Abstract

Three polymeric complexes $[Zn(pydz)(N_3)(SO_4)]_n[Na(H_2O)_4]_n(H_2O)_{4n}$ (**1**), $[Cd(3\text{-ampy})(N_3)Cl]_n$ (**2**), and $[Cd(DENA)Cl_2(H_2O)]_n$ (**3**), (pydz = pyridazine or 1,2-diazine, 3-ampy = 3-aminopyridine, DENA = *N*,*N*-diethylnicotineamide) have been synthesized and characterized by spectral and structural methods and their network topologies analysed. Complex **1** crystallizes in monoclinic C-centred space group *C*2/*m*, the Zn(1) center is octahedrally coordinated; and simultaneously bridged by EO-azido, *N*,*N*′-pydz, and *O*,*O*′-sulphato ligands. The ZnN_4O_2-octahedra form a 1D anionic chain along *b*-axis. The $Na(OH_2)_6$-octahedra have also common water molecules, thus also forming a 1D chain along *b*-axis. The cationic and anionic chains are connected via hydrogen bonds of type O–H···O including lattice water molecules to form a supramolecular 3D network structure. In complex **2**, the Cd(1) is six-coordinated by two EE-bridging azide groups, and two nitrogen atoms of bridging *N*,*N*′, 3-ampy ligand, and two bridging chloro ligands. The three different bridging ligands connect the distorted octahedra of the Cd(II) centres to form a 3D network structure with the topology of a square pyramidal net ($4^3 \cdot 6^6$-**sqp**). The centrosymmetric Cd_2Cl_2-rings are planar and the NH_2- of the 3-ampy groups forms additional hydrogen bonds of type N–H···N to the adjacent azido groups. In complex **3**, the octahedrally coordinated Cd(1) centres are occupied by alternating monodentate DENA ligand and a water molecule and the other four sites are occupied by four bridging chloro ligands. Thus the Cd_2Cl_2-rings form common edges to form 1D chains of Cd(II) octahedra along the *b*-axis of the monoclinic unit cell. 2D supramolecular sheets extended along the *bc*-planes of the unit cell are formed by the O–H···O hydrogen bond. The IR spectra of the three complexes were measured and they confirm the X-ray structural data.

1. Introduction

The pursuit of polymeric crystalline assemblies extending across a wide variety of organic–inorganic hybrid compounds has been motivated by creating structures with new topologies, cavities and channels of potential use in gas adsorption and storage, ion exchange, non-linear optical and magnetic materials [1,2]. Synthesis and studies of hybrid architecture via combination of organic bridging ligands and metallic nodes provides complexes with systematically tunable properties of interest [3]. In this context, the μ-aqua and azido-bridged complexes have became of high interest, due to the coordination versatility of the aqua and azido bridging modes. We have focused on

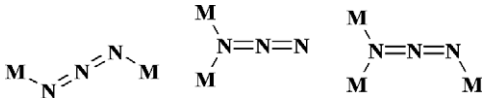
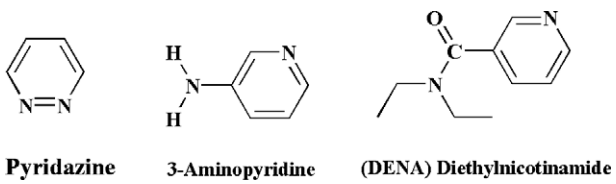
the magnetic diversity of the complexes where azide ion can link two or more metal ions in various modes and mediate magnetic exchange of different nature and magnitude [4–6] (Scheme 1).



These modes may simultaneously exist in the same compound in various alternating sequences or coexist with other bridging groups. An increasing number of 2D and sometimes 3D systems have been obtained by this strategy, and the second bridging ligands used thus far have been pyridyl-based ditopic ligands such as pyrazine, 4,4′-bipy and their analogues, with some exceptions that contain carboxylate groups [7].

On the other hand, although the ligands used in this work (see Scheme 2) are interesting from the structural point of view and can exhibit novel bridging networks different from other pyridine derivatives, and there are only a few known crystal structures. Pyridazine is well known as a *N*,*N*′-bridging ligand with Co(II), Ni(II), Cu(II), Pt(II), However, only one Zn(II) compound has been reported and then with pyridazine as a monodentate ligand [8]. Also bridging *N*,*N*′-3-ampy is seldom found in coordination chemistry [9].



Therefore, we extend our work to explore the different possible systems arising with these ligands. As part of our investigation on metal azides, we have recently reported a number of cadmium(II) azido and thiocyanato coordination polymers with some pyridine derivative ligands containing different bridging modes of $[Cd(N_3)_2]_n$ and $[Cd(NCS)_2]_n$ chains to construct coordination supramolecular frameworks [10–12]. Compared to the relatively large number of the azido-bridged polymers with Mn(II), Ni(II) and Cu(II) reported in the literature, the Cd(II) polymers are still very rare. Although diamagnetic, the cadmium and zinc systems are interesting from the structural point of view, since the systems can exhibit novel bridging networks different from other metal complexes [13]. From an applications point of view it can be noted that Cd(II) and Zn(II) coordination polymers forming 3D-nets have shown excellent non-linear optical properties [14].

Recently, such 3D-nets have been subject of renewed efforts of classification [15,2d], a very timely endeavour since such compounds may have important technological applications, as stated above.

Here, we present the reactions of zinc(II) ions with pyridazine and cadmium(II) ions with 3-aminopyridine and diethylnicotinamide in presence of azide ions, and the structure and network analysis of the three compounds; 1:1:1:1 for Zn:pyridazine:azide:sulphate (**1**) and Cd: 3-aminopyridine:azide:chloride (**2**) and 1:1:2:1 for Cd:diethylnicotinamide:Cl:H_2O (**3**).

Scheme 1.

Scheme 2.

2. Experimental

2.1. Materials and instrumentation

Infrared spectra were recorded in a Bruker IFS-125 model FT-IR spectrophotometer as KBr pellets [10]. C,H,N analyses were carried out using a Perkin–Elmer analyzer [12], Cd and Zn were analysed by a Perkin–Elmer Analyst 300, AAS atomic absorption spectrometer. Pyridazine, 3-aminopyridine and diethylnicotinamide ligands have been purchased from Aldrich Company and other chemicals were of analytical grade quality and used without further purification.

Caution: Metal azide complexes are potentially explosives. Only a small amount of material should be prepared and should be handled with caution.

2.2. Synthesis

2.2.1. $[Zn(pydz)(N_3)(SO_4)]_n[Na(H_2O)_4]_n(H_2O)_{4n}$

To an aqueous solution (20 cm^3) of $ZnSO_4 \cdot 7H_2O$ (0.57 g, ~2.0 mmol) and (0.32 g, 4 mmol) of pyridazine in ethanol (15 cm^3) were added, followed by a drop-wise addition of aqueous solution of NaN_3 (0.65 g, 10 mmol) with continuous stirring. The final clear mixture was allowed to stand at room temperature for several days. Colourless crystals suitable for X-ray measurement were collected, dried in air, with a yield 0.45 g, ~50.4% with respect to the metal. *Anal*. Calc. data: C, 10.66; H, 4.47; N, 15.54; Zn, 14.50, S, 7.11, Na, 5.10. Found: C, 10.50; H, 4.35; N, 15.60; Zn, 14.69; S, 7.09, Na, 5.15%. IR, KBr (cm^{-1}) (v, very; s, strong; m, medium; w, weak; br, broad): 3361 br, 3078 m, 2624 w, 2565 w, 2089 vs, 1643 w, 1629 br, 1575 s, 1450 m, 1422 s, 1408 w, 1356 m, 1291 s, 1195 br, 1110 br, 990 s, 972 w, 769 vs, 674 s, 655 w, 620 vs, 594 vs, 445 br, 395 m, 366 m, 345 m, 316 m, 293 m, 270 s.

2.2.2. $[Cd(3\text{-}ampy)(N_3)Cl]_n$

To an aqueous/methanolic solution (20 cm^3) of $CdCl_2 \cdot H_2O$ (0.2 g, ~1.0 mmol) and (0.2 g, 2.0 mmol) of 3-aminopyridine in (15 cm^3) methanol were added, then drops of a mixture of L-Asc (0.1 g., 0.6 mmol) and NaN_3 (0.5 g, 7.7 mmol) were added to the metal–ligand mixture. A white precipitate was formed, dissolved upon heating and stirring for 10 min. The clear solution was allowed to stand for few days, yellowish powder was obtained. Recrystallization of the precipitated powder in distilled

water gave deep yellow crystals suitable for X-rays measurements after four days with yield 0.23 g, ~82% with respect to the metal. *Anal*. Calc. data: C, 21.14; H, 2.12; N, 24.66; Cd, 39.57. Found: C, 21.32; H, 2.25; N, 24.48; Cd, 39.39%. IR, KBr (cm^{-1}) (v, very; s, strong; m, medium; w, weak; br, broad): 3405 m, 3313 s, 3254 s, 3160 s, 3058 m br, 2065 vs, 1585 vs, 1486 vs, 1447 vs, 1265 vs, 1195 s, 1145 m, 1099 m, 1055 s, 1031 s, 949 vs, 929 vs, 899 s, 827 s, 807 s, 698 s, 645 s, 627 m. 601 m, 534 m, 412 m, 385 m, 344 w, 316 w, 294 w, 270 m.

2.2.3. *[Cd(pyridine-N,N-diethylnicotinamide)Cl_2(H_2O)]$_n$*

To an aqueous mixture (15 cm^3) of L-ascorbic acid (0.1 g., 0.6 mmol) and NaN_3 (0.5 g, 7.7 mmol) an ethanolic solution (15 cm^3) of (0.35 g, 2.0 mmol) of pyridine-*N*,*N*-diethylnicotinamide (DENA) were added. Followed by the drop-wise addition of an aqueous solution (10 cm^3) of oxalic acid (0.2 g, 2.2 mmol), with continuous stirring and heating until clear solution was obtained. Further, an aqueous solution of $CdCl_2 \cdot H_2O$ (0.2 g, ~1.0 mmol) were added. The final clear mixture was allowed to stand for several weeks, white crystals suitable for X-rays measurements were collected, dried in air with yield 0.21 g, ~55.7% with respect to the metal. *Anal*. Calc. data: C, 31.64; H, 4.24; N, 7.38; Cd, 29.61. Found: C, 31.70; H, 4.33; N, 7.29; Cd, 29.47%. IR, KBr (cm^{-1}) (v, very; s, strong; m, medium; w, weak; br, broad): 3431 vs br, 3345 vs br, 3247 vs, 3097 s, 3069 s, 2996 s, 2978 s, 2935 m, 1635 vs, 1604 vs, 1585 vs br, 1500 s, 1455 vs br, 1424 vs, 1392 s, 1359 s, 1317 vs, 1289 vs, 1211 s, 1194 s, 1104 vs, 1075 s, 1048 s, 1032 s, 1005 m, 947 m, 880 s, 828 vs, 794 m, 748 s, 731 m, 707 s, 646 vs, 593 vs br, 503 s, 433 m, 404 m, 371 m, 344 w, 316 w, 295 w, 270 w.

2.3. X-ray crystallography

Single crystal X-ray data were measured at 100(2) K on a modified STOE four circle diffractometer using graphite crystal-monochromatized Mo Kα radiation ($\lambda = 0.71069$ Å). The intensities were corrected for Lorentz-polarisation effects and for absorption. Crystallographic data and processing parameters are given in Table 1. The structures were solved by direct methods and subsequent Fourier analyses. Programs used for computations: DIFABS [16], SHELXTL/PC program package [17] and MERCURY [18]. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated. Anisotropic displacement parameters were applied to non-hydrogen atoms in full-matrix least-squares refinements based on F^2. All hydrogen atoms were located from difference Fourier maps assigned with isotropic displacement factors and included in the final refinement cycles as follows: (a) pyrazine hydrogen atoms bonded to carbon by geometrical restraints using the HFIX utility of SHELXTL/PC package; (b) water hydrogens by use of O–H distance restraints. Split occupancy of 0.5 was applied to the disordered lattice water molecule O(9) of **1** . Selected bond distances and bond angles are given in Tables 2–4, for complexes **1**–**3**, respectively. Hydrogen bonds are listed in Table 5.

2.3.1. Network analysis

Abbreviations (three-letter codes) for 3D nets were taken from the web-based Reticular Chemistry Structure Resource, where crystallographic coordinates and other useful details for 3D-nets can be obtained [19]. For the less common nets we recommend adding the short (Schläfli) symbol before the three-letter code for clarity, as in

$4^3 \cdot 6^6$-**sqp** [3e]. This notation tells us the number of smallest rings found in the net, and, for nets with more than two nodes, also tells us the stoichiometry of the nodes, and thus gives a rough idea of the type of network in question. The topology of this net was established by computing the vertex symbol (extended Schläfli or long symbol) [20] giving $4 \cdot 4 \cdot 4 \cdot 4 \cdot 6 \cdot 6 \cdot 6_5 \cdot 6_5 \cdot 6_5 \cdot 6_5$ and comparing both the symbol and the experimental net with the ideal net. The computation was performed using the OLEX program [21], a good alternative is the TOPOS program [22].

3. Results and discussion

3.1. Structures

$[Zn(pydz)(N_3)(SO_4)]_n[Na(H_2O)_4]_n(H_2O)_{4n}$ (**1**) crystallizes in monoclinic C-centred space group $C2/m$ (no. 12) with 9iZ = 4; with following special positions: Zn(1) on inversion centre; pydz, azide, sulphato group, as well as water molecules O(5), O(6) and O(8) on mirror planes; Na(1) on diad. Water molecule O(9) is disordered with split occupancy of 0.5!

The Zn(1) centre is octahedrally coordinated; and simultaneously bridged by EO-azido, *N*,*N*′-pydz, and *O*,*O*′-sulphato ligands (Fig. 1). The ZnN_4O_2-octahedra are elongated, with Zn(1)–N(1) apical bond distances of 2.201(3) Å to pydz ligands, whereas Zn(1)–N(11) and Zn(1)–O(1) basal bond distances to N atoms of azide and O atoms of sulphato bridges are 2.095(2) and 2.120(2) Å, respectively. The Zn-octahedra form a 1D anionic chain (Fig. 2) along *b*-axis of monoclinic unit cell, with a Zn(1)...Zn(1′) separation of 3.5353(14) Å.

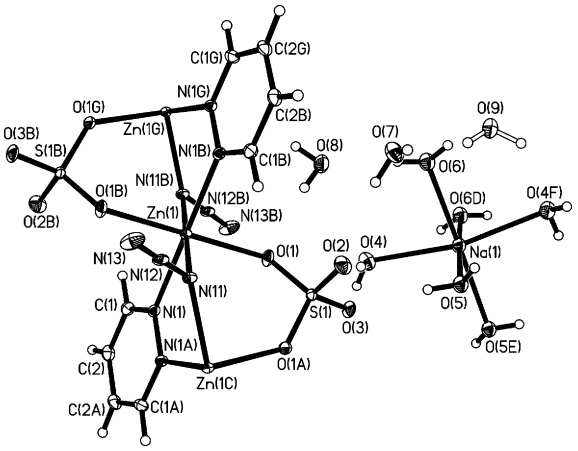

Fig. 1. Perspective view with atom labelling scheme of **1**.

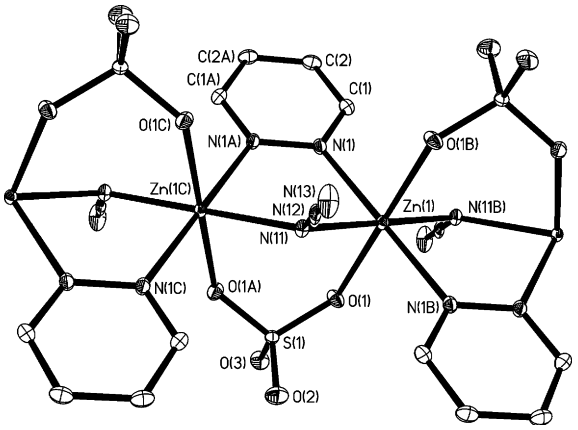

Fig. 2. Part of the chain structure of **1**.

The $Na(OH_2)_6$-octahedra have also common water molecules [O(4) and O(5)], thus also forming a 1D chain along *b*-axis [Na(1)...Na(1′) are 3.426(4) and 3.641(4) Å]. The Na–O distances are in the range from 2.397(3) to 2.447(3) Å. The cationic and anionic chains are connected via hydrogen bonds of type O–H···O including lattice water molecules [O(7), O(8) and O(9)] to form a supramolecular 3D network structure (Fig. 3, Table 5). The moiety of **1** may be formulated: $[Zn(pydz)(N_3)(SO_4)]_n$-$[Na(H_2O)_4]_n(H_2O)_{4n}$.

A picture of the asymmetric unit of [Cd(3-aminopyridine)$(N_3)Cl]_n$, compound **2**, is given in Fig. 4, and selected bond parameters are listed in Table 3. Cd(1) is six-coordinated by N(11) and N(13A) of EE-bridging azide group, N(1) and N(2B) of bridging 3-ampy ligand, and Cl(1) and Cl(1C) of bridging chloro ligands. The Cd(1)–N bond distances are in the range from 2.310(5) to 2.440(5) Å, whereas the Cd(1)–Cl bond distances are 2.590(2) and 2.665(2) Å. The three different bridging ligands connect the distorted octahedra of Cd(II) centers to form a 3D network structure (Fig. 5a and b). The Cd···Cd separations within the network structure are 3.7482(13) Å (via chloro-bridges), 6.310(2) Å (via azido), and 6.883(2) Å, (via 3-ampy), respectively. The centrosymmetric Cd_2Cl_2-rings are planar, with a Cd(1)–Cl(1)–Cd(1C) bond angle of 90.99(5)°. The EE-azido bridges are almost symmetric [N(11)–N(12) = 1.166(8) Å, N(12)–N(13) = 1.184(8) Å, N(11)–N(12)–N(13) = 178.6(7)°]. The Cd(1)–N(11)–N(12) bond angle is almost linear [167.6(5)°], while the Cd(1D)–N(13)–N(12) bond angle is close to 120° [121.3(5)°]. The Cd(1)–N(11)···N(13)–Cd(1D) torsion angle is 129.6(6)°. The 3-ampy ligand form a torsion angle of C(1)–C(2)–N(2)–Cd(1E) of 97.3(6)°. The NH_2-groups form additional hydrogen bonds of type N–H···N to N(13) atoms of adjacent azido groups.

A perspective view of [Cd(pyridine-*N*,*N*-diethylnicotinamide)$Cl_2(H_2O)]_n$ (**3**) is given in Fig. 6, selected bond parameters are summarized in Table 4. The apical positions of the octahedrally coordinated Cd(1) centers are occupied by N(1) of a monodentate DENA ligand [Cd(1)–N(1) = 2.360(3) Å], and by O(1) of a water molecule with Cd(1)–O(1) bond distance of 2.354(2) Å. The other four sites are occupied by bridging chloro ligands with Cd(1)–Cl bond distances in the range from 2.6203(8) to 2.6698(6) Å. Thus the Cl(1) and Cl(2) bridges form common edges to form 1D chains of Cd(II) octahedra along the *b*-axis of the monoclinic unit cell (Fig. 7). The Cd_2Cl_2-rings have similar Cd–Cl–Cd bridge angles of 97.77(3)° and 98.52(3)°. 2D

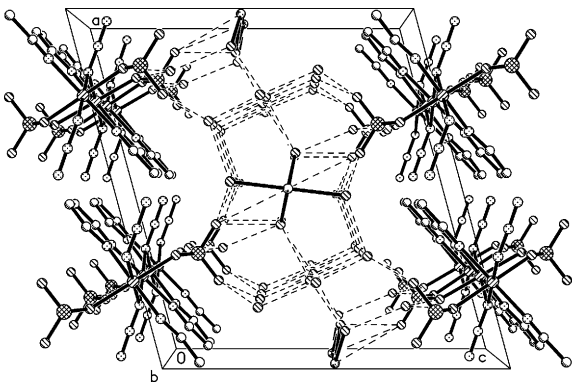

Fig. 3. Packing plot of **1**. Broken lines indicate hydrogen bonds.

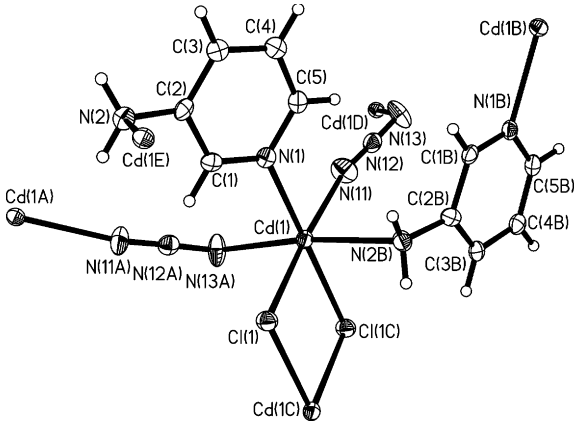

Fig. 4. ORTEP view of **2** with the atom labelling scheme.

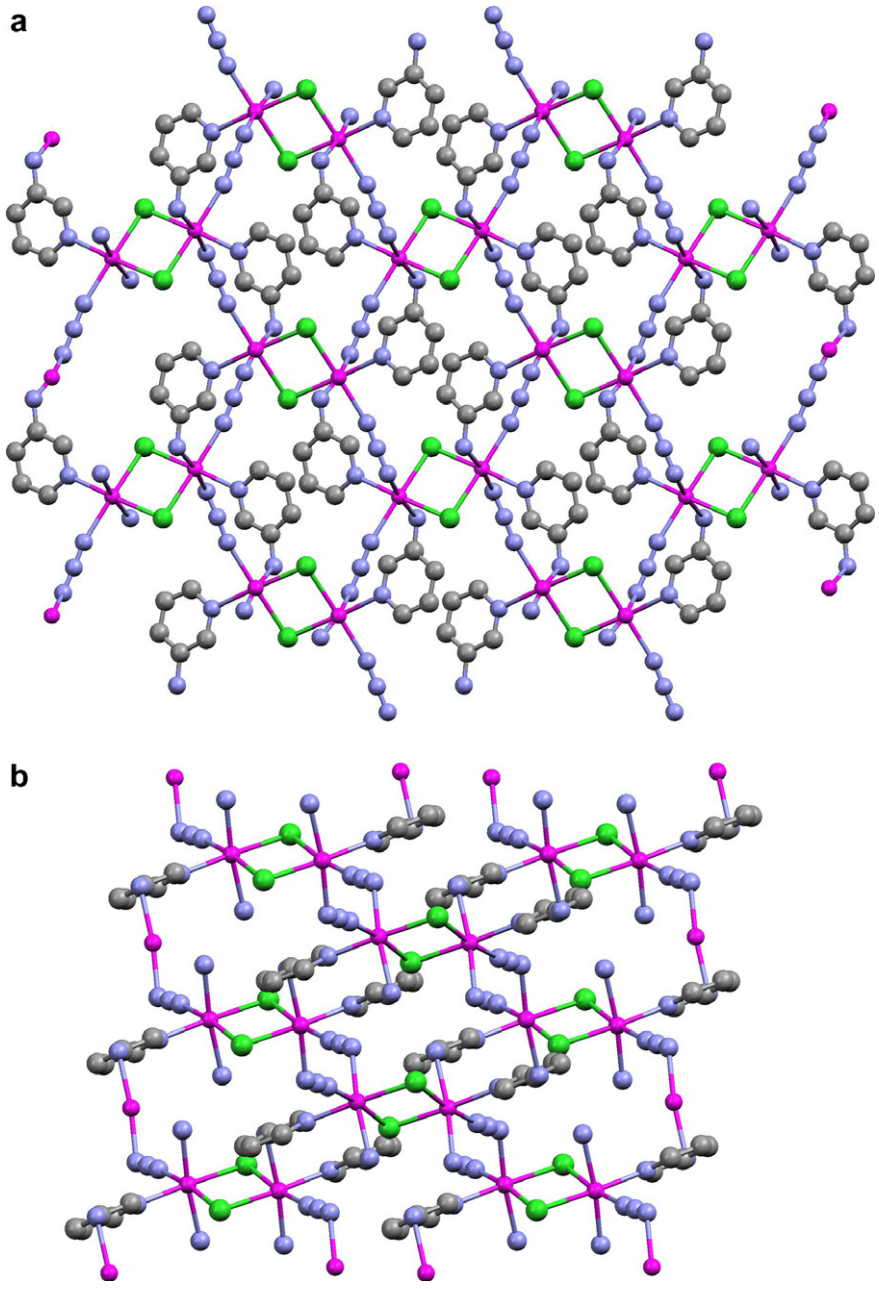

Fig. 5. Packing plots of **2** viewed along *a*- and *b*-axis of the unit cell.

supramolecular sheets extended along the *bc*-planes of the unit cell are formed by the O(1)–H(12)···O(2) $[x, 3/2 - y, -1/2 - z]$ hydrogen bond, whereas O(1)–H(11)···O(2) $[1 - x, -1/2 + y, 1/2 - z]$ is forming an intra-chain hydrogen bond.

The aromatic 6-membered rings in all three compounds show π–π stacking with the following Cg(ring)···Cg(ring) (Cg = centre of gravity) separations; (a) pyridazine ring(1) of complex **1**: [ring(1): N(1), C(1), C(2), N(1A), C(1A), C(2)]; Cg(1)···Cg(1)#1 and Cg(1)···Cg(1)#2 = 3.733(2) Å [#1: $-x, y, 1 - z$; #2 $-x, -y, 1 - z$]; (b) pyridine ring (2) of 3-aminopyridine ligand of complex **2**: [ring(2): N(1), C(1)–C(5)]; Cg(2)···Cg(2)#3 = 3.715(4) Å [#3: $1 - x, 1 - y, 1 - z$]; (c) pyridine ring(3) of *N*,*N*-diethylnicotinamide ligand of complex **3**: [ring(3): N(1), C(1)–C(5)]; Cg(3)···Cg(3)#4 = 3.601(2) Å [#4: $1 - x, 1 - y, 1 - z$].

3.2. Network analysis

All crystals are of course three-dimensional, and therefore a common misunderstanding is that any crystal will consist of a 3D-net, you just need to look hard enough. The three compounds in this report adequately illustrates that this is not the case.

First, we note that they are all built around a common structural theme, double (or triple) M–Y–M bridge (Y = O, N, N = N, Cl; M = Zn, Na, Cd) giving –M–Y–M–Y-rings.

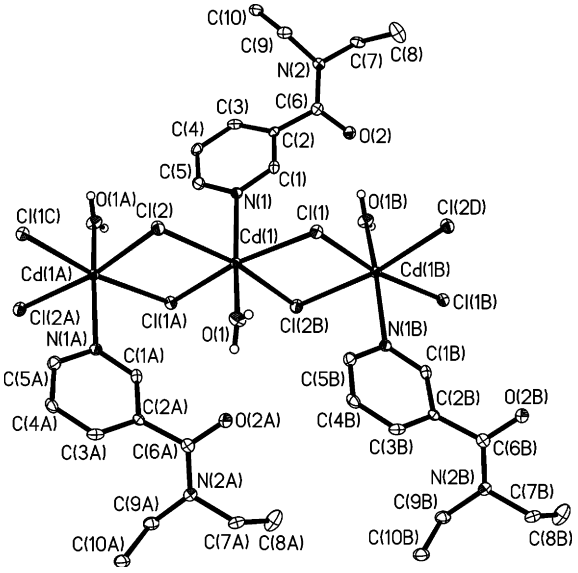

Fig. 6. ORTEP view of **3** with the atom labelling scheme.

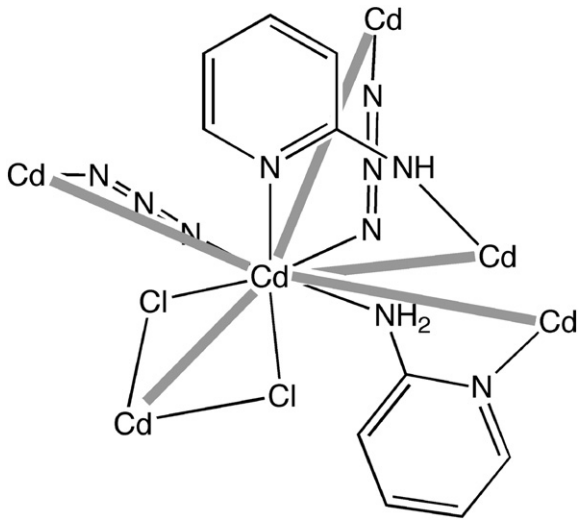

Fig. 8. Node assignment in **2**.

In compound **1** these bridges are directly connected giving both Na(I) and Zn(II) 1D coordination polymers extending along the *b*-axis. An intricate pattern of hydrogen bonds is then interconnecting these chains to give a three-dimensional crystal. However, as each Na(I) chain connects to four Zn(II) chains and two Na(I) chains with numerous attachment points using all the solvent water molecules and the coordinated waters as intermediates, there is no obvious way to single out some of these as network links and to assign nodes at specific atoms or groups of atoms. Instead, it seems much more profitable to view this structure as a parallel packing of anionic and cationic coordination polymers, a rare feature as coordination polymers are normally neutral or cationic (see Fig. 3).

Moreover, the linear $[Na(H_2O)_4]_n^{n+}$ ion is an archetypical precursor to the gel-type precipitates often formed when pH is raised in solutions of $[M(H_2O)_6]^{n+}$ although such species are rarely isolated in the solid state. Indeed, a zig-zag chain was recently found in tetradecaaquatetrasodium hexaaquanickel(II) decavanadate(V) trihydrate (see Fig. 8) [23].

In compound **2** we have a very different situation. Clearly this compound extends via covalent (dative) bonds in all three dimensions. Moreover, there is an obvious directionality of these links making node assignment easy: all links branch from the metal ions. Thus, we made the node assignment shown in Fig. 9. This results in a 3D-net comprising interconnected square pyramidal nodes with the $Cd(Cl)_2Cd$ short link in the apical position. It is rela-

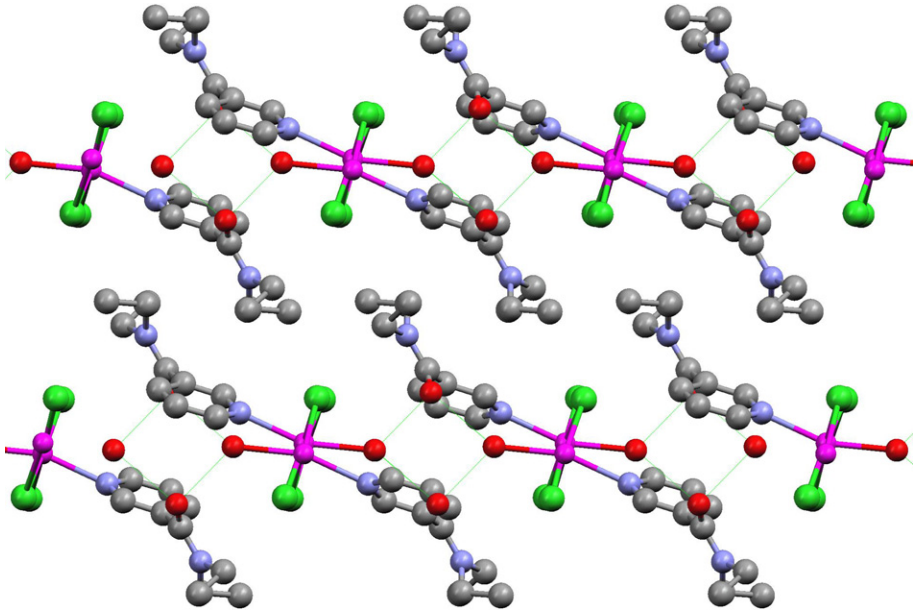

Fig. 7. Packing plot of **3** viewed along *b*-axis of the unit cell.

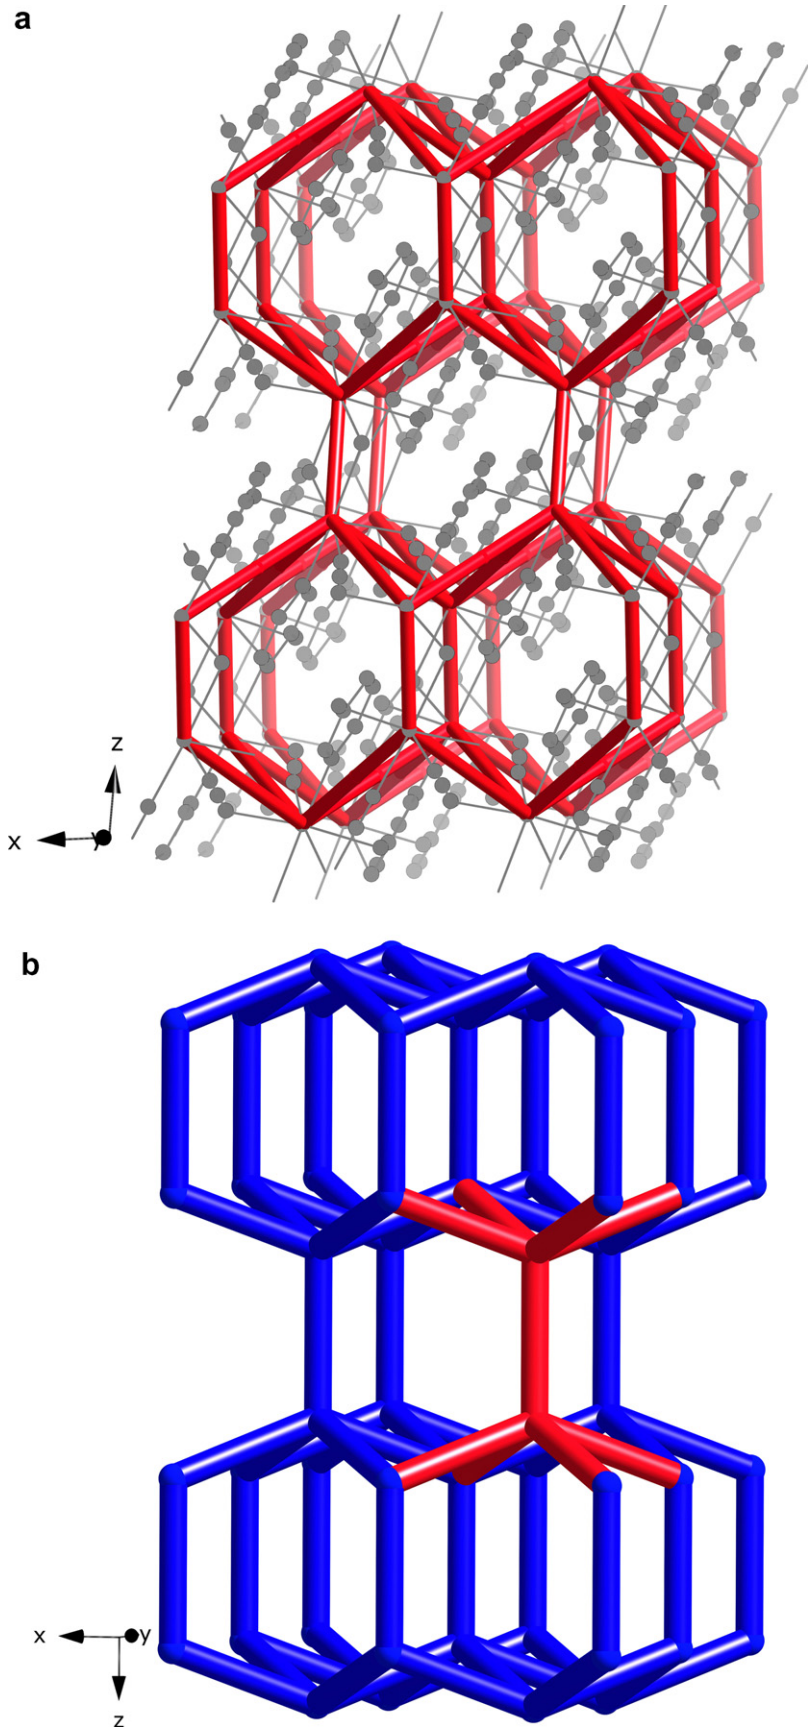

Fig. 9. (a) The $4^3 \cdot 6^6$-**sqp** net formed by compound **2**. (b) Idealized $4^3 \cdot 6^6$-**sqp** net with the characteristic staggered square pyramidal dimer highlighted in red. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

tively easy (although please refer also to Section 2) to visibly identify this net as the $4^4 \cdot 6^6$-**sqp** net (according to the new three-letter codes proposed by O'Keeffe and Yaghi [2f]. The figure preceding the code is the short (Schläfli) symbol telling us that this is a five-connected net with four and six membered rings as the smallest entities.). This is not all that surprising since this is the second most common net found with five-connected nodes, the most common being the $4^6 \cdot 6^4$-**bnn** (or boron nitride) net based on trigonal bipyramidal nodes [24]. The net superimposed on all atoms in the structure is shown in Fig. 9 together with its idealized form. We note that this might be a gemerla way to build these types of nets, a $M(Cl)_2M$ unit leaving four sites on an octahedral M^{n+} ion to propagate the net in four new directions, with an approximate square pyramidal geometry for the entire node.

Finally, compound **3** is a straightforward neutral 1D coordination polymer where parallel chains are hydrogen bonded to sheets where also ''π-stacking'' males a contribution. The ethyl groups of neighbouring sheets interdigitate each other. Thus it is difficult, and to no profit to try to impose a network on this structure.

Abstract

The reaction of $VO(acac)_2$ with 2-benzoylpyridine substituted aroylhydrazones is studied. Oxovanadium(IV) and (V) complexes are obtained, indicating the binding of ligands to the metal ion through the imine nitrogen, enolate oxygen and pyridyl nitrogen. The oxovanadium(IV) compound $[VOL^1(OCH_3)]\cdot 0.14H_2O$ (**1a**) gets oxidized to dioxovanadium(V) species $[VO_2L^1]$ (**1b**) upon crystal formation. The crystal structures of the ligand and the two vanadium complexes are reported. Single crystal X-ray diffraction studies of the compound $[VO(HL^2)(\mu_2\text{-}O)]_2$ (**2**) revealed a centrosymmetric dimer.

Keywords: 2-Benzoylpyridine; Aroylhydrazone; Crystal structures; Vanadium complexes; Dimer

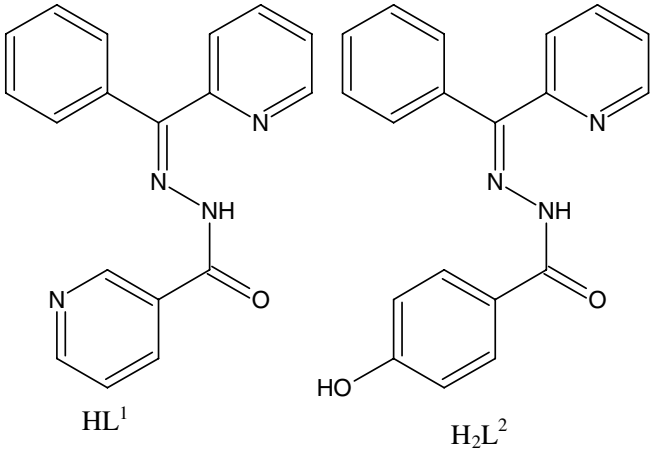
1. Introduction

Hydrazones and their metal complexes are widely studied due to their versatile applications in the field of analytical and medicinal chemistry [1–11]. Compounds containing hydrazide and acylhydrazone moieties and their complexes possess biological activity, especially as potential inhibitors for many enzymes [12,13]. Hydrazone ligands can act as bidentate, tridentate or tetradentate ligands depending on the nature of heterocyclic ring substituents attached to the hydrazone unit. These ligands due to their facile keto–enol tautomerization and the availability of several potential donor sites can coordinate with metals. Hydrazides and hydrazones have interesting ligation properties due to presence of several coordination sites.

The vanadium coordination compounds play an important role in nitrogen activation, fixation and other biologically important reactions [14–16]. The role of vanadium complexes in catalytically conducted redox reactions [17], potential pharmaceutical applications [18–20], studies on the metabolism and detoxification of vanadium compounds under physiological conditions [21] have stimulated the interest in the stereochemistry and reactivity of its coordination compounds.

As part of our research in the study of coordinating capabilities of aroyl hydrazones and their coordination compounds [22–26], we now report a new aroyl hydrazone ligand 2-benzoylpyridine 4-hydroxy benzoylhydrazone (H_2L^2) and two new vanadium compounds $[VOL^1(OCH_3)]$ and $[VO(HL^2)(\mu_2\text{-}O)]_2$.

2. Experimental



The chemicals 2-benzoylpyridine (Aldrich), 4-hydroxybenzhydrazide (Fluka), nicotinic acid hydrazide (Fluka) $VO(acac)_2$ (Merck) was of Analar grade and used without further purification.

2.1. Synthesis of ligands

The structures of the ligands are given in Fig. 1. The ligand HL^1 was synthesized as described in the literature [22]. For the preparation of H_2L^2, a mixture of 2-benzoylpyridine (0.3664 g, 2 mmol) dissolved in ethanol containing a few drops of glacial acetic acid and 4-hydroxybenzhydrazide (0.3043 g, 2 mmol) in DMF was refluxed for 6 h. The white shining crystalline precipitate obtained on cooling the reaction media was filtered, washed with ethanol and dried over P_4O_{10} in vacuo. Yield (0.415 g, 65.5%). The elemental *Anal.* Calc. for the compound: C, 71.91; H, 4.76; N, 13.24. Found: C, 70.93; H, 4.93; N, 13.13%.

HL^1 H_2L^2

Fig. 1. Structure of ligands.

2.2. Synthesis of vanadium complexes

$[VO(L^1)(OCH_3)]$ 0.14 H_2O (**1a**): A mixture of HL^1 (0.302 g, 1 mmol) in methanol and a solution of $VO(acac)_2$ (0.265 g, 1 mmol) in dimethylformamide was refluxed for 6 h. Reddish orange crystalline product separated out, which was filtered, washed with methanol, followed by ether and dried over P_4O_{10} in vacuo. Yield: 0.27 g (68.8%). Elemental *Anal.* Calc.: C, 56.72; H, 4.09; N, 13.93. Found: C, 56.05; H, 3.46; N, 13.98%.

$[VO(HL^2)(\mu_2\text{-}O)]_2$ (**2**): To a solution of H_2L^2 (0.317 g, 1 mmol) in DMF–methanol mixture, the metal salt VO $(acac)_2$ (0.265 g, 1 mmol) dissolved in dimethylformamide was added and refluxed for 6 h. The resulting deep brown solution was concentrated to half its volume and kept for evaporation. Reddish brown needle like product separated out, which was filtered, washed by ether and dried over P_4O_{10} in vacuo. Yield: 0.20 g (51%). Light yellow block shaped crystals suitable for diffraction were grown from a solution of the compound in methanol–DMF (1:1 v/v). Elemental *Anal.* Calc.: C, 57.15; H, 3.53; N, 10.52. Found: C, 57.05; H, 3.46; N, 10.66%.

2.3. X-ray crystallographic studies

Structural measurements for H_2L^2, compound **2** were performed on a Bruker Smart Apex CCD diffractometer and for compound **1b** on a Nonius MACH3 diffractometer, both equipped with fine-focused sealed tube. Crystallo-

graphic data for H_2L^2, **1b** and **2** are listed in Table 1. The unit cell parameters were determined and the data collections were performed using a graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. The data collected were reduced using SAINT [27] and MAXUS [28] programs correspondingly. The trial structure was obtained by direct methods [29] using SHELXS-97, which revealed the position of all non-hydrogen atoms and refined by full-matrix least squares on F^2 (SHELXL-97) [30] and the graphics tool used include DIAMOND (Version 3.0) [31] and ORTEP. Selected bond lengths and angles are listed in Tables 2 and 3.

3. Results and discussion

The ligand was synthesized by refluxing equimolar ratios of the corresponding hydrazide with the ketone. Complexes **1a** and **2** were synthesized in a straightforward fashion from solutions of the respective ligands and the metal salt. Oxovanadium(IV) compound **1a** oxidized to dioxovanadium(V) in the solution of the compound in DMF upon crystal formation.

3.1. Electronic spectra

The electronic spectrum of the ligand in DMF showed the $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions as a band as a shoulder at 327 and 282 nm respectively. For the dimeric oxovanadium(V) compound **2**, no d–d bands are expected as there are no d electrons. In compound **1a** the d–d bands observed in the higher frequency region are very weak. The shoulder viewed at 443 nm can be assigned to the d–d transition (Fig. 2). Compounds **1a** and **2** display an intense electronic spectral band with shoulders in the near-UV region. This band originates due to ligand to metal charge transfer transition. The values are 415 nm for **1a** and 420 nm for **2**. The other bands observed at 315 (sh) and 289 nm for **1a** and 244 and 216 nm **2** corresponds to intraligand transitions.

3.2. Infrared spectra

In the IR spectrum of the ligand H_2L^2, the bands at 3318 and 3197 cm^{-1} are assigned to O–H and N–H stretching frequencies. The carbonyl and azomethine spectral bands are observed at 1620 and 1590 cm^{-1} respectively. The band at 1537 cm^{-1} corresponds to amide II band. The bands in the range 1570–1325 cm^{-1} are difficult to assign due to crowding of bands. The IR spectra of the compounds exhibit significant alterations due to coordination of the tridentate ligand with the metal. The assignments done are tentative due to crowding of peaks. In compound $VOL^1(OCH_3)$, a medium intensity band observed with splittings at 1597 cm^{-1} is due to newly formed —C=N—N=C— moiety. The shifting of the $C{=}N_{azo}$ band,

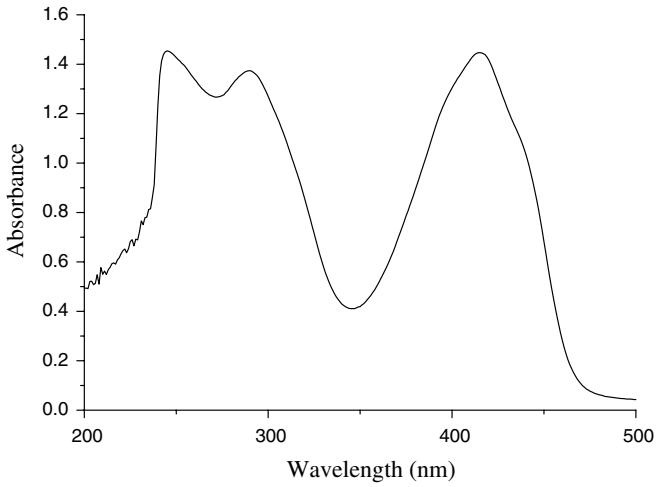

Fig. 2. Electronic spectrum of compound **1a.**

due to complexation is comparatively less when compared to that of the ligand and is found at 1580 cm^{-1}. A strong band observed at 1368 cm^{-1} is assigned to the amide III band. Strong bands are observed in the range 1510–1420 cm^{-1}. These are attributed to the aromatic ring vibrations. The band at 939 cm^{-1} is assigned to ν(V=O).

In the compound **2**, the —C=N—N=C— moiety is observed as a medium band at 1650 cm^{-1}. In the present compound, the band corresponding to the azomethine C=N bond is found to be shifted to higher frequency. The band was viewed as a strong band at 1607 cm^{-1}. Such shifting of the C=N band to higher frequencies are reported [32,33]. The amide III band is assigned for the band at 1365 cm^{-1} [34–36]. The dimeric compound exhibits the ν(V=O) band at 934 and the ν(V—(μ-O)—V) band at 898 cm^{-1} [37].

3.3. Electron paramagnetic studies

The EPR spectrum of the compound **1a** was recorded in polycrystalline state and in DMF solution at 77 K. The absence of a forbidden $\Delta M_s = \pm 2$ transition, at half the field of the allowed $\Delta M_s = \pm 1$, transition excludes the possibility for the dimeric species which would also split the resonant absorptions into 15 lines [$2nI + 1$; $n = 2$; $I = 7/2$]. In DMF solution at 77 K (Fig. 3), the compound displayed an axial spectrum. The g values calculated are $g_{\|} = 1.937$ and $g_{\perp} = 2.008$. The corresponding coupling constants are found to be 197.1 and 62.5 Gauss respectively.

3.4. Description of the structures

Colorless block shaped crystals suitable for X-ray diffraction study were grown from a solution of H_2L^2 in DMF–ethanol (1:1 v/v) media. The lattice is monoclinic in nature with $P2_1/n$ symmetry. The unit cell comprises of four molecules. The configuration along the C(6)–N(2) bond is *cis* thereby forming the intramolecular hydrogen bonded molecular structure (Fig. 4) given below. The torsion angle 2.61(19) perceived by C(5)–C(6)–N(2)–N(3) supports this. The presence of three aromatic rings and the steric requirements for the centroids Cg(1) and Cg(2) defined by atoms, N(1), C(1), C(2), C(3), C(4), C(5) and C(7), C(8), C(9), C(10), C(11), C(12) makes the molecule nonplanar. The dihedral angle value of 61.22° between these centroids supports this nonplanarity. The centroid Cg(1) makes a dihedral angle separation of 18.71° with the centroid Cg(3) defined by C(14), C(15), C(16), C(17), C(18), C(19). However, the central core of the molecule constituted by atoms C(6), N(2), N(3) and C(13) is planar as suggested by the torsion angle of −179.05° due to extensive conjugation. The C(6)–N(2) and C(13)–O(1) bond distances are within the usual range of double bonds, augmenting the fact that the molecule exists in keto form. The N(3)–N(2) bond length of 1.3658(14) is similar to the earlier reported benzoylhydrazone ligands [38,39].

In the unit cell, sets of two molecules are well arranged in an offset fashion. Each such set consisting of two molecules are then self assembled in a perpendicular fashion with the neighbouring set, which repeats to form a 3D network, by making use of intermolecular hydrogen bonding interactions. Table 4 lists the intermolecular interaction

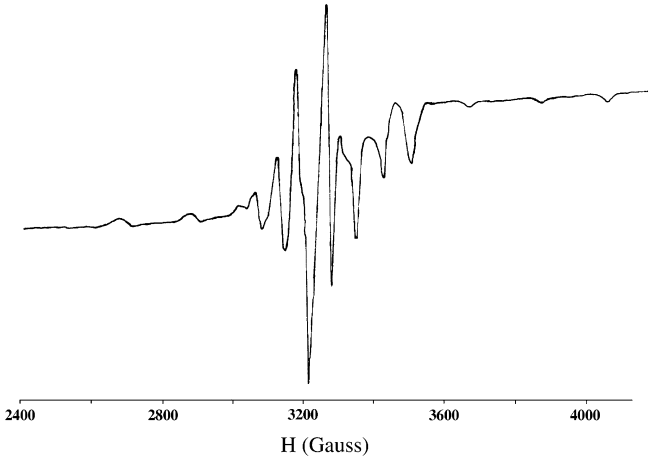

Fig. 3. EPR spectrum of compound **1a** in solution at 77 K.

X–H(I)···Cg(J)	H···Cg (Å)	X–H···Cg (°)	X···Cg (Å)	
C(18)–H(18)···Cg(3)[c]	3.393	114.52	3.873	

Equivalent position code a: $-1/2 + x, 3/2 - y, -1/2 + z$, b: $1/2 + x, 3/2 - y, -1/2 + z$, c: $1 - x, 1 - y, -z$ Cg(3) = C(14), C(15), C(16), C(17), C(18), C(19).

existing in the molecule. These intermolecular interactions perceived between the adjacent molecules in two layers leads to the tight packing of molecules in the unit cell.

The compound $VOL^1(OCH_3)$ crystallized as a dioxovanadium species **1b** due to aerial oxidation into a monoclinic lattice with $P2_1/c$ symmetry. Yellow block shaped crystals suitable for X-ray diffraction were grown from a solution of compound **1a** in a mixture of methanol and DMF (1:1 v/v). The ligand deprotonates and acts as a tridentate chelating species forming two 5-membered chelate rings surrounding the vanadium atom (Fig. 5). The oxygen atoms satisfy the other two sites of the square pyramid. Thus the compound exists in the VO_2^+ state. Comparing the bond angles, it is evident that the geometry is considerably distorted, with the axial site taken up by one of the terminal oxo atom O(2) of the VO_2 core. The $V{=}O_{apical}$ distance 1.606(2) is not exceptional [40,41]. The C(13)–O(1) bond length due to deprotonation extends to 1.307(3) Å in the complex from 1.2158(15) Å in the ligand, making the V(1)–O(1) distance, 1.969(2) Å. The V(1)=O(3) distance corresponds to 1.6495(19) Å. The *trans* angles O(3)–V(1)–N(2) 148.27(10)° and O(1)–V(1)–N(1) 145.99(8)° are reasonably compressed. As a result the basal plane constituted by atoms O(3), O(1), N(1), N(2) deviates significantly from planarity with the central vanadium atom shifted by 0.7041 Å from this plane towards the apical oxygen atom O(2).

The X-ray crystal structure of the dimeric compound $[VO(HL^2)(\mu_2\text{-}O)]_2$ **2** (Fig. 6) revealed that the one half of the molecule is related to the other half by an inversion centre [symmetry code: $2-x, -y, -z$]. The lattice is triclinic in nature with $P\bar{1}$ symmetry and the unit cell consists of one molecule and two water molecules. Our group has reported [42] a similar compound with a thiosemicarbazone derived from 2-benzoylpyridine. The centrosymmetric dimer is formed via the bridging oxygens connecting two vanadium atoms. Hence the vanadium atom adopts a distorted octahedral geometry. For dimeric vanadium chelates with an oxo bridging core, five configurations are possible in accordance with the orientation of the vanadyl groups with respect to the plane defined by the vanadium centers and the bridging oxygen atoms [43]. The configurations are *syn*-orthogonal, *anti*-orthogonal, *syn*-coplanar, *anti*-coplanar and twist. The present compound with the inversion centre, reveals that the disposition of the oxovanadium groups is *anti*-coplanar, a configuration usually found in dimeric oxovandium compounds [44,45]. The atoms O3, N2 and the bridging oxygen atoms constitute the equatorial plane, while the axial positions are occupied by the pyridyl nitrogen and enolic oxygen. Prominent deviations from the regular octahedron is evident from the bond angles O(1)–V(1)–N(1) 146.59(8)°, O(4)–V(1)–N(2) 152.75(10)°. The two 5-membered rings *viz.* V(1)–N(1)–C(5)–C(6)–N(2) (1) and V(1)–O(1)–C(13)–N(3)–N(2) (2) formed as a result of chelation exist with a dihedral angle of 6.38°. The planar central plane V(1)–O(4)–V(1a)–O(4a) consisting the inversion center, makes dihedral angles of 88.55° and 85.40° with the chelate rings (1) and (2). The

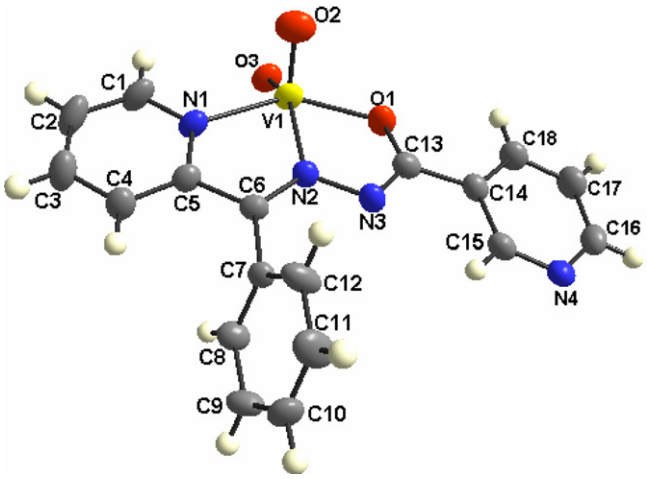

Fig. 5. Molecular structure of $VO_2(L^1)$.

Cg(3)–[1]···Cg(1)[a]	2.6956	88.55	57.36	
Cg(1)–[1]···Cg(4)[a]	3.8959	86.34	28.41	

Equivalent position code a: x, y, z.
Cg(1) = V1, O4, V1A, O4A; Cg(2) = V1, O1, C13, N3, N2; Cg(3) = V1, N1, C5, C6, N2; Cg(4) = N1, C1, C2, C3, C4, C5.
D, donor; A, acceptor; Cg, centroid; α, dihedral angles between planes I and J; β, angle Cg(I) and Cg(J).

dihedral angle between the pyridyl ring and the phenyl ring bearing the hydroxyl substituent O(2)–H is 18.12(1).

The packing in the unit cell is stabilized by short ring interactions (Table 5) and by a ring metal interaction between Cg(2) [V(1), O(1), C(13), N(3), N(2)] and V(1) at a ring metal distance of 3.962 Å. It is found that considerable π–π interactions exist between the centroids Cg(1) [V(1), O(4), V(1a), O(4a)] and Cg(2) [V(1), O(1), C(13), N(3), N(2)] and between Cg(1) and Cg(4) [N(1), C(1), C(2), C(3), C(4), C(5)] at distances of 2.6323 and 3.8959 Å respectively. The presence of water molecule leads to intermolecular hydrogen bonding. The oxygen atom O(5) of the water molecule is hydrogen bonded to O(2)–H. Also the hydrogen atoms attached to O(5) are involved in hydrogen bonding with O(4) and O(3).

Abstract

Complexes of Zn^{II} salts with 4,4′-bipyridine-*N*,*N*′-dioxide (bpdo) have been prepared by solvathermal and solvent layering methods. Three complexes were obtained from $ZnBr_2$: **1** is a 2D coordination polymer $[Zn_2Br_4(bpdo)_2]_n$, (**2**) a discrete trimetallic molecule $[Zn_3Br_6(H_2O)_2(bpdo)_4]$ and **3** a salt $[ZnBr_4][Zn(H_2O)_5(bpdo)]$. Complexes **2** and **3** contain Zn^{II} ions in both octahedral and tetrahedral coordination geometry. While in **2**, these are covalently linked by bridging bpdo ligands forming zwitterionic trimetallic molecules, in **3** there is complete charge separation into $[ZnBr_4]^{2-}$ anions and $[Zn(H_2O)_5(bpdo)]^{2+}$ cations. When $Zn(NCS)_2$ is used as starting material, a 1D coordination polymer $[Zn(H_2O)_2(bpdo)(NCS)_2]_n$ is obtained.

1. Introduction

Synthesis of metal-organic compounds attracts interest due their extensive structural diversity and potential functional properties [1–3]. A considerable amount of research has exploited bridging ligands which offer two or more donor units, such as 4,4′-bipyridine and its analogues, bound to different metals [4–8]. The metal-organic networks designed form a variety of network structures, including diamondoid [9], grids [4], honeycomb [9,10], helix [11] and brickwall [7] frameworks as well as other topological architectures. These complexes usually comprise building blocks held together by supramolecular interactions such as hydrogen bonding, van der Waals forces or π–π interactions, all of which play a role in the self-assembly process [12,13]. A number of coordination compounds of 4,4′-bipyridine-*N*,*N*′-dioxide (bpdo) with transition metals have recently been reported [14–20]. We have previously demonstrated that the topology and dimensionality of crystal structures is strongly dependent on the counteranion, while using the same metal, Co^{II} and spacer ligand, bpdo [21]. We have also undertaken studies on the effect of crystallisation conditions, including temperature and solvent systems, on the metal coordination complexes obtained. In this regard, we report here the effect of varying solvent mixtures on the complexation of Zn^{II} with bpdo. Four novel network solids $[Zn_2Br_4(bpdo)_2]_n$ (**1**), $[Zn_3Br_6(H_2O)_2(bpdo)_4]\cdot(bpdo)$ (**2**), $[ZnBr_4][Zn(H_2O)_5(bpdo)]\cdot 2(bpdo)\cdot(H_2O)$ (**3**) and $[Zn(H_2O)_2(bpdo)(NCS)_2]_n\cdot nH_2O$ (**4**) have been prepared using different crystallisation methods. Remarkably, three of these were prepared from the same salt, $ZnBr_2$. X-ray crystallographic characterisation of these products showed a diversity of structural types, including mono-, di- and tetrameric species with 0D, 1D and 2D-topologies.

Calorimetry was performed using a Perkin–Elmer DSC7 and Thermogravimetry on a Mettler Toledo TGA/sDTA 851[e], both using a heating rate of 10 °C min^{-1} under an atmosphere of dry N_2 flowing at 30 cm^3 min^{-1}.

Compound **1** was prepared by solvent layering of an ethanolic or methanolic solution of bpdo (28.23 mg, 0.15 mmol) on top of a layer of 5 mL $CHCl_3$ or CH_2Cl_2 in which $ZnBr_2$ (22.52 mg, 0.10 mmol) had been placed, but not fully dissolved. Compounds **2**–**4** were prepared by slow evaporation of a solution containing bpdo and the metal salt. In a typical preparation of **2**, 22.40 mg (0.10 mmol) $ZnBr_2$ was dissolved in 1.5 mL methanol. 27.53 mg (0.15 mmol) bpdo was dissolved in 3 mL methanol and added to the metal salt solution. The solvent was allowed to evaporate slowly at ambient temperatures and colourless crystals were achieved within a week. Similar preparations using same chemical quantities as above were done by replacing methanol with ethanol to acquire compound **3**. For compound **4**, ethanolic solutions of $Zn(NCS)_2$ (19.10 mg, 0.10 mmol, 2 mL) and bpdo (28.60 mg, 0.15 mmol, 4 mL) were mixed. The mixture was filtered through a 0.5 μm filter and the solvent was allowed to evaporate slowly at room temperature. Colourless crystals were afforded in two weeks.

Compound **1** was unstable to atmospheric conditions when removed from the mother liquor, while compound **4** was very hygroscopic making preparatory measures for microanalysis or powder X-ray diffraction (for **4**) impossible. PXRD (HUBER Guinier 670 Imaging Plate diffractometer with Cu Kα radiation, 1.542 Å) established that the bulk material of compounds **1**, **2** and **3** had the same crystal phase as the crystals selected for single-crystal analysis. Elemental analysis confirmed this: Compound **2**: Found: C, 36.62; H, 2.67; N, 8.39%, $[Zn_3Br_6(C_{10}H_8N_2O_2)_4(H_2O)_2]\cdot(C_{10}H_8N_2O_2)$ requires C, 36.34; H, 2.68; N, 8.48%; Compound **3**: Found: C, 32.39; H, 2.90; N, 6.99%, $[ZnBr_4][Zn(H_2O)_5(C_{10}H_8N\ {}_2O_2)]\cdot 2(C_{10}H_8\ N_2O_2)\cdot(H_2O)$ requires C, 32.09; H, 3.23; N, 7.48%. Thermal analysis of compounds **1**–**4** showed that all four begin to decompose at temperatures above 70 °C and decomposition is complete just above 300 °C. The mechanism of decomposition is complex, but seems to involve the loss of coordinated and guest water molecules in each case.

2.2. Crystal structure and refinement

All data for crystal and molecular structure determination were measured on a Nonius KappaCCD diffractometer using graphite-monochromated Mo Kα radiation (0.7107 Å) at 113 K. In each case, a series of frames were recorded with width ranging from 1° to 1.5° in ϕ or in ω (with $\kappa \neq 0$) to ensure completeness of the data collected to $\theta > 25°$. The unit cell was indexed from the first twenty frames and positional data were refined along with diffractometer constants to give the final cell parameters. Integration and scaling correction (DENZO, scalepack) [22] resulted in unique data sets corrected for Lorentz-polarization effects and for the effects of crystal decay and absorption by a combination of averaging of equivalence reflections and an overall volume and scaling correction. The structures were solved using SHELXS-97 and refined using the full-matrix least squares methods in SHELXL-97 [23], with the aid of the program XSEED [24].

Crystal structure refinement data are given in Table 1. Non-hydrogen atoms were modeled anisotropically. Hydrogens attached to water molecules were located in the difference electron density maps where possible and refined with a distance restraint for compounds **1**–**3** and independently in compound **4**. Other hydrogen atoms were assigned an isotropic thermal parameter 1.2 times that of their parent atom and refined using a 'riding' model. Images of crystal and molecular structures were rendered using the program POV-Ray [25].

3. Results and discussion

Crystals isolated from layered solutions of $ZnBr_2$ in chloroform and bpdo in alcohol were characterised as the 2D coordination polymer $[Zn_2Br_4(bpdo)_2]_n$ (**1**) in which both Zn^{II} metal centres are coordinated to two bromide ions and three bpdo ligands (Fig. 1). The Zn–Br bond lengths are 2.373 and 2.382 Å, respectively corresponding well with the literature value of 2.390 Å [26]. The metal ion adopts a distorted trigonal bipyramidal coordination geometry (O1–Zn1–O8 154.9°) with oxygen atoms in the equatorial plane and bromide ions in the axial positions. The bridging bpdo ligand is asymmetrically placed relative to the Zn ions, with Zn–O bond lengths of 2.039 and 2.353 Å. The third Zn–O length, to a third bpdo ligand is 2.100 Å. Compound **1** forms a planar layer with metal centres bridged by the bpdo ligands *via* terminal oxygen atoms forming double strand polymer chains (Fig. 2a). The bridged zinc metals are separated from each other by a distance of 3.659 Å and the bridging oxygen terminals are 2.449 Å apart. The bridging angle Zn1–O8–Zn1 is 112.66°. There are no classic hydrogen bonds in **1**, but there are $\pi\cdots\pi$ interactions between aromatic rings within each layer and adjacent layers are linked through weak C–H···O and C–H···Br hydrogen bonds (Fig. 2b, Table 2).

By contrast, slow evaporation of a methanol solution of $ZnBr_2$ and bpdo produced $[Zn_3Br_6(H_2O)_2(bpdo)_4]\cdot(bpdo)$ (**2**), while an ethanolic solution of the same stoichiometry produced $[ZnBr_4][Zn(H_2O)_5(bpdo)]\cdot 2(bpdo)\cdot(H_2O)$ **(3)** (Fig. 3). There are two zinc environments present in both **2** and **3**: one octahedral and one tetrahedral. In **2**, a centrosymmetric molecule is formed with a metal:ligand ratio of 3:4. This acts as host to a further bpdo molecule included as a guest. The octahedral Zn(1) ion is coordinated to two water molecules and four *trans*-bpdo's. Two of the latter form the bridges to two end groups consisting of tetrahedrally coordinated $[ZnBr_3]^-$ groups. At Zn(1), the Zn(1)–O(aqua) bond length is 2.080 Å, while the Zn(1)–O(bpdo) bond lengths are 2.072 Å and 2.110 Å. These values correspond well with literature values [26]. Bond angles around Zn(1) range from 86.85° to 93.15°. At the tetrahedral centre, Zn(2)–Br lengths average 2.397 Å and Zn(2)–O(bpdo) is 2.011 Å. Bond angles around Zn(2) range from 100.49° to −117.11°, a distortion from ideal tetrahedral geometry. The coordinated bpdo rings are twisted by between 15.2° and 27.8° while the guest bpdo rings are coplanar. The discrete molecules are connected by O–H···O hydrogen bonding (Fig. 4; Table 2) through coordinated water molecules and the oxygens of the coordinated bpdo

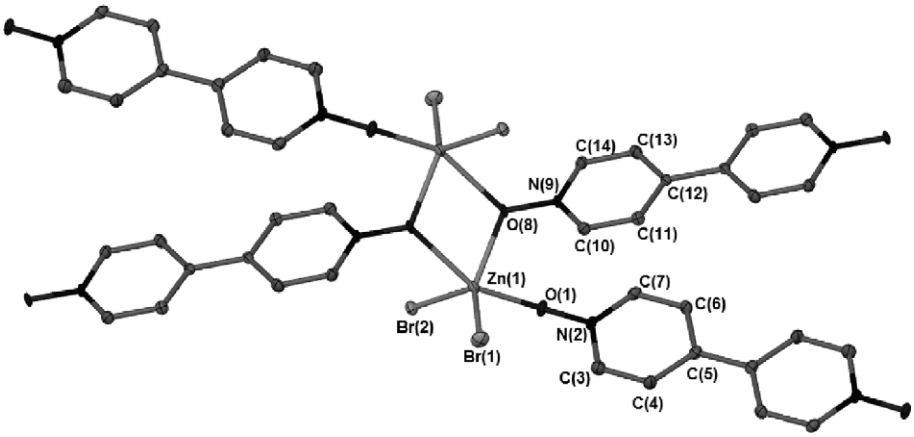

Fig. 1. Molecular structure of **1**. Ellipsoids shown at 50% probability.

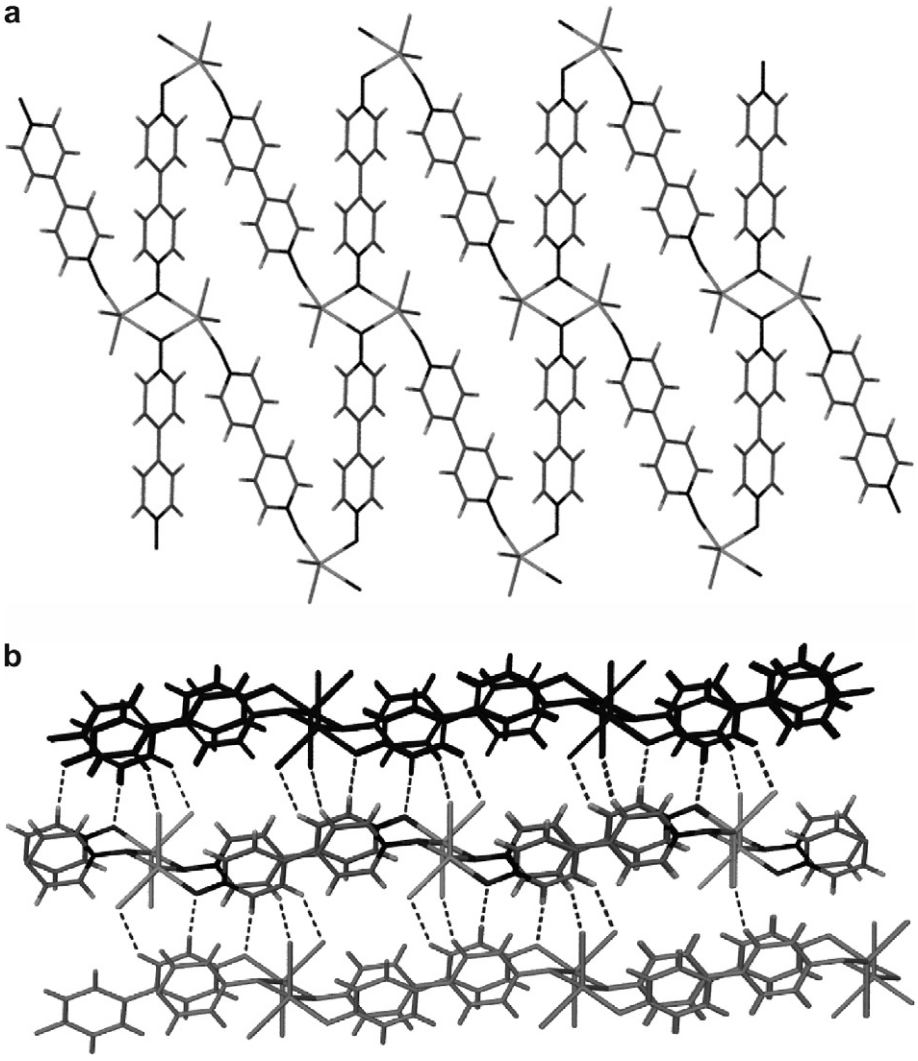

Fig. 2. (a) Two-dimensional polymer chains form a planar layer in **1** and (b) packing of layers in **1**, showing weak hydrogen bonds between layers.

ligands. Extensive weak C–H···O and C–H···Br interactions as well as π···π interactions between aromatic rings, contribute to the packing of the X-shaped molecules into a host framework which forms channels to accommodate bpdo guest molecules. These are held in place by π···π interactions between guest and host aromatic rings.

Interestingly a different compound, **3**, was formed when the components were crystallised from ethanol rather than methanol. Like **2**, **3** has two independent zinc ions with octahedral and tetrahedral coordination geometries, this time in separate entities. In **3**, the Zn(1) ion is coordinated to one bpdo ligand and five water molecules forming an octahedral cation $[Zn(bpdo)(H_2O)_5]^{2+}$ while Zn(2) is coordinated to four bromide counterions adopting a tetrahedral coordination geometry $[ZnBr_4]^{2-}$. A further two bpdo ligands are included without coordinating. Both guest and coordinated bpdo rings are twisted by between 15.3° and 17.9°. The Zn(1)–O(aqua) bond lengths range from 2.044 to 2.129 Å while Zn(1)–O(bpdo) is 2.092 Å. The bond angles deviate slightly from the expected value of 90° being between 84.75° and 93.06°. Around Zn(2), Zn–Br bond lengths are 2.414–2.424 Å (literature value 2.39 Å). Br–Zn–Br bond angles are between 108.29° and 110.35°. Discrete $[Zn(bpdo)(H_2O)_5]^{2+}$ are linked by a network of hydrogen bonding through coordinated water molecules, bpdo and guest water molecule (Fig. 5). These "host" molecules pack into layers parallel to the *c*-axis. Intercalated between these layers are the $[ZnBr_4]^{2-}$ anions as well as layers of bpdo guest molecules, packed in herringbone fashion, and hydrogen bonded to the host framework. The crystal structure is stabilized by extensive C–H···O, C–H···Br and π interactions (summarized in Table 2).

A search of the Cambridge Crystallographic Database (Version 5.27, May 2006) [27] found several examples of octahedral zinc complexes containing an associated $[ZnX_4]^-$ (X = Cl or Br) anion [28], but only one example of a zwitterionic trimetallic molecule [29]. In that case,

the Zn^{II} ions were coordinated to an ethylenediamine derivative of adenine. In **2**, the $[ZnBr_3]^-$ end moieties of the zwitterionic molecule are tucked into pockets between the aromatic rings of coordinated and guest bpdo molecules. As may be expected, there are several C–H···Br contacts holding these ends in place (Table 2, Fig. 4). In **3**, the individual cation complex interdigitates, forming chains running parallel to the *c*-axis with strong inter-ion O–H···O interactions. Hydrogen bonds crosslink these chains with water and bpdo guest molecules (Fig. 5, Table 2). The

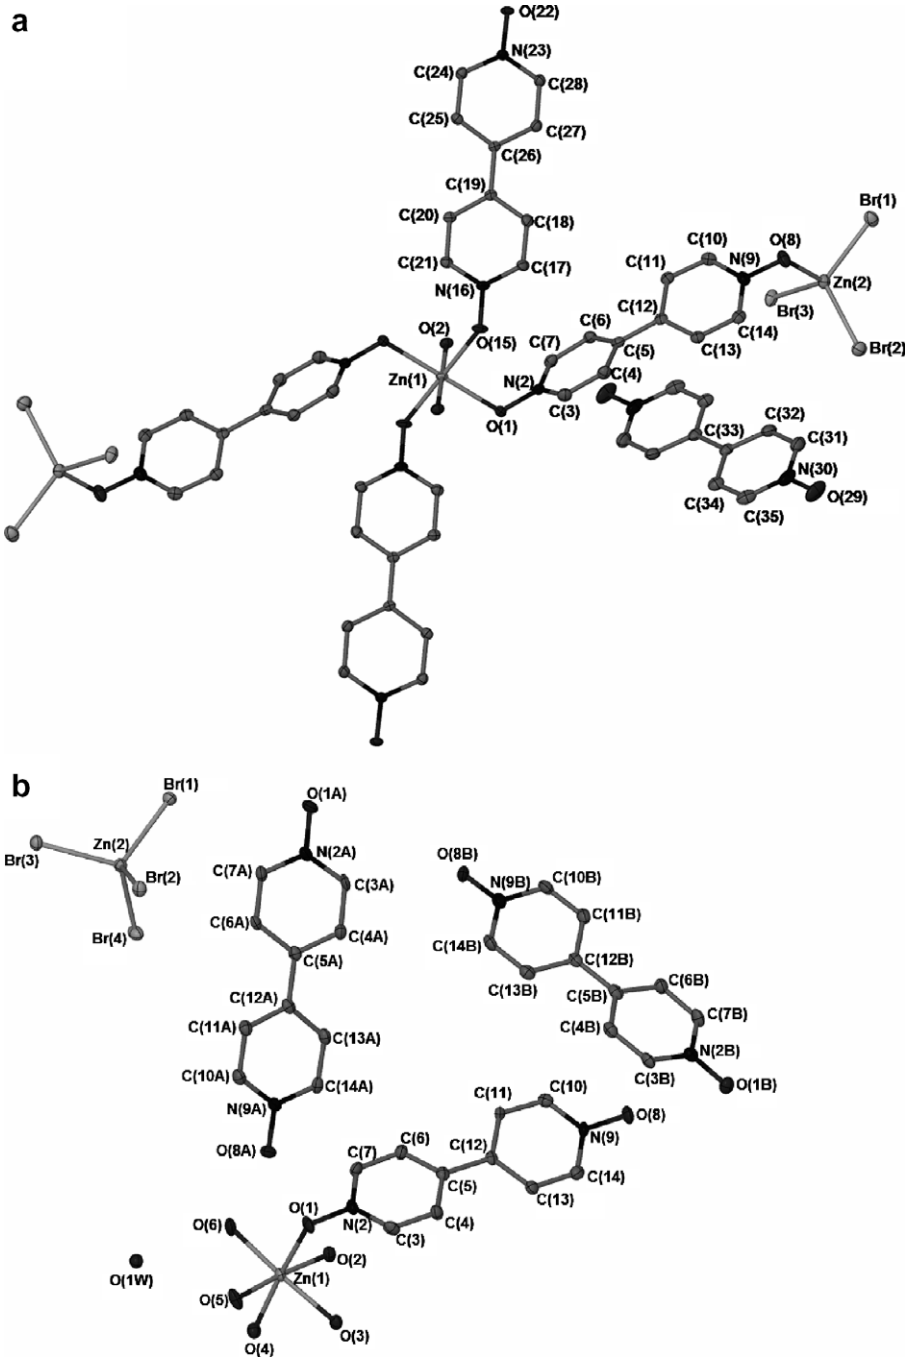

Fig. 3. X-ray structures of (a) **2** and (b) **3**. Ellipsoids shown at 50% probability.

environment around the $[ZnBr_4]^{2-}$ anions is similar to that in **2**. They are also surrounded by aromatic rings, with several C–H···Br contacts.

Changing the counterion, in **4**, gives rise to the formation of a 1D coordination polymer. Previous work [30] had suggested that using these starting materials in a similar method produced a coordination polymer characterised as $[Zn_2(bpdo)_3(NCS)_4]$. No crystal structure of this material was available but the infrared spectrum was consistent with a polymeric structure having terminal NCS groups. In this study we obtained material which is polymeric and has terminal NCS groups but has a metal:ligand ratio of 1:1, rather than 2:3. The central Zn ion is coordinated by two NCS^- counterions in the axial positions, while the equatorial positions are occupied by two water molecules and two bpdo ligands, resulting in octahedral coordination geometry (Fig. 6). All bond lengths and angles were within the expected ranges [26]. The Zn–N bond length is 2.034 Å, while Zn–O(bpdo) and Zn–O(aqua) are 2.154 Å and 2.169 Å respectively. Adjacent polymer chains are linked by a network of hydrogen bonds between the aqua and bpdo ligands (Fig. 7a). Coordinated water (O16)

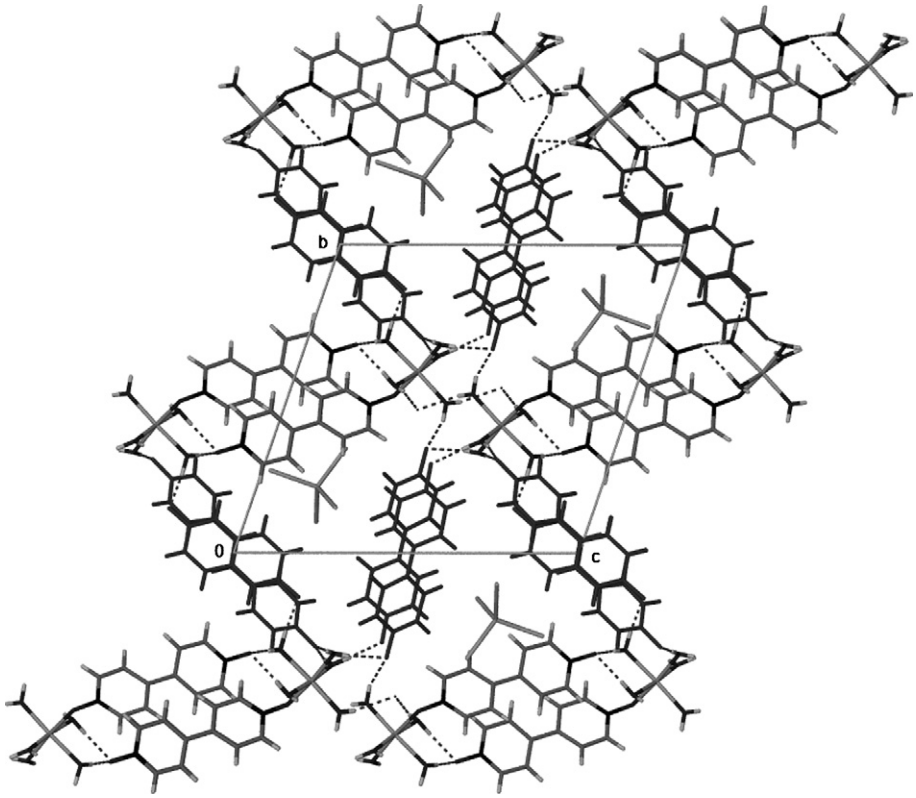

Fig. 5. Layers of $[Zn(bpdo)(H_2O)_5]^{2+}$ and bpdo guests in **3**. The latter are depicted in darker grey. Only O–H···O hydrogen bonds are shown.

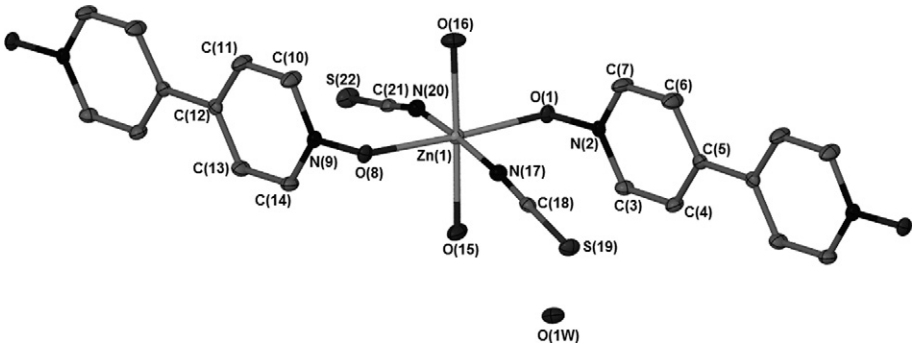

Fig. 6. Molecular structure of **4**. Ellipsoids shown at 50% probability.

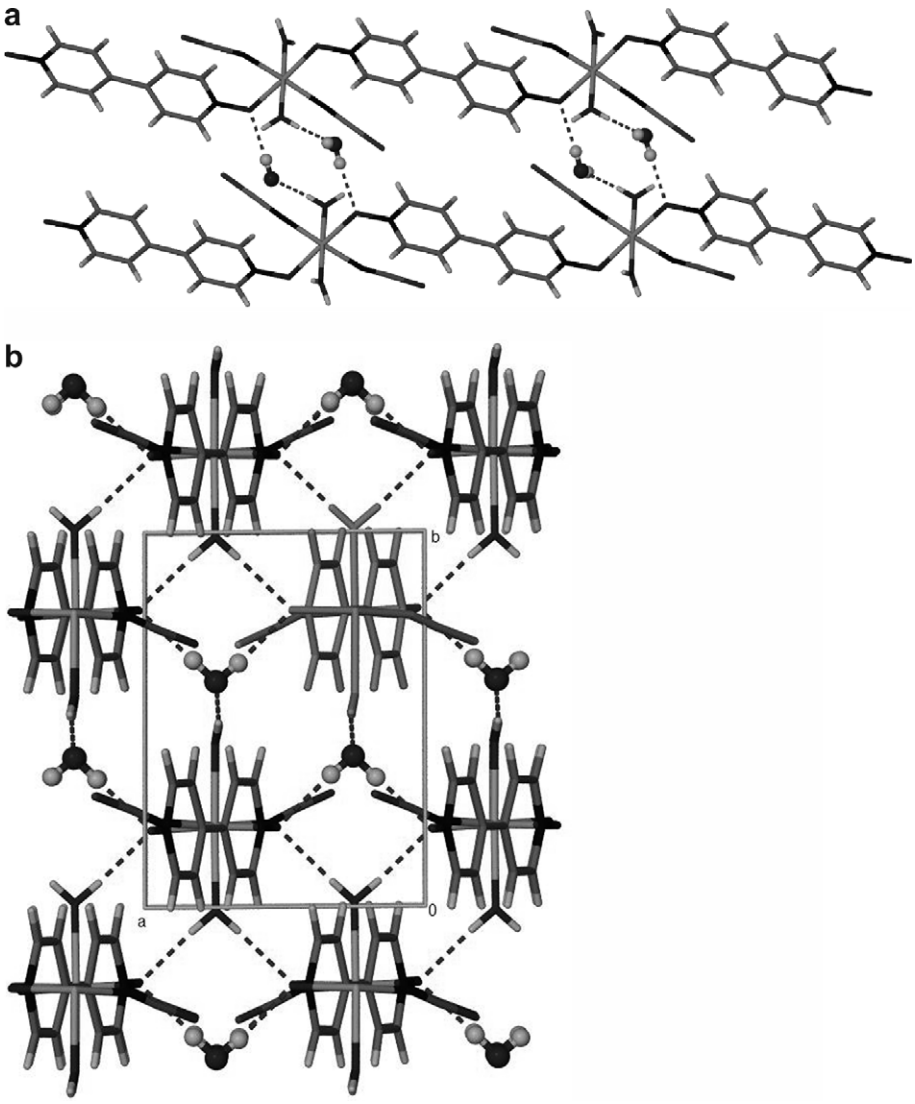

Fig. 7. (a) Hydrogen bonding interactions link adjacent 1D coordination polymers in **4** and (b) guest water molecules are located in channels between the 1D chains.

donates hydrogen bonds {O(16)–H(16A)···$O(1)_{bpdo}$ and O(16)–H(16B)···$O(8)_{bpdo}$} to the terminal oxygens of the coordinated bpdo ligand with the $O(16)_{aqua}$···$O(1)_{bpdo}$ distances of 2.839 Å and 2.853 Å, respectively. The *trans*-coordinated water molecule donates hydrogen bonds (O(15)–H(15B)···O(1W)) to guest water molecule with the O(15)···O(1W) guest distance of 2.662 Å. The guest water molecule in return donates hydrogen bonds, O(1W)–

H(1W1)···O(8) and O(1W)–H(1W2)···O(1), to two coordinated bpdo ligands linking the adjacent chains with the O···O distance of 2.793 Å for $O(1W)_{aqua}\cdots O(8)_{bpdo}$ and 2.848 Å for $O(1W)_{aqua}\cdots O(1)_{bpdo}$. A summary of hydrogen bonding and π interactions is given in Table 2. The water molecules are found in channels running parallel to [0 0 1] as shown in Fig. 7b.

4. Conclusion

4,4′-Bipyridine-*N*,*N*′-dioxide forms a neutral 1:1 metal to ligand 1D coordination polymer **4** with $Zn(NCS)_2$ but a trimeric molecule **2** and a monomeric cationic complex **3** with $ZnBr_2$ under the same conditions. When crystallisation conditions are altered, the neutral 2D coordination polymer (metal to ligand 1:2) **1** is obtained, also from $ZnBr_2$.

Complexes **2** and **3** contain both octahedral and tetrahedral Zn(II) ions: in **2** these are covalently linked by bridging bpdo ligands forming zwitterionic trimetallic molecules while in **3** there is complete charge separation into $[ZnBr_4]^{2-}$ anions and $[Zn(H_2O)_5(bpdo)]^{2+}$ cations. Although the packing of these two compounds is quite different, the $[ZnBr_3]^-$ entities are located in similar chemical environments and both compounds have included guest bpdo molecules in channels which run through the crystal structure. Complexes **1** and **4** are both coordination polymers which form layered structures. In **1**, planar layers are linked by weak hydrogen bonding but **4** consists of zigzag polymer layers which are linked by strong O–H···O hydrogen bonding through bridging water molecules.

While bpdo is often cited as a bidentate ligand which may be expected to form a bridge between metal centres, this work illustrates that this is not always the case. Bpdo serves as a bridging ligand in **1**, **2** and **4**, but there are also terminal bpdo ligands in **2** and **3**. A CSD search identified 50 structures with bpdo present: in 24 cases the bpdo acts as a bridging ligand, there are seven structures in which it is coordinated via only one end, eight structures in which it is not coordinated, even in the presence of a metal ion and eleven structures which contain bpdo but no metal species.

Abstract

A new dinuclear compound, $[Cu_2(bpdo)_2Br_4]$, (in which bpdo = 2,2′-Bipyridine-1,1′-dioxide), has been synthesized and fully characterized, including the X-ray and the magnetic susceptibility. Each copper(II) ion in the dinuclear compound has a distorted square pyramidal geometry with the basal plane formed by two oxygen atoms of two ligand molecules which are bridging between the Cu ions with Cu–O distances of 2.021(2) and 2.039(2) Å and two bromide atoms with Cu–Br distances of 2.3577(6) and 2.3665(7) Å. The fifth position is occupied by a non bridging oxygen atom of a ligand with a Cu–O distance of 2.197(2) Å. The distance between the Cu ions is 3.334 Å, while the Cu–O–Cu angle is 110.37(9)°. The magnetic susceptibility measurements (from 5 to 350 K) agree with a very strong antiferromagnetic interaction with a large singlet–triplet splitting (J) of $-905\ cm^{-1}$. At high T (above 250 K) a triplet powder EPR is observed.

1. Introduction

2,2′-Bipyridine-1,1′-dioxide (hereafter abbreviated as bpdo) is a useful tool in crystal engineering [1] and synthesizing new electroactive materials [2]. Also the chelating properties of this heterocyclic NO-donor ligand have been studied especially with copper(II) [3–6], however, without obtaining X-ray crystal structures. So far one X-ray crystal structure with Fe(III) [7] and only a few X-ray structures with Cu(II) and the bpdo ligand have been reported [8–13].

Baran and co-workers [8] published two isomeric structures with the general formula $[Cu_2(bpdo)_2Cl_4]$, a green isomer which contains a chloride bridge and an yellow-orange isomer containing an *N*-oxido-bridge. The magnetic susceptibility reveals a very weak antiferromagnetic interaction (with $J = -0.8\ cm^{-1}$) for the green isomer and a very strong antiferromagnetic interaction ($J = -730\ cm^{-1}$) for the yellow-orange isomer. To investigate the influence of the anion on the magnetism, we synthesize the bromide compound with bpdo, $[Cu_2(bpdo)_2Br_4]$. It appeared that in this case only one isomer can be obtained. In this paper we present the synthesis, spectroscopic measurements, X-ray crystal structure, as well as the magnetic susceptibility measurements of the bromide compound $[Cu_2(bpdo)_2Br_4]$, a dinuclear compound with 2*N*-oxido-bridges, in a comparable geometry as for the yellow-orange isomer of the corresponding chloride [8].

2. Experimental

2.1. General

C,H,N determinations were performed on a Perkin–Elmer 2400 Series II analyzer. Ligand field spectra were obtained on a Perkin–Elmer Lambda900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. X-band powder EPR spectra were obtained on a Jeol RE2x electron spin resonance spectrometer using DPPH ($g = 2.0036$) as a standard. FTIR spectra were obtained on a Perkin Elmer Paragon 1000 FTIR spectrophotometer equipped with a Golden Gate ATR device, using the reflectance technique (4000–300 cm^{-1}, res. 4 cm^{-1}). Magnetic susceptibility measurement (5–350 K) were carried out (at 0.1 T) using a Quantum Design MPMS-5S SQUID magnetometer. Data were corrected for the magnetisation of the sample holder and for diamagnetic contributions, which were estimated from Pascal constants.

2.2. Synthesis of the coordination compound

The ligand bpdo was used as commercially available and handled without additional purification. 1.2 mmol of $CuBr_2$ and 1.2 mmol of the ligand bpdo were each dissolved in 10 ml of methanol. The Cu(II) salt solution was then added slowly to the ligand solution and filtered to remove any undissolved material. After a few days crystalline brown-red products separate. The were isolated by filtration and dried in air.

Yield about 72%, Elemental *Anal.* Calc. for $C_{20}H_{16}Br_4Cu_2N_4O_4$: C, 29.2; H, 2.0; N, 6.8. Found: C, 29.0; H, 2.1; N, 6.8%. No other compounds were isolated from this solution, irrespective of the M:L ratio, and/or changing the solvent or temperature.

2.3. Crystal structure determination and refinement

A suitable crystal was selected from the mother liquid and mounted to a glass fibre using the oil-drop method; data were collected on a Nonius KappaCCD diffractometer (graphite-monochromated Mo Kα radiation). The intensity data were corrected for Lorentz and polarization effects, for absorption and extinction. The structures were solved by direct methods. The programs COLLECT [14], SHELXS-97 [15], SHELXL-97 [16] were used for data reduction, structure solution and structure refinement, respectively. Refinement of F^2 was done against all reflections. All non-hydrogen atoms were refined anisotropically. All H atoms were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms. Crystallographic data are presented in Table 1.

3. Results and discussion

3.1. Description of the crystal structure

A thermal ellipsoid plot, together with the numbering scheme is shown in Fig. 1, with selected bond lengths and bond angles given in Table 2. The centrosymmetric dinuclear unit has a centre of symmetry located between the Cu(II) ions. The basal plane of the 5-coordinated Cu ion is occupied by two oxygen atoms of two ligand molecules which are bridging between two Cu ions with Cu–O distances of 2.021(2) and 2.039(2) Å and two bromide atoms with Cu–Br distances of 2.3577(6) and 2.3665(7) Å. The fifth position is occupied by a non-bridging oxygen atom of a ligand with a Cu–O distance of 2.197(2) Å. The geometry of 5-coordinated compounds can be described by the

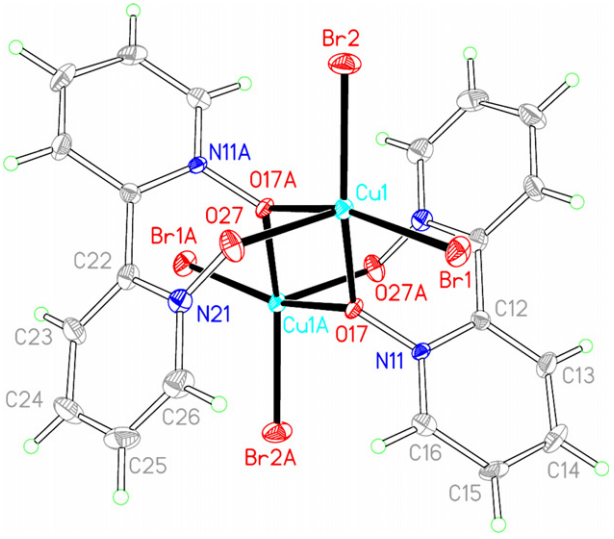

Fig. 1. Atomic displacement plot (50% probability level) of the molecular structure of $[Cu_2(bpdo)_2Br_4]$.

Table 2

A = symmetry operation $-x, -y, -z+1$.

parameter τ ($\tau = (\beta - \alpha)/60$, where β and α are the largest coordination angles, $\tau = 0$ for square pyramidal (SP) and $\tau = 1$ for trigonal bipyramidal (TBP) geometry) [17]. The two largest angles in this case are 162.00(6)° and 151.76(7)°, so the τ value is 0.17, agreeing with a distorted square-pyramidal geometry for the Cu ions. The distance between the Cu ions is 3.3339(9) Å, while the Cu–O–Cu angle is 110.37(9)°. The related yellow-orange chloride isomer [8] has a slightly smaller distortion, in that case the τ value = 0.13, a comparable Cu–Cu distance of 3.333(1) Å and a slightly smaller Cu–O–Cu angle of 109.2°.

3.2. Spectroscopy and EPR

The ligand-field transition measured as a solid with the diffuse reflectance technique is observed as a very broad band with a maximum at about 10.0×10^3 cm^{-1}. This is a normal ligand field transition for (distorted) square pyramidal geometries and weak ligands [18]. In the IR spectra the N–O stretching vibrations were observed at 1221 and 1204 cm^{-1} and the N–O bending vibrations at 844 and 833 cm^{-1}. The Cu–O vibration was observed at 408 cm^{-1}. These vibrations are in agreement with the vibrations found for the chloride isomer [8].

The EPR spectra of the compound was recorded as a polycrystalline powder at RT and 77 K from 0 to 800 mT at X-band frequency ($h\nu = 0.325$ cm^{-1}). The spectrum at RT reveals a typical $S = 1$ triplet spectrum with transitions observed at 140, 225, 340 mT as broad bands and a split broad band at 430, 470 and 525 mT (see Fig. 2). The signal at 140 mT can be assigned to the forbidden half-field signal ($\Delta M_s = \pm 2$), while the band at 340 mT is the $S = 1/2$ resonance from a mononuclear impurity, which usually is present in dinuclear Cu(II) compounds. The broad unresolved bands at 225 mT and the more or less split band at 430, 470, 525 mT can tentatively be assigned to the H_{x1y1z1} and the H_{x2}, H_{y2} and H_{z2}, respectively [24,25] The zero-field splitting parameter D can be estimated as 0.2 cm^{-1} (with $g_{av} = 2.19$) [26]. At 77 K the solid changed from red brown colour to yellow ochre and no signals were observed any more, only the $S = 1/2$ resonance at 340 mT from the monomeric impurity is present. These features are in agreement with the magnetic susceptibility measured (vide infra), as no triplet state is occupied any more at this low T. After re-synthesizing the yellow-orange chloride bridged isomer[1] also the same type of EPR spectrum was observed (see Fig. S1), with very similar parameters.

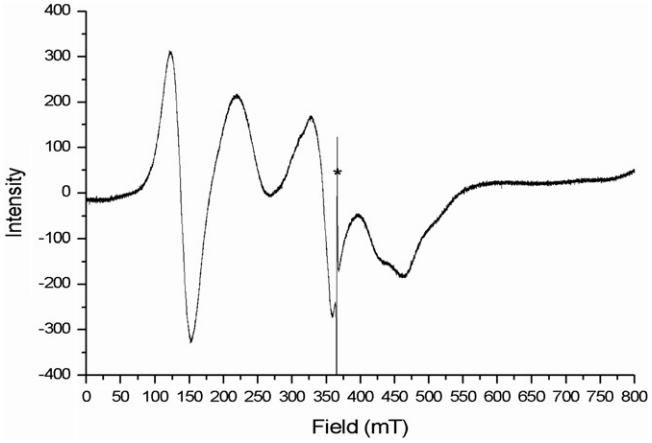

Fig. 2. EPR spectrum of the title compound at RT. A star denotes DPPH.

3.3. Magnetic properties

The magnetic susceptibility of a powdered sample was measured from 5 to 350 K. The magnetic properties of the title compound are depicted in Fig. 3 in the form of $\chi_m T$ versus T for two Cu(II) ions. At 350 K the $\chi_m T$ product has a value of 0.097 cm^3 mol^{-1} K (0.81 μ_B), which is far below the spin-only value for two non-interacting Cu(II) ions (0.75 cm^3 mol^{-1} K, 2.83 μ_B, at RT). From 350 K the $\chi_m T$ product decreases gradually to a value of 0.005 cm^3 mol^{-1} K (0.21 μ_B) at 5 K. This magnetic behaviour agrees with a very strong antiferromagnetic interaction.

The theoretical expression for the magnetic susceptibility for two interacting $S = 1/2$ centres, which is based on the general Hamiltonian [19] is: $H_{ex} = -JS_1S_2$, in which the exchange parameter J, is negative for antiferromagnetic and positive for ferromagnetic interaction. The magnetic data were fitted to the equation given in the literature [19] for dinuclear copper compounds:

$$X_m = (2Ng^2\beta^2)[kT - (2zJ'/(3 + \exp(-J/kT)))]^{-1} [3 + \exp(-J/kT)]^{-1}(1 - p) + X_p p,$$

in which N, g, β, k and T have their usual meanings [19]. The parameter p denotes the fraction of paramagnetic impurity in the sample and zJ' the interaction between neighbouring dinuclear identities. The fit was accomplished by minimisation of $R = (\chi_m \cdot T_{calc} - \chi_m \cdot T_{obs})^2/(\chi_m \cdot T_{obs})^2$ by a least-squares procedure. The best fit for the title

[1] The yellow-orange isomer $[Cu_2(bpdo)_2Cl_4]$ (from Ref. [8]) was resynthesized as described by Baran et al., although it appears that the solution had to be refluxed for at least 16 h in stead of the earlier reported 2.5 h to obtain the yellow-orange product. In the original article [8] only a broad peak at around 50 mT with no splitting was observed in the EPR spectrum at RT.

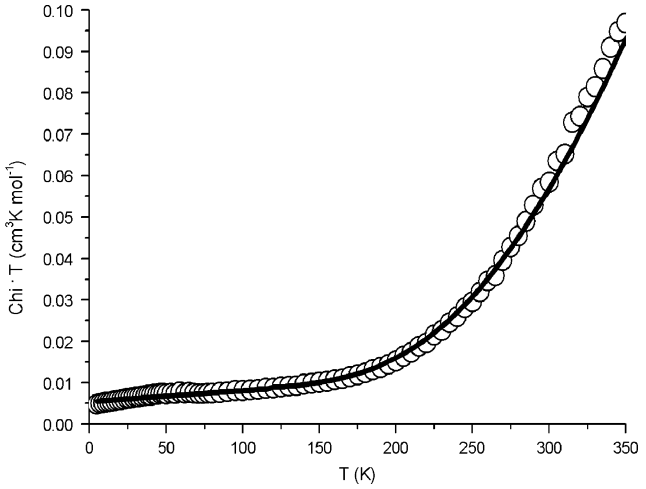

Fig. 3. A plot of the temperature dependence of $\chi_m T$ vs. T for $[Cu_2(bpdo)_2Br_4]$. The solid line represents the calculated curve for the parameters $J = -905$ cm^{-1}, $g = 2.15$ (see text).

compound, depicted in Fig. 3 as a solid line, was obtained for $J = -905$ cm^{-1}, $g = 2.15$, $zJ' = 0.02$ cm^{-1}, $p = 0.01$, with a final R of 2×10^{-2}. The R value appears a bit high, but that is ascribed to the fact that susceptibility measurements above 300 K are less accurate due to a reduced accuracy in temperature.

4. Conclusion

In this paper a new dinuclear compound with formula $[Cu_2(bpdo)_2Br_4]$ has been synthesized, characterized by infrared spectroscopy, EPR and also the X-ray structure and the magnetic susceptibility have been investigated. The compound has a double bridge consisting of the oxygen atom of the bpdo ligand and is isostructural with the related chloride compound $[Cu_2(bpdo)_2Cl_4]$ [8]. Unlike the case for the earlier reported chloride compound, no other isomer could be isolated for the bromide. Hatfield and Hodgson proposed a correlation between the Cu–O–Cu angle and the magnetic interaction for dinuclear planar hydroxido-bridged compounds [20,21]. This correlation considers the fact that for Cu–O–Cu angles greater then 97.6° the overall magnetic behaviour is antiferromagnetic and for smaller ones a ferromagnetic coupling is observed. Later the same type of correlations were also established for alkoxido-bridged compounds [22,23]. Hatfield and Hodgson [20,21] deduced a linear correlation between J and α (α = Cu–O–Cu angle) as $J = -74\alpha + 7270$. In our case the Cu–[O–O]–Cu chromophore is also planar, a good overlap of the magnetic orbitals can be proposed, even though the bridging ligands are N-oxides instead of hydroxide. The Cu–O–Cu angle for the bromide compound is 110.37° and according to the correlation formula a value of -897 cm^{-1} would be predicted, which fits well the observed value of -905 cm^{-1}. The analogues chloride compound [8] has a Cu–O–Cu angle of 109.2°, which would give a calculated value of -811 cm^{-1}, compared to an observed value of -730 cm^{-1} in the literature [8] and of -777 cm^{-1} by re-measuring of the chloride adduct [Ref. 1 and Fig. S2]. The difference in magnetic interaction is most probably related to the change in the Cu–O–Cu angle. The Cl and Br anions appear to play only a minor role in this, as e.g. the Cl–Cu–Cl and Br–Cu–Br angles are 102.2(1)° and 101.9(2)°, respectively.

Abstract

Ditopic oximehydrazonate iron(II) phthalocyaninoclathrochelates were synthesized by a transmetallation (a capping group exchange) reaction of the initial labile triethylantimony-capped clathrochelate iron(II) oximehydrazonates with lutetium(III) phthalocyanine as a Lewis acid. The complexes obtained were characterized using elemental analysis, PD and MALDI-TOF mass spectrometries, IR, UV–Vis, ^{57}Fe Mössbauer, and ^{1}H, ^{13}C{^{1}H} NMR spectroscopies. An encapsulated iron(II) ion was found to be in a low-spin state. The cyclic voltammograms show oxidation and reduction waves assignable to $Fe^{2+/3+}$ couples of macrobicyclic framework and to phthalocyanine macrocycles.

1. Introduction

The hybrid polytopic transition metal complexes, which molecules contain the distal and isolated fragments with relatively independent π- and σ-electronic systems, are the most promising precursors for molecular electronic devices [1–6] and the artificial photoexcited long-lived donor–acceptor charge separation systems with photosynthetic properties [7–13]. The recently synthesized tris-dioximate iron(II) phthalocyaninoclathrochelates belong to the type of ditopic complexes with highly intensive visible absorption bands of both the macrocyclic (phthalocyanine) and macrobicyclic (clathrochelate) fragments of the hybride molecule [14].

Unlike the clathrochelate tris-dioximate precursor, both capping fragments of which are reasonably labile in the transmetallation reactions [15,16], in case of the oximehydrazonate clathrochelates [16–23] only trioximate capping fragment may undergo transmetallation. However, the intramolecular rearrangements without destruction of the cage framework have been observed for clathrochelates with 1,3,5-triazacyclohexane hydrazonate capping fragment only (in particular, to give a tripodal methine fragment in case of triethyl orthoformate derivatives) [20]. The iron(II) ion has proved to be the most efficient template in the synthesis of such compounds. Moreover, among the synthesized earlier boron-, tin-, germanium- and antimony-capped iron(II) clathrochelates, the triorganylantimony-capped complexes undergo the

Scheme 1.

transmetallation reactions only. Therefore, we proposed the following strategy for the synthesis of the hybrid oximehydrazonate phthalocyaninoclathrochelates (Scheme 1): the initially obtained triethylantimony-capped clathrochelate iron(II) oximehydrazonates undergo transmetallation reactions with Lewis-acidic rare-earth metal(III) phthalocyanines (in particular, with diamagnetic lutetium(III) phthalocyanines). This allowed us to obtain intracomplex hybrid oximehydrazonate phthalocyaninoclathrochelates (the formal positive 2+ charge of the encapsulated iron(II) ion is compensated by the formal negative 2− charge of the capping O_3LuN_4 fragment). The formation of this intracomplex facilitated the isolation and purification of the resulting hybrid clathrochelate. On the other hand, the nature of this compound increases its solubility in aprotonic polar and apolar organic solvents (chloroform, methylene dichloride and benzene). Eight *n*-butyl substituents in the phthalocyanine fragment enhance significantly the solubility of both the initial lutetium(III) phthalocyanine and the target hybrid clathrochelate in these solvents as well. The use of the diamagnetic lutetium(III) ion as a capping one allowed us to control the course of the reactions by ^{1}H and ^{13}C NMR spectroscopies.

2. Experimental

2.1. General procedures

The reagents used, $NaClO_4$, paraformaldehyde, triethyl ortoformate (TOF), $CaCO_3$, sorbents, organic bases, and solvents were obtained commercially (Fluka). Complex $Fe(CH_3CN)_4Cl_2$ was prepared as described elsewhere [24]. The triethylantimony(V) dibromide and diacetylmonoxime hydrazone (HDXO) were synthesized by known procedures [25,26].

Analytical data (C, H, N content) were obtained with a Carlo Erba model 1106 microanalyzer. Iron content was determined spectrophotometrically.

The plasma desorption (PD) mass spectrum of $[FeDXO_3(HCOC_2H_5)_3(Sb(C_2H_5)_3)](ClO_4)$ complex was recorded in the positive spectral region using a BC MS SELMI time-of-flight mass spectrometer and an accelerating voltage of 20 kV. The ionization was induced by ^{252}Cf spontaneous decay fragments, and typically 20 000 decay acts were registered. The sample (approximately 1–2 mg) was applied to a gilded disk.

The MALDI-TOF mass spectra were recorded using a MALDI-TOF-MS Bruker Autoflex mass spectrometer in reflecto-mol mode. The ionization was induced by UV-laser with wavelength 336 nm. The samples were applied to a nickel plate, 2,5-dihydroxybenzoic acid was used as a matrix. The accuracy of measurements was 0.1%.

The IR spectra of solid samples (KBr tablets) in the range of 400–4000 cm^{-1} were recorded with a IR200 Thermo Nicolet FT-spectrophotometer.

The UV–Vis spectra of solutions in methylene dichloride were recorded in the range of 230–900 nm with a Lambda 9 Perkin–Elmer spectrophotometer. The individual Gauss components of these spectra were calculated using the SPECTRA program.

The ^{1}H and ^{13}C NMR spectra were recorded from CD_2Cl_2, DMSO-d_6 and $CDCl_3$ solutions with a Bruker AC-200 FT-spectrometer.

The ^{57}Fe Mössbauer spectra were obtained with a YGRS-4M spectrometer with a constant acceleration mode. The spectra were collected with a 256-multichannel

amplitude analyzer. The isomer shift was measured relative to sodium nitroprusside, and an α-Fe foil was used for the velocity scale calibration. ^{57}Co in a chromium matrix was used as the source, which was always kept at room temperature. The minimal absorption line-width in the spectrum of a standard sample of sodium nitroprusside was 0.24 mm/s.

Voltammetric experiments were performed with a potentiostat–galvanostat IPC-Win in a conventional one-compartment three-electrode cell. Working electrode was either platinum (Pt) or glassy carbon (GC) disk electrode with an active surface area of 0.085 cm^2. The electrodes were thoroughly polished and rinsed before measurements. A platinum wire counter electrode and Ag/AgCl/KCl with a salt bridge filled with 0.15 M $(Bu_4N)BF_4$ solution in *o*-dichlorobenzene as a reference electrode were used. The formal potential of the ferrocene Fc/Fc^+ couple versus RE is about 600 mV in *o*-dichlorobenzene. The scan rate was varied from 20 to 200 mV/s. All solutions in *o*-dichlorobenzene (10 ml) were thoroughly deaerated before the experiments and all measurements were made under argon.

2.2. Synthesis

Complex [Lu(Bu$_8$Pc)(CH$_3$COO)] was prepared as described in Ref. [27]. ^{1}H NMR ($CDCl_3$/DMSO-d_6 (3:1)): δ (ppm) 1.10 (t, 24H, CH_3(Bu)), 1.65 (m, 16H, γ-CH_2), 1.95 (m, 19H, CH_3 (acetate)+β-CH_2), 3.15 (m, 16H, α-CH_2), 9.20 (s, 8H, HAr). ^{13}C{^{1}H} NMR (CD_2Cl_2): δ (ppm) 14.3 (s, CH_3(Bu)), 23.3 (br s, CH_3(acetate)), 23.6 (s, CH_2(Bu)), 34.0 (s, CH_2(Bu)), 34.5 (s, CH_2(Bu)), 122.9 (br s, Pc), 137.1 (s, Pc), 142.8 (s, Pc), 155.3 (s, Pc). UV–Vis (CH_2Cl_2): λ_{max}/nm ($\varepsilon \times 10^{-3}$, mol^{-1} l cm^{-1}) 253 (48), 273 (37), 289 (27), 316 (28), 350 (80), 387 (15), 422 (8.2), 584 (4.9), 623 (27), 654 (20), 686 (145).

2.2.1. *[FeDXO$_3$ (Sb(C$_2$H$_5$)$_3$)](ClO$_4$)*

Complex $Fe(CH_3CN)_4Cl_2$ (2.9 g, 10 mmol), diacetylmonooxime hydrazone (3.4 g, 30 mmol), $CaCO_3$ (2 g) and $NaClO_4$ (6 g) were dissolved/suspended in acetonitrile (70 ml) under argon and the solution/suspension of $(C_2H_5)_3SbCO_3$, obtained by reaction of $(C_2H_5)_3SbBr_2$ (7.72 g, 20 mmol) with Ag_2CO_3 (8.27 g, 30 mmol) in acetonitrile (20 ml), was added. The reaction mixture was stirred for 1 h, heated to boiling and the solvent (~40 ml) was evaporated for 1.5 h. The reaction mixture was diluted with methylene dichloride (50 ml) and filtered. The filtrate was rotary evaporated to dryness and extracted with chloroform–acetonitrile 10:1 mixture. The extract was evaporated to a half-volume and precipitated with hexane. The precipitate was filtrated, washed with hexane and dried in vacuo (yield: 1.06 g, 15%). *Anal.* Calc. for $C_{18}H_{39}N_9O_7ClFeSb$: C, 30.59; H, 5.57; N, 17.84; Fe, 7.90. 2.2.2. *[FeDXO$_3$ (HCOC$_2$H$_5$)$_3$(Sb(C$_2$H$_5$)$_3$)] (ClO$_4$)*

Complex $[FeDXO_3(Sb(C_2H_5)_3)](ClO_4)$ (1.6 g, 2.26 mmol) was dissolved in chloroform (50 ml) and an excess of OIF (2 ml) was added. The reaction mixture was refluxed under argon with drier for 3 h, cooled to room temperature and left overnight. Then the reaction mixture was evaporated to ~20 ml, diluted with diethyl ether (100 ml) and filtered. The filtrate was evaporated to dryness, washed with hexane and extracted with methylene dichloride–hexane 1:2 mixture. The extract was evaporated to dryness, the solid residue was washed with hexane and dried in vacuo (yield: 0.40 g, 20%). *Anal.* Calc. for $C_{27}H_{51}N_9O_{10}ClFeSb$: C, 37.06; H, 5.89; N, 14.41; Fe, 6.38. 2.2.3. *[FeDXO$_3$ (CH$_2$)$_3$(Sb(C$_2$H$_5$)$_3$)](ClO$_4$)*

The dry freshly-distilled acetonitrile (10 ml) was saturated with gaseous formaldehyde, obtained by distillation of paraform (0.5 g), and 3 Å molecular sieves (2 g) were added. Then the solution of complex $[FeDXO_3(Sb(C_2H_5)_3)](ClO_4)$ (0.17 g, 0.24 mmol) in acetonitrile (5 ml) was added. The reaction mixture was left for 3 days, and then filtered. The filtrate was rotary evaporated to dryness, the solid residue was washed with methanol, hexane and dried in vacuo. The product was extracted with a small amount of methylene dichloride and the extract filtered was evaporated to dryness. The dark-violet product was reprecipitated from methylene dichloride solution with hexane, washed with hexane and dried in vacuo (yield: 0.12 g, 67%). *Anal.* Calc. for $C_{24}H_{39}N_9O_7ClFeSb$: C, 33.96; H, 5.30; N, 16.97; Fe, 7.52. 3. Results and discussion

3.1. Synthesis

The synthesis of the ditopic complexes is limited by several factors: the macrobicyclic tris-diiminates can be obtained by a template synthesis with cross-linking Lewis acids, which form the apical groups with a target geometry and a given size of the capping atoms (~0.25/0.8 Å). This is accounted for by the requirement of the geometrical complimentarity of an apical capping group and a target rigid macrobicyclic framework. Moreover, the successful self-organization in multicomponent template reaction is caused by the geometrical complimentarity of a template metal ion and the fragments of this macrobicycle. The deviations of the geometrical parameters of the initial entities of a macrobicyclic ligand from ideal ones direct this template reaction to the differ pathways and result in nonmacrocyclic by-products. Nevertheless, we have obtained relatively sterically strained clathrochelates via the modification reactions of the initially synthesized "regular" macrobicyclic precursors [14,16,28]. In particular, the complexes with an encapsulated cobalt(I) ion have been obtained by chemical reduction of the parent cobalt(II) clathrochelates [28].

We used successfully the transmetallation (exchange of the capping fragments) reaction of the triorganylantimony-capped clathrochelates, obtained by a direct template synthesis, in order to change apical capping groups. These clathrochelates undergo the unique (in the series of clathrochelate complexes) transmetallation reaction under mild conditions without destruction of the macrobicyclic framework. This approach allowed to obtain a series of the ditopic tris-dioximate phthalocyaninoclathrochelates one of the two apical capping groups of which contains the sevencoordinate Hf^{4+} and Zn^{4+} ions ($r_i \sim 0.9$ Å) [14].

In the present study this pathway (Scheme 1), using an antimony-capped clathrochelate as a macrobicyclic precursor (synthon), allows us to synthesize the ditopic oximehydrazonate clathrochelates whereas we failed to obtain these complexes by a direct template reaction. Our attempts to use the described earlier [21] triphenylantimony-capped oximehydrazonate iron(II) clathrochelate as

a precursor also gave no desired product: this clathrochelate is insufficiently labile in the transmetallation reactions with the weak Lewis-acidic rare-earth metal phthalocyanines. Additionally, the Shannon ionic radii of the apical rare-earth metal ions are essentially greater than the optimal ones (in particular, in case of the Lu^{3+} ion $r_i \sim 1.1$ Å). Therefore, we obtained much more labile oximehydrazonate clathrochelate synthon with triethylantimony capping group, the transmetallation reactions of which proceeded readily and in relatively high yields (~50–60%). It should be emphasized that a greater lability of the triethylantimony-capped clathrochelates is accounted for by a lower Lewis acidity of the trialkylantimony(V) compounds when compared with that of the triarylantimony(V) derivatives. This causes difficulties in the synthesis of such more labile clathrochelates. In particular, trying to obtain the triethylantimony-capped oximehydrazonate iron(II) semiclathrochelate, one should remove water in the course of reaction, which results in the equilibrium shift in the direction of the target complexes. In contrast, triphenylantimony-capped clathrochelate complexes are formed in high yields in aqueous solutions [21]. The synthesis of labile clathrochelates is also complicated by side reactions (in particular, by the reduction of antimony(V) to antimony(III)). These side reactions may be caused by a low equilibrium concentration of the triethylantimony-capped iron(II) semi- and clathrochelates in the reaction mixture and essentially decrease the yield of the target products. The high lability of triethylantimony capped fragment is the reason of relatively low (~20%) yield in the macrocyclization reaction of triethylantimony-capped semiclathrochelate with TOF. On the other hand, there are some difficulties in using of column chromatography on SiO_2 and Al_2O_3 for purification of the triethylantimony-capped complexes since they undergo the transmetallation reactions on surface of these Lewis-acidic sorbents.

3.2. Structure and spectra

The formation of the ditopic clathrochelate complexes was confirmed both by elemental analysis and MALDI-TOF mass spectra, which contained highly intensive peaks of the molecular ions of the hybrid oximehydrazonate phthalocyaninoclathrochelates. The relative intensities of the isotope peaks of molecular and fragment ions were calculated from the data on the abundance of natural isotopes of all elements forming a part of these ions. The composition of molecular or fragment ions in the experimental mass spectra was confirmed by comparing the isotope peak series of these ions with the calculated ones.

The ^1H and ^{13}C NMR spectra of hybrid compounds obtained were appreciably different from those for their clathrochelate and phthalocyanine precursors: these spectra contained no characteristic signals assigned to the triethylantimony capping fragment and the acetate counter ion, respectively. The ^{13}C NMR spectra showed the significant (by 20 ppm) lowfield shift of the signals of the carbon atoms of phthalocyanine macroring. In the ^1H NMR spectra the significant shift was also observed for the signals assigned to the methyl substituents of the oximehydrazonate fragments because of the magnetic field of the π-electron current in the conjugated phthalocyanine macrocycle. The formation of hybrid complexes has a more dramatic effect on ^{13}C NMR signals of both oxime and hydrazonate carbon azomethine atoms of the cage ligand donor groups. These signals are widened drastically due to the effects of the lutetium phthalocyanine-containing capping fragment and, therefore, were not observed in the spectra. In contrast, the ^1H and ^{13}C NMR signals of hydrazonate fragments, which shifted essentially after the transmetallation reaction, remained narrow. In particular, in the case of the formaldehyde derivative, the spin–spin interaction between nonequivalent axial and equatorial hydrogen atoms of the methylene fragment with characteristic constant $J_{^1H-^1H} \sim 20$ Hz was distinctly observed in the ^1H NMR spectrum. The ^{13}C NMR chemical shift of the signal of carbon methine atom ($\delta_{^{13}C} \sim 155$ ppm) of triethoxy-substituted 1,3,5-triazacyclohexane ring remains practically unchanged after transmetallation and is similar to those for tin-, germanium- and antimony-capped clathrochelate oximehydrazonates [16,20–22]. Such value of the chemical shift differs significantly from the chemical shift ($\delta_{^{13}C} \sim 90$ ppm) of this type carbon atoms in the ^{13}C NMR spectra of the boron-capped clathrochelate oximehydrazonates with *syn*, *syn*, *syn*-orientation of the ethoxy substituents at the 1,3,5-triazacyclohexane ring relative to the clathrochelate framework [20]. Thus, both the clathrochelate $[FeDXO_3(HOC_2H_5)_3(Sb(C_2H_5)_3)]^+$ precursor and the hybrid $[FeDXO_3(HCOC_2H_5)_3(Lu(Bu_8Pc))]$ complex are *anti*-, *anti*-, *anti*-isomers of the corresponding clathrochelates: all of the ethoxy groups and the clathrochelate framework are located on the different sides of the plane passing through the nitrogen atoms of the 1,3,5-triazacyclohexane fragment.

The isomeric shift (IS) values in the ^{57}Fe Mössbauer spectra (Table 1) of the triethylantimony-capped semiclathrochelate complex and the clathrochelate precursor as well as the hybrid oximehydrazonate phthalocyaninoclathrochelates obtained are typical for the low-spin iron(II) complexes. The quadrupole splitting (QS) values in these spectra have been used for deducing of a geometry of the low-spin iron(II) complexes in cases, when the direct X-ray crystallography data cannot be obtained (in particular, we failed to obtain the monocrystals of the complexes synthesized, suitable for X-ray crystallography, because of low symmetry of their molecules and, in case of hybrid compounds, due to their intracomplex character and high number of the aliphatic substituents in the macrocyclic fragment). As shown earlier [15,29], QS has a positive sign (level e_1 is higher than level a_1 in energy) in trigonal prismatic complexes (TP, $\varphi = 0°$) and decreases with an increase of the distortion angle φ of a coordination N_6-polyhedron up to ~30°. Then the inversion of the levels takes place (level a_1 becomes higher in energy than e_1 level;

Table 1

[a] X-ray data.

QS has a negative sign) and QS increases in absolute value with an increase of the φ value up to 60° (trigonal antiprism, TAP). As mentioned above, the passing from boron-capped iron(II) clathrochelates (TP geometry) to antimony-, tin- and germanium-containing analogues with a greater size of a capping atom leads, as a rule, to an increase of the φ value (TAP geometry). In all cases, QSs for complexes obtained are greater in absolute value than QS for their X-ray crystallographically characterized TP boron-capped $[FeDXO_3(HCOC_2H_5)_3(BC_6H_5)](BF_4)$ analog [20]. It is clear, that QSs for all complexes synthesized have a negative sign. This allowed us to deduce TAP geometry for all complexes obtained as well as to deduce the distortion angle φ values from 40° to 50°, listed in Table 1.

The solution UV–Vis spectra of the hybrid clathrochelates obtained (Fig. 1) contain bands of both chromophoric centers of the ditopic molecule. The intense ($\varepsilon \sim 3-8\times10^4\ mol^{-1}\ l\ cm^{-1}$) bands of the π,π*-transitions both in the dioximate fragments of the clathrochelate framework and in the phthalocyanine macrocycle are overlapped

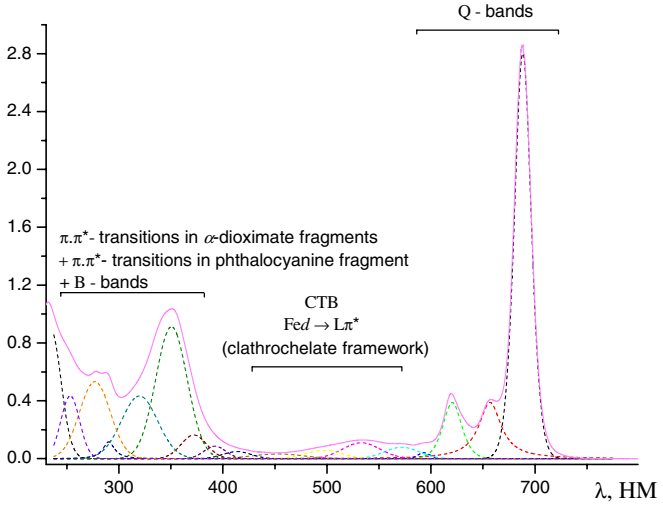

Fig. 1. UV–Vis spectrum of the methylene dichloride solution of $[FeDXO_3(HCOC_2H_5)_3(Lu(Bu_8Pc))]$ phthalocyaninoclathrochelate (—) and Gauss components of this spectrum (—).

with the phthalocyanine B-bands. The observed four intense ($\varepsilon \sim 5-9\times10^3 mol^{-1}\ l\ cm^{-1}$) bands at 500–600 nm in visible region were assigned to the Fed → Lπ* charge transfer bands in the clathrochelate fragment [15]. These bands are overlapped slightly with the most intensive ($\varepsilon \approx 2\times10^5\ mol^{-1}\ l\ cm^{-1}$) characteristic Q-bands of a phthalocyanine fragment.

3.3. Electrochemistry

The cyclic voltammetry data present the information concerning the stability of electrochemically generated cationic and anionic forms of iron(II) clathrochelates, which is important for the estimation of the influence of structural functionalization on the stability of the cage molecules and their photophysical and redox properties [14,15]. Electrochemical study of the new hybrid complexes with luthetium phthalocyanine as one of the capping groups as well as their antimony-capped precursors was performed. Due to the presence of two redox active centers (the encapsulated iron(II) ion and the luthetium phthalocyanine-containing capping group, which is well known as "electron sponge"), several redox transitions could be expected for these compounds.

The $[FeDXO_3(HCOC_2H_5)_3(Lu(Bu_8Pc))]$ and $[FeDXO_3(CH_2)_3(Lu(Bu_8Pc))]$ phthalocyaninoclathrochelates differ by the structure of hydrazonate capping group, hence, the difference in their electrochemical behavior can be explained by the variation of stabilizing effect of these apical fragments. In both cases three oxidation and two reduction peaks were observed in the potential range from −2.0 to 2.0 V (Fig. 2). First two oxidation processes are quasi-reversible, ΔEp is equal to 60–90 mV and the ratio of peak currents for direct (anodic) and reverse (cathodic) waves is close to 1. The most anodic third peak is irreversible at all scan rates investigated (up to 1 V/s) and this process is more likely accompanied by the chemical destruction of the clathrochelate framework. In the reverse scan after the third oxidation peak one can observe the additional reduction peak at a potential of −0.05 V which probably corresponds to the reduction of the products of chemical destruction. The first reduction process is quasi-

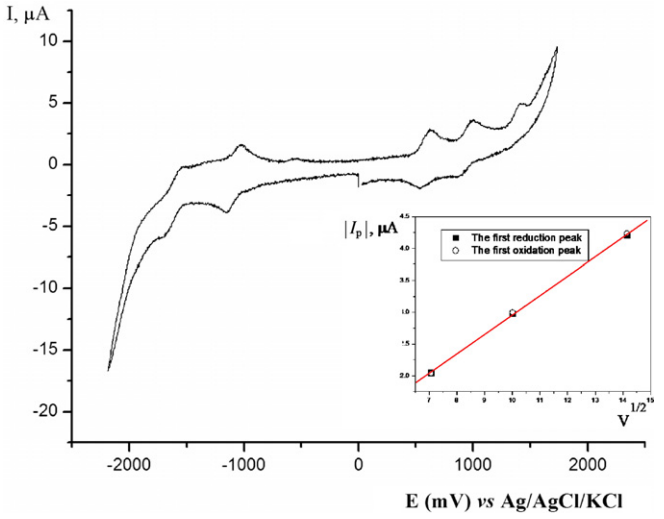

Fig. 2. Cyclic voltammogram for 0.52 mM solution of $[FeDXO_3(CH_2)_3(Lu(Bu_8Pc))]$ clathrochelate in *o*-dichlorobenzene (Pt, 0.15 M $(Bu_4N)BF_4$, 50 mV/s). In the insert: the linear $|I_p|$ vs. $v^{1/2}$ dependences for the first reduction and oxidation peaks.

reversible in case of $[FeDXO_3(CH_2)_3(Lu(Bu_8Pc))]$ clathrochelate and irreversible for $[FeDXO_3(HCOC_2H_5)_3(Lu(Bu_8Pc))]$ complex. This indicates that ditopic $[FeDXO_3(CH_2)_3(Lu(Bu_8Pc))]$ complex is more stable than $[FeDXO_3(HCOC_2H_5)_3(Lu(Bu_8Pc))]$ clathrochelate. As a seen from Table 1, the potentials of redox transitions for $[FeDXO_3(HCOC_2H_5)_3(Lu(Bu_8Pc))]$ phthalocyaninoclathrochelate are only slightly anodically shifted, respectively, to $[FeDXO_3(CH_2)_3(Lu(Bu_8Pc))]$ complex due to the presence of electron-withdrawing ethoxyl substituents in the capping 1,3,5-triazacyclohexane fragment. These data are in good agreement with previously obtained results [24,27] indicating that the redox potentials are much more sensitive to the structural changes in the chelate ribbed fragments than to the substituents in the capping groups.

Antimony-capped formaldehyde $[FeDXO_3(CH_2)_3(Sb(C_2H_5)_3)](ClO_4)$ precursor is more stable than triethyl ortoformate $[FeDXO_3(HCOC_2H_5)_3(Sb(C_2H_5)_3)](ClO_4)$ derivative: the former complex can be oxidized and reduced reversibly, the cation radical and anion radical species produced are sufficiently stable in cyclic voltammetry time scale at scan rates more than 50 mV/s. In contrast, the oxidation and reduction of $[FeDXO_3(HCOC_2H_5)_3(Sb(C_2H_5)_3)](ClO_4)$ clathrochelate are irreversible and followed by the destruction of the clathrochelate framework. However, the oxidized species are more stable than reduced ones because of the fact that at the reverse scan the corresponding reduction peak can be observed, though $I_c/I_a < 1$.

Trying to assign the redox transitions observed to the redox active centers of the hybrid phthalocyaninoclathrochelates, we compared their E_p values with those for their clathrochelate precursors. The first reduction and oxidation processes are more likely phthalocyanine-based. The differences between E_p values are typical for redox processes localized on the phthalocyanine macrocycle (1680 mV [30]). The second oxidation peaks for phthalocyaninochlatrochelates might be assigned to the encapsulated $Fe^{2+/3+}$ redox couples. Their potentials are cathodically shifted (see Table 1) relatively to the values for the antimony-capped precursors. This indicates that the stability of the clathrochelate oxidized form increase in the presence of rather polarizable phthalocyanine fragment with formal charge −2 of the capping group.

The first reduction and oxidation peaks for both clathrochelates are diffusionally controlled as follows from the linear I_p versus $v^{1/2}$ dependence (where v is the scan rate). As a seen from Fig. 2, the correlation is good enough ($r = 0.9998$ and 0.9997 for reduction and oxidation, respectively). Second and third oxidation peaks show a different kinetic behaviour. This may be an additional proof for the involvement of the different redox sites in the various electrochemical steps.

The simple comparison of the redox behavior of lutetium phthalocyanine-capped cage iron(II) complexes with obtained earlier [14] data for hafnium- and zirconium-containing phthalocyaninoclathrochelates (Table 1) is rather complicated since too many parameters are varied (the nature of both the capping groups and the chelate fragments). Nevertheless, the characteristic potential difference of the first oxidation and first reduction waves, which is equal to 1680–1700 mV, is the same for all four hybride clathrochelates. This supports our idea to assign these waves to phthalocyanine-based redox processes.

Abstract

Reaction of salicyldehyde thiosemicarbazone (H_2L^1), 2-hydroxyacetophenone thiosemicarbazone (H_2L^2) and 2-hydroxynapthaldehyde thiosemicarbazone (H_2L^3) (general abbreviation H_2L, where H_2 stands for the two dissociable protons, one phenolic proton and one hydrazinic proton) with $K_2[PtCl_4]$ afforded a family of polymeric complexes of type $[\{Pt(L)\}_n]$. Reaction of the polymeric species with two monodentate ligands (D), viz. triphenylphosphine (PPh_3) and 4-picoline (pic), yielded complexes of the type [Pt(L)(D)]. These mixed-ligand complexes were also obtained from the reaction of the thiosemicarbazones with $[Pt(PPh_3)_2Cl_2]$ and $[Pt(pic)_2Cl_2]$. The crystal structure of $[Pt(PPh_3)(L^2)]$ has been determined. The thiosemicarbazone ligands are coordinated, via dissociation of the two protons, as dianionic tridentate O,N,S-donors. The [Pt(L)(D)] complexes show characteristic ^1H NMR spectra and intense absorptions in the visible and ultraviolet region. They also fluoresce in the visible region at ambient temperature.

1. Introduction

The chemistry of transition metal complexes of thiosemicarbazones has been receiving considerable attention, largely because of their bioinorganic relevance [1]. Such complexes are of particular importance due to their potentially beneficial biological (viz. antibacterial, antimalarial, antiviral and antitumor) activities [2]. Thiosemicarbazones usually bind to a metal ion, via dissociation of the hydrazinic proton, as a bidentate N,S-donor forming a five-membered chelate ring (**1**) [3]. If a third donor site (D) is incorporated in such ligands, linked to the carbonylic carbon via one or two intervening atoms, then D,N,S-tricoordination (**2**) normally takes place [4]. In addition to displaying D,N,S-tricoordination, such ligands are also known to bridge a second metal ion through the sulfur [5]. It has also been observed that salicylaldehyde thiosemicarbazone, in spite of having the phenolic oxygen as a potential third donor site, coordinates as a bidentate N,S-donor forming a rather unusual four-membered chelate ring (**3**) [6]. This mode of binding (**3**) has also been displayed by some other thiosemicarbazones [7]. Formation of such a chelate ring (**3**) by salicylaldehyde thiosemicarbazone, leaving some potential donor sites unused, has been successfully utilized for the synthesis of interesting polynuclear complexes [8]. This variable binding mode of thiosemicarbazones has encouraged us to explore their coordination chemistry further [6,8,9], and the present work has originated from this exploration. Herein we have chosen three potentially tridentate thiosemicarbazones, viz. thiosemicarbazones of salicylaldehyde, 2-hydroxyacetophenone and 2-hydroxynaphthaldehyde. These thiosemicarbazones are abbreviated in general as H_2L, where H_2 stands for the two dissociable protons, the phenolic proton and the hydrazinic proton. Individual ligand abbreviations

are shown in **4**. To interact with the chosen thiosemicarbazones platinum has been selected as the metal. It may be mentioned here that although the chemistry of platinum complexes of some thiosemicarbazones has been studied [1,10], that of the chosen thiosemicarbazones (**4**) appears to have remained unexplored. Reaction of the three selected thiosemicarbazones (**4**) has been carried out with three platinum starting materials, viz. $K_2[PtCl_4]$, $[Pt(PPh_3)_2Cl_2]$ and $[Pt(pic)_2Cl_2]$ (pic = 4-picoline), which has afforded a family of interesting complexes containing the thiosemicarbazones coordinated in the tridentate fashion (**5**). The chemistry of these complexes is reported in this paper with special reference to their synthesis, structure and spectral properties.

2. Experimental

2.1. Materials

Chloroplatinic acid was purchased from Arora Matthey, Kolkata, India, and was converted to $K_2[PtCl_4]$ [11]. Salicylaldehyde, 2-hydroxyacetophenone and 2-hydroxynaphthaldehyde were obtained from S.D. Fine-chem, Mumbai, India. Thiosemicarbazide was procured from Loba Chemie, Mumbai, India. All other chemicals and solvents were reagent grade commercial materials and were used as received. $[Pt(PPh_3)_2Cl_2]$ and $[Pt(pic)_2Cl_2]$ were prepared from $K_2[PtCl_4]$ by following reported procedures [12,13]. The thiosemicarbazone ligands (H_2L^1, H_2L^2 and H_2L^3) were prepared by condensing the respective aldehyde or ketone with thiosemicarbazide in hot ethanol.

2.2. Synthesis

2.2.1. $[\{Pt(L^1)\}_n]$

To a solution of H_2L^1 (47 mg, 0.24 mmol) in hot methanol (30 mL) triethylamine (48 mg, 0.48 mmol) was added followed by $K_2[PtCl_4]$ (100 mg, 0.24 mmol). The mixture was heated at reflux for 24 h. A brown precipitate settled down on cooling, which was collected by filtration, washed with methanol and dried in air to afford $[\{Pt(L^1)\}_n]$ as a brown powder. Yield: 67 mg. *Anal.* Calc. for $(C_8H_7N_3SOPt)_n$: C, 24.67; H, 1.80; N, 10.79. Found: C, 24.78; H, 1.93; N, 10.82%.

The $[\{Pt(L^2)\}_n]$ and $[\{Pt(L^3)\}_n]$ complexes were prepared by following the same above procedure using HL^2 and HL^3 instead of HL^1.

$[\{Pt(L^2)\}_n]$: *Anal.* Calc. for $(C_9H_9N_3SOPt)_n$: C, 26.87; H, 2.24; N, 10.45. Found: C, 27.38; H, 2.32; N, 10.49%.

$[\{Pt(L^3)\}_n]$: *Anal.* Calc. for $(C_{12}H_9N_3SOPt)_n$: C, 32.88; H, 2.06; N, 9.59. Found: C, 32.14; H, 2.14; N, 9.63%.

2.2.2. $[Pt(PPh_3)(L^1)]$

Method A: The polymeric $[\{Pt(L^1)\}_n]$ species (100 mg) and triphenylphosphine (68 mg) were taken together in ethanol (30 mL) and the solution was refluxed for 24 h to yield a lemon yellow solution. Evaporation of this solution gave a yellow solid, which was subjected to purification by thin layer chromatography on a silica plate. With 1:40 acetonitrile–benzene as the eluant, a major yellow band separated, which was extracted with acetonitrile. Upon evaporation of the acetonitrile extract $[Pt(PPh_3)(L^1)]$ was obtained as a crystalline yellow solid. Yield: 95 mg (57%).

Method B: To a solution of H_2L^1 (20 mg, 0.10 mmol) in hot ethanol (30 mL) triethylamine (20 mg, 0.20 mmol) was added followed by *cis*-$[Pt(PPh_3)_2Cl_2]$ (100 mg, 0.13 mmol). The mixture was heated at reflux for 6 h to yield a lemon yellow solution. Evaporation of this solution gave a yellow solid, which was subjected to purification by thin layer chromatography on a silica plate. With 1:40 acetonitrile–benzene as the eluant, a major yellow band separated, which was extracted with acetonitrile. Upon evaporation of the acetonitrile extract $[Pt(PPh_3)(L^1)]$ was obtained as a crystalline yellow solid. Yield: 49 mg (60%). *Anal.* Calc. for $C_{26}H_{22}N_3SOPt$: C, 47.92; H, 3.38; N, 6.45. Found: C, 47.88; H, 3.42; N, 6.49%. ^1H NMR in $CDCl_3$, δ ppm: 4.87 (s, 2H), 6.86 (t, 1H, $J = 7.4$ Hz), 6.75 (d, 1H, $J = 8.5$ Hz), 7.20–7.32* (2H), 7.39–7.77* (PPh_3), 8.55 (d, 1H, $J = 11.8$ Hz).

The $[Pt(PPh_3)(L^2)]$ and $[Pt(PPh_3)(L^3)]$ complexes were prepared by following the same above procedure using H_2L^2 and H_2L^3 instead of H_2L^1.

$[Pt(PPh_3)(L^2)]$: *Anal.* Calc. for $C_{27}H_{24}N_3SOPt$: C, 48.71; H, 3.61; N, 6.31. Found: C, 48.74; H, 3.66; N, 6.33%. ^1H NMR in $CDCl_3$, δ ppm: 2.86 (s, 3H), 4.84 (s, 2H), 6.67–6.72* (2H), 7.17 (t, 1H, $J = 7.5$ Hz), 7.40–7.80 ($PPh_3 + 1H$).

$[Pt(PPh_3)(L^3)]$: *Anal.* Calc. for $C_{27}H_{24}N_3SOPt$: C, 51.20; H, 3.41; N, 5.97. Found: C, 51.23; H, 3.88; N,

6.92%. ^{1}H NMR in $CDCl_3$, δ ppm: 4.87 (s, 2H), 6.86 (d, 1H, $J = 9.1$ Hz), 7.26 (t, 1H, $J = 7.4$ Hz), 7.61 (d, 1H, $J = 9.2$ Hz), 7.67 (d, 1H, $J = 7.9$ Hz), 7.42–7-.78* (PPh_3 + 1H), 8.17 (d, 1H, $J = 8.6$ Hz), 9.57 (d, 1H, $J = 11.8$ Hz).

2.2.3. [Pt(pic)(L^1)]

Method A: The polymeric [{Pt(L^1)}$_n$] species (100 mg) and 4-picoline (24 mg) were taken in ethanol (30 mL) and the solution was refluxed for 24 h to yield a yellow solution. Evaporation of this solution gave a yellow solid, which was subjected to purification by thin layer chromatography on a silica plate. With 1:20 acetonitrile–benzene as the eluant, a prominent yellow band separated, which was extracted with acetonitrile. Upon evaporation of the acetonitrile extract [Pt(pic)(L^1)] was obtained as a crystalline yellow solid. Yield: 70 mg (56%).

Method B: To a solution of H_2L^1 (44 mg, 0.22 mmol) in hot ethanol (30 mL) triethylamine (45 mg, 0.44 mmol) was added followed by [Pt(pic)$_2$Cl$_2$] (100 mg, 0.22 mmol). The mixture was heated at reflux for 24 h to yield a yellow solution. Evaporation of this solution gave a yellow solid, which was subjected to purification by thin layer chromatography on a silica plate. With 1:20 acetonitrile–benzene as the eluant, a major yellow band separated, which was extracted with acetonitrile. Upon evaporation of the acetonitrile extract [Pt(pic)(L^1)] was obtained as a crystalline yellow solid. Yield: 54 mg (50%). *Anal.* Calc. for $C_{14}H_{14}N_4SOPt$: C, 34.63; H, 2.89; N, 11.54. Found: C, 34.45; H, 2.74; N, 11.34%. ^{1}H NMR in $CDCl_3$, δ ppm: 2.45 (s, 3H), 5.05 (s, 2H), 6.70–6.80* (2H), 7.13 (d, 1H, $J = 6.2$ Hz), 7.33–7.46* (3H), 8.30 (s, 1H), 8.81 (d, 2H, $J = 6.2$ Hz).

The [Pt(pic)(L^2)] and [Pt(pic)(L^3)] complexes were prepared by following the same above procedure using H_2L^2 and H_2L^3 instead of H_2L^1.

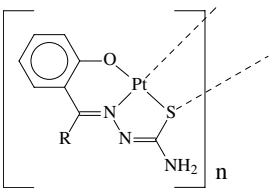
[Pt(pic)(L^2)]: *Anal.* Calc. for $C_{15}H_{16}N_4SOPt$: C, 36.36; H, 3.23; N, 11.32. Found: C, 36.54; H, 3.46; N, 11.13%. ^{1}H NMR in $CDCl_3$, δ ppm: 2.43 (s, 3H), 2.81 (s, 3H), 4.93 (s, 2H), 6.74 (t, 1H, $J = 7.5$ Hz), 7.14 (d, 1H, $J = 8.3$ Hz), 7.22 (d, 2H, $J = 5.6$ Hz), 7.30 (t, 1H, $J = 8.9$ Hz), 7.81 (d, 1H, $J = 8.3$ Hz), 8.78 (d, 2H, $J = 9.0$ Hz).

[Pt(pic)(L^3)]: *Anal.* Calc. for $C_{18}H_{16}N_4SOPt$: C, 40.67; H, 3.01; N, 10.54. Found: C, 40.43; H, 3.20; N, 10.32%. ^{1}H NMR in $CDCl_3$, δ ppm: 2.47 (s, 3H), 4.94 (s, 2H), 7.24–7.33* (4H), 7.53 (t, 1H, $J = 7.5$ Hz), 7.71–7.80* (2H), 8.14 (d, 1H, $J = 8.5$ Hz), 8.86 (d, 2H, $J = 6.1$ Hz), 9.30 (s, 1H).

2.3. Physical measurements

Microanalyses (C, H, N) were performed using a Heraeus Carlo Erba 1108 elemental analyzer. IR spectra were obtained on a Shimadzu FTIR-8300 spectrometer with samples prepared as KBr pellets. Electronic spectra were recorded on a JASCO V-570 spectrophotometer. Emission spectra were recorded on a Perkin–Elmer LS55 Luminescence Spectrometer. ^{1}H NMR spectra were recorded in $CDCl_3$ solutions on a Bruker Avance DPX 300 NMR spectrometer using TMS as the internal standard.

2.4. X-ray crystallography

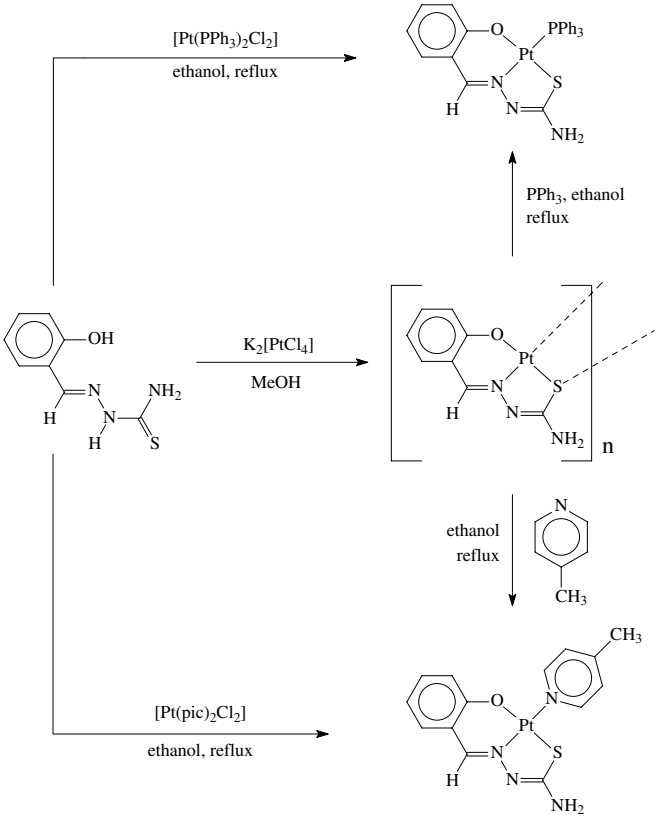


Single crystals of [Pt(PPh$_3$)(L^2)] were grown by slow evaporation of a solution of the complex in 1:1 dichloromethane–acetonitrile. Selected Crystal data and a summary of the data collection appear below, the full details are provided in Table S1. Data were collected on a Bruker SMART CCD diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) by ϕ and ω scans. X-ray data reduction, structure solution and refinement were done using the SHELXS-97 and SHELXL-97 packages [14]. The structure was solved by direct methods.

Crystal data for $C_{27}H_{24}N_3OPSPt$, $M = 664.61$, $0.55 \times 0.35 \times 0.12$ mm^3, monoclinic, space group $P2_1/c$, $a = 15.7537(12)$ Å, $b = 9.0719(6)$ Å, $c = 17.1657(13)$ Å, $\beta = 94.61(10)°$, $V = 2445.3(3)$ Å^3, $Z = 4$, $D_{calc} = 1.805$ Mg m^{-3}, $F(000) = 1296$, $\lambda = 0.71073$ Å, $T = 103$ K, $\mu = 5.915$ mm^{-1}, 17316 reflections collected, 5901 unique ($R_{int} = 0.049$). Final goodness-of-fit = 1.03, $R_1 = 0.0273$, $wR_2 = 0.0625$, R indices based on 4607 reflections with $[I > 2\sigma(I)]$.

3. Results and discussion

3.1. Syntheses and crystal structure



The reaction of the selected thiosemicarbazones (H_2L, **4**) has been first carried out with $K_2[PtCl_4]$ in refluxing methanol in the presence of triethylamine to afford a family of polymeric complexes of the type {Pt(L)}$_n$ in decent yields. Based on the composition of these complexes, as well as the +2 oxidation state of platinum in them, the thiosemicarbazones are believed to coordinate the metal center in the expected dianionic O,N,S-fashion (**5**). The fourth coordination position on platinum in the Pt(L) fragment is assumed to be taken up by the sulfur of a coordinated thiosemicarbazone belonging to another Pt(L) fragment (**6**). This bridging action of the thiosemicarbazone–sulfur, which is well documented in the literature [5], appears to be responsible for the formation of the polymeric species.

6

In order to explore the possibility of forming monomeric complexes by splitting the sulfur bridge in the {Pt(L)}$_n$ complexes, their reaction has been carried out with two

monodentate ligands (**D**), viz. 4-picoline (pic) and triphenylphosphine (PPh_3). From each of these reactions a monomeric complex of type [Pt(L)(D)] (D = pic or PPh_3) has been obtained. The same monomeric complexes have also been synthesized, in better yields, by the reaction of the thiosemicarbazones (**4**) with $[Pt(PPh_3)_2Cl_2]$ and $[Pt(pic)_2Cl_2]$ in refluxing ethanol in the presence of triethylamine. The synthetic methods of all the complexes are illustrated in Scheme 1. The observed elemental (C, H, N) analytical data of all the complexes are consistent with their compositions. It appears from the formulation of the monomeric complexes that the thiosemicarbazones are serving as tridentate ligands in them. In order to authenticate the coordination mode of the thiosemicarbazones in these complexes, the structure of a representative member of this family of monomeric complexes, viz. $[Pt(PPh_3)(L^2)]$, has been determined by X-ray crystallography. A selected view of the complex molecule is shown in Fig. 1 and some relevant bond parameters are listed in Table 1. The structure shows that the thiosemicarbazone ligand (L^2) is coordinated to platinum in the expected tridentate fashion (**5**), forming a six- and a five-membered chelate ring with O–Pt–N and N–Pt–S bite angles of 92.48(12)° and 85.09(9)°, respectively. A triphenylphosphine is coordinated to the metal center, which is trans to the nitrogen atom. Platinum is thus nested in a NOSP core, which is slightly distorted from an ideal square-planar geometry, as reflected in the bond parameters around the metal center. The Pt–N, Pt–O, Pt–P and Pt–S distances

Scheme 1.

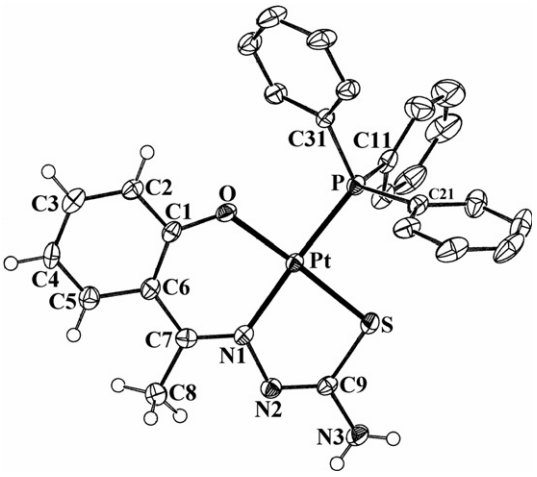


Fig. 1. Structure of the $[Pt(PPh_3)(L^2)]$ complex.

Table 1
Selected bond distances (Å) and angles (°) for $[Pt(PPh_3)(L^2)]$

Bond distances (Å)			
Pt–N(1)	2.038(3)	C(7)–N(1)	1.320(5)
Pt–P	2.2598(11)	C(9)–N(3)	1.386(5)
Pt–S	2.2575(10)	C(1)–O	1.325(5)
Pt–O	2.006(3)	N(1)–N(2)	1.403(5)
		C(9)–S	1.742(4)
Bond angles (°)			
N(1)–Pt–P	175.57(9)	N(1)–Pt–O	92.48(12)
O–Pt–S	175.71(8)	N(1)–Pt–S	85.09(9)

are normal, as observed in other structurally characterized complexes of platinum containing these bonds [10,15]. Bond distances within the coordinated thiosemicarbazone are also usual [9c]. The absence of any solvent of crystallization in the crystal lattice indicates possible existence of non-covalent interaction(s) between the individual complex molecules. A closer look at the packing pattern of the crystal reveals that non-covalent interactions of two types, viz. C–H···S and N–H···π interactions, are active in the lattice,

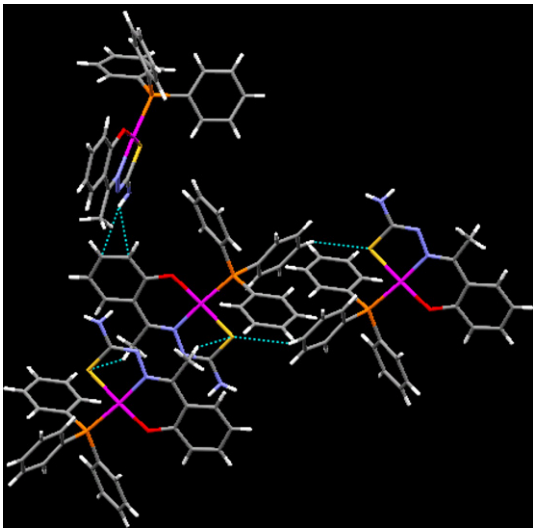

Fig. 2. Packing pattern in the lattice of the $[Pt(PPh_3)(L^2)]$ complex.

which is illustrated in Fig. 2. The sulfur of each coordinated thiosemicarbazone is hydrogen-bonded to two C–H fragments, a phenyl C–H of the PPh_3 and a methyl C–H of the thiosemicarbazone belonging to two different neighboring complex molecules. One N–H fragment of the thiosemicarbazone is involved in hydrogen-bonding with the π-cloud over a C–C bond of the phenol fragment of an adjacent complex molecule in a η^2-fashion. Each complex molecule is thus linked with three surrounding complex molecules through C–H···S and N–H···π interactions (Fig. 2), and this extended intermolecular hydrogen-bonding is responsible for holding the crystal together. All the monomeric [Pt(L)(D)] complexes are assumed to have similar structures to $[Pt(PPh_3)(L^2)]$.

3.2. Spectral properties

^1H NMR spectra of the $[Pt(PPh_3)(L)]$ complexes, recorded in $CDCl_3$ solutions, show all the expected signals. The phenyl protons of the PPh_3 ligands show broad signals within the range δ 7.39–7.80 ppm. In the $[Pt(PPh_3)(L^1)]$ and $[Pt(PPh_3)(L^3)]$ complexes the azomethine proton signal of the coordinated thiosemicarbazone is observed at δ 8.55 and 9.57 ppm, respectively. The methyl signal from the coordinated thiosemicarbazone in the $[Pt(PPh_3)(L^2)]$ complex is observed at δ 2.86 ppm. The NH_2 signal of the coordinated thiosemicarbazone is observed around δ 4.8 ppm. Most of the expected signals from the phenyl ring of the coordinated thiosemicarbazone are clearly observed in the aromatic region, whilst a few could not be detected due to their overlap with other signals. In the ^1H NMR spectra of the [Pt(pic)(L)] complexes, the methyl signal of the coordinated picoline is observed around δ 2.4 ppm. The NH_2 signal of the coordinated thiosemicarbazone is observed around δ 5.0 ppm and the azomethine proton signal (for $L = L^1$ and L^3) is observed between δ 8.3–9.3 ppm. The methyl signal from the coordinated thiosemicarbazone in the $[Pt(pic)(L^2)]$ complex is observed at δ 2.81 ppm. A distinct doublet observed near δ 8.8 ppm in all the three [Pt(pic)(L)] complexes is attributable to the α-proton of picoline. The other aromatic proton signals are observed in the expected region as overlapping signals. The ^1H NMR spectral data of the $[Pt(PPh_3)(L)]$ and [Pt(pic)(L)] complexes are therefore in well accordance with their compositions.

Infrared spectra of all the $[Pt(PPh_3)(L)]$ complexes show many vibrations of different intensities in the 1600–400 cm^{-1} region. Assignment of each individual band to a specific vibration has not been attempted. However, three strong bands displayed near 513, 694 and 743 cm^{-1} by each of these complexes are attributed to the coordinated PPh_3 ligands. Comparison with the spectrum of the *cis*-$[Pt(PPh_3)_2Cl_2]$ complex shows the presence of several new bands (e.g. near 1130, 1226, 1292, 1334, 1352, 1423, 1508, 1541 and 1560 cm^{-1}) in the spectra of the $[Pt(PPh_3)(L)]$ complexes, which must be due to the presence of the coordinated thiosemicarbazone ligands. Besides an absence of the three diagnostic bands for the PPh_3 ligands near 513, 694 and 743 cm^{-1}, the infrared spectral properties of the [Pt(pic)(L)] complexes are qualitatively similar to that of the $[Pt(PPh_3)(L)]$ complexes.

The $[Pt(PPh_3)(L)]$ and [Pt(pic)(L)] complexes are readily soluble in methanol, ethanol, acetone, acetonitrile, dichloromethane, chloroform, etc., producing intense lemon yellow solutions. Electronic spectra of these complexes have been recorded in dichloromethane solution. A selected spectrum is shown in Fig. 3 and spectral data are presented in Table 2. Each complex shows several intense absorptions in the visible and ultraviolet regions. The absorptions in the ultraviolet region are assignable to transitions within the ligand orbitals. To have an understanding of the nature of the transitions in the visible region, qualitative EHMO calculations have been performed [16] on computer generated models of the $[Pt(PPh_3)(L)]$ and [Pt(pic)(L)] complexes. The composition of selected molecular orbitals is given in Table 3 and a partial MO diagram for a representative $[Pt(PPh_3)(L)]$ complex is shown in Fig. 4. The partial

[Pt(pic)(L^2)]	364	610, 562, 432^s, 415	0.59×10^{-3}
[Pt(pic)(L^3)]	380	610, 432, 416	0.73×10^{-3}

s, shoulder.

MO diagram for a representative [Pt(pic)(L)] complex is deposited as Fig. S1. In the case of the [Pt(PPh$_3$)(L^1)] and [Pt(PPh$_3$)(L^2)] complexes the highest occupied molecular orbital (HOMO) has major contributions from the platinum d orbitals. The lowest unoccupied molecular orbital (LUMO) is delocalized almost entirely on the thiosemicarbazone ligand, and is largely concentrated on the imine fragment. Therefore the lowest energy absorption near 410 nm is assignable to a charge-transfer transition taking place from the filled metal orbital (HOMO) to the vacant π^*-orbital of the thiosemicarbazone ligand (LUMO). However, in case of the [Pt(PPh$_3$)(L^3)] complex the HOMO has only 11% metal character, while the LUMO is similar in nature as before. Hence the lowest energy absorption at 436 nm in this complex is assignable to a transition within the orbitals belonging primarily to L^3. It may be mentioned in this context that this absorption is much more intense compared to the lowest energy transition in the earlier two complexes. It may also be noted here that there is a second absorption at 413 nm, which may be assigned to a charge-transfer transition taking place from the filled metal orbital (HOMO − 1) to the vacant π^*-orbital of the thiosemicarbazone ligand (LUMO). The electronic spectral properties, as well as features of the molecular orbitals, of the [Pt(pic)(L)] complexes are similar to those of the [Pt(PPh$_3$)(L)] analogues.

The intensities of the charge-transfer transitions in the visible region have tempted us to explore the luminescence properties of these complexes and this has been carried out in dichloromethane solution at ambient temperature (298 K). All six complexes display emission in the visible region using an excitation wavelength of ~350 nm (Fig. 3). Quantum yields (ϕ) of these emissions have been evaluated (Table 4) with reference to [Ru(bpy)$_3$]Cl$_2$ ($\phi = 0.028$ at 298 K) [17].

4. Conclusion

The present study shows that salicylaldehyde thiosemicarbazones and similar ligands can smoothly bind to platinum as tridentate O,N,S-donors yielding stable complexes, which not only show intense absorptions in the visible region but also fluoresce at room temperature.

Acknowledgements

Financial assistance received from the Council of Scientific and Industrial Research, New Delhi, India [Grant No. 01(1952)/04/EMR-II] is gratefully acknowledged. The authors thank Prof. Chittaranjan Sinha and Dr. Asok Nath Mandal of the Department of Chemistry, Jadavpur University, for their help with the florescence and NMR spectral measurements, respectively. Sarmistha Halder thanks the University Grants Commission, New Delhi, India, for her fellowship [Grant No. 10-2(5)2004(1)-E.U.II].

Appendix A. Supplementary material

CCDC 626762 contains the supplementary crystallographic data for [Pt(PPh_3)(L^2)]. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Full details of data collection are provided in Table S1. A partial MO diagram of the [Pt(pic)(L^1)] complex has been deposited as Fig. S1. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.01.048.

Abstract

The optically active S-bridged dinuclear complex, [Pt(bpy){Co(D-pen)$_2$}]X (**1X**: bpy = 2,2′-bipyridine; pen = penicillaminate; X = NO_3^-, ClO_4^-, Br^-, or I^-), and its enantiomer, [Pt(bpy){Co(L-pen)$_2$}]X (**2X**), were prepared by the reactions of [$PtCl_2$(bpy)] with K[Co(D-pen)$_2$] and K[Co(L-pen)$_2$], respectively. The racemates, [Pt(bpy){Co(D-pen)$_2$}]$_{0.5}$[Pt(bpy){Co(L-pen)$_2$}]$_{0.5}$X (**3X**), were also obtained by the slow evaporation of aqueous solutions containing equimolar amounts of **1X** and **2X**. The crystal structures of **3**$NO_3 \cdot 3H_2O$, **3**$ClO_4 \cdot 2H_2O$, **3**$Br \cdot 2H_2O$ and **3**$I \cdot 5.5H_2O$ were determined by X-ray crystallography, and compared with those of **1**$ClO_4 \cdot H_2O$, **1**$Br \cdot 2H_2O$, **1**$I \cdot 2H_2O$, **2**$ClO_4 \cdot H_2O$, **2**$Br \cdot 2H_2O$ and **2**$I \cdot 2H_2O$. The optically active complexes **1X** and **2X** exist as monomers, accompanied by no intermolecular interactions in the π-electronic systems of the bpy moieties. In the crystals of **3**$Br \cdot 2H_2O$, on the other hand, the enantiomeric complex cations, [Pt(bpy){Co(D-pen)$_2$}]$^+$ (***D***) and [Pt(bpy){Co(L-pen)$_2$}]$^+$ (***L***), are arranged alternately with overlapping bpy planes along the *c* axis, and the π electronic system of the bpy framework in ***D*** interacts with those in ***L***. The remaining three racemates, **3**$NO_3 \cdot 3H_2O$, **3**$ClO_4 \cdot 2H_2O$ and **3**$I \cdot 5.5H_2O$, afford dimeric structures with π–π stacking contacts between the enantiomeric ***D*** and ***L*** complex cations. Differences in the crystal structures between the optically active complexes and the racemates significantly mirror the diffuse reflectance spectral behaviors.

1. Introduction

It has been shown so far that an octahedral metal chelated by plural β-aminoalkylthiolates acts as an S-donating bidentate metalloligand toward [MX_2(bpy)] (M = Pd(II) or Pt(II), X = Cl^- or NO_3^-, bpy = 2,2′-bipyridine), in which the two X^- ligands are susceptible to substitutions by other ligands, resulting in the formation of a dinuclear complex composed of a [M(μ-S)$_2$(bpy)] framework and an octahedral metal unit [1–5]. In the reaction of *fac*(*S*)-[Co(aet)$_3$] (aet = 2-aminoethanethiolate) with [$PtCl_2$(bpy)], for instance, a dinuclear complex, [Pt(bpy){Co(aet)$_3$}]$^{2+}$, is formed [1]. A similar reaction of [Ni{Co(aet)$_2$(en)}$_2$]$^{4+}$ (en = ethylenediamine), in which the two terminal *cis*(*S*)-[Co(aet)$_2$(en)]$^+$ units can be regarded as bidentate S-donors, with [$PtCl_2$(bpy)] gives [Pt(bpy){Co(aet)$_2$(en)}]$^{3+}$ [1]. Two absolute configurations, Δ and Λ, are possible for such octahedral S-donating metal units, and hence these dinuclear complexes are obtained as racemic crystals.

doi:10.1016/j.poly.2007.01.024

On the other hand, an optically active trinuclear analog, ΔΔ-[Ni{Co(aet)$_2$(*R*-pn)}$_2$]$^{4+}$ (pn = 1,2-propanediamine), reacts with [MX$_2$(bpy)] to form Δ-[M(bpy){Co(aet)$_2$(*R*-pn)}]$^{3+}$ stereoselectively [2,3]. A similar optically active S-bridged dinuclear complex, [M(bpy){Co(D-pen)$_2$}]$^+$ (pen = penicillaminate), is preferentially derived from the bidentate metalloligand, *trans*(*N*)-[Co(D-pen)$_2$]$^-$ [3]. While these optically active complexes exist as monomers in the crystalline states, the racemic complexes afford dimeric or higher dimensional linear-chain structures due to π–π stacking of the bpy frameworks in the dinuclear units [1–3]. This implies some enantioselective interaction between the π frameworks, which are rather distant from the chiral center of the octahedral metal unit, in these dinuclear complexes. In fact, a mixture of equimolar amounts of [Pt(bpy){Co(D-pen)$_2$}]Cl and [Pt(bpy){Co(L-pen)$_2$}]Cl in H$_2$O crystallizes as the racemic [Pt(bpy){Co(D-pen)$_2$}]$_{0.5}$[Pt(bpy){Co(L-pen)$_2$}]$_{0.5}$Cl with a linear-chained π–π stacking structure, in which two enantiomeric complex cations are arranged alternately [4]. In the racemic crystal of [Pt(bpy){Co(aet)$_2$(*R*-pn)}]$_{0.5}$[Pt(bpy){Co(aet)$_2$(*S*-pn)}]$_{0.5}$ (ClO$_4$)$_3$, which is grown from an aqueous solution containing equimolar amounts of Δ-[Pt(bpy){Co(aet)$_2$(*R*-pn)}](ClO$_4$)$_3$ and Λ-[Pt(bpy){Co(aet)$_2$(*S*-pn)}](ClO$_4$)$_3$, in addition, two enantiomers exist as a dimer through π–π interactions between the bpy frameworks [5]. Although dimers or linear-chains can be formed by π–π stackings between enantiomers in these dinuclear complexes, as remarked above, the factors governing such structures are still uncertain. In many cases of S-bridged polynuclear complexes with aromatic ligands, the counter ions and/or solvents of crystallizations hold control over π–π stacking structures [6]. It seems therefore that the counter anions exert some influence on the structures of such dinuclear complexes. In the present investigation, at the first onset, we have examined the effects of monovalent counter anions on the stereo- and spectrochemical characteristics for optically active [Pt(bpy){Co(D-pen)$_2$}]X (X = NO$_3^-$, ClO$_4^-$, Br$^-$, or I$^-$) and the enantiomeric [Pt(bpy){Co(L-pen)$_2$}]X, together with racemic [Pt(bpy){Co(D-pen)$_2$}]$_{0.5}$[Pt(bpy){Co(L-pen)$_2$}]$_{0.5}$X.

2. Experimental

2.1. Materials

2,2′-Bipyridine, K$_2$PtCl$_4$, CoCl$_2\cdot$6H$_2$O, NaNO$_3$, NaClO$_4\cdot$H$_2$O, NaBr, and KI were obtained from Wako Pure Chemical Ind. Co., Ltd. The optically active D- and L-penicillamines were purchased from Tokyo Chemical Co., Ltd. and Aldrich Chemical Co., Inc., respectively. K[Co(D-pen)$_2$]$\cdot$2.5H$_2$O, K[Co(L-pen)$_2$]$\cdot$2.5H$_2$O and [PtCl$_2$(bpy)] were prepared by modified methods from the literature [7–9]. The other chemicals were obtained from Wako Pure Chemical Ind. Co., Ltd. or Tokyo Chemical Co., Ltd. All of the chemicals were of reagent grade and were used without further purification.

