (4.713), 712 (5.262) nm. ^1H NMR ($CDCl_3$): δ, ppm 8.71–6.92 (m, 26H, arom.), 3.29–3.25 (t, 6H, OCH_3), 2.99 (d, 8H, Ar-CH_2), 2.59 (s, 6H, $COCH_3$), 1.99 (br s, 24H, SCH_2), 1.71–1.60 (t, 36H, *t*-BuCH_3), 1.27 (d, 96H, –CCH_2 C–), 0.84 (d, 36H, –CH_3). IR (KBr): ν, cm^{-1} 3046, 2919–2853 (CH aliph.), 2358, 2218, 1654 ($COCH_3$), 1585 (Ar C=C), 1540, 1508, 1453, 1401, 1283 (Ar–O–Ar), 1195, 1067, 1021, 939, 833, 755, 690, 540. *Anal.* Calc. for $C_{186}H_{238}N_{16}O_8S_{12}Lu_2$ (3556): C, 62.76; H, 6.69; N, 6.29; S, 10.79. Found: C, 62.27; H, 6.97; N, 5.94; S, 11.18%.

2.1.4. Synthesis of 1,3-bis[[2-oxa-9,10,16,17,23,24-hexa(hexylthio)][2,3,9,10,16,17,23,24-hexa(hexylthio)] phthalocyaninato lutetium(III)]-4-tert-butylcalix[4]arene [$Lu_2(Pc)_4$] (5)

Compound **3** (0.241 g, 0.64 mmol), 0.0082 g of lithium metal and dry amyl alcohol (3 ml) were stirred at 50 °C under an argon atmosphere until complete dissolution of Li. The mixture was then refluxed for 5 h more and to this reaction mixture compound **4** (0.114 g, 0.032 mmol) was added and refluxed for a further 24 h. Then, the reaction mixture was diluted with EtOH (15 ml), the precipitate was filtered off and washed with hot EtOH to remove unreacted organic materials. The dark green product was then heated at 80 °C with DMF (3 × 20 ml) and DMSO (3 × 20 ml) and filtered off, washed with EtOH, acetone and ethyl acetate, and it was dried. After that, the crude product was dissolved in $CHCl_3$ (40 ml) and the solution was filtered. After the filtrate had been evaporated to

dryness, the dark green residue was washed with EtOH, acetone and dried in vacuo. Pure **5** was isolated on a silica gel column with $CHCl_3$. This compound is soluble in DCM, $CHCl_3$ and diethyl ether but insoluble in ethyl acetate. Yield: 0.093 g, 46%, m.p. >300°C. UV–Vis λ_{max} ($CHCl_3$, 17.09 μM) ($\log \varepsilon/dm^3\,mol^{-1}\,cm^{-1}$): 328 (5.069), 360 (5.015), 430 (4.712), 636 (4.762), 669 (4.920), 702 (5.197), 732 (5.125) MS (MALDI-TOF): *m*/*z* 6319 $(M+H)^+$. ^1H NMR ($CDCl_3$): δ, ppm 8.37 (s, 42H, arom.), 3.35 (t, 6H, OCH_3), 3.05 (t, 8H, Ar-CH_2), 1.19–1.50 (t, 224H, –CCH_2C–), 1.99 (t, 56H, SCH_2), 1.7 (t, 36H, *t*-$BuCH_3$), 0.93 (t, 84H, –CH_3). IR (KBr): *v*, cm^{-1} 3046, 2920–2855 (CH aliph.), 2581, 2356, 1592 (Ar C=C), 1500, 1454, 1400, 1363, 1320, 1283 (Ar–O–Ar), 1111, 1070, 1017, 935, 865, 824, 745, 679, 537. *Anal*. Calc. for $C_{342}H_{456}N_{32}O_4S_{28}Lu_2$ (6318): C, 64.95; H, 7.21; N, 7.09; S, 14.18. Found: C, 65.21; H, 7.24; N, 7.64; S, 13.78%.

2.2. MALDI-TOF sample preparation

Supra molecular complex **5** was prepared at a concentration of 4 mg/ml in chloroform for MALDI-TOF MS analysis. 3,5-Dinitrobenzoic acid (DNB) was chosen as the best MALDI-TOF matrix and prepared in acetonitrile at a concentration of 20 mg/ml. MALDI-TOF samples were prepared by mixing the complex solution of **5** with the DNB matrix solution (1:10 v/v) in a 0.5 ml Eppendorf® microtube. Finally, 1 μL of these mixtures were deposited on the sample plate, dried at room temperature and then analyzed.

2.2.1. MALDI mass spectrometry

Mass spectra were acquired on a Voyager-DE™ PRO MALDI-TOF mass spectrometer (Applied Biosystems, USA) equipped with a nitrogen UV-Laser ($\lambda = 337$ nm) at 10^{-8} Torr using the delayed extraction mode (delay 375 ns) by changing the laser intensity, if necessary. The acceleration potential was 20 kV for the spectra recorded in the linear mode and all spectra were the average of 50 shots. Then, the data were transferred to a personal computer for further processing.

2.3. Electrochemical measurements

Tetrabutyammonium perchlorate (TBAP) (Electrochemical grade, Fluka Chemical Co.), as the supporting electrolyte, and triply distilled water and extra pure dichloromethane (DCM) (Fluka Chemical Co.) as the solvents were used in the voltammetric measurements. Electrochemical measurements were carried out with a Princeton Applied Research Model Versostat II potentiostat/galvanostat, controlled by an external PC, utilizing a three electrode configuration at 25 °C. A platinum spiral wire was used as the auxiliary electrode. The working electrode was platinum with an area of 0.12 cm^2 in the measurements in non-aqueous solution and an indium-tin oxide (ITO) conducting glass electrode (12 $\Omega\,cm^{-2}$) with an active area of 1.0 cm^2 in the measurements of cast film. The surface of the platinum working electrode was polished with an H_2O suspension of Al_2O_3 before each run. The last polishing was done with a particle size of 50 nm. The ferrocene/ferrocenium couple (Fc/Fc^+) was used as an internal standard, and potentials were also reported with respect to Fc/Fc^+. Solutions containing **4** and **5** were deoxygenated by a stream of high-purity nitrogen for at least 15 min prior to running the experiment, and the solution was protected from air by a blanket of nitrogen during the experiment. For the controlled-potential coulometry (CPC) studies, a platinum gauze working electrode, a platinum wire counter electrode separated with a bridge, a SCE as the reference electrode and a model 377/12 synchronous stirrer were used.

2.4. Electrical and gas sensing measurements

2.4.1. D.c conductivity and impedance spectra

The temperature dependence of the d.c. conductivity and impedance spectra of the films were measured by using an interdigital transducer structure with gold electrodes which consist of 10 finger pairs of electrodes having a width of 100 μm, spaced 100 μm from the adjacent electrode. A thin film of the compounds was obtained by spin-coating chloroform solutions of the compounds over the electrode arrays. For the spin coating of **4** and **5**, the compounds were dissolved in $CHCl_3$ at concentrations of $\sim 1 \times 10^{-3}$ M for both compounds. Fifteen microlitres of such solutions were added with a glass pipette onto the IDT structure held onto the spinner (Speciality Coatings Systems Inc., Model P6700 Series). The substrate spun at 2000 rpm for 10 s and then the films were dried under vacuum. The temperature of the samples was controlled with a Leybold LTC 60 temperature controller during the measurements. The measurement procedure for the temperature dependent d.c. conductivity and impedance spectra was described in [45].

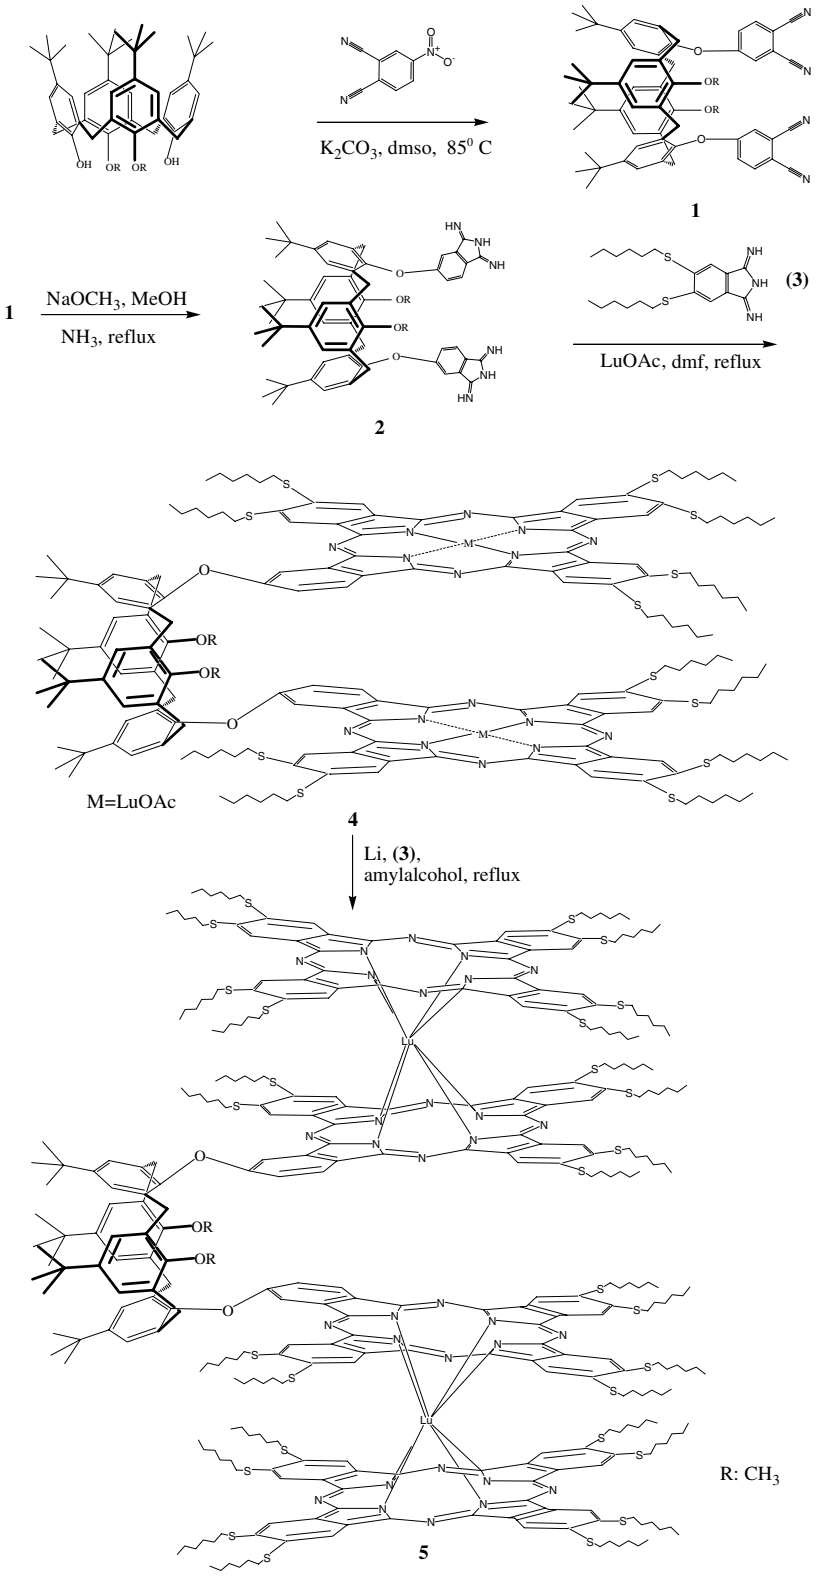
2.4.2. Gas sensing measurements

Due to the best temperature coefficient in combination with the highest mass sensitivity, AT-cut quartz crystals vibrating in the thickness shear mode with a fundamental resonant frequency of 10 MHz with Au electrodes were used in the gas sensing measurements. The sensitive layer was generated on one side of the quartz crystals by the spin coating technique. Typical thicknesses ranged from 100 to 300 nm. The sensors were placed in a homemade teflon chamber with a volume of approximately 20 cm^3. A dry nitrogen flow of 100 ml min^{-1} was passed through the test chamber until stabilization. A volume of 25 ml of the organic solvent was deposited in a 150 ml flask. The solvents selected for this study were ethanol, acetone, chloroform and carbon tetrachloride. Then, an appropriate flow of dry nitrogen was passed for 5 min through the solvent and then conducted to the measurement chamber. The test gases were mixed with dry nitrogen (N_2) using computer

driven mass flow controllers (Heastings 200/202 series). The carrier gas (dry nitrogen) used in the experiments had a purity level of 99%. The vapour effect on the fundamental resonant frequency of **4** and **5** coated QCR was monitored sequentially by using a Keithley 776 programmable frequency counter. A typical experiment consisted of exposure to VOC vapors and subsequent purging with dry nitrogen. The shifts in resonant frequency of the QCR were recorded using an IEEE 488 data acquisition system incorporated to a personal computer. The results obtained under these conditions were reproducible with an uncertainty less than 2%.

3. Results and discussion

3.1. Synthesis and characterization



As a first step, compound **1** was prepared by the reaction with 1,3-dimethoxy-4-*tert*-butylcalix[4]arene and 4-nitrophthalonitrile in dry DMSO in the presence of K_2CO_3 as the base. The reaction sequence was followed clearly by TLC. Compound **1** was converted to isoindoline derivative **2** by bubbling ammonia gas in dry MeOH in the presence of $NaOCH_3$ at reflux temperature in high yield followed by the reaction with six equiv. of 4,5-bis(hexylthio)-1,2-diiminoisoindoline (**3**) and lutetium acetate in refluxing DMF for 24 h to give dimeric dilutetium phthalocyanine (**4**) in 18% yield, without forming a sandwich-type complex [57]. The synthesis of bis double-decker lutetium(III) phthalocyanine (Lu_2Pc_4), namely compound **5**, was the most important step in these reaction sequences as shown in Scheme 1. It was achieved in situ by the reaction of dimeric dilutetium phthalocyanine (**4**) with two equiv. of symmetrical dilithium octakishexylthio phthalocyanine, which was prepared by **3** in amyl alcohol in the presence of lithium metal at reflux temperature.

All the new compounds were obtained sufficiently pure and gave satisfactory analytical results. Characterization of the products involved a combination of methods including elemental analysis, IR, ^{1}H NMR, UV–Vis, MALDI-TOF MS and ESR spectroscopy. The IR spectra taken with KBr pellets showed an aromatic C=C peak at around 1606–1585 cm^{-1}, an aromatic –CH peak at 3046 cm^{-1} and a Ar–O–Ar peak at around 1283–1240 cm^{-1} for all of the compounds. In addition, the comparison of the IR spectrum of **1** to that of **2** confirmed the proposed structure by the disappearance of the C≡N band at 2229 cm^{-1} for compound **1** and the appearance of a new absorptions at 3362 and 3192 cm^{-1} attributable to NH groups in compound **2**. The stretching peaks at around 2959–2853 cm^{-1} and the bending peaks at around 1476–1320 cm^{-1} confirmed the presence of –CH and $–CH_3$ groups, respectively, for all of the compounds. The additional peak at 1654 cm^{-1} in the IR spectrum of compound **4** indicated the presence of a $–COCH_3$ group that disappeared in the case of the compound **5**.

In the ^{1}H NMR analysis of compound **1** and **2** in d-chloroform, the aromatic protons appeared as multiplets at 7.78–6.31 and 7.27–6.20 ppm, respectively. In the spectra of **1**, the $–OCH_3$ protons appeared at 3.73–3.23 ppm, $–CH_2$ protons at 2.66 ppm and *t*-BuCH_3 protons at 1.63–1.12 ppm. The ^{1}H NMR spectrum of **2** was similar to that of compound **1**. The $–OCH_3$ protons appeared at 3.44–3.13 ppm, $–CH_2$ protons at 2.54 ppm and *t*-BuCH_3 protons at 1.58–1.23 ppm. The only difference is the signal at 3.64 ppm, corresponding to the –NH group, as expected for compound **2** which disappeared on D_2O exchange. When the ^{1}H NMR spectra of **4** and **5** in d-chloroform was investigated, aromatic protons appeared as multiplets at 8.71–6.92 and as a singlet at 8.37 ppm, respectively. In the ^{1}H NMR spectrum of **4**, the peaks at 3.29–3.25, 2.99 and 1.71–1.60 ppm indicated the presence of $–OCH_3$, $–CH_2$ and *t*-BuCH_3 groups of 1,3-dimethoxy-4-*tert*-butylcalix[4]arene, respectively, in the structure. The $–CH_3$ protons at the end of the chain appeared at 0.84 ppm, $–CCH_2C–$ protons at 1.27 ppm and the $–SCH_2$ group neighboring an aromatic ring at 1.99 ppm. The aliphatic protons of **5** exhibited the $–OCH_3$, $–CH_2$ and *t*-BuCH_3 groups of 1,3-dimethoxy-4-*tert*-butylcalix[4]arene at 3.35, 3.05 and 1.7 ppm, respectively. The $–CH_3$ protons at the end of the chain were found at 0.93 ppm, $–CCH_2C–$ protons at 1.19–1.50 ppm and the $–SCH_2$ group neighbouring an aromatic ring at 1.99 ppm. The only difference, which was the most important information indicating the formation of a bis double-decker lutetium(III) phthalocyanine (**5**), was the presence of the signal at 2.59 ppm in **4**, corresponding to the $COCH_3$ group, which disappeared in the spectrum of **5**.

Electronic spectra are especially fruitful in establishing the structures of **4** and **5**. The typical UV–Vis spectrum of **4** exhibited a characteristic Q band in the visible region at 712 nm. It is attributed to the $\pi \rightarrow \pi^*$ transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the Pc^{2-} ring (Fig. 1, solid line).

Compounds **4** and **5** show an additional band centered at 640 and 636 nm, respectively, as a result of aggregation through exciton coupling of the Pc units [58]. When the electronic spectrum of **5** was investigated, some peculiarities were observed. The intense Q band at 702 and 732 nm are somewhat distorted leading a third band of lower intensity at 669 nm in $CHCl_3$ (Fig. 1, dot line). This result might be interpreted in terms of the formation of HOMO–HOMO interactions of the two phthalocyanine rings. This fully agrees with the observation for the analogous Pc anions [59]. A characteristic absorption band for the radical phthalocyanine anion appears as a shoulder in the 400–500 nm region [60,61]. The band at 430 nm in the spectrum of **5** is assigned to a transition of a full level to the semi-occupied molecular orbital (SOMO) [62–65]. The B bands of **4** and **5** arising from the deeper π levels → LUMO transitions are observed in the UV region

Scheme 1. Summary of the synthetic pathway for the preparation of compounds **1**, **2**, **4** and **5**.

at 364 nm and with two maxima at 360 and 328 nm, respectively.

A close investigation of the mass spectrum of **5** confirmed the proposed structure. In the MALDI-TOF MS analysis of **5**, the protonated molecular ion peak at 6319 Da was observed (Fig. 2).

The free-radical nature of the green $Lu(Pc)_2$ complex is characterized by its ESR spectrum [23]. The spectrum of a

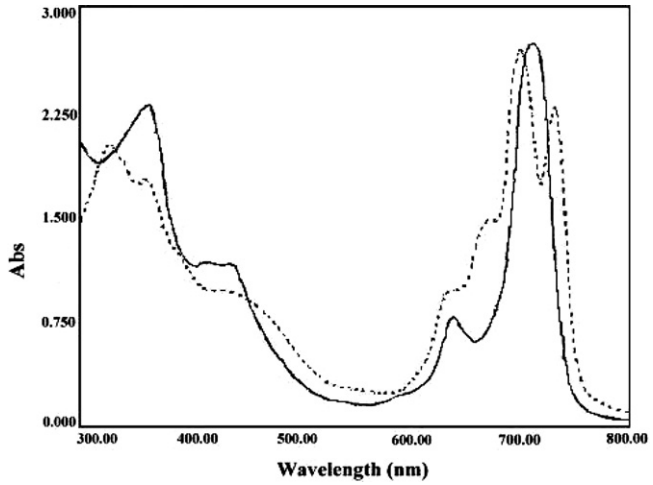


Fig. 1. UV–Vis spectra for **4** (——) and **5** (·····).

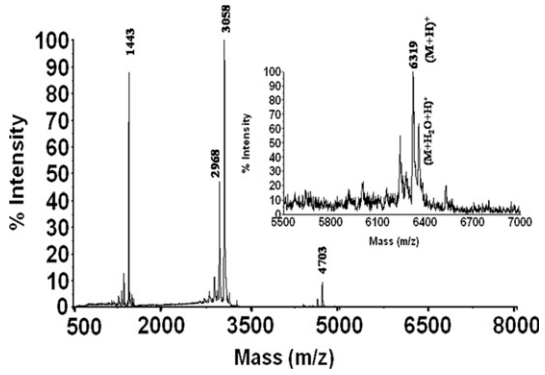

Fig. 2. Positive ion MALDI-MS spectrum of **5** in 3,5-dinitrobenzoic acid matrix.

solid sample of **5** at room temperature presented a strong signal at $g = 2.0022$ with a bandwidth of 5 G (Fig. 3). Very high signal intensity observed for the solid state of **5** likely witnesses the high amount of radicals per gram of this compound, producing an exchange narrowing on the linewidth. This confirms the presence of an unpaired spin, and thus is consistent with the occurrence of a phthalocyanine radical [66].

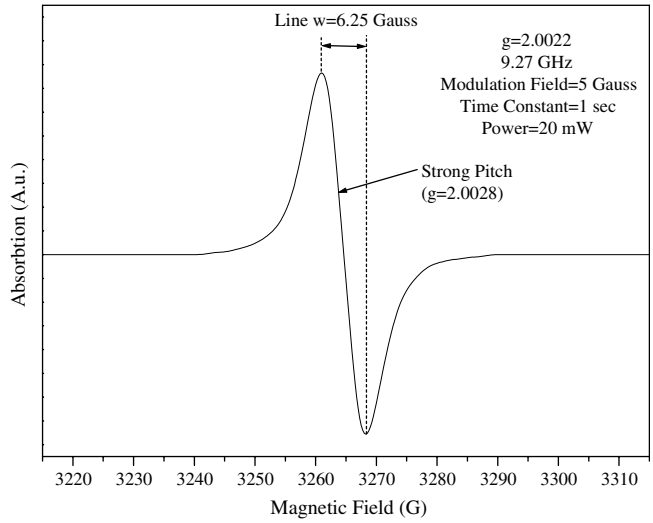

Fig. 3. ESR spectrum of **5**.

3.2. Electrochemistry

The voltammetric measurements for **4** and **5** were carried out on platinum in dichloromethane (DCM). The relevant data are given in Table 1.

Compound **4** undergoes up to two reductions at $E_{1/2} = -0.89$ V and $E_{1/2} = -1.15$ V versus SCE, and a single oxidation at $E_{1/2} = +0.65$ V versus SCE when dissolved in DCM. Controlled-potential coulometry studies showed that each redox process involves the transfer of two electrons. Typical cyclic voltammograms at several scan rates and a differential pulse voltammogram for **4** are shown in Fig. 4. All redox processes of **4** are related to ring-based processes because only the cerium derivatives in the series of lanthanide bis(phthalocyanines) and related double deckers display a metal-centered redox process.

The redox processes of **4** showed reversible or quasi-reversible behaviour at very slow scan rates but the cathodic to anodic peak separations, ΔE_p varied with scan rate indicating that the heterogeneous electron transfer rate was relatively slow at higher scan rates. The separation between the first ring oxidation and the first ring reduction, $\Delta E_{1/2}$ for **4** was found to be 1.54 V, a value approaching the average value for monomeric phthalocyanines [67].This value should be a consequence of very weak interactions between the phthalocyanine rings. The overall splitting of the molecular orbitals to a high degree are expected to occur only in the case where the rings are positioned in a face to face (cofacial) orientation as in the sandwich-type phthalocyanines. The weak interactions may be attributed to isolation of the two rings in **4** by the *tert*-butylcalix[4]arene bridge, and are compatible with the data reported recently for a similar lutetium phthalocyanine by our group [29b].

The voltammetric behaviour of **5** involving two sandwich-type diphthalocyanines differs from that of **4**. Typical cyclic voltammograms at different scan rates and a differential pulse voltammogram for **5** are shown in Fig. 5. Controlled-potential coulometry and cyclic voltammetry measurements indicated that at the positive potential side three one-electron redox couples were observed for **5** at $E_{1/2} = +0.13$ V, $E_{1/2} = +0.51$ V and $E_{1/2} = +0.77$ V versus SCE. On sweeping to negative potentials starting from 0.00 V, compound **5** displayed two two-electron redox processes at $E_{1/2} = -0.64$ V and $E_{1/2} = -0.86$ V versus SCE. All the redox processes are also ring-based. The voltammetric data for the redox processes are presented in Table 1. The peak separations and the variation of the peak potentials with the scan rate (Fig. 5) for these redox processes were usually within the range of quasi-reversible behaviour. As also was reported previously for $S_4(CH_2)_4$ bridged Lu_2Pc_2 and Lu_2Pc_4 compounds [29b], although in

Table 1

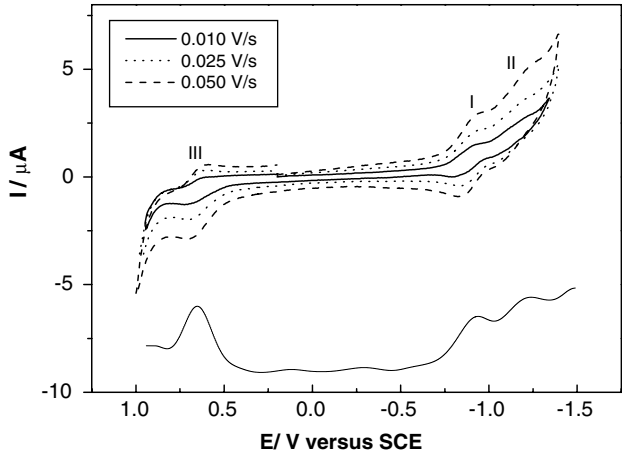

Fig. 4. Cyclic and differential pulse voltammograms of **4** (1.00×10^{-4} M) on Pt in DCM/TBAP.

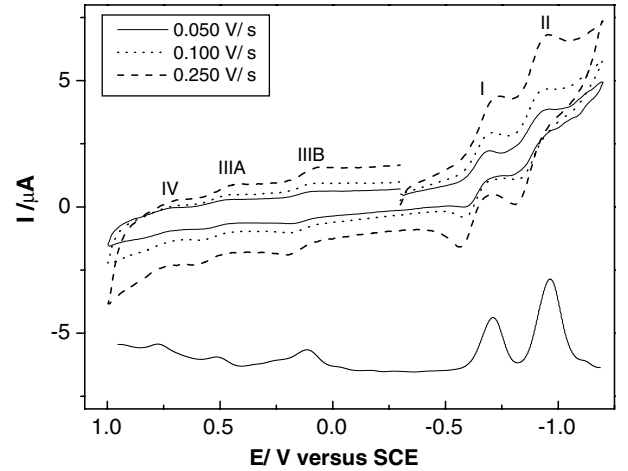

Fig. 5. Cyclic and differential pulse voltammograms of **5** (1.00×10^{-4} M) on Pt in DCM/TBAP.

the solid state compound **5** consists of two non-interacting free radicals, $[(Pc)(-1)Lu(Pc)(-2)]_2$, in solution at 0.00 V versus the SCE, it is in the form $[(Pc)(-2)Lu(Pc)(-2)]_2^{2-}$ with the extra two electrons per molecule coming from the electrode set–up in the cell. On scanning towards positive potentials, it is oxidized first to the original state, $[(Pc)(-1)Lu(Pc)(-2)]_2$ in two one-electron steps (IIIB and IIIA in Fig. 5), and then to $\{[(Pc)(-1)]_3Lu_2(Pc)(-2)\}^{+}$ (IV in Fig. 5), since it involves two phthalocyanine monoanions, $Pc(-1)$. Couple IV is well defined by the differential pulse voltammogram, and can be assigned to the oxidation of one of the sandwich units in the original compound. The couple for the oxidation of other sandwich unit is out of the solvent-limited potential range, and thus cannot be detected. We could not observe any oxidation couple for $S_4(CH_2)_4$ bridged Lu_2Pc_4 in the previous study for the same reason. The second and the third reduction couples (I and II, respectively), monitored for **5** at $E_{1/2} = -0.64$ V and $E_{1/2} = -0.86$ V versus SCE are also associated with the ring-based processes. Each of these couples was found to involve 2-electron transfer, suggesting that the two sandwich units are reduced at the same potential.

Half-wave potentials of *tert*-butylcalix[4]arene bridged Lu_2Pc_4, **5** are all more negative by 0.2–0.3 V than the measured $E_{1/2}$ values for previously reported $S_4(CH_2)_4$ bridged $Lu_2Pc_4(OAc)_2$ [29b]. This negative shift should be due to the benzene rings in the *tert*-butylcalix[4]arene bridges which increase the electron density of the phthalocyanine rings. Electrochemical measurements with cast films of **4** and **5** in aqueous and non-aqueous media on an ITO glass electrode are also continuing. These measurements suggest that the compounds display interesting electrochromic behaviour. The explicit discussion and comparison of electrochemical measurements in solution and in the film will be presented in a separate paper.

3.3. Electrical measurements

The dependence of the d.c. electrical conductivity of **4** and **5** versus inverse temperature, $\ln\sigma = f(1/T)$, were studied in the temperature range 290–420 K. The variation of d.c. conductivity with the inverse temperature at fixed voltage under forward bias (0.6 V) are shown in Fig. 6 for the films of **4** and **5** in a vacuum ($<10^{-3}$ mbar) in the dark. The

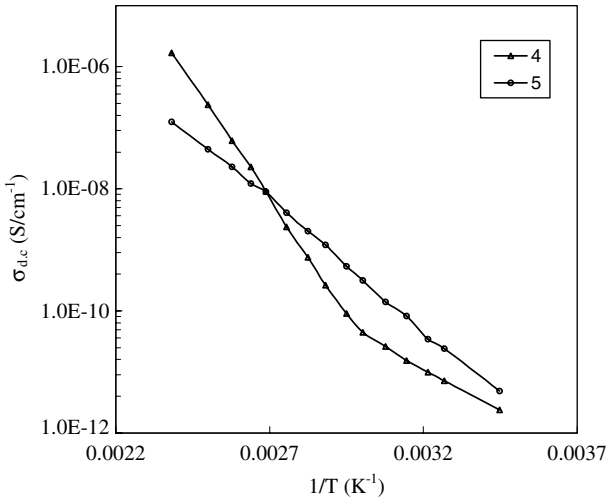

Fig. 6. Variation of d.c. conductivity as a function of temperature for the films of **4** and **5**.

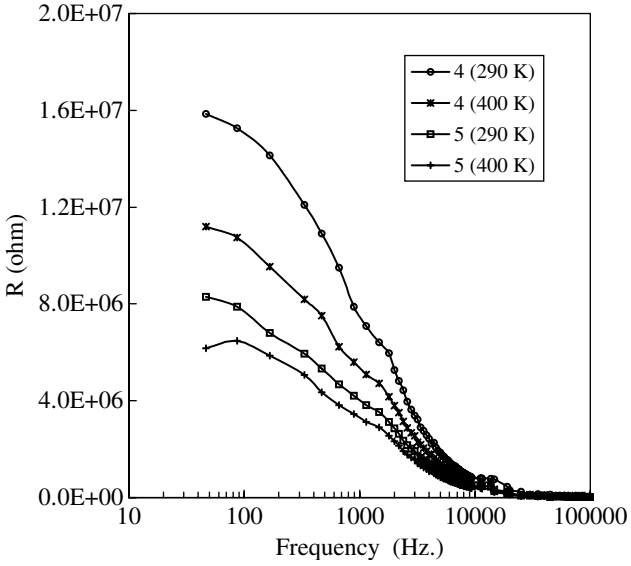

Fig. 7. Frequency dependence of the real part of the impedance for spin coated **4** and **5** films at the indicated temperatures.

conductivity measurements were carried out immediately after film deposition. The linear dependence in the Arrehenius plot suggests the presence of only one conduction mechanism, assuming that the dominant levels are the conduction and valence bands in the temperature range 290–420 K for film **5**.

In this case, it is reasonable to represent the temperature dependence of the conductivity for film **5** by the well known expression:

$$\sigma_{\mathrm{d.c.}} = \sigma_0 \exp(-E_{\mathrm{A}}/kT),$$

where E_{A} is the thermal activation energy of the electrical conduction, T is temperature, k is Boltzmann's constant and σ_0 is a parameter depending on the semiconductor nature. The value of the activation energy was derived from the slope of the $\log\sigma_{\mathrm{d.c.}}$ versus $1/T$ graph and is 0.77 eV for compound **5**. This E_{A} value for **5** matches well with that for the previously reported $S_4(CH_2)_4$ bridged Lu_2P-$c_4(OAc)_2$ [34]. There is a clear discontinuity in the $\log\sigma_{\mathrm{d.}c}$ versus $1/T$ plot at ~333 K for compound **4**. As can be seen from Fig. 6, the graph splits into two different linear regions, and each region can be ascribed to a different activation energy corresponding to a different dominant excitation. The activation energies obtained for region I and II were found to be 0.53 eV and 1.43 eV, respectively. A possible reason for the observed two different activation energy values in the Arrehenius plot could be a transition from extrinsic to intrinsic conduction. The variation of real part of impedance, $Z(\omega) = R(\omega) + \mathrm{i}X(\omega)$, as a function of frequency at room temperature and 400 K for the films of **4** and **5** is presented in Fig. 7. It becomes clear that there is a monotonic decrease in the real part of the impedance for the films at low frequencies. At higher frequency the value of $R(\omega)$ merges irrespective of temperature, which indicates the presence of space charge polarization. It can also be seen from Fig. 7 that the value of $R(\omega)$ is higher for the film of compound **4** than **5** for all frequencies. As the temperature rises, the value of $R(\omega)$ becomes less sensitive to frequency increase. Both the high impedance value at lower frequencies and the high frequency behaviour of $R(\omega)$ clearly indicate the presence of space charge polarization.

The temperature dependence of the imaginary part, $X(\omega)$, of the impedance (Fig. 8) of the films of **4** and **5** can be characterized by the following three important features: (i) at low temperatures, a monotonic decrease in the magnitude of the imaginary part, with increasing frequency without any peaks, (ii) presence of peaks at high temperatures, and (iii) a shift in the $X(\omega)$ peak to higher frequencies with increasing temperature. The decrease in $X(\omega)$ with the absence of any peak means that there is no

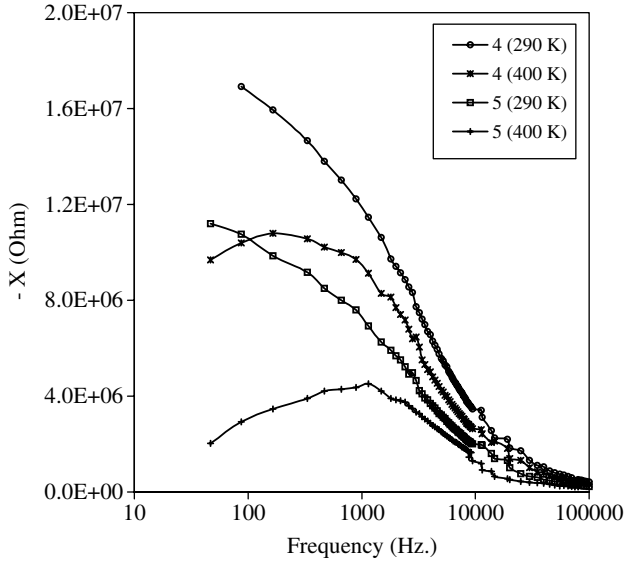

Fig. 8. The dependence of imaginary part of impedance on frequency for spin coated **4** and **5** films at room temperature and 400 K.

current dissipation in this temperature range. The appearance and broadening of peaks at high temperatures suggests the presence of an electrical relaxation phenomenon in the materials. The relaxation process can be attributed to the immobile species/electrons at low temperature and defects in the high temperature regions.

3.4. Sensor response for VOCs

In this part of the study, we concentrated on investigating the sensing properties of spin coated films of compounds **4** and **5** for VOCs vapors by using a quartz crystal microbalance transducer. The sensing principle of the quartz crystal microbalance sensor is based on changes in the fundamental resonant frequency, Δf, upon adsorption/absorption of molecules from the gas phase. In the adsorption experiments, the sensor response when exposed to different classes of organic solvent vapors over a wide range of concentrations (50–400 ppm) on the **4** and **5** coated sensors were examined. Typical responses of the 10 MHz QCM sensors coated with **4** and **5** to chloroform vapors are shown in Fig. 9. In this figure the frequency change Δf was plotted against time for six different chloroform concentrations. It can be seen from Fig. 9 that chloroform vapor causes a rapid frequency decrease, which represents a mass increase followed by saturation. It can also be seen that the response times for **4** and **5** coated sensors are typically one min. For example, in the case of 100 ppm of carbon tetrachloride, 90% of the maximum frequency change is attained in 68 s. The recovery times are also about one min. The sensor signals were completely reversible.

Fig. 10 shows the frequency change versus organic solvent vapor concentration for a **4** coated QCM sensor. The dependence of the frequency change on analyte concentration suggests that there are two kinds of adsorption behaviour onto the **4** coated sensor. The initial slopes in Fig. 10 indicate that the sensor responses linearly depend on organic solvent vapour concentration at the low concentration range. For a high concentration of analyte, the response of the **4** coated sensor does not increase any more with the increase of concentration. The high concentration region of Fig. 10 indicates that the analyte molecules were adsorbed as monolayers via hydrogen bonding. It is reasonable to assume that at higher concentration, the active adsorption sites on the surface of the coating (compound **4**) are occupied by the target molecules, and adsorption reaches a maximum.

The response characteristics of the **5** coated sensor was different from **4** (Fig. 11). A linear increase in the frequency

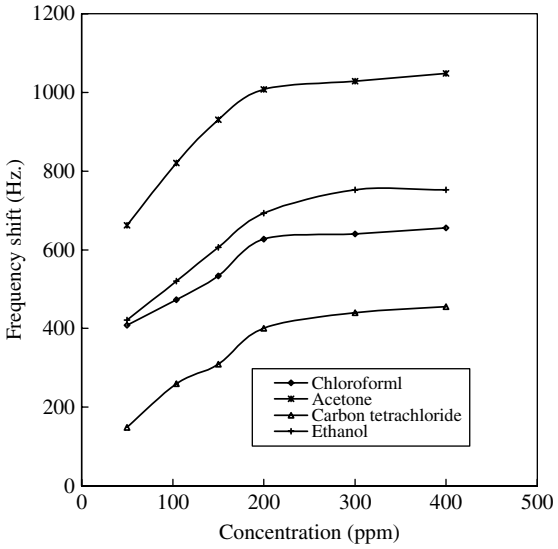

Fig. 10. Relationship between the solvent vapor concentration and frequency shift of the **4** coated QCM.

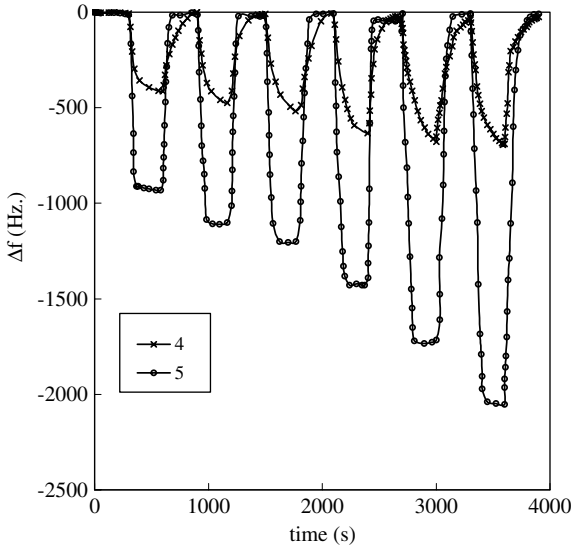

Fig. 9. Response of **4** and **5** coated QCM sensors to 50, 100, 150, 200, 300 and 400 ppm of chloroform vapors.

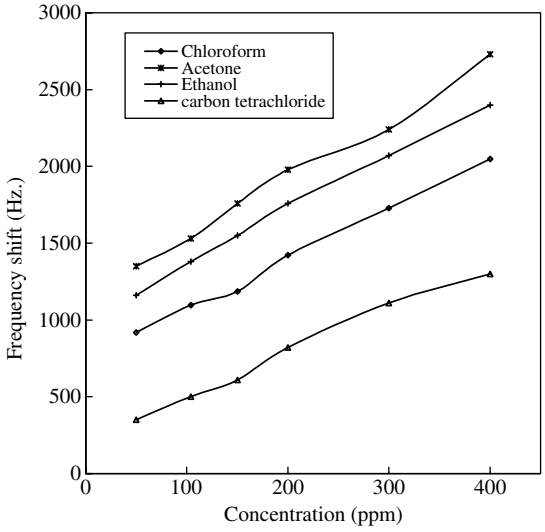

Fig. 11. Relationship between the solvent vapor concentration and frequency shift of the **5** coated QCM.

change with increase of vapour concentrations was obtained with the **5** coated sensor. The linear relationship between the frequency change and analyte concentration can be explained by multilayer adsorption. As the solvent vapour concentration increases, more analyte molecules are adsorbed on the sensitive layer by interacting with the previously trapped molecules on the surface of **5** to form multilayers.

We observed from aging experiments that the sensitive layers (**4** and **5**) were stable and have been used for three months without significant losses in sensitivity and selectivity.

The sensitivity S, which is an important parameter for any sensor, defined as

$$S = \frac{1}{C_V}\frac{\Delta f_V}{\Delta f_C}, \quad (2)$$

where Δf_V is the frequency change caused by exposure of the sensor to a concentration of an organic vapor, and Δf_C is the frequency shift in resonant frequency due to the coating. The results show less sensitivity for the non-polar organic molecules investigated, such as carbon tetrachloride. The higher sensor sensitivities are observed for the polar solvent molecules. The total response is in the order: acetone > ethanol > chloroform > carbon tetrachloride. This result may be due to dipole–dipole interactions between the adsorbed molecules and the coating material. The order of response is the same as that of the dipole moment of the analytes: acetone (2.91 D), ethanol (1.69 D), chloroform (1.08 D) and carbon tetrachloride (0 D).

4. Conclusions

In this study, a novel 1,3-bis(3,4-dicyanophenoxy)-4-*tert*-butylcalix[4]arene, namely compound **1** was prepared and used as a key compound for the preparation of a novel *tert*-butylcalix[4]arene bridged bis double-decker lutetium(III) phthalocyanine (**5**), which was achieved by the reaction of dimeric lutetium(III) phthalocyanine (**4**) with two equiv. of dilithium octakis (hexylthio) phthalocyanine in amyl alcohol, and produced in 46% yield. The ESR spectrum of **5** showed that this novel compound is radical in nature. The structures of the newly synthesized compounds were confirmed and characterized by elemental analysis as well as by IR, UV–Vis, ^{1}H NMR, MALDI-TOF MS and by ESR spectra. The electrochemical measurements suggested that π-orbital interactions between two Pc rings in **4** are very weak. On the other hand, the splitting of the first reduction process of a sandwich-type $LuPc_2$ was detected as a result of the strong HOMO–HOMO orbital interactions between the two rings of each sandwich unit in **5**. It can be concluded from the results of d.c., a.c. and gas sensing measurements performed on a spin coated film of **5** that the frequency dependent conductivity for the film can be represented by the power law relation. A QCR sensor showed high sensitivity for organic solvents with a high dipole moment, such as acetone.

Abstract

Copper(II) and palladium(II) complexes with 15-membered asymmetric 5,9-dihydro-2,4,10,12-tetramethyl-1,5,9,13-monobenzotetraazacyclo[15]tetradecine have been synthesized and characterized. The electrochemical behaviors of the complexes showed a reduction and two one-electron irreversible oxidation waves in given potential ranges due to the metal ion and macrocycle ring, respectively. The electrocatalytic reduction of dioxygen on glassy carbon electrodes electropolymerized by such 15-membered and 14-membered tetraazaannulene complexes occurred at 160–280 mV (versus SCE), less negative than on the bared one at pH 7.0. The catalytic activities of the copper(II) complexes in the oxidation of *p*-Xstyrene (X = OCH_3, CH_3, H, F, Cl) were higher than those of the palladium(II) ones. The structures of the 15-membered copper(II) and palladium(II) complexes were determined using the X-ray diffraction method.

1. Introduction

The chemistry of transition metal complexes with the dibenzotetraazacyclo[14]annulene macrocycle has been much studied largely because of the interaction between substrates and metal centers in biological systems [1–5]. However, the complexes mostly reported are symmetric 14-membered macrocycle compounds. On the other hand, the synthesis, electrochemistry and catalytic activity of 15-membered asymmetric monobenzotetraazaannulene complexes have rarely been studied [6,7,12,15]. The 15-membered complexes are expected undergo easier attack on the metal center by an oxidant than the14-membered complexes because the 15-membered complexes show square pyramidal structures. Some square planar Ni(II) complexes of macrocyclic ligands such as cyclam have been shown to act as catalysts for epoxidation of alkenes when PhIO or NaOCl was used as a terminal oxidant [9,10]. Various efforts have been made to elucidate the mechanism in which a Ni(III) species is involved, although there are some controversies of high valent metal-oxo intermediates [11]. The Cu(II) and Pd(II) complexes with such asymmetric ligands might be expected to show mostly similar processes, depending on the effect of the structure and electronic properties of the metal complexes. The crystal structures and characteristics for transition metal complexes with 15-membered asymmetric monobenzotetraazaannulenes have scarcely been reported until now because it is not easy to prepare the free ligands compared to the symmetric ones [8]. Previously [12–15], we have synthesized and reported nickel(II) complexes with a series of 14-membered

doi:10.1016/j.poly.2006.07.033

asymmetric tetraazaannulenes and also characterized the glassy carbon electrodes oxidatively electropolymerized by such complexes as modifiers.

In this paper, we have attempted to synthesize monobenzotetraazaannulene ligands with 15-membered asymmetric macrocyclic rings and then to synthesize the copper(II) and palladium(II) complexes from the reactions of the metal acetates with the free ligands in acetonitrile under nitrogen atmosphere. The spectral and electrochemical properties of the complexes prepared were characterized by means of infrared, mass, electronic absorption, ^{1}H and ^{13}C NMR spectra and cyclic voltammograms. The structures of the copper(II) and palladium(II) complexes with 2,4,10,12-tetramethyl-1,5,9,13-monobenzotetraazacyclo[15]tetradecine were identified by X-ray diffraction analysis. The catalytic activities of the metal complexes, varying with factors such as ring sizes and metal ions of the complexes and substituents of substrate, were preliminarily tested in the oxidation of *p*-Xstyrene (X = OCH_3, CH_3, H, F, Cl) in dichloromethane at room temperature. These studies will certainly help to better understand and summarize the properties and catalytic activities of tetraazaannulene metal complexes in the future.

2. Experiments

2.1. Materials and measurements

All chemicals used were obtained from commercial suppliers. The solvents such as CH_3OH, C_2H_5OH and CH_2Cl_2 were refluxed over calcium hydride under nitrogen, and their purities checked by GC just before use. Dimethylsulfoxide (DMSO) and acetonitrile (AN) were used as purchased without further purification. Tetraethylammoniumperchlorate (TEAP), used as a supporting electrolyte, was prepared and purified by the method described by Kolthoff and Coetzee [16]. All aqueous solutions for the measurements were prepared with deionized water purified using a Millipore Milli-Q water system (Bedford, MA).

Elemental analyses (C, H, N) of the complexes prepared were carried out on a Carlo-Ebra, EA 1108 instrument. Infrared spectra were recorded on a Matteson Instruments, Inc. Galaxy 7020A using KBr Pellets. ^{1}H and ^{13}C NMR (300 MHz) spectra were recorded on a Brucker instrument at room temperature and chemical shifts in $CDCl_3$ are given in ppm relative to tetramethylsilane as an internal reference. Electronic absorption spectra were obtained on a Shimadzu UV-265 spectrophotometer. EI mass spectra were determined with a JEOL MS-DX 300 GC–mass spectrometer at 70 eV using a direct inlet system.

Cyclic voltammetry was performed using a Bioanalytical System (BAS) CV-50W electrochemical analyzer and C2 cell stand at room temperature. The three-electrode system composed of a glassy carbon electrode (GCE) as a working electrode, Ag/Ag^+ (0.01 M $AgNO_3$ in 0.1 M TEAP-DMSO or AN solution) as a reference electrode and a platinum wire as an auxiliary electrode was used for the electrochemical measurements. Investigating the electrocatalytic activities of the modified electrodes, a saturated calomel electrode (SCE) was used as a reference electrode.

Analyses of organic products for the catalytic oxidation reaction were taken on a SHIMADZU GC-17A system. The column temperature was programmed from 80 to 100 °C (5–15 min) at rate of 5 °C/min. The products were identified by a comparison of their retention times with those of the pure compounds. *n*-Octane was used as an internal standard for the quantitative analysis of the product.

2.2. Synthesis

The nickel(II) complexes (**14-Ni** and **15-Ni**) as starting compounds and the free ligand (**L1**) and its 14-membered copper and palladium complexes were prepared as in processes described elsewhere [12,17–19].

The ligand 5,9-dihydro-2,4,10,12-tetramethylmonobenzo-1,5,9,13-tetraazacyclo[15]tetradecine (**L2**) was prepared by modifying the method previously used in **L1** [18,19]. At first, the starting complex **15-Ni** was dissolved in absolute ethanol and treated with excess anhydrous hydrochloric acid until the blue colored ligand salt precipitated. The reaction mixture was stirred at room temperature for 18 h. The solid was filtered, dissolved in water and neutralized by adding solid sodium cyanide. The bright yellow precipitate was recovered, washed with water and dried in vacuo. The yellow single crystal was obtained by recrystallisation from a 1:1 mixture of dichloromethane and methyl alcohol. Yield: 0.93 g (20% for **L2**). *Anal*. Calc. for $C_{19}H_{26}N_4$: C, 73.51; H, 8.44; N, 18.05; Found: C, 73.50; H, 8.40; N, 18.05%. IR (KBr disc, cm^{-1}): ν(C=C), 1552; ν(C=N), 1574; $\nu(C_6H_6)$, 723. UV–Vis: λ_{max} (nm) and ε_{max} ($M^{-1}\,cm^{-1}$) in $CHCl_3$ 316 and 37000. ^{1}H NMR ($CDCl_3$): 1.868 (s, 6H), 1.934 (s, 6H) (methyl); 4.613 (s, 2H) (methine); 2.152 (s, 2H), 3.415 (t, 4H, $J = 6.3$ Hz) (propylene); 6.812 ~ 6.965 (m, 4H) (aromatic); 11.220 (br, 2H) (N–*H*). ^{13}C NMR ($CDCl_3$): 19.721, 20.573 (methyl); 30.475, 45.841 (propylene); 95.378 (methine); 157.291, 162.421 (imine); 121.512, 122.370, 141.253 (aromatic). EIMS: *m*/*z* 310 $[M]^+$.

The 15-membered copper(II) and palladium(II) complexes could be prepared by modifying the method used for complexes **14-Cu** and **14-Pd**. The **15-Cu** and **15-Pd** complexes were prepared from the reaction of $M(OAc)_2 \cdot xH_2O$ ($M = Cu^{2+}$, Pd^{2+}) with **L2** in acetonitrile. The mixtures were heated under reflux for 2 h with stirring and bubbling of nitrogen gas to protect from moisture, and were then left to stand in a refrigerator for around 12 h. The solids were filtered and washed with acetonitrile. The products were chromatographed on aluminum oxide and eluted with chloroform. The effluents were collected, evaporated to dryness in vacuo and dried. The single crystals of **15-Cu**

and **15-Pd** obtained from 1:1 mixtures of dichloromethane and methyl alcohol were bright green and ruby red, respectively. Yield: 0.216 g (58% for **15-Cu**) and 0.228 g (55% for **15-Pd**). *Anal*. Calc. for $C_{19}H_{24}CuN_4$: C, 61.35; H, 6.50; N, 15.06; Found: C, 61.30; H, 6.50; N, 15.12%. UV–Vis: λ_{max} (nm) and ε_{max} ($M^{-1}\,cm^{-1}$) in $CHCl_3$ 380 and 20 000, 455 and 10 500. ^1H NMR ($CDCl_3$): 2.074 (s, 6H), 2.286 (s, 6H) (methyl); 4.779 (s, 2H) (methine); 2.174 (t, 2H, $J = 6.3$ Hz), 3.236 (t, 4H, $J = 6.3$ Hz) (propylene); 6.705–7.037 (m, 4H) (aromatic). ^{13}C NMR ($CDCl_3$): 22.306, 22.664 (methyl); 34.947, 52.463 (propylene); 102.925 (methine); 154.404, 158.943 (imine); 120.775, 121.410, 146.037 (aromatic). EIMS: m/z 414 $[M]^+$.

2.3. Electrochemical modification of GCE

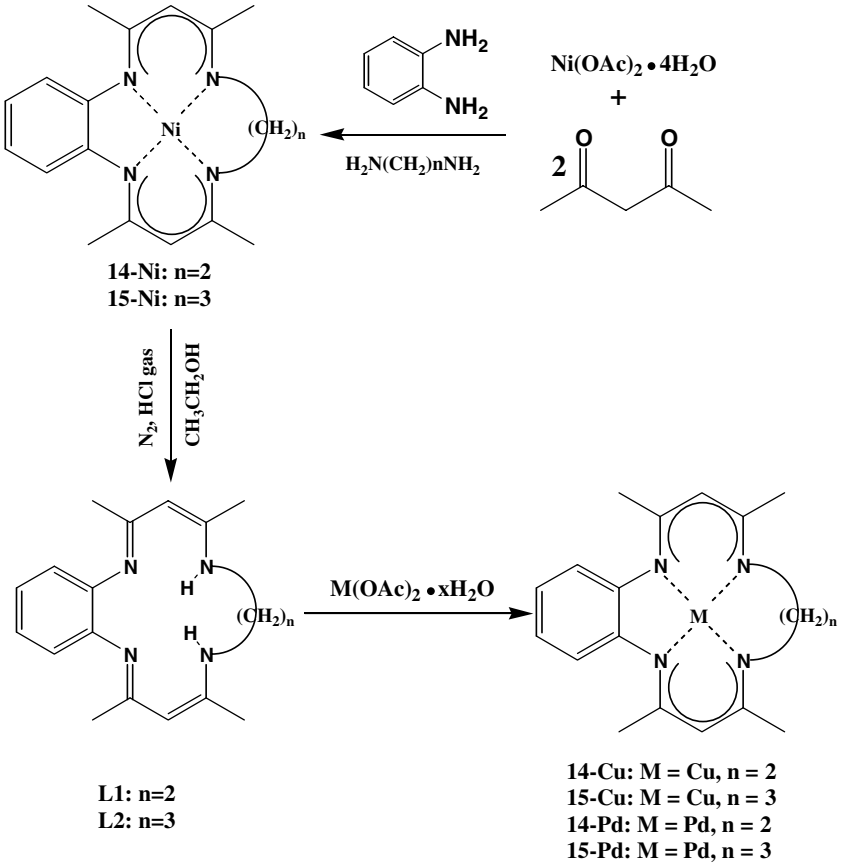
In order to fabricate the polymer modified glassy carbon electrode (GCE), glassy carbon rods (BAS model MF-1000, 2.0 mm in diameter) were used. Prior to the modifications, the GCE was polished with alumina slurry (0.05 μm, Buehler) on a microcloth pad, washed with deionized water, and dried. After the polishing procedure, the residual polishing material was removed by sonication for 30 s, and then dried. Electropolymerization of the complexes on the GCE was carried out by cycling in the range of +1.0 to −2.0 V at 100 mV/s in freshly prepared AN solutions containing 1.0 mM copper(II)- or palladium(II)-tetraazaannulene complexes and 0.1 M TEAP at 25 °C under a nitrogen atmosphere. After one cycle, the electrode was removed from the solution, rinsed with water and dried in air.

2.4. Catalytic reactions

Styrene oxidations catalyzed by the complexes **14-Cu**, **15-Cu**, **14-Pd** and **15-Pd** were carried out in a 25 mL round bottom flask equipped with side neck fitted with a screw capped silicon septum. In a typical experiment, a complex (0.2 mmol) was put into the flask and then dichloromethane (4 mL) was added, and followed by a substituted styrene (2 mmol) as substrates. After stirring for a few minutes, a solution of 10% NaClO (5 mmol) as the terminal oxidant was injected at the controlled temperature. The reaction was monitored with GC by periodically sampling. Relative oxidation rates of the substrates were calculated from the concentration of products and the conversion yields (%) were calculated using the following equation:

$$\text{Conversion } \% = 100 \times \{[\text{initial styrene}] - [\text{final styrene}]/[\text{initial styrene}]\}.$$

2.5. X-ray diffraction analysis



Preliminary examination and data collection for crystals of **15-Cu** and **15-Pd** were performed with Mo Kα radiation ($\lambda = 0.71069$ Å for **15-Cu** and $\lambda = 0.71073$ Å for **15-Pd**) on an Enraf-Nonius CAD4 computer controlled k-axis diffractometer equipped with a graphite crystal, incident-beam monochromator. Cell constants and orientation matrices for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections. The data were collected for Lorentz-polarization and absorption corrections were applied to the data. The structure was solved by direct methods using SHELXS-86 [20] and refined by full-matrix least-squares calculations with SHELXL-97 [21]. The final cycles of the refinements for **15-Cu** and **15-Pd** converged with $R_1 = 0.0351$ and $wR_2 = 0.0727$ and $R_1 = 0.0189$ and $wR_2 = 0.0492$, respectively.

3. Results and discussion

The free ligands (**L1** and **L2**) were obtained by demetallating the asymmetric 14-membered and 15-membered nickel(II)-tetraazaannulene complexes, respectively (Scheme 1) and their copper(II) and palladium(II) complexes (**14-Cu** and **15-Cu** and **14-Pd** and **15-Pd**) in 20–58% yields were prepared from the corresponding ligands with the metal acetates in acetonitrile under nitrogen atmosphere. Elemental analyses and mass data of the new compounds, collected in Section 2, were consistent with their formulations.

3.1. Spectral properties

The C=N, C=C and aromatic vibrational modes for the **15-Cu** and **15-Pd** complexes were at around 1550, 1570 and 745 cm^{-1}, respectively. The electronic absorption spectrum of **L2** exhibited only a band at 316 nm ($\varepsilon_{max} =$ 3!7 000 $M^{-1}\,cm^{-1}$) and a band ($\lambda_{max} = 322$ nm, $\varepsilon_{max} =$ 36 000 $M^{-1}\,cm^{-1}$) for **L1** was consistent with that previously reported [18]. The bands could be attributed to the $\pi \rightarrow \pi^*$ transitions of the macrocycle. The $\pi \rightarrow \pi^*$ transition bands of the new complexes, **15-Cu** and **15-Pd** moved to around 35 nm and 55 nm longer than that of the free ligand, reflecting some difference between the interactions of copper(II) and palladium(II) with the ligand. The visible spectrum of the complexes also had a band, which might be attributed to ligand to metal charge transfer (LMCT) transitions from the highest occupied ligand molecular orbital to the lowest empty d-orbital of the copper or palladium. The values of ε_{max} are much larger than those commonly assigned to ligand field transitions. This behavior is comparable to that observed for other nickel(II)-tetraazaannulene complexes, which have two bands at around 370 and 550 nm [12–15]. The electronic transition band of the copper(II) complexes (606 and 675 nm for **14-Cu** and **15-Cu**, respectively) appeared at wavelengths longer than those of the palladium(II) ones (432 and 455 nm for

Scheme 1.

14-Pd and **15-Pd**, respectively), as expected. The interaction between metal and macrocyclic ligand definitely increases in the order of copper < nickel < palladium.

The methyl and methine proton NMR peaks of **14-Pd** and **15-Pd** shifted downfield by about 0.2 ppm compared to those of **L1** and **L2**. The amine proton NMR peaks of **L1** and **L2** disappeared in the palladium(II) complexes. The peaks for the copper(II) complexes could not be measured due to the paramagnetic property of the copper(II) ion.

3.2. Electrochemical studies

The redox potentials of the new complexes measured in TEAP-DMSO (0.1 M) solutions *vs* Ag/Ag^+ (0.01 M) at 25 °C and sweep rates of 100 mV s^{-1} are listed in Table 1, and the cyclic voltammograms in the range +1100 to −3000 mV versus Ag/Ag^+ are drawn in Fig. 1. All the complexes showed a reduction peak (E_r) for the metal and two oxidation peaks ($E_{0(1)}$ and $E_{0(2)}$) for the macrocyclic ligand in the ranges −2000 to −2710 and −70 to +700 mV, respectively. The reduction potential of the metal decreased in the order Cu > Ni > Pd. The order is in accordance with the sequence shown in the electronic absorption spectra. The reduction peaks of the complexes with the 15-membered macrocylic ring appeared at less negative potentials compared to those with the 14-membered ring. This reflects that the increase in ring size makes the reduction easier because the 15-membered ring may be better able to stabilize the large M(I) ion. The 15-membered ring with a propylene group was be found to be more flexible than the 14-membered one with an ethylene group. The interaction between the metal and the tetraaza group on the 15-membered complex might be somewhat weaker than that of the 14-membered complex, which would cause the electron density on the metal center to be lower. The effect of ring size on the oxidation peaks is also similar to that on the reduction potential of the metals.

Table 1

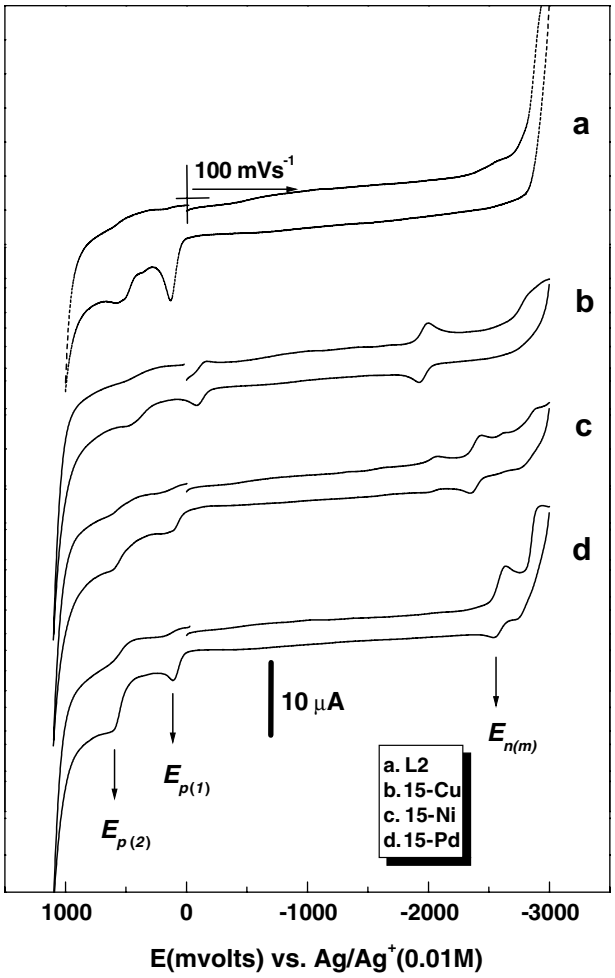

Fig. 1. Cyclic voltammograms of the new complexes in a 0.1 M TEAP-DMSO solution at 25 °C and 100 mV s^{-1}.

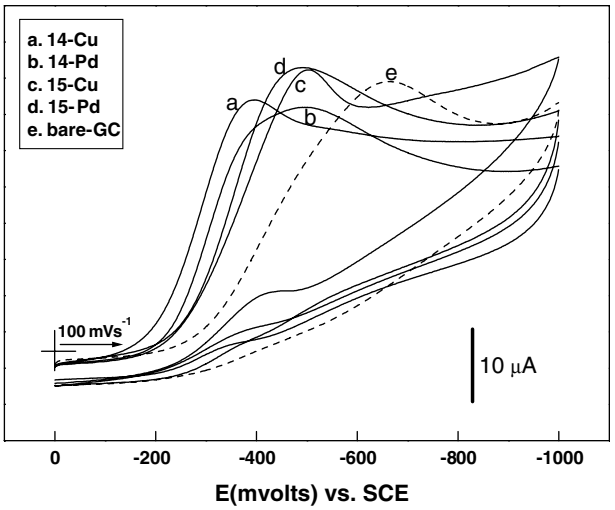

Fig. 2. Cyclic voltammograms of catalytic dioxygen reduction by the modified and bare-GC electrodes in a 0.1 M phosphate buffer (pH 7.0) water solution at 25 °C and 100 mV s^{-1}.

The GCEs modified by **14-Cu**, **15-Cu**, **14-Pd** and **15-Pd** were applied for dioxygen electroreduction, and the reduction potential differences between the modified and bare-GC electrodes were measured to evaluate the catalytic activity of the complexes as the electrode modifier. As shown in Fig. 2, the reduction potentials of dioxygen by the modified GCEs were reduced by 160–280 mV comparing to the bare-GCE. It could be shown that the electrodes modified by the new complexes have good catalytic activities for use of electrocatalytic reduction of dioxygen in water solution. The nucleophilic attack of dioxygen on the copper(II)-containing complex, **14-Cu**, might be readily available; that is the relatively hard metal Cu could effectively accept oxygen attack.

3.3. Epoxidation of styrene

To investigate the electronic effects of catalyst and substrate on the oxidation reaction, the copper(II)- and palladium(II)-tetraazaannulenes (**14-Cu**, **15-Cu**, **14-Pd** and **15-Pd**) and the styrene derivatives were used as catalysts and as substrate, respectively. The results of the reactions are listed in Table 2. As shown in Table 2, the % conversion by the copper(II) complexes were generally higher than those of the palladium(II) ones. Such an observation could be explained by the difference of the electron densities on the metal centers of the complexes, depending on the substituents, which affects the formation of the activated metal-olefin complexes as an intermediate. The about 40% conversion yield by the copper complexes for

Table 2

	X = CH_3	37	25	70	5
	X = H	25	16	53	31
	X = F	22	24	44	32
	X = Cl	11	35	38	27

[a] Experimental conditions: complex, 0.2 mmol; *p*-Xstyrene, 2 mmol; NaOCl, 5 mmol; solvent, dichloromethane 4 mL; temperature, 25 °C; reaction time, 48 h; product A, benzaldehyde; B, styreneoxide; C, phenylacetaldehyde + acetophenone; conversion (%) = 100 × [oxidation product]/[initial *p*-Xstyrene].

styrene indicated slightly better catalytic activities than the cyclam-nickel(II) one, which showed about a 30% conversion yield. The activities of the palladium complexes were similar to those of the Ni cyclam complex [9a]. The copper(II) complex can accept nucleophilic attack of styrene easier than the palladium(II) one due to the poor electron density. That is the π-electron in carbon double bond of styrene readily transfers to the copper(II) complex to form the activated metal-olefin. The palladium(II) complex, with rich electron density in comparison to the copper(II) complex, could not effectively manage the electrophilic attack on the olefin, therefore making the olefin less activated. The electronic effect of the complex on the conversion of substrate was in agreement with that for metal porphyrin complexes for olefin oxidation [25]. On the other hand, the substituent effect of *p*-Xstyrene on the substrate % conversion was consistent with the reverse order of the substituents σ_p values; X = *p*-OCH_3 (−0.27) < *p*-CH_3 (−0.17) < H (0) < *p*-F (+0.06) < *p*-Cl (+0.23) [22]. The electron withdrawing groups (F or Cl) of styrene decrease the electron density of the double bond in styrene, making it more difficult for nucleophilic attack on the metal center in comparison with the electron donating groups such as OCH_3 or CH_3. Thus the oxidation reaction of olefin should consider the electronic properties of the metal complexes together with those of olefins. Such basic experiments will certainly be useful to summarize the catalytic properties of the prepared teraazaannulene complexes in the future.

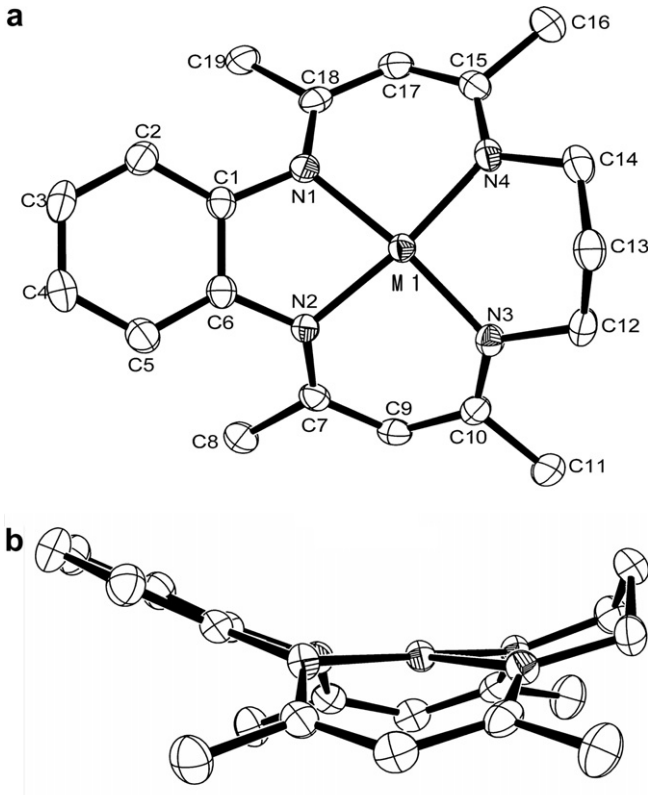

Fig. 3. Molecular structure (a) and side view (b) of **15-M** (M = Cu(II) or Pd(II)).

3.4. Crystal structures

The structures of 2,4,10,12-tetramethyl-1,5,9,13-monobenzotetraazacyclo[15]tetra-decinato(2-)copper(II) and -palladium(II) complexes were very similar and are illustrated in Fig. 3. Crystal data, details of the data collection and refinement parameters are listed in Table 3. Selected bond distances and bond angles are collected in Table 4. The **15-Cu** and **15-Pd** complexes have two molecules and a molecule in a cell, respectively, and both **15-Cu** and **15-Pd** showed like saddle-shaped structures. The average distances of N–Cu and N–Pd were 1.9692 ± 0.0066 and 2.0116 ± 0.0067 Å, respectively. The result is

consistent with the sequence of the radius of the metal ion ($Pd^{2+} = 1.28$ Å, $Cu^{2+} = 1.17$ Å). The bond distances of N(1)–C(18) (1.335 Å for **15-Cu** and 1.338 Å for **15-Pd**) and N(2)–C(7) (1.336 Å for both **15-Cu** and **15-Pd**) were longer than N(3)–C(10) (1.321 Å for **15-Cu** and **15-Pd**) and N(4)–C(15) (1.324 Å for **15-Cu** and 1.318 Å for **15-Pd**), which might be due to smaller basicities of phenylenediamine (pK_{a1} and pK_{a2}, 1.81 and 4.61) than those of propylenediamine (pK_{a1} and pK_{a2}, 9.03 and 10.94) [27,28]. The bond angles of the asymmetric15-membered macrocyclic complexes, **15-Cu** and **15-Pd**, having a five-membered and three six-membered chelate rings, were appreciably different in comparison with those of asymmetric 14-membered tetraaza[14]annulene nickel(II) [23,24,26] and palladium(II) [10]. In the five-membered ring of the symmetric tetraaza[14]annulene complexes, the bond angles (N–M–N) were about 83° for palladium [10] and 85.5° for nickel [23]. The values (N(1)–M(1)–N(2)) of the five-membered ring of **15-Cu** and **15-Pd** were 81.48° and 81.58°. The N(3)–M(1)–N(4) angles of **15-Cu** and **15-Pd** were 96.04° and 93.59°, and the average angles of N(1)–M(1)–N(4) and N(2)–M(1)–N(3) were 91.18° and 92.32°, respectively, while the average N(2)–M(1)–N(4) and N(1)–M(1)–N(3) angles are similar (172.02° for **15-Cu** and 172.48° for **15-Pd**). It should be able to be explained from these results that the metal and four nitrogen atoms in the asymmetric complexes definitely display more square-pyramidal geometries comparing to the symmetric tetraaza[14]annulene complexes, as illustrated in Fig. 3, owing to ring strain of the propylenediamine group [10,23,24].

Thermal behaviour of hexanuclear titanium(IV) oxo isopropoxide carboxylates, and their usability as a single-source TiO_2 CVD precursors

P. Piszczek *

Faculty of Chemistry, Nicolaus Copernicus University, 87-100 Toruń, ul. Gagarina 7, Poland

Received 16 May 2006; accepted 28 July 2006
Available online 24 August 2006

Abstract

Hexanuclear oxo titanium(IV) isopropoxide carboxylates, of the general formula $[Ti_6O_6(OPr^i)_6(O_2CR)_6]$ ($R = Bu^t$ (**1**), CH_2Bu^t (**2**)) and $[Ti_6O_6(OPr^i)_6(O_2CC(CH_3)_2Et)_6]\cdot 0.5(C_7H_8)$ (**3**), have been synthesized as polycrystalline powders in order to study their thermal properties and usability as TiO_2 CVD precursors. Analysis of thermogravimetric and variable temperature (VT-IR) data shows that the thermal stability of the synthesized complexes decreases as follows **3** > **2** > **1**. The composition of the vapors formed during the thermolysis of **1**–**3** were qualitatively analysed with VT-IR methods and mass spectrometry (MS-EI). According to obtained results, the decomposition of **1** and **2** proceeds with a partial decomposition and the formation of a volatile and stable titanium species, sufficient for their transport in vapors. The formation of volatile titanium-containing derivatives is an important factor that decides the application of **1** and **2** as precursors in CVD experiments. The high stability of **3** causes the thermal decomposition of this complex to be observed just above 573 K, and volatile titanium-containing derivatives were not detected in vapors. These results indicate that **3** could not be used as a precursor in CVD processes.

Keywords: Ti(IV) complexes; Volatile titanium species; Thermal analysis; MS and VT-IR studies; CVD precursors

1. Introduction

Multinuclear titanium(IV) alkoxy complexes of the general formula $[Ti_xO_y(OR)_i(L)_j]$ ($R = Et$, Pr^i, Bu, Bu^t; L – β-diketonates, carboxylates) are an interesting group of compounds consisting of a Ti(IV) oxide core surrounded by alkoxy and bridge ligands. They are often applied as sol–gel precursors for the preparation of new materials containing titanium dioxide, which are mainly used in microelectronics, optics, optoelectronics technologies [1–5], and also in photocatalytical processes [6–8]. Moreover physico-chemical properties of selected multinuclear Ti(IV) complexes allow for their application also as potential precursors in chemical vapor deposition methods (CVD). The examples are hexanuclear Ti(IV) oxo isopropoxide carboxylates with the general formula $[Ti_6O_6(OPr^i)_6(O_2CR)_6]$ ($R = Bu^t$, CH_2Bu^t) [9]. The application of these compounds as CVD precursors require knowledge about their thermal decomposition mechanisms and gas phase reactions enables the fabrication of pure titanium dioxide layers.

X-ray studies exhibited that the crystallographic structure of $[Ti_6O_6(OPr^i)_6(O_2CR)_6]$ ($R = H$, C_6H_4OPh, Bu^t) consists of clusters, where three μ_3-oxo, two μ-carboxylate bridges and a terminal alkoxide ligand surround each central cation [10–12]. The prismatic hexamers are associated through van der Waals interactions between the isopropoxide and carboxylate ligands (Fig. 1). The network of the weak intermolecular interactions seems to be responsible for the promising volatility of this compound.

In this paper, the results of the thermal behaviour of complexes synthesized in the 1:1 reaction of $Ti(OPr^i)_4$ with HO_2CR ($R = Bu^t$ (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**)) are discussed. Thermogravimetric analysis (TG/DTG/DTA), mass spectrometry (MS-EI) and variable temperature

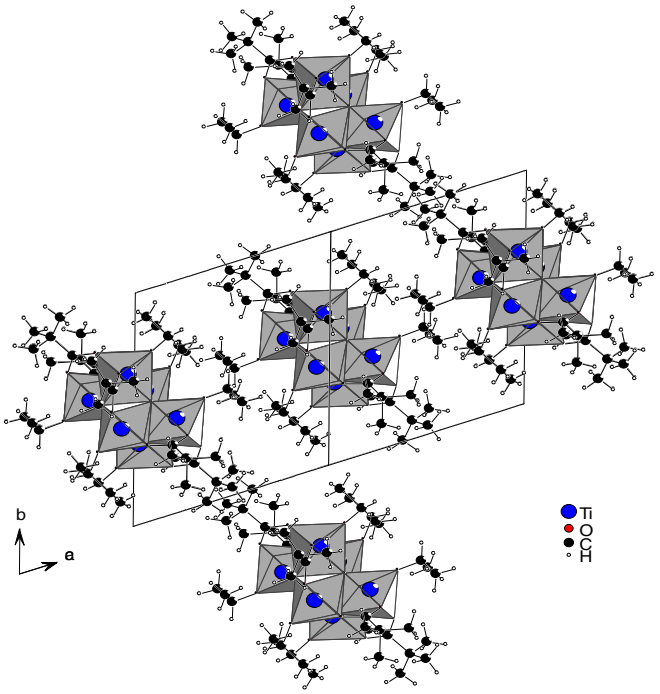

Fig. 1. The structure of $[Ti_6O_6(OPr^i)_6(O_2CBu^t)_6]$ (**1**).

infrared spectrometry (VT-IR) were used in order to study the thermolysis pathway and the identification of the vapor composition. The discussed results were compared with results of earlier CVD experiments [9].

2. Experimental

The studied complexes were synthesized as colourless polycrystalline powders in the direct reaction of titanium(IV) isopropoxide ($Ti(OPr^i)_4$) with the carboxylic acid (HO_2CR, R = Bu^t, CH_2Bu^t, $C(CH_3)_2Et$) in a 1:1 $Ti(OPr^i)_4$/RCO_2H molar ratio under the conditions described in the earlier report [12]. The powders were stored at room temperature under an argon atmosphere. The obtained compounds were slightly soluble in aromatic solvents. Themogravimetric analysis (TGA) was carried out using SDT 2960 TA Instruments, in nitrogen atmosphere from 298 to 773 K at a ramp rate of 3° min^{-1}. The complexes were characterized using IR and ^{13}C NMR spectroscopy. Infrared spectra (IR) were recorded on a Perkin Elmer Spectrum 2000 spectrometer within the range 400–4000 cm^1 with a medium slit width and a peak resolution of 4.0 cm^{-1}. The crystals were studied as a powder dispersed in a KBr pellet (400–4000 cm^{-1}). Solid state ^{13}C NMR spectra were recorded on a Bruker AMX 300. Solution ^1H NMR spectra (C_7D_8) were recorded using a 5 mm solution probe on a Varian Gemini 200.

The spectral data of $[Ti_6O_6(OPr^i)_6(OOCBu^t)_6]$ (**1**) were discussed in the earlier report [12], and therefore in this paper, only the spectral data of **2** and **3** have been presented. The elemental analysis (Vario Macro) has been used in order to determine carbon and hydrogen contamination. The % Ti was gravimetrically determined as TiO_2, according to the Meth-Cohn et al. method [13].

Variable temperature IR spectroscopic studies between 273 and 523 K, in the solid phase, were carried out with a SPECAC temperature variable cell. IR spectra of vapors transported with the carrier gas (Ar) were studied in the reactor described in the earlier report [14]. Mass spectra were recorded, in the temperature range 423–593 K with a MS AMD-604, MASPEC system using the EI method. The deposition experiments were carried out using a horizontal *hot-wall* CVD reactor as described in a previous publication [9,15].

3. Results and discussion

The results of the elemental analysis of polycrystalline powders suggest the formation of complexes of the general formula $[Ti_6O_6(OPr^i)_6(O_2CR)_6]$ (R = Bu^t (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et)_6$ (**3**). However, according to microanalysis data $[Ti_6O_6(OPr^i)_6(O_2CC(CH_3)_2Et)_6]\cdot 0.5(C_7H_8)$ as a general formula of **3** should be postulated. It is a consequence of the presence of toluene molecules in the crystal lattice of this complex. The structures of **2** and **3** were characterized by IR and ^{13}C NMR spectroscopy (detailed data are presented in the experimental part) and were compared with X-ray and spectroscopic data of **1** [12]. The medium intensity bands, which were detected in the IR spectra of **2** and **3** at 722–750 cm^{-1}, proved the formation of oxo bridges in the $[Ti_6O_6]$ clusters. The frequencies of stretching vibrations of the COO groups (ν_{as} = 1528–1574 cm^{-1} and ν_s = 1416–1479 cm^{-1}), and the chemical shifts of split peaks attributed to the carboxylate carbon (^{13}C NMR, δ = 178–188 ppm) indicates the formation of asymmetric

syn–syn carboxylate bridges. Moreover, both IR and ^{13}C NMR data confirm the presence of coordinated alkoxide ligands in the structure of **2** and **3**. Considering the spectroscopic data, in the structure of the studied complexes an analogous type of cluster is formed as is found in the crystal lattice of **1**.

3.1. Influence of temperature on the solid structure of $[Ti_6O_6(OPr^i)_6(O_2CR)_6]$ complexes

Thermogravimetric and variable temperature IR spectroscopy methods have been used in order to study the thermal changes in the solid structure of **1**–**3**. The results of TGA/DTG/DTA measurements are summarised in Table 1. The thermal decomposition (under an inert atmosphere) of **1**–**3** proceeds in three endothermic stages at 540–691 K, 499–689 K and 628–673 K (Table 1). In the case of **1** an additional weak decomposition stage at 365 K was also found. According to thermogravimetric data (Table 1), the thermal stability of the studied complexes decreases as follows: **3** > **2** > **1**. The complete weight loss reaches 64.7% (**1**), 64.5% (**2**) and 67.6% (**3**) at 703 K and is in agreement with the formation of titanium dioxide as the main decomposition product (theoretical weight loss: 64.3%, 66.4% and 66.4% for **1**–**3** respectively).

Variable temperature spectroscopy studies exhibit a significant frequency shift of the ν_{as}(COO) band from 1594 to 1590 cm^{-1}, and splitting of ν(Ti–OR) and ν_{as}(Ti–O–Ti) bands at ~1130 $cm^{-1}$and ~729 cm^{-1} respectively, during the heating of **1** between 293 and 523 K (Fig. 2). It was found that the dependence of ν_{as}(COO), ν(Ti–OR) and ν_{as}(Ti–O–Ti) frequencies versus temperature changes stepwise, the first step near 413 K and the second one at 473 K. Above effects can be assigned to phase transitions close to the above temperatures [16,17]. The analogous dependences of **2**, observed in VT-IR spectra between 373 and 523 K, were distinctly weaker.

Continuous changes of frequency and the integral intensity of bands assigned to vibrations of OOC, Ti–OR and Ti–O–Ti groups were observed in the spectra of **3**, which confirms its high thermal stability.

3.2. VT-IR studies of vapor composition

A potential application of **1**–**3** in CVD experiments requires the determination of changes in the composition of vapors formed during the thermolysis of these complexes under the conditions at which the deposition processes occur. The application of variable temperature IR spectroscopy enables the study of this problem and the obtained results have been presented in Fig. 3(a)–(c). Volatile titanium species containing the coordinated carboxylate or alkoxide groups were identified based on the presence of absorption bands at 1450–1700 cm^{-1} (ν_{as}(COO), ν_s(COO)), 1100–1200 cm^{-1} (ν(CO)) and 600–900 cm^{-1} (ν_{as}(TiOTi), ν_{as}(TiOR), δ(COO)) [18–21].

The overall studies of VT-IR spectra of the gas phase, formed during the thermolysis of **1**–**3**, make the determination of the temperature ranges in which the concentrations of volatile species are highest possible. This region was relatively narrow in spectra of **1**, strong bands of thermolysis products were detected in VT-IR spectra between 523 and 553 K (Fig. 3(a)). In the case of **2** they were found between 373 K and 533 K (Fig. 3(b)). Studies of **3** revealed that intense bands of volatile species appeared just above 573 K, as a result of the high thermal stability of this complex (Fig. 3(c)).

A detailed analysis of VT-IR spectra of **1** between 373 and 673 K (Fig. 3(a)) revealed changes in the vapor composition with the increase of the temperature. Weak bands of volatile species were detected in spectra registered near 413 K, which is the temperature region where, according to frequency changes in the solid structure of this complex, the first phase transition was observed. The hydrocarbon species (bands at 2890–3070, 1472, 1382, 1254 cm^{-1} assigned to vibrations of $-CH_2$, $=CH_2$ and $-CH_3$ groups), –OR and probable $Ti(OR)_4$ derivatives (bands at 1150, 1073, 953 cm^{-1}), have been identified as the main components of vapors at this temperature. Strong changes were noticed at 473 K (second phase transition). The appearances of bands at 1743, 1168 cm^{-1} (ester groups), 1117, 919 cm^{-1} (coordinated alkoxide groups) and also 1652, 1485 cm^{-1} (coordinated carboxylate groups) indicate the detachment of titanium alkoxides and titanium carboxylate

Table 1
Thermogravimetric results of the decomposition of hexanuclear oxo Ti(IV) carboxylate alkoxides

Complex	Stage	Temperature range (weight loss) [K]	DTA (K)
$[Ti_6O_6(OPr^i)_6(O_2CBu^t)_6]$ (**1**)	I	303–398 (4.4%)	365_{endo}
	II	398–573 (28.7%)	540_{endo}
	III	573–678 (22.3%)	672_{endo}
	IV	678–713 (9.3%)	691_{endo}
$[Ti_6O_6(OPr^i)_6(O_2CCH_2Bu^t)_6]$ (**2**)	I	343–523 (15.1%)	499_{endo}
	II	523–653 (38.2%)	641_{endo}
	III	653–713 (11.2%)	689_{endo}
$[Ti_6O_6(OPr^i)_6(O_2CC(CH_3)_2Et)_6]\cdot 0.5(C_7H_8)$ (**3**)	I	323–643 (32.6%)	628_{endo}
	II	643–683 (27.4%)	678_{endo}
	III	683–703 (7.6%)	673_{endo}

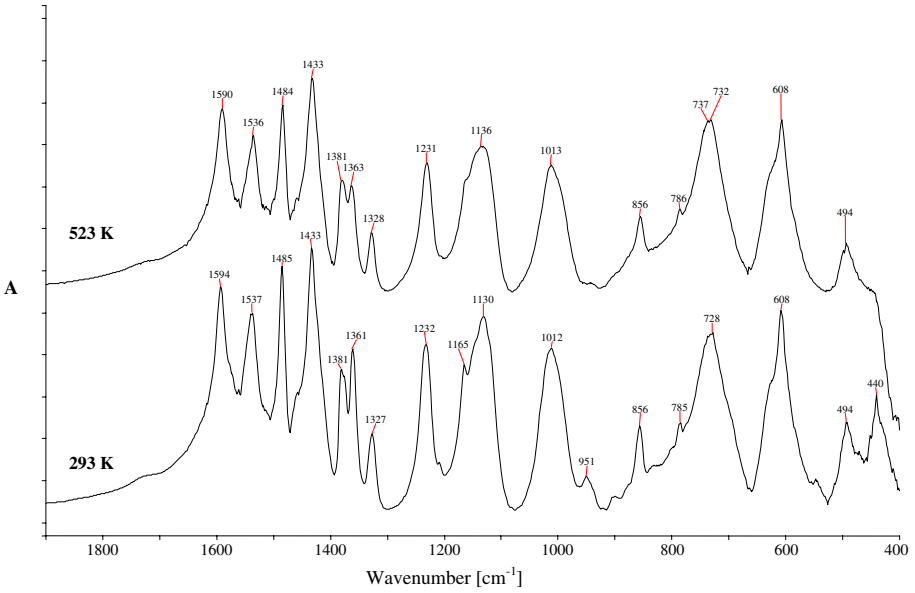

Fig. 2. IR spectra of $[Ti_6O_6(OPr^i)_6(O_2CBu^t)_6]$, registered at 293 and 523 K.

derivatives as well as esterification processes occurring. The intensities of the above mentioned bands are very weak at 473 K, but rapidly increase between 523 and 553 K. The complete decomposition of **1** at higher temperatures (613–673 K) causes the appearances of bands attributed to vibration of CO_2 (2360, 667 cm^{-1}), CO (2115, 2173 cm^{-1}), anhydride acid (1824, 1771 cm^{-1}), and also carboxylate and titaniumcarboxylate derivatives (1716, 1675, 1458 cm^{-1}). Considering the VT-IR data, the decomposition pathway of **1** as partial decomposition of this complex and formation of volatile and stable titanium-containing fragments (titanium alkoxide and titanium carboxylate derivatives), between 523 and 553 K has been proposed. Analysis of VT-IR data revealed that two potential sources of TiO_2 layers, of different thermal stability, are transported in vapors. The consequence of the postulated pathway is the deposition of TiO_2 films, which characterize the different polycrystalline structure. The formation of pure TiO_2 anatase films at lower deposition temperatures (713–753 K) can be caused by the majority of titanium alkoxide species in vapors. The presence of stable titanium carboxylate fragments in vapors, at higher temperatures, leads to deposition pure TiO_2 rutile layers between 833 and 873 K [9].

During the thermolysis of **2** only titanium alkoxide species (800–1120 cm^{-1}) and ester derivatives (1133, 1747 cm^{-1}) were found in the gas phase, in the wide temperature range 373–533 K (Fig. 3(b)). Appearances of the strong bands at 2360, 667 cm^{-1} (CO_2), 2050–2200 cm^{-1} (CO), and low intensity bands between 1830 and 1740 cm^{-1} (anhydride acid) indicate the complete decomposition of this compound above 573 K. Simultaneously absorption bands which can be assigned to volatile titanium carboxylate species, were not detected in the VT-IR spectra of the vapors. According to earlier reports [9] application of **2** as a CVD precursor allowed the deposition of pure TiO_2 anatase films (714–793 K) or a mixture of anatase/rutile films (>793 K). The pure TiO_2 rutile layers have not been obtained.

The high thermal stability of **3** caused only very weak bands, which can be attributed to titanium alkoxide (1034, 818 cm^{-1}), ester (1676, 1115 cm^{-1}) and other species containing carboxylate groups (1716 cm^{-1}), to be observed below 573 K (Fig. 3(c)). The intensity of absorption bands attributed to volatile decomposition fragments increases above 573 K. The appearance of a composite band between 1730 and 1770 cm^{-1}, which appears in IR spectra at 573–623 K can be assigned to vibrations of carboxylate groups of aldehyde, ketone or ester species. Bands derived from stretching vibrations of coordinated COO groups were not observed in spectra registered below 623 K. Spectral analysis of vapors formed during the thermolysis of **3** at 673 K shows that hydrocarbons, CO_2, CO and probable titanium carboxylate species (weak band at 1652 cm^{-1}) were the main components.

3.3. Results of MS studies

The main mass signals of titanium-containing fragments registered in the MS-EI spectra of **1**–**3** between 423 and 603 K and their relative intensities, are listed in Tables 2–4. Results of these investigations reveal clear differences in the way that complexes **1**–**3** fragment. In the case of **1** and **2**, the fragmentation of multinuclear clusters can be described as a result of the detachment of alkoxo, carboxylate ligands and the following volatile titanium derivatives: $[Ti(OPr^i)_4]$, $[TiO(OPr^i)_2]$, $[Ti(O_2CR)_2]$, $[OTi_2(O_2CR)_2]$ (Tables 2 and 3). According to data presented in Table 2 at 473–533 and 473–593 K for **1** and **2** respectively, the detachment of alkoxides and carboxylate

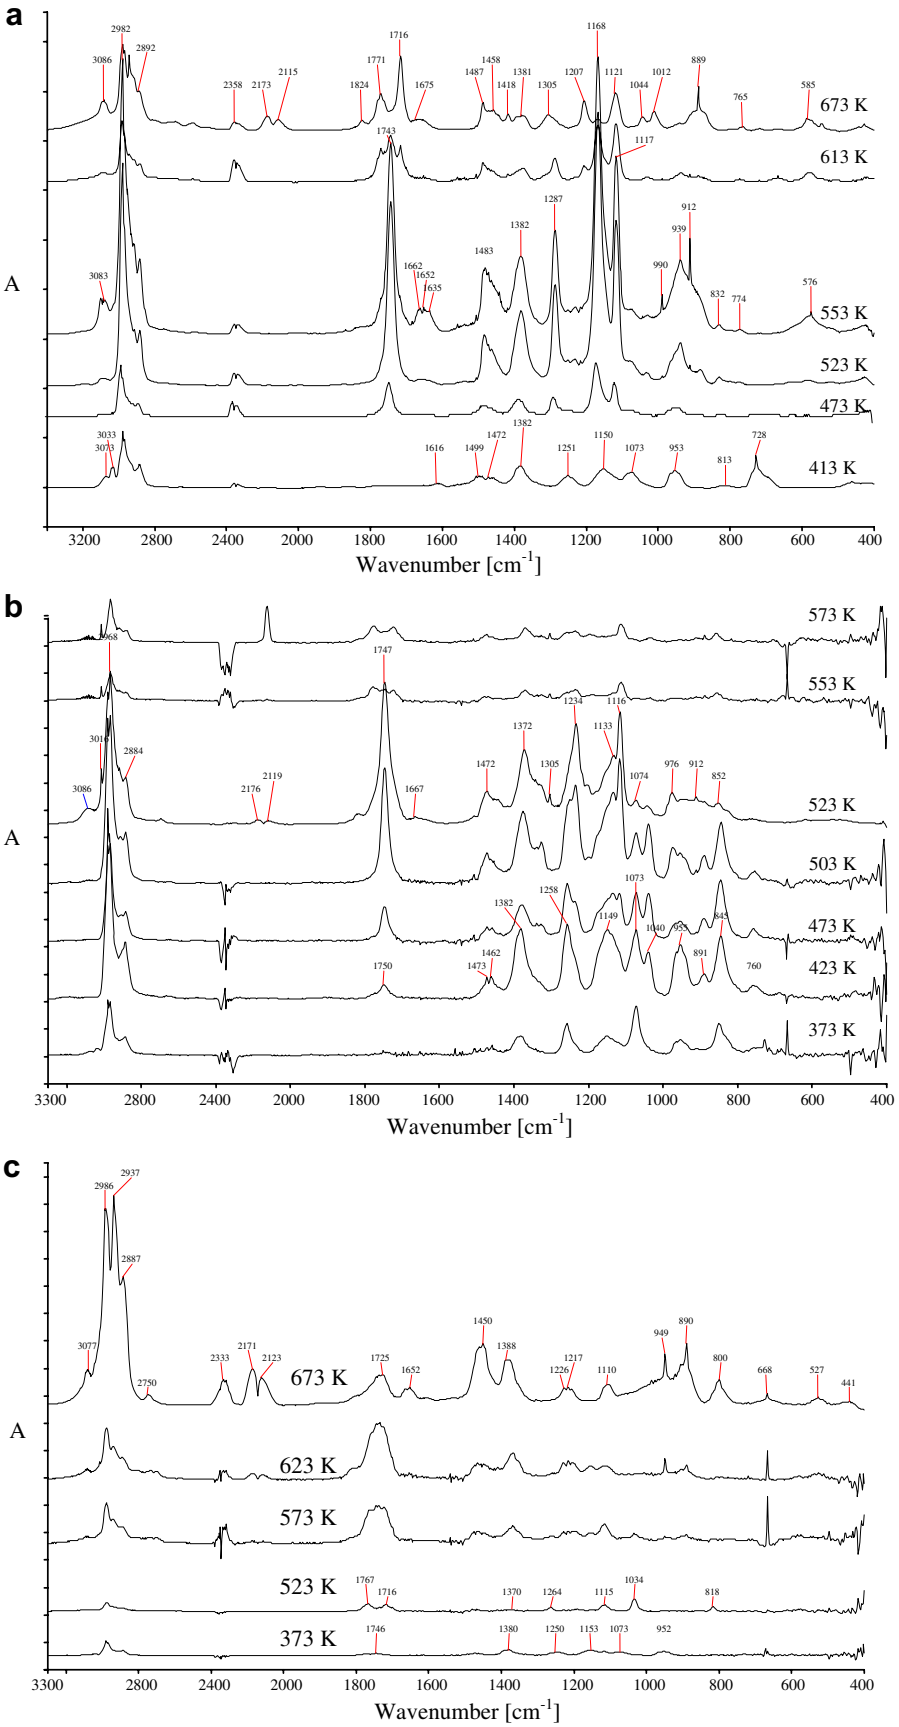

Fig. 3. Variable temperature IR spectra of vapors formed during the thermolysis of (a) **1**, (b) **2**, (c) **3** (VT-IR spectra registered between 353 and 693 K under Ar atmosphere and $p = 3$ mbar).

$[Ti_6O_6(OPr^i)_6(O_2CCH_2Bu^t)_5(O_2CCH_2)]^+$	1371	4.0	100	100	100	100	100	91.7

ligands leads to the formation of the following multinuclear fragments; $[Ti_6O_6(OPr^i)_5(O_2CR)_6]^+$ ($m/z = 1285$ (**1**), 1363 (**2**), 92–100%), $[Ti_6O_6(OPr^i)_6(O_2CR)_5]^+$ ($m/z = 1243$ (**1**), 1313 (**2**), 48–99%) and $[Ti_6O_6(OPr^i)_5(O_2CR)_5]^+$ ($m/z = 1184$ (**1**), 1254 (**2**), 12–13%).

Moreover, the loss of such fragments as $[Ti(OPr^i)_4]$, $[TiO(OPr^i)_2]$, $[Ti(O_2CR)_2]$, $[OTi_2(O_2CR)_2]$ conduce the formation of species containing $\{Ti_mO_n\}$ clusters: e.g. $[Ti_5O_6(OPr^i)_2(O_2CCH_2Bu^t)_5(O_2CCH_3)]^+$ ($m/z = 973$, 26–45%), $[Ti_5O_6(OPr^i)_2(O_2CR)_5]^+$ ($m/z = 959$ (**1**), 1031 (**2**) 11–20%), $[Ti_5O_6(OPr^i)_2(O_2CCH_2Bu^t)_2(O_2CCH_3)]^+$ ($m/z = 919$, 21–34%), $[Ti_5O_6(OPr^i)_2(O_2CBu^t)_4(Bu^t)]^+$ ($m/z = 917$, 34–37%), $[Ti_5O_6(OPr^i)_4(O_3CBu^t)_5]^+$ ($m/z = 875$, 24–27%), $[Ti_3O_3(OPr^i)_3(O_2CBu^t)_4]^+$ ($m/z = 773$, 3–17%), $[Ti_3O_3(OPr^i)_3(O_2CCH_2Bu^t)_2(OCH)]^+$ ($m/z = 628$, 1–36%), $[Ti(OPr^i)(O_2CCH_2Bu^t)_2]^+$ ($m/z = 337$, 2–29%). The possible fragmentation pathway of **1** presented in Scheme 1 and it suggests that the main components of vapors are the simple titanium alkoxide or carboxylate derivatives ($[Ti(OPr^i)_4]$, $[TiO(OPr^i)_2]$, $[Ti(O_2CR)_2]$, $[OTi_2(O_2CR)_2]$) and probable multinuclear fragments containing $\{Ti_mO_n\}$ clusters ($m = 2$–4, $n = 2$–6). It confirms the results of VT-IR investigations. A similar degradation pathway may be proposed for **2**, however the obtained results suggest a difference in stability of volatile titanium-containing fragments of **1** and **2** (Table 3). In the case of **1**, intense peaks assigned

Scheme 1. Proposed fragmentation pathway of **1**.

to multinuclear titanium species appear between 473 and 533 K, but at higher temperatures their intensity rapidly decreases. In MS spectra of **2**, the intense peaks attributed to fragments containing $\{Ti_xO_y\}$ clusters were registered between 473 and 593 K. It indicates higher thermal stability of volatile titanium-containing species in comparison with **1**.

Analysis of MS spectra of **3**, registered between 423 and 593 K, shows that the main fragmentation species are carboxylates ($m/z = 101$, 81–100), and the intensity of peaks attributed to titanium-containing fragments is less than 10% (Table 4).

4. Conclusions

In the presented study, the thermal decomposition and evaporation of hexanuclear Ti(IV) oxo isoproxide carboxylates (potential TiO_2 CVD precursors) of the general formula $[Ti_6O_6(OPr^i)_6(O_2CR)_6]$ ($R = Bu^t$ (**1**), CH_2Bu^t (**2**)) and $[Ti_6O_6(OPr^i)_6(O_2CC(CH_3)_2Et)_6]\cdot 0.5(C_7H_8)$ (**3**) were analysed using VT-IR and MS methods. Although, these complexes form a similar type of structure, their decomposition mechanisms are different. The partially thermal decomposition of **1** and **2** proceeds with the formation of volatile titanium-containing species and ester derivatives between 373 and 553 K. VT-IR studies of vapors formed during the thermolysis of **1** revealed that stable titanium alkoxide and titanium carboxylate derivatives are the main components (in terms of CVD processes) transported in vapors. However, only titanium alkoxide species were detected in vapors formed during the decomposition of **2**. The anhydride acids, aldehyde, ketone species, and also carboxylate derivatives (only in the case of **1**) were the main components of vapors formed at higher temperatures (>553 K). Analysis of spectral data revealed promising properties of **1** and **2** as TiO_2 precursors for thermal

inducted CVD methods. Variable temperature spectra indicate that thermolysis at 553 K will deliver titanium-containing fragments into the CVD reactor, as was confirmed in the earlier reports [9]. In contrast, the formation of the volatile and stable titanium derivatives during the thermolysis of **3** was not observed. The high thermal stability of this complex is the main reason why thermal decomposition occurs at just above 573 K, where stable titanium-containing fragments are not formed.

Abstract

L(+)-tartaric acid reacts with uranyl nitrate in the presence of KOH, under mild hydrothermal conditions, to give the complex $[UO_2(C_4H_4O_6)(H_2O)]$ (**1**), the first uranyl tartrate to be crystallographically characterized. Each tartrate ligand bridges three uranyl ions, one of them in chelating fashion through proximal carboxylate and hydroxyl groups. The resulting assemblage is two-dimensional, with the uranyl pentagonal bipyramidal coordination polyhedra separated from one another. Prolonged heating of an uranyl tartrate solution resulted in oxidative cleavage of the acid and formation of the oxalate complex $[(UO_2)_2(C_2O_4)_2(OH)Na(H_2O)_2]$ (**2**). The bis-bidentate oxalate and bridging hydroxide groups ensure the formation of sheets with corner-sharing uranyl pentagonal bipyramidal coordination polyhedra, in which six-membered metallacycles encompass the sodium ions. These sheets are assembled into a three-dimensional framework through further oxo-bonding of the sodium ions.

1. Introduction

The use of metal carboxylates in the design of open, porous assemblages has reached a high mark in recent years [1] and several groups were particularly active in the investigation of carboxylate-containing uranium-organic frameworks (UOFs), generally obtained via hydrothermal methods and in which uranium is in its most common dioxouranium(VI) (uranyl) form [2]. The peculiar geometric requirements of the linear uranyl ion also open many possibilities in molecular engineering, as illustrated by the synthesis of metallamacrocycles with a tetracarboxylic acid [3]. Most of the polymeric assemblages obtained with uranyl and polyacids involve diacids such as succinic [2b], glutaric [2b,2g], adipic [2c], 3,5-pyrazoledicarboxylic [2h], 2,4-, 2,6- and 3,4-pyridinedicarboxylic [2i,2l], 1,3- and 1,4-benzenedicarboxylic acids [2b,2j], and triacids such as benzene-1,3,5-tricarboxylic [2e], citric and tricarballylic acids [2n], with only one example of a tetra-acid, 1,2,4,5-benzenetetracarboxylic acid [2j,2m]. The assemblages formed with these polyfunctional ligands are one- [2b,2c,2e,2l], two- [2g,2h,2i,2j,2m,2n] or three-dimensional [2b,2c,2n], some of them incorporating also 3d-block [2h,2j,2l] or alkali metal ions [2n], and the uranium coordination polyhedron is always the usual pentagonal or hexagonal bipyramid. Considering the present development of uranyl structural chemistry, it appears somewhat surprising that the crystal structures of complexes with some common, naturally occurring polyacids have never been described. Such is the case of L(+)-tartaric [L(+)-2,3-dihydroxybutanedioic] acid which, being a chiral molecule, could give chiral UOFs, as recently reported for (1*R*,3*S*)-(+)-camphoric acid [4]. It was indeed possible to get crystals of uranyl tartrate under mild hydrothermal conditions, and the crystal structure of the complex is described herein. However, during the course of this study, it appeared that prolonged heating of uranyl

doi:10.1016/j.poly.2006.07.024

tartrate in the presence of NaOH resulted in the oxidation of the acid into oxalic (ethanedioic) acid. The crystal structure of the complex thus formed differs from those of the other polymeric forms of uranyl oxalate which are reported in the Cambridge Structural Database (CSD, Version 5.27) [5] and is also described herein.

2. Experimental

2.1. Synthesis

Uranyl nitrate hexahydrate and L(+)-tartaric acid were purchased from Prolabo and used without further purification.

2.1.1. $[UO_2(C_4H_4O_6)(H_2O)]$ (1)

Uranyl nitrate hexahydrate (205 mg, 0.41 mmol), L(+)-tartaric acid (62 mg, 0.41 mmol), KOH (46 mg, 0.82 mmol) and demineralized water (4.5 mL) were placed in a 15 mL tightly closed vessel and heated at 180 °C under autogenous pressure. Few light yellow crystals of complex **1** were obtained within 3 days. Attempts to increase the yield by lengthening the reaction time resulted in the deposition of an insoluble powder likely resulting from degradation of tartaric acid and in situ formation of oxalic acid, as described hereafter. It was thus not possible to isolate complex **1** in sufficiently large quantity to perform chemical analyses.

2.1.2. $[(UO_2)_2(C_2O_4)_2(OH)Na(H_2O)_2]$ (2)

Uranyl nitrate hexahydrate (200 mg, 0.40 mmol), L(+)-tartaric acid (60 mg, 0.40 mmol), NaOH (32 mg, 0.80 mmol) and demineralized water (3.2 mL) were placed in a 15 mL tightly closed vessel and heated at 140 °C under autogenous pressure. Few yellow crystals of complex **2** were obtained after 6 weeks.

2.2. Crystallography

Data were collected at 100(2) K with a Nonius Kappa-CCD area detector diffractometer [6] using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The crystals were placed inside glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from ten frames, then refined on all data. The data (φ- and ω-scans) were processed with HKL2000 [7]. The structures were solved by direct methods with SHELXS97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL97 [8]. Absorption effects were corrected empirically with SCALEPACK [7]. All non-hydrogen atoms were refined with anisotropic displacement parameters. All the hydrogen atoms bound to oxygen atoms were found on Fourier-difference maps, except those of the water oxygen atom O9 in **1**. The other hydrogen atoms were introduced at calculated positions and all were treated as riding atoms with a displacement parameter equal to 1.2 times that of the parent atom. The absolute configuration determined for **1** from the value of the Flack parameter [9] matches that expected. Crystal data and structure refinement details are given in Table 1 and selected bond lengths and angles in Table 2. The structural plots were drawn with SHELXTL [10] and BALLS AND STICKS [11].

3. Results and discussion

The crystal structure of the complex $[UO_2(C_4H_4O_6)(H_2O)]$ (**1**) is the first ever reported for uranyl tartrate. Complex **1** crystallizes in the chiral space group $P2_1$ with one uranyl ion, one tartrate and one coordinated water molecule in the asymmetric unit (Fig. 1a). The uranium atom is bound to the carboxylate atom O3 and to the proximal hydroxyl group O5 in chelating fashion, as previously observed in the uranyl complex with citric acid [2n], to two carboxylic groups from neighbouring molecules (O4′ and O7″) and to a water molecule (O9). The average U–O(carboxylate) and the U–O(hydroxyl) bond lengths, 2.366(6) and 2.493(5) Å, respectively, match those in the citric acid complex [2.38(2) and 2.496(10) Å], whereas the U–O(water) bond length, 2.407(4) Å, is intermediate between the values of 2.367(13) and 2.495(6) Å in the latter complex. The uranium environment is thus pentagonal bipyramidal, as very often observed in uranyl complexes with carboxylates, except when three bidentate carboxylate groups surround the metal to give a hexagonal bipyramidal environment, such as with tricarballylic acid [2n]. The five atoms O3, O5, O4′, O7″ and O9 define a plane with an r.m.s. deviation of 0.12 Å and the metal atom is located at 0.007(2) Å from this mean plane. As in the citric acid complex, the carboxylic, but not the hydroxyl groups, are deprotonated. The latter are involved in hydrogen bonds (Table 3): atom O5 is hydrogen bonded to the only uncoordinated carboxylate oxygen atom O8 of a neighbouring molecule whereas O6 is involved in a bifurcated hydrogen bond with atom O7 in the same molecule and atom O8 in a second neighbouring unit. The protons of the aqua ligand were not found, but two short contacts are indicative of hydrogen bonding, one with an uranyl oxo atom [O9···O2′ 2.798(6) Å, symmetry code $x-1, y, z$] and the other with the uncoordinated hydroxyl group of a neighbouring molecule [O9···O6″ 2.748(7) Å, symmetry code $x, y-1, z$].

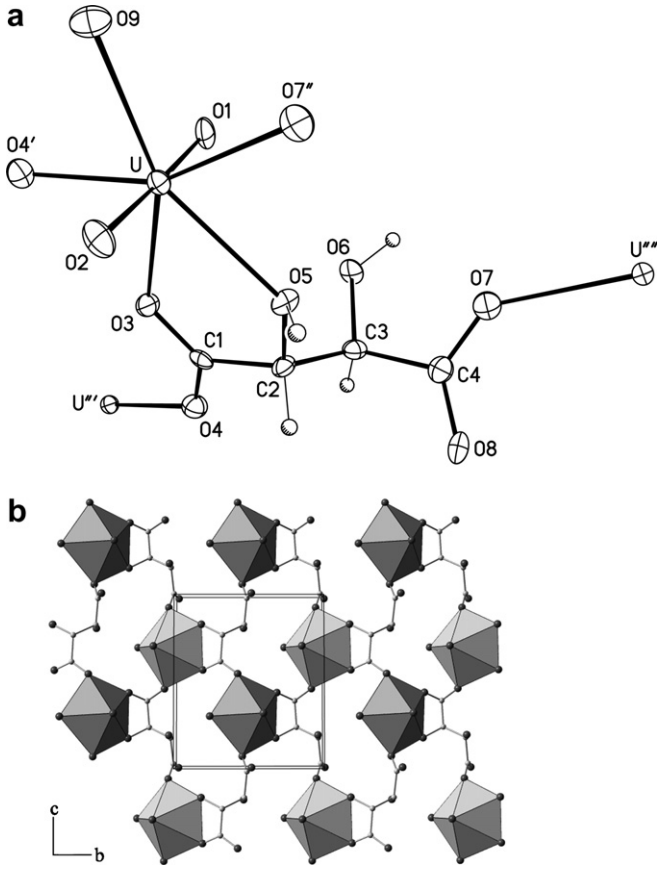

Fig. 1. (a) View of the complex $[UO_2(C_4H_4O_6)(H_2O)]$ (**1**). Displacement ellipsoids are drawn at the 70% probability level. Symmetry codes: $' = 1-x,\ y-0.5,\ 1-z$; $'' = 1-x,\ y-0.5,\ 2-z$; $''' = 1-x,\ y+0.5,\ 1-z$; $'''' = 1-x,\ y+0.5,\ 2-z$. (b) View of the bidimensional assemblage parallel to the *bc* plane. The uranium coordination polyhedra are represented. Other atoms are shown as spheres of arbitrary radii.

The three metal ions are bridged by the (μ_3-tartrato-1κ^2O,O':2$\kappa O''$:3$\kappa O'''$) species, a bridging mode which, to the best of our knowledge, has never before been observed with this ligand. The full metal-binding potential of the tartrate moiety is thus not reached, since one of the hydroxyl functions and one of the carboxylic oxygen atoms are not coordinated. This gives rise to the formation of undulated sheets parallel to the *bc* plane in which the uranium coordination polyhedra are separated from one another, having no edge or apex in common (Fig. 1b). Sheets stacked along the *a*-axis are tightly held by hydrogen bonds and the shortest U···U distance is along this axis [5.3614(3) Å] (the two metal atoms which are bound to the same carboxylate group are at a distance of 5.8966(3) Å from one another). No channel is formed in the packing, by contrast with the chiral channels formed in the uranyl complex with another enantiopure ligand, (1*R*,3*S*)-(+)-camphoric acid [4]. To the best of our knowledge, the present structure is the first for a tartrate of an actinide element. Eleven structures of lanthanide tartrates are reported in the CSD [5], in which three examples of chelation through one carboxylate and the proximal hydroxyl group are found [12], whereas all the other examples are mixed lanthanide/molybdenum chiral double helicates in which the lanthanide ion is bound to two ligands through one carboxylate oxygen atom [13]. In all cases, the hydration level is higher than in **1** since two to six water molecules are coordinated to the metal. It has been noted that hydrothermal methods generally yield

phases with higher dimensionality and lower water coordination than room temperature methods [14] and a recent example concerns the synthesis of microporous lanthanide tartrates with only one aqua ligand per metal ion [15].

Prolonged heating of an aqueous solution of L(+)-tartaric acid, uranyl nitrate and NaOH (1:1:2) at 140 °C (i.e. at a temperature lower than that leading to crystallization of complex **1**) resulted in the oxidative cleavage of the acid and in situ formation of oxalic acid. Similar formation of oxalic acid from 3,5-pyrazoledicarboxylic acid under hydrothermal conditions has been mentioned [2h] but, to the best of our knowledge, no details have been published. It was also reported that quinolinic acid could be decarboxylated into nicotinic acid under similar conditions [2m]. Formation of oxalic acid from tartaric acid oxidation has been known for long [16]. However, the enantiomeric stability of L(+)-tartaric acid in neutral solutions at 160 °C for several days has been demonstrated by circular dichroism spectroscopy [15]. The present experiment was conducted at pH ~ 2–3 and in the presence of an uranyl salt and it is thus possible that the metal plays a role in the oxidation reaction.

The oxalate complex $[(UO_2)_2(C_2O_4)_2(OH)Na(H_2O)_2]$ (**2**) is different from the other polymeric uranyl oxalate complexes reported in the CSD. The asymmetric unit in **2** comprises one uranyl ion and one oxalate dianion in general position, and one sodium atom, one hydroxide ion and two aqua ligands located on the symmetry plane (x, 1/4, z) of space group *Pnma* (Fig. 2a). The uranyl ion is bound, in its equatorial plane, to two (μ-oxalato-1κ^2O,O':2κ^2O'',O''') ligands and one bridging μ-OH anion, which results in a pentagonal bipyramidal environment for the uranium atom, with the five atoms in equatorial positions defining a mean plane with an r.m.s. deviation of 0.015 Å. The bis-bidentate, (μ-oxalato-1κ^2O,O':2κ^2O'',O''') ligand is frequently encountered in uranyl complexes, either binuclear

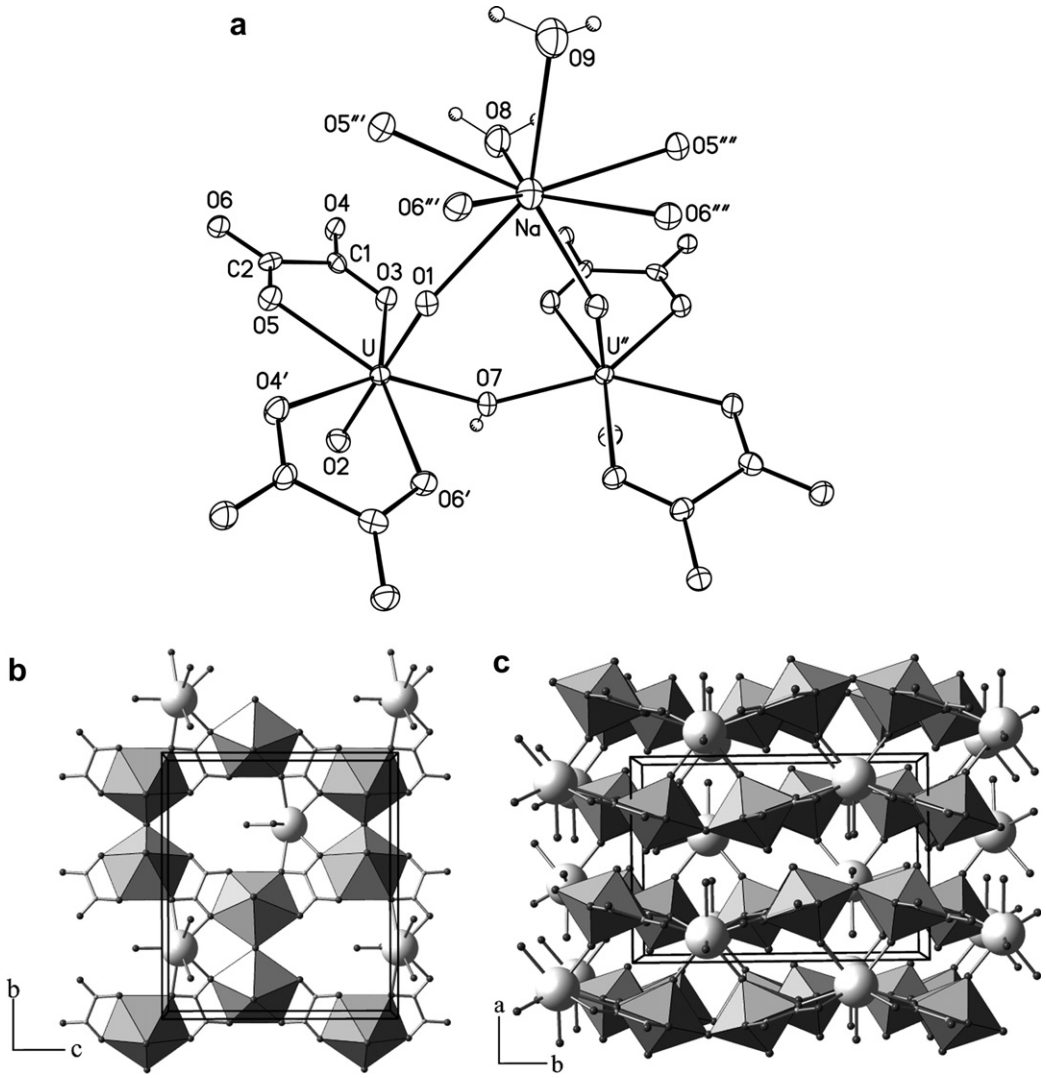

Fig. 2. (a) View of the complex $[(UO_2)_2(C_2O_4)_2(OH)Na(H_2O)_2]$ (**2**). Displacement ellipsoids are drawn at the 50% probability level. Symmetry codes: $' = 1.5 - x, 1 - y, z + 0.5$; $'' = x, 1.5 - y, z$; $''' = 1 - x, 1 - y, 1 - z$; $'''' = 1 - x, y + 0.5, 1 - z$. (b) Projection of one sheet in the *bc* plane. (c) View of the tridimensional assemblage. The uranium coordination polyhedra are represented. Other atoms are shown as spheres of arbitrary radii.

[17] or polymeric [18]. The average U–O(oxalate) and U–O(hydroxide) bond lengths in **2** are 2.431(11) and 2.2867(14) Å, in good agreement with the mean values from the CSD, 2.42(5) and 2.33(2) Å, respectively. The U–O–U angle around the hydroxide bridge is 138.67(19)° and the dihedral angle between the two corresponding mean O_5 equatorial planes is 37.58(5)°. This angle brings the uranyl oxo atom O1 and its image by the mirror plane at a rather short distance of 3.09 Å from one another and these atoms are thus apt to complex the sodium ion while forming a six-membered U_2NaO_3 ring. Such bonding of an alkali metal to the uranyl ion is possible due to the Lewis basicity of the oxo groups and has been previously observed in uranyl complexes with tricarballylic acid (although it was absent with citric acid in the same experimental conditions) [2n] or other ligands [19], as well as in other uranyl oxalate complexes [18c,18e,20]. Sodium bonding to neptunyl oxo groups is also found in a neptunium(V) oxalate complex [21]. The Na–O(oxo) bond length of 2.549(3) Å in **2** is in quite perfect agreement with that in $[(UO_2)_4(C_2O_4)_5Na_2(H_2O)_8]\cdot 2H_2O$, the other polymeric uranyl/sodium oxalate complex, which is 2.542 Å [18e] and both are intermediate between that measured in the tricarballylic acid complex [2.715(9) Å] [2n] and the mean value of 2.40(8) Å (2.20–2.50 Å range) for the other seven comparable bond lengths in the CSD. The sodium atom in **2** is located 0.593(5) Å from the mean plane defined by the uranium and oxygen atoms in the U_2NaO_3 ring (r.m.s. deviation of 0.015 Å). Its coordination sphere is completed by four carboxylate oxygen atoms, which are bridging the uranium and sodium atoms, and two water molecules, thus resulting in an eight-coordinate environment of very irregular geometry.

The hydroxide bridged uranyl groups in **2** can be considered as pseudo-dimeric basic units, which are further linked by oxalate ligands to form six-membered U_6 rings or metallacycles (Fig. 2b). Each of these rings contains one sodium ion bound to oxalate oxygen atoms and located on one side of the cavity. Larger, 10-membered rings were observed in the other polymeric uranyl/sodium complex [18e]. Conversely, the basic units in **2** can be viewed as oxalate-bridged chains directed along the *c*-axis, which are further linked by hydroxide ligands corresponding to the polyhedra apexes pointing out on each side of the chain. The oxalate- and hydroxide-bridged uranyl groups are thus arranged in sheets parallel to the *bc* plane. The U···U distances are 4.2791(4) Å for atoms separated by hydroxide links and 6.3004(3) Å for those separated by oxalate moieties; as expected, the former value is larger than those for double hydroxide bridges [mean value 3.84(7) Å from the CSD], but in good agreement with the value of 4.3152(12) Å reported for another oxalato/hydroxide complex [18f], whereas the latter value is in the range usually observed for oxalate-bridged UO_7 pentagonal bipyramids, ca. 6.08–6.55 Å [18f]. The sodium ions are bound both to oxalate groups of one sheet and to oxo groups from the neighbouring sheet along the *a*-axis, which results in the formation of a three-dimensional assemblage (Fig. 2c). The hydroxide and water moieties are involved in intra- or inter-sheets hydrogen bonds (Table 3). The three-dimensional organisation in **2**, as well as those previously described [18e,20], is at variance with the formation of a layered structure in the mixed uranyl/sodium complex of tricarballylic acid, in which the sodium ion has a higher hydration level, being bound to one oxo, one carboxylate and four water ligands and is thus less efficient an assembling unit than in **2** [2n].

4. Conclusion

The present work illustrates both the strengths and weaknesses of hydrothermal methods. On the first hand, crystallization under hydrothermal conditions permitted the first structural characterization of uranyl tartrate, in the form of a chiral two-dimensional assemblage in which the L(+)-tartrate ligand acts as a (μ_3-tartrato-1κ^2O,O':2$\kappa O''$:3$\kappa O'''$) assembler. On the other hand, oxidative cleavage of L(+)-tartaric acid on prolonged heating resulted in in situ formation of oxalic acid and crystallization of a mixed uranyl/sodium complex. A similar reaction was observed when replacing tartaric by citraconic (2-methyl-2-butenedioic) acid and heating at 180 °C in the presence of NaOH or KOH (1:1). In this case, the complex formed was $[(UO_2)_2(C_2O_4)(OH)_2(H_2O)_2]\cdot H_2O$, the synthesis (from oxalic acid) and crystal structure of which have recently been reported [18f]. Complex **2** is a rare example of a three-dimensional assemblage in the family of uranyl oxalates. The oxalate ligand is likely too small to give three-dimensional UOFs by itself. However, incorporation of oxo-bound sodium ions in the lattice increases the structure dimensionality. Both hydroxide complexation and sodium uptake are interesting features, considering the importance of uranyl oxalates in nuclear technology [17,18f].

Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 614325 and 614326. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk). Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.07.024.

Abstract

The solvothermal reactions of AgX (X = CN, SCN) with mbix [mbix = 1,3-bis(imidazole-l-yl-methyl)benzene] or bix [bix = 1,4-bis(imidazole-l-yl-methyl)benzene] afforded the polymers $[AgCN(mbix)]_n$ (**1**), $[(AgCN)_4(bix)_2]_n$ (**2**) and $[(AgSCN)_2(mbix)]_n$ (**3**). They were all characterized by infrared spectroscopy, elemental analysis and X-ray single-crystal analysis. The structure of **1** contains a 3-fold-interpenetrated 2D network, while that of **2** exhibits 2-fold parallel interpenetration. There is no interpenetration observed in **3**. Compounds **2** and **3** show 3D supramolecular structures built from 2D networks through weak $\pi \cdots \pi$ interactions. The photoluminescent properties of the present compounds were also investigated.

1. Introduction

The design and synthesis of inorganic–organic hybrid coordination polymers are currently receiving much attention due to their fascinating network topologies and their potential application as functional materials [1–14]. The hydro(solvo)thermal technique is a powerful method for the construction of supramolecular polymers through their self-assembly. Self-assembly is a complicated process, highly influenced by lots of factors, such as the coordination nature of metal ions, the structural characterization of organic ligands, solvent system, temperature, pH value of the solution, the ratio of metal to ligand, the templates and the counter ions. Besides these aspects, other forces such as hydrogen-bonding, π–π interactions, metal–metal interactions can also greatly influence the supramolecular topology and its dimensionality [15–17]. Therefore, much work should be done to extend the area of the relevant structural types and to strive to find out proper synthetic strategies leading to the anticipated compounds.

The CN^- and SCN^- anions, with their ambidexterous character, show considerable flexible coordination modes in the construction of supramolecular architectures. Silver (I) is a good candidate as a soft acid tending to coordinate to soft bases such as ligands containing sulfur and nitrogen atoms. On the other hand, Ag(I) ions are apt to form silver–silver interactions which are propitious to control supramolecular architectures and dimensionality. Although cyanate and thiocyanate are well-known bridging ligands, their silver (I) coordination polymers are rare. To our knowledge, most of the AgCN and AgSCN polymers are those involving pyridine derivatives, organic amines and chelating ligands [18–20]. There are only two examples of AgCN and AgSCN polymers constructed from bridging dipodal N-donor ligands [21,22].

The ligands mbix and bix, which have been considered to be highly flexible N-containing ligands, have been employed in recent years for the construction of numerous inorganic–organic hybrid supramolecular networks [23,24]. Enlightened from our previous work [25], we introduced mbix and bix into the silver cyanate or silver thiocyanate systems and isolated three polymeric compounds, namely, $[AgCN(mbix)]_n$ (**1**), $[(AgCN)_4(bix)_2]_n$ (**2**) and $[(AgSCN)_2(mbix)]_n$ (**3**).

2. Experimental

2.1. Materials

The ligands bix and mbix were synthesized according to the literature [24a]. Other chemicals were purchased from commercial sources and were used as received without further purification.

2.2. Physical measurements

The infrared spectra were recorded on a Perkin–Elmer FT-IR spectrophotometer in KBr matrices. Elemental analyses were carried out using a Perkin–Elmer 2400 II elemental analyser. Photoluminescence analyses were performed on an Edinburgh FLS920 fluorescence spectrometer.

2.3. Synthesis of the compounds

2.3.1. $[AgCN(mbix)]_n$ (1)

AgCN (33.47 mg, 0.25 mmol), mbix (30.00 mg, 0.13 mmol) and 2 mL of CH_3CN were placed in a 15 cm Pyrex tube. The tube was evacuated and sealed. The glass tube was heated at 120 °C for 24 h. After cooling to room temperature over 48 h, colorless crystals suitable for X-ray diffraction were formed, yielded: 13 mg, about 28% based on mbix. *Anal.* Calc. for $C_{15}H_{14}AgN_5$: C, 48.41; H, 3.79; N, 18.82. Found: C, 48.22; H, 3.98; N, 18.65%. FT-IR (cm^{-1}) (KBr disk): 3107m, 2102m, 2093m, 1611m, 1516vs, 1495s, 1450s, 1439s, 1392m, 1368m, 1274m, 1231m, 1242vs, 1112s, 1107vs, 1087m, 1076vs, 1030 m, 929m, 744s.

2.3.2. $[(AgCN)_4(bix)_2]_n$ (2)

Compound **2** was prepared in a similar manner as for **1** except that bix was used instead of mbix and the reaction was carried out at 160 °C. Yield: 21 mg, about 33% based on AgCN. *Anal.* Calc. for $C_{32}H_{28}Ag_4N_{12}$: C, 37.97; H, 2.79; N, 16.61. Found: C, 37.98; H, 3.09; N, 16.65%. FT-IR (cm^{-1}) (KBr disk): 3445m, 3134m, 3106m, 2928m, 2135s, 2113m, 2085m, 1512vs, 1437m, 1232vs, 1107vs, 1077vs, 757m, 720s, 656s, 618m.

2.3.3. $[(AgSCN)_2(mbix)]_n$ (3)

Pale yellow crystals of **3** were obtained in a similar way as for **1** except that AgSCN was employed instead of AgCN and the reaction temperature was 160 °C. Yield: 33 mg, about 46% based on AgSCN. *Anal.* Calc. for $C_{16}H_{14}Ag_2N_6S_2$: C, 33.70; H, 2.47; N, 14.74. Found: C, 34.03; H, 2.77; N, 14.73%. FT-IR (cm^{-1}) (KBr disk): 3435vs, 2104s, 2085s, 1631s, 1514s, 1441w, 1383w, 1368w, 1275w, 1236m 1103m, 1084m, 1078m, 830m, 770w, 743m, 657m.

2.4. X-ray crystallographic studies

Crystallographic data of **1**–**3** were collected on a Rigaku Mercury CCD diffractometer equipped with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Crystals of **1**–**3** suitable for X-ray crystallography were mounted on the top of a glass fiber with epoxy cement. The structure factors were obtained after Lorentz and polarization corrections. All the non-hydrogen atoms were located by the direct method and refined by full-matrix least-squares techniques. Crystallographic parameters, details of data collection and structure refinement for the crystals of **1**–**3** are summarized in Table 1.

3. Results and discussion

3.1. Syntheses and spectroscopic studies

The compounds $[AgCN(mbix)]_n$ (**1**), $[(AgCN)_4(bix)_2]_n$ (**2**) and $[(AgSCN)_2(mbix)]_n$ (**3**), were solvothermally prepared by mixing AgCN or AgSCN with corresponding ligands in vacuo. The reaction between AgSCN and bix failed to give any identified products. The IR spectra of **1**–**3** show characteristic CN groups around 2110 cm^{-1}. Other complicated peaks show the characteristic C–N and C–C vibrational frequencies for the bix and mbix ligands.

3.2. Structure of $[AgCN(mbix)]_n$ (1)

Fig. 1a shows the asymmetric unit of compound **1**, which consists of one Ag atom, one mbix ligand and one CN group. The Ag atom is in a deviated trigonal environment [the bond angles C1–Ag–N5A = 126.1(1)°, C1–Ag–N2 = 123.4(1)° and N5A–Ag–N2 = 103.46(9)°], coordinated by two different mbix ligands [Ag–N2 = 2.285(2), Ag–N5A = 2.284(2) Å], and one terminally bonded CN ligand [Ag–C1 = 2.113(3) Å, Ag–C1–N1 = 166.7(3)°] (Fig. 1b). The Ag ⋯ AgB distance is 2.888(1) Å, which is much shorter than twice the van der Waals radius of silver (3.4 Å), indicating significant silver–silver interactions [26–28]. The AgB–C1 distance is 2.87(3) Å, suggesting a non-negligible interaction compared to the Ag–C bond length [Ag2–C2B = 2.757(5) Å] found in $[Me_4N][Ag_2(CN)Cl]$ [26]. On the other hand, the direction of distortion from the terminal Ag–C1–N1 angle also indicates the existence of a weak interaction between AgB and C1. Thus, the cyanide group C1N1 can be described as having a semi-bridging coordination mode. Along the *a*-axis, the adjacent Ag

[b] $wR_2 = \left[\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2\right]^{0.5}$.

atoms are linked to each other through imidazole N atoms to form a zigzag chain with Ag ⋯ Ag separations along Ag ⋯ mbix ⋯ Ag being 14.93 Å (Fig. 1b). Two such zigzag chains are consolidated by silver–silver interactions to form a 2D layer structure with 50-membered rings, possessing an effective size of *ca.* 15 × 17 Å. It is worth mentioning that each layer network with (4, 4) topology is interlocked by two adjacent identical networks (above and below) as illustrated in Fig. 3c, forming a 3-fold-interpenetrated 2D framework. The nearest Ag ⋯ Ag separation between the 2D layers is 4.777 Å. There is no significant π ⋯ π stacking among these 3-fold-interpenetrated 2D networks (the centroid-centroid distance between benzene and imidazole rings being 4.802 Å).

3.3. Structure of $[(AgCN)_4(bix)_2]_n$ (**2**)

The asymmetric unit of compound **2** contains four crystallographically independent Ag atoms, four CN groups and two bix ligands. All the Ag atoms are in an approximately trigonal environment. The Ag1 atom is coordinated to N3 from the bix ligand [Ag1–N3 = 2.343(3) Å], C2 from the bridging cyanide [Ag1–C2 = 2.112(3) Å] and C1 from the μ-*C*,*C*-cyanide ligand [Ag1–C1 = 2.177(3) Å]. The Ag2 atom is surrounded by N5 from the other bix ligand [Ag2–N5 = 2.371(3) Å], N2 from the bridging cyanide [Ag2–N2 = 2.218(3) Å] and C1 from the μ-*C*,*C*-cyanide ligand [Ag2–C1 = 2.319(3) Å]. The distance of Ag1 ⋯ Ag2 [2.8462(4) Å] is a little shorter than that in **1**, but a little longer than that in the structure of $[Me_4N][Ag_2(CN)Cl]$ [26] and the compounds reported by Mak [29]. As shown in Fig. 2a, the bridging cyanide ligands and two pairs of Ag1 ⋯ Ag2 bonds form a 10-membered ring with the bond angles Ag2–C1–Ag1 78.5(1)° and Ag1–C2–N2A 171.1(3)°. The Ag3 atom is coordinated to C20 and N9 from the bridging cyanides [Ag3–C20 = 2.091(3), Ag3–N9 = 2.341(3) Å; Ag3–C20–N10D = 176.5(3), Ag3–N9–C21 = 176.8(3)°] and N8 from the bix ligand [Ag3–N8 = 2.215(3) Å]. The coordination environment of Ag4 is similar to that of Ag3. It is coordinated to C21 and N10 from the bridging cyanides [Ag4–C21 = 2.067(3), Ag4–N10 = 2.424(3) Å; Ag4–C21–N9 = 175.3(3), Ag4–N10–C20C = 175.1(3)°] and N11 from the bix ligand [Ag4–N11 = 2.195(2) Å]. As illustrated in Fig. 2b, the Ag3 atom set and Ag4 atom sets are bridged alternately by C20N10 and C21N9 group sets to make up an $[AgCN]_n$ infinite zigzag chain with the bond angles N10–Ag4–C21 116.41(1)° and N9–Ag3–C20 123.57(1)°. These zigzag chains connect the 10-membered rings through two bix

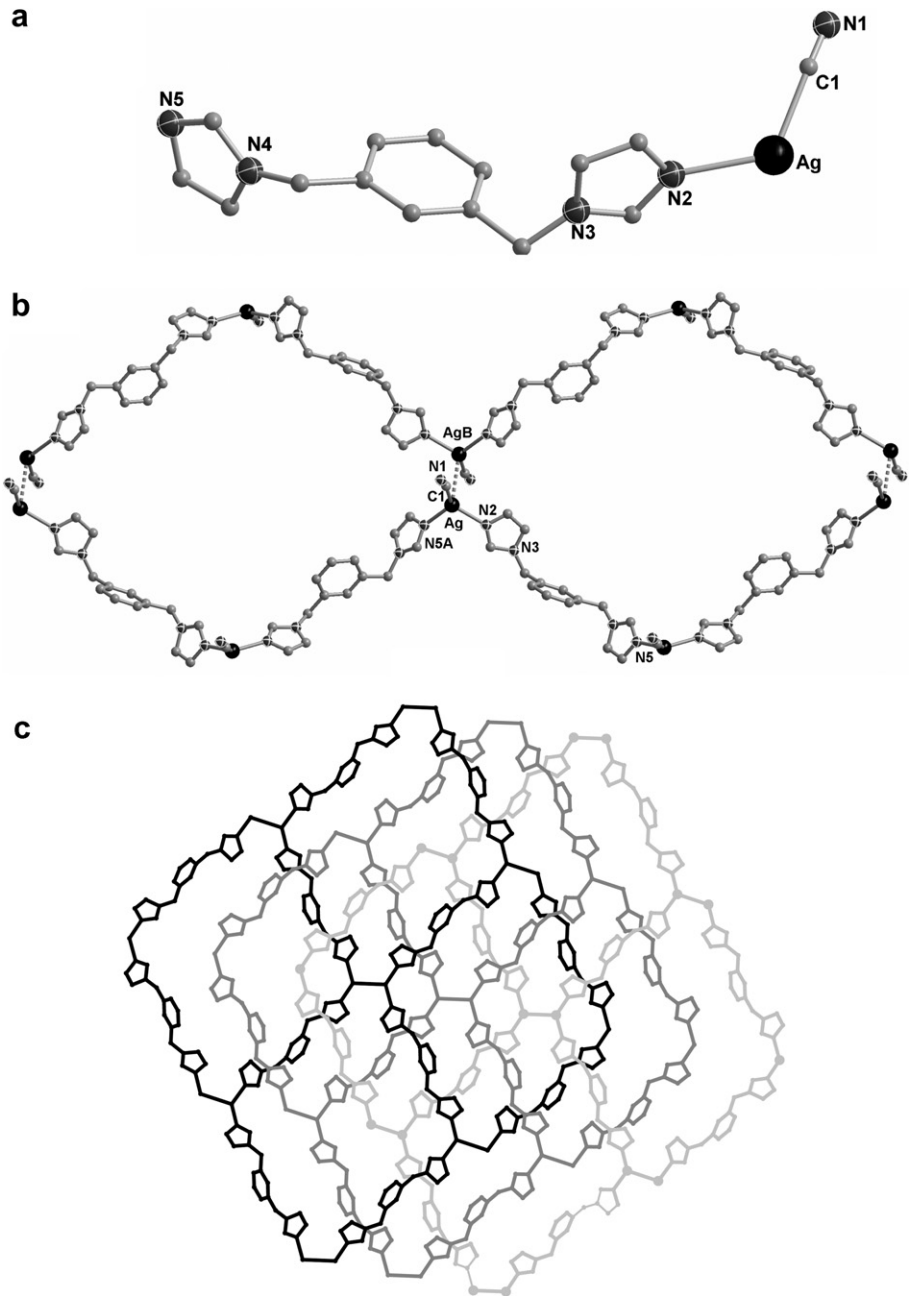

Fig. 1. (a) Representation of the asymmetric unit of **1**. (b) Representation of 50-membered rings in **1**. (c) View of the 3-fold interpenetrating 2D network, the CN groups are omitted for clarity. Hydrogen atoms are omitted for clarity. ligands to generate a 2D framework with cavities (*ca.* 16×13 Å) along the *a*-axis.

It is interesting and worth mentioning that the structure contains two independent layers that interpenetrate in a parallel manner. As shown in Fig. 2c, the two undulating layers pass through each other to generate an interpenetrating double-layer structure. The corrugations in the layers, which make the interpenetration possible, arise from the flexible bix ligands that adopt a*syn*-conformation coordination mode. Upon interpenetration, the total effective pore sizes have been drastically decreased for those 10-membered rings that are located in the cavities along the *a*-axis. These 2-fold interpenetrating 2D networks are stacked into a 3D supramolecular structure through two types of weak $\pi \cdots \pi$ interactions (the centroid–centroid distance of imidazole rings between the adjacent layers being 4.1 and 3.992 Å, respectively) [30–32].

3.4. Structure of $[(AgSCN)_2(mbix)]_n$ (3)

The structure of **3** crystallizes in the triclinic space group $P\bar{1}$. Each asymmetric unit of **3** includes two Ag atoms, two

(c) View of the 2-fold interpenetrating 2D network, the spacer stands for the bix ligand. Hydrogen atoms are omitted for clarity. Symmetry codes: (A) $-x+1, -y, -z-1$; (B) $-x+1, -y, -z+1$; (C) $x+1, y, z$; (D) $x-1, y, z$.

SCN groups and one mbix ligand. The Ag1 atom is coordinated to N3 from the mbix ligand [Ag1–N3 = 2.301 (2) Å], three different thiocyanate sulfur atoms [Ag1–S1 = 2.6133(8), Ag1–S2 = 2.6457(9) and Ag1–S2A = 2.6338(8) Å], resulting in a highly distorted tetrahedral coordination geometry for Ag1, with bond angles ranging from 92.09(3)° to 134.18(3)°. The environment of the Ag2 atom is also badly deviated from a tetrahedral coordination geometry, surrounded by two N and one S atoms from SCN groups [Ag2–N1C = 2.440(3), Ag2–N2B = 2.358(3) and Ag2–S1 = 2.5469(9) Å] and one N atom from the mbix ligand [Ag2–N5 = 2.211(2) Å], with bond angles in the range 87.38(1)–125.40(7)°.

The SCN groups act as triply-bridged ligands in the architecture of **3**. The Ag–S bond lengths varying from 2.5469(9)–2.6547(9) Å are in the normal range [18,33–35]. The Ag1 ⋯ Ag2 distance is 3.1882(4) Å, which is shorter than twice the van der Waals radius of silver (3.4 Å), suggesting the existence of an argentophilic interaction in **3** [18,26–28]. As shown in Fig. 3a, a pair of thiocyanate groups bridge a pair of Ag(I) atoms to form an eight-membered $Ag_2(SCN)_2$ macrocycle similar to the chair conformation of cyclohexane [Ag2–S1–C1 = 99.2(1), N1C–Ag2–S1 = 102.03(8) and S1–C1–N1 = 177.4(3)°]. Since the sulfur atoms of the SCN groups act in a bridging fashion, four Ag–S bonds make up a four-membered centrosymmetric Ag_2S_2 ring [Ag1–S2–Ag1A = 87.91(3), S2–Ag1–S2A = 92.086(3)°, Ag1 ⋯ Ag1A = 3.6708(5) Å]. The eight-membered macrocycle is connected to the four-membered ring through Ag1–S1 bonds and Ag2C–N2A–C2A–S2A edges to form a one-dimensional $[Ag_2(SCN)_2]_n$ chain, which is unprecedented in the literature. The chains are further interlinked by mbix ligands that bridge the Ag atoms to produce a two-dimensional $[(AgSCN)_2(mbix)]_n$ layer (Fig. 3c). Weak π ⋯ π interactions occur between adjacent layers to produce a 3D supramolecular structure (the centroid–centroid distance of the imidazole rings is *ca.* 4.048 Å, Fig. 3d) [30–32].

3.5. Luminescent properties

As illustrated in Fig. 4, **1** displays a sharp purple emission band in the solid state at 424 nm (λ_{ex} = 350 nm), while **2** exhibits a strong and broad emission band in the solid state at 440 nm (λ_{ex} = 376 nm). Compound **3** emits a very sharp and intense emission band in the solid state at 461 nm upon excitation at 380 nm. The origin of the emission bands of **1** and **2** is neither metal-to-ligand charge

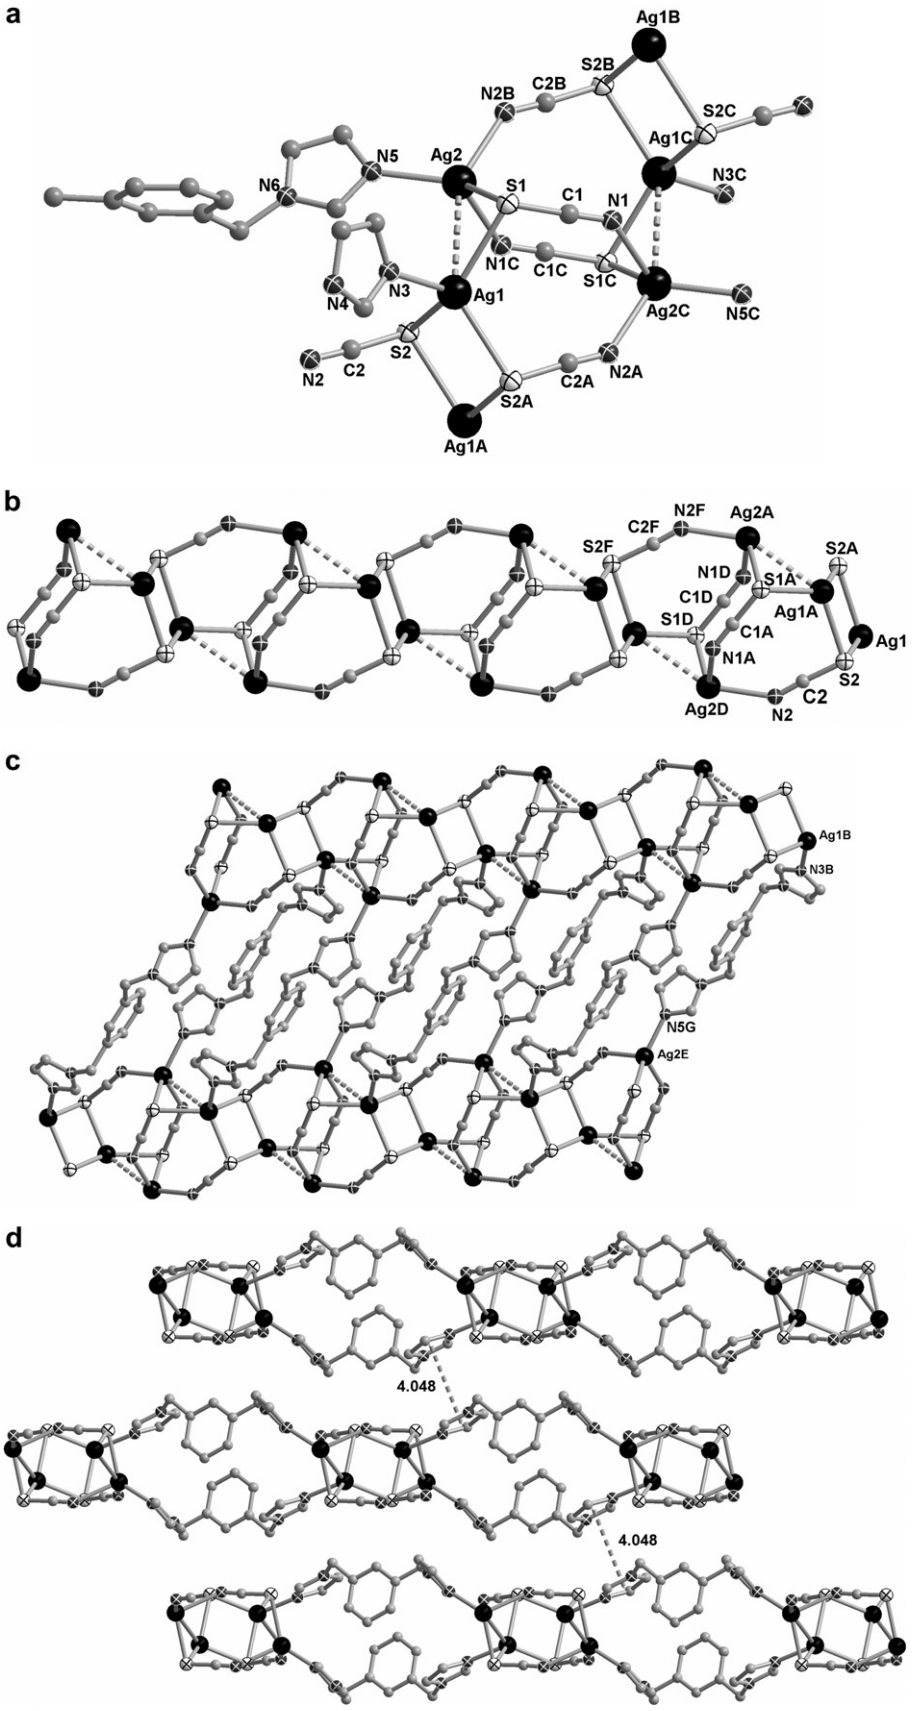

Fig. 3. (a) A portion of the structure of **3**. (b) Representation of a $[AgSCN]_n$ chain in **3**. (c) Representation of the 2D network of **3**. (d) Representation of the $\pi \cdots \pi$ interactions between adjacent layers. Hydrogen atoms are omitted for clarity. Symmetry codes: (A) $-x+1, -y+2, -z+1$; (B) $x+1, y, z$; (C) $-x+2, -y+2, -z+1$; (D) $x-1, y, z$; (E) $-x, -y+1, -z+2$; (F) $-x, 2-y, 1-z$; (G) $1-x, 1-y, 2-z$.

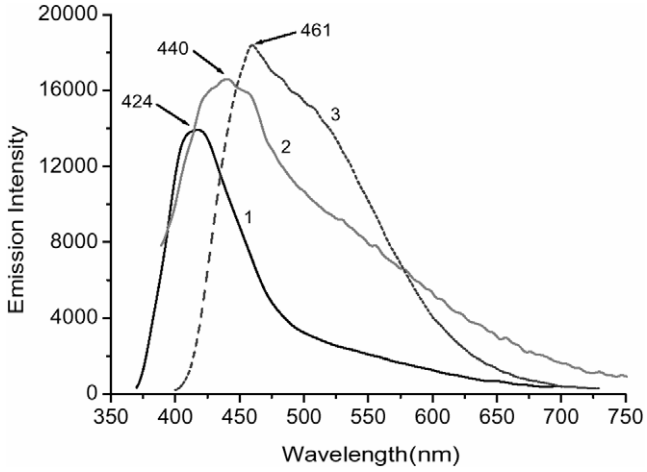

Fig. 4. Solid-state emission spectra of **1** ($\lambda_{ex} = 350$ nm), **2** ($\lambda_{ex} = 376$ nm) and **3** ($\lambda_{ex} = 380$ nm) at room temperature.

transfer (MLCT) nor ligand-to-metal charge transfer (LMCT) in nature and can be tentatively attributed to an intraligand emission because similar emissions are observed at 395 nm ($\lambda_{ex} = 334$ nm) for free mbix and 392 nm ($\lambda_{ex} = 340$ nm) for free bix ligands [24i]. The origin of the emission band of **3** may be attributed to the intraligand fluorescent emission where the electron is transferred from the π orbital of the thiocyanate groups to an unoccupied π^* orbital of the mbix ligands [36]. The clear red shift of the emission bands may be associated with aromatic $\pi \cdots \pi$ stacking interactions in the solid state.

4. Conclusion

The synthesis and crystal structures of **1**–**3** have been successfully synthesized via the solvothermal technique. In **1**, the 3-fold interpenetration of adjacent (4, 4) layers produces a 2D network structure in which the CN groups act as terminal ligands. In **2**, two undulating sheets interpenetrate each other to form a 2D network with the coexistence of linear-bridged CN groups and μ-*C*,*C*-cyanide bridging groups. In the structure of **3**, the SCN groups function as triply-bridging ligands and the structure of the $[AgSCN]_n$ subunit has not been previously observed for the silver thiocyanate system. The $\pi \cdots \pi$ interactions and silver–silver interactions play a significant role in the formation of the three polymers. Compounds **1**–**3** all exhibit strong photoluminescence at room temperature. The structures presented here show that the flexibility of the N-donor ligands can have dramatic effects on the structures of the silver–cyanide subunits. Further studies on the synthesis of related metal–cyanide polymers and their physical properties by using other imidazole ligands are already in progress.

Abstract

The synthesis and molecular structures of three new copper (II) complexes with the ligand 2,6-bis-[*N*-(2-pyridylethyl)-formidoyl]-4-methyl phenol (L–OH) are reported. The complexes were prepared by reaction of L–OH with $CuX_2 \cdot nH_2O$, affording $[Cu_2(L–O)(\mu\text{-}OH)(\mu\text{-}ClO_4)](ClO_4)$ (**I**); $X = CLO_4^-$, with KOH in the reaction media; or $[Cu_2(L–O)(\mu\text{-}Cl)_2][Cu_2Cl_6]_{0.5}$ (**II**); X = Cl, in neutral conditions. The presence of methyl 3,4-dihydroxy-benzoate (CAT-$(OH)_2$) during the synthesis of **I** leads to the complex $[Cu_2(L–O)(\mu\text{-}OH)(CH_3OH)][Cu(CAT\text{-}O_2)_2]_{0.5}(ClO_4)$ (**III**). This compound exhibits an uncommon anion consisting of a bis-(catecholate) cuprate (II) moiety. The complete series of complexes show bridging phenoxo groups between the copper centers, together with hydroxo and perchlorate bridges found in **I** or two chlorides found in **II**. Compound **I** exhibit a rather low catalytic activity for the oxidation of 3,5-ditertbutyl catechol under aerobic conditions (12% quinone formation after 48 h at room temperature, in methanol solution 1×10^{-3} M in catalyst and 1×10^{-2} M in catechol), which could be ascribed to steric limitations of the catechol to coordinate the central Cu_2O_2 core.

Keywords: Copper complexes; Molecular structure; Catecholase activity; Pyridyl Schiff-base ligand

1. Introduction

During the last years our group have been involved in the study of the oxidative catalytic properties of mono and binuclear copper complexes in the presence of molecular oxygen, with the final goal of designing new catalysts for the oxygenation of organic substrates with molecular oxygen, mimicking the activity of the metalloenzyme tyrosinase, Tyr [1]. This copper enzyme catalyses the *ortho*-hydroxylation of phenols (phenolase activity) and the further oxidation of the resulting catechols to quinones (catecholase activity) (Chart 1). It is responsible for the formation of melanin pigments and others polyphenolic natural products [2]. Catechol oxidase, CO [3] catalyses the oxidation of catechols to the corresponding quinones without acting on tyrosine. It has been proposed that the difference between both enzymes can be rationalized in terms of the more opened structure of the active site in tyrosinase compared with catechol oxidase.

It has been shown [4], using model systems, that the electron transfer from catechol to copper (II) can begin only after the catechol and the copper (II) species form a catecholate intermediate. The rate of the reaction is related to the redox potential and the steric match between the substrate and the complex. Substantial retardation of reactivity is evident if either steric or electronic factors do not match.

Numerous studies [5] have been reported on copper (II) complexes with different type of ligands, which mimic the catecholase activity of these two metalloproteins. Schiff-base ligands have also been used to study the activity of the resulting copper complexes in oxygenation and oxidation reactions [6]. 1,3-Benzene dicarboxaldehyde and 2,6-diformyl-4-methyl phenol have been used as building blocks

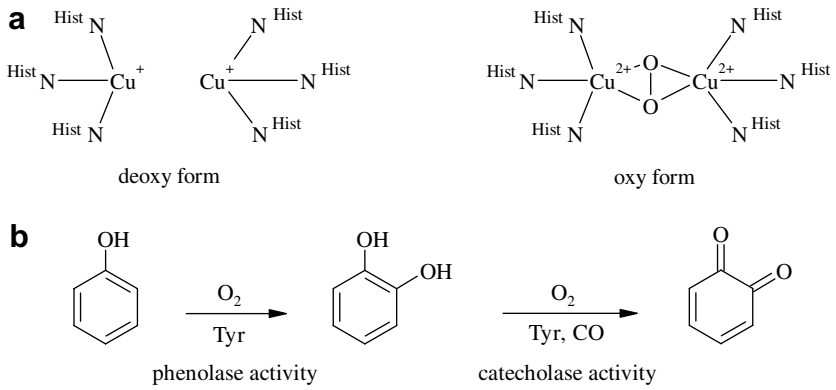

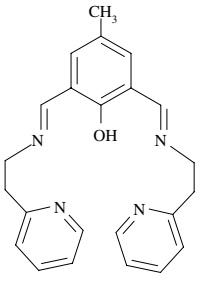

Chart 1. (a) Schematic diagram of the Cu coordination in the deoxy and oxy forms of tyrosinase and catechol oxidase and (b) pathway of the *o*-quinone formation from phenol precursors.

for the synthesis of macrocyclic and non-macrocyclic binucleating ligands. The copper complexes derived from these ligands have been the subject of numerous studies. We have reported the oxidation reaction of the copper (I) complexes with the binucleating Schiff-base ligand obtained from condensation of benzene-1,3-dicarboxaldehyde and di-(2-pyridyl)methyl amine [6a] and its methylated analogue [7].

Preliminary studies on the oxidation of 3,5-diterbutylcatechol using the copper (II) complexes obtained with the Schiff-base ligand derived from condensation of 2,6-diformyl-4-methyl phenol with (2-pyridyl)ethyl amine (L–OH) evidence a rather low catalytic activity. Since a catecholate intermediate is expected to be formed as a requirement for efficient catalytic activity, we tried to prepare and isolate such species in order to verify if the steric effect imposed by the ligand is responsible for the low activity. We used methyl 3,4-dihydroxybenzoate as the 'catechol' substrate, since the effect of the electron withdrawing ester group is known to prevent the oxidation to the quinone, making easier to isolate the proposed intermediate. Instead of the expected complex, we obtained a copper (II) species with an unusual anion consisting of a bis-(catecholate) cuprate (II) moiety. In this work, we wish to report the synthesis and molecular structure of this new copper (II) complex together with that obtained with copper (II) perchlorate and copper (II) chloride in the absence of the 'catechol'. In the last case we obtained a complex with a hexachloro dicuprate (II) anion, while the cation consist of a binuclear copper center bridged by the deprotonated phenol group of the ligand and two chloride atoms.

L-OH

2. Experimental

2.1. Materials and methods

All reagents were of reagent grade and were used without further purification unless stated otherwise. Solvents were of HPLC quality and were freshly distilled under nitrogen before use. Acetonitrile (CH_3CN) was distilled from calcium hydride. 3,4-Dihydroxy-benzoate (CAT-$(OH)_2$) was prepared by esterification of the acid in dry methanol in the presence of concentrated sulfuric acid as reported [8]. Elemental analysis for C, H, and N were performed at CEPEDEQ (University of Chile) on a Fison-Carlo Erba EA 1108 model analyzer. Copper was determined by Atomic Absorption Spectroscopy. IR spectra were obtained on a Bruker Vector 22 instrument. UV–Visible spectra were recorded in a Perkin–Elmer Lambda 11 equipment. ^1H NMR spectra were recorded in $CDCl_3$ on a Bruker AMX-300 NMR spectrometer. Chemical shifts are reported as δ values downfield an internal Me_4Si reference.

2.2. Synthesis of the ligand

The Schiff-base ligand 2,6-bis-[*N*-(2-pyridylethyl)-formidoyl]-4-methyl phenol (L–OH) was obtained as reported in reference [9] by reaction of 2,6-diformyl-4-methyl phenol with two equivalents of 2-aminoethyl pyridine in refluxing methanol. Evaporation of the solvent gives a yellowish oil that was characterized by IR and ^1H NMR spectroscopy.

IR (neat): 3386 (broad, ν OH) 1638 (ν C=N); 1591, 1569, 1474, 1460, 1436 (aromatic nuclei); 1255 (ν Ph–O), 760 (δ C–H).

^1H NMR ($CDCl_3$, 298 K): δ: 8.57 (2H, dd, pyridine alpha protons); 7.59 (2H, dt), 7.2 (2H, d), and 7.13 (2H, dd) (pyridine protons 3.96); (4H, t) and 3.12 (4H, t) (ethylene, $-CH_2-CH_2-$, protons); 2.2 (3H, s, methyl protons). 8.52 (~2H, s, broad, CH=N proton); 7.42 (~2H, s, broad, phenyl protons).

2.3. Syntheses of the complexes

2.3.1. $[Cu_2(L–O)(\mu\text{-}OH)(\mu\text{-}ClO_4)](ClO_4)$ (**I**)

1.48 g (4 mmol) of $Cu(ClO_4)_2(H_2O)_6$ were added to a solution of 2 mmol of the deprotonated (KOH) ligand in methanol (15 mL) and the mixture was refluxed for 30 min. Standing at room temperature affords a brown solid, yield 90%. Good quality crystals for X-ray diffraction studies were obtained by recrystallization from boiling methanol. *Anal.* Calc. for $C_{23}H_{24}N_4Cl_2O_{10}Cu_2$: C, 38.65; H, 3.39; N, 7.84; Cu, 17.78. Found: C, 38.12; H, 3.21; N, 7.64; Cu, 17.85%.

IR (KBr pellet): 1640, 1608, 1562, 1488, 1447, 1238, 1100, 770.

2.3.2. $[Cu_2(L–O)(\mu\text{-}Cl)_2][Cu_2Cl_6]_{0.5}$ (**II**)

To a solution of the ligand (2 mmol) in methanol (10 mL) were added $CuCl_2$ (0.54 g, 4 mmol) and the mixture was refluxed for 30 min. Standing at room temperature affords a brown solid, yield 70%. Recrystallization from hot acetonitrile gives crystals suitable for X-ray diffraction studies. *Anal.* Calc. for $C_{23}H_{23}N_4Cl_5OCu_3$: C, 37.34; H, 3.14; N, 7.58; Cu, 25.77. Found: C, 37.07; H, 3.10; N, 7.47; Cu, 25.58%.

IR (KBr pellet): 1638, 1607, 1564, 1485, 1445, 1237, 768.

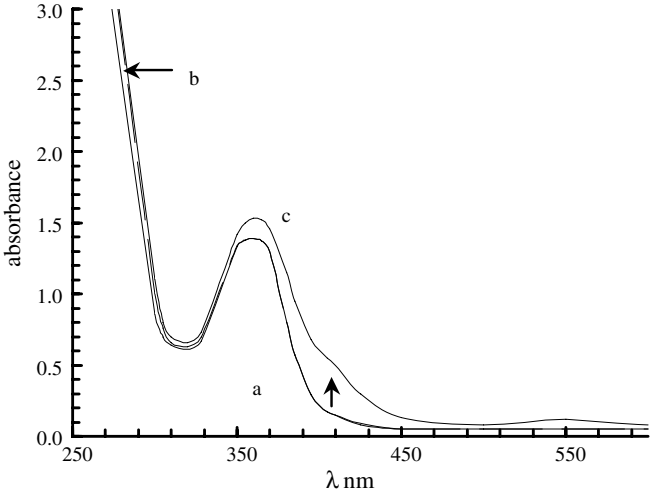

Fig. 1. (a) UV–Vis spectra of a 1.5×10^{-4} M solution of I in methanol and (b) in the presence of $DTBCH_2$ 2×10^{-3} M under nitrogen for 24 h (dotted line); (c) oxygen bubbled through the reaction mixture for 48 h.

2.3.3. $[Cu_2(L–O)(\mu\text{-}OH)(CH_3OH)][Cu(CAT\text{-}O_2)_2]_{0.5}(ClO_4)$ (**III**)

To a solution of the ligand (2 mmol) in methanol (10 mL) were added $Cu(ClO_4)_2(H_2O)_6$ (1.48 g, 4 mmol), 0.34 g of CAT-$(OH)_2$ (2 mmol) and 6 mL of a solution of KOH 1 M (6 mmol) in methanol and the reaction mixture was refluxed for 30 min. Standing overnight precipitate a crystalline green

Caution! Perchlorate salts are potentially explosive and should be handled with care.

2.4. Preliminary oxidation studies

The capacity of complex **I** to achieve the stoichiometric or catalytic oxidation of 3,5-ditertbutylcatechol (DTBC) was studied using UV–Vis spectroscopy following the characteristic band of the expected product, 3,5-ditertbutylquinone, at 400 nm. Compound **I** (1.5×10^{-4} M) was added to a 2×10^{-3} M solution of DTBC in methanol under nitrogen, and the spectrum of the mixture was recorded. No changes were observed after 24 h under nitrogen. Oxygen gas was bubbled through the solution and the increase in the absorbance at 400 nm was monitored for a 48-hour period. Fig. 1 shows the observed changes.

In a separated experiment 10 mL of the reaction mixture (1×10^{-3} M in catalyst and 1×10^{-2} M in catechol) was bubbled with oxygen and quenched with HCl after 48 h The solvent was evaporated and the residue was extracted with hexane, the extracts were diluted to 25 mL and the spectrum was recorded. The absorbance at 400 nm was assumed to depend only on the concentration of the formed quinone. A control experiment shows no significant absorbance at 400 nm.

2.5. X-ray crystallographic data collection and refinement details

For each compound a single crystal was mounted on the tip of a glass fiber. Diffracted intensities were collected on a

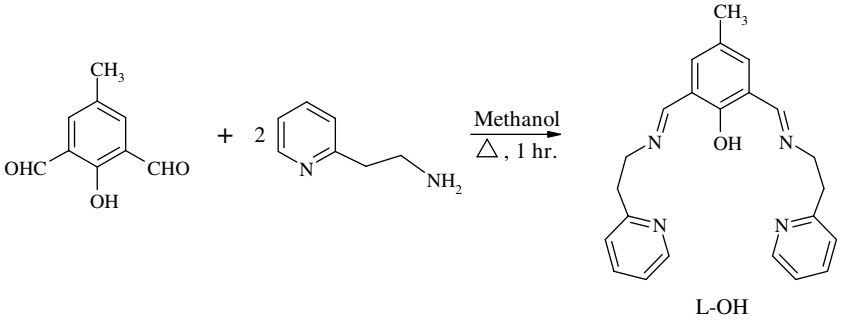
Bruker Smart Apex diffractometer, using separations of 0.3° between frames and 10 s by frame. Data integration and absorption corrections were made using SAINT [10a]. The structures were solved using XS in SHELXTL [10a] by means of direct methods and completed (non-H atoms) by Fourier difference synthesis. The hydroxo hydrogen atom was located in the Fourier map and then fully refined for **I**, while could not be confidently located for **III**. During the last stages of refinement some disorder on the perchlorate oxygen atoms of **I** and **III** was evident. In the case of **I** it was modeled using two positions (A and B) for three of the oxygen atoms of the perchlorate counter anion, with partial occupancies of 0.55 and 0.45, respectively. For compound **III**, two equally occupied positions (A and B) were considered for all the oxygen atoms. Refinement until convergence was obtained using XL SHELXTL and SHELXL97 [10b]. Additional crystallographic and refinement details are given in Table 1 and selected bond lengths and angles are given in Table 2.

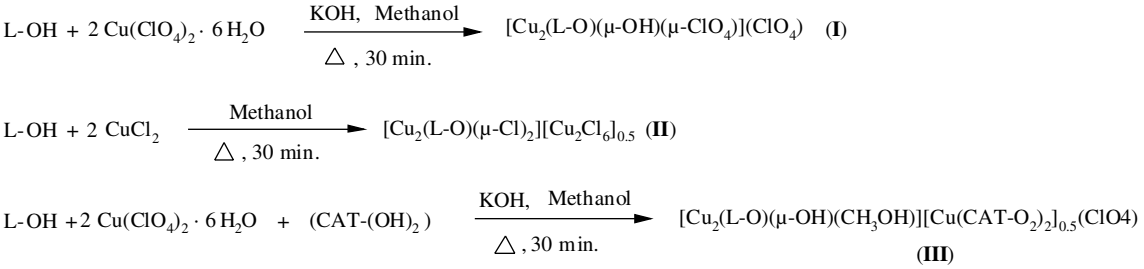
3. Results and discussion

3.1. Synthesis



The synthesis of the ligand L–OH was described previously (Scheme 1) [9], but the free base was not characterized. In this work, after the reaction was completed, the solvent was evaporated giving an oil that was characterized by IR and ^{1}H NMR spectroscopy. The IR spectrum shows the absence of the band due to the aldehyde carbonyl stretching frequency (*ca.* 1690 cm^{-1}) indicating complete formation of the azomethine C=N bond, whose stretching band is observed at 1638 cm^{-1}. The ^{1}H NMR spectrum of the base, at 298 K, shows the signals due to the protons of the pyridylethyl and the methyl groups. Besides, two broad bands are observed at 8.52 and 7.42 δ that were assigned to the CH=N and the phenyl protons, respectively. These signals become best resolved at higher temperature (318 K) (see supplementary material, Figure S1). The exact reason for the broadening of these signals at low temperature remains unclear.

The copper complexes were obtained straightforward by reaction of a solution of the ligand, prepared *in situ*, with the proper copper salt in methanol (Scheme 2, see Section 2).



The elemental analysis support the given stoichiometries, and the IR spectra show the expected bands for the coordinated ligand. All three complexes show the azomethine stretching frequency in the range 1630–1640 cm^{-1}, as expected for this type of complexes [11], and the typical bands owing to the pyridine and phenyl nuclei at 1600–1400 cm^{-1}. Besides, complex **I** and **III** show the bands due to the perchlorate anion at 1100 and 1085 cm^{-1}, respectively. Complex **III** also shows a band at 1685 cm^{-1} that is assigned to the carbonyl ester group.

3.2. Structural description

The structure determined for every one of the complexes show a deprotonated molecule of the 2,6-bis-[*N*-(2-pyridylethyl)-formidoyl]-4-methyl phenol (L–OH) ligand coordinating two cupric centers, which results in a close vicinity, 2.9929(8), 2.970(1), and 3.011(1) Å for **I**, **II**, and **III**, respectively. The molecular structures present then a central bi cupric core bridged by the phenolic oxygen atom of L–O in all cases and additional bridge(s), a hydroxo

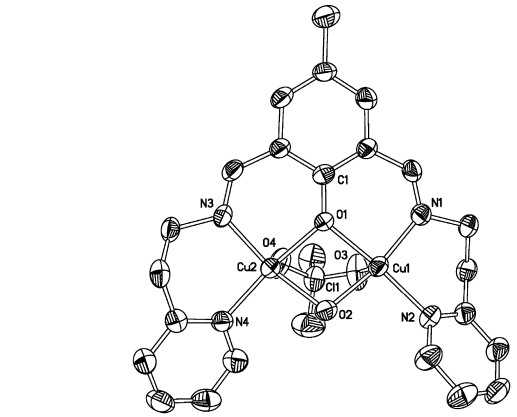
Scheme 1.

Scheme 2.

anion for **I** and **III**, two chloride anion for **II** and a O,O′ perchlorate for **I**, are observed. The coordination of each copper center is completed by two nitrogen atoms of each arm of L–O. The hydroxo-bridged compounds **I** and **III** show a planar Cu_2O_2 central core, while in **II** the chloride bridges lie out (and at opposite sides) of the Cu_2O plane.

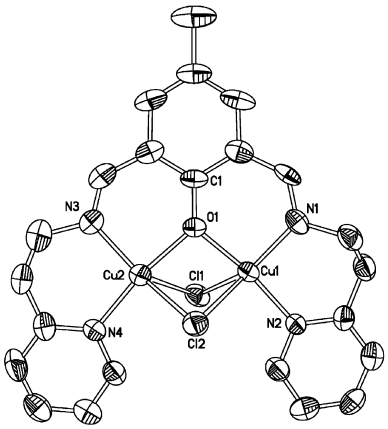
For compound **III**, an oxygen atom from a methanol molecule and a catecholate oxygen atom additionally coordinate the vicinal cupric centers, as shown in Fig. 2. In this way, complexes **I** and **III** exhibits two cupric centers with square based pyramid as coordination geometry, while the copper centers in complex **II** are intermediate between pyramidal and trigonal bipyramidal geometry, been Cu1 the more distorted from an ideal square-based pyramid (τ [12] = 0.42 and 0.27 for Cu1 and Cu2, respectively).

The Cu–O(phenolic)–Cu angles are similar for all the compounds, being 99.6(1), 99.6(2), and 99.7(2)° for **I**, **II**, and **III**, respectively, which is the same value compared to the 99.2(3)° described for $[Cu_2(L'–O)(\mu\text{-}ClO_4)](ClO_4)$ (L′–OH = 2,6-bis-[*N*-(2-(2′-pyridyl)ethyl) formidoyl]-4-hydroxy-phenol) [13].



The chloride bridges in **II** are quite asymmetric. Two of the measured copper – chloride distances, (Cu1–Cl1, 2.324(2) and Cu2–Cl2, 2.335(2) Å), compare well with the ones observed for [2,6-bis-((2-pyridyl)-methyliminomethyl)-*p*-cresolato-(μ-chloro)-di-copper (II)] dichloride (2.297 and 2.310 Å) [14], while the another two are significantly longer, (Cu1–Cl2, 2.689(2) and Cu2–Cl1, 2.802(2) Å), suggesting that each chloride ligand is mainly coordinated to one cupric center of the binuclear unit.

The $Cu_2Cl_6^{2-}$ moiety has been previously described to be present as uncoordinated counter anion of cationic copper (II) complexes [15,16]. In the same way the complex anionic $[Cu(CAT\text{-}O_2)_2]^{2-}$ moiety has been described to bridge between cupric [17] or cuprous centers [18]. The shortest Cu ··· Cu(counter anion) distance measured in this work is 5.921 Å for **II** and 3.817 Å for **III**.



3.3. Catalytic activity

A large number of copper (II) complexes react with 3,5-ditertbutylcatechol to give the corresponding quinone and the reduced copper (I) complexes in a two-electron transfer reaction. Subsequent reaction with oxygen re-oxidizes the cooper (I) to copper (II) leading to the catalytic oxidation of the catechol mediated by the copper complexes. The need for two copper centers in a binuclear complex for the oxidation of catechol substrates in terms of the complementarity in the number of electrons transferred and the steric fit advantages have been discussed by several authors [19].

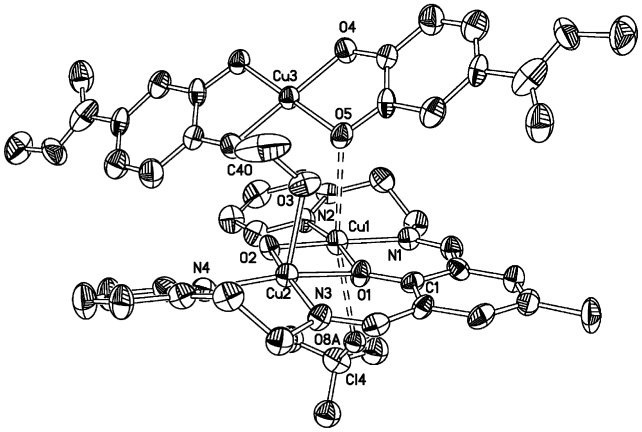


Fig. 1 shows the spectral changes observed when DTBC (2×10^{-3} M) was added to a 1.5×10^{-4} M solution of **I** in methanol, under anaerobic conditions. It can be seen that there is no major changes in the spectra even after reacting for 24 h, showing that the oxidation of the DTBC does not take place, in any significant extent. Bubbling the reaction mixture with oxygen produces the slow development of a band at 400 nm, indicative of the formation of the quinone. In a separated experiment (see Section 2) the amount of quinone formed, after reacting for a 48-hour period, was found to be roughly 12% of the theoretical value; a rather poor yield compared to other reported systems [5b,5c,19].

I

II

III

Fig. 2. Molecular structure diagram for **I**, **II**, and **III** with partial numbering scheme. Hydrogen atoms, perchlorate and hexachloro dicuprate (II) counter anions omitted for clarity. Displacement ellipsoids drawn at the 50% probability level.

A complex formulated as $Cu_2(L–O)(OH)(ClO_4)_2$, like complex **I**, was reported previously and the magnetic, electronic spectrum and conductance measurements were described. Reaction of this complex with sodium ascorbate in dearated aqueous solution gives an intense purple color that the authors attributed to the formation of a weak adduct $[(Cu_2L)OH]^{2+} \cdot (ascorbate)^-$. Qualitative O_2 uptake studies show that the complex catalyses the ascorbate oxidation, in air-saturated solution, but not as effectively as Cu^{2+} ions [9]. The oxidation of DTBC catalyzed by complex **I**, described in this work, is also a non-efficient process.

These results prompt us to study the reaction of the complex with methyl 3,4-dihydroxy benzoate, a 'catechol' that is not oxidized to the quinone due to the electron withdrawing effect of the ester group. Since many authors, on the base of mechanistic studies, have proposed a catecholate moiety as a key intermediate for an efficient catalytic activity, we tried to prepare such species to verify if the steric effect imposed by the ligand is responsible for the measured low catalytic activity of **I**. Efforts to isolate the proposed catecholate were unsuccessful. Instead, we isolate the binuclear copper (II) compound **III**, suggesting that the low catalytic activity may be due to the sterical limitation of the catechol to reach the first coordination sphere of **I**.

4. Conclusions

In conclusion, we have synthesized and structurally characterized three new copper (II) complexes with the Schiff-base binucleating ligand 2,6-bis-[*N*-(2-pyridylethyl)-formidoyl]-4-methyl phenol. The reported complexes show bridging phenoxo groups between the copper centers, and hydroxo and perchlorate bridges in **I** or two chlorides in **II**. The third complex **III** contains an uncommon bis-(catecholate) cuprate (II) complex species as the counter anion. Compound **I** exhibits a rather low catalytic activity for the oxidation of 3,5-ditertbutyl catechol under aerobic conditions, which could be ascribed to steric limitations of the catechol to coordinate the central Cu_2O_2 core.

Abstract

Five new compounds formulated as $[Ni^{II}(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (**1**), $[Cu^{II}(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (**2**), $[Cu^{II}(dca)_2(para\text{-}ABN)_2]_n$, (**3**), $[Cu^{II}(dca)_2(ortho\text{-}ABN)_2]_n$, (**4**) and $[Cd^{II}(dca)_2(meta\text{-}ABN)_2]_n$ (**5**), where dca = dicyanamide and ABN = aminobenzonitrile, have been synthesized and characterized by single crystal X-ray diffraction studies and low temperature (300–2 K) magnetic measurements. The structural analyses revealed that **1** and **2** are isomorphous where dca and *para*-ABN both act as monodentate ligands. **3** consists of infinite double stranded chains of Cu(II) ions connected through the *para*-ABN bridges whereas **4** and **5** consist of infinite double stranded chains of Cu(II) and Cd(II) respectively, connected through $\mu_{1,5}$-dca bridges. The compounds extend their geometries to three-dimensional for **1**–**3** and **5** and two-dimensional for **4** through hydrogen bonding interactions. All the metal ions Ni^{2+}, Cu^{2+} and Cd^{2+} are located on inversion centres and have distorted octahedral coordination geometries. The variable temperature magnetic susceptibility measurements show that the global feature of the $\chi_M T$ versus T curves for **3** and **4** is characteristic of very weak antiferromagnetic interactions and between 300 and 2 K the best fit parameters were determined as $J = -2.35$ and $-5.1\ cm^{-1}$, respectively.

1. Introduction

The bulk properties of a molecular material depend critically on its crystal structure and intermolecular interactions. Recently, enormous interests have been shown in coordination polymers, zeolitic structures, hydrogen-bonded networks and potentially important magnetic materials [1–3]. The main attractions for extended structures are their tunability and potential applications [4–6]. There is also an aesthetic perspective; chemists are attracted by the particular beauty and the intriguing diversity of the structures, which can be obtained by assembling metal ions and various multifunctional ligands. The coordination geometry of the metal ion is crucial in the self-assembling process [7–11]. Solvent molecules and counter ions will also influence the final supramolecular architectures. These can affect the size, shape and hydrophilic character of voids in zeolitic structures and hydrogen-bonded networks as well as the overall stability of the supramolecular systems [5,7,12,13]. Our study describes two types of ligands namely

dicyanamide (dca) and aminobenzonitrile (ABN) isomers for coordination with M(II) ions (M = Ni, Cu and Cd) in order to construct new and varied metal frameworks. The coordination polymers are formed when divalent first-row transition metals are linked with the generally bidentate (monodentate and tridentate coordination is also possible) dicyanamide (dca, $N(CN)_2^-$) ligand. This ligand has significant current interest for their structural diversities and potentially interesting magnetic properties [14]. Aminobenzonitrile isomers can coordinate to a metal centre through either the amine or nitrile nitrogen. Accordingly, we have obtained five different structures where the above two ligands show different bonding modes to metal(II) ions.

In this paper, we report five compounds with the following formula $[Ni^{II}(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (**1**), $[Cu^{II}(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (**2**), $[Cu^{II}(dca)_2(para\text{-}ABN)_2]_n$, (**3**), $[Cu^{II}(dca)_2(ortho\text{-}ABN)_2]_n$, (**4**) and $[Cd^{II}(dca)_2(meta\text{-}ABN)_2]_n$ (**5**) using dicyanamido (dca) and three isomers of aminobenzonitrile (ABN) ligands. A CSD search [15,16] yielded only ten complex compounds with aminobenzonitriles. The present work contains the first coordination polymers of Cu(II) with ABN ligands. Two monomeric isomorphous compounds **1** and **2** and three polymeric frameworks **3**–**5** have been characterized. All except **4** (2D hydrogen bonding network) have an extensive 3D hydrogen bonding network.

2. Experimental

All reagents were of commercial grade and were used as received. $Na[N(CN)_2]_2$, was purchased from the Aldrich Company.

2.1. Preparations

2.1.1. Synthesis of $[Ni(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (*1*)

para-Aminobenzonitrile (0.0590 g, 0.5 mmol) was dissolved in 3 mL of methanol. The resultant solution was added to 3 mL of a methanolic solution of $Ni(NO_3)_2\cdot 6H_2O$ (0.1454 g, 0.5 mmol). It was stirred for 1 h at room temperature. Then the mixture was placed in an ice-bath and the temperature maintained at 0 °C. Next, 5 mL aqueous solution of $NaN(CN)_2$ (0.0445 g, 0.5 mmol) was added to the mixture. Green cubic crystals suitable for X-ray diffraction study were obtained from the mother liquor by slow evaporation at room temperature after 10 days. They were filtered off, washed with a small amount of water and dried in air. Elemental analysis: Calc. for $NiC_{18}H_{16}N_{10}O_2$: C 46.64, H 3.45, N 30.23%. Found: for **1** C 46.63, H 3.44, N 30.25%. Infrared spectrum: $[N(CN)]^-$, ν_{sym}(C≡N) 2195, ν_{asym}(C≡N) 2237, ν_{sym}(C–N) 922 and ν_{asym}(C–N) 1370; ABN, ν(N–H) 3444 cm^{-1}.

2.1.2. Synthesis of $[Cu(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (*2*)

The preparation of **2** was the same as stated for compound **1**, using $Cu(NO_3)_2\cdot 3H_2O$ (0.1208 g, 0.5 mmol) instead of $Ni(NO_3)_2\cdot 6H_2O$. Dark green crystals suitable for X-ray diffraction were formed after 10 days. They were filtered off, washed with a small amount of water and dried in air. Elemental analysis: Calc. for $CuC_{18}H_{16}N_{10}O_2$: C 46.16, H 3.42, N 29.92%. Found: for **2** C 46.14, H 3.41, N 29.94%. Infrared spectrum: $[N(CN)]^-$, ν_{sym}(C≡N) 2195, ν_{asym}(C≡N) 2227, ν_{sym}(C–N) 915 and ν_{asym}(C–N) 1345; ABN, ν(N–H) 3443 cm^{-1}.

2.1.3. Synthesis of $[Cu(dca)_2(para\text{-}ABN)_2]_n$ (*3*)

para-Aminobenzonitrile (0.0590 g, 0.5 mmol) was dissolved in 5 mL of methanol. The resultant solution was added to 5 mL of a methanolic solution of $Cu(NO_3)_2\cdot 3H_2O$ (0.1208 g, 0.5 mmol). The mixture was heated under reflux for half an hour at 45–50 °C after which it was cooled and to it 3 mL aqueous solution of $NaN(CN)_2$ (0.0445 g, 0.5 mmol) was added and the resultant solution was stirred for 1 h at room temperature. It was filtered off and the filtrate was kept at room temperature. Green cubic crystals suitable for X-ray diffraction study were obtained after two weeks. They were filtered off, washed with a small amount of water and dried in air. Yield 68% Elemental analysis: Calc. for $CuC_{18}H_{12}N_{10}$: C 50.01, H 2.78, N 32.41%. Found: for **3**: C 50.02, H 2.77, N 32.39%. Infrared spectrum: $[N(CN)]^-$, ν_{sym}(C≡N) 2190, ν_{asym}(C≡N) 2235, ν_{sym}(C–N) 935 and ν_{asym}(C–N) 1357; ABN, ν(N–H) 3440 cm^{-1}.

2.1.4. Synthesis of $[Cu(dca)_2(ortho\text{-}ABN)_2]_n$ (*4*)

This compound was synthesized as for **3** but from $Cu(NO_3)_2\cdot 3H_2O$ (0.1208 g, 0.5 mmol) and *ortho*-aminobenzonitrile (0.0590 g, 0.5 mmol). Green cubic crystals suitable for X-ray diffraction study were obtained from the mother liquor by slow evaporation at room temperature after 7 days. They were filtered off, washed with a small amount of water and dried in air. Yield 65%. Elemental analysis: Calc. for $CuC_{18}H_{12}N_{10}$: C 50.01, H 2.78, N 32.41%. Found: for **4**: C 50.03, H 2.79, N 32.38%. Infrared spectrum: $[N(CN)]^-$, ν_{sym}(C≡N) 2186, ν_{asym}(C≡N) 2230, ν_{sym}(C–N) 900 and ν_{asym}(C–N) 1371; ABN, ν(N–H) 3440 cm^{-1}.

2.1.5. Synthesis of $[Cd(dca)_2(meta\text{-}ABN)_2]_n$ (*5*)

This compound was synthesized as for **3** but from $Cd(NO_3)_2\cdot 4H_2O$ (0.1542 g, 0.5 mmol) and *meta*-aminobenzonitrile (0.0590 g, 0.5 mmol). Colourless crystals were formed after 3–4 weeks. They were filtered off, washed with small amount of water and dried in air. Yield 66%. Elemental analysis: Calc. for $CdC_{18}H_{12}N_{10}$: C 44.93, H 2.50, N 29.12%. Found: for **5**: C 44.90, H 2.49, N 29.14%. Infrared spectrum: $[N(CN)]^-$, ν_{sym}(C≡N) 2185, ν_{asym}(C≡N) 2230, ν_{sym}(C–N) 905 and ν_{asym}(C–N) 1355; ABN, ν(N–H) 3440 cm^{-1}.

2.2. Physical measurements

The elemental analyses (C, H, N) were carried out with a Perkin Elmer 2400 II elemental analyser. For each sample

the analyses were carried out in duplicate. The FT-IR spectra were recorded on Perkin Elmer RX I FT-IR spectrophotometer from KBr pellets in range 4000–400 cm^{-1}. It is important for the characteristic bands of the dca ligand and amino group.

Magnetic susceptibility measurements for **3** and **4** were carried out on polycrystalline samples, with a Quantum Design SQUID MPMS-XL susceptometer apparatus working in the range 2–300 K under a magnetic field of approximately 500 G (2–30 K) and 10 000 G (35–300 K). Diamagnetic corrections were estimated from Pascal tables.

2.3. Crystal data collection and refinement

Single crystal diffraction data for **1**–**3** and **5** were collected on a Bruker Nonius X8 Apex 2 CCD diffractometer at 100 K, cooled by an Oxford Cryosystems Cryostream. The crystals were covered in Paratone-N oil and mounted in cryoloops. The structures were solved and refined using the SHELXTL [17] suite of programs. Amine and water H atoms were located in the difference Fourier map and isotropic displacement parameters were freely refined for **1** and **5**, and riding for **3** and **2**. The data for **4** were collected on a Nonius KappaCCD diffractometer; [18] the lattice constants were refined by least-square refinement using 2005 reflections ($2.1° < \theta < 27.8°$). No absorption correction was applied to the data sets. The structure was solved by direct methods [19] and refined [20] against F using reflections with $[I/\sigma(I) > 3]$. All non-hydrogen atoms were successfully refined with anisotropic displacement factors. Further experimental details for all the compounds are summarized in Table 1.

3. Results and discussion

In the five compounds, both dca and ABN ligands show varied bonding modes, i.e. (i) dca acts as bridging ligand for **4** and **5**, (ii) *para*-ABN acts as bridging ligand for **3** and (iii) both the dca and *para*-ABN ligands act as monodentate ligands for **1** and **2**. *ortho*- and *meta*-ABN act as monodentate ligands in **4** and **5**, respectively. These resulted in four generally different structural frameworks. The formation of compounds **2** and **3** was highly dependent on the reaction conditions. In both cases the starting materials were used in the same ratio, $Cu(NO_3)_2$:dca:*para*-ABN of 1:1:1, but the different synthetic methods employed yielded two new compounds. In the synthesis of **3** when an aqueous solution of $NaN(CN)_2$ was added to a methanolic solution of $Cu(NO_3)_2$ and *para*-aminobenzonitrile, a deep-green precipitate was formed within a few minutes, during the stirring. On filtration a green coloured solution was obtained which on keeping yielded **3**. The deep-green precipitate was characterized by IR and X-ray powder diffraction study and the found results were identical with those of **2**. From this it was concluded that **3** was the major and thermodynamically controlled product, whereas **2** was the minor and kinetically controlled product in the preparative process of **3**. The low temperature preparative process produced **2** exclusively.

3.1. Crystal structure analyses

Crystal structure analyses show that **1** and **2** are monomeric compounds and form two-dimensional hydrogen bonded sheets through the interaction of the *para*-ABN and dicyanamide ligands which further extend

the structures to three dimensions through weak π–π interactions from the aromatic group of *para*-ABN ligands. **3**–**5** revealed that one-dimensional double stranded polymeric chains were formed. These infinite chains were further connected via hydrogen bonding interactions to extend the network into 3D in **3** and **5** and 2D in **4**

Self-association has taken place in a variety of ways. Firstly intermolecular interactions have been propagated solely through ligand OH···N and NH···N hydrogen bonds (in **1** and **2**), secondly through two *trans*-coordinated dca ligands and two *cis* amine bonded *para*-ABN ligands (in **3**) and thirdly by *trans*-coordinated amine groups of two ABN and two *cis* dca ligands (in **4** and **5**). Selected bond lengths and angles for **1**–**5** are given in Tables 2–6, respectively. The compounds have an extensive 3D (**1**–**3** and **5**) or 2D (**4**) hydrogen bonding networks; these details are summarized in Table 7.

The structures of $[Ni(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (**1**) and $[Cu(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ (**2**) are virtually identical and are exemplified by **1**. The crystal structure of **1** consists of centrosymmetric, mononuclear $[Ni(dca)_2(para\text{-}ABN)_2(H_2O)_2]$ entities. Both *para*-ABN and dicyanamide act as terminal ligands (Figs. 1 and 2). The *para*-ABN ligand is coordinated to the metal ion through the amine nitrogen atom. The Ni–N bond lengths are Ni–N(dca) = 2.0351 Å and Ni–N(*para*-ABN) = 2.1513 Å. The two Ni–O (aqua) distances are 2.0700 Å. The nickel(II) ion exhibits a *trans* distorted octahedral stereochemistry. The C–N–C angle of the dicyanamide is 120.91°. The most intriguing features of the crystal structure of the compound arise from interactions at the supramolecular level. The *para*-ABN ligand acts as both a hydrogen donor (through the amine group) and a hydrogen acceptor (through the nitrile group) while the dicyanamide ligand acts as a hydrogen acceptor and the aqueous ligand acts as a hydrogen donor. The hydrogen bonding network for both **1** and **2** consists of layers. Each layer consists of interlocked parallelograms. One set of parallel sides is doubly-bridging *para*-ABN and the other doubly-bridging dca. In the latter, the bridge is formed between dca and *para*-ABN rather than with the metal ion. This supramolecular architecture is shown in Fig. 3. The interlayer interactions are of a weak π–π nature

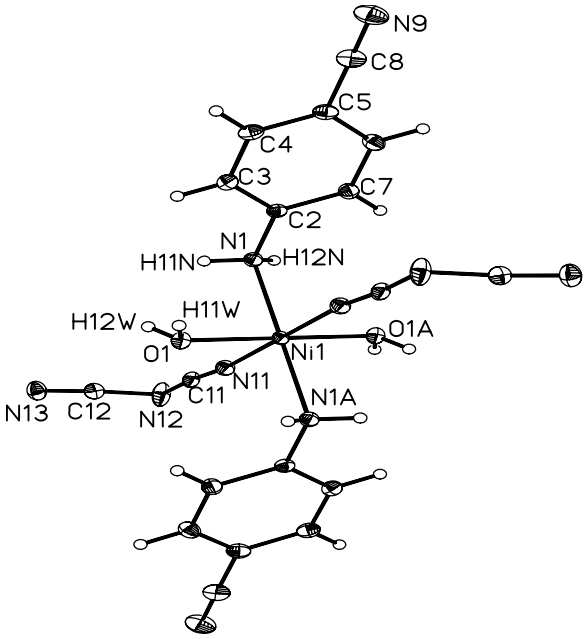

Fig. 1. Ortep view of **1** with the atom numbering scheme.

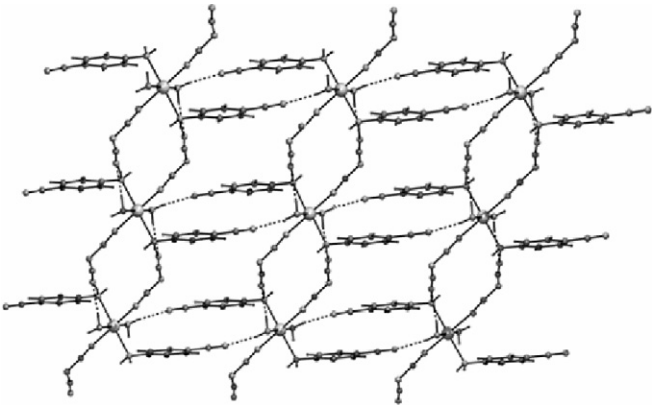

Fig. 3. Packing diagram of **1** with hydrogen bonding shown as a dotted line.

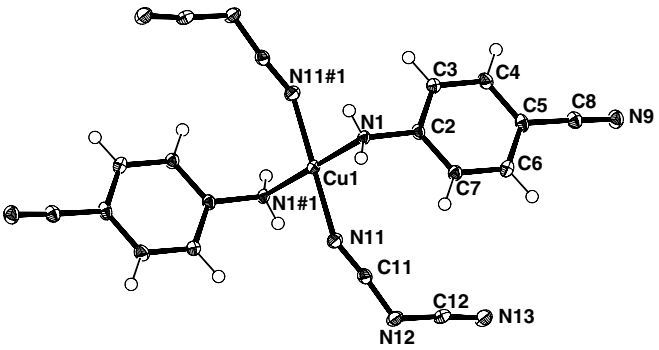

Fig. 4. Ortep view of **3** showing the atom numbering scheme.

Fig. 4 shows a perspective view of **3** which is found to be a $[Cu(dca)_2(para\text{-}ABN)_2]$ asymmetric unit. This unit contains two terminal dicyanamido ligands and four bridging *para*-ABN ligands which adopt a distorted octahedral coordination sphere. The terminal dca ligands coordinate through the nitrile N(11) atoms, occupying the axial positions with Cu(1)–N(11) 1.9763(12) Å, while the equatorial plane contains four nitrogen atoms from bridging *para*-ABN ligands which coordinate through the two amino N(1) atoms and two nitrile N(9) atoms [Cu(1)–N(1) 2.0550(12) and Cu(1)–N(9) 2.497 Å]. The $[Cu(dca)_2(para\text{-}ABN)_2]$ monomer units are linked through bridging *para*-ABN ligands to make a double stranded polymeric chain (Fig. 5). The coordination polymer runs parallel to

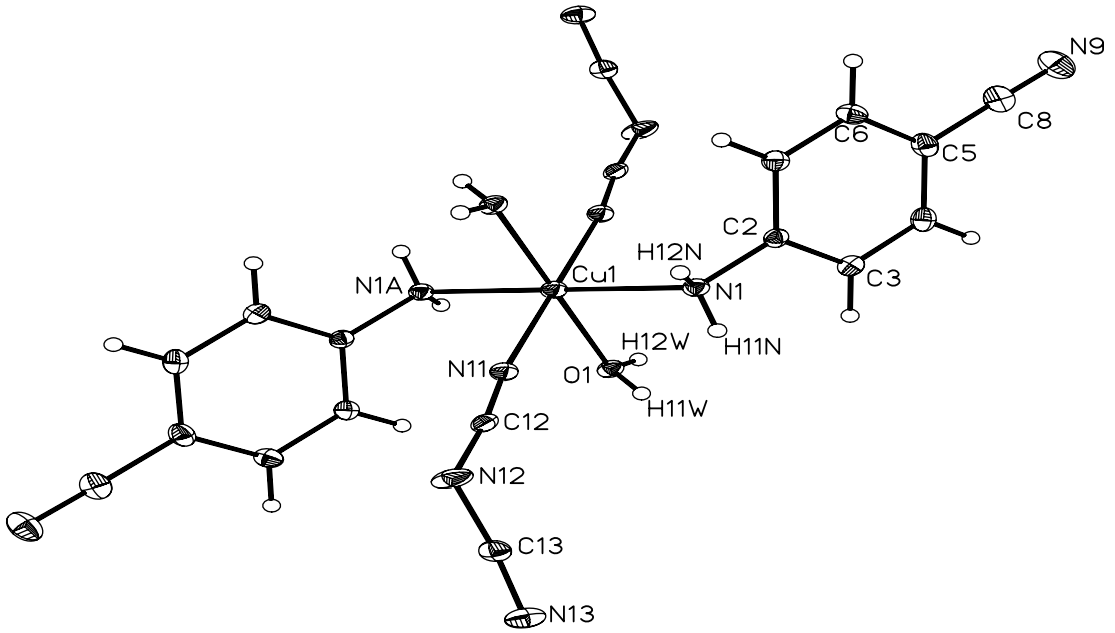

Fig. 2. Ortep view of **2** with the atom numbering scheme.

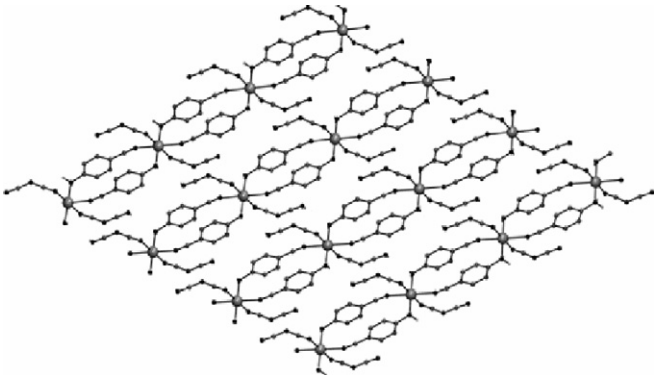

Fig. 5. Packing diagram of **3** omitting the H-bonding for clarity.

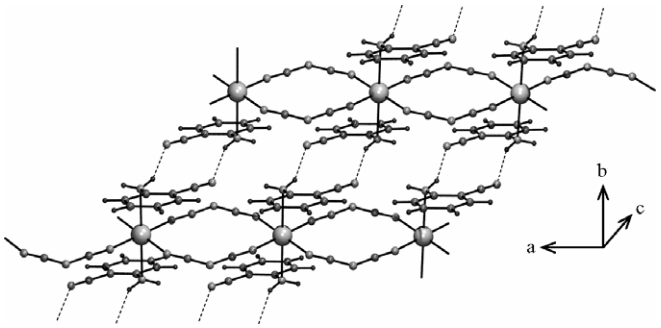

Fig. 7. View of the propagation of **4**.

the crystallographic *a*-axis (Fig. 5), which is also observed for compounds **4** and **5**. The metal–metal distance between adjacent Cu centres within one polymer strand is equal to 9.7020 Å, while the closest Cu···Cu distance between two neighbouring strands is 8.795 Å.

Compound **3** shows a rarely observed characteristic, namely doubly bridging of the *para*-ABN ligand which binds via both the amine and nitrile nitrogen atoms. Dicyanamide can also be considered as a doubly bridging ligand but the bridge is made by a NH···N hydrogen bond to a *para*-ABN amine, which extends the geometry into three dimensions (Supporting information 1). The cobalt and nickel thiocyanate complexes [11] also have double bridging ABN ligands and the SCN ligands remain terminally bound but are involved in NH···S hydrogen bonds.

In **4** (Fig. 6) the dca ligands form bridges and the *ortho*-ABN ligands are terminal in contrast to the coordination mode of dca and *para*-ABN ligands in **3**. The copper(II) ion coordination sphere is formed by two dca ligands bridging the pairs of Cu atoms while the amino groups from *ortho*-ABN ligands coordinate in the axial positions (Fig. 7). The metal–metal distance between adjacent Cu centres within one polymer strand is equal to 7.113 Å, while the closest Cu···Cu distance between two neighbouring strands is 7.173 Å. The NH···N hydrogen bond between two neighbouring polymer strands extend the structure of **4** into two-dimensions with the amine group from the *ortho*-ABN ligand acting as a hydrogen donor and nitrile group from the same ligand of another strand acting as a hydrogen acceptor (Fig. 7).

The structure of **5** (Fig. 8) is very similar to that of **4** and it is worthwhile to note that the metal–metal distance between adjacent Cd centres within the polymer strand is 7.705 Å, whilst the closest Cd···Cd distance between two neighbouring strands is 8.768 Å. The non-bridging *meta*-ABN ligands are bound to Cd with the amine group. They are orientated anti to each other with the torsion angle C(7A)–N(7A)–N(7)–C(7) being 180° as the Cd atom lies on an inversion centre.

The polymers strands of **3** and **5** are interconnected in three dimensions by an extensive network of NH···N hydrogen bonds. In **3** the amine group from the *para*-ABN ligand acts as the hydrogen donor and both nitrile and amide nitrogen atoms from dicyanamide ligands of another strand act as hydrogen acceptors (Fig. 5). While in **5** the amine group from *meta*-ABN acts as the hydrogen donor and the nitrogen atoms of the nitrile group from

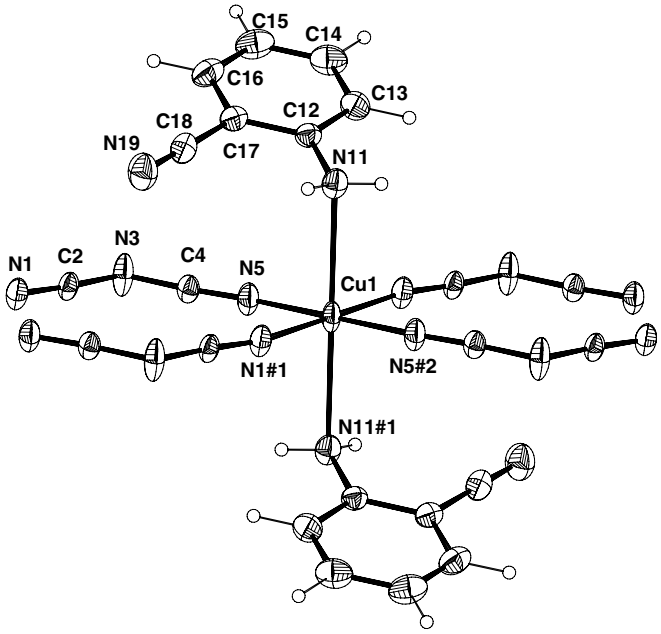

Fig. 6. Ortep view of **4** with the atom numbering scheme.

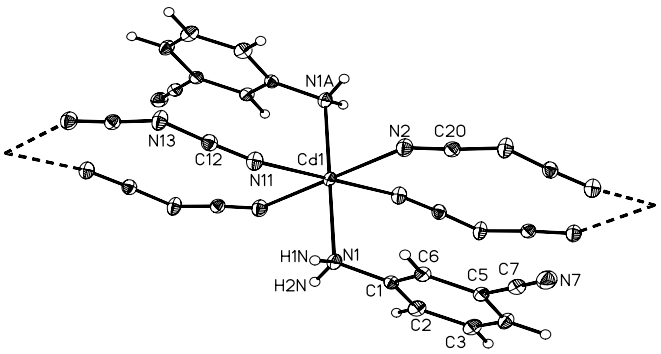

Fig. 8. Ortep view of **5** with the atom numbering scheme.

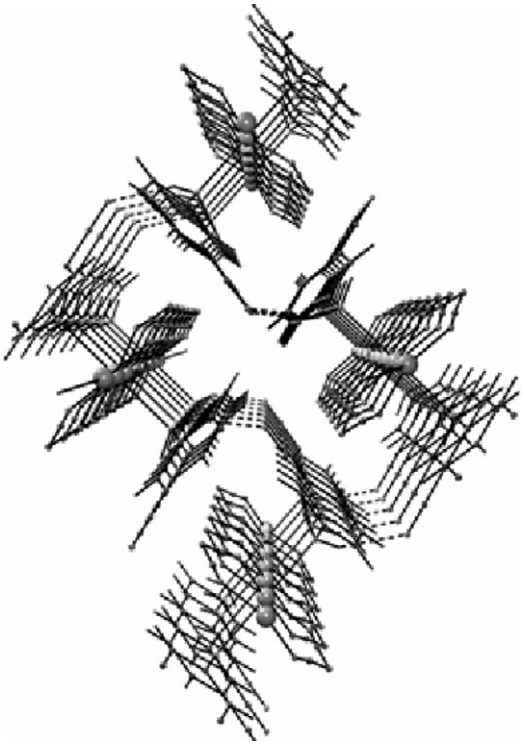

Fig. 9. Packing diagram of **5** with hydrogen bonding shown as a dotted line.

both *meta*-ABN and dicyanamide ligands of another strand act as hydrogen acceptors (Fig. 9). Although **4** and **5** show very similar connectivity, **4** has a hydrogen bonding network which extends into two dimensions and **5** extends into three dimensions. The position of the nitrile group of the ABN ligands for **4** and **5** is different i.e. *ortho*-ABN and *meta*-ABN respectively, so the *meta*-ABN isomer may be more able to form hydrogen-bonds compared to the *ortho*-ABN isomer, possibly for steric reasons.

3.2. Magnetochemistry

Variable temperature magnetic susceptibility measurements have been performed for **3** and **4**. The global feature of the $\chi_M T$ versus T curves in both compounds is characteristic of very weak antiferromagnetic interactions (Figs. 10 and 11). For **3** the value of $\chi_M T$ at 300 K is 0.384 cm^3 K mol^{-1} which is as expected for one uncoupled copper(II) ion (0.37 cm^3 K mol^{-1} per Cu(II) with $g = 2.0$). With decreasing temperature, the $\chi_M T$ value remains almost constant until ca. 70 K and then it decreases sharply, giving the minimum value of 0.170 cm^3 K mol^{-1} at 2 K. The drop in $\chi_M T$ at low temperatures indicates the presence of a very weak antiferromagnetic coupling between the copper(II) ions.

As is shown in Fig. 5, the structure of **3** consists of copper entities linked by two *para*-ABN ligands, which also acts as hydrogen donors via the amine groups, and both nitrile and amide nitrogen atoms of dicyanamide act as hydrogen acceptors to give a 3D compound. To interpret

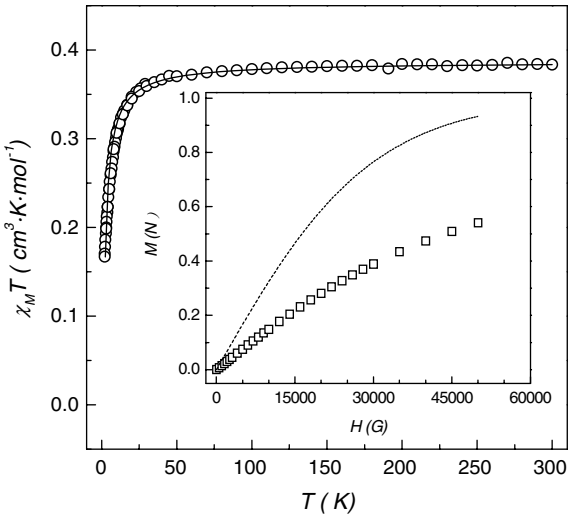

Fig. 10. Plot of $\chi_M T$ vs. T and $M(N_\beta)$ vs. $H(G)$ (inset) for **3**.

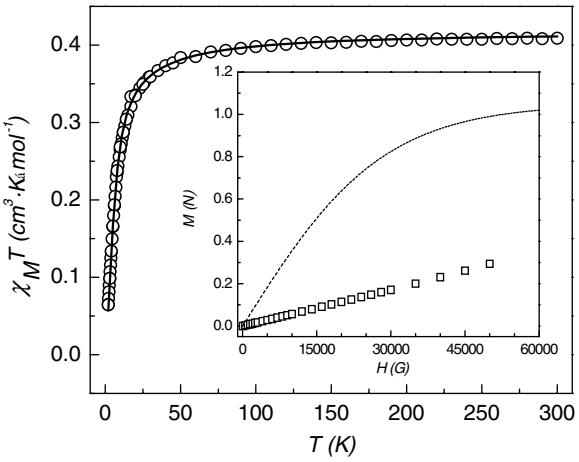

Fig. 11. Plot of $\chi_M T$ vs. T and $M(N_\beta)$ vs. $H(G)$ (inset) for **4**.

the magnetic behaviour of **3** we assume a negligible contribution from the interactions through the hydrogen bonding. The system may be treated in a simplified form as a uniform chain of Cu(II) atoms. Thus, only one coupling parameter (J) must be considered to interpret a possible magnetic interaction. The experimental magnetic data have been fitted using the equation, derived from the Bonner–Fisher [21] calculation based on the isotropic Heisenberg Hamiltonian: $H = -J\sum(S_i S_{i+1})$. The best fit parameters from 300 down to 2 K are found as $J = -2.35\ cm^{-1}$ and $g = 2.03$ with an error $R = 3.2 \times 10^{-5}$, where $R = \sum[(\chi_M T)_{exp} - (\chi_M T)_{calc}]^2 / \sum[(\chi_M T)_{exp}]^2$. The very low value of the superexchange parameter can be understood considering the large Cu···Cu distance (9.702 Å). The weak antiferromagnetic interaction was confirmed by magnetization measurements at 2 K up to an external field of 5 T. At higher field, the magnetization in M/Nβ units indicates a value of 0.54; (a quasi half saturated $S = 1/2$ system) (inset Fig. 10). Comparison of the overall shape

of the plot with the Brillouin plot (dashed plot) for one isolated ion with $S = 1/2$ system and $g = 2$ indicates slower magnetization which is consistent with a weak antiferromagnetic interaction.

For **4** the value of $\chi_M T$ at 300 K is 0.409 $cm^3\,mol^{-1}K$ which is as expected for one uncoupled copper(II) ion (0.413 $cm^3\,mol^{-1}$ K per one Cu^{II} with $g = 2.1$). The $\chi_M T$ values are constant over the temperature range, decreasing to 0.0644 $cm^3\,mol^{-1}$ K, at very low temperatures (2 K). The χ_M curve starts at 1.36×10^{-3} $cm^3\,mol^{-1}$ at room temperature and increases in a uniform way to 0.0322 $cm^3\,mol^{-1}$ at 2 K. The weak antiferromagnetic interaction was confirmed by magnetization measurements at 2 K up to an external field of 5 T. At higher field, the magnetization in M/Nβ units indicates a 0.2945 value for **4** (inset Fig. 11). Comparison of the overall shape of the plot with the Brillouin plot for one fully isolated ion with $S = 1/2$ system with $g = 2.1$ (dash curve) indicates very slow magnetization which consistent with a weak antiferromagnetic interaction.

Taking into account the structure of **4** (Fig. 7), which consists of copper ions linked by double $\mu_{1,5}$-dicyanamide groups in a 1D system, only one coupling parameter (J) was considered to interpret possible magnetic interactions in this compound (the interaction through the hydrogen bonding has not been considered). The experimental magnetic data have been fitted using the equation which was derived from the Bonner–Fisher [21] calculation based on the isotropic Heisenberg Hamiltonian: $H = -J\sum(S_i S_{i+1})$. The best fit parameters from 300 down to 2 K are found as $J = -5.1\ cm^{-1}$ and $g = 2.1$ with an error $R = 2.3 \times 10^{-5}$, where $R = \sum[(\chi_M T)_{exp} - (\chi_M T)_{calc}]^2/\sum[(\chi_M T)_{exp}]^2$. The low superexchange parameter value found can be understood perfectly, if we consider the data reported in the literature. Indeed, the dicyanamide ligand in the coordination mode $\mu_{1,5}$ normally leads to a very weak antiferromagnetic coupling in Mn(II) , Ni(II) or Cu(II) complexes and this interaction can even be zero or very weak ferromagnetic [22].

4. Conclusion

We have synthesized five new metal-organic frameworks including the first Cu(II) polymers with *para*- and *ortho*-ABN ligands. In these compounds dca and *para*-ABN ligands show the terminal as well as bridging bonding mode whereas *ortho*- and *meta*-ABN coordinated only in a monodentate fashion. The spin coupling constants, J, were estimated to be -2.35 and $-5.1\ cm^{-1}$ for **3** and **4**, respectively.

Abstract

Four *cis*-dioxomolybdenum complexes of general formula $[MoO_2(L^n)EtOH]$ ($n = 1$–4) and one oxomolybdenum(IV) complex $[MoO(L^4)EtOH]$, with potentially tridentate Schiff bases derived from 5-methyl pyrazole-3-carbohydrazide and salicylaldehyde/substituted salicylaldehyde/*o*-hydroxy acetophenone have been prepared. The Mo(IV) complex is derived from the Mo(VI) dioxo complex by oxotransfer reaction with PPh_3. The complexes are characterized by elemental analysis, electronic spectra, IR, ^1H NMR, and by cyclic voltammetry. All the Mo(VI) species are crystallographically characterized. The complexes have a distorted octahedral structure in which the ligand behaves as a binegative donor one, leaving the pyrazole –N uncoordinated towards the metal center. It is also revealed from the crystal structure that the Mo(VI) center enjoys an NO_5 donor environment.

1. Introduction

Recent years have witnessed a phenomenal growth in coordination chemistry literature of molybdenum(VI) because of its recently discovered biochemical significance [1–3] as well as involvement of Mo(VI) compounds in some industrial catalytic processes [4–6]. *cis*-Dioxomolybdenum cation is present in the oxidized form of certain oxotransferase enzymes like xanthine oxidase/dehydrogenase, DMSO reductase [7,8], etc. This has created a tremendous impetus in synthesis of a number of model complexes mimicking the oxotransferase molybdoenzymes [9–13]. In order to understand the activity of oxotransferase molybdoenzymes, several attempts have been made to monitor the oxotransfer reaction of dioxomolybdenum complexes to substrates such as PPh_3 [14]. Oxomolybdenum complexes have been isolated and characterized as end products of such reactions along with PPh_3O [15]. Some of these reactions have also been kinetically followed [16]. It is known that the molybdenum cycles between (VI) and (IV) states in the catalytic reaction of these molybdoenzymes [17,18] where Mo(V) coexists with Mo(VI) and Mo(IV) during the course of reaction [17,19,20]. Hence study of the redox properties of model dioxomolybdenum complexes has gained momentum steadily. Many dioxomolybdenum complexes of ligands having NS, SS, NSO (S– as common donor atom) [21–23] as well as ONO (non-sulfur donor atoms) have been prepared and characterized [24,25].