2.2. Preparation of [Pt(bpy){Co(D-pen)}]NO$_3\cdot$6H$_2$O (**1**NO$_3\cdot$6H$_2$O)

To a brown solution containing K[Co(D-pen)$_2$]$\cdot$2.5H$_2$O (0.13 g, 0.25 mmol) in 20 ml H$_2$O was added [PtCl$_2$(bpy)] (0.10 g, 0.25 mmol). After the mixture was stirred at 55 °C for 1 h, NaNO$_3$ (0.85 g, 10 mmol) in 5 ml H$_2$O was added to the resulting dark green solution. The whole was allowed to stand at 25 °C for several days, and the resulting green-brown crystals were collected by filtration. Yield: 0.15 g (68% based on Co). *Anal.* Calc. for C$_{20}$H$_{38}$N$_5$O$_{13}$S$_2$CoPt (**1**NO$_3\cdot$6H$_2$O): C, 27.46; H, 4.38; N, 8.01. Found: C, 27.50; H, 4.34; N, 7.96%. ^{1}H NMR (600 MHz, D$_2$O), δ = 1.55 (s, 6H, pen), 1.74 (s, 6H, pen), 3.96 (s, 2H, pen), 7.93 (t, 2H, bpy), 8.44 (t, 2H, bpy), 8.49 (d, 2H, bpy), 9.14 (d, 2H, bpy). ^{13}C NMR (150 MHz, D$_2$O), δ = 31.02 (pen), 34.56 (pen), 54.90 (pen), 75.85 (pen), 127.07 (bpy), 131.19 (bpy), 144.87 (bpy), 150.16 (bpy), 159.44 (bpy), 183.58 (pen). UV–Vis spectrum in H$_2$O [ν_{max}, 10^3 cm^{-1} (log ε/mol^{-1} dm^3 cm^{-1})]: 16.23 (2.09), 19.46 (2.11), 25.4 (3.3)^{sh}, 28.5 (3.7)^{sh}, 31.25 (4.27), 32.36 (4.26), 37.4 (4.2)^{sh}, 41.49 (4.43), 49.26 (4.69). 2.14. Measurements

Electronic absorption spectra were recorded with a Perkin–Elmer Lambda 19 spectrophotometer, and the CD spectra with a JASCO J-600 spectropolarimeter. These measurements were carried out in aqueous solu-

tions at room temperature. Diffuse reflectance spectra were measured with a JASCO Ubest V-570 spectrophotometer equipped with an integrating sphere apparatus JASCO ISN-470, using powder samples diluted with MgO. ^{1}H and ^{13}C NMR spectra were recorded with a Bruker AVANCE-600 NMR spectrometer in a 1:1 mixed solvent of CD_3CN and D_2O for **1**$ClO_4 \cdot H_2O$, **2**$ClO_4 \cdot H_2O$ and **3**$ClO_4 \cdot 2H_2O$, or in D_2O for **1**$NO_3 \cdot 6H_2O$, **1**$Br \cdot 2H_2O$, **1**$I \cdot 2H_2O$, **2**$NO_3 \cdot 6H_2O$, **2**$Br \cdot 2H_2O$, **2**$I \cdot 2H_2O$, **3**$NO_3 \cdot 3H_2O$, **3**$Br \cdot 2H_2O$ and **3**$I \cdot 5.5H_2O$, using sodium 4,4-dimethyl-4-silapentane-1-sulfonate (DSS) as an internal reference. Elemental analyses (C, H, N) were performed with a Perkin–Elmer 2400 CHN Elemental Analyzer.

2.15. X-ray structure determination

Single crystals of **1**$ClO_4 \cdot H_2O$, **1**$Br \cdot 2H_2O$, **1**$I \cdot 2H_2O$, **2**$ClO_4 \cdot H_2O$, **2**$Br \cdot 2H_2O$, **2**$I \cdot 2H_2O$, **3**$NO_3 \cdot 3H_2O$, **3**$ClO_4 \cdot 2H_2O$, **3**$Br \cdot 2H_2O$ and **3**$I \cdot 5.5H_2O$ were used for data collection on a Rigaku AFC5S automated four-circle diffractometer with graphite-monochromatized Mo Kα ($\lambda = 0.71069$ Å) radiation. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range $14° < \theta < 15°$ for **1**$ClO_4 \cdot H_2O$, **1**$Br \cdot 2H_2O$, **1**$I \cdot 2H_2O$, **2**$ClO_4 \cdot H_2O$, **2**$Br \cdot 2H_2O$, **2**$I \cdot 2H_2O$, **3**$NO_3 \cdot 3H_2O$, **3**$ClO_4 \cdot 2H_2O$, **3**$Br \cdot 2H_2O$ and **3**$I \cdot 5.5H_2O$. The data were collected at a

temperature of 296 ± 1 K using the ω–2θ scan technique to a maximum 2θ value of 55°. The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of 3 scans) and the counts were accumulated to ensure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The intensities of three representative reflections were measured after every 150 reflections. Over the course of the data collection, the standards decreased by 0.0–8.2%. Polynomial correction factors were applied to the data to account for this phenomenon. Empirical absorption corrections based on azimuthal scans of several reflections were applied. The data were corrected for Lorentz and polarization effects. Corrections for secondary extinctions were applied [10]. The crystal data and experimental parameters are summarized in Table 1.

The structures were solved by direct methods for $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, $\mathbf{2}I \cdot 2H_2O$, $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$ and $\mathbf{3}Br \cdot 2H_2O$, and heavy-atom Patterson methods for $\mathbf{3}I \cdot 5.5H_2O$, and expanded using Fourier techniques [11–13]. In the hexagonal structures of $\mathbf{1}X \cdot 2H_2O$ and $\mathbf{2}X \cdot 2H_2O$ (X = Br or I), Co and Pt lie on a crystallographic twofold axis and for these compounds the asymmetric unit comprises, in addition to the metal atoms, exactly one half of the bpy ligand, a single complete pen ligand, the oxygen atom of one water molecule and a halide counter anion, X, with occupancy of 0.5 due to its disorder over a pair of symmetry related sites. The non-hydrogen atoms were refined anisotropically, except for oxygen atoms of perchlorate anions in $\mathbf{1}ClO_4 \cdot H_2O$ and $\mathbf{2}ClO_4 \cdot H_2O$, which were refined isotropically. All the hydrogen atoms, except those of the water molecules which were not included in any of the structural models, were placed in calculated positions and refined with a riding model. The final cycle of full-matrix least-squares refinement on F was based on observed reflections ($I > 2.00\sigma(I)$) and variable parameters, and converged with unweighted and weighted agreement factors of R $(=\sum||F_o| - |F_c||/\sum|F_o|)$ and Rw $(= [\sum w(|F_o| - |F_c|)^2 / \sum wF_o^2]^{1/2})$. Neutral atom scattering factors were taken from Cromer and Waber [14]. Anomalous dispersion effects were included in F_c; the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley [15–17]. The absolute configurations for $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$ and $\mathbf{2}I \cdot 2H_2O$ were determined on the basis of the known S and R configurations of the asymmetric carbon atoms in the D- and L-pen ligands, respectively, and the structures were supported by the Flack parameters (0.03(2) for $\mathbf{1}ClO_4 \cdot H_2O$, 0.20(5) for $\mathbf{1}Br \cdot 2H_2O$, 0.04(5) for $\mathbf{1}I \cdot 2H_2O$, 0.10(2) for $\mathbf{2}ClO_4 \cdot H_2O$, 0.22(5) for $\mathbf{2}Br \cdot 2H_2O$ and −0.02(4) for $\mathbf{2}I \cdot 2H_2O$) [18]. All calculations were performed using the CrystalStructure crystallographic software package of the Molecular Structure Corporation [19].

3. Results and discussion

3.1. Crystal structures

An X-ray structural analysis for $\mathbf{1}ClO_4 \cdot H_2O$ revealed the presence of a discrete monovalent complex cation, one perchlorate anions and one water molecule. A perspective drawing of the complex cation **1** is given in Fig. 1a, and selected bond distances and angles are listed in Table 2. As shown in Fig. 1a, **1** is composed of one Co atom and one Pt atom to form an S-bridged dinuclear structure. Although two chiral configurations, R and S, are possible for each of the two bridging S atoms in **1**, both S atoms are stereoselectively unified to the S configuration. These structural features for $\mathbf{1}ClO_4 \cdot H_2O$ are essentially consistent with those for $\mathbf{1}Cl \cdot 3H_2O$, $\mathbf{1}Br \cdot 2H_2O$ and $\mathbf{1}I \cdot 2H_2O$, being independent of the nat-

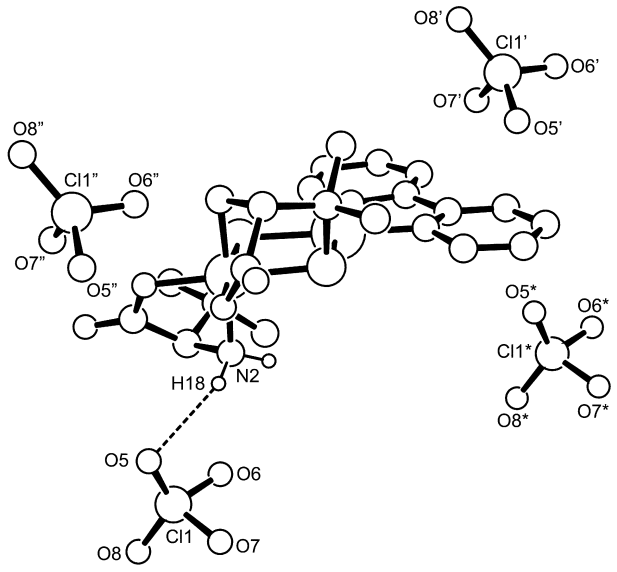

Fig. 2. Neighboring perchlorate anions around complex cation in $\mathbf{1}ClO_4 \cdot H_2O$. Symmetry codes for atoms with asterisks: x, y, $-1+z$; primes: $-x+y$, $-x$, $-2/3+z$; double primes: $-x+y$, $-x$, $1/3+z$.

ure of the counter anions [3]. On the other hand, each complex cation in $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$ and $\mathbf{2}I \cdot 2H_2O$ possesses the same structural features as those in $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$ and $\mathbf{1}I \cdot 2H_2O$, except for absolute configurations of the asymmetric carbons in the coordinated pen ligands, namely *S* and *R* configurations of the asymmetric carbon atoms in the D- and L-pen ligands, respectively (Fig. 1b). The two chiral S atoms in the complex cation of $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, or $\mathbf{2}I \cdot 2H_2O$ are stereoselectively unified to the *R* configuration, in contrast to those with *S* configurations in $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, or $\mathbf{1}I \cdot 2H_2O$.

In each crystal of $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, and $\mathbf{2}I \cdot 2H_2O$, one of the counter anions is located in the vicinity of one coordinated amino group of the complex cation. As shown in Fig. 2 and Table 3, for instance, the N2 atom in the ocatahedral Co(III) unit is placed close to the O5 atom of the perchlorate anion in the crystal of $\mathbf{1}ClO_4 \cdot H_2O$. The distance between the two atoms is 3.10(3) Å and the angle of N(2)–H(18)···O(5) is 134(1)°, suggesting hydrogen bond formation. Similar hydrogen bond formations are also observed for $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, and $\mathbf{2}I \cdot 2H_2O$ (Table 3). In each crystal of $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, and $\mathbf{2}I \cdot 2H_2O$, furthermore, one complex cation is surrounded by a total of four counter anions. In the case of $\mathbf{1}ClO_4 \cdot H_2O$, for example, four perchlorate anions are accessible to the complex cation **1** (Fig. 2). As a result, the complex cations are spaced out, whilst interfering with π–π stacking contacts between the bpy frameworks. Such trends are just as valid for $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, and $\mathbf{2}I \cdot 2H_2O$, and all of the optically active complexes show no intermolecular π–π stacking interactions.

The mixture of equimolar amounts of $\mathbf{1}ClO_4 \cdot H_2O$ and $\mathbf{2}ClO_4 \cdot H_2O$ in H_2O crystallizes as $\mathbf{3}ClO_4 \cdot 2H_2O$ in the centric space group of $P\bar{1}$, which is a remarkably contrast to the acentric space group of $P3_2$ for $\mathbf{1}ClO_4 \cdot H_2O$ and $P3_1$ for $\mathbf{2}ClO_4 \cdot H_2O$ (Table 1). In $\mathbf{3}ClO_4 \cdot 2H_2O$, a pair of enantiomeric complex cations, $[Pt(bpy)\{Co(D\text{-}pen)_2\}]^+$ (***D***) and $[Pt(bpy)\{Co(L\text{-}pen)_2\}]^+$ (***L***), forms a dimeric unit through a π–π stacking of the bpy frameworks, and the interplane distance between two π frameworks is 3.45 Å (Fig. 3). In both $\mathbf{3}NO_3 \cdot 3H_2O$ and $\mathbf{3}I \cdot 5.5H_2O$, dimeric units are also established by a pair of enantiomeric complex cations ***D*** and ***L***, accompanied by interplane distances of 3.61 Å for $\mathbf{3}NO_3 \cdot 3H_2O$ and 3.40 Å for $\mathbf{3}I \cdot 5.5H_2O$. The differences in interplane distances imply that such dimeric structures are influenced by the nature of the counter anions. Although the enantiomeric complex cations ***D*** and ***L*** also form a counterpart in $\mathbf{3}Br \cdot 2H_2O$, pairs of enantiomers develop a higher dimensional structure. As shown in Fig. 4, the enantiomeric complex cations ***D*** and ***L*** are arranged alternately whilst containing overlapping bpy planes along the *c* axis. All the bpy frameworks are placed evenly spaced apart by an interplane angle of 3.65 Å, in

[a] Symmetry codes: $a^1 = 1-x,\ 1-y,\ z$; $b^1 = y,-x+y,\ -1/3+z$; $c^1 = 1-x,\ -y,\ z$; $d^1 = 1-x,\ -y,\ z$; $e^1 = -x,\ -y,\ 1-z$; $f^1 = 1-x,\ -y,\ -z$; $g^1 = 1-x,\ y,\ 5/2-z$; $g^2 = 1-x,\ y,\ 3/2-z$; $g^3 = x,\ y,\ -1+z$; $h^1 = 1-x,\ -y,\ 1-z$.

contrast to **3**$Cl \cdot 7H_2O$, in which two interaction modes with different interplane distances (3.46 and 3.55 Å) result in the formation of a polymeric π–π stacked chain [4]. It seems therefore that the nature of the counter anions also impinges on such one dimensional chain structures.

In either dimer (**3**$NO_3 \cdot 3H_2O$, **3**$ClO_4 \cdot 2H_2O$, or **3**$I \cdot 5.5H_2O$) or one dimensional chain (**3**$Br \cdot 2H_2O$), it is obvious that the fundamental unit is absolutely a pair of enantiomeric complex cations ***D*** and ***L***. Similarly to the cases of monomeric **1**$ClO_4 \cdot H_2O$, **1**$Br \cdot 2H_2O$, **1**$I \cdot 2H_2O$, **2**$ClO_4 \cdot H_2O$, **2**$Br \cdot 2H_2O$, and **2**$I \cdot 2H_2O$, one of the counter anions is located in the vicinity of one coordinated amino group of each complex cation in **3**$NO_3 \cdot 3H_2O$, **3**$ClO_4 \cdot 2H_2O$, **3**$Br \cdot 2H_2O$, and **3**$I \cdot 5.5H_2O$ (Table 3). As shown in Fig. 3, for instance, the N2 atom in the ocatahedral Co(III) unit is placed close to the O5 atom of the perchlorate anion in the crystal of **3**$ClO_4 \cdot H_2O$, accompanied by N(2)–H(18)···O(5) hydrogen bond formation. It should

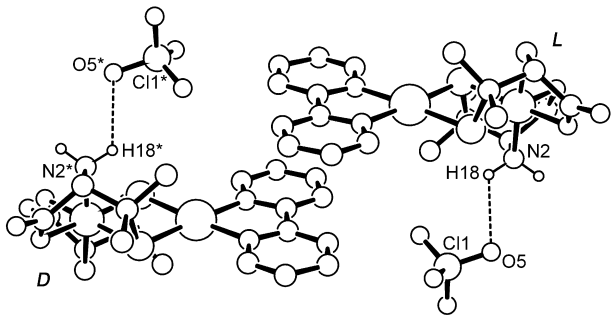

Fig. 3. Dimeric structure comprised of enantiomeric complex cations, $[Pt(bpy)\{Co(D\text{-pen})_2\}]^+$ (***D***) and $[Pt(bpy)\{Co(L\text{-pen})_2\}]^+$ (***L***), in **3**$ClO_4 \cdot 2H_2O$, together with hydrogen bonding perchlorate anions. Symmetry codes for atoms with asterisks: $1-x,-y,-z$.

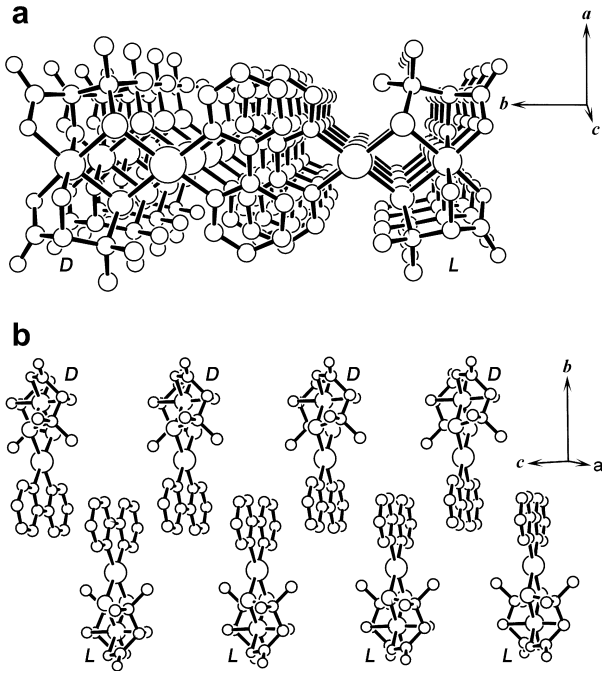

Fig. 4. Linear-chain structure comprised of enantiomeric complex cations, $[Pt(bpy)\{Co(D\text{-pen})_2\}]^+$ (***D***) and $[Pt(bpy)\{Co(L\text{-pen})_2\}]^+$ (***L***), in **3**$Br \cdot 2H_2O$ with respect to (a) *c* and (b) *a* axes.

be noted at this point that the hydrogen bonding amino group is on the opposite site of the π–π stacking phase. In addition, the extension of the hydrogen bonding counter anion depends on the nature of the counter anion itself. By comparison of the space-filling representation for each dimeric unit, the hydrogen bonding counter anion is, in fact, overhung to such an extent that further π–π stacking contacts with the bpy frameworks in the complex cations are blocked off (Fig. 5). Although inhibition by the hydrogen bonding counter anions in $\mathbf{3}NO_3 \cdot 3H_2O$ is far less than that in $\mathbf{3}ClO_4 \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$, another two anions are located on the vacant sites of the bpy frameworks and interfere with any stacking (Fig. 5a). As a result, higher dimensional structures are impossible for $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$. With regard to the monoatomic counter anion, such as I^-, on the other hand, expansion of the hydrogen bonded bromide anion in $\mathbf{3}Br \cdot 2H_2O$ is much less than that in $\mathbf{3}I \cdot 5.5H_2O$ (Fig. 6). This results in the retention of sufficient space for further π–π stacking contacts to form a linear-chain structure for $\mathbf{3}Br \cdot 2H_2O$. However, the interplane distance between the stacking bpy frameworks in $\mathbf{3}Br \cdot 2H_2O$ is much more elongated than that in $\mathbf{3}Cl \cdot 7H_2O$ due to the increment of the ionic radii [4]. It can be concluded that the crystal structures of these complexes are considerably determined by the nature of the counter anions.

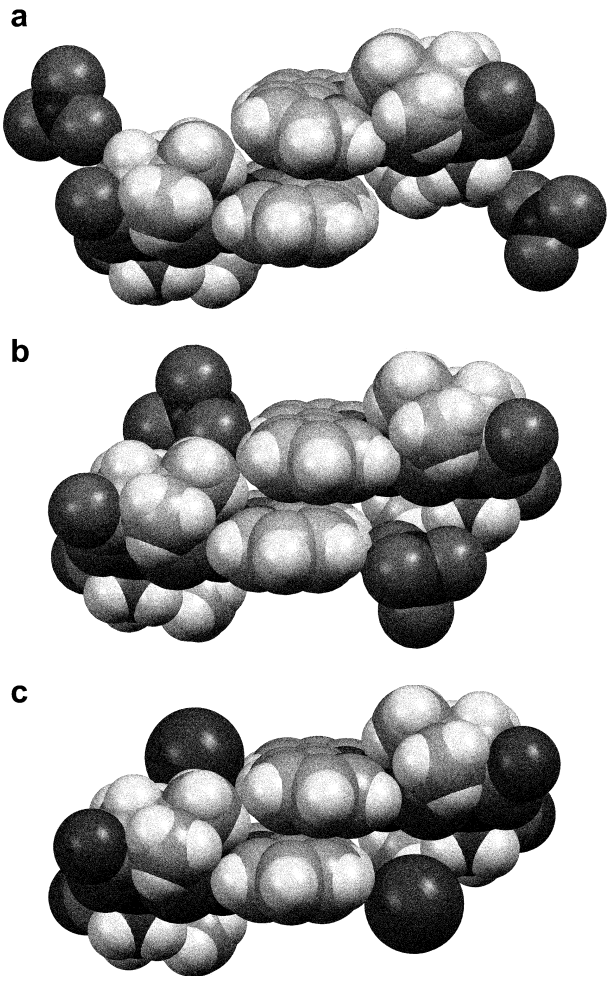

Fig. 5. Space-filling models for dimeric units of (a) $\mathbf{3}ClO_4 \cdot 2H_2O$, (b) $\mathbf{3}NO_3 \cdot 3H_2O$ and (c) $\mathbf{3}I \cdot 2H_2O$, together with the neighboring counter anions.

3.2. Characterization

In D_2O or a 1:1 mixed solvent of CD_3CN and D_2O, each of $\mathbf{1}NO_3 \cdot 6H_2O$, $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, and $\mathbf{1}I \cdot 2H_2O$ exhibits five ^{13}C NMR signals due to D-pen ligands and five signals characteristic for the bpy ligand [1–5,20]. In D_2O, for instance, $\mathbf{1}NO_3 \cdot 6H_2O$ shows signals due to D-pen at δ 31.02, 34.56, 54.90, 75.85, and 183.58 ppm, and those characteristic for bpy at 127.07, 131.19, 144.87, 150.16, and 159.44 ppm. Among the five signals for D-pen, two signals at δ 31.02 and 34.56 ppm are assigned to the carbon atoms of $-CH_3$ groups [3,4,21,22]. The remaining three signals at δ 54.90, 75.85 and 183.58 ppm are ascribed to the carbon atoms of $-C(CH_3)_2S$, $-CH(COO)N$, and $-COO$ groups, respectively. Similarly, the ^{13}C NMR spectra of $\mathbf{2}NO_3 \cdot 6H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, or $\mathbf{2}I \cdot 2H_2O$, which are enantiomers of $\mathbf{1}NO_3 \cdot 6H_2O$, $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, or $\mathbf{1}I \cdot 2H_2O$, respectively, consists of ten signals based on L-pen and bpy ligands. Although two kinds of complex cation, $[Pt(bpy)\{Co(D\text{-}pen)_2\}]^+$ (***D***) and $[Pt(bpy)\{Co(L\text{-}pen)_2\}]^+$ (***L***), exist in $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$, $\mathbf{3}Br \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$, the ^{13}C NMR spectra exhibits two sets of five signals due to pen and bpy ligands. Independent of counter anion, furthermore, the spectral pattern of **3** is quite similar to those of **1** and **2**. A similar trend is also observed for the hydrogen atoms of the bpy framework in the ^1H NMR spectra of **1**, **2**, and **3** [3,4]. These facts indicate that there are no intermolecular interactions under the present conditions, namely, concentrations of 10^{-2} mol dm^{-3}.

Electronic absorption and CD spectra of $\mathbf{1}ClO_4 \cdot H_2O$ are shown in Fig. 7, together with the CD spectra of $\mathbf{2}ClO_4 \cdot H_2O$ and $\mathbf{3}ClO_4 \cdot 2H_2O$ in H_2O. The first absorption band of $\mathbf{1}ClO_4 \cdot H_2O$ consists of three components at

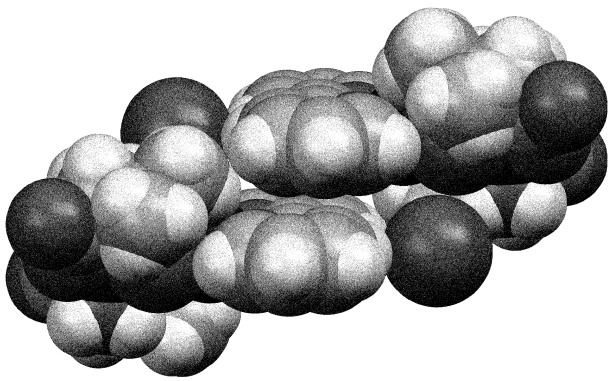

Fig. 6. Space-filling model for the clipping dimeric unit of $\mathbf{3}Br \cdot 2H_2O$.

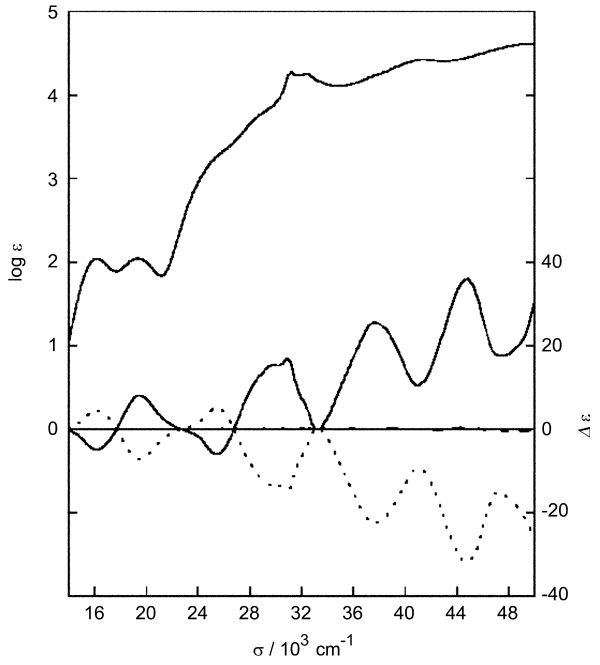

Fig. 7. Electronic absorption and CD spectra of $\mathbf{1}ClO_4 \cdot H_2O$ (solid line), together with CD spectra of $\mathbf{2}ClO_4 \cdot H_2O$ (dotted line) and $\mathbf{3}ClO_4 \cdot 2H_2O$ (broken line) in H_2O.

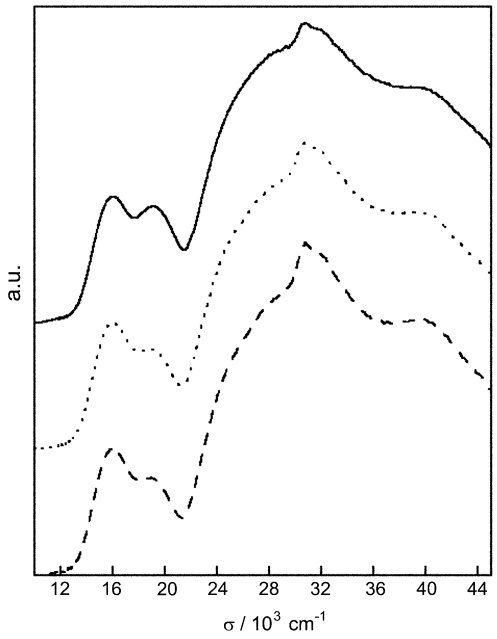

Fig. 8. Diffuse reflectance spectra of $\mathbf{1}ClO_4 \cdot H_2O$ (broken line), $\mathbf{2}ClO_4 \cdot H_2O$ (dotted line) and $\mathbf{3}ClO_4 \cdot 2H_2O$ (solid line).

16.16, 19.38, and 25.3×10^3 cm^{-1} [3,4]. The second d–d and sulfur-to-metal charge-transfer bands appear at 28.5 and 37.2×10^3 cm^{-1}, respectively. The characteristic electronic bands localized on the bpy framework are observed at 31.25 and 32.47×10^3 cm^{-1}. Reflecting the enantiomeric relationship, $\mathbf{2}ClO_4 \cdot H_2O$ shows the same absorption spectral behavior as $\mathbf{1}ClO_4 \cdot H_2O$. Although $\mathbf{3}ClO_4 \cdot 2H_2O$ involves two complex cation components, the spectral pattern is quite similar to that of $\mathbf{1}ClO_4 \cdot H_2O$ or $\mathbf{2}ClO_4 \cdot H_2O$. This result also supports that there is no significant interaction between the π electronic systems of $\mathbf{3}ClO_4 \cdot 2H_2O$. In the CD spectrum, $\mathbf{1}ClO_4 \cdot H_2O$ shows six positive signals at 19.46, 22.5, 29.4, 30.86, 37.74, and 44.84×10^3 cm^{-1}, and two negative signals at 16.21 and 25.51×10^3 cm^{-1}. While the absolute values of strengths and positions for CD bands in $\mathbf{2}ClO_4 \cdot H_2O$ correspond well with those in $\mathbf{1}ClO_4 \cdot H_2O$, each sign of the former is quite the opposite to the corresponding sign of the latter on the basis of the enantiomeric relationship. In contrast to the optically active $\mathbf{1}ClO_4 \cdot H_2O$ and $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$ shows no CD signals over the whole region in H_2O. Furthermore, similar trends in absorption and CD spectra are also observed for $\mathbf{1}NO_3 \cdot 6H_2O$, $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}NO_3 \cdot 6H_2O$, $\mathbf{2}Br \cdot 2H_2O$, $\mathbf{2}I \cdot 2H_2O$, $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}Br \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$. It can be concluded therefore that the crystal of $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$, $\mathbf{3}Br \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$ involve accurately equimolecular amounts of two enantiomers.

The reflectance spectrum of $\mathbf{1}ClO_4 \cdot H_2O$ consists of three peaks at 16.02, 18.92, and 30.82×10^3 cm^{-1}, and four shoulders at 25.2, 28.3, 32.0, and 40.0×10^3 cm^{-1} (Fig. 8). It is obvious that the 16.02, 18.92, 25.2, 28.3, 30.82, 32.0, and 40.0×10^3 cm^{-1} reflectance bands correspond to the 16.16, 19.38, 25.3, 28.5, 31.25, 32.47, and 41.32×10^3 cm^{-1} absorption bands in H_2O, respectively. Although all the bands are slightly shifted toward the lower-energy side than the corresponding absorption bands, an essential distinction is not found between both spectra. This implies that each cation in the solid state is comparatively put in a free environment, as well as in solution. While $\mathbf{2}ClO_4 \cdot H_2O$ shows the same reflectance spectral behavior as $\mathbf{1}ClO_4 \cdot H_2O$, some significant differences can be seen between the reflectance and absorption spectra of $\mathbf{3}ClO_4 \cdot 2H_2O$. It seems therefore that each complex cation in $\mathbf{3}ClO_4 \cdot 2H_2O$ is put under different surroundings in the two states. Furthermore, the reflectance spectral features for $\mathbf{3}ClO_4 \cdot 2H_2O$ are somewhat different from those for $\mathbf{1}ClO_4 \cdot H_2O$ or $\mathbf{2}ClO_4 \cdot H_2O$. In the $25–29 \times 10^3$ cm^{-1} region, for example, $\mathbf{1}ClO_4 \cdot H_2O$ and $\mathbf{2}ClO_4 \cdot H_2O$ show two well-resolved shoulders, while $\mathbf{3}ClO_4 \cdot 2H_2O$ has one broad shoulder at 26.9×10^3 cm^{-1}. Furthermore, the corresponding bands for the 30.82×10^3 cm^{-1} peak and 32.0×10^3 cm^{-1} shoulder in $\mathbf{1}ClO_4 \cdot H_2O$ or $\mathbf{2}ClO_4 \cdot H_2O$, which are assigned as localized electronic transitions on the bpy frameworks, shift slightly toward the lower-energy side in $\mathbf{3}ClO_4 \cdot 2H_2O$. These seem to reflect some distinction in the electronic natures between dimeric $\mathbf{3}ClO_4 \cdot 2H_2O$ and monomeric $\mathbf{1}ClO_4 \cdot H_2O$ or $\mathbf{2}ClO_4 \cdot H_2O$.

Responding to the dimeric structure in the crystalline state, as well as $\mathbf{3}ClO_4 \cdot 2H_2O$, each of $\mathbf{3}NO_3 \cdot 3H_2O$ and $\mathbf{3}I \cdot 5.5H_2O$ exhibits one broad shoulder in the $25–29 \times 10^3$ cm^{-1} region (Fig. 9). However, the band profiles and positions are considerably distinct from each other.

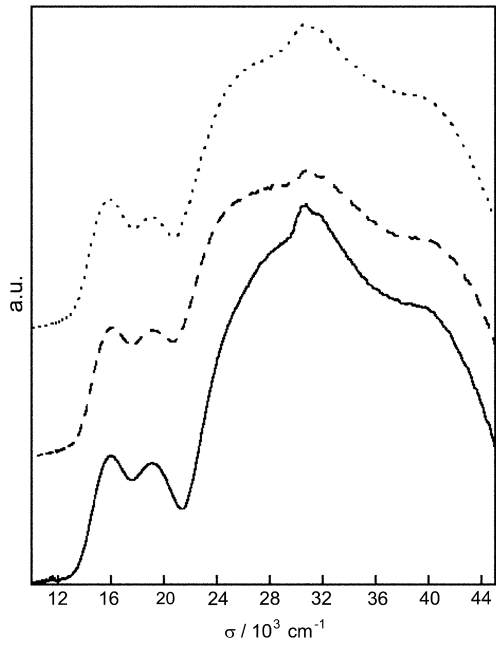

Fig. 9. Diffuse reflectance spectra of $\mathbf{3}NO_3 \cdot 3H_2O$ (solid line), $\mathbf{3}I \cdot 2H_2O$ (broken line) and $\mathbf{3}Br \cdot 2H_2O$ (dotted line).

The corresponding band for the $26.9 \times 10^3\ cm^{-1}$ band in $\mathbf{3}ClO_4 \cdot 2H_2O$ shifts toward the higher-energy side and appears at $27.3 \times 10^3\ cm^{-1}$ in $\mathbf{3}NO_3 \cdot 3H_2O$. In contrasted to $\mathbf{3}NO_3 \cdot 3H_2O$, the corresponding reflectance band of $\mathbf{3}I \cdot 5.5H_2O$ overhangs to the lower-energy side and is located at $25.4 \times 10^3\ cm^{-1}$. These indicate that the electronic natures of $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$ differ considerably from each other regardless of similar dimeric structures. In each crystal of $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$, as shown in Fig. 5, the dimeric unit is established by a pair of enantiomeric complex cations ***D*** and ***L***. In addition, the interplane distances between the bpy frameworks of $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$, and $\mathbf{3}I \cdot 5.5H_2O$ are 3.61, 3.45, and 3.40 Å, respectively, depending on the nature of the counter anion. It should be noted that the interplane distances correlate with the band positions of the above broad shoulders. The broad shoulder shifts toward the lower-energy side as the interplane distance shortens, namely, the interaction between the π electronic systems intensifies. Therefore, the broad shoulder in the $25–29 \times 10^3\ cm^{-1}$ region can be regarded as characteristic for the dimeric structure composed of a pair of enantiomeric complex cations ***D*** and ***L***. In the $25–29 \times 10^3\ cm^{-1}$ region, the reflectance spectrum of $\mathbf{3}Br \cdot 2H_2O$ does not show two well-resolved shoulders but a single broad band around $27.0 \times 10^3\ cm^{-1}$ (Fig. 9). Although the interplane distance between two π electronic systems in $\mathbf{3}Br \cdot 2H_2O$ (3.65 Å) is slightly longer than that in $\mathbf{3}NO_3 \cdot 3H_2O$, the broad shoulder of the former appears at the lower-energy side in comparison with the latter. This seems to reflect the dimensional distinctions in π–π stackings between linear-chains and dimers. Considering these facts, it can be concluded that fluctuations by counter anions are brought not only to crystal structures but to electronic natures as well.

4. Supplementary material

CCDC 627218, 627219, 627220, 627221, 627222, 627223, 627224, 627225, 627226 and 627227 contain the supplementary crystallographic data for $\mathbf{1}ClO_4 \cdot H_2O$, $\mathbf{1}Br \cdot 2H_2O$, $\mathbf{1}I \cdot 2H_2O$, $\mathbf{2}ClO_4 \cdot H_2O$, $\mathbf{2}Br \cdot 2H_2O$, $\mathbf{2}I \cdot 2H_2O$, $\mathbf{3}NO_3 \cdot 3H_2O$, $\mathbf{3}ClO_4 \cdot 2H_2O$, $\mathbf{3}Br \cdot 2H_2O$ and $\mathbf{3}I \cdot 5.5H_2O$. Abstract

The novel bis(cyclohexylaminium) cyclohexylaminebis(orotate–*N*,*O*)cuprate(II) dihydrate, $(C_6H_{15}N)_2[Cu(C_5H_2N_2O_4)_2(C_6H_{14}N)]\cdot 2H_2O$, has been prepared and characterized by elemental analysis, magnetic measurements, FT-IR and UV–Vis spectroscopy, thermal analysis and X-ray diffraction. The Cu(II) complex crystallizes in the monoclinic space group $P2_1/c$. The copper atom in the five-coordinated $(chaH)_2[Cu(HOr–N,O)_2(cha)]\cdot 2H_2O$ is chelated by a deprotonated pyrimidine nitrogen atom and carboxylate oxygen atom as a bis(bidentate) ligand and the cyclohexylamine ligand completes the square-pyramidal coordination. The thermal decomposition of the complex has been predicted by the help of thermal analysis (TG, DTG and DTA).

1. Introduction

Metal complexes of orotic acid (1,2,3,6-tetrahydro-2,6-dioxo-4-pyrimidine carboxylic acid, vitamin B13, H_3Or, Scheme 1a) and its substituted derivatives continue to attract attention because of its multidentate functionality and pivotal role in bioinorganic chemistry [1,2]. It is a precursor in the biosynthesis of pyrimidine bases and nucleic acids in living organisms [1,2]. It has been widely exploited in medicine [2,3]. It also exhibits bacteriostatic and cytostatic properties. The coordination chemistry of orotic acid was found to be very interesting. Its anions also are interesting multidentate ligands as they can coordinate through the pyrimidine nitrogen atoms, the carbonyl oxygen and the carboxyl oxygen. The incorporation of metals into supramolecular systems attracts much attention and some orotate complexes [4,5] have shown that the orotate ligand may be a good building block for the construction of supramolecular systems. The literature lists many reports on the coordinating presences of the orotate moiety in metal complexes. Although the most common coordination mode of H_3Or is ligation through the deprotonated carboxyl group and its adjacent nitrogen atom [4–15], no bis(orotate–*N*,*O*) metal complex is known. The first copper(II)–orotate complex, $[Cu(HOr)(NH_3)_2]$, was reported by Mutikainen and Lumme [6] in 1980. X-ray structures of other Cu(II)–orotate complexes, $[Cu(HOr)(H_2O)_2]_n$ [7], $[Cu(HOr)(phen)]$ [8], $[Cu(HOr)(H_2O)(en)]\cdot H_2O$ [9], $[Cu(HOr)(tea)]\cdot H_2O$ [10] and $[Cu(HOr)(bipy)(H_2O)]\cdot H_2O$ [11] (phen = 1.10-phenanthroline, en = ethylenediamine, tea = triethanolamine, bipy = 2,2′-bipyridine), have been studied.

In the present paper, we describe the synthesis, spectroscopic, thermal studies and crystal structure of the first *bis*(orotato–*N*,*O*) copper(II) complex with orotic acid and

Scheme 1. Structures of the ligands: (a) orotic acid, (b) cyclohexylamine.

cyclohexylamine (cha, Scheme 1b), $(chaH)_2[Cu(HOr\text{-}N,O)_2(cha)]\cdot 2H_2O$ (**1**).

2. Experimental

2.1. Preparation of the complex

The cha ligand (1.00 g, 10 mmol) was added dropwise to a solution of $CuCl_2\cdot 2H_2O$ (0.43 g, 2.5 mmol) and $H_3Or\cdot H_2O$ (0.87 g, 5 mmol) dissolved in water (30 ml), and stirred for 10 h at 60 °C. The reaction mixture was then cooled to room temperature. Green crystals were filtered off and then washed with 10 ml of water and dried in air. *Anal.* Calc. for $C_{28}H_{49}N_7O_{10}Cu$: C, 47.55; H, 6.98; N, 13.86. Found: C, 47.58; H, 7.02; N, 13.84%.

2.2. Materials and measurements

All the chemicals used were analytical reagent and were commercially purchased. IR spectra were obtained with a Bruker Tensor 27 FT-IR spectrometer using KBr pellets in the 4000–400 cm^{-1} range. Elemental analysis for C, H and N were performed using a Carlo Erba 1106 microanalyser. Magnetic susceptibility measurement at room temperature was performed using a Sherwood Scientific MXI model Gouy magnetic balance. The UV–Vis spectrum was obtained for an aqueous solution of the complex (10^{-3} M) with a Unicam UV2 spectrometer in the range 900–190 nm. A Perkin Elmer Diamond TG/DTA thermal analyzer was used to record simultaneous TG, DTG and DTA curves in static air atmosphere at a heating rate of 10 K min^{-1} in the temperature range 20–600 °C using platinum crucibles.

2.3. Crystallographic analysis

Diffraction experiments were carried out at 293 K on a Stoe IPDS diffractometer. The structure was solved by direct methods using the program SHELXS97 [16]. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares methods [16]. All hydrogen atoms except H1, H1w, H2w, H3w, H4w, H46 and H47 were located geometrically. The relevant crystal data and experimental conditions along with the final parameters are summarized in Table 1. Data collection: X-Area, cell refinement: X-Area, data reduction on: X-RED [17]; program(s) used to refine structure: SHELXL97 [16]; molecular graphics: ORTEP-3 for Windows [18]; software used to prepare material for publication: WINGX [19].

3. Results and discussion

3.1. UV–Vis spectrum and magnetic susceptibility

The UV–Vis spectrum of **1** in H_2O displays a broad absorption band at 766 nm ($\varepsilon = 70$ L $mol^{-1}cm^{-1}$). These values were assigned to an $a_1 \rightarrow b_1$ transition. The complex exhibits a magnetic moment value of 1.72 BM which corresponds to one unpaired electron.

3.2. IR spectrum

Selected IR bands of the copper(II) complex are listed in Table 2. A comparison between the IR spectrum of orotic acid and the copper(II) complex may provide important evidence for the coordination of the orotate ligand to the copper(II) ion. The infrared spectrum of the Cu(II) complex shows a strong band at 3487 cm^{-1} due to the O–H stretching vibrations of water molecules. The intense bands at 3271–3397 cm^{-1} are attributed to the ν(NH) vibration of both cyclohexylamine and the protonated NH_2 group of a cha molecule in the IR spectrum of **1**. The relatively weak bands between 2862 and 2995 cm^{-1} can be assigned to the CH and CH_2 stretching vibrations of the HOr ligand and cha molecules. The position of the characteristic stretching modes of the carbonyl and N–H of the orotate moiety can be used to characterize the coordination mode

[a] See [23].

of this ligand to metal ions. The carbonyl stretching band of orotic acid and ammonium orotate observed at 1729; 1719 and 1690 cm^{-1} of $[\nu_{C=O(acid)} + \nu_{C(2)=O}]$ and 1700; 1653 and 1650 cm^{-1} of $[\nu_{C(6)=O} + \nu_{ring} + \nu_{C=C}]$, respectively [20] were shifted to 1701 and 1639 cm^{-1} for the mono-deprotonated orotate ligand, $[Co(H_2Or)_2(H_2O)_4]\cdot 2H_2O$ [21], while the bis-deprotonated orotate ligand, $[Co(HOr)(H_2O)_4]\cdot H_2O$ [9], give a single and strong broad absorption band at 1632 cm^{-1} due to overlapping of the two bands. In the IR spectrum of $(chaH)_2[Cu(HOr–N,O)_2(cha)]\cdot 2H_2O$, two equally strong $\nu_{C=O}$ bands at 1654 and 1605 cm^{-1} correspond to the stretching of the carbonyl group in the bis-deprotonated orotate ligands. The band splitting of the stretching vibrations of the carbonyl group was attributed to the non-equivalence of the environment of these groups in the ring. The weak bands in the 450 and 593 cm^{-1} regions are due to Cu(II)–N and Cu(II)–O stretching vibrations, respectively [22]. From the IR spectrum, it can be assumed that in the copper(II) complex the orotate residues HOr are coordinated as bidentate ligands to the Cu(II) ion through the carboxylic oxygen and nitrogen (N_3) atoms from the pyrimidine ring.

3.3. Thermal analysis

The thermal decomposition behavior of **1** was followed up to 600 °C in static air atmosphere. The thermal analysis curves show that the complex exhibits a four stage mass loss process. The first stage is related to endothermic removal of two moles of crystal water molecules in the 87–141 °C temperature range (DTG_{max} = 138 °C). The experimental mass loss of 5.34% agrees well with the calculated mass loss of 5.09%. The second stage corresponds to the loss of one mole of cyclohexylamine molecule in the 142–237 °C temperature range (found 13.94, calcd. 14.16%), giving an exothermic effect (DTG_{max} = 211 °C). In the following endothermic stage between 228 and 443 °C, both cyclohexylamine and cyclohexylamine ligand were released and the orotate dianions decomposed, simultaneously. In the last stage, the strong exothermic mass loss process occurs in a single step. During this stage, the remaining organic part is abruptly burnt (DTG_{max} = 507 °C). The final decomposition product, namely CuO was identified by IR spectroscopy with corresponding spectra obtained under the same conditions as the pure oxide. The overall mass loss 88.16% (calcd. 88.75%) agrees with the proposed structure well.

3.4. Crystal structure of the complex

Details of the crystal structure are given in Table 1. The crystallographic analysis revealed that the complex, $(chaH)_2[Cu(HOr)_2(cha)]\cdot 2H_2O$, consists of a discrete $[Cu(HOr)_2(cha)]^{2-}$ anion, two protonated chaH cations and two crystal water molecules (Fig. 1). One of the interesting features of the structure is that the chaH molecules exhibit chemically different functions. While in one form they coordinate to the copper atom, in the other form they act as counter-ions. In addition, there are bis(deprotonated) HOr ligands coordinated to the Cu(II) ion. To the best of our knowledge, this has not been reported before, although there are many metal complexes of orotic acid. The Cu(II) ion has a distorted square-pyramidal coordination. The basal coordination plane is formed by atoms N3, N4, N7 and O4. The coordination is completed by atom O5 located at the pyramid apex. There are slight differences in Cu1–O5, Cu1–O4 bond distances and N3–Cu1–O5, N4–Cu1–O4 angles. This may be caused by the N(1)–H(1A)···O(4) hydrogen bond. The Cu–N_{HOr} bond distances are shorter than the Cu–N_{cha} bond distance. The Cu1–N3/N4 bond distances are in agreement with the

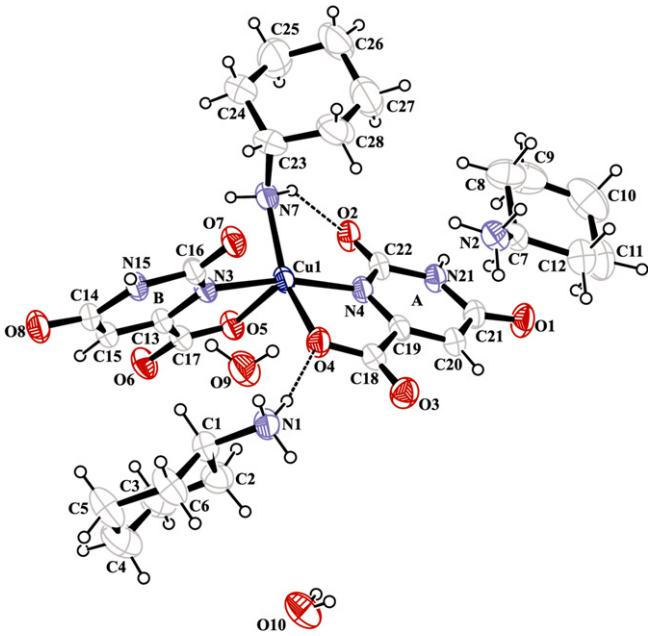

Fig. 1. Molecular structure of **1**.

corresponding values in related structures, while the Cu–O_{HOr} bonds are longer than previously reported values [8,9]. Although the bond distances of the coordinated cha and chaH ion are similar, the corresponding angles are different from each other [24,25,29]. The bond distances and angles of chaH ions are in agreement with the corresponding values in related structures [24,25]. Comparison of values of the M–O_{HOr}, M–N_{HOr}, M–N_{cha} distances, and of the O_{HOr}–M–N_{HOr} angle for similar orotate and cyclohexylamine metal complexes can be found in Table 3. The dihedral angle between the orotato ligands are 68.17(6)°. The angles of N3–Cu1–O5 [78.73(12)°] and N4–Cu1–O4 [81.16(13)°] are nearly equal. The orotato ligands are almost planar (the r.m.s deviations are 0.0218 and 0.0257 Å). The details of the hydrogen bonding geometry are given in Table 4. The nitrogen groups of the orotato ligands are involved in inter-molecular hydrogen bonding with the carbonyl oxygen of the orotate ligand. The cha ligands are involved in intra- and inter-molecular hydrogen bonding with the carbonyl oxygen and hydroxyl oxygen. The intra-molecular N(1)–H(1A)···O(4) and O(9)–H(4W)···O(3) bonds have H···O distances of 1.94 and 2.06(9) Å, respectively. The inter-molecular N21–H21···$O1^{ii}$, O10–H1W···$O6^{vi}$ and N1–H1C···$O9^{i}$ bonds have the H···O distances of 1.99, 1.72(8) and 1.92 Å, respectively. Some of these interactions are illustrated in Fig. 2.

4. Conclusion

We have successfully synthesized the first bis(orotate–*N*,*O*) complex, $(chaH)_2[Cu(HOr)_2(cha)]\cdot 2H_2O$, and have characterized it by elemental analysis, magnetic measurements, FT-IR and UV–Vis spectroscopy, thermal analysis and X-ray diffraction. The structure of $(chaH)_2[Cu(HOr)_2(cha)]\cdot 2H_2O$ displays several interesting features. Previous studies showed that all the aqua and mixed-ligand complexes of HOr with first-row divalent transition metal

ions consist of neutral complexes, containing only one coordinated HOr ligand within the coordination sphere, hence the presence of two HOr ligands in the primary coordination sphere, as seen in $(chaH)_2[Cu(HOr)_2(cha)]\cdot 2H_2O$, is unusual. Therefore, the most interesting aspect of this complex is the coordination of two HOr ligands around the copper(II) ion and this complex is the first example exhibiting two coordinated HOr ligands in the same coordination sphere of a mononuclear unit. Additionally, the chaH molecules exhibit chemically different functions – in one form they coordinate to the copper atom, in the other form they act as counterions. In previous studies the orotato complexes are neutral, whereas the title complex consists of two chaH cations and one $[Cu(HOr)_2(cha)]^{2-}$ anion. It can be said that the stabilization of the $[Cu(HOr)_2(cha)]$ anion in the solid state may be due to the presence of the chaH cations which have a relatively large ionic radius.

Abstract

The synthesis and spectroscopic properties of the following tetra- and octa-substituted aryloxy zinc(II) phthalocyanines are reported for the first time: 1,(4)-(tetrabenzyloxyphenoxyphthalocyaninato) zinc(II) (**7**); 2,(3)-(tetrabenzyloxyphenoxyphthalocyaninato) zinc(II) (**8**); 2,3-(octabenzyloxyphenoxyphthalocyaninato) zinc(II) (**9**). The new compounds have been characterized by elemental analysis, IR, ^{1}H NMR spectroscopy and electronic spectroscopy. Spectroscopic properties of these compounds were investigated in different solvents. Protonation of non-peripherally substituted complex **7** resulted in the splitting and red-shifting of the Q-band. The peripherally substituted derivatives **8** and **9**, did not show the split in the Q-band. Fluorescence spectra of the derivatives show Stokes shifts typical of MPc complexes.

1. Introduction

Phthalocyanines and metallophthalocyanines have been investigated in detail for many years because of their wide applications in many fields, including use and investigation in chemical sensors, liquid crystals, Langmuir–Blodgett films, nonlinear optics, optical data storage and as carrier generation materials in near-IR devices [1,2]. Substituted derivatives can also be used for photodynamic cancer therapy and other processes driven by visible light [1,2]. A decisive disadvantage of phthalocyanine and metal phthalocyanines is their low solubility in organic solvents or water. The solubility can be increased, however, by introducing alkyl or alkoxy groups into the peripheral and non-peripheral positions of the phthalocyanine framework [3]. Because of their lower degree of order in solid state, tetra-substituted phthalocyanines are more soluble than the corresponding octa-substituted ones. In contrast to octa-substituted systems, tetra-substituted phthalocyanines are obtained as a mixture of constitutional isomers by statistical synthesis starting from mono-substituted phthalonitriles or corresponding diiminoisoindolines. Depending on their substituent positions two types (non-peripherally and peripherally substituted) of tetra-substituted macrocycles which show significant differences in their chemical and physical behaviour can be obtained.

Recently, phthalocyanine complexes have found applications as photosensitisers in PDT since diamagnetic central metals, such as Zn or Mg enhance phototoxicity of phthalocyanines [4–7]. Zinc phthalocyanine complexes have attracted much interest because of their appreciably long triplet lifetimes [8–10]. Such long lifetimes constitute a great advantage since the number of diffusional encounters between the triplet excited state and ground state molecular oxygen increases with the lifetime of the excited

doi:10.1016/j.poly.2007.01.018

state. The introduction of peripheral and non-peripheral substituents onto the MPc ring is expected to affect both the triplet quantum yield and lifetime, hence it is desirable to carry out studies on the effects of substituents on these parameters.

Addition of groups to the peripheral positions of MPc complexes is known to influence the properties of the MPc to a large degree [11–15]. For instance, the peripheral substituents increase the distance between the planar macrocycle rings carrying the π-electrons thereby making solvation easier. Solvents affect aggregation in phthalocyanine complexes. Organic solvents are known to reduce aggregation whereas aqueous medium results in highly aggregated complexes. However, many phthalocyanine complexes remain aggregated even in non-aqueous solutions [16–18]. Aromatic solvents such as benzene or toluene are known to give narrow Q-bands for phthalocyanines whereas broadening is observed in non-aromatic solvents [19].

In this work, we have synthesized tetra- and octa-substituted new zinc phthalocyanine compounds. We report on the effects of tetra (peripheral and non-peripheral) and octa ring substituents on the spectroscopic and aggregation properties of zinc phthalocyanine derivatives in different solvents (toluene, dichloromethane, chloroform, THF, and DMSO). Fluorescence properties of these compounds were also investigated in these solvents.

2. Experimental

2.1. Materials

Dimethylsulphoxide (DMSO), methanol, hexane, chloroform ($CHCl_3$), dichloromethane (DCM), tetrahydrofuran (THF), toluene, acetone, ethanol dimethylformamide (DMF) and *n*-pentanol were dried as described in Perrin and Armarego [20] before use. Zinc acetate, K_2CO_3, deuterated $CDCl_3$, 4-benzyloxyphenol, 1,8-diazabicyclo-[5.4.0]-undec-7-ene (DBU) were purchased from Aldrich. Column chromatography was performed on silica gel 60 (0.04–0.063 mm) and preparative thin layer chromatography was performed on silica gel 60 P F_{254}. 3-Nitrophthalonitrile (**1**) [21], 4-nitrophthalonitrile (**2**) [22] and 4,5-dichlorophthalonitrile [23] were synthesised and purified according to literature procedure.

2.2. Equipment

UV–Vis spectra were recorded on a Cary 500 UV–Vis/NIR spectrophotometer. Fluorescence excitation and emission spectra, were recorded on a Varian Eclipse spectrofluoremeter using 1 cm pathlength cuvettes at room temperature. IR spectra (KBr pellets) were recorded on a Perkin–Elmer spectrum 2000 FTIR spectrometer. ^1H NMR spectra were recorded in $CDCl_3$ solutions using a Bruker EMX 400 MHz NMR spectrometer. Elemental Analyses were performed at the University of Cape Town.

2.3. Synthesis

2.3.1. 3-(4-Benzyloxyphenoxy)phthalonitrile (4)

In a stream of nitrogen, 4-benzyloxyphenol (3.50 g, 17.5 mmol) and 3-nitrophthalonitrile (**1**) (3.00 g, 17.5 mmol) were dissolved in DMF (30 ml) and the mixture stirred at room temperature for 15 min. Thereafter, finely ground K_2CO_3 (7.50 g, 0.052 mol) was added potion-wise over a period of 2 h and the reaction mixture left to stir for a further 12 h at room temperature. The mixture was added to water (100 ml) and stirred for 30 min. The resulting precipitate was filtered off, thoroughly washed with water, dried and recrystallised from ethanol. Yield: 4.39 g (77%). IR [(KBr) ν_{max}/cm^{-1}]: 3092 (Ar–CH), 3079 (Ar–CH), 3029 (Ar–CH), 2900–2864 (CH_2), 2229 (C≡N), 1574 (C=C), 1193 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 7.53 (1H, t, Ar–H), 7.31–7.47 (7H, m, Ar–H), 6.95–7.10 (4H, m, Ar–H), 5.08 (2H, s, CH_2).

2.3.2. 4-(4-Benzyloxyphenoxy)phthalonitrile (5)

Synthesis and purification was as outlined for **4** except 4-nitrophthalonitrile (**2**) instead of **1** was employed. The amounts of the reagents employed were: 4-benzyloxyphenol (3.50 g, 17.5 mmol), 4-nitrophthalonitrile (**2**) (3.00 g, 17.5 mmol) in DMF (30 ml). Yield: 4.63 g (82%). IR [(KBr) ν_{max}/cm^{-1}]: 3093 (Ar–CH), 3075 (Ar–CH), 3037 (Ar–CH), 2938-2876 (CH_2), 2230 (C≡N), 1588 (C=C), 1198 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 7.69 (1H, d, Ar–H), 7.32–7.46 (5H, m, Ar–H), 7.17–7.25 (2H, m, Ar–H), 6.97–7.06 (4H, m, Ar–H), 5.08 (2H, s, CH_2).

2.3.3. 4,5-Bis-(4-benzyloxyphenoxy)phthalonitrile (6)

Synthesis and purification was as outlined for **4** except 4,5-dichlorophthalonitrile (**3**) instead of **1** was employed. The amounts of the reagents employed were: 4-benzyloxyphenol (6.70 g, 30.4 mmol), 4,5-dichlorophthalonitrile (**3**) (3.00 g, 15.2 mmol) in DMF (50 ml). Yield: 5.34 g (67%). IR [(KBr) ν_{max}/cm^{-1}]: 3092 (Ar–CH), 3064 (Ar–CH), 3035 (Ar–CH), 2940-2868 (CH_2), 2235 (C≡N), 1585 (C=C), 1197 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 7.82 (2H, s, Ar–H), 7.33–7.47 (10H, m, Ar–H), 6.96–7.07 (8H, m, Ar–H), 5.09 (4H, CH_2).

2.3.4. 1,(4)-Tetrakis(4-benzyloxyphenoxyphthalocyaninato) zinc(II) (7)

A mixture of anhydrous zinc(II) acetate (2.25 g, 12.2 mmol), 3-(4-benzyloxyphenoxyphthalonitrile) (**4**) (2.00 g, 6.1 mmol) and dried *n*-pentanol (5 ml) was refluxed at 140 °C for 18 h under nitrogen atmosphere. After cooling, the solution was dropped in ethanol. The green solid product was precipitated and collected by filtration and washed with ethanol. The crude product was dissolved in CH_2Cl_2 and then filtered. After filtering and concentrating, the dark green waxy product was purified by passing through a silica gel column, using THF as the eluting solvent. Furthermore this product was purified with preparative thin layer chromatography (silica gel) using $CHCl_3$ as a solvent system. Yield:

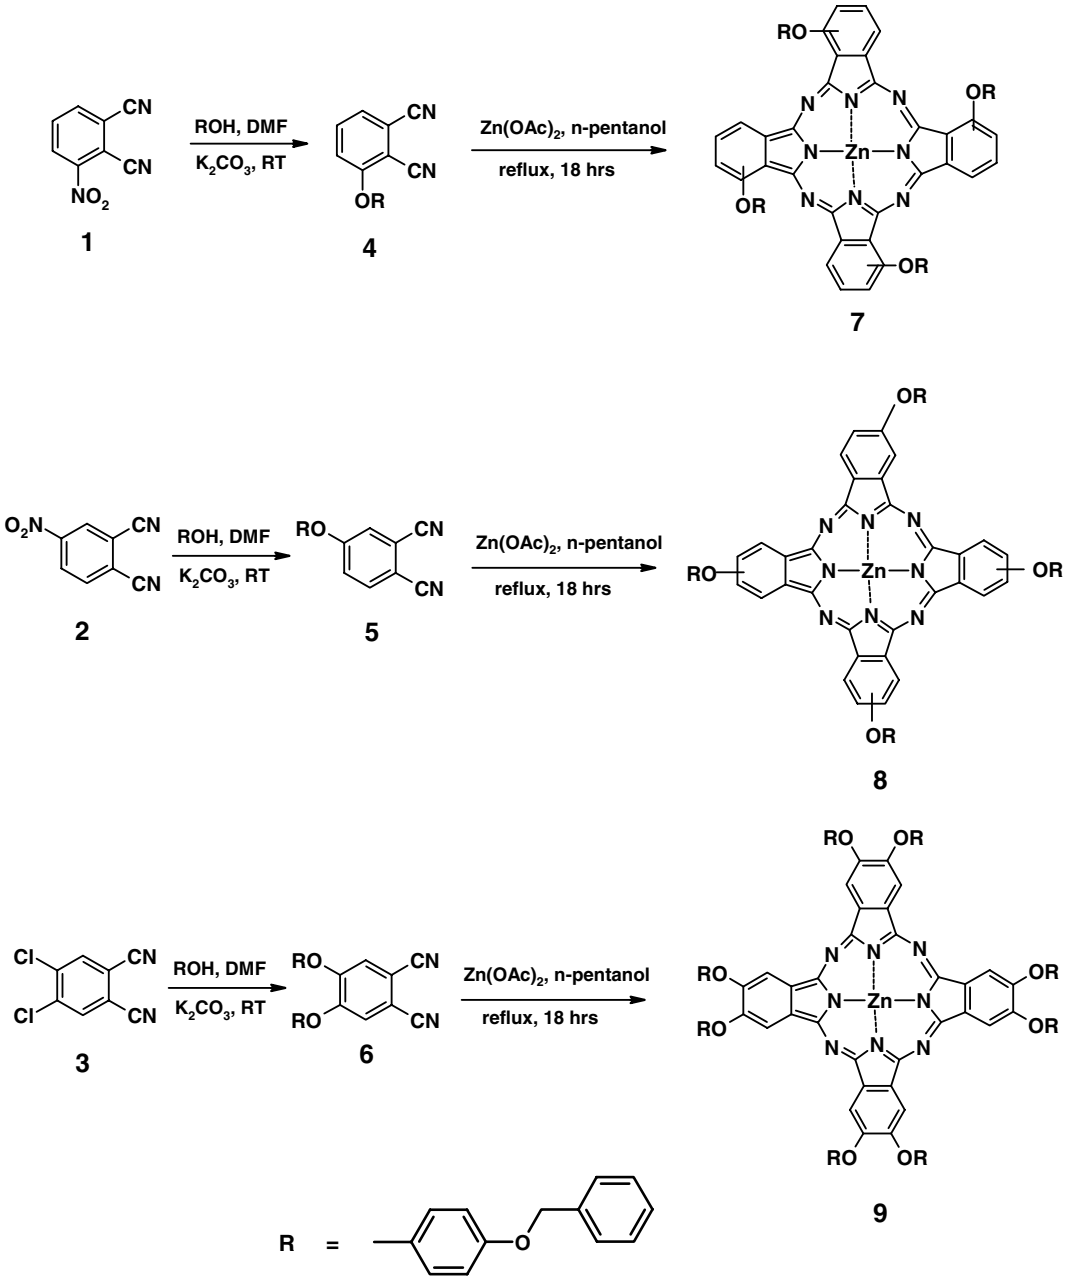
0.79 g (37%). UV–Vis (DMSO): λ_{max} nm (log ε) 340 (4.58), 629 (4.50), 699 (5.24). IR [(KBr) ν_{max}/cm^{-1}]: 3055(Ar–CH), 3027(Ar–CH), 2949-2856(CH_2), 1583(C=C), 1194(C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 8.11–8.94 (4H, m, Pc–H), 6.72–7.83 (44H, m, Pc–H, Phenyl–H), 4.96 (8H, s, CH_2). *Anal.* Calc. for $C_{84}H_{56}N_8O_8Zn$: C, 73.60; H, 4.12; N, 8.17. Found: C, 73.84; H, 4.15; N, 8.05%.

2.3.5. 2,(3)-Tetrakis(4-benzyloxyphenoxyphthalocyaninato) zinc(II) (8)

Synthesis and purification was as outlined for **7** except 4-(4-benzyloxyphenoxyphthalonitrile) (**5**) instead of 3-(4-benzyloxyphenoxyphthalonitrile) (**4**) was employed. The amounts of the reagents employed were: **5** (2.00 g, 6.1 mmol), anhydrous zinc(II) acetate (2.25 g, 12.2 mmol) in *n*-pentanol (5 ml). Yield: 0.93 g (44%). UV–Vis (DMSO): λ_{max} nm (log ε) 355 (4.81), 612 (4.52), 681 (5.23). IR [(KBr) ν_{max}/cm^{-1}]: 3056 (Ar–CH), 3027 (Ar–CH), 2949–2856 (CH_2), 1617 (C=C), 1193 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 7.19–7.46 (24H, m, Pc–H, Phenyl–H), 6.36–7.13 (24H, m, Pc–H, Phenyl–H), 4.75 (8H, s, CH_2). *Anal.* Calc. for $C_{84}H_{56}N_8O_8Zn$: C, 73.60; H, 4.12; N, 8.17. Found: C, 72.08; H, 3.96; N, 7.82%.

2.3.6. 2,3-Octakis(4-benzyloxyphenoxyphthalocyaninato) zinc(II) (9)

Synthesis and purification was as outlined for **7** except 4,5-bis(4-benzyloxyphenoxyphthalonitrile) (**6**) instead of 3-(4-benzyloxyphenoxyphthalonitrile) (**4**) was employed. The amounts of the reagents employed were: **6** (2.00 g, 3.8 mmol), anhydrous zinc(II) acetate (1.40 g, 7.6 mmol) in *n*-pentanol (5 ml). Yield: 0.67 g (32%). UV–Vis (DMSO): λ_{max} nm (log ε) 350 (5.03), 629 (4.90), 680 (5.18). IR [(KBr) ν_{max}/cm^{-1}]: 3058 (Ar–CH), 3027 (Ar–CH), 2948–2855 (CH_2), 1603 (C=C), 1190 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 7.18–7.81 (40H, br, Pc–H, Phenyl–H), 6.41–7.08 (40H, br, Phenyl–H), 4.81 (16H, s, CH_2). *Anal.* Calc. for $C_{136}H_{96}N_8O_{16}Zn$: C, 75.50; H, 4.47; N, 5.18. Found: C, 75.08; H, 4.26; N, 5.62%.



3. Results and discussion

Generally, substituted phthalocyanines are prepared by cyclotetramerization of substituted phthalonitriles or 1,3-diimino-1H-isoindoles. 2(3),9(10),16(17),23(24)-tetra-substituted phthalocyanines can be synthesized from 4-substituted phthalonitriles while 1(4),8(11),15(18),22(25)-tetra-substituted phthalocyanines are obtained from 3-substituted analogues [24]. Octa-substituted phthalocyanines can be synthesized from 4,5-dichlorophthalonitriles [23]. In both cases a mixture of four possible structural isomers are obtained for tetra-substituted phthalocyanines. The four probable isomers can be designed by their molecular symmetry as C_{4h}, C_{2v}, C_s and D_{2h}. The 2(3)-substituted compounds always occur in the expected statistical mixture of 12.5% C_{4h}, 25% C_{2v}-, 50% C_s- and 12.5% D_{2h}-isomer. But for the 1(4)-substituted complexes the composition depends on the central metal ion and the structure of the peripheral substituent [25]. In this study, synthesized tetra-substituted phthalocyanine compounds are obtained as mixtures of isomers as expected. No attempt was made to separate the isomers of **7** and **8**. 3-Nitrophthalonitrile (**1**), 4-nitrophthalonitrile (**2**) and 4,5-dichlorophthalonitrile (**3**) were used recently to prepare 3-monosubstituted, 4-monosubstituted and 4,5-disubstituted phthalonitrile derivatives, respectively, through base catalysed nucleophilic aromatic displacement [26–31]. The same route was applied to prepare 3-(4-benzyloxyphenoxyphthalonitrile) (**4**), 4-(4-benzyloxyphenoxyphthalonitrile) (**5**) and 4,5-bis(4-benzyloxyphenoxyphthalonitrile) (**6**) from 4-benzyloxyphenol and 3-nitrophthalonitrile (**1**), 4-nitrophthalonitrile (**2**), 4,5-dichlorophthalonitrile (**3**), respectively (Scheme 1). The reactions were carried out in dimethylformamide at room temperature and gave yields 77% for **4**, 82% for **5** and 67% for **6**.

The preparation of phthalocyanine derivatives from the aromatic nitriles occur under different reaction conditions. The syntheses of metallophthalocyanine complexes (**7**, **8** and **9**) were achieved by treatment of phthalonitriles **4**, **5** and **6** with zinc acetate in dried *n*-pentanol (Scheme 1). Complex **7** is non-peripherally (α) tetra-substituted, complex **8** is peripherally (β) tetra-substituted and complex **9** is octa-substituted. Column and preparative thin layer chromatography with silica gel was employed to obtain the pure products from the reaction mixtures.

Generally, phthalocyanine complexes are insoluble in most organic solvents; however introduction of substituents on the ring increases the solubility. All complexes (**7**, **8** and **9**) exhibited excellent solubility in organic solvents such as dichloromethane, chloroform, THF, toluene, acetone, DMSO. For comparative purposes, the 4-benzyloxyphenoxy group was tetra-substituted at the α and β positions and octa-substituted to the ring. The new compounds were characterized by UV–Vis, IR and NMR spectroscopies, elemental analysis and the analyses were consistent with the predicted structures as shown in the experimental section. The sharp peak for the C≡N vibrations of phthalonitriles **4**, **5** and **6** at ~2230 cm^{-1} disappeared after conversion into zinc phthalocyanines, indicative of metallophthalocyanine formation. The characteristic vibrations corresponding to ether groups (C–O–C) at ca. 1190–1198 cm^{-1}, aromatic CH stretching at ca. 3093–3027 cm^{-1} and aliphatic CH stretching at ca. 2949–2855 cm^{-1}.

^1H NMR investigations of phthalonitrile compounds **4**, **5** and **6** provide the characteristic chemical shifts for the structures as expected. In the ^1H NMR analysis of all these compounds in deuterated chloroform, methyl protons appear as a singlet at ca. 5.08 ppm. The aromatic protons appear as multiplets because the compounds contain different aromatic groups. The ^1H NMR spectra of phthalonitrile compound **4** shows as a triplet at 7.53 ppm, a multiplet at between 7.31 and 7.47 ppm and a multiplet at between 6.95 and 7.10 ppm, compound **5** shows as a

Scheme 1. Synthesis of 4-benzyloxyphenoxy tetra- and octa-substituted zinc phthalocyanine complexes.

doublet at 7.69 ppm, a multiplet at between 7.32 and 7.46 ppm, a multiplet at between 7.17 and 7.25 ppm and a multiplet at between 6.97 and 7.06 ppm for the aromatic hydrogens. On the other hand, the ^{1}H NMR spectrum of the other phthalonitrile compound **6** shows a singlet at 7.82 ppm, a multiplet at between 7.33 and 7.47 ppm and a multiplet at between 6.96 and 7.07 ppm for the aromatic hydrogens.

The ^{1}H NMR spectra of tetra-substituted phthalocyanine derivatives (**7** and **8**) show complex patterns owing to the mixed isomer character of these compounds and they have different aromatic protons. Octasubstituted derivative (**9**) also show complex patterns due to the different aromatic protons. The complexes were found to be pure by ^{1}H NMR with all the substituents and ring protons observed in their respective regions. The resonances belonging to aromatic protons were observed between 8.11–8.94 and 6.72–7.83 ppm as multiplets for non-peripherally tetra-substituted complex integrating for a total of 48 protons expected for aromatic protons. For the peripherally tetra-substituted complex (**8**) the resonances belonging to aromatic protons were observed between 7.19–7.46 and 6.36–7.13 ppm as multiplets integrating for a total of 48 protons expected for aromatic protons. For the octa-substituted complex (**9**) the resonances belonging to aromatic protons were observed between 7.18–7.81 and 6.41–7.08 ppm as broad peaks integrating for 40 protons each, making a total of 80 protons expected for aromatic

protons. The methyl protons were observed at 4.96 ppm for **7**, 4.75 ppm for **8** and 4.81 ppm for **9**; integrating for 8 protons for **7** and **8** and 16 protons for **9**. Although the presence of isomers for tetra-substituted complexes as well as phthalocyanine aggregation at the concentrations used for the NMR measurements may lead to broadening of the aromatic signals [32], the observed spectra of all the complexes were relatively well-resolved.

The electronic spectra of the complexes showed characteristic absorption in the Q-band region at 699 nm for **7**, 681 nm for **8** and 680 nm for **9** in DMSO, Table 1. The B band region was observed around 340–355 nm in DMSO (Fig. 1). The spectra showed monomeric behaviour evidenced by a single (narrow) Q-band, typical of metallated phthalocyanine complexes for **7** and **8** in DMSO [33]. Complex **9** showed a little bit aggregation in DMSO (Fig. 1). The Q-band of the non-peripheral tetra-substituted complex (**7**) is red-shifted 18 nm when compared to the corresponding peripherally tetra-substituted complex (**8**) and 19 nm when compared to the octa-substituted complex (**9**) in DMSO (Table 1). The observed red spectral shift is typical of phthalocyanines with substituents at the non-peripheral positions and has been explained [34,35] to be due to linear combinations of the atomic orbitals (LCAO) coefficients at the non-peripheral positions of the HOMO being greater than those at the peripheral positions. As a result, the HOMO level is destabilized more at the non-peripheral position that it is at the peripheral position. Essentially, the energy gap (ΔE) between the HOMO and LUMO becomes smaller, resulting in a ~20 nm bathochromic shift. The B-bands are broad due to the superimposition of the B_1 and B_2 bands in the 340–355 nm region.

9			
Toluene	681	352	
DCM	623,681	343	290
THF	675	351	
$CHCl_3$	681	352	289
DMSO	626,680	350	

Aggregation is usually depicted as a coplanar association of rings progressing from monomer to dimer and higher order complexes. It is dependent on the concentration, nature of the solvent, nature of the substituents, complexed metal ions and temperature [36]. In the aggregated state the electronic structure of the complexed phthalocyanine rings are perturbed resulting in alternation of the ground and excited state electronic structures [37]. In this study, the aggregation behaviour of the phthalocyanine complexes (**7**, **8** and **9**) are investigated at different solvents (toluene, dichloromethane, chloroform, THF, DMSO) (Fig. 2 for complex **7** and Fig. 3 for complex **9**). While complex **7** showed a single peak in DMSO and THF, it showed a new peak at 747 nm in toluene, DCM and chloroform (Fig. 2).

Generally in MPc complexes, the peak due to aggregation is blue shifted with respect to the monomer. However, a less common type of aggregation in solution (called the *J* aggregation) results in a red-shifted peak [38]. In order to investigate the possibility that the extra peak at 747 nm is due to *J* aggregates, we diluted the solution of complex **7** in chloroform. This complex showed faster decrease of the peak at 702 nm compared to the peak at 747 nm, also the peak at 702 nm showed 11 nm red-shift as the concentration decreased (Fig. 4). Thus, the fact that the peak at 747 nm did not increase with dilutions confirms that it is

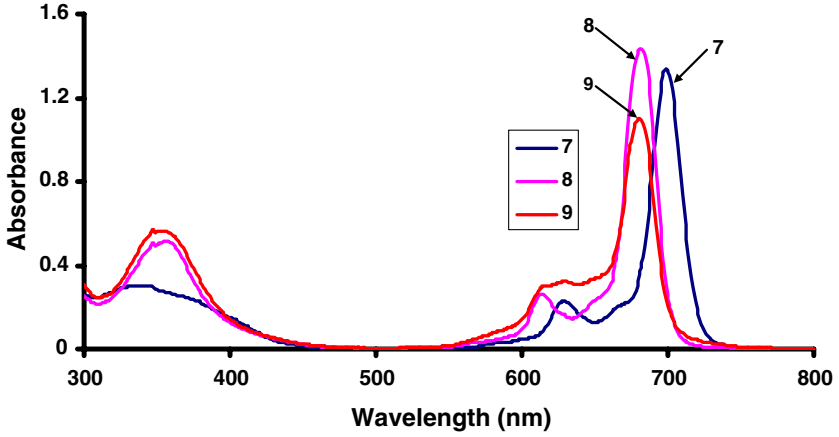

Fig. 1. Absorption spectra of the compound **7**, **8** and **9** in DMSO. Concentration = 4×10^{-6} mol dm^{-3}.

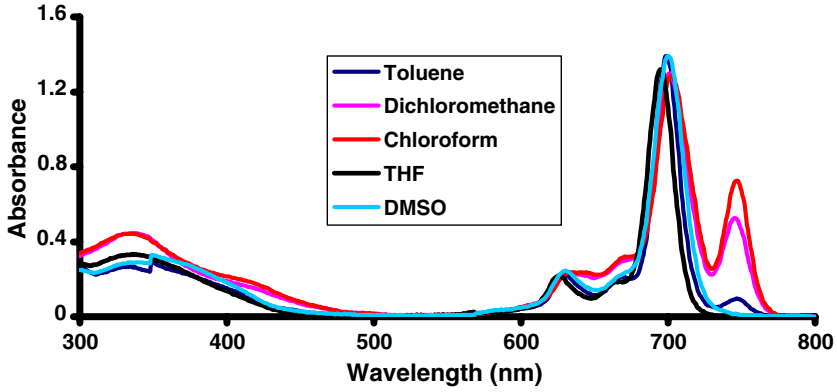

Fig. 2. Absorption spectra of the compound **7** in different solvents. Concentration = 4×10^{-6} mol dm^{-3}.

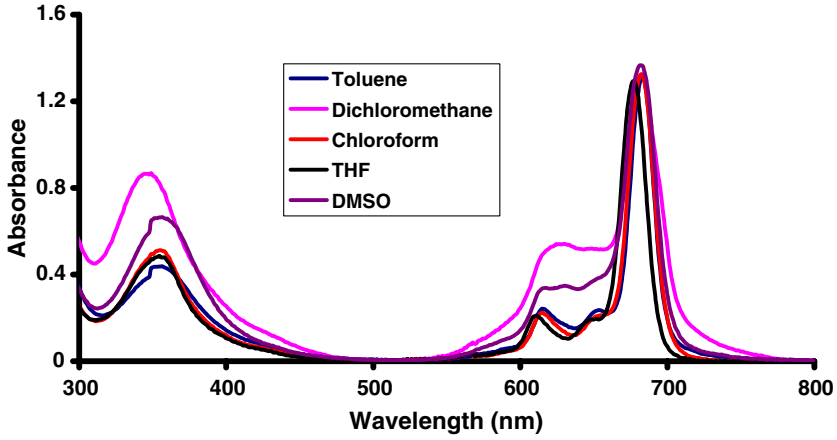

Fig. 3. Absorption spectra of the compound **9** in different solvents. Concentration = 4×10^{-6} mol dm^{-3}.

not due to aggregation. We suggest that this peak is a result of the splitting in the Q-band due to lowering in symmetry observed [39] due to protonation. Unprotonated Pcs are of D_{4h} symmetry. Monoprotonation of the nitrogen atoms leads to lowering of symmetry for the mono-, di- and triprotonated forms, resulting in splitting and a bathochro-

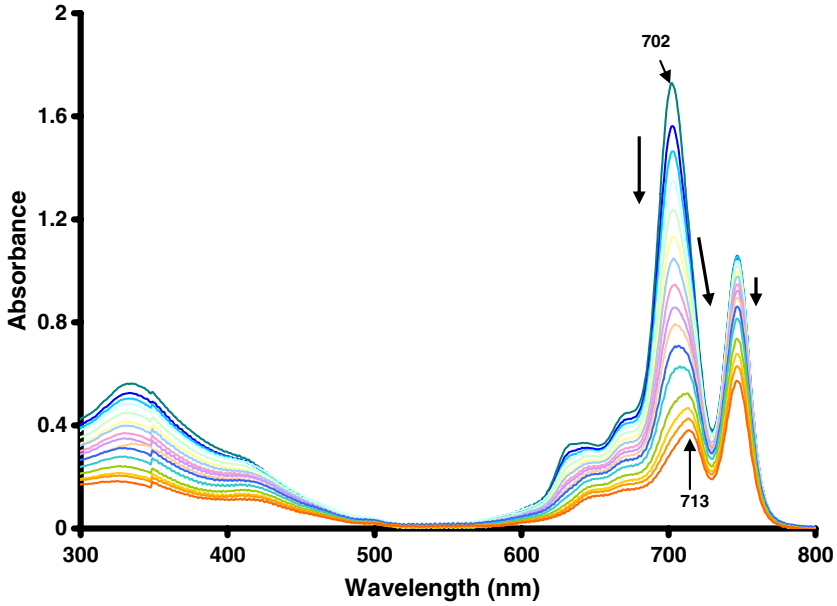

Fig. 4. Absorption spectra of **7** in chloroform at different concentrations. Concentrations from 1×10^{-5} to 2×10^{-6} mol dm^{-3}.

mic shift of the Q-band [8,39,40]. The tetra-protonated species then revert back to D_{4h} symmetry. In solvents which contain small amounts of acid such as DCM and chloroform (which contain some HCl), protonation of the inner nitrogen atoms may occur forming protonated MPc derivatives which are of lower symmetry than the parent MPc molecule, hence the Q-band is split. The fact that a small red shifted peak in addition to the Q-band is observed in toluene suggests this solvent also contains some limited amount of acid, hence complex **7** is also protonated (to a smaller degree compared to DCM and chloroform) in toluene. The spectral changes shown in Fig. 4 are similar to those observed on monoprotonation of MPc derivatives [40] and similar to spectral changes observed on addition of protonating agents such as: trifluoroacetic acid or using sulphuric acid. On dilution of the solution containing protonated derivatives in Fig. 4, the spectral changes show the prominence of the protonated derivatives relative to non-protonated MPc since with increase in solvents, there is increase of the protonating acid. In addition to protonation, a closer look at Fig. 2 shows an increase in absorption around 650 nm for complex **7** in chloroform and DCM, this is typical of aggregation in MPc complexes. Thus apart from the loss of symmetry due to protonation, there is also aggregation in DCM and chloroform. Complex **8** showed narrow Q-bands and there were no new peaks in all solvents. No formation of protonated derivatives was observed for both **8** and **9**, yet they were observed for **7**. Complex **7** contains electron donating groups at the alpha potion, hence close to the nitrogen atoms, making the latter more basic than for **8** and **9**, hence protonation occurs in **7** but not in **8** and **9**. Also complex **8** did not show aggregation in all solvents. This is surprising since complex **8**, which is peripherally substitute should show more aggregation than the non-peripherally substituted complex **7**. The latter are known to show less aggregation than the former [41]. The more pronounced aggregation of non-peripherally substituted complexes compared to peripherally substituted has been observed before [42].

Complex **9**, did not show aggregation in chloroform, THF and toluene but it showed broad band around 620 nm due to the aggregation in DMSO, Fig. 3. DMSO is known to prevent aggregation since it is strong coordinating solvent. However, it has been observed [42] before that aggregation occurs in DMSO and not in less coordinating solvents for some MPc complexes.

The aggregation behaviour of the phthalocyanine complexes (**7**, **8** and **9**) were also investigated at different concentrations in toluene (Fig. 5 for complex **9**). In toluene, as the concentration was increased, the intensity of absorption of the Q-band also increased and there were no new bands (normally blue shifted) due to the aggregated species for the all complexes (**7**, **8** and **9**) (Fig. 5 for complex **9**). The phthalocyanine derivatives (**7**, **8** and **9**) did not show aggregation in toluene at different concentrations. Beer–Lambert law was obeyed for all of these compounds in the concentrations ranging from 1.4×10^{-5} to 4×10^{-6} mol dm^{-3}.

All the complexes (**7**, **8** and **9**) showed similar fluorescence behaviour in DMSO. Fig. 6 shows the fluorescence emission spectra for complexes (**7**, **8** and **9**). In DMSO, emission peaks were observed at: 709 nm (**7**), 693 nm (**8**) and 691 nm (**9**) (Table 2). The excitation spectra were similar to absorption spectra and both were mirror images of the fluorescent spectra in DMSO (Fig. 7 for complex **8**). The proximity of the wavelength of each component of the Q-band absorption to the Q-band maxima of the excitation spectra for all complexes suggest that the nuclear configurations of the ground and excited states are similar and not affected by excitation in DMSO. The observed Stokes shift (Table 2) were typical of MPc complexes in DMSO. Fig. 8 shows the fluorescence emission spectra for complex **7** in different solvents (toluene, dichloromethane, chloroform, THF, DMSO). The spectra showed one peak in THF at 710 nm, in toluene at 711 nm and in DMSO at 718 nm. However, two peaks were evident in dichloromethane at 716 and 754 nm and in chloroform at 718 and 754 nm since it is the protonated derivative which

fluoresces. Fig. 9 shows the fluorescence excitation spectra using different emission wavelengths (712 and 751 nm) for complex **7**. The figure shows that the excitation spectra of protonated derivatives depends on the emission wavelength. We also studied the fluorescence of complex **7** at different concentrations in chloroform (Fig. 10). At the highest concentrations, complex **7** showed two peaks at 725 and 758 nm in chloroform. When the concentration is decreased, the peak at 725 nm marginal decreased and showed 19 nm blue-shift. Another peak at 758 nm showed a decrease in intensity a blue-shifted by 3 nm. These observations suggest different degree of protonation depending on the concentration of the MPc complex, each concentration will have a different amount of free acid.

4. Conclusion

In this study, we synthesized and characterized new non-peripheral and peripheral tetra-substituted and octa-substituted zinc phthalocyanine complexes. This work has also presented a comprehensive investigation of the effects of solvents on the aggregation and fluorescence properties of tetra- and octa-substituted zinc phthalocyanine complexes. We studied aggregation and fluorescence properties of these complexes in toluene, dichloromethane, chloroform, THF and DMSO. We studied the effect of the concentration on the aggregation and fluorescence properties in these solvents as well. All complexes did not show aggregation in toluene and THF. Complex **7** did not show aggregation in DMSO as well. It showed aggregation in chloroform and dichloromethane. Complex **7** showed split Q-band in the UV–Vis spectra. These split Q-band in the emission and excitation spectra of **7** was observed in chloroform and this is explained in terms of the lowering of symmetry by protonation in solvents containing some acid. Complex **8** did not show aggregation in all of these solvents and it showed similar fluorescence behaviour as typical MPc

complexes. Complex **9** showed aggregation in DMSO and interestingly in DCM.

Abstract

The coordination chemistry of a series of bis-bidentate ligands with cadmium(II) ions has been investigated. The ligands, containing two N,S-donor chelating (pyrazolyl/thioether) fragments, have afforded complexes of a variety of structural types (dinuclear M_2L_2 'mesocate' complexes, a one-dimensional chain coordination polymer and a simple mononuclear complex) according to whether the bis-bidentate ligands act as bridges spanning two metal ions, or a tetradentate chelate to a single metal ion. The *p*-phenylene and *m*-biphenyl spaced ligands L^1 and L^3 form dinuclear M_2L_2 complexes where the ligands are arranged in a 'side-by-side' fashion. In contrast the *m*-phenylene spaced ligand L^2 forms a one-dimensional coordination polymer where the ligands adopt a highly folded conformation. The 1,8-naphthalene spaced ligand L^4 adopts a tetradendate chelating mode and affords a simple mononuclear complex.

1. Introduction

The self-assembly of elaborate metallosupramolecular assemblies from relatively simple bridging ligands and labile metal ions continues to be an intensely popular area of study, partly because of the insight that these systems offer into control of self-assembly processes, and partly because the resulting assemblies can have a range of useful properties in materials and host-guest chemistry [1]. With regard to the ligands, a minimum condition is that the binding sites must be arranged so that they bridge two or more metal ions, otherwise simple mononuclear complexes may result. If a ligand is flexible, the competition between bridging and chelating coordination modes is an important factor in determining the course of a self-assembly reaction [2].

As part of our continuing studies into the coordination chemistry of flexible ligands containing bidentate chelating groups, we have recently reported the synthesis of a series of new ligands with potentially N,S-chelating arms derived from 3-[2-(methylsulfanyl)phenyl]pyrazole linked to central aromatic spacers by methylene units [3]. The reaction of these ligands with Ag(I) and Cu(I) ions resulted in a series of complexes with 1:1 metal:ligand stochiometry, in which each four-coordinate metal centre is bound by two coordinating arms to give one of three general structural types depending on the structure of the ligand and the nature of the spacer unit separating the two N,S-donor termini. These structural types are (i) dinuclear M_2L_2 complexes – either helicates, in which the ligands are twisted around one another, or mesocates, in which the ligands adopt a 'side-by-side' arrangement; (ii) infinite one-dimensional

Scheme 1.

coordination chains $[ML]_n$ which contain an alternating sequence M-(μ-L)-M-(μ-L)... along the chain, which may also have a chiral helicate structure; (iii) mononuclear complexes ML in which the ligand is flexible enough to coordinate both N,S-donor units to the same metal centre in a tetradentate chelating mode [3].

In this paper we describe the synthesis and structural characterisation of complexes of the potentially bis-bidentate ligands L^1–L^4 (see Scheme 1) with Cd(II). This metal ion commonly adopts a six-coordinate environment, so we may see either complexes with a M_2L_3 stoichiometry (or some higher multiple), or the involvement of additional ligands in the coordination sphere to complete the octahedral coordination environment. We note that bridging ligands based on two or more N,S-donor chelating units have recently been studied by several groups because of their propensity to form coordination networks and chains when coordinated to 'soft' metal ions [4].

2. Results and discussion

The ligands L^1–L^4 were prepared according to the previously described method, by reaction of 3-[2-(methylsulfanyl)phenyl]pyrazole with an appropriate bromomethylated aromatic compound (the spacer unit) in the presence of hydroxide ion under phase transfer conditions [3]. The crystal structures of L^1, L^2 and L^4 were reported previously [3]. The crystal structure of L^3 is shown in Fig. 1. The individual bond distances and angles within the molecule are unremarkable. The molecule lies across a centre of symmetry, such that the two halves are crystallographically equivalent. The (methylsulfanyl)phenyl/pyrazole units adopt a *cisoid* configuration with the methyl group pointing away from the lone pairs of the pyrazole nitrogen atoms resulting in an intramolecular N···S interaction. This is consistent with the known tendency of divalent S (and Se) atoms to interact with nucleophilic atoms [in this case the pyrazolyl N(2) nitrogen atom] giving short non-bonded contacts [5]. The non-bonded N(2)···S(1) distance of 2.878(2) Å is similar to that observed for L^1 [3] and the N(2)–S(1)–C(17) angle of 167.1(1)° shows a small deviation from linearity.

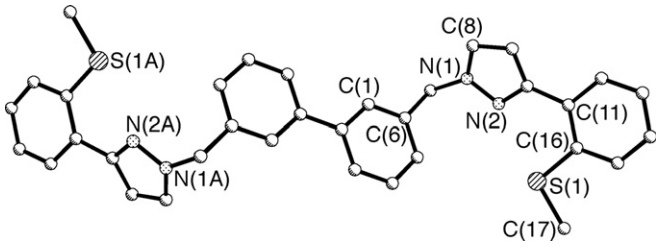

Fig. 1. Molecular structure of L^3. Symmetry operation to generate equivalent atoms: $(-x, -y, -z+1)$.

The reaction of tetradentate ligands L^1–L^4 with a metal ion that commonly displays six-fold coordination would be expected, in the absence of any coordinating anions or solvent molecules, to afford a complex with a 2:3 metal/ligand ratio. The reaction of the *p*-phenylene spaced ligand L^1 with $Cd(ClO_4)_2 \cdot H_2O$ in nitromethane gave a colourless solution; diisopropyl ether diffusion into this solution afforded crystals which analysed with a 1:1 metal/ligand ratio, independently of the starting M:L ratio used in the synthesis (2:3 or 1:1). The ES mass spectrum showed peaks at *m*/*z* 1489.0, 695.0 and 430.4 corresponding to the dinuclear species $[Cd_2(L^1)_2(ClO_4)_{4-x}]^{x+}$ ($x = 1, 2, 3$) showing sequential loss of ClO_4^- anions. An *m*/*z* value of 695.0 may also correspond to the mononuclear species $[CdL^1(ClO_4)]^+$, but the other two peaks are unambiguous. There are also peaks for fragmentation products at *m*/*z* 1177.2 and 1006.8 corresponding to $[Cd(L^1)_2(ClO_4)]^+$ and $[Cd_2(L^1)(ClO_4)_3]^+$, respectively.

The X-ray crystal structure shows that the crystalline material is the dinuclear complex $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2](ClO_4)_2$ (Fig. 2, Table 1). The complex is achiral with both bridging ligands spanning both metal centres in a 'side-by-side' arrangement commonly called a 'mesocate' [6]. This discrete dinuclear complex is in contrast to the polymeric coordination chains obtained from reaction of Cu(I) and Ag(I) with the same ligand [3]. The asymmetric unit contains one complete $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2]^{2+}$ cation [containing Cd(1) and Cd(2)], and another half-cation [containing Cd(3)] from which the second similar but crystallographically independent cation is generated by a two-

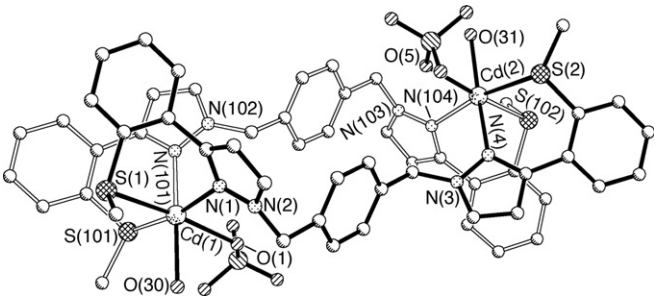

Fig. 2. Structure of the metal complex unit of $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2](ClO_4)_2 \cdot 4MeNO_2$. Only one of the two similar independent molecules is shown.

fold rotation. The six-coordinate Cd(II) ions are coordinated by one N,S-chelating arm from each ligand, with a water molecule and a ClO_4^- anion completing the distorted octahedral coordination. The Cd···Cd separations within the dinuclear complex cations of 10.8 Å [between Cd(1) and Cd(2)] and 10.4 Å [between Cd(3) and its symmetry equivalent] are longer than those observed in the polymeric complexes of L^1 with Cu(I) (9.8 Å) and Ag(I) (7.6 Å). The Cd–S (average 2.68 Å) bonds are longer than the Cd–N (average 2.34 Å), $Cd–O_{perchlorate}$ (average 2.30 Å) and $Cd–O_{water}$ bonds (average 2.35 Å). The bidentate (methylsulfanyl)phenyl/pyrazole units show large deviations from planarity with torsion angles between the rings in the range 32–53°. The central phenylene spacers of the ligands are inclined parallel to each other [angle of approx. 1° between the rings for the molecule with Cd(1) and Cd(2) and exactly parallel by symmetry for the molecule with Cd(3)] and show a π–π stacking interaction. The distance between these stacked rings is 3.5–3.6 Å for the molecule containing Cd(1) and Cd(2) and 3.2 Å for the molecule containing Cd(3).

The ^1H NMR spectrum of the redissolved crystals of $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2](ClO_4)_2$ shows a two-fold-symmetric environment for L^1 in solution. The pyrazole H^5 signal is shifted downfield by *ca.* 0.3 ppm compared to the free ligand but there is little shift in the other signals.

The reaction of the *m*-phenylene spaced ligand L^2 with $Cd(ClO_4)_2 \cdot H_2O$ in acetonitrile resulted in a colourless solution. Diethylether diffusion into the reaction mixture gave colourless crystals whose elemental analysis indicated a 1:1 metal/ligand ratio. The FAB mass spectrum showed peaks at *m/z* 596 for $\{CdL^2\}^+$ and 695 $\{CdL^2(ClO_4)\}^+$. The X-ray crystal structure shows that the crystalline material is the infinite one-dimensional coordination polymer $\{[CdL^2(CH_3CN)_2](ClO_4)_2\}_\infty$ (Figs. 3 and 4, Table 2). Each Cd(II) ion is coordinated by an N,S-chelating arm from each of two separate ligands. Two *cis*-coordinated acetontrile molecules make up the distorted octahedral coordination. The Cd–S and Cd–N bond lengths are similar to those of $[Cd_2(L^1)_2(ClO_4)(H_2O)](ClO_4)$. The Cd···Cd separation between metals linked by the same bridging ligand is 7.33 Å, slightly longer than in the copper complex $\{[CuL^2](BF_4)\}_\infty$ (6.17 Å) [3]. The ligands are folded such that the pyrazole rings are almost perpendicular to the central phenyl spacer (angles of 94° and 96° between the mean planes of the rings). This folding brings the Cd(II) ions closer together than in the complex with L^1 [the average Cd···Cd separation in $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2](ClO_4)_2$ is

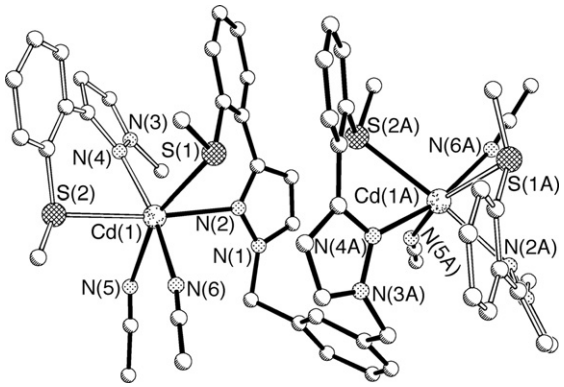

Fig. 3. Structure of the metal complex unit of $\{[CdL^2(CH_3CN)_2](ClO_4)_2\}_\infty$ showing the coordination geometry around the Cd(II) centres.

Fig. 4. Structure of the one-dimensional polymeric chain of $\{[CdL^2(CH_3CN)_2](ClO_4)_2\}_\infty$, with alternate ligands shaded differently for clarity. Only the N atoms of the coordinated MeCN ligands are shown.

10.6 Å] in which the ligand adopted a more extended conformation. The twist angles between the rings within each bidentate (methylsulfanyl)phenyl/pyrazole unit are *ca.* 34 and 28°. There is an angle of 24° between the planes of the pyrazole ring containging N(3) and a (methylsulfanyl)phenyl from the next ligand, for which the inter-ring separation covers the range 3.2–4.3 Å, possibly indicative of a weak π–π stacking interaction. The ^{1}H NMR spectrum of $\{[CdL^2(CH_3CN)_2](ClO_4)_2\}_\infty$ shows a two-fold-symmetric environment for L^2 in solution. The fact that the crystals dissolve in acetonitrile is indicative of the coordination polymer breaking up to form solvated $\{CdL^2\}^{2+}$ units.

The reaction of the *m*-biphenyl spaced ligand L^3 with one equivalent of $Cd(ClO_4)_2 \cdot H_2O$ in dry acetonitrile under an N_2 atmosphere followed by evaporation gave the crude complex as an oil. Recrystallisation by diethylether vapour diffusion into an acetonitrile/nitromethane (1:1) solution gave a crystalline material which was found to be the discrete dinuclear complex $[Cd_2(L^3)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (Fig. 5, Table 3), in contrast to the coordination polymers obtained from the reaction of the same ligand with Cu(I) and Ag(I) [3]. The complex lies astride a centre of symmetry such that the asymmetric unit contains one Cd(II) ion and one complete ligand; clearly therefore it is achiral and not a helicate. Both ligands bridge both metal centres with a Cd···Cd distance of 10.8 Å, almost identical to that

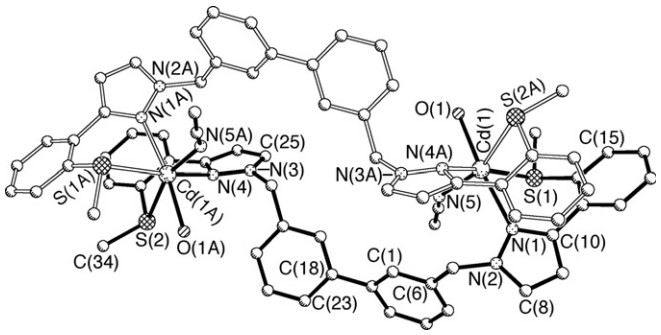

Fig. 5. Structure of the metal complex unit of $[Cd_2(L^3)_2(MeCN)_2(H_2O)_2](ClO_4)$.

Symmetry transformations used to generate equivalent atoms: $(-x+1, -y+1, -z+1)$.

in $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2](ClO_4)_2$ despite the longer spacer in L^3. The Cd(II) ions are in a distorted octahedral geometry with one acetonitrile and one water molecule completing the coordination. The acetonitrile molecules are attached at an angle with the Cd–N–C angles being 142.8(5)°. The bond lengths to Cd(II) are typical of complexes in this series. The twist angles within the biphenyl spacers are 41.8° and the twist angles within each bidentate (methylsulfanyl)phenyl/pyrazole units are 34.2 and 28.8°. There is a π–π stacking interaction between the pyrazole ring containing N(1) and the (methylsulfanyl)phenyl ring of the other ligand (angle of 20.6° between the mean planes of the two rings, distance of 3.2–4.1 Å between the rings). The biphenyl spacers are not involved in any π–π stacking interactions.

The electrospray mass spectrum of the crystals shows peaks at *m/z* 1641.1, 771.1 and 480.7 corresponding to the dinuclear species $[Cd_2(L^3)_2(ClO_4)_{4-x}]^{x+}$ ($x = 1$, 2, 3) with sequential loss of perchlorate anions. The *m/z* value of 771.1 may also correspond to the mononuclear species $\{Cd(L^3)ClO_4\}^+$ but the other peaks are unambiguous. There are also peaks for Cd_2L^3 and $Cd(L^3)_2$ fragments. The ^1H NMR spectrum of $[Cd_2(L^3)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ is broad, indicative of a dynamic process in solution.

The reaction of L^4 with one equivalent of $Cd(ClO_4)_2 \cdot H_2O$ in dry acetonitrile under an N_2 atmosphere resulted in a colourless solution. Diethylether diffusion into the reaction mixture gave colourless crystals whose elemental analysis was consistent with the formulation $[CdL^4(H_2O)_2](ClO_4)_4$. The electrospray mass spectrum showed peaks at *m/z* 744 $[\{CdL^4(ClO_4)\}^+]$ and 343 $[\{CdL^4(MeCN)\}^{2+}]$, consistent with formation of a mononuclear complex.

The X-ray crystal structure confirms that the crystalline material $[CdL^4(MeCN)_2](ClO_4)_2$ is a mononuclear complex (Fig. 6, Table 4) in contrast to the dinuclear structures obtained with L^1 and L^3 and the polymeric structure obtained with L^2. The complex has two-fold rotation symmetry such that the asymmetric unit contains half of a Cd(II) ion and half of a ligand. The Cd(II) ion is in a distorted octahedral N_4S_2 environment with L^4 acting as a tetradentate chelate. The donor atoms of L^4 form an approximate equatorial plane with an angle of 10.9° between the two Cd(NS) planes. The coordination environment is completed by two axially coordinated acetonitrile molecules. It is likely, on the basis of the elemental analysis, that these weakly bound solvent molecules are removed upon drying under vacuum and replaced by water from the atmosphere. The N,S-donor bidentate arms are not individually coplanar, with a substantial dihedral twist of 40.1° between the pyrazolyl and (methylsulfanyl)phenyl rings. The ^1H NMR spectrum $[CdL^4(MeCN)_2](ClO_4)_2$ shows two-fold symmetry in solution. The signals are shifted downfield from those of the free ligand and are consistent with complexation being retained in solution.

Symmetry transformations used to generate equivalent atoms: (y, x, $-z$).

In conclusion this set of ligands has afforded an interesting range of structural types in the complexes with Cd(II) ions. Depending on the separation between the N,S-donor units they can either bind to separate metal ions giving dinuclear complexes or one-dimensional chains, or chelate to a single Cd(II) centre giving a simple mononuclear complex. In all cases the Cd(II) centres are six-coordinate, bound by two N,S-donor units and two additional ligands (water, acetonitrile or perchlorate).

3. Experimental

3.1. General details

The ligands L^1–L^4 were prepared as previously described [3]. All other organic reagents and metal salts were purchased from Aldrich or Avocado and used as received. ^1H NMR spectra were recorded on Bruker AC-250, AMX-400 or DRX-500 spectrometers. Mass spectra (FAB and EI) were recorded on a VG AutoSpec magnetic sector instrument. Electrospray mass spectra were measured

at the University of Huddersfield on a Bruker MicroTOF instrument in positive ion mode, with capillary exit and first skimmer voltages of 30 V and 60 V, respectively. Samples were prepared at a concentration of *ca.* 2 mg/ml in MeCN or $MeNO_2$ and analysed by direct infusion using a Cole Parmer syringe pump at a flow rate of 3 μl/min. Spectra were acquired over an *m/z* range of 50–3000; several scans were averaged to provide the final spectrum. IR spectra were recorded on a Perkin–Elmer Spectrum One instrument. Samples for elemental analysis were vacuum-dried.

3.2. Preparation of $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2](ClO_4)_2$

A solution of $Cd(ClO_4)_2 \cdot H_2O$ (58 mg, 0.19 mmol) in $MeNO_2$ (2 cm^3) was added to a solution of L^1 (90 mg, 0.19 mmol) in $MeNO_2$ (2 cm^3). The colourless solution was stirred for 4 h. Diisopropyl ether diffusion into the solution gave colourless crystals of $[Cd_2(L^1)_2(ClO_4)_2(H_2O)_2](ClO_4)_2$ which were suitable for X-ray crystallography (Yield: 103 mg, 68%). *Anal.* Calc. for $C_{56}H_{52}Cd_2Cl_4N_8O_{16}S_4(H_2O)_2$ (1623.98): C, 41.42; H, 3.48; N, 6.90. Found: C, 41.39; H, 3.44; N, 6.82%. ES MS: *m/z* 1489.0 $\{Cd_2(L^1)_2(ClO_4)_3\}^+$, 1177.2 $\{Cd(L^1)_2(ClO_4)\}^+$, 1006.84 $\{Cd_2L^1(ClO_4)_3\}^+$, 695.0 $\{Cd_2(L^1)_2(ClO_4)_2\}^{2+}$ and/or $\{CdL^1ClO_4\}^+$, 430.4 $\{Cd_2(L^1)_2ClO_4\}^{3+}$. ^1H NMR (500 MHz, $MeNO_2$): δ (ppm) 7.65 (2H, d; pyrazolyl H^5), 7.48 (2H, m; methylthiophenyl H^3), 7.31–7.37 (4H, m; methylthiophenyl H^5, H^6), 7.25 (4H, s; phenyl), 7.20 (2H, ddd; methylthiophenyl H^4), 6.59 (2H, d; pyrazolyl H^4), 5.34 (4H, s; CH_2), 2.40 (6H, s; SMe). 3.3. Preparation of $\{[CdL^2(CH_3CN)_2](ClO_4)_2\}_\infty$

$Cd(ClO_4)_2 \cdot H_2O$ (64 mg, 0.21 mmol) was added to a solution of L^2 (99 mg, 0.21 mmol) in dry MeCN (20 cm^3) under N_2. The colourless solution was stirred overnight and the volume reduced to ~10 cm^3. Diethylether diffusion into the solution gave off-white crystals of $\{[CdL^2(CH_3CN)_2](ClO_4)_2\}_\infty$ which were suitable for X-ray crystallography (Yield: 124 mg, 74%). *Anal.* Calc. for $C_{28}H_{26}CdCl_2N_4O_8S_2 \cdot (H_2O)$ (811.99): C, 41.42; H, 3.48; N, 6.90. Found: C, 41.49; H, 3.34; N, 7.21%. FAB MS: *m/z* 596 $\{CdL^2\}$, 695 $\{CdL^2(ClO)_4\}$. ^1H NMR (500 MHz, CD_3CN): δ (ppm) 7.64 (2H, d, pyrazolyl H^5), 7.47 (2H, ddd, methylthiophenyl H^3), 7.31–7.37 (5H, m, methylthiophenyl H^5, H^6, phenyl), 7.16–7.23 (5H, m, methylthiophenyl H^4, phenyl), 6.58 (2H, d, pyrazolyl H^4), 5.34 (4H, s, CH_2), 2.39 (6H, s, SMe).IR (KBr disk): *ν* (cm^{-1}) 3143 (w), 2932 (w), 1627 (m), 1614 (m), 1592 (w), 1517 (m), 1504 (m), 1433 (s), 1406 (m), 1350 (m), 1328 (m), 1278 (w), 1221 (m), 1113 (s), 949 (w), 917 (m), 787 (w), 758 (s), 740 (w), 727 (w), 624 (s).

3.4. Preparation of $[Cd_2(L^3)_2(MeCN)_2(H_2O)_2](ClO_4)_4$

$Cd(ClO_4)_2 \cdot H_2O$ (40 mg, 0.13 mmol) was added to a solution of L^3 (72 mg, 0.13 mmol) in dry MeCN (15 cm^3). The colourless solution was stirred overnight under N_2 and the solvent removed *in vacuo*. The crude product was recrystallised by diethylether diffusion into an acetonitrile/nitromethane (1:1) solution to give colourless crystals of $[Cd_2(L^3)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ which were suitable for X-ray crystallography (yield: 90 mg, 75%). *Anal.* Calc. for $C_{72}H_{70}Cd_2Cl_4N_{10}O_{18}S_4(H_2O)_3$ (1912.33): C, 45.22; H, 4.01; N, 7.32. Found: C, 45.27; H, 3.73; N, 7.14%. ES MS: *m/z* 1641.1 $\{Cd_2(L^3)_2(ClO_4)_3\}^+$, 1329.3 $\{Cd(L^3)_2(ClO_4)\}^+$, 1080.9 $\{Cd_2L^3(ClO_4)_3\}^+$, 771.1 $\{Cd_2(L^3)_2(ClO_4)_2\}^{2+}$ and/or $\{CdL^3ClO_4\}^+$, 480.7 $\{Cd_2(L^3)_2ClO_4\}^{3+}$. ^1H NMR (500 MHz, CD_3CN): δ (ppm) 7.67 (2H, br s; pyrazolyl H^5), 7.43–7.56 (10H, br m), 7.36 (2H, br s), 7.29 (2H, br d), 7.01 (2H, br d), 6.61 (2H, br s; pyrazolyl H^4), 5.48 (4H, br s; CH_2), 2.41 (6H, br s; SCH_3). IR (KBr disk): *ν* (cm^{-1}) 3397 (s, br), 3141 (w), 3124 (w), 3014 (w), 2925 (w), 1676 (w), 1633 (w), 1605 (w), 1590 (w), 1517 (m), 1503 (m), 1463 (w), 1438 (m), 1404 (m), 1350 (m), 1343 (w), 1322 (w), 1223 (m), 1119 (s), 1104 (s), 1075 (s), 1016 (w), 931 (w), 882 (w), 789 (m), 770 (w), 754 (s), 727 (w), 695 (w), 623 (s).

3.5. Preparation of $[CdL^4(MeCN)_2](ClO_4)_4$

$Cd(ClO_4)_2 \cdot H_2O$ (47 mg, 0.15 mmol) was added to a solution of L^4 (80 mg, 0.15 mmol) in dry MeCN (20 cm^3) under N_2. The colourless solution was stirred overnight and the volume reduced to ~10 cm^3. Diethylether diffusion into the solution gave off-white crystals of $[CdL^4(MeCN)_2](ClO_4)_2$ which were suitable for X-ray crystallography. The crystals were dried *in vacuo* to yield, after exposure to air, $[CdL^4](ClO_4)_2 \cdot 2H_2O$ as a white powder (yield: 89 mg, 67%). *Anal.* Calc. for $CdC_{32}H_{28}N_4S_2Cl_2O_8 \cdot (H_2O)_2$ (880.07): C, 43.67; H, 3.66; N, 6.37%. Found: C, 44.09; H, 3.42; N, 6.44%. ES MS: 744 $\{CdL^4ClO_4\}^+$, 343 $\{CdL^4(CH_3CN)\}^{2+}$. ^1H NMR (500 MHz, $CDCl_3$): δ (ppm) 8.17 (2H, dd), 7.77 (2H, d), 7.67 (2H, dd), 7.61 (2H, dd), 7.60 (2H, dd), 7.54 (2H, td), 7.47 (2H, td), 7.43 (2H, d; pyrazolyl H^5), 6.66 (2H, d, pyrazolyl H^4), 5.78 (4H, s, CH_2), 2.63 (6H, s, SMe). IR (KBr disk): *ν* (cm^{-1}) 3146 (w), 3063 (w), 2932 (w), 1621 (w), 1600 (w), 1519 (m), 1505 (m), 1487 (m), 1460 (w), 1433 (s), 1406 (w), 1370 (m), 1328 (s), 1214 (m), 1101 (s), 961 (w), 950 (w), 849 (w), 823 (w), 785 (s), 769 (s), 729 (m), 681 (w), 623 (s).

3.6. X-ray crystallography

X-ray crystallographic data are summarised in Table 5. For each compound a suitable crystal was coated with hydrocarbon oil and attached to the tip of a glass fibre

Table 5
Crystallographic data for the five crystal structures[a]

Compound	L^3	$[Cd_2(L^1)_2(H_2O)_2(ClO_4)_2](ClO_4)_2 \cdot 4MeNO_2$	$\{[CdL^2(MeCN)_2](ClO_4)_2\}_\infty$	$[Cd_2(L^3)_2(H_2O)_2(MeCN)_2](ClO_4)_4$[a]	$[Cd(L^4)(MeCN)_2](ClO_4)_2$

[a] The X-ray wavelength was 0.71073 Å (Mo Kα) in all cases except for $[Cd_2(L^3)_2(H_2O)_2(MeCN)_2](ClO_4)_4$ where it was 0.6709 Å.
[b] The value of R_1 is based on selected data with $I > 2\sigma(I)$; the value of wR_2 is based on all data.

and transferred to a Bruker-SMART 1000 or APEX-2 CCD diffractometer (graphite- monochromated Mo Kα radiation, $\lambda = 0.71073$ Å) under a stream of cold N_2. The data for $[Cd_2(L^3)_2(MeCN)_2(H_2O)_2](ClO_4)_4$were collected at the Daresbury Synchrotron Radiation Source (station 9.8) using a Bruker SMART-APEX2 diffractometer and Si(1 1 1)-monochromated synchrotron radiation with a wavelength close to the Zr absorption edge. In all cases the data were corrected for Lorentz and polarisation effects and for absorption by semi-empirical methods (SADABS) [7] based on symmetry-equivalent and repeated reflections. The structures were solved by direct methods or heavy atom Patterson methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model and with U_{iso} constrained to be 1.2 (1.5 for methyl groups) times U_{eq} of the carrier atom. Structures were solved and refined using the SHELX suite of programs [8]. Significant bond distances and angles for the structures of the metal complexes are in Tables 1–4. Specific special features or problems associated with the structure determinations are as follows.

$[Cd_2(L^1)_2(ClO_4)(H_2O)](ClO_4) \cdot 4CH_3NO_2$: the asymmetric unit consists of one complete complex molecule, one half of another complex molecule, three non-coordinated anions and six nitromethane molecules. One of the ClO_4^- anions is disordered over two sites and was heavily restrained to ensure stable refinement. The SQUEEZE option of PLATON was used to account for severely disordered solvent molecules which could not be satisfactorily modelled. Diffraction was weak and only data with $2\theta \leqslant 50°$ were used in the final refinement.

$\{[CdL^2(CH_3CN)_2](ClO_4)_2 \cdot MeCN\}_\infty$: the asymmetric unit contains one Cd(II) ion, two half-ligands, two coordinated acetonitrile molecules, one acetonitrile solvent and two disordered ClO_4^- anions. Both anions were modelled with two parts and heavily restrained to ensure a stable refinement. Diffraction was weak and only data with $2\theta \leqslant 50°$ were used in the final refinement.

$[Cd_2(L^3)_2(MeCN)_2(H_2O)_2](ClO_4)_4$. The asymmetric unit contains one Cd(II) ion (with a coordinated MeCN and H_2O), one complete ligand and two ClO_4^- anions. One ClO_4^- anion is disordered over two parts and has been restrained accordingly. The hydrogen atoms on the coordinated H_2O molecule have not been located.

Abstract

Reaction of $ZnCl_2$ and 2-thiophenecarboxylic hydrazide (tch), in ethanol resulted in the crystalline product $[Zn(tch)_3][ZnCl_4] \cdot 2EtOH$, which slowly decomposes losing solvent molecules. The structure of the first compound has been determined by the single crystal X-ray method. Analysing the IR spectra of both compounds it has been found that the complex $[Zn(tch)_3]^{2+}$ cation and $[ZnCl_4]^{2-}$ anion are preserved after crystal decomposition. Vibrational spectra of the obtained substances were interpreted with the assistance of DFT calculations and metal isotope as well as deuterium replacement.

1. Introduction

The biological activity of the 2-thiophene moiety has been widely recognized and practically applied in several drugs [1–3], herbicides [4] and fungicides [5,6]. Among them, there are also thiophenecarboxylic hydrazides which have been tested for antituberculous activity [7,8]. The metal coordination abilities of the mentioned hydrazides and the enhancement of biological activity observed for similar substances upon their metal coordination [9] have stimulated the search for new complexes, frequently with metal ions of high biological importance. The solid state complexes of the title ligand, 2-thiophenecarboxylic hydrazide (tch) and some d-electron metal ions were first reported by Singh et al. [10]. Employing elemental analyses, magnetic, spectroscopic measurements and selectively X-ray powder diffraction studies, these authors proposed the structures of seventeen compounds including a zinc(II) complex of $[ZnCl_2(tch)]$ composition and with a $ZnCl_2NO$ coordination sphere. Based on the preparation procedure described in this article, we have repeated the Zn(II) – tch synthesis and found that unstable monocrystals were obtained at the first step. Thus, we attempted to obtain the full X-ray structure of these monocrystals and propose the structure of its decomposition product, applying elemental analysis and IR spectroscopy. The interpretation of vibrational spectra was enhanced by isotope substitution and DFT calculations.

2. Experimental

2.1. Preparation of the $[Zn(tch)_3][ZnCl_4]\cdot 2EtOH$ and $[Zn(tch)_3][ZnCl_4]$ complexes

The tch ligand (2-thiophenecarboxylic hydrazide) was purchased from Sigma Aldrich Chemical Co. The metal salt and solvent used were of analytical grade.

The complex synthesis was carried out according to the procedure described by Singh et al. [10], but a different product was obtained. An ethanolic solution of the ligand (0.05 mmol/2 cm^3) was mixed with 0.05 mmol $ZnCl_2$ dissolved in 1.5 cm^3 of the same solvent. The mixture was stored for two days at about 5 °C in a capped vial. Microscope observation of the obtained colourless monocrystals of $[Zn(tch)_3][ZnCl_4]\cdot 2EtOH$ revealed their partial decomposition in air, monitored by loss of transparency. Elemental analysis (given below) of the decomposition product suggested the escape of the solvent for the above process, leading to $[Zn(tch)_3][ZnCl_4]$.

Anal. Calc. for $C_{15}H_{18}N_6O_3S_3Cl_4Zn_2$: C, 25.77; H, 2.60; N, 12.02; S, 13.76. Found: C, 25.18; H, 2.49; N, 11.65; S, 13.84%. M.p. 197–202 °C.

The same complexes were also obtained for 2:3 metal:tch stoichiometry.

2.2. Preparation of isotopically substituted complexes

The ^{64}Zn–^{68}Zn labelled analogues were prepared according to the procedure for $[Zn(tch)_3][ZnCl_4]$ complexes of natural abundance, presented above.

The deuterated $[Zn(tch)_3][ZnCl_4]$ complex was synthesised using EtOD solutions of deuterated tch-ligand and anhydrous $ZnCl_2$. The ligand was previously deuterated by threefold recrystallization from D_2O.

2.3. Spectral measurements

Samples as Nujol mulls sandwiched between polyethylene plates were measured on a Perkin-Elmer FTIR 2000 spectrometer with 0.5 resolution and 200 scans applied for far-IR data acquisition. Middle-IR spectra were measured with 2 cm^{-1} resolution on a Perkin–Elmer FTIR 1600 instrument with the sample as a KBr pellet for $[Zn(tch)_3][ZnCl_4]$ powder and as Nujol or hexachlorobutadiene suspensions of $[Zn(tch)_3][ZnCl_4]\cdot 2EtOH$.

The Raman scattering was collected on a T64000 Jobin-Yvon instrument (0.5 cm^{-1} resolution) applying a 514.5 nm excitation of power below 100 mW, provided by an Ar–Kr laser. For better signal-to-noise ratio 300 scans were collected and averaged.

2.4. X-ray structure determination of $[Zn(tch)_3][ZnCl_4]\cdot 2EtOH$

The X-ray data were collected on a KUMA KM4CCD diffractometer system with Mo Kα radiation ($\lambda =$ 0.71073 Å). The structure was solved by the direct method option using the SHELXS 97 program [11] and developed using least-squares refinement and Fourier difference synthesis applying the SHELXL 97 software [12]. The thiophene rings in two crystallographically different ligand forms were disordered and modelled using two sets of positions. For this procedure, the ring distances and angles were restrained to constant values and the occupancy of two alternate orientations was constrained to unity. The refined occupancy was 0.762(6) and 0.238(6) for the ligand with the S1 atom and 0.882(7) and 0.118(7) for the ligand with the S2 atom. The hydrogen atoms were placed in geometrically calculated positions. Crystallographic parameters and structure refinement are summarized in Table 1. Selected crystal parameters were calculated employing the PARST 97 program [13], whereas all crystal structures were drawn with help of ORTEP 3 [14].

3. Results and discussion

3.1. Description of the complex ions

In the investigated ionic compound (Fig. 1), both the cation and anion are complex ions, of quasi-octahedral and quasi-tetrahedral structure respectively.

The $[Zn(tch)_3]^{2+}$ cation is build up of a metal ion and three ligand molecules coordinating via amine nitrogen and carbonyl oxygen atoms. The arrangement of the

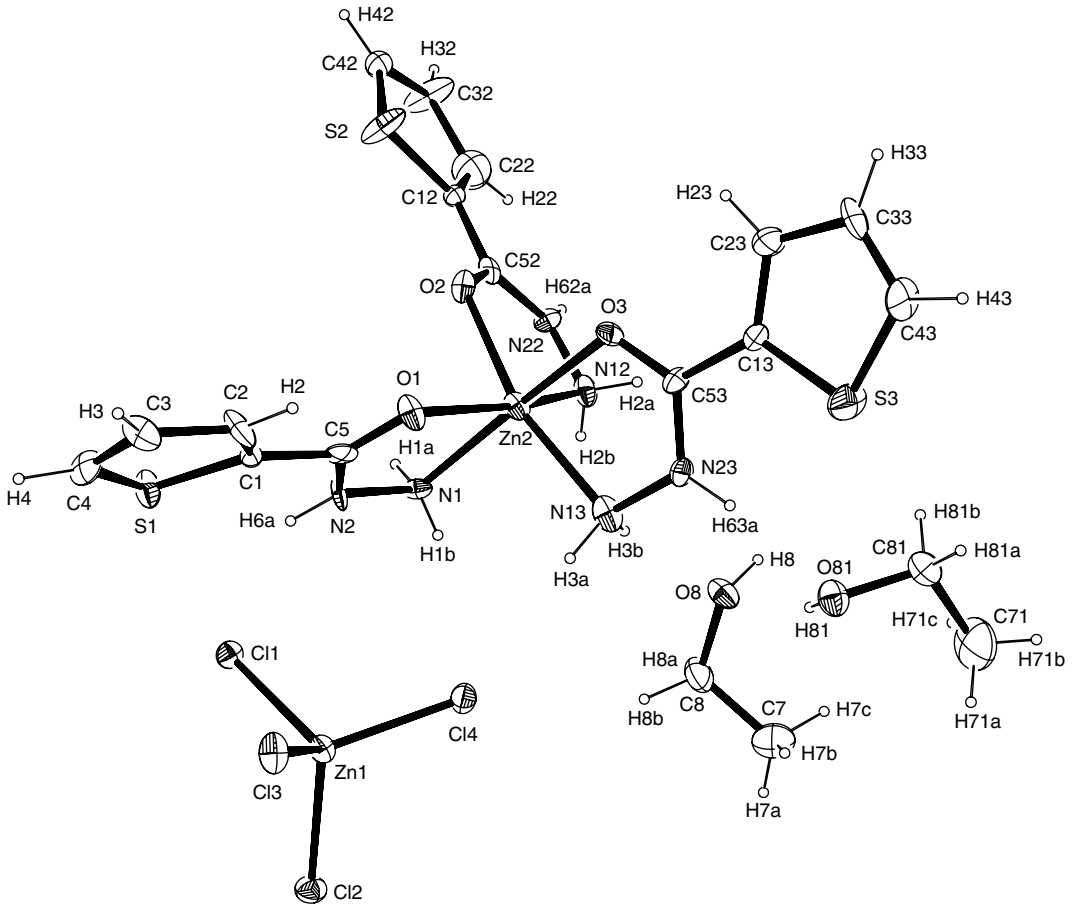

Fig. 1. Molecular structure of $[Zn(tch)_3][ZnCl_4] \cdot 2EtOH$. For better clarity, the thiophene rings of minor occupancy were omitted. Thermal ellipsoids are shown at 50% probability.

ligands around the central atom results in a fac-configuration of the $[ZnN_3O_3]$ centre. The distortion of the metal environment from an ideal octahedron is observed for coordination bond lengths as well as for the angles between them. As could be calculated from the structural data presented in Table 2, the average Zn–O distance (2.097(4) Å) is 0.075 Å shorter than that obtained for Zn–N bonds (2.172(6) Å). However, these distances vary from 2.069(4) Å (Zn2–O3) to 2.200(6) Å (Zn–N12).

The O–Zn–N angles located inside the chelate rings are about 77°, which is far from the right angle expected for an ideal octahedron and it is definitely due to the internal ring strain. In contrast, all angles between bonds belonging to different rings are above 90°, from 91.2(2)° to 101.2(2)°. Such an arrangement of the coordination bonds precludes any symmetry elements for the metal coordination sphere.

The chelate rings are close to planar. The most deviated atoms are the nitrogen atoms of the amine groups. These atoms are from 0.109(6) (N1 atom) to 0.142(6) Å (N12 atom) displaced from the respective best planes calculated for remaining chelate ring skeletal atoms, which are displaced by less than 0.025 Å. The orientations of the thiophene rings are more complicated. In ligands 1 and 2 (those with O1 and O2 atoms) the discussed units are structurally disordered with higher occupancies equal to 0.762(6) and 0.882(7), respectively. These positions will be discussed first. The thiophene rings are oriented almost parallel to the discussed chelate rings. The dihedral angles between the mentioned best planes of the chelate rings and thiophene rings are 14.2(2)°, 2.9(2)° and 7.6(2)° for ligands with O1, O2 and O3 atoms, respectively. Two thiophene rings of minor occupancy form dihedral angles of 5.2(1.3)° and 17.6(9)° with the corresponding major occupancy rings.

It is surprising that the S1 and S3 atoms are *trans*-oriented with respect to the O1 and O3 atoms, which is not typical for used ligand, where an attractive force between S1 and O1 atoms, together with repulsion of O1 and π electrons of the C1═C2 bond results mostly in a *cis*-configuration [15]. Such a configuration appears for the S2 and O2 atoms and also for the minor occupancy thiophene ring in ligand 1. In contrast, the minor occupancy thiophene ring in ligand 2 is *trans*-oriented. An explanation of the above problem will be proposed latter.

The structure of complex $[ZnCl_4]^{2-}$ ion is very close to tetrahedral. The observed Zn–Cl bond lengths differ less

[a] The corresponding bond lengths and angles of the thiophene ring belonging to ligand 2 are similar (within theirs e.s.d.) to that of ligand 1.

than 2%, the Cl–Zn–Cl angles are in the 106.5(1)–116.2 (1)° range.

3.2. Crystal packing

All structural units, namely both complex ions and ethanol molecules, are arranged in stacks parallel to the [0 1 0] direction. In the perpendicular direction, these units are organized into layers parallel to the (1 0 1) plane. Each layer built of $[ZnCl_4]^{2-}$ anions and accompanied ethanol molecules is surrounded by two parallel layers of $[Zn(tch)_3]^{2+}$ cations. The external parts of such a sandwich-like layer are occupied exclusively by thiophene rings. However, the structure projection normal to these rings shows that there is no ''face-to-face'' or ''offset'' π-stacking [16]. The shortest S–S distance is 3.59 Å, which excludes any attractive interactions between thiophene rings. More probable are weak repulsive forces between sulfur atoms carrying small positive charges. Thus, the interactions between the mentioned sandwich layers are mainly of van der Waals nature.

The most important feature for the above structural arrangement are hydrogen bonds between hydrazine groups and tetrachlorozincate ions. Each $[ZnCl_4]^{2-}$ ion interacts with three $[Zn(tch)_3]^{2+}$ ions and two ethanol molecules, as has been presented in Fig. 2. Complex cations are attracted to chlorine atoms only via N–H···Cl systems which provide at least two contacts between the $[ZnCl_4]^{2-}$ anion and one of the three ligands present in each complex cation. In one case (of three $[Zn(tch)_3]^{2+}$ ions interacting with a $[ZnCl_4]^{2-}$ ion), a third hydrogen bond has been found between H1a and Cl2 atoms. Among two ethanol molecules found in the vicinity of $[ZnCl_4]^{2-}$, one is bonded via two interactions between its O–H group and two chlorine (Cl2, Cl3) atoms. The second EtOH molecule is oriented such that one hydrogen atom of the methyl group points to the Cl4 atom at a distance of 2.841(2) Å, which is in the range of C–H···Cl hydrogen bonds [17].

The complete set of strong hydrogen contacts formed by each $[Zn(tch)_3]^{2+}$ ion has been presented in Fig. 3. This figure shows that ligands 1 and 2 (those with O1 and O2 atoms) interact only with Cl acceptors, whereas ligand 3 forms two hydrogen bonds with two ethanol oxygen acceptors. The carbonyl groups of tch ligands do not form hydrogen bonds with N–H groups of neighbour cations. This is due to competition between possible acceptors. The negatively charged $[ZnCl_4]^{2-}$ ions are much stronger acceptors than carbonyl groups whose electron density have been lowered by metal coordination. In the resultant crystal arrangement, the carbonyl groups are neighbours of thiophene rings and ethanol methyl groups only. Weak hydrogen interactions between these subunits and carbonyl oxygen atoms may be taken into account, as has been done in Table 3, presenting structural details of hydrogen bonds.

Close inspection of the crystal structure and possible interactions may explain the mentioned problem of *trans* orientation of thiophene sulfur atoms with respect to carbonyl groups. In ligands 2 and 3, the internal S2···O2 and S3···N23 distances are comparable, being 2.945(5) and 3.025(5) Å, respectively, which suggests that respective interactions will be of comparable strength. However, the position of the S3 atom is additionally stabilized by two intermolecular interactions, namely S3···O81 (3.462(5) Å) and S3···Cl4^{v} (3.335(3) Å). A similar *trans* position of the S1 atom is analogously stabilized by S1···Cl1 = 3.913(3) Å and S1··· N22 = 3.513(6) Å interactions (N22 at x, $y-1$,

Equivalent positions: (i) $-x+1/2+1, y+1/2, -z+1/2+1$; (ii) $-x+1/2, y-1/2, -z+1/2+1$; (iii) $x, y+1, z$; (iv) $-x+1/2, y+1/2, -z+1/2+1$; (v) $-x+1, -y+1, -z+2$.

z). For the atom S2, being at a *cis* position, only one weaker interaction with the Cl2 atom at $(x+1/2, -y+1/2, z+1/2)$ has been found at a distance less than 4.0 Å (S2···Cl2 = 3.816(3) Å). Thus, the *cis* configuration is forced here by the S1···O2 = 2.945(5) Å interaction.

The [Zn(tch)$_3$][ZnCl$_4$] · 2EtOH crystals are not stable in air, gradually losing the solvent molecules. Beside the intermolecular forces, this property is also due to the location of the ethanol molecules in less densely packed $[ZnCl_4]^{2-}$ layers, which allows for EtOH migration without destroying the main crystal frame.

3.3. Quantum calculations

The geometry optimization of $[Zn(tch)_3]^{2+}$ and $[ZnCl_4]^{2-}$ ions and subsequent computation of their normal vibrations were performed at the DFT level, employing the B3LYP functional [18] and LANL2DZ [19] basis set with d-polarization functions added to C, N, O, S and Cl atoms.

The optimized structures of both complex ions are close to those found by the X-ray method. The calculated Zn–Cl bonds lengths are about 0.1 Å longer than those observed. Similar differences are found between calculated and observed coordination bond lengths in the $[Zn(tch)_3]^{2+}$ cation. Calculated Zn–N bonds are longer than those observed, whereas the Zn–O bonds are shorter. The remain-

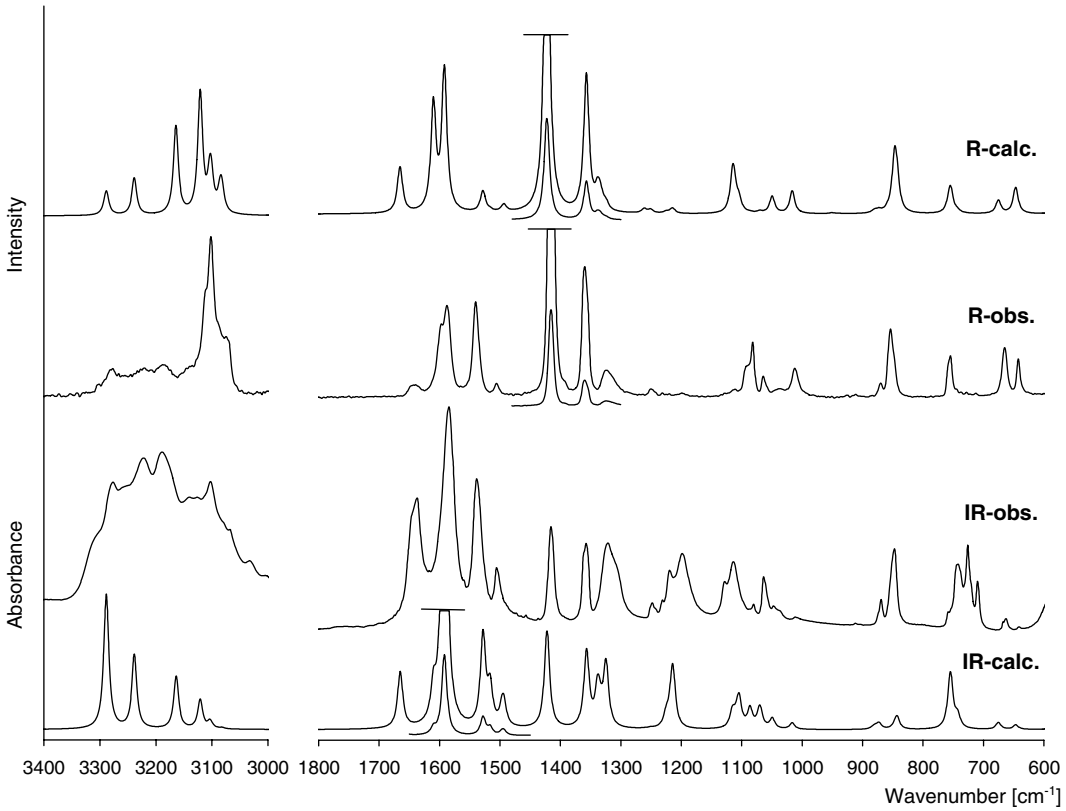

Fig. 4. Observed and DFT predicted vibrational spectra of [Zn(tch)$_3$][ZnCl$_4$]. Partially scaled frequencies (listed in Table 4) were used for the preparation of the theoretical spectra.

ing calculated skeletal bonds are mostly elongated, but their lengths deviate less than 0.05 Å from the observed values. Normal vibrations were computed applying the harmonic oscillator approximation. All computations were made using the GAUSSIAN 03 program [20]. The computation of theoretical spectra (with 5 cm^{-1} half-band-width) and animation of normal vibrations used for their description were performed by the CHEMCRAFT program [21]. For selected parts of the computed $[Zn(tch)_3]^{2+}$ spectra, the frequency scaling factors were applied as follows: 0.915 for stretching vibrations of NH and NH_2 groups, 0.955 for stretching C–H vibrations and 0.98 for normal vibrations of frequencies calculated between 1750 and 1350 cm^{-1}. For the scaled vibrations, the root-mean-square (RMS) of calculated–observed frequency correlation equals 15 cm^{-1}. Vibrations resulting from out-of-plane motions of NH_2 and NH groups were individually scaled to fit the observed positions of bands located unambiguously by deuterium substitution. The remaining vibrations were left unscaled, because they show a RMS of 13 cm^{-1}, which is within the range given in the literature for B3LYP theory level [22].

3.4. Vibrational spectroscopy

The structural resemblance of $[Zn(tch)_3][ZnCl_4] \cdot 2EtOH$ and its spontaneous decomposition product, $[Zn(tch)_3][ZnCl_4]$, is very well documented by their respective IR spectra, being practically the same in the far-IR region and exhibiting for the former compound only two additional mid-IR bands at 3490 and 1038 cm^{-1}, resulting from ethanol O–H and C–O stretching vibrations. This experiment confirms that both complex ions are preserved during decomposition. Since the latter compound is much more stable, its Raman and IR spectra were measured and will be further discussed.

The $[ZnCl_4]^{2-}$ anion vibrations were located at 296, 279 cm^{-1} (Raman) and 297, 145 cm^{-1} (IR) and well correspond to A_1 and T_2 species listed in the literature at 288, 298 and 130 cm^{-1} [23]. The attribution of the 297 cm^{-1} band was additionally confirmed by its 2.0 cm^{-1} metal isotope shift. For the second T_2 vibration, such a shift was not observed. Preliminary DFT calculations made for $[ZnCl_4]^{2-}$ revealed that this shift should be about four times smaller than the mentioned one, thus its detection may be difficult. The Raman active E mode, expected between 120 and 80 cm^{-1}, was not observed due to Rayleigh scattering.

The bands remaining after identification of $[ZnCl_4]^{2-}$ modes are generated by $[Zn(tch)_3]^{2+}$ vibrations. If an idealized C_{3v} symmetry is applied to the quasi-octahedral cation of *fac* configuration, the corresponding vibrations are classified into $A_1 + E$ irreducible representations. As results from the crystallographic data of $[Zn(tch)_3][ZnCl_4] \cdot 2EtOH$, $[Zn(tch)_3]^{2+}$ shows distortion from ideal C_{3v} symmetry. This distortion may cause the splitting of the degenerated E type vibrations, but it is difficult to evaluate how large this splitting is. In order to answer this question and to get some recognition about the vibrational behavior of the ZnN_3O_3 center and tch ligands, the DFT calculations were carried out for the $[Zn(tch)_3]^{2+}$ cation. Based on computed normal modes, the theoretical IR and Raman spectra were simulated and presented in Figs. 4 and 5, together with the observed ones. It should be emphasized that the observed spectra in Fig. 5 are the superposition of $[Zn(tch)_3]^{2+}$ and $[ZnCl_4]^{2-}$ absorptions, whereas the computed spectra are exclusively for the $[Zn(tch)_3]^{2+}$ cation. For this reason, the observed $[ZnCl_4]^{2-}$ bands were marked with asterisks and the corresponding $[Zn(tch)_3]^{2+}$ bands were joined with broken lines. Respective band wavenumbers are listed in Table 4, together with mode descriptions based on animation of computed normal vibrations. The calculations revealed that the mentioned splitting of the E modes is small and does not exceeds 5 cm^{-1}, which produces single peaks in the computed spectra. The wavenumbers of accompanying A_1 modes are also frequently close to the E ones. Thus, in Table 4, the one average frequency is listed if the discussed differences are below 10 cm^{-1}, otherwise two frequencies are typed, corresponding to A_1 and E modes, seen in the simulated spectra as two maxima.

Of most interest are the $[ZnN_3O_3]$ core vibrations. The calculations predict a predominant contribution of coordination bond stretching vibrations in normal modes at 527

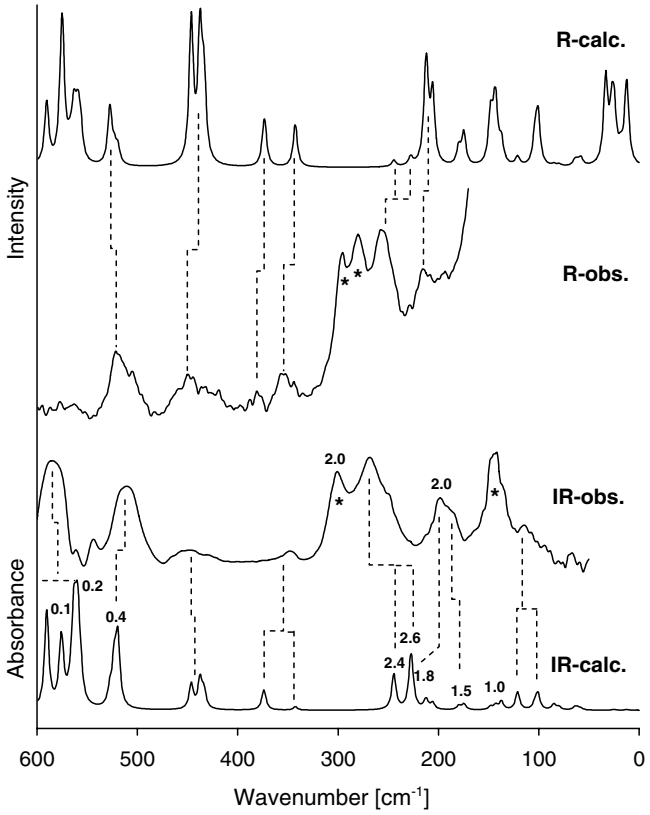

Fig. 5. Observed vibrational spectra of $[Zn(tch)_3][ZnCl_4]$ in the far-IR region, compared with calculated (scaled) spectra of the $[Zn(tch)_3]^{2+}$ cation. Observed bands attributed to $[ZnCl_4]^{2-}$ vibrations are marked with asterisks. The downshifts upon ^{64}Zn–^{68}Zn substitution are listed by the respective band maxima.

Abbreviations: ν, stretching; δ, in-plane bending; τ, torsion; π, out-of-plane bending; ρ_w, wagging; ρ_t, twisting; ρ_r, rocking; lib, librations; T, thiophene ring; R, chelate ring; L, ligand molecule; n.o., not observed; s, symmetric; a, asymmetric with respect to approximate local symmetry. Wavenumber shifts due to ^{64}Zn–^{168}Zn replacement are given in parentheses.

[a] Atomic numbering, given in Fig. 1, was used only when necessary.

[b] Scaling factors applied: 0.915 (vibrations nos. 1–3), 0.955 (4–6), 0.98 (7–12).

(A_1) and 521 cm^{-1} (E) for Zn–O bonds, and at 244, 228 (E) and 226 cm^{-1} (A_1) for Zn–N linkages. In the latter modes, the central atom is significantly displaced, which causes 1.8–2.6 cm^{-1} metal isotope shifts to be predicted for the corresponding theoretical bands. A similar shift was observed for the 195 cm^{-1} IR band, attributed to the ν_s(Zn–N) vibration. The ν_a(Zn–N) vibrations were assigned to the 270 cm^{-1} band of high intensity, enhanced probably by some lattice vibrations. However, this band shows a 12 cm^{-1} downshift upon NH and NH_2 group deuteration, which is typical for $\nu(Zn–NH_2)$ vibrations [24]. All ν(Zn–O) modes were assigned to a broad absorption with a maximum at 512 cm^{-1} and to a Raman transition at 521 cm^{-1}. The 512 cm^{-1} band shifts to 503 cm^{-1} upon H/D replacement, which is due to a small contribution of a $\rho_r(NH_2)$ vibration in this absorption. A metal isotope

shift was not observed for this band, which is probably caused by its small value, predicted as 0.4 cm^{-1}. Among four deformation modes expected for each five-membered chelate ring, only three were assigned to bands, at about 450, 380–350 and 214 cm^{-1} (Raman). The first δ_1(R) "in-plane" motion may roughly be described as C5–N2 bond displacement toward the zinc atom. In the second δ_2(R) mode, the same bond is moving parallel to its direction. The "out-of-plane" bending along the N2, O1 line characterizes the τ_1(R) mode, whereas similar bending along the N1, O1 direction is observed for the τ_2(R) vibration, overlapped in the IR spectrum by the $[ZnCl_4]^{2-}$ absorption.

Bands observed above 600 cm^{-1} result from the so-called "ligand vibrations", further presented for one example ligand with the lowest atom numbers. The stretching vibrations of C5–O1, C5–N2, N1–N2 bonds, being members of the chelate ring, contribute mainly in 1585, 1506 and 1047, 1035 cm^{-1} absorptions. The vibration of the C1–C5 bond, linking the chelate and thiophene rings, were computed at 1334 cm^{-1} and correlated with a 1310 cm^{-1} shoulder. The vibrations of the thiophene moiety may be compared with those of free thiophene [25], despite the fact, that in the present compound the thiophene ring is attached to the rest of the ligand at the C1 atom. The most visible difference concerns the splitting of the asymmetric (local symmetry) C–S bond vibrations, probably due to the mentioned ring attachment. In addition to typical ν_a(C–S–C) modes (coupled with ring deformation) calculated at about 755 cm^{-1}, the separate stretching vibrations of particular C–S bonds were predicted at 1016 cm^{-1} (C1–S) and 875 cm^{-1} (C4–S). The ligands also exhibit several normal modes, where thiophene rings librate (lib(T)), or whole ligands move (lib(L)), but these modes are of very low frequencies, being mostly below the observation limit.

Supplementary material

CCDC 627178 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

A new macrocyclic ligand, 1,3,5-triaza-2,4:7,8:16,17-tribenzo-9,12,15-trioxacyclooktadeca-1,5-dien (L) was synthesized by reaction of 2,6-diaminopyridine and 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane. Then, its Cu(II), Ni(II), Pb(II), Co(III) and La(III) complexes were synthesized by template effect by reaction of 2,6-diaminopyridine and 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane and $Cu(NO_3)_2 \cdot 3H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Pb(NO_3)_2$, $Co(NO_3)_2 \cdot 6H_2O$, $La(NO_3)_3 \cdot 6H_2O$, respectively. The ligand and its metal complexes have been characterized by elemental analysis, IR, ^1H and ^{13}C NMR, UV–Vis spectra, magnetic susceptibility, thermal gravimetric analysis, conductivity measurements, mass spectra and cyclic voltammetry. All complexes are diamagnetic and Cu(II) complex is binuclear. The Co(II) was oxidized to Co(III). The comparative electrochemical studies show that the nickel complex exhibited a quasi-reversible one-electron reduction process while copper and cobalt complexes gave irreversible reduction processes in DMSO solution.

Keywords: Macrocyclic Schiff base; Macrocyclic Schiff base complexes; 2,6-Diaminopyridine and 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane

1. Introduction

The field of the macrocyclic chemistry of metals is developing very rapidly because of its applications [1,2] and importance in the area of coordination chemistry [3]. Studies on complexes of Schiff-base macrocyclic ligands with different size, and number and donor atoms for coordination with a variety of metal centers have been published [4,5]. Many transition metal ions in living systems work as enzymes or carriers in a macrocyclic ligand environment; meaningful research in this direction might generate simple models for biologically occurring metaloenzymes [6,7], and thus help in further understanding biological systems. The development of the field of bioinorganic chemistry has been another important factor in spurring the growth in interest in macrocyclic compounds [8]. The formation of macrocyclic complexes depends significantly on the dimension of internal cavity, on the rigidity of macrocycles, on the nature of its donor atoms and on the complexing properties of the anion involved in the coordination [9]. The interest in such species stems from the application of these complexes ranging from modelling the active sites of many metaloenzymes, to hosting and carrying small molecules or catalysis [10]. The development of the field of bioinorganic chemistry has been another important factor in spurring the growth in interest in macrocyclic compounds [11]. An effective way to use the molecular recognition capability of macrocycles for metal ion separation is to incorporate such ligands into solvent extraction and liquid membrane

doi:10.1016/j.poly.2007.01.015

systems [12]. During the past years, the separation of heavy metals and organic substances has become more important in water purification applications owing to the drastic strengthening of environmental protection laws. In this field, various separation techniques, precipitation, extraction, distillation and electrodialysis have all been employed. Membrane processes such as liquid-membrane transport systems are potentially quite important in this area [13]. In practical applications, three main types of liquid membranes containing a mobile carrier have been studied: liquid surfactant, supported liquid a dissolvent polymeric membranes [14–18].

In the present work, we have synthesized a new macrocyclic Schiff base by reaction of 2,6-diaminopyridine and 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane. Then, its Cu(II), Ni(II), Pb(II), Co(III) and La(III) complexes were synthesized by template effect by reaction of 2,6-diaminopyridine and 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane and $Cu(NO_3)_2 \cdot 3H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Pb(NO_3)_2$, $Co(NO_3)_2 \cdot 6H_2O$, $La(NO_3)_3 \cdot 6H_2O$, respectively. Then the spectral, magnetic, electrochemical properties of all compounds were studied in detail.

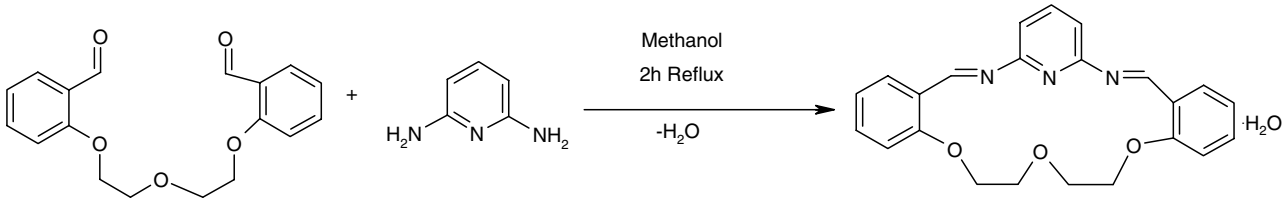
2. Experimental

2.1. Physical measurements

Elemental analysis was carried out on a LECO CHNS model 932 elemental analyzer. ^{1}H NMR and ^{13}C NMR spectra were recorded using a model BRUKER AVANCE DPX-400 NMR spectrometer. IR spectra were recorded on a PERKIN ELMER SPECTRUM RX1 FTIR spectrometer on KBr discs in the wave number range of 4000–400 cm^{-1}. Electronic spectral studies were conducted on a SHIMADZU model 160 UV Visible spectrophotometer in the wavelength 200–600 nm. Molar conductivity was measured with a WTW LF model 330 conductivity meter, using prepared solution of the complex in DMF–DMSO (1:1). Thermal gravimetric analysis was carried out on a TGA SHIMADZU model 50 thermal gravimetric analyzer. LC/MS-API-ES mass spectra were recorded using a AGILENT model 1100 MSD mass spectrophotometer. An EcoChemie Autolab-12 potentiostat with the electrochemical software package GPES 4.9 (Utrecht, The Netherlands) was used for voltammetric measurements. A three electrode system was used: a platinum wire counter electrode, an Ag/AgCl reference electrode, and a 2 mm sized platinum disc electrode as working electrode. The working electrode was polished with 0.05 μm alumina prior to each experiment. Throughout the experiment, oxygen-free nitrogen was bubbled through the solution for 10 min. Voltammetric experiments were performed at room temperature. Electrochemical grade tetraethylammonium perchlorate (TEAP) (0.1 mol dm^{-3}) was employed as the supporting electrolyte.

2.2. Materials

1,7-Bis(2-formylphenyl)-1,4,7-trioxaheptane was prepared by the literature method [19,20]. All the other chemicals and solvents were of analytical grade and used as received.



2.3. Preparation of 1,3,5-triaza-2,4:7,8:15,16-tribenzo-9, 15-dioxacycloheptadeca-1,5-diene (L)

The macrocyclic ligand (L) was prepared by the dropwise addition of a solution of the 2,6-diaminopyridine (0.22 g 2 mmol) in methanol (40 mL) to a stirred solution of 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane (0.63 g 2 mmol) in methanol (60 mL). After the addition was completed, the stirring was continued for 2 h. A yellow coloured compound was filtered. Then, CH_2Cl_2 was added to filtered compound and solved. Then, the solution was filtered and *n*-hexane was added to filtered solution. A yellow compound was obtained and filtered (Scheme 1). Yield: 0.47 g(%57). *Anal*. Calc. for $C_{23}H_{21}N_3O_3 \cdot H_2O$: C, 68.15; H, 5.68; N, 10.37. 2.4. Preparation of complexes

2.4.1. Preparation of the $[Cu_2(L)(NO_3)_2][NO_3]_2 \cdot H_2O$

To a stirred solution of 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane (0.63 g, 2 mmol) and $Cu(NO_3)_2 \cdot 3H_2O$ (0.96 g, 4 mmol) dissolved in methanol (60 mL) and then

Scheme 1.

added dropwise 2,6-diaminopyridine (0.22 g 2 mmol) in methanol (40 mL). After the addition was completed, the stirring was continued for 2 h. A brown coloured precipitation was filtered and washed with ethanol, $CHCl_3$ and diethylether, respectively. Then dried in air. Yield: 0.70 g (45%). *Anal*. Calc. for $Cu_2C_{23}H_{21}N_7O_{15}\cdot H_2O$: C, 35.38; H, 2.95; N, 12.56. Found: C, 35.75; H, 3.12; N, 12.24%. ^{1}H NMR (DMSO-d_6, δ ppm): $\delta = 3.5$ (H_2O), $\delta = 3.90$ (OCH_2), $\delta = 4.30$ (CH_2OPh), $\delta = 7.02$–8.10 (Ar–H), $\delta = 10.39$ (HC=N). Selected IR data (KBr, ν cm^{-1}): 3351 ν(H_2O), 3068 ν(Ar–CH), 2939, 2873 ν(Alph. –CH), 1615 ν(C=N), 1598 ν[(C=N)(pyridine)], 1488, 1455 ν(Ar–C=C), 1384 ν NO_3^-, 1287, 1242 ν(Ar–O), 1162, 1051 ν(R–O), 757 ν(Substitute benzene). $\Lambda_M = 161\ \Omega^{-1}\ mol^{-1}\ cm^2$. UV–Vis ($\lambda_{max}$, nm) (DMF–DMSO (1:1)): 272, 320. Mass spectra: m/z: 452 $[[Cu(L)] + H]^+$.

2.4.2. Preparation of the $[Ni(L)(NO_3)_2]\cdot 3H_2O$

To a stirred solution of 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane (0.63 g, 2 mmol) and $Ni(NO_3)_2\cdot 6H_2O$ (0.58 g, 2 mmol) dissolved in methanol (60 mL) and then added dropwise 2,6-diaminopyridine (0.22 g, 2 mmol) in methanol (40 mL). After the addition was completed, the stirring was continued for 2 h. A yellow coloured precipitation was filtered and washed with ethanol, $CHCl_3$ and diethylether, respectively. Then dried in air. Yield: 0.55 g (47%). *Anal*. Calc. for $NiC_{23}H_{21}N_5O_9\cdot 3H_2O$: C, 44.30; H, 4.65; N, 11.24. Found: C, 44.35; H, 4.67; N, 11.22%. ^{1}H NMR (DMSO-d_6, δ ppm): $\delta = 3.5$ (H_2O), $\delta = 3.92$ (OCH_2), $\delta = 4.30$ (CH_2OPh), $\delta = 7.07$–7.67 (Ar–H), $\delta = 10.38$ (HC=N). Selected IR data (KBr, ν cm^{-1}): 3358 ν (H_2O), 3065 ν (Ar–CH), 2938, 2872 ν (Alph. –CH), 1642 ν(C=N)1598 ν [(C=N)(pyridine)], 1487, 1450 ν (Ar–C=C), 1289, 1243 ν (Ar–O), 1160, 1125, 1050 ν (R–O), 754 ν (Sübstitue benzene). $\Lambda_M = 48\ \Omega^{-1}\ mol^{-1}\ cm^2$. UV–Vis ($\lambda_{max}$, nm) (DMF–DMSO (1:1)): 275, 323, 378. Mass spectra: m/z: 571 $[Ni(L)(NO_3)_2 + H]^+$.

2.4.3. Preparation of the $Pb(L)(NO_3)][NO_3]\cdot H_2O$

To a stirred solution of 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane (0.63 g, 2 mmol) and $Pb(NO_3)_2$ (0.66 g, 2 mmol) dissolved in methanol (60 mL) and then added dropwise 2,6-diaminopyridine (0.22 g 2 mmol) in methanol (40 mL). After the addition was completed, the stirring was continued for 2 h. A yellow coloured precipitation was filtered and washed with ethanol, $CHCl_3$ and diethylether respectively. Then dried in air. Yield: 0.81 g (55%). *Anal*. Calc. for $PbC_{23}H_{21}N_5O_9\cdot H_2O$: C, 37.50; H, 3.12; N, 9.51. Found: C, 37.56; H, 3.18; N, 9.60%. ^{1}H NMR could not be taken because of its insolubility. Selected IR data (KBr, ν cm^{-1}): 3355 ν(H_2O), 3068 ν(Ar–CH), 2931, 2873 ν(Alph. –CH), 1650 ν(C=N), 1598 ν[(C=N)(pyridine)], 1487, 1450 ν(Ar–C=C), 1384 νNO_3^-, 1289, 1243 ν(Ar–O), 1161, 1052 ν(R–O), 753 ν(Substitute benzene). $\Lambda_M = 89\ \Omega^{-1}\ mol^{-1}\ cm^2$. UV–Vis ($\lambda_{max}$, nm) (DMF–DMSO (1:1)): 276, 323, 378. Mass spectra: 627 $[Pb(L)-(NO_3)-(OCH_2)+H]^{+2}$.

2.4.4. Preparation of the $[Co(L)(NO_3)_2(OH)(H_2O)]\cdot H_2O$

To a stirred solution of 1,7-bis(2-formylphenyl)-1,4,7-trioxaheptane (0.63 g, 2 mmol) and $Co(NO_3)_2\cdot 6H_2O$ (0.58 g, 2 mmol) dissolved in methanol (60 mL) and then added dropwise 2,6-diaminopyridine (0.22 g 2 mmol) in methanol (40 mL). After the addition was completed, the stirring was continued for 2 h. A yellow coloured precipitation was filtered and washed with ethanol, $CHCl_3$ and diethylether, respectively. Then dried in air. Yield: 0.57 g (46%). *Anal*. Calc. for $CoC_{23}H_{24}N_5O_{11}\cdot H_2O$: C, 44.30; H, 4.17; N, 11.24. Found: C, 44.48; H, 4.32; N, 11.30%. ^{1}H NMR (DMSO-d_6, δ ppm): $\delta = 3.43$ (H_2O), $\delta = 3.94$ (OCH_2), $\delta = 4.31$ (CH_2OPh), $\delta = 7.03$–7.72 (Ar–H), $\delta = 10.39$ (HC=N). Selected IR data (KBr, ν cm^{-1}): 3381 ν(H_2O), 3066 ν(Ar–CH), 2934, 2879 ν(Alph. –CH), 1646 ν(C=N) 1598 ν[(C=N)(pyridine)], 1488, 1455 ν(Ar–C=C), 1286, 1238 ν(Ar–O), 1161, 1053 ν(R–O), 754 ν(Substitute benzene). $\Lambda_M = 36\ \Omega^{-1}\ mol^{-1}\ cm^2$. insoluble in most common solvents, including water, ethanol, ethyl acetate, and acetonitrile.

The IR spectrum of the ligand (L) shows a ν(C=N) peak at 1685 cm^{-1} and the absence of a ν(C=O) peak at around 1700 cm^{-1} is indicative of Schiff's base condensation. The IR spectra of all complexes show ν(C=N) bands at 1615–1684 cm^{-1} [3,5,21–23] and it is found that the ν(C=N)bands in the complexes are shifted by about 70–2 cm^{-1} to lower energy regions compared to that of the free ligand (L). This phenomenon appears to be due to the coordinated of azomethine nitrogen to the metal ion [5,24,25]. Also, a weak $\nu(H_2O)$ band of free ligand at about 3380 cm^{-1} is observed because of water molecule and the IR spectra of the Co(III) complex is characterized by the appearance of a broad band in the region at 3364 cm^{-1} due to OH groups [26–28]. The absorptions of the nitrate counterions, at ca. 1460–1452 (ν_5), 1300 (ν_1) and 1040 (ν_2) cm^{-1}, suggest the presence of bidentate nitrate groups: a intense band at ca. 1384 cm^{-1} attributable to ionic nitrate, is also present [4,7,29]. The IR spectra of the complexes clearly demonstrated that the COC and CCO stretching vibrations are altered compared to ligands due to conformational changes. The C–O–C absorption is shifted to lower wave numbers in complexes providing another evidence of complexing [30,31].

^{1}H NMR and ^{13}C NMR of the complexes in DMSO-d_6 solution show that they are NMR active. The ^{1}H NMR spectrum of the free ligand shows a multiplet in the range 7.1–8.0 ppm due to aromatic protons, 10.4 ppm due to imine protons and 3.4 ppm due to H_2O protons. ^{13}C NMR spectrum of the free ligand shows 161.3 ppm in the range due to imine carbon, 65.6 ppm due to OCH_2 carbon and 189.8 ppm due to pyridine carbon. The ^{1}H NMR spectra of the complexes exhibit almost the same values [32–34].

3.2. Electronic absorption spectroscopy

The electronic spectrum of the ligand (L) in DMSO–DMF (1:1) shows absorption bands at 276, 321, 376 nm. The bands are indicative of benzene and other chromophore moieties present in the ligand. The absorption bands of the complexes are shift to longer wave numbers compared to that of ligand [35]. No d–d transitions for the complexes were observed due to having low solubility of complexes. A moderately intensive band observed in the range of 320–380 nm is due to existence of a ligand-to-metal charge transfer transition, and the strong band observed in the range of 270–280 nm is due to an intraligand charge transition [32] for these complexes.

3.3. Magnetic and conductivity studies

The observed room-temperature magnetic moment value for the binuclear Cu(II) and the mononuclear other complexes are found to be diamagnetic. The diamagnetic behaviour of the binuclear complex may be explained by a very strong anti-ferromagnetic interaction in the Cu–Cu pair [36]. Co(II) complex was oxidised to Co(III) complex by O_2 in air [37]

$$2Co^{+2}+ \rightarrow 2Co^{+3} + 2e^-$$

$$1/2O_2 + 2e^- \rightarrow O^{-2}$$

$$O^{-2} + H_2O \rightarrow 2OH^-$$

Conductivity measurements of the lead(II) complex in DMF–D MSO resulted in Λ_M value 89 Ω^{-1} mol^{-1} cm^2, which indicate that it is of the 1:1 electrolyte type, and the binuclear copper(II) complex show Λ_M value in the range of 161 Ω^{-1} mol^{-1} cm^2 indicating that it is of 2:1 electrolyte type [4,8,23]. The other complexes are nonelectrolyte (Table 1).

It is seen that the complex formation reaction between ligand and relatively large Pb(II) and La(III) metal ions result in the $[Pb(L)(NO_3)][NO_3] \cdot H_2O$ and $[La(L)(NO_3)_3$-

$(H_2O)] \cdot H_2O$ complexes. The binding mode of the ligand for the $[Pb(L)(NO_3)][NO_3] \cdot H_2O$ complex is different than that of the $[La(L)(NO_3)_3(H_2O)] \cdot H_2O$ complexes. In the first case, the ligand behaves as a tetradentate ligand with the lone electron pairs of azomethine nitrogen atoms and the lone electron pairs of two oxygen in ether groups. In the second case, the ligand behaves as a bidentate ligand with the lone electron pairs of azomethine nitrogen atoms. The long distance binding process can be favoured for too large Pb(II) metal ion but not La(III) metal ion due to having smaller ion size than Pb(II) metal ion. So its coordination is satisfied with three NO_3^- and one H_2O in the second case. Similar binding mode was observed in literature for Pb(II) metal ions [9,30,36,38]. The absorptions of the coordinated nitrate ions, at ca. 1460–1452 (ν_5), 1300 (ν_1) and 1040 (ν_2) cm^{-1}, suggest the presence of the coordinated nitrate groups while a intense band at ca. 1384 cm^{-1} can be attributed to the ionic nitrate conterions [4,7,29]. Also, the conductivity measurements of the lead(II) complex in DMF–DMSO resulted in Λ_M value 89 Ω^{-1} mol^{-1} cm^2, which indicate that it is of the 1:1 electrolyte type. These results are clearly verify different binding mode of ligand in the case of the Pb(II) metal ion. As expected, in the case of the relatively small (Ni(II) and Co(III)) metal ions, the ligand behaves as a bidentate ligand with the lone electron pairs of azomethine nitrogen atoms and the inner coordination sphere is donated with NO_3^-, H_2O, and OH^- ligands. The conductivity measurements showed that these complexes are nonelectrolyte. On the other hand, the diamagnetic behaviour of the binuclear complex can be explained by a very strong anti-ferromagnetic interaction in the Cu–Cu pair [36]. Also, the structure was supported with the others spectroscopic data. Furthermore, the controlled potential coulometric (CPC) study indicated that the number of electrons transferred for the electrochemical reaction of the complex was two for the reduction process based on the copper metal as seen from the electrochemical study. Some Co(II), Ni(II), Ag(II), Zn(II) or Pb(II) complexes prepared with similar ligands have been known from literature.

3.4. Electrochemistry

The electrochemical behaviors of the nickel(II), copper(II), and cobalt(III) complexes were studied using cyclic voltammetric (CV) technique in DMSO solution containing 0.1 M TEAP. All CVs and their data are presented in Fig. 1 and Table 3. Fig. 1a shows the CV of the nickel complex which exhibited a quasi-reversible one-electron reduction in DMSO containing Ag/AgCl electrode system at 0.100 V s^{-1} scan rate with a corresponding anodic wave. This reduction wave is referred to the Ni(II)/Ni(I) couples. The quasi-reversibility of the reduction process are confirmed with the corresponding the peak separation value between cathodic peak potential and anodic peak potential ($\Delta E_p = 0.120$ V) and almost the unity of the ratio of the anodic peak current-to-cathodic peak current. The half-wave potential of the nickel complex was located at $E_{1/2} = -1.37$ V versus Ag/AgCl.

Table 4
TGA data of the complexes

Compounds	Weight loss %, Calc. (Found) Decomposition group		
	First step (°C)	Second step (°C)	Third step (°C)
$[CoL(NO_3)_2(OH)(H_2O)]\cdot H_2O$	95.0–320.0 11.68 (11.70) H_2O and NO_3		
$[NiL(NO_3)_2]\cdot 3H_2O$	48.0–330.0		
$[Cu_2L(NO_3)_2][(NO_3)_2]\cdot H_2O$	60.0–215.0 2.31 (2.50) H_2O		
$[PbL(NO_3)][NO_3]\cdot H_2O$	34.0–67.0 2.83 (2.50) H_2O	67.0–154.0 9.76 (10.83) NO_3	154.0–308.0 9.76 (8.33) NO_3
$[LaL(NO_3)_3(H_2O)]\cdot H_2O$	59.0–310.0 4.82 (5.00) $2H_2O$		

large peak separation value ($\Delta E_p = 0.300$ V) at 0.100 V s^{-1} scan rate. This reduction wave is assigned to the Cu(II)/Cu(I) couples. The cathodic electrode potential are displayed at $E_{pc} = -0.015$ V. The controlled potential coulometric (CPC) study indicated that the number of electrons transferred for the electrochemical reaction of the complex was two for the reduction process based on the copper metal [39–43].

Fig. 1c shows the CV of the cobalt complex, which displayed irreversible one-electron reduction in DMSO containing Ag/AgCl electrode system with a peak separation value ($\Delta E_p = 0.223$ V). The reduction wave could be assigned to metal-based Co(III)/Co(II) couples in the complex. The cathodic peak potential of complex is located at $E_{pc} = -0.739$ V versus Ag/AgCl [39–43].

3.5. Thermal studies

The thermal stability of the complexes were investigated using TGA. The thermogravimetric analysis (TGA) were carried out (Table 4) at a heating rate of 10 °C/min in a nitrogen atmosphere over a temperature range of 20–900 °C.

The decomposition and weight losses of Co(III), Cu(II) and La(III) complexes were occured at the temperature ranges of 95.0–320.0 °C, 60.0–215.0 °C and 59.0–310.0 °C, respectively. The calculated and found weight loses indicated the departure group to be H_2O mainly. Thermal decomposition of all complexes are seen to be irreversible. The weight loses of Ni(II) complex was not observed clearly.

The H_2O and NO_3 groups departured from Pb(II) complex at the temperature range of 34.0–308.0 °C. The amount of H_2O and NO_3 groups stoichometrically corresponding to the weight losses are given in the proposal chemical formulas of complexes (Table 4).

3.6. Mass spectra

Abstract

A series of five gold(I) halide complexes with the two isomeric methoxy-substituted triarylphosphines, tris(2-methoxyphenyl)phosphine [P(oanis)$_3$], [AuP(oanis)$_3$X] [for X = Cl, (**1**); X = Br, (**2**) and X = I, (**3**)] and tris(4-methoxyphenyl)phosphine [P(panis)$_3$], [AuP(panis)$_3$X] [for X = Br (**4**) and X = I (**5**)] have been synthesized and characterized by single crystal X-ray diffraction and solution $^{31}P\{^1H\}$ NMR spectroscopy. The structure determinations confirm the expected presence of linear two-coordination about the gold centres in all five complexes with bond distance and angle data typical of this type of compound [Au–P, 2.239(2)–2.259(3) Å; Au–Cl, 2.294(2) Å; Au–Br, 2.385(2)–2.402(2) Å; Au–I, 2.546(1)–2.554(1) Å; P–Au–X; 175.3(1)–180°]. All analogues except the iodo complex **5** crystallize with one complex molecule in the crystallographic asymmetric unit. The bromo and iodo complexes **2** and **3** constitute a trigonal isomorphous set while the bromo complex **4** is also isomorphous with the previously determined chloro complex [AuP(panis)$_3$Cl]. The 2-methoxy analogues are stabilized by significant methoxy-O···Au interactions.

1. Introduction

The linear two-coordinate complexes of the gold(I) halides with the tertiary-substituted arylphosphines of the type [AuP(Ar)$_3$X] (where X = Cl, Br, I) have received considerable attention with respect to the steric influence of substituent groups on the aryl groups of the phosphine and the variable electron donor properties of the chloride, bromide and iodide anions. To date a large number of crystal structures of this type of compound have been published, for example [1–20]. It has been observed that steric factors exert the most important influence on the packing environment about the Au centres, with possible Au···Au interactions only being reasonable in gold(I) halide complexes with small alkyl substituted phosphines, e.g. [P(Me)$_3$] and [P(Et)$_3$]. Thus among the total set of gold complexes of this type, only the isomorphous pair [AuP(Me)$_3$Cl] [17–19] and [AuP(Me)$_3$Br] [17–19] and [AuP(Et)$_3$Cl] [20] have short Au···Au interactions, varying from 3.27–3.98 Å. It was therefore very unusual to encounter in our previous series of compounds [6] a sterically encumbered ring-substituted triarylphosphinegold(I) complex, that with tris(4-methylphenyl)phosphine, [AuP(ptol)$_3$Cl] which had similar Au···Au interactions [3.375(1) Å], considering that the corresponding unsubstituted phosphine complex [AuP(Ph)$_3$Cl] [1–3] had none. Furthermore, a feature of that entire series of compounds was the common occurrence of isomorphous crystal sets among the halide complexes particularly with the bromide and iodide members, although isomorphous series which include all three halide homologues are known, e.g. with [P(Ph)$_3$] [1,2,19] and [P(otol)$_3$] [otol = tris(2-methylphenyl)phosphine] [6]. In addition, there is a high incidence of examples in which

doi:10.1016/j.poly.2007.01.014

there are two complex molecules in the crystallographic asymmetric unit, a phenomenon which appears to be a consequence of the conformational variability possible particularly in the aryl substituents on the phosphine ligand. This factor may be controlled to some extent by energetics, e.g. method of synthesis together with the conditions and solvents employed both in the synthesis and in recrystallization, e.g. $[AuP(otol)_3Cl]$ gives a monoclinic modification (the α-polymorph) from ethanol [5] while the orthorhombic β-polymorph [6] is obtained from dimethylformamide, and a similar dimorphism is observed with the isomeric $[AuP(p\text{-}tol)_3Cl]$ set [6,7].

It has also been noted that the methoxy oxygen atoms in tris(2,4,6-trimethoxylphenyl)phosphine $[P(tmp)_3]$ affect both the basicity of the ligand and the gold environment in the $[AuP(tmp)_3X]$ complexes [3,12]. Previously, it was also observed that the presence of *ortho*-methyl substituents in the $[P(otol)_3]$ complexes gave Au···H(methyl) interactions, resulting in regularity in the disposition of the phosphine phenyl rings [6]. We therefore were interested in determining the effect of a single methoxy substituent on both the intramolecular interactions (2-methoxy-O···Au) as well as upon intermolecular associations and crystal packing. With the unsymmetrically substituted complexes chloro(2-hydroxyphenyl)diphenylphosphinegold(I) [13], and iodo(2-aminophenyl)diphenylphosphinegold(I) [14], both the hydroxy oxygen and the amino proton give significant short Au···O [3.160(7) Å] and Au···N [3.61(3) Å] interactions. This effect is not present in the analogous but sterically demanding *ortho*-substituted phosphine complex, chloro[(2-trimethylsiloxyphenyl)diphenylphosphine]gold(I) [13] where no substituent group interaction is found. Similar steric effects are seen with the 2-iodo-substituted analogues iodo(2-iodophenyl)diphenylphosphinegold(I) [15] and iodo(2-iodo-3-methylphenyl)diphenylphosphinegold(I) [16].

We therefore set out to look at the structural effects of both *ortho*- and *para*-methoxy phosphine substitution on a series of gold(I) complexes. Reported here is the synthesis, the X-ray structures and solution $^{31}P\{^1H\}$ NMR spectra of the series of five halo-gold(I) complexes with the *ortho*- and *para*-anisyl-substituted phosphines, tris(2-methoxyphenyl)phosphine $[P(oanis)_3]$, $[AuP(oanis)_3X]$ [Series A: compounds **1**–**3**] and tris(4-methoxyphenyl)phosphine $[P(panis)_3]$, $[AuP(panis)_3X]$ [Series B: compounds **4**, **5**] (X = Br, I). The structure of the Series B chloro analogue $[AuP(panis)_3Cl]$ has been previously reported [11].

2. Experimental

2.1. Preparation of compounds

The complexes $[AuP(oanis)_3X]$ [Series A: for X = Cl (**1**); X = Br (**2**); X = I (**3**)] and $[AuP(panis)_3X]$ [Series B: for X = Br (**4**); X = I (**5**)] were synthesized using a previously described procedure [6] by the interaction of equimolar quantities of $[Bu_4N][AuX_2]$ (0.50 mmol; Cl, 0.255 g; Br, 0.300 g; I, 0.346 g) and the appropriate phosphine (0.50 mmol, 0.152 g) dissolved in 5 mL of dimethylformamide at ca. 50 °C. The resultant solutions were cooled to room temperature and allowed to stand for several days to yield well-formed colourless crystals of the expected complexes. Yields were 96%, 93%, 96%, 95% and 88% for **1**–**5**, respectively. Melting points and ν(Au–X) stretching frequencies obtained from FT raman data for **1**–**5** are listed in Table 1. No chemical analyses were completed.

Just as for the analogous Au(I) complex series with the isomeric *ortho*- and *para*-tolylphosphines [6,24], the chloride and bromide complexes **1**, **2** and **4** but not the iodide complexes **3** and **5** may be synthesized using either potentiostatic methods or galvanostatic methods.

2.2. Spectroscopy

Solution $^{31}P\{^1H\}$ NMR spectra were recorded in $CDCl_3$ solution on a Varian Gemini-2000 spectrometer at 80.86 MHz with 256 transients collected. Spectra were referenced internally to 85% H_3PO_4.

2.3. X-ray structure determinations

X-ray crystal data indicated that the Series A bromide and iodide complexes with $[P(oanis)_3]$ (**2** and **3**) appeared to comprise a trigonal isomorphous set. Similarly, in the Series B set the bromo complex with $[P(panis)_3]$ (**4**) had cell parameters and space group which indicated that it was isomorphous with the previously reported chloro analogue [11]. Both of these isomorphous series were confirmed in the structure analyses. With the iodo complex of $[P(panis)_3]$ (**5**), although having four molecules in a centrosymmetric triclinic cell could not be transformed into a higher symmetry cell, and this was subsequently justified in the analysis with the presence of two conformationally dissimilar molecules in the asymmetric unit.

Unique data sets for all compounds were measured at 297(2) K within the specified $2\theta_{max}$ limit using a Rigaku AFC 7R four-circle diffractometer [θ–2θ scan mode, monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å), from a 12 kW rotating anode source] yielding N independent reflections, N_0 with $I > 3.0\sigma(I)$ (compounds **1**, **4** and **5**) or $I > 2.0\sigma(I)$ (compounds **2** and **3**) being considered 'observed' and used in the expression of the conventional refinement residual R. Crystal decay was negligible in most cases [1.5% maximum in **5**] and in the worst cases was allowed for by using a linear correction. The structures were solved by direct methods and refined by full-matrix least-squares refinement {on F for **1**, **4** and **5** or on F^2 for **2** and **3** (the latter using SHELX-97) [25]} after semi-empirical absorption corrections based on ψ-scans. Anisotropic thermal parameters were refined for all non-hydrogen atoms while $(x, y, z, U_{iso})_H$ were included and constrained at estimated values. Neutral atom complex scattering factors were employed while computation used the TeXsan

3. Results and discussion

3.1. Structural chemistry

The series of five substituted triarylphosphine gold(I) halide complexes of the type [AuP(Ar)$_3$X] with isomeric tris(2-methoxyphenyl)phosphine [P(oanis)$_3$] and tris(4-methoxyphenyl)phosphine [P(panis)$_3$] have been characterized by X-ray diffraction and $^{31}P\{^1H\}$ NMR spectroscopy. Selected interatomic bond lengths and interbond angles for [AuP(oanis)$_3$X] (for X = Cl, Br and I) (Series A: compounds **1**–**3**) and [AuP(panis)$_3$X] (for X = Cl, Br and I) (Series B: compounds **4** and **5**) together with comparative data for the analogous [AuP(Ph)$_3$X] [1–3] and some mono-*ortho*-substituted phenyl phosphine complexes of the type [AuP(YPh)(Ph)$_2$X] (where Y = an interactive substituent, e.g. –OH, –NH$_2$), –OSi(Me)$_3$ [13,14], are given in Table 2.

All complexes have the expected linear two-coordination about the gold centres (see Figs. 1, 3, 5 and 6) with the mean P–Au–X bond angle [177.8°]. The largest deviation from linearity in the overall series of complexes of this type occurs with those members where packing allows short intermolecular Au···Au interactions, e.g. with the rare tris(4-methyltolyl)phosphine complex [AuP(ptol)$_3$Cl] [6] [Au···Au, 3.375(1) Å; P–Au–Cl, 173.2(2)°]. No examples of this type are found in the present Series A or B complexes. The mean Au–P and Au–X bond lengths are 2.25(1) Å (Au–P), 2.292(5) Å (Au–Cl), 2.394(5) Å (Au–Br) and 2.552(5) Å (Au–I) comparing with the series mean of 2.29(2), 2.29(2), 2.41(1) and 2.56(1) Å, respectively. With the Series A complexes (**1**–**3**), the *ortho*-substituted methoxy groups influence the conformational features of the substituted phosphine ligand. The triclinic chloro complex **1** [AuP(oanis)$_3$Cl] (Figs. 1 and 2), having one molecule in the asymmetric unit is significantly different from the bromo and iodo analogues (**2** and **3**) which constitute a trigonal isomorphous set, and have molecular C_3 symmetry coincident with crystallographic symmetry (Figs. 3 and 4), with the P–Au–X moiety lying on the three-fold axis and with the three methoxy groups in general positions. This implies that all methoxy groups adopt identical conformations in a perfect propeller conformation. It should be noted that although complexes **2** and **3** are isomorphous, the individual complex molecules in each have subtle conformational differences, one being right handed the other left [Fig. 1a and b]. This results from a simple rotation of the phenyl ring about the P1–C1 bond vector and is not a chiral relationship. In addition, the methoxy

[c] $[P(2\text{-}OSiMe3Ph)(Ph)_2Cl]$ = (2-trimethylsiloxyphenyl)diphenylphosphine.
[d] $[P(2\text{-}NH_2Ph)(Ph)_2]$ = (2-aminophenyl)diphenylphosphine.

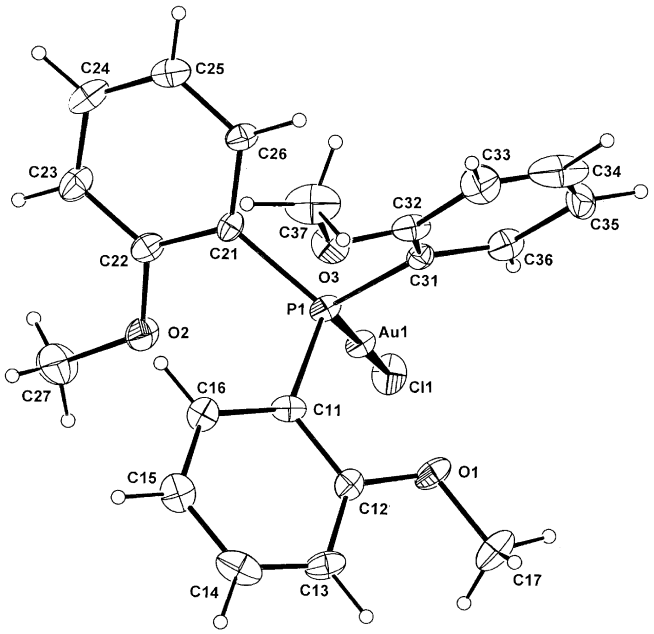

Fig. 1. Molecular configuration and atom numbering scheme for $[AuP(oanis)_3Cl]$ (**1**) with non-hydrogen atoms shown as 30% probability ellipsoids [27].

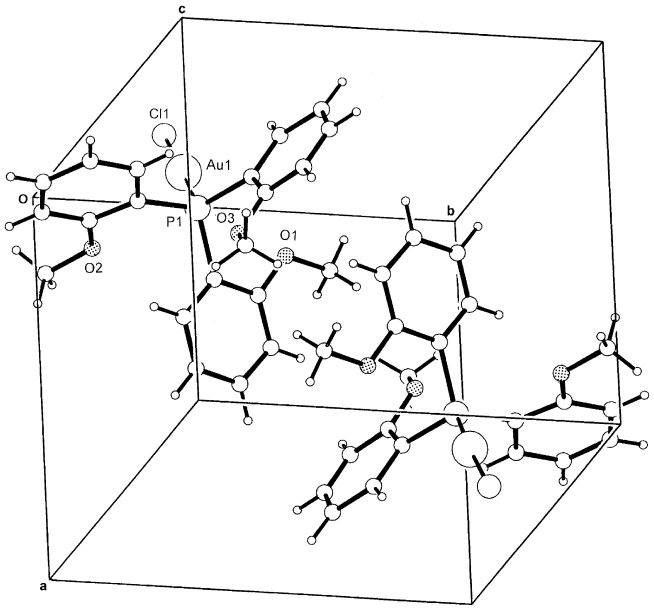

Fig. 2. Perspective view of the packing of **1** in the unit cell viewed down the approximate c-axial direction.

groups are essentially coplanar with the phenyl rings [torsion angle C1–C2–O2–C7, 178.1(8)° (**2**) and −177.2(7)° (**3**)] and have all three oxygen atoms directed towards the gold centre [Au···O, 3.250(6) Å (**2**) and 3.239(7) Å (**3**)]. In contrast, complex **1** has two methoxy groups directed towards and one away from the gold centre [torsion angles ($\tau_1 - \tau_3$), 56°, 55°, 178(1)°]. The Au···O distances for these *cis*-related methoxy groups are 3.27(1) and 3.36(1) Å indicating moderate interaction. Stronger interaction is certainly found with the (2-hydroxyphenyl)diphenylphosphinegold(I) chloride complex [13] where the single hydroxy group interacts with Au [Au···O, 3.160(7) Å] and has the hydroxy-H directed away from Au. The more sterically demanding (2-trimethylsiloxyphenyl)diphenylphosphine ligand in the gold(I) chloride complex [13] has a somewhat longer but still significant Au···O contact [3.353(2) Å]. With the corresponding tris(2,4,6-trimethoxy)phosphine analogues (Cl, Br, I) [3,12], one *o*-methoxy-O of each ring has an interactive Au···O contact [2.92–3.14(1) Å (Cl); 2.96–3.13(1) Å (Br); 3.01–3.10(1) Å

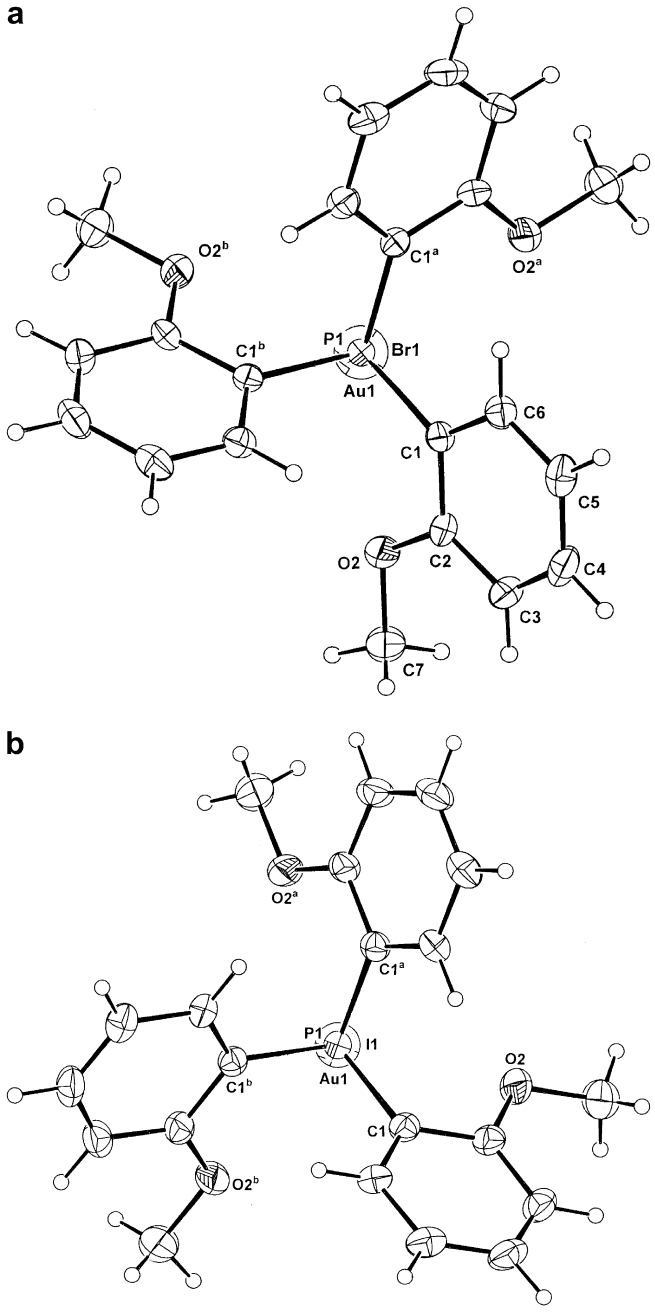

Fig. 3. Molecular configuration for the molecules of the isomorphous complexes (a) $[AuP(oanis)_3Br]$ (**2**), and (b) $[AuP(oanis)_3I]$ (**3**) viewed down molecular the C_3 axis of each, showing the subtle conformational difference between the two.

(I)]. The tris(*o*-tolyl)phosphine examples [6] in which the methyl-H···Au interactions are important in influencing conformation, have a mean Au···C distance of 3.44(1) Å. The effect of this conformational control can be gauged by inspecting the comparative torsion angles ($\tau_1 - \tau_3$) [corresponding to the angle Au–P–C(*m*1)–C(*m*2)] (Table 2). In examples having interaction, the angles are more regular, e.g. a 41–59° range for the $[AuP(otol)_3X]$ (X = Cl, Br and I) series cf. 17–57° for the $[AuP(ptol)_3X]$ (X = Cl, Br and I series) [6]. With the previous series the values were usually ordered small–large–small as is the case with the parent

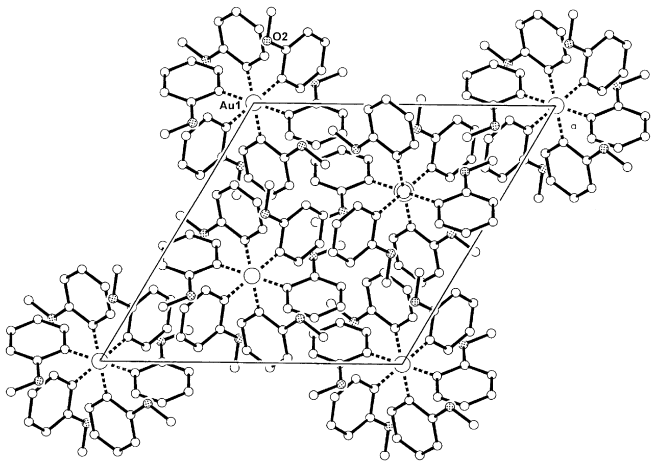

Fig. 4. Packing of the molecules of **2** in the unit cell viewed down the *c*-axial direction.

$[P(Ph)_3]$ [39°, 58°, 30° (X = Cl); 44°, 55°, 33° (X = Br); 41°, 58°, 32° (X = I) [1,2,19]. With the series (**1**–**5**) considered here, the same trend is observed, with values of 56.3(15)°, 55.0(18)°, −1.4(16)° for **1**, where only two methoxy groups are interactive [Au···O1, 3.356(12) Å and Au1···O2, 3.271(12) Å], compared to the constant values for the trigonal examples **2** [−46.3(8)°; Au···O1, 3.250(6) Å] and **3** [47.4(7)°; Au···O1, 3.239(7) Å]. In none of these three examples does the packing in the unit cell result in dimer formation through the back-to-back sextuple phenyl embrace (SPE) [6,21–23].

With the $[AuP(panis)_3X]$ examples in the Series B set, the bromo analogue $[AuP(panis)_3Br]$ (**4**) (Fig. 5) is found to be isomorphous with the previously reported first member of the series, $[AuP(panis)_3Cl]$ [11]. Both crystallize in *C*-centred monoclinic cells {comparative cell data for the chloro analogue [11]: $a = 14.2875(4)$, $b = 14.5396(4)$,

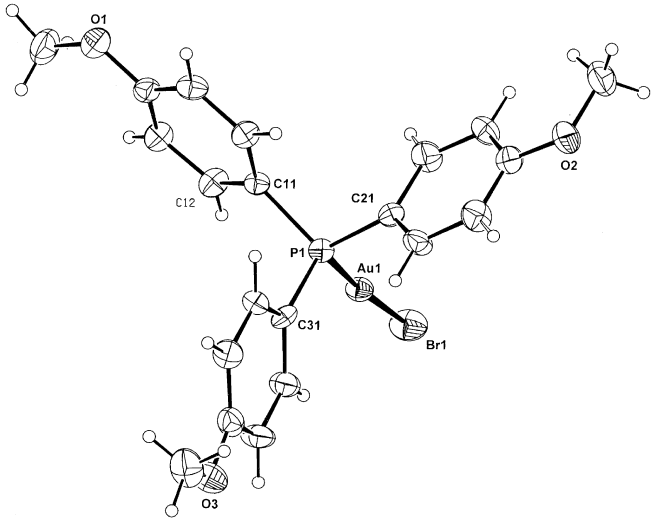

Fig. 5. Molecular configuration and naming scheme for the $[AuP(panis)_3Br]$ (**4**). Non-hydrogen atoms are drawn as 30% probability displacement ellipsoids.

$c = 20.2212(6)$ Å, $\beta = 101.504(1)°$, $Z = 8$; space group, $C2/c$} with one molecule in the asymmetric unit. This contrasts with the iodo analogue [AuP(panis)$_3$I] (**5**) which has two conformationally different molecules in the asymmetric unit, as indicated by the variation in the $\tau_1 - \tau_3$ values [−4°, 18°, 80(1)° (molecule 1) (Fig. 6a) and −38°, −21°, −43(1)° (molecule 2)] (Fig. 6b). These values compare with −29°, −62°, −3° for the Series B chloro complex [5] and −29.9(8)°, −62.7(8)° and −3.1(7)° for **4**. This variation is possible with the greater conformational freedom afforded by the absence of Au···O(*o*-methoxy) interactions cf. the *ortho*-anisyl-substituted phosphines.

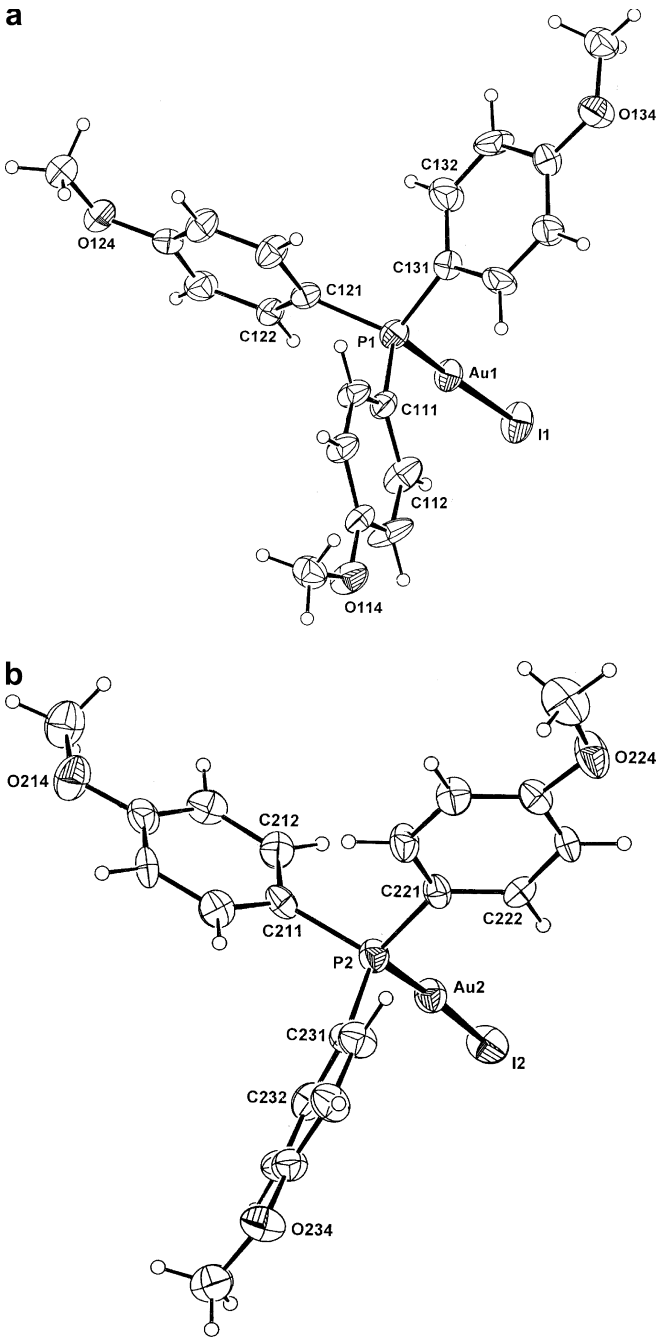

Fig. 6. The two conformationally different molecules of [AuP(panis)$_3$I] in the crystallographic asymmetric unit in **5**. (a) Molecule 1; (b) Molecule 2.

3.2. Solution NMR results

The solution $^{31}P\{^1H\}$ NMR spectra in $CDCl_3$ showed singlet peaks at 9.1, 12.6,19.1 ppm (Series A) and 32.2, 34.4, 38.9 ppm (Series B), respectively, which compare with 33.8, 34.6 and 38.4 ppm for the [P(Ph)$_3$] series of complexes (for X = Cl, Br, I, respectively) [1–3,6,17–19]. The corresponding coordination chemical shifts ($\Delta\delta = \delta$ complex $- \delta$ ligand), with the exception of that for **3** [38.1, 41.6, 48.1 ppm (Series A) and 39.4, 41.6, 45.7 ppm (Series B)] are similar to the [P(Ph)$_3$] complexes (38.5, 40.5, 43.1 ppm), respectively.

3.3. Conclusions

The presence of methoxy substituent groups in the triphenylphosphine molecule appears to have little influence on the nature of the gold(I) complex formed, but the presence of the *ortho*-methoxy substituent significantly affects the conformation of the phenyl rings, due to intramolecular methoxy-O···Au interactions. This is best seen with the isomorphous [AuP(oanis)$_3$Br] and [AuP(oanis)$_3$I] complexes where the rings adopt perfect C_3 symmetry. In addition the methoxy group appears to have less effect than the analogous methyl substituent group in triaryl phosphines upon the formation of crystals containing more than one independent complex molecule in the asymmetric unit. No short Au···Au interactions of the type found in [AuP(ptol)$_3$Cl] were expected or found in this series.

Abstract

Synthesis and characterization of a series of tin octabutoxy naphthalocyanines are presented, which show near infrared absorptions (900–930 nm) with high extinction coefficients (*ca.* 1×10^5 M^{-1} cm^{-1}). The position of the Q-band is more red-shifted with the heavier halogen, which corresponds to the HOMO–LUMO gaps calculated with density functional theory (0.932, 0.911, 0.905, 0.893 eV). The interaction with $SnNc(OBu)_8Br_2$ and C_{60} moves the Q-band further to the infrared region (928 nm). In ^{119}Sn NMR, the upfield shift (−120 ppm) of $SnNc(OBu)_8I_2$ represents a relatively electron-rich environment at the tin nucleus, and the ^{119}Sn-resonance (237 ppm) of $SnNc(OBu)_8F_2$ is different from the other halides, where ^{119}Sn–^{19}F coupling, a triplet splitting (1:2:1), was observed with 1820 Hz coupling constant. In the optimized structures obtained with BLYP, the distortion angles vary from F to I (N–Sn–N angles 178.8°, 173.1°). The tin naphthalocyanine with the heavy halide ligand becomes more concave, and the Sn–X bond is located at a longer distance out of ring. The difference of the two axial bonds varies significantly from 0.003 to 0.104 Å with the change of the axial ligands from F to I. The distorted shape is larger in the order I > Br > Cl > F with increase of the atomic size (1.33, 1.15, 0.99, 0.71 Å, respectively) and decrease of electronegativity (2.21, 2.74, 2.83, 4.10, respectively). $SnNc(OMe)_8X_2$ has an electric dipole moment perpendicular to the naphthalocyanine plane, and the magnitudes are, 0.81, 0.50, 0.35 and 0.01 for F, Cl, Br and I, respectively. The transition dipole moment lies in the naphthalocyanine plane along the *x*- or *y*-axis perpendicular to the permanent dipole moment in the *z*-axis, which indicates a $\pi \rightarrow \pi^*$ ligand–ligand transition. The energies of the molecular orbitals which are mainly contributed to by the naphthalocyanine ring, including the HOMO and LUMO, are slightly changed as the axial ligands change from F to I.

Keywords: Tin octabutoxy naphthalocyanine; Near infrared absorption; Q-band; Molecular orbitals

1. Introduction

Naphthalocyanines, extended conjugated macrocycles with high chemical and thermal stabilities, have been studied in many application areas for molecular electronics, non-linear optics, optical data storage, sensors, electrochromic devices, solar cells, electrocatalytic systems and photodynamic therapy [1–4]. As near infrared absorption (NIR) materials, napthalocyanine has chromophoric and low-band-gap properties, and the electronic structure of napthalocyanine can be tuned by the peripheral substitution of the ring, and the kind of central metal and axial ligands [5,6].

Our aim is to prepare a series of tin naphthalocyanine halides showing near infrared absorption and to understand their electronic and molecular structures.

2. Experimental

2.1. Materials

The tin halides (SnF_2, $SnCl_2 \cdot 2H_2O$, $SnBr_2$, SnI_2) and 1,4-dibutoxy-2,3-naphthalenedicarbonitrile were purchased

from Aldrich Chemical. Polystyrene beads used in gel permeation column chromatography were obtained from Bio-Rad Laboratories.

2.2. Spectroscopies

The electronic spectra were obtained with a UV–Vis–NIR spectrophotometer (JASCO). ^{1}H, ^{19}F, ^{119}Sn NMR spectra were recorded with Varian XL-200, Gemini 300 and Bruker MSL-400 spectrometers. The low- and high-resolution fast-atom-bombardment (LR FAB and HR FAB) mass spectra were obtained from either the Midwest Center for Mass Spectrometry (University of Nebraska-Lincoln, NE) or Washington University Resource for Biomedical and Bio-organic Mass Spectrometry. The elemental analyses were carried out by a commercial laboratory (Galbraith Laboratories, Knoxville, TN).

2.3. Calculation

Geometry optimizations of $SnNc(OMe)_8X_2$ (X = F, Cl, Br and I) were carried out without any symmetry constraints. We introduced a methoxy group instead of the butoxy group for relatively insignificant rotational conformations of the butoxy group. Our calculations were based on the density functional theory at the generalized gradient approximation level, BLYP functional [7]. Energy-adjusted relativistic effective core potentials were used for Br, I and the central Sn atom [8]. Double numerical plus polarization basis sets were used for the C, N, O, H, F, Cl atoms and the valence electrons for Br, I and Sn [9]. All calculations were performed using the DMOL^3 program [10]. In order to aid the interpretation of the absorption spectrum, spectroscopic calculations were performed at the BLYP-optimized geometries within the ZINDO approximation implemented in the VAMP program [11,12].

2.4. Synthesis

$H_2Nc(OBu)_8$. $H_2Nc(OBu)_8$ was prepared according to the literature [13].

$SnNc(OBu)_8F_2$. Under N_2, a mixture of $H_2Nc(OBu)_8$ (40 mg, 0.031 mmol), SnF_2 (220 mg, 1.40 mmol) and dry 2-ethylpyridine (5 mL) was refluxed for 100 min, cooled and evaporated to dryness with a rotary evaporator (~30 °C, ~1 Torr). The solid was chromatographed (Bio-Beads S-X4, 1.7 × 30 cm; toluene), dried (~60 Torr, ~60 °C) and weighed (12 mg, 0.0083 mmol, 27%). IR (Nujol): 558 (Sn–F) cm^{-1}. ^{1}H NMR (300 MHz, C_6D_6): δ 9.17 (m, 1,4-Nc H), 7.67 (m, 2,3-Nc H), 5.25 (t, α-CH_2), 2.30 (m, β-CH_2), 1.66 (m, γ-CH_2), 1.05 (t, CH_3). ^{13}C NMR (75 MHz, C_6D_6): δ 152.1 (s), 149.4 (s), 131.8 (s), 128 (s), 125.0 (s), 77.8 (s), 33.4 (s), 19.9 (s), 14.5 (s). ^{119}Sn NMR (75 MHz, C_6D_6): δ 237 J^1(Sn–F) = 1820.2 Hz (24.4 ppm). ^{19}F NMR (376 MHz, C_6D_6): δ −126. MS-FD, *m*/*z*: calc. for $C_{80}H_{88}N_8O_8F_2Sn$ $(M)^+$, 1446; found 1446. MS-HRFAB exact mass, *m*/*z*: calc. for $C_{80}H_{88}N_8O_8F_2Sn^{116}$ $(M)^+$, 1442.5711; found 1442.5713, 1442.5663. UV–Vis (λ_{max} (nm), ε ($M^{-1}\,cm^{-1}$)) (CH_2Cl_2): 906, 1.1×10^5. The compound is dark brown. It is soluble in CH_2Cl_2, toluene, and slightly soluble in hexane. It is insoluble in CH_3OH and H_2O.

$SnNc(OBu)_8Cl_2$. Under N_2, a mixture of $H_2Nc(OBu)_8$ (58 mg, 0.045 mmol) and $SnCl_2 \cdot 2H_2O$ (300 mg, 1.33 mmol) was refluxed in dry dimethylformamide (5 mL) for 4 h, cooled and evaporated to dryness with a rotary evaporator (~30 °C, ~1 Torr). The solid was extracted with toluene (5 mL), and the extract was evaporated to dryness with a rotary evaporator (~30 °C, ~1 Torr). The solid thus obtained was chromatographed (Bio-Beads S-X4, 1.5 × 20 cm; toluene), dried (~60 °C, ~60 Torr) and weighed (20 mg, 0.014 mmol, 31%). ^{1}H NMR (300 MHz, C_6D_6): δ 9.14 (m, 1,4-Nc H), 7.67 (m, 2,3-Nc H), 5.25 (t, α-CH_2), 2.24 (m, β-CH_2), 1.62 (m, γ-CH_2), 1.01 (t, CH_3). ^{13}C NMR (75 MHz, C_6D_6): δ 152.4 (s), 148.8 (s), 132.0 (s), 128 (s), 125.0 (s), 122.9 (s), 77.9 (s), 33.3 (s), 19.8 (s), 14.6 (s). ^{119}Sn NMR (75 MHz, C_6D_6): δ 266. MS-FD, *m*/*z*: calc. for $C_{80}H_{88}N_8O_8Cl_2Sn$ $(M)^+$, 1479; found 1478. MS-HRFAB exact mass, *m*/*z*: calc. for $C_{80}H_{88}N_8O_8Cl_2Sn^{116}$ $(M)^+$, 1474.5119; found 1474.5064, 1474.5087. UV–Vis (λ_{max} (nm), ε ($M^{-1}\,cm^{-1}$)) (CH_2Cl_2): 923, 1.0×10^5. The compound is dark brown. It is soluble in CH_2Cl_2, toluene, benzene, and slightly soluble in hexane. It is insoluble in CH_3OH and H_2O.

$SnNc(OBu)_8Br_2$. Under N_2, a mixture of $H_2Nc(OBu)_8$ (45 mg, 0.035 mmol), $SnBr_2$ (190 mg, 0.682 mmol), dry 2-ethylpyridine (0.3 mL) and dry xylenes (3 mL) was refluxed for 3 h, and evaporated to dryness with a rotary evaporator (~30 °C, ~1 Torr). The solid was extracted with toluene (5 mL), and the extract was evaporated to dryness with a rotary evaporator (~30 °C, ~1 Torr). The resulting solid was chromatographed (Bio-Beads S-X4, 1.5 × 20 cm; toluene), dried (~60 Torr, ~60 °C) and weighed (19 mg, 0.012 mmol, 34%). ^{1}H NMR (300 MHz, C_6D_6): δ 9.13 (m, 1,4-Nc H), 7.67 (m, 2,3-Nc H), 5.25 (t, α-CH_2), 2.21 (m, β-CH_2), 1.60 (m, γ-CH_2), 0.99 (t, CH_3). ^{13}C NMR (75 MHz, C_6D_6): δ 152.5 (s), 148.7 (s), 132.1 (s), 128 (s), 125.0 (s), 122.7 (s), 77.92 (s), 33.27 (s), 19.84 (s), 14.40 (s). ^{119}Sn NMR (75 MHz, C_6D_6): δ 142. MS-FD, *m*/*z*: calc. for $C_{80}H_{88}N_8O_8Br_2Sn$ $(M)^+$, 1568; found, 1568. MS-HRFAB exact mass, *m*/*z*: calc. for $C_{80}H_{88}N_8O_8Sn^{120}$ $(M-2Br)^+$, 1408.5747; found, 1408.5730, 1408.5748. UV–Vis (λ_{max} (nm), ε ($M^{-1}\,cm^{-1}$)) (CH_2Cl_2): 924, 1.2×10^5. The compound is dark brown. It is soluble in CH_2Cl_2, toluene, and slightly soluble in hexane. It is insoluble in CH_3OH and H_2O.

$SnNc(OBu)_8I_2$. Under N_2, a mixture composed of $H_2Nc(OBu)_8$ (50 mg, 0.039 mmol), SnI_2 (99.9%, 280 mg, 0.752 mmol), dry 2-ethylpyridine (0.3 mL) and xylenes (3 mL) was refluxed for 4 h, cooled and evaporated to dryness with a rotary evaporator (~30 °C, ~1 Torr). The solid was extracted with toluene (5 mL) and the extracted was evaporated to dryness with a rotary evaporator (~30 °C, ~1 Torr). The solid thus obtained was chromatographed

(Bio-Beads S-X4, 1.5 × 20 cm; toluene), dried (~60 °C, ~60 Torr) and weighed (36 mg, 0.022, 56%). ^{1}H NMR (300 MHz, C_6D_6): δ 9.12 (m, 1,4-Nc H), 7.67 (m, 2,3-Nc H), 5.27 (t, α-CH_2), 2.18 (m, β-CH_2), 1.56 (m, γ-CH_2), 0.96 (t, CH_3). ^{13}C NMR (75 MHz, C_6D_6): δ 52.6 (s), 148.7 (s), 131.2 (s), 128 (s), 125.1 (s), 122.5 (s), 78.2 (s), 33.2 (s), 19.8 (s), 14.4 (s). ^{119}Sn NMR (75 MHz, C_6D_6): δ-120. *Anal.* Calc. for $C_{80}H_{88}N_8O_8I_2Sn$: C, 57.80; H, 5.34; I, 15.27. Found: C, 57.43; H, 5.47; I, 15.37%. MS-FD, *m*/*z*: calc. for $C_{80}H_{88}N_8O_8I_2Sn$ $(M)^+$, 1662; found 1662. UV–Vis (λ_{max} (nm), ε (M^{-1} cm^{-1})) (CH_2Cl_2): 926, 1.0×10^5. The compound is dark brown. It is soluble in toluene, CH_2Cl_2, and slightly soluble in hexane. It is insoluble in CH_3OH and H_2O.

SnNc(OBu)$_8$(OSi(n-C$_6$H$_{13}$)$_3$)$_2$. Under N_2, a mixture composed of $SnNc(OBu)_8Br_2$ (30 mg, 0.019 mmol) and a mixture of $HOSi(n\text{-}C_6H_{13})_3$ (100 μL, 0.26 mmol), $NaOCH_3$ (10 mg, 0.19 mmol) and dry toluene (5 mL), which had previously been refluxed for 1 h, was refluxed for 2 h and evaporated to dryness with a rotary evaporator (~40 °C, ~1 Torr). The solid was washed with ethanol (50 mL), dried (~25 °C, ~60 Torr), chromatographed (Bio-Beads S-X4, 1.7 × 25 cm; toluene), dried (~60 °C, ~60 Torr) and weighed (22 mg, 0.011 mmol, 58%). M.p.: 156–8 °C. ^{1}H NMR (300 MHz, C_6D_6): δ 9.20 (m, 1,4-Nc H), 7.67 (m, 2,3-Nc H), 5.60 (t, C_4H_9 α-CH_2), 2.45 (m, C_4H_9 β-CH_2), 1.78 (m, C_4H_9 γ-CH_2), 1.11 (t, C_4H_9 CH_3), 0.67 (m, C_6H_{13} ε-CH_2), 0.41 (t, C_6H_{13} CH_3), 0.39 (m, C_6H_{13}γ- and δ-CH_2), −0.14 (m, C_6H_{13} β-CH_2), −1.11 (m, C_6H_{13}α-CH_2). The compound is dark brown. It is soluble in CH_2Cl_2, toluene and hexane. It is insoluble in CH_3OH and H_2O.

3. Results and discussion

3.1. Synthesis

The synthetic routes for the preparation of $SnNc(OBu)_8X_2$ (X = F, Cl, Br, I) were a template cyclization and a metal insertion. Lithium butoxide catalyzed and templated cyclization of 1,4-dibutoxy-2,3-napthalenedicarbonitrile, and the lithiated naphthalocyanine was converted to the metal-free naphthalocyanine in an acidic work-up step. The halo tin naphthalocyanines were obtained by reactions with the metal-free octabutoxy naphthalocyanine and the corresponding metal halides. Here, octabutoxy groups render good solubility in organic solvents such as toluene or dichloromethane. It is interesting that both SnX_2 and SnX_4 reacted well for tin insertion except SnF_4, and SnX_2 showed higher reactivity than SnX_4. The halide ligands can be exchanged by the highly soluble trihexylsiloxy. $SnNc(OBu)_8(OSiHx_3)_2$ was made by the ligand exchange reaction of $SnNc(OBu)_8Br_2$ and $NaOSiHx_3$ in toluene. The trihexylsiloxy ligands provide good solubility in non-polar solvents such as *n*-hexane, which is important in high concentration applications for recording disks.

3.2. NMR spectra

In the proton NMR resonances of $SnNc(OBu)_8X_2$ (X = F, Cl, Br, I, $OSi(n\text{-}C_6H_{13})_3$), the α- and β-methylene resonances of the butoxy groups are in the ranges δ 5.2–5.3 and 2.2–2.3 ppm, respectively, for the halides and δ 5.60 and 2.45 ppm for $OSi(n\text{-}C_6H_{13})_3$, as shown in Table 1. This suggests that the shieldings of α- and β-protons of the tin halo naphthalocyanines arising from ring-current effects are similar to one another, but are different from those of the trihexylsiloxy naphthalocyanine. ^{119}Sn NMR spectra, a very sensitive technique for determination of the coordination environment of the tin atom, are useful to study the structures of tin octabutoxy naphthalocyanine halides [14]. Of the 10 naturally occurring isotopes of tin, only ^{119}Sn (I = 1/2, 8.6% abundance) is a practical choice due to its slightly higher abundance and its greater sensitivity to NMR detection. ^{119}Sn NMR resonances of $SnNc(OBu)_8X_2$ are seen in Fig. 1. The trend in chemical shifts is not linear with respect to the electronegativity of the ligands. A downfield shift appears from F to Cl and then a linear upfield shift occurs from Cl to I. Simply explained, the ^{119}Sn chemical shifts would depend on the properties of the axial ligands and directly reflect the electron density at the tin nucleus. The upfield shifts of $SnNc(OBu)_8I_2$ represent a relative electron-rich environment at the tin nucleus. $SnNc(OBu)_8F_2$ exhibits a NMR spectrum different from the other halides. For the first-row element F the σ-bonding effect dominates, but for the other halides the π-bonding effect should be considered as well. These halides possess weak participation of Sn–X p_π–p_π bonding. The observed Sn–F coupling for $SnNc(OBu)_8F_2$, a triplet splitting (1:2:1), is 1820 Hz, which results from the ^{119}Sn–^{19}F *J* coupling. The ^{19}F NMR was taken to study the structure of $SnNc(OBu)_8F_2$, and $CFCl_3$ is used as the chemical shift reference [15]. A strong intense peak with two pairs of coupling peaks at −126 ppm was found. The two doublets correspond to ^{117}Sn and ^{119}Sn spin couplings to axial fluorines.

3.3. UV–Vis–NIR spectra

The tin octabutoxy naphthalocyanine halides have very strong bands in the near infrared region (>900 nm), as shown in Fig. 2. These bands are considerably red shifted as compared to the spectra of a simple naphthalocyanine

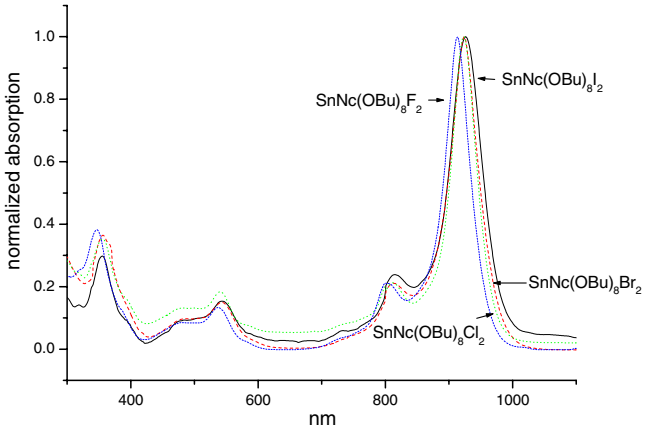

Fig. 2. UV–Vis spectra of $SnNc(OBu)_8X_2$ (X = F, Cl, Br, I).

(780 nm), octabutoxy naphthalocyanine (862 nm) or $PdNc(OBu)_8$ (892 nm). This result shows tin and halides (F, Cl, Br and I) can significantly influence the red shift of the Q-bands. The position of the Q-band in the series $SnNc(OBu)_8F_2$ (906 nm) to $SnNc(OBu)_8I_2$ (926 nm) is more shifted the heavier the halogen. The UV–Vis absorption data of a mixture of $SnNc(OBu)_8Br_2$ and C_{60} was obtained in CH_2Cl_2, as shown in Fig. 3. The extended aromatic surface of the naphthalocyanine will interact with C_{60} by π–π interactions. The Q band of $SnNc(OBu)_8Br_2$ was a little red-shifted to 928 nm (*ca.* 4 nm), and a peak at 330 nm appeared, partly attributed to C_{60}. The small red-shift would be the result of complexation of $SnNc(OBu)_8Br_2$ and C_{60}, lowering the π–π^* transition energy of the tin naphthalocyanine [16].

I	926	841.0	1388(0.893)

3.4. Theoretical calculation

For a better understanding the spectroscopic results, a theoretical calculation was carried out using density functional theory at the generalized gradient approximation level, BLYP functional. Geometry optimizations of $SnNc(OMe)_8X_2$ (X = F, Cl, Br and I) were carried out without any symmetry constraints. We introduced a methoxy group instead of the butoxy group for relatively insignificant rotational conformations of OC_4H_9. The direction of methoxy on naphthalocyanine changes the planarity of naphthalocyanine, and results in several isomers. In the most stable isomer, two adjacent methoxy groups are locate in opposite directions to each other to reduce steric repulsion. In the case where all eight methoxy groups are located on the same upside or downside of the naphthalocyanine plane, the isomers have higher energies than the most stable isomers by *ca.* 20 kcal/mol. The optimized structure of the most stable $SnNc(OMe)_8X_2$ is shown in Fig. 4, and the optimized bond lengths, distances and angles defined in the figure are compiled in Table 2. As two methoxy groups on an isobenzoindole moiety are located on the upside and downside of the naphthalocyanine plane, the four isobenzoindole moieties of naphthalocyanine spread outwards in a propeller-shaped distortion. The increase of steric repulsion between the oxygen lone pairs of the facing alkoxy ligands is thought to lead to the distortion. Two C_2–Sn–C_{20} and C_3–Sn–C_{21} angles represent the degree of both naphthalocyanine planarity and distortion of isobenzoindole.[1] From F to I, the distortion of isobenzoindole increases with a slight increase of the difference between the C_2–Sn–C_{20} and C_3–Sn–C_{21} angles, and the naphthalocyanine plane becomes more concave. The deformation of the naphthalocyanine plane is accompanied by a displacement of the Sn atom out of the plane. The side view in Fig. 4b shows that the Sn atom lies above the naphthalocyanine plane. The distance, h, is defined as the out-of-plane distance of the Sn atom from the center of the naphthalocyanine plane. As the axial ligands change from F to I, the distance h varies from 0.022 to 0.127 Å. The angle N–Sn–N defined as the average bond angle between the Sn and the N atoms, also indicates the out-of-plane nature of the Sn atom. As the N–Sn–N angles decrease from F to I, the naphthalocyanine ring becomes a deep saucer-shape. The distorted shape (Sn–N angle 178.8°, 175.9°, 175.0°, 173.1°) is larger in the order of I > Br > Cl > F, with increase of the atomic size (1.33, 1.15, 0.99, 0.71 Å, respectively) and decrease of electronegativity (2.21, 2.74, 2.83, 4.10, respectively).[2] The non-planarity of the naphthalocyanine generates the two different axial-bond lengths. The axial Sn–X bond located inside of the concave, elongates more than the other axial Sn–X bond. The difference of the two axial bonds varies significantly from 0.003 to 0.104 Å with the change of the axial ligands from F to I. $SnNc(OMe)_8X_2$ has an electric dipole moment perpendicular to the naphthalocyanine plane. The electric dipole moment of $SnNc(OMe)_8X_2$ points from the halide located on the inside of the concave to the central Sn atom along the z-axis, and the magnitudes are, 0.81, 0.50, 0.35 and 0.01 for F, Cl, Br and I, respectively. A strong electronegative halide shows a high magnitude of dipole moment and presents a permanent dipole moment along the z-axis which could be advantageously used to achieve molecular orientation and poling. In order to aid the interpretation of the absorption spectra, spectroscopic calculations were performed at the BLYP-optimized geometries within the ZINDO approximation implemented in the VAMP program [11,12]. The calculated absorption λ_{max} values are also listed in Table 3. The calculations have not taken the solution environment into account, which may affect the electronic transitions and geometry. Compared with the experimental data, the calculated λ_{max} values are red-shifted by about 85 nm under the average error of 9%. In spite of the λ_{max} difference, good qualitative agreement is found between the calculations and experiments. The HOMO and LUMO gap decreases from F to I. The HOMO and LUMO at the BLYP level of theory are depicted in Fig. 5. The HOMO, filled π-type orbital, has a highly symmetric flowerlike structure with a big hole at the Sn atom, and presents nodes at every nitrogen atom of the naphthalocyanine. The LUMO, an empty π^*-type orbital, was doubly degenerate with a twofold spatial

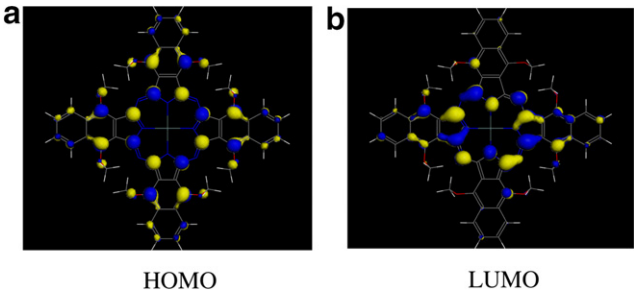

Fig. 5. The HOMO–LUMO at the BLYP level of theory (a) HOMO (b) LUMO.

symmetry. The LUMO + 1 has the same spatial structure but is rotated by 90° from the LUMO. The LUMO or LUMO + 1 consists mainly of π-orbitals, delocalized over the isobenzoindole moieties along the *x*- or *y*-axis. Disregarding the asymmetry introduced by the methoxy ligands, distortion and non-planarity, the symmetry of the HOMO and LUMO/LUMO + 1 are a_{2u} and e_g, respectively. The calculated absorption λ_{max} corresponds to the excitation from the HOMO(a_{1u}) to the LUMO or LUMO + 1(e_g). The transition dipole moment lies in the naphthalocyanine plane along the *x*- or *y*-axis, perpendicular to the permanent dipole moment in the *z*-axis, which also indicates λ_{max} results from a ligand–ligand transition ($\pi \rightarrow \pi^*$). The correlation diagram shows the molecular orbitals of $SnNc(OMe)_8X_2$ (X = F, Cl, Br and I) and their orbital energies in Fig. 6. The 4d subshell orbital of Sn is expected to be filled and is deep enough to form almost pure molecular orbitals. The overlap between the valence orbitals of Sn and the halogen ligands play a significant role in bonding, and the molecular orbitals mainly composed of the valence p orbitals of axial ligands are located under the HOMO. Moving down a column of the periodic table, valence s and p orbitals of halogen ligands are more extended with higher energy. The orbital energies of molecular orbitals mainly contributed from the valence p orbitals of axial ligands rise sharply as the axial ligands change from F to I. In the case of $SnNc(OMe)_8I_2$, the molecular orbitals mainly composed of p_x or p_y orbitals of the axial ligands are underneath the HOMO. The atomic charges on the axial ligands are expected to be distributed into the molecular orbital which is mainly composed of valence

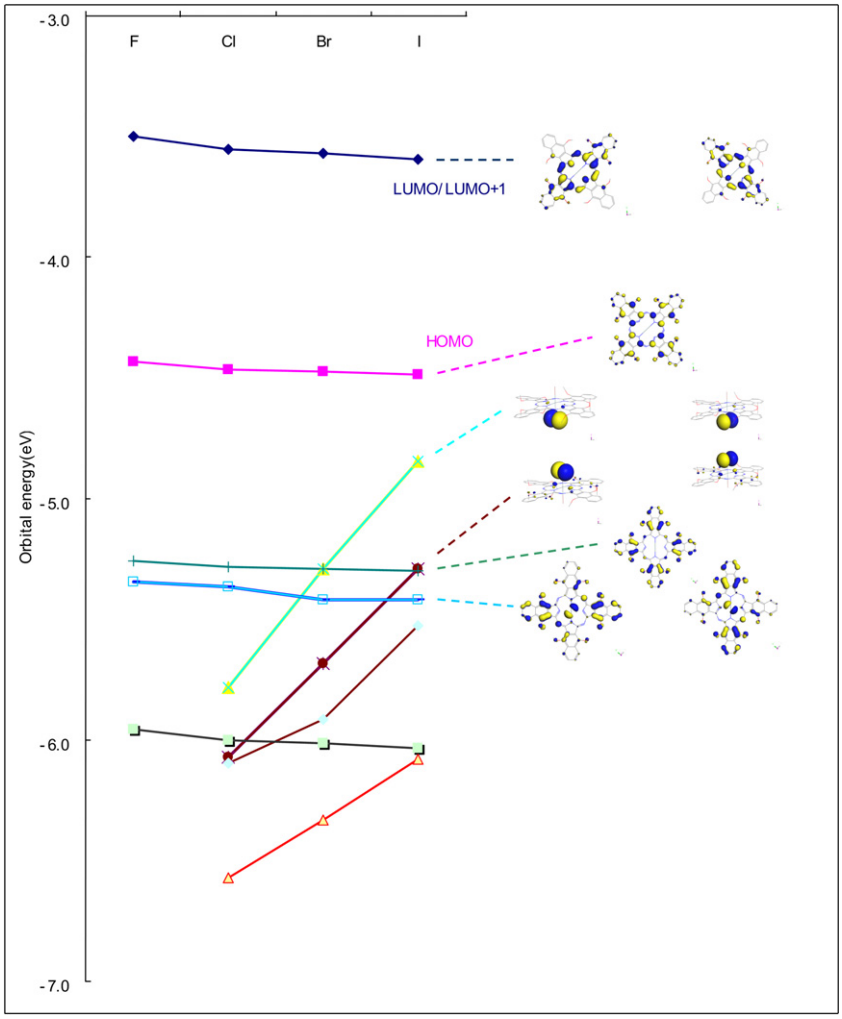

Fig. 6. The correlation diagram of the frontier molecular orbitals and their level ordering orbital energies for $SnNc(OBu)_8X_2$.

p_x and p_y orbitals. The bonding between Sn and the axial halogen ligands is described by the molecular orbitals whose main contribution is from the valence p_z orbitals of axial ligands and the Sn atom. As shown in Fig. 6, the energies of the molecular orbitals which are mainly contributed to by the naphthalocyanine ring, including the HOMO and LUMO, are slightly changed as the axial ligands change from F to I. As a result, the bonding between the Sn atom and the axial halogen ligands affects the structure of the naphthalocyanine ring and the shift of the Q-bands.

4. Conclusions

We have prepared and characterized a series of tin octabutoxy naphthalocyanines, which show near infrared absorption with a high extinction coefficient in the region 900–930 nm. The position of the Q-band in the series $SnNc(OBu)_8F_2$ (906 nm) to $SnNc(OBu)_8I_2$ (926 nm) is more red-shifted the heavier the halogen ligand. The tin naphthalocyanine with a heavy halide ligand becomes more concave, and the Sn–X bond is located at a longer distance out of the ring. The difference of the two axial bond lengths varies dramatically from 0.003 to 0.104 Å with the change of the axial ligands from F to I. The degree of the concave distortion is larger in the order $I > Br > Cl > F$, with the increase of atomic size and decrease of electronegativity. The transition dipole moment lies in the naphthalocyanine plane perpendicular to the permanent dipole moment in the tin–halide bond, which is related to the electronegativity of the axial halide. The energies of the molecular orbitals which are mainly contributed to by the naphthalocyanine ring, including the HOMO and LUMO, are slightly changed as the axial ligands change from F to I. As a result, the bonding between the Sn atom and the axial halogen ligands affects the structure of the naphthalocyanine ring and the shift of the Q-bands. The near-infrared absorption is further shifted to the infrared by the interaction with C_{60}. These tin halo naphthalocyanines could be a molecular engineering tool for spectral tuning in near infrared applications.

Abstract

The versatile coordination properties of the 2,2′ and 4,4′-long conjugated bidentate ligands 2,5-bis(2-pyridylethynyl)thiophene ($\mathbf{L_1}$), 2,2′-dipyridyldisulfide ($\mathbf{L_2}$) and 4,4′-dipyridyldisulfide ($\mathbf{L_3}$) with copper acetate has been investigated. Reactions with 2,5-bis(2-pyridylethynyl)thiophene ($\mathbf{L_1}$) and 4,4′-dipyridyldisulfide ($\mathbf{L_3}$) leads to two types of complexes. So, when methanol solutions of $Cu(OAc)_2 \cdot H_2O$ were allowed to diffuse into a solution of $\mathbf{L_1}$ or $\mathbf{L_3}$ (ratio 1:1), green crystals of the molecular 1:2 adduct $Cu_2(\mu\text{-}OAc)_4(L_1)_2$ (**1**) and the infinite coordination polymer $[Cu_2(\mu\text{-}OAc)_4(L_3)]_n$ (**2**) were obtained. The reaction with $\mathbf{L_2}$, under reflux in MeOH, affords the copper(I) cluster $Cu_6(SC_5H_4N)_6$ (**3**) and the dimer $[Cu(\mu\text{-}S)(L_2)]_2$ (**4**). Compound **3** was already known by reaction of the copper(I) salt $[Cu(NC\text{-}Me)_4]PF_6$ with SC_5H_4NH in acetone. The structures were determined by X-ray crystallography and their magnetic properties examined.

1. Introduction

Networks propagated through metal–ligand coordination bonds, known as coordination polymers or metal–organic frameworks (MOFs), comprise a large and diverse area of activity within inorganic crystal engineering [1]. In recent years, it has become an important area of research due to the growing need for novel solid-state architectures with potential applications in fields such as magnetism [2], catalysis and separation [3], non-linear optics [4] and molecular sensing [5].

The structures and properties of coordination polymers can be controlled by choosing appropriate bridging ligands and metal ions. In particular, much research has been concentrated on the use of bridging 4,4′-bipyridine based rodlike ligands [6] and bent ligands are relatively less used as building blocks due to the difficulty in predicting structure.

Previously, we have studied how the effect of the 2,2′-positional orientation of the nitrogen atoms in bis-pyridine-type ligands such as 1,2-bis(2-pyridyl)butadiyne, 2,5-bis(2-pyridylethynyl)thiophene (rigid ligands) and 2,2′-dipyridyldisulfide (flexible ligand) with $Cu(hfac)_2$ and $Cu(OAc)_2 \cdot H_2O$, influences on the coordination framework and to affects the polymeric architectures of the crystalline materials. Moreover, the reaction between $Cu(hfac)_2$ and 2,2′-dipyridyldisulfide showed new interesting transformations due to the reactivity and cleavage of S–S bond and formation of S–C bonds [7].

As a continuation of our research concerning the use of these kind of ligands in the synthesis of coordination polymers and to investigate the effect of the counterion upon these reactions, herein we report the synthesis, crystal

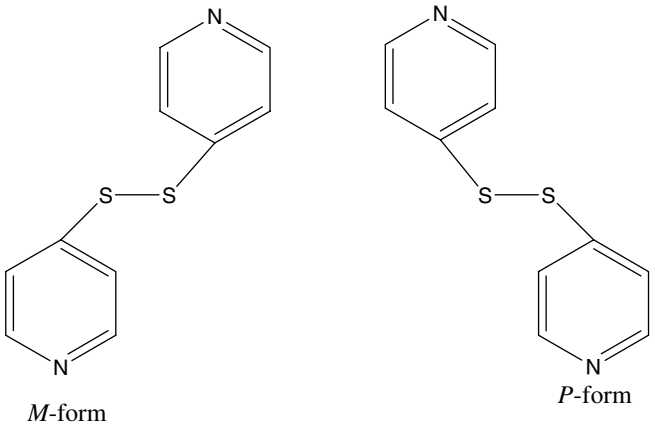

Fig. 1. Enantiomers forms of 4,4′-dipyridyldisulfide ($\mathbf{L_3}$).

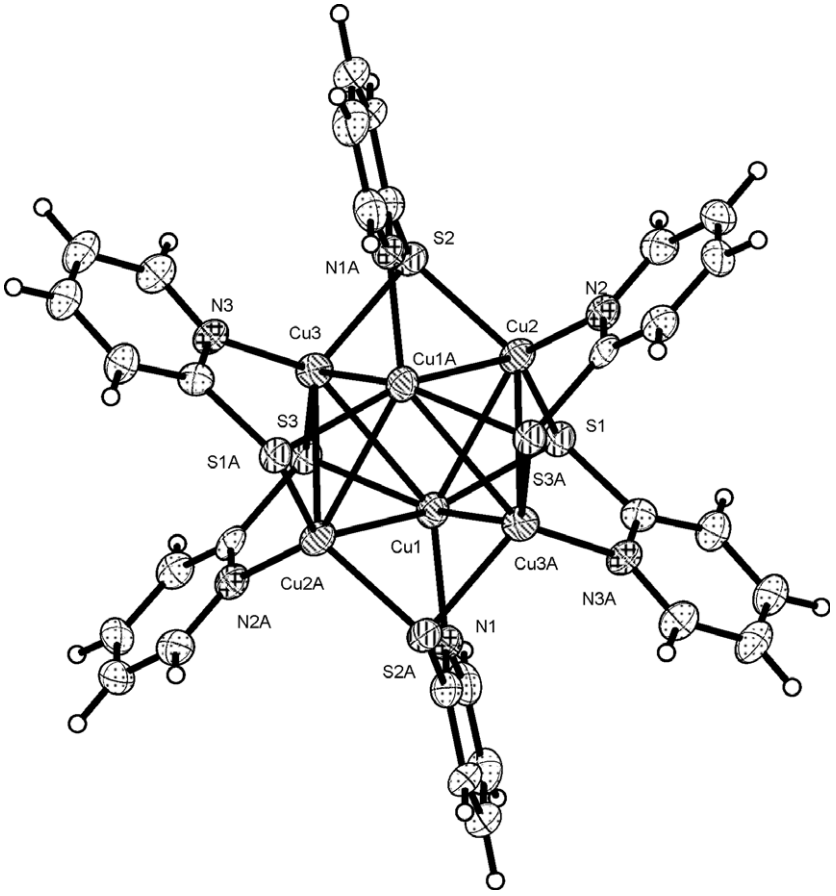
structures and magnetic properties of new Cu(II)-compounds prepared by reactions between $Cu(OAc)_2 \cdot H_2O$ and 2,5-bis(2-pyridylethynyl)thiophene ($\mathbf{L_1}$) and 2,2′-dipyridyldisulfide ($\mathbf{L_2}$). Further, in order to compare how affects the position of the nitrogen atoms in the pyridine rings upon complexation, we choose the 4,4′-dipyridyldisulfide ligand ($\mathbf{L_3}$), which has a twisted conformation similar to $\mathbf{L_2}$ because of the flexible –S–S– group, with its two C–S–S–C torsion angles of approximately 90°, and with axial chirality generating *M*- and *P*-enantiomers as shown in Fig. 1. A recent review of the structural diversity derived from 4,4′-dipyridyldisulfide ligand has been published [8].

2. Results and discussion

In our previous work, we found that the reaction between $Cu(OAc)_2 \cdot H_2O$ and 2,2′-dipyridyldisulfide in methanol at room temperature, in a 1:1 molar ratio, afford the molecular 1:2 adduct $[Cu_2(\mu\text{-}OAc)_4(L_2)_2]$ instead of the polymeric compound $[Cu_2(\mu\text{-}OAc)_4(L_2)]_n$ [7]. To investigate how the nature of the ligand could affects to assembly processes, we evaluated the dependence of the orientation of the ligands on the structures. Because of it, we choose a rigid ligand as 2,5-bis(2-pyridylethynyl)thiophene ($\mathbf{L_1}$), with the same orientation than 2,2′-dipyridyldisulfide ($\mathbf{L_2}$), and a flexible ligand, 4,4′-dipyridyldisulfide ($\mathbf{L_3}$), similar to $\mathbf{L_2}$ but with a different orientation.

So, when methanol solutions of $Cu(OAc)_2 \cdot H_2O$ were allowed to diffuse, at room temperature, into a solution of $\mathbf{L_1}$ in CH_2Cl_2 or $\mathbf{L_3}$ in MeOH (ratio 1:1), green crystals of the molecular 1:2 adduct $Cu_2(\mu\text{-}OAc)_4(L_1)_2$ (**1**) and the infinite coordination polymer $[Cu_2(\mu\text{-}OAc)_4(L_3)]_n$ (**2**) were obtained within 9 and 6 days, respectively. These results shown as the orientation of the ligands influences on the



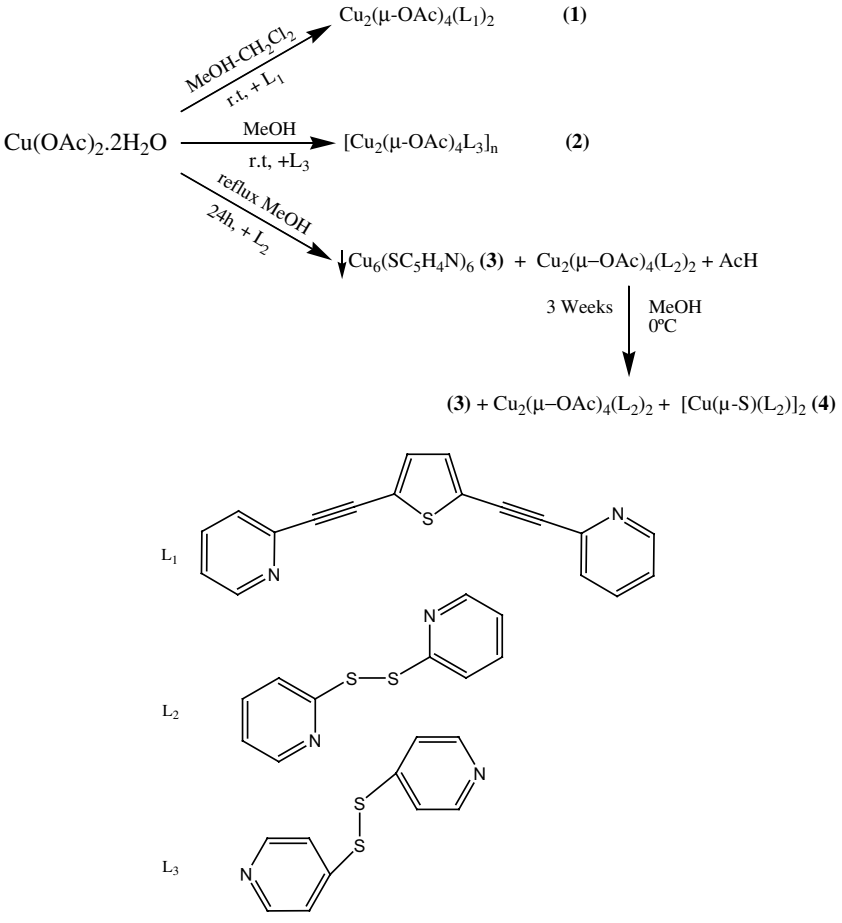


Fig. 2. ORTEP projection of the $Cu_6(SC_5H_4N)_6$ cluster, C and H atoms have no been labelled for clarity and displacement ellipsoids are shown at the 50% probability level.

self-assembly process. The dimeric compounds $[Cu_2(\mu\text{-}OAc)_4(L)_2]$ are obtained for $\mathbf{L_1}$ and $\mathbf{L_2}$, with 2,2′-orientation, probably due to steric factors, while the polymer $[Cu_2(\mu\text{-}OAc)_4(L_3)]_n$, is isolated for $\mathbf{L_3}$, with 4,4′-positions. While we were carrying out this study, a similar reaction between $Cu(OAc)_2 \cdot H_2O$ and $\mathbf{L_3}$, using also MeOH as solvent, was published. However, the product was recrystallized from DMF/diethyl ether giving $[Cu_4(OAc)_6(\mu_3\text{-}OH)_2(L_2)_2]_n$, with a ruffled ribbon topology [9]. These results demonstrate that not only the orientation of dipyridyl ligands but even also the recrystallizing solvent play important roles in the self-assembly processes.

On the other hand, we had previously observed in the reaction between 2,2′-dipyridyldisulfide and $Cu(hfac)_2$, under reflux in MeOH, the cleavage of the S–S bond in $\mathbf{L_2}$, giving new interesting transformations with formation of a zwitterionic organic compound and a mononuclear compound with Cu–C bond [7]. Likewise, the reaction with $Cu(NO_3)_2 \cdot 3H_2O$ in the same conditions, leads to an unexpected sulfinate–sulfonate mixed coordination polymer $[\{Cu(2\text{-}pySO_2)_2\}_n]$–$[\{Cu(2\text{-}pySO_3)_2\}_n]$ [10]. These observations led us to study in more detail the influence that the counteranions have on the cleavage of the S–S bond in $\mathbf{L_2}$.

When $Cu(OAc)_2 \cdot H_2O$ and $\mathbf{L_2}$ were allowed to react together under reflux in MeOH for one day, an orange solid readily precipitated and was isolated and characterized by X-ray diffraction as the copper(I) cluster $Cu_6(SC_5H_4N)_6$ (**3**) (Fig. 2). The structure of this compound was originally obtained by Kitagawa et al. [11], who prepared it by reaction of the copper(I) salt $[Cu(NCMe)_4]PF_6$ with SC_5H_4NH in acetone. In our reaction the green solution is slightly acid and has the characteristic odour of acetic acid. The IR spectrum shows a band at 1624 cm^{-1} attributable to ν(CO) of acetic acid. If the green solution is rapidly extracted to vacuum, only the dimer $[Cu_2(\mu\text{-}OAc)_4(L_2)_2]$ is isolated, but by standing of the solution at 0 °C for at least 3 weeks, the red compound $[Cu(\mu\text{-}S)(L_2)]_2$ (**4**) is isolated in a very low yield (4%) together with $Cu_6(SC_5H_4N)_6$ (**3**) and $[Cu_2(\mu\text{-}OAc)_4(L_2)_2]$ (Scheme 1).

One possible mechanism that could explain the formation of **3** and **4** involves the cleavage of the S–S bond in the $\mathbf{L_2}$ ligand, probably promoted by the Cu^{II} ion. It is known how the disulfide bond in R–S–S–R systems is broken by metal ions [12]. The nucleophilic attack by water gives pyridine-2-thiol, in tautomeric equilibrium with pyridine-2(1*H*)-thione [12,13], which produces the in situ reduction of copper(II) to copper(I) yielding the highly insoluble S,N-coordinated hexamer **3**, very stable termodynamically. The reaction of SC_5H_4NH with $Cu(OAc)_2 \cdot H_2O$

Scheme 1.

gives the same compound [14]. In order to test whether acetic acid plays a role in the formation of **3**, we have repeated the reaction in the same conditions, in the presence of acetic acid. We observe that the decomposition progress to **3** is retarded, due to the fact that in acidic conditions the nitrogen atom of the SC_5H_4NH ligand is protonated, preventing the involvement of the nitrogen atom in coordination.

The formation of **4** could be explained by carbon–sulfur bond cleavage of some thiolates; this processes constitute a classical route to obtain metal sulfides [15–18] and re-forming some disulfide as results of oxidation of pyridine-2-thiol.

All compounds have been characterized by analytical and IR spectroscopy data. Details are given in Section 5.

3. Description of the crystal structures

3.1. $[Cu_2(\mu\text{-}OAc)_4(L_1)_2]$ (**1**)

Fig. 3a shows the ORTEP drawing of the asymmetric unit of **1**, with the numbering scheme. Table 1 sums up its most important crystallographic data, and selected bond lengths and angles are summarized in Table 2. The structure consists of the molecular 1:2 adduct $Cu_2(\mu\text{-}OAc)_4(L_1)_2$ where the copper(II) ion is pentacoordinate to four oxygen atoms from four different acetate anions and one nitrogen atom from the pyridine ring of $\mathbf{L_1}$, in a square-based pyramidal fashion. The Cu(II) center deviates from the mean equatorial plane, defined by four coordinated oxygen atoms, towards the apical nitrogen atom by 0.207 Å, which is slightly longer than the same deviation of 0.1536 Å in the $[Cu_2(\mu\text{-}OAc)_4(L)_2]$ (L = 2,2′-dipyridyldisulfide) compound [7]. The Cu–O distances [1.9683(17)–1.9854(16) Å] are similar to those found in its analogous compounds [7,19,20] and the Cu–N distance [2.207(2) Å] is longer than the same distance for the polymer $[Cu(hfac)_2L_1]_n$ [2.0379(16) Å] and similar to the one for the dimer $[Cu_2(\mu\text{-}OAc)_4(L_2)_2]$ [2.252(3) Å] [7]. Four acetate anions bridge two Cu(II) center in *syn–syn* fashion to form a $[Cu_2(OAc)_4]$ binuclear building unit (Fig. 3b) with a Cu–Cu distance of 2.6528(6) Å, which is linked

by two $\mathbf{L_1}$ ligands in a *trans* disposition. The pyridyl groups of the $\mathbf{L_1}$ are not coplanar through the diyne portion and forming an angle of 79.35°. Two pyridyl rings within each $\mathbf{L_1}$ ligand are in a *cisoid* arrangement. This orientation leads to steric factors that could explain why the molecular compound $[Cu_2(\mu\text{-}OAc)_4(L_1)_2]$ (**1**) is formed instead of the polymeric complex $[Cu_2(\mu\text{-}OAc)_4(L_1)]_n$.

3.2. $[Cu_2(\mu\text{-}OAc)_4(L_3)]_n$ (**2**)

Fig. 4a shows an ORTEP drawing of the asymmetric unit of compound **2**. Apposed to **1**, compound **2** adopts a zig-zag chain structure, as it is shown in Fig. 4b. The crystallographic data are given in Table 1, while selected bond lengths and angles are listed in Table 3. As in **1**, for compound **2** the copper atom has a square-pyramid geometry with Cu–O bond

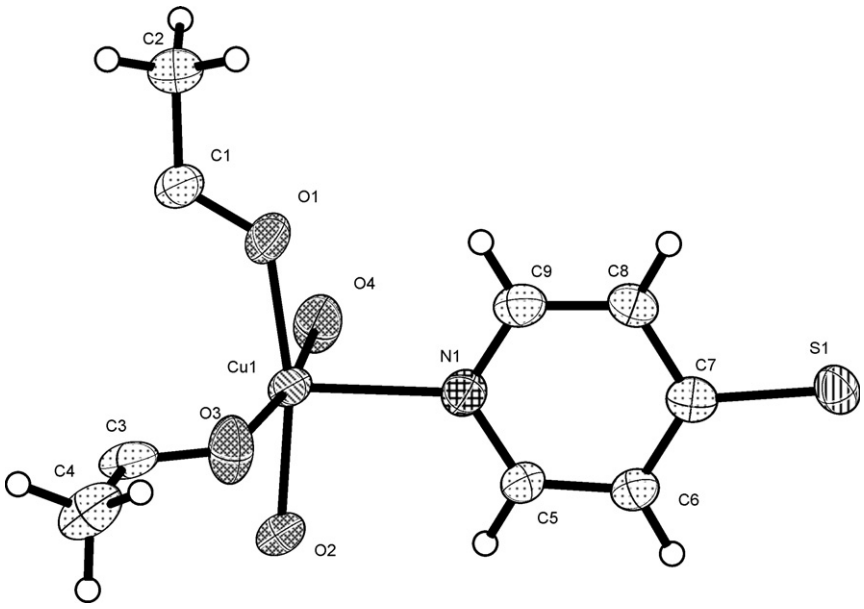

Fig. 4a. An ORTEP projection of the asymmetric unit of compound $[Cu_2(\mu\text{-}OAc)(L_3)]_n$ with displacement ellipsoids shown at the 50% probability level.

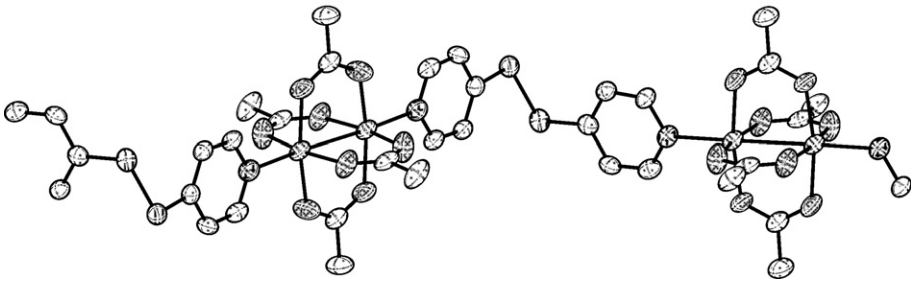

Fig. 4b. One of the zig-zag chains of compound **2**.

lengths very close to those found in compound **1** and Cu–N and Cu–Cu distances [2.162(4), 2.6088(14) Å] shorter than their equivalents found in **1** [2.207(2), 2.6528(6) Å], respectively. The $\mathbf{L_3}$ ligand supports its characteristic twisted conformation. The S–S distance [2.024(3) Å] and C–S–S–C torsion angles (89.59°) are comparable to those found in $[M(hfac)_2(\mathbf{L_3})]_n$(M = Cu,Mn,Co,Ni)and$[\{Cu(\mathbf{L_2})(H_2O)\} \cdot 2NO_3 \cdot 3H_2O]_n$ [21,22], and the angle between the two pyridine rings in each $\mathbf{L_3}$ ligand is 79.25°. Compared to the analogous structure which contains the 2,2′-dipyridyldisulfide ligand, the Cu–N distances [2.161(5) Å] is shorter than the same distance for $[Cu_2(\mu\text{-}OAc)_4(2,2'\text{-}dpds)_2]$ [2.252(3) Å] [7]. The polymer contains racemic components of $\mathbf{L_3}$ and chiral crystals of the coordination polymer have not been isolated.

3.3. *[Cu(μ-S)(L2)]2 (4)*

The crystallographic data for this compound are given in Table 1. Selected bond lengths and angles are listed in Table 4. Fig. 5a shows an ORTEP drawing of the asymetric unit of **4**. This is a molecular compound built up from two units $Cu(L_2)$ that are linked together by two μ-S atoms. In this case the copper center has a quasi-tetrahedral environment. Two positions of this tetrahedron are occupied by two nitrogen atoms from two pyridyl rings of $\mathbf{L_2}$ and at the other two positions two μ-S atoms are located. The first interactions result in the formation of a seven-membered chelate ring. The Cu–N distance [2.0170(2) and 1.9840(2) Å] are shorter than the same distances found for the polymer $[Cu(hfac)_2L_1]_n$ [2.0379(16) Å] and for the dimer $[Cu_2(\mu\text{-}OAc)_4(L_2)_2]$ [2.2520(3) Å] [7]. This binuclear building unit is shown in Fig. 5b, with a Cu–Cu distance of 3.1660(3) Å. The pyridyl groups of the $\mathbf{L_1}$ are not coplanar through the S–S bond, and form an angle of 138.8°. The S–S distance [2.0491(5) Å] is comparable to those found in $[M(hfac)_2(\mathbf{L_3})]_n$ (M = Cu, Mn,Co,Ni) and $[\{Cu(\mathbf{L_2})(H_2O)\} \cdot 2NO_3 \cdot 3H_2O]_n$ [21,22] whereas the C–S–S–C torsion angle (102.5°) is bigger than the others found for those compounds and shorter than the same angle for $[CuBr_2(L_2)]$ (108.9°) [23].

In Table 5 are summarized significant structural data for **2**, **4** and analogous Cu(II) complexes. From the values observed we can see that both $\mathbf{L_2}$ as $\mathbf{L_3}$ ligands support their characteristic twisted conformation and despite the rigidity of the S–S– bridging groups in $\mathbf{L_2}$ and $\mathbf{L_3}$, its compounds show various structures when assembled. The (S–S) bond lengths in all compounds present values very close to the typical values found in aromatic disulfides [24],

regardless of the metal species, coordination environment and counter anion, with exception of $[CuBr_2L_2]$ and $[Cu(\mu\text{-}S)(L_2)]_2$ (**4**), with longer distances and in which the 2,2′-dipyridyldisulfide ligand forms a seven-membered chelate ring. The same effect is observed if we compare the C–S–S–C torsion angle, maintaining a near 90° angle. However, $[CuBr_2L_2]$ and $[Cu(\mu\text{-}S)(L_2)]_2$ (**4**) are exhibiting angles significantly larger than 90°.

3.4. Magnetic properties

For complexes **1** and **2** the magnetic susceptibility curves show broad maximum from 330 to 125 K in both cases indicating a very strong antiferromagnetic interactions between the Cu(II) atoms of each dimetallic unit. At very low temperature, there is a very sharp increase of the magnetic susceptibility values indicating the presence of a paramagnetic impurity. Similar paramagnetic impurities are usually present in complexes with strong antiferromagnetic coupling. The temperature dependence of the magnetic moment towards temperature is also indicative of this antiferromagnetic coupling. Thus, the magnetic moment of **1** and **2** at room temperature are 1.65 and 1.82 μ_B, respectively. These magnetic moments are smaller than that expected for two magnetically isolated spin $S = 1/2$ centers per dicopper unit. The shape of the magnetic moment

L_2 = 2,2′-dipyridyldisulfide; L_3 = 4,4′-dipyridyldisulfide.

curves shows a pronounced decrease until 100 K and drops more slowly to 0.5 μ_B at 2 K in both complexes. The magnetic data of these compounds have been analysed [25] by a Bleaney–Bowers expression derived from the isotropic spin Hamiltonian of Eq. (1) with $S_1 = S_2 = 1/2$:

$$H = -JS_1S_2. \tag{1}$$

Terms corresponding to a paramagnetic impurity (P) and temperature independent paramagnetism (TIP) have been added [Eq. (2)]. N, g, β, k, and T have the usual meaning and P is the molar fraction of the non-coupled paramagnetic impurity. In this expression it is assumed that the paramagnetic impurity follows the Curie law and has the same molecular weight and the same g value as the respective complex:

$$\chi_M = \{2Ng^2\beta^2/kT[3 + \exp(-J/kT)] + \mathrm{TIP}\}(1 - P) + (Ng^2\beta^2/2kT)P. \tag{2}$$

A very good agreement between the experimental and calculated curves of the magnetic moment and the molar susceptibility for both complexes was observed with this model. The parameters obtained in these fits are collected in Table 6. Although in complex **1** the g value is slightly low (the value in Cu(II) complexes is usually greater than 2) and the TIP parameter is also low ($<10^{-5}$), the J value is consistent with those observed in analogous complexes and with the shape of the magnetic susceptibility curve. The large J value of -376 and $-363\ cm^{-1}$ for **1** and **2**, respectively, indicates very strong antiferromagnetic coupling between the Cu(II) centers of each dicopper unit. These coupling constants are in good agreement with those observed in other tetracarboxylatodicopper(II) complexes [7,25–28]. This interaction is probably produced through the carboxylate groups due to the large Cu–Cu distance as has been pointed out [28] in similar compounds. The other magnetic parameters are also analogous to described previously in others dicopper(II) compounds. Fig. 6 shows the experimental and calculated curves for complex **2**. Similar curves have been obtained for complex **1**.

3.5. Thermal properties

The thermal properties of compounds were examined by thermal gravimetric analysis (TGA/DTA) and differential scanning calorimetry (DSC). Compounds **1**–**4** were heated to 600 °C in a nitrogen atmosphere. TGA data suggest that the framework of **1** is stable up to 120 °C and shows a weight loss of 6.45% (calculated 6.30%) from 120 to 178 °C corresponding to the loss of one acetate ligand *per* formula unit. In the range 178–325 °C undergoes one weight loss step corresponding to remaining three acetate ligands (obsd. 18.6%, calcd. 18.9%) and in the range 325–500 °C the lost of one 2,5-bis(2-pyridylethynyl)thiophene ligand, $\mathbf{L_1}$ is observed (obsd. 30.36%, calcd. 30.66%). Above 500 °C, the weight loss observed is assigned to CuO (obsd. 8.82%, calcd. 8.50%). This behaviour is very similar that observed for 1D dimensional polymer [Cu(hfac)$_2$L$_1$]$_n$ [7].

The TG curve of **2** shows it is stable up to 195 °C; in the range 195–248 °C a sharp weight loss attributed to 4,4′-dipyridyldisulfide ($\mathbf{L_3}$) is observed (obsd. 38.20%, calcd. 37.75%) and between 248 and 310 °C, the weight loss is believed to be due to the loss of two acetate ligands (obsd. 21.70%, calcd. 20.22%).

Compound **3** is stable up to 385 °C. Above this temperature, weight loss attributed to six SC_5H_4N units is observed (obsd. 64.3%, calcd. 63.33%).

Compound **4** is stable up to 185 °C, in the 185–385 °C range, loss two 2,2′-dipyridyldisulfide ($\mathbf{L_2}$) ligands is observed (obsd. 67.98.3%, calcd. 69.74%). Above 400 °C, weight loss is also observed (9.4%) and is attributed to CuO (calcd. 9.52%). DSC analysis of hermetically sealed samples display sharp endothermic peaks at 137.0 °C which corresponds to the melting point.

Table 6
Magnetic parameters for complexes **1** and **2** obtained in the fits to the magnetic moment as a function of temperature

Compound	g	J (cm^{-1})	TIP (mL/mol)	P (%)	σ^{2a}
1	2.00	−376	3.5×10^{-9}	5.9	3.4×10^{-4}
2	2.07	−363	1.4×10^{-4}	1.99	1.12×10^{-4}

[a] $\sigma^2 = \sum(\mu_{\text{eff.calc.}} - \mu_{\text{eff. exp.}})^2 / \sum \mu^2_{\text{eff. exp.}}$.

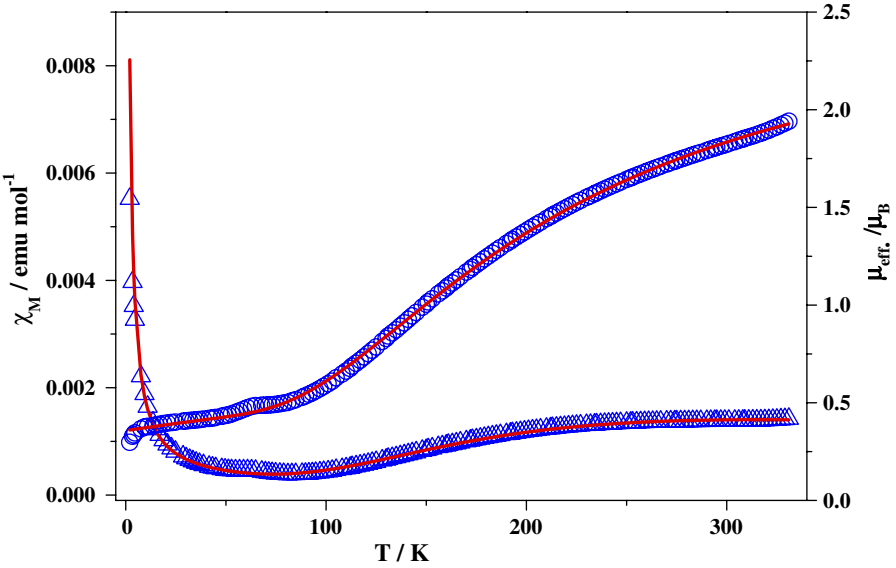

Fig. 6. Temperature dependence of the molar magnetic susceptibility χ_M (△) and μ_{eff} (○) for **2**. Solid lines result from least-squares fits using the model described in the text.

4. Conclusions

We have carried out a systematic study of chemistry of copper(II) salts with angular and linear dipyridyl ligands. The reactions with 2,5-bis(2-pyridylethynyl)thiophene (**L_1**) and 2,2′-dipyridyldisulfide (**L_2**) and copper acetate give the dimers $[Cu_2(\mu\text{-}OAc)_4(L)_2]$ whereas we had previously observed that the same reactions using $Cu(hfac)_2$ gave the one-dimensional polymers $[Cu(hfac)_2L]_n$. Likewise, the reaction with 4,4′-dipyridyldisulfide (**L_3**) gives the one-dimensional ziz-zag polymer $[Cu_2(\mu\text{-}OAc)_4(L_3)]_n$ (**2**) instead the one-dimensional helical chain structure obtained with $Cu(hfac)_2$. It is worth emphasizing that in the case of **2**, the **L_3** ligand chirality is independent of supramolecular topology, because both chiral and achiral combinations of the ligand can produce similar supramolecular structure.

Finally, the reactivity with the 2,2′-dipyridyldisulfide ligand shows varied and interesting coordination chemistry as consequence of cleavage of S–S and C–S bonds, giving the Cu(I) known cluster $Cu_6(SC_5H_4N)_6$ (**3**) and the dimer $[Cu(\mu\text{-}S)(L_2)]_2$ (**4**).

5. Experimental

5.1. General

All the solvents were of reagent grade quality and were used as received. 2,5-dibromothiophene (Aldrich), 2-ethynylpyridine (Aldrich), $PdCl_2$ (Aldrich), CuI (Aldrich) and $Cu(OAc)_2 \cdot H_2O$ (Aldrich), 2,2′-dipyridyldisulfide (**L_2**) and 4,4′-dipyridyldisulfide (**L_3**) (Lancaster) were used as received. Et_3N (Fluka) was distilled from KOH immediately before use. $Pd(PPh_3)_4$ [29] and **L_1** ligand [7] were prepared according to the literature procedure. Infrared spectra were measured on a Perkin–Elmer 1650 infrared spectrometer. Elemental analysis were performed by the Microanalytical of the University Autónoma of Madrid on a Perkin-Elemer 240 B microanalyzer. Single-crystal X-ray diffraction experiments were performed with samples mounted on a glass fiber and transferred to a Bruker SMART 6K CCD area-detector three-circle diffractometer with a Rigaku Rotating Anode (Cu Kα radiation, $\lambda = 1.54178$ Å) generator equipped with Goebel mirrors at settings of 50 kV and 100 mA. X-ray data were collected at 100 K, with a combination of six runs at different φ and 2θ angles, 3600 frames. The data were collected using 0.3° wide ω scans with a crystal-to-detector distance of 4.0 cm.

The substantial redundancy in data allows empirical absorption corrections (SADABS) to be applied using multiple measurements of symmetry-equivalent reflections [30].

The raw intensity data frames were integrated with the SAINT program, which also applied corrections for Lorentz and polarization effects [31].

The software package SHELXTL version 6.10 was used for space group determination, structure solution and refinement [32]. The space group determination was based on a check of the Laue symmetry and systematic absences and was confirmed using the structure solution. The structures were solved by direct methods (SHELXS-97), completed with difference Fourier syntheses, and refined with full-matrix least-squares using SHELXL-97 minimizing $w(F_o^2 - F_c^2)^2$. Weighted R factors (R_w) and all goodness of fit S are based on F^2; conventional R factors (R) are based on F. All scattering factors and anomalous dispersions factors are contained in the SHELXTL-6.10 program library. Table 1 contains crystal data for complexes **1**, **2** and **4**.

The variable-temperature magnetic susceptibilities were measured on polycrystalline samples with a Quantum Design MPMSXL SQUID (Superconducting Quantum Interference Device) susceptometer over a temperature range of 2–330 K at the constant field of 1 T (Complutense University of Madrid). All data were corrected for the diamagnetic contribution of both the sample holder and the compound to the susceptibility. The molar diamagnetic corrections for the complexes were calculated based on Pascal's constants.

5.2. Synthesis of $[Cu_2(\mu\text{-}OAc)_4(L_1)_2]$ (1)

A solution of $Cu(OAc)_2 \cdot H_2O$ (35 mg, 0.17 mmol) in MeOH (12 mL) was added to a solution of **L_1** (50 mg, 0.17 mmol) in CH_2Cl_2 (6 mL). The solution was left nine days at room temperature and green solid appeared. After recrystallization in CH_2Cl_2:MeOH (2:1) green crystals were isolated in a yield of 85% (153.3 mg). Mp: 240 °C. IR (KBr, cm^{-1}): 3053 (w), 2211 (s), 1617 (vs), 1590 (vs), 1559 (s), 1530 (m), 1482 (m), 1464 (vs), 1426 (vs), 1343 (w), 1286 (w), 1150 (w), 1046 (s), 1005 (s), 807 (s), 769 (vs), 736 (s), 678 (vs), 624 (s). *Anal.* Calc. for $C_{44}H_{32}Cu_2N_4O_8S_2$ (935.94 g/mol): C, 56.4; H, 3.4; N, 6.0, S, 6.8. Found: C, 56,3; H, 3,5; N, 6,1; S, 6,9%.

5.3. Synthesis of $[Cu_2(\mu\text{-}OAc)_4(L_3)]_n$ (2)

A solution of $Cu(OAc)_2 \cdot H_2O$ (45.4 mg, 0.23 mmol) in MeOH (16 mL) was layered onto a solution of 4,4′-dpds (50 mg, 0.23 mmol) in the same solvent (10 mL). Pale-green crystals were isolated when the solution was allowed to stand at room temperature for 2 days (65.6 mg, 90% yield). Mp: 225 °C (d). IR (KBr, cm^{-1}): 3055 (w), 1623 (vs), 1584 (vs), 1545 (m), 1482 (m), 1430 (vs), 1348 (w), 1221(w), 1064 (m), 1015 (m), 818 (m), 708 (s), 683 (vs), 629 (m), 501 (m). *Anal.* Calc. for $C_9H_{10}CuNO_4S$ (291.78 g/mol): C, 37.0; H, 3.4; N, 4.8; S, 11.0. Found: C, 37.2; H, 3.5; N, 4.7; S, 10.9%.

5.4. Synthesis of $[Cu(NC_5H_4N)]_6$ (3) and $[Cu(\mu\text{-}S)(L_2)]_2$ (4)

A solution of $Cu(OAc)_2 \cdot H_2O$ (272.3 mg, 1.36 mmol) in MeOH (30 mL) was added to a solution of L_2 (300 mg, 1.36 mmol) in the same solvent (15 mL). The resulting solution was heated to boiling and an orange solid was obtained. After 24 h, the green solution was filtered off,

the orange solid was isolated and characterized as the already known $[Cu(NC_5H_4N)]_6$ (**3**) (400 mg, 25% yield) and the solution was allowed to stand at 0 °C for 3 weeks. Red crystals were isolated in low yield (34.40 mg, 4%) and were identified as $[Cu(\mu\text{-}S)(L_2)]_2$ (**4**) together with $Cu_6(SC_5H_4N)_6$ (**3**) (240 mg, 15% yield) and the dimeric compound $[Cu_2(\mu\text{-}OAc)_4(L_2)_2]$ (129 mg, 15%). This last compound had previously been isolated and characterized as the only product when the reaction had been carried out at room temperature [7].

Compound **4**: IR (KBr, cm^{-1}): 3052 (w), 1575 (s), 1555 (s), 1455 (s), 1446 (vs), 1419 (vs), 1113 (m), 1087 (w), 1047 (m), 1007 (w), 785 (w), 762 (vs), 714 (w). *Anal*. Calc. for $C_{20}H_{16}Cu_2N_4S_6$ (631.81 g/mol): C, 38.0; H, 2.5; N, 8.9; S, 30.4. Found: C, 38.1; H, 2.6; N, 9.0; S, 30.3%.

Abstract

Five new interesting transition metal coordination polymers $[MnL_2(bpy)_2(H_2O)_2]_n$ (**1**) (H_2L = 4-carboxymethylbenzoic acid) (bpy = 4,4′-bipyidine), $[CoL(bpy)(H_2O)_3 \cdot H_2O]_n$ (**2**), $[CdL(bpy)(H_2O)_3 \cdot H_2O]_n$ (**3**), $[Cu_2L(bpy)_2 \cdot 3H_2O]_n$ (**4**) and $[Zn_2L_2(bpy) \cdot H_2O]_n$ (**5**) have been synthesized under solvothermal conditions and structurally characterized. This series of complexes has shown an intriguing variety of architectures, which firstly form zero- to two-dimensional frameworks by metal–ligand interactions, and secondly form three-dimensional supramolecular frameworks by intermolecular interactions such as hydrogen bonds. Compound **3** shows strong blue fluorescent emissions in the solid state upon photo-excitation at 359 nm at room temperature and may be an excellent candidate for blue-fluorescent materials. Compound **4** appears to be a good candidate for new hybrid inorganic–organic NLO materials.

1. Introduction

Recently, the area of coordination polymers has become one of intense research activity not only because of the enormous variety of interesting structural topologies [1–4], but also because of the potential applications as functional materials, for example, in electrical, conductivity, magnetism, host–guest chemistry, ion exchange, catalysis, nanotechnology, fluorescence and non-linear optics [5–11]. By utilizing polyatomic organic ligands as linkers and the well-defined coordination geometries of metal centers as nodes, a series of architectures are produced [12–14]. Metal–ligand interactions and intermolecular interactions such as hydrogen bonds, π–π stacking interactions are the two main strategies in the crystal engineering. Various flexible carboxylate ligands can often be employed due to their versatile coordination modes and high structural stability [15]. In particular, multibenzenecarboxylate ligands have been shown to be good building blocks in the design of metal-organic materials [16–20]. For example, 1,4-benzenedicarboxylic acid has been widely researched because it has a H-bonding site, aromatic π cloud and metal coordination site [21–24]. However, the unsymmetrical benzenedicarboxylate has seldom been investigated. Only 2-carboxymethylbenzoic acid and 3-carboxymethylbenzoic acid have been researched in the literature [25,26]. 4-Carboxymethylbenzoic acid, compared with 1,4-benzenedicarboxylic acid, has 'CH_2' added and its flexibility has been modified. Coordination polymers constructed from 4-carboxymethylbenzoic acid have been not reported until

doi:10.1016/j.poly.2007.01.026

now. So now we elaborate on some new coordination polymers constructed from 4-carboxymethylbenzoic acid, transition-metals and 4,4′-bpy. In this paper, we report five interesting coordination polymeric complexes $[MnL_2(bpy)_2(H_2O)_2]_n$ (**1**) (H_2L = 4-carboxymethylbenzoic acid) (bpy = 4,4′-bipyidine), $[CoL(bpy)(H_2O)_3 \cdot H_2O]_n$ (**2**), $[CdL(bpy)(H_2O)_3 \cdot H_2O]_n$ (**3**), $[Cu_2L(bpy)_2 \cdot 3H_2O]_n$ (**4**) and $[Zn_2L_2(bpy) \cdot H_2O]_n$ (**5**). This series of complexes shows an intriguing variety of architectures, which firstly form zero to two-dimensional frameworks by metal–ligand interactions, and secondly form three-dimensional supramolecular frameworks by intermolecular interactions such as hydrogen bonds. The spectroscopic, thermal, fluorescence and nonlinear optical properties of complexes **1**–**5** are investigated.

2. Experimental

2.1. General materials and techniques

The reagents and solvents employed were commercially available and used as received without further purification. H_2L was prepared according to a procedure described in the literature [27,28].

The C, H and N microanalyses were carried out with a Perkin–Elmer 240 elemental analyzer. The IR spectra were recorded in KBr disks on a Bruker Vector 22 spectrophotometer in the 4000–400 cm^{-1} region. Luminescence spectra for the solid samples were recorded with a Hitachi 850 fluorescence spectrophotometer. Thermogravimetric analyses were performed on a simultaneous SDT 2960 thermal analyzer under N_2 with a heating rate of 10 °C/min between ambient temperature and 750 °C. A pulsed Q-switched Nd:YAG laser at a wavelength of 1064 nm was used to generate an SHG signal from the samples. The backward scattered SHG light was collected using a spherical concave mirror and passed through a filter which transmits only 532 nm radiation.

2.2. Syntheses of the compounds

2.2.1. $[MnL_2(bpy)_2(H_2O)_2]_n$ (1)

A mixture of $Mn(Ac)_2 \cdot 4H_2O$ (0.1 mmol), H_2L (0.1 mmol), 4,4′-bpy (0.1 mmol), triethylamine (one half drop), CH_3CN (1 cm^3) and H_2O (9 cm^3) was placed in a Parr Teflon-lined stainless steel vessel (25 cm^3), and then the vessel was sealed and heated at 120 °C for 3 days. After the mixture was slowly cooled to room temperature, colorless crystals of **1** were obtained (yield: 67% based on Mn). *Anal*. Calc. for $C_{38}H_{34}N_4O_{10}Mn$: C, 59.92; H, 4.50; N, 7.36. Found: C, 60.00; H, 4.55; N, 7.30%. IR spectrum (cm^{-1}): 3416 (vs), 2928 (w), 1603 (vs), 1536 (s), 1381(vs), 1313 (m), 1225 (w), 1062 (w), 803 (m), 750 (s), 627 (m).

2.2.2. $[CoL(bpy)(H_2O)_3 \cdot H_2O]_n$ (2)

The synthesis was similar to that described for **1** except using $Co(NO_3)_2 \cdot 6H_2O$ instead of $Mn(Ac)_2 \cdot 4H_2O$ and red crystals of **2** were obtained (yield: 84% based on Co). *Anal*. Calc. for $C_{19}H_{21}N_2O_8Co$: C, 49.15; H, 4.56; N, 6.32. Found: C, 49.18; H, 4.60; N, 6.35%. IR spectrum (cm^{-1}): 3260 (s), 1608 (s), 1586 (s), 1560 (s), 1535 (s), 1380 (vs), 1228 (m), 1063 (w), 808 (m), 752 (m), 673 (m), 630 (m).

2.2.3. $[CdL(bpy)(H_2O)_3 \cdot H_2O]_n$ (3)

The synthesis was similar to that described for **1** except using $Cd(NO_3)_2 \cdot 4H_2O$ instead of $Mn(Ac)_2 \cdot 4H_2O$ and colorless crystals of **3** were obtained (yield: 54% based on Cd) *Anal*. Calc. for $C_{19}H_{22}N_2O_8Cd$: C, 43.99; H, 4.27; N, 5.40. Found: C, 44.05; H, 4.32; N, 5.36%. IR spectrum (cm^{-1}): 3386 (s), 1603 (vs), 1542 (s), 1491 (s), 1374 (vs), 1290 (m), 1221 (m), 807 (s), 748 (m), 629 (m).

2.2.4. $[Cu_2L(bpy)_2 \cdot 3H_2O]_n$ (4)

The synthesis was similar to that described for **1** except using $Cu(NO_3)_2 \cdot 3H_2O$ instead of $Mn(Ac)_2 \cdot 4H_2O$ and the reaction was carried out at 160 °C and orange crystals of **4** were obtained (yield: 89% based on Cu). *Anal*. Calc. for $C_{29}H_{28}N_4O_7Cu_2$: C, 51.86; H, 4.20; N, 8.34. Found: C, 51.90; H, 4.25; N, 8.40%. IR spectrum (cm^{-1}): 3423 (s), 3043 (m), 1601 (vs), 1550 (s), 1482 (s), 1383 (vs), 1215 (m), 818 (m), 799 (s), 724 (m), 633 (m).

2.2.5. $[Zn_2L_2(bpy) \cdot H_2O]_n$ (5)

The synthesis was similar to that described for **1** except using $Zn(NO_3)_2 \cdot 6H_2O$ instead $Mn(Ac)_2 \cdot 4H_2O$ and colorless crystals of **5** were obtained (yield: 32% based on Zn). *Anal*. Calc. for $C_{28}H_{22}N_2O_9Zn_2$: C, 50.86; H, 3.35; N, 4.24. Found: C, 50.90; H, 3.40; N, 4.20%. IR spectrum (cm^{-1}): 3423 (w), 3058 (m), 1637 (vs), 1492 (s), 1393 (vs), 1315 (m), 1223 (s), 1023 (m), 814w (m), 747 (s), 644 (m).

2.3. X-ray crystal structural determinations

Data for all of the complexes **1**–**5** were collected on a Siemens SMART-CCD diffractometer with graphite monochromatic Mo Kα radiation ($\lambda = 0.71073$ Å) using the SMART and SAINT programs [29]. The structures were solved by direct methods and refined on F^2 using full matrix least-squares methods with SHELXTL version 5.1 [30]. Anisotropic thermal parameters were refined for the non-hydrogen atoms. Hydrogen atoms attached to carbon and nitrogen were positioned geometrically (C–H = 0.93 Å, N–H = 0.86 Å), and included in the refinement in a riding model approximation with an isotropicthermal displacement parameter fixed at 1.2 times U_{eq} of the atom to which they are attached. Crystallographic data and other pertinent information for all of the compounds are summarized in Table 1. Selected bond lengths and bond angles with their estimated standard deviations are listed in Table 2. Selected hydrogen-bonded bond lengths and bond angles for compounds **1**–**4** are listed in Table 3.

3. Results and discussion

3.1. Crystal structures of the compounds

3.1.1. $[MnL_2(bpy)_2(H_2O)_2]_n$ (**1**)

Compound **1** crystallizes in the space group $P\bar{1}$ and the coordination geometry around the Mn(II) center is a distorted octahedron, the equatorial plane of which is comprised of four oxygen atoms from two monocoordinated carboxymethyl groups of H_2L and two coordinated water molecules, the remaining apical coordination sites of which are occupied by two N atoms from 4,4′-bpy (Fig. 1a). One molecular unit contains one six coordinated Mn(II) ion, two L ligands and two bpy ligands. These molecular (0D) units are interlinked by a hydrogen bond O3–H3···N2 $(2-x, 1-y, 1-z)$ along the c-axis (Fig. 1b). In the a–b plane the units are connected into a layered structure by hydrogen-bonds which are in a quadrangle (Fig. 1c). The quadrangle comprises of O9 from the coordinated water and O2 from the uncoordinated carboxymethyl group of H_2L. In the a–b plane, the layers can be classified topologically as a $(6^4\times10^2)$ $(6^2\times4)_4$ network. By the hydrogen-bond interactions, **1** produces a 3-D network.

3.1.2. $[CoL(bpy)(H_2O)_3\cdot H_2O]_n$ (**2**)

A single-crystal XRD study has revealed that **2** crystallizes in the monoclinic system, $P2_1$ space group. The coordination geometry around the Co(II) center is a distorted octahedron, the equatorial plane of which is comprised of four oxygen atoms from one monocoordinated carboxymethyl group of H_2L and three coordinated water molecules, the apical coordination sites of which are occupied by two N atoms from 4,4′-bpy (Fig. 2a). It is worthy of note that the O7–H7C···O2 hydrogen bond is very strong and the distance between O7 from the free water and O2 from the carboxymethyl group is 1.93 Å (Fig. 2b) [31]. By 4,4-bpy, the units are linked into a 1-D chain along [1 0 1]. In 3-D space, three such chains are connected by hydrogen-bonded tetrahedra formed by O8 and O1, O3, O4 and O6, respectively (Fig. 2c). O1 and O4 come from the carboxymethyl group and the carboxyl group of H_2L of the first chain respectively, O3 comes from the carboxyl of H_2L of the second chain, and O6 comes from the coordinated water of the third chain. O1, O4, O3 and O6 lie at the four vertices of a distorted tetrahedron centered at the free water O8. In addition, an inter-chain hydrogen bond O5–H5B···O4 $(2-x, y-1/2, 1-z)$ enhances the chain interactions. In this way, the 1-D chains produce a 3-D framework.

3.1.3. $[CdL(bpy)(H_2O)_3\cdot H_2O]_n$ (**3**)

A single-crystal XRD study has revealed that **3** crystalizes in the monoclinic system, $P\bar{1}$ space group. The coordination geometry around Cd(II) center is same of the Co(II) of complex **2** (Fig. 3a). In the same, the units are linked to 1-D chain by 4,4′-bpy along [1 1 −1]. Perpendicular to the chain, the units are connected by hydrogen-bonds of which some are in quadrangles and the others

[d] Symmetry code: (i) $-1+x, y, z$; (ii) $x, 1+y, z$; (iii) $1-x, y, 3/2-z$; (iv) $2-x, y, 3/2-z$.

are in six-membered rings (Fig. 3b) [32,33]. O8, O2 and O6 form one six-membered ring, and O8, O1 and O5 form the other one. The two types of six-membered rings are comprised of a ribbon by sharing O8 (Fig. 3c). O8 comes from the free water, O1 and O2 come from carboxyl of H_2L, and O5 and O6 come from the coordinated water. The quadrangle is comprised of O7 from the coordinated water and O4 from the uncoordinated carboxymethyl group of H_2L (Fig. 3d). In whole, the chains are further arranged into 3-D networks by these hydrogen-bonded networks.

3.1.4. $[Cu_2L(bpy)_2 \cdot 3H_2O]_n$ (**4**)

Compound **4** crystallizes in a non-centrosymmetric space group *Cc*. The Cu(I) ions have a slightly distorted trigonal coordination geometry, coordinated by one oxygen atom from the carboxymethyl group of H_2L and two nitrogen atoms from the 4,4′-bpy ligand (Fig. 4a). The coordination mode to Cu(I) is less-common. The carboxymethyl group of H_2L bridges two Cu(I) ions, while it is monocoordinated in compounds **1**–**3**. The distance between the two Cu(I) ions is 3.214 Å. Along the [1 0 1] direction the asymmetric units are linked into a 1-D ladder-like chain. O1

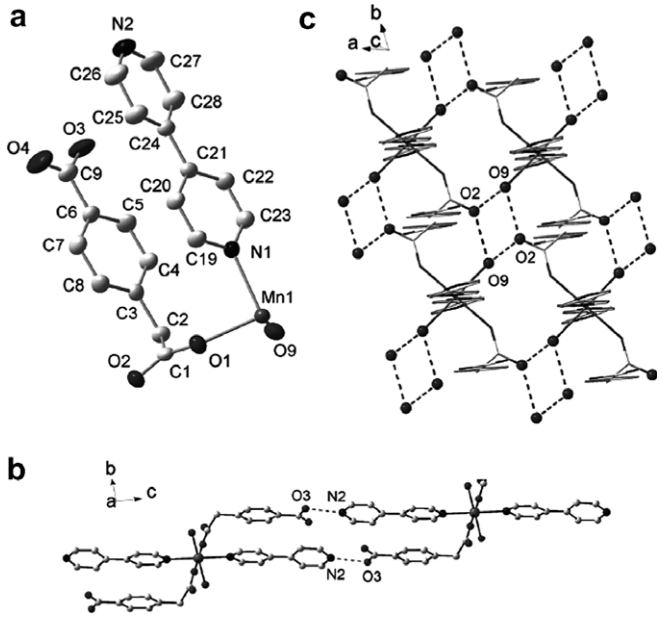

Fig. 1. (a) ORTEP view of compound **1**. Thermal ellipsoids are drawn at the 50% probability level. (b) 1-D chain of **1** along the *c*-axis. (c) Hydrogen-bonded networks in the *a*–*b* plane. Hydrogen atoms have been omitted for clarity.

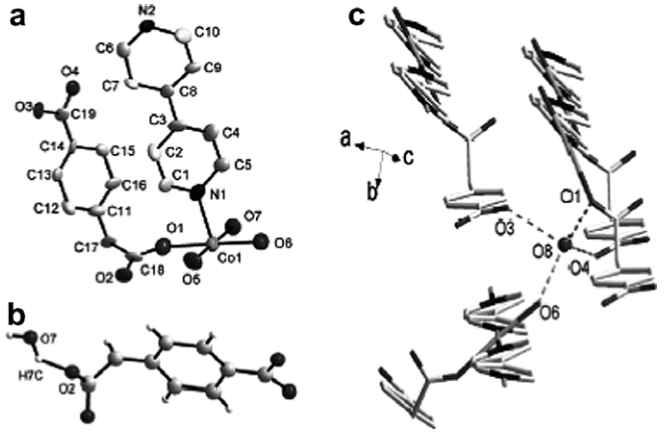

Fig. 2. (a) ORTEP view of compound **2**. Thermal ellipsoids are drawn at the 50% probability level. (b) O7–H7C···O2 hydrogen-bond in compound **2**. (c) Hydrogen-bonded tetrahedron in the three chains. Hydrogen atoms have been omitted for clarity.

from the carboxymethyl group of one chain and O4 from the carboxyl group of the other chain are linked to a short hydrogen-bonded chain by the free water O5. These short chains are linked into an infinite hydrogen-bonded chain by O5–H5B···O6 and O6–H6B···O4 $(-1+x, y, z)$ (Fig. 4b). Thus these ladder-like chains are further arranged to a 3-D supramolecular network by hydrogen-bonded chains composed of O1, O4, O5 and O6 (Fig. 4c).

3.1.5. $[Zn_2L_2(bpy)\cdot H_2O]_n$ (**5**)

Compound **5** crystallizes in the space group $P2/c$ and the coordination geometry around the Zn(II) center is a slightly distorted octahedron. Two oxygen atoms from the carboxymethyl group of H_2L and two oxygen atoms

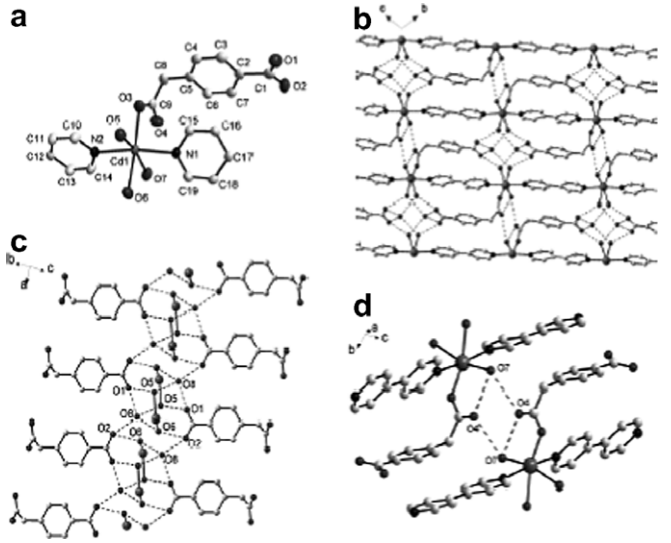

Fig. 3. (a) ORTEP view of compound **3**. Thermal ellipsoids are drawn at the 50% probability level. (b) 3-D hydrogen-bonded network of compound **3**. (c) A ribbon comprised of hydrogen-bonded six-membered rings in compound **3**. (d) Hydrogen-bonded quadrangle in compound **3**. Hydrogen atoms have been omitted for clarity.

from the carboxyl group of H_2L occupy the equatorial plane, and one nitrogen atom from the 4,4′-bpy and the other Zn atom occupy the axial positions (Fig. 5a). The two Zn(II) ions are bridged by two carboxymethyl groups and two carboxyl groups of H_2L to give binuclear clusters. The distance between the two Cu(I) ions is 2.927 Å. These clusters are interlinked by the ligands to form 1-D cluster chains. These chains are linked into 2-D sheets by 4,4′-bpy (Fig. 5b). The grid size is 4.8×8.3 Å^2. In whole, **5** is further arranged into a 3-D supramolecular network by hydrogen-bonding interactions. The free volume of **5** is estimated from the crystal structure to be 14%.

3.2. Thermal properties

Results of the thermogravimetric analysis (TGA) for frameworks **1**–**5** measured under a N_2 atmosphere are shown in Fig. 6. The TG curves indicate that compounds **1**–**4** lose all their water molecules below 130, 160, 147 and 177 °C. After the loss of the water molecules, the 3-D framework of compounds **1**–**4** begin to collapse. Compound **5** lost its free water molecules below 185 °C and then it began to decompose with a continuous weight loss up to 460 °C.

3.3. Photoluminescence properties

Coordination polymers containing cadmium and zinc usually exhibit photoluminescent properties [34,35], so we investigated the photoluminescent properties of **3** and **5** (Fig. 7). In the solid state, complex **3** exhibits strong fluorescent emission bands at ca. 421 and 393 nm upon excitation at ca. 359 nm. In addition, complex **5** displays intense blue fluorescent emission bands at ca. 411 nm upon excitation at ca. 362 nm. Because the Zn(II) or Cd(II) ions are difficult

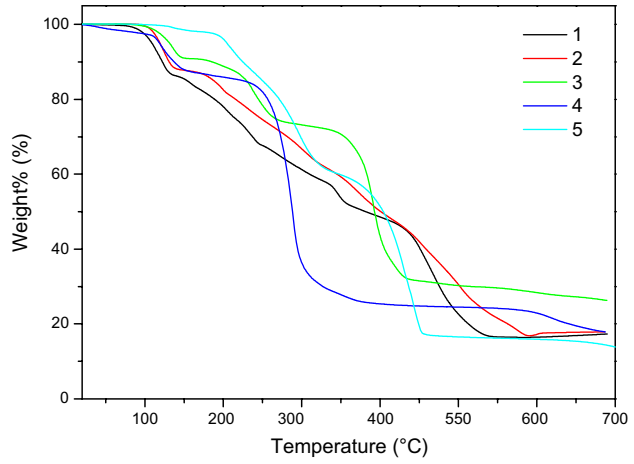

Fig. 6. TG curves for **1** (black), **2** (red), **3** (green), **4** (blue), **5** (cyan). (For interpretation of the references to colors in this figure legend, the reader is referred to the web version of this paper.)

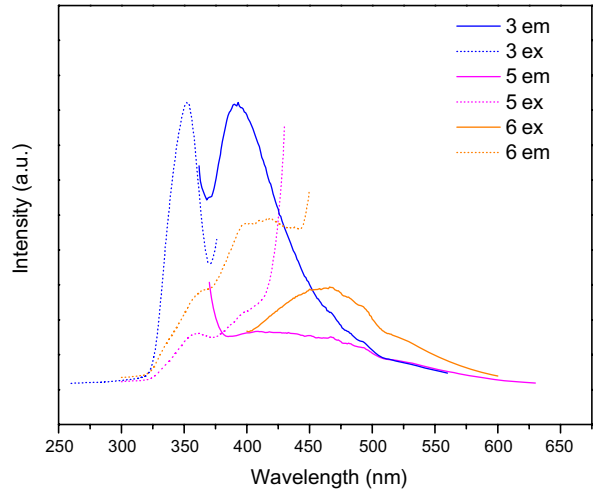

Fig. 7. The excitation (dotted line) and emission (solid line) spectra of **3** (blue), **5** (magenta), **6** (orange). (For interpretation of the references to colors in this figure legend, the reader is referred to the web version of this paper.)

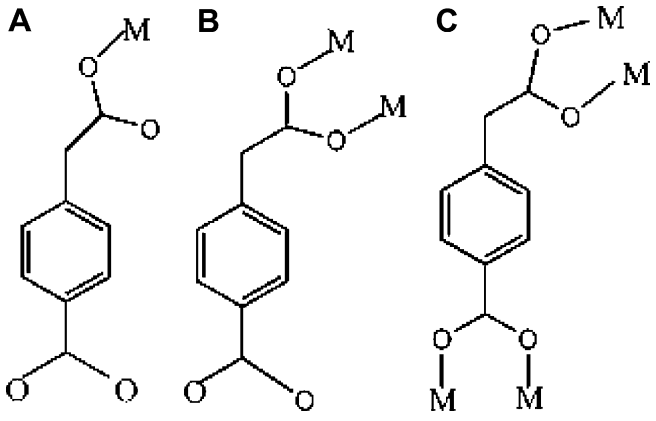
to oxidize or to reduce due to their d^{10} configuration, these emissions can probably be assigned to intraligand (π–π^*) fluorescent emissions. At the same time, free H_2L (compound **6**) exhibits weak fluorescent emission bands at ca. 466 nm upon excitation at ca. 368 nm, which further supports this interpretation. It is clear that a hypsochromic shift of the emission occurs in **3** compared to other compounds, which is probably due to the differences of the ligands and the coordination environment around the central metal ions, because photoluminescence behavior is closely associated with the local environment around the metal ion. It appears to be a good candidate for novel hybrid inorganic–organic photoactive materials.

3.4. SHG measurement

Given that compound **4** crystallizes in a non-centrosymmetric space group (*Cc*) which has a polar point group (C_2), an investigation of its optical properties were undertaken. The SHG responses of the H_2L ligand and compound **4** were estimated by measuring a powder sample (ca. 80–120 μm in diameter, Kurtz powder test [36]), relative to urea. A pulsed Q-switched Nd:YAG laser at a wavelength of 1064 nm was used to generate the SHG signal. The backward scattered SHG light was collected using a spherical concave mirror and passed through a filter that transmits only 532 nm radiation. The SHG efficiency of H_2L and **4** is estimated to be approximately 0.5 and 0.6 times of that of urea. It indicates that H_2L may crystallize in a non-centrosymmetric space group [37].



3.5. Discussion

As is well-known, the final structures of coordination polymers are influenced by the coordination modes, capabilities, size and shape of ligands and the coordination sphere of the metal centers. Although compounds **1**–**5** have been prepared with a molar ratio of 1:1:1 for metal salts/bpy/aromatic polycarboxylate, to our surprise, the final compounds all have different stoichiometries.

According to the above structural descriptions of our example compounds, the H_2L ligand exhibits three distinct kinds of coordination modes as shown in Scheme 1.

In compounds **1**–**3**, the L^- ligand monocoordinates the metal ions (A). In compound **4**, the L^{2-} ligand bridges two Cu(I) ions through two oxygen atoms of the carboxymethyl group (B). In compound **5**, the two carboxyl groups of the L^{2-} ligand both bridge two Zn(II) ions (C).

Aromatic polycarboxylate has good solubility in a mixture of water and CH_3CN, therefore, the superfluous reactant may remain in water under hydrothermal reactions. In most cases, water is not only a solvent but also acts as a competing ligand in these hydrothermal reactions. An interesting phenomenon can be observed whereby many coordination polymers constructed from polycarboxylate ligands usually contain water molecules as terminal or bridging ligands in the coordination sphere of the metal, thus increasing the variety of the assembled structural topologies of the polymers [38]. In compounds **1**–**5**, the

Scheme 1.

hydrogen-bonded frameworks exhibit different networks, for example, hydrogen-bonded quadrangle, hydrogen-bonded chain, hydrogen-bonded tetrahedron and hydrogen-bonded six-membered ring [39–41].

Compared with the complexes comprised of 1,4-benzenedicarboxylic acid, 4,4′-bipyidine and transition metals, the dimension of this series of complexes comprised of H_2L is lower, which may be a consequence of the more flexible configuration of H_2L.

4. Conclusion

In summary, five new polymers with different architectures, $[MnL_2(bpy)_2(H_2O)_2]_n$ (**1**), $[CoL(bpy)(H_2O)_3 \cdot H_2O]_n$ (**2**), $[CdL(bpy)(H_2O)_3 \cdot H_2O]_n$ (**3**), $[Cu_2L(bpy)_2 \cdot 3H_2O]_n$ (**4**) and $[Zn_2L_2(bpy) \cdot H_2O]_n$ (**5**), were constructed from the H_2L ligand and 4,4′-bpy, used as spacers, under mild hydrothermal conditions. For the first time, the H_2L ligand has been introduced into a trans-metal coordination polymer system. This study not only demonstrates that the nature of the ligand and the geometric needs of the metal atoms play an important role in the crystal packing of MOFs but also illustrates that hydrogen bonds affect the formation of supramolecular architectures. In addition, complex **3** may be an excellent candidate for blue-fluorescent materials and **4** appears to be a good candidate for novel hybrid inorganic–organic NLO materials.

Acknowledgments

Special thanks are offered to the reviewers for their constructive suggestions. We thank the National Nature Science Foundation of China (Grant No. 20490218), Jiangsu Science and Technology Department, and the Center of Analysis and Determining of Nanjing University for financial support.

Abstract

The reactions of $[ReOX_3(AsPh_3)_2]$ and $[ReOX_3(PPh_3)_2]$ with 8-hydroxyquinoline (Hhqn) have been examined and the complexes $[ReOX_2(hqn)(AsPh_3)]$ and $[ReOX_2(hqn)(PPh_3)]$ (X = Cl, Br) have been obtained, respectively. The crystal and molecular structures of $[ReOCl_2(hqn)(AsPh_3)]$ (**1**) and $[ReOBr_2(hqn)(PPh_3)]$ (**4**) have been determined. The electronic structure of **1** has been calculated with the density functional theory (DFT) method. The spin-allowed electronic transitions of **1** have been calculated with the time-dependent DFT method, and the UV–Vis spectrum of $[ReOCl_2(hqn)(AsPh_3)]$ has been discussed on this basis.

Keywords: Rhenium oxo complexes; 8-Hydroxyquinoline; X-ray and electronic structure; DFT calculations; NBO analysis

1. Introduction

There is considerable interest in the chemistry of inorganic compounds containing an oxygen atom that is multiply bonded to a transition metal in a high oxidation state. These compounds can transfer an oxygen atom to reductants such as phosphines, sulfides and alkenes. For many years they have been in the centre of interest to those scientists engaged in basic research and to those trying to employ these complexes in catalytic processes. Oxygen atom transfer chemistry has been implicated in various reactions of industrial and biological importance, including olefin epoxidation and catalysis by cytochrome P-450 [1–3].

The chemistry of oxo rhenium complexes arouses particular interest among these compounds. It results from the favourable nuclear properties of ^{186}Re and ^{188}Re nuclides, which make the radioisotopes useful for diagnostic nuclear medicine and applications in radioimmunotheraphy [4,5]. In this context, the design, synthesis and reactivity of novel rhenium oxocomplexes has become the aim of several laboratories, including ours.

Previously, we investigated the reactivity of oxorhenium(V) species – $[ReO(OEt)X_2(PPh_3)_2]$, $[ReOX_3(PPh_3)_2]$ and $[ReOX_3(AsPh_3)(OAsPh_3)]$ (X = Cl or Br) – towards pyrazole, 3,5-dimethylopyrazole and benzotriazole [6]. In this report we focus on the examination of the reactions of $[ReOX_3(AsPh_3)_2]$ and $[ReOX_3(PPh_3)_2]$ with 8-hydroxyquinoline (Hhqn) and present the synthesis and the spectroscopic data for the complexes $[ReOCl_2(hqn)(AsPh_3)]$ (**1**), $[ReOBr_2(hqn)(AsPh_3)]$ (**2**), $[ReOCl_2(hqn)(PPh_3)]$ (**3**) and $[ReOBr_2(hqn)(PPh_3)]$ (**4**). X-ray studies have been performed for **1** and **4**.

Recently, several oxocomplexes of the general formula $[ReOCl_2(O–N)(PPh_3)]$, including compounds with 2-, 5- and/or 7-substituted 8-quinolinolato ligands, have been structurally and spectroscopically characterized [7–

doi:10.1016/j.poly.2007.01.054

10]. The oxorhenium(V) chelates $[ReOCl_2(O–N)(PPh_3)]$ with pyridinecarboxylate ligands have also been examined as catalysts for the carboxylation of ethane by CO in the presence of potassium peroxodisulfate $K_2S_2O_8$ [10].

In addition, this paper includes DFT (density functional theory) and TD-DFT (time-dependent DFT) calculations for complex **1**. Currently, density functional theory (DFT) is commonly used to examine the electronic structure of transition metal complexes. It meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [11]. Recent calculations with the TD-DFT method for open- and closed-shell 5d-metal complexes (including rhenium complexes) have also supported the TD-DFT method to be applicable for such systems, giving good assignment of experimental spectra [12–14].

2. Experimental

2.1. General procedure

All reagents used for the synthesis were commercially available and were used without further purification. The $[ReOX_3(AsPh_3)_2]$ and $[ReOX_3(PPh_3)_2]$ complexes were prepared according to the literature methods [15].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 1000–200 nm in chloroform solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of [$ReOCl_2$(hqn)($AsPh_3$)] (**1**)

A mixture of $[ReOCl_3(AsPh_3)_2]$ (0.5 g, 0.54 mmol), Hhqn (0.09, 0.62 mmol) and acetone (70 ml) was stirred for 12 h. Acetone (50 ml) was distilled off and 100 ml of diethyl ether was added. $[ReOCl_2(hqn)(AsPh_3)]$ was filtered off, washed with ethanol, diethyl ether and dried. Yield 85%. The crystals of **1** for X-ray investigation were obtained by recrystallization from acetonitrile.

IR (KBr; ν/cm^{-1}): 1609 (w), 1598 (m), 1577 (s), 1499 (s) ν_{CN} and $\nu_{C=C}$; 975(s) $\nu_{Re=O}$.

UV–Vis ($CHCl_3$; $\lambda_{max}(\varepsilon)$): 862.8 (100), 692.2 (300), 401.6 (8.15×10^3), 254.4 (2.62×10^4), 233.6 (2.99×10^4).

Anal. Calc. for $C_{27}H_{21}AsCl_2NO_2Re$: C, 44.82; H, 2.93; N, 1.94. Found: C, 44.72; H, 2.95; N, 1.85%.

2.3. Preparation of [$ReOBr_2$(hqn)($AsPh_3$)] (**2**)

A procedure similar to that for $[ReOCl_2(hqn)(AsPh_3)]$ was used with $[ReOBr_3(AsPh_3)_2]$ (0.5 g, 0.47 mmol) and Hhqn (0.08 g, 0.55 mmol). A crystalline precipitate of $[ReOBr_2(hqn)(AsPh_3)]$ was collected in 90% yield.

Anal. Calc. for $C_{27}H_{21}PBr_2NO_2Re$: C, 42.20; H, 2.75; N, 1.82. Found: C, 42.35; H, 2.65; N, 1.70%.

2.6. Crystal structure determination and refinement

The X-ray intensity data of **1** and **4** were collected on a KM-4-CCD automatic diffractometer equipped with a CCD detector and graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at a temperature of 295(2) K. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and empirical absorption correction using spherical harmonics implemented in the SCALE3 ABSPACK scaling algorithm [16] were applied. The structures were solved by the Patterson method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix, least-squares technique. The hydrogen atoms were treated as "riding" on their parent carbon atoms and assigned isotropic temperature factors equal to 1.2 times the value of the equivalent temperature factor of the parent atom. SHELXS97 [17], SHELXL97 [18] and SHELXTL [19] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

3. Computational details

The GAUSSIAN03 program [20] was used in the calculations. The geometry optimisation of **1** was carried out with the DFT method with the use of the B3LYP functional [21,22]. The electronic spectrum of **1** was calculated with the TD-DFT method [23]. The calculations were performed by using the ECP basis set on the rhenium atom, the standard 6-31+G** basis for chlorine, oxygen, arsine and nitrogen, 6-31G* for carbon and 6-31G for hydrogen atoms. The Xe core electrons of Re were replaced by an effective core potential and a DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [24] was used for the valence electrons. An additional *d* function with exponent $\alpha = 0.3811$ and *f* function with exponent $\alpha = 2.033$ on the rhenium atom were added.

Natural bond orbital (NBO) calculations were performed with the NBO code [25,26] included in GAUSSIAN03.

4. Results and discussion

4.1. Preparation and infrared data

The $[ReOX_2(hqn)(EPh_3)]$ (X = Cl, Br; E = As, P) complexes were prepared in good yields by ligand exchange reactions starting from $[ReOX_3(EPh_3)_2]$ complexes and 8-hydroxyquinoline in acetone:

$$[ReOX_3(EPh_3)_2] + Hhqn \rightarrow [ReOX_2(hqn)(EPh_3)] + HX + EPh_3 \quad X = Cl, Br;\ E = As, P$$

They were isolated as greenish-brown microcrystalline solids, soluble in common organic solvents.

The strong ν(Re=O) stretching bands at 968–975 cm^{-1} are in the higher end of the range observed for $\{ReO\}^{3+}$ core complexes. This suggests that the Re–hydroxy bond *trans* to the oxo ligand does not compete effectively for the Re_d orbitals and the bond is relatively weak. Moreover, the narrow range in which the ν(Re=O) bands appear is very similar to those observed for Re(V)-oxo complexes with a monoanionic oxygen (RO^- and $R–COO^-$,) *trans* to the oxo group [27].

4.2. Crystal structures

Both complexes are isostructural and they crystallise in the triclinic space group $P\bar{1}$, and their structures consist of discrete and well-separated monomers. Intermolecular interactions with enough strength to govern crystal packing or molecule conformation were not found in the structures of **1** and **4**. Only intra- and intermolecular short contacts, which can be considered as weak C–H···O hydrogen bonds [28,29] were detected (Table 2).

The molecular structures of **1** and **4** are presented in Figs. 1 and 2, respectively, and selected bond distances and angles are collected in Tables 3 and 4, respectively. Both complexes show an octahedral geometry about the central rhenium atom defined by the terminal oxo-group, two halide ions in a *cis* arrangement, the phosphorus or arsine of the EPh_3 molecule, and the bidentate N,O donors of the hqn ligand. The oxygen atom of hqn is coordinated

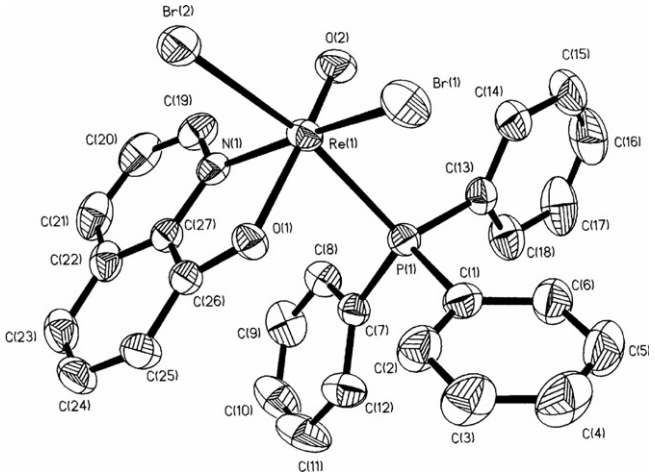

Fig. 2. The molecular structure of **4**. Displacement ellipsoids are drawn at 50% probability.

in a *trans* position to the terminal oxo ligand. The multiple bonding ligand (terminal oxo) and narrow bite angle of the chelating ligand contribute to clear distortions of the pseudooctahedral environment of the Re center in the $[ReOX_2(hqn)(EPh_3)]$ complexes. The high concentration of electronic density along the Re–O axis strongly influences the positions of the adjacent halogen atoms, which are pushed away.

A similar coordination geometry is observed for the other $[ReOCl_2(O–N)(PPh_3)]$ complexes with quinolinolato derivatives [7–9]. Accordingly, the 2-, 5- and/or 7-substituent of the 8-quinolinolato ligand does not affect the complexation.

Another geometry about the central atom can be noticed in the dibromooxo(*N*-phenylsalicylideneaminato)(triphenylphosphine)–rhenium(V) complex [30]. Similar to the $[ReOCl_2(O–N)(PPh_3)]$ complexes with 8-quinolinolato ligands, the oxygen atom of the *N*-phenylsalicylideneaminato ion occupies a *trans* position to the terminal oxo ligand, but the bromide ions are in a *trans* arrangement and the PPh_3 molecule is opposite the nitrogen atom of the *N*-phenylsalicylideneaminato ligand. It seems that electrostatic (not steric) factors are responsible for the changed geometry about the central atom in dibromooxo(*N*-phenylsalicylideneaminato)(triphenylphosphine)–rhenium(V) in comparison with the discussed 8-quinolinolato oxocomplexes. The pyridine ring of the 8-quinolinolato ligand is a good π acceptor, whereas the nitrogen atom of the *N*-phenylsalicylideneaminato ion is pure donor.

Cl(1)	−0.380
Cl(2)	−0.417
As(1)	1.394

The Re–O_t bond lengths of **1** and **4** fall in the range 1.639–1.76 Å, typical of mononuclear complexes of rhenium(V) having a $[ReO]^{3+}$ core, and indicate the presence of a triple Re≡O bond [31]. The interatomic distances between the rhenium atom and the oxygen atom of the hqn ligand are longer Re–O_{alkoxy} in the $[ReO(OR)X_2(PPh_3)_2]$ complexes [32], and only somewhat shorter than an ideal single Re–O bond length. The last bond length, predicted by the use of Pauling's covalent radius for oxygen and Cotton and Lippard's value for the octahedral covalent radius of rhenium(V), should be *ca.* 2.04 Å [33]. On the other hand, some differences of the Re–$O_{quinolinolato}$ bond

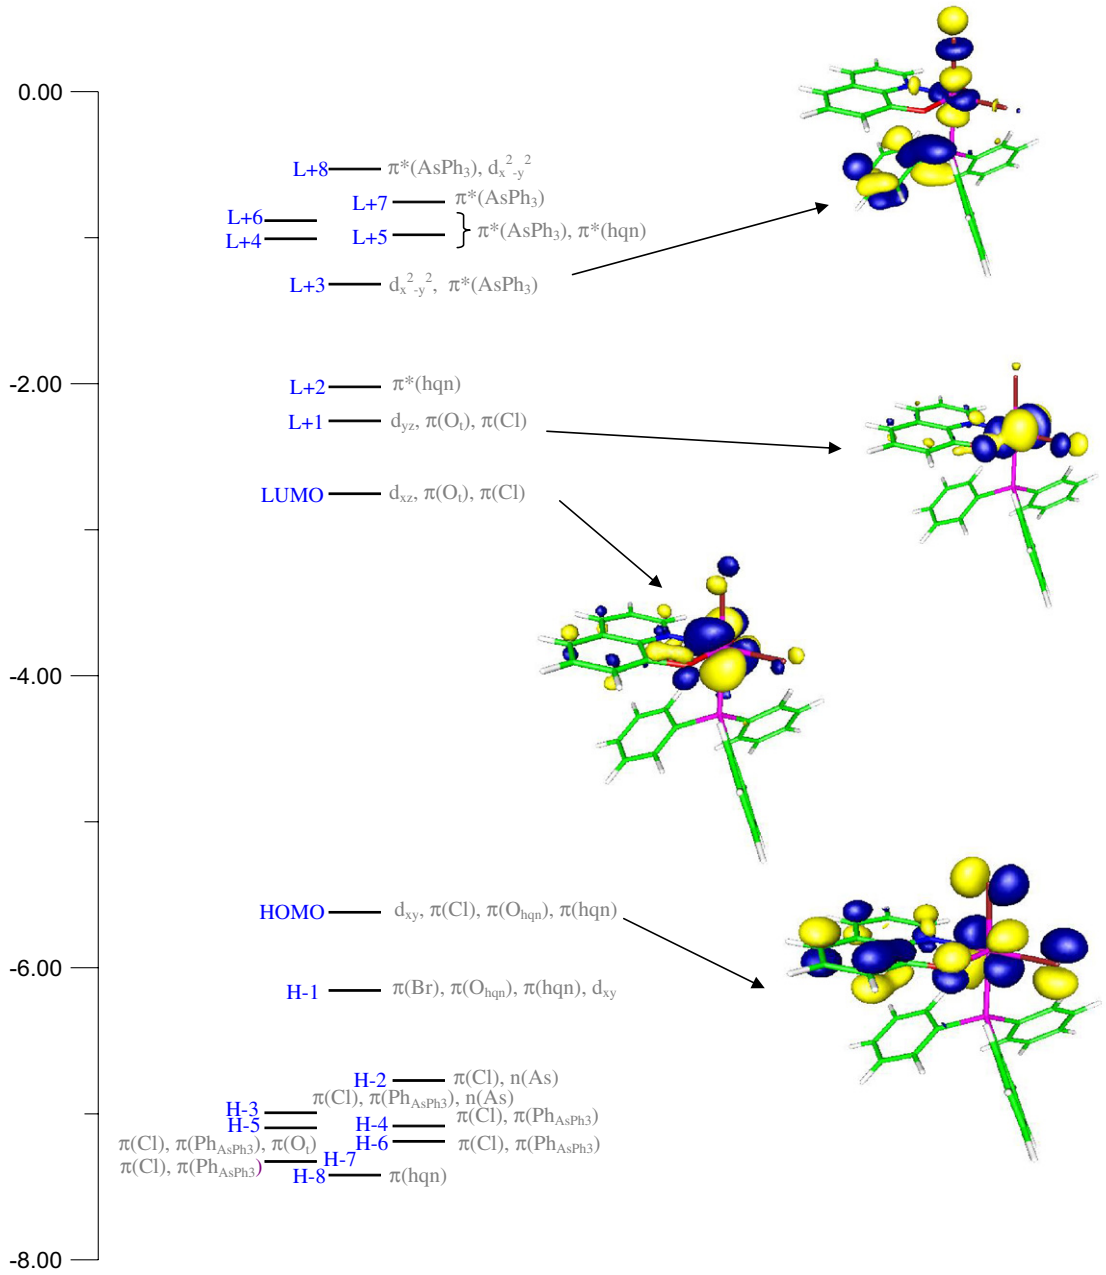

Fig. 3. The energy (eV), character and some contours of the molecular orbitals of **1**. Positive values of the orbital contour are represented in yellow (0.04 au) and negative values – in blue (−0.04 au). (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

are observed between [$ReOCl_2$(hqn)(PPh_3)], [$ReOCl_2$-(2-Me-hqn)(PPh_3)] and [$ReOCl_2$(5-Y-7-hqn)(PPh_3)]. The $Re–O_{quinolinolato}$ distances in complexes with 5- and 7-substituted 8-quinolinolato ligands are longer than those observed in [$ReOCl_2$(hqn)(PPh_3)] and [$ReOCl_2$(2-Me-hqn)(PPh_3)] [7,8].

The Re1–X(2) distances *trans* to the phosphorus or arsine atom of the EPh_3 molecule are slightly longer than the Re1–X(1) bonds *trans* to the quinoline nitrogen. It indicates a *structural trans* effect of the EPh_3 ligands. A similar trend is observed in all the oxorhenium(V) chelates [$ReOCl_2$(O–N)(PPh_3)] with 2-, 5- and/or 7-substituted 8-quinolinolato ligands [7,8].

4.3. Geometry optimisation, charge distribution, electronic structure and NBO analysis

The geometry of **1** was optimised in a singlet state by the DFT method with the B3LYP functional. The optimized geometric parameters of **1** are gathered in Table 3. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

Table 5 presents the atomic charges from the Natural Population Analysis (NPA) for **1**. The calculated charge on the rhenium atom in **1** is considerable lower than the formal charge of +5, and the populations of the d_{xy}, d_{xz}, d_{yz}, $d_{x^2-y^2}$ and d_{z^2} rhenium orbitals are as follows: 1.027, 0.925, 0.934, 1.722 and 0.855. It confirms significant charge donation from the ligands. The As atom is positively charged and the charges on the terminal oxo, chloride and oxygen atom of hqn^- are significantly smaller than −2, −1 and −1, respectively. The terminal oxo ion is less negative in comparison with the oxygen atom of the hqn ligand. It indicates higher electron density delocalization from the terminal ligands towards the rhenium centers and corresponds to the differences in the Re–O(2) and Re–O(1) bonds lengths.

Complex **1** is a closed-shell structure. Its molecular orbital diagram with several highest occupied MO and lowest unoccupied MO contours is presented in Fig. 3. The HOMO–LUMO gap equals 2.87 eV. The highest occupied MO of **1** is of d_{xy} type with some contributions from p_π chloride and hqn^- orbitals. The remaining four d-type orbitals of rhenium are found among the unoccuppied MOs. It confirms the d^2 configuration of the rhenium atom.

The rhenium–oxygen interaction in **1** is described as a triple bond. Assuming that rhenium uses its six valence orbitals, $5d_{x^2-y^2}$, $5d_{z^2}$, 6s, $6p_x$, $6p_y$ and $6p_z$ to form σ-bonds with the six ligands, empty $5d_{xz}$ and $5d_{yz}$ orbitals are available to overlap with $2p_x$ and $2p_y$ orbitals on the terminal oxygen to form an effective triple bond. The LUMO and LUMO + 1 (Fig. 3) are ascribed as π-antibonding rhenium–oxygen molecular orbitals.

Additional information about the nature of the rhenium–terminal oxygen bonding has been obtained by NBO analysis. The occupancy and composition of the calculated $Re–O_t$ natural bond orbitals (NBOs) are given in Table 6.

Each natural bond orbital (NBO) σ_{AB} can be written in terms of two directed valence hybrids (NHOs) h_A i h_B on atoms A and B:

$$\sigma_{AB} = c_A h_A + c_B h_B$$

where c_A and c_B are polarization coefficients. Each valence bonding NBO must in turn be paired with a corresponding valence *anti*-bonding NBO:

$$\sigma^*_{AB} = c_B h_A - c_A h_B$$

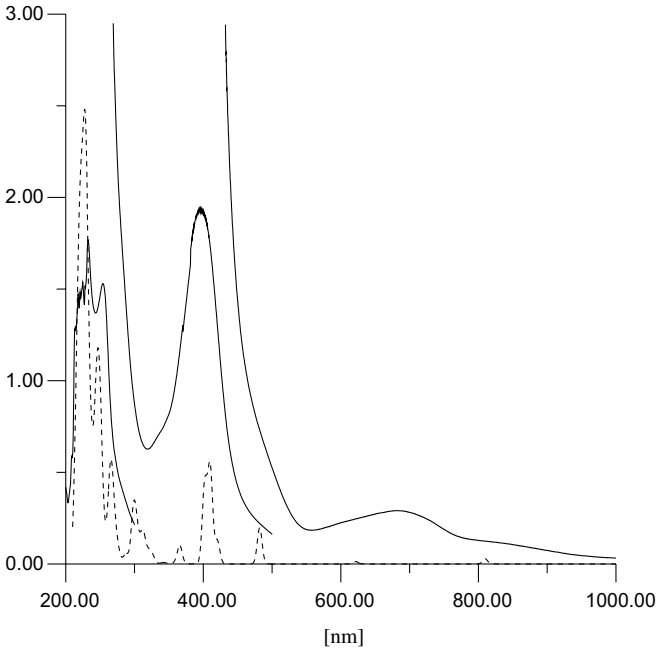

Fig. 4. The experimental (——) and calculated (----) electronic absorption spectra of **1**.

Table 6
The occupancy of the calculated natural bond orbitals (NBOs) between rhenium and the oxo ligand for **1**

BD	Occupancy	BD	BD[a]	Occupancy
$Re–O_t$	1.989	$0.562(d)_{Re} + 0.828(p)_O$	$0.828(d)_{Re} - 0.562(p)_O$	0.276
$Re–O_t$	1.993	$0.577(d)_{Re} + 0.817(p)_O$	$0.\ 817(d)_{Re} - 0.577(p)_O$	0.270

BD denotes 2-center bond.
[a] Denotes antibond NBO.

to complete the span of the valence space. The Lewis-type (donor) NBOs are thereby complemented by the non-Lewis-type (acceptor) NBOs that are formally empty in an idealized Lewis picture. The interactions between 'filled' Lewis-type NBOs and 'empty' non-Lewis NBOs lead to loss of occupancy from the localized NBOs of the idealized Lewis structure into the empty non-Lewis orbitals, and they are referred to as 'delocalization' corrections to the zeroth-order natural Lewis structure [34].

Although only two natural Re–O_t bond orbitals were detected for complex **1**, the rhenium–oxygen interaction can be described as a triple bond. Both the detected natural Re–O_t bond orbitals are orbitals of π character – the p_x and p_y oxygen orbitals and d_{xz} and d_{yz} rhenium orbitals are involved in their formation. The non-detected σ_{Re-O_t} bond has character of predominantly coulomb-type interactions between the central ion and ligands [35].

4.4. Electronic spectrum

The experimental and calculated electronic spectra of **1** are presented in Fig. 4. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}.

Table 7

ε – Molar absorption coefficient ($dm^3\ mol^{-1}\ cm^{-1}$).
f – Oscillator strength.
H – highest occupied molecular orbital.
L – lowest unoccupied molecular orbital.

The positions of the absorption bands for the other $[ReOX_2(hqn)(EPh_3)]$ complexes are given in Section 2.

The spin-allowed singlet–singlet electronic transitions calculated with the TD-DFT method for **1** are gathered in Table 7. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.015 are listed in Table 7.

The two longest wavelength experimental bands of **1** at 862.8 and 692.2 nm are attributed to the transitions of d → d character, with small oscillator strengths calculated at 809.8 and 621.9 nm, respectively.

The broad and intense absorption band with a maximum at 401.6 nm is assigned to the metal–ligand charge transfer (occurring from the rhenium ion to the π-antibonding orbitals of the hqn and $AsPh_3$ ligands) and ligand–metal charge transfer ($\pi_{hqn}/n_{As}/\pi_{Cl}/\pi_O \rightarrow d$) transitions.

The experimental bands at 253.8 and 233.6 nm result mainly from ligand–ligand charge transfer and interligand (IL) transitions.

5. Supplementary material

CCDC 632496 and 632497 contain the supplementary crystallographic data for **1** and **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgement

The GAUSSIAN03 calculations were carried out in the Wrocław Centre for Networking and Supercomputing, WCSS, Wrocław, Poland.

Abstract

The reactions of the title ylide $\{(C_6H_5)_3PCHCOC_6H_4OCH_3)\}$ (MBPPY) with mercury(II) chloride and mercury(II) bromide in equimolar ratios using methanol as the solvent produces crystals of $[(MBPPY)\cdot HgCl_2]_2$ (**1**) and $[(MBPPY)\cdot HgBr_2]_2$ (**2**), respectively. Single crystal X-ray analyses reveal the presence of centrosymmetric dimeric structures containing the ylide and HgX_2 (X = Cl or Br) in both cases. The IR and NMR data of the product $[(MBPPY)\cdot HgI_2]_2$ (**3**), formed by the reaction of mercury(II) iodide with the same ylide, are similar to those of **1** and **2**. Analytical data indicate a 1:1 stoichiometry between the ylide and Hg(II) halide in each of the three products.

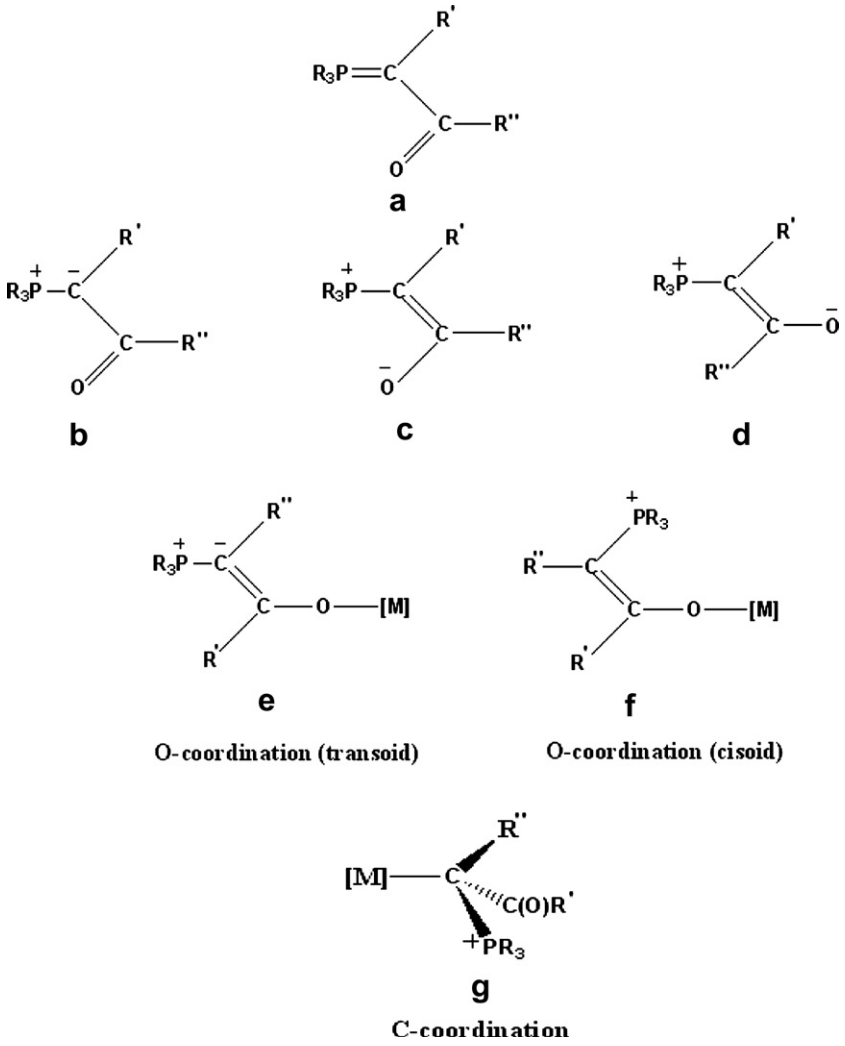
Keywords: Phosphorus ylide; Mercury(II) halide complexes; X-ray Crystal structure; Triphenylphosphine

1. Introduction

The organometallic chemistry of phosphorous ylides $R_3P=C(R')(R'')$ (R, R′, R″ = alkyl or aryl groups) has undergone a great growth in the last few years, mainly due to their interesting application as reactants in organometallic and metal-mediated organic synthesis [1–4]. On the whole, the α-keto-stabilized phosphorous ylides $R_3P=C(R')COR''$ show interesting properties such as high stability (which allows them to be easily handled in air) and ambidentate character as ligands (*C*- versus *O*-coordination). This ambidentate character can be rationalized in terms of the resonance forms **A**–**C**, together with the isomeric form **D** (Scheme 1). Form **B** would account for *C*-coordination to a metal (M = metal) (which is presented as **G**) while isomers **C** and **D** would explain *O*-coordination (which are presented as *cisoid*, form **F**, and *transoid*, form **E**, respectively).

In the compounds reported to date, the chemical behavior of the α-keto phosphorous ylides has been clearly dominated by the *C*-coordinated form [5–8], and very few examples of *O*-coordinated ylides are known [9–13]. Some of these examples contain the ylide *O*-coordinated to a hard, very oxophilic metal center, as Sn(IV) [9,10] or group 4 metals with a high oxidation number [11]. Only W(0) complexes of the type $W(CO)_5L$ (L = ylide) [12] and Pd(II) complexes of the stoichiometry $[Pd(C_6F_5)L_2)(APPY)](ClO_4)$ [13] [APPY = Ph_3CCOMe; L = PPh_3, PBu_3; L_2 = bipy] contain stable ylides *O*-linked to a soft metal center. Other attempts to obtain this kind of *O*-coordination to "classical" soft metals such as Pd(II), Pt(II) or Hg(II) [6,14,15] invariably gave *C*-coordination. In this study, we describe the preparation, spectroscopic characterization (IR and NMR) of complexes of mercury(II) with the title ylide. By a comparison of the data collected and single crystal X-ray diffraction of **1** and **2**, it demonstrates *C*-coordination of the ylide to the metal.



2. Experimental

2.1. Materials

Mercury halides, 4-methoxyacetophenone and triphenylphosphine were purchased from Merck. The ligand

Scheme 1.

was synthesised by the reaction of triphenylphosphine with a chloroform solution of 2-bromo-4′-methoxyacetophenone and dehydrogenated by NaOH [16]. All solvents were dried by the reported methods [17].

2.2. Physical measurements

Melting points were measured on a SMPI apparatus. Elemental analysis for C, H and N were performed using a Perkin–Elmer 2400 series analyzer. Fourier transform IR spectra were recorded on a Shimadzu 435-U-04 spectrophotometer and samples were prepared as KBr pellets. ^{1}H, ^{13}C and ^{31}P spectra were recorded on a 200 MHz Bruker spectrometer in DMSO-d_6 or $CDCl_3$ solution at 25 °C.

The single crystal X-ray diffraction analysis was performed on a STOE IPDS-II two circle diffractometer at 298 K, using graphite monochromated Mo Kα radiation ($\lambda = 0.7107$ nm). A suitable crystal, grown from a methanol-diethylether solution, was mounted on a glass fiber. The data collection was performed at room temperature using the ω-scan technique and using the STOE X-AREA software package [18]. The crystal structure was solved by direct methods and refined by full-matrix least-squares on F^2 by SHELX [19] and using the X-STEP32[11] crystallographic software package [20]. All non-hydrogen atoms were refined anisotropically using reflections $I > 2\sigma(I)$. Hydrogen atoms were inserted at calculated positions using a riding mode with fixed thermal parameters. Data collection and refinement parameters are given in Table 1. ORTEP views of the X-ray crystal structures of the two complexes are shown in Figs. 1 and 2. Selected bond lengths (Å) and bond angles (°) for complexes **1** and **2** are given in Table 2.

2.3. Synthesis of MBPPY

To a chloroform solution (25 ml) of triphenylphosphine (0.131 g, 0.5 mmol) was added 2-bromo-4′-methoxyacetophenone (0.114 g, 0.5 mmol) and the resulting mixture was stirred for 12 h. The solution was filtered off, the precipitate washed with diethelyether and dried. Further treatment with aqueous NaOH solution (0.5 M) led to elimination of HBr, giving the free ligand MBPPY. M.p: 153–158 °C. *Anal*. Calc. for $C_{27}H_{23}O_2P$: C, 67.24; H, 4.84. Found: C, 66.05; H, 4.88%.

2.4.3. $[MBPPY \cdot HgI_2]_2$ (3)

To a methanolic solution (5 ml) of MBPPY (0.102 g, 0.25 mmol) was added mercury(II) iodide (0.113 g, 0.25 mmol). The mixture was stirred for 12 h. On concentration by removing the solvent by vacuum, a pale yellow precipitate was obtained. The products were washed with benzene and dried in vacuo. Yield: 81%, m.p. 242–245 °C. *Anal.* Calc. for $C_{54}H_{46}O_4P_2Hg_2I_4$: C, 37.49; H, 2.67. Found: C, 36.80; H, 2.64%.

3. Results and discussion

3.1. Synthesis

The ligand was synthesised by treating 2-bromo-4′-methoxyacetophenone (prepared by reacting 4-methoxyacetophenone with bromide in glacial acetic acid) with triphenylphosphine and removal of the proton from the phosphonium salt. Reactions of HgX_2 with the ylide in a 1:1 stoichiometry afforded the *C*-coordinated complexes with a halo-bridged dimeric structure:

3.2. Infra-red spectra

The ν(CO) band, which is sensitive to complexation, occurs at 1601 cm^{-1} in the parent ylide, as in the case of other resonance stabilized ylides [21]. Coordination of the ylide through *C*-coordination causes an increase in ν(CO) while for *O*-coordination a lowering of ν(CO) is expected. The IR absorption bands observed for the three complexes at 1630, 1626 and 1620 cm^{-1} indicate coordination of the ylide thorough carbon. The $\nu(P^+–C^-)$ which is also diagnostic of the coordination occurs at 837 cm^{-1} in $(C_6H_5)_3P^+–C–H_2$ and at 878 cm^{-1} in $(C_6H_5)_3PCHCOC_6H_5$ [22]. These assignments were confirmed by comparing the IR spectra of the corresponding ^{13}C substituted ylides. In the present study, the $\nu(P^+–C^-)$ values for all three complexes were shifted to lower frequencies and were observed at 825, 820 and 812 cm^{-1} for **1**, **2** and **3**, respectively, suggesting some removal of electron density from the P–C bond.

3.3. NMR spectral data

3.3.1. ^1H NMR spectra

The chemical shifts corresponding to the protons of the ligand and the complexes are listed in Table 3. The signals due to methine protons, when recorded in $CDCl_3$, were either broad or unobserved probably due to the very low solubility of all the complexes in $CDCl_3$. Similar behaviour was observed earlier in the case of ylide complexes of platinium(II) chloride [23]. However, a sharp doublet for the above proton was obtained in DMSO-d_6 for each of the three complexes in the same region. This indicates that the complexes do not react with DMSO-d_6. The appearance of a sharp doublet signal and expected downfield shift for the CH proton show the coordination of carbon through the methine group.

3.3.2. ^{31}P NMR spectra

The proton decoupled ^{31}P NMR spectra show only one sharp singlet between δ 22.65–24.58 ppm for the complexes (Table 3). Chemical shift values for the complexes appear to be downfield by about δ 8–10 ppm with respect to the parent ylide (δ 14.061 ppm), indicating coordination of the ylide has occurred. The appearance of single signals for the PCH group in each of the ^{31}P and ^1H NMR spectra indicates the presence of only one isomer for all the three complexes, as expected for *C*-coordination. It must be noted that *O*-coordination of the ylide generally leads to the formation of *cis* and *trans* isomers, giving rise to two different signals in ^{31}P and ^1H NMR spectra [24].

3.3.3. ^{13}CNMR

The ^{13}CNMR data of the complexes and the title ylide are listed in Table 3, along with possible assignments. The most interesting aspect of the ^{13}CNMR spectra of the complexes is the upfield shift of the signals due to the ylidic carbon. Such an upfield shift observed in $PdCl(\eta^3–2\text{-}XC_3H_4)$ $(C_6H_5)_3PCHCOR$ ($X = H$, CH_3; $R = CH_3$, C_6H_5) was attributed to the change in hybridization of the ylidic carbon [25]. Similar upfield shifts of 2–3 ppm with reference to the parent ylide were also observed in the case of $[(C_6H_5)_3PC_5H_4HgI_2]_2$ [23]. The ^{13}C shifts of the CO group in the complexes are around 189 ppm, relative to 184.265 ppm noted for the same carbon in the parent ylide, indicating much lower shielding of the carbon of the CO group in these complexes. No coupling to Hg was observed at room temperature in the ^1H, ^{13}C and ^{31}P NMR spectra for all these complexes. Failure to observe satellites in the above spectra was previously noted in the ylide complexes of Hg(II) [26] and Ag(I) [27], which had been explained by fast exchange of the ylide with the metal.

3.4. Crystal structure

The solid state structures of complexes **1** and **2** have been established by single crystal X-ray analysis, which revealed triclinic units. The molecular structures are shown in Figs. 1 and 2, and selected interatomic parameters are collected in Table 2.

The dimeric structure adopted by complexes **1**, **2** and **3** is in contrast to the *O*-coordinated trinuclear mercury(II) complex of the phosphorus ylide $Ph_3PCHCOPh$ [28], but is similar to the structure of *trans*-di-μ-iododiiodobis(triphenylphosphoniumcyclopentadienylide) dimercury(II) reported by Baenziger et al. [29] and the *C*-coordinated dinuclear mercury(II) halide complexes of $Ph_3CHCOPh$ (BPPY) [30]. The *C*-coordination of MBPPY is in stark contrast to the *O*-coordination of the phosphorus ylide, $Ph_3PC(COMe)(COPh)$ (ABPPY), to a Hg(II) centre [31]. The difference in coordination mode between ABPPY and MBPPY to Hg(II) can be rationalized in terms of the electronic properties and steric requirements of the ylides. The nucleophilicity of the carbanion in ABPPY is less than for MBPPY; this is due to the additional delocalization of the ylide electron density in ABPPY which is facilitated by the second carbonyl group. This will reduce the ability of ABPPY to bind via the ylidic carbon. Belluco et al. have studied steric influences on the coordination modes of ylide molecules to Pt(II) systems [32]. These authors concluded that the preferred coordination mode is via the ylidic carbon, but that steric hindrance around the metal centre or the ylidic carbon will necessitate *O*-coordination. Indeed, this trend is reflected here, both BPPY and MBPPY are slightly less sterically demanding than ABPPY, and both are *C*-coordinated to Hg(II).

The Hg(II) centre forms four close contacts with sp^3 hybridization and has a 4-coordinate environment with one short Hg–X bond, one Hg–C bond and two asymmetric bridging Hg–X bonds at distances of 2.504(11) and 2.884(12) Å in **1** and 2.603(3) and 3.022(2) Å in **2**.

The significant shortening of the Hg–C bond length, 2.215(4) Å **1** and 2.218(11) Å **2** compared to analogous distances in $[(C_6H_5)_3PCHCOC_6H_5HgI_2]_2$ [30] and in $[(C_5H_4P(C_6H_5)_3HgI_2]_2$ [33] (2.312(13) and 2.292(8) Å, respectively) must be attributed to the use of mercury orbitals with high s character for bonding to the ylidic carbon. The use of non-equivalent hybrid orbitals with high s character to bond to low electronegative atoms was proposed by Bent in the concept of isovalent hybridization to account for the variation in bond lengths and bond angles around a central atom [34].

The terminal Hg–Cl bond length, 2.418(14) Å **1** is comparable to 2.400 Å observed in the case of $Hg_2Cl_5N_2C_{11}H_{12}$, which has a tetrahedral coordination environment around mercury with a bridging structure [35]. The two bridged Hg–Cl bonds fall within the range 2.620–3.080 Å reported for other structures [36] containing chloro bridged mercury.