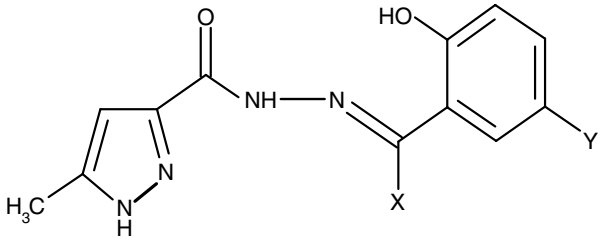
Although Schiff base complexes by and large dominate the chemistry of Mo(VI), dioxomolybdenum complexes of Schiff base ligands derived especially from heterocyclic bases are still ill-explored. In this work, we aim at the synthesis and characterization of a few dioxomolybdenum(VI) complexes of Schiff base ligands derived from 5-methyl pyrazole-3-carbohydrazide and salicylaldehyde/*o*-hydroxy acetophenone/substituted salicylaldehyde. Our goal is to arrive at a comparative study of the complexes regarding their structures, redox stability and spectral characteristics with the variation of electron donating nature of the ligands. Further we have studied the oxotransfer reaction of one of the representative complexes. The resultant Mo(IV) complex has been isolated and characterized.



2. Experimental

$MoO_2(acac)_2$ was prepared as described in the literature [26]. Reagent grade solvents were used as received. 5-Methyl pyrazole-3-carbohydrazide was prepared as described in the literature [27]. Salicylaldehyde, 5-bromo salicylaldehyde, 5-nitro salicylaldehyde and *o*-hydroxy acetophenone were purchased from Aldrich Chemical Company, USA and used as received. Tetraethyl ammonium perchlorate (TEAP) used for electrochemical work was prepared as reported in the literature [28].

2.1. Synthesis

2.1.1. Synthesis of ligands

All the four ligands H_2L^1, H_2L^2, H_2L^3, H_2L^4 were synthesized in a similar way by refluxing an ethanolic solution (20 ml) of 5-methyl pyrazole-3-carbohydrazide (10 mmol, 1.4 g) with salicylaldehyde (10 mmol, 1.22 g), *o*-hydroxy acetophenone (10 mmol, 1.36 g), 5-bromo salicylaldehyde (10 mmol, 2.01 g) and 5-nitro salicylaldehyde (10 mmol, 1.67 g), respectively, also taken in ethanol (20 ml). Reflux was continued for ca. 2 h at water bath temperature during which a solid compound separated. It was filtered, washed with ethanol and dried over fused $CaCl_2$. The crude product was recrystallized from ethanol–water mixture (4:1 V/V) (see Fig. 1).

2.1.2. Preparation of the complexes

The complexes [$MoO_2(L^1)$EtOH] (**1**), [$MoO_2(L^2)$EtOH] (**2**), [$MoO_2(L^3)$EtOH] (**3**), [$MoO_2(L^4)$EtOH] (**4**) were prepared in a similar way by refluxing an ethanolic solution (10 ml) of $MoO_2(acac)_2$ (0.5 mmol, 0.163 g) with ehthanolic solutions of H_2L^1 (0.5 mmol, 0.122 g), H_2L^2 (0.5 mmol, 0.129 g), H_2L^3 (0.5 mmol, 0.161 g) and H_2L^4 (0.5 mmol, 0.145 g), respectively. Initially on mixing the two components immediately an orange yellow color was observed. The mixture was refluxed for 1 h. The respective complex separated as an orange microcrystalline compound during reflux or afterwards on slow evaporation of the reaction mixture. It was filtered, washed with ethanol and dried over fused $CaCl_2$.

[$MoO_2(L^1)$EtOH] (**1**): Yield: 0.124 g (60%). Elemental analysis: *Anal*. Calc. for $C_{14}N_4O_5H_{16}Mo$: C, 40.57; H, 3.63; N, 13.3. Found: C, 39.51; H, 3.72; N, 13.30%. X-ray quality crystals of the composition [$MoO_2(L^1)H_2O$] (**1a**) were prepared from compound **1** by slow diffusion of *n*-hexane into a saturated solution of **1** in acetone. (The water molecule may have come from the solvents, acetone or *n*-hexane, as we used only purified solvents and not dehydrated solvents.)

[$MoO_2(L^2)$EtOH] (**2**): Yield: 0.107 g (50%). Elemental analysis: *Anal*. Calc. for $C_{15}N_4O_5H_{18}Mo$: C, 42.05; H, 4.20; N,13.08. Found: C, 42.1; H, 3.95; N, 12.95%.

[$MoO_2(L^3)$EtOH] (**3**): Yield: 0.12 g (50%). Elemental analysis: *Anal.* Calc. for $C_{14}N_4O_5H_{15}BrMo$: C, 34.07; H, 2.83; N, 11.35. Found: C, 33.8; H, 2.56; N, 11.53%. The crystals of **2** and **3** obtained from the reaction mixture were found suitable for X-ray diffraction.

[$MoO_2(L^4)$EtOH] (**4**): Yield: 0.116 g (50%). Elemental analysis: *Anal.* Calc. for $C_{14}N_5O_7H_{15}Mo$: C, 36.52; H,

3.26; N, 15.21. Found: C, 36.05; H, 3.57; N, 15.27%. X-ray quality crystals of **4a** were grown by slow evaporation of a solution of **4** in a mixed solvent of DMF–diethyl ether (1:3 V/V) at refrigerator temperature.

[MoO(L^4)EtOH] (**5**): Complex **4** (0.25 mmol, 0.115 g) was taken in a suspension of 40 ml degassed acetonitrile, PPh_3 (2.25 mmol, 5.5 g) was added and the mixture was refluxed at water bath temperature under dinitrogen atmosphere for 1 h. The green compound obtained as a residue was filtered on a sintered gooch crucible and washed with acetonitrile. It was dried in a vacuum desiccator over concentrated H_2SO_4. Yield: 0.055 g (52%). Elemental analysis: *Anal.* Calc. for $C_{14}N_5O_6H_{14}Mo$: C, 37.9; H, 3.16; N, 15.80. Found: C, 36.8; H, 3.55; N, 14.01%.

2.2. Physical measurements

Elemental analyses were performed at IACS, Kolkata on a Perkin–Elmer 2400 CHN analyzer. The ^1H NMR spectra of the complexes and the ligands were recorded on a Bruker AM300L (300 MHz) superconducting FT-NMR. IR spectra were recorded as a KBr pellet on a Perkin–Elmer FTIR spectrophotometer. UV–Vis spectra and DRS were measured on a Hitachi U-3501 spectrophotometer. Cyclic Voltammetry was carried out using a Sycopel model AEW2 1820F/L instrument. The measurements were carried out at 293 K in DMF solutions containing 0.2 M TEAP as supporting electrolyte and 10^{-3}–10^{-4} M solution of the respective complex deoxygenated by bubbling with nitrogen. The working, counter and reference electrodes used were a Pt wire, platinum coil and an SCE, respectively.

2.3. Crystallographic measurements

The crystals were measured on an Bruker SMART 1K CCD diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) and a graphite monochromator at −80 °C. Unit cell and reflection data were obtained by standard methods [29,30] and are summarized in Table 1. The structures were solved, refined, and prepared for publication using the SHEXTL package [31] (structure solution refinements and molecular graphics).

The structures were solved using direct methods and refined on F^2 using full matrix least squares techniques with anisotropic displacement factors for all non-hydrogen

atoms. Positions of the hydrogen atoms were calculated from the geometry of the molecular skeleton and their thermal displacement parameters were refined isotropically on a groupwise basis. Selected bond lengths and angles are reported in Table 2. H-bonding distances and angles are shown in Table 2A.

3. Results and discussion

3.1. Syntheses

All the four Schiff base ligands and their complexes were synthesized in a very facile and essentially identical way. Each ligand acts as a tridentate dianionic ONO donor one towards the MoO_2^{2+} core. All the Mo(VI) complexes were obtained from a refluxing mixture of the respective ligand and the bis(acetylacetonato)dioxomolybdenum(VI) precursor, taken in 1:1 molar proportion in purified ethanol. Complexes of the general formula $[MoO_2(L^n)EtOH]$ ($n = 1$–4, complexes **1**–**4**) were isolated as orange–yellow compounds from reaction mixture by slow evaporation at room temperature. These complexes were found to be fairly soluble in most of the common organic solvents. Magnetic susceptibility and molar conductance data show that the complexes are diamagnetic and electrically non-conducting in nature. The ligand H_2L^1 has been earlier employed by Syamal and Maurya to prepare the complex $[MoO_2(L^1)MeOH]$ from a methanol solution in a similar way [32]. Among the dioxomolybdenum(VI) complexes, the complex $[MoO_2(L^4)EtOH]$ (**4**) was found to be the most easily reducible by electrochemical studies and was chosen for the study of oxotransfer reaction. It undergoes oxoabstraction reaction at a fairly rapid rate at room temperature even at small concentration of about 10^{-4} mol/dm^3. The reaction progress was followed with respect to time in an acetonitrile solution using a UV–Vis spectrophotometer. The solid oxomolybdenum(IV) complex, $[MoO(L^4)EtOH]$ (**5**), was isolated from a refluxing mixture of **4** and excess PPh_3 in degassed acetonitrile at water bath temperature under dinitrogen atmosphere.

3.2. ^1H NMR studies

^{1}H NMR data of the ligands (cited in the experimental section) when compared with those of the complexes (Table 3) reveal that in every case the ligand serves as

Table 3

4	904, 939	9.06(s)(–N=CH–) 1.13(t)(C*H*$_3$CH$_2$OH) 3.59(m)(CH$_3$C*H*$_2$OH) 3.43(s)(CH$_3$CH$_2$O*H*	−1.02, −0.83	413.5(5189) 338(15700) 294.5(25690)	413

tridentate binegative ONO donor and the pyrazole unit remains free. The pyrazole residue of each ligand shows signal for N–H at δ12 ppm, C_5–CH_3 protons at δ2.3 ppm and ring C_4–H proton at δ6.58 ppm [33,34]. These signals are found unperturbed in the complexes.

The disappearance of the signal at δ3.34 ppm in the free ligands upon complexation suggests that during complexation the [–CO–NH–] group undergoes tautomerization to [–C(OH)=N–] followed by deprotonation of the –OH group. The absence of low field signal characteristic of aromatic –OH is ascribed to the fact that during complexation the ligand also undergoes deprotonation from phenolic –OH group.

The azomethine C–H signal in **1**, **3**, **4** is shifted downfield from its original position in the free ligands upon coordination of the (C=N–) group, on account of reduction of electron density at the azomethine C–H. The coordination of the nitrogen of (C=N–) group in **2** is supported by the shifting of CH_3 protons of acetophenone part in H_2L^2 towards the lower field, on complexation. The aromatic protons of salicylaldehyde or *o*-hydroxy acetophenone part appearing at δ6.7–7.9 ppm [35] also show a maximum deviation of δ0.25 ppm in the complexes as compared to free ligands since in the complexes they are in direct conjugation to the coordinated O and N of the hydrazone ligands. Appearance of characteristic signals for O–H at δ3.54 ppm, CH_2 at δ3.58–3.61 ppm and CH_3 at δ1.13 ppm indicates that the sixth coordination position is occupied by a solvent molecule (EtOH).

However, it has been observed that –OH signals of ligated ethanol are not affected by the difference in donating properties of the ligands.

3.3. IR spectral studies

IR spectra of the free ligands show multiple bands at 3274–3318 cm^{-1} for ν(N–H) of secondary amide group, 1652–1637.5 cm^{-1} for ν(C=O) and 3175–3193 cm^{-1} for ν(O–H) [36]. These peaks are absent in the spectra of complexes as each ligand binds in binegative mode losing protons from both carbohydrazide and phenolic O–H group. On the other hand strong peaks at 1602–1619 cm^{-1} (ν(C=N)) and another weak peak at 1528–1569 cm^{-1} (ν(C=C)) appear in both the spectra of complexes and the free ligands [37].

In addition to that all the four Mo(VI) complexes exhibit two characteristic bands at 900–904 cm^{-1} and 936–939 cm^{-1} for symmetric and antisymmetric stretching of *cis* MoO_2^{2+} core, respectively [38–40]. It has been found that the MoO_2^{2+} symmetric and antisymmetric stretching vibrations are independent of the donating capacity of the ligands. The ν(C=C) in the ligands are found to appear at ca. 20 cm^{-1} higher frequency compared to free ligands. However no real deviation was observed for values of ν(C=N). The absence of strong peaks at 1050 cm^{-1} indicates the nonparticipation of tertiary N of pyrazole end of the ligands in complexation [41], which is also further substantiated by crystal structure studies. In the complex [MoO(L^4)EtOH] (**5**) the ν(Mo=O) shows a single band at 912 cm^{-1}. The lower value compared to the Mo(VI) complex is due to the lowering of the Mo oxidation state [15]. Other peaks do not show any notable deviation from that of Mo(VI) complex.

3.4. UV–Vis, DRS spectral studies

Electronic spectra of the complexes recorded in DMF solution display two strong absorption bands in the regions 389–413 and 294–319 nm. These peaks are assigned as charge transfer transitions of the type N($p\pi$)–Mo($d\pi$) LMCT and O($p\pi$)–Mo($d\pi$) LMCT, respectively [42–44], as the ligand based orbitals are either N or O donor types. The slight change of λ values within each set of peaks may be due to the difference of electron donating capacity of the ligands. Between ligands H_2L^1 and H_2L^2, as the latter is more electron rich, the HOMO of H_2L^2 is of lower energy compared to that of H_2L^1. Thus in the complex **2**, HOMO(L) to LUMO(M) transition occurs at higher energy.

Again when H_2L^1 is compared to H_2L^3 and H_2L^4, i.e., salicylaldehyde derived ligand compared to its 5-bromo salicylaldehyde and 5-nitro salicylaldehyde counterparts, the ligands are progressively less electron rich due to the electron withdrawing nature of the substituents. This makes HOMO of H_2L^3 and H_2L^4 higher in energy compared to that of H_2L^1 for which the electronic transitions in the respective complex (**3** and **4**) suffer a red shift, compared to **1**. The DMF solution of each complex exhibits some additional bands in the electronic absorption spectra in the higher energy region 297–292 and 288–282 nm characteristic for intraligand transitions.

The spectrum of the individual complex **1**–**4** recorded in acetone (non-coordinating solvent) shows no substantial change in peak positions indicating that the coordinating nature of DMF does not grossly affect the coordination atmosphere of the complex in the solution.

The complex [MoO(L^4)EtOH] (**5**) shows a single, moderately intense, low energy charge transfer band at 623 nm in DMF solution, characteristic of Mo(IV)O^{2+} species [24]. Charge transfer absorption bands for the corresponding Mo(VI) complex **4** at 413.5 nm was found to be absent. This indicates that the Mo(VI) complex **4** has been completely reduced to a Mo(IV) complex during the course of oxo transfer reaction towards PPh_3. However bands lying around 260–340 nm are due to intraligand transition.

The changes in the spectral behavior of complex **4** as a result of oxoabstraction reaction, can be studied as a function of time, when spectral data are recorded at 5 min interval in a 10^{-4} M solution of **4** in acetonitrile with a 10-fold excess of PPh_3. Progress of the reaction was marked by gradual appearance of a band at 623 nm (Fig. 2a) and disappearance of a shoulder band at 413.5 nm (Fig. 2b). An interesting feature is that the reaction seems to complete within a time span of 40 min at room temperature (296 K) even at such low concentration.

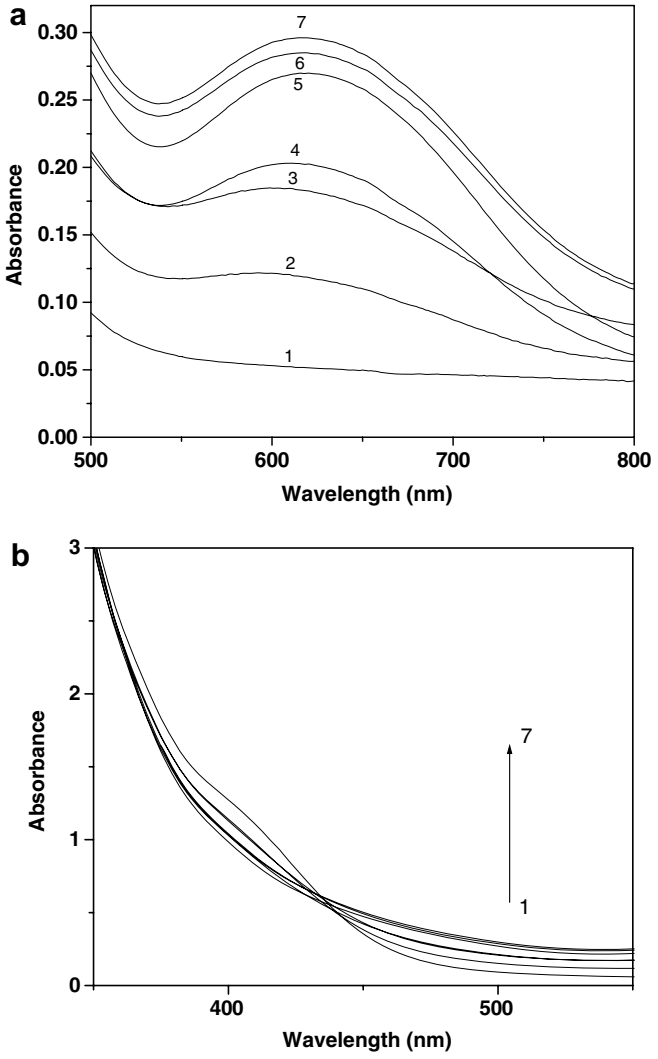

Fig. 2. Change in spectral behavior of complex **4** with time in a 10^{-4} M solution on addition of 10-folds excess of PPh_3 in acetonitrile at 298 K. Spectra taken at 5 min (1), 10 min (2), 15 min (3), 20 min (4), 25 min (5), 30 min (6), 35 min (7) shows gradual appearance of a peak at 623 nm (in **2a**) and disappearance of a shoulder at 413.5 nm (in **2b**).

The diffuse reflectance spectra of the complexes **1**–**4** show one broad band in the regions 413–444 nm. However, it is observed that complexes **1**–**3** show absorption band at lower energy compared to those in solution. This may be attributed to more destabilization of metal LUMO than the ligand HOMO in DMF solution. However in case of complex **4** no such deviations occur. Probably in this case, the ligand HOMO is destabilized to the same degree as the metal LUMO in solution. (Highly charge separated structures in resonance hybrid of the ligand.) The electron donating capacity of the ligands seems to have the same effect in diffuse reflectance spectra as in solution.

3.5. Electrochemistry

The electrochemical behavior of all the complexes $[MoO_2(L^n)EtOH]$ $(n = 1, 2, 3, 4)$, i.e., complexes **1**–**4** and complex **5** were examined in DMF solution using cyclic voltammetry at a platinum electrode with 0.1 M TEAP as supporting electrolyte. The corresponding data are supplied in Table 3. In the potential range −0.8 to 1.5 V the complexes show two irreversible reductive responses during a cathodic scan for Mo(VI)/Mo(V) and Mo(V)/Mo(IV). Each one is assigned to a one electron process established by comparison of current height with authentic one electron process. The corresponding oxidation peaks were found absent during an anodic scan. The ligands H_2L^1, H_2L^2, H_2L^3, H_2L^4 do not have any reductive response in the same potential window. Between H_2L^1 and H_2L^2, the latter is more electron donating. This results in an increase of electron density at the Mo(VI) center in **2** compared to **1**. As a consequence, the complex **2** is comparatively difficult to be reduced. E_{pc}s are shifted to more negative potential. Again among H_2L^1, H_2L^3 and H_2L^4 the ligands are gradually less electron donating. As the substituents at the 5- position of the phenyl ring in the ligands (–H, –Br, $–NO_2$, respectively) become more electron withdrawing, the e-density is shifted away from Mo(VI) center, the complexes (**1**, **3**, **4**) become easy to be reduced and the E_{pc}s are shifted towards the anodic direction. Though the substituents at the phenyl ring or azomethine carbon are not directly bonded to the MoO_2^{2+}, their effect is transmitted to the Mo-oxo core through the extended conjugation [45,46]. This is in direct correlation with the observation from the electronic spectra.

The redox behavior of the complex **5** has been shown in Table 4. It has to be mentioned here that the reduction potentials are only cathodic reduction potential not standard reduction potentials as the reductions are irreversible in nature.

3.6. Description of structures

The perspective view of the complexes **1a**, **2**, **3** and **4a** together with the atom numbering scheme are shown in Figs. 3–6 (atoms labeled O1S and O2S in the tables appears as O1s and O2s, respectively, in Figs. 3–6). Crystal parameters are presented in Table 1 and selected bond angles and bond distances are shown in Table 2.

The coordination geometry around the molybdenum(VI) atom in all the four complexes reveals a distorted octahedral environment with an NO_5 chromophore. Each ligand molecule behaves as dianionic tridentate one

Table 4
Characterization of complex **5**

IR (ν/cm^{-1}) (Mo=O)	UV–Vis (λ_{max}/nm) (ε/dm^3 mol^{-1} cm^{-1})	CV (E/V)
912	623(290)	[Mo(VI)/Mo(IV)] $E_{pa} = 1.53$ [Mo(IV)/Mo(III)] $E_{pc} = -1.18$ $E_{pa} = -0.67$ $\Delta E_p = 0.51$, $E_{1/2} = 0.925$

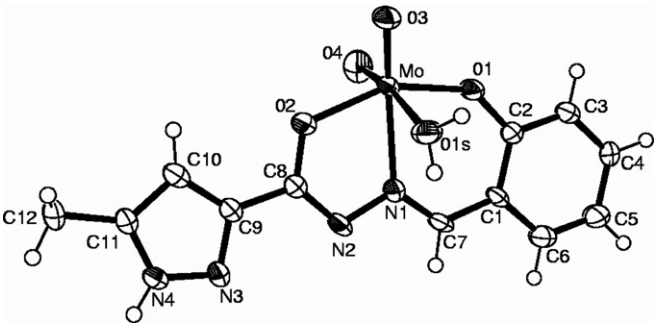

Fig. 3. ORTEP diagram of complex **1a** (50% thermal ellipsoid).

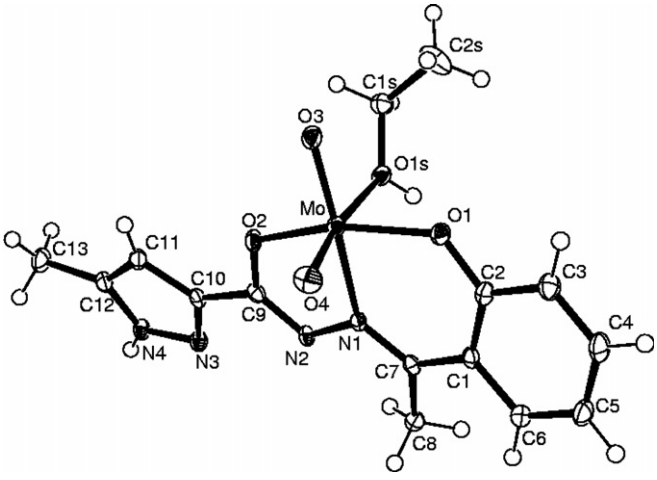

Fig. 4. ORTEP diagram of complex **2** (50% thermal ellipsoid).

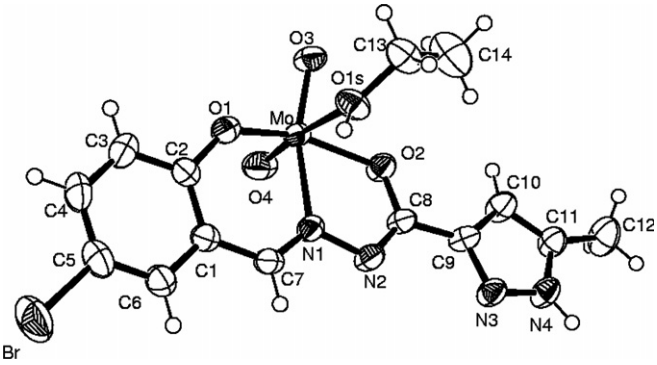

Fig. 5. ORTEP diagram of complex **3** (50% thermal ellipsoid).

binding through the phenolate oxygen (O1), the enolate oxygen (O2) and the imine nitrogen (N1) and occupies three positions in the meridional *XY* plane [43,47]. One oxo group (O3) is located *trans* to the imine nitrogen in the same plane. The other oxo group (O4) is located in the axial plane with the solvent molecule (EtOH, H_2O or DMF). The molybdenum is found to be deviated from the mean equatorial plane of O3, O2, O1 and N1 by 0.278–0.310 Å. The maximum deviation was observed in structure **2** and the minimum in structure **1a**. The Mo–O (H_2O, EtOH) bond lengths in structures **1a**, **2**, **3** are all

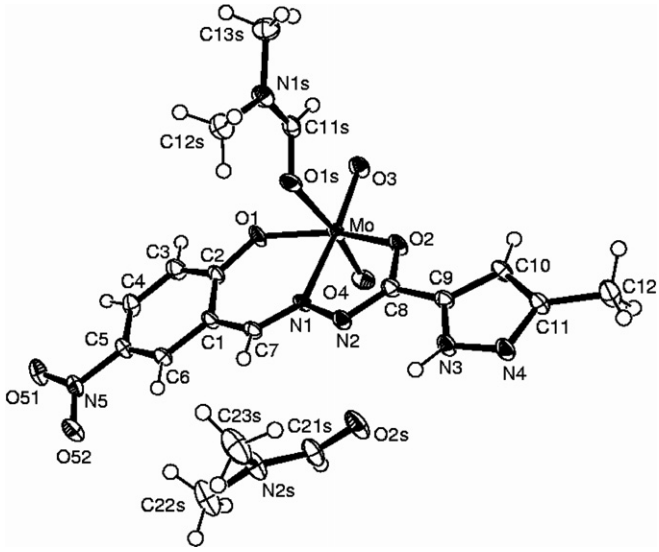

Fig. 6. ORTEP diagram of complex **4a** (50% thermal ellipsoid).

longer than the normal single bond lengths (2.30–2.35 Å against 1.9–2.0 Å). This shows that the solvent molecule is loosely attached to the Mo(VI) center. In structure **4a** the Mo–O (DMF) bond is comparatively shorter (2.26 Å) indicating that DMF acts as a better coordinating ligand. This also explains the exchange of solvent molecule (EtOH by DMF) in a DMF solution of complex **4** to give crystals of **4a**. The Mo–O(3), Mo–O(4) bond lengths are similar to other MoO_2^{2+} cores [3,48,49]. The bond between Mo and the azomethine nitrogen (N1) in the complexes are within a range of 2.22–2.25 Å which is comparatively longer than other Mo–N single bonds. This is due to the *trans* effect generated by the oxo group *trans* to the Mo–N(1) bond. The C(8)–O(2) bond length in **1a**, **3**, **4a** and the corresponding C(9)–O(2) length in **2** are 1.318–1.325 Å, which is closer to single bond length rather than C–O double bond length. However, the shorter length compared to C–O single bond may be attributed to extended electron delocalization in the ligands. Similarly shortening of C(8)–N(2) length in **1a**, **3**, **4a** and the corresponding C(9)–N(2) in **2** (1.306–1.29 Å instead of normal 1.385 Å) together with the elongation of N(2)–N(1) length also supports the electron cloud delocalization in the ligand system [50,51]. Each ligand molecule forms a five-membered and a six-membered ring with the Mo center. The electron donating capacity of the ligands does not influence the bond distances of the coordination sphere.

While examining the packing pattern in the crystals it was observed that in the crystals of **2** and **3** the heterocyclic pyrazole residue plays a vital role in building the H-bonded supramolecular structure of the crystals. The tertiary N atom of the pyrazole moiety is found to be intermolecularly H-bonded to the H atom of the coordinated O–H group of the weakly bonded ethanol. Again the H atom of the secondary nitrogen (N4) is found to be H-bonded with one of the oxo group of the MoO_2^{2+} core (Fig. 7).

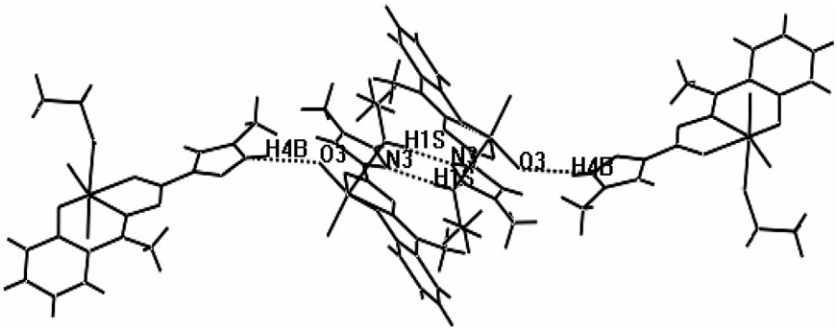

Fig. 7. Hydrogen bonding in complex **2** showing two types of interaction between [N(4)–H(4B)–O(3)] and [O(1S)–H(1S)–N(3)].

Packing pattern in the other two crystals (**1a**, **4a**) is quite different which may be attributed to the difference in their sixth coordination position. In **1a**, three intermolecular H-bonding interaction may be perceived between H atom of H_2O and azomethine nitrogen (N2) of another molecule, between H atom of water and the axial oxo atom (O4) and another weaker one between H atom of pyrazole nitrogen (N4) and the ligated phenolate oxygen (O1) (Table 2A). The packing in the crystals is also governed by a supramolecular π–π interaction involving the stacking of benzene rings as well as the pyrazole ring systems. This is observed when the molecules subjected through a translation symmetry operation along the X-axis (see Supplementary material).

The crystal structure **4a** contains one solvated DMF molecule along with one ligated DMF molecule per unit. The solvated DMF molecule is engaged in a H-bonding interaction involving the H atom of secondary pyrazole nitrogen (N3) and its oxygen (O2S). On a closer inspection, it is observed that solvated and ligated DMF molecules make solvent channels in this crystal.

4. Conclusion

A very common but facile way has been employed to synthesize the four Mo(VI) complexes. In all the complexes, the various Schiff base ligands differ only in the carbonyl part (in **1** and **2**) or by bearing different substituents at the phenyl ring (in **1**, **3** and **4**). The electron donating capacity of the ligands is related to the nature of the substituents. As the electron withdrawing capacity among H, Br and NO_2 follows the sequence H (in **1**) < Br (in **3**) < NO_2 (in **4**), in the corresponding complex, the Mo(VI) center becomes gradually electron poor. As a consequence, a less negative potential is necessary for reduction of the metal center. Again, between H (in **1**) and $-CH_3$ (in **2**), the latter being more electron donating, the metal center in **2** becomes more electron rich compared to that in **1**, for which **2** demands more negative potential to carry out the reduction process. Thus, since **4** is found to be most easily reducible Mo(VI) complex, we have chosen it to follow the oxotransfer reaction at room temperature leading to the Mo(IV) complex.

Mitigating repulsions in close quarters: Copper tells us how!

Ritu Ahuja, M. Nethaji, A.G. Samuelson *

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

Abstract

Four copper(I) complexes of short bite ligands, bis(diphenylphosphino)amine (dppa) and bis(diphenylphosphino)isopropylamine (dppipa) were synthesized from appropriate precursors. All complexes were characterized by single crystal X-ray crystallography and spectroscopic techniques. In each of these complexes, two filled shell cations are forced into close proximity (≈2.7–2.8 Å). With no strong π acid ligands to siphon electron density from the filled d shell, the unavoidable repulsive d^{10}–d^{10} interaction is mitigated when an unsymmetrical coordination environment around the copper atoms exists. The coordinatively saturated copper ion functions as a donor to the coordinatively unsaturated copper. A Cambridge Structural Database (CSD) search reveals the greater propensity of clusters with short contacts to adopt unsymmetrical coordination.

1. Introduction

Closed shell interactions in inorganic chemistry have been a challenge to experimental and theoretical chemists alike [1,2]. Group 11 monocations have been the subject of innumerable studies for they form many polynuclear complexes and extended lattices with short contacts in the solid state despite the formally closed shell (d^{10}) electronic configuration of the metals involved. The nature of this closed shell interaction has been an area of considerable debate. In the case of gold, the attractive nature of this interaction has been particularly well documented and accepted. The term ''aurophilicity'' is used to collectively describe Au–Au interactions [3–6]. Some of these interactions are unsupported by exogenous ligands. This attractive interaction has found its theoretical justification in the ligand-induced [7] and relativistically-supported [8] stabilization, which leads to favorable mixing of the empty 6s with 5d states to effectively reduce the population of the 5d valence shell. Whereas in the lighter congeners, the existence of analogous cuprophilicity and argentophilicity [1,4,5,9] have not been substantiated by many ligand-unsupported M(I)–M(I) (M = Cu, Ag) contacts in coordination compounds. Very short distances, for example 2.42 Å between two copper centers has been observed by White et al. [10] in a complex with a short bite ligand 2-((6-methyl)pyridyl)trimethylsilylamine. Another example of an unusually short Cu(I)–Cu(I) distance (2.35 Å) [11] is found in [Cu(tolyl-*NNNNN*-tolyl)]$_3$. This complex has been analyzed at different levels of theory and the Cu–Cu interaction has been shown to be attractive as a result of $s + p_z + d_{z^2}$ mixing [12]. In the few unsupported short contacts, strong electrostatic interactions between the subunits cloud the analysis. This has resulted in a controversy about the degree of stabilization, if any, offered by metal–metal contacts in ligand supported cases.

We have examined in this study, four complexes of a diphosphinoamines of the type $Ph_2PN(R)PPh_2$ (dppa; R = H, dppipa; R = ^{i}Pr). These ligands are well known for their short bite [13], which force short metal–metal contacts. There would be considerable difficulty in accommodating

doi:10.1016/j.poly.2006.08.004

the short-bite of the ligand with the closed shell repulsion of Cu(I). Yet copper(I) adopts another route for relieving the repulsive interactions in these examples. Unsymmetrical coordination makes one copper electron rich relative to the other by the presence of an extra ligand. This makes one copper a donor and the other an acceptor and masks the otherwise repulsive interaction. The generality of this phenomenon in complexes with a short contact was brought out by analysis of data readily available in the Cambridge Structural Database (CSD) [14].

2. Results and discussion

2.1. X-ray crystal structure determinations

Complex **1** consists of a cationic dppa bridged dimer with an unsymmetrical coordination. The perspective view is represented in Fig. 1. Although Cu1 and Cu2 have 3 and 4 coordinating atoms around them respectively, including the distant copper in the coordination sphere makes the description easy to follow. Cu1 has a distorted tetrahedral geometry with P1, P3, N3 and Cu2 around it. Cu1 is merely 0.2336(1) Å from the plane formed by two P atoms (P1 and P3) and the N3 of acetonitrile. The sum of the three angles in this trigonal plane is approximately equal to 360° (see Table 1). The tetrahedral coordination is provided by the second copper atom (Cu2). Cu2 is found to adopt a severely distorted trigonal bipyramidal geometry. It has two P atoms P2, P4 and an oxygen atom of the perchlorate anion in the equatorial plane. Cu2 deviates from this plane by 0.227(1) Å. The axial ligands around Cu2 are the oxygen atom of the water (Ow1) and Cu1 subtending an angle of 166.3(2)° along this axis. Cu1 and Cu2 deviate by −2.6182(1) Å and −0.010(1) Å from the P2, P4, and O5a plane respectively, while Cu2 has a deviation of 2.9766(1) Å from the P1 P3 N3 plane. The two trigonal planes P1, P3, N3 and P2, P4, O5a, have a dihedral angle of 14.82(6) Å. The eight membered ring formed by the two PNP bridges adopts a twist boat conformation. Nitrogen atoms of the ligand are almost planar with the angles not very different from those of the free ligand. There is no significant change in the metrical parameters of the ligand on complexation (P–N bond length in the free ligand is 1.692 Å with a PNP angle of 118.9°).

Table 1
Selected bond distances (Å) and bond angles (°) for complex **1**

Bond distances			
Cu1–Cu2	2.7483(9)	Cu2–Ow1	2.189(5)
Cu1–P1	2.235(1)	Cu2–O5a	2.172(19)
Cu1–P3	2.2213(12)	P1–N1	1.676(3)
Cu1–N3	1.965(4)	P2–N1	1.676(3)
Cu2–P2	2.2645(12)	P3–N2a	1.673(3)
Cu2–P4	2.2632(13)	P4–N2a	1.688(3)
Bond angles			
P1–Cu1–P3	131.95(5)	P2–Cu2–P4	139.46(5)
P1–Cu1–N3	107.56(13)	P2–Cu2–Ow1	101.50(15)
P3–Cu1–N3	116.87(13)	P4–Cu2–Ow1	98.80(14)
P1–Cu1–Cu2	95.87(4)	O5a–Cu2–Ow1	58.4(5)
P3–Cu1–Cu2	98.69(4)	O5a–Cu2–Cu1	108.4(5)
N3–Cu1–Cu2	93.49(14)	Ow1–Cu2–Cu1	166.31(17)
P2–Cu2–O5a	111.1(5)	P1–N1–P2	122.2(2)
P2–Cu2–Cu1	81.65(3)	P3–N2a–P4	121.8(2)
P4–Cu2–O5a	109.4(5)		

The second ClO_4^- is found outside the coordination sphere. The counter anion ClO_4^- shows weak intermolecular hydrogen bonding interactions with the aromatic protons, H of the acetonitrile and the NH protons. The bound water is found to have a short contact with a phenylic proton as well. Some of the short contacts are listed in the Supplementary information (Table S1).

The ORTEP plot of the dication of complex **2** is given in Fig. 2 and shows that complexes **1** and **2** are similar. Cu1 is

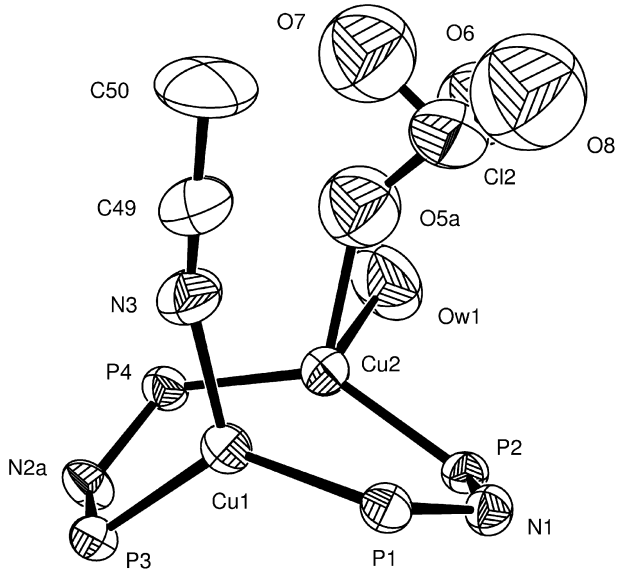

Fig. 1. Cationic fragment of complex **1** $[Cu_2(dppa)_2(CH_3CN)(H_2O)(OClO_3)]ClO_4$ with a Cu–Cu distance of 2.7483(9) Å (phenyl rings on phosphorus and hydrogen atoms removed for clarity).

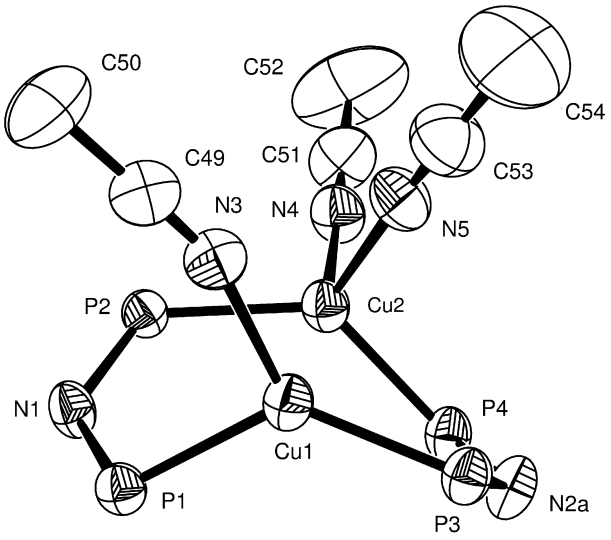

Fig. 2. Cationic fragment of complex **2** $[Cu_2(dppa)_2(CH_3CN)_3](BF_4)_2$ with a Cu–Cu distance of 2.8215(8) Å (phenyl rings on phosphorus and hydrogen atoms removed for clarity).

found in a severely distorted tetrahedral geometry. Cu1 deviates by −0.2237(5) Å from the P1, P3, N3 plane and Cu2 forms the fourth coordination site of the tetrahedron. The second metal atom Cu2 adopts an irregular trigonal bipyramidal geometry with Cu2 being −0.352(1) Å away from the P2, P4, N5 plane. The axial sites are occupied by Cu1 and N4 (CH_3CN) subtending an angle of 166.92(9)° at Cu2 (Table 2). The two counter anions lie far from the metal center.

Cu1 and Cu2 deviate by 2.4525(5) Å and −0.352(1) Å from the P2, P4, N5 plane respectively, −0.2237(5) Å and −3.043(1) Å from the P1, P3, N3 plane respectively. The two planes P1, P3, N3 and P2, P4, N5 have a dihedral angle of 6.92(7) Å. The short contacts formed by BF_4^- with phenylic protons and NH protons do not appear to affect the structure significantly and are listed in the Supplementary information (Table S2).

The movement of the two Cu atoms in complex **1** towards one other is quite striking. Complex **1** is also remarkable for it is the first example of a Cu(I) complex having a water molecule and a phosphine in the coordination sphere. Surprisingly, in spite of very similar synthetic conditions, they have different ancillary donors and Cu–Cu distances. Recently, an analogous complex with PF_6^- was characterized in both symmetrical (Cu–Cu distance = 3.341(2) Å) and unsymmetrical environments (Cu–Cu distance = 2.869(4) Å) [15]. Significantly, the shorter distance is associated with the unsymmetrical structure. While the unsymmetrical structure has donors similar to **2**, an entirely different orientation of the ligand leads to shorter Cu–Cu distance (2.8215(8) Å) in **2**. In **1** and **2**, the complex is coordinatively unsaturated in one of the metal centers although excess acetonitrile is present during the synthesis.

In a related study with the ligand dppipa, we isolated complexes **3** and **4**. The ORTEP plot of the dppipa complexes **3** and **4** are shown in Figs. 3 and 4 respectively. The two halide (chloride and bromide) dimers have highly unsymmetrical structures. There are two dppipa units, out of which one is found in a chelating and the other one in a bridging mode. Important bond lengths and bond angles for complex **3** and **4** are given in Tables 3 and 4 respectively. Both complexes have Cu–Cu distances within the sum of the Van der Waal's radii. The chloride complex **3** has two copper centers at a distance of 2.7664(14) Å and the bromide complex **4** has a Cu–Cu distance of 2.7675(8) Å.

In complex **3**, Cu1 has three of its coordination sites occupied by P1, P4 and Cl1 (bridged). The fourth coordination site is held by P3 at a comparatively longer distance of 2.263(1) Å. The other copper, Cu2 is trigonal planar with Cl1, Cl2 and P2 in its coordination sphere with sum of the three angles close to 360°. The two trigonal planes P2, Cl1, Cl2 and P1, P4, Cl1 are hinged by a chloride bridge, Cl1 and the dihedral angle is 69.59(2)°. The deviations of Cu1 and Cu2 from P1, P4, Cl1 planes are −0.358(1) Å and 2.115(1) Å respectively. On the other hand, Cu1 and Cu2 deviate by 2.161(1) Å and 0.1883(6) Å from P2, Cl1, Cl2 plane respectively. This indicates that Cu2 moves towards Cu1 in a cuprophilic fashion.

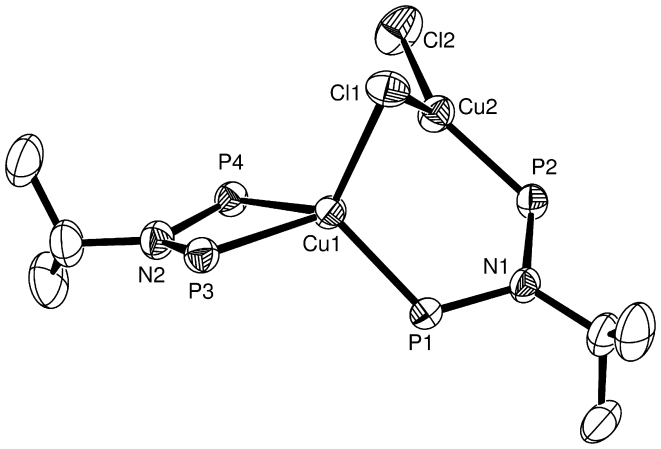

Fig. 3. Complex **3** $[Cu_2(dppipa)_2(Cl)_2]$ with a Cu–Cu distance of 2.7664(14) Å (phenyl rings on phosphorus and hydrogen atoms removed for clarity).

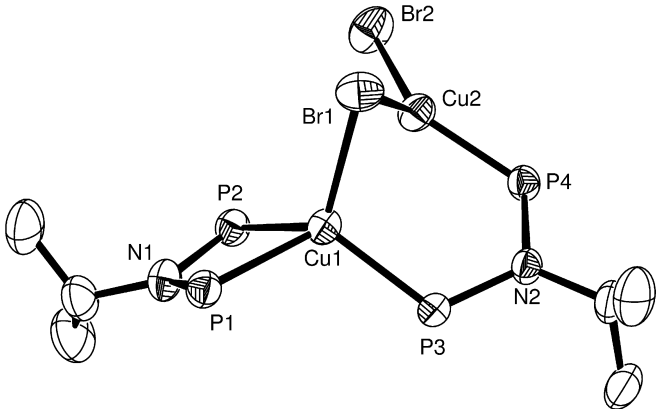

Fig. 4. Complex **4** $[Cu_2(dppipa)_2(Br)_2]$ with a Cu–Cu distance of 2.7675(8) Å (phenyl rings on phosphorus and hydrogen atoms removed for clarity).

[a] Bridging dppipa.
[b] Chelating dppipa.
[c] Terminal Br^-.
[d] Bridging Br^-.

Similarly in case of complex **4**, there are two trigonal planes Br1, Br2, P4 and P2, P3, Br1 (common vertex at Br1) at a dihedral angle of 67.66(2)°. Cu1 is four coordinate with three coordination sites, Br1, Br2 and P3 almost in a plane with a weak interaction at a distance of 2.3404(12) Å with P1. Cu1 and Cu2 deivate by 0.3613(4) Å and −2.1246(6) Å from P2, P3, Br1 plane respectively. The three coordinate Cu2 deviates by 0.2346(6) Å from Br1, Br2, P4 plane with Cu1 deviating by 2.2484(4) Å from the same plane. In this case also, one can find Cu2 moving towards Cu1.

One would expect the Cu–Cu distance in the case of the bromide bridged dimer to be longer than in the case of analogous chloride complex due to larger size of the bridging bromide ion. Surprisingly the two Cu–Cu distances are not very different. This behavior is reminiscent of the behavior of copper in trimeric complexes [16]. The greater π-donation of bridging chloride ligands leads to larger Cu–Cu distances.

2.2. Solution behavior

One expects that complex **1** would exhibit conductivity corresponding to a 1:1 electrolyte and complex **2** would show conductivity corresponding to that of a 1:2 electrolyte [17]. Indeed complex **2** showed a conductivity value of 220.64 S cm^{-1} mol^{-1} (10^{-3} M in acetone), which shows that it is a 1:2 electrolyte. On the other hand complex **1** gave a value of 203.64 S cm^{-1} mol^{-1} (10^{-3} M in acetone), which was considerably higher than that of a 1:1 electrolyte suggesting significant dissociation in solution. This observation clearly indicates that the perchlorate anion, which is η^1-bound to the metal center, dissociates in solution and a 1:2 electrolyte is formed. The dissociation of the perchlorate in solution suggests that the structure in solution could be symmetrical even though the solid state structure is unsymmetrical.

2.3. Cambridge Structural Database analysis

To probe the frequency of unsymmetrical coordination, we explored the CSD and found 1227 instances where Cu–Cu distances were below 2.8 Å. Out of these, 829 fragments were obtained when the search was limited to "symmetrical" dimers with coordination numbers 2,2; 3,3 and 4,4, etc. Among these symmetrically coordinated fragments, 530 of them have coordination numbers up to 4,4. The remaining have higher coordination numbers. Fragments with coordination number of four each (221) were analyzed in detail. Although the CSD lists them as having the same coordination number, and it was found that about 76% (163) have an unsymmetrical coordination by virtue of different coordinating atoms or very different bond distances around the metal centers. In addition, these apparently "symmetrically bridged" compounds several (143 out of 221) have single atom bridges with acute angles in structures that lead to 3c–$2e^-$ bonds and so promote attractive Cu–Cu interactions.

On the contrary, unsymmetrical coordination occurred in 398 cases, which accounts for about one-third of the total number. Of these, 305 fragments have coordination number less than or equal to 4. There are 142 hits for coordination number 3 and 4, 119 hits with coordination numbers 2 and 3 and the remaining 44 have 2 and 4 coordinate Cu^I ions. Fig. 5 represents the distribution of M–M distances in complexes with coordination numbers 3/4 and 2/3 respectively. The histograms clearly reflect a well-defined interaction between the metal ions around 2.6–2.7 Å. This is below the sum of the van der Waal's radii for two Cu^I ions (2.8 Å) suggesting the presence of an attractive interaction between the two copper(I) centers. A similar analysis of structures having Cu–Cu distances above 2.8 Å shows that the probability of encountering unsymmetrical coordination is less (1/4th).

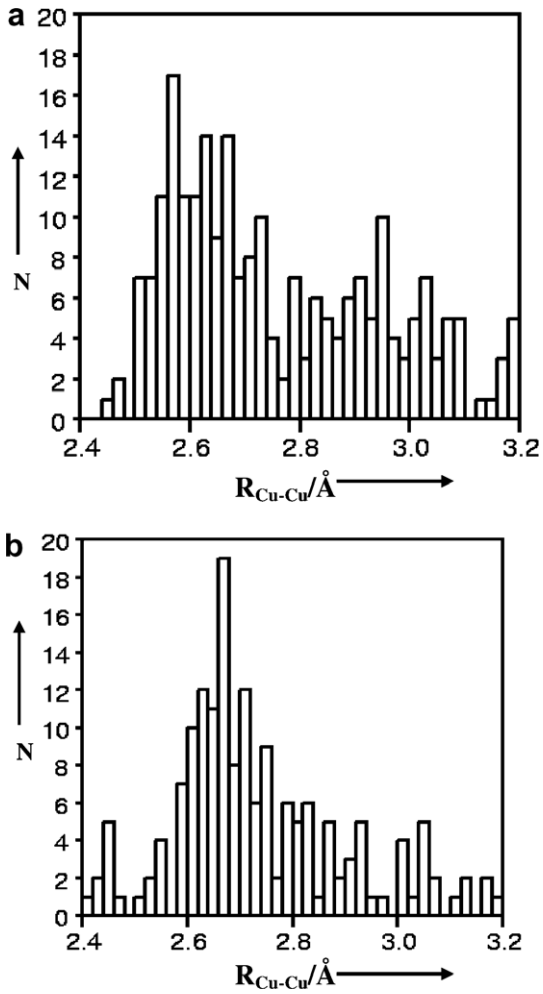

Fig. 5. Histograms of Cu–Cu distances in (a) CuL_3 and CuL_4 and (b) CuL_2 and CuL_3 complexes.

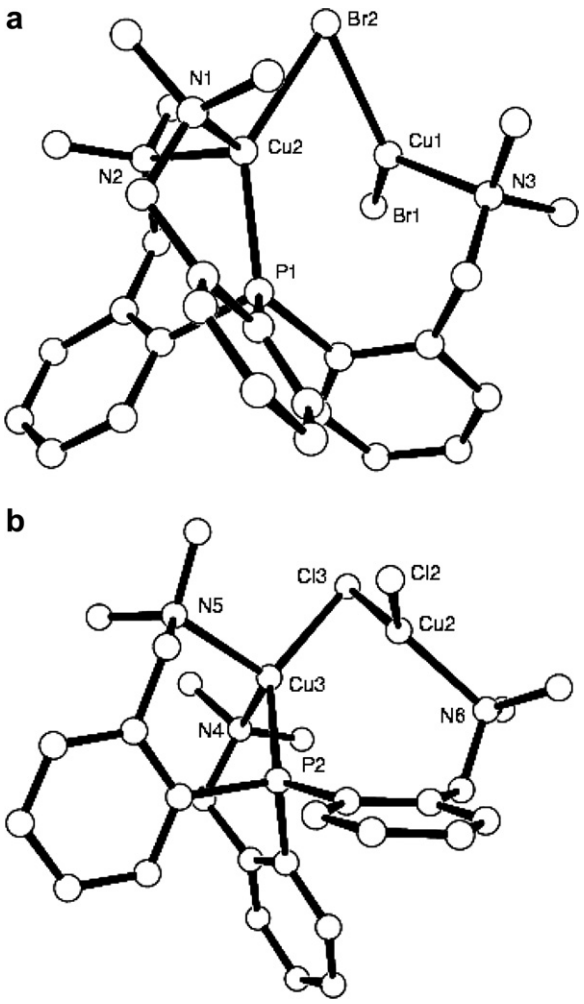

Fig. 6. Two unsymmetrical copper(I) dimers in wireframe style with refcodes: (a) CAGBIW and (b) ODODAM.

Among the complexes short listed from the CSD search, two complexes closely related to **3** and **4** were encountered with CCDC refcodes CAGBIW [18] and ODODAM [19] (Fig. 6(a) and (b)). These two structures have very similar coordination environments to those observed in the present study. The former has one copper having a coordination number of four with one bromide, two nitrogen atoms and one phosphorus bound to it. The three coordinate copper has two bromides (one terminal and one bridging) and one nitrogen in its coordination sphere. Similarly the latter structure has the three coordinate copper with two chlorides, one nitrogen and the four coordinate copper with one chloride, two nitrogen atoms and one phosphorus. The Cu–Cu distances are 2.658 and 2.665 Å respectively. These two examples again augment the fact that complexes that have Cu–Cu distances within the sum of the Van der Waal's radii of two copper centers tend to be unsymmetrically coordinated. A survey of short metal–metal contacts in systems with incomplete d shells, invariably reflected lesser preference for forming unsymmetrical dimers in comparison with the formation of symmetrical structures.

3. Conclusions

As expected for the short bite dppa as well as dppipa ligands, dinuclear copper(I) complexes formed have two copper(I) centers close to each other. In the absence of significant π-acceptor character in the ligand, such a short Cu–Cu distance is clearly repulsive and is forced by the ligand. Due to the plasticity of the coordination sphere in monovalent group 11 complexes, a change in the coordination number is energetically accessible. Hence, the coordination environment around only one of the copper(I) ions is altered to give a 4 coordinate–3 coordinate system. The four coordinate copper(I) can act as an electron donor and pump some electron density into a coordinatively unsaturated three coordinate copper. Computational work to justify this statement is underway. A CSD analysis reveals more frequent occurrence of unsymmetrical coordination in complexes with short contacts. Four complexes investigated in the present study along with two of the closely related copper(I) dimers with ((dimethylaminomethyl)phenyl)phosphine-*N*,*N*′,*N*″,*P* ligand and analogous

hexafluorophosphate copper(I) dppa dimers reinforce the importance of unsymmetrical coordination in relieving the repulsion between two closed shells. In spite of closed shell repulsions, a close contact results because the resourceful copper(I) adopts unsymmetrical coordination!

4. Experimental

4.1. General remarks

Dichloromethane, diethyl ether, acetonitrile, petroleum ether (b.p. 60–80 °C) and benzene (Caution: benzene is carcinogenic and should be handled with extreme caution!) were purified and dried under nitrogen atmosphere by conventional methods [20]. Bis(diphenylphosphino)amine [21] and bis(diphenylphosphino)isopropylamine [22] were synthesized using existing procedures and were further purified using column chromatography. $[Cu(CH_3CN)_4]ClO_4$ [23], $[Cu(CH_3CN)_4]BF_4$ [24], CuCl [25] and CuBr [26] were prepared by reported methods. All manipulations were carried out under an atmosphere of purified N_2 using a standard double manifold and Schlenk ware.

4.2. Physical measurements

^1H NMR spectra were recorded either on a Bruker ACF 200 MHz or AMX 400 MHz spectrometer with tetramethylsilane (TMS) as the internal reference. $^{31}P\{^1H\}$ NMR spectra were recorded either on a Bruker AMX 400 MHz spectrometer operating at 162.2 MHz or a Bruker ACF 200 MHz operating at 81.1 MHz with H_3PO_4 (85%) as the external reference. IR spectra were recorded in the solid state as KBr pellets on an Equinox 55 Bruker spectrometer. Elemental analyses were recorded with a Carlo Erba Elemental Analyzer model 1106 and HRESMS on Micromass Q-Tof micro. The conductivity measurements were carried out with a Control Dynamics Conductivity Meter with KCl (10^{-3} M) used as a standard solution.

4.3. Synthesis of complexes

Complex **1**: dppa (0.19 g, 0.5 mmol) was added to 15 ml CH_2Cl_2 containing $[Cu(CH_3CN)_4]ClO_4$ (0.16 g, 0.5 mmol) and stirred for 1 h at room temperature. Subsequently the solution was concentrated to about 7 and 15 ml of diethyl ether was allowed to diffuse through the solution to obtain colorless crystals (yield: 86%). ^1H NMR ($CDCl_3$, 25 °C): $\delta = 1.98$ (s, 3H, CH_3CN), 4.13 (s, 2H, NH), 7.12–7.43 (m, 40H, Ph); $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = 46.3$ (s); IR (KBr, cm^{-1}): 2303 (w), 2270 (w) (CH_3CN); 1099 (vs, br) 1064 (br) (ClO_4^-). Elemental *Anal.* Calc. for $Cu_2C_{50}H_{45}N_3P_4Cl_2O_8 \cdot H_2O \cdot CH_2Cl_2$: C, 49.15; H, 3.74; N, 3.16. Found: C, 49.3; H, 3.95; N, 3.38%.

Complex **2**: A similar procedure was adopted except that $[Cu(CH_3CN)_4]BF_4$ (0.15 g, 0.5 mmol) was used for the reaction which afforded colorless crystals (yield: 88%). ^1H NMR ($CDCl_3$, 25 °C): $\delta = 1.98$ (s, 9H, CH_3CN), 4.63 (s, 2H, NH), 7.12–7.45 (m, 40H, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = 47.8$ (s). IR (KBr, cm^{-1}): 2303 (w), 2264 (w) (CH_3CN); 1102, 1052 (vs, br) (BF_4^-). HRESMS: $[M-(CH_3CN)_3]^{2+}$ obsd. m/z 448.0487, calc. for $C_{48}H_{42}N_2P_4$ 448.0445.

Complex **3**: To 15 ml of CH_2Cl_2 was added dppipa (0.22 g, 0.50 mmol) followed by the addition of CuCl (0.025 g, 0.25 mmol). The reaction was stirred at room temperature for half an hour. Subsequently the obtained yellow colored solution was concentrated to 2 ml and about 7 ml of petroleum ether was allowed to diffuse through the dichloromethane solution. Bright yellow colored shaped crystal were obtained in about 10–12 h (yield: 91%). ^1H NMR ($CDCl_3$, 25 °C): $\delta = 0.06$, 0.50 (d, 6H, Me of ^{i}Pr) (1:1), 3.57 (sep., 2H, br, –CH of ^{i}Pr), 6.98–7.49 (m, 40H, Ph). $^{31}P\{^1H\}$ NMR: $\delta = 77.1$ (w), 55.9 (s). Elemental *Anal.* Calc. for $Cu_2C_{54}H_{54}N_2P_4Cl_2 \cdot 0.5CH_2Cl_20.5H_2O$: C, 59.26; H, 5.07; N, 2.54. Found: C, 59.28; H, 5.06; N, 2.53%.

Complex **4**: A similar procedure was adopted except that CuBr (0.036 g, 0.25 mmol) was used for the reaction that gave bright yellow single crystals (yield: 91%). ^1H NMR ($CDCl_3$, 25 °C): $\delta = 0.05$, 0.44 (d, 6H, Me of ^{i}Pr) (1:1), 3.54 (sep., 2H, br, –CH of ^{i}Pr), 6.97–7.51 (m, 40H, Ph). $^{31}P\{^1H\}$ NMR: $\delta = 77.1$ (w), 55.9 (s). Elemental *Anal.* Calc. for $Cu_2C_{54}H_{54}N_2P_4Br_2 \cdot CH_2Cl_2$: C, 53.84; H, 4.57; N, 2.28. Found: C, 53.78; H, 4.69; N, 2.20%.

4.4. X-ray crystallographic study

Single crystals of complex **1**, **3** and **4** were mounted in a Lindemann capillary with paraffin oil and crystal of complex **2** was glued to the tip of a glass fiber along the largest dimension and coated with paraffin oil. Data were collected on a Bruker AXS single crystal diffractometer equipped with SMART APEX CCD detector and a sealed Mo Kα source working at 1.75 kW. Intensity data were collected at room temperature. Crystallographic computations were performed using the WINGX package [27]. The data were corrected for Lorentz and polarization effects. Absorption correction was applied using Psi-Scan [28] for complex **1**, **3** and **4** and SADABS [29] for complex **2**. The positions of heavy atoms were determined by SHELXS86 [30]. The remaining atoms were located from the difference Fourier map using SHELXL-97 [31]. Hydrogen atoms were geometrically fixed for all four complexes.

Single crystal structure of complex **1** ($C_{51}H_{49}Cl_4Cu_2N_3O_9P_4$): ($0.42 \times 0.40 \times 0.38$ mm^3); triclinic; $P\bar{1}$; $a = 11.0536(16)$ Å, $b = 12.3546(18)$ Å, $c = 22.106(3)$ Å, $\alpha = 78.332(3)°$, $\beta = 84.031(2)°$, $\gamma = 68.189(2)°$; $V = 2743.5(7)$ Å^3; $Z = 2$; $\rho_{calc.} = 1.502$ Mg/m^3; $\mu_{calc.} = 1.143$ mm^{-1}; $R = 0.0594$ for 10753 independent reflections with ($I > 2\sigma(I)$).

Complex **2**: $C_{54}H_{51}B_2Cu_2F_8N_5P_4$: ($0.36 \times 0.32 \times 0.20$ mm^3); triclinic; $P\bar{1}$; $a = 11.169(3)$ Å, $b = 12.349(4)$ Å, $c = 22.083(7)$ Å, $\alpha = 94.374(5)°$, $\beta = 95.555(5)°$, $\gamma = 106.850(4)°$; $Z = 2$; $\rho_{calc.} = 1.376$ Mg/m^3; $\mu_{calc.} = 0.914$ mm^{-1}; $R = 0.0519$ for 13298 independent reflections ($I > 2\sigma(I)$).

Complex **3**: $C_{55}H_{56}Cl_4Cu_2N_2P_4$: ($0.45 \times 0.4 \times 0.38$ mm^3); monoclinic; $P21/c$; $a = 21.042(10)$ Å, $b = 13.733(7)$ Å, $c = 20.649(10)$ Å, $\alpha = 90°$, $\beta = 114.365(8)°$, $\gamma = 90°$; $V = 5435(5)$ Å^3; $Z = 4$; $\rho_{calc.} = 1.390$ Mg/m^3; $\mu_{calc.} = 1.135$ mm^{-1}; $R = 0.0502$ for 12748 independent reflections with ($I > 2\sigma(I)$).

Complex **4**: $C_{55}H_{56}Br_2Cl_2Cu_2N_2P_4$: ($0.24 \times 0.22 \times 0.21$ mm^3); monoclinic; $P21/c$; $a = 21.287(3)$ Å, $b = 13.678(2)$ Å, $c = 20.660(3)$ Å, $\alpha = 90°$, $\beta = 114.071$ (2)°, $\gamma = 90°$; $V = 5492.5(15)$ Å^3; $Z = 4$; $\rho_{calc.} = 1.483$ Mg/m^3; $\mu_{calc.} = 2.481$ mm^{-1}; $R = 0.0545$ for 13015 independent reflections with ($I > 2\sigma(I)$).

Abstract

The crystal structure of $[Cu(Bic)_2]$ (**1**) ($Bic^- = N,N$-bis(2-hydroxyethyl)glycinate), was determined by single-crystal X-ray diffraction techniques. $[Cu(Bic)_2]$: monoclinic system, space group $P21/n$. In the complex, the copper atom is tetra coordinated by two oxygen atoms of the carboxylato groups and two nitrogen atoms of the bicinate ligand, forming a distorted square planar coordination geometry. The molecular structure of the complex in solution is the same as that of the crystalline state, as supported by ESR and electronic spectra in solution. The blue complex **1** on heating at ~500 °C for 6 h results in the formation of black CuO (Tenorite) micro plates.

Keywords: Copper complexes; Bicine; Metallo-organic framework; CuO micro plates

1. Introduction

Formation of metal-organic framework (MOF) structures [1] is an active area of research, as these compounds can be potentially useful in several applications [2]. In constructing MOFs, carboxylate ligands are usually selected because they may act as both counteranions and bridging ligands to extend the architecture to 1-D chain, 2-D layer and 3-D network [3].

N,*N*-bis(2-hydroxyethyl)glycine (Bicine) is popularly known as a buffer substance through the work of Good et al., after being prepared by Kiprianov in 1926 [4]. The metal ion coordinating properties of the anion of bicine, i.e. bicinate ($Bicy^-$), having two hydroxyl oxygen atoms, one carboxyl oxygen atom and one nitrogen atom, have long been recognized. Bicinate act as a tetradentate ligand. Indeed, many stability constants of binary complexes have been determined [5,6]. However, no such binary metal complex of bicinate in the solid state has been studied yet to best of our knowledge. For constructing open frameworks, a tripodal ligand bearing one carboxylate group and two alcohol groups from the bridgehead tertiary amine nitrogen has been used (Bicine).

In this work, the binary complex $[Cu(Bic)_2]$ is prepared and characterized by X-ray single crystal structural analysis. The tetra-coordinate distorted square-planer structure for this copper(II) complex is studied in detail. Formation of micro plates CuO from this metallocycle has been studied with SEM, powder X-ray diffraction.

2. Experimental

2.1. Chemicals and reagents

$Cu(OH)_2$ was freshly prepared from $CuCl_2$. The metal salt and Bicine were obtained from Aldrich and were used as received. The solvents were purified prior to use by standard procedures.

2.2. Physical measurements

The IR spectra were recorded on a Perkin Elmer-Spectrum One FT-IR spectrometer with KBr disks in the range 4000–400 cm^{-1}. The thermogravimetric analyses (TGA) of the compounds were performed by using an

doi:10.1016/j.poly.2006.08.012

SDTA 851 e TGA thermal analyzer (Mettler Toledo) with a heating rate of 2 °C per min in a N_2 atmosphere. Scanning electron micrograph (SEM) images were obtained by means of a *LEO-1430 VP* electron microscope on samples glued on an aluminum stub and gold sputtered. PXRD data were recorded with Seifert powder X-ray diffractometer (XRD 3003TT) with Cu Kα source ($\lambda = 1.54$ Å) on glass surface of an air-dried sample. X-band EPR spectra were recorded with a Jeol JES-FA series EPR spectrometer equipped with a dual cavity and operating at X-band with 100 kHz modulation frequency. TCNE ($g = 2.0028$) was used as the field marker. Optical spectra were recorded in CH_3CN on a Perkin–Elmer-Lambda 25-UV–Visible spectrometer at 298 K. The solid-state magnetic susceptibility of the complex at room temperature was recorded using a Sherwood Scientific balance MSB-1. Solution electrical conductivity measurements were made with a Systronics Conductivity meter 306. Elemental analyses were done using a Carlo Erba 1108 and also by using a Perkin–Elmer series II 2400 instrument.

2.3. Preparation of the title complex, 1

A mixture of bicine (0.326 g, 2 mmol) and freshly prepared copper hydroxide (1 mmol, 0.097 g) were ground thoroughly with a pestle in an open mortar at room temperature in air. The mixture was ground occasionally for 30 min until the mixture turned into a melt. X-ray quality blue single crystals of the Cu(II) complex (**1**) were grown from ethanol/water (1:1) mixture within two days at room temperature in quantitative yield. *Anal*. Calc. for $Cu(C_6H_{12}NO_4)_2$: C, 37.15; H, 6.23; N, 7.22. Found: C, 37.74; H, 6.41; N, 7.36%.

2.4. X-ray crystallography

The intensity data for **1** were collected using a Bruker SMART APEX-II CCD diffracto-meter, equipped with fine focus 1.75 kW sealed tube Mo Kα radiation ($\lambda = 0.71073$ Å) at 273(3) K, with increasing ω (width of 0.3° per frame) at a scan speed of 3 s/frame. SMART software was used for data acquisition and SAINT software for data extraction. Absorption corrections were done using SDABS. The structure was solved and refined using SHELX 97. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located from the difference Fourier maps and refined. Selected crystallographic data are summarized in Table 1.

3. Results and discussion

The complex **1** was synthesized using a simple acid–base reaction in the solid phase and blue crystals were obtained from an ethanol/water (1:1) mixture. The structure of the title compound was determined by single-crystal X-ray crystallography. The structure is best described as a 3-D framework of $[Cu(Bic)_2]_n$. Selected bond lengths and angles are collected in Table 2.

The molecular structure, with the atomic numbering scheme, of complex **1** is shown in Fig. 1. In complex **1** the Cu(II) atom is in an N_2O_2 coordination environment. It is ligated by four atoms: two carboxylato oxygen atoms and two bridge head tertiary amine nitrogen atoms of bicinate.

The carboxylato oxygen atoms bond more strongly with the copper atom than the bridge head tertiary amine nitrogen atoms. The complex has two five-membered N,O-chelate rings which consist of one copper atom, one carboxylato oxygen atom, one nitrogen atom and two carbon atoms. Bond angles and distances of the mononuclear complex indicate a slightly distorted square-planar coordination with a *trans*-structure. The bond distances and bond angles involving the metal ions (Table 2) are within normal statistical errors [7,8]. The shortening of the Cu–O bond lengths agree with the stronger chelating ability of the carboxylate oxygen compared to tertiary amine nitrogen atoms. All the coordination atoms and the Cu atom lie

C6–H6a···O4	2.578	3.543	173.28

exactly on the N_2O_2 mean plane. There is no deviation of the donor atoms from the basal plane. This is consistent with a square planar structure of the metal centre. The conventional strong O–H···O and unconventional weaker C–HO type intermolecular hydrogen bonding plays a major role in stabilizing the molecules in the solid state (Table 3). It forms a linear array along the *c*-axis via C–H···O type interactions involving the alcohol group (O3) nearer to the Cu atom. Each of the parallel linear arrays propagates along the *a*-axis to form a 2D network via O–H···O type interactions (see supporting information).

The overall structure looks like (Fig. 2) an array of metallocycles joined via carboxylate groups of the podand extending along the crystallographic *ab*-plane in a zig-zag fashion. In the metallocyclic units, the two Cu(II) ions show a distance of either 7.126 or 9.516 Å while the distance between the bridgehead N atoms is 6.726 Å, forming an oval-shaped cavity.

The Cu(II) complex in acetonitrile solution shows a d–d band in the region 21 881 cm^{-1} due to a $^2B_{1g} \rightarrow {}^2A_{1g}$ transition which supports the square-planar geometry. The magnetic moment of the Cu(II) complex is 1.51 BM which shows the presence of one unpaired electron. This value is lower than the spin-only value and is due to mixing of orbital angular momentum from an excited state via spin-orbit coupling. The FT-IR spectrum of the complex shows two strong and sharp bands at 3310 cm^{-1} and 3140 cm^{-1} due to O–H and N–H stretching vibrations [9]. The bands at

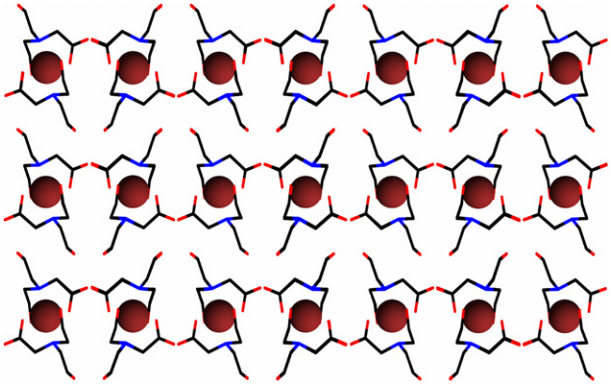

Fig. 2. Perspective view of the metallo-macrocyle in **1**, viewed along the *c*-axis.

1610 and 1405 cm^{-1} are attributed to the COO^- antisymmetric and symmetric stretching vibrations, respectively, which is confirmed by the crystal structural analysis; the carboxylato oxygen atom O(2) forms two hydrogen bonds with the hydroxyl hydrogen atoms of the neighboring units. Several new peaks appeared in the NIR region, which were absent in the ligand spectrum. The bands at 382 cm^{-1} and 318 cm^{-1} are assigned to the Cu–N and Cu–O stretching vibrations respectively. The molar conductivity measurements supported the non-electrolytic nature of complex **1**. EPR spectra of complex **1** were recorded in DMSO at 300 and 77 K. The spectrum of complex **1** at 300 K shows one intense absorption band in the high field region and is isotropic due to the tumbling motion of the molecules. However, this complex in the frozen state at 77 K shows four well-resolved peaks of low intensities in the low-field region and one intense peak in the high-field region. No band corresponding to the $Ms = \pm 2$ transition was observed in the spectrum, ruling out any Cu–Cu interactions, in the solution state. In square-planar complexes unpaired electrons lying in the $d_{x^2-y^2}$ orbital give $^2B_{1g}$ as the ground state with $g_{\|} > g_{\perp}$ while an unpaired electron lying in the d_{z^2} orbital gives $^2A_{1g}$ as the ground state with $g_{\perp} > g_{\|}$. The experimental values, $g_{\|}$ (2.341) > $g_{\perp}$ (2.041), indicates that the structure of the complex is square-planar and that the unpaired electron is predominantly in the $d_{x^2-y^2}$ orbital. The coordination in solution is thus the same as in the solid.

The PXRD patterns also confirm the crystalline nature of the complex. The macroscopic crystal shape and color of **1** remain unchanged after heating the crystals at 100 ± 1 °C for 3 h at atmospheric pressure. New powder X-ray data are collected every hour after the heat treatment. The PXRD data reveal that the crystalline nature of the complex framework is retained.

The robustness of the framework is reflected in the thermogravimetric analysis of **1** which shows negligible weight loss until about 140 °C. The sample decomposed in a number of steps. Two molecules of CO_2 were released in two well separated steps from coordinated carboxylic acid groups (150–168 °C; Δm = 11.34% calc.; 12.01% found; 176–205 °C; Δm = 12.79% calc.; 13.19% found), which is

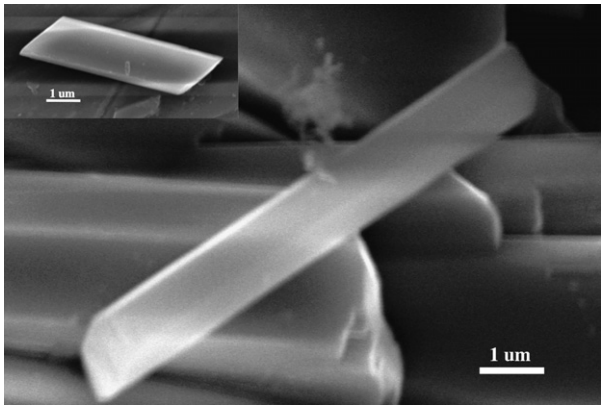

Fig. 3. Scanning electron micrograph of CuO after thermolysis of **1** at 500 °C (6 h).

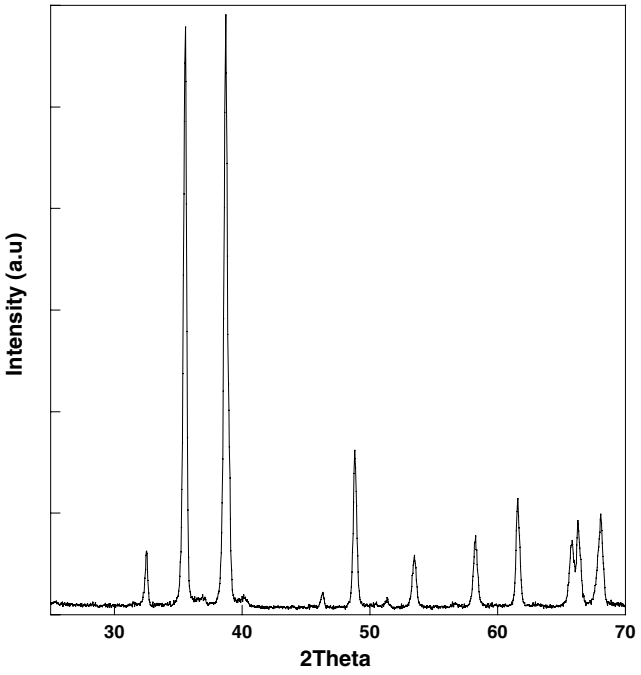

Fig. 4. Powder XRD pattern of CuO (tenorite) micro plates.

in good agreement with the X-ray crystal structure. Complete decomposition occurred at ~ 370 °C resulting in the formation of black CuO. The DSC-plot shows two exothermic peaks at 160 °C and 190 °C due to the loss of CO_2 molecules. It also shows an exothermic peak at 370 °C due to the decomposition of the complex.

Thermal decomposition of the blue colored complex **1** was carried out at 500 °C for 6 h in a muffle furnace. The reaction product, black colored copper(II) oxide, was obtained in micro-plates morphology (Fig. 3). The length and breadth of these plates range from 3 to 12 μm and 0.5 to 3 μm respectively. The average size and shape of these plates remains unchanged with longer reaction time, up to 14 h. SEM images taken of several batches of samples showed that the entire surface of the plates are clean without any fracture.

The crystallinity of these micro plates was analyzed by powder X-ray diffraction techniques. The diffraction peaks (Fig. 4) can be indexed as the Tenorite structure of CuO mineral (PDF No. 00-005-0661), indicating that the Cu(II)–bicine complex has been thermally decomposed into CuO.

X-ray diffraction pattern shows two enhanced (−111) and (111) peaks at 2θ values 35.554 and 38.731, resulting from the linear orientation of the micro plates.

4. Conclusion

We were able to synthesize and structurally characterize a binary Cu(II)–bicine complex of distorted square planar geometry. This geometry is retained in the solution too. It forms a 3D MOF made of an infinite array of Cu(II)-metallocycles in the solid state. We have also demonstrated a precursor synthesis of the Tenorite structure of CuO micro plates. The technique demonstrated here can be extended for synthesizing a wide range of inorganic materials having similar structures, which are currently ongoing in our laboratory.

Abstract

Four new ligands, (4-methyl-phenyl)-pyridin-2-ylmethylene-amine (A), (2,3-dimethyl-phenyl)-pyridin-2-ylmethylene-amine (B), (2,4-dimethyl-phenyl)-pyridin-2-ylmethylene-amine (C) and (2,5-dimethyl-phenyl)-pyridin-2-ylmethylene-amine (D), and their corresponding copper(I) complexes, $[Cu(A)_2]ClO_4$ (**1a**), $[Cu(B)_2]ClO_4$ (**1b**), $[Cu(C)_2]ClO_4$ (**1c**), $[Cu(D)_2]ClO_4$ (**1d**), $[Cu(A)(PPh_3)_2]ClO_4$ (**2a**), $[Cu(B)(PPh_3)_2]ClO_4$ (**2b**), $[Cu(C)(PPh_3)_2]ClO_4$ (**2c**) and $[Cu(D)(PPh_3)_2]ClO_4$ (**2d**), have been synthesized and characterized by CHN analyses, ^1H and ^{13}C NMR, IR and UV–Vis spectroscopy. The crystal structures of $[Cu(B)_2]ClO_4$ (**1b**), $[Cu(C)_2]ClO_4$ (**1c**) and $[Cu(A)(PPh_3)_2]ClO_4 \cdot 1/2CH_3CN$ (**2a**) were determined from single crystal X-ray diffraction. The coordination polyhedron about the copper(I) center in the three complexes is best described as a distorted tetrahedron. A quasireversible redox behavior is observed for the complexes.

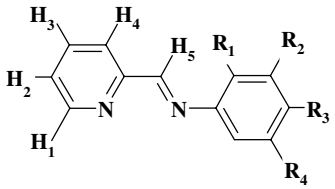
Keywords: 2-Pyridinecarbaldehyde; Diimine ligands; Copper(I) complexes; Distorted tetrahedral structure

1. Introduction



Monovalent copper (d^{10}) chemistry has drawn special attention because of its instability, unusual structural features, utility in solar energy and supramolecular devices, catalytic activity in photoredox reactions and the biological relevance of high potential copper complexes [1–8]. Most of the studies have been on four-coordinated tetrahedral Cu(I) complexes of the type $[Cu(LL)_2]^+$ or $[Cu(LL)(P)_2]^+$ where LL is a diimine and P is a phosphine, because of interdependence of their coordination geometry and their redox and photochemical behavior [9–12]. Recent reports have indicated that steric crowding and π-acidity in a well designed ligand are the most important prerequisites for the stability of copper(I) complexes and their redox, photophysical and photochemical behavior [13–16].

Although the coordination chemistry of symmetrical chelating diimines [e.g., 2,2-bipyridine, 1,10-phenanthroline and 2,9-dimethyl-1,10-phenanthroline] with copper(I) has been extensively studied [9,17–20], there are few data on complexes with unsymmetrical diimine ligands containing iminopyridine [21–26].

In a continuation of our work on the preparation of copper(I) diimine complexes with low lying MLCT transitions [27–29], here we report the synthesis and characterization of four ligands with extended conjugation, and their copper(I) complexes (Fig. 1). The structures, spectral properties and redox chemistry of these complexes are also discussed.

2. Experimental

2.1. General

Caution! Perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled with care.

All chemicals used were reagent grade and used as received. Solvents used for the reactions were purified by literature methods [30]. $[Cu(CH_3CN)_4]ClO_4$ was prepared according to the literature procedure [31].

Elemental analyses were performed by using a Heraeus CHN-O-RAPID elemental analyzer. Infrared spectra were recorded on a Bruker Tensor 27 instrument. Electronic absorption spectra were recorded on a JASCO V-570 spectrophotometer; λ_{max} ($\log\varepsilon$). NMR spectra were obtained on a BRUKER AVANCE DRX500 (500 MHz) spectrometer. Proton chemical shifts are reported in part per million (ppm) relative to an internal standard of Me_4Si. All voltammograms were recorded with a three electrodes system consisting of an Ag/AgCl reference electrode, a platinum wire counter electrode, and Au as a working electrode. A Metrohm multipurpose instrument model 693 VA processor with 694A Va stand was used. In all electrochemical experiments the test solution was purged with argon gas for at least 5 min.

2.2. Synthesis

2.2.1. (4-Methyl-phenyl)-pyridin-2-ylmethylene-amine (A)

To a solution of pyridine-2-carbaldehyde (107 mg, 1 mmol) in 10 ml diethylether was added a solution of 4-methylaniline (107 mg, 1 mmol) in 10 ml diethylether and the resulting mixture was stirred for 2 h. The ligand (4-methyl-phenyl)-pyridin-2-ylmethylene-amine was obtained as a white microcrystalline precipitate. It was then filtered off, washed with cold diethylether, and dried in air. Yield: 172 mg (90%). IR (KBr): 1623 cm^{-1} ν(C=N). ^1H NMR (500 MHz, $CDCl_3$): 2.31 (s, 6H, $2CH_3$), 6.85–7.15 (m, 3H, ArH, amine ring), 7.32 (dd, 1H, $J_{H1,2} = 4.75$, $J_{H2,3} = 7.50$, H_2), 7.79 (*t*, 1H, $J_{H3,2} = 7.50$, $J_{H3,4} = 7.75$, H_3), 8.19 (d, 1H, $J_{H4,3} = 7.75$, H_4), 8.62 (s, 1H, H_5), 8.69 (d, 1H, $J_{H2,1} = 4.75$, H_1). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 21.04 ($^{13}CH_3$), 121.12, 121.74, 124.91, 129.85, 136.54, 136.69, 148.37, 149.63, 154.77, 159.62 (^{13}C=N). *Anal.* Calc. for $C_{13}H_{12}N_2$: C, 79.56; H, 6.16; N, 14.27. Found: C, 79.55; H, 6.17; N, 14.28%.

2.2.2. (2,3-Dimethyl-phenyl)-pyridin-2-ylmethylene-amine (B)

This ligand was prepared by a procedure similar to **1** using 121 mg (1 mmol) of 2,3-dimethylaniline. Yield: 190 mg (90%). IR (KBr): 1630 cm^{-1} ν(C=N). ^1H NMR (500 MHz, $CDCl_3$): 2.31 (s, 6H, $2CH_3$), 6.85–7.15 (m, 3H, ArH, amine ring), 7.32 (dd, 1H, $J_{H1,2} = 4.12$, $J_{H2,3} = 7.30$, H_2), 7.76 (*t*, 1H, $J_{H3,2} = 7.30$, $J_{H3,4} = 7.90$, H_3), 8.24 (d, 1H, $J_{H4,3} = 7.90$, H_4), 8.50 (s, 1H, H_5), 8.68 (d, 1H, $J_{H2,1} = 4.12$, H_1). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 13.90 (3-$^{13}CH_3$), 21.12 (2-$^{13}CH_3$), 115.43, 121.62, 124.98, 126.16, 127.98, 130.77, 136.58, 137.56, 149.56, 150.10, 155.01, 159.77 (^{13}C=N). *Anal.* Calc. for $C_{14}H_{14}N_2$: C, 79.97; H, 6.71; N, 13.32. Found: C, 79.99; H, 6.70; N, 13.35%.

2.2.3. (2,4-Dimethyl-phenyl)-pyridin-2-ylmethylene-amine (C)

This ligand was prepared by a procedure similar to **1** using 121 mg (1 mmol) of 2,4-dimethylaniline. Yield: 185 mg (88%). IR (KBr): 1629 cm^{-1} ν(C=N). ^1H NMR ($CDCl_3$; δ): 2.33 (s, 3H, 4-CH_3), 2.37 (s, 3H, 2-CH_3), 6.93–7.05 (m, 3H, ArH, amine ring), 7.33 (dd, 1H, $J_{H1,2} = 4.5$, $J_{H2,3} = 7.50$, H_2), 7.76 (*t*, 1H, $J_{H3,2} = 7.50$, $J_{H3,4} = 8.00$, H_3), 8.24 (d, 1H, $J_{H4,3} = 8.00$, H_4), 8.50 (s, 1H, H_5), 8.68 (d, 1H, $J_{H2,1} = 4.12$, H_1). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 17.78 (4-$^{13}CH_3$), 20.96 (2-$^{13}CH_3$), 117.28, 121.54, 124.86, 127.3, 131.21, 132.49, 136.26, 136.55, 147.43, 149.53, 155.08, 159.03 (^{13}C=N). *Anal.* Calc. for $C_{14}H_{14}N_2$: C, 79.97; H, 6.71; N, 13.32. Found: C, 79.96; H, 6.70; N, 13.35%.

2.2.4. (2,5-Dimethyl-phenyl)-pyridin-2-ylmethylene-amine (D)

This ligand was prepared by a procedure similar to **1** using 121 mg (1 mmol) of 2,5-dimethylaniline. Yield:

200 mg (95%). IR (KBr): 1629 cm^{-1} ν(C=N). ^1H NMR ($CDCl_3$; δ): 2.34 (s, 3H, $2CH_3$), 6.83–7.13 (m, 3H, ArH, amine ring), 7.34 (dd, 1H, $J_{H1,2} = 4.8$, $J_{H2,3} = 7.65$, H_2), 7.79 (*t*, 1H, $J_{H3,2} = 7.65$, $J_{H3,4} = 7.90$, H_3), 8.24 (d, 1H, $J_{H4,3} = 7.90$, H_4), 8.50 (s, 1H, H_5), 8.69 (d, 1H, $J_{H2,1} = 4.80$, H_1). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 17.70 (5-$^{13}CH_3$), 20.99 (2-$^{13}CH_3$), 118.31, 121.57, 124.97, 127.09, 129.08, 130.25, 136.35, 136.60, 149.50, 149.92, 154.91, 159.59 (^{13}C=N). *Anal.* Calc. for $C_{14}H_{14}N_2$: C, 79.97; H, 6.71; N, 13.32. Found: C, 79.96; H, 6.70; N, 13.34%.

2.2.5. *[Cu^I(A)$_2$]ClO$_4$ (**1a**)*

To a stirring solution of (4-methyl-phenyl)-pyridin-2-ylmethylene-amine, A (19.6 mg, 0.1 mmol) in 5 ml acetonitrile was added $[Cu(CH_3CN)_4]ClO_4$ (16.4 mg, 0.05 mmol) in 5 ml acetonitrile and the resulting mixture was stirred for 10 min. The solution turned dark red rapidly. The volume of the solvent was reduced under vacuum to about 4 ml. The diffusion of diethyl ether vapor into the concentrated solution gave dark-red crystals. The resulting crystals were filtered off, washed with a mixture of diethylether–acetonitrile (9:1 v/v), and dried under vacuum. Yield: 25 mg (92%). IR (KBr): 1582 cm^{-1} ν(C=N), 1090 cm^{-1} ν(Cl–O). ^1H NMR ($CDCl_3$; δ): 2.28 (s, 3H, CH_3), 7.09–7.40 (m, 4H, ArH, amine ring), 7.60 (*t*, 1H, H_2), 8.04–8.21 (m, 2H, H_3, H_4), 8.48 (d, 1H, $J_{H2,1} = 4.0$, H_1), 9.20 (s, 1H, H_5). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 21.10 ($^{13}CH_3$), 118.21, 122.48, 123.49, 128.60, 130.40, 131.25, 138.47, 139.93, 144.05, 149.09, 151.28, 156.28 (^{13}C=N). *Anal.* Calc. for $C_{26}H_{24}ClCuN_4O_4$: C, 56.22; H, 4.35; N, 10.09. Found: C, 56.23; H, 4.34; N, 10.10%.

2.2.6. *[Cu^I(B)$_2$]ClO$_4$ (**1b**)*

This complex was prepared by a procedure similar to **1a** using 21 mg (0.1 mmol) of (2,3-dimethyl-phenyl)-pyridin-2-ylmethylene-amine, B. Dark-red crystals were collected by filtration and dried *in vacuo*. Yield: 27 mg (93%). IR (KBr): 1578 cm^{-1} ν(C=N), 1095 cm^{-1} ν(Cl–O). ^1H NMR ($CDCl_3$; δ): 2.03 (s, 3H, 3-CH_3), 2.22 (s, 3H, 2-CH_3), 6.58–7.06 (m, 3H, ArH, amine ring), 7.74 (*t*, 1H, H_2), 7.98–8.12 (m, 2H, H_3, H_4), 8.59 (s, 1H, H_5), 8.65 (d, 1H, $J_{H2,1} = 4.5$, H_1). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 14.90 (3-$^{13}CH_3$), 20.12 (2-$^{13}CH_3$), 116.52, 122.01, 126.98, 127.14, 128.08, 132.78, 136.58, 138.56, 150.50, 154.12, 156.32, 159.90 (^{13}C=N). *Anal.* Calc. for $C_{28}H_{28}ClCuN_4O_4$: C, 57.63; H, 4.84; N, 9.60. Found: C, 57.62; H, 4.86; N, 9.61%.

2.2.7. *[Cu^I(C)$_2$]ClO$_4$ (**1c**)*

This complex was prepared by a procedure similar to **1a** using 21 mg (0.1 mmol) of (2,4-dimethyl-phenyl)-pyridin-2-ylmethylene-amine, C. Dark-red crystals were collected by filtration and dried *in vacuo*. Yield: 25 mg (86%). IR (KBr): 1585 cm^{-1} ν(C=N), 1090 cm^{-1} ν(Cl–O). ^1H NMR ($CDCl_3$; δ): 2.09 (s, 3H, 4-CH_3), 2.28 (s, 3H, 2-CH_3), 6.69-6.91 (m, 3H, ArH, amine ring), 7.68 (*t*, 1H, H_2), 8.01–8.11 (m, 2H, H_3, H_4), 8.54 (d, 1H, $J_{H2,1} = 4.75$, H_1), 8.60 (s, 1H, H_5). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 17.80 (4-$^{13}CH_3$), 20.90 (2-$^{13}CH_3$), 120.54, 127.65, 128.14, 128.88, 130.57, 131.66, 137.67, 138.53, 154.52, 149.21, 150.47, 159.91 (^{13}C=N). *Anal.* Calc. for $C_{28}H_{28}ClCuN_4O_4$: C, 57.63; H, 4.84; N, 9.60. Found: C, 57.62; H, 4.85; N, 9.59%.

2.2.8. *[Cu^I(D)$_2$]ClO$_4$ (**1d**)*

This complex was prepared by a procedure similar to **1a** using 21 mg (0.1 mmol) of (2,5-dimethyl-phenyl)-pyridin-2-ylmethylene-amine, D. Dark-red crystals were collected by filtration and dried *in vacuo*. Yield: 26 mg (89%). IR (KBr): 1590 cm^{-1} ν(C=N), 1091 cm^{-1} ν(Cl–O). ^1H NMR ($CDCl_3$; δ): 2.05 (s, 3H, 3-CH_3), 2.12 (s, 3H, 2-CH_3), 6.50–7.16 (m, 3H, ArH, amine ring), 7.65 (*t*, 1H, H_2), 7.99–8.10 (m, 2H, H_3, H_4), 8.59 (s, 1H, H_5), 8.68 (d, 1H, $J_{H2,1} = 4.5$, H_1). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 13.85 (5-$^{13}CH_3$), 20.10 (2-$^{13}CH_3$), 116.86, 122.21, 125.98, 126.18, 128.17, 131.70, 135.49, 139.01, 151.10, 153.99, 156.88, 160.00 (^{13}C=N). *Anal.* Calc. for $C_{28}H_{28}ClCuN_4O_4$: C, 57.63; H, 4.84; N, 9.60. Found: C, 57.62; H, 4.83; N, 9.59%.

2.2.9. *[Cu^I(A)(PPh$_3$)$_2$]ClO$_4$ (**2a**)*

To a 3 ml MeCN solution of $[Cu(CH_3CN)_4]ClO_4$ (32.8 mg, 0.1 mmol), 2 equivalent of Ph_3P (52.2 mg, 0.2 mmol) were added, and the solution was stirred for 15 min. The solvent was evaporated under vacuum at room temperature. The dry product $[Cu(CH_3CN)_2(PPh_3)_2]ClO_4$ was added to a stirring solution of 19.6 mg (0.1 mmol) pyridin-2-ylmethylene-p-tolyl-amine, A, in 3 ml MeCN. The solution rapidly turned yellow and it was stirred for 20 min at room temperature. The reaction medium was concentrated under vacuum, until the first crystals appeared in the liquid phase. Bright-yellow crystals were obtained by diffusion of Et_2O vapor into the concentrated solution. Yield: 80 mg (91%). IR (KBr): 1580 cm^{-1} ν(C=N), 1092 cm^{-1} ν(Cl–O), ^1H NMR (500 MHz, $CDCl_3$): ^1H NMR ($CDCl_3$; δ): 2.33 (s, 3H, CH_3), 6.96–7.40 (m, 35H, ArH, amine ring, PPh_3), 8.04 (m, 2H, H_3, H_4), 8.38 (d, 1H, $J_{H2,1} = 7.5$, H_1), 9.01 (s, 1H, H_5). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 21.1 ($^{13}CH_3$), 122.71, 126.25, 127.59, 128.32 (d, $J = 4.2$, *ipso*-C of PPh_3), 128.94, 130.04, 130.32, 133.15, 138.48, 139.55, 148.70, 149.12, 150.12, 162.69 (^{13}C=N). *Anal.* Calc. for $C_{49}H_{42}ClCuN_2O_4P_2$: C, 66.59; H, 4.79; N, 3.17. Found: C, 66.58; H, 4.80; N, 3.16%.

2.2.10. *[Cu^I(B)(PPh$_3$)$_2$]ClO$_4$ (**2b**)*

This complex was prepared by a procedure similar to **1** using 21 mg (1 mmol) of (2,3-dimethyl-phenyl)-pyridin-2-ylmethylene-amine, B. Yellow-orange crystals were collected by filtration and dried *in vacuo*. Yield: 70 mg (79%). IR (KBr): 1591 cm^{-1} ν(C=N), 1088 cm^{-1} ν(Cl–O), ^1H NMR (500 MHz, $CDCl_3$): ^1H NMR ($CDCl_3$; δ): 1.55 (s, 3H, CH_3), 2.17 (s, 3H, CH_3), 6.74–7.39 (m, 34H, ArH, amine ring, PPh_3), 7.53 (*t*, 1H, H_2), 8.23 (m, 2H, H_3, H_4), 8.42 (d, 1H, $J_{H2,1} = 7.75$, H_1), 8.60 (s, 1H, H_5). ^{13}C {^1H} NMR (500 MHz, $CDCl_3$): 14.12 (4-$^{13}CH_3$), 21.1 (2-$^{13}CH_3$), 119.45, 126.02, 127.50, 128.47 (d, $J = 4.2$,

ipso-C of PPh3), 128.94, 130.24, 130.38, 133.14, 138.57, 139.87, 148.77, 149.66, 150.08, 162.98 (^{13}C=N). *Anal.* Calc. for $C_{50}H_{44}ClCuN_2O_4P_2$: C, 66.89; H, 4.94; N, 3.12. Found: C, 66.87; H 4.95; N, 3.11%.

2.2.11. $[Cu^{I}(C)(PPh_3)_2]ClO_4$ (**2c**)

This complex was prepared by a procedure similar to **1** using 21 mg (0.1 mmol) of (2,4-dimethyl-phenyl)-pyridin-2-ylmethylene-amine, C. Yellow-orange crystals were collected by filtration and dried *in vacuo*. Yield: 80 mg (90%). IR (KBr): 1595 cm^{-1} ν(C=N), 1091 cm^{-1} ν(Cl–O), ^{1}H NMR (500 MHz, $CDCl_3$): 1.45 (s, 3H, CH_3), 2.10 (s, 3H, CH_3), 6.70–7.59 (m, 34H, ArH, amine ring, PPh_3), 7.50 (*t*, 1H, H_2), 8.20 (m, 2H, H_3, H_4), 8.41 (d, 1H, $J_{H2,1} = 7.8$, H_1), 8.63 (s, 1H, H_5). ^{13}C {^{1}H} NMR (500 MHz, $CDCl_3$): 18.35 (4-$^{13}CH_3$), 20.30 (2-$^{13}CH_3$), 123.60, 124.30, 126.63, 128.28 (d, $J = 4.0$, *ipso*-C of PPh_3), 129.12, 130.56, 132.32, 133.23, 137.60, 139.12, 147.91, 149.56, 150.24, 162.55 (^{13}C=N). *Anal.* Calc. for $C_{50}H_{44}ClCuN_2O_4P_2$: C, 66.89; H, 4.94; N, 3.12. Found: C, 66.88; H, 4.95; N, 3.12%.

2.2.12. $[Cu^{I}(D)(PPh_3)_2]ClO_4$ (**2d**)

This complex was prepared by a procedure similar to **1** using 21 mg (0.1 mmol) of (2,5-dimethyl-phenyl)-pyridin-2-ylmethylene-amine, D. Yellow-orange crystals were collected by filtration and dried *in vacuo*. Yield: 75 mg (84%). IR (KBr): 1590 cm^{-1} ν(C=N), 1091 cm^{-1} ν(Cl–O), ^{1}H NMR (500 MHz, $CDCl_3$): ^{1}H NMR ($CDCl_3$; δ): 1.68 (s, 3H, CH_3), 1.92 (s, 3H, CH_3), 6.90–7.40 (m, 34H, ArH, amine ring, PPh_3), 7.53 (*t*, 1H, H_2), 8.24 (m, 2H, H_3, H_4), 8.43 (d, 1H, $J_{H2,1} = 7.25$, H_1), 8.63 (s, 1H, H_5). ^{13}C {^{1}H} NMR (500 MHz, $CDCl_3$): 17.30 (5-$^{13}CH_3$), 20.54 (2-$^{13}CH_3$), 123.00, 125.55, 127.84, 128.42 (d, $J = 4.1$, *ipso*-C of PPh3), 128.99, 130.40, 131.42, 133.12, 136.58, 139.87, 148.15, 149.64, 150.14, 162.70 (^{13}C=N). *Anal.* Calc. for $C_{50}H_{44}ClCuN_2O_4P_2$: C, 66.89; H, 4.94; N, 3.12. Found: C, 66.90; H, 4.93; N, 3.11%.

2.3. X-ray analysis

Crystals of **1b**, **1c** and **2a** suitable for X-ray analysis were obtained as described above. The single crystals were mounted on a Nonius Kappa-CCD area detector diffractometer (Mo Kα $\lambda = 0.71073$ Å). The complete conditions of data collection (Denzo software) and structure refinements are given below. The cell parameters were determined from reflections taken from one set of 10 frames (1.0° steps in phi angle), each at 20 s exposure. The structures were solved using direct methods (SHELXS97) and refined against F^2 using the SHELXL97 software [32]. The absorption was not corrected. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated according to stereochemistry and refined using a riding model in SHELXL97. The crystal data and refinement details are summarized in Table 1.

Table 1

3. Results and discussion

3.1. General characterization

The IR spectra of the free ligands exhibit the characteristic band of the imine group, which appears in the region 1623–1630 cm^{-1}. This band is shifted to lower frequencies in the IR spectra of the corresponding complexes due to the coordination of the imine nitrogen [33], and appears in the region 1580–1595 cm^{-1}. A strong band at about 1085 cm^{-1} in the IR spectra of the complexes is characteristic of the asymmetric Cl–O stretching mode of the perchlorate anion [34].

The electronic absorption spectra of the ligands and the corresponding complexes are presented in Table 2. Since no d–d transitions are expected for a d^{10} complex, the UV–Vis bands are assigned to metal to ligand charge transfer (MLCT) or ligand-centered $\pi \rightarrow \pi^*$ transitions [35].

The absorption spectrum of $[Cu(A)_2]ClO_4$ (**1a**), in chloroform features a band with a true maximum at 518 nm, whereas $[Cu(A)(PPh_3)_2]ClO_4$ (**2a**), shows a clear shoulder at 419 nm, which is shifted considerably (ca. 99 nm) relative to that of complex **1a**. A similar shift (90 nm) has been reported in going from $[Cu(dmp)_2]^+$ ($\lambda_{MLCT} = 454$ nm) to $[Cu(dmp)(PPh_3)_2]^+$ ($\lambda_{MLCT} = 365$ nm) [36] and also similar shifts were observed in the other $Cu(L)_2^+$ complexes **1b**–**1d** relative to the $Cu(L)(PPh_3)_2^+$ complexes **2b**–**2d** (Table 2).

The considerable red shift in the position of the first MLCT band of complexes **1a**–**1d** as compared to that of other bis(diimine) copper(I) complexes is quite interesting and points to the possible application of these complexes as more efficient charge transfer photosensitizers in the visible region. Additional absorption bands are also observed in the spectra of **1a**–**2d** in chloroform in the UV region (Table 2). The intensity of these bands are consistent with being assigned as ligand-centered $\pi \rightarrow \pi^*$ or/and charge-transfer transitions.

The ^1H NMR spectra and peak assignments are presented in the experimental section in each complex. These peaks are assigned based on the splitting of the resonance signals, spin coupling constants and the literature, and are clearly in accordance with the molecular structure determined by X-ray crystal structure analysis. The ^1H resonances of the coordinated ligands are commonly observed in complexes **1a**–**2d**. In complexes **2a**–**2d**, however, the aromatic H atoms of the coordinated Ph_3P ligands overlap to some extent with those of the phenyl H atoms of ligands A–D. Aside from the aromatic H-atoms, which appear at 7.00–8.15 ppm in the complexes, the imine protons appear as a singlet at 8.60–9.50 ppm in the complexes. The downfield shift of the iminic protons relative to the free ligands can be attributed to the deshielding effect resulting from the coordination of the ligands [29]. The singlet at about 2 ppm in the compounds is assigned to the CH_3 substitutions of the phenyl ring.

The sharp NMR peaks are indicative of diamagnetic Cu(I) complexes. The appearance of a unique signal for each type of proton in $CDCl_3$ solution indicates that the symmetry of the molecules is retained in solution, and only one isomer or exchange processes within the NMR timescale are present.

3.2. X-ray structures of $[Cu(B)_2]ClO_4$ (**1b**), $[Cu(C)_2]ClO_4$ (**1c**) and $[Cu(A)(PPh_3)_2]ClO_4 \cdot 1/2CH_3CN$ (**2a**)

The crystallographic data are summarized in Table 1 and selected bond distances and angles are given in Table 3. No classical H-bonding occurs in these three crystal structures.

A view of the cation of complex **1b**, including the atom-numbering scheme is illustrated in Fig. 2. While a tetrahedral geometry might be expected for a four coordinated copper(I) center, the coordination sphere around the metal ion in this complex is distorted by the restricting bite angles of the chelating ligand. The intraligand N1–Cu–N2 angle is much less than 109.5°, being only 81.07(7)°. On the contrary the N2–Cu–N2b and N1–Cu–N2b angles (134.31(10)°, 122.41(7)°) are much larger than those of a tetrahedral complex. The average Cu–N bond distance (2.037 Å) is similar to that found in the $[Cu(dpdmp)_2]^+$ cation (2.047 Å) at room temperature [37], and other Cu(I) pseudotetrahedral complexes (typical $Cu–N_{av} = 2.055$ Å) [38].

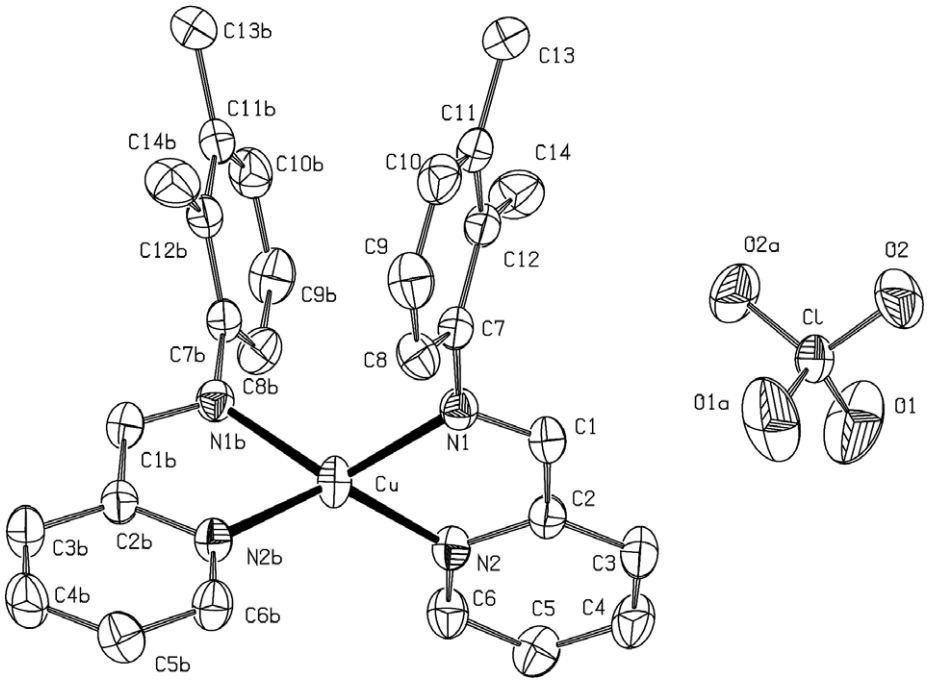

Fig. 2. ORTEP view of the crystal structure of $[Cu(B)_2]ClO_4$ (**1b**) showing the atom labelling scheme. The thermal ellipsoids enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity.

The dihedral angle between the two chelate rings is 85(1)°. The value for the dihedral angle of N1–C1–C2–N2 is 0.00(3)°, and comparison of the dihedral angles between the chelate rings and pyridine groups indicate the coplanarity of these moieties, resulting in a bite size of 3.233 Å of d(N(1)–N(2)) for the chelating ligand. The environment of the imine and pyridine nitrogen atoms is planar. The planarity is measured by three N atom bond angles ($\sum$N). For **1b**, the sum of these angles is 359.99° for N1 and N2. Despite the fact that the nitrogen atoms in **1b** are sp^2 hybridized, some strain in the chelate ring is suggested by the deviation from the 120° angle about the

nitrogen, Cu–N1–C1 (113.79(14)°), Cu–N1–C7 (126.23(11)°), C1–N1–C7 (119.97(16)°), Cu–N2–C2 (111.30(13)°), Cu–N2–C6 (131.61(13)°) and C2–N2–C6 (117.08(16)°). The dihedral angle of the chelate ring and phenyl ring (C7 → C12) is 69.4(3)°.

The cation of complex **1c**, along with the atom-numbering scheme, is shown in Fig. 3. As in complex **1b**, the geometry about Cu(I) in **1c** is also distorted by the restricting bite angles of the chelating ligand. The N1–Cu1–N2 and N3–Cu1–N4 angles are 82.1(2)° and 81.7(2)°, respectively. However, the N2–Cu1–N4, N1–Cu1–N4 and N1–Cu1–N3 angles are 140.0(2)°, 126.3(2)° and 125.3(2)° respectively.

The average Cu–N bond distance (2.0375 Å) is similar to that found in other Cu(I)(diimine) pseudotetrahedral complexes [37–39].

The dihedral angle between the two chelate rings is 83(1)°. Torsion angles in the chelating rings and the pyridine groups are listed in Table 4. This result demonstrates that the chelating rings are nearly planar and the pyridine groups are coplanar with the chelate rings. Despite the fact that the chelate ring are planar, the sum of three N atom bond angles is 359.4° for N1, 359.9 for N2, 360 for N3, and 359.3 N4, however, some strain in the chelate ring is suggested by the deviation from the 120° angle about the nitrogen, for example; Cu1–N1–C6 (130.2(4)°), Cu1–N2–C7 (126.3(4)°) and Cu1–N3–C20 (130.2(4)°). The planarity of the chelate rings results in a bite size of 3.233 Å for d(N(1)–N(2)) and 3.248 for d(N(3)–N(4)) for the two chelating ligands.

The cation of complex **2a**, along with the atom-numbering scheme, is shown in Fig. 4, and selected bond distances and angles are listed in Table 3. The compound **2a** crystallizes with two molecules per asymmetric unit, probably due to some small conformational differences. As in complex **1b** and **1c**, the coordination environment around the metal ion in this complex is pseudotetrahedral with large angular distortion arising from the low intraligand N1–Cu–N2 chelate angle, 79.39(18)° in I and N3–Cu–N4 chelate angle, 79.6(2)° in II. However, the P1–Cu–P2, 119.22(7)° angle in I and the P3–Cu–P4, 126.99(8)° angle in II have opened

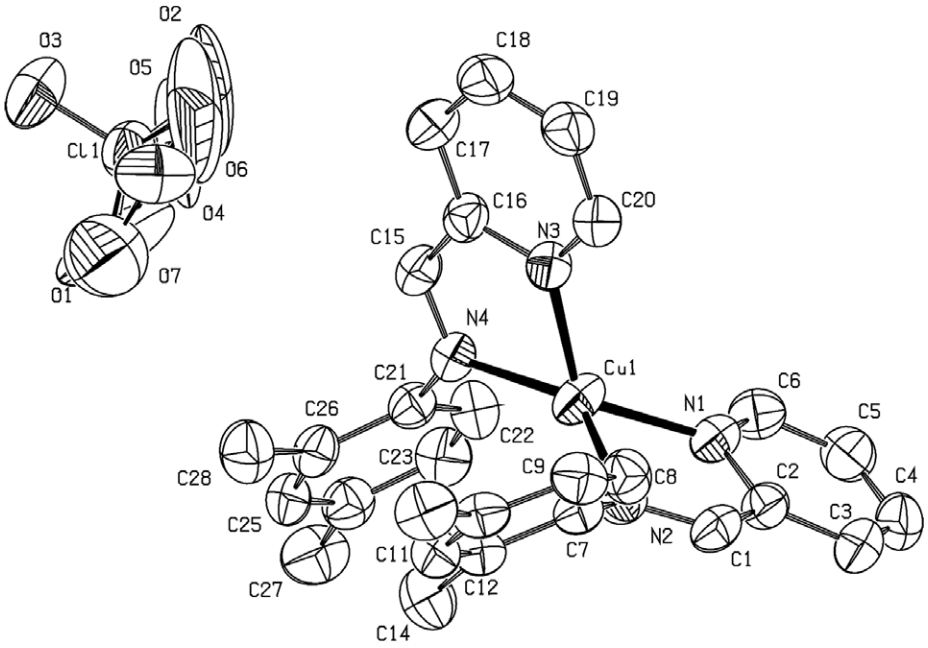

Fig. 3. ORTEP view of the crystal structure of $[Cu(C)_2]ClO_4$ (**1c**) showing the atom labelling scheme. The thermal ellipsoids enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity.

Table 4
Torsion angles for chelating rings

N1–C1–C2–C3	178.3(2)	N2–C1–C2–C3	169.1(5)	N1–C8–C9–C10	174.4(5)	N3–C57–C58–C59	−171.4(6)
Cu–N1–C1–C2	3.6(3)	Cu1–N1–C2–C1	4.3(5)	Cu1–N1–C8–C9	4.1(6)	Cu2–N3–C57–C58	0.1(7)
C1–C2–C3–C4	−177.0(2)	C1–C2–C3–C4	−179.2(5)	C1–C2–C3–C4	179.8(6)	C57–C58–C59–C60	175.9(7)
Cu–N2–C2–C1	−3.4(2)	Cu1–N2–C1–C2	13.7(6)	Cu1–N2–C9–C8	2.7(6)	Cu2–N4–C58–C59	169.7(6)
N1–Cu–N2–C2	4.01(14)	N2–Cu1–N1–C2	2.03(3)	N1–Cu1–N2–C9	−0.5(4)	Cu2–N3–C57–C58	0.1(7)

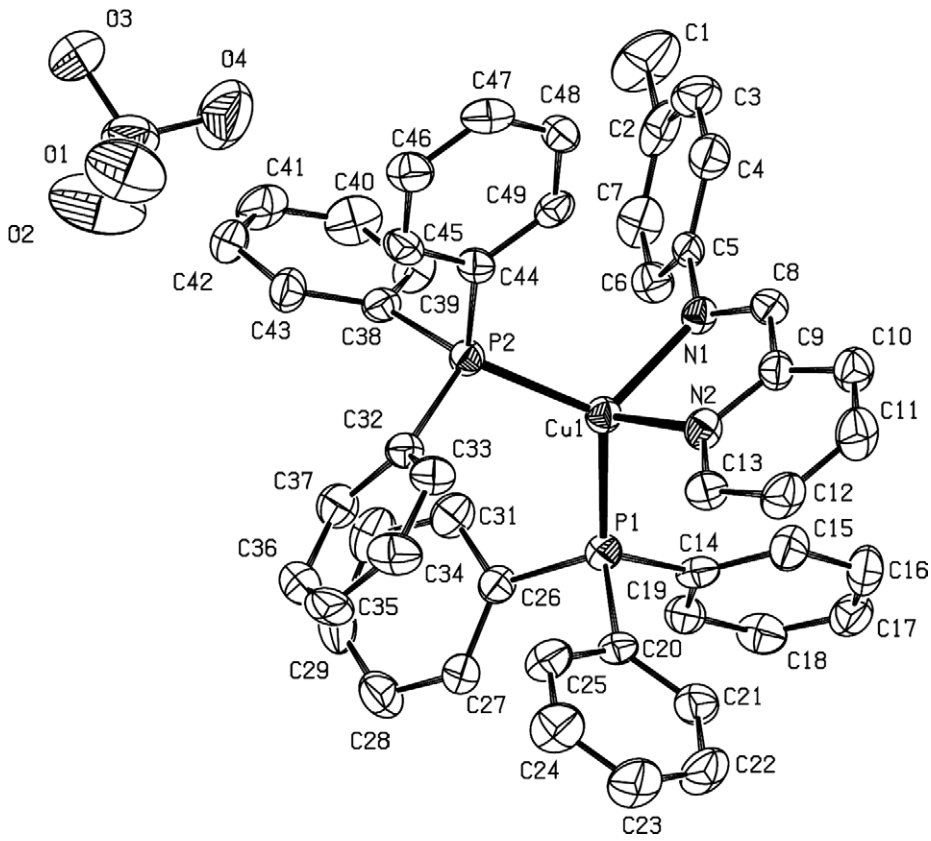

Fig. 4. ORTEP view of the crystal structure of $[Cu(A)(PPh_3)_2]ClO_4$ (**2a**) showing the atom labelling scheme. The thermal ellipsoids enclose 50% of the electronic density. Solvent molecules and hydrogen atoms are omitted for clarity.

up due to the steric effects from the bulky Ph_3P ligands. The average Cu–N and Cu–P bond distances are 2.098 and 2.251 Å, respectively, and are comparable to those reported for $[Cu(dmp)(PPh_3)_2]NO_3$ (2.117(6) and 2.294(2) Å) [29,40].

The chelate ring in complex **2a** is also nearly planar (Table 4) with some strain caused by the deviation from 120° angle about the N-atom (Cu1–N1–C5 126.1(3)°; Cu1–N2–C13 129.7(4)° in I; Cu2–N3–C54 128.7(4)°; Cu2–N4–C62 131.1(6)° in II). The dihedral angle between the chelate ring (Cu–N–C–C–N) and the plane defined by P1–Cu1–P2 is 75(1)° (and 73(1)° in the other molecule of the asymmetric unit) and agrees well with the 82.2° value for $[Cu(dmp)(PPh_3)_2]NO_3$ [25,36].

3.3. Electrochemistry

The electrochemical behavior of the complexes was examined by means of cyclic voltammetry in CH_2Cl_2. The four ligands are electroinactive in the working potential region. The complexes show a quasireversible $Cu^{II/I}$ couple (Table 2) and the ratio of the anodic and cathodic peak currents (i_{pa}/i_{pc}), approaches 1 as the scan rate increases. The peak-to-peak separations increase as the scan rate is changed from 50 mV/s to 500 mV/s.

The $Cu^{II/I}$ potential in a $Cu^{I}N_4$ chromophore is believed to increase with increasing π-acidity of the ligands and the resistance to tetrahedral distortion occurring in the corresponding $Cu^{II}N_4$ chromophore [20,41]. Although, a higher degree of conjugation exists in **1a**–**1d** relative to **2a**–**2d**, the existence of bulkier ligands in **2a**–**2d** which prevent the inner-sphere reorganization to a flattened tetrahedral, more appropriate to Cu(II) oxidation state, play a key role in shifting the oxidation potential to higher values for complexes **2a**–**2d** relative to **1a**–**1d**. However, the potential is approximately insensitive to the methyl substituents on the phenyl ring of ligands in the complexes **1a**–**1d** and/or **2a**–**2d**.

Abstract

Two new zinc(II)-complexes, dithiocarbimato $(Ph_4P)_2[Zn(CH_3SO_2N{=}CS_2)_2]$ (**1**) and trithiocarbimato $(Ph_4P)_2[Zn(CH_3SO_2N{=}CS_3)_2]$ (**2**), were obtained in the crystalline form by the reaction of potassium *N*-methylsulfonyldithiocarbimate ($RSO_2N{=}CS_2K_2$) with zinc(II) acetate dihydrate and tetraphenylphosphonium chloride in dimethylformamide. Both complexes crystallize in the monoclinic system. The central Zn(II) ion has a distorted tetrahedral coordination in both compounds. In **1** the dithiocarbimato ligand coordinates via two S atoms while in **2** the trithiocarbimato ligand coordinates via S and N atoms. Both complexes were also characterized by IR, ^1H NMR and ^{13}C NMR spectroscopies. Compound **2** is the first example of a zinc(II)-trithiocarbimato complex.

Keywords: Dithiocarbimate; Trithiocarbimate; Zinc complexes; Crystal structure

1. Introduction

Compounds containing zinc–sulfur-coordinated ligands have a wide range of applications. For example, several dithiocarbamate complexes and salts have been used as fungicides mainly due to their high efficiency in controlling plant fungal diseases, showing relatively low toxicity [1–7]. Furthermore, zinc(II)–dithiocarbamato complexes are worldwide used in the vulcanization process [7–14]. Anionic zinc(II)–dithiocarbamato complexes are also active, and the $[Zn(R_2NCS_2)_3]^-$ ($R = CH_3CH_2$) was found to be a fast accelerator for rubber vulcanization [8]. Zinc(II)–polythiocarbamato complexes that have one or more sulfur atoms inserted in the zinc–dithiocarbamato bond such as $[Zn(Me_2NCS_3)_2]$ are very important intermediates in the vulcanization process [8]. It is also known that correlate nickel(II)–bis(dithiocarbimato) complexes are anionic species, which can also react with sulfur [15,16]. Considering these facts we decided to prepare and study zinc(II) analogues. In a recent work we reported on the structures of compounds $(Ph_4P)_2[Zn(C_6H_5SO_2N{=}CS_2)_2]$ and $(Ph_4P)_2[Zn(4\text{-}CH_3C_6H_4SO_2N{=}CS_2)_2]$ that contain dithiocarbimate anions from aromatic sulfonamides [17].

In the present work, we investigate two new tetraphenylphosphonium salts of anionic zinc(II) complexes with dithio and trithiocarbimate: $(Ph_4P)_2[Zn(CH_3SO_2N{=}CS_2)_2]$ (**1**) and $(Ph_4P)_2[Zn(CH_3SO_2N{=}CS_3)_2]$ (**2**). To our knowledge **2** is the first example of a zinc(II)-trithiocarbimato complex.

2. Experimental

2.1. Methods and materials

The solvents were purchased from Merck and used without further purification. The methanesulfonamide, zinc

acetate dihydrate and tetraphenylphosphonium chloride were purchased from Aldrich. Carbon disulfide and potassium hydroxide were purchased from Vetec. The *N*-methylsulfonyldithiocarbimate potassium salt dihydrate was prepared in dimethylformamide from methanesulfonamide analogously as described in the literature [18,19]. Melting point was determined with a Mettler FP5 equipment. Microanalyses for C, H and N were obtained from a Perkin–Elmer 2400 CHN elemental analyzer. Zinc was analyzed by atomic absorption with a Hitachi Z-8200 Atomic Absorption Spectrophotometer. The IR spectra (4000–400 cm^{-1}) were recorded with a Perkin–Elmer 283 B infrared spectrophotometer using CsI pellets. Far-IR spectra (550–100 cm^{-1}) were recorded on a Bruker-IFS 113 V FT-IR spectrometer (polyethylene disks). The ^{1}H (400 MHz) and ^{13}C (100 MHz) NMR spectra were recorded with a Bruker Advance DRX-400 spectrophotometer in $CDCl_3$ with TMS as internal standard.

2.2. Syntheses

Zinc(II) acetate dihydrate (0.7 mmol) was added to a suspension of potassium *N*-methylsulfonyldithiocarbimate dihydrate (1.5 mmol) in DMF (15 mL). The mixture was stirred for 1.5 h at room temperature and filtered. Water (15 mL) and tetraphenylphosphonium chloride (1.5 mmol) was added to the solution obtained. The mixture was stirred for 15 min and the solid product was filtered, washed with distilled water and dried under reduced pressure for 1 day. The solid product was resolved in a mixture dichloromethane/methanol/water. After slowly evaporation of the solution two different crystals were obtained. The transparent colourless crystals are bis(tetraphenylphosphonium) bis(*N*-methylsulfonyldithiocarbimato)-zincate(II): $(Ph_4P)_2$-$[Zn(CH_3SO_2N{=}CS_2)_2]$ (**1**) (ca. 60%) while the other yellow crystals are bis(tetraphenylphosphonium) bis(*N*-methylsulfonyltrithiocarbimato)zincate (II): $(Ph_4P)_2[Zn(CH_3SO_2N{=}CS_3)_2]$ (**2**) (ca. 40%).

2.3. X-ray crystallography

X-ray intensity data for both crystals were collected using graphite monochromatic Mo Kα radiation on a four-circle κ-geometry KUMA KM-4 diffractometer with a two-dimensional area CCD detector at room temperature. The ω-scan technique with $\Delta\omega = 0.75°$ for each image was used for data collection. The 960 images for six different runs covered about 95% of the Ewald sphere were performed. Initially the lattice parameters were refined on about 150 reflections obtained from 40 images for eight runs with different orientation in the reciprocal space. Finally the lattice parameters were refined by least-squares methods based on all the reflections with $I > 2\sigma(F^2)$. One image was used as a standard for monitoring of the stability of the crystals as well as for monitoring the data collection after every 40 images, and no correction on the relative intensity variation was necessary. Integration of the intensities, correction for Lorenz and polarization effects were performed using a KUMA KM-4 CCD program system [20]. The face-indexed analytical absorption was calculated using the SHELXTL program [21]. The structures were solved by direct methods using the SHELXS of the SHELXL97 program [22]. The calculated E map revealed the Zn, S, P, O, N and most of the C atoms. The remaining C atoms were located from the difference Fourier synthesis. The structures were refined with the anisotropic thermal parameters for all non-hydrogen atoms. Difference Fourier maps gave electron density concentrations approximately located for all hydrogen atoms positions; these positions were idealized (HFIX 43 for all H atoms of the phenyl rings with isotropic thermal parameters of $1.2U_{eq}$ of the carbon atoms joined directly to the hydrogen atoms, and HFIX 137 for the CH_3 group in the compound **2** with isotropic thermal parameters of $1.5U_{eq}$ of the methyl carbon atom). Final difference Fourier maps showed no peaks of chemically significance. Details of the data collection parameters and final agreement factors are collected in Table 1. Selected bond lengths and angles and torsion angles are listed in Table 2.

3. Results and discussion

Compounds **1** and **2** are quite stable in the solid state at the ambient conditions. They are insoluble in water, slightly soluble in ethanol and are soluble in methanol, chloroform and dichloromethane. Compounds **1** and **2** were obtained by recrystallization of the crude product. The obtained crystals have different colours (colourless

and yellow) and morphologies, therefore it was possible to separate and characterize them. All intense bands of the Ph_4P^+ ion vibrations are present in the infrared spectrum of both **1** and **2** compounds. In the spectrum of **1** a strong band at 1375 cm^{-1} was assigned to the νCN vibration of the RSO_2NC group. Some vibrational bands due to the SO_2 group are observed between 1300 and 1100 cm^{-1}. A multiple band centred at 936 cm^{-1} observed in the

spectrum of **1** was assigned to $\nu_{ass}CS_2$. The spectrum also shows the expected band at 328 cm^{-1} assigned to the ZnS stretching vibration [23]. The IR spectrum of the complex **2** is similar to the spectrum of the compound **1** and shows some additional bands. The band at 505 cm^{-1} was assigned to ν(S–S). Due to N and S coordination of the trithiocarbimato ligand to Zn in **2** the band at 431 was assigned to ν(ZnN).

The ^1H NMR spectra of the compounds **1** and **2** showed the expected signals for the hydrogen atoms of the tetraphenylphosphonium cation, and the hydrogen atoms of the CH_3 group. The integration curves were consistent with a 2:1 proportion between the tetraphenylphosphonium cation and the bis(*N*-methylsulfonyldithiocarbimato)zincate(II) or bis(*N*-methylsulfonyltrithiocarbimato) zincate(II) anions.

The ^{13}C NMR spectra of the compounds **1** and **2** showed the expected doublets for the signals of the tetraphenylphosphonium cation in the aromatic region. The signal at 208.71 δ in the spectrum of **1**, assigned to the dithiocarbimate group (NCS_2), was observed in the same region of other zinc(II)–*R*-sulfonyldithiocarbimate complexes [17]. The methyl group signal of compound **1** was observed at 39.30 δ. The ^{13}C NMR spectrum of the compound **2** shows signals at 208.78 and 39.10 δ, which were assigned to the carbons of the NCS_3 and CH_3 groups.

The molecular structures of **1** and **2** are shown in Figs. 1 and 2, respectively. In both compounds the central Zn(II) atom has a distorted tetrahedral coordination. The asymmetric unit of **1** consists of two chemical equivalents but crystallographically independent *N*-methylsulfonyldithiocarbimate ligands coordinated to the Zn atom, and two tetraphenylphosphonium cations. The *N*-methylsulfonyldithiocarbimate ligands have similar bond lengths but different bond angles and torsion angles (Table 2) due to the interactions with the adjacent cations (Fig. 1). The distortion from the ideal tetrahedral geometry around Zn(II) in **1** is due to the coordination by the two sulfur atoms of each chelating ligand leading to the considerably smaller S1–Zn1–S2 and S4–Zn1–S5 bond angles when compared to the other S–Zn–S bond angles. The two Zn–S_2–C four membered rings are almost planar with a dihedral angle of 79.1(1)°. The average value of 1.731 Å for the C–S bonds within the rings is similar to those observed for other Ni(II) and Zn(II) *N*-*R*-sulfonyldithiocarbimate complexes [17,24]. The average length of 2.349 Å for the Zn–S bonds are also in the range of analogous Zn(II) complexes [17]. The chemical equivalent and crystallographic independent C1–N1 and C3–N3 bond lengths are equal within three e.s.d. and

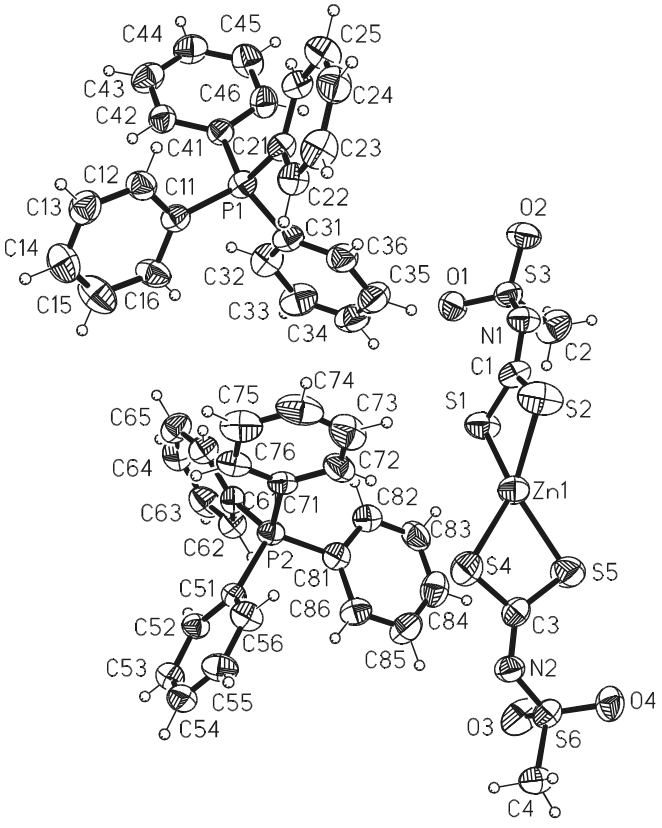

Fig. 1. X-ray molecular structure of tetraphenylphosphonium bis-(*N*-methylsulfonyldithiocarbimato)zincate(II).

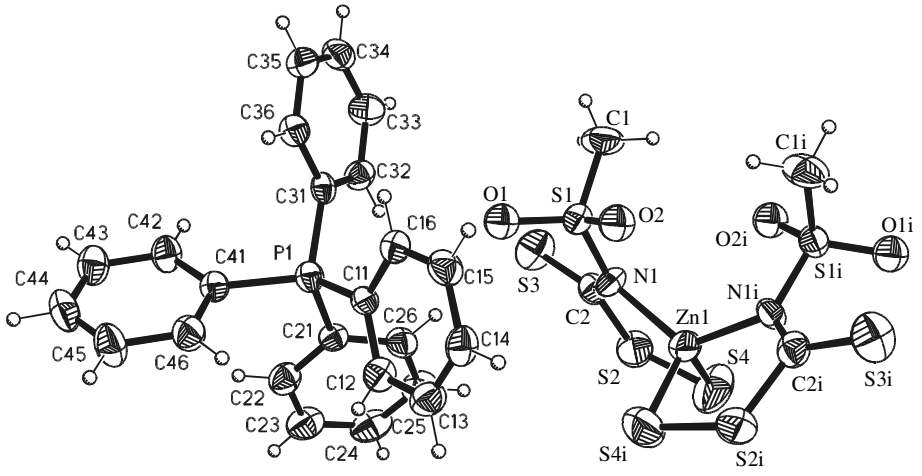

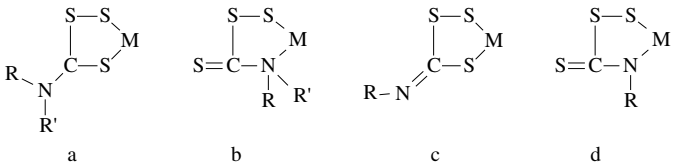

Fig. 2. X-ray molecular structure of tetraphenylphosphonium bis(*N*-methylsulfonyltrithiocarbimato)zincate(II), symmetry code: i = $-x$, y, 1/2 $-z$.

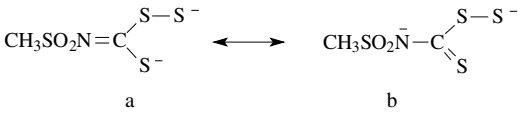

indicate a C(sp^2)–N(sp^2) double-bond character [25]. The S1–C1–N1 and S5–C3–N2 angles are about 10° greater than S2–C1–N1 and S4–C3–N2 due to the interaction between the two CH_3SO_2 groups and S1 and S5 atoms, respectively, which are in *cis* positions in relation to the C1–N1 and C3–N2 bonds. The steric effects of the two CH_3SO_2 groups are greater than the effects of non-bonding lone-pair of electrons at the N1 and N2 atoms, since the C1–N1–S3 and C3–N2–S6 angles are greater than 120°, differently than it would be predicted by the VSEPR theory [26,27].

The asymmetric unit of **2** consists of a half *N*-methylsulfonyltrithiocarbimate zincate(II) anion and a tetraphenylphosphonium cation (Fig. 2). The central zinc lies on a twofold axis and is coordinated by two nitrogen N1 and two sulfur S4 atoms of the anions $CH_3SO_2N{=}CS_3^{2-}$, in a considerably distorted tetrahedral geometry, with very distinct bond angles S–Zn–S, N–Zn–N and N–Zn–S (Table 2). However, the five-membered ring defined by Zn1–N1–C2–S2–S4 atoms is almost planar (maximum deviation atom to mean plane 0.11 Å) and forms a dihedral angle of 87.5° with its crystallographic equivalent plane Zn1–$N1^i$–$C2^i$–$S2^i$–$S4^i$. The Zn1–S4 bond length is slightly smaller than the Zn-S bond lengths in compound **1**, whereas the S2–C2 bond length is similar to the corresponding values observed in **1**. The bond length of S2–S4 is typical for single bond values observed in several organic compounds (2.03 Å) and the S3–C2 bond length is similar to those observed for thioureas S=C bonds [25]. The Zn1–N1 bond length of 2.021(2) Å is in the usual range for Zn–N coordination bonds [28]. The bond lengths and bond angles within the N-methylsulfonyl group are very similar to those in the structure of **1**. Different contributing forces count to the stabilization of the molecular structure of **2**: the oxygen atom O2 is approximately on the mean plane minimizing the stereo repulsion to S3; further repulsion between the sulfur and C1 and O1 can be seen in the bond angles on the C_{ring} carbon, namely, an enhancement of the S3–C2–N1 bond angle in comparison to S3-C2–S2; on the other hand, two equivalent H1c···O2···$H1c^i$ intermolecular contacts (2.72(1) Å) indicate an attractive interaction between the oxygen O2 and two methyl hydrogen atoms.

Some sulfur-rich dithiocarbamato complexes are known [29–31]. The osmium(II) dithiocarbamato complex $[Os_2(S_3CNMe_2)_2(S_2CNMe_2)_3]^+$ is an example of such compounds [30]. The single-crystal X-ray analysis of this cation showed that the trithiocarbamato ion is coordinated to de osmium cation by two sulfur atoms as shown in Scheme 1a. The same coordination mode was proposed for the structures of zinc(II)–trithiocarbamato complexes [31]. Examples of sulfur-rich-nickel(II)–dithiocarbimato complexes have been synthesized and in these cases the coordination of the trithiocarbimate anion can be as represented by the structure in Scheme 1c [15,16]. So, to our knowledge, compound **2** is the first example of a sulfur-rich-zinc(II)–dithiocarbimato, and also the first example of a sulfur-rich-trithio-complex where the metal is coordinated by the sulfur and nitrogen atoms (Scheme 1d).

Scheme 1. Possible ways of coordination of the sulfur-rich-dithiocarbamato (a, b) and sulfur-rich-dithiocarbimato (c, d) ligands.

Scheme 2. Two canonical forms for *N*-methylsulfonyltrithiocarbimate anion.

The strong electron withdrawing property of the SO_2 group might be important for this coordination fashion. The SO_2 neighbouring group stabilizes the negative charge in the nitrogen atom, and the canonical form (b) (Scheme 2) contributes appreciably to the resonance hybrid.

The structure determination of the compound **2** is very important since it has been proposed that correlated trithiocarbamate ligands ($R_2NCS_3^-$) are key intermediates in rubber vulcanization accelerated by zinc dithiolate compounds [8,31]. The formation of the compound **2** is under investigation. The potassium *N*-methylsulfonyldithiocarbimate precursor is not very stable. The oxidation of analogous salts, for example, potassium phenylsulfonyldithiocarbimate, involves dimerization of the anion by the formation of a S–S bond, followed by an intramolecular cyclization with elimination of sulfur [32]. This is a possible source of the third sulfur atom that gives rise to the trithiocarbimato ligand in compound **2**.

4. Conclusion

Two new zinc(II) complexes with dithiocarbimato (**1**) and trithiocarbimato (**2**) ligands as tetraphenylphosphonium salts were obtained in crystalline form and their structures were determined by single crystal X-ray diffraction technique. The compound **2** is the first example of a zinc–trithiocarbimato complex. Furthermore, it is the first example of a sulfur-rich-dithiolate in which the ligand coordinates to the metal cation by sulfur and nitrogen atoms, and not only by the sulfur atoms. The structure determination of **2** is very important since it has been proposed that trithiocarbamate ligands ($R_2NCS_3^-$) are key intermediates in rubber vulcanization accelerated by zinc dithiocarbamate compounds.

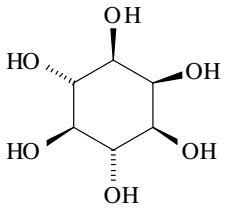
Abstract



The oxidation of D-*myo*-inositol (Myo) by Cr^{VI} yields the inosose and Cr^{3+} as final products when an excess of cyclitol over Cr^{VI} is used. The redox reaction takes place through the combination of $Cr^{VI} \rightarrow Cr^{IV} \rightarrow Cr^{II}$ and $Cr^{VI} \rightarrow Cr^{IV} \rightarrow Cr^{III}$ pathways. Intermediacy of Cr^{IV} was evidenced by the detection of CrO_2^{2+}, formed by reaction of Cr^{II} with O_2. The EPR spectra show that five- and six-coordinated oxo-Cr^{V} intermediates are formed, with the cyclitol acting as bidentate ligand. Penta-coordinated oxo-Cr^{V} species are present at any $[H^+]$, whereas hexa-coordinated ones are only observed at $pH < 1$, where rapidly decompose to the redox products. At higher pH, where hexa-coordinated oxo-Cr^{V} species are not observed, oxo-Cr^{V} bischelates are stable enough to remain long time in solution.

1. Introduction

Cr^{VI} is a well-established carcinogen and mutagen, and can be reduced to lower states with a wide variety of biological reductants [1–3]. Cr^{V} and Cr^{IV} intermediates have been observed in the selective oxidation of organic substrates by Cr^{VI} and might be implicated in the mechanism of Cr-induced cancers [4–6]. Ligands that posses two oxygen atoms able to form five-membered rings about the metal ion, such as 1,2-diols and α-hydroxy-acids, are effective as non-enzymatic reductants (at low pH) and complexation agents towards high valent chromium and can stabilize the labile oxidation states of chromium [7–10].

Inositols are essential growth factors for rapidly dividing cells and a simple polyol precursor in a second messenger system important in the brain [11,12]. In particular, *myo*-inositol (Myo) is a naturally occurring inositol found in all plant and animal tissues. In this work, we have chosen Myo as a model for investigating the coordination and redox chemistry of chromium with cyclitols, and compare the ability of this kind of compounds to reduce and stabilize high valent chromium with that of other polyols, such as aldoses and alditols.

Myo-inositol (Myo)

2. Experimental

2.1. Materials

myo-Inositol, D-gluconic acid sodium salt, D-glucose, acrylamide (Sigma grade), 2,4-dinitrophenylhydrazine (Riedel-de Haën c.a.), potassium dichromate (Cicarelli c.a.), glutathione (GSH), perchloric acid, and sulfuric acid (Merck) were used without purification.

Aqueous solutions were prepared in double-distilled deionized water. In experiments performed at pH $\leqslant$ 3, the pH of the solution was adjusted by addition of 2.0 M $HClO_4$. The concentration of stock solutions of $HClO_4$ was determined using standard analytical methods [13]. 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffer was used to adjust the pH value of the solution to 7.4. Acetate buffer was used for experiments at pH 4.4. The stability of the organic substrate under conditions used in the kinetic studies was tested by paper chromatography and high performance liquid chromatography (HPLC).

Caution: Cr^{VI} are human carcinogens, and Cr^{V} complexes are mutagenic and potential carcinogens [14]. Contact with skin and inhalation must be avoided. Acrylamide is a carcinogen and must be handled in a well-ventilated fume hood [15].

3. Spectrophotometric measurements

Kinetic measurements were performed by monitoring absorbance changes using a Jasco V-530 spectrophotometer with fully thermostated cell compartment (±0.2 °C). The reactions were followed under pseudo-first-order conditions, using an excess of substrate over Cr^{VI}. Reactant solutions were previously thermostated and transferred into a 1-cm path length cell immediately after mixing. Experiments were performed at 33 °C unless otherwise stated and mixtures of sodium perchlorate and perchloric acid were used to maintain a constant ionic strength (I) of 1.0 M.

The disappearance of Cr^{VI} was followed at 350 nm until at least 80% of the Cr^{VI} was consumed. In the kinetic measurements, the initial concentration of Cr^{VI} was kept constant at 6.0×10^{-4} M, while [Myo] and [H^+] were varied from 0.06 to 0.24 M and from 0.1 to 0.4 M, respectively. The observed pseudo-first-order rate constants were averages of multiple determinations and were within ±8% of each other. The first-order dependence of the rate upon [Cr^{VI}] was verified in a set of experiments where the $[Cr^{VI}]_0$ was varied but temperature, $[Myo]_0$, [H^+] and I were kept constant.

The formation of Cr^{III} from mixtures of 15×10^{-3} M Cr^{VI} and 24×10^{-2} M Myo in 0.10–0.40 M $HClO_4$, was monitored by following the growth of the 570 nm absorption band The final absorption spectrum of the reaction solution showed two d–d bands at $\lambda_{max} = 408$ nm ($\varepsilon = 18\ M^{-1}\ cm^{-1}$) and 574 nm ($\varepsilon = 15\ M^{-1}\ cm^{-1}$), which are distinctive of the free Cr^{3+} aqua-ion [16], and are attributable to the octahedral $^4A_{2g} \rightarrow {}^4T_{1g}$ and $^4A_{2g} \rightarrow {}^4T_{2g}$ transitions in O_h symmetry.

Chromate esters were investigated by UV–Vis spectrophotometry in the 350–400 nm region in which they show characteristic absorption bands. Reactions were performed at pH 3.0, where the redox reaction is slow enough to enable the observation of the ester formation. The instrument was zeroed to an arrangement of the reference and sample beams passing through matched cells, both containing Cr^{VI} at pH = 3.0. The solution in the sample cell was replaced with the reaction solution containing 6×10^{-4} M Cr^{VI} and 0.03–0.24 M Myo at pH 3, $I = 1.0$ M, and $T = 33$ °C. Spectra obtained within 30 min after mixing revealed a distinctive absorption band at 371 nm.

The formation of CrO_2^{2+} (Cr^{III} superoxide) was examined by periodic scanning of O_2-saturated solutions containing 0.13 M Myo and 0.03 mM Cr^{VI} in 0.40 M $HClO_4$. The band at 350 nm decreased in intensity over a period of 30 min, while two new peaks at 290 nm and 249 nm grew in and then slowly decreased. These two peaks were attributed to CrO_2^{2+} [17], formed as a long-lived intermediate.

3.1. Polymerization test

The presence of free radicals in the reactions of Myo with Cr^{VI} was tested by the acrylamide polymerization test. In a typical experiment, acrylamide (0.5 g) was added to a solution of Cr^{VI} (0.024 mmol) and Myo (1.25 mmol) in $HClO_4$ 0.1 M (5 mL). After a few minutes a white precipitate appeared. Control experiments (without Cr^{VI} or reductant present) did not show the formation of a precipitate. The possible reaction of Cr^{V} or Cr^{IV} with acrylamide was tested with $Na[Cr^{V}O(ehba)_2]$ [18] and $[Cr^{IV}O(ehba)_2]$ [19] (ehba = 2-ethyl-2-hydroxybutanoic acid). No precipitation occurred on mixing the Cr^{V} or Cr^{IV} complexes with acrylamide under the same conditions as those used in the Cr^{VI} + Myo reaction.

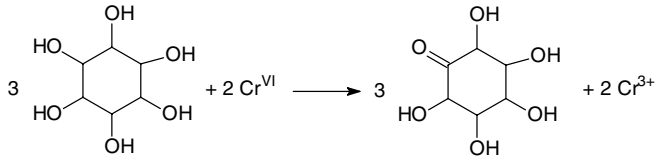
3.2. Product analysis

HPLC was employed to detect the reaction products under the conditions used in the kinetic measurements (excess of Myo over Cr^{VI}). The chromatograms were obtained on a KNK-500A chromatograph provided with a 7125 HPLC pump. The separation was carried out on Aminex HPX-87H HPLC column (300 × 7.8 mm, Bio-Rad Laboratories) using 3.2×10^{-2} M H_2SO_4 as eluent and a flow rate of 0.4 mL/min, at 33 °C. The effluent was monitored with refractive index (ERC-7522, ERMA INC) and UV (115 UV Gilson, $\lambda = 220$ nm) detectors. Standard solutions and reaction mixtures were prepared in 0.2 M $HClO_4$. All the samples were thermostated at 33 °C during 2 h, and filtered through a 0.2 μm membrane prior to injection into the chromatographic system.

Standard solutions of Myo, D-*epi*-inosose (synthesized according to a described method [20]), D-glucose and D-gluconic acid were prepared individually in 0.2 M

$HClO_4$ and chromatographed separately to determine the chromatographic retention times (t_R) of each sample: t_R(Myo) = 8′41″, t_R(D-*epi*-inosose) = 13′22″, t_R(D-glucose) = 8′48″, t_R(D-gluconic acid) = 12′40″.

Reaction solutions containing 0.075–0.15 M Myo and 0.015 M Cr^{VI} in 0.2 M $HClO_4$ were stirred at 33 °C during 2 h and then chromatographed. The chromatograms of the reaction mixtures showed one peak at t_R = 13′22″ in addition to the peak of excess Myo at t = 8′41″. The retention time of the new peak is coincident with that of the standard solution of D-*epi*-inosose. Furthermore, co-chromatography of a Cr^{VI}/Myo reaction mixture with added D-*epi*-inosose resulted in the increase of the peak at 13′22″. This result indicates that Cr^{VI} oxidizes one of the C–OH groups of the ring to yield the inosose as the reaction product (Scheme 1).



The formation of the inosose as the reaction product was confirmed spectrophotometrically. The final electronic spectrum of mixtures of 0.075 M Myo + 0.015 M Cr^{VI} in 0.2 M $HClO_4$, showed one absorption band with λ_{max} = 271 nm in the 200–350 nm spectral region, analogous to that observed for a solution of D-*epi*-inosose (λ_{max} = 271 nm, ε = 45 M^{-1} cm^{-1}). The possible chromic oxidation of the inosose formed in the Myo + Cr^{VI} reaction mixture through a competitive pathway was also checked. Treatment of 0.015 M D-*epi*-inosose with 0.003 M Cr^{VI} in 0.2 M $HClO_4$ yields a product with a 20-times more intense band at λ_{max} 310 nm. The absence of this band in the reaction mixture of excess of Myo and Cr^{VI} indicates that the inosose does not compete with Myo for Cr^{VI}. Alternatively, the formation of the inosose as the reaction product was tested spectrophotometrically by addition of 2,4-dinitrophenylhydrazine to the Cr^{VI}/Myo reaction mixtures, following a method described in the literature [21]. The ketone was identified by the observation of two absorbance bands at 430 and 510 nm characteristic of the 2,4-dinitrophenylhydrazone derivative.

Under all experimental conditions, CO_2 and HCOOH were never observed as reaction products, indicating the absence of C–C bond cleavage.

3.3. EPR measurements

The EPR spectra were obtained on a Bruker Elexsys spectrometer operating at X-band frequencies (~9–10 GHz). Spectra were recorded as first derivatives of the microwave absorption of a total of 5–20 scans, at 25 ± 1 °C, using 10 mW microwave power, modulation frequency = 100 kHz, modulation amplitude = 0.4–4 G and conversion time = 5.12 ms. g-Values were determined by reference to diphenylpicrylhydrazyl radical (g = 2.0036) as an external standard. Spectra were obtained from mixtures of 8.0 mM Cr^{VI} and 510 mM Myo in 0.2 M $HClO_4$ or from reactions carried out by addition of 1.0 mM Cr^{VI} + 1.0 mM GSH to 25–500 mM solutions of Myo in 100 mM acetate buffer (pH 4.4) or 100 mM HEPES buffer (pH 7.4). Aqueous stock solution (100 mM) of GSH was freshly prepared before each series of experiments.

All the EPR spectra were simulated with the PEST WinSIM [22] program using 100% Lorentzian line shapes. The spectral parameters for each Cr^{V} species were similar in all simulations, with maximum deviations of ±0.0001 units in the g_{iso} values. In the simulations, values for a_{iso} (^{1}H) were included only when they were greater than the line width of the Cr^{V} species.

Scheme 1.

4. Results and discussion

4.1. Myo + Cr^{VI} reaction intermediates

4.1.1. Intermediate Cr^{VI}ester

Differential UV–Vis spectra of mixtures of Cr^{VI} and Myo exhibit an absorption band with λ_{max} = 371 nm, consistent with that ascribed to Cr^{VI} oxo-esters [23,24]. At pH 3.0, the redox reaction of Cr^{VI} with Myo proceeds very slowly, with negligible reduction of Cr^{VI} within the first hour. Thus, at this pH the ester formation step can be distinguished clearly from the electron transfer reaction. Spectra obtained within 2 min after mixing revealed a distinctive absorption band at 371 nm. Continued scanning for 30 min showed no further change in the spectra. Varying the excess concentration of Myo at pH 3.0 showed that the absorbance at 371 nm increased with increasing [Myo] (Fig. 1), probably as result of a shift toward the ester in the esterification equilibrium.

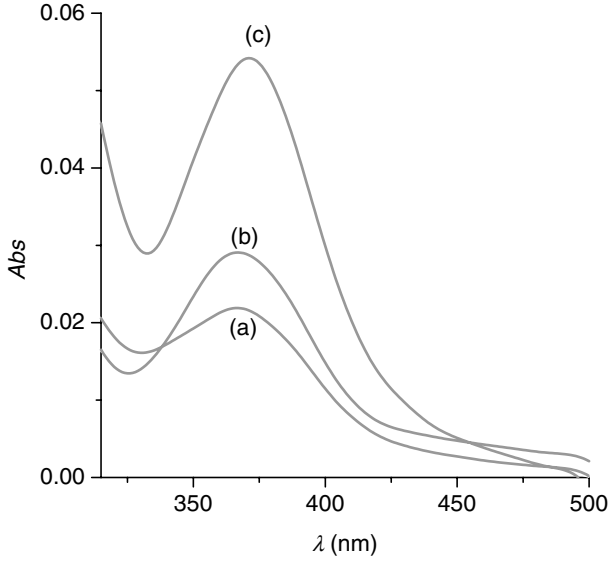


Fig. 1. UV–Vis difference spectra of Cr^{VI}/Myo solutions at pH 3.0, showing the increasing band at 371 nm with increasing [Myo]: (a) 0.06, (b) 0.12, and (c) 0.18 M. [Cr^{VI}] = 6.0×10^{-4} M, T = 33 °C, I = 1.0 M. Spectra taken 20 min after preparation of solutions.

4.1.2. Intermediacy of Cr^{II}

It is known that Cr^{IV} oxidizes alcohols as a two-electron oxidant to yield Cr^{II} and the oxidized organic product [17,25–27]. The participation of Cr^{II} in the mechanism of the oxidation of several alcohols by Cr^{IV} and Cr^{VI} in $HClO_4$ has been demonstrated by conversion to CrO_2^{2+} upon reaction with molecular oxygen [17,25]. At high $[O_2]$ and low $[Cr^{VI}]$ the reaction of Cr^{II} with O_2 can compete successfully with the reaction of Cr^{II} with Cr^{VI}, and if formed, Cr^{II} should yield the CrO_2^{2+} product [25,27]. The presence of intermediate Cr^{II} in the reaction of Myo with Cr^{VI} was examined by monitoring the formation of CrO_2^{2+}, using a $[Cr^{VI}]_0$ lower than employed in the kinetic studies. A periodic scanning of the O_2-saturated solution (1.26 mM O_2) of a Cr^{VI} + Myo reaction mixture in 0.40 M $HClO_4$ showed the appearance of two bands at 290 and 245 nm (Fig. 2). These two bands are characteristic of CrO_2^{2+} and persisted in solution after all the Cr^{VI} had been consumed. These spectroscopic results reveal that Cr^{II} forms in the redox reaction, and can be taken as evidence that Cr^{IV} is implied in the redox mechanism of the reaction between Cr^{VI} and Myo, such as observed in the reduction of Cr^{VI} by alcohols, linear polyols, saccharides, and hydroxyacids [17,25–29].

The yield of CrO_2^{2+} is expected to approach 100% if the reaction should take place exclusively through the $Cr^{VI} \rightarrow Cr^{IV} \rightarrow Cr^{II}$ pathway [27]. In the Myo + Cr^{VI} reaction, the percent yield of CrO_2^{2+} reaches a value of 50% suggesting that one half of the $HCrO_4^-$ is reacting through a pathway that involves Cr^{II}.

4.1.3. Intermediacy of Cr^{V}

EPR spectroscopy was used to detect intermediate Cr^{V} species formed in the reaction of Myo with Cr^{VI}. In 0.2 M $HClO_4$, the EPR spectra of Myo + Cr^{VI} reaction mixtures consist of one major signal at $g_{iso} = 1.9800$ and a weak (<10% of total Cr^{V}) signal at $g_{iso} = 1.972$. At this $[H^+]$, a modulation amplitude of ≈4 G was required to observe the Cr^{V} species; therefore, the superhyperfine (shf) pattern of the EPR signal (the ^1H shf splitting (a_H) for Cr^{V}-alcoholato species is usually <1 G) could not be resolved. The structure of the Cr^{V} intermediates was then analyzed from the EPR spectral features of 25–500 times excess of Myo over a mixture of chromate with GSH (1:1 ratio) at pH 4.4 and 7.4. Under these conditions, Cr^{V} generated by rapid reaction of GSH with Cr^{VI} was trapped by the inositol yielding Cr^{V}–Myo species that remain long time in solution. At pH 7.4 and 25–500:1:1 Myo:Cr^{VI}:GSH ratio, the EPR spectra were composed (signals were deconvoluted by fitting the spectra to Lorentzian derivatives) of one triplet at $g_{iso} = 1.9801$ ($a_H = 1.03 \times 10^{-4}$ cm^{-1}) and one doublet at $g_{iso} = 1.9799$ ($a_H = 0.95 \times 10^{-4}$ cm^{-1}) (Fig. 3(a)). The same two components were observed at pH 4.4 in 1:1: > 100 GSH:Cr^{VI}:Myo reaction mixtures (Fig. 3(b)). At this pH, and [Myo] = 25–100 mM, a third weak signal was observed at $g_{iso} \sim 1.979$ (Fig. 3(c) and (d)).

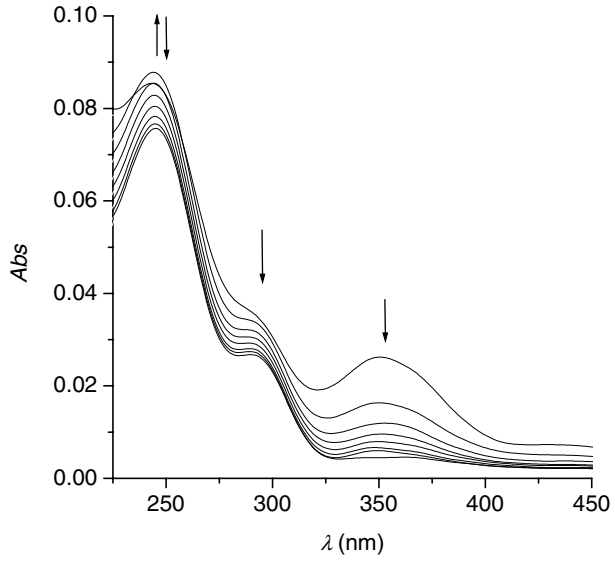

Fig. 2. Formation of CrO_2^{2+} (λ_{max} 290, 249) from the reaction between 0.130 M Myo, 1.26 mM O_2 and 3.0×10^{-2} mM Cr^{VI}, in 0.40 M $HClO_4$.

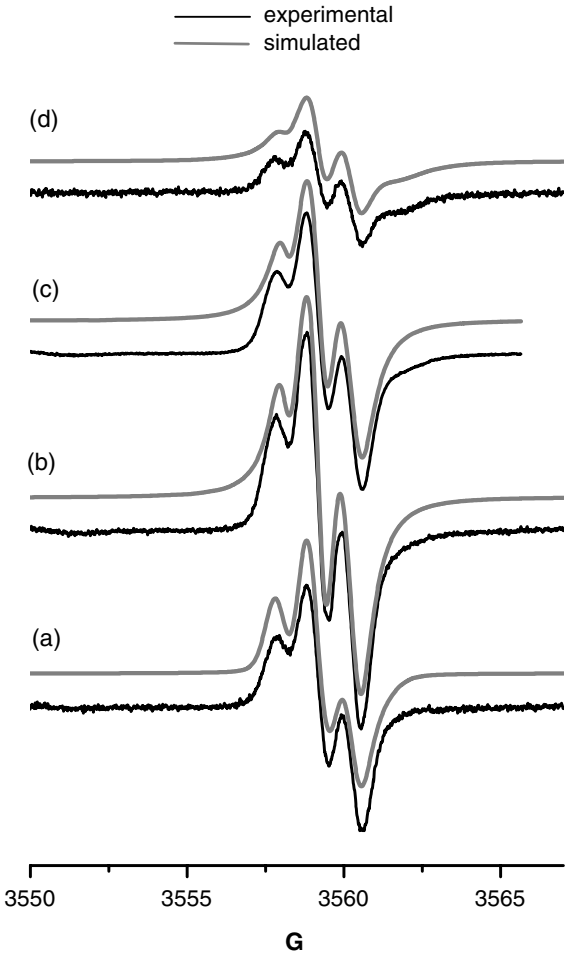

Fig. 3. Experimental and simulated X-band EPR spectra from mixtures of 1 mM GSH + 1 mM Cr^{VI} and: (a) 100 mM Myo, pH 7.4; (b) 250 mM Myo, pH 4.4; (c) 100 mM Myo, pH 4.4; (d) 25 mM Myo, pH 4.4. Frequency = 9.8640 GHz, mod. ampl. = 0.4 G.

4.2. Characterization of intermediate Cr^V species by EPR spectroscopy

The EPR spectral parameters together with the proton shf coupling have been shown to be useful in determining the binding modes of O-donor ligands in Cr^V complexes [7,12]. The g_{iso} value of the EPR signal of Cr^V complexes depends on the coordination number and the nature of the donor groups bound to Cr^V [30]. The estimation of Cr^V species present in solution was made taking into account empirical correlations between the structure of the Cr^V complexes and the EPR parameters together with [substrate] and pH dependencies of the EPR signals of the Cr^V complexes formed in Cr^{VI}/GSH/Myo mixtures.

It has been found that the multiplicity of the EPR signal of Cr^V-diolato complexes is dependent upon whether the ligand is cyclically strained or not. It was observed that in Cr^V-diolato complexes formed with linear diols, all the protons are equivalent in the isotropic EPR spectra [31], but the strain of a six membered rings imparts inequivalence to the magnetic environment of the protons in the second coordination sphere [32]. Thus, the EPR spectra of $[CrO(cis\text{-}1,2\text{-cyclohexanediol})_2]^-$ and $[CrO(trans\text{-}1,2\text{-cyclohexanediol})_2]^-$ exhibit a triplet and a singlet, respectively, and the difference was explained by arguing that only when the protons lie in the Cr^V-ligand plane there is a maximal overlap between the proton orbital and the Cr^V orbital containing the unpaired electron density.

It is known that five-membered Cr^V chelates are favored over six-membered ones [7,33,34]. Therefore, any of the *vic*-diolato groups of Myo are potential binding modes to afford five-membered Cr^V species. The two components at g_{iso} 1.9801 and 1.9799 of the EPR signal observed in the reaction of Cr^{VI} with GSH (1:1 ratio) in the presence of 25- to 500-times molar excess of Myo, at pH 7.4, correspond to those calculated for five-coordinated oxochromate(V) complexes with four alcoholato donors ($g_{calc} = 1.9800$) [30]. The shf splitting found for the two components of the EPR signal are in agreement with those expected for oxo-Cr^V-diolato$_2$ species with one and two (one from each chelate ring) carbinolic protons coupled to the Cr^V electronic spin [33]. The triplet can be attributed to the bis-chelate with oxo-Cr^V bound to the *cis*-diolato moiety of two Myo ligands $[Cr(O)(cis\text{-}O,O\text{-Myo})_2]^-$ (**I**), while the doublet can correspond to the $[Cr(O)(trans\text{-}O,O\text{-Myo})(cis\text{-}O,O\text{-Myo})]^-$ (**II**) bis-chelate (Fig. 4). At any [Myo], the ratio of the triplet (Cr^V-*cis*/*cis*-diol$_2$) to the doublet (Cr^V-*cis*/*trans*-diol$_2$) was 30:70, which means that 65% of the ligand is bound to Cr^V through the *cis*-diolato moiety. However, the ratio of *cis*:*trans* diol sites in Myo is 2:4. The marked preference of the CrO^{3+} ion for binding *cis*-rather than *trans*-diolato groups of cyclic diols explains the higher proportion of the Cr^V-*cis*-diolato binding mode in the mixture [33].

At pH 4.4, the EPR spectra of mixtures of 1:1: > 100 GSH:Cr^{VI}:Myo are composed of the same two signals at g_{iso} 1.9801 and 1.9799, in 30:70 ratio. But when [Myo] ⩽ 100 mM, the EPR spectra show, besides the two main components, a minor unresolved signal at $g_{iso} \sim 1.979$. The proportion of this third signal decreases from 20% to 3% of total Cr^V present in solution, when [Myo] varies from 25 to 100 mM. Although the lack of resolution disable the assignment of this signal, the decrease of its proportion with increasing [Myo] suggests that this species corresponds to a Cr^V monochelate (i.e. oxo-Cr^V–Myo) that transforms into the bis-chelate as the [Myo] increases.

In 0.2 M $HClO_4$ and 500:1 Myo:Cr^{VI} ratio, ($[Cr^{VI}]_0 = 8.0$ mM), one additional signal at $g_{iso} = 1.972$ appeared along with the signal centered at $g_{iso} = 1.9800$. At this $[H^+]$, rapid redox reaction between Cr^V and the ligand takes place affording a low intensity EPR signal that can be observed over a short time period. Therefore, to obtain good signal/noise ratios, a high modulation amplitude value is required and the shf pattern of the signals is not observed. The signal at g_{iso} 1.9800 corresponds to $[Cr(O)(vic\text{-}O,O\text{-diolato})_2]^-$ species (**I**, **II**), also observed at higher

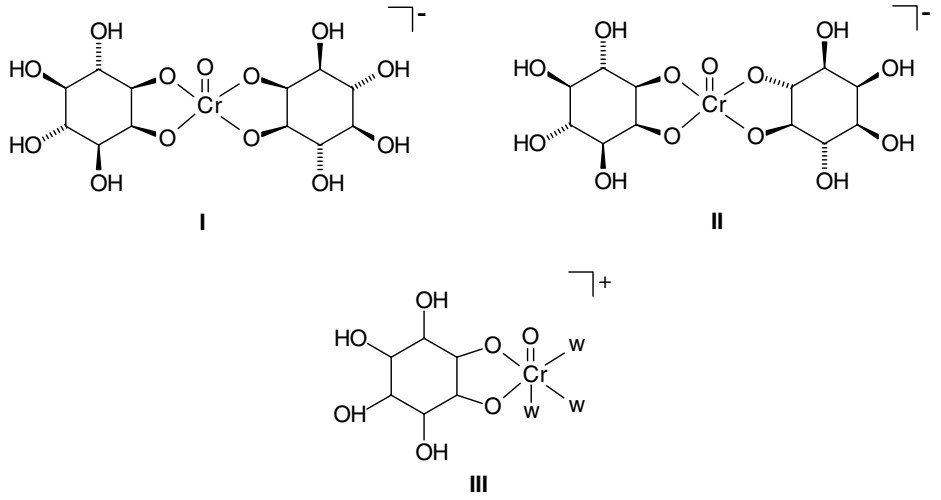

Fig. 4. Proposed structures of Cr^V complexes formed with Myo. For each complex only one of the possible binding isomers is shown.

pH values. The g-value of the weak signal at g_{iso} 1.972 and its observation at high [H^+], affords some information on its nature. Firstly, the low g_- value suggests a six-coordinated oxo-Cr^V species, possibly $[Cr(O)(O,O\text{-Myo})(H_2O)_3]^+$ (**III**, Fig. 4), since the calculated g_{iso} value for a six-coordinated oxo-Cr^V species with one *vic*-diolato donor and three water molecules (1.972) is in agreement with the observed g_{iso} value [30]. Furthermore, the positive charge is consistent with its appearance at high [H^+].

4.3. Rate studies

The reduction of Cr^{VI} by Myo is strongly dependent on pH. Although the reaction is slow at pH > 1, Cr^{VI} is rapidly consumed when the [H^+] > 0.1 M. For this reason, the 0.10–0.40 M [H^+] range was chosen to study the kinetics of this reaction. In 0.1–0.4 M $HClO_4$, the time-dependent UV–Vis spectra showed that the reaction of Myo with Cr^{VI} resulted in an absorbance band at 350 nm and a shoulder at 420–500 nm, characteristic of Cr^{VI} in acidic medium. The absorbance vs. time curves exhibited a monotonic decrease of absorbance at 350 nm that could not be described by a single exponential decay. It is known that Cr^V species absorb strongly at 350 nm and may superimpose Cr^{VI} absorbance. This Cr^V contribution to Abs^{350} becomes significant especially when the Cr^{VI} and Cr^V decay rates are of the same order [35]. In the redox reaction between Cr^{VI} and Myo relatively long-lived Cr^V species were observed in the EPR spectra. Therefore, the kinetic profiles for the Myo/Cr^{VI} system were fitted on the basis of the formation of Cr^V intermediate species and the reaction could be adequately described by the two consecutive first-order reactions of Scheme 2.

$$2\,Cr^{VI} \xrightarrow{k_6} Cr^{V} \xrightarrow{k_5} Cr^{III}$$
$$+$$
$$Cr^{III}$$

Scheme 2.

Taking into account the Cr^V and Cr^{VI} absorption superimposition, the absorbance at 350 nm, at any time during the reaction, is given by

$$Abs^{350} = \varepsilon^{VI}[Cr^{VI}] + \varepsilon^{V}[Cr^{V}] \quad (1)$$

Combining Eq. (1) with rate expressions [36] derived from Scheme 2 yields

$$Abs^{350} = Abs_o e^{-2k6t} + k_6\varepsilon^{V}[Cr^{VI}]_o(e^{-k5t} - e^{-2k6t})/(2k_6 - k_5) \quad (2)$$

In this equation, ε^V refers to the molar absorptivity of Cr^V at 350 nm. Values of ε^V depend on pH and were assumed to be the same as those found for the complex $[Cr^VO(ehba)_2]^-$ in the same [H^+] range (ε^V = 900–1100 M^{-1} cm^{-1}) [28]. Parameters k_6 and k_5 refer to the rate of disappearance of Cr^{VI} and Cr^V, respectively, and were evaluated from a non-linear iterative computer fit of Eq. (2). In this equation, k_6 appears in the numerator of the pre-exponential term and $2k_6$ appears in the denominator and in the exponential term because, according to the proposed reaction scheme, only one half of the Cr^{VI} reaches Cr^{III} through a Cr^V intermediate. Fig. 5(a) shows a typical curve for one run at 350 nm and the curve fit according to Eq. (2). The calculated kinetic parameters, k_6 and k_5, for various concentrations of Myo at fixed concentrations of $HClO_4$ are summarized in Table 1.

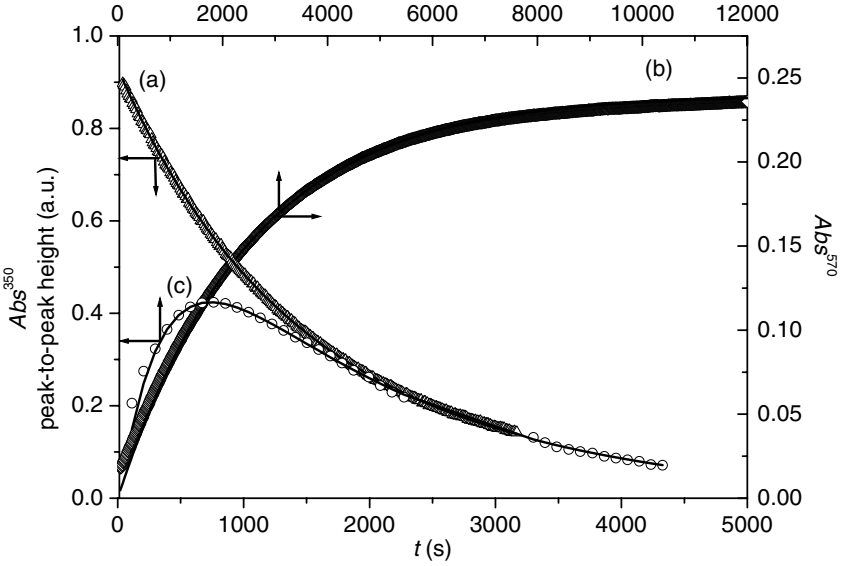

Fig. 5. Curves showing absorbance and EPR signal height vs. time for the oxidation of Myo by Cr^{VI}, I = 1.0 M, [H^+] = 0.20 M. (a) λ = 350 nm, [Cr^{VI}] = 6.0×10^{-4} M, [Myo] = 0.24 M; T = 33 °C; (b) λ = 570 nm, [Cr^{VI}] = 1.5×10^{-2} M, [Myo] = 0.24 M, T = 33 °C; (c) g_{iso} = 1.9800, [Cr^{VI}] = 8.0×10^{-3} M, [Myo] = 0.51 M, T = 20 °C. Fitted lines were calculated using Eqs. (2)–(4).

Table 1
Observed pseudo-first-order rate constants (k_6 and k_5) for different concentrations of $HClO_4$ and Myo

[Myo] (M)	0.06	0.12	0.15	0.18	0.24	
					350 nm	570 nm[a]
$[HClO_4]$ (M) 10^4k_6 (s^{-1})

0.30	3.34 (9)	5.91 (9)	7.18 (4)	9.80 (1)	12.5 (1)	11.5 (1)
0.40	7.95 (1)	9.31 (3)	13.4 (7)	15.4 (6)	23.9 (1)	19.6 (1)

$T = 33$ °C; $[Cr^{VI}]_0 = 6 \times 10^{-4}$ M; $I = 1$ M.
[a] $[Cr^{VI}] = 15 \times 10^{-3}$ M.

The possible contribution of a Cr^{IV} intermediate species to Abs^{350} was disregarded because the rate constant for the formation of CrO_2^{2+} (k_f) equals $k_6 - k_f$ was calculated from the $Abs^{245}(CrO_2^{2+})$ vs. time curve, where $Abs^{245}(CrO_2^{2+}) = Abs^{245} - Abs^{245}(Cr^{VI} + Cr^{V})-$. This result means that the $Cr^{IV} \rightarrow Cr^{II}$ is a fast step in the $Cr^{VI} \rightarrow Cr^{IV} \rightarrow Cr^{II}$ pathway and Cr^{IV} reacts much rapidly than forms.

The electronic and EPR spectra show that the final Cr species in the reaction mixture is the free aqueous Cr^{3+}. At 570 nm, where only Cr^{3+} absorbs, the experimentally observed Cr^{3+} growth curves could be fitted to the expression derived from Scheme 2 for the Cr^{3+} present in the mixture at any time (Eq. (3))

$$Abs^{570} = Abs_\infty\{1 + [(k_5 - k_6)e^{-2k6t} - k_6e^{-k5t}]/(2k_6 - k_5)\} \quad (3)$$

Values of k_5 and k_6 obtained with Eq. (3) are in good agreement with those calculated from Eq. (2), for 0.24 M Myo and 0.10 to 0.40 M $HClO_4$ (Table 1). A typical fit of experimental data at 570 nm by using Eq. (3) is shown in Fig. 5(b).

The values of k_6 and k_5 were independently confirmed by monitoring the redox reaction by EPR spectroscopy. In 0.20 M $HClO_4$ and 500:1 Myo:Cr^{VI} molar ratio, the Cr^{V} EPR signal at $g_{iso} = 1.9800$ was found to grow, reach a maximum and then decay (Fig. 5(c)). The peak-to-peak height of the EPR signal as a function of time could be fitted to the expression derived from Scheme 2 for the total Cr^{V} present in the reaction mixture (Eq. (4))

$$EPR_{height} = k_6[Cr^{VI}]_0U(e^{-k5t} - e^{-2k6t})/(2k_6 - k_5) \quad (4)$$

In this equation, the U parameter depends on the EPR spectrometer acquisition conditions (gain, power, modulation, etc.). The calculated rate constants for the formation and disappearance of the intermediate Cr^{V}, k_6, and k_5, are consistent with those obtained from the spectrophotometric measurements. The lower temperature (25 °C, instead of 33 °C) used in the EPR measurements accounts for the slightly delayed t_{max} observed by this technique. The intensity of the minor signal decayed with time at the same rate as the major one.

4.4. k_6 and k_5 dependencies on [Myo] and [H^+]

In the range of $[H^+]$ used in the kinetic studies, plots of k_6 vs. [Myo] gave good straight lines from which values of k_{6H} were determined (Fig. 6). The bimolecular rate constant k_{6H} varied with $[H^+]$ (inset in Fig. 6) according to Eq. (5)

$$k_{6H} = k_I[H^+] + k_{II}[H^+]^2 \quad (5)$$

where $k_I = (3.22 \pm 1.3) \times 10^{-3}$ M^{-2} s^{-1}, and $k_{II} = (31.9 \pm 4.5) \times 10^{-3}$ M^{-3} s^{-1}.

At constant $[H^+]$, plots of k_5 vs. [Myo] showed a linear dependence on [Myo] (Fig. 7), from which the bimolecular rate constants k_{5H} were calculated. k_{5H} showed a second-order dependence on $[H^+]$ (inset in Fig. 7), with a slope $k_{III} = (56.67 \pm 1.83) \times 10^{-3}$ M^{-3} s^{-1}.

The complete rate laws for the Cr^{VI} and Cr^{V} disappearance are then given by

$$-d[Cr^{VI}]/dt = 2k_6[Cr^{VI}] = 2(k_I[H^+] + k_{II}[H^+]^2)[Myo][Cr^{VI}] \quad (6)$$

$$-d[Cr^{V}]/dt = k_5[Cr^{V}] = k_{III}[H^+]^2[Myo][Cr^{V}] \quad (7)$$

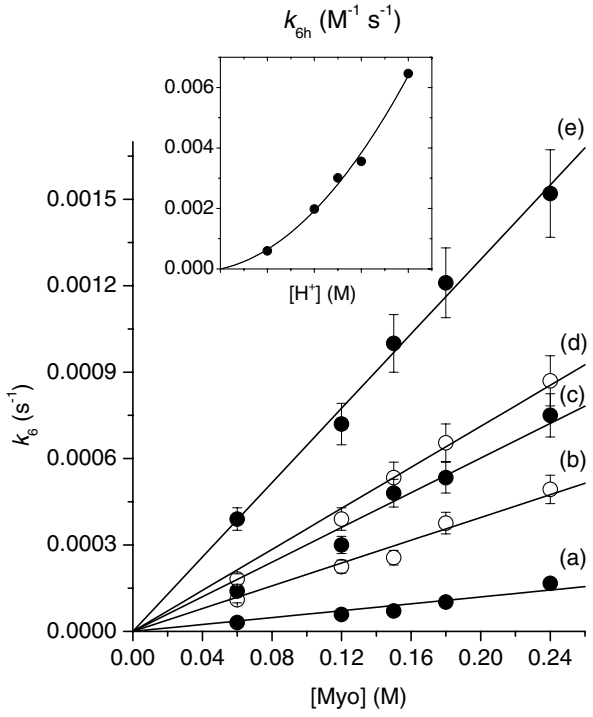

Fig. 6. Effect of [Myo] on k_6 at 33 °C, $I = 1.0$ M and $[H^+]$: (a) 0.10; (b) 0.20; (c) 0.25; (d) 0.30 and (e) 0.40 M. Inset: dependence of k_{6h} on $[H^+]$.

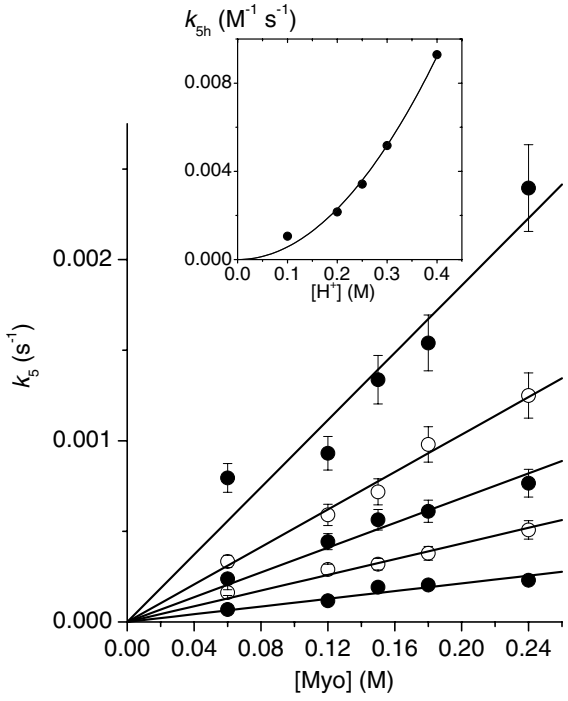

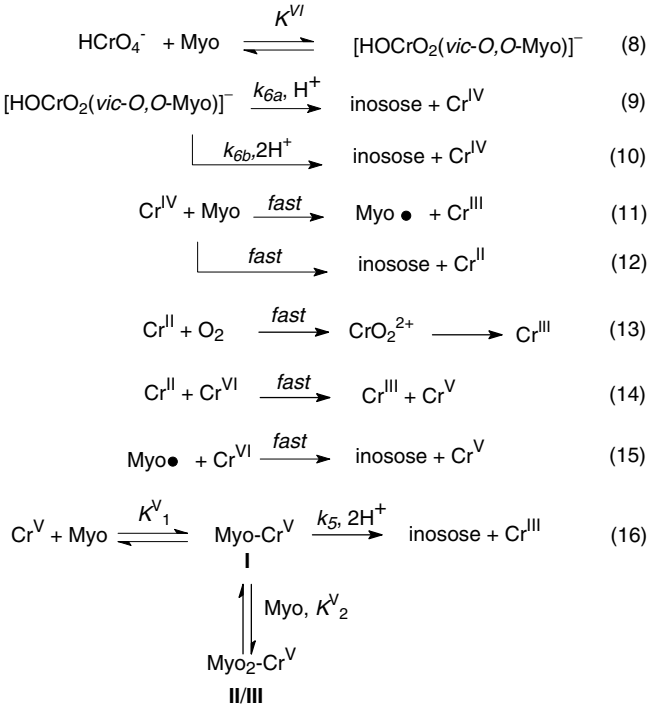

Fig. 7. Effect of [Myo] on k_5 at 33 °C, $I = 1.0$ M and [H^+]: (a) 0.10; (b) 0.20; (c) 0.25; (d) 0.30 and (e) 0.40 M. Inset: effect of acidity on k_{5h}.

Scheme 3.

4.5. Mechanism of the oxidation of Myo by Cr^{VI} and Cr^V

In the range of substrate and acid concentration used in this work, the oxidation of Myo by Cr^{VI} is a complex multistep reaction yielding Cr^{3+} and inosose as final redox products. In Scheme 3, we propose a mechanism that takes into account (a) the kinetic results, (b) the polymerization of acrylamide added to the reaction mixture, (c) the detection of an intermediate Cr^{VI} ester and oxochromate(V) species, (d) the reaction products, and (e) the 50% yield of CrO_2^{2+}.

In the [H^+] range under study, Cr^{VI} may exist as $HCrO_4^-$ [37], and this species is proposed as the reactive form of Cr^{VI}, in agreement with the first-order dependence of the reaction rate on [Cr^{VI}]. It is known that the chromic oxidation of alcohols and glycols are preceded by the formation of a chromate ester [23,24]. The observation of the absorbance band characteristic of chromate ester around 371 nm a few minutes after mixing Myo and Cr^{VI}, under conditions where the redox reaction is extremely slow, reveals that such an intermediate Cr^{VI} complex is rapidly formed prior to the redox step. Thus, the first step of the mechanism proposed in Scheme 3 (Eq. (8)) can be interpreted as the formation of a Myo–Cr^{VI} monochelate, with the cyclitol acting as a bidentate ligand bound to Cr^{VI} via any pair of appropriately disposed hydroxyl groups.

The two terms in the rate law result from the fact that there are at least two transition states, through which the reduction of Cr^{VI} can proceed. Thus, the oxidation of Myo by Cr^{VI} is proposed to occur through two parallel slow steps, catalyzed by one or two protons, respectively, leading to the redox products (Eqs. (9) and (10)). These slow steps are proposed to involve a two-electron intramolecular transfer to yield Cr^{IV} and the inosose. The formation of Cr^{IV} is consistent with the observation of CrO_2^{2+}, the product of the reaction of Cr^{II} with O_2, which is taken as evidence of the Cr^{IV} formation [17,25].

After the slow redox steps, Cr^{IV} is predicted to react with excess Myo to yield Cr^{III} and a Myo radical or Cr^{II} and inosose through two competitive fast steps (Eqs. (11) and (12)). The first is supported by the observed polymerization of acrylamide when it is added to the reaction mixture, while the second, by the formation of CrO_2^{2+}. Cr^{IV} + Myo is proposed to be faster than reaction Cr^{VI} + Myo, a fact supported by the $[CrO_2^{2+}]/[Cr^{VI}]_0$ ratio of 0.5. The 50% yield of CrO_2^{2+} means that Eqs. (11) and (12) are fast reactions and that CrO_2^{2+} and Myo radical are formed at the rate of Cr^{VI} consumption (slow step).

Cr^V can form by fast reaction of Cr^{II} with Cr^{VI} (Eq. (14)) – the [Cr^{VI}] used in the kinetic experiments is higher than used for the detection of CrO_2^{2+}, therefore Cr^{VI} can successfully compete with O_2 for Cr^{II} –, and, alternatively, by rapid reaction of the Myo radical with Cr^{VI} (Eq. (15)). Under the experimental conditions used in the kinetic experiments (more diluted Cr^{VI} solutions than used to detect CrO_2^{2+}), Eq. (13) can be neglected [25].

The kinetic data indicate that Cr^V formed in the fast steps can further oxidize Myo through an acid catalyzed step to yield Cr^{III} and the inosose as the final redox products. In the scheme, it is proposed that Cr^V reacts with Myo to form an oxo-Cr^V–Myo monochelate (species **III**

observed in the EPR spectra) that yield the redox products through an acid catalyzed step (Eq. (16)). At higher pH, this redox path is much slower than reaction with a second Myo molecule to yield the oxo-Cr^{V}–Myo_2. This proposal is in agreement with the EPR spectra at pH 4.4 and 7.4 that show the oxo-Cr^{V}–Myo_2 species (**I**, **II**) as the main Cr^{V} species present in the mixture.

5. Conclusions

The present study shows that Myo is able to stabilize Cr^{VI} and Cr^{V} species at pH 4–7, but at higher $[H^+]$ redox reaction occurs and Cr^{III} and the inosose are the final redox products. The kinetic results show that all the redox steps, involving either Cr^{VI} or Cr^{V}, require one or two protons, thus explaining the lack of redox reaction at the higher pH and the formation of oxo-Cr^{VI}/Myo and oxo-Cr^{V}/Myo species that remain in solution long time (days to months). This behavior is analogous to that of alditols [38] and aldoses [39], which are oxidized by Cr^{VI} (and Cr^{V}) at pH < 1 – at rates similar to Myo –, and form stable Cr^{VI} and Cr^{V} chelates at pH > 2.

Abstract

The $[Ru^{II}(trpy)(pic)(H_2O)]^+$ (**1**) was synthesized and characterized by analytical, spectral (UV–Vis and IR), molar conductivity, magnetic moment and electrochemical studies. Complex **1** catalyzes the epoxidation of styrene and stilbenes in presence of *tert*-butyl hydroperoxide (*t*-BuOOH) in dichloromethane at room temperature. No epoxide formation was observed in presence of the radical trapping agent (benzoquinone). A mechanism involving formation of [Ru–O(*t*-Bu)–O]˙ type of radicaloid intermediate as an active intermediate responsible for epoxide formation is proposed for the catalytic epoxidation process.

Keywords: Ruthenium(II)-complex; Ruthenium(IV)-complex; Terpyridine ligand; *t*-BuOOH; Alkene epoxidation

1. Introduction

Over the past two decades it has been shown that the polypyridyl complexes of ruthenium are of great significance as they are coordinatively stable both in higher and lower oxidation states, and a variety of polypyridyl complexes of ruthenium are reportedly known to be effective stoichiometric and/or catalytic reagents toward oxidation of a variety organic and inorganic substrates. In this regard ruthenium-oxo-polypyridyl complexes such as $[Ru(bipy)_2(py)(O)]^{2+}$ (biy = 2,2′-bipyridine) [1] and $[Ru^{IV}(trpy)(bipy)(O)]^{2+}$ (tpy = 2,2′,6′,2″-terpyridine) [2] are reportedly known to be a very powerful oxidants toward oxidation of various organic substrates. However, catalytic application of $[Ru^{II}(tpy)(XY)(H_2O)]$ type of complexes toward hydrocarbon oxidation using a terminal oxidant has not been reported till date. Recently, we have been engaged in developing [Ru(TDL)(XY)(H_2O)] type of ruthenium(III) catalyst complexes (where TDL = tridentate ligands; XY = bidentate ligands) that exhibit selectivity toward oxo-functionalization of saturated and unsaturated hydrocarbons [3]. The use of mixed-ligand complexes of ruthenium of the type $[Ru^{III}(TDL)(XY)(H_2O)]$ are particularly intriguing in view of exploiting a combined effects with regards to the metal redox chemistry and geometry. Incorporation of nearly 'flat' TDL in the metal complexes could afford a near planar geometry for the catalytic species for which side-on-approach for the organic substrate would be easier stereochemically. Moreover, TDL's provide sites that can undergo stereogenic as well as chiral substitution, thus rendering promising chiral controlling shapes for asymmetric catalysis [3c,3d]. Secondly, the electrophilicity of the ruthenium center could be tuned by changing the ancillary ligand (XY). The present investigation is undertaken to examine the catalytic properties of $[Ru^{II}(tpy)(XY)(H_2O)]$ type of complexes toward olefin epoxidation using a terminal oxidant. We wish to report herein, the synthesis and characterization of a new $[Ru^{II}(tpy)(pic)(H_2O)]^+$ ($pic^- =$ picolinate) complex and its catalytic application, first instance of any $[Ru^{II}(tpy)(XY)(H_2O)]$ complex, toward epoxidation of various alkenes (viz. styrene and substituted styrenes, stilbenes, cyclohexene, 1,2-dihydronaphthalene) in presence of *t*-BuOOH as a terminal

oxidant under ambient conditions. The use of *t*-BuOOH is of significance in regard to its by-product, environmentally friendliness and price.

2. Experimental

2.1. Materials

The starting compound $[Ru(tpy)Cl_3]\cdot 2H_2O$ was prepared by following the literature procedure [4] and characterized by elemental analysis and spectral data which were in agreement with data reported in the literature [4]. $[Ru^{II}(trpy)(pic)H_2O]ClO_4$ (**1**) was synthesized by adopting the procedure reported for $[Ru^{II}(trpy)(bipy)H_2O]ClO_4$ [5]. All other chemicals used were of AR grade and doubly distilled H_2O was used to prepare all solutions.

2.2. Synthesis of $[Ru^{II}(trpy)(pic)H_2O]ClO_4$ (1)

To a solution of $[Ru(tpy)Cl_3]\cdot 2H_2O$ (442.5 mg, 1 mmol) in water–ethanol mixture (40 ml, 75:25) containing LiCl (0.25 g, 6 mmol) and triethylamine (0.25 ml) was added picolinic acid (123.1 mg, 1 mmol), and the resultant mixture was refluxed for 4 h and filtered hot. The filtrate was cooled and the volume was reduced in rotary evaporator. A dark brown precipitate so obtained was collected on a frit and washed with chilled 3 M HCl followed by washing with acetone and finally by ether. The product [Ru(trpy)-(pic)Cl] so obtained was treated with $AgClO_4$ to obtain the desired aquo-product, $[Ru(trpy)(pic)H_2O]ClO_4$. To a hot solution of $[Ru(trpy)(pic)Cl]\cdot 3H_2O$ (1 mmol, 550.5 mg) was added $AgClO_4$ (1 mmol, 225.3 mg) and the reaction mixture was heated for 15 min. AgCl produced was filtered off and the volume of the filtrate was reduced in rotary evaporator. A brown mass was obtained which was washed with a minimum amount of cold water and dried in air. Yield. (65%). *Anal.* Calc. for $C_{21}H_{17}N_4O_7RuCl$: Calc. C, 43.9; H, 2.96; N, 9.76. Found. C, 44.2; H, 3.1; N, 9.5%. Λ_M ($\Omega^{-1}\,M^{-1}\,cm^2$) in $H_2O = 86$. $m/z = 473.98$. 2.3. Instrumentation

The UV–Vis electronic absorption spectra were obtained on a Perkin–Elmer (Model Lambda 35) spectrophotometer. IR spectra were collected on a Perkin–Elmer (Model 783) spectrometer using KBr pellets. NMR studies were performed on a Bruker 300AC NMR spectrometer. Cyclic voltammetric experiments were conducted in a glass cell equipped with a glassy carbon working electrode, platinum-wire auxiliary electrode and standard calomel electrode (SCE) as reference electrode. A CH Electrochemical Instruments (CHI-660B) was used for this purpose. Coulometric experiments were performed using a platinum gauge working electrode. A sample of **1** (5 mg) dissolved in 25 ml of an aqueous solution of $NaClO_4$ (0.2 M) was used for constant potential electrolysis. Electrolysis of the bulk solution was carried out at pH 6.7. The values of '*n*' estimated from the coulomb readings were found to lie in the range 0.95–0.98. The oxidized solution was suitably diluted for spectrophotometric measurements. Magnetic susceptibility was measured by using a PAR-155 vibrating sample magnetometer. A Perkin–Elmer 240C elemental analyzer was used to collect microanalytical (C,H,N) data.

2.4. Kinetic studies

The kinetics of the reaction of **1** with terminal oxidant *t*-BuOOH was studied spectrophotometrically under pseudo-first order condition of excess oxidant (10–40 times) at 500 nm where appreciable spectral changes exist. The solution temperature was maintained to within ±0.1 °C using a circulating water bath (JEIO TECH RW-1025G). The pH of the solutions was measured with a Mettler Delta 350 pH meter. Phosphate buffer was used to maintain the pH at 6.2 during the kinetic studies.

2.5. Procedure of catalytic studies

In a typical experiment 0.01 mmol of the catalyst complex (**1**), 1.0 mmol of 70% aqueous *t*-BuOOH oxidant and 1.0 mmol of substrate in 5 ml of CH_2Cl_2 were rapidly magnetically stirred at room temperature (25 °C). For radical trapping experiments 1.0 mmol of benzoquinone (used as radical trapping agent) was added to the above catalytic system. At the end of the reaction an internal standard (decane) was added and an aliquot was taken for GC analysis. GC analysis was performed with a Carlo Erba GC 8000^{Top} series on Tenax column fitted with FID. GC parameters were quantified with authentic samples of product prior to the analysis.

3. Results and discussion

3.1. Characterization of ruthenium complexes

Complex **1** together with the NMR numbering scheme is pictorially represented in Fig. 1. A strong band in the IR spectra of the **1** appeared in the region 1590–1600 cm^{-1} is assigned to ν(C=N) stretching, whereas, the strong band in the region 1630–1635 cm^{-1} is assigned to the coordinated carboxylate group. The absorption spectrum of **1** in H_2O exhibited a number of bands in the UV–Vis region. The bands appearing in the UV region are characterized by intra-ligand ($\pi \rightarrow \pi^*$) charge transition, whereas, spectral features in the visible region (Fig. 2a) are attributed to the metal to ligand, $d\pi(Ru) \rightarrow \pi^*$(polypyridyl) charge

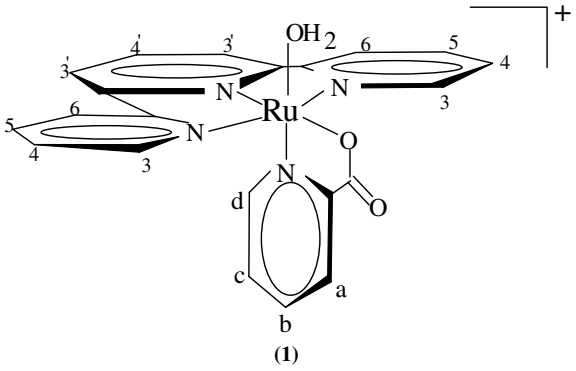

Fig. 1. Pictorial representation of $[Ru^{II}(tpy)(pic)(H_2O)]^+$ (**1**).

transitions. In the ^1H NMR spectrum of the **1**, signals for the 'tpy' ring protons as well as for the pyridyl protons of 'pic$^-$' appeared in a narrow chemical shift range (6.92–8.54 ppm). It had been reported earlier that in the $[Ru(tpy)(bipy)Cl]^+$ the two pyridyl rings of the 'bipy' moiety are non-equivalent, while the 'tpy' ligand is split into two equivalent parts by a plane of symmetry. The 6′ proton of the 'bipy' ligand which is closest to coordinated CD_3CN, has a quite low field chemical shift (9.6 ppm) with regard to other bipy protons [2a]. Absence of resonance in such a low field region plausibly indicates that the coordinated pyridyl moiety of the 'pic$^-$' is positioned *trans* to the H_2O in **1**, as shown in Fig. 1. Conductance data (see Section 2) established the 1:1 electrolyte nature of **1**.

Cyclic voltammogram of **1** in aqueous solution buffered at pH 3.8 displayed two distinct reversible waves (Fig. 3) and, the $E_{1/2}$ values corresponding to the Ru^{IV}/Ru^{III} and Ru^{III}/Ru^{II} redox couples estimated from cyclic voltammetric studies are 0.60 and 0.41 V, respectively. The potentials for two redox waves varied with the pH of the solution as recorded in Table 1. The reversibility of the Ru(IV)/(III)/(II) couples observed in the present studies is consistent with one electron, one proton transfer process as proposed in Scheme 1.

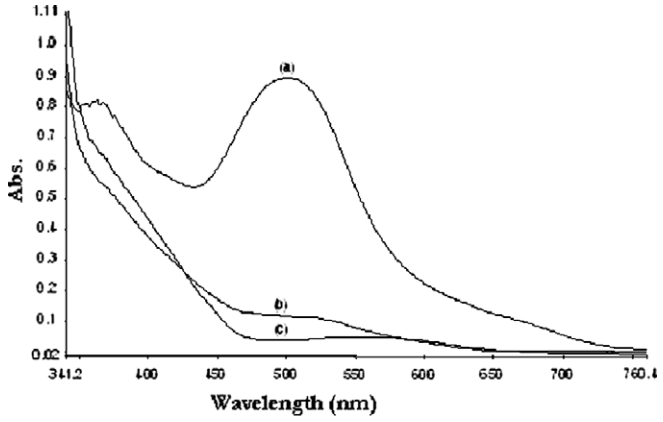

Fig. 2. Absorption spectra (a) $[Ru^{II}(tpy)(pic)(H_2O)]^+$, (b) $[Ru^{III}(tpy)(pic)(OH)]^+$ and (c) $[Ru^{IV}(tpy)(pic)(O)]^+$ in H_2O at pH 6.2.

The spectrum of $[Ru^{III}(tpy)(pic)OH]^+$ species generated electrochemical oxidation (bulk electrolysis at 0.42 V , pH 3.8) is shown in Fig. 2b.

3.2. Catalysis of alkene epoxidation

Prior to the catalytic experimentation we performed a brief kinetic study of the reaction of **1** with *t*-BuOOH demonstrated by the spectral changes as shown in Fig. 4. The rate of the reaction was found to be first order with respect to [**1**] and the values of pseudo-first order rate constant (k_{obs}) increased linearly by increasing [*t*-BuOOH]. The temperature dependence studies of the reaction yielded rate-constant (k) values of 3.26, 3.85, 4.46, 5.31 and 6.20 M^{-1} s^{-1} at 25, 30, 35, 40 and 45 °C, respectively at pH 6.2. The values of activation parameters obtained from the above studies are $\Delta H^{\neq} = 21 \pm 0.4$ kJ mol^{-1} and $\Delta S^{\neq} = -161 \pm 1.3$ J mol^{-1} deg^{-1}. Comparison of the spectral feature of the resultant solution at the end of the reaction (Fig. 4) with that of shown in Fig. 2b, indicative of the formation of ruthenium(III)-species in the solution. The results of epoxidation of selected alkenes catalyzed by **1** using *t*-BuOOH as a precursor oxidant are summarized in Table 2. In all cases, epoxides were found to be the major product, however, minor amounts of benzaldehyde was also obtained in each case (Table 2). In presence of the radical trap (BQ) negligible amount of product (<1%) formation was observed after 10 h of reaction. A mixture

	trans-stilbeneoxide	55
	benzaldehyde	13
Cyclohexene	cyclohexene oxide	43
1,2-Dihydronaphthalene	1,2-dihydronapthalene oxide	54

[a] Identification and quantification of epoxides of stilbenes were carried out by following an earlier report on the ^{1}H NMR analysis of stilbene epoxides [13], wherein, the peaks at 3.90 and 4.31 ppm were assigned to *trans*-stilbene oxide and *cis*-stilbene oxide, respectively.
[b] Based on alkene taken. Reaction time 5 h.

of *cis*- and *trans*-epoxides was produced (Table 2) during epoxidation of *cis*-stilbene. The loss of stereoselectivity necessarily indicates the radicaloid character of the intermediate species formed during epoxidation, which allowed a limited amount of rotation through –C–C– bond prior to the epoxide formation. The results of the above investigation taken together provide a qualitative picture of the alkene epoxidation in presence of **1** and *t*-BuOOH in dichloromethane. The formation of a [Ru–O(*t*-Bu)–O]$^{\bullet}$ type of radicaloid intermediate species in resemblance to that of reported earlier in the catalytic oxidation of alkanes with *t*-BuOOH using *cis*-$[Ru^{II}(L)_2(H_2O)_2]^{2+}$ (L = polypyridyl ligands) [6a] and $[Ru^{III}(Me_3tacn)(H_2O)(CF_3CO_2)]^{2+}$ [6b] as catalysts, is proposed in the plausible stepwise mechanisms (Scheme 2) for complex-**1** catalyzed epoxidation of alkenes in the present case. No product formation in presence of BQ (radical trap) further substantiates the formation such intermediate.

In the first step of the proposed mechanism (Scheme 2), **1** reacts with *t*-BuOOH to form an intermediate $[Ru^{II}(tpy)(pic)(OHO^tBu)]^+$ (**I**) species in a rate determining aquo-substitution step. Coordinated *t*-BuOOH undergoes

Scheme 2.

[a] terpy = 2,2′,6′,2″-terpyridine; pydic = pyridyl dicarboxylate. Reaction conditions: catalyst = 0.025 mmol, oxidant = 2.0 mmol, substrate = 0.5 mmol, solvent = CH_2Cl_2, temp. = room temperature.

[b] pybox = pyridinebisoxazoline. Reaction conditions: catalyst = 0.025 mmol, oxidant = 1.5 mmol, substrate = 0.5 mmol, solvent = CH_2Cl_2, temp. = room temperature.

[c] [(1*R*,2*R*)-P(NH)(NH)P] = (1*R*,2*R*)-*N*,*N*′-bis(diphenylphosphanyl)benzylidene]-1,2-diaminocyclohexane]. Reaction conditions: catalyst = 0.001 mmol, oxidant = 3.2 mmol, substrate = 1.5 mmol, solvent = benzene, temp. = ambient temperature; major reaction products are 2,3-diphenyloxirane (58%), benzoic acid (17%) and benzaldehyde (15%).

[d] dppm = diphenylphosphinomethane. Reaction conditions: catalyst = 12 μmol, oxidant = 5.8 mmol, substrate = 10 mmol, solvent = CH_3Cl, temp. = 50 °C.

[e] bipy = 2,2′-bipyridine. Reaction conditions: catalyst = 0.05 mmol, oxidant = 6.0 mmol, substrate = 3 mmol, solvent = CH_2Cl_2, temp. = 0 °C.

[f] Me_3tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane. Reaction conditions: catalyst = 0.01 mmol, oxidant = 1 mmol, substrate = 1 mmol, solvent = CH_2Cl_2, temp. = 25 °C.

[g] Reaction conditions: catalyst = 600 mg (1% w/w), oxidant = 2.3 mmol, substrate = 1 mmol, solvent = CH_2Cl_2, temp. = room temperature.

deprotonation **Ia** and oxidize metal center to from the radicaloid intermediate **II** through an inner-sphere electron transfer pathway. Interaction between **II** and alkene appears to be the plausible route for the catalytic epoxidation of styrenes and stilbenes studied in the present work. The catalytic cycle is further repeated by the generation of **II** in the reaction between $[Ru^{II}(tpy)(pic)(OBu^t)]$ and another molecule of *t*-BuOOH as shown in Scheme 2.

The efficacy of the present system is shown with that of other reported Ru-complex/*t*-BuOOH catalytic system, taking *trans*-stilbene as a test substrate (Table 3). Since, product yield and selectivity are dependent on so many factors like, variability of solvent, reaction time and most importantly the nature of the active intermediate formed in the catalytic process, it is difficult to make any significant comparison of one system with another. However, the efficacy of the present catalytic system in terms of product yield and selectivity seems to be prospective.

4. Conclusions

The results of the present studies reveal that the $[Ru^{II}(tpy)(pic)(H_2O)]^+$ can effect alkene epoxidation in presence of *t*-BuOOH (as precursor oxidant). This work taken collectively with those on Ru-complex/*t*-BuOOH catalytic systems [6b–12] indicate the intermediacy of a radicaloid species, [Ru–O(t-Bu)–O•] in the catalytic oxidation process. This is regardless of the fact that the high-valent Ru-oxo species is capable of transferring O-atom to the alkenes, or not.

Abstract

The reaction between uranyl nitrate hexahydrate and phenolic ligand precursor [(*N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-4-amino-1-butanol) · HCl], $H_3L1 \cdot HCl$, leads to a uranyl complex $[UO_2(H_2L1)_2]$ (**1a**) and $[UO_2(H_2L1)_2] \cdot 2CH_3CN$ (**1b**). The ligand [(*N*,*N*-bis-(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-4-amino-1-butanol)$H_3L2 \cdot HCl$], $H_3L2 \cdot HCl$, yields a uranyl complex with a formula $[UO_2(H_2L2)_2] \cdot CH_3CN$ (**2**). The ligand [(*N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-5-amino-1-pentanol) · HCl], $H_3L3 \cdot HCl$, produces a uranyl complex with a formula $[UO_2(H_2L3)_2] \cdot 2CH_3CN$ (**3**) and the ligand [(*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-5-amino-1-pentanol) · HCl], $H_3L4 \cdot HCl$, leads to a uranyl complex with a formula $[UO_2(H_2L4)_2] \cdot 2CH_3CN$ (**4**). The ligand [(*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-6-amino-1-hexanol) · HCl], $H_3L5 \cdot HCl$, leads to a uranyl complex with a formula $[UO_2(H_2L5)_2] \cdot 4$toluene (**5**). The complexes **1**–**5** are obtained using a molar ratio of 1:2 (U to L) in the presence of a base (triethylamine). The molecular structures of **1a**, **1b**, **3**, **4** and **5** were verified by X-ray crystallography. All complexes are neutral zwitterions and have similar centrosymmetric, mononuclear, distorted octahedral uranyl structures with the four coordinating phenoxo ligands in an equatorial plane. In uranyl ion extraction studies from water to dichloromethane with ligands $H_3L1 \cdot HCl$–$H_3L5 \cdot HCl$, ligands $H_3L1 \cdot HCl$, $H_3L4 \cdot HCl$ and $H_3L5 \cdot HCl$ are the most effective ones.

1. Introduction

The world production of uranium over the past few years has been about 36 000 t (about 42 000 t of U_3O_8). This is used mainly as fuel for nuclear reactors and in different kinds of military uses, small amounts have been used as a pigment to color ceramics and glass [1]. The production and consumption of uranium on this scale causes different kinds of needs for its removal from e.g. wastes or the human body because it poses a threat to human health and environment due to its toxicity and radioactivity [2]. After an exposure to uranium, the treatment of the person afflicted consist of chelation therapy, which is aimed at binding the metal and subsequently favoring its excretion as a metal–chelate complex [3]. For that purpose chelating agents such as catechols, β-diketones and hydroxy ketones have been proposed [4]. Also other kinds of chelators which contain nitrogen in addition to oxygen have been studied in certain laboratories [5]. A common feature in these is that they are organic multidentate ligands with hard oxygen donor atoms and possibly nitrogen atoms.

The coordination chemistry of the linear UO_2^{2+} ion is dominated by between four to six donor atoms, all occupying equatorial positions resulting in octahedral, pentagonal bipyramidal or hexagonal bipyramidal coordination, respectively, for U(VI). Typical hard Lewis bases such as F^- or O-donors like phenolate O are good ligands for the hard UO_2^{2+} ion [6,7]. However, the Lewis basicity of uranyl oxo ligands is generally quite weak and they very

doi:10.1016/j.poly.2006.08.006

rarely produce, for example, polynuclear complex units by forming an oxo bridge between the U(VI) ions [8]. For uranyl extraction many kinds of ligands have been prepared and are in current use. For example, organic phosphorous oxides are used in a commercial uranyl extraction system [9] and other functional groups bound to a solid matrix have also been used for the extraction of uranyl and actinide ions [10,11]. Agents specific for sequestering the uranyl ion from biological systems are generally based on ligands containing catecholate functional groups and ligands containing keto and hydroxyl groups like hydroxypyridinones [5] and -pyridones [4]. Calixarenes and modified calixarenes have also been prepared for uranyl extraction [12]. The uranyl complexes of calixarenes possess several phenolato ligands, many such complexes have been prepared and their structures have been reviewed recently [13].

We have earlier prepared and reported on four aminoalcohol (2-aminoethanol and 3-aminopropanol) based bisphenolate ligands, which easily form complexes with the UO_2^{2+}-ion [14]. In this paper we report a set of five new ligands of a similar series, which are potential uranium chelators and have better uranyl ion extraction properties than those reported earlier. Each of the ligands contains two phenol oxygens, one alcohol oxygen and one amine nitrogen, thus there is the possibility of the ligand functioning as up to a tetradentate ligand (Scheme 1).

The syntheses of these new ligands and their uranyl ion complexes are reported below. The X-ray diffraction structures are given for five uranyl complexes. Information about the ability of these ligands to extract uranyl ions from water to dichloromethane is also presented.

2. Experimental

2.1. General information

4-Amino-1-butanol (98%), 5-amino-1-pentanol (97%), 6-amino-1-hexanol (97%) (Aldrich), 4-*tert*-butyl-2-methylphenol (98%) (Fluka), triethylamine (Riedel), 2,4-dimethylphenol, 37% formaldehyde and uranyl nitrate hexahydrate (Merck) were used as supplied. The ligands were synthesized by following a procedure for methylamino-*N*,*N*-bis(1-methylene-2-naphthol) [15], but in the separation process we treated the ligands with HCl making the relevant salt of the ligand. This helped the separation of the ligand from the starting materials and byproducts. Syntheses of the ligands ($H_3L1 \cdot HCl$–$H_3L5 \cdot HCl$) were not optimized. The NMR spectra were recorded on a Bruker AVANCE DPX 250 FT-NMR spectrometer or a Bruker AVANCE DRX 500 FT-NMR spectrometer. ^1H and ^{13}C NMR spectra were recorded either in $CDCl_3$, MeOD-d_4 or DMSO-d_6 at 30 °C. Chemical shifts are reported in parts per million and referenced internally using the residual protio solvent resonances relative to tetramethylsilane ($CDCl_3$ δ 7.26, ^1H NMR; δ 77.0, ^{13}C NMR; MeOD-d_4 δ 3.30, ^1H NMR; δ 49.15, ^{13}C NMR and DMSO-d_6 δ 2.50, ^1H NMR; δ 39.50, ^{13}C NMR). Mass spectrometric measurements were performed using a Micromass LCT time of flight (TOF) mass spectrometer with electrospray ionization (ESI). Elemental analysis was performed using a VarioEl III elemental analyzer. Single crystal X-ray measurements were performed using an Enraf Nonius Kappa CCD diffractometer. Melting points were measured by a Mettler Toledo FP62 Melting Point instrument. The uranyl extraction samples were analyzed with inductively coupled plasma optical emission spectrometry (ICP-OES) at 385.958 nm using a Perkin Elmer Optima 4300DV instrument.

2.2. $H_3L1 \cdot HCl$ [(*N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-4-amino-1-butanol) · HCl]

To a solution of 2,4-dimethylphenol (2.44 g, 0.020 mol) in ethanol (15 ml) and water (3 ml) was added aqueous formaldehyde (37%, 3.26 g, 0.040 mol), 4-amino-1-butanol (0.89 g, 0.010 mol) and triethylamine (0.5 ml, 0.004 mol). The resulting solution was kept in a water bath (50 °C) for 118 h. The solution was then cooled down and 5 ml of 6 M HCl was added. To that solution was added 300 ml of water and it was then extracted three times with 20 ml of diethyl ether. The water phase was left to evaporate down to 100 ml of solution and it was then extracted three times with 40 ml of $CHCl_3$. The chloroform phase was evaporated and the remaining white solid was filtered, washed with diethyl ether (40 ml) and recrystallized from a mixture of CH_3CN (3 ml) and MeOH (1 ml). The solid was filtered off, washed with 10 ml of diethyl ether and dried. The yield was 0.52 g (13%). The white solid ($H_3L1 \cdot HCl$) is soluble in MeOH, EtOH and DMSO. Mp 197–199 °C.

^{1}H NMR (MeOD-d_4, 250 MHz): 1.51 (m, 2H, NCH_2CH_2), 1.90 (m, 2H, OCH_2CH_2), 2.19 (s, 6H, aryl-*Me*), 2.21 (s, 6H, aryl-*Me*), 3.18 (t, $J = 7.5$ Hz, 2H, NCH_2CH_2), 3.50 (t, $J = 6.1$ Hz, 2H, OCH_2CH_2), 4.33 (s, 4H, N–CH_2-aryl), 6.91 (s, 2H, aryl), 6.99 (s, 2H, aryl). ^{13}C NMR (MeOD-d_4, 63 MHz): 16.50, 20.53 (aryl-*Me*), 22.24, 30.26 (NCH_2CH_2, OCH_2CH_2), 54.84, 56.90, 61.88 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 118.83, 126.39, 131.03, 131.41, 134.78, 152.93 (aryl). The ESI-MS measurement showed the following ion for H_3L1: $m/z = 358.20$ $[H_3L1 + H]^+$. The calculated figure was: $m/z = 358.24$ $[H_3L1 + H]^+$. Elemental *Anal.* Calc. for $C_{22}H_{32}NO_3Cl$: C, 67.07; H, 8.19; N, 3.56. Found: C, 66.67; H, 8.28; N, 3.36%.