The angles around mercury vary from 83.90(4)° to 129.16(10)° for the chloride and 89.84(7)° to 132.9(3)° for the bromide, a very distorted tetrahedral environment. This distortion must be due to the higher s character of the sp^3 hybrid mercury orbitals involved in the above bonds and the formation of a strong halogen bridge between the Hg atoms which requires the internal XHgX angle to be considerably smaller.

The stabilized resonance structure for the title ylide is destroyed by the complexes formation. Thus, the C(8)–C(9) bond length (1.498(5) Å, **1** and 1.470(16) Å, **2**) is significantly longer than the corresponding bond found in a similar uncomplexed phosphorane (1.407(8) Å) [37]. On the other hand, the bond length of P(1)–C(9) in the similar ylide is 1.706 Å [24] which shows that the above bond is considerably elongated to 1.785(4) Å and 1.827(11) Å in complexes **1** and **2**, respectively. The plane defined by the two mercury atoms and the two bridging halogens is perfectly planar in both structures. The internuclear distances between mercury atoms were found to be 3.901(7) Å and 3.994(8) Å in structures **1** and **2**, respectively. These distances are much longer than the sum of Van der Waals radii (1.5 Å) of the two mercury atoms [38] indicating the absence of significant bonding interactions between the mercury atoms in the molecular structures. The adaptation of dimeric structures in Hg(II) ylide complexes may be explained by both the preference of Hg(II) to four coordination and the stability of the 18 electron configuration around Hg(II).

4. Conclusions

The present study describes the synthesis and characterization of a series of mercury ylide complexes. On the basis of the physico-chemical and spectroscopic data we propose that MBPPY herein exhibits monodentate *C*-coordination to the metal center, which is further confirmed by the X-ray crystal structures of the complexes.

5. Supplementary material

CCDC 622081 and 620129 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

We are grateful to the Bu-Ali Sina for a Grant and Mr. Zebarjadian for recording the NMR spectra.

Abstract

Hydrolysis and speciation of aluminium sulfate octadecahydrate $Al_2(SO_4)_3 \cdot 18H_2O$ was studied by electrospray time of flight mass spectrometry (ESI TOF MS). Several novel polymeric species were determined. Highly charged polymers, characterized by other methods, such as the Keggin cation $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ and the octameric aluminium hydroxide cluster $[Al_8(OH)_{14}(H_2O)_{18}](SO_4)_5\ 16H_2O$, were found using ESI-MS as the anions $[Al_{13}O_4(OH)_{25}(SO_4)_4]^{2-}$ and $[Al_8O(OH)_{14}(SO_4)_5(H_2O)_4]^{2-}$. All the main species identified contained sulfate or hydrogen sulfate. The compositions of the determined ions mimicked those of several stable mineral forms.

1. Introduction

Purified water is arguably the most precious chemical for mankind by far. In the industrialized world, its consumption per person per day can be several hundreds of litres. Meanwhile, billions of people have considerably insufficient drinking water, which in turn is a major reason, for example, for high infant death rates. In this light, there is astonishingly little research that focuses on the aqueous behavior of water treatment chemicals.

The present investigation is focused on the by far most used coagulation chemical, aluminium sulfate or alum. The major aim is to figure out complex species emerging when alum is dissolved in water. The current process optimization of coagulating flocculating units is based predominantly on single experiments, not on detailed speciation studies. Variations in composition of raw water cause problems, which can be managed if the most efficiently functioning species and particles are known. Improved the understanding of the impact of process parameters on purification results will provide a key to enhancing the material efficiency of processes. This can be achieved with an increased understanding of the chemistry behind the process.

On the other hand, many solid species are crystallized in aqueous aluminium sulfate environments [1–6]. Our secondary aim was to clarify to what extent the emerging aqueous species resemble elementary units of typical crystal aluminium minerals.

We have earlier [7–10] used electrospray mass spectrometry in order to investigate speciation of aqueous aluminium chloride solutions. The studies have offered new information on the hydrolysis chemistry of aluminium, because the speciation found by MS differs from that observed using conventional solution phase analyses [11,12].

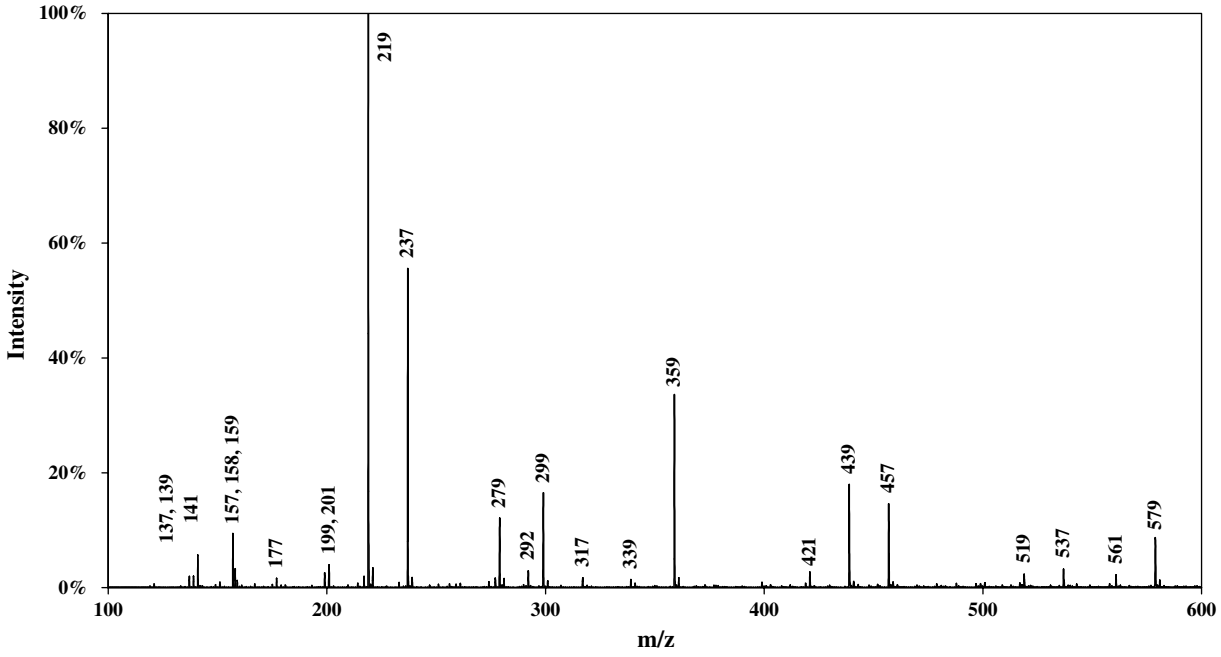

Fig. 1. The cationic spectrum of aluminium sulfate octadecahydrate $Al_2(SO_4)_3 \cdot 18H_2O$, 5 mM at pH 3.76.

2. Experimental

Aluminium sulfate octadecahydrate $Al_2(SO_4)_3 \cdot 18H_2O$ (Merck, purum) 0.3 g exposed to an open atmosphere was dissolved in 100 mL of deionized, distilled water (10 mM Al^{3+}). The solution was divided into two parts. The first part of the solution was left at its initial pH of 3.76 and the other part of the solution was adjusted to pH 3.95, by a drop-wise addition of concentrated tetramethyl ammonium hydroxide pentahydrate, $(CH_3)_4NOH \cdot 5H_2O$, (TMA, Fluka, reinst). TMA was found to be the only useful base, since alkali metals formed several intense chloride aggregate signals that interfere with the interpretation of the spectra. The pH was determined with a Mettler Toledo MP 220 pH meter using a Mettler Toledo InLab 410 Ag/AgCl-electrode calibrated with FF-Chemicals' buffer solutions pH 4.00 and 7.00. The samples were allowed to equilibrate prior to recording for 3 h. We note that more than one day may be needed for aluminium solutions to reach their complete equilibria [11,12], but in our previous studies [7,9] there was little difference between spectra of fresh and 2-week-aged 100 mM $AlCl_3$ solutions.

The ESI TOF mass spectra were recorded by a Micromass LCT mass spectrometer equipped with a Z-spray electrospray interface. The solutions were introduced into the spectrometer by a Harvard Apparatus Model 11 syringe pump at flow-rates of 10 μL/min. The operating conditions (Table 1) used were tested by an experimental design calculated by MODDE 3.0 software. Signals from both pH values were recorded for 2 min and combined to a sum spectrum. All the ESI mass spectral data in the positive and negative ion modes were acquired using Masslynx NT software (version 3.4).

Source temperature	120.0 °C
Cone gas flow (N_2)	300 L/h
Desolvation gas flow	750 L/h

The interpretation of the spectra was done with the aid of compositions and structures of aluminium sulfate minerals [13] equilibrium calculations [14,15] and computational chemistry [16]. The most probable assignments have been chosen in Table 2 and written as structural formulas. When the structure has no calculated confirmation, the formulas were written according to the protonation order: first oxo, followed by sulfate ligands. Thus, the protonation of the sulfate group could be different than the one suggested: e.g. $[Al_2(OH)_3(SO_4)]^+$ could be $[Al_2O(OH)_2(HSO_4)]^+$. The calculation details are presented in our earlier study [17].

According to normal mass spectrometric practice sodium and potassium impurities were utilized in the interpretation. Sodium originates from the glass equipment used, whereas potassium is a major impurity in reagents.

[a] Only in raised pH.

Especially the potassium proved to be very informative. Despite many investigations of sulfuric acid [18–23], $[SO_4]^{2-}/[SO_3]^{2-}$ redox reactions have not been observed in mass spectrometric studies and therefore have been ignored.

Isotopic patterns and ratios appeared to be the most informative aspect in this study. Aluminium and sodium are monoisotopes (^{27}Al and ^{23}Na) and give only single signals to mass spectra. Potassium, oxygen and sulfur have one minor isotope, in addition to the major isotopes. Hence they show duplets with characteristic relative intensities in mass spectra. All the following isotopes were considered in this study: ^{39}K and ^{41}K (6.73%), ^{16}O and ^{18}O (0.21%), and ^{32}S and ^{34}S (4.29%). Considering, e.g. the sulfate ion, for instance, the first isotopic signal, 5.11%, was thus a sum signal assigned to both $[^{34}S^{16}O_4]^{2-}$ (98u) and $[^{32}S^{16}O_3{}^{18}O]^{2-}$ (98u), 4.29% and $4 \times 0.21\%$, respectively, from the main signal $[^{32}S^{16}O_4]^{2-}$ (96u).

The charges were determined by examining the differences between isotopic signals. Differences of 2u, 1u and 0.66u in an isotopic pattern refer to singly-, doubly- and triply-charged complexes, respectively. The relative intensities of signal pairs helped to confirm the amount of sulfate ions in the complex. For example signals *m/z* 400.9 (10.7%) and 401.9 (3.1%, 29% of the *m/z* 400.9) were assigned to a double charged complex with a mass of 801.8 containing six sulfate ligands as $[Al_6O_4(SO_4)_6]^{2-}$, in agreement with theoretical abundance calculations.

As an example of assignation we will give here a detailed pathway for identification of the pentameric complex $[Al_5O_3(OH)(SO_4)_5]^{2-}$: first, we know all the elements injected in the instrument. The major part of the elements is bound as water, the secondary part as aluminium species and sulfate. Additionally, there are trace quantities of potassium and sodium impurities. The duplet signal at *m/z* values 340 and 341 (Fig. 3) had an intensity of over 20%, therefore it should be a rational mixture of the major elements Al, O and H as well as $SO_4{}^{2-}$.

The first isotopic *m/z* value 340 is even. The mass values of aluminium oxo-hydoxides, -sulfates and -chlorides are also always even (AlO(OH) 60u, $Al_2(SO_4)_3$ 342u, for instance). If the charge of the complex is even so is the *m/z* value. Since non-charged species cannot be detected by the mass spectrometer, the charge of this complex must be even.

There was a second signal of m/z 341 with relative intensity of 27.9% from the major signal of m/z 340. The 1u difference between the signals reveals that the charge of the complex is −2 and the ratio of the signals is near 25% which reveals that there are five sulfate groups (relative intensity of 5.11%). Hence, the assignation so far is $[Al_xO_y(OH)_z(SO_4)_5]^{2-}$ and the mass of the complex is $2 \times 340 = 680$u.

Since the charge of this preliminary complex is −2, detracting one sulfate from it we have an uncharged species $[Al_xO_y(OH)_z(SO_4)_4]^0$ with a mass of 584u. Thus the easiest way to figure out the rest of the complex is to divide it to calculatory pieces. We point out, that these pieces are relevant only in terms of matching the mass, they therefore have nothing to do with the structure or protonation order of the final assignation. We therefore next attempt to subtract the sulfates as neutral compounds: $Al_2(SO_4)_3$ 342u and $Al_2O_2(SO_4)$ 182u. The remaining mass is 582u – 342u – 182u = 60u, and the last piece should not contain anything besides aluminium, oxygen or hydroxide and possibly sodium. The neutral species AlO(OH) fulfills this requirement. After finding matching pieces they are combined to one species = $Al_2(SO_4)_3$ 342u + $Al_2O_2(SO_4)$ 182u + AlO(OH) 60u + SO_4^{2-} 96u = $[Al_5O_3(OH)(SO_4)_5]^{2-}$ m/z 340.

Now the simulated intensity of isotopic peak is $4 \times 0.21 + 5 \times 5.11 = 26.4$ which is close enough to the measured 27.9 and there are two signals with distances of 40u and 80u revealing a change of one oxygen to one sulfate and two oxygens to two sulfates. Their isotopic peaks also suit the pattern and therefore confirm the assignation.

3. Results and discussion

Aluminium salts precipitate in the neutral pH range [3]. The sulfate systems now studied showed transient opacity beginning at pH 3.95. The turbidity vanished quite rapidly and after 3 h the solution was clear again. Since at this pH value the chloride solution has earlier been perceived to be clear, consisting principally of dimeric and trimeric oxido and hydroxido variants [7,9], the now observed opacity originated probably from TMA sulfate interactions and not from precipitating aluminium hydroxide.

The differences in the mass spectra between pHs 3.76 and 3.95 were not significant. No new major signals were observed and no existing signals vanished in the spectra when the pH was raised. In the cationic spectra only minor signals, with intensities less than 1%, increased slightly in the m/z range 600–1000, corresponding to larger complexes, perhaps colloidal TMA-SO_4 adducts. In the anionic spectra, the effect of pH was more versatile. The number of minor signals was considerably higher in the whole spectral range, probably due to the exchange of neutral aqua ligands with counter anions during the spraying/nebulation process. The intensity of these signals decreased when the pH was raised from 3.76 to 3.95, indicating that the free sulfate forms diminished. Also, several minor signals in the m/z range 400–600 vanished, and instead new signals appeared in the m/z range 600–1000. The cationic and anionic spectra at the initial pH are illustrated in Figs. 1 and 3, respectively.

In contrast to the chloride systems, few signals assigned to TMA were observed and with very low intensities: the highest intensity, 6%, was m/z 512 $[H_2TMA_3(SO_4)_3]^-$. This refers to colloidal or uncharged TMA – sulfate compositions. Thus sulfate may play an unexpectedly active role in water purification processes if it is forming colloids with amine containing impurities such as biological decomposition products. This observation could also confirm that the coagulation principle of polyaluminium chlorides is different to that of alum, due to the remarkable role of the sulfate anion. There is also evidence from NMR-studies concerning the alteration of the pathway of aluminium polymerization to form polymeric and solid materials in the presence of sulfate ions [24]. The fact that all the main species identified in this study contained sulfate or hydrogen sulfate, as revealed in Table 2, also refers to this.

Only the monomers $[Al(H_2O)_6]^{3+}$, $[Al(SO_4)]^+$, $[Al(SO_4)_2]^-$, $[AlOH]^{2+}$, $[Al(OH)_2]^+$, $Al(OH)_3(aq)$, $[Al(OH)_4]^-$, and precipitating minerals are generally considered in equilibrium calculations, because knowledge of thermodynamic stability constants and heats of formation for polymeric aluminium species are not completely available. Due to this fact, these calculations [14,15] have limited relevance to our investigations: at the studied pH values, 3.76 and 3.95, according to the calculations the solution would be supersaturated towards precipitating minerals such as amorphous $Al(OH)_3$, *diaspore* (AlO(OH)) and *jurbanite* ($AlOHSO_4$) and the most stable aqueous species would be monomeric the Al^{3+} hexa aqua ion. Hence, the equilibrium approach was of limited benefit in the case of studying oligomeric aluminium chemistry, due to the absence of the suggested solid phases, (e.g. jurbanite has never been identified in soils and therefore remains a hypothetical equilibrium phase [25]), the slow kinetics of the suggested solid phases, polynuclear ions, as well as the high variability of apparent solubility constants [26–28].

An additional major difference to the chloride system [7–9] was the lack of a series of ions corresponding to the attachment of water to aluminium cores. In chloride systems the Gaussian distribution of signals, with a difference of 18u, suggests how many aqua ligands are attached to one species and helps to confirm the charge of the species [7–9]. Because in sulfate systems those distribution patterns are missing, rapid movement of aqua and hydroxide ligands in outer spheres takes place to a minor extent as compared to the chloride systems.

Most of the cationic assignments were of the form $[Al_n(OH)_x(HSO_4)_y]^+$ where $n = 1$–4 and $(x + y) = (n/3 - 1)$. With the ESI technique multiply charged ions can be obtained depending on the chemical structure of the analyte. Furthermore, the high polarity of water (dielectric constant ε_r 80.4152) stabilizes high charges in the solution [29]. However, there is the possibility of charge

reduction, which can take place during the evaporation due to protonation or deprotonation [30–32]. The other possible charge reduction process is ion pairing of the aluminium oxo hydroxide species with a counter anion during the evaporation [33–35]. The latter phenomenon explains quite well our findings, where almost all species found contained sulfate. Also the fact that in dilute solutions, where the amount of free counter anions is diminished, more pure oxo hydroxo species were found than in more concentrated solutions [9]. All the phenomena in the ESI process are still under intensive investigations [36,37].

The only cationic monomer with aqua ligands was $[Al(OH)(HSO_4)]^+$. The unhydrolyzed octahedral cation $[Al(OH_2)_6]^{3+}$ (m/z 45) was not observed due to the low m/z value, outside the measuring range of the instrument used. The trimeric cations were the most abundant species with the largest versatility. In the cations the number of hydroxo groups was on a regular basis equal or higher than that of aluminium ($x \geqslant n$). On the contrary, in the same core the number of aluminium atoms was equal or greater than the number of sulfates ($y \leqslant n$), except in two cases: with low intensity signals: m/z 519 and 537 assigned to $[Al_3(OH)_3(HSO_4)_3(SO_4)]^+$ and $[Al_3(OH)_4(HSO_4)_4]^+$, respectively (Table 2). *This could indicate that aluminium formes oxo hydroxo cores with sulfate terminal ligands*. Also, presence of the hydroxide in all the cationic assignments refers to this. Small size cationic complexes in which sulfates exist as a bridging ligands have been identified by Raman spectroscopy [38]. However, due to their low m/z-ratio, these species were beyond of the scope of this investigation.

Due to the lack of complete isotopic distribution for any single species, the signals with m/z values 157, 158 and 159 were probably combinations of three overlapping signals. In addition to the dimeric species $[Al_2(OH)_5(H_2O)]^+$ (Table 2) there could exist a pentameric complex $[Al_5(OH)_{11}(HSO_4)_2(H_2O)_6]^{2+}$, but probably at most to a minor extent because of the six aqua ligands. The number of those was two or less in other sulfate containing cations. $[Al\text{-}(HSO_4)(H_2SO_4)_4(H_2O)_6]^{2+}$ was also a possible assignation, but likely also to be minor because in our aluminium studies these kind of large cluster ions with no aluminium oxo hydroxide core structure have not been observed earlier and they could hardly survive in ESI with these measuring parameters.

The main cationic signal m/z 219 was assigned to the dimeric $[Al_2H_5O_4(SO_4)]^+$, because there is a clear 4% isotope peak with a difference of 2u at m/z 221. Writing the formula otherwise, $[Al_2(OH)_4(HSO_4)]^+$, the composition resembles *aluminite* [39], $Al_2(SO_4)(OH)_4 \cdot 7H_2O$. The only differences in the observed species as compared to aluminite are a proton in the sulfate and the lack of aqua ligands. Those are only ambiguously defined in solution and may evaporate easily during the measurement.

The second highest signal m/z 237 could be assigned to the same complex, but now with one aqua ligand $[Al_2(OH)_4(HSO_4)(H_2O)]^+$. We used computational ab initio methods [16] to investigate the minimum energy structure for this aluminite analogue ion to confirm the protonation of the sulfate group. The calculated structure of $[Al_2(OH)_4(HSO_4)]^+$ is illustrated in Fig. 2. The aluminium atoms are connected mainly by two hydroxide bridges associated with one bridging sulfate group.

Nine major signals were assigned to trimers and the most intensive one, m/z 359, was assigned to $[Al_3O(OH)_4(HSO_4)_2]^+$. This structure could be the precursor of precipitating minerals like *alunites* $MAl_3(SO_4)_2(OH)_6$, where M is an ammonium, oxonium or alkali metal cation [40–43]. The trimeric species are also considered precursors of the Keggin structure [44].

The monomeric aluminium hydroxo sulfate is known as a mineral; *jurbanite*, $AlSO_4(OH) \cdot 5H_2O$. An analogous composition was found in this study as the protonated cation m/z 159 $[Al(OH)(HSO_4)(H_2O)_{0-2}]^+$ and the deprotonated anion m/z 139 $[AlO(SO_4)]^-$, again missing the aqua ligands [45].

The main anionic signal m/z 219 with 7% isotope signal m/z 221 could be assigned to $[Al(SO_4)_2]^-$ as a precursor in solution to $MAl(SO_4)_2 \cdot 12H_2O$, where M is an ammonium or alkali metal cation [46–48], which also is called *alum* in geological literature. Also *mendozite*, $NaAl(SO_4)2 \cdot 11H_2O$ and *tamarugite*, $NaAl(SO_4)_2 \cdot 6H_2O$ have similar formulas, differing only in the number of water molecules in the crystal structure [49–51].

There was also a minor 2% signal at m/z 220, indicating that the main signal m/z 219 could be a sum signal of mono charged $[Al(SO_4)_2]^-$ and some double charged sulfate containing complex. The best assignation was $[Al_2(SO_4)_4]^{2-}$

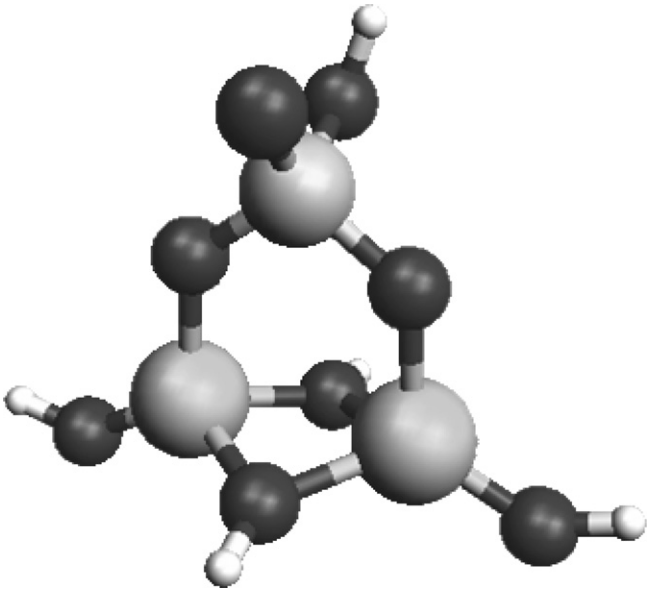

Fig. 2. The structure of the *aluminite* analogue $[Al_2(OH)_4(HSO_4)]^+$ calculated in the gas phase using the BP86 density functional with the polarized valence triple ζ (TZVP) basis set (Turbomole 5.6 program suite). The two aluminium atoms (light grey) are linked together with two hydroxo bridges (O dark grey and H white) and with one bridging protonated sulfate group (S grey). Both aluminium atoms have hydroxo groups as terminal ligands.

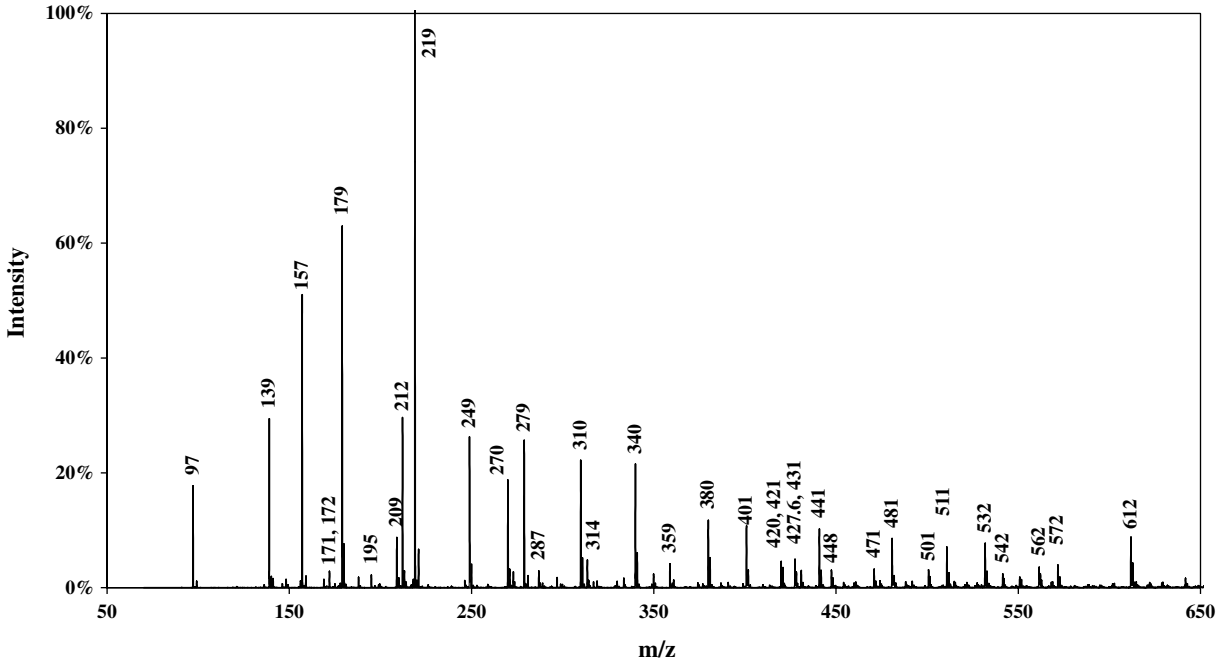

Fig. 3. The anionic spectrum of aluminium sulfate octadecahydrate $Al_2(SO_4)_3 \cdot 18H_2O$, 5 mM at pH 3.76.

since this dimeric four sulfate containing compound had the same composition as, for example, *dietrichite*, $ZnAl_2(SO_4)_4 \cdot 22H_2O$, and *apjohnite*, $MnAl_2(SO_4)_4 \cdot 22H_2O$ [52,53]. The now observed dimeric ion could be the precursor of these minerals.

In the anionic spectrum *m*/*z* 279 (20%) had a possible isotope peak at *m*/*z* 281, with a relative intensity of 12%, indicating mono charged species with one potassium (7%) and one sulfate (4%) or three sulfates. However, no sum formula for those assignations were found and these signals were considered individual signals. They were assigned to $[Al_2O(OH)(SO_4)_2]^-$ (Table 2) and $[Al_5O_7(OH)_2]^-$, respectively.

The trimeric species were absent in the anionic assignment. Instead, there were several polymeric aluminium complexes with a rising series of sulfate ligands and with only a few oxo or hydroxo ligands. Those anionic complexes had to contain bridging sulfate ligands because the number of oxo bridges was now not adequate to hold the structure together. The origin of these complexes is ambigious. It is possible, that they are cluster anions born during the evaporation due to the competition of aqua ligands and sulfate groups in free coordination places, or on the other hand they could be undissociated alum.

In Fig. 4 the structure of the double charged *m*/*z* 270 $[Al_4O_3(SO_4)_4]^{2-}$ is illustrated. Three of the aluminium atoms (I, II and III) are linked together with unhydrolyzed oxo bridges (A, B and C) forming a stable six-membered ring with one terminal unprotonated sulfate group (a) attached bidentally to aluminium (I). The fourth aluminium atom (IV) is connected to the trimer core via a common oxo bridge (B) and two bridging sulfate groups (b and c). These form two six-membered ring structures (Al_{II}–O_B–Al_{IV}–$O_{b'}$–S_b–$O_{b''}$ and Al_{III}–O_B–Al_{IV}–$O_{c'}$–S_c–$O_{c''}$). The fourth sulfate group (d) bridges tridentally the trimeric group and the fourth aluminium forming one six (Al_{II}–O_B–Al_{III}–$O_{d'}$–S_d–$O_{d''}$) and two eight-membered rings (Al_{II}–$O_{d''}$–S_d–$O_{d'''}$–Al_{IV}–$O_{b'}$–S_b–$O_{b''}$ and Al_{III}–$O_{d'}$–S_d–$O_{d'''}$–Al_{IV}–$O_{c'}$–S_c–$O_{c''}$). The six-membered rings are almost in the same plane and the fourth sulfate is above the plane. This two layered structure resembles lausenite [54].

Among the most interesting findings were highly charged polymers, which have been synthesized before from aqueous solution as sulfate salts and characterized by X-ray crystallography and ^{27}Al NMR spectroscopy: the Keggin cation [1,2] $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ now found as the anion $[Al_{13}O_4(OH)_{25}(SO_4)_4]^{2-}$ and the recently found octameric cluster [55] $[Al_8(OH)_{14}(H_2O)_{18}](SO_4)_5 \cdot 16H_2O$, now found as the anion $[Al_8O(OH)_{14}(SO_4)_5(H_2O)_4]^{2-}$. When the counter sulfate anions are attached to the aluminium oxo-hydroxo cores in the gas phase during the measurement, they reduce the high positive charges (in the forms of $[Al_{13}O_4(OH)_{25}]^{6+}$ and $[Al_8O(OH)_{14}]^{8+}$) and the cationic species in solution are observed as anions. If this reaction occurs already in bulk solution, the coagulating ability of these species diminish and the active agent of alum could be some other species.

In our previous studies concerning exclusively chloride environments [7–9], very stable Al_{13} structures were clearly observed, but always with an Al/unhydrolyzed oxo ratio 0.8–1.9, which is 3.25 in the solid Keggin system (see above) and 2.2–3.25 in the Al_{13} species found in this study. Also the Al_{14} which was always found in pure chloride systems [1] with Al_{13}, is now missing. This could indicate that sulfate forces aluminium to form more organized, compressed, solid like species even in an aqueous environment,

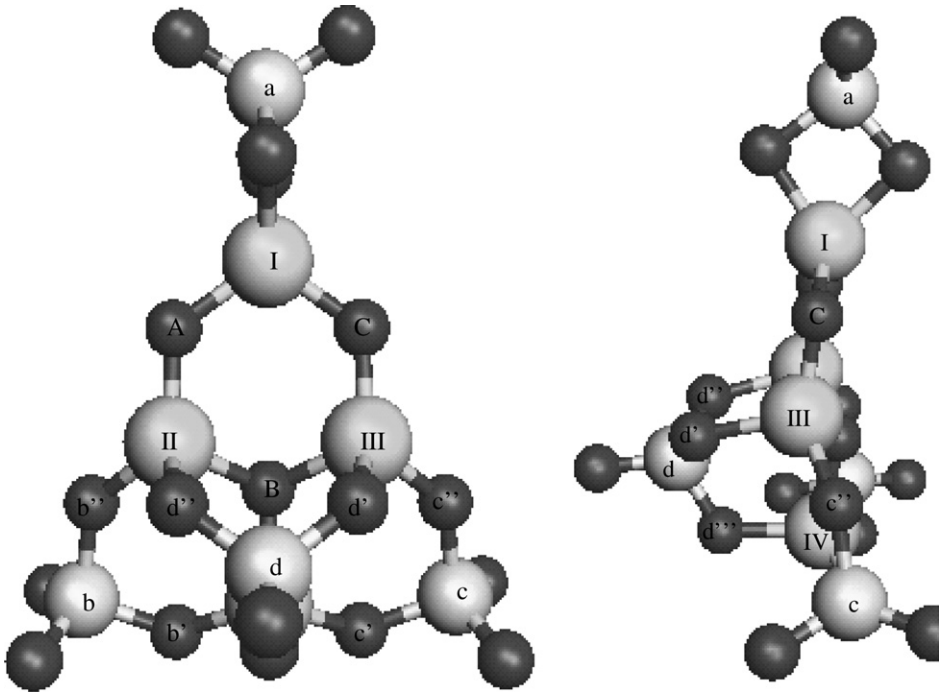

Fig. 4. The structure of the double charged, four aluminium and four sulfate group containing anion, m/z 270$Al_4O_3(SO_4)_4]^{2-}$, calculated in the gas phase using the BP86 density functional with the polarized valence triple ζ (TZVP) basis set (Turbomole 5.6 program suite). The aluminium atoms (light grey, I–IV) are linked together with unhydrolyzed oxo bridges (dark grey, A, B, C) and bridging sulfate groups (S, grey, a–d). Left, the front view, rights the side view.

whereas the chloride systems prefer more flexible speciation where hydroxo and chlorido ligands compete for free coordination places [56].

4. Conclusions

The variety of aqueous species is rich, and many new species were introduced and the presence of sulfate in those was evident. The various polymeric species may play a remarkable role while evaluating functional mechanisms involved in water treatment processes. The polyions may also have biological effects like abilities to increase cell membrane rigidities and cross link biomolecules. In general, resemblance between the observed aqueous polyions and the elementary units of typical natural aluminium compounds proved to be astonishingly high. In addition to water treatment applications this observation may play a role in geochemistry, for evaluating the formation of minerals, for instance.

The high ratio of unhydrolyzed oxygen ligands and aluminium and the lack of an Al_{14} complex in this study could indicate that sulfate forces aluminium to form more organized, compressed, solid like species even in an aqueous environment, whereas the chloride systems prefer more flexible speciation where hydroxo and chlorido ligands competite for free coordination places [56].

Also the lack of TMA-sulfate adducts indicates that sulfate may play an unexpectedly active role in water purification processes if it forms colloids with amine contain impurities like biological decomposition products. This observation could also indicate that the coagulation principle of polyaluminium chlorides is different than that of alum due to the remarkable role of the sulfate anion.

Abstract

The synthesis, crystal structure and magnetic properties of the cyano-bridged complex $[\{Cu(cyclam)\}_3\{Fe(CN)_6\}_2]\cdot 6H_2O$ are reported. Its structure is made up of centrosymmetric S-shaped pentanuclear $[\{Cu(cyclam\}_3\{Fe(CN)_6)\}_2]$ units, in which three $[Cu(cyclam)]^{2+}$ units are alternatively bridged by two *trans*-CN groups of $[Fe(CN)_6]^{3-}$ anions and water molecules. The pentanuclear Fe_2Cu_3 units are held together by two complementary and very weak Fe–CN···Cu1 bonds, forming a rope-ladder chain along the *c* axis. The compound exhibits a ferromagnetic interaction between the Cu(II) and Fe(III) ions as a consequence of the orthogonality of their magnetic orbitals of σ and π nature, respectively. The magnetic data were fitted to the calculated magnetic susceptibility equation for a pentanuclear model, leading to the following magnetic parameters: $J_1 = 9.0(3)\ cm^{-1}$, $J_2 = 3.8(4)\ cm^{-1}$, $g = 2.2$, $\theta = -1.2$ K. These results show that the interactions through the long Cu–N axial bonds are not so weak as is usually assumed.

1. Introduction

In the last two decades, the synthesis and characterization of multidimensional cyano-bridged metal complexes has attracted much interest [1]. The most common and controlled strategy to prepare this kind of system consists of the self-assembly of specifically designed precursors, typically a cyanometallate complex that acts as a ligand and a transition metal complex with free or available coordination sites for the nitrogen atoms of the cyanide groups. Following this route, a great variety of cyano-bridged bimetallic compounds have been prepared, which are playing an important role in areas such as high-Tc magnetic materials [2], SMM (single-molecule magnets) [3], SCM (single-chain magnets) [4], photo-induced magnetism [5], spin-crossover (SCO) materials [6], host-guest chemistry [7], vapochromic materials [8], magnetochirality [9], etc. The dimensionality and topology of these assemblies strongly depends on the nature of ML_x (number and disposition of empty or available coordination positions on M, coordination geometry, volume of the ligands, etc.) and the connectivity of the cyanometallate building block (number and arrangement of ML_x units around M′). As a continuation of our studies in this field [10], we have decided to use hexacyanoferrate(III) units to connect the highly thermodynamically stable $[Cu(cyclam)]^{2+}$ complex, which adopts the *trans*-configuration. In this paper, we are reporting the magneto-structural results for the complex $[\{Cu(cyclam)\}_3\{Fe(CN)_6\}_2]\cdot 6H_2O$ (**1**). These results are compared to those of the isostructural complex $[\{Cu(cyclam)\}_3\{Cr(CN)_6\}_2]\cdot 5H_2O$, which was recently reported by Sallah et al. [11]. This complex exhibits a J_{CrCu} value of $4.33\ cm^{-1}$, which is much higher than those usually observed for cyano-bridged complexes with similar Cu–NC–Cr pathways and long $Cu–N_{axial}$ bond distances.

2. Experimental

2.1. Materials

[Cu(cyclam)](ClO$_4$)$_2$ was prepared according to experimental methods already described [12–14]. All other reagents were purchased from commercial sources and were used as received.

2.2. Synthesis of *1*

A solution of tetraethylamonium ferricyanide (0.055 g, 0.18 mmol) in a water–methanol–acetonitrile mixture (2:1:1, 20 ml) was added with continuous stirring to a solution of [Cu(cyclam)](ClO$_4$)$_2$ (0.042 g, 0.09 mmol) in the same mixture of solvents. The resulting mixture was stirred for 20 min and then filtered. The solution was left standing at room temperature for two days and then crystals of **1** formed, which were filtered off and air dried. Yield: 73%. IR (KBr pellets): $\nu_{CN} = 2153, 2143, 2110\ cm^{-1}$. *Anal.* Calc. for $C_{42}H_{82}N_{24}Cu_3Fe_2O_5$: C, 38.64; H, 6.33; N, 25.75. Found: C, 38.45; H, 6.23; N, 25.68%.

2.3. Physical characterisation

Elemental analyses were carried out at the Instrumentation Scientific Centre of the University of Granada on a Fisons-Carlo Erba analyser model EA 1108. The analysis of metals was performed by SEM on a LEO, mod. GEMINI-1530 microscope at the Instrumentation Scientific Centre of the University of Granada. IR spectra were recorded on powdered samples with a ThermoNicolet IR200FTIR by using KBr pellets. Magnetisation and variable-temperature (1.9–300 K) magnetic susceptibility measurements were carried out on polycrystalline samples with a Quantum Design SQUID operating at different magnetic fields. Magnetization versus applied field measurements were carried out at 2.0 K in the field range 0–5 T. Alternating current susceptibility measurements were performed in the frequency range 10–100 Hz and under an oscillating magnetic field of 1 Oe. The experimental susceptibilities were corrected for diamagnetism of the constituent atoms by using Pascal's tables [15].

2.4. X-ray crystallography

X-ray data were collected on a Bruker Smart Apex CCD diffractometer, using graphite monochromatized Mo Kα radiation. All data sets were corrected for Lorentz and polarization effects. A summary of the crystallographic data and structure refinements is given in Table 1. The structure was solved by direct methods and refined on F^2 by the SHELXL97 program [16] or SHELXTL [17]. The asymmetric unit contains 1.5{[Cu(cyclam)]$^{2+}$ cations, one [Fe(CN)$_6$)]$^{3-}$ anion and 2.5 disordered crystal water molecules. Non-hydrogen atoms were refined with anisotropic thermal displacement parameters. The hydrogen atoms of the macrocyclic ligands were treated as riding atoms using the SHELX97 default parameters. Hydrogen atoms of the water molecules could not be reliably positioned.

3. Results and discussion

The reaction of (NEt$_4$)$_3$[Fe(CN)$_6$] with [Cu(cyclam)](ClO$_4$)$_2$ in a water–methanol–acetonitrile mixture (2:1:1) afforded brown crystals of the compound [{Cu(cyclam)}$_3$-{Fe(CN)$_6$}$_2$]·6H$_2$O. The IR spectrum of this complex exhibits υ(CN) bands at 2110, 2143 and 2153 cm^{-1}. The lower frequency band, which is only slightly shifted as compared to the corresponding υ(CN) = 2100 cm^{-1} band of the [Fe(CN)$_6$]$^{3-}$ anion, is, therefore, reasonably assigned to the terminal cyanides. The higher energy bands, which appear 40–50 cm^{-1} higher than υ(CN) for the [Fe(CN)$_6$]$^{3-}$ anion, are assigned to the cyanide bridging ligands. This increase is due to the mechanical constraint of the motion of the CN group, originating from the presence of the Cu(II) metal centre (kinematic effect).

The structure of **1** is made up of centrosymmetric S-shaped pentanuclear [{Cu(cyclam}$_3${Fe(CN)$_6$)}$_2$] units, in which three [Cu(cyclam)]$^{2+}$ units are alternatively bridged by two *trans*-CN groups of [Fe(CN)$_6$]$^{3-}$ anions and water molecules (Fig. 1). The Cu2 ion, which is located on an inversion centre, and the Cu1 ion, both exhibit elongated tetragonal geometries, with the four nitrogen atoms of the macrocycle occupying the equatorial positions and the nitrogen atoms of the cyanide bridging ligands at the axial positions. In the bridging regions, the Cu1–N and Cu2–N bond distances are 2.573(3) and 2.451(3) Å, respectively, whereas the Fe···Cu1 and Fe···Cu2 distances are 5.322(1) and 5.037(1) Å, respectively. The Cu1–N–C and Cu2–N–C bond angles deviate significantly from linearity with values of 141.2(2)° and 134.5(2)°, respectively. The pentanuclear Fe$_2$Cu$_3$ units are held together by two com-

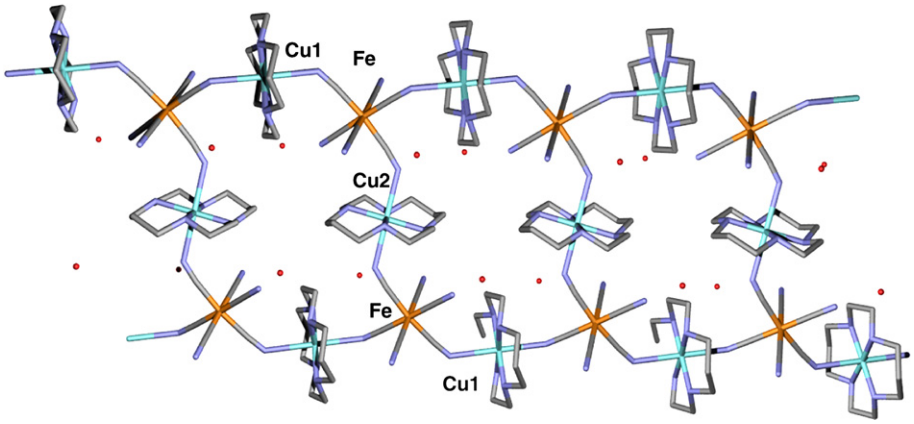

Fig. 1. Perspective view of the rope-ladder structure of **1**. Labelled metal atoms are those of the pentanuclear S unit.

plementary and very weak Fe–CN···Cu1 bonds (Cu1–N distance of 2.620(3) Å and Cu1–N–C angle of 133.2(2) Å and Fe···Cu1 distance of 5.175(1) Å) to form a rope-ladder chain along the *c* axis. In this description, each $[Fe(CN)_6]^{3-}$ is linked to three $[Cu(cyclam)]^{2+}$ units, in which the cyanide-bridging groups adopt a *mer* configuration.

The water molecules are located in between the chains and are involved in hydrogen bond interactions with the terminal cyanide groups and some NH macrocyclic groups.

This structure is similar to those observed for the compounds $[Ni(en)_2]_3[M(CN)_6]_2 \cdot 2H_2O$ (where en = ethylenediamine and M^{III} = Fe, Co, Mn, Cr) [18] and $[Cu(cyclam)]_3[Mo(CN)_8]_2 \cdot 5H_2O$ [19] and is isostructural to that of the compound $[Cu(cyclam)]_3[Fe(CN)_6)]_2] \cdot 6H_2O$ [11].

4. Magnetic properties

The magnetic properties of **1** in the form of a $\chi_M T$ versus T plot (χ_M is the susceptibility per Fe_2Cu_3 unit at a magnetic field of 1 T) is given in Fig. 2. The $\chi_M T$ product at room temperature (2.79 $cm^3\ mol^{-1}$ K) is higher than that calculated for magnetically non-interacting Fe^{III} and Cu^{II} ions (3.87 $cm^3\ mol^{-1}$ K with an average $g = 2$), thus indicating a significant orbital contribution from the octahedral low-spin Fe^{III} atoms. Upon cooling down, the $\chi_M T$ value decreases to reach a minimum at around 36 K, which is due to the spin–orbit coupling effects of the low-spin octahedral Fe^{III} atoms with a $^2T_{2g}$ ground term. In fact, when the $\chi_M T$ product between 40 K and room temperature for the compound $(rac\text{-}CTH_3)_3[Fe(CN)_6]_2 \cdot 8H_2O$ [20] (whose magnetic properties are essentially due to isolated Fe^{III} ions of the $[Fe(CN)_6]^{3-}$ units) is subtracted from the $\chi_M T$ versus T curve for **1**, the resulting $\chi_M T$ values remain almost constant in this temperature range with a value of 1.366 $cm^3\ mol^{-1}$ K, as expected for three isolated Cu(II) ions with $g = 2.2$. This result confirms that the magnetic behaviour of **1** in the high temperature range is due to spin–orbit coupling effects. Below 36 K, $\chi_M T$ increases to reach a maximum at 3 K (3.1 $cm^3\ mol^{-1}$ K), thus indicating a ferromagnetic exchange interaction between the Fe(III) and Cu(II) ions. Below 3 K, $\chi_M T$ decreases sharply to 2.88 $cm^3\ mol^{-1}$ K at 2 K, because of the intermolecular interactions and/or ZFS of the ground state.

In order to analyze the experimental $\chi_M T$ data in a suitable way, we removed the contribution of the spin–orbit coupling effects of the three Fe^{III} ions. For this we subtracted from the experimental $\chi_M T$ data of **1** those of the

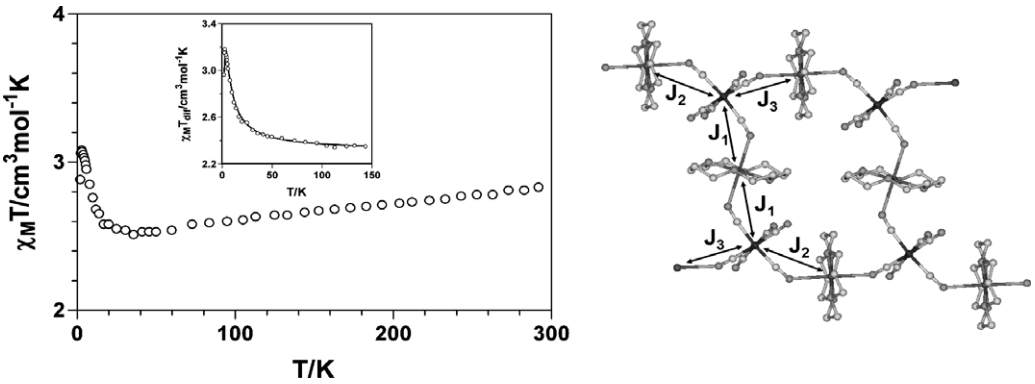

Fig. 2. Temperature dependence of the $\chi_M T$ product of **1** (left). The inset is the temperature dependence of the corrected $\chi_M T$ product of **1**. The solid line is the best-fit curve to the theoretical equation for a Fe_2Cu_3 linear system with $J_3 = 0$. Scheme showing the magnetic exchange pathways in **1** (right).

compound (*rac*-CTH–H_2)$_3$[Fe(CN)$_6$]$_2$ · 8H_2O and then the contribution of two isolated metal ions with $S = 1/2$ and $g = 2$ was added,

$$\chi_M T = \chi_M T\{[Cu(rac\text{-}CTH)]_3[Fe(CN)_6]_2\} - \chi_M T(CTH_3)_3[Fe(CN)_6]_2 \cdot 8H_2O\} + 2\frac{Ng^2\beta^2}{4k}$$

As can be observed in the corrected plot (Fig. 2, inset), upon cooling down $\chi_M T$ increases continuously from room temperature until reaching the maximum at 7 K, as expected for a weak ferromagnetic interaction between the paramagnetic centres. The Cu1 and Cu2 ions, with elongated octahedral geometries, have a $d_{x^2-y^2}$ magnetic orbital (directed toward the nitrogen atoms of the macrocycle) of σ symmetry. The t_{2g} (d_{xy}, d_{xz} and d_{yz}) magnetic orbitals of the low spin Fe^{III} ion are of π symmetry. Therefore, the interaction between orthogonal σ and π magnetic orbitals leads to the observed ferromagnetic interaction.

In keeping with the structural data for this compound, in principle, the magnetic properties should be interpreted through a model with three J parameters (see scheme Fig. 2). However, because the Cu1–$N_{cyanide}$ axial bond and Cu1–N–C angle involving the J_3 exchange pathway are, respectively, longer and sharper than those involving the J_1 and J_2 exchange pathways, the interaction between pentanuclear neighbouring units (J_3) must be much weaker than the intrapentanuclear interactions J_1 and J_2. In view of this and to simplify the model we have considered that $J_3 = 0$. On the basis of this approximation, the magnetic data were fitted to the calculated magnetic susceptibility equation for the pentanuclear unit using the MAGMUM program[1] with the spin Hamiltonian:

$$H = -J_1(FeCu_1 + Fe_ACu_{1A}) - J_2(Fe_ACu_2 + FeCu_2) + g\beta H(SCu_1 + SCu_{1A} + SCu_2 + SFe + SFe_A)$$

To assess the interpentanuclear magnetic interactions, a θ value was included into the magnetic model. The best least-squares fit, gives $J_1 = 9.0(3)$ cm^{-1}, $J_2 = 3.8(4)$ cm^{-1}, $g = 2.2$, $\theta = -1.2$ K. The calculated J_1 value appears to be too high, taking into account that: (i) the Cu_2–N bond distance is rather long (2.451 Å) and the Cu_2–N–C is relatively small (141.15°) and (ii) the nitrogen atom of the cyanide-bridging group is linked in an axial position. Also, the literature values for exchange coupling constants through similar Cu–N–C–Fe pathways (with long Cu–N_{axial} bond distances) are, in general, much smaller. It should be noted, however, that for the isostructural complex [Cu(cyclam)]$_3$[Cr(CN)$_6$]$_2$ · 5H_2O [11], with Cu–N_{axial} bond lengths in the range 2.474(9)–2.638(8) Å, a J value of 4.33 cm^{-1} was reported. Taking into account that in isostructural compounds J_{CrCu} values are smaller than J_{FeCu} values, the J_1 value for **1** might be considered as normal. Nevertheless, the obtained J values must be taken with some caution because of the adopted approximations: (i) the correction of the experimental data to eliminate the spin–orbit coupling effects and (ii) the J_3 exchange pathway was neglected.

In conclusion, the above magnetic results confirm that, in some cases, the magnetic exchange interactions through long Cu–N axial bonds are not so weak as is usually assumed and consequently caution should be exercised when this type of interaction is forced to be zero in the fitting procedure.

[1] MAGMUN4.0/OW0L is available as a combined package free of charge from the authors at http://www.ucs.mun.ca/~lthomp/. MAGMUN has been developed by Dr. Zhiqiang Xu and Laurence K. Thompson (Memorial University), and OW01.exe by Dr. O. Waldmann (University of Bern). The software calculates the total spin state values (S') and their associated energies (E') using the Kambe approach [21] and then substitutes the S' and E' values into the van Vleck equation to generate the variable temperature susceptibility profile (degenerate states are accounted for).

Abstract

Treatment of decamethylzirconocene dichloride $(\eta^5\text{-Cp}^*)_2ZrCl_2$ with amalgamated magnesium in pyridine results in formation of the *o*-C–H bond activation product $[\eta^5\text{-}C_5Me_5]_2ZrH[\eta^2\text{-}\kappa C,N\text{-}C_5H_4N]$ (**1**). X-ray diffraction analysis (solid state) and NMR spectroscopy data (solutions) reveal the lateral positioning of the nitrogen atom in **1**. At elevated temperatures, complex **1** smoothly rearranges into its isomer **2** with medial positioning of the N-atom. The parameters of equilibrium between **1** and **2** were measured at different temperatures. A reaction of **1** or a mixture of **1** and **2** (*ca.* 1:10) with $CDCl_3$ smoothly and under mild conditions leads to one and the same η^2-pyridyl chloride complex $[\eta^5\text{-}C_5Me_5]_2ZrCl[\eta^2\text{-}\kappa C,N\text{-}C_5H_4N]$ (**3**) with medial positioning of the N-atom. The thermodynamic and mechanistic concepts of the paper are discussed with application of the DFT computational data.

1. Introduction

The reduction reactions of decamethylzirconocene dichloride, $Cp^*_2ZrCl_2$, as well as of its parent counterpart Cp_2ZrCl_2, were rather broadly studied under a variety of conditions. As it was clarified previously, in presence of ligands that exhibit not only *n*-donor, but, at least, weak π-acid properties, formation of true Zr(II) compounds of general type $Cp^*_2ZrL_2$ occurs. The most illustrative example is the reduction of $Cp^*_2ZrCl_2$ with sodium amalgam in presence of 1 atm. of molecular dinitrogen, yielding an dinuclear complex (N_2)–$(\eta^5\text{-Cp}^*)_2$Zr–N ≡ N–$(\eta^5\text{-Cp}^*)_2$-Zr–(N_2) [1–3]. Alternatively, reduction of $Cp^*_2ZrCl_2$ without the "support" of any π-acidic compounds processes ambiguously, with the fulvene-hydride type products of the oxidative addition of one of the C–H bonds from methyl groups, $(\eta^5\text{-Cp}^*)(\eta^5{:}\eta^1\text{-}\kappa C\text{-}C_5Me_4\text{–}CH_2\text{–})ZrH$, postulated as the dominating components of reaction mixtures [1,3].

While cationic Zr(IV) biscyclopentadienyl complexes are known to provide intermolecular CH-activation of pyridine type systems at the 2-position [4–8], by now there are not very many examples of the selective reduction-induced intermolecular activations of C–H or other inert (e.g., C–F) bonds in organic substrates with *in situ* generated low-valent zirconocenes (or titanocenes) [9–15]. In this paper, we report the unambiguously proceeding stochiometric *ortho*-activation of the C–H bond in pyridine with $Cp^*_2ZrCl_2$ and amalgamated magnesium.

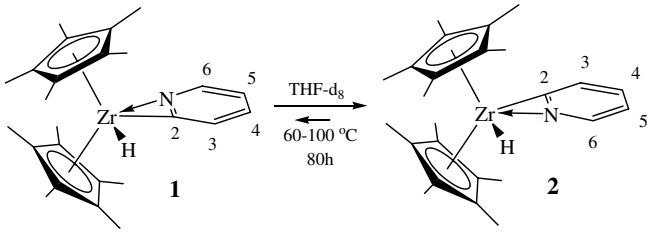
2. Results and discussion

2.1. Reduction-induced *o*-C–H bond activation in pyridine

Treatment of $Cp^*_2ZrCl_2$ with amalgamated magnesium in pyridine at 20 °C smoothly produces the *o*-C–H pyridine bond activation product **1** (see Scheme 1).

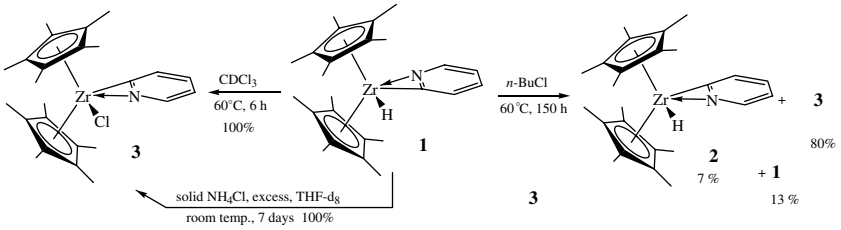


The product **1** was isolated in pure state from hexane in a good yield as colorless crystals. In ^{1}H NMR spectrum, the assignment of the signals is unambiguous due to the fact that, in pyridines, the H(2 or 6) peak always appears at the lowest field, with ^3J(H(6)–H(5)) being considerably smaller than ^3J(H(5)–H(4)) (~5 Hz versus 7–8 Hz, respectively). Coordination of the nitrogen atom and its lateral positioning was unambiguously established both in solutions (NMR data: irradiation of Zr–H proton reveals NOE enhancement of H(3) [$\eta_{H(3)}$(ZrH) = 1.1%], but not H(6), proton in the pyridine ring; the numbering is given in Scheme 1) and in crystalline state (X-ray diffraction analysis for an adduct of **1** with one-half molecule of pyridine, *vide infra*).

The lateral position of the N-atom in the initially formed **1** is somewhat untypical. For instance, analogous CH-bond activations in [η^5-$C_5(CH_3)_4CH_2CH_2N(CH_3)_2$]-[$\eta^5$-$C_5(CH_3)_5$]$ZrCl_2$ [16] and in [η^5-1,3-$(Me_3Si)_2$Indenyl]$_2ZrCl_2$ in presence of 4-*N*,*N*-dimethylaminopyridine [17] give only the η^2-κC,*N*-products with medially located N-atom. Thus, the question persisted if the rearrangement of **1** into its isomer with medially located N-atom is possible or not.

Scheme 1.

At room temperature, complex **1** in a THF-d_8 solution exhibits no tendency to any changes within months. However, if heated (60–100 °C), rearrangement of **1** into its isomer **2** with medially located N-atom takes place (see Scheme 2). The structure of isomer **2** in solution was proved by NMR data. Unlike in **1**, irradiation of Zr–H proton reveals NOE enhancement of H(6) [$\eta_{H(6)}$(Zr–H) = 1.4%], but not H(3) proton in the pyridine ring. The numbering is given in Scheme 2.



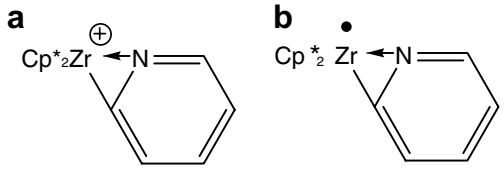
Scheme 2.

At elevated temperatures, complexes **1** and **2** are in equilibrium, with isomer **2** dominating in the mixture. However, this equilibrium is achieved rather slowly (80 h at 100 °C). The estimated equilibrium constant of the process little depends upon temperature (10, 9.8 and 8.7 at 66 °C, 80 °C and 100 °C, respectively), with ΔG lying within 6.5–6.8 kJ/mol range (for the details see Section 3). Noteworthy, no other reactions for both **1** and **2** were observed in this case.

The similar interconversion of the lateral/medial heteroatom isomers was reported earlier for formally related η^2-acetyl and η^2-iminoacyl complexes (η^5-$C_5H_5)_2$Zr[η^2-C(=X)R]R′ as a kinetically fast process [18]. The significantly lower rate for **1** ↔ **2** isomerization, evidently, is due to the sterical effect of the methyl groups at the Cp^*-rings.

Treatment of complex **1** with chloroform-*d* or with solid NH_4Cl in THF-d_8 quantitatively yields the corresponding chloride complex **3** as the only product (the only isomer) (see Scheme 3). Moreover, treatment of the equilibrium mixture of **1** and **2** (*ca.* 1:9) with $CDCl_3$ gives exclusively the same complex **3** as the only one of two possible isomers. η^2-Pyridyl–chloride complex **3** exhibits considerable resistance to oxidation and hydrolysis in the presence of air. This fact underlines the 18-electron nature of coordinatively saturated metal center.

The analogous process takes place if *n*-BuCl (3.5 equiv. in THF-d_8; concentration of **1** is taken approximately the same) is applied as a chlorinating agent. In this case the process is slow and even after 150 h at 60 °C the reaction is still rather far from completeness, with 13% of initial **1**



Scheme 3.

along with 7% of **2** (the product of the parallel **1** ↔ **2** interconversion) persisting in the mixture. However, comparison of $CDCl_3$ (pure solvent) and *n*-BuCl concentrations suggests that the rate constants in both of these cases are of the same order.

The molecular structure of complex **3** was established by NMR spectroscopy (in solutions) and X-ray diffraction analysis (*vide infra*). Independent on the preparation method, in complex **3** the N-atom occupies the medial position.

As far as it is difficult to imagine that **1** is unreactive towards chloroform itself and that intermediate conversion of it into **2** is required, the explanation should be given on the basis of some adequate mechanistic hypothesis. With evidence, the general mechanism is a multistep and complicated one. However, two possible alternatives should be considered. The first one involves formation of cationic particles (a), while the second one assumes formation of Zr(III) intermediates (b), as depicted in Scheme 4.

Quantum-chemical estimates provided us the optimized geometries for model $\{[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-pyridyl}]\}^+$ and $[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-pyridyl}]$ species (see Fig. 1).

Scheme 4.

The values of the principle geometrical parameters for these computed structures are compared in Table 1.

As it is clear from Fig. 1 and Table 1, the spatial organization of cationic and trivalent Zr species is markedly different. In the cation, the N-atom is positioned nearly exactly in the $Cp_{cent}(1)$–Zr–$Cp_{cent}(2)$ plane (deviation 0.131 Å), with the whole bond C–N situated on one side in respect to this plane. Thorough examination revealed that it is also the only stationary point for this cation (i.e., a structure where C- and N-atoms are changed in places is not realized). Contrarily, the Zr(III) hypothetical intermediate is rather "symmetrical" and in this case the $Cp_{cent}(1)$–Zr–$Cp_{cent}(2)$ plane intersects the C–N bond at its middle (deviation of the Cent(CN) 0.087 Å). In the $\{[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-pyridyl}]\}^+$ cation, the access to the Zr-center is provided only from the "N-side", whereas in the Zr(III) structure an approach of a reagent may happen from both C- and N-sides. Thus, taking into account both the experimental and computational data, participation of cationic particles **a**, at least as components of contact ion pairs, should be considered.

The hypothesis on the heterolytic mechanism finds arguments in literature data. Thus, cationic complex $\{[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-(6-methylpyridyl)}](THF)\}^+$ in CH_2Cl_2 was reported to degrade slowly to a mixture of two isomeric chlorides $[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-(6-methylpyridyl)Cl}$ and $[\eta^5\text{-}C_5H_5]_2ZrCl_2$ [8]. Meanwhile, when in presence of $[Me_3NCH_2Ph]Cl$ (provision of the chloride anion source), the only isomer of $[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-(6-methylpyridyl)Cl}$ was formed rapidly.

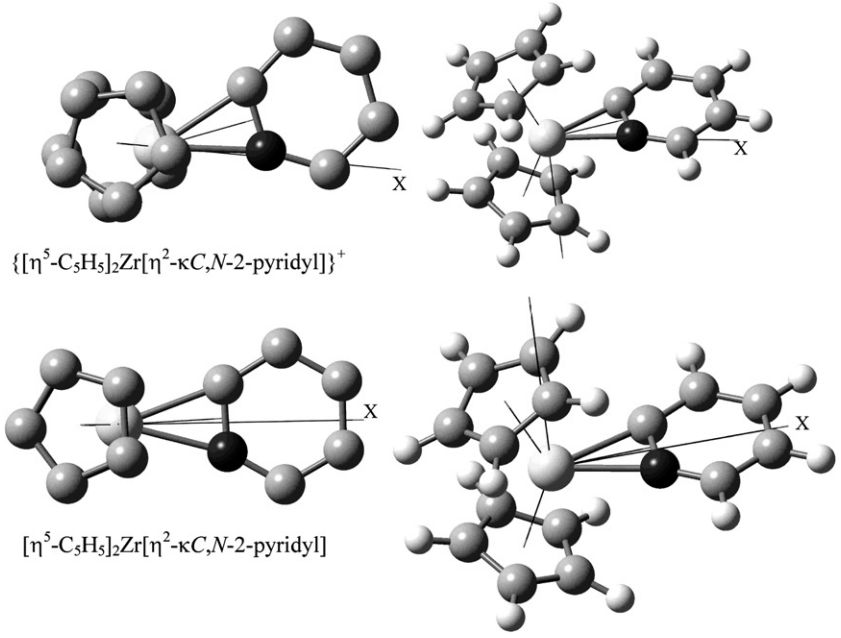


Fig. 1. Comparison of the DFT optimized structures for $\{[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-pyridyl}]\}^+$ and $[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-pyridyl}]$ (restricted and unrestricted B3LYP methods, basis set 3-21G**). The projections to the left are given along the $Cp_{cent}(1)$–$Cp_{cent}(2)$ axes, with all hydrogen atoms not depicted for clarity. Line Zr–X is the intersection of the $Cp_{cent}(1)$–Zr–$Cp_{cent}(2)$ plane and the mean plane of the pyridyl ring.

Table 1
Comparison of the structural parameters for DFT optimized geometries of $\{[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-pyridyl}]\}^+$ and $[\eta^5\text{-}C_5H_5]_2Zr[\eta^2\text{-}\kappa C,N\text{-}2\text{-pyridyl}]$

	$[Cp_2Zr(C_5H_4N)]^+$	$[Cp_2Zr(C_5H_4N)]$
$Zr–Cp_{cent}1$ (Å)	2.217	2.233
Zr–PL1 (Å)	2.217	2.232
$Zr–Cp_{cent}2$ (Å)	2.219	2.233
Zr–PL2 (Å)	2.219	2.232
Zr–C (Å)	2.204	2.273
Zr–N (Å)	2.215	2.215
Zr–Cent(CN) (Å)	2.102	2.168
$PL(Cp_{cent}1–Zr–Cp_{cent}2)–N$ (Å)	0.131	0.597
$PL(Cp_{cent}1–Zr–Cp_{cent}2)–C$ (Å)	1.392	0.770
$PL(Cp_{cent}1–Zr–Cp_{cent}2)$–Cent(CN) (Å)	0.761	0.087
PL(1)–PL(2)[a] (°)	136.27	135.90
X–Zr–N (°)	3.379	15.22
X–Zr–Cent(CN) (°)	21.23	2.29
C–Zr–N (°)	35.80	35.03
PL(Pyr)–Zr (Å)	0.009	0.000

[a] PL1 and PL2 are the mean planes of the first and the second Cp rings, respectively.

2.2. X-ray structural investigation of complexes *1* (adduct with pyridine) and *3*

Molecular structure of complex **1** is presented in Fig. 2. The selected bond lengths and angles are listed in Table 2. The molecule of **1** presents a bent-metallocene sandwich, with the angle $Cp^*_{cent}(1)–Zr–Cp^*_{cent}(2)$ [$Cp^*_{cent}(1)$ and $Cp^*_{cent}(2)$ mean the centroids of the C(11)–C(15) and C(21)–C(25) rings, respectively] equal to 141.9° that is within the range observed previously for Cp^*_2Zr fragments (129.4–145.1°, average value 137.5°; Cambridge Structural Database (release: August 2006) [19], 148 entries, 169 fragments). The distances Zr–PL(1) and Zr–PL(2) [PL(1) and PL(2) are the mean planes of the C(11)–C(15) and C(21)–C(25) rings, respectively] consist 2.2390(15) and 2.2400(14) Å that also matches the range typical for Cp^*_2Zr-moieties (2.171–2.420 Å, CSD [19]).

Table 2
Selected bond lengths (Å) and angles (°) for **1** and **3**

	1	**3a**	**3b**
Zr–N(1)	2.244(3)	2.222(3)	2.204(3)
Zr–C(1)	2.258(3)	2.233(4)	2.235(4)
$Zr–Cp^*_{cent}$	2.239, 2.240	2.258, 2.268	2.259, 2.265
C(1)–N(1)	1.344(4)	1.336(5)	1.323(5)
Zr–H	1.77(5)		
Zr–Cl		2.556(1)	2.549(1)
$Cp^*_{cent}–Zr–Cp^*_{cent}$	141.9	137.0	137.1
N(1)–Zr–C(1)	34.7(1)	34.9(1)	34.7(1)
N(1)–C(1)–Zr	72.1(2)	72.1(2)	71.4(2)
C(1)–N(1)–Zr	73.2(2)	73.0(2)	74.0(2)
C(1)–Zr–H	82(2)		
N(1)–Zr–Cl		82.16(8)	80.62(9)

Both C_5 rings are planar within 0.020(2) Å. As expected, all ten methyl group carbons are deviated 0.058(7)–0.292(7) Å in respect to the corresponding mean C_5-planes outwards from the Zr atom, with the greatest deviation values observed for the rare-positioned atoms C(20) and C(30).

The pyridyl ligand exhibits η^2-coordination mode towards the central atom, with the Zr–N(1) and Zr–C(1) distances equal to 2.244(3) and 2.258(3) Å, respectively. This agrees well with the same distances for similar complex $[(\eta^5\text{-Cp})_2Zr(PMe_3)(\eta^2\text{-}\kappa N,C\text{-}C_5H_3N\ (6\text{-}CH_3)]^+BPh_4^-$ 2.21(1) and 2.29(2) Å, respectively) [8]. All three atoms H, C(1), and N(1) lay in the bisector plane of the zirconocene, with the hydride atom H and N(1) atom occupying the lateral positions. The fragment {Zr,C(1)–C(5),N(1)} is planar within 0.012(3) Å, with the angles between its mean

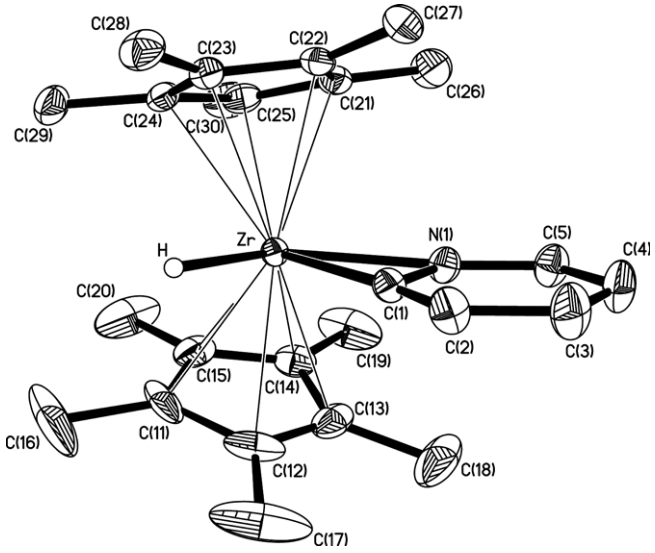

Fig. 2. Molecular structure of **1**. Displacement ellipsoids are shown at 50% probability level. All hydrogen atoms (except hydride) are omitted for clarity.

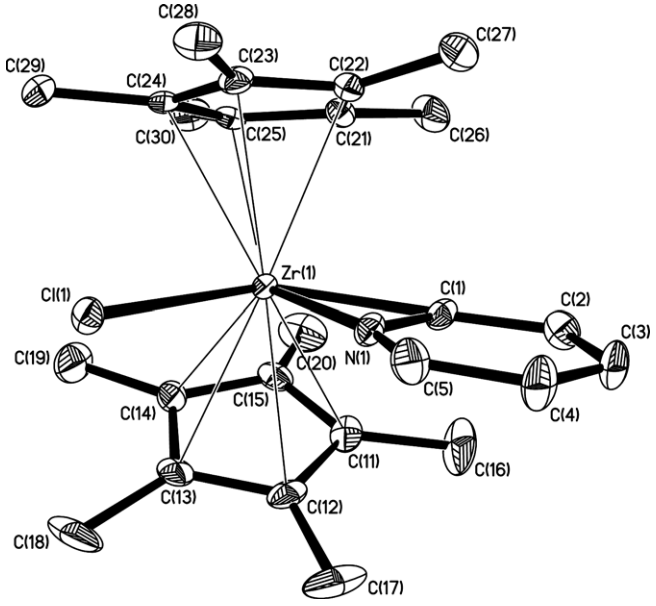

Fig. 3. Molecular structure of **3** (one independent molecule). Displacement ellipsoids are shown at 50% probability level. All hydrogen atoms are omitted for clarity.

plane and the planes PL(1) and PL(2) being nearly equal (19.3(2) and 19.1(2)°, respectively). The distance Zr–H is 1.77(5) Å and is close to observed previously for terminal Cp_2Zr–H bonds (1.68(8) Å [20] and 1.78(2) Å [21]).

In the crystal of **1**, the disordered solvent pyridine molecule is sited on crystallographic inversion center.

Molecular structure of complex **3** is shown in Fig. 3. In **3**, the asymmetric unit contains two independent molecules **3a** and **3b**. The geometry of both **3a** and **3b** are similar to that of **1** (see Table 2). However, in contrast to **1**, nitrogen atoms occupy medial sites. The Zr–Cl distances (2.549(1) and 2.556(1) Å) are in a good agreement with the one in $[\eta^5{:}\eta^2\text{-}\kappa C,N\text{-}C_5Me_4CH_2CH_2N(CH_3)CH_2](\eta^5\text{-}C_5Me_5)ZrCl$ [16] (see Table 3).

3. Experimental

3.1. General remarks

All procedures were performed in sealed-off evacuated glass vessels. The employed solvents (and their perdeuterated analogues) were dried with and distilled from conventional agents (namely: diethyl ether and THF – with sodium benzophenone ketyl; hydrocarbons – with Na–K alloy; pyridine and chlorinated hydrocarbons – with CaH_2). When performing procedures in evacuated vessels, the degassed solvents were stored in evacuated reservoirs over corresponding drying agent and transferred on a high vacuum line directly into reaction vessels by trapping them with liq. N_2. ^{1}H and ^{13}C NMR spectra were recorded on "Varian VXR-400" and "Bruker Avance-400" spectrometers at 400 and 100 MHz, respectively. For ^{1}H and ^{13}C spectra, the solvent resonances [$\delta_H = 7.24$ and $\delta_C = 77.0$ ($CDCl_3$), $\delta_H = 7.15$ and $\delta_C = 128.0$ (C_6D_6), $\delta_H = 1.73$ and $\delta_C = 25.3$ (THF-d_8)] were used as internal reference standards. Mass spectra were measured on "Bruker Autoflex II" spectrometer (N_2 lazer, 337 nm). The elemental analyses were performed on the Carlo-Erba automated analyser.

3.2. $[\eta^5\text{-}C_5Me_5]_2ZrH[\eta^2\text{-}\kappa C,N\text{-}C_5H_4N]$ (**1**)

A solution of decamethylzirconocene dichloride (306 mg, 0.707 mmol) in pyridine (20 mL) along with amalgamated magnesium powder (340 mg, 14.0 mmol) was stirred at room temperature for 10 days. Pyridine was removed by trapping with liq. N_2 and finally – on the high vacuum line. The residue was taken with hexane (20 mL), the extract was concentrated until crystallization started and left to stay at −15 °C. Crystalline **1** was flushed with minimal portion of cold hexane and dried on the high-vacuum line. Colorless crystals. Yield 240 mg (77%). ^{1}H NMR (30°C, THF-d_8): $\delta = 1.66$ [s, 30H, $C_5(CH_3)_5$], 3.96 (s, 1H, ZrH), 7.15 (dd, 1H, $^3J_{HH} = 7.3$ Hz, $^3J_{HH} = 5.2$ Hz, H^5), 7.50 (t, 1H, $^3J_{HH} = 7.3$ Hz, H^4), 7.81 (d, 1H, $^3J_{HH} = 7.3$ Hz, H^3), 8.60 (d, 1H, $^3J_{HH} = 5.2$ Hz, H^6). NOE data: $\eta_{H3}(ZrH) = 1.1\%$. $^{13}C\{^1H\}$ NMR (30 °C, THF-d_8): $\delta = 11.64$ [$C_5(CH_3)_5$], 113.87 [$C_5(CH_3)_5$],

123.16, 133.53, 136.09, 144.15 (CH in py), 203.60 (C^2). ^{1}H NMR (30 °C, C_6D_6): $\delta = 1.76$ [s, 30H, $C_5(CH_3)_5$], 4.43 (s, 1H, ZrH), 6.60 (ddd, 1H, $^3J_{HH} = 7.3$ Hz, $^3J_{HH} = 5.0$ Hz, $^4J_{HH} = 1.3$ Hz, H^5), 7.02 (td, 1H, $^3J_{HH} = 7.3$ Hz, $^4J_{HH} = 1.3$ Hz, H^4), 7.88 (dt, 1H, $^3J_{HH} = 7.3$ Hz, $^4J_{HH} = {}^5J_{HH} = 1.3$ Hz, H^3), 8.10 (dt, 1H, $^3J_{HH} = 5.0$ Hz, $^4J_{HH} = {}^5J_{HH} = 1.3$ Hz, H^6). $^{13}C\{^1H\}$ NMR (30°C, C_6D_6): $\delta = 11.61$ [$C_5(CH_3)_5$], 113.61 [$C_5(CH_3)_5$], 122.10, 133.20, 135.17, 143.11 (CH in py), 203.63 (C^2). *Anal.* Calc. for $C_{25}H_{35}NZr$ (440.77): C, 68.12; H, 8.00; N, 3.18. Found: C, 68.05; H, 8.10; N, 3.08%.

3.3. Isomerization of 1 (complex 2)

A solution of **1** (80 mg) in THF-d_8 (0.7 mL) was heated in a sealed-off NMR tube at 100 °C. Periodically, the sample was removed from the bath, and the ^{1}H NMR spectrum at 27 °C was measured. After 80 h (total heating time) there were no changes in the spectra. The relative molar ratio of **2** in respect to **1** was 8.7 (integration of the signals in ^{1}H NMR spectra). The same sample was used to measure the relative content of isomers **1** and **2** at 80 °C (total heating time 36 h, molar ratio **2** in respect to **1** 9.8) and 60 °C (total heating time 36 h, molar ratio **2** in respect to **1** 10.0). ^{1}H NMR (27°C, THF-d_8): $\delta = 1.67$ [s, 30H, $C_5(CH_3)_5$], 4.08 (s, 1H, ZrH), 7.10 (dd, 1H, $^3J_{HH} = 7.3$ Hz, $^3J_{HH} = 5.0$ Hz, H^5), 7.55 (t, 1H, $^3J_{HH} = 7.3$ Hz, H^4), 7.96 (d, 1H, $^3J_{HH} = 7.3$ Hz, H^3), 8.30 (d, 1H, $^3J_{HH} = 5.0$ Hz, H^6). NOE data: η_{H6}(ZrH) = 1.4%. $^{13}C\{^1H\}$ NMR (27°C, THF-d_8): $\delta = 11.74$ [C5(*C*H3)5], 113.70 [*C*5(CH3)5], 123.29, 130.35, 136.03, 147.04 (CH B py), 203.62 (C2).

3.4. Reactions of 1 and 2 with chlorinating agents (compound 3)

(A) Compound **1** (50 mg) was dissolved in $CDCl_3$ (0.7 mL), transferred into an NMR tube, sealed off and kept at room temperature. Content of **3** (molar %): 20 h – 85%, 7 days – reaction complete (^{1}H NMR monitoring data).

(B) A mixture of **1** and **2** (total amount 80 mg, molar ratio *ca.* 1:10) was dissolved in $CDCl_3$ (0.7 mL), transferred into an NMR tube, sealed off heated at 60 °C for 5 h. Reaction complete (^{1}H NMR monitoring data).

(C) Compound **1** (50 mg) was dissolved in THF-d_8 (0.7 mL) and excess of solid powdered NH_4Cl was added. The slurry was stirred for 7 days and the solution was transferred into an NMR tube by decantation. The reaction is complete (NMR spectroscopy data).

(D) Complex **1** (100 mg) was dissolved in $CHCl_3$ (5 mL) and heated at 60 °C for 5 h. The volatiles were removed by trapping with liq. N_2 and the product was dried on the high-vacuum line. Yield 110 mg (quantitatively). ^{1}H NMR (30°C, THF-d_8): $\delta = 1.63$ [s, 30H, $C_5(CH_3)_5$], 7.19 (ddd, 1H, $^3J_{HH} = 7.3$ Hz, $^3J_{HH} = 5.0$ Hz, $^4J_{HH} = 1.3$ Hz, H^5), 7.60 (td, 1H, $^3J_{HH} = 7.3$ Hz, $^4J_{HH} = 1.3$ Hz, H^4), 7.95 (dt, 1H, $^3J_{HH} = 7.3$ Hz, $^4J_{HH} = {}^5J_{HH} = 1.3$ Hz, H^3), 8.39 (dt, 1H, $^3J_{HH} = 5.0$ Hz, $^4J_{HH} = {}^5J_{HH} = 1.3$ Hz, H^6). $^{13}C\{^1H\}$ NMR (30°C, THF-d_8): $\delta = 11.61$ [$C_5(CH_3)_5$], 117.64 [$C_5(CH_3)_5$], 124.12, 129.26, 135.89, 142.89 (CH in py), 206.65 (C^2). ^{1}H NMR (30°C, $CDCl_3$): $\delta = 1.66$ [s, 30H, $C_5(CH_3)_5$], 7.16 (ddd, 1H, $^3J_{HH} = 7.3$ Hz, $^3J_{HH} = 5.1$ Hz, $^4J_{HH} = 1.0$ Hz, H^5), 7.58 (td, 1H, $^3J_{HH} = 7.3$ Hz, $^4J_{HH} = 1.3$ Hz, H^4), 7.91 (dt, 1H, $^3J_{HH} = 7.3$ Hz, $^4J_{HH} = {}^5J_{HH} = 1.2$ Hz, H^3), 8.46 (dt, 1H, $^3J_{HH} = 5.1$ Hz, $^4J_{HH} = {}^5J_{HH} = 1.3$ Hz, H^6). $^{13}C\{^1H\}$ NMR (30°C, $CDCl_3$): $\delta = 11.32$ [$C_5(CH_3)_5$], 117.32 [$C_5(CH_3)_5$], 123.30, 128.29, 135.12, 142.21 (CH in py), 205.53(C^2). MS (MALDI) (N_2 laser, 337 nm) *m/z* (%):473 (44.5) $[M]^+$, 458 (99.3) $[M - CH_3]^+$, 438 (100) $[M - Cl]^+$, 394 (58.8) $[M - C_5H_5N]^+$, 360 (5.3) $[(C_5Me_5)_2Zr]^+$, 338 (40.1) $[M - C_5Me_5]^+$. *Anal.* Calc. for $C_{25}H_{34}ClNZr$ (475.22): C, 63.19; H, 7.21; N, 2.95. Found: C, 63.29; H, 7.28; N, 2.71%.

3.5. X-ray crystallographic study

Experimental intensities for both **1** (an adduct with 0.5 molecule of pyridine, from hexane) and **3** (from hexane) were measured on a Bruker SMART CCD diffractometer (graphite monochromatized Mo Kα radiation, $\lambda = 0.71073$ Å) at 120 K. Semi-empirical absorption corrections based on the measurements of equivalent reflections were applied. The structures were solved by direct methods [22] and refined by full matrix least-squares on F^2 [23] with anisotropic thermal parameters for all non-hydrogen atoms. All hydrogen atoms (except hydride in the structure of **1**) were placed in calculated positions and refined using a riding model. Hydride atom was located from difference Fourier map and refined isotropically. The positions of N(1) and C(1) atoms were undoubtedly assigned by analysis of isotropic displacement parameters and confirmed by the best obtained final *R*-values. The possibility of partial positional disorder of N(1) and C(1) was also checked; no evidence of such disorder was found.

4. Computational details

The DFT calculations were performed using the GAUSSIAN-G03W program package [24].

5. Supplementary material

CCDC 619986 and 619987 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

New platinum complexes have been synthesized by the reaction of Na_2PtCl_4 with 2-acetylpyridine-4-cyclohexyl-thiosemicarbazone, HAc4CyclHexyl (**1**). The new complexes [Pt(Ac4CyclHexyl)Cl] (**2**) and [Pt(Ac4CyclHexyl)$_2$] (**3**) have been characterized by elemental analyses and spectroscopic studies. The crystal structure of the complex [Pt(Ac4CyclHexyl)Cl] · DMF has been solved by single-crystal X-ray diffraction. The anion of Ac4CyclHexyl coordinates in a planar conformation to the central platinum(II) through the pyridyl N, azomethine N and thiolato S atoms. The crystal packing is determined by double intermolecular hydrogen interactions, π–π, Pt–C and Pt–π contacts. The cytotoxic activities of **1**–**3** have been evaluated for antiproliferative activity in vitro against the cells of three human cancer cell lines: MCF-7 (human breast cancer cell line), T24 (bladder cancer cell line), A-549 (non-small cell lung carcinoma) and a mouse L-929 (a fibroblast-like cell line cloned from strain L). The compounds **1**–**3** display IC_{50} values in a μM range better than that of the antitumor drug cisplatin and are considered as agents with potential antitumor activity candidates for further stages of screening in vitro and/or in vivo.

Keywords: Platinum(II) complexes; Thiosemicarbazonato complexes; Crystal structure; Spectroscopic studies; Antineoplastic activity

1. Introduction

The chemistry of transition metal complexes of thiosemicarbazone, Tsc's, has been receiving considerable attention largely because their broad profile of pharmacological activity affords a diverse variety of compounds with different activities [1]. Tsc's are among the most potent inhibitors of ribonucleotide reductase, RR, activity. RR catalyses the synthesis of deoxyribonucleotides from their ribonucleotide precursors and as such is responsible for maintaining a balanced supply of the deoxyribonucleotides required for DNA synthesis and repair. Strong positive correlation has been established between RR activity and the rate of replication of cancer cells [2].

The combination of Tsc's with agents like platinum(II) or palladium(II) that damage DNA produces synergistic inhibition of tumour growth and may lead to improvements in the effectiveness of cancer chemotherapy regimens [3–8]. *cis*-Diamminadichloroplatinum(II) (cisplatin) has for a long time been of major significance in cancer therapy. In addition, several derivatives of this parent drug, such as iproplatin and carboplatin [9], have been tested clinically. The goal of reducing toxic side effects while maintaining therapeutical efficacy can be accomplished by improving the solubility of the complexes, by slowing down degradation processes through shielding of the platinum with bulky ligands, and by increasing membrane permeability with more lipophilic ligands.

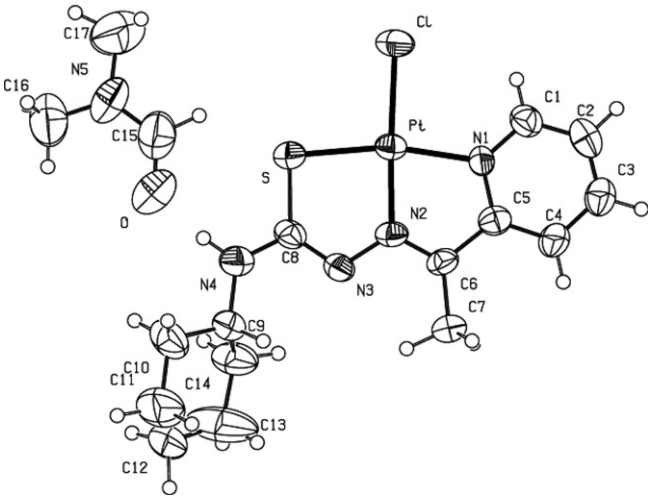

Fig. 1. ORTEP diagram for the complex [PtCl(Ac4CyclHexyl)] · DMF.

The present work is an extension of previously studied platinum(II) and palladium(II) complexes of 2-acetylpyridine-thiosemicarbazones with potentially interesting biological activities [5–8]. The present paper includes synthesis and spectral characterization of the newly prepared platinum(II) complexes with 2-acetylpyridine-4-cyclohexyl-thiosemicarbazone, HAc4CyclHexyl (**1**) (see Fig. 1) and the Pt(II) complexes [Pt(Ac4CyclHexyl)Cl] (**2**) and [Pt(Ac4CyclHexyl)$_2$] (**3**) and the crystal structure of the complex [Pt(Ac4CyclHexyl)Cl] · DMF. The cytotoxic activities of **1**–**3** have been evaluated for antiproliferative activity in vitro against the cells of three human cancer cell lines: MCF-7 (human breast cancer cell line), T24 (bladder cancer cell line), A-549 (non-small cell lung carcinoma) and a mouse L-929 (a fibroblast-like cell line cloned from strain L).

2. Experimental

2.1. General and instrumental

Solvents were purified and dried according to standard procedures. For the platinum(II) compounds a stock 0.02 M $[PtCl_4]^{2-}$ solution was prepared by dissolving $PtCl_2$ (2.66 g, 10 mmol) in concentrated HCl under reflux, filtering to remove a turbidity of undissolved material, neutralizing with Na_2CO_3 and diluting with distilled water up to 500 ml (pH 6.0–6.5). Infrared and far-infrared spectra were recorded on a Nicolet 55XC Fourier transform spectrophotometer using KBr pellets (4000–400 cm^{-1}) and nujol mulls dispersed between polyethylene disks (400–40 cm^{-1}). UV spectra were acquired with a JASCO V-570 UV/Vis/NIR spectrophotometer. The ^{1}H (250.13 MHz) spectra were obtained on a Bruker AMX-400 spectrometer at room temperature with the signal of free DMSO (at 2.49 ppm) as reference. Elemental analyses, C, H, N and S were performed on a Carlo Erba EA (model 1108).

2.2. Preparation of the ligand and platinum complexes

2.2.1. Preparation of the ligand HAc4CyclHexyl (*1*)

The ligand was prepared according to the method described in the literature [8], m.p. 160 °C. Compound **1**: IR (cm^{-1}): 3244s, 3139s, ν(NH); 2910, 2852s, ν(CH$_2$); 1561s, 1535mw, ν(C=N); 1110ms, ν(NN); 854s, ν(C=S); 588ms, δ(py); ^{1}H NMR: δ (ppm) = 10.18 (s, 1H, N(3)H); 8.56 (d, 1H, C(1)H); 8.05 (t, 1H, C(2)H); 8.21 (t, 1H, C(3)H); 7.75 (d, 1H, C(4)H); 3.26 (s, 3H, C(7)H$_3$); 7.33 (b, 1H, N(4)H); 4.02 (s, 1H, C(9)H); 2.46 (d, 2H, C(10)H, C(14)H); 2.33 (s, 2H, C(10)H, C(14)H); 1.65 (br, 2H, C(11)H, C(13)H); 1.61 (br, 2H, C(11)H, C(13)H); 1.22 (m, H, C(12)H); 1.17 (m, 1H, C(12)H); UV–Vis for **1** ($CHCl_3$) λ/nm (ε) 330 sh (30 000); 314 (45 000).

2.2.2. Preparation of the complexes

[PtCl(Ac4CyclHexyl)] (2): To a solution of HAc4CyclHexyl (0.55 mmol) in methanol (10 ml) was added the stock solution of $[PtCl_4]^{2-}$(30 ml, 0.6 mmol). The reaction mixture was stirred for 3 days at 24 °C and then left at 3–4 °C for 1 day. The red powder was filtered off, washed with cold methanol and ether, dried in vacuo over silica gel, and re-dried at 70 °C in vacuo over P_4O_{10}. Yield: 70%. D.p.256 °C. IR (cm^{-1}): 3315s, ν(NH); 2985, 2927s, ν(CH$_2$); 1556w, 1518vs, ν(C=N); 1159ms, ν(NN); 757s, ν(C=S); 627ms, δ(py); 427ms, ν(Pt–N); 388mw, ν(Pt–S) 338s, ν(Pt–Cl); 223ms, ν(Pt–N$_{py}$); ^{1}H NMR: δ (ppm) = 8.73 (d, 1H, C(1)H); 7.62 (t, 1H, C(2)H); 8.11 (t, 1H, C(3)H); 7.69 (d, 1H, C(4)H); 3.39 (s, 3H, C(7)H$_3$); 8.6 (b, 1H, N(4)H); 3.63 (s, 1H, C(9)H); 2.46 (t, 2H, C(10)H, C(14)H); 2.25 (br, 2H, C(10)H, C(14)H); 1.85 (br, 2H, C(11)H, C(13)H); 1.86 (br, 2H, C(11)H, C(13)H); 1.50 (m, H, C(12)H); 1.20 (m, 1H, C(12)H); UV–Vis for **2** ($CHCl_3$) λ/nm (ε) 500 (1100); 388 (17 000); 326 (21 300). Elemental *Anal*. Calc. for $C_{14}H_{19}N_4SPtCl$ (**2**): C, 33.2; H, 3.8; N, 11.1; S, 6.4. Found: C, 33.0; H, 3.8; N, 11.0; S, 6.3%. Slow evaporation of a dimethylformamide solution of **2** provided orange crystals of [PtCl(Ac4CyclHexyl)] · DMF suitable for X-ray crystallography.

[Pt(Ac4CyclHexyl)$_2$] (3): To a solution of HAc4CyclHexyl (0.62 mmol) in methanol (10 ml) was added the stock solution of $[PtCl_4]^{2-}$(15 ml, 0.3 mmol). The pH of the solution was adjusted to 9.0–10.0 by the addition of drops of Et_3N and the reaction mixture was stirred for 3 days 24 °C and then left at 3–4 °C for 1 day. The orange powder was filtered off, washed with cold methanol and ether, dried in vacuo over silica gel, and re-dried at 70 °C in vacuo over P_4O_{10}. Yield: 60%. dp 152 °C. Elemental analyses were consistent with the stoichiometry $C_{28}H_{38}N_8S_2Pt$: C, 45.1; H, 5.1; N, 15.0; S, 8.6. Found:C, 45.5; H, 5.7; N, 15.8; S, 8.8. IR (cm^{-1}): 3329s, 3221s, ν(NH); 2932vs, 2851s, ν(CH$_2$); 1580ms, 1565vw, 1523vs, ν(C=N); 1159ms, 1112ms, ν(NN); 779s, 761mw, ν(C=S); 657ms, 583s, δ(py); 442m, ν(Pt–N); 423m, 408m, ν(Pt–S); 246ms, ν(Pt–N$_{py}$). ^{1}H NMR: δ (ppm) = 10.24s (s, 1H, N(3)H); 8.54 (d, 1H, C(1)H); 7.82 (t, 1H, C(2)H); 8.13

(t, 1H, C(3)H); 8.23 (t, 1H, C(3)H); 7.38 (d, 1H, C(4)H); 3.32 (s, 3H, C(7)H_3); 8.70 (b, 1H, N(4)H); 4.16 (s, 1H, C(9)H); 2.49 (s, 2H, C(10)H, C(14)H); 2.33 (s, 2H, C(10)H, C(14)H); 2.33 (br, 2H, C(10)H, C(14)H); 1.81 (br, 2H, C(11)H, C(13)H); 1.85 (br, 2H, C(11)H, C(13)H); 1.54 (m, H, C(12)H); 1.32 (m, 1H, C(12)H); 1.454 (m, H, C(12)H); 1.22 (m, 1H, C(12)H); UV–Vis for **3**: ($CHCl_3$) λ/nm (ε) 497 (2000); 380sh (41 000); 316 (55 000).

2.3. X-ray crystallography

A summary of the crystal data, experimental details and refinement results are listed in Table 1. The crystals were not of excellent quality and even the best showed indications of splintering. A crystal of dimensions $0.60 \times 0.25 \times 0.08$ mm. was glued to a glass fibre and mounted on the head of an Enraf-Nonius CAD4 diffractometer. Graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation was used. The unit cell was found to be triclinic from analysis of 25 centred reflections in the range of $21.5° < \theta < 23.6°$ ($a = 6.9856(19)$ Å, $b = 9.517(2)$ Å, $c = 17.777(3)$ Å, $\alpha = 86.895(17)°$, $\beta = 80.111(18)°$, $\gamma = 70.75(2)°$), $V = 1062.5(5)$ Å^3, $Z = 2$. Space group $P\bar{1}$ (No. 2) was assigned, with μ(Mo Kα) 6.91 mm^{-1}, d_{calc} 1.70 g cm^{-3}, temperature 291(1) K. 4560 reflections were collected ($h = 0$–8, $k = -10$–11, $l = -20$–21) in ω–2θ mode in the range $2° < \theta < 26°$. 3 standard reflections were collected every 2 h. Decay of ca. 51% was observed and corrected during processing [10,11]. Lorentz and polarization effects were corrected. An empirical absorption correction was made using ψ-scans of 9 reflections ($T_{max} = 0.999$, $T_{min} = 0.504$) [12]. 4181 unique reflections were measured ($R_{int} = 0.034$), with 3247 observed ($I_o > 2.0\sigma(I_o)$). The structure was solved by the Patterson heavy atom method and successive cycles of full-matrix refinement and Fourier difference syntheses [12–14]. All non-hydrogen atoms were refined anisotropically on F^2 by full-matrix least-squares. Hydrogen atoms were placed in calculated positions and used in structure factor calculations but not refined. Refinement converged to $R_1 = 0.058$, $wR = 0.14$, $S = 1.18$, $(\Delta/\sigma)_{max} < 0.001$. The final Fourier difference synthesis showed maximum and minimum peaks at 3.66 and -2.95 e Å^{-3}, respectively. The data did not show evidence for extinction. There were 4 strong difference peaks at the corners of a rhombus in the molecular plane approximately 1.0 Å from the Pt atom and two others at approximately 2.3 Å on either side of the plane. They could not be reasonably assigned to atoms and it is thought that they are errors due to series termination and to the inherently poor quality of the crystal. Molecular graphics were performed from PLATON [15].

2.4. Calculations

All calculations were carried out using GAUSSIAN-03W [16] software package and the results were obtained by employing density functional methods (DFT). The initial geometry was fully optimized with the B3LYP [17,18] level of theory using the LANL2DZ [19] effective core potential basis set. Applying planarity restraints to molecule did not alter the results while attempts to use mixed basis sets LANL2DZ/6-31G** and LANL2DZ/6-311G** for S and Cl in order to increase the accuracy, were not succeeded to converge. To characterize the nature of the stationary points, harmonic vibrational frequencies are calculated with the method mentioned above and no imaginary frequencies were computed. TDDFT calculations [20a] were performed to study electronic excitation energies and oscillator strengths using the energy-adjusted relativistic pseudo-potentials proposed by Andrae et al. [21] for describing the Pt atom. Its valence basis set was extended with a set of diffuse functions $\alpha_s = 0.0075$, $\alpha_p = 0.013$, and $\alpha_d = 0.025$, and with optimized polarization functions $\alpha_f = 0.98$ [22]. For TDDFT calculations the fully optimized geometries of **1** and **2** were used. The solvent effect was simulated using the polarizable continuum model (PCM), in which the solvent cavity is seen as a union of interlocking atomic spheres [23]. All the calculations described here were carried out with the GAUSSIAN-03W package.

2.5. Antiproliferative assay in vitro

Compounds: Test solutions of the compounds tested (1 mg/ml) were prepared by dissolving the substance in 100 μl of DMSO completed with 900 μl of tissue culture

medium. Afterwards, the tested compounds were diluted in culture medium to reach the final concentrations of 100, 10, 1, and 0.1 μg/ml. The solvent (DMSO) in the highest concentration used in test did not reveal any cytotoxic activity.

Cells: The established in vitro human cancer cell line MCF-7 (human breast cancer cell line), T24 (bladder cancer cell line), A-549 (non-small cell lung carcinoma) and a mouse L-929 (a fibroblast-like cell line cloned from strain L) were applied: The cell lines are maintained in the Cell Culture Collection of the University of Ioannina. Twenty-four hours before addition of the tested agents, the cells were plated in 96-well plates at a density of 10^4 cells per well. The T-24 and MCF-7 cells were cultured in the DMEM (Dulbeco's modified Eagle's medium) medium supplemented with 1% antibiotic and 10% fetal calf serum. L-929 cells were grown in Hepes-buffered RPMI 1640 medium supplemented with 10% fetal calf serum, penicillin (50 U/ml) and streptomycin (50 mg/ml). A-549 cells were grown in F-12K Ham's medium supplemented with 1% glutamine, 1% antibiotic/antimycotic, 2% $NaHCO_3$ and 10% fetal calf serum. The cell cultures were maintained at 37 °C in a humid atmosphere saturated with 5% CO_2. Cell number was counted by the Trypan blue dye exclusion method. MCF-7, L-929 and A-549 cells were determined by the sulforhodamine B assay [24], and T24 cells by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay [25].

SRB assay: The details of this technique were described by Skekhan et al. [24]. The cytotoxicity assay was performed after 72-h exposure of the cultured cells to varying concentrations (from 0.1 to 100 μg/ml) of the tested agents. The cells attached to the plastic were fixed by gently layering cold 50% trichloroacetic acid (TCA) on the top of the culture medium in each well. The plates were incubated at 4 °C for 1 h and then washed five times with tap water. The background optical density was measured in the wells filled with culture medium, without the cells. The cellular material fixed with TCA was stained for 30 min with 0.4% sulforhodamine B dissolved in 1% acetic acid. Unbound dye was removed by rinsing with 1% acetic acid. The protein-bound dye was extracted with 10 mM unbuffered Tris base for determination of optical density (at 540 nm) in a computer-interfaced, 96-well microtiter plate.

MTT: This technique was applied for cytotoxicity screening against T-24 cells growing in suspension culture. An assay was performed after 72 h exposure to varying concentrations (from 0.1 to 100 mg/ml) of the tested agents. For the last 3–4 h of incubation 20 μl of MTT solution was added to each well [MTT: 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (Sigma); stock solution: 5 mg/ml]. The mitochondria of viable cells reduce a pale yellow MTT to a navy blue formazan, so if more viable cells are present in the well, more MTT will be reduced to formazan. When the incubation time was completed, 80 μl of the lysing mixture was added to each well (lysing mixture: 225 ml dimethylformamide, 67.5 g sodium dodecylsulfate (both from Sigma) and 275 ml of distilled water). After 24 h, when formazan crystals had dissolved, the optical densities of the samples were read on an Eliza spectra max 190 photometer at 570 nm wavelength. Each compound at a given concentration was tested in triplicate in each experiment, which was repeated three times.

3. Results and discussion

3.1. Description of structure

Interatomic distances, bond angles and hydrogen bonds for [PtCl(Ac4CyclHexyl)] · DMF are compiled in Table 2. Fig. 1 shows an ORTEP diagram of the molecular structure and the atom labelling scheme. The anionic Ac4CyclHexyl acts as a tridentate ligand which coordinates to platinum(II) through the pyridyl nitrogen, N(1), the azomethine nitrogen, N(2) and the thiolato sulfur atom. The tridentate ligand shows a *Z*,*E*,*Z* configuration for the donor centres nitrogen, nitrogen and sulfur, respectively. The stronger coordination of the metal to the azomethine nitrogen compared to the pyridyl notrogen is attributed to the higher basicity of N(2). The S–C bond distances are consistent with increased single-bond character while both thioamide C–N distances indicate increased double bond character. The negative charge of the deprotonated ligand is delocalized over the thiosemicarbazonato moiety. This delocalization reduces any basic properties which N(4) may otherwise possess, and allows N(4) to act as a hydrogen donor to the oxygen atom of the DMF solvent of crystallization.

The dihedral angles between the planes of the two five-membered chelate rings PtSC(8)N(3)N(2) and PtN(2)C(6)-C(5)N(1) and the five-membered ring PtSC(8)N(3)N(2) and the pyridyl ring are 1.4(4)° and 2.6(5)°, respectively. The dihedral angle between the PtSC(8)N(3)N(2) and DMF molecule is 3.1(12)°, while of PtSC(8)N(3)N(2) and

Table 2

cyclohexyl ring is 56.1(9)°. The cyclohexyl ring is bonded equatorially to N(4) and adopts the usual chair conformation. Ring puckering analysis and least square planes calculations show that the cyclohexyl ring adopts a chair conformation.

There is an intermolecular hydrogen bond between the amido hydrogen, H(4N), of the tridentate ligand and the oxygen atom of DMF. The DMF molecules are connected by double intermolecular bonds of the type C–H···O The monomers of DMF form hydrogen bonded dimers linked by two O···H–C hydrogen bonds involving the methyl C(16)H(16B) hydrogen atom and the adjacent oxygen atom and vice versa of centrosymetrically related pairs of molecules. The observed pattern is of the DA = AD type, Fig. 2. The crystal packing is determined by π–π, Pt–π and Pt–C interactions. The monomers of [Pt(Ac4CyclHexyl)Cl] are linked in dimers in a head to tail fashion by double strong π–π interactions. The most significant $\pi \rightarrow \pi$ interaction is that between the pair of rings Pt–N(2)–C(6)–C(5)–N(1), Cg(2) and N(1)–C(1)–C(2)–C(3)–C(4)–C(5), Cg(3) and between the rings Pt–N(2)–C(6)–C(5)–N(1) {Cg(2)–Cg(3); symmetry operation; $1-x$, $1-y$, $1-z$; and $Cg(2) \rightarrow Cg(2)$ symmetry operation; $2-x$, $1-y$, $1-z$} at a centre to centre separation of 3.571(7) and 3.500(6) Å, respectively, Table 3, Fig. 3.

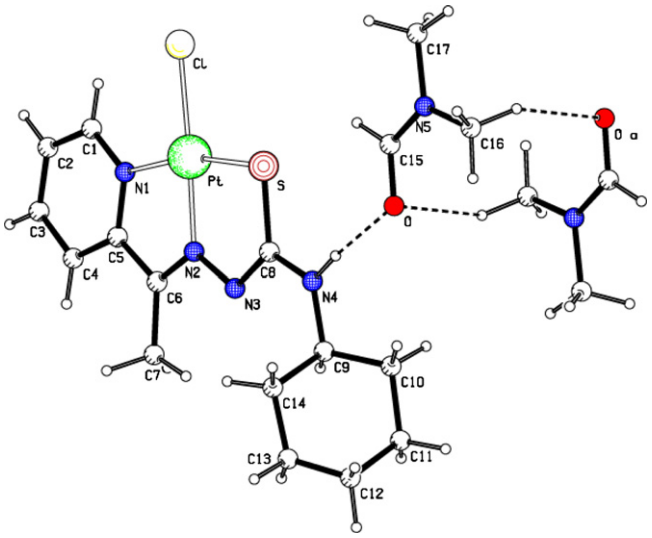

Fig. 2. Arrangement of the intermolecular hydrogen bonds in [PtCl(Ac4CyclHexyl)] · DMF.

The calculations were carried out on isolated molecules through the GAUSSIAN-03W [16] software package and the results were obtained by employing density functional methods (DFT). The optimized geometry is in good agreement with the experimental one, the largest differences are found for the Pt–Cl and Pt–S bond distances. The computed bond distances for Pt–Cl and Pt–S are 2.409 and 2.398 Å, respectively and are longer than the corresponding experimental values 2.311(3) and 2.250 (3) Å, respectively. The significant elongation of the calculated Pt–Cl (0.098 Å) and Pt–S (0.148 Å) bond length in comparison with the experimental ones, could be explained in part by contributions of Cl to a C(1)–H···Cl hydrogen bond and of S to a C(15)–H···S hydrogen bond. The formation of these hydrogen bonds causes local deficiency of electron density on the chloro and thiolato atoms and consequently these atoms are closer to the central metal ion in the experimental structure. The elongation of the M–chlorine bond lengths (up to 0.25 Å) in the B3LYP with different basis sets has been found in other rhenium–chlorine and

Symmetry transformations: (i) $1-x$, $1-y$, $1-z$; (ii) $2-x$, $1-y$, $1-z$; (iii) $2-x$, $1-y$, $2-z$.

[a] Cg(1), Cg(2) and Cg(3) refer to the centroids of rings Pt–S–C8–N3–N2, Pt–N2–C6–C5–N1 and, N1–C1–C2–C3–C4–C5, respectively.

[b] Cg–Cg is the distance between ring centroids or ring centroid and Pt(1).

[c] β is the angle between the Cg(I)–Cg(J) or Cg(I)–Pt vector and the normal to plane I.

[d] Cg(I)–Perp is the perpendicular distance of Cg(I) to ring J and Cg(J)–Perp is the perpendicular distance of Cg(J) or Pt to ring I.

[e] Cg(I)–Perp is the perpendicular distance of Cg(I) to ring J and Cg(J)–Perp is the perpendicular distance of Cg(J) or Pt to ring I.

[f] Where D is donor and A is acceptor.

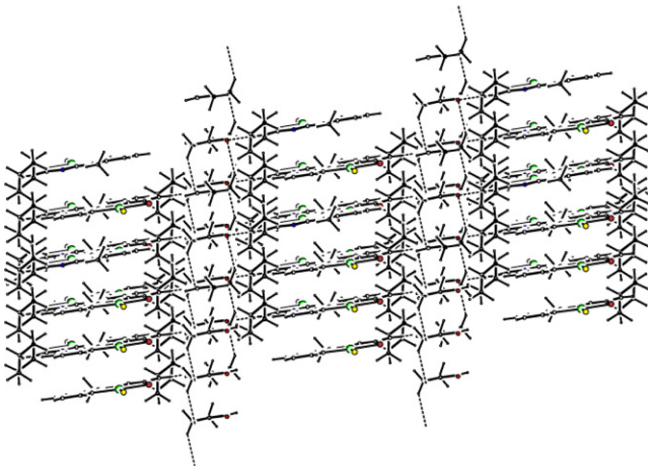

Fig. 3. A view of the extended network of [PtCl(Ac4CyclHexyl)] · DMF along the *b*-axis.

platinum–chloride complexes [20b,20c]. The computed bond distances for Pt–N(1) and Pt–N(2) are 2.050 and 1.997 Å and are in excellent agreement with the experimental values 2.032(9) and 1.946(8) Å.

3.2. Spectroscopy

Infrared spectroscopy: The significant IR bands of Pt(II) complexes are close in energy to those found in other compounds with tridentate coordination [3–8,26]. The bands assigned in the spectrum of HAc4Hexyl shift in the spectra of Pt(II) complexes. Coordination of the azomethine nitrogen to Pt(II) is reflected by the shift of the ν(C=N) band to lower frequencies along with the increase of the ν(N–N) band to higher frequency in the IR spectra of the complexes compared to those in the protonated ligand. The breathing motion of the pyridine ring is shifted to a higher frequency upon complexation and is consistent with pyridine nitrogen coordination. The thioamide band, which contains considerable ν(CS) character, is less intense in complexes and is found at a lower frequency, consistent with coordination of the metal through sulfur. Coordination of the imine nitrogen is also consistent with the presence of bands at 427 and 442 cm^{-1}, assignable to ν(Pt–N) for **2** and **3**, respectively. Bands at 388 cm^{-1} for **2** and at 423, 408 cm^{-1} for **3** are assigned to ν(Pt–S) while bands at 223 and 246 cm^{-1} to $\nu(Pt–N_{pyr})$ for **2** and **3**, respectively. In **3** the bands ν(C=N), ν(N–N), and the breathing motion of the pyridine ring are consistent with both complexed and uncomplexed azomethine and pyridine nitrogen coordination, suggesting tridentate and monodentate behaviour for the two deprotonated ligands [8].

UV/Vis absorption spectra: The two complexes are distinctly coloured, orange and red. Broad but relatively weak bands in the visible region are responsible for the colour. Table 4 shows the spin-allowed singlet–singlet electronic transitions calculated with the TDDFT method for **1** and **2** and the absorption data in chloroform solution; studies in dimethylformamide (DMF) showed essentially similar absorption features within experimental uncertainty (±3 nm) of λ_{max}.

Table 4
Selected calculated TDDFT singlet excitation energies for **1** and **2** in $CHCl_3$ solution, together with experimentally observed values

Compound	Experimental λ/nm (ε/M^{-1} cm^{-1})	Calculated[a] λ (nm)	Oscillator strength, *f*	Composition[b]
1	330 (30000)	333.36	0.1591	H-1 → L (+93%)
	314 (45000)	290.45	0.5921	H-2 → L (+79%) H-3 → L (+7%)
2	500 (1100)	551.9	0.0172	H → L (+90%)
		443.0	0.0022	H-2 → L (+95%)
	388 (17000)	406.3	0.1315	H-1 → L (+46%) H-3 → L (34%) H → L + 1 (10%)
	388 (17000)	380.5	0.3374	H-3 → L (+55%) H-1 → L (+30%)
	326 (21300)			

[a] G03W/B3LYP (PCM).
[b] H = HOMO, L = LUMO. Percentage contributions to wavefunctions of excited states are given in parenthesis.

Considering that the solution spectrum of **1** exhibits intense absorption bands in the 330–310 nm range some additional intraligand transitions are expected at higher energies in the calculation. The assignment of the calculated transitions to the experimental bands is based on the criterion of the energy and oscillator strength of the calculated transitions. The results are presented in Table 4, where selected transitions, with significant oscillator strengths, are listed. Due to the complex character of the MOs of **1** and **2**, only the main contributions were taken into consideration for the discussion of the electronic transitions.

The computed spectrum of **1** has major peaks at 333 and 290 nm (oscillator strengths 0.159 and 0.592, respectively) comparing well with the experimental shoulder at 330 and the band 314 nm (in $CHCl_3$). The shoulder at 330 nm is due to the HOMO − 1 → LUMO transition while the peak at 290 nm is due to the HOMO − 2 → LUMO transition. These bands correspond to intraligand charge transfer from sulfur to pyridyl ring.

The experimental band of **2** at 500 nm is assigned to the calculated transition at 552 nm (oscillator strength 0.0172). The lowest-energy absorption band at 500 nm is assigned to the spin-allowed HOMO → LUMO transition, which can be characterized as a d(Pt)/p(Cl/p(S)p(N2)/pN(3) → π^* (pyr) transition and thus as MLCT mixed with LLCT

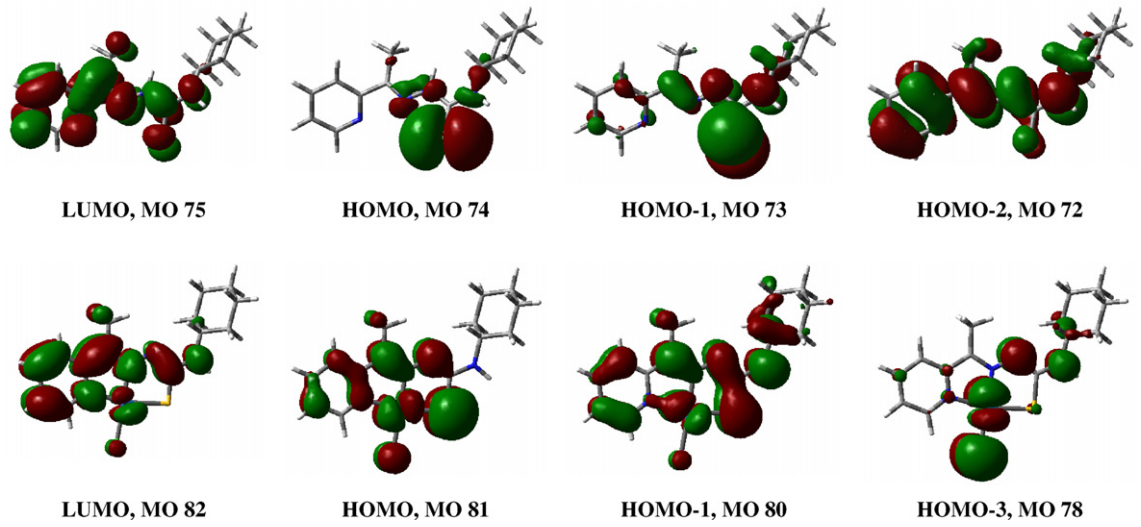

Fig. 4. Plots of relevant molecular orbitals involving in the electronic transitions of **1** and **2**.

(LLCT/MLCT) and a small contribution of d–d electronic transitions. The experimental band of **2** at 388 nm is assigned to the calculated transitions at 406 and 380 nm (oscillator strengths 0.135 and 0.337, respectively). The band at 388 nm is assigned to the spin-allowed HOMO − 3 → LUMO and HOMO − 1 → LUMO transitions. The HOMO − 3 MO has contributions from d(Pt)/p(Cl)/p(N4) and the HOMO − 1 from d(Pt)/p(S) and the function CNNCN, respectively. The transition at 388 nm is thus assigned as MLCT mixed with LLCT (LLCT/MLCT) and a contribution of d–d electronic transitions, Fig. 4. The shortest wavelength experimental band of 326 nm cannot be assigned completely to the calculated transitions.

3.3. Pharmacology: antiproliferative activity in vitro

Pd(II) and Pt(II) complexes of HFoTsc were found active in vivo against leukemia P388 cells and Pt(II) complexes of *N*-4-ethyl-2-formyl and 2-acetylpyridine thiosemicarbazones showed cytotoxicity and were found to be able to overcome the cisplatin resistance of A2780/Cp8 cells [6–8]. Also, Zn(II) complexes of HFoTsc and HAcTsc were found active against the MCF-7 (human breast cancer cell line), T24 (bladder cancer cell line) and a mouse L-929 (a fibroblast-like cell line cloned from strain L) [27].

The results of cytotoxic activity in vitro are expressed as ID_{50} – the concentration of compound (in M) that inhibits a proliferation rate of the tumor cells by 50% as compared to control untreated cells, Table 5. The compounds **1**–**3** were tested for their antiproliferative activity in vitro against the cells of three human cancer cell lines: MCF-7 (human breast cancer cell line), T24 (bladder cancer cell line), A-549 (non-small cell lung carcinoma) and a mouse fibroblast L-929 cell line and the results are compared with zinc(II) complexes of 2-acetylpyridine Thiosemicarbazone, HAcTsc [27].

The thiosemicarbazone and the two Pt(II) metal complexes exhibited cytotoxic activity against the MCF-7 cell line in a μM range better than that of cisplatin. It was found that [Pt(Ac4CyclHexyl)$_2$] in a concentration of 0.134 μM inhibits the proliferation rate of the MCF-7 cancer cells by 65% as compared to control untreated cells. The IC_{50} value for HAc4CyclHexyl against the MCF-7 cell line is 0.36 μM and for **2** is 0.63 μM. The IC_{50} value for HAc4CyclHexyl against the A-549 cell line is 11.1 μM and for **2** and **3** is 6.87 and 1.17 μM, respectively.

In the case of T-24 cell line the ligand and [PtCl(Ac4CyclHexyl)] are in the same μM range compared to cisplatin while the complex **3** is more cytotoxic. The IC_{50} value for HAc4CyclHexyl against the T-24 cell line is

Table 5
The antiproliferative activity in vitro of HAc4CyclHexyl, its Pt(II) and related Zn(II) complexes [27] (expressed as ID_{50} (M) against MCF-7, T-24, A-549 and L-929 cancer cell lines

Compounds	MCF-7	T-24	A-549	L-929
HAc4CyclHexyl	0.36×10^{-6}	10.10×10^{-6}	11.10×10^{-6}	3.31×10^{-6}
HAcTsc	3.29×10^{-6}	2.16×10^{-6}		2.06×10^{-6}
[PtCl(Ac4CyclHexyl)]	0.63×10^{-6}	9.17×10^{-6}	6.87×10^{-6}	6.06×10^{-6}
[Pt(Ac4CyclHexyl)]$_2$	$<0.13\times10^{-6}$	0.37×10^{-6}	1.17×10^{-6}	0.21×10^{-6}
[ZnCl$_2$(HAcTsc)]	1.36×10^{-6}	1.57×10^{-6}		1.06×10^{-6}
[Zn(AcTsc)$_2$]	0.88×10^{-6}	1.18×10^{-6}		4.65×10^{-6}
Cisplatin	8.00×10^{-6}	41.7×10^{-6}	1.53×10^{-6}	0.70×10^{-6}

10.10 μM and for the Pt(II) complexes of **2** and **3** is 9.17 and 0.13 μM, respectively. The IC_{50} value for HAc4CyclHexyl against the L-929 cell line is 3.31 μM and for the Pt(II) complexes of **2** and **3** is 6.06 and 0.21 μM, respectively. These values are in the same μM range compared to cisplatin.

The two zinc(II) complexes compared to the Pt(II) complexes are less active against these three cell lines, while the HAcTsc is more cytotoxic than HAc4CyclHexyl.

The compounds **1**–**3** display IC_{50} values in a μM range better than that of the antitumor drug cisplatin. Complex **3** was found to be 10, 16, and 30 times more cytotoxic than the parent Tsc against the A-549, L-929 and T24 cancer cell lines. All the zinc(II) and Pt(II) complexes are very active against MCF-7 cell line and the most cytotoxic of all was found to be the complex **3**. The best results were found against the MCF-7 and T-24 cell lines and the platinum complex **3**. Thus, compounds **1**–**3** are considered as agents with potential antitumor activity, and can therefore be candidates for further stages of screening in vitro and/or in vivo.

Appendix A. Supplementary material

CCDC 293435 contains the supplementary crystallographic data for **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.01.039.

Abstract

Reaction of the disodium salt of 2,5-dihydroxy-1,6-benzenedicarboxylic acid (DHBDC) and zinc sulfate in aqueous solution at room temperature yields complex $[Zn(H_2O)_2(DHBDC)]_n$. The coordination tetrahedron around Zn center exhibits a highly irregular geometry, two carboxylato oxygen atom and two water–ligand oxygen atoms occupying the coordination sites. Structural analyses of this complex reveal that the individual zero-dimensional units (0D) are covalently linked through their metal ends, forming infinite 1D zigzag chains. These chains, in turn, are engaged in 2D hydrogen bonding, resulting in a 3D supramolecular architecture.

1. Introduction

Zinc salicylate and homologues are of considerable interest, due to their wide potential applications. For example, they have been selected for use as anti-oxidants and stabilizers for polymers. They have also been employed in the coatings on paper used in carbonless copying paper [1]. In other respects, the anti-inflammatory and anti-convulsant activities of zinc salicylates were found to be more effective than their parent ligands in animal models of inflammation and epilepsy [2]. As part of a systematic program devoted to the study of structure–activity relationships of (salicylato)metal complexes [3], we were recently interested in the preparation of metal complexes of 2,5-dihydroxy-1,6-benzenedicarboxylic acid (DHBDC, **1**). Because of the presence of two salicylate sites, the latter ligand can accommodate two metallic centers, thereby possibly generating various molecular architectures.

Recently, a Zn(II) complex of ligand **1** has been synthesized via the solvothermal method (heating at 105 °C in a sealed tube a mixture of **1** and zinc nitrate in DMF/2-propanol/water). The individual units of this complex $[Zn_2(DHBDC)(DMF)_2 \cdot (H_2O)_2]$ self-assemble via covalent bonds, resulting in helical rods consisting of edge-sharing ZnO_6 octahedra alternately opposite and next-neighbor to form either a 3_1 or a 3_2 helix [4]. In the present paper, we show that a new type of Zn(II) complex of DHBDC was formed by mixing aqueous solutions of the disodium salt of **1** and of zinc sulfate at room temperature. The individual units of this complex $[Zn(H_2O)_2(DHBDC)]$ are covalently linked, forming infinite zigzag chains, the ZnO_4 tetrahedra being at the vertices of the zigzag. These

chains, in turn, are further engaged in two-dimensional hydrogen bonding, yielding a 3D supramolecular architecture.

2. Experimental

2.1. Materials

High purity 2,5-dihydroxy-1,6-benzenedicarboxylic acid (2,5-dihydroxyterephthalic acid) and zinc sulfate heptahydrate were purchased from Aldrich (USA) and used without further purification.

2.2. Physical measurement

Elemental analyses (C, H, and N) were performed on a Perkin–Elmer 2400 analyzer. The IR spectra were recorded with Bruker Vector 22 spectrometer. Thermogravimetric analysis (TGA) and magnetization study were carried out on a TA Instruments TGA Q500 apparatus. Calibration was performed at different temperatures using Curie magnetic transitions for the recommended materials: alumel (163 °C), nickel (354 °C); calibration (mass) was carried out using a standard mass of 100 mg, calibration of the furnace was made between 100 and 900 °C to verify thermocouple operation. All the experiments were performed under dry nitrogen, with a flow rate of 6×10^{-2} l min^{-1}. Analysis of compounds out of nitrogen purging was conducted at heating rate of 20 °C min^{-1}, in order to determine the percentage of mass loss with the best precision. Differential scanning calorimetry (DSC) experiment has been carried out with a TA Instruments Universal V4.2E apparatus under nitrogen flow. Samples are introduced in aluminum pans and covered with holed caps in view to avoid uncontrolled variation of pressure. Calibration of temperature has been performed with indium (156.6 °C) and tin (231.9 °C) of quality 5 N at heating rate of 10 °C min^{-1}.

2.3. Preparation of the complex $[Zn(H_2O)_2(C_8H_4O_6)]$ (2)

The disodium salt of 2,5-dihydroxy-1,6-benzenedicarboxylic acid was prepared by neutralizing the acid (0.400 g, 2 mmol) with 4 ml of 1 M NaOH (4 mmol). A solution of $ZnSO_4 \cdot 7H_2O$ (0.575 g, 2.1 mmol) in water (3 ml) was added, resulting in the immediate precipitation of transparency ivory crystals. These were filtered off, successively washed with acetic acid and water, and dried at room temperature under vacuo (20 Torr) over anhydrous magnesium sulfate. Yield: 0.545 g (90%). The product is stable in air and insoluble in water and common organic solvents such as ethanol, acetonitrile, acetone, chloroform, DMF, DMSO, pyridine, and acetic acid. *Anal.* Calc. for $C_8H_8O_8Zn$ (**2**): C, 32.30; H, 2.69. 2.4. X-ray diffraction study

Diffraction data were collected on a Bruker SMART three axis diffractometer equipped with a SMART 1000 CCD area detector using graphite monochromated Mo Kα X-radiation (wavelength $\lambda = 0.71073$ Å) at 100.0(1) K. The low temperature was reached by an evaporated liquid nitrogen stream over the crystal, provided by the Oxford Cryosystem device. Data collection and processing were carried out using Bruker SMART programs [5] and empirical absorption correction was applied using SADABS computer program [5]. The structure was solved by direct methods SIR97 [6], and refined by full-matrix least-squares based on F^2 using CRYSTALS software [7]. All non-hydrogen atoms were anisotropically refined. The hydrogen atoms were located in difference Fourier maps. H atoms were refined isotropically with $U_{iso} = 1.20 U_{eq}$ where U_{eq} is the equivalent isotropic atomic displacement parameter of the attached atom. The crystal parameters, data collection and the refinement details of compound **2** reported in Table 1.

3. Results and discussion

3.1. Description of the crystal structure

The structure determination show that this complex crystallizes in $C2/c$ monoclinic space group. The asymmet-

ric unit contains one half of the formula unit, that can be represented by $[Zn(H_2O)_2(C_8H_4O_6)]$ (**2**). The canonical drawing and the CAMERON [8] molecular structure are represented in Figs. 1 and 2, respectively, with the atom numbering system used in Table 2, which lists the most relevant bond distances and angles. The coordination tetrahedron around Zn center is depicted in Fig. 3. In **2**, Zn^{II} is covalently bonded to one 2,5-dihydroxy-1,6-benzenedicarboxylate ligand and harnessed to two water molecules. Compound **2** is a monomeric complex in which the coordination tetrahedron around Zn^{II} exhibits a highly irregular geometry, two carboxylato oxygen atoms [O(1) and $O(1^i)$] and two water–ligand oxygen atoms [O(4) and $O(4^i)$] occupying the coordination sites. Zn–O(1) and Zn–O(4) bond distances are equal to 2.001(2) and 1.986(2) Å, respectively, values significantly different with respect to the estimated standard deviations. Since Zn–O(1) and Zn–O(2) distances are highly different [2.000(2) and 2.575(2) Å, respectively] it is clear that the 2,5-dihydroxy-1,6-benzenedicarboxylate anion acts as a monodendate ligand. Regarding angles around Zn(II) center, O(1)–Zn–$O(4^i)$ and $O(1^i)$–Zn–O(1) are significantly different (127.47° and 124.63°, respectively) while $O(4^i)$–Zn–O(1) and O(4)–Zn–$O(1^i)$ are identical (89.98°). The crystal packing is mainly governed by intermolecular hydrogen bonds implying each hydrogen atom of the water molecules [H(41) and H(42)] and the carboxylato and the phenoxo oxygen atoms of neighbor ligand molecules [$O(3^i)$ and $O(2^{ii})$; symmetry codes: (i) $x+1/2$, $y-1/2$, z; (ii) x, $y-1$, z], and one intramolecular hydrogen bond implying H(3) and O(1) (Fig. 4 and Table 3).

Symmetry codes: (i) $x+\frac{1}{2}, y-\frac{1}{2}, z$; (ii) $x, y-1, z$.

The individual zero-dimensional units (0D) are linked together in a covalent fashion through their metal ends, forming infinite 1D zigzag chains (Fig. 5). It is noteworthy that the cohesion of these chains is strengthened by the presence of internal hydrogen bonds. The intrachain separation of Zn centers is 10.93 Å, the metal atoms being at the vertices of the zigzag, with a Zn–Zn–Zn angle of 92.09°. The parallel chains are further engaged in hydrogen bonding implying H(42) with an interchain separation of 8.18 Å, resulting in 2D corrugated sheets (Fig. 6). These, in turn, self-assemble via hydrogen bonds implying H(41) with an interplanar separation of 6.12 Å, yielding a 3D

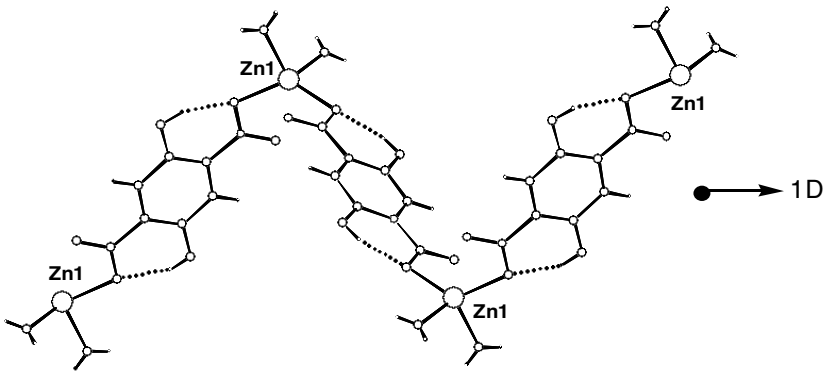

Fig. 5. Structure of part of $[Zn(H_2O)_2(C_8H_4O_6)]_n$ (**2**)$_n$, indicating the 1D zigzag chain structure with intrachain hydrogen bonds (dashed lines).

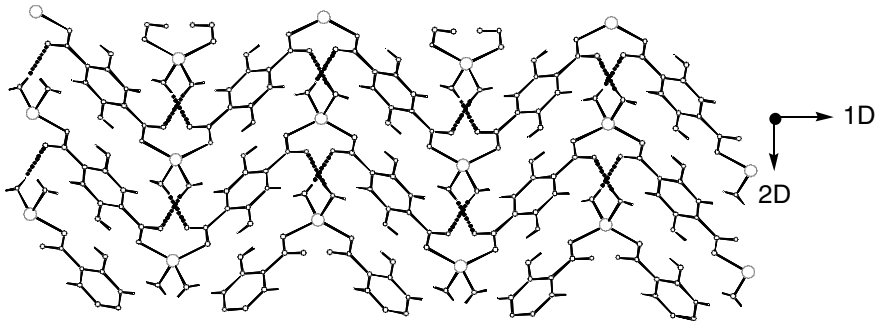

Fig. 6. 2D perspective diagram of packing of $[Zn(H_2O)_2(C_8H_4O_6)]_n$ (**2**)$_n$, showing the interchain H-bonded network (broken lines). Zn centers are symbolized by large circles.

supramolecular architecture (Fig. 7). The marked compactness of this architecture was reflected by the exceptionally high calculated density of compound **2** (2.14 g cm^{-3}, Table 1). In contrast, previously reported Zn(II) salicylates exhibited much lower densities, in the range of 1.26–1.76 g cm^{-3} [1,2a,2b,2c,3]. Note, however, that a density of 1.92 g cm^{-3} was reported for the above-mentioned Zn(II) complex of ligand **1**, elaborated according to the solvothermal method [4].

3.2. Thermal analysis

3.2.1. Thermolysis

Compound **2**, placed in a "vacuum sublimation apparatus", was heated gently until 320 °C (Woods metal bath) under reduced pressure (20 Torr). A white solid collected on the "cold finger" of the apparatus, consisting of pure hydroquinone (1,4-dihydroxybenzene). This was unambiguously identified by comparison with an authentic sample (melting point, R_f in TLC and ^{1}H NMR spectrum).

3.2.2. TGA, DSC, and magnetization studies

TGA analysis of **2** reveals a weight loss of 73.5% at 50–500 °C, with a rapid decrease between 260 and 280 °C, corresponding to loss of one molecule of water, two molecules of CO_2, and one molecule of hydroquinone (Calc. 72.6%). The non-volatile residue (26.5% of the starting material) corresponds to one molecule of ZnO (Calc. 27.4%). The DSC study of **2** reveals, as the main event, a narrow exotherm centered at 279 °C. Magnetization study of **2** reveals a rapid decrease between 270 and 288 °C. It is noteworthy that the TGA, DSC, and magnetization data match the thermal decomposition pattern of starting complex **2** (Section 3.2.1.).

4. Conclusion

We have shown that a new Zn(II) complex (**2**) of 2,5-dihydroxy-1,6-benzenedicarboxylic acid was formed by mixing aqueous solutions of the disodium salt of this acid and of zinc sulfate at room temperature. The individual units of this complex self-assemble in a covalent fashion, forming infinite zigzag chains which are further engaged in hydrogen bonding, leading to a 3D supramolecular architecture. There existed, as prior art, several compelling examples of salicylato(metal) complexes forming one-dimensional polymeric chains, particularly copper(II) [9], manganese(II, III) [10], and manganese(II) [11] derivatives. This work is being continued. The original metallo-organic framework of the present complex might be of peculiar interest in the design of functional materials. In particular, the close metal–metal distances observed in **2** (shortest separations: 6.12 and 8.18 Å) could be exploited for the elaboration of molecular conductors and/or magnetic materials.

5. Supplementary material

CCDC 630833 contains the supplementary crystallographic data for **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Four mercury(II) thiocyanate–organic polymeric complexes, $[Hg(\mu\text{-}4,4\text{-bipy})(SCN)_2]_n$ (**1**), $[Hg(\mu\text{-bpa})(SCN)_2]_n$ (**2**), $[Hg(\mu\text{-bpe})(SCN)_2]_n$ (**3**), $[Hg(\mu\text{-bpp})(SCN)_2]_n$ (**4**) {4,4-bipy = 4,4′-bipyridine, bpa = 1,2-bis(4-pyridyl)ethane, bpe = 1,2-bis(4-pyridyl)ethene and bpp = 1,3-di(4-pyridyl)propane} were prepared from reactions of mercury(II) thiocyanate with four rigid and flexible organic nitrogen donor-based ligands under thermal gradient conditions, brunched tube method. All these compounds were structurally determined by X-ray single-crystal diffraction. The thermal stabilities of compounds **1**–**4** were studied by thermal gravimetric (TG) and differential thermal analyses (DTA). Solid state luminescent spectra of compounds **1** and **3** indicate intense fluorescent emissions at 430 and 468 nm, respectively.

1. Introduction

The metal coordination polymers have been studied widely due to an important interface between synthetic chemistry and materials science. Synthesis of metal coordination polymers is attracting interest in understanding how molecules can be organized and how functions can be achieved. Up to now, many attempts have been made to synthesize a variety of transitional metal complexes using the different oxobidentate ligands, and their structures and properties have been physically and chemically determined [1,2]. In contrast to coordination polymers of transition metal ions, the formation of polymers with heavy metal ions such as mercury(II) is unreasonably sparse when compared with that of some other metals. Mercury(II) compounds also offer attractive properties in terms of their potential applications as paper industry, paints, cosmetics, preservatives, thermometers, manometers, fluorescent lamps and mercury batteries [3]. Typically, the Hg(II) complexes with the rigid or flexible organic nitrogen donor-based ligands rarely reported until recently [4–7]. A search in the Cambridge Structural Database shows only 123 mercury(II) thiocyanate complexes [8] and the most of these mercury thiocyanate compounds are monomeric structures and coordination polymers type are rare. Continuing with our previous work on mercury(II) thiocyanate coordination polymers [9–17], in this paper, we report four new 1D coordination polymers of mercury(II) thiocyanate with organic nitrogen donor-based ligands, 4,4′-bipyridine (4,4-bipy), 1,2-bis(4-pyridyl)ethane (bpa), 1,2-bis(4-pyridyl)ethane (bpe) and 1,3-di(4-pyridyl)propane (bpp) (Fig. 1).

In this series of compounds four nitrogen donor-based ligands have been used. These ligands can be bridged and formed polymeric structures. In other hand, the SCN^- anions has been used as a counter-ion in these Hg(II) coordination polymers. This anion is a highly versatile ambidentate ligand with two donor atoms. It can coordi-

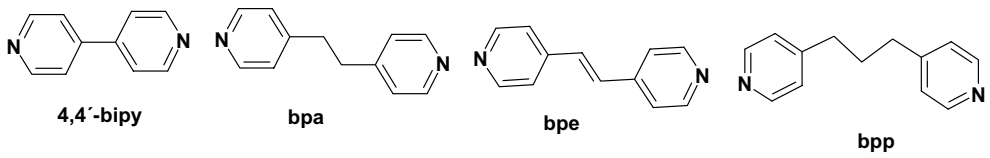

Fig. 1. Rigid and flexible organic nitrogen donor-based ligands used in the construction of mercury thiocyanate coordination polymer frameworks.

nate through either the N or the S atom, or both, giving rise to linkage isomers or polymers. The presence of thiocyanate anions as a bridging ligand and other different bridging ligands in one coordination system can form 1D, 2D or 3D coordination polymers either through thiocyanate-, or nitrogen donor-based ligand-bridging and or through both thiocyanate- and nitrogen donor-based ligand-bridging. Thus, in this context, it is still a great challenge to obtain the predicted products at these compounds. However, the rational construction of new structurally defined metal–organic frameworks using the thiocyanate- and nitrogen donor-based ligand-bridging strategy seems to be an excellent success.

2. Experimental

2.1. Materials and physical techniques

All reagents and solvents for the synthesis and analysis were commercially available and used as received. IR spectra were recorded using Perkin–Elmer 597 and Nicolet 510P spectrophotometers. Microanalyses were carried out using a Heraeus CHN-O-Rapid analyzer. Melting points were measured on an Electrothermal 9100 apparatus and are uncorrected. The thermal behavior was measured with PL-STA 1500 apparatus. ^{1}H and ^{13}C NMR spectra were measured with a BRUKER DRX-500 AVANCE spec-

trometer at 500 MHz and all chemical shifts are reported in δ units downfield from Me_4Si. The luminescent properties were measured with spectrofluorophotometer Shimadzu RF-5000.

Crystallographic measurements were made using a Bruker CCDC area detector system. The intensity data were collected using graphite monochromataed Mo Kα radiation ($\lambda = 0.71073$ Å). Accurate unit cell parameters and an orientation matrix for data collection were obtained from least-squares refinement. The structures were solved by direct methods and refined by full-matrix least-squares techniques on F^2. The structures were solved and refined with the program system SHELXTL [18]. The molecular structure plots were prepared by using the ORTEP III [19] and Mercury [20]. Crystallographic data and details of the data collection and structure refinements are listed in Table 1. Anisotropy thermal parameters, observed and calculated structure factors, full lists of bond distances, bond angles and torsion angles are given in the supplementary material. ORTEP diagrams and perspective view of the packing are shown in Figs. 2–4.

2.2. Syntheses of the compounds *1–4*

The different synthetic approaches have been offered for preparation of coordination polymers that some of them are (1) slow diffusion of the reactants into a polymeric matrix, (2) diffusion from the gas phase, (3) evaporation of the solvent at ambient or reduced temperatures, (4) precipitation or recrystallisation from a mixture of solvents, (5) temperature controlled cooling and (6) hydrothermal synthesis. I this paper, we use another simple method for construction of multi-dimensional heavy metal ion coordination polymers, brunched tube method [13,21]. The brunched tube method was employed for synthesis and preparation of suitable single crystals. This method is a straight forward, chip and trouble-free and can be used for preparation of all of this type coordination polymer, $HgL(SCN)_2$.

2.2.1. General procedure

The ligand (0.5 mmol) and mercury(II) thiocyanate (0.5 mmol) were placed in the bottom of main of a brunched tube. Methanol was carefully added to fill both arms, the tube sealed and the main arm immersed in oil bath at 60 °C while the brunched arm was at ambient temperature. After 2–7 days, very suitable single crystals had deposited in the cooler arm which was filtered off, washed with acetone and air dried.

3. Results and discussion

3.1. Synthesis and spectroscopy

Reaction between mercury(II) thiocyanate and four rigid or flexible organic nitrogen donor-based ligands under thermal gradient conditions, brunched tube method, provided crystalline materials analyzing as $[Hg(\mu\text{-}4,4\text{-bipy})(SCN)_2]_n$ (**1**), $[Hg(\mu\text{-bpa})(SCN)_2]_n$ (**2**), $[Hg(\mu\text{-bpe})(SCN)_2]_n$ (**3**) and $[Hg(\mu\text{-bpp})(SCN)_2]_n$ (**4**). The relatively weak absorption bands around 3025–3055 cm^{-1} in IR spectra is due to the C–H modes involving the aro-

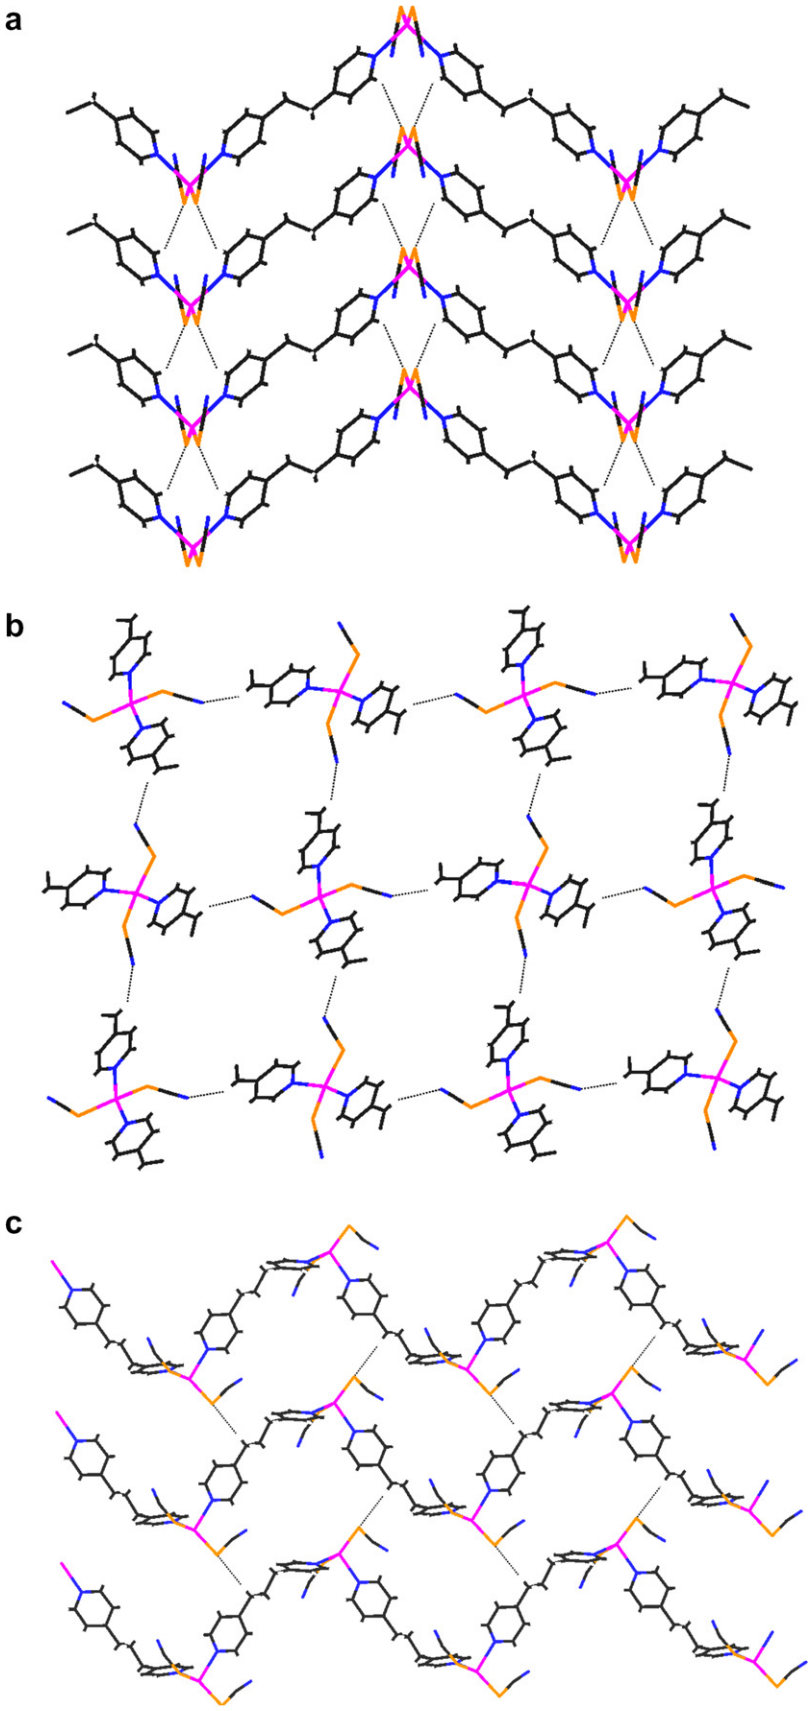

Fig. 4. Showing crystal packing of (a) S···HC interactions in the $[Hg(\mu\text{-bpa})(SCN)_2]_n$ (**2**) and (b) N···HC interactions in the $[Hg(\mu\text{-bpe})(SCN)_2]_n$ (**3**) (c) S···HC interactions in the $[Hg(\mu\text{-bpp})(SCN)_2]_n$ (**4**).

matic ring hydrogen atoms.The absorption bands with variable intensity in the frequency range 1404–1600 cm^{-1} correspond to vibrations of the pyridyl rings of ligands. The strong sharp singles stretching at 2095, 2070, 2055 and 2080 cm^{-1} are due to $\nu(SCN^-)$ in the infrared spectra of compounds **1**–**4**, respectively. These bands confirm the thiocyanato-S coordination with the mercury atom [22]. The SCN^- anion is a highly versatile ambient ligand with two donor atoms. It can coordinate through either the nitrogen or the sulfur atom, or both, giving rise to linkage isomers or polymers. The modes of mercury(II) coordination of thiocyanate anion is the best understood in terms of the hard and soft acid–base concept developed by Pearson, Basolo, and Burmeister. In accordance with the hard-soft acid–base concept, the S atom of the SCN^- ligand, being a soft base, preferentially coordinates to the soft acid whereas the N atom, being a hard base, preferentially coordinates to the hard acid. In the Zn–Cd–Hg triad, the Zn(II) complexes tend to be N-bonded, while the Hg(II) complexes are almost always S-bonded. Our findings together with the results concerning SCN^- in **1**–**4** suggest that the thiocyanate ligand has a strong tendency to coordinate mercury(II) ions through its sulfur atoms. The FT–IR results are consistent with the crystallographic study. The ^1H NMR spectrum of the DMSO solution of the compounds **1**–**4** displays two distinct resonance signals assigned to two different protons of ''py'' groups of the ligands 4,4-bipy, bpa, bpe and bpp. The ^1H NMR spectrum of the compounds **2** and **3** displays one other signals at 3.00 and 7.50 ppm assigned to protons of —CH=CH— and —CH_2—CH_2— group of ligands bpa and bpe molecules, respectively. The ^1H NMR spectrum of the compound **4** displays two other signals at 2.10 and 2.80 ppm assigned to protons of —CH_2—CH_2—CH_2— of ligand bpp. The ^{13}C NMR spectrum of the DMSO solution of the compounds **1**–**4** displays three distinct resonance signals assigned to the aromatic carbons of ''py'' groups of the ligands 4,4-bipy, bpa, bpe and bpp. The ^{13}C NMR spectrum of the **2** and **3** displays one other signals at 34.4 and 121.7 ppm assigned to carbons of —CH=CH— and —CH_2—CH_2— group of ligands bpa and bpe, respectively. The ^{13}C NMR spectrum of the compound **4** displays two other signals at 29.76 and 33.74 ppm assigned to carbons of —CH_2—CH_2—CH_2— of ligand bpp. However, the NMR data of the compounds **1**–**4** are not significantly different from free ligands, 4,4-bipy, bpa, bpe and bpp. This point shows that the compounds break up in DMSO solution and polymeric structures may retain in the DMSO solution and we use from NMR data only for characterization of new compounds.

3.2. Structural analysis of compounds *1*–*4*

Crystal data and structure refinements for compounds **2**–**4** are given in Table 1. Selected bond distances and angles for compounds **2**–**4** are listed in Table 2. Single X-ray crystal analysis reveals that $[Hg(\mu\text{-bpa})(SCN)_2]_n$ (**2**) and $[Hg(\mu\text{-bpp})(SCN)_2]_n$ (**4**) crystallize in monoclinic with space groups of $P2_1/c$ whereas the $[Hg(\mu\text{-bpe})(SCN)_2]_n$ (**3**) crystallize in orthorhombic with space groups *Pbnn*. The crystal structure **2**, **3** and **4** consists of one-dimensional zigzag chain type (Figs. 2 and 3). The ligands bpa, bpe and bpp as well as two thiocyanate anions in compounds **2**, **3** and **4** generate angular nodes of metal moieties. The nitrogen atoms of ligands ''bpa'', ''bpe'' and ''bpp'' are linked to two different mercury atoms and the thiocyanate atoms are coordinated to mercury *via* S atoms but are not bridged to two mercury atoms. The coordination number of Hg atoms is four (two of ''bpa'', ''bpe'' and ''bpp'' and two of sulfur atoms) and the environment is a distorted tetrahedral. The Hg–N and Hg–S bond lengths in the compounds **2**, **3** and **4** are nearly comparable whereas N–Hg–N and S–Hg–S bond angles in the compounds **2**, **3** and **4** are diverse, the N–Hg–N and S–Hg–S are 94.3(2)° and 137.46(8)° in the compound **2**, respectively, the N–Hg–N and S–Hg–S are 85.08(15)° and 123.27(9)° in the compound **3**, and the N–Hg–N and S–Hg–S are 92.55(19)° and 149.65(17)° in the compound **4**, respectively. This may be consistent with the assumption that bpa and bpp are the more flexible than bpe and may impose a better positioning of the donor atoms for forming one-dimensional zigzag chain and reduce the strict effect.

To find the packing controller factors a search was generally made for weak interactions of compounds **2** and **3**. The interesting feature compounds **2** and **3** is that, there are the weak hydrogen bonding of $C–H_{py}\cdots S_{thiocyanate}$

Table 2

				S(2)–Hg(1)–N(1)	107.80(18)
				N(2)–Hg(1)–S(1)	106.28(17)
				S(2)–Hg(1)–S(1)	148.65(17)

and $C–H_{py}\cdots N_{thiocyanate}$ interactions in the compound **3** and **4**, respectively, as shown in Fig. 4. In compound **2** (Fig. 4a), there are C–H···S interactions between sulfur atoms of thiocyanate anions and hydrogen atoms of pyridyl with the distances of S···HC(py) = 2.698 Å, {HC(py)···S = 3.604 Å and ∠S···H–C = 133.75°}. In compound **3** (Fig. 4b), there are C–H···N interactions between nitrogen atoms of thiocyanate anions and hydrogen atoms of $–CH_2–$ with the distances of N···HC = 2.682 Å, {HC···N = 3.435 Å and ∠N···H–C = 138.49°}. In compound **4** (Fig. 4c), there are C–H···S interactions between sulfur atoms of thiocyanate anions and hydrogen atoms of $–CH_2–$ with the distances of S···HC = 2.989 Å, {HC···S = 3.754 Å and ∠S···H–C = 147.33°}.

In compounds **2**, **3** and **4** the C–H···S and C–H···N distances suggest strong interactions within this class of weak non-covalent contacts [23]. Consequently, C–H···S and C–H···N interactions, grow the 1D structures compounds **2**–**4** into a hybrid two- and three-dimensional networks, respectively. The thiocyanate anion in the compound **4** is disordered.

Meanwhile the other analogue of compounds **2**, **3** and **4** with ligand 4,4-bipyridine (4,4-bipy), $[Hg(\mu\text{-}4,4\text{-bipy})(SCN)_2]_n$ (**1**), has been synthesized by this method too and has been structurally characterized [13]. The structural of $[Hg(\mu\text{-}4,4\text{-bipy})(SCN)_2]_n$ (**1**) complex is also 1D Zigzag chain type, similar to compounds **2**, **3** and **4**. The thermal and fluorescence studies of compound **1** in this paper are reported.

3.3. Thermogravimetric analysis

In order to examine the thermal stability of the four compounds, thermal gravimetric (TG) and differential thermal analyses (DTA) were carried out for compounds **1**–**4** between 30 and 700 °C in the static atmosphere of air. Compound **1** is stable up to 197 °C at which temperature it begins to decompose. The TG curve of compound **1** indicates the release of 4,4-bipy molecule take place at 197–260 °C with one exothermic effect at 200 °C (Fig. 5). Decomposition of the thiocyanate anions seems to take place at 274 °C with one exothermic effect at 380 °C. The solid residue formed at around 400 °C is suggested to be HgO that under higher temperature is evaporated. The thermal decomposition behavior of compounds **2**–**4** is fairly similar with compound **1** and in the all compounds first the ligand release at 197–260 °C. The solid residue formed at around 265 °C suggested to be ligand-free $Hg(SCN)_2$ which is stable up to 390 °C and under higher temperature with one exothermic effect is decomposed (Figures S1–S3). In summary, the thermogravimetric analysis shows that all four frameworks have a remarkably thermal stability and only decompose above temperature of ca. 200 °C.

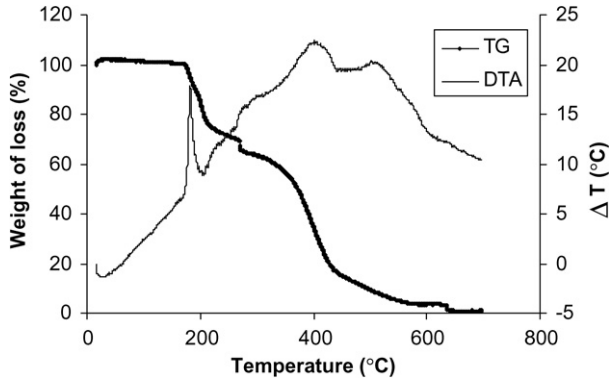

Fig. 5. Thermal behaviour of $[Hg(\mu\text{-}4,4'\text{-bipy})(SCN)_2]_n$ (**1**).

3.4. Luminescent properties

The fluorescence spectra of compounds **1**–**4** have been studied in the solid state. From the four compounds reported here only the compounds **1** and **3** have shown luminescent properties in solid (Figures S4 and S5) and however the UV/Vis and fluorescence spectra of the compounds **1** and **3** were studied. The UV/Vis spectra of compounds **1** and **3** in methanol display intense absorption bands with $\lambda_{max} = 265$ and $\lambda_{max} = 239$ nm (Figures S4 and S5), respectively, indicating that electronic transitions are mostly π–π^*, originating from the pyridyl groups of ligands 4,4′-bipy and bpe. The compounds **1** and **3** show broad emission bands with the maximum intensities at 430 and 468 nm upon excitation at 300 nm, respectively (Figures S4 and S5). These fluorescent emissions can be tentatively assigned to the intraligand fluorescence emission as similar emissions at 430 and 470 nm upon the same excitation at 300 nm (Figures S4 and S5) can also be observed for the free ligands 4,4′-bipy and bpe, respectively.

4. Conclusions

Four mercury(II) coordination polymers with the ligands 4,4-bipy, bpa, bpe and bpp, $[Hg(\mu\text{-}4,4\text{-bipy})(SCN)_2]_n$ (**1**), $[Hg(\mu\text{-bpa})(SCN)_2]_n$ (**2**), $[Hg(\mu\text{-bpe})(SCN)_2]_n$ (**3**), $[Hg(\mu\text{-bpp})(SCN)_2]_n$ (**4**), have been synthesized and characterized. The compounds are structurally similar showing one-dimensional zigzag motifs. In all four compounds the thiocyanate ions are coordinated as unidentate ligand via only sulfur atom. It is found that these 1D coordination polymers further extends into 2D and 3D networks via non-classical hydrogen bonding and extensive weak non-covalent interactions seem to play an important role in the crystal packing of the non-covalent frameworks. It seems that, in contrast to other previously reported $M(SCN)_2$ coordination polymers of the different ligands [24–29] that the thiocyanate anions are bridged and contain two- or three-dimensional polymers. In other word, the Hg^{II} coordination polymers with other counter-ions such as I^- and CN^- have been reported and showed that these anions were bridged and could increase structural dimensionality [30–32]. The

$Hg(SCN)_2$ coordination polymers with these ligands reported here result in the formation of only one-dimensional polymers, and thiocyanate thus seems to be the counter-ion of choice when one wants to prepare one-dimensional of rarely reported Hg^{II} coordination polymers. However this research not only shows the significant influences of the coordination modes and flexibilities of the ligands 4,4-bipy, bpa, bpe and bpp on the structural topology but also illustrates the effect of the counter-ions, here thiocyanate ions, on the polymeric components, which provides valuable instructions for the rational design of coordination polymers with desired molecular architectures. Also this study demonstrates the mercury(II) thiocyanate tend to form compounds with coordination number of four and consequently act in same form of coordination polymers with bridging bidentate ligands.

Abstract

A series of cobalt(III) anionic complexes with hydroxyimino analogs of dipeptides – oximes of pyruvylglycine, pyruvyl-L-alanine, pyruvyl-L-methionine and pyruvyl-L-phenylalanine (H_2pamaco, amac = amino acid) of composition $Cat_3[Co(H_{-1}pamaco)_2]\cdot nH_2O$ (Cat – a monovalent metal cation) has been synthesized and investigated by UV–Vis, CD and ^{1}H NMR spectroscopy. It was established that for the two latter ligands, non-racemic mixtures of two diastereomeric complexes were formed as a result of synthesis. In comparison with the complex containing pyruvyl-L-alanine, in which the relative content of R (C_2) and S (C_2) isomers is approximately equal, the presence of bulky substituents in the molecules of Met- and Phe-containing ligands results in a significant discrimination in formation of the S (C_2) isomer. This conclusion was drawn upon analysis of the CD and NMR spectral data as well as from molecular modeling. The relative content of the diastereomers was evaluated on the basis of NMR data. The protonation constants of the ligands have been determined in aqueous solution by glass electrode potentiometry, whereas their interactions with Co(II) were studied both under argon and oxygen atmosphere.

Keywords: Chiral pyruvylaminoacid oximes; Cobalt(III); Synthesis; Cobalt(II); Aqueous solution; Equilibria

1. Introduction

Pyruvylamino acid oximes represent a perspective class of polyfunctional ligands which can be regarded as hydroxyimino analogs of dipeptides. Both "free" ligands and their Co(III) complexes were shown to exhibit marked hypotensive effect, significantly exceeding this of the reference theobromine [1].

Earlier we have reported about the synthesis, study of molecular structure and spectral investigations of cobalt (III) anionic complexes with pyruvylaminoacid oximes of composition $Cat_3[Co(H_{-1}L)_2]\cdot nH_2O$ (Cat – a monovalent metal cation) [2,3]. These compounds contain triply deprotonated residues of the ligands, tridentately coordinated to the metal ion *via* the nitrogen atoms of the oxime and amide groups and the oxygen atom of the carboxyl group. We have also shown that upon formation of the anionic complexes in aqueous solution ionization of the oxime and amide groups proceeds cooperatively and is promoted by cobalt ions [1].

Herein, in continuation of research of pyruvylaminoacid oximes, we report a study of peculiarities of formation of diastereomeric cobalt(III) anionic complexes with chiral pyruvylaminoacid oximes by means of electronic, CD

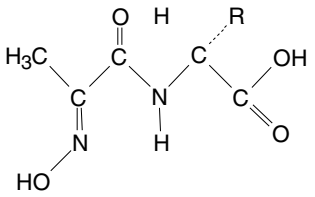
and NMR spectroscopy. Moreover, we describe the complex formation of H_2pamaco with Co(II) inorganic salts in alkali aqueous solution under oxygen-free conditions and also in presence of dioxygen.

2. Experimental



2.1. Additional abbreviations

H_2pgo – Pyruvylglycine oxime –CH_3–C(=NOH)–C(O)NH–CH_2–COOH; R=H.

H_2pao – Pyruvyl-L-alanine oxime – CH_3–C(=NOH)–C(O)NH–CH(CH_3)–COOH; R=CH_3.

H_2pmo – Pyruvyl-L-methionine oxime – CH_3–C(=NOH)–C(O)NH–CH($CH_2CH_2SCH_3$)–COOH; R=CH_2-CH_2SCH_3.

H_2ppo – Pyruvyl-L-phenylalanine oxime – CH_3–C(=NOH)–C(O)NH–CH(C_6H_5)–COOH; R=C_6H_5.

2.2. Measurement procedures

Preparation of cobalt(III) anionic complexes: $Na_3[Co(H_{-1}pgo)_2]\cdot 10H_2O$ (**1**), $K_3[Co(H_{-1}pao)_2]\cdot 5H_2O$ (**2**), $Na_3[Co(H_{-1}pmo)_2]\cdot 5H_2O$ (**3**) and $Tl_3[Co(H_{-1}ppo)_2]\cdot H_2O$ (**4**) was reported in [1,2]. UV–Vis absorption spectra of the prepared complexes in aqueous solution were recorded here on a Specord UV–Vis M 40 (Carl Zeiss, Jena) device in the range 50 000–11 000 cm^{-1}. ^1H and ^{13}C NMR spectra (solutions in D_2O and DMSO-d_6) were registered on a Bruker 300 MHz spectrometer using TMS as an internal standard.

CD spectra of the synthesized anionic complexes in aqueous solutions (1×10^{-3} M) were recorded on a MARK III Jobin Yvon dichrograph in the range 200–790 nm in cuvettes of different thickness (1, 0.1, 0.01 cm). In order to avoid trapping of aerial oxygen during the spectra recording, a steam of extra pure nitrogen was blown through the optical system. The obtained spectra were processed by calculation of $\Delta\varepsilon$ using formula: $\Delta\varepsilon = n\cdot A/c\cdot\alpha$ where $\Delta\varepsilon$ – the difference between extinction coefficients of left- and right-handed circular polarized light, n – distance from the top of maximum of Cotton effect to the base line (mm), A – sensitivity, c – concentration (mol dm^{-3}), α – thickness of the cuvette (cm).

The potentiometric equilibria studies were carried out by a precision PHM 85 pH-meter Radiometer (Copenhagen) with a combined electrode GK 241 C. The constant temperature 0.5 °C and ionic strength 0.1 (KNO_3) were in conformity with the conditions of dioxygen uptake. The protonation and formation constants were determined by pH-metric titration of 30.0 cm^3 samples. The glass electrode was calibrated in the $-\log[H^+]$ scale by titration of 0.005 M HNO_3 with 0.1 M NaOH, temp. 25 °C. Then concentration overall protonation constants $\beta_{lh} = [L_lH_h]/[L]^l[H]^h$ were calculated by SUPERQUAD [11]. The total concentration of the ligand in each sample ranged within $0.5–1.0\times10^{-2}$ mol dm^{-3}. The metal–ligand interaction was studied at ligand in excess and total metal concentration within $3.3–6.6\times10^{-3}$ mol dm^{-3}. $Co(NO_3)_2$ pa of POCh Gliwice was used. The standard solution was titrated with disodium salt of EDTA in presence of murexide.

Volumetric and simultaneously pH-metric measurements in presence of dioxygen were carried out by means of an isobaric laboratory set at 0.5 °C, $I = 0.1$ (KNO_3). The absorption spectra under O_2 atmosphere were recorded on a Specord UV–Vis M 40 spectrophotometer.

3. Results and discussion

Structure of the cobalt(III) anionic complex with $H_{-1}pgo^{3-}$ was determined earlier by single crystal X-ray analysis [3] as shown in Fig. 1.

C_2 point symmetry of the complex anion suggests its existence in two enantiometric forms (Fig. 2).

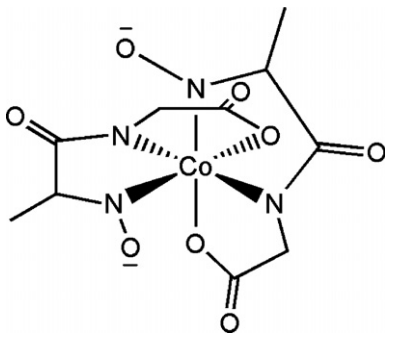


Fig. 1. View of the molecular structure of complex anion $[Co(H_{-1}pgo)_2]^{3-}$.

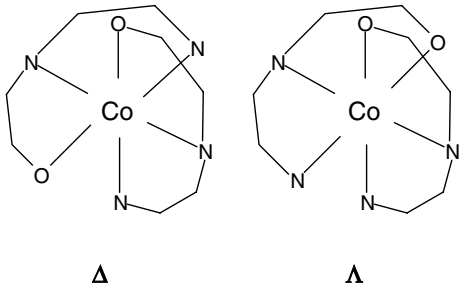

Fig. 2. Conformational isomers of cobalt(III) anionic complexes with pyruvylamino acid oximes.

In the centrosymmetric unit cell of the crystals **1** (space group $P\bar{1}$) the anions of both forms are to be found, so that the aqueous solution of the complex does not exhibit any optical activity as it contains a racemic mixture.

3.1. CD and UV–Vis spectra

The presence of an additional chiral center in the optically active ligands in $[Co(H_{-1}pao)_2]^{3-}$, $[Co(H_{-1}pmo)_2]^{3-}$ and $[Co(H_{-1}ppo)_2]^{3-}$ results in the fact that in the regarded complexes the configurational isomers become diastereomers. This allows making some *a priori* conclusions about their expected CD spectra. Taking into account the fact that contribution of the configurational and vicinal effects in total optical activity is regarded to be additive [4], one can conclude that the configurational effects of both isomers should be opposite, and an equal quantitative ratio of the isomers should result in quenching the optical activity.

Vicinal activity of both diastereomers in general case should be equal and the observed optical activity of their equimolar mixture should be equal to the double vicinal effect. Taking into account the planar conformation of rigid five-membered rings in $[Co(H_{-1}pgo)_2]^{3-}$ one should not expect any noticeable contribution of conformational effects in optical activity.

UV–Vis and CD spectra of aqueous solutions of **2** and **3** are presented in Fig. 3.

In the CD spectrum of **2** a negative Cotton effect with a minimum at 17200 cm^{-1} is registered in the region of $^1T_{1g} \leftarrow {}^1A_{1g}$ transition of Co(III). A more weak positive effect with a maximum at 18900 cm^{-1} is registered along with a strong negative band spreading over the region of $^1T_{1g} \leftarrow {}^1A_{1g}$ transition (with a minimum at 21700 cm^{-1}). Judging from the shape and the position of minimum of dichroism and $\Delta\varepsilon$ value, the latter represents an overlap of the third component of the *d-d* transition and charge transfer, the both bands being of negative sign. The $\Delta\varepsilon$ value in the CT region is significantly larger than in the case of the first two bands, so that the third component appears to be completely obscured. The intensities of the bands are in agreement with those expected for d–d transitions. It is worth to note, that the negative Cotton effect dominates in all the considered region. The $\Delta\varepsilon$ values and the character of alternation of two bands $(-+-)$ can be regarded as an expected situation for vicinal optical activity induced by the dipetide-like ligand containing L-amino acid residue in the C-terminal moiety [5]. The views of the spectrum and $\Delta\varepsilon$ values are close to those reported for the dipetide complexes possessing only vicinal activity [6]. The total negative rotatory strength of the $^1T_{1g} \leftarrow {}^1A_{1g}$ transition is characteristic for L-amino acid C-terminal residues [4,7].

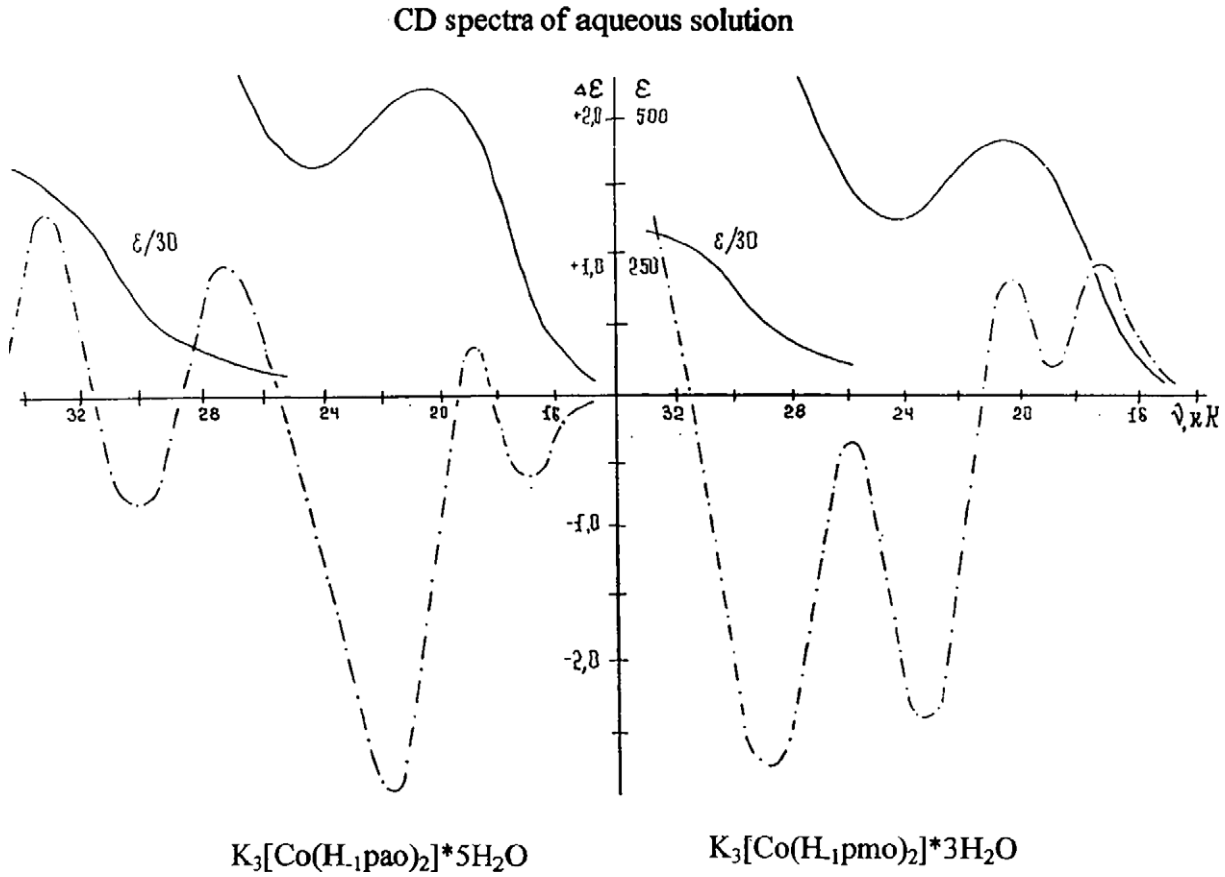

Fig. 3. UV–Vis (–––) and CD (–·–·–) spectra of aqueous solutions of: **2** and **3**.

In the considered spectrum the two low energy bands can be ascribed to the components of transition on ^1E; the $^1T_{2g} \leftarrow {}^1A_{1g}$ transition, as mentioned above, is obscured by the CT band. In the region of intraligand transitions and CT the Cotton effects of alternating signs are registered; their total rotatory strength is negative.

The CD spectrum of **3** is significantly different. First of all, this regards to the d–d transition region. In the spectrum a positive Cotton effect at 17 700 cm^{-1}, a band of positive dichroism with minimum at 19 100 cm^{-1} and another one, following the latter, positive band at 20 600 cm^{-1} are registered. At higher wave numbers a strong negative Cotton effect caused by charge-transfer is observed, the position of the corresponding maximum and $\Delta\varepsilon$ value is close to that in the spectrum of **2**. It is evident that the observed effects in the spectrum of **3** cannot be conditioned only by vicinal contribution. The registered spectrum is a result of overlapping of several Cotton effects of the opposite signs. Note, that within the whole considered region the negative dichroism predominates. Taking into account the total negative contribution of vicinal effect of L-isomer in the observed rotatory strength, one can make a conclusion about the existence of strong configurational contribution which in the present case can be caused only by configurational chirality. This is confirmed by noticeably higher $\Delta\varepsilon$ values in comparison with **2**.

Thus, it may be concluded that in **3** one of the possible configurational isomers is more abundant, so that enantioselectivity takes place rather on formation of complex **2** [8]. Contrariwise, during formation of **2** the diastereomers are indeed formed in approximately equal amounts [1].

3.2. ^1H NMR investigations

The last conclusion of CD studies is confirmed by ^1H NMR spectral investigations. Thus, the spectrum of **2** (Fig. 4) is characterized by the presence of two sets of signals, expected for the protons of the methyl and methane groups of the ligand.

In the spectrum of **2** one can register two singlets of the methyl {CH_3–C(NO)} protons (1.63 and 1.67 ppm), two doublets of the methyl protons of the side chain {CH_3–CH} {1.45 and 1.55 ppm, $^3J = 6.8$ Hz} and two quartets of the methine protons {4.06 and 4.22 ppm}. Comparison of integral intensity of the signals makes it possible to estimate quantitatively the content of the configurational isomers. As one can see from Fig. 4, the intensities of the corresponding signals in both sets are in fact equal (ratio of the integral intensities is 1:1.11). This corresponds to the relative content of the diastereomers in ratio of 52.6–47.4% which suggests their approximately equal quantities. In the ^{13}C NMR spectrum of **2** also two sets of signals are registered: 12.55 (12.64) ppm, {CH_3–C(NO)}, 19.52 (19.64) ppm {CH_3–CH}, 55.13 (55.90) ppm {CH}, 152.60 (153.25) ppm {C(N=O)}, 172.18 (173.05) ppm {C=O}, 186.40 (186.86) ppm {COO}.

^1H NMR spectra of complexes **3** and **4** are characterized by the presence of a relatively large number of signals in the region of the expected resonances of the methane and methylene groups, which complicates significantly their interpretation. Judging by view of the spectra in the region of singlets of the methyl {CH_3–C(NO)} groups, the spectra contain more than two sets of signals. The ratio of the corresponding integral intensities suggests noticeable domination of one of the isomers. It seems that in the regarded

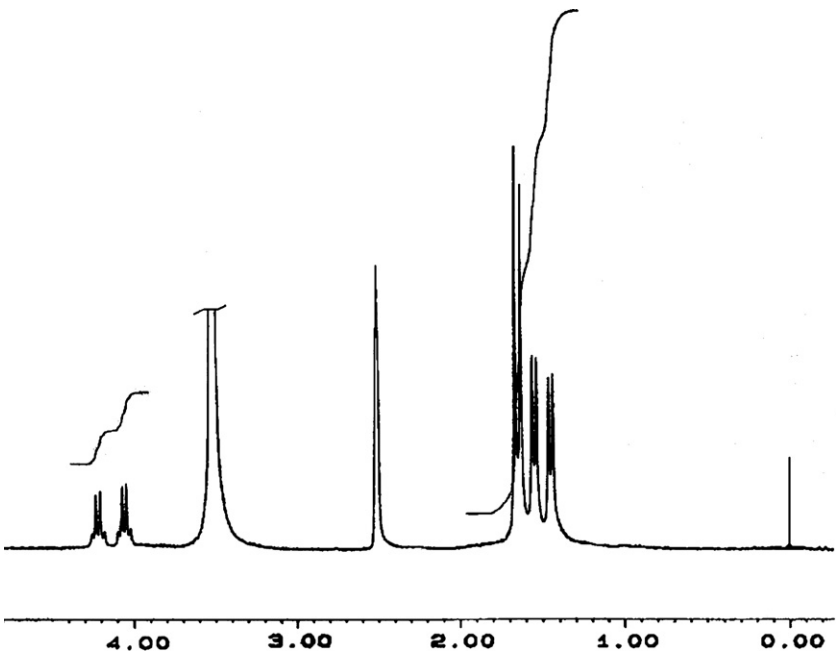

Fig. 4. ^1H NMR spectrum of **2** (solution in DMSO-d_6).

systems some additional effects take place, which results in non-equivalence of protons of the corresponding groups of two different ligands within the same coordination polyhedron. Such phenomena can be determined by peculiarities of solvatation of the complex anions in solutions and also by realization of non-equal conformations of the side chains of the ligands in bis(ligand) complexes. By their nature the mentioned effects are close to those observed in non-racemic mixtures of enantiomers, where no signals splitting is expected *a priori* [9]. This additional non-equivalence results in further splitting which contributes to further complication of the spectra. This conclusion is confirmed by the ^{13}C NMR spectra of **3** and **4**, in which in the region of the expected signals of each carbon atom 3–5 resonances are registered.

Note, that the intensity of the most intensive signal in each set is more than sum of intensities of more weak signals. The total positive rotary force of $^1T_{1g} \leftarrow {}^1A_{1g}$ transition under condition of negative contribution of the vicinal effect in the CD-spectrum of **2** makes it possible to assume, according to known empirical rules, a predominant formation of the configuration isomer possessing right screw chirality along the C_2 axis (i.e., R(C_2) isomer). Analysis of molecular models revealed that in the case of the S(C_2)-isomer the side chains appear to be situated in significantly more close proximity than in the case of R(C_2) isomer, which can result in intramolecular interligand interactions limiting conformational flexibility of the chains. Note, that a similar stereospecificity was noticed before for configurationally chiral Co(III) complexes [10]. Earlier, a preferential formation of R(C_2)-isomers it was also established in the Co(III)-dipeptide systems with an amino acid residue possessing L-configuration [5]. The mentioned interligand interactions are the reason of chiral discrimination in reactions of anionic complex formation in the systems containing ligands with bulky substituents in the side chain (i.e. derivatives of L-methionine and L-phenylalanine). At the same time in the complex with L-alanine derivative, the side chains (methyl groups) are quite compact and in the case of both R(C_2) and S(C_2) isomers significantly separated from each other, which thus results in prevention of noticeable interligand interactions between them. As a result, formation of Co(III) anionic complexes with this ligand is not accompanied by discrimination of one of the formed configurational isomers.

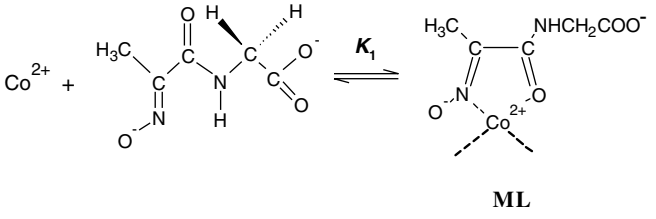
3.3. Equilibrium studies under inert atmosphere

The protonation constants of the oxime groups $\log K_{2H} = \log \beta_{011}$ (Table 1) are of two orders of magnitude higher than the constants characterizing the corresponding amino groups in dipeptides. E.g., for GlyGly under the same conditions: $\log \beta_{011}$ (–NH_2) = 8.31 [12]. On contrary, the stepwise protonation constants of the carboxyl functions (resulting from the total formation constants, $\log K_{2H} = \log \beta_{012} - \log \beta_{011}$) are similar – for GlyGly: $\log K_{2H} = 3.14$ [12]. Moreover, the deprotonation of the amide group has not been found within pH < 12, just like it is the case for dipeptides.

Table 1
Protonation and formation constants $\log \beta_{MLH}$ in Co(II)–H_2PyruvylAmacOxime (H_2pamaco) systems under inert atmosphere

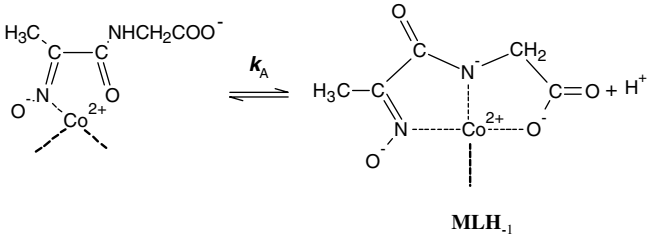
Species[a,b]	H_2pgo	H_2ppo	H_2pmo
LH	10.55(3)	10.86(1)	10.72(1)
LH_2	13.83(4)	14.03(2)	13.91(3)
ML	5.38(5)	4.19(2)	4.20(3)
ML_2	8.90(8)	8.22(2)	–
MLH_{-1}	–	–	−4.47(1)
$ML(LH_{-1})$	−1.45(10)	−3.75(6)	−1.87(3)
$M(LH_{-1})_2$	–	−14.85(3)	–

Solv. H_2O. $I = 0.1$ (KNO_3), temp. 0.5 °C. Standard deviations in parentheses.
[a] L = pamaco – the carboxyl and oxime deprotonated ligand.
[b] $LH_{-1} = H_{-1}$pamaco – fully deprotonated ligand (also amide deprotonation).



A higher basicity of the nitrogen containing oxime group leads to enhanced values of ML stability constants (Table 1). A comparison of $\log K_1$ with GlyGly ($\log K_1 = \log \beta_{110} = 3.41$) confirms this observation [12] (see Scheme 1).

In the presence of the Co^{2+} central ion a metal promoted amide deprotonation becomes possible already at pH > 8 (see Scheme 2).



The symbol k_A denotes the amide deprotonation constant:

$$pk_A = -\log k_A = \log \beta_{110} - \log \beta_{11-1}$$

However, the MLH_{-1} species has been confirmed only for H_2pmo (Table 1). Other deprotonated complexes of composition M:L = 1:2 (i.e. $ML(LH_{-1})$ and $M(LH_{-1})_2$) may be formed via coordination of the second ligand molecule in a plane perpendicular to the first chelation plane. Indeed, the refinements confirmed the amide deprotonated complex $ML(LH_{-1})$ for all the ligands studied (cf. Table 1).

Scheme 1.

Scheme 2.

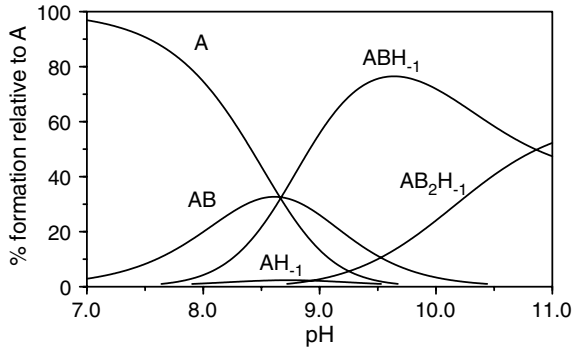


Fig. 5. Complex species distribution as a function of pH in the Co(II)–H_2pmo system in aqueous solution. $C_{Co} = 3.33 \times 10^{-3}$, $C_L = 1.0 \times 10^{-2}$ mol dm^{-3}. A = Metal, B = ligand = pmo.

The doubly deprotonated $M(LH_{-1})_2$ species was accepted only for H_2ppo but low contents in solution could not be excluded also for the other pyruvylaminoacid oximes at higher pH. The hydrolysis of the uncomplexed metal aquo-ion has been regarded by equilibrium:

$M \rightleftharpoons MH_{-1} + H$, where $\beta_{10-1} = [MH_{-1}][H][M]^{-1}$. The value of the hydrolysis constant under corresponding conditions $\log\beta_{10-1} = -9.80$ was taken from [13].

An exemplary distribution of complexes versus pH is presented in Fig. 5.

3.4. Reactions under O_2 atmosphere

The presence of at least three nitrogen donors in the inner coordination sphere makes it possible, in accordance to Fallabs 3N rule, to foresee an uptake of dioxygen by $ML(LH_{-1})$ or $M(LH_{-1})_2$ [14].

The titration curves in presence of molecular oxygen displayed a buffer zone within pH 6–8. This buffer zone corresponds to the straight line segment of the mmol $O_2 = f(V_{NaOH})$ dependence (Fig. 6a).

The mean slope $\Delta OH/\Delta O_2$ of five titrations amounted to $8.02 \approx 8$, thus indicating 8 protons being neutralized in the summary reaction. At the same time the number of mmoles of bound dioxygen attains a maximum: 0.42 per 1 mmol of cobalt at L:M = 2.0 (Fig. 6b). The value 0.42 is close to 0.5

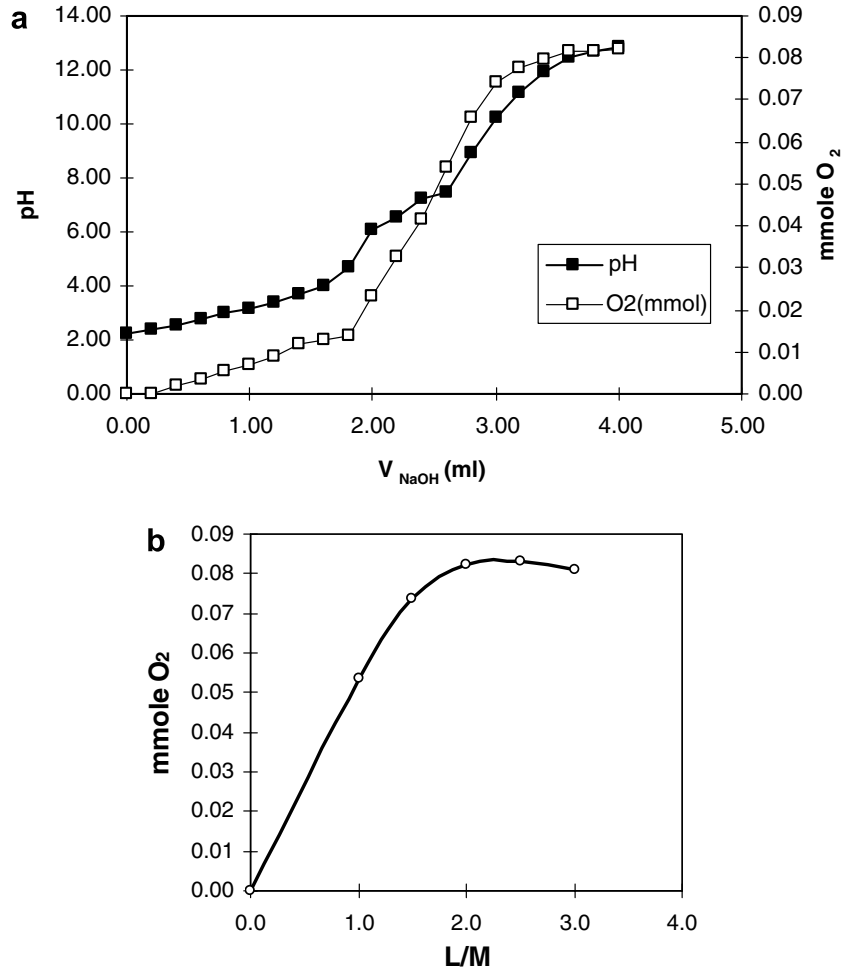

Fig. 6. (a) pH-metric and volumetric titration in the Co(II)–H_2pgo-O_2 system. Initial volume 40 cm^3. $C_{NaOH} = 0.4037$ M. The sample contained 0.2 mmol of $Co(NO_3)_2$ and 0.4 mmol of H_2pgo, (b) total amount of bound oxygen vs. ligand to metal concentration ratio.

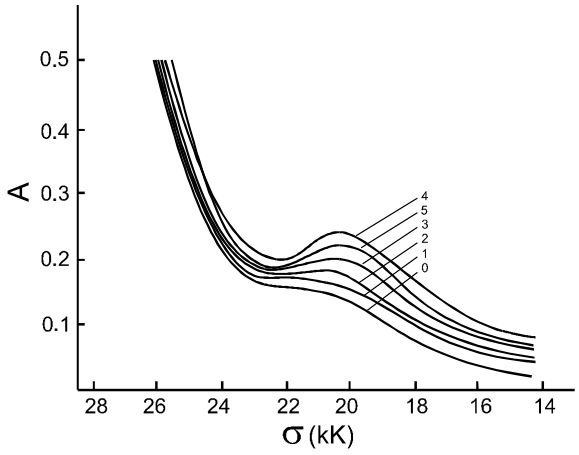

Fig. 7. UV–Vis absorption in aqueous solution after oxygenation of a sample containing Co(II) and pgo. Path length 1 cm. Temp. 0.5 °C. $C_{Co} = 5.0 \times 10^{-3}$, $C_L = 1.0 \times 10^{-2}$ mol dm^{-3}. Curves after: 0–3 min, 1–10 min, 2–20 min, 3–65 min, 4–72 h, 5–7 days since initiation of reaction.

expected for dimer formation. Hence the following summary reaction may be proposed for L = pamaco:

$$4H_2L + 8OH^- + 2Co^{2+} + O_2 = (LH_{-1})_2CoO_2Co(LH_{-1})_2^{4-} + 8H_2O$$

Although it may be concluded that $Co(LH_{-1})_2$ is the "active" complex able to take up dioxygen, also the $CoL(LH_{-1})$ complex should be taken into account. Hence two of the neutralized 8 protons may stem from the deprotonation:

$$2CoL(LH_{-1})^{2-} + O_2 = Co_2(LH_{-1})_4O_2^{4-} + 2H^+$$

Unlike the reactions of the corresponding dipeptides, the reaction of oxygen uptake studied herein was almost in 90% irreversible. The autooxidation of Co(II) to Co(III), concomitant to oxygen uptake, yields irreversibly inert Co(III) complexes. The peroxo dioxygen bridge is transformed to hydrogen peroxide:

$$(LH_{-1})_2Co^{III}O_2^{2-}Co^{III}(LH_{-1})_2^{4-} + 2H^+ \rightarrow 2Co^{III}(LH_{-1})_2^- + H_2O_2$$

and then dioxygen is re-emitted in a relatively slower reaction:

$$H_2O_2 \rightarrow H_2O + 1/2O_2$$

As a result it can be seen in Fig. 6b that the amount of bound dioxygen is less than 0.5 mmol per 1 mmol of cobalt, particularly when L/M is higher (then the duration time of titrations under oxygen is longer).

Spectrophotometric measurements in presence of O_2 also indicated the formation of a final violet solution in alkali medium which may be attributed to Co(III) species with the $^1T_{1g} \leftarrow {}^1A_{1g}$ band at $\sigma \approx 21 \times 10^3$ cm^{-1} – Fig. 7. The higher energetic spin allowed d^6 band $^1T_{2g} \leftarrow {}^1A_{1g}$ predicted by the crystal field theory is obscured by an intensive LMCT transition from the auxiliary ligand – pamaco.

Abstract

The reactions of $RCoL^1(H_2O)^{2+}$ (R = CH_3, C_2H_5 and *n*-C_3H_7; L^1 = 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene) and $CH_3CoL^2(H_2O)^{2+}$ (L^2 = 1,4,8,11-tetraazacyclotetradecane) with Cr^{2+} in aqueous solution were studied. The reaction products were $CoL^1(H_2O)_2^{2+}$ (or $CoL^2(H_2O)_2^{2+}$) and RCr^{2+}, following which the related alkanes were obtained via acidolysis. The reaction mechanism appears to consist of an S_H2 displacement at the saturated carbon. The reactivity is clearly dependent on the size of the alkyl group, the ligand and the configuration of the complex. The kinetics for this reaction were also studied at various temperatures. The reaction of $RCoL^1(H_2O)^{2+}$ with V^{2+} was investigated as well in this study.

1. Introduction

Coenzyme B_{12}(cobalamin) has attracted attention since the structure determination of a cobalt–carbon bond in the early 1960s [1,2]. Transition metal-alkyl bond dissociation energies are of importance in the context of a variety of organometallic and catalytic systems [3]. It is known that the steric hindrance around the metal center affects this metal–carbon bond [4–7]. Among the various alkylcobalt macrocyclic complexes prepared recently [8,9], the complex $CH_3CoL^1(H_2O)^{2+}$ (L^1 = 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene) had three configurational isomers, as shown in the following diagrams [10,11]. These complexes provide a good opportunity to examine the dependence of configurationally steric hindrance on their reactivity. The isomerization of these isomers reveals that *pri,rac-* is the most stable configuration and the isomerization rate is truly dependent on the alkyl group at the cobalt centre [12]. The substitution of SCN^- with H_2O for these three isomers of $CH_3CoL^1(H_2O)^{2+}$ also shows a remarkable steric effect with the following reactivity order: *sec,rac-* ≫ *meso-* ∼*pri,rac-* [13].

Although the dissociation energy of the cobalt–carbon bond was well determined through a kinetic study of the unimolecular homolysis of *meso*-$RCoL^1(H_2O)^{2+}$ (R = C_2H_5, *n*-C_3H_7), there is no information about the bond dissociation energy of the other configurational isomers of $RCoL^1(H_2O)^{2+}$. Both unimolecular and bimolecular homolysis were observed in the reaction of *meso*-$RCoL^1(H_2O)^{2+}$ with Cr^{2+} (R = C_2H_5, *n*-C_3H_7) [8]. The

doi:10.1016/j.poly.2007.01.032

bimolecular homolytic reaction is interesting since homolytic metal–carbon bond cleavage and atom transfer is involved. In the present study, the reactions of alkylcobalt complexes with different ligands and various configurations with the metal ions Cr^{2+} and V^{2+} were investigated. The kinetics and the activation parameters for the reaction of *sec*,*rac*-$CH_3CoL^1(H_2O)^{2+}$, *pri*,*rac*-$RCoL^1(H_2O)^{2+}$ (R = CH_3, C_2H_5 and *n*-C_3H_7) and $CH_3CoL^2(H_2O)^{2+}$ (L^2 = 1,4,8,11-tetraazacyclotetradecane) with Cr^{2+} in aqueous solution are reported.

2. Experimental

2.1. Reagents

The macrocycle Me_6[14]4,11-dieneN_4 (L^1) was prepared by the condensation of 1,2-diaminoethane and acetone [14]. [14]aneN_4 (L^2) was purchased from Aldrich and used directly. *meso*-$CoL^1(H_2O)_2(ClO_4)_2$, *sec*,*rac*-$CH_3CoL^1(H_2O)(ClO_4)_2$, *meso*-$RCoL^1(H_2O)(ClO_4)_2$, *pri*,*rac*-$RCoL^1(H_2O)(ClO_4)_2$ (R = CH_3, C_2H_5, *n*-C_3H_7) and an aqueous solution of $CH_3CoL^2(H_2O)^{2+}$ were prepared according to a published procedure [6,8,12,15]. (*Caution*: Perchlorate salts of metal complexes with organic ligands are potentially explosive.) The products of the alkylcobalt macrocycles were characterized by UV–Vis and ^1H NMR spectra [13,16]. *t*-Butyl hydroperoxide was commercially available and used directly. The other alkyl hydroperoxides were prepared from the appropriate alcohol and hydrogen peroxide [17,18]. The concentration of the V^{2+} solution was determined from the absorbance at a wavelength (λ) of 850 nm [19]. All the other chemicals purchased were of reagent grade and were used directly. Water was purified using a Millipore Milli-Q SP system and was used for all the kinetic measurements.

2.2. Spectroscopy and kinetics

The UV–Vis spectra and single-wavelength absorbance versus time data were acquired by using the Hitachi 3000 or HP 8453 spectrophotometer. Temperature control of ±0.5 °C was maintained by circulating water from a constant-temperature bath through the jacket of a cell holder. All the kinetic measurements were made using sodium perchlorate and perchloric acid adjusted to $\mu = 0.5$ M in most cases. The ^1H NMR spectra were studied using a Varian GEMINI-200 spectrometer. The NMR experiments were carried out in D_2O with HOD as the reference. The gas products of the hydrolysis of the organochromium complexes were determined by GC (Perkin–Elmer) and a column of GS-GASPRO.

3. Results and discussion

The typical visible spectral changes observed on mixing *pri*,*rac*-$C_2H_5CoL^1(H_2O)^{2+}$ with Cr^{2+} are shown in Fig. 1. The increase in absorption at λ 330 and 390 nm corresponds to the formation of $CoL^1(H_2O)_2^{2+}$ and $C_2H_5Cr^{2+}$, respectively. However, the subsequent decrease in absorption at λ 390 nm is caused by the slow acidolysis of $C_2H_5Cr^{2+}$ [20,21]. The related alkanes were obtained as the gas products for the eventual reactions of Cr^{2+} with various $RCoL^1(H_2O)^{2+}$ complexes. The reactions involved are shown in:

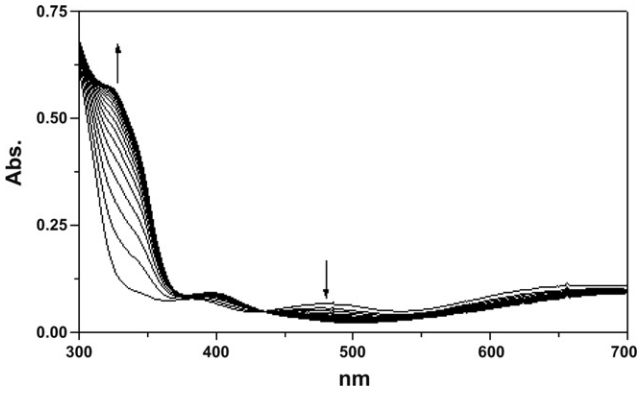

Fig. 1. Visible spectrum for the reaction of *pri*,*rac*-$C_2H_5CoL^1(H_2O)^{2+}$ with Cr^{2+}. The time interval is 60 s. [*pri*,*rac*-$C_2H_5CoL^1(H_2O)^{2+}$] = 2.5×10^{-4} M, [Cr^{2+}] = 0.02 M ($\mu = 0.5$ M, $T = 25$ °C).

$$RCoL^1(H_2O)^{2+} + Cr^{2+} \rightarrow RCr^{2+} + CoL^1(H_2O)_2^{2+} \quad (1)$$

$$RCr^{2+} + H^+ \rightarrow RH + Cr^{3+} \quad (2)$$

The kinetics of these reactions were studied under pseudo-first-order conditions with Cr^{2+} in excess and monitored by measuring the increase in absorption at $\lambda = 330$ nm as a function of time. The plots of $\ln(A_\infty - A_t)$ versus time showed a good linear behavior for at least three to four half-lives to establish the first order dependence on [$RCoL^1(H_2O)^{2+}$]. The observed rate constants depend linearly on the concentration of the excess chromous ions, as shown in Figs. 2 and 3. The plots for the reaction of *meso*-$C_2H_5CoL^1(H_2O)^{2+}$ and *meso*-$C_3H_7CoL^1(H_2O)^{2+}$ are

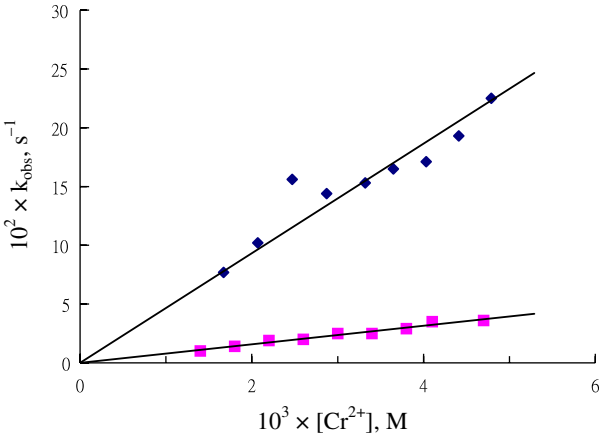

Fig. 2. Dependence of k_{obs} on [Cr^{2+}] for the reaction of $CH_3CoL^1(H_2O)^{2+}$ with Cr^{2+} at 25 °C and $\mu = 0.5$ M. ◆, *pri*,*rac*-$CH_3CoL^1(H_2O)^{2+}$; ■, *sec*,*rac*-$CH_3CoL^1(H_2O)^{2+}$.

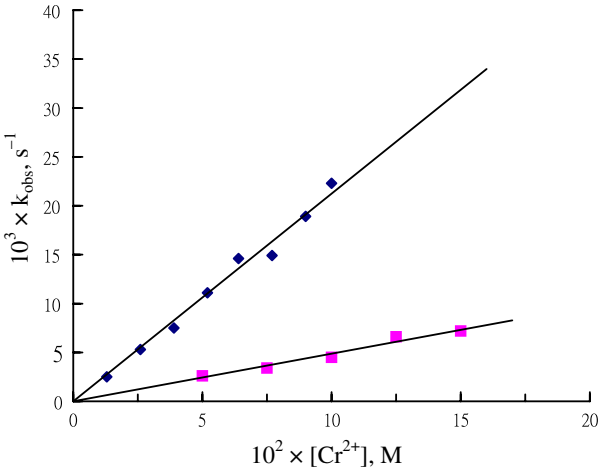

Fig. 3. Dependence of k_{obs} on $[Cr^{2+}]$ for the reaction of *pri,rac*-$RCoL^1(H_2O)^{2+}$ with Cr^{2+} at 25 °C. ◆, R = C_2H_5 ($\mu = 0.5$ M); ■, R = *n*-C_3H_7 ($\mu = 1.0$ M).

linear but with a significant intercept that corresponds to unimolecular homolysis, as shown in Eq. (3). The value of the unimolecular homolysis rate constant k_h for

$$\textit{meso}\text{-}RCoL^1(H_2O)^{2+} \rightarrow {}^{\cdot}R + CoL^1(H_2O)_2^{2+} \quad (R = C_2H_5 \text{ or } n\text{-}C_3H_7) \tag{3}$$

meso-$C_2H_5CoL^1(H_2O)^{2+}$ calculated in this study (9.1×10^{-4} s^{-1}, $\mu = 1.0$ M) is consistent with the value obtained in a previous report (3.5×10^4 s^{-1}, $\mu = 0.14$ M) [8]. These results suggest a general rate law for the reactions of Cr^{2+} with these alkylcobalt complexes:

$$-d[RCoL^1(H_2O)^{2+}]/dt = (k_h + k[Cr^{2+}])[RCoL^1(H_2O)^{2+}]$$

$$k_{obs} = k_h + k[Cr^{2+}]$$

The unimolecular homolysis rate constant k_h does not exist for these alkylcobalt complexes, except for *meso*-$C_2H_5CoL^1(H_2O)^{2+}$ and *meso*-$C_3H_7CoL^1(H_2O)^{2+}$. These results suggest that the configuration of the complex affects the bond energy of the cobalt–carbon bond in these alkyl cobalt complexes. *sec,rac*-$C_2H_5CoL^1(H_2O)^{2+}$ could not be prepared successfully probably due to the unstable cobalt–carbon bond. The values of the second-order rate constants k measured at 25 °C are listed in Table 1. The reactivity of *pri,rac*-$RCoL^1(H_2O)^{2+}$ with Cr^{2+} is clearly dependent on the size of the alkyl group R with the order $CH_3 > C_2H_5 > n\text{-}C_3H_7$. A larger alkyl group would prevent the attack by Cr^{2+}. This is consistent with the reactivity of $RCo(dmgBF_2)_2$ with Cr^{2+} [22]. Among the three different configurational isomers of $CH_3CoL^1(H_2O)^{2+}$, the *pri,rac*-form has the least steric hindrance and shows the highest reactivity with Cr^{2+}. However, the difference between the rate constants of *meso*- and *sec,rac*- is small. The larger hindrance of the *sec,rac*-configuration would certainly prevent the attack by Cr^{2+} and reduce the reaction rate. On the other hand, it would also decrease the cobalt–carbon bond energy and accelerate the reaction. The experimental results show a combination of these two factors and therefore the difference is not large. The kinetics of the reactions of $CH_3CoL^1(H_2O)^{2+}$ with Cr^{2+} were studied at different temperatures. The second-order rate constants are listed in Table 2. The data were fit to the Eyring equation with plots of $\ln(k/T)$ against $1/T$. The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are listed in Table 3.

The reaction of $CH_3CoL^2(H_2O)^{2+}$ with Cr^{2+} was also studied under pseudo-first-order kinetic conditions with Cr^{2+} in excess. Since the absorption of $CoL^2(H_2O)_2^{2+}$ in the visible region is small, the reaction was monitored at λ 390 nm, which was the maximum absorption of CH_3Cr^{2+}. A typical biphase kinetic trace was observed; the increase in absorption was followed by a decrease due to acidolysis (Eq. (2)). The slow acidolysis was caused by the first-order dependence on $[H^+]$, and it gave a second-order rate constant of 5×10^{-3} M^{-1} s^{-1}, which was in good agreement with the literature value of 4.94×10^{-3} M^{-1} s^{-1} [21]. The consecutive reaction analysis of the fast increase absorption established a first-order dependence on $[CH_3CoL^2(H_2O)^{2+}]$. The plot of k_{obs} versus $[Cr^{2+}]$ was linear with a slope equal to 0.268 ± 0.005 M^{-1} s^{-1}, as shown in Fig. 4. This reactivity is much slower than that of $CH_3CoL^1(H_2O)^{2+}$. This reactivity results from the stronger cobalt–carbon bond in $RCoL^2(H_2O)^{2+}$ [6,8]. No attempt to study the kinetic rate of the reaction of Cr^{2+} with

$C_2H_5CoL^2(H_2O)^{2+}$ was made since the reaction was expected to be even slower.

The present kinetic studies clearly indicate that there is a bimolecular reaction between $RCoL(H_2O)^{2+}$ and Cr^{2+}. The reaction mechanism appears to consist of an S_H2 displacement at the saturated carbon [23]. The second-order rate constants for the methyl cobalt macrocyclic complexes with Cr^{2+} are summarized in Table 4. The reactivity shows a clear dependence on the structure of the ligand. It is noteworthy that the rate constant for the diene ligand (L^1) is higher than that for the saturated macrocycle Me$_6$[14]aneN$_4$(5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazatetradecane). This probably indicates that the former is less sterically crowded owing to the double bonds that cause the ring configuration to become more planar.

The reaction of $RCoL^1(H_2O)^{2+}$ with V^{2+} was also studied under pseudo-first-order kinetic conditions with V^{2+} in excess. A significant absorption change was observed only for the reactions with *meso*-$C_2H_5CoL^1(H_2O)^{2+}$ and *meso*-$C_3H_7CoL^1(H_2O)^{2+}$. The first-order kinetic plots of $\ln\Delta A$ versus time were linear for the reactions with both *meso*-$C_2H_5CoL^1(H_2O)^{2+}$ and *meso*-$C_3H_7CoL^1(H_2O)^{2+}$. However, the maximum value of the pseudo-first-order rate constants measured in these reactions ($[V^{2+}] = 5.5$–27.4 mM) were not even close to the values of the unimolecular homolysis rate constant, k_h, for these two complexes. The major gas products in the reaction with *meso*-$C_2H_5CoL^1(H_2O)^{2+}$ were ethylene and ethane. This shows that the reaction of ethyl radicals with *meso*-$C_2H_5CoL^1(H_2O)^{2+}$ was still effective under these conditions. This is due to V^{2+} which is not an effective scavenger for ethyl radicals. The slow rate of exchange with solvent results in the lower reactivity of $V(H_2O)_6^{2+}$ in electron transfer reactions [19]. The reactions involved were probably the following:

$$\textit{meso}\text{-}C_2H_5CoL^1(H_2O)^{2+} \rightarrow {}^{\cdot}C_2H_5 + CoL^1(H_2O)_2^{2+} \quad (4)$$

$$\textit{meso}\text{-}C_2H_5CoL^1(H_2O)^{2+} + {}^{\cdot}C_2H_5 \rightarrow C_2H_6 + C_2H_4 + CoL^1(H_2O)_2^{2+} \quad (5)$$

$$V^{2+} + {}^{\cdot}C_2H_5 + H^+ \rightarrow C_2H_6 + V^{3+} \quad (6)$$

The kinetics study was therefore repeated with a high concentration of V^{2+} ($[V^{2+}] = 0.08$–0.31 M). In this case, C_2H_6 was the sole gas product. The plot of k_{obs} versus $[V^{2+}]$ is linear with an intercept of $4.37 \times 10^{-4}\,M^{-1}\,s^{-1}$, which is consistent with the value of the homolysis rate constant of *meso*-$C_2H_5CoL^1(H_2O)^{2+}$. The slope of the line is $4.04 \times 10^{-4}\,M^{-1}\,s^{-1}$. Due to the poor linearity and small value of the slope for the plot of k_{obs} versus $[V^{2+}]$ and no change in absorption of the reaction of $CH_3CoL^1(H_2O)^{2+}$ with V^{2+} under similar conditions, a direct reaction between *meso*-$C_2H_5CoL^1(H_2O)^{2+}$ and V^{2+} was probably non-existent.

4. Conclusion

The kinetic studies clearly show that there is a bimolecular reaction between $RCoL^1(H_2O)^{2+}$ and Cr^{2+}. The reaction rates show a strong dependence on steric effects of the alkyl group, consistent with an S_H2 mechanism. The reactivity is also clearly dependent on the configuration of the complex. However, the difference between the rate constants of *meso*- and *sec*,*rac*- is small.

Abstract

Two new carboxylato complexes, $[Re(CO)_3(DAB)(OCOCF_3)]$ (DAB = substituted aromatic diazabutadiene ligands), were prepared by the reaction of $[Re(CO)_5Cl]$ with the DAB ligands, and the subsequent reaction with $AgOCOCF_3$ gave the related carboxylate complexes. These new complexes were characterized by FTIR, NMR, UV–Vis spectra and elemental analysis. In both complexes, the Re atom has a distorted octahedral configuration and is coordinated by two carbonyl groups and the diimine group of the organic ligand in the equatorial plane. Octahedral coordination is completed at the axial positions by another carbonyl ligand and a carboxyl O atom of the trifluoroacetate anion. Electrochemical behaviour of the investigated complexes has been studied by cyclic voltammetry.

1. Introduction

The d^6 transition metal Re(I), Ru(II), Os(II) or Rh(III) complexes with α-diimine ligands have been the subject of intense investigations [1–4]. Complexes of the type $[Re(CO)_3(\alpha\text{-diimine})(X)]^{0/+}$, in which X is a halide, bridging ligand, organic donor/acceptor, nitrogen donor or some other monodentate ligand, have been the subject of a large number of studies. Furthermore, this permanently growing interest stems from the ability of these complexes and their reduced form to act as efficient sensitizers for energy and electron transfer processes [5], and as catalysts in the selective reduction of CO_2 [6], a process of interest in the conversion and storage of solar energy, and serve as models for natural photosynthesis [7,8]. Control of the excited state resulting from metal-to-ligand charge transfer (MLCT) and the redox properties of these complexes, through structural and electronic modifications in the α-diimine chelate and/or axial ligands, has been proposed as a way to improve the photo- and electrocatalytic properties of these compounds. Therefore, knowledge of the molecular and crystal structure of such complexes is essential for understanding and explaining their properties. Significant research has focused on common chelating ligands such as bipyridine (bpy) and phenanthroline (phen), but the chemistry of the *fac*-$[Re(CO)_3(X)]$ complexes with other bidentate α-diimine ligands remains largely unexplored. Bearing in mind all the above mentioned facts, we decided to pursue studies on the *fac*-$[Re(CO)_3(DAB)(OCOCF_3)]$

complexes in which DAB = [*N*,*N*-bis(2,4,6-trimethylbenzene)-1,4-diazabutadiene] (2,4,6-Me_3G), and [*N*,*N*-bis(2,4-dimethylbenzene)-2,3-dimethyl-1,4-diazabutadiene] (2,4-Me_2D). To the best of our knowledge, these complexes are the first reported Re(I)(tricarbonyl) carboxylate complexes with aromatic diazabutadiene ligands which were characterized by X-ray diffraction analysis, and the complex [$Re(CO)_3$(2,4-Me_2D)($OCOCF_3$)] is the first metal complex containing the *N*,*N*-*bis*(2,4-dimethylbenzene)-2,3-dimethyl-1,4-diazabutadiene ligand. The crystal structure of [$Re(CO)_3$(2,4-Me_2D)($OCOCF_3$)] has been reported elsewhere [9].

2. Experimental

2.1. General

All chemicals used were reagent grade and were used as received. Solvents used for the reactions were purified by literature methods [10]. The diazabutadiene ligands were prepared according to a modified literature procedure [11]. NMR spectra were obtained on a Bruker Avance DRX500 (500 MHz) spectrometer. The chemical shifts (δ) are reported in part per million (ppm) relative to an internal standard of Me_4Si. The UV–Vis spectra were recorded on a Shimadzu UV-160 spectrophotometer with quartz cells (1 cm path length). Elemental analyses were performed using a Heraeus elemental analyzer. IR spectra were recorded as KBr pellets on a Nicolet Impact 400D spectrophotometer. Electrochemical data were obtained by cyclic voltammetry (CV) with a three-electrode cell containing an Ag/AgCl reference electrode, a Pt wire counter electrode and a Pt working electrode. A Metrohm multipurpose instrument model 757 was used. CV measurements were performed in CH_2Cl_2 with 25 mM of Bu_4NClO_4 (TBAP) as a supporting electrolyte. In all electrochemical experiments, the solutions were purged with Ar gas for at least 5 min.

2.2. X-ray crystallography

Suitable single crystals of [Re(2,4,6-Me_3G)$(CO)_3$($OCOCF_3$)] (**1**) were obtained by diffusion of *n*-hexane vapour into a CH_2Cl_2 solution at −18 °C. Crystal data and refinement parameters for complex **1** are summarized in Table 1. Intensity data for complex **1** were collected on a Rigaku R-AXIS RAPID image plate diffractometer (λ(Mo Kα radiation) = 0.71070 Å) at 295 ± 2 K. Several scans in the ϕ and ω directions were made to increase the number of redundant reflections, which were averaged over the refinement cycles. An empirical (multi-scan) absorption correction was applied (ABSCOR) [12]. The structure was solved by the direct method (SIR92) [13] and refined by full-matrix least-squares (SHELXL-97) [14]. All calculations were carried out using the WINGX package of the crystallographic programs [15]. The benzene rings were restrained to be flat within a standard deviation of 0.1 Å (FLAT 0.10 instruction of SHELXL). The carbon atoms of the benzene rings were refined with distance restraints (SADI 0.002 instruction of SHELXL). All non-hydrogen atoms were refined anisotropically in the F^2 mode. Hydrogen atoms were constrained to idealized geometries and refined isotropically. The riding model was applied for the hydrogen atoms. In addition, the riding methyl hydrogen atoms were allowed to rotate freely during refinement.

2.3. Synthesis

2.3.1. [*N*,*N*-bis(2,4,6-trimethylbenzene)-1,4-diazabutadiene] (2,4,6-Me_3G)

To a 500 ml round-bottom flask equipped with a magnetic stir bar was added 250 ml of ethanol and (15.115 g, 111.8 mmol) of 2,4,6-Me_3PhNH_2. Glyoxal (8.406 g, 40 wt% solution, 55.86 mmol) was added to the clear, faint yellow solution, and the resulting yellow solution was stirred at room temperature for 14 h. The solution was filtered and the bright yellow solid thus obtained was washed with cold ethanol and dried in vacuo. IR (KBr, cm^{-1}): υ_{max} 1617, 1479 (sym, asym C=N). ^{1}H NMR (500 MHz, $CDCl_3$): 2.21 (s, 12H, 2,6-(CH_3)$_2$); 2.34 (s, 6H, 4-(CH_3)); 6.94 (s, 4H, aromatic hydrogens); 8.15 (s, 2H, iminic hydrogens). ^{13}C{^{1}H} NMR (500 MHz, $CDCl_3$): 18.68; 21.23; 127.00; 129.42; 134.72; 147.85; 163.94 (^{13}C=N). UV–Vis: λ_{max}, ε (nm, M^{-1} cm^{-1}): 248 (12444); 370 (4445).

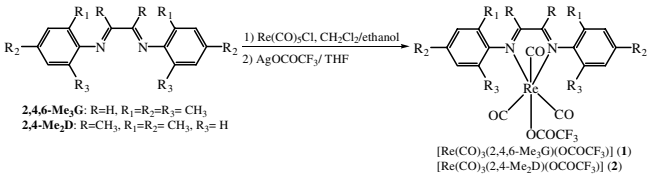
2.3.2. [N,N-bis(2,4-dimethylbenzene)-2,3-dimethyl-1,4-diazabutadiene] (2,4-Me_2D)

This ligand was prepared by a procedure similar to 2,4,6-Me_3G using (14.4 g, 118.8 mmol) of 2,4-Me_2PhNH_2 and (4.80 g, 55.80 mmol) of diacetyl. The bright yellow solid was washed with cold ethanol and dried in vacuo. IR (KBr, cm^{-1}): υ_{max} 1633, 1488 (sym, asym C=N). ^1H NMR (500 MHz, $CDCl_3$): 2.14 (s, 6H, 2-(CH_3)); 2.17 (s, 6H, 2-(CH_3)); 2.37 (s, 6H, iminic methyls); 6.58–6.60 (d, 2H, aromatic hydrogens); 7.04–7.05 (d, 2H, aromatic hydrogens); 7.09 (s, 2H, aromatic hydrogens). UV–Vis: λ_{max}, ε (nm, $M^{-1}\,cm^{-1}$): 243 (11 360); 345 (3973).

2.3.3. [Re(CO)$_3$(2,4,6-Me_3G)(OCOCF$_3$)] (1)

A mixture of $Re(CO)_5Cl$ (0.5 mmol, 111 mg) and 2,4,6-Me_3G (0.5 mmol, 146 mg) in 20 ml CH_2Cl_2 and 30 ml of absolute ethanol was heated at reflux for 3 h to give a red-brown solution. The solution was concentrated to half volume and a solution of $AgOCOCF_3$ (0.5 mmol, 110 mg) in THF was added. The mixture was refluxed for 4 h in the dark. After cooling, the AgCl precipitate was removed by filtration and the crude material was recrystallized from CH_2Cl_2/hexane to give the carboxylate complex **1** as pure dark-red crystals.

Anal. Calc. for $C_{24}H_{24}F_3N_2O_5Re$: C, 44.44; H, 3.58; N, 4.15. Found; C, 44.45; H, 3.56; N, 4.20%. IR (KBr, cm^{-1}): υ_{max} 2031, 1931, 1921 (CO). ^1H NMR (500 MHz, $CDCl_3$): 2.24 (s, 6H, CH_3); 2.29 (s, 6H, CH_3); 2.38 (s, 6H, CH_3); 7.03 (s, 4H, aromatic hydrogens); 8.79 (s, 2H, iminic hydrogens). UV–Vis: λ_{max}, ε (nm, $M^{-1}\,cm^{-1}$): 239 (13 720); 480 (8773).

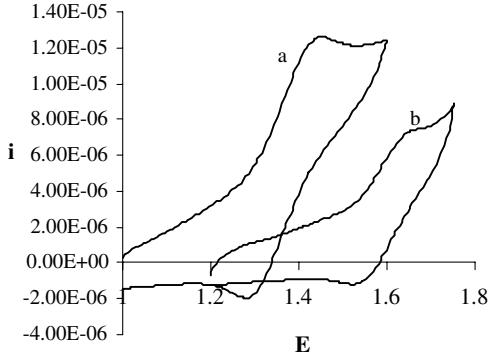


2.3.4. [Re(CO)$_3$(2,4-Me_2D)(OCOCF$_3$)] (2)

This complex was prepared by a procedure similar to **1**using 146 mg (0.5 mmol) of 2,4-Me_2D. The crude material was recrystallized from CH_2Cl_2/hexane to give [Re(CO)$_3$(2,4-Me_2D)(OCOCF$_3$)] as pure dark-red crystals. *Anal.* Calc. for $C_{25}H_{24}F_3N_2O_5Re$: C, 44.44; H, 3.58; N, 4.15. Found; C, 44.46; H, 3.60; N, 4.15%. IR (KBr, cm^{-1}): υ_{max} 2023, 1929 (CO). ^1H NMR (500 MHz, $CDCl_3$): 2.07–2.40 (s, 18H, 6CH_3); 6.7–7.2 (6H, aromatic hydrogens). $^{13}C\{^1H\}$ NMR (500 MHz, $CDCl_3$): 16.76, 17.25, 17.53, 20.16–20.18, 20.30, 20.90–20.94, 119.95–120.04, 120.55, 126.06, 126.62, 127.76, 127.96, 128.35–128.40, 131.90, 131.97, 132.26, 137.61–137.66, 145.73–145.78, 146.12, 176.59–176.80, 195.48. UV–Vis: λ_{max}, ε (nm, $M^{-1}\,cm^{-1}$): 239 (14 386); 430 (9573).

3. Results and discussion

3.1. General characterization



The new *fac*-[Re(CO)$_3$(DAB)(OCOCF$_3$)] (DAB = substituted aromatic diazabutadiene ligands) complexes were obtained via substitution reactions, as outlined in Scheme 1. The trifluoroacetateo complexes were synthesized by allowing the in situ reaction of the halide carbonyl with 1 equivalent of $AgOCOCF_3$ in a mixture of ethanol and THF in the dark. After cooling, the AgCl that formed during the reaction was removed by filtration. The partial removal of the solvent and addition of *n*-hexane resulted in the formation of the corresponding complexes **1** and **2** in good yield. These new complexes are stable in the solid state and in solution at room temperature and they were characterized by the usual spectroscopic techniques. The IR spectra of the free ligands exhibit the characteristic bands of the symmetrical and asymmetrical stretching of the imine group at 1617 and 1479 cm^{-1} for 2,4,6-Me_3G and 1633 and 1488 cm^{-1} for 2,4-Me_2D. The IR spectra of complexes exhibit the characteristic bands in the carbonyl stretching region as a sharp intense band at 2031 and 2023 cm^{-1} for complexes **1** and **2**, respectively, and two lower-energy bands closely spaced at 1936 and 1921 cm^{-1} for complex **1** and 1929 cm^{-1} for complex **2**, typical of Re(I) α-diimine tricarbonyl complexes [16,17]. The nature of the axial ligand in the [Re(CO)$_3$(NN)(X)] complexes influences, to some extent, the position and the shape of the absorption band in the IR spectra. The π-donor character of the oxygen atom in the trifluoroacetate group increases the Re → CO back-bonding, which decreases the energy of υ(CO) [18]. The NMR spectra and peak assignments of the ligands and their complexes are presented in Section 2. For complexes **1** and **2**, the signal due to the methyl groups in the *ortho* and *para* positions of the phenyl ring appears at about 2.24–2.38 and 2.07–2.40 ppm, respectively. The signal due to the iminic methyl in complex **2** appears at about 2.36 ppm. For complex **1**, the signal due to the iminic hydrogen appears at about 8.79 ppm. The signal due to the aromatic hydrogens appears at about 7.03 and 7.30 ppm for complex **1** and at about 6.72–7.25 ppm for complex **2**. All the signals due to the different hydrogens in the ^1H NMR spectra of complexes **1** and **2** are shifted to the low-field region with respect to the free ligands as a result of ligand coordination. The UV–Vis spectral data of the ligands and their complexes are presented in Table 2. The UV–Vis bands of the ligands are assigned to ligand-centered π → π* and n → π* transitions [11]. The absorption spectra of the complexes can be interpreted by comparison with other Re(I) complexes with ligands structurally related to those used in this work [19–21]. The higher energy bands observed in the spectra have been considered as intraligand π → π* transitions, and these are also present for the free ligands in the same spectral regions. The longer wavelength absorption bands show a maximum in the range 400–500 nm. These bands have been assigned partly to metal-to-ligand charge-transfer (MLCT)

Scheme 1.

Table 2
UV–Vis spectral data of the DAB ligands, and complexes **1** and **2**

Compound	Concentration (M)	Solvent	UV–Vis λ_{max} (nm) [ε] ($M^{-1}\,cm^{-1}$)
2,4,6Me_3G	9×10^{-5}	CH_2Cl_2	248 [12444], 370 [4445]
2,4Me_2D	1.5×10^{-3}	CH_2Cl_2	243 [11360], 345 [3973]
Complex **1**	7.5×10^{-5}	CH_2Cl_2	239 [13720], 480 [8773]
Complex **2**	7.5×10^{-5}	CH_2Cl_2	239 [14386], 430 [9573]

(a) Complex (**1**) and (b) Complex (**2**)

Fig. 1. Cyclic voltammograms of **1** (a) and **2** (b) in CH_2Cl_2 at 293 K (scan rate, 100 mV/s, $C = 2.5\times10^{-4}$ M).

transitions, mixed with a $\pi \rightarrow \pi^*$ transition of the Re(DAB) chelate. The electrochemical behaviour of complexes **1** and **2** was examined by means of cyclic voltammetry (CV) in CH_2Cl_2 (Fig. 1). Anodic scans reveal a single reversible oxidation at 1.44 and 1.66 V versus Ag/AgCl for the complexes **1** and **2**, respectively. This is assigned to the Re(II)/Re(I) redox couple, which is similar to the anodic peak potential reported for similar systems [22]. Complexes **1** and **2** show quasireversible redox couples with $E_{1/2}$ values of 1.36 and 1.59 V, respectively. The cyclic voltammetry peak-to-peak separations (ΔE_p) of 160 and 130 mV were observed at a scan rate (υ) of 100 mV^{-1} for complexes **1** and **2**, respectively.

*3.2. X-ray structure of [Re(CO)$_3$(2,4,6-Me$_3$G)(OCOCF$_3$)] (**1**)*

The molecular structure of **1** is shown in Fig. 2, selected bond lengths and angles are listed in Table 3. The Re atom has a distorted octahedral configuration and is coordinated by two carbonyl groups and the diimine group of the 2,4,6-Me_3G ligand in the equatorial plane. Octahedral coordination is completed at the axial positions by another carbonyl ligand and a carboxyl O atom of the trifluoroacetate anion. The equatorial Re–C distances are 1.909(6) and 1.923(5) Å, respectively. The equatorially disposed *N*,*N*′-bidentate chelating 2,4,6-Me_3G ligand forms a ReN_2C_2 five-membered chelate ring and the mean deviation of these atoms from the least-square plane is only 0.0274 Å. In this five-membered chelate ring the

Table 3
Selected bond distances (Å) and angles (°) for complex **1**

Complex **1**			
Re(1)–N(1)	2.186(4)	C(1)–Re(1)–O(4)	179.7(2)
Re(1)–N(2)	2.160(4)	C(2)–Re(1)–C(3)	88.3(2)
Re(1)–O(4)	2.153(3)	C(3)–Re(1)–N(1)	99.4(2)
Re(1)–C(1)	1.896(6)	N(1)–Re(1)–N(2)	74.1(2)
Re(1)–C(2)	1.909(6)	N(2)–Re(1)–C(2)	98.3(2)
Re(1)–C(3)	1.923(5)		

Table 4
Parameters of hydrogen bonding interactions in complex **1**

Complex **1**	D–H···A	H···A (Å)	D···A (Å)	D–H···A (°)
	C(151)–H(15B)···O(4)	2.44	3.308(8)	150
	C(6)–H(6)···O(5)^{i}	2.13	2.940(8)	145
	C(131)–H(13A)···F(1)^{ii}	2.48	3.399(10)	159

Symmetry codes: (i) $1+x, y, z$; (ii) $1-x, -1/2+y, 1/2-z$.

N(1)–Re(1)–N(2) bite angle is 74.1(2)° and Re–N (N1, N2) bond lengths are 2.186(4) and 2.160(4) Å, respectively. Owing to the steric requirements of the *N*,*N*′-bidentate chelating 2,4,6-Me_3G ligand the equatorial bond angles range from 74.1(2)° to 99.4(2)°. The axial C(1)–Re(1)–O(4) bond angle is 179.7(2)°. Due to the π-donor character of the trifluoroacetate ligand, the axial Re–C bond length of 1.896(6) Å is slightly shorter than the corresponding equatorial Re–C distances. The CF_3 group has high thermal motion consistent with some unresolved rotational disorder, as is often found in other trifluoroacetate compounds [9,23,24]. The overall structural similarity of **1** with the previously reported [Re(CO)$_3$(2,4-Me_2D)(OCOCF$_3$)] complex [9] reflects the strong tendency of substituted diazabutadiene ligands to enforce a distorted-octahedral geometry at Re. In addition, there are weak intra- and intermolecular C–H···O, as well as intermolecular C–H···F interactions (Table 4) in the crystal lattice of **1**.

4. Conclusion

The *fac*-[$Re(CO)_3$(DAB)($OCOCF_3$)] (DAB = 2,4,6-Me_3G, 2,4Me_2D) rhenium(I) complexes have been prepared and characterized by IR, UV–Vis, NMR, electrochemical and X-ray diffraction techniques. Variations in the electronic properties related to rhenium(I), the carbonyl and X ligands, such as electronic transitions, CO stretching and some crystallographic parameters of the complexes, were interpreted on the basis of the DAB and X ligands. It is clear from the data that, by varying the nature of the DAB ligands attached to rhenium, the electronic properties of the *fac*-[$Re(CO)_3$(DAB)($OCOCF_3$)] complexes could be tuned.

Abstract

The dimeric starting material [Ru(η^6-*p*-cymene)(μ-Cl)Cl]$_2$ reacts with the phosphino-amides *o*-Ph_2P–C_6H_4CO–NH–R [R = ^{i}Pr (**a**), Ph (**b**), 4-MeC_6H_4 (**c**), 4-FC_6H_4 (**d**)] to give the mononuclear compounds **1a**–**d** [RuCl(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–NH–R)]Cl. The subsequent reaction of these complexes with KPF_6 produced the cationic species **2a**–**d** [RuCl(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–NH–R)][PF_6] in which phosphino-amides also act as rigid *P*,*O*-chelating ligands. The molecular structures of **2b**–**d** were determined crystallographically. Amide deprotonation is achieved when complexes **2a**–**d** were made react with 1 M aqueous solution of KOH, affording the corresponding neutral species **3a**–**d** [RuCl(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–N–R)] in which a P,N-coordination mode is suggested.

1. Introduction

Hybrid ligands that contain distinct chemical functions [1–5], such as soft phosphine and hard (e.g., N or O) donor atoms, have attracted continuous interest during last years as a result of their versatile coordination behaviour [6,7] and its potential hemilability [3–5]. These properties have been exploited in several ways, as the ''weak-link approach'' for the synthesis of supramolecular structures [8] or the use of some ligands and its complexes in chemical sensing [9–11] and catalytic processes. It is in this last field that phosphine–amide ligands have received growing attention: the asymmetric 1,4-addition reaction of arylboronic acids with cycloalkenones is catalysed by an amidophosphine rhodium(I) complex [12], amide derived phosphines possessing various *N*,*N*-dialkyl aromatic amide scaffolds have shown to be highly effective in Suzuki cross-coupling reactions [13,14], and 2-diphenylphosphinobenzamido nickel complexes have found application in ethylene polymerization, showing that slight variations in the ligand frame produce drastic changes in the catalytic behaviour [15].

On the other hand, half-sandwich ruthenium(II) complexes bearing hemilabile ligands have been studied as efficient catalyst in hydrogen transfer reactions [16–21], and the hemilabile properties of several P,N- or P,O-donor ligands have been investigated synthesizing complexes in which these ligands adopt different coordination modes to the ruthenium atom [22–26]. No analogous studies concerning the phosphino-amides *o*-Ph_2P–C_6H_4–CO–NH–R have been reported and, as far as we are aware, the ligand 1,2-bis-N[2′-(diphenylphosphinobenzoyl)]diaminonaphthalene and its dimeric *p*-cymene ruthenium complex is the closest precedent described to date [26].

We have recently studied the coordination properties of these mixed-donor bidentate ligands in their first described palladium(II) complexes, containing cyclometallated [27] or pentafluorophenyl co-ligands [28]. As a extension of our work on *o*-Ph_2P–C_6H_4–CO–NH–R ligands in this paper we present the preparation and characterization of new neutral and cationic (η^6-*p*-cymene)–ruthenium(II) complexes.

2. Experimental

2.1. Methods and materials

C, H, and N analyses were carried out with a Carlo Erba instrument. IR spectra were recorded on a Perkin–Elmer spectrophotometer 16F PC FT-IR, using Nujol mulls between polyethylene sheets. NMR data (^1H, ^{31}P) were recorded on Bruker Avance 200 and 300 spectrometers. Mass spectrometric analyses were performed on a Fisons VG Autospec double-focusing spectrometer, operated in positive mode. Ions were produced by fast atom bombardment (FAB) with a beam of 25 keV Cs atoms. The mass spectrometer was operated with an accelerating voltage of 8 kV and a resolution of at least 1000. All the solvents were dried by conventional methods.

The diphenylphosphinobenzamides *o*-Ph_2P–C_6H_4–CO–NH–R (R = ^{i}Pr (**a**), Ph (**b**), 4-MeC_6H_4 (**c**), 4-FC_6H_4 (**d**)) were prepared by a reported procedure [28]. The starting dinuclear dichloro complex [Ru(η^6-*p*-cymene)(μ-Cl)Cl]$_2$ was prepared according to a published method [29].

2.2. Synthesis

2.2.1. Preparation of complexes [RuCl(η^6-p-cymene)-(o-Ph_2P–C_6H_4–CO–NH–R)]Cl (R = ^{i}Pr (**1a**); R = Ph (**1b**); R = 4-MeC_6H_4 (**1c**); R = 4-FC_6H_4 (**1d**))

The new complexes were obtained by treating [Ru(η^6-*p*-cymene)(μ-Cl)Cl]$_2$ with previously prepared 2-diphenylphosphine benzamides in molar ratio 1:2, using CH_2Cl_2 as solvent and according to the following general method. To a dichloromethane solution (15 mL) of the precursor (250 mg; 0.40 mmol) was added solid 2-diphenylphosphinebenzamide (0.80 mmol). The resulting solution was stirred for 60 min. at room temperature and then concentrated to half volume under reduced pressure. Addition of diethyl ether caused precipitation of the new complexes, which were filtered off, air dried and recrystallized from dicholoromethane–ether.

a Bruker Smart CCD diffractometer with a nominal crystal to detector distance of 6.2 cm. Diffraction data were collected based on a ω scan run. A total of 2524 frames were collected at 0.3° intervals and 10 s per frame. The diffraction frames were integrated using the SAINT package [30] and corrected for absorption with SADABS [31].

The structures were solved by direct methods [32] and refined by full-matrix least-squares techniques using anisotropic thermal parameters for non-H atoms [32] (Table 1). Hydrogen atoms were introduced in calculated positions and refined during the last stages of the refinement.

3. Results and discussion

In dichloromethane, the precursor [Ru(η^6-*p*-cymene)(μ-Cl)Cl]$_2$ reacts at room temperature with *o*-Ph_2P–C_6H_4–CO–NH–R: (R = ^{i}Pr (**a**); R = Ph (**b**); R = 4-MeC_6H_4 (**c**); R = 4-FC_6H_4 (**d**)) (see Section 2 for details) yielding the orange compounds of general formula [RuCl(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–NH–R)]Cl (R = ^{i}Pr (**1a**); R = Ph (**1b**); R = 4-MeC_6H_4 (**1c**); R = 4-FC_6H_4 (**1d**)) in which an κ^2-*P*,*O* coordination mode for diphenylphosphine–benzamide ligands is observed. The characterizing spectroscopic and analytical data are in agreement with the proposed structures presented in Scheme 1. The appearance of the *ν*(CO) absorptions lowered by approximately 30 cm^{-1} with respect to those of the free ligands gives a first support to the formation of a P^O chelate around the Ru centre [27,28]. A medium *ν*(NH) vibration, shifted towards higher wavenumbers than free ligands, is the other remarkable aspect found in the IR spectra. The FAB mass spectrometry displays fragments corresponding to ($M^+ - Cl$) and ($M^+ - 2Cl$). The presence of diphenylphosphine–benzamide ligands is also confirmed by $^{31}P\{^1H\}$ NMR spectroscopy, the spectra consisting of singlets around 33 ppm. This range of chemical shift is typical of a P^O coordination of these ligands to palladium [27] (P-monodentate around 40 ppm) and is coincidental with the one shown later for **2a–d** ruthenium complexes. Further evidence of the proposed coordination comes from the ^1H NMR spectroscopy. It has been reported that heterobidentate P^X chelates produce chiral metal centers when bound to arene–ruthenium complexes, and such chirality in *p*-cymene complexes produces diasterotopic methyls in the isopropyl fragment, which serve as detector of the chirality at the metal [17,33]. Also four different aromatic CH

Scheme 1. Preparation of phosphino-amide derivatives.

groups are usually seen when P^X chelates are present, whereas only two CH's and one isopropylic methyl resonance are observed if the ligand acts as P-monodentate. In our case, the ^{1}H NMR spectra of complexes **1a**–**d** display two doublets attributed to diasterotopic methyl groups in the isopropyl of *p*-cymene, as well as four CH aromatic resonances.

It is worth it to mention that no evidence of equilibrium between coordination isomers [RuCl(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–NH–R)]Cl and [$RuCl_2$(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–NH–R)] was observed. The strong chelating ability of diphenylphosphine–benzamide ligands towards ruthenium is emphasized by the fact that our attempts to open the chelate ring with pyridine or bipyridine produced mixtures of compounds in which the arene had been removed.

This result is in contrast to our previous studies on the behaviour of these ligands coordinating palladium(II) [27], since κ^1-*P* binding mode was adopted when chloride ion was in competition for a position around the metal center. Only forcing the chloride exit with a silver salt that provided an appropriate counteranion the chelating coordination was achieved. Regarding ruthenium(II) arene complexes with potentially N̂P or ÔP hemilabile ligands, most of the studies reported lately starting from [Ru(η^6-*p*-cymene)(μ-Cl)Cl]$_2$ show that direct reaction with this precursor yields neutral complexes where the ligand is κ^1*P*-coordinated to the metal [16–25]. Once again the subsequent treatment with halide abstractors such silver or sodium salts (mostly BF_4^-, BPh_4^-, $CF_3SO_3^-$, PF_6^- or SbF_6^-) preferably in polar solvents provided a route to the chelating cationic compounds. Strong dependence with the solvent has been reported in the preparation of complexes [Ru(η^6-arene)(κ^1-*P*-N*)Cl_2]/[Ru(η^6-arene)(κ^2-*P*-*N**)Cl]Cl [34]. Thus, neutral complexes were obtained in dichloromethane while same reactions in methanol afforded the corresponding chelate complexes, that also were prepared by adding small amounts of methanol to solutions of [Ru(η^6-arene)(κ^1-*P*-N*)Cl_2] in chloroform. A mixture of neutral and cationic complexes has been reported when the P^N ligand was 2-(diphenylphosphinomethyl)pyridine [35]. In complexes **1a**–**d** even working in dichloromethane the chelating mode of diphenylphosphine–benzamides is preferred. Such behaviour has been previously found for chiral ruthenium complexes of bidentate bisphosphine monoxide ligands [Ru(η^6-arene)(κ^1-Ph_2PC(R)P(O)Ph_2)Cl_2]/[Ru(η^6-arene)(κ^2-Ph_2PC(R)P(*O*)Ph_2)Cl]Cl [33], for which an equilibrium in dichloromethane between the κ^1-*P* complexes and their respective κ^2-*P*,*O* coordination isomers is reported. The steric bulk in the ligands backbones seems to drive the chelation, and cationic κ^2-complexes were obtained with bulkier ligands, the κ^1-*P* complex with the lighter and mixtures of two coordination isomers for middle sized. In this previous study, as happens for complexes **1a**–**d**, conversion of the chloride salts to those with another counteranion allowed the preparation of crystals suitable for X-ray diffraction.

The reaction in acetone of compounds **1a**–**d** with stoichiometric KPF_6 under the mild conditions described in the experimental section yielded complexes [RuCl(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–NH–R)][PF_6] (R = ^{i}Pr (**2a**); R = Ph (**2b**); R = 4-MeC_6H_4 (**2c**); R = 4-FC_6H_4 (**2d**)) (Scheme 1). The presence of a P,O-chelate is supported by the appearance of the *ν*(CO) vibration in the same range

mentioned above for complexes **1a**–**d**. Other features of IR spectra are a sharp NH absorption around 3355 cm^{-1} and a single band at ca. 845 cm^{-1} that indicates the presence of PF_6^- also detected by ^{19}F and ^{31}P NMR. The rest of NMR data confirm the proposed formulae and, as expected, are quite similar to those of precursor complexes in chemical shift, number and multiplicity of signals and therefore have not been included in experimental section. Thus, again the asymmetry of the MLL′L″ three-legged fragment and consequent chirality at Ru centre raised diasterotopic isopropylic methyl groups and differentiated aromatic CH resonances.

As mentioned above, changing chloride by PF_6^- made possible to grow X-ray quality crystals that after diffraction study have confirmed the structures of **2b**–**d**. Each of them consisted of a cationic complex [RuCl(η^6-*p*-cymene)-(*o*-Ph_2P–C_6H_4–CO–NH–R)]$^+$ (Figs. 1–3, respectively) and an anion $[PF_6]^-$. While **2c** crystallizes with 1/2 molecule of dichoromethane, **2b** and **2d** also contain some unrefined solvent that causes high values of maximum $\Delta\rho$. As can be inferred from data in Table 1 the three complexes are isomorphous. Selected bond lengths and angles listed in Table 2 are very similar. Moreover, molecular conformation in the three compounds are similar, the phenyl ring bonded to the iminic group is oriented towards the isopropyl group from the η^6-arene, with distances from the centroid to the (Me)$_2$C–*H* hydrogen atom of 3.081, 2.948 and 3.010 Å for complexes **2b**, **2c**, and **2d**, respectively. The molecules displayed a pseudooctahedral three-legged piano-stool geometry around the ruthenium atom with the arene, the corresponding diphenylphosphine–benzamide ligand and the chloride completing the coordination. The distortion of the octahedral geometry is shown by the values of the O(1)–Ru(1)–P(1), O(1)–Ru(1)–Cl(1), and P(1)–Ru(1)–Cl(1) angles, in the range 82.49(8)–88.02(5)° (see Table 2).

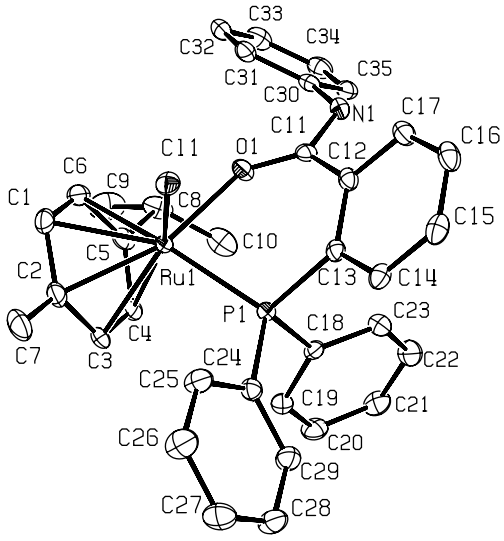

Fig. 1. ORTEP diagram of cation complex **2b** with the atom numbering scheme; thermal ellipsoids are drawn at the 50% probability level.

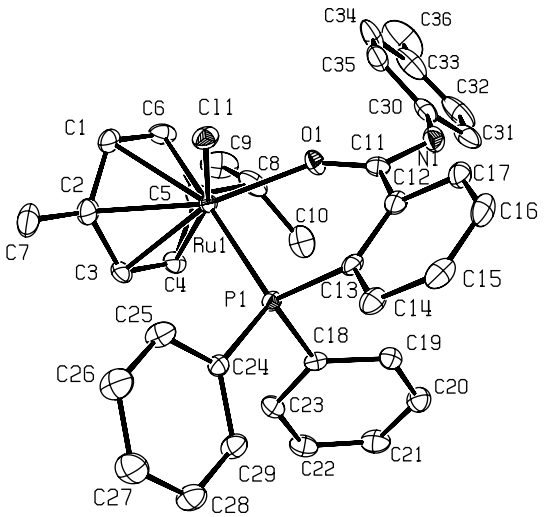

Fig. 2. ORTEP diagram of cation complex **2c**; thermal ellipsoids are drawn at the 50% probability level.

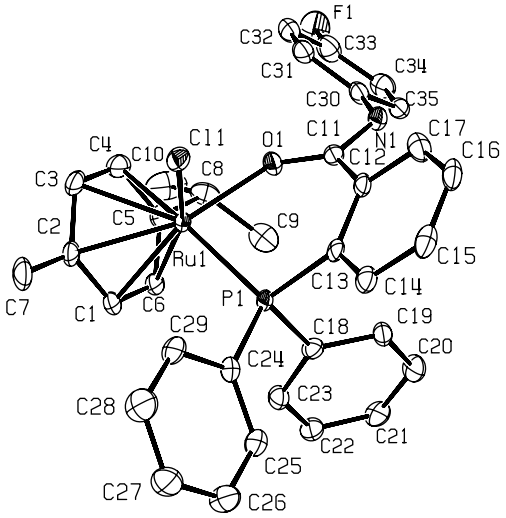

Fig. 3. ORTEP diagram of cation complex **2d**. Thermal ellipsoids are drawn at 50% probability.

The angles between the centroid of the arene ring, Ru, O, P, and Cl atoms are in the 125–133° range. The Ru–Cl bond distances fall within the range of reported values [16,24]. The average Ru–C bond distance is around 2.209 Å, whereas the distance between the ruthenium atom and the centroid of the ring is 1.693 Å for the three compounds. As has been previously reported [17 and references therein] a heterogeneous distribution of the Ru–C(*p*-cymene) bond distances was observed in the sense that distances *trans* to the more strongly donating phosphine group are longer that those *trans* to the chlorine atoms.

The diphenylphosphine–benzamide ligands are κ^2-*P*,*O* bonded to ruthenium forming a six-membered metallacycle that in the three compounds display a 10° distorted *screw–boat* conformation, according to the classification of Allen and Taylor [36].

Table 2
Selected distances (Å) and angles (°) of the new complexes

	2b	2c	2d
Ru(1)–O(1)	2.114(3)	2.114(2)	2.109(4)
Ru(1)–P(1)	2.3191(10)	2.3167(8)	2.3194(15)
Ru(1)–Cl(1)	2.3930(9)	2.3926(8)	2.3936(15)
Ru(1)–C(1)	2.237(4)	2.235(3)	2.166(6)

Ru(1)–$C_{(average)}$	2.209	2.208	2.209
Ru(1)–$Cent_{(p-cimeno)}$	1.693	1.693	1.693
O(1)–C(11)	1.256(5)	1.250(4)	1.258(7)
O(1)–Ru(1)–P(1)	82.49(8)	82.56(7)	82.73(12)
O(1)–Ru(1)–Cl(1)	87.09(8)	87.41(7)	86.96(12)
P(1)–Ru(1)–Cl(1)	87.85(3)	87.75(3)	88.02(5)
O(1)–Ru(1)–Centr	125.73	125.30	125.62
P(1)–Ru(1)–Centr	132.29	132.34	132.04
Cl(1)–Ru(1)–Centr	126.32	126.49	126.46

The most significant difference between the solid state conformation of the free ligand **b** and the coordinated ligand in **2b** is the angle between planes O(1)–C(11)–C(12) and C(12)–C(13)–P(1) (53.11(13)° and 30.9(4)°, respectively). Similar values are found for complexes **2c** 30.6(3)° and **2d** 30.0(6)°. This value also diminishes slightly once the ligand is complexed to Ni or Pd: 38.4(2)°, 33.3(2)° and 41.3(2)° [28]. The relative position of the phenyl rings bonded to the N–CO-moiety stays without major variation upon coordination. In the free ligand both rings are nearly perpendicular (81.7°) and so happens in **2b** (79.8°), **2c** (81.8°) and **2d** (81.3°) while in the reported Ni complex the phenyl bonded to N rotated, becoming both rings parallels (10.2°) [28].

The new complexes exhibit intermolecular hydrogen bonding between F from PF_6^- and N(1) atoms (distance N(1)···F ranges 2.912–2.916 Å and angle N(1)–H···F ranges 152.37–155.01°).

In order to induce amide deprotonation in the ligands, and a likely κ^2-*P*,*N* coordination mode according to our previous studies with other metals, compounds **2a**–**d** were treated with KOH(aq) in acetone, as explained in the experimental section, to yield neutral complexes [RuCl(η^6-*p*-cymene)(*o*-Ph_2P–C_6H_4–CO–N–R)] (R = ^{i}Pr (**3a**); R = Ph (**3b**); R = 4-MeC_6H_4 (**3c**); R = 4-FC_6H_4 (**3d**)) (Scheme 1). The loss of both *ν*(NH) and *ν*(PF) bands in their IR spectra with regards to precursor compounds confirmed that the proposed reactions took place. The characterization in solid state was completed with the FAB mass spectrometry, that shows fragments at [M^+] and [$M^+ - Cl$]. A singlet shifted at ca. 7 ppm highfield compared to P^O-chelated compounds characterizes the $^{31}P\{^1H\}$ NMR spectra, and the expected pattern is observed in the ^1H NMR with significant absence of amidic proton resonance at low field. The solutions of new complexes turned black after 48 h thus preventing the obtention of crystals suitable for a diffraction analysis and a conclusive assertion about the coordination mode. Absence of arene was observed in the subsequent decomposition products.

4. Conclusion

Twelve new (η^6-*p*-cymene)–ruthenium(II) complexes with diphenylphosphine–benzamide ligands exhibiting different coordination modes have been prepared and characterized by spectroscopic techniques and single crystal X-ray diffraction analysis. Stronger κ^2-*P*,*O* chelating ability towards ruthenium can be attributed to these ligands in comparison with our previous results dealing with nickel and palladium. Also if compared with other potentially hemilabile P,O- or P,N-ligands in its reaction with the precursor [Ru(η^6-*p*-cymene)(μ-Cl)Cl]$_2$, that usually yields P- monodentate compounds.

The authors would like to add the following two sentences to their article at the end of the second paragraph (starting with: "The results...") on page 2752.

The conclusion that the good linear correlations obtained for the whole series of Ln(III) ions with some pairs of nuclei may be misleading, is strengthened by the fact that Eq. (6) is valid only for axial systems (we thank Prof. Claude Piguet for drawing our attention to the problem of applicability of Eq. (6) to non-axial systems), while in the present case considerable rhombic contribution is observed (vide infra). The analysis based on the crystal-field independent three-nuclei method developed by Prof. Claude Piguet's group for rhombic systems, confirms the conclusions above regarding the isostructurality of the discussed complexes. (See Supplementary material for details.)

Abstract

The reaction between 1,2-bis[3-(3,5-dimethyl-1-pyrazolyl)-2-thiapropyl]benzene (**bddf**) and $[MCl_2(CH_3CN)_2]$ (M = Pd(II), Pt(II)) in a 1:1 M/L ratio in CH_2Cl_2 or acetonitrile solution, respectively, gave the complexes *trans*-$[MCl_2(bddf)]$ (M = Pd(II) (**1**), Pt(II) (**4**)), and in a 2:1 M/L ratio led to $[M_2Cl_4(bddf)]$ (M = Pd(II) (**2**), Pt(II) (**5**)). Treatment of **1** and **4** with $AgBF_4$ and $NaBPh_4$, respectively, gave the compounds $[Pd(bddf)](BF_4)_2$ (**3**) and $[Pt(bddf)](BPh_4)_2$ (**6**). When complexes **3** and **6** were heated under reflux in a solution of Et_4NBr in CH_2Cl_2/CH_3OH (1:1) for 24 h, analogous complexes to **1** and **4** with bromides instead of chlorides bonded to the metallic centre were obtained. These complexes were characterised by elemental analyses, conductivity measurements, infrared, ^1H, $^1H\{^{195}Pt\}$, $^{13}C\{^1H\}$, $^{195}Pt\{^1H\}$ NMR, HSQC and NOESY spectroscopies. The X-ray crystal structure of the complex $[Pd(bddf)](BF_4)_2 \cdot H_2O$ has been determined. The metal atom is tetracoordinated by the two azine nitrogen atoms of the pyrazole rings and two thioether groups.

1. Introduction

Ligands that contain significantly different chemical functions, such as hard and soft donors (hybrid ligands) find increasing use in chemistry because of the selectivity introduced in the metal–ligand interactions and their possible dynamic behaviour [1]. Pyrazole containing molecules are attractive potential hybrid ligands since they are relatively easy to prepare. Moreover, their steric and electronic properties can be tuned in a straightforward manner [2].

The use of flexible ligands to form supramolecular arrays has been circumspect, due to the less predictable nature of such systems. Taking into account the choice of organic ligands, researchers have shown thioether ligands containing a flexible backbone to be among the most important types of organic ligands, because their flexibility and conformational freedom allow for greater structural diversity. Thioether ligands bearing S- and N-coordinating sites may incline to coordinate metals with different modes, forming a great variety of molecular structures. The use of thioether–pyridine moieties in the preparation of new extended-reach ligands has been investigated for the construction of metallosupramolecular arrays [3].

We have focused our interests on the synthesis and characterisation of pyrazolic ligands with two donor groups, among others S- and N-, (1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane (bddo), 1,9-bis(3,5-dimethyl-1-pyrazolyl)-3,7-dithianonane (bddn), 1,6-bis(3,5-dimethyl-1-pyrazolyl)-2,5-dithiahexane (bddh), 1,7-bis(3,5-dimethyl-1-pyrazolyl)-

2,6-dithiaheptane (bddhp) and 1,5-bis(3,5-dimethyl-1-pyrazolyl)-3,7-thiapentane (bdtp)), and the study of their reactivity with Pd(II) [4], Pt(II) [4] and Rh(I) [5].

We have recently reported the synthesis and coordinating properties of a new mixed pyrazole-thioether ligand, incorporating benzene in the thioether chain sub-unit, with Rh(I) [5]. In particular, the tetradentate ligand 1,2-bis[3-(3,5-dimethyl-1-pyrazolyl)-2-thiapropyl]benzene (**bddf**) has chelating properties strictly dependent on the conformational constraints imposed by the benzene unit on the S-donor thioether linker of the ring [5]. We report herein the results of our investigation on its coordination to platinum group metals, in particular Pd(II) and Pt(II).

2. Results and discussion

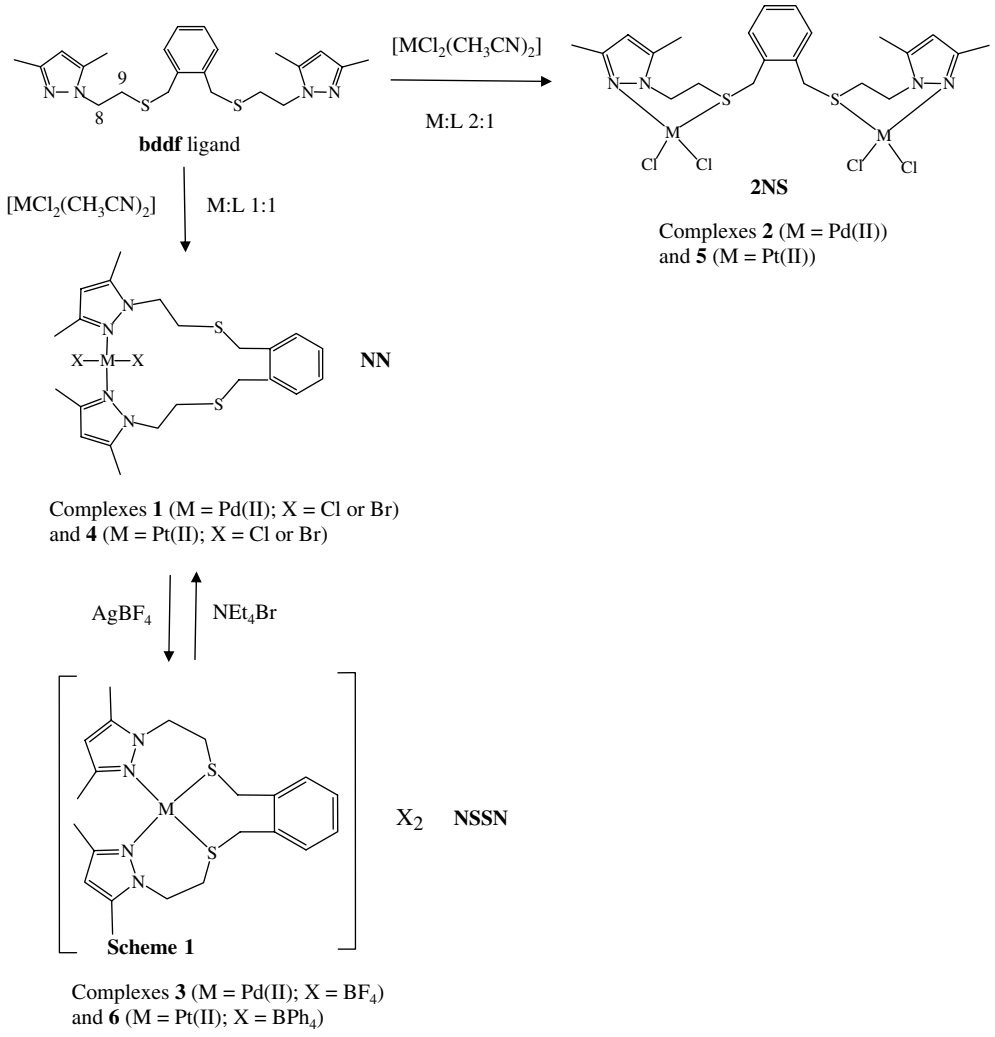
2.1. Synthesis and spectroscopic properties

Reaction of 1,2-bis[3-(3,5-dimethyl-1-pyrazolyl)-2-thiapropyl]benzene (**bddf**) with $[PdCl_2(CH_3CN)_2]$ in a 1:1 M/L ratio in CH_2Cl_2 solution led to $[PdCl_2(bddf)]$ (**1**). The complex $[Pd_2Cl_4(bddf)]$ (**2**) was obtained by the use of a 2:1 M/L ratio in CH_2Cl_2 solution. Treatment of **1** with $AgBF_4$ in CH_2Cl_2/CH_3OH (1:1) solution, gave compound $[Pd(bddf)](BF_4)_2$ (**3**).

Reaction of **bddf** with $[PtCl_2(CH_3CN)_2]$ in a 1:1 M/L ratio in acetonitrile solution led to $[PtCl_2(bddf)]$ (**4**). The complex $[Pt_2Cl_4(bddf)]$ (**5**) was obtained by the use of a 2:1 M/L ratio in acetonitrile solution. Treatment of **4** with $NaBPh_4$ in acetonitrile/CH_3OH (1:1) solution, gave compound $[Pt(bddf)](BPh_4)_2$ (**6**). When complexes **3** and **6** were heated under reflux in the presence of Et_4NBr in CH_2Cl_2/CH_3OH (1:1) for 24 h, analogous complexes to **1** and **4** with bromides instead of chlorides bonded to the metallic centre were obtained. This behaviour indicates that this ligand is hemilabile towards Pd(II) and Pt(II) [1a,1b].

Compounds **1**–**6** were characterised by elemental analyses, conductivity measurements, IR, ^1H, $^{13}C\{^1H\}$ NMR spectroscopies, and for compounds **4**–**6** $^1H\{^{195}Pt\}$ and $^{195}Pt\{^1H\}$ NMR spectroscopy, and mass spectrometry. All six compounds gave satisfactory C, H, N and S elemental analyses.

Conductivity data in acetonitrile are in agreement with a non-electrolytic nature for compounds **1**, **2**, **4** and **5** (9–37 Ω^{-1} cm^2 mol^{-1}), and 2:1 electrolytes for compounds **3** and **6** (280 Ω^{-1} cm^2 mol^{-1} and 250 Ω^{-1} cm^2 mol^{-1}, respectively). The reported values for 10^{-3} M solutions of non-electrolytic compounds are lower than 120 Ω^{-1} cm^2 mol^{-1} and between 220 and 300 Ω^{-1} cm^2 mol^{-1} for 10^{-3} M solutions of 2:1 electrolytic compounds in acetonitrile [6].



The positive ionisation spectrum of **1** gave a peak with a *m*/*z* value of 557 (100%; $[PdCl(bddf)]^+$). For **2**, three peaks at 793 (40%; $[Pd_2Cl_4(bddf)+Na]^+$), 735 (48%; $[Pd_2Cl_3(bddf)]^+$) and 557 (100%; $[PdCl(bddf)]^+$) are obtained. For **3**, a peak at 557 (100%; $[PdCl(bddf)]^+$) is obtained. The mass spectrum of **4** gives a peak at 645 (100%; $[PtCl(bddf)]^+$) and for **5**, a peak at 969 (100%; $[Pt_2Cl_4(bddf)+Na]^+$) is observed. Finally, the mass spectrum of compound **6** displays a peak at 645 (100%; $[PtCl(bddf)]^+$). The molecular peaks of the cations are observed with the same isotopic distribution as the theoretical ones.

The IR spectra of complexes **1**–**6** in the range 4000–400 cm^{-1} show that the **bddf** ligand is coordinated to Pd(II) or Pt(II). The ν(C=C), ν(C=N) and $\delta(C–H)_{oop}$ bands of the pyrazolic ligands increase their frequency when they are part of the complexes [5,7]. The IR spectrum of complex **3** presents a band that was assigned to ν(B–F) at 1054 cm^{-1}, and the IR spectrum of complex **6** presents a band that was assigned to ν(B–C) at 612 cm^{-1} [7]. The IR spectra of complexes **1**–**6** in the region 600–100 cm^{-1} were also studied. The presence of bands between 489 and 454 cm^{-1} assigned to ν(M–N) (M = Pd(II), Pt(II)) confirms the coordination of N_{pz} of the ligand to the metallic atom. The complexes **1** and **4** display one ν(M–Cl) band at 337 cm^{-1} (**1**) and 319 cm^{-1} (**4**). These bands indicate that the chlorine atoms are coordinated to Pd(II) or Pt(II) in a *trans* disposition. Complexes **2** and **5** display two well-defined ν(M–Cl) (M = Pd(II), Pt(II)) bands at 342, 323 cm^{-1} (**2**) and 319, 310 cm^{-1} (**5**). These bands clearly indicate that the chlorine atoms are coordinated to Pd(II) or Pt(II) in a *cis* disposition [8]. For complexes **2** and **3** the band ν(Pd–S) appears at 358 cm^{-1} (**2**) and 353 cm^{-1} (**3**), and for complexes **5** and **6** at 371 cm^{-1} (**5**) and 374 cm^{-1} (**6**). These bands confirm the coordination of the S atoms of the ligand to the metallic centre [8].

The ^1H NMR, $^{13}C\{^1H\}$NMR, HSQC, COSY and NOESY spectra were recorded in $CDCl_3$ for **1** and **4**, and acetonitrile for **2**, **3**, **5** and **6**, and show the signals of the ligand **bddf**. It is remarkable to note that Pt(II) complexes are less soluble than Pd(II) ones. NMR spectroscopic data are shown in Section 4. No significant differences between $^{13}C\{^1H\}$ NMR spectra of the free and coordinated ligands were observed. HSQC spectra of **1**–**3** were used to assign 8-H, 9-H and 10-H (Scheme 1). Coupling constants for complexes **2**, **3**, **5** and **6** could not be obtained due to the broadness of the bands. The ^1H NMR spectra of complexes **2**–**6** at 298 K show only sharp resonances for the CH and CH_3 groups of the pyrazolyl cycles.

For compound **1**, at room temperature, the methylene protons of the SCH_2ph chain appear as a singlet ($\delta = 4.10$ ppm) and the methylene protons of the $N_{pz}CH_2CH_2S$ chain appear as two triplets ($\delta = 3.50$ ppm, 4.95 ppm, $^3J = 8.2$ Hz). This behaviour is similar to that found for the free ligand.

The ^1H NMR spectrum of complex **4** shows broad bands at 4.98 and 3.50 ppm, attributable to methylene protons of the $N_{pz}CH_2CH_2S$ chain. The presence of broad bands is due to the coupling between Pt(II) and the hydrogens of the ethylenic chains. To corroborate this, we have registered the $^1H\{^{195}Pt\}$ NMR spectrum of **4** and we can observe that the methylene protons of the $N_{pz}CH_2CH_2S$ appear as two triplets ($\delta = 3.44$ ppm, 4.92 ppm, $^3J = 8.0$ Hz).

Scheme 1.

The room temperature ^{1}H NMR spectra of complexes **2** and **5** are little informative since, except for the sharp resonances of the pyrazolyl cycles, only broad resonances are observed. Lowering of the temperature to 233 K did not improve the shape of the signals.

For compound **3**, at 298 K the methylene protons of the $N_{pz}CH_2CH_2S$ chain appear as four poorly defined broad bands and the methylene protons of the SCH_2ph chain appear as two poorly defined broad bands. This led us to record variable-temperature ^{1}H NMR spectra in acetonitrile. At the higher temperature (333 K), only one signal can be observed for each CH_2 of the $N_{pz}CH_2CH_2S$ and SCH_2ph chains, whereas lowering of the temperature (233 K) provokes that the two NCH_2CH_2S and the two SCH_2ph chains become non-equivalents. Moreover, we observed the splitting of each CH_2 of each chain into two signals (four signals for each NCH_2CH_2S chain and two signals for each SCH_2ph chain). This suggests that at 333 K there is a fluxional process in which, with ring-flipping, the two hydrogens of each CH_2 are interconverted and only one signal can be observed (at this temperature both NCH_2CH_2S and both SCH_2ph chains are also equivalent). This process would take place with a $\Delta G^{\ddagger}$ value of ca. 57 kJ mol^{-1}, as deduced from the coalescence behaviour of the methylene resonances ($T_c = 273$ K) [9]. This behaviour is also observed in acetone solution ($T_c = 273$ K, $\Delta G^{\ddagger} = 58$ kJ mol^{-1}). These energy values could also be consistent with a mechanism that implies an inversion of the sulfur atom configuration [10] (Fig. 1).

Additional ^{195}Pt{^{1}H} NMR experiments for complexes **4**–**6** at 298 K revealed only one band for each complex ($\delta = -2247$ ppm for **4**, -2857 ppm for **5**, and -3884 ppm for **6**), confirming the presence of a single complex in solution and illustrating how the platinum chemical shifts are sensitive to the average ligand environment. The chemical shifts for a PtN_2Cl_2 core are expected between -1998 and -2279 ppm [11], a $PtNSCl_2$ core between -2868 and -3083 ppm [4b,12], and a PtN_2S_2 core between -3261 and -3884 ppm [4a,12c,13].

2.2. Crystal structure of $[Pd(bddf)](BF_4)_2 \cdot H_2O$ (**3**)

The structure of **3** (Fig. 2) consists of cationic units of $[Pd(bddf)]^{2+}$, BF_4^- anions and solvent molecules (H_2O).

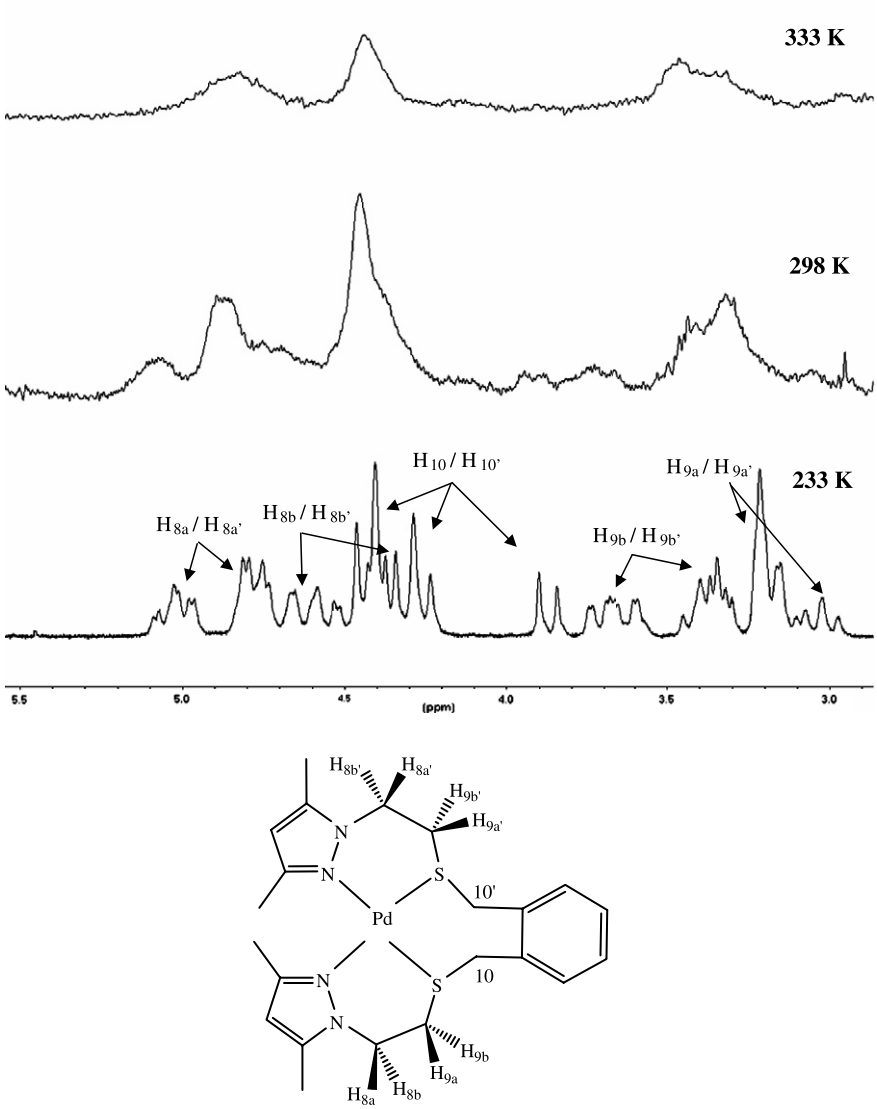


Fig. 1. ^{1}H NMR spectra (250 MHz) of complex **3** in acetonitrile at variable temperatures (233–333 K).

The BF_4^- anions are disordered. Two nitrogen atoms of the pyrazolyl groups and two thioether groups coordinate the palladium atom in a slightly distorted square-planar geometry. The pyrazolyl groups are *cis* to each other. The tetrahedral distortion of the square-planar geometry can be observed in the mean separation of the atoms linked to Pd from the mean plane, which is 0.014(14) Å. The dihedral angle between the two planes N1–Pd–N3 and S1–Pd–S2 is 25.28(8)°. Some selected bond lengths and bond angles for this complex are listed in Table 1.

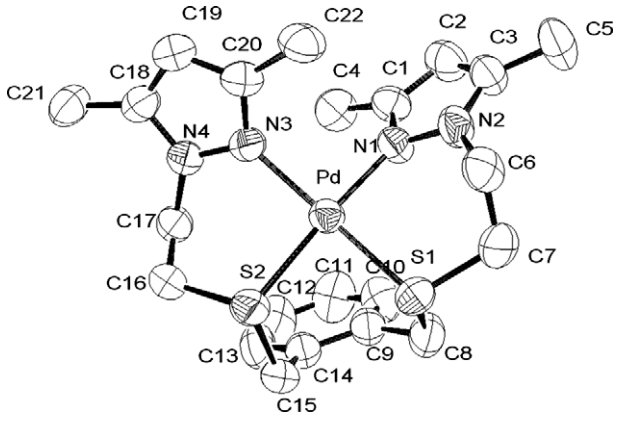

Fig. 2. ORTEP drawing of the cationic $[Pd(bddf)]^{2+}$ part of **3**, showing all non-hydrogen atoms and the atom numbering scheme; 50% probability amplitude displacement ellipsoids are shown.

The PdN_2S_2 core (N aromatic and S thioether) is found in 10 complexes in the literature [4d,4f,14]. The Pd–N (2.026(2) Å, 2.043(2) Å) and Pd–S (2.2803(10) Å, 2.3071(10) Å) distances are of the same order as those found in the literature for this kind of complex. The Pd–N_{pz} bond lengths are 1.990–2.086 Å [4d–f,14], and the Pd–S bond lengths are 2.257–2.897 Å [4d–f,14].

The **bddf** ligand acts as tetradentate chelate and forms two PdNNCCS six-membered rings and one PdSCCCCS seven-membered ring. The Pd–S2–C16–C17–N4–N3 six-membered ring has a boat conformation and the Pd–S1–C7–C6–N2–N1 six-membered ring has a twist-boat conformation. Bite angles are 91.55(8)° and 92.54(8)° for

Table 1
Selected bond lengths (Å) and bond angles (°) for $[Pd(bddf)](BF_4)_2 \cdot H_2O$ (**3**)

Pd–N(1)	2.026(2)	Pd–S(1)	2.2803(10)
Pd–N(3)	2.043(2)	Pt(1)–S(2)	2.3071(10)
N(1)–Pd–N(3)	90.92(11)	N(1)–Pd–S(1)	91.55 (8)
S(1)–Pd–S(2)	85.71(4)	N(3)–Pd–S(1)	172.52(8)
N(3)–Pd–S(2)	92.54(8)	N(1)–Pd–S(2)	173.50 (8)

N(1)–Pd–S(1) and N(3)–Pd–S(2), respectively. These bite angles are higher than those reported for $[Pd(bddo)](BF_4)_2 \cdot H_2O$, 88.2(2)° and 86.1(1)° (bddo = 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane) [4f], and $[Pd(bddn)](BF_4)_2$, 86.81(12)° and 85.81(11)° (bddn = 1,9-bis(3,5-dimethyl-1-pyrazolyl)-3,7-dithianonane) [4d]. The S(1)–Pd–S(2) bite angle is 85.71(4)° and it is of the same order as that reported for $[PdCl_2L]$ 85.231° (L = 4-benzyloxy-2-(2′-pyridyl) phenoxydiphenylphosphinite) [15] and smaller than the bite angle found for the complex $[PdCl_2L']$ 90.03(9)° (L′ = 2-(3,5-dimethyl-1*H*-pyrazole-1-yl)ethyldiphenylphosphinite) [16].

3. Conclusion

The results presented here reveal that the ligand 1,2-bis[3-(3,5-dimethyl-1-pyrazolyl)-2-thiapropyl]benzene (**bddf**) shows similar behaviour towards Pd(II) and Pt(II). We have obtained complexes with the formula $[MCl_2(bddf)]$, $[M_2Cl_4(bddf)]$ and $[M(bddf)]X$ (M = Pd(II), X = BF_4; Pt(II), X = BPh_4). In complexes **1**–**6**, this ligand shows didentate coordination (*NN*) (**1**, **4**), or tetradentate coordination (*2NS*) (**2**, **5**) or (*NSSN*) (**3**, **6**). The reactivity of the ligand **bddf** with Pd(II) shows the same behaviour as the ligands bddo, and bddn, whereas the reactivity of the ligand **bddf** with Pt(II) is different, as mixtures of isomers were obtained with the aforementioned ligands and Pt(II). The presence of the benzene unit on the S-donor thioether chain produces pure products. Furthermore, we have demonstrated the hemilabile properties of this ligand when coordinated to Pd(II) and Pt(II).

4. Experimental

4.1. General details

The reactions were carried out under nitrogen atmosphere using vacuum line and Schlenk techniques. Solvents were dried and distilled according to standard procedures and stored under nitrogen. Elemental analyses (C, H, N, S) were carried out by the staff of the Chemical Analyses Service of the Universitat Autònoma de Barcelona on a Carlo Erba CHNS EA-1108 instrument. Conductivity measurements were performed at room temperature in 10^{-3} M acetonitrile solutions, employing a CyberScan CON 500 (Euthech instrument) conductimeter. Infrared spectra were run on a Perkin–Elmer FT spectrophotometer, series 2000 cm^{-1} as KBr pellets or polyethylene films in the range 4000–100 cm^{-1}. ^1H NMR, $^{13}C\{^1H\}$ NMR, HSQC, COSY and NOESY spectra were recorded on NMR-FT Bruker AC-250 MHz and DPX-360 Bruker spectrometers in $CDCl_3$ and acetonitrile solution at variable temperature. $^{195}Pt\{^1H\}$ NMR spectra were recorded at 298 °C and 77.42 MHz on a DPX-360 Bruker spectrometer in acetonitrile using aqueous solutions of $[PtCl_6]^{2-}$ (0 ppm) as an external reference and a delay time of 0.01 s. All chemical shifts values (δ) are given in ppm. Mass spectra were obtained with an Esquire 3000 ion-trap mass spectrometer from Bruker Daltonics. Samples of $[MCl_2(CH_3CN)_2]$ (M = Pd(II) [17], Pt(II) [18]) were prepared as described in the literature. 1,2-Bis[3-(3,5-dimethyl-1-pyrazolyl)-2-thiapropyl]benzene (**bddf**) was prepared according to the published methods [5] (Scheme 1).

4.2. Synthesis of the complexes

4.2.1. Synthesis of the complex [$PdCl_2$(bddf)] (*1*)

0.20 mmol (0.083 g) of the ligand **bddf**, dissolved in 15 ml of dry CH_2Cl_2, were added to a solution of 0.20 mmol (0.052 g) of $[PdCl_2(CH_3CN)_2]$ in 15 ml of dry CH_2Cl_2. The solution was stirred at room temperature for 12 h. When the volume of the resultant solution had been reduced to roughly 5 ml, diethyl ether (5 ml) was added to induce precipitation. The resulting precipitate was filtered and washed with 5 ml of diethyl ether, and dried in vacuum.

Yield: 0.085 g (75%). *Anal*. Calc. for $C_{22}H_{30}Cl_2N_4PdS_2$: C, 44.64; H, 5.11; N, 9.46; S, 10.83. Found: C, 44.19; H, 5.06; N, 9.19; S, 10.75%. MS(ESI): *m*/*z* (%) = 557 (100) $[PdCl(bddf)]^+$. Conductivity (Ω^{-1} cm^2 mol^{-1}, 1.13×10^{-3} M in acetonitrile): 16. IR (KBr, cm^{-1}): 3115 ν(C–H)$_{ar}$, 2978, 2924 ν(C–H)$_{al}$, 1554 (ν(C=C), ν(C=N))$_{ar}$, 1467, 1421 (δ(C=C), δ(C=N))$_{ar}$, 1040, 1014 δ(C–H)$_{ip}$, 758 δ(C–H)$_{oop}$. (Polyethylene, cm^{-1}): 459 ν(Pd–N), 337 ν(Pd–Cl). ^1H NMR ($CDCl_3$ solution, 250 Hz, 298 K) δ: 7.36 [4H, m, ph], 5.94 [2H, s, C*H*(pz)], 4.95 [4H, t, ^3J = 8.2 Hz, $N_{pz}CH_2CH_2S$], 4.10 [4H, s, SCH_2ph], 3.50 [4H, t, ^3J = 8.2 Hz, $N_{pz}CH_2CH_2S$], 2.92 [6H, s, CH_3(pz)], 2.31 [6H, s, CH_3(pz)] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$ solution, 63 MHz, 298 K) δ: 150.3 (pz-*C*), 142.7 (pz-*C*), 135.7–127.6 (ph-*C*), 107.7 (*C*H(pz)), 49.2 ($N_{pz}CH_2CH_2S$), 33.9 (SCH_2ph), 31.6 ($N_{pz}CH_2CH_2S$), 14.8 (CH_3(pz)), 11.7 (CH_3(pz)) ppm.

4.2.2. Synthesis of the complex [Pd_2Cl_4(bddf)] (*2*)

0.20 mmol (0.083 g) of the ligand **bddf** dissolved in 15 ml of dry CH_2Cl_2 were added to a solution of 0.40 mmol (0.104 g) of $[PdCl_2(CH_3CN)_2]$ in 15 ml of dry CH_2Cl_2. The solution was stirred at room temperature for 12 h. When the volume of the resultant solution had been reduced to roughly 5 ml, diethyl ether (5 ml) was added to induce precipitation. The resulting precipitate was then filtered and washed with 5 ml of diethyl ether, and dried in vacuum.

4.2.3. Synthesis of the complex [Pd(bddf)](BF$_4$)$_2\cdot H_2O$ (3)

A solution of 0.25 mmol (0.050 g) of $AgBF_4$ in 10 ml of CH_2Cl_2/CH_3OH (1:1) was added with vigorous stirring to a solution of $[PdCl_2(bddf)]$ (0.12 mmol, 0.080 g) in 10 ml of CH_2Cl_2/CH_3OH (1:1). The reaction was carried out in the dark to prevent reduction of Ag(I) to Ag(0). After 5 min, stirring was stopped and AgCl was filtered off. When the volume of the resultant solution had been reduced to roughly 5 ml, diethyl ether (5 ml) was added to induce precipitation. The resulting precipitate was then filtered and washed with 5 ml diethyl ether.

4.2.4. Synthesis of the complex [PtCl$_2$(bddf)] (4)

0.20 mmol (0.083 g) of the ligand **bddf** dissolved in 15 ml of dry acetonitrile were added to a solution of 0.20 mmol (0.070 g) of $[PtCl_2(CH_3CN)_2]$ dissolved in 15 ml of dry acetonitrile. The mixture was refluxed for 24 h. The solvent was evaporated to dryness yielding a yellow solid. The resulting solid was washed with 10 ml of CH_2Cl_2/diethyl ether (1:1) and dried in vacuum. The product was recrystallised with a dichloromethane/*n*-pentane (1:1) mixture, and yellow crystals were obtained.

Yield: 0.058 g (50%). *Anal*. Calc. for $C_{22}H_{30}Cl_2N_4PtS_2$: C, 38.82; H, 4.44; N, 8.23; S, 9.42. Found: C, 38.53; H, 4.58; N, 8.46; S, 9.65%. MS(ESI): m/z (%) = 645 (100) $[PtCl(bddf)]^+$. (Polyethylene, cm^{-1}): 464 ν(Pt–N), 374 ν(Pt–S). $^1H\{^{195}Pt\}$ NMR (acetonitrile solution, 360 Hz, 298 K) δ: 7.76, 7.64 [1H/1H, d, ^3J = 7.2 Hz, ph(L)], 7.46, 7.36 [1H/1H, t, ^3J = 7.2 Hz, ph(L)], 7.31–6.78 [40H, br, ph(BPh$_4$)], 6.07 [1H, s, C*H*(pz)], 4.63 [7H, br, $N_{pz}CH_2CH_2S$, SCH_2ph], 3.86 [1H, d, ^2J = 14.0 Hz, SCH_2ph], 3.57 [1H, br, $N_{pz}CH_2CH_2S$], 3.32 [1H, br, $N_{pz}CH_2CH_2S$], 2.95 [1H, br, $N_{pz}CH_2CH_2S$], 2.71 [1H, br, $N_{pz}CH_2CH_2S$], 2.35 [6H, s, CH_3(pz)], 2.10 [6H, s, CH_3(pz)] ppm. $^{13}C\{^1H\}$ NMR (acetonitrile solution, 63 MHz, 298 K) δ: 165.9–123.0 (Ph), 150.0 (pz-*C*), 141.8 (pz-*C*), 134.9–128.8 (ph-*C*), 108.7 (*C*H(pz)), 48.3 ($N_{pz}CH_2CH_2S$), 42.3 (S*C*H$_2$ph), 36.2 ($N_{pz}CH_2CH_2S$), 12.0 (*C*H$_3$(pz)) ppm. $^{195}Pt\{^1H\}$ NMR (acetonitrile solution, 77.42 MHz, 298 K) δ = singlet at −3884 ppm.

4.3. X-ray crystal structure for compound [Pd(bddf)](BF$_4$)$_2$ · H$_2$O (3)

Suitable crystals for X-ray diffraction of the compound [Pd(bddf)](BF$_4$)$_2$ · H$_2$O (**3**) were obtained through crystallisation from acetonitrile solution. A prismatic crystal was selected and mounted on a MAR345 diffractometer with an image plate detector. Unit-cell parameters were determined from 681 reflections ($3° < \theta < 31°$) and refined by least-squares method. Intensities were collected with graphite-monochromatised Mo Kα radiation. 27417 reflections were measured in the range $1.73° \leqslant \theta \leqslant 30.00°$, 8088 of which were non-equivalent by symmetry (R_{int} (on I) = 0.038). 7271 reflections were assumed as observed applying the condition $I > 2\sigma(I)$. Lorentz-polarisation but no absorption corrections were made.

Table 2
Crystallographic data for [Pd(bddf)](BF$_4$)$_2$ · H$_2$O (**3**)

Empirical formula	$C_{22}H_{32}B_2F_8N_4OPdS_2$
Formula weight	712.66
Temperature (K)	293(2)
Crystal System	monoclinic
Space group	$P2_1/c$
Unit cell dimensions	
a (Å)	10.460(4)
b (Å)	18.064(6)
c (Å)	15.950(5)
α (°)	90
β (°)	103.07(2)
γ (°)	90
V (Å^3)	2935.7(17)
Z	4
D_{calc} (g cm^{-3})	1.612
μ (mm^{-1})	0.849
F(000)	1440
Crystal size (mm)	0.2 × 0.1 × 0.1
θ Range (°)	1.73–30.00
Index range	$-13 \leqslant h \leqslant 13$, $0 \leqslant k \leqslant 25$, $0 \leqslant l \leqslant 22$
Reflections collected/unique (R_{int})	27417/8088 (0.0383)
Completeness to θ_{max} (%)	94.4
Absorption correction	none
Data/restraints/parameters	8088/3/340
Goodness-of-fit on F^2	1.037
Final R_1, wR_2	0.0541, 0.1621
R_1 (all data), wR_2	0.0583, 0.1669
Maximum and minimum residual electron density (e Å^{-3})	0.707 and −0.814

The structure was solved by direct methods, using the SHELXS-97 computer program [19], and refined by full-matrix least-squares method with SHELX-97 computer programs [20] using 27417 reflections (very negative intensities were not assumed). The function minimised was $\sum w(|F_o|^2 - |F_c|^2)^2$ where $w = [\sigma^2(I) + (0.1115P)^2 + 1.2853P]^{-1}$, and $P = (F_o^2 + 2F_c^2)/3$. All H atoms were computed and refined, using a riding model, with an isotropic temperature factor equal to 1.2 times the equivalent temperature factor of the atom to which they are linked. The final $R(F)$ factor and $R_w(F^2)$ values as well as the number of parameters and other details concerning the refinement of the crystal structure are gathered in Table 2.

5. Supplementary material

CCDC 631793 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Addition of $M_2SCN(CH_2R)_2$ to $D(C_6H_4S)_2SbCl$ in methylene chloride solution leaded to the formation of the stable compounds $D(C_6H_4S)_2SbS_2CN(CH_2R)_2$ (D = O, R = Me, **1**; D = S, R = Me, **2**; R = Ph, **3**). The new dibenzostibocines derivatives containing two different types of dithioligands were characterized by elemental analysis and spectroscopic studies (IR, ^1H and ^{13}C NMR). Single crystal X-ray diffraction determinations of complexes **1**–**3** revealed that the antimony atom acts as an acceptor atom exhibiting an intramolecular transannular interaction with the donor D atom, expanding its coordination from three to five and displaying a skew trapezoidal local geometry.

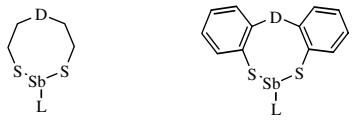
1. Introduction



The preparative and structural chemistry of 1,1-dithioligands has been widely explored [1,2]. With regard to the structural studies, these ligands often display unsymmetrical bidentate coordination patterns toward heavier 15 group elements; the difference between the two metal–sulfur bond lengths diminishes as the metallic character increases in the order As, Sb, Bi. It has been surveyed that dithiocarbamate ligands mainly lead to the formation of discrete monomeric aggregates with lighter 15 elements (P, As) when they are surrounded by organic groups, and to polymeric associations in the case of heavier elements (Sb and Bi) [3].

On the other hand, the structural study of the antimony(III) complexes in sulfur rich environments has been dominated by the synthesis of tris–chelate complexes [4–13]. In order to study the influence of the usually strong coordination of the 1,1-dithioligands to the central acidic Sb atom in several intra- and intermolecular structural features, some antimony(III) compounds in a fully chalcogenate coordination sphere have been synthesized by means of potentially tridentate ligands containing chalcogen donors like oxygen or sulfur. One of these structural features is the transannular interaction between a chalcogen donor atom (D) and an acceptor atom in compounds of the types I and II (Scheme 1). In the case of type I complexes, several studies comprising exocyclic monoanionic 1,1-dithioligands $S_2PR_2^-$ attached to Sb have shown a weakening in the D–Sb transannular interaction when these complexes are compared with the halogen derivatives [14–16].

In contrast, to our knowledge there are not examples of complexes of the type II containing 1,1-dithioligands. We have studied by means of X-ray diffraction studies and theoretical calculations the nature of the transannular interaction D → Sb (D = O, S) in monohalogenated dibenzostibocines and have shown the existence of a strong transannular

Scheme 1.

interaction, revealing that the antimony atom is in a distorted ψ-bipyramidal tetracoordinate geometry [17]. These results prompt us to analyze the influence of a potentially bidentate ligand linked to the antimony atom in that interaction. Here we report the synthesis and structural study of type II complexes with antimony(III) as acceptor atom in a chalcogen rich environment. After the description of the synthesis of the dithiocarbamatedibenzoestibocines, NMR and X-ray crystallographic data are presented and discussed.

2. Experimental

2.1. Reagents and general procedures

Unless noted otherwise, all reactions and operations were carried out under argon or dinitrogen at room temperature with use of standard Schlenk techniques. Solvents were dried and distilled before use. $NaS_2CNEt_2 \cdot 3H_2O$ was obtained commercially (Aldrich) and used as received. $KS_2CN(CH_2Ph)_2$ was prepared from the reaction of carbon disulfide, dibenzylamine and KOH in methylene chloride by modified procedures [18]. $D(C_6H_4S)_2SbCl$ (D = O, S) compounds were prepared as reported [17]. Melting points were determined on a Melt-Temp II instrument and are uncorrected. Elemental analyses were performed on a Perkin–Elmer Series II CHNS/O Analyzer. The IR spectra were recorded in the 4000–400 cm^{-1} range on a Perkin–Elmer System 2000 FT-IR spectrometer, as KBr pellets. The ^1H and ^{13}C NMR spectra were recorded on a Jeol Eclipse 400 spectrometer; with the residual protio-solvent signal used as referenced for ^1H NMR spectra. $^{13}C\{1H\}$ NMR spectra were referred through the solvent peaks. Chemical shifts are quoted on the δ scale (downfield shifts are positive) relative to tetramethylsilane (^1H, $^{13}C\{1H\}$). Spectra were recorded at 25 °C. ^1H; 399.78 MHz, $^{13}C\{1H\}$; 100.53 MHz. Suitable single crystals of the complexes **1**– **3** were grown by slow evaporation from a methylene chloride solution and were analyzed by single crystal X-ray diffraction. The data were collected at room temperature on a CCD Smart 6000 diffractometer through the use of Mo Kα radiation ($\lambda = 0.71073$ Å, graphite monochromator). Data were integrated, scaled, sorted, and averaged using the SMART software package. The structure of **1** was solved by heavy atom method and the structures of **2** and **3** were solved by direct methods using SHELXTL NT Version 5.10 and refined by full-matrix least squares against F^2 [19]. An empirical absorption correction based on the multiple measurement of equivalent reflections was applied by using the program SADABS [20]. The displacement parameters of non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were kept fixed with a common isotropic displacement parameter.

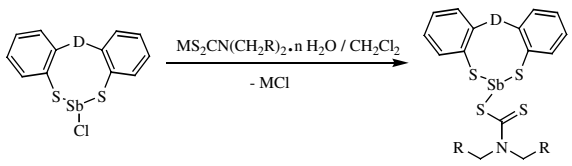
2.2. Synthesis of the dithiocarbamatedibenzostibocine derivatives

2.2.1. Synthesis of $O(C_6H_4S)_2SbS_2CN(CH_2CH_3)_2$ (1)

$NaS_2CNEt_2 \cdot 3H_2O$ (130 mg, 0.58 mmol) was added to a solution containing $O(C_6H_4S)_2SbCl$ (200 mg, 0.51 mmol) in methylene chloride (25 mL) at 25 °C. The yellow suspension was refluxed for 5 h, and then the resultant heterogeneous reaction mixture was allowed to cool to room temperature. The NaCl was removed by means of a column of Celite and Na_2SO_4. The solution was left under a dynamic dinitrogen flow to provide yellow crystals of **1**, which were washed with *i*PrOH (20 mL) and filtered by suction. Yield: 180 mg (70%). M.p. 198–201 °C. *Anal.* Calc. for $O(C_6H_5S)_2SbS_2CN(CH_2CH_3)_2$: C, 40.64; H, 3.61. Found: C, 41.27; H, 3.58%. IR (KBr, cm^{-1}): $\upsilon = 3058$, 2971, 2924, 2866, 1568, 1500, 1454, 1427, 1351, 1270, 1246, 1196, 1196, 1147, 1060, 986, 864, 800, 748, 730.

2.2.2. Synthesis of $S(C_6H_4S)_2SbS_2CN(CH_2CH_3)_2$ (2)

2 was prepared in a similar procedure. $NaS_2CNEt_2 \cdot 3H_2O$ (120 mg, 0.53 mmol) was added to a solution containing $S(C_6H_4S)_2SbCl \cdot 0.5C_6H_6$ (200 mg, 0.45 mmol) in methylene chloride (25 mL). Yield: 165 mg (71%). M.p. 174–176 °C. *Anal.* Calc. for $S(C_6H_5S)_2SbS_2CN(CH_2CH_3)_2$: C, 39.39; H, 3.50. Found: C, 39.49; H, 3.41%. IR (KBr, cm^{-1}): $\upsilon = 3046$, 2979, 2929, 2851, 1559, 1500, 1439, 1427, 1353, 1268, 1243, 1197, 1145,1073, 1037, 982, 907, 835, 755, 744.



2.2.3. Synthesis of $S(C_6H_4S)_2SbS_2CN(CH_2C_6H_5)_2$

3 was prepared in a similar procedure. $KS_2CN(CH_2Ph)_2$ (130 mg, 0.42 mmol) was added to a solution containing $S(C_6H_4S)_2SbCl \cdot 0.5C_6H_6$ (150 mg, 0.34 mmol) in methylene chloride (25 mL). Yield: 115 mg (66%). M.p. 188–194 °C. *Anal.* Calc. for $S(C_6H_5S)_2SbS_2CN(CH_2CH_3)_2$: C, 50.47; H, 3.45. Found: C, 50.38; H, 3.52%. IR (KBr, cm^{-1}): $\upsilon = 3054$, 3042, 3028, 2921, 1492, 1467, 1452, 1438, 1418, 1350, 1245, 1212, 1079, 1028, 964, 803, 751, 697, 627.

3. Results and discussion

3.1. Synthesis of $D(C_6H_4S)_2SbS_2CN(CH_2R)_2$ (D = O, R = Me; D = S, R = Me, Ph)

The $D(C_6H_4S)_2SbCl$ (D = O, S) starting materials were prepared following the reported method [17]. Treatment of $O(C_6H_4S)_2SbCl$ or benzene solvate $S(C_6H_4S)_2SbCl \cdot 0.5C_6H_6$ with the corresponding dithiocarbamate salt in CH_2Cl_2 yielded $O(C_6H_4S)_2SbS_2CN(CH_2CH_3)_2$ (**1**), $S(C_6H_4S)_2SbS_2CN(CH_2CH_3)_2$ (**2**) and $S(C_6H_4S)_2SbS_2$-

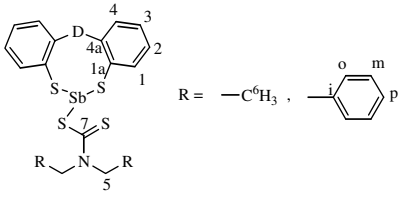
2	S	Na	3	Me
3	S	K	0	Ph



Scheme 2.

$CN(CH_2C_6H_5)_2$ (**3**), respectively, as yellow crystals (see Scheme 2 and Section 2 for details). All complexes are air-stable, soluble in methylene chloride, benzene and chloroform, and insoluble in pentane, hexane and 2-propanol.

3.2. NMR spectra of $D(C_6H_4S)_2SbS_2CN(CH_2R)_2$ (D = O, R = Me; D = S, R = Me, Ph)

The NMR spectra of the three complexes were recorded in $CDCl_3$ solutions at 25 °C and the chemical shifts are relative to TMS. The assignments of these complexes were carried out by heteronuclear and homonuclear correlation two dimension experiments (HETCOR, COLOC and COSY) and are shown in the Table 1. In solution the two DC_6H_4SSb halves are equivalent. In all compounds the two ethyl or benzyl groups in the dithiocarbamate moiety are also equivalent,

In order to describe the local geometry of the Sb central atom is convenient to discuss several structural features observed in the title compounds. Firstly, can be envisaged two different sets of antimony-sulfur distances. The first set comprises two Sb–S thiolate-like and one Sb–S dithiocarbamate-like distances that are close to the covalent radii sum [$\sum r_{cov}$(Sb,S) = 2.42 Å] [21], and, in spite of the similar Sb–S bond lengths, their bond angles are quite different, being the S2–Sb1–S3 angle the smallest [the bond angles range from 80.52(4)° to 83.48(4)°]. The other set of Sb–S distances comprises the second sulfur atom of the dithiocarbamate moiety and they are only 18–20% longer than the covalent radii sum. Secondly, in addition to these two types of Sb–S distances in each complex, there is a transannular intramolecular Sb···D interaction that is 32%, 25% and 24% longer than the Sb–D covalent radii sum for **1** (D = O), **2** and **3** (D = S) respectively, but significantly shorter than the van der Waals radii sum [$\sum_{vdW}$(Sb,O) = 3.64 Å [23]; $\sum_{vdW}$(Sb,S) = 3.92 Å [22]] and can be described as a secondary interaction [23]. Considering the three covalent bonds and the two secondary interactions, the Sb atom in all complexes is penta-coordi-

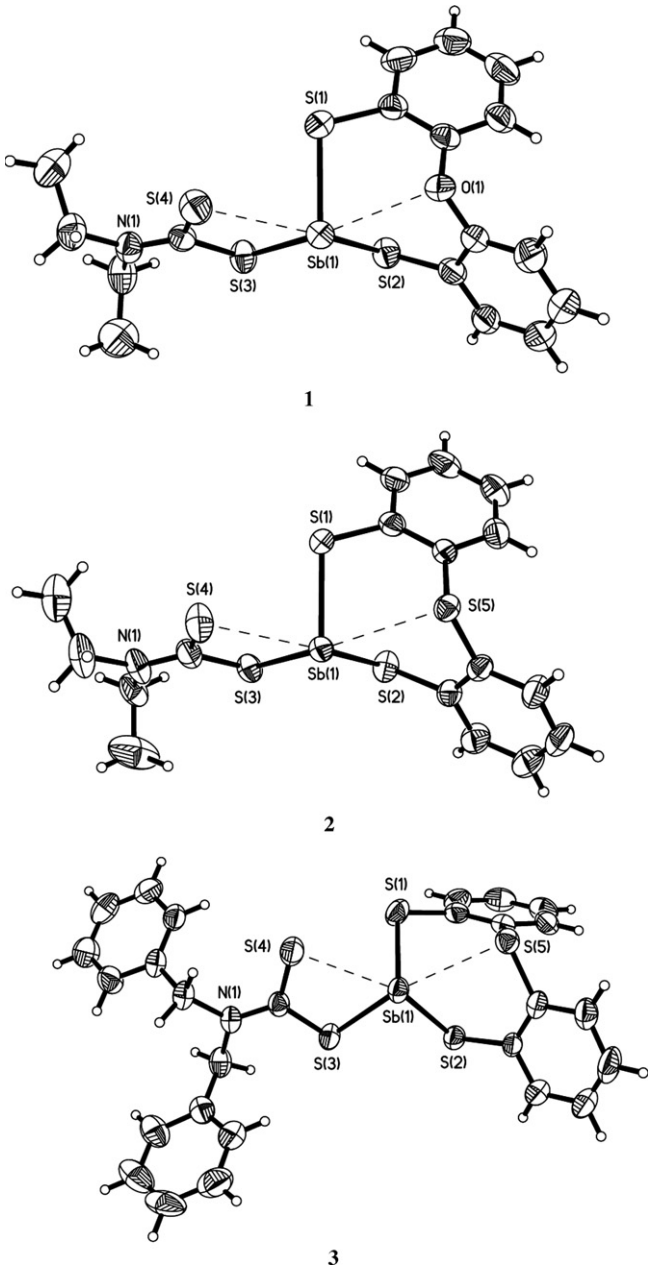

Fig. 1. ORTEP diagrams of $D(C_6H_4S)_2SbS_2CN(CH_2R)_2$ (D = O, R = Me, **1**; D = S, R = Me, **2**; R = Ph, **3**; 50% probability ellipsoids).

nate and its local geometry can be described as pyramidal with a skew-trapezoidal basis. Moreover, in terms of the VSEPR model, the local geometry of the penta-coordinate antimony atom in all complexes can be described as pyramidal pentagonal with a stereochemically active lone pair in a basal position.

In order to compare the magnitude of the transannular interaction in the complexes **1**–**3** we have calculated the Pauling-type bond order (BO) [24–26]. The bond order was calculated according to $BO = 10^{-[1.41(d_{exp}-\sum r_{cov})]}$ where d_{exp} is the D–Sb transannular distance. The BO are 0.1078, 0.1430 and 0.1482 for **1**, **2** and **3**, respectively, indicating that sulfur is a better donor than the oxygen atom towards antimony. Nevertheless these BO are even smaller than those calculated for the $D(C_6H_4S)_2SbCl$ starting materials (0.2195 for D = O and 0.2738 for D = S) [17]. These data indicate that the $D(C_6H_4S)_2^{2-}$ and the $(RCH_2)_2CNS_2^-$ ligands compete for the central antimony atom.

In relation to the coordination mode of the dithiocarbamate ligand, beside to the different Sb–S distances, the two C(13)–S bond lengths are significantly different. These data are consistent with an unsymmetrical bidentate mode.

On the other hand, the conformation of the eight-membered central ring in the dibenzostibocine system is highly distorted, as can be observed from the torsion angles listed in the Table 2, denoting the great flexibility of the potentially tridentate ligand $D(C_6H_4S)_2^{2-}$ to adopt several arrangements.

3.3.2. Crystal structures of complexes *1*, *2* and *3*

In order to analyze the intermolecular interactions we have adopted a similar conservative criterion as the proposed by Tiekink[3] with respect to the Sb···S distances operating in the crystal structures of group 15 dithiolates. Thus, those intermolecular distances lesser than 4.0 Å have been evaluated.

The solid state structures revealed polymeric associations in all cases which are shown in the Figs. 2–4.

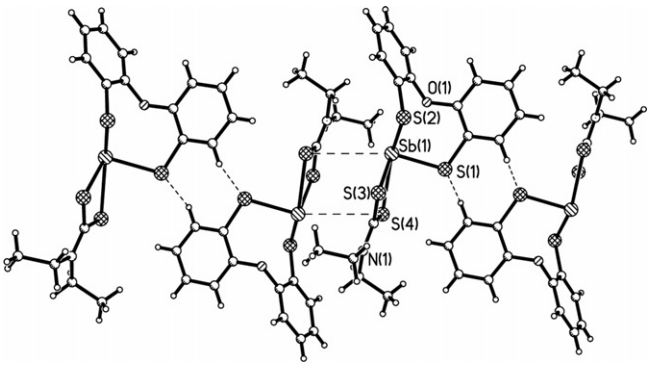

Fig. 2. Molecular associations of $O(C_6H_4S)_2SbS_2CN(CH_2CH_3)_2$ (**1**).

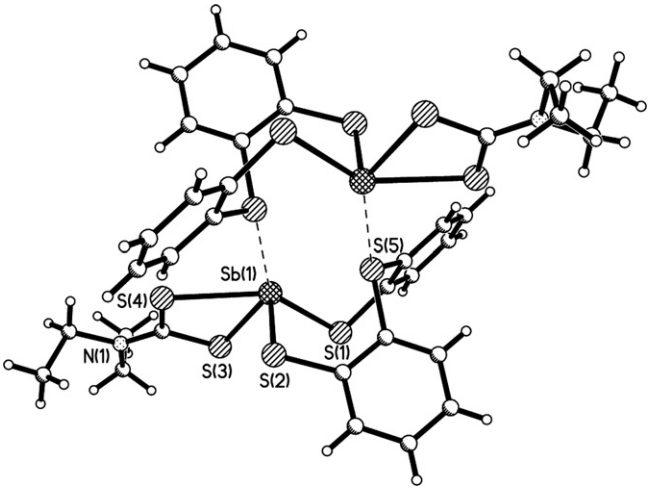

Fig. 3. Molecular associations of $S(C_6H_4S)_2SbS_2CN(CH_2CH_3)_2$ (**2**).

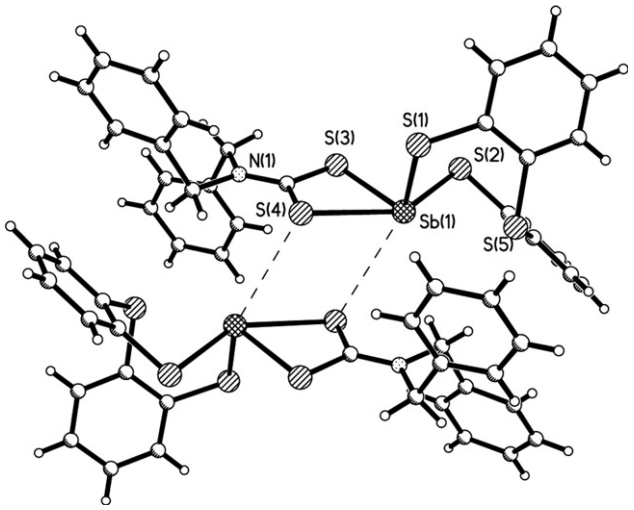

Fig. 4. Molecular associations of $S(C_6H_4S)_2SbS_2CN(CH_2C_6H_5)_2$ (**3**).

As shown in the Figs. 2–4 centrosymetric pairs of $D(C_6H_4S)_2SbS_2CN(CH_2R)_2$ associate via Sb···S interactions of 3.712(1), 3.639(1) and 3.897(1) Å for **1**, **2** and **3** respectively, which are shorter than the corresponding van der Waals radii sum ($\sum r_{vdW}$(Sb,S) = 3.92 Å). In compounds **1** and **3** the centrosymetric association is formed by the interaction of the antimony atom and a sulfur from the CS_2 fragment. On the other hand, in **2** the dimer is formed by the antimony atom and the sulfur thioether-like present in the $S(C_6H_4S)_2^{2-}$ ligand. In all cases the donor ability of the oxygen D atom towards antimony to establish intermolecular associations in **1** is overwhelmed by the sulfur ability donor, according to their hard and soft basic properties.

We also observed some weak C–H···S interactions spanning from 2.94 to 3.18 Å, which are shown in the Fig. 2.

Abstract

The present paper describes the synthesis and spectral properties of Rh(III) and Pd(II) coordination compounds with *N*-(pyridine-2-yl)morpholine-4-carbothioamide (PMCTA). The compounds have the general composition $[RhL_2Cl_2]Cl \cdot C_2H_5OH$ (**1**), $[PdL_2]Cl_2$ (**2**), $[PdL_2](ClO_4)_2 \cdot 2C_3H_6O$ (**2a**), $[PdLCl_2] \cdot 2H_2O$ (**3**). All complexes were characterized by elemental analysis, IR, ^1H NMR, ^{13}C NMR, XPS and UV–Vis spectra. It has been shown that PMCTA behaves as a bidentate (N,S)-ligand, forming six membered metallocycles and coordinating to the metal ion through the carbothioamide sulfur atom and the pyridine nitrogen atom. The UV–Vis spectra suggest that the Pd(II) complexes are square planar, while the Rh(III) complex has an octahedral geometry. The molecular structure of the Pd(II) complex with PMCTA (M:L = 1:2) was determined by single-crystal X-ray diffraction.

Keywords: Rhodium(III); Palladium(II); Morpholine; Carbothioamide; X-ray crystal structure

1. Introduction

The carbothioamide derivatives, especially thiosemicarbazones and thioureas, and their metal complexes are of considerable current interest because of their potentially beneficial pharmacological properties and wide variation in their modes of bonding and stereochemistry [1–5]. Some thiourea derivatives are selective analytical reagents, especially for the determination of transition metals [6,7]. The biological activity of some thiourea complexes have been successfully screened for various biological actions. In addition, the coordination chemistry of heterocycles containing thiones –N(H)–C(=S) ↔ –N=C–SH– is of immense interest because such compounds mimic cysteine sulfur coordination in metalloenzymes; show electronic and structural properties of the active sites in copper blue proteins involving S,N-coordination and comprise purine and pyrimidine bases. Similarly, thiourea derivatives containing this group are important ligands due to their coordination ability to form different kinds of complex compounds with a wide variety of donor atoms and their numerous biochemical properties [8].

In addition, the number of platinum complexes that show antitumor activity is still rapidly growing because of attempts to find complexes with greater potency and less toxicity than the existing clinical drugs. As a consequence, attention has turned to other platinum metals, like ruthenium, rhodium and palladium. Some platinum(II) and palladium(II) complexes with thiosemicarbazone derivatives have a wide spectrum of medicinal properties, including activity against tuberculosis, leprosy, different bacterial and viral infections [5,9,10]. A careful literature survey showed that there are only a few reports about platinum

metal complexes with thiourea morpholine derivatives [11,12].

The present paper describes the synthesis and spectral characteristics of PMCTA complexes with Rh(III) and Pd(II). The X-ray crystal structure of a palladium(II) complex (M:L = 1:2) is reported.

2. Experimental

2.1. Preparation of N-(pyridine-2-yl)morpholine-4-carbothioamide

The ligand was prepared by refluxing a solution containing 1.84 g (0.01 mol) *S*-methyl-*N*-(2-pyridyl)dithiocarbamate and 0.96 ml (0.011 mol) morpholine in 5 ml ethanol for 2 h. The white precipitate thus formed, after the solution was cooled to room temperature, was filtered out and washed with small amounts of icy ethanol and pentane. The obtained powder was recrystallized from ethanol and dried in a desiccator with $CaCl_2$. Yield: 85% (1.89 g):

S-Methyl-*N*-(2-pyridyl)dithiocarbamate was obtained from 2-aminopyridine, carbon disulfide and methyl iodide by a known method [13]. Melting point 79 °C. *Anal.* Calc. for $C_{10}H_{13}N_3SO$: C, 53.81; H, 5.83; S, 14.35; N, 21.52. Found: C, 53.46; H, 6.04; S, 14.52; N, 21.67%. UV–Vis (DMSO) λ_{max}, nm: 260, 282, 357. IR KBr (cm^{-1}): ν(N–H) 3225; [δ(C–H) + δ(N–H) + ν(C–C) + ν(C–N)] 1595, 1535; [ν(C=S) + ν(C–N) + δ(C–H)] 1240; δ(N–C–S) 1128; ν(C=S) 780. ^{1}H NMR (DMSO-d_6): 3.65 (4H, t, $J = 4.8$ Hz, CH_2–N–CH_2); 3.89 (4H, t, $J = 4.8$ Hz, CH_2–O–CH_2); 7.06 (1H, dd, $J = 4.0$, 7.6 Hz, H_5); 7.61 (1H, d, $J = 8.1$ Hz, H_3); 7.71 (1H, dd, $J_1 = 2.0$, 7.9 Hz, H_4); 8.29 (1H, d, $J = 4.0$ Hz, H_6); 9.88 (1H, br, s, NH).

2.2. Preparation of the metal complexes

2.2.1. $[RhL_2Cl_2]Cl \cdot C_2H_5OH$ (**1**)

The complex was prepared by dissolving $RhCl_3 \cdot 4H_2O$ (1 mmol, 0.143 g) in 25 cm^3 of ethanol with heating and then adding an ethanol solution (25 cm^3) of the ligand (2 mmol, 0.223 g) in the molar ratio M:L = 1:2. The reaction mixture was heated under reflux for about 35 min with constant stirring. After the complex precipitated the brown product was filtered and washed several times with small portions of ethanol, Et_2O and dried in vacuum over $CaCl_2$. Melting point 303 °C. Yield: 69% (0.245 g). *Anal.* Calc. for $C_{22}H_{32}N_6S_2O_3Cl_3Rh$: Rh, 14.68; C, 37.63; H, 4.56; Cl, 15.18; S, 9.12; N, 11.97. Found: Rh, 14.21; C, 37.08; H, 4.85; Cl, 15.02; S, 9.56; N, 12.09%. UV–Vis (DMSO) λ_{max}, nm: 270, 365, 431, 476. IR KBr (cm^{-1}): ν(N–H) 3450; [δ(C–H) + δ(N–H) + ν(C–C) + ν(C–N)] 1615, 1550; [ν(C=S) + ν(C–N) + δ(C–H)] 1250; δ(N–C–S) 1120; ν(C=S) 760; ν(Rh–N) 460; ν(Rh–S) 360. ^{1}H NMR (DMSO-d_6): 3.53 (4H, t, $J = 4.2$ Hz, CH_2–N–CH_2); 3.75 (4H, t, $J = 4.2$ Hz, CH_2–O–CH_2); 7.47 (2H, m, H_3 and H_5); 8.08 (1H, m, H_4); 9.43 (1H, d, $J = 4.5$ Hz, H_6); 12.28 (1H, br, s, NH).

2.2.2. $[PdL_2]Cl_2$ (**2**)

The salt $PdCl_2$ (1 mmol, 0.097 g) was dissolved in 0.1 cm^3 of 6 N HCl by heating at 60 °C and then diluted to 25 cm^3. Twenty five millilitres of the ligand in ethanol solution (2 mmol, 0.223 g) was added dropwise to the Pd(II) solution. The reaction mixture was stirred and heated at 80 °C for about 30 min. Right away a yellow precipitate was isolated. The product was then filtered and washed with small portions of ethanol, Et_2O and dried in vacuo over $CaCl_2$. Melting point 212 °C. Yield: 54% (0.171g). *Anal.* Calc. for $C_{20}H_{26}N_6S_2O_2Cl_2Pd$: Pd, 17.01; C, 38.52; H, 4.17; Cl, 11.40; S, 10.27; N, 13.48. Found: Pd, 16.24; C, 37.85; H, 4.39; Cl, 11.28; S, 10.42; N, 13.61%. UV–Vis (DMSO) λ_{max}, nm: 284, 338, 400. IR KBr (cm^{-1}): ν(N–H) 3450; [δ(C–H) + δ(N–H) + ν(C–C) + ν(C–N)] 1615, 1550; [ν(C=S) + ν(C–N) + δ(C–H)] 1245; δ(N–C–S) 1125; ν(C=S) 770; ν(Pd–N) 440; ν(Pd–S) 380. ^{1}H NMR (DMSO-d_6): 3.77 (4H, t, $J = 4.7$ Hz, CH_2–N–CH_2); 4.03 (4H, t, $J = 4.7$ Hz, CH_2–O–CH_2); 7.43 (1H, dd, $J = 3.9$, 7.6 Hz, H_5); 7.52 (1H, d, $J = 8.2$ Hz, H_3); 8.10 (1H, dd, $J = 2.2$, 8.0 Hz, H_4); 8.97 (1H, d, $J = 4.2$ Hz, H_6); 11.46 (1H, br, s, NH).

2.2.3. $[PdL_2](ClO_4)_2 \cdot 2C_3H_6O$ (**2a**)

The salt $PdCl_2$ (1 mmol, 0.097 g) was dissolved in 0.1 cm^3 of 6 N HCl by heating at 60 °C and then diluted with acetone up to 25 cm^3. Twenty five millilitres of the ligand in acetone solution (2 mmol, 0.223 g) was added dropwise to the Pd(II) solution. After that, $NaClO_4$ (0.2 g) was added to the obtained mixture. The reaction mixture was stirred and heated at 55 °C for about 30 min, and then it was put to a desiccator with diethyl ether. After a few days of standing, yellow crystals were grown. Melting point 207 °C Yield: 36% (0.123 g). *Anal.* Calc. for $C_{26}H_{38}N_6S_2O_{12}Cl_2Pd$: Pd, 12.23; C, 35.99; H, 4.38; Cl, 8.19; S, 7.38; N, 9.69. Found: Pd, 11.85; C, 35.24; H, 5.03; Cl, 8.04; S, 7.44; N, 9.81%. UV–Vis (DMSO) λ_{max}, nm: 284, 338, 400. IR KBr (cm^{-1}): ν(N–H) 3480; [δ(C–H) + δ(N–H) + ν(C–C) + ν(C–N)] 1616, 1555; [ν(C=S) + ν(C–N) + δ(C–H)] 1245; $\nu(ClO_4^-)$ 1100; ν(C=S) 765; ν(Pd–N) 440; ν(Pd–S) 380. ^{1}H NMR (DMSO-d_6): 3.75 (4H, t, $J = 4.9$ Hz, CH_2–N–CH_2); 4.00 (4H, t, $J = 4.8$ Hz, CH_2–O–CH_2); 7.41 (1H, dd, $J = 3.8$, 7.5 Hz, H_5); 7.51 (1H, d, $J = 8.2$ Hz, H_3); 8.09 (1H, dd, $J = 2.1$, 7.8 Hz, H_4); 8.98 (1H, d, $J = 3.9$ Hz, H_6); 11.48 (1 H, br, s, NH).

2.2.4. $[PdLCl_2]\cdot 2H_2O$ (**3**)

The salt $PdCl_2$ (2 mmol, 0.194 g) was dissolved in 0.5 cm^3 of 6 N HCl by heating at 60 °C and then diluted to 25 cm^3. Twenty five millilitres of the ligand in ethanol solution (2 mmol, 0.223 g) was added dropwise to the Pd(II) solution in the molar ratio M:L = 1:1. The reaction mixture was stirred and heated at 80 °C for about 30 min. Right away a bright yellow precipitate was isolated. The product was then filtered and washed with small portions of ethanol, Et_2O and dried in vacuo over $CaCl_2$. Melting point 236 °C. Yield: 65% (0.271g). *Anal.* Calc. for $C_{10}H_{17}N_3SO_3Cl_2Pd$: Pd, 24.31; C, 27.52; H, 3.90; Cl, 16.28; S, 7.34; N, 9.63. Found: Pd, 23.78; C, 27.34; H, 4.32; Cl, 16.13; S, 7.47; N, 9.95%. UV–Vis (DMSO) λ_{max}, nm: 284, 338, 400. IR KBr (cm^{-1}): ν(N–H) 3510; [δ(C–H) + δ(N–H) + ν(C–C) + ν(C–N)] 1616, 1555; [ν(C=S) + ν(C–N) + δ(C–H)] 1240; δ(N–C–S) 1120; ν(C=S) 765; ν(Pd–N) 440; ν(Pd–S) 380; ν(Pd–Cl) 320–310. ^{1}H NMR (DMSO-d_6): 3.65 (4H, t, J = 4.8 Hz, CH_2–N–CH_2); 3.92 (4H, t, J = 4.7 Hz, CH_2–O–CH_2); 7.48 (1H, dd, J = 3.6, 7.7 Hz, H_5); 7.61 (1H, d, J = 8.1 Hz, H_3); 8.12 (1H, dd, J = 2.1, 7.9 Hz, H_4); 8.91 (1H, d, J = 4.1 Hz, H_6); 11.36 (1H, br, s, NH).

2.3. Physical measurements

Chemical analyses for carbon, hydrogen, nitrogen, sulfur and chlorine were performed by an analytical procedure [14]. ^{1}H NMR and ^{13}C NMR spectra were measured on Varian-VXR 300 MHz and Bruker AVANCE 400 spectrometers, respectively, using DMSO-d_6 as a solvent with Me_4Si as an internal standard. The IR spectra were recorded on a Specord M80 in the range 4000–200 cm^{-1} from KBr in pellets. Electronic spectra of DMSO solutions of PMCTA and its complexes (10^{-3} mol L^{-1}) were recorded on a Specord M40 spectrophotometer in the range 200–900 nm (50 000–11 000 cm^{-1}) using a 1 mm quartz cell. X-ray photolectron spectra (XPS) were measured on an ES-2402 device using Mo Kα radiation. Samples were prepared as thin films from an acetone suspension on a 10 × 10 mm aluminum base plate.

2.4. Crystal structure determination

The X-ray structure data of **2a** were collected at room temperature on a SMART APEX II diffractometer. Cell parameters were obtained from least-squares treatment of 2734 reflections. Intensity data were collected within the range $1.50 \leqslant \theta \leqslant 31.53°$ using Mo Kα radiation (λ = 0.71073 Å). The intensities of 9817 reflections have been collected (5291 unique reflections, R_{merg} = 0.0306). Data were corrected for Lorenz and polarisation effects. The structure was solved by direct methods and refined by the full-matrix least-squares technique in an anisotropic approximation for non-hydrogen atoms using SHELXS97 and SHELXS97 programs [15,16]. Relevant crystal data are given in Table 1. Data were corrected for absorption effects using the multiscan technique (SADABS) [17]. The ratio of minimum to maximum apparent transmission was 0.597137.

3. Results and discussion

PMCTA is a thiourea morpholine derivative containing nucleophilic nitrogen and sulfur atoms at the stoichiometric advantageous positions. Thus, it can coordinate to metal ions as a bidentate ligand by forming metallochelates. Changing the reaction conditions (pH, temperature, heating time, molar ratio and concentrations of the parent compounds) affects only the number of coordinated molecules of PMCTA and chlorine anions. The melting points of all the synthesized complexes are above 200 °C, and melting occurs with the decomposition of the compound. All the complexes are soluble in DMSO and DMF, whereas the palladium complexes **2** and **2a** are also soluble in water and alcohols.

3.1. IR spectra

In order to study the binding mode in the complexes, their IR spectra were investigated in comparison with the IR spectrum of PMCTA. The IR spectrum of the ligand shows bonds in the regions 3225, 3070–2900, 1595–1535,

1240, 1128 and 780 cm^{-1}, which are assigned to ν(N–H), ν(C–H), [δ(C–H) + δ(N–H) + ν(C–C) + ν(C–N)], [ν(C=S) + ν(C–N) + δ(C–H)], δ(N–C–S) and ν(C=S) of PMCTA, respectively [3,4,18].

Depending on synthesis conditions, the ligand can exist in thione, thiol, or in both tautomeric forms at the same time due to the presence of the –NH–C=S functional group. The IR spectrum recorded for PMCTA in the solid state does not show a ν(S–H) band but exhibits a medium ν(N–H) band at 3225 cm^{-1}. This shows that in the solid state the ligand remains only in the thione form. However, the IR spectra of all the obtained complexes contain no ν(S–H) bands, which can be accounted for by the presence of only the thione tautomeric form of the ligand [4]. The considerable shift of absorption band (15–25 cm^{-1}) occurring at 1616, 1555 and 760 cm^{-1} indicates that the pyridine ring and the thiocarbamide group participate in coordination to the metal ion. The long-wave IR spectral region (1000–200 cm^{-1}) is practically the same both in ligand and in the complexes, except that some new medium-to-weak intensity bands appear in the spectra of the complexes at 460–440, 380–360 and 320–310 cm^{-1}, assigned to ν(M–N), ν(M–S) and ν(M–Cl) vibrations, which are in good agreement with references [3,4]. The appearance of only one ν(Rh–Cl) vibration in the Rh(III) complex (**1**) indicates that the chlorine anions are located at opposite positions to each other in the Rh(III) octahedral environment. On the other hand, the presence of two absorption bands at 320–310 cm^{-1} confirms the *cis*-configuration of the Pd(II) complex (**3**).

3.2. Electronic spectra

The UV–Vis spectrum of the Rh(III) complex (**1**) shows faint absorption bands at 431 (23 200 cm^{-1}) and 476 nm (21 000 cm^{-1}), which appear to be the split components of the transitions $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1A_{2g}$, expected for octahedral complexes [19]. This may be due to the lowering of the symmetry from O_h to D_{4h}, which is expected with the set of N, S and Cl donor atoms [19,20]. A third band at 373 nm (26 800 cm^{-1}) may be attributed to the transition $^1A_{1g} \rightarrow {}^1T_{2g}$, which is similar to related Co(III) complexes (d^6 system). However, there is a broad band in this region at 355–373 nm (28 170–26 800 cm^{-1}), which can be assigned to $\pi \rightarrow \pi^*$ (C=S) transitions of the ligands [19,21]. Therefore there is an overlap between the band which corresponds to an electron transition of the metal ion and other bands which are assigned to a charge-transfer of ligand functional groups. In addition, the ligand shows bands at ca. 260–280 nm (38 460–35 710 cm^{-1}), which are assigned to $n \rightarrow \pi^*$ transitions, associated with NH and Py groups. The splitting of the $^1A_{1g} \rightarrow {}^1T_{1g}$ band suggests that this complex has a trans structure, which is also supported by the IR spectrum. These bands are also observed in the UV–Vis spectra of all the complexes.

The electronic spectra of the Pd(II) complexes show bands in the regions 400 nm (25 000 cm^{-1}), 337–340 nm (29 670–29 400 cm^{-1}) and 282–287 nm (35 460–34 840 cm^{-1}). The first two bands are assigned to a combination of $^1A_{1g} \rightarrow {}^1A_{2g}$ and $^1A_{1g} \rightarrow {}^1E_g$ transitions by assuming a difference in the energies of $b_{2y}(xy)$ and $e_g(xz, yz)$ levels, which is very small [4]. The other spin-allowed bands for these Pd^{2+} complexes (**2** and **2a**) were assigned to the $^1A_{1g} \rightarrow {}^1B_{1g}$ transition. The absorption bands occuring at 357 nm (28 000 cm^{-1}) and 256–282 nm (39 060–35 460 cm^{-1}), are attributable to $\pi \rightarrow \pi^*$ (C=S) and $\pi \rightarrow \pi^*$ ($n \rightarrow \pi^*$) transitions in the ligand. The UV–Vis spectra of these complexes are comparable to other platinum complexes involving similar donor atoms [4,19]. The electronic spectra of PMCTA and its palladium complex (**2**) are shown in Fig. 1.

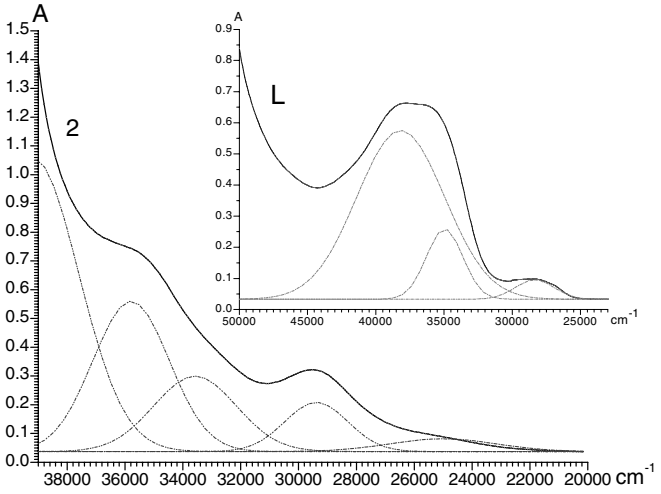

Fig. 1. Electronic spectra of PMCTA (L) and its Pd(II) (**2**) complex.

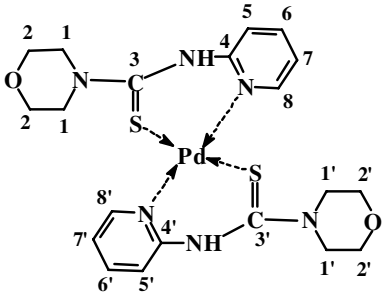

3.3. ^1H NMR and ^{13}C NMR spectra

The ^1H NMR spectrum of the ligand show signals at 7.06, 7.61, 7.71 and 8.29 ppm which are due to pyridine ring protons. A broad singlet corresponding to one proton at 9.88 ppm is assigned to the NH group. The morpholine ring protons give two triplets at 3.65 and 3.89 ppm, which correspond to –N–CH_2 and –O–CH_2 groups, respectively.

In the spectra of the complexes, the multiplets of the pyridine ring are observed at 7.41–7.61 ppm (H3 and H5) and 8.10–8.97 ppm (H4 and H6). This is due to involvement of the pyridine nitrogen in coordination to the metal ion. The NH group is included in the six membered metallocycle and the NH proton occupies an extended state in the S=C–NH system of the ligand. As a consequence, the peak observed at 9.88 ppm in the spectrum of the ligand is shifted downfield in the complexes and suggest, taking a belied view of the weak intensity, the involvement of the carbothioamide group in coordination to the metal. The morpholine proton signals are observed at 3.75 ppm (–N–CH_2) and 4.12 ppm (–O–CH_2).

The ^{13}C NMR spectrum of PMCTA shows the expected carbon structure of the compound (Table 2). The morphol-

Table 2
^{13}C NMR spectral data of PMCTA and **2**

Assignment	Values (ppm) PMCTA (**2**)
C_1, C_1'	48.35/50.03
C_2, C_2'	65.14/64.54
C_3, C_3'	180.67/170.15
C_4, C_4'	146.74/148.69
C_5, C_5'	136.22/139.89
C_6, C_6'	117.22/117.97
C_7, C_7'	118.74/121.21
C_8, C_8'	153.36/151.63

ine carbons of the ligand show peaks at 48.35 ppm (C_1, C_1') and 65.14 ppm (C_2, C_2'). Values of 117.22, 118.74, 136.22, 146.74 and 153.36 ppm can be assigned to the carbons of the pyridine ring – C_6, C_7, C_5, C_4 and C_8, respectively. The singlet corresponding to one carbon at 180.67 ppm is assigned to carbothioamide group (C_3) of the ligand, appreciable shifting of which in the spectrum of **2** to 170.15 ppm ($\Delta C_3 = 9.48$ ppm) confirms the coordination of the ligand through the sulfur atom of the carbothioamide group. Signals of the morpholine and pyridine carbons in the spectra of **2** are only slightly shifted [11,21].

3.4. XPS spectra

Table 3 shows the electron binding energies (eV) of the ligand and its complexes **1** and **2**. The position of the spectrum line of the element to be determined allows one to distinguish not only the valency of the element, but also the coordination manner and its location in the complex [22,23]. This is proved by the N1s, S2p and M3$d_{5/2}$ signals in the spectra of the compounds under investigation. The electron binding energies of N1s of the ligand show a doublet signal at 400.0 and 400.5 eV and a shoulder at 401.5 eV, which is assigned to three types of nitrogen atom in the ligand molecule: (NH), N_{morph} and N_{Py}. We have found three components at 399.0, 400.2 and 400.9 eV after the decomposition of the N1s line, which is assigned to three states of nitrogen. The shift of the N1s signals in the spectra of complexes **1** and **2** indicates that the pyridine and carbothioamide nitrogen of the ligand are involved in donor–acceptor interactions with metal ions.

The increase in the S2$p_{3/2}$ electron binding energy in the spectra of complexes **1** and **2** is in agreement with [22] and is accounted for by coordination of the carbothioamide sulfur atom to the metal ions. This means that the sulfur atom of the thiourea group binds to the central atom through (C=S) → M bond formation.

The positions of Rh3$d_{5/2}$ and Pd3$d_{5/2}$ signals at 311.1 eV and 339.0 eV are assigned to tri- and bi-valent states of the metal ions, respectively. There are three components assigned to different bonds (states) of Rh^{3+} and Pd^{2+} surrounded by non-equivalent nitrogen and sulfur atoms of the ligand (see Table 2).

3.5. X-ray structure determination

The molecular structure of compound **2a** was determined by single-crystal X-ray diffraction. A perspective view of molecule **2a** with the atom numbering is shown in Fig. 2.

One molecule of complex **2a** per unit cell is observed, and the atom Pd1 occupies a special position at the centre of inversion. The palladium atom is bound by two S and two N atoms with bond angles N1a–Pd1–N1 180.0°, S1a–Pd1–S1 180.0°, N1a–Pd1–S1a 85.74(7)° and N1a–Pd1–S1 94.26(7)° in a square-planar coordination geometry. The Pd1–Sl and Pd1–N1 bond distances are 2.315(8) and 2.029(2) Å, respectively. The bonding parameters agree with the coordinate patterns in [7,24,25]. The atoms N2 and N3 have planar configurations (the sum of bond angles is 360°) and C6–N2 and C6–N3 bond lengths are shorter than standard single C–N bond because of conjugation

Table 3

4. Conclusion

Allocation of the carbothioamide group to the α-position of the pyridine ring of *N*-(pyridine-2-yl)morpholine-4-carbothioamide enables the ligand to coordinate through the pyridine nitrogen atom and the sulfur atom of the thioamide group, forming six member metallocycles. Variation of the syntheses conditions (pH = 2–4, temperature, heating time) effects only a number of the coordinated ligand molecules. In all the newly synthesized complexes the ligand coordinates in the thione tautomeric form. Therefore, generally cationic complexes (**1**, **2** and **2a**) are formed. They are soluble in water, which enables the investigation of their biological activity.

Periodic trends in metal–metal bonding in edge-shared $[M_2Cl_{10}]^{4-}$ systems

Germán Cavigliasso, Chung-Yen Yu, Robert Stranger *

Abstract

Periodic trends in metal–metal interactions in edge-shared $[M_2Cl_{10}]^{4-}$ systems, involving the transition metals from groups 4 through 8 and electronic configurations ranging from d^1d^1 through d^5d^5, have been investigated by calculating metal–metal bonding and spin-polarization (exchange) effects using density functional theory. The trends found in this study are compared with those for the analogous face-shared $[M_2Cl_9]^{3-}$ systems reported in earlier work. Strong linear correlations between the metal–metal bonding and spin-polarization terms have been obtained for all groups considered. In general, spin polarization and electron localization are predominant in 3d–3d species whereas electron delocalization and metal–metal bonding are favoured in 5d–5d species, with more variable results observed for 4d–4d systems. As previously found for face-shared $[M_2Cl_9]^{3-}$ systems, the strong correlations between the metal–metal bonding and spin polarization energy terms can be related to the fact that both properties appear to be similarly affected by the changes in the metal orbital properties and electron density occurring within the d^nd^n groups. A significant difference between the face-shared and edge-shared systems is that while the 4d metals in the former show a strong tendency for delocalized metal–metal bonded structures, the edge-shared counterparts display much greater variation with both metal–metal bonded and weakly coupled complexes observed. The tendency for weaker metal–metal interactions can be traced to the inability of the edge-shared bridging structure to accommodate the smaller metal–metal distances required for strong metal–metal bonding.

1. Introduction

Dinuclear and polynuclear transition metal complexes exhibit great diversity in metal–metal interactions, ranging from weak magnetic coupling through to multiple metal–metal bonding [1]. Such interactions are intrinsically interesting for fundamental reasons, but are also important due to their potential applications in a variety of fields spanning metal surfaces, electronic and magnetic devices, catalysis, and bioinorganic chemistry [2–4].

The extent of the interaction between the metal centres is clearly dependent on the electronic properties of the constituent metals but the nature of the bridging ligand framework, if present, can also play a significant role. Among the species displaying metal–metal interactions, the dinuclear compounds represented by the face-shared $[M_2X_9]^{z-}$ and edge-shared $[M_2X_{10}]^{z-}$ (dimer) species are particularly noteworthy as they are formed by many transition metals and exhibit considerable variation in structural, electronic, and magnetic properties due to the competing effects of the metal–metal and metal–bridge interactions.

Although from a computational perspective, dinuclear face-shared $[M_2X_9]^{z-}$ and edge-shared $[M_2X_{10}]^{z-}$ systems are amenable to reasonably high-level calculations due to their relatively small size and high symmetry, the large range of metal–metal interactions makes the theoretical treatment of these complexes particularly challenging. Nevertheless, we have shown in our previous work that density

doi:10.1016/j.poly.2007.01.034

functional theory in combination with the broken-symmetry approach of Noodleman and coworkers [5,6] can accurately describe the entire range of metal–metal interactions, from weak antiferromagnetic coupling through to multiple metal–metal bonds, as well as encompassing both high-spin and low-spin metal configurations. The success of this procedure can be exemplified by noting that our broken-symmetry density functional calculations have accurately reproduced experimentally observed properties in a large number of $[M_2X_9]^{z-}$ dimers with electronic configurations ranging from d^1d^1 through to d^5d^5 [7–14] as well as mixed-valence d^1d^2, d^2d^3, d^3d^4 and d^4d^5 configurations [15,16]. We have also used this methodology to successfully investigate metal–metal interactions in a variety of other dimer systems, including edge-shared $[M_2X_{10}]^{z-}$ and phosphine-bridged $[M_2X_6(P–P)_4]^{z-}$ systems [17,18], indicating that this theoretical approach is broadly applicable across many dinuclear transition metal complexes.

We have recently completed a detailed investigation of periodic trends in metal–metal interactions across an extensive series of $[M_2Cl_9]^{z-}$ species [19]. In this study, the periodic trends were investigated by means of density functional calculations on a large number of even-electron (same-valence) $[M_2Cl_9]^{3-}$ and $[M'M''Cl_9]^{3-}$ and odd-electron (mixed-valence) $[M_2Cl_9]^{2-}$ dimers involving the transition metals of groups 4 through 8. The degree of metal–metal bonding in these systems is determined by the relative magnitudes of two opposing terms, namely the spin polarization (exchange stabilization) energy which favours localization of the metal-based electrons and weak magnetic coupling, and the metal–metal bonding energy which favours delocalization of the metal-based electrons and thus (strong) metal–metal bonding. Remarkable linear correlations between the metal–metal bonding and spin polarization energy terms were obtained for all group and period series considered, and were rationalized on the basis that both properties appear to be similarly affected by changes in the metal orbital properties and electron density occurring within groups and across periods.