2.3. $H_3L2 \cdot HCl \cdot H_2O$ [(N,N-bis(2-hydroxy-5-tert-butyl-3-methylbenzyl)-4-amino-1-butanol) · HCl · H_2O]

To a solution of 4-*tert*-butyl-2-methylphenol (4.55 g, 0.028 mol) in ethanol (15 ml) and water (3 ml) was added aqueous formaldehyde (37%, 3.26 g, 0.040 mol), 4-amino-1-butanol (0.89 g, 0.010 mol) and triethylamine (0.5 ml, 0.004 mol). The resulting solution was kept in a water bath (50 °C) for 118 h. The solution was then cooled down and 5 ml of 6 M HCl was added, leading to the formation of a white precipitate. This latter was filtrated, washed with cold water (200 ml), hot water (300 ml), diethyl ether (80 ml) and recrystallized from ethanol (4 ml). The solid was filtered off, washed with 10 ml of diethyl ether and dried. The yield was 1.69 g (35%). The product is soluble in $CHCl_3$, MeOH, EtOH, DMSO and acetone. Mp 180–181 °C. ^{1}H NMR ($CDCl_3$, 250 MHz): 1.25 (s, 18H, aryl-*t-bu*), 1.59 (m, 2H, NCH_2CH_2), 1.95 (m, 2H, OCH_2CH_2), 2.41 (s, 6H, aryl-*Me*), 3.18 (t, $J = 6.1$ Hz, 2H, NCH_2CH_2), 3.59 (t, $J = 5.6$ Hz, 2H, OCH_2CH_2), 4.21 (s, 4H, N–CH_2-aryl), 6.98 (s, 2H, aryl), 7.18 (s, 2H, aryl). ^{13}C NMR ($CDCl_3$, 63 MHz): 17.10, 21.97, 29.30, 31.45, 33.94 (aryl-*Me*, NCH_2CH_2, OCH_2CH_2, aryl-$C(CH_3)_3$, aryl-$C(CH_3)_3$), 54.40, 56.60, 61.03 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 116.03, 125.64, 126.13, 130.29, 143.44, 151.28 (aryl). The ESI-MS measurement showed the following ion for H_3L2: $m/z = 442.35$ $[H_3L2 + H]^+$. The calculated value was: $m/z = 442.33$ $[H_3L2 + H]^+$. Elemental *Anal.* Calc. for $C_{28}H_{46}NO_4Cl$: C, 67.79; H, 9.35; N, 2.83. Found: C, 67.98; H, 9.27; N, 2.63%.

2.4. $H_3L3 \cdot HCl \cdot 0.5H_2O$ [(N,N-bis(2-hydroxy-3,5-dimethylbenzyl)-5-amino-1-pentanol) · HCl · $0.5H_2O$]

To a solution of 2,4-dimethylphenol (5.49 g, 0.045 mol) in methanol (25 ml) was added paraformaldehyde (1.65 g, 0.055 mol) and 5-amino-1-pentanol (2.66 g, 0.025 mol) with stirring. The resulting solution was refluxed for 25 h. After that the solution was evaporated, the resulting oil was dissolved in 15 ml CH_2Cl_2 and extracted three times with 10 ml of water. CH_2Cl_2 was evaporated, the obtained oil was dissolved in 10 ml of MeOH and to that solution was added 4 ml of 6 M HCl with stirring. The MeOH was evaporated and the resulting oil was dissolved in 10 ml of CH_3CN, during which a white solid separated. The solid was filtered and recrystallized with a solution of CH_3CN (8 ml) and EtOH (6 ml). The yield was 1.60 g (18%). The product is soluble in MeOH and DMSO. Mp 186–188 °C. ^{1}H NMR (MeOD-d_4, 250 MHz): 1.42 (m, 4H, $NCH_2CH_2CH_2$), 1.82 (m, 2H, OCH_2CH_2), 2.20 (s, 6H, aryl-*Me*), 2.22 (s, 6H, aryl-*Me*), 3.14 (t, $J = 7.6$ Hz, 2H, NCH_2CH_2), 3.50 (t, $J = 6.1$ Hz, 2H, OCH_2CH_2), 4.32 (s, 4H, N–CH_2-aryl), 6.90 (s, 2H, aryl), 7.00 (s, 2H, aryl). ^{13}C NMR (MeOD-d_4, 63 MHz): 16.47, 20.51 (aryl-*Me*), 23.84, 25.11, 32.75 ($NCH_2CH_2CH_2CH_2$), 54.80, 57.13, 62.44 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 118.85, 126.40, 130.98, 131.46, 134.82, 152.91 (aryl). The ESI-MS measurement showed the following ion for H_3L3: $m/z = 372.23$ $[H_3L3 + H]^+$. The calculated figure was: $m/z = 372.25$ $[H_3L3 + H]^+$. Elemental *Anal.* Calc. for $C_{23}H_{35}NO_{3.5}Cl$: C, 66.25; H, 8.46; N, 3.36. Found: C, 66.75; H, 8.48; N, 3.25%.

2.5. $H_3L4 \cdot HCl \cdot 0.5H_2O$ [(N,N-bis(2-hydroxy-5-tert-butyl-3-methylbenzyl)-5-amino-1-pentanol) · HCl · $0.5H_2O$]

To a solution of 4-*tert*-butyl-2-methylphenol (3.28 g, 0.020 mol) in ethanol (15 ml) and water (3 ml) was added aqueous formaldehyde (37%, 3.26 g, 0.040 mol), 5-amino-1-pentanol (1.03 g, 0.010 mol) and triethylamine (0.5 ml, 0.004 mol). The resulting solution was kept in a water bath (50 °C) for 118 h. The solution was then cooled down and 5 ml of 6 M HCl was added, leading to the formation of a white precipitate. This latter was filtrated, washed with cold water (200 ml), hot water (200 ml), diethylether (80 ml) and recrystallized from ethanol (4 ml). The solid was filtered off, washed with 20 ml of diethylether and dried. The yield was 1.65 g (34%). The product is soluble in $CHCl_3$, MeOH, EtOH and DMSO. Mp 179–182 °C. ^{1}H NMR ($CDCl_3$, 250 MHz): 1.25 (s, 18H, aryl-*t-bu*), 1.36–1.59 (m, 4H, $NCH_2CH_2CH_2$), 1.87 (m, 2H, OCH_2CH_2), 2.42 (s, 6H, aryl-*Me*), 3.14 (t, 2H, NCH_2CH_2), 3.63 (t, $J = 5.0$ Hz, 2H, OCH_2CH_2), 4.24 (s, 4H, N–CH_2-aryl), 6.98 (s, 2H, aryl), 7.18 (s, 2H, aryl). ^{13}C NMR (CDCl3, 126 MHz): 17.16 (aryl-*Me*), 22.65, 23.84, 31.32, 31.45, 33.97 ($NCH_2CH_2CH_2CH_2$, aryl-$C(CH_3)_3$, aryl-$C(CH_3)_3$), 53.34, 56.93, 61.36 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 115.85, 125.33, 126.17, 130.38, 143.58, 151.04 (aryl). The ESI-MS measurement showed the following ion for H_3L4: $m/z = 456.28$ $[H_3L4 + H]^+$. The calculated figure was: $m/z = 456.35$ $[H_3L4 + H]^+$. Elemental *Anal.* Calc. for $C_{29}H_{47}NO_{3.5}Cl$: C, 69.50; H, 9.45; N, 2.79. Found: C, 69.18; H, 9.44; N, 2.60%.

2.6. $H_3L5 \cdot HCl \cdot 0.5H_2O$ [(N,N-bis(2-hydroxy-5-tert-butyl-3-methylbenzyl)-6-amino-1-hexanol) · HCl · $0.5H_2O$]

To a solution of 4-*tert*-butyl-2-methylphenol (3.28 g, 0.020 mol) in ethanol (15 ml) and water (3 ml) was added

aqueous formaldehyde (37%, 3.26 g, 0.040 mol), 6-amino-1-hexanol (1.17 g, 0.010 mol) and triethylamine (0.5 ml, 0.004 mol). The resulting solution was kept in a water bath (50 °C) for 118 h. The solution was then cooled down and 6 ml of 6 M HCl was added, leading to the formation of a white precipitate. This latter was filtrated, washed with cold water (200 ml), hot water (300 ml), diethylether (80 ml) and recrystallized from ethanol (4 ml). The solid was filtered off, washed with 10 ml of diethylether and dried. The yield was 1.78 g (35%). The product is soluble in $CHCl_3$, MeOH, EtOH and DMSO. Mp 180–182 °C. ^{1}H NMR ($CDCl_3$, 250 MHz): 1.25 (s, 18H, aryl-*t-bu*), 1.33 (m, 4H, $NCH_2CH_2CH_2CH_2$), 1.55 (m, 2H, NCH_2CH_2), 1.83 (m, 2H, OCH_2CH_2), 2.44 (s, 6H, aryl-*Me*), 3.07 (t, $J = 7.0$ Hz, 2H, NCH_2CH_2), 3.62 (t, $J = 6.1$ Hz, 2H, OCH_2CH_2), 4.21 (s, 4H, N–CH_2-aryl), 6.95 (s, 2H, aryl), 7.19 (s, 2H, aryl). ^{13}C NMR ($CDCl_3$, 63 MHz): 17.25, 23.85, 24.90, 25.63, 31.46, 31.67, 33.98 (aryl-*Me*, $NCH_2CH_2CH_2CH_2CH_2$, aryl-$C(CH_3)_3$, aryl-$C(CH_3)_3$,), 53.18, 56.96, 61.79 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 115.85, 125.13, 126.63, 130.48, 143.62, 151.16 (aryl). The ESI-MS measurement showed the following ion for H_3L5: $m/z = 470.36$ $[H_3L5 + H]^+$. The calculated value was: $m/z = 470.36$ $[H_3L5 + H]^+$. Elemental *Anal.* Calc. for $C_{30}H_{49}NO_{3.5}Cl$: C, 69.94; H, 9.59; N, 2.72. Found: C, 69.74; H, 9.60; N, 2.54%.

2.7. $[UO_2(H_2L1)_2]$ (**1a**)

The complex **1a** was prepared by dissolving 0.036 g (0.090 mmol) of $H_3L1 \cdot HCl$, 0.023 g (0.045 mmol) of $UO_2(NO_3)_2 \cdot 6H_2O$ and 25.0 μl (0.180 mmol) of NEt_3 in 5 ml of CH_3CN. $H_3L1 \cdot HCl$ does not dissolve in CH_3CN but after addition of NEt_3 it is soluble. To that solution was added $UO_2(NO_3)_2 \cdot 6H_2O$ which immediately turned the solution orange-red. The resulting orange-red solution was kept at room temperature for 3 weeks leading to the formation of orange crystals. The crystals were filtered off and washed once with 5 ml of cold diethyl ether and air-dried. The yield was 0.027 g (61%). The crystals are soluble in DMSO. ^{1}H NMR (DMSO-d_6, 250 MHz) 0.91, 1.32 (m, 4H, NCH_2CH_2), 1.56 (m, 4H, OCH_2CH_2), 2.09, 2.15, 2.31, 2.59 (s, 24H, aryl-*Me*), 2.40, 2.83 (t, 4H, NCH_2CH_2), 3.13, 3.31 (t, 4H, OCH_2CH_2), 3.60 (s, 4H, N–CH_2-aryl), 4.20 (m, 4H, N–CH_2-aryl), 6.73, 6.78, 6.91, 6.98 (s, 8H, aryl). ^{13}C NMR (DMSO-d_6, 63 MHz): 16.07, 16.15, 16.99, 20.03, 20.06, 21.80, 30.20, 30.48 (aryl-*Me*, $NCH_2CH_2CH_2$), 49.80, 52.42, 54.29, 59.16, 60.35, 60.57 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 122.67–164.74 (aryl). The ESI-MS measurement showed the following ion for **1**: $m/z = 983.73$ $[\mathbf{1} + H]^+$. The calculated value for **1** was: $m/z = 983.49$ $[\mathbf{1} + H]^+$. Elemental *Anal.* Calc. for $C_{44}H_{60}N_2O_8U$: C, 53.76; H, 6.15; N, 2.85. Found: C, 53.10; H, 6.09; N, 3.18%. Single crystal X-ray analysis was performed on one of these crystals.

2.8. $[UO_2(H_2L1)_2] \cdot 2CH_3CN$ (**1b**)

During the preparation of $[UO_2(H_2L1)_2]$ also an other type of crystals formed. After keeping for more than 3 weeks the solution for the preparation of **1a** produced also other type of orange crystals, an X-ray measurement showed those to be an acetonitrile adduct of **1a** i.e. $[UO_2(H_2L1)_2] \cdot 2CH_3CN$ **(1b)**.

2.9. $[UO_2(H_2L2)_2] \cdot CH_3CN$ (**2**)

The complex **2** was prepared by dissolving 0.043 g (0.090 mmol) of $H_3L2 \cdot HCl$, 0.023 g (0.045 mmol) of $UO_2(NO_3)_2 \cdot 6H_2O$ and 25.0 μl (0.180 mmol) of NEt_3 in 10 ml of CH_3CN. $H_3L2 \cdot HCl$ does not dissolve in CH_3CN but after addition of NEt_3 it is soluble. To that solution was added $UO_2(NO_3)_2 \cdot 6H_2O$ which immediately turned the solution orange-red. The resulting orange-red solution was kept at room temperature for 3 weeks leading to the formation of orange crystals. The crystals were filtered off and washed twice with 5 ml of diethyl ether and air-dried. The yield was 0.036 g (69%). The crystals are soluble in DMSO. ^{1}H NMR (DMSO-d_6, 250 MHz): 0.84, 1.32 (m, 4H, NCH_2CH_2), 1.22, 1.28 (s, 36H, aryl-*t-bu*), 1.57 (m, 4H, OCH_2CH_2), 2.13, 2.62 (s, 12H, aryl-*Me*), 2.41, 2.75 (t, 4H, NCH_2CH_2), 3.11, 3.31 (t, 4H, OCH_2CH_2), 3.64 (s, 4H, N–CH_2-aryl), 4.18 (m, 4H, N–CH_2-aryl), 6.94, 6.99, 7.13, 7.19 (s, 8H, aryl). ^{13}C NMR (DMSO-d_6, 63 MHz): 16.21, 16.39, 17.36, 22.03, 30.25, 31.36, 31.87, 33.15, 33.45 (aryl-*Me*, aryl-*t-bu*, $NCH_2CH_2CH_2$), 49.52, 52.47, 54.36, 59.50, 60.35, 60.81 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 122.10–164.80 (aryl). The ESI-MS measurement showed the following ions for **2**: $m/z = 1151.97$ $[\mathbf{2} + H]^+$, 1173.93 $[\mathbf{2} + Na]^+$. The calculated values for **2** are: $m/z = 1151.68$ $[\mathbf{2} + H]^+$, 1173.66 $[\mathbf{2} + Na]^+$. Elemental *Anal.* Calc. for $C_{58}H_{87}N_3O_8U$: C, 58.42; H, 7.35; N, 3.52. Found: C, 57.55; H, 7.28; N, 3.57%.

2.10. $[UO_2(H_2L3)_2] \cdot 2CH_3CN$ (**3**)

The complex **3** was prepared by dissolving 0.037 g (0.090 mmol) of $H_3L3 \cdot HCl$, 0.023 g (0.045 mmol) of $UO_2(NO_3)_2 \cdot 6H_2O$ and 25.0 μl (0.180 mmol) of NEt_3 in 10 ml of CH_3CN. $H_3L3 \cdot HCl$ does not dissolve in CH_3CN but after addition of NEt_3 it is soluble. To that solution was added $UO_2(NO_3)_2 \cdot 6H_2O$ which immediately turned the solution orange-red. The resulting orange-red solution was kept at room temperature for two days leading to the formation of orange crystals. The crystals were filtered off which caused almost immediate decomposition of crystals due to the escape of acetonitrile. The yield was 0.030 g (63%). The crystals are soluble in DMSO. ^{1}H NMR (DMSO-d_6, 250 MHz): 0.79, 1.14, 1.33, 1.52 (m, 12H, $NCH_2CH_2CH_2CH_2$), 2.09, 2.15, 2.31, 2.59 (s, 24H, aryl-*Me*), 2.39, 2.84 (t, 4H, NCH_2CH_2), 3.20, 3.32 (t, 4H, OCH_2CH_2), 3.60 (s, 4H, N–CH_2-aryl), 4.16 (m, 4H, N–CH_2-aryl), 6.72, 6.79, 6.91, 6.98 (s, 8H, aryl). ^{13}C NMR

(DMSO-d_6, 63 MHz): 16.07, 16.99, 19.07, 20.02, 20.06, 23.17, 23.26, 25.02, 32.00, 32.17 (aryl-*Me*, NCH_2CH_2-CH_2CH_2), 49.69, 52.46, 54.41, 59.21, 60.46 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 122.70–164.77 (aryl). The ESI-MS measurement showed the following ions for **3**: $m/z = 1011.78$ $[\mathbf{3} + H]^+$, 1033.73 $[\mathbf{3} + Na]^+$. The calculated values for **3** are: $m/z = 1011.52$ $[\mathbf{3} + H]^+$, 1033.51 $[\mathbf{3} + Na]^+$. Elemental *Anal.* Calc. for $C_{46}H_{64}N_2O_8U$: C, 54.65; H, 6.38; N, 2.77. Found: C, 53.73; H, 6.34; N, 3.08%. Single crystal X-ray analysis was performed on one of these crystals.

2.11. $[UO_2(H_2L4)_2] \cdot 2CH_3CN$ (4)

The complex **4** was prepared by dissolving 0.045 g (0.090 mmol) of $H_3L4 \cdot HCl$, 0.023 g (0.045 mmol) of $UO_2(NO_3)_2 \cdot 6H_2O$ and 25.0 μl (0.180 mmol) of NEt_3 in 5 ml of CH_3CN. $H_3L4 \cdot HCl$ does not dissolve in CH_3CN but after addition of NEt_3 it is soluble. To that solution was added $UO_2(NO_3)_2 \cdot 6H_2O$ which immediately turned the solution orange-red. The resulting orange-red solution was kept at room temperature for two days leading to the formation of the orange crystals, which were filtered off. The yield was 0.036 g (64%). The crystals decompose easily, but are soluble in DMSO and THF. ^{1}H NMR (DMSO-d_6, 250 MHz): 0.71, 1.17, 1.32, 1.53 (m, 12H, $NCH_2CH_2CH_2CH_2$), 1.22, 1.28 (s, 36H, aryl-*t-bu*), 2.13, 2.62 (s, 12H, aryl-*Me*), 2.40, 2.70 (t, 4H, NCH_2CH_2), 3.16, 3.32 (t, 4H, OCH_2CH_2), 3.64 (s, 4H, N–CH_2-aryl), 4.13 (m, 4H, N–CH_2-aryl), 6.94, 6.99, 7.13, 7.19 (s, 8H, aryl). ^{13}C NMR (DMSO-d_6, 63 MHz): 16.40, 17.35, 23.23, 23.39, 25.18, 31.35, 31.87, 32.20, 32.44, 33.14, 33.45 (aryl-*Me*, aryl-*t-bu*, $NCH_2CH_2CH_2CH_2$), 49.42, 51.66, 52.49, 54.48, 59.54, 60.50 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 122.14–164.84 (aryl). The ESI-MS measurement showed the following ions for **4**: $m/z = 1180.04$ $[\mathbf{4} + H]^+$, 1202.03 $[\mathbf{4} + Na]^+$. The calculated values for **4** are: $m/z = 1179.71$ $[\mathbf{4} + H]^+$, 1201.69 $[\mathbf{4} + Na]^+$. Elemental *Anal.* Calc. for $C_{58}H_{88}N_2O_8U$: C, 59.07; H, 7.52; N, 2.38. Found: C, 57.39; H, 7.31; N, 2.09%. Single crystal X-ray analysis was performed on one of these crystals.

2.12. $[UO_2(H_2L5)_2] \cdot 4$toluene (5)

The complex **5** was prepared by dissolving 0.046 g (0.090 mmol) of $H_3L5 \cdot HCl$, 0.023 g (0.045 mmol) of $UO_2(NO_3)_2 \cdot 6H_2O$ and 25.0 μl (0.180 mmol) of NEt_3 in 20 ml of CH_3CN. $H_3L5 \cdot HCl$ does not dissolve in CH_3CN but after addition of NEt_3 it is soluble. To that solution was added $UO_2(NO_3)_2 \cdot 6H_2O$ which immediately turned the solution orange-red. This solution was kept at room temperature for three days leading to formation of orange starlike crystals. These crystals were filtered off (yield 0.032 g (59%)) and dissolved in toluene and this solution was left to evaporate slowly at room temperature. Better shaped orange crystals were formed and they were filtered off. The crystals are soluble in DMSO, $CHCl_3$, THF and toluene.^{1}H and ^{13}C NMR were made from crystals obtained from CH_3CN. ^{1}H NMR (DMSO-d_6, 250 MHz): 0.69, 1.02. 1.17, 1.52 (m, 16H, $NCH_2CH_2CH_2CH_2CH_2$), 1.22, 1.28 (s, 36H, aryl-*t-bu*), 2.13, 2.62 (s, 12H, aryl-*Me*), 2.40, 2.74 (t, 4H, NCH_2CH_2), 3.21, 3.32 (t, 4H, OCH_2CH_2), 3.64 (s, 4H, N–CH_2-aryl), 4.17 (m, 4H, N–CH_2-aryl), 6.94, 6.99, 7.13, 7.19 (s, 8H, aryl). ^{13}C NMR (DMSO-d_6, 63 MHz): 16.50, 17.43, 25.27, 25.41, 31.41, 31.92, 33.20, 33.52 (aryl-*Me*, aryl-*t-bu*, NCH_2CH_2-$CH_2CH_2CH_2$), 54.52, 59.57, 60.51, 60.60 (NCH_2CH_2, N–CH_2-aryl, OCH_2CH_2), 122.20–164.87 (aryl). The ESI-MS measurement showed the following ions for **5**: $m/z = 1208.03$ $[\mathbf{5} + H]^+$, 1230.05 $[\mathbf{5} + Na]^+$. The calculated values for **5** are: $m/z = 1207.74$ $[\mathbf{5} + H]^+$, 1229.73 $[\mathbf{5} + Na]^+$. Elemental *Anal.* Calc. for $C_{60}H_{92}N_2O_8U$: C, 59.68; H, 7.68; N, 2.32. Found: C, 57.63; H, 7.41; N, 2.02%. Single crystal X-ray analysis was performed on one of the crystals, which was obtained by crystallization from toluene.

2.13. Uranyl extraction

Two-phase extraction studies were performed to determine the UO_2^{2+} cation uptake from water layer to CH_2Cl_2 layer by the ligands $H_3L1 \cdot HCl$, $H_3L2 \cdot HCl$, $H_3L3 \cdot HCl$, $H_3L4 \cdot HCl$, $H_3L5 \cdot HCl$, $H_3L6 \cdot 1/3$toluene, H_3L7 and $H_3L8 \cdot HCl$ (the results for three last ones were published in our earlier paper [14]). The experimental setup was as follows: into the bottom of a test tube was placed 3 ml of CH_2Cl_2 with ligand (0.210 mmol), and 0.210 mmol NEt_3 to neutralize HCl was added except in cases of H_3L6 and H_3L7, which were used as neutral ligands. At the top of the organic layer was placed 2 ml of water with uranyl nitrate ($c(U) = 6.25$ mg/ml, $n(U) = 0.0525$ mmol) leading to a ratio of U to ligand of 1:4. Furthermore one test tube with CH_2Cl_2 containing no ligand was prepared. The samples for ICP (V = 50 μl, diluted to 10 ml) were taken from the water layer over 54 h period of time. The samples were analyzed with ICP-OES at 385.958 nm using a Perkin Elmer Optima 4300DV instrument.

2.14. X-ray crystallography

Crystals suitable for single crystal X-ray measurements were obtained directly from the reaction vessels. The crystal data for compounds **1a**, **1b**, **3**–**5** along with other experimental details, are summarized in Table 1. The crystallographic data were collected at 173 K on an Enraf Nonius Kappa CCD area-detector diffractometer using graphite monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). Data collection was performed using φ and ω scans and the data processed using DENZO-SMN V0.93.0 [16]. SHELXA [17] absorption correction was applied to the data of **1a**, **3**–**5**. The structures were solved by direct methods using the SHELXS-97 program [18] and full-matrix least-squares refinements on F^2 were performed using the SHELXL-97 program [18]. For all compounds the heavy atoms were refined

anisotropically. The CH hydrogen atoms were included at fixed distances using fixed displacement parameters from their host atoms whilst other H atoms were refined using fixed displacement parameters. Structure figures were drawn using ORTEP-3 for *Windows* [19].

3. Results and discussion

3.1. Syntheses of ligands and uranyl complexes

The details of the ligand syntheses are described in Section 2. Generally, the yields of the new ligands were quite low. One reason for this is the fact that the solubility properties of the product and the phenol in question are quite similar. Also, the reaction itself does not readily go to completion and intermediates with only one phenol moiety attached to the aminoalcohol were present. Thus the separation of the product from the sticky oil (especially with 2,4-dimethylphenol derivatives), which was generally formed at the end of the reaction, was quite difficult and as a result part of the product was lost together with the starting phenol during the separation process.

In order to make the separation process easier the reaction mixtures were treated with HCl (6 M) in order to make the product more polar with respect to the phenol (the formation of the hydrochloride). This led to an immediate formation of a white solid (the hydrochloride) with 4-*tert*-butyl-2-methylphenol derivatives. In the case of 2,4-dimethylphenol the white solid formed slowly and it seems to be more soluble during the separation process and thus 4-*tert*-butyl-2-methylphenol derivatives gave better yields than 2,4-dimethylphenol derivatives.

Generally, the crystals of the uranyl complexes formed quite easily following the dissolution of the uranyl nitrate hexahydrate in acetonitrile together with an appropriate amount of the ligand. The quick formation of the complex was clearly indicated by the immediate change in color of the solution from the yellow of uranyl nitrate to red. The reaction vessels, however, were left to stand at room temperature from two days to up to 3 weeks to allow for the formation of crystals. The filtrates, though, were still red or orange in color after removal of the crystals indicating that the crystallization was incomplete. The crystals of compounds **3** and **4** decompose quite quickly after they are removed from the reaction solution indicating that acetonitrile molecules are quite loosely bonded in these crystals. Furthermore, it seems that ligands $H_3L1 \cdot HCl$ and $H_3L2 \cdot HCl$ form two kinds of crystals with the uranyl ion from acetonitrile, with or without acetonitrile. This leads to some discrepancy in the results of elemental analysis as it was difficult to separate these crystals on the basis of their outlook. In order to get homogeneous crystals of **1a**, ethanol was tried as solvent but the crystals formed were not better than the crystals from acetonitrile as they contained loosely bonded ethanol molecules.

The solubility of the complexes into organic solvents was best in the case of **5**, which dissolved easily at room temperature in DMSO, $CHCl_3$, THF and toluene.

The ESI-MS measurements for compounds **1**–**5** were done in a solution of CH_2Cl_2 and CH_3OH. In this procedure the compounds **1**–**5** mainly broke down to the corresponding ligands but the complex ions of compounds **1**–**5** could still be identified, although the peaks were of very low intensity.

3.2. NMR studies

Although some of the complexes are slightly soluble in $CHCl_3$ (or other NMR solvents), the NMR spectra were recorded in DMSO where all the complexes dissolve readily making possible comparisons of the spectra 1–5. In the compounds where CH_3CN molecules were present in the crystal structure it could be identified from the NMR spectra.

The NMR spectra of compounds **1**–**5** were quite similar indicating that all the complexes behave similarly in DMSO. The ^1H NMR spectrum of **1** in DMSO is presented in Fig. 1a.

In order to find out what happens to these uranyl complexes in a DMSO solution we did a thorough NMR-analysis for **1**. Its DMSO solution was analyzed with ^1H, ^{13}C, ^1H–^1H COSY, NOESY, HMQC and HMBC NMR techniques. Furthermore, in order to find out if other uranyl complexes form during the reactions of uranyl ion with H_3Ln ($n = 1$–5) ligands in DMSO, we followed with the ^1H NMR spectroscopy the stepwise reaction of $H_3L1 \cdot HCl$ with $UO_2(NO_3)_2 \cdot 6H_2O$ in DMSO in the presence of

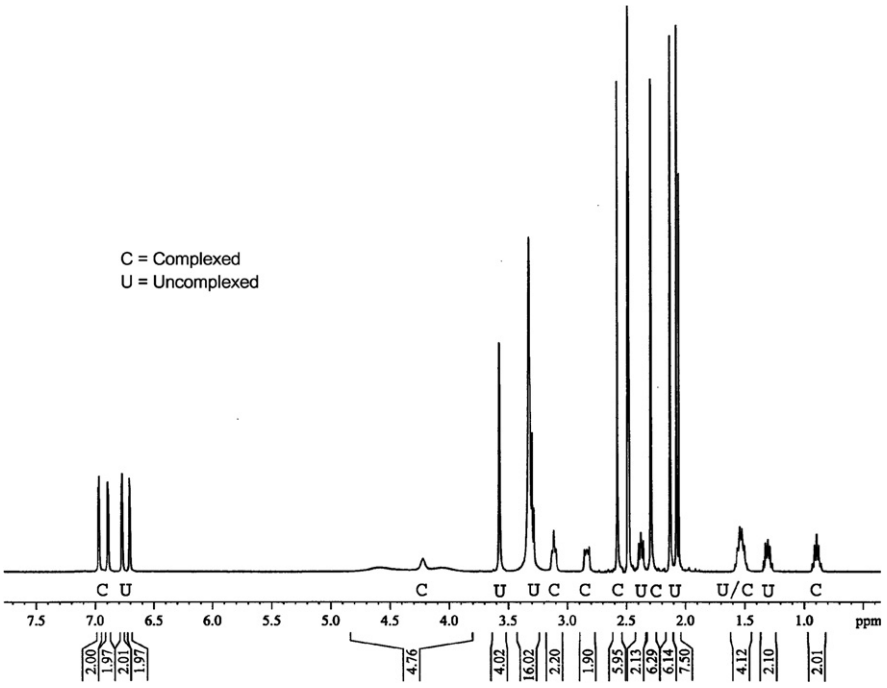

Fig. 1a. The ^1H NMR spectrum of compound **1** in DMSO.

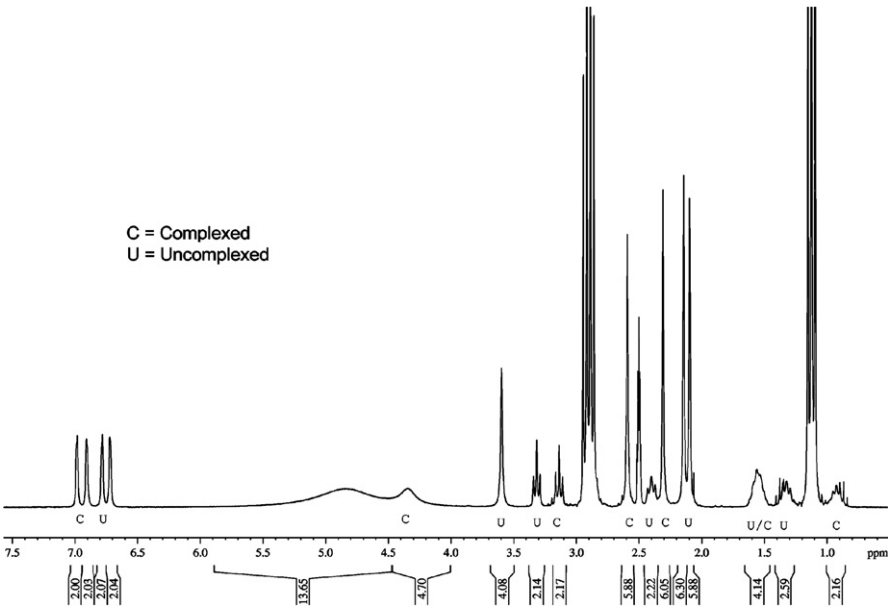

Fig. 1b. The ^1H NMR spectrum of the DMSO solution, where the ratio of $[UO_2]^{2+}$:$H_3L1 \cdot HCl$:NEt_3 is 1:2:4.

NEt_3, which was used as a base in order to avoid extra use of $H_3L1 \cdot HCl$. We started from pure $UO_2(NO_3)_2 \cdot 6H_2O$ in DMSO and then gradually added $H_3L1 \cdot HCl$ and NEt_3 (to produce H_3L1 and H_2L1^-). The main interesting compositions are the $[UO_2]^{2+}$:$H_3L1 \cdot HCl$:NEt_3 being 1:1:2 and 1:2:4. In Fig. 1b is presented a ^1H NMR spectrum of this stepwise reaction follow-up where the $[UO_2]^{2+}$:$H_3L1 \cdot HCl$:NEt_3 composition is 1:2:4.

From these data it seems obvious that at first mainly the $[UO_2(H_2L1)(DMSO)_x]^+$ complex (x is 2 or 3) is formed when the ratio $[UO_2]^{2+}$:H_2L1^- is 1:1. The addition of H_2L1^- up to a ratio of $[UO_2]^{2+}$:H_2L1^- of 1:2 does not lead to the formation of $[UO_2(H_2L1)_2]$ complex, but instead the peaks of the free H_2L1^- ligand grow, leading to the ratio $[UO_2(H_2L1)(DMSO)_x]^+$:H_2L1^- being 1:1.

In Fig. 1b the extra peaks, compared to the spectrum in Fig. 1a, are from NEt_3 (δ 1.1 and 2.9) and in Fig. 1a the peak in δ 3.30 originates from HOD, which is not seen in the spectra 1b, possibly due to the presence of the $[NH(Et)_3]^+$ ion. In NOESY of **1** there is a strong correlation between the NH^+–CH_2-aryl group peaks of the coordinated ligand and the HOD peaks, due to the hydrogen bond between the NH^+ hydrogen of the ligand and the HOD oxygen atom. The round shape of the signals of the NH^+–CH_2-aryl hydrogens of the coordinated ligand (δ 4.10–4.30) is possibly due to conformational changes of the $PhCH_2NCH_2Ph$ chains in the coordinated ligand in the DMSO solution.

The similar stepwise reaction follow-up was done also with ligand H_3L7 (*N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-3-amino-1-propanol), for which the uranyl complex was prepared earlier [14], the results were in accordance with the observations for compound **1**.

On the basis of the previously mentioned data, two types of the ligands, complexed (C) and uncomplexed (U), seem to be present in a DMSO solution of complexes prepared in this study. It means that only one type of uranyl complex is found in a DMSO solution, and in the dissolution of $[UO_2(H_2L1)_2]$ in DMSO the following reaction occurs [reaction (1)]:

$$[UO_2(H_2L1)_2] + nDMSO \rightarrow [UO_2(H_2L1)(DMSO)_x]^+ + H_2L1^- + (n\text{-}x)DMSO \quad (1)$$

3.3. Structural studies of the uranyl complexes

The solid-state structures of compounds **1a**, **1b**, **3**–**5** were verified by single crystal X-ray analysis. The crystals of **1a**, **1b**, **3**–**5** were obtained from an acetonitrile solution. The triclinic unit cell of **1a** contains one complex unit. The triclinic unit cells of **1b**, **3** and **4** contain one complex unit and two acetonitrile molecules and the monoclinic (C-type) unit cell of **5** contains four complex units and 16 toluene molecules.

The complexes have a centrosymmetric structure in which the uranium ion has a compressed octahedral symmetry (Figs. 2–5). Selected bonding parameters for these five molecules are compared in Table 2. The asymmetric unit of all compounds contains a UO unit with a negative H_2L^- ligand, which binds to the UO unit via two phenoxide groups. The aliphatic nitrogen atom accepts a proton and thus it does not form a bond with the U(VI) ion. The proton on the nitrogen atom, however, forms weak intramolecular H-bonds to O2 and O3. The complexes are neutral zwitterionic units with four negative charges at the oxygen atoms, two positive charges at the uranyl ion and two positive charges on the nitrogen atoms (one per nitrogen). The aliphatic alcohol groups do not take part in bonding with the uranyl ion, but do form H-bonds in all compounds (Table 3). The overall structures are similar to the uranyl homoazacalixarene complex [20], where the uranyl ion is located inside the cage, and to the earlier reported complexes of uranyl ion with the similar shorter chain aminoalcohol ligands [14].

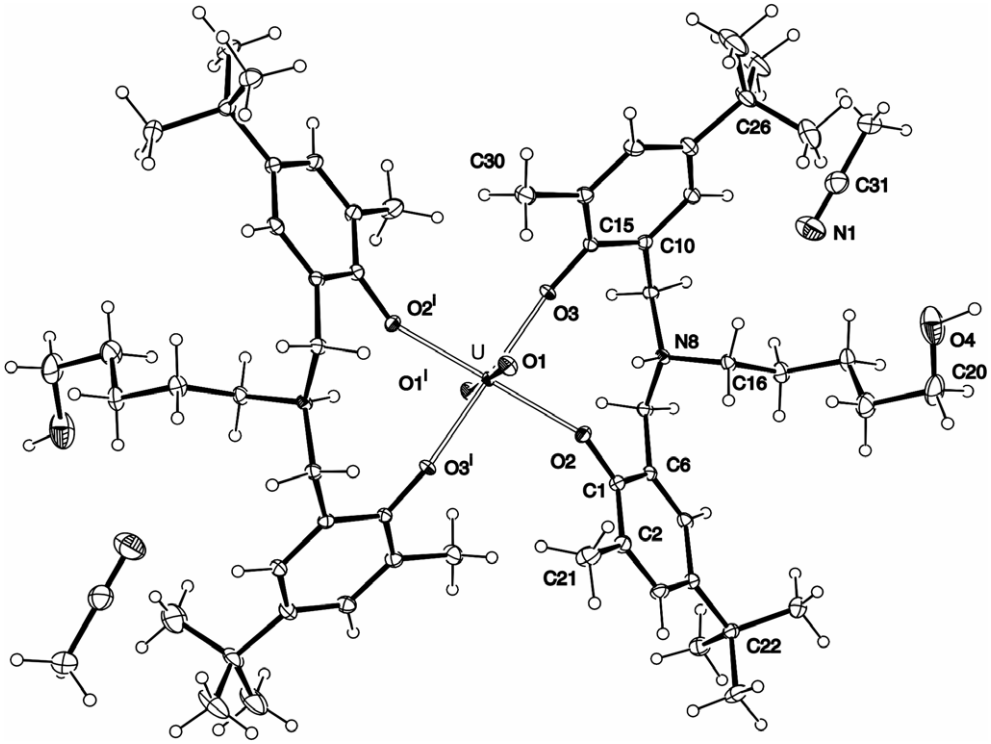

Fig. 4. Molecular structure of $[UO_2(H_2L4)_2]\cdot 2CH_3CN$ (**4**). Thermal ellipsoids have been drawn at 30% probability level. Symmetry operation i = $-x$, $-y$, $-z$.

The U=O distances are almost the same in all studied compounds; they range from 1.795(2) to 1.807(2) Å. Only compound **5** forms a hydrogen bond to O1 (see Table 3), and as the U=O bond length in **5** is near the average of all five compounds, the hydrogen bonding does not significantly influence the U=O bond lengths.

The extreme values of the U–O(phenoxide) bond distances are from 2.202(2) to 2.307(2) Å in the studied compounds. These values are near the estimated "ideal" value of 2.2 Å found in U(VI) compounds with unrestricted, unidentate alkoxide ligands [13,21]. Also in U(VI) compounds with Schiff base ligands similar values have been found [22]. This suggests that now reported ligands bind to the UO_2^{2+} ion quite effectively.

The U–O–C bond angles in **1b** are 132.2(2)° and 175.5(2)°. The relevant U–O(phenoxide) bond distances

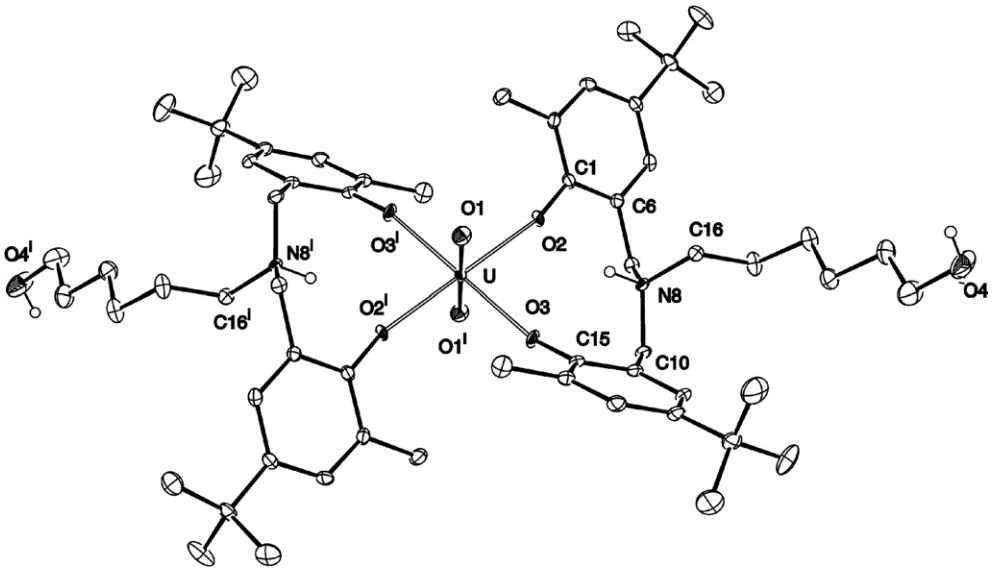

Fig. 5. Molecular view of $[UO_2(H_2L5)_2]$ in the solvate $[UO_2(H_2L5)_2]\cdot 4$toluene (**5**). Thermal ellipsoids have been drawn at 30% probability level. Toluene molecules are not shown and the CH hydrogen atoms have been omitted for clarity. Symmetry operation i = $-x$, $-y$, $-z$.

are 2.303(2) and 2.202(2) Å. In the rest of the compounds the U–O–C angles vary from 135.8(2)° to 167.3(2)° and roughly we can say that if the U–O–C angles are about 130°, 150° and 170°, then the U–O(phenoxide) distances are about 2.30, 2.25 and 2.20 Å. Thus the general finding: the larger the U–O–C angle is, the shorter is the U–O bond distance, is valid in these compounds and also in $[Na(THF)_2]_2[UO_2(O\text{-}2,6Me_2C_6H_3)_4]$ [21]. The found distortions of the U–O(phenoxide) bond angles and distances are caused mainly by packing effects as reasoned below.

Conformational differences of the coordinated ligands in **1a**, **1b**, **3**–**5** were evident in the analysis of the torsion and dihedral angles in the structures (see Tables 2 and 4). In particular, the dihedral angles between the phenyl rings (formed by the atoms C1,...,C6 and C10,...,C15) vary and the angles between these planes in **1a**, **1b**, **3**–**5** are from 32.1(1)° to 60.6(1)° (Table 2). These deviations indicate that the frameworks of the ligands are flexible and have enough freedom to accommodate slightly different arrangements in the solid state for packing reasons. In compounds **1a** and **1b** there is the same ligand, but **1b** contains in the unit cell two acetonitrile molecules. This presence of acetonitrile molecules causes several conformational changes to the ligand as the dihedral angles between the phenyl rings are 57.1(3)° for **1a** and 37.8(1)° for **1b**. Also the aminoalcohol chains have different conformations as seen from Fig. 2. These conformational changes influence on the bond parameters of the uranyl ion in **1a** and **1b** (see Table 2). Especially the U–O2 bonds are slightly different. In **1a** and **1b** there are also similar, moderately strong intermolecular hydrogen bonds to O3 from the aminoalcohol hydrogen atoms (at O4) and these H-bonds can influence on the U–O3 bond distances and U–O3–O15 bond angles.

3.4. Uranyl ion extraction studies

The decrease of the uranyl ion concentration in water layer during the extraction studies at room temperature (22–23 °C) with the ligands $H_3L1 \cdot HCl$–$H_3L8 \cdot HCl$ (H_3L6 = *N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-2-aminoethanol · 1/3toluene, H_3L7 = *N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-3-amino-1-propanol and H_3L8 = *N*,*N*-bis(2-hydroxy-5-*t*-butyl-3-methylbenzyl)-3-amino-1-propanol · HCl) [14] are shown in Table 5 and Fig. 6. The extraction was done without mixing the extraction tube at the pH of the uranyl nitrate in water solution (around 3). The concentration ratio of the uranyl ion to the ligand was 1:4 during the extraction process. The concentration of the uranyl ion in the water layer of the control sample was constant after the 54 h follow-up.

With ligands $H_3L1 \cdot HCl$, $H_3L3 \cdot HCl$, $H_3L4 \cdot HCl$, $H_3L5 \cdot HCl$, $H_3L6 \cdot 1/3$toluene, H_3L7 and $H_3L8 \cdot HCl$ red or orange crystals formed into the CH_2Cl_2 layer. The crystals of $H_3L1 \cdot HCl$, $H_3L3 \cdot HCl$, $H_3L4 \cdot HCl$, $H_3L5 \cdot HCl$ in CH_2Cl_2 layer were not of X-ray quality, but we assume that they have the formula of $[UO_2(H_2Ln)_2]$, the same as the uranyl complexes with the ligands $H_3L6 \cdot 1/3$toluene and H_3L7 was found [14]. The reason for the low quality is possibly the fact that generally $[UO_2(H_2Ln)_2]$ crystals contain two acetonitrile molecules in the lattice per one $UO_2(H_2Ln)_2$ molecule, and as the extraction system does not contain acetonitrile these type of crystals cannot form. On the other hand there is a possibility that the uranyl complexes in dichloromethane are the 1:1 complexes, for example the $[UO_2(H_2Ln)(NO_3)]$ complexes, which are suggested by the formation of the $[UO_2(H_2L1)(solvent)_x]^+$ complexes (solvent = DMSO, acetonitrile, alcohol or other hard Lewis base).

Fig. 6 (Table 5) shows that the transfer of the uranyl ion from the water layer to the CH_2Cl_2 during the 54 h was

$H_3L6 \cdot 1/3$toluene, *N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-2-aminoethanol · 1/3toluene; H_3L7, *N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-3-amino-1-propanol; $H_3L8 \cdot HCl$, *N*,*N*-bis(2-hydroxy-5-*t*-butyl-3-methylbenzyl)-3-amino-1-propanol · HCl.

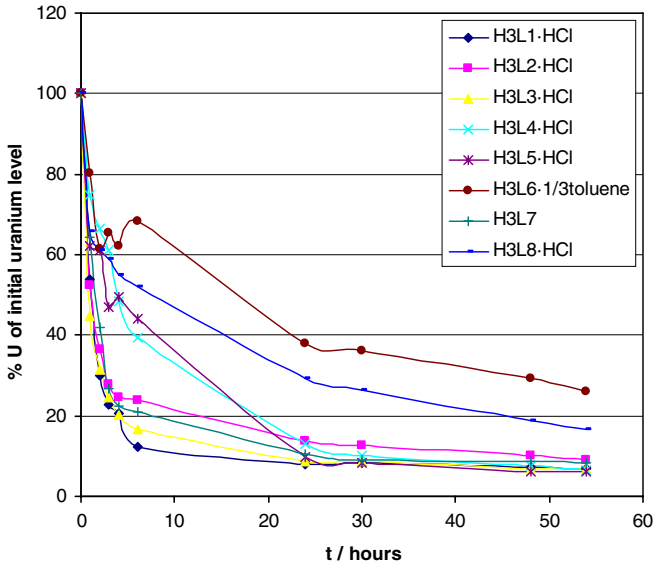

Fig. 6. Decrease of the uranium concentration (%) in the water layer as a function of time during extraction process.

best with $H_3L5 \cdot HCl$ (93.9%) although the ligands $H_3L1 \cdot HCl$, $H_3L3 \cdot HCl$ and $H_3L4 \cdot HCl$ were at the same efficiency level (93.3%, 93.1% and 93.6%, respectively).

However, already after 4 h extraction with $H_3L1 \cdot HCl$ and $H_3L3 \cdot HCl$, 80% of uranyl ions were in the CH_2Cl_2. About the same extraction level after 4 h was obtained also with ligands $H_3L2 \cdot HCl$ and H_3L7 (76% and 77%, respectively), but the ligands $H_3L4 \cdot HCl$ and $H_3L5 \cdot HCl$ had transferred only 52% and 51%. After 24 h all these ligand had extracted over 90% of the uranyl ions. The lower solubility of $H_3L5 \cdot HCl$ in water possibly explains its low extraction speed.

The uranyl ion extraction efficiency of the ligands in a equilibrium situation can be described by using the distribution coefficient (D), which expresses the ratio of the total mass of the extracted substance in all of its possible forms in the organic and aqueous layers. It was calculated modifying the equation given in Ref. [23]:

$$D = \frac{m(U)_o}{m(U)_w}, \quad (2)$$

where $m(U)_o = m(U)$ in all possible forms in the CH_2Cl_2 layer at equilibrium (54 h), $m(U)_w = m(U)$ in the water layer at equilibrium (54 h).

The D values given in Table 6 are calculated from the numerical values presented in Table 5. Table 6 gives the efficiency of each ligand in the extraction uranyl ions from water to organic solvent (CH_2Cl_2) during 54 h. The best ligand, $H_3L5 \cdot HCl$ has $D = 15.4$ and the second, $H_3L4 \cdot HCl$ has $D = 14.7$. The worst extractor is $H_3L6 \cdot 1/3$toluene ($D = 2.9$). On the other hand the extraction speed of the ligands is also important and that point has been discussed earlier.

4. Conclusions

In the solid state the neutral uranyl complexes form structures in which the uranyl ion is almost ideally bonded to four phenolato oxygen atoms of two ligands. The formed complex is a zwitterion as one of the phenolic protons moves to the nitrogen atom. By formulating the aminoalcohol part of the ligands it is possible to regulate the solubility of ligands and their complexes, but the actual coordination sphere around the uranyl ion changes only slightly. Although the yields of the ligand syntheses are low, compared to yields of some calixarene molecules, these ligands are reasonably easy to prepare; furthermore, the complexation of the new ligands mainly produce only one crystalline complex of type $[UO_2(H_2L1)_2]$ with a similar structure. It is shown that in the solution $[UO_2(H_2L1)(solvent)_x]^+$ complexes are also present. The solvent can be DMSO, acetonitrile, alcohol or other hard Lewis base solvent.

It seems obvious that the ligand with good extraction properties for UO_2^{2+} from water layer to organic water immiscible solvent needs to have a good balance between its hydrophilic and hydrophobic properties [24,25]. The three fastest ligands (about 50–60% extraction level after 1 h) have medium length carbon chains (4–5 carbons) in the aliphatic alcohol (Scheme 1 describes the ligands). If the ligand is too hydrophobic (*tert*-butyl-group in the phenyl ring and long CH_2 chain in the aliphatic alcohol) it cannot migrate to the water layer very quickly; this leads to a slower extraction rate, although the extraction level after 54 h can be good (in this case best with $H_3L5 \cdot HCl$). In this respect all the ligands presented in this article seem quite suitable for the extraction of uranyl ion from water to organic solvents: $H_3L1 \cdot HCl$ is the quickest and almost as effective as $H_3L5 \cdot HCl$.

Although some of these ligands are quite good uranyl ion extractors, the search for new better ligands, as well as optimizing studies of the uranyl extraction process are still under way. The selectivity of these new ligands towards uranyl ion in the presence of other metals has not yet been studied. This is an important point, as other metal ions are always present in the elimination process of uranyl ions from biological systems. We have started uranyl ion selectivity studies with these ligands under extraction process in the presence of other metal ions such as iron(III).

Abstract

The synthesis of the novel chelator 'tamepyr' (*N*,*N*′,*N*″-tris(2-pyridylmethyl)-1,1,1-tris(aminomethyl)ethane) and properties of its complexes with Fe(II), Co(II), Ni(II), Cu(II), Zn(II) and In(III) are reported. Tamepyr was prepared as a complex with Ni(II) by the $NaBH_4$ reduction of the tamepyr-trisimine complex, $[Ni((2\text{-py-}C(H){=}NCH_2)_3CMe)]^{2+}$. The decomposition of $[Ni(tamepyr)]^{2+}$ with excess sodium cyanide affords tamepyr in 40% overall yield from tame. Structural study of $[Zn(tamepyr)](ClO_4)_2$ shows similar Zn–N distances with reference to the aminopyridyl tripod tachpyr (*N*,*N*′,*N*″-tris(2-pyridylmethyl)-*cis*,*cis*-1,3,5-triaminocyclohexane), being $d(Zn\text{–}N_{amine,py}) = 216.9(2)$, 212.8(2) pm versus 216.0(3), 216.5(4) pm for $[Zn(tachpyr)](ClO_4)_2$. However, the $[Zn(tamepyr)]^{2+}$ data indicate a greater propensity to octahedral coordination in a tame-framework chelator compared to a tach-framework chelator: the trigonal twist angle in the ZnN_6 coordination sphere of $[Zn(tamepyr)]^{2+}$ is 46.5(2)° versus 43.7(2)° for $[Zn(tachpyr)]^{2+}$. When presented with larger metals such as In(III), tamepyr shows greater flexibility than tachpyr, thus, $[In(tamepyr)]^{3+}$ is completely fluxional at ambient temperature while $[In(tachpyr)]^{3+}$ is static up to 107 °C as shown by ^1H NMR in DMSO-d_6.

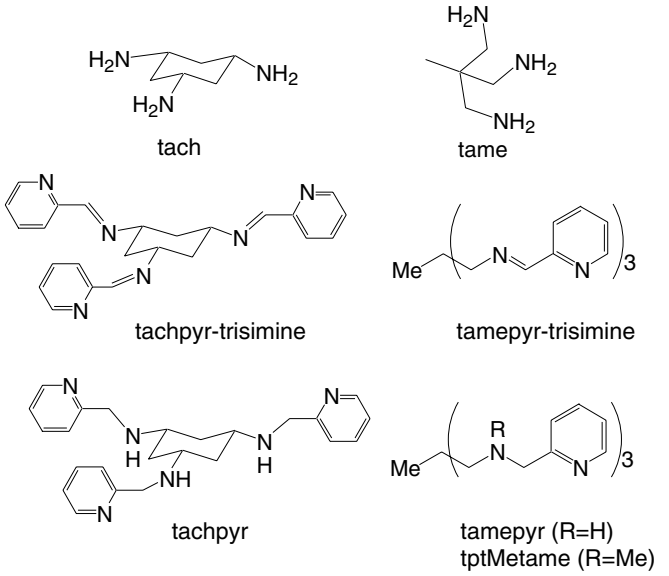
Keywords: Tripodal chelator; Templating reaction; Fe(II); Ni(II); Zn(II)



1. Introduction

In the design of metal chelators, the ligand geometry and conformational properties as well as the donor atom character are key to controlling thermodynamics and kinetics of the metal–ligand interaction [1–4]. A number of chelators that are based on triamines with zero to three pendant donor groups have been studied, with objectives that include modulating the reactivity of a supported metal (in analogy to the cyclopentadienyl or tris(pyrazolylborate) ligands), sequestering a metal (analogous to DTPA or DOTA) and the synthesis of polynuclear structures [5–17]. An understanding of metal-binding dynamics and structure is essential to tailor these chelators to such applications. We report the preparation of the novel hexadentate tripod tris(2-pyridylmethyl)-1,1,1-tris(aminomethyl) ethane (tamepyr) and complexation, structural and dynamic information for the metal ions Fe(II), Co(II), Ni(II), Cu(II), Zn(II) and In(III).

The particular motivation to develop tamepyr derived from our studies of tripodal aminopyridyl chelators such as tachpyr (Scheme 1) as intracellular Fe- and Zn-complexing agents [18,19]. We determined that air oxidation plays a role in Fe(II) complexation by tachpyr, leading to Fe-imino species including Fe–tachpyr-trisimine via iron-mediated oxidative dehydrogenation [20,21]. These complexes liberate iron by hydrolysis due to structural strain. We observed this strain in the structure of an Fe(II)-tachpyr-trisimine derivative [22] and saw that it arises from the strong

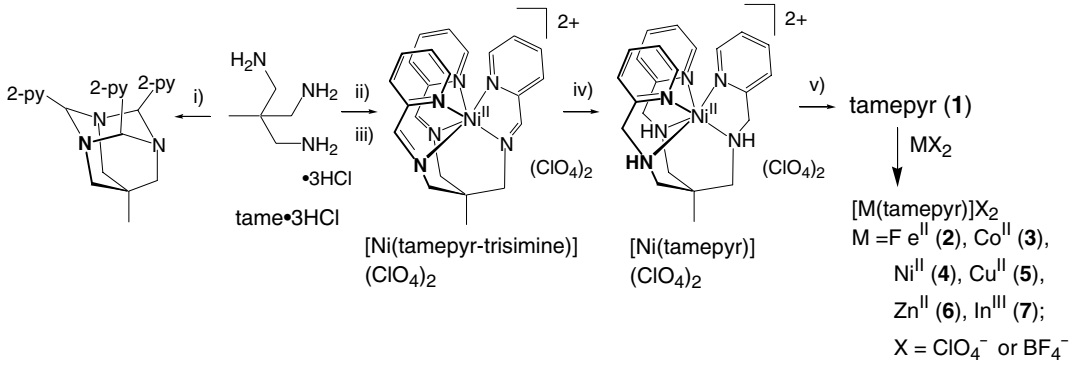
Scheme 1. The tripodal amines tach and tame and their corresponding methinyl-2-py and methyl-2-py derivatives.

preference of tachpyr-trisimine for trigonal-prismatic geometry, for example in $[Zn(tachpyr\text{-}trisimine)]^{2+}$, which has a trigonal twist angle of 4.6°, where values of an ideal trigonal-prism are 0° and of an octahedron, 60° [23–26]. Fe(II) in the low-spin state prefers the octahedral geometry and so its geometry preferences are in opposition to the tachpyr-trisimine ligand. In order to retain and sequester iron as Fe(II), it was thus desirable to prepare chelators whose products of iron-mediated oxidative dehydrogenation would bind Fe(II) well. The structure of Fe(tamepyr-trisimine) is known and is quite octahedral (trigonal twist angle = 43°) [27], but surprisingly the hexahydro analogue tamepyr has not been previously reported, although an *N*-methylated derivative of tamepyr, tptMetame is known (Scheme 1). Herein, we describe use of Ni(II) templating to stabilize the tris-imine condensation product of tame with pyridine-2-carboxaldehyde which then allows synthesis of the novel ligand tamepyr by reduction of Ni(II)-tamepyr-trisimine (Scheme 2). The coordination chemistry of tamepyr with Fe(II), Co(II), Ni(II), Cu(II), Zn(II) and In(III), and comparison of its rigidity to tachpyr are presented.



2. Results and discussion

The direct condensation of tame with 3 equiv. of pyridine-2-carboxaldehyde yielded a triazaadamantane, whereas reaction of tame, Ni(II) and 3 equiv. of pyridine-2-carboxaldehyde affords $[Ni(tamepyr\text{-}trisimine)]^{2+}$, according to the template reaction previously reported [28]. However, reduction of $[Ni(tamepyr\text{-}trisimine)]^{2+}$ with $NaBH_4$ forms $[Ni(tamepyr)]^{2+}$, accompanied by a color change from orange to pink and disappearance of a C=N stretching frequency at 1650 cm^{-1}. Workup with $HClO_4$ and recrystallization from $MeCN/Et_2O$ provides fuchsia prisms of $[Ni(tamepyr)](ClO_4)_2$ (40% yield) from which free tamepyr is displaced in 96% yield with aqueous NaCN.

The Fe(II), Co(II), Cu(II), Zn(II) and In(III) tamepyr complexes are prepared straightforwardly by reactions of the metal salts and the ligand in MeOH with Et_2O cosolvent to improve precipitation and yields, followed by recrystallization from a $MeCN/Et_2O$ solvent system. A 1:1 M:L composition was verified for all complexes by elemental analysis and electrospray mass spectrometry. Work with Fe(II) was conducted under inert atmosphere, due to the tendency of Fe to mediate oxidative dehydrogenation of aminopyridyl ligands [20,29].

2.1. Structural study

Crystallographic study of $[Zn(tamepyr)](ClO_4)_2$ helps elucidate the influence of the ligand on the metal ion coordination geometry, because Zn(II) has no electronic geometry preferences (Fig. 1) [30]. The cation possesses crystallographic C_3 symmetry where the C_3 axis passes through C9, C8 and Zn1. Tame appears better suited to providing an octahedral geometry, because $[Zn(tamepyr)](ClO_4)_2$ has

Scheme 2. Left of tame · 3HCl, formation of a triazaadamantane; right of tame · 3HCl, synthesis of $[Ni(tamepyr\text{-}trisimine)](ClO_4)_2$ and $[Ni(tamepyr)](ClO_4)_2$. (i) 3 equiv. NaOH, 2-pyridinecarboxaldehyde, $-H_2O$; (ii) 3 equiv. NaOH, EtOH; (iii) 2-pyridinecarboxaldehyde, $Ni(ClO_4)_2 \cdot 6H_2O$; (iv) $NaBH_4$, H_2O, EtOH; (v) NaCN(aq), CH_2Cl_2 extraction and evaporation.

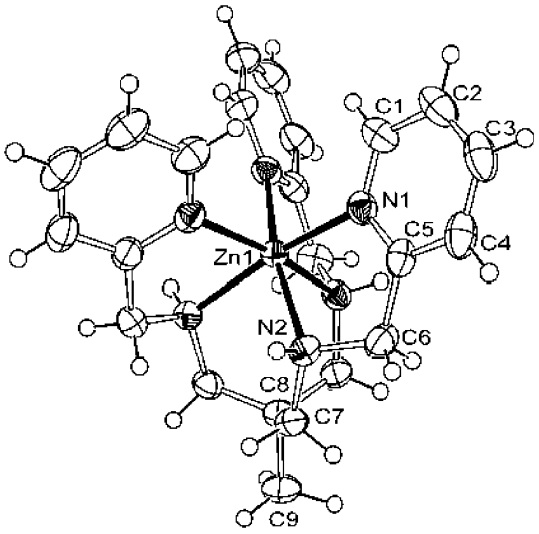


Fig. 1. Structure of $[Zn(tamepyr)](ClO_4)_2$ (ORTEP; 50% probability ellipsoids) showing the atom-numbering scheme. Selected bond lengths (Å) and angles (°): Zn–N(2) = 2.169(2), Zn–N(1) = 2.128(2), N(2)–Zn–N(1) = 79.16(8), trigonal twist angle = 46.47°.

a larger trigonal twist angle (46.5(2)°) than $[Zn(tachpyr)](ClO_4)_2$ (43.7(2)° [30]). Complex $[Zn(tamepyr)](ClO_4)_2$ also has significantly shorter Zn–N_{py} bond lengths than $[Zn(tachpyr)](ClO_4)_2$ (2.128(2) Å versus 2.165(4) Å). A greater twist angle is consistent with shorter bond lengths to the metal ion because steric interactions between coordinating pyridines are reduced. The other striking comparison is with $[Fe(tptMetame)](ClO_4)_2$, the Fe(II) complex of the tri-*N*-methylated tamepyr analog tptMetame (Scheme 2) [31]. This complex was structurally characterized at 153 K, where it Fe(II) is in the low-spin state and the trigonal twist angle is nearly octahedral at 51.0°.

The ability of tamepyr to attain a conformation close to octahedral is clearly attributable to twisting of the framework and so an analysis according to the formalisms that Al-Obaidi et al. applied to $[Fe(tptMetame)]^{2+}$ [31] is appropriate. There are multiple conformational possibilities in tamepyr chelates because left- and right-handed twists with respect to the C_3-axis of both the tame cap (atoms C8, C7, C7A, C7B) and the three aminopyridyl arms are possible. The twist configuration of the three six-membered rings in the tame cap portion of $[Zn(tamepyr)]^{2+}$ is assigned as δ^{cap}. Further, λ or δ configurations of the five-membered aminopyridyl chelate rings (e.g., Zn1–N2–C6–C5–N1) are possible, and finally, the three aminopyridyl arms may have a Λ or a Δ twist. In $[Zn(tamepyr)]^{2+}$, the conformations of the five-membered chelate rings are λλλ and the twist of the three aminopyridyl arms is Δ. Together these last two constraints require an *SSS* stereochemistry at the three chiral nitrogen (amine) donor atoms, as is observed. The complex crystallizes in the chiral space group $P2_13$. Because the Flack parameter refined to a value of 0.015(14), the enantiomer reported in this paper is the correct one. While the crystal studied is of the δ^{cap}–Δ(λλλ) enantiomer, crystals of the λ^{cap}–Λ(δδδ) enantiomer are probably also present. In sum, crystallography shows that the pyridyl-pendant chelator of the tame framework has a greater tendency to octahedrality than the tach framework, accompanied by shorter Zn–N bond lengths and consistent with previous results findings for $[Fe(tptMetame)](ClO_4)_2$.

2.2. Electronic structure

The solution spectra of $[M(tamepyr)]^{2+}$ are fully consistent with a pseudooctahedral coordination geometry and strong metal–ligand interactions including effective $d\pi \rightarrow p\pi$ metal–ligand donation. The room temperature ^1H NMR spectrum of $[Fe(tamepyr)]^{2+}$ (CD_3CN solvent) is not paramagnetically shifted, indicating a low spin electronic configuration ($^1A_1$ ground-state). Whereas, spin-crossover behavior is exhibited by $[Fe(tptMetame)]^{2+}$ in propionitrile solution or the solid-state at temperatures greater than 153 K [31]. Thus, tertiary coordinating amines are substantially more hindered than secondary amines in the tamepyr system, as we observed in the tach system, where the Fe(II) complex of *N*,*N*′,*N*″-trimethyltachpyr ($[Fe((N\text{-}Me)_3tachpyr)](ClO_4)_2$) is a high-spin Fe(II) complex while $[Fe(tachpyr)]^{2+}$ is a low-spin complex [20,32].

The electronic structures of the Fe(II), Co(II), Ni(II), and Cu(II) complexes of tamepyr have been assessed with UV–Vis–NIR spectroscopy. The complex $[Fe(tamepyr)]^{2+}$ exhibits an absorption band at 24 000 cm^{-1} (Table 1). This absorption is often assigned as a metal to ligand charge transfer band (MLCT) characteristic of LS Fe(II) complexes [33,34]. The MLCT band masks all d–d transitions of low-spin Fe(II) except for a low-energy shoulder (18 000 cm^{-1}, $\varepsilon = 300\ cm^{-1}\ M^{-1}$), which is often assigned as an obscured $^1A_{1g} \rightarrow {}^1T_{1g}$ transition [34]. The $[Ni(tamepyr)]^{2+}$ spectrum compares well with other octahedral d^8 metal complexes, although only two of the three possible d–d bands could be assigned. The third band ($^3A_{2g} \rightarrow {}^3T_{1g}$) was obscured by a charge transfer band beginning at

Table 1
Spectral properties of tamepyr complexes[a]

M(II)	ν, cm^{-1} (ε, $M^{-1}\ cm^{-1}$)	Transition	Δ_o (cm^{-1})	Color
Fe	24 000 (70 000)	MLCT		bronze
Co	21 100(63), 18 400(28), 10 650(21)	$^4T_{1g} \rightarrow {}^4A_{2g}$, $^4T_{1g} \rightarrow {}^4T_{1g}(P)$, $^4T_{1g} \rightarrow {}^4T_{2g}$	11 100	orange
Ni	19 600(16), 12 600(12)	$^3A_{2g} \rightarrow {}^3T_{1g}$, $^3A_{2g} \rightarrow {}^3T_{2g}$		pink
Cu	16 100(107)	$^2E_g \rightarrow {}^2T_{2g}$		blue

[a] Recorded at ambient temperature in MeCN for all complexes except Fe where the spectrum was recorded in degassed H_2O; assignments in octahedral pseudosymmetry.

approximately 27 000 cm^{-1}. The $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ transition in $[Ni(tamepyr)]^{2+}$ occurs at 19 600 cm^{-1}. The corresponding transition for $[Ni(ampy)_3]^{2+}$ is red-shifted and occurs at 18 800 cm^{-1} [35]. This is consistent with the additional field strength imparted to $[Ni(tamepyr)]^{2+}$ via a chelate-effect originating from the presence of the tame framework. The $^3A_{2g} \rightarrow {}^3T_{2g}$ transition is mixing with the spin-forbidden $^3A_{2g} \rightarrow {}^1E_g$ transition, so the value of Δ_o reported in Table 1 is only approximate [35]. The energy of this transition is similar to those found for $[Ni(trenpyr)]^{2+}$ and $[Ni(tachpyr)]^{2+}$ [36,37]. The spectrum of $[Cu(tamepyr)]^{2+}$ is typical of distorted octahedral Cu(II) complexes, with the presence of one asymmetric band at 16 100 cm^{-1} [37]. The asymmetry in this band can be attributed to Jahn–Teller distortions of this complex in solution. All three possible d–d transitions are seen in the spectrum of $[Co(tamepyr)]^{2+}$. The $^4T_{1g} \rightarrow {}^4A_{2g}$ band often lies under the $^4T_{1g}(P)$ transition, but in the case of $[Co(tamepyr)]^{2+}$ both transitions can be seen at 21 100 cm^{-1} and 18 400 cm^{-1} respectively. The lowest energy transition, which is equal to Δ_o, lies at 10 650 cm^{-1}, which is consistent with the reported range of 6500–10 500 cm^{-1} [38]. A ligand field strength $\Delta_o \geqslant 15\,000$ cm^{-1} can cause a LS octahedral Co(II) complex, which would however be Jahn–Teller distorted [39]. It is possible that the octahedral-enforcing nature of tamepyr would lead to additional strain in a Jahn–Teller distorted complex which would outweigh the stabilization difference of low-spin d^7 relative to high-spin d^7 electron configurations.

2.3. Solution conformation

Proton NMR spectra show that tamepyr maintains a rigid pseudooctahedral geometry at room temperature when coordinated to 3d metal ions, but as the metal–ligand size fit worsens (in the case of In(III)) the tamepyr coordination sphere is apparently more flexible than that of tachpyr. The ^1H NMR of the Fe(II) and Zn(II) tamepyr complexes show a sharp doublet of doublet spin pattern for the pyridyl-CH_2–N protons, indicative of conformational rigidity in solution at room temperature [40]. The ^1H NMR spectrum for $[In(tamepyr)]^{3+}$ (DMSO-d_6) shows a single doublet for each of the two types of CH_2 (pyridyl–methylene and aminomethylene), thus the geminal H's are chemically equivalent but split by the neighboring amino proton. This is consistent with the racemization of the chelate rings between the Λ and Δ forms, and is not observed in the ^1H NMR spectrum of $[In(tachpyr)]^{3+}$ (DMSO-d_6) until the temperature of the solution is raised to 107 °C [40].

3. Conclusions

We have synthesized the novel ligand tamepyr and studied its coordination chemistry with several 3d transition-metal elements. Investigations of aqueous metal ion complexation processes and thermodynamics of tamepyr's interaction with 3d-transition metals are underway.

4. Experimental section

4.1. General

All the materials listed below were of a research grade or a spectro-grade in the highest purity available and were generally used without further purification except diethyl ether, which was distilled from sodium benzophenone. Anhydrous methanol, acetonitrile, and the salts $Zn(ClO_4)_2 \cdot 6H_2O$, $Cu(ClO_4)_2 \cdot 6H_2O$, $Ni(ClO_4)_2 \cdot 6H_2O$, $Co(BF_4)_2 \cdot 6H_2O$, and $Fe(ClO_4)_2 \cdot 6H_2O$ were obtained from Aldrich. Anhydrous grade EtOH was obtained from Pharmco. DMSO-d_6, $CDCl_3$, CD_3CN, and D_2O were obtained from Cambridge Isotope Laboratories. All of the UV–Vis spectra were measured using a Varian Cary 50 Bio spectrometer with 1 cm^3 quartz cuvettes (1 cm path-length). Electrospray ionization (ESI) mass spectra in the positive ion detection mode were obtained on a Finnegan LCQ Classic instrument with dual optical Paul traps and Picoview nanospray source. Assignments were based on calculations by the program developed by Scientific Instrument Services (http://www.sisweb.com/cgi-bin/mass10.pl, accessed 8 August 2006). ^1H and ^{13}C NMR were obtained using a Varian Mercury 400 MHz NMR instrument and chemical shifts are reported in ppm on the δ scale relative to TMS or DSS. Proton chemical shifts are annotated as follows: ppm (integral, multiplicity, coupling constant (Hz), assignment). The magnetic moment was measured by Evan's method using residual CD_2HCN or CD_2HSOCD_3 as indicator in both the sample and closed capillary. Elemental analysis was performed by Atlantic Microlabs (Atlanta, Georgia). Drying was accomplished under a stream of nitrogen or under reduced pressure (*ca.* 10^{-2} Torr) with a standard Schlenk line. Anaerobic manipulations were accomplished under a nitrogen atmosphere in a glovebox (VAC model HE-43 with HE-493 purifier).

Caution: perchlorate salts can be explosive and should be handled with care. No explosions occurred during the course of this work.

4.2. Preparations of compounds

4.2.1. *[Ni(tamepyr)](ClO$_4$)$_2$ (**4**)*

An aqueous solution of NaOH (265 mg, 6.63 mmol) was added to 1,1,1-tris(aminomethyl)ethane · 3HCl (0.500 g, 2.21 mmol). The resulting solution was then brought to dryness on a rotary evaporator affording colorless oily solids. Absolute ethanol (25 mL) was then added to the solids, and the mixture was sonicated for 5 min and cooled to 4 °C for 1 h. The cold ethanolic solution was filtered through a glass frit. The filtrate was then diluted with 100 mL of water and transferred to a flask that contained $Ni(ClO_4)_2 \cdot 6H_2O$ (808 mg, 2.21 mmol). The resulting sky blue solution

was stirred with slow addition of an ethanolic solution (40 mL) of 2-pyridinecarboxaldehyde (710 mg, 6.63 mmol). The resulting solution was stirred under nitrogen for 16 h where a color change from blue to orange took place. The reaction mixture afforded significant amounts of orange colored precipitate, which was collected on a glass frit and dried under vacuum to afford 614 mg of [Ni(tamepyr-trisimine)]-$(ClO_4)_2$. This complex was added to a mixture of 150 mL of doubly distilled water and 20 mL of EtOH (0.5 g, 0.8 mmol) and $NaBH_4$ (2.2 g, 58 mmol). The reaction mixture was stirred for 16 h to give a pale pink solution. The pH of the mixture was dropped to 6.7 with addition of 70% perchloric acid. The pink precipitate that formed was collected on a glass frit and washed with small portions of Et_2O. The resulting powder was recrystallized by Et_2O diffusion from CH_3CN yielding fuchsia colored prisms. The prisms were isolated and dried under vacuum to give 473 mg (40%) of the product. (*Anal.* Calc. for $C_{23}H_{30}N_6NiCl_2O_8$: C, 42.62; H, 4.67; N, 12.97. Found: C, 42.68; H, 4.71; N, 12.94%.) MS(ESI/methanol): *m*/*z* 547 ($M - ClO_4^-$). $\mu_{eff} = 3.2$ BM at 23 °C. λ_{max}/cm^{-1} (MeCN) 12600 (12.0 cm^{-1} M^{-1}), 19600 (15.8 cm^{-1} M^{-1}). IR (KBr/Nujol): 3275 s, 1611 s, 1576 m, 1095 s, br.

4.2.2. *N,N′,N″-tris(2-pyridylmethyl)-1,1,1-tris(aminomethyl)ethane (tamepyr) (**1**)*

To a sample of $[Ni(tamepyr)](ClO_4)_2$ (50 mg, 80 μmol) was added 5 mL of hot aqueous sodium cyanide (21 mg, 420 μmol). The mixture was shaken for 5 min affording a pale yellow solution. The solution was extracted with methylene chloride (3 × 5 mL); the organic fractions were combined, and dried over anhydrous Na_2SO_4. The supernatant was decanted and the solvent was removed on a rotary evaporator. The resulting colorless oil was dried further under vacuum to afford 30 mg (96%) of the product. ^1H NMR [$CDCl_3$]: δ 8.51 (3H, m, pyridyl H); 7.60 (3H, m, pyridyl H); 7.33 (3H, d, $^3J = 7.6$ Hz, pyridyl H); 7.13 (3H, m, pyridyl H); 3.91 (6H, s, pseudobenzylic H); 2.62 (6H, s, methylene H); 2.50 (3H, s, N*H*); 0.95 (3H, s, methyl H). ^{13}C NMR [$CDCl_3$]: δ 160.6, 149.3, 136.6, 122.4, 122.0, 56.9, 56.2, 38.7, 22.1.

4.2.3. *[Fe(tamepyr)](ClO4)2 (**2**)*

A pale yellow degassed methanolic solution (1 mL) of $Fe(ClO_4)_2 \cdot 6H_2O$ (29 mg, 80 μmol) was added to a colorless degassed methanolic solution (1 mL) of tamepyr (31 mg, 80 μmol) under the protection of a nitrogen atmosphere. The reaction mixture was allowed to deposit solids for 16 h. The supernatant was removed and the resulting dark colored crystalline solids were washed with small portions of degassed Et_2O, and then dried under a stream of nitrogen. The solids were then recrystallized by Et_2O diffusion from CH_3CN affording chestnut colored prisms. The crystals of the complex were stable to air indefinitely whereas a sealed oxygenated aqueous solution of the complex decomposed when incubated at 37 °C overnight. ^1H NMR [CD_3CN degassed]: δ 7.81 (3H, m, pyridyl H); 7.52 (6H, m, pyridyl H); 7.20 (3H, t, $^3J = 6.4$ Hz, pyridyl H); 4.46 (3H, m, N*H*); 4.31 (3H, dd, diastereotopic pseudobenzylic H); 4.05 (3H, dd, diastereotopic pseudobenzylic H); 2.97 (3H, dd, diastereotopic methylene H); 2.49 (3H, dd, diastereotopic methylene H); 0.812 (3H, s, methyl H). IR (CsI pellet): 3267 m, 1615 w, 1577 w, 1088 s, br, 761 s, 624 s. (*Anal.* Calc. for $C_{23}H_{30}N_6FeCl_2O_8$: C, 42.81; H, 4.69; N, 13.02. Found: C, 43.10; H, 4.75; N, 13.13%.)

4.2.4. *[Co(tamepyr)](BF4)2 (**3**)*

A pale red degassed methanolic solution (1 mL) of $Co(BF_4)_2 \cdot 6H_2O$ (19 mg, 55 μmol) was added to a colorless degassed methanolic solution (1 mL) of tamepyr (21 mg, 55 μmol) under the protection of a nitrogen atmosphere. The reaction mixture was then subjected to Et_2O diffusion for 5 days to afford orange colored prismatic crystals. The supernatant was removed and the resulting crystalline solids were washed with small portions of degassed Et_2O, and then dried under a stream of nitrogen to give 21 mg (63%) of the product. The crystals of the complex were stable to air indefinitely but decomposed rapidly in CH_3CN when exposed to air. (*Anal.* Calc. for $C_{23}H_{30}N_6CoB_2F_8$: C, 44.34; H, 4.85; N, 13.49. Found: C, 44.28; H, 5.05; N, 13.35%.) $\mu_{eff} = 4.9$ BM at 23 °C. IR (CsI pellet): 3172 m, 1606 m, 1565 w, 729 s, 478 s. IR (KBr/Nujol): 3275 s, 1611 s, 1576 m, 1095 s, br. λ_{max}/cm^{-1} (CH_3CN degassed) 10650 (21 cm^{-1} M^{-1}), 18400 (28 cm^{-1} M^{-1}), 21100 (63 cm^{-1} M^{-1}).

4.2.5. *[Cu(tamepyr)](ClO4)2 (**5**)*

A pale blue isopropanolic solution (1 mL) of $Cu(ClO_4)_2 \cdot 6H_2O$ (30 mg, 80 μmol) was added to a colorless isopropanolic solution (1 mL) of tamepyr (31 mg, 80 μmol) resulting in the formation of a sky blue powder. The solvent was removed on a rotary evaporator and the resulting powder was recrystallized by Et_2O diffusion from CH_3CN, isolated and dried under vacuum, to afford 47 mg (91%) of the product as royal blue needles. (*Anal.* Calc. for $C_{23}H_{30}N_6CuCl_2O_8$: C, 42.31; H, 4.63; N, 12.87. Found: C, 42.21; H, 4.58; N, 12.77%.) MS(ESI/methanol): *m*/*z* 552 ($M - ClO_4^-$). $\mu_{eff} = 2.1$ BM at 23 °C. IR (KBr/Nujol): 3249 m, 1613 m, 1574 w, 1096 s, br. λ_{max}/cm^{-1} (CH_3CN) 16100 (107 cm^{-1} M^{-1}) asymmetric peak.

4.2.6. *[Zn(tamepyr)](ClO4)2 (**6**)*

A colorless methanolic solution (1 mL) of $Zn(ClO_4)_2 \cdot 6H_2O$ (30 mg, 80 μmol) was added to a colorless methanolic solution (1 mL) of tamepyr (31 mg, 80 μmol) resulting in the formation of a colorless precipitate. The solvent was diluted with a small portion of Et_2O and the solids were isolated, washed with additional ether, and then recrystallized by Et_2O diffusion from CH_3CN to afford 30 mg (58%) of colorless prisms. ^1H NMR [CD_3CN]: δ 8.07 (3H, m, pyridyl H); 7.88 (3H, d, $^3J = 4.8$ Hz, pyridyl H); 7.57 (3H, d, $^3J = 8$ Hz, pyridyl H); 7.46 (3H, t, $^3J = 6.8$ Hz, pyridyl H); 4.35 (3H, dd, pseudobenzylic H); 3.95 (3H, dd, diastereotopic H); 3.53 (3H, m, N*H*); 3.32 (3H, dd, diastereotopic methylene H);

2.85 (3H, dd, diastereotopic methylene H); 0.77 (3H, s, methyl H). IR (KBr/Nujol): 3249 m, 1613 m, 1574 w, 1096 s, br. (*Anal*. Calc. for $C_{23}H_{30}N_6ZnCl_2O_8$: C, 42.19; H, 4.62; N, 12.83. Found: C, 41.90; H, 4.60; N, 12.68%.) MS(ESI/methanol): *m/z* 553 ($M - ClO_4^-$). Suitable crystals for X-ray crystallography were prepared by slow Et_2O diffusion into an CH_3CN solution of the complex.

4.2.7. *[In(tamepyr)](NO$_3$)$_3$ · MeOH (7)*

A colorless methanolic solution (0.90 mL) of $In(NO_3)_3 \cdot 5H_2O$ (8.0 mg, 20 μmol) was added to a colorless methanolic solution (0.90 mL) of tamepyr (7.8 mg, 20 μmol) resulting in the formation of a colorless solution. The solution was allowed to stand for 18 h. The complex was crystallized from solution as feather-like white needles by Et_2O diffusion. The needles were isolated and dried under vacuum to afford 10.1 mg (73%) of the desired product. ^{1}H NMR [DMSO-d_6]: δ 8.25–8.21 (3H, m, pyridyl H); 8.04 (3H, s, pyridyl H); 7.79 (3H, d, $^3J = 8.0$ Hz, pyridyl H); 7.66 (3H, t, $^3J = 6.0$ Hz, pyridyl H); 5.86 (3H, m, N*H*); 4.31 (6H, d, $^3J = 6.0$ Hz, pseudobenzylic H); 3.17 (6H, d, $^3J = 7.2$ Hz, methylene H); 0.84 (3H, s, methyl H). IR (KBr pellet): 3163, 1609 m, 1571 w, 1365 vs, 1279 s. (*Anal*. Calc. for $C_{23}H_{30}N_6InN_3O_9$: C, 39.85; H, 4.74; N, 17.43. Found: C, 39.99; H, 4.47; N, 17.72%.)

4.3. Crystallography

Crystallographic data for [Zn(tamepyr)]$(ClO_4)_2$: colorless prisms, crystal dimensions $0.30 \times 0.40 \times 0.40$ mm, $C_{23}H_{30}Cl_2N_6O_8Zn$, cubic, space group $P2_13$, $a = b = c = 13.9397(3)$ Å, $\alpha = \beta = \gamma = 90°$, $V = 2708.70(10)$ Å^3, $Z = 4$, $\lambda = 0.71073$ Å, $D_{calc} = 1.606$ g/cm^3, $T = 213(2)$ K, μ(Mo Kα) = 1.163 mm^{-1}. A total of 2147 independent reflections were used with $2.53° < \theta < 28.26°$, of which 2041 reflections had $I > 2\sigma(I)$. Final results: $R(F, I > 2\sigma(I)) = 0.0326$, $R_w(F,\ I > 2\sigma(I)) = 0.0944$, Goodness-of-fit = 1.020, maximum residual electronic density = 0.530 e Å^{-3}.

Synthesis, characterisation and biological activity of cycloaurated organogold(III) complexes with imidate ligands

Kelly J. Kilpin, William Henderson *, Brian K. Nicholson

Department of Chemistry, University of Waikato, Private Bag 3105, Hamilton, New Zealand

Received 13 June 2006; accepted 14 August 2006
Available online 18 August 2006

Abstract

The reactions of the cycloaurated gold(III) complexes (2-bp)$AuCl_2$ (2-bp = 2-benzylpyridyl) or (damp)$AuCl_2$ (damp = Me_2NCH_2-C_6H_4) with an excess of sodium saccharinate (Nasacc), potassium phthalimidate (Kphth), or with isatin and trimethylamine in refluxing methanol results in the successful isolation of a series of new gold(III) imidate complexes. These were characterised by NMR and IR spectroscopies, and by X-ray structure determinations on (2-bp)Au(sacc)$_2$ and (2-bp)Au(phth)$_2$. In both structures, the planes of the saccharinate and the phthalimidate ligands are orientated almost perpendicular to the gold coordination plane. As expected from *trans*-influence considerations, the Au–$N_{(imidate)}$ bond lengths *trans* to the aryl carbon atoms are longer than the Au–$N_{(imidate)}$ bond lengths *trans* to the pyridyl groups. The complexes have also been characterised by electrospray ionisation MS; in the presence of halide ligands, one imidate ligand is readily displaced. Anti-tumour (P388 murine leukemia) and selected anti-microbial data for the new complexes are reported. Surprisingly, all three damp complexes had low anti-tumour activity, which is likely to be a consequence of the poor solubility of these complexes. The synthesis and characterisation of a related gold(III) bis(amidate) complex derived from sulfathiazole is also described.

1. Introduction

The search for potent anti-tumour activity has been one of the driving forces for recent activity in the chemistry of cycloaurated gold(III) complexes [1–3], in light of the well-developed medicinal chemistry of platinum(II), and the similarities between this metal centre and gold(III), imparted by their isoelectronic nature. In cycloaurated complexes, the ligand, typically a bidentate nitrogen–carbon donor, stabilises the square-planar gold(III) state towards reduction. Most work has been carried out with the damp complex **1** [1], because of its typical good solubility characteristics and tendency to promote good anti-tumour activity in the corresponding acetate derivative. Developments in this area have been thoroughly reviewed [4,5].

We have been investigating the synthesis and biological properties of cycloaurated complexes that contain a range of ancillary ligands, derived from both the damp system as well as other cycloaurated complexes that are more readily prepared in one step from $HAuCl_4$. Complexes containing chelating thiosalicylate ($SC_6H_4CO_2$) ligands have been found, by ourselves [6,7] and others [8], to show promising biological activity, and we have recently turned our attention to the investigation of complexes with nitrogen and oxygen donor ligands. Examples of catecholate [9], amidophenolate [9], ureylene [10], lactam [11], and auracyclic bis(amidate) [12] complexes have all been prepared, with a number showing promising anti-tumour activity. In this paper, we report studies on the synthesis, characterisation and biological activity of cycloaurated gold(III) complexes containing monodentate imidate ligands derived from saccharin, phthalimide and isatin.

Although imidate derivatives of cycloaurated complexes are new, gold(III) imidate complexes have a long

doi:10.1016/j.poly.2006.08.009

history. As long ago as 1929, Pope filed a patent claiming to have synthesised a range of gold(III) succinimidate complexes [13]. Subsequently, Kharasch and Isbell reported [14] the formation of gold(III) imidate complexes $[Au(imidate)_4]^-$ (imidate = anion of succinimide, phthalimide, saccharin or diethyl barbituric acid), which were reformulated by Tyabji and Gibson [15]. Malik et al. [16] demonstrated that the product of the reaction between $[AuCl_4]^-$ and *N*-methylhydantoin was actually a gold(I) complex, and suggested that Kharasch's original Au(III) tetrasuccinimidate complex was also a gold(I) bis(imidate) complex. Only recently, a stable gold(III) complex **2** was reported [17], containing four deprotonated hydantoin ligands, an arrangement thought to be impossible (on steric grounds) by Tyabji and Gibson. Few other gold(III) imidate complexes have been reported, though there are many examples of both gold(I) [18–23] and platinum(II) [24–29] imidate complexes, derived from a range of ligands such as saccharin, phthalimide, and isatin.

2. Results and discussion

2.1. Synthesis and characterisation of gold(III) imidate complexes derived from saccharin, phthalimide and isatin

The reactions of (damp)$AuCl_2$ (**1**) or (2-bp)$AuCl_2$ (**3**) with an excess of either sodium saccharinate (Nasacc), potassium phthalimidate (Kphth) or isatin (Hisa) in refluxing methanol afforded products **4**–**9** in good yields. The reactions involving isatin required the use of Me_3N to remove the imide proton whereas preformed salts of saccharin and phthalimide were used, and additional base was unnecessary for these ligands. The products **4**–**9** were characterised by ESI MS, NMR and IR spectroscopies, together with elemental microanalysis. The damp complexes **5** and **9** were, surprisingly, only sparingly soluble in $(CH_3)_2SO$ and $CDCl_3$, but the other complexes were soluble in common organic solvents such as dichloromethane, acetone and $(CH_3)_2SO$.

^{1}H NMR spectroscopy of the 2-benzylpyridyl derivatives was used to determine sample purity, however full assignment proved difficult due to the presence of four non-equivalent aromatic rings and hence the presence of complex multiplets in the aromatic region. The methylene protons of the benzylpyridyl ligand are expected to appear as a doublet of doublets, due to geminal coupling between protons in equatorial and axial environments of a puckered six-membered ring, as previously described by Fuchita et al. [30] In the phthalimide **6** and isatin **8** derivatives, the CH_2 signals were very broad and barely visible above the baseline, as illustrated in Fig. 1 for (2-bp)Au(phth)$_2$ (**6**); heating effected convergence of the two broad methylene proton signals, giving a broad singlet (Fig. 1). For the saccharin derivative **4** the CH_2 resonances were resolved into two broad doublets.

The ^{1}H NMR spectrum of (damp)Au(phth)$_2$ (**7**) showed two singlets at δ 3.32 and 4.53 due to the methyl and

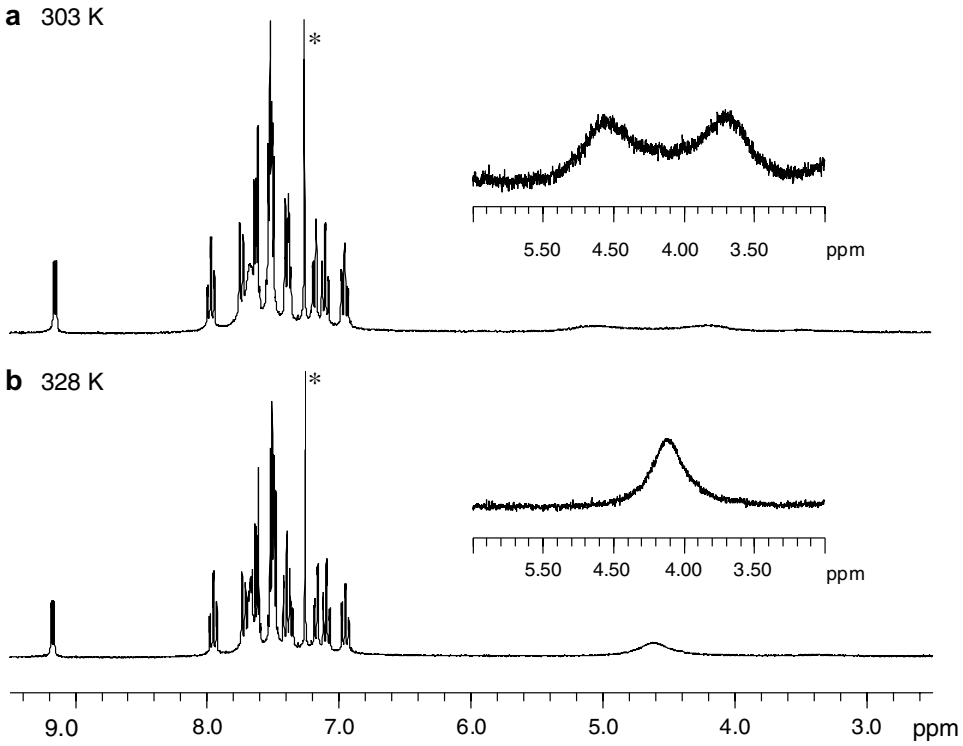

Fig. 1. ^{1}H NMR spectra (300 MHz) of the complex (2-bp)Au(phth)$_2$ (**6**) at temperatures of (a) 303 K and (b) 328 K, in $CDCl_3$ solution, showing the fluxionality of the benzylpyridyl group. The peaks marked * are due to $CHCl_3$ (7.26 ppm).

methylene protons of the damp ligand, respectively; this complex contains a plane of symmetry co-planar to the gold coordination plane. However, both (damp)Au(sacc)$_2$ (**5**) and (damp)Au(isa)$_2$ (**9**) were poorly soluble in all common NMR solvents with the exception of $CDCl_3$, in which they were soluble enough to acquire very weak spectra. In contrast to the bis(phthalimidate) species, these complexes do not have a plane of symmetry through the Au plane, due to the unsymmetrical nature of the saccharin and isatin ligands. As a result, the methylene and methyl group protons are in different chemical environments giving rise to two singlets from the methyl protons and two doublets (due to geminal H–H coupling) from the methylene protons.

The IR spectrum of isatin shows strong absorptions in the carbonyl region at 1748, 1728 and 1617 cm^{-1}; coordination to gold results in a decrease in the stretching frequency of these bands to 1736, 1692 and 1605 cm^{-1} for the benzylpyridyl derivative **8**, and to 1730, 1701, 1682 and 1603 cm^{-1} for the damp derivative **9**. The NH stretch, present at 3192 cm^{-1} in the free ligand, is absent in the spectra of the gold complexes, indicating coordination through the nitrogen atom. This effect was less pronounced in the saccharin and phthalimide complexes, as the regions of interest contained a large number of strong overlapping bands.

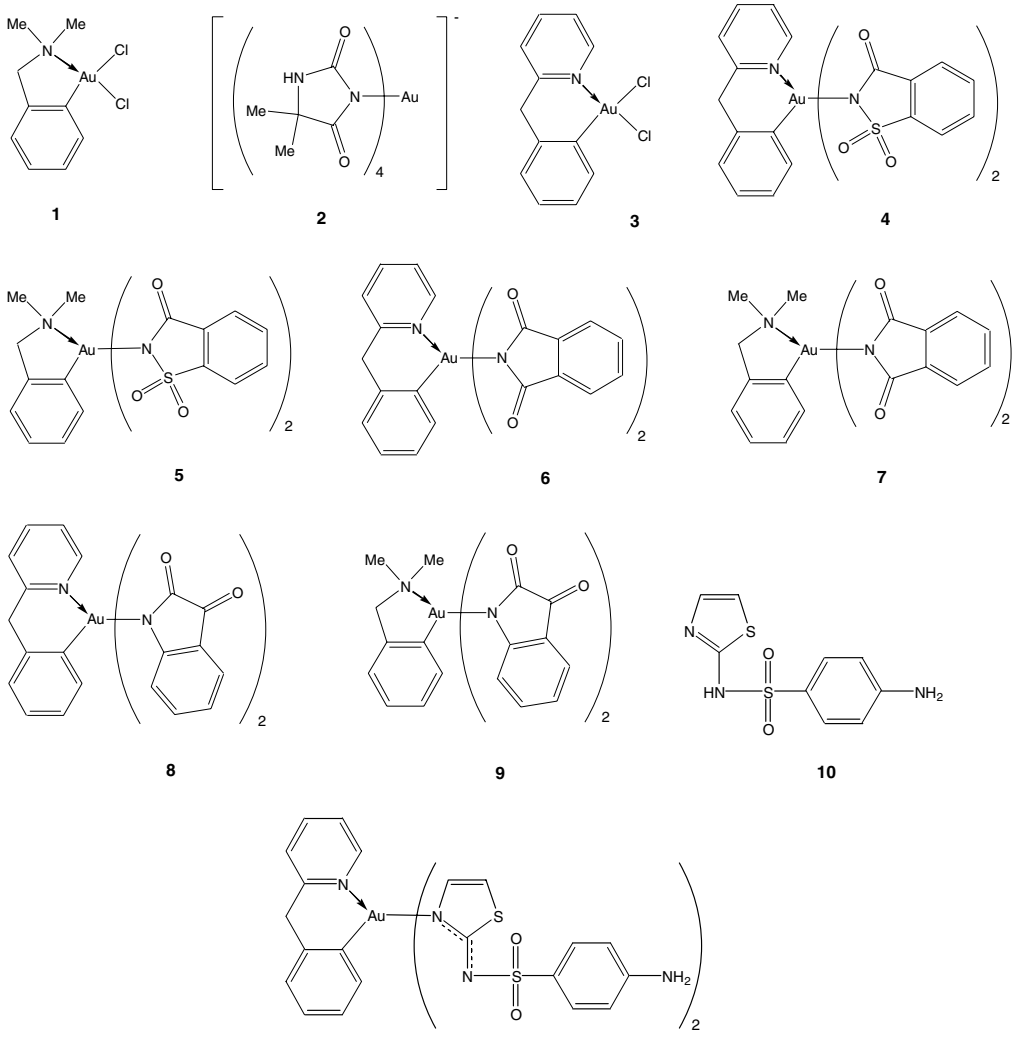
The imidate complexes have also been characterised by ESI MS. As the bis(imidate) complexes **4**–**9** are neutral, NaCl was typically added as an ionisation aid. However, along with the anticipated $[M+Na]^+$ ions, a common ion assigned as $[M\text{-imidate}+Cl+Na]^+$ was visible, even at low cone voltages. This ion could either arise from the mono(imidate) complex (as an impurity in the sample) or displacement of an imidate ligand by chloride during ESI MS analysis. The fragment ion $[M\text{-imidate}]^+$ was also often observed and, in some cases, $[M\text{-imidate} + OMe + Na]^+$. In order to ascertain if the chloride ion was displacing the imidate ligand a small amount of $NaBPh_4$ was added as a (chloride-free) sodium source to complex **6**. The ion $[M\text{-imidate}+Cl+Na]^+$ was no longer detected, suggesting that such species are only formed when chloride ions are present. Addition of small amounts of Et_4NX (X = Cl, Br) to **6** also produced additional ions corresponding to $[M\text{-imidate}+X+Et_4N]^+$, providing further evidence that halide ions can displace the imidate ligand. Table 1 details the range of ions observed when complex **6** was analysed in the presence of various ionisation aids. Addition of pyridine (py) exclusively produced the ion $[M-phth+py]^+$. Together, these ESI MS investigations appear to suggest that one of the monodentate imidate ligands is labile towards displacement by halide and other ligands. This is likely to be the imidate ligand *trans* to the high *trans*-influence aryl carbon; studies of the dissociation of acetate from (damp)Au(OAc)$_2$ have previously shown that one acetate, presumably the one *trans* to the aryl group, was also readily labilised [31]. Labilisation of one amidate donor ligand by halide was previously observed for certain auracyclic bis(amidate) species [7], but in general, auracyclic systems are much more robust towards MS-induced fragmentation, or reaction with halide ligands [6,7,9–11].

Table 1
Ions observed in positive-ion ESI mass spectra for the complex (2-bp)Au(phth)$_2$ (**6**) (=M) at a cone voltage of 20 V

Ionisation aid	Observed ions (*m*/*z*)
NaCl	680 (100%, $[M+Na]^+$), 565 (78%, $[M-phth+MeO+Na]^+$), 569 (35%, $[M-phth+Cl+Na]^+$), 1337 (28%, $[2M+Na]^+$)
Pyridine (py)	590 (100%, $[M-phth+py]^+$)
$NaBPh_4$	680 (100%, $[M+Na]^+$), 511 (60%, $[M-phth]^+$)
Et_4NCl	676 (100%, $[M-phth+Cl+Et_4N]^+$), 787 (85%, $[M+Et_4N]^+$), 511 (63%, $[M-phth]^+$)
Et_4NBr	787 (100%, $[M+Et_4N]^+$), 722 (67%, $[M-phth+Br+Et_4N]^+$)

At a cone voltage of 20 V, the compound (damp)Au(sacc)$_2$ (**4**) showed a strong peak in the ESI mass spectrum at *m*/*z* 465 (100% relative intensity) which was assigned as the cation $[(damp)_2Au]^+$. This ion was not observed at higher cone voltages (>40 V), and had considerably reduced intensity when NaCl was added to promote ionisation of the neutral **4**. The cation $[(damp)_2Au]^+$ was not detected in the ^1H NMR spectrum but is visible in the ESI spectrum due to it having a high ionisation efficiency, exacerbated by the low solubility of **4**. The analogous methoxy-substituted cation $[(MeO\text{-}damp)_2Au]^+$ has previously been observed in ESI MS analyses [32].

2.2. Synthesis and characterisation of a gold(III) sulfathiazole complex



The complex (2-bp)AuCl$_2$ (**3**) was also reacted with sulfathiazole [4-amino-*N*-(thiazol-2-yl)benzenesulfonamide, stzH (**10**)], giving the bis(sulfathiazole) complex **11** in excellent yield as a yellow solid. This complex was poorly soluble in all solvents with the exception of $(CH_3)_2SO$ and $HC(O)NMe_2$ (DMF), but was successfully characterised by NMR, ESI MS, IR, and elemental microanalysis. The mode of co-ordination to the gold is unclear, as sulfathiazole has three available nitrogen binding sites. Attempts at growing X-ray quality single crystals (by slow evaporation of a saturated DMF solution, or by vapour diffusion of methanol into a DMF solution) were unsuccessful thus the structure was unable to be assigned unambiguously. An X-ray crystal structure of the isoelectronic platinum(II) sulfathiazole complex *cis*-[Pt(stz)$_2$(PPh$_3$)$_2$] has confirmed bonding of the sulfathiazole anions through the thiazole nitrogen [33]. Structures of other transition metal [Co(II) [34] and Cu(II) [35]] sulfathiazole complexes indicate the ligand bonded to the metal centre via the thiazole nitrogen. However, an X-ray crystal structure has also been solved showing sulfathiazole bridging two independent Cu atoms through amide and thiazole nitrogens [36].

The ^{1}H NMR spectrum of complex **11** was very complicated, however the signal from the amino (NH_2) protons was visible, only very slightly shifted ($\delta = 5.69$) from free sulfathiazole ($\delta = 5.75$), indicating that bonding to the gold centre is not through the amino group. The IR spectrum of **11** provides evidence for coordination to the gold through the thiazole nitrogen. Sulfathiazole has a strong absorption at 3350 cm^{-1} due to NH_2 stretching and **11** also has absorptions in this region (3430 cm^{-1}) suggesting that the NH_2 group remains intact. Likewise, the absorptions due to SO_2 stretching and bending modes are not greatly shifted upon coordination (1136 and 1323 cm^{-1} in sulfathiazole compared with 1131 and 1323 cm^{-1} in **11**). However, the S–N stretching frequency of the thiazole ring has decreased from 1531 to 1459 cm^{-1} upon coordination, indicating that coordination probably occurs through $N_{thiazole}$. The values obtained are very comparable to the Pt(II) sulfathiazole complexes, again supporting binding through the thiazole nitrogen. This observation has been noted before in other metal-sulfathiazole compounds [37,38].

2.3. X-ray crystal structures of (2-bp)Au(sacc)$_2$ (4) and (2-bp)Au(phth)$_2$ (6)

Structure determinations of **4** and **6** were carried out in order to ascertain the geometry and orientation of the saccharinate and phthalimidate ligands around the gold centre. Views of the structures are shown in Figs. 2–5 along with the atom numbering schemes. A comparison of important bond lengths and angles is presented in Table 2, while comparisons of the geometric parameters of the coordinated ligands with free saccharin [39] and phthalimide [40] are given in Tables 3 and 4, respectively.

In both cases, the geometry around the gold atom is essentially square-planar. No atom deviates from the least-squares plane [defined by N(1), N(2), N(3), Au(1) and C(41) for the saccharin derivative **4**; N(1), N(2), N(3), Au(1) and C(12) for the phthalimide derivative **6**] by more than 0.040 or 0.0675 Å, respectively. The Au–$N_{imidate}$ bond lengths in the structures are very comparable; as expected, the Au–$N_{imidate}$ bond lengths *trans* to the benzylpyridyl

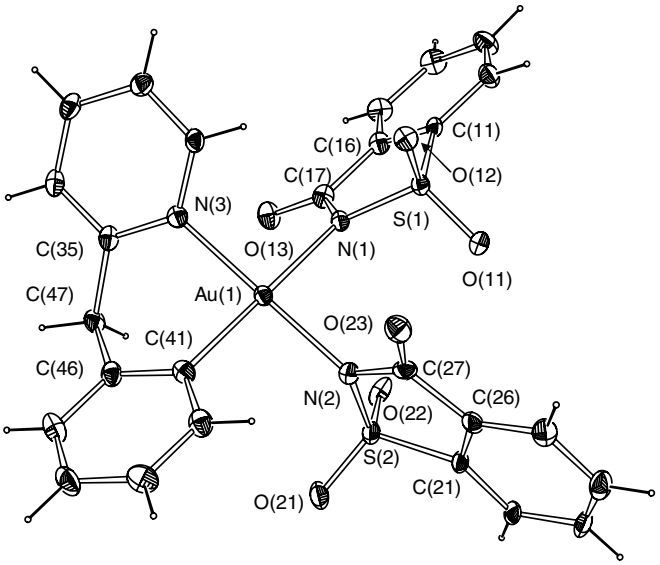


Fig. 2. Perspective view of the X-ray crystal structure of the complex (2-bp)Au(sacc)$_2$ (**4**) showing the atom labelling scheme. Thermal ellipsoids are shown at the 30% probability level. The solvent of crystallisation has been omitted for clarity.

carbon are longer than those *trans* to the benzylpyridine nitrogen due to the phenyl ligand having a higher *trans* influence than the pyridyl nitrogen ligand [41].

Both saccharinate and phthalimidate ligands are essentially planar. Tables 3 and 4 compare selected bond lengths of the free saccharin and phthalimide molecules with those of the coordinated ligands. Upon coordination to gold, the

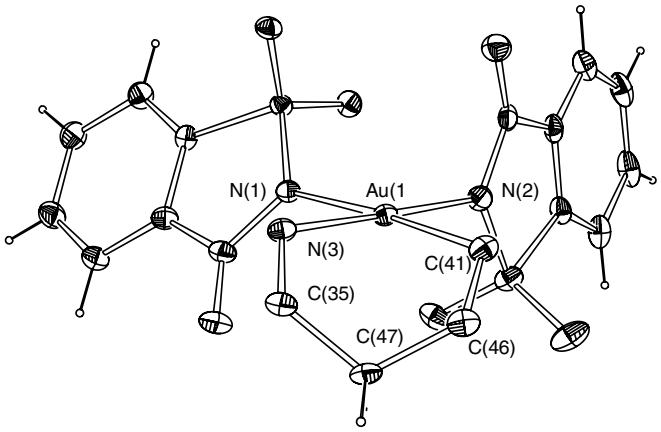

Fig. 4. Side view of the X-ray crystal structure of the complex (2-bp)Au(sacc)$_2$ (**4**) showing the orientation of the saccharinate ligands with respect to the gold coordination plane. Thermal ellipsoids are shown at the 30% probability level. Solvent of crystallisation and the atoms completing the benzyl and pyridyl rings have been omitted for clarity.

C=O and S=O bond lengths in the saccharin ligand significantly increase. This effect is less pronounced in the phthalimidate complex.

In both structures, the planes of the saccharin and the phthalimide ligands are orientated almost perpendicular to the coordination plane of the gold (Figs. 4 and 5), most probably to reduce steric interactions between the bulky imidate ligands. This particular ligand orientation has been observed previously in the similar square-planar platinum(II) isatin complex *cis*-[Pt(isat)$_2$(PPh$_3$)$_2$] [42]. In the structure of the saccharin complex **4**, the plane of the ligand coordinated through N(1) has a dihedral angle of 58.70° relative to the gold co-ordination plane, whereas the ligand coordinated through N(2) has an angle of 85.21°. The bis(phthalimide) structure is such that the plane of the phthalimide ligand co-ordinated through

N(2) is at an angle of 71.60°, while the N(3)-coordinated ligand is at an angle of 89.53°, with respect to the gold coordination plane.

Interestingly, the saccharin ligands are orientated so that the SO_2 groups are *trans* to each other, as seen in Fig. 4. Although no crystal structures of square-planar bis(saccharin) metal complexes could be found in the literature, the arrangement of the two SO_2 groups *trans* to each other appears to be a common trend. Examples of six co-ordinate octahedral structures where the SO_2 groups occupy opposite binding sites in a *trans* configuration are vast [43]. In square pyramidal complexes there are examples of both *cis* [44] and *trans* [45] arrangements of the saccharinate ligands. Interestingly, in the linear Hg(saccharinate)$_2$ molecule the saccharinate ligands are orientated so the SO_2 groups are positioned on the same side [46].

3. Biological activity

The anti-tumour and anti-microbial activities of the bis(imidate) complexes were determined and data are reported in Table 5. The benzylpyridyl complexes **6** and **8** have IC_{50} values that are very comparable to the auracyclic bis(amidate) products reported by us in a previous paper [12]. The other bis(imidate) complexes show low anti-tumour activity towards the P388 murine leukaemia cell line. There are two likely reasons for this. Firstly, the damp complexes **5**, **7** and **9** all have surprisingly low solubilities in common solvents when compared to other damp complexes reported in the literature, where there are many examples often showing excellent anti-tumour activity [1–5]. Secondly, the greater lability of monodentate ligands relative to the more stable and less labile metallacyclic products may have an influence on the biological activity. ESI MS results indicate that one imidate ligand is lost very easily, and such reactions might prevent the complex from reaching its biological target. Continuing the analogy with platinum(II) systems, it is known that replacement of monodentate ligands (such as chloride in cisplatin) with a bidentate chelating ligand (such as cyclobutane-1,1-dicarboxylate in carboplatin) slows the rate of hydrolysis and moderates the toxicity of the platinum-based drug [47].

4. Conclusions

New gold(III) bis(imidate) complexes (imidate = anion of saccharin, phthalimide, isatin) have successfully been synthesised and characterised. To the best of our knowledge, these are the first gold compounds of this type to

be reported. The X-ray crystal structures of (2-bp)Au(sacc)$_2$ (**4**) and (2-bp)Au(phth)$_2$ (**6**) have been solved and indicate that the imidate anions are co-ordinated to the gold centre through Au–N bonds. In both cases, the planar imidate ligands are orientated perpendicular to the gold co-ordination plane.

5. Experimental

5.1. General

General experimental techniques were as previously described [9]; routine ESI mass spectra were recorded on a VG Platform II instrument, using methanol as the mobile phase. Assignment of mass spectrometric isotope patterns was aided by the ISOTOPE program [48]. All NMR spectra were acquired in $CDCl_3$, with the exception of **11** [$(CD_3)_2SO$]. Integration of the ^{1}H NMR spectra indicated that **7** and **8** crystallised with approximately 1.0 and 0.12 mol of dichloromethane, respectively.

All reactions were carried out with no attempts to exclude light or air. The solvents used were LR grade. Trimethylamine (Eastman, 25% aqueous solution), sodium saccharinate (Aldrich), potassium phthalimidate (Merck), isatin (BDH) and sulfathiazole (BDH) were used as supplied. The cycloaurated gold(III) complexes (2-bp)$AuCl_2$ (**3**) [49] and (damp)$AuCl_2$ (**1**) [50,51] were prepared by modified literature methods.

5.2. Synthesis of (2-bp)Au(sacc)$_2$ (4)

The complex (2-bp)$AuCl_2$ (**3**) (100 mg, 0.23 mmol) and sodium saccharinate (190 mg, 93 mmol) were added to methanol (25 mL) and refluxed with stirring for 2 h. After cooling to room temperature, water (50 mL) was added, resulting in the rapid deposition of white microcrystals. These were filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) and dried under vacuum to give 158 mg (93%) of product. For microanalysis the crude product was recrystallised by vapour diffusion of diethyl ether into a dichloromethane solution of the product at room temperature to give white crystals. M.p. 131–134 °C. *Anal.* Calc. for $C_{26}H_{18}N_3O_6S_2Au$: C, 42.8; H, 2.5; N, 5.8. Found: C, 42.2; H, 2.8; N, 5.5%. IR: υ(C=O) 1686 cm^{-1} (s); $\upsilon(SO_2$, sym) 1291 cm^{-1} (s), $\upsilon(SO_2$, asym) 1155 cm^{-1} (br s). ESI MS: Cone voltage 20 V: NaCl added, *m*/*z* 605 (100%, [M-sac+Cl+Na]$^+$). ^{1}H NMR, δ 4.17 (d, 1H), 5.11 (d, 1H), 7.01–8.04 (m, 15H), 9.26 (d, 1H). ^{13}C–{^{1}H} NMR, δ 47.5 (CH_2), 120.5–157.3 (aryl C), 182.7, 184.5 (*C*=O).

5.3. Synthesis of (damp)Au(sacc)$_2$ (5)

The complex (damp)$AuCl_2$ (**1**) (100 mg, 0.25 mmol) and sodium saccharinate (206 mg, 1 mmol) were dissolved in refluxing methanol (30 mL) to give a colourless solution. During two hours of refluxing with stirring, white microcrystals were deposited. These were filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) then dried under vacuum to give 142 mg (84%) of product. M.p. 196–198 °C (decomp.). *Anal.* Calc. for $C_{23}H_{20}N_3O_6S_2Au$: C, 39.7; H, 2.9; N, 6.0. Found: C, 39.7; H, 3.1; N, 5.9%. IR: υ(C=O) 1695 cm^{-1}; $\upsilon(SO_2$, sym) 1317, 1291 cm^{-1}; $\upsilon(SO_2$, asym) 1159, 1167 cm^{-1}. ESMS: Cone voltage 20 V: NaCl added, *m*/*z* 571 (100%, [M-sac+Cl+Na]$^+$), 465 (30%, [(damp)$_2$Au]$^+$), 718 (10%, [M+Na]$^+$); pyridine added, *m*/*z* 592 (100%, [M-sac+py]$^+$). ^{1}H NMR, δ 3.43 (s, 3H), 3.49 (s, 3H), 4.20 (br d, 1H), 5.06 (br d, 1H), 7.09 (t, 1H), 7.13–7.24 (m, 4H), 7.68–7.71 (m, 6H), 8.0 (d, 1H). The compound was too insoluble for a satisfactory ^{13}C–{^{1}H} NMR spectrum.

5.4. Synthesis of (2-bp)Au(phth)$_2$ (6)

The complex (2-bp)$AuCl_2$ (**3**) (200 mg, 0.46 mmol) and potassium phthalimidate (340 mg, 1.8 mmol) were added to methanol (50 mL) and refluxed with stirring for 1 h, during which time a pale yellow solution formed. Water (30 mL) was added, resulting in the immediate deposition of white microcrystals. After cooling to room temperature, the suspension was filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) then dried under vacuum to give 254 mg (84%) of product. *Anal.* Calc. for $C_{28}H_{18}N_3O_4Au$: C, 51.2; H, 2.8; N, 6.4. Found: C, 50.4; H, 2.8; N, 6.4%. IR: υ(C=O) 1690 cm^{-1} (s) and 1664 cm^{-1} (s). ESI MS: Cone voltage 20 V, NaCl added: *m*/*z* 680 (100%, [M+Na]$^+$), 565 (78%, [M−phth+MeO+Na]$^+$), 569 (35%, [M−phth+Cl+Na]$^+$), 1337 (27%, [2M+Na]$^+$). ^{1}H NMR, δ 4.15 (br d, 1H), 5.15 (br d, 1H), 6.95 (t, 1H), 7.10 (t, 1H), 7.17 (d, 1H), 7.38 (m, 3H), 7.51 (m, 5H), 7.62 (m, 2H), 7.69 (d, 1H), 7.97 (t, 1H), 9.15 (d, 1H). ^{13}C–{^{1}H} NMR, δ 47.6 (CH_2), 122.1–157.8 (aryl *C*), 177.3, 172.8 (*C*=O).

5.5. Synthesis of (damp)Au(phth)$_2$ (7)

The complex (damp)$AuCl_2$ (**1**) (100 mg, 0.25 mmol) and potassium phthalimidate (186 mg, 1 mmol) were added to methanol (30 mL) and refluxed with stirring for 2 h, during which time white microcrystals were deposited. The mixture was cooled, filtered then washed with methanol (2 × 10 mL) and diethyl ether (10 mL). The crude product was recrystallised by vapour diffusion of pentane into a dichloromethane solution of the crude product. The colourless crystals were filtered, washed (petroleum spirits) then dried under vacuum to give 133 mg (86%) of product. M.p. 192 °C (decomp.). *Anal.* Calc. for $C_{25}H_{20}N_3O_4Au \cdot 1.06CH_2Cl_2$: C, 43.9; H, 3.1; N, 5.9. Found: C, 44.3; H, 3.1; N, 6.1%. IR: υ(C=O) 1686 cm^{-1} (s) and 1655 cm^{-1} (s). ESI MS: Cone voltage 20 V: *m*/*z* 646 (100%, [M+Na]$^+$), 477 (82%, [M−phth]$^+$), 1269 (27%, [2M+Na]$^+$). ^{1}H NMR, δ 3.32 (s, 6H), 4.53 (s, 2H), 5.30 (s, 2.11H, from CH_2Cl_2), 6.69 (d, 1H), 7.01 (t, 1H), 7.19, (d, 1H), 7.25 (t, 1H), 7.56 (m, 4H), 7.68 (m, 4H).

^{13}C–{^{1}H} NMR, δ 53.5 (CH_2Cl_2), 53.0 (CH_3), 75.5 (CH_2), 122.4–144.5 (aryl *C*), 172.7, 177.5 (*C*=O).

5.6. Synthesis of (2-bp)Au(isa)$_2$ (**8**)

The complex (2-bp)$AuCl_2$ (**3**) (200 mg, 0.46 mmol) and isatin (270 mg, 1.84 mmol) were added to refluxing methanol (40 mL). While stirring, trimethylamine (2 mL, excess) was added, resulting in the solution changing from deep red to bright orange. The solution was further refluxed with stirring for 20 min. Water (50 mL) was added, resulting in the deposition of orange microcrystals which were collected by filtration. The crude product was recrystallised from dichloromethane and pentane, filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) and dried under vacuum to give 266 mg (88%) of **8**. M.p. 225 °C (decomp.). *Anal.* Calc. for $C_{28}H_{18}N_3O_4Au \cdot 0.12CH_2Cl_2$: C, 50.6; H, 2.8; N, 6.3. Found: C, 49.7; H, 3.0; N, 6.3%. IR: υ(C=O) 1736 cm^{-1} (s), 1692 cm^{-1} (s) and 1605 cm^{-1} (s). ESI MS: Cone voltage 20 V: *m*/*z* 680 (100%, $[M+Na]^+$), 569 (67%, [M-isa + Cl + Na]), 565 (56%, $[M\text{-isa}+MeO+Na]^+$). ^{1}H NMR, δ 4.35 (br. s, 2H), 5.33 (s, 0.24H, from CH_2Cl_2), 6.87 (t, 1H), 6.95 (t, 1H), 7.01 (d, 1H), 7.18–7.51 (m, 11H), 7.81 (d, 1H), 8.06 (t, 1H). ^{13}C–{^{1}H} NMR, δ 47.7 (CH_2), 53.5 (CH_2Cl_2), 112.4–157.3 (aryl *C*), 162.9, 166.8, 185.1, 189.0 (*C*=O).

5.7. Synthesis of (damp)Au(isa)$_2$ (**9**)

The complex (damp)$AuCl_2$ (**1**) (100 mg, 0.25 mmol) and isatin (148 mg, 1 mmol) were stirred in refluxing methanol (30 mL). Trimethylamine (2 mL, excess) was added, resulting in the solution turning from orange to deep red, and the mixture was refluxed for a further 10 min during which time orange microcrystals were deposited. After cooling to room temperature, the product was filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) and dried under vacuum to give 117 mg (75%) of product. M.p. 210–212 °C (decomp.). *Anal.* Calc. for $C_{25}H_{20}N_3O_4Au$: C, 48.2; H, 3.2; N, 6.7. Found: C, 47.7; H, 3.4; N, 6.7%. IR: υ(C=O) 1730 cm^{-1} (s), 1701 cm^{-1} (m), 1682 cm^{-1} (s), 1603 cm^{-1} (s). ESI MS: Cone voltage 20 V: *m*/*z* 646 (100%, $[M+Na]^+$), 465 (55%, $[(damp)_2Au]^+$), 678 (35%, $[M+Na+MeOH]^+$), 1269 (27%, $[2M+Na]^+$). ^{1}H NMR, δ 3.24 (s, 3H), 3.48 (s, 3H), 4.17 (d, 1H), 4.89 (d, 1H), 6.85 (t, 1H), 6.92 (t, 1H), 7.06–7.39 (m, 13H), 7.43 (t, 1H). The compound was too insoluble for a satisfactory ^{13}C–{^{1}H} NMR spectrum.

5.8. Synthesis of (2-bp)Au(stz)$_2$ (**11**)

The complex (2-bp)$AuCl_2$ (**3**) (200 mg, 46 mmol) and sulfathiazole (**10**) (257 mg, 1 mmol) were stirred in refluxing methanol (25 mL). Trimethylamine (2 mL, excess) was added, resulting in the rapid deposition of pale yellow microcrystals. The mixture was refluxed with stirring for a further 2 h before being cooled in ice and filtered. The product was then washed with ice-cold methanol (2 × 10 mL) and diethyl ether (10 mL) before being dried under vacuum giving 324 mg (81%) of **11**. M.p. 194–196 °C (decomp.). *Anal.* Calc. for $C_{30}H_{26}N_7O_4S_4Au$: C, 41.2; H, 3.0; N, 11.2. Found: C, 40.8; H, 3.0; N, 10.9%. IR: υ(NH) 3430 cm^{-1} (w), υ(SN) 1459 cm^{-1} (vs), υ(SO_2, sym) 1323 cm^{-1} (s), υ(SO_2, asym) 1131 cm^{-1} (s). ESI MS: Cone voltage 20 V: NaCl added, *m*/*z* 677 (100%, $[M\text{-stz}+Cl+Na]^+$), 896 (72%, $[M+Na]^+$). ^{1}H NMR, δ 4.64 (br s, 2H), 5.69 (s, 4H, NH_2), 5.75 (br s, 2H), 6.51 (d, 2H), 6.56 (d, 1H), 6.66 (d, 1H), 6.77 (d, 1H), 6.90 (t, 1H), 7.13 (d, 1H), 7.21 (t, 1H), 7.31 (d, 1H), 7.36 (d, 1H), 7.52 (t, 1H), 8.02 (d, 1H), 8.22 (t, 1H), 8.55 (d, 1H). The compound was too insoluble for a satisfactory ^{13}C–{^{1}H} NMR spectrum.

6. X-ray crystallography

X-ray intensity data were collected on a Bruker CCD diffractometer using standard procedures and software. Empirical absorption corrections were applied (SADABS) [52]. Structures were solved by direct methods and developed and refined on F_o^2 using the SHELX programmes [53] operating under WinGX [54,55]. Hydrogen atoms were included in calculated positions. For both structures there was potential pseudo symmetry which could have led to disorder between the phenyl and pyridyl rings of the cyclometallated ligand. However, as found for other examples [12], the assignment of the metallated C and N atoms could be done unambiguously, showing there was no disorder. As discussed earlier [12]: (i) the N position was revealed with higher electron density than the C in the difference map; (ii) the U_{iso} values for the atoms were similar when refined as allocated, but were quite different if the assignment was reversed, and R_1 values increased in each case on changing the assignment; (iii) the differences in the Au–N distances to the sacc or phth ligands were consistent with the expected *trans* influences of C and N as assigned.

6.1. Structure of (2-bp)Au(sacc)$_2$ (**4**)

White prism crystals of **4** (M.p. 131–134 °C) were obtained from CH_2Cl_2/Et_2O.

Crystal data: $C_{26}H_{18}AuN_3O_6S_2 \cdot 0.5CH_2Cl_2 \cdot 0.5C_4H_{10}O$, $M = 809.04$, orthorhombic, space group *Pccn*, $a = 15.7051(2)$, $b = 18.7045(3)$, $c = 19.5764(1)$ Å, $V = 5750.7(1)$ Å^3, $T = 84(2)$ K, $Z = 8$, $D_{calc} = 1.869$ g cm^{-3}, μ(Mo Kα) = 5.405 mm^{-1}, $F(000) = 3168$; 32 131 reflections collected with $2° < \theta < 26°$, 5862 unique ($R_{int} = 0.0309$) used after correction for absorption ($T_{max,min} = 0.521$, 0.385). Crystal dimensions = 0.22 × 0.20 × 0.14 mm^3.

When the main molecule had been refined, there was significant residual electron density around special positions with 2-fold symmetry at $\frac{1}{4}, \frac{1}{4}, z$. These appeared to be a mixture of CH_2Cl_2 and Et_2O, but were very disordered and could not be sensibly modelled. This electron density was

excluded using the SQUEEZE procedure of PLATON [56] and refinement was continued against the modified *hkl* data with just the main molecule.

Refinement on F_o^2 converged at $R_1 = 0.0327$ [$I > 2\sigma(I)$] and $wR_2 = 0.0569$ (all data), GoF = 1.140. The structure of **4** is illustrated in Fig. 2, with selected bond parameters summarised in Tables 2 and 3.

6.2. Structure of (2-bp)Au(phth)$_2$ (6)

White plate-like crystals of **6** were obtained from CH_2Cl_2/pentane at 4 °C.

Crystal data: $C_{28}H_{18}AuN_3O_4 \cdot CH_2Cl_2$, $M = 742.35$, monoclinic, space group $P2_1/c$, $a = 12.1739(11)$, $b = 11.9101(9)$, $c = 21.597(2)$ Å, $\beta = 104.58(3)°$, $V = 3030.4(5)$ Å^3, $T = 84(2)$ K, $Z = 4$, $D_{calc} = 1.627$ g cm^{-3}, μ(Mo Kα) = 5.06 mm^{-1}, $F(000) = 1440$; 32 727 reflections collected with $2° < \theta < 26°$, 6333 unique ($R_{int} = 0.0779$) used after correction for absorption ($T_{max,min} = 0.687, 0.230$). Crystal dimensions $0.41 \times 0.20 \times 0.08$ mm^3.

Residual electron density once the main molecule had been refined appeared to come from CH_2Cl_2 in the lattice. Although these features were not very well defined, they could be reasonably successfully modelled as two half-solvent molecules over two sites.

Refinement on F_o^2 converged at $R_1 = 0.0717$ [$I > 2\sigma(I)$] and $wR_2 = 0.1942$ (all data), GoF = 1.219. The structure of **6** is illustrated in Fig. 3, with selected bond parameters summarised in Tables 2 and 4.

7. Biological assays

Details of the biological assays have been published previously [9].

Acknowledgements

We thank the University of Waikato (UW) for financial support of this work, including a scholarship to K.J.K. We also thank Dr. Tania Groutso (University of Auckland) and Dr. Jan Wikaira (University of Canterbury) for collection of the X-ray data sets, and Gill Ellis (University of Canterbury) for the biological assay data. Professor Alistair Wilkins is thanked for NMR expertise, and Pat Gread for technical support with mass spectrometry.

Appendix A. Supplementary data

CCDC 610499 and 610498 contain the supplementary crystallographic data for (**4**) and (**6**). These data can be obtained free of charge via www:http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; or e-mail deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2006.08.009.

Preface

It is a great pleasure for us to see the completion of this special issue of *Polyhedron* showcasing the current status of inorganic chemistry in Australia and New Zealand. The idea for this issue came from the recognition that the nature of inorganic chemistry research in these countries has undergone a major change over the last decade or so, for the obvious reason, of course, that this period has seen significant changes to the Australasian inorganic chemistry community. A rash of university appointments in the late 1950s and 1960s has now resulted in the partial or full retirement of a large number of academics over the past 10 or so years. In their place has been appointed a new generation of people with their own new research ideas and directions, and they are currently helping to shape the future of inorganic chemistry in Australasia. The calibre of the people they have replaced can be conveniently recognised with reference to previous winners of the Burrows Award, awarded jointly by the Royal Australian Chemistry Institute (RACI) and the New Zealand Institute of Chemistry (NZIC). The list of winners since the inception of the award in 1975 is as follows (in alphabetical order):

Martin A. Bennett
Alan M. Bond
Michael I. Bruce
David A. Buckingham
Ian G. Dance
Brian N. Figgis
Hans C. Freeman
Clifford J. Hawkins
David L. Kepert
Peter A. Lay
Leonard F. Lindoy
Raymond L. Martin
Keith S. Murray
Colin L. Raston
Richard Robson
Warren R. Roper
Alan M. Sargeson
Donald R. Stranks
Bruce O. West
Alan White

Many of these chemists are now either semi- or fully retired, while Don Stranks passed away at a tragically early age. The names on this impressive list are known worldwide, as indeed are those of a previous age in Australasian inorganic chemistry who acted as mentors to many of the above: Eustace Turner, George Burrows, Ronald Nyholm, Frank Dwyer and Arthur Birch. In addition, many recent retirees do not appear on this list, but their loss is felt no less keenly. It might therefore be thought that this enormous loss of experience would be difficult to overcome. However, as this special issue of *Polyhedron* shows, the currently active researchers of all ages are continuing to ensure that inorganic chemistry in Australia and New Zealand maintains an extremely healthy state. Indeed, the new generation of inorganic chemists are upholding the considerable reputation that Australasian inorganic chemistry has always enjoyed and are, like those before them, creating a legacy to be passed on to succeeding generations.

Abstract

The cations in the solid-state structures of *meso*-(ΛΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$, *meso*-(ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ · 2CH$_3$OH · 4H$_2$O and *meso*-(ΛΔ)-[{Ru(Me$_4$bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ · 26H$_2$O (bpm = 2,2′-bipyrimidine; bpy = 2,2′-bipyridine; Me$_2$bpy = 4,4′-dimethyl-2,2′-bipyridine; Me$_4$bpy = 4,4′,5,5′-tetramethyl-2,2′-bipyridine; tos$^-$ = toluene-4-sulfonate anion) exhibit similar features including comparable bond lengths and angles, and metal–metal separations of 5.56–5.59 Å. The counter-ions present in the structures reside in the clefts above and below the plane of the bridging ligand, but show considerable variation in location compared with their known occupancy in solution.

Keywords: Stereochemistry; Dinuclear; Ruthenium; Anion interactions

1. Introduction

A rigid dinuclear ligand-bridged complex containing a symmetrical di-bidentate bridging group {such as 2,2′-bipyrimidine (bpm); point group symmetry D_{2h}} and symmetrical bidentate terminal ligands {such as 2,2′-bipyridine (bpy); point group symmetry C_{2v}} may exist in three possible stereoisomeric forms – *meso* (ΔΛ ≡ ΛΔ; point group symmetry C_{2h}), and *racemic* (*rac*) (point group symmetry D_2), where the latter comprises an enantiomeric pair ΔΔ and ΛΛ (Fig. 1) [1]. While the identity and coordination environments of the metal centres are identical in the two diastereoisomeric forms, a significant difference may be discerned between them in terms of the nature of the "clefts" formed between the planes of the terminal bpy ligands. "Interior clefts" are formed between the bpy ligands immediately above and below the plane of the bridging ligand, which are approximately orthogonal in the *meso* form and parallel in the *rac* form. In addition, "exterior clefts" are evident between the planes of the terminal bpy ligands at either end of the complex, but these are identical for two diastereoisomeric forms.

The description is somewhat more complicated if the orientation of the axes of the two "bites" of the bridging ligands is angular or stepped-parallel (rather than linear, as in the case of bpm), or if the two metal centres are no longer equivalent because of different metal centres or different coordination environments, but the general principles remain pertinent [1].

We have developed a general cation-exchange chromatographic method for the separation of stereoisomeric mixtures of the genre of complexes, using SP Sephadex C-25 as the support [1,2]. The mechanism for the separation involves the differential association between the diastereoisomers of the same complex and eluent anions such as toluene-4-sulfonate {CH$_3$(C$_6$H$_4$)SO$_3^-$; tos$^-$}, and the nature of the interaction has been ascribed to a combination of

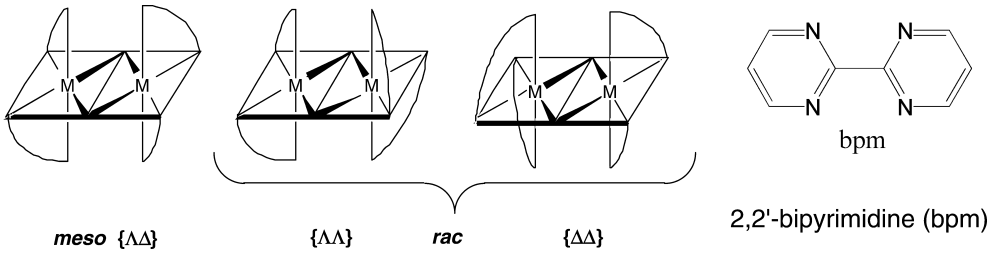

Fig. 1. Stereoisomeric forms of $[\{Ru(bpy)_2\}_2(\mu\text{-bpm})]^{4+}$.

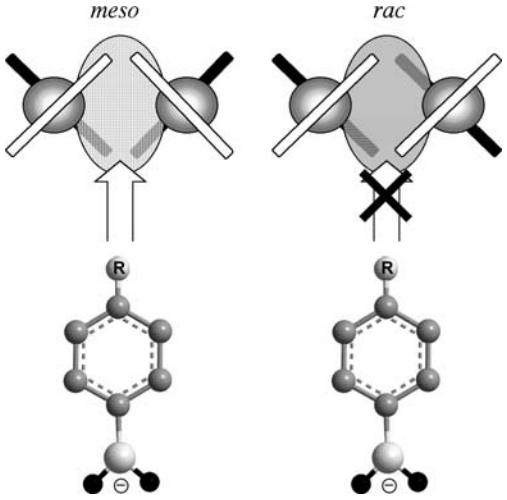
specific π-stacking and hydrophobic effects [3]. Detailed solution-phase NMR titration studies on the diastereoisomers of $[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpm})]^{4+}$ ($Me_2bpy = 4,4'$-dimethyl-2,2′-bipyridine) revealed that the hydrophobic aryl ring of the toluene-4-sulfonate counter-ion is positioned within the interior cleft, with the SO_3^- terminus orientated away from the bridging ligand [3,4]. Exterior associations also occur in the cavities created by the terminal ligands, but such interactions are identical for the diastereoisomers [3]. However, the associations are different for the interior clefts – arising from the access available as a consequence of the shape of the cavity (illustrated schematically in Fig. 2) – and this allows the observed chromatographic separation on the basis of the overall charge of the complex-anion entity.

A limited number of crystal structures of dinuclear polypyridylruthenium complexes have been reported to date. Three examples of dinuclear species containing symmetrical linear bridging ligands have been described [5–7] where crystallisation afforded the *meso* forms preferentially, and Ward and coworkers [8,9] described the isolation of the *rac* form of an alkoxide-bridged species. Keene et al. [4] reported the first example of a crystal structure in which the *meso* diastereoisomer of $[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpm})]^{4+}$ was isolated via chromatography prior to crystal growth.



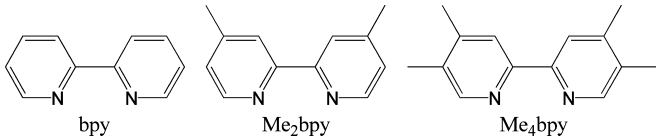


Fig. 2. A schematic representation of the discrimination by the diasatereoisomers of $[\{Ru(bpy)_2\}_2(\mu\text{-bpm})]^{4+}$ for the toluene-4-sulfonate anion (R = H), based on the dimension of the interior cavity above (and below) the bridging bpm ligand [3].

Scheme 1. 2,2′-bipyridine (bpy), 4,4′-dimethyl-2,2′-bipyridine (Me_2bpy) and 4,4′,5,5′-tetramethyl-2,2′-bipyridine (Me_4bpy) terminal ligands.

Structures of complexes involving angular [10,11] and stepped-parallel [12] bridging ligands have recently been reported, as well as examples of dinuclear species incorporating unsymmetrical bridges [13–15], including two containing the 3,5-bis(2-pyridyl)-1,2,4-triazolate (bpt^-) bridging ligand.

We were interested in whether the strong specific complex-anion interactions observed in solution were reflected in the solid-state structures. There is significant interest in the observation of stereochemically-directed anion interactions and the influence of such "supramolecular" effects on the intramolecular electron transfer properties of polymetallic assemblies [11]. The present study reports an examination of the interactions between toluene-4-sulfonate (tos^-) and hexafluorophosphate (PF_6^-) anions in the solid-state structures of the *meso* diastereoisomers of $[\{Ru(pp)_2\}_2(\mu\text{-bpm})]^{4+}$ {pp = bpy, Me_2bpy, and 4,4′,5,5′-tetramethyl-2,2′-bipyridine (Me_4bpy); Scheme 1}. In the case of *meso*-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpm})]^{4+}$, the results are contrasted with those obtained from previous solution-phase NMR titration studies [3,4].

2. Experimental

2.1. Materials

DOWEX® 1 × 8, 50–100 mesh anion exchange resin (Aldrich) and QAE Sephadex A-25 anion exchanger (Amersham Pharmacia Biotech), 2,2,2-trifluoroethanol (TFE; Aldrich) and laboratory reagent solvents were used as received.

2.2. Synthesis and diastereoisomer separation

The synthesis, separation and structural characterisation of the diastereoisomeric forms of $[\{Ru(pp)_2\}_2(\mu\text{-bpm})](PF_6)_4$ (pp = bpy, Me_2bpy, Me_4bpy) were performed as

described previously [4,16,17]. In all cases, the identity of the first band eluted in the diastereoisomer separation as the *meso* form (consistent with a previous literature report) [4] was confirmed by determination of the crystal structures reported herein.

2.3. X-ray crystallography

Crystals of *meso*-[{Ru(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$ were grown by slow evaporation of a 70:30 TFE/H$_2$O solution of the complex under ambient conditions in the absence of light. The rod-shaped dichroic crystals were deep green/red: a single crystal of dimensions $0.2 \times 0.2 \times 0.15$ mm was coated with paratone-N and mounted onto a glass fibre.

Single crystals of the related complex *meso*-[{Ru(Me$_2$-bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ were obtained by preliminary anion exchange of the PF_6^- to the toluene-4-sulfonate salt using QAE Sephadex A-25 anion-exchanger in the tos^- form. An aqueous solution of the Cl^- form of *meso*-[{Ru(Me$_2$-bpy)$_2$}$_2$(μ-bpm)]$^{4+}$ (ca. 10 mg in 2 cm^3) – obtained by stirring a suspension of the hexafluorophosphate salt in water/methanol with DOWEX® anion-exchange resin – was subsequently loaded onto the Sephadex column. The narrow green band of the dinuclear complex was eluted with water and the eluate permitted to evaporate under ambient conditions the absence of light for several weeks to yield dichroic dark green/red plate-like crystals. A single crystal of dimensions $0.15 \times 0.15 \times 0.15$ mm was quickly coated with polyacrylamide (to avoid rapid methanol loss) and mounted onto a glass fibre for X-ray structural determination.

Single crystals of the complex *meso*-[{Ru(Me$_4$bpy)$_2$}$_2$-(μ-bpm)](tos)$_4$ were obtained in the same manner. A single crystal of dimensions $0.20 \times 0.20 \times 0.15$ mm was sealed in a capillary to avoid solvent loss during the structural determination.

For each structure, a hemisphere of data was collected at room temperature on a Bruker SMART CCD diffractometer using the omega scan mode with total reflections and unique data listed below. The data sets were corrected for absorption using the program SADABS [18]. Structural solution and refinement was carried out using SHELXL-97 [19] and SHELXS97 [19] utilising the graphical interface WINGX [20] (bpy and Me$_2$bpy complexes) or X-Seed [21] (Me$_4$bpy complex). All non-hydrogen atoms were located and were refined with anisotropic thermal parameters. Due to a low data:parameters ratio, the structure of *meso*-[{Ru(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$ was refined with the C atoms isotropic. This resulted in an increase in R and wR_2, and a data:parameter ratio of 8.14. Hydrogen atoms were placed in calculated positions (riding model) and were not refined, except for the hydrogen atoms on the lattice water molecules which were not located. For the Me$_4$bpy complex, the sulfonate oxygen atoms on the anions were rotationally disordered and these were successfully modelled over two sites, although the oxygen atoms maintained large thermal envelopes, as did the oxygen atoms of the lattice water molecules. Such disorder was less significant for the Me$_2$bpy analogue. Crystal data and a summary of data collection appear below; the full details are provided Table S1 (Supplementary Material).

2.4. [{Ru(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$

Crystal data for $C_{48}H_{38}N_{12}F_{24}P_4Ru_2$, $M = 1564.9$, $0.2 \times 0.2 \times 0.15$ mm, monoclinic, space group C_2/c (no. 15), $a = 19.367(5)$ Å, $b = 17.679(4)$ Å, $c = 18.321(5)$ Å, $\beta = 111.228(5)°$, $V = 5847(3)$ Å^3, $Z = 4$, $D_c = 1.778$ g/cm^3, $F_{000} = 3096$, Mo Kα radiation, $\lambda = 0.71069$ Å, $T = 293$ K, $2\theta_{max} = 53.0°$, 6054 reflections collected, 6054 unique ($R_{int} = 0.1967$). Final Goodness-of-fit = 0.869, $R_1 = 0.0681$, $wR_2 = 0.2073$, R indices based on 2355 reflections with $I > 2\sigma(I)$ (refinement on F^2), 289 parameters, $\mu = 0.750$ mm^{-1}.

2.5. [{Ru(Me$_2$bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ · 2CH$_3$OH · 4H$_2$O

Crystal data for $C_{86}H_{98}N_{12}O_{18}Ru_2S_4$, $M = 1918.14$, $0.15 \times 0.15 \times 0.15$ mm, orthorhombic, space group *Pcab* (no. 61), $a = 13.681(5)$ Å, $b = 19.968(5)$ Å, $c = 33.090(5)$ Å, $V = 9040(4)$ Å^3, $Z = 4$, $D_c = 1.409$ g/cm^3, $F_{000} = 3911.4$, Mo Kα radiation, $\lambda = 0.71069$ Å, $T = 293$ K, $2\theta_{max} = 50.6°$, 8194 reflections collected, 8194 unique ($R_{int} = 0.1305$). Final Goodness-of-fit = 1.129, $R_1 = 0.0653$, $wR_2 = 0.1987$, R indices based on 4899 reflections with $I > 2\sigma(I)$ (refinement on F^2), 558 parameters, $\mu = 0.499$ mm^{-1}.

2.5.1. [{Ru(Me$_4$bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ · 26H$_2$O

Crystal data for $C_{92}H_{150}N_{12}O_{38}Ru_2S_4$, $M = 2362.62$, $0.20 \times 0.20 \times 0.15$ mm, triclinic, space group $P\bar{1}$ (no. 2), $a = 13.0310(13)$ Å, $b = 14.6320(15)$ Å, $c = 15.1356(15)$ Å, $\alpha = 104.240(2)°$, $\beta = 96.112(2)°$, $\gamma = 98.970(2)°$, $V = 2731.2(5)$ Å^3, $Z = 1$, $D_c = 1.436$ g/cm^3, $F_{000} = 1242$, Mo Kα radiation, $\lambda = 0.71073$ Å, $T = 296(2)$ K, $2\theta_{max} = 46.6°$, 12 832 reflections collected, 7855 unique ($R_{int} = 0.0568$). Final Goodness-of-fit = 1.046, $R_1 = 0.0578$, $wR_2 = 0.1442$, R indices based on 5951 reflections with $I > 2\sigma(I)$ (refinement on F^2), 733 parameters, 72 restraints. Lp and absorption corrections applied, $\mu = 0.440$ mm^{-1}.

3. Results and discussion

Meso-(ΛΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$ crystallised in the monoclinic space group C_2/c, *meso*-(ΛΔ)-[{Ru(Me$_2$-bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ · 2CH$_3$OH · 4H$_2$O in the orthorhombic space group *Pcab*, and *meso*-(ΛΔ)-[{Ru(Me$_4$bpy)$_2$}$_2$-(μ-bpm)](tos)$_4$ · 26H$_2$O in the triclinic space group $P\bar{1}$. The asymmetric units of all three complexes contain one half of the dinuclear cation, which resides on a crystallographic axis, along with two anions and associated lattice water molecules for the tosylate complexes.

The ORTEP structures of the dinuclear cations *meso*-(ΛΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpm)]$^{4+}$, *meso*-(ΛΔ)-[{Ru-(Me$_2$-bpy)$_2$}$_2$(μ-bpm)]$^{4+}$ and *meso*-(ΛΔ)-[{Ru(Me$_4$bpy)$_2$}$_2$-(μ-bpm)]$^{4+}$ are shown in Figs. 3(a), 4(a) and 5(a), respectively, and the full atom labelling is provided in Figures S1–S3 (Supplementary Material). The cations in the three structures *meso*-(ΛΔ)-[{Ru(pp)$_2$}$_2$(μ-bpm)]$^{4+}$ (pp = bpy, Me$_2$bpy, Me$_4$bpy) exhibit comparable Ru–N distances and N–Ru–N angles which are consistent with those reported previously for *meso*-(ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$-(μ-bpm)](Cl)$_4$ [4] and related polypyridyl complexes of ruthenium [5,6,8,9,13,14]. In all structures, the Ru centres reside in slightly distorted octahedral environments. The "bite angles" of the terminal chelating ligands vary between ca 78° and 79°, which is typical for the polypyridyl ligands bpy and Me$_2$bpy [13,22–24], and the metal centres

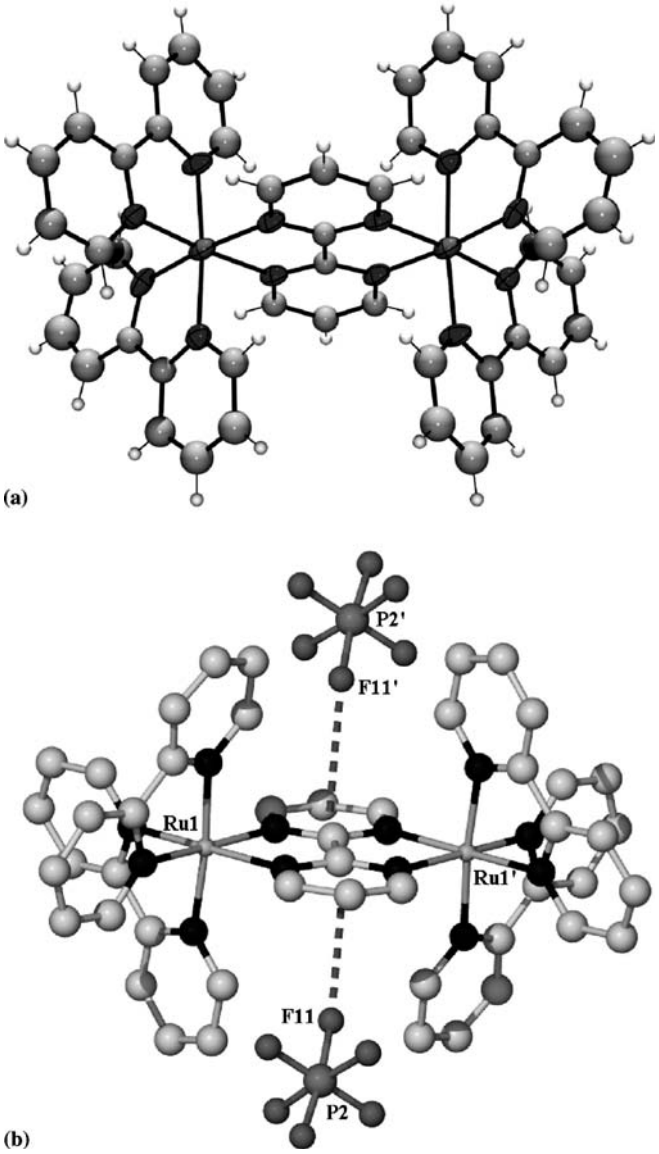

Fig. 3. (a) ORTEP view (30% probability) of the cation in *meso*-(ΛΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$. (b) A perspective view showing the position of the PF$_6^-$ anions (two shown) relative to the clefts between the ligands.

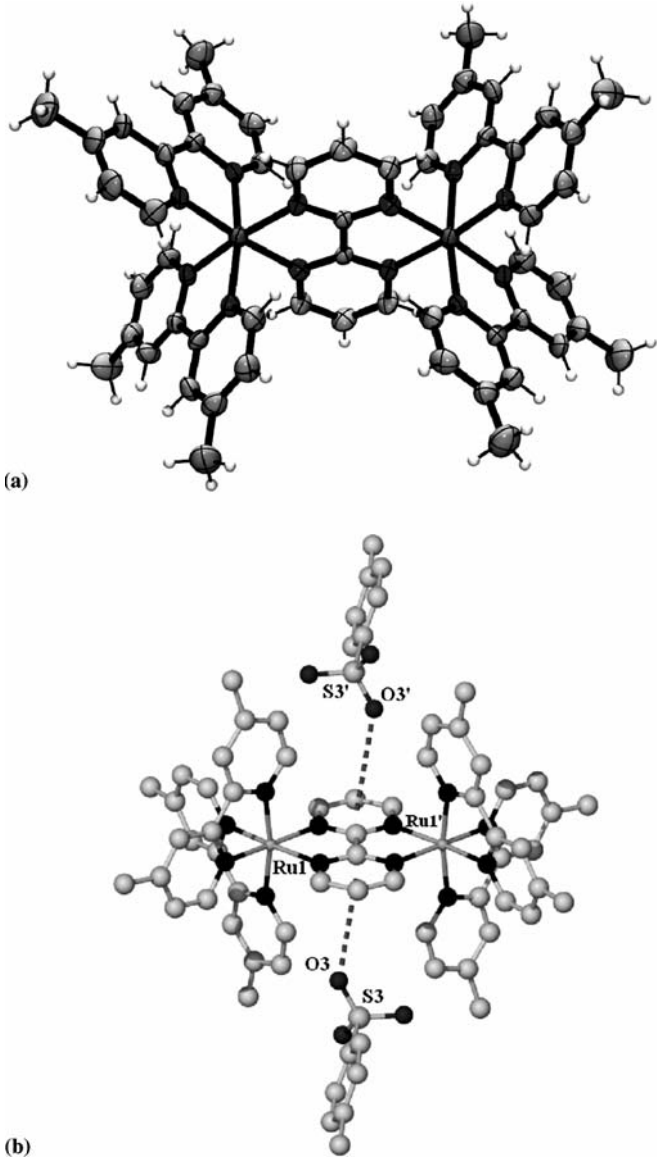

Fig. 4. (a) ORTEP view (50% probability) of the cation in *meso*-(ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$(μ-bpm)](tos)$_4$. (b) A perspective view showing the position of the tos$^-$ anions (two shown) relative to the clefts between the ligands.

are coordinated at each bidentate coordination site of bpm with average N–Ru–N angles of 79.9(3)°, 80.2(3)° and 79.6(3)° , for the complexes incorporating the bpy, Me$_2$bpy and Me$_4$bpy terminal ligands, respectively. The bridging bpm ligand maintains planarity in all three structures, with Ru···Ru separations of 5.565(5), 5.564(5) and 5.586(5) Å, for the bpy, Me$_2$bpy and Me$_4$bpy complexes.

As shown in Fig. 3(b), two PF$_6^-$ counter-ions are located close to the clefts between the bpy ligands above and below the bridging bpm ligand in *meso*-(ΛΔ)-[{Ru-(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$. The distance of 3.050 Å between F(11) and the centroid of bpm confirms that the PF$_6^-$ anions are involved in van der Waals interactions with the complex cation. The crystal packing diagram reveals that the additional PF$_6^-$ counter-ions reside in layers

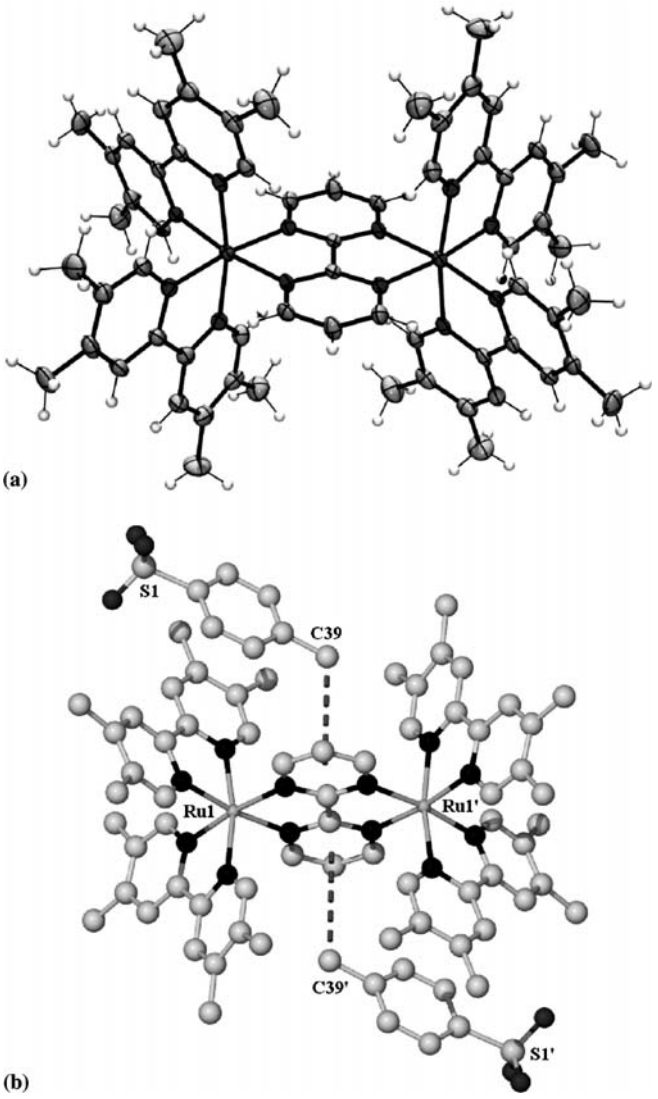

Fig. 5. (a) ORTEP view (50% probability) of the cation in *meso*-(ΛΔ)-[{Ru(Me$_4$bpy)$_2$}$_2$(μ-bpm)](tos)$_4$. (b) A perspective view showing the position of the tos$^-$ anions (two shown) relative to the clefts between the ligands.

between the predominantly organic layers of the complex. The presence of these distinct layers may account for the brittle nature of the crystals. Similar observations were noted previously in the crystal structure determination of *meso*-(ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$(μ-bpm)](Cl)$_4$ [4], and may account for the limited number of crystal structures for complexes of this genre in the literature.

The positions of two toluene-4-sulfonate counter-ions relative to the cations in *meso*-(ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$-(μ-bpm)](tos)$_4$ and [{Ru(Me$_4$bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ are shown in Figs. 4(b) and 5(b), respectively. For the Me$_2$bpy complex, two tos$^-$ anions are located symmetrically either side of the plane of the bridging ligand, with the hydrophilic SO_3^- termini of the anions oriented inwards towards the relatively open orthogonal shaped cavities of the cation. The O(3)···centroid distance of 3.568 Å is consistent with van der Waals interactions between the counter-ions and the complex cation. The additional tos$^-$ counter-ions do not engage in any intermolecular interactions with the cation.

In the Me$_4$bpy complex the two tos$^-$ anions are also located symmetrically either side of the bridging ligand plane; however, the CH_3 termini of the counter-ions are directed inwards towards the ruthenium centres. The C(39)···centroid and H(39B)···centroid distances are 3.988 and 3.095 Å, respectively. The aromatic moiety of the counter-ion engages in π-stacking interactions with the bpy ligands which are oriented along the long axis of bpm. The SO_3^- termini are directed towards the periphery of the dinuclear cation and experience extensive H-bonding interactions with water molecules which are located in layers between the predominantly organic layers of the complex. While H-bonding interactions between the tos$^-$ counter-ions and water molecules are also evident in the structure involving the Me$_2$bpy terminal ligands, the water molecules do not form discernable layers and are evenly distributed about periphery of the complex.

The orientation adopted by the toluene-4-sulfonate counter-ions in the solid-state structure of the Me$_4$bpy complex is analogous to that determined by solution-phase NMR titration studies for complexes of this type, where the counter-ion is positioned with the hydrophobic aryl ring in the cavity and the SO_3^- terminus orientated away from the bridge [3,4]. This contrasts to the situation for the Me$_2$bpy complex where the orientation of the tos$^-$ anions in the solid state is different to that in the solution phase.

4. Conclusions

The cations in the solid-state structures of *meso*-(ΛΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$, *meso*-(ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$-(μ-bpm)](tos)$_4$ and *meso*-(ΛΔ)-[{Ru(Me$_4$bpy)$_2$}$_2$(μ-bpm)]-(tos)$_4$ exhibit similar features including comparable bond lengths and angles, and metal-metal separations of 5.56–5.59 Å. The counter-ions present in the structures reside within the clefts formed between the planes of the terminal polypyridyl ligands in each case. For the methylated-bpy derivatives, the tos$^-$ counter-ions adopt different orientations, contrary to their location in solution-phase deduced from NMR titration studies [3,4]. Accordingly, despite strong specific anion associations, these examples illustrate that the packing forces in the solid state are significant, and provide a salutary warning on the comparison of interactions in the two phases.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-288380 for [{Ru- (bpy)$_2$}$_2$(μ-bpm)](PF$_6$)$_4$, CCDC-288379 for [{Ru(Me$_2$-bpy)$_2$}$_2$(μ-bpm)](tos)$_4$ · 2CH$_3$OH.4H$_2$O, and CCDC-288378

for $[\{Ru(Me_4bpy)_2\}_2(\mu\text{-bpm})](tos)_4 \cdot 26H_2O$. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 336 033, email: deposit@ccdc.cam.ac.uk.

Abstract

The synthesis and crystal structures of five new analogues of the supramolecular copper(II) organophosphonate $[Cu^{II}(phen)_2Cl][(C_6H_5PO(OH)_2)((OH)O_2PC_6H_5)]$ (**1**) are presented. The structures contain substituted phenylphosphonic acids, and are of the general formula $[Cu^{II}(phen)_2Cl][(XPO(OH)_2)((OH)O_2PX)]\cdot Z$, where $X = o\text{-}CH_3(C_6H_5)$ (**2**); $X = p\text{-}CH_3(C_6H_5)$, $Z = H_2O\cdot 2CH_3CH_2OH$ (**4**); $X = o\text{-}NO_2(C_6H_5)$, $m\text{-}NO_2(C_6H_5)$ (**5**); $X = m\text{-}NO_2(C_6H_5)$ (**6**); $X = C_{10}H_7$ (**7**).

Single-crystal analysis revealed structures of similar molecular unit to **1**, with the exception of **4** which contained lattice solvent. The general assembly strategy of 'ribbons' of $[Cu^{II}(phen)_2Cl]^+$ cations interleaved with dimeric H-bonded anionic acid 'chains' seen in **1** was maintained in some form for **2**, **4**, **5** and **6**. Perturbations to packing were found largely to be related to the position of the substituent (rather than the chemical nature), where the *para* substituent was the most disruptive. This forced the adoption of alternate π–π bonding motifs between the anion and cation, which was especially apparent in the grid-like assembly of the naphthyl group in **7**. A sixth product **3** containing $m\text{-}CH_3(C_6H_5)$ was atypical to the series, having phosphonic acid bound to the metal centre and no halide.

Keywords: Copper(II) complexes; Arylphosphonic acids; Ring substituents; Supramolecular networks; H-bonding

1. Introduction

One of the lesser studied functionalities in crystal engineering is the phosphonate group ($R–P(O)(OH)_2$). Like sulphonic acids, phosphonic acids are strong acids, with the first $pK_a \approx 1–2$, and so they remain ionised over a wide pH range in aqueous media. Each phosphonic acid group can provide one-, two- or three-oxygen atoms to coordinate metal ions, and thus the principal uses of these acids include chelation, e.g. to remove heavy metals from bleaching solutions in the paper, pulp and textile industry, and also scale inhibition [1]. Another fertile area of research has been the development of metal phosphonates, a class of organic–inorganic hybrid materials with a wide range of applications encompassing ion-exchange, intercalation, catalysis, light-harvesting, molecular magnetic devices, and the ability to form thin films [2]. Phosphonic acids also form extremely strong hydrogen bonds. However, the rapid growth of metal phosphonates has overshadowed the potential of phosphonic acids to form supramolecular arrays. Although this ability has been well-studied in nucleic acids and other biological molecules, crystal engineers have not invoked the use of phosphonate groups for the design of organic and organic–inorganic solids, in comparison to its carbon counterpart, the carboxylate group.

Structural studies on phosphonate groups, with the aim of designing organic solids, have only recently been reported in the literature. These studies have examined only a small selection of acids, principally phenylphosphonic acid $[C_6H_5PO(OH)_2]$ [3–5], and those acids that have multiple functionalities and may form zwitterions, e.g. *N*-nitrilotri(methylphosphonic) acid, NTMP [6–8]. Some work has also been carried out on diphosphonic

acids [9]. Deprotonation of organophosphonic acids, by amines (e.g. aniline, phenanthrolines, etc.) [3–7] or metal(II) salts (e.g. Mn, Co, Cu, Ni, Zn, Cd and mixtures of these ions) [3,4,8], appears to trigger a self-assembly process and lead to the formation of very strong and predictable aggregates.

We have recently reported the synthesis of a range of copper(II)amine arylphosphonates with supramolecular architecture. These materials have the general formula: $[Cu^{II}(phen)_2X][((OH)_2OPC_6H_5)((OH)O_2P_6H_5)]$ (where X = I, Br, Cl (**1**), NCS), and contain a 5-coordinate copper(II) cation, counterbalanced by a hydrogen-bonded phenylphosphonic acid dimer anion [4]. The complexes are associated through hydrogen bonding interactions between the phosphonic acids, and π–π interactions between phen–phen, phen–acid, and acid–acid aromatic rings, resulting in 'ribbons' of copper cations interleaved between 'sheets' of phosphonate anions. The supramolecular motifs observed in these systems are shown in Chart 1: (a) symmetrical O···H···O hydrogen bonds, with the classic R2,2(8) ring motif – analogous to that found in carboxylic and sulphonic acids [10–12]; and (b) hydrogen-bonded dimers – a less common motif. The H-bonds in the dimers are exceptionally short, perfectly linear, and strong (typical O···O distances of 2.44–2.46 Å). Indeed, these bonds have stabilisation energies ten times those of normally occurring hydrogen bonds.

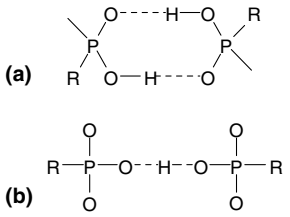

Chart 1. Supramolecular synthons of phenylphosphonic acid observed in the halobis(phen)copper(II) phenylphosphonate series [4]: (a) paired, regular H-bonds (R2,2(8) ring) and (b) hydrogen-bonded dimer.

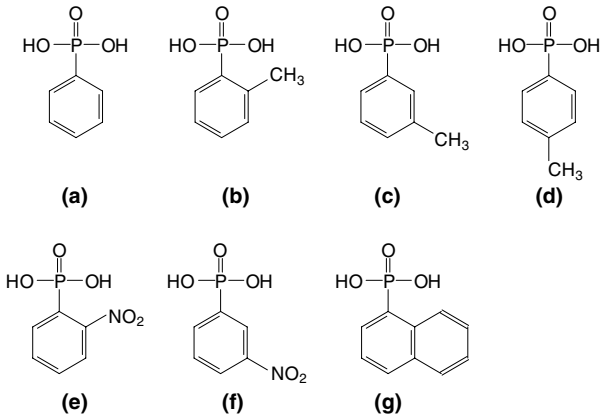

Chart 2. The acids used in this study: (a) phenylphosphonic; (b) *o*-tolylphosphonic; (c) *m*-tolylphosphonic; (d) *p*-tolylphosphonic; (e) *o*-nitrophenylphosphonic; *m*-nitrophenylphosphonic; and (f) 1-naphthylphosphonic acid.

The aims of the present study were to synthesise analogues of $[Cu^{II}(phen)_2Cl][((OH)_2OPC_6H_5)((OH)O_2P_6H_5)]$ (**1**), containing a range of substituted phenylphosphonic acids, and to explore the hydrogen-bonding and packing characteristics of the new structures. Whilst some work has been done on the effect of substituents on the pK_a values of arylphosphonic acids [13], to our knowledge, this has not been considered in the context of crystal engineering. The introduction of substituents on the acid ring will have several impacts: (a) on the ability of the phosphonic acid to form hydrogen bonds, due to changes in electron density; (b) on the π–π interactions observed between acids, and those between acid and phen; and (c) on spatial requirements for the substituent for crystal packing. Hence, a global impact on structure may be expected.

The seven acids used in this preliminary study (Chart 2a–g) were chosen because they represent a range of characteristics. The possible impacts of the substituents on intermolecular interactions (based on the criteria above) are summarised in Table 1. Substituents on an aromatic

Table 1
Characteristics of substituent groups on the aromatic ring

Substituent	P(O)(OH)$_2$ (**1**)	*o*-CH$_3$ (**2**)	*m*-CH$_3$ (**3**)	*p*-CH$_3$ (**4**)	*o*-NO$_2$ (**5**)	*m*-NO$_2$ (**6**)	1-Naphthyl (**7**)

Potential strength	strong	weak	weak	weak	strong	strong	
Steric influence							
Position		*ortho*	*meta*	*para*	*ortho*	*meta*	
Likely influence		low	medium	high	low	medium	
Additional π–π interactions							yes

ring affect the electron density of the ring, either via withdrawal or donation of electrons. This can occur through induction (movement of σ electrons) and/or resonance (movement of π electrons). The influence of the substituent on the electronic distribution of the ring may extend to the phosphonate group, which in turn may affect its hydrogen bonding character. The closer the substituent is to the phosphonate, the stronger the influence may be (i.e. *ortho* > *meta* > *para*). Whether this serves to create a stronger or weaker H-bond can only be postulated at this point. However, if the substituent is to have any significant influence, its activating/deactivating capacity must be fairly strong compared to the phosphonate group. Thus, the nitro group might be expected to have the greatest impact in the current series. The π–π interactions may also be perturbed via the steric influence of both the bulk and position of the substituent. A *para* substituent is protruded, an *ortho* substituent is more discreet, and the *meta* position intermediate. Finally, one must also consider the potential for the substituent itself to participate in intermolecular interactions: the nitro group oxygen atoms can participate in H bonding; the methyl group C–H can also undergo very weak H bonding; and the extended aromatics can undergo additional OFF (Offset-Face-to-Face) and EF (Edge-to-Face) π–π dispersion interactions [32].

2. Experimental

2.1. Materials

Copper(I) chloride was prepared according to published procedures [14]. *m*-Bromotoluene was prepared by the bromination of *p*-toluidine followed by deamination [15]. All starting materials were obtained from Aldrich and were used without any further purification (~98–99% pure).

2.2. Preparation of substituted phenylphosphonic acids

2.2.1. *o*-Tolylphosphonic acid [*o*-CH_3–$C_6H_4PO(OH)_2$]

ortho-Tolylphosphonic acid was prepared via the diethyl phosphonate, using the procedure of Mateeva et al. [16]. The ester was then hydrolysed according to Grabiak [17]. Yield: 0.44 g (40%); white solid; m.p. 138–141 °C.

2.2.2. *m*-Tolylphosphonic acid [*m*-CH_3–$C_6H_4PO(OH)_2$]

Under an atmosphere of dry argon, a solution of *m*-bromotoluene (5.13 g, 0.03 mol) in ether (20 mL) was stirred at −78 °C. To this, butyl lithium (1.6 M in hexanes, 18.7 mL, 0.03 mol) was added dropwise, and the resulting pale yellow solution stirred for 30 min., then allowed to warm to room temperature. This solution of *m*-tolyl lithium was added dropwise to a cooled solution (−78 °C) of diethyl chlorophosphate (10.35 g, 0.06 mol) in ether (40 mL). After stirring at −78 °C for 2 h the solution was warmed to room temperature and left to stir overnight. The turbid mixture was washed with dilute hydrochloric acid and the organic layer separated. This was washed with water, dried with $MgSO_4$, and the solvent removed to give a pale yellow oil which was distilled in vacuo to give diethyl *m*-tolylphosphonate as a colourless oil (b.p. 87–90 °C/0.1 mm Hg). The diethyl ester was suspended in concentrated hydrochloric acid (15 mL) and refluxed overnight. The pale yellow solution was evaporated to dryness and the solid recrystallised from hot concentrated hydrochloric acid. The white precipitate obtained was filtered, washed with concentrated hydrochloric acid and air dried. Finally, drying over P_2O_5 gave *m*-tolylphosphonic acid. Yield 3.5 g (68%); white solid; m.p. 122–124 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 7.2–7.4, 7.5–7.7 (m, 4H, aromatic); δ 4.07 (m, 4H, $POCH_2C$); δ 2.35 (s, 3H, CH_3); δ 1.28 (t, $J_{HH} = 7.1$ Hz, 6H, $POCCH_3$). ^{31}P NMR (121 MHz, d^6-DMSO): δ 14.32 (s).

2.2.3. *p*-Tolylphosphonic acid [*p*-CH_3–$C_6H_4PO(OH)_2$]

The preparation initially required the synthesis of the appropriate diazonium salt, using the method of Broxton et al. [18]. The acid was then prepared via the Diazo reaction [19], using the modification suggested by Ashby and Kosolapoff [20]. Yield = 8.6 g (41%); white solid; m.p. 184–186 °C.

2.2.4. *o*-/*m*-Nitrophosphonic acid [*o*-NO_2–$C_6H_4PO(OH)_2$]/[*m*-NO_2–$C_6H_4PO(OH)_2$] (15:85%)

The mixed isomer acid was prepared by direct nitration of phenylphosphonic acid [21]. Yield: 61.4 g (96%); pale-yellow flakes; m.p. 138–140 °C. ^{31}P NMR (121 MHz, NaOD/D_2O): δ 8.37 (s), δ 4.69 (s) (85% *m*-NO_2:15% *o*-NO_2).

2.2.5. *m*-Nitrophosphonic acid [*m*-NO_2–$C_6H_4PO(OH)_2$]

The pure acid was prepared via the Diazo reaction [19]. Yield: 4.9 g (16%); white solid; m.p. 150–154 °C.

2.2.6. 1-Naphthylphosphonic acid [$C_{10}H_7PO(OH)_2$]

1-Naphthyl phosphonic acid was prepared via the diethyl phosphonate [17], followed by hydrolysis. Yield: 0.95 g (32%); white solid; m.p. 204–206 °C.

2.3. Preparation of supramolecular copper complexes

2.3.1. [$Cu^{II}(phen)_2Cl$][($C_6H_5PO(OH)_2$)-(($OH)O_2PC_6H_5$)] (**1**)

Compounds **1**–**7** were prepared according to a published method [4]. The general procedure is as follows: to a suspension of copper(I) chloride (0.19 g, 0.00095 mol, 20 mL ethanol) was added an ethanolic solution of 1,10-phenanthroline (0.73 g, 0.0040 mol, 20 mL). The mixture was stirred for 2 h at room temperature, and then phenylphosphonic acid solution (0.64 g, 0.0040 mol, 20 mL EtOH) was added to the red-brown suspension, and stirred for 1 h. The resulting olive-green precipitate was filtered, then recrystallised from milli-Q water (40 mL), giving aqua needle-like

crystals of **1**. These were filtered off, washed with cold milli-Q water and dried over P_2O_5. Yield: 0.186 g (13%).

*2.3.2. ($[Cu^{II}(phen)_2Cl][(o\text{-}CH_3)C_6H_4PO(OH)_2)$-$((OH)O_2PC_6H_4(o\text{-}CH_3))]$ (**2**)*

Similar procedure to **1**, using *o*-tolylphosphonic acid. The resulting aqua-green powdery precipitate was filtered, and recrystallised from ethanol (99%) to give a grass-green solution. On standing three days, the solution produced aqua block-like crystals, which were washed in cold ethanol and dried over P_2O_5. Yield: 0.1 g (20%).

*2.3.3. $[Cu^{II}(phen)((m\text{-}CH_3)C_6H_4PO_2(OH))$-$((OH)O_2PC_6H_4(m\text{-}CH_3))]$ (**3**)*

Similar procedure to **1**, using *m*-tolylphosphonic acid. Fine aqua-green solid was produced from the aqua-blue solution on standing for three days. This solid was collected by filtration and recrystallised from ethanol/water. After two weeks, small, blue, slab-like crystals formed, which were washed in cold ethanol and dried over P_2O_5. Yield: 0.1 g (20%).

*2.3.4. $([Cu^{II}(phen)_2Cl][(p\text{-}CH_3)C_6H_4PO(OH)_2)$-$((OH)O_2PC_6H_4(p\text{-}CH_3))] \cdot H_2O \cdot 2CH_3CH_2OH$ (**4**)*

Similar procedure to **1** except that *p*-tolylphosphonic acid was added and stirred for $3\frac{1}{2}$ h. The resultant solution was rotary evaporated to dryness, the remaining oily-solid was then dissolved in 40 mL of hot 1:2 ether:ethanol (95%) solution. On standing undisturbed at room temperature for one month, the solution produced several large green diamond-shaped crystals of $([Cu^{II}(phen)_2Cl][(p\text{-}CH_3)C_6H_4PO(OH)_2)((OH)O_2PC_6H_4(p\text{-}CH_3))] \cdot H_2O \cdot 2CH_3CH_2OH$ (**4**). The crystals were carefully removed, washed in water and ethanol, and due to their instability towards solvent loss, stored in a sample vial containing a 5 mL volume of filtered reaction solution. Yield: 0.024 g (2%). Elemental *Anal.* Calc.: C, 55.3; H, 5.2; N, 6.1; P, 6.8. Found: C, 56.2; H, 4.2; N, 6.8; P, 7.4%.

*2.3.5. $([Cu^{II}(phen)_2Cl][(m\text{-}NO_2)C_6H_4PO(OH)_2)$-$((OH)O_2PC_6H_4(o\text{-}NO_2))]$ (**5**)*

Similar procedure to **1**, using *o*-/*m*-nitrophosphonic acid. A pale aqua powder was filtered from the pale green solution, the volume was then reduced by 25 mL on a rotary evaporator. On standing undisturbed for one week, the solution yielded mid-green square crystals of **5**. Yield: 9.3%.

*2.3.6. $([Cu^{II}(phen)_2Cl][(m\text{-}NO_2)C_6H_4PO(OH)_2)$-$((OH)O_2PC_6H_4(m\text{-}NO_2))]$ (**6**)*

Similar procedure to **1**, using pure *m*-nitrophenylphosphonic acid. Following filtration of the grey precipitate, the volume of the pale green-aqua solution was reduced by 20 mL on a rotary evaporator. On standing, green rhomboid crystals of **6** were produced within a few days. Yield: 0.009 g (1.3%).

*2.3.7. $[Cu^{II}(phen)_2Cl][(H_7C_{10}PO(OH)_2)$-$((OH)O_2PC_{10}H_7)]$ (**7**)*

Similar procedure to **5**, using 1-naphthylphosphonic acid. The resultant aqua-powder was filtered off, and also the first crop of crystalline material. The filtrate was then reheated to boiling. Green rectangular shard crystals of **7** were formed after 3 days. Yield: 0.051 g (7.4%).

2.4. Spectroscopic measurements

All solids were analysed by FTIR, which provided an excellent initial qualitative means to identify the phen ligand (which was nearly always present due to its strong co-ordinating nature) and most importantly, the likely presence of the intercalated acid. Spectra could generally be used to indicate the similarity, or otherwise, of two products where there was a difference in crystal habit or colour. It was also discovered, notably with the nitro series, that subtle differences in similar spectra could indicate polymorphism. FTIR spectra were obtained on a Perkin–Elmer 1725X spectrometer, using KBr disks, with a spectral resolution of 4 cm^{-1}. ^1H, ^{13}C and ^{31}P NMR spectra were collected on a Bruker Avance DRX 300 MHz instrument. Chemical shifts are given in ppm relative to TMS or phosphoric acid.

2.5. Crystal structure determination

In the present study, the structures of products **2**–**7** were determined and analysed for the first time by single crystal X-ray diffraction. Crystal data was collected at 293 K for structures **1** and **6**, and 130 K for structures **2**–**5** and **7**, using graphite monochromated Mo Kα radiation for compounds **1**–**5**, **7** and Cu Kα radiation for **6** (see Table 2). Data for **2** and **6** were collected and integrated using an Enraf–Nonius CAD4 diffractometer [22], whilst for compounds **1**, **3**–**5** and **7** the data were collected and integrated using a Bruker SMART CCD area detector system [23]. In all cases, structures were solved by direct methods, using SHELXS-97 [24] (**2** and **6**) or SHELXTL [25] (**1**, **3**–**5** and **7**), and refined using SHELXL-97 [24] (**2** and **6**) or SHELXTL [25] (**1**, **3**–**5** and **7**). A mixed strategy was used for the refinement of hydrogen atoms. Hydrogen atoms attached to carbon were placed in calculated positions with a C–H distance of 0.93 Å, whilst hydrogen atoms attached to oxygen were located from difference Fourier maps, and refined without constraint. Molecular graphics were performed using ZORTEP [26], SHELXTL [25] and MERCURY [27] programs.

3. Results and discussion

3.1. Synthesis

The reaction of copper(I) chloride with 1,10-phenanthroline and the substituted phenylphosphonic acids shown in Chart 2, led to the corresponding supramolecular

copper(II) structures **2**, **4**–**7**. The parent compound, $[Cu^{II}(phen)_2Cl][(C_6H_5PO(O\ H)_2)((OH)O_2PC_6H_5)]$ (**1**) (Fig. 1a), was prepared according to Clarke et al. [4]. The *o*-tolyl product, $([Cu^{II}(phen)_2Cl][(o\text{-}CH_3)C_6H_4PO(OH)_2)((OH)O_2PC_6H_4(o\text{-}CH_3))]$ (**2**), was synthesised with relative ease, forming blue-green block-like crystals within a few days. Blue slab crystals of the *m*-tolyl product, $[Cu^{II}(phen)(m\text{-}CH_3)C_6H_4PO_2(OH))((m\text{-}CH_3)C_6H_4PO_3)]$ (**3**), were also readily synthesised, but their formula and structure (Fig. 1b) were the least typical of the series. The first attempt at producing a *p*-tolylphosphonic acid derivative yielded a crystalline product with no intercalated acid, as well as the desired product **4**. The former were poorly diffracting but are believed to have the formula $[Cu^{II}(phen)_2Cl][OH]\cdot 6H_2O\cdot CH_3CH_2OCH_2CH_3$, and a structure and unit-cell size similar to the reported structures: $[Cu^{II}(phen)_2Cl][OH]\cdot 2CH_3OH\cdot 6H_2O$ [29]; $[Cu^{II}(phen)_2Cl][OH]\cdot 6H_2O$ [30]; and $[Cu^{II}(phen)_2Cl][Cl]\cdot 2CH_3OH\cdot 4.5H_2O$ [31]. Product **4** was difficult to isolate and analyse (unstable in air), and gave an early indication of the disruptive influence of a *para*-oriented substituent. X-ray analysis revealed a solvated product $[Cu^{II}(phen)_2Cl][(p\text{-}CH_3)C_6H_4PO_2(OH)][(p\text{-}CH_3)C_6H_4PO(OH)_2]\cdot 2C_2H_5OH\cdot H_2O$.

Two attempts were made to produce *m*-nitrophenylphosphonic acid. The first approach [21] yielded a mixed isomer acid, determined to be 85% *m*-NO_2 plus 15% *o*-NO_2 via ^{31}P NMR. This approach led to product **5** which contained a mixed *o*-/*m*-NO_2 acid dimer, $([Cu^{II}(phen)_2Cl][(o\text{-}NO_2)C_6H_4PO(OH)_2)((OH)O_2PC_6H_4(m\text{-}NO_2))]$. The second synthesis [19] produced a pure *m*-nitro acid, which led to product **6**. The major solid product obtained from this synthesis was a grey powder, which on recrystallisation from ethanol yielded green needles (**6a**) (10% yield). Meanwhile, the pale aqua mother liquor was concentrated and also produced crystalline material. The latter were of two types, needles (**6a***) and block-like crystals. This difference in crystal habit was further supported by differences in FTIR spectra. The needle specimens of **6a** and **6a*** gave similar spectra (in terms of spectrum shape and peak positions) and were thus considered the same product; while the spectrum of the block-like crystals exhibited subtle, but key, differences (Table 3), suggesting polymorphism. However, despite the quantity and apparent quality of the needle crystals of **6a**/**6a***, they did not diffract sufficiently to obtain a crystal structure. Fortunately, the block crystals did diffract, and were subsequently identified as $([Cu^{II}(phen)_2Cl][(m\text{-}NO_2)C_6H_4PO(OH)_2)((OH)O_2PC_6H_4$-

(m-NO_2))] (**6**). Thus, at this stage, the presence of polymorphism cannot be proven, but the differences in crystal habit and FTIR provide persuasive evidence for its existence. While **6** and **6a** were both recrystallised from ethanol, **6** was formed from a concentrated reaction mixture – i.e. a more dynamic system which is more conducive to the formation of polymorphs. The naphthyl product, [Cu^{II}-$(phen)_2Cl$][$(H_7C_{10}PO(OH)_2)((OH)O_2PC_{10}H_7)$] (**7**) (Fig. 1c), formed as rectangular shard crystals from the mother liquor on standing for 10 days.

3.2. Structure

3.2.1. Structure of *1*

The crystal structure of **1** was previously solved by Clarke et al. [4]. The molecular unit consists of a 5-coordinate $[Cu(phen)_2Cl]^+$ cation, counterbalanced by a phenylphosphonic "dimer" anion (Fig. 1a). The Cu(II) ion exhibits distorted trigonal bipyramidal stereochemistry, in which the equatorial Cu–Cl bond lies along a 2-fold crystallographic axis. Each phen ligand occupies an axial (N2) and equatorial (N1) position. This 'symmetrical' complex is assembled into 'ribbons' via a continuous OFF interaction between the outer surfaces of the phen rings (Fig. 2a). This is a common motif for phenanthroline complexes, which has been explored and quantified by Dance [32]. Looking closely, the phen overlap involves the perfectly parallel overlap of the middle rings (C4–C5–C6–C7–C11–C12) giving the ribbon a circular cross-section when viewed down the c-axis (Fig. 3a). Adjacent ribbons are perfectly aligned.

The acid dimer consists of a hydroxyl proton (H2a) shared equally (centrosymmetric) between the O2 and O2′ atoms, resulting in an ionic, strong, perfectly linear hydrogen-bond (d(O···H) = 1.21(7) Å, O2–H2a–O2 = 180.00°), with H2a lying on a centre of inversion. Adjacent acid dimers are connected through pairs of regular strength H-bonds (d(H3a···O1) = 1.784 Å, O3–H3a–O1 = 169.22°), see Fig. 4a and Table 4. The alternation of these motifs forms H-bonded acid 'chains', which further associate via EF interactions of the phenyl rings (E = H14, H15), to form acid 'sheets' (Fig. 5a). Further EF interaction is seen between the acid phenyl and phen rings, as shown in Fig. 6a. Overall, the packing is that of anionic acid sheets interleaved by cationic phen ribbons (Fig. 7a), with the assembly assisted by electrostatic attraction and dispersion forces.

3.2.2. Substituted acid products

3.2.2.1. Overview. Apart from the m-tolyl derivative **3** (Fig. 1b), the structures of compounds **2**, **4**–**7** exhibit an analogous molecular unit to the parent **1**. With regard to packing, changes were subtle to significant. While the phosphonate oxygen and HO– groups continued to participate in the formation of acid chains, a range of variation was observed. Likewise, there was much diversity in the π–π motifs of the substituted acid phenyl rings. The phen OFF "ribbon" being maintained in all but products **3** and **7**.

Product **2**, the o-tolyl derivative, is the most similar analogue to **1**, both in terms of the molecular unit and the packing strategy. The nitro-substituted products **5** and **6** have similar molecular units to **1** and **2**, but contain a phosphonic acid and phosphonate anion linked by a strong H-bond, i.e. the proton is not shared equally. The effect of the naphthyl group on packing is quite profound. The usual alternation of two-dimensional regions of acid and phen are not seen in **7**. Rather, there is a more intimate and intricate interlocking of the two components, through an extensive range of OFF and EF interactions. The assembly is best described as a grid of intersecting planes (Fig. 8a and b). The packing of the p-tolyl derivative **4** is very different to both **1** and **2** since it contains cavities constructed from acid and solvent, filled by metal–phen ribbons. However, by far the most puzzling structure is that of the m-tolyl derivative **3**, which contains only one phen molecule,

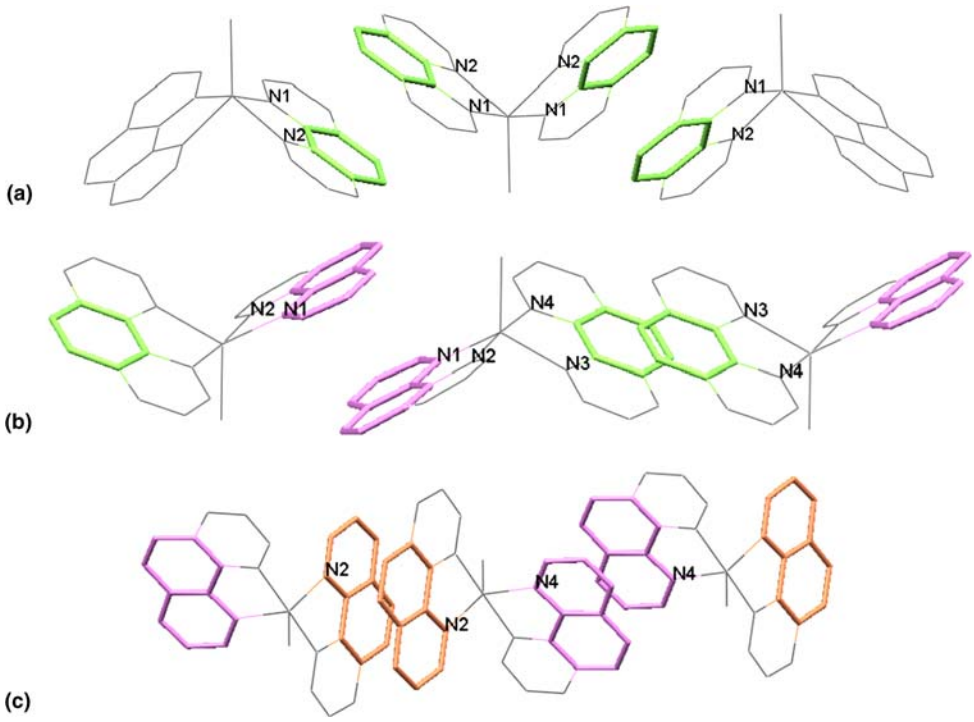

Fig. 2. (a) The 'outer OFF phen ribbon' of **1**, showing the middle ring overlap, in comparison to the phen ribbons of (b) **5**, showing the alternation of middle- and 2-ring OFF overlaps, and (c) **4**, showing the alternation of two different two ring OFF overlaps.

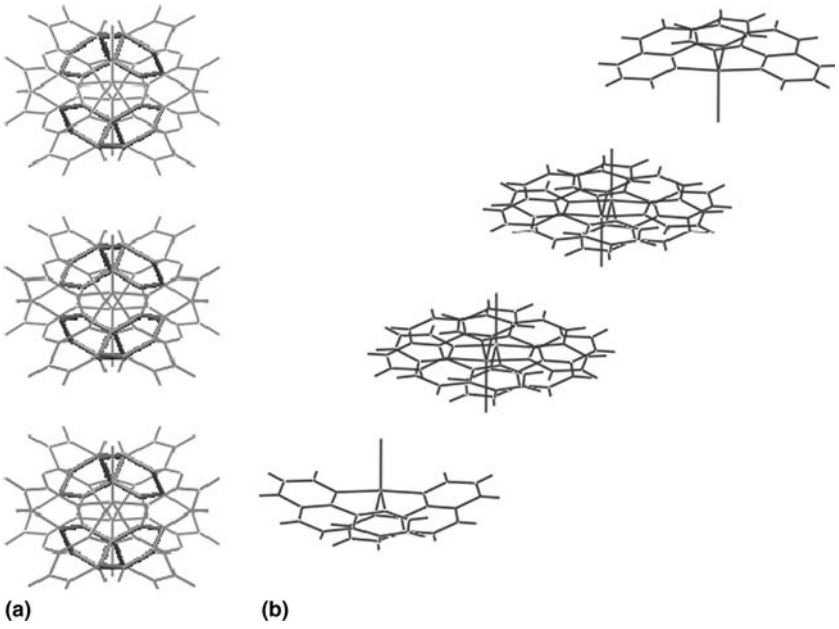

Fig. 3. (a) In **1**, the perfect alignment of phen ribbons via alignment of Cu–Cl bonds leads to a circular type ribbon cross-section. (b) The offset arrangement of phen ribbons in **5** and **6** leads to elliptical cross-sections, which are stacked diagonally.

no halogen, and two 'bound' acids per molecular unit. Product **3** serves as a reminder that there can be quite surprising outcomes in crystal design, and that we still have a way to go until crystal engineering becomes an 'exact' science. However, we must realise that in such multi-component synthetic systems a multitude of chemical equilibria exist, so that temperature, solvent, structure of nucleation interfaces, and concentration factors often lead to the kinetically controlled product being isolated as it precipitates from solution. Thus, in most instances it is the least soluble species that is isolated, and this may be the case in **3**.

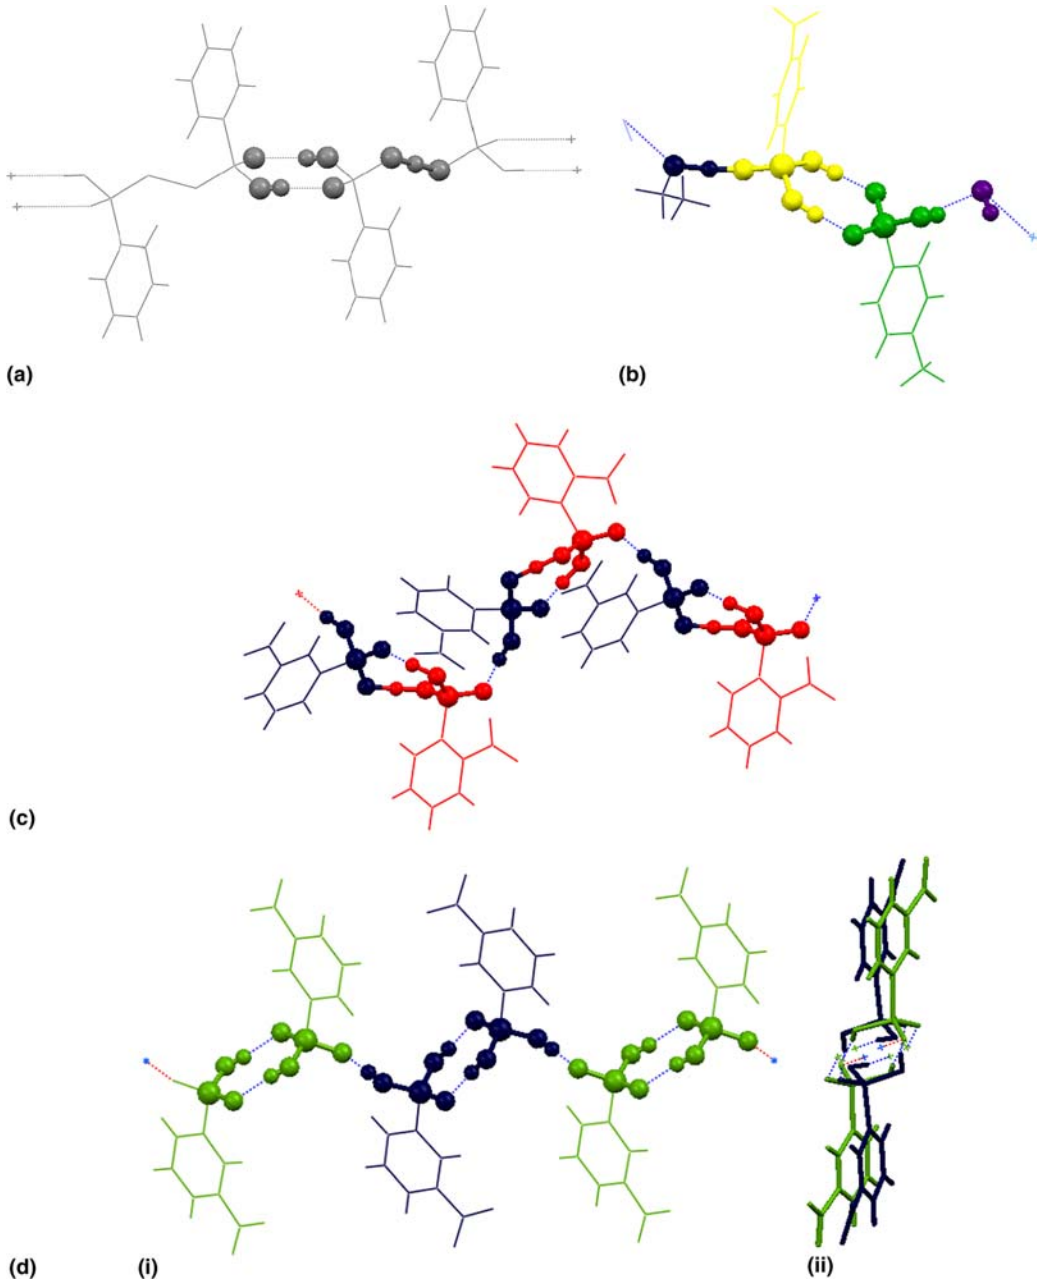

Fig. 4. (a) Acid chain of **1** showing alternation of strong H-bonded dimer and pair of symmetrical H-bonds. (b) The pair of non-symmetrical H-bonds between the anionic (green) and neutral (yellow) *p*-tolyl acids of **4** – anion donates both protons and paired acids are connected by a H-bonded bridging system with water (purple) and ethanol (blue). (c) The alternation of the doubly H-bonded acid dimer with a single H-bond in **5** forms a 'zigzag' acid chain – *meta* rings (blue) occupy the centre of the chain. (d) (i) Pairs of anionic (green) acids are connected to pairs of neutral (blue) acids in the acid chain of **6**, (ii) rings are angled gently in plane, with the anionic ring at a sharper angle. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

3.2.2.2. The copper cation. In the case of the $[Cu^{II}(phen)_2Cl]^+$ cation component, it was generally observed that the equatorial N–Cu–N angles became more regular (approaching 120°), improving the trigonal bipyramidal stereochemistry of **1**. The 2-fold axis of symmetry along the Cu–Cl bond was maintained in only two cases **2** and **7** – the other cations exhibited non-equivalent phen rings. Other angles (i.e. the phen bite angles) were found to vary insignificantly. Changes were also observed in the OFF interactions of the phen rings, which was unexpected. All interactions involved the parallel overlap of planes, but the two-ring overlaps were generally stronger interactions, with closer centroid-to-plane distances, than those of the single-ring overlaps.

The $[Cu^{II}(phen)_2Cl]^+$ cation in **2** has similar geometry to **1**. The cation is still symmetric about the Cu–Cl bond, and the phen rings also participate in a middle-ring OFF interaction to yield a fairly circular ribbon cross-section. In

contrast, the cations of **4**, **5** and **6** are asymmetric. In each case, the non-equivalent phen rings form two outer OFF interactions, which alternate to give the ribbon. The overlaps are quite different (Fig. 2). In **4**, two different, two-ring OFF interactions are observed: middle and N2 (*d*(plane to centroid) = 3.41(6) Å), and middle and N3 (*d*(plane to centroid) = 3.38(0) Å). In **5** and **6** a two-ring overlap alternates with a significantly weaker one-ring overlap. The former involves the middle and N2 rings (*d*(plane to centroid) = 3.41(2) Å) in **5**, and the middle and N1 rings in **6** (*d*(plane to centroid) = 3.574 Å). Whilst the latter involves the N3 rings in **5** (*d*(plane to centroid) = 3.56(9) Å), and the middle rings in **6** (*d*(plane to centroid) = 3.68(3) Å). The alternation of stronger and weaker interactions in **5** and **6** have broadened the ribbon, forming an elliptical rather than circular cross-section. These ribbons are not aligned along the Cu–Cl axis as in **1**, rather they are offset, giving a diagonal type stacking (Fig. 3b). The naphthyl product **7** contains two different $[Cu^{II}(phen)_2Cl]^+$ cations: symmetric (G), and asymmetric (B), with Cu2 (B) lying on a 2-fold axis at 0, *y*, 1/4. Neither cation undergoes continuous outer face OFF interactions to form ribbons – the first clue to the dominance of the acid in the structure – or more specifically, the important role of the naphthyl group in building π–π connections that replace the usual phen ribbon motif.

3.2.2.3. The acid. The acid dimer (O2–H2a···O2) in the *o*-tolyl derivative **2**, is almost identical to **1**, with H-bonded pairs (O3–H3a–O1′) more linear by 8°. The EF interaction between acid chains also appears to involve the methyl hydrogens (edge atoms H19a, H19c), rather than the unsubstituted edge interacting with the face.

The acid dimer anion of the *o*-NO_2/*m*-NO_2 derivative **5**, contains one strong H bond (O3–H3a···O6), and one weaker bond (O2–H2a···O7). In the former, the proton is not shared equally as in **1**, but lies closer to the *o*-acid (*d*(O3–H3a) = 1.19(5) Å, *d*(H3a···O6) = 1.25(8) Å), and the paired dimers are connected via regular H bonding (O8–H8a···O1, *d*(H8a···O1) = 1.582 Å, 172.34°) to form exaggerated 'zigzag' chains, Fig. 4c. This conformation is very different to the usual linear conformation seen. The pure *m*-NO_2 derivative **6**, also contains one acid anion and one neutral acid joined by a strong H-bond. The anion forms a pair of equivalent H-bonds with another anion; and the neutral acid forms a weaker pair with another neutral acid. Both pairs are stronger than the pairing of **1** (Fig. 5d(i–ii)). In both **5** and **6**, some weak H-bonding is observed between the phen protons and the NO_2 groups (C8–H8···O4 *d*(H8···O4) = 2.503 Å, 164.99°; C13–H13···O10 *d*(H13···O10) = 2.713 Å, 137.10° in **5**). However, this is thought to be a less important contributor to assembly.

The *p*-tolyl derivative **4** contains an acid anion, a neutral acid, together with ethanol and water. Consequently, the H-bonding networks are very different to those in other products: the usual strong acid dimer connection being replaced by a bridging system of H-bonds with solvent molecules (Fig. 4b). A pair of H-bonds exists between the anionic and neutral acid, where the neutral species donates both protons. The (neutral) O3–H3a···O5 (anion) bond

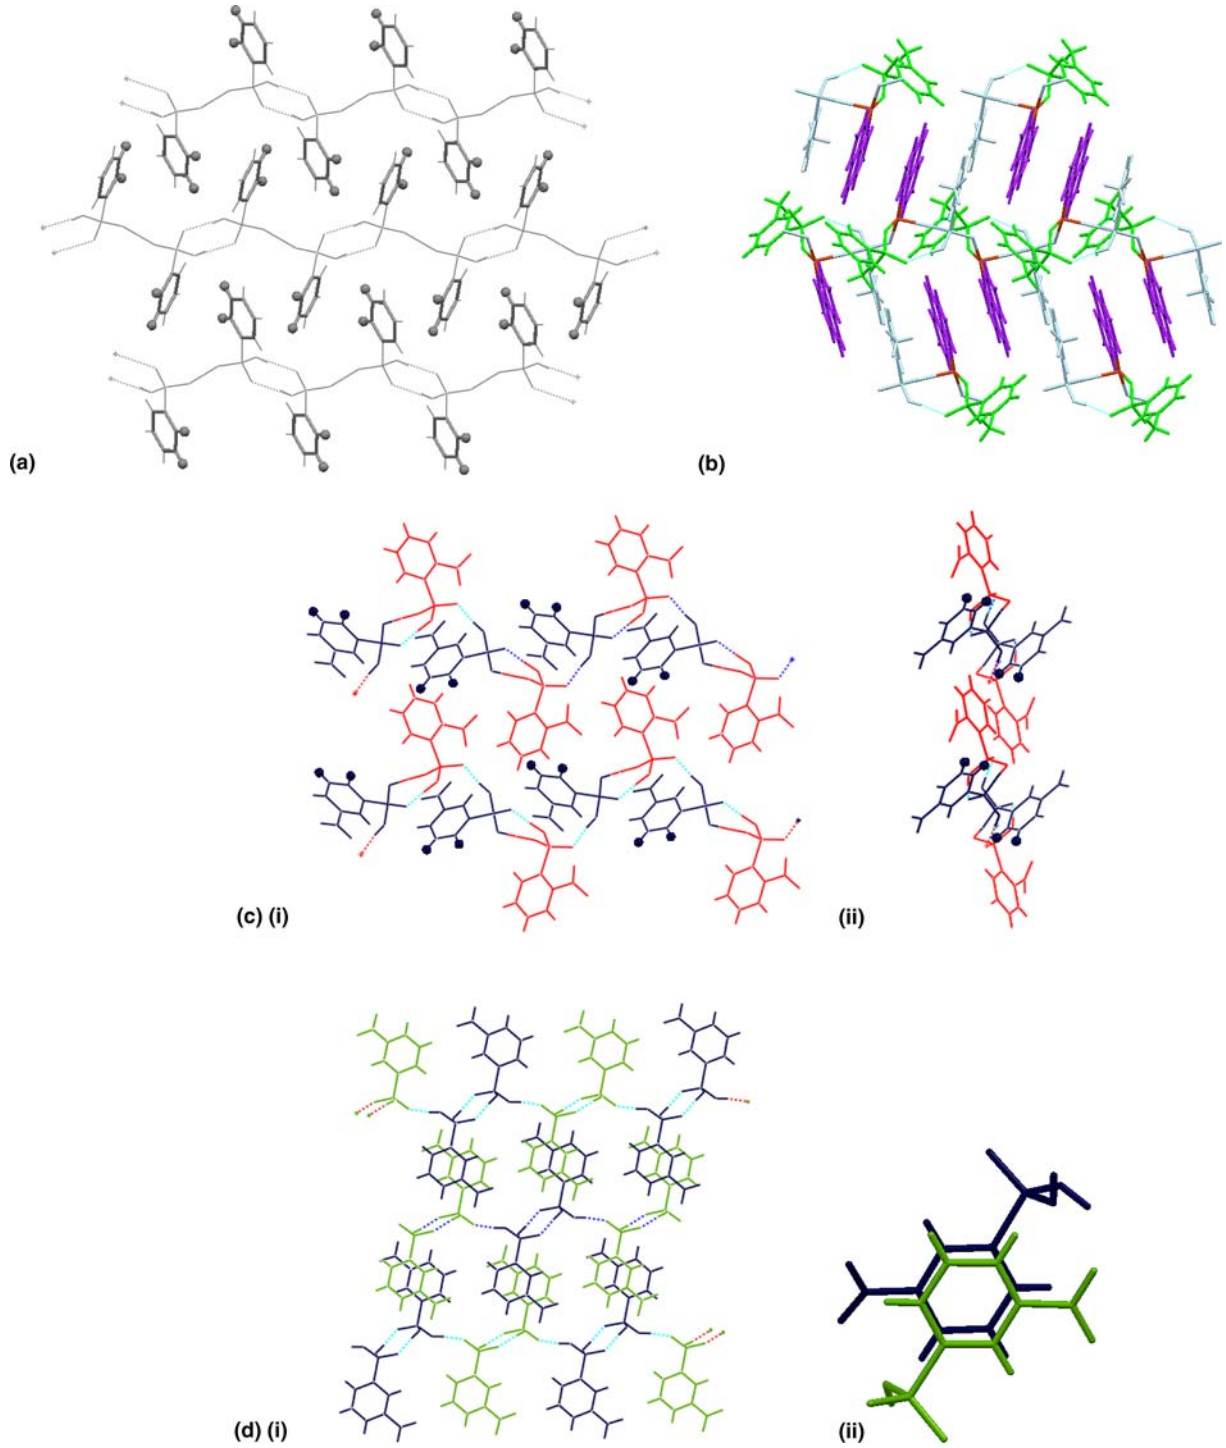

Fig. 5. (a) The H-bonded acid chains of **1** are assembled into sheets via EF interaction of phenyl rings – 'edge' H-atoms shown as spheres; aromatic 'face' as bolded ring. (b) The OFF pairing of phen–phen (purple–purple) and phen–acid (purple–blue) in **3**. (c) (i) The zigzag acid chains of **5** meshed together via non-continuous EF interaction to form a sheet, (ii) the *meta* rings (blue) protrude from the layer, while the *ortho* rings (red) are in-plane. (d) (i) Acid chains of **6** are connected into sheets via OFF overlapping of the rings, (ii) the overlap is noticeably offset, with nitro groups *trans* to one another. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

(176.31°) is significantly more linear than the (neutral) O2–H2a···O6 (anion) (161.74°).

There are two acid species in the naphthyl derivative **7**: a dimer acid anion (P) (O8–H8a···O8, d(O8···H8a) = 1.22(4) Å) which forms pairs of identical H-bonds (O9–H9a···O7, d(H9a···O7) = 1.633 Å, 174.69°); and a pair of neutral (R) and anionic (Y) acids connected by a regular H bond (O2–H2a···O4, d(H2a···O4) = 1.612 Å, 167.00°) (Fig. 1c). The pairing of the P dimer anion is stronger then in **1** and **2**. In both YR and P acid chains, the naphthyl

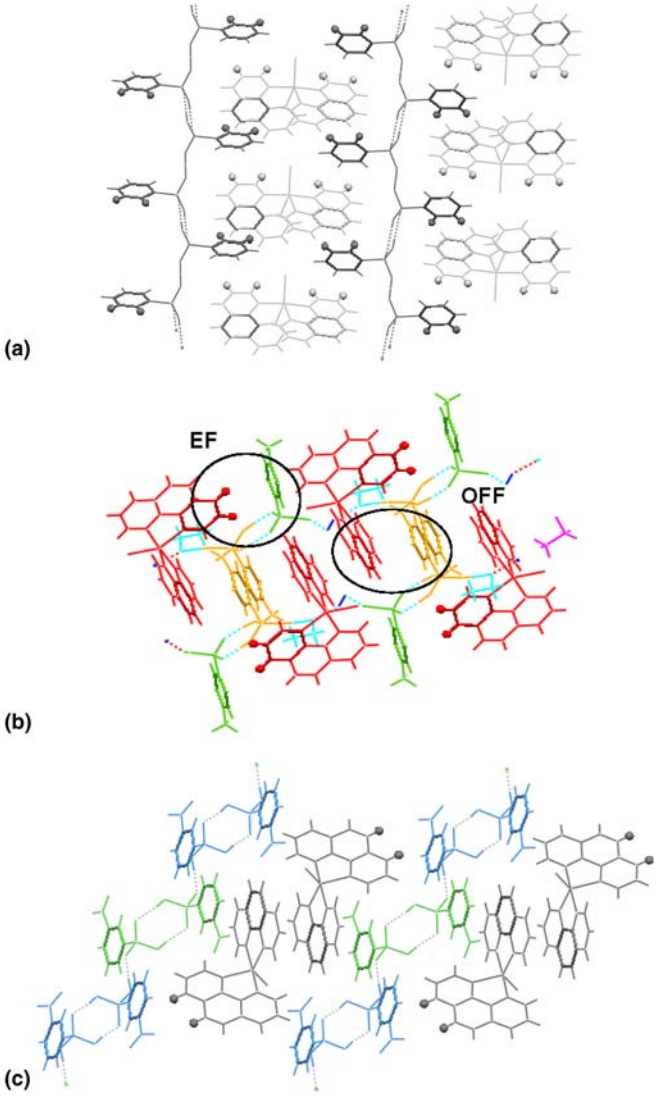

Fig. 6. (a) The continuous EF interactions between acid chains and phen in **1**. (b) EF and OFF interactions between phen and acid in **4**. (c) OFF stacking between anionic (green) acid rings and phen, and the EF interaction between neutral (blue) acid rings and phen in **6**. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

groups are angled from the linear type chains in a similar orientation to the phenyl rings of **1**. This orientation, and the fact the naphthyl group gives a wider face and edge to undergo π–π interactions, are thought responsible for the range of EF and OFF motifs seen.

In summary, whilst the acid participates in three H-bonding motifs in all structures, there are some notable variations in bond lengths and angles. Examining the data in Table 4, it appears that only the centrosymmetric inter-dimer bonds of **1**, **2** and **7** satisfy Jeffrey's criteria [33] for a strong (almost covalent) hydrogen bond: H···A = 1.2–1.5 Å; D···A = 2.2–2.5 Å; DHA = 170–180 °; and X–H ∼ H···A. Amongst the remaining structures, the H-bonds of the mixed *o*-/*m*-NO_2 derivative **5**, the *m*-NO_2 derivative **6**, and the P═O1···H7–O7 bonds between ethanol and the *p*-tolyl acid in **4** are the strongest, but can only be classified as moderate with respect to their X–H:H···A ratios. From current evidence, the *o*-NO_2 bond of **5** appears to have formed stronger H-bonds than its *m*-NO_2 partner and **1**. This tends to support the notion that electronic 'inductive' effects have a role to play in the overall structure assembly.

However, the effects on H-bonding motifs might be better traced to steric reasons, i.e. that the acid chains orient to place the substituted ring in a position where the π–π networking can self-assemble. This conclusion is supported by Nagarajan et al. [13] who determined the acid dissociation constants of 36 substituted phenylphosphonic acids, and also in the work of Russell and Ward on substituted arylsulphonic acids [10]. Nagarajan found that unlike benzoic acid, where virtually any *ortho* group has an acid strengthening effect, in the majority of cases, substituted arylphosphonic acids are either slightly weaker acids (*ortho*-) or have pK_{a1} and pK_{a2} values comparable (*meta*- and *para*-) to the unsubstituted form (H $pK_a = 1.86$; *o*-CH_3 $pK_a = 2.08$; *m*-CH_3 $pK_a = 1.95$; *p*-CH_3 $pK_a = 2.00$ [13]). The only exceptions being NO_2-substituted acids, which have significantly lower dissociation constants (*o*-NO_2 $pK_a = 1.28$; *m*-NO_2 $pK_a = 1.20$, *p*-NO_2 $pK_a = 1.19$ [13]). Therefore, as we have observed, alkyl groups are fairly benign in their effect on the hydrogen bonding ability of the acid, whereas acids substituted with electron-withdrawing groups, such as NO_2, may form slightly stronger hydrogen bonds.

3.2.2.4. Global observations. Looking along the *c*-axis, the overall packing of **2** is extremely similar to **1** (Fig. 7b). The *ortho*-position results in the methyl substituent being contained within the acid layer, so the EF acid-to-phen interactions are not disrupted. The unit cell is more square than **1** (*β* more acute by 7.2°), but otherwise only a slight expansion is observed.

The symmetry of the overall packing in **5** has been disrupted (Fig. 7e). Adjacent acid sheets are not aligned, being rotated 54° in the *a*–*b* plane with respect to one another. The phen layers are not aligned either – there is a 70° rotation in the *a*–*b* plane. If viewed along the *b*-axis, the *meta*-acids protrude sharply either side of the chain, while the *ortho*- are more in line (Fig. 5c(i)). One might expect that the protruding *meta*-acids would be more favourable participants in acid–phen π–π interactions, but this does not appear to occur. They are actually projected into the spacings between ribbons, which is possible because of the offset arrangement of the phen ribbons and the previously mentioned plane rotations. It is the *ortho*-acid ring, rather than the *meta*-, which undergoes an EF interaction with phen protons (H20, H21) (Fig. 6c). In summary, the *ortho*-acid ring is the greater contributor to assembly – participating in both the assembly of acid sheets and the binding of acid to phen.

The rings of **6** are angled gently in-plane (Fig. 4d), and the nitro groups are '*trans*' to one another. This enables an OFF interaction between acid rings of adjacent chains

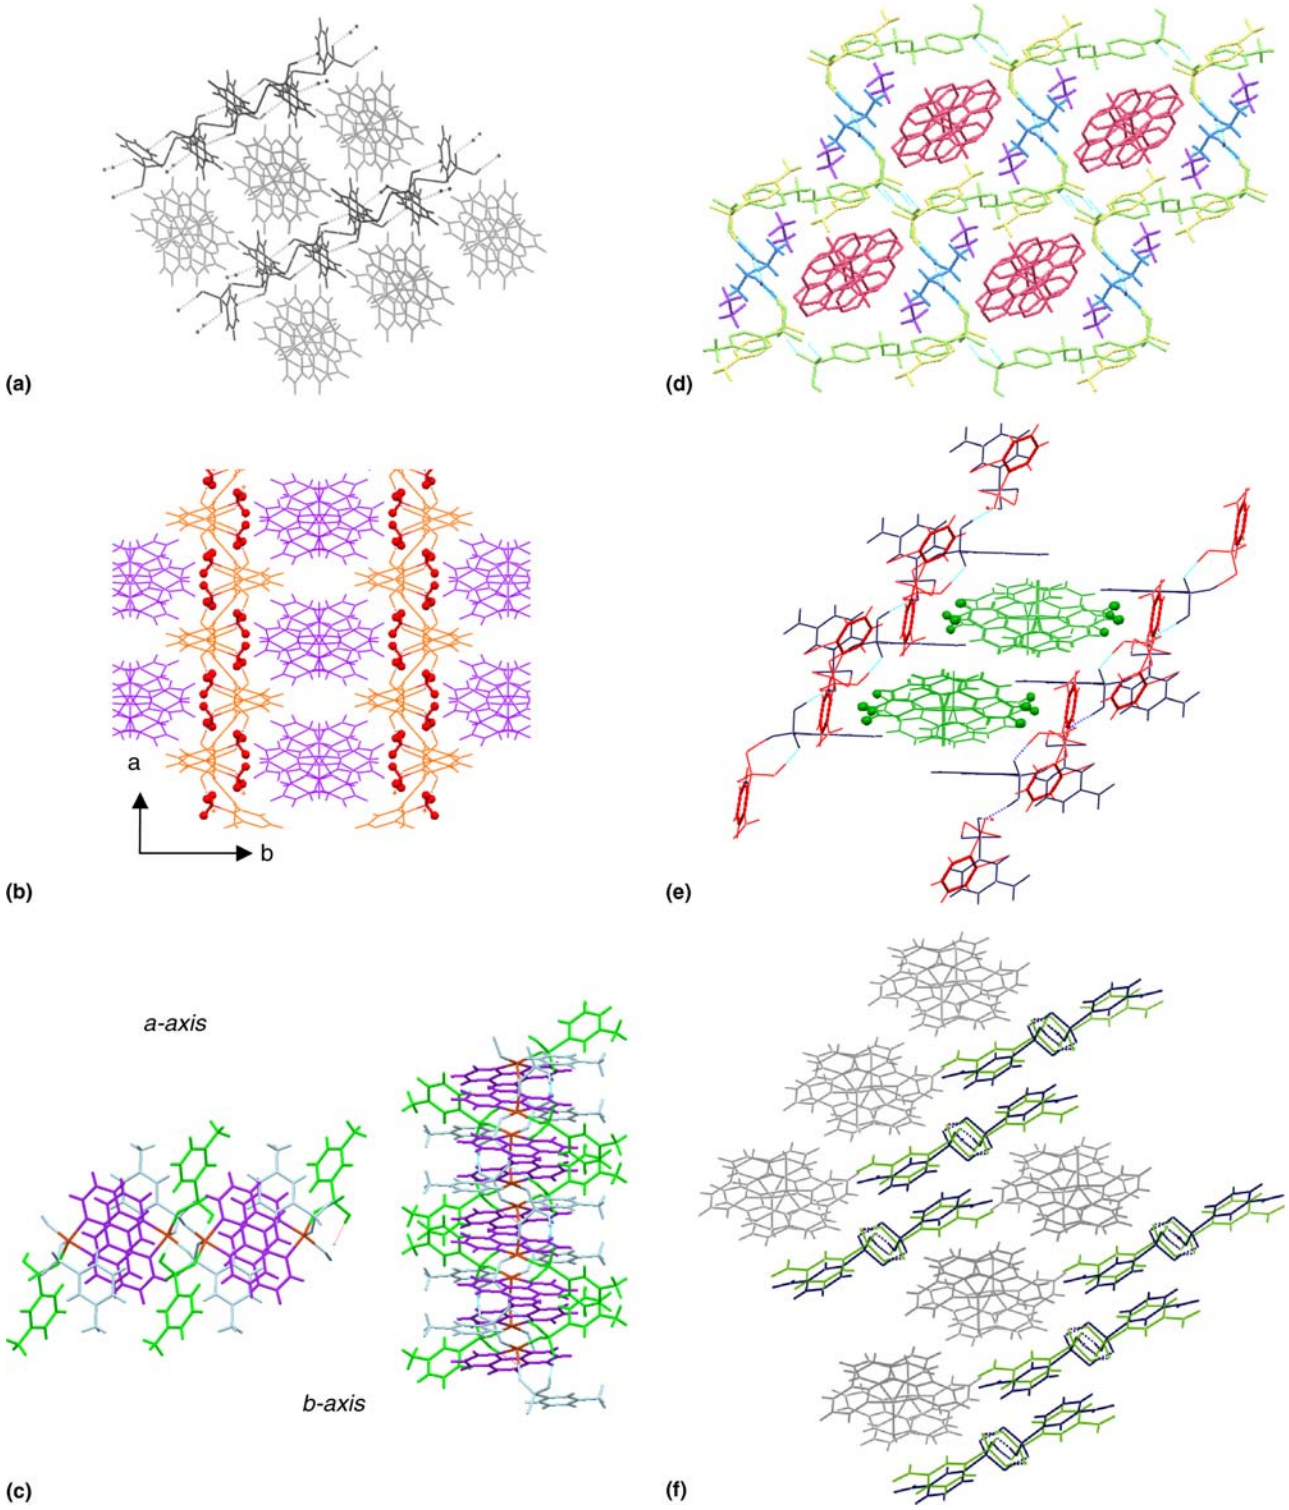

Fig. 7. Overall packing for: (a) **1** showing the acid layers interleaved by phen ribbons. (b) **2** – The presence of the methyl substituent has not interfered with the continuous EF interactions between acid chains and phen. (c) **3** Along the *a* and *b*-axes. (d) **4** – The methyl groups protrude to create cavities, which are filled by the phen ribbons. (e) **5** – The acid sheets and adjacent phen sheets are rotated with *meta* (blue) rings projected between ribbons, while the *ortho* (red) rings EF interact with phen. (f) **6** Where the phen ribbons run in the same direction as the acid chains. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

(Fig. 5d), as opposed to the usual continuous EF interaction. The OFF assembly has major effects on overall packing. Firstly, the acid sheet is thicker, and consequently the spacing between adjacent phen layers is expanded. Secondly, the acid chains now run in the same direction as the phen ribbons (Fig. 7f). The anionic and neutral acid

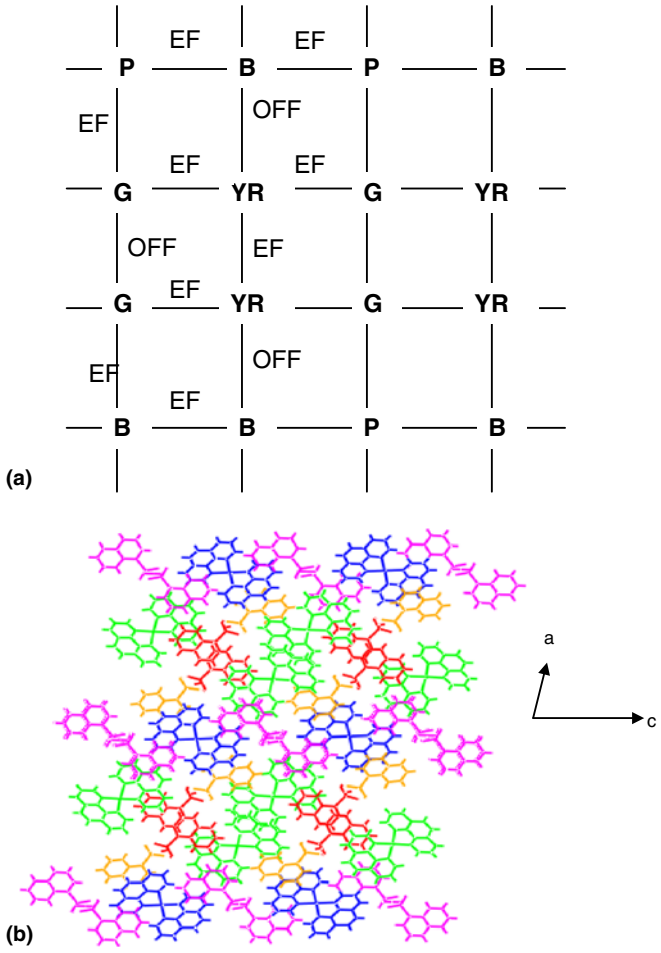

Fig. 8. (a) The structure of **7** contains multiple OFF/EF interactions and is best represented graphically as an intersecting grid (P, B, G, and YR are defined in Fig. 1c). (b) Packing in the *a*–*c* plane reveals four unique, intersecting lines of π–π interactions.

rings protrude between the phen ribbons. The anion forming an OFF interaction with the middle ring of phen (*d*(plane to centroid) = 3.729 Å, 3.39°), and the neutral acid forming a weaker EF interaction with the phen edge of H3, H5 (angle = 64.74°). Thus, the assembly of **6** is dominated by OFF interactions.

No π–π interactions are observed between adjacent chains of acid/solvent in **4**. The methyl groups are not orientated to allow this, rather they protrude to create cavities (Fig. 7d). These stack behind one another to give two-dimensional voids, which are filled by the phen ribbons. This is possible because of two types of π–π interactions between the acid and phen, which are best viewed along the *b*-axis (Fig. 6b). There is an OFF overlap between the neutral acid and the middle ring of the N3/N4 phen (*d*(centroid to plane) = 3.47(3) Å, 5.2°); while an EF interaction exists between the N1/N2 phen (edge = H8, H9) and the anionic acid plane.

When observed in the *a*–*c* plane (Fig. 8a and b), the unit cell of **7** contains a series of interlocking planes. In Plane 1: B–YR–RY–B–YR, the B acid forms OFF pairs with the Y acid. This is a one-ring overlap between the middle phen ring and the Y 'original' ring, which is a strong interaction (3.381 Å, 5.19° divergence). Adjacent acid chains are connected by a continuous EF interaction between R acid groups. In Plane 2: YR–G–YR–G–YR–G, on one side of the acid chain, a continuous EF interaction occurs between R acid and G phen, and on the other side, there is a continuous EF interaction between Y acid and D phen. In Plane 3: B–P–B–P–B–P, there is a continuous EF interaction between the B phen and P acid. Finally, in Plane 4: P–G–G–P–G–G, the G phens form perfectly parallel OFF pairs, involving the two ring overlap of middle and N4 rings (*d*(plane to centroid) = 3.462 Å). These pairs form continuous EF interactions with the P acid. In total, the naphthyl group in product **7** participates in 11 different π–π interactions, with approximately half involving the 'fused' ring.

3.2.3. *Molecular structure and packing of* ***3***

As mentioned previously, the structure of **3** is very different from the rest of the series, and consists of a neutral molecule instead of an ion pair (Fig. 1b). Trigonal bipyramidal stereochemistry is retained, as is typical of copper(II) compounds, but the copper is connected to one phen molecule (N1 and N2), and three phosphonate oxygens: two from the two phosphonate ions in the molecular unit (O3 and O6); and one from a P1 phosphonate ion (O1′) in an adjacent molecular unit. The latter connecting neighbouring molecular units, via a P1–O3–Cu1–O1′–P1′ link, which results in a mixed inorganic/organic polymeric chain in the *a*-direction (Fig. 7c).

There are two hydrogen bonding interactions: an intramolecular strong H-bond between O2–H2a···O5 (*d*(O2···O5) = 2.477 Å); and an intermolecular H-bond of moderate strength between O4–H4a···O1′ (*d*(O4···O1′) = 2.613 Å). Both bonds are almost linear with angles of 170.34° and 176.08°, respectively.

There are three different π–π interactions: an intramolecular OFF interaction between the N2 phen ring and the C13–C18 acid ring (*d*(centroid to plane) = 3.391 Å; 5.23 °); an intermolecular, parallel OFF interaction between phen molecules in adjacent molecular units, via overlap of the N1 and N2 rings (*d*(centroid to plane) = 3.387 Å; and a weak intermolecular EF interaction 45.03 °) between methyl protons H26a and H26b of the P2 acid, and the acid ring of P2′ (*d*(H26a to H20′–H25′ centroid) = 4.40 Å; *d*(H26b to H20′–H25′ centroid) = 4.842 Å). All of the former are single, not continuous interactions, such that only phen–phen, phen–acid and acid–acid pairing occurs (Fig. 5b).

4. Conclusion

The successful synthesis and structure determination of the six new compounds reported here has provided valuable data for the investigation of the variety of supramolecular motifs of phen and phenylphosphonic acid metal derivatives. Most importantly, they have emphasised the

potential of phenylphosphonic acids (the $P(O)(OH)_2$ group and the unsubstituted/substituted aromatic rings) to be used in the context of intermolecular design, rather than, or in addition to, the well known use of phosphonates in co-ordination networks. With the exception of the *m*-tolyl derivative **3**, the structural unit – a 5-coordinate $[Cu^{II}(phen)_2Cl]^+$ cation, with two acids functioning as counter-anion, was maintained in the series – indicating that the major role of the acid has not changed. The general assembly strategy of acid sheets with phen ribbons interleaved, seen in **1**, has been maintained in four structures (*o*-tolyl (**2**), *o*-/*m*-NO_2 (**5**–**6**) and naphthyl (**7**)). In three cases (*m*-tolyl (**3**), *p*-tolyl (**4**) and naphthyl (**7**)), the substituent has disrupted the symmetry of overall packing, and has greatly impacted on the arrangement of phen ribbons. This disruption can be traced to moderate to strong perturbations of the H-bonding motifs, and π–π interactions. The substituent *type* had a lesser influence on the structure than the substituent *position*. The substituent *type* had only minor effects on H-bonding character, with the strongest intra- and inter-dimer H-bonds being observed in the nitro acids. The *position* of the substituent had a considerable influence on π–π motifs, and hence on global packing. The degree of disruption to packing increased from *ortho* to *meta* to *para*. The *o*-CH_3 structure **2** is a very close structural analogue to the unsubstituted parent **1**, where the phen–acid EF motifs were maintained, but in structure **4** a completely different packing style was adopted due to the protruding *p*-CH_3 group. The inadvertent formation of the mixed isomer product **5** provided an opportunity to study *ortho* versus *meta* substitution. The *o*-NO_2 group appeared to adopt the assembly roles seen in **2**, whilst the *m*-NO_2 group had to be accommodated. Therefore, in the pure *m*-NO_2 product **6**, a different assembly strategy was required, which utilised more OFF interactions. Significant changes were observed in π–π interactions in the naphthyl product **7**. The larger aromatic group forms a range of EF and OFF motifs, to create a completely different assembly. Attempts to produce a *p*-phenyl acid derivative were unsuccessful, lending further evidence for the disruption of the structure by *para* substituents. The need to satisfy π–π networking requirements of the acid, appears to indicate that the substituted acid has a more dominant role in the overall assembly then the unsubstituted form, i.e. the substituent has given the acid greater control in the self-assembly of the supramolecular structure.

Appendix A. Supplementary data

CCDC Reference Nos. 602676–602681 contain the supplementary crystallographic data for this paper. These data are available free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Product **1** has been previously reported (CCDC No. 216752) [4]. Stabilisation of heterobimetallic networks by crown ethers and hydrogen-bonding in $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$: Structure and magnetism

Abstract

$[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$ can be conveniently prepared by the interaction of $NiCl_2 \cdot 6H_2O$, $CuCl_2 \cdot 2H_2O$ and 15-crown-5 in water. The X-ray crystal structure reveals an ionic complex involved in a hydrogen-bonded two dimensional network with the $[Ni(H_2O)_6]^{2+}$ and $[Cu_3Cl_8(H_2O)_2]^{2-}$ ions sandwiched between the 15-crown-5 macrocycles. The magnetic susceptibility data (4–300 K) and magnetisation isotherms (2–5.5 K; 0–5 T) are best interpreted in terms of intra-trimer ferromagnetic coupling within the $[Cu_3Cl_8(H_2O)_2]^{2-}$ moieties, with $J \sim 6\ cm^{-1}$, and antiferromagnetic coupling between the trimers, the latter mediated by H-bonding pathways. Comparisons are made to other reported quaternary ammonium salts of $[Cu_3Cl_8]^{2-}$ and $[Cu_3Cl_{12}]^{6-}$, most of which display structures that involve close stacking of such Cu(II) trimers, rather than being of the present isolated, albeit H-bonded, types.

1. Introduction

Molecular based magnets have been the subjects of intense interest in heterobimetallic complexes in recent years. Paramagnetic metal based compounds offer distinct advantages over organic radical counterparts in this respect due to the magnetic nature being tunable based on choices of metal, ligands and bridging groups, electron spin being reserved to each metal centre and the possibility of networks being constructed by judicious choice of stereochemistry about the metal centres [1].

As part of our research into the coordination of metal ions with crown ethers [2] and in particular the stabilisation of unusual $[(H_2O)_5Fe(\mu\text{-}O)Fe(OH_2)_5]^{4+}$ species in $[(H_2O)_5Fe–O–Fe(OH_2)_5][NO_3]_4 \cdot (18\text{-crown-}6)_2$ [3] and second sphere coordination complexes of the transition metals [4], we now present the synthesis, structure and magnetism of a heterobimetallic, non-covalent species involving Ni^{2+}, Cu^{2+} and 15-crown-5; viz the trinuclear anionic copper species $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$. The crown ether and associated hydrogen-bonding has enabled the halide-rich trinuclear Cu(II) cluster to be stabilised and, in contrast to the situation commonly found in crystalline $[Cu_3Cl_8]^{2-}$ compounds that do not contain a crown ether, the trinuclear $[Cu_3Cl_8(H_2O)_2]^{2-}$ moiety does not stack to neighbours via semi-coordinate 2.9 Å long Cu···Cl interactions along the apical Cu(II) direction [5,6].

2. Results and discussion

Treatment of equimolar amounts of $NiCl_2 \cdot 6H_2O$ and $CuCl_2 \cdot 2H_2O$ with 15-crown-5 in water resulted in a brown solution from which large brown crystals and small green acicular crystals deposited. Manual separation of the two sets of crystals was possible and the latter were shown by unit cell determination to be the previously reported

$[\{Ni(H_2O)_4\}_2(\mu\text{-}Cl)_2]Cl_2 \cdot$ 15-crown-5 [4c]. An infrared spectrum of the brown material showed strong broad bands around 3360 and 1650 cm^{-1} attributable respectively to OH stretches and bending of either water ligands or water of crystallization. The presence of the crown ether is indicated by moderate to high intensity C–O stretches in the 1000–1500 cm^{-1} region. To ascertain the true nature of the brown crystals, they were subjected to an X-ray crystal structure determination and their composition found to be $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$. Microanalysis of the bulk sample confirmed this composition.

$[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$ crystallises in the triclinic space group *P*-1 with one half of the structural entity comprising the asymmetric unit. The complex ions do not exist as discrete ionic units, rather they are involved in extended hydrogen bonding networks. The $[Ni(H_2O)_6]^{2+}$ octahedral cation which resides on an inversion centre is unexceptional (Table 1). The water ligands are however, multiply hydrogen bonded to two 15-crown-5 molecules, resulting in the complex ion being sandwiched centrally between two of the macrocyclic ligands in a second sphere coordination mode (Fig. 1). Thus, the $[Ni(H_2O)_6]^{2+}$ ion is involved in six hydrogen bonds with two 15-crown-5 hydrogen bond acceptors (Fig. 1), being closely related to the type of interaction in $[Ni(H_2O)_6](ClO_4)_2 \cdot (15\text{-crown-}5) \cdot 2H_2O$ [4c]. In a similar fashion, the $[Cu_3Cl_8(H_2O)_2]^{2-}$ anion is also sandwiched between two 15-crown-5 molecules through hydrogen bonding between the coordinated water molecules and the O atoms of the crown ether (Fig. 2). The $[Cu_3Cl_8(H_2O)_2]^{2-}$ polynuclear anion has been previously structurally characterised in $[Mg(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$ [7] which is isomorphous to the present nickel analogue. Thus, the anion has a central $CuCl_2(H_2O)_2$ unit which has very close to square planar geometry (Table 1), but Cl(2) and its symmetry generated partner are predisposed in axial positions (relative to the $CuCl_2(H_2O)_2$ plane) at a "semi-coordinate" distance of 2.862(1) Å, representing extreme Jahn–Teller distortion about Cu(2). Cu(1) is coordinated by four chloride ligands in a flattened tetrahedral array (see Fig. 2, Table 1). The geometric parameters of this ion are very similar to the previous Mg analogue [7]. While both the $[Ni(H_2O)_6]^{2+}$ and the $[Cu_3Cl_8(H_2O)_2]^{2-}$ ions are sandwiched between 15-crown-5 molecules, they take up alternate positions in the overall structure, such that the 15-crown-5 molecules bridge successive $[Ni(H_2O)_6]^{2+}$ and the $[Cu_3Cl_8(H_2O)_2]^{2-}$ ions (Fig. 3). These $[Ni(H_2O)_6]^{2+}$–15C5–$[Cu_3Cl_8(H_2O)_2]^{2-}$–15C5 ladders are cross-linked through a Cl···H–O hydrogen bond arising through Cl(3) and a proton on O(3s), an equatorial water ligand on $[Ni(H_2O)_6]^{2+}$ (see Fig. 3). Thus, overall, the structure is a two dimensional hydrogen bonded grid.

Magnetic susceptibilities of polycrystalline $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$ were measured in a field of 1 T over the temperature range 4–300 K. The susceptibilities over the range 4–300 K showed a Curie–Weiss temperature dependence ($C = 2.16\ cm^3\ mol^{-1}\ K^{-1}$; $\theta = -1.0$ K) and the corresponding plot of $\chi_M T$ versus temperature, shown in Fig. 4, varies from 2.43 $cm^3\ mol^{-1}$ K (4.40 μ_B), per $NiCu_3$, at 300 K, to a broad maximum of 2.53 $cm^3\ mol^{-1}$ K, at ~40 K, before decreasing rapidly to reach 1.60 $cm^3\ mol^{-1}$ K (3.56 μ_B) at 5.4 K, and still decreasing. There appears to be a very broad, gentle minimum in $\chi_M T$ at ~200 K, such observations being sometimes indicative of ferrimagnetic coupling. This seems unlikely to be the case here in view of the Ni(II) $S = 1$ centres being not covalently bonded to the Cu(II) ions, even though they are H-bonded via the long Cl(3)···O(3S)(H_2O) interactions. It more likely reflects the superposition of $\chi_M T$ contributions

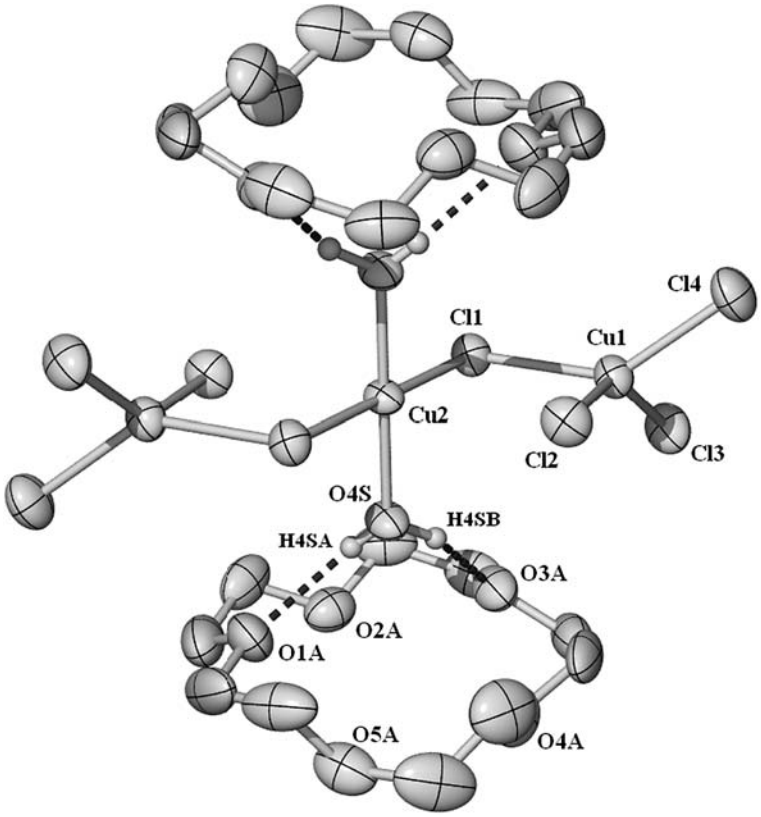

Fig. 2. X-ray structure of the $[Cu_3Cl_8(H_2O)_2]^{2-}$ polynuclear anion sandwiched by hydrogen bonding between two 15-crown-5 molecules.

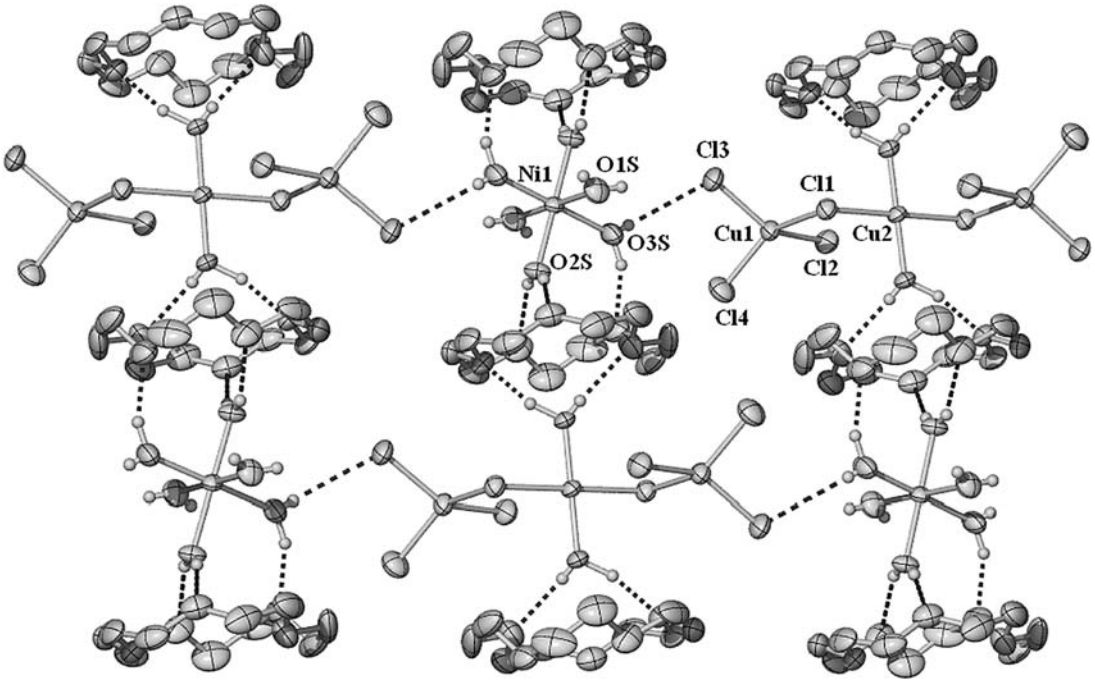

Fig. 3. Crystal packing diagram of $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2]\cdot(15\text{-crown-}5)_2\cdot 2H_2O$ showing the extensive hydrogen bonding network.

from the $S = 1$ ions and from the $Cu_3Cl_8^{2-}$ trinuclear spin-coupled moieties. The overall shape of the $\chi_M T$ plot, particularly in the range 300–40 K, is suggestive of weak ferromagnetic coupling, with a combination of zero-field splitting of the ground state(s) and antiferromagnetic trimer–trimer coupling being responsible for the rapid decrease observed below 40 K.

Probing the low temperature region, further, by measurements of magnetisation (M) isotherms (2–5.5 K) yielded the plots shown in Fig. 5. The M versus H dependence is almost linear at 2 K and shows a slight downward curvature for the 3–5.5 K isotherms. Clearly, saturation in M does not occur and the behaviour is indicative of either paramagnetic (i.e. M proportional to H) or, more likely, of antiferromagnetic coupling occurring in this temperature region, as was seen in the $\chi_M T$ plot. An M value of 3.37 Nβ obtained at 2 K and $H = 5$ T, is less than the expected value of ~5 Nβ if all four metal ions are uncoupled and, also, saturation would also be anticipated under these conditions. A similar M value of ~5 Nβ would be anticipated if the $[Cu_3Cl_8(H_2O)_2]^{2-}$ unit had a coupled $S = 3/2$ ground state at 2 K, combined with M for the $S = 1$ Ni(II) aqua ion. Whereas, if the $[Cu_3Cl_8(H_2O)_2]^{2-}$ unit has a $S = 1/2$ ground state, a value of ~3 Nβ would be expected. The observed value, together with the linear behaviour and lack of saturation noted in Fig. 5, is also probably indicative of the thermal population of M_S Zeeman levels that are close to the ground state, rather than being indicative of an isolated ground state.

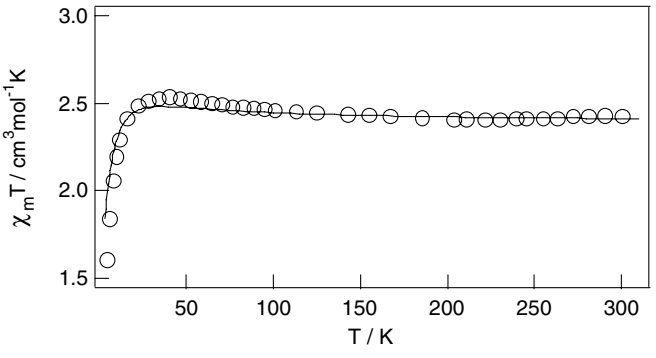

Fig. 4. Plot of $\chi_M T$ (per $NiCu_3$) vs. temperature, in a field of 1 T, for $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2]\cdot(15\text{-crown-}5)_2\cdot 2H_2O$. The solid line is that calculated using a linear $S = 1/2$ trimer model plus a Curie-like Ni(II), $S = 1$ contribution, with the best-fit parameters discussed in the text. The trimer model includes a trimer–trimer interaction parameter, θ'.

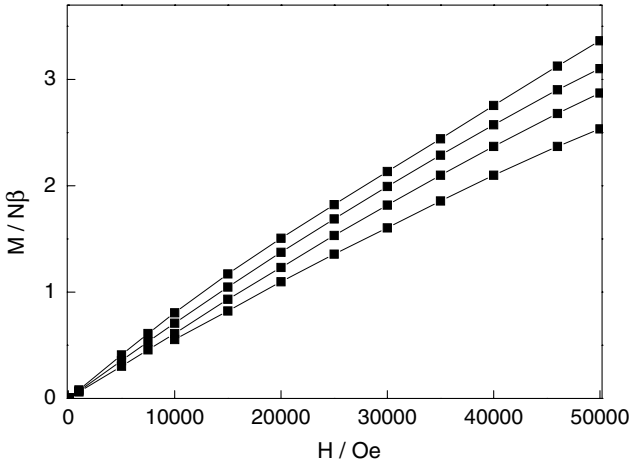

Fig. 5. Magnetisation isotherms for $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2]\cdot(15\text{-crown-}5)_2\cdot 2H_2O$ at temperatures of 2 (top), 3, 4 and 5.5 K (bottom) in the field range shown. The solid lines simply join the points.

The $\chi_M T$ data of Fig. 4 could be fitted well by use of a linear $S = 1/2$ trimer model (employing a $-2J\,\mathbf{S}_1 \cdot \mathbf{S}_2$ Hamiltonian) [8] plus a Curie susceptibility contribution ($\chi_M T = 1.20\ \mathrm{cm^3\ mol^{-1}\ K}$) for the $S = 1$ $[Ni(H_2O)_6]^{2+}$ centre. The best fit parameters were $g = 2.06(1)$, $J = 13.8(1)\ \mathrm{cm^{-1}}$ and $\theta' = -7.3(1)$ K. J is the coupling parameter between the terminal Cu(1) atoms and the central Cu(2), across the Cu(1)–Cl(1)–Cu(2) bridges. Importantly, the θ' term that is incorporated as $(T - \theta')$ in the trimer susceptibility equation, represents a trimer–trimer interaction and allows the simulation of the maximum and the low temperature decrease in $\chi_M T$ (Fig. 4). The inclusion of θ' has a significant correlative effect upon the value of J needed to reproduce the 300–40 K data as well as the 4–40 K region. This can be seen in Fig. 6, where θ' is not included in the susceptibility equation and the best fit J is now $6.0(1)\ \mathrm{cm^{-1}}$. The rapidly increasing calculated $\chi_M T$ plot at low temperatures would level to a $S = 3/2(Cu_3) + 1(Ni(aq))$ value of $\sim 3.1\ \mathrm{cm^3\ mol^{-1}\ K}$. Interestingly, it is also possible to get a good fit of the data, over the whole 300–4 K range, by use of a positive J(Cu(1)–Cu(2)) $= 16.6(1)\ \mathrm{cm^{-1}}$, and a negative J(Cu(1)–Cu(1′)) $= -12.0(1)\ \mathrm{cm^{-1}}$, but there is no structural or exchange-pathway reason for such a (Cu(1)–Cu(1′)) interaction.

In making comparisons with related trimeric $Cu_3Cl_n^{x-}$ species, we note that Willett et al. [5] have reported ferromagnetic coupling in $[Cu_3Cl_{12}]^{6-}$, and related 'semi-coordinate' Cu···Cl–Cu bridged compounds in which the central, square-planar disposed $CuCl_4^{2-}$ moiety is weakly bridged in the axial positions (Cu···Cl = ~2.9 Å; Cu···Cl–Cu angle = ~117°) to the distorted tetrahedral $CuCl_4^{2-}$ terminal groups; J values of 7–20 $\mathrm{cm^{-1}}$ being noted in such cases. Weak, antiferromagnetic trimer–trimer coupling was again noted, but the magnetisation isotherm at 2 K showed $S = 3/2$ saturation occurring in fields near 5 T, different, therefore, to the present case. In contrast, the present compound displays symmetrical/bent Cl bridging via the in-plane Cl of the central planar $CuCl_2(H_2O)_2$ group bonding directly to the distorted tetrahedral $CuCl_3^-$ terminal groups (with d(Cu–Cl) ~ 2.33 Å; Cu(1)–Cl(1)–Cu(2) angle = 99.65(4)°). As indicated in the structural discussion, semi-coordinate Cu(2)···Cl(2) separations of ~2.8 Å do occur in both axial positions around the central Cu(2), thus giving potential magnetic exchange pathways using a $\{Cu(2)(d_{x^2-y^2})$–Cl(1)–Cu(1)$(d_{xy})\}$ orbital overlap combination as well as the weaker $\{Cu(2)(d_{z^2})\cdots Cl(2)$–Cu$(d_{xy})\}$ combination.

$[Cu_3Cl_8]^{2-}$ trimeric units are also known in pyridinium salts such as (1,1,4-trimethylpiperazinium)$[Cu_3Cl_8]$ [6] but these have structures involving stacking of the trimer units, via semi-coordinate ~2.8 Å long Cu···Cl links, in to ladder type motifs. Planar $CuCl_4^{2-}$ groups in such trimers are joined by di-μ-chloro bridging (Cu–Cl–Cu angle ~94°) and are coplanar, yielding approximate D_{2h} symmetry within the linear trimer. The present compound possesses much more isolated trimeric Cu(II) units by virtue of the H-bonded $\{$crown ether $Ni(H_2O)_6^{2+}\}$ millieu surrounding the trimers. The magnetism of Fig. 4 is quite different to the antiferromagnetic behaviour noted for these stacked $[Cu_3Cl_8]^{2-}$ species for which was found $J = -23\ \mathrm{cm^{-1}}$ and a $S = 1/2$ ground state within the trimer.

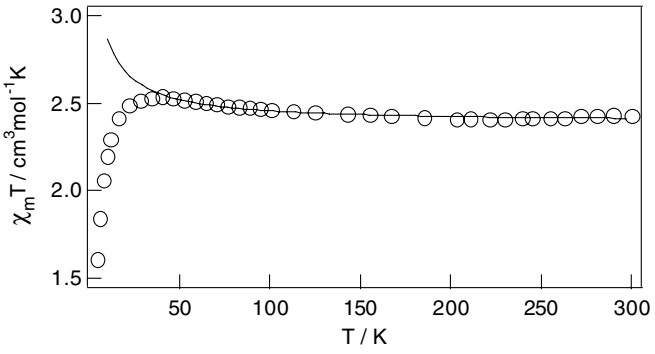

Fig. 6. Plot of $\chi_M T$ (per $NiCu_3$) vs. temperature, in a field of 1 T, for $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2]\cdot(15\text{-crown-}5)_2\cdot 2H_2O$. The solid line is that calculated using a linear $S = 1/2$ trimer model plus a Curie contribution from Ni(II) of 1.20 $\mathrm{cm^3\ mol^{-1}\ K}$; with $g = 2.06$ and $J = 6.0\ \mathrm{cm^{-1}}$. It does not include the θ' parameter.

3. Conclusion

$[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2]\cdot(15\text{-crown-}5)_2\cdot 2H_2O$ can be conveniently prepared by the reaction of $NiCl_2\cdot 6H_2O$, $CuCl_2\cdot 2H_2O$ and 15-crown-5 in water. The X-ray crystal structure reveals an ionic complex involved in a hydrogen-bonded two dimensional network with the cations and trinuclear anions sandwiched between the crown macrocycles. The magnetic susceptibility and magnetisation data result from a combination of the spin-coupled $[Cu_3Cl_8(H_2O)_2]^{2-}$ moiety and the magnetically isolated $S = 1$ Ni(II) hexaaqua cation. While different in detail to a recently reported Cu(II) trimer, [5] $[Cu_3Cl_{12}]^{6-}$, as far as the structure and bridging is concerned, the magnetism of the two systems are not too dissimilar, both displaying ferromagnetic coupling. The present compound shows a stronger antiferromagnetic trimer–trimer interaction, presumably modulated by the intricate H-bonding pathways to the $[Ni(H_2O)_6]^{2+}$ cations.

4. Experimental

Nickel chloride hexahydrate, copper chloride dihydrate and 15-crown-5 were purchased from Aldrich and used without further purification. Deionised water was used as solvent. The infrared spectrum was recorded as a Nujol mull using sodium chloride plates on a Nicolet Nexus FTIR spectrophotometer. Microanalysis (C, H) was undertaken at the University of Otago, P.O. Box 56, Dunedin, New Zealand. Magnetic susceptibility was measured on a powdered sample contained in a calibrated gelatine capsule using a Quantum Design MPMS 5 SQUID magnetometer operating in a field of 1 T. The instrument was calibrated

against a standard Pd sample supplied by the company and against a chemical calibrant $CuSO_4 \cdot 5H_2O$.

4.1. Synthesis of $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$

Samples of $NiCl_2 \cdot 6H_2O$ (0.125 g, 0.53 mmol), $CuCl_2 \cdot 2H_2O$ (0.09 g, 0.53 mmol) and 15-crown-5 (0.33 g, 1.5 mmol) were dissolved in H_2O (5 cm^3) forming a brown solution which was allowed to evaporate at room temperature. Large brown crystals of the title compound were isolated amongst green crystals of $[\{Ni(H_2O)_4\}_2(\mu\text{-}Cl)_2]Cl_2 \cdot$ 15-crown-5. The brown crystals were collected manually for analysis. FTIR (Nujol)/cm^{-1}: 3364s (br), 1711m, 1654m, 1295m, 1256m, 1092vs, 943s, 839m. *Anal.* Calc. for $C_{20}H_{60}Cl_8Cu_3NiO_{20}$: C, 20.82; H, 5.24. Found: C, 21.22; H, 5.10%.

5. Crystal structure determination

A crystal of $[Ni(H_2O)_6][Cu_3Cl_8(H_2O)_2] \cdot (15\text{-crown-}5)_2 \cdot 2H_2O$ was mounted on a glass fibre using epoxy resin, and a hemisphere of data were collected at room temperature on a Bruker SMART CCD diffractometer using the omega scan mode with total reflections and unique data listed below. Data were collected to a 2θ value of 23.3°, and at this value the structure solution and refinement were very satisfactory. Data were corrected for absorption using the program SADABS [9]. The position of the heavy atoms were found using the Patterson method and refined on F^2 using SHELXL 97-2 [10] with X-SEED [11] as a graphics interface. All non-hydrogen atoms were located and were refined with anisotropic thermal parameters. All hydrogen atoms on water molecules were located and refined with isotropic thermal parameters while those on the crown ether were placed in calculated positions (riding model) and were not refined. Selected bond distances and angles appear in Table 1 and hydrogen bonding parameters are compiled in Table 2.

Abstract

Direct treatment of HOdbp (= 2,6-dibenzylphenol) with strontium or barium metal in the absence of solvent at high temperature provides the corresponding phenolates $Sr(Odbp)_2$ and $Ba(Odbp)_2$. Recrystallisation of $Ba(Odbp)_2$ from THF gave a good yield of the crystalline dimer $[Ba(Odbp)_2(THF)]_2 \cdot 2THF$. Attempted recrystallisation of $Sr(Odbp)_2$ from THF mostly yielded microcrystalline material characterized as $[Sr(Odbp)_2]_n$ but on one occasion gave a small crop of crystalline $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2] \cdot 6THF$ derived from the adventitious reaction of $Sr(Odbp)_2$ with dimethylsilicone grease ($\{OSiMe_2\}_\infty$). In the solid-state $[Ba(Odbp)_2(THF)]_2 \cdot 2THF$ displays significant intramolecular Ba···π-arene interactions with the pendant benzyl substituents. $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2] \cdot 6THF$ features a square prismatic $[Sr(O_2SiMe_2)_4]^{6-}$ core capped by two *inverse crown*-like square $[Sr_4(Odbp)_4(OH)(L)_4]^{3+}$ units, where L = OH_2 or THF, that are staggered with respect to the cuboidal core.

Keywords: Strontium; Barium; Phenolates; X-ray crystal structures

1. Introduction

There has been significant recent interest in alkaline earth phenolate chemistry, focussing particularly on strontium and barium, due to their potential use as precursors to form binary and ternary oxides via sol–gel or MOCVD processes [1]. By a judicious choice of ligands, complexes may be isolated that have significant but weak M···π-arene interactions. These interactions can have implications for reactivity due to their potential displacement by stronger binding, small molecules. Phenolate ligands with aryl groups in the 2,6-positions have the inherent functionality to induce such interactions and this has been the subject of many of our previous investigations. Primarily we have been concerned with the 2,6-diphenylphenolate (Odpp) ligand and have uncovered some interesting interactions in the solid state with both rare earth [2,3] and alkaline earth metals [4].

The phenolate chemistry of strontium and barium is dominated by the formation of aggregates or insoluble polymeric material, particularly when relatively non-bulky phenolate ligands are used. In most cases, isolable material is only obtained when polar donor solvents such as THF [5], HMPA (= hexamethylphosphoramide) [6,7] or TMEDA (=*N*,*N*′-tetramethylethylenediamine) [7] are used to de-aggregate the clustered compounds. When bulkier phenols such as 2,6-di-*tert*-butyl-4-X-phenol (X = methyl, *tert*-butyl) are used, monomeric and dimeric complexes can be isolated, but again, solvated species dominate [8]. We have recently shown that homoleptic calcium, strontium and barium 2,6-diphenylphenolate (Odpp) complexes can be synthesised by the high temperature, solvent-free

doi:10.1016/j.poly.2006.05.003

reactions of the metals with HOdpp. In the absence of coordinating solvent these compounds display M···π-interactions with the adjacent phenyl rings [4]. The Odpp ligand has shown great versatility in displaying π-arene interactions in homoleptic complexes, and more recently we have been pursuing the chemistry of a closely related ligand system; 2,6-dibenzylphenolate (Odbp) where the 2,6-positions of the phenol are occupied by functional groups that not only possess the capacity for π-arene coordination, but also the rotational flexibility to occupy spatial voids about the metal centre [9]. We now turn our attention to Odbp chemistry involving the heavier alkaline earth metals strontium and barium, and describe the direct high temperature treatment of these elements with the phenol (HOdbp) in the absence of solvent.

2. Experimental

2.1. General procedures

2,6-Dibenzylphenol was prepared via literature procedures [10]. The alkaline earth metals used were purchased from Aldrich Chemical Co. as metal ingots which were manually filed into metal powder in an inert atmosphere for use in reactions. Hexane, toluene and THF were dried over sodium and distilled over sodium or sodium benzophenone ketyl prior to use. All manipulations were performed using conventional Schlenk or glovebox procedures under an atmosphere of high purity dinitrogen in flame-dried glassware. IR spectra were recorded as Nujol mulls on sodium chloride plates on a Perkin–Elmer 1600 FTIR spectrophotometer. ^{1}H NMR spectra were recorded at 300.13 MHz and ^{13}C{^{1}H} NMR spectra were recorded at 75.46 MHz using a Bruker DPX 300 spectrometer with chemical shifts referenced to the residual ^{1}H or ^{13}C resonances of the *deutero*-benzene solvent (δ 7.16 and 128.39 ppm, respectively). Melting points were determined in sealed glass capillaries under dinitrogen and are uncalibrated. Satisfactory microanalyses for compounds **1** and **3** could not be obtained due to consistent solvent loss for **3** and problems associated with incomplete combustion of the samples [11].

2.2. Synthesis of $Sr(Odbp)_2$ (**1**)

HOdbp (0.20 g, 0.729 mmol), strontium metal (0.063 g, 0.364 mmol) and Hg metal (two drops) were sealed in an evacuated Carius tube. The reaction vessel was heated at 180 °C for 4 days yielding a pale yellow solid. The solid was extracted into THF (30 ml) and concentrated (2 ml). The solution changed to pale green upon standing at room temperature and very small colourless crystals of **1** deposited (0.18 g, 40%) m.p.: 159–162 °C. ^{1}H NMR (C_6D_6, 298 K): δ 7.16–6.92 (m, 20H, *o*,*m*,*p*-H(Ph)), 6.89 (m, 4H, *m*-H central ring), 6.75 (m, 2H, *p*-H central ring), 3.76 (s, 8H, CH_2–Ph); ^{13}C{^{1}H} NMR (C_6D_6, 298 K): δ 147.9, 139.0, 128.3, 127.8, 127.6, 126.5, 125.3, 119.7 (s, Ar*C*), 35.5 (s, *C*H_2–Ph); IR (Nujol) ν/cm^{-1}: 1601m, 1452m, 1389s, 1326m, 1270s, 1229s, 1073m, 1030s, 977s, 911s, 856w, 822w, 793w, 756s, 699s.

2.3. Isolation of $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2]\cdot 6THF$ (**2**)

In one reaction involving the synthesis of compound **1** (0.23 g, 0.839 mmol HOdbp, 0.037 g, 0.419 mmol strontium metal), several small diamond shaped crystals grew during recrystallisation from THF over several weeks. Other than the crystal structure there was insufficient material for further analysis.

2.4. Synthesis of $[Ba(Odbp)_2(THF)]_2\cdot 2THF$ (**3**)

HOdbp (0.20 g, 0.729 mmol) was heated to 180 °C for 4 days with barium metal (0.05 g, 0.36 mmol) and Hg metal (two drops) in an evacuated and sealed Carius tube resulting in the formation of a pale yellow solid. This was extracted into THF (30 ml) and concentrated (2 ml). Colourless rectangular-shaped crystals formed at room temperature (0.26 g, 43%) m.p.: 238–242 °C. ^{1}H NMR (C_6D_6, 298 K): δ 7.16–6.86 (m, 48H, *Ph* + *m*-H central ring), 6.72 (m, 4H, *p*-H central ring) (s, 16H, CH_2–Ph), 3.59 (m, 8H, OCH_2, THF), 1.44 (m, 8H, CH_2, THF); ^{13}C{^{1}H} NMR (C_6D_6, 298 K): δ 155.6, 151.8, 129.7, 127.9, 126.3, 120.2, 119.2, 109.4 (s, Ar*C*), 71.0, 35.7 (s, THF), 29.7 (s, *C*H_2–Ph); IR (nujol) ν/cm^{-1}: 1600m, 1451m, 1389s, 1311m, 1264s, 1230s, 1073m, 1030s, 950w, 922w, 895w, 848w, 830w, 794w, 755s, 734m, 698s.

2.5. X-ray crystallography

Crystalline samples of compounds **2** and **3** were mounted on glass fibres in highly viscous silicone oil at 123(2) K. A summary of crystallographic data can be found below. Hydrogen atoms were refined in calculated positions (Riding model) for both compounds. Data were collected on an Enraf-Nonius Kappa CCD diffractometer using graphite monochromated Mo Kα X-ray radiation ($\lambda = 0.71073$ Å). Data were corrected for absorption by the DENZO-SMN package [12]. Lorentz polarisation and absorption corrections were applied. Structural solution and refinements were carried out using the SHELX suite of programs [13] with the graphical interface X-Seed [14].

2.6. X-ray crystal data for $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2]\cdot 6THF$ (**2**)

$C_{216}H_{256}O_{32}Si_4Sr_9$, $M = 4265.14$, diamond-shaped pale yellow, $0.20 \times 0.20 \times 0.20$ mm, monoclinic, space group $P2_1/n$ (no. 14), $a = 23.393(5)$ Å, $b = 17.550(4)$ Å, $c = 24.936(5)$ Å, $\beta = 99.59(3)°$, $V = 10094(4)$ Å^3, $Z = 2$ (nonanuclear units), $D_c = 1.403$ g/cm^3, $F_{000} = 4412$, $2\theta_{max} = 50°$, 65469 reflections collected, 17708 unique ($R_{int} = 0.1916$). Final GooF = 1.012, $R_1 = 0.0984$, $wR_2 = 0.1932$, R indices based on 8005 reflections with $I > 2\sigma(I)$ (refinement on F^2),

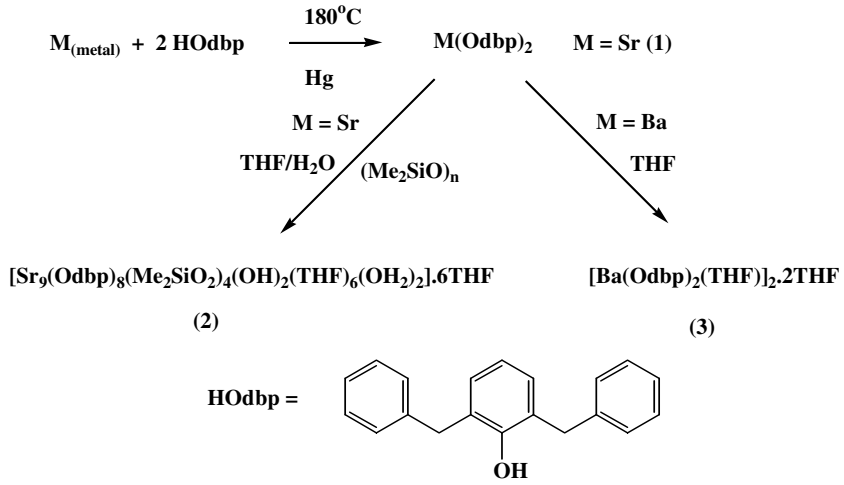
Symmetry operation used to generate equivalent (#) atoms: $-x, -y, -z$.

1135 parameters, 153 restraints. Lp and absorption corrections applied, $\mu = 2.451$ mm^{-1} (see Table 1).

Variata. The dataset was poor but the connectivity is irrefutable. The phenyl group of one benzyl group of one phenolate was disordered over two sites of partial occupancy that are coincident at the *ipso* carbon (C722). These were refined with partial occupancies of 55 and 45%. To obtain satisfactory thermal parameters an ISOR refinement (0.01) was necessary for carbon atoms 82, 86, 121, 122, 123, 124, 726, 727, 762–767, 861, and THF oxygen O12. The hydrogen atoms on O10 and O13 were not located from difference maps despite repeated attempts to do so.

2.7. X-ray crystal data for $[Ba(Odbp)_2(THF)]_2\cdot 2THF$ (**3**)

$C_{48}H_{50}BaO_4$, $M = 828.22$, colourless rectangular prism, $0.20 \times 0.10 \times 0.10$ mm, triclinic, space group $P\bar{1}$ (no. 2), $a = 10.179(2)$ Å, $b = 12.514(3)$ Å, $c = 16.174(3)$ Å, $\alpha = 82.26(3)°$, $\beta = 73.54(3)°$, $\gamma = 85.21(3)°$, $V = 1955.6(7)$ Å^3, $Z = 2$, $D_c = 1.407$ g/cm^3, $F_{000} = 852$, $T = 2\theta_{max} = 56.4°$, 22 763 reflections collected, 9427 unique ($R_{int} = 0.0675$). Final GooF = 1.024, $R_1 = 0.0520$, $wR_2 = 0.0986$, R indices based on 7022 reflections with $I > 2\sigma(I)$ (refinement on F^2), 488 parameters, 0 restraints. Lp and absorption corrections applied, $\mu = 1.060$ mm^{-1}.



Variata. There was disorder in one THF carbon (C42) and this was modelled over two sites with 75:25% occupancy.

3. Results and discussion

The high temperature (180 °C) treatment of strontium or barium metal with HOdbp (ratio 1:2) in the presence of two drops of mercury for four days in a sealed Carius tube results in the complete consumption of metal to yield pale yellow solids (Scheme 1). Several drops of mercury metal were added to the reaction mixture to form a reactive group 2 amalgam. After extraction of the residues from the Carius tubes using THF (both compounds had negligible solubility in the relatively non-polar solvents hexane or toluene) $Sr(Odbp)_2$ (**1**) and $[Ba(Odbp)_2(THF)]_2\cdot 2THF$ (**3**) (latter composition based on X-ray crystallography) were isolated in moderate yields. Both compounds were characterised by IR, ^{1}H and ^{13}C{^{1}H} NMR spectroscopy. ^{1}H and ^{13}C{^{1}H} NMR spectra were performed in *deuterated* benzene in which the compounds had only slight solubility. The ^{1}H NMR spectra of both compounds showed no resonances for the phenolic protons at approximately 4.6 ppm and the IR spectra also had no indication of O–H stretching at 3560 cm^{-1} [9b] demonstrating complete deprotonation of 2,6-dibenzylphenol in both reactions. The ^{1}H NMR spectrum of compound **1** did not display any resonances for THF, indicating that any THF of solvation was easily lost upon isolation. The integration of the ^{1}H NMR spectrum of compound **3** shows a THF to phenolate ratio of 1:2, indicating that lattice THF was lost during isolation from the mother liquor. Although observation of a single set of ^{1}H resonances is inconsistent with the dimeric structure of **3** (below), which has both terminal and bridging Odbp ligands, and the likely structure of **1**, analogous behaviour has been observed for $[M(Odpp)_2]_2$ (M = Ca, Sr, Ba [4], Yb [2]). Thus, either the bridging and terminal resonances are not resolved, there is rapid ligand exchange, or C_6D_6 cleaves the bridges to give symmetrical monomeric structures. π-Interactions from benzene rings to the heavier alkaline earth metals are receiving increasing attention [15], e.g. $[Ba(\eta^6\text{-PhMe})_2\{Zn(SiMe_3)(CH_2SiMe_3)_2\}_2]$ [15c], hence bridge cleavage at high dilution in C_6D_6 is plausible. We have also found that monomeric Ca and Sr formamidinates with unsymmetrical solid state environments also show a single set of ^{1}H (and ^{13}C) resonances in solution [16].

In one reaction involving the synthesis of compound **1** a few small crystals of $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2]\cdot 6THF$ (**2**) were isolated after leaving the product in THF over several weeks (see Section 2.3). The presence of O_2SiMe_2 groups in the structure is indicative of reaction between $Sr(Odbp)_2$ and the high vacuum dimethylsilicone grease used to seal ground glass joints. This grease is generally regarded as chemically inert, though there are a number of examples in the literature where $OSiMe_2$ and $O(SiMe_2O)_n$ groups have been incorporated into structures [17]. The presence of water and hydroxide in the structure highlights the water sensitivity of these complexes and indicates that **2** was isolated following partial hydrolysis.

The strontium phenolate–siloxane cluster/cage complex, $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2]\cdot 6THF$ (**2**) (Fig. 1), Table 1 for selected bond lengths and angles crystallised in the monoclinic space group $P2_1/n$. Half of the molecule is symmetry generated to give a nonanuclear

Scheme 1.

species (Fig. 1a) comprised of a central $[Sr(O_2SiMe_2)_4]^{6-}$ (see Fig. 1b) core surrounded by eight $Sr(Odbp)^+$ units and two hydroxide ligands (O(13), O(13′)) bound in central clefts of two square faces of the cage. THF and water molecules complete the coordination spheres of the strontium atoms (Fig. 1a). The core (Fig. 1b) consists of an eight coordinate close to ideal cuboid strontium ion, Sr1, which is chelated by four O_2SiMe_2 groups. The oxygen atoms of

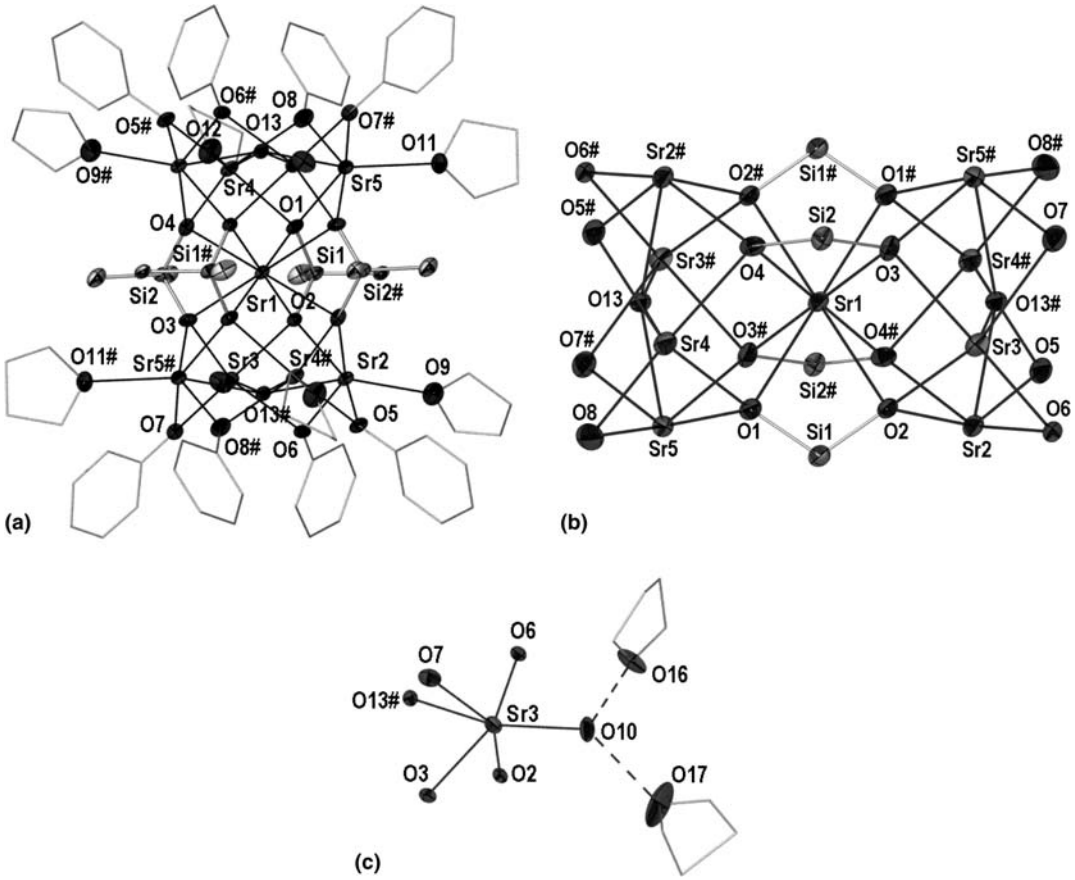


Fig. 1. Molecular structure of the centrosymmetric nonanuclear $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2] \cdot 6THF$ (**2**). Thermal ellipsoids are shown at the 40% level. (a) Entire molecule. '#' Atoms generated using symmetry transformation $-x, -y, -z$. All hydrocarbons (except methyl groups of O_2SiMe_2) groups represented as wire frames. Benzyl groups of phenolates, lattice THF molecules and hydrogen atoms omitted for clarity. (b) Central cage (side view). '#' Atoms generated using symmetry transformation $-x, -y, -z$. All neutral donors, O_2SiMe_2 methyl groups and phenolate hydrocarbon groups omitted. (c) Illustration depicting proposed H-bonding interaction between O10 (coordinated OH_2 on Sr3) and two lattice THF molecules. Distances (Å) and angles (°): O10···O16 2.713(17), O10···O17 2.754(27); O16···O10–Sr3 125.5(6), O17···O10–Sr3 138.1(9), O16···O10···O17 99.6(9).

the O_2SiMe_2 groups μ_3-bridge to the remaining eight strontium ions on the exterior of the central SrO_8. These strontium ions are in two square units (each with two symmetry generated and two non-symmetry generated Sr atoms) that sandwich and are staggered with respect to the cuboidal $[Sr(O_2SiMe_2)_4]^{6-}$ core. Four phenolate ligands bridge the four edges of each square tetrastrontium unit. Within these, Sr2 is bound to a THF molecule and a phenolate bridges to Sr3. Sr3 is bound to two oxygen atoms of the O_2SiMe_2 groups, as well as to a phenolate that bridges to Sr5, which is bound to a terminal THF molecule, two oxygen atoms (O_2SiMe_2) and a bridging phenolate (to Sr4). Sr4 is bound to two bridging phenolates (bridging to Sr2 and Sr5) and three oxygen atoms. Two belong to O_2SiMe_2 groups and one to a lone hydroxide oxygen atom O13. Each of the four exterior Sr atoms is six coordinate and has distorted octahedral geometry. O10 is considered to be a water molecule bound to Sr3 and is hydrogen bonded to two THF molecules using the two water protons (Fig. 1c). This implies that the μ_4-O O13 is an OH^- ion for correct charge balance (see Table 1).

Compound **3**, $[Ba(Odbp)_2(THF)]_2 \cdot 2THF$ (Fig. 2, Table 2a), crystallises in the triclinic space group $P\bar{1}$ with one half of the centrosymmetric dimer as the asymmetric unit. The dimer is comprised of one terminal phenolate, one terminal THF molecule and two bridging phenolates generating an oxygen coordination number of four for the barium atom. Supplementing the O–Ba bonds are Ba···π-arene interactions from one of the pendant phenyl rings on the bridging phenolate, and another from a phenyl ring on the terminal phenolate, increasing the coordination number formally to seven. The Ba–O (bridging phenolate) bond distances are 2.649(3) and 2.655(3) Å, respectively. The Ba–O (terminal) bond distance is 2.475(3) Å, which is shorter than the bridging Ba–O bond distances as expected. The structural motif of compound **3** is significantly different from that of $[Ba(Odpp)_2]_2$ which contains three bridging phenolates between the two metal centres and one terminal phenolate at one barium, leaving the second barium atom formally 'naked' on one face [4]. The Ba–O (terminal) bond distance for $[Ba(Odpp)_2]_2$ is 2.488(2) Å, whilst the average

'#' Atoms generated using symmetry transformation: $-x+2$, $-y+2$, $-z+1$.

Ba–O (bridging) bond distance is 2.750(2) Å which is significantly longer than in **3**. The metal oxygen array leaves the metal naked allowing arene interactions to occur between the pendant phenyl rings on the bridging phenolates (η^1 and η^6). The Ba···C average distance is 3.33(4) Å, with the longest distance being 3.434(4) Å. A cut-off distance of distance for Ba···π-arene interactions of 3.48 Å was formulated based on limits set for $[(\eta^6\text{-PhMe})BaSn_3(\mu\text{-PSiBu}^t_3)_4]$ [18]. If these limits are used for compound **3**, then there would be only an η^2 interaction between Ba1 and C8, C9 of the phenyl group on the bridging phenolate. However, closer inspection of the Ba···C distances (Table 2b) indicates that there are further plausible contacts. Thus, if the limit is extended beyond 3.48 Å to ca. 3.52 Å, then the barium atom is bound in an η^4 fashion to one aromatic ring and η^1 to another. Further inspection of the Ba···C distances indicates a demarcation in distances at this point (Table 2b), wherein any further Ba···C contacts would be considerably longer. An interesting feature of compound **3** is that the barium atom involves itself in π-arene interactions preferentially over further THF coordination. This has been previously been observed in alkali metal complexes involving these ligands [9c]. The only other barium phenolate Lewis acid adduct that does not contain other donor

Table 2b

atoms (e.g. I, Br, Cl) is the monomeric complex $[Ba(OC_6H_2Bu^t_2\text{-}2,6\text{-}Me\text{-}4)_2(THF)_3] \cdot THF$ of Hanusa et al. [8b] The three Ba–O(THF) bond distances for $[Ba(OC_6H_2Bu^t_2\text{-}2,6\text{-}Me\text{-}4)_2(THF)_3] \cdot THF$ are 2.72(1), 2.73(1) and 2.75(1) Å and are shorter than the Ba–O(THF) distance found in compound **3** (2.796(3) Å), which has a higher formal coordination number.

4. Conclusions

$M(Odbp)_2$(M = Sr, Ba) complexes were prepared by the solvent-free, high temperature reaction between Sr or Ba metal and HOdbp. Extraction and crystallisation of the compounds from THF resulted in the isolation of $Sr(Odbp)_2$ and $[Ba(Odbp)_2(THF)]_2 \cdot 2THF$. Crystals of the former of suitable quality for X-ray structure determination were not obtained but the absence of THF from the compound was evidenced spectroscopically. A small yield of $[Sr_9(Odbp)_8(O_2SiMe_2)(OH)_2(THF)_6(OH_2)_2] \cdot 6THF$ was obtained from one recrystallisation of $Sr(Odbp)_2$. The X-ray crystal structures of $[Sr_9(Odbp)_8(O_2SiMe_2)_4(OH)_2(THF)_6(OH_2)_2] \cdot 6THF$ and $[Ba(Odbp)_2(THF)]_2 \cdot 2THF$ show interesting features. The former is constructed from a $[Sr(O_2SiMe_2)_4]^{6-}$ core surrounded by eight THF/H_2O coordinated "$Sr(Odbp)^{+}$" units with two hydroxide ligands residing in clefts. $[Ba(Odbp)_2(THF)]_2 \cdot 2THF$ displays significant Ba···π-arene interactions with pendant benzyl substituents on both bridging and terminal phenolates.

5. Supplementary material

Crystallographic data (excluding structure factors) for **2** and **3** have been deposited with the Cambridge Crystallographic Data Centre as supplementary numbers CCDC – 601930 for compound **2** and CCDC – 601929 for compound **3**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk).

Abstract

We report density functional theoretical investigations of the experiments described by Pilgrim and Duncan [J.S. Pilgrim, M.A. Duncan, J. Am. Chem. Soc., 115 (1993) 6958] in which $[Fe_xC_y]^+$ clusters are generated by laser vapourisation of Fe atoms in a plasma containing acetylene. Many possible structures for the clusters $[Fe_{12}C_{12}]$, $[Fe_{10}C_{12}]$, $[Fe_8C_{12}]$, $[Fe_6C_{12}]$, $[Fe_4C_{12}]$, $[Fe_3C_{12}]$ and $[Fe_2C_{12}]$ are evaluated, with the following conclusions: $[Fe_{12}C_{12}]$ is a slightly distorted $2 \times 3 \times 4$ nanocrystallite fragment of a face-centered cubic FeC lattice; $[Fe_{10}C_{12}]$ is distorted $[Fe_{12}C_{12}]$ depleted by two three-coordinate Fe atoms; $[Fe_8C_{12}]$, with the prototypical composition for metallocarbohedrenes, has a C_{3v} structure containing only C_2 groups and with a short axial Fe—Fe bond; $[Fe_6C_{12}]$ has the $[Fe_8C_{12}]$ structure but without the two axial Fe atoms, such that each C_2 group has two end-on Fe—σ—C_2 bonds and one side-on Fe—π—C_2 interaction; at $[Fe_4C_{12}]$ there are two cumulenic C_6 chains separated by four Fe atoms; $[Fe_3C_{12}]$ is a monocyclic alternation of cumulenic C_4 chains and Fe atoms, while $[Fe_2C_{12}]$ is a monocyclic alternation of cumulenic C_6 chains and Fe atoms. Mechanisms are proposed for the experiments in which photodissociation of Fe atoms converts $[Fe_{12}C_{12}]$ to $[Fe_8C_{12}]$, and in which $[Fe_8C_{12}]$ photodissociates to $[Fe_6C_{12}]$, $[Fe_4C_{12}]$, and $[Fe_2C_{12}]$. The formation of C—C bonds and of C_n chains initiated by the withdrawal of Fe atoms in these processes is related to the Fe catalysed formation of carbon nanotubes.

1. Introduction

In the last decade a variety of types and instances of metal carbon binary molecules have been uncovered experimentally, including (1) endohedral, exohedral, and networked metallofullerenes MC_n [1–9], (2) graphitic and ring structures MC_n [1,5,7,10], (3) metallocarbohedrenes (metcars) M_xC_y with C_2 groups [11–52] and (4) nanodimensional fragments of MC lattices containing C atoms [25,28,30,40–42,52–55]. These unprecedented and unpredictable systems raise many fundamental questions, and suggest opportunities for further scientific and technological development. All of this experimental work has involved molecules or ions in the gas phase: the principal experimental information on them involves their stabilities to dissociation [19,21,35,45,53], and their reactions with a range of molecules including oxygen, water, acetonitrile, ammonia, benzene, alkyl halides, alcohols, and acetone [14,15,26,31–33,37,39,42,45,55,56]. Bowers et al. have determined their collisional cross-sections, measured as drift times through inert gas [57–59]. Wang et al. have applied a photoelectron spectroscopic technique to measure electron affinities of a range of species [47,49]. Duncan and coworkers have reported IR data for several M_xC_y species [60–63].

Since the first report of Ti_8C_{12} in 1992 [13], most attention has concentrated on the dominant metallocarbohedrene $M_8(C_2)_6$, and on the nanocrystallite class of clusters M_xC_y in which $y/x \sim 1$. The metallocarbohedrenes are polyhedral frameworks of M atoms and C_2 groups

(in some cases with C_n higher than C_2). In contrast, the gas-phase nanocrystallites are regarded as fragments of the face-centered cubic lattice adopted by the non-molecular solid MC compounds, and are believed to contain only (or predominantly) C atoms bonded to M. Experimentally the classification of M_xC_y clusters as metallocarbohedrenes or nanocrystallites is based largely on the stable compositions observed mass spectrometrically, and on their dissociation behavior. The structural differentiation (not proven experimentally) is that metallocarbohedrenes possess C—C bonds while nanocrystallites do not, although this is an oversimplification because it is likely that many observed clusters contain both isolated C atoms and C—C bonded groups. A significant type of experiment is the photoextrusion of metal atoms from M_xC_y, because these processes must at some stage involve C—C bond formation. The sequence of photoextrusions from $[Ti_{14}C_{13}]^+$ to $[Ti_8C_{13}]^+$ has been described experimentally [53] and theoretically [64]. This paper models photoextrusion experiments for $[Fe_xC_y]^+$ clusters [35].

One of the questions in this research is the influence of the electronic properties of the metal in the formation and stabilisation of the various types of M_xC_y clusters. Early first transition series metals such as titanium show super-abundance of the composition $[M_8C_{12}]^+$ and to a lesser extent the composition $[M_{14}C_{13}]^+$. Tantalum shows only compositions with $y/x \sim 1$ [65,66], while Nb [54,40] and Fe [35] have complicated abundance distributions that are highly sensitive to formation conditions.

The $[Fe_xC_y]$ clusters are generated in pulsed laser vapourisation sources, in which ablated Fe atoms aggregate while cooling in the presence of hydrocarbon, which is dehydrogenated [35]. The experimental distribution of cations $[Fe_xC_y]^+$ (Fig. 1) has a range of abundant species with a C/Fe ratio between 1 and 1.5. The most abundant $[Fe_xC_y]^+$ species have $x/y = 7/8$, 8/9, 8/10, 8/11, 8/12, 9/10, 10/11, 11/12 and 12/12. While the 8/12 composition

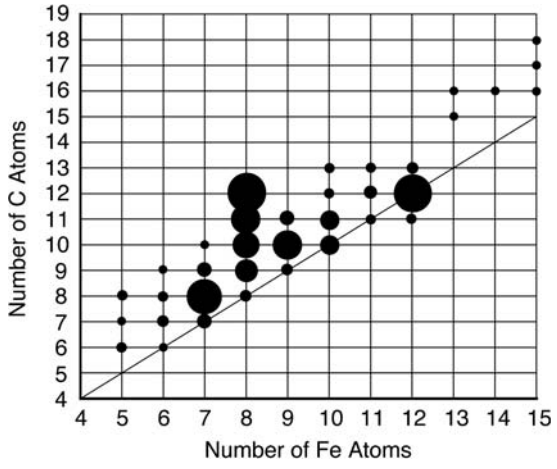

Fig. 1. Map of the observed compositions of binary $[Fe_xC_y]^+$ clusters produced by laser vapourisation of Fe metal and cooling/clustering in acetylene (from Ref. [35]). Dot size indicates observed relative abundance. The diagonal line emphasises the 1:1 Fe:C ratio.

is strong for Fe it does not display the super-abundant behaviour observed for Ti, V, Hf, and Cr. The $[Fe_{14}C_{13}]^+$ species is not observed, while $[M_{14}C_{13}]^+$ is often particularly abundant for earlier transition metals.

Pilgrim and Duncan [35] have made photodissociation measurements on $[Fe_{12}C_{12}]^+$ and $[Fe_8C_{12}]^+$ and report the following results:

$$[Fe_{12}C_{12}]^+ \rightarrow [Fe_8C_{12}]^+ \text{ (major)},\ [Fe_7C_{12}]^+ \text{ and } [Fe_6C_{12}]^+ \text{ (both minor)}$$

$$[Fe_8C_{12}]^+ \rightarrow [Fe_xC_{12}]^+ \quad \text{for } x = 7, 6, 5, 4, 3, 2.$$

Each of the intermediates in the photoextrusion sequence from $[Fe_8C_{12}]^+$ to $[Fe_2C_{12}]^+$ is observable, but intermediates in the $[Fe_{12}C_{12}]^+ \rightarrow [Fe_8C_{12}]^+$ transformation were not observed. Similar results were obtained for photodissociation of $[Cr_8C_{12}]^+$ [35]. The long sequences of metal dissociation from $[M_8C_{12}]^+$ when M is Fe and Cr are not observed for other metals Ti, V, Mo [35]. The photodissociation experiments were not time-resolved and so differentiation between sequential and concerted loss of metal atoms was not possible.

The observed $[Fe_xC_y]$ clusters (Fig. 1) and their photodissociation behaviour raise the following questions: (1) What are the probable geometric structures of the observed $[Fe_xC_y]$ clusters, and what are the important structural principles for these species? (2) What are the general bonding principles of these species? (3) What are the mechanisms for the dissociative rearrangements of these clusters and why is carbon–carbon bond formation seemingly more efficient in the iron and chromium systems?

In this paper we report density functional calculations on $[Fe_{12}C_{12}]$, $[Fe_{10}C_{12}]$, $[Fe_8C_{12}]$, $[Fe_6C_{12}]$, $[Fe_4C_{12}]$, $[Fe_3C_{12}]$, and $[Fe_2C_{12}]$, with the primary aim of determining the most favourable structures for the $[Fe_xC_{12}]^+$ compositions observed in the dissociation series, and the probable mechanisms for the transformations between these compositions. The $[Fe_xC_{12}]$ species discussed here are larger than those already treated theoretically in the literature. For smaller $[Fe_xC_y]$ clusters ($x = 1,2,3$, $y = 2$–8), gas phase ion mobility experiments have yielded some structural information, and favour segregation of atoms of the same element in cyclic or bicyclic structures [57].

We note that C—C bond formation catalysed by Fe clusters is a significant part of the generation of carbon nanotubes. While the systems described here are smaller than those involved in catalysed nanotube growth, the extrusion of Fe atoms concomitant with C—C bond formation is analogous to the process where the growing nanotube is separating from the Fe nanoparticle [67,68].

2. Methodology

The general strategy for structure investigation involved postulation of possible structures for each composition, optimisation of those structures by energy minimisation, and comparison of binding energies for each isomer: this

follows previous investigations of MnS [69] and NbC clusters [70]. The postulation of structures for the $[Fe_xC_y]$ clusters was based on knowledge of: (1) geometrical isomerism for other carbohedrenes of the early transition metals; (2) the structural principles for Nb_xC_y clusters [71]; (3) the regular fragments of the cubic MC lattice, as suggested by Duncan [53]. In addition, we use the similarities between the structures of clusters M_xE_y for E = S, O and $E = C_2$ [71].

Density functional calculations used the program DMol, v2.36 and v960 [72–74]. The density functionals used are the Lee–Yang–Parr functional for correlation [75] and Becke for exchange [76], including non-local corrections which were applied post-SCF: this has been validated for metal acetylide clusters [77]. Double numerical basis sets [74] included polarisation functions for metals and carbon. Calculations were spin-restricted, and core orbitals were frozen. The electronic states of the molecules were not specified in the initial calculations: by use of smearing of electron population close to the Fermi level, the optimisation was allowed access to low-lying electronic states. This is desirable in the initial investigation of the gross features of the geometry–energy surfaces, where various electronic states could be involved, and the objective is to locate the most stable structures. Subsequent energy minimisation for each principal geometrical isomer focussed on its electronic ground state, by reducing any population smearing to zero. Energy surfaces for specific ground or excited electronic states have not been explicitly evaluated.

Postulated structures were initially optimised in the highest possible Abelian symmetry. For each structure, once the overall geometry was optimised in this symmetry, the structure was evaluated further by optimisation after distortion and reduction of symmetry. This provided insight into the quality of the stationary point on the energy hypersurface (saddle point or minimum), and the steepness of the gradients. The energies presented and tabulated do not include zero-point or thermal corrections.

In order to locate transition states and determine activation energies, a reaction path following (RPF) methodology was employed. Our procedure started by testing various structures near a postulated transition state until two structures were found, one (**P**) which optimised without constraints to the product and one (**R**) which optimised to the reactant. The geometrical average of these two structures (**A1**) was then optimised, resulting in the geometry of either the product or reactant via **P** or **R**. The geometrical average of **A1** and the member of the set **P**, **R** to which **A1** does not optimise is the next estimate of the transition state, **A2**. This hill-climbing algorithm is repeated until two consecutive geometrically averaged structures (**Ax** and **Ax + 1**) are identical.

3. Results

The results for the geometric structures of species in the dissociation series are presented in sequence from the largest composition $[Fe_{12}C_{12}]$ to the smallest $[Fe_2C_{12}]$, as many of the structures for smaller species are conceived in terms of depletion of larger structures. Isomeric structures for the composition Fe_xC_y are labelled as **x/yA**, **x/yB**, **x/yC**, etc., in order of decreasing stability for each x/y. The energies E_R (kcal mol^{-1}) are for the uncharged species, relative to the most stable isomer for each composition. In the figures (Fe black, C grey throughout), Fe—Fe bonds are generally not drawn in order to clarify the figures and to emphasise the Fe—C and C—C bonding. Relatively short Fe—Fe distances occur in many structures, and are given on the figures or in captions.

3.1. $Fe_{12}C_{12}$

The $[M_{12}C_{12}]$ composition is of particular interest as it is either not abundant or unobserved for M other than Fe, and because feasible structures (in terms of coordination number and geometry) may be generated both as nanocrystallite fragments and as metallocarbohedrene analogues. The regular nanocrystallite structure is simply the $2 \times 3 \times 4$ fragment of the cubic crystal lattice, while several distinct metallocarbohedrene structures are generated by capping the M_4 faces of a cuboctahedron of metal atoms with C_2 groups. As in the series of $[Ti_8C_{12}]$ metcar isomers [30], the $[Fe_{12}C_{12}]$ metallocarbohedrene isomers are conceptually related by ca. 90° rotations of C_2 groups. The nanocrystallite structures are calculated to be most stable overall, with relative energies $E_R < 15$ kcal mol^{-1}. The metcar analogues lie in several groupings from 40 to 170 kcal mol^{-1} higher in energy than the nanocrystallite structures. Other less regular species are energetically well above these two structure types.

For $[Fe_{12}C_{12}]^0$ the most stable structure is the $2 \times 3 \times 4$ face-centred cubic crystal fragment with C_{2h} symmetry **12/12A**. However there are two closely related local energy minima, **12/12B** and **12/12C** (Fig. 2), that result from the breaking of Fe—C bonds in **12/12A** (two bonds broken in **12/12B**, four in **12/12C)**, and **12/12C** attains threefold rotational symmetry. The energy minima for these three structures differ by less than 2 kcal mol^{-1}. There is a gap of ~15 kcal mol^{-1} to the next most stable isomer found, **12/12D**, which is generated by removal of the central Fe atom and two apical C atoms from a standard $3 \times 3 \times 3$ nanocrystallite, and results in a structure with D_{3d} symmetry which can also be described as a cuboctahedron of Fe atoms with all six Fe_4 faces capped with a C atom and six of the eight Fe_3 faces capped with a C atom. Capping a regular icosahedron in similar fashion generates **12/12N** which is 200 kcal mol^{-1} less stable; however, if **12/12N** is modified to form six C—C bonds, with retention of symmetry, optimisation leads to **12/12I** which is more than 100 kcal mol^{-1} more stable.

The lowest energy of the metallocarbohedrene structures with C_2 groups is **12/12E**, at $E_R = 42$ kcal mol^{-1}. The six Fe_4 faces of an Fe_{12} cuboctahedron provide likely coordination sites for six C_2 units. It is evident that the C_2 units

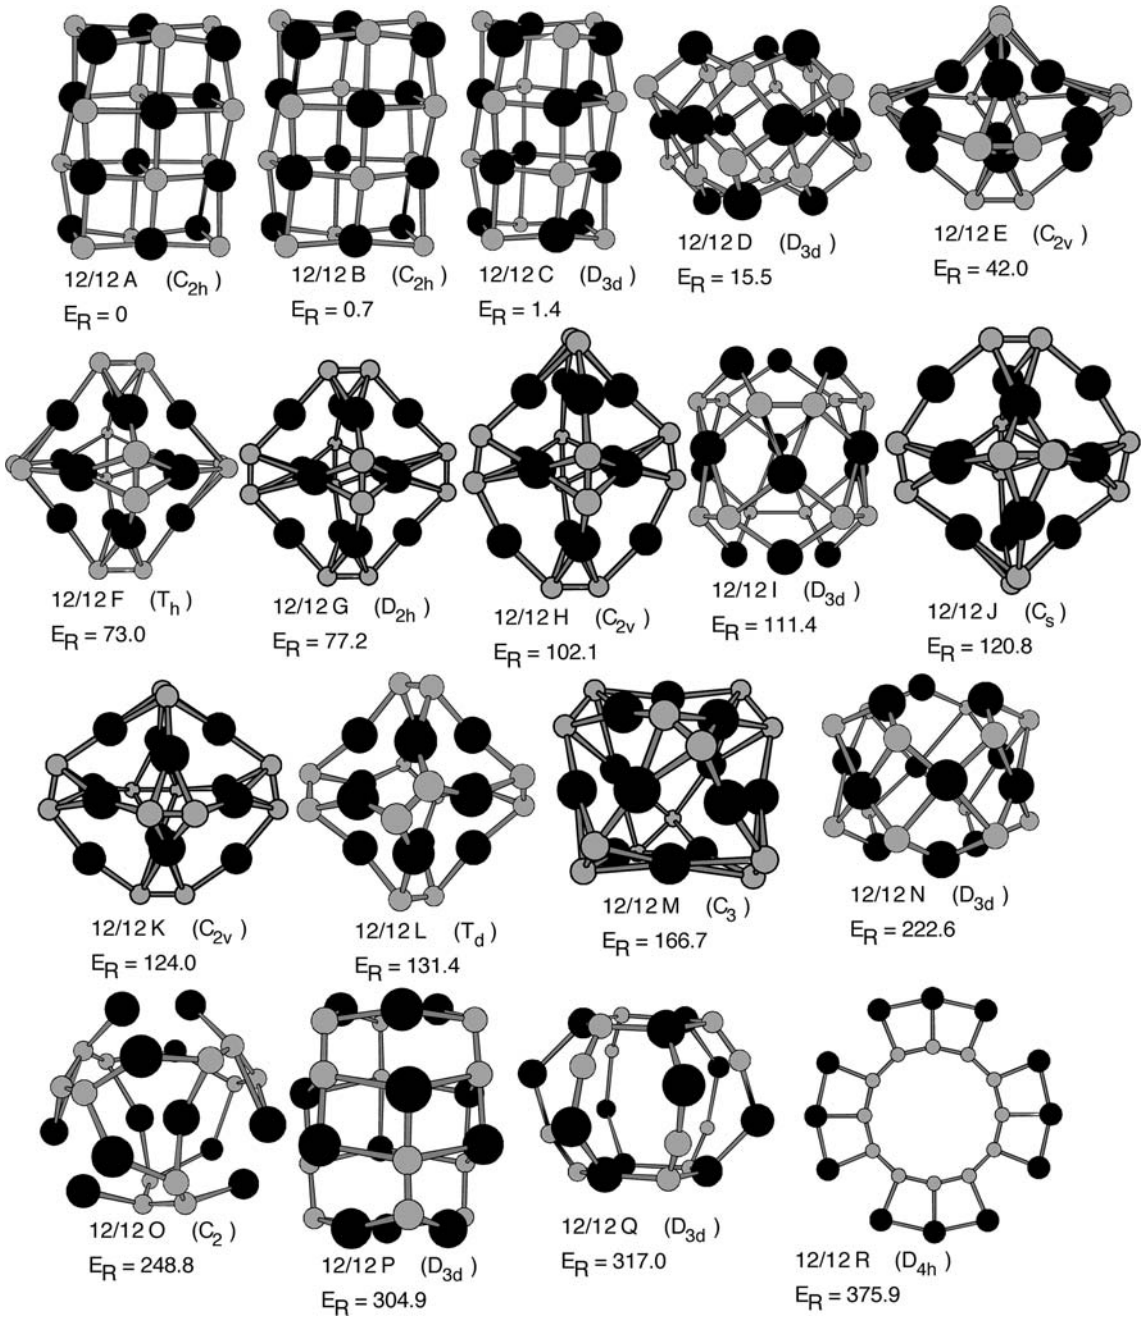

Fig. 2. Optimised structures for $[Fe_{12}C_{12}]^0$ (Fe black, C grey), arranged in order of decreasing stability. E_R is the energy (kcal mol^{-1}) of the uncharged species, relative to that of the most stable structure. Primary symmetry elements of each structure are oriented approximately vertically and in the plane of the page, except as follows: **12/12A** and **B**, horizontal and in the plane of the page; **12/12J** vertical and perpendicular to the plane of the page; **12/12R** perpendicular to the plane of the page. Shortest Fe—Fe distances (Å) are: **12/12A**, **12/12B**, and **12/12C**, upwards from 2.48 to 2.50; **12/12D**, 2.50 around the equator and 2.49 between equatorial and polar Fe atoms; **12/12E**, 2.49 and 2.53; **12/12F** all 20 immediate Fe—Fe distances (edges of icosahedral Fe_{12}) are 2.35 Å; **12/12G**, 2.35, 2.39 for Fe_{equat}—Fe_{polar}, 2.46 for Fe_{polar}—Fe_{polar}; **12/12H**, Fe_{equat}—$Fe_{polar} = 2.46$, Fe_{polar}—$Fe_{polar} = 2.42$; **12/12I**, Fe_{equat}—$Fe_{equat} = 2.41$, Fe_{equat}—$Fe_{polar} = 2.40$, Fe_{polar}—$Fe_{polar} = 2.47$; **12/12J**, Fe_{equat}—$Fe_{polar} = 2.38$, 2.47, Fe_{polar}—$Fe_{polar} = 2.45$, 2.49; **12/12K**, Fe_{equat}—$Fe_{polar} = 2.42$, 2.45, Fe_{polar}—$Fe_{polar} = 2.42$, 2.46; **12/12L**, 2.29, 2.42; **12/12M**, 2.31, 2.37, 2.41.

aligned with the long diagonal of Fe_4 faces provides much greater stability than C_2 bound parallel to the edge of an Fe_4 face (i.e. **12/12L**, $E_R = 131$ kcal mol^{-1}): this agrees with the principle established for the orientations of C_2 groups in $M_8(C_2)_6$ structures [30,78,79]. The other polyhedral metallocarbohedrene structures, **12/12F**, **12/12G**, **12/12H**, **12/12J**, **12/12K**, and **12/12M** have relative energies ranging from 73 to 167 kcal mol^{-1}. Structure **12/12F**, with the high symmetry T_h, is the $M_{12}C_{12}$ analog of the highly symmetric T_d isomer for M_8C_{12}. What is remarkable about **12/12F** is the short Fe—Fe distance, 2.35 Å, indicative of strong Fe—Fe bonding and occurring 20 times in the

icosahedral cluster. Fe—Fe distances of order 2.4–2.5 Å occur throughout all of the stable structures shown in Fig. 2. The shortest Fe—Fe interaction, 2.29 Å, occurs in **12/12L** (neglecting the uncompetitive structures **12/12O** to **12/12R**), which is appreciably less stable, and the most stable metallocarbohedrene structure, **12/12E**, has Fe—Fe distances of 2.48, 2.53 Å, so there is not a correlation between overall stability and short Fe—Fe distances in the range 2.3–2.5 Å. This conclusion is supported by the Fe—Fe distances in the more stable nanocrystallite structures, which are fewer and upwards of 2.48 Å, and suggests the unknown Fe—Fe bonding energy in the $Fe_{12}C_{12}$ clusters is maximized at about 2.45 Å.

The calculated HOMO–LUMO gap for the neutral of **12/12A** is extremely small at 0.02 eV. In fact the orbital manifolds of all three isomers **12/12A**, **B** and **C** in the vicinity of the Fermi level are extremely complex. For **12/12A**$^+$ there are 10 orbitals lying within a range of 0.3 eV at the Fermi level and many other orbitals within 2 eV above and below this. This complex electronic structure complicates determination of the barriers between the isomers as the interconversions may traverse several electronic states. Calculation of the size of the barrier between the isomers is complicated further by the result that optimisation of the geometrical average of **12/12A** and **12/12C** yields **12/12B**. The distortions required to interconvert these three 12/12 isomers are not the same as the distortions noted for the Nb_xC_y nanocrystallites [70] (indeed such distortions are not evident in the Fe_xC_y series). The differences between **12/12A**, **12/12B** and **12/12C** seem to be a compromise between the number of Fe—C bonds and the amount of stereochemical strain at each atom.

In attempt to rationalise the pronounced abundance of $[Fe_{12}C_{12}]$ in the $[Fe_xC_y]^+$ spectra we have calculated the binding energies per atom and ionisation energies (IE) of the $2\times3\times4$ and $3\times3\times3$ nanocrystallites for Fe, in comparison with Ti (Table 1). The calculated normalised binding energies for $[M_{12}C_{12}]$ and $[M_{14}C_{13}]$ are very similar for M = Fe and Ti. The reason for the superabundance of $[Ti_{14}C_{13}]^+$ is traced to the low ionisation energy of the neutral, which is almost identical to the calculated IE for $[Ti_8C_{12}]^0$ of 4.42 eV. While the calculated IE of $[Fe_{14}C_{13}]$ is much closer to that of the more experimentally abundant $[Fe_{12}C_{12}]$, it is still the lower of the two by almost 0.5 eV, and therefore the reason behind the disparate relative abundances of $[Fe_{12}C_{12}]^+$ and $[Fe_{14}C_{13}]^+$ remains unclear.

Table 1
Calculated ionisation energies (eV) and binding energies (kcal mol^{-1}) per atom for titanium and iron nanocrystallites, assuming the favourable regular nanocrystallite geometries

Species	Binding energy per atom (uncharged species)	Ionisation energy
$Ti_{12}C_{12}$	−136.4	5.64
$Ti_{14}C_{13}$	−137.6	4.41
$Fe_{12}C_{12}$	−110.9	6.81
$Fe_{14}C_{13}$	−112.9	6.35

3.2. $Fe_{10}C_{12}$

The cluster $[Fe_{10}C_{12}]^+$ is not observed in the photodissociation spectrum of $[Fe_{12}C_{12}]^+$ and has only minor abundance in the nascent ablation spectrum. It is, however, a possible intermediate in the dissociation process $[Fe_{12}C_{12}]^+ \rightarrow [Fe_8C_{12}]^+$, and the structures proposed (Fig. 3) are generated with this transformation in mind.

Isomers **10/12B** and **10/12C** are generated by the removal of one Fe atom from each end of **12/12A**. Isomer **10/12A** is generated from **10/12C** by displacing two end C atoms towards nearby C atoms (see Fig. 3) to form C_2 groups. Formation of these new C—C bonds during energy minimisation results in the breaking of two Fe—C bonds along the short axis of the molecule. A similar result is achieved if the same steps are performed on **10/12B**, again resulting in the breaking of the two Fe—C bonds through the centre of the molecule, again with **10/12A** as the resultant geometry. The relationship between **10/12B** and **10/12C** is similar to that between **12/12A** and **12/12C**, indeed **10/12A** may be generated from **12/12C** by removing Fe atoms and bringing the appropriate C atoms into close proximity, followed by optimisation. The binding energies are very similar for **10/12A** which contains two C_2 units and **10/12B** which does not.

3.3. Fe_8C_{12}

The majority of the isomers (all except **8/12L**, **N**, and **P**) considered for Fe_8C_{12} have been previously considered for Nb_8C_{12} [70]. Two of the new isomers that are proposed for Fe_8C_{12} (**8/12N** and **P**) are based on depleted $Fe_{12}C_{12}$ structures.

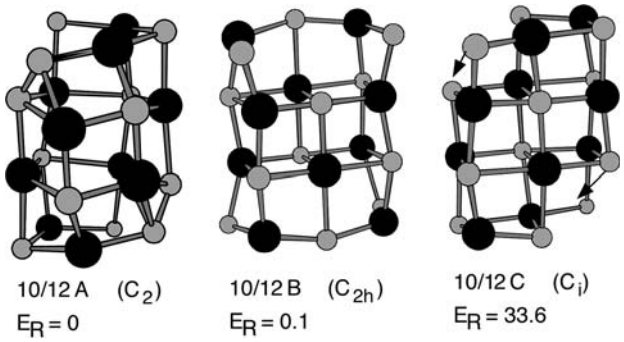

Fig. 3. Optimised structures for $[Fe_{10}C_{12}]$: E_R is the relative energy (kcal mol^{-1}) of the uncharged species. Primary symmetry elements of each structure are oriented horizontally and in the plane of the page, except **10/12A** whose C_2 axis is perpendicular to the plane of the page. **10/12A** is generated from **10/12C** by displacement of two C atoms as marked by the arrows.

Surprisingly, of the 19 structures evaluated (see Fig. 4), two structures, **8/12A** (C_{3v}) and prolate **8/12B** (D_{3d}) are calculated to be 11 kcal mol^{-1} more stable than the T_d tetracapped tetrahedron structure **8/12D** found to be so stable for earlier transition metals [30,70,78,80], and the C_s isomer **8/12C** is also slightly more stable than the T_d structure. All seven isomers (**8/12B-H)** which are generated by 45° rotations of the C_2 groups in Castleman's T_h isomer [30] **8/12K**, are within 17 kcal mol^{-1} of **8/12A**. This is a small energy range in comparison with that of these isomers of Nb_8C_{12} where the range is roughly 54 kcal mol^{-1} [70]. **8/12F** with symmetry D_{3d} is not a true minimum, because when optimised in symmetry C_{3v} structure **8/12A** is obtained (discussed in more detail below). There is a gap in energy of more than 40 kcal mol^{-1} from **8/12H** to the next most stable isomer, **8/12I**. **8/12I** contains C_3 groups arranged over an Fe_5 face and has greater relative stability for Fe_8C_{12} than calculated for the same isomer of Nb_8C_{12} [70]. The structures proposed for M_8C_{12} by Castleman [13] (**8/12K**), and Fowler [81] (**8/12M**), have unfavourable binding energies, whilst Khan's [82] structure **8/12R** reverts to **8/12O** on optimisation, and Pauling's [83] structure **8/12S** attains the same geometry as **8/12K**. A 3° rotation of the C_2 groups of **8/12K** (rotating opposite groups in different directions yielding a structure with threefold rotational symmetry) followed by optimisation results in **8/12A**: the

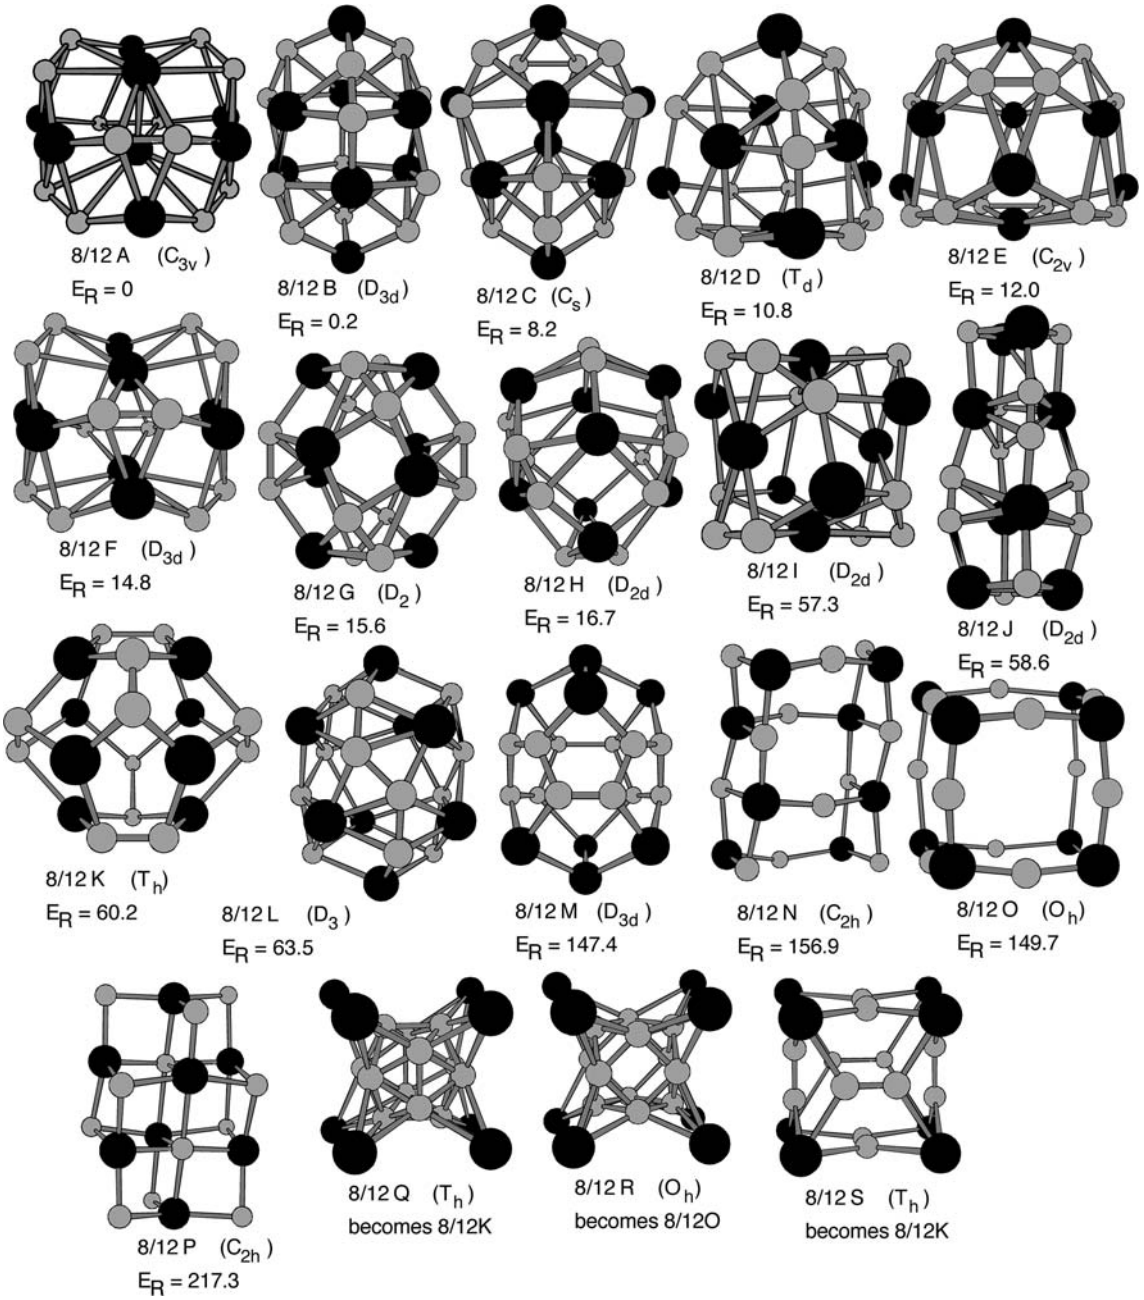

Fig. 4. Optimised structures for $[Fe_8C_{12}]^0$, arranged in order of decreasing stability: E_R is the relative energy (kcal mol^{-1}) of the uncharged species.

energy change associated with this initial distortion is 9 kcal mol^{-1}, and the barrier for conversion of **8/12K** to **8/12A** is estimated to be of similar magnitude. **8/12L** is generated from **8/12B** by removal of the vertical mirror planes and the formation of three new C—C bonds by a slight rotation of one of the horizontal halves of the molecule. Note from **8/12Q** and **8/12R** that a symmetrical C_{12} core with multiple C—C bonds is unstable to C—C bond breaking. **8/12O**, **N**, and **P** are depleted nanocrystallites, **8/12O** from the $3\times3\times3$ nanocrystallite, **8/12N** and **8/12P** from the $2\times3\times4$ nanocrystallite: these last two are important intermediates in consideration of the transformation from $[Fe_{12}C_{12}]$ to $[Fe_8C_{12}]$ (see Section 4, below).

We delve further into reasons for the energetic ordering of the more stable isomers for $[Fe_8C_{12}]$. The calculated structure for **8/12A** has one very short Fe—Fe bond (2.27 Å) along the threefold axis. It is the shortening of this bond that drives the energy minimisation from **8/12F** to **8/12A** on symmetry reduction from D_{3d} to C_{3v}, as shown in Fig. 5. One consequence of this is a straining of the associated Fe—C_2 bonding. A characteristic of many metallocarbohedrene structures is the occurrence of local cradle structures, in which a C_2 group lies over the diagonal of an M_4 rhombus, forming two M—σ—C_2 bonds and two M—π—C_2 bonds (Fig. 6). Normal cradle geometry is **1A**. The shortening of one Fe—Fe bond in **8/12A** causes a contraction of the Fe^{π}—Fe^{π} distances in three Fe_4C_2 cradles, distorting them to **1B**, and introducing angular distortion of the ideally linear C_2—σ—Fe bonding: in addition the Fe^{π}—C—Fe^{π} angles are distorted from 84.9° in **8/12F** to 72.4° in **8/12A**.

The stability of **8/12A** and **8/12B** relative to **8/12D** can be correlated with more general shortening of Fe—Fe distances, with implied Fe—Fe bonding. Distances are presented in Table 2, and Fig. 5. In the T_d isomer **8/12D** all 18 Fe—Fe bonds are about 2.77 Å in length, for **8/12B** (D_{3d}) six of these shorten to 2.5 Å and six lengthen to 3.1 Å. In **8/12A** (C_{3v}) three are shortened to 2.4 Å and three lengthen to 3.4 Å, together with the formation of a very short new Fe—Fe bond at 2.3 Å. Thus the stabilisation **8/12D** ⇒ **C** ⇒ **B** ⇒ **A** appears to be associated with a strengthening of Fe—Fe bonds, and it is understandable that this effect is greater than would occur with the early transition metals. A caveat is that the energies of the short Fe—Fe interactions in these structures are not known.

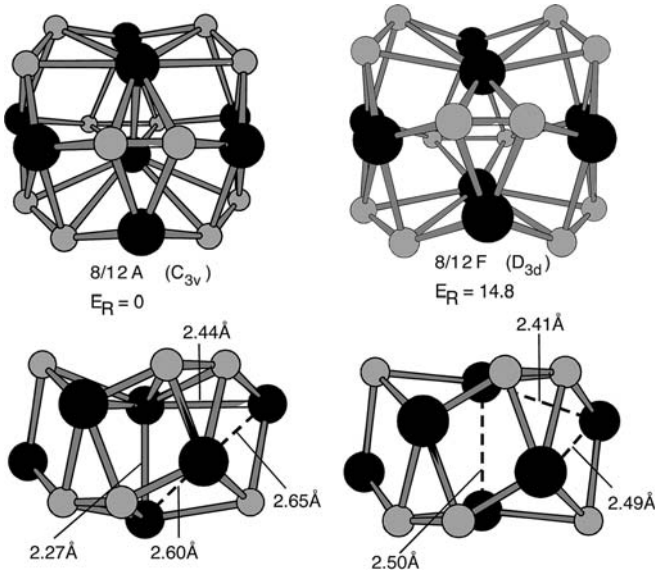

Fig. 5. Comparison of the two closely related structures **8/12A** (left) and **8/12F** (right): the lower left picture is upside down relative to the upper left picture. **8/12F** optimises to **8/12A** on removal of the D_{3d} symmetry constraint. Both lower views are normal to a mirror plane, and so two rear Fe atoms and six rear C atoms are obscured by front atoms.

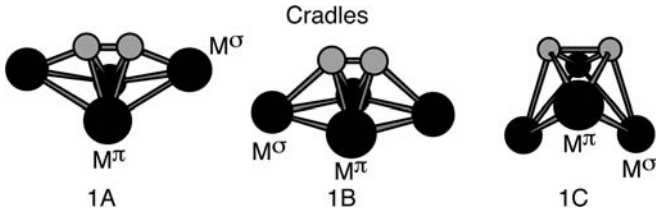

Fig. 6. The cradle motif **1A** commonly present in calculated $[M_xC_y]$ structures, and increasingly distorted forms **1B** and **1C**.

3.4. Fe_6C_{12}

The structures considered and optimised for $[Fe_6C_{12}]$ are shown in Fig. 7. There is a very wide range of stability, and some of the structures that are intriguing and symmetrical (such as the monocycles **6/12K** and **6/12L**, the chain **6/12P**, and the O_h polyhedron **6/12N**) are energetically uncompetitive. The polyhedron **6/12F** (D_{6h}) with two C_6 hexagons and all atoms four-coordinate is probably destabilised by the stereochemistry at C and Fe. We will focus attention on the more stable isomers. Six of the more stable structures, **6/12A**, **B**, **C**, **D**, **G** and **H**, are generated by the removal of Fe atoms from stable isomers of $[Fe_8C_{12}]$. Structure **6/12A**, which is 40 kcal mol^{-1} more stable than all of the others, is generated by the removal of the two Fe atoms on the threefold rotation axis of **8/12A**.

The depletion by two Fe atoms, $[Fe_8C_{12}]$ to $[Fe_6C_{12}]$, means that C_2 groups in the more stable structures for $[Fe_6C_{12}]$ are not all fully coordinated by four Fe atoms, as they are in the more stable $[Fe_8C_{12}]$ structures. Thus each of the C_2 groups in **6/12A** has two Fe—σ—C_2 bonds but only one Fe—π—C_2 bond: the cradles (Fig. 6) are

Table 2
Fe—Fe distances (Å) for the four most stable isomers of $[Fe_8C_{12}]^0$

8/12D T_d	**8/12C** C_s	**8/12B** D_{3d}	**8/12A** C_{3v}
6 at 2.779	1 at 2.422	6 at 2.525	1 at 2.266
12 at 2.764	2 at 2.477	6 at 2.709	3 at 2.441
	2 at 2.480	6 at 3.085	3 at 2.581
	2 at 2.518		3 at 2.600
	2 at 2.533		
	2 at 2.750		
	2 at 3.048		

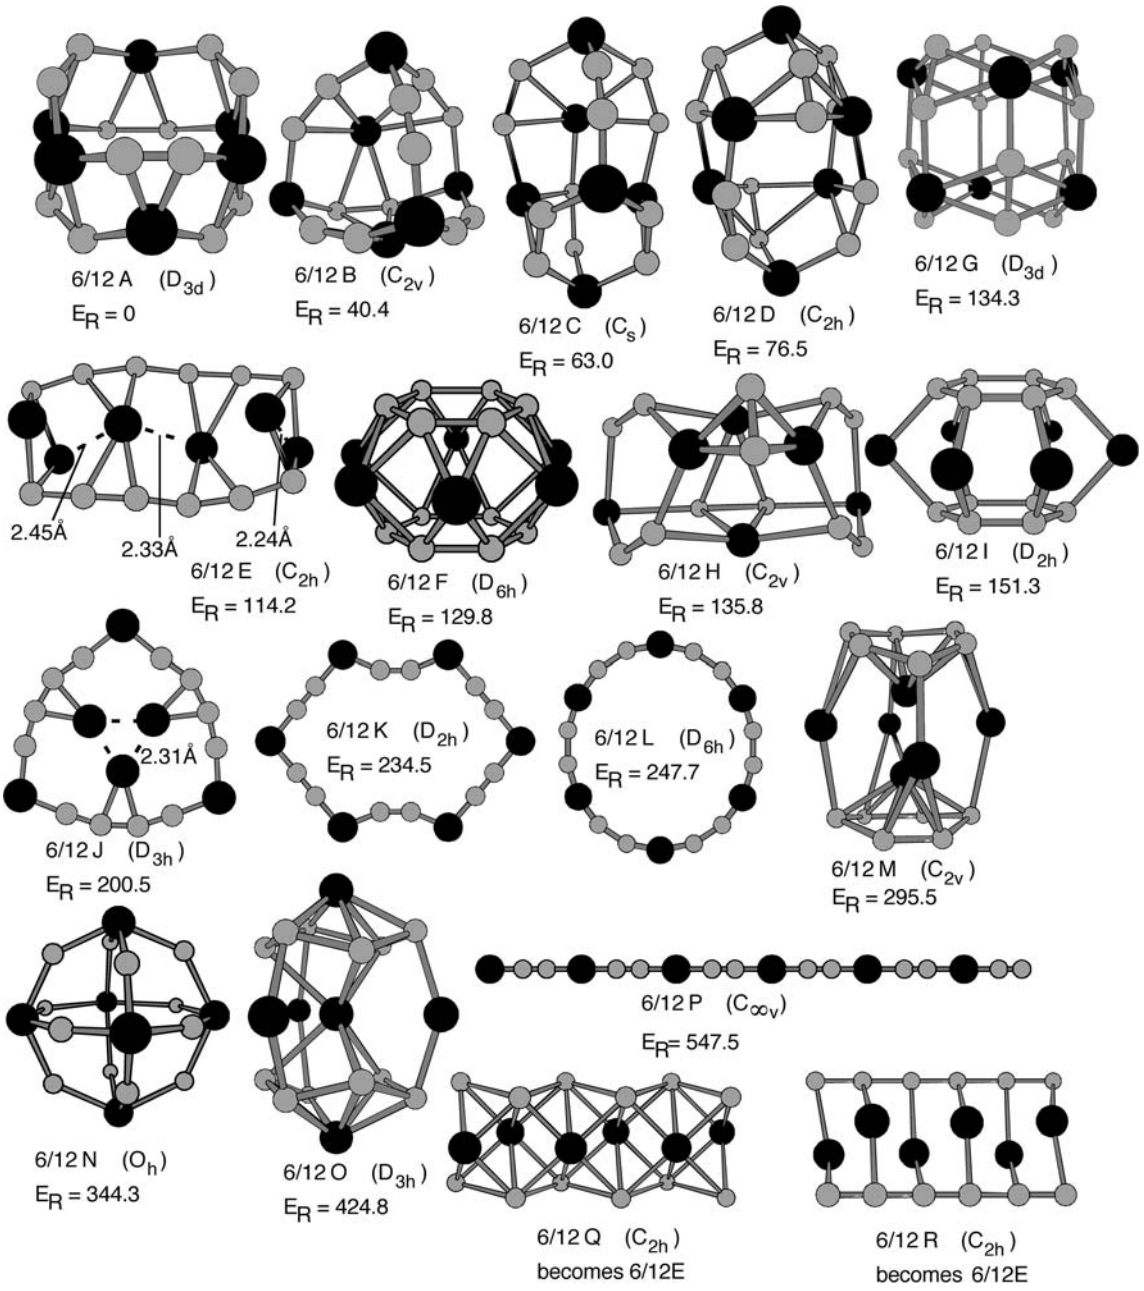

Fig. 7. Optimised structures for $[Fe_6C_{12}]^0$. Primary symmetry elements of each structure are oriented close to vertically and in the plane of the page, except as follows; **6/12C**, vertical and perpendicular to the plane of the page; **6/12D**, horizontal and in the plane of the page; **6/12H**, **6/12J**, **K**, **L**, perpendicular to the plane of the page. E_R is the relative energy (kcal mol^{-1}) of the uncharged species.

metal-deficient. The decreasing stability of the structures with C_2 groups in the sequence **6/12A**, **B**, **C**, **D**, **G**, **H**, **K**, **L** correlates with the nature and degree of Fe deficiency around C_2: **6/12B** has one less Fe—π—C_2 bond than **6/12A**, at a cost of 40 kcal mol^{-1}; further degradation of the Fe—π—C_2 bonding in **6/12C** costs an additional 20 kcal mol^{-1}; **6/12D** has more Fe—π—C_2 bonding, but two Fe—σ—C_2 bonds are missing, while in **6/12G** all of the C_2 groups are fully Fe—π—C_2 bonded but only half Fe—σ—C_2 bonded, which costs 134 kcal mol^{-1} relative to **6/12A**. In general the Fe—σ—C_2 bonding contributes more to the overall stability than does the Fe—π—C_2 bonding. Comparison of the binding energies of **6/12A** (with 12 Fe—σ—C_2 bonds and six Fe—π—C_2 bonds) and **6/12G** (with six Fe—σ—C_2 bonds and 12 Fe—π—C_2 bonds) suggests that a Fe—σ—C_2 bond contributes roughly 20 kcal mol^{-1} more than a Fe—π—C_2 bond.

The general openness of the stable 6/12 structures is due to the favourability of the extended Fe—σ—C_2—σ—Fe bonding. Structure **6/12E**, the most stable with C_6 chains, is generated by optimisation of **6/12Q** and **R** in which Fe atoms bridge the chains. Because Fe—Fe is longer than

C—C, the central Fe_6 set in **6/12E** zig-zags through the central domain, with relatively tight Fe—Fe bonding.

3.5. Fe_4C_{12}

A further significant change in structures occurs in the transition from $[Fe_6C_{12}]$ to $[Fe_4C_{12}]$. For $[Fe_6C_{12}]$ metal-depleted metallocarbohedrenes are the most stable, but this is not the case for Fe_4C_{12}. Instead, **4/12A** (see Fig. 8) which contains two C_6 chains is 48 kcal mol^{-1} more stable than any other structure. The second most stable structure, **4/12B**, contains C_3 chains with Fe—σ—C_3 bonding, but the low coordination of Fe will be a destabilising influence: the related non-cyclic structure, **4/12J**, is much less stable. The most metallocarbohedrene-like structure is **4/12C**, with complete Fe—σ—C_2 bonding but no Fe—π—C_2 bonding, and is 54 kcal mol^{-1} less stable than **4/12A**. We note in passing that the highly symmetric T_d structure **4/12K**, which complements **4/12C** in having only Fe—π—C_2 bonding and no Fe—σ—C_2 bonding, is almost 300 kcal mol^{-1} less stable, reinforcing the earlier conclusion that a Fe—σ—C_2 bond contributes roughly 20 kcal mol^{-1} more than a Fe—π—C_2 bond.

We describe the consequences of the three distinct ways to remove two Fe atoms from **6/12A**. (1) Removal of two adjacent Fe atoms followed by optimisation yields **4/12I** (see below for transformation of **4/12I** to **4/12A**). (2) Removal of two Fe atoms which are related by a threefold rotation axis yields **4/12E**. (3) Removal of two opposite Fe atoms results in **4/12F** after rearrangement of two C_2 groups to increase the number of Fe—σ—C_2 interactions. The most stable of these three product isomers is **4/12E** which gains its stability from the spontaneous formation of two new C—C bonds on optimisation. **4/12F** is also generated directly by removal of two Fe atoms from either **6/12B** or **C** followed by optimisation.

While both **4/12B** and **4/12C** contain metal atoms which are Fe—σ—C_n bound to all nearby carbon units, the lower energy **4/12A** has all metal atoms side bound to carbon chains. It seems likely that the stability of **4/12A** is due to an increased number of C—C bonds, ten for **4/12A** versus six for other stable structures. **4/12D** which contains two C_6 rings now has a competitive stability, in comparison to that of those $[Fe_6C_{12}]$ structures that contain C_6 rings.

3.6. Fe_3C_{12}

Optimised structures for $[Fe_3C_{12}]$ are shown in Fig. 9. Two characteristic features are extended carbon chains (in **3/12A**, **B**, **F**, **H**, **I**) or C_n cycles, mainly C_6. The two most stable structures, **3/12A** and **3/12B**, contain cumulenic C_4 and C_6 chains respectively, slightly bent or kinked. Structures containing C_6 cycles are generally less stable, and **3/12J**, inspired by established $(\eta^6\text{-}C_6H_6)_2M$ complexes, is clearly not a structure type to be considered in the present

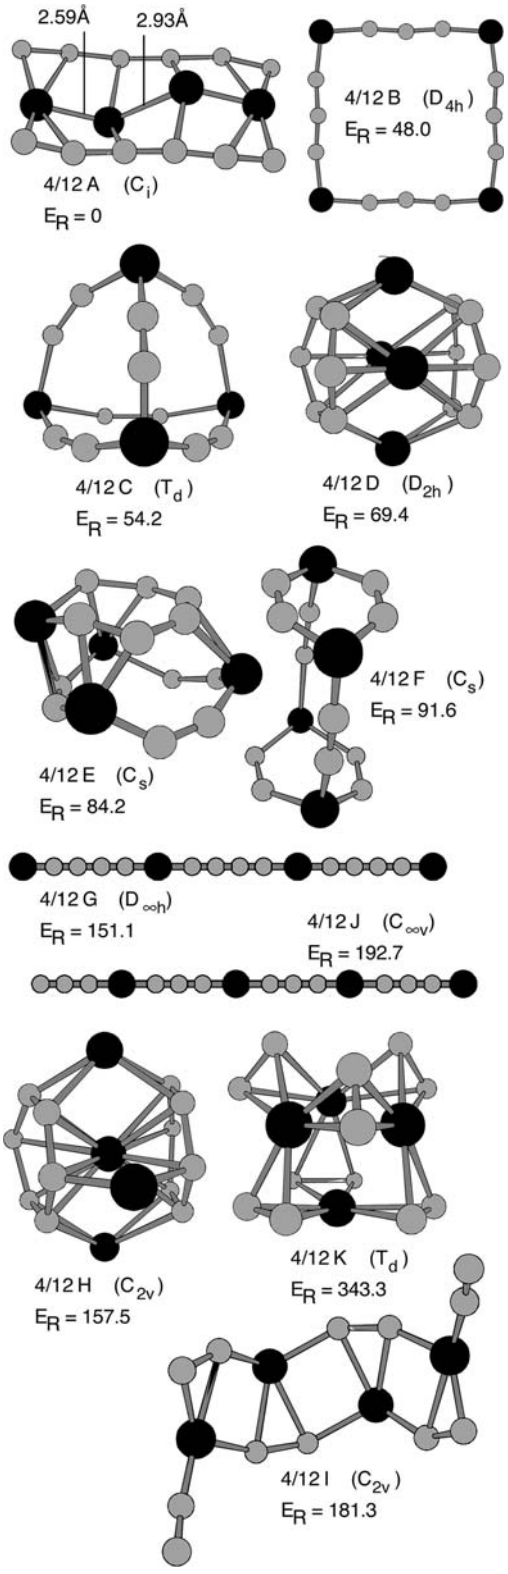

Fig. 8. Optimised structures for $[Fe_4C_{12}]^0$. Primary symmetry elements of each structure are oriented approximately vertically and in the plane of the page, except as follows; **4/12B**, **H**, and **I**, perpendicular to the plane of the page; **4/12F**, vertical and perpendicular to the plane of the page; **4/12G** and **J**, horizontal and in the plane of the page. E_R is the relative energy (kcal mol^{-1}) of the uncharged species.

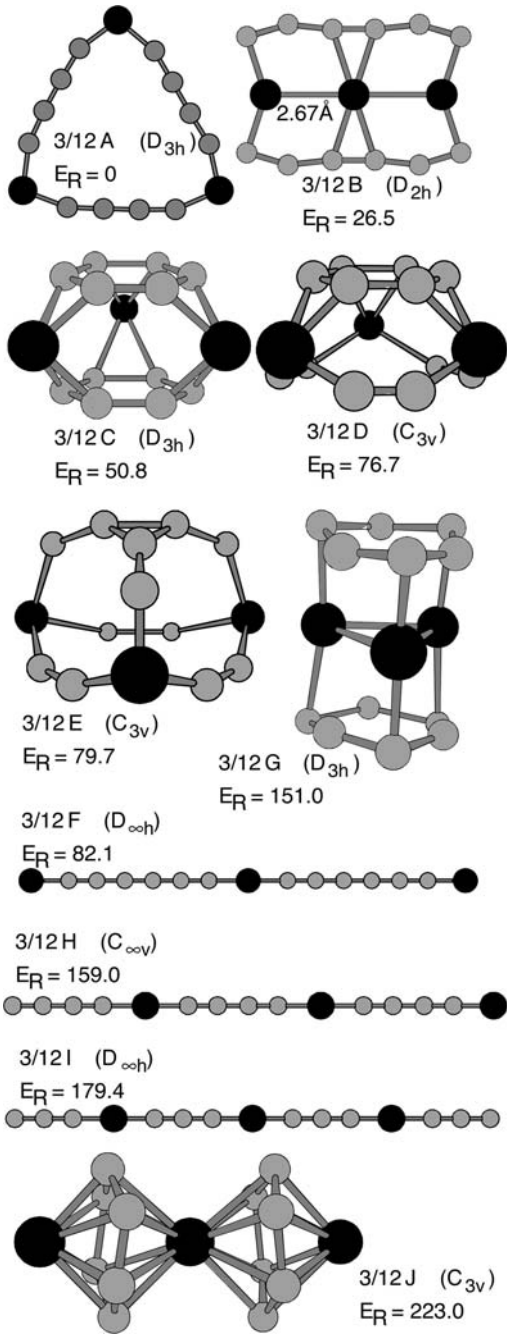

Fig. 9. Optimised structures for $[Fe_3C_{12}]^0$. Primary symmetry elements of each structure are oriented close to vertically and in the plane of the page, except as follows; **3/12A**; perpendicular to the plane of the page; **3/12F**, **H**, **I**, and **J**, horizontal and in the plane of the page. In **3/12A** the C—C distances are 1.30, 1.31 Å; C—C distances in **3/12B** alternate 1.30, 1.35, 1.29, 1.35, 1.30 Å; C—C distances in **3/12H** and **3/12I** are in the range 1.28–1.32 Å. E_R is the relative energy (kcal mol^{-1}) of the uncharged species.

context. Some insight into the bonding of three Fe to cyclic C_6 is obtained from the fact that **3/12C** with widely separated (>4 Å) Fe atoms is obtained on optimisation of the same connectivity with a smaller (2.9 Å) Fe_3 triangle. The difference in energy between **3/12D** and **3/12C** is probably a consequence of the fewer C—C bonds in **3/12D**.

The basis for the relative stabilities of the favourable structures **3/12A** and **3/12B** is probably the occurrence of Fe—σ—C_n bonding in **A** but not **B**, countered by the occurrence of some Fe—Fe bonding in **B** but not in **A**. We note that the two most stable structures for $[Fe_3C_{12}]$ resemble in connectivity the two most stable structures for $[Fe_4C_{12}]$, but that the stability ordering is reversed. Why might this be? The lengths of the C_n chains are relevant, because C_{even} chains (C_4 and C_6) occur in the relatively stable isomers **4/12A**, **3/12A** and **3/12B** while the less stable isomer **4/12B** contains C_3. The relative energies of the linear isomers **3/12F**, **3/12H**, **3/12I** with C_6, C_4, C_3, respectively, also manifest the favourable influence of C—C bonds and C_{even} chains.

3.7. Fe_2C_{12}

The most stable structure found for $[Fe_2C_{12}]$ is the planar monocyclic structure, **2/12A** (Fig. 10), consisting of two Fe atoms (separated by >7 Å) connected by two slightly curved cumulenic C_6 chains. This is analogous to the best structure for $[Fe_3C_{12}]$. Two tricyclic versions of **2/12A** are **2/12B** and **2/12C**, retaining bent cumulenic C_{even} chains and Fe—σ—C_n bonding, and are ca. 25 kcal mol^{-1} less stable. The linear structures **2/12D** and **2/12K** clearly demonstrate the importance of terminating C_n chains with Fe atoms. Structures **2/12E** and **2/12F** were initiated by placing an Fe_2 unit over a C_{12} group which is two C_5 rings fused to opposite edges of a C_6 ring: the two starting structures differed by a 90° rotation of the Fe_2 unit. Optimisation of **2/12G′** results in the destruction of the two ring-shared C—C bonds giving the near planar **2/12G**. The differences between the three related structures **2/12E**, **F** and **G** are in the numbers of Fe—C and C—C bonds, which when maximized in **2/12E** provide an energetic advantage. **2/12F** is related to **4/12A** by the removal of the two central Fe atoms.

Before moving to investigation of a structural interpretation of the experimental photodissociations of Fe atoms, we summarise the main principles that have evolved so far for the structures of $[Fe_xC_{12}]$ clusters. With the largest complement of Fe atoms, $[Fe_{12}C_{12}]$ and $[Fe_{10}C_{12}]$, the stable structures contain isolated C atoms in a distorted nanocrystallite fragment. The stability associated with C_2 groups is intimated at $[Fe_{10}C_{12}]$, and is dominant in the metallocarbohedrene isomers of $[Fe_8C_{12}]$ and the Fe-deficient metallocarbohedrene structures of $[Fe_6C_{12}]$. At composition $[Fe_4C_{12}]$ there are longer C_n chains, decorated or terminated by Fe atoms, while for $[Fe_3C_{12}]$ and $[Fe_2C_{12}]$ the stable structures are monocycles containing cumulenic C_4 and C_6 chains respectively. It appears that Fe—Fe bonding, at distances <ca. 2.5 Å, is significant in the metallocarbohedrene structures, but the C—C and Fe—C bonds contribute greater stabilisation, and the stable structures tend to maximize the number of C—C and Fe—C bonds. In metallocarbohedrene structures the Fe—σ—C_2 bonding is more favourable than Fe—π—C_2 bonding.

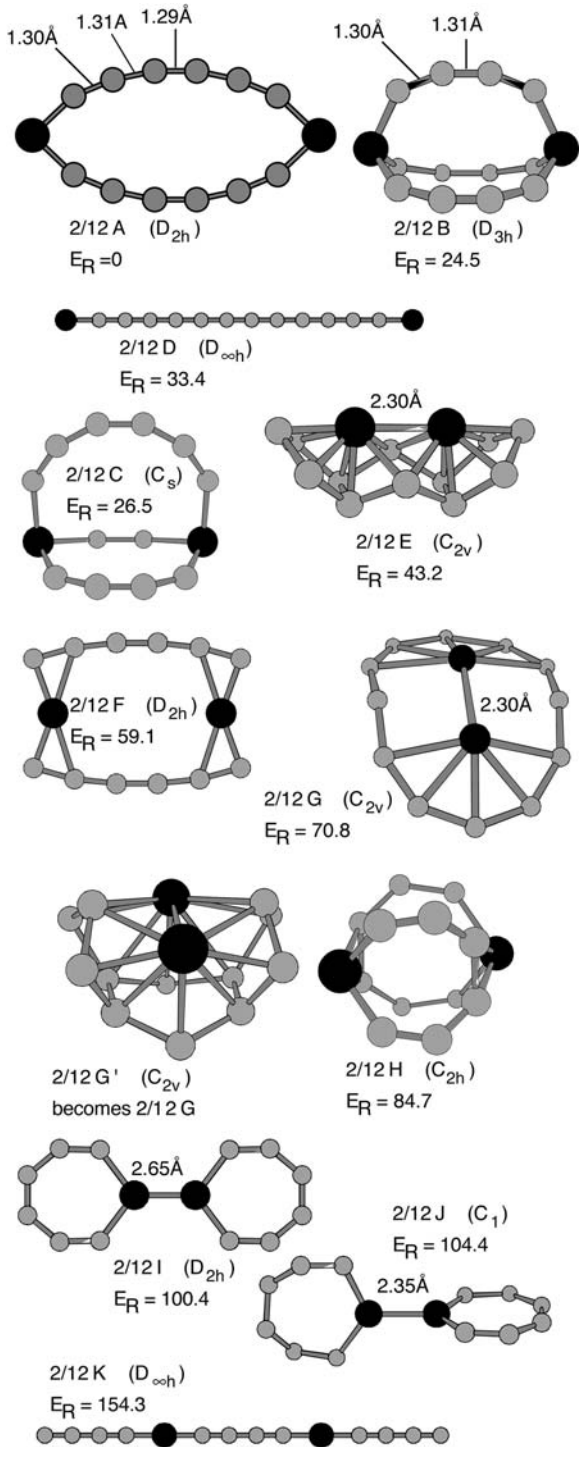

Fig. 10. Optimised structures for $[Fe_2C_{12}]^0$. Primary symmetry elements of each structure are oriented approximately vertically and in the plane of the page, except as follows; **2/12A**, **2/12G**, perpendicular to the plane of the page; **2/12B**, **C**, **D**, and **K** horizontal and in the plane of the page. E_R is the relative energy (kcal mol^{-1}) of the uncharged species.

4. Dissociation mechanisms

4.1. $Fe_{12}C_{12}$ to Fe_8C_{12}

Whilst the photodissociation spectrum of $[Ti_{14}C_{13}]^+$ clearly shows the presence of the intermediates with progressively lost Ti atoms, intermediate compositions are not clearly resolved in the dissociation spectrum of $[Fe_{12}C_{12}]^+$. The transformation $[Fe_{12}C_{12}]^+$ to $[Fe_8C_{12}]^+$ is considered in two possible compositional pathways, one-step concerted dissociation, and sequential dissociation from $[Fe_{12}C_{12}]^+$ to $[Fe_{10}C_{12}]^+$ to $[Fe_8C_{12}]^+$. The $[Fe_{11}C_{12}]^+$ and $[Fe_9C_{12}]^+$ intermediates are ignored to retain the convenience of twofold symmetry throughout the calculations of the process.

Fig. 11 illustrates the proposed mechanism for the concerted transformation of **12/12A** to **8/12A**. The first step in this process is the removal of the four apical Fe atoms, giving **8/12P′** with C_{2h} symmetry. Note that it is the three-coordinate Fe atoms that are proposed to dissociate, while the retained Fe atoms are four-coordinate. Loss of these four Fe atoms allows the retention of C_2 symmetry and yields an Fe_8 framework which is similar in topology to that in **8/12A**. Optimisation of **8/12P′** gives **8/12P** along with a net stabilisation of ca. 80 kcal mol^{-1}, very little geometric change occurs during this optimisation. If **8/12P′** is to be converted to a metallocarbohedrene then six new C—C bonds must be formed, and this is modeled by moving the positions of six C atoms in the directions indicated on **8/12P′** in Fig. 11. The transition state **8/12TS** shown in Fig. 11 for the transformation between **8/12P′** and the final product **8/12A** was calculated by the RPF method, and lies 25 kcal mol^{-1} above **8/12P′** and ca. 320 kcal mol^{-1} above **8/12A**. In the transition state the six nascent C—C interactions are ca. 2.1 Å. Details of the geometry and energy changes during the transformation from the transition state to the product, including the change in symmetry, are provided in the Supplementary material.

A mechanism proposed for sequential transformation of $[Fe_{12}C_{12}]$ to $[Fe_8C_{12}]$ via $[Fe_{10}C_{12}]$ is illustrated in Fig. 12. It is based on the observation that the central Fe_6C_6 segments of structures of **12/12C, 10/12A** and **8/12B** are very similar. The first stage (Fig. 12(a)) involves the removal of two three-coordinate Fe atoms from **12/12C**, followed by conversion through the transition state which involves moving only one symmetry independent C atom, to the product **10/12A**. This conversion has an activation barrier of at least 70 kcal mol^{-1}, while the product is 165 kcal mol^{-1} below the transition state. Two C—C bonds are formed (2.79 to 2.08 to 1.36 Å), with minor changes elsewhere. The second stage (Fig. 12(b)) involves removal of two three-coordinate Fe atoms, leaving two dangling C atoms, but then shortening four C—C distances and two Fe—Fe distances as shown in Fig. 12(b) and performing an RPF transition state search gives a transition state which lies 133 kcal mol^{-1} above the undistorted structure, and 400 kcal mol^{-1} above the product **8/12B**.

In comparing this sequential mechanism for the photodissociation of $[Fe_{12}C_{12}]$ to form $[Fe_8C_{12}]$ with the concerted mechanism suggested above, we note that the reactant nanocrystallite **12/12C** is only 1.4 kcal mol^{-1} less stable than **12/12A**, the intermediate **10/12A** is the most stable for this composition, and the product **8/12B** is only

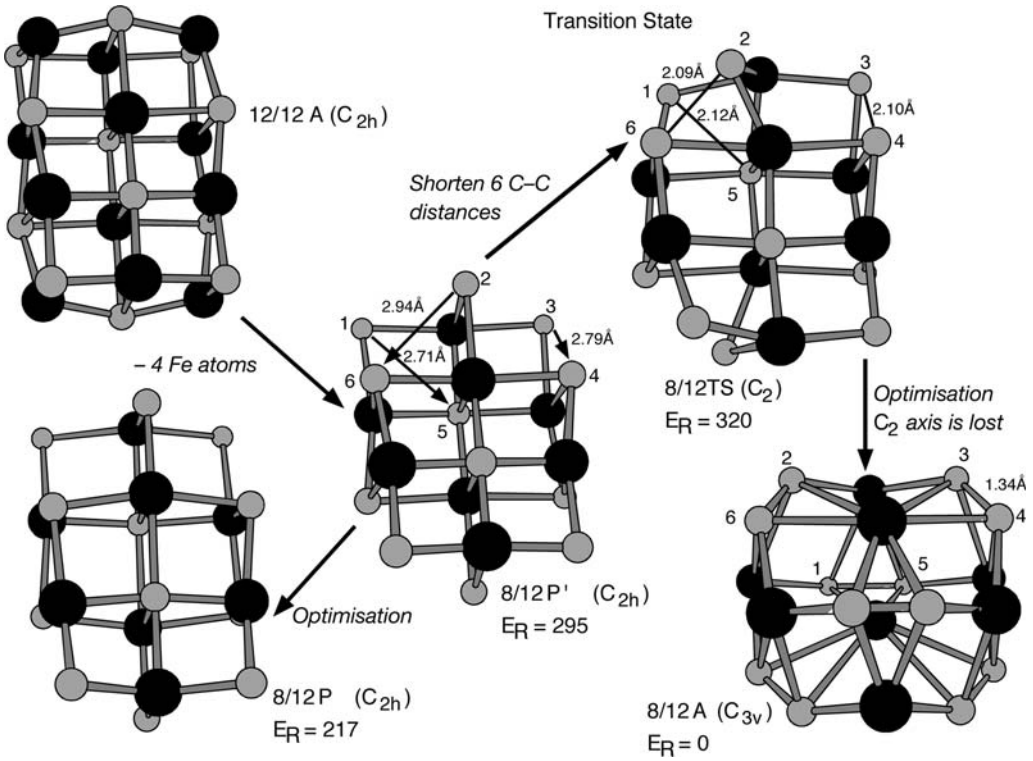

Fig. 11. Proposed mechanism for the concerted transformation of $[Fe_{12}C_{12}]$ to $[Fe_8C_{12}]$. Relative energies E_R are given in kcal mol^{-1}. The primary symmetry elements of all species are aligned horizontally and in the plane of the page except **8/12M** whose C_3 axis is vertical (the molecule is not rotated in space but the horizontal C_2 axis is lost whilst a perpendicular C_3 axis is gained). The calculated transition state is **8/12TS**.

0.2 kcal mol^{-1} less stable than **8/12A**. However, the activation barriers for the sequential mechanism are significantly larger, favouring the concerted mechanism, which is consistent with the non-observation of $[Fe_{10}C_{12}]^+$ in the photodissociation experiment [35].

4.2. Fe_8C_{12} to Fe_2C_{12}

This process requires formation of C—C bonds, concomitant with the dissociation of Fe atoms. Based on the results of the structure determinations described above, we propose a mechanism for the conversion of **8/12A** to **6/12A** to **4/12A** to **2/12A**. It is likely that the formation of these species occurs via distinct concerted single-step or cascading processes that occur after the absorption of one or more photons and may be perpetuated by stabilising rearrangement energy at each step: however modelling as a sequence of 2Fe losses allows for easier calculation and comprehension of the process. The proposed mechanism is illustrated in Fig. 13. The Fe atoms most easily removed from **8/12A** are probably those that lie on the threefold rotation axis because they are involved in Fe—π—C_2 bonding only, and subsequent optimisation gives the most stable structure found for $[Fe_6C_{12}]$, **6/12A**. If two adjacent Fe atoms are removed from **6/12A** and the resultant structure is optimised without alteration, the opened structure **4/12I** is the product. It seems likely that the removal of two adjacent Fe atoms where only two Fe—Fe bonds must be broken, will be a lower energy process than the removal of two non-adjacent Fe atoms where four Fe—Fe bonds are destroyed. The conversion of **4/12I** to **4/12A** is the next step and requires the formation of four new C—C bonds. The only uphill component of this conversion is the requirement that eight Fe—C bonds (marked "X" in Fig. 13) be converted from end-bound Fe—σ—C_2 bonds to side-bound Fe—π—C2 bonds. The exact transition state has not been determined, but it is likely that the activation barrier associated with this process is considerably less than that for the loss of Fe atoms throughout the process. Conversion of **4/12A** to **2/12F** requires only the removal of the two central Fe atoms followed by optimisation. The final step to yield stable **2/12A** requires only the breaking of four side-bound Fe—π—C bonds, which is achieved by moving C atoms as shown in Fig. 13. The transition state for this process has not been determined, but as it is only a slight rearrangement requiring the breaking of only four relatively weak bonds while forming four stronger Fe—σ—C bonds, the activation barrier is assumed to be readily overcome.

5. Discussion and summary

While we have not investigated probable structures for all of the observed $[Fe_xC_y]$ clusters, and have focused on the species involved in the photodissociation experiments, our results provide insight into the structural principles for the larger $[Fe_xC_y]$ clusters. It is clear that when $x \sim y$

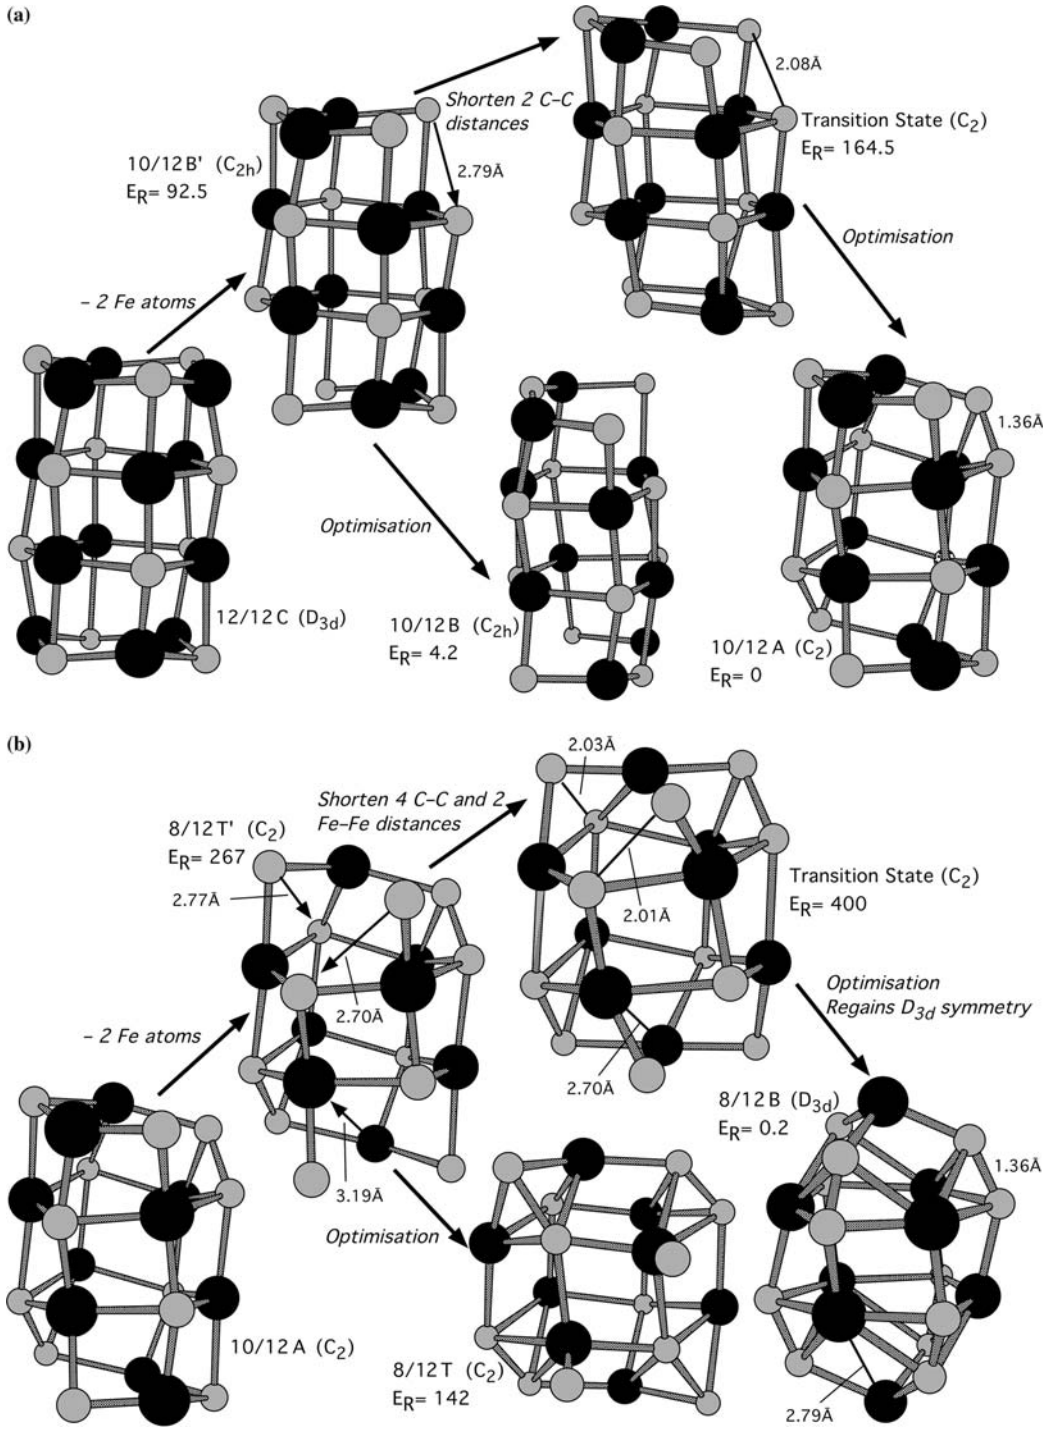

Fig. 12. The two stages in the mechanism for sequential dissociation of two pairs of Fe atoms in the conversion of $[Fe_{12}C_{12}]$ to $[Fe_{10}C_{12}]$ to $[Fe_8C_{12}]$. (a) The first stage conversion from **12/12C** to **10/12A** involves the loss of two three-coordinate Fe atoms, and progresses via the transition state pictured, which was calculated by the RPF method. The threefold rotation axis of **12/12C** is aligned vertically and in the plane of the page, whilst the twofold rotation axes of the remaining species are perpendicular to the plane of the page. (b) In the second stage two three-coordinate Fe atoms are removed from **10/12A**, leading to the transition state shown (determined by the RPF method), which leads to the product **8/12B**. The primary symmetry elements of all species are perpendicular to the plane of the page, except **8/12B** whose C_3 axis is vertical and in the plane of the page.

the probable structures contain isolated C atoms, and that cluster stability derives principally from Fe—C bonding. For the prototypical composition $[Fe_8C_{12}]$, and probably for closely related compositions, carbon is present only in C_2 groups that are bound end-on (i.e. σ) and side-on (i.e. π) to Fe, with the metal array approximating a regular polyhedron. It appears that the Fe—σ—C_2 bonding is stronger than Fe—π—C_2 bonding. As the y/x ratio changes from 2 to 3 (i.e. $[Fe_6C_{12}]$, $[Fe_4C_{12}]$) the C_n chains lengthen, and by $[Fe_3C_{12}]$ and $[Fe_2C_{12}]$ the stable structures are

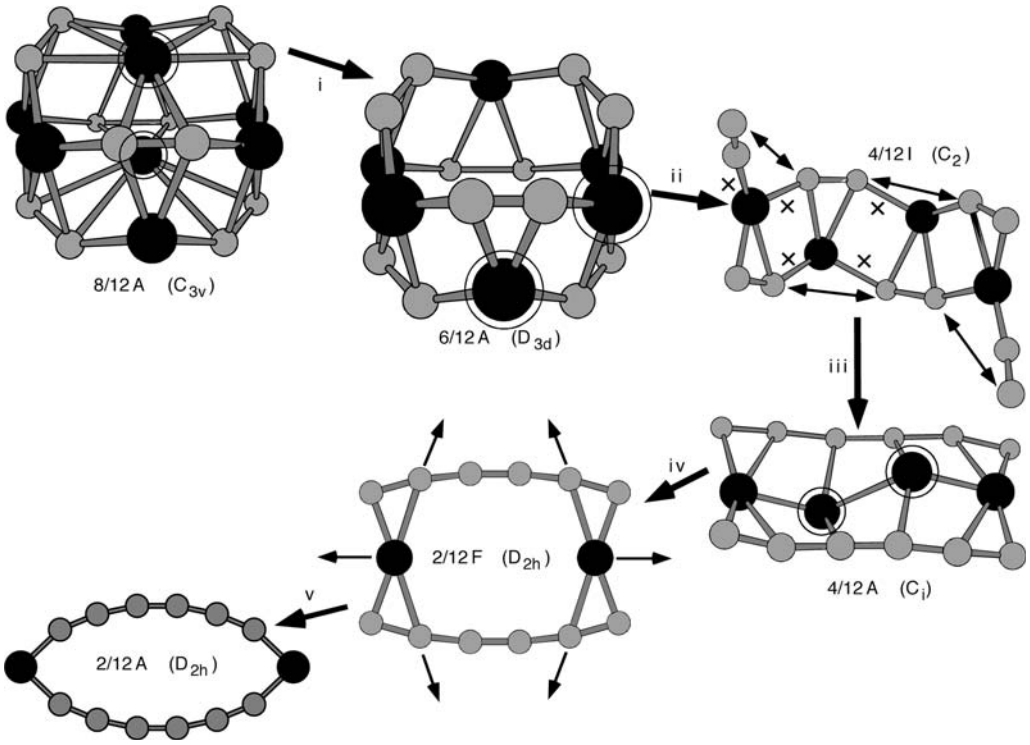

Fig. 13. Proposed sequential mechanism for the transformation of **8/12A** to **2/12A**. (i) **8/12A** is converted to **6/12A** by removal of the two Fe atoms (circled) that lie on the threefold axis, followed by optimisation. (ii) Removal of two adjacent Fe atoms (circled) from **6/12A** followed by optimisation yields **4/12I**. (iii) It is envisaged that the conversion of **4/12I** to **4/12A** may be achieved by small atomic displacements in the directions indicated followed by optimisation. The energy and geometry of the transition state has not been investigated. (iv) **2/12F** is generated from **4/12A** by removal of the two central Fe atoms followed by optimisation. (v) The conversion of **2/12F** to **2/12A** is achieved by elongation of the Fe—Fe distance in **2/12F**. The energy and geometry of the transition state has not been investigated.

monocycles containing long cumulenic C_{even} chains and Fe—σ—C bonds.

These principles are similar to those presented previously for over 50 $[Nb_xC_y]$ clusters [70], with the significant exception that Fe—Fe bonding at shorter distances is more influential than Nb—Nb interactions at longer distances. The influence of Fe—Fe bonding is evident through comparison of the structures 8/12A (C_{3v}) with one variable axial M—M interaction and 8/12D (T_d) with four necessarily equivalent M—M interactions (see Fig. 4). When M = Fe the C_{3v} structure is the more stable by 11 kcal mol^{-1} with Fe—Fe = 2.27 Å, while when M = Nb the C_{3v} structure is less stable by 46 kcal mol^{-1} and Nb—Nb = 3.30 Å. The role of Fe—Fe bonding in determining the structures of $[Fe_xC_y]$ metallocarbohedrenes is evident in a number of the results described above.

Bowers et al. used gas phase ion-mobility measurements to obtain experimental information on the structures of small $[Fe_xC_y]^+$ clusters ($x = 1,2,3$, $y = 2$–8) [57]. While no compositions are common to this investigation and to our calculations reported here, there is general agreement that mono- or bi-cyclic structures occur for the smaller carbon-rich species.

The proposed mechanisms for the observed photodissociative transformations of $[Fe_{12}C_{12}]^+$ to $[Fe_8C_{12}]^+$, and of $[Fe_8C_{12}]^+$ to $[Fe_6C_{12}]^+$, of $[Fe_6C_{12}]^+$ to $[Fe_4C_{12}]^+$, and of $[Fe_4C_{12}]^+$ to $[Fe_2C_{12}]^+$, all pass through energy minima (possibly global minima) for each composition. The mechanisms involve the loss of metal atoms followed by exergonic and low activation energy rearrangements. Other pathways with odd numbers of metal atoms may exist.

In the photodissociation of Fe atoms from $[Fe_{12}C_{12}]^+$ and from $[Fe_8C_{12}]^+$, we can speculate about three types of reaction:

(i) absorption of one or more photons, followed by the concerted loss of the required number of Fe atoms, followed by structural rearrangements activated by the excess energy from the initial absorption;
(ii) absorption of one or more photons, followed by cascading sequential single Fe atom losses, each with associated structural rearrangements. The activation energy for each Fe atom expulsion is provided by the previous exergonic structural rearrangement;
(iii) absorption of one or more photons, each absorption event being followed by sequential single Fe atom loss and associated structural rearrangements. The activation energy for each Fe atom loss is provided by the multiple distinct photon absorption events.

Reaction types (i) and (ii) cannot be ruled out because the original experiment does not provide definite

information about the number of photons absorbed by each molecule, although Pilgrim and Duncan [35] argue that the photodissociation involves multiple photons. The photodissociation experiments are not time-resolved which also leaves pathway (iii) as a distinct possibility. Further experimental data such as the effect of variation of laser energy and pulse duration should provide elucidation of this issue. At this point the cascading pathway seems favourable as it does not rely as heavily on initial energy absorbed nor on the need for multiple absorption events.

Abstract

$\{Os(bpy)_2\}^{2+}$ and $\{Ru(CN)_4\}^{2-}$ mononuclear and binuclear complexes with ligands 2,3-di-(2-pyridyl)quinoxaline (dpq) and dipyrido[2,3-*a*:3′,2′-*c*]phenazine (ppb) have been prepared. For the binuclear complexes a splitting in oxidation potentials is observed consistent with the formation of mixed-valence species with comproportionation constants (K_{com}) ranging from 2.5×10^4 to 1.8×10^6. The electronic absorption spectra of the mixed-valence species reveal IVCT transitions in the near infrared region. The absorption maximum for the IVCT band ranges from 5800 to 9980 cm^{-1} and the extinction coefficients from 80 to 6300 M^{-1} cm^{-1}. In general the $\{Os(bpy)_2\}^{2+}$ complexes show larger K_{com} values and more intense IVCT bands than the corresponding $\{Ru(CN)_4\}^{2-}$ complexes.

1. Introduction

The chemistry of ligand-bridged binuclear metal complexes is dictated to a significant extent by the nature of the ligand(s) that bridge the two metal centres. Of particular interest over the past few decades has been the elucidation of the electronic nature of mixed valent binuclear complexes through studies of the way in which the bridging ligand in such complexes facilitates or hinders electronic communication between the metal centres [1–19]. Bridging ligands which allow unimpeded communication between the metal centres result in completely delocalised (Class III) metal complexes, while conversely, bridging ligands which contain orbitals orthogonal to those on the metal ions and which thus cannot effect electron transfer between the two centres give localised (Class I) complexes [20]. We have been interested in attempting to identify and understand the features of bridging ligands that are important in determining the overall electronic nature of mixed valent binuclear metal complexes in which the metal ions are bridged by polypyridyl-type ligands [1,21–24] and in this paper we report our findings concerning the optical and electrochemical properties of a number of binuclear Os(II) and Ru(II) complexes. The bridging ligands used, dpq and its fused planar counterpart ppb (Fig. 1), were chosen because of their interesting steric characteristics. dpq and its derivatives undergo significant distortion on coordination to metal ions, so as to avoid steric clashes between protons on the pyridyl substituents [25–27] while ppb, despite its significantly more rigid nature, also displays large deviations from planarity in its complexes [28,29] and we were interested to see what, if any, effects such distortions would have on the electronic nature of the mixed valent Os_2 and Ru_2 species.

2. Results and discussion

2.1. Synthesis

The binuclear Os complex $[(bpy)_2Os(ppb)Os(bpy)_2](PF_6)_4$ was prepared by reaction of equimolar amounts of $[(bpy)_2OsCl_2]$ and ppb in refluxing ethylene glycol, a method similar to that previously used for the preparation of

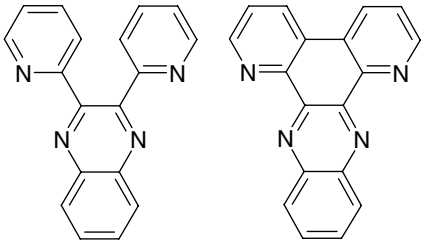

Fig. 1. The bridging ligands ppb and dpq.

$[(bpy)_2Os(dpq)Os(bpy)_2](PF_6)_4 \cdot 2H_2O$ [30]. In this case, however, purification was achieved by chromatography on Sephadex SP-C25 cation exchange resin with sodium *p*-tolylsulfonate as eluent. Subsequent addition of NH_4PF_6 gave the complex in moderate (48%) yield. ^1H NMR spectral data were consistent with the isolated material being an essentially equimolar mixture of two diastereoisomers, each of which contains an axial mirror plane bisecting the ppb ligand, and all attempts to separate these isomers were unsuccessful. The mononuclear complexes $[(bpy)_2Os(dpq)](PF_6)_2$ and $[(bpy)_2Os(ppb)](PF_6)_2$ were prepared as previously reported [29,31].

The $\{Ru(CN)_4\}^{2-}$ complexes were prepared as their sodium salts by an adaptation of the synthesis of $K_2[(bipy)Ru(CN)_4] \cdot 2H_2O$ [32] and related complexes [33] involving 254 nm irradiation of a mixture of $Na_4[Ru(CN)_6]$ and the appropriate ligand in aqueous methanol, and subsequent purification using Sephadex DEAE A-25 anion exchange resin. Use of excess ligand gave predominantly the monomeric species while excess $Na_4[Ru(CN)_6]$ was used to obtain the binuclear complexes.

2.2. Electrochemistry

Electrochemical data for the mononuclear and binuclear Os and Ru complexes in MeCN, MeOH and DMF are presented in Table 1.

Reduction potentials in MeCN of −1.27 V and −1.56 V (versus SCE) for ppb and dpq, respectively, have been reported previously [29,34], and increases in these potentials have been observed on coordination to either one or two metal ions. For example the reduction potentials for the dpq ligands in $[(bpy)_2Ru(dpq)]^{2+}$ and $[(bpy)_2Ru(dpq)Ru(bpy)_2]^{4+}$ in MeCN are −0.8 V and −0.37 V versus SCE, respectively [34–36]. The magnitude of the increase in ligand reduction potential is a function of the metal moiety and the ability of the metal to facilitate metal(dπ) to ligand(π^*) mixing [37].

$[(bpy)_2Os(dpq)]^{2+}$ and $[(bpy)_2Os(dpq)Os(bpy)_2]^{4+}$ (Table 1, MeCN solvent) show increases in the ligand reduction potentials of 650 mV and 1100 mV, respectively, relative to the free ligand, while the corresponding values for $[(bpy)_2Os(ppb)]^{2+}$ and $[(bpy)_2Os(ppb)Os(bpy)_2]^{4+}$ are 760 mV and 900 mV. The binuclear complexes were also examined in MeOH in which the increase in reduction potential is 50–100 mV less than in MeCN.

Similar trends are also observed in the $[(CN)_4Ru(L)]^{2-}$ and $[(CN)_4Ru(L)Ru(CN)_4]^{4-}$ (L = dpq, ppb) complexes (Table 1). The reduction potential is increased by 300–350 mV in the mononuclear complexes, but, in contrast to the Os complexes above, the binuclear systems display essentially identical reduction potentials to the mononuclear complexes. This behaviour is unusual and differs from that usually observed in similar systems. For example, $[(CO)_3ClRe(dpq)]$ and $[(CO)_3ClRe(dpq)Re(CO)_3Cl]$ display reduction potential increases of 800 mV and 1200 mV, respectively, relative to the free dpq ligand [38,39]. In the heterobimetallic system $[(tpy)RuCl(dpq)PtCl_2]$ (tpy = 2,2′:6′,2″-terpyridine), reported by Williams et al. [40] the reduction potential showed a cathodic shift of 1000 mV relative to dpq. This increase in potential was attributed to the presence of an electron-rich Ru centre bound to five polyazine nirogens. For heterobimetallic systems such as $[(bpy)_2Ru(dpq)Cu(PPh_3)_2]^{3+}$ the second metal, in this case Cu, increases the potential by 100 mV. This small increase was

Table 1

$[(CN)_4Ru(ppb)Ru(CN)_4]^{4-}$	MeOH	0.80	0.50		
$[(CN)_4Ru(dpq)Ru(CN)_4]^{4-}$	DMF	0.65	0.37	−1.19	
$[(CN)_4Ru(ppb)Ru(CN)_4]^{4-}$	DMF	0.7	0.36	−1.01	−1.51

attributed to the weak π-acid character of $\{Cu(PPh_3)_2\}^+$ [25]. One possible explanation for the trends in the reduction potentials of the $\{Ru(CN)_4\}^{2-}$ complexes is that the coulombic effect of the negatively charged metal moieties counterbalances the metal(dπ) to ligand(π*) mixing. The mixing increases the reduction potential.

The mononuclear Os complexes show a single oxidation wave assigned to oxidation of the Os(II) centre (Table 1) [29,41]. The binuclear Os complexes show two oxidation waves separated by 300–400 mV, which are assigned to the Os(II)Os(II)/Os(III)Os(II) and Os(III)Os(II)/Os(III)-Os(III) couples [30]. The product of the first oxidation is a mixed-valent state. The first oxidation potential for the binuclear complexes is <100 mV shifted from that of the corresponding mononuclear complex, indicating that addition of a second metal ion has little effect on the energy of the valence orbitals of the mononuclear complex. The effect of solvent on these potentials is modest, with shifts of <100 mV observed. The observation of two separate one-electron oxidation processes indicates a degree of inter-metal coupling in the binuclear complexes, which may be quantified by the comproportionation constant (K_{com})[1] and these data are presented in Table 4. K_{com} for $[(bipy)_2Os(ppb)Os(bipy)_2]^{4+}$ is an order of magnitude greater than that for $[(bipy)_2Os(dpq)Os(bipy)_2]^{4+}$ suggesting that the ppb ligand offers a communication conduit which facilitates production of a more stable mixed-valence species.

The mononuclear Ru complexes display a single oxidation wave that is insensitive to the bridging ligand, and which is assigned to oxidation of the Ru(II) centre, by comparison with previously reported data (Table 1) [32]. However, these oxidation potentials shift to significantly more positive potentials on changing the solvent from DMF to MeOH, and such behaviour appears to be a feature of Ru(II) complexes containing cyano ancillary ligands. Timpson et al. found that the π* MOs on the CN^- ligands in solvents of high acceptor number are stabilised. This causes the metal dπ MOs to shift to higher energy thus decreasing the oxidation potential [42].

The binuclear complexes show sequential one-electron oxidations and, in contrast to the Os complexes, the first oxidation is 130–200 mV less than that of the corresponding mononuclear compound, showing that the presence of the second metal has an effect on the redox orbitals of the mononuclear metal–ligand assembly. The K_{com} values for the binuclear $[Ru(CN)_4]^{2-}$ complexes in MeOH (Table 4) show that $[(CN)_4Ru(ppb)Ru(CN)_4]^{4-}$ is more stable than the analogous dpq complex, and both complexes display larger K_{com} values in DMF.

[1] The comproportionation constant may be evaluated from the electrochemical data by application of the equation $K_{com} = e^{\Delta E_{1/2}/25.69}$, where $\Delta E_{1/2}$ is the splitting (mV) between the sequential oxidation potentials.

2.3. Electronic absorption spectroscopy

The electronic absorption spectra of the mononuclear and binuclear $[Os(bpy)_2]^{2+}$ complexes and their oxidation products are presented in Table 2, while data for the analogous $[Ru(CN)_4]^{2-}$ complexes are given in Table 3.

The lowest energy transitions of the $[Os(bpy)_2]^{2+}$ complexes are charge-transfer in nature, and both ^{3}MLCT and ^{1}MLCT transitions (Os → ppb or Os → dpq) are observed [31]. Os → bpy MLCT transitions are also observed over the wavelength range 430–450 nm [43].

In the visible region the $[Ru(CN)_4]^{2-}$ complexes show strong MLCT transitions which are very solvatochromic. The MLCT transitions of $[(CN)_4Ru(dpq)]^{2-}$ and $[(CN)_4Ru(ppb)]^{2-}$ complexes show shifts of ~2100 cm^{-1} to longer wavelength when the solvent is changed from water to MeOH, and 4600 and 4800 cm^{-1}, respectively, on going from water to DMF. The binuclear complex $[(CN)_4Ru(ppb)Ru(CN)_4]^{4-}$ shows similar behaviour (a shift of ~4400 cm^{-1}) but the shift observed for $[(CN)_4Ru(dpq)Ru(CN)_4]^{4-}$ (~2500 cm^{-1}) is markedly smaller.

A plot of the electronic absorption band energies for the lowest energy MLCT transition, M → L (E_{op}) against the difference between first oxidation and first reduction potentials (ΔE) for each of the complexes (Fig. 2) reveals a correlation between these parameters.

A number of researchers have investigated the relationship between the energy of the optical transition (E_{op}) and the electrochemical parameters of the metal and ligand involved in the optical transition (ΔE) [44–46]. For a series of related complexes the plots of E_{op} versus ΔE are often linear. The slope may be altered by the extent of mixing between the donor, in these systems metal(dπ), and acceptor, ligand(π*), MOs [47]. Meyer et al. showed that the gradient is $1/(1-\Delta\alpha)$ where $\Delta\alpha$ is the change in extent of mixing between donor and acceptor orbitals caused by the charge-transfer process [47]. For our data the gradient for the osmium complexes is 0.7 ± 0.1 but for the ruthenium complexes is 1.2 ± 0.4. This implies that the $\Delta\alpha$ is greater in the osmium complexes than in the ruthenium, consistent with the electrochemical data which suggest little stabilisation of the ligands in the presence of the ruthenium moiety.

2.4. Spectroelectrochemistry

The electrochemical oxidation of $[(CN)_4Ru(dpq)]^{2-}$ in MeOH and DMF leads to a depletion of the MLCT transition with the concomitant growth of a less intense blue-shifted transition (Fig. 3 and Table 3). This new absorption is similar to those observed in oxidised Os and Ru dpq complexes [31,36,48] which are attributed to an LMCT transition. The LMCT transition shifts to lower energy in MeOH relative to DMF. This solvatochromic behaviour is in the opposite direction to that observed for the MLCT transition of the parent complex. This is consistent with

the LMCT assignment for the oxidised species as the metal(dπ) orbitals are *acceptor* MOs in this transition; they are destabilised in DMF relative to MeOH thus increasing the transition energy. Similar changes are observed for $[(CN)_4Ru(ppb)]^{2-}$ (Table 3).

The spectral changes that accompany the oxidation of $[(bpy)_2Os(ppb)]^{2+}$ are similar to those observed for the previously reported complex $[(bpy)_2Os(dpq)]^{2+}$ and are presented in Table 2 [31].

The binuclear complexes show a depletion of their MLCT transitions upon oxidation (Table 2). The first oxidation leads to the formation of a mixed-valent state and an IVCT band is observed at 1092 nm for $[(bpy)_2Os(ppb)Os(bpy)_2]^{5+}$. This is slightly red-shifted from the corresponding

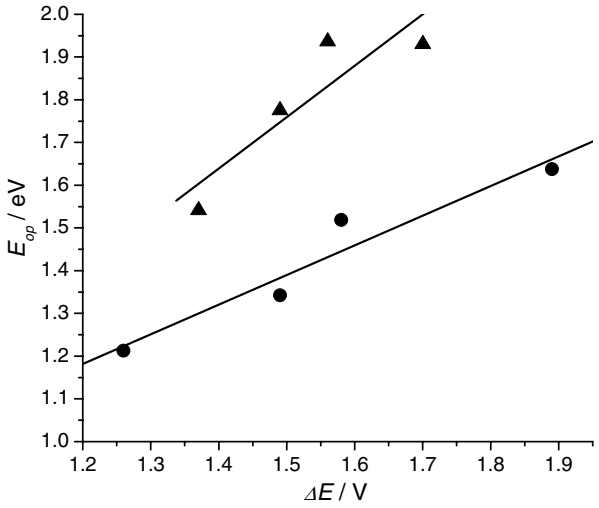

Fig. 2. Plots of the energy of the lowest energy ^{3}MLCT transition (E_{op}) vs. the thermodynamic energy difference between first oxidation and first reduction potentials (ΔE) for $\{Os(bpy)_2\}^{2+}$ (●) and Ru (▲) complexes. Plotted lines are the least squares regression for each data set.

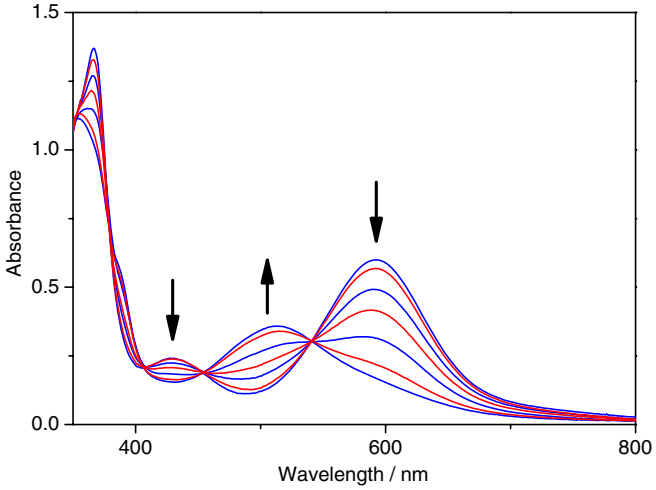

Fig. 3. The electronic absorption spectral changes (indicated by arrows) for $[Ru(CN)_4(ppb)]^{2-}$ in MeOH with application of an oxidising potential.

$[(bpy)_2Os(dpq)Os(bpy)_2]^{5+}$ IVCT band and is about 3 times more intense [30]. Further oxidation results in depletion of the IVCT transition and the growth of new features attributed to LMCT transitions [24,30]. The electrochemically prepared mixed-valence species $[(CN)_4Ru(dpq)Ru(CN)_4]^{3-}$ shows a weak IVCT transition which is red-shifted on going from MeOH (1318 nm) to DMF (1469 nm). The IVCT transition of $[(CN)_4Ru(ppb)Ru(CN)_4]^{3-}$ also red-shifts on going from MeOH to DMF and the transitions are an order of magnitude more intense than in the dpq complex. However, the IVCT transitions observed in the ruthenate complexes are significantly less intense than those observed for the Os complexes (Tables 2 and 3).

Subsequent oxidation of the mixed-valent ruthenate complexes causes the bleaching of the IVCT transitions and formation of new bands (Table 3) that are assigned as LMCT transitions. These transitions, red-shift, in DMF (relative to MeOH) in contrast to those observed in the mononuclear complexes.

The bandwidth (full width half height, $\nu_{1/2}$/cm^{-1}) values for the IVCT transition in a mixed-valence species can be used to obtain information about the nature of the mixed valence state [5,49–51] and such data for the Os and Ru complexes are given in Table 4. For each of the $\{Ru(CN)_4\}^{2-}$ complexes, the bandwidth of the IVCT band is close to that predicted by Hush theory [52–54]. For $[Ru(CN)_4(dpq)]^{2-}$, $\nu_{1/2}$ is 4500 and 4000 cm^{-1} in MeOH and DMF, respectively, close to the predicted values of 4200 and 4000 cm^{-1}. For $[Ru(CN)_4(ppb)]^{2-}$ the observed (and predicted) values are 3400 (4000) cm^{-1} in MeOH and 4300 (3700) cm^{-1} in DMF. However, both $[Os(bpy)_2(dpq)]^{2+}$ (2500 cm^{-1}) and $[Os(bpy)_2(ppb)]^{2+}$ (1700 cm^{-1}) complexes display significantly narrower transitions than predicted (>4000 cm^{-1}) (Table 4). Hush theory is generally considered to be very effective in accurately predicting the IVCT transition bandwidths of weakly coupled Class II systems [55–58] and the observation of transitions narrower than those predicted by the theory suggests strong coupling and hence Class III systems. Thus our data suggest that the Os complexes are Class III while the Ru complexes are weakly coupled Class II systems (see Fig. 4).

The spectroscopic and electrochemical data show that the ppb complexes form more stable mixed-valence systems than the dpq complexes, as evidenced by more intense and spectrally narrower IVCT transitions. The increase in stability ranges between 4 and 15 times (Table 4). Comparing dpq and ppb ruthenate complexes, the IVCT transitions of the ppb complex are 8 times more intense – the effect is less for the Os systems (about 2.5 times).

We were unable to obtain crystallographic structural data for these systems but the structure of the ruthenate complexes may be modelled using density functional theory. These calculations reveal that the ppb complex is

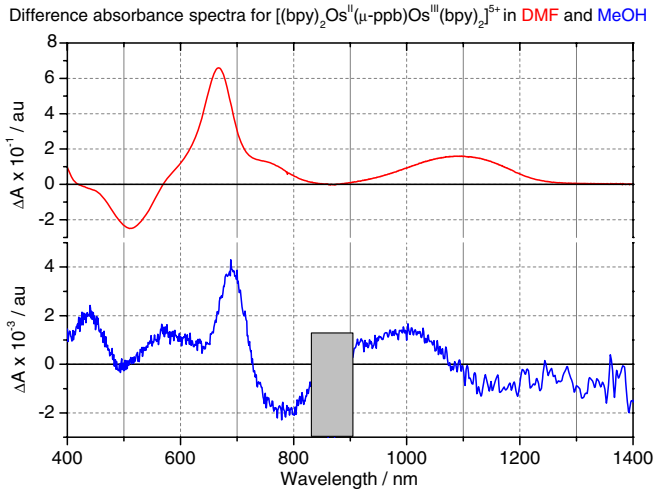

Fig. 4. Absorbance difference spectra for $[(bpy)_2Os^{III}(\mu\text{-ppb})Os^{II}(bpy)_2]^{5+}$ minus $[(bpy)_2Os^{II}(\mu\text{-ppb})Os^{II}(bpy)_2]^{4+}$ in DMF (top trace) and MeOH (bottom trace). Spectra were generated in a spectroelectrochemical cell using the parent species as the background trace. A strong MeOH solvent feature has been blocked in the lower trace difference spectrum.

much more planar than that with dpq (Fig. 5). In the case of $[(CN)_4Ru(ppb)Ru(CN)_4]^{4-}$ the axial CN groups on adjacent Ru centres are essentially co-linear; however, for $[(CN)_4Ru(dpq)Ru(CN)_4]^{4-}$ these groups are rotated 42°. The dpq ligand is also non-planar with the pyridyl rings splayed 70° apart. This loss of planarity in the case of dpq is consistent with the reduction in inter-metal coupling as evidenced in the IVCT transitions.

3. Conclusions

The behaviours of mixed valence complexes prepared from binuclear complexes of $[Ru(CN)_4]^{2-}$ and $[Os(bpy)_2]^{2+}$ differ as a function of metal and bridging ligand. The $[Os(bpy)_2]^{2+}$ complexes appear to be Class III in nature with those of $[Ru(CN)_4]^{2-}$ being closer to Class II. It is clear for these data that the $[Os(bpy)_2]^{2+}$ complexes are more strongly coupled than those of $[Ru(CN)_4]^{2-}$. The effect of the bridging ligand is also pronounced, with the less sterically flexible bridging ligand providing greater inter-metal stabilisation (by an order of magnitude in K_{com}), as evidenced by increases in the intensity of the IVCT and by the width of the IVCT. These data provide an example of control of the structure giving control over electronic properties. Calculations suggest that the ppb ligand has a much less distorted structure than that of dpq, this may explain the greater coupling in the case of complexes with the former bridging ligand.

4. Experimental

Synthetic reagents were LR or AR grade and were used without further purification unless otherwise specified. All solvents used for spectroscopic and electrochemical measurements were Aldrich spectroscopic or HPLC grade and were used without further purification.

$[(bpy)_2OsCl_2]$ [59] and ppb [29] were prepared by the literature methods. $[(bpy)_2Os(dpq)Os(bpy)_2](PF_6)_4$ was prepared by the method of Richter and Brewer [31] while

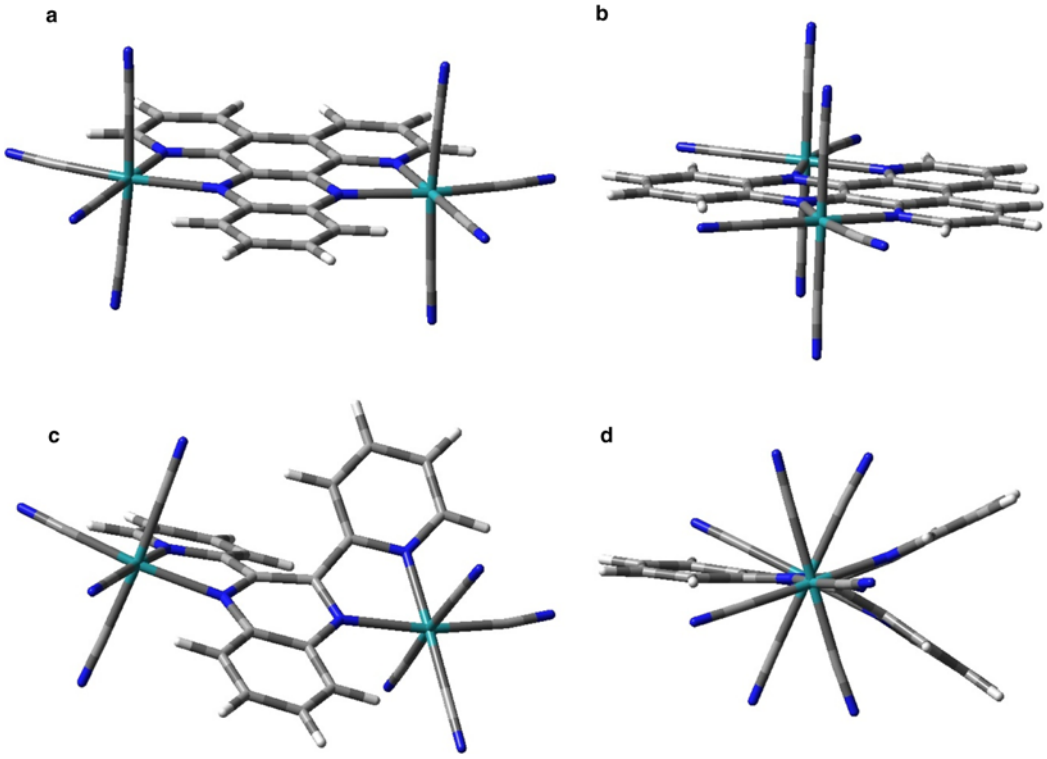

Fig. 5. Calculated structures of $[(CN)_4Ru(ppb)Ru(CN)_4]^{4-}$ (a, b) and $[(CN)_4Ru(dpq)Ru(CN)_4]^{4-}$ (c, d).

$[(bpy)_2Os(ppb)](PF_6)_2$ and $[(bpy)_2Os(dpq)](PF_6)_2$ were prepared as previously described [29]. The samples of $[(bpy)_2Os(dpq)Os(bpy)_2](PF_6)_4$, $[(bpy)_2Os(ppb)](PF_6)_2$ and $[(bpy)_2Os(dpq)](PF_6)_2$ were used from our previous study [29].

5. Instrumentation

Spectroscopic and electrochemical data were obtained as previously reported [29]. Calculations (B3LYP/3-21G) were performed using the GAUSSIAN-03W suite of programmes [60].

5.1. $[(bpy)_2Os(ppb)Os(bpy)_2](PF_6)_4$

$[(bpy)_2OsCl_2]$ (200 mg, 0.349 mmol) and ppb (100 mg, 0.354 mmol) were gently heated in ethylene glycol (50 ml) until completely dissolved. The solution was then heated to reflux for 2 h. On cooling, dichloromethane (100 ml) and water (200 ml) were added. The organic layer was separated and discarded and the aqueous layer again extracted with dichloromethane (100 ml). The aqueous layer was diluted, loaded on to a Sephadex SP-C25 column (10 cm × 2 cm diameter) and washed well with water and 0.05 M sodium *p*-tolylsulfonate to remove an uncharged species. The binuclear complex was eluted with 0.3 M sodium *p*-tolylsulfonate. The complex was separated from the eluant by addition of solid NH_4PF_6 (1 g) followed by extraction with 5 × 100 ml of dichloromethane. The resulting intensely coloured organic solution was taken to dryness (rotavap), dissolved in a minimum volume of acetonitrile and reprecipitated by addition to an aqueous NH_4PF_6 solution. The solid was collected by filtration, dissolved in acetonitrile and reprecipitated by addition to ether. Yield: 120 mg (48%). *Anal.* Calc. for $C_{58}H_{42}N_{12}Os_2P_4F_{24}$: C, 37.30; H, 2.27; N, 9.00. Found: C, 37.00; H, 2.85; N, 8.81%. ^{1}H NMR (500 MHz, MeCN-d_3): 9.14 (d, $J^d = 8.5$ Hz, 1H), 9.09 (d, $J^d = 8.5$ Hz, 1H), 8.75 (d, $J^d = 8.5$ Hz, 1H), 8.68 (d, $J^d = 8.5$ Hz, 1H), 8.64 (d, $J^d = 8.0$ Hz, 1H), 8.57 (d, $J^d = 8.0$ Hz, 1H), 8.54 (d, $J^d = 8.0$ Hz, 1H), 8.50 (d, $J^d = 8.5$ Hz, 1H), 8.30 (d, $J^d = 8.5$ Hz, 1H), 8.12 (m, 2H), 8.05 (m, 6H), 7.96 (ddd, $J^{d1} = 8.5$ Hz, $J^{d2} = 8.0$ Hz, $J^{d3} = 1.0$ Hz, 1H), 7.88 (m, 4H), 7.79 (d, $J^d = 5.5$ Hz, 1H), 7.67 (m, 2H), 7.56 (d, $J^d = 5.0$ Hz, 1H), 7.50 (m, 7H), 7.37 (AA′BB′, $J = 3.5$ Hz, 1H), 7.31 (d, $J^d = 5.0$ Hz, 1H), 7.23 (m, 3H), 7.16 (d, $J^d = 8.5$ Hz, 1H), 7.12 (ddd, $J^{d1} = 5.0$ Hz, $J^{d2} = 4.0$ Hz, $J^{d3} = 1.0$ Hz, 1H), 6.97 (ddd, $J^{d1} = 7.5$ Hz, $J^{d2} = 6.0$ Hz, $J^{d3} = 1.0$ Hz, 1H), 6.71 (d, $J^d = 5.0$ Hz, 1H). ES-MS: *m/z* 1723, $\{M-PF_6\}^+$; 789, $\{M-2PF_6\}^{2+}$; 477.7, $\{M-3PF_6\}^{3+}$; 322, $\{M-4PF_6\}^{4+}$.

5.2. $Na_4Ru(CN)_6$

$RuCl_3 \cdot xH_2O$ (1.00 g) was dissolved in the minimum volume of water (10 ml) and added to a solution of NaCN (10 g) in ethylene glycol (50 ml). The solution was refluxed for 30 min, cooled and added to methanol (100 ml) to precipitate the crude product. This was collected by filtration, dissolved in the minimum volume of water and filtered. NaI (5 g) was added to the aqueous solution which was layered with methanol (200 ml) and left undisturbed for one week. Large crystals formed which were filtered, washed with ether and air dried. Yield: 1.25 g. ^{13}C NMR (50 MHz, D_2O): 164.0. IR (KBr disc): 2064 cm^{-1}. ES-MS: *m/z* 278, $\{M-(Na_2CN)\}^-$; 255, $\{M-(Na_3CN)\}^-$; 229, $\{M-(Na_3(CN)_2)\}^-$; 206, $\{M-(Na_4(CN)_2)\}^-$; 180, $\{M-(Na_4(CN)_3)\}^-$; 154, $\{M-(Na_4(CN)_3)\}$.

5.3. $Na_2[Ru(CN)_4(L)]$

To the appropriate ligand (270 mg, 0.96 mmol) in methanol (250 ml) was added $Na_4Ru(CN)_6$ (200 mg, 0.57 mmol) dissolved in water (250 ml). The resulting clear solution was thoroughly purged with argon in a quartz reaction vessel and irradiated with 254 nm light in a Rayonet reactor for 32 h. The now red (dpq) or purple (ppb) solution was concentrated and extracted 3 times with dichloromethane (50 ml). The desired product was separated from unreacted $Na_4Ru(CN)_6$ and the binuclear product on a Sephadex DEAE-A25 column, the red product eluting with 0.3 M NaI. The solution was concentrated and the product precipitated by slow addition to acetone. This was repeated to ensure no NaI remained.

5.4. $Na_2[Ru(CN)_4(ppb)]$

Yield: 220 mg (72%). *Anal.* Calc. for $Na_2[Ru(CN)_4(ppb)]1.5NaI \cdot 4H_2O$ ($C_{22}H_{18}I_{1.5}N_8Na_{3.5}O_4Ru$): C, 31.82; H, 2.19; N, 13.50. Found: C, 31.41; H, 1.99; N, 14.08% [61,62]. ^{1}H NMR (300 MHz, D_2O): 9.54 (d, $J^d = 9.0$ Hz, 2H), 9.40 (d, $J^d = 5.5$ Hz, 2H), 8.04 (m, 4H), 7.86 (d, $J^d = 8.0$ Hz, 1H), 7.70 (dd, $J^{d1} = 6.0$ Hz, $J^{d2} = 5.5$ Hz, 1H), 7.59 (d, $J^d = 8.0$ Hz, 1H), 7.51 (t, $J^t = 5.5$ Hz, 1H), 6.99 (d, $J^d = 7.5$ Hz, 1H). ^{13}C NMR (50 MHz, D_2O): 164.7, 163.9, 163.4, 163.2, 156.3, 154.5, 151.5, 150.8, 149.9, 144.8, 141.3, 141.2, 140.7, 137.2, 134.4, 133.2, 13.4, 129.4, 129.3, 127.3, 127.1, 126.9. ES-MS: *m/z* 513, $\{M-Na\}^-$; 491, $\{M-2Na\}^-$; 465, $\{M-(Na_2CN)\}$. IR (KBr disc): 2097(w), 2068(w), 2059(m), 2044(m).

5.5. $Na_2[Ru(CN)_4(dpq)]$

Yield: 270 mg (88%). *Anal.* Calc. for $Na_2[Ru(CN)_4(dpq)]1.7NaI \cdot 4H_2O$ ($C_{22}H_{20}I_{1.7}N_8Na_{3.7}O_4Ru$): C, 30.64; H, 2.34; N, 12.99. Found: C, 30.34; H, 2.15; N, 14.10%. ^{1}H NMR (300 MHz, D_2O): 9.94 (d, $J^d = 8.0$ Hz, 1H), 9.60 (d, $J^d = 4.0$ Hz, 2H), 8.41 (d, $J^d = 10.0$ Hz, 1H), 8.22 (m, 3H), 8.03 (m, 2H), 7.66 (t, $J^t = 8.0$ Hz, 1H), 6.44(t, $J^t = 7.0$ Hz, 1H). ^{13}C NMR (50 MHz, D_2O): 164.7, 163.8, 163.3, 162.1, 154.3, 151.7, 148.1, 145.9, 145.8, 144.0, 143.7, 142.2, 134.5, 133.8, 133.2, 132.0, 131.7, 131.0, 128.9, 127.4, 125.5, 125.0. ES-MS: *m/z* 511,

{M−Na}$^-$; 489, {M−2Na}$^-$; 462, {M−(Na_2CN)}$^-$. IR (KBr disc): 2100(w), 2077(w), 2066(m), 2052(m).

5.6. $Na_4[Ru(CN)_4(ppb)Ru(CN)_4]$

To dpq (155 mg) in methanol (200 ml) was added $Na_4Ru(CN)_6$ (400 mg) dissolved in water (300 ml). The resulting clear solution was thoroughly purged with argon in a quartz reaction vessel and irradiated with 254 nm light in a Rayonet reactor for 48 h. The now purple solution was concentrated and extracted 3 times with dichloromethane (50 ml). The desired product was separated from unreacted $Na_4Ru(CN)_6$, the mononuclear product and a contaminating possibly trinuclear complex on a Sephadex DEAE-A25 column, the purple product eluting with 1.0 M NaI. The solution was concentrated and the oily product precipitated by slow addition to acetone. This solid was redissolved in methanol and reprecipitated by addition to acetone. Yield: 180 mg (48%). *Anal*. Calc. for $Na_4[Ru(CN)_4(ppb)Ru(CN)_4]0.5NaI \cdot 11H_2O$ ($C_{26}H_{32}I_{0.5}N_{12}Na_{4.5}O_{11}Ru_2$): C, 29.53; H, 3.05; N, 15.89. Found: C, 29.91; H, 3.06; N, 15.24%. ^{1}H NMR (300 MHz, D_2O): 9.31 (m, 4H), 8.05 (d, $J^d = 8.5$ Hz, 2H), 8.00 (AA′BB′, $J = 3.0$ Hz, 2H), 7.75 (t, $J^t = 8.0$ Hz, 2H), 7.53 (t, $J^t = 6.0$ Hz, 2H). ^{13}C NMR (50 MHz, D_2O): 163.3, 162.7, 162.1, 162.0, 157.4, 153.9, 152.6, 143.6, 136.9, 133.4, 131.6, 129.8, 126.9. ES-MS: *m/z* 347, {M}$^{2-}$; 334, {M−CN}$^{2-}$. IR (KBr disc): 2099(w), 2068(w), 2050(m), 2046(m).

5.7. $Na_4[Ru(CN)_4(dpq)Ru(CN)_4]$

To ppb (155 mg) in methanol (200 ml) was added $Na_4Ru(CN)_6$ (400 mg) dissolved in water (300 ml). The resulting clear solution was thoroughly purged with argon in a quartz reaction vessel and irradiated with 254 nm light in a Rayonet reactor for 48 h. The now blue solution was concentrated and extracted 3 times with dichloromethane (50 ml). The desired product was separated from unreacted $Na_4Ru(CN)_6$ and the mononuclear product on a Sephadex DEAE-A25 column, the purple product eluting with 1.0 M NaI. The solution was concentrated and the product precipitated by slow addition to acetone. This solid was found to contain a green, possibly trinuclear contaminant which was removed by size exclusion chromatography on a Sephadex LH-20 column by eluting with methanol. Yield: 27 mg (7%). *Anal*. Calc. for $Na_4[Ru(CN)_4(dpq)Ru(CN)_4]0.5NaI \cdot 11H_2O$ ($C_{26}H_{34}I_{0.5}N_{12}Na_{4.5}O_{11}Ru_2$): C, 29.47; H, 3.23; N, 15.86;. Found: C, 29.84; H, 3.16; N, 15.13%. ^{1}H NMR (300 MHz, D_2O): 9.97 (AA′BB′, $J = 3.5$ Hz, 2H), 9.63 (d, $J^d = 4.5$ Hz, 2H), 8.66 (d, $J^d = 5.5$ Hz, 2H), 8.28 (AA′BB′, $J = 3.5$ Hz, 2H), 7.75 (dd, $J^{d1} = 5.5$ Hz, $J^{d2} = 4.5$ Hz, 2H). ^{13}C NMR (50 MHz, D_2O): 165.4, 163.5, 162.0, 161.2, 154.3, 148.2, 146.2, 145.9, 133.7, 131.9, 131.5, 127.8, 126.9. ES-MS: *m/z* 346, {M}$^{2-}$; 333, {M−CN}$^{2-}$. IR (KBr disc): 2099(w), 2081(w), 2072(m), 2051(m).

Abstract

Minerals in the rosasite mineral group namely rosasite, glaucosphaerite, kolwezite, mcguinnessite have been studied by powder X-ray diffraction, scanning electron microscopy and infrared spectroscopy. X-ray diffraction shows the minerals to be complex mixtures with more than one rosasite mineral observed in each sample. SEM analysis shows the minerals to be fibrous in nature and the use of EDAX enabled the chemical composition of the minerals to be determined. The spectral patterns for the minerals rosasite, glaucosphaerite, kolwezite and mcguinnessite are similar to that of malachite implying the molecular structure is similar to malachite. A comparison is made with the spectrum of malachite. The rosasite mineral group is characterised by two OH stretching vibrations at ~3401 and 3311 cm^{-1}. Two intense bands observed at ~1096 and 1046 cm^{-1} are assigned to v_1 $(CO_3)^{2-}$ symmetric stretching vibration and the δ OH deformation mode. Multiple bands are found in the 800–900 and 650–750 cm^{-1} regions attributed to the v_2 and v_4 bending modes confirming the symmetry reduction of the carbonate anion in the rosasite mineral group as C_{2v} or C_s. A band at ~560 cm^{-1} is assigned to a CuO stretching mode.

Keywords: Glaucosphaerite; Kolwezite; Mcguinnessite; Nullaginite; Rosasite; Hydroxycarbonate; Infrared spectroscopy

1. Introduction

The carbonates are a group of over 60 naturally occurring minerals containing the essential structural building block $(CO_3)^{2-}$. Most of these minerals are relatively rare and often in association with other building blocks such as hydroxyls, halogens, sulphate, silicate, phosphate, etc. The common simple rock-forming carbonates can be divided into three main groups: (a) the calcite group, (b) the dolomite group and (c) the aragonite group. Peter Williams reports that whilst metal substitution in azurite is extremely uncommon, such is not the case for malachite [1]. Substitution of Cu(II) by other cations gives rise to the rosasite mineral group. In minerals related to malachite, ions identified together with Cu(II) are: Zn(II), Co(II), Ni(II) and Mg(II). The rosasite mineral group is monoclinic or triclinic hydroxy carbonates with the general formula $A_2(CO_3)(OH)_2$ or $AB(CO_3)(OH)_2$ where A and B is cobalt, copper, magnesium, nickel and zinc [2]. The most common congener of malachite is rosasite. Rosasite forms in the oxidation zones of zinc–copper deposits and the crystals are often fibrous and found in tufted aggregates. No single crystal study of rosasite has been forth coming. Powder diffraction studies of rosasite suggest the mineral is triclinic [3]. The chemical composition of the rosasite minerals means that the minerals are highly colourful, often green to blue. Minerals in the rosasite group are related to the mineral malachite [4,5]. Minerals in this group include rosasite $[(Cu,Zn)_2(CO_3)(OH)_2]$ [6–8], glaucosphaerite $[(Cu,Ni)_2(CO_3)(OH)_2]$ [9–11], kolwezite $[(Cu,Co)_2(CO_3)(OH)_2]$ [12], mcguinnessite $[(Mg,Cu,)_2(CO_3)(OH)_2]$ [13–16], and nullaginite $[(Ni)_2(CO_3)(OH)_2]$ [17–19]. Apart from rosasite the minerals are rare secondary minerals.

Besides the chemical composition, the structural relationships between these minerals are demonstrated by the similarity of their powder diffraction patterns [20]. The space group symmetry and cell parameters are mainly derived from powder pattern indexing. Apart from that of malachite, no other structural determinations are available for the rosasite minerals. Rosasite as with the other minerals of this group form spheroidal aggregates in extremely thin fibrous crystals. Rosasite may be associated with aurichalcite, smithsonite and hemimorphite.

Infrared and Raman spectroscopy have been used to investigate carbonates including azurite and malachite [21,22]. A detailed single crystal Raman study has been undertaken [5,21]. However the vibrational spectroscopy of minerals of the rosasite group has not been undertaken. No infrared spectra of the minerals of the rosasite group have been forthcoming [22–25]. Also no NIR research on these minerals has been reported. An infrared stretching vibration of the hydroxyl unit of azurite was observed at 3425 cm^{-1}, whereas two bands were reported for malachite at 3400 and 3320 cm^{-1}. The observation of two bands for malachite suggests coupling of the hydroxyl stretching vibrations [5]. This coupling was not observed for azurite [5]. Azurite and malachite form the basis of pigments in samples of an archaeological or medieval nature [26–29]. Malachite has a characteristic intense band at ~430 cm^{-1} and for azurite an intense band at ~400 cm^{-1}. The deformation modes of azurite were reported at 1035 and 952 cm^{-1} and at 1045 and 875 cm^{-1} for malachite [22,30]. Thus even though the two carbonate minerals have the same space group, the molecular structure of the minerals is sufficiently different to show infrared bands at slightly different wavenumbers. Differences between the spectra of malachite and azurite may be explained by the molecular structure of azurite being based upon a distorted square planar arrangement compared with a distorted octahedral arrangement about the copper in malachite.

The symmetric stretching bands of carbonate for azurite and malachite were observed at 1090 and 1095 cm^{-1}. Goldsmith and Ross reported the infrared bending modes of carbonate at 837 and 817 cm^{-1} for azurite and at 820 and 803 cm^{-1} for malachite [21]. Two v_3 modes were observed at 1490 and 1415 cm^{-1} for azurite and at 1500 and 1400 cm^{-1} for malachite [4,5]. The observation of these two bands shows a loss of degeneracy. Such a conclusion is also supported by the observation of two v_4 modes at 769 and 747 cm^{-1} for azurite and 710 and 748 cm^{-1} for malachite. The vibrational spectroscopy of these two minerals is complicated by this loss of degeneracy. Schmidt and Lutz report some vibrational spectroscopic data [31]. Two infrared bands at 3415 and 3327 cm^{-1} were observed for malachite. Although the Raman spectra of the mineral brochantite [$Cu_4(OH)_6SO_4$] have been reported, the Raman spectra of malachite and azurite were not [31].

In this work we report the X-ray diffraction, SEM analysis and infrared spectroscopy of minerals of the rosasite group and relate the spectroscopy to the mineral structure.

2. Experimental

2.1. Minerals

The minerals, their formula and origin used in this study are listed in Table 1. Selected minerals were obtained from the Mineral Research Company and other sources including Museum Victoria. The samples were phase analysed by X-ray diffraction for phase analysis and for chemical composition by EDX measurements.

2.2. X-ray diffraction

X-ray diffraction (XRD) patterns were recorded using Cu Kα radiation ($n = 1.5418$ Å) on a Philips PANalytical X' Pert PRO diffractometer operating at 40 kV and 40 mA with 0.125° divergence slit, 0.25° anti-scatter slit, between 3° and 15° (2θ) at a step size of 0.0167°. For low angle XRD, patterns were recorded between 1° and 5° (2θ) at a step size of 0.0167° with variable divergence slit and 0.5° anti-scatter slit.

2.3. SEM analysis

Mineral samples of the rosasite were coated with a thin layer of evaporated carbon and secondary electron images were obtained using an FEI Quanta 200 scanning electron microscope (SEM). For X-ray microanalysis (EDX), three

Table 1
Table of the hydroxycarbonate minerals, their chemical formulae and origin

Mineral	Locality of origin	Formulae	Analysis (% by mass)
Rosasite	Mapimi, Durango, Mexico	$(Cu,Zn)_2(CO)_3(OH)_2$	CuO 35.7 ZnO 36.5
Glaukosphaerite	Carr Boyd Nickel Mine, Carr Boyd Rocks, W.A. [17,19]	$(Cu,Ni)_2(CO_3)(OH)_2$	CuO 41.6 NiO 25.2
Kolwezite	Mupine, Shaba Province, Zaire [33]	$(Cu,Co)_2(CO)_3(OH)_2$	CuO 48.4 CoO 23.0
McGuinnessite	Red Mountain, Mendocino County, CA [16]	$(Mg,Cu)_2(CO_3)(OH)_2$	CuO 39.6 MgO 23.7

samples were embedded in Araldite resin and polished with diamond paste on Lamplan 450 polishing cloth using water as a lubricant. The samples were coated with a thin layer of evaporated carbon for conduction and examined in a JEOL 840A analytical SEM at 25 kV accelerating voltage. Preliminary analyses of the rosasite mineral samples were carried out on the FEI Quanta SEM using an EDAX microanalyser, and microanalysis of the clusters of fine crystals was carried out using a full standards quantitative procedure on the JEOL 840 SEM using a Moran Scientific microanalysis system. Oxygen was not measured directly but was calculated using assumed stoichiometries to the other elements analysed.

2.4. Mid-IR spectroscopy

Infrared spectra were obtained using a Nicolet Nexus 870 FTIR spectrometer with a smart endurance single bounce diamond ATR cell. Spectra over the 4000–525 cm^{-1} range were obtained by the co-addition of 64 scans with a resolution of 4 cm^{-1} and a mirror velocity of 0.6329 cm/s. Spectra were co-added to improve the signal to noise ratio.

Spectral manipulation such as baseline adjustment, smoothing and normalisation were performed using the Spectracalc software package GRAMS (Galactic Industries Corporation, NH, USA). Band component analysis was undertaken using the Jandel 'Peakfit' software package

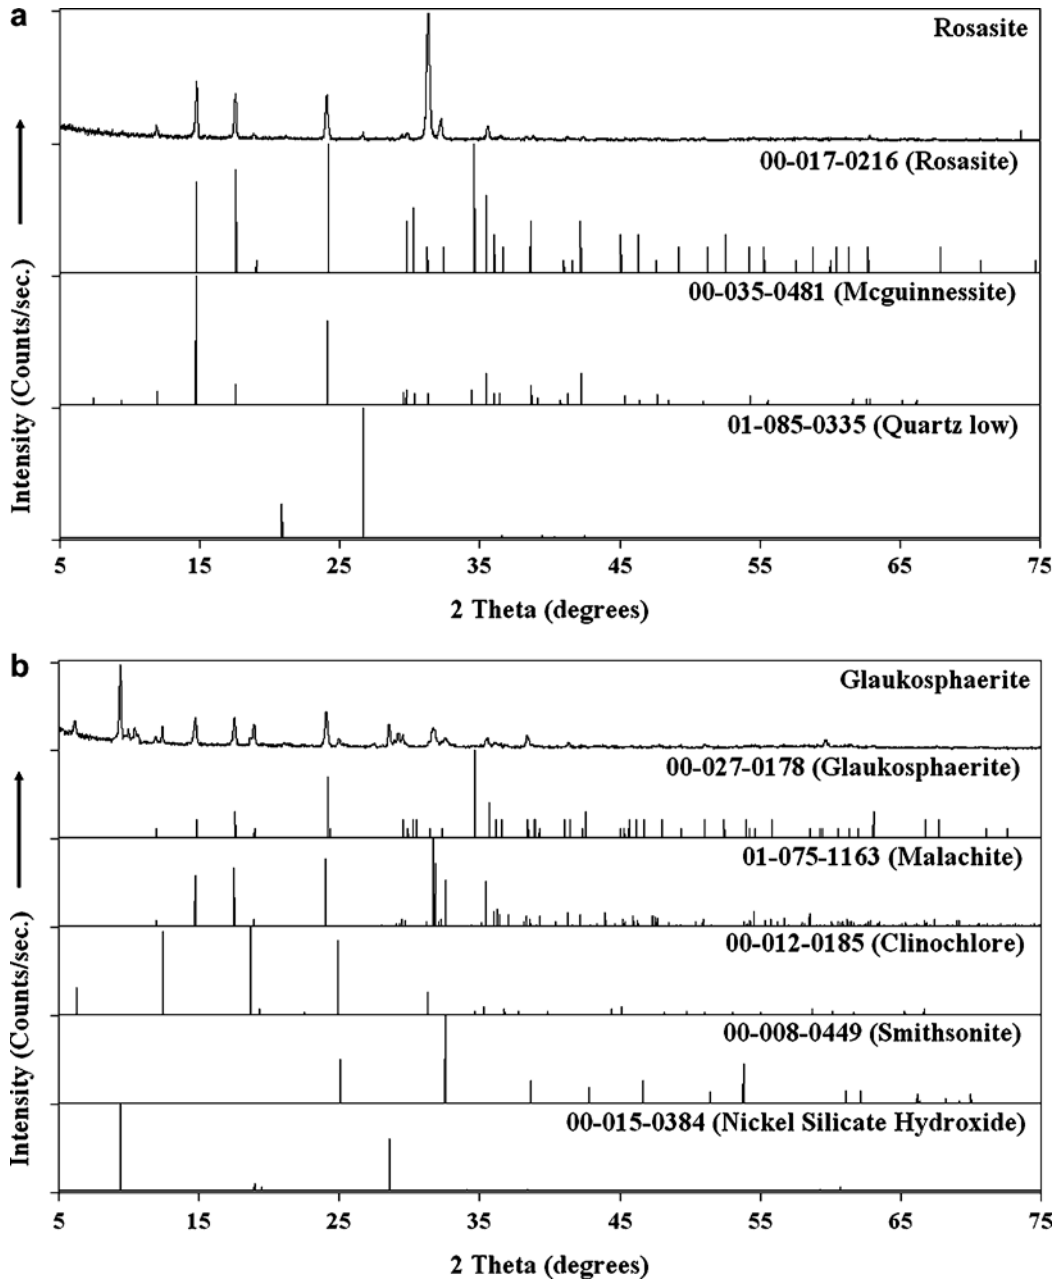

Fig. 1. (a and b) XRD patterns for rosasite and glaukosphaerite.

which enabled the type of fitting function to be selected and allows specific parameters to be fixed or varied accordingly. Band fitting was done using a Lorentz–Gauss cross-product function with the minimum number of component bands used for the fitting process. The Gauss–Lorentz ratio was maintained at values greater than 0.7 and fitting was undertaken until reproducible results were obtained with squared correlations of r^2 greater than 0.995.

3. Results and discussion

3.1. X-ray diffraction

The XRD patterns of the rosasite mineral group are illustrated by those of rosasite and glakosphaerite which are shown in Fig. 1a and b. What is observed from the XRD patterns is that the mineral rosasite appears to be a mixture of rosasite, quartz and mcguinnessite. Glaukosphaerite appears to be a mixture of glaukosphaerite with some malachite and other impurities. In order to run an XRD pattern the mineral is scraped off a host rock and is ground before the XRD pattern is collected. This means that all minerals present will be collected and analysed. In terms of SEM and spectroscopy a more judicious selection can be made and only specific crystals analysed. In this instance the correct mineral is obtained. Roberts et al showed that the mineral rosasite was monoclinic [32].

3.2. SEM images

SEM images of rosasite, glaucosphaerite, kolwezite and pokrovskite are shown in Fig. 2a–d. The crystals of the three minerals are acicular and may be up to 0.5 mm in length. The minerals appear to be fibrous in nature. The images show the hydroxycarbonates to be botryoidal and forming crusts. This is best illustrated by the SEM image of pokrovskite (Fig. 2d). Fig. 3 show the typical EDAX analyses of rosasite, gluakosphaerite, kolwezite and mcguinessite. The results of the analyses are reported in Table 1.

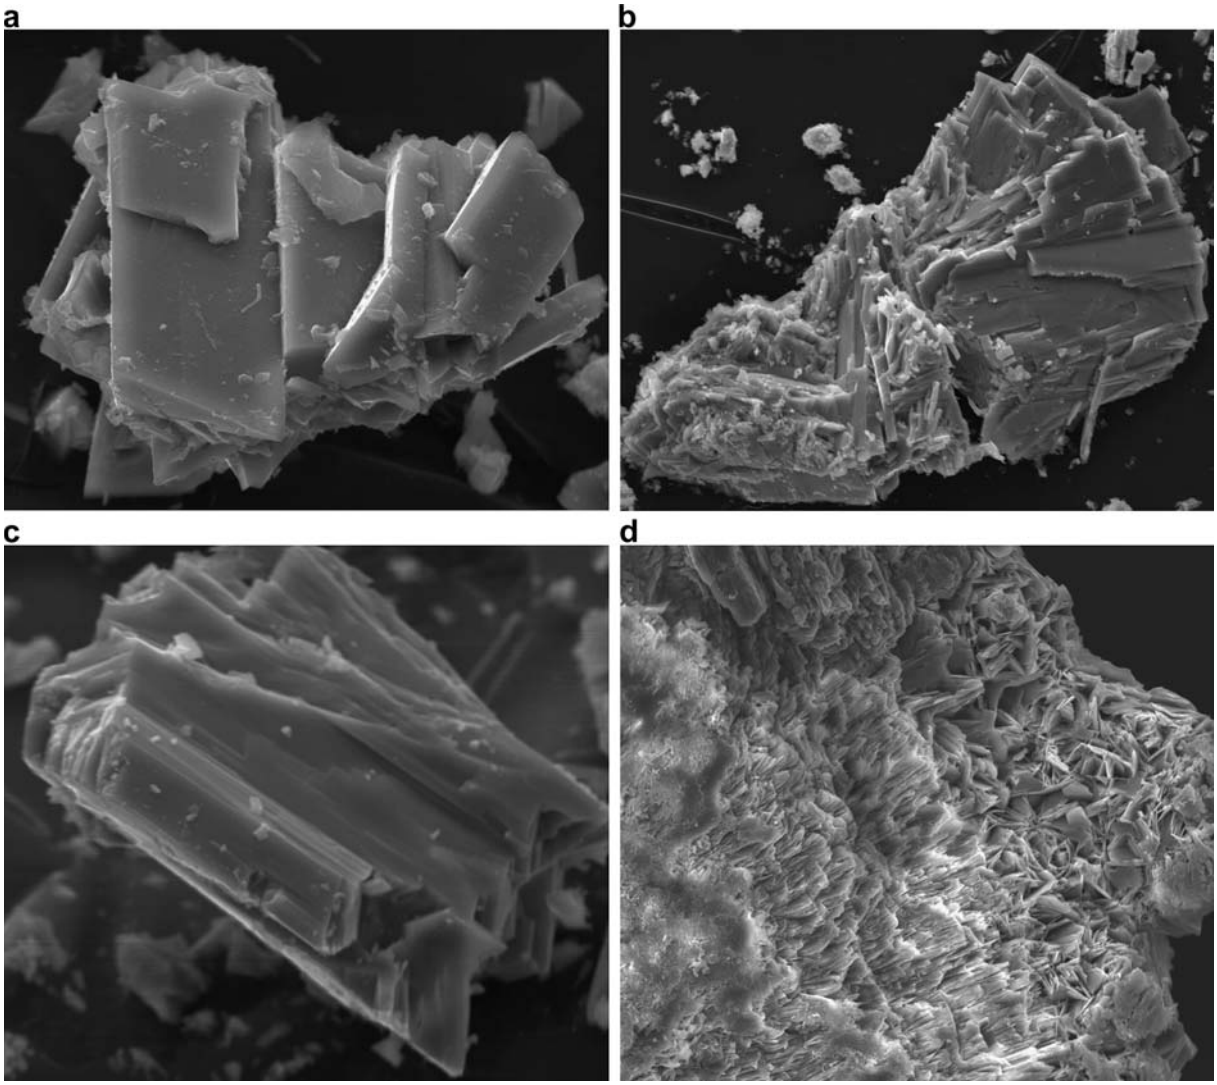

Fig. 2. (a–d) SEM images of rosasite, glaucosphaerite, kolwezite and pokrovskite (magnification 1500×).

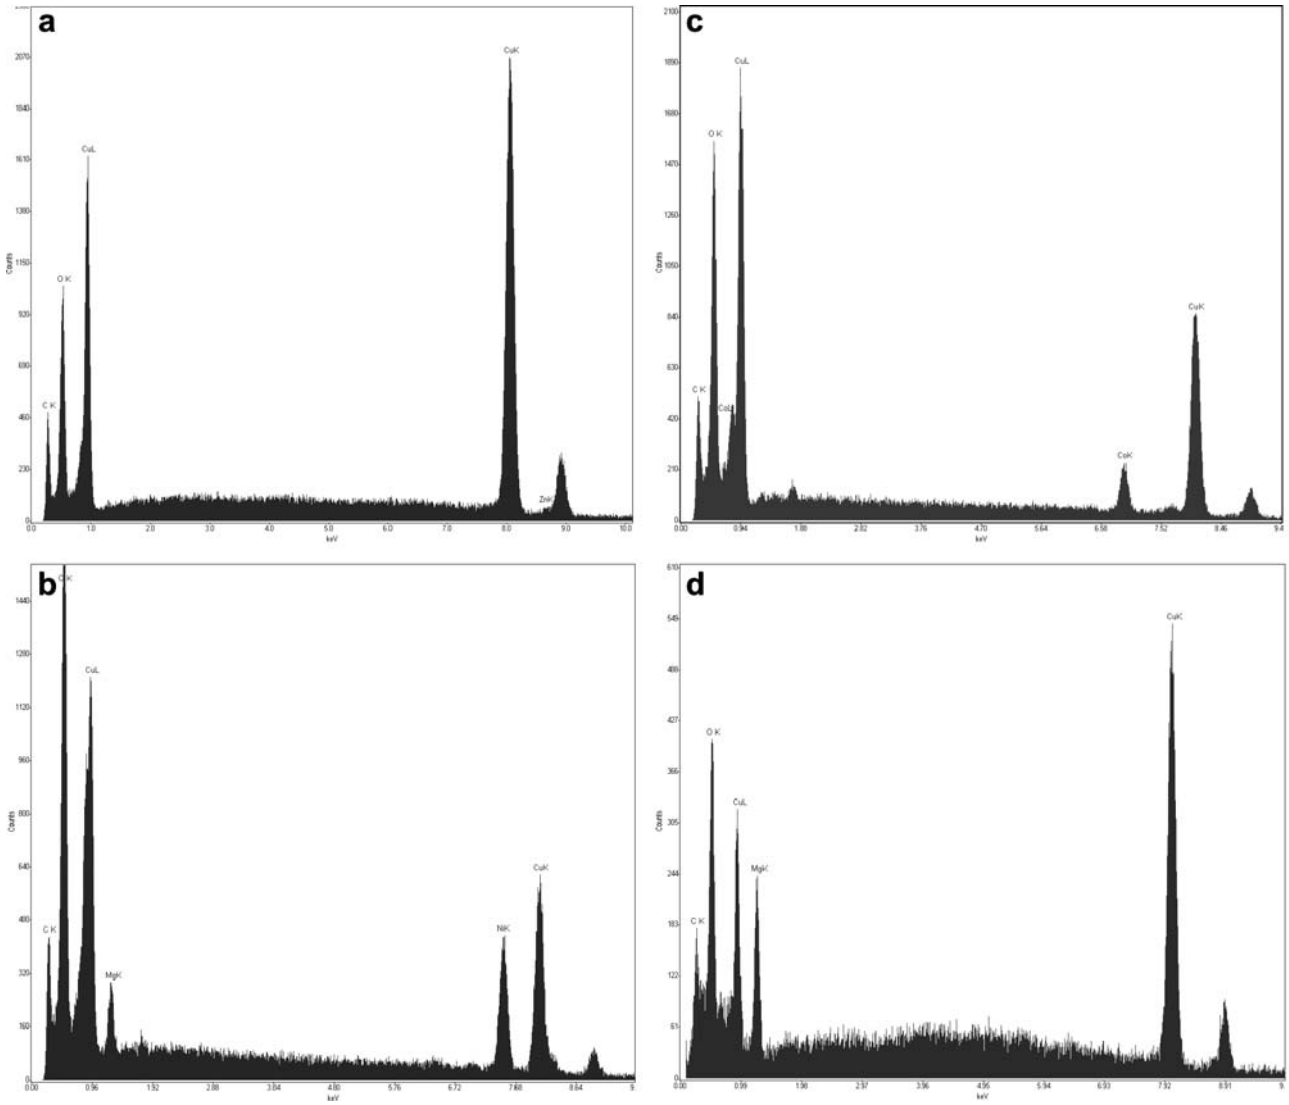

Fig. 3. (a–d) EDAX spectra of rosasite, glaucosphaerite, kolwezite and mcguinessite.

The rosasite sample used in this work analysed to a Cu/Zn ratio of close to 1:1. As such if the atom ratio of Cu/Zn is 1:1 then every second position in the model will be taken up by a Zn atom. Rosasite does not necessarily maintain a ratio of 1:1. For example the rosasite from Rosas mine, Narcao, Cagliari, Sardegna (Sardinia), Italy analyses as CuO 53.7% and ZnO 18.3%. This gives a formula of the Narcao rosasite as $(Cu_{1.5}Zn_{0.5})_2(CO)_3(OH)_2$. According to Anthony et al. a glaucosphaerite sample from Kasompi, Congo gave a formula of $(Cu_{1.23}Zn_{0.71})_2(CO)_3(OH)_2$ [33]. It is noted that the Cu/Zn ratio is not 1:1 and the total cations is not 2.0, but 1.94. The mineral glaucosphaerite from the Carr Boyd Nickel mine analyses as CuO 41.6% and NiO 25.2%. This gives the formula of glaucosphaerite as $(Cu_{1.1}Ni_{0.7}Mg_{0.06})_2(CO)_3(OH)_2$. A similar formula exists for the mineral kolwezite from Zaire namely $(Cu_{1.33}Co_{0.67})_2(CO)_3(OH)_2$. The fact that the two cation ratio is not 1:1 may have implications for the structure of the mineral and therefore for the vibrational spectroscopy of the mineral. The mcguinnessite from California gives a cation ratio of Cu/Mg as 1:1. Other measurements record a ratio of Mg/Cu as 1.5/0.5.

3.3. Infrared spectroscopy

The minerals of the rosasite group have not been studied by single crystal X-ray diffraction. Invariably because most of the crystals are composed of thin fibres. Extensive powder X-ray diffraction suggests the minerals are triclinic, although Anthony et al. states the minerals are monoclinic [33]. This statement is apparently based upon the assumption the structures are similar to that of malachite. The structure shows that two of the three oxygens bond to separate copper atoms but one carbonate oxygen bonds to two copper atoms. The OH unit serves to bridge two copper atoms. The model of the structure of malachite shows that the carbonate anion is of C_{2v} symmetry if the two cations bonding to the carbonate anion are identical [4,5]. If however the two cations are different (e.g. Cu and Ni or Cu and Zn) then the symmetry of the carbonate anion would be C_s.

The mineral glaucosphaerite is equally enigmatic and may be monoclinic. Williams reported the structure of the rosasite group of minerals to be triclinic [1]. It is not neccessarily true that rosasite has the same structure as malachite [1]. In the structure of rosasite some of the copper atoms in the model of malachite are replaced by zinc atoms.