In the present work, the investigations of periodic trends in metal–metal interactions, using the concepts of metal–metal bonding energy and spin polarization energy, are extended to edge-shared $[M_2Cl_{10}]^{4-}$ systems. Computational studies of $[M_2L_{10}]^{z-}$ species have been reported previously, and include the work by Cotton and Feng [20] on Mo complexes ($[Mo_2Cl_6(PH_3)_4]$, $[Mo_2Cl_6(PH_2CH_2PH_2)_2]$, $[Mo_2Cl_6(CHO_2)_2(PH_3)_2]$, $[Mo_2Cl_6(NHCHNH)_2(PH_3)_2]$) using configuration interaction techniques, and our density functional investigations of Cr, Mo, and W complexes ($[M_2Cl_{10}]^{4-}$, $[M_2Cl_6(PH_3)_4]$, $[M_2Cl_6(PH_2CH_2PH_2)_2]$) [17,18]. However, all of these studies have focused on species with a formal d^3d^3 metal-based configuration, whereas in this work we consider $[M_2Cl_{10}]^{4-}$ systems involving all transition metals from group 4 through 8 and electronic configurations ranging from d^1d^1 through d^5d^5. Although both edge-shared and face-shared systems can in principle accommodate metal–metal bonds, the different bridging architectures give rise to fundamentally different orbital interactions. In the edge-shared system σ, π and δ bonds are possible, whereas in the face-shared complexes only σ and δ_π ($2/3\delta + 1/3\pi$) interactions are feasible. Due to the inherent differences in metal–metal interactions compared to the previously investigated face-shared complexes, the present study involving an extensive series of edge-shared dimers, provides an additional and useful check on the applicability of our approach to the analysis of periodic trends in metal–metal bonding across various classes of dinuclear systems.

2. Calculation details

All density-functional calculations reported in this article were carried out with the Amsterdam Density Functional (2004) package [21–23]. Functionals based on the Volko–Wilk–Nusair (VWN) form [24] of the local density approximation (LDA) [25] were utilized, and no gradient corrections or relativistic effects were included, as previous work has shown that these normally result in poorer agreement with experimental structural data [8,26]. Basis sets of triple-zeta quality and one polarization function (TZP or type IV), incorporating frozen cores (Cl.2p, and M.2p, M.3d, M.4f for the first, second, and third transition series, respectively), were employed [21–23].

3. Results and discussion

The molecular structure of edge-shared $[M_2Cl_{10}]^{4-}$ systems (shown in Fig. 1) is characterized by D_{2h} symmetry, with the metal sites lying in a distorted octahedral environment corresponding to C_{2v} local symmetry. This distorted environment implies that the metal-based octahedral t_{2g} d-type orbitals relevant to metal–metal bonding possess a_1, b_2, and a_2 (C_{2v}) symmetry and generate, respectively, bonding [σ, π, δ] and antibonding [σ*, π*, δ*] molecular orbitals that transform as the a_g, b_{2u}, b_{3g}, b_{3u}, b_{1g}, and a_u irreducible representations in the full D_{2h} symmetry of the $[M_2Cl_{10}]^{4-}$ systems. The correlation between the C_{2v}

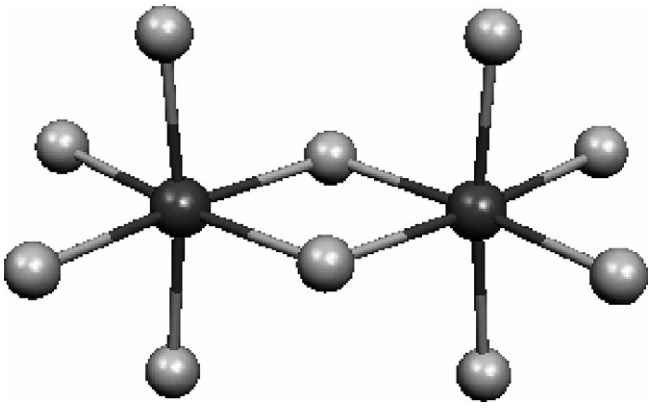

Fig. 1. Molecular structure of edge-shared $[M_2Cl_{10}]^{4-}$ dimers.

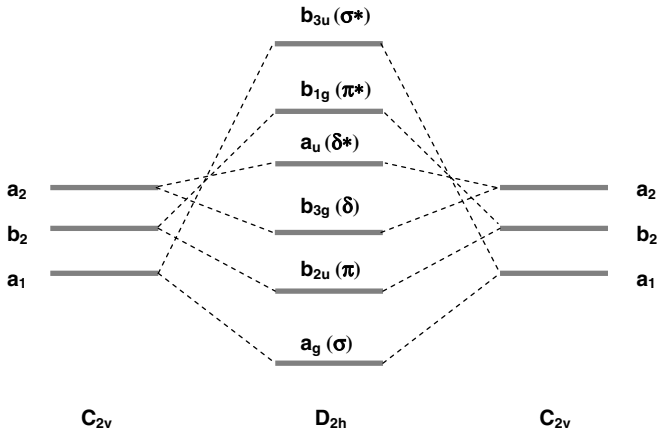

Fig. 2. Correlation between the metal-based molecular orbitals in C_{2v} and D_{2h} descriptions of edge-shared $[M_2Cl_{10}]^{4-}$ dimers.

and D_{2h} orbital descriptions is shown in Fig. 2 and plots of the metal–metal bonding and antibonding molecular orbitals obtained from calculations on (d^3d^3) $[W_2Cl_{10}]^{4-}$ are given in Fig. 3.

3.1. General results

In previous studies [19], periodic trends in metal–metal interactions have been described and analyzed in terms of two factors, namely, the metal–metal bonding (ΔE_{mbe}) energy and the spin-polarization (ΔE_{spe}) energy.

The metal–metal bonding term can be defined as the stabilization energy arising from bond formation between opposite metal centres, whereas the spin-polarization term represents the exchange stabilization energy associated with the presence of unpaired electron density on the metal centres. Significant bonding interaction between the metal atoms favours electron delocalization over both metal sites, whereas the spin-polarization effects favour electron localization on the opposite metal centres. The difference between the two terms (denoted $\Delta E_{spe} - \Delta E_{mbe}$) measures the tendency of the metal-based electrons to delocalize and thus determines the degree of metal–metal bonding.

Three separate calculations are required to determine the metal–metal bonding and spin-polarization terms (Fig. 4). These correspond to the $S = 0$ state, where complete delocalization of the metal-based electrons in metal–metal bonds occurs, the $S = S_{max}$ state, in which all metal-based electrons are unpaired and therefore weakly coupled, and the reference state (RS), which is defined so that the contributions from metal–metal bonding and spin polarization cancel. The energy of the reference state can be obtained from a spin-restricted calculation on an electronic configuration where the metal–metal bonding and antibonding orbitals are evenly occupied.

The metal–metal bonding energy and the spin-polarization energy are defined in terms of these three states as follows

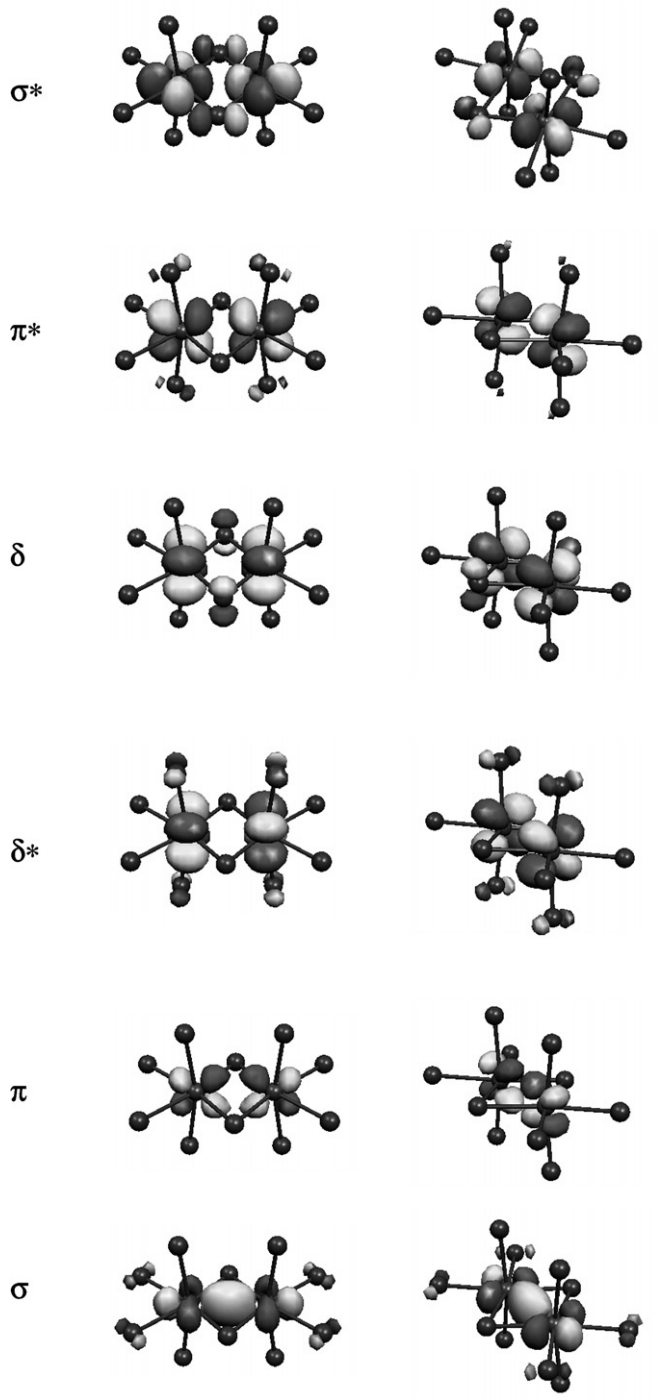

Fig. 3. Plots of the molecular orbitals representing the metal–metal interactions in $[W_2Cl_{10}]^{4-}$.

$$\Delta E_{mbe} = E(S = 0) - E(RS) \quad (1)$$

$$\Delta E_{spe} = E(S = S_{max}) - E(RS) \quad (2)$$

The occupancy of the metal-based orbitals in the metal–metal bonded $S = 0$ state for the five d^nd^n configurations can be schematically described as follows

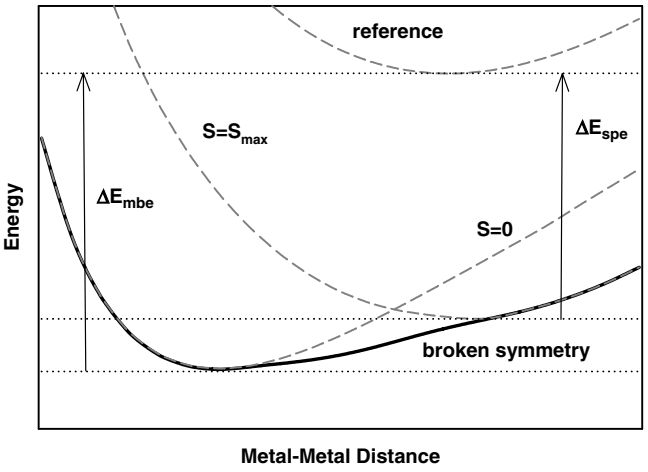

Fig. 4. Schematic definition of the metal–metal bonding (ΔE_{mbe}) energy and spin polarization (ΔE_{spe}) energy in relation to the $S = 0$, $S = S_{max}$, and reference states of $d^n d^n$ systems.

$d^1d^1 \quad (\sigma)^2(\pi)^0(\delta)^0(\delta^*)^0(\pi^*)^0(\sigma^*)^0$

$d^2d^2 \quad (\sigma)^2(\pi)^2(\delta)^0(\delta^*)^0(\pi^*)^0(\sigma^*)^0$

$d^3d^3 \quad (\sigma)^2(\pi)^2(\delta^*)^2(\delta)^0(\pi^*)^0(\sigma^*)^0$

$d^4d^4 \quad (\sigma)^2(\pi)^2(\delta)^2(\delta^*)^2(\pi^*)^0(\sigma^*)^0$

$d^5d^5 \quad (\sigma)^2(\pi)^2(\delta)^2(\delta^*)^2(\pi^*)^2(\sigma^*)^0$

where it should be noted that, for d^3d^3 systems, the most favourable occupation corresponds to an inversion of the δ and δ* orbitals [17,18].

For the "completely localized" $S = S_{max}$ states, the occupancy of the metal-based orbitals corresponds to the configurations

$d^1d^1 \quad (\sigma)^1(\pi)^0(\delta)^0(\delta^*)^0(\pi^*)^0(\sigma^*)^1 \quad (S = 1)$

$d^2d^2 \quad (\sigma)^1(\pi)^1(\delta)^0(\delta^*)^0(\pi^*)^1(\sigma^*)^1 \quad (S = 2)$

$d^3d^3 \quad (\sigma)^1(\pi)^1(\delta)^1(\delta^*)^1(\pi^*)^1(\sigma^*)^1 \quad (S = 3)$

$d^4d^4 \quad (\sigma)^1(\pi)^1(\delta)^2(\delta^*)^2(\pi^*)^1(\sigma^*)^1 \quad (S = 2)$

$d^5d^5 \quad (\sigma)^1(\pi)^2(\delta)^2(\delta^*)^2(\pi^*)^2(\sigma^*)^1 \quad (S = 1)$

The electronic configurations for the reference states are obtained by evenly distributing the metal-based electrons over the six relevant orbitals, as follows:

$d^1d^1 \quad (\sigma)^{1/3}(\pi)^{1/3}(\delta)^{1/3}(\delta^*)^{1/3}(\pi^*)^{1/3}(\sigma^*)^{1/3}$

$d^2d^2 \quad (\sigma)^{2/3}(\pi)^{2/3}(\delta)^{2/3}(\delta^*)^{2/3}(\pi^*)^{2/3}(\sigma^*)^{2/3}$

$d^3d^3 \quad (\sigma)^1(\pi)^1(\delta)^1(\delta^*)^1(\pi^*)^1(\sigma^*)^1$

$d^4d^4 \quad (\sigma)^{4/3}(\pi)^{4/3}(\delta)^{4/3}(\delta^*)^{4/3}(\pi^*)^{4/3}(\sigma^*)^{4/3}$

$d^5d^5 \quad (\sigma)^{5/3}(\pi)^{5/3}(\delta)^{5/3}(\delta^*)^{5/3}(\pi^*)^{5/3}(\sigma^*)^{5/3}$

Geometrical parameters for the reference, $S = 0$, and $S = S_{max}$ states, and the calculated values of the ΔE_{mbe}, ΔE_{spe}, and $\Delta E_{spe} - \Delta E_{mbe}$ terms for all species studied in the present work are given in Tables 1 and 2, respectively.

3.2. Periodic trends

Periodic trends in the metal–metal bonding (ΔE_{mbe}) and spin polarization (ΔE_{spe}) energy terms in all $[M_2Cl_{10}]^{4-}$ systems studied are schematically represented in the plots shown in Fig. 5.

For all five transition metal groups investigated, qualitatively similar trends in the variation of the metal–metal bonding and spin-polarization terms are observed. On descending each group, the calculated values of the metal–metal bonding energy increase while those of the spin polarization energy decrease, with the most significant differences found between 3d–3d and 4d–4d species.

An explanation for these qualitative trends can be given in terms of how the changes in the metal properties affect the two energetic factors [19]. As a group is descended,

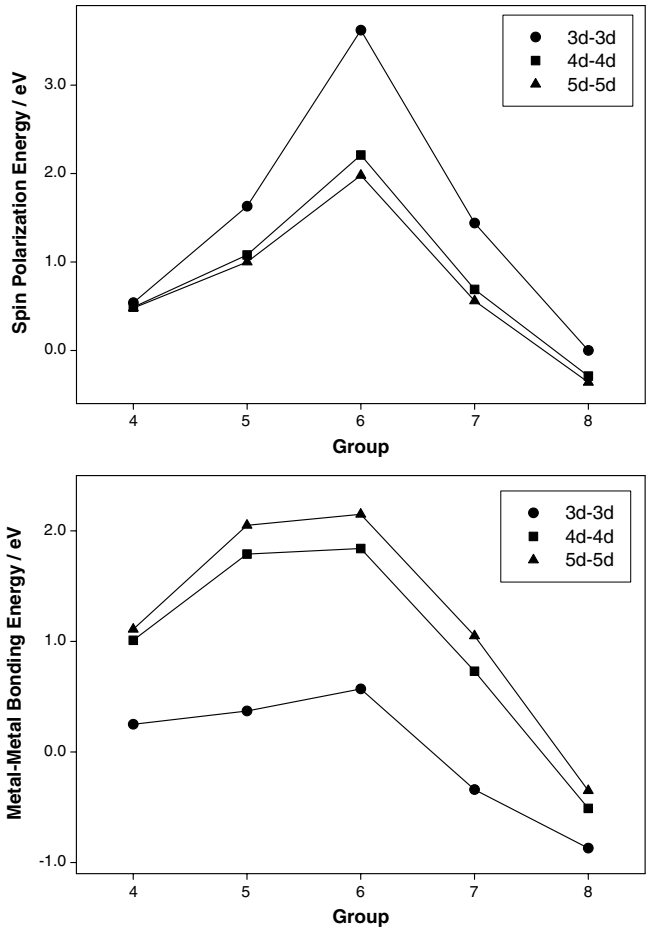

Fig. 5. Periodic variation of the spin-polarization and metal–metal bonding energy terms.

the greater size of the metal atoms and the more diffuse nature of the metal orbitals lead to an enhancement of the metal–metal bonding interactions, but to a reduction in spin polarization as a consequence of the increased average interelectronic separation.

Across a period, the changes in the spin-polarization energy reflect its dependence on the number of like-spin electrons, the calculated values increasing from d^1d^1 through to d^3d^3 configurations, and subsequently decreasing from d^3d^3 through to d^5d^5 configurations. For $[M_2Cl_9]^{3-}$ systems, the variation of the spin-polarization energy across a period is mirrored around the values for group 6, and an explanation for this result has been proposed [19] in terms of the electron–hole equivalence of the d^1d^1–d^5d^5 and d^2d^2–d^4d^4 configurations, and the relationship between the spin-polarization energy and the number (n) of like-spin electrons, represented by the expression

$$\Delta E_{spe} \propto (n!/2) \tag{3}$$

Unlike the $[M_2Cl_9]^{3-}$ systems, the variation in the spin-polarization energy is not symmetrical across the $[M_2Cl_{10}]^{4-}$ series. Although the results are similar for (d^2d^2) $[V_2Cl_{10}]^{4-}$ and (d^4d^4) $[Mn_2Cl_{10}]^{4-}$, in general, the values for d^4d^4 and d^5d^5 species are significantly smaller than those for d^2d^2 and d^1d^1 systems, respectively. A comparison of the structural data in Table 1 for the reference and $S = S_{max}$ states reveals structural differences between the $[M_2Cl_9]^{3-}$ and $[M_2Cl_{10}]^{4-}$ dimers that may account for the different trends observed in the spin-polarization energy results. In the former, the optimized metal–metal distances in the reference and $S = S_{max}$ states are almost identical, whereas in the latter, this pattern generally holds for d^1d^1 and d^2d^2 dimers, but not for d^4d^4 and d^5d^5 dimers, which exhibit shorter metal–metal bond lengths in the reference state than in the $S = S_{max}$ state.

In the case of the metal–metal bonding energy, the greater values obtained for d^2d^2 and d^4d^4 species relative to d^1d^1 and d^5d^5 systems, respectively, correlate with the increase in formal metal–metal bond order from 1.0 to 2.0. For d^3d^3 dimers, the δ–δ* orbital inversion implies that there is no formal triple bond despite the presence of six metal-based electrons, and the metal–metal interaction is more appropriately described as a formal double bond [20]. Accordingly, a comparative examination of the results for d^2d^2 and d^3d^3 species, in both the 4d–4d and 5d–5d series, reveals that the metal–metal bonding energy and the optimized bond lengths in the $S = 0$ state are largely similar. The metal–metal interaction appears somewhat stronger in $[Cr_2Cl_{10}]^{4-}$ than $[V_2Cl_{10}]^{4-}$, but a more significant change in the metal–metal distances is observed in this case. Analogous to the $[M_2Cl_9]^{3-}$ systems, the values of the metal–metal bonding energy for d^4d^4 and d^5d^5 dimers are smaller than those obtained for d^2d^2 and d^1d^1 dimers, respectively, and this result can be attributed to the influence of factors such as the occupation of antibonding orbitals and the expected contraction of the metal-based orbitals across a period.

Plots showing the variation of the metal–metal bonding energy as a function of the spin-polarization energy are shown in Fig. 6. Strong linear correlations have been obtained for all groups considered, as previously observed for face-shared $[M_2X_9]^{z-}$ series involving a variety of metals and ligands [19,27]. The dashed line corresponds to

$$\Delta E_{mbe} = \Delta E_{spe} \tag{4}$$

and thus separates the systems exhibiting a preference for electron delocalization and metal–metal bonding ($\Delta E_{mbe} > \Delta E_{spe}$) from those where electron localization and weak magnetic coupling is more favourable ($\Delta E_{mbe} < \Delta E_{spe}$). In general, delocalization and metal–metal bonding preferably occur in 5d–5d species whereas localization and weaker coupling between the metal atoms are favoured in 3d–3d species, with the results being more variable across 4d–4d systems. Although the general trends for the 3d–3d and 5d–5d series are similar to those described previously for $[M_2Cl_9]^{3-}$ systems [19], the behaviour of the 4d–4d dimers is rather different, as evidenced by the fact that metal–metal bonding is clearly preferred by all 4d–4d face-shared $[M_2Cl_9]^{3-}$ species whereas only the $[Zr_2Cl_{10}]^{4-}$ and $[Nb_2Cl_{10}]^{4-}$ edge-shared systems exhibit a definitive tendency

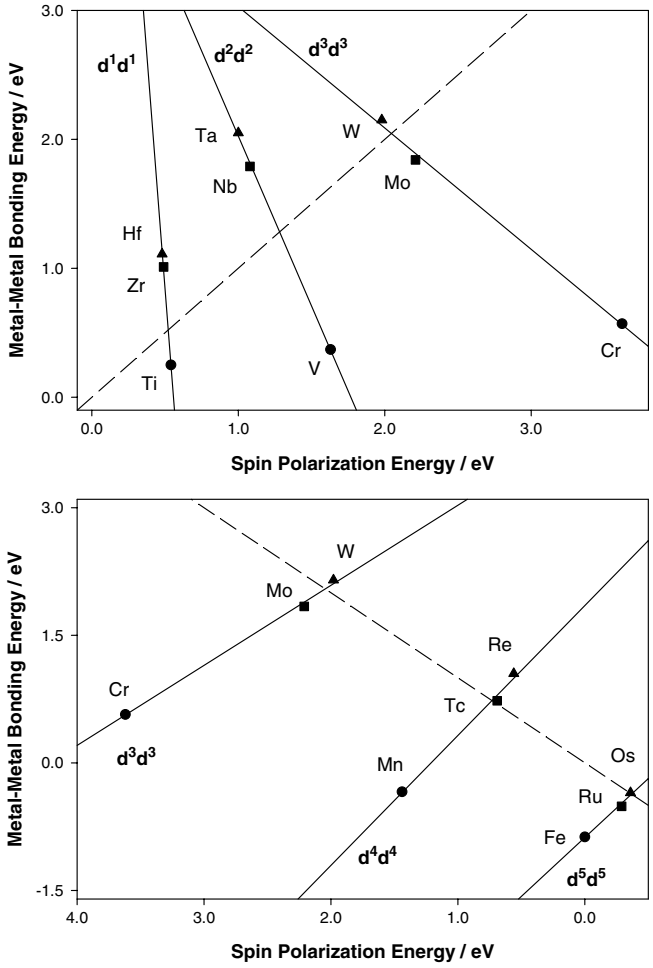

Fig. 6. Variation of the metal–metal bonding energy as a function of the spin-polarization energy.

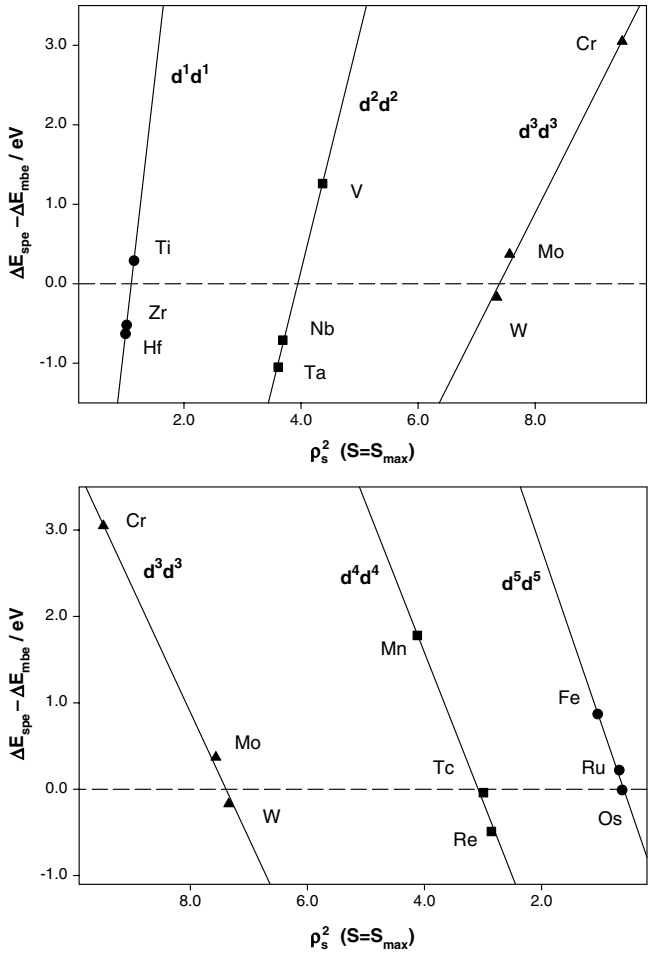

Fig. 7. Representation of the difference ($\Delta E_{spe} - \Delta E_{mbe}$) between the spin polarization and metal–metal bonding terms as a function of the square of the spin density (ρ_s^2) in the $S = S_{max}$ state.

towards electron delocalization and metal–metal bond formation. As previously noted [17], this result is related to the apparent inability of the edge-shared bridging structure to support the short metal–metal separations required for strong metal–metal bonding.

The strong correlation between the metal–metal bonding and spin polarization energy terms has been previously [19] rationalized on the basis that both properties appear to be similarly affected by changes in the metal orbital properties and electron density within each group. As found for the $[M_2Cl_9]^{3-}$ systems, a connection between the two energy terms and the electron density is also observed for the $[M_2Cl_{10}]^{4-}$ species, as revealed by the strong linear correlations between the $\Delta E_{spe} - \Delta E_{mbe}$ values and the square of the metal spin density (ρ_s^2) obtained from a Mulliken population analysis for the $S = S_{max}$ state (Fig. 7).

For all d^nd^n groups, the importance of metal–metal bonding relative to spin polarization is found to increase as the spin density decreases. Thus, the tendency towards metal–metal bond formation becomes stronger upon descending a given group, as indicated by the diminishing values of the $\Delta E_{spe} - \Delta E_{mbe}$ term, and can be correlated with the decrease in the spin density on the metal centres in the $S = S_{max}$ state.

Across the 3d–3d series, spin polarization effects become increasingly important as the number of unpaired electrons in the $S = S_{max}$ state and, consequently, the spin density on the metal centres, increases from d^1d^1 (Ti) and d^5d^5 (Fe), through d^2d^2 (V) and d^4d^4 (Mn), to d^3d^3 (Cr) systems. As observed in Fig. 5, the spin polarization and metal–metal bonding energy terms exhibit similar trends across the 3d–3d series, but the steeper variation displayed by the former leads to its increasingly dominant role across the [d^1d^1, d^2d^2, d^3d^3] and [d^5d^5, d^4d^4, d^3d^3] sets of systems within this period.

More variable results are observed across the 4d–4d and 5d–5d series but, in all cases, the smallest values of the $\Delta E_{spe} - \Delta E_{mbe}$ term, and therefore the most delocalized structures, have been obtained for the species with d^2d^2 and d^4d^4 configurations. Within their respective [d^1d^1, d^2d^2, d^3d^3] series, the d^3d^3 $[Mo_2Cl_{10}]^{4-}$ and $[W_2Cl_{10}]^{4-}$ dimers exhibit the largest $\Delta E_{spe} - \Delta E_{mbe}$ values, in accord with the observation that these systems have the highest number of unpaired electrons and metal spin density values

in the $S = S_{max}$ state, and the fact that their capacity for metal–metal bonding seems to be somewhat unfavourably affected by the δ–δ* orbital inversion. The Zr, Hf, Nb, and Ta dimers all show a preference for metal–metal bonding over electron localization, but a greater tendency towards delocalization is predicted for the d^2d^2 species ($[Nb_2Cl_{10}]^{4-}$ and $[Ta_2Cl_{10}]^{4-}$) than the d^1d^1 species ($[Zr_2Cl_{10}]^{4-}$ and $[Hf_2Cl_{10}]^{4-}$), respectively, due to fact that the greater strength of the metal–metal bonds in the former appears to dominate over the increased spin polarization resulting from a higher number of unpaired electrons and metal spin density in the $S = S_{max}$ state. These observations also apply to the 4d–4d species within the [d^5d^5, d^4d^4, d^3d^3] series, with the d^3d^3 dimer ($[Mo_2Cl_{10}]^{4-}$) displaying the greatest preference for electron localization while metal–metal bonding is more favourable in the d^4d^4 dimer ($[Tc_2Cl_{10}]^{4-}$) than the d^5d^5 dimer ($[Ru_2Cl_{10}]^{4-}$). In the case of the 5d–5d analogues, the greatest tendency towards delocalization and metal–metal bond formation is also predicted for the d^4d^4 dimer ($[Re_2Cl_{10}]^{4-}$), but in contrast with the trends for the 3d–3d and 4d–4d species, the d^5d^5 dimer ($[Os_2Cl_{10}]^{4-}$) is calculated to be the most localized system, rather than the d^3d^3 dimer ($[W_2Cl_{10}]^{4-}$).

4. Conclusion

Periodic trends in metal–metal interactions have been investigated by means of density functional calculations on a large number of edge-shared $[M_2Cl_{10}]^{4-}$ dimer systems, involving the transition metals from groups 4 through 8 and electronic configurations ranging from d^1d^1 through d^5d^5.

The tendency for metal–metal bond formation or electron localization has been analyzed in terms of periodic trends in metal–metal bonding and spin polarization effects. As found in a previous study of face-shared $[M_2Cl_9]^{z-}$ systems, remarkably strong linear correlations between these two energy terms have been obtained for all d^nd^n groups considered, and can be traced to a similar dependence of both factors on the radial dilation of the metal d orbitals and electron density within a given group.

Strong linear correlations are also observed, within all groups, between the square of the spin density on the metal centres (obtained from calculations on the $S = S_{max}$ state) and both the metal–metal bonding and spin polarization terms . However, unlike the $[M_2Cl_9]^{3-}$ systems, across the nd-nd series, the relationship between the two terms, and the dependence of both terms on the electron density, are, in general, not characterized by (similarly strong) linear correlations, possibly due to the influence of the δ–δ* orbital inversion in the $[M_2Cl_{10}]^{4-}$ dimers.

Not unexpectedly, the relative magnitudes of the metal–metal bonding and spin polarization terms indicate that delocalization and metal–metal bond formation are most favourable in the 5d–5d species whereas localization and weaker coupling between the metal atoms are preferred in the 3d–3d species. The results are more variable across the 4d–4d systems with the Zr and Nb dimers showing a tendency towards metal–metal bonding, but electron localization being favoured in the Ru and Mo dimers. This contrasts with the analogous face-shared systems where all 4d–4d dimers are predicted to be delocalized.

Overall, the $[M_2Cl_{10}]^{4-}$ dimers exhibit less delocalized structures than their face-shared $[M_2Cl_9]^{3-}$ counterparts, and this tendency can be attributed to the more inflexible nature of the edge-shared bridging structure, which is less able to accommodate the shorter metal–metal separations required for strong metal–metal bonding.

Abstract

Trinuclear $M_3tdt_3(PEt_3)_3$ ($M = Fe^{II}$ for **I**, Co^{II} for **II**) clusters have been synthesized from the reaction between $M(PEt_3)_2Cl_2$ and Na_2tdt (tdt = toluene-3,4-dithiolate) in MeCN. Both complexes have been characterized by elemental analyses, FT-IR, UV–Vis, FAB-MS, ^1H NMR and cyclic voltammetry. Structures of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) were determined by single crystal X-ray crystallography. The Fe_3 triangular core of the 48-electron complex **I**, with an isosceles triangular geometry, showed very short Fe–Fe distances of 2.4014(13) and 2.4750(12) Å, which are comparable to the extensive M–M frameworks found in the FeMo-cofactor in nitrogenase. The isostructural $Co_3tdt_3(PEt_3)_3$ (**II**), with an analogous Co_3 coordination geometry, showed short Co–Co distances of 2.4442(9) and 2.5551(10) Å. The slightly longer M–M distances in complex **II** were explained by a total valence electron counting argument. Cyclic voltammetry of $Fe_3tdt_3(PEt_3)_3$ (**I**) showed robust reduction waves compared to $Co_3tdt_3(PEt_3)_3$ (**II**). Temperature-dependent effective magnetic moment measurements of **I** and **II** showed both clusters behave similarly and the magnetic property of the M_3 equilateral triangle core with extensive metal–metal interactions was characterized as degenerate frustration.

1. Introduction

The FeMo-cofactor in the MoFe protein of nitrogenase is a key complex for biological N_2 reduction [1]. The chemical formula of (*R*-homocitrate)$MoFe_7S_9X$ (X = unknown element) is unprecedented in biological or synthetic systems (Fig. 1). The identity of the unknown μ_6-atom was suggested as C, N or O by protein X-ray crystallography [2]. Although a nitrogen atom was favored by theoretical calculations [3], ENDOR and ESEEM spectroscopic studies did not find any evidences of a nitrogen atom [4]. One of the structural characteristics of the FeMo-cofactor is an extensive metal–metal (M–M) bonded framework. The Mo–Fe distances are found to be between 2.67 and 2.73 Å [2]. Especially, the trigonal prism of six Fe atoms shows very short Fe–Fe distances in a range between 2.58 and 2.67 Å. By comparison, most Fe/S clusters show Fe–Fe distances longer than 2.75 Å. The Fe–Fe bond lengths in the H-cluster of all-Fe hydrogenases are found between 2.57 and 2.62 Å, probably due to the π-acceptor CO and CN^- ligands [5–8]. The short M–M bonds in the FeMo-cofactor are unusual among biological inorganic clusters and the possible biological function of the M–M bonds in nitrogenase has been discussed [9]. Although it is controversial, synthetic Mo/Fe/S or Fe/S clusters with short M–M bonds may be of interest in understanding the mechanism of N_2 fixation in nitrogenase.

A plethora of metal-chalcogenide organometallic clusters have been reported, but inorganic clusters with a short Fe–Fe distance are rare. Recently, reactions under reducing conditions have been reported to produce $(Cl_4\text{-cat})_2Mo_2Fe_6S_8(PR_3)_6$ (R = Et, ^{n}Pr and ^{n}Bu) [10] and $(Cl_4\text{- cat})_2Mo_2Fe_3S_5(PEt_3)_5$ [11] compounds with short Mo–Fe and Fe–Fe bonds. These compounds were reported to show interesting chemical reactivity and physical properties.

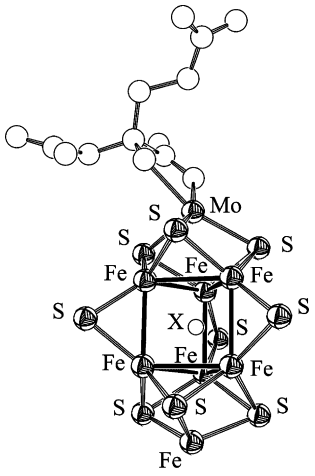

Fig. 1. Structure of FeMo-cofactor. The unknown atom is shown within the Fe_6 prismane frame (shown in solid bonds). The picture was generated by ORTEP-3 for Windows [35] after processing PDB data (1M1N) using Swiss-PdbViewer [36].

To understand the physical properties of clusters with short M–M bonds, we have prepared $M_3tdt_3(PEt_3)_3$ (**I** for M = Fe, **II** for M = Co) complexes from the reaction between $M(PEt_3)_2Cl_2$ and the bidentate thiolate ligand, Na_2tdt (where tdt = toluene-3,4-dithiolate). Although closely related complexes of $M_3tdt_3(P^nBu_3)_3$ (M = Fe or Co) and $Fe_3bdt_3(PEt_3)_3$ have been synthesized [13,14],[1] the synthetic method adopted here is different. Besides, due to the instability of the P^nBu_3 derivatives, these trinuclear Fe and Co clusters have never been completely characterized. The $M_3tdt_3(PEt_3)_3$ (**I** for M = Fe, **II** for M = Co) complexes were characterized structurally and physically by various methods. Complexes **I** and **II** are isostructural but have a different number of total valence electrons, so that shows different formal bond orders of the M–M bonds. These trinuclear $M_3tdt_3(PEt_3)_3$ complexes also are found to show interesting temperature-dependent magnetic properties.

2. Experimental

2.1. General

All experiments and reactions were carried out under a dinitrogen atmosphere using standard Schlenk line techniques or in an inert atmosphere glove box. All solvents were distilled under dinitrogen and nitrogen gas was bubbled through the solvents before each use in a glove box. $FeCl_2$, PEt_3 and toluene-3,4-dithiol were purchased from Aldrich and were used without further purification. Na_2tdt was prepared from the reaction between Na and toluene-3,4-dithiol in MeOH. The 2:1 molar ratio reaction resulted in a quantitative yield. $Fe(PEt_3)_2Cl_2$ was prepared from a 1:2 molar ratio of $FeCl_2$ and PEt_3 in THF. Anhydrous $CoCl_2$ was prepared by drying the hydrate form of $CoCl_2$ in a vacuum oven. A MeCN solution of $Co(PEt_3)_2Cl_2$ was prepared *in situ* from a 1:2 ratio of $CoCl_2$ and PEt_3.

^1H NMR spectra were recorded in $CDCl_3$ with a Bruker 400 MHz NMR spectrometer using non-deuteriated solvent as the internal standard. FT-IR spectra were collected on a Nicolet DX V. 4.56 FT-IR spectrometer in KBr pellets and the spectra were corrected for background effects. UV–Vis spectra were obtained on a Shimadzu UV-1601 UV–VIS spectrometer in the range 200–1000 nm. Elemental analyses were performed in the Microanalytical Laboratory at the University of Michigan. The data were corrected using acetanilide as a standard. FAB-Mass spectra were obtained with a 3-nitrobenzoyl alcohol matrix. Cyclic voltammetry was performed on a BAS-voltammograph. Three electrodes consisting of a glassy carbon working electrode, Pt auxiliary electrodes and a saturated calomel electrode (SCE) as a reference electrode were used for the measurements. $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) were dissolved in 1,2-dichloroethane together with 0.1 M tetrabutylammonium hexafluorophosphate as a supporting electrolyte, and the scanning rate was 100 mV/s. Under the same conditions, 0.1 M of ferrocene in MeCN showed an oxidation wave at 480 mV. Magnetic susceptibilities of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) were measured in the temperature range of 4–300 K with a Quantum Design MPMS SQUID. The magnetic field of the measurements was 5000 G for the temperature-dependent experiments. The crystalline sample was put into a cellophane capsule under a dinitrogen atmosphere. The magnetic susceptibility of the holder was determined separately and diamagnetic corrections were estimated from Pascal's constants [15]. Magnetic moments per trinuclear cluster of **I** and **II** were reported.

2.2. $Fe_3tdt_3(PEt_3)_3$ (*I*)

$Fe(PEt_3)_2Cl_2$ (726 mg, 2.0 mmol) was dissolved in MeCN (30 mL) and Na_2tdt (400 mg, 2.0 mmol) was added into the solution. The reaction mixture turned immediately dark black and was stirred for 2 h, whereupon it turned reddish black. After overnight reaction, a reddish black precipitate was isolated by filtration. The product was extracted with diethyl ether (10 mL × 4) and the extract was dried under N_2. The black crystalline product was isolated in a 76.5% yield (500 mg, 0.51 mmol). ^1H NMR (CD_2Cl_2): $\delta = 32.5$ (br s, 9H, PCH_2CH_3), 14.6 (br s, 6H, PCH_2), 9.2 (br s), 8.2 (br d), 6.4 (br d), 1.6 (br d), 0.6 (br s), 0.08 (br s, 3H, tdt-CH_3), −0.1 (br s), −0.64 (br s), −11.2 (br s, 12H, PCH_2), −14.5 (br t, 18H, PCH_2CH_3). ($CDCl_3$): $\delta = 44.3$ (br s), 43.4 (br s), 14.75 (br s, 12H, PCH_2), 11.0 (t, 9H, PCH_2CH_3), 6.9 (br s), 6.6 (br s), 5.16 (br s, 9H, PCH_2CH_3), 2.24 (br s), 1.98 (br s), 0.58 (br s), 0.05 (br s, 9H, tdt-CH_3), −2.46 (br s, 9H, PCH_2CH_3), −4.94 (br s, 6H, PCH_2), −17 (br s), −43 (br s). FT-IR (KBr, cm^{-1}, relative intensity) 3032(m), 2956(m), 2929(s), 2897(m), 2873(s), 1450(s), 1031(vs) 761(s). Far-IR (KBr, cm^{-1}, relative intensity) 408(s), 356(s), 333(s). FAB^+-MS

2.3. $Co_3tdt_3(PEt_3)_3$ (**II**)

Anhydrous $CoCl_2$ (650 mg, 5.0 mmol) was dissolved in 15 mL of MeCN and stirred for 30 min to dissolve the $CoCl_2$. To this sky blue solution, PEt_3 (1.5 mL, 10.0 mmol) was added and the color of the solution changed to dark blue. The reaction mixture was filtered through a glass filter after 5 min. To the *in situ* prepared $Co(PEt_3)_2Cl_2$ MeCN solution was added Na_2tdt (1.0 g, 5 mmol) and the reaction mixture changed color immediately to yellowish black. After about 2 h, the reaction mixture turned greenish black. After stirring overnight, the reaction was stopped by filtration and a black precipitate was isolated. The precipitate was extracted with diethyl ether (20 mL × 4). The diethyl ether solvent was removed under N_2 and a golden black crystalline product was isolated in a 72.6% yield (1.2 g, 1.21 mmol). ^1H NMR (CD_2Cl_2): δ = 92.2 (br s), 8.0 (br s), 6.9 (br s), 6.6 (br s), 6.4 (br s), 4.1 (br s), 3.75 (br s), 3.44 (br s, 6H, PCH_2), 2.1(m), 1.83(m), 1.64(m), 1.27 (br s), 1.11 (t, 18H, PCH_2CH_3), 0.053 (br s, 9H, tdt-CH_3), −0.37 (br s, 9H, PCH_2CH_3), −1.16 (br s, 6H, PCH_2), −1.84 (br s, 6H, PCH_2), −2.44 (br s). FT-IR (KBr, cm^{-1}, relative intensity) 3030(m), ν(C–H of PEt_3); 2956(m), 2929(s), 2899(m), 2874(s), 1447(s), 1030(vs) 762(s). Far-IR (KBr, cm^{-1}, relative intensity) 414(s), 345(s), 333(s). FAB^+-MS (NBA, *m/z*) 993.2 ($[Co_3tdt_3(PEt_3)_3]^+$), 875.1 ($[Co_3tdt_3(PEt_3)_2]^+$), 756.9 ($[Co_3tdt_3(PEt_3)]^+$), 638.8 ($[Co_3tdt_3]^+$). *Anal.* Calc. for $C_{41}H_{68}Co_3O_{0.5}P_3S_6$ (**II**, MW 1031.10): C, 47.76; H, 6.65. Found: C, 47.34; H, 6.42%. UV–Vis (nm ($M^{-1}\,cm^{-1}$), green in Et_2O): λ_{max} (ε) = 263 (6000), 275 (sh, 5200), 328 (sh, 2400), 391 (2060). 2.4. X-ray crystallography

Black rhombic-shaped crystals of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) were obtained from the ether extract of the reaction precipitate. The diffraction data were collected at 158(2) and 123(2) K for **I** and **II**, respectively, using a Bruker SMART area diffractometer. The crystal data and structural parameters are shown in Tables 1 and 2. The structures for compounds **I** and **II** were solved by direct methods to locate heavy atoms, and the non-hydrogen atoms were located through subsequent difference Fourier syntheses. Structural refinement was carried out by full-matrix least squares on F^2. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were placed in calculated positions, allowed to ride on their corresponding atoms and refined isotropically except those on disordered carbon atoms. The carbon atoms of diethyl ether solvent molecules in **I** and **II** were severely disordered and the geometry restraints did not improve the refinement. All calculations were performed using SHELXTL-NT V. 5.1 software.

synthesized. These complexes were mainly achieved through self-assembly, exploiting the thermodynamic stability of the products [16,17], or rational assembly of simple building blocks under reducing conditions [11,18–20]. The complexes from the reducing conditions usually possess a reduced core with short M–M bonds. Although trigonal M_3 (M = Fe, Co) complexes with bidentate thiolate bridging ligands and trialkylphosphine terminal ligands have been reported [12–14], the synthesis of $M_3tdt_3(PEt_3)_3$ (M = Fe, Co) has never been published. The complex $Fe_3tdt_3(P^nBu_3)_3$ prepared from EtOH was reported to be unstable, but its PEt_3 analog, **I**, was stable enough for various physical characterizations. Although it was suggested that the electron-donating methyl group on the phenyl ring would destabilize the complex [14], the effect of methyl substitution seems to be negligible because it stays too remote from the metal ions. Rather, the relative electron-donating property of P^nBu_3 would be a more significant contributor to the stability of the complex [21]. Since PEt_3 is a comparatively stronger electron-withdrawing ligand than P^nBu_3, when we introduced PEt_3 to stabilize the M_3 core, the product $Fe_3tdt_3(PEt_3)_3$ (**I**) could be isolated even at room temperature. The Co analog, $Co_3tdt_3(PEt_3)_3$ (**II**), was also successfully prepared using anhydrous $CoCl_2$ under the same reaction conditions. The product **II** from the reaction was very soluble in MeCN. Diethyl ether extraction of the reaction precipitate was an efficient method to purify complex **II**. It should be pointed out that a minimum amount of MeCN is necessary to produce enough precipitate for the isolation of **II**. Both products were very soluble in most organic solvents.

The reaction conditions of using a 1:2 ratio of $FeCl_2$ and PEt_3 is reminiscent of $Fe(PEt_3)_2Cl_2$ in Mo/Fe/S and Fe/S chemistry. The reaction of $[(Cl_4\text{-cat})Mo(MeCN)Fe_3S_4Cl_3]^{2-}$ with $Fe(PEt_3)_2Cl_2$ produces the $(Cl_4\text{-cat})_2Mo_2Fe_6S_8(PEt_3)_6$ cluster and the reaction between $[Fe_4S_4Cl_4]^{2-}$ and $Fe(PEt_3)_2Cl_2$ produces the $Fe_6S_6(PEt_3)_4Cl_2$ cluster [11].

3.2. Structure

The single crystal X-ray structures of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) are shown in Figs. 2 and 3, respectively. The crystal data and structure refinement details, and selected bond lengths (Å) and angles (°) for complexes **I** and **II** are shown in Tables 1 and 2, respectively. Both structures are isostructural and crystallized in the same unit cell system with the same space group. Even the diethyl ether solvent molecules are found in the same positions for both X-ray structures.

Due to the asymmetric methyl position of the bridging tdt ligands, two different structural isomers of **I** were found in the triclinic unit cell (Fig. 2). The first molecule (**IA**) has a *cis*-arrangement of two methyl groups of tdt ligands on the Fe(1) center, while the second molecule (**IB**) shows a *trans*-arrangement of tdt ligands around the Fe(4) center. The same type of isomerism is found in the solid structure of $Co_3tdt_3(PEt_3)_3$ (**II**). The structure of the $Fe_3tdt_3(PEt_3)_3$ (**I**) cluster can be described as an isosceles triangle Fe_3 metal cluster with two long Fe–Fe bonds and one short Fe–Fe bond. The formation of the Fe_3 isosceles triangle geometry, instead of an equilateral triangle geometry, can be explained by different bridging modes of the tdt ligands (see Fig. 3). The Fe centers in **I** show coordination geome-

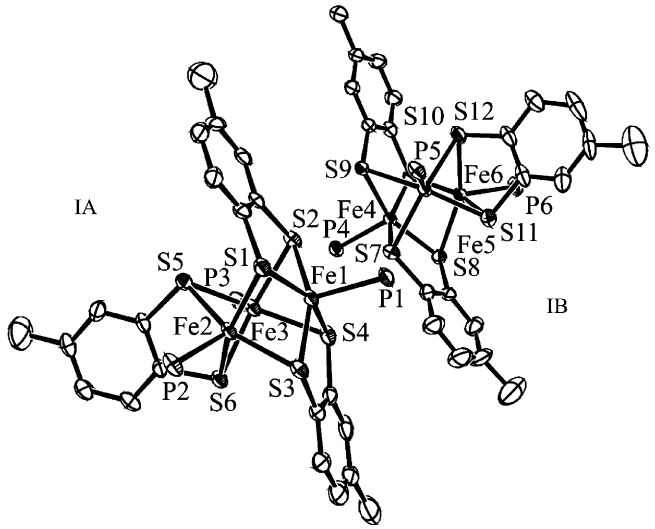

Fig. 2. Single-crystal X-ray structure of $Fe_3tdt_3(PEt_3)_3$ (**I**). Fe–Fe bonds, hydrogen atoms and ethyl groups of PEt_3 were omitted for clarity. Two unique molecules generated by different positions of the toluene methyl groups are shown.

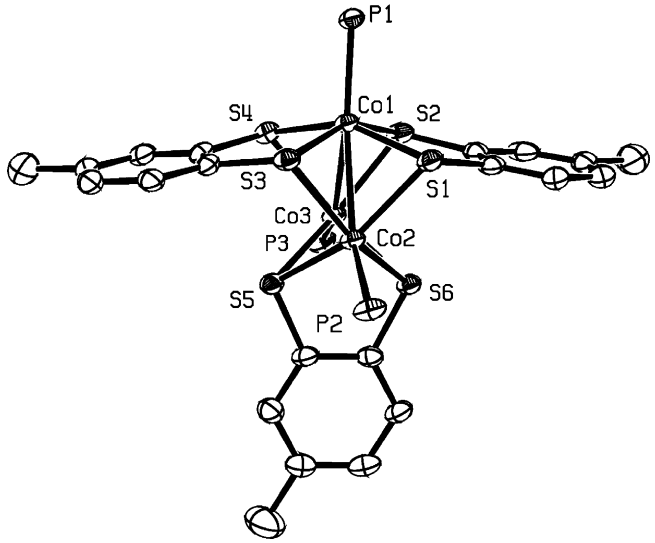

Fig. 3. Single-crystal X-ray structure of $Co_3tdt_3(PEt_3)_3$ (**II**). Hydrogen atoms and ethyl groups of PEt_3 were omitted for clarity.

tries of distorted square pyramids with a phosphorus axial ligand and four sulfur equatorial ligands. The toluene-3, 4-dithiolate ligand, with two bridging thiolates, is a eight-electron donor and the triethylphosphine terminal ligand is a two-electron donor [22]. The total number of valence electrons of 48 in **I** is six electrons fewer than the number expected for three-metal clusters based on the Wade–Mingos–Lauher rule [23]. Therefore, the Fe–Fe bonds in the $Fe_3tdt_3(PEt_3)_3$ (**I**) cluster are expected to have three formal metal–metal single bonds. Likewise, the total number of valence electrons in **II** is 51 and the complex is expected to have three Co–Co bonds with a formal bond order of 0.5. Such formal M–M bond order arguments can explain the differences of the bond distances between **I** and **II**.

The short Fe–Fe bond distances in **I** are 2.4016(13) and 2.4014(13) Å, which is longer than the value of 2.380(2) Å found for the $Fe_3tdt_3(P^nBu)_3$ complex [14]. The other long Fe–Fe distances are found to be in the range 2.4635(12)–2.4750(12) Å, and those of $Fe_3tdt_3(P^nBu)_3$ are 2.493(2) and 2.499(2) Å. The Fe–Fe bonds in the $Fe_3tdt_3(PEt_3)_3$ (**I**) cluster are even shorter than those found in the FeMo-cofactor of nitrogenase. Fe–Fe bonds distances in the FeMo-cofactor are found in the range between 2.58 and 2.67 Å. Two different ranges of Fe–S distances are found in complex **I**. The dithiolate ligands on the Fe(1) and Fe(4) centers have short Fe–S distances with an average value of 2.2258(10) Å.[3] The thiolate ligands on the other Fe centers show an average Fe–S distance of 2.285(4) Å. The difference of 0.06 Å is significant and implies a multiple Fe–S bond order between Fe(1)/Fe(4) and thiolate S [24]. Therefore, all three Fe–Fe bonds in the $Fe_3tdt_3(PEt_3)_3$ (**I**) cluster do not seem to have equally single-bond character and, instead, some Fe–S bonds also have multiple bond character. It could be another reason why the Fe_3 core has an isosceles triangular geometry.

Two unique molecules of the $Co_3tdt_3(PEt_3)_3$ (**II**) cluster in the unit cell do not exhibit significant differences from those of **I** and isosceles triangles of three cobalt ions are found. The Co_3 geometry is slightly different from the Fe_3 geometry, and the average vertex angle of the Co_3 and Fe_3 cores are found to be 57.54(3)° and 58.13(7)°, respectively. The Co–Co distances of **II** are significantly different, and are compared to **I** in Table 2. While the Fe–Fe distances of the legs of the isosceles Fe_3 core in **I** are in the range 2.4635(12)–2.4750(12) Å, the corresponding Co–Co distances of the isosceles Co_3 core in **II** are in the range 2.5308(10)–2.5551(10) Å. The base of the isosceles Co_3 core in **II** has an average Co–Co distance of 2.4456(14) Å , which is much longer than 2.4015(13) Å, the average distance of the isosceles base of the Fe_3 core in **I**. The average distance of the long Co–Co bonds is 2.541(5) Å and the average distance of the long Fe–Fe bonds is 2.472(3) Å. Average M–M distances of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) are 2.472(3) and 2.541(5) Å, respectively. Like complex **I**, two types of Co–S bonds are found in **II**. Co–S bonds around Co(1) and Co(4) atoms have an average distance of 2.2185(14) Å, which is shorter than the average distance of the other Co–S bonds (2.294(5) Å), and even shorter than the short Fe(1)/Fe(4)–S bond (average 2.2258(10) Å). It seems the Co(1)/Co(4)–S bonds of the $Co_3tdt_3(PEt_3)_3$ (**II**) cluster have more multiple bond character than **I** due to the non-integer bond order among the Co–Co bonds; three Co–Co bonds have a formal bond order of 0.5. It should be pointed out that each Co atom in

[3] The number in parenthesis represents the larger of the individual standard deviations or the standard deviation from the mean, $\sigma = [\sum_{i=1}^{n}(x_i - x)^2/n(n-1)]^{1/2}$, where x_i is an individual standard deviation, x is the average of individual standard deviations, and n is the number of individual standard deviations.

complex **II** has one more valence electron than each of the Fe atoms in complex **I**. Because both complexes are exactly same except for the metal ions, complex **II** may need less Co–Co bonding.

In organometallic clusters [25], the Fe–Fe distances of compounds with Fe–Fe double bonds are found in the range 2.215–2.326(4) Å. For the dinuclear organometallic clusters $Fe_2(NO)_2(\eta\text{-}C_5H_5)_2$ and $Co_2(NO)_2(\eta\text{-}C_5H_5)_2$, M–M distances of 2.326 and 2.372 Å are found for formal bond orders of 2 and 1.5, respectively [22,26]. The Fe_4S_4 cluster of the all-ferrous Fe protein, formally a 56-electron complex with two Fe–Fe double bonds and two Fe–Fe single bonds, shows two Fe–Fe distances at 2.52 Å and one Fe–Fe distance at 2.77 Å [27]. FeMo-cofactor with a $[Mo^{4+}4Fe^{2+}3Fe^{3+}(\mu\text{-}S)_3(\mu_3\text{-}S)_6(\mu_6\text{-}X)_6]$ core is supposed to have multiple M–S and M–M bonds and shows Fe–Fe distances between 2.58 and 2.67 Å [9,28]. The Fe–Fe bonds with distances of 2.4683(9) and 2.4721(9) Å found in $(Cl_4\text{-}cat)_2Mo_2Fe_3S_5(PEt_3)_5$ were suggested as intermediate of single and double bonds [11]. The average M–M distances of **I** and **II** are 2.448(15) and 2.509(20) Å, respectively. For comparison, the $Ni_3(S_2C_{10}Cl_6)_3(PPh_3)_3$ complex prepared from Ni(0) was reported to have a similar isosceles Ni_3 core as complexes of **I** and **II** do [29]. The Ni–Ni distance in this 54-electron complex was to be 2.641(4) Å.

3.3. Physical properties

^{1}H NMR spectra of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) in CD_2Cl_2 showed a broad distribution of the peaks. The chemical shifts of protons in complex **I** were found between 33 and −15 ppm, and those in complex **II** were found between 93 and −3 ppm. The wide range of chemical shifts can be attributed to paramagnetism and the high spin configuration of the complexes. Peaks from tdt were almost unassignable and only verified the asymmetric chemical environments of the protons. The dark red KBr pellet of **I** showed aromatic C–H stretching at 3032 cm^{-1} and the characteristic C–H stretching of PEt_3 at 2956, 2929, 2897 and 2873 cm^{-1}. The IR spectra of **I** and **II** are almost identical in both mid- and far-IR ranges. The chemical compositions of **I** and **II** were confirmed by CHN analysis and FAB^+-MS, and the isotope distributions of the molecular ion peaks of **I** and **II** were well matched to those of theoretical expectation.

UV–Vis spectra were measured in diethyl ether (Fig. 4). The purple solution of $Fe_3tdt_3(PEt_3)_3$ (**I**) showed absorptions at 258, 275, 326 and 650 nm and the green solution of $Co_3tdt_3(PEt_3)_3$ (**II**) showed similar absorptions at 263, 275, 328 and 391 nm. The absorption at 391 nm in **II** was found in place of the 650 nm absorption in **I**. Whilst the spectrum of **II** did not change, **I** in diethyl ether changed on exposure to air. The purple diethyl ether solution of **I** turned to dark blue upon air-oxidation and showed absorptions at 216, 252, 320, 370 and 522 nm (Fig. 5), which is reminiscent of the air-oxidation of the FeMo-cofactor. The dark green solution of the FeMo-cofactor was reported to show an absorption band at around 510 nm upon air-oxidation [30].

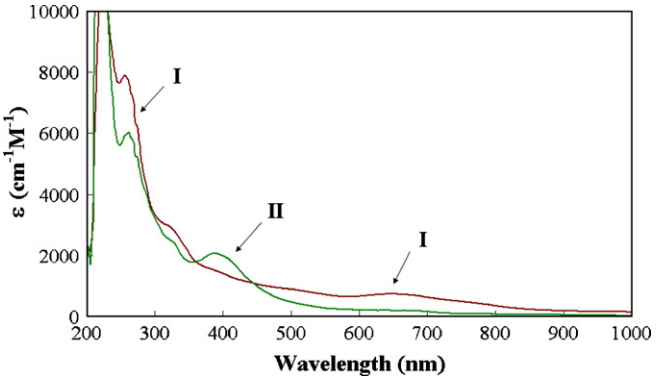

Fig. 4. UV–Vis spectra of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) in diethyl ether.

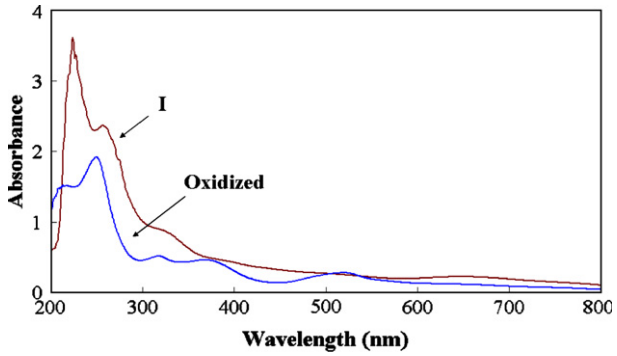

Fig. 5. UV–Vis spectrum change of $Fe_3tdt_3(PEt_3)_3$ (**I**) upon air-oxidation in diethyl ether.

3.4. Electrochemistry

The cyclic voltammetry of the complex $Fe_3tdt_3(PEt_3)_3$ (**I**) showed multiredox waves (Fig. 6). In CH_2ClCH_2Cl, **I** showed three reversible reduction waves at −0.30, −0.52 and −0.76 V and three irreversible oxidation waves at 0.74, 0.42 and 0.08 V. The three reversible reductions are very close, within a 460 mV potential spread, and corre-

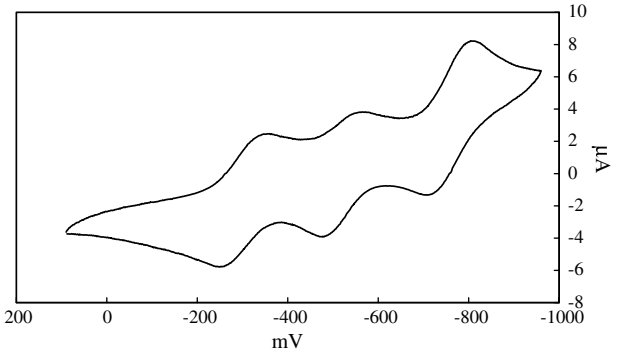

Fig. 6. Cyclic voltammetric responses of $Fe_3tdt_3(PEt_3)_3$ (**I**) in CH_2ClCH_2Cl.

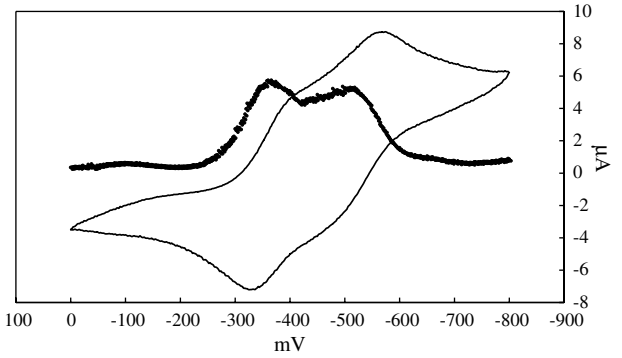

Fig. 7. Cyclic voltammetric responses of $Co_3tdt_3(PEt_3)_3$ (**II**) in CH_2ClCH_2Cl. The overlaid plot shows differential pulse voltammetry at the same potential.

spond to $\mathbf{I}^{0/-1}$, $\mathbf{I}^{-1/-2}$ and $\mathbf{I}^{-2/-3}$ reductions, respectively. Reduction of Fe(II) centers to Fe(I) ions is not physically feasible and only a two-electron reduction process is possible.[4] The observed three reversible reductions of **I** may be explained by the fact that the three M–M single bonds can accept multi-electrons. Such an exploitation of a M–M bond for electron transfer is very important for the catalytic mechanism of nitrogenase FeMo-cofactor and the direct possibility has been suggested before [9]. The complex $Co_3tdt_3(PEt_3)_3$ (**II**) showed a smaller number of redox waves than **I** (Fig. 7). The reduction waves of **II** are found at −0.37 and −0.51 V, and are only 0.14 V apart. Two independent reductions were confirmed by differential pulse voltammetry. Two irreversible oxidations at 0.72 and 0.5 V also were observed. Complex **I** showed much more versatile redox waves compared to complex **II**, which can be explained by the fact that $Fe_3tdt_3(PEt_3)_3$ (**I**) is more coordinatively unsaturated by total valence electron count arguments. It seems that the M–M bonds in the clusters are able to act as an electron reservoir and accept multi-electrons within a short range of potentials. This may be the reason why the FeMo-cofactor shows an extensive M–M bonding framework, so that multi-electron reduction of N_2 is possible.

3.5. Magnetic study

The magnetic susceptibilities of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**) were measured over various temperatures at 5000 G, and field dependency experiments showed almost linear responses. $Fe_3tdt_3(PEt_3)_3$ (**I**) with three Fe(II) ions in an isosceles triangular geometry showed $\mu_{eff} = 2.60$ BM at 310 K, and the value is close to that for a $S_T = 1$ spin-state. The paramagnetic property of **I** is evident by ^{1}H NMR measurement at room temperature, which shows broad proton resonances between −43 and 45 ppm in $CDCl_3$. The mononuclear $Fe(bdt)_2(PMe_3)$ complex with a square pyramidal geometry was reported to show a low-spin/high-spin equilibrium [24]. Although it has a Fe(IV) center, this report suggests a possible spin-transition of the dithiolate phosphine Fe complex. The magnetic moment of **I** decreased to 0.31 μ_B when the temperature was lowered to 100 K (Fig. 8), which shows a strong antiferromagnetic coupling of the spin system. Below 100 K, the magnetic moment increases to 0.66 μ_B (15 K) and decreases again slightly to 0.60 μ_B (up to 4.2 K). The exchange coupling constants from the magnetic susceptibility data could not be obtained with the isotropic Heisenberg model [15].

Complex **II** showed temperature-dependent magnetic susceptibility similar to complex **I**, but with small exchange couplings (Fig. 8). This may be because complex **II** ia a three $S = 3/2$ system while complex **I** is a three $S = 2$ system. The magnetic moments of **I** and **II** at room temperature happen to be similar to each other. The magnetic moment of **II** (2.52 μ_B at 300 K) decreases to 1.76 μ_B at 80 K, probably due to the antiferromagnetic couplings. Below 80 K, the magnetic moment increases slowly to 1.84 μ_B (10 K) and decreases again slightly to 1.83 μ_B (up to 4 K). The complex $Co_3(bdt)_3(P^nBu_3)_3$ was reported to show an effective magnetic moment μ_{eff} of 2.6 μ_B at room temperature. Although it was suggested to have three low-spin Co^{II} (d^7, $S = 1/2$) atoms [14], our measurements, including ^{1}H NMR, suggest that complex **II** has three antiferromagnetically coupled high-spin Co^{II} centers. Similar temperature-dependent magnetic susceptibility was observed from the $(Cl_4\text{-cat})_2Mo_2Fe_3S_5(PEt_3)_5$ complex, which also has strong M–M interactions with a very short Fe–Fe distance. The complex has three Fe(II) centers with the same coordination environments as complexes **I** and **II**. The magnetic moment of the $(Cl_4\text{-cat})_2Mo_2Fe_3S_5(PEt_3)_5$ complex increased from 9.10 μ_B at 325 K to 10.96 μ_B at 95 K, and then decreased steeply to 3.08 μ_B at 4 K [11].

This type of temperature-dependent magnetic susceptibility change is unusual, and the observed spin-state

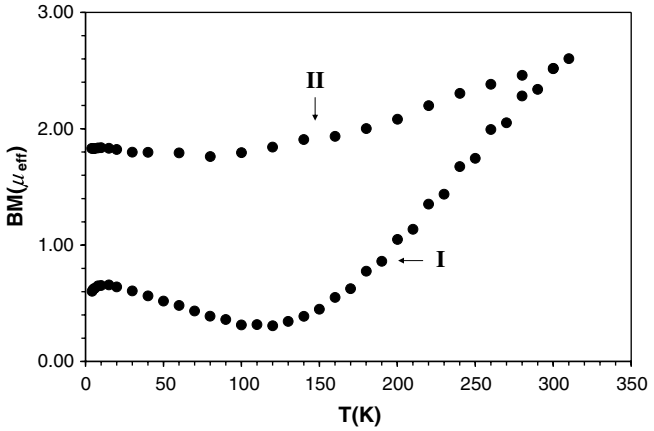

Fig. 8. Molar magnetic susceptibility of $Fe_3tdt_3(PEt_3)_3$ (**I**) and $Co_3tdt_3(PEt_3)_3$ (**II**), plotted μ_{eff} (per trinuclear cluster) versus temperature.

[4] Standard reduction potentials for Fe(III)/Fe(II) and Fe(II)/Fe(0) are 0.77 and −0.44 V, respectively.

transition has three possible explanations, namely spin crossover [31], spin-frustration [32] and degenerate frustration [33]. Thermal spin crossover for the magnetic properties of **I** and **II** can be excluded due to the complicated temperature-dependent magnetic susceptibility changes. Usual thermal spin crossover shows a directional magnetic moment change at a certain temperature. Spin-frustration is a status where geometric constraints of the molecule prevent neighboring spins from adopting a configuration of minimized magnetic energy [34]. But the strict meaning of spin-frustration is a state where the system cannot remain in a single ground state, which does not seem to be the case of the M_3 equilateral triangle complex [33]. Kahn also pointed out that this type of magnetic phenomena occurs whenever the symmetry of the system forces the magnetic ground state to be degenerate and not correspond to any defined spin coupling scheme. Therefore, the more precise terminology for the magnetism would be degenerate frustration. Although some of the clusters with short M–M distances, $(Cl_4\text{-cat})_2Mo_2Fe_3S_5(PEt_3)_5$ and complexes **I** and **II**, have shown the interesting magnetic property of degenerate frustration, there is no physical evidence that such a property is related to the metal–metal bonds.

In summary, we have successfully synthesized and characterized trinuclear $M_3tdt_3(PEt_3)_3$ ($M = Fe^{II}$, Co^{II}) clusters. These clusters show short M–M bonds and the M–M distance differences between **I** and **II** were explained by total valence electron counting arguments. Versatile redox behavior of the $M_3tdt_3(PEt_3)_3$ ($M = Fe^{II}$, Co^{II}) clusters is probably due to the valence unsaturation characteristics of the complexes, which may be relevant to the catalytic mechanism of nitrogenase FeMo-cofactor. The temperature-dependent magnetic susceptibility of these trinuclear clusters were also characterized as a degenerate frustration system, but the strong M–M interactions do not seem to be related to the unusual magnetic properties.

Abstract

The reactions of $[ReO(OEt)X_2(PPh_3)_2]$ (X = Cl or Br) with 8-hydroxyquinoline (Hhqn) have been examined and the $[ReOX(hqn)_2]$ complexes have been obtained. The crystal and molecular structures of $[ReOBr(hqn)_2]$ have been determined. The electronic structure of $[ReOBr(hqn)_2]$ has been calculated with the density functional theory (DFT) method, and additional information about binding in the ReO^{3+} unit has been obtained by NBO analysis. The spin-allowed electronic transitions of $[ReOBr(hqn)_2]$ have been calculated with the time-dependent DFT method, and the UV–Vis spectra of the $[ReOX(hqn)_2]$ compounds have been discussed on this basis.

Keywords: Rhenium oxo complexes; 8-Hydroxyquinoline; X-ray and electronic structure; DFT calculations; NBO analysis

1. Introduction

There is considerable interest in the chemistry of inorganic compounds containing an oxygen atom that is multiply bonded to a transition metal in a high oxidation state. These compounds can transfer an oxygen atom to reductants such as phosphines, sulfides and alkenes. For many years they have been in the centre of interest to those scientists engaged in basic research and to those trying to employ these complexes in catalytic processes. Oxygen atom transfer chemistry has been implicated in various reactions of industrial and biological importance, including olefin epoxidation and catalysis by cytochrome P-450 [1–3].

The chemistry of oxo rhenium complexes arouses particular interest amongst these compounds. It results from the favourable nuclear properties of ^{186}Re and ^{188}Re nuclides, which make the radioisotopes useful for diagnostic nuclear medicine and applications in radioimmunotherapy [4,5].

In this context, the design, synthesis and reactivity of rhenium oxocomplexes has become the aim of several laboratories, including ours.

This work forms part of a program on the synthesis and characterization of new families of oxorhenium compounds with N–donor ligands [6]. Studies on rhenium oxocomplexes incorporating 8-hydroxyquinoline have been relatively rare and this provided us the initial lead for starting an examination of the reactions of $[ReO(OEt)X_2(PPh_3)_2]$ with 8-hydroxyquinoline (Hhqn). Additionally, we were encouraged by recent reports concerning investigations on the reactivity of $[(n\text{-}Bu)_4N][ReOX_4]$ towards 2-(2′-hydroxyphenyl)-2-oxazoline, 2-(2′-hydroxyphenyl)-2-thiazoline and 2-(2′-hydroxyphenyl)-2-benzoxazoline [7].

Here we present the synthesis and spectroscopic data for $[ReOX(hqn)_2]$ complexes (X = Cl or Br). X-ray studies have been performed for $[ReOBr(hqn)_2]$, and the electronic structure of the bromo oxocomplex has been calculated with the density functional theory (DFT) method. The spin-allowed singlet–singlet electronic transitions of $[ReOBr(hqn)_2]$ have been calculated with the time-dependent DFT method (TDDFT method), and the UV–Vis

spectra of the $[ReOX(hqn)_2]$ compounds have been discussed on this basis.

Currently density functional theory (DFT) is commonly used to examine the electronic structure of transition metal complexes. It meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [8]. Recent calculations with the TD-DFT method for open- and closed-shell complexes have also supported the TD-DFT method to be applicable for such systems, giving good assignment of experimental spectra [9–11].

Some theoretical investigations have been carried out on rhenium compounds. The electronic structures of nitrido, oxo, carbonyl, nitrosyl and nitrile rhenium complexes, as well as their spectroscopic properties, bonding and reactivity have been theoretically studied at the HF, MP2, EHT and DFT levels of theory using various basis sets [12–21]. Gancheff and co-workers [14] have performed extended tests on the ability of the B3LYP method in LANL2DZ basis set for geometry optimization and the calculation of spectral properties of rhenium compounds. Although this is not a very extended basis set, its use with DFT has shown to be sufficient for the geometry optimization and calculation of spectral properties. It gives good agreement with the experimental data and its use is justified in the case of large molecules.

2. Experimental

2.1. General procedure

All the reagents used in the synthesis were commercially available and were used without further purification. The $[ReO(OEt)X_2(PPh_3)_2]$ complexes were prepared according to the literature methods [22].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–VIS 8500 in the range 1000–200 nm in dichloromethane solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of $[ReOCl(hqn)_2]$

$[ReO(OEt)Cl_2(PPh_3)_2]$ (0.5 g, 0.57 mmol) was added to 8-hydroxyquinoline (Hhqn) (0.30 g, 2.1 mmol) in ethanol (100 ml) and the reaction mixture was refluxed for 6 h. Sixty milliliters of ethanol was distilled off and 100 ml of diethyl ether was added. This produced a green crystalline precipitate of $[ReOCl(hqn)_2]$ that was collected by filtration. Yield 85%.

IR (KBr): 1608(m), 1594(w), 1573(m) and 1500(s) ν_{CN} and $\nu_{C=C}$; 975(vs) $\nu_{Re=O}$. *Anal.* Calc. for $C_{18}H_{12}ClN_2O_3Re$: C, 41.11; H, 2.30; N, 5.33. Found: C, 41.25; H, 2.28; N, 5.43%.

2.3. Preparation of $[ReOBr(hqn)_2]$

A procedure similar to that for $[ReOCl(hqn)_2]$ was used with $[ReO(OEt)Br_2(PPh_3)_2]$ (0.5 g, 0.5 mmol) and Hhqn (0.30 g, 2.1 mmol). A green crystalline precipitate of $[ReOBr(hqn)_2]$ was collected in 90% yield. Crystals suitable for X-ray structure determination were obtained by slow evaporation from an acetonitrile solution of $[ReOBr(hqn)_2]$.

IR (KBr): 1608(m), 1593(m), 1572(s) and 1500(vs) ν_{CN} and $\nu_{C=C}$; 970(vs) $\nu_{Re=O}$. *Anal.* Calc. for $C_{18}H_{12}BrN_2O_3Re$: C, 37.90; H, 2.12; N, 4.91. Found: C, 37.88; H, 2.25; N, 4.80%.

2.4. Crystal structure determination and refinement

The X-ray intensity data $[ReOBr(hqn)_2]$ were collected on a KM-4-CCD automatic diffractometer equipped with a CCD detector. Twenty-six seconds exposure time was used and all reflections inside the Ewald sphere were collected up to $\theta = 25.1°$. The unit cell parameters were determined from least-squares refinement of the setting angles of 4766 strongest reflections. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and numerical absorption corrections [23] were applied. The structure was solved by the Patterson method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the

full-matrix, least-squares technique. The hydrogen atoms were treated as "riding" on their parent carbon atoms and assigned isotropic temperature factors equal to 1.2 times the value of the equivalent temperature factor of the parent atom. SHELXS97 [24], SHELXL97 [25] and SHELXTL [26] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

3. Computational details

The GAUSSIAN03 program [27] was used in the calculations. The geometry optimisation of the neutral [ReOBr-(hqn)$_2$] complex in a singlet state was carried out with the DFT method with the use of the B3LYP functional [28,29]. The electronic spectrum of [ReOBr(hqn)$_2$] was calculated with the TDDFT method [30]. The calculations were performed using the ECP basis set on the rhenium atom, and the standard 6-31G basis set for other atoms. For bromine, oxygen, nitrogen and carbon atoms, diffuse and polarization functions were added [31,32]. The Xe core electrons of Re were replaced by an effective core potential and a DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [33] was used for the valence electrons. An additional *d* function with exponent $\alpha = 0.3811$ and *f* function with exponent $\alpha = 2.033$ on the rhenium atom were added [34].

Natural bond orbital (NBO) calculations were performed with the NBO code [35,36] included in GAUSSIAN03.

4. Results and discussion

4.1. Preparation and infrared data

The [ReOX(hqn)$_2$] complexes were prepared by refluxing [ReO(OEt)X$_2$(PPh$_3$)$_2$] with a large excess of 8-hydroxyquinoline in ethanol. They were isolated as air-stable, microcrystalline solids, soluble in common organic solvents.

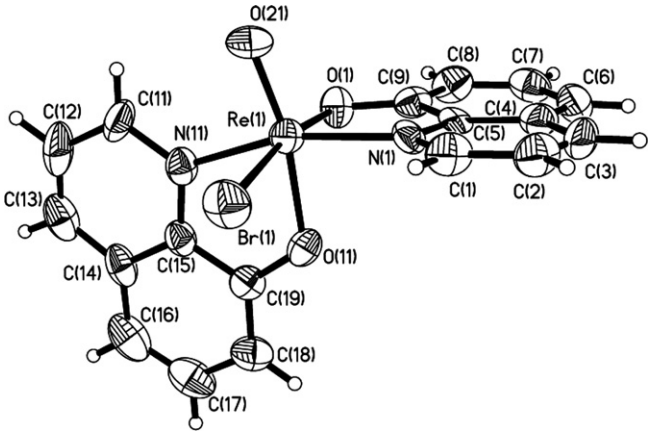

Fig. 1. The molecular structure of [ReOBr(hqn)$_2$].

The strong ν(Re=O) stretching bands at 970–975 cm^{-1} are in the higher end of the range observed for $\{ReO\}^{3+}$ core complexes. This suggests that the Re–hydroxy bond *trans* to the oxo ligand does not compete effectively for the d_{Re} orbitals and the bond is relatively weak. Moreover, the range in which the ν(Re=O) bands appear is very similar to those observed for [ReOXL$_2$] complexes with 2-(2′-hydroxyphenyl)-2-oxazoline, 2-(2′-hydroxyphenyl)-2-thiazoline and 2-(2′-hydroxyphenyl)-2-benzoxazoline [7].

4.2. Crystal structure

The crystallographic data for [ReOBr(hqn)$_2$] are given in Table 1, and the molecular structure of the complex is presented in Fig. 1. The complex crystallizes in a distorted octahedral configuration with two bidentate ligands, one halide ion and a terminal oxo (O$_t$) ligand about the metal center. The rhenium atom is displaced 0.259(4) Å from the equatorial plane formed by the two nitrogens, one oxygen and one bromide atom (plane A) and 0.079(3) and 0.0404(4) Å from the axial planes formed respectively by the three oxygen, one bromide atom (plane B) and two nitrogens and two oxygen atoms (plane C). The least

N(11)	−0.469
Br1(1)	−0.592

squares plane A is inclined at 89.77(19)° to plane B and at 88.47(18)° to plane C. The planes B and C are inclined at 85.60(17)°. The oxyquinoline ring systems can be considered as planar (maximum deviating atoms C(8) and C(13) are displaced 0.044(7) and 0.036(9) Å from their respective least squares planes) and are inclined at 85.24(17)°. The two bound nitrogens are coordinated *trans* to one another, while the bromide is *trans* to the equatorial coordinated oxygen. Clear distortions of the pseudooctahedral environment of the Re center in $[ReOBr(hqn)_2]$ is induced by the multiple bonding ligand (oxo) and narrow bite angle of the chelating ligands. Selected bond lengths and angles of $[ReOBr(hqn)_2]$ are given in Table 2. The Re–O_t bond length falls in the range 1.639–1.76Å, which is typical of mononuclear complexes of rhenium(V) having a $[ReO]^{3+}$ core, and indicates the presence of a triple Re≡O bond [37]. The interatomic distance between the rhenium atom

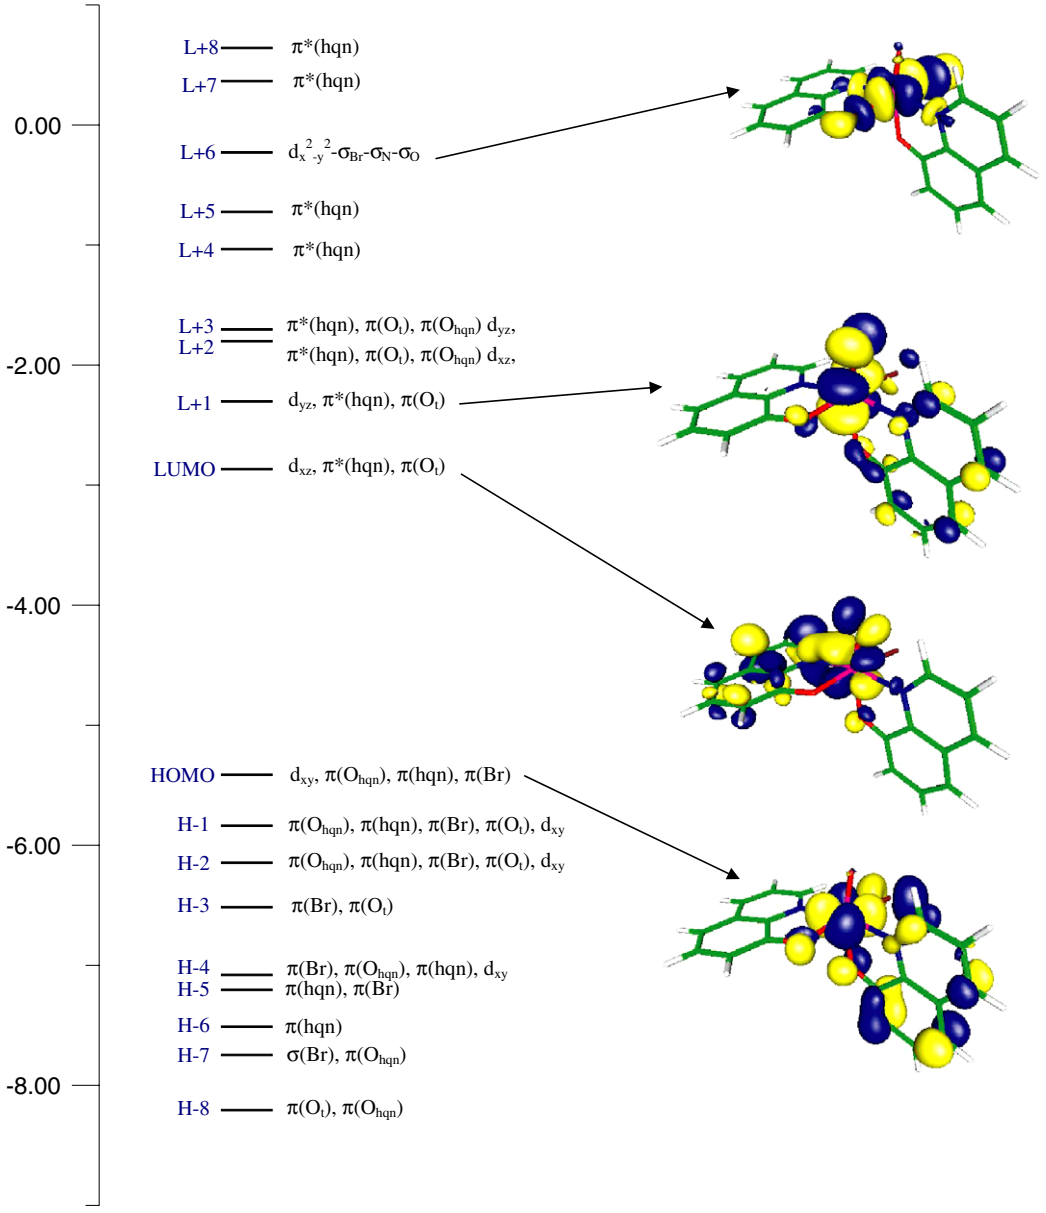

Fig. 2. The energy (eV), character and some contours of the occupied molecular orbitals of $[ReOBr(hqn)_2]$. Positive values of the orbital contours are represented in yellow (0.04 a.u.) and negative values – in blue (−0.04 a.u.). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

and the oxygen atom of hqn in the *trans* position to the terminal oxo ion, is somewhat longer than the Re(1)–O(1) bond length. It indicates a small delocalization in the O(21)–Re(1)–O(1) moiety, and a similar trend is observed for many Re(V)–oxo complexes with a monoanionic oxygen *trans* to the oxo group [7].

4.3. Geometry optimisation, charge distribution, electronic structure and NBO analysis

The geometry of $[ReOBr(hqn)_2]$ was optimised in a singlet state by the DFT method with the B3LYP functional. The optimized geometric parameters of $[ReOBr(hqn)_2]$ are gathered in Table 2. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations. Plane A is inclined at 89.79° to plane B and at 89.32° to plane C, and planes B and C are inclined at 85.63°. The oxyquinoline ring systems are planar and they are inclined at 85.44°.

Table 3 presents the atomic charges from the natural population analysis (NPA) for $[ReOBr(hqn)_2]$. The calculated charge on the rhenium atom in $[ReOBr(hqn)_2]$ is considerable lower than the formal charge of +5. It indicates significant charge donation from the ligands. The charges on the terminal oxo, oxo atoms of hqn^- and the bromide are significantly smaller than −2, −1 and −1, respectively.

The $[ReOBr(hqn)_2]$ complex is a closed-shell structure. Its molecular orbital diagram with several highest HOMO and lowest LUMO contours is presented in Fig. 2. The HOMO–LUMO gap equals 2.55 eV. The highest occupied MO of $[ReOBr(hqn)_2]$ is of d_{xy} type with some contributions from p_π bromide and hqn^- orbitals. The remaining four d-type orbitals of rhenium are found among unoccuppied MOs. It confirms the d^2 configuration of the rhenium atom.

The rhenium atom uses its six valence orbitals, $5d_{x^2-y^2}$, $5d_z^2$, 6s, $6p_x$, $6p_y$ and $6p_z$ to form σ-bonds with the six ligands, empty $5d_{xz}$ and $5d_{yz}$ orbitals are available to overlap with $2p_x$ and $2p_y$ orbitals on the terminal oxygen to form an effective triple bond. The participation of the π^*_{Re-O} interaction is visible in the LUMO, LUMO + 1, LUMO + 2 and LUMO + 3 orbitals.

The presence of a triple rhenium-terminal oxygen bond confirms the NBO analysis. The occupancy and composition of the calculated $Re–O_t$ natural bond orbitals (NBOs) are given in Table 4. The detected natural $Re–O_t$ bond orbitals of $[ReOBr(hqn)_2]$ are orbitals of π character – the p_x and p_y oxygen orbitals and d_{xz} and d_{yz} rhenium orbitals are involved in their formation. The not detected σ_{Re-O_t} bond has character of predominantly Coulomb-type interaction between the central ion and ligand [38]. Similarly, the Re–O(11), Re–O(21), Re–N(1), Re–N(11) and Re–Br(1) bonds have predominant ionic character, they all were not detected in the NBO analysis.

4.4. Electronic spectra

The experimental and calculated electronic spectra of $[ReOBr(hqn)_2]$ are presented in Fig. 3. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}. The shape of the UV–Vis spectrum of $[ReOCl(hqn)_2]$ is the same as for the bromo analogue; the absorption bands of the chloro complex were recorded at 870.8, 724.0, 406.2 and 255.0 nm.

The spin-allowed singlet–singlet electronic transitions calculated with the TDDFT method for $[ReOBr(hqn)_2]$ are gathered in Table 5. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.020 are listed in Table 5.

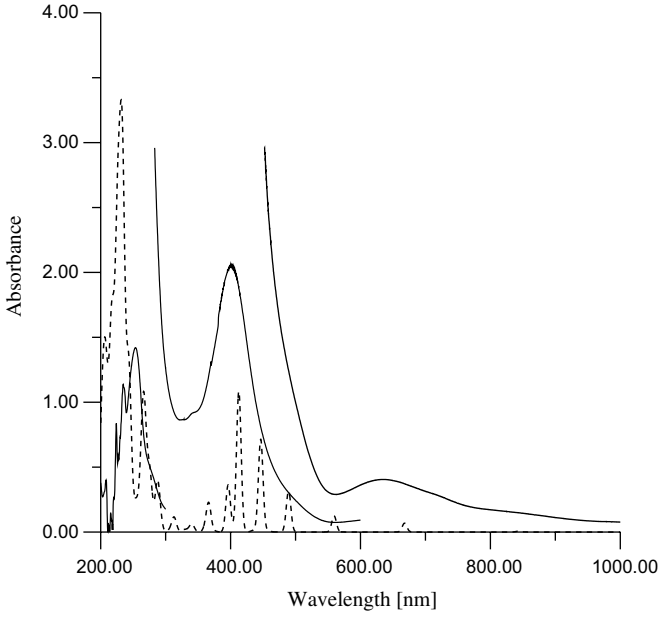

Fig. 3. The experimental electronic absorption spectrum of $[ReOBr(hqn)_2]$.

Table 4
The occupancies and composition of the calculated natural bond orbitals (NBOs) between the rhenium and the oxo ligands for $[ReOBr(hqn)_2]$

ε, molar absorption coefficient (dm^3 mol^{-1} cm^{-1}]; f, oscillator strength; H, highest occupied molecular orbital; L, lowest unoccupied molecular orbital.

The two longest wavelength experimental bands of [ReOBr(hqn)$_2$] at 843.4 and 668.0 nm are attributed to the transitions of d → d character with small oscillator strengths calculated at 865.4 and 639.0 nm, respectively. In comparison with the bromo analogue, the ligand field (LF) absorption bands of [ReOCl(hqn)$_2$] are red shifted. This can indicate a slight decrease of the HOMO–LUMO energy gap for the chloro complex.

The broad and intense absorption band with a maximum at 414.4 nm is assigned to the *metal–ligand charge transfer* (occurring from the rhenium ion to the π-antibonding orbitals of the hqn ligands) and *ligand–metal charge transfer* ($\pi_{hqn}/\pi_{Br}/\pi_O \rightarrow$ d) transitions. For the chloro analogue, the band is slightly shifted to the higher energy range.

The experimental band at 253.6 nm results from *ligand-metal charge transfer* ($\pi_{hqn}/\pi_{Br}/\pi_O \rightarrow$ d), *ligand–ligand charge transfer* and interligand (IL) transitions. For the chloro complex, the band is observed at 255.0 nm.

5. Supplementary material

CCDC 631275 contains the supplementary crystallographic data for $C_{18}H_{12}BrN_2O_3Re$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

The GAUSSIAN03 calculations were carried out in the Wrocław Centre for Networking and Supercomputing, WCSS, Wrocław, Poland.

The crystallographic part was financed by funds allocated by the Ministry Science and Higher Education to the Institute of General and Ecological Chemistry, Technical University of Łódź.

Abstract

The minerals mimetite $Pb_5(AsO_4)_3Cl$, arsenian pyromorphite $Pb_5(PO_4,AsO_4)_3Cl$ and hedyphane $Pb_3Ca_2(AsO_4)_3Cl$ have been studied by Raman spectroscopy complimented with infrared spectroscopy. Mimetite is characterised by a band at 812–3 cm^{-1} attributed to the A_g mode. For the arsenian pyromorphite this band is observed at 818 cm^{-1} and for hedyphane at 819 cm^{-1}. For mimetite and hedyphane bands at 788 and 765 cm^{-1} are attributed to A_u and E_{1u} vibrational modes and are both Raman and infrared active. For the arsenian pyromorphite, Raman bands at 917–1014 cm^{-1} are attributed to phosphate stretching vibrations. Raman spectroscopy clearly identifies bands attributable to isomorphous substitution of arsenate by phosphate. The observation of low intensity bands in the 3200–3550 cm^{-1} region are assigned to adsorbed water and OH units, thus indicating some replacement of chloride ions with hydroxyl ions.

1. Introduction

Mimetite lead chloroarsenate $Pb_5(AsO_4)_3Cl$ was named in 1835 from the Greek *mimethes*, meaning "imitator" because of its resemblance to pyromorphite $Pb_5(PO_4)_3Cl$. Mimetite is a secondary mineral of lead formed through mineralisation of the ore bodies. It is formed by the oxidation of galena and arsenopyrite. The mineral consists of small hexagonal crystals with colours ranging from pale yellow to yellowish-brown to orangish-yellow to orangish-red, white and colourless. Studies of the mimetite–pyromorphite series have been undertaken for nearly 100 years [1–3]. Mimetite has an apatite structure and forms solid solutions with pyromorphite and vanadinite [4–6]. Most crystals of mimetite–pyromorphite system are chemically zoned. Recently, the chemical variability in hedyphane was also reported in the journal American Mineralogist [7]. Although the crystal system of mimetite is known as a hexagonal (space group $P63/m$), mimetite has a dimorphic relationship with clinomimetite [8], which is a monoclinic system (space group $P2_1/m$). The phase transition between hexagonal system and monoclinic system shifts O(3) atom position in the crystal structure of mimetite [9,10].

Early investigations of the vibrational spectra of apatites including vanadinite were limited to mid-IR studies. Some early Raman studies of calcium apatites led to some questionable interpretations. Much work has been undertaken on the apatite-type minerals including mimetite, pyromorphite and vanadinite, containing the V group elements, namely As, P and V. In the apatite structure, isomorphous substitution can occur with replacement of F^- by Cl^- and also by OH groups, as in the case for selected mimetites and pyromorphites. The As(V) is replaceable by P(V) or V(V) and the Pb(II) is replaceable by for example Ca(II). Ross reported the infrared and Raman spectra of the free AsO_4^{3-} ion [11]. The v_1 band was observed at 810 cm^{-1}; v_2 at 342 cm^{-1}; v_3 at 810 cm^{-1} and v_4 at 398 cm^{-1}. Ross also reported the v_3 modes of vanadinites at 800 and

Table 1
Table of the minerals, their origin and formula

Code	Mineral	Formula	Origin
Mime 1	Mimetite	$Pb_5(AsO_4)_3Cl$	Tsumeb, Namibia
Mime 2	Mimetite	$Pb_5(AsO_4)_3Cl$	Geronimo Mine, Yuma Co., Arizona, USA
Mime 3	Mimetite	$Pb_5(AsO_4)_3Cl$	Mount Bonnie Mine, NT
Pyro 8	Arsenian pyromorphite	$Pb_5(PO_4,AsO_4)_3Cl$	Bunker Hill Mine, Kellogg, Idaho, USA
Hedy 1	Hedyphane	$Pb_3Ca_2(AsO_4)_3Cl$	Puttapa Mine, Beltana, SA

736 cm^{-1} and the v_4 modes around 419, 380 and 322 cm^{-1}. In the work mentioned by Ross the position of the v_1 and v_2 vibrations were not reported. Gadsdsen also reported the infrared spectrum of the mimetite [12]. The v_3 mode is reported as lying between 700 to 900 cm^{-1} and the v_4 mode between 300 and 410 cm^{-1}. The v_1 mode, which was not observed in the infrared spectrum as the vibration is inactive, was suggested to be at around 870 cm^{-1}. Griffith reported the Raman spectra of mimetite [13]. Levitt and Condrate reported the infrared and Raman spectra of lead apatite powdered minerals [6]. They reported the v_2 bands for mimetites at 341 and 314 cm^{-1} [6,14–16]. Single crystal Raman spectra of a mimetite at 298 K have been reported [17]. Some arsenates as for sulphates have their symmetry reduced through acting as monodentate and bidentate ligands. In the case of bidentate behaviour both bridging and chelating ligands are known. This reduction in symmetry is observed by the splitting of the v_3 and v_4 in infrared spectra into two components under C_{3v} symmetry and into three components under C_{2v} symmetry. Single crystal spectra of mimetite were reported [18]. In this paper, the v_1 band for mimetite was observed at 816 cm^{-1}, the v_3 at 809 and 787 cm^{-1}, the v_2 at 414, 390 and 335 cm^{-1} and v_4 at 424, 373 and 314 cm^{-1}.

In this work we have obtained Raman and infrared spectra of selected mimetites, arsenian pyromorphite and hedyphane and related the spectra to the structure of the minerals.

2. Experimental

2.1. Minerals

The minerals used in this work, their formula and origin are listed in Table 1. The composition of the minerals was checked by X-ray diffraction and the chemical composition by EDX measurements.

Sample 2 appears to contain some wulfenite and possibly some oxide, very low in mimetite (Arsenic low).
Sample 3 especially mimetite3b may be a mixture of mimetite and oxide (Again arsenic low, and lead higher).
Sample called mimetite3black is unusually high in Al.

2.2. Raman spectroscopy

The crystals of mimetite were placed and oriented on the stage of an Olympus BHSM microscope, equipped with 10× and 50× objectives and part of a Renishaw 1000 Raman microscope system, which also includes a monochromator, a filter system and a Charge Coupled Device (CCD). Raman spectra were excited by a HeNe laser (633 nm) at a resolution of 2 cm^{-1} in the range between 100 and 4000 cm^{-1}. Repeated acquisition using the highest magnification was accumulated to improve the signal to noise ratio. Spectra were calibrated using the 520.5 cm^{-1} line of a silicon wafer. In order to ensure that the correct spectra are obtained, the incident excitation radiation was scrambled. Raman spectra of mimetite and related arsenate minerals have been collected using a very low powered HeNe laser as the excitation radiation. The beam was slightly defocused to prevent the destruction of the samples due to self-absorption of the incident beam and consequential damage to the mineral.

Previous studies by the authors provide more details of the experimental technique. Spectra at liquid nitrogen temperature were obtained using a Linkam thermal stage (Scientific Instruments Ltd., Waterfield, Surrey, England). Details of the technique have been published by the authors [19–22].

2.3. Mid-IR spectroscopy

Infrared spectra were obtained using a Nicolet Nexus 870 FTIR spectrometer with a smart endurance single bounce diamond ATR cell. Spectra over the 4000–525 cm^{-1} range were obtained by the co-addition of 64 scans with a resolution of 4 cm^{-1} and a mirror velocity of 0.6329 cm/s. Spectra were co-added to improve the signal to noise ratio.

Spectral manipulation such as baseline adjustment, smoothing and normalisation were performed using the Spectracalc software package GRAMS (Galactic Industries Corporation, NH, USA). Band component analysis was undertaken using the Jandel 'Peakfit' software package which enabled the type of fitting function to be selected and allows specific parameters to be fixed or varied accordingly. Band fitting was done using a Lorentz–Gauss cross-product function with the minimum number of component bands used for the fitting process. The Gauss–Lorentz ratio was maintained at values greater than 0.7 and fitting was undertaken until reproducible results were obtained with squared correlations of r^2 greater than 0.995.

3. Results and discussion

3.1. EDX analyses

The predicted molecular masses of mimetite, wulfenite and lead oxide are given in Table 2. A comparison of the average of three measurements is shown. Sample 1 seems to have an analysis close to mimetite. Sample 2 is not pure and may contain some wulfenite. Sample 3 is apparently a mixture of mimetite and lead oxide.

The XRD patterns of the mimetite show that the mimetite is hexagonal, and as the phosphate increased the structure changed to monoclinic. Most crystals in the mimetite, pyromorphite series are dimorphic and the crystals show zoning.

4. Raman spectroscopy

4.1. High wavenumber region

The Raman spectra of selected mimetites and hedyphane in the 700–1050 cm^{-1} region are shown in Fig. 1. The results of the band component analysis of the Raman spectra are reported in Table 3. The Raman spectra of mimetites 1 and 3 show a strong band at 812–3 cm^{-1}. The band is attributed to the A_g mode of mimetite. For the arsenian pyromorphite the band is observed at 818 cm^{-1} and for hedyphane at 819 cm^{-1}. The mode was assigned by Adams and Gardner to both the A_g and E_{2g} modes [17]. The spectrum of mimetite 2 is not that of mimetite but a mixture of minerals. It is probably related

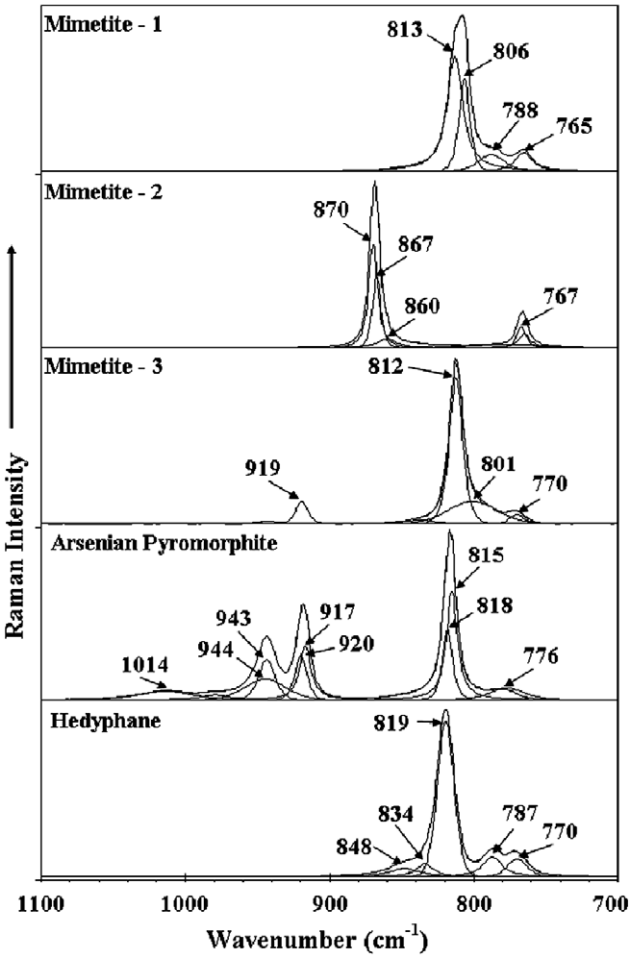

Fig. 1. Raman spectra of mimetite, arsenian pyromorphite and hedyphane in the high wavenumber region.

to the dimorphic nature of the mimetite–pyromorphite series. A second band is resolved at 806 cm^{-1} for mimetite 1 sample and 801 cm^{-1} for mimetite 3. Adams and Gardner reported a band at 808 cm^{-1} for a mimetite from Wheal Alfred Cornwall, England. For hedyphane other bands are observed on the higher wavenumber side at 834 and 848 cm^{-1}. In the Raman spectra a low intensity band is observed at around 765 cm^{-1} which Adams and Gardner also assigned to the AsO_4 stretching vibration. For mimetite 1 sample two bands are observed at 788 and 765 cm^{-1}. Similarly for hedyphane two bands are found at 787 and 770 cm^{-1}. Bands in these positions are intense in the infrared spectra and are ascribed to A_u and E_{1u} vibrational modes.

The Raman spectrum of mimetite 3 sample shows a low intensity band at 919 cm^{-1} which is ascribed to the PO symmetric stretching mode of phosphate anions in the mimetite structure. For the arsenian pyromorphite, a series of bands in the 917–1014 cm^{-1} are attributed to phosphate stretching vibrations. The bands at 917 and 920 cm^{-1} of the arsenian pyromorphite are attributed to the phosphate PO v_1 stretching vibrations. Adams and Gardner observed bands for pyromorphite at 920 and 919 cm^{-1} and assigned these bands to A_g and E_{2g} vibrational modes. These authors also stated that bands in these positions could be attributable to both v_1 and v_3 modes.

The infrared spectra of the mimetites, arsenian pyromorphite and hedyphane are shown in Fig. 2. All three

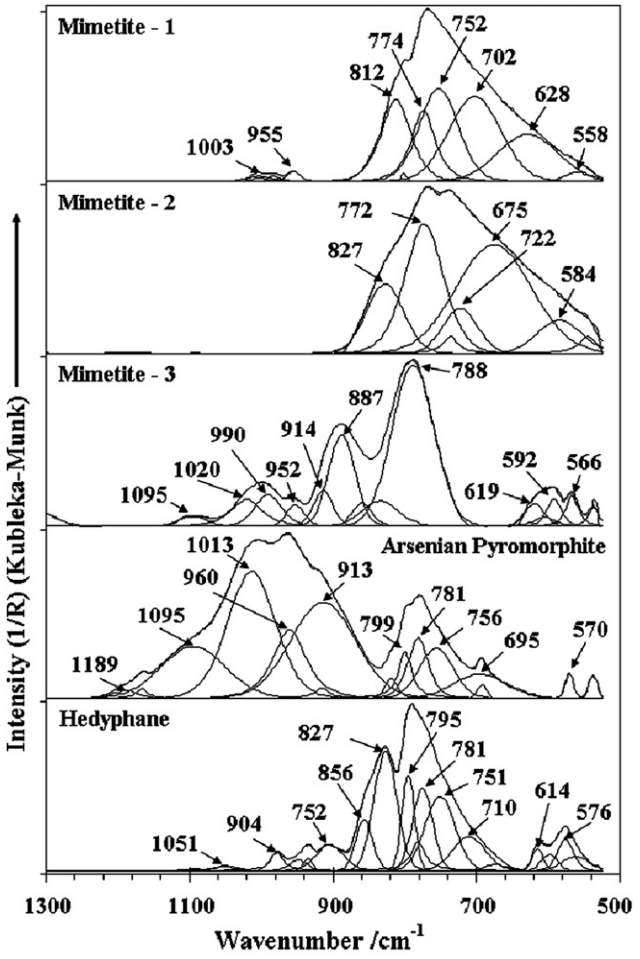

Fig. 2. Infrared spectra of mimetite, arsenian pyromorphite and hedyphane in high wavenumber region.

mimetites show a broad spectral profile in the 500–850 cm^{-1} region. Infrared bands for the mimetite 1 and 2 samples are observed at around 812, 774 and 752 cm^{-1} and are attributed to $(AsO_4)^{3-}$ stretching vibrations. Farmer published the results of the infrared spectra for mimetite at 810 and 875 cm^{-1} which are in good agreement with these results [23]. The infrared spectrum of mimetite-3 shows a series of infrared bands in the 900–1095 cm^{-1} region. These bands are attributed to $(PO_4)^{3-}$ stretching vibrations. This mimetite has substitution of the phosphate anion for arsenate. The spectrum of this mimetite closely resembles that of the arsenian pyromorphite. The infrared spectrum of this mineral shows bands at 799 and 781 cm^{-1} which are assigned to the $(AsO_4)^{3-}$ stretching vibrations. Farmer published the results of the infrared spectrum of pyromorphite [23] and stated that the ν_1 band occurred at 920 cm^{-1} and the ν_3 bands at 970 and 1030 cm^{-1}. The infrared spectrum of hedyphane shows intense bands at 827 and 795 cm^{-1} attributed to $(AsO_4)^{3-}$ stretching vibrations. Some low intensity bands at 904 and 1051 cm^{-1} are observed and these bands may be ascribed to $(PO_4)^{3-}$ stretching vibrations. Thus this is evidence for the replacement of the arsenate anion by phosphate in this mineral.

4.2. Low wavenumber region

The Raman spectra of the low wavenumber region are shown in Fig. 3. The spectra of the mimetite minerals are complex and many bands are observed. One way of addressing this complexity is to divide the spectra into sections (a) 400–450 cm^{-1} (b) 300–400 cm^{-1} and (c) less than 300 cm^{-1}. Regions (a) and (b) may be assigned to $(AsO_4)^{3-}$ bending modes; region (c) is best described as lattice vibrations. Four bands at 422, 408, 385 and 371 cm^{-1} are observed for mimetite sample 1. For mimetite sample 3 four bands are found at 425, 411, 388 and 371 cm^{-1}. These four bands are assigned to arsenate ν_4 bending modes. For the arsenian pyromorphite four bands are observed at 433, 414, 409 and 391 cm^{-1}. These bands may be ascribed to both $(AsO_4)^{3-}$ and $(PO_4)^{3-}$ bending modes. For the mineral hedyphane four bands are observed at 452, 432, 394 and 372 cm^{-1}. The effect of isomorphic substitution of Pb by Ca shifted the band positions by approximately 30 cm^{-1} when compared with mimetite. This effect could be due to zoning of the hedyphane in which the structure of the hedyphane alters from hexagonal to monoclinic. Further the effect of shielding of the arsenate anions by Ca instead of Pb results in a shift of 15–20 cm^{-1} for the arsenate bands.

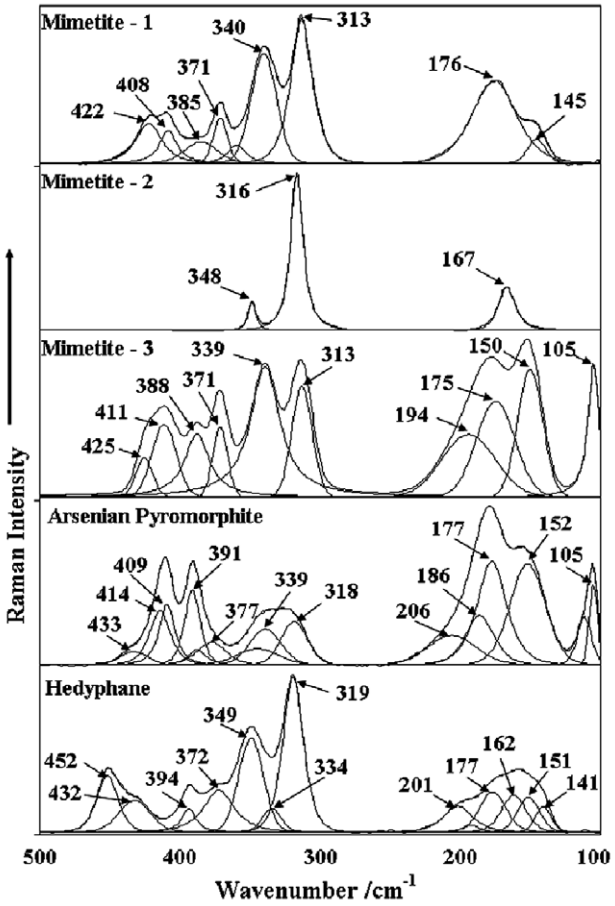

Fig. 3. Raman spectra of mimetite, arsenian pyromorphite and hedyphane in the low wavenumber region.

For mimetite sample 1 two bands are observed at 340 and 313 cm^{-1}; for mimetite sample 3 339 and 313 cm^{-1}; for arsenian pyromorphite 339 and 318 cm^{-1}; and for hedyphane 349 and 319 cm^{-1}. These bands are attributed to the v_2 bending modes. The two bands at 348 and 316 cm^{-1} for mimetite 2 are also assignable to this mode. Adams and Gardner observed Raman bands for mimetite at 335 and 314 cm^{-1} and assigned these bands to O–As–O bending modes [17].

4.3. OH stretching region

The Raman spectra of mimetite, arsenian pyromorphite and hedyphane are shown in Fig. 4. The results of the Raman spectra are reported in Table 2. The Raman spectra of mimetite shows a series of overlapping bands which are partially resolved into bands at 3716, 3548, 3420 3381 3344 and 3266 cm^{-1}. The observation of hydroxyl stretching bands is interesting in itself as according to the formula of mimetite $Pb_5(AsO_4)_3Cl$ there should be no OH bands observed at all. The observation of OH bands means that there is some isomorphic replacement of the Cl with OH units. Another explanation is that the lower wavenumber bands are ascribed to adsorbed water. The Raman spectrum in the OH stretching region of the arsenian pyromorphite also shows Raman bands at 3378, 3325 and 3256 cm^{-1}. The Raman spectrum in the OH stretching region of hedyphane $Pb_3Ca_2(AsO_4)_3Cl$ shows a band at around 3400 cm^{-1} superimposed upon a broad background. This suggests that there is some isomorphic replacement of the Cl units for OH units.

Studies have shown a strong correlation between OH stretching frequencies and both O···O bond distances and H···O hydrogen bond distances [24–27]. Libowitsky (1999) showed that a regression function can be employed relating the above correlations with regression coefficients better than 0.96 [28]. The function is $v_1 = 3592–304 \times 10^9 \exp(-d(O–O)/0.1321)$ cm^{-1}. What this means is that the variation in the water hydroxyl stretching frequency is a measure of the hydrogen bond strength between the OH unit of the water and the arsenate or phosphate anion. If the band positions of the OH stretching vibrations are used in the calculations then estimates of the hydrogen bond distances can be made. For the band at 3400 cm^{-1} for hedyphane a hydrogen bond distance of 2.80 Å is calculated, for arsenian pyromorphite the bands at 3256, 3325 and 3378 cm^{-1} give hydrogen bond distances of 2.72, 2.75 and 2.78 Å; for mimetite hydrogen bond distances of 2.72 Å (3266 cm^{-1}), 2.76 Å (3304 cm^{-1}), 2.78 Å (3381 cm^{-1}) and 2.99 Å (3548 cm^{-1}). The hydrogen bond distances are of the same order of magnitude for each of the mimetites and vary between 2.72 and 2.99 Å. It is possible that some substitution of OH units for Cl in the mimetite structure is required for stability.

Infrared bands are observed at around 628 cm^{-1} for mimetite 1, 675 for mimetite 2, in the 590–619 cm^{-1} region for mimetite 3. These bands are attributed to OH librational modes and although not of a high intensity confirm the presence of OH units in the mimetite structure and thus confirms the replacement of Cl by OH units.

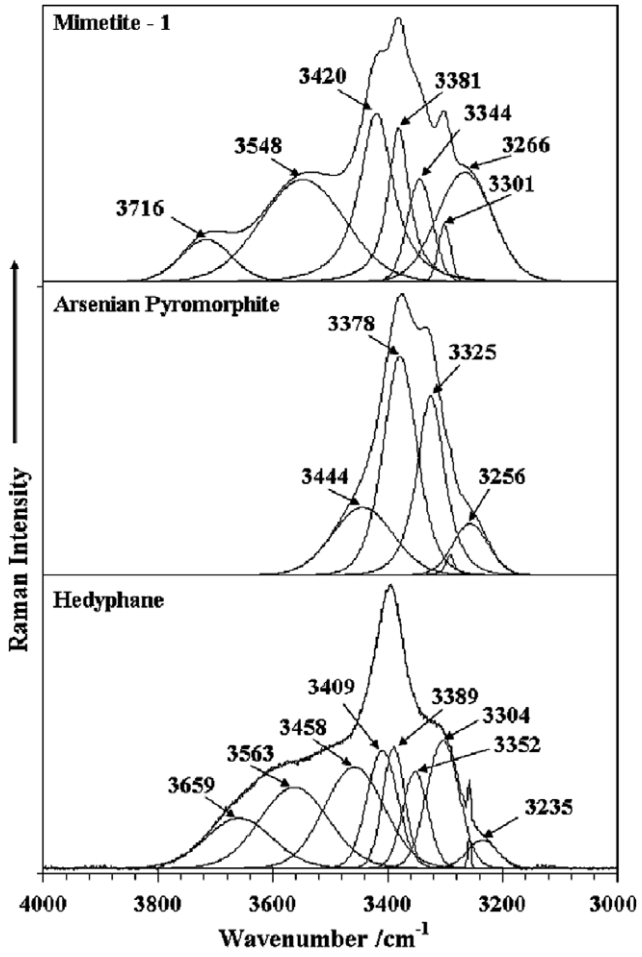

Fig. 4. Raman spectra of mimetite, arsenian pyromorphite and hedyphane in the OH stretching region.

5. Conclusions

A comparison of Raman spectra of mimetites with published infrared and Raman data of similar minerals has been made. Crystals of the mimetite–pyromorphite series are chemically zoned, resulting in changes in the crystal structure with the isomorphic replacement of arsenate by phosphate with the consequential change in crystal structure from hexagonal to monoclinic. Such dimorphic relationships are exemplified by the shift in the Raman spectral band positions of arsenate with increasing phosphate substitution.

This work clearly demonstrates the power of Raman spectroscopy as compared to infrared spectroscopy in determining the vibrational spectrum of these arsenates with an apatite structure. Isomorphous substitution of arsenate by phosphate in the case of mimetite and the substitution of phosphate by arsenate in the case of the arsenian pyromorphite are clearly identified. Further the replacement of Cl with OH units is also observed in the Oh stretching region

of the Raman spectra and the librational region of the infrared spectra. The application of Raman microscopy to the study of closely related mineral phases has enabled their molecular characterisation using their Raman spectrum thus enabling the rapid identification of phases in complex mixtures of secondary lead containing arsenates from the oxidised zones of base metal ore bodies.

Abstract

Reaction of aqueous solutions of $Ni(NO_3)_2$ and pyridoxal semicarbazone (PLSC) in the presence of NaN_3 afforded two complexes, viz. green, paramagnetic binuclear octahedral $[Ni_2(PLSC)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]\cdot 2H_2O$ (**1**) and, as admixture, red, octahedral $[Ni(PLSC–H)_2]\cdot 2H_2O$ (**2**) complex. Under the same reaction conditions, pyridoxal thiosemicarbazone (PLTSC) gave only one diamagnetic square-planar, red complex $[Ni(PLTSC–H)N_3]\cdot H_2O$ (**3**). In the absence of NaN_3, the reaction of PLTSC and $Ni(NO_3)_2$ yielded brown paramagnetic octahedral complex $[Ni(PLTSC)_2](NO_3)_2\cdot H_2O$ (**4**).

The complexes were characterized by elemental analysis, conductometric and magnetochemical measurements, IR and UV–Vis spectra, and the octahedral complexes **1**, **2** and **4** also by X-ray monocrystal diffraction method.

1. Introduction

Because of their simple preparation, excellent complexation of not only transition but also non-transition p-elements, interesting structural characteristics of their complexes, along with the possibility of their analytical application, semi- and thiosemicarbazones have become a subject of intense research interest of coordination chemists. This has resulted in a large number of papers and several reviews [1–4] that summarized various aspects of the chemistry of these compounds, such as methods of their synthesis, spectral, magnetic, stereochemical, structural, and other characteristics. An enhanced interest in these compounds has undoubtedly aroused the discovery of their biological activity. This is especially related to thiosemicarbazones and their complexes, which show a wider spectrum of biological activity than semicarbazones. Namely, it has been shown that many thiosemicarbazones and their complexes are active against viruses, bacteria, cancer, fungi, and malaria, which has been summarized in the reviews of West et al. [5,6] and Beraldo and Gambino [7]. Some thiosemicarbazones and their metal complexes such as marboran or triapine, are already used in medical practice [8].

One of thiosemicarbazone ligands that have been attracting attention of coordination and structural chemists for more than 20 years, and more recently of pharmacologists too, is the tridentate ONS, unsubstituted and substituted PLTSC (pyridoxal thiosemicarbazone). Namely, this ligand appeared to be a good complexing agent for various metals, and some of its derivatives showed a certain biological activity [8]. In contrast to this ligand, the interest in the coordination and structural

doi:10.1016/j.poly.2007.01.041

chemistry of its oxygen analogue, i.e. tridentate ONO pyridoxal semicarbazone (PLSC), is of a much recent date, so that the number of its investigated complexes is significantly smaller and limited to the complexes of Cu, Fe and Pt.

The most important results gained in studying metal complexes of these two ligands, including also complexes with pyridoxal isothiosemicarbazone, have been reviewed by Leovac et al. [9].

In our most recent work [10] we described the syntheses and some physical and structural characteristics of first mono(ligand) complexes of Ni(II) with PLSC, of the general formula $Ni(PLSC)X_2 \cdot nH_2O$ (X = Cl, NO_3, NCS), as well as two new complexes with PLTSC, [Ni(PLTSC–H)py]NO_3 and [Ni(PLTSC–H)NCS]. In this work we report the syntheses and structures of the first bis(ligand) complexes of Ni(II) with the mentioned Schiff bases, as well as of two mono(ligand) complexes.

2. Experimental

All commercially obtained reagent-grade chemicals were used without further purification, except for the ligands, which were prepared according to the previously described procedures [11].

Elemental (C, H, N) analysis of air-dried samples was carried out by standard micromethods in the Center for Instrumental Analysis, Faculty of Chemistry, Belgrade.

2.1. Synthesis of complexes

2.1.1. $[Ni_2(PLSC)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2] \cdot 2H_2O$ (**1**) and $[Ni(PLSC–H)_2] \cdot 2H_2O$ (**2**)

A mixture of 0.26 g (1 mmol) of $PLSC \cdot 2H_2O$ and 0.29 g (1 mmol) of $Ni(NO_3)_2 \cdot 6H_2O$ was dissolved by heating in 10 cm^3 of H_2O and 0.16 g (2.5 mmol) NaN_3 added to the warm solution. After 5 h, the green-reddish solution afforded dark-green crystals of complex **1** and a small amount of red crystals of compound **2**. The crystals were filtered off and washed with H_2O. Yield: 0.26 g (67%).

Complex **1** – *Anal.* Calc. for $Ni_2C_{18}H_{28}N_{20}O_8$: C, 28.07; H, 3.64; N, 36.39. Found: C, 27.67; H, 4.01; N, 35.68%. Λ_M (DMSO): 30.5 S cm^2 mol^{-1}. $\mu_{eff} = 2.80$ BM. λ_{max}/nm ($\varepsilon \times 10^{-3}$/$mol^{-1}$ dm^3 cm^{-1}) (DMF): 288 (28.5); 401 (16.2); 420 (5.0); 635 (0.063); 965 (0.030).

Complex **2** – *Anal.* Calc. for $NiC_{18}H_{26}N_8O_8$: C, 39.96; H, 4.84; N, 20.71. Found: C, 39.63; H, 4.92; N, 20.95%. Λ_M (DMF): 7.2 S cm^2 mol^{-1}. λ_{max}/nm ($\varepsilon \times 10^{-3}$/$mol^{-1}$ dm^3 cm^{-1}) (DMF): 286 (21); 404 (14); 421 (2.5); 636 (0.033); 949 (0.028).

2.1.2. $[Ni(PLTSC–H)N_3] \cdot H_2O$ (**3**)

A mixture of 0.15 g (0.5 mmol) of $PLTSC \cdot 2H_2O$ and 0.15 g (0.5 mmol) of $Ni(NO_3)_2$ was dissolved by heating in 10 cm^3 of H_2O and the warm solution of 0.07 g (1 mmol) of NaN_3 in 5 cm^3 of H_2O added to it. Red microcrystals that appeared already from the warm solution were filtered after 3 h and washed with H_2O and MeOH. Yield: 0.07 g (70%).

Anal. Calc. for $NiC_9H_{13}N_7O_3S$: C, 30.19; H, 3.66; N, 27.39. Found: C, 30.32; H, 3.61; N, 26.98%. Λ_M (DMF): 7.5 S cm^2 mol^{-1}. $\mu_{eff} = 0$ BM (diamagnetic). λ_{max}/nm ($\varepsilon \times 10^{-3}$/$mol^{-1}$ dm^3 cm^{-1}) (DMF): 296 (11.1); 328 (8.9); 400 (17.1); 474sh (1.7) (sh – shoulder).

2.1.3. $[Ni(PLTSC)_2](NO_3)_2 \cdot H_2O$ (**4**)

The mixture of 0.20 g (0.7 mmol) of $Ni(NO_3)_2$ and 0.15 g (0.5 mmol) of $PLTSC \cdot 3H_2O$ was poured over with 5 cm^3 H_2O and dissolved by heating. After 24 h, the obtained brown crystals were filtered and washed with H_2O and EtOH. Yield: 0.15 g (43%).

Anal. Calc. for $NiC_{18}H_{26}N_{10}O_{11}S_2$: C, 31.18; H, 3.92; N, 20.37. Found: C, 31.52; H, 3.81; N, 20.19%. Λ_M (H_2O): 202 S cm^2 mol^{-1}. $\mu_{eff} = 3.01$ BM. λ_{max}/nm ($\varepsilon \times 10^{-3}$/$mol^{-1}$ dm^3 cm^{-1}) (DMF): 336bp (12); 357 (1.4); 409 (7.0); 425(1.5); 472sh (1.0); ~836 (0.016); 977 (0.012); 1060 (0.008); 1200 (0.044) (bp – broad peak).

2.2. Physical measurements

Magnetic susceptibilities were measured at room temperature using a magnetic susceptibility balance MSB-MKL (Sherwood Scientific Ltd. Cambridge, England).

Molar conductivities of the freshly prepared 1×10^{-3} M solutions were measured on a Jenway 4010 conductivity meter.

IR spectra (KBr disk) were recorded on a Thermo Nicolet (NEXUS 670 FT-IR) instrument.

Electronic spectra of DMF solutions of complexes were recorded on a Secomam (Anthelie 2, Advanced, for the spectral range of 270–900 nm) spectrophotometer and on a Thermo Nicolet instrument (NEXUS 670 FT-IR, for the range 900–1400 nm).

2.3. Crystal structure determination

A single crystal, of the dimensions $0.2 \times 0.2 \times 0.1$ mm, $0.3 \times 0.3 \times 0.2$ mm, and $0.3 \times 0.2 \times 0.2$ mm, of complexes **1**, **2** and **4**, respectively, was mounted on a SMART (complex **1** and **2**) and Philips diffractometer (complex **4**) with Mo Kα radiation [$\lambda = 0.7107$ Å]. The structure was solved by direct methods using SIR97 [12] and refined using SHELXL97 [13] on F_2 by full matrix least squares with anisotropic displacement parameters for all atoms but the hydrogen atoms. All hydrogen atoms were found on a difference map. Final refinement converged to an $R_1 = 0.0256$ and a $wR_2 = 0.0699$ (complex **1**), $R_1 = 0.0283$ and a $wR_2 = 0.0817$ (complex **2**), and $R_1 = 0.0505$ and a $wR_2 = 0.1068$ (complex **4**). Experimental details for the X-ray data collection are reported in Table 1. The refinement procedure was carried out using the WINGX package [14] with the program PARST [15] for the geometrical description of the structures and ORTEP [16] and PLUTO [17] for the structure drawings.

3. Results and discussion

3.1. Syntheses and physical characteristics of complexes

As can be seen from the coordination formula of the newly prepared Ni(II) complexes with PLSC and PLTSC, we are concerned with two mono- and two bis(ligand) complexes, of which complex **1**, thanks to the bridging role of the two azide ligands, represents the first authentic binuclear Ni(II) complex involving PLSC ligand.

Also, the first, but bis(PLSC/PLTSC) complexes of Ni(II) represent the compounds **2** and **4**. All complexes, including bis(ligand) complexes, were obtained from aqueous solutions, by the reaction of Ni(II) and Schiff base in a mole ratio 1:1 (Scheme 1) except for **4** where $Ni(NO_3)_2$ is in a 40% excess. It should be noticed that both PLSC complexes were obtained from the same reaction mixture, that is warm aqueous solutions of $Ni(NO_3)_2\cdot 6H_2O$, PLSC and NaN_3, whereby binuclear complex **1** was obtained as the main product and complex **2** as admixture. In the absence of azide, PLSC and $Ni(NO_3)_2$ would produce a complex of the formula $[Ni(PLSC)(H_2O)_3](NO_3)_2$ [10].

Scheme 1.

In contrast to PLSC, under the same reaction conditions, the reaction of PLTSC and $Ni(NO_3)_2$ in the presence of NaN_3 gave only one complex, viz. **3**. In the absence of NaN_3, the reaction of PLTSC and $Ni(NO_3)_2$ gave the brown bis(PLTSC) complex **4**. All complexes are stable in air. In contrast to complex **4**, which is well soluble in H_2O, DMF and DMSO and less soluble in alcohols, the other complexes are much less soluble. This is especially characteristic of complex **1**, which is in agreement with its dimeric structure. Molar conductivities correspond to the coordination formulas of the complexes. With the exception of complex **3**, which is diamagnetic, complexes **1** and **4** are paramagnetic, with the μ_{eff} values corresponding to octahedral Ni(II) complexes. The poor yield of complex **2**, whose crystals for the purpose of the analyses had to be separated mechanically from **1**, was the reason why it could not be characterized by magnetic measurements.

The presence of one or more bands in the IR spectra of complexes about 2850 cm^{-1} has been ascribed [18,19] to the $\nu(NH^+)$ vibrations, i.e. to the dipolar nature of the PL moiety, with a certain contribution of the ν(OH) of the hydroxyl group. In view of the fact that in the IR

spectrum of complex **2** there exist a medium-intensity band at 2876 cm^{-1} it can be concluded that it belongs to the ν(OH) of the CH_2OH group. It should be pointed out that the ν(C=O) band, which in the spectrum of free ligand occurs at 1680 cm^{-1}, is in the spectra of both PLSC complexes shifted due to coordination to lower energies by 15 cm^{-1} (complex **1**) and 39 cm^{-1} (complex **2**).

In the IR spectra of both azide complexes there is one $\nu_a(N_3)$ band, recognizable by its strong intensity, occurring at 2049 cm^{-1} (complex **1**) and 2064 cm^{-1} (complex **3**). It is interesting to note that this band in complex **1**, which contains differently coordinated azide ligands, two monodentate and two $\mu_{1,1}{}^{-}N_3$, is not split as in the case of the spectrum of the similar dimeric complex $[Ni_2(L)_2(\mu_{1,1}\text{-}N_3)_2(N_3)_2]$ (L = tridentate NNN ligand) [20].

3.2. Electronic spectra

The spectra of the complexes in DMF (in the range of 270–1200 nm) display several electronic transitions.

The spectrum of the diamagnetic azide complex **3** in DMF (as well in DMSO, not presented because of negligible difference) is the simplest. The bands at $\lambda < 360$ nm belong to intraligand transitions ($\pi \rightarrow \pi^*$, $n \rightarrow \pi^*$). Two bands at 400–474 nm may originate from LMCT and d–d electron transfer, respectively. Since no other d–d bands were observed up to 1200 nm, the simplicity of the spectra and the corresponding band intensities suggest the square-planar rather than tetrahedral configuration of the complex in solution [21].

The spectra of the other three complexes have certain similarities arising from their close geometric configuration. The spectrum of $[Ni(PLTSC)_2](NO_3)_2$ (**4**) in UV range is rather unresolved, consisting of two complex bands which are due to intraligand and LMCT transitions, respectively. On the other hand, the d–d spectral data (the bands at $\lambda_{max} > 470$ nm) for this complex in solution seem to support its distorted octahedral geometry.

The semicarbazone complexes **1** and **2** are slightly soluble in DMF, forming yellow solution. The spectra of both complexes are very similar in the whole range: the intraligand transitions (up to about 300 nm), those of CT (about 400 nm) and d–d transitions with three main bands corresponding to a distorted octahedral structure: at about 420, 635, and 940 nm. The first band, which is complex, is partly due to LMCT transition as was recorded for the mono(ligand) semicarbazone complexes [10].

3.3. Description of the structure of $[Ni_2(PLSC)_2\text{-}(\mu_{1,1}N_3)_2(N_3)_2]\cdot 2H_2O$ (1)

Experimental details are given in Table 1 and bonds and angles in Table 2. The analysis of the crystal structure of **1** shows its dimeric nature. The asymmetric unit consists of a tridentate ONO neutral ligand chelating the nickel atom together with three azides, two of which end-on (EO) bridging. The two halves of the dimer are related by a crystallographic inversion center, which lies at the center of the four-membered ring formed by the two Ni atoms and the coordinating atoms of the two bridging azide anions. An ORTEP view of the complex is shown in Fig. 1.

Table 2
Selected bond distances (Å) and angles (°) for complex **1**

Ni1–Ni1′	3.227(1)	Ni1′–Ni1–O1	97.65(4)
Ni1–O1	2.082(2)	Ni1′–Ni1–O2	90.12(4)
Ni1–O2	1.989(1)	Ni1′–Ni1–N3	136.09(5)
Ni1–N3	2.029(2)	Ni1′–Ni1–N5	41.46(5)
Ni1–N5	2.078(2)	Ni1′–Ni1–N8	136.78(5)
Ni1–N8	2.132(2)	O1–Ni1–O2	167.48(7)
Ni1A–N5	2.164(2)	O1–Ni1–N3	78.98(7)
		O1–Ni1–N5	100.67(7)
		O1–Ni1–N8	88.08(7)
		O2–Ni1–N3	88.61(7)
		O2–Ni1–N5	91.66(7)
		O2–Ni1–N8	92.97(7)
		N3–Ni1–N5	177.52(8)
		N3–Ni1–N8	87.11(7)
		N5–Ni1–N8	95.34(8)
		Ni1–Ni1′–N5	39.49(5)

′ = −x + 1, −y + 1, −z + 2.

The nickel atom presents a distorted octahedral geometry, where the N3–Ni–N5 and N8–Ni–N5′ are 177.52(7)° and 176.02(7)° respectively, very close to the theoretical 180°, but the O1–Ni–O2 is 167.48(6)°, due to the chelation rings strain.

In this compound the C–N–C angle of the pyridoxal ring is 124.4(2)°, revealing thus the protonation of the nitrogen (deprotonation of the phenolic oxygen), which is in agreement with the presence of two azides for each Ni(II) ion, to balance the metal positive charges. For the protonated pyridoxal nitrogen, angles reported in the literature are larger than 120° [9,22].

The whole ligand molecule, due to the extended system of conjugated double bonds, is almost planar, whereby the angle between the average planes of the hydrazone moiety and that of the pyridoxal ring is 11.40(8)°. The five-membered chelation ring has a $q_2 = 0.102(2)$ Å and a $\varphi_2 = -18(1)°$, corresponding to a twist ($^1T_5$) conformation, while the six-membered ring has a $\varphi_2 = 109.1(8)°$ and a

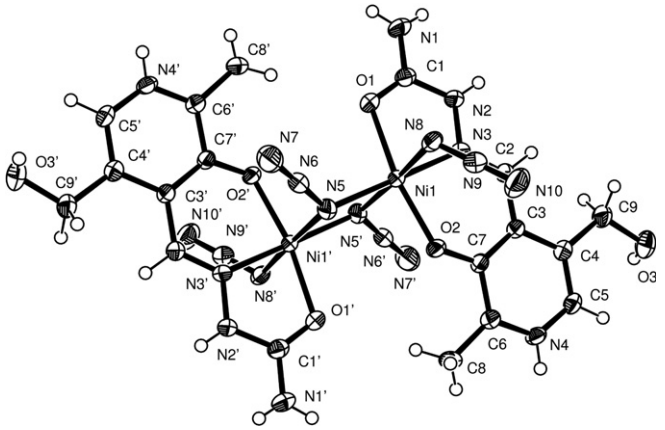

Fig. 1. ORTEP view of complex **1**.

total puckering amplitude of 0.141(2) Å [$\Theta_2 = 102.9(9)°$], corresponding to a boat (^{3,6}B) conformation.

The Ni···Ni′ separation is 3.227(1) Å, that is too long for a metal–metal bond [23] and in perfect agreement with the average value of 3.22(1) Å found for the Ni···Ni′ distances in the CSD (Cambridge Structural Database) [24] for azido-bridged Ni dimers. Ni(II) complexes with EO bridge(s) are ferromagnetically coupled, with the Ni–N–Ni angle(s) close to 103° or in any case in the range from 100° to 105° [25]. In this case, it is interesting to note that the Ni–N5–Ni° angle is 99.05(8)°.

The packing (Fig. 2) is determined by an extended network of hydrogen bondings as can be seen from Table 3.

3.4. Description of the structure of $[Ni(PLSC–H)_2]\cdot 2H_2O$ (2)

The analysis of the crystal structure of **2** has been carried out and the experimental details are presented in Table 1, whereas its geometrical features (bond distances and angles) are given in Table 4. The asymmetric unit consists of a tridentate monodeprotonated ligand molecule chelating the nickel atom, which lies in a special position on a binary axis, and a water molecule (see Fig. 3).

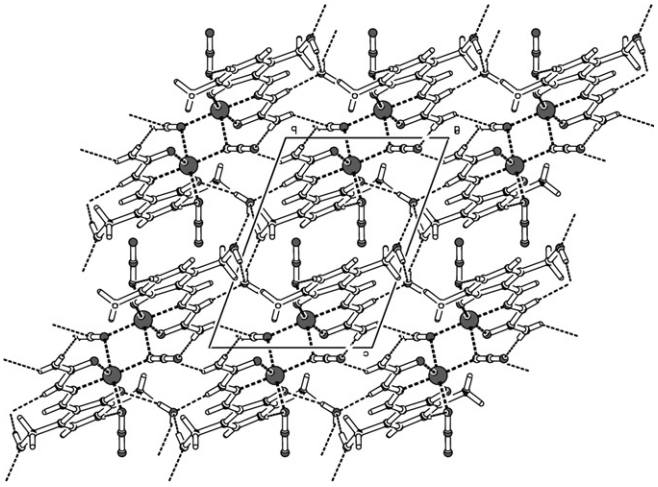

Fig. 2. Crystal structure of complex **1**, view in the *yz* plane.

Table 3
Hydrogen bonds for compound **1**

Donor···acceptor	donor–H···acceptor

2.870(4)	164(3)

Equivalent positions: (0) x, y, z; (1) $x+1$, $+y$, $+z$; (2) $-x+2$, $-y+1$, $-z+1$; (3) $x+1$, $+y-1$, $+z$; (4) x, $+y-1$, $+z$.

Table 4
Selected bond distances (Å) and angles (°) for complex **2**

Ni1–O1	2.109(2)	O1–Ni1–O1^{I}	87.4(1)
Ni1—O2	1.976(2)	O1–Ni1–O2	166.9(1)
Ni1–N3	2.002(2)	O1–Ni1–O2^{I}	90.4(1)
		O1–Ni1–N3	78.5(1)
		O1–Ni1–N3^{I}	97.3(1)
		O2–Ni1–O2^{I}	94.6(1)
		O2–Ni1–N3	88.9(1)
		O2–Ni1–N3^{I}	94.9(1)
		N3–Ni1–N3^{I}	174.3(1)

$' = -x, y, -z + 1/2$.

The nickel atom presents a distorted octahedral geometry: in fact, the N3–Ni–N3′ angle [174.32(8)°] is very close to the theoretical 180°, but the other two, symmetry-related, O1–Ni–O2′ and O2–Ni–O1′ are 166.86(5)°, due to the chelation rings strain. In the ligand, the pyridoxal nitrogen is deprotonated and this is confirmed by the narrow angle C5–N4–C6 of 118.4(2)° (in protonated pyridoxal moieties, as said before, the reported angles are larger than 120° [9,22]). The whole ligand molecule, which possesses an extended system of conjugated double bonds and should be planar, is on the contrary significantly distorted, and the angle between the average planes of the hydrazone moiety and that of the pyridoxal ring is 26.07(8)°. The strain due to the coordination accounts for the larger distortion observed for the five-membered compared to the six-membered chelation ring. The five-membered ring has a $q_2 = 0.132(2)$ Å and a $\varphi_2 = 22.2(9)°$, corresponding to a twist (^{1}T$_2$) conformation while the six-membered ring has a $\varphi_2 = -30.4(4)°$ and a total puckering amplitude of 0.359(2) Å [$\varphi_2 = 62.2(3)°$] that corresponds to a skew

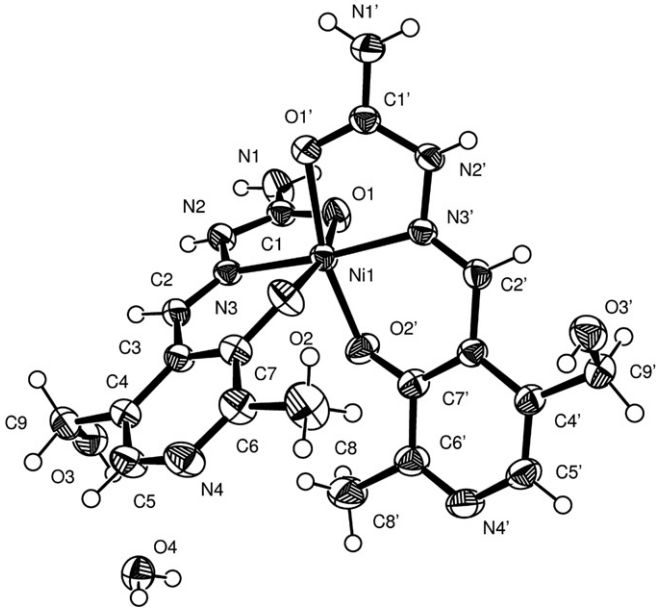

Fig. 3. ORTEP view of complex **2**.

(1S2) conformation. The packing (Fig. 4) is determined by an extended network of hydrogen bondings, as can be seen from Table 5.

3.5. Description of the structure of $[Ni(PLTSC)_2](NO_3)_2 \cdot H_2O$ (4)

The crystal structure of this complex was also determined and the corresponding experimental details are given in Table 1, while the bonds and angles are presented in Table 6. The asymmetric unit consists of a tridentate neutral ligand chelating the nickel atom, two nitrate ions, and one water molecule (see Fig. 5).

In this complex, the angles between the mean plane of the pyridoxal ring and that of the thiosemicarbazide moiety in the two ligands are 33.10(9)° and 31.65(8)°, and this is larger than reported for the hydrazone ligands, probably because of the larger strain due to a bulkier sulfur atom in the five-membered chelation ring. In this compound, the C5–N4–C6 angles of the pyridoxal rings are larger than 120° [124.7(3)° and 125.2(3)°], suggesting the protonation of the nitrogen, which is in agreement with the presence of two nitrates that balance the nickel positive charges.

2.663(.004)	156.1(2)

Equivalent positions: (0) x, y, z; (1) $-x+1, -y+1, -z+1$; (2) $-x, -y+1, -z$; (3) $-x, -y, -z$; (4) $x, +y+1, +z$; (5) $-x+1, -y, -z+1$; (6) $-x+1, -y+1, -z$.

The packing (Fig. 6) of this compound is determined by a large network of hydrogen bonds, a few of which are bifurcated among the complex molecules, the nitrate ions and the water molecule, the corresponding values being given in Table 7.

4. Conclusion

On the basis of the previous [9] and present X-ray structures it can be concluded that both ligands are coordinated via the ONX (X = O, PLSC; X = S, PLTSC) set of donor atoms, that is oxygen atom of the phenolic hydroxyl, hydrazine nitrogen, and oxygen or sulfur atom of the semi-/thiosemicarbazide moiety, forming thus one five- and one six-membered metallocycle. Also, it was found that both ligands can coordinate not only in neutral and monoanionic but also in their dianionic forms. The monoanionic form appears as a result of deprotonation of the enol/thiol form of the semi-/thiosemicarbazide moiety, while the dianionic form results from the additional deprotonation of the zwitterion PL moiety. Isolation of complex **2**, which contains monoanionic form of both PLSC molecules with deprotonated pyridine nitrogen atom, and not the enol form of the SC-residue, which has been proved by X-ray analysis, is in contrast to the above sequence of PLSC deprotonation. It should be noted that the order of PLTSC deprotonation is not questionable, since it has been confirmed by the X-ray analysis of several complexes [9].

Available online 20 February 2007

Abstract

Two novel three-dimensional (3-D) heterometallic frameworks containing dinuclear p-block metal–oxygen clusters, formulated as $[Na_2(H_2O)_3Cu_2(H_2O)_6(sip)_2]\cdot H_2O$ **1** and $[K_2(H_2O)_2Cu_2(H_2O)_5(sip)_2]\cdot H_2O$ **2** (sip^{3-} = 5-sulfoisophthalic anion), have been synthesized at room temperature. Single-crystal X-ray diffraction revealed that similar structural motifs (one-dimensional zigzag chain built by copper atoms and sip^{3-} ligands, and dinuclear p-block metal–oxygen clusters) can be found within their crystal structures. Compound **1** shows an interesting 3-D structure constructed from copper-sip chains interconnected by two kinds of dinuclear sodium–oxygen clusters adopting 4- and 6-connected fashions. Compound **2** displays a 3-D framework formed by cross-linking copper-sip chains via 6-connected dinuclear potassium–oxygen clusters. Interestingly, an irreversible structural conversion from **1** to **2** was observed.

1. Introduction

Crystal engineering of metal-organic frameworks (MOFs) is realizable by the choice of metals and the numerous choice and design of ligands [1–5], which bears the weight of prospective applications in new chemical separation, molecular selection, ion exchange, gas adsorption and storage [6–9]. Recently, research targets have been focused upon the chemical design of heterometallic MOFs (denoted HMOFs hereafter) with intriguing topologies and fascinating properties. An increasing number of HMOFs containing d- and f-block metals, especially 3d–4f ones, have been successfully isolated and well investigated [10–14].

At the same time, alkali cations have captured more and more research attention from chemists and materials scientists owing to their low polarizability and various coordination modes to construct polymer materials featuring robust structures and predominant properties. Integration of p-block alkali metals into HMOFs may result in new materials with potential applications in magnetic ordering, catalytic and biological recognition [15]. However, HMOFs based on p-block metals have not been well exploited until now, and the successful preparation of p–d HMOFs still remains a synthetic challenge not only because of the difficulties in controlling the synergistic interactions between two kinds of distinct metal cations, but also in exploring organic ligands or co-ligands as suitable linkers.

In this work, a bifunctional (carboxylate and sulfonate) ligand, the 5-sulfoisophthalic anion (sip^{3-}), has been chosen to build HMOFs owing to the following two considerations: (a) it is well known that mixed ligands or a multifunctional ligand is required to realize the combination of metals with distinct electric configurations in HMOFs. However, the introduction of mixed ligands may lead to the occurrence of coordination competition

doi:10.1016/j.poly.2007.01.057

between different kinds of ligands, and a simple MOF built of a metal and organic ligand with a coordination preference is more likely to be obtained. In this regard, employment of a multifunctional ligand is a reasonable choice to achieve a HMOF by means of its distinctive functional groups; and (b) carboxyl ligands have been demonstrated to be a predominant structural linkage to construct MOFs with transition metals [1–5,10–14], and organic sulfonates prefer to coordinate to main group metals, especially alkaline metals and alkaline earth metals [16–18]. Very recently, Kitagawa and co-workers have reported a p–d HMOF prepared by using mixed carboxylate and sulfonate group ligand and proved that the alkali metal acts as an affinity site on the pore surface for guests and their adsorption [19]. On examination of the literature, it is found that the sip ligand adopts complicated coordination modes in transition metal-organic polymers because of its various coordination fashions and high coordination numbers that made it difficult to predict the final framework structures on the basis of rational design [20–23]. However, what captured our attention is that the sulfonate groups of sip ligands often remain uncoordinated, and thus the sip ligands exhibit relatively simple coordination modes similar to isophthalato ligands, when it coordinates to copper atoms. Furthermore, these resulting low-dimensional (0- or 1-D) copper-organic frameworks, partly a consequence of the chelating coordination fashion of the sip ligand, possess uncoordinated sulfonate groups pointing outward a cluster [24] or throwing out a chain like a fish-bone [25]. Such kind of arrangement of free sulfonate groups can offer effective coordination positions and a considerable spatial void for secondary p-block metals, favoring the formation of p–d HMOFs.

Inspired by our early research experience of the sip ligand and other sulfonate containing ligands [21–23,25,26], we isolated successfully two novel HMOFs by trial and error, formulated as $[Na_2(H_2O)_3Cu_2(H_2O)_6(sip)_2]\cdot H_2O$ **1** and $[K_2(H_2O)_2Cu_2(H_2O)_5(sip)_2]\cdot H_2O$ **2** (sip^{3-} = 5-sulfoisophthalic anion). Structural analyses indicate that **1** and **2** feature similar 3-D frameworks comprising dinuclear p-block metal–oxygen clusters. **1** possesses an interesting framework constructed from copper-sip chains interconnected by two kinds of dinuclear sodium–oxygen clusters adopting 4- and 6-connected fashions. **2** displays a 3-D framework formed by cross-linking similar 1-D copper-sip chains via 6-connected potassium–oxygen clusters. Interestingly, an irreversible structural conversion from **1** to **2** was observed.

2. Experimental

2.1. General

All chemicals were commercially purchased and were used without purification. Elemental analyses were carried out on an Elementar Vario EL III analyzer. Infrared (IR) spectra were recorded with Perkin–Elmer Spectrum One as KBr pellets in the range 400–4000 cm^{-1}. Thermogravimetric analysis was recorded with a NETZSCH STA 449C unit at a heating rate of 10 °C min^{-1} under nitrogen. Variable-temperature (2.0–300.0 K) magnetic susceptibility measurements were carried out on a Quantum Design PPMS60000 in a magnetic field of 10 kOe, and the diamagnetic corrections were evaluated using Pascal's constants. Single crystal X-ray diffraction was carried out using Rigaku Mercury CCD/AFC and Bruker SMART 1K diffractometers.

2.2. Syntheses of the complexes

2.2.1. $[Na_2(H_2O)_3Cu_2(H_2O)_6(sip)_2]\cdot H_2O$ (1)

A mixture of $Cu(NO_3)_2\cdot 3H_2O$ (0.049 g, 0.2 mmol) and NaCl (0.03 g, 0.5 mmol) was added to 10 ml water, and the pH value of the solution was adjusted to about 5.0 using dilute NaOH. After several minutes of stirring, the clear solution was transferred to a test tube. Another portion of NaH_2sip (0.054 g, 0.2 mmol) in 10 ml methanol was placed carefully on the surface, and allowed to diffuse. Blue block crystals of **1** suitable for single crystal X-ray diffraction analysis formed 2 weeks later, yielding 26 mg (31% based on Cu). *Anal.* Calc for $C_{16}H_{26}Cu_2Na_2O_{24}S_2$: C, 22.89; H, 3.12; Na, 5.48; Cu, 15.14. Found: C, 24.21; H, 3.16; Na, 5.42; Cu, 14.35%. IR characteristics (KBr, cm^{-1}): 3500m, 3198m, 1616s, 1461s, 1357s, 1251w, 1105s, 1026w, 890w, 871w, 834m, 786m, 609w, 655m, 554w, 507w.

2.2.2. $[K_2(H_2O)_2Cu_2(H_2O)_5(sip)_2]\cdot H_2O$ (2)

Compound **2** was prepared from a reaction procedure similar to **1**. KCl (0.035 g, 0.5 mmol) was used instead of NaCl, and the pH value of the reaction mixture was adjusted to about 5.0 using dilute KOH. Blue prism crystals of **2** suitable for single crystal X-ray diffraction analysis formed after several weeks, yielding 32 mg (38% based on Cu). *Anal.* Calc for $C_{16}H_{22}Cu_2K_2O_{22}S_2$ (%): C, 23.00; H, 2.65; K, 9.36; Cu, 15.21. Found (%): C, 23.54; H, 2.28; K, 9.66; Cu, 14.04%. IR characteristics (KBr, cm^{-1}): 3454m, 3172m, 1655s, 1556s, 1425s, 1373m, 1219w, 1039s, 1001m, 874m, 816w, 791m, 675m, 586w, 501w.

2.2.3. Structural conversion process

0.01 g (10 mg) crystals of **1** were dissolved in saturated KCl aqueous solution with stirring, and the pH value was kept at about 5.0. Blue crystals of **2** formed after a week (yielding 0.0047 g, 4.7 mg) and were characterized by single-crystal X-ray diffraction. However, no successful trials were observed when crystals of **2** were treated to obtain crystalline **1** by the same process.

2.3. X-ray structure determination

Diffraction intensities for **1** and **2** were collected on Rigaku Mercury CCD/AFC and Bruker SMART 1000 CCD

diffractometers, respectively, equipped with graphite-monochromated Mo Kα radiation with a radiation wavelength of 0.71073 Å by using the ω-scan technique. Absorption corrections were performed using CrystalClear and SADABS [27], respectively. Structures were solved by direct methods and refined on F^2 by full-matrix least-squares using the SHELXTL-97 program package [28]. All non-hydrogen atoms were refined anisotropically. The organic hydrogen atoms were positioned geometrically and the hydrogen atoms bonded to water oxygen atoms were not located. The crystallographic data for complexes **1** and **2** are listed in Table 1, and selected bonds are in Table 2.

3. Results and discussion

3.1. Crystal structure of $[Na_2(H_2O)_3Cu_2(H_2O)_6(sip)_2]\cdot H_2O$ (**1**)

X-ray crystallography reveals that the structure of **1** is constructed from individual one-dimensional (1-D) $\{Cu_2(H_2O)_6(sip)_2\}_n$ chains interconnected by two types of dinuclear sodium–oxygen clusters into a 3-D heterometallic framework. The basic building block of compound **1** is shown in Fig. 1a. There are two crystallographically independent copper sites and two unique sodium positions in the asymmetric unit. The Cu(1) atom links to two carboxyl oxygen atoms from two sip^{3-} ligands and three aqua ligands with Cu(1)–O distances in the range 1.921–2.291 Å. The O–Cu(1)–O bond angles are in the range 83.99–103.07°, which demonstrates that the basic plane of the $\{Cu(1)O_5\}$ square pyramid is a little distorted. The Cu(2) atom, possessing a similar coordination geometry to Cu(1), coordinates to two carboxyl oxygen atoms belonging to two sip^{3-} ligands and three aqua ligands with Cu(2)–O distances in the range 1.952–2.435 Å and O–Cu(2)–O bond angles in the range 86.51–99.23°, giving birth to a $\{Cu(2)O_5\}$ square pyramid. There is a weak interaction between Cu(2) and Ow7 (2.608 Å), if it is considered, the Cu(2) center may also be regarded as residing in an elongated octahedral environment on account of a considerable Jahn–Teller effect. The Na(1) atom, residing in a roughly distorted square pyramid, connects to one sulfonate O donor and four coordination water molecules. The other Na site is occupied by two disordered $\{NaO_5\}$ square pyramids with two Na atoms with 50% probability for each, sharing four O atoms located in the basic plane, and the separation between the two Na positions is 0.905 Å. Thus, the overall Na(2) site can be regarded as a $\{NaO_6\}$ octahedra with Na–O bonds varying from 2.302 Å to 2.474 Å. There are also two crystallographically independent sip^{3-} ligands and a non-coordinated water molecule.

In the structure of compound **1**, three types of individual building blocks, namely 1-D copper-organic chain, type I and type II dinuclear sodium–oxygen clusters, can be observed. Two $\{Na(1)O_5\}$ square pyramids connect to each

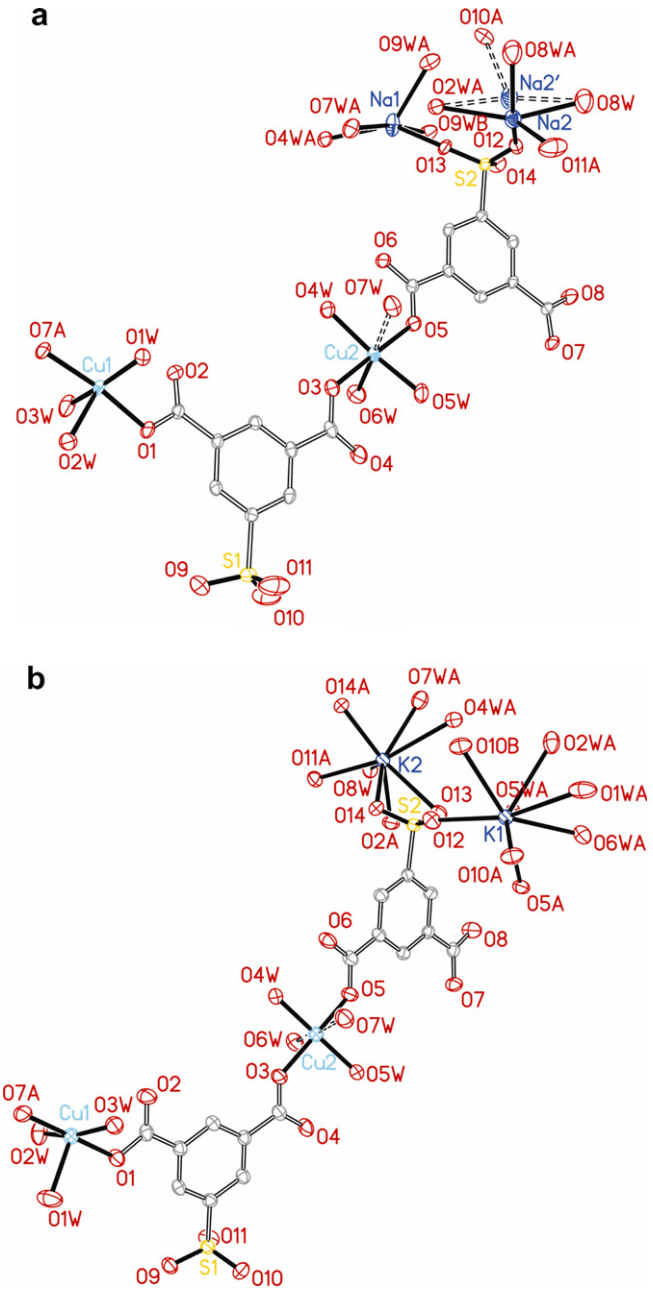

Fig. 1. ORTEP drawing of the basic building block in (a) **1** and (b) **2** showing the coordination environment around the metal centers with thermal ellipsoids at 50% probability. For the sake of clarity, only atoms coordinated to metal centers are labelled. Hydrogen atoms and non-coordinated water molecules are omitted.

other by sharing an edge to form the type I $\{Na_2O_8\}$ cluster. Similarly, two $\{Na(2)O_6\}$ octahedra link together in an edge-sharing mode to give the type II $\{Na_2O_{10}\}$ cluster. Adjacent Cu atoms are jointed together by the carboxyl groups of sip^{3-} ligands adopting a bis-monodented manner to generate a 1-D zigzag copper-organic chain running along the b axis. The individual 1-D chain built by copper atoms and sip^{3-} ligands assembles with uncoordinated sulfonate groups pointing outside as expected, very similar to the chains observed in our previous work [22]. The copper atoms in the zigzag chain are located nearly in line and the shortest copper-copper intra-chain separation is 9.335 Å. Such a pair of chains is held together via type I 4-connected $\{Na_2O_8\}$ clusters to give a double chain (Fig. 2a), and the double chains pack in layers with neighboring pairs of chains sharing their $\{Na_2O_8\}$ clusters (Fig. 2c). Alternatively, each $\{Na_2O_8\}$ cluster acts as a tetradented ligand bonding to four individual zigzag chains (Fig. S1a) generating a 2-D network (Fig. 2b). These four 1-D chains connect by a $\{Na_2O_8\}$ cluster are not orientated in planar positions due to the stereo geometry of the clusters, and therefore the layer is best described as a pleat net with mean planes of double chains inclined to the plane of the layer (Fig. 2c). It is also notable that strong intra-layer π–π interactions exist between neighboring double chains because of their sine–cosine arrangements (Fig. 2b), which may help to stabilize the structure, and the nearest distance

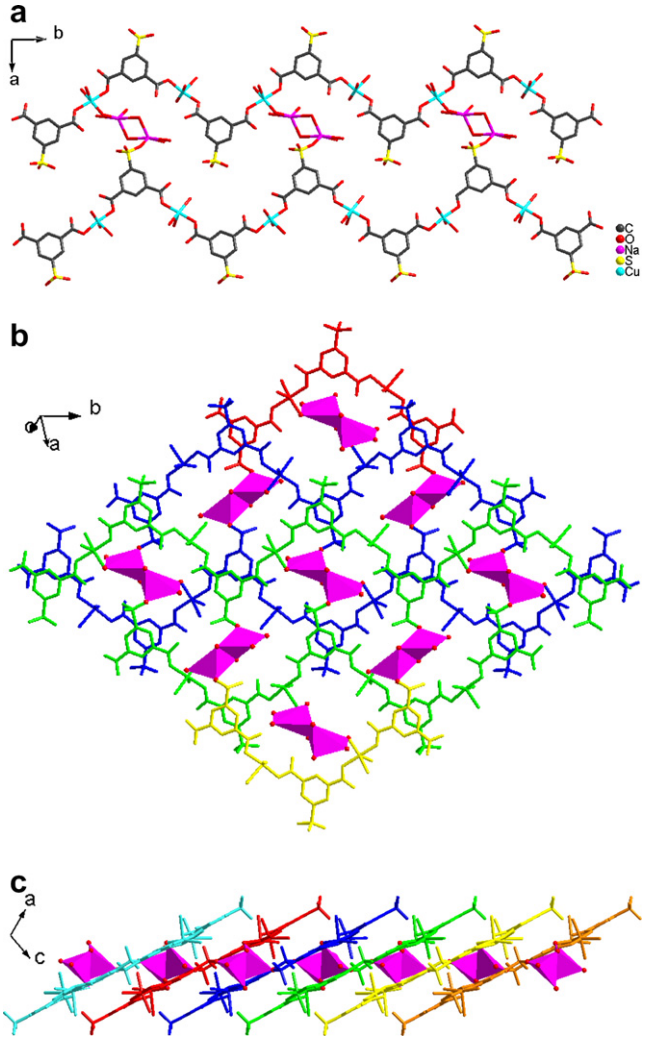

Fig. 2. (a) The double chain ribbon in **1** containing 4-connected type I dinuclear sodium–oxygen clusters. (b) The 2-D net built by double chain ribbons extended via type I cluster nodes. (c) A side view of the 2-D net with double chain ribbons distinguished by different colors. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

of parallel benzene rings is 3.460 Å. These 2-D layers are further connected into a 3-D framework via type II 6-connected $\{Na_2O_{10}\}$ clusters. Each $\{Na_2O_{10}\}$ cluster joints two adjacent layers by coordinating to six 1-D zigzag chains with three in one layer and three in the other, giving rise to a pillar-layered 3-D pattern, as shown in Fig. 3.

3.2. Crystal structure of $[K_2(H_2O)_2Cu_2(H_2O)_5(sip)_2]\cdot H_2O$ (2)

The structure of **2** features a 3-D heterometallic framework similar to **1**. There are two crystallographically independent copper sites and two potassium atoms in the asymmetric unit of **2** (Fig. 1b). The Cu(1) atom connects two carboxyl oxygen atoms from two sip^{3-} ligands and three aqua ligands with Cu(1)–O distances in the range 1.938–2.153 Å, to finish its square pyramidal geometry. The Cu(2) atom, adopting a square planar coordination mode, coordinates to two carboxyl oxygen atoms belonging to two sip^{3-} ligands and two aqua ligands with Cu(2)–O distances in the range 1.967–2.0 Å. There are weak interactions between Cu(2) and Ow6 (2.480 Å) and between Cu(2) and Ow7 (2.489 Å), and if they are taken into consideration, the Cu(2) center may also be regarded as residing in an elongated octahedral environment on account of a considerable Jahn–Teller effect, similar to the Cu(2) center in **1**. The K(5) atom, displaying a bi-capped triprismatic geometry, bonds to one carboxyl O atom, three sulfonate O atoms and four coordination water molecules. The K(6) atom links one carboxyl O donor, four sulfonate O atoms and three aqua ligands, showing a distorted bi-capped triprismatic coordination fashion (Fig. S3). The K–O bonds vary from 2.648 Å to 3.316 Å. There are also two crystallographically independent sip^{3-} ligands and a lattice water molecule.

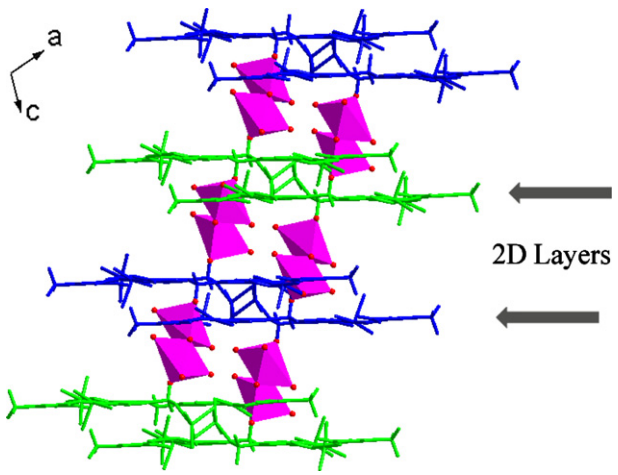

Fig. 3. A view of the 3-D framework of **1** along the *b* axis, showing the 6-connected type II sodium–oxygen clusters anchoring to the pleat 2-D nets. For the sake of clarity, each 2-D sheet is represented by one double chain ribbon.

In the structure of **2**, only two types of building blocks are observed, that is a 1-D copper-sip zigzag chain and a 6-connected dinuclear potassium–oxygen clusters. Similarly, Cu atoms are jointed together by the carboxyl groups of sip^{3-} ligands, giving birth to a 1-D zigzag copper-organic chain with uncoordinated sulfonate groups running along the *b* axis. Such a pair of chains is held together via 6-connected $\{K_2O_{14}\}$ clusters to give a double chain (Fig. 4a). The double chains pack in layers with neighboring pairs sharing their $\{K_2O_{14}\}$ clusters to form a 2-D net (Fig. 4b). There are also strong intra-layer π–π interactions between neighboring double chains because of their sine–cosine arrangements (Fig. 4b), with the nearest distance of parallel benzene rings being 3.467 Å. The 2-D nets extend into a 3-D framework by means of the connection of free sulfonate groups and $\{K_2O_{14}\}$ clusters belonging to adjacent layers (Fig. 4c). As a consequence, each $\{K_2O_{14}\}$ cluster links six individual 1-D copper-sip chains with four in a layer and other two from two adjacent layers, respectively.

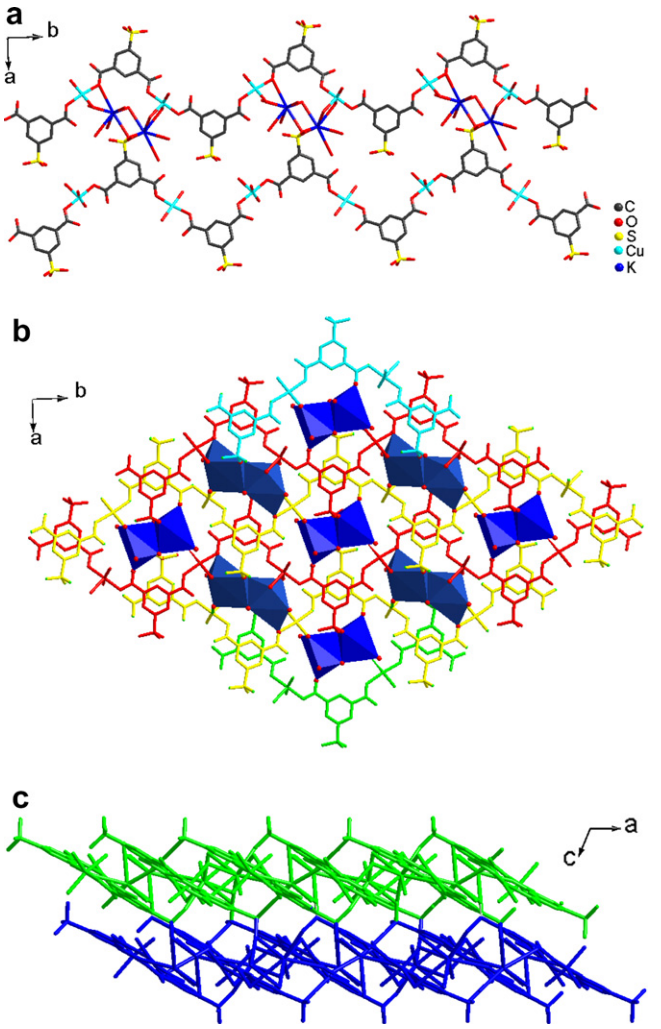

Fig. 4. A view of (a) the double chain ribbon in **2** containing dinuclear potassium–oxygen clusters; (b) the 2-D net in **2**, and (c) the 3-D framework of **2**.

3.3. Discussion

In the crystal structure of **1**, the type II $\{Na_2O_{10}\}$ cluster is a more commonly found dinuclear sodium–oxygen unit than the type I $\{Na_2O_8\}$ cluster [29–37]. Although, these two clusters have been observed as discrete cluster units in previously reported crystal structures [29,31] and known to be optional linkers of organometallic fragments, high-dimensional (2-D and 3-D) frameworks constructed by the linkages of dinuclear sodium–oxygen clusters are still rare. To our knowledge, the co-existence of the two sodium–oxygen clusters in a single structure has not been documented in the literature to date. In the structure of **2**, only one kind of dinuclear $\{K_2O_{14}\}$ cluster is observed. Although all the $\{K_2O_{14}\}$ clusters in **2** are 6-connected to zigzag chains, the $\{K_2O_{14}\}$ clusters display two kinds of linking manner, acting as hexa- and octa-dented ligands (Fig. S2a and S2b, respectively).