The infrared spectra of selected minerals of the rosasite group in the OH stretching region are shown in Fig. 4. The results of the band component analysis of the infrared spectra are reported. Rosasite is characterised by two intense bands at 3401 and 3311 cm^{-1} with two additional bands at 3139 and 3486 cm^{-1}. The bands at 3486, 3401 and 3311 cm^{-1} are attributed to OH stretching vibrations whereas the bands at 3228 and 3139 cm^{-1} are ascribed to adsorbed water. If we use a Libowitzky type empirical formula [34] calculation of the hydrogen bond distances in the structure can be estimated. The bands at 3486, 3401, 3311 and 3139 cm^{-1} lead to hydrogen bond distances of 2.877, 2.80, 2.75 and 2.68 Å. The conclusion may be made that there are three different hydrogen bond distances of the OH units which are a weaker hydrogen bond strength than the hydrogen bond formed from adsorbed water. The mineral glaukosphaerite has infrared bands at 3529, 3402, 3309, 3191 and 3022 cm^{-1}. The bands at 3402 and 3309 cm^{-1} are in almost identical positions to those of rosasite. Because of the broad spectral profile in the OH stretching region variation in the bands at 3191 and 3022 cm^{-1} may occur. This makes the fitting of bands difficult. Similarly for the mineral kolwezite the two OH stretching vibrations are observed at 3401 and 3307 cm^{-1}. The infrared spectrum of mcguinnessite appears different. The two bands at 3407 and 3316 $cm^{-1}$are in common with the spectra of the other minerals. The other intense band at 3545 cm^{-1} may be due to an impurity. Powder X-ray diffraction shows that these minerals are not 100% pure and are often mixed with other minerals of the rosasite group or related minerals.

The infrared spectra of selected rosasite minerals in the 900–1200 cm^{-1} region are shown in Fig. 5. For rosasite two intense bands are observed at 1096 and 1046 cm^{-1}. The first band is assigned to the ν_1 symmetric stretching mode of the carbonate unit. Bands have been observed in the infrared spectra of malachite at 1095 and 1090 cm^{-1} for azurite [4,5]. The infrared spectrum of hydrocerrusite showed an intense band at 1090 cm^{-1} [35]. Interestingly the $(CO_3)^{2-}$ ν_1 band of the rosasite minerals should not

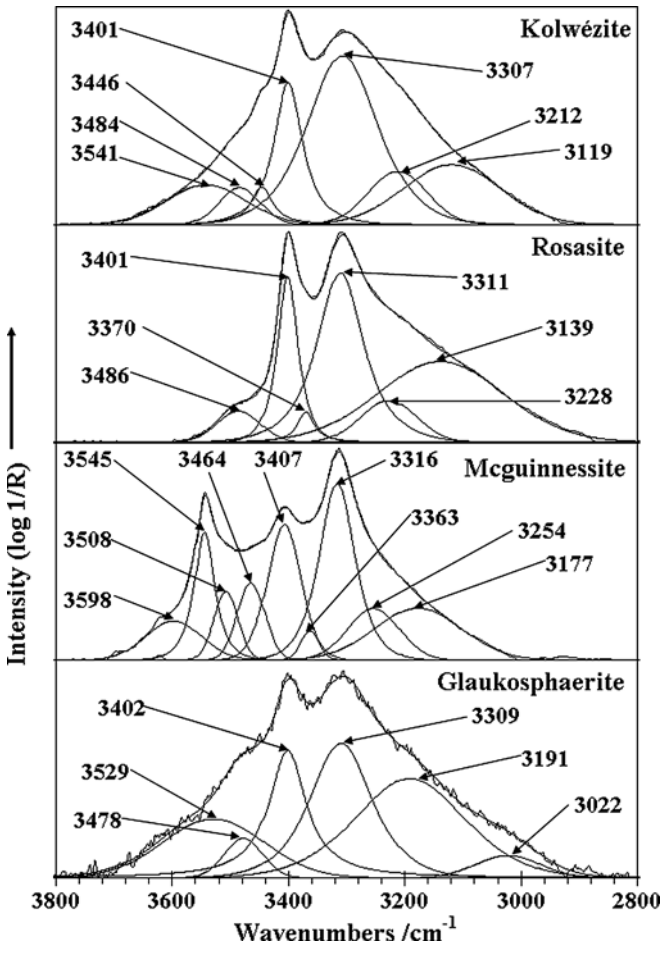

Fig. 4. Infrared spectra of rosasite, glaukosphaerite, kolwezite and mcguinessite in the 2800–3800 cm^{-1} region.

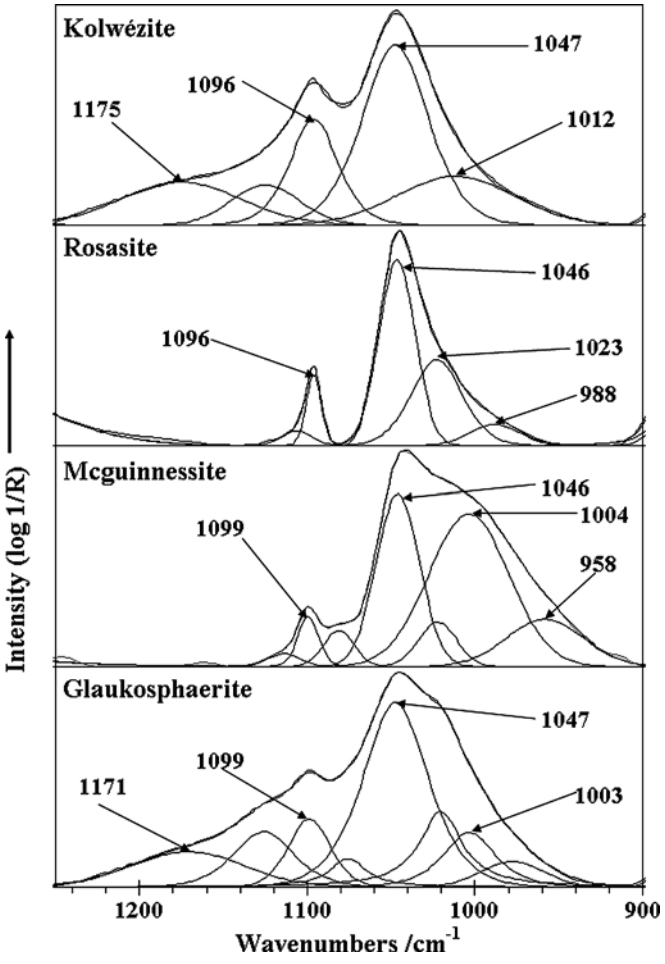

Fig. 5. Infrared spectra of rosasite, glaukosphaerite, kolwezite and mcguinessite in the 900–1200 cm^{-1} region.

be infrared active [5,36–38]. However because of symmetry reduction of the carbonate anion the band becomes activate. An intense Raman band is observed at 1096 cm^{-1} for rosasite and is assigned to the v_1 $(CO_3)^{2-}$ symmetric stretching vibration [5,36–38]. The intense band at 1046 cm^{-1} is assigned to the δ OH deformation mode. For malachite two bands attributed to OH deformation modes are found at 1045 and 875 cm^{-1} [5]. For hydrocerrusite the OH deformation modes were observed at 1047 and 1040 cm^{-1}. It is noted that in the infrared spectrum of rosasite an intense shoulder occurs at 1023 cm^{-1}. This band is also assigned to an OH deformation mode [39,40]. In the Raman spectrum of rosasite a low intensity band is observed at 1056 cm^{-1} and is ascribed to this vibrational mode [5,36,38,41].

For the mineral kolwezite two intense infrared bands are observed at 1096 and 1047 cm^{-1}. The first band is assigned to the v_1 $(CO_3)^{2-}$ vibrational mode and the second band to a δ OH deformation mode. As for rosasite in the infrared spectrum a long tail on the low wavenumber side is observed and a component band may be resolved at 1012 cm^{-1}. This band is a second δ OH deformation mode. The position of this second band appears to vary between the rosasite minerals. In the IR spectrum of mcguinnessite, two bands are observed at 1046 and 1004 cm^{-1}. Both bands are ascribed to δ OH deformation modes. The v_1 $(CO_3)^{2-}$ symmetric stretching mode is observed at 1099 cm^{-1}. A second band is observed at 1084 cm^{-1}. The observation of a second band supports the concept of two different carbonate units in the mcguinnessite structure. In the Raman spectrum the intensity of bands assigned to δ OH deformation modes is low and for mcguinnessite a band is observed at 1060 cm^{-1}. In the infrared spectrum of glaukosphaerite the δ OH deformation mode is observed at 1047 cm^{-1}. However the spectral profile on the lower wavenumber side of this band is complex and may be resolved into a series of overlapping bands. Two bands are observed at 1099 and 1078 cm^{-1} and are assigned to the v_1 symmetric stretching modes; again supporting the concept of two different carbonate units in the glaukosphaerite structure. Only a single v_1 symmetric stretching mode band for rosasite was observed.

The infrared spectra of selected rosasite minerals in the 1225–1625 cm^{-1} region are shown in Fig. 6. The infrared spectrum of rosasite in this spectral region are characterised by strong bands centered upon 1488 and 1388 cm^{-1} which may be resolved into four bands at 1522, 1488, 1425 and 1388 cm^{-1}. These bands are attributed to the v_3 antisymmetric $(CO_3)^{2-}$ stretching modes. In the IR spectrum of malachite two bands are observed at around 1500 and 1400 cm^{-1} [5]. For hydrozincite two bands are observed at 1515 and 1400 cm^{-1}. It would appear that there are two pairs of bands for rosasite namely (1522 and 1425 cm^{-1}) and (1488 and 1388 cm^{-1}). The observation of two sets of bands for rosasite suggests that there are two independent carbonate units in the crystal structure. Such sets of bands are also observed for each of the

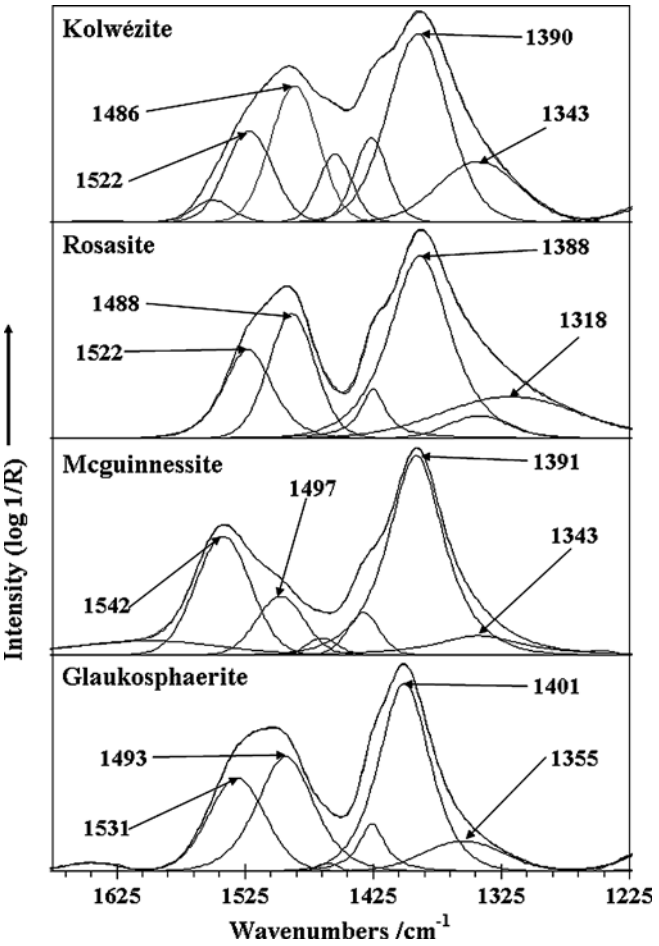

Fig. 6. Infrared spectra of rosasite, glaukosphaerite, kolwezite and mcguinessite in the 1225–1625 cm^{-1} region.

other rosasite minerals. For kolwezite two sets of bands are found at (1522 and 1426 cm^{-1}) and (1486 and 1390 cm^{-1}) and for glaukosphaerite (1531 and 1425 cm^{-1}) and (1493 and 1401 cm^{-1}). The intensities for mcguinnessite are opposite to that of rosasite in this spectral region; bands are observed for this mineral at (1542 and 1432 cm^{1}) and (1497 and 1391 cm^{-1}).

The infrared spectrum of the low wavenumber region are shown in Fig. 7. The infrared spectrum is limited to the cut-off point at 550 cm^{-1} at which point the diamond ATR cell absorbs the infrared radiation. However such a cut off point does not effect the infrared spectroscopy of minerals containing carbonate as all of the bands are above 550 cm^{-1}. The mineral rosasite shows two intense infrared bands at 870 and 818 cm^{-1}. These bands are assigned to the v_2 bending modes of the $(CO_3)^{2-}$ units. The observation of two v_2 bands is in harmony with the observation of two sets of bands in the v_3 antisymmetric stretching region. The infrared spectrum of malachite shows two bands at 820 and 803 cm^{-1} ascribed to v_2 bending modes as does azurite at 837 and 817 cm^{-1}[5]. Hydrocerrusite infrared spectrum shows two bands at 850 and 834 cm^{-1}. The ~880 cm^{-1} band for rosasite is not symmetrical and may be resolved

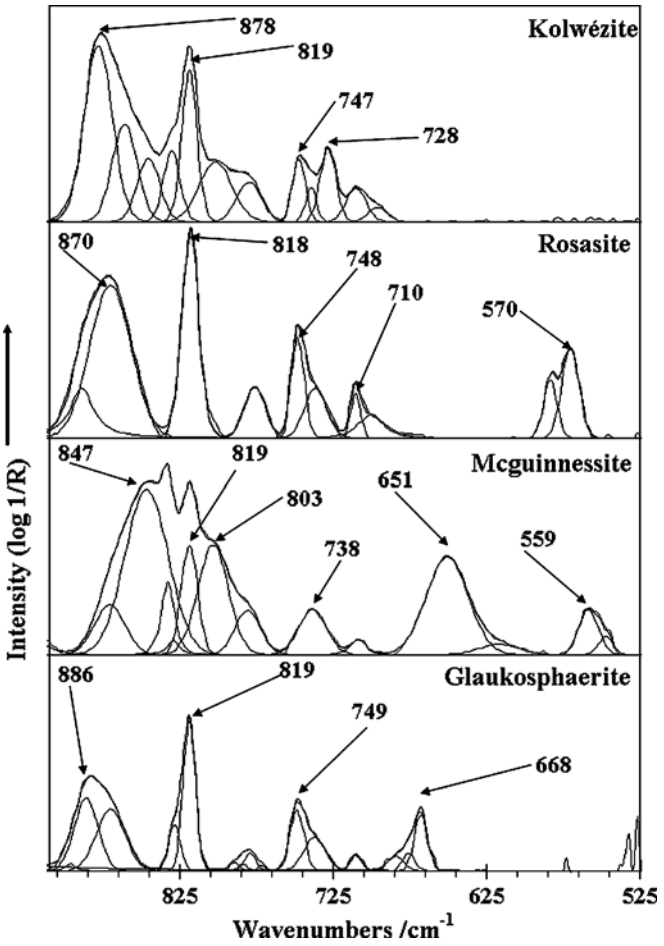

Fig. 7. Infrared spectra of rosasite, glaukosphaerite, kolwezite and mcguinessite in the 525–900 cm^{-1} region.

into two component bands at 889 and 870 cm^{-1}. The infrared spectrum of the mineral glaucosphaerite is very similar to that of rosasite with two bands observed at 886 and 819 cm^{-1}. The infrared spectrum of the mineral kolwezite is also similar in this spectral region, even though the profile is more complex. The spectrum of mcguinnessite is more complex with a number of bands observed at 870, 847, 833, 819 and 803 cm^{-1}. The bands at 870 and 819 cm^{-1} are related to the v_2 bending modes. The other bands may be due to impurities.

For rosasite a number of bands are observed at 781, 748 and 710 cm^{-1}. These bands are assigned to the v_4 $(CO_3)^{2-}$ bending modes. For malachite two infrared bands are observed at 748 and 710 cm^{-1} which are assigned to this vibration [4,5]. Another mineral with similar formulation to rosasite, hydrozicite has bands in this region at 738 and 710 cm^{-1}. The infrared spectrum of hydrocerrusite has v_4 $(CO_3)^{2-}$ bending modes at 700, 687 and 676 cm^{-1}. Two bands are observed around 570 cm^{-1} for rosasite; it is not known if these bands are due to v_4 $(CO_3)^{2-}$ bending modes. However this assignment seems unlikely. These bands are due to CuO stretching vibrations [41–45]. The infrared spectrum of kolwezite displays bands at 747, 728 and 710 cm^{-1}. The results for glaukosphaerite include bands at 749, 737 and 668 cm^{-1}. A low intensity band is observed at 570 cm^{-1} and is ascribed to the CuO stretching vibration. The IR spectrum of mcguinnessite also shows an intense band at 559 cm^{-1} which is assigned to CuO stretching vibration [42,43,45,46].

4. Conclusions

XRD studies of the rosasite mineral group showed the minerals are mixtures of members of the rosasite mineral group. Normally one of the rosasite minerals is predominant. EDAX has been used to determine the chemical composition of the mineral. The rosasite from Rosas mine, Narcao, Cagliari, Sardegna (Sardinia), Italy analysed as CuO 53.7% and ZnO 18.3% giving rise to the formula $(Cu_{1.5}Zn_{0.5})_2(CO)_3(OH)_2$. Glaucosphaerite from the Carr Boyd Nickel mine analysed as CuO 41.6% and NiO 25.2% giving rise to the formula $(Cu_{1.1}Ni_{0.7}Mg_{0.06})_2(CO)_3(OH)_2$. Similarly the mineral kolwezite from Zairehas a formula $(Cu_{1.33}Co_{0.67})_2(CO)_3(OH)_2$.

The infrared spectral patterns for the minerals rosasite, glaucosphaerite, kolwezite and mcguinnessite are similar and may be compared with that of malachite. This implies the molecular structure is similar to malachite. The single crystal structure of the members of the rosasite mineral group remains undetermined. The question arises as to why there are similar infrared spectral patterns for the rosasite minerals. It means the minerals must have the same structure or at least related structures. Malachite is monoclinic with point group 2/*m*. Therefore it can be inferred that the structure of the rosasite group of minerals is monoclinic. This conclusion is in agreement with the assumptions of Anthony et al. who state that rosasite and related minerals have monoclinic structure by analogy with malachite [33].

Abstract

The complexes *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)Cl(PMe$_2$Ph)$_2$] (**1**), 1,3,5-C$_6$H$_3${C≡CC$_6$H$_4$-4-C≡C-*trans*-[PtCl(PMe$_2$Ph)$_2$]}$_3$ (**2**) and 1,3,5-C$_6$H$_3$(C≡CC$_6$H$_4$-4-C≡C-*trans*-[Pt(PMe$_2$Ph)$_2$]C≡C-4-C$_6$H$_4$C≡C-3,5-C$_6$H$_3$-{C≡C-*trans*-[Ru(C≡CPh)(dppe)$_2$]}$_2$)$_3$ (**3**) have been synthesized and the identity of **1** confirmed by a single-crystal X-ray diffraction study. The optical limiting merit of **1** and **2** has been assessed at 523 nm employing 40 ns pulses; the effective absorption cross-section for **1** is low, while that of **2** is larger, but the complex is susceptible to photo-damage. The third-order nonlinearity of the Ru$_6$Pt$_3$ dendrimer **3** has been examined at 800 nm using 150 fs pulses; it is larger than that of a related Ru$_6$ dendrimer, but smaller than that of a Ru$_9$ dendrimer under the same conditions, suggesting that increasing metal content and electron richness is correlated to increased nonlinearity in these complexes.

Keywords: Ruthenium; Platinum; Dendrimer; Nonlinear optics; Optical limiting

1. Introduction

Organotransition metal dendrimers have attracted enormous interest over the past few years [1]. Although most examples are peripherally-metallated organic dendrimers, several dendrimers with metals in each generation and an arylethynyl-derived framework have been reported. The focus of our studies has been ruthenium-containing arylalkynyl dendrimers [2–10], while other groups have reported related platinum-containing examples [11–15]. We report herein the synthesis of a mixed-metal arylalkynyl dendrimer incorporating both ruthenium and platinum, together with an assessment of its third-order nonlinear optical (NLO) properties.

2. Experimental

2.1. General conditions and reagents

All reactions were performed under a nitrogen atmosphere with the use of Schlenk techniques. Dichloromethane was dried by distilling over calcium hydride; other solvents were used as received. Chromatography was performed on ungraded basic alumina.

The following were prepared by literature procedures: HC≡CC$_6$H$_4$-4-C≡CPh [16], 1,3,5-C$_6$H$_3$(C≡CC$_6$H$_4$-4-C≡CH)$_3$ [9], 1,3-{*trans*-[(dppe)$_2$(PhC≡C)RuC≡C]}$_2$-5-(HC≡C-4-C$_6$H$_4$C≡C)C$_6$H$_3$ [6]. PtCl$_2$(PMe$_2$Ph)$_2$ was a gift from Dr E. Wenger and Prof. A.F. Hill, RSC, Australian National University. CuCl (J.T. Baker) was used as received.

Microanalyses were carried out at the Australian National University. UV–Vis spectra of solutions in tetrahydrofuran in 1 cm cells were recorded using a Cary 5 spectrophotometer. Infrared spectra were recorded as dichloromethane solutions using a Perkin–Elmer System 2000 FT-IR. ^{1}H (300 MHz) and ^{31}P NMR (121 MHz) spectra were recorded using a Varian Gemini-300 FT NMR spectrometer and are referenced to residual chloroform (7.24 ppm) or external H_3PO_4 (0.0 ppm), respectively. Fast atom bombardment mass spectra (FAB MS) were recorded on a VG ZAB-2SEQ hybrid sector (BEqQ) MS instrument (30 kV Cs^+ ions, current 1 mA, accelerating potential 8 kV, matrix 3-nitrobenzyl alcohol) at the ANU.

2.2. Syntheses

2.2.1. *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)Cl(PMe$_2$Ph)$_2$] (**1**)

A solution of *cis*-[PtCl$_2$(PMe$_2$Ph)$_2$] (45 mg, 0.083 mmol), HC≡CC$_6$H$_4$-4-C≡CPh (8.8 mg, 0.044 mmol) and CuCl (6.6 mg, 0.067 mmol) in CH_2Cl_2 (10 mL) and NEt_3 (10 mL) was stirred for 17 h. The reaction mixture was passed through a short pad of alumina with CH_2Cl_2, and the eluate was taken to dryness under reduced pressure. Diffusion of MeOH into a CH_2CH_2 solution of the residue afforded yellow needles (28 mg, 90%). *Anal.* Calc. for $C_{32}H_{31}ClP_2Pt$: C, 54.28; H, 4.41. Found: C, 54.21; H, 3.82%. IR: ν(C≡C) 2119 cm^{-1}. UV–Vis: λ 342 nm, ε 33 600 M^{-1} cm^{-1}. ^{1}H NMR: δ 1.93 (12H, t, 4 Hz, Me), 6.98–7.81 (19H, m, phenyl). ^{31}P NMR: δ −6.84 (s, J_{PtP}: 2396 Hz). FAB MS; *m*/*z* (fragment, relative intensity): 708 ([M]$^+$, 100), 672 ([M]$^+$−Cl, 20), 471 ([Pt(PMe$_2$Ph)]$^+$, 100).

2.2.2. 1,3,5-C$_6$H$_3${C≡CC$_6$H$_4$-4-C≡C-*trans*-[PtCl(PMe$_2$Ph)$_2$]}$_3$ (**2**)

A solution of *cis*-[PtCl$_2$(PMe$_2$Ph)$_2$] (48 mg, 0.089 mmol), 1,3,5-C$_6$H$_3$(C≡CC$_6$H$_4$-4-C≡CH)$_3$ (7.4 mg, 0.016 mmol) and CuCl (15 mg, 0.15 mmol) in CH_2Cl_2 (15 mL) and NEt_3 (10 mL) was stirred for 17 h. The reaction mixture was passed through a short pad of alumina with CH_2Cl_2 as eluent, and the eluate was taken to dryness under reduced pressure. The residue was purified by solvent diffusion of MeOH into a CH_2Cl_2 solution to afford a pale yellow powder (27 mg, 83%). *Anal.* Calc. for $C_{84}H_{81}Cl_3P_6Pt_3$: C, 51.27; H, 4.15. Found: C, 51.01; H, 4.23%. IR: ν(C≡C) 2117 cm^{-1}. UV–Vis: λ 345 nm, ε 123 000 M^{-1} cm^{-1}. ^{1}H NMR: δ 1.94 (36 H, t, 4 Hz, Me), 6.98–7.84 (45 H, m, phenyl). ^{31}P NMR: δ −6.84 (s, J_{PtP}: 2400 Hz). FAB MS; *m*/*z* (fragment, relative intensity): 1970 ([M]$^+$, 2), 471 ([Pt(PMe$_2$Ph)]$^+$, 40).

2.2.3. 1,3,5-C$_6$H$_3$(C≡CC$_6$H$_4$-4-C≡C-*trans*-[Pt(PMe$_2$Ph)$_2$]C≡C-4-C$_6$H$_4$C≡C-3,5-C$_6$H$_3$-{C≡C-*trans*-[Ru(C≡CPh)(dppe)$_2$]}$_2$)$_3$ (**3**)

A solution of **2** (21 mg, 11 μmol), 1,3-{*trans*-[(dppe)$_2$(PhC≡C)RuC≡C]}$_2$-5-(HC≡C-4-C$_6$H$_4$C≡C)C$_6$H$_3$ (73 mg, 0.034 mmol) and CuCl (15 mg, 0.15 mmol) in CH_2Cl_2 (20 mL) and NEt_3 (5 mL) was stirred for 19 h. The reaction mixture was passed through a short pad of alumina with CH_2Cl_2 as eluent, and the eluate was taken to dryness under reduced pressure. The residue was purified by vapour diffusion of MeOH into a solution in CH_2Cl_2 to afford a yellow powder (53 mg, 56 %). *Anal.* Calc. for $C_{504}H_{420}P_{30}Pt_3Ru_6$: C, 70.41; H, 4.92. Found: C, 69.51; H, 5.02%. IR: ν(C≡CPt) 2101 cm^{-1}, ν(C≡CRu) 2060 cm^{-1}. UV–Vis: λ 357 nm, ε 52 300 M^{-1} cm^{-1}. ^{1}H NMR: δ 2.13 (36 H, t, 4 Hz, Me), 2.68 (48 H, m, CH_2), 6.67–7.90 (336 H, m, phenyl). ^{31}P NMR: δ −11.62 (6 P, s, J_{PtP}: 2380 Hz), 54.25 (24 P, s). FAB MS; *m*/*z* (fragment, relative intensity): 898 ([Ru(dppe)$_2$]$^+$, 55), 471 ([Pt(PMe$_2$Ph)$_2$]$^+$, 35).

2.3. X-ray structural study of **1**

A suitable crystal of **1** was obtained by slow diffusion of hexane into a dichloromethane solution. A single crystal was mounted on a fine glass capillary, and data collected on a Nonius KappaCCD diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.7107_3$ Å). The unit cell parameters were obtained by least-squares refinement [17] of 31 726 reflections with $3 \leqslant \theta \leqslant 27°$. The reduced data were corrected for absorption using numerical methods [18] implemented from within maXus [19]; equivalent reflections were merged. The structure was solved by heavy atom methods [20], and refined using the software package CRYSTALS [21].

Crystal/refinement data: $C_{32}H_{31}ClP_2Pt$, $M = 708.09$. Triclinic, space group *P*-1, $a = 5.9924(1)$ Å, $b = 9.6522(1)$ Å, $c = 25.7727(3)$ Å, $\alpha = 91.905(1)°$, $\beta = 95.940(1)°$, $\gamma = 105.910(1)°$, $V = 1422.93(3)$ Å^3. D_c ($Z = 2$) = 1.653 g cm^{-3}. $\mu_{Mo} = 5.156$ mm^{-1}; specimen: 0.48 × 0.34 × 0.21 mm; $T_{min/max} = 0.23/0.45$. $2\theta_{max} = 55°$; $N_{total} = 28\,704$ (CCD diffractometer, monochromatic Mo Kα radiation, $\lambda = 0.7107_3$ Å; T 200 K) merging to $N = 6513$ unique ($R_{int} = 0.04$), $N_o = 5067$ ($I > 3\sigma(I)$) refining to $R = 0.020$, $R_w = 0.020$. The crystallographic asymmetric unit consists of one [Pt(C$_{16}$H$_9$)(C$_8$H$_{11}$P)$_2$Cl] molecule. The largest peaks in the final difference electron density map were located near the Pt atom.

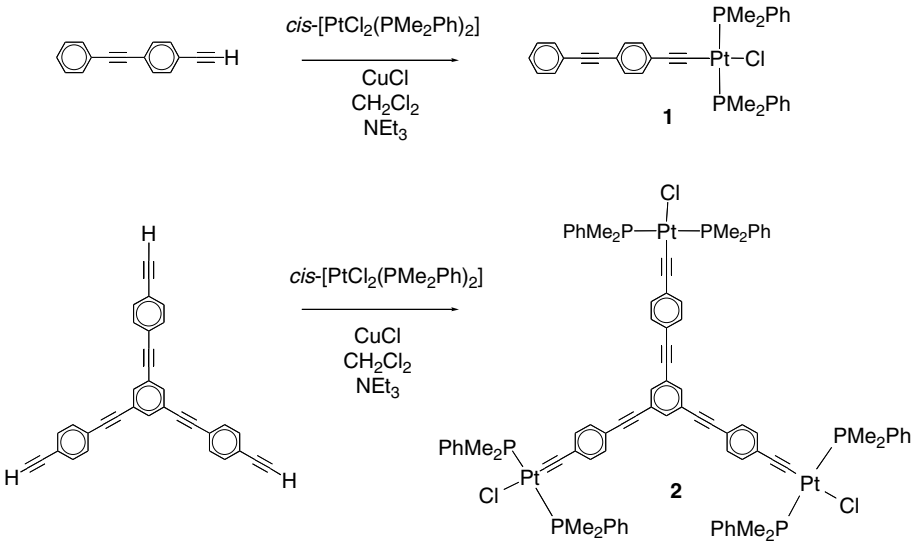
2.4. Z-scan measurements

Z-scan measurements [29] were performed using a femtosecond laser system based on a Coherent Mira-900D Ti–sapphire oscillator and including a chirped pulse

Ti–sapphire amplifier operating at a repetition rate of 30 Hz. This system operated at a wavelength of 800 nm and provided ca. 150 fs FWHM pulses. The Z-scan set-up used lenses with the focal lengths suitable for creating focal spots with the $1/e^2$ radius, w_0, being in the range 40–65 μm. This resulted in the Rayleigh lengths, $z_R = \frac{\pi w_0^2}{\lambda}$, being greater than 3 mm; the measurements of tetrahydrofuran solutions in 1 mm thick glass cells with ca. 1 mm thick glass walls could therefore be treated in the thin sample approximation. All measurements were calibrated against Z-scans taken on the pure solvent and on silica and glass plates of thicknesses in the range 1–2.5 mm; the value $n_2 = 3 \times 10^{-16}$ cm^2 W^{-1} was adopted for silica nonlinear index. Nonlinear phase shifts for the measured samples were in the range 0.5–1.0 rad, corresponding to peak intensities of the order of 100 GW cm^{-1}.

2.5. Optical limiting measurements

The measurements were performed using the Z-scan technique at 523 nm, with about 5 μJ, 40 ns pulses from a frequency-doubled Q-switched Nd:YLF diode-pumped laser. Solutions of both compounds were placed in 1 mm path length glass cells. The open-aperture Z-scans were converted into transmission–fluence plots using an assumption of Gaussian beam propagation and the spot size determination made on the basis of numerical fitting of the closed-aperture Z-scan obtained simultaneously with the open-aperture measurement (the signal in the closed-aperture Z-scan was due to thermal nonlinearity of the solutions). The data were analyzed assuming that excited-state absorption is responsible for the effect.



3. Results and discussion

The bis(phosphine)platinum-containing core of the dendrimer (**2**), together with a linear analogue (**1**), was synthesized by reaction of *cis*-[$PtCl_2(PMe_2Ph)_2$] with the relevant alkynyl ligand in the presence of a CuCl catalyst (Scheme 1). There is no inherent means of avoiding generation of the bis-alkynyl complex – to minimize its formation, an excess of *cis*-[$PtCl_2(PMe_2Ph)_2$] was added, no trace of the bis-alkynyl product being observed in the ^{31}P NMR spectrum. The products were characterized by ^{1}H and ^{31}P NMR, UV–Vis, IR, FAB mass spectrometry and (in the case of the linear analogue) a single-crystal X-ray diffraction study.

Selected bond distances and angles are listed in Table 1, and an ORTEP plot is displayed in Fig. 1. The crystallographic asymmetric unit consists of one molecule of **1**. The complex shows square-planar geometry around the metal center, with only small deviations from the idealized geometry. An example of an octupolar platinum–alkynyl complex incorporating a C≡CC_6H_4-4-C≡CPh motif, 1,3,5-[Cl(PEt_3)$_2$PtC≡CC_6H_4-4-C≡C]$_3C_6H_3$, has been reported previously and structurally characterized [22]. Reported bond lengths for this octupolar complex [Pt–Cl: 2.358(6) Å, Pt–C: 1.95(2) Å, Pt–P: 2.276(9)–2.297(8) Å and C≡C: 1.14(3) Å] are similar to those observed with **1**.

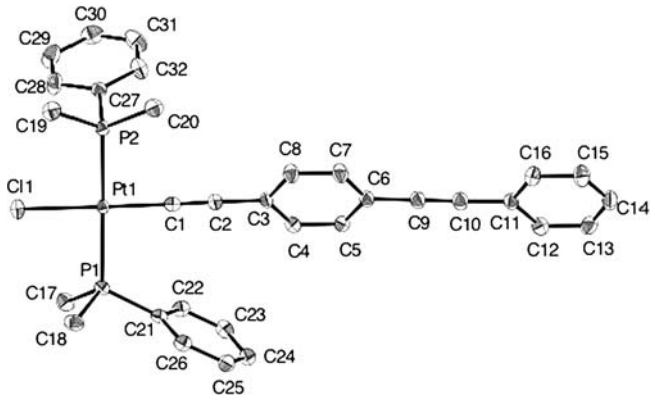
Scheme 1. Syntheses of **1** and **2**.



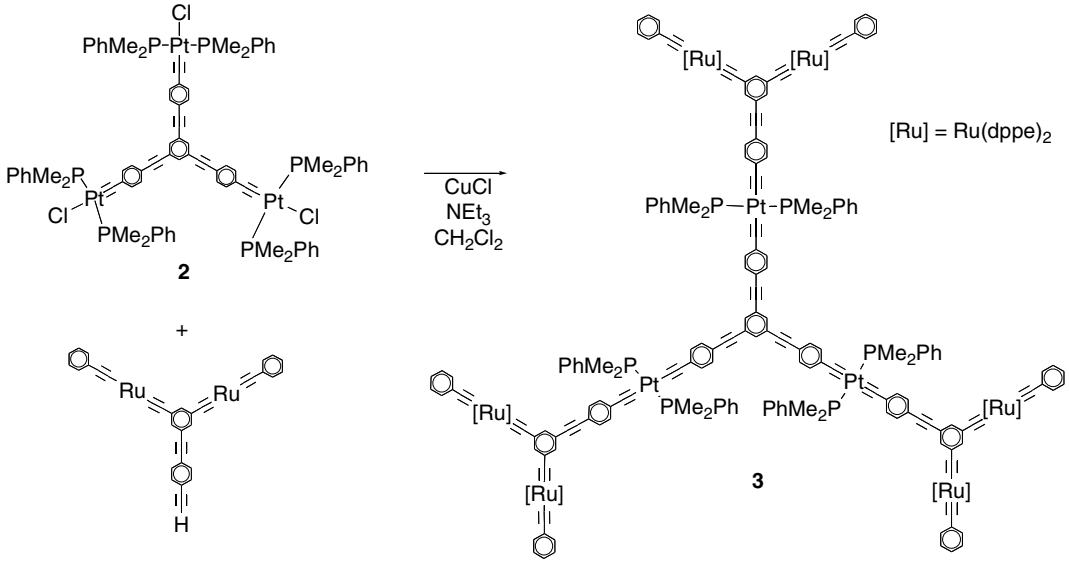


Fig. 1. Thermal ellipsoid diagram of *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)Cl(PMe$_2$Ph)$_2$] with labeling of selected atoms. Ellipsoids show 30% probability levels. H atoms have been omitted for clarity.

The triplatinum dendritic core, **2**, was reacted with the wedge, 1,3-{*trans*-[(dppe)$_2$(PhC≡C)RuC≡C]}$_2$-5-(HC≡C-4-C$_6$H$_4$C≡C)C$_6$H$_3$, in the presence of CuCl to give the mixed-metal dendrimer complex, 1,3,5-C$_6$H$_3$(C≡CC$_6$H$_4$-4-C≡C-*trans*-[Pt(PMe$_2$Ph)$_2$]C≡C-4-C$_6$H$_4$C≡C-3,5-C$_6$H$_3$-{C≡C-*trans*-[Ru(C≡CPh)(dppe)$_2$]}$_2$)$_3$ (**3**) (Scheme 2). The dendrimer was characterized by ^{1}H and ^{31}P NMR, UV–Vis, IR, and FAB mass spectrometry.

Examination of the ^{31}P NMR spectroscopic data for **1**, **2** and **3** reveals a ^{31}P chemical shift of −6.8 ppm in the case of complexes containing a chloro-ligand (**1** and **2**), which moves to −11.6 ppm upon replacement of the chloro ligand by an alkynyl group on conversion of **2** to **3**. These figures are consistent with literature values for *trans*-[Pt(C≡CPh)-Cl(PMe$_2$Ph)$_2$] and *trans*-[Pt(C≡CPh)$_2$(PMe$_2$Ph)$_2$], which have ^{31}P NMR spectral shifts of −7.5 and −12.4 ppm, respectively [23]. Complex **3** also contains a resonance at 54.4 ppm, consistent with a bis-alkynyl ruthenium unit; the integral of the resonances is 1:2, as expected. The IR spectra of the platinum-containing complexes **1** and **2** each show a band at approximately 2119 cm^{-1}, which is consistent with similar platinum complexes: *trans*-[Pt(C≡CPh)$_2$(PMe$_2$Ph)$_2$]-2106 cm^{-1} [24], *trans*-[Pt(C≡CCH$_2$OH)$_2$(PMe$_2$Ph)$_2$] 2120 cm^{-1}, *trans*-[Pt(C≡CCH$_2$CH$_2$OH)$_2$(PMe$_2$Ph)$_2$] 2110 cm^{-1} and *trans*-[Pt(C≡CCH$_2$OPh)$_2$(PMe$_2$Ph)$_2$] 2115 cm^{-1} [25]. The mixed platinum/ruthenium dendrimer **3** contains two bands at 2060 and 2101 cm^{-1}, assigned to the ruthenium- and platinum-bound alkynyl groups, respectively.

Measurement of the third-order molecular nonlinearity of **3** was performed using the Z-scan technique at 800 nm; results are presented in Table 2, together with previously-reported data for related ruthenium-containing dendrimers. The mixed-metal dendrimer, **3**, possesses a $|\gamma_{800}|$ of $7200 \pm 2900 \times 10^{-36}$ esu. This is substantially higher than that of the phenylalkynyl-containing dendrimer 1,3,5-{3,5-(*trans*-[(dppe)$_2$(PhC≡C)RuC≡C])$_2$C$_6$H$_3$C≡CC$_6$H$_4$-4-C≡C}$_3$C$_6$H$_3$ ($1600 \pm 2400 \times 10^{-36}$ esu) [26], but lower than that of 1,3,5-C$_6$H$_3$(C≡CC$_6$H$_4$-4-C≡C-*trans*-[Ru(dppe)$_2$]-C≡C-3,5-C$_6$H$_3$-{C≡CC$_6$H$_4$-4-C≡C-*trans*-[Ru(C≡CPh)-(dppe)$_2$]}$_2$)$_3$ ($20700 \pm 2000 \times 10^{-36}$ esu) [3]. Increasing the metal loading (proceeding from the Ru$_6$ to Ru$_6$M$_3$ dendrimers, M = Ru, Pt) and increasing electron richness (proceeding from Ru$_6$Pt$_3$, with a mixture of 18 and 16 valence electron metals, to Ru$_9$, with 18 electron metal centers only) both result in an increase in $|\gamma_{800}|$.

Platinum-alkynyl complexes possess interesting optical properties [22,26–28]. Of particular relevance to the current studies, *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)$_2$(PBu$_3$)$_2$] has been shown to act as a broadband optical limiter [28]. In view of the close structural similarities between the linear platinum complex *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)Cl(PMe$_2$Ph)$_2$] (**1**), its octupolar analogue **2**, and *trans*-[Pt(C≡CC$_6$H$_4$-4-

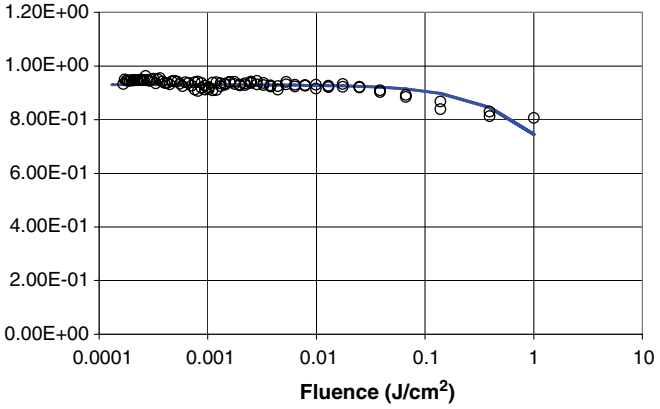

Fig. 2. Transmission–fluence plot for **2**.

C≡CPh)$_2$(PBu$_3$)$_2$], the optical limiting performance of **1** and **2** was examined at 523 nm.

Only poor optical limiting behavior was exhibited by **1**; the effective excited state absorption cross-section at 523 nm was determined to be no larger than 4×10^{-20} cm^2. In comparison, the effective absorption cross-section of *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)$_2$(PBu$_3$)$_2$] is reported to be 7×10^{-17} cm^2 [28]. The octupolar platinum–alkynyl complex **2** shows a considerably larger effective absorption cross-section than its linear analogue (7×10^{-19} cm^2). However, it is still significantly smaller than the effective absorption cross-section of *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)$_2$(PBu$_3$)$_2$]. A plot of transmission versus fluence for complex **2** is shown in Fig. 2, illustrating the drop-off in transmission as the fluence increases. A significant problem, however, exists in photodecomposition of the sample. The effective absorption cross-section value reported above applies to a fresh sample. Subsequent measurements on the same spot of the solution cell show considerably stronger changes of transmission, consistent with the formation of absorbing species. Similar photodecomposition is observed for *trans*-[Pt(C≡CC$_6$H$_4$-4-C≡CPh)$_2$(PBu$_3$)$_2$] [28].

4. Conclusion

The mono- and triplatinum complexes reported herein are readily accessible by straightforward syntheses, but their low optical limiting merit and lack of photostability mitigate against potential use. The triplatinum complex is a dendritic core in convergent dendrimer synthesis. Coupling the triplatinum core complex **2** to three equivalents of the triruthenium dendron complex has afforded a hexaruthenium triplatinum dendrimer. The cubic optical nonlinearity of this dendrimer is lower than that of a nonaruthenium dendrimer that we reported previously [3], suggesting that a search for organometallic dendrimers with larger NLO coefficients should focus on those with electron-rich (18 valence electron) metal centers. The synthetic methodology that we have employed in the current studies is, in principle, applicable to higher generation species, which will be the subject of a future report.

Abstract

Oxide/fluoride ordering in three families of 'disordered' transition metal oxyfluoride compounds is carefully investigated and used to obtain insight into why the constituent inherently acentric octahedral units do not usually order in a long range ordered polar sense. Observed highly structured diffuse intensity distributions are used in each case to analyze the local crystal chemistry and orientational ordering rules governing the way in which the dipole moments from the individual polar pseudo-octahedral units add together. The common local oxide/fluoride ordering rules, the consequences of these rules for polar behaviour on the local scale as well as the role of configurational entropy and energy minimization in suppressing long range polar order are highlighted.

1. Introduction

The synthesis and control of polar behaviour in crystalline materials is an increasingly important objective for solid state chemists as a result of the strong correlation of polarity with a range of useful physical properties including pyroelectricity, ferroelectricity, piezoelectricity and second harmonic generation (SHG) [1–3]. Early transition metal d^0 cations in octahedral environments (such as *e.g.* the Ti^{4+} ion in the TiO_6 octahedra of $BaTiO_3$, $KTiOPO_4$, *etc.* or the Nb^{5+} ion in the NbO_6 octahedra of $LiNbO_3$) have a well known susceptibility to move off-centre in a correlated fashion as a result of a second-order Jahn–Teller (SOJT) effect [3] giving rise to inherently polar materials and technologically very useful physical properties – in particular, ferroelectricity and SHG. An important strategy for synthesizing new polar materials is therefore to include transition metal MO_6 octahedral units susceptible to such a SOJT distortion [3].

An alternative, closely related approach is to use inherently polar, or acentric, anions such as, for example, pseudo-octahedral $Nb^{V}OF_5^{2-}$, (*cis*-)$Mo^{VI}O_2F_4^{2-}$ or (*fac*-)$Mo^{VI}O_3F_3^{3-}$ (see Fig. 1) to mimic such off-centre behaviour [4–9]. The arrangement of strong π-donor oxygen atoms to the unoccupied t_{2g}-type d orbitals of the transition metal atom required for the maximization of p_π—d_π bonding in pseudo-octahedral units typically leads to the *cis*-dioxo and *fac*-trioxo isomers shown in Fig. 1b and c being preferred to their respective *trans*-dioxo and *mer*-trioxo isomers in transition metal oxyfluoride structures [10,11]. Such anions are inherently strongly polar, particularly the (*fac*-)MO_3F_3 anion [1]. They might therefore be expected to be capable of giving rise to strongly polar materials upon their incorporation into non-centrosymmetric crystalline compounds, provided that it is possible to control the relative orientations of the inherently polar anions from one octahedral unit to the next *i.e.* to prevent

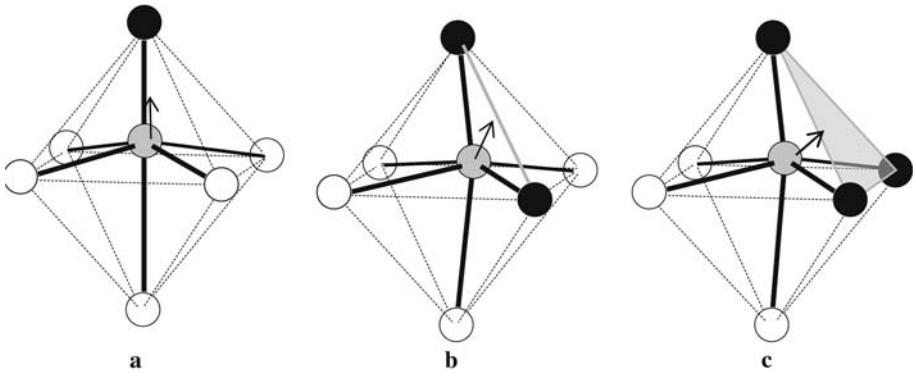

Fig. 1. Shows the inherently polar pseudo-octahedral (a) MOF_5^{2-}, (b) (*cis*-)$MO_2F_4^{2-}$ and (c) (*fac*-)$MO_3F_3^{3-}$ transition metal oxyfluoride anions. The initially central transition metal ion moves off-centre away from the fluoride ions and towards the oxide ions.

the dipole moments of separate octahedra from cancelling each other [1].

In practice, however, many if not most transition metal oxyfluoride compounds incorporating such polar anions have turned out to be inherently orientationally disordered [4–9,12–25] giving rise to crystal structures where there is no resultant polarity and where there appears to be no oxide/fluoride ordering at all, at least from a conventional 3-d crystallographic point of view. Examples include $(NH_4)_3MoO_3F_3$ [12], $CsMMoO_3F_3$ [13], $A_2BMoO_3F_3$, $A, B =$ Na, K, Rb, Cs [14–16], FeOF [17], *etc.*

In order to obtain insight into strategies for the design and synthesis of polar transition metal oxyfluoride compounds, it is helpful to characterize the oxide/fluoride and orientational ordering rules in a range of such apparently 'disordered' transition metal oxyfluorides in order to understand why the constituent inherently acentric octahedral units do not usually want to order up in a long range ordered sense. In this contribution, we review recent results obtained via the analysis of highly structured diffuse intensity distributions in some relatively simple, high symmetry, 'disordered' transition metal oxyfluorides. The aim is to highlight the common local oxide/fluoride ordering rules, the consequences of these rules for polar behaviour on the local scale as well as the roles of configurational entropy and free energy in suppressing long range polar order.

2. The M^{3+}OF family of transition metal oxyfluorides

One disordered family of transition metal oxyfluoride compounds containing locally polar pseudo-octahedral units is the family of M^{3+}OF ($M =$ Fe, Ti, V, *etc.*) oxyfluoride compounds [26–30]. They crystallize in the well-known tetragonal $P4_2/mnm$, rutile type average structure (see Fig. 2a). A single crystal X-ray diffraction study of one member of this family, FeOF, reported no evidence for oxide/fluoride ordering [17]. Mössbauer spectroscopy studies of FeOF, on the other hand, clearly show a single unique environment of $3O^{2-}$ ions and $3F^-$ ions surrounding each Fe^{3+} cation [28,29].

Furthermore, a bond valence sum analysis of FeOF using the refined average structure again showed that O^{2-} is significantly under-bonded while F^- is significantly over-bonded in the average structure anion position [31]. From the crystal chemical point of view, this implies that opposite corners of each FeO_3F_3 octahedron must necessarily be of opposite type *i.e.* if one corner is occupied by a F^- ion then the opposite corner is necessarily occupied by an O^{2-} ion thus allowing the central Fe^{3+} ion to move off-centre away from the local F_3 octahedral face and towards the opposite O_3 octahedral face with a shift magnitude estimated to be of ~0.12–0.13 Å [31]. Taken in conjunction with the Mossbaüer results, is clear that FeOF is composed of a network of locally polar *fac*-type octahedral ($M^{III}O_3F_3$) units.

As for the majority of the oxyfluorides discussed in this paper, direct evidence as to the nature of oxide/fluoride ordering on the local scale in these compounds is to be found in the existence of a highly structured diffuse intensity distribution – this time in the form of continuous 1-d rods of diffuse intensity running along the $[1\,1\,0]^*$ and $[1\,\bar{1}\,0]^*$ directions of reciprocal space through the $(h + k + l)$ odd parent rutile type Bragg reflections [31] (see Fig. 3a and b). Continuous $\langle 1\,1\,0\rangle^*$ rods of diffuse intensity in reciprocal space require the existence of 2-d, long range oxide/fluoride ordered $\{1\,1\,0\}$ planes in real space that are uncorrelated from one such $\{1\,1\,0\}$ plane to the next.

There are two distinct patterns of 2-d, oxide/fluoride ordering compatible with the bond valence sum implied constraint that an O^{2-} ion must always be opposite a F^- ion and these are shown in Figs. 3c and d [31]. Note that the tetragonal symmetry of the rutile average structure type divides the 8 potential faces of the *fac*-type pseudo-octahedral ($M^{III}O_3F_3$) units (which might be thought of as potential directions for the local dipole moment) into two sets of 4 crystallographically equivalent faces. The two distinct patterns of oxide/fluoride ordering shown in Figs. 3c and d correspond to the central Fe cation moving towards one or other of these two sets of crystallographically inequivalent faces. Only the latter (Fig. 3d), however, is compatible with the observed diffraction evidence that the diffuse rods only run through the $(h + k + l)$ odd parent rutile type Bragg reflections [31]. The tetragonal strain distortion of the individual *fac*-type pseudo-octahedral

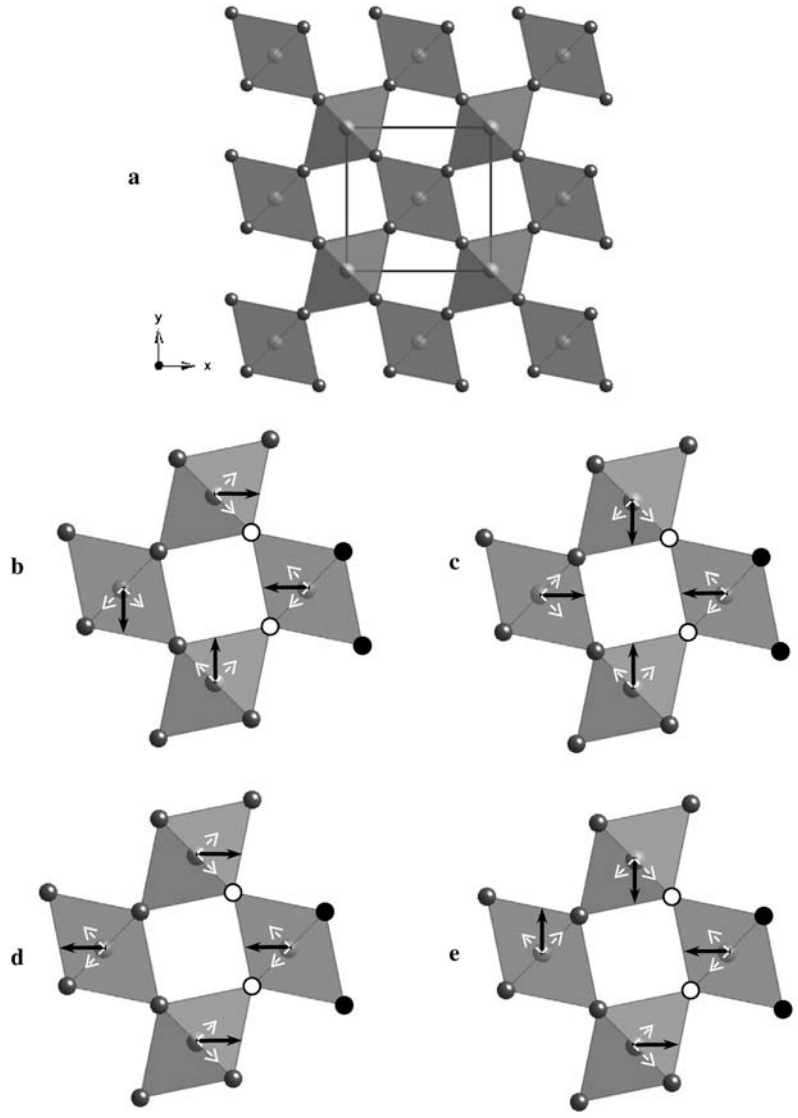

Fig. 2. (a) Shows the well-known tetragonal $P4_2/mnm$, rutile type average structure in which the family of M^{3+}OF (M = Fe, Ti, V, *etc.*) oxyfluoride compounds crystallize in projection along the [0 0 1] direction. The unit cell is outlined. Figs. 4b–e show the four distinct local configurations possible having chosen an initial displacement direction for the right hand pseudo-octahedral unit. Note that the sum of the dipole moments of the 4 polar ($M^{III}O_3F_3^{3-}$) units sum to zero in each of these 4 cases.

($M^{III}O_3F_3$) units associated with crystallizing in the rutile type average structure has thus selectively differentiated between the original 8 possible faces.

On the local scale, the Fe^{3+} (and hence the local dipole moment) can thus only point along either ±**a** or ±**b** *i.e.* towards one or other of four crystallographically equivalent faces of the *fac*-type pseudo-octahedral ($M^{III}O_3F_3$) units (see Fig. 2). Given the constraints imposed by Fig. 3d, it is not difficult to show that the sum of the dipole moments of any four polar ($M^{III}O_3F_3$) units immediately surrounding any 4_2 axis in the average structure type must necessarily always add to zero. Having chosen an initial displacement direction for the octahedral unit on the right hand side of these four pseudo-octahedral units, there are only four local configurations possible and these are shown in Fig. 2b–e, respectively. Note that the sum of the dipole moments is zero in each case. There are, in general, 16 possible local configurations for each cluster of four *fac*-type pseudo-octahedral ($M^{III}O_3F_3$) units. All, however, have the property that the sum of their dipole moments is zero. It is thus not possible to have a resultant polar structure of this type. The observed diffuse distribution ensures that the inherent dipole moments associated with each (*fac*)-FeO_3F_3 octahedral unit not only sum to zero macroscopically but also on the local unit cell scale. Indeed this is a recurrent theme for oxyfluoride compounds.

3. The *Re*O_3-type oxyfluorides $MO_{3-x}F_x$ ($M^{IV,V,VI}$ = Nb, Ta, Ti, Mo and W)

A further disordered (non-polar) family of transition metal oxyfluoride compounds containing locally polar

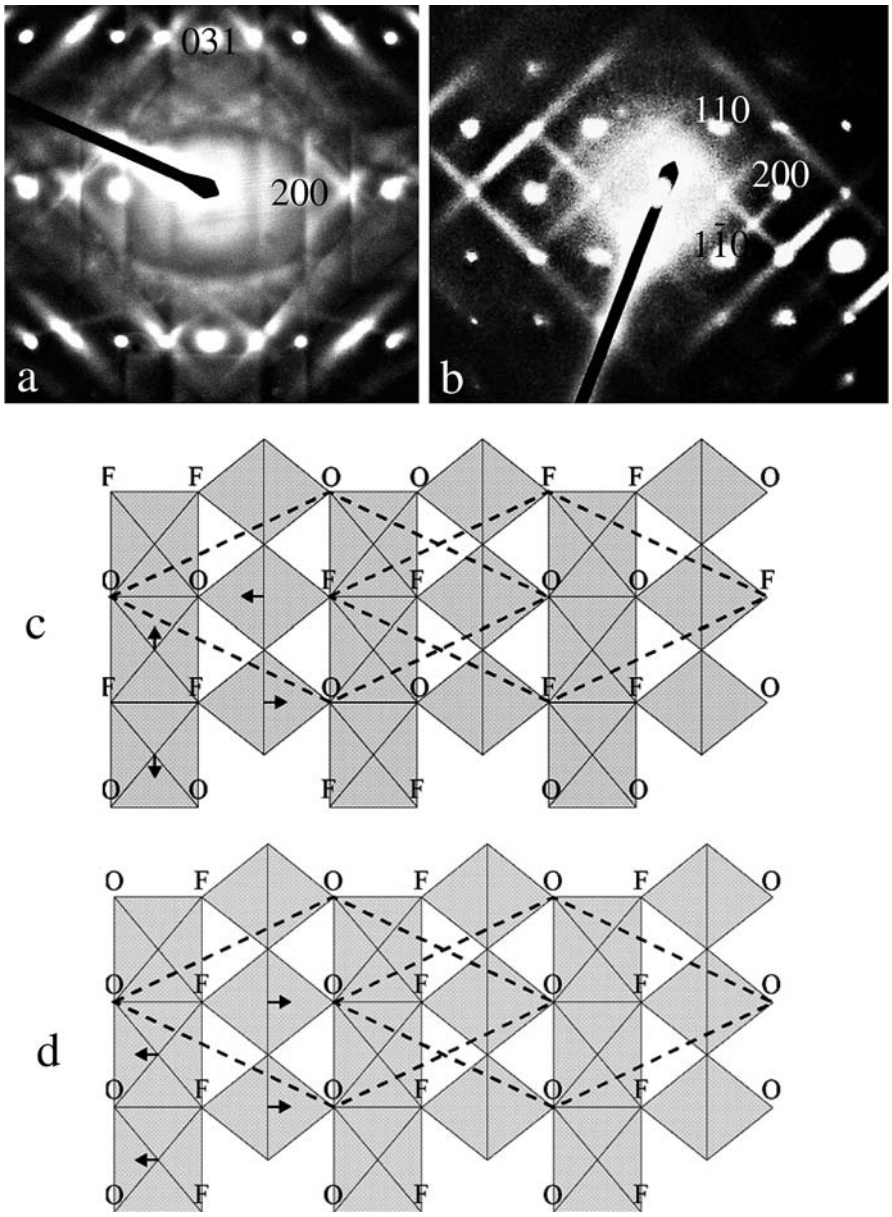

Fig. 3. Typical (a) ⟨0 1 3⟩ and (b) close to [0 0 1] zone axis EDP's of FeOF showing the continuous rods of diffuse intensity running along the ⟨1 1 0⟩* directions of reciprocal space through the $(h+k+l)$ odd parent rutile type Bragg reflections. These continuous ⟨1 1 0⟩* rods of diffuse intensity in reciprocal space require the existence of 2-d, long range oxide/fluoride ordered {1 1 0} planes in real space that are uncorrelated from one such {1 1 0} plane to the next. (c,d) show the two distinct patterns of 2-d, oxide/fluoride ordering in the {1 1 0} planes compatible with the constraint that an oxide ion must always be opposite a fluoride ion. Only the latter, however, is compatible with the observation that the diffuse rods only run through the $(h+k+l)$ odd parent rutile type Bragg reflections.

pseudo-octahedral units is the family of $MO_{3-x}F_x$ (M = Nb, Ta, Ti, Mo, W) oxyfluoride compounds which crystallize in the well known cubic $Pm\bar{3}m$, ReO_3 average structure-type (see Fig. 4a). Until recently, all of these transition metal oxyfluoride compounds were again reported as exhibiting random anion site occupation [26,32,33]. Bond valence sum calculations on the disordered average structures of $Nb^{V}O_2F$ and $Ta^{V}O_2F$, however, show clearly that O^{2-} is significantly under-bonded whilst F^- is again over-bonded in the average structure anion position [34,35]. Hence one should again expect that F^- ions will, as far as is possible, always occupy corners opposite to O^{2-} in each octahedra, thus allowing the central cation to move off-centre and thereby simultaneously improve the underbonding of the O^{2-} as well as the overbonding on the F^- ions.

Direct evidence for oxide/fluoride ordering is again found in a structured diffuse distribution, this time in the form of characteristic transverse polarized planes of diffuse intensity running through the $\mathbf{G} \pm \langle hk\,1/3\rangle^*$ (h,k continuous) regions of reciprocal space (see *e.g.* the ⟨1 1 6⟩ zone axis EDP of NbO_2F shown in Fig. 4b). Diffuse sheets in reciprocal space imply the existence of 1-d, long range O^{2-}/F^- ordered ⟨0 0 1⟩ columns of atoms in real space that are

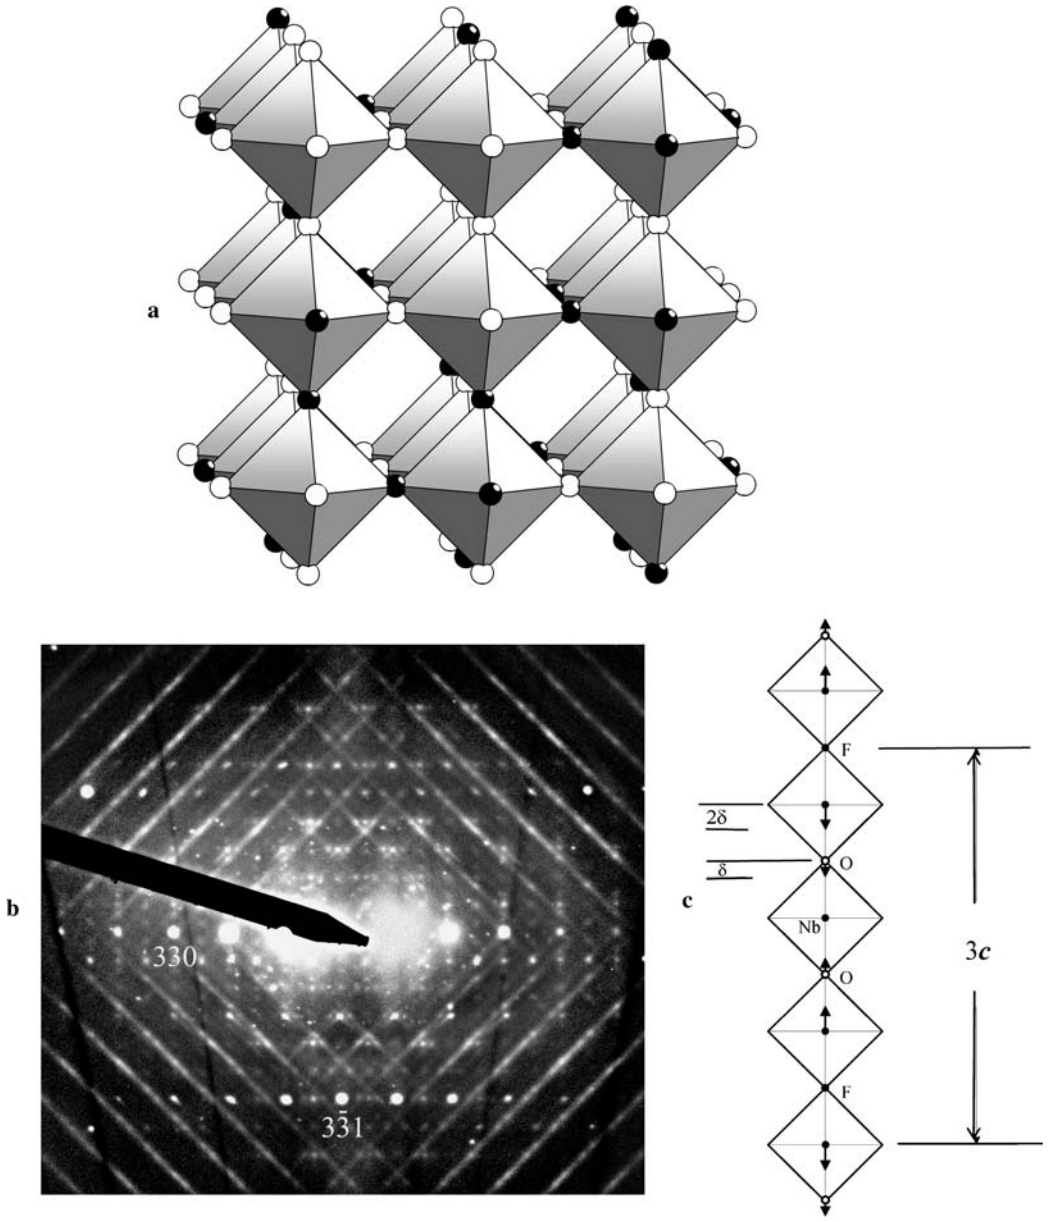

Fig. 4. (a) Shows a $3\times3\times3$ array of the cubic $Pm\bar{3}m$, ReO_3 type average structure of the family of $MO_{3-x}F_x$ (M = Nb, Ta, Ti, Mo, W) oxyfluoride compounds. The small black balls represent F^- ions while the small open circles represent O^{2-} ions. (b) A $\langle 1\,1\,6\rangle$ zone axis EDP of NbO_2F showing typical diffuse streaking along $\langle h\,0\,l\rangle^*$ directions of reciprocal space perpendicular to the $\langle 0\,1\,0\rangle$ directions of real space. (c) the ordered along $\langle 0\,0\,1\rangle$ ...$O^{2-}O^{2-}F^-$... arrangement implied by the observed diffuse distribution along with the associated induced atom shifts. Note that the component of the net dipole moment of three neighbouring octahedral units along the column direction is necessarily zero.

uncorrelated from one such column to the next while the $1/3\langle 0\,0\,1\rangle^*$ component of the diffuse distribution repeat implies an ordered —OOFOOFOOF— anion arrangement along the $\langle 0\,0\,1\rangle$ column direction (see Fig. 4c). Bond valence sum considerations suggest that the magnitude of the shift parameter, 2δ, in Fig. 4c is ~0.14 Å [34]. Note furthermore that the component of the net dipole moment of three neighbouring octahedral units along the column direction is necessarily zero.

Given the diffraction evidence for perfect 1-d, ...OOF... ordering along each of the three $\langle 0\,0\,1\rangle$ directions without any correlation from anion string to anion string running along the same $\langle 0\,0\,1\rangle$ direction or between anion strings of differing $\langle 0\,0\,1\rangle$ directions, the probability of an inherently polar (*cis*-)$Nb^VO_4F_2$ octahedral unit is $3\cdot(1/3)\cdot(2/3)^2 = 12/27$, of an inherently polar (*fac*-)$Nb^VO_4F_2$ octahedral unit is $(2/3)^3 = 8/27$, of an inherently polar Nb^VO_5F octahedral unit is $3\cdot(2/3)\cdot(1/3)^2 = 6/27$ while the probability of a non-polar Nb^VO_6 unit is 1/27. Thus the Nb^VO_2F and Ta^VO_2F compounds can be described as a corner-connected network of (overwhelmingly) inherently polar octahedral units. Nonetheless, the sum of the dipole moments of the 27 octahedra in any $3\times3\times3$ array (see Fig. 4a) necessarily must always sum to zero given Fig. 4c *i.e.* it is again

the case that the inherent dipole moments associated with the constituent $Nb^{V}O_{6-n}F_n$ octahedral units not only sum to zero macroscopically but also on the smallest possible $(3\times3\times3)$ local unit cell scale.

4. The $A_2BMoO_3F_3$, A,B = Na, K, Rb, Tl and Cs, family of oxyfluorides

A final disordered (non-polar) family of transition metal oxyfluoride compounds containing locally polar pseudo-octahedral units is the relatively large family of $A_2{}^{+}B^{+}M^{VI}O_3F_3$ (A,B = Na, K, Rb, Tl, Cs; M^{VI} = Mo, W) oxyfluoride compounds which crystallize at high temperature in the ideal cubic, $Fm\bar{3}m$, A_2BMX_6, structure type shown in Fig. 5a, or in closely related displacive variants thereof at lower temperatures [12–23]. A ⟨0 0 1⟩ projection of one half of the unit cell of this orientationally disordered, high temperature polymorphic form is shown in Fig. 5a. (The second half of the unit cell is exactly the same as that shown, just translated by $1/2(\mathbf{a}_p+\mathbf{c}_p)$, subscript p for parent. It has not been shown for the purposes of clarity). The octahedra shown represent the isolated, orientationally disordered $M^{VI}O_3F_3{}^{3-}$ octahedra while the large (open) and medium (shaded) balls represent the interstitial A and B alkali ions respectively.

Bond valence sum calculations performed on this average, ideal cubic structure type for several such materials, *e.g.* $K_3MoO_3F_3$ [24] and $Rb_2KMoO_3F_3$ [25], finds clear evidence of the need for large amplitude octahedral rotations as well as evidence that the F^- ions are invariably significantly over-bonded while the O^{2-} ions are invariably significantly under-bonded in the average structure anion positions [24,25]. The latter strongly suggests that opposite vertices in each $Mo^{VI}O_3F_3{}^{3-}$ octahedra will again always be occupied the one by O^{2-} and the other by F^-, thus confirming the existence of local *fac*-type octahedral $M^{VI}O_3F_3{}^{3-}$ units in these materials. As there are eight distinct octahedral faces associated with each *fac*-$M^{VI}O_3F_3{}^{3-}$ pseudo-octahedral unit, there are therefore eight different possible ⟨1 1 1⟩ real space directions along which the local dipole moment can point. There is thus plenty of scope for local orientational disorder.

On cooling, this high temperature γ polymorph typically undergoes two instantaneously reversible, displacive structural phase transitions – at temperature T_2 to a β polymorph and at temperature T_1 to a lowest temperature, usually room temperature, α polymorph [13–16,18–25]. The instantaneously reversible nature of these phase transitions shows that they are purely displacive in nature (associated with octahedral rotations and associated displacements of the interstitial A and B cations) but not with oxide/fluoride ordering and associated structural relaxation. This has recently been confirmed by the fact that the room temperature polymorphic form of K_3AlF_6 [36] exhibits exactly the same complex superstructure unit cell and space group symmetry as the α polymorph of $K_3MoO_3F_3$ [25]. In the case of K_3AlF_6, there is of course no possibility of oxide/fluoride ordering and associated off-centre transition metal shifts being responsible for the observed additional satellite reflections.

Evidence for oxide/fluoride ordering and associated off-centre displacements of the Mo ions in these $A_2{}^{+}B^{+}M^{VI}O_3F_3$ compounds is not to be found in the sharp additional satellite reflections associated with these lower temperature polymorphic forms but rather in the existence of a highly structured, quite sharp, continuous diffuse intensity distribution with inherent cubic symmetry (see the right hand sides of the four panels shown in Fig. 6) [25]. A virtually identical 3-d diffuse distribution has been found for $K_3MoO_3F_3$ [25], $Tl_3MoO_3F_3$ [37] as well as $Rb_2KMoO_3F_3$ [37]. It thus appears to be quite characteristic of $A_2{}^{+}B^{+}M^{VI}O_3F_3$ oxyfluoride compounds except in the special case where A and B = Na (see below).

The shape of this sharp, highly structured, diffuse intensity distribution takes the form

$$\exp 2\pi i\mathbf{q}\cdot\tfrac{1}{2}\mathbf{a}+\exp 2\pi i\mathbf{q}\cdot\tfrac{-1}{2}\mathbf{a}+\exp 2\pi i\mathbf{q}\cdot\tfrac{1}{2}\mathbf{b}+\exp 2\pi i\mathbf{q}\cdot\tfrac{-1}{2}\mathbf{b}+\exp 2\pi i\mathbf{q}\cdot\tfrac{1}{2}\mathbf{c}+\exp 2\pi i\mathbf{q}\cdot\tfrac{-1}{2}\mathbf{c}=2(\cos\pi h+\cos\pi k+\cos\pi l)=0$$

(where $\mathbf{q}=h\mathbf{a}^*+k\mathbf{b}^*+l\mathbf{c}^*$) [24,25]. The local constraint responsible for the observed diffuse distribution thus necessarily corresponds to a six-body octahedral cluster relationship involving atoms located at $\pm1/2$ $\mathbf{a}_p$, $\pm1/2$ $\mathbf{b}_p$ and $\pm1/2$ $\mathbf{c}_p$ around a central atom, specifically to a requirement that the sum of the dipole moments of the six $Mo^{VI}O_3F_3{}^{3-}$ octahedra surrounding any central B ion (equivalently the sum of the associated off-centre displacements of the Mo ions) must always sum to zero (see *e.g* Figs. 5b and c). Note that there are six, inherently acentric $M^{VI}O_3F_3{}^{3-}$ octahedra surrounding each central B cation (and vice-versa) at $\pm1/2$ $\mathbf{a}_p$, $\pm1/2$ $\mathbf{b}_p$ and $\pm1/2$ $\mathbf{c}_p$ respectively (see Fig. 5a).

Monte–Carlo simulation of Mo ion distributions satisfying such a local rule give corresponding diffraction patterns in excellent agreement with the experimentally observed diffuse distributions (*cf. e.g.* the coloured left hand side of the four panels shown in Fig. 6 with the corresponding right hand side of the same panels) [24]. Thus the inherent dipole moments associated with each (*fac*-)$MoO_3F_3{}^{3-}$ octahedra not only sum to zero macroscopically but also on the local unit cell scale (see *e.g.* Figs. 5b and c). This very strong local ordering rule, while extremely restrictive, nonetheless does not lead to conventional long range 3-d order (see Fig. 6). The reason is the numerous distinct local configurations which can still satisfy the required constraint.

Given that there are eight orientations possible for each local octahedron and six octahedra in each local cluster, there are therefore $8^6=262\,144$ distinct local configurations possible. Of these $8^6=262\,144$ local configurations possible for a random distribution, only some 8000 (or 3.05 %) satisfy the local constraint that the sum of the dipole moments must be zero (one out of these 8000

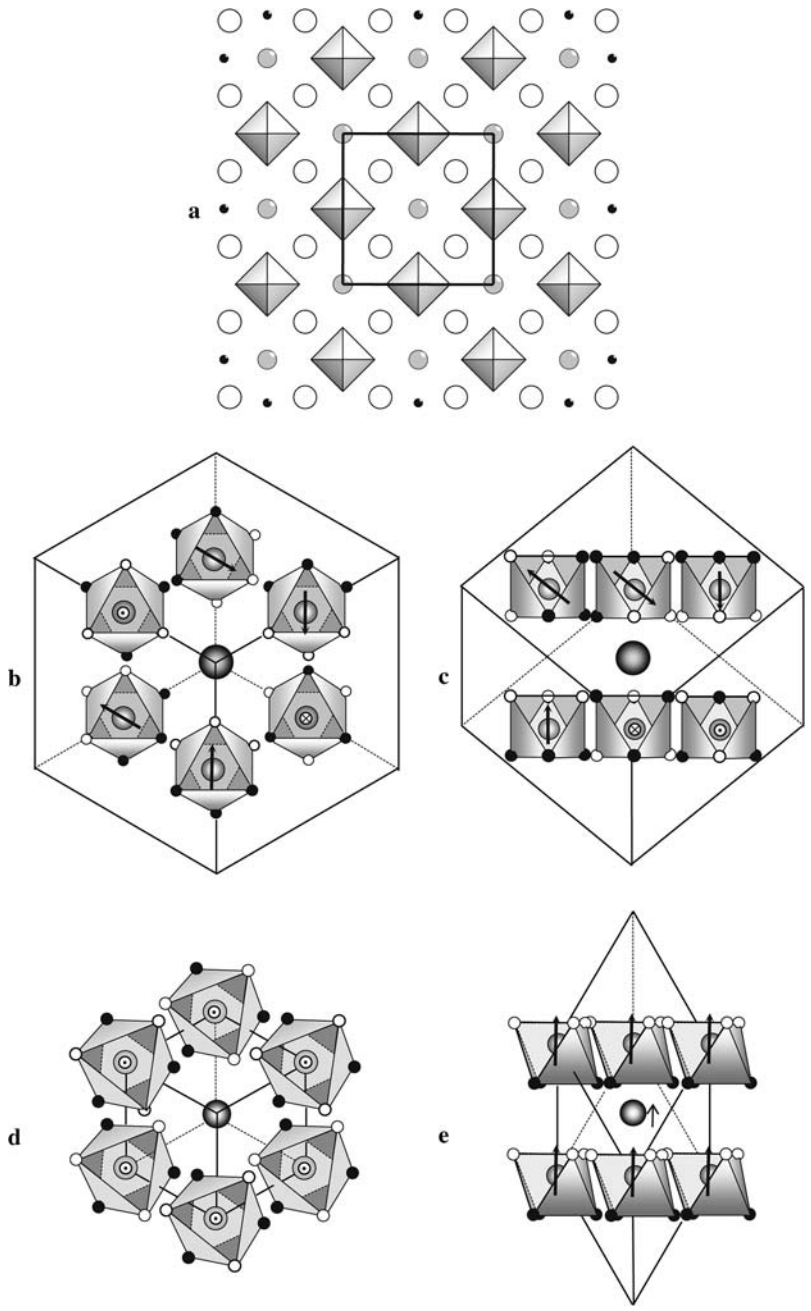

Fig. 5. (a) An ⟨0 0 1⟩ projection of one half of the unit cell of the ideal cubic $Fm\bar{3}m$, high temperature polymorphic form of the $A_2{}^{+}B^{+}M^{VI}O_3F_3$ family of transition metal oxyfluoride compounds. (The second half of the unit cell is exactly the same as that shown, just translated by 1/2 ($\mathbf{a}_p + \mathbf{c}_p$), subscript p for parent.) The octahedra represent the isolated, orientationally disordered, $M^{VI}O_3F_3{}^{3-}$ octahedra while the large (open) and medium (shaded) balls represent the interstitial *A* and *B* alkali ions, respectively. (b,c) Show one of the 8000 possible local configurations which satisfy the local constraint that the sum of the dipole moments of the six $Mo^{VI}O_3F_3{}^{3-}$ octahedra surrounding any central *B* ion (equivalently the sum of the off-centre displacements of the Mo ions) must sum to zero. The F^- ions are represented by the small dark balls while the O^{2-} ions are represented by the small open balls. The induced off-centre shifts of the metal ions are represented by the arrows. The projection axis is along a [1 1 1] direction in (b) and along the orthogonal [1 $\bar{1}$ 0] direction in (c). (d,e) Show equivalent projections of the fully dipole ordered α-$Na_3MoO_3F_3$ compound along and perpendicular to the polar axis.

possible local configurations is shown in projection along a ⟨1 1 1⟩ direction in Fig. 5b and along an orthogonal ⟨1 $\bar{1}$ 0⟩ direction in Fig. 5c). The configurational entropy associated with complete orientational disorder of the (*fac*-)$MoO_3F_3{}^{3-}$ octahedra is thus very considerably reduced by the imposition of the local constraint. It is not, however, removed altogether. The removal of ~97% of the potential local configurations shows that there must clearly be a genuine energy lowering, rather than entropy, advantage which explains why the local constraint is so strongly obeyed. Possibilities include the minimization of the overall dipole–dipole interaction energy, minimization of the dipole–interstitial B^+ monopole interaction energy or even mimization of local strain.

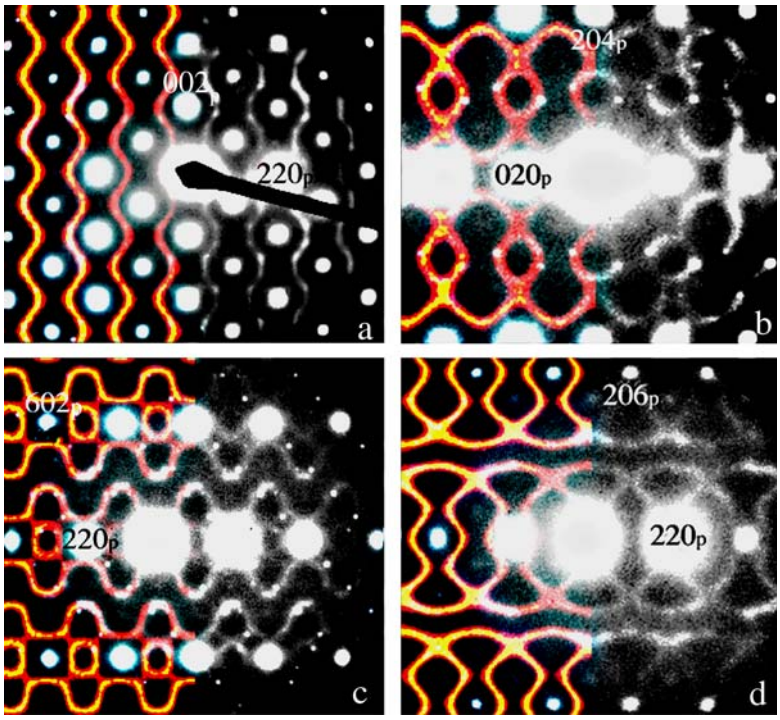

Fig. 6. Shows experimental (on the right hand side) and simulated (coloured on the left hand side) zone axis EDP's of $K_3MoO_3F_3$ at the (a) $\langle 1\,1\,0\rangle_p$, (b) $\langle 2\,0\,1\rangle_p$, (c) $\langle 1\,1\,3\rangle_p$ and (d) $\langle 3\,3\,1\rangle_p$ zone axis orientations [25]. Note the highly structured, quite sharp, continuous diffuse intensity distribution characteristic of the oxide/fluoride ordering and associated displacive shifts in these $A_2{}^+B^+M^{VI}O_3F_3$ compounds.

From the point of view of designing inherently polar transition metal oxyfluorides, the observed constraint that the inherent dipole moments associated with each (*fac*-)$MoO_3F_3{}^{3-}$ octahedra not only sum to zero macroscopically but also on the local unit cell scale is not a very encouraging result. There is, however, one counter-example from this family of compounds. The recent discovery of a fully dipole ordered $A_2{}^+B^+M^{VI}O_3F_3$ compound of this type, namely $Na_3MoO_3F_3$ (see Fig. 5d and e), demonstrates that it is quite possible for the constituent (*fac*-)$MoO_3F_3{}^{3-}$ octahedra in materials of this type to orientationally order if the local crystal chemistry (size of the interstitial alkali ions and the amplitude of octahedral rotation) is appropriate [38]. It is interesting in this context to note that a similar phenomenon also appears to take place in the case of the $A_2WO_2F_4$ oxyfluorides in that the $[WO_2F_4]^{2-}$ anion is orientationally disordered when the alkali ion is large, $A = Cs$, but becomes orientationally ordered when the much smaller alkali ion $A = Na$ is used [9].

That the room temperature polymorph of α-$Na_3MoO_3F_3$ is indeed inherently polar had already been shown by Chaminade *et al.* [21] who performed non linear optical testing and reported the harmonic yield to be about 40 times that of α-quartz. Note that neutron refinement of the crystal structure of α-$Na_3MoO_3F_3$ shows that the oxide-fluoride ordering is also accompanied by relatively large amplitude octahedral rotation of the constituent (*fac*-)$MoO_3F_3{}^{3-}$ octahedra around the resultant $[1\,1\,1]_R$, *R* for rhombohedral, axis [38], displacive shifts of the interstitial Na^+ ions along the same $[1\,1\,1]_R$ axis as well as significant rhombohedral metric distortion of the underlying cubic unit cell.

5. Conclusions

Whilst we have by no means covered, nor even attempted to cover, the wide and ever-growing spectrum of known transition metal oxyfluoride compounds ([1,2,26,39–41] and references contained therein), there are nonetheless valuable conclusions that can be drawn from the results of this paper.

First, bond valence sum calculations performed on available refined average crystal structures of 'disordered' oxyfluorides provide invaluable insight into local transition metal co-ordination environments if interpreted carefully (preferably in conjunction with spectroscopic and chemical evidence, if available [28,29,40–42]). In the three classes of transition metal oxyfluorides discussed above, such calculations invariably show O^{2-} ions to be significantly underbonded and F^- ions significantly overbonded in the average structure anion positions. A logical consequence of this is that O^{2-} and F^- ions should, as far as is possible, locally arrange themselves to be at opposite corners of each pseudo-octahedral unit. This allows the transition metal ions to move off-centre towards the O^{2-} and away from the F^- ions thereby simultanuously decreasing the overbonding of the F^- ion and the underbonding of the O^{2-} as well as providing a strong driving force for local O^{2-}/F^- ordering. It also generally leads to the expected, and desired, polar pseudo-octahedral units shown in Fig. 1.

Second, such oxide/fluoride ordering is rarely contained to the immediate co-ordination environment of the transition metal ions but usually extends considerably further depending upon factors such as the topological connectivity of the polar pseudo-octahedral units (corner- or face-sharing *etc.*) or, if not directly connected to one another, to their immediate co-ordination environment. Orientational 'ordering' of the individual polar pseudo-octahedral units rarely takes a conventional long range ordered crystallographic form (presumably as a result of configurational entropy). It rather usually manifests itself in the form of a highly structured diffuse intensity distribution. Electron diffraction, with its proven ability to detect weak, highly structured features of reciprocal space, is an invaluable tool in the search for such longer range orientational ordering rules.

Third, the concept of 'order' is a much richer concept than is usually thought. In this paper, examples have been provided of 3-d, 2-d, 1-d and 0-d order (see Table 1). In each case, the dimensional order (D) of the diffuse features of reciprocal space has implied a (3-D) dimensional order in real space. In the case of FeOF, for example, 1-d rod like diffuse was observed ($D = 1$) in reciprocal space corresponding to long range 2-d order (*i.e.* 3–1) in real space. Likewise, in the case of NbO_2F, planar diffuse ($D = 2$) implied 1-d order (*i.e.* 3–2) in real space. In the more complex case of $K_3MoO_3F_3$, a complex diffuse surface was observed in reciprocal space ($D = 3$) implying 0-d order in real space. This does not mean there is no order but rather that the extent of the order is localized in all 3 real space directions. Lastly, in the case of $Na_3MoO_3F_3$, sharp Bragg reflections in reciprocal space ($D = 0$) imply conventional 3-d long range order in real space.

Finally, the presence of inherently polar pseudo-octahedral units in transition metal oxyfluorides by no means guarantees polar macroscopic behaviour. Indeed, it would seem without appropriate intervention or clever adjustment of local crystal chemistry [1], that the local dipole moments associated with the constituent polar pseudo-octahedral units invariably not only sum to zero macroscopically but also on a very close to the average structure unit cell scale. This was the general case for each of the three classes of transition metal oxyfluorides discussed above and is clearly so for a very definite energy reason.

Table 1
Relationship between the dimensional order of real and reciprocal space

Oxyfluoride system	Dimensional order of weak scattering in reciprocal space	Implied dimensional order in real space
	(D)	(3-D)
$Na_3MoO_3F_3$	0	3
FeOF	1	2
NbO_2F	2	1
$K_3MoO_3F_3$, $Tl_3MoO_3F_3$, $Rb_2KMoO_3F_3$	3	0

The structure-directing influence of guanidinium cations in the crystal structures of $[C(NH_2)_3]_2[M^{II}(H_2O)_4(VO_3)_4]\cdot 4H_2O$ (M = Mn, Co, Ni)

Abstract

The combination of guanidinium, vanadate and the divalent transition metals Mn^{II}, Co^{II} and Ni^{II} in aqueous solution leads to the generation of crystals of formula $[C(NH_2)_3]_2[M^{II}(H_2O)_4(VO_3)_4]\cdot 4H_2O$ (M = Mn, Co, Ni). The structures consist of undulating anionic $[M^{II}(H_2O)_4(VO_3)_4{}^{2-}]$ sheets which stack in an ABAB fashion. Guanidinium ions bind pairs of sheets together by a combination of electrostatic attraction and hydrogen bonding to generate a 3D coordination/hydrogen-bonded network. TGA studies of the compounds reveal that upon heating, water molecules are first lost and this process is followed by the decomposition of the guanidinium ion.

1. Introduction

The guanidinium cation is a very versatile hydrogen bonding building block showing much promise for the construction of a variety of network structures. Reports from Ward and co-workers [1–3], describing the elegant crystal engineering of a series of guanidinium sulphonates with reliable and predictable connectivities, suggested that the guanidinium ion might possess a much more widely applicable potential for framework construction. We have been attempting to exploit some of these possibilities and have reported (a) a very extensive series of carbonate-based networks with cubic symmetry and with a topology based on that of sodalite [4,5], in which the guanidinium cation behaves as a 3-connecting node in a very predictable manner, (b) a series of composition $[C(NH_2)_3][N(CH_3)_4][XO_4]$ (X = S, Cr and Mo) again with cubic symmetry but with the (10,3)-*a* topology [6], in which the guanidinium cation plays a similar 3-connecting role, (c) a series of composition $\{[B(OCH_3)_4]_3[C(NH_2)_3]_4\}^+X^-$ (X^- = a range of anions) in which the guanidinium cation yet again plays a very similar role and yet again the crystals have cubic symmetry, but in this case the topology is that of the boracite net [7] and (d) the structure of guanidinium rhodizonate in which the guanidinium ion plays essentially the same 3-connecting role, but in which the network nevertheless adopts an unexpected and new type of 3D topology [8]. In all of these examples, including those of Ward [1–3], the guanidinium ion forms three pairs of hydrogen bonds to three separate oxyanions as depicted in Fig. 1. In the present report, we describe a new series of guanidinium transition metal vanadates, in which the guanidinium cation cements undulating anionic sheets together (see Table 1).

2. Results and discussion

The reaction of sodium metavanadate, guanidinium chloride and metal(II) nitrate in water affords crystals of formula, $[C(NH_2)_3]_2[M(H_2O)_4(VO_3)_4]\cdot 4H_2O$ (M = Mn, Co, Ni) which were orange–red in the Mn and Co cases

and green in the Ni case; yellow crystals of guanidinium decavanadate which also formed were easily distinguished and separated. Full X-ray single crystal structural analyses were performed on the Co and Ni compounds which showed that the compounds were isomorphous. The crystals of the Mn analogue were too small for a full structure determination but its powder diffraction pattern revealed the same structure.

Within the structure, the vanadate ion exists in the form of ladder-like chains that extend in the *a*-direction (Fig. 2). The vanadium centre is coordinated by five oxygen atoms with a coordination geometry somewhere between trigonal bipyramidal and square pyramidal. The sides of the ladder are formed from –V–O–V– chains involving oxygen atoms that lie in the axial coordination sites of a distorted trigonal bipyramid. Vanadium–oxygen links between these chains

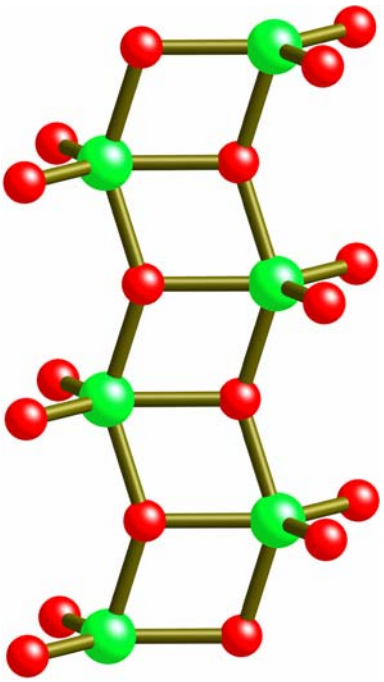

Fig. 2. A $[VO_3^-]_n$ ladder within $[C(NH_2)_3]_2[M(H_2O)_4(VO_3)_4]\cdot 4H_2O$ [M = Mn, Co, Ni]. The large spheres represent vanadium atoms, small spheres represent oxygen atoms.

form the rungs of the ladder. These ladder-like chains are common in 1D, 2D and 3D vanadium(V) oxide materials [9–13] including V_2O_5 itself [14]. Individual ladders are linked through $M^{II}(H_2O)_4$ units to form an undulating 2D network as depicted in Fig. 3. Intra-sheet hydrogen bonding between terminal oxo groups and coordinated water molecules, shown in Fig. 3, strengthens the connections between ladders within a sheet.

The fact that the vanadate ion is present as ladder-like units prevents the types of highly symmetrical interactions between the anion and guanidinium, which were a feature of the cubic networks mentioned in Section 1. As a consequence the vanadate structures described in the manuscript do not possess cubic symmetry.

Fig. 3 indicates two types of vanadium centre, one type with two terminal oxo groups and the second type with only a single terminal oxo group and an oxo bridge to the M^{II} centre. Despite this difference in coordination, both types of vanadium centres are crystallographically equivalent, with the $M^{II}(H_2O)_4$ units disordered over two symmetry related positions. As a consequence of this disorder the relative positions of the $M^{II}(H_2O)_4$ units on either side of a ladder are not certain. One possible arrangement is depicted in Fig. 3.

The mean planes of the $[VO_3^-]_n$ ladders within a sheet are equally inclined to the mean plane of the sheet, however the ladders in adjacent sheets are inclined in opposite directions as shown in Fig. 4. The sheets stack in the ABAB fashion with adjacent sheets related by a 2-fold axis. The troughs in one sheet are directly opposed to crests in the sheet below creating expanded and narrowed regions

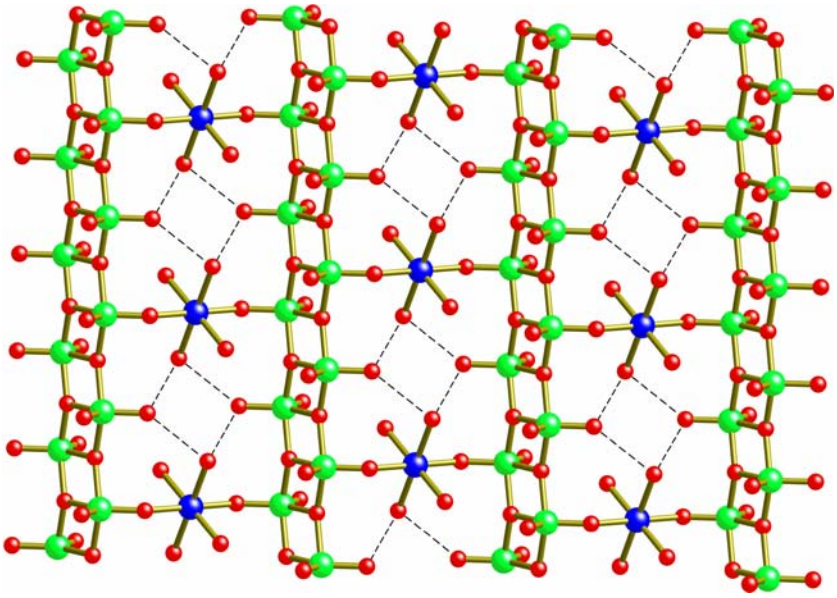

Fig. 3. A $[M(H_2O)_4(VO_3)_4^{2-}]$ (M = Co, Ni) sheet. The large pale spheres, large dark spheres and small dark spheres represent V, M and O atoms, respectively. Hydrogen bonds are represented by dashed lines. Hydrogen atoms are not shown.

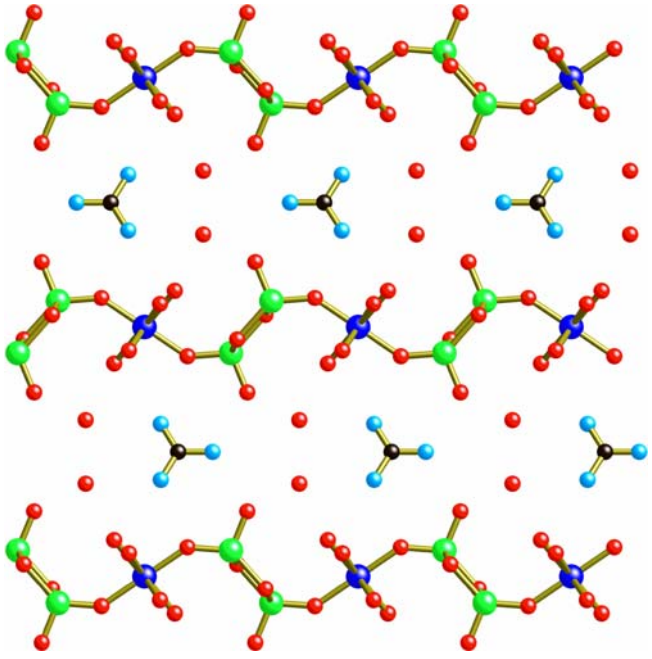

Fig. 4. The arrangement of the anionic sheets in $[C(NH_2)_3]_2[M(H_2O)_4(VO_3)_4]\cdot 4H_2O$ [M = Mn, Co, Ni]. The trigonal units between the sheets are guanidinium ions. The isolated spheres represent the oxygen atoms of non-coordinated water molecules. Hydrogen atoms are not shown.

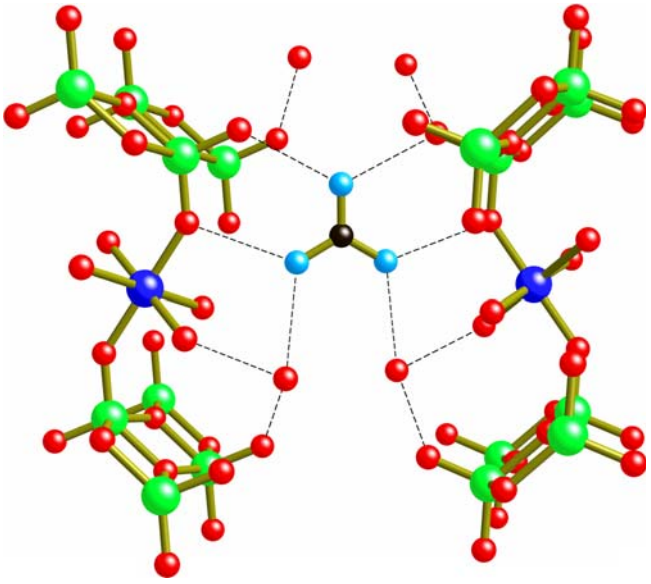

Fig. 5. A representation of the hydrogen bonding between the guanidinium ions, the anionic sheets and non-coordinated water molecules. Hydrogen atoms are not shown.

between the sheets. The guanidinium cations are situated near the narrow regions, oriented in a plane that is almost perpendicular to the mean plane of the sheets. Non-coordinated water molecules lie in the expanded regions.

Each guanidinium ion lies on a 2-fold axis and participates in six hydrogen bonds as indicated in Fig. 5. Pairs of hydrogen bonds extend to vanadate units belonging to different sheets. The guanidinium ions are further hydrogen bonded to pairs of uncoordinated water molecules which in turn are hydrogen bonded to water molecules coordinated to the divalent metal ions. The hydrogen bonding role played by the guanidinium cation seen here is closely similar to that seen in Fig. 1. It appears that this interaction plays a major role in the relative orientation of adjacent sheets within the structure.

Thermogravimetric analysis of $[C(NH_2)_3]_2[Mn(H_2O)_4(VO_3)_4]\cdot 4H_2O$ shows two distinct mass losses up to 350 °C (see Fig. 6). The first mass loss is already underway at 25 °C and is complete at 120 °C. This corresponds to the

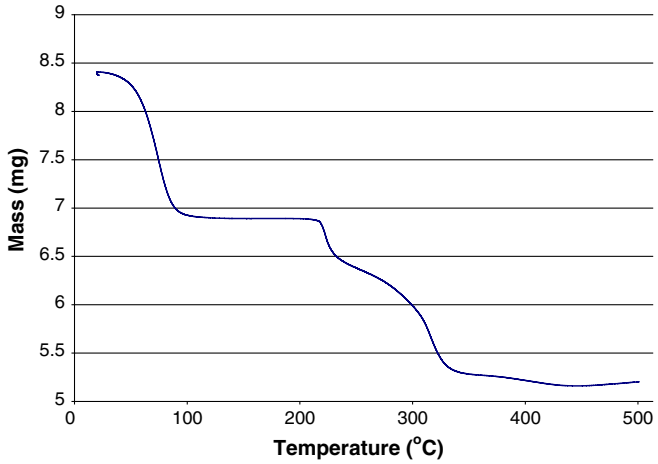

Fig. 6. TGA trace for $[C(NH_2)_3]_2[Mn(H_2O)_4(VO_3)_4]\cdot 4H_2O$.

loss of the uncoordinated and coordinated water molecules (18.0% found, 20.2% calculated). At 200 °C a second mass loss begins which is likely to correspond to the decomposition of the guanidinium ion. This is a multi-step process, occurring in the range 200–350 °C and is consistent with the loss of ammonia followed by cyanamide and water. It is proposed that the water molecule lost in this process is formed from an oxide anion and guanidinium protons. Similar behaviour is observed with the Co and Ni compounds although the second mass loss process is less well-defined. Further thermogravimetric details are presented in the Supplementary data.

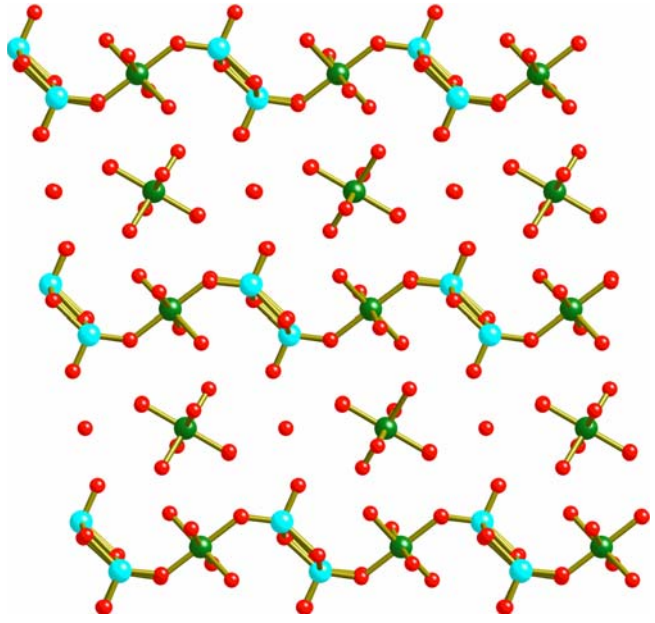

Fig. 7. The structure of $[Mg(H_2O)_6]_2[Mg(H_2O)_4(VO_3)_4]$ (dickthomsenite). The large pale spheres, large dark spheres and small dark spheres represent V, Mg and O atoms, respectively. Hydrogen atoms are not shown. (Dickthomsenite cell dimensions and space group: $a = 38.954(2)$, $b = 7.2010(4)$, $c = 16.3465(9)$ Å, $\beta = 97.602(1)°$, $C2/c$.)

The structures reported here are related to that of dickthomsennite [15], but differ from it in an important respect which reveals the structure-directing role played by the guanidinium cation. One view of the structure of dickthomsennite, $[Mg(H_2O)_6][Mg(H_2O)_4(VO_3)_4]$ is shown in Fig. 7, in which it can be seen that the individual $[Mg(H_2O)_4(VO_3)_4^{2-}]$ sheets stack in what may be described as an AAAA fashion. In this case the average planes of all the ladders in all the sheets are parallel to each other, in contrast to the ABAB-stacked structures reported above. The origin of the different stacking is plain – only by having alternating A and B sheets related by a 2-fold axis are the hydrogen bonding capabilities of the guanidinium cation maximised in the manner seen in Fig. 5.

3. Experimental

3.1. $[C(NH_2)_3]_2Mn(H_2O)_4(VO_3)_4\cdot 4H_2O$ (1)

A solution of $Mn(NO_3)_2\cdot 4H_2O$ (200 mg, 1.12 mmol) and $C(NH_2)_3Cl$ (530 mg, 5.6 mmol) in H_2O (5 ml) was added to a slurry of NH_4VO_3 (260 mg, 2.24 mmol) in H_2O (10 ml) to produce a soupy yellow suspension. After several days, orange crystals of (**1**) were separated from an inhomogeneous reaction mixture by repeated washing and decanting finer solid, leaving the larger, more dense desired product free of impurity. The crystals were washed with water and dried in air. *Anal.* Calc.: C, 3.3; H, 3.9; N, 11.7. Found: C, 3.5; H, 3.9; N, 11.7%.

3.2. $[C(NH_2)_3]_2Co(H_2O)_4(VO_3)_4\cdot 4H_2O$ (2) and $[C(NH_2)_3]_2Ni(H_2O)_4(VO_3)_4\cdot 4H_2O$ (3)

Cobalt and nickel analogues were prepared in a similar manner, differing by only replacing $Mn(NO_3)\cdot 4H_2O$ with either $Co(CH_3COO)_2\cdot 4H_2O$ or $Ni(NO_3)_2\cdot 6H_2O$. After a few days, red crystals of (**2**) and green crystals of (**3**), which selectively adhered to the walls, were isolated by flushing away the finer suspended material with water. *Anal.* Calc. for (**2**): C, 3.3; H, 3.9; N, 11.7. Found: C, 3.6; H, 4.0; N, 12.1%. *Anal.* Calc. for (**3**): C, 3.3; H, 3.9; N, 11.7 . Found: C, 3.5; H, 4.0; N, 11.7%. Powder diffraction patterns are consistent with single crystal data although there is perhaps evidence of very minor contamination of the product by the co-precipitated solid (see supplementary data).

Single crystal X-ray data were collected on a Bruker CCD diffractometer. The structures were solved using direct methods and refined using a full-matrix least-squares refinement procedure based on F^2 [16]. All data were used in the refinement process. Absorption corrections were applied using the multi-scan procedure [17].

Abstract

The syntheses, structures and magnetic characterisations of the hexadecanuclear manganese(III/IV) carboxylate cluster $[Mn_{16}O_{16}(OMe)_6(OAc)_{16}(MeOH)_3(H_2O)_3]\cdot 6H_2O$ (**1** · $6H_2O$) and a linear chain Mn^{III} complex $[Mn(\mu\text{-}OMe)(\mu\text{-}OAc)_2]_n$ (**2**) are reported. AC magnetic susceptibility measurements confirm **1** to be a single-molecule magnet with relaxation parameters of $\tau_0 = 3.00\times10^{-9}$ s and energy barrier, ΔE, of 52.2 cm^{-1}. Complexes **1** · $6H_2O$ and **2** were obtained by reaction of *n*-Bu_4NMnO_4 with $Mn(NO_3)_2\cdot 4H_2O$ in a mixture of methanol and acetic acid. Complex **1** · $6H_2O$ crystallises in the triclinic space group $P\bar{1}$ and the cluster structure consists of six Mn^{IV} and 10 Mn^{III} ions held together by 14 μ_3-O^{2-}, two μ_2-O^{2-}, four μ_2-OMe^- and two μ_2-OAc^- groups to give a roughly elliptical planar $[Mn_{16}O_{16}(OMe)_4(OAc)_2]^{16+}$ core. Peripheral ligation consists of the remaining 14 μ_2-OAc^-, two μ_2-OMe^- groups and three axial water and methanol molecules. Complex **2** crystallises in the orthorhombic space group *Pbcn* and consists of infinite linear 1D chains of manganese(III) atoms bridged by two μ-OAc^- ligands and one μ-OMe^-. The magnetic data on **1** · $6H_2O$ and **2** are compared with those of other recently reported Mn_{16} and Mn(III) μ-carboxylate chain analogues.

1. Introduction

The discoveries of magnetically coupled clusters of d-block ions that display nanoscale magnetism of the single-molecule magnetic (SMM) type continue apace. In the case of the most abundant metal to form such molecular species, manganese, the carboxylate clusters known to display SMM behaviour include particular examples of Mn_4 [1,2], Mn_9 [3–5], Mn_{10} [6], Mn_{12} [7], Mn_{18} [8], Mn_{21} [9], Mn_{22} [10], Mn_{26} [11,12], Mn_{30} [13] and Mn_{84} (the largest Mn carboxylate cluster isolated to date) [14]. Other nuclearities such as Mn_3, Mn_6 [15,16], Mn_7 [17] Mn_8 [5,16,18,19], Mn_{13} [20] $(Ba_8Na_2)Mn_{16}$(II/III) [21] and Mn_{21} [22] do not, even though some have high-spin ground states, one of the key prerequisites for being an SMM. Another key prerequisite for SMM behaviour is a negative anisotropy in the axial zero-field splitting term *D*, which in the Mn clusters is introduced into the cluster ground state by Mn^{III} single-ion centres. A limited number of examples of SMM clusters containing metals other than manganese also exist. These include Fe_4 [23], Fe_8 [24–28], Fe_{10} [29,30], Fe_{19} [31] and V_4 [32] complexes, and recently, particular Ni_{12} [33], Ni_{21} [34], Co_4 [35] and Ni_4 [36] clusters have been reported to display SMM behaviour, albeit in the millikelvin temperature range. The SMM materials are not limited to oxo/carboxylato-based species, and now include a few examples of cyano-bridged clusters [37,38].

During attempts to link Mn_3 or Mn_4 carboxylate clusters together using the dicyanamide ($N(CN)_2^-$) ligand, in work aimed at making long-range ordered cluster arrays,

doi:10.1016/j.poly.2006.05.044

a new manganese(III/IV) carboxylate cluster $[Mn_{16}O_{16}(OMe)_6(OAc)_{16}(MeOH)_3(H_2O)_3]\cdot 6H_2O$ (**1** · $6H_2O$) and a new linear chain Mn^{III} complex $[Mn(\mu\text{-}OMe)(\mu\text{-}OAc)_2]_n$ (**2**) were obtained, neither of which contained the dicyanamide group! Our preliminary results were communicated [39]. The deliberate synthesis and detailed physical properties of these compounds are now described and the results are compared to those of related species including the family of new Mn_{16} carboxylate/alkoxo SMM clusters $[Mn_{16}O_{16}(OMe)_6(O_2CCH_2R)_{16}(MeOH)_6]$, where R = Ph, Cl and Br, recently discovered by Christou et al. during a study of the use of reductive aggregation methods, in methanol, to make high nuclearity Mn(III)/(IV) clusters [40].

2. Experimental

All manipulations were performed under aerobic conditions using chemicals as received, unless otherwise stated. *n*-Bu_4NMnO_4 was prepared as previously reported [41].

Warning. Extreme caution should be taken in the use of organic permanganates.

2.1. Synthesis of $[Mn_{16}O_{16}(OMe)_6(OAc)_{16}(MeOH)_3(H_2O)_3]\cdot 6H_2O$ (**1** · $6H_2O$)

To a stirred methanolic solution (120 mL) of $Mn(NO_3)_2\cdot 4H_2O$ (2.90 g, 11.57 mmol), and glacial acetic acid (10 mL), *n*-Bu_4NMnO_4 (1.14 g, 3.15 mmol) was added in small portions over a period of 30 min. The solution was then left to stand. After several weeks a small amount of block-like black crystals of **1** · $6H_2O$ formed. The solution was decanted, the crystals collected by filtration and washed quickly with methanol (0.20 g, 8% based on total available Mn). IR (Nujol, cm^{-1}): 3600 m, 3387 mbr, 1558 s, 1335 m, 1027 w, 960 vw. Many repeats of the reaction show that crystals of **1** · $6H_2O$ decompose with time to yield species containing low content of carbon and poor diffraction quality despite a good external morphology. Presumably slow hydrolysis of OMe^- and OAc^- groups occurs in the solid state. Analysis of a fresh sample, Calc. for $C_{41}H_{96}Mn_{16}O_{66}$ (hexahydrate): C, 19.6; H, 3.8; N, 0.0 [Calc. for $C_{41}H_{96}Mn_{16}O_{66}\cdot 14H_2O$: C, 18.5: H, 4.2; N, 0.0]. Found: C, 18.8; H, 3.8; N, 0.0%.

2.2. Synthesis of $[Mn(\mu\text{-}OMe)(\mu\text{-}OAc)_2]_n$ (**2**)

When the above reaction also had sodium dicyanamide (2.23 g, 25.0 mmol) and Me_4NBr (3.85 g, 25.0 mmol) added, black crystals of **1** · $6H_2O$ formed first, followed by smaller red rectangular block-like crystals of **2**. They were obtained free of the larger black **1** · $6H_2O$ crystals by successive filtration of the reaction to remove mixtures of **1** · $6H_2O$ and **2** that formed, and leaving the filtrate to stand until the product appeared homogenous with respect to the smaller red crystals by inspection under microscope. The crystals were collected by filtration and washed quickly with methanol. (Typical yield 0.25 g, 8% based on total available Mn.) IR (Nujol, cm^{-1}): 3603 vw, 1568 s, 1401 s, 1355 m, 1340 s, 1018 w, 992 m, 945 w. *Anal*. Calc. for $C_5H_9O_5Mn$: C, 29.4; H, 4.4; N, 0.0. Found: C, 29.2; H, 4.6; N, 0.0%.

2.3. X-ray crystallographic studies

Crystal data for **1** · $6H_2O$ and **2** are summarised in Table 1. Data were collected using a Nonius KappaCCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Integration was carried out by the program DENZO-SMN [42], and data were corrected for Lorentz polarisation effects using the program SCALEPACK [42]. No absorption corrections were applied. Solutions were obtained by direct methods (SHELXS 97) [43] followed by successive Fourier difference methods, and refined by full-matrix least-squares on F^2_{obs} (SHELXL 97) [43] with the aid of the graphical interface program X-SEED [44]. All non-hydrogen atoms were refined anisotropically unless otherwise stated. All hydrogen atoms attached to carbons for **1** · $6H_2O$ and **2** were included at calculated positions with isotropic thermal parameters fixed at 1.5 times the U_{eq} of the adjoining carbon atom. For **1** · $6H_2O$, the hydrogens (where assigned) attached to oxygen atoms were located in the difference maps and refined isotropically. The O–H

bond distances were restrained with the SHELX [43] (anti-bumping restraint) DFIX instruction to be 0.90(2) Å.

The asymmetric unit of $\mathbf{1}\cdot 6H_2O$ was found to contain half a Mn_{16} complex as well as three water molecules. Two of the water molecules were disordered. The first disordered water was modelled over two positions, O(540) and O(541), with site occupancies refined to be 0.702 and 0.298, respectively. O(540) and O(541) were refined with isotropic and anisotropic thermal parameters, respectively. The second disordered water was modelled over three positions: O(530), O(531) and O(532), with site occupancies of 0.33(1), 0.36(1) and 0.38(1), respectively. The sum of the occupancies was restrained to be 1.00(1) (calculated 1.07) using the SHELX [43] SUMP instruction. O(530–532) were refined with anisotropic thermal parameters. The third water, O(52), was ordered and refined with anisotropic thermal parameters. Its hydrogen atoms, H(52A) and H(52B), were located in successive iterations of least-squares refinements and difference Fourier maps and refined isotropically with the aforementioned anti-bumping restraints on the O–H bond distances. No hydrogen atom positions were assigned for the two disordered lattice water molecules.

Three areas of disorder were located within the cluster. Firstly, an axial μ-OAc^- and an adjacent methanol ligand, both on the outer Mn^{III}_{10} perimeter, were disordered over two positions. The three oxygen donor atoms O(39), O(41) and O(44) were refined at full occupancy. The positions of the two carbon atoms of the acetate group, C(420) and C(421), C(430) and C(431), and the two positions for the methyl carbon of the methanol, C(400) and C(401), were refined to site occupancies in the ratio of 0.684/0.316.

Secondly, two coordinated oxygens (O(45) and O(47)) were initially assigned as two water ligands, however peaks near each oxygen were located at positions consistent with partially occupied methanol carbon atoms. They were consequently assigned as such and site occupancies of these carbon atoms and the attached hydrogen atoms were fixed at 0.25. Thus over the entire cluster four axial positions are occupied by three waters and one methanol. One hydrogen atom for O(45) and two hydrogen atoms for O(47) were located and refined isotropically with the aforementioned anti-bumping restraints applied. Finally, the carbon atom of the μ-OMe^- bridging between Mn(6) and Mn(7) was disordered over two positions. The site occupancies of these carbon atoms (C(260) and C(261)), and the attached hydrogen atoms, were refined to the ratio of 0.496/0.504, respectively.

As O(1) and C(2) of the bridging methoxide of **2** lie along a 2-fold rotational axis the methyl hydrogens are disordered over two positions with equal site occupancies.

2.4. Magnetic measurements

DC susceptibilities were measured using a Quantum Design Magnetic Properties Measurement System (MPMS 5) SQUID magnetometer calibrated by use of a standard palladium sample (Quantum Design) of accurately known magnetisation or by use of magnetochemical calibrants such as $CuSO_4\cdot 5H_2O$ and $[Ni(en)_3]S_2O_3$. AC susceptibilities were measured with a Quantum Design Physical Property Measurement System (PPMS 7) fitted with an Option P-500 (ACMS) attachment, with an AC field of 1 Oe and frequencies varying over the range 10–1500 Hz, at temperatures between 1.75 and 4 K. Powder samples were dispersed in vaseline, contained in a calibrated gelatine capsule held at the centre of a drinking straw fixed to the end of the sample rod in order to avoid torquing of the crystallites. Crystalline samples of $\mathbf{1}\cdot 6H_2O$ were removed from their mother liquor (and briefly washed with methanol) immediately prior to placement in the cooled sample chamber of the instrument in order to minimise the amount of decomposition undergone by the sample before being measured.

3. Results and discussion

3.1. Synthesis and characterisation

As previously reported [39], $\mathbf{1}\cdot 6H_2O$ was initially obtained accidentally when attempting to expand our dicyanamide (dca^-, $N(CN)_2^-$) molecule-based magnet work into networks of Mn_3 or Mn_4 clusters bridged by dca^- ligands. It was subsequently found that dca^- was not necessary for its formation. Thus, addition of solid *n*-Bu_4NMnO_4 to a stirred solution of $Mn(NO_3)_2\cdot 4H_2O$ in a mixture of methanol and acetic acid yielded a dark brown solution which was allowed to stand for several weeks, with the formation of black block-like crystals of $\mathbf{1}\cdot 6H_2O$. If Na(dca) and Me_4NBr are included in the reaction, $\mathbf{1}\cdot 6H_2O$ is formed first followed by small red crystals of **2**. Successive filtrations of the reaction to remove the product mixture formed, and subsequent standing yields a pure sample of **2**. Infrared spectra show an absorption due to ν(C=O) at 1558 and 1568 cm^{-1} for $\mathbf{1}\cdot 6H_2O$ and **2**, respectively. The crystals of the two products are readily differentiated by visual inspection. In similar work with a related pseudohalide ligand, dicyanonitrosomethanide ($dcnm^-$, $^-ONC(CN)_2$) we reported the synthesis of a linear chain complex, $\{[Mn(\mu\text{-}OH)(\mu\text{-}OAc)_2]\cdot HOAc\cdot H_2O\}_n$ [45], that also did not contain the $dcnm^-$ ligand. Christou et al. [46] simultaneously reported $\{[Mn(\mu\text{-}OH)(\mu\text{-}OAc)_2]\cdot HOAc\cdot H_2O\}_n$, prepared by reacting $Mn(OAc)_2\cdot 4H_2O$ with $KMnO_4$, in a 2.5 to 1 ratio, in methanol–acetic acid mixtures.

Attempts were made to synthesise the benzoate analogue of the $\mathbf{1}\cdot 6H_2O$ complex. One method involved using similar reaction conditions to those for $\mathbf{1}\cdot 6H_2O$, but replacing benzoic acid for acetic acid. Another route explored was to attempt to replace the acetate groups of $\mathbf{1}\cdot 6H_2O$ with benzoate, in a similar method utilised by Christou et al. and other groups to synthesise a series of $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ derivatives of Mn_{12}-acetate, where R groups include Ph, CH_2Ph, CH_2Bu^t, Et, *p*-Tol, and *m*-Cl-Ph, by substituting acetate groups on Mn_{12}-acetate [47–50]. However, these attempts were unsuccessful

and were not pursued further. The latter method presents difficulties as the $\mathbf{1}\cdot 6H_2O$ complex decomposes when removed from its mother liquor, and it did not dissolve in a range of common solvents tried.

The synthetic method utilised here differs in a number of ways from that employed by Christou and co-workers to prepare their $[Mn_{16}O_{16}(OMe)_6(O_2CCH_2R)_{16}(MeOH)_6]$ complexes, where R = Ph, Cl and Br [40]. Most notably, their method uses a single source of Mn, viz. n-Bu_4NMnO_4, and reactions were performed in solutions of comparatively higher concentration. It is clear from our experience and that of Christou and Hendrickson [5,7,51,52] that these reactions affording high nuclearity Mn clusters are complex, with several variables, which perhaps, with only minor shifts such as slightly higher or lower Mn^{II}/Mn^{VII} ratios can result in widely different outcomes, such as the formation of Mn oxides as opposed to the desired large Mn clusters. The roles of Na(dca) and Me_4NBr, here, in the sequential formation of $\mathbf{1}\cdot 6H_2O$ and the chain complex, **2**, are not known.

3.2. Crystal structures

3.2.1. $[Mn_{16}O_{16}(OMe)_6(OAc)_{16}(MeOH)_3(H_2O)_3]\cdot 6H_2O$ ($\mathbf{1}\cdot 6H_2O$)

$\mathbf{1}\cdot 6H_2O$ crystallises in the triclinic space group $P\bar{1}$. The cluster lies on an inversion centre relating one half of the cluster to the other. The asymmetric unit contains half of the molecule and three lattice water molecules. The complex consists of six Mn^{IV} and 10 Mn^{III} ions held together by 14 μ_3-O^{2-}, two μ-O^{2-}, four μ-OMe^- and two μ-OAc^- groups to give an approximately elliptical planar $[Mn_{16}O_{16}(OMe)_4(OAc)_2]^{16+}$ core (Fig. 1). Peripheral ligation consists of the remaining 14 μ-OAc^-, two μ-OMe^- groups and three axial water and methanol molecules.

The Mn_{16} core can be divided into two sub-units, a central $[Mn^{IV}_6O_6(OMe)_4]^{8+}$ unit connected to an outer perimeter of 10 Mn^{III} ions by 10 μ_3-O^{2-} ions in the plane of the molecule and two μ-OAc^- groups perpendicular (above and below) to the plane of the molecule. The central unit contains six Mn^{IV} ions in two rows of three (Mn(1),

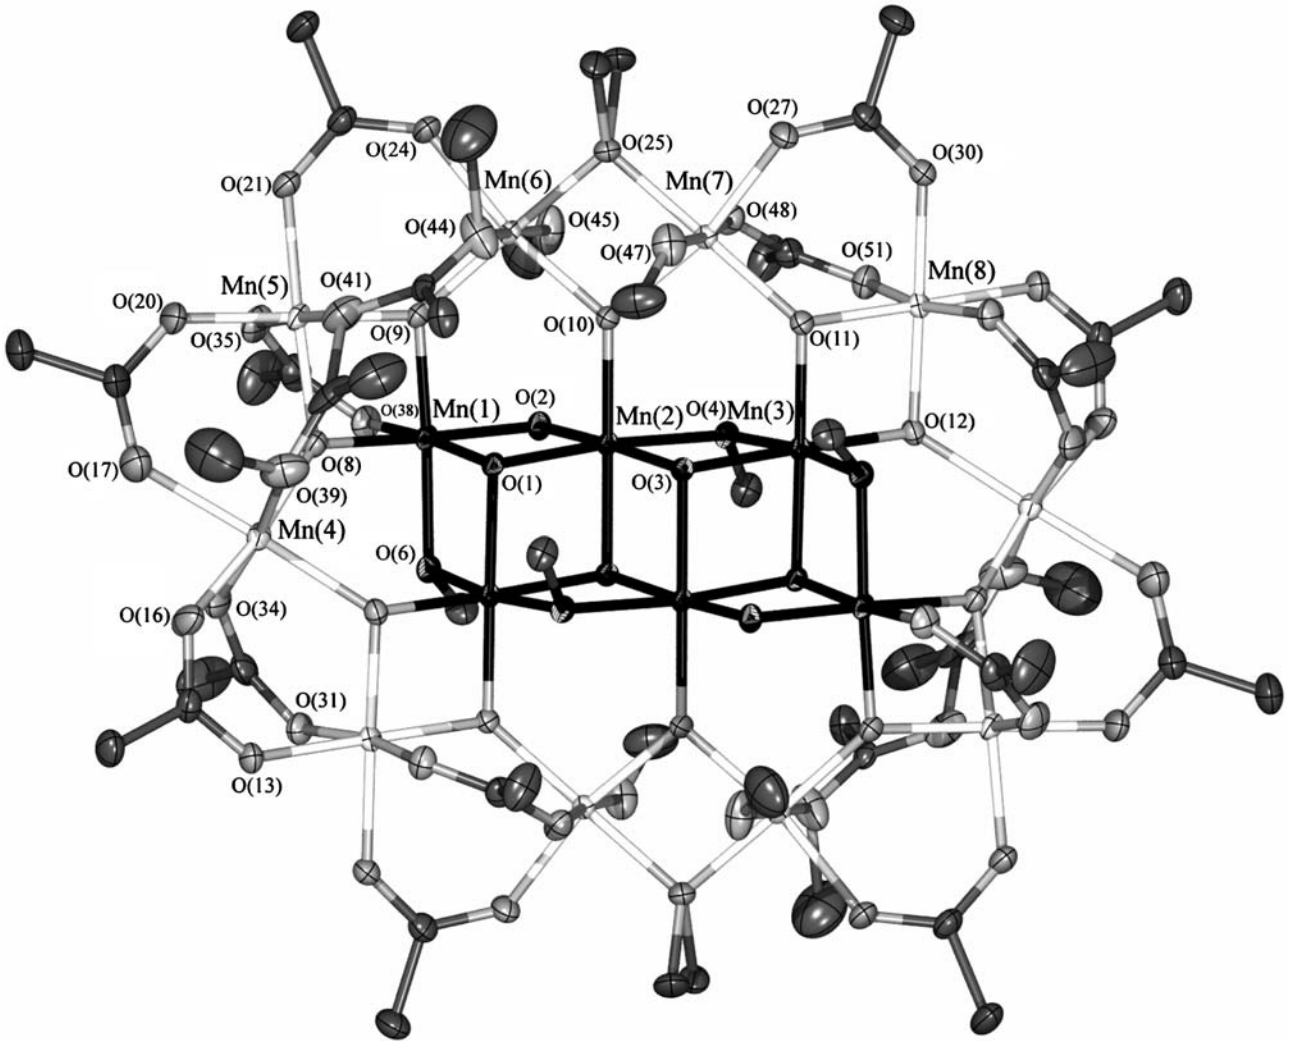

Fig. 1. The crystal structure of $[Mn_{16}O_{16}(OMe)_6(OAc)_{16}(MeOH)_3(H_2O)_3]\cdot 6H_2O$ ($\mathbf{1}\cdot 6H_2O$) with atom labelling scheme of manganese and oxygen atoms only (hydrogen atoms are omitted for clarity and thermal ellipsoids shown at 50% probability). The central $[Mn^{IV}_6O_6(OMe)_4]^{8+}$ sub-unit is emphasised in black with octant slices.

Mn(2), Mn(3) and the symmetry related Mn(1^i), Mn(2^i), Mn(3^i)) lying in a plane that is sandwiched between two planes of oxygen atoms. Each oxygen plane contains two μ_3-O^{2-}, one μ-O^{2-} and two μ-OMe^- ions. One oxygen plane contains O(1) and O(3) (μ_3-O^{2-}), O(2^i) (μ-O^{2-}) and O(4^i) and O(6^i) (μ-OMe^-). The other oxygen plane contains O(1^i) and O(3^i) (μ_3-O^{2-}), O(2) (μ-O^{2-}) and O(4) and O(6) (μ-OMe). The Mn^{IV} ions occupy distorted octahedral sites between these two hexagonal close-packed O layers, in the manner seen in many layered manganese oxide minerals [53–55], metal dihalides, dihydroxides and disulphides [56]. A recent review by Winpenny [33] describes this phenomenon, whereby the cores of many large polynuclear complexes adopt a layered mineral or general CdI_2 type structure. For example, two Fe_{17} and Fe_{19} oxyhydroxide clusters are related to fragments of goethite or lepidocrocite [31,57]. The CdI_2 structure is also present in several examples of manganese clusters, $Mn_6^{III}Na$ [58], Mn_7 ($4Mn^{II}$, $3Mn^{III}$) [17], Mn_{10} [51], and Mn_{19} (albeit all Mn^{II}) [59] clusters and in a recently reported Mn_{21} ($12Mn^{III}$, $9Mn^{IV}$) cluster [22]. Winpenny et al. reported a large Co_{24} cluster, in which the core bears a very obvious relationship to $Co(OH)_2$ [60]. Therefore, just as the Fe_{17} and Fe_{19} complexes have been termed "captured rusts" or "crusts" [31,57], $\mathbf{1}\cdot 6H_2O$ could be thought of as a captured portion of a manganese oxide mineral. The Mn_{12}-acetate cluster, $[Mn_{12}O_{12}(OAc)_{16}(H_2O)_4]\cdot 2HOAc\cdot 4H_2O$ [61], can be described as consisting of two subunits, a central $[Mn_4^{IV}O_4]^{8+}$ cubane unit connected to an outer ring of $[Mn_8^{III}O_8]^{8+}$.

Peripheral ligation around the Mn_{10}^{III} perimeter in the $\mathbf{1}\cdot 6H_2O$ cluster consists of eight equatorial μ-OAc^- groups, six axial μ-OAc^- groups (three either side of the cluster in an alternating up–down–up fashion) and two μ-OMe^- ligands (bridging Mn(6) and Mn(7)). In addition there are three axially coordinated monodentate water and methanol molecules. Eight of the 10 perimeter Mn^{III} ions experience Jahn-Teller (JT) axial elongation in the direction perpendicular to the plane of the cluster (Fig. 2).

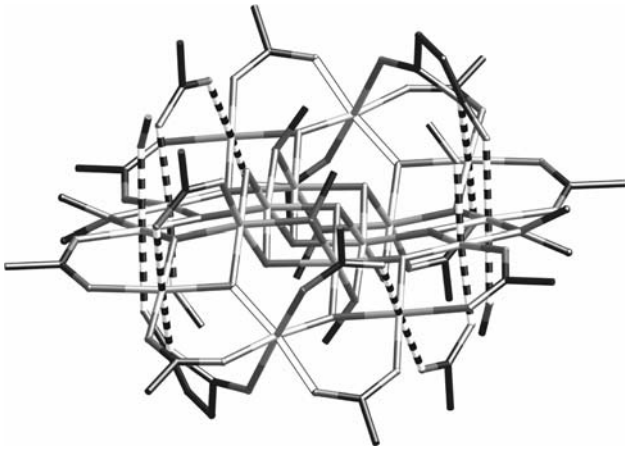

Fig. 2. The crystal structure of $\mathbf{1}\cdot 6H_2O$ showing Jahn-Teller elongation (dashed bonds) and compression (open bonds) distortions, of the perimeter Mn^{III} atoms of $\mathbf{1}\cdot 6H_2O$.

The remaining two (Mn(4) and Mn(4^i)) experience JT axial compression roughly parallel to the plane of the cluster in the direction of a μ-OAc^- and a core μ_3-O^{2-}. Christou and co-workers' three Mn_{16} carboxylate clusters are essentially isostructural with $\mathbf{1}\cdot 6H_2O$ with some notable exceptions [40]. Firstly, here there are three terminal H_2O and MeOH ligands as opposed to their six MeOH ligands. More significantly perhaps, in terms of the magnetic properties, are the disposition of the JT axes of the perimeter 10 Mn^{III} ions. Christou observes all 10 elongation JT axes aligning roughly parallel to each other and perpendicular to the plane of the molecule [40]. The orientation of the JT axes of SMMs has been shown to be important to the overall cluster magnetic anisotropy and consequently the AC χ'' behaviour [62], described later (see Tables 2 and 3 for Mn–O bond distances and Table 6 for SMM parameters).

Several regions of disorder were observed in $\mathbf{1}\cdot 6H_2O$ and in the lattice waters. Full details of this disorder are given in Section 2. There is positional disorder of the peripheral ligands. In particular, three terminal water ligands and one methanol ligand are disordered over four axial coordination sites (O(45), O(47) and symmetry related partners). Also, another terminal methanol and adjacent acetate group are disordered over two positions (Fig. 3). A similar type of disorder has also been seen in mixed carboxylate derivatives of Mn_{12}-acetate, observed by ^1H NMR solution studies by Christou et al. Axial H_2O and RCO_2^- ligands exchange rapidly at room temperature [63].

Several hydrogen bonding interactions were located in the $\mathbf{1}\cdot 6H_2O$ structure (Table 4). They can be divided into two types: intra-cluster and inter-cluster. Intra-cluster hydrogen bonding exists on the Mn_{10}^{III} perimeter (Fig. 3). The axially coordinated terminal disordered water/methanol (O(45)) on Mn(6) hydrogen bonds to the adjacent μ-OAc^- oxygen (O(48)) coordinated to Mn(7). In addition, the coordinated water/methanol (O(47)) on Mn(7) (*trans* to the aforementioned acetate) hydrogen bonds to the adjacent disordered methanol/acetate oxygen (O(44)) on Mn(6). Each Mn_{16} cluster is hydrogen bonded to two adjacent Mn_{16} clusters through two lattice water molecules (O(52)) located between each cluster. The lattice waters hydrogen bond to adjacent clusters via the axial water/methanol, O(47), on Mn(7) and an axial μ-OAc^- oxygen, O(31) on Mn(6). The lattice water molecules also hydrogen bond to their symmetry related neighbour. These hydrogen-bonded chains of clusters propagate parallel to the *c*-axis direction (Fig. 4). The role that hydrogen-bonding might play in the properties of these high-spin polynuclear manganese clusters is now being studied more closely. Recently Cornia and Gatteschi et al. reported the crystal structure of $[Mn_{12}O_{12}(OAc)_{16}(H_2O)_4]\cdot 2HOAc\cdot 4H_2O$ at 83 K [64,65] in an effort to explain the significant magnetic anisotropy displayed by this complex despite it being highly structurally symmetrical (S_4 crystallographic symmetry). They found the two disordered acetic acid molecules of solvation transfer this disorder to the cluster by hydrogen bonding interactions thus lowering the effective

Symmetry transformation: (i) $1-x$, $1-y$, $1-z$.

symmetry of the cluster, hence increasing magnetic anisotropy. They also reported that the water of solvation hydrogen bonds to a water ligand coordinated to one of the peripheral Mn^{III} atoms. The water ligand also hydrogen bonds to an adjacent bridging acetate. This pattern of hydrogen bonding is very similar to that seen in $\mathbf{1}\cdot 6H_2O$. However, no mention is made of inter-cluster hydrogen bonding interactions in the Mn_{12}-OAc structure [64,65].

In the context of cluster–cluster effects, Wernsdorfer and Christou et al. have also reported a supramolecular dimer of Mn_4 SMMs [1,2]. They find that due to antiferromagnetic coupling between the two components, the dimer displays quantum behaviour different from that of the individual tetranuclear components, possibly via six C–H···Cl hydrogen bonds and a Cl···Cl interaction. Importantly, the dimer displays an exchange-bias of the quantum tunnelling transition with no tunnelling (i.e. no hysteresis step) at $H = 0$. Hendrickson et al. [35,36] have also made similar observations on M_4 cubane clusters of Co^{II} and Ni^{II}.

3.2.2. $[Mn(\mu\text{-}OMe)(\mu\text{-}OAc)_2]_n$ (2)

Complex **2** crystallises in the orthorhombic space group *Pbcn*. The asymmetric unit contains one bridging acetate ligand, half a manganese(III) atom and half a bridging methoxide ligand. The structure (Fig. 5) consists of infinite linear 1D chains of manganese(III) atoms bridged by two μ-OAc^- ligands and one μ-OMe^-. Each manganese(III) is coordinated in a distorted octahedral environment. As expected for a high-spin d^4 ion, the metal centres are Jahn-Teller distorted with elongation of the axial bonds to one oxygen atom each of the two μ-OAc^- ligands (Mn(1)–O(6^{ii}) = 2.171(2) Å). The equatorial coordination plane consists of two oxygen atoms from two μ-OMe^- ligands (Mn(1)–O(1) = 1.946(1) Å) and the other two oxygens of the two μ-OAc^- ligands (Mn(1)–O(3) = 1.932(2) Å). The hydrogen atoms of the bridging methoxide group are disordered over two positions due to the methoxide lying on a rotational 2-fold axis. The chains run parallel to the *c*-axis direction. The intra-chain Mn···Mn distance is equal to half the unit cell length *c* (3.4433(1) Å). The inter-chain Mn···Mn distance to adjacent chains in the *b*-axis direction is equal to the unit cell length *b* (7.1796(2) Å). The next shortest inter-chain Mn···Mn distance is equal to half the diagonal of the *ab*-unit cell face (7.9803(2) Å). Fig. 6 shows five chains viewed parallel to the *c*-axis (see Table 5 for selected bond distances and angles).

The structure of **2** is similar to a related complex, $\{[Mn(\mu\text{-}OH)(\mu\text{-}OAc)_2]\cdot HOAc\cdot H_2O\}_n$, reported previously by ourselves [45] and by Christou et al. [46]. This

chain also consists of a triply bridged linear chain of manganese(III) atoms and these chains hydrogen bond to adjacent chains via the μ-OH and lattice acetic acid and water molecules to form pseudo 2D sheets. It displays long-range antiferromagnetic order ($T_N = 6.1$ K) that is probably facilitated by the hydrogen bonding pathways. The lack of magnetic order in the complex described here would seem to support this conclusion, as it is superficially identical but without the hydrogen bonding network.

3.3. Magnetism

3.3.1. $[Mn_{16}O_{16}(OMe)_6(OAc)_{16}(MeOH)_3(H_2O)_3] \cdot 6H_2O$ ($\mathbf{1} \cdot 6H_2O$)

DC magnetic susceptibilities were measured as a function of temperature on freshly isolated samples of $\mathbf{1} \cdot 6H_2O$ in a field of 1 T over the range 2–300 K (Fig. 7). The same results were obtained on neat powders and on Vaseline mulls. The effective magnetic moment, per Mn_{16}, decreases gradually

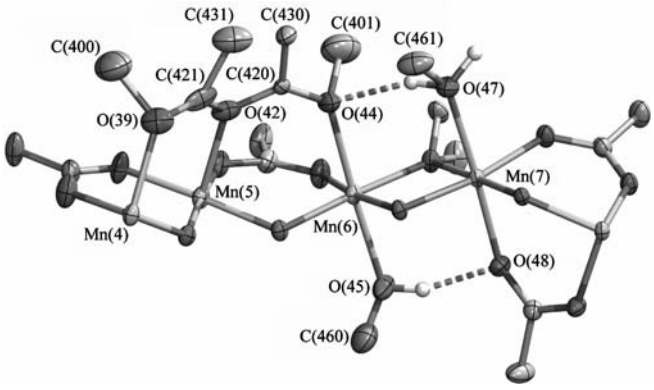

Fig. 3. The crystal structure of a portion of the Mn^{III} perimeter of $\mathbf{1}\cdot 6H_2O$, showing intra-cluster hydrogen bonding (dashed), and disordered methanol/acetate and water/methanol (see text).

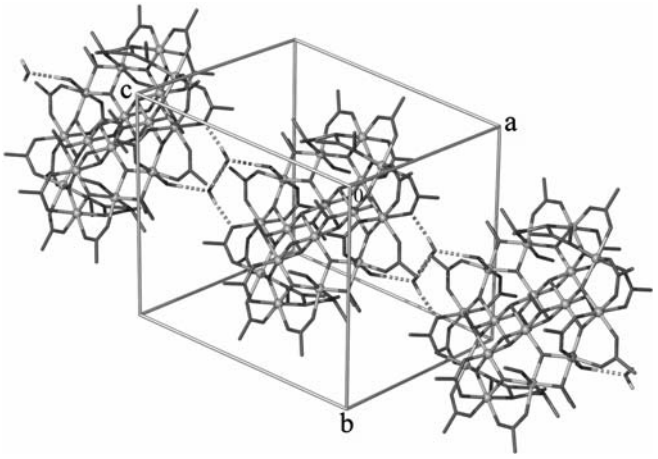

Fig. 4. A single hydrogen-bonded chain of $\mathbf{1}\cdot 6H_2O$ running parallel to the *c*-axis direction (hydrogen bonds shown in dashed bonds).

from 14.0 μ_B ($\chi_M T = 24.53\ cm^3\ mol^{-1}\ K$) at 300 K to ca. 10.5 μ_B at ~30 K, then more rapidly, reaching 5.7 μ_B ($\chi_M T = 4.06\ cm^3\ mol^{-1}\ K$) at 2 K and still decreasing. The value of μ_{eff} at 300 K compares to the value of 18.16 μ_B (41.25 $cm^3\ mol^{-1}\ K$) calculated for six uncoupled Mn^{IV} ($S = 3/2$) and 10 Mn^{III} ($S = 4/2$) and is thus indicative of overall antiferromagnetic coupling. The Mn_{16}-O_2CCH_2R analogues of Christou et al. show very similar $\mu_{eff}(\chi_M T)$ versus temperature behaviour to $\mathbf{1}\cdot 6H_2O$ [40].

To try to identify the ground spin state of $\mathbf{1}\cdot 6H_2O$, magnetisation (M) measurements were made in the ranges of $H = 0$–5 T and temperature = 2–20 K (Fig. 8). It can be seen that, at 2 K, the M values increase in a smooth, curved fashion between 0 and 5 T to reach ca. $7N\beta$ in the 5 T field. The M values are still increasing and saturation is not achieved. This is most likely due to thermal population of the ground-state and of other low lying spin-states occurring even at 2 K. Zero-field splitting and Zeeman effects will also influence the shape and size of the M versus H plots. Weak cluster–cluster interactions, via hydrogen bonding pathways, may also play a part. It is therefore not possible, without fitting of the M/H data, to unambiguously assign the ground state spin and the weaknesses of using DC magnetisations to obtain S in this way have been recognised previously [40]. When the M/H data are plotted as M versus H/temperature, in the way commonly employed by Hendrickson and Christou, Fig. 9 is obtained. The separation of the lines indicates zero-field splitting is occurring.

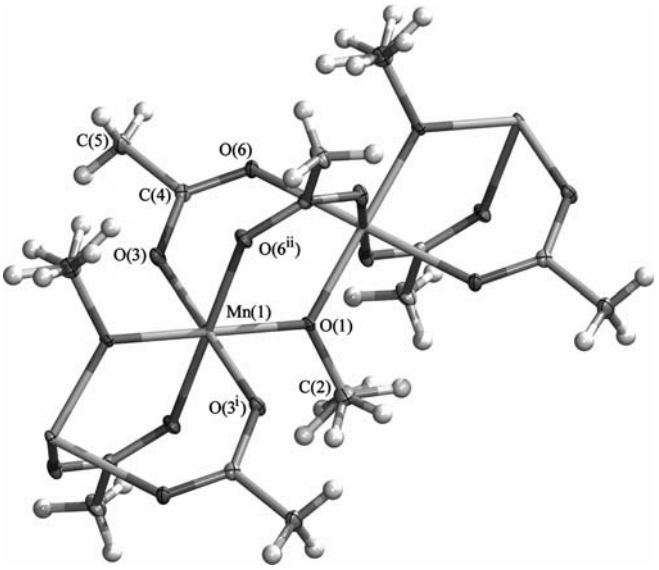

Fig. 5. The crystal structure of $[Mn(\mu\text{-}OMe)(\mu\text{-}OAc)_2]_n$ (**2**) with atom labelling scheme shown (thermal ellipsoids shown at 50% probability). Disorder of methoxide hydrogen atoms is due to site symmetry (see text).

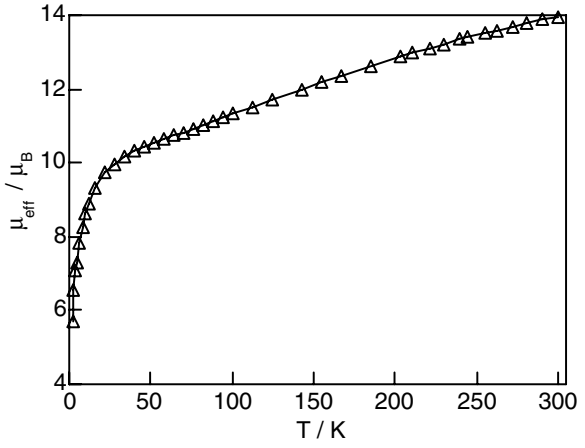

Fig. 7. Plot of μ_{eff} vs. temperature in $H = 1$ T for $\mathbf{1} \cdot 6H_2O$. The solid line just joins the points.

A hysteresis loop measured in low fields (±0.2 T) on a neat powder at 2 K shows a rapid increase in M in the ±250 Oe region with very small coercive field (Fig. 10). To observe the characteristic 'stepped' hysteresis loops of SMMs, due to quantum tunnelling, requires the use of single crystals or collections of oriented crystals and so, despite using a powder, this rapid increase through zero field might be such a step because of its similarity to those observed using a micro-Squid system on the $PhCH_2CO_2^-$ analogue of **1**, measured between 1.0 and 0.04 K at a field sweep rate of 0.07 T/s [40].

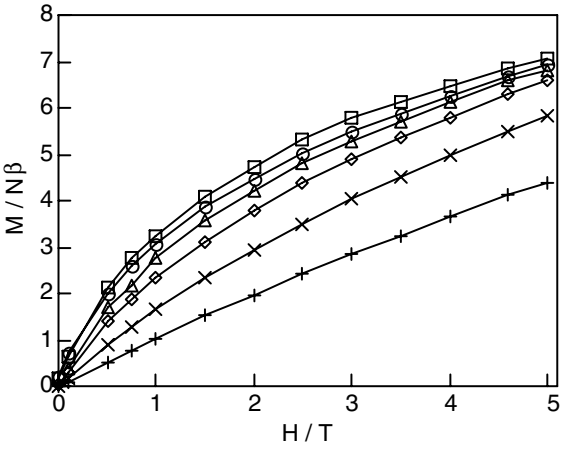

Fig. 8. Plots of magnetisation, M vs. applied field (Tesla) for $\mathbf{1} \cdot 6H_2O$, at various temperatures 2 K (□), 3 K (○), 4 K (△), 5.5 K (◇), 10 K (×), and 20 K (+). The solid lines simply join the isothermal points and are not fitted curves.

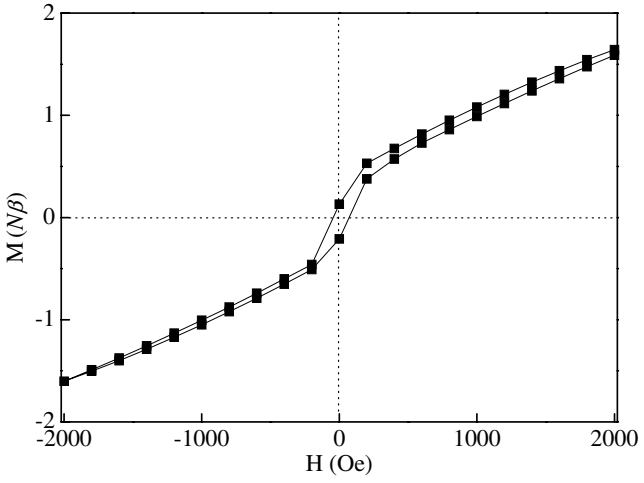

Fig. 10. Hysteresis plot of a powder sample of $\mathbf{1} \cdot 6H_2O$ dispersed in Vaseline, at 2 K.

Detailed AC susceptibility studies were made as a function of frequency (50–1500 Hz) in the temperature range 2–10 K, and these are plotted as $\chi'_M T$ versus T and χ''_M versus T in Fig. 11. The $\chi'_M T$ values between 8 and 10 K (~8.5 $cm^3\ mol^{-1}\ K$) are independent of frequency and are of similar magnitude to the DC values of $\chi_M T$ in this temperature range. If all the Mn_{16} molecules were populating an isolated $S = 3$ ground state, and assuming $g = 2.0$, the $\chi'_M T$ value would be 6.01 $cm^3\ mol^{-1}\ K$, while population of only an $S = 4$ ground state would yield $\chi'_M T$ = 10.01 $cm^3\ mol^{-1}\ K$. The observed $\chi'_M T$ value is of an intermediate value, as is the DC magnetisation value, M, at a temperature of 2 K and a field of 5 T ($M \sim 7N\beta$). Thus, as indicated earlier, the data suggest that there is not an isolated ground S level, but that levels are close together and zero-field splitting and Zeeman level thermal depopulation effects play a part. Below 8 K the $\chi'_M T$ values for $\mathbf{1} \cdot 6H_2O$ decrease rapidly, indicative of the onset of slow magnetic relaxation. At higher frequencies, the decrease in $\chi'_M T$ occurs at higher temperatures. The Mn_{12}-carboxylates behave similarly [7,62]. There is a hint of another such decrease in $\chi'_M T$ occurring below ~3 K. In Fig. 11(b), the out-of-phase χ''_M values show maxima in the region 5–7 K, which vary in position, width and magnitude as the frequency is varied, typical of SMM behaviour and similar to that in Mn_{12}-acetate type clusters. In contrast to the Mn_{12} species, the values of the maxima in χ''_M, of 0.25–0.20 $cm^3\ mol^{-1}$, are much smaller than in the Mn_{12} clusters but of similar size to those observed for a Mn_{30} cluster [13]. It is possible that a second series of maxima occur below 2 K, but further measurements on an ultra low temperature instrument would be required to confirm this and to obtain the relative intensity compared to the 5–7 K maxima. Two such series of maxima, at 4–7 and 2–3 K, have been observed in some of the Mn_{12}-carboxylate clusters [47,66] and these originated from the presence of two Jahn-Teller isomers in the samples. In that study each isomer could be isolated separately and assigned to the relevant series of maxima in χ''_M. More recently, Mn_{12} clusters have been isolated the structures of which have axial (tetragonal) symmetry and contain a majority, individual Jahn-Teller isomer [67]. It is possible that such isomers can exist in $\mathbf{1} \cdot 6H_2O$, as can be seen in the structural discussion (see above). Perusal of the $\chi'_M T$ and χ''_M data for the $PhCH_2CO_2^-$ analogue [40] (shown at 5, 10 and 50 Hz, measured to 1488 Hz) reveal no frequency dependent drop in $\chi'_M T$ between 5 and 7 K, but show a similar start of a decrease below 2 K to that shown in Fig. 11. Likewise, there are no maxima in χ''_M in the 5–7 K range, but just the beginnings of such below 2 K. This is intriguing and, in view of the different Jahn-Teller axes patterns noted between the acetate ($\mathbf{1} \cdot 6H_2O$) and phenylacetate Mn_{16} derivatives, lends support to the observation of two sets of maxima in χ''_M and to SMM behaviour in the acetate cluster.

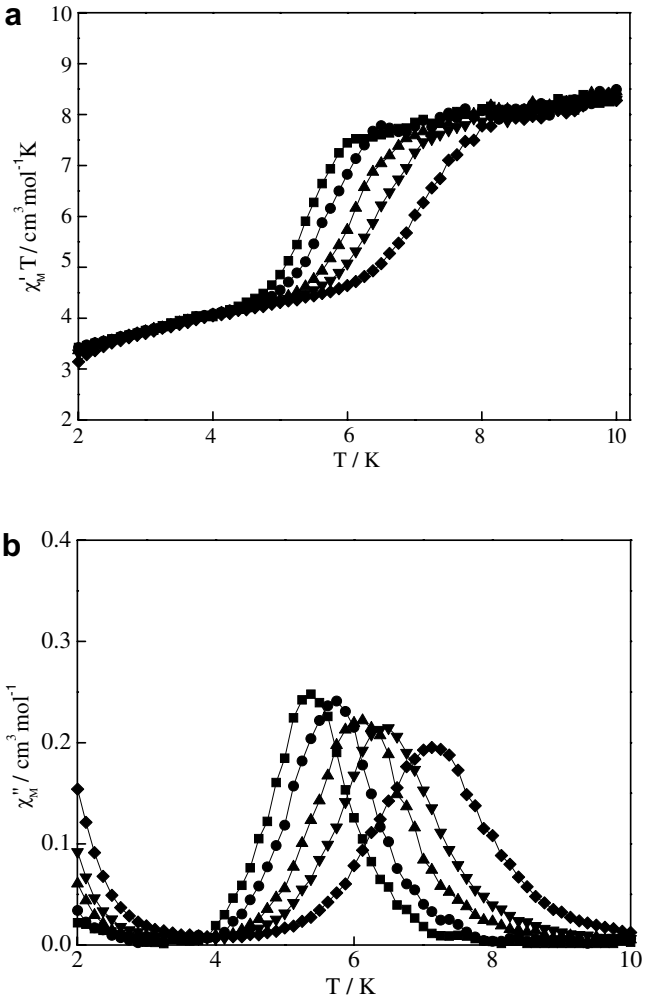

Fig. 11. (a) In-phase AC susceptibilities, $\chi'_M T$ vs. temperature and (b) out-of-phase AC susceptibilities, χ''_M vs. temperature for $\mathbf{1} \cdot 6H_2O$ measured at frequencies 50 (■), 100 (●), 250 (▲), 500 (▼), 1500 (◆) Hz in a DC field of 10 Oe.

The magnetisation relaxation data for $\mathbf{1} \cdot 6H_2O$ were analysed using the Arrhenius law for the relaxation time, τ (Eq. (1)):

$$\tau = \tau_0 e^{-\Delta E/kT}. \quad (1)$$

The values of T are the temperatures of the maxima in Fig. 11(b). The relaxation times, τ, are obtained from the frequencies (ν in Hz) of each χ''_M measurement using the relation $\tau = 1/(2\pi\nu)$, since at each maximum the relaxation frequency of an SMM is equal to the operating AC frequency, ν (τ_0 = pre-exponential factor, k = Boltzmann constant). From the least-squares fit to a plot of $\ln(1/\tau)$ versus $1/T$, the energy barrier, ΔE, was found to be 52.2 cm^{-1} (c.f. Mn_{12}-acetate 43 cm^{-1} = 62 K) [52,62] with a pre-exponential factor of 3.00×10^{-9} s. Table 6 compares these values with those of other SMMs of Mn.

In the absence of fitting of the M/H data to an appropriate Spin Hamiltonian it is possible to estimate the size of $|D|$, the axial zero-field splitting parameter for the coupled ground state, by use of the relationship $|D|S_z^2 = \Delta E$, where ΔE is the barrier height [68,69]. Since the precise value of S is not known, it was assumed to be 4. Thus a $|D|$ value of

Table 6

$52/16 = 3.2\ cm^{-1}$ is predicted, which is much larger than those determined for Mn_{12}-acetate systems having a ground $S = 10$ and $D \approx -0.5\ cm^{-1}$. It is much more akin to values obtained for Mn^{III} monomeric complexes [70]. Christou et al. [40] were not able to deduce $|D|$ in the $PhCH_2CO_2^-$ and other haloacetate cases that were thought to have $S = 2$ ground states, but concluded that $|D|$ was larger than in Mn_{12}-OAc.

Use of the above ΔE relationship assumes that only the ground S state, and its M_S components 0, ±1, ±2,..., ±S, are thermally populated. In the present $\mathbf{1}\cdot 6H_2O$ cluster there are other low-lying S states as indicated by the nature of the M versus H isotherms in Fig. 8. In attempts to try to simulate the M/H data and thus obtain the ground state levels and the D values in a more direct manner, it is clear, despite the limitations mentioned earlier, that calculations of M, at 2 K and 5 T, for an $S = 4$ level yield, as expected, $8N\beta$ for $D = 0$; $6.3N\beta$ for $D = -1\ cm^{-1}$ and $4N\beta$ for $D = -3.5\ cm^{-1}$. Thus, the D value obtained from the AC relaxation data, assuming it is negative ($-3.2\ cm^{-1}$), is not compatible with the Brillouin calculation of M which limits D to being less than $\sim -1\ cm^{-1}$. The $S = 3$ (or $S = 2$) calculations gave an even bigger discrepancy, and hence there appears to be a dilemma.

Güdel et al. [34] have recently discussed somewhat related anomalies in a Ni_{21}-citrate SMM cluster in which an $S = 3$ state was lowest, but with many other excited states (up to $S = 9$) close in energy and thermally populated in high-fields (up to 8 T) at temperatures below 1 K. The ΔE value obtained from the χ''_M versus frequency Arrhenius plot was ~3 K in this Ni_{21}-cluster and D was estimated to be $-0.22\ cm^{-1}$ (along the crystallographic *c*-axis). Rhombic ligand-field terms, E, were thought to be partly responsible for differences in the D value compared to that of Mn_{12}-acetate, and transverse anisotropy terms were also thought to be important, thus rendering the relationship $\Delta E = |D|S^2$ invalid because of admixture of M_S levels. It is also interesting to note that excited S states are now thought to be important in the Mn_{12}-acetate system, e.g. $S = 9$ close to $S = 10$ and $S > 10$ under very high fields [62].

A possible, though unlikely explanation for the AC data and the consequent estimated $|D|$, is that traces of Mn_{12}-acetate are present in the samples and responsible for the frequency dependent AC behaviour. Certainly, there is no evidence for Mn_{12} in the μ_{eff}/T plot of Fig. 7, since it would show a ferromagnetic-like increase in μ_{eff} as the temperature is decreased towards 2 K. A powder XRD measured on one sample showed, by comparison to calculated line positions that $\mathbf{1}\cdot 6H_2O$ was the major species present, with traces of the chain **2** and only a hint of Mn_{12}-acetate. Finally, these Mn_{16} clusters would benefit from detailed probing by single crystal micro-Squid measurements [1,2,5,8,14] as well as by high frequency/high field EPR studies, at variable temperatures, to attempt to better delineate the ground and nearby energy levels and elucidate any trace impurities that contribute.

3.3.2. *[Mn(μ-OMe)(μ-OAc)$_2$]$_n$ (**2**)*

The variation of susceptibility and effective magnetic moment, per Mn^{III}, with temperature is given in Fig. 12. A broad maximum in χ_M occurs at ~70 K typical of the behaviour of a Heisenberg antiferromagnetically coupled $S = 2$ chain [71]. The rapid increase in χ_M at low temperature could be due to monomer impurity or to ferromagnetic chain–chain interactions. The corresponding μ_{eff} values decrease gradually from 4.16 μ_B at 300 K (less than the uncoupled 4.87 μ_B value) to 0.98 μ_B at 2 K. The inflection below 10 K is due to monomer impurity or chain–chain effects.

The data were fitted to an $S = 2$ Fisher chain ($-2JS_i\cdot S_j$) model [72], modified by a $(T-\theta)$ term to give an approximate way of expressing inter-chain interactions. The fit is good and is shown in Fig. 12. The parameters are

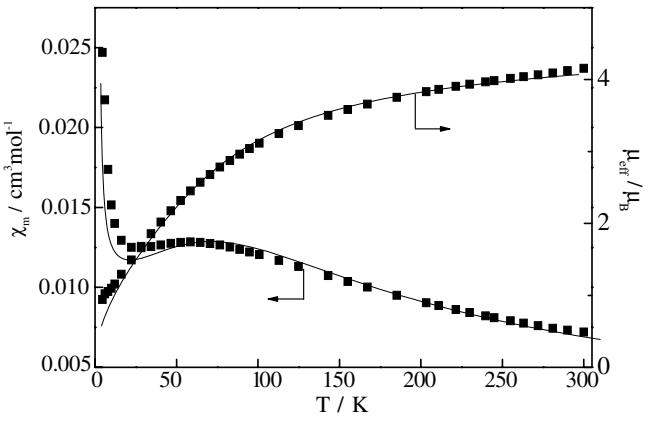

Fig. 12. Plots of μ_{eff} (■) and χ_M (●), per Mn, vs. temperature for **2**. The solid lines are the calculated best-fits using the Heisenberg, $-2JS_i\cdot S_j$, linear chain model (see text).

$g = 1.91$, $J = -7.0\ cm^{-1}$ and $\theta = +1.95$ K. The J value is of similar magnitude to those of some $[Mn^{III}(Schiff\text{-}base)X]_n$ chains ($X = OAc^-$, N_3^-) [68,69], but much bigger than those obtained in the dca^- bridged $[Mn^{III}(Schiff\text{-}base)(dca)]_n$ systems [73].

Complex **2** resembles $\{[Mn(\mu\text{-}OH)(\mu\text{-}OAc)_2] \cdot HOAc \cdot H_2O\}_n$ [45,46], which displays hydrogen bonding between ligands on adjacent chains to form a 2D sheet structure. Probably as a result of these hydrogen-bonding pathways the complex displays long-range antiferromagnetic order, whereas **2** displays antiferromagnetic coupling with no subsequent magnetic order. The benzoate analogue of **2**, $[Mn(\mu\text{-}OMe)(\mu\text{-}O_2CPh)_2]_n$, has recently been isolated from methanol solution using a reductive aggregation method and shown to adopt the same 1-D chain structure with π-stacking occurring between benzoate rings of neighbouring chains [74]. The magnetic data were very similar to those of **2** and were likewise indicative of medium strength antiferromagnetic coupling, with no evidence for long-range magnetic order.

Received 22 March 2006; accepted 2 June 2006
Available online 10 June 2006

Abstract

A potential anticancer heterodinuclear ruthenium(II)–platinum(II) complex, [ruthenium(II)(4,4′-dimethyl-2,2′-bipyridine)$_2$(5-(L-cysteine-methyl ester)-1,10-phenanthroline)-*trans*-chlorodiammineplatinum(II)] chloride, [Ru(Me$_2$bipy)$_2$(5-(L-cysteine-Me)-phen)-*trans*-Pt(NH$_3$)$_2$Cl]Cl$_3$, was synthesised. L-Cysteine methyl ester was used to link the two metal centres, as more conventional straight chain diaminoalkanes and 2-mercaptoethylamine failed to couple to the phenanthroline ligand. From the precursor mononuclear ruthenium(II) complexes, which were separated into their Δ- and Λ-isomers by column chromatography, the dinuclear complex was synthesised and characterised by ^{1}H and ^{13}C NMR, UV–Vis, circular dichroism, fluorescence and electrospray ionisation mass spectrometry.

Keywords: Ruthenium(II); Platinum(II); Heterodinuclear; L-Cysteine methyl ester; Phenanthroline; Anticancer

1. Introduction

Cisplatin, carboplatin and oxaliplatin are the only platinum-based drugs widely approved for the treatment of human cancers [1]. Over the last decade, multi-nuclear platinum drugs, like BBR3464 (a novel trinuclear complex having two mono-functional *trans*-[PtCl(NH$_3$)$_2$] units coupled by a central *trans*-[Pt(NH$_3$)$_2$(H$_2$N(CH$_2$)$_6$NH$_2$)$_2$] linker), have demonstrated clinical potential, but are limited by toxic side-effects and in vivo degradation before reaching their cellular target, DNA [1,2]. Both mono- and multi-nuclear drugs derive their anticancer activity by forming coordinate covalent adducts with DNA, thereby preventing replication and transcription [3]. By changing the structure of the DNA adducts, or increasing the DNA binding affinity, new complexes may be developed that are able to overcome drug resistance.

Over the last 20 years many researchers have examined the synergistic properties of combining a DNA intercalating compound with a moiety capable of covalent binding to DNA. These new complexes include: organic intercalators linked to cisplatin-like molecules [4–21], octahedral metal intercalators coupled to cisplatin-like molecules [22–27], and organic intercalators linked to DNA-alkylating agents like mustards [28–32]. Recently, carborane cages have been attached to intercalators for use in radiation therapy [33–36]. These synergistic compounds have been developed to increase the DNA binding affinity and drug transport properties of conventional chemotherapeutic drugs and/or to modify their DNA adducts and sequence selectivity. There has been little research, however, into heteronuclear metal complexes which link platinum groups capable of forming DNA coordinate covalent adducts to other groups capable of DNA groove binding.

In this paper we report the synthesis of a heterodinuclear ruthenium(II)–platinum(II) metal complex, [Ru(Me$_2$bipy)$_2$(5-(L-cysteine-Me)-phen)-*trans*-Pt(NH$_3$)$_2$Cl]Cl$_3$,

Λ-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$			285 (+2505)	456 (1.45×10^4) 334 (1.17×10^4) 257 (2.88×10^4) 282 (6.09×10^4) 206 (6.03×10^4)	

containing a platinum moiety attached to a DNA groove binding ruthenium moiety via a modified amino acid linker. This metal complex was designed as a potential anticancer agent that may display increased DNA binding affinity compared to native mononuclear platinum complexes (Table 1).

2. Experimental

2.1. Materials and methods

2.1.1. Materials

Deuterated acetonitrile (d_3-CD_3CN) and dimethylsulphoxide (d_6-DMSO) were obtained from Cambridge Isotope Laboratories. (−)-*O*,*O*′-dibenzoyl-L-tartaric acid and Sephadex® LH20 were obtained from Fluka. Silica gel 60 was obtained from Merck. 2-Mercaptoethylamine hydrochloride, 1,6-diaminohexane, 1,3-diaminopropane, L-cysteine methyl ester (*tert*-butoxy)carbonate (L-cysteine-MeBOC), DOWEX® 550A OH^- anion exchange resin (DOWEX®), Amberlite® IRA-400(Cl^-) ion exchange resin (Amberlite®), potassium hexafluorophosphate, SP Sephadex® C25, 4,4′-dimethyl-2,2′-bipyridine (Me_2bipy), 5-chloro-1,10-phenanthroline (5-Cl-phen) and deuterated methanol (d_4-CD_3OD) were all purchased from Aldrich. Ruthenium(II) trichloride hydrate {$RuCl_3\cdot xH_2O$ (Ru 40–43%)} and *trans*-diamminedichloroplatinum(II) (transplatin) were purchased from Precious Metals Online. $[Ru(Me_2bipy)_2Cl_2]$ was prepared as previously described [37,38]. All other reagents and solvents were of analytical grade and were used as received, except trifluoroacetic acid (TFA) which was redistilled before use. Aqueous solutions were prepared with Milli-Q water (Millipore, MA).

2.1.2. Nuclear magnetic resonance spectroscopy

^1H NMR spectra were obtained with a 300 MHz Varian Mercury VX spectrometer, a 400 MHz Varian Mercury VX spectrometer, or a Varian 300 MHz Unity*Plus* spectrometer. All spectra were recorded at 25 °C, unless otherwise stated and were internally referenced to the solvent resonances. All final and precursor metal complexes were characterised using NOESY, g-DQCOSY, HMBC and HMQC experiments. Spectra were obtained over a spectral width of 4200 Hz with a mixing time of either 300 or 800 ms using 2048 points in the t_2 dimension with 256 increments and a total recycle time of 1.5 s.

2.1.3. UV–Vis spectrophotometry

Absorption spectra were measured with a Varian Cary 300 Bio UV–Vis double-beam spectrophotometer. Spectra were obtained over the range of 200–800 nm with samples in 1 cm quartz cells, which were referenced to water. A scan rate of 600 nm/min, data interval of 1 nm and average time of 0.1 s were utilised. Extinction coefficients were determined by repeated measurement of the absorbance of known concentrations of the metal complexes (as PF_6^- salts) in a 3% acetone/water solution. All absorbances were within the range 0.3–0.8, and the average of repeated measurements at λ_{max} gave the extinction coefficient, ε_{max}.

2.1.4. Circular dichroism spectropolarimetry

CD spectra were acquired with a JASCO J-810 spectropolarimeter equipped with J-800 for Windows®. Samples were prepared in either 3% acetone/water or in water and were placed in 0.1 cm cylindrical quartz cells. Data collection was performed at room temperature, between 200 and 650 nm, and at a speed of 500 nm/min. A sensitivity setting of 100 mdeg, data pitch of 0.5 nm, response time of 1 s and bandwidth of 1 s were used. Spectra are given as an average of 10 scans. From the angle of ellipticity (θ, mdeg), the molar absorptivity ($\Delta\varepsilon$, mdeg/M cm) was calculated using Eq. (1), where c is the concentration (mol/L) and l is the path length

$$\Delta\varepsilon = \frac{\theta}{32\,982 \times c \times l} \tag{1}$$

2.1.5. Fluorescence spectroscopy

Fluorescence spectra were acquired with a Varian Cary Eclipse spectrofluorimeter with Windows® based software, at an excitation wavelength of 450 nm. The emission was monitored over the range 500–800 nm. Slit widths of 5 nm were used for both the excitation and emission slits, with a medium scan speed and voltage over an average of five scans. Quartz cuvettes (1 cm pathlength) were used and the metal complex samples were dissolved in acetonitrile (~0.167 mg/mL) at room temperature.

Fluorescence quantum yields were calculated using ratios of the integrated fluorescence intensities to that of $[Ru(Me_2bipy)_3]^{2+}$ in acetonitrile ($\Phi_r = 0.062$) [39], using Eq. (2) [40]:

$$\Phi_{unk} = \Phi_{std}\left(\frac{I_{unk}}{A_{unk}}\right)\left(\frac{A_{std}}{I_{std}}\right)\left(\frac{\eta_{unk}}{\eta_{std}}\right)^2 \tag{2}$$

where Φ_{unk} is the radiative quantum yield of the sample, Φ_{std} is the radiative quantum yield of the standard, and I_{unk} and I_{std} are the integrated emission intensities of the sample and standard, respectively. A_{unk} and A_{std} are the absorbances of the sample and standard, respectively, at a common excitation wavelength (nm), and η_{unk} and η_{std} are the indexes of refraction of the sample and standard solutions, respectively. Values of η corresponding to the pure solvent were used, and as all measurements were performed in the same solvent, therefore $\eta_{unk}/\eta_{std} = 1$.

2.1.6. Electrospray ionisation mass spectrometry

Mass spectra were acquired with a Micromass (Wyntheshaw, UK) Qtof 2 spectrometer with a Z-spray probe. All samples were diluted with 5 mM ammonium acetate (pH 6.8) in acetonitrile, to a final concentration of approximately 1 μM. These were injected directly into the spectrometer using a Harvard model 22 syringe pump (Natick, MA, USA) at a flow rate of 20 mL min^{-1}. Positive ion ESI mass spectra were acquired using a probe tip potential of 2500 V, a cone voltage of either 40 or 50 V, and the source block and desolvation temperatures were set to 60 and 150 °C, respectively. The transport and aperture were set to 2.0 and 13.0, respectively. In most experiments spectra were acquired over the range 200–2000 m/z. Typically, 50–70 scans were summed to obtain representative spectra. The data points were calibrated against a standard CsI solution (750 mM) over the same m/z range.

2.1.7. Elemental analysis

Elemental analysis (C, H, and N) were conducted using a Carlo Erba 1106 automatic analyser by the Microanalytical Unit, Research School of Chemistry, of the Australian National University.

2.2. Metal complex synthesis

2.2.1. $[Ru(Me_2bipy)_2(5\text{-}Cl\text{-}phen)](PF_6)_2 \cdot H_2O$

$[Ru(Me_2bipy)_2Cl_2]$ (0.30 g, 0.56 mmol) and 5-Cl-phen (0.13 g, 0.58 mmol) were dissolved in methanol (100 mL) and refluxed for 45 min. Once cooled, the solvent was removed under reduced pressure yielding the product as a red solid. Purification was achieved by applying the product, dissolved in a minimal amount of water, to an SP Sephadex® C-25 column (5 × 10 cm). The metal complex was eluted with a sodium chloride gradient (0.1–0.3 M) using 0.1 M increments. KPF_6 was then added to the fractions to induce precipitation. The resulting precipitate was extracted into dichloromethane (3 × 30 mL), the extracts dried over anhydrous sodium sulphate and the organic solvent removed under reduced pressure. Yield: 0.42 g (77%). *Anal.* Calc. for $C_{37}H_{34}F_{12}N_6P_2RuCl \cdot H_2O$: C, 44.12; H, 3.61; N, 8.35. Found: C, 44.12; H, 3.43; N, 8.29%. λ_{max}/nm (ε/mol^{-1} dm^3 cm^{-1}) (H_2O/$(CH_3)_2CO$): 451 (8.91×10^3); 261 (4.58×10^4). MS (ESMS, CH_3CN, MW $[Ru(Me_2bipy)_2(5\text{-}Cl\text{-}phen)](PF_6)_2 = 974.12$) m/z: 341.7 $[M-(1H+2PF_6)]^{2+}$. 2.2.2. Resolution of isomers

Rac-$[Ru(Me_2bipy)_2(5\text{-}Cl\text{-}phen)](PF_6)_2 \cdot H_2O$ (0.25 g, 0.26 mmol) was converted to the chloride salt by dissolving in acetone, diluting with water, then stirring with Amberlite® anion exchange beads (Cl^- form) for 1 h. The solution was filtered to remove the beads, and the

resin washed with water to elute any residual metal complex. The solvent was then removed by rotary evaporation before the red coloured residue was dissolved in water.

Rac-[Ru(Me_2bipy)$_2$(5-Cl-phen)]Cl_2 was loaded onto an SP Sephadex® column (2.6 × 100 cm). The isomers were eluted with 75 mM disodium-*O*,*O*′-dibenzoyl-L-tartrate (pH 8), which was prepared by neutralising *O*,*O*′-dibenzoyl tartaric acid with sodium hydroxide. The solution was also filtered prior to use through 0.45 μm nylon membranes. Extraction of each fraction into dichloromethane (3 × 30 mL) after the addition of KPF_6 gave each isomer. Optical purity was then established by circular dichroism. Δ-[Ru(Me_2bipy)$_2$(5-Cl-phen)](PF_6)$_2$: *Anal*. Calc. for $C_{37}H_{34}F_{12}N_6P_2RuCl$: C, 44.93; H, 3.46; N, 8.50. 2.2.3. *Rac*-[*Ru*(*Me*$_2$*bipy*)$_2$(5-(L-*cysteine-MeBOC*)-*phen*)](PF_6)$_2$

[Ru(Me_2bipy)$_2$(5-Cl-phen)](PF_6)$_2$ (0.03 g, 0.03 mmol) and L-cysteine methyl ester butoxy carbamate (L-cysteine-MeBOC) (22 μL, 0.30 mmol) were dissolved in DMF (3 mL) and de-aerated for 5 min under N_2, after which time a degassed solution of Na_2CO_3 (0.030 g, 0.30 mmol) in water (3 mL) was added via syringe. The solution was then heated to 55 °C for 1.5 h. The reaction mixture was allowed to cool to room temperature and the solvent removed under reduced pressure. The product was purified by silica gel chromatography [41] with an eluent of 1–3% KNO_3 in 10% water/acetonitrile. The eluted product was rotary evaporated to dryness, dissolved in a minimum amount of water then KPF_6 added. The resultant precipitate was extracted into dichloromethane and dried over sodium sulphate. The solvent was removed and the residue dried under reduced pressure. Yield: 19 mg (54%). 2.2.4. *Deprotection of rac-[Ru(Me*$_2$*bipy)*$_2$*(5-(L-cysteine-MeBOC)-phen)](PF*$_6$*)*$_2$

Rac-[Ru(Me_2bipy)$_2$(5-(L-cysteine-MeBOC)-phen)](PF_6)$_2$ (50 mg, 0.040 mmol) was dissolved in dichloromethane (2 mL) and added to a solution of trifluoroacetic acid/dichloromethane (1:1, 2.2 mL) containing water (40 μL) which was stirred for 1.5 h. The reaction was monitored by TLC {3% KNO_3 in 10 % H_2O/CH_3CN, ninhydrin stain (0.2% w/v in ethanol)}. Upon completion, the solvent was removed under reduced pressure and the residue stirred with DOWEX® 550A OH^- anion exchange resin

(148 mg, loading capacity 3.44 mmol/g, washed with methanol). The solution was filtered to remove the resin, and the solvent removed to yield a red solid that was dried under vacuum. Yield: 46 mg (100%). ^{1}H NMR (300 MHz, CD_3CN) δ: 8.81 (H4; 1H, dd, $J_1 = 1.32$ Hz, $J_2 = 8.42$ Hz), 8.50 (H7; 1H, dd, $J_1 = 1.11$ Hz, $J_2 = 8.31$ Hz), 8.39 (H6; 1H, s), 8.36 (A/B3; 2H, s), 8.32 (A/B3; 2H, s), 8.14 (H2; 1H, dd, $J_1 = 1.06$ Hz, $J_2 = 5.22$ Hz), 8.08 (H9; 1H, dd, $J_1 = 1.22$ Hz, $J_2 = 5.22$ Hz), 7.80 (H3; 1H, dd, $J_1 = 5.20$ Hz, $J_2 = 8.55$ Hz), 7.71 (H8; 1H, dd, $J_1 = 5.20$ Hz, $J_2 = 8.36$ Hz), 7.62 (A/B6; 2H, m), 7.31 (A/B6; 2H, m), 7.27 (A/B5; 2H, m), 7.03 (A/B5; 2H, m), 5.42 (OCH_3; 3H, s), 4.48 (Δ-N–CH; 1H, bs), 4.38 (Λ-N–CH; 1H, bs), 3.22 (Δ-CH_2; 2H, m), 2.96 (Λ-CH_2; 2H, m), 2.55 (A/BMe; 6H, s), 2.46 (A/BMe; 6H, s), 1.26 (NH_2; 2H, s).

2.2.5. *Rac-[Ru(Me$_2$bipy)$_2$(5-(L-cysteine-Me)-phen)-trans-Pt(NH$_3$)$_2$Cl]Cl$_3$*

Trans-[$PtCl_2(NH_3)_2$] (0.013 g, 0.040 mmol) was suspended in water (5 mL), acidified with 1 M HCl to pH 5, then heated to ~95 °C to dissolve the metal complex. Over a period of 1.5 h, [$Ru(Me_2bipy)_2$(5-(L-cysteine-Me)-phen)]-Cl_2 (0.037 g, 0.040 mmol) in water (10 mL) was added drop wise to the solution, in the dark, after which time the temperature (95 °C) was maintained for 5 h. The solution was then cooled to 0 °C and filtered to remove any precipitate. The solution volume was reduced under vacuum and the remaining water removed by lypholysation. The red/orange precipitate was dissolved in a minimum of methanol and applied to a Sephadex® LH20 column (3 × 15 cm, 70 g packing material). Fractions (3 mL) were collected and monitored by TLC (3% saturated potassium nitrate, 10% water/acetonitrile, ninhydrin stain). *Rac*-[$Ru(Me_2bipy)_2$(5-(L-cysteine-Me)-phen)-*trans*-$Pt(NH_3)_2Cl]^{3+}$ eluted first, and fractions containing the product were combined before the solvent was removed under reduced pressure. Yield: 37 mg (78%). 3. Results and discussion

3.1. Metal complex synthesis

The heterodinuclear metal complex was synthesised using a six step method as shown in Scheme 1 (where the proton numbering scheme is shown after step 2 and the carbon numbering scheme is shown after step 3). All reactions were initially performed with unresolved mononuclear complexes then repeated with the Δ- and Λ-isomers once the reaction conditions had been optimised.

[$Ru(Me_2bipy)_2Cl_2$] was synthesised using alternative methods [37,38]. The phenanthroline ligand was then coordinated to the [$Ru(Me_2bipy)_2Cl_2$] complex by refluxing in methanol for approximately half an hour. Completion of the reaction was signified by a change in colour of the solution from deep purple to red. Upon removal of the solvent a red/brown solid resulted.

Two methods of purifying *rac*-[$Ru(Me_2bipy)_2$(5-Cl-phen)][PF_6)$_2$ were trialed. Dissolution of the ruthenium complex as a hexafluorophosphate salt in acetonitrile and elution through an aluminum oxide column produced an impure product; however, further purification on a cation exchange column enabled isolation of the desired purified metal complex. Purification using an

Scheme 1.

SP Sephadex® C-25 column alone (sodium chloride eluent) was also trialed. Before loading onto the Sephadex column, the ruthenium complex was converted to the chloride salt by stirring with Amberlite® anion exchange beads. The first band to be eluted with water from the column was a golden brown colour, followed by a yellow band that eluted with 0.1 M NaCl. The remaining deep red band eluted with 0.3 M NaCl and was the desired product. A residual brown band, thought to comprise $[Ru(Me_2bipy)_2Cl_2]$, remained bound to the column head. A column 10–15 cm in length and 5 cm in width was found to be sufficient to attain separation between the bands. The metal complex was isolated by the addition of potassium hexafluorophosphate and extracted into dichloromethane.

The isomers of $[Ru(Me_2bipy)_2(5\text{-Cl-phen})]^{2+}$ were resolved using solvent-recycled solution cation exchange chromatography [42]. Using SP Sephadex® C25 and 75 mM disodium-*O*,*O*′-dibenzoyl-L-tartrate as the eluent, two discreet bands were observed after an effective column length of 0.9 m, indicating baseline-to-baseline separation. After collection, the metal complexes were precipitated by the addition of potassium hexafluorophosphate and extracted into dichloromethane, to remove the tartrate salt.

Two diaminoalkanes of varying carbon chain lengths were protected using BOC [43], with the intention of observing the effect of linker length on the DNA binding affinity of the heterodinuclear complex. Diaminoalkanes were selected for their flexibility, which would allow the different metal centres to bind at preferential DNA structures,

and because of their relevance in multi-nuclear platinum agents [44–46]. Attempts were made to couple the single amine BOC-protected linkers 1,6-diaminohexane, 1,3-diaminopropane and 2-mercaptoethylamine to free 5-Cl-phen before addition of the ligand to $[Ru(Me_2bipy)_2Cl_2]$. Unfortunately the coupling attempts were unsuccessful as the phenanthroline-linker bond was degraded upon coordination of the ligand to the metal centre. Subsequent attempts were made to couple the linkers to phenanthroline in $[Ru(Me_2bipy)_2(5\text{-Cl-phen})]^{2+}$, however, degradation of the phenanthroline-linker C–N bond was again observed.

The method of Hurley et al. [47] which involved the coupling of L-cysteine to 3-bromo-1,10-phenanthroline containing ruthenium complexes under mildly basic conditions was therefore attempted, but instead using BOC-protected L-cysteine methyl ester (L-cys-MeBOC) to couple to the phenanthroline ligand of $[Ru(Me_2bipy)_2(5\text{-Cl-phen})]^{2+}$. After the reaction, two distinct bands were observed with silica gel column chromatography, one eluting with 1% ($R_f = 0.57$) and the other with 3% ($R_f = 0.33$) saturated potassium nitrate solutions. Excess L-cys-MeBOC moved with the solvent front. ^{1}H NMR spectra subsequently showed that the desired compound was contained within the second fraction.

The BOC-protecting group was cleaved from $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})](PF_6)_2$ using strongly acidic conditions. Initially, de-protection was achieved using a solution of concentrated hydrochloric acid in methanol (48 h) to isolate the amine as a hydrochloride salt. Alternatively, the use of trifluoroacetic acid (TFA) in dichloromethane also achieved de-protection, in a shorter length of time (1 h) with 100% recovery of $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})](PF_6)_2$, and was thus the preferred option of the two reactions. Stirring over DOWEX® Monosphere 550A® (OH^- form) in methanol neutralised the TFA/amine salt complex.

The coupling of transplatin {*trans*-diamminedichloroplatinum(II)} to the amine group of $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})]^{2+}$ proved more difficult than first anticipated. After purification on Sephadex® LH20, the presence of light during the reaction was found to result in a very low yield of $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$. Repeated experiments with altered exposure to light demonstrated that formation of the heterodinuclear complex was photosensitive. Consequently, the synthesis and purification of the final metal complex were performed in the dark.

The separation of the mononuclear reactant and the heterodinuclear product was achieved using Sephadex® LH20 support media as the stationary phase with methanol. TLC was used to verify the contents of the fractions, with *rac*-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$ displaying an R_f value of 0.67 and the unreacted *rac*-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})]^{2+}$ stained purple with ninhydrin at R_f 0.38.

The final product was precipitated by the addition of potassium hexafluorophosphate, and extracted into dichloromethane. Conversion to the water soluble chloride salt was then achieved by stirring with Amberlite® anion exchange beads, followed by filtration in order to remove the resin, and finally freeze drying, which yielded the heterodinuclear complex as a red solid.

3.2. Characterisation

The heterodinuclear metal complex and the precursor mononuclear complexes were fully characterised by ^{1}H and ^{13}C NMR, circular dichroism, and electrospray ionisation mass spectrometry, and are described in more detail in Sections 3.2.1, 3.2.2, 3.2.3. UV–Vis spectra were measured to determine the molar extinction coefficients, fluorescence spectra were used to determine quantum yields and elemental analysis to confirm bulk purity. Unfortunately, the use of Eq. (2) for the determination of the quantum yields of fluorescent samples in comparison to a standard, at a common excitation wavelength, was not applicable for the heterodinuclear complex. This was because its excitation wavelength had shifted dramatically from the excitation wavelength of tris(bipyridine) ruthenium(II) (the standard). The method is thus limited in use, and another standard of known quantum yield is required to calculate the relative fluorescence of $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$. Elemental analysis demonstrated bulk purity of *Rac*-$[Ru(Me_2bipy)_2(5\text{-Cl-phen})]\cdot 2PF_6$ with one water of crystallisation, but which is lost upon separation into its isomers. Bulk purity of the boc-protected ruthenium complex and the final heterodinuclear complex could not be obtained by elemental analysis; however, purity is indicated by both ^{1}H and ^{13}C NMR and high resolution mass spectrometry. Bulk and isomeric purity was also confirmed by CD with the spectrum of each isomer of all metal complexes synthesised showing peaks in almost equal proportion, in opposite directions, at the same wavelength. In addition, the CD spectra also confirm the purity of the samples through the presence of isosbestic points, where the two spectra intercept on the *x*-axis.

3.2.1. NMR spectroscopy

All metal complexes in this study were characterised using one-dimensional ^{1}H and ^{13}C NMR and two-dimensional NOESY, g-DQCOSY experiments. ^{13}C assignments were made using heteronuclear multiple quantum correlation spectroscopy (HMQC) and heteronuclear multiple bond correlation spectroscopy (HMBC) experiments. Full details of the ^{1}H NMR spectrum of the heterodinuclear complex, *rac*-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$, including proton assignments are presented here as an example of how all the metal complexes were characterised.

The ^{1}H NMR spectrum of *rac*-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$ displays 13 resonances in the aromatic region and six resonances in the

aliphatic region. The two singlets at 2.46 and 2.54 ppm each integrate for six protons, and are assigned as the two methyl groups on the Me_2bipy rings. The NOESY spectrum shows NOE cross-peaks from the A/BMe resonance at 2.54 ppm to the singlet at 8.38 ppm and a multiplet at 7.27 ppm, which are assigned as the A/B3 and A/B5 protons, respectively. In the g-DQCOSY spectrum, the A/B5 resonance also displays cross-peaks with a multiplet 7.63 ppm, which is assigned as the A/B6 proton (Fig. 1). Similar cross-peaks were observed from the A/BMe resonance at 2.46 ppm, to the A/B3 resonance at 8.34 ppm, A/B5 at 7.04 ppm and from this latter resonance to the A/B6 at 7.31 ppm. It was hoped that cross-peaks might be observed in the NOESY spectrum from the A/B6 resonances to either H2 or H9 on the phenanthroline ring, allowing the definitive assignments of the Me_2bipy proton resonances to particular protons, but no NOE cross-peaks were observed.

The substitution of a chloro group at the 5-position in 1,10-phenanthroline results in seven separate proton resonances for this ligand. The H6 proton resonance couples to no other proton (δ 8.39 ppm), and is the only aromatic singlet in the spectrum integrating for one proton. Both H3 and H8 each have two neighbouring protons and can be identified by their doublet of doublet resonances (see Fig. 1). The remaining resonances for the H2, H4, H7 and H9 protons all appear as doublets. Definitive assignments can be made using NOESY spectra. The H6 resonance gives one NOE cross-peak to the resonance at 8.50 ppm (assigned as H7), which in turn gives an NOE to H8 at 7.73 ppm, and from H8 to H9 at 8.10 ppm. The remaining doublet of doublet resonance at 7.82 is assigned as the H3 proton. The H2 and H4 resonances can be assigned based on the coupling constants. In pyridine rings, the proton nearest the nitrogen atom exhibits the smallest coupling constant (typically 5–6 Hz), whilst a proton further away exhibits a larger coupling constant (typically 7–9 Hz) [48]. On this basis, the resonance at 8.81 ppm is assigned as H4 and the resonance at 8.16 ppm as H2. The remaining unassigned proton resonances in the spectrum are the $–NH_2$, –CH, $–OCH_3$, and $–CH_2$ protons of the L-cysteine methyl ester. The resonance at 4.35 ppm is assigned to $–NH_2$, due to its broadness, the singlet at 3.50 ppm to $–OCH_3$, the triplet at 3.16 ppm to $–CH_2$ and the multiplet at 4.07 ppm to –CH proton. Coordination of the platinum to the cystiene-NH_2 group is confirmed

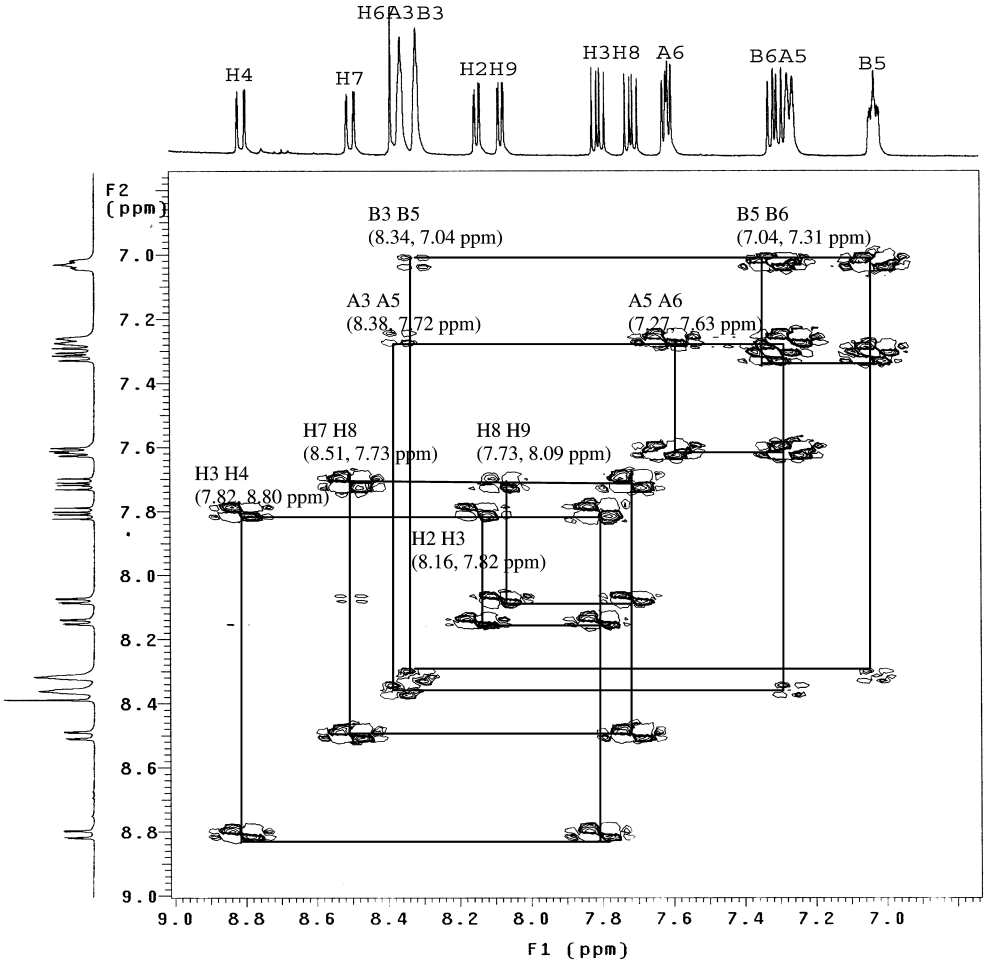

Fig. 1. ^{1}H g-DQCOSY NMR spectrum showing the assignment of the aromatic proton resonances of $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]^{3+}$.

by the large downfield movement of the proton resonance, which moves from 1.26 to 4.35 ppm, upon reaction with transplatin.

It is of note that there are slight differences in the ^{1}H NMR spectra of the Δ- and Λ-ruthenium complexes compared to that of the racemic solutions for all metal complexes synthesised in this study. For instance, a significant chemical shift change of the H6 resonance (8.29–7.91 ppm) is observed in the spectra of the resolved isomers of $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})]^{2+}$ in comparison to the spectrum of the racemic complex (Fig. 2). There is also a large movement of the $-NH_2$ resonance (4.35–3.89 ppm). All other resonances undergo less significant chemical shift changes upon resolution of the isomers.

3.2.2. Circular dichroism spectrophotometry

CD spectra were recorded for each of the metal complex isomers by plotting the angle of ellipticity (θ mdeg) versus wavelength (nm). This was converted to the change in molar absorptivity by Eq. (1). All metal complexes synthesised in this study show four major peaks at 210, 226, 264 and 285 nm, and one broad peak at 410 nm (Fig. 3). In comparison to $[Ru(Me_2bipy)_2(5\text{-Cl-phen})]^{2+}$, attachment of the amino acid and then the platinum metal centre do not change either the wavelength, nor shape of the CD peaks, however, the intensities are increased.

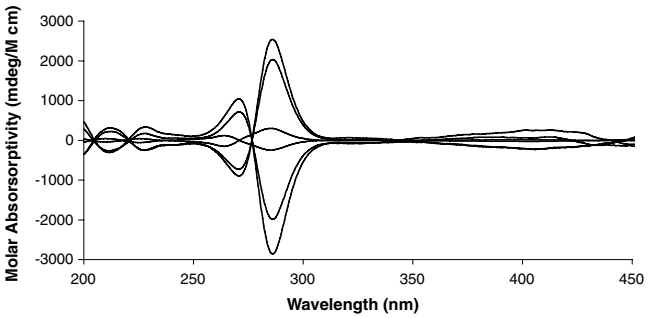

Fig. 3. Circular dichroism spectra of the isomeric complexes from top to bottom (at 285 nm): Λ-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$, Λ-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})](PF_6)_2$, Λ-$[Ru(Me_2bipy)_2(5\text{-Cl-phen})](PF_6)_2$, Δ-$[Ru(Me_2bipy)_2(5\text{-Cl-phen})](PF_6)_2$, Δ-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})](PF_6)_2$ and Δ-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$.

The assignments of the absolute configuration of the metal complexes are based on previous studies of analogous compounds [42]. The metal complex exhibiting a positive value of θ at 250 nm corresponds to the Δ-isomer, while the Λ-isomer exhibits a negative peak at the same wavelength. The elution profile of the isomers from the Sephadex® column further supported this finding, with the Δ-isomer eluting prior to the Λ-isomer.

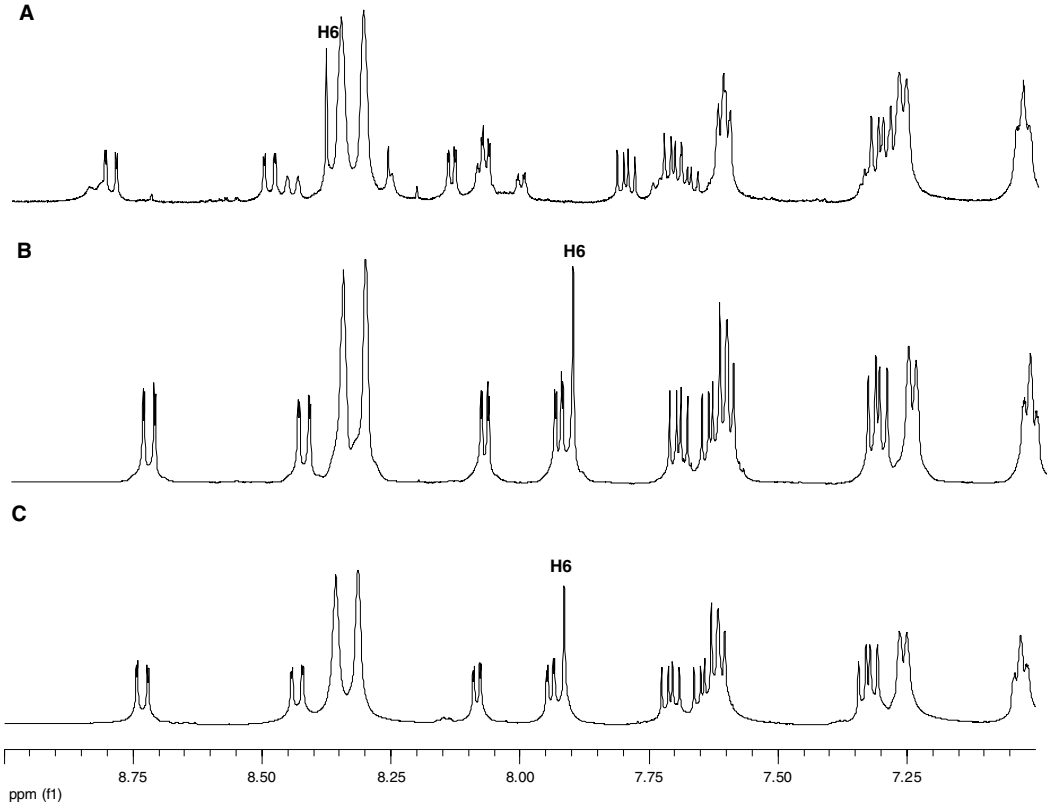

Fig. 2. ^{1}H NMR spectra of (a) *rac*-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})](PF_6)_2$ (b) Λ-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})](PF_6)_2$ (c) Δ-$[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})](PF_6)_2$ demonstrating the chemical shift change of the phenanthroline H6 proton resonance in a racemic solution and when separated into its Δ- and Λ-isomers.

3.2.3. Mass spectrometry

The synthesis of the precursor mononuclear complexes and the final heteronuclear complexes were also confirmed by electrospray ionisation mass spectrometry. $[Ru(Me_2bipy)_2(5\text{-Cl-phen})]^{2+}$ shows a molecular ion at 341.7 m/z which corresponds to the metal complex with a 2+ charge and the loss of one proton and both hexafluorophosphate counter ions. For $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})]^{2+}$, five peaks are observed for the parent and daughter ion fragments. For instance, a molecular ion at 1028.2 m/z is consistent with the $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-MeBOC)-phen})]^{2+}$ cation and one PF_6^- counterion. Finally, the heterodinuclear complex was confirmed by the observance of a molecular ion at 342.1 m/z, corresponding to the charged parent ion minus both counterions and one ammine group. This is characteristic of charged metal complexes of this type and matched the expected isotopic pattern for a ruthenium(II)–platinum(II) complex.

4. Summary

The heterodinuclear complex, $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$, was synthesised using a six step method, as a potential agent to overcome platinum resistance in human cancer treatment. The heterodinuclear complex, and its mononuclear precursors were characterised by ^1H and ^{13}C NMR, UV–Vis, circular dichroism, fluorescence and electrospray ionisation mass spectrometry. The cytotoxicity and DNA binding studies of $[Ru(Me_2bipy)_2(5\text{-(L-cysteine-Me)-phen})\text{-}trans\text{-}Pt(NH_3)_2Cl]Cl_3$ are currently under examination, with the results to be used to develop a family of heterodinuclear complexes with anticancer activity.

Abstract

The diol, 1D-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**D-9**), can be conveniently prepared from 1D-*chiro*-inositol using a series of standard protection/deprotection steps. Treatment of **D-9** with Ph_2PCl gives the chiral diphosphinite, 1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**D-10**). The structure of **D-10** has been determined by X-ray crystallography. Using 1L-*chiro*-inositol as starting material and following the same synthetic sequence used to produce **D-10**, the other enantiomer of this diphosphinite, 1L-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**L-10**) can also be obtained. Ruthenium complexes of these diphosphinite ligands can be conveniently prepared through ligand substitution reactions with appropriate substrate complexes. Thus, treatment of $[RuCl_2(COD)]_n$ with **D-10** in the presence of triethylamine produces the bis(diphosphinite) complex, $RuHCl\{\kappa^2(P,P)$-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol$\}_2$ (**11**). In addition, reaction between $RuCl_2(PPh_3)_3$, **D-10** and (1*R*,2*R*)-(+)-1,2-diphenylethylenediamine gives the mono(diphosphinite) complex, $RuCl_2\{\kappa^2(P,P)$-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol$\}\{\kappa^2(N,N)$-(1*R*,2*R*)-(+)-1,2-diphenylethylenediamine$\}$ (**12**). The closely related complex $RuCl_2\{\kappa^2(P,P)$-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol$\}\{\kappa^2(N,N)$-(1*S*,2*S*)-(−)-1,2-diphenylethylenediamine$\}$ (**13**) can be obtained in a similar manner using (1*S*,2*S*)-(−)-1,2-diphenylethylenediamine in place of the corresponding (+)-isomer. These new chiral, diphosphinite complexes catalyse the hydrogenation of the ketones acetophenone and 3-quinuclidinone to give the corresponding alcohols with low to moderate enantiomeric excesses. The complexes are not catalytically active for the hydrogenation of the olefin dimethylitaconate or the α-ketoester methyl benzoylformate.

1. Introduction

The study of transition metal complex catalysed asymmetric transformations of prochiral substrates is an active area of research that is of both fundamental and practical significance. Although this was recently emphasised by the award of the 2004 Nobel Prize for Chemistry to Knowles, Noyori and Sharpless [1] for their seminal work in this area, there are still no universal ligands and catalysts for asymmetric transformations [2]. Even within a specific reaction type such as metal-catalysed asymmetric hydrogenation of prochiral alkenes, catalysts incorporating a given chiral ligand will not form products of high enantiomeric purity with all prochiral substrates. Therefore, the synthesis of new classes of chiral ligands, especially those in which the electronic and steric properties can be easily and rationally modified, is an important goal.

doi:10.1016/j.poly.2006.06.016

A wide range of chiral, phosphorus-donor ligands have been synthesised and these are the most common ligands that are used in the formation of metal complexes that catalyse asymmetric transformations [2,3]. A number of these ligands have been derived from carbohydrate molecules [4–9], although factors that often reduce the efficacy of carbohydrate-based ligands are the complexity of the syntheses, the reactivity of the masked acetal groups present in reducing sugar derivatives, and the difficulty in obtaining both enantiomers of the carbohydrate. *Chiro*-inositol is a carbohydrate with C_2 symmetry that does not suffer from these potential drawbacks. The cyclohexane backbone is chemically robust, both the D- and L-enantiomers are readily available from the natural products 1D-pinitol (**1**) and 1L-quebrachitol (**2**), respectively (see Chart 1), and the six hydroxyl groups provide extensive scope for selective functionalisation. Despite these attractive features, chiral inositols have been rarely studied in the context of chiral ligand synthesis for transition metal catalysed asymmetric transformations [10]. In an earlier communication we briefly described the syntheses and properties of some new *chiro*-inositol based phosphinite ligands [11]. In this paper, which extends and expands this work, we present full details of: (i) the synthesis and characterisation of the chiral ligands 1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**D-10**) and 1L-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**L-10**) which are the two enantiomers of a diphosphinite ligand based on D- and L-*chiro*-inositol, respectively; (ii) the X-ray crystal structure of **D-10**; (iii) the synthesis of the ruthenium complexes $RuHCl\{\kappa^2(P,P)$-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*- inositol$\}_2$ (**11**), $RuCl_2\{\kappa^2(P,P)$-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol$\}\{\kappa^2(N,N)$-(1*R*,2*R*)-(+)-1,2-diphenylethylenediamine$\}$ (**12**), and $RuCl_2\{\kappa^2(P,P)$-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol$\}\{\kappa^2(N,N)$-(1*S*,2*S*)-(−)-1,2-diphenylethylenediamine$\}$ (**13**) that all incorporate the chiral ligand **D-10**; and (iv) the results of catalytic asymmetric hydrogenation studies of the prochiral ketones acetophenone, 3-quinuclidinone and methyl benzoyl formate, as well as the prochiral alkene dimethyl itaconate, in the presence of **11**, **12** or **13**.

2. Results and discussion

2.1. Syntheses of the chiro-inositol derived diphosphinite ligands, 1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol (D-10) and 1L-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol (L-10), and the crystal structure of D-10

The synthetic pathway that was employed to obtain the diphosphinite ligands **D-10** and **L-10** that have C_2 symmetry is depicted in Scheme 1. Starting from 1D-*chiro*-inositol (**D-3**), which can be obtained from naturally occurring 1D-pinitol, and by utilising the different reactivities of the six hydroxyl groups, selective attachment of diphenylphosphine groups to the oxygen atoms at ring positions 3 and 4, and methyl groups to the other four ring oxygen atoms can be conveniently achieved. The first step in the reaction sequence involves treatment of **D-3** with 2,2′-dimethoxypropane to yield the tris-isopropylidene derivative, **D-4** [12]. The 3,4-isopropylidene group is then selectively removed by treatment with acetic acid to produce 1,2: 5,6-di-*O*-isopropylidene-(D)-*chiro*-inositol (**D-5**) [12]. Protection of the two hydroxyl groups in **D-5** by benzylation and subsequent removal of the remaining isopropylidene groups yields **D-7**. Methylation of **D-7** with NaH/MeI followed by removal of the protecting benzyl groups yields the diol, **D-9**. Treatment of this diol with Ph_2PCl/pyridine then smoothly gives the chiral diphosphinite ligand, 1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**D-10**).

If 1L-*chiro*-inositol (which can be obtained from naturally occurring 1L-quebrachitol) is used as starting material and the same synthetic sequence described above is followed, 1L-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**L-10**), the enantiomer of **D-10**, is obtained. The ready availability of both enantiomers of the diphosphinite ligand, **10**, in principle means that for catalytic asymmetric transformations of prochiral substrates either *R*- or *S*-products could be selectively obtained depending on which enantiomer of ligand **10** is incorporated in the chiral catalyst.

Spectroscopic data for **D-10** and all other new compounds reported in this paper are collected in Section 4. In the ^1H NMR spectrum of **D-10** singlet signals at 2.67

Scheme 1. Synthesis of 1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol (**D-10**).

and 3.46 ppm that each integrate for six protons are assigned to the four methyl groups. Signals each integrating for two protons are observed for the saturated ring protons at 3.38 (multiplet, H-2 and H-5), 3.67 (doublet, $J(HH) = 1.7$ Hz, H-1 and H-6) and 4.35 (multiplet, H-3 and H-4) ppm. In the ^{13}C NMR spectrum two methyl carbon resonances are observed at 56.6 and 59.8 ppm. All these data are consistent with the C_2 symmetry of the molecule. In the ^{31}P NMR spectrum of **D-10**, a singlet resonance at 113.4 ppm is observed for the two equivalent phosphorus atoms. Solutions of **D-10** in chloroform slowly react with the oxygen in air (over a period of minutes) to give several products with the major one having a characteristic resonance in the ^{31}P NMR spectrum at 21.4 ppm. This oxidised product has not been fully characterised, but the chemical shift of the new phosphorus resonance is consistent with the phosphorus atoms having undergone oxidation to P(V).

A colourless crystal of **D-10** suitable for X-ray crystallographic structure determination was obtained from diethylether solution under nitrogen. Crystallographic data for **D-10** are listed in Section 4. The molecular structure is depicted in Fig. 1 and selected bond distances and angles are presented in Table 1. The inositol ring adopts a chair conformation with Q 0.565(3) Å, θ 171.4(3)° and φ 133.9(3)° [13]. All bond lengths and bond angles fall within normal ranges and do not warrant further discussion. The molecules are packed utilising weak C–H···π-bond interactions to form dimer units (see Table 2). All other close contacts are intramolecular H···O interactions, e.g. C5–H5···O1 where H···O is 2.49 Å and the angle C–H–O is 101°.

*2.2. Synthesis of RuHCl{κ²(P,P)-1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol}₂ (**11**), $RuCl_2${κ²(P,P)-1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol}{κ²(N,N)-(1R,2R)-(+)-1,2-diphenylethylenediamine} (**12**) and $RuCl_2${κ²(P,P)-1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol}{κ²(N,N)-(1S,2S)-(−)-1,2-diphenylethylenediamine} (**13**)*

Ruthenium complexes containing chiral diphosphinite ligands (i.e. $R_2PO–X–OPR_2$, where X is a chiral bridging group) are very rare, although complexes of these ligands with other metals, especially rhodium, are well known [14]. Nevertheless, ruthenium complexes of the chiral diphosphinite ligand, **D-10**, can be conveniently prepared by direct reaction between appropriate ruthenium substrate complexes and **D-10**. Thus, treatment of $[RuCl_2(COD)]_2$ with **D-10** and triethylamine in toluene at reflux for 12.5 h produces the yellow/orange complex RuHCl{κ²(*P*,*P*)-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol}₂ (**11**) in 34% yield after column chromatography (see Scheme 2). The triethylamine was added to help dissolve the $[RuCl_2(COD)]_n$ [15], but under the vigorous conditions employed it may also have been responsible for the formation of the hydride ligand in the product, perhaps through β-hydride elimination from coordinated triethylamine.

In the ^1H NMR spectrum, the hydride ligand in **11** is observed at a characteristically high field position (−16.26 ppm) and has the appearance of a second order, seven line, multiplet signal. This signal collapses to a singlet in the ^{31}P decoupled ^1H NMR spectrum. The methyl signals of the two diphosphinite ligands are observed as four singlet signals at 2.49, 3.31, 3.37 and 3.67 ppm that each integrate for six protons. In the ^{13}C NMR spectrum the methyl carbon resonances are also observed as four singlet signals at 58.6, 58.6, 59.0 and 59.7 ppm. In the ^{31}P NMR spectrum, two, three-line multiplet signals with very similar shapes are observed at 120.4 and 148.6 ppm. The structure of **11** in solution cannot be unambiguously assigned on the basis of this NMR information. However, the results are consistent with octahedral coordination geometry about ruthenium where the hydride and chloride ligands are arranged mutually *trans* and the two bidentate diphosphinite ligands are positioned in the equatorial plane (see representation of **11** in Scheme 2). The two phosphorus

atoms within any one of the two bidentate diphosphinite ligands are not related by a C_2 axis as they are in the free diphosphinite ligand, **D10**. Therefore, the two phosphorus atoms within each of the two bidentate diphosphinite ligands are inequivalent. There is a C_2 axis that passes through H, Ru and Cl in the idealised structure drawn in Scheme 2. This means that the four equatorial phosphorus atoms form an AA′BB′ spin system and the two multiplet signals observed in ^{31}P NMR spectrum of **11** are entirely consistent with this.

In other work we have prepared the closely related complex, RuHCl{κ^2(*P*,*P*)-1,2-bis(*O*-diphenylphosphino)cyclohexane}$_2$ in which the phosphorus donors of each of the two bidentate, diphosphinite ligands are attached to a cyclohexane ring instead of a six-membered inositol ring. The hydride resonance of RuHCl{κ^2(*P*,*P*)-1,2-bis(*O*-diphenylphosphino)cyclohexane}$_2$ in the ^{1}H NMR spectrum and the phosphorus resonances in of this complex in the ^{31}P NMR spectra are strikingly similar in multiplicity and chemical shifts to the corresponding signals observed for **11**. The crystal structure of RuHCl{κ^2(*P*,*P*)-1,2-bis-(*O*-diphenylphosphino)cyclohexane}$_2$ has been determined and in the solid state the ligands form an approximately octahedral arrangement about ruthenium with the hydride and chloride ligands arranged mutually *trans*. The two diphosphinite ligands are positioned approximately in the equatorial plane [16]. The adoption of a similar structure for **11** in solution would be consistent with the observed NMR data, and it is therefore tentatively proposed that the structure of **11** is similar to this complex, as is depicted in Scheme 2.

In the solid state, **11** can be exposed to air for extended periods (months), although in solution **11** is degraded by atmospheric oxygen over a period of hours. Nevertheless, solutions of **11** can be exposed to the atmosphere for short periods of time (minutes) during procedures such as column chromatography and recrystallisation without significant degradation occurring.

Treatment of $RuCl_2(PPh_3)_3$ with **D-10** and (1*R*,2*R*)-(+)-1,2-diphenylethylenediamine ((1*R*,2*R*)-(+)-DPEN) in

Scheme 2. Syntheses of the ruthenium complexes RuHCl{κ²(*P*,*P*)-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol}$_2$ (**11**), $RuCl_2${κ²(*P*,*P*)-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol}{κ²(*N*,*N*)-(+)-1,2-diphenylethylenediamine} (**12**) and $RuCl_2$ {κ²(*P*,*P*)-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol}{κ²(*N*,*N*)-(−)-1,2-diphenylethylenediamine} (**13**).

toluene at room temperature for 30 min produces the yellow complex, $RuCl_2${κ²(*P*,*P*)-1D-3,4-bis(*O*-diphenyl phosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol}{κ²(*N*,*N*)-(1*R*,2*R*)-(+)-1,2-diphenylethylenediamine} (**12**) in 71% yield after chromatography. Under the milder reaction conditions used for the synthesis of this compound and with no triethylamine present, neither of the chloride ligands in $RuCl_2(PPh_3)_3$ are replaced by hydride during the reaction to produce **12** (see Scheme 2). In the ^{1}H NMR spectrum of **12** the methyl signals of the single diphosphinite ligand are observed as two singlets at 3.13 and 3.39 ppm. In the ^{13}C NMR spectrum the methyl carbon resonances are observed as two singlets at 59.0 and 59.7 ppm. A singlet resonance at 150.4 ppm is observed for the two equivalent phosphorus atoms in the ^{31}P NMR spectrum. The equivalence of two phosphorus atoms in the ^{31}P NMR spectrum strongly supports the structure depicted in Scheme 2 in which the two chloride ligands are mutually *trans*. Complex **12** is much more resistant to reaction with atmospheric oxygen than **11**, both in the solid state and in solution. Solutions of **12** are only degraded by oxygen over a period of days.

Reaction between $RuCl_2(PPh_3)_3$, **D-10** and (1*S*,2*S*)-(−)-1,2-diphenylethylenediamine ((1*S*,2*S*)-(−)-DPEN) under the same conditions used for the synthesis of **12** produces the closely related complex, $RuCl_2${κ²(*P*,*P*)-1D-3,4-bis(*O*-diphenylphosphino)-1,2,5,6-tetra-*O*-methyl-*chiro*-inositol}{κ²(*N*,*N*)-(1*S*,2*S*)-(−)-1,2-diphenylethylenediamine} (**13**). The NMR spectral properties of **13** are very similar to those observed for **12**. Also, the stability of **13** to atmospheric oxygen, both in solution and in the solid state, is very similar to that of complex **12**.

2.3. Investigation of the catalytic activity of the ruthenium complexes 11, 12 and 13 for asymmetric hydrogenation reactions of selected prochiral substrates

Preliminary investigations of the catalytic activity of the complexes **11**, **12** and **13** towards asymmetric hydrogenation reactions were carried out on the ketones acetophenone (to give *sec*-phenylethyl alcohol) and 3-quinuclidinone (to give 3-quinuclidinol), the α-ketoester methyl benzoylformate (to give methyl mandelate) and the alkene dimethyl itaconate (to give dimethyl methyl succinate) (see Chart 2 for structures of the substrates). 3-Quinuclidinone is an important pharmaceutical intermediate and the other three substrates are frequently used in profiling studies of potential metal hydrogenation catalysts [17].

The hydrogenation reactions were carried out in toluene/isopropanol solution (1:1) for acetophenone and 3-quinuclidinone and in toluene solution for methyl benzoylformate and dimethyl itaconate with a substrate to catalyst ratio of 200:1, hydrogen pressure of 1000 psi, temperature of 60 °C and a time period of 3 h. In addition, KO^{t}Bu (2 mole equivalent versus the ruthenium complex) was added to each reaction since it has been shown that the presence of this base can significantly improve the yield of product formed in hydrogenation reactions, especially with catalysts that incorporate a diamine ligand [18]. Indeed this was found to be the case for complexes **12** and **13** where no conversion of acetophenone was observed in reactions without added KO^{t}Bu.

The results of the hydrogenation reactions are collected in Table 3. The prochiral alkene dimethyl itaconate was not hydrogenated in the presence of any of the three complexes, **11**, **12** or **13** under the stated conditions. This suggests that in general the catalytic activity of these

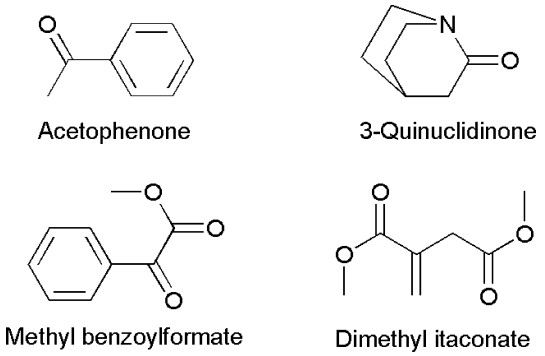

Chart 2.

Table 3
Results of the hydrogenation studies

Complex	Substrate	Conversion (%)	ee (%)
11	acetophenone	20	2

	methyl benzoylformate	7	20
	dimethyl itaconate	0	
12	acetophenone	100	25
	3-quinuclidinone	100	20
	methyl benzoylformate	0	
	dimethyl itaconate	0	
13	acetophenone	100	24
	3-quinuclidinone	100	50
	methyl benzoylformate	0	
	dimethyl itaconate	0	

Conditions: Substrate:catalyst ratio, 200:1; hydrogen pressure 1000 psi; temperature, 60 °C; time, 3 h; solvent, toluene/isopropanol (1:1) (3 mL) for acetophenone and 3-quinuclidinone and toluene (3 mL) only for methyl benzoylformate and dimethyl itaconate; KO^{t}Bu, 2 mole equivalent vs. the ruthenium complex.

three complexes for alkene hydrogenation may be low or non-existent. Clearly the study of other alkene substrates is needed to confirm this, and work in this area is planned for the future. The α-ketoester, methyl benzoylformate, was also not hydrogenated in the presence of **12** or **13** and only very small conversions were observed in the presence of **11**. In contrast to these results, hydrogenation reactions of the ketones acetophenone and 3-quinuclidinone to the corresponding alcohols were catalysed by all three complexes, **11**, **12** or **13** under the reported reaction conditions. Complex **11** was not very effective as a catalyst for acetophenone hydrogenation (20% conversion, no enantioselectivity), but complete hydrogenation of this ketone with low enantioselectivity (ca. 25%) was observed in the presence of **12** or **13**. For 3-quinuclidinone, complete conversion (97–100%) was observed in the presence of all three catalysts, **11**, **12** or **13**. However, in each case the products were formed with very different enantioselectivities. The hydrogenation of 3-quinuclidinone in the presence of **11** proceeded with no enantioselectivity. In the presence of **12**, the product was formed with 20% ee, and in the presence of **13**, product with 50% ee was obtained.

The higher enantioselectivity observed for the catalytic hydrogenation of 3-quinuclidinone in the presence of **13** as opposed to **12** indicates that in **13**, the chiral diphosphinite ligand derived from D-pinitol and the chiral (1*S*,2*S*)-(−)-DPEN ligand work in concert as a "matched pair" to effect asymmetric hydrogenation. In **12**, the same chiral diphosphinite ligand does not form such an effective combination with the chiral (1*R*,2*R*)-(+)-DPEN ligand, and the product is formed with significantly lower enantioselectivity. The large difference in enantioselectivities of product formation for these reactions catalysed by **12** and **13** suggests that both chiral ligands are still coordinated to ruthenium in the active catalytic species.

3. Conclusions

It has been demonstrated that the carbohydrate *chiro*-inositol is a very useful building-block from which chiral, diphosphinite ligands can be conveniently prepared. *chiro*-Inositol has a number of features that makes its use in the construction of chiral ligands very attractive. For example, the two enantiomers of *chiro*-inositol are both readily available in high purity from natural resources, the cyclohexane ring is chemically robust and the six hydroxyl groups present important opportunities for extensive, selective functionalisation. The chiral diphosphinite ligands **D-10** and **L-10** reported in this paper can be used to synthesise the chiral complexes **11**, **12** and **13** through simple ligand substitution reactions of appropriate ruthenium substrate complexes. Asymmetric hydrogenation of the prochiral ketones acetophenone and 3-quinuclidinone is catalysed by **11**, **12** and **13**. Although only low (25%) to modest (50%) ee values were observed for some of the products, these results are significant in that they demonstrate chiral diphosphinite ligands based on *chiro*-inositol can successfully be used to produce asymmetric hydrogenation catalysts.

It is well established that key factors that influence the enantioselectivity of transition metal catalysed hydrogenation reactions include the stereochemistry, steric bulk, and electronic properties of the chiral ligands [6,19]. Importantly, it is possible in principle to synthesise analogues of the diphosphinite ligands **D-10** and **L-10** in which all these properties are changed in a rational way through the selective use of alternate substituents in place of the O-bound methyl groups and the phenyl groups on the two phosphorus atoms. Compound **7** (see Scheme 1) could serve as a convenient starting point from which these alternate substituents could be introduced to facilitate the production of a wide range of new chiral diphosphinite ligands with C_2 symmetry that are related to **D-10** and **L-10**. Work in this area is currently underway.

4. Experimental

4.1. General synthetic procedures and instruments

Manipulations of air sensitive materials were conducted in an argon atmosphere by using either Schlenk techniques or an Innovative Technology inert atmosphere glove box. Tetrahydrofuran, ether and toluene were distilled from sodium benzophenone ketyl under nitrogen and stored over activated 4 Å molecular sieves. Dichloromethane was distilled from calcium hydride. Triethylamine was distilled from calcium hydride and stored over potassium hydroxide. Flash column chromatography [20] was carried out on 230-400 silica (Scharlau). ^{1}H, ^{13}C, and ^{31}P NMR spectra were obtained on a Bruker Avance 300 at 25 °C operating at 300.13 (^{1}H), 75.48 (^{13}C), and 121.5 (^{31}P) MHz, respectively. Resonances are quoted

in ppm and the ^{1}H NMR is referenced to the proteo-impurity in the solvent (7.25 ppm for $CDCl_3$) or TMS (0.00 ppm). ^{13}C NMR spectra were referenced to $CDCl_3$ (77.00 ppm) and ^{31}P NMR spectra to 85% orthophosphoric acid (0.00 ppm) as an external standard. Elemental analyses were obtained from the Microanalytical Laboratory, University of Otago. FAB+ mass spectra were obtained from a VG-70SE machine. (1*R*,2*R*)-(+)-DPEN and (1*S*,2*S*)-(−)-DPEN were obtained commercially, 1L-quebrachitol was obtained from the Rubber Research Instiutute of Malaysia, Kuala Lumpur, Malaysia, 1D-pinitol was obtained from New Zealand Pharmaceuticals Ltd., Palmerston North, New Zealand. 1D-*chiro*-Inositol (**D-3**) and 1L-*chiro*-inositol (**L-3**) were prepared from 1D-pinitol and 1L-quebrachitol, respectively [21]. 1D-1,2: 3,4: 5,6-tri-*O*-isopropylidene-*chiro*-inositol (**D-4**), 1L-1,2: 3,4: 5,6-tri-*O*-isopropylidene-*chiro*-inositol (**L-4**) [12], 1D-1,2: 5,6-di-*O*-isopropylidene-*chiro*-inositol (**D-5**), and 1L-1,2: 5,6-di-*O*-isopropylidene-*chiro*-inositol (**L-5**) [12] were all prepared according to the literature methods. 1L-3,4-Di-*O*-benzyl-1,2: 5,6-di-*O*-isopropylidene-*chiro*-inositol (**L-6**) and 1L-3,4-di-*O*-benzyl-*chiro*-inositol (**L-7**) were prepared using the same procedures that were reported for the corresponding D-isomers and the spectroscopic properties of **L-6** and **L-7** are identical to those of the corresponding D-isomers apart from the optical rotations which are of opposite sign [22]. $[RuCl_2(COD)]_n$ [23] and $RuCl_2(PPh_3)_3$ [24] were prepared according to the literature methods.

4.2. General procedures and instruments employed for the hydrogenation reactions

Hydrogenations were carried out in 12 mL glass vials equipped with a magnetic stirrer bar. The vials were filled with catalyst (0.005 mmol), substrate (1.0 mmol), KO^{t}Bu (0.01 mmol) and 1:1 toluene/isopropanol (3 mL) for acetophenone and 3-quinuclidinone, and toluene only (3 mL) for dimethyl itaconate and methyl benzoyl formate inside an inert atmosphere glove box (Innovative technologies) and then placed inside a 300 mL Parr autoclave made from Hastelloy C. In this way several hydrogenation experiments could be carried out at the same time. The autoclave was sealed, taken outside the glovebox and heated to 60 °C using a thermostatic heating mantle. The autoclave was then flushed with hydrogen 3 times before being filled with hydrogen (1000 psi).

After the required reaction time the autoclave was cooled, and the pressure reduced to atmospheric pressure. The autoclave was then opened, and samples of the crude reaction mixture were analysed by GC. The GC analysis to obtain conversion and enantiomeric excess values were performed on a HP 6890 Series gas chromatography apparatus using a capillary Supelco GAMMA-DEX 225 (30 m × 0.25 mm × 0.25 μm) column or a SGE CYDEX-B (2 m × 0.32 mm × 0.25 μm) column.

4.3. Preparation of 1L-3,4-di-O-benzyl-1,2,5,6-tetra-O-methyl-chiro-inositol (*L-8*)

Compound **L-7** (10.0 g, 28 mmol) was dissolved in dry DMF (200 mL) under argon and the flask was cooled to 0 °C. Sodium hydride (2.99 g of a 60% w/w suspension in oil, 75 mmol) was added followed by iodomethane (5.18 mL, 83.2 mmol) under argon and the flask was allowed to warm to room temperature and stand for 1 h. The flask was cooled to 0 °C and another portion of sodium hydride (2.99 g of 60% w/w in oil, 75 mmol) was added followed by another portion of iodomethane (5.18 mL, 83.2 mmol) under argon. The flask was warmed to room temperature and stirred overnight under argon. Ethanol (100 mL) was added to quench the reaction and the solvents were removed under vacuum. The residue was purified by Flash Chromatography (EtOAc:hexanes, 1:2) to give pure **L-8** (7.50 g, 95%) as a pale yellow oil; $[\alpha]_D$ +20.3 (*c* 1.1, $CHCl_3$). *Anal*. Calc. for $C_{24}H_{32}O_6$: C, 69.21; H, 7.74. Found: C, 68.82; H, 7.75%. MS (*m*/*z*, referred to the most abundant isotopes): (NBA/DCM): Calcd. for $C_{24}H_{31}O_6$ ($M-H^+$) 415.2121 *m*/*z*. Found: 415.2111. ^{1}H NMR ($CDCl_3$, δ): 3.49 (s, 6H, Me), 3.51 (2H, H-3 and H-4), 3.53 (s, 6H, Me), 3.73 (dd, 2H, *J* 7.1, 2.6 Hz, H-2 and H-5), 3.75 (d, 2H, *J* 2.6 Hz, H-1 and H-6), 4.79 (d, 2H, *J* 10.8 Hz, CH*H*′), 4.85 (d, 2H, *J* 10.8 Hz, C*H*H′), 7.22–7.36 (m, 10H, Ar). ^{13}C NMR ($CDCl_3$, δ): 59.4 (Me), 59.5 (Me), 76.1 (CH_2), 76.2 (C-1 and C-6), 82.2 (C-3 and C-4), 82.3 (C-2 and C-5), 127.7, 128.3, 128.6, 139.2 (Ar).

4.4. Preparation of 1L-1,2,5,6-tetra-O-methyl-chiro-inositol (*L-9*)

Compound **L-8** (7.50 g, 18.0 mmol) in ethanol (64 mL) and trifluoroacetic acid (7 mL) was hydrogenated at atmospheric pressure for 24 h at room temperature in the presence of palladium on carbon catalyst (2.3 g, 10% w/w). The catalyst was removed by filtration through Celite (pre-washed with ethanol) and the solvents were removed from the filtrate under vacuum. The residue was purified by Flash Chromatography (CH_2Cl_2:EtOAc:MeOH, 5:4:1) to give pure **L-9** (3.80 g, 89%). *Anal*. Calc. for $C_{10}H_{20}O_6$: C, 50.84; H, 8.53. Found: C, 49.94; H, 8.41%. $[\alpha]_D$ −67 (*c* 1.4, $CHCl_3$); ^{1}H NMR ($CDCl_3$, δ): 3.38 (br s, 2H, H-2 and H-5), 3.49 (s, 6H, Me), 3.51 (s, 6H, Me), 3.78 (dd, 2H, *J* 6.8, 2.1 Hz, H-3 and H-4), 3.82 (d, 2H, *J* 2.1 Hz, H-1 and H-6). ^{13}C NMR ($CDCl_3$, δ): 58.5 (Me), 59.7 (Me), 72.6 (C-3 and C-4), 75.4 (C-1 and C-6), 81.5 (C-2 and C-5).

4.5. Preparation of the compounds *D-6*–*D-9*

The D-enantiomers of compounds **L-6**–**L-9**, were prepared using the same procedures that are detailed in Sections 4.3–4.6, only using the corresponding D-enantiomer starting materials in each case. The spectral properties for all the compounds **D-6**–**D-9** are identical within experimental error to those reported for **L-6**–**L-9**.

4.6. Preparation of 1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol (**D-10**)

The diol **D-9** (536 mg, 2.27 mmol) (which had been predried azeotropically with dry toluene (2 × 5 mL)) and dry pyridine (410 μL, 5.07 mmol) were added to dry THF (5 mL). The resulting solution was transferred by cannula into a Schlenk tube containing freshly distilled chlorodiphenyl phosphine (830 μL, 4.62 mmol) in dry THF (3.5 mL) under argon. The resulting suspension was stirred at room temperature overnight. The solution was filtered under argon and the solvent removed from the filtrate under vacuum. The remaining solid was washed with dry toluene and filtered. The filtrate was collected and the solvent removed under vacuum to give the diphosphinite **D-10** as a white solid (1.30 g, 95%). Compound **D-10** was used in subsequent metal complex synthesis without further purification. ^{1}H NMR ($CDCl_3$, δ): 2.67 (s, 6H, Me), 3.38 (m, 2H, H-2 and H-5), 3.46 (s, 6H, Me), 3.67 (d, 2H, J 1.7 Hz, H-1 and H-6), 4.35 (m, 2H, H-3 and H-4), 6.96–7.55 (m, 20H, Ar). ^{13}C NMR ($CDCl_3$, δ): 56.6 (Me), 59.8 (Me), 74.5 (C-1 and C-6), 81.4 (C-2 and C-5), 127.9, 128.2, 128.3, 129.0, 129.2, 129.5, 130.9, 131.2 (Ar). ^{31}P NMR ($CDCl_3$, δ): 113.4.

4.7. Preparation of RuHCl(1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol)$_2$ (**11**)

Compound **D-10** (0.20 g, 0.33 mmol), $[RuCl_2(COD)]_n$ (0.043 g, 0.16 mmol) and triethylamine (0.10 mL, 0.74 mmol) were added to toluene (20 mL) under nitrogen and the mixture heated under reflux for 12.5 h. The toluene was then removed under reduced pressure and the resulting residue dissolved in a minimum amount of acetone and purified by column chromatography on basic alumina using acetone as eluant. The yellow/orange band was collected and the acetone was removed under reduced pressure. The resulting residue was recrystallised from dichloromethane/*n*-hexane to give pure **11** as yellow/orange crystals (0.080 g, 34%). *Anal*. Calc. for $C_{68}H_{77}ClO_{12}P_4Ru$: C, 60.64; H, 5.76. Found: C, 60.03; H, 5.74%. ^{1}H NMR ($CDCl_3$, δ): −16.26 (m, 1H, hydride), 2.49 (s, 6H, Me), 3.31 (s, 6H, Me), 3.37 (s, 6H, Me), 3.67 (s, 6H, Me), 3.70 (m, 2H, –CH–), 3.89 (m, 2H, –CH–), 3.89 (m, 2H, –CH–), 3.95 (m, 2H, –CH–), 4.82 (m, 2H, –CH–), 5.58 (m, 2H, –CH–), 6.55–7.81 (m, 40H, Ph). ^{13}C{^{1}H} NMR ($CDCl_3$, δ): 58.6 (s, Me), 58.6 (s, Me), 59.0 (s, Me), 59.7 (s, Me), 63.6 (s, –CH–), 74.3 (s, –CH–), 76.3 (s, –CH–), 77.2 (s, –CH–), 80.4 (s, –CH–), 80.5 (s, –CH–), 123.2–138.9 (Ph). ^{31}P{^{1}H} NMR ($CDCl_3$, δ): 120.4 (m), 148.6 (m).

4.8. Preparation of RuCl$_2$(1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol){(1R,2R)-(+)-DPEN} (**12**)

Compound **D-10** (0.336 g, 0.556 mmol) and $RuCl_2(PPh_3)_3$ (0.266 g, 0.278 mmol) were added to toluene (10 mL) under nitrogen and the resulting mixture stirred at room temperature for 5 min, (1*R*,2*R*)-(+)-DPEN (0.0580 g, 0.273 mmol) was then added and the solution was stirred at room temperature for an additional 25 min. The toluene was removed under reduced pressure to give a green residue. This was dissolved in a minimum amount of dichloromethane and purified by column chromatography on basic alumina using dichloromethane as eluant. The bright yellow band was collected and the dichloromethane removed under reduced pressure. The resulting residue was recrystallised from diethylether/*n*-hexane to give pure **12** as yellow crystals (0.195 g, 71%). *Anal*. Calc. for $C_{48}H_{54}Cl_2N_2O_6P_2Ru$: C, 58.30; H, 5.50; N, 2.83. Found: C, 58.32; H, 5.68; N, 2.55%. ^{1}H NMR ($CDCl_3$, δ): 3.13 (s, 6H, Me), 3.39 (s, 6H, Me), 3.45 (m, 2H, –CH–), 3.63 (m, 2H, –CH–), 4.39 (m, 2H, –CH–), 4.79 (m, 2H, –CH–), 6.96–7.76 (30H, Ph). ^{13}C{^{1}H} NMR ($CDCl_3$, δ): 59.0 (s, Me), 59.7 (s, Me), 62.9 (s, –CH–), 76.2 (s, –CH–), 77.0 (s, –CH–), 80.7 (s, –CH–), 126.9–140.2 (m, Ph). ^{31}P{^{1}H} NMR ($CDCl_3$, δ): 150.4 (s).

4.9. Preparation of RuCl$_2$(1D-3,4-bis(O-diphenylphosphino)-1,2,5,6-tetra-O-methyl-chiro-inositol){(1S,2S)-(−)-DPEN} (**13**)

The same procedure that was used for the synthesis of **12** in Section 4.8 was followed except that (1*S*,2*S*)-(−)-DPEN was used instead of (1*R*,2*R*)-(+)-DPEN. After recrystallisation from chloroform/*n*-hexane, pure **13** was obtained as yellow crystals (0.0667 g, 76%). *Anal*. Calc. for $C_{48}H_{54}Cl_2N_2O_6P_2Ru \cdot 0.5CHCl_3$: C, 55.53; H, 5.28; N, 2.67. Found: C, 55.23; H, 5.31; N, 2.56%. ^{1}H NMR ($CDCl_3$, δ): 3.12 (s, 6H, Me), 3.38 (s, 6H, Me), 3.44 (m, 2H, –CH–), 3.63 (m, 2H, –CH–), 4.40 (m, 2H, –CH–), 4.76 (m, 2H, –CH–), 6.9–7.75 (30H, Ph). ^{13}C{^{1}H} NMR ($CDCl_3$, δ): 59.0 (s, Me), 59.8 (s, Me), 64.1 (s, –CH–), 76.3 (s, –CH–), 76.9 (s, –CH–), 80.7 (s, –CH–), 127.0–140.2 (m, Ph). ^{31}P{^{1}H} NMR ($CDCl_3$, δ): 151.6 (s) ppm.

4.10. X-ray crystal structure determination for compound **D-10**

A suitable crystal of compound **D-10** was isolated from diethylether. X-ray data were collected on a Siemens SMART CCD diffractometer using graphite monochromated Mo Kα ($\lambda = 0.71073$ Å). Data collection method: ω-scan, range 0.8°, crystal to detector distance 5 cm. Data reduction and cell determination were carried out with the SAINT and XPREP (SMART) programs [25]. Absorption corrections were applied by the use of the SADABS program [26]. The structures were determined and refined using the SHELXS-97 and SHELXL-97 program packages [27]. All non-H atoms were refined with anisotropic thermal parameters. All carbon-bound H atoms were constrained to their expected geometries (C–H 0.95, 0.98 and 1.0 Å) and refined with U_{iso} 1.2 times the U_{eq} of their parent atom.

Crystal data for $C_{34}H_{38}O_6P_2$ (**D-10**): $M = 604.58$, orthorhombic, $P2_12_12_1$, $a = 10.6945(11)$ Å, $b = 13.5855(14)$ Å,

$c = 21.992(2)$ Å, $V = 3195.3(6)$ Å^3, $Z = 4$, $D_{calc} = 1.257$ Mg m^{-3}, $\mu = 0.179$ mm^{-1}, $T = 163(2)$ K, measured 40719 reflections (6492 unique) in θ range 1.8–26.4°. $R_{int} = 0.087$. Final R indices $[I > 2\sigma(I)]$ $R_1 = 0.041$, $wR_2 = 0.070$. Absolute structure parameter (Flack [28]) = 0.11(8).

Abstract

The preparation and characterisation of the free-base and zinc metallated derivatives of 5,10,15,20-tetrakis(4-(2-(2-hydroxyethoxy)ethoxy)phenyl)porphyrin **1** is described. The X-ray crystal structure of the Zn(II) adduct **2** dimerises in the solid state *via* an intermolecular polyether oxygen–Zn(II) interaction (O...Zn = 2.124(4) Å). The porphyrin dimers form discrete layers defined by a distance of 5.10 Å between the porphyrin planes in adjacent layers. A bilayer sheeting arrangement of the porphyrin macrocyclic units is achieved through cooperative hydrogen bonding of the ethoxyethanol arms to form 11-membered macrocycles containing four hydrogen bonds.

Keywords: Metalloporphyrins; Zn(II) complex; Hydrogen bonding; Coordination network; X-ray structure

1. Introduction

Controlling the arrangement of porphyrin macrocycles into well-defined solid-state arrays through the processes of self-assembly and self-organisation is necessary to advance the development of surface bound porphyrin devices with applications in surface sensing, size exclusion, light harvesting and heterogeneous porphyrin catalysis [1–6]. Desired control may be executed by utilising ''intelligent'' porphyrins in which non-covalent interactions are pre-programmed into the porphyrin structure to aid molecular alignment in either a *pseudo* 1-D or 2-D and 3-D arrays [7–10]. In particular, new porphyrin systems capable of forming either hydrogen bonded or coordinative 2D sheet networks from a single molecular entity are desirable. In this paper we report on preliminary studies using ethoxyethanol side chains for this goal (Fig. 1). Such functionality could potentially self-assemble at the porphyrin periphery in a non-covalent way cooperatively, forming two distinct intermolecular hydrogen bonds per ethoxyethanol set leading to discrete assemblies or 2-D supramolecular arrays.

2. Results and discussion

5,10,15,20-Tetrakis(4-(2-(2-hydroxyethoxy)ethoxy)phenyl)porphyrin (**1**, H_2TEEP) was prepared in 83% yield by the alkylation of 5,10,15,20-tetrakis(4-hydroxyphenyl)porphyrin with 2-(2-chloroethoxy)ethanol [11]. Compound **1** is surprisingly insoluble in the usual aprotic solvents used for dissolving porphyrins ($CHCl_3$, CH_2Cl_2, toluene, etc). This insolubility can be attributed to extensive intermolecular hydrogen bonding interactions, which are desirable but uncontrolled to this point. The problem is alleviated by the addition of a small amount of a solvent capable of interfering with hydrogen bonding (e.g., methanol or pyridine)[1]. Zinc metallation of **1** was achieved using the acetate method [12] producing 5,10,15,20-tetrakis(4-(2-(2-hydroxyethoxy)ethoxy)phenyl)porphinato zinc(II) (**2**, ZnTEEP) in 89% yield as a light purple solid. Solubility of the porphy-

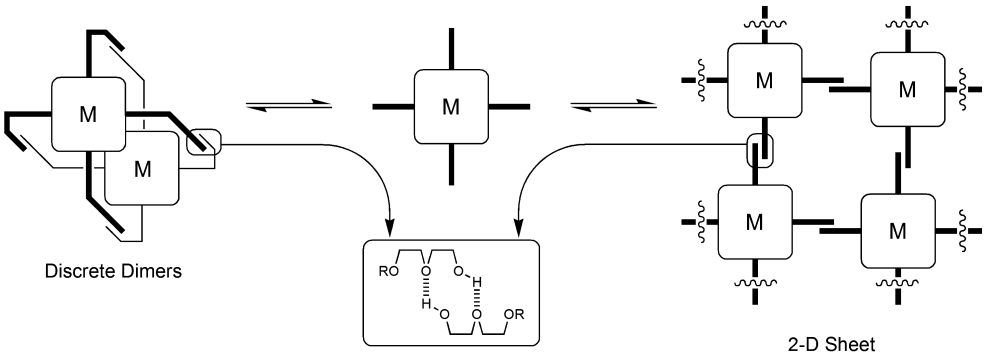

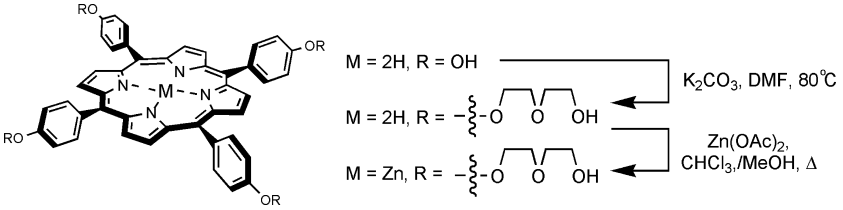

Fig. 1. Utilising the potential of ethoxyethanol groups on the porphyrin periphery could lead to a range of supramolecular constructs through concentration and surface dependency.

Scheme 1.

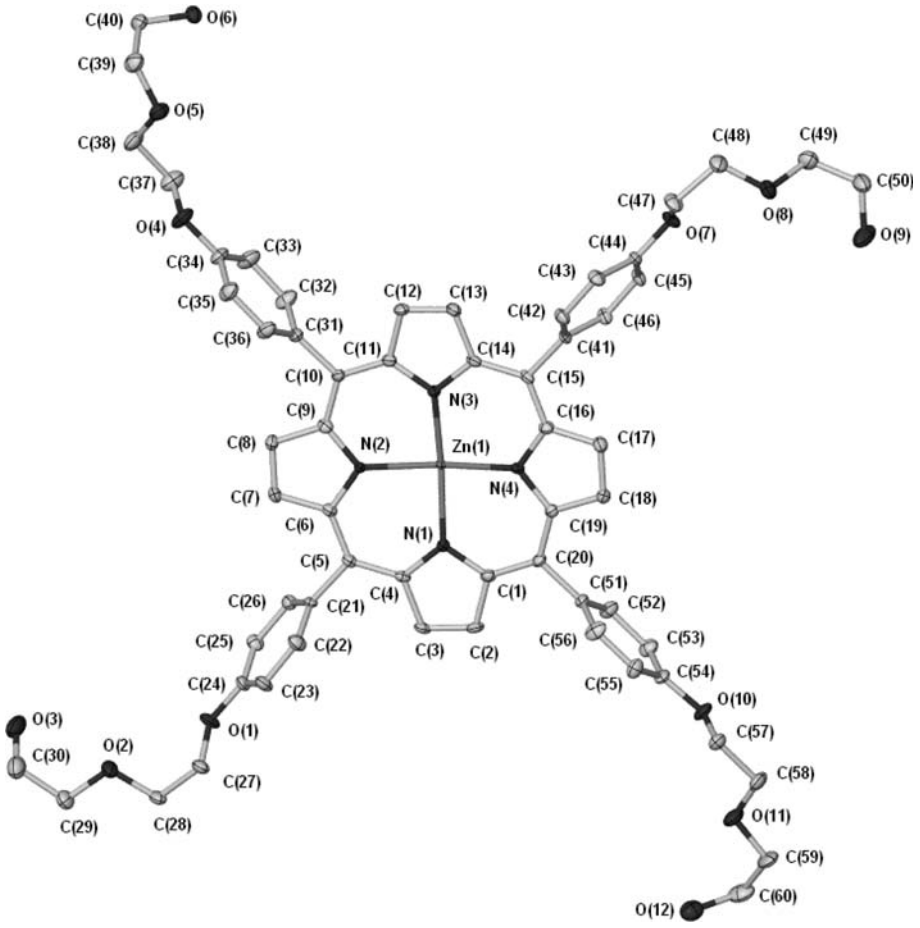

Fig. 2. ORTEP diagram of the molecule displaying the atom labelling scheme used with in paper. Ellipsoids are drawn at 50% probability level. Coordinating alcohol removed for clarity.

Table 1
Selected bond lengths (Å) and bond angles (°) for **2**

Bond distances			
M–N(1)	2.056(4)	M–N(4)	2.071(4)
M–N(2)	2.059(4)	M–O(6)	2.124(4)
M–N(3)	2.050(4)		
Bond angles			
N1–Zn1–N2	88.76(14)	N3–Zn1–O6	99.34(14)
N1–Zn1–N3	163.25(15)	N1–Zn1–O6	97.41(14)
N1–Zn1–N4	88.86(14)	N2–Zn1–O6	97.84(14)
N2–Zn1–N3	89.23(14)	N4–Zn1–O6	98.35(14)
N2–Zn1–N4	163.80(15)		
N3–Zn1–N4	88.45(14)		

rin **2** was also only possible in a mixed solvent system in which a solvent capable of competing with ethoxyethanol hydrogen bonding was employed. Using this technique, crystals suitable for X-ray crystallography were grown by the slow diffusion of diethyl ether into dichloromethane/methanol (see Scheme 1).

ZnTEEP (**2**) crystallises in the triclinic space group $P\bar{1}$. The molecular structure of **2** is shown in Fig. 2 and selected bond distances and angles for **2** are listed in Table 1. The square pyramidal Zn(II) centre is somewhat distorted with the four inner peripheral nitrogens of the porphyrin defining the pyramid base and the apical position occupied by a coordinated (intermolecularly) alcohol side chain (see Fig. 3). The metal to nitrogen bond distances vary from 2.050(4) to 2.071(4) Å (average value 2.059 Å), with the axially coordinated Zn–O bond displaying a longer distance of 2.124(4) Å. These values fall into the ranges observed in other Zn(II) porphyrin systems [13]. The Zn(II) metal ion resides 0.29 Å above the porphyrin least squares plane and toward the coordinating alcohol. The large dihedral angles observed between the *meso* phenyl rings and the mean porphyrin plane (69.9–88.3°) are also typical, the difference from orthogonal attributed to crystal packing forces [14]. Despite their inherent flexibility, the ethoxyethanol chains are extended and relatively well ordered. Each

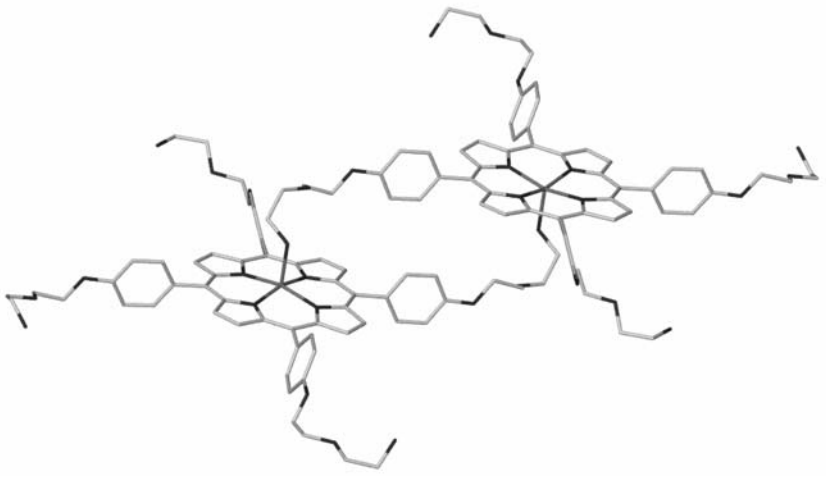

Fig. 3. Representation of the dimer formed in the crystal structure of **2** (H-atoms and CH_2Cl_2 solvent molecule have been omitted for clarity).

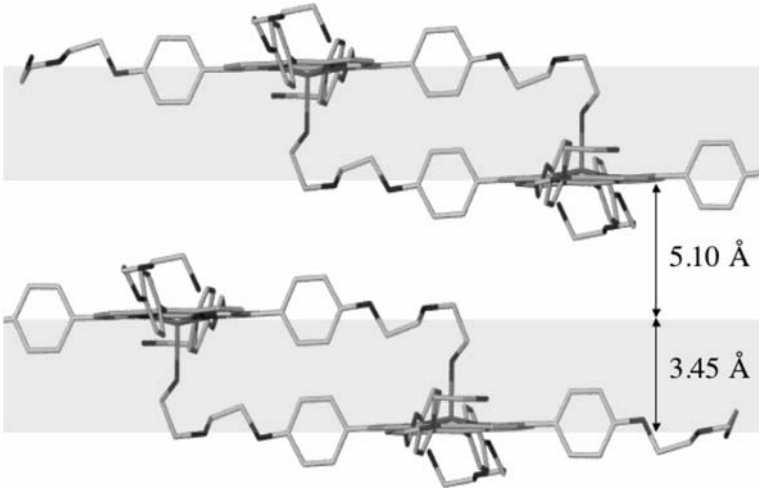

Fig. 4. Bilayer sheeting arrangement observed in the crystal structure of **2**. The shaded area highlights the organisation and intra-layer thickness (3.45 Å), with inter-layer separation of 5.10 Å (H-atoms have been omitted for clarity).

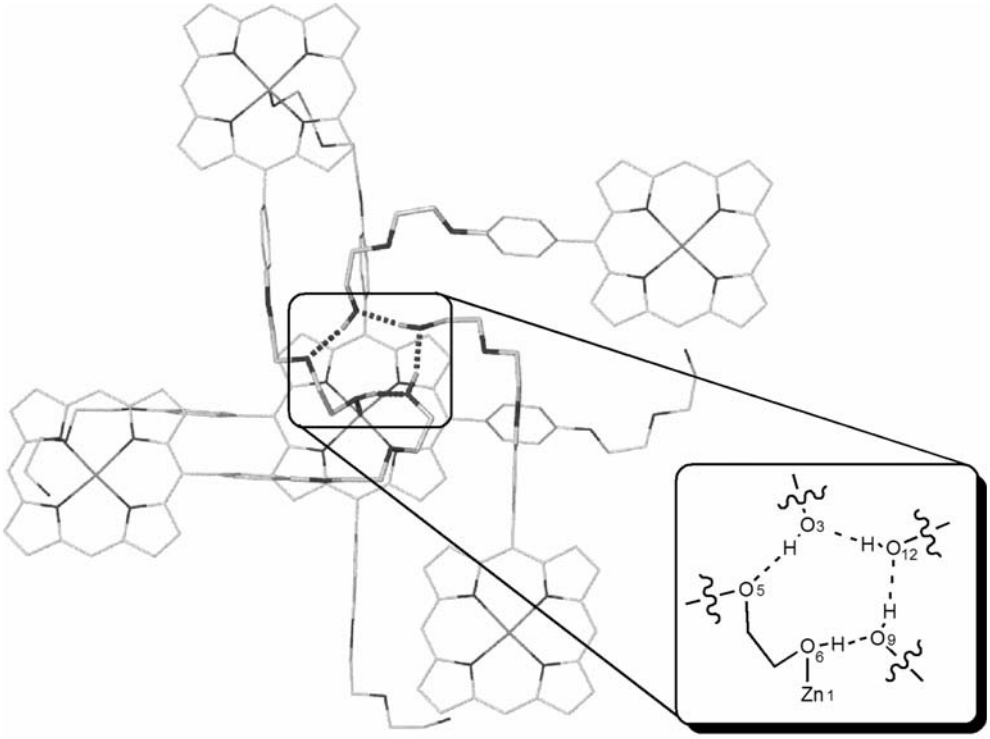

Fig. 5. Representation of the hydrogen bonding motif observed above the zinc coordination site (hydrogen atoms have been omitted for clarity).

Table 2
Hydrogen bonding parameters of **2**

O–H	O	O–H (Å)[a]	H···O (Å)	O···O (Å)	O–H···O (°)
O–H(3)	O5	0.84	2.16	2.791(6)	132.2
O–H(6)	O9	0.84	1.92	2.626(6)	159.8
O–H(9)	O12	0.84	1.89	2.677(6)	155.9
O–H(12)	O3	0.84	1.82	2.686(6)	150.2

[a] All non-hydrogen atoms were refined anisotropic, while all hydrogen atoms were fixed in idealised positions and allowed to ride on the atom to which they are attached.

OCH_2CH_2OH group forms a staggered *gauche* arrangement while the internal OCH_2CH_2O groups are not as well defined, forming both *extended* and *gauche* arrangements.

Interestingly, ZnTEEP forms a C_2 symmetric dimer in which the OH group from the ethoxyethanol side chain of one porphyrin coordinates to the Zn(II) centre of an adjacent porphyrin molecule [15]. A representation of this dimer is shown in Fig. 3. The observed Zn...Zn separation between the two porphyrins within the dimer is 13.39 Å, with the mean plane of the porphyrins aligned parallel to one another at a distance of 3.45 Å (Fig. 3). The two *meso* phenyl groups used to form the 28-membered macrocycle are parallel to each other but do not provide further Van der Waals stabilisation through π–π interactions.

The dimeric arrays occur within a plane represented by the grey regions in Fig. 4 and alternate in an up-and-down fashion. Each bilayer is separated by an intervening space of thickness 5.10 Å (porphyrin plane to porphyrin plane). The dimers within one layer are interconnected through a hydrogen bonding motif involving the ethoxyethanol chains not involved in dimerisation. A representation of this motif and the extended layer is shown in Fig. 5. Selected hydrogen bonding data are listed in Table 2.

The bilayer sheeting arrangement of the porphyrin macrocyclic units is achieved through cooperative hydrogen bonding of the ethoxyethanol arms to form 11-membered macrocycles containing four hydrogen bonds. Hence, all ethoxyethanol groups are employed in the formation of the overall structure. The longest of the hydrogen bonds O3–H...O5 differs from the others (Table 2) in that it is an ether oxygen rather than hydroxy oxygen atom that partakes in the noncovalent bonding.

3. Concluding remarks

A novel supramolecular structure utilising hydrogen bonding and Zn(II)–N and Zn(II)–O coordination was determined. Despite the use of hydrogen bonding (avail-

able through the ethoxyethanol side chains) to form a layered structure, this present result was more complex than anticipated by design. We are continuing our quest to form hydrogen bonded arrays based on the ethoxyethanol motif for surface adhesion, but recognise that the use of free-base or metalloporphyrins in which axial coordination is not possible (i.e. using four coordinate metal ions or strong donor ligands) may be necessary to achieve this goal. These experiments are underway.

4. Experimental

4.1. General

Synthesis reagents including solvents were used as purchased. Melting points (m.p.) were measured on a Stuart Scientific SMP 3 melting point apparatus. UV–Vis spectra were recorded on a Varian model Cary 100 Bio UV–Visible Spectrophotometer, with the solvent systems used stated in the synthesis description. ^{1}H and ^{13}C nuclear magnetic resonance (n.m.r.) spectra were recorded using a Bruker DPX 300 MHz spectrometer (300 MHz ^{1}H, 75 MHz ^{13}C) or a Bruker DRX 400 MHz spectrometer (400 MHz ^{1}H, 100 MHz ^{13}C), as solutions in the deuterated solvents specified. Deuterated chloroform ($CDCl_3$) was base washed with anhydrous Na_2CO_3 prior to use. High-resolution electrospray mass spectra (HRMS) were recorded on a Bruker BioApex 47e Fourier transform mass spectrometer.

4.1.1. 5,10,15,20-Tetrakis(4-(2-(2-hydroxyethoxy) ethoxy)phenyl)porphyrin (*1*)

To a stirred DMF solution (50 mL) of 5,10,15,20-tetrakis(4-hydroxyphenyl)porphyrin (100 mg, 0.15 mmol), anhydrous K_2CO_3 (410 mg, 2.96 mmol) and 2-(2-chloroethoxy)ethanol (0.2 mL, 1.89 mmol) were added and the resulting solution was heated to 80 °C and left to stir for 4 days. After cooling, the porphyrin was precipitated by the addition of water (50 mL), filtered and washed with water (3 × 5 mL). Further purification by column chromatography (SiO_2, $CHCl_3$/MeOH, 9:1 ratio) eluted **1** as a purple solid (128.5 mg, 83%). m.p. 261–262 °C, UV–Vis ($CHCl_3$/MeOH, 9:1) λ_{max} (log ε): 403 sh (4.79); 422 (560); 520 (4.16); 556 (4.09); 594 (3.88); 649 nm (3.90). ^{1}H n.m.r (400 MHz, $CDCl_3$/MeOH, 4:1): δ 3.66 (m, 8H, OCH_2); 3.72 (m, 8H, OCH_2); 3.19 (t, *J* 4.6 Hz, 8H, OCH_2); 4.29 (t, *J* 4.5 Hz, 8H, OCH_2); 7.17 (ABq, *J* 8.2 Hz, 8H, ArH); 7.98 (ABq, *J* 8.2 Hz, 8H, ArH); 8.69 (s, 8H, β-pyrrolic-H); inner NH not observed. HR-MS (ESI, +ve, DCM/MeOH): calculated *m*/*z* 1053.4262; observed *m*/*z* 1053.4230 $[M+Na]^+$.

4.1.2. [5,10,15,20-Tetrakis(4-(2-(2-hydroxyethoxy) ethoxy)phenyl)porphinato]zinc(II) (*2*)

To a solution of **1** (15 mg, 0.015 mmol) in $CHCl_3$/MeOH (3 mL, 4:1 ratio) was added a saturated $Zn(OAc)_2$ in MeOH (5 mL) and stirred at reflux for 3 h in darkness. Upon completion, the solvent system was removed by rotary evaporation. Water and THF were added and the THF was removed by rotary evaporation to precipitate the porphyrin. The purple suspension was filtered and washed with water (3 × 5 mL). The sample was dried under high vacuum pump to remove the residual solvent giving **2** as a purple solid (14.2 mg, 89%). X-ray quality crystals were grown by the slow diffusion of diethyl ether into a CH_2Cl_2/MeOH solvent system (4:1), resulting in elongated hexagonal red plates. m.p. 223–225 °C. UV–Vis (THF) λ_{max} (log ε): 406 sh (4.63); 426 (6.07); 558 (4.94); 599 nm (4.60). ^{1}H n.m.r (400 MHz, $CDCl_3$/MeOD 9:1): δ 3.53 (m, 16H, OCH_2); 3.76 (m, 8H, OCH_2); 4.14 (m, 8H, OCH_2); 7.00 (ABq, *J* 8.6 Hz, 8H, ArH); 7.83 (ABq, *J* 8.6 Hz, 8H, ArH); 8.56 (s, 8H, β-pyrrolic-H). ^{13}C n.m.r (75 MHz, $CDCl_3$/MeOD 9:1): δ 61.5, 67.8, 69.9, 73.0, 112.6, 120.1, 131.5, 135.6, 136.4, 150.3, 158.2. HR-MS (ESI, +ve, DCM/MeOH): calculated *m*/*z* 1115.3397; observed *m*/*z* 1115.3414 $[M+Na]^+$.

4.1.3. X-ray structure determination

4.1.3.1. Data collection and processing. X-ray measurements were made using a Bruker X8 Apex II CCD diffractometer using monochromated Mo Kα radiation (0.71073 Å). The collection temperature was maintained at 123 K using an Oxford Cryostream open-flow N_2 cryostat. Solution was obtained by direct methods (SHELXS 97)[15] followed by successive Fourier-difference methods, and refined by full matrix least squares on F^2_{obs} (SHELXL 97) [16]. Hydrogen atom thermal parameters were tied to those of the atom to which they are attached.

Crystal data for **2**: $C_{61}H_{62}Cl_2N_4O_{12}Zn$, $M = 1179.42$, red plate, $0.20 \times 0.20 \times 0.02$ mm, triclinic, space group $P\bar{1}$, $a = 11.6110(5)$, $b = 13.3604(5)$, $c = 17.6703(8)$ Å, $\alpha = 87.943(2)$, $\beta = 86.938(2)$, $\gamma = 88.317(2)°$, $V = 2734.4(2)$ Å^3, $Z = 2$, $D_c = 1.432$ g/cm^3, $F_{000} = 1232$, $T = 123(2)$ K, $2\theta_{max} = 55.1°$, 60 320 reflections collected, 12 539 unique ($R_{int} = 0.0751$). Final Goodness-of-fit = 1.117, $R_1 = 0.0891$, $wR_2 = 0.1995$, *R* indices based on 9409 reflections with $I > 2\sigma(I)$ (refinement on F^2), 721 parameters. Lp and absorption corrections applied, $\mu = 0.616$ mm^{-1}.

Abstract

A series of new asymmetrically *N*-substituted derivatives of the 1,4,7-triazacyclononane (tacn) macrocycle have been prepared from the common precursor 1,4,7-triazatricyclo[5.2.1.$0^{4,10}$]decane: 1-ethyl-4-isopropyl-1,4,7-triazacyclononane (**L1**), 1-isopropyl-4-propyl-1,4,7-triazacyclononane (**L2**), 1-(3-aminopropyl)-4-benzyl-7-isopropyl-1,4,7-triazacyclononane (**L3**), 1-benzyl-4-isopropyl-1,4,7-triazacyclononane (**L4**) and 1,4-*bis*(3-aminopropyl)-7-isopropyl-1,4,7-triazacyclononane **(L5)**. The corresponding monomeric copper(II) complexes were synthesised and were found to be of composition: $[Cu(\mathbf{L1})Cl_2]\cdot 1/2\,H_2O$ (**C1**), $[Cu(\mathbf{L4})Cl_2]\cdot 4H_2O$ (**C2**), $[Cu(\mathbf{L3})(MeCN)](ClO_4)_2$ (**C3**), $[Cu(\mathbf{L5})](ClO_4)_2\cdot MeCN\cdot NaClO_4$ (**C4**) and $[Cu(\mathbf{L2})Cl_2]\cdot 1/2\,H_2O$ (**C5**). The X-ray crystal structures of each complex revealed a distorted square-pyramidal copper(II) geometry, with the nitrogen donors on the ligands occupying 3 (**C1** and **C2**), 4 (**C3**) or 5 (**C4**) coordination sites on the Cu(II) centre. The metal complexes were tested for the ability to hydrolytically cleave phosphate esters at near physiological conditions, using the model phosphodiester, *bis*(*p*-nitrophenyl)phosphate (BNPP). The observed rate constants for BNPP cleavage followed the order $k_{C1} \approx k_{C2} > k_{C5} \gg k_{C3} > k_{C4}$, confirming that tacn-type Cu(II) complexes efficiently accelerate phosphate ester hydrolysis by being able to bind phosphate esters and also form the nucleophile necessary to carry out intramolecular cleavage. Complexes **C1** and **C2**, featuring asymmetrically disubstituted ligands, exhibited rate constants of the same order of magnitude as those reported for the Cu(II) complexes of symmetrically tri-*N*-alkylated tacn ligands ($k \sim 1.5\times10^{-5}\ s^{-1}$).

1. Introduction

The coordination chemistry of 1,4,7-triazacyclononane (tacn) has been a fertile field of endeavour over the last 30 years, with over 1400 publications describing the chemistry of this ligand and its derivatives. Recognition that this macrocycle could mimic functional groups that bind metals in many proteins, particularly histidine residues, led to its use in numerous bio-inorganic chemistry studies [1–7]. Moreover, the possibility that bridged metal complexes could also be conveniently assembled using tacn-based ligands attracted the attention of magnetochemists [8–12]. These interests led to the modification of the tacn macrocycle, primarily but not exclusively through *N*-functionalisation, and to the detailed study of the coordination properties of the resulting derivatives. Initially, the focus was on symmetric, tri-substituted derivatives, since these could be readily prepared directly from the parent macrocycle [13], however a number of partially substituted or asymmetrically functionalised tacn derivatives soon began to appear in the scientific literature [14–16]. Early syntheses of these types of ligands generally yielded mixtures of products and/or involved complicated preparative routes utilising, for example, *p*-tosyl protecting groups [14]. Introduction of the highly versatile synthon, 1,4,7-triazatri-

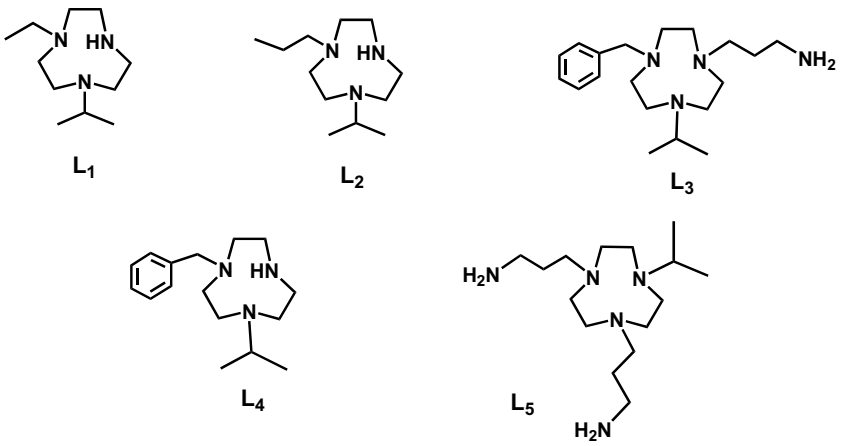

Fig. 1. Derivatives of 1,4,7-triazacyclononane investigated in this study.

cyclo[5.2.1.$0^{4,10}$]decane (''tacn orthoamide''), subsequently revolutionised the field, providing much more clean and efficient routes to tacn derivatives incorporating different functional groups [17,18], in addition to multi(tacn) assemblies that can simultaneously bind two or more metal ions [8,19]. As well as yielding interesting systems for magnetochemists to study [20,8,19,21], the complexes of these ligands have recently begun to be explored as models for phosphatase enzymes with significant success [22–30].

The possibility of attaching different functional groups to the tacn macrocycle in a highly controlled fashion has been the stimulus for much of our recent work in the area of tacn coordination chemistry. For example, we have recently reported the structure and properties of complexes formed by 'amino acid' derivatives of tacn, our ultimate interest being the incorporation of the macrocycle into natural peptide sequences [18,31]. In addition, exciting reports that the copper(II) complexes of *N*-alkylated derivatives of tacn, *viz.*, $[Cu(Me_3tacn)(OH_2)_2]^{2+}$ and $[Cu(^{i}Pr_3tacn)(OH_2)_2]^{2+}$ (Me_3tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane and $^{i}Pr_3tacn$ = 1,4,7-triisopropyl-1,4,7-triazacyclononane) [26,32], are able to cleave phosphate esters much more efficiently than $[Cu(tacn)(OH_2)_2]^{2+}$ recently led us to begin to explore the hydrolytic activity of the copper(II) complexes of symmetrically and asymmetrically functionalised derivatives of tacn [22]. As part of this work, we now report the synthesis and characterisation of five new asymmetrically functionalised ligands (**L1**–**L5**) (see Fig. 1) and their copper(II) complexes, together with an examination of the ability of the copper(II) complexes to hydrolyse the model phosphate ester, *bis*(*p*-nitrophenyl)phosphate (BNPP).

2. Experimental

Reagent or analytical grade chemicals were used as supplied. Acetonitrile, DMF and chloroform were dried over 4 Å molecular sieves and used without further purification. THF was pre-dried with sodium, distilled from Na/benzophenone and used immediately. Distilled H_2O was used throughout. 1,4,7-triazatricyclo[5.2.1.$0^{4,10}$]decane was synthesised according to published methods [33]. The synthesis of 1-benzyl-4-formyl-1,4,7-triazacyclononane has been described by Warden et al. [18] and the syntheses of 1-ethyl-4,7-diaza-1-azoniatricyclo[5.2.1.0^{10}]decane iodide and 1-propyl-4,7-diaza-1-azoniatricyclo[5.2.1.0^{10}]decane iodide have been described by Battle and Spiccia [34].

Instrumentation and methods: Organic solutions were dried with anhydrous $MgSO_4$ before concentration, which were performed under reduced pressure at 50 °C (water bath). All NMR spectra were recorded using Bruker and Varian Spectrometers. ^{1}H and ^{13}C spectra were performed in $CDCl_3$ or D_2O at 25 °C using 200, 300 or 400 MHz instruments. Samples were calibrated using TMS as an internal standard. Electrospray ionisation (ESI) mass spectra were recorded on a Micromass Platform *II* quadrupole mass spectrometer fitted with an ESI source. The capillary voltage was at 3.5 eV and the cone voltage at 35 V. UV–Vis spectra were recorded using Varian Cary 300 or Cary 5G spectrophotometers. IR spectra were recorded using a Perkin–Elmer FTIR 1600 series spectrometer at 4.0 cm^{-1} resolution, using either KBr discs, nujol mulls, or neat liquid as listed. Cation exchange chromatography of complexes was performed using Sephadex™ SP C25 columns of 30 mm diameter. Column chromatography of ligands was performed using Merck 60 silica gel. 10 mL fractions were collected and analysed by TLC, using silica gel 60 F-254 (Merck) plates, with detection of species present by UV irradiation or $KMnO_4$ spray.

!!Caution!! Although no problems were encountered in this work, transition metal perchlorates are potentially explosive and should be prepared in small quantities and handled with care.

2.1. 1-Ethyl-4-isopropyl-1,4,7-triazacyclononane trihydrochloride (*L1* · 3HCl)

1-Ethyl-4,7-diaza-1-azoniatricyclo[5.2.1.0^{10}]decane iodide (8.29 g, 28.1 mmol) was dissolved in 50 mL H_2O and refluxed for 24 h. The solvent was then removed under

reduced pressure to yield a colourless oil. Yield of 1-ethyl-4-formyl-1,4,7-triazacyclononane: 4.94 g, 95%. ^{1}H NMR spectrum (D_2O): δ 8.14 (s, 1H, formyl C*H*), 3.36–2.78, (m, 2H, ethyl CH_2; 12H, CH_2 tacn ring), 1.11 (t, 3H, ethyl CH_3). ^{13}C NMR spectrum ($CDCl_3$): δ 165.8 (d, *C*H formyl), 52.3–43.6 (m, *C*H_2, ring atoms, 6C, ethyl *C*H_2, 1C) 12.16 (s, 1C, ethyl *C*H_3).

1-Ethyl-4-formyl-1,4,7-triazacyclononane (4.94 g, 26.6 mmol) was dissolved in 50 mL acetonitrile, and to this solution was added 7.5 g of Na_2SO_4 (drying agent) and 10 equivalents of Na_2CO_3. A solution of 2-iodopropane in 10 mL acetonitrile was then added to this solution, and the mixture stirred at 60 °C for 72 h. The mixture was then cooled to room temperature and filtered through celite, resulting in an orange filtrate. The solvent was removed under reduced pressure to yield an orange oil containing a white precipitate. Chloroform was added to the mixture, and the solution filtered to remove any inorganic salts. The solvent was removed *in vacuo* to afford 1-ethyl-4-formyl-7-isopropyl-1,4,7-triazacyclononane as a yellow oil. Yield: 4.74 g, 80%. ^{1}H NMR spectrum (D_2O): δ 8.05 (d, 1H, formyl CH), 3.57 (m, 2H, ethyl CH_2), 3.33 (m, 1H, ^{i}Pr C*H* group), 3.1–2.5 (m, 12H, CH_2 tacn ring), 1.01 (m, 6H, ethyl and ^{i}Pr CH_3). ^{13}C NMR spectrum (D_2O): δ 164.32 (d, *C*H formyl), 54.23 (s, ^{i}Pr*C*H,) 54.75–46.93 (m, 6C, *C*H_2 ring), 18.80 (s, ethyl *C*H_3), 18.47 (2C, ^{i}Pr*C*H_3). ESI mass spectrum (H_2O): $m/z = 228.2$, $[M + H]^+$.

1-Ethyl-4-formyl-7-isopropyl-1-4-7-triazacyclononane (4.70 g, 20.7 mmol) was dissolved in 5 M HCl (50 mL) and the solution was refluxed while stirring for 18 h. The solvent was removed under reduced pressure after this time. The resulting brown oily solid was dissolved in 100 mL water, and the pH adjusted to 11 using a 5 M NaOH solution. The desired 1-ethyl-4-isopropyl-1,4,7-triazacyclononane was extracted into chloroform (3×50 mL) and the chloroform layer dried over Na_2SO_4. The solvent was removed under reduced pressure to yield a yellow oil. Suspension of this oil in water, followed by drop wise addition of conc. HCl and concentration of the solution afforded 1-ethyl-4-isopropyl-1,4,7-triazacyclononane · 3HCl. Yield: 4.11 g, 64%. ^{1}H NMR spectrum (D_2O): δ 3.54 (septet, $J = 6.6$ Hz, 1H, ^{i}Pr C*H*), 3.23–3.42 (m, 12H, CH_2 tacn ring), 3.06 (q, $J = 7.2$ Hz, 2H, ethyl CH_2), 1.28 (d, $J = 6.6$ Hz, 6H, ^{i}Pr CH_3), 1.19 (t, $J = 7.2$ Hz, 3H, ethyl CH_3). ^{13}C NMR spectrum (D_2O): δ 58.98 (1C, ^{i}Pr *C*H), 51.5–42.5 (6C, *C*H_2 tacn ring), 17.02 (ethyl *C*H_3), 9.48 (^{i}Pr *C*H_3). ESI mass spectrum (H_2O): $m/z = 200.2$, $[M + H]^+$.

2.2. 1-Isopropyl-4-propyl-1,4,7-triazacyclononane trihydrochloride (*L2* · 3HCl)

1-Propyl-4,7-diaza-1-azaniatricyclo[5.2.1.0^{10}] decane iodide (7.41 g, 23.9 mmol) [34] was dissolved in 50 mL H_2O and stirred under reflux for 24 h. The solvent was then removed under reduced pressure, affording 1-formyl-4-propyl-1,4,7-triazacyclononane as a colourless oil. Yield: 4.49 g, 94%.

Reaction of 1-formyl-4-propyl-1,4,7-triazacyclononane with 2-iodopropane followed by hydrolysis in 5 M HCl and work-up as described above for 1-ethyl-4-isopropyl-1,4,7-triazacyclononane gave the product as a trihydrochloride salt. Yield: 2.81 g, 60%. ^{1}H NMR spectrum (D_2O): δ 3.53 (septet, $J = 6.7$ Hz, 1H, ^{i}Pr C*H*), 3.38–3.22 (m, 12H, tacn ring CH_2), 2.933–2.878 (m, 2H, Pr CH_2), 1.654–1.575 (m, 2H, Pr CH_2), 1.264 (d, $J = 6.7$ Hz, 6H, ^{i}Pr CH_3), 0.86 (t, $J = 7.4$ Hz, 3H, Pr CH_3). ESI mass spectrum (D_2O): $m/z = 214.3$, $[M + H]^+$.

2.3. 1-(3-Aminopropyl)-4-benzyl-7-isopropyl-1,4,7-triazacyclononane tetrahydrochloride (*L3* · 4HCl) and 1-benzyl-4-isopropyl-1,4,7-triazacyclononane (*L4*)

1-Benzyl-4-formyl-1,4,7-triazacyclononane (3.25 g, 13.1 mmol) was reacted with 2-iodopropane and, following work-up as described in the multi-step synthesis of **L1**, afforded 1-benzyl-4-formyl-7-isopropyl-1,4,7-triazacyclononane. Yield: 2.91 g, 76%. ^{1}H NMR spectrum ($CDCl_3$): δ 8.04 (s, 1H, formyl C*H*), 7.31–7.22 (m, 5H, benzyl C*H*), 3.66 (d, $J = 3.86$ Hz, 2H, benzyl CH_2), 3.48–2.38 (m, 12H, CH_2 tacn ring), 0.952 (dt, 6H, CH_3 isopropyl).

Acid hydrolysis of 1-benzyl-4-formyl-7-isopropyl-1,4,7-triazacyclononane (2.91 g, 10.1 mmol) and work-up as in the case of 1-ethyl-4-formyl-7-isopropyl-1-4-7-triazacyclononane gave the desired 1-benzyl-4-isopropyl-1,4,7-triazacyclononane as a yellow oil. Some of this product was used for coordination to copper(II), the rest being used for further derivatisation reactions. Yield of 1-benzyl-4-isopropyl-1,4,7-triazacyclononane (**L4**): 1.93 g, 73%. ^{1}H NMR spectrum (D_2O): δ 7.48 (m, 5H, benzylic), 3.97 (s, 2H, benzylic CH_2), 3.66–3.60 (m, 4H, tacn ring CH_2), 3.39–3.28 (m, 4H, tacn ring CH_2), 3.20–3.08 (m, 4H, tacn ring CH_2), 1.36–1.30 (m, 1H, ^{i}Pr C*H*), 1.30 (d, $J =$ 6.6 Hz, 6H, ^{i}Pr CH_3).

Reaction of 1-benzyl-4-isopropyl-1,4,7-triazacyclononane (1.00 g, 3.83 mmol) with a 1.5 molar equivalent of 3-bromopropylphthalimide, as described for **L1**, gave 1-(3-phthalimidopropyl)-4-benzyl-7-isopropyl-1,4,7-triazacyclononane as an orange/yellow oily solid. Yield: 1.65 g, 96%. Hydrolysis and work-up as described for 1-ethyl-4-formyl-7-isopropyl-1-4-7-triazacyclononane gave 1-(3-aminopropyl)-benzyl-7-isopropyl-1,4,7-triazacyclononane as a yellow-brown oil. This impure oil, containing *bis*(3-aminopropyl)-7-isopropyl-1,4,7-triazacyclononane (**L5**) as a side-product, was used in the synthesis of copper(II) complexes **C3** and **C4** (*vide infra*). In order to purify the ligand, this oil was then suspended in water and conc. HCl was added dropwise until no more white solid precipitated. Yield of **L3** · 4HCl: 0.83 g, 45%. ^{1}H NMR spectrum (D_2O): δ 7.34–7.18 (5H, m, benzylic C*H*), 3.64 (s, 2H, benzylic CH_2), 2.95–2.39 (m, 17H, tacn ring CH_2, amine arm CH_2 and ^{i}Pr C*H*), 1.06–0.95 (m, 2H, amine arm CH_2), 0.94 (d,

$J = 5.2$ Hz, 6H, ^{i}Pr CH_3). ESI mass spectrum (H_2O): $m/z = 319.3$ $[M + H]^+$.

2.4. [Cu(L1)Cl$_2$] · 1/2 H$_2$O (C1)

A 10 mL solution of $CuCl_2 \cdot 2H_2O$ (1.53 g, 9.04 mmol) in water was added to a solution of **L1** (1.60 g, 8.03 mmol) in 10 mL absolute ethanol, resulting in a pale green solution. Dropwise addition of 3 M NaOH to increase the pH to 9 caused the colour to deepen to royal blue, with precipitation of $Cu(OH)_2$. The solution was filtered, and the solvent removed under reduced pressure to yield a dark blue solid. Addition of absolute ethanol to this solid caused it to dissolve, affording a bright green solution with a white solid. The solution was filtered and diethyl ether diffused into it to afford dark green crystals of **C1**. Yield: 1.02 g, 33%.

Microanalysis Calc. for **C1**, $C_{11}H_{26}N_3O_{0.5}Cl_2Cu$: C, 38.5; H, 7.6; N, 12.3. Found: C, 38.2; H, 7.1; N, 12.6%. Selected IR bands (ATR) ν (cm^{-1}): 3227s, 2967s, 2920s, 2875s, 1644m, 1493m, 1451m, 1379m, 1352w, 1290w, 1165m, 1135m, 1101m, 1038m, 1024w, 958m, 888m, 827w, 744w. ESI mass spectrum (EtOH): $m/z = 297.3$ $[Cu(\mathbf{L1})Cl]^+$, 307.3 $[Cu(\mathbf{L1})(OEt)]^+$. UV–Vis spectrum (MeCN: λ_{max} (nm) [ε_{max}] ($M^{-1}\,cm^{-1}$)): 1110 [60], 799 [100], 685 [140], 350 [980], 298 [3600], 273 [4200], 216 [1300].

2.5. [Cu(L4)Cl$_2$] · 4H$_2$O (C2)

This complex was prepared in an analogous fashion to **C1**, starting from a solution of **L4** (1.22 g, 4.67 mmol) in 10 mL absolute ethanol and a solution of $CuCl_2 \cdot 2H_2O$ (0.87 g, 5.1 mmol in 10 mL of absolute ethanol). Vapor diffusion of ether into this solution afforded dark green crystals suitable for X-ray crystallography. Yield: 1.18 g, 64%.

Microanalysis Calc. for **C2**, $C_{16}H_{35}N_3O_4Cl_2Cu_2$: C, 36.4; H, 5.9; N, 8.0. Found: C, 36.5; H, 5.8; N, 8.5%. ESI mass spectrum (EtOH): $m/z = 323.3$ $[Cu(\mathbf{L4})]^+$, 369.3 $[Cu(\mathbf{L4})(OEt)]^+$, 279.2 $[Cu\mathbf{L4}(-^{i}Pr)]^+$. Selected IR bands (ATR) ν (cm^{-1}): 3404s br., 3202s br., 2967s, 2931s, 2874s, 1596s, 1490m, 1453s, 1367s, 1288m, 1129w, 1098w, 980w, 870w, 706m. UV–Vis spectrum (MeCN: λ_{max} (nm) [ε_{max}] ($M^{-1}\,cm^{-1}$)): 609 [140], 247 [5100].

2.6. [Cu(L3)(MeCN)](ClO$_4$)$_2$ (C3) and [Cu(L5)](ClO$_4$)$_2$ · MeCN · NaClO$_4$ (C4)

A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1.82 g, 4.94 mmol) in 10 mL H_2O was added dropwise to a solution of crude **L3** (1.43 g, 4.45 mmol) in 10 mL absolute ethanol, resulting in a pale blue solution. The pH was increased to 9 using 3 M NaOH solution, resulting in a darker blue solution. Any precipitated $Cu(OH)_2$ was removed via filtration, and the solution diluted to 1 L with water. The solution was loaded onto a Sephadex SP C25 column (Na^+ form) and then eluted with $NaClO_4$. A pale blue band of $[Cu(OH_2)_6]^{2+}$ eluted first, followed by a pale purple band (which upon concentration did not produce appreciable crystals). A royal blue band of $[Cu(\mathbf{L3})(MeCN)](ClO_4)_2$ eluted with 0.3–0.4 M $NaClO_4$ solution, followed by a further blue band of $[Cu(\mathbf{L5})](ClO_4)_2$ with 0.6 M $NaClO_4$. For each of the collected fractions, excess $NaClO_4$ was removed by successive concentrations of solvent, and removal of the precipitated sodium perchlorate. Blue crystals formed upon cooling when the solvent had been almost evaporated to dryness. These were dissolved in acetonitrile and ether diffused into the resulting solution, yielding royal blue crystals. These were collected at the pump and washed with ether, then air dried. Yield of **C3**: 0.95 g, 34%. Yield of **C4**: 0.59 g, 22%.

Microanalysis Calc. for **C3**, $C_{21}H_{37}N_5Cl_2O_8Cu$: C, 40.6; H, 6.0; N, 11.3. Found: C, 40.8; H, 5.9; N, 11.3%. ESI mass spectrum (H_2O): 409.3 $[Cu(\mathbf{L3})(OH)_2(ClO_4)]^+$. Selected IR bands (ATR) ν (cm^{-1}): 3274m, 2945m, 1587m, 1496m, 1456m, 1396w, 1352w, 1292m, 1051s br., 931m, 850w, 724m, 708m, 622m. UV–Vis spectrum (MeCN: λ_{max} (nm) [ε_{max}] ($M^{-1}\,cm^{-1}$)): 599 [90], 292 [4200].

Microanalysis Calc. for **C4**, $C_{17}H_{38}N_6Cl_3O_{12}CuNa$: C, 28.7; H, 5.4; N, 11.8. Found: C, 28.6; H, 5.6; N, 11.0%. ESI mass spectrum (H_2O/EtOH): $m/z = 347.0$ $[Cu(\mathbf{L5})]^+$. Selected IR bands (KBr) ν (cm^{-1}): 3480s, 3410s, 3230m, 2955m, 3920m, 1618s, 1460m, 1380m, 1086s br, 940m, 630m, 480m. UV–Vis spectrum (MeCN: λ_{max} (nm) [ε_{max}] ($M^{-1}\,cm^{-1}$)): 625 [70], 282 [3500].

2.7. [Cu(L2)Cl$_2$] · 1/2 H$_2$O (C5)

This complex was prepared in an analogous fashion to **C1**, starting from a solution of **L2** (2.55 g, 12 mmol) in 10 mL of absolute ethanol and a solution of $CuCl_2 \cdot 2H_2O$ (2.24 g, 13.0 mmol) in 10 mL of water. Yield: 2.20 g, 54%.

Microanalysis Calc. for **C5**, $C_{12}H_{28}N_3O_{0.50}Cl_2Cu$: C, 40.4; H, 7.9; N, 11.8. Found: C, 40.1; H, 7.7; N, 11.8%. ESI mass spectrum (MeOH/formic acid): $m/z = 321.2$ $[(Cu(\mathbf{L2}))(\mu\text{-}Cl)_2(Cu(\mathbf{L2}))(OH_2)]^{2+}$. Selected IR bands (ATR) ν (cm^{-1}): 3480m br., 3230s br., 2963s, 2873s, 1636w br., 1492m, 1454s, 1385m, 1289w, 1163w, 1133w, 1098m, 1057m, 1014m, 977m, 910w, 826w, 719w. UV–Vis spectrum (MeCN: λ_{max} (nm) [ε_{max}] ($M^{-1}\,cm^{-1}$)): 1110 [68], 802 [103], 686 [153], 351 [1000], 297 [3700], 275 [4100].

2.8. Kinetic studies

The rate of cleavage of *bis*(*p*-nitrophenyl)phosphate (BNPP) by the Cu(II) complexes was measured at pH 7.4 (MOPS buffer) and $T = 50$ °C by following the formation of *p*-nitrophenylate ion in a solution containing 15 μM BNPP, 1 mM Cu(II) complex and $I = 0.15$ M ($NaClO_4$). The experimental procedure and data analysis has been described in detail elsewhere [25,32]. Briefly, in each experiment, a solution of the Cu(II) complex (3 mM, 1 mL) and buffer MOPS (pH 7.4, $T = 50$ °C, $I = 0.382$ M, 1 mL) were placed into a 1 cm cuvette, the cuvette stoppered with a Teflon stopper was inverted to allow the solutions to mix.

The solution temperature was allowed to come to equilibrium (10 min) before the solution of BNPP (0.045 mM, 1 mL) was added to the cuvette. The release of *p*-nitrophenylate from BNPP was followed by monitoring the formation of the *p*-nitrophenylate ion ($\lambda_{max} = 400$ nm, $\varepsilon_{max} = 18\,700\ M^{-1}cm^{-1}$) [35] at 400 nm on a Varian Cary 300 spectrophotometer. Absorbance measurements were commenced after 2 min and were continued for 8000 min with a reading taken every 5 min. As the complex was in large excess compared to BNPP, for complexes **C1**, **C2** and **C5** the appearance of NP (and cleavage of BNPP) was modelled as a first order process $Abs = A + Be^{-k_{obs}t}$, as done in these previous studies [25,32]. These reactions were followed for at least three-half lives and excellent fits to the data were obtained as indicated by the low errors in the first order rate constants. For the complex **C3**, the extremely slow reaction was followed for 5–10% conversion of BNPP and the variation in absorbance with time appeared to be linear. In this case, the initial rates method, applied by Burstyn et al. [26] was used to determine the initial rate constants, which were then converted to first order rate constants.

2.9. Crystal structure determinations

Intensity data for a dark green crystal of **C1** (0.21 × 0.20 × 0.17 mm), a dark green crystal of **C2** (0.75 × 0.65 × 0.20 mm), a royal blue crystal of **C3** (0.19 × 0.18 × 0.15 mm) and dark blue crystal of **C4** (0.31 × 0.27 × 0.19 mm) were measured at 123 K on a Nonius Kappa CCD fitted with graphite-monochromated Mo Kα radiation (0.71073 Å). The data were collected to a maximum 2θ value of 55° and processed using the Nonius software. Crystal parameters and details of the data collection and refinement for **C1**–**C4** are summarised in Table 1.

Each structure was solved by direct methods and expanded using standard Fourier routines in the SHELX-97 software package [36,37]. All non-hydrogen atoms were refined anisotropically and all hydrogen atoms were placed and refined in idealised positions. The structure of **C1** had a small disorder on one of the isopropyl pendant arms of the complex cations in the ASU, consequently C(20) and C(22) were modeled as half occupancy. For **C4**, there was a 11% disorder of the complex cation, with it residing in another position. The site occupancies of the two components were refined against each other and the disorder was successfully modeled, with the bond lengths and angles of the 11% part restricted with the SAME restriction to the 89% part, also all the isotropic displacement parameters of the 11% part were assumed to be similar and the SIMU restriction was placed upon them. The anisotropically refined Cu1′ (11% disordered copper) also had an isotropic restriction placed upon it. The other atoms in the 11% disordered part were refined isotropically (see Table 2).

3. Results and discussion

Despite the higher activities of $[Cu(Me_3tacn)(OH_2)_2]^{2+}$ and $[Cu(^iPr_3tacn)(OH_2)_2]^{2+}$ in affecting phosphate ester hydrolysis when compared to the non-substituted analogue, $[Cu(tacn)(OH_2)_2]^{2+}$ [25,32,26], little attention has been paid thus far to examining the activity of further copper(II) complexes of substituted tacn ligands, particularly those of the asymmetrically-functionalised kind. We thus set out in this study to prepare a series of new tacn derivatives, incorporating alkyl, aryl and amine pendant groups, in order to elucidate the structure–activity relationship between the type and degree of *N*-alkylation of the tacn ligand and the ability of its corresponding copper complex to perform phosphate ester bond scission.

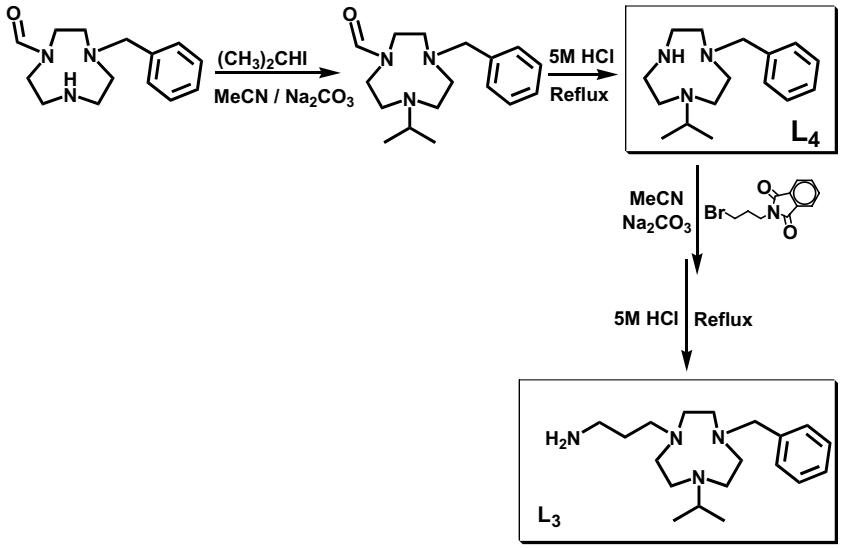
Ligands **L1** and **L2** were prepared using a standard procedure from the respective amidinium salts (Scheme 1), which were available from a previous study [34]. The synthesis of **L3**–**L5** used 1-benzyl-4-formyl-1,4,7-triazacyclononane as starting material [18]. This was reacted with 2-iodopropane to give 1-benzyl-4-formyl-7-isopropyl-1,4,7-triazacyclononane. Acid hydrolysis of this product then gave **L4**. Further reaction with 3-bromopropylphthalimide, followed by acid hydrolysis, yielded **L3** (Scheme 2), which could be isolated in pure form as its hydrochloride salt. The products were obtained in good yields and all returned satisfactory spectroscopic data (see Section 2). **L5** was found to be an impurity in the crude oil from which **L3** was obtained.



Copper(II) complexes of ligands **L1**–**L5** (see Fig. 2) were formed by reacting the ligands (usually dissolved in ethanol) with an aqueous or alcohol solution of a copper(II) salt and adjustment of the pH to ~9. In some cases the complexes were isolated directly from solution (**C1**, **C2** and **C5**), while in other cases purification by cation-exchange chromatography was necessary prior to isolation of the products as their perchlorate salts. In the case of the preparation of the Cu(II) complex of **L3** from a batch of crude ligand, cation exchange chromatography yielded two copper(II) complexes, corresponding to **C3** and **C4**. The formation of **C4** can only have occurred as a result of partial loss of the benzylic side arm from the 1-benzyl-4-formyl-1,4,7-triazacyclononane intermediate formed during the synthesis of **L3**. We have recently reported a crystallographic and kinetic study on the hydrolysis of tacn amidinium salts in water to their corresponding formyl derivatives, which indicated faster rates of hydrolysis for salts containing the benzyl group [34].

3.1. Crystal structure determinations

The asymmetric unit of **C1** contains two molecules, both of the composition [Cu**L2**Cl_2] and both featuring

Scheme 1. Synthetic route to L_1 and L_2.

Scheme 2. Synthetic route to **L3**–**L4**.

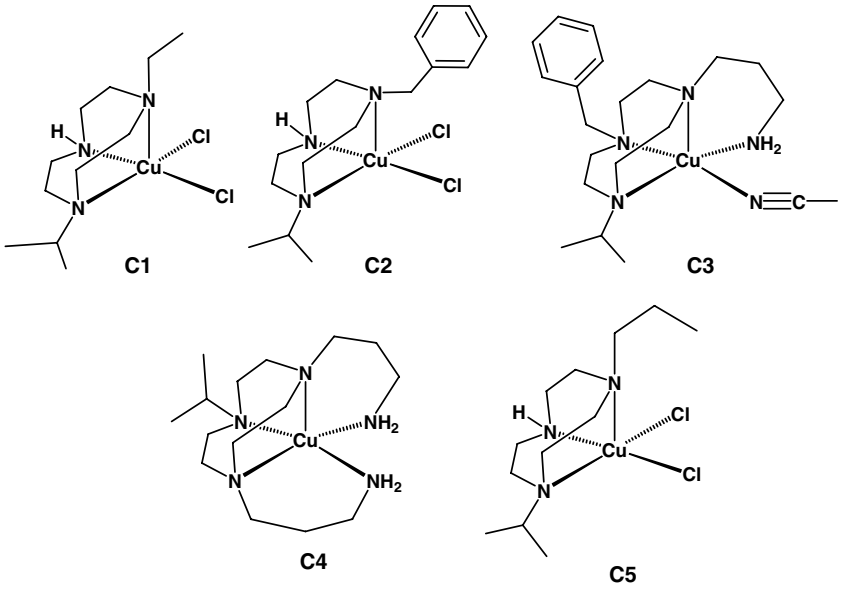


Fig. 2. Copper(II) complexes of asymmetrically-functionalised tacn ligands reported herein.

square-planar CuN_3Cl_2 coordination polyhedra, with the tacn ring facially coordinating the copper(II) centre in a tridentate manner. One of the complex units is distinguished by the fact that the ethyl and isopropyl arms are disordered between two locations (50% occupancy) (Fig. 3). As a consequence, atoms C(20) and C(22) have each been modeled with 50% occupancy. In the figure, the two complexes are discriminated by the labels 'A' and 'B' for the ordered and disordered complexes, respectively. The basal plane coordination environments (defined by two amine donors of the macrocycle and the two chloro ligands) are identical for both complex units, however the mean deviation from the least-squares basal plane in complex A is significantly lower than that of complex B (0.0949 and 0.2119 Å, respectively). The apex of the square-pyramid is occupied by a tertiary nitrogen in each case (involving the ethyl pendant in complex A and the disordered ethyl/isopropyl arm in complex B), with the Cu–N(apical) bond distances being 2.227(5) and 2.234(4) Å for complexes A and B, respectively (Table 3). The complex units exhibit the usual distortion from idealised square planar geometry found for tacn complexes, with all the N–Cu–N angles lying well below 90°, as a result of the constraints imposed by the tridentate coordination mode of the tacn ring. This distortion is evident from the value of the geometric parameter, $\tau = 0.12$, used by Addison et al. [38] to measure the degree of distortion from ideal square-pyramidal geometry ($\tau = 0$) towards trigonal bipyramidal geometry ($\tau = 1$). Adjacent molecular units in the crystal lattice of **C1** are paired up in a "head-to-head" arrangement (Fig. 4), due to two intermolecular

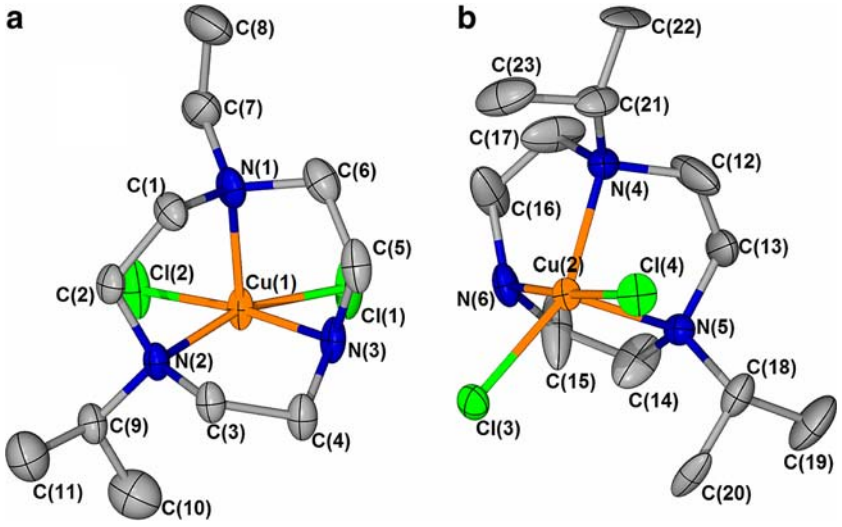

Fig. 3. Thermal ellipsoid plot of the asymmetric unit of **C1**, with ellipsoids drawn at the 50% probability level. The alkyl substituents in molecule 'B' are disordered over two locations (50% occupancy).

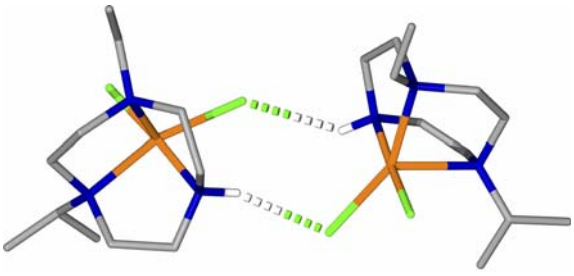

Fig. 4. Stick representation of the hydrogen bonding in **C1** (view down *b* axis).

hydrogen bonding interactions (N(3)–H(3)...Cl(3): 3.234(4) Å, 145.1°; Cl(1)...(H6)–N(6): 3.345(5) Å, 142.1°) (see Table 4).

As for **C1**, an X-ray crystal structure determination of **C2** established that the distorted square-pyramidal copper(II) coordination sphere of the neutral complex is occupied by three amine donors from the macrocycle, which are located on a triangular face of the polyhedron, and two chloride ligands (Fig. 5). There is a distortion from ideal square-pyramidal geometry with $\tau = 0.09$. Within the base of the square-pyramidal coordination sphere, the N(1)–Cu(1)–N(2) bond angle is 81.8(2)°, the contraction resulting from the 5-membered chelate ring, while the Cl(1)–Cu(1)–Cl(2) angle is slightly larger than expected (92.44(5)°). The deviation of the copper centre from the least-squares basal plane (defined by the atoms N(1), N(2), Cu(1), Cl(1) and Cl(2)) towards the apical nitrogen (N(3)) is 0.2505 Å. The apical position is occupied by the nitrogen bearing the isopropyl group, the Cu(1)–N(3) bond

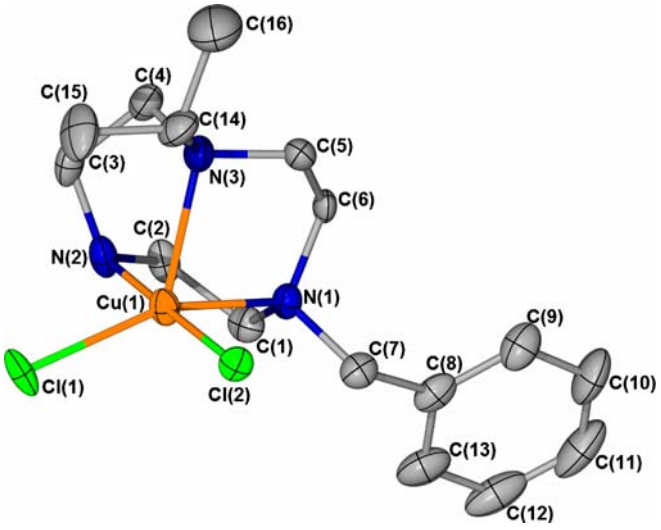

Fig. 5. Thermal ellipsoid plot of **C2**, thermal ellipsoids drawn at the 50% probability level.

length being 2.281(5) Å. All other bond lengths are within the expected ranges, and are detailed in Table 3. Pairs of hydrogen bonds occur between adjacent molecules in the crystal lattice of **C2** (N(2)–H(2)...Cl(1)* and N(2)*–H(2)*...Cl(1), with heteroatom-to-heteroatom distances of 3.317(5) Å, * denoting the symmetry operator ($-x$, $1-y$, $-z$)). This is depicted in Fig. 6, which shows the head-to-head arrangement of the molecules in the crystal lattice.

In the crystal structure of **C3**, shown in Fig. 7, the asymmetric unit consists of a cationic copper complex and two perchlorate anions that balance the charge. The distorted square-pyramidal coordination sphere consists of five nitrogen donors, three from the facially coordinating tacn ring, one from the pendant aminopropyl arm and one from an *N*-coordinated acetonitrile molecule. In this case, the apex of the square-pyramid is occupied by the amine bearing the benzyl arm, with a Cu(1)–N(1) distance of 2.21(1) Å. All other bond lengths and angles are within the expected range. The out-of-plane distance of the copper centre from the least-squares basal plane defined by N(2), N(3), N(4) and N(5) (0.072 Å) is less than in **C2** (0.2505 Å), most likely due to the presence of the N donor atom from the acetonitrile molecule in place of the larger

Table 4
Selected bond lengths (Å) and angles (°) for **C3** (esd values in parentheses)

Cu(1)–N(4)	2.008(2)	N(4)–Cu(1)–N(5)	85.2(1)

chloro group. The six-membered ring defined by the aminopropyl arm coordinating to the copper centre is in a chair-like conformation. The degree of distortion from ideal square-pyramidal geometry about metal centre is given by the parameter $\tau = 0.18$. Within the crystal lattice, there are hydrogen bonds formed between the amino group of the aminopropyl pendant and neighbouring perchlorate anions (N(4)–H(36)...O(8): 2.971(4) Å, 143.2°; N(4)–H(37)...O(2): 3.129(3) Å, 158.6°) (Fig. 8).

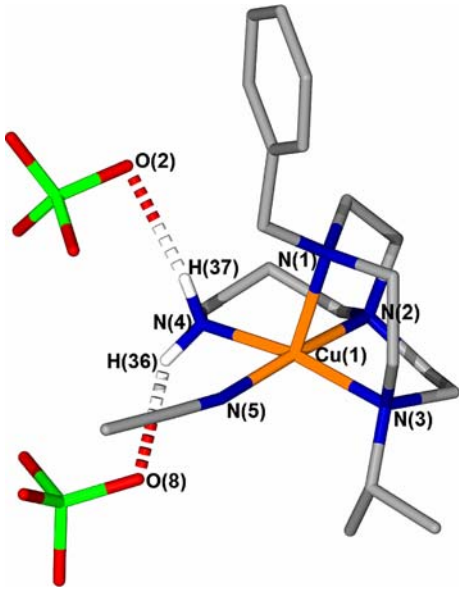

Fig. 8. Stick representation of the H-bonding in **C3**.

The asymmetric unit of **C4** (Fig. 9) contains a square-pyramidal Cu(II) complex in which the Cu(II) coordination sphere is occupied by five nitrogen donors, three from the tacn ring and two from the two aminopropyl pendant groups, i.e., in contrast to **C1**–**C3**, all the sites in the coordination sphere are occupied by the ligand. The divalent cation charge is balanced by two perchlorate anions. As with **C3**, the chelate rings involving the aminopropyl arms adopt a chair conformation. The apex of the square-pyramid is occupied by the tacn nitrogen atom bearing the isopropyl pendant, giving a very long Cu(1)–N(1) bond length of 2.37(1) Å (see Table 5). The degree of deviation from ideal square-pyramidal geometry for this complex is the largest of the complexes reported in this study ($\tau = 0.2$). As in **C3**, hydrogen bonding occurs, between the amino groups of the aminopropyl pendants and the oxygens located on the perchlorate anions (see Table 6 and Fig. 10).

3.2. Phosphate ester cleavage studies

The established ability of the copper(II) complexes of the trialkylated tacn ligands, Me_3TACN and $^iPr_3TACN$ [32,26], to effectively cleave phosphate esters prompted us to explore the cleavage characteristics of the complexes reported herein. The complexes were examined for their ability to cleave BNPP, a model phosphate ester whose cleavage releases the *p*-nitrophenolate ion, a chromophore which absorbs strongly at 400 nm. As indicated in the experimental section, the rates of BNPP hydrolysis were estimated from plots of absorbance versus time following the procedure elaborated in the literature by Burstyn et al. [25] and Fry et al. [27]. Four of the copper(II) complexes (**C4** being the exception) demonstrated some ability to hydrolyse BNPP (Table 7). However, the rate of appearance of NP varied from complex to complex and indicated that some complexes were more efficient at accelerating BNPP cleavage than others.

A mechanism for the hydrolytic cleavage of phosphate esters by Cu(II) complexes has been proposed by Burstyn and co-workers (Scheme 3) [30]. According to this mechanism, for a complex to be active (in its monomeric form) it needs to possess one aqua ligand that can be deprotonated to generate a coordinated hydroxyl nucleophile, as well as at least one weakly binding ligand that can be displaced by the phosphate ester to enable substrate binding. This hypothesis is consistent with the observed BNPP hydrolysis rate constants for complexes **C1**–**C5** (Table 7). In complexes **C3** and **C4**, four or five of the coordination sites about the square-pyramidal copper centre (a common geometry for Cu(II) complexes of such ligands) are occupied by the supporting tacn-type ligand. This leaves only one site for the binding of either the phosphate ester substrate or a metal-bound hydroxo group in **C3**, and none in the case of **C4** (see Section 2.9). As a consequence, for these complexes there is no possibility for *intra*molecular attack of a metal-bound hydroxo group on a coordinated phosphate ester, and therefore they are inactive or poorly active.

Scheme 3. Mechanism for the cleavage of BNPP by Cu(II) tacn-type complexes [30].

In contrast to the case for **C3** and **C4**, the aqua complexes formed from **C1, C2** and **C5** were found to significantly accelerate the rate of BNPP hydrolysis, with observed rate constants within 10-fold of those reported for the Cu(II)–Me_3TACN and Cu(II)–$^iPr_3TACN$ complexes. Burstyn and co-workers have suggested that the enhanced hydrolytic activities of these latter complexes relative to the Cu(II) complex of tacn might be due to the three alkyl substituents hindering dimerisation of monomeric aquo forms of the complexes in solution to produce hydrolytically-inactive species (see Scheme 3). Our results suggest that the attachment of only two substituents to the tacn ring is sufficient to significantly suppress such

dimerisation, leading to enhanced rates of BNPP hydrolysis relative to that of the parent Cu(II)-tacn complex. Complex **C2**, incorporating a benzyl group, displayed the fastest rate under the screening conditions. This is consistent with results from our previous work, which showed that the copper(II) complex of 1,4,7-*tris*(3-cyanobenzyl)-1,4,7-triazacyclononane is the fastest monomeric copper(II)-based tacn system for phosphate ester cleavage [22]. The benzyl group may be the most effective at sterically inhibiting the formation of inactive dihydroxo-bridged dimeric species in solution. It may also contribute to substrate binding via hydrophobic interactions with the aromatic rings of BNPP.

In addition to steric effects, the lower rate constants observed for **C1** and **C2** relative to that of the Cu(II)-Me_3tacn complex could also be due partly to electronic effects. It has been shown that the pK_a of the coordinated water in $[LCu(OH_2)_2]^{2+}$ (L = tacn, Me_3tacn, $^iPr_3$tacn) increases on progressing from the native tacn ligand to the Me_3tacn and $^iPr_3$tacn analogues, and that pK_{dim} (dimerisation constant) decreases similarly [32]. The lowering in the pK_a could be due to the poorer binding ability of the bulky tertiary nitrogens, which cause the metal centre to coordinate water more strongly. The observed decrease in pK_a, and hence in pK_{dim}, would lead to an increase in observed rate constant. In the case of **C1** and **C2**, the presence of a secondary nitrogen could result in slightly higher pK_a and pK_{dim} values, leading to a slightly higher concentration of inactive species of complex at the pH of the BNPP hydrolysis reaction.

4. Conclusion

A series of new asymmetrically *N*-substituted tacn ligands were synthesised and used to prepare the corresponding copper(II) complexes. These complexes were structurally characterised via X-ray crystallography, confirming that the Cu(II) centres reside in square-pyramidal geometries, with one face of the coordination polyhedron occupied by the three nitrogen donors from the tacn ring. This structural information was then used to rationalise the ability to of these complexes carry out hydrolysis on a model phosphodiester (BNPP). The copper(II) complexes of the disubstituted ligands, 1-benzyl-4-isopropyl-1,4,7-triazacyclononane (**L4**) and 1-ethyl-4-isopropyl-1,4,7-triazacyclononane (**L1**), were found to exhibit the fastest rates of hydrolysis at near physiological conditions ($k = 1.5 \times 10^{-5}\ s^{-1}$ and $1.4 \times 10^{-5}\ s^{-1}$, respectively). These rates are only three times slower than those found for the copper complexes of Me_3tacn and $^iPr_3$tacn. This level of hydrolytic activity is encouraging, since disubstituted ligands are ideal candidates for attachment, via the sole remaining secondary amine, to oligonucleotides and peptides targeting specific biomolecules. The resultant bioconjugates could then be used to selectively cleave these biomolecules, leading to new therapeutic agents for the treatment of various diseases.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC # 604324 for **C1**, 604325 for **C2**, 604326 for **C3**, and 604327 for **C4**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Abstract

Three-dimensional photonic crystals made of close-packed polymethylmethacrylate (PMMA) spheres or air spheres in silica, titania and ceria matrices have been fabricated and characterized using SEM, XRD, Raman spectroscopy and UV–Vis transmittance measurements. The PMMA colloidal crystals (opals) were grown by self-assembly from aqueous suspensions of monodisperse PMMA spheres with diameters between 280 and 415 nm. SEM confirmed the PMMA spheres crystallized uniformly in a face-centred cubic (fcc) array, and UV–Vis measurements show that the colloidal crystals possess pseudo photonic band gaps in the visible and near-IR regions. Inverse opals were prepared by depositing silica (SiO_2), titania (TiO_2) or ceria (CeO_2) in the voids of the PMMA colloidal crystals using sol-gel procedures, then calcining the resulting structure at 550 °C to remove the polymer template. The resulting macroporous materials showed fcc ordering of air spheres separated by thin frameworks of amorphous silica, nanocrystalline titania or nanocrystalline ceria particles, respectively. Optical measurements confirmed the photonic nature of the inverse opal arrays. UV–Vis data collected for the opals and inverse opals obeyed a modified Bragg's law expression that considers both diffraction and refraction of light by the photonic crystal architectures. The versatility of the colloidal crystal template approach for the fabrication of macroporous oxide structures is demonstrated.

1. Introduction

Photonic crystals are highly ordered materials that possess a periodically modulated dielectric constant, with periods on the scale of visible light wavelengths (380–750 nm). Periodicity affects the propagation of electromagnetic waves in the material due to Bragg reflections on lattice planes. The result is a photonic band gap (PBG or stop band), a band of frequencies where light propagation in the photonic crystal is forbidden (the optical analogue of electronic band gaps in semiconductors). A complete photonic band gap occurs when a range of wavelengths is forbidden for every state of polarization and propagation direction [1]. Ever since Yablonovitch [2] and John [3] first demonstrated the possibility of a photonic band gap in such periodic structures, there has been determined effort from the scientific community to develop materials with complete photonic band gaps in various optical regimes and in particular in the visible region [4]. Complete photonic band gap materials could potentially be used to produce waveguides, laser resonant cavities, or to inhibit spontaneous emission [5]. Before their full potential can be realized, improved methods for the fabrication of highly ordered three-dimensional photonic crystals must be developed.

Experimentalists have traditionally used two approaches to fabricate photonic crystals: nanolithography and self-assembly of colloidal crystals. Engineers have used nanolithography (the so-called "top-down" approach) to etch

successively smaller features into various solid substrates with remarkable precision [6,7]. However, this method is expensive, slow and capable only of producing materials of a few structural layers thickness. The self-assembly of colloidal crystals (the so-called "bottom-up" approach) is the more preferred route as it is simpler, inexpensive and can yield crystalline samples of a few to several hundred structural layers thickness [8,9]. This approach involves the crystallization of a colloidal dispersion of monodisperse spheres of silica, polystyrene or polymethylmethacrylate (PMMA) to form a material with a three-dimensional periodic structure in which 24% of the volume is air (a colloidal crystal or opal). Natural opal is an example of such a periodic colloidal crystal, and is composed of face-centred cubic (fcc) arrays of monodisperse amorphous silica spheres with average diameter in the range 15–900 nm. Theoretical [2,3,10–13] and experimental [8,9] studies have shown that a pseudo photonic band gap exists in the [1 1 1] direction for fcc arrangements of silica or polymer spheres. These opals do not possess a complete photonic band gap, since the band gap position, and hence frequencies of light allowed to propagate within the crystal, vary with the angle of incidence of incoming photons. Most of the technological applications envisaged for photonic crystals require materials that possess a complete photonic band gap. Theoretical requirements to achieve a complete band gap in opaline structures include a refractive index contrast higher than 2.9 and long range three-dimensional crystalline order (see above). The refractive index ratios for colloidal crystals of silica ($n_{silica}/n_{air} = 1.45$), polystyrene ($n_{PS}/n_{air} = 1.59$) and PMMA ($n_{PMMA}/n_{air} = 1.492$) are all well below the value of 2.9 needed for the realization of a full gap, thus they exhibit only pseudo photonic band gaps. A complete PBG is more easily achievable in materials with inverse opal structures, comprising fcc arrays of air spheres in materials with high refractive indices (e.g. Si $n = 3.5$ or Ge $n = 4.5$). The filling fraction of the dielectric in such structures is around 26%. A silicon inverse opal with a complete three-dimensional PBG at 1460 nm has been demonstrated [14]. Inverse opal structures can readily be fabricated from colloidal crystal (opal) templates, by filling the voids in the opal with a dielectric material, and then removing the original opal template by wet chemical etching in the case of SiO_2 or calcination in the case of polymer spheres [9]. The failure to date of researchers to realize a complete PBG in systems other than silicon is due to experimental difficulties in fabricating inverse opals with a large enough refractive index contrast and the required degree of crystalline order.

Macroporous oxides fabricated using the colloidal crystal template approach may also prove useful in other areas of materials science. Recently, dye-sensitized solar cells of the Grätzel type, based on inverse opal TiO_2 films, have been developed [15–17]. The cells show improved power conversion efficiency under simulated solar light compared to Grätzel cells prepared by conventional methods using nanocrystalline titania particles. The improved performance is attributed to the inherent uniformity and macroporosity of inverse opal TiO_2 architectures. Efficiencies could be further improved if technical difficulties related to the fabrication of inverse opal TiO_2 films with uniform thickness and large area could be overcome. The combination of high surface area and macroporosity (hence facile gas flux) suggest that inverse opal structures may also be useful in the field of heterogeneous catalysis [18–20]. It is envisaged that the colloidal crystal template approach could be used to fabricate highly efficient TiO_2 photocatalysts or CeO_2-based catalysts for CO oxidation, the water-gas shift reaction (WGS), the reforming of hydrocarbons and the partial oxidation of methane. To our knowledge, only one previous study of inverse opal ceria has appeared in the literature [21] justifying further research in this area.

In view of the discussion above, we have commenced a comprehensive programme aimed at the fabrication opal and inverse opal thin films with ordered structure extending over large areas. Here we describe the synthesis and characterization of PMMA colloidal crystals (opals) with long range three-dimensional order, and then show how the colloidal crystals can be used as templates for the fabrication of macroporous SiO_2, TiO_2 and CeO_2 structures (inverse opals) possessing comparable order and strong photonic behaviour in the visible and near-IR regions.

2. Experimental

2.1. General

Methyl methacrylate (MMA, 99%), 2,2′-azobis(2-methylpropionamidine) dihydrochloride (97%), tetraethylorthosilicate (TEOS, 98%), titanium (IV) isopropoxide (97%), concentrated HCl (37% in water), $Ce(NO_3)_3 \cdot 6H_2O$ (99%), hexamethylenetetramine (99%), TiO_2 powder (99%, anatase form) and CeO_2 powder (99.9%, <5 μm) were all obtained from Aldrich and used without further purification. CeO_2 nanoparticles were prepared from $Ce(NO_3)_3 \cdot 6H_2O$ and hexamethylenetetramine using a literature procedure [22]. The CeO_2(1 1 1) single crystal was obtained from Commercial Crystal Laboratories Inc. (USA).

2.2. Synthesis of polymethylmethacrylate spheres

Batches of monodisperse PMMA spheres with diameters between 280 and 415 nm were prepared by the method of Schroden et al. [9]. The size of the PMMA spheres produced using this method is highly dependent on the composition of the synthesis mixture and the reaction temperature (see Section 3.1). Syntheses were carried out in a 5-necked round-bottomed flask (3 L volume), fitted with a mechanical stirrer (glass shaft with Teflon stirrer blade), thermometer, water-cooled reflux condenser, nitrogen bubbler and a glass quickfit stopper. The procedure used is outlined below. Milli Q water (1.6 L) and methyl methacrylate (MMA, 200–400 mL) were added to the 5-necked round-bottomed flask.

Nitrogen gas was then slowly bubbled through the resulting two-phase system and vigorous mechanical stirring of the mixture commenced. The mixture was then heated to either 70, 75 or 80 °C, whereupon 2,2′-azobis(2-methylpropionamidine) dihydrochloride (0.75–3 g) was added as an azo initiator and polymerisation of the MMA commenced. The temperature of the reaction mixture increased initially on introduction of the initiator, but then stabilized after approximately 30 min. After stabilization, the reaction mixture was maintained at the initial temperature of either 70, 75 or 80 °C for 2 h. Heating was then discontinued, and the reaction mixture allowed to cool to room temperature over 3–4 h under a nitrogen purge. The resulting colloidal suspensions of PMMA spheres were then filtered through a glass wool plug to remove any large agglomerates and then stored in PET plastic bottles for later use.

2.3. Colloidal crystal preparation

Colloidal crystals of PMMA spheres were fabricated by three methods. Several preparation methods were used in order to determine which method afforded colloidal crystals of the best quality.

(1) *Gravitational sedimentation*: PMMA colloidal suspensions (typically 50 mL) were left in open glass beakers at 25 °C. After 3–5 weeks, water in the colloidal suspensions evaporated to leave well-ordered PMMA photonic crystals. The colloidal crystals were then left to dry in air at 25 °C for a further 1–2 weeks.
(2) *Centrifugation*: PMMA colloidal suspensions were loaded into 50 mL plastic falcon tubes, then centrifuged at 1500 rpm (rcf 369) and 10 °C for 24 h. The supernatant was then carefully removed by decantation, and the colloidal crystals left to dry in air at 25 °C for 1–2 weeks.
(3) *A flow-controlled vertical deposition method* [23,24]: This method was used to deposit thin PMMA colloidal crystals on glass microscope slides for UV–Vis transmittance measurements. Briefly, a colloidal suspension of PMMA spheres was prepared (200 mL, 1–10 wt% PMMA in H_2O) and ultrasonicated for 1 h to break up any agglomerated particles. The colloidal suspension was then poured into a clean glass beaker. Several pre-cleaned glass microscope slides were immersed vertically in the colloidal suspension, after which a peristaltic pump was used to remove the colloidal suspension (pump rate about 0.2 mL min^{-1}). As the liquid level in the beaker decreased, a thin colloidal crystal layer was deposited on the glass slide. This technique proved very effective for uniformly covering large areas. Film thickness could be varied by changing the concentration of PMMA in the colloidal suspension or by changing the pump speed. The 3D colloidal crystals were dried in air for 1–2 weeks before optical measurements.

2.4. Inverse opal preparation

Inverse opals of were prepared by filling the voids in PMMA colloidal crystal templates with SiO_2 or TiO_2 sol-gel precursors, or CeO_2 nanoparticles, then carefully calcining the resulting composite structure to remove the PMMA template. Filling of the voids in the colloidal crystal template was achieved using vacuum assisted infiltration of a sol-gel precursor. Briefly, PMMA colloidal crystals (10 g) prepared by gravitational sedimentation or centrifugation were lightly crushed with a metal spatula to give fractured pieces of size <2 mm, which were then deposited in a thin layer on filter paper in a Büchner funnel. With a strong vacuum applied to the Büchner funnel, a solution of either silica precursor (6 mL TEOS, 4 mL Abs. EtOH, 3 mL H_2O and 1 mL conc. HCl), titania precursor (6 mL titanium (IV) isopropoxide and 6 mL Abs. EtOH) or ceria nanoparticles (12 nm diameter, 10 wt% in ethanol) was applied dropwise over the surface of the PMMA layer. Infiltrated samples were then left to dry in air at 25 °C for 24 h. PMMA templates were then removed by calcination in air using the following protocol; samples were ramped from 25 to 300 °C at 2 °C min^{-1}; held at 300 °C for 5 h; then ramped from 300 to 550 °C at 2 °C min^{-1}; held at 550 °C for 12 h; then finally allowed to cool to room temperature over 3–4 h. The resulting products all displayed strong opalescence under incident light.

For UV–Vis measurements, inverse opals of SiO_2 were prepared from thin film PMMA colloidal crystals grown on glass microscope slides using the flow-controlled vertical deposition method. PMMA templates were infiltrated by carefully placing a few drops of a silica precursor (6 mL TEOS, 4 mL Abs. EtOH, 3 mL H_2O and 1 mL conc. HCl) on each edge of the colloidal crystal. Capillary forces quickly drew the sol-gel mixture into the voids in the PMMA template. The infiltrated crystal was then aged for 24 h under ambient conditions, and then calcined in accordance with procedure described above.

2.5. Product characterization

2.5.1. Particle size determination

PMMA sphere size and polydispersity were determined by dynamic light scattering on a Zetasizer Nano ZS (Malvern Instruments Limited). PMMA colloidal suspensions were diluted approximately 1000-fold with Milli Q water before measurements.

2.5.2. SEM

Opal and inverse opal morphologies were examined using a Philips XL-30 field emission gun scanning electron microscope (FEGSEM). All micrographs were collected at an electron gun accelerating voltage of 5 kV. Specimens were mounted on black carbon tape and platinum sputter coated for analysis.

2.5.3. UV–Vis

UV–Vis transmittance spectra were recorded over the range 200–1000 nm on Shimadzu U-3101PC spectrophotometer, equipped with a custom-built sample holder for angle-resolved UV–Vis measurements.

2.5.4. XRD

Powder X-ray diffraction patterns were acquired using a Philips PW-1130 diffractometer, equipped with a Cu anode X-ray tube and curved graphite filter monochromator. XRD data were collected at room temperature, using monochromatised Cu Kα X-rays ($\lambda = 1.5418$ Å). Additional acquisition parameters were: 2θ range, 2–90°; step size, 0.02°; and scan rate, 2° min^{-1}. Diffraction patterns were referenced against the JCPDS database for sample identification.

2.5.5. Raman

Raman spectra were taken on a Renishaw RM-2 Raman microscope system, fitted with an Olympus 20× objective lens. Raman spectra were excited using 785 nm radiation from a diode laser, and scattered light collected in the 180° backscattering sampling geometry. The laser power at the sample for data collection was ~5 mW. Spectra were collected over the range 200–2000 cm^{-1} and at a resolution of ca. 2 cm^{-1}.

3. Results and discussion

3.1. Synthesis of monodisperse PMMA spheres

The optical quality of colloidal crystals (opals) and their inverted structures is highly dependent on the size uniformity of the spheres used to fabricate the colloidal crystal. In this study, uniformly sized PMMA spheres where fabricated by the free radical induced polymerization of MMA in water. Table 1 shows the effect of synthesis conditions on the size and polydispersity of the PMMA spheres obtained by this method.

Results show that the reaction parameters can be adjusted to produce PMMA spheres of average size, Z_D, from 280 to 415 nm. Small spheres are prepared by using less MMA, higher temperatures or more azo initiator. Conversely, large spheres are obtained by using more MMA, lower temperatures or less azo initiator. The polydispersity of the preparations may be gauged from two indices; the polydispersity index (PDI) which measures width of the particle size distribution (the relative variance in the particle size)

$$\mathrm{PDI} = \frac{\sigma^2}{Z_D^2} \tag{1}$$

and the % polydispersity (%Pd) which measures the coefficient of variation

$$\%\mathrm{PD} = \sqrt{\mathrm{PDI}} \times 100. \tag{2}$$

As a rule of thumb, samples with PDI <0.04 and thus %PD <20% are considered to be monodisperse. From the PDI and %PD values given in Table 1, it is apparent that each PMMA sphere preparation is monodisperse and thus suitable for colloidal crystal construction.

3.2. Fabrication and characterization of PMMA colloidal crystals (opals)

PMMA colloidal crystals (opals) were fabricated by three different methods in order to determine that which afforded the best quality three-dimensional structures. Methods used were gravitational sedimentation, centrifugation and a flow-controlled vertical deposition method (see Section 2.3 for details). All three methods produced high quality colloidal crystals, as determined by SEM and evidenced by the visual colour play of the prepared samples under incident white light. We conclude that preparation method had little effect on the quality of PMMA colloidal crystals, at least for the three methods used here. On account of their shorter fabrication time, centrifugation and the flow-controlled vertical deposition method are preferred.

Fig. 1 shows SEM micrographs for PMMA colloidal crystals deposited on glass microscope slides using the flow-controlled vertical deposition method. Three different PMMA sphere preparations were used to fabricate the colloidal crystals shown in the images. In all cases, close-packed arrays of PMMA spheres are observed, whose (1 1 1) planes are parallel to the underlying substrate. Interestingly, the images show necking of the spheres to their nearest neighbours. Fig. 1f shows the arrangement of spheres in the underlying layer, and clearly demonstrates the close-packed nature of the packing. Sphere diameters measured directly from the SEM images were smaller than those determined by dynamic light scattering (see Table 1)

Table 1
Effect of synthesis conditions on the size and polydispersity of PMMA spheres

Preparation #	Volume MMA (L)	Volume H_2O (L)	Mass initiator (g)	Temperature (°C)	Mean diameter, Z_D (nm)[a]	PDI[a]	% PD
1	0.3	1.6	1.5	80	316	0.019	13.8
2	0.4	1.6	1.5	70	415	0.016	12.6
3	0.3	1.6	1.5	70	364	0.034	18.4
4	0.2	1.6	3	80	280	0.015	12.2
5	0.4	1.6	0.75	75	408	0.025	15.8

[a] Determined by dynamic light scattering.

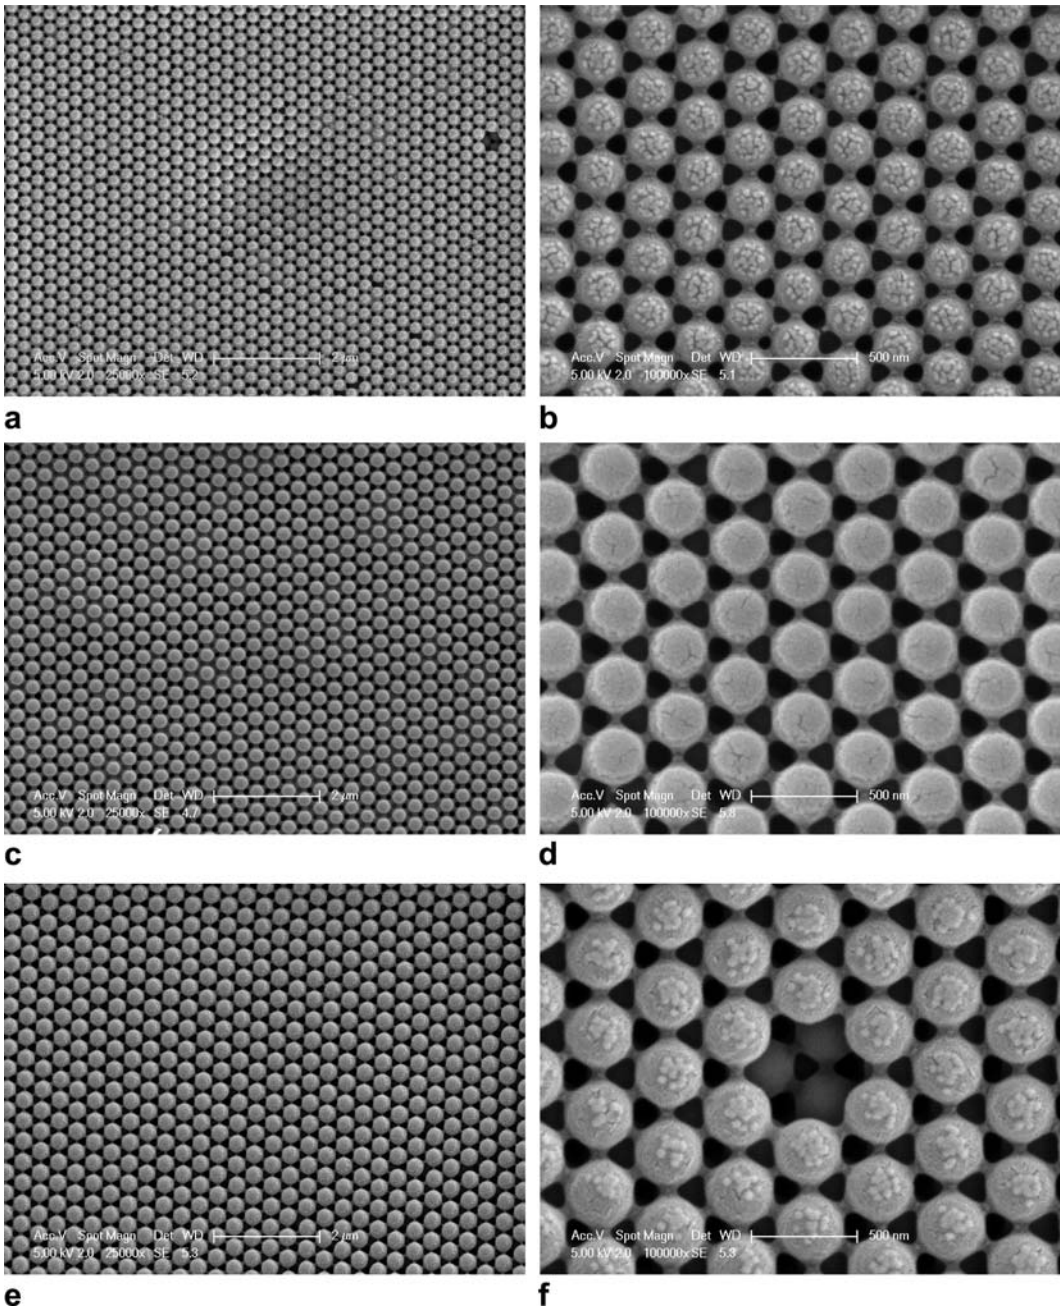

Fig. 1. SEM images of PMMA colloidal crystals fabricated using the flow-controlled vertical deposition method from (a), (b) Prep. 4 PMMA spheres; (c), (d) Prep. 3 PMMA spheres; and (e), (f) Prep. 5 PMMA spheres. Images on the left were taken at 25000× magnification and demonstrate close-packed (1 1 1) planes and long range order, images on the right were taken at 100000× magnification and reveal necking of the individual PMMA spheres to their nearest neighbours.

by approximately 20–22%. This difference is attributed to shrinkage of the PMMA spheres on drying in the colloidal crystal.

Although the images of Fig. 1 confirm a regular close-packed sphere arrangement, they cannot be used to distinguish between the face-centred cubic (ABCABC...) and hexagonal close-packed (ABABAB...) structures. Energetically the fcc structure is preferred over the hcp structure [25], although the energy difference is small. Valuable information about the packing structure of the colloidal crystals can be gained by examining images of a fractured colloidal crystal surface. Fig. 2a was taken from a colloidal crystal prepared by gravitational sedimentation, and exhibits structures that are consistent with the fcc packing arrangement. Note that the close-packed order extends throughout the colloidal crystal, and that fractures occur along well-defined planes in the lattice. All these points reflect the high degree of crystalline order achieved in PMMA colloidal crystals.

In a few of the colloidal crystals prepared, domains of both (1 1 1) and (1 0 0) orientation were observed on the same surface (Fig. 2b). It is unclear why (1 0 0) domains form, although the thermodynamic stability of the (1 1 1)

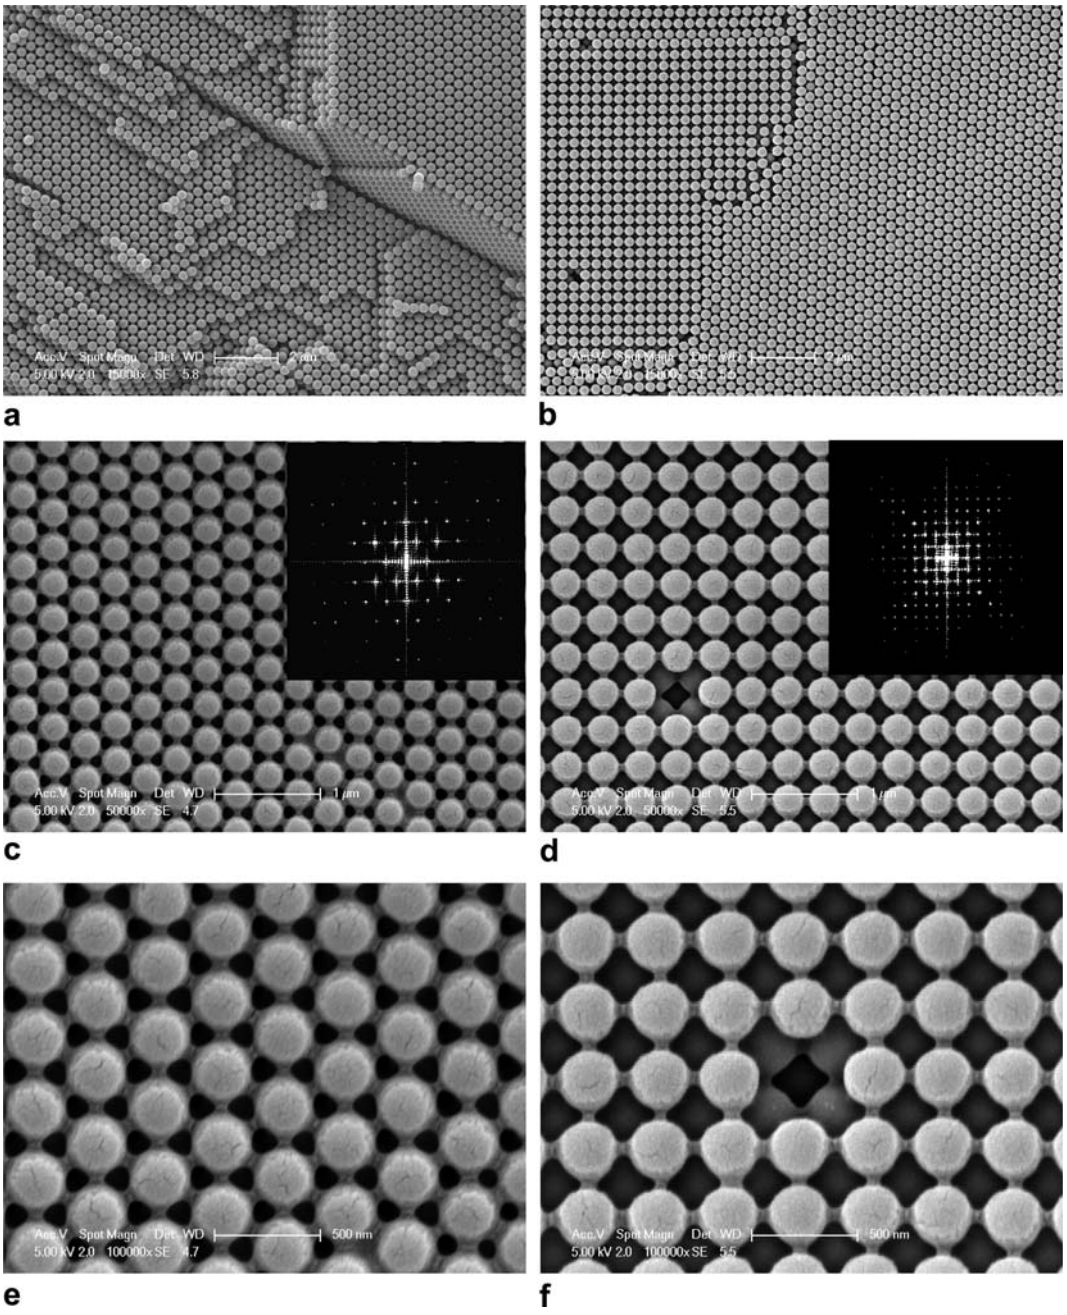

Fig. 2. SEM images of PMMA colloidal crystals fabricated using gravitational sedimentation and Prep 3 PMMA spheres. (a) Fractured surface showing fcc array of spheres, 15000×; (b) colloidal crystal exhibiting domains of both (1 1 1) and (1 0 0) orientations, 15000×; (c), (d) magnified views of the (1 1 1) and (1 0 0) domains, respectively, 50000×; insets show Fourier transforms performed on the images; (e), (f) further magnified views of the (1 1 1) and (1 0 0) domains, respectively, showing the of necking of spheres, 100000×.

and (1 0 0) structures are known to be similar. Figs. 2c and d show magnified views of the (1 1 1) and (1 0 0) faces, respectively. The insets show Fourier transforms (FT) of Fig. 2c and d, performed to examine the geometric structure in the spatial domain of each image. The FTs confirm the hexagonal and square registry, respectively, of the (1 1 1) and (1 0 0) crystallographic domains. The sharpness of the points on the reciprocal lattice and the absence of noise elsewhere indicate the extent of the long-range order. Figs. 1d and 2e demonstrate the similarity between colloidal crystals prepared using two different fabrication methods, while Fig. 2f shows the underlying structure in the (1 0 0) domains.

3.3. Optical properties of the PMMA colloidal crystals (opals)

The position of stop bands (band gaps) in fcc photonic crystals can be estimated using a modified form of Bragg's law (3) which takes into account refraction of light in the composite structure and the incident angle of the incoming light.

$$\lambda_{max} = \frac{2d_{hkl}}{m}\sqrt{n_{avg}^2 - \sin^2\theta}, \quad (3)$$

where λ_{max} is the wavelength of the reflectance peak maximum (i.e. the position of the photonic band gap), d_{hkl} is the interplanar spacing between hkl planes, m is the order of the Bragg diffraction, n_{avg} is the average refractive index of the photonic structure and θ is the angle between the incident light and the surface normal of the sample. For a PMMA colloidal crystal in air at 25 °C, $n_{avg} = n_{PMMA} f_{PMMA} + n_{air} f_{air}$, where $n_{PMMA} = 1.492$, $n_{air} = 1.000$, and f_{PMMA} and f_{air} are the volume fractions occupied by PMMA spheres and air in the structure (generally taken as 74% and 26%, respectively, for a fcc lattice). The SEM micrographs of Fig. 1 show the PMMA colloidal crystals to expose predominantly (1 1 1) planes. In the case of first order Bragg diffraction from fcc (1 1 1) planes, $d_{hkl} = 0.8165D$, where D is the average centre-to-centre distance between spheres on the (1 1 1) planes. Thus, Eq. (3) simplifies to give

$$\lambda_{max} = 1.633D\sqrt{n_{avg}^2 - \sin^2\theta}. \quad (4)$$

For fcc arrays of spheres, D would generally be taken as $2r$, where r is the sphere radius. Here, however, our PMMA spheres are necked. Necking increases the distance between spheres and hence increases the interplanar spacing in the [1 1 1] direction. For this reason, our D values will exceed $2r$. Eq. (4) shows that by using monodisperse spheres of different size, we can vary the wavelengths of light allowed to propagate through the photonic crystal. Experimentally d_{hkl} and n_{avg} are determined by measuring the position of the reflectance maximum (λ_{max}) at different angles of incidence, and plotting λ_{max}^2 against $\sin^2\theta$. If Bragg diffraction conditions are satisfied, a straight line will result with slope $= -(2d_{hkl})^2$ and y-axis intercept $= (2d_{hkl})^2 n_{avg}^2$.

Table 2 summarizes physical and UV–Vis transmittance data for colloidal crystals fabricated from the 5 PMMA preparations described in Table 1. The second and third columns of Table 2 give PMMA sphere diameters and centre-to-centre distances between spheres on the (1 1 1) planes (D), respectively, measured directly from SEM images. Column 4 gives a calculated λ_{max} for diffraction at normal incidence ($\theta = 0°$) from the (1 1 1) planes, obtained using Eq. (4), D values from column 3 and assuming an average refractive index of 1.364. Columns 5–9 give physical parameters determined experimentally from angle-resolved UV–Vis transmittance measurements on the colloidal crystals (see text below). The contents of Table 2 are discussed in conjunction with Figs. 3–5.

UV–Vis transmittance spectra collected at normal incidence ($\theta = 0°$) from colloidal crystals fabricated using preparation 1, 3 and 5 PMMA spheres are shown in Fig. 3a. D values determined experimentally for each preparation are 299, 347, 397 nm (see Table 2 and text below for their determination), respectively. For each preparation, five distinct stop bands are observed (reflectance maxima appear as dips in the transmittance spectra), superimposed on a background of intense sample absorption at low wavelengths. The most intense stop band in each spectrum, located at 689, 774 and 857 nm, respectively, arises from first order Bragg diffraction from (1 1 1) planes of the fcc colloidal crystal lattices. The other bands, with wavelength ratios with respect to the (1 1 1) stop band wavelength of 0.483, 0.500, 0.522, 0.556, are tentatively assigned to diffraction from other planes of the fcc lattice. The stop bands are red-shifted as D (and hence the interplanar spacing in the [1 1 1] direction) increases. According to Eq. (4), a direct proportionality should exist between the two parameters. Fig. 3b shows that the experimentally determined λ_{max} increases linearly with D (open triangles), satisfying the Bragg diffraction criteria. Stop band positions calculated using D values measured directly from SEM images and $n_{avg} = 1.364$ are also shown (closed triangles). Both sets of data are in excellent accord, demonstrating the close association between the geometric and optical properties of the colloidal crystals. At normal incidence, the ratio of the FWHM of the stop band reflection peak (ΔE) to the position of the stop band reflection peak (E) gives a normalised measure of the photonic band gap. For all PMMA colloidal crystal samples prepared, $\Delta E/E$ values between 0.085 and 0.1 were observed.

Figs. 4a and b show UV–Vis transmittance spectra measured at different angles of incidence with respect to the surface normal for colloidal crystals fabricated from Prep. 1 and Prep. 5 PMMA spheres ($\theta = 0°$, $\lambda_{max} = 689$ and 857 nm, respectively). The reflectance maxima for diffraction from the (1 1 1) planes shift to shorter wavelengths as θ increases, as predicted by Eqs. (3) and (4). These samples do not possess a complete photonic band gap, since wavelengths of incident light forbidden at normal incidence can

Table 2
Summarized physical and optical data for the PMMA colloidal crystals prepared in this work

Preparation #	Sphere diameter[a] (nm)	D[a] (nm)	Calculated λ_{max} $\theta = 0°$ (nm)	Experimental d_{111} (nm)	Experimental D (nm)	Experimental n_{avg}	Experimental f_{PMMA}	Experimental λ_{max} $\theta = 0°$ (nm)

[a] Measured directly from SEM images.

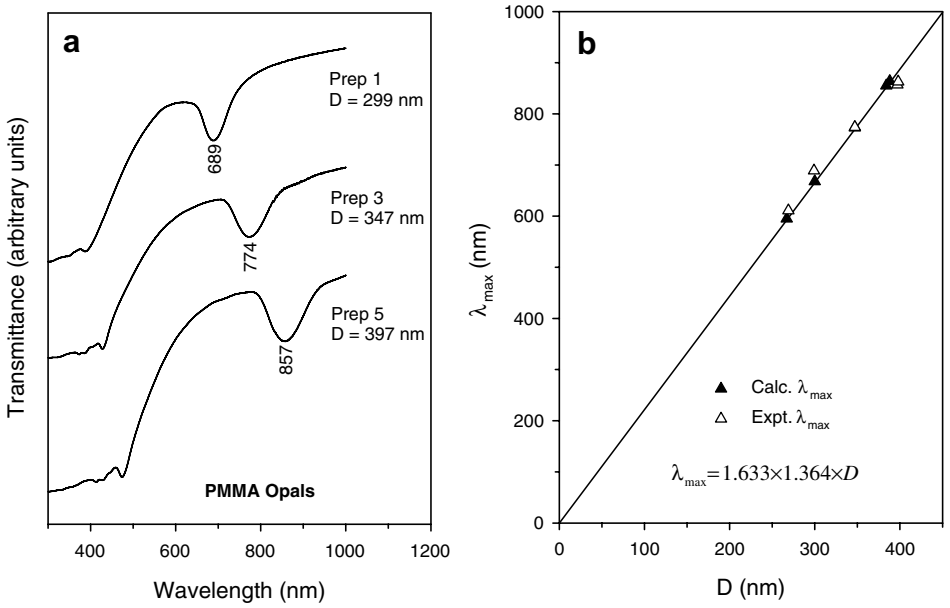

Fig. 3. (a) UV–Vis transmittance spectra collected from PMMA colloidal crystals of different sphere size. D values indicate the centre-to-centre distance between spheres on the (1 1 1) planes, determined from angle-resolved UV–Vis transmittance measurements. Spectra were taken at normal incidence to the (1 1 1) plane, and show the positions of the pseudo photonic band gaps in the colloidal crystals. (b) shows the position of the reflectance maximum (λ_{max}) for diffraction from (1 1 1) planes versus D for colloidal crystals fabricated from our five different PMMA preparations. λ_{max} values calculated from D values measured directly from SEM images are also shown (solid triangles). The linearity of the plot indicates Bragg diffraction conditions are satisfied (see Eq. (4)).

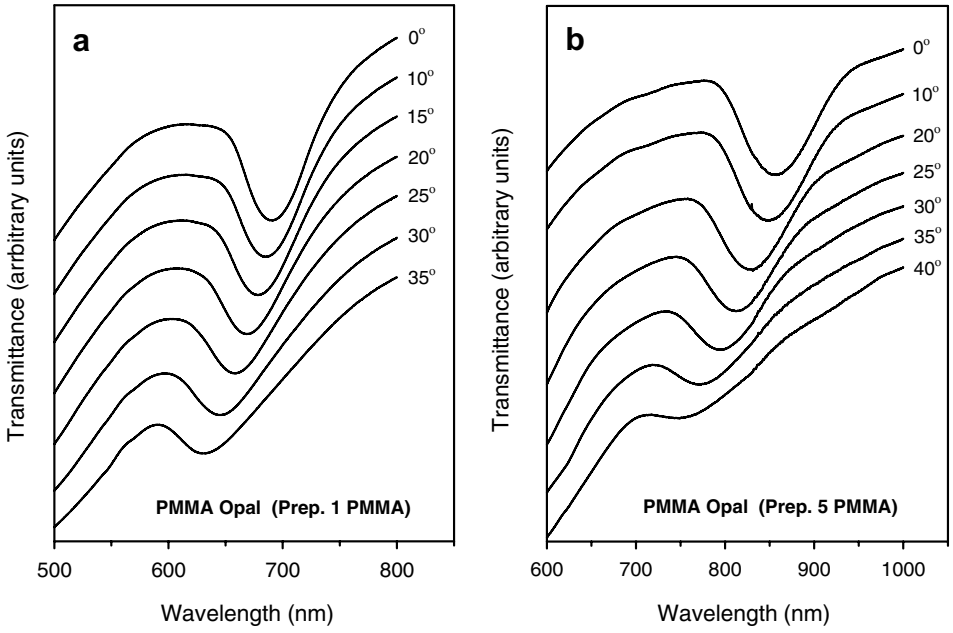

Fig. 4. UV–Vis transmittance spectra recorded at different angles of incidence from colloidal crystals of (a) Prep. 1 PMMA spheres ($D = 299$ nm) and (b) Prep. 5 PMMA spheres ($D = 397$ nm). Angles of incidence were measured with respect to the surface normal of the (1 1 1) planes. The figures show that the position of λ_{max} shifts to shorter wavelength as the angle of incidence increases, as predicted by Eq. (4).

transmit easily through the crystal at other angles. The interplanar spacing d_{111} and average refractive index of the photonic crystals can be determined from a plot of λ^2_{max} versus $\sin^2\theta$, as shown in Fig. 5. As mentioned above, if Bragg diffraction conditions are satisfied, a straight line will result with slope $= -(2d_{111})^2$ and y-axis intercept $= (2d_{111})^2 n^2_{avg}$. The data clearly obey the modified Bragg's law expression given in Eq. (3). From the experimentally determined d_{111}, the average centre-to-centre distance (D) between spheres on the (1 1 1) planes can be calculated ($D = d_{111}/0.8165$). Similarly, the volume fractions of PMMA and air in the colloidal structure can be calculated

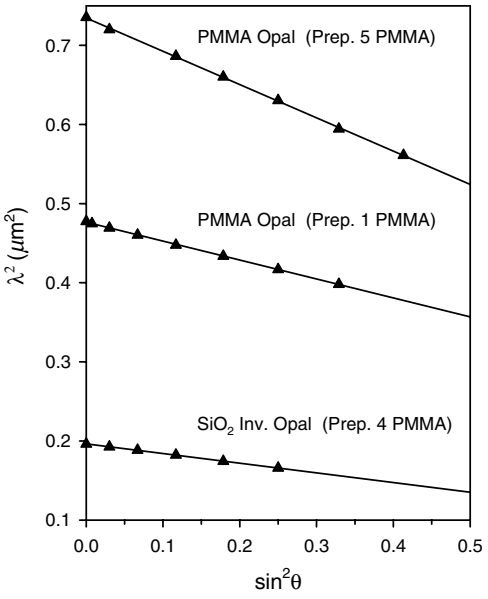

Fig. 5. Plot of λ^2_{max} versus $\sin^2\theta$, where λ_{max} is the reflectance maximum for diffraction from (1 1 1) planes and θ is the angle of incidence with respect to the surface normal of the (1 1 1) plane. Data for a SiO_2 IO are also given. A linear-least squares fit has been applied to each data set. From Eq. (3), it can be shown that the slope of the lines $= -(2d_{111})^2$ and the y-axis intercept $= (2d_{111})^2 n^2_{avg}$.

once the average refractive index is known. Data extracted from Fig. 5, and similar figures for colloidal crystals fabricated from our 5 PMMA sphere preparations, were used to complete the right-hand side of Table 2.

3.4. Fabrication and characterization of SiO_2, TiO_2 and CeO_2 inverse opals

Using the self-assembled PMMA colloidal crystals as a starting point, fcc lattices of air spheres embedded within SiO_2, TiO_2 or CeO_2 matrices were fabricated. PMMA colloidal crystals were first infiltrated with a sol-gel precursor, then carefully calcined at 550 °C to remove the PMMA template (see Section 2 for full details). All samples exhibited strong opalescence under light illumination, confirming the success of the inversion procedure.

Silica inverse opals from three different colloidal crystal templates, each of a different PMMA sphere size, are shown in the SEM micrographs of Fig. 6. PMMA templates were prepared by the centrifugation method, then crushed lightly with a metal spatula before SiO_2 infiltration. At low magnification, well-defined terrace structures can be discerned on the colloidal crystals (Figs. 6a, c and e). These structures are the result of crushing the PMMA crystals before infiltration (cf. Fig. 2a, which shows a fractured surface of a PMMA crystal). At high magnification, well-ordered inverse opal structures are observed (Figs. 6b, d and f), comprising fcc arrays of air spheres in silica. XRD showed the walls to be composed of amorphous silica (XRD pattern not shown). According to theory, the SiO_2 inverse opal should be approximately 24% silica and 76% air by volume. Note the small holes that connect each air sphere to its nearest neighbours. These holes conveniently indicate the position of the air spheres in the underlying layer of the inverse opal, and are the result of necking between spheres in the original PMMA template (cf. Fig. 1). The silica fraction of the inverse opals varies depending on infiltration conditions. The inverted part of the structure densified with additional infiltrations of sol-gel precursor into the PMMA template. Removal of the polymer template by calcination causes a large shrinkage of the inverted framework. This can be seen by directly comparing Figs. 1b, d and f with Figs. 6b, d and f, respectively (all images were taken at the same magnification). For each inverse opal preparation, the centre-to-centre distance between neighbouring air spheres (D) was 10–20% smaller than that between the spheres in the original PMMA template. Similar results have been reported for inverse opals prepared from polystyrene colloidal crystal templates [26].

Angle-resolved UV–Vis transmittance spectra for a SiO_2 inverse opal fabricated from a colloidal crystal of Prep. 4 PMMA spheres ($D = 269$ nm) are shown in Fig. 7. At normal incidence ($\theta = 0°$), the inverse opal exhibited a reflectance maximum (hence transmittance minimum) at 443 nm. We assign this feature to first order Bragg diffraction from the (1 1 1) planes of the fcc inverse opal structure (λ_{max}). The normalized band gap width in the inverse opal is $\Delta E/E = 0.1$, and of similar size to that of the PMMA template ($\Delta E/E = 0.85$). In agreement with behaviour observed for the PMMA colloidal crystals, the position of λ_{max} shifted to shorter wavelengths as the incident angle increased from 0° to 30°. Following the procedure above, we plotted λ^2_{max} versus $\sin^2\theta$ and achieved a straight line fit (see Fig. 5). From the plot, a d_{111} spacing of 174 nm and n_{avg} of 1.267 were obtained. A value $D = 214$ nm was calculated from the d_{111} spacing ($D = d_{111}/0.8165$). This value is in excellent agreement with a value of $D = 217$ nm measured directly from Fig. 6b. Comparing the values of D for the polymer template ($D = 269$ nm) and the SiO_2 inverse opal ($D = 214$ nm), it can be shown that the centre-to-centre distance between spheres in the fcc arrays decreased by approx 20% on inversion. The average refractive index of the inverse opal structure was higher than that predicted by theory ($n_{avg} = 0.74 \times 1 + 0.26 \times 1.45 = 1.117$), and suggests a silica fraction of 60%. Thickening of the silica walls, caused by lattice shrinkage during inversion, could be expected increase the silica content. However, the SEM images of Fig. 6 show that the filling fraction of silica in similar preparations to be significantly less than 60%, suggesting an alternative explanation is required. The presence of residual PMMA template in the voids of the inverse opal, instead of air, is one possible explanation.

To achieve a complete PBG for the visible and infrared regions, inverse opal structures with refractive index contrast of at least 2.9 are required. Inverse opals of TiO_2 ($n = 2.5$) and CeO_2 ($n = 2.4$) are interesting materials in

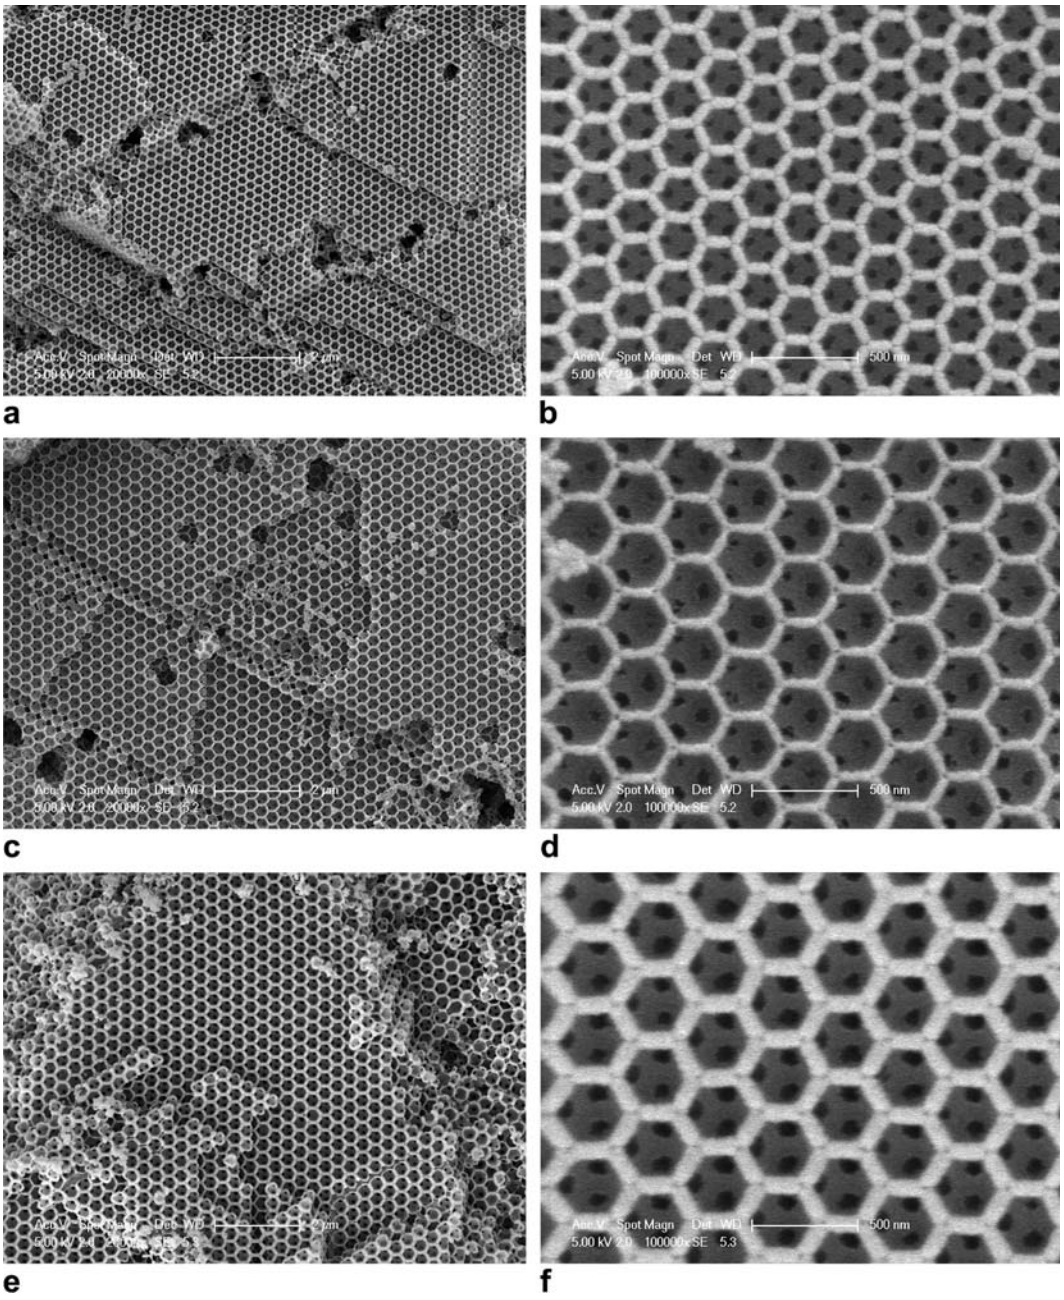

Fig. 6. SEM images showing SiO_2 inverse opals made from colloidal crystals templates of (a), (b) Prep. 4 PMMA spheres; (c), (d) Prep. 3 PMMA spheres; and (e), (f) Prep. 5 PMMA spheres. Images on the left were taken at 20 000× magnification, images on the right were taken at 100 000× magnification. Note the holes in the walls of the inverse opals where necks existed between PMMA spheres in the colloidal crystal templates.

this regard as their refractive contrasts are just below the required threshold. Potential also exists to exploit these materials in photovoltaic systems and catalytic applications, justifying a thorough investigation of their properties. Fig. 8 shows SEM micrographs of the TiO_2 and CeO_2 inverse opals fabricated from Prep. 3 PMMA colloidal crystals ($D = 347$ nm). The same template was used to fabricate the SiO_2 inverse opal shown in Figs. 6c and d. As was observed for SiO_2, the TiO_2 and CeO_2 inverse opals exhibited well-ordered fcc arrays of air spheres. Note the "clover leaf" like structure in the lower part of Fig. 8d, showing where a single PMMA sphere was positioned on top of an underlying (1 1 1) plane of PMMA spheres in the polymer template. Interestingly, all the inverse opal structures underwent a comparable degree of shrinkage during the inversion process (D decreased by approx. 15%).

Of interest were the structural forms of TiO_2 and CeO_2 in the inverted structures, since for many envisaged applications nanocrystalline titania and ceria are preferred. The XRD pattern for a TiO_2 inverse opal (Fig. 9a) was consistent with the anatase form of TiO_2 (space group $I4_1/amd$, $Z = 4$). Peak-widths were considerably broader than those determined for an anatase powder of micron-sized particles (Fig. 9b). The line broadening indicates the

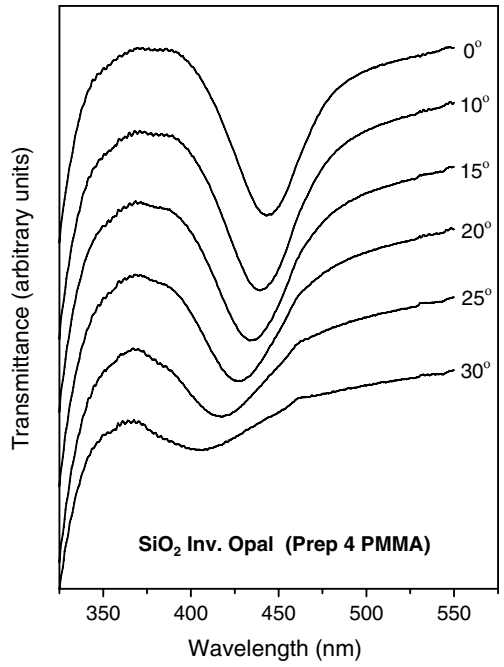

Fig. 7. UV–Vis transmittance spectra recorded at different angles of incidence from a SiO_2 inverse opal prepared from a colloidal crystal template of Prep. 4 PMMA spheres. The spectra show that the position of λ_{max} shifts to shorter wavelength as the angle of incidence increases, as predicted by Eq. (4).

TiO_2 network is composed of anatase nanoparticles. Line broadening for particles of nanometer dimension is well understood, and is caused by size-induced lattice relaxation and an increase in the lattice parameter(s). The average crystallite size of the TiO_2 nanoparticles was determined using the Scherrer equation

$$D_{avg} = \frac{K\lambda}{\beta \cos\theta}, \tag{5}$$

where D_{avg} is the mean crystallite diameter (in metres), K is the shape factor (typically 0.89), λ is the wavelength of the X-ray source (here $\lambda = 1.5148$ Å), θ is the Bragg angle of the diffraction peak (in degrees) and β is the linewidth of the diffraction peak corrected for instrument broadening (in radians)

$$\beta = \sqrt{B_M^2 - B_I^2}, \tag{6}$$

where B_M is the measured linewidth (in radians) and B_I is the instrumental broadening (also in radians). B_I is determined by measuring the linewidth for any standard particle of size >200 nm. From the FWHM of the anatase (1 0 1) reflections in Figs. 9a and b, we determined the TiO_2 particle size in the inverse opals to be approximately 31 nm. Inverse opals of ceria were also composed of nanocrystalline CeO_2, as evidenced by the relative linewidths of the

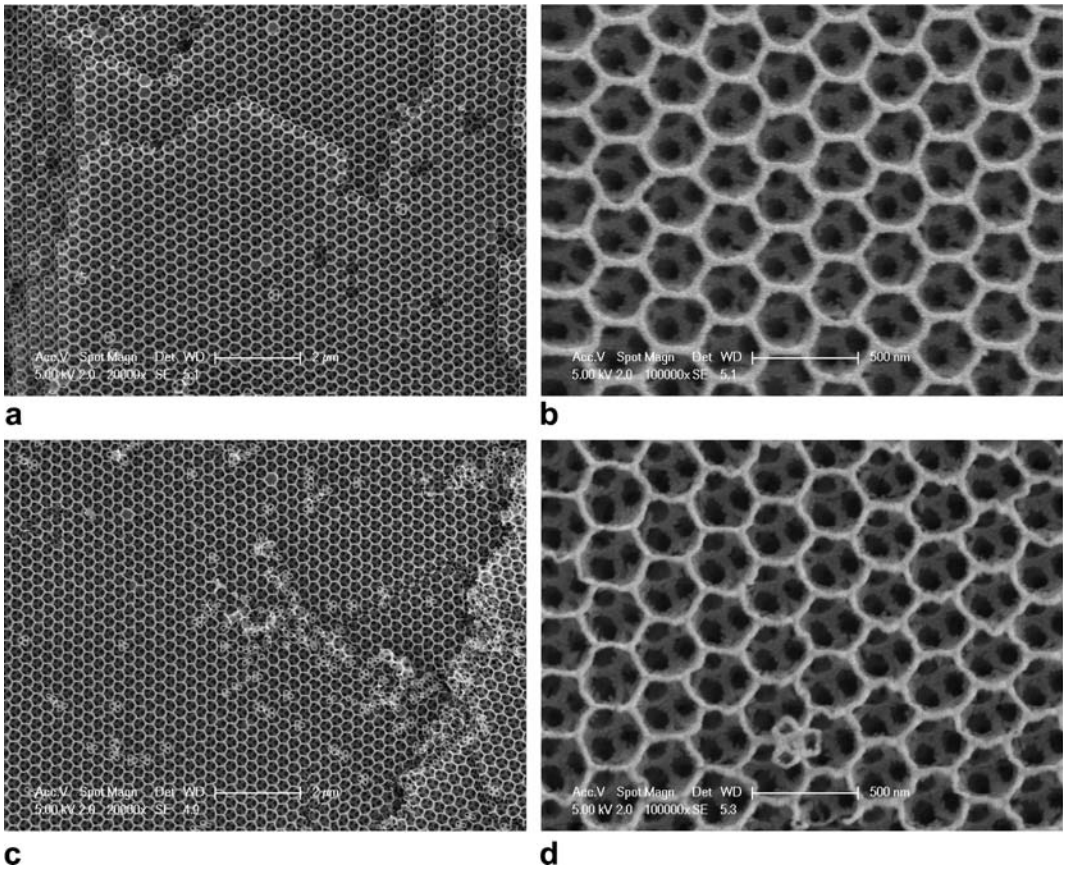

Fig. 8. SEM images showing inverse opals of (a), (b) TiO_2 and (c), (d) CeO_2 made from colloidal crystals templates of Prep. 3 PMMA spheres. Images on the left were taken at 20000× magnification, images on the right were taken at 100000× magnification.

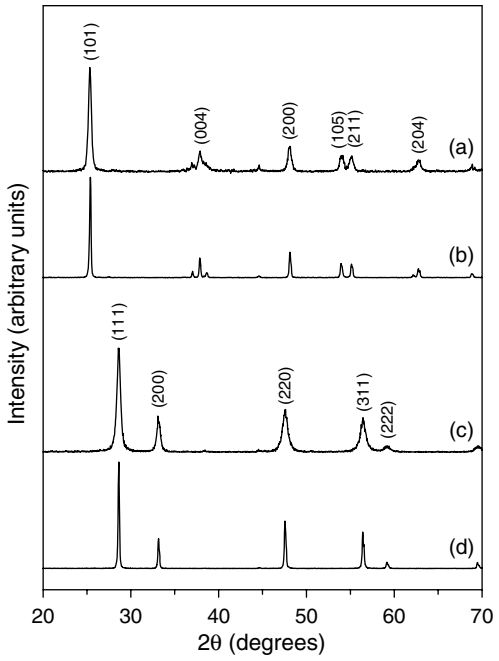

Fig. 9. XRD patterns for (a) TiO_2 inverse opal; (b) TiO_2 micron size powder (anatase form); (c) CeO_2 inverse opal; and (d) CeO_2 micron size powder. Line broadening observed for the inverse opals indicates the presence of nanocrystalline particles.

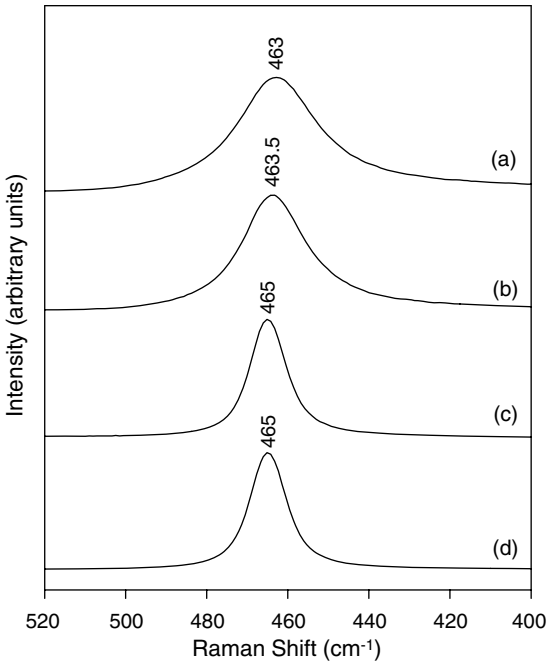

Fig. 10. Raman spectra for (a) CeO_2 nanoparticles of average size 12 nm; (b) CeO_2 inverse opal; (c) CeO_2 micron size powder; and (d) CeO_2(1 1 1) single crystal.

XRD patterns shown in Figs. 9c and d. Using the FWHM of the (1 1 1) reflections, the average size of ceria particles in inverse opal network was determined to be around 17 nm. This is an interesting result, since nanocrystalline CeO_2 has been shown to increase the activity of ceria-based catalysts for the WGS reaction and CO oxidation by several orders of magnitude.

Line broadening caused by the presence of nanocrystalline ceria in the CeO_2 inverse opal networks is also evidenced by Raman spectroscopy. CeO_2 crystallizes with the fluorite structure, space group $Fm3m$ (O_h^5) with $Z = 4$. On account of the high symmetry, the CeO_2 lattice shows only one infrared active phonon (T_{1u} symmetry) and one Raman active phonon (T_{2g} symmetry). The triply degenerate Raman active phonon is reported to appear at 465 cm^{-1} for micron-sized CeO_2 powders [27]. Raman spectra collected from CeO_2 nanoparticles of average size 12 nm, the CeO_2 inverse opal, a micron-sized CeO_2 powder and a CeO_2(1 1 1) single crystal are shown in Figs. 10a–d, respectively. All samples exhibit a single Raman band centred between 463 and 465 cm^{-1}, the position, FWHM and symmetry of the band being highly sample dependent. For the ceria nanoparticles and the ceria inverse opals, broad asymmetric peaks are observed at low energy, reflecting size-induced relaxation effects and an increase in the lattice parameter (i.e. Ce–O bonds are weakened due to lattice relaxation) [28,29]. For the micron-sized CeO_2 powder and the CeO_2(1 1 1) single crystal (Figs. 10c and d), sharp symmetric peaks of high energy are seen on account of the high crystalline order and rigidity in the bulk. In future work, the optical properties of the TiO_2 and CeO_2 inverse opal will be examined, and potential applications for these materials explored.

4. Conclusions

The fabrication of well-ordered photonic crystals with opal and inverse opal structures has been demonstrated. These materials have intrinsically interesting optical properties (such as photonic band gaps) that may be exploited in applications such as solar energy conversion or light-emitting devices. We are currently developing conducting polymer and piezoelectric oxides with inverse opal structures. In general, the well-ordered colloidal crystal templates provide an excellent route for the preparation of a wide variety of macroporous inorganic oxides.

Abstract

The reaction of $Ni(OAc)_2$, NiX_2 (X = Cl, Br) or $CoCl_2$ with the proligand 2-amino-2-methyl-1,3-propanediol ($ampdH_2$) affords a new family of tetranuclear complexes. The syntheses of $[Ni_4(OAc)_4(ampdH)_4]$ (**1**) and $[M_4X_4(ampdH)_4]$ (M = Ni, X = Cl, **2**; M = Ni, X = Br, **3**; M = Co, X = Cl, **4**) are reported, together with the single crystal X-ray structures of **1**, **2** and **4** and the magnetochemical characterization of **1**, **3** and **4**. Each member of this family of complexes displays a low symmetry structure that incorporates a $\{M_4O_4\}$ core unit based on a distorted cubane. Magnetic measurements reveal ferromagnetic exchange interactions for **1**, **3** and **4**. These give rise to $S = 4$ ground state spins for the tetranuclear Ni complexes and an anisotropic effective $S' = 2$ ground state for the Co complex.

Keywords: Spin clusters; Polynuclear complexes; Nickel; Cobalt; Tripodal ligands; Magnetochemistry

1. Introduction

Polynuclear complexes of paramagnetic metal centers, or "spin clusters", are key components of the active sites of a number of metalloproteins and are therefore of considerable interest to the field of bioinorganic chemistry [1]. In addition, an important new branch of molecular materials chemistry is concerned with the investigation of spin clusters that act as "single-molecule magnets" (SMMs) [2–6]. These species display slow magnetic relaxation at low temperature that arises from the molecular properties of a high ground state spin and an easy-axis (Ising) type of magnetic anisotropy. The synthesis and investigation of new spin clusters is of fundamental importance to both these research fields, with the accessibility of new complexes, and particularly examples with novel structures, relying on the exploitation of new families of ligands. The potentially polynucleating tripodal proligand 2-amino-2-methyl-1,3-propanediol ($ampdH_2$) contains an (N,O,O)-donor set and is suitable for binding to a range of transition metals. Although tripodal triol-based ligands have been successfully incorporated in spin clusters [7], the coordination potential of $ampdH_2$ has been little explored, with only a single Mo_2 complex [8] having been structurally characterized prior to our recent reports of Fe_7, Co_6 and $\{Co_8\}_n$ complexes [9]. As part of our exploration of new spin clusters that contain polyalcohol/alkoxide ligands [4,9–11], we report here a new family of tetranuclear Co and Ni complexes that incorporate the monoanionic ligand $ampdH^-$. It is noteworthy that tetranuclear spin clusters of Mn, Fe, V, Ni and Co have been found to act as SMMs [3–6]

ampdH$_2$

2. Experimental

2.1. Compound preparation

All manipulations were performed under aerobic conditions, using materials as received.

2.1.1. [$Ni_4(OAc)_4(ampdH)_4$] (**1**)

$Ni(OAc)_2 \cdot 4H_2O$ (3.00 g, 12.1 mmol) was added to a solution of $ampdH_2$ (1.26 g, 12.1 mmol) in ^iPrOH (50 cm^3) and the resulting mixture was stirred overnight, evaporated to dryness and recrystallized by layering a concentrated MeCN solution with Et_2O. Blue-green cuboidal crystals formed after one week. The crystals were isolated by filtration and washed with MeCN/MeOH; yield 9%. *Anal.* Calc. for $[Ni_4(OAc)_4(ampdH)_4]$, $C_{24}H_{52}N_4Ni_4O_{16}$: C, 32.48; H, 5.91; N, 6.31. Found: C, 32.45; H, 5.90; N, 6.34%. Selected IR data (cm^{-1}): 3333 (s), 3302 (s), 3265 (s), 3161 (s), 2956 (s), 2935 (s), 2879 (s), 2850 (s), 2703 (m), 2598 (m), 2019 (m), 1918 (m), 1589 (s), 1466 (s), 1416 (s), 1385 (s), 1336 (s), 1328 (s), 1290 (m), 1226 (w), 1203 (w), 1187 (w), 1157 (m), 1151 (m), 1065 (s), 1018 (s), 1004 (s), 945 (m), 914 (s), 899 (m), 794 (m), 736 (w), 711 (m), 690 (m), 666 (s), 652 (s), 616 (m), 606 (m), 536 (m), 483 (m), 445 (m), 420 (s).

2.1.2. [$Ni_4Cl_4(ampdH)_4$] (**2**)

$NiCl_2 \cdot 6H_2O$ (2.00 g, 8.42 mmol) was added to solution of NEt_3 (1.17 ml, 8.42 mmol) and $ampdH_2$ (0.88 g, 8.4 mmol) in MeOH (40 cm^3) and the resulting mixture was stirred overnight, evaporated to dryness and recrystallized by layering a concentrated MeOH solution with Et_2O. Light-green cuboidal crystals formed after three weeks. The crystals were isolated by filtration and washed with MeOH/Et_2O; yield 25%. A sample for crystallography was maintained in contact with mother liquor to prevent the loss of interstitial solvent. The sample was vacuum dried overnight at room temperature to remove the solvent of crystallization, but appears to be hygroscopic. *Anal.* Calc. for $[Ni_4Cl_4(ampdH)_4] \cdot 3H_2O$, $C_{16}H_{46}N_4Ni_4O_{11}Cl_4$: C, 22.69; H, 5.47; N, 6.61. Found: C, 22.81; H, 5.51; N, 6.23%. The hydration level was confirmed by thermogravimetric analysis. Selected IR data (cm^{-1}): 3436 (s), 3310 (s), 3247 (s), 2960 (s), 2860 (s), 2758 (m), 2567 (w), 2097 (w), 1633 (m), 1600 (m), 1475 (m), 1465 (m), 1385 (m), 1343 (m), 1291 (m), 1229 (w), 1202 (w), 1147 (m), 1105 (m), 1059 (s), 1018 (s), 996 (s), 957 (m), 917 (m), 898 (m), 793 (s), 734 (m), 659 (s), 606 (s), 527 (m), 483 (m), 419 (s).

2.1.3. [$Ni_4Br_4(ampdH)_4$] (**3**)

This was synthesized in a manner analogous to that employed for **2** using $NiBr_2 \cdot 3H_2O$ in place of $NiCl_2 \cdot 6H_2O$; yield 16%. Drying under vacuum at room temperature afforded a fully desolvated sample. *Anal.* Calc. for $[Ni_4Br_4(ampdH)_4]$, $C_{16}H_{40}N_4Ni_4O_8Br_4$: C, 19.79; H, 4.15; N, 5.77. Found: C, 19.71; H, 4.23; N, 5.75%. Selected IR data (cm^{-1}): 3401 (s), 3325 (s), 3271 (s), 3233 (s), 2962 (s), 2933 (s), 2860 (s), 2743 (m), 1653 (m), 1635 (m), 1589 (m), 1465 (m), 1383 (m), 1338 (m), 1290 (m), 1223 (w), 1199 (w), 1148 (m), 1052 (s), 1014 (m), 996 (s), 914 (m), 897 (m), 789 (m), 656 (m), 603 (s), 526 (m), 484 (m), 418 (s).

2.1.4. [$Co_4Cl_4(ampdH)_4$] (**4**)

$CoCl_2 \cdot H_2O$ (0.71 g, 3.0 mmol) was added to a solution of NEt_3 (0.425 ml, 3.00 mmol) and $ampdH_2$ (0.32 g, 3.0 mmol) in MeCN (60 cm^3). Stirring the resulting mixture overnight afforded a pink precipitate, which was recrystallized by layering a concentrated EtOH solution with Et_2O. After five days, purple plate-like crystals formed. These were isolated by filtration and washed with Et_2O; yield 20%. A sample for crystallography was maintained in contact with mother liquor to prevent the loss of interstitial solvent. Drying under vacuum at room temperature afforded a fully desolvated sample. *Anal.* Calc. for $[Co_4Cl_4(ampdH)_4]$, $C_{16}H_{40}N_4Co_4O_8Cl_4$: C, 24.19; H, 5.08; N, 7.05. Found: C, 24.11; H, 5.02; N, 6.97%. Selected IR data (cm^{-1}): 3435 (s), 3324 (s), 3276 (s), 3246 (s), 2962 (m), 2936 (m), 2883 (m), 2858 (m), 2750 (w), 2092 (w), 1632 (m), 1595 (m), 1466 (m), 1384 (m), 1340 (w), 1293 (w), 1229 (w), 1183 (w), 1147 (m), 1054 (s), 995 (m), 914 (w), 898 (w), 790 (m), 633 (m), 600 (m), 515 (m), 474 (m), 411 (m).

2.2. General and physical measurements

Infrared spectra (KBr disk) were recorded on a BioRad 175 FTIR spectrometer. Elemental analyses were performed at Chemical and Microanalytical Services, Belmont, Australia. Thermogravimetric analyses were performed on a Mettler Toledo thermal analyser.

Variable temperature magnetic susceptibility and magnetization measurements were performed with Quantum Design MPMS SQUID magnetometers equipped with a 5 T magnet. Data were collected on small dried crystals restrained in petroleum jelly. Two sets of DC magnetic susceptibility data were collected with magnetic fields of 0.1 T and 0.01 T. Pascal's constants were used to estimate the diamagnetic correction for each complex. The experimental susceptibility data for complexes **1** and **3** were fit using MAGMUN [12]. AC magnetic susceptibility measurements were performed on **4** at frequencies up to 1000 Hz.

2.3. X-ray crystallography

The intensity data of all compounds were collected on a Bruker CCD diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Crystals were transferred directly from the mother liquor to a protective oil, which was used to prevent solvent loss. The structures were solved using direct methods and refined using a full-matrix least squares procedure based on F^2 using all data [13] (see Table 1).

3. Results and discussion

3.1. Syntheses

The overnight treatment of an ^{i}PrOH solution of $Ni(OAc)_2$ with one equivalent of ampdH_2 affords a dark green solution. Evaporation of this to dryness, re-dissolution of the residue in the minimum volume of MeCN and layering the resulting solution with Et_2O, yields crystals of **1** in 9% yield after one week. The reaction may be written as:

$$4Ni(OAc)_2 + 4ampdH_2 \rightarrow [Ni_4(OAc)_4(ampdH)_4] + 4AcOH \quad (1)$$

Formation of **1** involves loss and protonation of acetate ligands in conjunction with deprotonation and coordination of the polyalcohol ampdH_2 proligand. This process commonly occurs during the formation of polynuclear metal complexes with mixed carboxylate and chelating alkoxide ligands from metal carboxylate complexes and is likely driven by the chelate effect associated with the polynuclear product [9,10]. Addition of one equivalent of base (NEt_3 or NaOMe) to the above reaction also affords crystals of **1**, albeit with lower yield. In addition the product is contaminated with a white solid, which is probably NaOAc or Et_3NHOAc. In either case a highly concentrated MeCN solution is required to produce a crystalline sample of **1** in moderate yield, due to its high solubility. A similar reaction between $Co(OAc)_2$ and ampdH_2 in MeOH affords a hexanuclear complex that is reported elsewhere [9b].

Overnight treatment of a methanolic solution of NiX_2 (X = Cl, Br) with one equivalent each of ampdH_2 and NEt_3 results in a light green solution. Evaporation of this to dryness, re-dissolution of the residue in the minimum volume of MeOH, and layering the resulting solution with Et_2O, yields crystals of **2** and **3** in 25% and 16% yield, respectively, after three weeks. The reaction may be written as:

$$4MX_2 + 4ampdH_2 + 4Et_3N \rightarrow [M_4X_4(ampdH)_4] + 4Et_3NHX \quad (M = Ni, Co; X = Cl, Br) \quad (2)$$

After several additional weeks, the formation of a white precipitate of Et_3NHX can be observed. Again the high solubility of the products necessitates highly concentrated MeCN solutions to produce crystalline samples in moderate yield. Analogous reactions without base do not yield crystalline samples of **2** and **3**.

A similar reaction between $CoCl_2$ and one equivalent each of ampdH_2 and NEt_3 in MeCN produces a pink precipitate. Recrystallization from EtOH layered with Et_2O provides purple crystals of **4** in 20% yield after approximately five days. The formation of **4** is also summarized in reaction (2). A crystalline sample of **4** can also be

isolated from similar reactions without the addition of base, although the yields are around one quarter of those obtained with base. Crystals of complex **4** always appear simultaneously with a pale-colored amorphous precipitate of Et_3NHCl and efforts to remove this by washing typically also dissolve the crystals of **4**. Fortunately in batches where large crystals of **4** form, the precipitate can be removed by suspending it in Et_2O and removing the Et_2O by decantation. Repeating this several times affords analytically pure samples.

3.2. Description of structures

Labeled structural diagrams of complexes **1**, **2** and **4** are presented in Fig. 1. A summary of the interatomic distances and angles is provided in Table 2, while a more extensive listing is available in the Supplementary Information.

Complex **1** crystallizes in the orthorhombic space group *Pbca* with one tetranuclear complex in the asymmetric unit. Four Ni and four O atoms occupy the vertices of a distorted $\{Ni_4(\mu_3\text{-}O)_4\}$ cubane core, where the μ_3-O atoms (O4, O5, O11, O12) are from the deprotonated arms of four ampdH$^-$ ligands. Bond valence sum (BVS) calculations (Supplementary Material) are consistent with four Ni^{II} centers [14]. In addition to the three μ_3-O(alkoxo) O atoms, the coordination sphere of each Ni center is completed by one N(amino) atom and one O(alcohol) atom from the ampdH$^-$ ligands and an O atom from the monodentate acetate ligands, to give a distorted octahedral geometry. All four ampdH$^-$ ligands bind to the Ni atoms in a $\eta^1{:}\eta^1{:}\eta^3{:}\mu_3$-fashion (Fig. 2a). The ampdH$^-$ ligands are disposed in an asymmetrical manner about the cubane, such

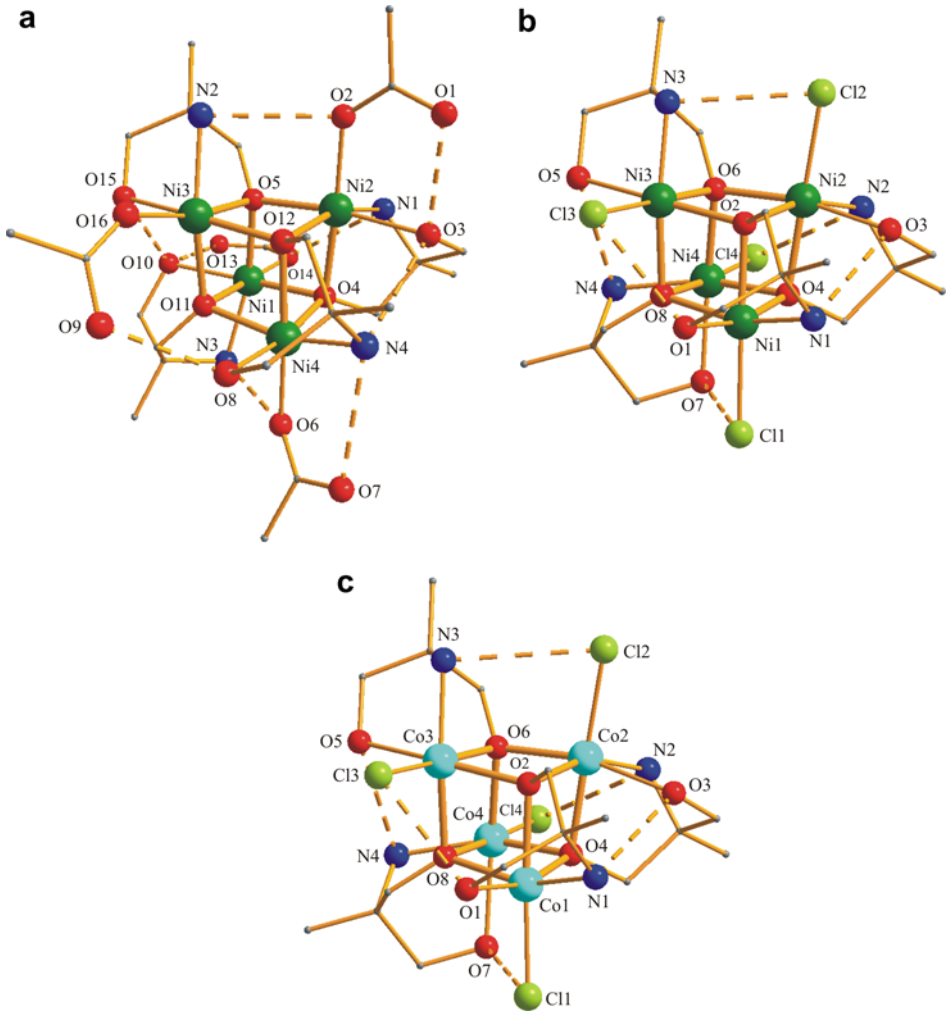

Fig. 1. Molecular structures of (a) **1**, (b) **2** in **2** · 4.25MeOH and (c) **4** in **4** · 3EtOH · Et_2O.

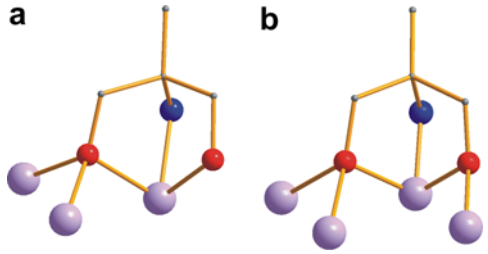

Fig. 2. Binding modes of (a) ampdH$^-$ in **1**–**4** and (b) ampd^{2-} in reported Co and Fe complexes [9].

that two bridging O atoms (O5 and O12) are each bound *trans* to a single N atom, one bridging O atom (O11) is *trans* to two N atoms and the remaining bridging O atom (O4) has no *trans*-N atoms. The four acetate ligands all bind in a terminal monodentate manner and the molecule has C_1 point symmetry. Multiple intramolecular N–H···O and O–H···O hydrogen bonds are evident (Table 3), involving O atoms from both alcohol and acetate moieties. In addition, extensive intermolecular hydrogen bonding is observed **1** between the non-coordinated O(acetate) atoms and the N(amino) atoms, with N···O distances of 2.602(5)–3.071(5) Å (Supplementary Material). Each tetranuclear complex is hydrogen bonded to six neighbouring complexes to form a three-dimensional cubic network.

Compounds **2** · 4.25MeOH and **4** · 3EtOH · Et_2O crystallize in the monoclinic space groups $C2/c$ and $P2_1/c$, respectively, each with one tetranuclear complex in the asymmetric unit. The structural data reveal that complexes **2** and **4** are isostructural. The strong similarity between the infrared spectra of **2** and **3** (Supplementary Material) and the elemental analysis data for **3** are consistent with isostructural character for **3** also. Four M (M = Ni, **2**; M = Co, **4**) and four O atoms occupy the vertices of a distorted {$M_4(\mu_3\text{-}O)_4$} cubane core, where the μ_3-O atoms (O2, O4, O6, O8) are from the deprotonated arms of four ampdH$^-$ ligands. BVS calculations (Supplementary Material) are consistent with four M^{II} centers for both complexes. In addition to the three μ_3-O(alkoxo) O atoms, the distorted octahedral coordination sphere of each metal center is completed by one N(amino) atom and one O(alcohol) atom from the ampdH$^-$ ligands and a chloro ligand. All four ampdH$^-$ ligands bind in a similar $\eta^1{:}\eta^1{:}\eta^3{:}\mu_3$-fashion (Fig. 2) to that observed in **1**. The ampdH$^-$ ligands are also arranged in a manner similar to that observed in **1**, such that two bridging O atoms (O2 and O4) are each *trans* to one N atom, one bridging O atom (O8) is *trans* to two N atoms and the remaining bridging O atom (O6) has no *trans*-N atoms. The molecules both have C_1 point symmetry. Multiple intramolecular hydrogen bonding is again evident in the structures of both **2** and **4** as N–H···Cl and O–H···Cl interactions (Table 3). Complexes **2** and **4** each display intermolecular O–H···N hydrogen bonds between O(alcohol) atoms and N(amino) atoms of the ampdH$^-$ ligands, with O···N separations of 3.047(11) and 3.005(3) Å for **2** and **4**, respectively (Supplementary Material). Each complex is bound to two neighbours to form extended chains along the *c*-direction. In addition, numerous hydrogen bonds are also evident between the ligands of **2** and **4** and the solvent molecules of crystallization.

Table 3
Intramolecular hydrogen bonding distances (Å) for **1**, **2** · 4.25MeOH and **4** · 3EtOH · Et_2O

Parameter	**1**	**2** · 4.25MeOH	**4** · 3EtOH · Et_2O
O···O	2.496(5)–2.681(5)		
N···O	2.939(5)–3.043(5)	2.95(1)–3.02(1)	2.967(3)–3.050(3)
O···Cl		2.990(8)–3.068(8)	3.025(2)–3.038(2)
N···Cl		3.225(8)–3.284(8)	3.356(2)–3.371(2)

The complexes reported here display a coordination mode that has not been previously reported for the coordinatively versatile tripodal amino-alcohol proligand $ampdH_2$ (Fig. 2). A $\eta^1{:}\eta^1{:}\eta^3{:}\mu_3$ binding mode is evident for monodeprotonated ampdH$^-$ in complexes **1**–**4**, while a $\eta^1{:}\eta^2{:}\eta^3{:}\mu_4$ binding mode is displayed by dianionic ampd^{2-} in $Fe^{II}Fe^{III}_6$, $Co^{II}_4Co^{III}_2$ and $\{Co^{II}_5Co^{III}_3\}_n$ complexes that we have reported elsewhere [9]. All of these complexes possess structures comprised of complete or face-sharing monovacant distorted cubane units and it appears that these structural units are favored by the tripodal nature of the ligand. The only other complex of ampd^{2-} whose structure has been reported is a Mo^{VI}_2 species featuring a $\eta^1{:}\eta^1{:}\eta^2{:}\mu_2$ binding mode [8].

3.3. Magnetochemistry

Variable temperature DC susceptibility measurements were performed at 0.01 and 0.1 T on a collection of randomly oriented small crystals of **1** and **3**, in the temperature range 2.0–300 K. Magnetic data were collected and analyzed for **3** rather than **2** due to complications associated with the hygroscopic nature of **2**. As discussed above, the two complexes are assumed to be isostructural. The data obtained at 0.1 T are plotted as $\chi_M T$ and χ_M versus T in Figs. 3a and 4a for **1** and **3**, respectively. For **1** $\chi_M T$ increases progressively from a value of 4.8 $cm^3\ mol^{-1}\ K$ at 300 K to 10.4 $cm^3\ mol^{-1}\ K$ at 8 K before decreasing to 9.5 $cm^3\ mol^{-1}\ K$ at 2.0 K. For **3** $\chi_M T$ increases progressively from a value of 4.8 $cm^3\ mol^{-1}\ K$ at 300 K to 9.3 $cm^3\ mol^{-1}\ K$ at 14 K before decreasing to 5.5 $cm^3\ mol^{-1}\ K$ at 2.0 K. The spin-only value of $\chi_M T$ for four non-interacting Ni^{II} centers is 4.8 $cm^3\ mol^{-1}\ K$ ($g = 2.2$) and the observed behavior is consistent with overall ferromagnetic intramolecular interactions for both species. The data collected above 20 K for **1** and **3** were fit to the exchange Hamiltonian:

$$\hat{H}_{ex} = -2J(\hat{S}_1\hat{S}_4 + \hat{S}_2\hat{S}_3 + \hat{S}_1\hat{S}_2 + \hat{S}_1\hat{S}_3 + \hat{S}_2\hat{S}_4 + \hat{S}_3\hat{S}_4) \quad (3)$$

where a single coupling constant, J, characterizes exchange across the six faces of the cubane. Although the C_1 point symmetry of these molecules strictly demands six different coupling constants, the minimal variation in crystallographically determined Ni···Ni distances and Ni–O–Ni angles (Table 2) is consistent with the use of a single coupling

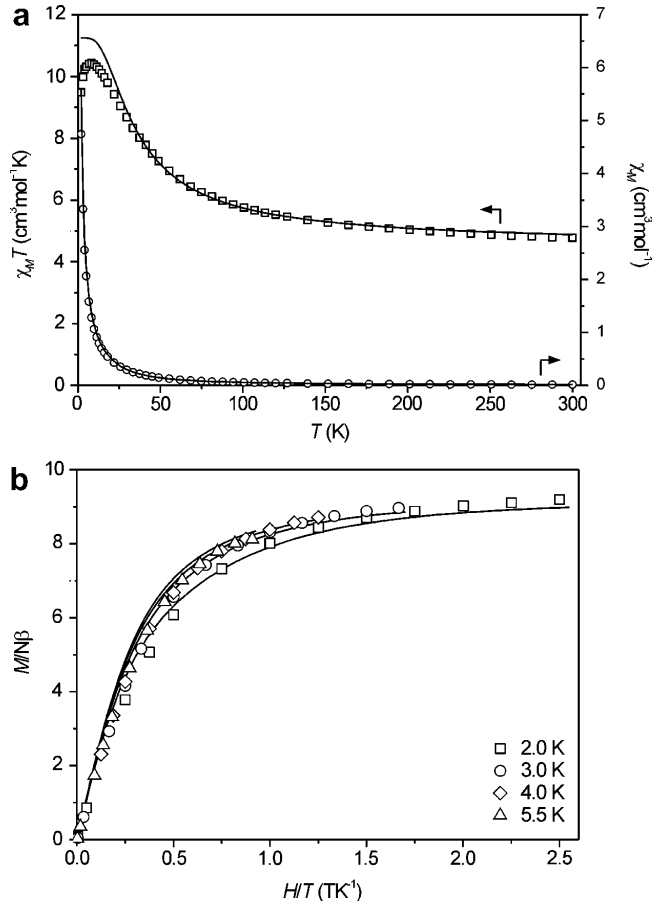

Fig. 3. Plots of magnetic data for **1**: (a) χ_M and $\chi_M T$ vs. T with an applied magnetic field of 0.1 T; and (b) $M/N\beta$ vs. H/T; the solid lines are fits or simulations as described in the text.

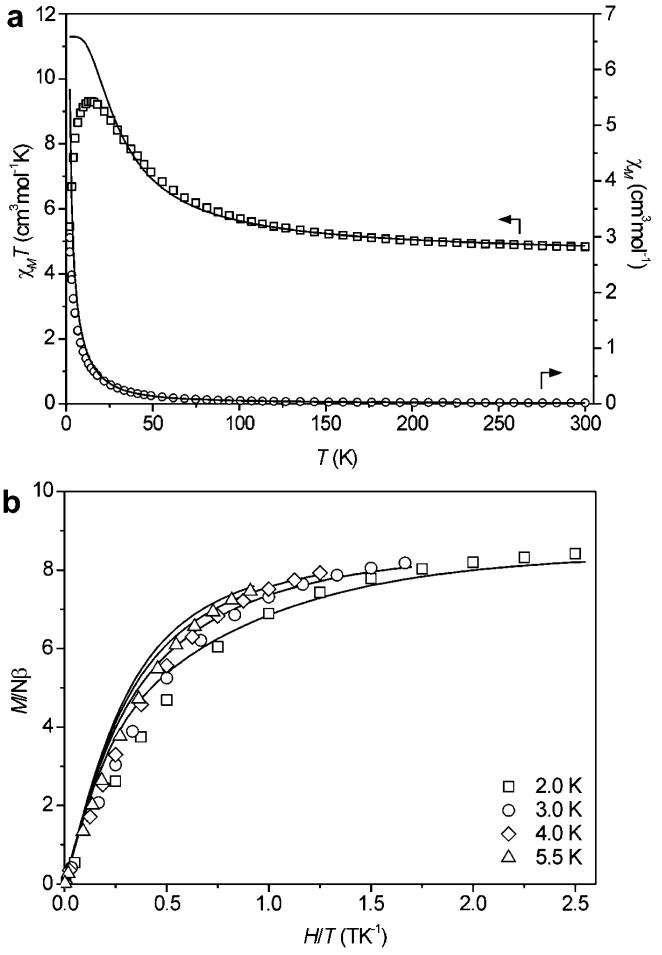

Fig. 4. Plots of magnetic data for **3**: (a) χ_M and $\chi_M T$ vs. T with an applied magnetic field of 0.1 T; and (b) $M/N\beta$ vs. H/T; the solid lines are fits or simulations as described in the text.

constant to fit the susceptibility data for both complexes. The data below 20 K were excluded from the fit, with the decrease in $\chi_M T$ at low temperatures consistent with the effects of zero field splitting (ZFS) and/or antiferromagnetic intermolecular interactions. The fits yielded the parameters $J = 4.3(2)$ cm^{-1} and $g = 2.12(2)$ for **1** and $J = 3.9(1)$ cm^{-1} and $g = 2.13(2)$ for **2**. These afford an $S = 4$ ground state for both complexes, which is the maximum possible for a Ni_4^{II} complex. The determined values of g are consistent with those typically observed for Ni^{II} complexes ($g = 2.1$–2.3) [11,15]. The study of a number of Ni_4 complexes with distorted cubane structures and bridging O atoms has revealed that the observed exchange interactions between Ni centers makes a transition from ferromagnetic to antiferromagnetic as the Ni–O–Ni bridging angles increase above ~98° and the Ni–O–O–Ni dihedral angles increase above ~170° [11,15]. The relevant angles (Table 2) observed for **1** and **2** apparently just fall within this range for ferromagnetic exchange. Ferromagnetic coupling constants are typically less than 20 cm^{-1} for Ni_4 complexes and the values determined for **1** and **3** are consistent with this [11,15].

Variable temperature magnetization measurements were performed on **1** and **3** in the temperature range 2.0–10 K, with fields up to 5 T. The data are presented in Figs. 3b and 4b as plots of $M/N\beta$ versus H/T. Magnetization values of 9.2 and 8.4 $N\beta$ were obtained at 5 T and 2.0 K for **1** and **3**, respectively, and are consistent with $S = 4$ ground states for both complexes. It was possible to simulate the data for the two compounds using the ZFS Hamiltonian:

$$\hat{H}_{ZFS} = D\left[\hat{S}_z^2 - \frac{1}{3}S(S+1)\right] \quad (4)$$

assuming axial anisotropy and a well-isolated $S = 4$ ground state. Two sets of parameters were found to give a reasonable reproduction of the data for each compound, one with $D > 0$ and one with $D < 0$. These parameters are: $g = 2.29(7)$, $D = -0.33(9)$ cm^{-1} and $g = 2.29(8)$, $D = 0.38(9)$ cm^{-1} for **1**; $g = 2.13(3)$, $D = -0.43(6)$ cm^{-1} and $g = 2.09(3)$, $D = 0.44(11)$ cm^{-1} for **3**. An examination of the literature suggests that $D < 0$ is more commonly observed for Ni_4 complexes with similar structures based on distorted cubanes [5], so the simulations provided in Figs. 3b and 4b are for the parameter sets with $D < 0$. The equivalent plots with $D > 0$ are available in the Supplementary Material. As the sign and magnitude of D values cannot

be unequivocally determined from powder magnetic measurements, further studies involving magnetic measurements on oriented single crystals, high field EPR spectroscopy or inelastic neutron scattering would be required to ascertain the D values for **1** and **3**. In addition, the simulations do not reproduce the data exceptionally well, particularly in the low H/T regime. Moreover, close examination of the plots, especially that of **3**, reveals a slight sigmoidal shape to the magnetization curves in the low H/T region. This is consistent with the presence of antiferromagnetic intermolecular interactions [4], which likely account for the deviations between the simulated and experimentally observed behavior. Given that extensive hydrogen bonding is observed crystallographically, multiple pathways probably exist to mediate such interactions. Some unaccounted for rhombic ZFS may also contribute to the discrepancy. Finally, the Ni_4 complexes that have been reported to act as SMMs have been found to do so only at temperatures significantly less than 1 K [5], so ultra-low temperature ac magnetic susceptibility or magnetization relaxation measurements would be required to investigate this possibility.

Variable temperature DC susceptibility measurements were performed at 0.01 and 0.1 T on a collection of randomly oriented small crystals of **4** in the temperature range 2.0–300 K. The data measured at 0.1 T are plotted as $\chi_M T$ and χ_M versus T in Fig. 5a. As the temperature decreases, $\chi_M T$ increases gradually from 13.2 cm^{-3} mol^{-1} K at 300 K. Between 50 and 30 K $\chi_M T$ exhibits a plateau, followed by a steep increase with a maximum value of $\chi_M T =$ 15.2 cm^{-3} mol^{-1} K at 10 K. Further cooling produces an abrupt decrease in $\chi_M T$ to 11.8 cm^{-3} mol^{-1} K at 2 K.

Complex **4** consists of four octahedrally coordinated Co^{II} ions. The ground state of high spin Co^{II} in O_h symmetry is $^4T_{1g}$. Spin–orbit coupling splits the ground state, and this first order effect considerably complicates the analysis of magnetic data of Co^{II} compounds. The room temperature value of $\chi_M T = 13.2$ cm^{-3} mol^{-1} K observed for **4** is much higher than the spin only value of 7.5 cm^{-3} mol^{-1} K calculated for four Co^{II} ($S_i = 3/2$) with $g = 2$ (A in Fig. 5a). The measured high temperature value compares well with the value of 13.6 cm^{-3} mol^{-1} K (B in Fig. 5a) calculated for four uncoupled Co^{II} ions with both spin and orbital contributions to the magnetic susceptibility [16,17]. However, this is not physically reasonable as part of the orbital contribution is undoubtedly quenched due to the distorted octahedral coordination geometries of the Co^{II} centers in **4**. Thus, a second effect has to be jointly responsible for the high $\chi_M T$ value measured at 300 K. The gradual increase in $\chi_M T$ with decreasing temperature is consistent with ferromagnetic intramolecular interactions, which need to be strong to influence the susceptibility at room temperature. The behavior of **4** is similar to that observed previously for another cuboidal Co_4^{II} complex [18], where a high $\chi_M T$ value at room temperature is attributed to the effect of strong intramolecular ferromagnetic interactions on two opposite faces of the cubane (J estimated to be > 300 cm^{-1}). This leads to a hypothetical molecule comprised of two coupled $S = 3$ moieties. Neglecting orbital contributions in this case, a room temperature $\chi_M T$ value of 12.0 cm^{-3} mol^{-1} K is calculated with $g = 2$ (C in Fig. 5a), which is close to the value obtained experimentally for **4**. We conclude that above 30 K the magnetic behavior of **4** originates from the interplay of ferromagnetic intramolecular interactions and spin–orbit coupling, as has been suggested for related complexes [18,19]. As is the situation for the related Ni complexes, the Co–O–Co bond angles in **4** (Table 2) are consistent with ferromagnetic interactions.

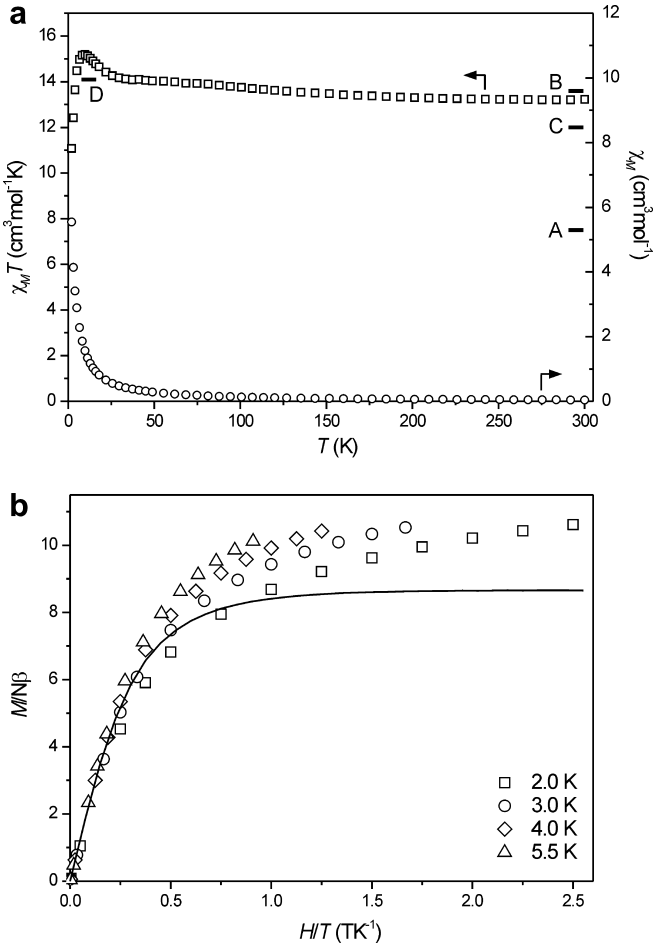

Fig. 5. Plots of magnetic data for **4**: (a) $\chi_M T$ vs. T and χ_M vs. T with an applied magnetic field of 0.1 T, A to D correspond to calculated $\chi_M T$ values as mentioned in the text; and (b) $M/N\beta$ vs. H/T, the solid line is a simulation of the 2 K data calculated with an effective cluster spin $S' = 2$ and $g' = 13/3$.

The sharp increase of $\chi_M T$ as the temperature is decreased below 33 K emphasizes the overall ferromagnetic interactions within the cluster. At temperatures below 30 K only the lowest lying doublet of the spin–orbit split $^4T_1$ ground state of the Co^{II} single ions is occupied. A model with an effective spin $S_i' = 1/2$ per Co^{II} with large g values ($g' = 13/3$ in O_h symmetry) is thus appropriate [17]. For an $S' = 2$ (ferromagnetic coupling of four $S_i' = 1/2$ centers) cluster ground state with isotropic $g' = 13/3$, $\chi_M T =$ 14.1 cm^{-3} mol^{-1} K (D in Fig. 5a), which is close to the

observed experimental maximum. This is a very crude estimate, because the distorted geometry of the Co^{II} positions in **4** will lead to anisotropy splitting of the $S' = 2$ cluster ground state, as well as anisotropic g tensors. However the present data do not allow the introduction of more parameters. The sharp decrease of $\chi_M T$ below 10 K is consistent with anisotropy splitting of the $S' = 2$ ground state and likely also weak antiferromagnetic intermolecular interactions.

Variable temperature magnetization measurements were performed on **4** at four different temperatures with fields up to 5 T. The data are shown in Fig. 5b as $M/N\beta$ versus H/T. The magnetization curve measured at 2 K is not saturated at the high-field limit of our instrument and at 5 T the experimental value is 10.6 $N\beta$. A simulation of the magnetization at 2 K for an $S' = 2$ ground state with $g' = 13/3$ is shown as a solid line in Fig. 5b. The shape of the simulated curve deviates significantly from the experimental data, saturating at 3 T with a saturation value of 8.7 $N\beta$ that is considerably lower than the highest value measured at 2 K. A model with O_h symmetry is oversimplified and distortions and consequently magnetic anisotropy need to be introduced for a quantitative description of the system. The presence of anisotropy is clearly indicated by the differences between the isothermal magnetization plots and their deviation from the calculated curve in Fig. 5b. They indicate splitting of the $S' = 2$ ground state and a higher average g value. Based on the observed magnetization value of 10.6 $N\beta$ at 2 K and 5 T an average g' of 5.3 or higher can be deduced. This order of magnitude is not uncommon for Co^{II} compounds [20].

The large magnetic anisotropy intrinsic to systems with distorted Co^{II} centers in combination with the observed ferromagnetic ground state raises the question whether complex **4** could act as a SMM, as has been observed for another Co_4^{II} cuboidal complex [6]. However, AC magnetic measurements did not show any sign of a peak in the out-of-phase magnetic susceptibility down to 1.8 K. Thus measurements at lower temperatures would be necessary to definitively answer this question.

4. Conclusions

An investigation of the coordination chemistry of the tripodal ligand ampdH_2 with 3d transition metals has afforded a new family of tetranuclear nickel and cobalt spin clusters. A novel binding mode for ampdH^- has been identified and the tendency of this ligand to provide polynuclear species with structures based on cuboidal units has become apparent. This structural preference promotes ferromagnetic exchange interactions in these complexes due to orthogonality of the magnetic orbitals.

A new series of potentially hexadentate ligands derived from 2,2′-bipyridine

Lynton J. Baird, Cory A. Black, Allan G. Blackman *

Department of Chemistry, University of Otago, P.O. Box 56, Dunedin, New Zealand

Received 5 April 2006; accepted 23 June 2006
Available online 30 June 2006

Abstract

Reaction of 2,2′-bipyridine-6-carboxaldehyde with the appropriate aliphatic diamine in MeOH and subsequent reduction with $NaBH_4$ gives the new, potentially hexadentate, ligands *N*,*N*′-bis(2,2′-bipyridin-6-ylmethyl)ethane-1,2-diamine (bmet), *N*,*N*′-bis-(2,2′-bipyridin-6-ylmethyl)propane-1,3-diamine (bmpp) and *N*,*N*′-bis(2,2′-bipyridin-6-ylmethyl)hexane-1,6-diamine (bmhx). The syntheses and characterisation of these ligands are reported; the ligands are isolated as the hydrochloride salts, with purification effected by either recrystallisation or cation exchange chromatography. $[Co(bmet)](ClO_4)_3 \cdot H_2O$ is obtained on reaction of bmet $\cdot$ 4.25HCl $\cdot$ 2.5H_2O with $Na_3[Co(O_2CO)_3] \cdot 3H_2O$, and X-ray structural analysis shows this to have a pair of very short Co–N bonds. The synthesis and characterisation of the first coordination complex containing 6-(aminomethyl)-2,2′-bipyridine (amb) is also described.

Keywords: Hexaamine; Hexadentate ligand; Co(III); Crystal structure; 2,2′-Bipyridine

1. Introduction

The concept of ligand design has become increasingly important in all facets of coordination chemistry [1–5]. Rational ligand design now allows some degree of control over the nuclearity, geometry, magnetic behaviour, spectroscopic properties and reactivity of transition metal complexes, and the advent of metallosupramolecular chemistry has further emphasised the importance of ligand design in the synthesis of transition metal assemblies. One area of that has received particular attention is the synthesis of multidentate ligands that are predisposed to form helical complexes on coordination to two or more metal ions. Oligopyridine-based ligands have shown particular utility in this respect, and ligands such as 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine [6,7] and 2,2′:6′,2″:6″,2‴:6‴,2⁗:6⁗,2⁗′-sexipyridine [8,9] have been shown to form double-helical dimeric complexes with a variety of metal ions. These ligands were chosen as likely candidates for the formation of helical complexes because of their inherent structural limitations; rotation within the ligands is restricted to the interannular C–C bond, and this places significant constraints on the possible positionings of the N donor atoms, therefore limiting the ways in which the ligands can coordinate to a metal ion.

As part of our investigations into the synthesis of new multidentate N-donor ligands [10,11], we herein report the synthesis and characterisation of a new series of potentially hexadentate ligands which contain terminal 2,2′-bipyridine units and central aliphatic diamine spacers whose length can be easily varied. These ligands are more flexible than the corresponding hexadentate oligopyridine 2,2′:6′,2″:6″,2‴:6‴,2⁗:6⁗,2⁗′-sexipyridine, and should therefore be able to adopt a wider variety of binding modes to one or more transition metal ions. We also report the synthesis and crystal structure of the mononuclear complex $[Co(bmet)](ClO_4)_3 \cdot H_2O$, which displays two remarkably short Co–N bonds and, in addition, we undertake the first investigation of the coordination chemistry of 6-(aminomethyl)-2,2′-bipyridine.

2. Experimental

2.1. General

All chemicals used were of LR grade or better. ^{1}H and ^{13}C NMR spectra were obtained using either a Varian VXR 300 MHz or Varian Europa 500 MHz spectrophotometer. All spectra were recorded at room temperature with chemical shifts reported in ppm relative to NaTSP (^{1}H, 0.00 ppm) and dioxane (^{13}C, 67.8 ppm). Visible spectra were recorded in H_2O on a Varian Cary 500 Scan UV–vis NIR spectrophotometer at room temperature. Electrospray mass spectra were obtained on a Shimadzu LCMS-QP8000α (mass range m/z 10–2000, resolution $R = 2$ M, 50% valley) using direct infusion via a manual Rheodyne injector (5 μL loop). Positive ionisation techniques were used on an ESI probe (H_2O mobile phase, 0.2 m/min, CDL temp 250 °C, 4.5 kV). Elemental analyses were performed by the Campbell Microanalytical Laboratory, University of Otago. Reported elemental percentages (C, H, N, Cl, Br) are accurate to within ±0.4%.

Caution: Although no difficulties were experienced with the perchlorate complexes described herein, all perchlorate species should be treated as potentially explosive and handled with care.

2.2. X-ray data collection and refinement

X-ray data for $[Co(bmet)](ClO_4)_3 \cdot H_2O$ were recorded using a Bruker SMART diffractometer at 98(2) K. The structure was solved by direct methods using SIR97 [12] running within the WINGX package [13], with the resulting Fourier map revealing the location of all non-hydrogen atoms. Weighted full matrix refinement on F^2 was carried out using SHELXL-97 [14] with all non-hydrogen atoms being refined anisotropically. With the exceptions noted below, hydrogen atoms were included in calculated positions and were refined as riding atoms with individual (or group, if appropriate) isotropic displacement parameters. H10A and H10B, the hydrogen atoms of the water molecule, were located in a search of the Fourier map and were allowed to refine freely. Crystal data and collection parameters are given in Table 1.

Table 1
Crystal data and structure refinement for $[Co(bmet)](ClO_4)_3 \cdot H_2O$

Empirical formula	$C_{24}H_{26}Cl_3CoN_6O_{13}$
Formula weight	771.79
T (K)	98(2)
λ (Å)	0.71069
Crystal system	triclinic
Space group	$P\bar{1}$
Unit cell dimensions	
a (Å)	10.992(5)
b (Å)	11.267(5)
c (Å)	12.831(5)
α (°)	81.754(5)
β (°)	70.248(5)
γ (°)	75.023(5)
V (Å^3)	1442.0(11)
Z	2
D_{calc} (Mg m^{-3})	1.777
Absorption coefficient (mm^{-1})	0.954
$F(000)$	788
Crystal size (mm)	0.40 × 0.33 × 0.26
θ Range for data collection (°)	1.87 to 26.38
Index ranges	$-13 \leqslant h \leqslant 12$, $-14 \leqslant k \leqslant 13$, $-15 \leqslant l \leqslant 15$
Reflections collected	12474
Independent reflections (R_{int})	5705 (0.0273)
Completeness to $\theta = 25.00°$	97.5%
Absorption correction	semi-empirical from equivalents
Maximum and minimum transmission	1.000000 and 0.846643
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	5705/0/432
Goodness-of-fit on F^2	1.061
Final R indices ($I > 2\sigma(I)$)	$R_1 = 0.0307$, $wR_2 = 0.0736$
R indices (all data)	$R_1 = 0.0386$, $wR_2 = 0.0766$
Largest difference in peak and hole (e Å^{-3})	0.322 and −0.448

2.3. Syntheses

$Na_3[Co(O_2CO)_3] \cdot 3H_2O$ [15], 6-methyl-2,2′-bipyridine [16], 6-(bromomethyl)-2,2′-bipyridine [17] and 2,2′-bipyridine-6-carbaldehyde [17,18] were prepared as described. 6-(Dibromomethyl)-2,2′-bipyridine was prepared by modification of the reported method [17], with the product being separated from 6-(bromomethyl)-2,2′-bipyridine by chromatography on partially deactivated (5% v/v H_2O) silica gel (CH_2Cl_2 eluent). 6-(Aminomethyl)-2,2′-bipyridine (amb) was prepared by the method of Ziessel and Lehn [19], and was isolated as amb.2HCl · H_2O.

2.3.1. N,N′-bis(2,2′-bipyridin-6-ylmethyl)ethane-1,2-diamine · 4HCl · H_2O (bmet · 4HCl · H_2O)

A solution of 1,2-diaminoethane (9.06 μL, 0.136 mmol) and 2,2′-bipyridine-6-carbaldehyde (50.0 mg, 0.271 mmol) in MeOH (2 mL) was heated at reflux for 10 min with stirring. $NaBH_4$ (12.1 mg, 0.321 mmol) was then added slowly to the cooled solution and the mixture was stirred for 2 h. After this time, the solution was reduced (rotavap) to dryness yielding a white solid, which was dissolved in water (10 mL) and extracted with $CHCl_3$ (3 × 5 mL). The organic fractions were combined, dried over $MgSO_4$ and reduced (rotavap) to dryness. The resulting white solid was dissolved in 1 M HCl (1 mL) and reduced (rotavap) to dryness. The product was recrystallised by dissolution in the minimum volume of EtOH and cooling to ca. −20 °C for 72 h to give a white solid which was filtered, washed with cold ethanol and dried under vacuum (29.0 mg, 54%): MS (H_2O/MeCN): $m/z = 397$ $[M + 1\ H]^+$. *Anal.* Calc. for $C_{24}H_{30}N_6OCl_4$: C, 51.44; H, 5.40; N, 15.00; Cl, 25.31. Found: C, 51.55; H, 5.63; N, 14.80; Cl, 25.07%. ^{1}H NMR (500 MHz, D_2O): δ 8.91 (2H, t d, $J = 1$, 6 Hz), 8.77 (4H, m), 8.41 (2H, d, $J = 8$ Hz), 8.23 (2H, t,

$J = 8$ Hz), 8.14 (2H, m), 7.78 (2H, d, $J = 8$ Hz), 4.78 (4H, s), 3.90 (4H, s) ppm; ^{13}C NMR (500 MHz, D_2O): δ 152.1, 148.6, 147.8, 146.3, 142.2, 141.1, 128.0, 126.6, 125.1, 123.3, 51.5, 43.7 ppm.

Purification of the ligand could also be effected by chromatography on Dowex 50 W-X2 cation exchange resin instead of recrystallisation. The product was eluted from the column using 4 M HCl, and removal of solvent (rotavap) gave the product bmet · 4.25HCl · 2.5H_2O as a pale-brown solid in 76% yield. *Anal*. Calc. for $C_{24}H_{33.25}N_6O_{2.5}Cl_{4.25}$: C, 48.33; H, 5.58; N, 14.10; Cl, 25.28. Found: C, 48.05; H, 5.63; N, 14.20; Cl, 25.67%.

2.3.2. *N,N′-bis(2,2′-bipyridin-6-ylmethyl) propane-1,3-diamine · 4.25HCl · 2.5H_2O (bmpp · 4.25HCl · 2.5H_2O)*

A solution of 1,3-diaminopropane (22.7 μL, 0.271 mmol) and 2,2′-bipyridine-6-carbaldehyde (100 mg, 0.542 mmol) in MeOH (2 mL) was heated at reflux with stirring for 10 min. $NaBH_4$ (24.3 mg, 0.642 mmol) was added slowly to the cooled solution and the mixture was stirred for 2 h. After this time the solution was reduced (rotavap) to dryness. The crude product was dissolved in 1 M HCl (1.00 mL) and reduced (rotavap) to dryness to give a white solid which was dissolved in H_2O (200 mL) and loaded onto a Dowex 50 W-X2 cation exchange column. The product was eluted with 4 M HCl (aq) and the band was reduced to dryness (rotavap) to give a pale pink solid (90.0 mg, 54%): ^{1}H NMR (300 MHz, D_2O): δ 9.00 (2H, d, $J = 6$ Hz), 8.82 (4H, m), 8.44 (2H, d, $J = 8$ Hz), 8.26 (2H, t, $J = 8$ Hz), 8.21 (2H, dt, $J = 3$, 6 Hz), 7.82 (2H, d, $J = 8$ Hz), 4.76 (4H, s), 3.55 (4H, t, $J = 8$ Hz), 2.58 (2H, d, $J = 6$ Hz) ppm; ^{13}C NMR (300 MHz, D_2O): δ 152.5, 148.5, 147.7, 146.1, 142.3, 141.0, 128.0, 126.7, 125.0, 123.2, 51.2, 45.3, 23.5 ppm. MS (MeOH): m/z = 411 $[M + 1H]^+$, 206 $[M + 2H]^{2+}$. *Anal*. Calc. for $C_{25}H_{35.25}N_6O_{2.5}Cl_{4.25}$: C, 49.19; H, 5.78; N, 13.77; Cl, 24.70. Found: C, 49.33; H, 5.70; N, 13.79; Cl, 24.35%.

2.3.3. *N,N′-bis(2,2′-bipyridin-6-ylmethyl)hexane-1,6-diamine · 4.5HCl· 2H_2O(bmhx · 4.5HCl · 2H_2O)*

A solution of 1,6-diaminohexane (31.5 mg, 0.271 mmol) and 2,2′-bipyridine-6-carbaldehyde (100 mg, 0.542 mmol) in MeOH (2.00 mL) was heated at reflux with stirring for 10 min. $NaBH_4$ (24.3 mg, 0.642 mmol) was added slowly to the cooled solution and the mixture was stirred for 2 h. After this time, the solution was reduced (rotavap) to dryness. The crude product was dissolved in 1 M HCl (1.00 mL) and reduced (rotavap) to dryness to give a white solid which was dissolved in H_2O (200 mL) and loaded onto a Dowex 50 W-X2 cation exchange column. The product was eluted with 4 M HCl (aq) and the band was reduced to dryness (rotavap) to give a pale green solid (162 mg, 92%): ^{1}H NMR (300 MHz, D_2O): δ 8.93 (2H, d, $J = 6$ Hz), 8.77 (4H, m), 8.40 (2H, d, $J = 8$ Hz), 8.22 (2H, t, $J = 8$ Hz), 8.16 (2H, dt, $J = 3$, 6 Hz), 7.76 (2H, d, $J = 8$ Hz), 4.63 (4H, s), 3.29 (4H, t, $J = 8$ Hz), 1.89 (4H, m), 1.52 (4H, m) ppm; ^{13}C NMR (300 MHz, D_2O): δ 152.8, 148.5, 148.0, 146.3, 142.3, 140.9, 128.0, 126.7, 125.1, 123.1, 51.0, 48.2, 26.1, 26.0 ppm; MS (H_2O/MeCN): $m/z = 453$ $[M + 1H]^+$, 227 $[M + 2\ H]^{2+}$. *Anal*. Calc. for $C_{28}H_{40.5}N_6O_2Cl_{4.5}$: C, 51.53; H, 6.21; N, 12.88; Cl, 24.47. Found: C, 51.36; H, 6.16; N, 12.76; Cl, 24.10%.

2.3.4. *[Co(bmet)](ClO$_4$)$_3$*

$Na_3[Co(O_2CO)_3] \cdot 3H_2O$ (30.4 mg, 83.9 μmol) was added to a solution of bmet · 4.25HCl · 2.5H_2O (50.0 mg, 83.9 μmol) in H_2O (2 mL). The mixture was heated at 65 °C until the colour changed to orange (ca. 5 min). The mixture was then filtered through celite and the filtrate was diluted to 500 mL with distilled water and loaded onto a Sephadex SP C-25 cation exchange column. Elution with 0.3 M $NaClO_4$(aq) removed a yellow band which was reduced to low volume (rotavap) and cooled. The resulting yellow solid was filtered off, washed with MeOH and Et_2O and dried under vacuum. (29.0 mg, 46%): MS (H_2O/MeCN): $m/z = 453$ $[M - 2H]^+$, 227 $[M - 1H]^{2+}$, 151 $[M]^{3+}$. *Anal*. Calc. for $C_{24}H_{24}N_6O_{12}Cl_3Co$: C, 38.23; H, 3.19; N, 11.15; Cl, 14.12. Found: C, 38.00; H, 3.49; N, 10.81; Cl, 13.83%. ^{1}H NMR (500 MHz, D_2O): δ 8.82 (2H, d, $J = 8$ Hz, H_a), 8.74 (2H, t, $J = 8$ Hz, H_b), 8.66 (2H, dd, $J = 8$, 1 Hz, H_d), 8.36 (2H, dt, $J = 1$, 8 Hz, H_e), 8.21 (2H, d, $J = 8$ Hz, H_c), 7.59 (2H, ddd, $J = 8$, 6, 1 Hz, H_f), 7.40 (2H, dd, $J = 6$, 1 Hz, H_g), 5.20 (2H, d, $J = 19$ Hz, $-C^{11}H_2$), 4.72 (1H, d, $J = 19$ Hz, $-C^{11}H_2$), 3.03 (1H, m, $-C^{12}H_2$) ppm; ^{13}C NMR (500 MHz, D_2O): δ 164.4 (C^{10}), 158.1 (C^5), 155.8 (C^6), 151.9 (C^1), 144.7 (C^8), 143.7 (C^3), 130.4 (C^2), 126.8 (C^4), 126.1 (C^7), 125.0 (C^9), 63.0 (C^{11}), 55.5 (C^{12}) ppm; UV–vis (H_2O) (λ_{max}, nm): 440. Crystals of [Co(bmet)]$(ClO_4)_3 \cdot H_2O$ suitable for X-ray structural determination were obtained by slow cooling of a hot, concentrated aqueous solution of the product.