The basic 1-D copper-sip chains in both **1** and **2** have similar structures to those found in supramolecular polymers stabilized by organic amine molecules involving hydrogen bonds [22], previously observed by our group, in which the protonated sulfonate groups do not participate in the coordination. However, the sulfonate groups coordinate to p-block alkaline metals as expected in the current instance. We tried to isolate the individual copper-sip chain structure under similar reaction conditions but lacking the secondary organic ligands or alkaline metals, but all attempts failed. It is therefore believed the extra covalent or supramolecular contacts, or a combination of the two, may play crucial roles in the stabilization of the formation of the 1-D polymer structures.

1 and **2** were originally prepared from similar reactions, and an irreversible structural conversion from **1** to **2** controlled by p-block alkali metals was observed when a crystalline sample of **1** was treated with saturated KCl solution. Although the individual 1-D copper-sip chain has not been isolated, the successful structural conversion from **1** to **2** demonstrates that the 1-D copper-sip chain is controllable with the existence of alkali metals. Moreover, the possible reason for an irreversible structural conversion is ascribed to the formation of p-block metal–oxygen clusters as according to the structures the $\{K_2O_{14}\}$ cluster is larger than either a $\{Na_2O_8\}$ or $\{Na_2O_{10}\}$ cluster with more surface O donors, offering more coordination sites and displaying complicated coordination fashions, also it possesses stronger coordination ability and affinity to the host framework, resulting in an irreversible transformation process [38]. Another possible reason for the irreversible structural conversion may be the low solubility of **2** compared to **1**.

3.4. Thermal gravimetric analyses

The thermal gravimetric (TG) curve for compound **1** (Fig. 5a) exhibits a continuous mass loss in the temperature range from 30 °C to 800 °C. The first two steps, with a weight loss of 19.59% and a slight distinction between 50 °C and 250 °C, correspond to the dehydration of the non-coordinated and coordinated water molecules (calc. 21.46%). Other steps with a mass loss of 49.62% arise from the decomposition of organic ligands and further decomposition of the sample (calc. 50.30%). The total weight loss of 69.21% is in accordance with the calculated value 71.76%. The TG curve for **2** (Fig. 5b) exhibits a continuous mass loss in the temperature range from 30 °C to 800 °C. The first two steps, with a weight loss of 16.98% and a slight distinction between 60 °C and 280 °C, correspond to the dehydration of the non-coordinated and coordinated water molecules (calc. 17.23%). The mass loss of 51.44% in the temperature range from 280 to 750 is assigned to the decomposition of organic ligands and further decomposition of the sample (calc. 50.58%). The total weight loss of 68.42% is in accordance with the calculated value 67.81%.

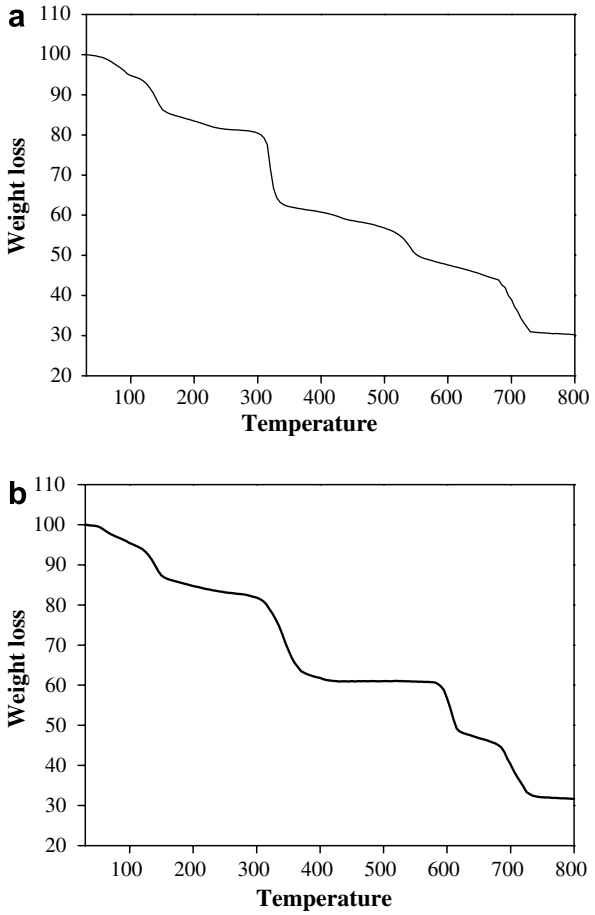

Fig. 5. TG curves for (a) **1**, and (b) **2**.

3.5. Magnetic properties of compound *1*

Considering the similar coordination environment around the copper centers and the Cu...Cu separations in **1** and **2**, only the magnetic properties of **1** were studied. The temperature dependence of the magnetic susceptibility of **1** is plotted in Fig. 6. A non-linear fit $\chi_M = C/$

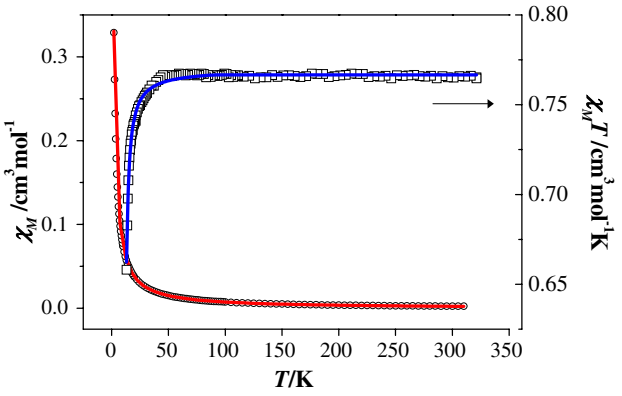

Fig. 6. Temperature dependence of χ_M and $\chi_M T$ for **1** with the solid line showing the best fit obtained through χ_M (red) and $\chi_M T$ (blue) values. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

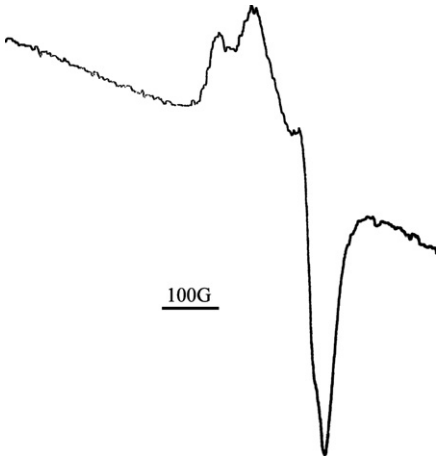

Fig. 7. EPR spectrum for **1**.

$(T-\theta)+\chi_0$ in the temperature range from 2 to 300 K reveals a Curie–Weiss behavior with a Curie constant $C = 0.77(7)\ \mathrm{cm^3\ mol^{-1}\ K}$ and Weiss constant $\theta = -0.3(3)$ K (background susceptibility $\chi_0 = -2.6\times10^{-4}\ \mathrm{cm^3\ mol^{-1}}$). The room-temperature $\chi_M T$ value of $0.766\ \mathrm{cm^3\ mol^{-1}\ K}$ is in good accordance with the value of $0.75\ \mathrm{cm^3\ mol^{-1}\ K}$ expected for two spin-only Cu(II) ions per formula unit. Upon cooling the system, $\chi_M T$ decreases smoothly until approximately 40 K and then it decreases at a faster rate, reaching a value of $0.658\ \mathrm{cm^3\ mol^{-1}\ K}$ at 2 K, showing a paramagnetic behavior for **1**. The EPR spectrum of **1** at 77 K shows a Cu^{2+} signal with $g_{\|} = 2.185$ and $g_{\perp} = 2.116$ (Fig. 7), which further confirms the structural analysis of five-coordinated Cu(II) centers. A fitting result by a mononuclear Cu(II) model gives a g factor of 2.126, which is in accordance with the EPR results.

4. Conclusion

In short, we report here two new HMOFs containing p- and d-block metals by the introduction of a multifunctional organic ligand. **1** shows an interesting 3-D structure constructed from copper-sip chains interconnected by two kinds of dinuclear sodium–oxygen clusters adopting 4- and 6-connected fashions. **2** displays a 3-D framework formed by cross-linking similar 1-D zigzag chains via 6-connected potassium–oxygen clusters. Furthermore, the structures exhibit an irreversible structural conversion from **1** to **2** via ion exchange. The successful preparation of compounds **1** and **2** indicate that use of organic ligands with multifunctional groups in constructing HMOFs is both promising and attractive.

Abstract

A series of cobalt-containing alcohols and diols were prepared and characterized. Intramolecular hydrogen-bonding was observed for the cobalt-containing diols $[Co_2(CO)_6(\mu\text{-}\eta\text{-}(HO)R_1R_2CC{\equiv}CCR_1R_2(OH)]$ (**1**: $R_1 = CH_3$, $R_2 = C_2H_5$; **2**: $R_1 = CH_3$, $R_2 = C_3H_7$), $[Co_2(CO)_6(\mu\text{-}\eta\text{-}(HO)Ph_2CC{\equiv}CCPh_2(OH)]$ (**3**) and $[(\mu\text{-}PPh_2CH_2PPh_2)Co_2(CO)_4(\mu\text{-}\eta\text{-}(HO)Ph_2CC{\equiv}CCPh_2(OH)]$ (**4**). Potentially all the four compounds could serve as chelating O,O-ligands. In principle, it is possible for compounds $[(\mu\text{-}PPh_2NHPPh_2)Co_2(CO)_4(\mu\text{-}\eta\text{-}HC{\equiv}CCPh_2OH)]$ (**5b**), $[Co_2(CO)_6(\mu\text{-}\eta\text{-}HC{\equiv}CC_2H_4OH]$ (**6**) and $[Co_2(CO)_6(\mu\text{-}\eta\text{-}HC{\equiv}CC_3H_6OH)]$ (**7**) in their *syn*-conformations to behave as chelating O,N-ligands. To the best of our knowledge, compounds **5b**, **6** and **7** are the first reported examples of PPh_2NHPPh_2-bridged dicobalt complexes.

1. Introduction

Alkynes are highly reactive building blocks in organic synthesis. The fact that alkyne-bridged dicobalt system has been studied extensively is in part due to its indisputable role played in the Pauson–Khand reaction [1]. Complexes of this class are usually obtained from the direct reaction of dicobalt octacarbonyl ($Co_2(CO)_8$) with alkynes [2]. The bridging alkyne makes use of both sets of filled π- and unfilled π^*-orbitals in bonding to the dicobalt framework. The former set is responsible for donation of the electron-density to the metal center; meanwhile, the latter one accepts the electron-density from the metal through back-bonding [3]. This synergetic effect enhances the rigidity of the Co_2C_2 core. The character and reactivity of the bridging alkyne is significantly changed after the coordination to the metal moiety. A general methods of preparation of cobalt-containing mono- or bidentate phosphine ligands has been established in our previous studies (Scheme 1) [4]. It has also been revealed that ligands of this type can be characterized as authentic phosphine ligands with bulky, and, in some cases, electron-rich, character [4b]. Moreover, some of the palladium complexes with type II ligands have been demonstrated to perform as effective catalysts in the renowned Suzuki reactions [5].

Alcohols or diols are readily accessible precursors of alkoxides. The alkoxy ligands have been long known to stabilize metals in high oxidation states [6]. Metal alkoxides are also of great interest due to their current and potential uses in catalysis. For example, $Al(O^iPr)_3$ has been widely used as a catalyst in organic synthesis as well as in the ring-opening polymerization of aliphatic cyclic esters [7]. Numerous organic alkoxides as well as their metal-containing counterparts were prepared. Their chemical reactivities toward metals were thoroughly examined. Much rich chemistry of the letter were demonstrated [8]. Herein, we

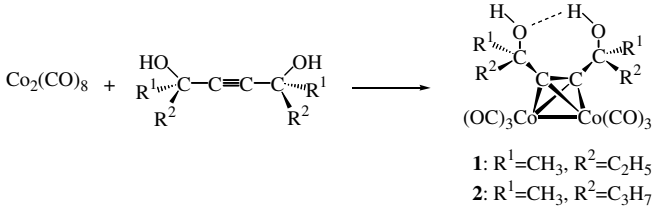
Scheme 1.



report the preparation and characterization of a series of cobalt-containing alcohols and diols using a methodology similar to the one shown in Scheme 1.

2. Results and discussion

2.1. Preparation of cobalt-containing diols

The room temperature reaction of $(HO)R_1R_2CC{\equiv}CCR_1R_2(OH)$ with $Co_2(CO)_8$ in toluene furnished $[Co_2(CO)_6(\mu\text{-}\eta\text{-}(HO)R_1R_2CC{\equiv}CCR_1R_2(OH)]$ (**1**: $R_1 = CH_3$, $R_2 = C_2H_5$; **2**: $R_1 = CH_3$, $R_2 = C_3H_7$) in good yields in 4 h (Scheme 2). Compounds **1** and **2** were characterized by spectroscopic means as well as by single-crystal X-ray diffraction. The molecular structures of both compounds revealed a pseudo-tetrahedral Co_2C_2 core typical for an alkyne-bridged dicobalt complex (Table 1, Figs. 1 and 2). Both substituents of the alkyne are bent away from the dicobalt moiety, as predicted by Dewar–Chatt–Duncanson's model, and reside on the same side [9]. In this regard, **1** and **2** can be considered as potentially chelating metal-containing diols.

All carbonyl ligands of compound **1** and other cobalt-containing alcohols and diols mentioned below are in terminal positions. The C(1)–C(2)–C(3) and C(2)–C(1)–C(7) angles are 138.6(4)° and 139.6(3)°, respectively, deviated from the 180° angle characteristic of their free states as predicted. The C–C bond distance of the bridging alkyne is 1.341(5) Å, which is within the regular double bond range. The Co–Co bond distance is 2.472 Å, which is comparable to alkyne-bridging dicobalt complex reported earlier (Table 1, Fig. 1). In general, the cluster core "$-Co_2(-C{\equiv}C-)$" of a common dicobalt complex of this type is a tetrahedron where the alkyne unit is almost perpendicular to the metal-metal bond. The structure also shows that the acetylenic ligands fold in upon coordination to the cluster core. The distance between the oxygen and hydrogen atoms of two hydroxyl groups are 2.052 Å for **1**, which is well within the intramolecular hydrogen-bonding range [10]. The ^1H and ^{13}C NMR spectra of **1** are trivial. In contrast with the observed two non-equivalent hydroxyl protons in solid state, two hydroxyl protons are equivalent on the NMR timescale giving rise to a broad signal at 2.99 ppm in ^1H NMR in $CDCl_3$. In the structure of **2**, the C(2)–C(1)–C(3) and C(1)–C(2)–C(8) angles are 137.5(2)° and 136.9(2)°, respectively. The C–C bond distance of the bridged alkyne is 1.324(3) Å. The Co–Co bond distance is 2.4639(5) Å. The distance between oxygen atoms of the two hydroxyl groups are 2.637 Å for **2** (Table 1, Fig. 2). Again, in solution two hydroxyl protons are equivalent and give rise to a broad signal at 2.98 ppm in ^1H NMR in $CDCl_3$.

Scheme 2.

As seen above, the two hydroxyl groups of the coordinated alkyne come closer in a well-defined rigid geometry in these alkyne dinuclear clusters. This observable fact suggests that any charged functional groups at these positions will be disposed in a clamp-like fashion and are potentially capable of binding ions of the opposite charge [11]. Unfortunately, attempts to isolate the expected aluminum complexes were not successful (Scheme 3). The reactions of both **1** and **2** with trimethyl aluminum always led to precipitation of compounds of unknown composition. Besides, the complex would undergo an elimination reaction in acidic medium and produce the related olefinic compounds [12].

Subsequently, the heating $Co_2(CO)_8$ with $(HO)Ph_2CC{\equiv}CCPh_2(OH)$ in toluene at 60 °C for 3 h produced $[Co_2(CO)_6(\mu\text{-}\eta\text{-}(HO)Ph_2CC{\equiv}CCPh_2(OH)]$ (**3**). Further reaction of **3** with $PPh_2CH_2PPh_2$ (dppm) in toluene at 100 °C for 16 h yielded $[(\mu\text{-}PPh_2CH_2PPh_2)Co_2(CO)_4(\mu\text{-}\eta\text{-}(HO)Ph_2CC{\equiv}CCPh_2(OH)]$ (**4**) (Scheme 4). In several occasions, the bridging dppm is a necessity, especially when the reaction is conducted at elevated temperatures. Without the protection provided by the bridging dppm, intermolecular attacks among $Co_2(CO)_6(\mu\text{-}\eta\text{-}RC{\equiv}CR)$

Scheme 4.

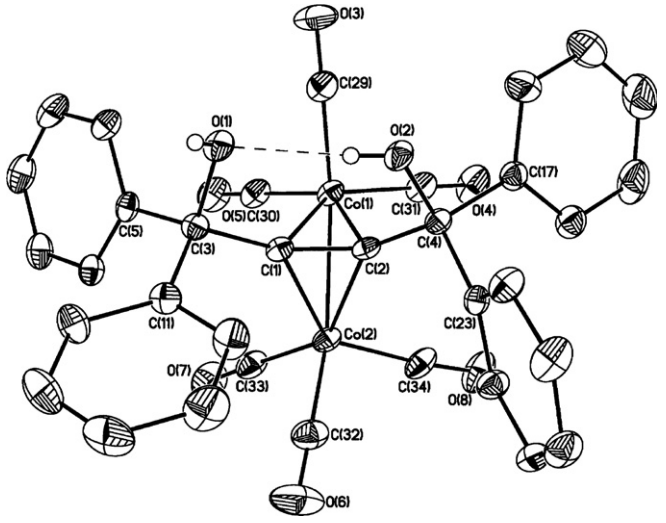

Fig. 3. ORTEP drawing of **3**. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and bond angles (°): Co(1)–C(1) 1.972(3); Co(1)–C(2) 1.978(3); Co(1)–Co(2) 2.4472(6); Co(2)–C(1) 1.952(3); Co(2)–C(2) 1.985(3); O(1)–C(3) 1.445(4); O(2)–C(4) 1.435(3); C(1)–C(2) 1.346(4); C(1)–C(3) 1.521(4); C(2)–C(4) 1.536(4); C(1)–Co(1)–C(2) 39.84(11); C(1)–Co(2)–C(2) 39.98(11); Co(2)–C(1)–Co(1) 77.15(10); Co(1)–C(2)–Co(2) 76.28(10); C(2)–C(1)–C(3) 140.4(3); C(1)–C(2)–C(4) 138.2(3); O(1)–C(3)–C(1) 102.8(2); O(2)–C(4)–C(2) 106.9(2).

molecules do occur and the self-aggregation process always lead to a great amount of precipitation. The sequence of reactions shown in Scheme 1 is reversed in the synthesis of **4**. Firstly, the alkynyl alcohol is allowed to bridge to the dicobalt fragment. As predicted by the Dewar–Chatt–Duncanson's model, bulky substituents of the alkyne bend away from the dicobalt center. Then, the dppm is added to the alkyne bridged dicobalt fragment. The dppm-alkynyl alcohol sequence will not lead to **4**

due to the bulkiness of the latter. Compounds **3** and **4** were characterized by spectroscopic means. In addition, the molecular structure of **3** was determined by a single-crystal X-ray diffraction method. As revealed from the crystal structure, there is an intramolecular hydrogen-bonding between the oxygen atom of one and the hydrogen atom of another hydroxyl group. The H···O distance is 1.934 Å for **3**. Two hydroxyl protons of **3** and **4** are equivalent resulting in broad signals at 4.31 ppm and 2.51 ppm, respectively, in their ^{1}H NMR spectra in $CDCl_3$. A triplet signal at 3.69 ppm ($J_{P\text{-}H} = 10.5$ Hz) observed in the ^{1}H NMR spectra of **4** is assigned to the methylene protons (Figs. 3 and 4).

2.2. Preparation of cobalt-containing alcohols

Several cobalt-containing alcohols were prepared using a procedure similar to the one for synthesis of diols. The reaction of $Co_2(CO)_8$ with $HCC{\equiv}CCPh_2OH$ in toluene at 60 °C for 2 h furnished $[Co_2(CO)_6(\mu\text{-}\eta\text{-}HC{\equiv}CCPh_2OH]$ (**5a**). Further reaction of **5a** with PPh_2NHPPh_2 in toluene at 80 °C for 16 h produced $[(\mu\text{-}PPh_2NHPPh_2)Co_2(CO)_4(\mu\text{-}\eta\text{-}HC{\equiv}CCPh_2OH)]$ (**5b**) (Scheme 5). The alkynyl alcohol was first allowed to bridge to the dicobalt fragment. Then, PPh_2NHPPh_2 was added to alkyne-bridged dicobalt fragment. Again, reversing the sequence did not lead to the formation of **5b**. Here PPh_2NHPPh_2 was chosen

Scheme 6.

as a bridging ligand to stabilize the dicobalt complex as the dppm did in the case of compound **4**. This choice is due to the PPh_2NHPPh_2 ability to function as an amine-like ligand, which dppm does not have. In addition to the characterization by spectroscopic means the molecular structures of **5a** and **5b** were determined by the single-crystal X-ray diffraction method. The structure of **5b** revealed that the –OH and -NH groups point at different directions. In $CDCl_3$, a hydroxyl proton is observed at 2.60 and 3.00 ppm for **5a** and **5b**, respectively, in ^1H NMR. A broad signal at 3.62 ppm and a triplet signal at 5.75 ppm ($J_{PH} = 9.0$ Hz) are assigned to the acetylenic proton and NH proton, respectively, of **5b** (see Figs. 5 and 6).

The reaction of $Co_2(CO)_8$ with PPh_2NHPPh_2 in toluene at 65 °C produced $[Co_2(CO)_6(\mu\text{-}\eta\text{-}PPh_2NHPPh_2]$ in 12 h. Further reaction of the latter compound with HC≡CR (R = CH_2OH or C_2H_4OH) in toluene at 65 °C furnished $[Co_2(CO)_6(\mu\text{-}\eta\text{-}HC{\equiv}CR]$ (**6**: R = CH_2OH; **7**: R=C_2H_4-OH) in 12 h (Scheme 6). Compounds **6** and **7** were characterized by spectroscopic means. Their molecular structures were determined by the single-crystal X-ray diffraction method. To the best of our knowledge, compounds **5b**, **6** and **7** are the first reported examples of PPh_2NHPPh_2-bridged dicobalt complexes. The crystal structures of **6** and **7** show that the –OH and –NH groups point at different directions as those in **5b** does (see Fig. 7).

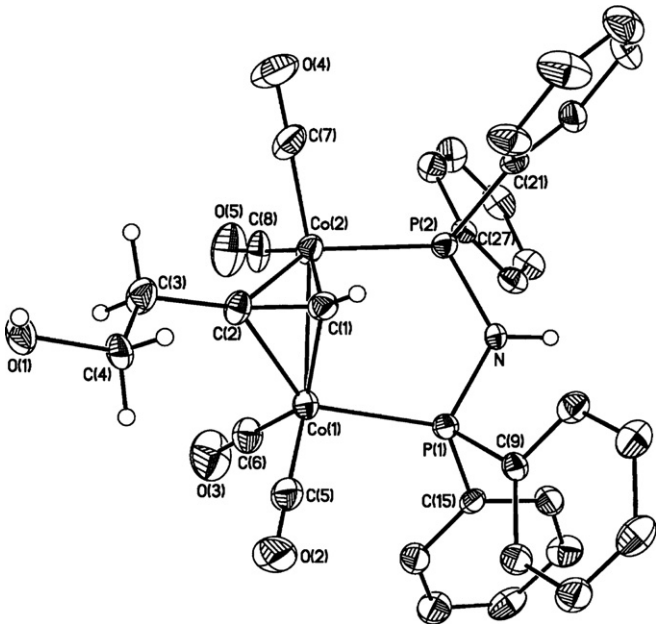

Fig. 7. ORTEP drawing of **7**. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and bond angles (°): Co(1)–Co(2) 2.4701(10); Co(1)–C(1) 1.925(6); Co(1)–C(2) 1.965(6); Co(1)–P(1) 2.2017(15); Co(2)–C(2) 1.944(6); Co(2)–C(1) 1.947(6); Co(2)–P(2) 2.2023(16); O(1)–C(4) 1.445(5); P(1)–N 1.669(4); P(2)–N 1.687(4); C(1)–C(2) 1.313(7); C(2)–C(3) 1.505(7); C(3)–C(4) 1.458(7); C(2)–Co(2)–C(1) 39.5(2); C(1)–Co(1)–C(2) 39.4(2); N–P(1)–Co(1) 112.24(15); N–P(2)–Co(2) 110.88(15); P(1)–N–P(2) 123.3(2); Co(1)–C(1)–Co(2) 79.3(2); C(1)–C(2)–C(3) 140.1(6); Co(2)–C(2)–Co(1) 78.4(2); C(4)–C(3)–C(2) 113.1(5); O(1)–C(4)–C(3) 111.4(5).

Signals observed at 1.69 and 2.01 ppm in the ^1H NMR spectra of **6** and **7**, respectively, in $CDCl_3$ are assigned to the corresponding hydroxyl protons. Broad signals appearing at 3.60 ppm for **6** and 3.52 ppm for **7** are assigned to terminal acetylene protons. The triplet signals at 5.34 ppm for **6** and 5.30 ppm for **7** are assigned to the NH protons of the bridging PPh_2NHPPh_2.

2.3. Structural comparison of cobalt-containing diols and alcohols

Selected structural parameters of **1**, **2**, **3**, **5a**, **5b**, **6**, and **7** are given in Table 2 for the purpose of comparison. The atom numbering scheme of the framework of all these compounds is the same. As shown in Table 2, these frameworks are not very different. Again, it shows that the alkyne-bridging dicobalt framework (Co_2C_2) is a rigid structure (Diagram 1).

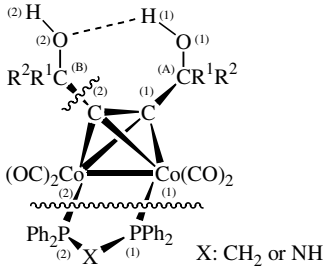

Diagram 1. A generalized structure for **1**, **2**, **3**, **5a**, **5b**, **6**, and **7**.

2.4. Summary

Several cobalt-containing alcohols and diols were prepared and characterized by NMR spectroscopic and single-crystal X-ray diffraction. Their molecular structures were compared. Unfortunately, reactions of the metal-containing diol ligands with aluminum complexes such as $AlEt_3$ or $AlMe_3$ resulted in a number of unidentified products.

3. Experimental

General information: All manipulations were carried out under a dry nitrogen atmosphere. Solvents including deuterated solvents were purified before use. Most of separations were performed by Centrifugal Thin Layer Chromatography (CTLC, Chromatotron, Harrison model 8924). The ^1H and ^{31}P NMR spectra were recorded on a Varian-400 spectrometer at 400.44 and 162.10 MHz, respectively; ^{13}C NMR spectra were recorded on a Varian VXR-300 S spectrometer at 75.43 MHz. Chemical shifts are reported in ppm relative to the residual proton signals of deuterated $CHCl_3$ or CH_2Cl_2. Mass spectra were recorded on a JOEL JMS-SX/SX 102A GC/MS/MS spectrometer. Elemental analyses were obtained on a Heraeus CHN-O-S-Rapid instrument.

3.1. Synthesis of *1* and *2*

$Co_2(CO)_8$ (0.342 g, 1.000 mmol), 3,6-dimethyl-4-octyn-3,6-diol (0.170 g, 1.000 mmol) and 10 mL of THF were placed in a 100 mL round-bottomed flask charged with a magnetic stirrer. The solution was stirred at 25 °C for 4 h. Then the solvent was removed under reduced pressure, and the resulted dark-red residue was separated by CTLC. A red band was eluted out using a mixed solvent system (CH_2Cl_2/EA = 1:1). The product was identified as **1** (0.437 g, 0.96 mmol, 96%). A similar procedure was used for the preparation of **2**. $Co_2(CO)_8$ (0.342 g, 1.000 mmol), 4,7-dimethyl-5-decyn-4,7-diol (0.198 g, 1.000 mmol) and

10 mL of THF were placed in 100 mL round-bottomed flask charged with a magnetic stirrer. The solution was stirred at 25 °C for 4 h followed by workup. A dark-red band was eluted out using a mixed solvent system (EA:CH_2Cl_2 = 1:1). The product was identified as **2** (0.460 g, 0.95 mmol, 95%).

1: ^{1}H NMR ($CDCl_3$, δ/ppm): 1.09(br., 6H, C–CH_2–CH_3), 1.54(br., 6H, C–CH_3), 1.83(br., 4H, C–CH_2), 2.99(br., 2H, OH); ^{13}C NMR ($CDCl_3$, δ/ppm): 8.76(s, C–CH_2–CH_3), 28.79(s, C–CH_2), 37.90(s, C–CH_3), 75.15(s, C≡C), 106.89(s, C–OH), 199.83(s, CO); *Anal*. Calc. for **1**: C, 42.13; H, 3.98. Found: C: 41.17, H: 3.84%. IR(KBr/cm^{-1}): 2017.7(s), 2052.5(s), 2093.0(s), 3332.0(br.); color: red (solid state).

2: ^{1}H NMR ($CDCl_3$, δ/ppm): 0.99(br., 6H, C–CH_2–CH_3), 1.56(br., 10 H, C–CH_2, C–CH_3), 1.77(br., 4H, C–CH_2), 2.98(br., 2H, OH); ^{13}C NMR ($CDCl_3$, δ/ppm): 14.40(s, C–CH_2–CH_2-CH_3), 17.70(s, C–CH_2–CH_3), 29.48, 29.66(d, C–CH_2), 47.77(s, C–CH_3), 75.13(s, C≡C), 106.96(s, C–OH), 199.8(s, CO); *Anal*. Calc. for **2**: C, 44.65; H, 4.58. Found: C: 44.48, H: 4.70%; IR(KBr/cm^{-1}): 2022.6(s), 2053.5(s), 2091.7(s), 3257.9(br.); color: red (solid state).

3.2. Synthesis of *3*

A 100 cm^3 flask was charged with dicobalt octacarbonyl, $Co_2(CO)_8$ (0.171 g, 0.500 mmol) and 1,1,4,4-tetraphenyl-2-butyn-1,4-diol (0.195 g, 0.500 mmol) in 5 ml of THF. The mixture was stirred at 60 °C for 3 h resulting in a red solution. The solvent was removed under reduced pressure, and the resulting residue was chromatography by CTLC. A red band was eluted out using a mixed solvent system (CH_2Cl_2/hexane = 1:1). The product was identified as **3** (0.316 g, 0.467 mmol, 93.4%).

3: ^{1}H NMR ($CDCl_3$, δ/ppm): 4.31(s, 2H, OH), 7.28 (br., 12H, Ph), 7.61(br., 8H, Ph); ^{13}C NMR ($CDCl_3$, δ/ppm): 80.62(s, C≡C), 108.23(s, C–(OH)Ph_2), 126.93(s, arene), 127.67(s, arene), 128.03(s, Ph), 146.12(s, *ipso* of arene), 198.46(br., COs); *Anal.* Calc. for **3**: C, 60.37, H, 3.28. Found: C, 59.60; H, 3.62%; color: red (solid state).

3.3. Synthesis of *4*

A 100 cm^3 flask was charged with complex **3** (0.344 g, 0.509 mmol) and dppm (0.196 g, 0.509 mmol) in 5 ml of toluene. The mixture was stirred at 100 °C for 16 h yielding a dark-brown solution. The solvent was removed under reduced pressure, and the resulting residue was chromatography by CTLC. The first band was eluted out using a mixed solvent system (CH_2Cl_2/hexane = 2:1). The product was identified as the title compound **4** (0.501 g, 0.499 mmol, 97.9%).

4: ^{1}H NMR ($CDCl_3$, δ/ppm): 2.51(s, 2H, OH), 3.69(t, J_{PH} = 10.5 Hz, 2H, CH_2), 7.15–7.46(br. 40 H, arene); ^{13}C NMR ($CDCl_3$, δ/ppm): 36.28(t, J_{PC} = 82.5 Hz, CH_2), 81.09(s, C≡C), 109.81(s, C–(OH)Ph_2), 126.95–131.52(br., arene), 146.72(s, *ipso* of arene), 204.68(br., COs); ^{31}P NMR ($CDCl_3$, δ/ppm): 35.8(s, dppm); *Anal.* Calc. for **4**: C, 68.14; H, 4.14. Found: C, 64.64; H, 4.55%; IR(KBr/cm^{-1}): 1966.5(s), 1992.7(s), 2022.8(s); MS (*m*/*z*): 977(M^+−CO). color: brown (solid state).

3.4. Synthesis of *5a* and *5b*

$Co_2(CO)_8$ (0.171 g, 0.500 mmol), 1,1-diphenyl-2-propyn-1-ol (0.104 g, 0.500 mmol) and 5 ml of toluene were placed in a 100 mL round-bottomed flask charged with a magnetic stirrer. The red colored solution was stirred at 60 °C for 2 h. To the mixture was then added *N*,*N*-bis(diphenylphosphino)amine (0.192 g, 0.500 mmol) with 5 cm^3 of toluene followed by stirring at 80 °C for additional 16 h. The solvent was removed under reduced pressure, and the resulting residue was chromatography by CTLC. Complex **5a** was obtained from the first red band eluted by hexane, while complex **5b** from the second red-pink band by CH_2Cl_2/hexane (1/1) solution. The yields for **5a** and **5b** were 33.9% (0.084 g, 0.170 mmol) and 39.1% (0.161 g, 0.196 mmol), respectively.

5a: ^{1}H NMR ($CDCl_3$, δ/ppm): 2.60(s, 1H, OH), 6.52(s, 1H, CH), 7.23–7.25(br., 2H, arene), 7.30–7.32(br., 4H, arene), 7.69–7.71(br., 4H, arene); ^{13}C NMR ($CDCl_3$, δ/ppm): 73.06, 80.08(s, C≡C), 105.80(s, C–(OH)Ph_2), 125.71(s, arene), 127.48(s, arene), 128.26(s, Ph), 146.71(s, *ipso* of arene), 198.88(br., COs); Anal. Calc. for **5a**: C, 51.04; H, 2.45. Found: C, 50.07; H, 2.99%; IR(KBr/cm^{-1}): 1977.7(w), 2002.7(s), 2027.8(s), 2051.8(s), 2093.9(m); MS (*m*/*z*): 466 (M^+−CO); color: red (solid state).

5b: ^{1}H NMR ($CDCl_3$, δ/ppm): 3.00(s, 1H, OH), 3.61(br. 2 H, CH_2 or NH), 5.75(t, J_{PH} = 9.0 Hz, 1H, CH), 7.15–7.78(br., 30 H, arene); ^{13}C NMR ($CDCl_3$, δ/ppm): 73.12(s, C≡CH), 80.61(s, C≡C(OH)Ph_2), 126.31–130.90(br., arene), 147.92(s, *ipso* of arene), 201.20(br., COs), 206.24(br., COs); ^{31}P NMR($CDCl_3$, δ/ppm): 98.6(s, 2 P, dppm); *Anal*. Calc. for **5b**: N, 1.70; C, 62.71; H, 4.04. Found: N, 2.89; C, 61.85; H, 4.21%; IR(KBr/cm^{-1}): 1977.0(s), 2003.0(s), 2027.7(s); MS (*m*/*z*): 823 (M^+); color: red (solid state).

3.5. Synthesis of *6* and *7*

A 100 cm^3 round flask was charged with $Co_2(CO)_8$ (0.342 g, 1.000 mmol) and *N*,*N*-bis(diphenylphosphino)amine (0.385 g, 1.000 mmol) with 15 cm^3 of THF. The mixture was warmed up to 65 °C and stirred for 12 h. Then, one molar equivalent of 2-propyn-1-ol (0.056 g, 1.000 mmol) was added. The mixture was stirred at 65 °C for another 12 h. The resulting green solution was purified by centrifugal thin-layer chromatography (CTLC). The second red-colored band was eluted out with CH_2Cl_2. The solvent was removed in vacuo, and the resulting solid was identified as **6** (0.618 g, 0.920 mmol, 92% yield). A similar procedure was used for the preparation

of **7**. $Co_2(CO)_8$ (0.342 g, 1.000 mmol), *N*,*N*-bis(diphenylphosphino)amine (0.385 g, 1.000 mmol) and 15 mL of THF were placed in a 100 mL round-bottomed flask equiped with a magnetic stirrer. The solution was stirred at 65 °C for 12 h. Then, one molar equivalent of 3-butyn-1-ol (0.070 g, 1.000 mmol) was added. The solution was stirred at 65 °C for another 12 h. The resulting green solution was purified by centrifugal thin-layer chromatography (CTLC). The second red-colored band was eluted out with CH_2Cl_2. The solvent was removed in vacuo, and the residual solid was identified as **7** (0.589 g, 0.86 mmol, 86% yield).

6: ^{1}H NMR ($CDCl_3$, δ/ppm): 1.69(s, 1H, OH), 3.60(s, 1 H, NH), 4.76(d, $J_{H-H} = 6.0$ Hz, 2H, CH_2), 5.34(t, 1H, ≡CH), 7.38–7.46(br., 10H, arene); ^{13}C NMR ($CDCl_3$, δ/ppm): 65.10(s, CH_2–OH), 71.10(s, C–CH_2–OH), 101.84(s, ≡CH), 128.47–130.41(arene), 140.10(d, $J_{p-c} = 36.6$ Hz, *ipso*-arene), 202.6 (br, COs), 206.3 (br, COs); ^{31}P NMR ($CDCl_3$, δ/ppm): 33.7(s, PNP); *Anal.* Calc. for **6**: C, 55.46, H, 3.75, N, 2.09%. Found: C, 54.54, H, 3.90, N, 2.71%; M.S.(FAB): 643(M^+−CO); color: red (solid state).

7: ^{1}H NMR ($CDCl_3$, δ/ppm): 2.01(s, 1H, OH), 3.12(d, $J_{H-H} = 6.0$ Hz, 2H, CH_2–OH), 3.52(s, 1H, NH), 3.98(d, $J_{H-H} = 6.0$ Hz, 2H, CH_2–CH_2), 5.30(t, 1 H, ≡CH), 7.37–7.44(br., 10H, arene); ^{13}C NMR ($CDCl_3$, δ/ppm): 38.32(s, CH_2–CH_2–OH), 64.44(s, CH_2–OH), 71.10(s, C–CH_2–CH_2–OH), 98.61(s, ≡CH), 128.65–130.87(arene), 140.64(d, $J_{p-c} = 73.9$ Hz, *ipso*-arene), 203.4(s, CO), 206.7 (s, CO); ^{31}P NMR ($CDCl_3$, δ/ppm): 33.8(s, PNP); *Anal.* Calc. for **7**: C, 56.08; H, 3.97; N, 2.04%; Found: C, 56.36; H, 4.12; N, 2.25%; M.S.(FAB): 685(M^++1); color: red (solid state).

3.6. X-ray crystallographic studies

Suitable crystals of **1**, **2**, **4**, **5a**, **5b**, **6**, and **7** were sealed in thin-walled glass capillaries under nitrogen atmosphere and mounted on a Bruker AXS SMART 1000 diffractometer. Intensity data were collected in 1350 frames with increasing ω (width of 0.3° per frame). The absorption correction was based on the symmetry equivalent reflections using SADABS program. The space group determination was based on a check of the Laue symmetry and systematic absences, and was confirmed using the structure solution. The structure was solved by direct methods using a SHELXTL package [13]. All non-H atoms were located from successive Fourier maps and hydrogen atoms were refined using a riding model. Anisotropic thermal parameters were used for all non-H atoms, and fixed isotropic parameters were used for H atoms[1]. Crystallographic data for compounds **1**, **2**, **3**, **5a**, **5b**, **6**, and **7** are summarized in Table 1.

[1] The hydrogen atoms were ride on carbons or oxygens in their idealized positions and held fixed with the C–H distances of 0.96 Å.

Abstract

A new complex of bis-axially coordinated iron(II) phthalocyanine by 4-cyanopyridine (4-CNpy) has been obtained in crystalline form as an adduct with two 4-CNpy molecules. The $[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy)$ crystallises in the monoclinic system, space group $P2_1/c$ with two molecules in the unit cell. The iron(II) coordinates four isoindole nitrogen atoms of the almost planar phthalocyaninato(2−) macroring and axially two nitrogen atoms of 4-CNpy molecules. The coordination polyhedron around the Fe(II) atom approximates to a tetragonal by-pyramid. Four equatorial Fe–N bonds are shorter (1.936(2) Å) than two axial Fe–N bonds (2.027(2) Å). The centrosymmetric $FePc(4\text{-}CNpy)_2$ molecules form alternating sheets parallel to the *bc* crystallographic plane and solvated 4-CNpy molecules that are anti-parallel oriented by their polar cyano groups are located between the sheets of $FePc(4\text{-}CNpy)_2$ molecules. Ligation of the intermediate-spin iron(II) phthalocyanine by 4-CNpy molecules leads to the low spin Fe(II) complex. The importance of the $d(\pi) \rightarrow \pi^*(Pc)$ back donation is manifested in the difference between the values of C–N isoindole and C–N azamethine bond lengths of the Pc macrocycle. The thermal analysis of the crystals of $[FePc(4\text{-}CN)_2]\cdot 2(4\text{-}CNpy)$ shows two steps responsible for a loss of solvated (∼170 °C) and coordinated (∼235 °C) 4-CNpy molecules.

1. Introduction

Iron phthalocyanine and its additive complexes are still of wide interest because of its close analogy to the iron porhyrin and blood hemine [1]. We are especially interested in this study, trying to explore how the ligand bis-axially bonded to the phthalocyanine metal influences the feature and stability of the complex formed. A few years ago, we have synthesised and characterised the metal(II) phthalocyanine complexes with bis-axially coordinated pyridine molecules: $MgPc(py)_2$ [2], $FePc(py)_2$ and $CoPc(py)_2$ [3] and $MnPc(py)_2$ [4]. These all dipyridinated M(II)Pc complexes are structurally isomorphic and crystallise in the monoclinic system.

Previously, the iron and cobalt phthalocyanine crystalline complexes with 4-methylpyridine (4-Mepy) with the formula of $[MPc(4\text{-}Mepy)_2]\cdot 2(4\text{-}Mepy)$ (where M = Fe(II) or Co(II)) have been studied by Cariati et al. [5]. These compounds are also structurally isomorphic, but orthorhombic. Several crystal structures of bis-axially coordinated iron phthalocyanine derivatives have been reported [6–14] but they contain iron(III) or iron(IV) in the center of phthalocyaniniato ligand. Besides above-mentioned bis-axially ligated iron(II) phthalocyanines, the crystal structure of a low-spin iron(II) phthalocyanine complex ligated by 4-methylpiperidine (4-Mepip) with the composition of $[FePc(4\text{-}Mepip)_2]\cdot 2(4\text{-}Mepip)$ has been described [15].

In this paper, we describe the synthesis, thermal stability, crystal structure and magnetic properties of bis-axially coordinated iron(II) phthalocyanine complex by another pyridine derivative, i.e. 4-cyanopyridine (4-CNpy).

2. Experimental

2.1. Synthesis of the [FePc(4-CNpy)$_2$].2(4-CNpy) complex in the crystalline form

Iron phthalocyanine (FePc) and 4-cyanopyridine (4-CNpy) compounds were mixed in the molar proportion of 1:5, respectively. Next the mixture was pressed into pellets of 2 g in mass. The pellet was inserted into a glass ampoule, ca. 10 cm in length, which next was degassed and sealed off. The sample in the ampoule was thermally processed by about one weak. At first the temperature was increased to 120 °C. After as apparently uniform suspension was formed, the temperature was increased again to 180 °C and held constant by one day and next lowered to 150 °C by a second day. As only the well developed iron phthalocyaninato complex crystals were seen (up to 1 mm in edge), the ampoule was firstly cooled to room temperature and next placed into temperature gradient, with 50 °C at the hot zone. After several days the excessive 4-CNpy migrates to the cold zone. At such state the ampoule was opened and the crystals of iron phthalocyanine complex were selected for further experiments. Elemental analysis of the crystalline iron phthalocyanine complex has been performed on an energy dispersive spectrometer. *Anal.* Calc. for $C_{56}H_{32}N_{16}Fe$: Fe, 5.67; C, 68.30; N, 22.75; H, 3.28. Found: Fe, 5.72; C, 68.41; N, 22.68, H, 3.19%. We want to add that another pellets with the various excesses of 4-cyanopyridine were processed at lower and at higher temperatures as well, however, these attempts were not satisfactory, regarding the [FePc(4-CNpy)$_2$].2(4-CNpy) complex formation.

2.2. Thermal measurements

Thermal analysis was carried out on a Lineis L81 thermobalance apparatus with Pt crucibles. The powdered Al_2O_3 has been used as a standard reference. The measurements were performed on samples of 15–20 mg under static air atmosphere on heating from room temperature to 300 °C with the heating rate of 5 °C min^{-1}.

2.3. X-ray single crystal measurement

Data collection was carried out on a KUMA KM-4 diffractometer with a two-dimensional area CCD detector. The graphite-monochromatised Mo Kα radiation ($\lambda = 0.71073$ Å) and ω-scan technique with $\Delta\omega = 0.75°$ for one image were used for data collection. The 960 images for six different runs covering over 99% of the Ewald sphere were performed. One image as a standard was used for monitoring the stability of the intensities after every 40 images. Integration of the intensities, corrections for Lorenz and polarisation effects were made using a KUMA KM-4 CCD program package [16]. The face-indexed analytical absorption was calculated using the SHELXTL program [17]; maximum and minimum transmission factors being 0.941 and 0.910. 5975 independent reflections (a total of 30 225 reflections were integrated, $R_{int} = 0.0579$) were used for crystal structure solution and refinement. The structure was solved by direct methods. The hydrogen atoms of the phenyl rings were located from the $\Delta\rho$ maps, but in the final refinement their positions were constrained using HFIX 43 with the isotropic thermal parameters of $1.2U_{eq}$ of the carbon atoms linked directly to the H atoms. The structure was refined with anisotropic thermal parameters for all non-hydrogen atoms by full-matrix least-squares methods using SHELXL-97 program [18]. The final difference map calculation showed no peaks of chemical significance; the largest were +0.294 and −0.215 e Å^{-3}. More details of the data collection parameters and the final agreement factors are collected in Table 1. Selected bond lengths and angles are listed in Table 2.

2.4. Magnetic susceptibility measurements

The temperature dependence of the magnetic susceptibility of [FePc(4-Mepy)$_2$] · 2(4-Mepy) was recorded from 300 to 1.8 K on Quantum Design SQUID magnetometer (San Diego, CA) on the sample of 85 mg. The magnetisation on magnetic field dependence was recorded from 0 to 5 T at 1.9 K.

3. Results and discussion

3.1. Characterisation of the FePc recrystallisation process in the 4-cyanopyridine

According to our observations during several days of thermal processing of the iron phthalocyanine with 4-cyanopyridine (in excess), roughly three characteristic temperature ranges could be distinguished. In the range above the melting point of the 4-cyanopyridine (∼80 °C) and to ca. 150 °C, the suspension is formed, which again completely separates, as soon as the temperature falls below the 4-cyanopyridine solidification point. At the temperature range 150–180 °C the most characteristic products registered are the parallelepipedal violet crystals of the additive complex of the iron phthalocyanine, [FePc(4-CNpy)$_2$].2(4-CNpy) and individual colourless crystals of 2,4,6-tris-(4′-pyridyl)-triazine molecules that are formed by the cyclotrimerisation of 4-cyanopyridine molecules. The 2,4,6-tris-(4′-pyridyl)-triazine crystallises in *C*2/*c* space group of the monoclinic system and the structure was earlier described [19]. When the mixture containing the violet and colourless crystals is quickly cooled from the above-mentioned temperature (150–180 °C) to the room temperature, the crystals of iron phthalocyanine complex with 4-cyanopyridine are preserved and can be separated for the X-ray analysis. Otherwise, i.e. if the temperature of the sample is slowly lowered (during a few days), the crystals of iron phthalocyanine complex with 4-cyanopyridine vanish and again non-coordinated iron phthalocyanine (FePc), in the form of fine crystalline needles, is present in the sample.

Symmetry code: (i) $-x$, $-y$, $-z$.

At temperature 200 °C and above, the processing firstly leads to the 2,4,6-tris-(4′-pyridyl)-triazine crystals growth, which is the catalytic effect of the FePc presence in the sample (similar catalytic effect is observed in presence of MgPc and has been registered by us [19]). However, progressively with the time the thermal processing leads markedly to the demetallation of iron phthalocyanine and destructive decomposition (the violet phthalocyanine colour vanishes). If the processing is interrupted at a proper moment, the evolved nano-dispersed iron particles cause that the sample moves under a solid magnet (the effect does not vanish even after several months). Prolonged heating, however, causes further, destructive transformation of the sample, leading to the oxidation of the iron particles, and in the result the sample does not show magnetic behaviour.

3.2. Thermal analysis of $[FePc(4\text{-}CNpy)_2].2(4\text{-}CNpy)$ complex

The first marked step on TG (see Fig. 1), registered in the range of 165–175 °C, is ascribed to the loss of two lattice held 4-cyanopyridine molecules from the complex, $[FePc(4\text{-}CNpy)_2](4\text{-}CNpy)_2 \rightarrow [FePc(4\text{-}CNpy)_2] + 2(4\text{-}CNpy)$. The further mass loss is observed at about 230 °C. Above this temperature two axial equivalent Fe–N(4-CNpy) bonds break simultaneously giving FePc in a powder form. Both processes are endothermic and characteristic of the loss of the 4-CNpy molecules as a lattice solvent (first step) or the loss of coordinated 4-CNpy molecules. Further increase of the temperature leads to oxidative destruction of the sample, since above 275 °C the mass loss of the sample is observed.

3.3. Description of the structure

The molecular structure of $[FePc(4\text{-}CNpy)_2] \cdot 2(4\text{-}CNpy)$ complex is illustrated in Fig. 2. The central iron cation lies at the inversion center, thus the $[FePc(4\text{-}CNpy)_2]$ molecule is centrosymmetric. The coordination polyhedron around Fe(II) approximates to a tetragonal bypyramid. The central iron atom and the four isoindole nitrogen

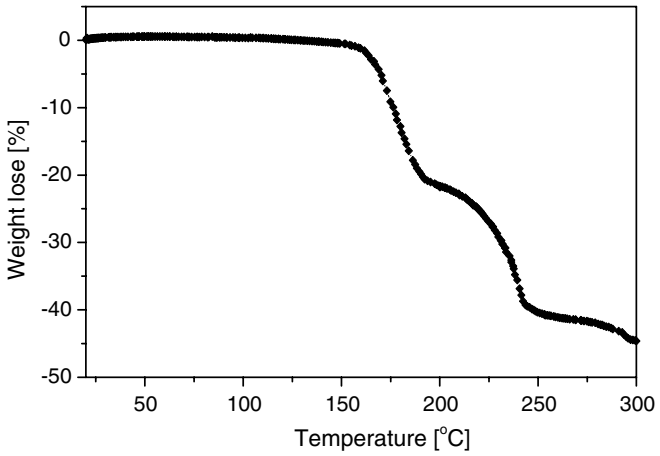

Fig. 1.

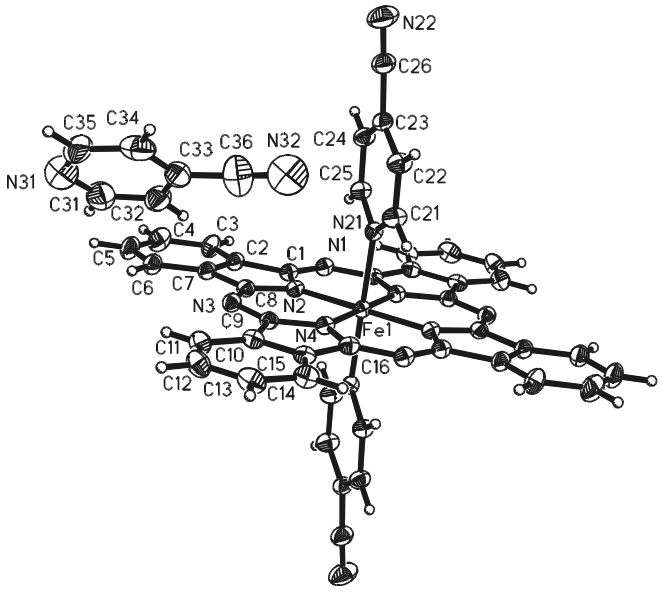

Fig. 2.

atoms of the phthalocyaninato(2−) macrocycle lie on a plane. As shown in Fig. 2, the two axial 4-CNpy molecules are coordinated by their lone-electron pair at the ring nitrogen atoms to the central Fe(II) atom. The dihedral angle between the N_4-isoindole plane of phthalocyaninato(2−) macrocycle and that containing the axially coordinated 4-CNpy molecules is close but markedly different from 90°, i.e. 85.2(1)°. For comparison the respective value of the deviation is not greater than 1°, when the 4-Mepy or py molecules are ligated [3,5]. The orientation of the axial 4-CNpy ligands relative to the phthalocyaninato(2−) macroring is well described by the torsion angle of N4–Fe1–N21–C21. The rotation of 4-CNpy ligand around the Fe1–N21 axis would reduce the steric hindrance, i.e. the non-bonding distances between the hydrogen atoms of the axial 4-CNpy ligand in *ortho* positions and the atoms of phthalocyaninato(2−) macrocycle. In particular, if the rotation angle is equal 0, the 4-CNpy molecule is parallel to the Fe1–N4 bond or at equivalent position rotated by 90°, the 4-CNpy molecule is parallel to the Fe1–N2 bond, making the non-bonding C···H distances greater than 2.6 Å. The second orientation, with the rotation angle of 45°, makes the axial 4-CNpy ligand plane parallel to the Fe1···N(azamethine) axis and reduce the non-bonding distances between the hydrogen atoms of 4-CNpy (H in *ortho* positions) and the azamethine nitrogen atoms of phthalocyaninato(2−) macrocycle. This conformation is the most stable, and is preferable in the solution, due to the strongest interaction between the *ortho*-H atoms of 4-CNpy molecules and the *N*-azamethine atoms of phthalocyaninato(2−) macroring. This conformation is also present in the crystal, however, due to the intermolecular interactions and crystal packing forces this angle is slightly different from 45° (see Table 3). This angle is comparable to that observed in the crystal of $[FePc(4\text{-}Mepy)_2]\cdot 2(4\text{-}Mepy)$ [5] but significantly different from those in the crystal of $FePc(py)_2$ [3]. The differences between the rotation angle of the axially coordinated 4-CNpy (or 4-Mepy) and pyridine molecules, are likely due to the interaction with the solvated 4-CNpy (or 4-Mepy) molecules present in the structure.

The axial Fe1–N21 bond distance is longer by ~0.1 Å than equatorial four Fe–N bonds [average 1.936 Å]. A similar pattern of the Fe–N bonds is observed in the other axially coordinated iron phthalocyanine derivatives (see Table 3). The values of the axial Fe–N bond lengths in axially coordinated FePc derivatives point to their strength and correlate well with their thermal stability. For example, in this complex, the Fe–N(4-CNpy) bond length is shorter than Fe–N(py) in $FePc(py)_2$ and correlate with the thermal breaks of the axial Fe–N bond (~235 °C and ~225 °C for $[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy)$ and $FePc(py)_2$, respectively). In the crystal of $[FePc(4\text{-}Mepip)_2]\cdot 2(4\text{-}Mepip)$ complex the elongation of the axial Fe–N bond (2.119(3) Å) can be explain by a steric effect of the 4-methylpiperidine ligand rather than the electronic structure.

The C–C and C–N bond lengths of the phthalocyaninato(2−) macrocycle in the $[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy)$ are normal in the sense that their values are not very different from the corresponding values found in various metallophthalocyanines [20]. However, it should be noted that small differences between the values of C–N(isoindole) and C–N(azamehtine) bond lengths are observed (see Table 2). These differences indicate an accumulation of the charge density on the outer carbon atoms of pyrrole rings as well as on the bridging azamethine N atoms and can, therefore, be explained by an important electron back donation from the metal d(π) orbitals to the ligand $\pi^*(e_g)$ antibonding orbital, since the maximum charge density is mainly located at those atoms. The accumulation of the charge density on the outer carbon atoms of pyrrole rings and on the bridging azamethine nitrogen atoms of phthalocyaninato(2−) macroring has also been evidenced in the

Table 3
Comparison of the bis-axially ligated iron(II) phthalocyanine complexes and FePc

Compound	Fe–N_{iso} (Å)	Fe–N_{axial} (Å)	Rotation angle (°)	C–N_{iso} (Å)	C–N_{aza} (Å)	Thermal stability (°C)	Reference
$[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy)$	1.936(2)	2.027(2)	47.1(2)	1.374(3)	1.330(3)	~170–235	this work
$[FePc(4\text{-}Mepy)_2]\cdot 2(4\text{-}Mepy)$	1.935(3)	2.040(3)	42.6(4)	1.373(7)	1.328(4)		[5]

$[FePc(4\text{-}Mepip)]\cdot 2(4\text{-}Mepip)$	1.931(3)	2.119(2)		1.376(3)	1.324(3)		[15]
FePc	1.926(2)			1.378(3)	1.322(3)		[24]

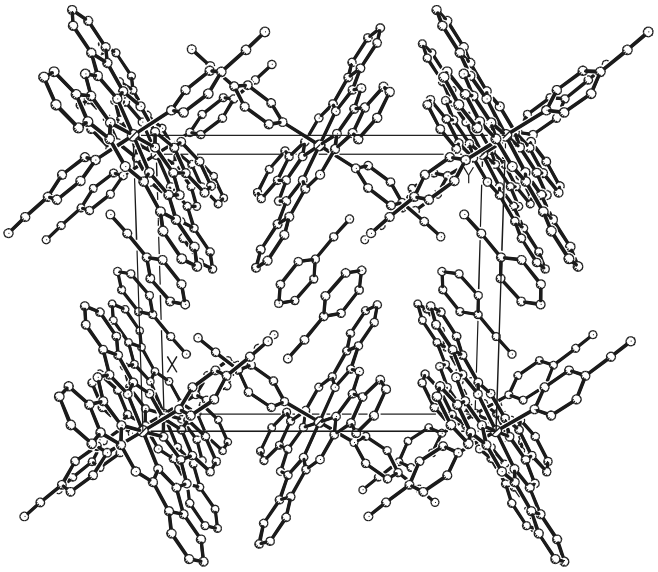

Fig. 3.

experimental density maps derived from the low temperature high resolution X-ray experiment [21–23].

The arrangement of the $[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy)$ molecules in the unit cell is illustrated in Fig. 3. The crystal is built up from isolated $FePc(4\text{-}CNpy)_2$ molecules that are related by screw axis and glide plane, which form alternating sheets parallel to the *bc* crystallographic plane, and solvated 4-CNpy molecules (Fig. 3). The rings of solvated 4-CNpy molecules related by an inversion center are parallel to each other, but oriented anti-parallel by their polar cyano groups. This orientation of solvated 4-CNpy molecules reduces the repulsive forces between the dipoles of 4-CNpy molecules. The dihedral angle between the plane of solvated 4-CNpy molecule and phthalocyaninato(2−) macroring of 42.9(2)° and the plane of the ligated 4-CNpy molecule of 73.8(2)° as well as the intermolecular nonbonding distances that are greater than the sum of the commonly accepted van der Waals radii indicate that there are no π–π interactions in the structure. The geometry of ligated and solvated 4-CNpy molecules are comparable, however, the both N–C lengths in the ring of coordinated 4-CNpy molecule are longer than in solvated one.

3.4. Magnetic properties

The magnetic susceptibility measurement on the sample of $[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy)$ shows its diamagnetic character. This experiment clearly evidenced that ligation of the iron phthalocyanine with the intermediate state $(d_{xz}, d_{yz})^3$-$(d_{xy})^2(d_{z^2})^1$ with two unpaired electrons [24–28] leads to the change of the ground-state from $S = 1$ (for $FePc, e_g^3 b_{2g}^2 a_{1g}^1$) to $S = 0$ (for $[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy), e_g^4 b_{2g}^2$). Thus the $[FePc(4\text{-}CNpy)_2]\cdot 2(4\text{-}CNpy)$ complex is a low-spin complex, according to the molecular orbital diagram of Fe(II) in a strong-field tetragonal environment [29].

4. Conclusion

The formation of the Fe–N(4-CNpy) bond, between the central iron ion of FePc and the ring nitrogen of the 4-CNpy, in the early stages of dissolution the iron phthalocyanine grains is relatively easy reversible, i.e. as long as the bonding is not complete and not stabilised by an intermolecular order of the units in the assembly. It is so, because both FePc, as well as the ligated 4-CNpy molecules, characterise a distinct planarity and strong rigidity. Moreover, the axially coordinated 4-CNpy molecules preserve, in spite of their marked extension in relation to that of Pc edge value, a strong propensity for close to perpendicular orientation to the Pc plane. For such extended units as building blocks, there are only limited opportunities to arrange themselves into a tightly packed configuration. Therefore, the newly formed molecules composing the building block may go again apart, and for that moment they are in the excited state. In a consequence of it, when FePc is thermally processed (recrystallised) in 4-CNpy, both components show highly time and temperature dependent behaviour. Here we want to add, that according to Hanack et al. [30] one could expect also that the freshly formed 2,4,6-tris-(4′-pyridyl)-triazine molecules, if it is the cause, as -tridenadate ligand will form very stable complexes with the FePc present in the system. However, we have not observed the 2,4,6-tris-(4′-pyridyl)-triazine splitting at 342 °C or at higher temperature as mentioned in [30].

Appendix A. Supplementary material

Details on data collection and refinement, fractional atomic coordinates, anisotropic displacement parameters and full list of bond lengths and angles in CIF format have been deposited at the Cambridge Crystallographic Data Centre. CCDC 628342 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Abstract

A yellow compound which was crystallised from a solution of (6,8,8,14,16,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,13-diene)bis(isothiocyanato)nickel(II) in aqueous zinc(II) chloride has cations with singlet ground state nickel(II) in square-planar coordination by the nitrogen atoms of the macrocycle. The asymmetric unit has two similar cations. The N_4 group of one cation is near coplanar (r.m.s. displacements ±0.009(1) Å, with Ni displaced by 0.048(1) Å from this plane) while the other cation has significant tetrahedral twisting of the N_4 group (r.m.s. displacements of N atoms ±0.126(2) Å, with Ni displaced by 0.027(2) Å from this plane). The mean Ni–N distances are $Ni–N_{amine} = 1.950(6)$ and $Ni–N_{imine} = 1.897(6)$ Å. Both cations have *N-meso* configurations with saddle conformations, with the substituted chelate rings in boat conformations tilted to one side of the NiN_4 'plane' and the unsubstituted chelate rings tilted to the other side, one in a boat conformation and the other with the central methylene group disordered, the components forming boat {s.o.f. 0.70(1) and 0.74(1) for the two cations} and chair conformation chelate rings. The counter-ions have tetrahedrally coordinated zinc(II) ions, one as $[ZnCl_2(NCS)_2]^{2-}$ ions and the other with one ligand site with disordered Cl^- {s.o.f. 0.78(1)} and NCS^- ligands, i.e. with disordered $[ZnCl_2(NCS)_2]^{2-}$ and $[ZnCl(NCS)_3]^{2-}$ ions, with an overall composition of [Ni(*trans*-Me_6[16]diene)]-$[ZnCl_{1.9}(NCS)_{2.1}]$.

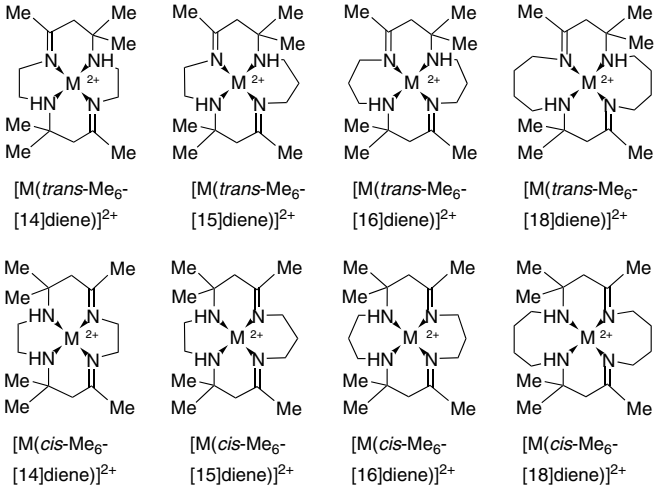
1. Introduction



The preparations of compounds of nickel(II) and copper(II) with hexamethyl-substituted diimine–diamine tetraaza-macrocycles with 14- to 18-ring members, by reactions of diamine compounds of the cations with acetone, have been reported [1].

For both metal ions the reactions of ethane-1,2-diamine compounds with acetone yield a mixture of isomeric tetraaza-cyclotetradecadiene macrocyclic cations with 4,14(1)-diimine functions, [M(*cis*-Me_6[14]diene)]$^{2+}$, and with 4,11-diimine functions, [M(*trans*-Me_6[14]diene)]$^{2+}$ [2,3], see Scheme 1. Structures have been reported for numerous compounds of both isomeric cations for both metal ions (below).

Reactions of copper(II) compounds of butane-1,4-diamine with acetone form both 6,18(1)-diimine, [Cu(*cis*-Me_6[18]diene)]$^{2+}$, and 6,15-diimine, [Cu(*trans*-Me_6[18]-diene)]$^{2+}$, tetraaza-cyclooctadecadiene macrocyclic ligand cations [4]. Structures of the isomeric copper(II) cations, as perchlorate salts, were reported [5]. With nickel(II) only the 6,15-diimine cation, [Ni(*trans*-Me_6[18]diene)]$^{2+}$, was isolated [4].

Scheme 1. 14–18-membered tetraaza-cyclo-diene cations formed by reaction of copper(II) and nickel(II) diamine compounds with acetone.

Reactions with acetone of compounds of the cations with propane-1,3-diamine form compounds of homologous tetraaza-cyclohexadecadiene macrocycles [6,7]. For nickel(II) the *trans*-structure of the product was supported by a structural study of the disordered perchlorate salt [8] and by proton magnetic resonance studies for the cyclic tetraiimine oxidation product [9]. The imine functions of the nickel(II) cation were reduced by hydrogenation [10] and by $NaBH_4$ [11] to yield the cyclic tetraamine ligand cation. This was demetallated, by reaction with hydrochloric acid, to give the cyclic amine hydrochloride, from which compounds with cobalt(II) and copper(II) were prepared [11]. Structures of compounds of the cyclic tetraamine with cobalt(II), nickel(II) and copper(II) were reported [11].

A structural study of the perchlorate salt of the copper(II) tetraaza-cyclohexadecadiene cation shows a disordered structure with both *cis*- and *trans*-diimine cations present, indicating that the preparation yields a mixture of the isomeric cations [12]. The structure of N-*rac*-[Cu(*cis*-Me_6[16]diene)][$ZnCl_4$], prepared from the mixed perchlorate salt, unambiguously confirms the presence of the *cis*-diimine isomer [12].

2. Results

When a soluble thiocyanate salt is added to an aqueous solution of [Ni(*trans*-Me_6[16]diene)](ClO_4)$_2$ the sparingly water-soluble blue–violet dithiocyanato compound *trans*-[Ni(*trans*-Me_6[16]diene)(NCS)$_2$] precipitates. This dissolves in aqueous solutions of zinc(II) salts to form yellow solutions, apparently by reduction of the thiocyanate ion concentration by complexation with the zinc(II) ions. When zinc(II) chloride is used, sparingly water-soluble, yellow crystals can be isolated and these have been characterised by the structural study below. When other, non-halide, zinc(II) salts, e.g. zinc(II) nitrate or acetate, are substituted for the chloride the *trans*-Ni(*trans*-Me_6[16]diene)(NCS)$_2$] dissolves to form yellow solutions, but crystalline products are generally not formed. When additional thiocyanate is added then a sparingly soluble yellow crystalline product forms, of probable composition [Ni(*trans*-Me_6[16]diene)]-[$Zn(NCS)_4$].

3. Structural study

The structure of the yellow crystalline product obtained from the reaction of [Ni(*trans*-Me_6[16]diene)-(NCS)$_2$] with zinc chloride, and recrystallised from water, was determined by X-ray diffractometry (see Section 4.1 for details) to establish the configuration of the macrocycle, and to permit comparison of the structural parameters of homologous azamacrocycle cations with varying ring size.

The asymmetric unit of the compound contains two independent singlet ground state square-planar (tetraazacyclohexadecadiene)nickel(II) cations. Cation 1, with configuration 1*R*,9*S*, includes atom Ni1 and ring atoms N1–C16. Cation 2, with configuration 21*R*,29*S*, includes atom Ni2 and ring atoms N21–N36. Two independent tetrahedral chloro-(thiocyanato)zincate anions are present. Anion 2 includes zinc atom Zn5, two thiocyanate ions (N51, C51, S51) and (N52, C52, S52) with two chloride ions Cl51 and Cl52. Anion 1, with zinc atom Zn4, is disordered, see below, with two full occupancy thiocyanate ions with atoms (N41, C41 and S41) and (N42, C42 and S42) and chloride ion Cl41. Partial occupancy thiocyanate ion with atoms (N43, C43, and S43) and chloride ion Cl42 occupy one coordination site, with complementary s.o.f., see Fig. 1.

Both cations have 5,13-diimine (*trans*) structures, with the *N-meso* configuration (with the secondary amine

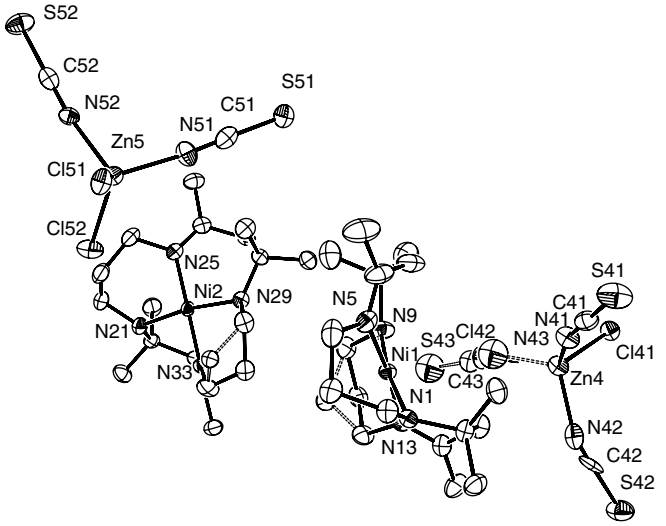

Fig. 1. Asymmetric unit, drawn with displacement ellipsoids at 50% confidence level. Hydrogen atoms are omitted for clarity. Site C11 has s.o.f. of 0.70(1), C31 of 0.74(1) and Cl42 of 0.779(4), with complementary s.o.f. for C11a, C31a and (N43, C43 and S43).

hydrogen atoms H1 and H9 on opposite sides of the Ni1, N1, N5, N9, N13 'plane'), and with the axially oriented methyl groups C82 and C162 both oriented to the same side of this plane as H9, see Fig. 2. which shows cation 1. Cation 2 is similar with N29, C262 and C282 oriented to the same side of the Ni2N21, N25, N29, N33 'plane' as H29.

The N_4 donor atom group of cation 1 is appreciably tetrahedrally twisted (r.m.s. displacements of N atoms ±0.126(2) Å, with atom Ni1 displaced by 0.027(2) Å from this plane). The N_4 donor atom group of the cation 2 is near coplanar (r.m.s. displacements ±0.009(1) Å, with atom Ni2 displaced by 0.048(1) Å from this plane).

The short bond lengths N5–C6, N1–C16, N25–C26 and N21–C36 and the near trigonal bond angles about these atoms (Table 1) confirm the locations of the imine functions. There is no indication of the orientational disorder in the location of the imine functions and axially oriented methyl substituents observed for [Cu(*cis*-Me_6[16]diene)]-[Cu(*trans*-Me_6[16]diene)]$(ClO_4)_4$ [12] and related compounds [13].

The Ni–N distances (Table 1) are only marginally longer than those observed for singlet ground state compounds of homologous [Ni(*trans*-Me_6[14]diene)]$^{2+}$ and [Ni(*trans*-Me_6[15]diene)]$^{2+}$ cations (Table 2), with Ni–N shorter for the imine than secondary amine nitrogen atoms, as is usual. While the calculated minimal strain "hole size" of amine–imine tetraaza-macrocycles for planar N_4 conformations increases significantly with ring size, the observed Ni–N distances for coordinated 14- to 16-membered rings increase only marginally, with the resulting strain accommodated by tetrahedral twisting of the N_4 group and/or increased buckling of the macrocycle, the latter being most significant for the [Ni(*trans*-Me_6[16]diene)]$^{2+}$ cations. The mean displacements of the ring atoms from the least-squares best plane for all ring atoms, is 1.06 Å for both cations, indicative of similar levels of ring puckering. The tetrahedral twisting of the NiN_4 group for cation 1 is appreciable and for the cation 2 is small, indicative of the flexibility of these macrocycles. There are no significant axial interactions with the nickel ions, the only atom closer than 4 Å is partial occupancy S43 (x, $-y+1/2$, $z+1/2$) at 3.66 Å from Ni1.

C43–N43–Zn4	136(2)		

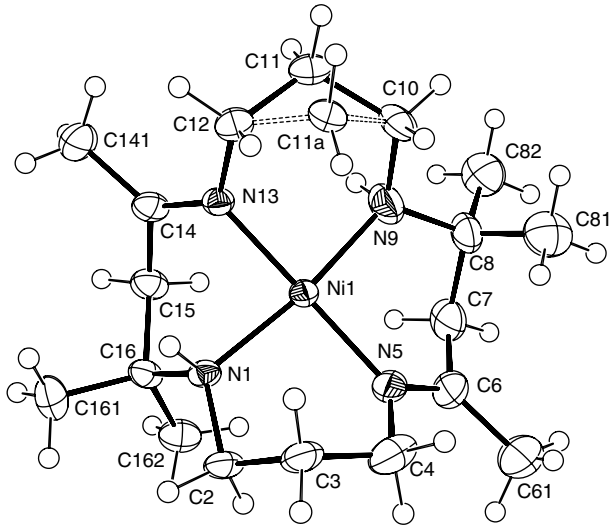

Fig. 2. Cation 1, drawn as for Fig. 1 but with hydrogen atoms shown as circles of arbitrary radii. Site C11 has s.o.f. of 0.70(1), C11a of 0.30(1). The cation 2 is similar.

Both cations have the macrocycle in 'saddle' conformations, with the substituted (hexamethyl-1,3-amine–imine) and the unsubstituted (1,3-diamine) chelate rings tilted to opposite sides of the NiN_4 'plane'. The amine–imine chelate rings all have asymmetrical boat conformations. The 1,3-diamine chelate rings Ni1, N1, N5 and Ni2, N21, N25 have boat conformations, while the opposing chelate rings (Ni1, N9, N13 and Ni2, N29, N33) have the central methylene group disordered. The major components C11 {s.o.f. = 0.65(1)} for the Ni1, N9, N13 chelate ring and C31 {s.o.f. = 0.73(1)}

Table 2
Structural parameters for related compounds (mean values, Å)

Compound	Distance, Ni–N_{amine}	Distance, Ni–N_{imine}	r.m.s. Tetrahedral displacement of N_4 group	Reference

N29–H29···Cl51	2.44	3.354(3)	177	$x+1, y+1/2, -z+3/2$

for the Ni2, N29, N33 chelate ring form a chair conformation chelate ring, while the minor components {C11A and C31A, respectively} complete a boat conformation chelate ring.

The anion 2 has Zn5 in approximately tetrahedral coordination by two chloride and two *iso*-thiocyanate ligands, with the Zn–N–C groups appreciably bent (see Table 1). When the anion 1 was modeled as a similar $[ZnCl_2(NCS)_2]^{2-}$ ion then persistent residual electron density peaks were associated with the Cl42 site. This ion was modeled with partial substitution of chloride Cl42 by a thiocyanate ion N43–C43–S43, with complementary s.o.f. {s.o.f. = 0.78(1) for Cl42, 0.22(1) for N43, C43 and S43}. The s.o.f. for the atoms of the other chloride and thiocyanate ions around Zn4 are normal, excluding possible structures with rotational disorder of a stiochiometric $[ZnCl_2(NCS)_2]^{2-}$ ion. The structure is considered to have disordered $[ZnCl_2(NCS)_2]^{2-}$ and $[ZnCl(NCS)_3]^{2-}$ ions, with overall stiochiometry $[ZnCl_{1.89}(NCS)_{2.11}]^{2-}$. Alternatively, the major residual electron density peak was less satisfactorily modeled as a fractional (s.o.f. 0.33) water molecule. The Zn···O distance was approximately the same as the Zn···S distances for a coordinated thiocyanato group, but the Cl42···O distance at 2.3 Å was unreasonably short and no associated hydrogen atoms could be located. The partial occupancy site S43 lies between the partial occupancy sites C11 and C31A on the two cations (S43···C11 = 3.00; S43···C31A = 3.18 Å), so the disorder at the three sites is probably correlated. Significant hydrogen bonding interactions are shown in Table 3.

Compounds with mixed chloro-thiocyanato-zincate anions have been reported [14–16], including the structure of a compound with a $[ZnCl(NCS)_3]^{2-}$ anion [16].

4. Experimental

4.1. (6,8,8,14,16,16-Hexamethyl-1,5,9,13-tetraazacyclothexadeca-5,13-diene)nickel(II)perchlorate, [Ni(Me_6[16]diene)]$(ClO_4)_2$

The compound was prepared by reaction of Tris-(propane1,3-diamine)nickel(II) perchlorate with acetone [6,7].

4.2. (6,8,8,14,16,16-Hexamethyl-1,5,9,13-tetraazacyclothexadeca-5,13-diene)(dithiocyanato)-nickel(II), [trans-Ni(Me_6[16]diene)$(NCS)_2$]

Sodium thiocyanate was added to a hot aqueous solution of [Ni(Me_6[16]diene)]$(ClO_4)_2$ when the sparingly water-soluble blue–violet product precipitated. This was filtered off, washed with cold water and recrystallised from dichloromethane/propan-2-ol.

4.3. N-meso-(trans-6,8,8,14,16,16-Hexamethyl-1,5,9,13-tetraazacyclothexadeca-5,13-diene)nickel(II)chloro-(isothiocyanato)zinc(II), N-meso-[Ni(trans-Me_6[16]diene)][$ZnCl_{1.91}(NCS)_{2.08}$]

A hot aqueous solution of zinc chloride was added to a hot aqueous solution/suspension of [Ni(*trans*-Me_6[16]-diene)$(NCS)_2$] when it dissolved to form a yellow solution from which yellow crystals separated upon cooling. The sparingly water-soluble yellow solid was filtered from the cold solution, washed with a little cold water then ethanol. The product recrystallised from hot water was usually contaminated with [Ni(*trans*-Me_6[16]diene)-$(NCS)_2$]. Alternatively it could be recrystallised from DMF/propan-2-ol. The crystal used in the structural study was obtained by slow evaporation of an aqueous solution. IR spectrum: ν(NH) 3132; ν(C≡N) 2078 vs ν(C=N) 1637 cm^{-1}. Analytical results for different batches varied, but were consistent with formation of a range of products with varying proportions of chloride and thiocyanate ions.

5. Structure determination

5.1. Crystal data

$[(C_{18}H_{36}N_4)Ni][(CNS)_{1.9}Cl_{2.1}Zn]$	$Z = 8$
$M_r = 621.97$	$D_x = 1.507$ Mg m^{-3}
Monoclinic, $P2_1/c$	Mo Kα radiation
$a = 18.80(1)$ Å	Cell parameters from 3215 reflections
$b = 15.368(8)$ Å	$\theta = 2.5$–$28.6°$
$c = 19.02(1)$ Å	$\mu = 1.93$ mm^{-1}
$\beta = 92.39(1)°$	$T = 273(2)$ K
$V = 5488(5)$ Å^3	Block, orange, $0.27 \times 0.17 \times 0.16$ mm

5.2. Data collection

Bruker CCD diffractomer	8954 reflections with $I > 2\sigma(I)$
phi and omega scans	$R_{int} = 0.070$
Absorption correction: multi-scan (based on symmetry-related measurements) [23]	$\theta_{max} = 30.2°$
$T_{min} = 0.525$, $T_{max} = 0.735$	$h = -26 \rightarrow 26$
77 334 measured reflections	$k = -21 \rightarrow 20$
16 135 independent reflections	$l = -26 \rightarrow 26$

5.3. Ref. [16]

Refinement on F^2	H atoms constrained to parent site
$R[F^2 > 2\sigma(F^2)] = 0.045$	Calculated weights $w = 1/[\sigma^2(F_o^2) + (0.0585P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$
$wR(F^2) = 0.096$	$S = 0.86$
16 135 reflections	612 parameters

Hydrogen atoms are in calculated positions and riding on their parent atom. Atoms C11 and C11A, C31 and C31A, and Cl42 and (N43, C43 and S43) were refined with complementary s.o.f., N43, C11A, C31A, C43 and S43 were refined with isotropic parameters. Distance restraints (DFIX with default parameters) were applied to C10–C11A, C12–C11A, C30–C31A and C32–C31A (1.54 Å), Zn4–Cl142 (2.26 Å), Zn4–N43 (2.00 Å), N43–C43 (1.13 Å) and C43–S43 (1.64 Å).

Abstract

Mononuclear copper(II) complexes, [Cu L1] $(ClO_4)_2$ (**1**), [Cu L2] $(ClO_4)_2$ (**2**) and [Cu L3] $(ClO_4)_2$ (**3**) with quadridentate Schiff base ligands L1 (*N*,*N*′-bis-pyridin-2-ylmethyl-butane-1,4-diimine), L2 (*N*,*N*′-bis-pyridin-2-ylmethyl-pentane-1,5-diimine) and L3 (*N*,*N*′-bis-pyridin-2-ylmethyl-hexane-1,6-diimine) have been synthesized and characterized. The crystal structure data of **1** reveals the existence of the complex in two different geometries, namely a square pyramid and a distorted octahedron, which eventually leads to the packing of the molecule into helical and anti-parallel structures respectively. Absorption titration studies with calf thymus DNA for all three complexes are suggestive of groove binding with binding constant values for **1**, **2** and **3** being $2.6 \pm 0.2 \times 10^4$ M^{-1}, $11.5 \pm 0.2 \times 10^4$ M^{-1} and $1.83 \pm 0.2 \times 10^4$ M^{-1} respectively. Control cleavage experiments using pBR 322 plasmid DNA and distamycin suggest minor groove binding for these complexes. In the presence of ascorbic acid, the complexes show efficient DNA cleavage, the order of efficiency being **1** > **2** ≅ **3**.

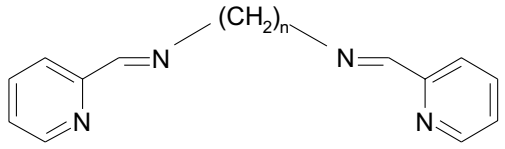
Keywords: Copper(II) complex; Tetradentate ligand; Crystal structure; DNA binding; Nuclease activity

1. Introduction

Studies on the interaction of small molecules with DNA continue to attract considerable attention due to their importance in cancer therapy and molecular biology [1–3]. In this respect, transition metal complexes have attracted special attention due to their unique spectroscopic and electrochemical signatures [4–6]. The interest in the DNA recognition by transition metal complexes has been substantially aided by the DNA cleaving ability of some of these metal complexes [7–15]. Artificial metallonucleases have proven to be efficient tools for the footprinting and sequence-specific targeting of nucleic acids [16–18]. They are composed of a transition or lanthanide metal ion and a ligand which plays two major roles – it modulates the reactivity of the metal ion and, by interacting with the nucleic acid, it delivers the reactive metal ion species to the vicinity of the sensitive functionalities of the biopolymer.



Copper is a bioessential element with relevant oxidation states +1 and +2. Coordination compounds of copper, in both its oxidation states, have been extensively used in metal mediated DNA cleavage through the generation of hydrogen abstracting activated oxygen species [19–25]. Copper(II) complexes under certain ligand environments have also been shown to bring about photocleavage of DNA as well as RNA and DNA scission via phosphodiester transesterification [26–32]. Among the various copper complexes so far investigated, those of phenanthroline

Abbreviations: CT DNA, calf thymus DNA; Tris, tris(hydroxymethyl)methylamine; DMSO, dimethyl sulphoxide; TBE, tris-boric acid-EDTA; DPPH, diphenylpicrylhydrazyl.

doi:10.1016/j.poly.2007.02.020

and its derivatives have attracted much attention for their various functions. Copper(II) complexes of 1,10-phenanthroline have been shown to inhibit DNA and RNA polymerase activities and induce strand scission of DNA in the presence of H_2O_2 or thiol [33–36]. The substitution of the phenanthroline has been shown to influence the reactivity of the complexes with DNA [37]. Because of the fact that copper(II) is a substitutionally labile metal ion, multidentate ligands are believed to be better than bidentate ligands in keeping the copper(II) ion chelated in solution. We have been investigating the metallonuclease property of copper(II) complexes of N_3 tridentate ligands [38–40]. In this communication we describe the synthesis and DNA cleaving abilities of a homologous series of copper(II) complexes of N_4 tetradentate ligands L1, L2 and L3.

2. Materials and methods

2.1. Chemicals

2-Pyridine carboxaldehyde, 1,4-diaminobutane, 1,5-diaminopentane and 1,6-diaminohexane were obtained from Sigma Aldrich, USA and were used as received. Tris (hydroxymethyl) methylamine (Tris) and Calf Thymus DNA (CT DNA) were obtained from SRL chemicals, Mumbai. All chemicals and reagents used were of analytical grade and were received from Ranbaxy, Mumbai. A stock solution of DNA was prepared by stirring a sample dissolved in 10 mM Tris buffer (pH 7.5) at 4 °C. The solution was dialyzed exhaustively against Tris buffer for 48 h. and filtered using a membrane filter obtained from Sartorius (0.45 μm). The filtered DNA solution in the buffer gave a UV absorbance ratio (A_{260}/A_{280}) of about 1.9, indicating that the DNA was sufficiently free from protein [41]. The concentration of DNA was determined using an extinction coefficient of 6600 M^{-1} cm^{-1} at 260 nm [42].

2.2. Syntheses

2.2.1. [Cu L1](ClO4)2 (1)

1,4 Diaminobutane (0.88 g, 10 mmol) was added to 2-pyridine carboxaldehyde (2.14 g, 20 mmol) and refluxed in methanolic medium for 15 min. To this solution copper(II) perchlorate (3.70 g, 10 mmol) dissolved in methanol was added and refluxing was continued for another half an hour. The bluish-green solid that separated out on cooling, was filtered and washed with diethyl ether and dried in vacuo over $CaCl_2$. Slow evaporation of an acetonitrile solution of the complex yielded single crystals suitable for X-ray diffraction. *Anal. Calc.* for $[C_{16}H_{18}CuN_4](ClO_4)_2$: C, 36.29; H, 3.40; N, 10.58; Cu, 12.00; Found: C, 36.21; H, 3.33; N, 10.68; Cu, 12.05%. IR spectra [KBr disc, cm^{-1}]: 2933 (w), 1600 (s), 1088 (br), 781 (s), 622 (s); (s-strong, br-broad, w-weak). FAB MS, base peak at *m/z*: 329 $(ML1-H)^+$. The complex is freely soluble in water and acetonitrile.

2.2.2. [Cu L2](ClO4)2 (2)

This complex was prepared by a similar procedure to that of complex **1** by taking 1,5 diaminopentane (1.02 g, 10 mmol), 2-pyridine carboxaldehyde (2.14 g, 20 mmol) and copper(II) perchlorate (3.7 g, 10 mmol) in the molar ratio 1:2:1. The complex separates out as a dark brown solid from the methanolic medium. Our attempts to grow single crystals of the complex have not been successful so far. *Anal. Calc.* for $[C_{17}H_{20}CuN_4](ClO_4)_2$: C, 37.56; H, 3.68; N, 10.31; Cu, 11.69; Found: C, 37.50; H, 3.72; N, 10.26; Cu, 11.63%. IR spectra [KBr disc, cm^{-1}]: 2939 (w), 1598 (s), 1093 (br), 775 (s), 623 (s). FAB MS, base peak at *m/z*: 343 $(ML2\text{-}H)^+$. The complex is partially soluble in water and freely soluble in acetonitrile and DMSO.

2.2.3. [Cu L3](ClO4)2 (3)

This complex was prepared by a similar procedure to that of complex **1** by taking 1,6 diaminopentane (1.16 g, 10 mmol), 2-pyridine carboxaldehyde (2.14 g, 20 mmol) and copper(II) perchlorate (3.7 g, 10 mmol) in the molar ratio 1:2:1. The complex separates out as brown solid from the reaction medium. *Anal. Calc.* for $[C_{18}H_{22}CuN_4](ClO_4)_2$: C, 38.78; H, 3.95; N, 10.05; Cu, 11.39; Found: C, 38.59; H, 3.85; N, 10.09; Cu, 11.30%. IR spectra [KBr disc, cm^{-1}]: 2937 (w), 1598 (s), 1100 (br), 776 (s), 623 (s). FAB MS, base peak at *m/z*: 357 $(ML3\text{-}H)^+$. The complex is partially water soluble and completely soluble in acetonitrile and DMSO.

2.2.4. Instrumentation

UV–visible spectra of the complex and DNA binding studies were recorded on a Perkin–Elmer Lambda 35 double beam spectrophotometer at 25 °C. The infrared spectra of the complexes were recorded on a Perkin–Elmer FTIR spectrometer. The FAB mass spectra were recorded on a JEOL SX 102/DA-6000 mass spectrometer using argon (6 kV, 10 mA) as the FAB gas. m-Nitrobenzyl alcohol was used as the matrix. Elemental analyses were performed using a Heraeus CHN–O– rapid analyzer. Cyclic voltammetry was performed on CH-Instruments, electrochemical analyzer, CH-620 B. X-band electron paramagnetic resonance (EPR) spectra at room temperature and liquid-nitrogen temperatures were recorded on a Bruker EMX 6/1 spectrometer and the g calibration was done using

diphenylpicrylhydrazyl (DPPH). Circular dichroic spectra were recorded using a J-715 spectropolarimeter (Jasco) at 25 ° C with a 0.1 cm pathlength cuvette.

2.2.5. X-ray crystallography of [Cu L1](ClO$_4$)$_2$

A green crystal of an approximate size of $0.71 \times 0.27 \times 0.18$ mm was mounted on a glass fiber and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 23 reflections in the range of $1.5 < \theta < 27.99°$ on an Enraf Nonius MACH3 automatic diffractometer. Data were collected at 293 K using Cu Kα radiation ($\lambda = 1.54184$ Å) and the $\omega/2\theta$-scan technique, and corrected for Lorentz and polarization effects. A semi-empirical absorption correction (Psi-scans) was made. The structure was solved by the Patterson method and subsequent difference Fourier maps and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [43]. All hydrogen atoms were included in geometrically idealized positions employing appropriate riding models with isotropic displacement parameters constrained to 1.2U ~ (eq) of their carrier atoms. Criteria of a satisfactory complete analysis were the ratios of rms shifts to standard deviations of less than 0.001 and no significant features in the final difference maps. Atomic scattering factors were from the ''International Tables for Crystallography'', molecular graphics from PLATON and SCHAKAL. A summary of the crystal data is given in Table 1.

2.2.6. DNA-binding and cleavage experiments

The electronic spectra of complexes **1** and **2** were monitored both in the absence and presence of DNA at around 281 and 275 nm, respectively. Absorption titration experiments were performed by maintaining a constant metal complex concentration (20 μM) and varying the nucleic acid concentration (0–200 μM). The same DNA concentration was maintained in the reference cell so as to nullify the absorbance due to DNA at the measured wavelength. From the absorption titration data, the binding constant was determined using:

$$[\mathrm{DNA}]/(\varepsilon_a - \varepsilon_f) = [\mathrm{DNA}]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_b - \varepsilon_f), \quad [44]$$

where ε_a, ε_f and ε_b correspond to A_{obsd}/[Cu], the extinction coefficient for the free copper complex and the extinction coefficient for the copper complex in the fully bound form, respectively. A plot of [DNA]/($\varepsilon_a - \varepsilon_f$) versus [DNA] gives $K_b$as the ratio of the slope to the intercept.

Voltammetric experiments were carried out using a standard three electrode system comprising of a glassy carbon working electrode, platinum auxillary electrode and saturated calomel reference electrode (SCE). The samples were prepared in DMSO and the solutions were deoxygenated by purging nitrogen gas for 10 min. prior to measurement. Cyclic and differential pulse voltammetric investigations on complexes **1**–**3** have been carried out with a complex concentration of 0.2×10^{-3} M using 1 mM Tris buffer, 100 mM NaCl (pH 7.5) as a supporting electrolyte. The formal potentials, E^0 (or voltammetric $E_{1/2}$) values were determined from the DPV peak potential, E_p, using the relation $E_{1/2} = E_p + \Delta E/2$, where $E_{1/2}$ is the equivalent of the average of E_{pc} and E_{pa} in CV experiments and ΔE is the pulse amplitude (50 mV).

The cleavage of plasmid DNA was monitored using agarose gel electrophoresis. Supercoiled pBR322 DNA (0.25 μg) in (Tris) buffer (50 mM, pH 7.5) with 50 mM NaCl was treated with the copper(II) complexes (80 μM) and ascorbic acid (300 μM). The samples were incubated for 90 min at 37 °C. In the inhibition reactions, additives like distamycin or DMSO were added to the supercoiled DNA and the incubation carried out for 15 min. at 37 °C prior to the addition of the complex and ascorbic acid. A loading buffer containing 0.25% bromophenol blue, 40% (w/v) sucrose and 0.5 M EDTA was added and the electrophoresis of the DNA cleavage products was performed on 0.8% agarose gel containing 0.5 μg/mL ethidium bromide. The gels were run at 50 V for 3 h in Tris-boric acid-ethylenediamine tetraacetic acid (TBE) buffer and the bands were photographed by a gel documentation system. The relative amounts of plasmid DNA were quantified using the Bio Rad Quantity one package.

3. Results and discussion

3.1. Synthesis

The complexes **1**–**3** could be prepared through template condensation of the corresponding diamine and aldehyde in a 1:2 mole ratio in the presence of copper(II) perchlorate.

The authenticity of the compounds prepared was ascertained from mass spectral data and could be formulated as $[CuL](ClO_4)_2$, and was confirmed by the single crystal X-ray structure determination of complex **1**. In the present series of complexes, there is a systematic increase in the chain length of the alkyl backbone of the ligand and this is expected to influence the structure, electronic and redox properties of the complexes. Hence they are expected to show variations in their DNA binding affinity and cleavage activity.

3.2. Crystal structure of complex *1*

Complex **1** crystallizes as monoclinic crystals with the space group $P2_1/n$. The unit cell contains four asymmetrically independent molecules with two different geometries. The molecular structure of the two different molecules A and B are shown in Fig. 1. The copper(II) ion in molecule A is five coordinate with a square pyramidal geometry. The four nitrogen atoms of the Schiff base form the basal plane and the oxygen of the perchlorate ion occupies the apical position. The four Cu–N bond lengths vary in the range 1.980(4)–1.996(4) Å. The perchlorate oxygen occupies the apical position with an elongated Cu–O bond length of 2.457(4) Å. The N–Cu–N bond angles vary from 82.1(18)° to 166(2)°. The bridging tetramethylene group of the Schiff base is found to exhibit a boat conformation and induces steric hinderance for the adjacent packing of the molecules. As a result, the molecule takes a helical shape with the assistance of the perchlorate ion as shown in Fig. 2a.

In the case of molecule B, the copper atom is six coordinate with four nitrogens of the Schiff base and two perchlorate oxygens forming a distorted octahedral geometry. The Cu–N bonds in molecule B has been found to vary from 1.962(4) to 2.010(4) Å and the two Cu–O bond lengths are 2.602(5) and 2.612(5) Å. In this molecule, three of the four Cu–N bond distances are much shorter than the fourth one. This is due to the fact that the bridged tetramethylene group in molecule B exhibits a chair conformation. The perchlorate anion assists the packing of molecule B in anti-parallel sheets in contrast to the helical shape of molecule A (Fig. 2b). The perchlorate anion not only assists the packing of the complex in two different geometries, but also it participates in bridging of molecules A and B. The important bond lengths and bond angles for complex **1** are given in Table 2. It is of importance to note that the capability of the bridging tetramethylene group to exist in chair as well as boat conformations is one of the reasons for the crystallization of complex **1** with two different structural parameters. The perchlorate ion subsequently brings about the assembly of the two types of molecules into helical as well as sheet structures.

3.3. Electronic and EPR spectra

The electronic spectra of all the three complexes exhibit intra-ligand transitions in almost the same spectral region (275–280 nm) but their ligand field transitions appear at different regions (Table 3). While complex **1** shows only one broad band in the visible region, **2** and **3** show one broad and one sharp band indicating that the increase in the number of methylene groups in the backbone of the ligand results in a change in the geometry around the metal ion. This fact is further supported by EPR spectral studies. The X-band EPR spectrum of complex **1** (Fig. 3a) taken at 77 K, examined as a frozen DMSO solution, reveals the presence of axial symmetry out of a distorted tetragonal copper(II) site in the complex. The spectrum shows four $g_{\|}$ components and a broad $g_{\perp}$ component. The 77 K EPR spectra of complexes **2** and **3** in DMSO exhibit almost similar spectral features, but they are qualitatively different from that of complex **1.** Fig. 3b shows the EPR spectrum of complex **2**. The simulation fits the experimental spectrum

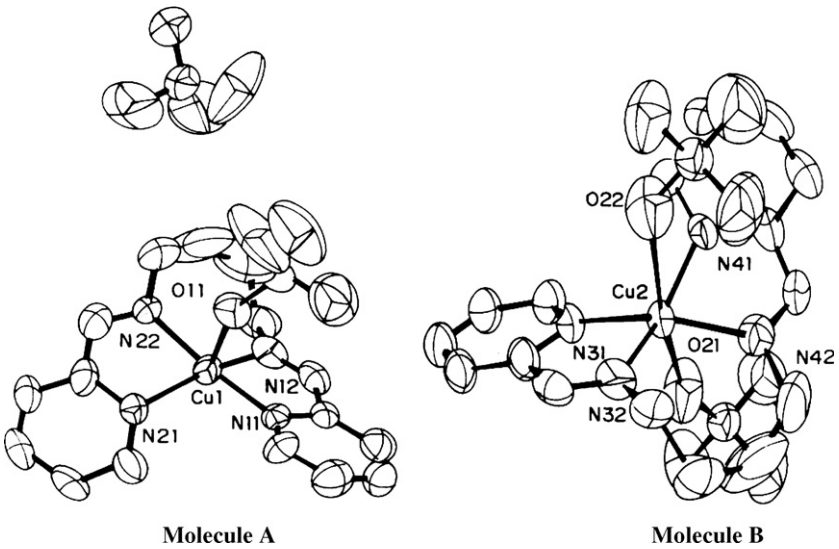

Fig. 1. ORTEP diagram of complex **1**.

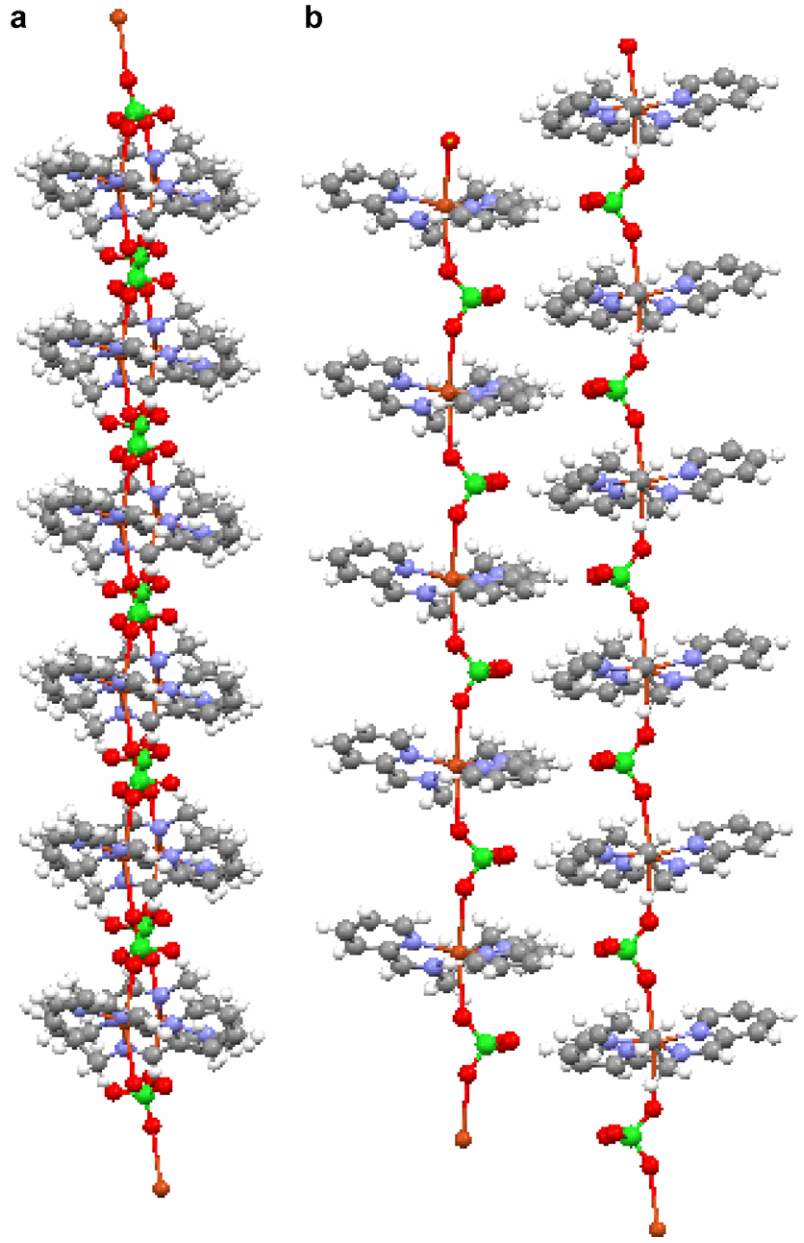

Fig. 2. Packing of complex **1** in two different geometries: (a) helical assembly and (b) anti-parallel sheet.

best assuming rhombic character. The EPR spectral parameters for all three complexes are listed in Table 3. The rhombic character of complexes **2** and **3** suggests considerable deviation from the square planar geometry as compared to **1**. Also, on comparing the A_Z values of **2** and **3**, we find that **3** has a lower A_Z value which is indicative of an increase in the degree of distortion as we move from **2** to **3**.

3.4. DNA binding studies

Even though in its crystalline form the perchlorate ion is coordinated to copper(II) in complex **1**, in aqueous

solution the perchlorate will be replaced by water. The complexes will therefore exist as $[CuL(H_2O)_2]^{2+}$. DNA binding capabilities of the complexes were investigated by monitoring their intraligand spectral band as a function of DNA concentration. Binding of the complexes leads to perturbation of their ligand centered band. Spectral bands of complexes **1**–**3** show hyperchromism with increasing concentrations of DNA, as depicted in Fig. 4. Such spectral behaviour clearly rules out intercalative binding of the complexes to DNA, since intercalation leads to hypochromism in the spectral band of the intercalating molecule [45–48]. No detectable changes in the energy of ligand field bands of these complexes were observed in the presence of DNA, ruling out binding of these complexes to DNA bases. The spectral changes observed in the presence of DNA can be rationalized in terms of groove binding [49]. However since all the three complexes contain aromatic rings in their ligand structure, partial intercalation of these molecules cannot be fully ruled out. Analysis of the spectral data in the presence of DNA gave binding constants, K_b, of $2.6 \pm 0.2 \times 10^4$ M^{-1}, $11.5 \pm 0.2 \times 10^4$ M^{-1} and $1.83 \pm 0.2 \times 10^4$ M^{-1} for complexes **1**, **2** and **3** respectively. From the binding constant values, it is clear that the complexes are moderate binders and complex **2** shows the highest binding affinity amongst them.

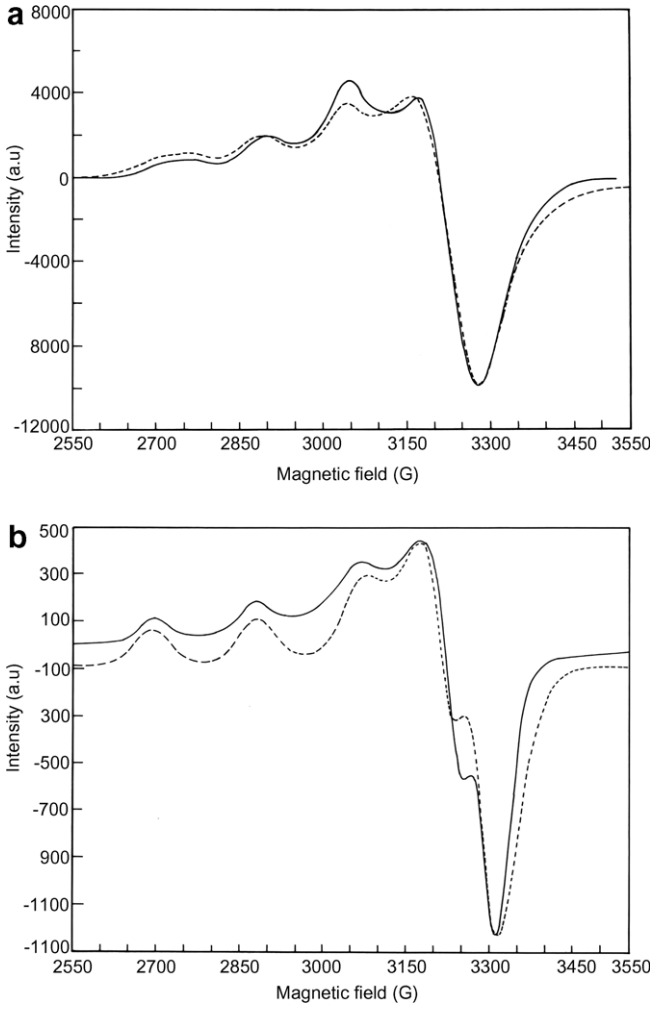

Fig. 3. (a) EPR spectra of a frozen solution of complex **1** and (b) complex **2** at 77 K (Microwave frequency = 9.23 GHz, power = 1 mW, modulation frequency = 100 kHz, modulation amplitude = 3 G). Solid line represents experimental spectrum and dotted line, simulated spectrum.

3.5. Electrochemical studies

Cyclic and differential pulse voltammetric techniques have been employed to study the interaction of the redox

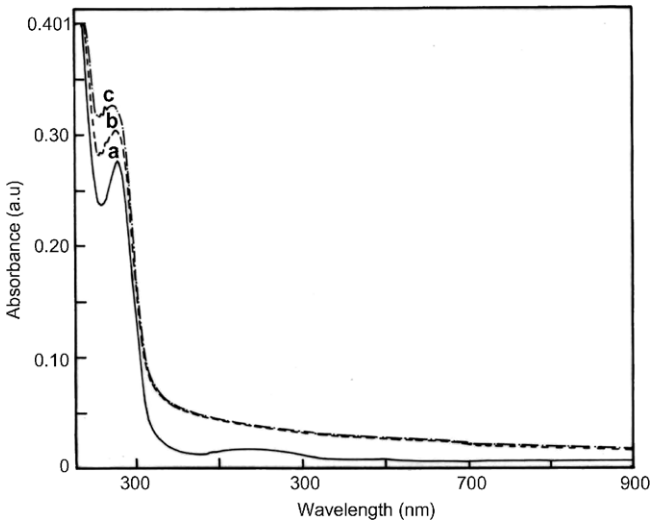

Fig. 4. Absorption spectra of complex **2** (20 μM) in the absence (a) and presence (b and c) of increasing concentrations of CT DNA (40 and 80 μM).

[b] Based on the $E_{1/2}$ values of DPV.

active copper(II) complexes with DNA to further explore the DNA binding modes. Electrochemical studies carried out for all three complexes is summarised in Table 4. The cyclic voltammograms of the complexes in the absence of DNA reveal a non-Nernstian but a fairly reversible/quasi-reversible one electron redox process involving the Cu(II)/Cu(I) couple, as judged from the peak potential separation of 72–103 mV (59 mV for a one electron transfer process). It is seen that the reduction potential of the Cu(II)/Cu(I) couple becomes more positive on moving from complex **1** to **3** and also becomes more reversible as can be seen from the ΔE_p values. This clearly shows that the tetragonal distortion increases as one goes from complex **1** to **3**. Hence as we move from complex **1** to **3**, the nuclear reorganization energy for Cu(II) to Cu(I) conversion decreases. A reduction in the diffusion current is also seen as we move from **1** to **3** for a fixed concentration of the complex. This again reflects the fact that the bulky nature of the ligand increases from **1** to **3**.

In the presence of DNA ([DNA]/[Cu] = 5), there is a decrease in the reduction peak current indicating that the complexes are bound to the macromolecule. The $E_{1/2}$ values of the DNA-bound complexes follow the same order as the free complexes (Table 4).

The DPV for all three complexes in the absence and presence of DNA is shown in Fig. 5. The observed shifts in the $E_{1/2}$ values to more positive potentials on binding to DNA suggests that the complex displays better binding affinity in the Cu(I) state compared to the Cu(II) state. This is illustrated by the ratio of the equilibrium constants (K_{+1}/K_{+2}) for the binding of Cu(I) and Cu(II) species to DNA. These values (Table 4) have been estimated from the net shift in $E_{1/2}$ (DPV) on the addition of DNA, assuming reversible electron transfer, using the following equation: $E_b^0 - E_f^0 = 0.0591 \log(K_{+1}/K_{+2})$ where E_b^0 and E_f^0 are the formal potentials of the redox couple in the DNA bound and free form respectively [50] and K_+ and K_{2+} are the corresponding binding constants for the binding of the 1+ and 2+ species to DNA, respectively. The values of K_{+1}/K_{+2} for all the complexes have been found to be greater than unity, suggesting preferential stabilization of the Cu(I) form over the Cu(II) form on binding to DNA.

3.6. CD spectral studies

Circular dichroic spectral techniques give us useful information on how the conformation of DNA is influenced by the binding of the metal complex to DNA. The observed CD spectrum of calf thymus DNA consists of a positive band at 277 nm due to base stacking and a negative band at 245 nm due to helicity, which is characteristic of DNA in the right-handed B form. While groove binding and electrostatic interaction of small molecules with DNA show little or no perturbations on the base stacking and helicity bands, intercalation enhances the intensities of both the bands, stabilizing the right-handed B conformation of CT DNA. The CD spectra of DNA taken after incubation of the complexes with CT DNA are shown in Fig. 6. In all three cases, there is a decrease in the intensity of the positive band while the negative band is relatively less perturbed. These changes are indicative of a non-intercalative mode

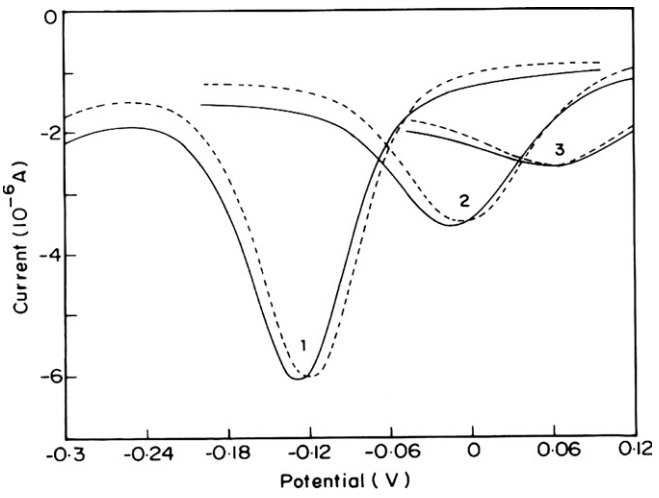

Fig. 5. Differential pulse voltammogram of complexes **1**, **2** and **3** (0.2 mM) in the absence (———) and presence of 1 mM of CT DNA (— — —); Supporting electrolyte, 1 mM Tris/ 100 mM NaCl buffer (pH 7.5).

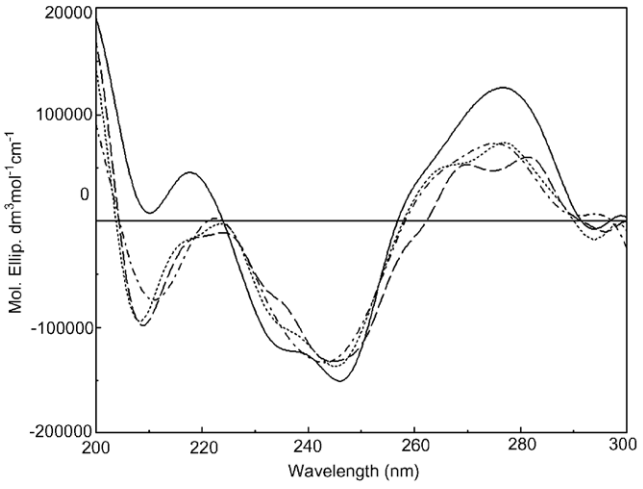

Fig. 6. CD spectra of CT DNA (200 μM) in the absence (——) and presence of 50 μM of **1** (. . . . . .), **2** (-·-·-·-·-·-) and **3** (– – – –).

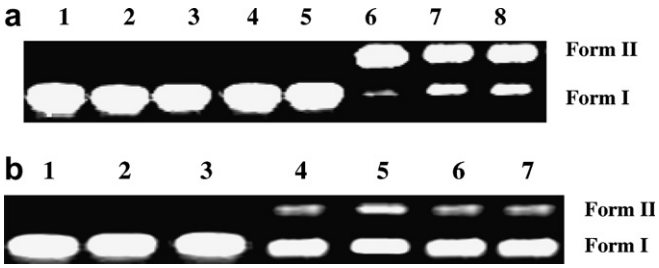

Fig. 7. (a) Cleavage of pBR322 DNA by complexes **1**–**3** in the presence of ascorbic acid. DNA (0.25 μg) was incubated with the complexes for 60 min. in Tris buffer (pH 7.5). Lane 1, DNA control; lane 2, DNA + **1** (80 μM) alone; lane 3, DNA + complex **2** (80 μM) alone; lane 4, DNA + **3** (80 μM) alone; lane 5, DNA + ascorbic acid (300 μM); lane 6, DNA + **1** (80 μM) + ascorbic acid (300 μM); lane 7, DNA + **2** (80 μM) + ascorbic acid (300 μM); lane 8, DNA + **3** (80 μM) + ascorbic acid (300 μM) and (b) Cleavage of pBR322 DNA by complexes in the presence of minor groove binder distamycin. DNA (0.25 μg) was incubated with 100 μM distamycin for 15 min. in Tris buffer (7.5). Lane 1, DNA control; lane 2, DNA + DMSO (2 μL) alone; lane 3, DNA + distamycin (100 μM) alone; lane 4, DNA + **1** (80 μM) + ascorbic acid (300 μM) + DMSO (2 μL); lane 5, DNA + **1** (80 μM) + ascorbic acid (300 μM) + distamycin (100 μM); lane 6, DNA + **2** (80 μM) + ascorbic acid (300 μM) + distamycin (100 μM); lane 7, DNA + **3** (80 μM) + ascorbic acid (300 μM) + distamycin (100 μM).

of binding of these complexes and offer support to their groove binding nature [51].

3.7. DNA cleavage studies

The oxidative cleavage of DNA in the presence of a reducing agent (ascorbic acid 300 μM) has been studied with supercoiled pBR322 DNA (SC DNA) and the extent of cleavage monitored by agarose gel electrophoresis. Fig. 7a shows the results of a gel electrophoresis experiment carried out with SC DNA in the absence and presence of complexes **1**–**3**. Lane 1 in the figure shows the control DNA without any additives. Incubation of DNA with ascorbic acid or with a complex alone does not bring about any apparent cleavage of DNA, as seen in lanes 2–5. Hence it is clear that these copper(II) complexes are not capable of bringing about any hydrolytic cleavage of DNA. This is not surprising since hydrolytic cleavage requires coordinative binding of the copper(II) complex to the phosphate moiety of the nucleic acid [52]. Since these complexes do not interact coordinatively with either DNA bases or phosphate, one cannot expect them to promote hydrolytic cleavage. Lanes 6–8 represent the cleavage brought about by complexes **1**–**3** at a concentration of 80 μM in the presence of 300 μM of ascorbic acid, wherein the conversion of SC DNA to the open circular form is clearly seen by the disappearance of form I and the appearance of form II. We have investigated the mechanistic aspects of the DNA cleavage reactions using inhibiting reagents like hydroxyl radical scavenger DMSO and minor groove binder distamycin. The gel electrophoresis results are given in Fig. 7b. Control experiments performed with SC DNA in the presence of DMSO and distamycin show the absence

Table 5
Extent of DNA cleavage by complexes **1**–**3**

Complexes	Without distamycin		Pretreated with distamycin	
	% SC[a]	% NC[a]	% SC	% NC
1	30	70	70	30
2	39	61	74	26
3	40	60	73	27

[a] SC – supercoiled, NC – nicked circular.

of any significant cleavage (lanes 2 and 3). In the presence of DMSO, the DNA cleavage brought about by the complexes is inhibited to a large extent, as observed in lanes 4 and 5. This observation validates the involvement of hydroxyl radical in DNA cleavage promoted by these complexes. The mechanistic pathway is summed up in the scheme shown below and is similar to that proposed by Sigman and coworkers for the nuclease activity of bis(phen) copper species [53].

$$[\text{Copper(II)complex}] \xrightarrow{\text{Reducingagent}} [\text{Copper(I)complex}] \xrightarrow{O_2} [OH^{\cdot}]$$

$$[OH^{\cdot}] \xrightarrow{\text{SCDNA}} \text{Nicked DNA}$$

The percentage of cleavage for all three complexes is given in Table 5. It is seen that the cleavage efficiency of **1** is marginally greater than that of **2** and **3**, both of which exhibit almost equal efficiency. Considering the fact that the cleavage mechanism goes through a Cu(I) intermediate for the generation of a hydroxyl radical, the decrease in the efficiency of DNA damage among the complexes could be thus explained. The reduced Cu(I) complex could be partly oxidized by O_2 solvated in the solution before it binds to DNA causing considerable reduction in the DNA damage, and this process is more feasible in complexes **2** and **3** as compared to **1** because of their greater electrochemical reversibility. Treatment of SC DNA with distamycin prior to the addition of the complexes inhibited the DNA cleaving ability of these complexes to a large extent (lanes 5–7). These results clearly show that the complexes prefer minor groove binding and binding of the complexes to DNA is a prerequisite for their DNA cleaving ability.

4. Conclusion

In summary, the present work describes the synthesis, characterization and DNA binding studies of copper(II) complexes **1**, **2** and **3** with N_4 Schiff base ligands containing a flexible alkyl spacer. The crystal structure of complex **1** shows that the compound exists in two different geometries, namely a square pyramid and a distorted octahedron, in its unit cell and this leads to the packing of the molecule in helical and anti-parallel structures respectively. As the number of $-CH_2-$ groups in the backbone increases along the series, the geometry of the copper complex is found to acquire more rhombic nature. Even though the change in spacer length does not affect the mode of DNA binding of these complexes, it does affect the binding constant

value. The complexes prefer binding at the minor groove of DNA. They exhibit efficient nuclease activity in presence of ascorbic acid and the cleavage efficiency is dictated mainly by the reversibility of the Cu(II)/Cu(I) couple.

Abstract

The unprecedented transition metals (TMs) bridged 1,4-dititanium(IV)-substituted Keggin-type polyoxotungstates $K_3\{M(H_2O)_4\}_2PTi_2W_{10}O_{40}\cdot 8H_2O$ (M = Co^{II} (**1**), Ni^{II} (**2**), Mn^{II} (**3**)) have been synthesized and characterized by FT-IR, UV, element analyses, X-ray powder diffraction analyses, ^{183}W NMR spectroscopy, cyclic voltammetry, TG and X-ray single-crystal analyses. It is the first time that Ti-containing polyoxotungstate $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$ fragments are linked by TMs based on novel Ti–O–M bonds, and it is the first example of a three-dimensional (3D) two-fold interpenetrating pure inorganic framework structure based on Keggin polyoxometallates and TMs.

Keywords: Polyoxometallates; Ti-substituted; Transition metals bridged; Entangled network

1. Introduction

Entangled network structures have rapidly attracted current attention, not only for their intriguing variety of topologies and entanglement motifs, but also for their potential applications in porous materials, gas storage, non-linear optics and catalysis [1]. Up until now, most of the reported entangled structures are based on metal-organic frameworks (MOFs) and have been extensively discussed in comprehensive reviews by Batten and Robson [2]. In contrast to the interpenetrating networks based on MOFs, those constructed from polyoxometallates (POMs) are much more attractive, whilst relatively rare. POMs, known as metal–oxygen clusters, are of current interest due to the enormous structural variety combined with interesting properties. They can be viewed as multi-dentate anionic ligands [3], and have capabilities similar to those of organic ligands in linking metal centers to construct molecular structures with cavities encapsulating guest molecules or ions. Such structures can be regarded as zeolite-related nets, which have important applications as molecular sieves and heterogeneous catalysts. Recently, our group and others have determined *n*-fold interpenetrating networks containing POMs connected through a bridging metal organic subunit [4]. However, it is difficult to construct a 3D pure inorganic entangled network incorporating POMs without organic ligands. The main reason is probably that the large molecular size essentially baffles the steric extension. To the best of our knowledge, there is only one example of $\{V_{18}O_{42}\}$ cages linked by a $M(H_2O)_4$ (M = Fe, Co) group into two interpenetrating 3D inorganic networks [5]. Therefore, constructing pure inorganic interpenetrating frameworks containing POMs remains a challenge.

Among the wide varieties of POMs, the Keggin series, represented by the general formula $[XM_{12}O_{40}]^{n-}$ (X =

P^{5+}, Si^{4+}; M = W^{6+}, Mo^{6+}), have been studied most [6]. Although connections through either rare-earth cations or TM ions have been widely presented in the vacancies of POMs [7], the intact Keggin units are difficult to link by additional pure inorganic lanthanides or TM cations. However, substituted Keggin anions containing peripheral heteroatoms with an oxidation state less than 6 have more surface negative charge than integer Keggin anions and exhibit enhanced coordinating active sites [8]. Ti substituted POM complexes have been the subject of much interest, and are especially valuable for studies in medicine and catalysis [9]. The known examples include substituted Ti derivative POMs, $[(C_2H_5)_2NH_2]_4Na[H_2PTi_2W_{10}O_{40}]\cdot H_2O$ [9c], $K_4H_{2.2}PTi_{1.60}W_{10.40}O_{40}\cdot 13H_2O$ [9f], α-[(η^5-C_5H_5)Ti($PW_{11}O_{39}$)]$^{4-}$ [11], [(η^5-C_5H_5)Ti($P_2W_{18}O_{61}$)]$^{7-}$ [12], $K_5H_2[FeW_{11}TiO_{40}]\cdot 17H_2O$ [13], $K_5H_2[CrW_{11}TiO_{40}]\cdot 17H_2O$ [13], dimeric forms of POMs [α-1,2-$PW_{10}Ti_2O_{39}$]$_2^{10-}$ [10], $Ti_6Si_2W_{18}O_{77}^{14-}$ [14], $Ti_6Ge_2W_{18}O_{77}^{14-}$ [15], $K_{10}H_2[P_2W_{18}Ti_6O_{77}]\cdot 17H_2O$ [16], [($TiP_2W_{15}O_{55}OH$)$_2$]$^{14-}$ [19], [{γ-$SiTi_2W_{10}O_{36}(OH)_2$}$_2$(μ-O)$_2$]$^{8-}$ [21], tetrameric forms of [($P_2W_{15}Ti_3O_{60.5}$)$_4$]$^{36-}$ [17], [(α-1,2,3-$P_2W_{15}Ti_3O_{62}$)$_4${$Ti(OH)_3$}$_4$Cl]$^{45-}$ [18], [{$Ti_3P_2W_{15}O_{57.5}$ $(OH)_3$}$_4$]$^{24-}$ [19], [{β-$Ti_2SiW_{10}O_{39}$}$_4$]$^{24-}$ [20]. Interestingly most of the species mentioned above are reported as being polymeric with Ti–O–Ti bridged anhydride formation. Indeed the titanium atoms incorporated into the polyoxoanions with reactive sites have a strong tendency to form polymers through Ti–O–Ti bonds as shown above. However, observing Ti-containing POMs without Ti···Ti polymerization in aqueous solution is a challenge in POM synthetic chemistry. In this paper we have isolated a new kind of Ti-containing POM, which contains a Ti–O–M bond without Ti···Ti converging. It was originally reported that [α-$PTi_2W_{10}O_{40}$]$^{7-}$ reacts with divalent manganese, iron, cobalt, nickel, copper and zinc to form isolable complexes $MTi_2PW_{10}O_{40}^{5-}$ on the basis of visible spectra and element analyses [9b]. We have now succeeded in isolating three complexes with 3D two-fold interpenetrating network structures constructed from [α-$PTi_2W_{10}O_{40}$]$^{7-}$ and TMs. It is the first time that a Ti–O–M bond coordination fashion for POMs has been reported, and also it is the first report on higher dimensional *n*-fold interpenetrating network compounds incorporating titanium substituted POMs and TMs.

2. Experimental

2.1. Materials and physical methods

All reagents were used as purchased commercially without further purification. The starting sample of $K_4H_{2.2}PTi_{1.60}W_{10.40}O_{40}\cdot 13H_2O$ was prepared according to a recently reported method and the purity was confirmed by IR [9f]. Elemental analyses of K, P, W, Ti, Co, Ni and Mn were determined by a Leaman inductively coupled plasma (ICP) spectrometer. IR spectra were obtained on a Nicolet 205 FT/IR spectrometer with KBr pellets in the 400–4000 cm^{-1} region. UV spectra were recorded on a 756 CRT UV–Vis spectrophotometer. ^{183}W NMR spectra were recorded on a Bruker Am-500 spectrometer and were referenced to an external standard of saturated Na_2WO_4–D_2O solution. TG analyses were performed on a Perkin–Elmer TGA7 instrument in flowing N_2 with a heating rate of 10 °C/min^{-1}. Powder X-ray diffraction measurements were performed on a Rigaku D/MAX-3 instrument with Cu Kα radiation in the angular range $2\theta = 3$–90° at 293 K. Cyclic voltammetry measurements were carried out on a CHI 660 electrochemical workstation using a conventional three-electrode single compartment cell at room temperature. The working electrode was a glassy carbon disc electrode. The surface of the glass carbon electrode was polished with 0.3 μm alumina and washed with distilled water before each experiment. Platinum gauze was used as counter electrode and an Ag/AgCl was used as a reference electrode. The solutions were degassed with pure nitrogen for 15 min before use and blanketed with nitrogen gas during the voltammetric scans. All experiments were performed at room temperature.

2.1.1. Synthesis of K_3{$Co(H_2O)_4$}$_2PTi_2W_{10}O_{40}\cdot 8H_2O$ (1)

A sample of $K_4H_{2.2}PTi_{1.60}W_{10.40}O_{40}\cdot 13H_2O$ (3 g, 1 mmol) (synthesized according to ref [9f]) was dissolved in 20 mL aqua solution, and then $CoCl_2$ (0.260 g, 2 mmol) was added. To this solution, 3 M HCl was dropped in slowly with vigorous stirring until the pH was adjusted to 5. The solution was heated at 80 °C for 2 h and after cooling to room temperature it was filtered. The filtrate was allowed to evaporate at room temperature. After 7 days a pink crystalline product started to appear. (Yield: 60%, based on Co). *Anal.* Calc. for $K_3H_{32}Co_2PTi_2W_{10}O_{56}$ (3128.49): K, 3.75; P, 0.99; W, 58.76; Co, 3.76; Ti, 3.06. Found: K, 3.73; P, 0.95; W, 58.74; Co, 3.72; Ti, 3.03%. IR (KBr): $\tilde{\nu} = 958$ (s), 879 (s), 813 (s), 685 (w), 526 (m), 456 (s) cm^{-1}.

2.1.2. Synthesis of K_3{$Ni(H_2O)_4$}$_2PTi_2W_{10}O_{40}\cdot 8H_2O$ (2)

This compound was prepared similarly to **1**, with 0.259 g (2 mmol) $NiCl_2$ solid instead of $CoCl_2$. Green crystals were formed after four days (Yield: 65%, based on Ni). *Anal.* Calc. for $K_3H_{32}Ni_2PTi_2W_{10}O_{56}$ (3128.01): K, 3.75; P, 0.99; W, 58.77; Ni, 3.75; Ti, 3.06. Found: K, 3.74; P, 0.97; W, 58.71; Ni, 3.73; Ti, 3.04%. IR (KBr): $\tilde{\nu} = 943$ (s), 816 (m), 689 (m), 526 (s), 473 (s), 457 (s), 419 (w) cm^{-1}.

2.1.3. Synthesis of K_3{$Mn(H_2O)_4$}$_2PTi_2W_{10}O_{40}\cdot 8H_2O$ (3)

This compound was also prepared similarly to **1**, with 0.306 g (2 mmol) $MnSO_4$ solid instead of $CoCl_2$. Yellow crystals were formed after 7 days (Yield: 70%, based on Mn). *Anal.* Calc. for $K_3H_{32}Mn_2PTi_2W_{10}O_{56}$ (3120.50): K, 3.76; P, 0.99; W, 58.91; Mn, 3.52; Ti, 3.07. Found: K, 3.73; P, 0.98; W, 58.87; Mn, 3.50; Ti, 3.04%. IR (KBr): $\tilde{\nu} = 934$ (s), 815 (s), 699 (s), 473 (m), 419 (w) cm^{-1}.

2.2. X-ray crystallography

The reflection intensity of **2** was collected on a Rigaku R-AXIS RAPID IP diffractometer with graphite monochromatic Mo Kα radiation at 293 K. The reflection intensities of **1** and **3** were collected on a SMART CCD diffractometer equipped with graphite monochromatic Mo Kα radiation at 293 K, and empirical absorption corrections by SADABS were applied to the intensity data. All the structures were solved by direct methods and refined using the full-matrix least-squares method on F^2 with the SHELXTL crystallographic software package. Anisotropic thermal parameters were refined for all non-hydrogen atoms, except for the water oxygen atoms. No attempt was made to locate the hydrogen atoms of water. A summary of the crystallographic data and structure refinements for compounds **1**–**3** are given in Table 1.

3. Results and discussion

In contrast to the entangled hybrid POMs, which are synthesized by hydrothermal methods, we have made use of classical open-air techniques to isolate compounds **1**–**3**. Although in most cases the exact reaction mechanisms in one pot methods remain elusive, the pH value, starting materials, reaction time and concentrations can directly influence the final product. Our interest is to obtain new inorganic materials utilizing POMs. Choosing a suitable POM cluster as a building block is crucial for obtaining the extended structure. We select a Ti-substituted Keggin POM that has enhanced surface reaction activity which could make it possible to construct a high dimensional structure.

Single-crystal X-ray diffraction revealed that **1**–**3** are isomorphic with only slight differences in bond lengths and angles, **1** is described as an example below. The crystal structure of **1** consists of a $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$ cluster, two Co^{II} cations, three potassium cations and eight guest water molecules, as shown in Fig. 1. The $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$ anion shows crystallographic disorder as found in many crystal structures with Keggin anions [8]. The central atom P is surrounded by a cube of eight oxygen atoms, with each oxygen site half-occupied, and the W atoms situated at the corners of a regular cubic octahedron. The P–O bonds are all 1.551 Å, which are in the usual P–O range. The two Ti atoms in the Keggin unit are disordered over four positions, with the occupancy factors all being 50% for W/Ti. Thus, two of the 12 octahedrally coordinated W atoms are substituted by Ti atoms statistically. The two-substituted Keggin anion has five possible isomers with C_s, C_2, C_{2v}, and C_1 symmetry (As shown in Fig. S1). The ^{183}W NMR spectrum of **1** shows five lines with an intensity ratio of 2:2:2:2:2, which is similar to that of $[\alpha\text{–}PTi_2W_{10}O_{40}]^{7-}$ and can be ascribed to C_2 symmetry formed by 1,4-substitution

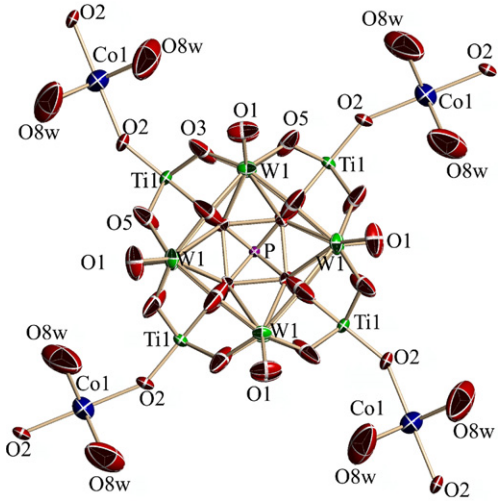

Fig. 1. Crystal structure of compound **1**. Only some of the atoms are labelled. All H atoms are omitted for clarity.

[9]. For **1**, all tungsten sites exhibit a +6 oxidation state, which is confirmed by bond valence sum calculations. The Ti/W–O bond lengths are found in the 1.695–1.706 Å range, which is a little shorter than the normal Ti–O bond lengths [10,16,18]. This result may be due to the influence of the outer coordination environment in compound **1**. As shown in Fig. 1, the corresponding terminal oxygen atom of W/Ti is coordinated by the divalent TM cation, Co^{II}. The Co–O distances are in the range 1.966–2.078 Å, which are comparable to those observed for metal oxygen bond lengths. The Ti–O–Co angles are in the 150.811–153.420° range, comparable with those in the recently reported Ti–O–Ti 136.4–176.4° [10,18]. As described above, the TM in complex **1**, as $\{CoO_6\}$ units, bridges $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$, leading to the formation of a two-dimensional anionic $[Co_2PTi_2W_{10}O_{40}]^{3-}$ layer running parallel to the *ab*-plane of the unit cell (Fig. 2), which is just like a beautiful of hound's-tooth formation. Potassium cations link the layers to form a three-dimensional structure (Fig. S2). In other words, this structure can also be described as a series of two-dimensional layers, and the neighboring layers are held together by potassium cations, forming a 3D framework. X-ray powder diffraction (XRPD) patterns of compounds **1**–**3** have been recorded, and their diagrams are presented in Fig. S3. The computer-simulated patterns, obtained using the single crystal X-ray data for **1**–**3**, match very well with the respective experimentally observed patterns, which confirm the homogeneity and the purity of the bulk samples of **1**, **2** and **3**.

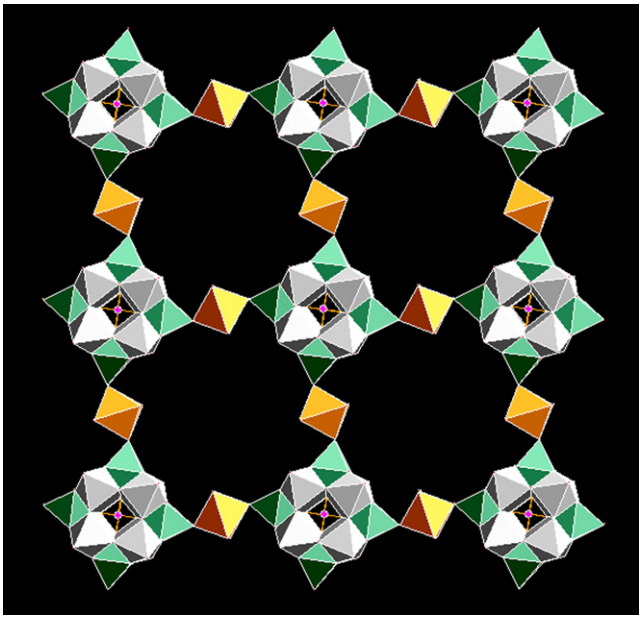

Fig. 2. Polyhedral 2D view of compound **1** along the *c* axis.

The most fascinating feature of **1** is that it exhibits two sets of structures, as described above, penetrating each other to form a two-fold interpenetrating network (Fig. 3). The molecular squares with a Co···Co separation of 14.1680(5) Å contain large cube like boxes of approximate dimensions $7.3 \times 7.3 \times 7.5$ Å^3. These cavity spaces are large enough to hold the other set of $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$ globes. This kind of entanglement is quite uncommon in POM chemistry. Therefore, compound **1** provides a remarkable new structural motif, and represents the first example of a 3D array of a Keggin series in an interpenetrating manner. It is also a rare example having both POM and TM characteristics and could equally well be considered as being formed by interconnected interpenetrating factions. The overall structure can be seen as a porous framework containing channels that approximate constitute 13.5% of the crystal volume (calculated by PLATON), which are filled by guest water molecules. In order to examine the stability of these frameworks, thermal gravimetric (TG) analyses were carried out for **1**–**3** between 20 and 600 °C (Fig. S4). The TG curves show a weight loss step (20–300 °C) corresponding to the release of the guest H_2O molecules and coordinated H_2O molecules (found: (**1**) 9.96% (**2**) 9.47% (**3**) 9.33%; calculated: (**1**) 9.21% (**2**) 9.21% (**3**) 9.23%). The total weight losses are in good accordance with the calculated values. The curves also prove that the frameworks of **1**–**3** are stable in the range 300 to 600 °C. To further investigate the porosity of **1**, the as-synthesized crystalline sample was placed in a vacuum oven at

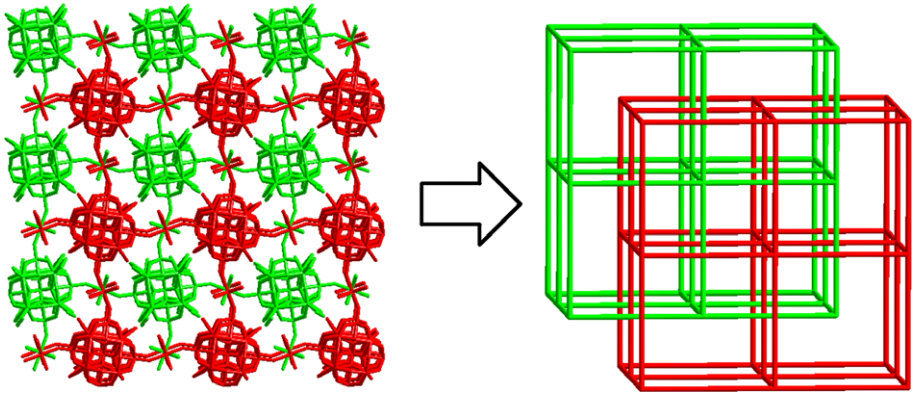

Fig. 3. Simplified schematic representation of the 3D twofold interpenetrating network of **1**.

120 °C for 6 h to release the guest water molecules (with a 9.69% weight loss) and to get the evacuated solid. In the XRPD pattern of the evacuated solid, the main sharp diffraction peaks are consistent with those of the as-synthesized solid (Fig. S5). This fact may be used to confirmed that the framework is still stable and retains high periodicity.

The infrared spectrum of $K_4H_{2.2}PTi_{1.6}W_{10.4}O_{40}\cdot 13H_2O$ (Fig. 4a) in the range 400–1200 cm^{-1} measured as a KBr disk shows the characteristic asymmetric stretching vibrational peaks of the Keggin anion as $\{PW_{12}\}$. The most notable difference between $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$ and $\{PW_{12}\}$ is that the asymmetric phosphate stretch is split into three peaks for $\upsilon_{as}(P\text{–}O_a)$, which can be explained by some W atoms being replaced by Ti atoms to depress the symmetry $T_d \rightarrow C_2$. FT-IR spectra of **1**–**3** (Fig. 4b–d) are closely related to that of the parent compound $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$, with the exception of a 10 cm^{-1} shift to lower wave numbers of the strong $\upsilon_{as}(P\text{–}O_a)$ bands. This effect is a common feature already observed for metal-bridged POM derivatives by comparison with their parent analogues, and has been assigned to the framework cohesion through metals, leading to a decrease of the stretching force constants.

The UV spectra of the compounds **1**–**3** checked in aqueous solution in the 200–350 nm region are similar to that of $K_4H_{2.2}PTi_{1.6}W_{10.4}O_{40}\cdot 13H_2O$ (Fig. S6). All of the spectra display two intense absorption bands, appearing at 262 and 216 nm (224 nm for $K_4H_{2.2}PTi_{1.6}W_{10.4}O_{40}\cdot 13H_2O$). The weaker absorption bands at 262 nm (Fig. S6 a–d) are attributed to a charge-transfer absorption $O_{b(c)} \rightarrow W$, whereas the stronger absorption peaks are assigned to a charge-transfer absorption of $O_t \rightarrow W$ in the polyoxoanions. It is noteworthy that the stronger absorption bands at about 216 nm of compounds **1**–**3** are blue-shifted by 8 nm relative to the absorption peak at 224 nm for that of the parent compound $K_4H_{2.2}PTi_{1.6}W_{10.4}O_{40}\cdot 13H_2O$. This may be due to the affect of the incorporated TMs.

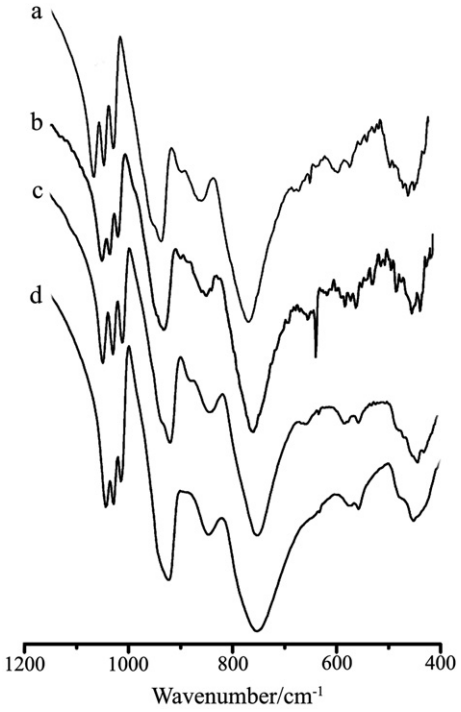

Fig. 4. FT-IR spectra of the di-Ti-substituted Keggin polyoxoanion in the region 400–1200 cm^{-1}, measured as KBr disks, of: (a) $K_4H_{2.2}PTi_{1.6}W_{10.4}O_{40}\cdot 13H_2O$, (b) $K_3\{Co(H_2O)_4\}_2PTi_2W_{10}O_{40}\cdot 8H_2O$ (**1**), (c) $K_3\{Ni(H_2O)_4\}_2PTi_2W_{10}O_{40}\cdot 8H_2O$ (**2**) and (d) $K_3\{Mn(H_2O)_4\}_2PTi_2W_{10}O_{40}\cdot 8H_2O$ (**3**).

The electrochemical behaviors were investigated by cyclic voltammetry in 1 M (CH_3COONa/CH_3COOH) pH 4.8 buffer under a nitrogen atmosphere at the scan rate of 20 mV s^{-1} (Fig. S7). In the potential range 0 to −1000 mV, the parent compound $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$ exhibits one quasi-reversible redox wave and the mean peak potential $E_{1/2} = (E_{pa} + E_{pc})/2$ is −805 mV. The reduction wave can be attributed to the reduction of W^{VI} to W^{V}, however, stepwise reduction of the W centers is not observed in contrast to the saturated Keggin structure PW_{12} (the electrochemistry behavior of $\{PW_{12}\}$ has been described previously [22]). The cyclic voltammetric run of **1**–**3** under the same experimental conditions reveals the analogical redox activities but no electrochemical activity was detected for the transition metals. **1**–**3**, upon reduction of the W centers, parallels the behavior of $[\alpha\text{-}PTi_2W_{10}O_{40}]^{7-}$, which also indicates that the transition metals have no obvious effect on the electrochemical behavior of the W centers.

4. Conclusion

In summary, compounds **1**–**3** provide unprecedented 3D two-fold interconnecting frameworks formed by di-Ti-subsitituted Keggin polyoxotungstates and transition metals, Co^{II}, Ni^{II} and Mn^{II}. The successful syntheses of **1**–**3** not only confirm the formation of a Ti–O–M bond faction without Ti···Ti polymerization in aqueous solutions, but also provide examples of multidimensional pure inorganic frameworks incorporating POMs with a highly symmetric structure, which were synthesized by open-air techniques. In view of the rapidly expanding pool of well-characterized metal oxide clusters, this work has provided access for the further synthesis of POM-based purely inorganic porous framework materials.

Abstract

The syntheses of two new polynuclear Tb^{III} compounds are reported. A tetranuclear complex $[Tb_4(H_2L)_2(H_4L)_2(OAc)_8]$ (**1**), with H_4L = 2-((2-hydroxy-benzylidene)-amino)-2-hydroxy-methyl-propane-1,3-diol, has a butterfly-type structure, while $[Tb(OAc)_3MeOH]_\infty$ (**2**) is a linear chain. A novel binding mode for H_2L^{2-} is observed in **1**, with two alkoxides each bridging three Tb^{III} ions. The magnetic properties of **1** are determined by the superposition of the ligand field split $^7F_6$ states of Tb^{III} single-ions located on two crystallographically distinct sites. Weak antiferromagnetic exchange interactions possibly contribute to the lowering of the magnetic moment at the lowest temperatures.

1. Introduction

The discovery in the early 1990s of the first single-molecule magnet (SMM), a dodecanuclear Mn complex (Mn_{12} acetate), has prompted considerable research in this area [1]. SMMs are isolated high spin molecules that exhibit magnetization hysteresis at low temperatures, which is otherwise a property of bulk magnets. Large spin ground states combined with predominantly uniaxial anisotropy are responsible for this behavior. The quantum nature of SMMs is manifested by quantum tunneling of the magnetization. In the last 15 years more than a hundred new examples of SMMs have been prepared by synthetic chemists, many of them containing Mn and belonging to the same structural family as Mn_{12} acetate [2,3], or to a family of Mn_4 SMMs [4]. SMM synthesis has also been extended to other transition metal ions such as Fe, Ni, V and Co [5,6]. Below the so-called blocking temperature, SMMs display slow relaxation of the magnetization. However, despite the large number of new molecules, no significant increase has been achieved in the blocking-temperature. Very recently, the first SMMs containing rare earth ions were reported [7,8]. Rare earth ions can provide up to seven unpaired electrons and introduce a large magnetic anisotropy. The most striking examples among this new class of SMMs have been described by Ishikawa et al. [8]. Tb, Dy or Ho ions sandwiched between two phthalocyanine molecules were the first mononuclear SMMs, and slow relaxation of the magnetization was observed at significantly higher temperatures than for conventional transition metal SMMs. These findings have triggered the exploration of new molecular clusters containing rare earth ions.

We have turned our attention to the Schiff base proligand 2-((2-hydroxy-benzylidene)-amino)-2-hydroxymethyl-propane-1,3-diol (H_4L, Chart 1). It has a potentially pentadentate $\{O_4N\}$ donor set and possesses both chelating and bridging capacities. The large number of potential binding sites is suitable for rare earth ions, which often have coordination numbers of eight or nine. H_4L is a member of a family of Schiff base ligands that we have successfully employed in the synthesis of new transition metal spin

clusters [9]. Several clusters incorporating derivatives of H_4L and Mn, Ni and Cu have been reported in the literature [10]. Although the ability of H_4L to coordinate rare earth ions has not previously been explored, it would appear to be an excellent candidate as O and N are good donor atoms for rare earth ions.

2. Experimental

2.1. Syntheses

All manipulations were performed under aerobic conditions, using materials as received. 2-((2-hydroxy-benzylidene)-amino)-2-hydroxymethyl-propane-1,3-diol (H_4L) was prepared as described [11].

2.1.1. $[Tb_4(H_2L)_2(H_4L)_2(OAc)_8]$ (1)

$Tb(OAc)_3 \cdot H_2O$ (0.68 g, 2.0 mmol) and H_4L (0.46 g, 2.0 mmol) were dissolved in MeOH (50 cm^3), and the resulting mixture was stirred overnight. The white precipitate was removed by filtration and the filtrate was evaporated to dryness and redissolved in a minimum amount of MeOH. After two days, a mixture of crystals of **1** and **2** was filtered off and the remaining yellow solution was layered with Et_2O. After a further three days, pale yellow plate shaped crystals of $\mathbf{1} \cdot 2Et_2O$ formed. The crystals were isolated and washed with minimum MeOH and Et_2O; 25% yield. A sample for crystallography was maintained in contact with mother liquor to prevent the loss of interstitial solvent. *Anal.* Calc. for $[Tb_4(H_2L)_2(H_4L)_2(OAc)_8] \cdot Et_2O$, $C_{64}H_{90}N_4O_{33}Tb_4$: C, 36.97; H, 4.36; N, 2.69. Found: C, 37.20; H, 4.28; N, 2.36%. Selected IR data (cm^{-1}): 3401 (s), 2931 (w), 2874 (w), 1642 (s), 1631 (s), 1558 (s), 1493 (m), 1453 (m), 1345 (w), 1311 (w), 1242 (w), 1199 (w), 1154 (w), 1057 (m), 1019 (m), 946 (w), 763 (w), 668 (m), 615 (w), 574 (m), 473 (w).

2.1.2. $[Tb(OAc)_3MeOH]_\infty$ (2)

Under the same reaction conditions as for **1**, needle shaped crystals of **2** could be manually isolated from the mixture of crystals formed from a concentrated methanolic solution. A pure sample of **2** could not be obtained for physical measurements, as the crystallization conditions enhanced the simultaneous formation of $\mathbf{1} \cdot 2H_2O$. A sample for crystallography was maintained in contact with mother liquor to prevent loss of interstitial solvent.

2.2. Physical measurements

2.2.1. X-ray crystallography

The intensity data of compounds $\mathbf{1} \cdot 2Et_2O$ and **2** were collected on a Bruker CCD diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Crystals were transferred directly from the mother liquor to a protective oil, which was used to prevent solvent loss. The structures were solved using direct methods and refined using a full-matrix least squares procedure based on F^2 using all data [12]. Crystallographic data for $\mathbf{1} \cdot 2Et_2O$ and **2** are given in Table 1.

2.2.2. Magnetic measurements

Variable temperature magnetic measurements were performed on a Quantum Design MPMS-XL SQUID magnetometer equipped with a 5 T magnet. Data were collected on a randomly oriented polycrystalline sample of $\mathbf{1} \cdot Et_2O$ restrained in eicosane to prevent torquing. Diamagnetic corrections were made using Pascal's constants and a value of $\mu_{Dia} = -1.3 \times 10^{-8}$ emu/g for the sample and eicosane, respectively. DC susceptibility measurements were performed with measuring fields of 0.01, 0.1 and 3 T. AC susceptibility data were collected with an alternating field of 3×10^{-4} T and frequencies ranging between 10 and 10^3 Hz. Isothermal magnetization measurements were performed at 2, 3, 4, 5, 10 and 20 K in a field range of 0–5 T.

3. Results and discussion

3.1. Syntheses

The overnight treatment of $Tb(OAc)_3 \cdot nH_2O$ with a methanolic solution of 1–2 equiv. of H_4L affords a yellow solution and a white precipitate. Filtration followed by evaporation of the solvent produces a yellow oil, re-dissolution of the residue in a minimum amount of MeOH yields a mix of crystals of $\mathbf{1} \cdot 2Et_2O$ and **2** after two days. Subsequent filtration and layering of the filtrate with Et_2O affords plate shaped crystals of $\mathbf{1} \cdot 2Et_2O$ after three days in 25% yield. The reactions may be written as

$$4Tb(OAc)_3 \cdot nH_2O + 4H_4L \rightarrow [Tb_4(H_2L)_2(H_4L)_2(OAc)_8] + 4HOAc + 4nH_2O \quad (1)$$

$$Tb(OAc)_3 \cdot nH_2O + MeOH \rightarrow [Tb(OAc)_3MeOH] + nH_2O \quad (2)$$

The formation of **1** involves the protonation of acetate ligands in conjunction with double deprotonation and coordination of the H_4L ligand. This is commonly observed during the synthesis of polynuclear complexes. A likely driving force is the chelate effect attributed to the multidenticity of the ligand. The formation of **2** involves the substitution of H_2O ligands with MeOH as well as the change of the binding modes of the acetate ligands. The ligand H_4L is not incorporated in the structure.

3.2. Structure descriptions

Compound $\mathbf{1} \cdot 2Et_2O$ crystallizes in the triclinic space group $P\bar{1}$ with one molecule per unit cell, together with disordered solvent. The molecule has C_i point symmetry. A summary of interatomic distances and angles is given in Table 2. A complete list can be obtained from the authors. The structure of **1** in $\mathbf{1} \cdot 2Et_2O$ is shown in Fig. 1a.

Bond valence sum calculations [13] are in good agreement with the expected oxidation state of 3+ for the Tb ions in the cluster. The Tb centers are arranged in a planar rhomb (Fig. 1b), linked by four μ_3 alkoxide bridges from two Schiff-base ligands and four μ_2-O atoms from acetate ligands. The coordination sphere is completed by N-atoms from the central Schiff-base ligands, acetates and two additional Schiff-base ligands. The structure comprises two crystallographically distinct Tb^{III} sites, both with C_1 point symmetry. Two different binding modes can be observed for H_4L and H_2L^{2-} (Fig. 2). The central doubly deprotonated ligands bind in a $\eta^1{:}\eta^1{:}\eta^2{:}\eta^4{:}\mu_4$-fashion with four out of five potential binding sites complexing Tb. The peripheral H_4L ligands bind to Tb only via the phenol

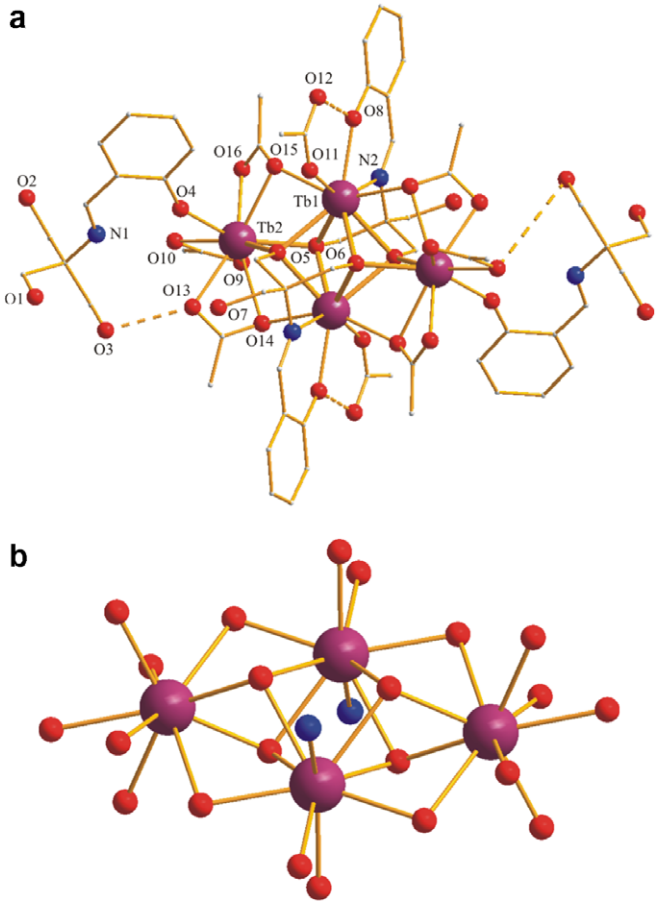

Fig. 1. (a) Ball and stick representation of complex **1** in $\mathbf{1} \cdot 2Et_2O$. Hydrogen atoms are omitted for clarity. (b) Coordination spheres of the Tb^{III} ions in $\mathbf{1} \cdot 2Et_2O$. Tb purple; O, red; N, blue; C, gray. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Table 2
Selected bond distances (Å) and angles (deg) for $\mathbf{1} \cdot 2Et_2O$ and **2**

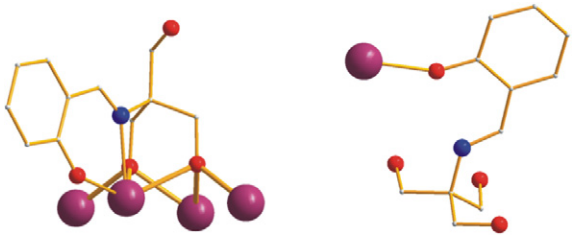

Fig. 2. Binding modes of H_2L^{2-} and H_4L in **1**: $\eta^1{:}\eta^1{:}\eta^2{:}\eta^4{:}\mu_4$ and η^1.

alcohol group. Two of the alcohol arms are linked by an intramolecular hydrogen bond and bind to an acetate group via a further intramolecular hydrogen bond (Table 2). Four of the acetates act as bridges between Tb ions in a $\eta^1{:}\eta^2{:}\mu_2$-fashion, two acetates act as η^2 chelates and two of the acetates bind as terminal ligands in *syn* η^1-fashion (Chart 2). An intramolecular hydrogen bond is formed between the latter and the phenol alcohol of a H_2L^{2-} ligand.

The Tb_4 plane of **1** lies perpendicular to the crystallographic *a*-axis. Adjacent clusters in the *a*-direction are linked by intermolecular hydrogen bonds between the remaining alcohol arm of H_2L^{2-} (O7) and one of the acetates (O16). In addition, one of the alcohol arms of H_4L (O2) is involved in hydrogen bonding with disordered solvent.

Several tetranuclear terbium complexes are reported in the literature [14], but the core structure of **1** is unique. Similar core topologies have been described for transition metal complexes, especially the so-called butterfly structures with a $[M_4O_2]$ core [6,15]. The rhombic arrangement of transition metal ions comprises only two μ_3 alkoxide bridges, as the metal ions are six-coordinate. Owing to the higher coordination number of rare earth ions (all Tb^{III} ions in **1** are nine-coordinate) additional bridging atoms are necessary to obtain the same butterfly type arrangement of the magnetic centers.

Compound **2** crystallizes in the monoclinic space group $P2_1/c$. It comprises Tb^{III} ions linked by acetate groups to form chains (Fig. 3). The ligand H_4L is not incorporated in the structure of **2** [13]. Bond valence sum calculations are consistent with the standard oxidation state of 3+ for Tb. The structure contains only one crystallographic Tb^{III} site with C_1 point symmetry. The asymmetric unit contains two chain fragments, each consisting of two Tb^{III} ions. The Tb^{III} centers are linked by three acetates, two bridging in

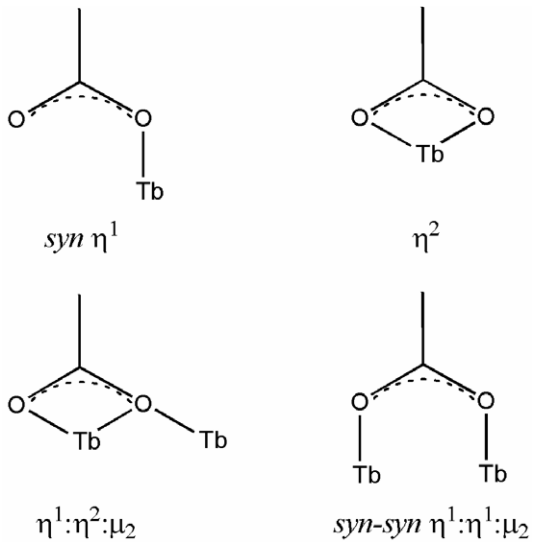

Chart 2. Binding modes of the acetate groups in complexes **1** and **2**.

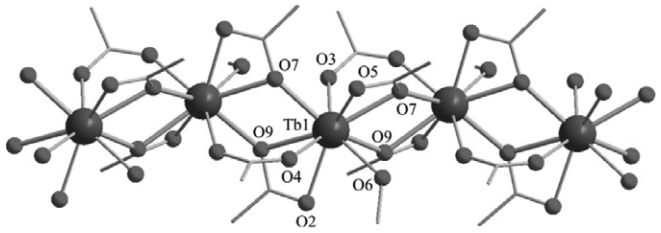

Fig. 3. Section of the chain structure of **2**, showing the coordination sphere of the Tb^{III} ions. Hydrogen atoms are omitted for clarity. Tb, purple; O, red; C, gray. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

$\eta^1{:}\eta^1{:}\mu_2$ fashion and one in a *syn–syn* $\eta^1{:}\eta^1{:}\mu_2$-arrangement. The remaining peripheral ligation is completed with a MeOH molecule. A summary of interatomic distances and angles is given in Table 2. It is worthwhile to compare the structure of **2** with the crystal structure of the starting material $Tb(OAc)_3 \cdot nH_2O$ [16], in which Tb^{III} dimers are linked by two acetates in $\eta^1{:}\eta^2{:}\mu_2$-fashion, while the other four acetates chelate a single Tb. The four remaining positions are occupied by H_2O. In **2**, the water molecules are replaced by two MeOH ligands, the free coordination sites are occupied by two $\eta^1{:}\eta^2{:}\mu_2$ bridges and there are two acetate links with a *syn–syn* $\eta^1{:}\eta^1{:}\mu_2$-mode instead of four chelating acetates.

The chains in **2** are parallel to the crystallographic *c*-axis of the monoclinic structure. They are well isolated from each other, no hydrogen bonding pathway can be observed. The shortest distance between Tb^{III} ions of different chains is 8.2 Å. A Tb chain similar to **2** has been reported in the literature, namely $[Tb(O_2CPh)_3(MeOH)_2(H_2O)]_\infty$ [17]. Interestingly, it was also obtained as a co-crystallized product from a reaction mixture containing other ligands. This complex incorporates benzoate, with binding modes different to those observed for acetate in **2**. The chains form hydrogen-bonded sheets. The fact that the chains in **2** are well isolated makes the structure unique.

3.3. Magnetic study of $1 \cdot Et_2O$

Variable temperature AC and DC susceptibility measurements were performed on a sample of randomly oriented crystals of $1 \cdot Et_2O$. The DC data measured at 0.1 T are plotted as χT versus T and χ versus T in Fig. 4. Between 300 and 100 K, χT stays nearly constant at the room temperature value of 44.4 emu mol^{-1} K. Upon further cooling, χT decreases first gradually and then steeply below 5 K. Isothermal magnetization data collected at six temperatures between 2 and 20 K are plotted in Fig. 5 as M versus H/T. The isotherms do not superimpose and the magnetization at 2 K does not completely saturate at the high-field limit of our instrument; it reaches a value $M = 19.3\ N\mu_B$ at 5 T.

Tb^{III} has a $4f^8$ electron configuration, and the ^7F ground term is split by spin–orbit coupling, leading to seven ^7F_J

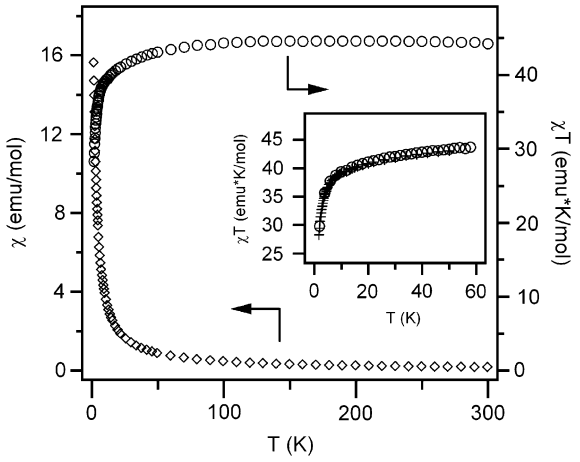

Fig. 4. χT vs. T and χ vs. T for $\mathbf{1}\cdot Et_2O$, measured in an applied field of 0.1 T. The inset shows the low temperature regime of χT vs. T for $\mathbf{1}\cdot Et_2O$. Plus signs correspond to DC measurements with a measuring fields of 0.1 T, circles denote data from an AC measurement with a field of 3×10^{-4} T oscillating with a frequency of 60 Hz.

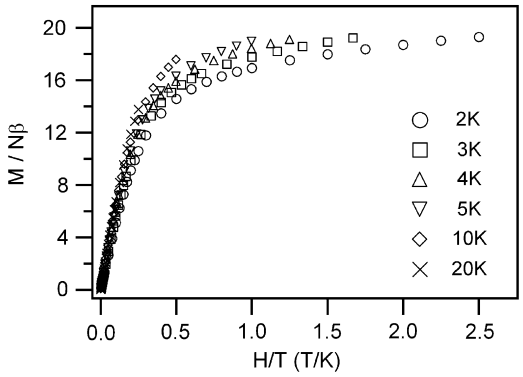

Fig. 5. Isothermal magnetization measurements on a sample of randomly oriented crystals of $\mathbf{1}\cdot Et_2O$, measured in a field range of 0–5 T at six temperatures between 2 and 20 K.

states. The ground state is $^7F_6$, which is separated by approximately 2000 cm^{-1} from the first excited $^7F_5$ state. $^7F_6$ is further split into a maximum of 13 sublevels by the low symmetry ligand field. The total splitting is expected to be of the order of 300–600 cm^{-1} [18]. A superposition of the splittings of the two crystallographically distinct Tb^{III} ions determines the magnetic properties of $\mathbf{1}\cdot Et_2O$. We restrict ourselves to a mainly qualitative discussion, as a more quantitative approach would be pointless in the absence of suitable information on the anisotropy of the magnetic properties of $\mathbf{1}\cdot Et_2O$.

The room temperature value of $\chi T = 44.4$ emu mol^{-1} K is lower than $\chi T = 47.3$ emu mol^{-1} K calculated for four uncoupled Tb^{III} ions in a free-ion approximation with an isolated and degenerate $^7F_6$ ground state and a Landé-factor $g_J = 3/2$ [19]. An almost identical room temperature value $\chi T = 44.3$ emu mol^{-1} K was measured for a Tb_4 cube [14a], as well as for a mononuclear Tb^{III} complex ($\chi T =$ 11.1 emu mol^{-1} K for one Tb^{III}) [20], both containing eight-coordinate Tb^{III} in a low symmetry ligand field. The reduction from the free-ion value indicates that all the crystal-field levels of $^7F_6$ are not equally populated at 300 K. Upon cooling below 100 K, higher crystal field levels are depopulated, leading to the observed decrease in χT. The same behavior was found in the above mentioned mononuclear and tetranuclear Tb^{III} compounds [14a,20]. The superposition of the χT versus T curves measured with $H = 0.1$ T and in AC mode with no applied DC field (inset of Fig. 4) indicates that the low temperature decrease in χT is not due to the effect of the applied field. In addition to the dominant ligand field effects, a contribution of antiferromagnetic exchange interactions to the magnetic susceptibility at the lowest temperatures cannot be excluded. These interactions are generally very small between rare earth ions, for example. $J = -0.040$ cm^{-1} was determined for a Tb^{III} dinuclear complex by inelastic neutron scattering [21]. The divergence of the isothermal magnetization curves in the M versus H/T plot (Fig. 5) indicates that more than one of the sublevels of $^7F_6$ are populated in the temperature range 2–20 K. The magnetization is not saturated at 5 T, but the absolute value $M = 19.3\ N\mu_B$ at 2 K and 5 T is much lower than the maximum value $M = 36\ N\mu_B$ for $^7F_6$ [19]. This suggests that the wavefunctions of the lowest energy substates are predominantly built up from basis functions with small M_J values. A further interpretation is difficult, especially because the measured properties are a superposition of the properties of the two distinguishable Tb^{III} ions in the cluster. Site selective low-temperature luminescence spectroscopy might be a way to disentangle the two contributions and determine the individual energy splittings.

Sensitized by the phthalocyanine rare earth sandwich SMMs [8], we performed AC magnetic measurements to look for slow relaxation of the magnetization in $\mathbf{1}\cdot Et_2O$. No out-of-phase signal was detected in the full temperature range down to 1.8 K. In the Tb^{III} sandwich complex reported by Ishikawa et al. the ligand field of the two phthalocyanines generates a fortunate situation with the two lowest substates separated by an energy gap of more than 400 cm^{-1} from the next excited substates [8]. In the exceptional case of the sandwich compound SMM behavior can be attributed to the quasi-axial symmetry of the ligand field. A considerable mixing of basis functions with different M_J values and a more complex energy level scheme are expected for Tb^{III} ions with C_1 point symmetry.

4. Conclusions

Complex **1** was successfully prepared by incorporating the proligand H_4L in two different binding modes in its neutral and double deprotonated state. The displayed chelating and bridging properties of this ligand make it an ideal candidate for the synthesis of spin clusters. In addition to **1**, compound **2** was also isolated from the reaction mixture, exhibiting a novel Tb-chain structure. Cluster **1** did not show SMM behavior. This is mainly attributed to

the low symmetry of the ligand field, as compared to the quasi-axial symmetry of the ligand field in the Tb^{III} sandwich complex [8]. In order to impose axial-type coordination of the rare earth centers it seems necessary to use more rigid ligands than H_4L.