The complex was also obtained as the more soluble chloride salt by elution with 0.3 M NaCl(aq) (Sephadex) and 3 M HCl(aq) (Dowex).

2.3.5. *[Co(amb)$_2$](ClO$_4$)$_3$*

$Na_3[Co(O_2CO)_3] \cdot 3H_2O$ (32.8 mg, 0.0906 mmol) was added to a solution of amb · 2HCl · H_2O (50.0 mg, 0.181 mmol) in H_2O (2 mL) with stirring. The mixture was heated at 65 °C until the colour changed to orange (ca. 10 min). The mixture was filtered through celite, the filtrate was diluted to 200 mL with distilled water and loaded onto a Sephadex SP C-25 cation exchange column. The yellow band that eluted with 0.3 M NaCl (aq) was loaded onto a Dowex 50 W-X2 cation exchange column, eluted with 3 M HCl (aq) and the elaute was reduced to dryness (rotavap). The product was dissolved in H_2O (1.00 mL) and a saturated solution of $NaClO_4$ (aq) was added dropwise until no more yellow solid precipitated. The yellow solid was filtered and washed with isopropanol. The product was recrystallised by dissolution in the minimum volume of hot water and cooling at 4 °C overnight. The product was filtered off, washed with isopropanol and

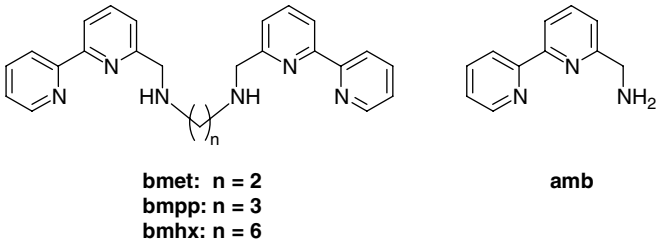
Et_2O and dried under vacuum (46.1 mg, 70%): ^1H NMR (500 MHz, DMSO-d^6): δ 8.98 (2H, d, $J = 8$ Hz, H_a), 8.82 (2H, d, $J = 8$ Hz, H_d), 8.72 (2H, t, $J = 8$ Hz, H_b), 8.36 (2H, dt, $J = 1$, 8 Hz, H_e), 8.16 (2H, d, $J = 8$ Hz, H_c), 7.54 (2H, ddd, $J = 6$, 3, 2 Hz, H_f), 7.37 (2H, d, $J = 6$ Hz, H_g), 5.95 (2H, br s, $–CH_2–NH_2$), 5.83 (2H, br s, $–CH_2–NH_2$), 4.77 (2H, br d, bipy-CH_2–), 4.51 (2H, br d, bipy-CH_2–) ppm; ^{13}C NMR (500 MHz, DMSO-d^6): δ 166.0 ($C^{5,6,10}$), 157.0 ($C^{5,6,10}$), 154.2 ($C^{5,6,10}$), 150.9 (C^1), 142.6 (C^8), 142.0 (C^3), 129.1 (C^2), 125.4 (C^4), 124.7 (C^7), 123.5 (C^9), 52.4 (C^{11}) ppm; UV–vis (H_2O) (λ_{max}, nm): 440; MS (H_2O/MeCN): $m/z = 427$ $[M - 2H]^+$. *Anal.* Calc. for $C_{22}H_{22}N_6O_{12}Cl_3Co$: C, 36.29; H, 3.02; N, 11.54; Cl, 14.62. Found: C, 36.43; H, 3.06; N, 11.42; Cl, 14.41%.

3. Results and discussion

3.1. Synthesis of bmet, bmpp and bmhx

The new ligands bmet, bmpp and bmhx (Fig. 1) were prepared by the reaction, in methanol, of two equivalents of 2,2′-bipyridine-6-carboxaldehyde with 1,2-diaminoethane, 1,3-diaminepropane and 1,6-diaminohexane, respectively, with reduction of the resulting diimine effected by $NaBH_4$ (Scheme 1). Initial attempts to prepare the ligands utilised the reaction of 6-(bromomethyl)-2,2′-bipyridine with the appropriate diamine, but these reactions proved unsuccessful, in contrast to the previous work, where 6-(bromomethyl)-2,2′-bipyridine was used as the starting material for the synthesis of a number of 2,2′-bipyridin-6-ylmethyl-appended multidentate amine ligands [19]. The ligands were isolated in moderate yields as hydrochloride salts, with purification being achieved by either crystallisation from ethanol, or cation exchange chromatography. Microanalytical data were in all cases consistent with the proposed formulations of the ligands, and both ^1H and ^{13}C NMR data were consistent with a symmetrical structure in which the two halves of the ligands are equivalent.

While the ligands bmet, bmpp and bmhx each contain six N donor atoms, they are not all expected to exhibit the same modes of coordination to transition metals. Each ligand contains, in effect, two tridentate binding domains, linked by an aliphatic carbon chain, and it is the length of this carbon chain which may determine the mode of binding of the ligand. Coordination of the two aliphatic N atoms to the same metal ion will form a chelate ring having 5, 6 and 9 members for bmet, bmpp and bmhx, respectively. Formation of the latter is very unlikely, as evidenced by the mere six examples of a chelated $–N(CH_2)_6N–$ fragment in the Cambridge Structural Database [20–24] (this contrasts with 11 156 examples of a chelated $–N(CH_2)_2N–$ fragment) and therefore it would be expected that the bmhx ligand should bind separately to two metal ions in preference to acting as a hexadentate ligand towards a single metal ion. In contrast, the relatively unstrained 5- and 6-membered chelate rings formed by chelation of the aliphatic N atoms of bmet and bmpp should allow these ligands to coordinate to a single metal ion, but will not necessarily preclude formation of dimeric species. With this in mind, we undertook preliminary investigations of the coordination behaviour of the bmet ligand.



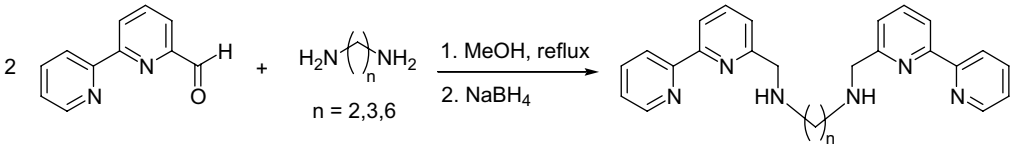


Fig. 1. Structures of the hexadentate ligands bmet, bmpp and bmhx, and the tridentate ligand amb.

3.2. Synthesis and characterisation of $[Co(bmet)](ClO_4)_3$

The mononuclear complex $[Co(bmet)](ClO_4)_3$ was prepared by the reaction of $Na_3[Co(O_2CO)_3] \cdot 3H_2O$ with one equivalent of bmet $\cdot$ 4.25HCl $\cdot$ 2.5H_2O in hot water. The reaction was evidenced by a colour change from dark green to orange over 5 min and purification of the product was achieved by chromatography on Sephadex SP-C25 cation exchange resin ($NaClO_4$ eluent) and subsequent crystallisation on reduction of the volume of the eluate. The complex moved as a 3+ ion on the column, suggesting that it was a mononuclear, rather than binuclear, species. X-ray quality crystals of the monohydrate were obtained on slow cooling of a hot, concentrated aqueous solution and the identity of the complex was confirmed by successful solution and refinement of the structure. Fig. 2 shows an ORTEP diagram of the $[Co(bmet)]^{3+}$ cation, while selected bond lengths and angles are given in Table 2. The structure consists of a central Co^{3+} ion coordinated to all six N atoms of a bmet ligand. The charge is balanced by three ClO_4^- counterions, and a single water of crystallisation is involved in H-bonding interactions with one of the ClO_4^- counterions. While there are potentially a number of ways in which the bmet ligand could fold about the metal ion,

the presence of the terminal 2,2′-bipyridine fragments essentially constrains the CH_2 groups at the 6′ positions to be coplanar with the attached pyridine ring. This means that both N3 and N4 must, of necessity, coordinate in a *meridional* manner with respect to their neighbouring 2,2′-bipyridine fragments and the overall conformation of the complex can therefore be described as *mffm* [25]. Such a conformation gives rise to the possibility of a single enantiomeric pair, and both enantiomers are observed in the crystal structure. The Co^{3+} ion displays a distorted octahedral geometry; the Co(1)–N(2) (1.8653(19) Å) and Co(1)–N(5) (1.8636(19) Å) bonds involving the non-terminal pyridine rings are significantly shorter than the other four, and in fact are amongst the shortest known Co^{III}–N_{amine} bonds. A search of the Cambridge Structural Database for Co^{III} bonded to amine N found 826 structures containing 8660 Co–N bonds ($R_1 < 5\%$, no errors and not disordered) with the average distance being 1.967 Å (standard deviation 0.031 Å). Only 29 of the 8660 bonds were shorter than 1.867 Å, with all of these being bonds to deprotonated N atoms. It therefore appears that the Co–N bonds to the non-terminal pyridine rings in $[Co(bmet)](ClO_4)_3 \cdot H_2O$ are remarkably short, and this is presumably due to steric constraints imposed by the ligand. Similar shortening of the Co–N bonds to non-terminal pyridine rings has also been observed in $[Co(terpy)_2]Cl_3.$"$11H_2O$" [26], and appears to be a feature of metal complexes of terpy in general. The quarterpy complex $[Co(quaterpy)(OH_2)(SO_3)]NO_3 \cdot H_2O$ also exhibits short Co–N bonds to the two N atoms of the central pyridine rings [27]. The pair of very short Co–N bonds in $[Co(bmet)](ClO_4)_3 \cdot H_2O$ help to make the average Co–N bond length (1.927 Å) in this CoN_6 system shorter than any reported in an extensive review of CoN_6 complexes [28], and the very strong-field nature of the bmet ligand is further reflected in the λ_{max} value of 440 nm found in the UV/vis spectrum, a shorter wavelength than previously found in CoN_6 complexes [28]. The bond angles around the metal ion in $[Co(bmet)](ClO_4)_4 \cdot H_2O$ attest to the deviations from strict octahedral geometry, with the angles subtended by the N atoms of the two sets of neighbouring pyridine rings (82.52(8)° and 82.49(8)°) typical of the angles found in Co(III) complexes containing bipyridine [29–31]. In contrast to the solid-state structure, the ^1H and ^{13}C NMR spectra of $[Co(bmet)]^{3+}$ are consistent with a solution structure having a C_2 rotation axis; the ^1H NMR spectrum exhibits 11 well-separated signals, while the ^{13}C NMR spectrum shows 12 peaks. A combination of HSQC and gCOSY spectra allowed complete assignment of the ^1H and ^{13}C spectra, and the assignments are given in Section 2, according to the numbering scheme given in Fig. 3.

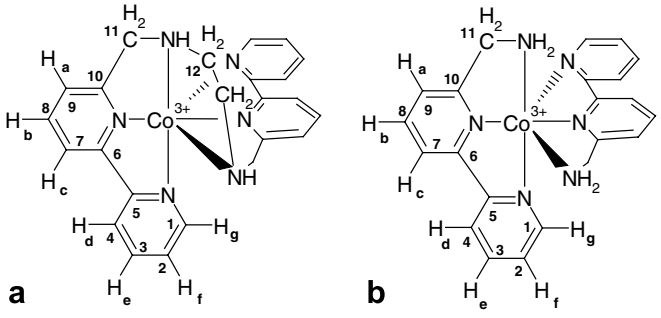

Fig. 3. Numbering schemes for: (a) $[Co(bmet)]^{3+}$ and (b) $[Co(amb)_2]^{3+}$.

3.3. Synthesis and characterisation of $[Co(amb)_2](ClO_4)_3$

The amb ligand (Fig. 1) represents essentially half of the bmet ligand, and we were therefore interested in comparing the coordination chemistry of amb to bmet, to see what, if any, effect the ethyl linker in bmet had on the geometry of the respective Co(III) complexes. Reaction of 2 equivalents of amb · 2HCl · H_2O with $Na_3[Co(O_2CO)_3] \cdot 3H_2O$ in water at elevated temperature and subsequent purification using cation exchange chromatography gave $[Co(amb)_2](ClO_4)_3$ in good yield. Elemental analysis and ESI-MS data were consistent with the formulation of the complex as a 6-coordinate Co(III) complex containing two tridentate amb ligands, and the complex was further characterised by ^1H and ^{13}C NMR spectroscopy. Unfortunately, crystals of the complex suitable for X-ray crystallography could not be obtained.

To the best of our knowledge $[Co(amb)_2](ClO_4)_3$ represents the first reported transition metal complex of the amb ligand, although complexes of ligands derived from amb are known [32,33]. The amb ligand is constrained to coordinate in a *meridional* tridentate fashion as found above for the two tridentate binding domains of bmet. Both the ^1H and ^{13}C NMR spectra are consistent with a solution structure in which the complex cation contains a C_2-axis. The rigid nature of the coordinated amb ligand is reflected in the ^1H NMR spectrum of $[Co(amb)_2]^{3+}$; the $-CH_2-$ protons appear as separate geminally coupled signals at 4.77 and 4.51 ppm, each of which also show coupling to one of the neighbouring $-NH_2$ protons. The $-NH_2$ protons are observed as separate broad signals at 5.95 ppm and 5.83 ppm in DMSO-d^6, and these signals are absent when the spectrum is obtained in D_2O. The ^{13}C NMR spectra of both $[Co(amb)_2]^{3+}$ and $[Co(bmet)]^{3+}$ are similar, the one distinct difference being the peak due to the isolated methylene carbon C11, which appears at 52.4 ppm and 63.0 ppm in the amb and bmet complexes, respectively. Like bmet, amb also appears to act as a very strong-field ligand, with $[Co(amb)_2]^{3+}$ displaying a λ_{max} value of 440 nm, possibly again indicative of a very short Co–N bond to the central pyridine ring. It therefore appears that both $[Co(amb)_2]^{3+}$ and $[Co(bmet)]^{3+}$ display similar spectral properties and hence similar geometries.

4. Conclusions

The successful synthesis of bmet, bmpp and bmhx should allow the synthesis of many other potentially hexadentate ligands using the same synthetic scheme, simply by changing the aliphatic diamine. We are currently investigating the synthesis of such ligands. We are also extending our studies into the coordination chemistry of the bmpp and (particularly) bmhx ligands with a variety of metal ions, in the hope of preparing dinuclear helical systems. Finally, we have shown that the amb ligand is useful as a very strong-field *meridional* tridentate ligand, and its coordination chemistry deserves further investigation.

Abstract

The title compounds, $[Ln(PDC)(HPDC)]_\infty$ (H_2PDC = pyridine-3,4-dicarboxylic acid, Ln = La, Ce, Pr), have been prepared and have been characterised by IR, MS, TGA, X-ray crystallography and powder diffraction. These isostructural complexes display both bridging and chelating carboxylate binding modes including a highly unusual chelation in which both carboxylate substituents bind to the same Pr atom, imparting chirality around the metal despite the non-chiral crystal setting. This system represents the first fully characterised metal complex containing the N-protonated ligand derivative ($N\text{-}HPDC^-$). A polymorph of the ligand precursor, pyridine-3,4-dicarboxylic acid is also reported.

1. Introduction

Metal-organic coordination networks are increasingly coming under the spotlight for their potential to exhibit useful bulk properties such as nonlinear optical (NLO) behaviour [1], novel magnetism [2] and guest sorption [3]. On top of these properties they often possess aesthetically attractive architectures, a factor which adds to their appeal for many researchers. The deliberate design of functional materials, crystal engineering, has seen many metal-organic networks formed that utilise the rigidity provided by predictable metal coordination geometries combined with 'semi-predictable' bridging ligands, such as dicarboxylates, bipyridyls and poly-alcohols [4–6]. Lanthanoids have received somewhat less attention in the crystal engineering field due to their less predictable coordination geometries, however, many properties of rare-earths, such as luminescence and some magnetic properties, are worth harnessing in solid-state networks [7,8].

Carboxylate networks in particular have received a great deal of attention due to their ability to both chelate to a metal and simultaneously bridge to an adjacent metal, especially with the larger and less rigid coordination spheres of rare-earth elements [9]. More recently, complexes of bi-functional ligands containing both the carboxylate appended to a pyridyl ring have been examined structurally. Within our own sphere of research, mixed functionality pyridyl/carboxylate ligands have been employed as corrosion inhibitors when part of rare-earth coordination complexes [10] and cerium carboxylates are known to be less toxic alternatives to chromate-based inhibitors to steel corrosion [11,12].

One of the least studied pyridyl/carboxylate ligands is that derived from the unsymmetrical pyridine-3,4-dicarboxylic acid (H_2PDC). Several structures are known of the related pyridine-3,5-dicarboxylate with rare-earth metals [13–15], including a Tm structure with an N-protonated

ligand [16]. Pyridine-2,6-dicarboxylate (dipicolinate) has also been well studied forming anionic [17,18], cationic [19] and neutral [20] networks with rare-earths including ones that incorporate mixed carboxyl/carboxylate ligands, $[NC_5H_3(CO_2)(CO_2H)]^-$ [21,22]. The first structures containing PDC ligated rare-earths have only emerged very recently [23] (structurally characterised transition metal PDC complexes are better known [24–28]). These first rare-earth/PDC complexes are heteroleptic, incorporating either nitrate or oxalate anions into the coordination network, e.g., $[La_2(PDC)_2(NO_3)_2(H_2O)_3]_n$. The hetero-anions bridge between metals to form 'dimers' which are then repeated in 2D sheets held together by the PDC^{2-} ligands. Since completion of this present study, a compound class resulting from hydrothermal synthesis was reported to be of the form $[Ln(III)(PDC)_2]_\infty$ (Ln = La, Nd) [29]. However, this represents a system with an unbalanced charge across the coordination framework.

Herein, we report the synthesis and structure of an 'isostructural' series, synthesised by standard aqueous chemistry, and determine that the correct formulation of these compounds is $[Ln(PDC)(HPDC)]_\infty$ (Ln = La, Ce, Pr), with protonation of a pyridine of one of the PDC ligands.

2. Experimental

2.1. General

Starting materials and solvents were of standard reagent grade and used as purchased with no further purification. Prior to analyses, products were dried under vacuum for 2 h, over a steam bath for a further 2 h and in a desiccator for a minimum of 24 h. IR data were collected of Nujol mulls with a Perkin–Elmer 1600 FTIR instrument in the range 500–4000 cm^{-1}. TGA analyses were obtained with a Perkin–Elmer Pyris 1 instrument under flowing N_2 at a heating rate of 10 °C/min. Microanalyses were conducted by the Campbell Microanalytical Laboratories at the University of Otago, New Zealand. Lanthanoid content was determined by EDTA titration with xylenol orange indicator following acid digestion and buffering with hexamine. XRD powder diffraction data were collected at ambient temperature using a Phillips 1140 diffractometer equipped with a monochromated Cu source (1.5418 Å). X-ray powder simulation of **3** was generated using the program PULVERIX from experimental single crystal data [30].

2.2. Synthesis

A standard solution of Na_2PDC was prepared and used in all subsequent syntheses. Sodium hydroxide (2.81 g, 70.3 mmol) was added to a stirred solution of pyridine-3,4-dicarboxylic acid (6.60 g, 39.26 mmol) in water (350 ml). Further NaOH (0.5 M solution in H_2O) was added until the pH of the solution was ~7. The solution was diluted to give a final concentration of 0.079 mol dm^{-3}.

2.2.1. $\{[La(PDC)(N\text{-}HPDC)]\cdot xH_2O\}_\infty$ (**1**)

A solution of Na_2PDC (85 ml, 6.67 mmol) was added to a solution containing an excess of $LaCl_3\cdot 6H_2O$ (3.56 g, 9.70 mmol) in water (100 ml). The pH was adjusted to 5.0 (using 0.5 M NaOH) and the solution stirred for 8 h at 90 °C. Upon cooling a pale yellow precipitate was isolated, washed with water and dried. Yield, 2.61 g, 79% (based on Na_2PDC). *Anal.* Calc. for $C_{14}H_{11}N_2O_{10}La$ ($[La(PDC)(N\text{-}HPDC)]\cdot 2H_2O$): C, 33.22; H, 2.19; N, 5.53; La, 27.44. Found: C, 33.40; H, 2.26; N, 5.46; La, 28.45%. IR (ν/cm^{-1}): 3420(s), 2243(w), 2200(m), 1997(w), 1957(w), 1557(s), 1493(s), 1417(s), 1282(s), 1172(m), 1121(s), 1061(s), 880(s), 839(s). XRD *d*-spacings (Å, relative intensity in parentheses): 14.00(m), 7.14(m), 6.61(m), 6.11(s), 4.92(m), 4.61(m), 4.17(s), 3.39(s), 3.33(m), 3.14(w), 3.00(w).

2.2.2. $\{[Ce(PDC)(N\text{-}HPDC)]\cdot xH_2O\}_\infty$ (**2**)

The compound was prepared in a similar manner to **1** from a solution of Na_2PDC (85 ml, 6.67 mmol) and $CeCl_3\cdot 7H_2O$ (3.91 g, 10.49 mmol) in water (100 ml) giving a yellow precipitate. Yield, 2.39 g, 71% (based on Na_2PDC). *Anal.* Calc. for $C_{14}H_{11}N_2O_{10}Ce$ ($[Ce(PDC)(N\text{-}HPDC)]\cdot 2H_2O$): C, 33.14; H, 2.18; N, 5.52; Ce, 27.6. Found: C, 32.13; H, 2.05; N, 5.25; Ce, 28.54%. IR (ν/cm^{-1}): 3425(m), 2239(w), 2188(w), 1996(w), 1957(w), 1601(s), 1571(s), 1550(s), 1418(s), 1378(s), 1164(s), 1129(w), 1060(s), 878(s), 840(s), 813(m). XRD *d*-spacings (Å, relative intensity in parentheses): 14.37(m), 7.21(w), 6.68(m), 6.13(s), 4.94(m), 4.62(m), 4.19(s), 3.39(s), 3.34(m), 3.14(w), 2.99(w).

2.2.3. $\{[Pr(PDC)(N\text{-}HPDC)]\cdot xH_2O\}_\infty$ (**3**)

The compound was prepared in a similar manner to **1** from a solution of Na_2PDC (50 ml, 3.93 mmol) and $Pr(NO_3)_3\cdot 6H_2O$ (2.01 g, 4.62 mmol) in water (100 ml) giving a pale green precipitate. Yield, 1.56 g, 78%. *Anal.* Calc. for $C_{14}H_{11}N_2O_{10}Pr$ ($[Pr(PDC)(N\text{-}HPDC)]\cdot 2H_2O$): C, 33.09; H, 2.18; N, 5.51; Pr, 27.70. Found: C, 33.33; H, 2.18; N, 5.56; Pr, 27.16%. IR (ν/cm^{-1}): 3416(m), 2250(w), 2201(m), 1997(w), 1957(w), 1602(s), 1574(s), 1568(s), 1551(s), 1419(m), 1311(m), 1169(m), 1120(w), 1062(w), 900(w), 840(m), 818(w). XRD *d*-spacings on bulk powder (Å, relative intensity in parentheses): 14.40(m), 7.23(m), 6.68(m), 6.15(s), 4.95(m), 4.62(m), 4.18(m), 3.39(s), 3.33(m), 3.15(w), 2.99(w). Single crystals were obtained by crystallisation from aqueous ethanol (1:1, v/v), vide infra. Calculated XRD *d*-spacings from single crystal data (Å, relative intensity in parentheses): 14.43(s), 7.22(m), 6.65(m), 6.10(s), 4.93(m), 4.59(m), 4.16(m), 3.37(s), 3.33(m), 3.14(w), 2.97(w).

2.3. X-ray crystallography

Crystals were mounted on a fine glass fibre using viscous hydrocarbon oil. Data were collected on a Bruker X8 Apex II CCD diffractometer using monochromated Mo Kα

radiation (0.71073 Å). The collection temperature was maintained at 123 K using a Oxford Cryosystem open-flow N_2 cryostat. Data sets were corrected for Lorentz and polarisation effects and for the effects of absorption. Structures were solved by Patterson synthesis (Pr complex) or direct methods (pyridine-3,4-dicarboxylic acid) using SHELXS-97 [31] and refined using conventional alternating cycles of least-squares refinement with SHELXL-97 [32] and difference Fourier synthesis with the aid of the graphical interface program X-Seed [33,34]. In all cases non-hydrogen atoms were refined anisotropically. Hydrogen atoms attached to carbon were fixed in idealised positions and allowed to ride on the atom to which they are attached. Hydrogen atom thermal parameters were tied to those of the atom to which they are attached. In both structures the pyridinium NH could be experimentally located, however these were fixed in calculated positions for refinement purposes. The OH proton in the structure of pyridine-3,4-dicarboxylic acid was also placed in a fixed position (see Section 3).

Crystal data for $\{[(PDC)(HPDC)Pr]\cdot H_2O\}_n$: $C_{14}H_9N_2O_9Pr$, $M = 490.14$, colourless block, $0.12 \times 0.12 \times 0.10$ mm^3, monoclinic, space group $P2_1/m$ (No. 11), $a = 7.2439(14)$ Å, $b = 6.7374(13)$ Å, $c = 14.488(3)$ Å, $\beta = 94.13(3)°$, $V = 705.3(2)$ Å^3, $Z = 2$, $D_c = 2.308$ g/cm^3, $F_{000} = 476$, $2\theta_{max} = 54.9°$, 5707 reflections collected, 5725 unique ($R_{int} = 0.0438$). Final GooF = 1.107, $R_1 = 0.0348$, $wR_2 = 0.0961$, R indices based on 5410 reflections with $I > 2\sigma(I)$ (refinement on F^2), 173 parameters, 0 restraints, $\mu = 3.516$ mm^{-1}. All of the crystals in the sample displayed evidence of twinning (see Section 3). The initial solutions were conducted on a simulated HLKF-4 file and final refinements were carried out using the full HLKF-5 data.

Crystal data for pyridine-3,4-dicarboxylic acid: $C_7H_5NO_4$, $M = 167.12$, colourless block, $0.20 \times 0.17 \times 0.12$ mm^3, monoclinic, space group $P2_1/c$ (No. 14), $a = 7.564(3)$ Å, $b = 7.305(3)$ Å, $c = 12.120(5)$ Å, $\beta = 104.310(10)°$, $V = 648.9(5)$ Å^3, $Z = 4$, $D_c = 1.711$ g/cm^3, $F_{000} = 344$, $2\theta_{max} = 50.0°$, 1585 reflections collected, 1103 unique ($R_{int} = 0.0280$). Final GooF = 1.095, $R_1 = 0.0699$, $wR_2 = 0.1840$, R indices based on 866 reflections with $I > 2\sigma(I)$ (refinement on F^2), 123 parameters, 1 restraint, $\mu = 0.144$ mm^{-1}. One oxygen atom, O(3), is disordered over two positions with refined occupancies of 66:34.

3. Results and discussion

The reaction of disodium pyridine-3,4-dicarboxylate with $LnX_3 \cdot xH_2O$ salts (X = Cl, NO_3) in water at pH 5 resulted in the precipitation of pure samples of the title complexes, $[Ln(PDC)(N\text{-}HPDC)]_\infty$ (Ln = La **1**, Ce **2** and Pr **3**). A publication in the recent literature reports the structure of the charge-unbalanced complex "$[Nd(PDC)_2]_\infty$" obtained through the hydrothermal reaction of pyridine-3,4-dicarboxylic acid and $Nd(NO_3)_3$ [29]. The harsh, hydrothermal synthesis gives rise to decarboxylated side-products, whereas our aqueous synthesis affords the present pure complexes in good yields. An examination of the crystal structure of "$[Nd(PDC)_2]_\infty$"[1] compared to that of our own complex $[Pr(PDC)(N\text{-}HPDC)]_\infty$ (**3**) shows that these two compounds are essentially isostructural, hence the neodymium complex is $[Nd(PDC)(N\text{-}HPDC)]_\infty$.

Infra-red analysis of the series $[Ln(PDC)(N\text{-}HPDC)]_\infty$ shows, in all cases, a very weak band attributable to the pyridinium NH^+ group at around 2200 cm^{-1} [35], making the complex charge neutral. There is no absorption in the region of 1700 cm^{-1} confirming that carboxylate groups are not protonated. The pyridinium proton was also observable by X-ray crystallography, as described later. The IR spectra of the three complexes all display several peaks corresponding to carboxylate stretching absorptions in the region 1300–1600 cm^{-1}, suggestive of several binding modes in the structure, and also peaks suggestive of the presence of water. Thermo-gravimetric analyses carried out on the precipitated products (powders) confirm the presence of water of crystallisation (all products were dried thoroughly before analysis). Complexes **1** and **3** show weight losses of 7.63% and 6.87%, respectively, within one steady process that occurs between approximately 110 and 300 °C. TGA carried out on a sample of the crystals of **3** showed a similar weight loss of 7.96%. These values correspond to the loss of two water molecules per formula unit if the empirical formula of the complex is taken to be $[Ln(PDC)(N\text{-}HPDC)]\cdot 2H_2O$ (calculated loss for $2H_2O$ = La (7.11%), Ce (7.10%), Pr (7.09%); if formulations were $[Ln(PDC)(N\text{-}HPDC)]\cdot H_2O$ the loss should be ~3.37%). Elemental analyses (C, H, N, Ln) also strongly support this formulation. TGA of complex **2** shows a somewhat lower weight loss of 5.96%, although the temperature range involved is the same. This may be due to a lesser degree of hydration in the structure. As one of the water molecules is not structurally significant/detectable, see below, partial occupancy is plausible. The slight spread of weight-loss values for **1**–**3** also suggests that this may be the case.

X-ray quality single crystals were obtained of the praseodymium complex **3** and the structure was determined by X-ray crystallography. Only one molecule of water per formula unit, $[Pr(PDC)(N\text{-}HPDC)]\cdot H_2O$, could be located. However, the possibility of a second lattice water in the crystal structure exists, as discussed below and the TGA data from both crystals and powder of **3** indicate that two water molecules are present. The La and Ce complexes were only obtained as microcrystalline powders and were determined to be isostructural with the Pr complex by comparison of the calculated powder pattern from the single crystal diffraction data of **3** with the experimental XRD patterns of **1** and **2** (see Section 2). The bulk product of **3** obtained before recrystallisation was also determined to be identical with the crystals by XRD data.

The polymeric complex $[Pr(PDC)(N\text{-}HPDC)]\cdot xH_2O$ crystallises from water/ethanol (1:1) in the space group

[1] Reported cell parameters of $[Nd(PDC)_2]$: $P2_1/c$, $a = 14.424(1)$ Å, $b = 6.761(1)$ Å, $c = 14.522(1)$ Å, $\beta = 94.25(1)°$, $V = 1412.22(15)$ Å^3.

$P2_1/m$. The asymmetric unit contains half of one repeating chemical unit ([Pr(PDC)(N-HPDC)]) due to the presence of the mirror plane, upon which the N-HPDC ligand lies and which the PDC ligand straddles. Each praseodymium ion is charge balanced by one fully deprotonated ligand (PDC^{2-}) and one N-protonated ligand ($N\text{-}HPDC^{-}$) (Fig. 1). The two ligands each have only one mode of coordination. To the best of our knowledge these systems represent the first examples of structurally characterised coordination complexes containing the N-protonated version of the PDC ligand. The previously known structure of the free acid, H_2PDC, contains the molecule in one of its potential zwitterionic forms, with the *para*-carboxylate group deprotonated [36] and the new polymorph of this di-acid also exists in this zwitterionic form, vide infra.

The praseodymium atoms are nine coordinate with a distorted tri-capped trigonal prismatic geometry. Each praseodymium atom has attached two chelating carboxylates, one oxygen atom from each of four bridging carboxylates and one pyridyl nitrogen, (Fig. 2). There are no aqua ligands within the structure, despite the syntheses being carried out in aqueous media and there was no nitrate coordination from the counter-ions by contrast with earlier studies [23]. The Pr–O bond lengths for the chelating carboxylate groups lie within the expected range with lengths of 2.554(5)–2.612(3) Å. These Pr–O lengths are comparable to those observed in $[Pr(H_2O)_9]^{3+}$ with an average of 2.525 Å, value obtained from the structures of $[Pr(H_2O)_9](CF_3SO_3)_3$ [37] and $[Pr(H_2O)_9](EtOSO_3)_3$ [38]. The Pr–O distances involving bridging carboxylates are, in all cases, shorter than their chelating counterparts, within the range 2.393(5)–2.486(5) Å (Table 1).

The long-range structure consists of pseudo-2D sheets, aligned parallel to the 0 0 1 plane, in which offset rows of Pr atoms are connected by both PDC^{2-} and $N\text{-}HPDC^{-}$ ligands, (Fig. 3). These ligands exist in distinct environments with the $N\text{-}HPDC^{-}$ ions located exclusively on the exterior of the sheets and the PDC^{2-} ions located within the sheets. Along the 'outside' of the 2D sheets the

Symmetry equivalents used are shown in Fig. 2.

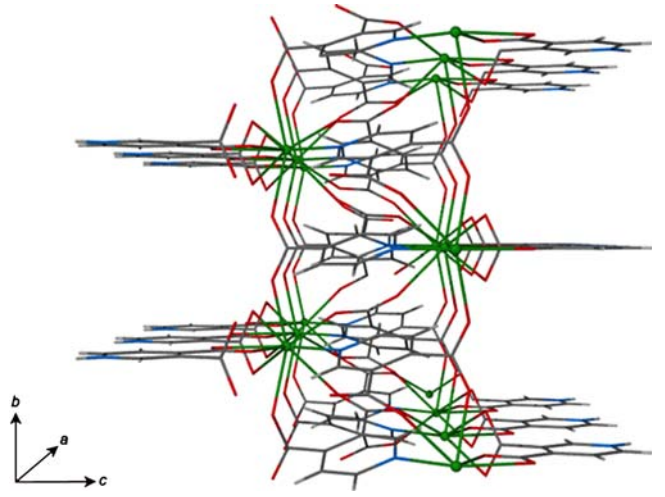

Fig. 3. The pseudo-2D sheets propagate parallel to the *a*/*b* plane and are held together by the ligands PDC^{2-} (internally) and $N\text{-}HPDC^{-}$ (externally). Pr atoms are represented by spheres.

$N\text{-}HPDC^{-}$ ligands bridge between pairs of adjacent Pr atoms by means of chelating carboxylates that are orientated perpendicular with respect to each other, effectively

'zipping' together the Pr atoms within rows. These ligands adopt a μ-η^2(*m*-CO_2):η^2(*p*-CO_2) binding geometry, bridging between lanthanoid atoms using only a bidentate chelating binding mode at each metal centre (Fig. 1). The pyridinium ring of this ligand lies on a crystallographic mirror plane with the protonated nitrogen atom facing towards carboxylate groups on the exterior of the adjacent sheets.

The interior of the sheets contains the doubly deprotonated PDC^{2-} ligands, connecting the offset Pr rows exclusively through bridging carboxylates and the Pr–N interaction. Overall the PDC^{2-} ligand displays μ_4 binding. Each carboxylate group is in a μ_2 bridging mode between two lanthanoid atoms. One Ln atom is common to both carboxylate groups, chelating within a seven-membered [OCCCCOLn] ring (Fig. 1). This mode of metal chelation between the two adjacent carboxylates has only been observed previously in $[Zn(PDC)]_\infty$ [26,39] and $[Mn_2(PDC)_2(4,4'\text{-bipy})_2]$ [40]. The nitrogen bonds to a further Ln atom to complete the μ_4 coordination; μ_4-(η^1:η^1:η^2:η^1). Each ligand links four metal atoms between three rows; two adjacent Pr atoms within the same row and one Pr each on the offset rows above and below (Fig. 4a). The PDC^{2-} ligand is disordered 50:50 across a mirror plane upon which the nitrogen, *p*-carbon and the *p*-carboxylate carbon atom lie. The pyridyl ring is rotated approximately 23° from this mirror plane. The *p*-carboxylate is perpendicular to the mirror plane and bridges between Pr atoms that lie directly over each other. The disorder of the ligand results in chelation to one of two praseodymium atoms, either above or below, (Fig. 4a). The PDC^{2-} ligands lie in stacks perpendicular to the *b*-axis and when the disorder in the structure is rationalised it can be seen that ligands within each stack are orientated in the same direction. The orientations of the PDC^{2-} ligands alternate throughout the stacks that comprise the 2D sheets (Fig. 4b).

A fascinating aspect of the structure is the interaction between adjacent 2D sheets. The exterior of each individual sheet consists of parallel pyridinium groups. When the sheets are viewed next to each other, these pyridinium groups are observed to interdigitate by means of face-to-face π–π interactions, (Fig. 5). There are also donor bifurcated CH···O_2C hydrogen bonds [41] between the pyridyl ring and a carboxylate group. The observed water molecule in the structure exists in the void between sheets and assists in the hydrogen bonding that holds the sheets together. The water molecule receives hydrogen bonds from both the protonated pyridinium nitrogen and a CH donor and appears to hydrogen bond to carboxylate acceptors, although the hydrogen atoms of the water could not be experimentally located by X-ray diffraction. The weak interactions holding the sheets together may explain the twinned nature of all of the crystalline samples that were obtained. Analysis of the twin components shows that they are related by a 180° rotation about the *c*-axis. This can readily be seen to correspond to the 2D sheets being rotated by 180°. As previously mentioned, TGA and microanalytical results are suggestive of a second water molecule being present within the structure. It is believed that this may exist within the centre of the 2D sheets in a shared position with a carboxylate ligand although the disorder that is manifest within the structure makes any definitive assignment impossible and no large residual Fourier peaks are evident.

During the course of our investigation, crystals were also obtained of a second polymorph of pyridine-3,4-dicarboxylic acid whilst attempting the synthesis of an ytterbium complex of PDC^{2-}. The existing compound crystallises in the chiral space group $P2_12_12_1$ and exists in a zwitterionic form, with the carboxylate in the *para*-position being deprotonated, and forms an interpenetrating hydrogen-bonded network [36]. The new polymorph exists in the space group $P2_1/c$, with the pyridinium rings all lying parallel to one another. As with the previously known

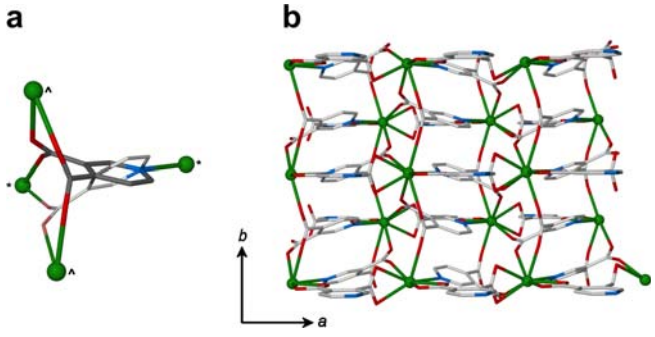

Fig. 4. (a) The PDC^{2-} ligand is disordered over two positions rotated around the N···CO_2^- axis (one unique position shown in bold). The μ_4 ligand bridges between two adjacent Pr atoms in the same row (*) and two Pr atoms in the offset rows immediately above and below (^). (b) The orientation of the ligands within one stack along the *b*-axis remains the same with alternate stacks in the a-direction having opposing orientations. The disorder is removed for clarity.

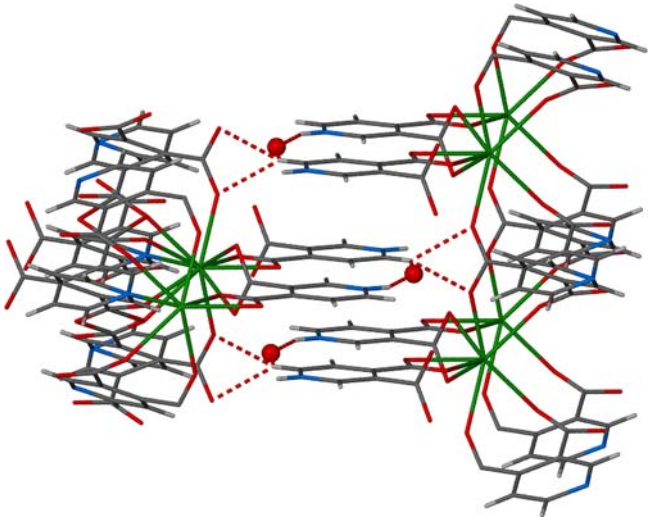

Fig. 5. Adjacent sheets interdigitate by means of π–π stacking and hydrogen bonding involving enclathrated water (shown as spheres).

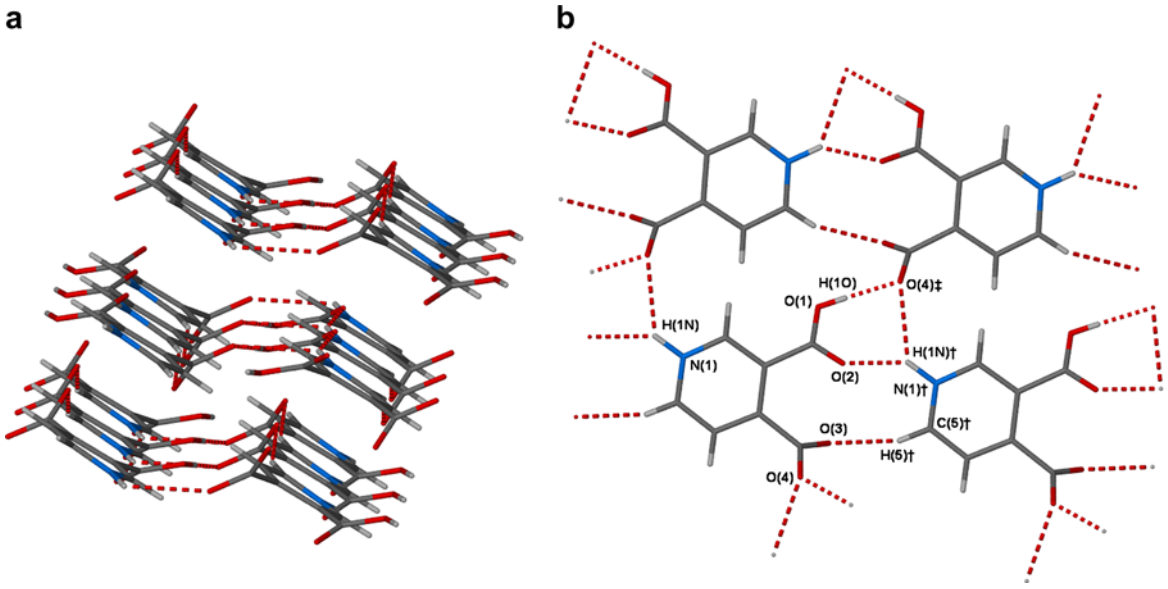

Fig. 6. (a) 2D sheets in the structure of H_2PDC viewed along the *b*-axis and (b) the hydrogen bonding motif within one sheet (only one of the disordered O(3) positions is shown for clarity). Symmetry equivalents used: $^{\dagger}x, 1+y, z$; $^{\ddagger}x, -y+3/2, z-1/2$. Selected hydrogen bond lengths (D···A) (Å): N(1)†···O(2), 2.797(5); N(1)†···O(4)‡, 3.217(5); C(5)†···O(3A), 3.23(3); C(5)†···O(3B), 2.78(8); O(1)···O(4)‡, 2.470(4); O(1)···O(3A)‡, 3.281(9); O(1)···O(3B)‡, 3.19(3).

structure the molecule exists as a zwitterion, deprotonated at the same position.[2] The structure forms 2D hydrogen-bonded sheets held together predominantly by NH···O and OH···O interactions (Fig. 6), of which the major interaction is the $R_2^2(6)$ interaction (using Graph Set notation [42]) involving the pyridinium proton as a bifurcated hydrogen-bond donor group.

4. Conclusions

We have presented the first fully characterised rare-earth complexes using exclusively ligands derived from pyridine-3,4-dicarboxylic acid. The structure displays interesting bonding modes of the dicarboxylate ligand and is held together by virtue of weak interactions between infinite 2D sheets. A second polymorph of pyridine-3,4-dicarboxylic acid is also reported.

5. Supplementary information

Full crystallographic data have been deposited with the CCDC (603746 and 603747). These data may be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033 or e-mail: deposit@ccdc.cam.ac.uk).

[2] The quality of the crystallographic data, whilst not excellent, is sufficient to show a residual peak present almost midway between the *meta*- and *para*-carboxylate groups of two adjacent molecules. This peak lies closest to the *m*-carboxylate and has therefore been fixed in this position.

Macrocyclic cobalt(III) complexes as precursors for metal-polythiophene hybrid materials

Paul V. Bernhardt *, Nathan L. Kilah

Department of Chemistry, University of Queensland, Brisbane, Qld 4072, Australia

Received 31 March 2006; accepted 6 July 2006
Available online 14 July 2006

Abstract

A thiophene-functionalised macrocyclic ligand *trans*-6,13-dimethyl-6-((thiophen-3-ylmethyl)amino)-1,4,8,11-tetraazacyclotetradecane-13-amine (L^1) has been prepared and complexed with Co^{III}. The ligand L^1 binds as a pentadentate in the crystallographically characterised complexes $[CoL^1(OAc)](ClO_4)_2$ and $[CoL^1Cl]Cl_2$. Electro-copolymerisation of $[CoL^1Cl]Cl_2$ with 3,4-ethylenedioxythiophene (EDOT) in a 1:2 ratio on a preformed poly-3,4-ethylenedioxythiophene (PEDOT) film resulted in metal–polymer hybrid films of high quality, consistency and uniformity in appearance. The copolymerised films were characterised by XPS indicating a 1:11 ratio of incorporation of complex to EDOT. Electrochemistry of the Co-PEDOT film (cast on an indium-doped tin oxide working electrode) in water revealed a $Co^{III/II}$ redox couple at a potential ca. −600 mV (vs Ag/AgCl) which is similar to that seen in solution for the monomeric aqua complex $[CoL^1(OH_2)]^{3+}$.

1. Introduction

Functional materials based on conductive (conjugated) polymers have received much attention in the years following the discovery of conductive polyacetylene to include many π-conjugated organics such as polythiophene, polypyrrole and polyaniline [1–4]. These polymeric materials are often referred to as synthetic metals due to their high conductivity when doped with appropriate agents. The range of dopants has developed from simple counter ions to a wide range of specialised transition metal complexes.

Polythiophene is a particularly popular scaffold for the development of functional materials [5–7]. The incorporation of redox active and/or spectroscopically active metal ions into a poly-thiophene architecture may engender useful properties to the polymer [8,9]. To mention but a few, these including light harvesting [10] and electrochemoluminescent materials [11] and sensors [12]. The metal may be dispersed within a polythiophene polymer or precomplexed with a thiophene-modified monomer which then undergoes a polymerisation or copolymerisation reaction with a different monomer [10–20].

Substituents on the thiophene ring influence the electronic bandgap and hence the observed colour of the polymer film. The commercially available monomer 3,4-ethylenedioxythiophene (EDOT, Chart 1) has been used extensively in polymerisation and copolymerisation reactions [21]. The ethylenedioxy bridge restricts polymerisation to the 2- and 5-positions while the ether O-atoms also alter the electronic properties of the polymer e.g. lowering the band gap energy.

Oxidative polymerisation may be achieved by chemical or electrochemical means [22], with anodic electrochemical growth of hybrid materials being an effective route when the polymer is to be integrated with an electrical circuit. This is most commonly achieved on a platinum electrode or optically transparent indium-doped tin oxide (ITO) electrode deposited as a thin layer on a glass support.

The redox properties of the film vary depending on the interactions between the metal centre and the conjugated organic chain. These varying morphologies have been

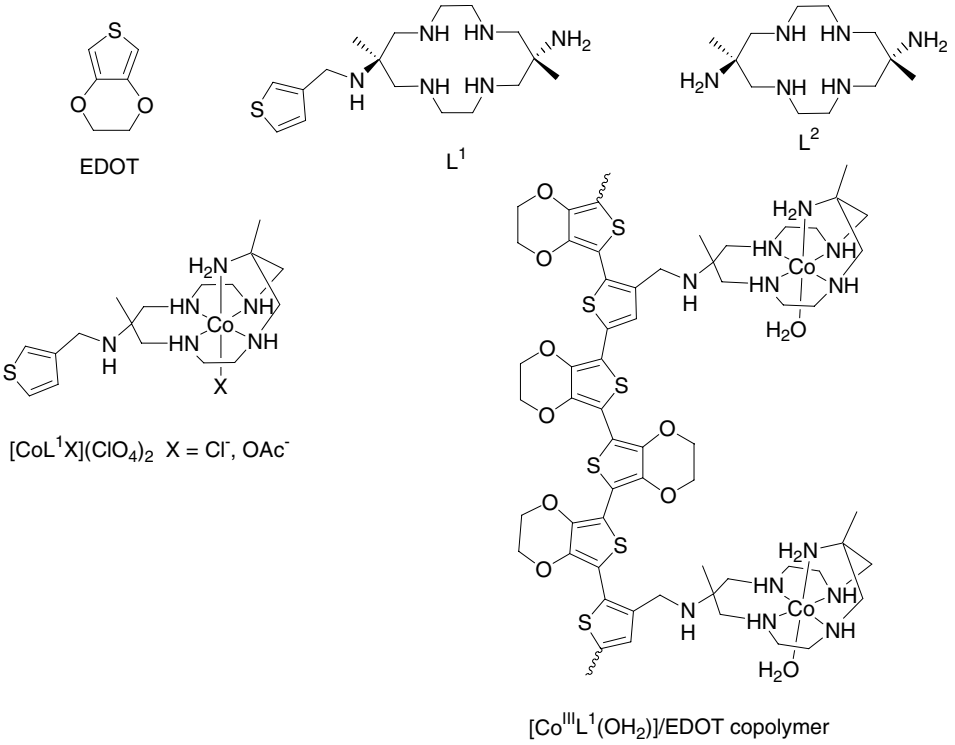

Chart 1.

classified into three types [8]. Briefly, the metal centres may be connected to the polymeric chain through a saturated link (Type I), attached through an unsaturated link to the conjugated backbone (Type II) or form part of the polymeric chain (Type III). Here we demonstrate that the new thiophene-appended macrocycle L^1 (Chart 1) can be utilised in the covalent incorporation of tightly bound transition metal ions into a Type I conductive polymer film. This was achieved through copolymerisation of a Co^{III} complex of L^1 with EDOT by electrochemical oxidation.

2. Experimental

2.1. Safety notes

Perchlorate salts are potentially explosive. Although no problems were experienced with the compounds synthesised, they should only be handled in small quantities, never scraped from sintered glass frits, nor heated in the solid state. Solutions containing sodium cyanoborohydride liberate toxic HCN gas when acidified and should only be used in a well ventilated fume hood.

2.2. Precursors

The precursors *trans*-6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine hexahydrochloride ($L^2 \cdot 6HCl$) [23] and sodium triscarbonatocobaltate trihydrate ($Na_3[Co(CO_3)_3] \cdot 3H_2O$) [24] were prepared from the literature procedures. All remaining chemicals were used as purchased.

2.3. The monomeric ligand L^1 and its Co^{III} complexes

2.3.1. *trans*-6,13-Dimethyl-13-((thiophen-3-ylmethyl)-amino)-1,4,8,11-tetraazacyclo-tetradecane-6-amine, L^1

The parent hexamine $L^2 \cdot 6HCl$ (4.77 g, 10 mmol) was suspended in $EtOH/H_2O$ (9:1 v/v, 300 mL) with dissolution occurring upon adjustment of the pH to 5.5 with NaOH (3 M). Sodium cyanoborohydride (1.88 g, 30 mmol) was added and the pH readjusted to 5.5 with further NaOH solution (3 M). Thiophene-3-carboxaldehyde (0.912 mL, 10 mmol) was added with stirring, and the resulting mixture was kept at pH 5.5 through the periodic addition of aliquots of HCl solution (1 M) for 3 h. After 16 h of stirring at room temperature a precipitate of the crude disubstituted by product *trans*-6,13-bis((thiophen-3-ylmethyl)amino)-6,13-dimethyl-1,4,8,11-tetraaza-cyclotetradecane as its $[BH_3(CN)]^-$ salt was filtered off and not characterised further. Ethanol was evaporated from the filtrate at reduced pressure and water (200 mL) added. The solution was acidified to ca. pH 2 through the addition of HCl solution (1 M) and extracted with CH_2Cl_2 (3×75 mL) to remove the contaminant thiophen-3-ylmethanol. The pH of the aqueous phase was adjusted to ca. 12 with NaOH solution (3 M) and the free ligand L^1 now in its charge neutral form was extracted with CH_2Cl_2 (3×100 mL). The combined extracts were dried over anhydrous sodium sulfate and evaporated at reduced pressure to leave an oil (1.2 g, 3.38 mmol, 34%). MeCN (50 mL) and CH_2Cl_2 (10 mL) were added to the oil with gentle warming to assist dissolution. The mixture was evaporated at reduced pressure to remove CH_2Cl_2, and Et_2O (50 mL) was added, resulting in precipitation of

the desired product. X-ray quality crystals were obtained through slow evaporation of a 1:5 $MeCN/CH_2Cl_2$ solution of the ligand. Elemental *Anal.* Calc. for $C_{17}H_{34}N_6S \cdot 2.5H_2O$: C, 51.51; H, 9.84; N, 21.03. Found: C, 51.51; H, 9.69; N, 20.72%. ^1H NMR ($CDCl_3$): δ (ppm vs TMS) 1.01 (s, 3H, CH_3), 1.04 (s, 3H, CH_3), 2.05 (broad s, 6H, NH), 2.42–2.67 (m, 16H, CH_2-macrocyclic), 3.70 (s, 2H, linker CH_2), 7.01 (dd, 1H, thiophene) 7.11 (dd, 1H, thiophene), 7.19 (dd, 1H, thiophene). ^{13}C NMR ($CDCl_3$): δ (ppm vs TMS) 22.92, 27.25, 41.12, 48.62, 48.66, 51.28, 54.99, 57.64, 60.61, 121.07, 125.46, 127.70, 142.29.

2.3.2. Chloro(trans-6,13-dimethyl-6-((thiophen-3-ylmethyl)-amino)-1,4,8,11-tetra-azacyclo-tetradecane-6-amine)-cobalt(III) chloride, $[CoL^1Cl]Cl_2$

L^1 (1.20 g, 3.38 mmol) was dissolved in water (400 mL) through the addition of aliquots of HCl solution (1 M) to bring the pH to ca. 8. $Na_3[Co(CO_3)_3] \cdot 3H_2O$ (1.45 g, 4.00 mmol) was added with stirring. The resulting mixture was heated at ca. 60 °C for 16 h. A black precipitate of cobalt oxide was filtered off, the filtrate was diluted to 10 L and loaded onto a Sephadex C-25 cation exchange column (75 cm × 2.5 cm, Na^+ form). Elution was achieved with 0.2 M NaCl, resulting in three bands; yellow (minor), orange (major) and finally yellow (minor). The first and third bands were not characterised further. The dominant orange band was concentrated to 100 mL which led to substitution of the aqua ligand by chloride to give a red solution. On standing a coprecipitate of NaCl and $[CoL^1Cl]Cl_2$ (as crystals suitable for X-ray work) formed. These crystals were removed by hand and the remaining mixture was purified by washing on a sintered glass frit under vacuum filtration with a minimal quantity of water. Elemental *Anal.* Calc. for $CoN_6C_{17}H_{34}SCl_3 \cdot H_2O$: C, 37.98; N, 15.62; H, 6.75. Found: C, 38.10; N, 15.71; H, 6.64%. Electronic spectrum (H_2O, pH 5): λ_{max}, nm (ε, M^{-1} cm^{-1}) 522 (75), 428 (43), 324 (149). ^1H NMR (D_2O): δ (ppm vs TSP) 1.28 (s, 3H, CH_3), 1.30 (s, 3H, CH_3), 2.23–3.71 (m, 16H, macrocyclic CH_2), 3.88 (s, 2H CH_2), 7.26 (t, 1H, thiophene), 7.46 (m, 2H, thiophene). ^{13}C NMR (D_2O): δ (ppm vs TSP) 20.67, 23.72, 43.11, 54.76, 55.01, 58.97, 60.53, 62.38, 68.12, 125.50, 129.51, 131.26, 144.43. The yield of isolated complex was limited by the amount of complex that crystallised from the NaCl solution and ultimately isolation of further crops of pure complex was prevented by contamination with NaCl. However, on the basis of the solution absorbance of the orange band obtained from the column, the yield of complex (based on L^1) was greater than 75%.

2.3.3. Acetato(trans-6,13-dimethyl-6-((thiophen-3-ylmethyl)amino)-1,4,8,11-tetra-azacyclotetradecane-6-amine)cobalt(III) perchlorate, $[CoL^1(OAc)](ClO_4)$

This complex was prepared in an identical manner to the chloro complex except the eluent for chromatography was 0.2 M NaOAc solution. Upon concentrating the orange eluent, crystallisation was achieved by the addition of excess $NaClO_4$ to afford X-ray quality crystals of the desired product. Elemental *Anal.* Calc. for $CoC_{19}H_{37}N_6SCl_2O_{10}$: C, 33.99; N, 12.52; H, 5.55; S, 4.78. Found: C, 33.47; N, 12.31; H, 5.58; S, 4.64%. Electronic spectrum (H_2O): λ_{max}/nm (ε/M^{-1} cm^{-1}) 489 (58), 352 (83). ^1H NMR (D_2O): δ (ppm vs TSP) 1.24 (s, 3H, CH_3), 1.32 (s, 3H, CH_3), 1.99 (s, 3H, acetato) 2.34–3.62 (m, 16H, macrocyclic CH_2) 3.90 (s, 2H CH_2), 7.22 (dd, 1H, thiophene), 7.42 (dd, 1H, thiophene), 7.48 (dd, 1H, thiophene). ^{13}C NMR (D_2O): δ (ppm vs TSP) 23.06, 26.13, 29.58, 45.32, 56.87, 57.31, 61.55, 62.48, 64.16, 70.12, 127.31, 131.96, 133.28, 147.10, 190.67. As above, the yield of complex was in excess of 75% but limited by co-precipitation with $NaClO_4$.

2.4. Electropolymerisation

Electropolymerisation of 3,4-ethylenedioxythiophene (EDOT) was adapted from a published procedure [22] employing cyclic voltammetry of a solution containing 0.1 M EDOT, 0.2 M sodium dodecylsulfate (SDS) and 0.1 M $NaClO_4$ as electrolyte in deionised water with a transparent indium tin oxide (ITO) glass slide as the working electrode. A Pt counter and Ag/AgCl reference electrode were also employed. Electrodeposition was preceded by a conditioning procedure which involved 10 cycles to successively positive potentials i.e. −200 to 600, then −200 to 700 and finally −200 to 800 mV (vs Ag/AgCl) at a scan rate of 50 mV s^{-1}. Polymerisation was finally achieved through sweeping the potential between −200 and 900 mV for five complete cycles, resulting in the oxidation and electrodeposition of a polymer thin film on the electrode.

This preformed poly-3,4-ethylenedioxythiophene (PEDOT) film cast on the ITO electrode was placed in a solution of $[CoL^1Cl]Cl_2$ (0.015 M), 3,4-ethylenedioxythiophene (0.030 M) and *n*-Bu_4NBF_4 (0.1 M) in freshly distilled MeCN. The potential was swept between −200 and 600 mV (vs the non-aqueous reference electrode Ag/$AgNO_3$ 0.01 M in MeCN) for 10 complete cycles at a scan rate of 50 mV s^{-1}. Further series of 10 cycles were completed in +100 mV increments to a limit of 1000 mV (−200 to 700, 800, 900 and 1000 mV, respectively).

2.5. Physical methods

Electronic spectra were recorded on a Perkin–Elmer Lambda 40 spectrophotometer. Nuclear magnetic resonance spectra were measured on a Bruker AC400 at 400.13 MHz for ^1H and 100.62 MHz for ^{13}C. Samples run in D_2O were referenced through the addition of sodium-(trimethylsilyl)propionate while spectra run in $CDCl_3$ were referenced to residual $CHCl_3$ peaks and cited vs TMS. Electrochemical examination of metal complexes was undertaken with a BAS100B/W potentiostat utilising an auxiliary platinum wire, Ag/AgCl reference electrode (+196 mV vs NHE) and either a glassy carbon (BAS C2 cell stand) or mercury drop working electrode (EG and G PARC Model 202 SMDE). Solutions contained approximately millimolar

concentrations of analyte and 0.1 M $NaClO_4$ in H_2O, and *n*-Bu_4NBF_4 or Et_4NClO_4 electrolyte in acetonitrile respectively. XPS data were acquired using a Kratos Axis ULTRA X-ray Photoelectron Spectrometer incorporating a 165 mm hemispherical electron energy analyser and utilising incident monochromatic Al X-rays (1486.6 eV) at 150 W (15 kV, 10 mA). Survey (wide) scans were taken at analyser pass energy of 160 eV and multiplex (narrow) high-resolution scans at 20 eV. Base pressure in the analysis chamber was 1.0×10^{-9} torr and during sample analysis was of 10^{-8} torr in magnitude.

2.6. Crystallography

Cell constants were determined by a least-squares fit to the setting parameters of 25 independent reflections measured on an Enraf-Nonius CAD4 four-circle diffractometer employing graphite-monochromated Mo Kα radiation (0.71073) and operating in the ω–2θ scan mode. Data reduction and empirical absorption corrections (ψ-scans) [25] were performed with the WINGX [26] package. Structures were solved with SHELXS 86 [27] through heavy atom methods for metal complexes and direct methods for the free ligand then refined by a full-matrix least-squares analysis with SHELXL-97 [28]. All non-hydrogen atoms were modelled with anisotropic thermal parameters. Hydrogen atoms were modelled for all water molecules where apparent from the difference map. All other H atoms were included at estimated positions using a riding model. Drawings of all molecules were prepared with ORTEP3 [26]. Crystal data are summarised in Table 1. The data have been deposited in CIF format with the Cambridge Crystallographic Data Centre (CCDC Nos. 603168–603170).

3. Results and discussion

3.1. Characterisation of the free ligand L^1

The reductive alkylation of the parent hexaamine L^2 with 3-thiophene carbaldehyde proceeded efficiently to give the monosubstituted ligand L^1. The procedure followed well established methods in our laboratory that have been used in the past to introduce a variety of substituents such as crown ethers [29], polycyclic aromatics [30–35], ferrocenes [36,37], aromatic and aliphatic carboxylic acids [38,39] onto an exocyclic primary amine. Despite the presence of six potentially reactive amines on L^2, the desired monosubstitution procedure requires no formal protecting groups other than protons. We have reported the first five protonation constants of the parent hexaamine to be 11.0, 9.9, 6.3, 5.4 and 2.9 [40], and through crystallography it is known that the third and fourth protonation constants are associated with the two exocyclic amines [41]. Therefore, control of the reaction pH at approximately 5.5 permits only one primary amine (in its free base form) to react with 3-thiophenecarbaldehyde. Cyanoborohydride is a selective reductant for imines over aldehydes at this pH and thus can be present at the start of the reaction. Nevertheless a small amount of disubstituted macrocycle was identified as an unwanted byproduct, but it was not characterised further.

The crystal structure of the free ligand $L^1 \cdot 2H_2O$ was determined and a view of the compound is shown in Fig. 1. The structure contains no unusual features. Intra- and intermolecular H-bonds abound; in fact all six N-atoms and two O-atoms are paired in H-bonding interactions with either water or amine protons. The asymmetric

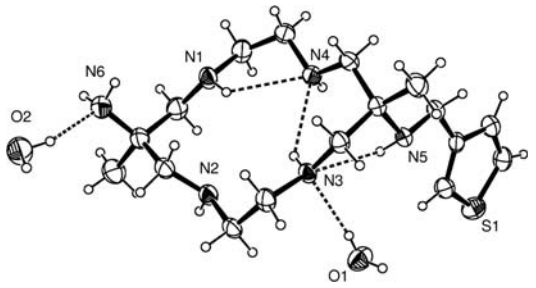

Fig. 1. ORTEP view of $L^1 \cdot 2H_2O$ (30% probability ellipsoids) showing intramolecular and selected intermolecular H-bonds. N1–H1···N4 2.37 Å, 124.0°; N3–H3···N4 2.40 Å, 132.5°; N5–H5···N3 2.43 Å, 110.2°; O1–H1C···N3 2.13 Å, 170.6°; O2–H2C···N6 1.93 Å, 164.7°.

conformation of the macrocycle is similar to that seen previously in structures of other unprotonated, metal free derivatives of L^2 [36,37]. Intramolecular N–H···N contacts within the macrocyclic ligand are apparent and determine the overall ring conformation. The lone pairs of N1 and N2 accept H-bonds from N–H groups of adjacent macrocycles (not shown).

3.2. Coordination chemistry

Coordination of the ligand L^1 to Co^{III} was straightforward and led initially to a complex $[CoL^1(OH_2)]^{3+}$ where the macrocycle was bound in a pentadentate manner. The substituted exocyclic amine remains free from the metal. The two complexes isolated as solids $[CoL^1Cl]^{2+}$ and $[CoL^1(OAc)]^{2+}$ formed through anation reactions in the presence of high concentrations of chloride and acetate respectively following column chromatography. The two isolated complexes exhibited electronic spectra consistent with $Co^{III}N_5Cl$ and $Co^{III}N_5O$ chromophores respectively. The coordination sphere of these two ions are consistent with their electronic spectra as the lowest energy spin allowed electronic transition of Co^{III} complexes ($^1T_{1g} \leftarrow {}^1A_{1g}$, O_h) is very sensitive to changes in the donor atoms. Asymmetric broadening of this transition is due to the influence of the low symmetry ligand field. The spectrum of the chloro complex was run in weakly acidic solution to suppress base catalysed hydrolysis of the monodentate ligand. It has generally been found [29,31,32] that attachment of bulky substituents onto the exocyclic amines of ligands such as L^2 precludes their participation as donor atoms and here again the pentadentate coordinated form is the dominant product.

Pentadentate coordination of the ligand L^1 to Co^{III} was confirmed by X-ray crystallographic analysis of $[CoL^1Cl]Cl_2$ (Fig. 2) and $[CoL^1(OAc)](ClO_4)_2$ (Fig. 3). The structures of each complex cation are rather similar and each find the monodentate ligand *trans* to the exocyclic primary amine. The four macrocyclic amines are coplanar with the metal and all macrocyclic amine H-atoms appear on the same side of the ring; the so-called *trans*-I configuration. The bond lengths and angles within the two complexes are very similar (see captions of Figs. 2 and 3).

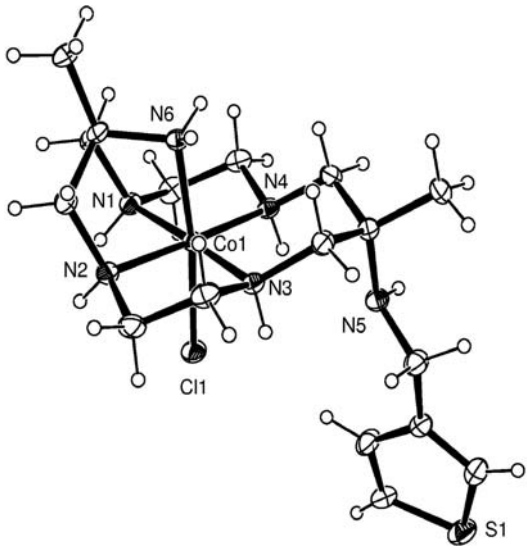

Fig. 2. ORTEP view of the $[CoL^1Cl]^{2+}$ cation (30% probability ellipsoids). Selected bond lengths (Å): Co1–N1 1.938(2), Co1–N2 1.943(2), Co1–N3 1.948(2), Co1–N4 1.954(2), Co1–N6 1.961(2), Co1–Cl1 2.2469(9).

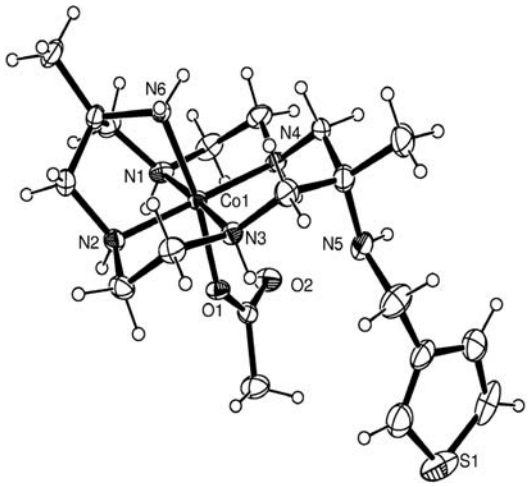

Fig. 3. ORTEP view of the $[CoL^1(OAc)]^{2+}$ cation (30% probability ellipsoids). Selected bond lengths (Å): Co1–N1 1.951(4), Co1–N2 1.954(4), Co1–N3 1.957(4), Co1–N4 1.939(4), Co1–N6 1.961(3), Co1–O1 1.898(3).

Cyclic voltammetry of $[CoL^1(OH_2)]^{3+}$ in aqueous solution at pH 7 was conducted on a static Hg drop working electrode (Fig. 4). A reversible $Co^{III/II}$ couple was identified at −550 mV vs Ag/AgCl. The voltammetry at pH 12 revealed a shift in the couple to −704 mV vs Ag/AgCl which is consistent with deprotonation of the aqua ligand to give the hydroxo analogue $[CoL^1(OH)]^{2+}$.

3.3. Electropolymerisation

Polymerisation of micellular 3,4-ethylenedioxythiophene (EDOT) was undertaken as listed in Section 2. Typical cyclic voltammograms for this stepwise polymerisation are shown in Fig. 5. Sweeping the potential to increasingly positive values resulted in a gradual increase in current

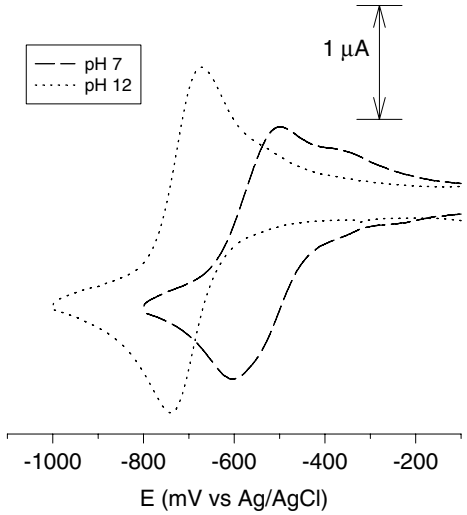

Fig. 4. Cyclic voltammograms of $[CoL^1(OH_2)]^{3+}$ (at pH 7, dashed curve) and $[CoL^1(OH)]^{2+}$ (at pH 12, dotted curve) on a static Hg drop electrode (sweep rate 100 mV s^{-1}). The minor peaks at −400 mV on the voltammogram at pH 7 are due to adsorption of the complex on the Hg electrode.

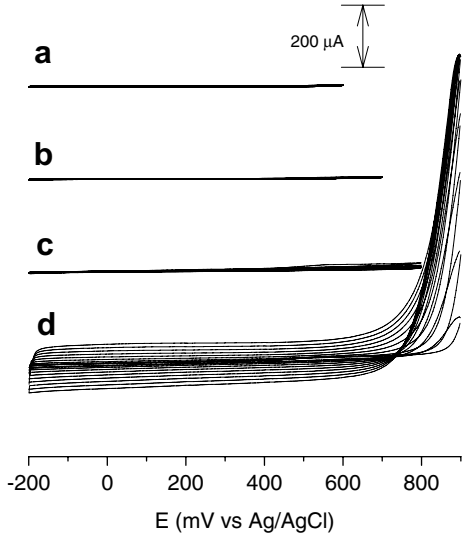

Fig. 5. Electropolymerisation of EDOT on an ITO working electrode. The three conditioning voltammograms (a)–(c) show the successive increase in the anodic potential limit leading eventually to polymerisation (d).

flow, increasing dramatically upon oxidation and electrodeposition of the polymer film. This is observed in the thousand-fold increase of current with the change in oxidative potential from +800 mV to +900 mV (lower panels Fig. 5). Homogeneous growth of the polymer film is observed with an incremental increase in current with subsequent cycles.

Metal–polymer hybrid films of uniform colour, surface coverage and strength were produced through an incremental increase in the anodic potential limit in a similar fashion to that of the PEDOT base layer. The resulting electrodeposited copolymeric film of EDOT and $[CoL^1Cl]^{2+}$ was blue as expected for polythiophene and can be described as a Type I hybrid material [8]. Attempted polymerisation of $[CoL^1Cl]^{2+}$ as the sole monomer in the absence of EDOT resulted in no electrodeposition onto the electrode surface.

Analysis of the copolymer film was assisted through the use of X-ray photoelectron spectroscopy (XPS), which has been shown to be an exceptionally powerful technique in the analysis of electropolymerised films [42]. The XPS spectrum of the $[CoL^1Cl]Cl_2$/EDOT copolymer film was charge corrected to the sulfur $2p^{3/2}$ photoelectron (thiophene, 164.3 eV), with reported values rounded to the nearest electron volt [43]. Observed photoelectrons for the $[CoL^1Cl]^{2+}$/EDOT copolymer film included: Co^{III} 797 eV ($2p^{1/2}$), 783 eV ($2p^{3/2}$); oxygen 534 eV (1s); nitrogen 401 eV (1s); carbon 286 eV (1s); sulfur 170 eV ($2p^{1/2}$), 165 eV ($2p^{3/2}$). The ratio of Co^{III} to sulfur was calculated at 1:12, indicating an incorporation of one complex unit per 11 EDOT monomer in the polymer film. Direct comparison of the initial monomer concentrations in solution and within the final polymer film reveals a preference for inclusion of EDOT monomer over $[CoL^1Cl]Cl_2$, (ca. 1:11 (complex:EDOT) from a 1:2 solution). This preference for EDOT inclusion is thought to be due to steric hinderance, however electrostatic interactions between the cationic complex and the oxidising electrode surface may also represent an important contribution.

Cyclic voltammetry of the CoL^1/EDOT copolymer film in neutral aqueous solution (Fig. 6) revealed the presence of the expected $Co^{III/II}$ redox couple at a similar potential to that seen in the solution voltammetry of the monomer $[CoL^1(OH_2)]^{3+}$ (Fig. 4). That is, the chloro ligand present during polymerisation appears to have been substituted by an aqua ligand during the electrochemical experiment. The peak currents increased linearly with sweep rate which is consistent with the voltammetric response to a surface confined molecule [44].

The broad nature of the anodic and cathodic maxima is indicative of a dispersion of orientations of the complex

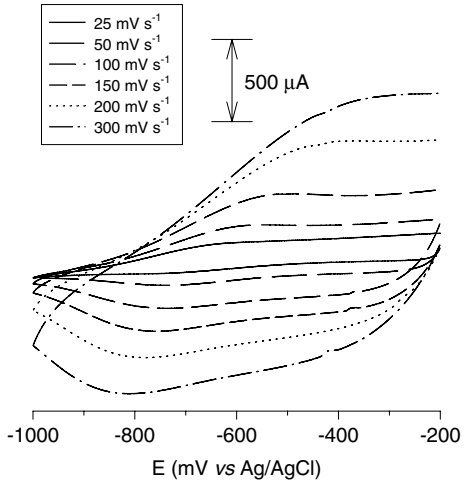

Fig. 6. Cyclic voltammograms (aqueous solution) of the $[CoL^1(OH_2)]^{3+}$/EDOT copolymer film at sweep rates between 25, 50, 100, 150, 200 and 300 mV s^{-1} (currents increase with sweep rate).

within the film, each with a slightly different apparent redox potential. Furthermore the peak potentials shift considerably with sweep rate which is indicative of sluggish heterogeneous electron transfer with the Co centres appended to the polymer.

We have found that preconditioning of the ITO surface through an incremental increase in the voltammetric positive potential limit was important in ensuring homogeneity of the initial PEDOT film deposited on the electrode. Films produced through either poising the potential at a polymerising voltage or sweeping directly over the range for oxidation resulted in opaque films with poor homogeneity. Polymerisation and electrodeposition of the highly uniform PEDOT films involves initial electrostatic attraction of the negatively charged micelles towards the positively charged surface of the oxidative working electrode. At a suitable oxidation potential, EDOT contained within this micelle undergoes polymerisation and electrodeposition onto the ITO electrode. This process can be repeated through continuing cycles, increasing the thickness of the PEDOT layer. The polymerisation of EDOT within micelles has a number of advantages in the generation of high quality films, such as lowering the oxidation potential and increasing the solubility of the monomer in aqueous solution [45–48].

Copolymerisation of EDOT and $[CoL^1(OH_2)]^{3+}$ onto a preformed PEDOT film was straightforward and resulted in a film of consistent colour and also uniform surface coverage. Attempts to copolymerise films directly onto bare ITO coated glass from acetonitrile solution produced films of uneven coverage and thickness. Nucleation of polymer growth was observed with these films as isolated regions of growth across the surface of the ITO coated glass slide. Continuation of electrochemical cycling to improve the surface coverage led to darkening (film growth) at the nucleated regions without a noticeable improvement in surface coverage. This is consistent with previous attempts to produce polythiophene films from acetonitrile solution, which were reported to give brittle or powdery deposits [1,49].

It is believed that precoating the ITO slide with PEDOT allows for surface grafting and homogeneous electrodeposition. This is achieved through the conducting PEDOT layer acting as the working electrode, oxidising EDOT monomer (or thiophene appended transition metal complex) directly for inclusion in the growing chain. This technique could potentially be applied to a number of systems, such as where a complex of interest cannot be directly polymerised to a conductive surface or in the production of metal–polymer hybrid films in a reproducible manner.

4. Conclusions

A versatile method has been reported for the incorporation of transition metal ions into a polythiophene film. Using well established chemistry, a thiophene monomeric residue has been introduced to the non-coordinating exocyclic amine of a macrocyclic ligand. This group is able to undergo co-polymerisation with 3,4-ethylenedioxythiophene to produce a redox active film laid down on an ITO electrode. Electroactivity of the Co complex within the polymer film has been demonstrated. One particularly important feature is that the macrocyclic ring not only binds its metal tightly, but it is also capable of binding to a number of other transition metal ions in various oxidation states. The ability to construct polymeric films with tunable redox potentials is apparent and the subject of ongoing work.

Received 5 April 2006; accepted 28 June 2006
Available online 14 July 2006

Abstract

A new synthesis of 2,2′-bi-1,5-naphthyridine (**1**) is described along with its reactions with copper(II) nitrate, silver(I) tetrafluoroborate and palladium(II) chloride. X-ray crystal structures are described of a mononuclear copper complex, in which **1** acts as a convergent ligand chelating through the two internal nitrogens, and an unusual M_4L_3 silver complex containing both two- and three-coordinate silvers and with ligand **1** acting in two different bridging modes.

1. Introduction

Metallosupramolecular chemistry [1] involves the use of combinations of metal ions and multidentate organic ligands for the construction of both discrete and polymeric assemblies that possess diverse topologies. By far the most commonly employed ligands are those containing aromatic nitrogen heterocycles [2]. Two archetypal ligands are 2,2′-bipyridine, which has been classified [3] as a *convergent* ligand wherein the two nitrogen donors chelate to a single metal, and 4,4′-bipyridine, which is a *divergent* ligand that acts as a bridge between two metals (Scheme 1). However, some ligands can perform both these roles and we call these *ambivergent* ligands. A well-known example is bipyrazine, which can chelate to a single metal through the central more hindered nitrogen donors but also use the external nitrogens to bridge other metals. Many structurally-diverse supramolecular architectures have been assembled using this ligand [4], which can display a variety of coordination modes, including a recently reported case of μ_4-coordination [5].

An important aspect for control of the topology within metallosupramolecular architectures is the spatial arrangement of the binding domains in multidentate ligands. In particular, the distance between the donor groups and their angular disposition determine the size and shape of the assembly. In a continuation of our work on the design and synthesis of heterocyclic ligands [1c,1d], we now report the use of 2,2′-bi-1,5-naphthyridine (**1**) as a ligand. This compound was prepared almost half a century ago [6] and reported to form a copper complex, but has not been studied since. It is potentially an ambivergent ligand related to bipyrazine, but has the external bridging nitrogens separated by a greater distance. The most closely related ligand recently studied is 2,2′-bi-1,6-naphthyridine, which was shown to produce both interpenetrated coordination nets and helical coordination polymers [7]. However, this ligand differs in that the external bridging nitrogens are arranged in a linear fashion, rather than the 60° angular arrangement in **1**. We describe below the preparations of three metal complexes of **1** and the X-ray structures of two discrete coordination compounds, including an intriguing M_4L_3 tetranuclear silver complex.

Scheme 1.

2. Experimental

2.1. General procedures

NMR spectra were recorded with a Varian INOVA 500 spectrometer at 23 °C with a 3 mm probe and operating at 500 MHz. Melting points were determined using an Electrothermal melting point apparatus and are uncorrected. Elemental analyses were performed by the Campbell Microanalytical laboratory at the University of Otago. 1-Methyl-1,5-napthyridin-2(1H)-one [8] and nickel(II) bistriphenylphosphine bromide [9] were prepared by literature procedures. Solvents were purified according to standard procedures. Other reagents were obtained from commercial sources and used as supplied.

2.2. Ligand synthesis

2.2.1. Preparation of 2-chloro-1,5-naphthyridine

1-Methyl-1,5-naphthyridin-2(1H)-one (0.96 g, 6.0 mmol) and phosphorus pentachloride (1.25 g, 6.0 mmol) were refluxed in phosphorus oxychloride (50 mL) for 24 h. The solvent was evaporated *in vacuo* to give a brown solid. This was suspended in water (75 mL) and neutralized ($NaHCO_3$). This suspension was extracted with $CHCl_3$ (2×75 mL) and the organic phase washed (2×20 mL H_2O, 20 mL brine), dried (Na_2SO_4) and the solvent evaporated *in vacuo*. The solid formed was recrystallized from 1:1 pet-ether/ethyl acetate to give 2-chloro-1,5-naphthyridine as an orange solid. Yield 0.58 g (59%). M.p. 109–111 °C (lit. [10] 112°). ^{1}H NMR (500 MHz, $CDCl_3$): 8.98 (H, dd, H6), 8.34 (2H, m, H8, H4), 7.63 (2H, m, H3, H7).

2.2.2. Preparation of 2,2′-bi-1,5-naphthyridine (1)

Nickel(II) bistriphenylphosphine bromide (0.79 g, 1.1 mmol), zinc powder (0.45 g, 6.9 mmol) and tetraethylammonium iodide (0.90 g, 3.4 mmol) were stirred at room temperature in dry THF (15 mL) under argon for 30 min. 2-Chloro-1,5-naphthyridine (0.57 g, 3.5 mmol) was added in dry THF (10 mL) and the mixture stirred at 50 °C for 22 h under argon. The mixture was poured onto 100 mL 2 M aq. NH_3 and extracted with $CHCl_3$ (2×75 mL). The organic phase was washed (H_2O, 50 mL), dried (Na_2SO_4) and the solvent removed *in vacuo* to give a brown solid. This was purified via chromatography (10 g Silica, EtOAc), and the product recrystallized (1:1 pet ether/EtOAc) to give a yellow solid. Yield 0.10 g (22%). M.p. 275–276 °C (lit. [6] 282–284 °C) ^{1}H NMR (300 MHz, $CDCl_3$): 9.08 (2H, d, H3), 9.03 (2H, d, H6), 8.58 (2H, d, H4), 8.55 (2H, d, H8), 7.71 (2H, dd, H7).

2.3. Complex synthesis

2.3.1. Preparation of copper(II) nitrate complex 2

Reaction of **1** (13.0 mg, 0.05 mmol) dissolved in hot acetonitrile with copper(II) nitrate (25.1 mg, 0.10 mmol) dissolved in hot acetonitrile gave a green solution. Crystals suitable for X-ray diffraction were deposited after 4 h. Yield 15.7 mg (70%). M.p. >270 °C (dec.). *Anal.* Calc. for $C_{16}H_{10}N_6O_6Cu$: C, 43.10; H, 2.43; N, 18.85. Found: C, 42.93; H, 2.43; N, 19.00%.

2.3.2. Preparation of silver(I) tetrafluoroborate complex 3

Reaction of **1** (13.0 mg, 0.05 mmol) dissolved in hot acetonitrile with silver tetrafluoroborate (20.5 mg, 0.11 mmol) dissolved in hot acetonitrile gave a light yellow solution. Crystals suitable for X-ray diffraction were obtained by diffusion of pentane into the reaction mixture. Yield 11.19 mg (29%). M.p. >200 °C (dec.). *Anal.* Calc. for $C_{52}H_{36}N_{14}Ag_4B_4F_{16}$: C, 38.18; H, 2.22; N, 11.99. Found: C, 38.59; H, 2.19; N, 11.82%.

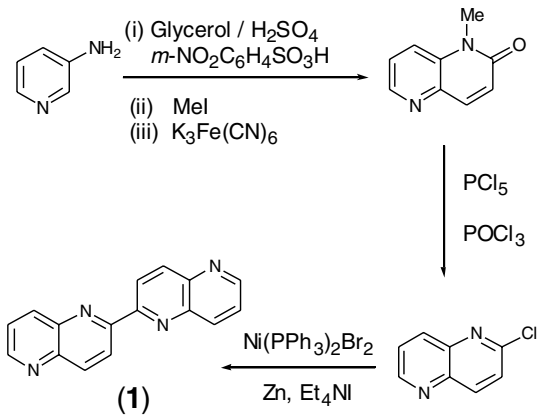
*2.3.3. Preparation of palladium(II) chloride complex **4***



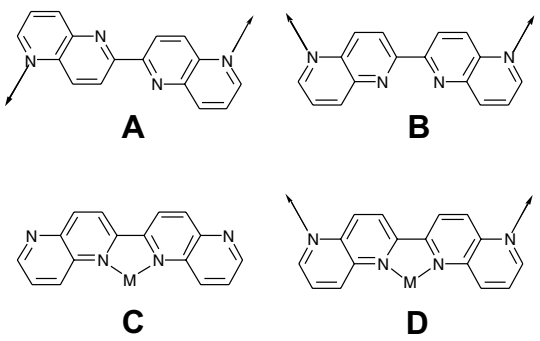
Reaction of **1** (12.0 mg, 0.047 mmol) in methanol with a methanolic solution of 0.1511 M Li_2PdCl_4 (0.7 ml, 0.10 mmol) gave a yellow solid. Yield 13.0 mg (42%). M.p. >300 °C (dec.). *Anal.* Calc. for $C_{16}H_{10}N_4Pd_2Cl_4$: C, 31.35; H, 1.64; N, 9.14. Found: C, 31.49; H, 1.74; N, 9.14%.

2.4. X-ray crystallography

The crystal data and details of the data collections and refinements for the two structures are listed in Table 1. Measurements were made with a SMART CCD area detector using graphite-monochromatized Mo Kα ($\lambda = 0.71073$ Å) radiation. The structures were solved by direct methods using SHELXS [11] and refined on F^2 using all data by full-matrix least-squares procedures with SHELXL-97 [12]. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in calculated positions with isotropic displacement parameters 1.2 times the isotropic equivalent of their carrier atoms. The functions minimised were $\sum w(F_o^2 - F_c^2)$, with $w = [\sigma^2(F_o^2) + aP^2 + bP]^{-1}$, where $P = [\max(F_o)^2 + 2F_c^2]/3$.

3. Results and discussion

The only literature reference to 2,2′-bi-1,5-naphthyridine involves its formation, in very low yield, by the oxidative dimerization of 1,5-naphthyridine using activated Pd/C at 220 °C [6]. We have prepared it by the method outlined in (Scheme 2). Thus, 3-aminopyridine was converted to 1,5-naphthyridine by a Skraup reaction and this was reacted in a methylation, oxidation, chlorination sequence to afford 2-chloro-1,5-naphthyridine, which was then subjected to the Ni^0-catalyzed coupling procedure pioneered by Iyoda et al. [13]. The downfield position (9.08 ppm) of H3 in the ^1H NMR spectrum clearly showed that the free ligand exists in the conformation, shown in Scheme 2, with a s-*trans* arrangement about the central inter-ring bond. This is the normal conformation observed in both solution and the solid state for biheterocycles of this type [14].



Scheme 2.

The conformation of the ligand has important consequences for the topology of any metal complexes. One could envisage *inter alia* several possible coordination modes for **1** (Scheme 3). When acting as a divergent ligand, the s-*trans* conformation would result in a stepped-linear bridging arrangement (A), whereas the s-*cis* conformation would provide a 60° angular bridge (B). In a convergent mode (C) or ambivergent mode (D) the s-*cis* conformation is enforced.

In a continuation of our long-standing interest in the study of copper(II) [15], silver(I) [16] and palladium(II) [17] complexes, we reacted **1** with two equivalents of salts of each of these metals. Reaction with copper(II) nitrate in acetonitrile solution furnished a green crystalline product (**2**) in 70% yield, which elemental analysis showed to be a 1:1 M:L complex. The complex crystallizes in the triclinic space group $P\bar{1}$, with one molecule of **1**, one copper(II) nitrate and an acetonitrile solvate molecule in the asymmetric unit. The mononuclear structure of **2** is shown in Fig. 1, and has one molecule of **1** chelating one copper atom through the most hindered internal nitrogen atoms. The ligand (**1**) is held in a s-*cis* planar conformation, with a mean deviation of 0.041(5) Å from planarity. The nitrate anions chelate the copper atom asymmetrically, with each having one short and one long bond. This gives the copper atom a severely distorted octahedral geometry. The bond lengths and angles are within normal ranges for a complex of this type [18].

The molecules pack in ribbons with adjacent molecules held together by centrosymmetric pairs of C–H···N interactions [19] involving the non-coordinated external nitrogens of **1** and hydrogen atoms of adjacent molecules, the shortest being 2.416(6) Å between H4 and N5 (Fig. 2). Further π–π stacking interactions exist between adjacent ribbons, with the aromatic molecules coplanar and in an offset stacked arrangement. The slight offset has C4 of one ligand lying above the centre of the N1–C8 ring, at a distance of 3.440(4) Å. The acetonitrile solvate molecule occupies the spaces between the stacks of molecules. Thus, we have shown that ligand **1** readily acts as a chelating convergent ligand (Scheme 3, mode C).

Silver(I) salts have been extensively used as versatile synthons for the construction of a diverse myriad of metallo-supramolecular assemblies [20]. Multidentate ligands

Scheme 3.

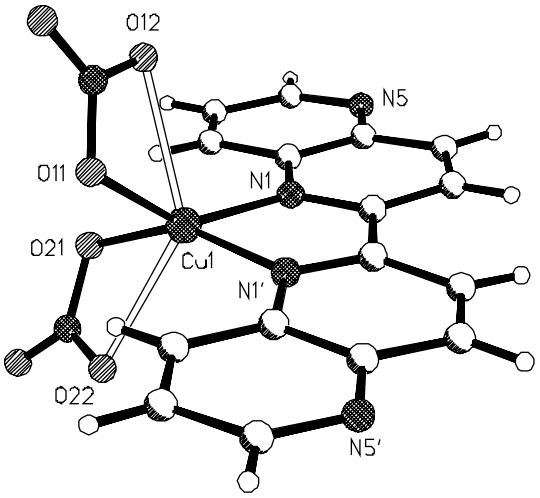


Fig. 1. Perspective view of the crystal structure of **2**, with the long Cu–O bonds of the chelating nitrate anions shown as hollow bonds. The non-coordinated acetonitrile molecule is not shown. Selected bond lengths (Å) and bond angles (°): Cu1–N1′ 1.983(2), Cu1–N1 2.004(2), Cu1–O21 1.984(2), Cu1–O11 2.005(2), Cu1–O22 2.371(2), Cu1–O12 2.461(2), N1′–Cu1–O21, 152.29(10), N1′–Cu1–N1 82.40(9), O21–Cu1–N1 102.58(9), N1′–Cu1–O11 97.2(1), N1–Cu1–O11 143.45(10), N1′–Cu1–O22 96.38(9), N1–Cu1–O22 123.54(9).

usually react with silver to produce 1-, 2- or 3-dimensional coordination polymers. With the expectation that ligand **1** would act in an ambidentate fashion with silver, we react it with two equivalents of silver tetrafluoroborate and obtained a crystalline product (**3**) that elemental analysis showed to have an intriguing M_4L_3 stoichiometry. In order to determine unambiguously the structure of this compound a single-crystal X-ray structure analysis was carried out.

Once again this complex crystallizes in the triclinic space group $P\bar{1}$ and has two silver tetrafluoroborates, one and a half molecules of **1** and a coordinated acetonitrile molecule in the asymmetric unit. The structure of **3** (Fig. 3) is a remarkable discrete tetranuclear complex with four silver atoms bridged by three molecules of **1**. The central ligand lies on a centre of inversion and hence has a s-*trans* planar conformation. It bridges two silver atoms, separated by 12.759(7) Å, using the least hindered external nitrogens. Thus, it acts as a stepped-linear divergent ligand (Scheme 3, mode A). The two remaining ligands are in a s-*cis* planar conformation, and chelate one silver atom and bridge to another through one external nitrogen; these silvers are separated by 7.716(7) Å. The internal silver atom, Ag2, is coordinated by two molecules of **1** with a distorted linear geometry [N5C-Ag2-N5B 167.9(1)°]. The external silver atom, Ag1, is chelated by one molecule of **1** and coordinated to a molecule of acetonitrile with an overall trigonal-planar geometry. The full tetranuclear structure is remarkably planar, with a mean deviation of only 0.092(7) Å from the non-hydrogen atom meanplane.

The tetranuclear units stack in a coplanar fashion, with two linear Ag2 atoms adjacent to one another (Fig. 4). The silver atoms are separated by a distance of 3.556(4) Å, indicating a relatively weak interaction [21]. Adjacent units are offset by one molecule of **1**, such that the s-*cis* ligands stack atop the s-*trans* ligands. The distance between the planes of the tetranuclear units is only 3.258(7) Å, indicating strong face-to-face π–π interactions between the aromatic ligands [22]. Such combinations of Ag···Ag and π–π interactions between heterocyclic ligands have often been observed in silver coordination polymers [4b]. The tetrafluoroborate counterions are held in place via numerous weak

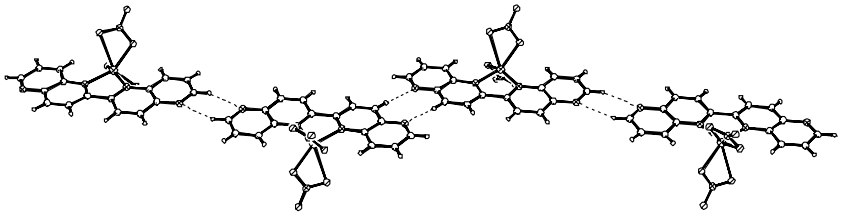

Fig. 2. Perspective view of a hydrogen bonded ribbon of **2**.

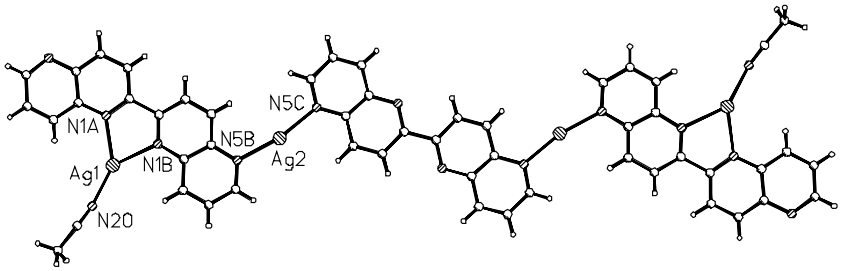

Fig. 3. Perspective view of the tetranuclear silver complex **3**. Tetrafluoroborate counterions have been omitted for clarity. Selected bond lengths (Å) and bond angles (°): Ag1–N20 2.114(4), Ag1–N1A 2.293(4), Ag1–N1B 2.292(4), Ag2–N5C 2.175(4), Ag2–N5B 2.181(4), N20–Ag1–N1A 144.9(1), N20–Ag1–N1B 142.8(1), N1A–Ag1–N1B 72.3(1), N5C–Ag2–N5B 167.9(1).

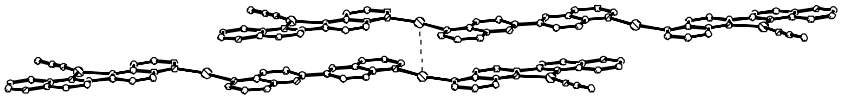

Fig. 4. View showing the association of two adjacent molecules of **3** with the Ag–Ag interaction indicated by a dashed line. Hydrogen atoms and tetrafluoroborate counterions are not shown.

C–H···F interactions, the shortest being 2.40(5) Å. In this novel discrete tetranuclear complex each of the two components acts in two different modes; the silver atoms have linear two-coordinate and trigonal three-coordinate geometries and the bridging ligands show stepped-linear divergent and ambivergent behaviours.

Finally, the reaction of **1** with two equivalents of palladium(II) chloride was investigated. This reaction furnished a highly insoluble complex that was shown, by elemental analysis, to have a 2:1 M:L stoichiometry. Since palladium(II) almost invariably adopts a square planar four-coordinate geometry, this would suggest that this complex is a coordination polymer in which the ligand **1** acts in an ambivergent manner using all four of its donor nitrogens.

4. Conclusion

2,2′-Bi-1,5-naphthyridine (**1**) has been prepared by a new synthetic route and shown to act in a variety of coordination modes. Reaction with copper(II) nitrate produced a discrete mononuclear complex in which the copper atom is chelated to the central internal nitrogens. Reaction with silver(I) tetrafluoroborate gave an intriguing discrete M_4L_3 tetranuclear complex with both two- and three-coordinated silvers and the ligand acting in two different bridging modes.

5. Supplementary material

Full tables of atom coordinates, thermal parameters, and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre. CCDC 603159 and 603160 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk].

Aqueous chemistry of the five-coordinate zirconocene dichloride $PhP(CH_2CH_2–\eta^5\text{-}C_5H_4)_2ZrCl_2$: X-ray structure of the sulfato complex $PhP(CH_2CH_2–\eta^5\text{-}C_5H_4)_2Zr(\eta^2\text{-}SO_4)$

Abstract

ES-MS of dilute solutions of $(bcep)ZrCl_2$ (**1**) (bcep = $PhP(CH_2CH_2–\eta^5\text{-}C_5H_4)_2$) in acetonitrile–water indicates the presence of three species in solution: $[(bcep)Zr(H_2O)_2]^{2+}$ (**2**), $[\{(bcep)Zr(\mu\text{-}OH)\}_2]^{2+}$ (**3**), and the singly deprotonated form of dimer **3**, $[\{(bcep)Zr\}_2(\mu\text{-}O)(\mu\text{-}OH)]^+$ (**4**). In aqueous solutions, reactivity studies investigated largely by ^{31}P NMR spectroscopy support the presence of **2**, **3** and **4**. One equivalent of fluoride was found to react immediately with **2**, but slowly with **3** and **4**, to give the monofluoro complex $[(bcep)ZrF]^+$ which was isolated as the BPh_4^- salt. Addition of aqueous sodium sulphate gave insoluble crystals of the sulfato complex $(bcep)Zr(SO_4)$ which was characterised by X-ray crystallography. Addition of acids HX (X = Br, NO_3, HSO_4, HCO_3) to aqueous solutions of **1** gave species observed by ES-MS corresponding to $[(bcep)ZrX]^+$.

1. Introduction

The chemistry of zirconocene dichlorides is currently one of the most significant areas of research in organometallic chemistry [1]. The area of functionalised bis(cyclopentadienyl) ligands capable of chelation is an active field of organometallic chemistry [2–4]. Notable zirconocenes are the complexes $MeN(CH_2CH_2C_5H_4)_2ZrCl_2$ and $\{C_5H_3N(CH_2C_5H_4)_2\text{-}2,6\}ZrCl_2$ in which amine and pyridine coordination, respectively, is proposed on the basis of ^1H NMR spectroscopy and XPS studies [2]. A crystallographically characterized hydrolysis product of $\{C_5H_3N(CH_2C_5H_4)_2\text{-}2,6\}ZrCl_2$ is the cationic chloro-aqua complex $[\{C_5H_3N(CH_2C_5H_4)_2\text{-}2,6\}ZrCl(H_2O)]^+$ in which the pyridine substituent is coordinated to the metal center [3].

Ansa-metallocenes with a P bridging atom directly bonded to the C_5 ring are known for a number of iron [5] and zirconium [6] complexes. The number of bis(cyclopentadienyl) phosphine ligands capable of chelation is very small [7,8]. The ligand $C_6H_{11}P(CHMe\text{-}2\text{-}PPh_2C_5H_3^-)_2$ [7] could exhibit phosphine chelation, but this has not yet been demonstrated. We recently communicated the preparation of $PPh(CH_2CH_2C_5H_5)_2$ ($bcepH_2$) and the synthesis of ferrocene complexes derived from this compound in which the P atom is not coordinated to the Fe center [8]. The P atom can, however, coordinate to a second metal center as in the complex *trans*-$PdCl_2\{(bcep)Fe\}_2$ [8].

The aqueous chemistry of zirconocenes has been investigated by a small number of workers (in contrast to that of the titanocenes [9]) with the identification of species in solution largely dependent upon crystallographic characterisation of the compounds isolated in the solid state. Addition of two equivalents of water to $Cp_2Zr(C_7H_7SO_3)_2$ gives the toluenesulfonatodiaqua cation $[Cp_2Zr(C_7H_7SO_3)(H_2O)_2]^+$ [10], whereas addition of three equivalents of water to the bistriflate complex $Cp_2Zr(CF_3SO_3)_2$ (THF) gives the triaqua dication $[Cp_2Zr(H_2O)_3]^{2+}$ [11] and addition of six

doi:10.1016/j.poly.2006.06.031

equivalents gives a 30% yield of the dinuclear hydroxo-bridged complex $[Cp_2Zr_2(\mu\text{-}OH)_2(H_2O)_6]^{4+}$ in which one Cp ligand has been hydrolysed from each Zr atom [12]. Other zirconocene dichloride hydrolysis products have been reported by Thewalt and co-workers in which one Cp ligand has been hydrolysed and there are oxo/hydroxo bridges: $\{CpZr(NO_3)_2\}_2(\mu\text{-}OH)_2$ was isolated from nitric acid in chloroform [13] and $[Cp_3Zr_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}PhCOO)_3]^+$ was isolated from sodium benzoate in water/chloroform [14]. Fischer and co-workers obtained the dicationic dinuclear di-μ-hydroxo complex $[\{Cp_2Zr(\mu\text{-}OH)(n\text{-}PrCN)\}_2]^{2+}$ by addition of *n*-PrCN to a mixture they formulated as $[\{Cp_2Zr(H_2O)\}_2O][BPh_4]_2 \cdot pH_2O$ and/or $[Cp_2Zr(OH)(H_2O)_n][BPh_4] \cdot mH_2O$ (this was prepared by addition of $Na[BPh_4]$ to Cp_2ZrCl_2 dissolved in water) [15]. A related neutral dinuclear di-μ-hydroxo complex, $[Cp_2Zr(\mu\text{-}OH)(CF_3COO)]_2$, was obtained by Klima and Thewalt by treatment of Cp_2ZrCl_2 with CF_3COOH in a $CHCl_3/H_2O$ two-phase system [16]. Erker and co-workers reported that treatment of $[Cp_2ZrCH_3(THF)]^+$ with excess water in CH_2Cl_2/THF gave the trinuclear cluster $[(Cp_2Zr)_3(\mu\text{-}OH)_3(\mu_3\text{-}O)]^+$ in which the cyclopentadienyl ligands are still intact [17]. Using chloride potentiometry, Toney and Marks studied the aqueous chemistry of Cp_2ZrCl_2: the rate of the second chloride loss was found to be 1.31 h^{-1} for 1–3.5 mM solutions with an equilibrium $[Cl^-]$:[Zr] ratio of 1.75 [18]. Thus, significant amounts of $[Cp_2ZrCl(H_2O)_x]^+$ and $[Cp_2Zr(H_2O)_x]^{2+}$ are present in these solutions. Some aqueous polymerisation studies of styrene and methyl methacrylate using Cp_2ZrCl_2 have also been reported [19]. Hillhouse and Bercaw have reported some stoichiometric reactions of bis(pentamethylcyclopentadienyl)-zirconium and -hafnium hydrides to give a variety of hydroxo and oxo complexes [20].

We recently reported the preparation and structure of $(bcep)ZrCl_2$ (**1**) along with some initial chemical investigations [21]: crystals of $[(bcep)ZrCl(H_2O)]Cl$ were isolated by evaporation of a wet methanol solution of **1**; the ES-MS of a CH_3CN/H_2O solution of **1** with added HCl(aq) gave peaks corresponding to the expected species $[(bcep)Zr(OH)]^+$ and $[(bcep)ZrCl]^+$ in addition to species of the formulae $[(bcep)Zr(OH)O]^+$ and $[(bcep)ZrClO]^+$ (no peak corresponding to the crystallographically characterised cation $[(bcep)ZrCl(H_2O)]^+$ has been observed).

In this paper, we detail further aqueous chemistry of complex **1** which has been studied using ^{31}P NMR spectroscopy, ES-MS, and X-ray crystallography.

2. Results and discussion

Positive-ion ES-MS of dilute (ca. 10^{-4} M) solutions of complex **1** in 1:1 acetonitrile–water shows the presence of three species (Fig. 1). The masses are consistent with the hydroxo complex $[(bcep)Zr(OH)]^+$ (**5**) (derived from the diaqua dicationic complex $[(bcep)Zr(H_2O)_2]^{2+}$ (**2**)) and its dimer $[\{(bcep)Zr(\mu\text{-}OH)\}_2]^{2+}$ (**3**), as well as the singly-deprotonated form of **3**, $[\{(bcep)Zr\}_2(\mu\text{-}O)(\mu\text{-}OH)]^+$ (**4**) (Scheme 1). Although the diaqua dication $[(bcep)Zr(H_2O)_2]^{2+}$ (**2**) is not observed directly by ES-MS, this is not surprising: under ES-MS conditions, as the solvent evaporates and the charge density increases, the dication **2** can both lose solvent and reduce charge by the loss of H_3O^+ to give the hydroxo complex **5**. There is no evidence in these dilute solutions for any chloro complexes such as the crystallographically-characterised cation $[(bcep)ZrCl(H_2O)]^+$ [21].

The aqueous chemistry of **1** was investigated with reactivity studies that were followed by ^{31}P NMR spectroscopy. Results are summarised in Table 1. Three major species, in a 14:2:1 ratio, are observed. These are proposed to be the diaqua dication $[(bcep)Zr(H_2O)_2]^{2+}$ (**2**) (δ 32.32), and the dinuclear complexes **3** (δ 33.14) and **4** (δ 34.36). The assignment of the resonance at δ 32.32 as the diaqua dication **2** rather than the mononuclear hydroxo complex **5**, as is observed under ES-MS conditions, or the hydroxo-aqua complex

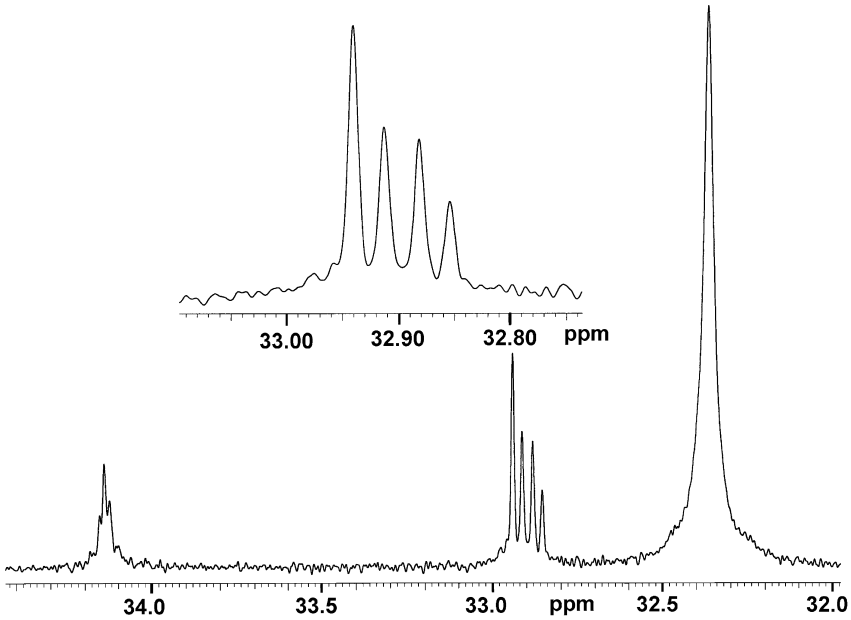
[a] Chemical shift in ppm, integral given in parentheses.

$[(bcep)Zr(OH)(H_2O)]^+$ (**6**) is based on the following observations: addition of one half equivalent of NaOH(aq) rapidly converts **2** to **3** and **4** (more than one equivalent of hydroxide rapidly leads to hydrolysis of bcep from the complex) whereas addition of aqueous HCl converts **3** and **4** to **2** over several minutes – a possible equilibrium between **3** and its monomer **5** (or a complex such as **6**) would not be affected by addition of acid or base. Balzarek et al. have reported that the monomer/dimer equilibrium between $[Cp_4Mo_2(\mu\text{-}OH)_2]^{2+}$ and $[Cp_2Mo(OH)(H_2O)]^+$ (equivalent to an equilibrium between **3** and **6**) is independent of pH [22]. Dicationic species such as **2** also have precedence in the form of the triaqua complex $[Cp_2Zr(H_2O)_3]^{2+}$ [11]. Dissolving complex **1** in 0.1 M HCl(aq) gives only **2**.

The assignment of the resonance at δ 33.14 to the di-μ-hydroxo complex **3**, with the phosphorus atoms *trans* about the $Zr_2(OH)_2$ core, is supported by its ^{31}P NMR spectrum in 2:1 D_2O/H_2O which shows four peaks in a 4:2:2:1 ratio (Fig. 2). The downfield resonance at 32.94 ppm is assigned to $[\{(bcep)Zr(\mu\text{-}OD)\}_2]^{2+}$, the resonances at 32.91 and 32.88 ppm to the mixed species $[\{(bcep)Zr\}_2(\mu\text{-}OH)(\mu\text{-}OD)]^{2+}$, and the resonance at 32.85 ppm to $[\{(bcep)Zr(\mu\text{-}OH)\}_2]^{2+}$. Complex **4** could also give four peaks in this solvent mixture, but they would be in a 2:2:1:1 ratio. Accidental degeneracy of two of these peaks could give a 1:3:2 pattern, unfortunately, we have been unable to resolve the resonances at ca. 34 ppm sufficiently well to confirm this unambiguously. The resonance due to **2** is essentially



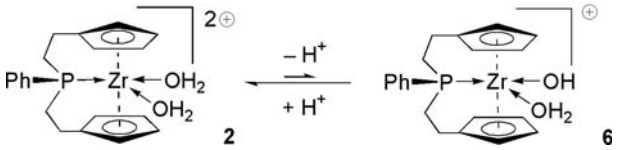


Fig. 2. ^{31}P NMR spectrum of complex **1** dissolved in a 2:1 D_2O/H_2O mixture.

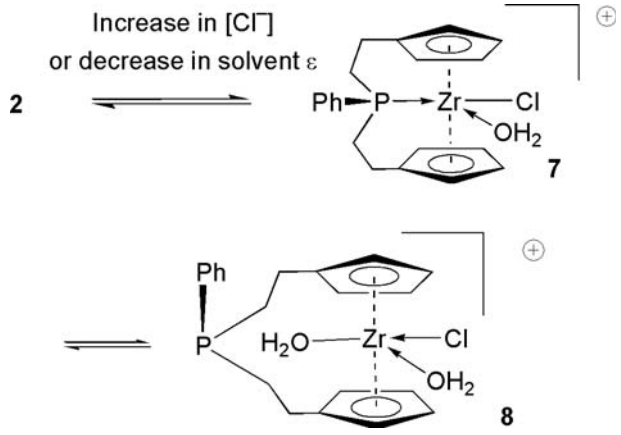
unchanged, as would be expected for rapid proton exchange in this complex. In a 1:1 solvent mixture, both **3** and **4** would have four peaks in a 1:1:1:1 ratio; this is observed for **3** but, again, is unresolved for **4**. The related complex $[\{Cp_2Zr(n\text{-PrCN})(\mu\text{-OH})\}_2]^{2+}$, has been crystallographically characterized and also found to have the *n*-PrCN substituents *trans* about the $Zr_2(OH)_2$ core [15]. The observation of this isotope effect deserves some comment. The average isotope effect on the ^{31}P NMR chemical shift is 0.045 ppm per H/D substitution, which is quite significant considering that the substitution is made three bonds away from the P atoms. A comparison can be made with $P(CH_3)_3$ versus $P(CD_3)_3$ in which the chemical shifts are −61.9 and −64.9 ppm, respectively [23]. This is an average isotope effect of 0.33 ppm per H/D exchange, for which the P atom is two bonds from the H/D atoms.

To confirm the absence of chloro complexes, $Ag(NO_3)$-(aq) was added to the aqueous solution of **1**. Although the expected precipitate of AgCl rapidly formed, there was no change in the ^{31}P NMR spectrum. Thus, the presence of chloro complexes can be ruled out.

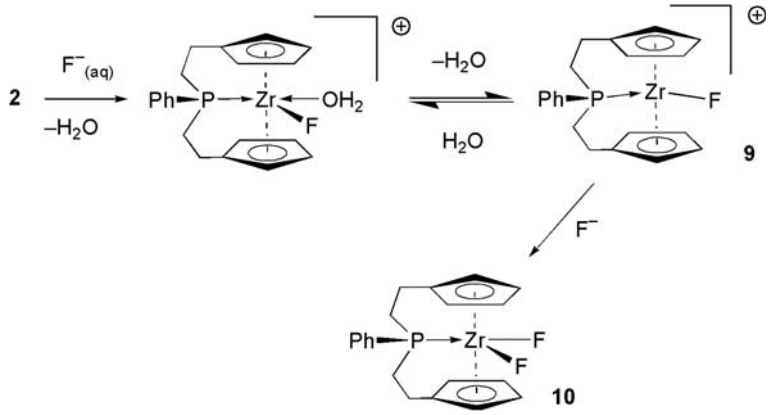
Further evidence in support of the proposed structures for **2**, **3** and **4** is provided by the treatment of aqueous **1** with aqueous $HClO_4$. One equivalent immediately precipitates out only **3** and **4**, as is expected from their larger size and hydrophobic exterior (the Zr_2O_2 cores are sterically shielded by the four cyclopentadienyl rings and two phenyl groups, as evidenced by the slow rate of proton exchange in the mixed D_2O/H_2O solvent systems). The concentration of **2** is unaffected and it seems reasonable to suggest that hydrogen bonding with the solvent keeps this species in solution.



Potentiometry measurements were also carried out to support the proposed mixture of compounds. Complex **1** dissolves in water over several minutes to give an acidic solution for which a stable pH reading can be taken after about 30 min. For a 10^{-3} M solution, the equilibrium pH is 3.3. This is lower than the expected pH calculated using the ^{31}P NMR peak ratios, which gives a pH of 3.7, but is higher than would be expected if **2** was in fact a hydroxo species like **5** or **6**, in which case, the expected pH would be less than 3.0. Similarly, a 10^{-2} M solution gives a pH of 2.2, rather than 2.7. The discrepancy could be accounted for by an equilibrium between **2** and **6**, which would be expected to be rapid and which could also provide a proton exchange mechanism. Attempts to measure the free chloride concentration using a chloride-ion selective electrode were prevented by chronic electrode fouling.

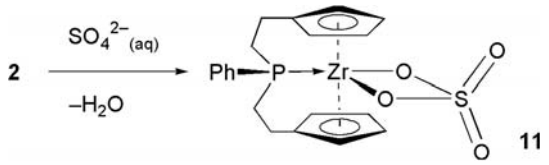
2 **6**

In an attempt to observe a species such as $[(bcep)ZrCl(H_2O)]^+$ (**7**), aqueous NaCl was added to an aqueous solution of **1**. Although no new peaks were observed in the ^{31}P NMR spectrum and the peaks assigned to **3** and **4** remained unchanged, the peak assigned to **2** at ca. 32 ppm broadened from 6 Hz with no added chloride to 60 Hz at 1.2 M chloride. A similar broadening effect was seen upon addition of acetonitrile (Table 1). We believe that this broadening is due to the formation of an equilibrium in which the **7** is in rapid equilibrium with the dication **2**. The chloroaqua cation may also have a largely non-coordinated phosphorus atom as in complex **8** since a non-coordinated P atom would be expected to have a



chemical shift considerably upfield of **2** and similar to that of the ferrocene complex (bcep)Fe at −16.8 ppm [8].

Unlike the addition of chloride, the addition of one equivalent of fluoride to aqueous solutions of **1** immediately converts **2** to the monofluoro species $[(bcep)ZrF(H_2O)_x]^+$ (**9**) ($x = 0$ or 1), while **3** and **4** react only slowly to give the same product (Scheme 2). Following the reaction by ^{31}P NMR spectroscopy, a doublet is observed for **9** at 27.3 ppm with a P–F coupling constant of 67 Hz. A small doublet of doublets is also observed at 18.3 ppm with coupling constants of 95 and 84 Hz. This compound is assigned as the difluoro complex $PhP(CH_2CH_2C_5H_4)_2ZrF_2$ (**10**). This compound disappears after several minutes and attempts to isolate a difluoro complex failed: only the oxide of the free ligand is observed in solution and a white precipitate that forms after addition of a second equivalent of fluoride contains no carbon or hydrogen. ES-MS of aqueous **1** with added CsF(aq) gives cation **9** as the major species with the difluoride observed as a Cs^+ adduct, $[PhP(CH_2CH_2C_5H_4)_2ZrF_2Cs]^+$ ($m/e = 553$) with a relative intensity of 8%. Significant peaks for hydrolysis products $[PHPh(CH_2CH_2C_5H_5)_2]^+$ (75%) and $[C_{20}H_{22}FPO]^+$ (50%) are also observed. The chemistry with fluoride contrasts with that of isothiocyanate in which the diisothiocyanato complex readily forms, but the monoisothiocyanato complex cannot be isolated, even with only one equivalent of thiocyanate [21]. This difference in chemistry can be attributed to the π-donor effect of fluoride which disfavours (relative to isothiocyanate) coordination of an additional ligand.



The fluoro complex **9** was precipitated from aqueous solution as the tetraphenylborate salt. It is important to do this reaction in the presence of added acid (as HCl(aq)), otherwise, an increase in pH as F^- substitutes OH^- in **3** and **4** eventually leads to hydrolysis of the zirconocene. Spectroscopic evidence indicates that there is no water coordinated in the solid state: no υ_{OH} in the infrared spectrum or additional proton resonances in the ^1H NMR spectrum (CD_3CN solvent) were observed and TGA/DSC shows no changes below 175 °C – above 175 °C, there are significant mass losses (>25%). In solution, however, a weakly coordinated water molecule cannot be ruled out. Fluoride is a much better π-donor ligand than chloride and, thus, electronic factors may disfavour coordination of water. As would be expected for ES-MS conditions, the highest mass ion (401 m/e (^{90}Zr isotopomer) for $[PhP(CH_2CH_2C_5H_4)_2ZrF]^+$) does not contain coordinated water.

Treatment of an acidified aqueous solution of (bcep)$ZrCl_2$ with sulfate gives a precipitate of (bcep)$Zr(SO_4)$ (**11**) that is insoluble in common solvents. Fortunately, the precipitate appears over several minutes and X-ray quality crystals were obtained directly from the reaction mixture. The infrared S=O stretch was observed at 1263 cm^{-1}, similar to other Zr(IV) complexes [24]. Under dilute conditions, complex **11** can be observed by ES-MS at 479 m/e as a bisulfato complex, $[(bcep)Zr(SO_4H)]^+$. A single crystal of **11** was subjected to an X-ray crystallographic analysis. The structure contains one independent molecule in the asymmetric unit. The structure is similar to other mononuclear (bcep)Zr complexes: the zirconium atom is approximately trigonal bipyramidal with the two cyclopentadienyl rings and one oxygen atom of the sulfato ligand occupying the equatorial positions and the axial positions occupied by the phosphorus atom and another sulfato oxygen atom. The sulfato ligand is O,O′ chelated. Fig. 3 shows an ORTEP plot of **11** with the atomic

Scheme 2. Reaction of aqueous **1** with fluoride.

labelling scheme and selected bond distances and angles. Table 2 gives the crystallographic data and structure refinement details.

The Zr–O distances in **11** are very similar with the axial distance of 2.2010(12) Å only very slightly longer than the equatorial distance of 2.1944(12) Å. These distances are similar to those found in other chelated Zr(IV) sulfato complexes, for example, in $[Zr(SO_4)_4]^{4-}$, the Zr–O distances range from 2.180(4) to 2.220(5) Å [25] and in $[\{CpCo(P(OEt)_2O)_3\}Zr(NO_3)_2(SO_4)]^-$, the Zr–$O_{sulfato}$ distances are 2.232(3) and 2.164(4) Å [24]. The Zr–P distance of 2.7793(5) Å is in the middle of the range of distances found in other (bcep)Zr complexes: 2.7810(8), 2.7499(7) and 2.794(2) Å for $(bcep)ZrCl_2$, $(bcep)Zr(NCS)_2$ and $[(bcep)ZrCl(H_2O)]Cl$, respectively [21]. Similarly, the Zr–CNT distances and the CNT–Zr–CNT angle are typical of (bcep)Zr complexes reported to date [21]. The *trans* angle, P–Zr–O2, of 139.54(3)° is small compared to the other (bcep)Zr complexes in which the smallest *trans* angle of 148.55(8)° is found in $(bcep)Zr(NCS)_2$ [11]. However, this is simply due to the chelating nature of the sulfato ligand since the P–Zr–O1 angle of 75.68(3)° is actually larger than the corresponding angle in $(bcep)Zr(NCS)_2$ (71.14(8)°). Notably, the *trans* angles in the five-coordinate di-μ-hydroxo complexes $[Cp_2Zr(CF_3COO)(\mu\text{-}OH)]_2$ [16] and $[\{Cp_2Zr(^nPrCN)(\mu\text{-}OH)\}_2]^{2+}$ [15] are similar (141.9° and 139.5°, respectively) to those found in **11**. The ligand conformation is similar to that found in $[(bcep)ZrCl(H_2O)]^+$ in which $\alpha_x = -69.8°$ and 95.9° (α_x = Cl–Zr–CNT(x)–C(x2), (CNT(x) = centroid of atoms C(x3) to C(x7)) and $\beta = 2.6°$ (β = Cl–Zr–P–C11) [21]. The corresponding angles in **11** are $\alpha_2 = -67.3°$, $\alpha_3 = 98.7°$ and $\beta = -3.1°$. The difference in $|\alpha_x|$ of 31.4° corresponds to staggered cyclopentadienyl rings. The most significant difference is that in $[(bcep)ZrCl(H_2O)]^+$ the phenyl plane lies between the chloro ligand and a cyclopentadienyl ring which forces one ring to be further from the equatorial chloro ligand than the other: CNT–Zr–Cl angles of 120.0° and 111.9°. In **11**, the phenyl ring is approximately perpendicular to the $ZrPO_2$ plane (Zr–P–C(11)–C(12) = −94.7°) and the CNT–Zr–O1 angles are consequently similar to each other (116.44° and 115.42°).

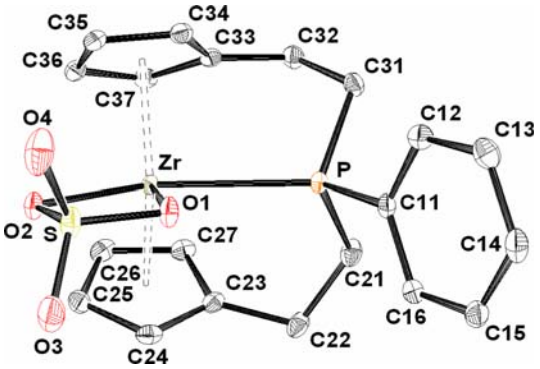


Fig. 3. ORTEP of $(bcep)Zr(SO_4)$ (**11**) with 40% thermal ellisoids. Selected bond distances and angles are Zr–O1 = 2.1944(12), Zr–O2 = 2.2010(12), Zr–P = 2.7793(5), Zr–CNT(C23–C27) = 2.225(1), Zr–CNT(C33–C37) = 2.223(1), S–O1 = 1.5341(12), S–O2 = 1.5209(12), S–O3 = 1.4382(15), S–O4 = 1.4412(16) Å, O1–Zr–O2 = 63.87(4)°, O1–Zr–P = 75.68(3)°, O2–Zr–P = 139.54(3)°, Zr–P–C11 = 125.05(5)°, Zr–P–C21 = 105.91(6)°, Zr–P–C31 = 108.57(6)°, CNT–Zr–CNT = 128.13°, CNT(2)–Zr–O1 = 116.44°, CNT(2)–Zr–O2 = 100.24°, CNT(2)–Zr–P = 96.82°, CNT(3)–Zr–O1 = 115.42°, CNT(3)–Zr–O2 = 102.91°, CNT(3)–Zr–P = 94.62°.

Largest difference in peak/hole (e Å^{-3})	0.477/−0.422

2.1. Other electrospray mass spectrometry studies

Addition of acids HX (X = Br, NO_3, HSO_4, HCO_3) to 10^{-4} M CH_3CN/H_2O solutions of **1** eliminates the peaks due to the dinuclear complexes **3** and **4** and gives only peaks corresponding to **2** and $[(bcep)ZrX]^+$ (Table 3). Since the structure of $(bcep)Zr(SO_4)$ contains a chelated sulfato ligand, it seems reasonable that the complexes $[(bcep)Zr(HCO_3)]^+$, $[(bcep)Zr(HSO_4)]^+$, and $[(bcep)Zr(NO_3)]^+$ would also contain chelated ligands to give five-coordinate

Table 3
Summary of ES-MS experiments with H_2O/CH_3CN solutions of **1** at low cone voltage (20 V)

Reagent added	*m/e* (rel. int.)	Assignment
None	399(100)	$[\{(bcep)Zr(OH)\}_n]^{n+}$ ($n = 1, 2$)[a]

[a] Ratio of approximately 1:2 for $n = 1$ and 2, respectively.

zirconocene complexes. After 1 h, the solution containing added HBr has additional peaks corresponding to $[(bcep)ZrOBr]^+$ (479 *m/e*, rel. int. = 100) and $[(bcep)ZrO(OH)]^+$ (415 *m/e*, rel. int. = 65), which may contain oxidised phosphine, while $[(bcep)ZrOH]^+$ and $[(bcep)ZrBr]^+$ are now much weaker with relative intensities of 13 and 10, respectively. Similar behaviour was observed for solutions containing added HCl [21].

3. Conclusions

In this paper, we have described some aqueous chemistry of the five-coordinate zirconocene dichloride complex **1**. Its speciation in water and water/acetonitrile solvents was investigated by ^{31}P NMR and ES-MS studies and shown to give three species in solution. Some reactivity studies were also carried out: treatment of aqueous solutions of **1** with various acids HX produced cationic complexes $[(bcep)ZrX]^+$ which were observed by ES-MS; addition of fluoride allowed the isolation of the monofluoro complex **9**, but not the difluoro complex **10**; addition of sulphate allowed the isolation of the sulfato complex **11** which was crystallographically characterised. These reactions thus demonstrate the potential to carry out reactions of this zirconocene in aqueous solutions.

4. Experimental

4.1. General considerations

Solvents were distilled prior to use. Complex **1** was prepared by the published procedure [21]. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR data were collected on a Varian XL-300 spectrometer operating at 300, 75 and 121 MHz, respectively. Unless otherwise stated, spectra were measured at ambient temperature with residue solvent peaks as internal standard for ^1H and $^{13}C\{^1H\}$ NMR. $^{31}P\{^1H\}$ NMR chemical shifts are reported relative to external 85% H_3PO_4, positive shifts representing deshielding. ES-MS were collected on a VG Platform MS8 and *m/e* are reported for the ^{90}Zr isotopomer. IR spectra were obtained on a Shimadzu FTIR-8201PC spectrophotometer. Elemental analyses were done by Campbell Microanalysis Services, University of Otago, Dunedin.

4.2. Speciation of 1 in H_2O, D_2O and CD_3CN solutions by ^{31}P NMR spectroscopy

In a typical NMR experiment, **1** (2.5 mg) was dissolved in the solvent (0.6 mL) to give a 10^{-2} M solution in Zr. H_2O solutions were locked with a D_2O insert. A 10 s delay was used to ensure accurate determination of integrals. The results for a variety of solvent mixtures are given in Table 1.

4.3. Reactions of 1 followed by ^{31}P NMR spectroscopy

(a) Addition of one half equivalent of NaOH(aq) gave only peaks at δ 34.4 and 33.1 in the ratio 1:1.6.
(b) Addition of one equivalent of $AgNO_3$(aq) immediately gave a white precipitate of AgCl. The ^{31}P resonances were unchanged.
(c) Addition of one equivalent of $HClO_4$(aq) gave an immediate precipitate with loss of the ^{31}P resonances of the dinuclear complexes while the resonance due to $[(bcep)Zr(H_2O)_2]^{2+}$ was unchanged.
(d) Addition of NaCl broadens the resonance of the diaqua dication while the other resonances are unaffected: $[Zr] = 1.4 \times 10^{-2}$; $[Cl^-]$ ($w_{1/2}$): 2.8×10^{-2} M (6 Hz), 5.4×10^{-2} M (8 Hz), 16.8×10^{-2} M (14 Hz), 60×10^{-2} M (27 Hz), 120×10^{-2} (60 Hz).

4.4. Speciation and reactions of 1 in CH_3CN/H_2O solutions by ES-MS

In a typical experiment, a dilute solution of the reagent was added to 10^{-4} M solutions of **1** in 1:1 CH_3CN/H_2O. The reagents and results are summarised in Table 3.

4.5. Preparation of $[PhP(CH_2CH_2C_5H_4)_2ZrF]BPh_4$ (9)

Complex **1** (0.0339 g, 0.0745 mmol) was dissolved in water and HCl(aq) (0.55 mmol) added after the complex had dissolved. One equivalent of NaF (1 mL of a 0.0313 g/10 mL solution, 0.0745 mmol) was slowly added and the solution stirred at ambient temperature for 1 h. $^{31}P\{^1H\}$ NMR (H_2O): δ 27.3 (d, $^2J_{PF} = 62$ Hz) (s). An aqueous solution of $NaBPh_4$ (0.0291 g, 0.0850 mmol) was slowly added to give immediately a white precipitate, this was stirred for 1 h before collection by filtration and drying in air to give 0.050 g (93% yield) of **9**. ^1H NMR (CD_3CN): δ 7.75 (m, 3H, Ph), 7.52 (m, 2H, Ph), 7.27 (m,

8H, BPh_4^-), 6.98 (t, $J = 7.5$ Hz, 8H, BPh_4^-), 6.83 (t, $J = 7.2$ Hz, 4H, BPh_4^-), 6.53 (m, 2H, Cp), 6.20 (m, 2H, Cp), 6.13 (m, 2H, Cp), 5.97 (m, 2H, Cp), 3.2–2.7 (m, 8H, CH_2); $^{13}C\{^1H\}$ NMR (CD_3CN): δ 137.0 (s, BPh_4^-), 133.7 (d, $J_{PC} = 9$ Hz, Ph), 132.3 (s, Ph), 130.1 (d, $J_{PC} = 9$ Hz, Ph), 126.7 (m, BPh_4^-), 123.7 (s, Cp), 122.9 (s, BPh_4^-), 113.0 (s, Cp), 111.9 (s, Cp), 104.3 (s, Cp), 32.7 (d, $^1J_{PC} = 23$ Hz, PCH_2), 25.5 (d, $^2J_{PC} = 11$ Hz, PCH_2CH_2), (*i*-Ph and *i*-Cp not observed); $^{31}P\{^1H\}$ NMR (CD_3CN): δ 24.3 (d, $^2J_{PF} = 55$ Hz). *Anal.* Calc. for $C_{44}H_{41}BFPZr$: C, 73.22; H, 5.73. Found: C, 72.41; H 5.59%.

4.6. Attempted preparation of (bcep)ZrF_2 (**10**)

Complex **1** (0.015 g, 0.033 mmol) was dissolved in D_2O and one equivalent of NaF added (1.4 mg, 0.033 mmol). The ^{31}P resonance at 32.77 ppm, assigned as the dication **2**, rapidly disappeared with the formation of a doublet due to the monofluoro complex **9** and a small doublet of doublets at 18.31 ppm ($^2J_{PF} = 95$ and 84 Hz), assigned as the difluoro complex **10**. This doublet of doublets disappeared after several minutes as the resonances due to the dinuclear complexes **3** and **4** slowly converted to that of **9**. Addition of a second equivalent of NaF rapidly gave an insoluble white precipitate and resonances consistent with the oxide of the free ligand (^{31}P NMR: δ 40.28, 40.12 and 39.96 in a ratio of 1:2:1).

4.7. Preparation of $PhP(CH_2CH_2C_5H_4)_2ZrSO_4$ (**11**)

Complex **1** (0.011 g, 0.024 mmol) was dissolved in aqueous HCl (3 mL of 0.1 M HCl). After 20 min, Na_2SO_4 (0.0034 g, 0.024 mmol) was added. Over several minutes, small colourless plates of the product **11** appeared (0.01 g, 87%). The product was found to be insoluble in common solvents. IR (KBr) (cm^{-1}): 1263 (s), 1155 (s) 935 (s), 918 (s). *Anal.* Calc. for $C_{20}H_{21}O_4PSZr$: C, 50.08; H, 4.41. Found: C, 50.06; H, 4.62%.

4.8. Potentiometry experiments

Dissolution of complex **1** (0.227 g, 0.5 mmol) in H_2O (50 mL) to give a 10^{-2} M solution was followed by pH measurement. Total dissolution occurred within 10 min and a stable pH reading (pH 3.3) was obtained after about 30 min. Neutralisation required two equivalents of NaOH(aq) with a white precipitate forming at this pH (7–8). Attempts to follow the dissolution process or to measure chloride-ion equilibria using a chloride-ion selective electrode were prevented by chronic electrode fouling.

4.9. Crystal structure determination

X-ray crystallographic data for **11** were collected from a single crystal sample which was mounted on a glass fibre. Data were collected using an APEX-II diffractometer equipped with a Bruker SMART CCD area detector (using the program SMART [26]). Processing was carried out by use of the program SAINT [26] which applied Lorentz and polarisation corrections to three-dimensionally integrated diffraction spots. The program SADABS [26] was utilised for the scaling of diffraction data, the application of a decay correction, and empirical absorption correction based on redundant reflections. The structure was solved by the direct methods procedure [27] and refined by least-squares methods on F^2 with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were added as riding contributors, at calculated positions with isotropic thermal parameters based on the attached carbon atom. Crystal data and structure refinement parameters are given in Table 2.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC reference number 299554. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web: http://www.ccdc.cam.ac.uk.

Acknowledgements

We thank Professor Brian K. Nicholson, University of Waikato, for assistance with the ES-MS work and Dr. Cees Lensink, Industrial Research Laboratories, Lower Hutt, New Zealand, for the TGA/DSC results.

Abstract

The synthesis and X-ray structures of four neutral copper(II) complexes and one cationic complex incorporating bidentate alkyl *N*-(4-oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-yl)imidocarbamate ligands are reported. The neutral complexes, which possess potential doublet (DA) hydrogen bonding motifs, form supramolecular structures based on synthons involving hydrogen bonding or phenyl embraces. The formation of sheets within the crystal through combination of these synthons, and the occurrence of guest molecules trapped in cavities between the sheets, are described. The cationic complex forms an extended hydrogen-bonded structure that incorporates nitrate ions. The structures of the five complexes are compared with others reported previously for complexes of related ligands.

1. Introduction

In recent times there has been a growing interest in the rational design of crystals containing linked transition metal complexes, both by the formation of coordination polymers [1–4] as well as by using hydrogen bonding and other weak interactions between coordinated ligands [5–10]. In earlier papers we have described the incorporation of a number of transition metal complexes into supramolecular arrays using complementary hydrogen bonding motifs [11–13]. The complexes were based on the structurally similar bidentate ligands *N*-(4-oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-yl)alkanimidamide (where alk = Me, Et), methyl *N*-(4-oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-yl)imidocarbamate, *N*,*N*-dimethyl-*N*′-(4-oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-yl)guanidine and *N*-(4-oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-yl)-*N*′-phenyl guanidine (Scheme 1). These ligands, which are structurally related to biguanide, readily form neutral pseudo-macrocyclic complexes with self-complementary DA hydrogen bonding motifs and hence are well suited for use in structural studies concerned with investigating supramolecular interactions in crystals of transition metal complexes.

The above ligand type possesses a number of features that can be synthetically altered to affect significantly the supramolecular assembly of their complexes [11–13]. As a consequence, investigation of structural and electronic aspects of their complexation behaviour has the potential to contribute to a better understanding of rational crystal design. A common feature of these systems is that the anionic forms of the ligands that occur in the corresponding neutral divalent metal complexes exhibit self-complementary doublet donor–acceptor (DA) hydrogen bonding motifs. Also, the potential for hydrogen bonding between neighbouring complexes is restricted to the use of these motifs because the remaining ligand hydrogen bond donors and acceptors are

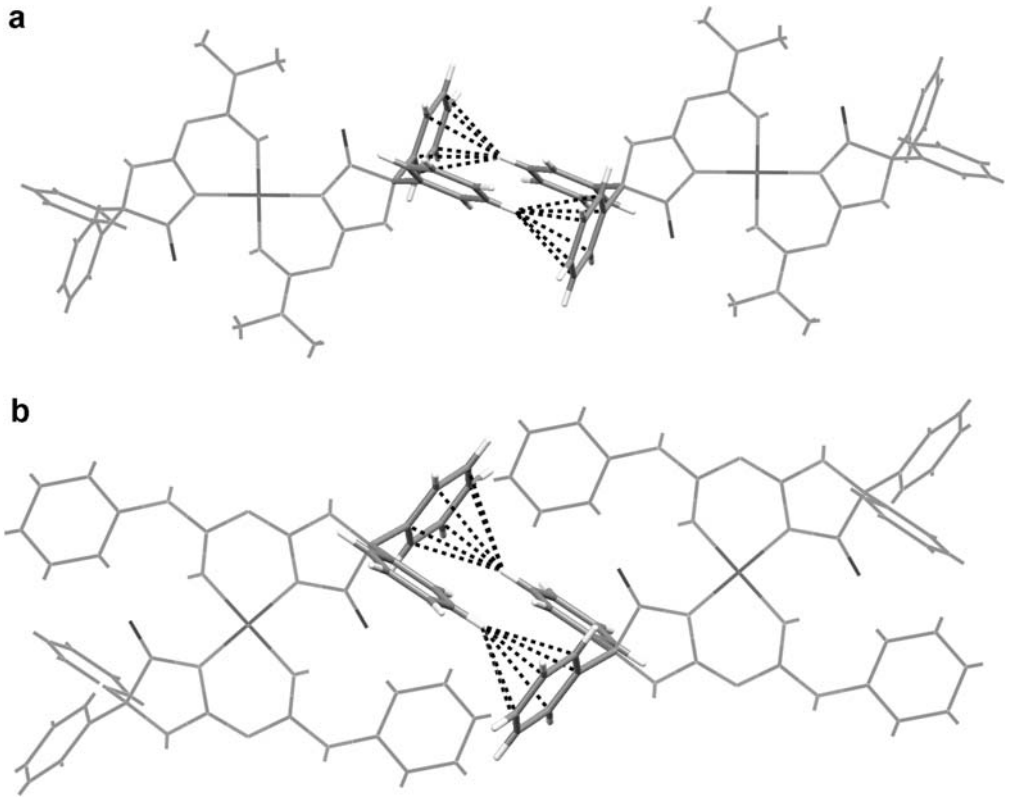
used in the formation of pseudo-macrocyclic rings. Where intermolecular interaction between the potential doublet hydrogen bonding motifs is not prevented by solvation of the motif or by steric hindrance involving ligand substituents, the complexes link together into chains by $R_2^2(8)$ hydrogen bond patterns. While the complex units forming the hydrogen-bonded chains were often found to be approximately coplanar, twisting of the chains was also observed in particular instances. It is noted that in these species, conformational changes involving the bound ligands are required to allow efficient hydrogen bond formation to occur [11–13].

In addition to the above, the geminal diphenyl motif on the ligand provides an alternative means of assembling the complexes into chains through the formation of phenyl embraces [14,15]. The phenyl embraces consist of complementary CH to π-facial interactions (CHπ) and offset face-to-face (OFF) interactions between pairs of aromatic rings on adjacent ligands. Although such an assembly is clearly based on weak interactions, it is noted that in favourable cases such phenyl embraces can be as significant as hydrogen bonds [14–16]. There are two ways in which embraces can form in these systems (see Fig. 1) and both have been observed in our studies so far.

The –X and –OR (alkoxy) substituents in ligands of the present type (Scheme 1) have different steric requirements that may preclude the formation of the hydrogen-bonded rings, and will also to some degree vary the electronic properties of the ligand.

The potential doublet hydrogen bonding motif may also be extended to a potential triplet. Namely, when X was made a –NHR group the corresponding pseudo-macrocyclic complex contains a potential DAD triplet hydrogen bonding motif [13]. Co-crystallisation with 1,8-naphthalimide, a molecule with a complementary ADA motif, resulted in the component units assembling into chains using phenyl embraces. When the complex was crystallised in the absence of 1,8-naphthalimide, the structure obtained then consisted of twisted hydrogen-bonded chains linked by $R_2^2(8)$ patterns formed by self-complementary DA–AD motifs. There are two ways in which a triplet DAD motif might do this and both were observed to occur experimentally on growing the crystals from different solvents (benzonitrile and



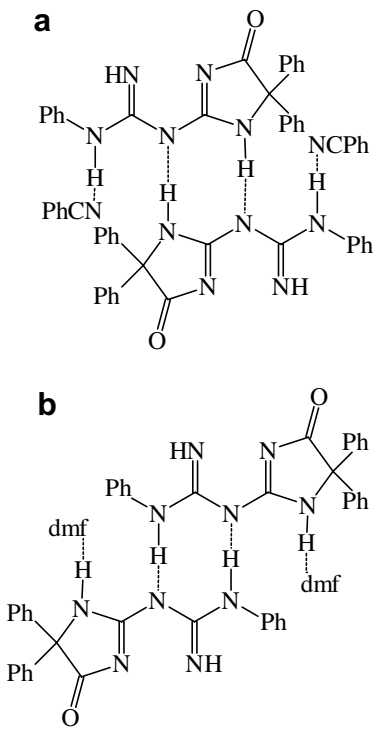


Fig. 1. Two types of phenyl embrace that may form between the gem diphenyl groups on adjacent macrocycles [11,12].

Scheme 2. The two ways in which the potential DAD triplet may form self-complementary DA–AD motifs.

N,*N*-dimethylformamide, respectively); both crystalline complex species were found to incorporate the corresponding solvent molecules (see Scheme 2, which also shows the respective hydrogen bonding patterns).

Two further features of these systems are of relevance to the discussion that follows. First, complexes of different ligands differed in the ease with which the hydrogen-bonded form could be obtained from a solution of the strong hydrogen bond acceptor, dimethylsulfoxide. Second, it was frequently observed that methyl groups attached to heteroatoms (O, N, S) showed a tendency to form contacts with the faces of adjacent phenyl rings.

In this paper, by employing a series of alkyl *N*-(4-oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-yl)imidocarbamate ligands (Scheme 1, X = –OR) for copper(II) complexation we keep the potential hydrogen bonding motif as a doublet (DA) while introducing side-chains with different steric requirements. In addition, we examine the inclusion of nitrate ions in an extended structure that incorporates a cationic pseudo-macrocyclic complex showing a potential DD hydrogen bonding motif.

2. Experimental

2.1. Synthesis

4-Oxo-5,5-diphenyl-4,5-dihydro-1H-imidazol-2-ylcyanamide was prepared in good yield (66%) from benzil and dicyandiamide as described in the literature [17].

2.1.1. (Dimethylformamide)bis(methyl N-(4-oxo-5,5-diphenyl-4,5-dihydro-1H-imidazol-2-yl)imidocarbamato)-copper(II) (**1**)

This complex was prepared as reported previously [12] and recrystallised from *N*,*N*-dimethylformamide. *Anal.* Calc. for $C_{37}H_{37}CuN_9O_5 \cdot 1/4H_2O$: C, 58.79; H, 5.00; N, 16.68. Found: C, 58.61; H, 4.83; N, 16.46%.

2.1.2. General methods

Method A. 4-Oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-ylcyanamide (0.138 g, 0.5 mmol) dissolved in the required hot alcohol (15 mL) was added to $Cu(NO_3)_2 \cdot 21/2H_2O$ (0.058 g, 0.25 mmol) in similar hot alcohol (20 mL). The solution was heated under reflux for 2–3 h during which time the colour turned deep blue. The solution was allowed to cool and concentrated aqueous ammonia added until precipitation was complete. The solid product was filtered off, washed with alcohol and ether, then air dried. The solid was recrystallised from *N*,*N*-dimethylformamide before microanalysis.

Method B. 4-Oxo-5,5-diphenyl-4,5-dihydro-1*H*-imidazol-2-ylcyanamide (0.138 g, 0.5 mmol) in the required hot alcohol (15 mL) was added to $Cu(NO_3)_2 \cdot 21/2H_2O$ (0.058 g, 0.25 mmol) in similar hot ethanol (20 mL). The solution was heated under reflux for 2–3 h during which the colour turned deep blue. The solution was allowed to cool and let stand until the blue (or blue-green) crystals formed. The crystals were isolated by filtration and air dried before microanalysis.

*2.1.2.1. Bis(isopropyl N-(4-oxo-5,5-diphenyl-4,5-dihydro-1H-imidazol-2-yl)imidocarbamato)copper(II) · 2dimethylformamide (**2**). Method A*. Yield 33 mg, 15%. *Anal.* Calc. for $C_{44}H_{52}CuN_{10}O_6$: C, 59.44; H, 5.34; N, 17.05. Found: C, 59.44; H, 5.34; N, 17.05%.

*2.1.2.2. Bis(1-butyl N-(4-oxo-5,5-diphenyl-4,5-dihydro-1H-imidazol-2-yl)imidocarbamato)copper(II) · 2dimethylformamide (**3**). Method A*. Yield 21 mg, 9%. *Anal.* Calc. for $C_{43}H_{49}CuN_9O_5$: C, 61.81; H, 5.91; N, 15.09. Found: C, 61.91; H, 6.06; N, 15.06%.

*2.1.2.3. (1-Butanol)bis(1-butyl N-(4-oxo-5,5-diphenyl-4,5-dihydro-1H-imidazol-2-yl)imidocarbamate)copper(II) nitrate (**4**). Method B*. Yield 15 mg, 6%. *Anal.* Calc. for $C_{44}H_{54}CuN_{10}O_{11}$: C, 54.91; H, 5.65; N, 14.55. Found: C, 55.15; H, 5.33; N, 14.63%.

*2.1.2.4. (1-Propanol)bis(1-propyl N-(4-oxo-5,5-diphenyl-4,5-dihydro-1H-imidazol-2-yl)imidocarbamato)copper(II) · 1/4(1-propanol) · 1/4water (**5**). Method A*. Sample was recrystallised from 1-propanol not *N*,*N*-dimethylformamide; yield 15 mg, 7%. *Anal.* Calc. for $C_{38}H_{38}CuN_8O_4$: C, 62.15; H, 5.22; N, 15.26. Found: C, 62.59; H, 5.19; N, 15.40%.

*2.1.2.5. (1-Propanol)bis(1-propyl N-(4-oxo-5,5-diphenyl-4,5-dihydro-1H-imidazol-2-yl)imidocarbamate)copper(II) nitrate (**6**). Method B*. yield 15 mg, 7%. *Anal.* Calc. for

$C_{41}H_{46}CuN_{10}O_{11}$: C, 53.61; H, 5.05; N, 15.25. Found: C, 53.59; H, 5.32; N, 15.17%.

2.2. X-ray crystal structure determinations

Single crystal diffraction data were collected with a Bruker SMART 1000 CCD diffractometer employing graphite monochromated Mo Kα radiation from a sealed tube, and equipped with an Oxford Cryosystems Cryostream. In general the data collections were undertaken at 150(2) K, with the exception of complex **2** for which data were collected at 200 K as the crystals were found to undergo a destructive phase transition between 150 and 200 K. Cell constants were obtained from a least squares refinement against at least 1000 reflections located between 4° and 56°, 2θ, and data were collected with ω scans to at least 56°, 2θ.

The data integration and reduction were undertaken with SAINT and XPREP [18], and in general subsequent computations were carried out with the WINGX [19] and XTAL [20] graphical user interfaces. The XP SHELXTL-PLUS [18] graphical user interface was used to model the structure for complex **1**. A recollection of the first 50 CCD frames at the end of each collection showed no evidence for crystal decay. A Gaussian absorption correction [18,21] was applied to the data for all but that of complex **1**, for which a multi-scan correction was applied with SADABS [22].

In general the structures were solved by direct methods with SIR-97 [23], and extended and refined with SHELXL-97 [24]. The solution for complex **1** was obtained with SHELXS-97 [24]. Full occupancy non-hydrogen atom sites were modelled with anisotropic displacement parameters, and partially occupied sites were modelled with isotropic displacement parameters. In general a riding atom model with group displacement parameters was used for the hydrogen atoms. Hydrogen atoms were not included for water solvate molecules. ORTEP [25] depictions for complexes **1**–**5** with 20% displacement ellipsoids were created (Figs. 2–4, 5a, 5b, 6a, 6b).

2.2.1. Complex *1*

Data were obtained from a purple plate-like crystal. The asymmetric unit contains the complex molecule together with a site modelled as the oxygen of a partial occupancy water molecule.

2.2.2. Complex *2*

Data were obtained from a purple tablet-like crystal. The asymmetric unit contains half a complex molecule centred on an inversion site, together with a DMF solvate molecule linked to the complex through hydrogen bonding to the N(2) hydrogen. An ether residue on the complex is disordered about two locations related by rotation about the C(4)–O(2) bond, with site occupancies refined and then fixed at 0.5.

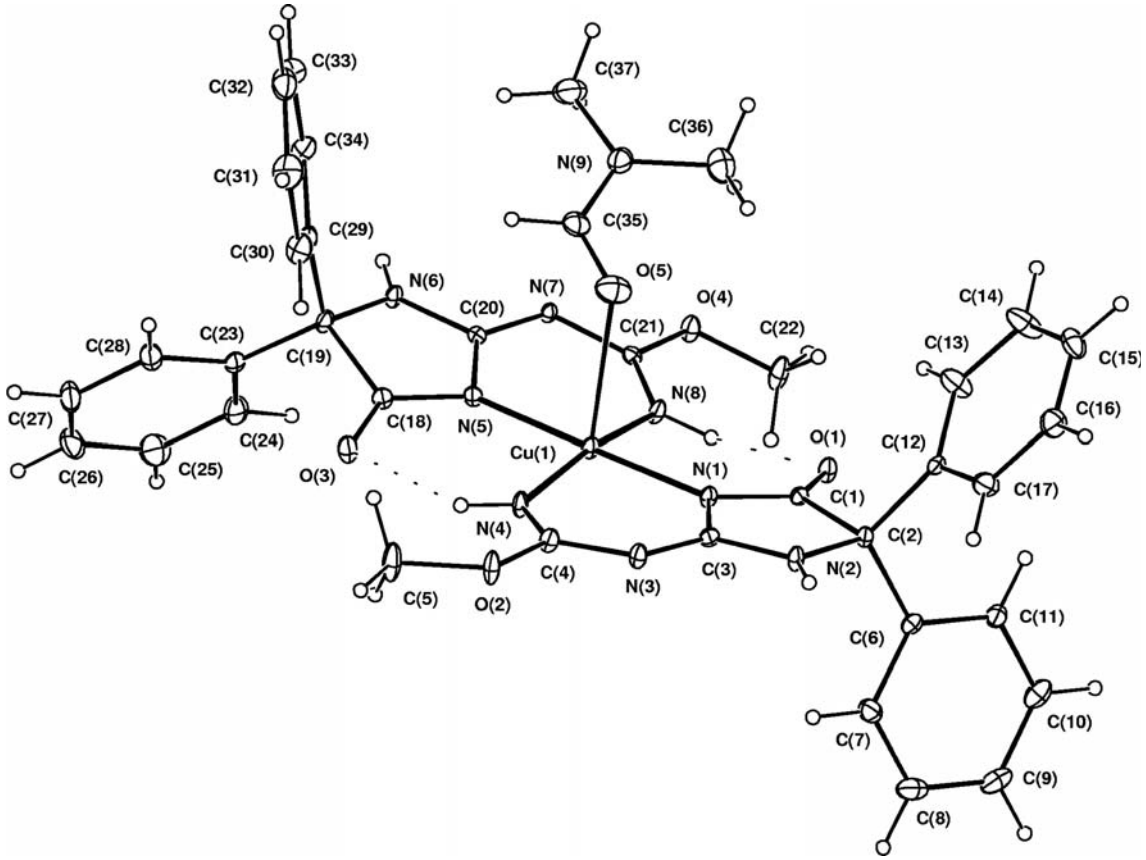

Fig. 2. An ORTEP [25] depiction of the complex in **1**. Displacement parameters are drawn at the 20% level.

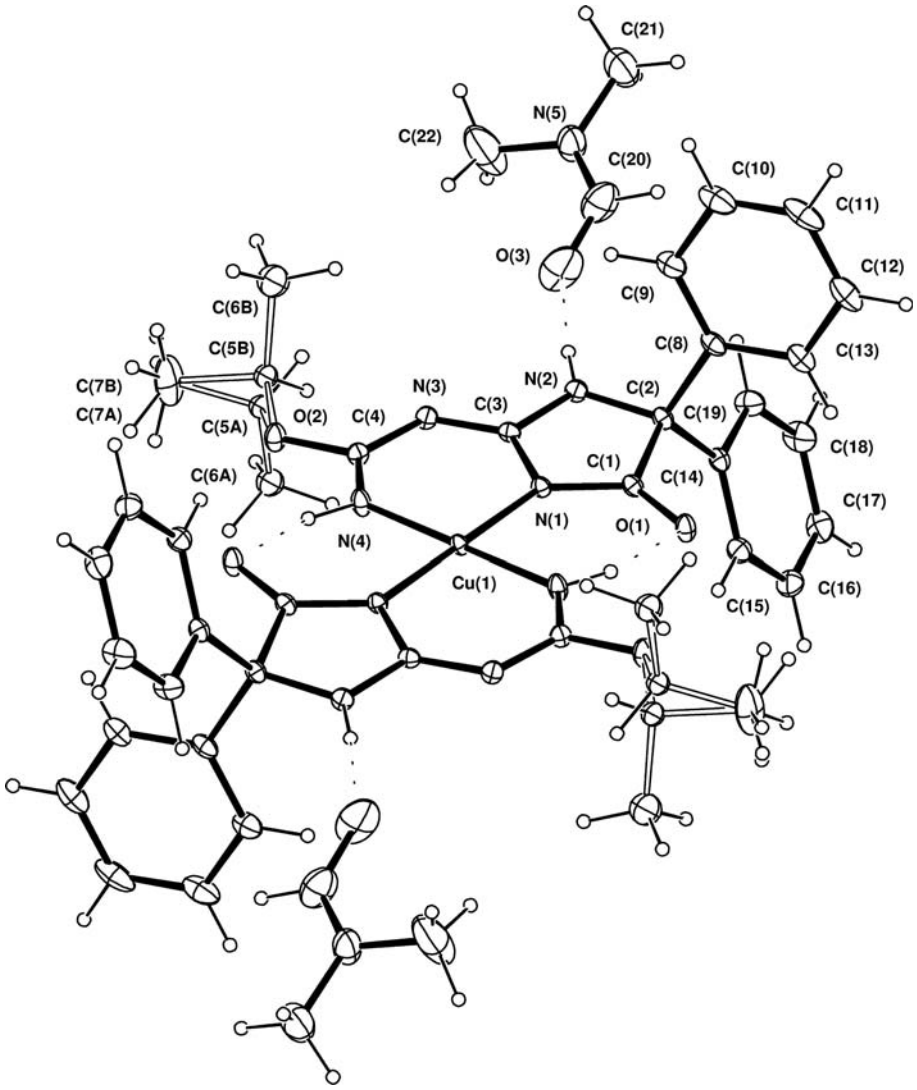

Fig. 3. An ORTEP [25] depiction of the complex in **2**. Displacement parameters are drawn at the 20% level.

*2.2.3. Complex **3***

Data were obtained from a purple tablet-like crystal. The asymmetric unit contains half a complex molecule centred on an inversion site, together with a DMF solvate molecule linked to the complex through hydrogen bonding to the N(2) hydrogen. The amine hydrogen sites were located and modelled with isotropic displacement parameters and weak distance restraints. A terminal ethyl residue on the complex is disordered about two locations related by bond rotation about C(5)–C(6), with site occupancies refined and then fixed at 0.7 and 0.3 respectively.

*2.2.4. Complex **4***

Data were obtained from a blue plate-like crystal. The asymmetric unit contains two crystallographically independent complex molecules and their nitrate counterions. A butanol molecule is axially coordinated to each complex to complete a square pyramidal coordination environment. One of the axial ligands is disordered about two orientations with site occupancies refined and then fixed at 0.6 and 0.4. The butyl ether residues of one of the complexes are similarly disordered. The structure was treated as an inversion twin, with the Flack parameter [26] refining to 0.374(7). An attempt to model the structure in the centrosymmetric space group $P\bar{1}(\#2)$ (with the origin shifted to −0.31020, −0.49160, −0.03150) was unsatisfactory with, for instance, the butyl ether residues of the complex not being resolved. The statistics for the reflections were intermediate between centric and non-centric and were interpreted as pseudo-centric.

*2.2.5. Complex **5***

Data were obtained from a purple prismatic crystal. The asymmetric unit contains a complex molecule that includes a weakly coordinated propanol ligand disordered over 3 closely spaced orientations with occupancies refined and then fixed at 1/3. A set of persistent residual density peaks near an inversion site were modelled as a partially occupied propanol solvate molecule site and a partially occupied water site, with occupancies refined and then fixed at

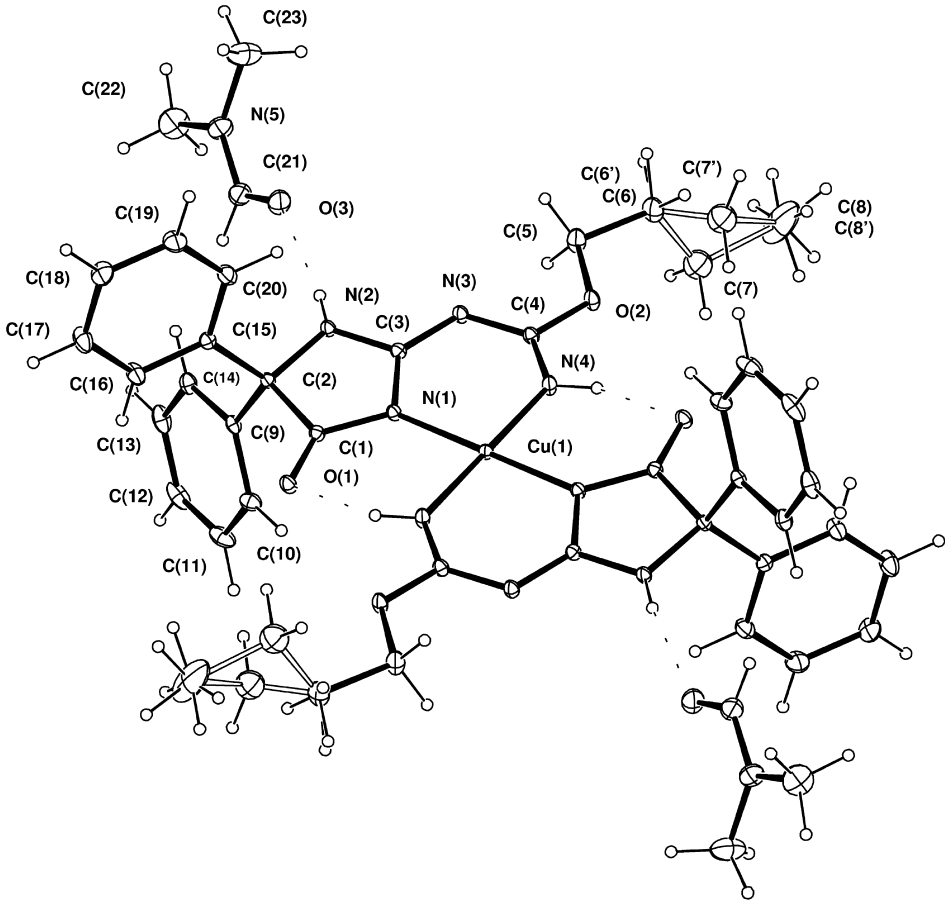

Fig. 4. An ORTEP [25] depiction of the complex in **3**. Displacement parameters are drawn at the 20% level.

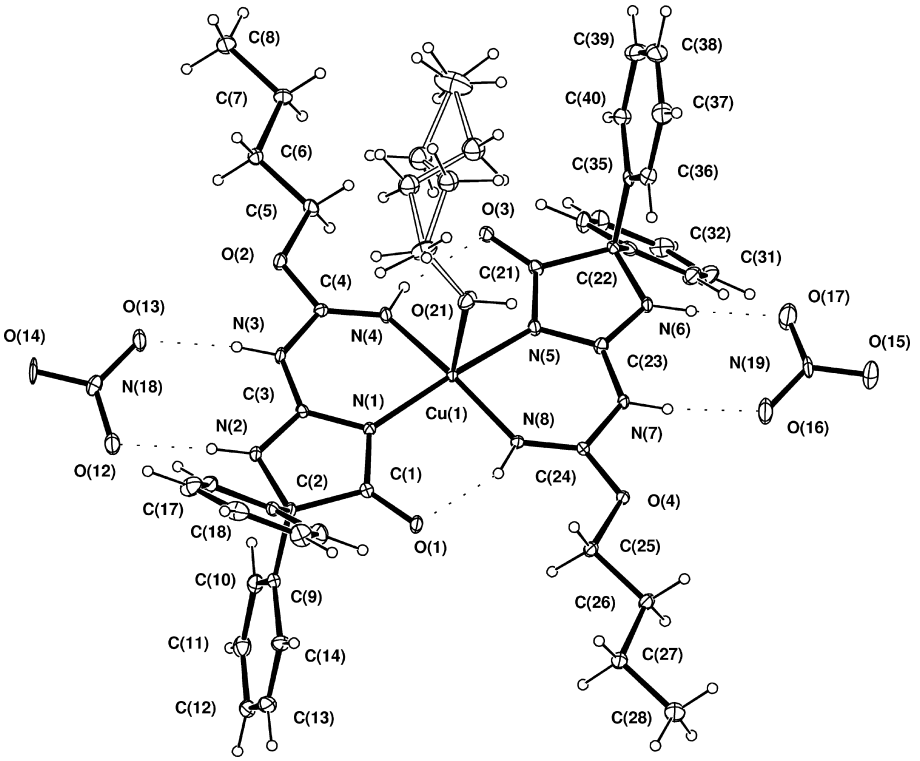

Fig. 5a. An ORTEP [25] depiction of the Cu(1) complex in **4**. Displacement parameters are drawn at the 20% level.

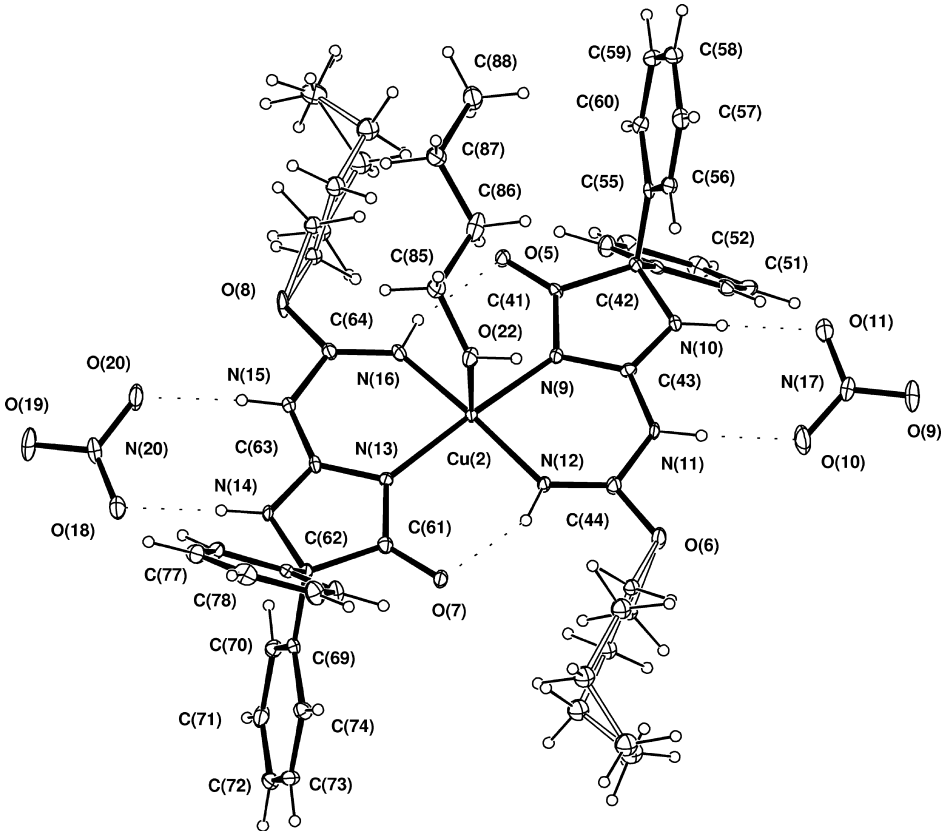

Fig. 5b. An ORTEP [25] depiction of the Cu(2) complex in **4**. Displacement parameters are drawn at the 20% level.

0.25. The model is somewhat unsatisfactory, as it results in unrealistically short hydrogen to hydrogen contacts between the solvate and a neighbouring complex molecule. Repeated attempts to avoid these contacts without the appearance of further significant residual density were unsuccessful. The contacts could be removed by swapping the identity of the terminal oxygen and carbon atoms, however this model seems even less likely. The contacts are attributed as artefacts of a limited model for disorder about an inversion site.

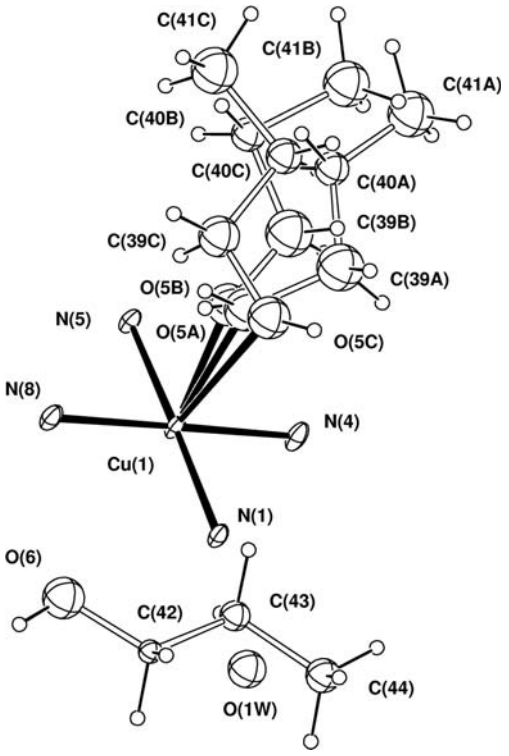

Fig. 6b. An ORTEP [25] depiction of the coordinated propanol and the guest molecules in **5**. The copper ion and its nitrogen donor atoms are shown for reference. Displacement parameters are drawn at the 20% level.

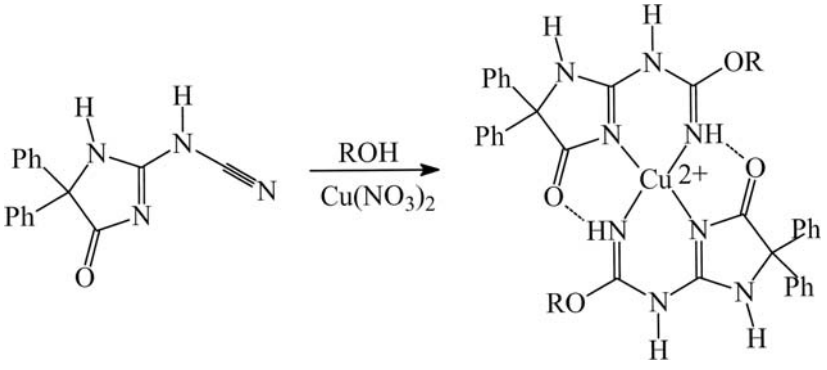
3. Results and discussion

3.1. Synthesis and X-ray studies



The synthetic method used to obtain the neutral complexes **1**, **2**, **3** and **5** is similar to that used for the cationic complex **4** (illustrated in Scheme 3) save that strong ammonia was added to the reaction solution to induce deprotonation of the bound ligands. The procedure for **4** incorporating neutral **I** (X = OBu^n) seems from the evidence of elemental analysis also to have been successful for **6** (X = OPr^n).

Crystallographic details for the structures determined during the study are listed in Table 1. Coordination bond lengths are presented in Table 2 and hydrogen bond interactions appear in Table 3. Metallaring bond lengths for the complexes of the neutral and anionic forms of the ligands (X = OBu^n) are compared in Table 4. ORTEP depictions are provided in Figs. 2–4, 5a, 5b, 6a, 6b.

3.2. Structure of *1*

The copper(II) species **1** was prepared for comparison with similar products reported earlier [12]. For these latter cases complex crystallisation occurred from methanol or dimethylsulfoxide. When crystallisation occurred from methanol, the pseudo-macrocyclic complexes yielded hydrogen-bonded chains, with similar chain formation also being observed in one of the crystal forms obtained from dimethylsulfoxide. In a minor phase obtained from the above dimethylsulfoxide crystallisation, the two hydrogen bond donors present in the potential DA motif were observed to be hydrogen bonded to dimethylformamide molecules rather than forming an $R_2^2(8)$ hydrogen bond ring pattern. In the present study, product **1** was found to resemble the major crystalline product obtained above from dimethylsulfoxide. The copper(II) is five-coordinate, with a dimethylformamide molecule occupying its apical site at a distance of 2.5475(27) Å from the metal. The maximum and minimum deviations of the four nitrogen donor atoms from their least squares plane are 0.0915(14) and 0.0927(14) Å and Cu(1) lies 0.0800(15) Å from the plane. In addition there is a site partially occupied (0.25) by water. The O(5)–O(6) distance is 2.91 Å, consistent with the water being hydrogen bonded to the coordinated dimethylformamide oxygen. The copper ion lies 0.2077(39) and 0.3960(38) Å from the mean planes of the ligand atoms that make up the metallarings; and these planes make an angle of 19.02(16)° with one another.

The individual pseudo-macrocyclic complexes are linked together into chains by $R_2^2(8)$ rings formed by the complementary DA motifs on the bound ligands. The hydrogen bond rings are approximately planar with the maximum deviation from the plane being 0.0918(25) Å. The coordinated dimethylformamide molecules all lie on the same side of the chain (Fig. 7) and in this respect the chains differ from those formed by the neutral pseudo-macrocyclic copper(II) complexes formed by **I** (X = OMe) and **I**

(X = Me) with dimethylsulfoxide in the apical position; where, in the former case the dimethylsulfoxide molecules alternate above and below the chain and in the latter they alternate pair wise two above, two below and so on [11,12].

There are CHπ and OFF interactions between neighbouring phenyl groups and methyl-π–facial interactions between the ligand methoxy methyl groups and phenyl groups. The *O*-methyl groups on the ligands are in the *anti* conformation, which, although it is expected to be less favourable energetically than the *syn*, is necessary for the formation of the $R_2^2(8)$ hydrogen bonding patterns [27].

3.3. Complexes linked by phenyl embraces

As mentioned above, products **2** and **3** are neutral copper(II) pseudo-macrocyclic complexes based on **I** (X = OPr^i) and **I** (X = OBu^n) respectively. In both cases, although the ligands possess complementary DA doublet motifs, chains in which the complexes are linked by $R_2^2(8)$ hydrogen bonding patterns are not present. Instead, molecules of dimethylformamide act as hydrogen bond acceptors for the imidazole NH donors and the complexes are linked into chains by phenyl embraces of the type shown in Fig. 1a.

It is interesting that the only occasion on which we have seen the second type of embrace (Fig. 1b) has been with a ligand that contains a further phenyl group that also interacts with the aryl groups that make up the phenyl embrace. It is possible that collectively these interactions are sufficient to stabilise this latter type of embrace over the more frequently observed embrace. This above structure type, in which the potential doublet motif is solvated, has been observed previously when the formation of $R_2^2(8)$ hydrogen bonding patterns is prevented by steric hindrance (X = NMe_2) and also as a minor phase present amongst crystals containing hydrogen-bonded chains (X = NHPh).

In both **2** and **3**, the *O*-alkyl groups are in the *syn* conformation, which is expected to be more energetically favourable than the *anti* [17]. The copper(II) ion is four-coordinate and square planar in both these complex species and in each case Cu(1) lies on an inversion centre so that there is only one crystallographically distinct ligand. In **2**, the maximum deviation of a ligand atom in the metallaring from the least squares plane is 0.0377(11) Å, and the Cu(1) lies 0.1124(21) Å from this plane. In **3**, the maximum deviation is 0.0431(14) Å, with the Cu(1) lying 0.1651(24) Å from the plane.

Interpreting these structures in the light of the 'best donor joining with the best acceptor rule' suggests that the formation of the hydrogen-bonded chains depends on successful competition between the N(3) hydrogen bond acceptor and the solvent for the imidazole NH hydrogen bond donor. It would be expected on this basis that the choice of solvent might influence the adoption of one or other of these arrangements; that is, between forming hydrogen-bonded chains or chains formed through phenyl embraces.

3.4. The inclusion of an anion

Product **4** is composed of cationic pseudo-macrocyclic copper(II) complexes of **I** (X = OBu^n). There are two crystallographically distinct complexes per unit cell and both are five-coordinate square pyramidal, with a butanol molecule occupying the apical site; Cu(1)–O(21) and Cu(2)–O(22) distances are 2.2993(25) and 2.3252(26) Å respectively. Cu(1) and Cu(2) lie 0.1220(20) and 0.1265(21) Å from the least squares planes of their respective nitrogen donor atoms. The ligand metallarings within each complex are effectively coplanar, with the least squares planes making angles of just 0.57(0.20)° and 0.95(0.21)° with each other.

The ligands that form the pseudo-macrocycle now have a DD hydrogen bonding motif, and each ligand is hydrogen bonded to two oxygen atoms of a nitrate ion in a $R_2^2(8)$ pattern. The third oxygen on one of the two nitrate ions acts as a hydrogen bond acceptor, with the coordinated butanol in a neighbouring complex being the donor. The third oxygen of the other of the two nitrates is not involved in any short interactions and lies 4.2 Å from the copper ion in a neighbouring complex. The hydrogen-bonded chains interact with neighbouring chains through offset face-to-face phenyl interactions (Fig. 8). The atoms

forming the hydrogen bonded $R_2^2(8)$ patterns are effectively planar. The maximum deviations from the least squares planes of the six non-hydrogen atoms in each ring are 0.1388(28) and 0.1499(29) Å for the rings in which all three nitrate oxygen atoms are hydrogen bond acceptors and 0.0850(30) and 0.1229(33) Å in the other two respectively.

Product **6** with X = OPr^n was also prepared and, although its structure was not determined, the microanalysis is consistent with it adopting a structure analogous to that of **4**.

The incorporation of anions into these arrays requires that the anion be a sufficiently weak base such that the 'acidic' N(3) proton remains attached to the ligand. If this nitrogen were deprotonated on addition of the anion one

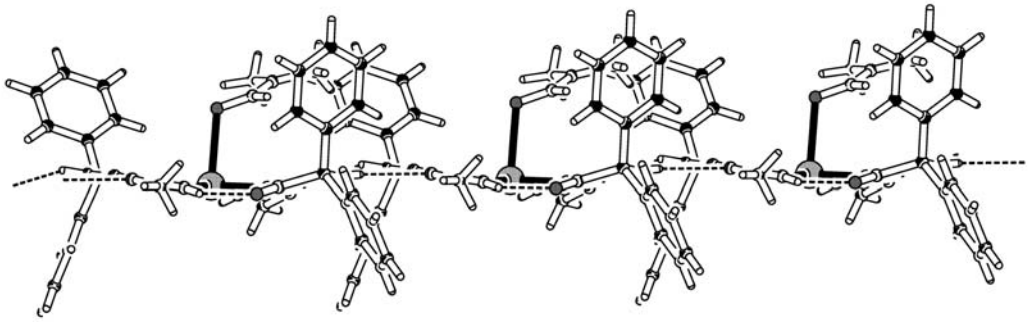

Fig. 7. A PLATON [28] depiction of a side-on view of the hydrogen-bonded chains in **1**. All the apical dmf molecules can be seen to be on the same side of the chain.

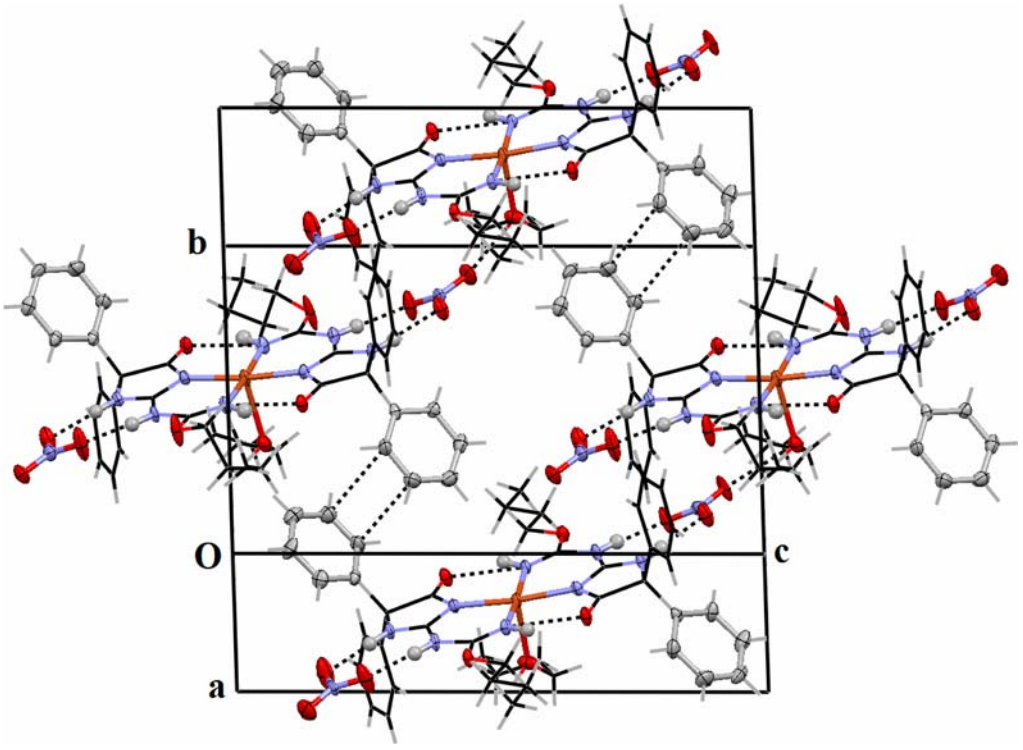

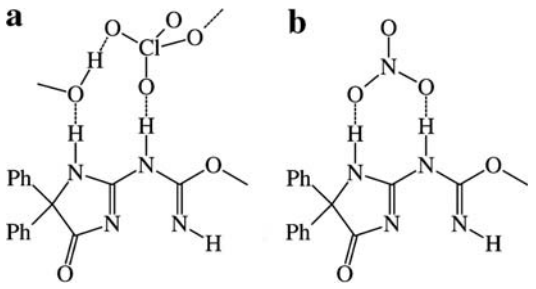

Fig. 8. A Mercury v1.4.1 [29] depiction of hydrogen bonding and phenyl–phenyl interactions in **4**. Hydrogen bonds and offset face-to-face (OFF) interactions are shown with dotted lines; the disorder, present in some of the butyl groups, is not shown. Heteroatoms are shown as thermal ellipsoids at 50% level as are the phenyl rings involved in OFF phenyl–phenyl interactions.

would expect the neutral complex to link into chains through the complementary DA motifs generated.

We have previously described the incorporation of a perchlorate ion into an array based on **I** (X = OMe) [12]. In this product each ligand formed a $R_3^3(10)$ hydrogen bonding pattern which included two of the perchlorate oxygens and the –OH group from a methanol (Scheme 4). This product, when left in the mother liquor, transformed spontaneously into a material consisting of chains of neutral pseudo-macrocyclic complexes linked by hydrogen bonding between the complementary motifs; the crystals of the new phase contained solvent methanol that was neither coordinated nor involved in hydrogen bonding interactions. One of the other two perchlorate oxygens formed a long contact with a copper(II) ion in a neighbouring complex. The nitrate ions in **4** do not interact directly with the copper ions.

Scheme 4. (a) Diagram showing the $R_3^3(10)$ ring formed by a perchlorate ion, methanol molecule and the ligand (X = OMe) in the cationic complex [12]. A perchlorate oxygen atom forms a long (2.816 Å) contact with a copper ion in a neighbouring complex. (b) Diagram of the $R_2^2(8)$ ring formed by a nitrate ion in **4**. There are different types of nitrate in the crystal; in one, the third nitrate oxygen is hydrogen bonded to a propanol molecule in an adjacent complex; in the other, it does not form a hydrogen bond.

3.5. The inclusion of guest molecules

Crystals of **5** were prepared by crystallisation of the corresponding neutral pseudo-macrocyclic complex from 1-propanol. The copper ions in this product are five-coordinate square pyramidal with a propanol molecule occupying the apical site; as shown in Fig. 6b, this coordinated propanol molecule is highly disordered. Cu(1) lies 0.0331(17) Å from the least squares plane of the nitrogen donors. The ligand atoms in the metallarings are effectively planar with the maximum deviations from the least squares planes being respectively 0.0372(29) and 0.0217(25) Å; Cu(1) lies 0.2936(46) and 0.3490(44) Å out of these planes. The planes make an angle of 23.10(9)° with each other.

The bound ligands are linked by hydrogen bonding between the complementary DA pairs on neighbouring complexes via $R_2^2(8)$ hydrogen bonding patterns. The six non-hydrogen atoms in these patterns are approximately coplanar with the maximum deviation from the least squares plane being 0.1668(24) Å. In addition, there are alkyl-to-π-facial contacts between the ligand propyl groups

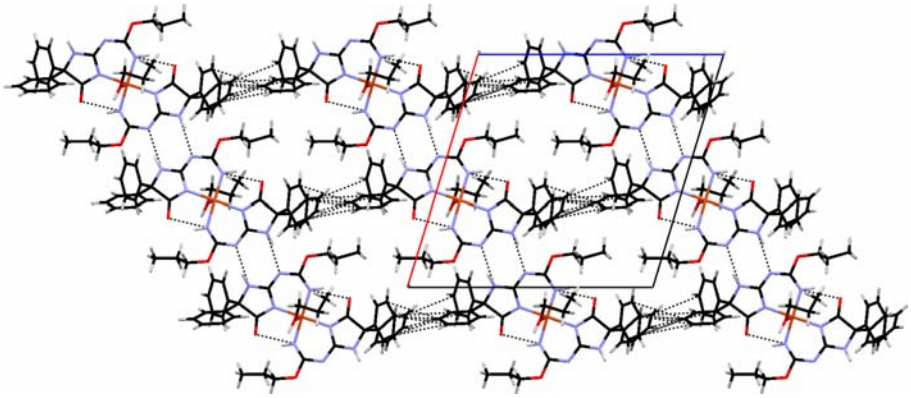

Fig. 9. A Mercury 1.4.1 [29] depiction of a supramolecular sheet of complexes in **5**. The view is along the *b*-axis and the guest molecules are not shown; neither is the disorder associated with the coordinated propanol molecules. Hydrogen bonds and phenyl–phenyl interactions are shown as dotted lines. The horizontal axis is the *c*-axis.

and phenyl rings on the neighbouring hydrogen-bonded complex. Thus chains of complexes are formed that run through the crystal. The position of the apical propanol molecules alternates on opposite sides of the chain. As well as being linked by hydrogen bonds, the pseudo-macrocycles are linked by phenyl embraces (based on edge to face interactions) into chains running parallel to the *c*-axis. As a result, the complexes form sheets that run perpendicular to the *b*-axis. Phenyl edge-to-face interactions occur between complexes in adjacent sheets (Fig. 9).

As shown in Fig. 10, the hydrogen-bonded chains lie directly one above another so that there are channels running through the crystal. Within these channels lie coordinated propanol molecules and non-coordinated guest molecules. The guests sit within centrosymmetric cavities, the walls of which are formed by both complex units and phenyl rings. Coordinated propanol molecules lie at the ends of each cavity. The occupancy of these cavities by propanol guests is 0.25; water molecules are also found in the cavities with this same occupancy. The centre of symmetry means that there are two possible orientations of the guest propanol molecules, the oxygen atoms (O6) of which lie 3.47 Å from Cu(1). The guests are not centrally placed within the cavity, but lie closer to one pair of adjacent faces. A view of the environment of one of the guest propanol molecules is shown in Fig. 11, which also depicts some of the short contacts between a propanol molecule and the walls of the cavity. A side-on view of the cavity is shown in Fig. 12.

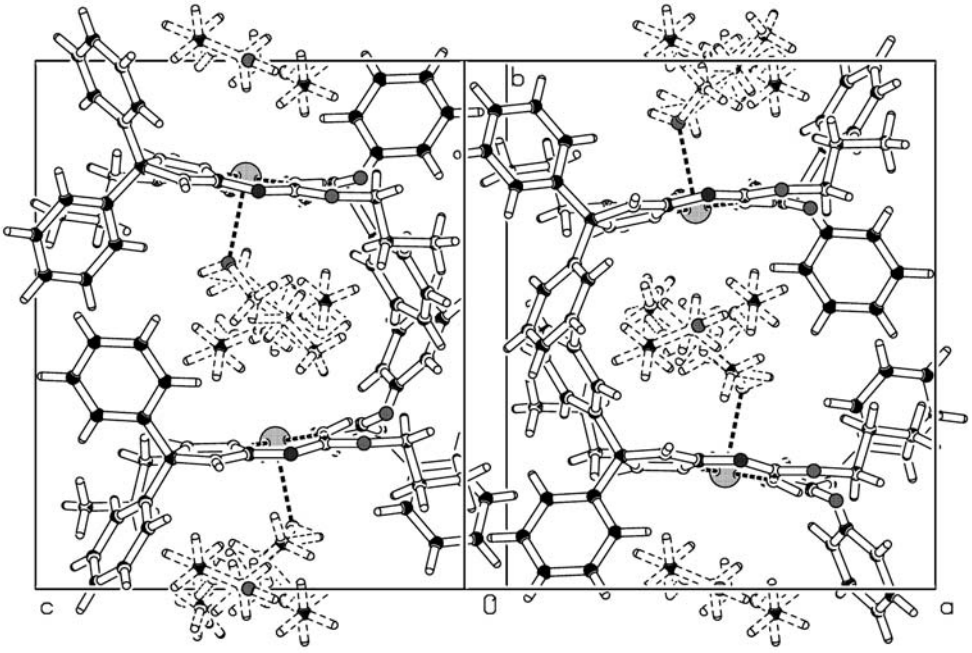

Fig. 10. A PLATON [28] depiction of the unit cell of **5** showing the view down the channels between adjacent supramolecular sheets of complexes.

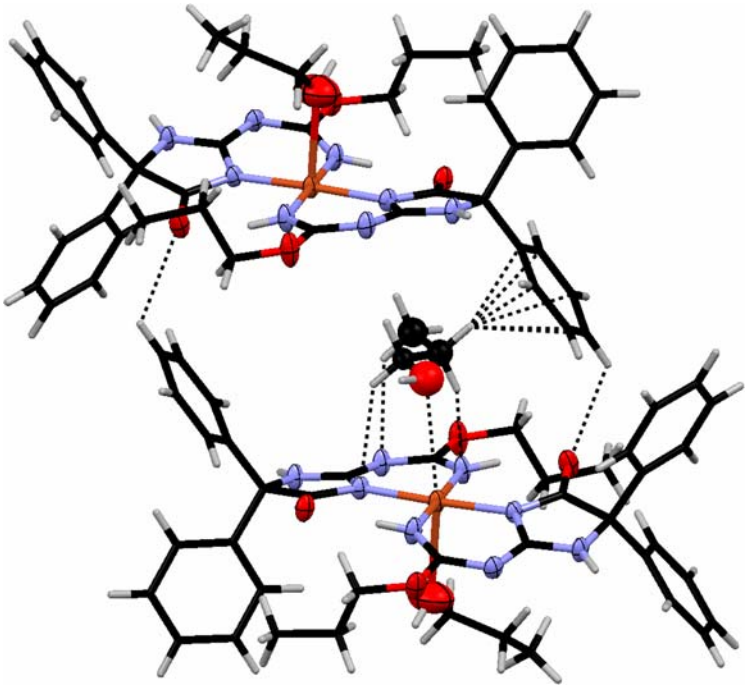

Fig. 11. A view, generated by Mercury v1.4.1 [29], of the environment of a guest propanol in a cavity in product **5**. The heteroatoms are drawn as thermal ellipsoids at the 50% level and no disorder has been shown.

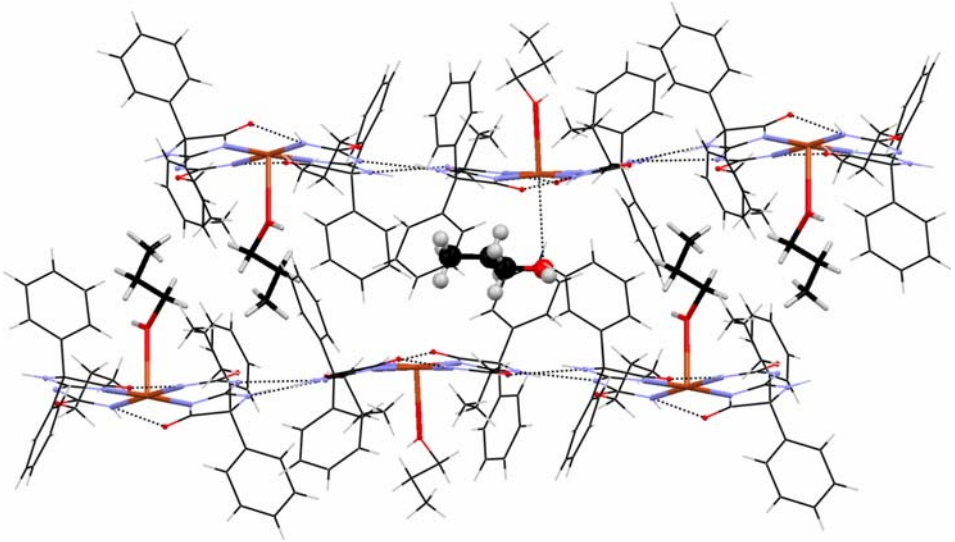

Fig. 12. A view, generated by Mercury v1.4.1 [29], that shows a side on view of a cavity containing a guest propanol molecule (shown in ball and stick mode in one of the two possible orientations) in product **5**. Coordinated propanols are drawn in capped stick mode, other atoms in wireframe. The long interaction between the guest oxygen and a copper is shown with a dotted line. No disorder is shown.

4. Final remarks

In this study we have examined the supramolecular structures of a series of copper complexes of bidentate guanidino derivatives. The anionic forms of the ligands, as present in the neutral complexes, possess a doublet (DA) hydrogen bonding motif, and were shown to form extended supramolecular structures linked by either hydrogen bonding or phenyl embraces (or both). The synthons were also observed to assemble into sheets, in some instances with the inclusion of guest molecules in cavities between the sheets. In the case of the cationic complex, the doublet (DD) hydrogen bonding motif allowed the incorporation of linking hydrogen-bonded nitrate ions in its structure.

5. Supplementary data

CIF files for all structures are deposited with the Cambridge Crystallographic Data Centre, CCDC Nos.

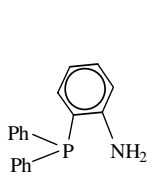
Available online 14 July 2006

Abstract



Thermal reaction of $[H_3Mn_3(CO)_{12}]$ with $Ph_2PC_6H_4NH_2$-2 gives good yields of $[Mn_2(CO)_6(PPh_2C_6H_4NH)_2]$, an X-ray single crystal structure determination of which reveals a P,N-chelating ligand with each of the NH groups, formed by deprotonation of the amine groups, bridging the two metal atoms.

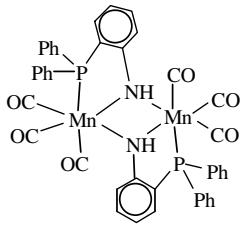
Keywords: Manganese carbonyl; Hemilabile; X-ray crystal structure; 2-Aminophenyldiphenylphosphine



1. Introduction

Many bidentate hemilabile ligands have been explored for their ability to combine a stabilising effect on the metal centre with the possibility of readily generating a vacant coordination site for catalysis [1–5]. The most common ligating atom combinations are P,O or P,N which exploit the mismatch in bonding tendencies between soft P and hard O or N. Recent summaries giving examples are available [6–8].

One readily prepared ligand which has had some application in organometallic chemistry is $Ph_2PC_6H_4NH_2$-2 (**1**), which not only includes a soft-hard P,N combination but also retains potentially reactive N–H bonds [9,10].

1

2

Metal carbonyl complexes derived from **1** have been reported for both mononuclear and cluster compounds [11–18]. However, there are as yet no reports that we are aware of where derivatives of manganese have been prepared with **1**. Our longer term interest stems from the possibility of controlling the reactivity of the Mn–C bond in cyclomanganated compounds with such ancillary ligands [19], but here we describe a novel complex (**2**) from initial explorations of the reactions of **1** with simpler manganese carbonyls.

2. Experimental

2.1. General

Reactions were carried out under a nitrogen atmosphere using Schlenk techniques and solvents that were distilled under nitrogen from appropriate drying agents before use. Electrospray mass spectra were recorded on a VG Platform II spectrometer, operated as detailed elsewhere [20,21]. Assignments were confirmed by simulation of the characteristic isotope patterns using the ISOTOPE program [22]. NMR spectra were obtained on a Bruker AC300 instrument operating under standard conditions. IR spectra were recorded on a Digilab Scimitar instrument.

$Ph_2PC_6H_4NH_2$-2 and $[H_3Mn_3(CO)_{12}]$ were prepared by the literature methods [23,24].

2.2. Preparation of 2

$[H_3Mn_3(CO)_{12}]$ (40 mg, 0.079 mmol) was dissolved in heptane (5 mL) in a Schlenk flask. (2-Aminophenyl)diphenylphosphine (45 mg, 0.16 mmol) was added to the flask and the temperature of the reaction mixture was gradually increased to between 80 and 90 °C over a period of 50 min. During this time a colour change from orange–red to orange–yellow was observed, with a yellow precipitate starting to form at 80 °C. After cooling to room temperature, the solvent was removed in vacuo and the residue was redissolved in a small amount of dichloromethane. A similar volume of diethyl ether was added and the mixture was placed in the freezer. After one week, yellow crystals of **2** were obtained (40 mg, 61%). M.p. 110–116 °C. *Anal.* Calc. for $C_{42}H_{30}N_2O_6P_2Mn_2$ ($M_r = 830$) requires C, 60.74; H, 3.65; N, 3.37. Found: C, 59.99; H, 3.62; N, 3.38%. ν_{CO} (CH_2Cl_2) 2002 (s), 1923(s), 1898(s); ESI-MS, (MeOH, added NaOMe [20,21]), positive ion *m/z* 853 $[M+Na]^+$, 825 $[M+Na-CO]^+$, negative ion *m/z* 801 $[M-H-CO]^-$, 773 $[M-H-2CO]^-$. NMR ($CDCl_3$; 300 MHz): ^1H: δ 7.0–8.5 (m); the NH signal was either too broad to be observed or was amongst the aryl proton signals and could not be assigned. ^{13}C: owing to decomposition over the period of accumulation, the spectrum was poor and singlet signals were not resolved; doublet signals assigned to the ring carbons *ortho* and *para* to the amino group were at 111.0 ($J = 7$ Hz) and 118.9 ppm ($J =$ 11 Hz), the remainder overlapping at 128–135 ppm. ^{31}P: 65.4 ppm.

2.3. X-ray crystallography

X-ray intensity data were collected on a Siemens SMART CCD diffractometer using standard procedures and software. Multiscan absorption corrections were applied (SADABS [25]). Structures were solved by direct methods and developed and refined on F^2 using the SHELX programmes [26] operating under WINGX [27,28]. Hydrogen atoms were included in calculated positions, except for the hydrogen attached to N(1), which was located as the highest peak in a penultimate difference map and was refined with an isotropic temperature factor.

2.3.1. Structure of $[Mn_2(CO)_6(Ph_2PC_6H_4NH)_2] \cdot CH_2Cl_2$ ($2 \cdot CH_2Cl_2$)

Yellow crystals of **2** as the mono-solvate were obtained from CH_2Cl_2.

Crystal data: $C_{42}H_{30}N_2O_6P_2Mn_2 \cdot CH_2Cl_2$, $M = 1000.36$, monoclinic, space group $P2_1/n$, $a = 10.8871(1)$, $b = 14.7066(1)$, $c = 14.1506(2)$ Å, $\beta = 97.744(1)°$, $U =$ 2245.0(1) Å^3, $T = 190$ K, $Z = 2$, $D_{calc} = 1.48$ g cm^{-3}, μ(Mo Kα) = 0.921 mm^{-1}, $F(000)$ 1016; 12 596 reflections collected with $2° < \theta < 26°$, 4520 unique ($R_{int} = 0.0433$) used after correction for absorption ($T_{max,min} = 0.7697$, 0.7329). Crystal dimensions $0.36 \times 0.30 \times 0.30$ mm^3. Refinement on F^2 gave R_1 0.0563 [$I > 2\sigma(I)$] and $wR_2 = 0.1580$ (all data), GoF = 1.027. The structure of **2** is illustrated in Fig. 1, with selected bond parameters summarised in the caption to the figure.

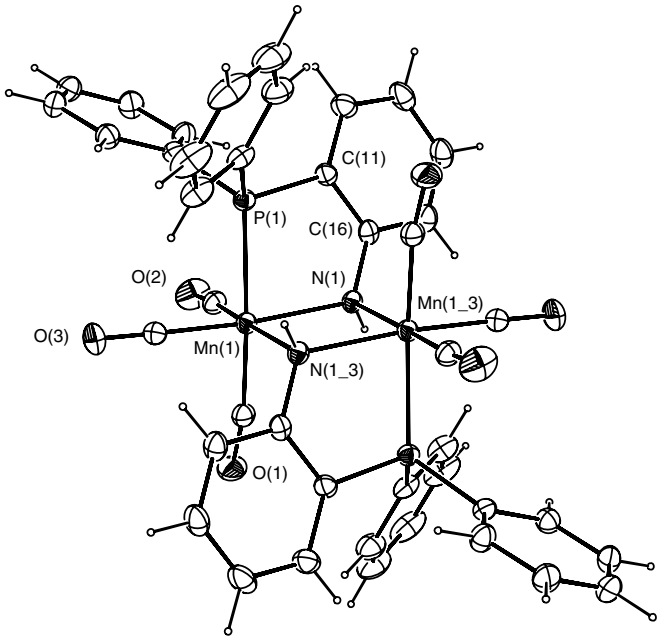

Fig. 1. The structure of the centrosymmetric dimer **2**. Bond parameters include bond lengths (Å): Mn–P 2.317(1), Mn–N(1) 2.084(3), Mn–N(1)′ 2.150(3), Mn...Mn 3.267(1); bond angles (°): Mn–P–C(11) 101.3(2), N(1)–Mn–N(1)′ 79.0(2), Mn–N(1)–Mn′ 100.9(2), Mn–N(1)–C(16) 112.1(2).

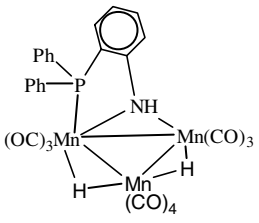
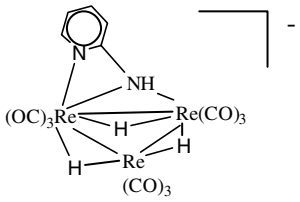
3. Results and discussion



3.1. Synthesis and properties of 2

We were unable to isolate any new compounds from the thermal reaction between the ligand **1** and $Mn_2(CO)_{10}$, decomposition to insoluble brown residues taking place under conditions needed for reaction. However, the trinuclear species $H_3Mn_3(CO)_{12}$ underwent a smooth reaction at 80 °C with **1** to give good yields of a new species as yellow crystals. These were reasonably air-stable as a solid, but solutions tended to decompose giving a green product. ^1H and ^{13}C NMR of **2** gave little useful information, while ^{31}P NMR gave a signal at δ 65.4, well-shifted from that of the free ligand at δ −19.6. This indicated that a five-membered chelate ring had formed [29], though the shift of 75 ppm is unusually large [30]. The ESI mass spectrum suggested a mass of 830 from an $[M+Na]^+$ ion at *m/z* 853, corresponding to an empirical formula of $[Mn_2(CO)_6(Ph_2PC_6H_4NH)_2]$. To characterise the complex a single crystal X-ray determination was carried out. The structure is shown in Fig. 1. This shows a centrosymmetric molecule consisting of two $Mn(CO)_3$ units each coordinated to a phosphorus atom of a mono-deprotonated form of the



ligand **1**. The two halves of the molecule are linked only by the N atoms from the two ligands; the Mn...Mn distance of 3.267 Å precludes any direct metal–metalbond. The central Mn_2N_2 core of the molecule has strict planarity imposed by the space group symmetry, while the five-membered metallocyclic ring formed by Mn(1)P(1)C(11)-C(16)N(1) has a slightly folded envelope conformation, with deviations up to 0.18 Å from the least-squares plane. The Mn–N bonds differ slightly with Mn(1)–N(1) and Mn(1)–N(1)′ being 2.084(3) and 2.150(3) Å, respectively.

Deprotonation of the ligand **1** to provide a bridging amido group has been observed before, notably in reactions with $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{12}]$ [16–18]. However in these cases the clusters remain intact and the amido group bridges a formal M–M bond. A doubly bridged Rh–Rh bond is also retained in the complex $[Rh_2Cl_2(CO)_2(Ph_2PC_6H_4NH)_2]$ [31]. Structural characterisation of two metal carbonyl centres linked only by two amido groups appears to be unique to compound **2**, though a related rhenium example derived from 2-aminopyridine has been spectroscopically established [32].

The route to **2** presumably involves initial replacement of a CO ligand on $[H_3Mn_3(CO)_{12}]$ by the P atom of **1**. Oxidative addition of an N–H bond of the $-NH_2$ group across a metal-metal bond, followed by elimination of H_2 would give a species **3**, which would be related to the known rhenium anion **4** [32].

3

4

Repeating the process with a second ligand molecule apparently leads to fragmentation of the cluster and formation of **2**.

Other species can be detected in the reaction mixture, for example ESI-MS of the reaction mixture shows additional peaks to those associated with **2** at *m*/*z* 665 corresponding to the formula $[Mn(CO)_2(Ph_2PC_6H_4NH_2)_2]^+$, undoubtedly containing two intact bidentate ligand molecules, but we have as yet been unable to isolate this in a pure form for characterisation. This cation would be isoelectronic with the structurally characterised $[W(CO)(NO)(Ph_2PC_6H_4NH_2)_2]^+$ [33].

Abstract

Reactions of cycloaurated gold(III) dichloride complexes, with 1,2-$C_6H_4(NHCOMe)_2$ and silver(I) oxide, or with $C_2H_4(NHSO_2Tol)_2$ (Tol = *p*-tolyl) or 1,2-$C_6H_4(NHSO_2Tol)_2$ and trimethylamine, give a series of new auracyclic complexes containing the Au–NR–CH_2CH_2–NR (R = SO_2Tol) and Au–NR–C_6H_4–NR (R = COMe or SO_2Tol) five-membered ring systems. An X-ray structure determination on (2-bp)Au{N(COMe)C_6H_4N(COMe)} (2-bp = cycloaurated 2-benzylpyridine) shows the presence of puckered metallacyclic rings, with both acetyl substituents positioned below the Au(III) coordination plane. The complex (2-bp)Au{N(COMe)C_6H_4N(COMe)} undergoes ring cleavage in the presence of halide and water, to give the complex (2-bp)Au{N(COMe)C_6H_4NH(COMe)}Cl, which was characterised crystallographically, and shown to contain a monodentate amidate ligand. Biological activity studies of the new auracyclic complexes are also reported, against P388 murine leukaemia cells and a range of bacteria and fungi, with a number of complexes showing high activity.

1. Introduction

The chemistry of cyclometallated gold(III) complexes has been attracting recent interest [1], in part due to the isoelectronic nature of this metal centre with platinum(II), and the thoroughly established anticancer activity of the latter [2–7]. Since gold(III) is considerably more labile than platinum(II) [8,9], we have been investigating the synthesis and biological activity of cycloaurated complexes that also contain a chelating ligand, and have found that certain systems, notably thiosalicylate **1** [10,11] and catecholate **2** [12] derivatives show promising anticancer activity. To date, little is known about the chemistry of cycloaurated complexes that also contain ancillary amidate ligands, with the only Au(III) cyclometallated species containing a chelating bis(amidate) ligand being the ureylene complexes **3**, and an insertion product thereof with PhNCO [13]. In this contribution we report the synthesis and characterisation of some auracyclic derivatives containing the phenylenediamide and ethylenediamide moieties, with the nitrogen atoms bearing electron-withdrawing COMe or SO_2Tol (Tol = *p*-tolyl) groups. Although they are formally similar to the catecholate complexes **2**, the presence of a (variable) group on the amide nitrogen introduces the possibility of tuning the physical (e.g. solubility) and chemical properties of the ligands. Isoelectronic platinum(II) complexes containing such ligands have been well described, and many have been tested for anticancer activity [14,15]. Complexes containing chelating sulfonamide ligands have attracted much interest; there is a vast literature on the application of chiral metal–sulfonamide complexes as catalysts for organic transformations such as asymmetric hydrogenation (Ru) [16], amination [17] and alkylation [18] (Ti), Diels–Alder [19] and [2+2] cycloaddition [20] (Al), Claisen rearrangements (B) [21], and the synthesis of aryl glycines (Mg) [22]. Tungsten Schrock-type complexes, containing

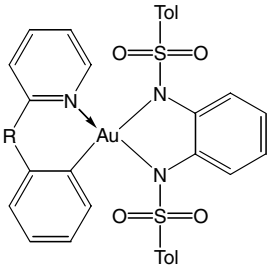
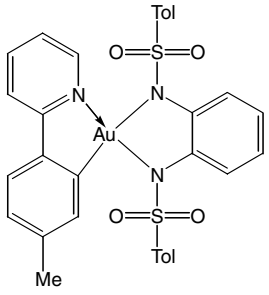
a W–N sulfonamide bond to increase the stability of the complex, have been developed to cleave hydrazine to ammonia [23]. Bis(sulfonamides) have also been explored as ligands for the extraction of lead(II) from aqueous to organic solutions via synergistic ion-exchange mechanisms with 2,2′-bipyridine, giving species such as **4** [24]; incorporation of the dansyl group gives derivatives that allow sensing of lead ions by fluorescence quenching [25].

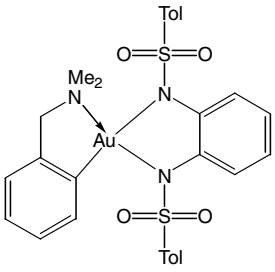


2. Results and discussion

2.1. Synthesis and characterisation of auracyclic amidate complexes



The reaction of the cycloaurated gold(III) dihalide starting materials (2-bp)$AuCl_2$ (**5**), (2-anp)$AuCl_2$ (**6**), (tolpy)-$AuCl_2$ (**7**) and (damp)$AuCl_2$ (**8**) with 1,2-diacetamidobenzene



(**9**) and silver(I) oxide in refluxing dichloromethane gave the auracyclic products **10**–**13**, in moderate yields as pale yellow to yellow solids. The reaction time of 24 h was notably longer than the 2 h previously required for similar gold(III) ureylene systems [13] synthesised by the same method. When the same gold(III) dihalide starting materials, together with the cycloaurated picolinamide complex **14** was reacted with the sulfonamide ligand **15** or **16** in refluxing methanol with excess trimethylamine, the auracyclic complexes **17**–**25** were readily isolated in good yields, by precipitation with water. This suggests that the more strongly electron-withdrawing sulfonamide group facilitates proton removal from the amide nitrogen, and stabilises the Au–N bond. Reaction times were considerably less than those required for analogous platinum compounds [15]. The attempted synthesis of diacetamidobenzene complexes using trimethylamine in refluxing methanol was unsuccessful.

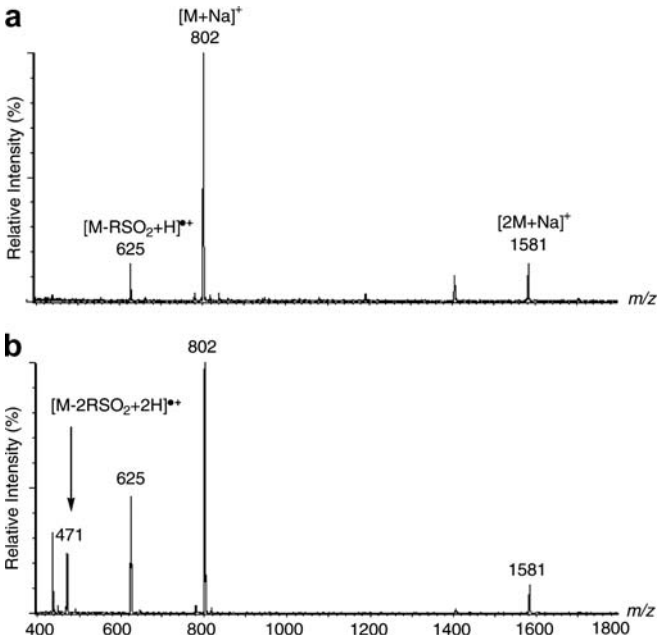
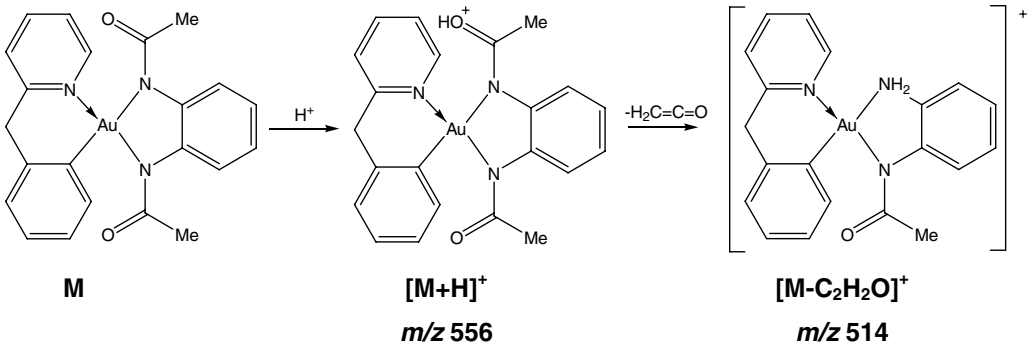
^{1}H, ^{13}C and DEPT135 NMR spectra were acquired for all compounds with the exception of the anilinopyridine complexes **11**, **18** and **23** which were too insoluble in common deuterated solvents [$CDCl_3$, D_2O and $(CD_3)_2SO$] to acquire satisfactory spectra. The low solubility of complexes containing this ligand has been noted previously [1,12]. Due to the complex overlapping of signals in the aromatic regions of the ^{1}H spectra, full NMR assignments were not made, however, integration of the aromatic region was used to ascertain that the expected number of signals were present, and hence as an indication of sample purity. Compounds **10**, **17** and **22** containing the benzylpyridyl ligand displayed the characteristic AB doublet of doublets due to the two methylene protons having different chemical environments in a puckered six-membered ring; Fuchita et al. have previously discussed the ring inversion process in the Au–benzylpyridyl system [26]. The pattern indicates that there is no inversion (at 30 °C, on the NMR timescale) between the two boat conformations. The compounds containing the damp ligand (**13**, **20** and **25**) contained two singlets corresponding to the *N*-methyl and -methylene protons. This was as expected, as all three compounds contain a plane of symmetry through the Au co-ordination plane.

The 1,2-diacetamidobenzene derivatives **10**–**13** showed strong stretches in the C=O region (1603–1630 cm^{-1}), at a lower wavenumber than the ν(C=O) in the free ligand **9** (1668 cm^{-1}). The sulfonamide derivatives **17**–**25** showed the expected strong peaks in the S=O stretching regions of the spectra, i.e. ~1160 cm^{-1} (symmetric) and ~1350 cm^{-1} (asymmetric) [27]. Upon co-ordination of the sulfonamide ligands to the gold(III) centre, the band due to NH stretching (3222 cm^{-1} and 3289 cm^{-1} for the free phenylenediamide and ethylenediamide ligands **15** and **16**, respectively) was lost, confirming that the ligands bind in the deprotonated form.

The auracyclic complexes have also been characterised by electrospray ionisation mass spectrometry (ESI-MS). At low cone voltages (20 V) complexes **10**–**13** all showed strong ions due to either $[M+H]^+$ or $[M+Na]^+$ (from adventitious Na^+ ions) with much less intense $[2M+H]^+$ and $[2M+Na]^+$ species. Increasing the cone voltage (40–60 V) produced fragmentation and the loss of $COCH_2$, possibly as ketene (Scheme 1, shown for (2-bp)Au{N(COMe)C_6H_4N(COMe)} (**10**)) as observed with the free ligand [28]. The ESI-MS behaviour of these complexes in the presence of added alkali metal halides is described later.

At low cone voltages (20 V) the sulfonamide complexes **17**–**25** showed ions assigned as $[M+Me_3NH]^+$ (presumably from the Me_3N used in synthesis, although not present in ^{1}H NMR) along with less intense $[M+Na]^+$ and $[M+H]^+$ adducts. Addition of NaCl as an ionisation aid produced much cleaner spectra, dominated by $[M+Na]^+$ ions. Aggregate ions $[2M+Na]^+$ and $[3M+Na]^+$ were also present at lower intensities. At higher cone voltages the Me_3NH^+ adduct disappeared and fragmentation of the parent ion by successive loss of *p*-toluenesulfonyl moieties was observed, as shown for complex **17** in Fig. 1. Oxidation produced radical cations, as proposed in Scheme 2. Confirmation of these ions was achieved using a Bruker Daltonics MicrOTOF high-resolution mass spectrometer; data are summarised in Table 1, and show excellent agreement between observed





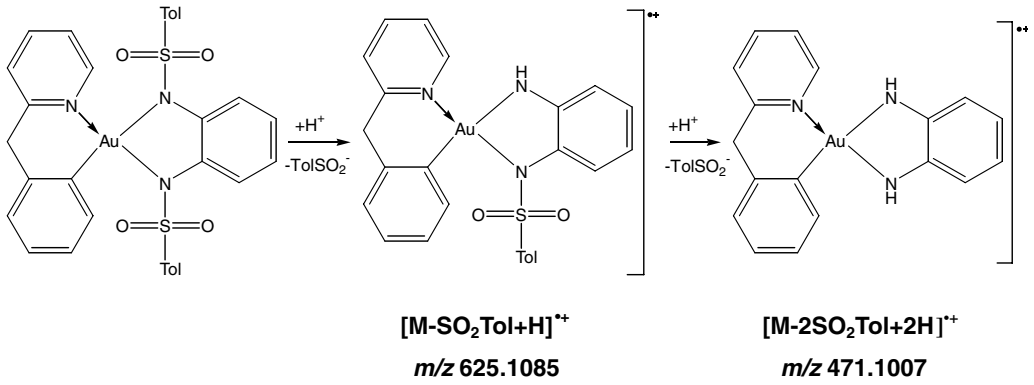


Fig. 1. ESI-MS Spectra of (2-bp)Au{N(SO_2Tol)C_6H_4N(SO_2Tol)} (**17**) (=M) in MeOH, recorded at cone voltages of: (a) 20 V; (b) 80 V, showing successive losses of *p*-toluenesulfonyl moieties, and the formation of radical cation fragment ions.

$[M-2SO_2Tol+2H]^{\bullet+}$	$C_{18}H_{16}N_3Au$	471.1007	471.1004	0.01

[a] Obtained using a Bruker Daltonics MicrOTOF mass spectrometer.
[b] A combined value for the standard deviation of masses and the intensities of all peaks in the isotopic envelope, compared to the calculated values.

and calculated accurate masses for the major observed ions. To determine if the added hydrogen originates from the solvent, spectra were obtained in CD_3OD solution; the ions at *m/z* 625 and 471 produced isotope patterns containing peaks respectively 1 or 2 mass units heavier which were tentatively assigned as the deuterium adducts (hence protonation from the solvent). However, due to the overlapping nature of the isotope patterns (from species containing hydrogen or deuterium) precise assignment was difficult.

It is well established that the metal electrospray capillary can act as an electrochemical cell allowing neutral molecules to be oxidised (when in positive ion mode); oxidation of the analyte is promoted by a low mobile phase flow rate, which increases the time the compound has to diffuse to the surface of the capillary [29,30]. Decreasing the rate of injection of **17** into the mass spectrometer, in the absence of added NaCl ionisation aid, resulted in the appearance of a small peak at *m/z* 779 (corresponding to the radical cation $[M]^{\bullet+}$ [M = (2-bp)Au{N(SO_2Tol)C_6H_4N(SO_2Tol)} (**17**)]), in addition to the $[M+H]^+$ ion at *m/z* 780, indicating that the parent metallacycle could also be oxidised. The same effect has been seen previously with analogous Pt(II) compounds [15] and oxidation of coordinated phenylenediamine ligands is well documented [31,32]. As expected, this was not seen for the gold–sulfonamide derivatives containing the ethylene backbone.

2.2. X-ray crystal structure determination of (2-bp)Au{N(COMe)C_6H_4N(COMe)} (**10**)

The crystal structure of **10** was determined in order to verify that the complex was the predicted auracycle. This was confirmed with the 1,2-diacetamidobenzene ligand coordinated to the gold through the amidate nitrogen donors. Views of the structure are shown in Figs. 2 and 3 along with the atom numbering scheme; selected bond lengths and bond angles are given in Table 2. The geometry around the gold atom is approximately square planar, with slight deviations; no atom deviates from the least-squares plane defined by N(1), N(2), Au(1), N(3) and C(31) by more than 0.0612(12) Å. Due to C(31) having a higher *trans*-influence than N(3) [33], the Au(1)–N(2) bond

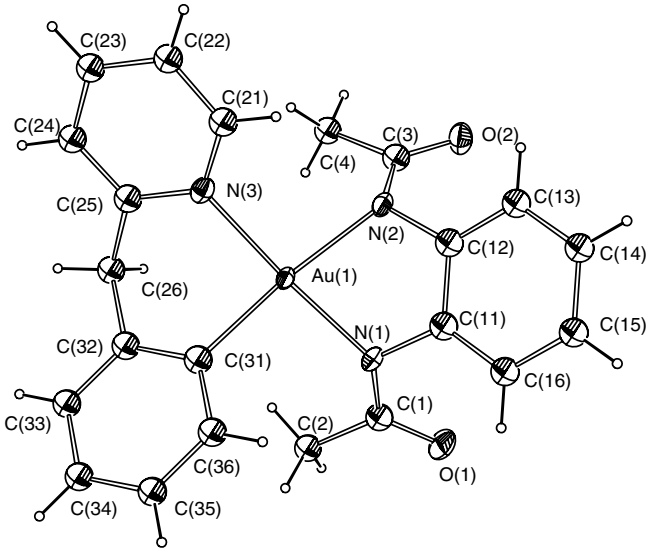

Fig. 2. Perspective view of the X-ray crystal structure of the complex (2-bp)Au{N(COMe)C_6H_4N(COMe)} (**10**), showing the atom labelling scheme. Thermal ellipsoids are shown at the 50% probability level.

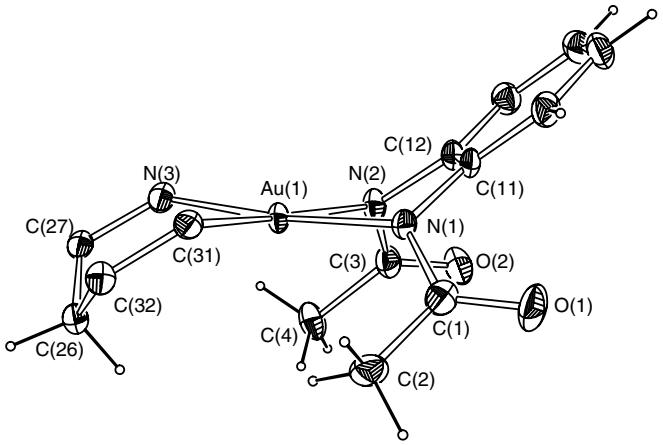

Fig. 3. Side view of the X-ray crystal structure of the complex (2-bp)Au{N(COMe)C_6H_4N(COMe)} (**10**), showing the non-planarity of 1,2-diacetamidobenzene nitrogen atoms and the orientation relative to the benzylpyridine ring system. Thermal ellipsoids are shown at the 50% probability level and atoms completing the benzyl and pyridyl rings have been omitted for clarity.

Table 2
Selected bond lengths (Å) and bond angles (°) (estimated standard deviations in parentheses) for (2-bp)Au{N(COMe)C_6H_4N(COMe)} (**10**)

Bond	Length (Å)	Bond	Angle (°)
Au(1)–N(1)	2.022(3)	N(1)–Au(1)–C(31)	94.76(12)
Au(1)–N(2)	2.089(3)	N(3)–Au(1)–N(2)	97.23(11)
Au(1)–N(3)	2.058(3)	C(31)–Au(1)–N(3)	88.11(12)
Au(1)–C(31)	2.031(3)	N(1)–Au(1)–N(2)	79.61(11)
1,2-Diacetamidobenzene ligand			
N(1)–C(1)	1.366(4)	C(1)–N(1)–C(11)	118.6(3)
N(1)–C(11)	1.435(4)	C(1)–N(1)–Au(1)	129.8(2)
N(2)–C(12)	1.433(4)	C(11)–N(1)–Au(1)	107.3(2)
N(2)–C(3)	1.356(5)	C(3)–N(2)–C(12)	118.0(3)
		C(3)–N(2)–Au(1)	129.1(2)
		C(12)–N(2)–Au(1)	105.9(2)

[2.089(3) Å] *trans* to C(31) is significantly longer than the Au(1)–N(1) bond [2.022(3) Å] *trans* to N(3). The benzylpyridyl moiety has a puckered boat configuration (Fig. 3), as seen with similar gold systems. Both acetyl moieties of the metallacycle are positioned below the Au(III) coordination plane (Fig. 3), in contrast to the uncoordinated ligand where the two acetyl groups are orientated in opposite directions [34]. Due to the puckering of the metallacycle, the aromatic ring of the amidate ligand [C(11)–C(16)] is orientated *trans* to the benzylpyridyl system, possibly to reduce steric interactions between acetyl groups of the acetamidobenzene ligand and the *ortho* ring protons of the benzylpyridyl ligand. The bite angle of the benzylpyridine ligand is 88.11(12)°. This is greater than that observed in compound **26** [35] (85.8°) which has two monodentate chloride ligands attached, but smaller than when a similar *O*,*N*-donor bidentate ligand is coordinated in **27** [89.7(3)°] [12]. The bite angle of the 1,2-diacetamidobenzene ligand is 79.61(11)°, which is less than the idealised 90° of a square-planar complex. This is a general feature of metallacyclic complexes.

The sums of the bond angles around the amidate nitrogens N(1) and N(2) are 355.7° and 353.0°, respectively, indicating a slight deviation from the planarity expected for formally sp^2 hybridised nitrogen atoms. Fully planar sp^2 nitrogen atoms would result in the auracyclic ring [defined by Au(1)–N(1)–C(11)–C(12)–N(2)] being planar, hence the distortion of the amidate nitrogen towards a tetrahedral geometry is most probably to reduce steric interactions. Non-planarity of formally sp^2 nitrogens was first reported in the Re–amide system CpRe(NO)(PPh_3)(NHPh) [36] and has since been observed in similar Pt(II) [15] and Zn [37] sulfonamide compounds along with Pd(II) *N*-sulfonylamino acid complexes [38]. X-ray crystal structures of bis-coordinated sulfonamide complexes of Ru(IV) [39], Os(VI) [40], Cu(II) [32,41,42], Ni(II), Zn(II) and Cd(II) [42] have been reported, however, no comments were offered on the geometry of the coordinating amide nitrogen. Investigation into the geometry around the nitrogen atoms in these structures was conducted using MERCURY [43] and defined as being in a planar environment.

2.3. Synthesis and characterisation of the monodentate amidate complex *28*

Addition of 1 molar equivalent of NaCl to a $CDCl_3$ solution of the auracyclic complex **10** (with monitoring by NMR spectroscopy) resulted in no reaction, but with subsequent addition of 1 molar equivalent of benzoic acid, reaction took place readily giving a new set of signals, subsequently identified as the monodentate complex **28**. Furthermore, this species was also observed in ESI mass spectra of **10**, in the presence of alkali metal halides, added as an ionisation aid. Here, it is significant to note that the electrospray process is known to result in a pH decrease [44,45], so the ESI-MS observations of ring cleavage do parallel those from NMR. Thus, in addition to the expected $[\mathbf{10}+\text{cation}]^+$ and $[2(\mathbf{10})+\text{cation}]^+$ ions (cation = Na or K), an additional ion 36 mass units higher was observed, which by analysis of the isotope pattern, was shown to contain a chloride ion. Fig. 4 shows the spectrum observed for complex **10** upon addition of NaCl. Interestingly, this effect was seen for all the acetamidobenzene metallacycles with the exception of **11**. Addition of small amounts of either Me_4NCl or Me_4NBr to the metallacycle **10** also resulted in cleavage of one Au–amidate bond in the ESI mass spectra.

When (2-bp)$AuCl_2$ (**5**) was reacted with **9** and Ag_2O using a shorter reaction time (2 h) than for the synthesis of the metallacycle **10**, a mixture of the monodentate amidate complex **28** with some metallacyclic complex was obtained. Unambiguous characterisation of **28** was achieved by carrying out a single-crystal X-ray structure determination. The structure of complex **28** is shown in Figs. 5 and 6, along with the atom numbering scheme; selected bond lengths and bond angles are given in Table 3. The structure confirms monodentate coordination of the 1,2-diacetamidobenzene ligand to the Au(III) centre

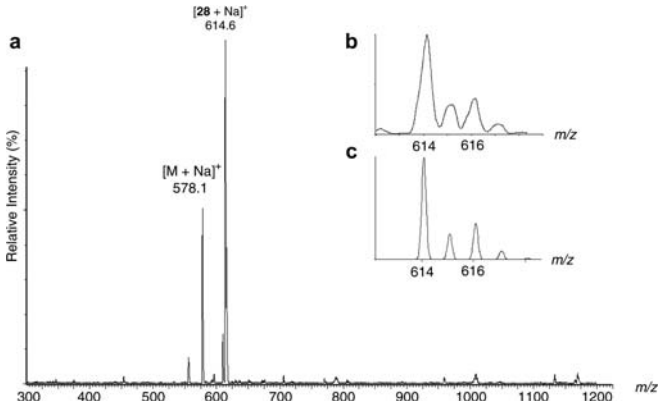

Fig. 4. (a) Positive-ion ESMS spectrum of (2-bp)Au{N(COMe)C_6H_4N-(COMe)} (**10**) (=M) in MeOH, recorded at a cone voltage of 20 V with aqueous NaCl added; (b) and (c) experimental and calculated isotope patterns of *m*/*z* 614 ion, [**28**+Na]$^+$.

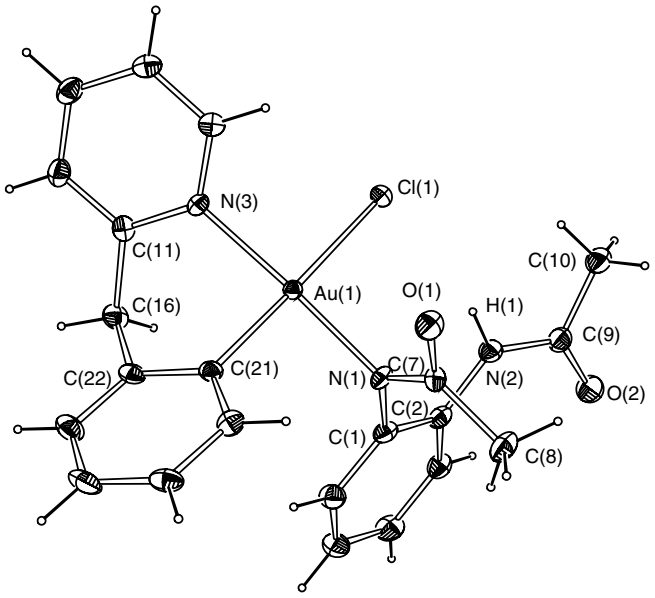

Fig. 5. Perspective view of the X-ray crystal structure of the complex (2-bp)Au{N(COMe)C_6H_4NH(COMe)}Cl (**28**), showing the atom labelling scheme. Thermal ellipsoids are shown at the 50% probability level.

through an Au–N bond. The geometry around the gold atom is essentially square-planar and the sum of the angles around the gold is 359.95°. No atom deviates from the least-squares plane that is defined by N(1), C(21), N(3), Cl(1) and Au(1) by more than 0.0229(7) Å. H(1) is in a position to form a hydrogen bond with Cl(1) (Fig. 6). The H···Cl and N···Cl distances are 2.48(4) Å and 3.302(2) Å, respectively, and the N···H···Cl angle is 153(3)°. These parameters are comparable to those which have recently been characterised as strong hydrogen bonds in organic compounds [46]. The benzylpyridyl moiety is in the expected puckered boat conformation. The bite angle of the benzylpyridine ligand is 87.41(9)° which is not significantly less than in the metallacyclic species **10**. The plane of the 1,2-diacetamidobenzene ligand [defined by C(1)–

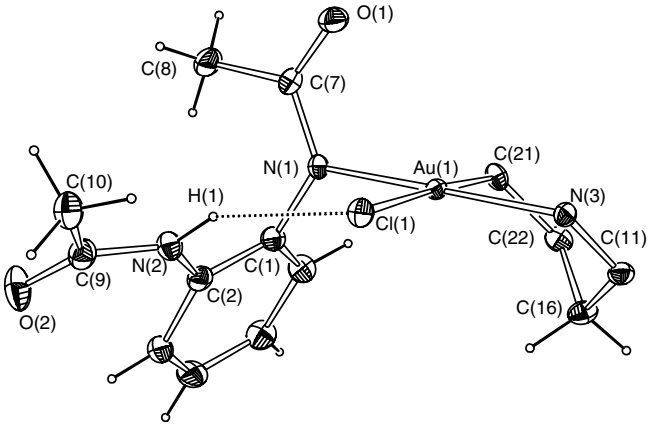

Fig. 6. Side view of the X-ray crystal structure of the complex (2-bp)Au{N(COMe)C_6H_4NH(COMe)}Cl (**28**), showing the puckering of the benzylpyridine ligand, orientation of the 1,2-diacetamidobenzene ligand and the hydrogen bond between H(1) and Cl(1). Thermal ellipsoids are shown at the 50% probability level and atoms completing the benzyl and pyridyl rings have been omitted for clarity.

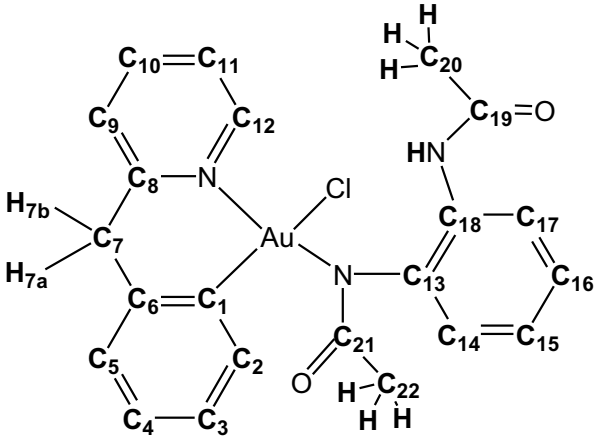
Table 3
Selected bond lengths (Å) and bond angles (°) (estimated standard deviations in parentheses) for (2-bp)Au{N(COMe)C_6H_4NH(COMe)}Cl (**28**)

Bond	Length (Å)	Bond	Angle (°)
Au(1)–N(3)	2.053(2)	N(1)–Au(1)–C(21)	89.95(9)
Au(1)–C(21)	2.013(3)	C(21)–Au(1)–N(3)	87.41(9)
Au(1)–N(1)	2.014(2)	Cl(1)–Au(1)–N(3)	90.87(6)
Au(1)–Cl(1)	2.3941(6)	N(1)–Au(1)–Cl(1)	91.73(7)
1,2-Diacetamidobenzene ligand			
N(1)–C(1)	1.434(3)	Au(1)–N(1)–C(1)	119.6(2)
N(1)–C(7)	1.353(3)	C(1)–N(1)–C(7)	124.8(2)
N(2)–C(2)	1.410(3)	C(7)–N(1)–Au(1)	115.6(2)
N(2)–C(9)	1.366(4)		

C(6)] is perpendicular to the plane of the gold atom and the two acetyl groups point in opposite directions which differs from that in **10** but not in the free ligand [34].

The geometry around the coordinated nitrogen N(1) is essentially planar, with the sum of the angles adding to 360.03°. This differs from the metallacyclic species where both of the amidate nitrogen atoms show significant deviations from planarity, suggesting that the formation of a five-membered ring forces the nitrogen atoms towards a tetrahedral geometry in an effort to reduce strain on the ring. Digression towards a tetrahedral structure has been reported in Pd(II) complexes where decreasing the ring size from six atoms in **29** to five in **30** resulted in the sum of the bond angles around the sulfonamide nitrogen decreasing from 352.7(8)° to 332.2(3)° [38]. The Au(1)–N(1) bond of 2.014(2) Å in **28** is shorter than the Au(1)–N(2) (2.089 Å) and Au(1)–N(1) (2.022 Å) bonds in the metallacyclic complex **10**. The chlorine atom is in a position *trans* to C(21); this is presumably due to C having a higher *trans* effect than N, making the rate of ligand substitution *trans* to the C higher. The two low *trans* influence ligand atoms, Cl(1) and N(3), are also mutually *cis* due to antisymbiosis

[47]. This effect has been seen in many gold(III) cyclometallated compounds [1] including thiosalicylate [10,11], auralactam [48], and amidophenolate [12] systems, as well as in the interesting structurally characterised thiocyanate complex [LAu(NCS)(SCN)] (L = cycloaurated 2-phenylpyridyl), where the thiocyanate ligand *cis* to the aryl carbon is *S*-bonded, but the other thiocyanate is *N*-bonded [49].



^{1}H NMR of the impure product containing **10** and **28** clearly indicated the presence of two sets of CH_2 AB resonances in the region δ 3.7–4.7 and all other signals showing a less intense partner. Peaks arising from **28** were more poorly resolved, which may be indicative of the auracyclic species **10** being more rigid. The ^{1}H NMR spectrum of **28** was fully assigned using a combination of ^{1}H, ^{13}C, DEPT135, ^{1}H–^{1}H COSY, HSQC, HMBC and 2D-NOESY experiments; data and the NMR atom numbering scheme are summarised in Table 4. A singlet peak at δ 9.43 in the ^{1}H spectrum was assigned to the amide NH proton, which shows no correlation to any other proton or carbon signals in the COSY or HSQC spectra, respectively. It did, however, show a weak correlation in the HMBC spectrum to a carbon in the phenylenediamido aromatic ring.

The ^{1}H–^{1}H COSY spectrum of **28** showed three distinct aromatic ring systems with most protons showing ^3J and ^4J coupling. In conjunction with HSQC and HMBC experiments, the chemical shifts of the ring protons and carbons could be assigned. The 2D-NOESY experiment was used to differentiate between the two acetyl moieties. The methyl protons at δ 2.30 produced a correlation to the amide proton whereas those at δ 1.88 showed correlations to the amide proton and protons in both the phenylenediamine and benzyl rings. The uncoordinated $NHC(O)CH_3$ group is located too far from the phenyl ring of the benzylpyridyl ligand to show an NOE correlation, but the coordinated $NC(O)CH_3$ group, in closer proximity, does show a correlation, placing the coordinated amidate ligand *cis* to the cycloaurated phenyl ring. As expected, the proton at δ 7.60 (H9, Table 4) showed a strong NOE to the proton at δ 7.96 (H10), its neighbour in the pyridyl ring. Inspection of the crystal structure revealed that H9 is closer to the methylene proton in the *pseudo*-equatorial position than in the *pseudo*-axial position. The larger NOE to the proton at δ 3.87 suggests it is the *pseudo*-equatorial proton, leaving the proton at δ 4.26 in the *pseudo*-axial position, assuming that the structure in solution is the same as in the crystalline state. This is to be expected, as the *pseudo*-axial proton is in closer proximity to the gold atom and thus more deshielded.

Two independent samples of **28**, recrystallised from dichloromethane and diethyl ether and dried under vacuum prior to analysis, produced microanalytical data with

carbon, nitrogen and hydrogen compositions lower than expected. The difference in composition does not appear to be due to organic solvents as the ^{1}H NMR spectra lack signals due to dichloromethane or diethyl ether.

2.4. Biological activity

The anti-tumour activity of all compounds was determined against a P388 leukemia cell line, and results are reported in Table 5. The results show no clearly discernible pattern in anti-tumour activity. However, as a group the *N*,*N*′-bis(*p*-toluenesulfonyl)ethylenediamide derivatives appear to have a higher activity, possibly due to greater solubility. IC_{50} values were very comparable to those of catecholate, ureylene and thiosalicylate Au(III) metallacycles. With the exception of complexes **13**, **18** and **19**, all of the gold(III) amidate complexes demonstrated anti-tumour activity that was higher than cisplatin, under the screening conditions. The anti-microbial activities of the damp derivatives, and a selection of other complexes which showed good anti-tumour activity (defined by $IC_{50} < 500$ ng mL^{-1}) was also determined, and are listed in Table 6. The acetamido derivatives **12** and **13** show a broad spectrum activity which appears higher than other derivatives. It is also apparent that a higher anti-cancer activity gives lower anti-microbial activity although the reasons are unclear. Again, anti-microbial activity is probably due to the gold metallacycle as the 1,2-diacetamidobenzene (**9**) ligand itself shows no anti-microbial activity.

3. Conclusions

A series of new gold(III) metallacyclic complexes containing Au–N–C–C–N rings has been synthesised and characterised by NMR, ESI-MS, IR and micro-elemental analysis. Auracycles containing the acetamidobenzene ligand undergo protonolysis to give the monodentate amidate complex; in the case involving the benzylpyridyl ligand this was also synthesised as an intermediate in the Ag_2O-mediated reaction, and characterised by X-ray crystallography. All new auracyclic compounds were assayed in order to assess their anti-tumour activity. Seven of the complexes had an activity higher than cisplatin in the P388 assay, with the more soluble ethylenediamide derivatives showing the best activity. Three of the compounds also show good broad-spectrum anti-microbial activity.

4. Experimental

4.1. General

All reactions were carried out with no efforts at excluding air or light. Solvents were LR grade with the exception of dichloromethane (which was distilled from P_4O_{10}) when used in the workup. The sulfonamides [15] and silver(I) oxide [50] were prepared by the literature methods, the former from *p*-toluenesulfonyl chloride and *o*-phenylenediamine, or ethylenediamine (BDH) as appropriate. 1,2-Diacetamidobenzene was prepared by acetylation of 1,2-diaminobenzene (*o*-phenylenediamine, BDH) using acetic anhydride. Trimethylamine (Eastman, 25% aqueous solution) was used as supplied. The cycloaurated gold(III) complexes (2-bp)$AuCl_2$ (**5**) [35], (2-anp)$AuCl_2$ (**6**) [51], (tolpy)$AuCl_2$ (**7**) [10], (damp)$AuCl_2$ (**8**) [52,53], and (pic)$AuCl_2$ (**14**) [54] were prepared by modified literature methods.

General experimental techniques were as previously described [12]; routine ESI mass spectra were recorded on a VG Platform II instrument, using methanol as the mobile phase. A small quantity of aqueous NaCl solution was often added as an ionisation aid. Confirmation of the formation of oxidised ions was achieved using a Bruker Daltonics MicrOTOF high-resolution mass spectrometer, capable of achieving an accurate *m*/*z* value to ±5 ppm; calibration was achieved using a sodium formate solution. Assignment of mass spectrometric isotope patterns was aided by the ISOTOPE program [55].

4.2. Synthesis of (2-bp)Au{N(COMe)C_6H_4N(COMe)} (*10*)

The complex (2-bp)$AuCl_2$ (**5**) (200 mg, 0.45 mmol), 1,2-diacetamidobenzene (**9**) (88 mg, 0.45 mmol) and silver(I) oxide (400 mg, excess) were added to dichloromethane (30 mL) and refluxed with stirring for 24 h. The resulting

solution was filtered to give a pale yellow solution which was evaporated to give yellow crystals. These were dissolved in dichloromethane (~5 mL) and filtered through an alumina column. Slow addition of diethyl ether to the filtrate resulted in formation of yellow microcrystals which were filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) and dried under vacuum to give 178 mg (69%) of the product. *Anal.* Calc. for $C_{22}H_{20}N_3O_2Au$: C, 47.6; H, 3.6; N, 7.6. Found: C, 47.8; H, 3.8; N, 7.5%. M.p. 176–178 °C (dec.). IR: ν(C=O) region: 1611 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 578 (100%, $[M+Na]^+$), 556 (45%, $[M+H]^+$), 1133 (30% $[2M+Na]^+$). ^1H NMR: δ 1.87 (s, 3H), 2.14 (s, 3H), 4.03 (d, 1H), 4.67 (d, 1H), 6.9–7.2 (m, 6H), 7.38 (t, 1H), 7.48 (d, 1H), 7.68 (d, 1H), 7.95 (t 1H), 8.98 (d, 1H). $^{13}C–\{^1H\}$ NMR: δ 23.0 (CH_3), 27.7 (CH_3), 47.7 (CH_2), 122.1–156.1 (aryl C), 173.5 (C=O), 174.1 (C=O).

4.3. Synthesis of (2-anp)Au{N(COMe)C_6H_4N(COMe)} (**11**)

The complex (2-anp)$AuCl_2$ (**6**) (201 mg, 0.46 mmol), 1,2-diacetamidobenzene (**9**) (89 mg, 0.46 mmol) and silver(I) oxide (400 mg, excess) were added to dichloromethane (30 mL) and refluxed with stirring for 24 h. The solution was filtered, and the filtrate evaporated under reduced pressure to give orange crystals. These were dissolved in dichloromethane (~5 mL) and the solution filtered through a column of neutral alumina. Diethyl ether was slowly added to the filtrate, resulting in the formation of yellow crystals which were filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) and dried under vacuum to give 142 mg (55%) of the product. *Anal.* Calc. for $C_{21}H_{19}N_4O_2Au$: C, 45.3; H, 3.4; N, 10.1. Found: C, 45.3; H, 3.6; N, 10.0%. M.p. 232–236 °C (dec.). IR: ν(C=O) region: 1604 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 579 (100%, $[M+Na]^+$), 1135 (30%, $[2M+Na]^+$). The complex was too insoluble in the common deuterated solvents [$(CD_3)_2SO$, D_2O and $CDCl_3$] to acquire satisfactory NMR spectra.

4.4. Synthesis of (tolpy)Au{N(COMe)C_6H_4N(COMe)} (**12**)

The complex (tolpy)$AuCl_2$ (**7**) (100 mg, 0.23 mmol), 1,2-diacetamidobenzene (**9**) (44 mg, 0.23 mol) and silver(I) oxide (200 mg, excess) were suspended in dichloromethane (30 mL) and refluxed with stirring for 24 h. The resulting mixture was filtered and the filtrate evaporated to give yellow crystals. These were then dissolved in dichloromethane (~5 mL) and the solution filtered through an alumina column to remove remaining silver impurities. Addition of diethyl ether to the filtrate resulted in formation of pale yellow fluffy crystals which were filtered, washed with water (2 × 10 mL) and diethyl ether (2 × 10 mL) and dried under vacuum to give 86 mg (68%) of the product. *Anal.* Calc. for $C_{22}H_{20}N_3O_2Au$: C, 47.6; H, 3.6; N, 7.6. Found: C, 46.3; H, 3.8; N, 7.4%. M.p. 270–273 °C (dec.). IR: ν(C=O) region: 1607 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 578 (100%, $[M+Na]^+$), 556 (50%, $[M+H]^+$), 1133 (25%, $[2M+Na]^+$). ^1H NMR: δ 2.23 (s, 3H), 2.36 (s, 3H), 2.44 (s, 3H) 6.9–7.4 (m, 8H), 7.77 (d, 1H), 9.46 (s, 1H). $^{13}C–\{^1H\}$ NMR: δ 14.1 (CH_3), 22.2 (CH_3), 22.4 (CH_3), 119.5–164.8 (aryl C), 173.6 (C=O), 174.7 (C=O).

4.5. Synthesis of (damp)Au{N(COMe)C_6H_4N(COMe)} (**13**)

The complex (damp)$AuCl_2$ (**8**) (100 mg, 0.25 mmol), 1,2-diacetamidobenzene (**9**) (48 mg, 0.25 mol) and silver(I) oxide (200 mg, excess) were suspended in dichloromethane (30 mL) and refluxed for 24 h. The solution was filtered and evaporated to give yellow crystals. These were dissolved in a minimum amount of dichloromethane and slow addition of diethyl ether resulted in the formation of yellow crystals which were filtered, washed with diethyl ether (10 mL) and water (2 × 10 mL) and dried under vacuum to give 64 mg (50%) of the product. *Anal.* Calc. for $C_{19}H_{22}N_3O_2Au \cdot 0.15CH_2Cl_2$: C, 43.1; H, 4.2; N, 7.9. Found: C, 42.3; H, 4.4; N, 7.7%. M.p. 202 °C (dec.). IR: ν(C=O) region: 1612 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 544 (100%, $[M+Na]^+$), 522 (78%, $[M+H]^+$), 580 (68%, $[M+HCl+Na]^+$), 1065 (45%, $[2M+Na]^+$), 1101 (38%, $[2M+HCl+Na]^+$), 1043 (25%, $[2M+H]^+$). ^1H NMR: δ 2.15 (s, 3H), 2.23 (s, 3H), 3.39 (s, 6H), 4.21 (s, br, 2H), 5.32 (s, CH_2Cl_2), 6.86–6.89 (m 4H), 6.97–7.00 (m, 2H), 7.05 (m, 2H), 7.17 (m, 2H), 7.60 (d, 1H). $^{13}C–\{^1H\}$ NMR: δ 22.7 (CH_3), 52.6 (NCH_3), 53.4 (CH_2Cl_2), 74.9 (CH_2), 122.2–146.6 (aryl C), 173.5 (C=O), 174.1 (C=O).

4.6. Synthesis of (2-bp)Au{N(SO_2Tol)C_6H_4N(SO_2Tol)} (**17**)

The complex (2-bp)$AuCl_2$ (**5**) (100 mg, 0.229 mmol) and bis(sulfonamide) (**15**) (142 mg, 0.341 mmol) were stirred in refluxing methanol (30 mL). Aqueous trimethylamine (2 mL, excess) was added and the resulting bright orange solution was further refluxed for 15 min. Distilled water (50 mL) was added, resulting in the formation of a milky yellow suspension. This was stirred until cool, filtered, and the product washed with water (2 × 10 mL) and diethyl ether (10 mL) then dried under vacuum to give (88 mg, 49%) of bright yellow solid. *Anal.* Calc. for $C_{32}H_{28}N_3O_4S_2Au$: C, 49.3; H, 3.6; N, 5.4. Found: C, 48.0; H, 3.7; N, 5.5%. M.p. 151–155 °C. IR: ν(SO_2, asym) 1301 cm^{-1}; ν(SO_2, sym) 1145 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 802 (100%, $[M+Na]^+$), 1581 (20%, $[2M+Na]^+$). Cone voltage 60 V: *m/z* 802 (100%, $[M+Na]^+$), 625 (20%, $[M-SO_2Tol+H]^{\bullet+}$), 471 (15%, $[M-2SO_2Tol+2H]^{\bullet+}$), 1581 (20%, $[2M+Na]^+$). ^1H NMR: δ 2.33 (s, 3H), 2.39 (s, 3H), 4.08 (d, 1H), 4.77 (d, 1H), 6.8–7.5 (m, 15H), 7.56 (d, 1H), 7.70 (d, 2H), 7.80 (t, 1H), 9.15 (d, 1H). $^{13}C–\{^1H\}$ NMR: δ 21.6 (CH_3), 21.7 (CH_3), 48.1 (CH_2), 121.6–156.8 (aryl C).

4.7. Synthesis of (2-anp)Au{N(SO$_2$Tol)C$_6$H$_4$N(SO$_2$Tol)} (**18**)

The complex (2-anp)AuCl$_2$ (**6**) (100 mg, 0.229 mmol) and bis(sulfonamide) (**15**) (143 mg, 342 mmol) were mixed in refluxing methanol (30 mL). Aqueous trimethylamine (2 mL, excess) was added, resulting in the rapid formation of yellow/brown micro-crystals. The mixture was refluxed for a further 20 min then left to cool and filtered. The yellow solid was washed with water (2 × 10 mL) and diethyl ether (10 mL) and then dried under vacuum to give 150 mg (84%) of product. *Anal*. Calc. for $C_{31}H_{27}N_4O_4S_2Au$: C, 47.7; H, 3.5; N, 7.2. Found: C, 47.5; H, 3.6; N, 7.2%. M.p. 264–265 °C (dec.). IR: ν(SO$_2$, asym) 1284 cm^{-1}, ν(SO$_2$, sym) 1140 cm^{-1}; ν(NH) 3294 cm^{-1}. ESI-MS: cone voltage 20 V; *m*/*z* 803 (100%, [M+Na]$^+$), 1583 (20%, [2M+Na]$^+$). Cone voltage 60 V: *m*/*z* 803 (100%, [M+Na]$^+$), 625 (20%, [M−SO$_2$Tol+H]$^{\bullet+}$), 471 (15%, [M−2SO$_2$Tol+2H]$^{\bullet+}$), 1583 (20%, [2M+Na]$^+$). ^{1}H NMR: δ 2.36 (s, 3H), 2.44 (s, 3H), 6.84 (t, 1H), 6.77 (t, 1H), 6.93–7.25 (m, 6H), 7.36 (d, 1H), 7.55 (d, 1H), 7.63 (d, 2H), 7.80 (t, 1H), 8.02 (d, 2H), 8.87 (d, 1H), 8.76 (s, NH). Due to the insolubility of this compound in common deuterated NMR solvents [(CD$_3$)$_2$SO, D$_2$O, CDCl$_3$], satisfactory ^{13}C NMR spectra could not be acquired.

4.8. Synthesis of (tolpy)Au{N(SO$_2$Tol)C$_6$H$_4$N(SO$_2$Tol)} (**19**)

The complex (tolpy)AuCl$_2$ (**7**) (100 mg, 0.231 mmol) and bis(sulfonamide) (**15**) (144 mg, 0.290 mmol) were mixed in refluxing methanol (30 mL). Aqueous trimethylamine (2 mL, excess) was added, resulting in the rapid deposition of yellow microcrystals. The solution was left to cool, then filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) then dried under vacuum to give 117 mg (65%) of yellow solid. *Anal*. Calc. for $C_{32}H_{28}N_3O_4S_2Au$: C, 49.3; H, 3.6; N, 5.4. Found: C, 49.5; H, 3.7; N, 5.5%. M.p. 262 °C (dec.). IR: ν(SO$_2$, asym) 1300 cm^{-1}; ν(SO$_2$, sym) 1140 cm^{-1}. ESI-MS: cone voltage 20 V; *m*/*z* 802 (100%, [M+Na]$^+$). Cone voltage 60 V: *m*/*z* 802 (100%, [M+Na]$^+$), 1581 (20%, [2M+Na]$^+$). ^{1}H NMR: δ 2.36 (s, 3H), 2.39 (s, 3H), 2.41 (s, 3H), 6.82 (t, 1H), 6.89 (t, 1H), 7.06 (d 1H), 7.18–7.24 (m, 3H), 7.34 (d, 1H), 7.40 (d, 1H), 7.72 (d, 2H), 7.79–7.81 (m, 3H), 8.00 (t, 1H), 9.31 (d, 1H). ^{13}C–{^{1}H} NMR: δ 21.8 (*C*H$_3$), 21.9 (*C*H$_3$), 23.4 (*C*H$_3$), 120–165 (aryl *C*).

4.9. Synthesis of (damp)Au{N(SO$_2$Tol)C$_6$H$_4$N(SO$_2$Tol)} (**20**)

The complex (damp)AuCl$_2$ (**8**) (75 mg, 0.19 mmol) and bis(sulfonamide) (**15**) (120 mg, 0.28 mmol) were mixed in refluxing methanol (30 mL), resulting in a clear yellow solution. Aqueous trimethylamine (2 mL, excess) was added resulting in a rapid colour change to give an orange solution which was further refluxed for 5 min. Water (75 mL) was added, resulting in the immediate formation of yellow microcrystals. After cooling, the mixture was filtered and the product washed with water (2 × 10 mL) and diethyl ether (10 mL) and dried under vacuum giving 57 mg (41%) of product. *Anal*. Calc. for $C_{29}H_{30}N_3O_4S_2Au$: C, 46.7; H, 4.1; N, 5.6. Found: C, 46.6; H, 3.9; N, 5.7%. M.p. 196–198 °C (dec.). IR: ν(SO$_2$, asym) 1302 cm^{-1}; ν(SO$_2$, sym) 1147 cm^{-1}. ESI-MS: cone voltage 20 V; *m*/*z* 767 (100%, [M+Na]$^+$), 465 (100%, unidentified), 1511 (32%, [2M+Na]$^+$). Cone voltage 60 V: *m*/*z* 767 (100%, [M+Na]$^+$), 591 (32%, [M−SO$_2$Tol+H]$^{\bullet+}$), 1511 (30%, [2M+Na]$^+$). ^{1}H NMR: δ 2.39 (s, 3H), 2.42 (s, 3H), 3.36 (s, 6H), 4.30 (s, 2H), 6.70 (t, 1H), 6.86 (t, 1H), 6.93 (d, 1H), 7.11 (m 2H), 7.2–7.3 (m, 6H), 7.70 (d, 2H), 7.80 (d, 2H), 8.02 (d, 1H). ^{13}C–{^{1}H} NMR: δ 21.5 (*C*H$_3$), 21.5 (*C*H$_3$), 53.2 (N*C*H$_3$), 75.7 (*C*H$_2$), 121.6–144.0 (aryl *C*).

4.10. Synthesis of (pic)Au{N(SO$_2$Tol)C$_6$H$_4$N(SO$_2$Tol)} (**21**)

The complex (pic)AuCl$_2$ (**14**) (75 mg, 0.19 mmol) and bis(sulfonamide) (**15**) (120 mg, 0.28 mmol) were mixed in refluxing methanol (30 mL), resulting in a colour change to give a red solution. Aqueous trimethylamine (2 mL, excess) was added, resulting in the rapid deposition of red/brown microcrystals. The solution was left to cool while stirring and then filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) then dried under vacuum to give 101 mg (72%) of red solid. *Anal*. Calc. for $C_{26}H_{23}N_4O_5S_2Au$: C, 42.6; H, 3.2; N, 7.7. Found: C, 41.6; H, 3.2; N, 7.4%. M.p. 226 °C. 4.11. Synthesis of (2-bp)Au{N(SO$_2$Tol)C$_2$H$_4$N(SO$_2$Tol)} (**22**)

The complex (2-bp)AuCl$_2$ (**5**) (100 mg, 0.23 mmol) and bis(sulfonamide) (**16**) (100 mg, 28 mmol) were suspended in refluxing methanol (30 mL). Aqueous trimethylamine (2 mL, excess) was added and the solution further refluxed for 15 min. Water (50 mL) was added which resulted in the deposition of a white precipitate. After cooling to room temperature, the solid was filtered, washed with water (2 × 10 mL) and diethyl ether (10 mL) to give a pale grey solid. This was further purified by dissolving in minimal dichloromethane and filtering through a Pasteur pipette containing florisil. The compound was then isolated by slow addition of diethyl ether, filtered and washed with water (2 × 10 mL) and diethyl ether (10 mL) to give

59 mg (35%) of white microcrystals. *Anal.* Calc. for $C_{28}H_{28}N_3O_4S_2Au$: C, 46.0; H, 3.9; N, 5.8. Found: C, 45.9; H, 4.0; N, 5.8%. M.p. 215–219 °C (dec.). IR: $\nu(SO_2$, asym) 1280 cm^{-1}; $\nu(SO_2$, sym) 1139 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 791 (100%, $[M+Me_3NH]^+$), 732 (95%, $[M+H]^+$), 754 (80%, $[M+Na]^+$), 1485 (35%, $[2M+Na]^+$), 1463 (30%, $[2M+H]^+$). Cone voltage 60 V: *m/z* 732 (100%, $[M+H]^+$), 754 (95%, $[M+Na]^+$), 1485 (40%, $[2M+Na]^+$). ^{1}H NMR: δ 2.37 (s, 3H), 2.38 (s, 3H), 3.10 (m, 2H), 3.51 (m, 2H), 4.01 (d, 1H), 4.55 (d, 1H), 6.80 (t, 1H), 7.06–7.33 (m, 9H), 7.42 (t, 1H), 7.63 (d, 1H), 7.75 (d, 2H), 7.94 (t, 1H), 9.16 (d, 1H). ^{13}C–{^{1}H} NMR: δ 21.4 (CH_3), 21.5 (CH_3), 47.9 (CH_2), 51.0 (CH_2), 56.6 (CH_2), 123.2–156.0 (aryl *C*).

4.12. Synthesis of (2-anp)Au{N(SO$_2$Tol)C$_2$H$_4$N-(SO$_2$Tol)} (*23*)

The complex (2-anp)$AuCl_2$ (**6**) (100 mg, 0.23 mmol) and bis(sulfonamide) (**16**) (100 mg, 0.28 mmol) were added to refluxing methanol (30 mL). While stirring, aqueous trimethylamine (2 mL, excess) was added and the solution was refluxed for a further 15 min. Water (50 mL) was added resulting in the formation of a pale yellow precipitate. After cooling, the solid was filtered and washed with water (2 × 10 mL) and diethyl ether (10 mL), and dried under vacuum to give 111 mg (54%) of yellow product. *Anal.* Calc. for $C_{27}H_{27}N_4O_4S_2Au$: C, 44.3; H, 3.7; N, 7.7. Found: C, 44.1; H, 3.8; N, 7.8%. M.p. 244–246 °C (decomp). IR: $\nu(SO_2$, asym) 1276 cm^{-1}, $\nu(SO_2$, sym) 1140 cm^{-1}; ν(NH) 3295 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 755 (100%, $[M+Na]^+$), 1487 (20%, $[2M+Na]^+$), 1121 (20%, $[3M+2Na]^{2+}$). Cone voltage 60 V: *m/z* 755 (100%, $[M+Na]^+$), 1487 (25%, $[2M+Na]^+$). ^{1}H NMR: δ 2.44 (s, 6H), 3.29 (m, 2H), 3.62 (m, 2H), 6.69 (t, 1H), 6.76 (t, 1H), 7.03 (m, 2H), 7.22–7.35 (m, 4H), 7.45 (d, 1H), 7.63 (m, 3H), 7.42 (t, 1H), 7.90 (d, 2H), 8.73 (d, 1H), 8.83 (s, NH). Due to the insolubility of this compound in common deuterated NMR solvents [$(CD_3)_2SO$, D_2O, $CDCl_3$], satisfactory ^{13}C NMR spectra could not be acquired.

4.13. Synthesis of (tolpy)Au{N(SO$_2$Tol)C$_2$H$_4$N(SO$_2$Tol)} (*24*)

The complex (tolpy)$AuCl_2$ (**7**) (100 mg, 23 mmol) and bis(sulfonamide) (**16**) (100 mg, 0.23 mmol) were stirred in refluxing methanol (30 mL) and aqueous trimethylamine (2 mL, excess) was added, and the solution refluxed for 5 min. Water (50 mL) was added and the mixture cooled. The resulting pale yellow precipitate was filtered and washed with water (2 × 10 mL) and diethyl ether (10 mL) and dried under vacuum to give 135 mg (80%) of pale yellow microcrystals. *Anal.* Calc. for $C_{28}H_{28}N_3O_4S_2Au$: C, 46.0; H, 3.9; N, 5.8. Found: C, 45.7; H, 3.9; N, 5.8%. M.p. 186–188 °C (dec.). IR: $\nu(SO_2$, asym) 1303 cm^{-1}; $\nu(SO_2$, sym) 1138 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 754 (100%, $[M+Na]^+$), 1485 (25%, $[2M+Na]^+$), 791 (20%, $[M+Me_3NH]^+$), 732 (15%, $[M+H]^+$). 4.14. Synthesis of (damp)Au{N(SO$_2$Tol)C$_2$H$_4$N(SO$_2$Tol)} (*25*)

The complex (damp)$AuCl_2$ (**8**) (75 mg, 0.19 mmol) and bis(sulfonamide) (**16**) (83 mg, 0.26 mmol) were mixed in refluxing methanol (30 mL), producing a pale yellow solution. Aqueous trimethylamine (2 mL, excess) was added and the mixture refluxed for 5 min. Water (75 mL) was added, resulting in the deposition of pale yellow microcrystals which were cooled, filtered and washed with water (2 × 10 mL) and diethyl ether (10 mL) and then dried under vacuum to give 115 mg (88%) of **25**. *Anal.* Calc. for $C_{25}H_{30}N_3O_4S_2Au$: C, 43.0; H, 4.3; N, 6.0. Found: C, 42.9; H, 4.3; N, 5.9%. M.p. 184–187 °C (dec.). IR: $\nu(SO_2$, asym) 1276 cm^{-1}; $\nu(SO_2$, sym) 1138 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 719 (100%, $[M+Na]^+$), 1415 (35%, $[2M+Na]^+$). Cone voltage 60 V: *m/z* 719 (100%, $[M+Na]^+$), 1415 (30%, $[2M+Na]^+$). ^{1}H NMR: δ 2.40 (s, 6H), 3.13 (m, 2H), 3.18 (m, 2H), 3.40 (s, 6H), 4.34 (s, 2H), 6.97 (t, 1H), 7.12 (d, 1H), 7.17–7.25 (m, 5H), 7.38 (d, 1H), 7.65 (d, 2H), 7.73 (d, 2H). ^{13}C–{^{1}H} NMR: δ 21.5 (CH_3), 21.5 (CH_3), 52.0 (CH_2), 52.5 (NCH_3), 58.1 (CH_2), 77.1 (CH_2), 123.0–147.4 (aryl *C*).

4.15. Synthesis of (2-bp)Au{N(COMe)C$_6$H$_4$NH-(COMe)}Cl (*28*)

The complex (2-bp)$AuCl_2$ (**5**) (200 mg, 0.46 mmol), 1,2-diacetamidobenzene (**9**) (90 mg, 0.46 mmol) and silver(I) oxide (400 mg, excess) were added to dichloromethane (50 mL) and refluxed with stirring for 2 h. The solution was then filtered and the filtrate evaporated to dryness under reduced pressure. The resulting yellow crystals were dissolved in the minimum amount of dichloromethane and filtered through an alumina column. Slow addition of diethyl ether gave a pale yellow precipitate which was subsequently filtered and washed with diethyl ether (10 mL) and water (2 × 10 mL). ^{1}H NMR of the sample showed it to be a mixture of mainly **28** plus the metallacyclic complex **10**. X-ray quality crystals of **28** were grown by vapour diffusion of diethyl ether into a dichloromethane solution of the mixture at room temperature. M.p. 180–182 °C (dec.). *Anal.* Calc. for $C_{22}H_{21}N_3O_2AuCl$: C, 44.6; H, 3.5; N, 7.10. Found: C, 42.1; H, 3.4; N, 6.1%. *Anal.* Calc. for $C_{22}H_{21}N_3O_2AuCl \cdot 2H_2O$: C, 42.1; H, 3.4; N, 6.7%. IR: ν(N–H) 3303 cm^{-1}, ν(C=O) region 1693, 1611 cm^{-1}. ESI-MS: cone voltage 20 V; *m/z* 614

(100%, $[M+H]^+$), 556 (85%, $[M-HCl+Na]^+$), 578 (20%, $[M+Na]^+$).

4.16. Alternative synthesis of **28**

To the metallacyclic complex **10** (16.6 mg, 0.03 mmol) in dichloromethane (5 mL), sodium chloride (1.7 mg, 0.03 mmol) in methanol (2 mL) was added and stirred for 24 h. Benzoic acid (3.6 mg, 0.03 mmol) was then added, resulting immediately in the solution changing from dark to pale yellow. The solution was then filtered, reduced in volume and diethyl ether was added forming a precipitate that was identified as **28** by ^{1}H NMR.

4.17. X-ray crystal structure of (2-bp)Au{N(COMe)-C_6H_4N(COMe)} (**10**)

Yellow needles (m.p. 178 °C (dec.)) were obtained by vapour diffusion of diethyl ether into a dichloromethane solution of the crude product, at room temperature. Intensity data and unit cell dimensions were obtained on a Bruker SMART CCD diffractometer. Crystal size: $0.24 \times 0.10 \times 0.10$ mm, 23 180 total reflections, 3991 unique reflections (R_{int} 0.0378), range: $1.49° < \theta < 26.88°$, empirical absorption correction $T_{max,min}$: 0.518, 0.264. *Crystal data*: $C_{22}H_{20}AuN_3O_2$, M_r 555.38, tetragonal, space group $I4_1/a$. $a = 14.721(3)$ Å, $c = 35.971(1)$ Å, $V = 7795.4(3)$ Å^3, $D_{calc} = 1.893$ g cm^{-3}, $Z = 16$, $F(000) = 4288$, μ(Mo Kα) = 7.6 mm^{-1}.

The structure was solved using the direct methods option of SHELXS-97 [56]. The gold atom was initially located and then all other non-hydrogen atoms were located (SHELXL-97) by a series of difference maps. The full-matrix least-squares refinement was based upon F_o^2 with all non-hydrogen atoms anisotropic and hydrogen atoms in calculated positions; convergence gave $R_1 = 0.0214$ $[I \geqslant 2\sigma(I)]$, $wR_2 = 0.0427$ (all data), goodness-of-fit = 1.144. A final difference map showed no feature greater than 0.76 e Å^{-3}.

Due to potential *pseudo* symmetry in the molecule it was expected that the benzyl and pyridyl rings could show disorder. This was discounted since N(3) and C(31) were found to be in well-defined positions, based upon the following:

1. In the initial difference map the peak assigned to N(3) was 10 e Å^{-3} whereas for C(31) it was 8.8 e Å^{-3}.
2. When both positions were refined as carbon atoms, the U_{iso} values were 0.02 for the C(31) position and 0.07 for the N(3) (which are very similar to the other N atoms in the molecule when they were treated as carbon atoms).
3. The Au(1)–N(3) distance of 2.058 Å was significantly longer than the Au(1)–C(31) distance of 2.031 Å. The Au(1)–N(2) bond *trans* to C(31) was 2.089 Å, which is longer than the Au(1)–N(1) distance *trans* to N(3) of 2.022 Å. If the molecule had shown disorder presumably these distances would have been similar.
4. When the assignment of C(31) and N(3) was reversed the R factors increased from 0.0214 and 0.0427 to 0.0227 and 0.0466 for R_1 and wR_2, respectively.

4.18. X-ray crystal structure of (2-bp)Au{N(COMe)C_6H_4NH(COMe)}Cl (**28**)

Colourless prisms were obtained by vapour diffusion of diethyl ether into a dichloromethane solution containing the crude product at room temperature. M.p. 180–182 °C (dec.). Intensity data and unit cell dimensions were obtained on a Bruker SMART CCD diffractometer. Crystal size: $0.04 \times 0.32 \times 0.32$ mm, total reflections 11 252, unique reflections 4764 (R_{int} 0.0359), range: $1.73° < \theta < 27.13°$, empirical absorption correction $T_{max,min}$: 0.466, 0.389. *Crystal data*: $C_{22}H_{21}AuClN_3O_2$, M_r 591.83, triclinic, space group $P\bar{1}$. $a = 9.0334(1)$ Å, $b = 10.7766(1)$ Å, $c = 12.3915(1)$ Å, $\alpha = 88.846(1)°$, $\beta = 72.812(1)°$, $\gamma = 72.057(1)°$, $V = 1093.040(18)$ Å^3, $D_{calc} = 1.798$ g cm^{-3}, $Z = 2$, $F(000) = 572$, μ(Mo Kα) = 6.9 mm^{-1}.

The structure was solved by the direct methods option of SHELXS-97 [56], with the gold atom being located. All other non-hydrogen atoms were located by a series of difference maps. Full-matrix least-squares refinement (SHELXL-97) was based upon F_o^2 with all non-hydrogen atoms anisotropic and hydrogen atoms in calculated positions (with the exception of H(1) which was located by a difference map) converged with $R_1 = 0.0170$ $[I \geqslant 2\sigma(I)]$, $wR_2 = 0.0417$ (all data), goodness-of-fit = 1.072. A final difference map showed no feature greater than 0.99 e Å^{-3}. All calculations were carried out by the SHELX-97 suite of programs.

4.19. Biological assays

Details of the biological assays have been published previously [12].

Acknowledgements

We thank the University of Waikato (UW) for financial support of this work, including a scholarship to K.J.K. We also thank Tania Groutso (University of Auckland) for collection of the X-ray data sets, and Gill Ellis (University of Canterbury) for the biological assay data. Professor Alistair Wilkins is thanked for NMR expertise, and Pat Gread for technical support with mass spectrometry.

Abstract

This paper describes the orbital configuration which provides a basis for the understanding of the electronic structure and spectroscopic properties of 17e and 18e FcC_2R and FcC_4R dyads, where R is H, 1-naphthyl, 9-anthryl, 3-pyrenyl, perylenyl. DFT calculations show that destabilisation of the ferrocenyl π orbitals upon binding a C≡CR group to a Cp ring leads to the metal-based a_1 orbital dropping below the e_1-a so that the frontier orbital configuration is $(e_2'\text{-a},\pi)^2(e_2'\text{-b},\text{metal})^2(e_1'\text{-a},\pi)^2$, $(a_1,\text{metal})^2$. The contribution of the aryl group to the π e_2-a and e_1-a orbitals varies with the annelation of the ring. The LUMO is aryl based. The calculations are consistent with the spectroscopic data for the 18e species. Oxidation to the 17e cations does not change the orbital configuration but the orbital energies are lowered by the positive charge centred on the Fe. A strongly solvatochromic transition in the near-IR, a signature for the 17e cations, is best described as an LMCT transition but the contribution of C_2R and C_4R to the donor and acceptor levels depends on the ionization energy of the aryl π orbital. LMCT energies decrease from FcC_2R to FcC_4R dyads.

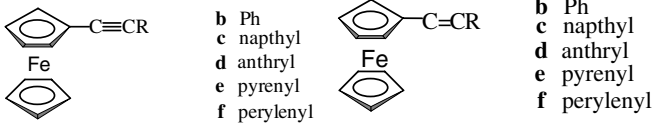
1. Introduction



Many aspects of the electronic structure of closed shell metallocenes, especially ferrocene [1–5], have been investigated, both theoretically and experimentally. With the current focus on ferrocenyl materials with second-order NLO properties [6,7], these studies have extended into ferrocenyl derivatives where electron acceptors are bound to one or two cyclopentadienyl rings, especially via a π-linkage [2,8–10]. A detailed description of the electronic structure for this class of compound has evolved, the salient features being an understanding of the ferrocenyl-(π-link)-acceptor energy levels and consequential optical transitions. The electronic structure of compounds with strong donors on a Cp ring [11] or dyads with a ferrocenyl-(π-link)-donor motif [12] have not received the same attention. Barlow and Marder [2] have commented that a $D_{5h/5d}$ metallocene can interact with a π-bridge both via a cyclopentadienyl ring and through a metal-based orbital when an organic acceptor was involved. Whether this situation also pertains in electron-rich π-linked dyads, and/or with ferrocenium analogues, is the thrust of this paper. This was of interest to us as any change in the electronic structure, either in the neutral or oxidized molecule, may enable the classical quenching effect of the metallocene to be modified if a fluorophore is bound to a cyclopentadienyl ring via a π-conjugated bridge. This has been achieved where the fluorophore is a strong electron acceptor [13–15].

In a previous paper [16] we reported the synthesis and molecular structure of the ferrocenyl dyads **1a**–**f** and **2a**–**f** and [FcC═C–C═CR]. Spectroscopic and structural data indicated that there was little mutual perturbation of the Fc and aryl groups via the unsaturated link in the ground

state of the dyad. But this was not true when the ferrocenyl group was oxidized to the ferrocenium analogue. Absorption bands in the 400–700 nm region of the visible spectrum were not typical of ferrocenium compounds and all oxidized dyads had weak bands in the near-IR. Similar NIR bands have been reported for a number of ferrocenium derivatives [10,11,17] and the effects of donors on the ferrocenium LMCT band have been documented [17]. We subsequently found that these near-IR bands were also a feature of dyads with FcC≡C– or FcC=C-group, even when R was a strong acceptor (e.g. naphthalimide [16]). They were also observed in oxidized dyads of general type, Mc^{+}–C≡C–R or Mc^{+}–C≡C–R, where Mc is a donor metallocene fragment such as the isolobal η-$C_5H_4Co(Ph_4C_4)$. In order to gain an insight into the origin of the NIR bands, DFT calculations were performed on the dyads **1a**–**f** [18] and **2a**–**f**. The π link between the ferrocenyl and aryl groups significantly perturbs the ferrocenyl energy levels leading to a different orbital configuration to that of ferrocene. This one-electron configuration provides an explanation of the interesting spectroscopic properties and electrochromism displayed by these dyads

2. Results and discussion

2.1. DFT calculations on 18e dyads

Density functional theory (DFT), which is well-performed for ferrocene [4,5] and derivatives [9b], was used to probe the influence of the –C≡C and aryl group on the frontier orbitals of ferrocene. B3LYP calculations were carried out on **1a**–**f** and **2a**–**f**. Iso-surfaces for the frontier orbitals for **1d** are represented in Fig. 1a; surfaces for the other molecules are available from the authors. Calculated orbital energies are given in Table 1 and schematically represented in Fig. 2. B3LYP/6.31G(d) calculations of the optimised geometries were in good agreement with those found in the X-ray crystal structures [16]. An eclipsed geometry for the Cp rings was found for all dyads so the appropriate ferrocenyl point group is D_{5h} but the subgroup D_5 is adequate. For the dyads the symmetry is C_{2v}.

Ferrocene (D_5) has an e_2' (x^2-y^2, xy) HOMO, which is predominately a δ bond and metal in character. The e_2' lies 0.35 eV above the metal-based a_1 (d_{z^2}) orbital. The e_1' ($Cp + d_{xz/yz}$) is the strongest bonding interaction. Ionization potentials for the e_2, a_1, e_1 frontier orbitals of ferrocene are, respectively, 6.88, 7.23 and 8.72 eV [4]. The addition of a C≡C to an aromatic ring raises the ionization energy of the π HOMO and for HC≡CR the IP's range from 9.12 eV for ethynylbenzene to 8.12 eV for the larger annelated rings [19]. Consequently, the π orbitals of the C≡CR group are ideally placed for a strong π interaction with ferrocene orbitals, with the aromatic HOMO having a stronger interaction with the e_2 orbital as the ring size increases; this was confirmed by the B3LYP calculations (vide infra). The DFT calculations show that the introduction of a conjugated substituent does indeed have a significant impact on the relative energies of the ferrocene orbitals, particularly the strongly bonding e_1' level (Fig. 2).

[a] Energies in au.
[b] Energies are given for the α or β one-electron orbitals.

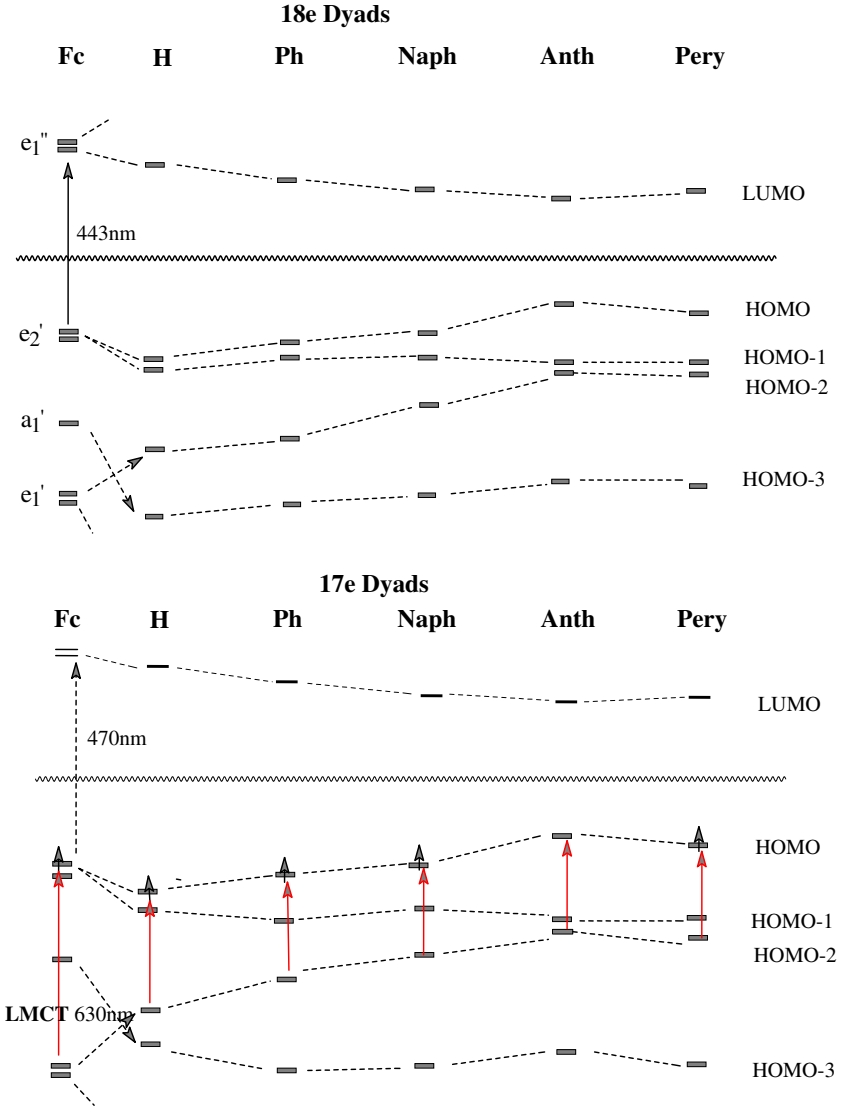

Fig. 2. Calculated orbital energies for 18e and 17e dyads compared to ferrocene.

For ease of tracing the perturbation of the ferrocenyl orbitals, the dyad frontier orbitals arising from the degenerate ferrocenyl orbitals in lower symmetry will be designated as e'_2-a/e'_2-b and e'_1-a/e'_1-b rather than a formal C_{2v} designation. One of the degenerate e'_2 or e'_1 orbitals has the correct nodal symmetry (e'_2-a and e'_1-a) to interact with the HOMO of the C≡CR substituent.

We first consider the effect of adding a –C≡CH group to the Cp ring of ferrocene. The energies of both orbital pairs, e'_2-a/e'_2-b and e'_1-a/e'_1-b, are lowered relative to the parent ferrocene orbital. There is an orbital mismatch for the ferrocenyl-π-substituent interaction (Fig. 1) and the orbital involved in the π interaction, the e'_2-a, is slightly destabilised relative to the e'_2-b orbital which is entirely metal-based. This is the reverse of that found when the C_1 substituent is an electron-withdrawing group [9b]. Similarly the strongly interacting e'_1-a orbital is higher in energy than the metal-based e'_1-b. This destabilisation of the π e'_1-a orbital has an extremely important consequence for the relative energy of the e'_1-a and a_1 (d_{z^2}) orbitals. For **1a**, mixing of these two orbitals occurs with the result that the one-electron HOMO − 2 and HOMO − 3 both have d_{z^2} and d_{xz} character. The orbital configuration for **1b–f** is more simple. For these dyads the increase in energy of the π (e'_1-a) orbital leads to a *crossover of energy such that the HOMO − 2 orbital is now the* e'_1-a *combination and the HOMO − 3 the* a_1 (see Fig. 2). The frontier orbital configuration for **1b–f** is thus $(e'_2\text{-a})^2$, $(e'_2\text{-b})^2$, $(a_1)^2$, $(e'_1\text{-a})^2$, $(e'_1\text{-b})^2$ (Figs. 2 and 5).

There is a progressive destabilisation of the HOMO e'_2-a π orbital as the annelation of the aryl ring increases. Since there is little variation in the energy of e'_2-b, the energy difference between HOMO and HOMO − 1 increases as the ionization energy of the aryl decreases, 0.035 eV (**1a**) to 0.43 eV (**1d**), although it is still relatively small. More significant is the increasing destabilisation of the strongly bonding HOMO − 2 (e'_1-a) orbital such that the HOMO − 2/HOMO − 3 separation increases from 0.45 eV for **1a** to 1.06eV for **1e**; in fact, the HOMO − 1/HOMO − 2 orbitals for **1e** are almost degenerate (separation 0.05 eV) (Table 1). Concomitant with the increase in energy of the HOMO, there is an increasing –C≡CR contribution to the HOMO; by **1d** the HOMO has a large –C≡CR component. This trend nicely correlates with the decreasing ionization potential of the C≡CR group. Conversely, there is an increase in the metal character of HOMO − 2 (e'_1-a) (Fig. 1b).

Calculations on the ethenyl dyads **2a**, **2c** and **2d** indicated that the orbital configuration $(e'_2\text{-a},\pi)^2(e'_2\text{-b, metal})^2$-$(e_1\text{-a},\pi)^2$, $(a_1$, metal$)^2$ also held for the ethenyl series. An ethenyl group interacts more strongly with the ferrocene moiety than an ethynyl group and this is reflected in the higher energy of the π orbitals for the ethenyl series. As a consequence, the HOMO for ferrocene and **2a** have almost the same energy which accounts for the observation that the potentials for the $[Fc]^{+/0}$ couple for ferrocene and **2a** are similar (0.55 V and 0.52 V, respectively) whereas that the ethynyl dyad **1a** is more difficult to oxidise (0.63 V).

Calculations show that the LUMO in all the dyads is entirely aryl-based and this is consistent with experimental data. Their reduction potentials were similar to the free arene in the same solvent and simulation of the EPR spectra of the radical anions **1**(**b–f**)$^{-\cdot}$ and **2**(**a–e**)$^{-\cdot}$ was achieved using the values obtained from EPR spectra of the HC≡CR$^{-\cdot}$ and HC=CR$^{-\cdot}$ radical anions.

3. Electronic spectra

Identification of the lowest energy bands in the UV–Vis spectra was hampered by the overlap with the very intense π–π* transition of the aryl group. Nevertheless, the weak lowest energy band does not change significantly in energy as the annelation of the ring increases; the energies are all $22\,500 \pm 200$ cm^{-1} compared to 22 700 cm^{-1} for ferrocene. These bands can be given an assignment analogous to the lowest energy spin-allowed d–d transition ($^1A_1 \rightarrow aE_1$) of ferrocene [1] and the invariant character of this transition is consistent with the relatively constant HOMO–LUMO band gap across the series. Resonance Raman spectra ($\lambda_{exc} = 457.9$ nm) supported this assignment for the low-energy band as there was a weak enhancement of the $\nu_{C\equiv C}$ band, the ferrocenyl ring breathing mode at 1100 cm^{-1} and ν_{Fe-C} at 298 cm^{-1} and aryl modes. As noted previously [16], the small red-shift in the π–π* transition of the C≡CR group shows that there was not strong perturbation by the ferrocenyl moiety.

Electrochemical oxidation of **1a–f** and **2a–f** at the potential of their $[Fc]^{+/0}$ couple generated the respective green-blue [**1a–f**]$^+$ and green [**2a–f**]$^+$ 17e cations. The C_4 species, $[Fc\text{-}(CH{=}CH)_2R]^+$ (R = Ph, naph, pyr, anthryl), were also produced to study the effect of extending the unsaturated link. For [**1b–f**]$^+$ constant isosbestic points, complete spectral reversibility when the potential is cycled in an OTTLE experiment, and the fact that identical spectra were obtained by controlled chemical oxidation, attest to the stability of the 17e species. There was spectroscopic evidence that the lifetime of **1a**$^+$ was much shorter due to decomposition to the butadiene species $(FcC{\equiv}C)_2$. Representation of the cations as $Fc^+C{\equiv}CR$ in the ground state is vindicated by the vibrational data which show that shifts in the ferrocenyl vibrational bands are similar to those that occur with the formation of a ferrocenium ion [20]. For example, the Raman spectrum of **1d**$^+$ shows a shift of the Fc ring-breathing mode of +7 cm^{-1} and there is a typical Fc^+ band at 1113 cm^{-1} in the infrared spectrum.

In the ferrocenium cation [1,21–23], the $^2E_2$ state is 0.46 eV more stable than $^2A_1$ state and the ground state configuration is $e_2^3\,(xy, x^2-y^2)a_1^2\,(z^2)$. Previous calculations on ferrocenium derivatives [9b], and PE data indicate that the orbital ranking does not change from that in the 18e parent. Our DFT calculations on [**1a–b**]$^+$, and preliminary results for the ethenyl series, also confirmed that the frontier orbital energy sequence was also unchanged upon oxidation, $[(e'_2\text{-a})^1(e'_2\text{-b})^2(e_1\text{-a})^2, (a_1)^2]$, and that aryl contribution to the one-electron orbitals in the 17e and

18e species was similar. Overall, the energies of the occupied orbitals are lower than in the 18e analogues due to the coulombic effect of the positive charge. The HOMO–LUMO gap is significantly smaller than for the corresponding neutral species and it decreases from Fc^+ to $\mathbf{1a}^+$ and as the ring size increases.

Broad ($v_{1/2} \sim 2100\ cm^{-1}$), weak bands ($\varepsilon$ 700–1550 $M^{-1}cm^{-1}$), with energies from 7600 to 14 300 cm^{-1} (band **A**, Fig. 3, Table 2), were a feature of the electronic spectra of all 17e C_2 and C_4 dyads. The energies for the ethenyl compounds are red-shifted relative to the ethynyl series (Table 2) indicative of a stronger π interaction. Interestingly, the intensity and energy of these bands *increased* from the C_2 to the C_4 analogue; that is, with the interpolation of another –C=C group between the donor arene and acceptor (Table 2). So rather than distance reducing the increase in the energy of the e_1-a orbital, it has the opposite effect, implying that longer conjugated-chain ferrocenium dyads could have significantly more intense NIR bands. The anomalous behaviour of $\mathbf{2e}^+$ in the trend data, discussed elsewhere [16], is probably due to steric hindrance involving the ethenyl α-H atoms restricting the π interaction.

Support for an LMCT assignment for these NIR bands came from several sources. (1) The energy of **A** was dependent on the annelation of the aryl group (Table 2) and plots of these energies against the first vertical ionization energy of the respective aryl group are linear. The intensity also increases as the IP of the aryl group decreases. (2) A large negative solvatochromic shift ΔE_{solv} of 900–1200 cm^{-1} between CH_2Cl_2 ($\varepsilon = 9.1$) to MeCN ($\varepsilon = 37.5$) is indicative of a larger dipole in the ground state of the cations than the excited state. This is consistent with a CT assignment as in the excited state configuration of the cations have the

positive charge spread throughout the π system; in the ground state it is localised on the ferrocenyl acceptor. (3) For a CT transition the energy should be related to the electrochemical parameters of the donor and acceptor moieties; this is indeed the case (Fig. 4). (4) The Raman spectrum resonant with these bands shows an enhancement of modes associated with both Fc^+ and aryl units. The ring-breathing modes of the Fc/Fc^+ component show an *increase* in resonance enhancement on going from **1b–f** → $[\mathbf{1b–f}]^+$ whereas there is a threefold *decrease* in enhancement in the equivalent modes for FcH to FcH^+. These data imply that the Fc-based modes are deriving enhancement from an additional electronic transition that is not isolated on the metallocene.

Assignment of the lowest energy transition at 15900 cm^{-1} (in CH_2Cl_2) in the visible spectrum of the ferricenium ion and ferrocenium derivatives to a LMCT ($^2E_2 \rightarrow {}^2E_1$), corresponding to a $e_1 \rightarrow e_2$ one-electron transition, is well-founded [1,21,22]. Clearly, the same one-electron assignment e_1-a → e_2-a (Fig. 5) can be made for the lowest energy transition observed for these 17e dyads. What makes the LMCT energies so remarkable is the magnitude of their red-shift from the $^2E_2 \rightarrow {}^2E_1$ transition in Fc^+ (e.g. 8200 cm^{-1} for $\mathbf{2f}^+$). Previous work has found that the 'ferrocenium' transition is red-shifted by *donor* Cp-substituents [17]. Substitution by two butyl groups causes a red-shift of 800 cm^{-1} for example [20], and with the strong donor, N(*p*-tol)$_2$ the red-shift is 3250 cm^{-1} in CH_3CN with negative solvatochromism $\Delta E_{solv} = 427$ cm^{-1} for CH_2Cl_2/CH_3CN [11]. Aryl groups are not strong donors so we need to look to the electronic configuration for an explanation of the large red shifts. From the DFT calculations both the singly occupied HOMO and, especially the HOMO − 2, are the strongly perturbed orbitals because of conjugation of a C≡C–R group to the ferrocenyl ring. It is reasonable to assign the donor energy level as one related to the e_1-a orbital and the energy of this will be heavily dependant on the ionization potential of the C≡CR group. In the excited state the acceptor energy level, approximated by the $[Fc]^{+/0}$ potential, while perturbed strongly by the incorporation of the C≡C, is relatively invariant with aryl group. Therefore, the linear correlation of the CT energies seen in Fig. 4 is consistent with an assignment of a HOMO − 3 (donor) → HOMO (acceptor) CT transition. While a description as an LMCT transition is appropriate it is important to recognise that the contribution of the C≡CR π orbital to the donor and acceptor levels depends on the ionization energy of this π orbital. For the small ring aryl, the donor level has a significant input from the C≡CR π orbital; the reverse holds for the acceptor level.

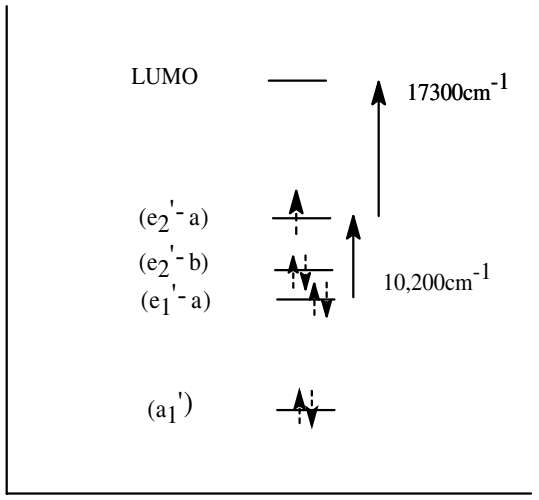

Fig. 5. NIR band assignment for $1d^+$; CH_2Cl_2, 15000–8000 cm^{-1}.

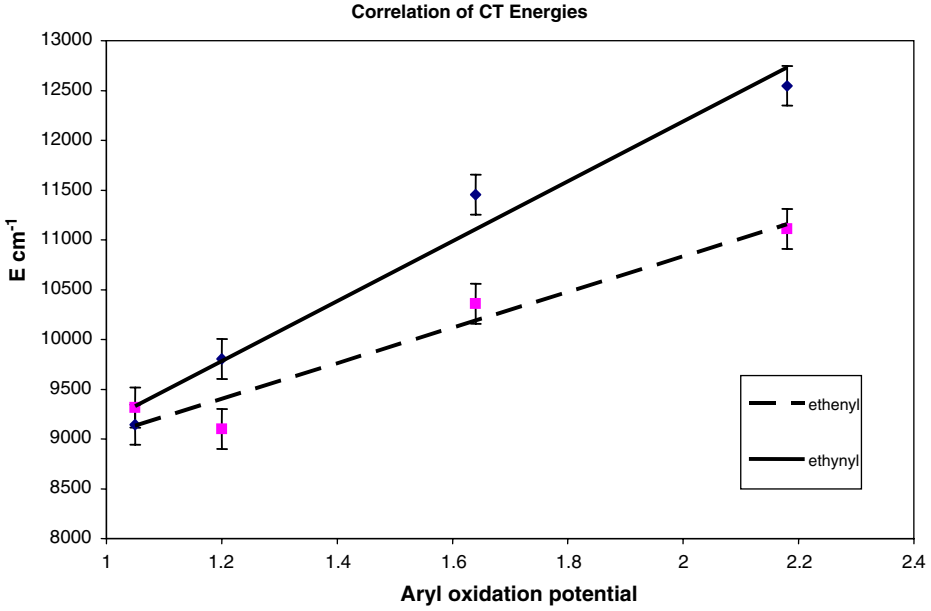

Fig. 4. Correlation of CT energies with oxidation potential of aryl group; CH_2Cl_2.

New bands in the OTTLE UV–Vis spectra above 22 000 cm^{-1} were generally shoulders on the intense aryl transitions and were not studied in detail nor were the weak transitions which were observed (Fig. 3) from 20 000 cm^{-1} to the LMCT band. The energy of some was dependent on the annelation of the ring and were solvatochromatic. Of greatest interest were the weak bands at ~17 200 cm^{-1} the energy of which varied little with aryl and were not solvatochromic (Table 2). These weak bands are assigned to HOMO–LUMO transitions (Fig. 5) but because both energy levels have considerable aryl character they cannot be described as spin-allowed d–d transitions as is the case for FcH^+ [1,21,22,24]. The calculated HOMO–LUMO gap for the 17e species is significantly smaller than for the corresponding 18e, consistent with the lower energy for the HOMO–LUMO transition in the 17e species.

4. Conclusion

Perturbation of a ferrocenyl moiety by an unsaturated RC_2 or RC_4 (R = aryl) group leads to an increase in the energy of the ferrocenyl π bonding orbitals such that the frontier orbital configuration for both 17e and 18e species has the dyad π orbitals at HOMO and HOMO − 2. The relative importance of the aryl contribution to the π orbitals is dependent on the ionization potential of the –C≡CR group and the HOMO has a significant aryl contribution with large annelated rings. Both the HOMO and HOMO − 2 provide a delocalised system for communication between the ferrocenyl and aryl groups but the experimental data suggest that there is not a strong π interaction in the ground state. Low-energy LMCT are ubiquitous in 17e $(metallocenyl)^+$-C_nR systems; R is a formal π donor and includes aromatic derivatives such as naphthalimide [13] generally regarded as acceptors. A wide range of metallocenyl groups, e.g. η-$C_5H_4Ni(PPh_3)$ [25], η-$C_5H_4Co(Ph_4C_4)$ [26] can be involved. As the LMCT energies range from 12 500 to 4000 cm^{-1} these systems represent a tunable electrochromic series. The challenge is to increase the intensity of the LMCT bands.

5. Experimental

The synthesis and characterisation of the compounds discussed herein have been published elsewhere [16]. *Calculations:* All *ab initio* calculations were performed using the B3LYP hybrid density functional theory with a 6-31G(d) basis set. All calculations were run within Spartan '02 and then QChem quantum module. The unrestricted B3LYP was used for calculations on the non-18 electron systems. *Spectroelectrochemistry:* Cyclic and square wave voltammetry in CH_2Cl_2 were performed for all compounds using a three-electrode cell with a polished disk, Pt (2.27 mm^2) as the working electrode; solutions were ~10^{-3} M in electroactive material and 0.10 M in supporting electrolyte (triply recrystallised $TBAPF_6$). Data were recorded on an EG&G PAR 273A computer-controlled potentiostat. Scan rates of 0.05–1 V s^{-1} were typically employed for cyclic voltammetry and for Osteryoung square-wave voltammetry, square-wave step heights of 1–5 mV, a square amplitude of 15–25 mV with a frequency of 30–240 Hz. All potentials are referenced to decamethylferrocene; $E_{1/2}$ for sublimed ferrocene was 0.55 V. EPR spectra were obtained using a Bruker EMX X-band spectrometer equipped with a Bruker variable temperature accessory, a Systron-Donner microwave frequency counter and a Bruker gaussmeter; ca 5 mM THF/$TBAPF_6$ solutions of the compound were reduced electrochemically *in situ*.

Abstract

Neutron irradiation of Cp_2MoCl_2 for 24 h afforded the radiotracer $Cp_2{}^{99}MoCl_2$ which was characterised by UV–Vis spectroscopy and thin layer chromatography. Binding experiments with the thiol containing protein human serum albumin (HSA) or calf thymus DNA, were monitored for ^{99}Mo using a gamma counter. Under the conditions investigated, molar ratios of binding of 0.2:1 (Cp_2MoCl_2:DNA) and 9.4:1 (Cp_2MoCl_2:HSA) were calculated. The results are consistent with in vitro coordination studies that have shown strong preferential interaction of Cp_2MoCl_2 with thiols versus other donor sites in biomolecules including DNA.

1. Introduction

The development of new inorganic and organometallic complexes that interact with DNA and other biomolecules in a different way to cisplatin is an important goal in current medicinal chemistry [1–3]. A number of metallocene dihalides (Cp_2MCl_2, M = Ti, V, Mo, Nb) have provided promising lead compounds [4–6], notably titanocene dichloride, which completed phase II clinical trials [7,8]. While the mechanism of antitumor action of titanocene dichloride is not fully understood, current evidence suggests that the Cp ligands serve as hydrophobic ligands that protect the metal centre by allowing hydrolytic release of Ti into the vacant Fe binding sites of transferrin [9] which delivers the active metal species into the cell and the chromatin [10–12]. In contrast, molybdocene dichloride does not target transferrin as the Cp ligands in Cp_2MoCl_2 are stable to hydrolysis at physiological pH [13–15] (Fig. 1). This complex exhibits a different profile of biological activity to Cp_2MCl_2 (M = Ti, V, Nb) [4,16] and a number of studies have shown that, despite their structural similarity, each of the metallocene dihalides exhibits different bioinorganic chemistry [17,18].

We have performed detailed studies on the bioorganometallic chemistry of molybdocene dichloride in order to provide insight into the mechanism of antitumor action and to aid in the design of second generation derivatives that may have improved biological activity [18–24]. These studies have demonstrated that biological activity is dependent on generation of "Cp_2Mo^{2+}" as the putative active species in vivo [20] which rapidly and irreversibly coordinates with deprotonated thiols in preference to N-donor, O-donor and phosphate binding sites in DNA and proteins [21]. A number of thiol derivatives, $Cp_2Mo(SR_2)$, designed to maximize cell uptake and release the active species, were prepared and tested for activity [20]. Graphite furnace atomic absorption spectroscopy (GFAAS) [20] and X-ray fluorescence (XRF) studies [22] were used to study the uptake and cellular distribution of Mo derived from these

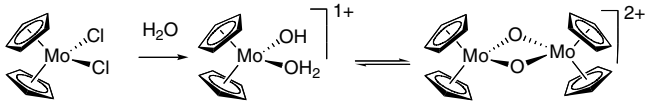

Fig. 1. Aqueous chemistry of molybdocene dichloride. The general formula $Cp_2MoCl_{2(aq)}$ is used as the relative amounts of aquated monomer and dimer and the exact species present in each solution depends on the concentration, salt and ionic strength.

complexes in V79 Chinese hamster lung cells. While the results were consistent with Mo being distributed fairly uniformly throughout the cells including in the nucleus, the sensitivity of the X-ray fluorescence images did not allow accumulation of Mo in specific organelles to be determined, or allow conclusions to be made regarding whether Mo targeted nuclear proteins or nucleic acids within the nucleus.

In this paper, the potential of radiotracer techniques for studying the interactions of $Cp_2{}^{99}MoCl_2$ with biomolecules was assessed by performing studies with calf thymus DNA and HSA. These biomolecules were chosen to parallel previous studies of Mo using GFAAS and inductively coupled plasma mass spectrometry (ICP-MS) [20,25,26]. While the preparation of the radioactive form of Cp_2MoCl_2 has been reported [27], there have been no applications of this chemistry in biological studies. The results with isolated biomolecules demonstrate that the use of radiotracers for monitoring the cellular distribution of Cp_2MoCl_2 warrants further study and has potential to providing new mechanistic information on molybdocenes.

2. Results

2.1. Characterisation of $Cp_2{}^{99}MoCl_2$

^{99}Mo has a half life of 65.94 h and decays predominantly to ^{99m}Tc ($t_{1/2} = 6.02$ h) as illustrated by Fig. 2a. The radiotracer $Cp_2{}^{99}MoCl_2$ was prepared by neutron irradiation of Cp_2MoCl_2 for 24 h. The gamma spectrum of the irradiated product in buffer showed there were no significant contaminating radionuclides (Fig. 2b). Characterisation of the radiotracer was required to ensure that structural integrity was maintained and to ensure that neutron irradiation and subsequent radioactive decay reactions had not led to the breakage of bonds.

TLC analysis of the radiotracer, $Cp_2{}^{99}MoCl_2$, showed a strong aromatic chromophore that fluoresced at 254 nm, consistent with aromatic cyclopentadienyl rings and an intact Cp–Mo bond. Degradation of Cp–Mo bonds leading to the formation of free cyclopentadiene would result in the absence, or significant reduction, of the aromatic chromophore.

Comparison of the UV spectra of buffered solutions of the resultant $Cp_2{}^{99}MoCl_{2(aq)}$ and control $Cp_2MoCl_{2(aq)}$ gave similar results, taking into account slight differences that result in the UV spectrum due to the concentration dependent monomer–dimer equilibrium [14,15] (Fig. 1). A standard curve of the $Cp_2MoCl_{2(aq)}$ concentration versus

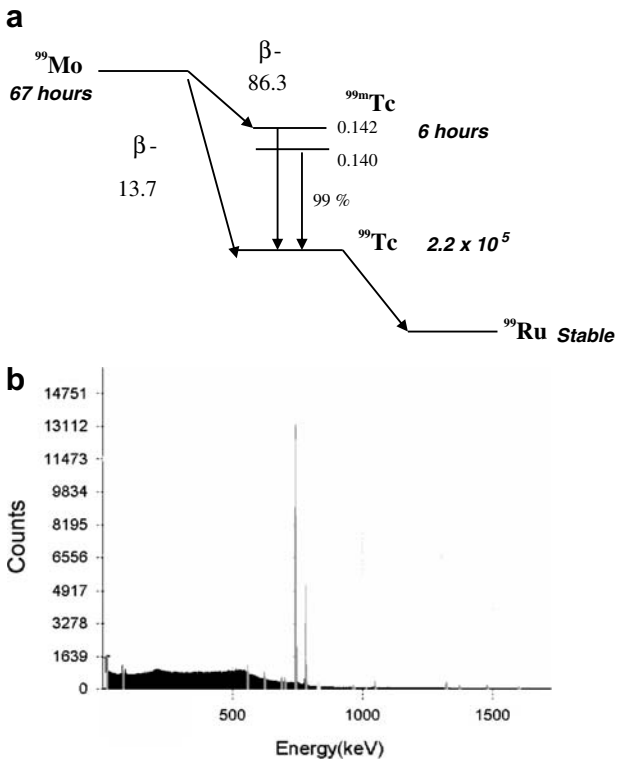

Fig. 2. (a) Decay scheme for ^{99}Mo. (b) Gamma spectrum of irradiated Cp_2MoCl_2 showing ^{99}Mo peak at 739.5 and 788 keV emissions (^{99m}Tc emission was shielded using a thin wall lead container).

UV absorption at 210 nm was generated and used to determine the concentration of $Cp_2{}^{99}MoCl_2$ in the $Cp_2{}^{99}MoCl_{2(aq)}$ solutions added to the HSA and DNA samples.

2.2. Binding studies of $Cp_2{}^{99}MoCl_2$ with HSA versus DNA

The results of binding studies of $Cp_2{}^{99}MoCl_2$ with HSA or DNA for 3 h are shown in Fig. 3. The results, reported as nmol of bound Cp_2MoCl_2, show that despite much higher concentrations of DNA, there is significantly more binding of Cp_2MoCl_2 to HSA than to DNA. There was no non-specific binding to DNA at $t = 0$ and with the exception of the data point that represents 18.75 nmol, binding to DNA increased with concentration and to a lesser extent, with incubation time. All errors were within 10%, with the exception of the 18.75 nmol sample of DNA at $t = 0.5$, which was attributed to experimental error.

In the case of HSA, a high degree of non-specific binding was present at all concentrations of HSA, as shown by binding at $t = 0$ (Fig. 3). HSA binding peaked at $t = 0.5$ h for most concentrations with a maximum binding of 102 nmol of Cp_2MoCl_2. In contrast, after 3 h incubation, maximum binding of Cp_2MoCl_2 was reached at only 1 nmol of HSA. The precipitation of protein at lower concentrations may not be as efficient as precipitation at higher concentrations where nucleation of small amounts of precipitate assists in extensive precipitation of the rest of the protein, and also aids in the formation of a tight pellet during centrifugation. For these reasons, the results from the highest

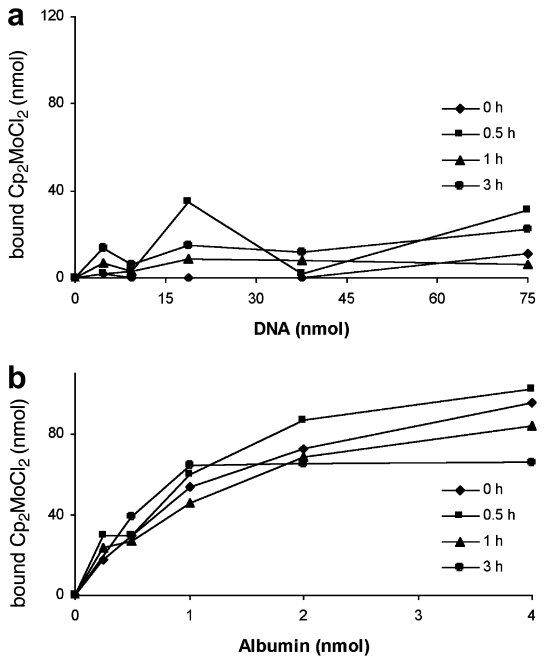

Fig. 3. Comparison of moles of $Cp_2{}^{99}MoCl_2$ bound to (a) DNA and (b) HSA over time at 37 °C. The concentration of Cp_2MoCl_2 in the reaction mixture was 298 nmol.

concentrations of HSA and DNA, were considered to be the most reliable data to illustrate the Mo binding trends.

Under the conditions investigated, molar ratios of binding of 0.2:1 (Cp_2MoCl_2:DNA) and 9.4:1 (Cp_2MoCl_2:HSA) were calculated. These ratios demonstrate that DNA binding is extremely low in comparison to HSA. Immediate, non-specific binding to HSA is followed by a small increase at $t = 0.5$ h, after which binding decreases by approximately 29 nmol, equivalent to 10%, over 3 h.

3. Discussion

Definitive tests that monitor the localisation of metal ions derived from metal based drugs in vivo are essential tools for mapping the uptake and distribution of drugs in cells and hence providing insight into the mechanism(s) of antitumor activity. In the case of Cp_2MCl_2 (M = Ti, V, Nb), a number of these techniques including GFAAS, ICP-MS, atomic emission spectroscopy, and electron energy loss spectroscopy have been used to study binding with biomolecules and cell update [20,22,25,26,28]. The use of radiolabelled metal complexes offers a potentially rapid, convenient and highly sensitive method of determining the binding of metals to biomolecules and monitoring their cellular distribution.

While the preparation and characterisation of radioactive Cp_2MoCl_2 has been reported [27] previously, to our knowledge the radiotracer has not been used in any applications to date. It was reported that the technetium-99 m daughter product $Cp_2{}^{99m}TcCl_2$ that resulted from decay to the ^{99}Mo retained the molecular structure of the parent complex. Any evidence of decomposition products were the direct result of 'shake-off' process rather than the beta decay. In the present study only the behaviour of the $Cp_2{}^{99}MoCl_2$ species was monitored.

The subcellular localisation of molybdenum is an important step in determining the molecular targets of molybdocene dichloride. While XRF studies have shown that Mo does enter the nucleus [22], we have hypothesised that Mo observed in the nucleus is associated with nuclear proteins, and not nucleic acids [22,24]. We have also highlighted the need for additional assays that distinguish between DNA damage and tubulin damage as related to the genotoxicity of molybdocene dichloride [24].

The binding studies (Fig. 3) showed clear preferential interaction of $Cp_2MoCl_{2(aq)}$ with HSA versus DNA, a result that correlates well with recently reported ICP-MS results that showed <5% binding of $Cp_2MoCl_{2(aq)}$ to DNA [26]. These results with isolated biomolecules also agree with our NMR studies with oligonucleotides and amino acids that show clear preferential coordination to deprotonated thiols under physiological conditions [21,29] and show no evidence for hydrolysis of the Cp ligands. The internal consistency between the results of this study and independent studies with other techniques, strongly suggests that further application of the assay to studies with cancer cells and the analysis of specific organelles and subcellular fractions, will provide informative data on the localisation of Mo derived from $Cp_2MoCl_{2(aq)}$ within cancer cells.

4. Conclusions

A direct measure of the Mo content in samples from gamma emissions of Mo-99 showed minimal association between $Cp_2{}^{99}MoCl_{2(aq)}$ and calf thymus DNA. In contrast, significantly higher binding to HSA, a protein with a free cysteine thiol group, was detected. These results are consistent with in vitro coordination studies that have demonstrated formation of irreversible adducts between $Cp_2MoCl_{2(aq)}$ with deprotonated thiols compared with other donor sites present in DNA and proteins.

While handling radioactive material requires access to a suitable laboratory, the binding studies of $Cp_2MoCl_{2(aq)}$ with DNA and HSA have demonstrated that this technique offers significant potential for the analysis of subcellular fractions such as mitochondria and other organelles at a higher sensitivity and improved time-scale compared with the measurement of metal concentrations in cell samples using traditional techniques such as GFAAS and ICP-MS. This methodology would allow the uptake and distribution of molybdocene dichloride in different cancer cell types to be monitored, and may also yield invaluable information on the pharmacology of the complex in vivo.

5. Experimental

5.1. Materials

Cp_2MoCl_2 was purchased from the Sigma–Aldrich Chemical Company and used as provided. All solutions

were prepared by sonication in sterile Milli-Q water, phosphate buffered saline (PBS, pH 7.4, 0.172 M, Oxoid) or 0.1 M Tris–HCl/10 mM NaCl buffer (pH 7.4), as specified.

5.2. Preparation of molybdocene dichloride radiotracer

Cp_2MoCl_2 (~50 mg) was irradiated in a thermal neutron flux of 1×10^{13} n cm^{-2} s^{-1} for 24 h in the High Flux Australian Reactor at the Australian Nuclear Science and Technology Organization. At the end of bombardment, the irradiated sample was left to decay for 9 h to eliminate any short-lived high energy gamma emitting radioisotopes. $Cp_2{}^{99}MoCl_2$ was sonicated in buffer (6 mL) for 2 h and the resultant dark maroon solution was filtered (0.2 μm, Millipore). The radioisotopic purity of $Cp_2{}^{99}MoCl_2$ was assessed by gamma spectrometry. Radioactivity measurements were performed on a Perkin–Elmer/Wallac 1480 gamma counter equipped with a thallium activated sodium iodide detector. The 739.5 and 778 keV gamma emission was monitored over the range 710–750 keV on the gamma counter as it represented a unique signal of ^{99}Mo in the region. The UV spectra of the irradiated sample (diluted with buffer 1:100 and 1:1000) were compared to spectra of Cp_2MoCl_2 (10–100 μM). The concentration of Cp_2MoCl_2 in the solution of irradiated $Cp_2{}^{99}MoCl_2$ was determined from a standard curve of Cp_2MoCl_2 at 210 nm. TLC of Cp_2MoCl_2 and $Cp_2{}^{99}MoCl_2$ dissolved in buffer were performed on F_{254} silica plates (Merck) (chloroform:methanol:ammonia, 80:18:2).

5.3. Radiotracer binding studies of $Cp_2{}^{99}MoCl_2$ with DNA or proteins

Stock solutions of human serum albumin (HSA) (0.15 mM, Tris–HCl) and calf thymus DNA (2.5 mM, Tris–HCl) were prepared. The purity of the DNA solution was determined from the $A_{260\,nm}/A_{280\,nm}$ ratio (1.85) and the concentration determined using the absorbance value $A_{260\,nm}$, ($\sum = 6600$ M^{-1} cm^{-1}). Stock solutions were serially diluted with buffer 1:2, to produce DNA solutions of 36, 18, 9, 4.5 and 2.25 mg/mL and HSA solutions of 0.30, 0.15, 0.075, 0.038 and 0.019 mg/mL. Each of these solutions (30 μL) (in quadruplicate) was diluted with buffer (30 μL) in low-protein binding micro centrifuge tubes and stored at 4 °C. An aliquot of the irradiated metallocene in buffer (20 μL) was added to each of the DNA and HSA solutions which were then vortexed and incubated at 37 °C. After set intervals ($t = 0$, 1 and 3 h) the DNA or HSA was precipitated by the addition of ammonium acetate (50 μL, 3 M) and ethanol (1 mL). The suspension was centrifuged (14000 rpm, 5 min) and aliquots (100 μL × 3) of the supernatant were removed and monitored for ^{99}Mo using a gamma counter. Radioactive standards were prepared in an identical manner, except that buffer was substituted for DNA or HSA solutions. The portion of $Cp_2{}^{99}MoCl_2$ associated with the DNA or the protein precipitate for each time interval was determined by the following equation

$$R_P = \frac{R_S \text{ at } T_0 - R_S \text{ at } T_X}{R_S \text{ at } T_0} \quad (1)$$

where R_S is the $Cp_2{}^{99}MoCl_2$ counts in solution, R_P is $Cp_2{}^{99}MoCl_2$ counts in pellet, T_0 is time zero and T_X is time at varying time intervals. The $Cp_2{}^{99}MoCl_2$ counts were correlated with the concentration of Cp_2MoCl_2 in solution (determined by UV spectroscopy) and hence the moles of Cp_2MoCl_2 associated with the protein or DNA were calculated.

Abstract

The synthesis of two ligands, L^1 and L^2, each containing two 2-oxy-1,10-phenanthroline moieties attached to the same phosphorus atom of a substituted cyclotriphosphazene ring via an oxy-bridge, but differing in substitution on the biphenyl capping groups, is described. The single-crystal X-ray structure of $L^1 \cdot 2CH_2Cl_2$ shows an ordered structure in the lattice with channels, containing dichloromethane molecules, running parallel to the *a*-axis. The reactions of L^1 and L^2 with $[Cu(MeCN)_4](PF_6)$ afford the dimetallic copper(I) derivatives, $[(CuL^1)_2](PF_6)_2 \cdot CH_2Cl_2$ and $[(CuL^2)_2](PF_6)_2$. The single-crystal X-ray structure of the former complex shows that the L^1 ligands of the cation $[(CuL^1)_2]^{2+}$ act as a bridges coordinating to the two copper(I) centres in a helical fashion. The copper atoms have distorted tetrahedral geometries with the interligand dihedral angle being 85°. With copper(II) chloride and copper(II) perchlorate, the monomeric copper(II) complexes, $[CuL^1Cl]Cl \cdot 2CH_2Cl_2$, $[CuL^2Cl]Cl \cdot CH_2Cl_2$, $[CuL^1(OMe)]PF_6 \cdot 2H_2O$, $[CuL^2(OMe)]PF_6 \cdot 2H_2O$, $[CuL^1(OH_2)](ClO_4)_2$ and $[CuL^2(OH_2)](ClO_4)_2 \cdot H_2O$ are obtained. The single-crystal X-ray structure of $[CuL^1Cl]Cl \cdot 2CH_2Cl_2$ shows the copper to be in a square-base pyramidal distorted trigonal-bipyramidal (SBPDTB) environment ($\tau = 0.57$) with L^1 acting as a κ^4N donor, coordinating via the four nitrogen atoms of the two tethered 1,10-phenanthrolines. In CH_3CN, this complex undergoes hydrolysis via the presence of adventitious water losing one oxyphenanthroline arm to form the centrosymmetric dimetallic species, $[(CuL^3Cl)_2] \cdot 4CH_3CN \cdot 3H_2O$ ($L^3 = [N_3P_3(biph)_2(ophen)O]^-$ where biph = 2,2′-dioxybiphenyl and O replaces an oxyphenanthroline and is attached to the phosphorus of the phosphazene ring). The two monomeric units, which are linked by bridging chlorine atoms, have a distorted square-based pyramidal geometry about the copper with the basal plane made by the 'ON_2Cl' ligand set. Spectroscopic (mass spectral, electronic and ESR) and magnetic moment data for the complexes are discussed.

1. Introduction

The ability of cyclotriphosphosphazenes to engage in coordination to transition metals is a developing area of interest [1] and a great variety of complexes can be attained by attaching different pendant donor groups to the phosphazene skeleton. For example, we have placed 2-oxypyridine groups onto the cyclotriphosphazene skeleton, hence demonstrating that *hexakis*(2-pyridyloxy)cyclotriphosphazene is a versatile multimodal ligand which displays a range of coordination modes such as uni-, bi-, tri-, tetra- and pentadentate [2–5]. Others have attached six [6], four [7,8] and two [9] 3,5-dimethylpyrazolyl groups to the cyclophosphazene ring and the predominant mode of binding is *non-gem*-κ^3N tridentate, using one phosphazene ring nitrogen while the hexa-substituted cyclotriphosphazene samarium complex displays the *gem*-κ^3N_5 mode [10].

The coordination chemistry of cyclic phosphazenes that contain polydentate ligand moieties is less established.

doi:10.1016/j.poly.2006.07.007

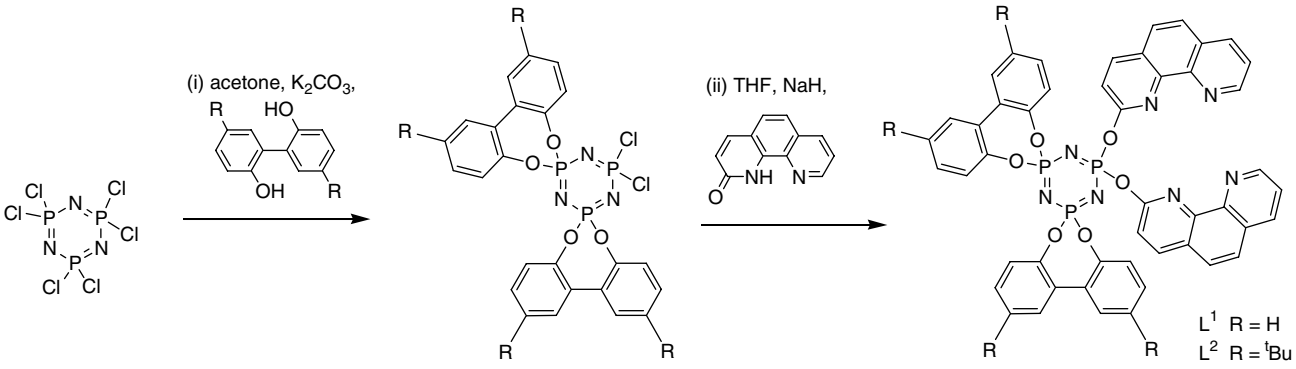
Several phosphazene ligand systems based on 2-pyridylalkylamines have been prepared [11–18] that demonstrate coordination modes using various combinations of amine, pyridine and ring nitrogens. More recently, a lanthanum complex prepared from a phosphazene containing two pyrazolylpyridine ligands was reported [19].

There has been interest in ligands containing two 2,2′-bipyridine or 1,10-phenanthroline units linked at their ortho carbon atoms by linkers such as $–CH_2OCH_2–$ [20–22], $–CH_2CH_2–$ [23,24] or $–OCH_2CH(NH_2)CH_2O–$ and related bridges [25]. Their copper(II) and copper(I) complexes have been explored because of their interesting redox behaviour, luminescence properties, ability to form double-helicates and, in the presence of hydrogen peroxide, ability to mediate the single-strand cleavage of double-stranded DNA by oxidative attacks at C-1′ and C-4′ of 2-deoxyribose units. By tethering phenanthrolines to a cyclotriphosphazene platform and by investigating their coordinating properties towards copper, we can extend these previous studies. The phenanthroline substitutions would be expected to lead to conformational rigidity in these chelating systems.

Hence we have synthesised cyclotriphosphazene ligands containing two 2-oxyphenanthroline (ophen) moieties, which are attached to the same phosphorus atom via the oxy-bridge, effectively producing an OPO bridged bis-phenanthroline ligand. The remaining two ring phosphorus atoms are blocked with 5,5′-di-*tert*-butyl-2,2′-dioxybiphenyl (^{t}Bubiph) or 2,2′-dioxybiphenyl (biph) groups giving the new ligands $[N_3P_3(biph)_2(ophen)_2]$ and $[N_3P_3(^tBubiph)_2(ophen)_2]$ (L^1 and L^2, Scheme 1).

In this paper we examine the coordinating behaviour of these new ligands with copper(I) and (II) and compare their behaviour with the un-hinged diimine counterparts. Whether this ligand type forms a double helicate structure with copper(I) and copper(II), and whether the tethered phenanthroline moieties give more strained structures, and hence are more reactive will be addressed. These studies may also provide model systems for the interaction of copper ions with the phenanthroline-substituted linear-chain polymeric phosphazenes, in the quest for new metal-rich materials.

2. Experimental



2.1. Materials and instrumentation

Analytical grade solvents were used without further purification with the exception of tetrahydrofuran (THF), which was distilled from sodium/benzophenone. $CuCl_2 \cdot xH_2O$ was dehydrated at 140 °C before use, $Cu(ClO_4)_2 \cdot 6H_2O$, $Cu(CH_3COO)_2 \cdot H_2O$, $NaPF_6$ and $[N_3P_3Cl_6]$ were used as supplied. 2-Methoxy-1,10-phenanthroline [26] was prepared from 2-chloro-1,10-phenanthroline [27] and demethylated [28] to give 2-hydroxy-1,10-phenanthroline (HOphen). 5,5′-Di-*tert*-butyl-2,2′-dihydroxybiphenyl (^{t}BubiphH$_2$) [29], $[N_3P_3(biph)_2Cl_2]$ [30] and $[Cu(MeCN)_4]PF_6$ [31] were prepared according to literature procedures. All manipulations were carried out under nitrogen using standard Schlenk techniques. Microanalyses were performed by the Campbell Microanalytical Laboratory, University of Otago. NMR spectra were recorded on a Bruker Avance A400 spectrometer; ^{1}H data were referenced internally to TMS; $^{31}P\{^1H\}$ data were referenced to an external sample of 85% aqueous H_3PO_4. IR spectra were run as KBr discs on a Perkin–Elmer FT-IR Paragon 1000 spectrometer and electronic absorption spectra were recorded using a Shimadzu UV-310-310PC scanning spectrometer. Electrospray mass spectra were obtained from MeCN solutions on a Micromass ZMD spectrometer run in positive ion mode. Listed peaks correspond to the most abundant isotopomer; assignments were made by a comparison of observed and simulated spectra. Magnetic susceptibility measurements were performed on a Faraday balance at room temperature. X-band EPR spectra were recorded at 113 K on a Varian E-104A spectrometer equipped with a E-257 variable-temperature controller and operating at about 9.0 GHz. The spectral g values were calibrated with (diphenylpicryl)hydrazyl (DPPH) as a standard.

2.2. Ligand syntheses

2.2.1. $[N_3P_3(^tBubiph)_2Cl_2]$

To a solution of ^{t}BubiphH$_2$ (859 mg, 2.9 mmol) in acetone (15 mL), cooled to 0 °C, was added K_2CO_3 (1 g, 7.2 mmol)

Scheme 1. Syntheses of L^1 and L^2.

and $[P_3N_3Cl_6]$ (500 mg, 1.4 mmol). The mixture was stirred at room temperature for 2 h and then taken to dryness on a rotary evaporator. The residue was extracted with CH_2Cl_2 (125 mL) and taken to dryness to give a white solid. Recrystallisation from CH_2Cl_2/hexane afforded analytically pure material. Yield: 522 mg (45%). ^{31}P NMR ($CDCl_3$): δ 30.3 (t, P, $J_{PP} = 79$ Hz), 20.6 (d, 2P, $J_{PP} = 78$ Hz). ^1H NMR ($CDCl_3$): δ 7.52 – 7.46 (m, 8H), 7.26 (s, 4H), 1.37 (s, 36H). IR ν_{max} (cm^{-1}): 1254, 1232, 1203, 1188. *Anal.* Required for $C_{40}H_{48}Cl_2N_3O_4P_3$: C, 60.15; H, 6.06; N, 5.26. Found: C, 60.40; H, 6.22; N, 5.30%.

2.2.2. $[N_3P_3(biph)_2(ophen)_2] \cdot CH_2Cl_2$ ($L^1 \cdot CH_2Cl_2$)

To a solution of HOphen (310 mg, 1.5 mmol) in THF (60 mL), NaH (63 mg of a 60% dispersion in oil, 1.6 mmol NaH) was added. The mixture was allowed to stir at room temperature for 3 h, during which time a white precipitate of NaOphen developed. $[N_3P_3(biph)_2Cl_2]$ (430 mg, 0.75 mmol) was added and the mixture was heated at reflux over 20 h. The crude reaction mixture was filtered through Celite and the filtrate was discarded. The Celite pad was washed well with CH_2Cl_2 and the washings were taken to dryness on a rotary evaporator to give the crude phosphazene. Recrystallisation from CH_2Cl_2/hexane affords the solvated material, which was then dried under vacuum. Yield 380 mg (55%). ^{31}P NMR ($CDCl_3$): δ 25.39 (d, 2P, $J_{PP} = 99$ Hz), 7.66 (t, P, $J_{PP} = 99$ Hz). ^1H NMR ($CDCl_3$): δ 9.20 (dd, 2H, Ophen H^{11}), 8.33 (d, 2H, Ophen H^4), 8.24 (dd, 2H, Ophen H^9), 8.09 (d, 2H, Ophen H^3), 7.77 (m, 4H, Ophen H^6 and H^7), 7.62 (dd, 2H, Ophen H^{10}), 7.44 (m, 4H, biphenyl), 7.31–7.17 (m, 12H, biphenyl). IR ν_{max} (cm^{-1}): 1230, 1174. *m/z* (ESMS): 894 $[MH]^+$. *Anal.* Required for $C_{49}H_{32}Cl_2N_7O_6P_3$: C, 60.14; H, 3.30; N, 10.02. Found: C, 60.12; H, 3.28; N, 9.97%. Crystals of $L^1 \cdot 2CH_2Cl_2$ suitable for X-ray diffraction were grown from a CH_2Cl_2/hexane solution of the ligand.

2.2.3. $[N_3P_3(^tBubiph)_2(ophen)_2] \cdot CHCl_3$ ($L^2 \cdot CHCl_3$)

To a solution of HOphen (600 mg, 3.1 mmol) in THF (60 mL), NaH (122 mg of a 60% dispersion in oil, 3.1 mmol NaH) was added. The mixture was allowed to stir at room temperature for 3 h, during which time a white precipitate of NaOphen developed. $[N_3P_3(^tBubiph)_2Cl_2]$ (1200 mg, 1.5 mmol) was added and the mixture was heated at reflux over 20 h. The mixture was filtered through Celite and the THF removed from the filtrate on a rotary evaporator. Chromatography on alumina using CH_2Cl_2/MeOH (96:4) as eluent yields a spectroscopically clean fraction of L^2. Yield: 1000 mg (58%). An analytical sample of $L^1 \cdot CHCl_3$ was obtained by vapour diffusion of pentane into a $CHCl_3$ solution of the phosphazene. ^{31}P NMR ($CDCl_3$): δ 25.32 (d, 2P, $J_{PP} = 97$ Hz), 7.80 (t, P, $J_{PP} = 97$ Hz). ^1H NMR ($CDCl_3$): δ 9.20 (dd, 2H, Ophen H^{11}), 8.33 (d, 2H, Ophen H^4), 8.24 (dd, 2H, Ophen H^9), 8.12 (d, 2H, Ophen H^3), 7.77 (m, 4H, Ophen H^6 and H^7), 7.62 (dd, 2H, Ophen H^{10}), 7.40 (m, 4H, biphenyl), 7.19 – 7.13 (m, 8H, biphenyl), 1.30 (s, 36H, ^{t}Butyl). ν_{max} (cm^{-1}): 1230, 1182. *m/z* (ESMS): 1118 $[MH^+]$. *Anal.* Required for $C_{65}H_{63}Cl_3N_7O_6P_3$: C, 63.09; H, 5.13; N, 7.92. Found: C, 63.18; H, 4.95; N, 7.97%.

2.3. Complex syntheses

2.3.1. $[(CuL^1)_2](PF_6)_2 \cdot CH_2Cl_2$ (**1** $\cdot CH_2Cl_2$)

To a solution of L^1 (90 mg, 0.1 mmol) in CH_2Cl_2 (6 mL) was added $[Cu(MeCN)_4]PF_6$ (40 mg, 0.1 mmol) dissolved in CH_2Cl_2 (6 mL). The solution was allowed to stir at room temperature for 1 h. Hexane was added to produce an orange precipitate that was collected by filtration and dried under vacuum. Yield: 87 mg (74%). ^{31}P NMR (CD_3CN): δ 25.36 (d, 2P, $J_{PP} = 96$ Hz), 7.40 (t, P, $J_{PP} = 96$ Hz), −143.38 (sept, P, $J_{PF} = 706$ Hz). IR ν_{max} (cm^{-1}): 1227(s), 1175(vs). *m/z* (ESMS): 956 $[CuL^1]^+$. *Anal.* Required for $C_{49}H_{32}Cl_2CuF_6N_7O_6P_4$: C, 49.57; H, 2.72; N, 8.26. Found: C, 49.87; H, 2.75; N, 8.34%. Crystals of **1** $\cdot 6CH_2Cl_2$ suitable for X-ray diffraction were grown from the slow evaporation of a CH_2Cl_2/hexane solution of the complex.

2.3.2. $[(CuL^2)_2](PF_6)_2$ (**2**)

To a solution of L^2 (112 mg, 0.1 mmol) in CH_2Cl_2 (10 mL) was added $[Cu(MeCN)_4]PF_6$ (47 mg, 0.1 mmol) dissolved in CH_2Cl_2 (10 mL). The solution was allowed to stir at room temperature for 20 min. Hexane was added to produce an orange precipitate that was collected by filtration and air dried. Yield 108 mg (82%). A purple microcrystalline analytically pure sample was prepared by vapour diffusion of diethylether into an acetonitrile solution of the complex. ^{31}P NMR ($CDCl_3$): δ 24.84 (d, P, $J_{PP} = 96$ Hz), 5.21 (d, P, $J_{PP} = 96$ Hz), −142.43 (sept, P, $J_{PF} = 712$ Hz). *m/z* (ESMS): 1180 $[CuL^2]^+$. IR ν_{max} (cm^{-1}): 1228(s), 1182(vs). *Anal.* Required for $C_{64}H_{62}CuF_6N_7O_6P_4$: C, 57.94; H, 4.71; N, 7.39. Found: C, 57.83, H, 4.56; N, 7.27%.

2.3.3. $[CuL^1Cl]Cl \cdot 2CH_2Cl_2$ (**3** $\cdot 2CH_2Cl_2$)

To a solution of L^1 (275 mg, 0.31 mmol) in CH_2Cl_2 (20 mL), $CuCl_2$ (41 mg, 0.3 mmol) was added. The mixture was heated at reflux for 24 h producing a green precipitate that was collected by filtration, washed with CH_2Cl_2, Et_2O and dried under vacuum. Yield 160 mg (43%). IR ν_{max} (cm^{-1}): 1277(s), 1227(s), 1170(vs). *m/z* (ESMS): 991 $[CuL^1Cl]^+$. *Anal.* Required for $C_{50}H_{34}Cl_6CuN_7O_6P_3$: C, 50.13; H, 2.86; N, 8.18. Found: C, 50.37; H, 2.92; N, 8.38%. Crystals of **3** $\cdot 2CH_2Cl_2$ suitable for X-ray diffraction were obtained from CH_2Cl_2. Crystals of **9** $\cdot$ 4MeCN $\cdot 3H_2O$, the hydrolysis product of **3**, were obtained in low yield by dissolving the complex **3** in hot CH_3CN and allowing the solution to stand for 2–3 weeks.

2.3.4. $[CuL^2Cl]Cl \cdot CH_2Cl_2$ (**4** $\cdot CH_2Cl_2$)

To a solution of L^2 (112 mg, 0.1 mmol) in CH_2Cl_2 (20 mL), $CuCl_2$ (13 mg, 0.1 mmol) was added. The mixture was heated at reflux for 24 h producing a green solution that was filtered and reduced in volume by approximately half. Hexane was added and the solution refrigerated

overnight to produce a green precipitate that was collected by filtration and dried under vacuum. Yield 104 mg (78%). *m/z* (ESMS): 1217 $[CuL^2Cl]^+$ IR ν_{max} (cm^{-1}): 1228(s), 1182(vs). *Anal.* Required for $C_{65}H_{64}Cl_4CuN_7O_6P_3$: C, 58.37; H, 4.82; N, 7.33. Found: C, 58.38; H, 4.91; N, 7.34%.

2.3.5. $[CuL^1(OMe)]PF_6 \cdot 2H_2O$ (**5** · $2H_2O$)

A mixture of L^1 (195 mg, 0.22 mmol) and $Cu(MeCOO)_2 \cdot H_2O$ (39 mg, 20 mmol) in MeOH (10 mL) was heated at reflux for 2 h. The turquoise solution was filtered and a solution of $NaPF_6$ in methanol was added to produce a pale turquoise precipitate that was collected by filtration, washed with Et_2O and dried under vacuum. Yield 161 mg (63%). *m/z* (ESMS): 987 $[CuL^1(OMe)]^+$. IR ν_{max} (cm^{-1}): 1227(s), 1193(s), 1172(vs). *Anal*. Required for $C_{49}H_{37}CuF_6N_7O_9P_4$: C, 50.33; H, 3.19; N, 8.39. Found: C, 50.34; H, 2.82; N, 8.35%.

2.3.6. $[CuL^2(OMe)]PF_6 \cdot 2H_2O$ (**6** · $2H_2O$)

A solution of L^2 (120 mg, 0.11 mmol) and $Cu(MeCOO)_2 \cdot H_2O$ (21 mg, 0.11 mmol) in methanol (10 mL) was heated at reflux for 2 h. The turquoise solution was filtered and a solution of $NaPF_6$ in methanol was added to produce a pale turquoise precipitate that was collected by filtration, washed with Et_2O and dried under vacuum. Yield 55 mg (36%). IR ν_{max} (cm^{-1}): 1230(s), 1196(s), 1181(vs). *m/z* (ESMS): 1211 $[CuL^2(OMe)]^+$. *Anal*. Required for $C_{65}H_{69}CuF_6N_7O_9P_4$: C, 56.02; H, 4.99; N, 7.03. Found: C, 56.00; H, 4.81; N, 7.10%.

2.3.7. $[CuL^1(OH_2)](ClO_4)_2$ (**7**)

To a solution of L^1 (46 mg, 0.05 mmol) in CH_2Cl_2 (10 mL), $Cu(ClO_4)_2 \cdot 6H_2O$ (20 mg, 0.05 mmol) was added. The mixture was allowed to stir at room temperature for 4 days during which time a pale green precipitate developed. The precipitate was filtered, washed with Et_2O and air dried. Yield 35 mg (58%). IR ν_{max} (cm^{-1}): 1285(s), 1225(s), 1175(vs). *Anal*. Required for $C_{48}H_{32}Cl_2CuN_7O_{15}P_3$: C, 49.10; H, 2.75; N, 8.35. Found: C, 49.18; H, 2.66; N, 8.31%.

2.3.8. $[CuL^2(OH_2)](ClO_4)_2 \cdot H_2O$ (**8** · H_2O)

To a solution of L^2 (50 mg, 0.045 mmol) in CH_2Cl_2 (10 mL), $Cu(ClO_4)_2 \cdot 6H_2O$ (17 mg, 0.045 mmol) was added. The mixture was allowed to stir at room temperature for 4 days during which time a pale green precipitate developed. The precipitate was filtered, washed with Et_2O and dried under vacuum. Yield 33 mg (52%). IR (cm^{-1}) 1227(s), 1184(vs). *Anal*. Required for $C_{64}H_{66}Cl_2CuN_7O_{16}P_3$: C, 54.26; H, 4.70; N, 6.92. Found: C, 54.15; H, 4.74; N, 6.91%.

2.4. Crystallography

The X-ray data were collected on a Siemens P4 four circle diffractometer, using a Siemens SMART 1 K CCD area detector. The crystals were mounted in an inert oil and irradiated with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) X-rays. The data were collected by the SMART program and processed with SAINT to apply Lorentz and polarisation corrections to the diffraction spots (integrated three dimensionally). Crystal data are given in Table 1. The structures were solved by direct methods and refined using the SHELXTL program [32]. Hydrogen atoms were calculated at ideal positions. Complexes **1** and **3** contained disordered solvent that could not be modelled satisfactorily.

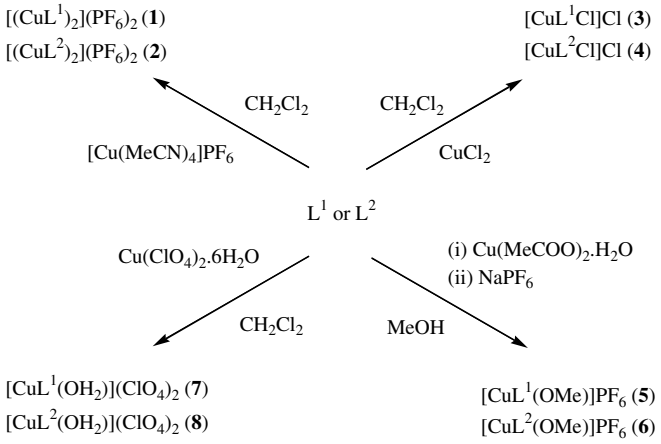
The contributions in each case were removed using PLATON/SQUEEZE [33]. In the case of **3**, the chloride anion is disordered over three positions and a site with low occupancy is in the disordered solvent region. The contribution from this anion was also removed. Complex **1**: 331 electrons per cell corresponding to four CH_2Cl_2 molecules were removed and 1260.8 Å^3 was left by the void. The remaining two solvent molecules were modelled satisfactorily. The reported formula is $\mathbf{1}\cdot 6CH_2Cl_2$. Complex **3**: 109 electrons per cell corresponding to $2CH_2Cl_2$ molecules and one Cl anion per molecule were removed and 521.3 Å^3 was left by the void.

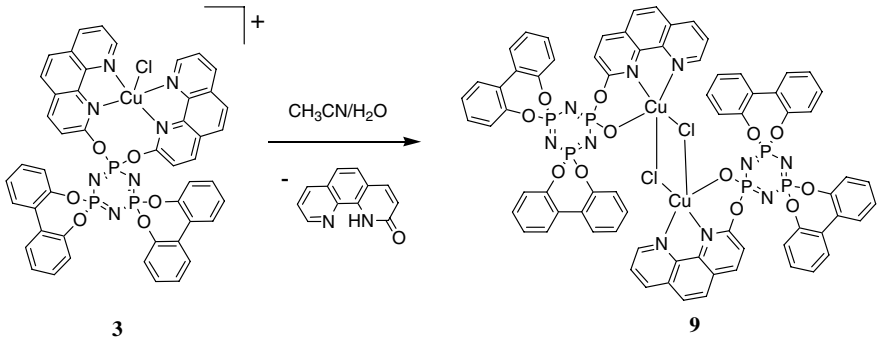


3. Results and discussion

3.1. Ligand syntheses

The bis-spiro derivatives $[N_3P_3(biph)_2Cl_2]$ or $[N_3P_3(^tBubiph)_2Cl_2]$ were reacted with two mole equivalents of the sodium salt of 2-hydroxy-1,10-phenanthroline (Hophen) in THF to give L^1 or L^2, respectively. Analytically pure samples of the ligands were obtained by recrystallisation. The ability of cyclotriphosphazenes with aromatic substituents to entrap solvents and form inclusion compounds is a common feature [34–39] and the ligands remained solvated even after drying under vacuum. The presence of solvent was confirmed by microanalyses and ^{1}H-NMR spectra and for L^1, X-ray crystallography. The ^{31}P NMR spectra for the ligands were, as expected, first order. The resonances for the two equivalent phosphorus atoms with biph or ^{t}Bubiph groups attached were observed as doublets at 23.39 and 25.32 ppm ($^2J_{PP} = 99$ and 97 Hz) while the resonance arising from third phosphorus was observed as a triplet at 7.66 and 7.80 ppm ($^2J_{PP} = 99$ and 97 Hz). The ^{1}H NMR resonances for the phenanthroline moieties were assigned using 2D correlation experiments. For both L^1 and L^2 the *m*/*z* peaks observed under ESMS conditions correspond to the protonated parent ions at 894 and 1118 mass units, respectively.

3.2. Complex syntheses



The reactions of L^1 and L^2 with copper salts reported here are shown in Scheme 2. The helical copper(I) complexes, $[(CuL^1)_2](PF_6)_2$ (**1**) and $[(CuL^2)_2](PF_6)_2$ (**2**), were prepared in high yield by reacting the appropriate ligand with $[Cu(MeCN)_4]PF_6$ at room temperature in CH_2Cl_2. ^{31}P NMR spectra were recorded for **1** and **2** in CD_3CN and $CDCl_3$, respectively, and the expected resonances for the phosphazene and hexafluorophosphate phosphorus atoms are observed (see Section 2). The room temperature ^{1}H NMR spectra of **1** in CD_3CN and **2** in either CD_3CN or $CDCl_3$ exhibit broad, poorly resolved signals. When samples of **1** were prepared in $CDCl_3$ to collect NMR data, a gel formed. The formation of a gel in the chlorinated solvent can be understood in terms of the layered structure (see Section 3.3.2) with its many intermolecular interactions which would persist in the less polar solvent but be broken by the polar acetonitrile molecules as the sample dissolves.

Scheme 2. The reactions of L^1 and L^2 with copper salts.

The ligands L^1 and L^2 react with anhydrous $CuCl_2$ in CH_2Cl_2 to give the copper(II) complexes, $[CuL^1Cl]Cl$ (**3**) and $[CuL^2Cl]Cl$ (**4**). The crystal structure of $\mathbf{3}\cdot 2CH_2Cl_2$ shows the complex to have a square-based pyramidal-distorted trigonal-bipyramidal geometry. When allowed to stand in acetonitrile, complex **3** undergoes hydrolysis (Scheme 3) to form the bimetallic species $[(CuL^3Cl)_2]$ (**9**, $L^3 = [N_3P_3(biph)_2(ophen)O]^-$). Ab initio molecular orbital calculations [40,41] on cyclophosphazene rings show the ring skeleton to be highly polar with a build up of charge density on the nitrogen atoms and nodes at the phosphorus atoms. This is in line with the experimental observation that the more positive phosphorus atoms are the preferred sites for nucleophilic attack [42]. Therefore hydrolysis is likely to occur at the phosphorus atom with a hydroxide ion replacing an oxyphenanthroline pendant group. Proton exchange followed by the formation of the ring oxygen copper(II) bond and dimerization through the two bridging chloro groups would give the final product, **9**. The observation that 2-hydroxy-1,10-phenanthroline is observed in the reaction mixture is consistent with this reaction scheme.

When L^1 or L^2 react with $Cu(MeCOO)_2$ in methanol followed by metathesis with $NaPF_6$, pale turquoise precipitates are formed, the elemental analyses of which are consistent with the formulations $[CuL^1(OMe)]PF_6\cdot 2H_2O$ ($\mathbf{4}\cdot 2H_2O$) and $[CuL^2(OMe)]\ PF_6\cdot 2H_2O$ ($\mathbf{5}\cdot 2H_2O$). In the presence of the acetate ion, the methoxide anion appears to be abstracted from the methanol solution and coordinates to the copper. The $[CuL^1(OMe)]^+$ and $[CuL^2(OMe)]^+$ species are also observed in the electrospray mass spectra and we have observed the formation of the corresponding ethoxide complexes from the reactions in ethanol. Although unusual, the abstraction of alkoxide ions during the reactions of copper acetate in alcohols is not unprecedented. Bimetallic complexes of the form $[Cu_2(bpy)_2(\mu\text{-}OAc)_2(\mu\text{-}OR)]$ (R = Me, Et) from the reaction of copper(II) acetate with bpy have been reported previously [43]. The reactions of L^1

Scheme 3. Hydrolysis of **3** to the dimetallic species **9**.

and L^2 with $Cu(ClO_4)_2 \cdot 6H_2O$ produces the complexes $[CuL^1(OH_2)](ClO_4)_2$ (**7**) and $[CuL^2(OH_2)](ClO_4)_2 \cdot H_2O$ (**8** $\cdot H_2O$). These complexes are obtained cleanly as precipitates from CH_2Cl_2.

3.3. Description of structures

3.3.1. $L^1 \cdot 2CH_2Cl_2$

The single-crystal structure of L^1 is shown in Fig. 1 and selected bond lengths and angles are given in Table 2. The P–N bond lengths [1.578(4)–1.591(4) Å] and both N–P–N and P–N–P angles [117.9(2)–118.11(19)° and 120.9(2)–121.2(3)°, respectively] are typical for cyclotriphosphazenes. The mean deviation of atoms from the plane of the N_3P_3 phosphazene ring is 0.0728 Å and the maximum deviation is 0.112 Å for P(3).

Intermolecular π-stacking interactions between phenanthroline rings are prevalent in the crystalline structure. For example, C(7) lies approximately 3.4 Å from the centre of the C(6)–C(9) bond on an adjacent molecule and the centroid of the fused pyridine ring containing N(4) is ca. 3.5 Å from C(19) of another molecule. The planes of the phenanthroline rings belonging to the same molecule lie at about 52° to one another. A consequence of these geometrical arrangements in the crystal packing is that two structurally distinct regions occur. Two-dimensional layers are generated by the stacked phenanthroline moieties while biphenyl groups on adjacent molecules are involved in π–π and π-H interactions which gives rise to 'back-to-back' layering of the phosphazene rings (Fig. 2). The arrangement creates channels running parallel to the *a*-axis that contain two molecules of dichloromethane per molecule of L^1. Also the nitrogen atoms N(4) and N(5) from one phenanthroline moiety participate in hydrogen bonds in a chelating manner with H(90A) of one of the dichloromethane molecules [N(4)···H(90A) and N(5)···H(90A) are 2.759 and 2.392 Å]. In this, and other work, we have often found it difficult to drive volatile solvents, such as CH_2Cl_2, from solid samples of both our phosphazene ligands and complexes [5]. It is likely that this is due to the persistence of packing motifs and non-covalent interactions such as those just described. The ability of cyclic phosphazenes bearing aromatic substituents to act as clathrates and inclusion compounds is well documented [34–39].

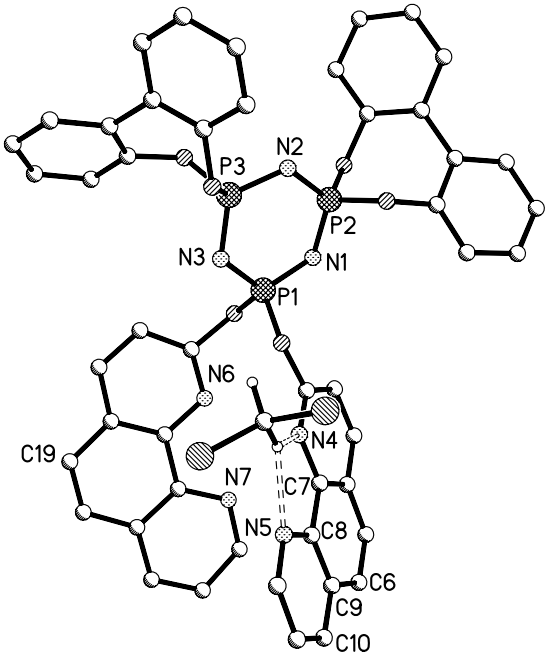


Fig. 1. Structure of the cyclotriphosphazene L^1, showing hydrogen bonding interaction with a CH_2Cl_2 solvate molecule. Most hydrogen atoms have been removed for clarity.

Table 2

3.3.2. Structure of $[(CuL^1)_2](PF_6)_2 \cdot 6CH_2Cl_2$ ($\mathbf{1} \cdot 6CH_2Cl_2$)

The structure of the $[(CuL^1)_2]^{2+}$ dication is shown in Fig. 3 and selected bond lengths and angles are given in Table 3. In this complex L^1 acts as a bridging ligand with two ligands coordinating to two copper(I) centres in a

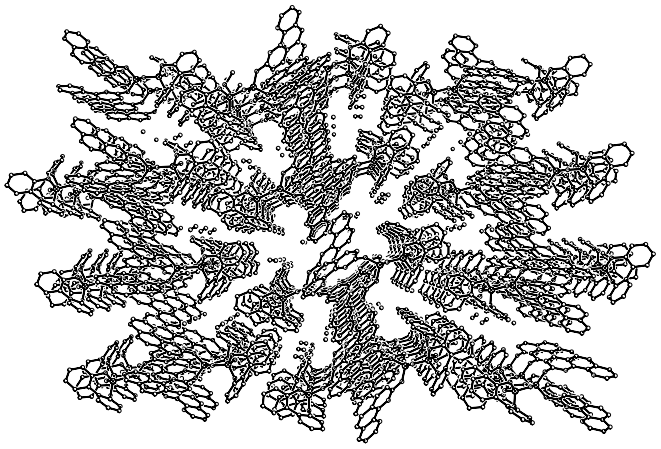

Fig. 2. Packing diagram of $L^1 \cdot 2CH_2Cl_2$ showing the channels along the *a*-axis. Individual carbon atoms of the CH_2Cl_2 solvate molecules occupying the channels are shown; chlorine atoms are omitted for clarity.

helical fashion similar to that observed for other bis-phenanthroline ligands that are linked by a spacer through the 2,2′-positions [20–25]. Both copper(I) centres have highly distorted tetrahedral geometry. The interligand N–Cu–N bond angles vary between 112.81(11)° and 143.14(12)° for Cu(1) and between 112.02(12)° and 134.02(12)° for Cu(2). Similarly there is a wide range in the Cu–N bond lengths: between 2.009(3) and 2.087(3) Å for Cu(1) and between 1.996(3) and 2.066(3) Å for Cu(2). The dihedral angles are 85.2° and 85.7° for Cu(1) and Cu(2). There is also a strong intramolecular π–π stacking interaction between the phenanthroline ring containing N(6) and N(7) and the phenanthroline ring containing N(13) and N(14); the angle between the mean planes of these rings is 8° and the closest contact between atoms in the rings is 3.364 Å for C(18)···C(65). Secondary intermolecular interactions within the crystal are numerous and give rise to an interesting longer range structural motif:

the view along the *c*-axis is shown in Fig. 4. The cations are arranged so that they create continuous sheets of molecules that undulate along *b*-axis and stack along the *a*-axis. Many intermolecular contacts between adjacent cations occur from the close packing of the cations within the sheets. For example, in contrast to the phenanthroline rings described above, the phenanthroline rings containing N(11), N(12) and N(4), N(5) are involved in intermolecular stacking interactions with the equivalent phenanthroline rings on adjacent molecules. In the case of the ring containing N(11) and N(12), further stacking is observed with the phenyl ring bonded to O(6) resulting in a four ring interlocking stack (Fig. 5). This array is strengthened further by hydrogen bonds from phenanthroline H(58) to phosphazene N(3). In a direction roughly perpendicular to these interlinking stacking interactions there are close approaches between biphenyl rings; for instance, the distance between H(82) and O(6) is 2.384 Å and between C(88) and O(12) is 3.384 Å in adjacent molecules.

Between the sheets lie the hexafluorophosphate anions and solvent molecules [Fig. 4(b) is the view in Fig. 4(a) but with carbon and hydrogen atoms removed]. Both of the unique hexafluorophosphate anions have well defined atomic coordinates with the fluorine atoms being involved in numerous hydrogen-bonding interactions with aromatic hydrogen atoms, some of which cause the anions to bridge the sheets while others bridge cations within the sheets. In contrast only two of the six dichloromethane molecules have atomic coordinates defined well enough to include in the model and the remaining four molecules are disordered in the large voids left between the sheets. The self

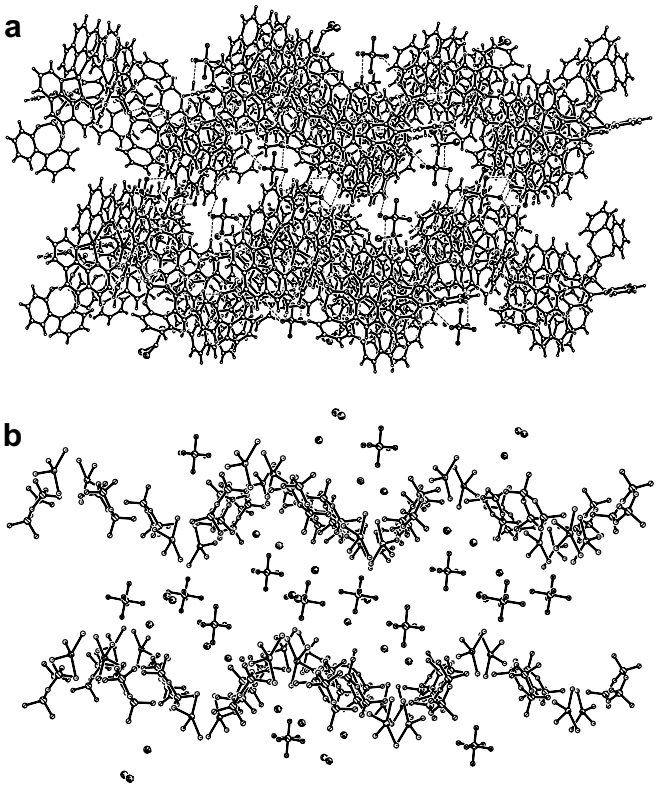

Fig. 4. (a) View along the *c*-axis of **1** showing the undulating sheets of $[(CuL^1)_2]^{2+}$ cations and the channels between the sheets containing PF_6^- anions and CH_2Cl_2 solvate molecules. (b) The same view with the carbon atoms removed.

assembly of cations and anions here is reminiscent of the motifs we reported previously for the structures of two silver(I) coordination polymers of *hexakis*(2-pyridyloxy)cyclotriphosphazene ligands [4].

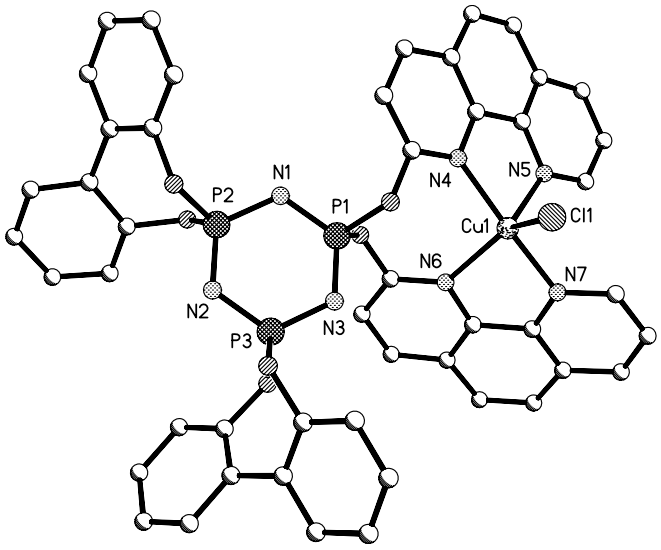

Fig. 6. Structure of the complex cation of $[CuL^1Cl]Cl$ (**3**) with the hydrogen atoms removed for clarity.

3.3.3. Structure of $[CuL^1Cl]Cl \cdot 2CH_2Cl_2$ ($\mathbf{3} \cdot 2CH_2Cl_2$)

The crystal structure of the $[CuL^1Cl]^+$ cation is shown in Fig. 6 and selected bond lengths and angles are given in Table 4. The copper(II) centre is five-coordinate with a 'N_4Cl' donor set arising from the two phenanthroline arms of L^1 and a chloride ion. The value of the structural index, τ [44], measured for this complex is 0.57 ($\tau = 1$ for perfect trigonal bipyramid, $\tau = 0$ for a perfect square-based pyramid) implying square-based pyramidal-distorted trigonal-bipyramidal (SBPDTB) geometry. However, the geometry about the copper differs from many reported $[Cu(phen)_2Cl]^+$ chromophores [45,46] in that the largest equatorial angle does not lie opposite the longest equatorial Cu–N bond length. The Cu–N(5) distance of 2.145(4) Å, opposite N(6)–Cu(1)–Cl(1) [137.24(10)°], is comparatively long and similar to the distance of 2.166(4) Å for Cu–N(6) opposite N(5)–Cu(1)–Cl(1) [112.58(11)°]. The contribution of crystal packing forces on the coordination geometry of this structure may be important. The cations are arranged such that the spirocyclic biphenyl ring bonded to P(3) forms an offset intermolecular π–π stack (ca. 3.48 Å) with its inversion related symmetry equivalent. Hence, a phenyl ring from the biphenyl moiety bound to P(3) is sandwiched between the phenanthroline ring bound through O(2) and the biphenyl moiety bound to P(3) of an adjacent molecule and the steric clash causes slightly larger thermal motion in the atoms of the participating phenanthroline.

The phosphazene ring in this structure is essentially planar and P–N bonds, P–N–P and N–P–N angles are unremarkable. There are small but concerted changes in the bond lengths of the oxyphenanthroline moieties upon coordination compared with the free ligand. The P–O(phen) bonds in L^1 have an average length of ca. 1.592 Å but in the complex they are slightly longer at an average of ca. 1.615 Å. The C(phen)–O(phen) bond lengths are slightly

shorter on coordination, average ca. 1.391 Å compared with an average of ca. 1.417 Å in the free ligand.

3.3.4. Structure of $[(CuL^3Cl)_2] \cdot 4CH_3CN \cdot 3H_2O$ ($\mathbf{9} \cdot 4CH_3CN \cdot 3H_2O$)

The hydrolysis product of $[CuL^1Cl]Cl$ (**3**) is the chloro-bridged bimetallic species $[(CuL^3Cl)_2]$ ($L^3 = [N_3P_3(biph)_2(ophen)O]^-$ (**9**)) (Scheme 3) and crystals of $\mathbf{9} \cdot 4CH_3CN \cdot 3H_2O$ grew from acetonitrile in the presence of adventitious water. The structure of **9** is depicted in Fig. 7 and selected bond lengths and angles are given in Table 4. The copper(II) ions have a 'N_2OCl_2' coordination sphere that arises from phenanthroline, phosphazenate and chloride ligands. The geometry about the copper is distorted square-based pyramidal with the Cu–Cl(1A) bond forming the apex. The atoms in the basal plane made by the 'N_2OCl' ligand set have a mean deviation of 0.1517 Å from planarity and Cu(1) lies 0.1011 Å out of this plane towards Cl(1A). The copper(II) ions are 3.313 Å apart with the copper(II) environment being similar to the polymeric compound $[Cu_2(phen)_2Cl_2(C_6H_8O_4)]_n \cdot 4H_2O$ [47].

The phosphazene ring in **9** is only slightly more distorted from planarity [the mean deviation of atoms from the plane of the N_3P_3 phosphazene ring is 0.089 Å and the maximum deviation is ca. 0.152 Å for P(1)] than those in L^1 and **3**, although the P–N bond lengths, P–N–P and P–N–P angles fall within the expected ranges. The most significant changes in geometry compared with the above two structures occur around P(1) of phosphazene ring. The P–O(phen) bond length in **9** is 1.657 Å and longer than the average 1.615 Å seen in **3**. The P–O(Cu) bond length of 1.502 Å is considerably shorter and comparable with the P–O(Cu) bond length of 1.520(2) Å observed in the copper(II) bound phosphazenate tetraanion, $[Cu\{(PO_2NH)_3\}_2]^{4-}$ [48].

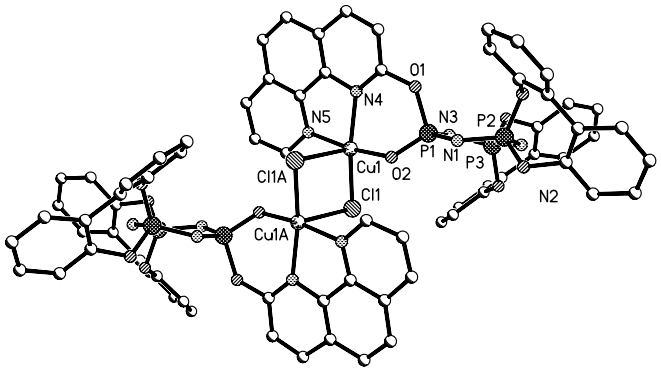

Fig. 7. Crystal structure of the bimetallic complex $[(CuL^3Cl)_2]$ (**9**) with the hydrogen atoms removed for clarity.

As with the structure of the parent ligand, L^1, an interesting feature of the long-range order in this structure is the existence of distinct regions in the crystal lattice as a result of non-covalent interactions. Both of the phenanthroline units in the dimer are involved in intermolecular stacking interactions with adjacent molecules which effectively result in a two-dimensional layer containing the copper ions. The biphenoxy residues of each ligand are involved in non-covalent interactions with the biphenoxy moieties of adjacent layers in a direction roughly perpendicular to the interactions between the phenanthroline moieties. The overall effect is a series of alternating layers of biphenoxy, phosphazene ring and copper-rich regions (Fig. 8).

3.4. Physicochemical studies

3.4.1. IR and electronic spectroscopy

The $P–N_{phosphazene}$ stretching frequencies for L^1 at 1230(s) and 1170(vs) cm^{-1} are altered only a little in the complexes, the ranges being 1226–1227 cm^{-1} for the first and 1170–1175 cm^{-1} for the second band. Similar changes occur in the $P–N_{phosphazene}$ stretching frequencies of L^2, at 1230(s) and 1182(vs) cm^{-1}, upon coordination to the copper centres. These data are consistent with the phosphazene rings not being distorted significantly from planarity upon copper coordination to the phenanthroline moieties [3].

The electronic spectra for the complexes are given in Table 5. For the copper(I) double-helicate compounds,

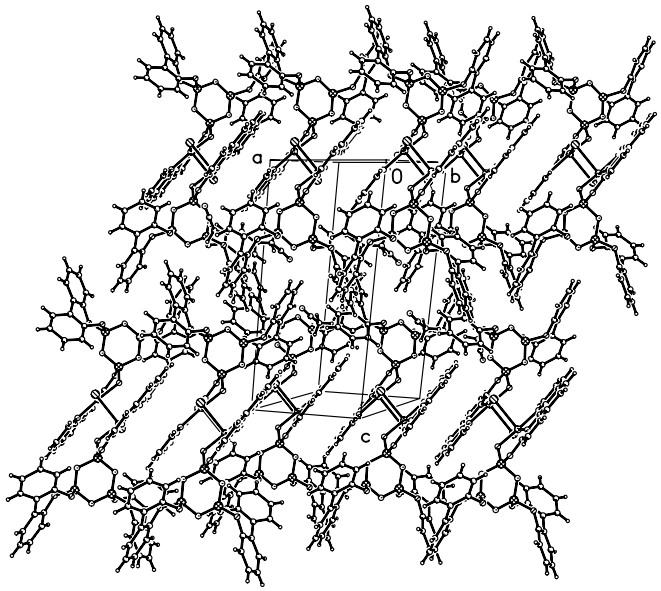

Fig. 8. Packing diagram of **9** showing alternating copper(II) and oxybiphenyl regions.

Table 5
Electronic spectral and ESR data for the complexes[a]

Complex	λ_{max}/nm (ε/l mol^{-1} cm^{-1})		ESR		
	d–d	MLCT	$g_{\parallel}$	$g_{\perp}$	$A_{\parallel}$ (cm^{-1})
1		465, 540sh[b] 444 (6250) 518 (4370)[c]

8	800br (200)		2.26	2.09	158×10^{-4}

[a] In CH_2Cl_2 unless otherwise indicated; sh = shoulder, br = broad.
[b] As nujol mull.
[c] In acetone.
[d] Not sufficiently soluble to determine ε.
[e] In CH_3CN/CH_2Cl_2.
[f] Major species.
[g] Minor species
[h] In acetone the parameters are $g_{\parallel} = 2.43$, $g_{\perp} = 2.09$ and $A_{\parallel} = 141 \times 10^{-4}$ cm^{-1}.

$[(CuL^1)_2](PF_6)_2$ (**1**) and $[(CuL^2)_2](PF_6)_2$ (**2**) bands in the 400–550 nm region can be assigned to metal-to-ligand charge-transfer (MLCT) [49]. For **1** in the solid state, the presence of a maximum at 465 nm with a weak shoulder at ca. 540 nm is typical of a so-called Class I spectrum [49,50] and implies a slight distortion from tetrahedral which is consistent with the single-crystal X-ray structure where the interligand dihedral angle at 85° is close to 90°. In acetone solution, the conductivity of **1** is 260 S cm^2 mol^{-1}, which is consistent with a 2:1 electrolyte [51], and confirms the retention of the double helicate structure. However, the solution displays two distinct bands at 444 and 518 nm which, with the well-formed band at a wavelength longer than 500 nm, are typical of a Class II type $[Cu(NN)_2]X$ compound [49,50] with the interligand dihedral angle considerably less than 90°. In the solid state, examples are given by $[Cu(phen)_2]ClO_4$ (dihedral angle 49.9°) and $[Cu(dpdmp)_2]PF_6$ (dpdmp = 2,9-diphenyl-4,7-dimethyl-1,10-phenanthroline) (dihedral angle 68.4°) [50]. The origin of the two bands in monomeric copper(I) diimine systems has been addressed [49,50] where the emphasis was placed on the variance of the dihedral angle between the equivalent ligands. If the copper centres show large distortions from D_{2d} symmetry then the d_{π} orbitals are non-degenerate and the two absorptions $b_2(xz) \rightarrow b_2(\pi^*)$ and $b_3(yz) \rightarrow b_3(\pi^*)$ are observed. For compound **2** in both the solid and acetone solution, the observation of two well resolved bands is consistent with a Class II spectrum and would suggest that the interligand dihedral angle is far removed from 90° in both states.

The copper(II) compounds all display d–d bands at wavelengths greater than 700 nm. In both the solid and dichloromethane solution, the complex $[CuL^1Cl]Cl$ (**3**) displays a broad d–d band at about 820 nm, which tails into the infrared, characteristic of a trigonal-bipyramidal geometry around copper(II) in solution [47]. A 10^{-3} M solution of **3** in CH_2Cl_2 has a conductivity of 23 S cm^2 mol^{-1} typical of a 1:1 electrolyte [51] supporting the retention of a monomeric structure in solution. The spectra of **4**, and of compounds **7** and **8** (where H_2O replaces the chloride ion) can be similarly assigned. However, each of the compounds **5** and **6** displays a single d–d band near 700 nm as well as in the 905–920 nm region with the shorter wavelength band having a greater extinction coefficient. These data are more characteristic [52] of a square-pyramidal distortion in the structures.

3.4.2. Magnetic moments and electron spin resonance spectra

The room temperature magnetic moments for **3**, **4**, **5** and **7** are 1.80, 1.93, 2.06 and 2.20 μ_B, respectively, consistent with the normal spin-only values for copper(II) [53].

X-Band ESR spectra (Table 5) of the complexes were generally recorded in CH_2Cl_2 at liquid nitrogen temperature. The spectra of **3**, **4**, **5**, **6** and **8** are similar and typical for monomeric axial copper(II) complexes with $d_{x^2-y^2}$ ground states with $g_{\parallel} > g_{\perp}$ ($g_{\parallel}$ 2.23–2.33, $g_{\perp}$ 2.08–2.14 and $A_{\parallel}$ in the range $130–171 \times 10^{-4}$ cm^{-1}). Well-resolved copper hyperfine lines in the $g_{\perp}$ region were not observed. These data are consistent with a square-based distortion

of a trigonal-bipyramidal structure [52], as found in the X-ray crystal structure of $[CuL^1Cl]Cl$ (**3**) described above. The ESR spectrum for **7** in a CH_3CN/CH_2Cl_2 glass was more complex, showing the presence of two species. The major one exhibited two identifiable magnetic g values, together with the corresponding copper ($I = 3/2$) hyperfine splitting constants ($g_\perp = 2.23$, $A_\perp = 105 \times 10^{-4}\,cm^{-1}$; $g_\parallel = 2.01$, $A_\parallel = 67 \times 10^{-4}\,cm^{-1}$). The g and A values match other reported examples of trigonal bipyramidal copper(II) complexes [24,25] which have 'reversed' axial spectra, i.e. $g_\perp > g_\parallel$ and $A_\perp > A_\parallel$. For the minor species, $g_\parallel = 2.42$, $g_\perp = 2.09$ and $A_\parallel = 142 \times 10^{-4}\,cm^{-1}$. These g and A values are in agreement with an axial spectrum with a $d_{x^2-y^2}$ ground state and suggest a species that has a square-based distortion of a trigonal-bipyramidal structure [52]. Hence in the glass, it appears that cation distortion isomerism exists with the two structures in equilibrium with each other. The equilibrium may be altered by the nature of the solvent, e.g. in acetone glass the major species now has very similar ESR parameters to the minor species in the CH_3CN/CH_2Cl_2 glass, which is the square-based isomer, while the minor species is the trigonal-bipyramidal isomer. The equilibrium is also affected by the substituents on the biphenolato moiety.

4. Conclusions

The new compounds, L^1 and L^2, represent the first examples of ligands with two 1,10-phenanthroline moieties tethered to a cyclotriphosphazene platform. A series of five-coordinate copper(II) complexes has been prepared by reacting L^1 or L^2 with copper chloride and copper perchlorate, and the single-crystal X-ray structure of one of these, i.e. $[CuL^1Cl]Cl \cdot 2CH_2Cl_2$ (**3** $\cdot 2CH_2Cl_2$) shows the copper to have a SBPDTB environment ($\tau = 0.57$) with L^1 acting as a κ^4N donor. The conformational rigidity of L^1 probably aids in the hydrolysis of **3** where one phenanthroline ligand is cleaved from L^1 to afford $[(CuL^3Cl)_2]$ (**9**). We have previously observed a P–O bond cleavage, coupled with a redox reaction, of the coordinated phosphazene ligand, hexakis(2-pyridyloxy)cyclotriphosphazene [4], and recently Chandrasekhar et al. have reported another such reaction [54]. The rigidity of the ligands, L^1 and L^2, does give good control over dihelicate copper(I) formation seen in $[(CuL^1)_2](PF_6)_2$ (**1**) and $[(CuL^2)_2](PF_6)_2$ (**2**) but not with copper(II) with its higher coordination number requirement.

Available online 3 August 2006

Abstract

Beryllium has been successfully incorporated into a naphthalene containing Schiff base ligand. Evidence from ^{9}Be and ^{1}H NMR data and model compounds indicate that the ligand completely encapsulates the beryllium cation via tetra-dentate tetrahedral coordination using both phenol and imine donors. Calculated ^{9}Be NMR data at the B3LYP/6-311G+(2d,p) DFT level of theory is in agreement with this conclusion.

1. Introduction

Despite the well established toxicity of beryllium [1], it is employed in a variety of industrial applications due to the fact that it is three times lighter than aluminium, six times stiffer than steel and displays remarkable heat/corrosion resistance. Inhalation of beryllium particles and alloys is directly linked to chronic beryllium disease (CBD) [2] and skin contact with small particles of beryllium has been reported to lead to beryllium sensitisation [3]. Current treatment for beryllium exposure involves the application of immunosuppressive drugs to control the Be(II) induced immune response; this treatment only serves to slow the advance of CBD [4]. At present, no cure exists for this sometimes fatal disease. Chelation therapies are commonly employed to treat other forms of metal toxicity; however no selective chelating agent presently exists for the Be(II) cation. For example, EDTA which binds most other metals with some degree of strength, has been established to be a poor binder of beryllium [5]. A suitably selective encapsulating agent for Be(II) would therefore serve as a notable advance in the areas of Be(II) chelation therapy and environmental remediation.

We have observed that ligands with mixed N/O donors such as pyridine-phenol and 10-hydroxybenzoquinoline sulphate (HBQS) show promise as selective coordinators of beryllium (Fig. 1) [6].

Bidentate ligands that bind the Be(II) cation (such as those shown in Fig. 1) are quite common; however, ligands which completely chelate beryllium providing all four donor atoms are extremely rare. Complex ligand architectures that provide all four coordination sites for the beryllium tetrahedron in a small binding pocket are likely to be the key elements in the design of a Be(II)-specific chelator. An extensive search of the literature and the Cambridge Crystallographic Database Centre found only two examples (Fig. 2) of ligands providing the complete coordination sphere for the Be(II) cation [7]. The Be-phthalocyanine structure seems to be an unlikely geometry given the fact that no other square planar structure of Be(II) has been reported [8]. The nitrilotripropionate (NTP) structure creates an ideal tetrahedral binding environment however, the flexibility of the alkyl backbone will reduce the ability

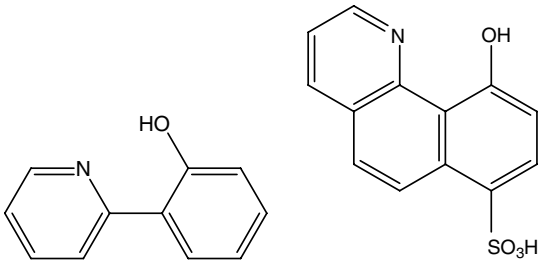

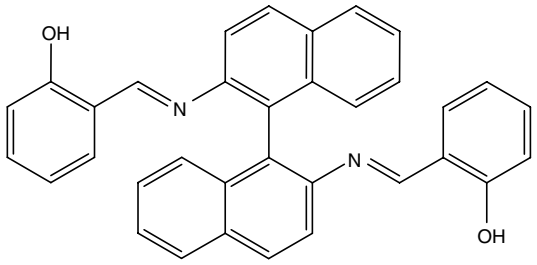

Fig. 1. Proven binders of Be(II).

of NTP to act as a selective sequestering agent for beryllium [9].

In this report, we describe our investigations on the rotationally hindered 2,2-disubstituted 1,1-binapthalene as a beryllium complexing agent (Fig. 3). Ligands containing 2,2-iminobiphenyl (or 2,2-iminobinapthalene) are well suited for binding tetrahedral metal cations. The steric repulsion of the opposing α-protons adjacent to the 1,1 aromatic linker forces the aromatic rings to sit perpendicular to one another, predisposing the ligand for a tetrahedral arrangement of donors, given a metal (for example, Be(II) or Zn(II)) that prefers such an arrangement. Our choice of binapthalene over the analogous biphenyl was dictated by its commercially available precursors and higher energy barrier to rotation. This ligand contains two hard phenolate donors in addition to the slightly softer imine donor atoms and potentially provides a fully encapsulating ligand donor set for beryllium (Fig. 4). The N/O mixed donor set is similar to HBQS, potentially forming a six-membered chelate ring on binding beryllium. In addition, incorporation of beryllium within this molecule would result in a neutral complex, eliminating the need for an attendant anion and the potential complication of competition with the ligand for the beryllium cation.

We have used density functional theoretical (DFT) methods in past studies to predict the NMR properties of

H_2L

Fig. 3. The ligand used in the present study.

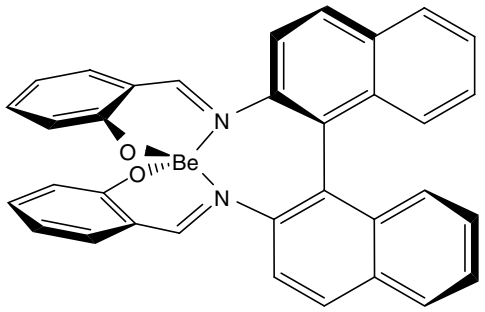

Fig. 4. Schematic of the binding of beryllium by **L**.

a variety of beryllium complexes [10]. We will employ these same techniques to predict the geometries and NMR chemical shifts (^{9}Be and ^{1}H) of this complex (Fig. 4).

2. Experimental

2.1. Starting materials and reaction procedures

(*R*)-(+)-2,2′-diamino-1,1′-binaphthalene (9%) and 2-hydroxybenzaldehyde (99%) were purchased from Acros Organics and used without further purification.

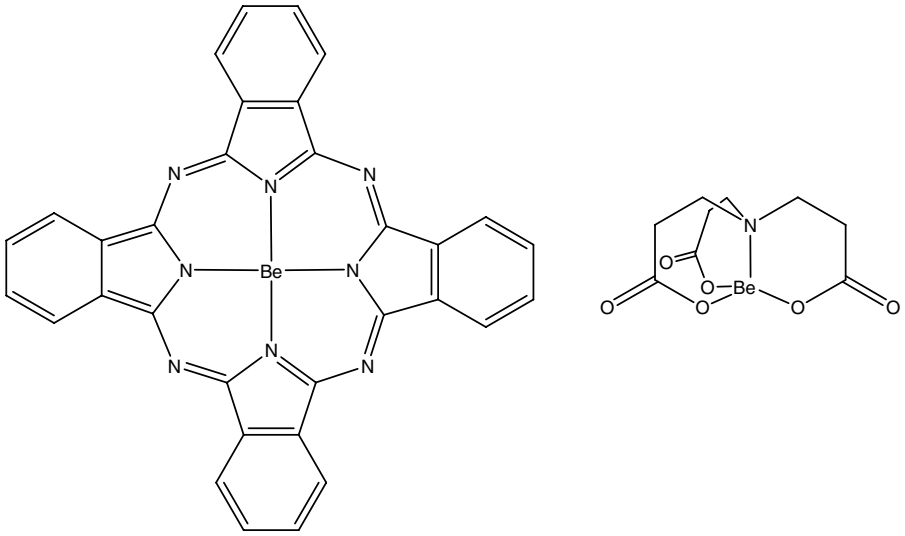

Fig. 2. Previously known tetra-chelating complexes of beryllium(II) as determined by X-ray crystallography.

Basic beryllium acetate was prepared via the synthesis of Moeller et al. [11].

Caution! Beryllium salts are extremely toxic and should be handled with appropriate care. All beryllium solid manipulations were handled in a Plas-Labs 818 Series, HEPA filtered (0.4 μm prefilter), reversed-pressure glove box. All beryllium solution work was performed in a dedicated HEPA filtered chemical hood. ^{9}Be NMR spectra were recorded on a Bruker Avance 300 at 42.17 MHz and referenced to an internal standard of $Be(H_2O)_4^{2+}$ (as the sulfate salt). All NMR samples containing beryllium were contained within Teflon sleeves in addition to the standard NMR glass tube. The alternative synthesis of $\mathbf{H_2L}$ has been reported previously [12].

2.2. H_2L

To a solution of *R*-(+)-2,2′-diamino-1,1-binapthalene (0.500 g, 1.76 mmol) in ethanol (40 mL) was added a solution of 2-hydroxy-benzaldehyde (0.434 g, 3.516 mmol) in ethanol (10 mL). The resulting orange solution was brought to reflux and within minutes an orange precipitate was formed. Refluxing was continued for 4.5 h. The solution was cooled and the resulting orange precipitate was filtered, washed with ice cold ethanol and dried (0.553 g). Reduction of the supernatant (10 mL) resulted in a further precipitation which was treated as above (0.256 g). Total yield: 0.804 g, 93%. M.p. > 300 °C. The data for this compound have been reported previously [12]. ^{1}H NMR ($CDCl_3$, TMS, 300 MHz) δ 12.08 (s, 2H, OH), 8.66 (s, 2H, H_{imine}), 8.10 (d, $J = 8.8$ Hz, 2H), 7.96 (d, $J = 8.8$ Hz, 2H), 7.64 (d, $J = 8.8$ Hz, 2H), 7.45 (dd, $J = 8.1$, 8.4, 2H), 7.31–7.15 (m, 8H), 6.77 (t, $J = 7.8$, 2H), 6.70 (d, $J = 7.8$, 2H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 162.1, 161.0, 144.0, 133.4, 133.0, 132.7, 132.4, 130.2, 129.8, 128.5, 127.2, 126.7, 126.1, 119.5, 118.9, 117.3, 117.1.

2.3. BeL

To a bright yellow solution of $\mathbf{H_2L}$ (0.121 g, 0.246 mmol) in a 1:1 ethanol (25 mL):chloroform (25 mL) mixture was added a few crystals of $Be_4O(COOCH_3)_6$ (0.025 g, 61.5 μmol). The beryllium crystals quickly dissolved and the solution was left to reflux doing which time the solution colour reduced in intensity to a pale yellow. After 5 h the solution was left to cool, then covered and left to evaporate. Yield: 25.4% based on NMR analysis. ^{1}H NMR ($CDCl_3$, TMS, 300 MHz) δ 8.27 (s, 2H, H_{imine}), 7.97 (d, $J = 8.4$ Hz, 2H), 7.53 (d, $J = 8.4$ Hz, 2H), 7.49–7.35 (m, 2H), 7.32–7.08 (m, 6H), 7.04 (d, $J = 8.4$ Hz, 2H), 6.86 (d, $J = 8.5$, 2H), 6.55 (t, $J = 7.4$, 2H); ^{9}Be NMR ($CDCl_3$, $Be(H_2O)_4^{2+}$, 42.17 MHz) δ 4.84 (complex), 0.90 ($Be_4O(OAc)_6$).

3. Computational

Computational calculations were performed using the program Gaussian 03 [13]. We found that Becke's three-parameter hybrid exchange correlation functional [14] containing the non-local gradient correction of Lee, Yang and Parr (B3LYP) [15], in conjunction with the 6-31(d) basis set, gave a satisfactory geometry for the most part. All optimized structures were confirmed as minima by calculation of the vibration frequencies. NMR shieldings for beryllium were evaluated at the minima using B3LYP with 6-311+G(2d,p) as the basis set and the GIAO (gauge-including atomic orbital) NMR method [16] as implemented by Cheeseman et al. [17] in the Gaussian 03 package. The complex $Be(H_2O)_4^{2+}$ is the standard reference for ^{9}Be NMR spectroscopy and is defined as 0.00 ppm. Structure determination for this complex (B3LYP/6-31(d)) followed by calculation of the magnetic shielding (B3LYP/6-311G+(2d,p)) gave a value of 108.96 ppm. The calculated chemical shift reported in this study is in relation to $Be(H_2O)_4^{2+}$, using the expression $\delta_{complex} = \sigma_{reference} - \sigma_{complex}$.

4. Results and discussion

4.1. Synthesis of H_2L

The ligand was easily prepared by the Schiff-base condensation of the commercially available precursors. Successful condensation was confirmed by the lack of a carbonyl proton signal and the presence of a new proton signal at 8.66 ppm in the ^{1}H NMR.

4.2. Molecular structure of H_2L

At the time this work was done, no single crystal X-ray determination had been reported for $\mathbf{H_2L}$, so we determined this structure to both aid in the characterisation of this ligand and more importantly so that we could compare the free ligand with that of our modelled beryllium structure to give an indication of the accuracy (as measured by C–C bond lengths) of the computed structure of the complexed model (see later). During the preparation of this manuscript however, Gao et al. [18] published a lower temperature crystal structure determination of $\mathbf{H_2L}$ which upon analysis had a slightly better fit of the data than our own determination. Therefore it is the structural parameters of Gao that we will use for our comparison with our calculated structure.

4.3. Complexation of H_2L

Complexing beryllium to ligand systems in organic media is challenging. Not withstanding the issue of toxicity but in addition, finding a suitable beryllium organic soluble starting material is somewhat limited given both the lack of availability and also the inherent inertness to

substitution of the few examples that do exist. For instance, $\mathbf{H_2L}$ was refluxed for some days in ethanol with the organic soluble starting material $Be(acac)_2$ with no reaction as monitored by ^{9}Be NMR analysis. In contrast, basic beryllium acetate can be used as a suitable source for Be(II) if it is reacted in the presence of an alcoholic reaction medium [19]. Subsequently, reaction of $\mathbf{H_2L}$ with basic beryllium acetate in an equal volume $CHCl_3$/ethanol mix lead to the formation of the neutral chloroform soluble complex Be**L**. Attempts to grow single crystals from the slow evaporation of a chloroform solution of Be**L** were unsuccessful.

4.4. ^{9}Be NMR of Be**L**

Analysis of the ^{9}Be NMR spectrum (Fig. 5) reveals that the chemical shift of 4.84 and a line width of ~40 Hz is consistent with a 4-coordinate complex [10b].

4.5. Modelling (structural)

We have shown that computational calculations can be a useful prediction of both structure and properties for beryllium complexes [10b]. In an effort to provide further evidence for beryllium complexation of $\mathbf{H_2L}$, the predicted structure of the complex was optimised and the ^{9}Be NMR chemical shift calculated. The calculated geometry is shown in Fig. 7 and the space filling model is provided in Fig. 8. Optimisation of the gas phase model at the B3LYP/6-31G(d) level was in good agreement with solid state data (as measured by bond lengths) from both the free ligand [18] and previously reported structural determinations of non-beryllium containing complexes and also with comparison to the much smaller sample size of related beryllium complexes (see Table 1 and Fig. 6) [7].

Comparison of the Be–X, (X = N, O) donor bond lengths of the model are in excellent agreement (<0.2% difference), within those of known beryllium containing complexes with similar heteroatom donor sets (Table 1). Examining one bond length further from the coordination sphere shows that the model still has very good agreement with comparable solid state bond lengths (<4% difference

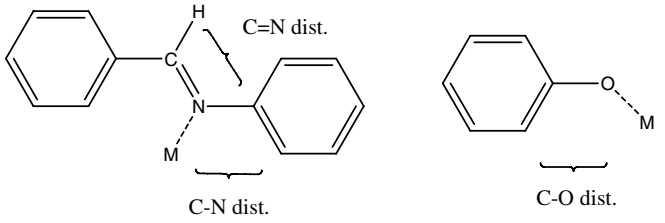

Fig. 6. Bond distances from the CCDC used for comparison with the model complex and the free ligand $\mathbf{H_2L}$.

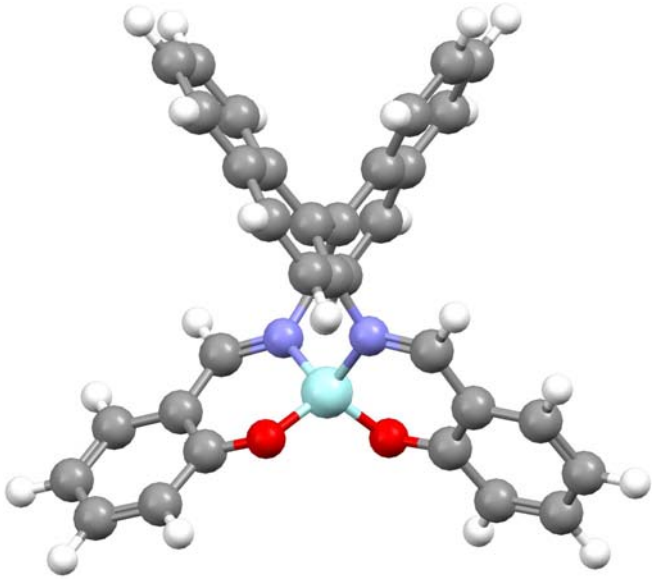

Fig. 7. Optimised structure of Be**L** showing the tetrahedral coordination of beryllium.

for the C–O and C=N bond lengths). The C–O bond length of the Be**L** model is 3.7% shorter than that of the corresponding average distance for solid state structures containing this bond in the presence of oxygen bound metal. We believe this is not significant as this difference is comparable to the difference between Gao's solid state structure of $\mathbf{H_2L}$ with that of the corresponding average C–O bond length in the absence of any coordinating metal (2.2% shorter). The beryllium atom adopts a near ideal tetrahedral geometry with angles (N/O–Be–N/O) of 104.2–

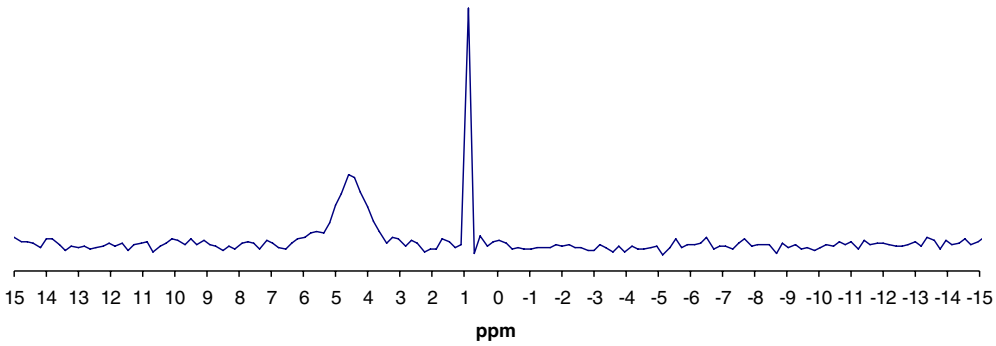

Fig. 5. ^{9}Be NMR spectrum of Be**L**. The $Be_4O(CH_3COO)_6$ cluster at 0.90 ppm is included as reference. ($CDCl_3$, 42.17 MHz, $T = 298.2$ K).

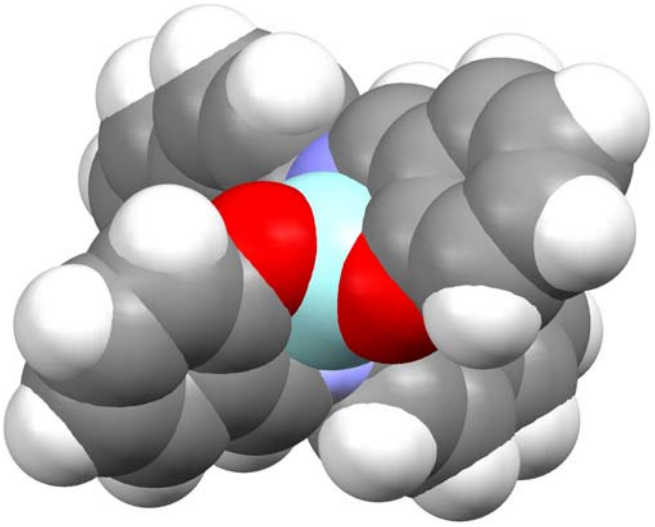

Fig. 8. Space filling model of Be**L** looking towards the beryllium binding site and showing the protection around the beryllium atom by the donor atoms (red = oxygen, blue = nitrogen) and the aromatic rings (grey = carbon, white = hydrogen). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

115.1° (average 109.5). The naphthalene groups are at an angle of 65° to one another, with the N···N and O···O distances now at 2.759 and 2.651 Å, respectively.

The space filling model shows that beryllium sits well within the coordination pocket and is almost completely encapsulated by the ligand (Fig. 8).

A search of the Cambridge structural database indicates that tetrahedral metal coordination to this ligand type is surprisingly rare. Even cations of similar size to beryllium, such as Al(III) prefer to adopt an octahedral donor set with $\mathbf{H_2L}$, utilising deprotonated solvent (methoxide) and/or a second equivalence of $\mathbf{H_2L}$ to make this possible, this suggests that selective binding of beryllium in a metal-rich competitive environment may be possible. In fact of the seventeen known metal complexes crystallographically characterised using **L** or a slight derivation of **L**, only one example, a cobalt(II) complex, adopts a heavily distorted tetrahedral geometry (av. 110.0°, range 94.4–128.3) [20]. In contrast to these crystallographically characterised complexes, the beryllium gas phase model complex (**BeL**) adopts a slightly distorted tetrahedral geometry (Fig. 7 and Table 1).

4.6. Modelling (NMR)

Due to the toxic nature of solid beryllium and beryllium dust the manipulation of beryllium solids should be handled with extreme caution or not at all. Unfortunately many characterisation techniques used to determine the nature and structure of inorganic complexes require the manipulation of solids. An alternative to working with these solids is to use solution-based characterisation techniques. We have shown that NMR prediction using computational chemistry, coupled with ^{9}Be experimental solution data can be a valuable tool in predicting the binding motif of beryllium complexes in solution for simple molecules [10]. The accuracy of the NMR prediction largely lies with the accuracy by which the complexes can be structurally optimised. We and others [10a,21] have shown that good agreement between calculated structural parameters with crystallographic data is a prerequisite for accurate NMR predictions. In addition, it has been shown previously that the NMR prediction is also dependent on the level of theory employed for the calculation with a more complete basis set increasing the accuracy of the predicted NMR results [17].

The ^{9}Be NMR chemical shift has been determined for Be**L** at two different levels of theory. In addition, at the higher level of theory (6-311G+(2d,p)), a second

Table 2
Calculated ^{9}Be NMR parameters using the GIAO method and B3LYP as implemented in GAUSSIAN03™ [13]

Basis set	Solvent model	$\delta_{complex}$	δ_{ref}	NMR shift (ppm)[b]
6-31G(d)		107.32	114.21	6.89
6-311G+(2d,p)		103.50	108.96	5.46
6-311G+(2d,p)	SCRF=$CHCl_3$	103.62	108.96[a]	5.34

[a] Experimentally the aqueous reference $Be(H_2O)_4^{2+}$ is sealed and does not make contact with the $CHCl_3$ solution.
[b] The experiment NMR chemical shift value for Be**L** is 4.84 ppm.

calculation was performed with the inclusion of a solvent ($CHCl_3$) model, to determine the effect that this has on the predicted chemical shift value (Table 2).

The NMR chemical shift calculation for Be**L** is least accurate at the 6-31G(d) level of theory and most accurate at the 6-311G+(2d,p) level of theory incorporating the solvent $CHCl_3$ model, however it must be noted that the difference between solution and the gas phase model is only very slight (~0.1 ppm). The difference in the ^{9}Be chemical shift value between the more accurate calculations and that of the experiment value is approx. 0.5 ppm, a typical discrepancy in these types of calculations [10,22].

5. Conclusion

We have shown that the rotationally hindered bis-imino/phenol naphthalene ligand **H_2L** binds to beryllium resulting in an encapsulated environment. ^{1}H and ^{9}Be NMR data provide evidence for a 4-coordinate Be(II) centre. DFT modelling indicates that this structure is a tetra-dentate complex whereby all four of the donors are bound to beryllium, therefore, beryllium appears to bind to **H_2L** in a nearly ideal tetrahedral geometry as compared to other metal cations. The GIAO NMR prediction corroborates this interpretation. This geometry has been shown to be an extremely rare Be(II)-ligand binding motif and promises to be instrumental as a synthetic platform for the development of Be(II) chelators for physiological and environmental applications. The zero-point energy calculation of this complex will be compared to other Be(II) complexes for which binding constants are known – a process that once tested may provide the basis for *in silico* screening of potential candidates. Work continues on competition studies, synthesis of water soluble derivatives and more rigid systems that will serve to prevent larger cations from competing for the binding pocket provided by this ligand.

Abstract

In order to probe the ability of the bis-bidentate ligand 4-isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt) to form mononuclear complexes of the 1:2 type, $[M^{II}(ibdpt)_2(X)_2]^{y+}$, a metal-to-ligand molar ratio of 1:2 has been employed in reactions with $Co(ClO_4)_2 \cdot 6H_2O$, $Ni(ClO_4)_2 \cdot 6H_2O$ and $Zn(ClO_4)_2 \cdot 6H_2O$. A high yield of the pure mononuclear complex $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ is obtained when $Zn(ClO_4)_2 \cdot 6H_2O$ is employed. In contrast, when $Co(ClO_4)_2 \cdot 6H_2O$ is employed a mixture of mono- and dinuclear complexes, $[Co^{II}(ibdpt)_2(X)_2]^{y+}$ and $[Co^{II}_2(ibdpt)_2(X)_4]^{y+}$, respectively, results. Even more dramatically, when $Ni(ClO_4)_2 \cdot 6H_2O$ is employed, no mononuclear $[Ni^{II}(ibdpt)_2(X)_2]^{y+}$ complex is obtained despite the 1:2 ratio. It is clear from these studies that stoichiometry alone does not control the outcome of such complexation reactions but that other factors, including the nature of the N^4 substituent and the relative solubility of the various possible products, also influenced by the N^4 substituent, are also important. The X-ray crystal structures of the mononuclear complexes $[Co^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot Et_2O$, $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ and $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$ and of the dinuclear complex $[Zn_2(ibdpt)_2(H_2O)_4](ClO_4)_2$ are presented. In all of these complexes the metal centres are octahedrally N_4O_2 coordinated by two in-plane ibdpt molecules and axial H_2O or ClO_4^- co-ligands. The *trans*-$(N',N^1)_2$ coordination mode is adopted in all three mononuclear complexes and the *trans*-$(N',N^1,N^2,N'')_2$ double bridging coordination mode is adopted in the dinuclear complex.

1. Introduction

Among the handful of 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole ligands known before our work [1] only NH_2dpt [2,3] and pldpt [4] (Fig. 1) were reported to afford dinuclear complexes, while dinucleating behaviour was not observed for 4-aryl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles [5–13] until very recently when a dinuclear silver(I) complex of ppdpt (Fig. 1) was structurally characterised [14]. It is important to note that in all of the structurally characterised complexes of 4-aryl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles, all but one of which is mononuclear, the aryl substituents on N^4 form angles of about 68–84° with the triazole ring so no significant π-interactions are expected between them [5–14]. Given our interest in preparing 1,2,4-triazole-bridged dinuclear complexes we decided to develop access to a new group of such ligands, specifically those featuring an alkyl substituent on N^4, *i.e.* an electron-donating group, as it was anticipated that this should increase the electron density of the central triazole ring and hence promote the dinucleating ability of the ligand. We recently reported the first examples of 4-alkyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles [15]. Our studies of the coordination chemistry of one of these ligands, namely 4-isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt) (Fig. 1), have shown that, unlike their 4-aryl-substituted congeners, such ligands can readily form dinuclear complexes [16]. However, even though those studies employed a metal-to-ligand molar ratio of 2:2, in one case,

specifically using $Cu(ClO_4)_2 \cdot 6H_2O$, a small amount of a mononuclear complex, $[Cu^{II}(ibdpt)_2(ClO_4)_2]$, was obtained along with the desired dinuclear product [16]. This indicates that an electron-rich substitutent on N^4 can promote concomitant coordination of both N^1 and N^2 of the central triazole ring to metal ions, and thus the formation of dinuclear complexes, but that mononuclear complexes are also accessible. It should also be noted that the 4-isobutyl substituent gives rise to highly soluble complexes. Here we explore the possibility of using reaction stoichiometry to encourage the formation of mononuclear ibdpt complexes of the $[M^{II}(ibdpt)_2(X)_2]^{y+}$ type (Fig. 2).

2. Experimental

2.1. General

$Co(ClO_4)_2 \cdot 6H_2O$, $Ni(ClO_4)_2 \cdot 6H_2O$ and $Zn(ClO_4)_2 \cdot 6H_2O$ were purchased from Aldrich and used as received. The ibdpt ligand was prepared as described elsewhere [15]. All solvents used were laboratory reagent grade. Elemental analyses were carried out by the Campbell Microanalytical Laboratory at the University of Otago.

Caution: While no problems were encountered in the course of this work, perchlorate salts are potentially explosive and should be handled with appropriate care!

2.2. Reaction of $Co(ClO_4)_2 \cdot 6H_2O$ with ibdpt in a 1:2 molar ratio: synthesis of $[Co^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot Et_2O$

An orange solution of $Co(ClO_4)_2 \cdot 6H_2O$ (183 mg, 0.50 mmol) in MeCN (5 mL) was added to a colourless solution of ibdpt (279 mg, 1.00 mmol) in MeCN (35 mL). The resulting orange solution was stirred at room temperature for 2 h before it was subjected to vapour diffusion of Et_2O. This resulted in the formation of a mixture of orange and yellow crystals along with some orange oily drops. The yellow material was identified by X-ray diffraction as the mononuclear complex $[Co^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot Et_2O$. A sample of the yellow material could be collected and gave, after drying in vacuo (188 mg, 44% yield), an elemental analysis consistent with the composition $Co^{II}(ibdpt)_2(H_2O)_2(ClO_4)_2$. *Anal.* Calc. for $C_{32}H_{38}Cl_2CoN_{10}O_{10}$ (852.54 g mol^{-1}): C, 45.08; H, 4.49; N, 16.43. Found: C, 45.42; H, 4.65; N 16.38%. A sample of the solid orange material was dried in vacuo (46 mg, 8% yield) and subsequently analysed as a dinuclear complex with the composition $Co_2^{II}(ibdpt)_2(MeCN)_2(H_2O)(ClO_4)_4$. *Anal.* Calc. for $C_{36}H_{42}Cl_4Co_2N_{12}O_{17}$ (1174.48 g mol^{-1}): C 36.82, H 3.60, N 14.31. Found: C 36.50, H 3.77, N 14.26%.

2.3. Reaction of $Ni(ClO_4)_2 \cdot 6H_2O$ with ibdpt in a 1:2 molar ratio

A blue solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (183 mg, 0.50 mmol) in MeCN (5 mL) was added to a colourless solution of ibdpt (279 mg, 1.00 mmol) in MeCN (35 mL). The resulting pink solution was stirred at room temperature for 2 h before it was subjected to vapour diffusion of Et_2O. This afforded purple crystals which were identified by X-ray diffraction as the known dinuclear complex $[Ni_2^{II}(ibdpt)_2(MeCN)_4](ClO_4)_4$ [16]. A sample of this material gave, after drying in air (133 mg, 23% yield), an elemental analysis consistent with the composition $Ni_2^{II}(ibdpt)_2(H_2O)_4(ClO_4)_4$. *Anal.* Calc. for $C_{32}H_{42}Cl_4N_{10}Ni_2O_{20}$ (1145.93 g mol^{-1}): C, 33.54; H, 3.69; N, 12.22. Found: C, 33.65; H, 3.74; N, 12.22%.

2.4. Reaction of $Zn(ClO_4)_2 \cdot 6H_2O$ with ibdpt in a 1:2 molar ratio: synthesis of $[Zn^{II}(ibdpt)_2(ClO_4)_2]$

A colourless solution of $Zn(ClO_4)_2 \cdot 6H_2O$ (20 mg, 0.053 mmol) in MeCN (3 mL) was added to a colourless solution of ibdpt (30 mg, 0.107 mmol) in MeCN (3 mL). The resulting yellowish solution was stirred at room temperature for 2 h before it was subjected to vapour diffusion of Et_2O. This resulted in the formation of colourless crystals which were identified by X-ray diffraction as the

mononuclear complex $[Zn^{II}(ibdpt)_2(ClO_4)_2]$. A sample of this material gave, after drying in vacuo (35 mg, 80% yield), an elemental analysis consistent with the composition $[Zn^{II}(ibdpt)_2(ClO_4)_2]$. *Anal.* Calc. for $C_{32}H_{34}Cl_2N_{10}O_8Zn$ (822.97 g mol^{-1}): C, 46.70; H, 4.16; N, 17.02. Found: C, 46.91; H, 4.12; N, 17.05%.

2.5. Reaction of $Zn(ClO_4)_2 \cdot 6H_2O$ with ibdpt in a 1:1 molar ratio: synthesis of $[Zn_2^{II}(ibdpt)_2(H_2O)_4](ClO_4)_4$ and $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$

A colourless solution of $Zn(ClO_4)_2 \cdot 6H_2O$ (40 mg, 0.107 mmol) in MeCN (3 mL) was added to a colourless solution of ibdpt (30 mg, 0.107 mmol) in MeCN (3 mL). The resulting yellowish solution was stirred at room temperature for 2 h before it was subjected to vapour diffusion of Et_2O. This resulted in the formation of two colourless crystal forms, namely blocks and rods. The blocks were found to be the major product with trace amounts of rods. Both crystal types were studied by X-ray diffraction. The blocks were found to be the dinuclear complex $[Zn_2^{II}(ibdpt)_2(H_2O)_4](ClO_4)_4$ and the rods were found to be the mononuclear complex $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$. A bulk sample gave, after drying in air (50 mg, 81% yield), an elemental analysis consistent with the composition $[Zn_2^{II}(ibdpt)_2(H_2O)_4](ClO_4)_4$. *Anal.* Calc. for $C_{32}H_{42}Cl_4N_{10}O_{20}Zn_2$ (1159.31 g mol^{-1}): C 33.15, H 3.65, N 12.08. Found: C 33.19, H 3.57, N 11.96%.

2.6. X-ray crystallography

Data were collected on a Bruker SMART {$[Co^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot Et_2O$, $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ and $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$} or Bruker Kappa Apex II {$[Zn_2^{II}(ibdpt)_2(H_2O)_4](ClO_4)_4$} CCD area detector diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structures of mononuclear complexes were all solved by direct methods with SIR-92 [17] while the structure of $[Zn_2^{II}(ibdpt)_2(H_2O)_4](ClO_4)_4$ was solved using SHELXS-97 [18]. All structures (Table 1) were refined against F^2 using all data by full-matrix least-squares techniques with SHELXL-97 [19]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms, except those of the H_2O co-ligands, were placed at calculated positions and refined using a riding model with thermal parameters 1.2 times the equivalent isotropic thermal parameters of the atom to which they were bonded. The hydrogen atoms of the H_2O co-ligands were located from the difference maps and allowed to refine freely.

3. Results and discussion

3.1. Complex syntheses (Table 2)

With the intention of preparing a mononuclear complex, $Co(ClO_4)_2 \cdot 6H_2O$ was reacted with ibdpt in a 1:2 molar

[b] The yields of these experiments were not optimised.

ratio in MeCN. Vapour diffusion of Et_2O into the orange reaction mixture resulted in the separation of some orange oily drops, a small amount of orange crystalline material and clusters of bushy yellow crystals. A specimen of the latter, the main product present, was found to be suitable for an X-ray diffraction study which revealed the identity of this material to be the mononuclear complex $[Co^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot Et_2O$ (Figs. 3 and 4, Table 1). After the crystallographic sample was returned, samples of both the yellow and the orange crystalline material were obtained by physical separation. After drying in vacuo the elemental analysis of the yellow material was in very good agreement with a mononuclear composition of $Co^{II}(ibdpt)_2(H_2O)_2(ClO_4)_2$, thus confirming the result of the X-ray diffraction study (see below). The orange sample, after drying in vacuo, was found to have the dinuclear composition $Co^{II}_2(ibdpt)_2(MeCN)_2(H_2O)(ClO_4)_4$. It is noteworthy that on repeating this reaction on a smaller scale and at lower concentrations, *i.e.* after diffusion of Et_2O into a more dilute reaction solution, the yellow mononuclear complex was found to be the almost exclusive product, with only trace amounts of the orange dinuclear material present.

Allowing $Ni(ClO_4)_2 \cdot 6H_2O$ to react with ibdpt in a 1:2 molar ratio in MeCN afforded a pink solution, in contrast to the more intense purple solution obtained when a 2:2 molar ratio was employed [16]. Nevertheless, vapour diffusion of Et_2O into this solution afforded purple crystals. Several of these single crystals were studied by X-ray diffraction which unambiguously revealed that the product was the dinuclear complex $[Ni^{II}_2(ibdpt)_2(MeCN)_4](ClO_4)_4$ which had previously been obtained from the 2:2 reaction

of ibdpt and $Ni(ClO_4)_2 \cdot 6H_2O$ [16]. Subsequently, after the crystallographic sample was returned, the elemental analysis of an air-dried sample of the purple material confirmed the dinuclear nature of these crystals, with a composition of $Ni^{II}_2(ibdpt)_2(H_2O)_4(ClO_4)_4$. Hence, using $Ni(ClO_4)_2 \cdot 6H_2O$, there was no evidence of the formation of any solid mononuclear complex of the $[Ni^{II}(ibdpt)_2(X)_2]^{y+}$ type, although its presence in solution certainly cannot be ruled out. This is in contrast to the above observations using the cobalt(II) salt, to our earlier reported observations for the reaction of ibdpt with $Cu(ClO_4)_2 \cdot 6H_2O$ [16] and to the observations reported below for $Zn(ClO_4)_2 \cdot 6H_2O$.

The 1:2 molar reaction of $Zn(ClO_4)_2 \cdot 6H_2O$ with ibdpt led to the clean formation of almost colourless needles of $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ in high yield (Fig. 5). This is in stark contrast to the results obtained with $Co(ClO_4)_2 \cdot 6H_2O$ and $Ni(ClO_4)_2 \cdot 6H_2O$ as in the case of the zinc(II) salt no evidence of any formation of a dinuclear complex was observed, although it must be noted that it would not be as easily identified, especially if it formed in trace amounts (see below).

For completeness, the reaction of $Zn(ClO_4)_2 \cdot 6H_2O$ with ibdpt in a 2:2 molar ratio in MeCN was also carried out. By subjecting the resulting yellowish solution to vapour diffusion of Et_2O two forms of colourless crystals, namely rods and blocks, were obtained. The blocks were found to be the major, almost exclusive, product while only trace amounts of the rods were isolated. Single crystals of both crystal forms were found to be suitable for X-ray diffraction studies. The rod-like crystals (minor product) were found to be the mononuclear complex $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$ (Fig. 6) while the block like crystals (major product) were found to be the dinuclear complex $[Zn^{II}_2(ibdpt)_2(H_2O)_4](ClO_4)_4$ (Fig. 7). Physical separation of the two crystal types was impossible as the mononuclear complex was present in such negligible quantities. The elemental analysis of the bulk material gave results which were entirely consistent with the dinuclear formulation.

The results obtained from the 1:2 and 2:2 molar ratio reactions of $Zn(ClO_4)_2 \cdot 6H_2O$ with ibdpt are entirely consistent with those observed by this group for $Cu(ClO_4)_2 \cdot 6H_2O$ [16]. Specifically, when a 2:2 molar ratio is employed the bulk product is the dinuclear complex but a small amount of the mononuclear $[M^{II}(ibdpt)_2(X)_2]^{y+}$ complex forms along with it. That this had occurred was more easily identified in the case of the copper(II) salt

due to the significantly different colour and crystal form of the mono- and dinuclear complexes.

When a metal-to-ligand molar ratio of 1:2 was employed, both the copper(II) and the zinc(II) salts cleanly formed the anticipated mononuclear $[M^{II}(ibdpt)_2(X)_2]^{y+}$ complex while $Co(ClO_4)_2 \cdot 6H_2O$ formed mostly the expected mononuclear complex with only a trace of the dinuclear complex present (Table 2). In contrast, and rather surprisingly, with $Ni(ClO_4)_2 \cdot 6H_2O$ there was no evidence of the formation of a mononuclear $[Ni^{II}(ibdpt)_2(X)_2]^{y+}$ complex despite the 1:2 ratio employed (Table 2). The difficulties sometimes experienced in trying to obtain a completely clean bulk sample of a complex of desired stoichiometry simply by employing the correct metal-to-ligand molar ratio are consistent with a tendency of first row transition metal ions and ibdpt to set up a complex set of equilibria in solution. Supporting evidence for this comes from the fact that often the colour of the reaction solution is different from the colour of the solid state products isolated, as noted here for cobalt(II) and nickel(II) and previously noted for copper(II) [16]. Along with M:L stoichiometry, the relative concentrations of the many possible products in solution and their relative solubilities appear to be important factors in determining the nature of the solid products obtained.

3.2. Description of the crystal structures

The distances and angles of the N_4O_2 coordination sphere about the cobalt centre in the yellow complex $[Co^{II}(ibdpt)_2(H_2O)](ClO_4)_2 \cdot Et_2O$ (Figs. 3 and 4) are very similar to those observed in analogous complexes incorporating 4-aryl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles [12,13]. As could be expected from the fact that this complex adopts the *trans*-(N',N^1)$_2$ coordination mode (Fig. 2), the Co–N_{pyr} distance [2.1373(18) Å] is longer than the Co–N_{trz} distance [2.0900(18) Å]. The bidentate pyridine–triazole moiety is almost perfectly planar [1.5(1)°] while the non-coordinated pyridine ring, whose nitrogen atom faces towards the isobutyl group, is tilted by 15.4(1)° with respect to the triazole mean plane. The ClO_4^- ion forms hydrogen bonds to the H_2O co-ligand of its own and a neighbouring unit in a bridging fashion [O(1)···O(11) 2.78 and O(1)···O(12B) 2.77 Å] giving rise to a two-dimensional network of interlinked mononuclear units (Fig. 4). The shortest Co···Co separation between neighbouring units within this network is 9.6235(25) Å to each of four equally distant cobalt(II) centres.

Prior to this work only one mononuclear zinc(II) complex incorporating a 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole, specifically $[Zn^{II}(NH_2dpt)_2(H_2O)_2](ClO_4)_2$ reported by Hartmann and Vahrenkamp in 1995 [20], was known. In this study we obtained two different mononuclear zinc(II) complexes of ibdpt, namely $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ (Fig. 5) and $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$ (Fig. 6). In both of these complexes, and in $[Zn^{II}(NH_2dpt)_2(H_2O)_2](ClO_4)_2$, the *trans*-($N'$,$N^1$)$_2$ coordination mode (Fig. 2) is realised and the zinc(II) centre resides within an N_4O_2 coordination sphere made up of two bidentate 1,2,4-triazole-based ligands and of two axial oxygen donors (either ClO_4^- or H_2O co-ligands). The Zn–N_{pyr} and Zn–N_{trz} distances {2.1494(14) and 2.0574(14) Å, respectively, in $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ and 2.1502(15) and 2.0961(15) Å, respectively, in $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$} are in good agreement with the corresponding distances observed in $[Zn^{II}(NH_2dpt)_2(H_2O)_2](ClO_4)_2$ [2.169(3) and 2.067(3) Å, respectively]. The coordinated pyridine–triazole moieties in $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ and $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$ show relatively large deviations from planarity [11.20(11) and 16.77(13)°, respectively]. The non-coordinated pyridine rings of each complex are tilted by 7.97(12) and 30.61(10)° with respect to the triazole mean plane, each with the non-coordinated nitrogen atom pointing towards the isobutyl group. The axial co-ligands for $[Zn^{II}(ibdpt)_2(ClO_4)_2]$ are ClO_4^- ions while in $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$ they are H_2O molecules. Their respective Zn–O distances are 2.2609(13) and 2.1551(14) Å. The H_2O molecules in $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$ are also hydrogen bonded to one of the oxygen atoms of the non-coordinated ClO_4^- counterions and to the nitrogen atom of one of the MeCN solvates in the crystal lattice [O(1)···O(11) 2.82 and O(1)···N(20) 2.88 Å, respectively].

The dinuclear zinc(II) complex of ibdpt (Fig. 7) also has an octahedral N_4O_2 coordination sphere. The zinc(II) centres are bridged by the two triazole moieties. The ibdpt ligand adopts the common *trans*-(N',N^1,N^2,N'')$_2$ double bridging coordination mode (Fig. 2). The Zn–N_{trz} distances are shorter than the Zn–N_{pyr} distances (Fig. 7). This is due to the double bridging coordination mode of the triazole ring which results in a distortion of the octahedral geometry. This distortion is a feature common to all of the dinuclear complexes previously characterised by this group [16]. The distortion also causes a slight twist in the ibdpt ligand which can be seen by examining the angles between the mean plane of the triazole ring and each of the flanking pyridine rings [14.53(5) and 10.20(9)°]. The Zn··· Zn separation in this dinuclear complex is 4.353(2) Å. There are two axial H_2O co-ligands on each zinc(II) centre. These are engaged in hydrogen bonding interactions with the four non-coordinated ClO_4^- counterions.

4. Conclusion

Unlike most other 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole ligands, ibdpt has been found to show a remarkable ability to form dinuclear 2:2 complexes. With $Co(ClO_4)_2 \cdot 6H_2O$, $Ni(ClO_4)_2 \cdot 6H_2O$, $Cu(ClO_4)_2 \cdot 6H_2O$ and $Zn(ClO_4)_2 \cdot 6H_2O$ predominantly the dinuclear complexes, $[Co^{II}_2(ibdpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$, $[Zn^{II}_2(ibdpt)_2(H_2O)_4](ClO_4)_4$, $[Ni^{II}_2(ibdpt)_2(MeCN)_4](ClO_4)_4$, and $[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2 \cdot 2MeCN$ are isolated from reactions employing a metal-to-ligand molar ratio of 2:2, but for cobalt(II), copper(II) and zinc(II) small to negligible

amounts of their respective mononuclear complexes, $[Co^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot Et_2O$, $[Zn^{II}(ibdpt)_2(H_2O)_2](ClO_4)_2 \cdot 3MeCN$ and $[Cu^{II}(ibdpt)_2(ClO_4)_2]$, are also isolated. Analytically pure samples of these mononuclear complexes are readily obtained when the zinc(II) or copper(II) salts are employed in a 1:2 molar ratio. In contrast, the cobalt(II) salt, employing the same 1:2 molar ratio, affords small amounts of the dinuclear complex in addition to the desired mononuclear complex, with the amount obtained depending on the concentrations of the reactants in solution. Surprisingly, the use of the nickel(II) salt, in the same 1:2 molar ratio, results in the isolation of the 2:2 dinuclear complex, albeit in low yield, with no evidence of the formation of a mononuclear $[Ni^{II}(ibdpt)_2(X)_2]^{y+}$ complex. This variable behaviour of ibdpt towards different metal salts warrants further attention as it clearly indicates that in addition to factors such as the reaction stoichiometry and the electronic effect of the N^4 substituent, other factors such as the relative solubilities of the many and various possible products, also influenced by the N^4 substituent, and relative concentration in solution also play a part in determining the nature of the solid products obtained. Our focus is currently on exploring the rich iron(II) coordination chemistry of this and related ligands and the magnetochemistry of the resulting complexes [21].

Abstract

Group 7 trioxides LRO_3 with perfluorated ligands L (L = CF_3, C_5F_5 and C_6F_5) are investigated using density based (BP86) and wavefunction based (MP2) methods together with energy-adjusted scalar relativistic pseudopotentials for the metal atoms Mn, Tc and Re. The C_6F_5 compounds have short metal-carbon bond distances and are more stable than the η^1-C_5F_5 and the CF_3 compounds. The perfluorinated cyclopentadienyl compounds, $C_5F_5MO_3$, all are η^1 coordinated in contrast to the $C_5Me_5MO_3$ homologues. Our calculations indicate that $C_6F_5MnO_3$ might be a stable complex and therefore a promising target for future synthesis.

1. Introduction

Transition metal complexes containing terminal oxo ligands are very important as both oxidants and catalysts in organic synthesis [1]. One reason is that oxo ligands stabilize high oxidation states of transition element complexes, e.g. organic vanadium (V), molybdenum (VI) or rhenium (VII) oxo complexes have been prepared in the past [1]. After the synthesis of CH_3ReO_3 [2–4] and (η^5-CMe_5)ReO_3 [5,6] high oxidation state rhenium oxides have been studied intensively in the past [7,8]. Rhenium trioxide complexes have shown catalytic activity for a variety of reactions, including the oxidation of olefins and aromatic systems as well as metathesis reactions and olefination of aldehydes [9,10]. The homologous technetium compounds CH_3TcO_3 [11,12] and (η^5-CMe_5)TcO_3 [11,13] are known while the reported (η^5-CMe_5)Tc_2O_3 [15] was unfortunately a misinterpretation of X-ray data [16]. Compared to the rhenium species the technetium compounds have far greater oxidizing strengths and Lewis acidities [11,12]. Homologous manganese trioxo compounds should have greater oxidizing strengths and Lewis acidities compared to their heavier congeners. Unfortunately, these manganese trioxo organyl complexes are experimentally not known and have eluded synthesis so far. The known inorganic compounds MnO_4^- and $FMnO_3$ are a strong oxidant or very explosive [17]. CH_3MnO_3 and (η^5-CMe_5)MnO_3 have been predicted to be unstable on the basis of HF results [13,14]. DFT calculations on CH_3MnO_3 have also been performed [18]. The group 7 tetroxide anions [19,25], trioxide chlorides [20] and different organyl group 7 trioxides [21], rhenium compounds in particular [22], have been the subject of various theoretical studies [23–25].

The purpose of this study is to determine the influence of perfluorated ligands on the structure and stability of group 7 trioxo compounds. Transition metal complexes with perfluorated ligands often show increased thermal stability compared to the unfluorinated complexes [26] because of the high electronegativity of the ligand L. This is often

attributed both to thermodynamic and kinetic factors, which include a higher bond dissociation energy of the metal–ligand bond. A stabilisation of the resulting trioxo compounds leading to a manganese trioxo organyl complex that can be isolated experimentally is desired. CF_3, C_5F_5 and C_6F_5 are chosen as perfluorated ligands. CF_3 acts as a σ-acceptor, the other two compounds are also involved in π-bonding. For comparison, the stable inorganic FMO_3 and MO_4^- compounds as well as the CH_3MO_3 compounds are also investigated.

2. Computational details

All calculations were performed with GAUSSIAN98 [27]. For the group 7 metal atoms, scalar relativistic pseudopotentials of the Stuttgart group with their respective valence basis sets were employed in all calculations, i.e. (311111s/22111p/411d/1f) [28] for manganese, (311111s/22111p/411d) for technetium [29], and (311111s/22111p/411d) for rhenium [29]. For the lighter elements H, C, O and F all electron basis sets were used, and Dunning's cc-pVTZ basis sets for the smaller molecules (basis set 1) and the cc-pVDZ basis sets [30,31] for the C_5F_5 and C_6F_5 compounds (basis set 2). We mention that it was often difficult to achieve SCF convergence for some of the Mn compounds in the Hartree–Fock calculations, as the wavefunction becomes multi-reference in character.

We optimized all geometries at the density functional theory (DFT) using the BP86 functional and second-order Møller–Plesset perturbation theory (MP2). The molecules LMO_3 (L = H, F, CH_3, CF_3; M = Mn, Tc, Re) were optimized within the restriction of C_{3v} symmetry, while for the MO_4^- (M = Mn, Tc, Re) anions T_d symmetry was assumed. The C_6F_5 compounds were optimized with C_2 symmetry with the BP86 functional, but the MP2 calculations gave only transition states for the C_2 symmetric compounds. As a consequence the C_6F_5 compounds at the MP2 level and the C_5F_5 compounds were optimized without symmetry constraints. Frequencies, calculated at all levels of theory, confirmed the calculated structures to be true minima. A natural bond orbital analysis (NBO) [32,33] has been performed at the BP86 level in order to discuss the importance of metal s- and d-contributions for the ligand-to-metal bonding.[3] The charge distribution of a natural population analysis (NPA) in the LMO_3 compounds is also addressed in this context.

3. Results and discussion

The structural parameters and energies for all calculated compounds and a few available experimental data are collected in Tables 1–3 and example geometries are shown in

[3] Metal p-contributions were found to be not important for metal-to-ligand bonding an are therefore not listed.

Fig. 1. For the fluorides FMO_3 as well as CH_3ReO_3 and CH_3TcO_3 calculated data are already available. For the other compounds, e.g. the tetroxide anions MO_4^-, $FMnO_3$, $FReO_3$ and CH_3ReO_3, experimental data exists. The calculated M–O bond lengths for the MO_4^- and FMO_3 molecules are in good agreement with the experimentally observed values. The BP86 geometries are closer to the experimental geometries than the MP2 values and MP2 always gives smaller O–M–O bonding angles than BP86. It is well known that MP2 as a single-reference method may not lead to accurate results for transition metal compounds, especially when high oxidation states are involved [34]. The bonding parameters of the HMO_3 molecules show little differences between the two basis sets employed at the BP86 level. At the MP2 level, basis set 2 gives longer bond lengths than basis set 1. The BP86 bonding parameters will be used for further discussion since they are closer to the known experimental values.

CH_3MnO_3 does not have the expected minimum structure at the MP2 level. During optimization, the O–Mn–O bonding angle decreases and the Mn–C bond length elongates until the molecule dissociates. This is in agreement with earlier predictions [13,14] that CH_3MnO_3 is thermodynamically not stable. DFT finds a minimum at the expected structure, but with a rather long Mn–C bond length of 1.98 Å. For perfluorinated cyclopentadienyl compound, $C_5F_5MnO_3$, a minimum structure was found with BP86 as well, but at the MP2 level the Mn–C bond distance again elongates, the O–Mn–O angle gets wider and one oxygen moves close to the C_5F_5 ring, eventually forming a carbon oxygen bond. This shows that $C_5F_5MnO_3$ is thermodynamically not stable. In order to shed some light on this behavior, we calculated the structures of the MO_3 radicals as discussed later (see Table 5 and Fig. 1).

At the BP86 level of theory, all three metal-trioxides have C_{3v} structures with $^2A_1$ ground states, agreeing with earlier calculations for MnO_3 [37] employing the PW91 functional. The O–M–O angles widen from Re to Mn. The SOMO is located at the metal centers for all three atoms. Fig. 2 shows a greater upward extension of the metal centered orbital for the more pyramidal technetium and rhenium compounds, thus allowing a better interaction with the ligands. At the MP2 level MnO_3 moves into the high symmetry D_{3h} arrangement. Here, the orbital containing the radical electron is lower in energy compared to the heavier analogs, and the SOMO shows only small upward extension with significant radical character at the oxygen atoms. Hence, we obtain smaller metal–ligand interactions.

These radical geometries are mirrored in the corresponding organyl compounds. The O–M–O angles increase from Re over Tc to Mn. The Mn–O distances of the perfluorated compounds are around 1.58 Å. The Mn–C distances are 2.035 Å for CF_3MnO_3 and 1.940 Å for $C_6F_5MnO_3$. No crystal structures of manganese compounds with perfluorated ligands have been reported yet. Reported Mn–C distances from crystal structures of η^5 manganocenes

range from 2.09 to 2.45 Å [38]. η^1 Phenyl-manganese compounds have Mn–C bond lengths of 2.055–2.097 Å [39], η^6 phenyl-manganese compounds Mn–C bond lengths range between 2.154 and 2.273 Å [40]. For bonds between manganese and aliphatic carbon atoms we found distances between 1.969 and 2.419 Å [41]. This leads us to the conclusion that both compounds show manganese carbon bonds, in case of the C_6F_5 compound even a stronger bond.

In contrast to the manganese compounds, both the experimentally known CH_3TcO_3 and $C_5F_5TcO_3$ have minimum structures at the BP86 and MP2 levels of theory. The η^1-coordinated $C_5F_5TcO_3$ compound is a true minimum and 12 kcal/mole more stable than the corresponding η^5-coordinated isomer which is a second-order saddle point on the energy hypersurface. As for the rhenium compound, the C_5F_5 compound only shows η^1-coordination. The η^5 coordinated species is only a very shallow minimum lying about 20 kcal/mole higher in energy than the η^1-coordinated global minimum. The experimentally known cyclopentadienyl technetium and rhenium oxides all show η^5 coordination[9] and a gas electron diffraction study of Ru(η^5-C_5F_5)($\eta^5C_5Me_5$) [42] also shows a η^5-coordinated C_5F_5 ring. Tc–C distances in structurally characterized η^5-technetium metallocenes are between 2.26 and 2.33 Å [43], and in (η^1-Cp)Tc(NAr_3) the Tc–C distance is 2.156 Å [44]. The calculated Tc–C bond lengths of 2.158 (CF_3), 2.152 (C_5F_5) and 2.067 (C_6F_5) fit well into the range of structurally characterized technetium compounds. As found for manganese, the C_6F_5 compound has the shortest bond length and promises to be remarkably stable.