Abstract

New ligand 2-(4′-biphenyl)imidazo[4,5-*f*][1,10]phenanthroline (BPIP) and its complexes $[Ru(bpy)_2(BPIP)]^{2+}$ (**1**) (bpy = 2,2′-bipyridine) and $[Ru(phen)_2(BPIP)]^{2+}$ (**2**) (phen = 1,10-phenanthroline) have been synthesized and characterized by mass spectroscopy, ^1H NMR and cyclic voltammetry. The interaction of two Ru(II) complexes with calf thymus DNA (CT-DNA) was investigated by spectroscopic and viscosity measurements. Results indicate that both complexes bind to DNA via an intercalative mode and the DNA-binding affinity of complex **2** is much greater than that of complex **1**. Furthermore, when irradiated at 365 nm, both complexes have also been found to promote the photocleavage of plasmid pBR 322 DNA.

1. Introduction

During the past decades, metal complexes have been the subjects of tremendous research interest owing to the interactions of complexes with nucleic acids [1–3]. In particular, ruthenium(II) complexes with polypyridine ligands, due to a combination of easily constructed rigid chiral structures spanning all three spatial dimensions and a rich photophysical repertoire, have attracted considerable attention [1,4–10]. However, it is noticed that the investigations of intercalative ligand size has been very limited [11–18]. In fact, molecular shape contributes to stabilizing the metal complex on the DNA helix is one of the most significant factors [19]. Some of these complexes also exhibit interesting properties upon binding to DNA [20,21]. Varying substitutive group or substituent position in the intercalative ligand can create some interesting differences in the space configuration and the electron density distribution of Ru(II) polypyridyl complexes, which will result in some differences in spectral properties and the DNA-binding behaviors of the complexes, and will be helpful to more clearly understand the binding mechanism of Ru(II) polypyridyl complexes to DNA. Therefore, further studies using different structural ligands to evaluate and understand the factors that determine the DNA-binding mode are necessary.

We recently reported $[Ru(phen)_2(NMIP)]^{2+}$ (NMIP = 2′-(2″-nitro-3″,4″-methylene-dioxyphenyl)imidazo[4′,5′-*f*]-[1,10]-phenanthroline) [20] bind to DNA via partial intercalative mode. Furthermore, irradiation at 456 nm, complex $[Ru(phen)_2(NMIP)]^{2+}$ is efficient photocleavers of the plasmid pBR 322 DNA. Based on this, a novel ligand 2-(4′-bphenyl)imidazo[4,5-*f*][1,10]phenanthroline (BPIP, Scheme 1) has been prepared by condensation of 1,10-phenanthroline-5,6-dione and 4-biphenylcarbaldehyde to spread the planarity of phenanthroline. In this paper, we report the synthesis and characterization for the two

Scheme 1. Synthetic routes for the preparation of the BPIP ligand and Ru(II) complexes **1** and **2**.

ruthenium(II) complexes $[Ru(bpy)_2(BPIP)]^{2+}$ (bpy = 2,2′-bipyridine) (**1**) and $[Ru(phen)_2(BPIP)]^{2+}$ (phen = 1,10-phenanthroline) (**2**), and also explore the interactions of the complexes with DNA and DNA cleavage assay.

2. Experimental

2.1. Materials

All the experiments involving interaction of the complex with DNA were conducted in twice distilled buffer containing tris(hydroxymethyl)-aminomethane (Tris, 5 mM) and NaCl (50 mM) and adjusted to pH 7.2 with hydrochloric acid. A solution of calf thymus DNA in the buffer gave a ratio of UV absorbance at 260 and 280 nm of about 1.8–1.9:1, indicating that the DNA was sufficiently free of protein [22]. The DNA concentration per nucleotide was determined by absorption spectroscopy using the molar absorption coefficient (6600 $M^{-1}\,cm^{-1}$) at 260 nm [23].

2.2. Synthesis

The compounds 1,10-phenanthroline-5,6-dione [24], *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ [25] and *cis*-$[Ru(phen)_2Cl_2]\cdot 2H_2O$ [25] were synthesized according to the literature methods.

2.2.1. 2-(4′-biphenyl)imidazo[4,5-f][1,10]phenanthroline (BPIP)

A mixture of 4-biphenylcarbaldehyde (0.275 g, 1.5 mmol), 1,10-phenanthroline-5,6-dione (0.105 g, 1.5 mmol), ammoniumacetate (2.31 g, 30 mmol) and glacial acetic acid (15 mL) was refluxed with stirring at 130 °C for 2 hours. The cooled solution was filtered, diluted with water (ca, 20 mL) and neutralized with concentrated aqueous ammonia. The orange precipitate was collected and purified by column chromatography on alumina with ethanol-toluene (14:1 v/v) as eluent to give the title compound as amorphous yellow solid. Yield, 0.46 g, 87%. *Anal.* Calc. for $C_{20}H_{14}N_4O_3$: C, 73.88; H, 4.46; N, 13.78. Found: C, 73.67; H, 4.54; N, 13.69%. FAB-MS: *m/z* 373.4 [M+1].

2.2.2. $[Ru(bpy)_2(BPIP)](ClO_4)_2\cdot 2H_2O$ (1)

A mixture of *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (0.13 g, 0.25 mmol, BPIP (0.093 g, 0.25 mmol) and ethylene glycol (15 mL) was thoroughly deoxygenated. The purple mixture was heated for 8 h at 120 °C under argon. When the solution finally turned brown, it was cooled to room temperature and equal volume of saturated aqueous sodium perchlorate solution was added under vigorous stirring. The brownish solid was collected and washed with small amounts of water, ethanol and diethyl ether, then dried in 50 °C. Purification by chromatography on a neutral alumina column was performed with a mixture of acetonitrile and methylbenze (v/v, 1:1) as eluent. Yield: 0.21 g, 81%. *Anal.* Calc. for $C_{45}H_{35}Cl_2N_8O_{10}Ru$: C, 53.00; H, 3.46; N, 10.99. Found: C, 52.84; H, 3.61; N, 10.83%. UV λ_{max}/nm ($\varepsilon/M^{-1}\,cm^{-1}$, CH_3CN): 458 (20215), 289 (77540), 240 (36410). ^1H NMR (400 MHz, ppm, d_6-DMSO): δ 9.00 (d, 2H, $J = 8.5$), 8.86 (d, 2H, $J = 8.5$), 8.82 (d, 2H, $J = 8$), 8.65 (d, 2H, $J = 2$), 8.20 (t, 2H), 8.09 (t, 2H), 7.87 (t, 4H), 7.85–7.52(m, 8H), 7.59 (dd, 2H, $J_1 = 6.5$, $J_2 = 6$), 7.50 (t, 4H), 7.33 (s, 1H), 7.35–7.41 (m, 1H). ES–MS (CH_3CN): *m/z* 886.0 ($[M-ClO_4]^+$), 785.3 ($[M-2ClO_4-H^+]^+$), 393.3 ($[M-2ClO_4]^{2+}$).

2.2.3. $[Ru(phen)_2(BPIP)](ClO_4)_2\cdot 2H_2O$ (2)

This red complex was synthesized in a manner identical to that described for complex **1**, with *cis*-$[Ru(phen)_2Cl_2]\cdot 2H_2O$ (0.15 g, 0.25 mmol) in place of *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$. Yield: 0.22 g, 87%. *Anal.* Calc. for $C_{49}H_{35}Cl_2N_8O_{10}Ru$: C, 55.11; H, 3.30; N, 10.49. Found: C, 54.97; H, 3.48; N, 10.32%. UV λ_{max}/nm ($\varepsilon/M^{-1}\,cm^{-1}$, CH_3CN): 456 (23145), 290 (60925), 263 (68375). ^1H NMR (400 MHz, ppm, d_6-DMSO): δ 9.08 (d, 2H, $J = 8$), 8.77 (d, 4H, $J = 8$), 8.44 (d, 2H, $J = 6$), 8.39 (s, 4H,), 8.13 (d, 2H, $J = 6.5$), 8.09 (d, 2H, $J = 6$), 7.95 (dd, 2H, $J_1 = 4.5$, $J_2 = 8.5$), 7.81–7.76 (m, 7H), 7.82 (d, 1H, $J = 1.5$), 7.75 (dd, 2H), 7.58 (t, 4H), 7.53 (t, 4H), 7.43 (t, 1H). ES–MS (CH_3CN): *m/z* 933.00 ($[M-ClO_4]^+$), 833.33 ($[M-2ClO_4-H+]^+$), 417.40 ($[M-2ClO_4]^{2+}$).

2.3. Physical measurements

Microanalyses (C, H and N) were carried out on a Perkin–Elmer 240Q elemental analyzer. UV–Vis (UV–visible) spectra were recorded on a Perkin–Elmer Lambda-25 spectrophotometer and emission spectra were recorded on a Perkin–Elmer LS-55 luminescence spectrometer at room temperature. Fast atom bombardment (FAB) mass spectra were recorded on a VG ZAB-HS spectrometer in a 3-nitrobenzyl alcohol matrix. Electrospray mass spectra (ES–MS) were recorded on a LQC system (Finngan MAT, USA) using CH_3CN as mobile phase. ^1H NMR spectra were recorded on a Avance-400 spectrometer with d_6-DMSO (dimethyl sulfoxide) as solvent at room temperature and TMS (tetramethylsilane) as the internal standard. Circular dichroism (CD) spectra were measured on a JASCO-J810 spectropolarimeter. Cyclic voltammetric measurements were performed on a CHI 660A Electrochemical Workstation. All samples were purged with nitrogen prior to measurements. A standard three-electrode system comprising of platinum microcylinder working electrode, platinum-wire auxiliary electrode and a saturated calomel reference electrode (SCE) was used.

2.4. DNA-binding and cleavage experiments

Viscosity experiments were carried out using an Ubbelodhe viscometer maintained at a constant temperature at 30.0 ± 0.1 °C in a thermostatic water-bath. Calf thymus DNA samples approximately 200 base pairs in average length were prepared by sonicating in order to minimize complexities arising from DNA flexibility [26]. Flow time was measured with a digital stopwatch, and each sample was measured three times, and an average flow time was calculated. Data were presented as $(\eta/\eta_0)^{1/3}$ versus binding ratio [27], where η is the viscosity of CT DNA in the presence of complex, and η_0 is the viscosity of CT DNA alone.

Equilibrium dialyses were conducted at ambient temperature with 10 cm^3 of CT-DNA (1.0 mM) sealed in a dialysis bag and 10 cm^3 of the complex (50 μM) outside the bag with the solution stirring for 38 h. The dialysis membrane was purchased from Union Carbide Co. and treated by means of the general procedure before use.

For the gel electrophoresis experiments, supercoiled pBR 322 DNA (0.1 μg) was treated with Ru(II) complexes in 50 mM Tris–acetate, 18 mM NaCl buffer, pH = 7.2, and the solutions were incubated for 1 h in the dark, then irradiated at room temperature with a UV lamp (365 nm, 10 W). The samples were analyzed by electrophoresis for 30 min at 75 V in Tris–acetate buffer containing 1% agarose gel. The gel was stained with 1 $\mu g/mL^{-1}$ ethidium bromid and then photographed under UV light.

3. Results and discussion

3.1. Synthesis and characterization

An outline of the synthesis of the ligand and Ru(II) complexes is presented in Scheme 1. The ligand BPIP was synthesized on the basis of the method for imidazole ring preparation established by Steck et al. [28]. Ru(II) complexes were prepared by direct reaction of the ligand BPIP with the appropriate mole ratios of the precursor complexes *cis*-$Ru(bpy)_2Cl_2$or *cis*-$Ru(phen)_2Cl_2$ in ethylene glycol in relative high yield, respectively. The yields were good to moderate in each case. The desired ruthenium(II) complexes were isolated as the perchlorates and purified by column chromatography. In the ES–MS spectra for the complex, the signals $[M–ClO_4^-]^+$, $[M–2ClO_4^-–H^+]^+$ and $[M–2ClO_4^-]^{2+}$ were observed. The measured molecular weights were consistent with expected values.

The Ru(II) complexes **1** and **2** give well-defined ^1H NMR spectra (Fig. 1), which permit unambiguous identification and assessment of purity. The proton chemical shifts are assigned with the aid of ^1H–^1H COSY experiments and comparison with those of similar compounds [16,20]. Due to the shielding influences of the adjacent BPIP and bpy (or phen), the bpy (or phen) protons of complexes exhibit two distinct sets of signals. In addition, the proton resonance on the nitrogen atom of the BPIP imidazole ring was not observed, because the proton is active and exchanges quickly between the two nitrogens of the imidazole ring. A similar example has been reported previously [16].

The absorption spectra of the complexes are shown in Table 1 and characterized by intense π–π* ligand transitions in the UV and metal-to-ligand charge transfer (MLCT) transition in the visible region. The broad MLCT absorption bands appear at 458 and 456 nm for complexes **1** and **2**, respectively. These bands are bathochromically shifted by comparison with that of $[Ru(bpy)_3]^{2+}$ (452 nm) [29], in accord with the extension of the corresponding π framework. The peak below 320 nm is assigned to the internal π–π* transition of the ligands.

The electrochemical behaviors of the two complexes have been determined in acetonitrile. Each complex exhibits one oxidation and three reduction waves in the sweep range from −2.0 to +2.0 V (Table 1). The electrochemical behavior of the Ru(Π) polypyridyl complex has been rationalized in terms of a metal-based oxidation and a series of reductions which are ligand-based occurring in a stepwise manner for each π* system [30]. As expected, the oxidation potentials of complexes **1** and **2** are more positive than that of $[Ru(bpy)_3]^{2+}$ in according with the extension of the corresponding π framework. With reference to previous studies on similar systems [16,20,31–33], the first reduction, which is usually controlled by the ligand having the most lowest unoccupied molecular orbital (LUMO), is assigned to a reduction centered on

BPIP and the last reductions are characteristic of the co-ligand (bpy or phen).

3.2. Electronic absorption titration

The application of electronic absorption spectroscopy in DNA-binding studies is one of the most useful techniques [34]. Complex binding with DNA through intercalation usually result in hypochromism and bathchromism, due to the intercalative mode involving a strong stacking interaction between an aromatic chrommphore and the base pairs of DNA. The extent of the hypochromism commonly parallels the intercalative binding strength. The absorption spectra of complexes **1** and **2** in the absence and presence of CT-DNA (at a constant concentration of complexes, [Ru] = 20 μM) are given in Fig. 2. As the concentration of DNA is increased, for complex **1**, the hypochromism in the MLCT band reaches as high as 39.4% at 467 nm with a red shift of 7 nm at a ratio of [DNA]/[Ru] of 32.4. For complex **2**, upon addition of DNA, the MLCT band at 465 nm exhibits hypochromism of about 30.6% with a 6 nm red shift at a ratio of [DNA]/[Ru] of 24.3. These spectral characteristics suggest that there are some interactions between the complexes and DNA.

In order to compare quantitatively the binding strength of the two complexes, the intrinsic binding constants K_b of the two complexes with DNA were obtained by monitoring the changes in absorbance at 467 nm for complex **1** and

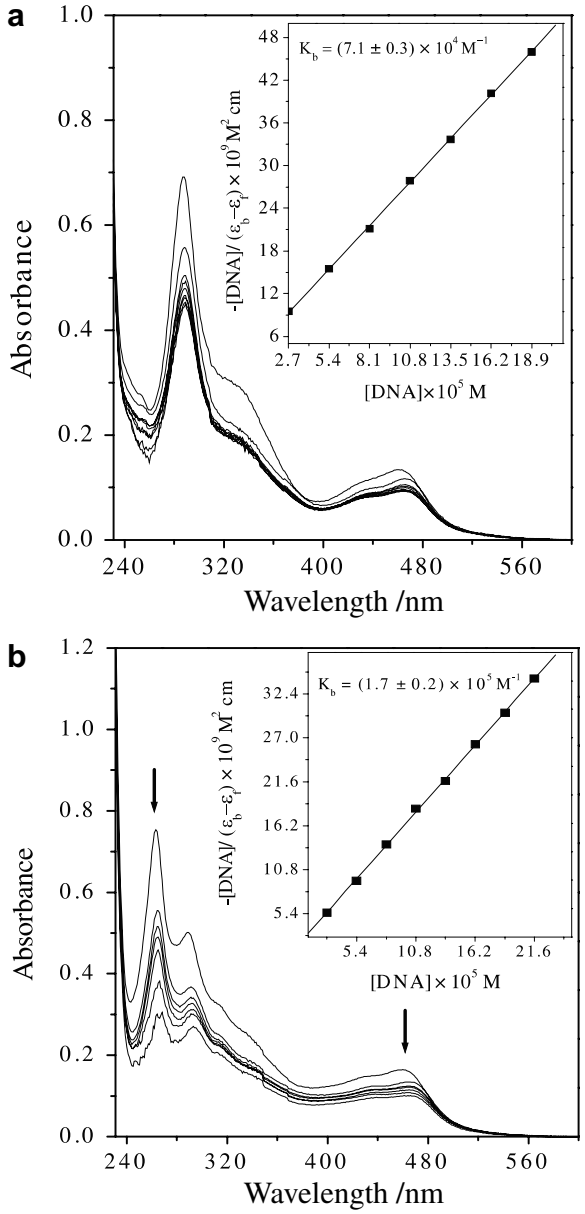

Fig. 2. Absorption spectra of complex **1** (a) and **2** (b) in Tris–HCl buffer upon addition of CT DNA. [Ru] = 20 μM, [DNA] = 0-216 μM. Arrow shows the absorbance changing upon the increase of DNA concentration. Plots of [DNA]/($\varepsilon_a - \varepsilon_b$) vs. [DNA] for the titration of DNA with Ru(II) complexes.

465 nm for complex **2** with increasing concentration of DNA using the following equation [35]:

$$[DNA]/(\varepsilon_a - \varepsilon_f) = [DNA]/(\varepsilon_b - \varepsilon_f) + 1/[K_b(\varepsilon_b - \varepsilon_f)]$$

where [DNA] is the concentration of DNA in base pairs, the apparent absorption coefficient ε_a, ε_f and ε_b correspond to A_{obsd}/ [Ru], the extinction coefficient for the free ruthenium complex and the extinction coefficient for the ruthenium complex in the fully bound form, respectively. In plots of [DNA]/(ε_a–ε_f) versus [DNA], K_b is given by the ratio of slope to the intercept. The intrinsic binding constants K_b of complexes **1** and **2** were $(1.70 \pm 0.2) \times 10^5\ M^{-1}$ and $(7.03 \pm 0.3) \times 10^4\ M^{-1}$, respectively. The values are bigger than that of those so-called DNA-intercalative Ru(II) complexes (1.1×10^4–$4.8 \times 10^4\ M^{-1}$) [21,36], but smaller than that observed for $[Ru(bpy)_2(dppz)]^{2+}$ (>10^6) [8]. The different DNA-binding properties of complexes **1** and **2** are due to the ancillary ligand. On going from bpy to phen, the plane area and hydrophobicity increase, leading to a greater DNA-binding affinity for complex **2**.

3.3. Steady-state emission studies

In the absence of DNA, complexes **1** and **2** can emit luminescence in Tris buffer at ambient temperature, with a maximum appearing at 599 and 591 nm, respectively. Upon addition of CT DNA, the emission intensities of complexes **1** and **2** increase to around 1.97 and 2.59 times larger than the original, respectively (Fig. 3). This implies

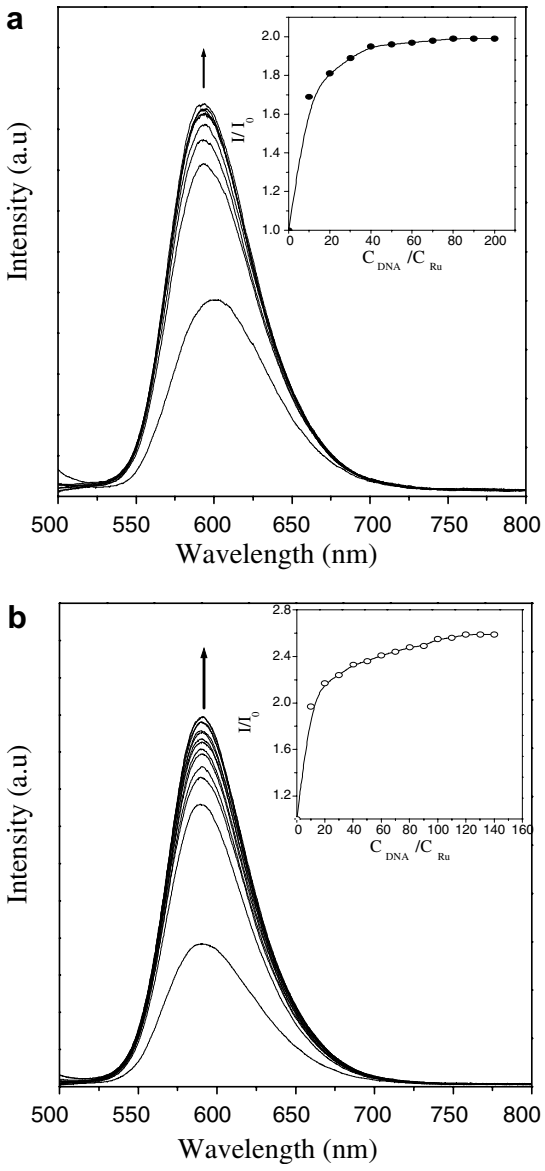

Fig. 3. Emission spectra of complex **1** (a) and **2** (b) in Tris–HCl buffer in the absence and presence of CT DNA. Arrow shows the intensity change upon increasing DNA concentrations.

that both complexes can interact with DNA and be protected by DNA. Compared **1** with **2**, complex **2** can be protected by DNA more effectively, which due to the stronger binding affinity of it with DNA.

Steady-state emission quenching experiments using $[Fe(CN)_6]^{4-}$ as quencher may provide further information about the binding of complexes with DNA. As illustrated in Fig. 4, in the absence of DNA, the emission of complexes **1** and **2** was efficiently quenched by $[Fe(CN)_6]^{4-}$ and the plots are not linear which imply that the quenching process is both dynamic and static [37]. However, in the presence of DNA, the Stern–Volmer plots are changed drastically (slopes 0.37 and 0.30, respectively), and the emission intensity was hardly affected by the addition of anionic quencher. This may be explained by repulsion of the highly negative $[Fe(CN)_6]^{4-}$ from the DNA polyanion backbone which hinders access of $[Fe(CN)_6]^{4-}$ to the DNA-bound complexes [38]. The plots for the DNA-bound complexes become linear, indicative of only dynamic quenching, which is consistent with the strong DNA-binding affinity of complexes **1** and **2** hence the complex is difficult to form between the two ruthenium(II) complexes and ferrocyanide. The curvature reflects different degrees of protection or relative accessibility of bound cations, a larger slope for the Stern–Volmer curve parallels poorer protection and low binding. From the results, complex **2** binds to DNA more strongly than does complex **1.**

3.4. Viscosity measurements

To further clarify the nature of the interaction between the complexes and DNA, viscosity measurements were carried out. Optical photophysical probes provide necessary, but not sufficient, evidence to support the binding model of Ru(II) complexes with DNA. Hydrodynamic measurements that are sensitive to length change (i.e. viscosity and sedimentation) are regarded as the least ambiguous and the most critical tests of a binding model in solution in the absence of crystallographic structural data [39,40]. A classical intercalation model demands that the DNA helix must lengthen as base pairs are separate [39,40]. The effects of complexes **1** and **2**, together with $[Ru(bpy)_3]^{3+}$ and ethidium bromide (EB) on the viscosity of rod-like DNA were shown in Fig. 5. As expected, EB

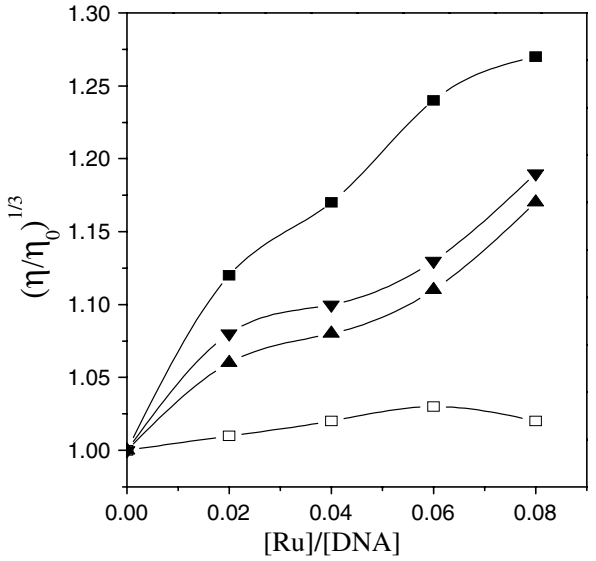

Fig. 5. Effect of increasing amounts of ethidium bromide (■), $[Ru(bpy)_3]^{2+}$ (□), complex **1** (▲) and complex **2** (▼) on the relative viscosity of calf thymus DNA at 30 (±0.1) °C. The total concentration of DNA is 0.5 mM.

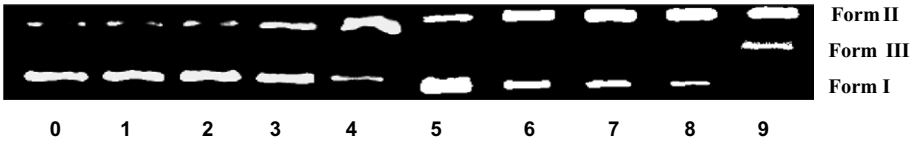

Fig. 7. Photoactivated cleavage of pBR 322 DNA in the presence of Ru(II) complexes, light after 60 min irradiation at 365 nm. Lane 0 and Lane 5, DNA alone; Lanes 1–4, in the different concentrations of complex **1**: (1) 20; (2) 40; (3) 60; (4) 80 μM; Lanes 6–9, in the different concentrations of complex **2**: (6) 20; (7) 40; (8) 60; (9) 80 μM.

increase the relative specific viscosity for the lengthening of the DNA double helix resulting from intercalation. While for complex $[Ru(bpy)_3]^{2+}$, which has been known to bind with DNA in electrostatic mode, it exerts essentially no effect on DNA viscosity. On increasing the amounts of **1** and **2**, the relative viscosity of DNA increasing steadily, which is similar to the behavior of the ethidium bromide. The results suggest that complex **1** and **2** intercalates between the base pair of DNA, which are consistent with our foregoing hypothesis.

3.5. Enantioselective binding

Equilibrium dialysis experiments may offer the opportunity to examine the enantioselectivity of complexes binding to DNA. According to the proposed binding model [41,42], the Δ enantiomer of the complex, a right-handed propeller-like structure, will display a greater affinity than the *Λ* enantiomer with the right-handed calf thymus DNA helix, due to the appropriate steric matching. The CD spectra in the UV region of complexes **1** and **2** after their racemic solution have been dialyzed against CT DNA are shown in Fig. 6. The dialysate for complexes **1** and **2** show two CD signals with a positive peak at 271 and 263 nm, and a negative peak at 291 and 295 nm, respectively. Although both complexes have not been resolved into their pure enantiomers, and we cannot determine which enantiomer binds DNA enantioselectively for both complexes, it is certain that complexes **1** and **2** interact with CT DNA enantioselectively. The stronger CD signals of complex **2** suggest the large difference between interactions of its two isomers with DNA.

3.6. Photoactivated cleavage of pBR 322 DNA by Ru(II) complexes

There is substantial and continuing interest in DNA endonucleolytic cleavage reactions that are activated by metal ions [43,44]. The cleavage reaction on plasmid DNA can be monitored by agarose gel electrophoresis. When circular plasmid DNA is subject to electrophoresis, relatively fast migration will be observed for the intact supercoil form (Form I). If scission occurs on one strand (nicking), the supercoil will relax to generate a slower-moving open circular form (Form II). If both strands are cleaved, a linear form (Form III) that migrates between Form I and Form II will be generated [45]. Fig. 7 shows gel electrophoresis separation of pBR 322 DNA after incubation with two Ru(II) complexes and irradiation at 365 nm. No DNA cleavage was observed for controls in which complex was absent (lane 0, 5). With increasing concentration of the Ru(II) complexes (lanes 1–4, 6–9), the amount of Form I of pBR322 DNA diminish gradually, whereas Form II increases and Form III is also produced (lane 9). Under comparable experimental conditions, complex **2** exhibits more effective DNA cleavage activity than complex **1**. This may be related to the molecular structure of these complexes, which has been testified in other cases [14,18]. Although DNA photocleavage by $[Ru(phen)_3]Cl_2$ has been reported to involve an $^1O_2$-based mechanism [43,46], the nature of reactive intermediates involved in the efficient DNA photocleavage by complexes **1** and **2** observed here is not clear. Further studies in detail are currently underway to clarify the cleavage mechanism.

4. Conclusions

Two new ruthenium(II) complexes of $[Ru(bpy)_2BPIP]^{2+}$ and $[Ru(phen)_2BPIP]^{2+}$ have been synthesized and characterized. Their DNA-binding and photocleavage properties were also investigated. Spectroscopic studies and viscosity experiments supported that the two complexes can intercalate into DNA base pairs via BPIP ligand. When irradiated at 365 nm, two Ru(II) complexes are efficient photocleavers of the plasmid pBR 322 DNA.

Abstract

Two new oxovanadium (IV) complexes $VO(HB(pz)_3)(H_2B(pz)_2)$ (**1**) and $VO(B(pz)_4)_2$ (**2**) have been obtained by the reaction of oxovanadium sulfate with the corresponding ligands $KHB(pz)_3$, $KH_2B(pz)_2$ and $KB(pz)_4$, respectively. The two complexes were characterized by elemental analyses, IR, UV–Vis and X-ray diffraction. Complex **1** crystallizes in the orthorhombic space group, $Pca2_1$. Complex **2** crystallizes in the orthorhombic space group, $Pna2_1$. In both complexes, five nitrogen atoms and one oxygen atom coordinate to the vanadium atom, forming a distorted octahedral geometry (VON_5). In addition, related spectra characterization, hydrogen-binding properties, structural configuration and quantum chemistry calculations are also discussed.

1. Introduction

Vanadium is a bioessential element that is found in abiotic and biotic systems [1]. Since two classes of vanadium enzymes, vanadium-nitrogenases which are used to fix nitrogen and vanadium-haloperoxidases which can catalyze the oxidation of bromide to hypobromite [2], are found in nature, vanadium biochemistry and its potential biological roles have received more and more attention. In recent years, the study of vanadium's antidiaetic action has been widely developed. The antidiaetic action of vanadium may be due to the inhibition of several enzymes involved in carbohydrate and fat metabolism such as phosphodiesterase and tyrosine phosphatases [3,4]. Vanadium compounds have long been known to lower diabetic hyperlipidemia in rats with STZ-induced diabetes [5]. Vanadium complexes with organic ligands are often less toxic and can have improved aqueous solubility and lipophilicity [3]. Also chelated vanadium complexes have the property of increasing permeation into tissues by passive diffusion and correspondingly increased insulin mimetic efficacy. Some vanadium complexes with several kinds of organic ligands have been proposed for clinical use for humans. For example, bis(maltolato)oxovanadium (IV) [3,6], which is under clinical trials, is three times more effective in vivo as an insulin mimetic agent than $VOSO_4$.

Poly(pyrazolyl)borate ligands $[H_xB(pz)_{4-x}]$, introduced by Trofimenko [7], are utilized extensively in organometallic and coordination chemistry for their outstanding chelating power and unusual structural features. Because of the close similarity between the imidazole moiety of the amino acid histidine and pyrazole, the poly(pyrazolyl)borate complexes

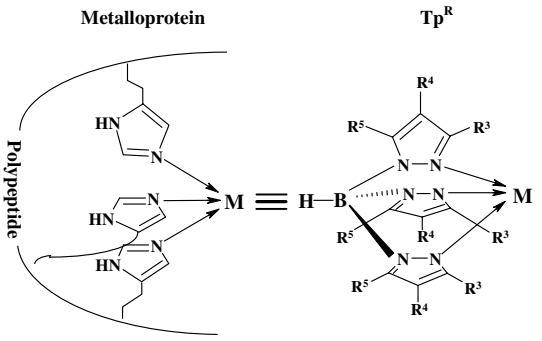

Fig. 1. Concept of the application of Tp^R to biological inorganic chemistry.

can be considered as model complexes of metalloenzymes [8] (Fig. 1). Concerning its biomimetic chemistry, many complexes with the mono-tris(pyrazolyl)borate ligand were synthesized as can be considered as complexes of metalloenzymes such as carbonic anhydrase (CA), nitrite reductases (NiR), hemocyanin (Hc) and blue copper proteins [9].

In the course of our ongoing studies on vanadium complexes containing the tris(pyrazolyl)borate ligand, we are exploring bis(pyrazolyl)borate-vanadium and tetra(pyrazolyl)borate-vanadium. To our knowledge, no vanadium complexes with bis(pyrazolyl)borate or tetra(pyrazolyl)borate as ligands have been reported. Complex **1** contains mixed poly(pyrazolyl)borate ligands, and the coordination environment of the complexes can be considered full-sandwich-like complexes. Many vanadium complexes containing poly(pyrazolyl)borate ligands have been reported [10], but it is worth noting that these reported vanadium complexes contain only one tris(pyrazolyl)-borate or one tris(3,5-dimethylpyrazolyl)borate ligand, forming a half-sandwich structure, except $[(Tp')_2V]BPh_4$, a sandwich vanadium (III) complex reported by Carrano and co-workers [10b]. Due to the steric effects of the poly(pyrazolyl)borate ligands, it is difficult to synthesize oxo-vanadium complexes with a full-sandwich structure.

As a part of the coordination chemistry and bioactivity of our research series on oxo-vanadium complexes, we report in this paper the syntheses, structures, luminescence properties, quantum chemistry and thermal stability of original oxovanadium (IV), '3+2' mixed-ligand complexes carrying both a common N3 tridentate and N2 bidentate ligand, namely, $VO(HB(pz)_3)(H_2B(pz)_2)$ (**1**) and $VO(B(pz)_4)_2$ (**2**).

2. Experimental

2.1. Methods and materials

The reactions were carried out at room temperature. Solvents were dried by molecular sieves (4 Å). All other reactants were used as purchased. The infrared spectra were recorded on a FT/IR-480 PLUS Fourier Transform spectrometer with pressed KBr pellets in the range 4000–200 cm^{-1}. The UV–Vis spectra were recorded on JASCO V-570 spectrometer (200–1100 nm, CH_2Cl_2 solution). Luminescence spectra were recorded on Spectrofluorometer JASCO FP-6500 (1100–200 cm^{-1}) with solid samples. Elemental analyses was performed on a PE 240C automatic analyzer. The thermal curves were recorded on a Perkin–Elmer Diamond TG/DTA. $KHB(pz)_3$, $KHB(3,5\text{-}Me_2pz)_3$ and $KB(pz)_4$ were prepared according to the literature methods [11].

2.2. Syntheses of complexes *1* and *2*

2.2.1. Synthesis of complex *1*

$VOSO_4 \cdot nH_2O$ (0.23 g, 1 mmol, based on 70% $VOSO_4$), potassium tris(pyrazolyl)borate (0.26 g, 1 mmol) and potassium bis(pyrazolyl)borate (0.20 g, 1 mmol) were dissolved in MeOH (15 mL). The mixture was stirred for 4 h at room temperature to obtain a dark-green suspended mixture. Then the precipitate was filtered and dissolved in CH_2Cl_2/MeOH solution. The solution was stood at room temperature overnight, after which blue crystals suitable for X-ray diffraction were obtained. Yield: 0.26 g, 62% (based on V). *Anal.* Calc. for $C_{15}H_{18}B_2N_{10}OV$ (FW 426.95): C, 42.16; H, 4.22; N, 32.79. Found: C, 41.56; H, 4.01; N, 32.17%. IR (KBr, ν, cm^{-1}): 3144, 2510, 2408, 2288, 1504, 1406, 1308, 1213, 1190, 1152, 1118, 1059, 988, 973, 922, 884, 764, 717, 667, 635, 395, 361, 311.

2.2.2. Synthesis of complex *2*

$VOSO_4 \cdot nH_2O$ (0.23 g, 1 mmol, based on 70% $VOSO_4$) and potassium tetra(pyrazolyl)borate (0.33 g, 1 mmol) were dissolved in MeOH, and the resulting mixture was stirred for 7 h at room temperature, forming a blue suspended mixture. The resultant solution was filtered, and the blue filtrate was stood at room temperature. From the mother liquid, blue crystals suitable for X-ray diffraction were discovered after 4 days. Yield: 0.36 g, 58% (based on V). *Anal.* Calc. for $C_{24}H_{27}B_2N_{16}OV$ (FW 628.18): C, 45.85; H, 4.30; N, 35.66. Found: C, 45.56; H, 4.11; N, 35.23%. IR (KBr, ν, cm^{-1}): 3430, 3137, 1505, 1435, 1408, 1389, 1297, 1212, 1197, 1108, 1070, 982, 921, 889, 855, 837, 823, 788, 759, 751, 678, 655, 617, 407, 378, 352, 307.

2.3. Crystal structure determination and refinement of the structure

The crystals of **1** and **2** were mounted on glass fibres for X-ray measurement. Reflection data were collected at room temperature on an APEX II CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.7107$ Å) and the ω scan mode. All the measured independent reflections were used in the structural analyses, and semi-empirical absorption corrections were applied using the SADABS program. The crystal data and refinement details are summarized in Table 1.

The structures were solved by the direct method using SHELXS-86 and refined using SHELXL-97. All the non-hydrogen atoms were refined anisotropically and the contributions

Table 1
A summary of the fundamental crystal and refinement data of complexes **1** and **2**

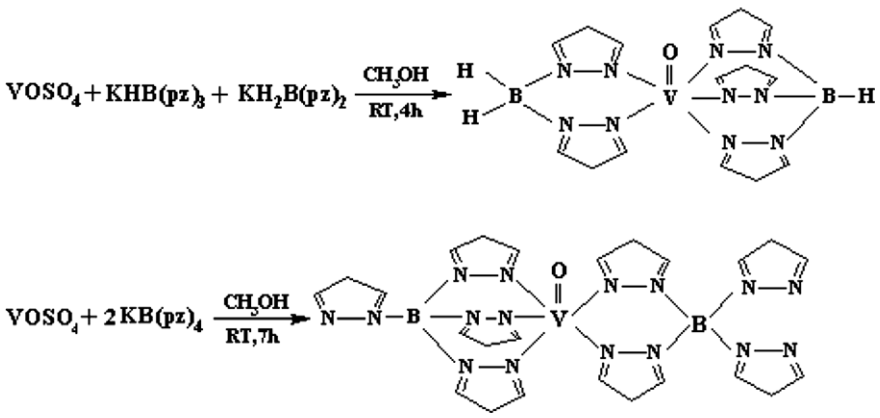
[a] $R = \sum\|F_o| - |F_c\|/\sum|F_o|$, $wR_2 = [\sum w(F_o^2 - F_c^2)^2/\sum(w(F_o^2)^2)]^{1/2}$; $[F_o > 4\sigma(F_o)]$.
[b] Based on all data.

of the hydrogen atoms were included in calculated positions, constrained to ride on their carbon atoms with group U_{iso} values assigned. Atomic scattering factors and anomalous dispersion terms were as in SHELXL-97. The drawings were made with DIAMOND 2.1c, and all calculations were performed on a pentium4 computer.

2.4. Thermal analysis

Thermogravimetric analyses (TGA) experiments were carried out on a Perkin–Elmer Diamond TG/DTA instrument. The samples were initially heated for 1 h at 50 °C. During the simple ramping experiment, weight changes were recorded as a function of temperature for a 10 °C/min temperature ramp between 50 and 750 °C in a nitrogen environment. The mass weight was 1.839 mg for complex **1** and 5.880 mg for complex **2**.



3. Results and discussion

3.1. Syntheses

In this work, the tridentate ligand of potassium tris(pyrazolyl)borate ($KHB(pz)_3$), bidentate ligand of potassium bis(pyrazolyl)borate ($KH_2B(pz)_2$) and tetradentate ligand of potassium tetra(pyrazolyl)borate ($KB(pz)_4$) were used. They were prepared by the sublimation reaction of pyrazole and KBH_4 with stoichiometric ratios of 3:1, 2:1 and 4:1, respectively. The complexes **1** and **2** were obtained from the mixture of $VOSO_4$ and the corresponding ligands in a MeOH solution at room temperature. Metal:ligand molar ratios of 1:1:1 for **1** and 1:2 for **2** were used for the syntheses of the complexes. The synthetic process of both complexes can be simplified as in Scheme 1.

For complex **1**, crystals for X-ray analysis can be obtained by the slow evaporation of a CH_2Cl_2/MeOH solution of the complex. Some other solvents, MeOH, CH_2Cl_2, CH_3CN, etc., were also used for recrystallization, but no suitable crystals for X-ray diffraction were separated. So we can conclude that the solvents play an important role in the crystallization for complex **1**.

In addition, using V_2O_5 as a starting material to react with the $KHB(pz)_3$ and $KH_2B(pz)_2$ or $KB(pz)_4$ ligands, respectively, both title complexes were also obtained (proved by the IR data). In the reaction process, an oxidation–reduction process occurs, the oxidation state of vanadium changes from V to IV. Complexes **1** and **2** are stable in air at room temperature and are readily soluble in CH_3Cl, CH_2Cl_2, CH_3CN, THF and CH_3COCH_3, slightly soluble in MeOH and EtOH, and insoluble in water, ether and hexane.

Scheme 1. Reaction process of complexes **1** and **2**.

3.2. IR spectra

The IR spectrum of complex **1** (Fig. S1) can be assigned as follows: the signal at 3144 cm^{-1} is assigned to the vibration of C–H from pyrazole rings, the characteristic bands of B–H vibrations are found at 2510, 2408 and 2288 cm^{-1} [12], the bands at 1059–1504 cm^{-1} are assigned to C=N and C=C vibrations from the pyrazole rings. The band at 988 cm^{-1} is the characteristic vibration of V=Ot [10b,g,h], and the bands at 311–395 cm^{-1} are assigned to the vibrations of V–N [13].

For the IR spectrum of complex **2** (Fig. S2), the signal at 3430 cm^{-1} can be attributed to the N–H vibration, the signal at 3137 cm^{-1} is assigned to the C–H vibration from pyrazole rings, The C=N and C=C vibrations from the pyrazole rings appear at 1070–1505 cm^{-1}. The characteristic band of V=Ot is found at 982 cm^{-1} [10b,g,h], and the bands at 307–407 cm^{-1} are assigned to the V–N vibrations [13].

3.3. UV spectra

The UV spectra (Figs. S1 and S4) for both complexes are recorded in CH_2Cl_2. The strong and broad absorption signals at 240 nm are assigned to the π–π^* transitions of the ligands (LLCT). However, no absorption bands could be observed in the region of 310–400 nm, suggesting that all LMCT (or MLCT) transitions in complexes **1** and **2** are probably hidden in the UV region of the strong intraligand π–π^* transitions. Two weak and broad split peaks at 496 and 668 nm for complex **1**, 500 and 652 nm for complex **2** are attributed to the $d \rightarrow d^*$ transition of the centre vanadium (MMCT). The characterization of the UV spectra for complexes **1** and **2** is similar to that of the complexes $VO(HB(pz)_3)(pzH)(SCN)$ and $VO(HB(3,5\text{-}Me_2pz)_3)(3,5\text{-}Me_2pz)(SCN)(SCNH)_2$ [13].

3.4. Emission spectra

The fluorescence (Figs. S5 and S6) of both complexes were also tested with excitation at 260 nm, and luminescence bands at 302, 398–469, 743 nm and 302, 416–469, 742 nm for **1** and **2**, respectively, were present. The spectra exhibit three distinct regions. The first region presents a sharp band at 302 nm; in the second and the third regions there are some broad bands (398–469 and 743 nm for **1**; 416–469, 742 nm for **2**) at longer wavelengths. On comparison of the corresponding absorption and emission spectra, the emission peaks of complexes **1** and **2** can be assigned as follows: two emission bands in the UV region (302, 398–469 nm for **1**; 302, 416–469 nm for **2**) come from the π–π^* transitions of the ligands (LLCT); the weak and broad emission bands at 743 nm for **1** and 742 nm for **2** should be attributed to the $d \rightarrow d^*$ transition of the central vanadium (MMCT). On comparing the luminescence bands of complexes **1** and **2** with the complexes $VO(HB(pz)_3)(pzH)(SCN)$ and $VO(HB(3,5\text{-}Me_2pz)_3)(3,5\text{-}Me_2pz)(SCN)(SCNH)_2$ [13], it is found that the emission band in the high energy region (302 nm) has a blue shift of about 53 nm, and those in the low energy region (742, 743 nm) have a red shift of about 43 nm.

3.5. Crystal structures of $VO(HB(pz)_3)(H_2B(pz)_2)$ (1) and $VO(B(pz)_4)_2$ (2)

The overall view and labelling of the atoms for complex **1** in two independent molecules (designated as molecule 1 and molecule 2) are displayed in Fig. 2. Each vanadium atom has a six-coordinated structure with three nitrogen atoms provided by one tridentately ligating $HB(pz)_3^-$, two nitrogen atoms from one bidentately ligating $H_2B(pz)_2^-$ and an oxo oxygen atom. Around the mental center, a distorted octahedral geometry is formed. Two nitrogen atoms from the tridentate $HB(pz)_3^-$ ligand with the other two nitrogen atoms from the bidentate $H_2B(pz)_2^-$ ligand form an equatorial plane (N4, N6, N8, N10 and N14, N16, N18, N20 for molecules 1 and 2, respectively). The axial positions are occupied by the remaining one nitrogen (N2 and N12 for molecules 1 and 2, respectively) from the tridentate $HB(pz)_3^-$ ligand and a terminal oxygen atom (O1 and O2 for molecules 1 and 2, respectively). As for complex **2**, the coordination environment is similar to that of complex **1**. The structure and atomic labelling scheme for complex **2** are presented in Fig. 3.

For complex **1**, the deviations from the least-squares plane containing the N4, N6, N8 and N10 atoms are −0.026(1), 0.026(1), 0.025(1) and −0.026(1) Å, respectively, showing that these atoms are almost on one plane. The atoms V1, O1 and N2 lie 0.319(2), 1.911(2) and −1.981(3) Å out of this plane, respectively, indicating that V1 lies towards the apical oxo atom O1, *trans* to N2. The deviations from the least-square plane containing the N14, N16, N18 and N20 atoms are −0.012(1), 0.012(1), 0.012(1) and −0.012(1) Å, respectively, showing that these atoms are also almost on a plane. The atoms of V2, O2 and N12 lie 0.297(2), 1.884(2) and −1.999(2) Å out of this plane, respectively, indicating that V2 lies towards the apical oxo atom O2, *trans* to N12. For complex **2**, the deviations from the least-squares plane containing the N4, N6,

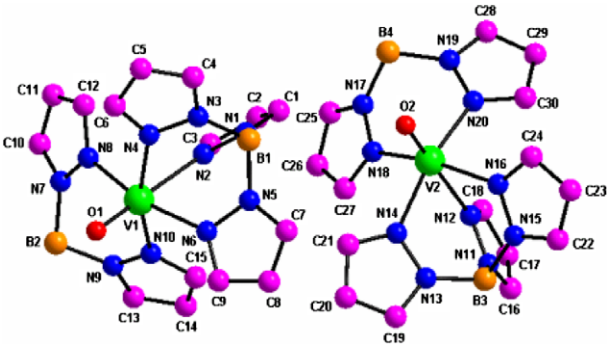


Fig. 2. A view of the molecular structure of complex **1**.

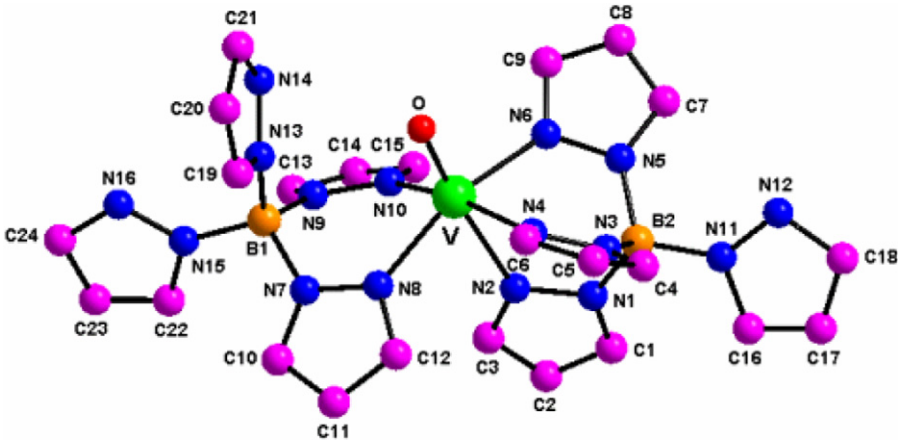

Fig. 3. A view of the molecular structure of complex **2**.

N8 and N10 atoms are −0.023(2), 0.023(2), 0.023(2) and −0.023(2) Å, respectively, showing that these atoms are almost on a plane. The atoms of V, O and N2 lie −0.297(2), −1.880(3) and 1.975(4) Å out of this plane, respectively, indicating that V lies towards the apical oxo atom O, *trans* to N2.

Some selected bond distances and angles for complexes **1** and **2** are listed in Table 2. For complex **1**, the V–O distances in complex **1** are 1.592(2) Å (for molecule 1) and 1.590(2) Å (for molecule 2), which are close to those reported previously [10h,14]. The average V–N_{cis} bond distance is 2.105(2) Å for molecules 1 and 2; and the V–N_{trans} bond distance is 2.298(2) Å for molecules 1 and 2. For complex **2**, the V–O distance is 1.588(3) Å. The average V–N_{cis} bond distance is 2.100(3) Å and the V–N_{trans} distance is 2.274(3) Å. There is no difference between the V–N_{cis} distance of the two complexes, while the V–O and V–N_{trans} distances of complex **1** are slightly longer than the corresponding bond distances of complex **2**. This may be attributed to the fact that the donor electron ability of tetra(pyrazolyl)borate is stronger than that of tris(pyrazolyl)borate or bis(pyrazolyl)borate.

The O–V–N_{trans} angle (177.0(1)°) for molecule 1 (in complex **1**) is bigger than that of complex **2** (173.2(1)°),

Table 2
Some selected bond distances (Å) and angles (°) for complexes **1** and **2**

Complex **1**				Complex **2**	
V(1)–O(1)	1.592(2)	V(2)–O(2)	1.590(2)	V–O	1.588(3)

N(8)–V(1)–N(6)	164.0(1)	N(18)–V(2)–N(16)	163.2(1)	N(8)–V–N(6)	162.4(1)
N(10)–V(1)–N(6)	89.6(1)	N(20)–V(2)–N(16)	91.4(1)	N(6)–V–N(10)	92.6(1)
N(8)–V(1)–N(10)	87.3(1)	N(18)–V(2)–N(20)	86.6(1)	N(10)–V–N(8)	85.4(11)
N(1)–N(2)–V(1)	120.5(2)	N(11)–N(12)–V(2)	120.3(2)	N(1)–N(2)–V	123.1(2)
N(3)–N(4)–V(1)	121.7(2)	N(13)–N(14)–V(2)	122.2(2)	N(3)–N(4)–V	122.1(2)
N(5)–N(6)–V(1)	121.8(2)	N(15)–N(16)–V(2)	121.6(2)	N(5)–N(6)–V	125.0(2)
N(7)–N(8)–V(1)	122.7(2)	N(17)–N(18)–V(2)	123.0(2)	N(9)–N(10)–V	125.0(2)
N(9)–N(10)–V(1)	123.1(2)	N(19)–N(20)–V(2)	122.5(2)	N(7)–N(8)–V	125.8(2)

while the O–V–N_{trans} angle (174.4(1)°) for molecule 2 (in complex **1**) is close to that of complex **2**. The average O–V–N_{cis} angle of complex **1** (97.9(1)° for molecule 1, 98.4(1)° for molecule 2) is close to that of complex **2**(98.1(1)°).

It is worthy noting that each of two pyrazoles from a poly(pyrazolyl)borate can provide four nitrogen atoms forming a plane, and both V and B atoms lie above or below of the plane, showing that the $V(N–N)_2B$ rings are arranged in shallow boat configurations (Fig. S7). The V1···B1, V1···B2, V2···B3 and V2···B4 distances are 3.302(3), 3.363(3), 3.304(3) and 3.345(3) Å, respectively, somewhat similar to the coordination environment of the complex $M(H_2B(pz)_2)_2$ (M = Cu, Ni), which we have reported previously [15]. Similarly for complex **2**, the $V(N–N)_2B$ rings are arranged in shallow boat configurations (Fig. S8), and the V1···B1, V1···B2 distances are 3.416(4) and 3.327(4) Å, respectively.

As shown in Fig. 4, two kinds of weak interactions between adjacent molecules were observed in complex **1**, C–H···O hydrogen bonds and C–H···B hydrogen bonds. The C19A–H19A···O2 (H19A: $-0.5 + x$, $3 - y$, z) and C1B–H1B···O2 (H1B: x, $1 + y$, z) distances are 2.646 and 2.545 Å, respectively, and the C–H···B hydrogen bond distances are 2.902 Å (C29A–H29A···B2) (H29A: $0.5 - x$, $1 + y$, $0.5 + z$) and 3.129 Å (C17A–H17A···B2) (H17A: $1 - x$, $2 - y$, $0.5 + z$). It is obvious that the C–H···O hydrogen bonds are stronger than the C–H···B hydrogen bonds.

For complex **2**, C–H···O hydrogen bonding is also observed between the molecules (Fig. 5). The C–H···O hydrogen bond distance is 2.585 Å (C23A–H23A···O, H23A: $0.5 - x$, $0.5 + y$, $0.5 + z$). Adjacent molecules are connected by C–H···O hydrogen bonds, forming a one-dimension chain structure. No C–H···B hydrogen bonds were observed.

3.6. Thermal decomposition process

As shown in Fig. 6, the thermal decomposition of complex **1** exhibits a two-step process. In the range 296–325 °C, there is a 10.58% weight loss, which is attributed to the release of one pyrazole moiety (10.67% theoretical weight loss). This step is followed by a weight loss of 41.18%, which can be attributed to the release of four pyrazole moieties (42.68% theoretical weight loss) in the range 325–439 °C.

The thermal decomposition of complex **2** (Fig. S9) also exhibits a two-step process. In the range 245–288 °C, there is a 23.53% weight loss, which is attributed to the release of one pyrazole moiety (23.54% theoretical weight loss). This step is followed by weight loss of 31.42%, which can be attributed to the release of two pyrazole moieties (31.38% theoretical weight loss) in the range 290–441 °C.

On comparison of the starting decomposition temperature of both complexes, 296 °C for complex **1** and 245 °C for complex **2**, we can see that complex **1** is more stable than complex **2**.

3.7. Quantum chemistry calculations of the complexes

According to molecular orbital theory, the frontier orbitals and nearby molecular orbitals are the most important factors to the stability. The larger the difference between the frontier orbitals, the more stable the molecular structure is. The energy values of ΔE ($\Delta E = E_{LUMO} - E_{HOMO}$)

Table 3
The atomic net charge for complexes **1** and **2** calculated with NBO analysis

Atom	Complex **1**	Complex **2**
V1(V)	2.38744	1.8881
O1(O)	−0.87793	−1.09264
N2	−0.47855	−0.44354
N4	−0.51023	−0.43566
N6	−0.51023	−0.43392
N8	−0.53253	−0.40766
N10	−0.53253	−0.41272
N12		−0.49439
N14		−0.24644
N16		−0.37501
B1	0.83565	1.27705
B2	0.40870	1.28075

are 0.2332 and 0.01273, respectively, for complex **1** and **2** (Table S1), which show that the order of stability of the complexes is **1** > **2**. This result corresponds to the results of the thermal decomposition.

The atomic net charges for the complexes calculated in the NBO analysis are listed in Table 3. The charge of the central V metal for complex **1** is 2.38744. The net change of the terminal oxygen (O1) is −0.87793. The net charge of the coordinated N atoms (N2, N4, N6, N8, N10) range from −0.47855 to −0.53253, and N4/N6, N8/N10 share the same net charges, respectively. The charge of the central V metal for complex **2** is 1.8881. The net charge of the terminal oxygen (O) is −1.09264. The net charges of the coordinated N atoms (N2, N4, N6, N8, N10) range from −0.40766 to −0.44354, the net charges of the uncoordinated N atoms (N12, N14, N16) range from −0.24644 to −0.49439. Comparing both complexes, the net charges of the central V metal are less than +4, showing that the V atom has been coordinated by the ligand and its charge transfers to the ligand, and the net charge of complex **1** is more positive than that of complex **2**. The net charges of the coordinated N atoms for complex **1** are more negative than those of complex **2**. The net charges of the B atoms for complex **1** are less positive than those of complex **2**. From the data above we can see the net charges of the V atom for complexes **1** and **2** are different, attributed to the fact that the donor electron ability of tetra(pyrazolyl)-borate is stronger than that of tris(pyrazolyl)borate or bi(pyrazolyl)borate.

The NBO bond order (Table 4) between V and O is greater than that between V and N (N2, N4, N6, N8, N10), showing V–O possesses double bond character, while the V–N bonds (N2, N4, N6, N8, N10) have single bond character.

Table 4
Selected NBO bond order for complexes **1** and **2**

Bond	Complex **1**	Complex **2**
V1–O1(V–O)	0.7129	0.6908
V1–N2	0.1204	0.0947
V1–N4	0.1808	0.1560
V1–N6	0.1808	0.1541
V1–N8	0.1934	0.1509
V1–N10	0.1934	0.1491

Dedicated to the memory of Professor Tong-In Ho who passed away at his prime time.

Abstract

With the readily available fluorous alkanols R_fCH_2OH, a series of novel fluorous-ponytailed bpy ligands, 4,4′-bis($R_fCH_2OCH_2$)-2,2′-bpy (**1a**–**e**), were prepared and treated with $[PdCl_2(CH_3CN)_2]$ to result in the corresponding novel Pd complexes [$PdCl_2$(4,4′-bis-($R_fCH_2OCH_2$)-2,2′-bpy)] (**2a**–**e**) where $R_f = n\text{-}C_3F_7$ (**a**), $HCF_2(CF_2)_3$ (**b**), $HCF_2(CF_2)_7$ (**c**), $n\text{-}C_8F_{17}$ (**d**), $n\text{-}C_{10}F_{21}$ (**e**). The new ligands and Pd complexes were spectroscopically characterized by multi-nuclei NMR (^1H, ^{19}F and ^{13}C), FTIR and high resolution mass (FAB). The structure for the Pd complex **2b**, the first with fluorinated ponytails on bpy and not on phosphine, was also established by a single crystal X-ray diffraction study. The TGA data of both ligands and Pd complexes indicated that the Pd-complexes were resistant to higher temperatures than the corresponding ligands. The Pd catalysts derived from **2a**–**c** showed an almost quantitative conversion and could be reused for eight runs with Heck reactions, in that the products and unspent reactants were directly removed by distillation. With the highest fluorine content in the series, Pd complex **2e** was successfully applied in the Heck reaction using the fluorous biphasic catalysis strategy.

Keywords: Fluorinated palladium complexes; Bis(fluorous ponytailed)bipyridine; X-ray structure analysis; Heck reaction; Catalyst recycling; Fluorous biphasic catalysis

1. Introduction

The concept of fluorous biphasic catalysis (FBC) was first introduced by Horvath and Rabai in 1994 [1]. In the past decade, this field has evolved rapidly [2] and fluorous biphasic catalysis [3,4] has become nowadays one of the important strategies in the design and reuse of homogeneous metal catalysts.

As a common bidentate ligand, 2,2′-bipyridine (2,2′-bpy) upon coordination to a metal center is known to maintain its bonding geometry at the metal center even when the metal center is oxidized or reduced. It is also known that modification of a molecule with fluorous segments alters the physical properties of the original molecule. Furthermore, Pd complexes are amongst the most popular transition metal compounds as catalysts in organometallics [5]. Thus, the combination of a Pd metal center with fluorous-ponytailed 2,2′-bpy ligands should result in a rich chemistry [6,7].

In this study, a series of fluorous-ponytailed 2,2′-bpy ligands have been prepared, whose partitions between organic and fluorous solvents were measured, and the

doi:10.1016/j.poly.2007.02.009

catalytic properties of the resultant metal complexes with light fluorine content ligands and those of metal complexes with high fluorine content ligands were studied. The ligands with high fluorine content and the associated metal complexes are expected to be only soluble in perfluorinated solvents and insoluble in common organic solvents, a property applicable to the abovementioned fluorous biphasic catalysis.

Previously reported single crystal X-ray structures carrying fluorous segments are mainly based on phosphine ligands [8–11], none being based on fluorous-ponytailed 2,2′-bpy ligands [12,13]. Along with our recycling studies of the fluorous-ponytailed 2,2′-bpy Pd catalysts using the Heck reaction as the test reaction, an X-ray diffraction study on one of the Pd complexes prepared was carried out.

2. Experimental

2.1. General

Gas chromatographic/mass spectrometric data were obtained using an Agilent 6890 Series gas chromatograph with a series 5973 mass selective detector. The GC monitoring employed a HP 6890 GC using a 30 m × 0.250 mm HP-1 capillary column with a 0.25 μm stationary phase film thickness. Infrared spectra were obtained on a Perkin–Elmer RX I FT-IR Spectrometer. NMR spectra were recorded on Bruker AM 500 and Joel AM 200 using 5 mm sample tubes. The residual peaks of CD_3OD, CD_2Cl_2, $CDCl_3$ and deuterated Me_2SO were used as the reference peaks for both ^1H and ^{13}C NMR spectra; Freon® 11 ($CFCl_3$) for ^{19}F NMR spectra. Thermogravimetric analyses (TGA) were obtained on a TA Instruments TGA51.

2.2. Starting materials

Chemicals, reagents and solvents employed were commercially available and were used as received. $HCF_2(CF_2)_3CH_2OH$ and $HCF_2(CF_2)_7CH_2OH$ were obtained from Daikin, Taiwan. $C_3F_7CH_2OH$, $C_8F_{17}CH_2OH$ and $C_{10}F_{21}CH_2OH$ were purchased from Aldrich and SynQuest.

2.3. Preparation of 4,4′-bis($R_fCH_2OCH_2$)-2,2′-bpy **1a–e**, where R_f = n-C_3F_7 (**a**), $HCF_2(CF_2)_3$ (**b**), $HCF_2(CF_2)_7$ (**c**), n-C_8F_{17} (**d**), n-$C_{10}F_{21}$ (**e**)

2.3.1. General procedure

Thirty percent of CH_3ONa/CH_3OH (1.1 g) and R_fCH_2OH (6.0 mmol) were charged into a round-bottomed flask, then continuously stirred at 65 °C under N_2 atmosphere for 4 h before CH_3OH was vacuum removed to drive the reaction to the fluorinated alkoxide side. The resultant fluorinated alkoxide (6.0 mmol) was then dissolved in 20 mL of dry CH_3CN (or HFE 7100), and 4,4′-bis($BrCH_2$)-2,2′-bpy (5.8 mmol) added. The mixture was brought to reflux for 4 h, and the completeness of the reaction was checked by sampling the reaction mixtures and analyzing the aliquots with GC/MS. The product was purified by vacuum sublimation to obtain a white solid.

2.3.2. Analytical data of **1a**

Yield 86.2%; ^1H NMR (500 MHz, *d*-Me_2SO) δ 8.67 (2H, d, $^3J_{HH} = 4.5$ Hz, H_6), 8.37 (2H, s, H_3), 7.38 (2H, d, $^3J_{HH} = 4.5$ Hz, H_5), 4.84 (4H, s, bpy-CH_2), 4.34 (4H, t, $^3J_{HF} = 14.5$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, *d*-Me_2SO) δ −80.4 (t, $^3J_{HF} = 9$ Hz, CF_3), −119.7 (m, $CF_3CF_2CF_2$), −126.8 (s, $CF_3CF_2CF_2$); ^{13}C NMR (113 MHz, *d*-Me_2SO) δ 71.9 (bpy-CH_2), 66.5 (CH_2CF_2), 118.6, 122.2, 147.5, 149.6, 155.2 (bpy), 113.0–117.0 ($CF_2CF_2CF_3$); GC/MS (EI): 580 (M^+), 382 ($M^+-OCHC_3F_7$), 183 ($C_5H_3NCH_2C_5H_3NCH_3^+$), 91 ($C_5H_3NCH_2^+$); FT-IR (cm^{-1}): 1596, 1558 (*ν*bpy, m), 1225, 1120 (*ν*CF_2, vs); m.p.: 68–70 °C.

2.3.3. Analytical data of **1b**

Yield 71.1%; ^1H NMR (500 MHz, *d*-Me_2SO) δ 8.67 (2H, d, $^3J_{HH} = 4.5$ Hz, H_6), 8.37 (2H, s, H_3), 7.39 (2H, d, $^3J_{HH} = 4.5$ Hz, H_5), 7.06 (2H, tt, $^2J_{HF} = 51.9$ Hz, $J_{HF} = 5.5$ Hz, CF_2CF_2H), 4.84 (4H, s, bpy-CH_2), 4.29 (4H, t, $^3J_{HF} = 13.7$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, *d*-Me_2SO) δ −119.5 (2F, t, $^3J_{HF} = 14$ Hz, CH_2CF_2), −125.3 (2F, s, $CH_2CF_2CF_2$), −130.1 (2F, t, $^3J_{HF} = 5.5$ Hz, HCF_2CF_2), −137.2 (2F, d, $^2J_{HF} = 52$ Hz, HCF_2); ^{13}C NMR (113 MHz, *d*-Me_2SO) δ 73.0 (bpy-CH_2), 67.6 (CH_2CF_2), 119.4, 121.9, 147.1, 149.4, 155.7 (bpy), 105.0–116.0 (CF_2)$_4$; GC/MS (*m*/*z*; EI): 644 (M^+), 414 ($M^+-OCH_2C_4F_8$), 183 ($C_5H_3NCH_2C_5H_3NCH_3^+$), 91 ($C_5H_3NCH_2^+$); FT-IR (cm^{-1}): 1599, 1463 (*ν*bpy, m), 1208, 1144 (*ν*CF_2, vs); m.p.: 42 °C.

2.3.4. Analytical data of **1c**

Yield 85%; ^1H NMR (500 MHz, $CDCl_3$) δ 8.69 (2H, d, $^3J_{HH} = 4.5$ Hz, H_6), 8.33 (2H, s, H_3), 7.36 (2H, d, $^3J_{HH} = 4.5$ Hz, H_5), 6.03 (1H, tt, $^2J_{HF} = 51.9$ Hz, $^3J_{HF} = 5.5$ Hz CF_2H), 4.78 (4H, s, bpy-CH_2), 4.04 (4H, t, $^3J_{HF} = 13.7$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, $CDCl_3$) δ −119.1 (s, 2F, –CH_2CF_2), −121.9 (s, 6F), −123.0 (s, 4F), −128.9 (s, 2F, HCF_2CF_2–), −138.5 (d, 2F, $^2J_{HF} = 52$ Hz, HCF_2–); ^{13}C NMR (113 MHz, $CDCl_3$) δ 72.4 (bpy-CH_2), 67.1 (CH_2CF_2), 118.9, 122.7, 146.9, 149.6, 156.1 (bpy), 108.0–116.3 (CF_2)$_8$; GC/MS (*m*/*z*; EI): 614 ($M^+-OCH_2C_8F_{16}$), 198 ($C_5H_3NCH_2C_5H_3NCH_2O^+$), 183 ($C_5H_3NCH_2C_5H_3NCH_3^+$), 91 ($C_5H_3NCH_2^+$); FT-IR ($cm^{-1}$): 1596, 1558 (*ν*bpy, m), 1208, 1140 (*ν*CF_2, vs); m.p.: 86–88 °C.

2.3.5. Analytical data of **1d**

Yield 80%; ^1H NMR (500 MHz, $CDCl_3$) δ 8.67 (2H, d, $^3J_{HH} = 4.9$ Hz, H_6), 8.40 (2H, s, H_3), 7.34 (2 H, d, $^3J_{HH} = 4.9$ Hz, H_5), 4.77 (4H, s, bpy-CH_2), 4.04 (4H, t, $^3J_{HF} = 13.5$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, $CDCl_3$) δ −80.8 (3F), −119.3 (2F), −121.9 (6F), −122.7 (2F), −123.2 (2F), −126.1 (2F); ^{13}C NMR (113 MHz, $CDCl_3$) δ 73.0 (bpy-CH_2), 67.7 (CH_2CF_2), 119.2, 121.9, 146.9,

149.6, 156.1 (bpy), 108.0–119.0 (C_8F_{17}); GC/MS (*m*/*z*; EI): 632 ($M^+-OCHC_8F_{17}$), 198 ($C_5H_3NCH_2C_5H_3NCH_2O^+$), 183 ($C_5H_3NCH_2C_5H_3NCH_3^+$), 91 ($C_5H_3NCH_2^+$); FT-IR ($cm^{-1}$): 1602, 1560, 1465 (*v*bpy, m), 1204, 1145 (*v*CF_2, vs); m.p.: 113–115 °C.

2.3.6. Analytical data of **1e**

Yield 65%; ^1H NMR (500 MHz, $CDCl_3$) δ 8.69 (2H, d, $^3J_{HH} = 5.1$ Hz, H_6), 8.40 (2H, s, H_3), 7.38 (2H, d, $^3J_{HH} = 4.2$ Hz, H_5), 4.80 (4H, s, bpy-CH_2), 4.06 (4H, t, $^3J_{HF} = 13.3$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, $CDCl_3$) δ −80.7 (3F), −119.3 (2F), −121.7 (6F), −121.8 (4F), −122.6 (2F), −123.1 (2F), −126.0 (2F); ^{13}C NMR (113 MHz, $CDCl_3$) δ 73.1 (bpy-CH_2), 68.1 (CH_2CF_2), 119.8, 122.2, 144.7, 149.4, 154.1 (bpy), 105.5–116.2 ($C_{10}F_{21}$); GC/MS (*m*/*z*; EI): 732 ($M^+-OCHC_{10}F_{21}$), 198 ($C_5H_3NCH_2C_5H_3NCH_2O^+$), 183 ($C_5H_3NCH_2C_5H_3NCH_3^+$), 91 ($C_5H_3NCH_2^+$); FT-IR ($cm^{-1}$): 1602, 1562 (*v*bpy, m), 1215, 1151 (*v*CF_2, vs); m.p.: 140–142 °C.

2.4. Preparation of Pd complexes **2a**–**e** where $R_f = n\text{-}C_3F_7$ (**a**), $HCF_2(CF_2)_3$ (**b**), $HCF_2(CF_2)_7$ (**c**), $n\text{-}C_8F_{17}$ (**d**), $n\text{-}C_{10}F_{21}$ (**e**)

Equal molar amounts of $[PdCl_2(CH_3CN)_2]$ (134.9 mg, 0.52 mmol) and the respective ligands **1a**–**e** (0.52 mmol) for the different reactions were charged into a round bottomed flask, and CH_2Cl_2 (3 mL) added as a solvent. The color of solution changed from red to yellow after mixing for several minutes. The solution was further stirred at room temperature for 24 h before the solvents and volatiles were removed under vacuum. The resulting yellow solids were collected as spectroscopically pure products.

2.4.1. Analytical data of **2a**

Yield 98%; ^1H NMR (500 MHz, *d*-Me_2SO) δ 9.08 (2H, d, $^3J_{HH} = 5.9$ Hz, H_6), 8.37 (2H, s, H_3), 7.74 (2H, d, $^3J_{HH} = 5.9$ Hz, H_5), 4.96 (4H, s, bpy-CH_2), 4.42 (4H, t, $^3J_{HF} = 14.6$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, *d*-Me_2SO) δ −119.8 (2 F, CH_2CF_2), −127.1 (2F, s, $CH_2CF_2CF_2$), −80.4 (3F, t, $^3J_{HF} = 9.2$ Hz, CF_3); ^{13}C NMR (113 MHz, *d*-Me_2SO) δ 70.4 (bpy-CH_2), 65.5 (CH_2CF_2), 121.0, 124.7, 149.6, 152.1, 156.1 (bpy), 115.0–119.0 ($CF_2CF_2CF_3$); FT-IR (cm^{-1}): 1623, 1560 (*v*bpy, m), 1232, 1197 (*v*CF_2, vs); HR-MS (FAB): (M^+; *m*/*z*=) $C_{20}N_2H_{14}F_{14}O_2Pd^{35}Cl_2$ Calc. 755.9244. found 755.9266. $C_{20}N_2H_{14}F_{16}O_2Pd^{35}Cl^{37}Cl$ Calc. 757.9190; found 757.9199. $C_{20}N_2H_{14}F_{16}O_2Pd^{37}Cl_2$ Calc. 759.9185, found 757.9192.

2.4.2. Analytical data of **2b**

Yield 98%; ^1H NMR (500 MHz, *d*-Me_2SO) δ 9.05 (2H, d, $^3J_{HH} = 6.0$ Hz, H_6), 8.40 (2H, s, H_3), 7.72 (2H, d, $^3J_{HH} = 6.0$ Hz, H_5), 7.04 (2H, tt, $^2J_{HF} = 50.3$ Hz, $^3J_{HF} = 5.5$ Hz, HCF_2), 4.95 (4H, s, bpy-CH_2), 4.36 (4H, t, $^3J_{HF} = 14.7$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, *d*-Me_2SO) δ −119.3 (2F, t, $^3J_{HF} = 14$ Hz, CH_2CF_2), −124.8 (2F, s, $CH_2CF_2CF_2$), −129.7 (2F, t, $^3J_{HF} = 5.5$ Hz, HCF_2CF_2), −138.4 (d, 2F, $^2J_{HF} = 52$ Hz, HCF_2); ^{13}C NMR (113 MHz, $CDCl_3$) δ 71.7 (bpy-CH_2), 67.3 (bpy-CH_2OCH_2), 105.0–116.2 (CF_2)$_4$, 116.2, 121.7, 150.1, 152.7, 156.5 (bpy); FT-IR: 162, 1560 (*v*bpy, m), 1173, 1147 (*v*CF_2, vs) cm^{-1}; HR-MS (FAB): (M^+; *m*/*z*=) $C_{22}N_2H_{16}F_{16}O_2Pd^{35}Cl_2$ Calc. 819.9368, found 819.9363; $C_{22}N_2H_{16}F_{16}O_2Pd^{35}Cl^{37}Cl$ Calc. 821.9339, found 821.9348; $C_{22}N_2H_{16}F_{16}O_2Pd^{37}Cl_2$ Calc. 823.9343, found 823.9343.

2.4.3. Analytical data of **2c**

Yield 96%; ^1H NMR (500 MHz, *d*-Me_2SO) δ 9.08 (2H, d, $^3J_{HH} = 5.8$ Hz, H_6), 8.34 (2H, s, H_3), 7.73 (2H, dd, $^3J_{HH} = 5.8$ Hz, H_5), 7.19 (2H, tt, $^2J_{HF} = 50.3$ Hz, $^3J_{HF} = 5.3$ Hz, CF_2H), 4.96 (4H, s, bpy-CH_2), 4.41 (4H, t, $^3J_{HF} = 14.6$ Hz, CF_2CH_2); ^{19}F NMR (470.5 MHz, *d*-Me_2SO) δ −119.1 (s, 2F, CH_2CF_2), −121.9 (s, 6F), −122.9 (s, 4F), −128.7 (s, 2F, HCF_2CF_2), −138.5 (d, 2F, $^2J_{HF} = 52$ Hz, HCF_2); ^{13}C NMR (113 MHz, *d*-Me_2SO) δ 71.0 (bpy-CH_2), 66.8 (CH_2CF_2), 120.6, 124.3, 149.3, 151.6, 155.6 (bpy), 106.5–118.2 (CF_2)$_8$; FT-IR (cm^{-1}): 1654, 1560 (*v*bpy, m), 1210, 1147 (*v*CF_2, vs); HR-MS (FAB): (M^+; *m*/*z*=) $C_{30}N_2H_{16}F_{32}O_2Pd^{35}Cl_2$ Calc. 1219.9113, found 1219.9169; $C_{30}N_2H_{16}F_{32}O_2Pd^{35}Cl^{37}Cl$ Calc. 1221.9041, found 1221.9041; $C_{30}N_2H_{16}F_{32}O_2Pd^{37}Cl_2$ Calc. 1223.9054, found 1223.9009.

2.4.4. Analytical data of **2d**

(NMR data collected in *d*-DMF at 90 °C because of solubility): Yield 96%; ^1H NMR (500 MHz, *d*-DMF) δ 9.29 (2H, d, $^3J_{HH} = 5.9$ Hz, H_6), 8.48 (2H, s, H_3), 7.82 (2H, d, $^3J_{HH} = 5.9$ Hz, H_5), 5.08 (4H, s, bpy-CH_2), 4.47 (4H, t, $^3J_{HF} = 14.3$ Hz, C_8F_{17}–CH_2); ^{19}F NMR (470.5 MHz, *d*-DMF) δ −80.9 (3F), −119.1 (2F), −121.3 (6F), −122.1 (2F), −122.7 (2F), −125.5 (2F); ^{13}C NMR (113 MHz, *d*-DMF) δ 72.4 (bpy-CH_2), 68.3 (CH_2CF_2), 121.7, 125.3, 151.6, 153.1, 157.2 (bpy), 105.0–120.0 (C_8F_{17}); FT-IR (cm^{-1}): 1623, 1559, 1437 (*v*bpy, m), 1204, 1148 (*v*CF_2, vs); HR-MS (FAB): (M^+; *m*/*z*=) $C_{30}N_2H_{14}F_{34}O_2Pd^{35}Cl_2$ Calc. 1255.8924, found 1255.8920; $C_{30}N_2H_{14}F_{34}O_2Pd^{35}Cl^{37}Cl$ Calc. 1257.8928, found 1257.8954; $C_{30}N_2H_{14}F_{34}O_2Pd^{37}Cl_2$ Calc. 1259.8899, found 1259.8844.

2.4.5. Analytical data of **2e**

(NMR data collected in *d*-DMF at 90 °C because of solubility): yield 96%; ^1H NMR (500 MHz, *d*-DMF) δ 9.29 (2H, d, $^3J_{HH} = 5.8$ Hz, H_6), 8.47 (2H, s, H_3), 7.81 (2H, d, $^3J_{HH} = 5.8$ Hz, H_5), 5.08 (4H, s, bpy-CH_2), 4.47 (4H, t, $^3J_{HF} = 14.6$ Hz, $C_{10}F_{21}$–CH_2); ^{19}F NMR (470.5 MHz, *d*-DMF) δ −80.9 (3F), −119.1 (2F), −121.0 (10F), −122.1 (2F), −122.7 (2F), −125.5 (2F); ^{13}C NMR (113 MHz, *d*-DMF) δ 74.2 (bpy-CH_2), 68.2 (CH_2CF_2), 120.3, 124.5, 140.9, 151.8, 157.3 (bpy), 105.0–116.0 ($C_{10}F_{21}$); FT-IR (cm^{-1}): 1623, 1558 (*v*bpy, m), 1208, 1151 (*v*CF_2, vs); HR-MS (FAB): (M^+; *m*/*z*=) $C_{34}N_2H_{14}F_{42}O_2Pd^{35}Cl_2$ Calc. 1455.8869, found 1455.8842; $C_{34}N_2H_{14}F_{42}O_2Pd^{35}Cl^{37}Cl$

2.5. Heck reaction experiments

2.5.1. Complexes **2a–c** as the catalyst precursors

In a typical run, the reaction vessel was charged with C_6H_5I (102.0 mg, 0.50 mmol), $H_2C{=}CHCO_2Me$ (64.5 mg, 0.75 mmol), NEt_3 (50.6 mg, 0.50 mmol) and the respective Pd-catalysts **2a–c** (0.5 mol%) or the recovered Pd-catalyst after distillation. Then the reaction mixture was set to reflux in DMF (4 mL), at 140 °C for 3 h before GC analysis then work-up. The DMF solvent, products and unspent reactants were vacuum removed initially at 100 °C and later between 150 and 200 °C. The Pd catalysts stayed in the reaction vessel for reuse in the next run.

2.5.2. Complex **2e** as the catalyst precursor

Under the fluorous biphasic system, the vessel was charged with DMF (3 mL), FC77 (3 mL), C_6H_5I (102 mg, 0.50 mmol), $H_2C{=}CHCO_2Me$ (64.5 mg, 0.75 mmol), NEt_3 (50.6 mg, 0.50 mmol) and the Pd-catalyst **2e** (0.5 mol%; 3.64 mg). Then the reaction mixture was set to reflux at 140 °C for 6 h before the reaction was stopped and the two layers separated using a separating funnel at 0 °C. The FC77 fraction was retained for recycling experiments.

2.5.3. Partition ratio determination [14]

A 10 mL vial was charged with the fluorinated ligand (0.0160 mmol), FC77 (2.000 mL), and organic solvent (2.000 mL), fitted with a min-inert valve, and vigorously shaken (2 min). After 12 h (24 °C), a 0.400 mL aliquot of each layer was added to a hexane solution of eicosane

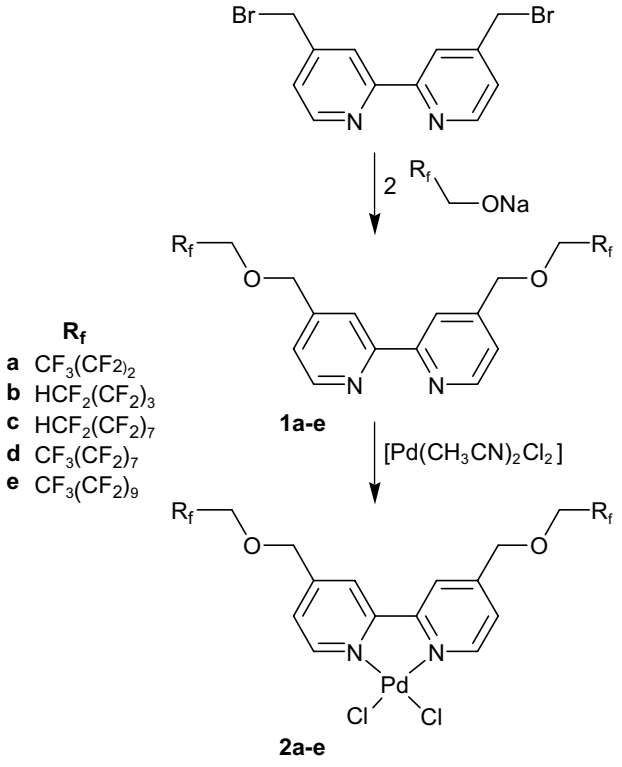
[a] U (equiv) is defined as one third of the trace of the orthogonalized U_{ij} tensor.

(2.000 mL, 0.0273 M). Then GC analysis was used to determine the partition ratios.



2.6. X-ray crystallography of Pd complex **2b**

Single crystals of Pd complex **2b** were obtained as yellow needles after 10 days at room temperature when the pure yellow powder of **2b** was dissolved in Me_2SO and then CH_3OH layered on top. The resultant yellow needles, with the residual Me_2SO solvent washed away using a large quantity of CH_3OH, were collected for single crystal structure determination. The crystal data and structure refinement for the Pd complex **2b** are listed in Table 1 and final fractional coordinates are in Table 2.

3. Results and discussion

3.1. Synthesis and spectroscopic characterization

The preparation of fluorous-ponytailed 2,2′-bpy ligands started from deprotonation of readily available fluorous alkanols R_fCH_2OH, where $R_f = n\text{-}C_3F_7$ (**a**), $HCF_2(CF_2)_3$ (**b**), $HCF_2(CF_2)_7$ (**c**), $n\text{-}C_8F_{17}$ (**d**), $n\text{-}C_{10}F_{21}$ (**e**). Fluorous alkanols R_fCH_2OH were treated with 30% CH_3ONa/CH_3OH to give the corresponding alkoxides. The alkoxides were then reacted with 4,4′-bis($BrCH_2$)-2,2′-bpy [15–17] to result in [(4,4′-bis($R_fCH_2OCH_2$)-2,2′-bpy)] (**1a**–**e**). An early preparation by Pozzi and co-workers [12] resulted in mixtures of mono-and bis-substituted bpy, presumably in their preparations the alkoxides were generated in situ without isolation. As shown in Scheme 1, equal molar amounts of [$PdCl_2(CH_3CN)_2$] and the fluorous bpy ligands **1a**–**e** were stirred in CH_2Cl_2 for 24 h at room temperature to yield the Pd complexes [$PdCl_2$(4,4′-bis($R_fCH_2OCH_2$)-2,2′-bpy)] (**2a**–**e**), which were all pale yellow solids, air and moisture stable. Both [$PdCl_2(CH_3CN)_2$] and ligands **1a**–**e** are more soluble in CH_2Cl_2 than the corresponding complexes **2a**–**e**.

Scheme 1.

The new Pd complexes **2a**–**e** have been characterized by multi-nuclei NMR, IR and high resolution FAB, with the data listed in Section 2. The ^1H NMR spectra are also used in monitoring the progress of the reaction. There are three kinds of bpy protons in the fluorous bpy ligands and Pd complexes, the assignments being the low field most signal for *H6*, the second low field signal for *H3* and the third for *H5*. As one example, shown in Fig. 1, the top and bottom spectra are the expanded ^1H NMR spectra for **1b** and **2b**, respectively, in the region ranging δ 9.2–3.8. The signals at *ca* δ 7.1 (triplet of triplets) are assigned to the ω-proton of the $-CF_2H$ group. The singlets at *ca* δ 4.9 are assigned to the bpy-CH_2 and the triplets at *ca* δ 4.3 to CF_2CH_2. Upon complex formation, the signals of H6 and H5 are downfield shifted by *ca* 0.3 δ-units and the signals of H3 stay almost at the same chemical shift.

3.2. Structure of **2b**

The structure of **2b** was established by single crystal X-ray diffraction. Fig. 2 reveals a molecular plot of **2b**, which is believed to be the first structure of a (2,2′-bpy)$PdCl_2$ type molecule carrying a fluorous ponytailed bipyridine skeleton. In **2b** the structural parameters around the square planar Pd coordination sphere conform to those found in the common (2,2′-bpy)$PdCl_2$, without noticeable differences [18].

A search of the Cambridge Structural Database reveals that there are many reported (2,2′-bpy)$PdCl_2$ structures, among those the ones with 4,4′- or 5,5′-substitutions were compared, but not the ones with 6,6′-substitutions that are structurally more distorted because of more steric interactions. Scheme 2 shows the reported (2,2′-bpy)$PdCl_2$ structures. In addition to the parent compound (**4**) [19,20], there are structures with varying ponytails including alkyls (**5**–**6**) [21–23], amides (**7**) [24], esters (**8**–**9**) [25,26] and ethers (**10**) [27]. The Pd–N lengths in **4**–**10** range from 2.002 to 2.041 Å, and the Pd–Cl lengths in **4**–**10** range from 2.271 to 2.319 Å. Both Pd–N and Pd–Cl bond distances in **2b** are at the low end of the range, partly because the temperature was experimentally maintained at 100 K when the diffraction data of **2b** was collected. The N–Pd–N angle in **2b** is 79.8(2)°, whereas it ranges from 79.6° to 81.6° in **4**–**10**.

There are two different crystal structures of parent **4** reported. One structure shows CH_2Cl_2-solvate separated (2,2′-bpy)$PdCl_2$ molecules in the solid state without any noted supramolecular π–π interactions. The other, without solvate in the crystalline state, exhibits a supramolecular π–π interaction between the (2,2′-bpy)$PdCl_2$ molecules at a distance of *ca* 3.42 Å. The structures **5**–**10** exhibit similar

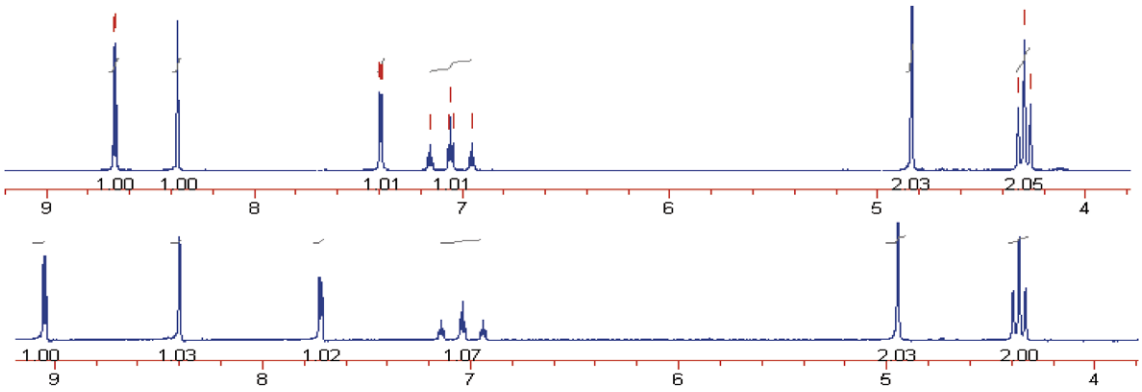


Fig. 1. ^{1}H NMR spectra of ligand **1b** (top) and Pd complex **2b** (bottom).

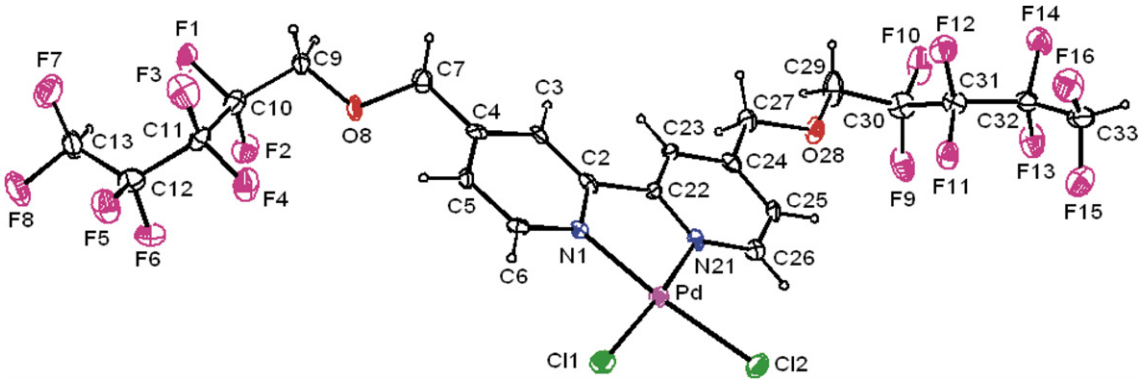

Fig. 2. Molecular plot of **2b.** Selected bond lengths (Å) and angles (°): Pd–N(1) 2.008(3), Pd–N(21) 2.014(3), Pd–Cl(1) 2.274(1), Pd–Cl(2) 2.274(1); N(1)–Pd–N(21) 79.8(2), N(1)–Pd–Cl(1) 94.9(1), N(1)–Pd–Cl(2) 174.4(1), N(21)–Pd–Cl(1) 173.7(1), N(21)–Pd–Cl(2) 95.2(1), Cl(1)–Pd–Cl(2) 90.2(1).

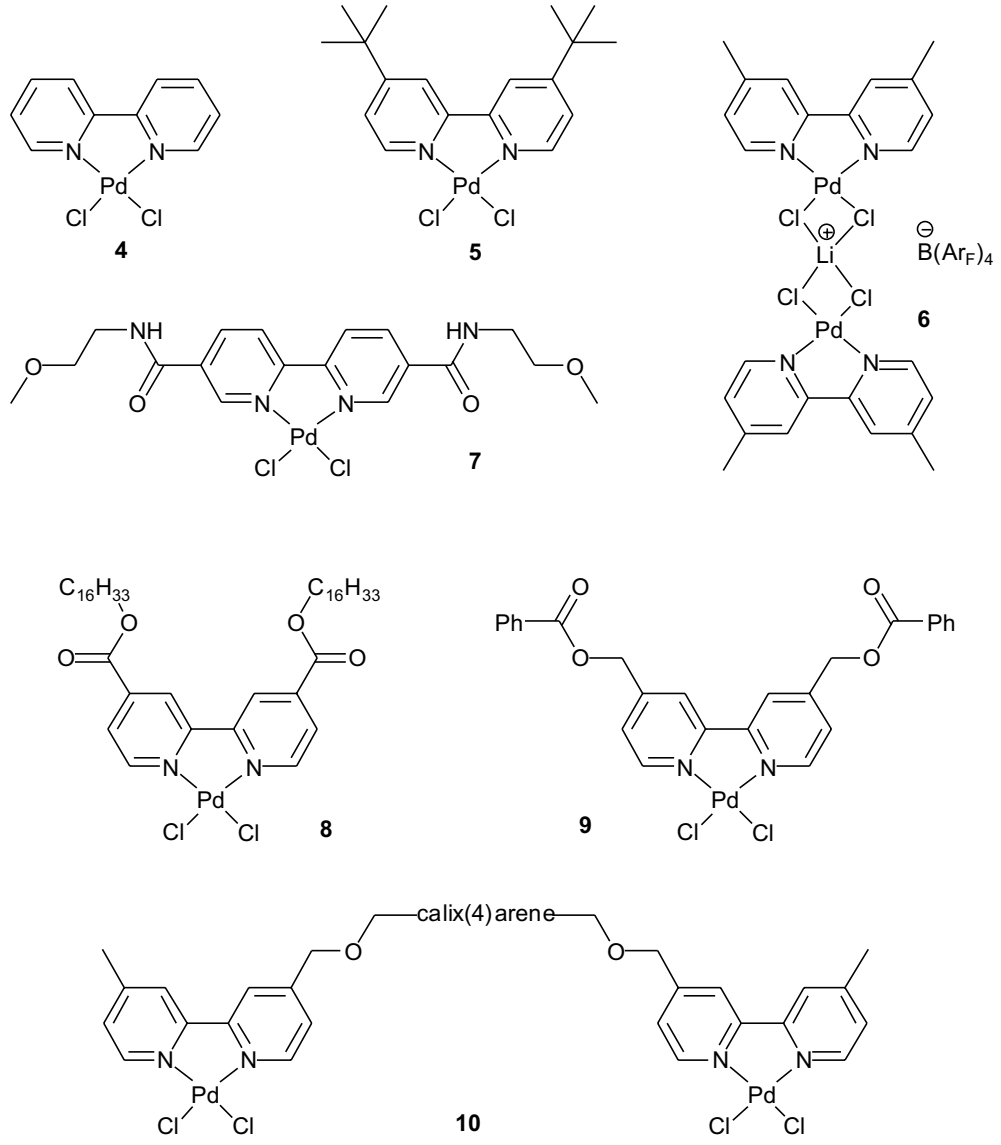
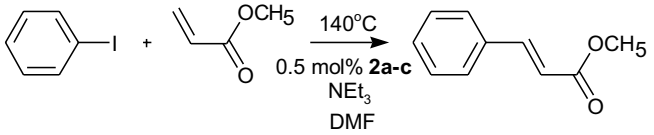


supramolecular π–π interactions in the solid state. In the structure of **5**, the separation is *ca* 3.54 Å between the (2,2′-bpy)$PdCl_2$ molecules; in **7**, *ca* 3.46 Å; in **8**, *ca* 3.44 Å; in **9**, *ca* 3.46 Å; in **10**, *ca* 3.42 Å. In **6**, the supramolecular π–π interactions exhibit a distance of *ca* 3.43 Å between the dimeric (2,2′-bpy)$PdCl_2$ and the $B(Ar_f)_4^-$ anion. In the crystal structure of **2b**, a supramolecular π–π interaction could be evidenced with a separation of *ca* 3.26 Å between the (2,2′-bpy)$PdCl_2$ molecules. The shorter distance in **2b** results from the low temperature on data collection at 100 K.

According to Bennett et al. [7], the fluorous modification of an aromatic ligand coordinated to a transition metal center may be accomplished without impacting the electronic character by replacement of an aromatic –H with a fluorinated substituent $–(CH_2)_3R_f$, $R_f = CF_3$, C_6F_{13}, etc. In **2b**, the $–CH_2OCH_2–$ spacer has been introduced between the fluorous ponytail and the bpy skeleton. In Fig. 2, the fluorous regions in **2b** are seen to be distal to the Pd center.

3.3. Fluorine content of the ligands

When a fluorous ponytail is introduced into the bpy skeleton, a spacer, such as the $–CH_2OCH_2–$ linkage, in between is needed in order to minimize the electron-withdrawing effect of the fluorinated segment on bpy, and hence on the donor N atom [7]. Indeed, the $–CH_2OCH_2–$ spacer does, to some extent, isolate the electronic effect of the fluorous ponytail, as reflected by the fact that the catalytic activity of the Pd complexes **2a**–**e** does not change very much in the Heck reactions [28].



In this study, there are five different numbers of F-atoms on the fluorous ponytail, namely, 7, 8, 16, 17 or 21 F-atoms. Table 3 lists the fluorine percentage of ligands **1a**–**e**. According to their fluorine content, they could be divided into two subgroups, those below 50% [29,30] and those above [31]. Correspondingly, the Pd complexes **2a**–**b** are light in ligand fluorine content [29,30] and the Pd complexes **2c**–**e** high in ligand fluorine content [31]. It is well known that Pd complexes with light fluorine content ligands are still soluble in organic solvents in general. Alternatively, when the fluorine content of ligand is greater than 50%, the resultant Pd complex is then more soluble in perfluorinated solvents. For instance, Pd complex **2e** has been found to be soluble in perfluorinated solvents, but insoluble in organic solvents. With a high ligand fluorine content, Pd complex **2c**, however, has also the presence of the ω-CF_2H group. This terminally polar $–CF_2H$ group makes ligand **1c** only soluble in organic solvents and not in perfluorinated solvents, for instance FC77 (mainly C_8F_{18} in

Scheme 2.

Table 3
The fluorine percentage of ligands **1a**–**e**

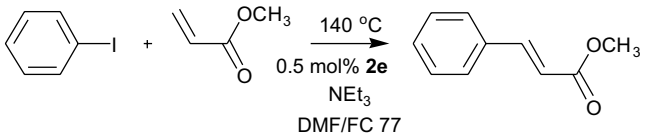
Ligand	Fluorine content (%)
1a	45.9
1b	47.2
1c	58.3
1d	59.8
1e	62.3

Scheme 3.

composition). Thus the solubility properties of ligand **1c** are different from those of ligands **1d**–**e**.

3.4. Pd complexes *2a*–*c* as recyclable catalysts in Heck reactions

The Pd complexes **2a**–**b**, with light ligand fluorine contents, are soluble in organic solvents. The Pd complex **2c**, containing the polar ω-CF_2H group, is also soluble in organic solvents. Apparently, Pd complexes **2a**–**c** are not suitable homogeneous catalysts to be recovered with the fluorous biphasic strategy. Nonetheless, Pd complexes **2a**–**c** have been tested as catalyst precursors in the recycling Heck reaction of C_6H_5I and $H_2C{=}CHCO_2CH_3$, as shown in Scheme 3.



The high T_{90} points (*vide infra*) suggested that Pd-complexes **2a**–**c** should allow their isolation when everything else in the reaction mixture is distilled away. Accordingly,

at the end of reaction, the condenser was adjusted towards distillation instead of reflux. The more volatile materials were vacuum removed and the Pd catalysts stayed in the reaction vessel. Without further treatment, the reaction vessel was charged with a new batch of substrates, base and DMF, for the new run of the Heck reaction.

Table 4 shows the results from the above recycling usage of Pd-catalysts derived from **2a–c** in the Heck reaction, with the yields being based on GC analysis (with NMP as the internal standard). The product was 100% *trans*-PhCH=CHCO$_2$Me selectively. We noticed that for eight consecutive runs in all cases studied, the yields after 3 h were constantly greater than 99%. The simple recovery procedure kept, in the reaction vessel, Pd-containing materials that still maintain the catalytic activity.

3.5. Heck reaction under the fluorous biphasic system using Pd complex 2e

The ligands **1d–e** have a high fluorine content and are insoluble in organic solvents. The ligand **1d** is not very soluble in FC77 at room temperature in a partition experiment for measuring the coefficients under CH_2Cl_2/FC77 and DMF/FC77 conditions. The Pd complex **2d** was sparingly soluble in FC 77. When Pd complex **2d** was used as the catalyst precursor for the Heck reaction under the DMF/FC 77 biphasic condition, a very low yield resulted in the second run, which was attributed to the fact that the Pd catalyst derived from **2d** was more soluble in DMF. In comparison, the ligand **1e** shows a good solubility in FC77, giving reasonable partition ratios in the binary systems of CH_2Cl_2/FC77 (=1/42) and DMF/FC77 (=~0.1/100). Derived from ligand **1e**, the Pd complex **2e** was judged to be the choice for use as the catalyst precursor in Heck reactions under the fluorous biphasic system [6]. Thus, the reaction shown in Scheme 4 was performed for the Pd catalyst recycling experiments under the fluorous biphasic system, in order to see to what extent the Pd catalyst stays in the fluorous layer. The results are shown in Table 5, indicating that the Pd catalyst derived from **2e** could be recycled up to 8 times with an average yield of 93% before a drop in reactivity [32].

Scheme 4.

As the purpose of this study was to investigate the recyclability of the catalysts, no detailed study on the nature of the active Pd catalysts was made. It was assumed that the Pd catalysts derived from **2a–c** and **2e** are homogeneous molecules. However, it could not be ruled out that the true catalysts are nanoparticles as indicated by Gladysz and coworkers [14,33] or Pd colloids reported by de Vries et al. [34,35].

3.6. Thermal properties

The thermal stabilities of ligands **1a–e** and their corresponding Pd metal complexes **2a–e** were measured. The TGA weight loss curves of ligands **1a–e** exhibited the stability of general hydrocarbons despite the fact that they have fluorinated segments. The T_{90} points in weight loss for all five ligands were observed between 225 and 275 °C, the T_{90} points increasing with increasing molecular weights.

The weight loss curves of Pd complexes **2a–e** revealed that upon coordination, the Pd complexes have greater T_{90} points than the corresponding ligands. As one example shown in Fig. 3, the ligand **1b** started to lose weight at 250 °C and the complex **2b** at 330 °C, i.e., the Pd complex **2b** is about 80 °C more heat resistant than the corresponding ligand **1b**. The TGA data of **2b** suggested that **2b** loses its fluorous chain at 330 °C, followed by its bipyridine skeleton, resulting in Pd-oxychlorides with 18% of the original weight in the sample holder. The reason for the increase of

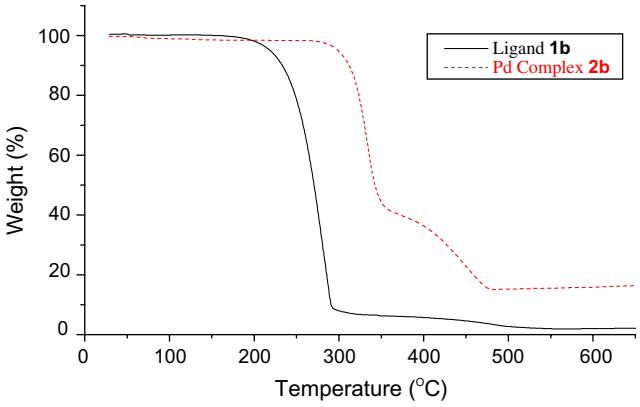

Fig. 3. The weight loss curves of ligand **1b** and Pd complex **2b**.

thermal stability upon bpy coordination to a Pd metal center is likely the requirement of *N*,*N*′-*cis* bpy for bonding to the Pd metal center and the supramolecular π–π interactions in the solid state Pd complexes.

4. Conclusions

The fluorous bpy ligands **1a**–**e** and Pd complexes **2a**–**e** were prepared and characterized by spectroscopic methods and the single crystal X-ray structure of **2b** was determined. The novel Pd complexes show nice catalytic activity in the Heck reaction and are recyclable. A part of the properties arises from the fact that the Pd complexes are thermally more stable than the corresponding ligands.

Abstract

The reactions of the $[ReOX_3(PPh_3)_2]$ (X = Cl, Br) complexes with pyridazine (pyd) have been examined and $[\{ReOX_2\}_2(\mu\text{-}O)(\mu\text{-}pyd)_2]$ dinuclear oxocomplexes with a bent $Re_2O_3^{4+}$ core have been obtained. The X-ray structures of $[\{ReOCl_2\}_2(\mu\text{-}O)(\mu\text{-}pyd)_2]\cdot C_6H_6$ (**1** · C_6H_6) and $[\{ReOBr_2\}_2(\mu\text{-}O)(\mu\text{-}pyd)_2]\cdot CH_3CN$ (**2** · CH_3CN) have been determined. The electronic structure of **1** has been calculated with the density functional theory (DFT) method, and additional information about binding in the $Re_2O_3^{4+}$ unit has been obtained by NBO analysis. The spin-allowed electronic transitions of **1** have been calculated with the time-dependent DFT method, and the UV–Vis spectrum of $[\{ReOCl_2\}_2(\mu\text{-}O)(\mu\text{-}pyd)_2]$ has been discussed on this basis.

1. Introduction

During the last decade the preparation, structures and properties of dinuclear rhenium complexes with a $(ReO)_2(\mu\text{-}O)$ core have attracted much attention since these species can produce specific structures, properties and reactivities, not found for mononuclear complexes. Generally, these compounds can be divided into two groups: (i) complexes with a linear Re–O–Re core, and (ii) species with a bent Re–O–Re bridge. The preparation, structures and properties of the dinuclear rhenium complexes with the $(ReO)_2(\mu\text{-}O)$ core have been discussed in detail in paper [1].

Most diaza ligands can coordinate in a monodentate way or act as bridging ligands [2]. Treatment of $[ReOX_3(PPh_3)_2]$ with 3,5-Me_2pzH in acetone at room temperature leads to the isolation of the symmetrically substituted dinuclear rhenium complexes of the $[\{Re(O)\text{-}X(PPh_3)\}_2(\mu\text{-}O)(\mu\text{-}3,5\text{-}Me_2pz)_2]$ composition, whereas refluxing of $[ReO(OEt)X_2(PPh_3)_2]$ with 3,5-Me_2pzH in ethanol gives the unsymmetrically substituted dinuclear rhenium $[\{Re(O)X(PPh_3)\}(\mu\text{-}O)(\mu\text{-}3,5\text{-}Me_2pz)_2\{Re(O)X(3,5\text{-}Me_2pzH)\}]$ complexes. Both $[\{Re(O)X(PPh_3)\}_2(\mu\text{-}O)(\mu\text{-}3,5\text{-}Me_2pz)_2]$ and $[\{Re(O)X(PPh_3)\}(\mu\text{-}O)(\mu\text{-}3,5\text{-}Me_2pz)_2\{Re(O)X(3,5\text{-}Me_2pzH)\}]$ contain the bent $Re_2O_3^{4+}$ unit. Treatment of the $[ReOX_3(AsPh_3)(OAsPh_3)]$ complexes (X = Cl or Br) with 3,5-Me_2pzH in acetone at room temperature leads to replacement of $AsPh_3$ and $OAsPh_3$ ligands and formation of $[\{Re(O)X_2(3,5\text{-}Me_2pzH)_2\}_2(\mu\text{-}O)]$ with the nearly linear O═Re–O–Re═O moiety [3]. For benzotriazole, only the

doi:10.1016/j.poly.2007.02.019

symmetrically substituted dinuclear rhenium [{Re(O)X-(PPh$_3$)}$_2$(μ-O)(μ-C$_6$H$_4$N$_3$)$_2$] complexes with the bent Re–O–Re bridge have been isolated [4]. Refluxing [ReOX$_3$(PPh$_3$)$_2$] with pyrazole in ethanol leads to [{Re(O)X(PPh$_3$)}$_2$(μ-O)(μ-N$_2$C$_3$H$_3$)$_2$], but treatment of [ReOX$_3$(PPh$_3$)$_2$] with pzH in acetone at room temperature gives the mononuclear rhenium(V) complexes – [Re(O)-X$_2$(PPh$_3$)(η^2-N$_2$C$_6$H$_9$O-N,O)]. In the second case, pyrazole firstly adds to acetone yielding the C$_3$H$_3$N$_2$C(CH$_3$)$_2$OH adduct, which reacts with the starting oxo complex [5]. Treatment of the [ReOBr$_3$(AsPh$_3$)(OAsPh$_3$)] complex with pyrazine (pyz) in acetone at ambient temperature leads to the [{ReOBr$_2$(pyz)$_2$}$_2$(μ-O)] complex, with a nearly linear O═Re–O–Re═O moiety, whereas the reaction of [ReOBr$_3$(AsPh$_3$)(OAsPh$_3$)] with pyridazine (pyd) affords [{ReOBr$_2$}$_2$(μ-O)(μ-pyd)$_2$] with a bent Re$_2$O$_3^{4+}$ unit [6].

The studies show dependence of these reactions on the starting material, ring size and positions of the nitrogen atoms in the rings of the N-donor ligands, solvent and temperature. The [ReOX$_3$(AsPh$_3$)(OAsPh$_3$)] compounds generally form dinuclear oxorhenium complexes with a linear O═Re–O–Re═O moiety, whereas dinuclear oxorhenium compounds with a bent Re$_2$O$_3^{4+}$ unit are usually formed in the reactions with [ReOX$_3$(PPh$_3$)$_2$]. However, treatment of the [ReOBr$_3$(AsPh$_3$)(OAsPh$_3$)] complex with pyridazine leads to [{ReOBr$_2$(pyd)$_2$}$_2$(μ-O)] with a bent Re–O–Re bridge.

In this report we focus on the examination of the reactions of [ReOX$_3$(PPh$_3$)$_2$] with pyridazine and present the synthesis and spectroscopic data for [{ReOX$_2$(pyd)$_2$}$_2$-(μ-O)] complexes. For pyridazine, the course of the reaction does not depend on the starting material – both [ReOX$_3$(AsPh$_3$)(OAsPh$_3$)] and [ReOX$_3$(PPh$_3$)$_2$] react with pyridazine to give dinuclear [{ReOX$_2$(pyd)$_2$}$_2$(μ-O)] complexes with the bent Re$_2$O$_3^{4+}$ unit. X-ray studies have been performed for [{ReOCl$_2$}$_2$(μ-O)(μ-pyd)$_2$]·C$_6$H$_6$ (**1**·C$_6$H$_6$) and [{ReOBr$_2$}$_2$(μ-O)(μ-pyd)$_2$]·CH$_3$CN (**2**·CH$_3$CN). The first one is a novel compound, whereas **2**·CH$_3$CN is another solvate of [{ReOBr$_2$}$_2$(μ-O)(μ-pyd)$_2$]. The [{ReOBr$_2$}$_2$(μ-O)(μ-pyd)$_2$]·CH$_3$COCH$_3$ complex has been isolated in the reaction of [ReOBr$_3$(AsPh$_3$)(OAsPh$_3$)] with pyridazine in acetone at ambient temperature. The electronic structure of [{ReOCl$_2$}$_2$(μ-O)(μ-pyd)$_2$] has been calculated with the density functional theory (DFT) method. Currently density functional theory (DFT) is commonly used to examine the electronic structure of transition metal complexes. It meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [7]. The singlet–singlet electronic transitions of [{ReOCl$_2$}$_2$(μ-O)(μ-pyd)$_2$] have been calculated with the time-dependent DFT method (TD-DFT method), and the UV–Vis spectrum of **1** has been discussed on this basis. Recent calculations with the TD-DFT method for open- and closed-shell 5d-metal complexes have supported the TD-DFT method to be applicable for such systems giving good assignment of experimental spectra [8,9].

were used as received. Ammonium perrhenate, triphenylphosphine and pyridazine were purchased from Aldrich and were used as received. The $[ReOX_3(PPh_3)_2]$ complexes were prepared according to the literature method [10].

Infrared spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of potassium bromide pellets. The electronic spectrum of **1** was measured on a spectrophotometer Lab Alliance UV–VIS 8500 in the range 1000–200 nm in CH_3CN solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of $[\{ReOCl_2(pyd)_2\}_2(\mu\text{-}O)]\cdot C_6H_6$ ($\mathbf{1}\cdot C_6H_6$)

$[ReOCl_3(PPh_3)_2]$ (0.83 g, 1 mmol) was suspended in a solution of pyridazine (0.2 g, 2.5 mmol) in acetone (50 ml) and the reaction mixture was stirred for 24 h. Diethyl ether (100 ml) was added and the black precipitate thus obtained was filtered. Good quality crystals for X-ray investigation were obtained by recrystallization from benzene. Yield 85%.

2.4. Crystal structure determination and refinement

The X-ray intensity data $1 \cdot C_6H_6$ and $2 \cdot CH_3CN$ were collected on a KM-4-CCD automatic diffractometer equipped with a CCD detector. 20 and 60 s exposure times were used respectively and reflections were collected up to $\theta = 25°$. The unit cell parameters were determined from the least-squares refinement of the setting angles of 8946 and 6685 strongest reflections respectively for **1** and **2**. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and numerical absorption corrections [11] were applied. The structures were solved by the partial structure expansion method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix least-squares technique. The hydrogen atoms bonded to the aromatic atoms were treated as "riding" on their parent carbon atoms and assigned isotropic temperature factors equal to 1.2 times the value of equivalent temperature factor of the parent atom. The methyl groups were allowed to rotate about their local threefold axis. SHELXS97 [12], SHELXL97 [13] and SHELXTL [14] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

3. Computational details

The GAUSSIAN03 program [15] was used in the calculations. The geometry optimization of **1** was carried out with the DFT method with the use of the B3LYP functional [16,17]. The electronic spectrum of **1** was calculated with the TD-DFT method [18]. The calculations were performed by using the ECP basis set on the rhenium atom, the standard 6-31+G** basis for chlorine, oxygen and nitrogen, 6-31G* for carbon and 6-31G for hydrogen atoms. The Xe core electrons of Re were replaced by an effective core potential and a DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [19] was used for the valence electrons. An additional d function with exponent $\alpha = 0.3811$ and f function with exponent $\alpha = 2.033$ on the rhenium atom were added.

Natural bond orbital (NBO) calculations were performed with the NBO code [20] included in GAUSSIAN03.

4. Results and discussion

4.1. Preparation

The $[ReOX_3(PPh_3)_2]$ complexes react with pyridazine (pyd) in acetone at ambient temperature to give $[\{ReOX_2\}_2(\mu\text{-}O)(\mu\text{-}pyd)_2]$. The formation of the dinuclear compounds doubtlessly involves water and intermediate

hydroxo-species. A water elimination reaction between two hydroxo complexes affording the oxygen bridged dinuclear species has been proposed and accepted and probably represents an alternative route to the direct deprotonation of an hydroxo intermediate affording the O=Re=O unit. Factors determining the formation and stabilization of μ-oxo dinuclear complexes as well as the conversion of the dinuclear complex to the mononuclear complex have not yet been investigated systematically and are dependent on reaction conditions [1].

4.2. Infrared data

The IR spectra of **1** and **2** show sharp bands at 958 and 956 cm^{-1} assignable to the symmetric Re=O stretch. The strong bands at 692 cm^{-1} for **1** and 680 cm^{-1} for **2** result

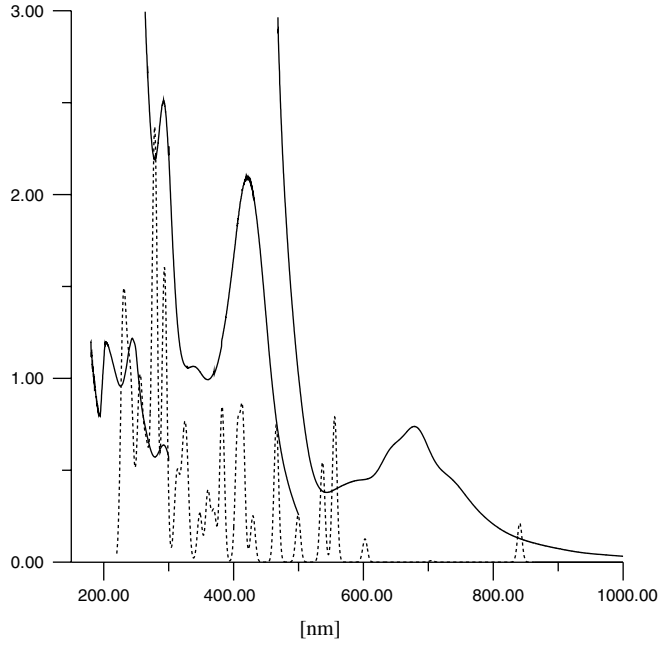

Fig. 3. The experimental (—) and calculated (----) electronic absorption spectra of **1**.

from overlapping of the antisymmetric Re–O–Re stretching modes with the aromatic ring out-of-plane deformation vibrations. In comparison with the $[(ReCl_5)_2(\mu\text{-}O)]^{4-}$ complex with an antisymmetric ν_{as}(Re–O–Re) stretching mode in the range 850–855 cm^{-1} [21], a significant reduction in the frequency of ν_{as}(Re–O–Re) is observed for compounds **1** and **2**. It is a consequence of the electron-withdrawing effect of the terminal Re=O groups causing a relative weakening of the bridging Re–O bonds.

4.3. Crystal structure

Both complexes are isostructural and isomorphic despite the fact that they crystallize as different solvates, $\mathbf{1}\cdot C_6H_6$ and $\mathbf{2}\cdot CH_3CN$. The molecules have an internal crystallographic mirror plane going through the bridging oxygen atom (special position c with site symmetry *m* of the orthorhombic space group *Pnma*) and mid-points of the pyridazine N–N bonds. Additionally, solvents molecules in both cases also have an internal crystallographic mirror plane. The benzene solvate molecule in **1** shows the symptoms of disorder which is exhibited in relatively large values of some orthogonalized displacement parameters (larger than 0.10) and a slight shortening of C–C distances. Because of the perpendicular mirror plane going through the benzene ring, it was difficult to unambiguously determine the reason of the disorder. Solving the structure in a lower symmetry space group leads to an insignificant decrease of the displacement parameters, but a shortening of C–C distances was not observed. Additionally, in the refined structure the benzene ring diagonal was inclined at 1.2° to the higher symmetry space group mirror plane direction. In both cases of refinement, introducing two or a multipositional disorder model did not improve the quality of the displacement parameters, thus it can be supposed that the disorder is mainly dynamical in character and the symmetry plane insignificantly influences the quality of solvate refinement, and thus the higher symmetry space group was chosen as a correct one. To prevent the distances from abnormal shortening, the benzene C–C bonds were restrained to 1.395(1) Å.

The accurate cell parameters and crystal data for $\mathbf{1}\cdot C_6H_6$ and $\mathbf{2}\cdot CH_3CN$ are given in Table 1. The solvent molecules from crystallization are not bonded to any other atom, with the exception of some rather weak hydrogen bonds. The weak intra- and intermolecular hydrogen bonds [22,23] of $\mathbf{1}\cdot C_6H_6$ and $\mathbf{2}\cdot CH_3CN$ are presented in Table 2. The synthesis, crystal and molecular structure of the monoclinic acetone solvate of $[\{ReOBr_2\}_2(\mu\text{-}O)(\mu\text{-}pyd)_2]$ has been presented in a previous paper [6]. In both polymorphs (orthorhombic and monoclinic), the complex molecules are isomorphic and have an internal symmetry plane, but the existence of solvent dimethylketone molecules in the monoclinic form prevents the existence of higher crystallographic symmetry. Slight differences in the unit cell volume and density of both forms result from differences in molecular mass and molecular volumes of the solvent molecules.

The structures of **1** and **2** reveal the presence of two rhenium(V) centers linked through two bridging pyridazine molecues and an oxo group (Fig. 1). Each rhenium atom is in a pseudooctahedral environment of two pyridazine molecules and two halide ions in the equatorial plane, and the terminal and bridging oxo ligands in axial positions. The considerable distortions from ideal octahedron in **1** and **2** result from both electronic repulsion of the short Re=O bond and steric interactions of bridging N–N ligands.

The most important bond lengths and angles for compounds **1** and **2** are reported in Tables 3 and 4, respectively. The Re–N, Re–O_t and Re–O_b bond lengths in **1** and **2** agree well with comparable values found in rhenium compounds with the O=Re–O–Re=O framework [1]. The Re–O_t bond lengths fall in the range 1.639–1.76 Å, typical of mononuclear complexes of rhenium(V) having a $[ReO]^{3+}$ core, and indicate the presence of a triple Re≡O_t bond [24]. The Re–O_b bond distances of 1.8995(19) and 1.913(3) Å for **1** and **2** suggest that a small amount of overlap also occurs between the d_{xz} and d_{yz} rhenium orbitals and the suitable p orbitals of the bridging oxygen. An ideal single Re–O bond length, predicted by the use of Pauling's covalent radius for oxygen and Cotton and Lippard's value for the octahedral covalent radius of rhenium(V), should be *ca.* 2.04 Å [25].

4.4. Geometry optimization

The optimized geometric parameters of **1** are gathered in Table 3. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray

crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

4.5. Charge distribution and NBO analysis

Table 5 presents the atomic charges from the natural population analysis (NPA) for **1**. The calculated charges on the rhenium atoms are considerable lower than the formal charge of +5. The populations of the d_{xy}, d_{xz}, d_{yz}, $d_{x^2-y^2}$ and d_{z^2} orbitals of the central atoms in **1** are as follows: 0.864, 1.122, 0.929, 1.374 and 1.054. This is a result of significant charge donation from the oxo ligands and chloride ions. The charges on the oxo ligands and chloride ions are significantly smaller than −2 and −1, respectively. Considerable differences in values of charges are observed for the terminal and bridging oxo ligands – the terminal oxo ligands are less negative. It indicates higher electron density delocalization from the terminal ligands towards the rhenium centers and corresponds to differences in the Re–O_t and Re–O_b bonds lengths.

Table 6 presents the occupancy and hybridization of the calculated natural bond orbitals (NBOs) between the rhenium and the oxo ligands for **1**.

For each Re atom of **1**, two natural Re–O_t bond orbitals were detected. They are polarized towards the oxygen atom, and the p oxygen orbitals and d rhenium orbitals are involved in the Re–O_t bond formation. The atomic orbital compositions of the detected Re–O_t bond orbitals indicate their π character. The non-detected σ_{Re-Ot} bonds have character of predominant Coulomb-type interactions between the central ion and ligands [26]. Each terminal oxo

ligand of **1** has two lone pairs, and the electron density from one of them is strongly delocalized into the non-Lewis rhenium orbitals. The bridging oxygen ligand has three lone pairs (LP) and one Re–O_b bond orbital was detected. The detected Re(1)–O(1) bond is strongly polarized towards the bridging oxygen atom, and the s and p oxygen orbitals and s and d rhenium orbitals take part in the bond formation. The non-detected Re(1A)–O(1) bond has predominantly ionic character.

4.6. Electronic structure

The energy and character of the selected unoccupied and occupied MOs for **1** are presented in Fig. 2. The local symmetry of the rhenium centers has been considered in the discussion. The z axis goes along the O_t–Re–O_b linkage, x and y axes – through the Cl–Re–N bonds. The HOMO–LUMO gap equals 2.25 eV. The two highest MOs of **1** are of d_{xy} type with an antibonding contribution from p_π chlorine and oxygen orbitals. The remaining eight d-type orbitals of rhenium are found among the unoccuppied MOs. It confirms the d^2 configuration of the rhenium atoms. The d_{xz} and d_{yz} rhenium orbitals are dispersed amongst a large number of molecular orbitals. Significant participation of the d_{xz} and d_{yz} orbitals is visible in the LUMO, LUMO + 1, LUMO + 2, LUMO + 3, LUMO + 6 and LUMO + 7 orbitals. The d_{xz} and d_{yz} orbitals bear antibonding character towards the oxygen atoms, and some participation of π-antibonding orbitals of the pyridazine rings is visible in these molecular orbitals. The LUMO + 8 and LUMO + 9 are of $d_{x^2-y^2}$-σ_{Cl}–σ_N character. As can be seen from Fig. 3, each molecular orbital is a plus or minus combination of the symmetry equivalent d orbitals of the two rhenium atoms.

4.7. Electronic spectrum

The experimental and calculated electronic spectra of **1** are presented in Fig. 3. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}.

Table 7 shows the singlet-singlet electronic transitions calculated with the TDDFT method for **1**. For the high energy part of the spectrum, only transitions with oscillator strenghts larger than 0.010 are listed in Table 7. The investigated complex is of a large size, the number of basis functions is equal to 430. A hundred electron transitions calculated with the TD-DFT method do not comprise all the experimental absorption bands. The UV–Vis spectrum of **1** was calculated to ~228 nm, so the shortest wavelength experimental band is not assigned to the calculated transitions. Some additional intraligand and interligand transitions are expected to be found at higher energies in the calculations for this complex.

The longest wavelength experimental bands at 748.2, 679.0 and 591.0 nm correspond to the transitions from the HOMO and HOMO − 1 to LUMO, LUMO + 1 and LUMO + 3 orbitals. Due to significant participation of π^* orbitals of the pyridazine ligands in the unoccupied molecular orbitals, the character of these electronic transitions is ascribed as d → d/π^*(pyd).

The absorption band at 428.8 nm is assigned to the electronic transitions calculated in the range 500–360 nm. These transitions are of π(Cl)/π(O) → d/π^*(pyd), π(Cl) → d/π^*(pyd), d → π^*(pyd) and d → d origin.

The experimental bands at 338.4, 292.2 and 244.0 nm correspond mainly to the transitions of LMCT (π(Cl)/π(O) → d) and LLCT (π(Cl)/π(O) → π^*(pyd)) character.

5. Supplementary material

CCDC 634230 and 634231 contain the supplementary crystallographic data for $C_{14}H_{14}Cl_4N_4O_3Re_2$ and $C_{10}H_{11}Br_4N_5O_3Re_2$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Hydrolysis of 1,2-diphenyl-4-R-cyclopentadienyl titanium trichloride (R = Me (**1**), *n*-Bu (**2**)) affords the corresponding oxo-bridged monocyclopentadienyl titanium compounds (1,2-Ph_2-4-R-$CpTiCl_2)_2(\mu$-O) (R = Me (**3**), *n*-Bu (**4**)), new dinuclear species. The molecular structures of complexes **3** and **4** have been confirmed by single-crystal X-ray diffraction. Both complexes have been characterized by elemental analysis, ^{1}H and ^{13}C NMR spectroscopy. When activated with $Al(^iBu)_3$ and $Ph_3C^+B(C_6F_5)_4^-$, complexes **3** and **4** show reasonable catalytic activity for ethylene polymerization, producing polyethylenes with moderate molecular weights, and upon activation with methylaluminoxane (MAO), complexes **3** and **4** exhibit high catalytic activity and syndiospecificity for the polymerization of styrene.

1. Introduction

Group 4 metallocene catalysts have attracted extensive interest due to their applications in the fields of organometallic chemistry, catalysis and polymer science [1–3]. In particular titanium catalysts based on the cyclopentadienyl ligand have been widely studied as active catalysts employed in industry and academic institutions [4–15]. It is well known that even minor modification of the ligands can result in remarkable changes in catalytic activity, as well as polymer properties, such as molecular weight, comonomer incorporation and stereoregularity [16–20]. Thus, it is of great significance to develop new homogeneous catalysts producing a number of high performance polyolefins. Recently we have reported a series of diphenyl substituted cyclopentadienyl titanium trichloride complexes as precatalysts for styrene polymerization [21]. Further study on these titanium systems found that these complexes could be readily hydrolyzed to produce corresponding dimeric compounds in solution. In previous instances, dinuclear complexes bearing a cyclopentadienyl ligand play a significant role in some catalytic processes, because a cooperative effect of two close reactive metal centers is generated to accomplish unusual coordination modes [22]. Herein we report the synthesis and structural characterization of the oxo-bridged binuclear complexes, as well as their catalytic performance in ethylene and styrene polymerization.

2. Experimental

2.1. General comments

All manipulations involving air and moisture sensitive compounds were carried out under a nitrogen atmosphere (ultra-high purity) using either standard Schlenk techniques or glovebox techniques. Et_2O and toluene were

doi:10.1016/j.poly.2007.02.007

dried over sodium/benzophenone under nitrogen and were freshly distilled prior to use. CH_2Cl_2 and *n*-hexane were refluxed under nitrogen over calcium hydride and distilled before use. Methylaluminoxane (MAO, 10 wt.% solution in toluene, $M = 800\ g\ mol^{-1}$, Al = 5.3 wt.%) was purchased from Wtico. Al(^{i}Bu)$_3$, methyl lithium, *n*-butyl lithium and titanium tetrachloride were purchased from Aldrich. 1,2-Diphenyl-4-methyl-cyclopentadienyl titanium trichloride (**1**), 1,2-diphenyl-4-*n*-butyl-cyclopentadienyl titanium trichloride (**2**) [21] and $Ph_3C^+B(C_6F_5)^-$ [23–25] were prepared according to the literature procedures. The crystal structure was determined with a CCD diffraction apparatus. NMR spectra were measured using a Varian Mercury-300 NMR spectrometer. Elemental analyses were performed on a Perkin–Elmer 240c element analyzer. Viscosity-average molecular weights of the polyethylenes were determined in decahydronaphthalene at 135 °C using a Schott Gerate Mod. AVS/T2 Ubbelohde viscosimeter. Viscosity-average molecular weights of the polystyrenes were determined in *o*-dichlorobenzene at 135 °C using a Schott Gerate Mod. AVS/T2 Ubbelohde viscosimeter. Melting transition temperatures (T_m) of the polyethylenes and polystyrenes were determined by DSC (Du Pont 910 differential scanning calorimeter) at a heating rate of 10 °C min^{-1}.

2.2. Synthesis of (1,2-Ph$_2$-4-Me-CpTiCl$_2$)$_2$(μ-O) (3)

A mixture of Et_2O (20 mL) and distilled H_2O (9.0 μL, 0.50 mmol) was slowly added at −15 °C to solid complex **1** (385.5 mg, 1.00 mmol), and the obtained solution was warmed to room temperature and stirred for 48 h (Scheme 1). The solvent was removed *in vacuo*, and the resulting residue was extracted with a mixed solvent of CH_2Cl_2/*n*-hexane (1:3, 15 × 2 mL). The solution was concentrated to give a red solid (317.3 mg, 88.6%). Red crystals of the complex suitable for X-ray diffraction were obtained by recrystallization from a mixture of CH_2Cl_2/*n*-hexane (1:5) at room temperature. *Anal.* Calc. for $C_{36}H_{30}Cl_4OTi_2$ (716.20): C, 60.37; H, 4.22. Found: C, 60.31; H, 4.18%. ^{1}H NMR ($CDCl_3$, 300 MHz, 298 K): δ 2.40 (s, 6H, CH_3), 6.87 (s, 4H, C_5H_2), 7.28–7.50 (m, 20H, C_6H_5). ^{13}C NMR ($CDCl_3$, 75 MHz, 298 K): δ 17.2 (CH_3), 128.9, 133.4, 137.9 (C_5H_2), 123.2, 128.4, 129.7, 136.3 (C_6H_5).

Scheme 1. Synthetic procedure of complexes **3**–**4**.

2.3. Synthesis of (1,2-Ph$_2$-4-*n*-Bu-CpTiCl$_2$)$_2$(μ-O) (4)

Compound **4** was prepared in the same manner as described above for the synthesis of **3** (Scheme 1), and isolated in 89.2% as a red crystalline solid. *Anal.* Calc. for $C_{42}H_{42}Cl_4OTi_2$ (800.36): C, 63.03; H, 5.29. Found: C, 63.05; H, 5.21%. ^{1}H NMR ($CDCl_3$, 300 MHz, 298 K): δ 0.91 (t, $^3J_{HH} = 7.7$ Hz, 6H, CH_3), 1.35 (m, $^3J_{HH} = 7.5$ Hz, 4H, CH_2), 1.60 (m, $^3J_{HH} = 7.6$ Hz, 4H, CH_2), 2.73 (t, $^3J_{HH} = 7.8$ Hz, 4H, CH_2), 6.88 (s, 4H, C_5H_2), 7.27–7.50 (m, 20H, C_6H_5). ^{13}C NMR ($CDCl_3$, 75 MHz, 298 K): δ 14.1, 22.6, 31.4, 32.7 (C_4H_9), 128.9, 133.4, 143.3 (C_5H_2), 122.3, 128.4, 129.8, 136.1 (C_6H_5).

2.4. X-ray structure determination of 3 and 4

Crystals of **3** and **4** suitable for X-ray structure determination were obtained from a saturated solution of CH_2Cl_2/*n*-hexane (1:5, v/v) at room temperature. Diffraction data were collected at 293 K on a Bruker SMART-CCD diffractometer using Mo Kα radiation. The structures were solved using direct methods and refined by full-matrix least-squares procedures [26]. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in ideal positions. All calculations were performed using the SHELXTL crystallographic software packages [27]. Relevant crystallographic data are summarized in Table 1.

2.5. Polymerization of ethylene

The ethylene polymerizations (runs 1–8) were carried out according to the following procedure: A dry 250 mL steel autoclave with a magnetic stirrer was charged with 70 mL of toluene, thermostated at the desired temperature and saturated with ethylene (1.5 bar). The polymerization reaction was initiated by addition of a mixture solution of precatalyst and Al(^{i}Bu)$_3$ in toluene (5 mL) and a solution of $Ph_3C^+B(C_6F_5)_4^-$ in toluene (5 mL) at the same time. The gaseous ethylene was then admitted into the reactor vessel through a gas purification column. The gas pressure was maintained at 6 bar throughout the polymerization period by means of a pressure manometer. After 15 min, the polymerization was quenched by addition of 120 mL of 1:1 (v/v) methanol and HCl solution. The white polymer was collected by filtration, washed several times with water, methanol, and dried to a constant weight under vacuum.

2.6. Polymerization of styrene

The styrene polymerizations (runs 1–10) with complexes **3** and **4** were carried out according to the following procedure: A 250 mL Schlenk flask with a magnetic stirrer was attached to high vacuum line and then sealed under a nitrogen atmosphere. Fifty milliliters of toluene, 5 mL of freshly distilled styrene and an appropriate amount of MAO were added to the flask which was placed in an oil bath at the

desired temperature, and the mixture was stirred for 10 min. The titanium catalyst (2.5 μmol) in toluene was injected into the flask and the polymerization was performed at 25 °C, 50 °C or 75 °C for the desired reaction times. The polymerization was terminated by addition of 10% HCl in methanol. The precipitated polymer was washed three times with methanol and dried at 80 °C *in vacuo* to a constant weight. The polymer was extracted with refluxing 2-butanone for 24 h in a Soxhlet extractor to remove any atactic polymer and dried again at 80 °C for 24 h.

3. Results and discussion

3.1. Synthesis and analysis of complexes 3 and 4

Complexes **3** and **4** were synthesized readily via the hydrolysis reaction of complexes **1** and **2** in solution, and obtained after recrystallization in good yields as red crystalline solids. These titanium complexes are quite soluble in most organic solvents, such as Et_2O, CH_2Cl_2 and toluene. Both complexes can be stored at room temperature, under an inert nitrogen atmosphere, without obvious change, either in the solid state or solution. It is noteworthy that they also exhibit good thermostability and can be heated to about 90 °C in toluene without decomposition. The stability of titanium complexes to water-induced metathesis has been reported previously [28–30]. Complexes **3** and **4** have been confirmed by X-ray diffraction, elemental analysis, ^{1}H and ^{13}C NMR spectroscopy.

The ^{1}H and ^{13}C NMR spectra indicate higher symmetry in solution than in the solid state, and complexes **3** and **4** have similar resonance signals, with just slight shifts to higher field, compared to those of **1** and **2**. The ^{1}H NMR spectra show only one single signal for the protons of the Cp groups (6.87 ppm for **3**, 6.88 ppm for **4**), since they are equivalent in solution for C_{2c} symmetric complexes, and the ^{13}C NMR signals for the Cp groups of complexes **3** and **4** shift 0.5–2.6 ppm to higher field compared to the signals of the Cp groups of complexes **1** and **2** [21].

3.2. Crystal structures of 3 and 4

The molecular structures of complexes **3** and **4** were confirmed by single-crystal X-ray diffraction analysis. The ORTEP drawing of the molecular structure is shown in Fig. 1 and Fig. 2. Selected bond lengths and angles are summarized in Table 2. The molecular structure shows a dimetallic moiety with two (1,2-Ph_2-4-R-$CpTiCl_2$)$_2$(μ-O) (R = Me (**3**), *n*-Bu (**4**)) units linked by Ti–O bonding. The coordination geometry around the titanium atom can be described as pseudo-tetrahedral, formed by a substituted cyclopentadienyl ring, two chloride atoms and an oxygen atom (oxo-bridge). The Ti1–C distances for **3** and **4** are in the range of 2.336(3)–2.430(2) Å, which are similar to the corresponding values of **1** and **2** [21]. The average

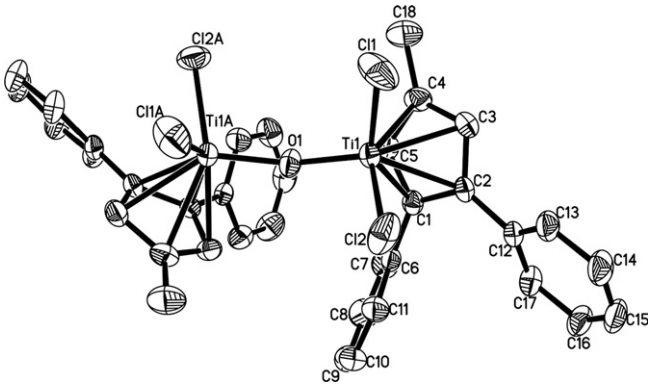

Fig. 1. Structure of complex **3** (thermal ellipsoids are drawn at the 30% probability level).

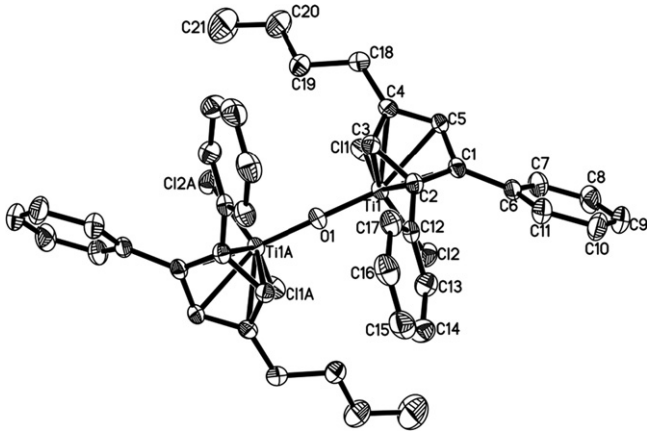

Fig. 2. Structure of complex **4** (thermal ellipsoids are drawn at the 30% probability level).

Ti–Cl distance of 2.219 (1) Å in **3** is shorter than that of 2.247(1) Å in **4**, which could be attributed to the difference in the crowded environment on the titanium atoms. The Ti–O bond lengths (1.786(1) Å for **3** and 1.800(1) Å for **4**) are slightly shorter than the average Ti–O distance in other known complexes [31–34]. For this reason, we suggest that there is relatively higher electron density at the metal atoms of **3** and **4**, which is responsible for the high stability of **3** and **4**. The Ti–O–Ti angles of complexes **3** and **4** (157.0(2)°, 159.6 (2)° respectively) fall within the range of observed values (154–180°) in similar structures, which indicates that there exists different π back-bonding affected by intramolecular steric effects [35,36] (Fig. 2).

3.3. Ethylene polymerization studies

Ethylene polymerizations were carried out in toluene using complexes **3** and **4** as precatalysts under different conditions, and the results of the polymerization catalyzed by complexes **3** and **4** are summarized in Table 3. When activated with $Al(^iBu)_3$ and $Ph_3C^+B(C_6F_5)_4^-$, complexes **3** and **4** both show good catalytic activity for ethylene polymerization, producing moderate molecular weight polyethylene

[a] Polymerization conditions: [Ti] 2 μM, B/Ti ratio 1.2, reaction time 15 min, polymerization temperature 80 °C, ethylene pressure 6 bar.
[b] Activity = g PE (mol Ti)$^{-1}$ bar^{-1} h^{-1}.
[c] Measured in decahydronaphthalene at 135 °C.
[d] Determined by DSC at a heating rate of 10 °C min^{-1}.

with melting temperatures in the range 123–135°. As seen in Table 3, the catalytic activity increases in the order **3** < **4**, which indicates that the activity is influenced by the nature of the substituents on the cyclopentadiene ring. It is well known that the electron-donating effect and steric effect of the *n*-Bu group would stabilize the active species and hence increase the catalytic activity of complex **4**. For both **3** and **4**, the catalytic activity is affected by the Al/Ti molar ratio and the highest catalytic activity is reached at an Al/Ti ratio of about 200. A further increase in the Al/Ti ratio results in a decrease in the catalytic activity. During the polymerization, the molecular weight of the polymer gradually decreases with an increase in the Al/Ti molar ratio, which points out that a high Al/Ti molar ratio results in premature chain termination of the polymer, influenced by the relative rates of the two competing processes: β-hydride elimination and chain propagation.

3.4. Styrene polymerization studies

Styrene polymerizations were carried out in toluene using complexes **3** and **4** as precatalysts under different conditions, and the results of the styrene polymerization with complexes **3** and **4** are summarized in Table 4. The **3** or **4**/MAO systems show good catalytic performance for styrene polymerization in terms of catalytic activity and polymer properties, such as syndiotacticity, melting temperature and molecular weight of the produced polystyrene. In comparison with the **1** or **2**/MAO systems [21], the title catalyst systems were found to be active for syndiotactic polymerization of styrene at a low Al/Ti ratio of 2000, thus reducing the costs of the catalysts. The findings could be attributed to the important factor of the cooperative effect caused by the two adjacent metal centers in this type of catalyst. One catalytically active site can construct a crowded environment around the other site in the catalyst systems, which effectively protects the active species, resulting in a reduction in the amount of MAO in regard to the reactivation of the dormant catalyst species.

The catalytic activity of the title type catalyst is dependent on the polymerization temperature. The catalytic activity of complexes **3** and **4** increases with an increase in polymerization temperature, and the highest activity observed is about 1.35×10^7 g PS (mol Ti)$^{-1}$ (mol styrene)$^{-1}$ h^{-1} at 50 °C. The catalytic activity then decreases at higher polymerization temperatures. These findings are similar to the polymerization behavior of the mother titanium catalyst [21]. The catalytic performance of the title type catalyst is dependent on the polymerization time too. For complexes **3** and **4**, better catalytic behavior was observed for 10 min polymerization experiments, which indicates the partial decomposition of the syndiospecific active species and/or increased viscosity during the polymerization. Furthermore, the results in Table 4 are also consistent with the fact that the catalytic activity and polymer properties depend greatly on the electronic and steric effects of the substituted cyclopentadiene ligands in half-sandwich titanocenes as homogeneous catalysts. The catalytic activity is in the order **3** < **4**, which indicates that both the electronic and steric factors of the substituted cyclopentadiene group play a remarkable role in the styrene polymerizing process.

4. Conclusion

Two new oxo-bridged dinuclear titanium complexes **3** and **4** have been synthesized by hydrolysis of the corresponding monocyclopentadienyl titanium compounds **1** and **2**. The structures of **3** and **4** have been confirmed by ^{1}H and ^{13}C NMR spectra and X-ray crystallography. Upon activation with Al(^{i}Bu)$_3$ and $Ph_3C^+B(C_6F_5)_4^-$, complexes **3** and **4** exhibit reasonable catalytic activity for ethylene polymerization, producing moderate molecular weight polyethylene with melting temperatures in the range 123–135°. The **3** or **4**/MAO systems show good catalytic performance for styrene polymerization in terms of catalytic activity, syndiotacticity, melting temperature and molecular weight of the produced polystyrene.

Abstract

The kinetics of the oxidation of cysteine and captopril via octacyanomolybdate(V) and octacyanotungstate(V) in a buffered acidic media (pH range 2.20–4.80) have been studied spectrophotometrically. The rate law for the oxidation is: Rate $= k$ [RSH] [Ox] $[H^+]^{-1}$, where RSH is cysteine or captopril and Ox is $Cs_3[Mo(CN)_8]$ or $Cs_3[W(CN)_8]$. The activation parameters (E_a, $\Delta H^{\#}$, $\Delta G^{\#}$, $\Delta S^{\#}$) for the oxidation of cysteine and captopril via $Cs_3[Mo(CN)_8]$ or $Cs_3[W(CN)_8]$ have been determined. The results indicate that $Cs_3[Mo(CN)_8]$ is more reactive than $Cs_3[W(CN)_8]$ as an oxidizing agent. Effects of pH, ionic strength, temperature, dielectric constant of the reaction medium and copper(II) ions on the oxidation rate have been studied. Mechanisms for the oxidation of cysteine to cystine and captopril to the corresponding disulfide have been proposed.

Keywords: Cysteine; Captopril; Octacyanomolybdate(V) ion; Octacyanotungstate(V) ion; Copper catalysis; Copper inhibition

1. Introduction

Thiol-containing compounds are effective antioxidants and act as scavengers for reactive oxygen species [1]. In biological systems, cysteine (an amino acid with a thiol group) plays an important role as an antioxidant and thus helps in the protection of cells from the destructive effect of free radicals [2]. Additional interest has been focused on cysteine in biological systems due to the effect of its oxidation on cell immune function [3]. Kinetic studies of the oxidation of cysteine *in vitro* are expected to shed light on its oxidation in biological systems. A large variety of oxidizing agents, such as cobalt(III) complexes [4–6], iron(III) complexes [6,7], vanadium(V) complexes [8], per-manganate ion [9], copper(II) complexes [10], sodium *N*-chlorotoluenesulphonamide [11], penta-cyanonitrosyl ferrate(III) ion [12], and manganese(III) ion [13], have been employed in the study of the kinetics of oxidation of cysteine. Oxidizing agents involving molybdenum have been used [14–16] in an attempt to mimic enzymatic oxidation of cysteine in biological systems. The catalytic role of trace amounts of copper(II) ions in the oxidation of cysteine has been reported by many researchers [17–19].

Herein, we report on the oxidation of cysteine and captopril [20] in acidic media (pH 2.20–4.80). Captopril is a thiol compound (1-[(2*S*)-3-mercapto-2-methyl-1-oxopropyl]-L-proline) widely used as antihypertensive drug [21–25].

2. Experimental

2.1. Materials

The cyano complexes, $K_4[Mo(CN)_8]\cdot 2H_2O$ [26], $K_4[W(CN)_8]\cdot 2H_2O$ [27], $Cs_3[Mo(CN)_8]\cdot 2H_2O$ and $Cs_3[W(CN)_8]\cdot 2H_2O$ [28,29], were prepared following the literature procedures. The above cesium salts were recrystallized from water and were used without further purification.

Analytical grade reagents and distilled water were used. The aqueous solutions of cysteine, captopril and oxidizing agents were freshly prepared. The desired buffer solutions for varying the pH of the reaction medium were prepared by mixing suitable volumes of 0.10 M HCl and 0.10 M potassium hydrogen phthalate to give pH values in the range (2.20–3.80), while for the pH range (4.20–4.80) suitable volumes of 0.10 M NaOH and 0.10 M potassium hydrogen phthalate were mixed. The pH was measured with a WTM 3000 pH meter.

2.2. Kinetic measurements

Reactions were carried out in buffered acidic media using thermostatted bath (HAAK, MD-BRUE/PU) to regulate the temperature to ±0.2 °C. Kinetic measurements were carried out in aqueous solutions unless otherwise specified. The pH was measured with a WTM 3000 pH meter. The pH meter was calibrated using standard pH solutions. The measured pHs were corrected for 50% v/v aqueous/methanol using the relationship [30,31]: $PH_{corr.} = PH_{meas.} + 0.08$. The ionic strength was adjusted to a constant value of 0.0800 M or 0.100 M by the addition of $NaClO_4$. The progress of the reaction was followed by measuring the absorbance (A_t) of the unconsumed $[Mo(CN)_8]^{3-}$ or $[W(CN)_8]^{3-}$ at 390 and 356 nm, respectively. The absorption measurements were carried out with use of a thermostatted Jasco V530 UV/Vis spectrophotometer. Solutions of cysteine, captopril and the cyano complexes were protected from light. By maintaining stoichiometric amounts of (1:1) of the thiol (RSH = cysteine, captopril) and the oxidizing agent ($Cs_3[Mo(CN)_8]$, $Cs_3[W(CN)_8]$) and performing spectrophotometric measurements at the proper wavelength. The following stoichiometric equation was found to hold for the two oxidants:

$$2RSH + 2[M(CN)_8]^{3-} = RSSR + 2[M(CN)_8]^{4-} + 2H^+$$

where M = Mo or W; RSSR = cystine or the corresponding disulfide of captopril. The disulfide compounds, cystine (m.p. = >250 °C) and the corresponding disulfide of captopril (m.p. = 220–224 °C) precipitated from reacted solutions were identified by their melting points. Formation of $[Mo(CN)_8]^{4-}$ and $[W(CN)_8]^{4-}$ in the oxidation reactions was evidenced in the oxidation reaction by the gradual increase of the absorption bands at $\lambda = 410$ and 428 nm, respectively.

3. Results and discussion

3.1. Effect of thiol concentration

The oxidation of cysteine and captopril were investigated at a constant pH and ionic strength. The concentration of the oxidants, $[Mo(CN)_8]^{3-}$ or $[W(CN)_8]^{3-}$, was kept constant at 1.00×10^{-3} M, while the concentration of cysteine or captopril was varied to study the effect of thiol concentration on reaction rate. For each run a plot of ln A versus time gave a good straight line, and the corresponding observed first-order rate constant (k) was obtained. The results for the oxidation of cysteine via the two oxidants are shown in Table 1. The effect of cysteine concentration on the reaction rate indicates a first-order kinetics with respect to cysteine.

However, when the reaction was carried out at stoichiometric amounts of the reactants (thiol-to-$[M(CN)_8]^{3-}$ = 1:1, where thiol = cysteine or captopril; M = Mo, W), absorption measurements for about 70% completion indicated second-order kinetics as shown in Fig. 1.

3.2. Effect of H^+ concentration

With other variables constant, the rate constant for the oxidation of cysteine has been found to decrease with increasing acidity (Table 2).

Plotting the second-order rate constant (k') versus $1/[H^+]$ for the oxidation of cysteine by $[Mo(CN)_8]^{3-}$, in the pH range 2.20–2.80, gave a straight line indicating first-order kinetics with respect to $1/[H^+]$ (Fig. 2). Similar behavior was observed for the oxidation of captopril by both oxidants.

3.3. Effect of ionic strength

The variation of the rate constant with ionic strength was investigated in the presence of $NaClO_4$ over a range of ionic strength $I = 0.100$–0.250 M. The results are shown in Table 3. A Plot of log k versus $\sqrt{I}$ gave a straight line in both cases. From the slope of such plots, values of $Z_A Z_B$

2.80	10.3	3.09

[a] $[Mo(CN)_8]^{3-} = [W(CN)_8]^{3-} = [cys] = 1.00 \times 10^{-3}$ M, $T = 15.0$ °C, $I = 0.0800$ M, 50% aqueous methanol.
[b] k' = second-order rate constant from plot of $1/A$ vs. time at different pH values.

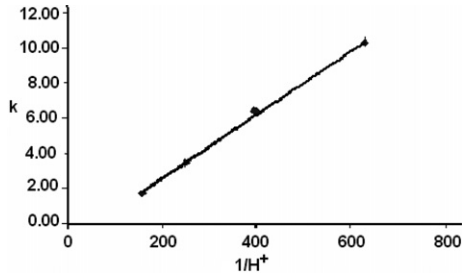

Fig. 2. A plot of k vs. $1/[H^+]$ for the oxidation of cysteine by $[Mo(CN)_8]^{3-}$ in 50% aqueous methanol. $[Mo(CN)_8]^{3-} = [cys] = 1.00 \times 10^{-3}$ M, $I = 0.0800$ M, $T = 15.0$ °C.

Table 3
Ionic strength dependence of the kinetics of oxidation of cysteine via $[Mo(CN)_8]^{3-}$ and $[W(CN)_8]^{3-}$

I (M)	$[Mo(CN)_8]^{3-}$[a] 10^3 k (s^{-1})	$[W(CN)_8]^{3-}$[b] 10^3 k (s^{-1})
0.100	22.3	5.50
0.150	25.0	6.54
0.200	27.5	7.44
0.250	30.5	8.54

[a] $[Mo(CN)_8]^{3-} = 1.00 \times 10^{-3}$ M, $[cys] = 5.00 \times 10^{-3}$ M, $T = 15.0$ °C, pH 2.20.
[b] $[W(CN)_8]^{3-} = 1.00 \times 10^{-3}$ M, $[cys] = 5.00 \times 10^{-3}$ M, $T = 15.0$ °C, pH 2.20.

for the reacting species at the rate determining step were obtained. These values are: +1.61 (cystein/$[Mo(CN)_8]^{3-}$), +1.00 (cystein/$[W(CN)_8]^{3-}$) and +0.570 (captopril/$[W(CN)_8]^{3-}$). This is an indication of a positive salt effect which implies that the reacting species at the rate determining step are RS- and the ion-pairing of the form $Na_n[M(CN)_8]^{n-3}$, where M = Mo or W. Values of n in the range 1.4–2.4 were experimentally obtained. Attempts to study the effect of ionic strength on the oxidation of captopril by $[Mo(CN)_8]^{3-}$ were unsuccessful due to precipitation problems.

3.4. Effect of dielectric constant

The influence of the solvent dielectric constant has been studied by varying the dielectric constant using aqueous methanol solutions with different compositions. The results show no significant effect on the reaction rate with the dielectric constant of the reaction medium.

3.5. Evaluation of E_a, $\Delta H^{\#}$, $\Delta G^{\#}$ and $\Delta S^{\#}$

Reactions were investigated at 10.0, 15.0, 20.0 and 25.0 °C for the oxidation of captopril by $[Mo(CN)_8]^{3-}$ at stoichiometric amounts of reactants, constant pH (4.80) and constant ionic strength (0.100 M). Values of $\Delta H^{\#}$ and E_a (Table 4) were evaluated from plots of $\ln k$ versus $1/T$, where k is the second-order rate constant (Fig. 3). Applying Eyring equation at $T = 25.0$ ° C values of $\Delta G^{\#}$ and $\Delta S^{\#}$ were calculated.

The higher reactivity of $[Mo(CN)_8]^{3-}$ as an oxidizing agent in comparison with $[W(CN)_8]^{3-}$ is shown clearly from the values of the rate constants for the oxidation of cysteine via both oxidizing agents. The rate constant for the former is about four times greater than that for the latter under the same conditions (Table 1). This is consistent with the higher reduction potential [32] of $[Mo(CN)_8]^{3-}$ and lower activation energy for the oxidation process (Table 4).

3.6. Effect of trace metal ions

Trace elements, that are usually present in the reagents or buffers used in the kinetic studies, seem to play a catalytic role in the oxidation process of cysteine and related thiols [17–19]. Reports about the catalytic role of copper ions in the oxidation of cysteine and the low values of activation energies for the oxidation of cysteine determined in this study, encouraged us to study the catalytic

40.0	3.7

$[Mo(CN)_8]^{3-} = [\text{captopril}] = 1.00 \times 10^{-3}$ M, $T = 15.0$°C, pH 2.80, $I = 0.100$ M.

effect of $[Cu^{2+}]$. Table 5 shows how the rate constant for the oxidation of captopril by $[Mo(CN)_8]^{3-}$ increases with increasing Cu^{2+} ions concentration. Same effects have been observed for the oxidation of captopril by $[W(CN)_8]^{3-}$ and for the oxidation of cysteine by the two oxidants.

3.7. Effect of dipicolinic acid on the oxidation rate

Dipicolinic acid (a dibasic acid with $pK_{a_1} = 2.07$ and $pK_{a_2} = 4.66$) is known for its strong binding with Cu^{2+} and thus acts as an inhibitor for the Cu^{2+} catalytic role [17,18,33,34]. In this study it is observed that $t_{1/2}$ is 310 s for the oxidation of cysteine (1.00×10^3 M) via $[Mo(CN)_8]^{3-}$ (1.00×10^3 M) at pH 2.20 and 15.0 °C. Under these conditions, $t_{1/2}$ is increased up to 405 s upon using a 1.00×10^3 M concentration of dipicolinic acid.

Increasing the concentration of dipicolinic acid to 2.00×10^3 M indicates no further inhibition to the oxidation rate. It seems that a concentration of 1.00×10^3 M of dipicolinic acid is sufficient to mask the catalytic effect due to the impurity levels of Cu^{2+} ions.

In view of the above results the following mechanism is proposed:

$$RSH \underset{k_{-1}}{\overset{k_1}{\leftrightarrows}} RS^- + H^+$$

$$Cu^{2+} + RS^- \overset{k_2}{\rightarrow} Cu^+ + RS^{\cdot}$$

$$Cu^+ + [M(CN)_8]^{3-} \underset{k_{-3}}{\overset{k_3}{\leftrightarrows}} Cu^{2+} + [M(CN)_8]^{4-}$$

$$RS^- + [M(CN)_8]^{3-} \underset{\text{(slow)}}{\overset{k_4}{\leftrightarrows}} RS^{\cdot} + [M(CN)_8]^{4-}$$

$$2RS^{\cdot} \overset{k_5}{\rightarrow} RSSR$$

Assuming that the fourth step is the rate determining step and applying the steady state assumption for the thiolate anion (RS^-), the rate law can be derived as follows:

$$-\frac{d[M(CN)_8]^{3-}}{dt} = k_4[RS^-][M(CN)_8]^{3-}$$

$$k_1[RSH] = k_{-1}[RS^-][H^+] + k_2[Cu^{2+}][RS^-] + k_4[M(CN)_8]^{3-}[RS^-]$$

$$[RS^-] = \frac{k_1[RSH]}{k_2[Cu^{2+}] + k_{-1}[H^+] + k_4[M(CN)_8]^{3-}}$$

$k_{-1}[H^+] \gg k_2[Cu^{2+}] + k_4[M(CN)_8]^{3-}$, the $[H^+]$ is sufficiently high.

$$-\frac{d[M(CN)_8]^{3-}}{dt} = k_4k_1/k_{-1}[RSH][M(CN)_8]^{3-}[H^+]^{-1},$$

$$-\frac{d[M(CN)_8]^{3-}}{dt} = k_{obs}[RSH][M(CN)_8]^{3-}[H^+]^{-1}$$

where $k_{obs} = k_4k_1/k_{-1}$.

Abstract

Two structurally related flexible imidazolyl ligands, bis(*N*-imidazolyl)methane (L_1) and 1,4-bis(*N*-imidazolyl)butane (L_2), were reacted with Cu(II), Co(II) and Ni(II) salts of aliphatic/aromatic dicarboxylic acids resulting in the formation of a number of novel metal–organic coordination architectures, $[CuB_2(ox)_2(L_1)_2(H_2O)_2]\cdot 4H_2O$ (**1**) (ox = oxalate), $[Cu(pdc)(L_2)_{1.5}]\cdot 4H_2O$ (**2**, pdc = pyridine-2, 6-dicarboxylate), $[Co(L)_2(H_2O)_2](tp)\cdot 4H_2O$ (**3**, tp = terephthalate), $[Ni(L_1)_2(H_2O)_2](ip)\cdot 5H_2O$ (**4**, ip = isophthalate), $[Cu_2(L_1)_4(H_2O)_4](tp)_2\cdot 7H_2O$ (**5**), $[Co(mal)(L_1)(H_2O)]\cdot 0.5MeOH$ (**6**, mal = malonate), $[Co(pdc)(L_1)(H_2O)]$ (**7**). All the complexes have been structurally characterized by X-ray diffraction analysis. The different coordination modes of the dicarboxylate anions, due to their chain length, rigidity and diimidazolyl functionality, lead to a wide range of different coordination structures. The coordination polymers exhibit 1D single chain, ladder, 2D sheet and 2D network structures. The aliphatic and aromatic dicarboxylates can adopt chelating μ_2 and chelating-bridging μ_3 coordination modes, or act as uncoordinated counter anions. The central metal ions are coordinated in N_2O_4, N_4O_2, N_2O_3 and N_3O_3 fashions, depending on the ancillary ligands. The topology of **1** gives rise to macrocycles which are connected through hydrogen bonds to form 1D chains, whereas compound **2** exhibits a 1D polymeric ladder in which the carboxylate acts as a pincer ligand. Compounds **3**–**5** show doubly bridged 1D chains, and the dicarboxylate groups are not coordinated but form 2D corrugated sheets with water molecules intercalated between the cationic layers. Compound **6** has a 2D network sheet structure in which each metal ion links three neighboring Co atoms by the bis(*N*-imidazolyl)methane ligand. The cobalt compound **7**, with a 2D polymeric double sheet structure, is built from pincer carboxylate (pdc) and 1,4-bis(*N*-imidazolyl)methane ligands.

1. Introduction

The design and synthesis of metal–organic framework structures have received enormous attention [1] in recent years due to their potential applications in diverse areas such as electrical conductivity [2], magnetism [3], host–guest chemistry [4], molecular separation [5], gas storage [6], sensors [7] and catalysis [8]. The framework structure of the coordination polymers is primarily dependent upon the coordination preferences of the central metal ions and the functionality of the ligands. Aside from the coordination bonding interactions, the hydrogen bonding and π–π stacking interactions, the solvent molecules, counterions and the ratio of metal salt to organic ligand also influence the formation of the ultimate architectures.

It is well known that carboxylate ligands play an important role in coordination chemistry and can adopt various binding modes such as terminal monodentate, chelating to one metal center, bridging bidentate in a *syn–syn*, *syn–anti* and *anti–anti* configuration to two metal centers, and bridging tridentate to two metal centers [9]. The rigid rod-like spacer molecules 4,4′-bipyridine (bipy) and pyrazine (pz) have been widely used as building blocks for the construction of metal–organic coordination frameworks [10]. The use of organic spacers, particularly flexible

dicarboxylates ($R(COO)_2^{2-}$ anion) bridging ligands and rigid planar bidentate diimines (bipy or pyz) as building blocks to construct various metal assemblies is of growing interest in the field of molecular materials [11]. Recently, great success has been achieved by the combination of flexible aliphatic dicarboxylates and bipy as chelating bridging ligands, which resulted in compounds having 1–3D frameworks and unique physicochemical properties [12–20]. A large number of novel architectures assembled through this combination, such as extended networks having grid [21], honeycomb [22], brick wall [23] and other geometries [24], have been reported in recent years. In contrast to rigid spacers, flexible ligands, which can adopt various conformations, may induce coordination polymers with novel topologies. However, flexible ligands containing imidazolyl groups and polycarboxylate ligands have not been well studied to date [25–30]. 1,1′-bis(*N*-imidazolyl)methane (L_1) and 1,4-bis(*N*-imidazolyl)butane (L_2) can be used as flexible divergent ligands to construct coordination polymer materials. The remarkable coordination abilities of dicarboxylic acid ligands and flexible bidentate diimines have prompted us to design and synthesize new coordination polymeric compounds containing both ligands.

To examine the influence of the chain length and the rigidity of the ligands, here we report the preparation of a few novel metal–organic coordination polymers by reacting transition metal salts of dicarboxylates with flexible bidentate ligands. Their structures are fully characterized by IR and X-ray diffraction.

2. Experimental

2.1. Materials and methods

All reagents and solvents were purchased from commercial sources and were used as received. L_1 and L_2 were prepared according to the reported procedure [31]. Elemental analyses were determined with a Carlo Erba 1110 instrument. IR spectra were measured as KBr discs using a Bruker Vector 22 spectrophotometer. Thermogravimetric analyses (TGA) were studied by a Delta Series TA-SDT Q600 in a N_2 atmosphere in the temperature range from room temperature to 800 °C (heating rate = 10 °C min^{-1}) using Al crucibles.

2.2. Synthesis

2.2.1. $[Cu_2(ox)_2(L_1)_2(H_2O)_2]\cdot 4H_2O$ (**1**)

A mixture of $CuCl_2\cdot 2H_2O$ (17.1 mg, 0.1 mmol), NaOH (8 mg, 0.2 mmol), and oxalic acid (12.7 mg, 0.1 mmol) in water was stirred for 10 min at 60 °C, then L_1 (15 mg, 0.1 mmol) was added to the mixture. After stirring for 30 min, a blue precipitate was collected and dissolved in a minimum amount of ammonia. Blue single crystals of **1** were obtained by slow evaporation of the ammonia solution at ambient temperature. Yield: 30 mg, 42.4%. *Anal.* Calc. for $C_{18}H_{28}Cu_2N_8O_{14}$: C, 30.56; H, 3.99; N, 15.84. Found: C, 30.50; H, 3.91; N, 15.75%. IR data (KBr, cm^{-1}): 3451s, 3117s, 1673s, 1513s, 1401s, 1288s, 1238s, 1099s, 1035w, 952m, 856m, 785s, 713s, 657m, 615m, 545m, 478m.

2.2.2. $[Cu(pdc)(L_2)_{1.5}]\cdot 4H_2O$ (**2**)

Compound **2** was prepared similarly using $CuCl_2\cdot 2H_2O$ (17.1 mg, 0.1 mmol), NaOH (8 mg, 0.2 mmol), and pyridine-2,6-dicarboxylic acid (16.7 mg, 0.1 mmol), L_2 (19 mg, 0.1 mmol). The resulting blue precipitate was collected and dissolved in a minimum amount of ammonia. Blue single crystals of **2** were obtained by slow evaporation of the ammonia solution at ambient temperature. Yield: 40 mg, 68.3%. *Anal.* Calc. for $C_{22}H_{32}CuN_7O_8$: C, 45.08; H, 5.50; N, 16.73. Found: C, 45.04; H, 5.46; N, 16.72%. IR data (KBr, cm^{-1}): 3419s, 3106m, 2941w, 1649s, 1586m, 1523m, 1453w, 1420w, 1375m, 1351m, 1276, 1240w, 1184w, 1104m, 1034m, 946w, 903w, 855w, 789w, 766w, 750w, 726w, 698w, 663m, 629w.

2.2.3. $[Co(L_1)_2(H_2O)_2](tp)\cdot 4H_2O$ (**3**)

An aqueous solution of terephthalic acid (16.7 mg, 0.1 mmol) and NaOH (8 mg, 0.2 mmol) were treated with $Co(NO_3)_2\cdot 6H_2O$ (29.1 mg, 0.1 mmol). After the mixture was stirred for a few minutes, L_1 (14.8 mg, 0.1 mmol) was added to give a violet solution. Slow evaporation of the resulting solution yielded violet crystals after a few days, which were collected and washed with water and ethanol. Yield: 40 mg, 63.7%. *Anal.* Calc. for $C_{22}H_{32}CoN_8O_{10}$: C, 42.11; H, 5.14; N, 17.86. Found: C, 42.07; H, 5.10; N, 17.72%. IR data (KBr, cm^{-1}): 3214s, 3114w, 1636w, 1567s, 1527w, 1503w, 1393m, 1284m, 1234m, 1091m, 935w, 829w, 747m, 713w, 660m, 508w.

2.2.4. $[Ni(L_1)_2(H_2O)_2](ip)\cdot 5H_2O$ (**4**)

This compound was prepared similarly as for **3** from isophthalic acid (16.7 mg, 0.1 mmol), NaOH (8 mg, 0.2 mmol), $NiCl_2\cdot 6H_2O$ (24 mg, 0.1 mmol) and L_1 (14.8 mg, 0.1 mmol). Light blue crystals were isolated after slow evaporation of its solution. Yield: 45 mg, 69.7%. *Anal.* Calc. for $C_{22}H_{34}N_8NiO_{11}$: C, 40.95; H, 5.31; N, 17.37. Found: C, 40.88; H, 5.23; N, 17.29%. IR data (KBr pellet, cm^{-1}): 3382s, 3128w, 1602m, 1551s, 1422w, 1365s, 1286m, 1232m, 1089m, 1032w, 939m, 751m, 713w, 659m, 612w.

2.2.5. $[Cu_2(L_1)_4(H_2O)_4](tp)_2\cdot 7H_2O$ (**5**)

This compound was prepared by the same procedure as for compound **1** from $CuCl_2\cdot 2H_2O$ (17.1 mg, 0.1 mmol), NaOH (8 mg, 0.2 mmol), terephthalic acid (16.7 mg, 0.1 mmol) and L_1 (15 mg, 0.1 mmol). The resulting blue precipitate was collected and dissolved in a minimum amount of ammonia. Blue single crystals of **5** were obtained by slow evaporation of the ammonia solution at ambient temperature. Yield: 40 mg, 32%. *Anal.* Calc. for $C_{44}H_{62}Cu_2N_{16}O_{19}$: C, 42.40; H, 5.01; N, 17.98. Found: C, 42.34; H, 4.95; N, 17.92%. IR data (KBr, cm^{-1}): 3415s, 3115s, 1646m, 1573s, 1530s, 1508s, 1373s, 1290s, 1229s, 1096s, 1025w, 1012w, 948m, 885w, 824m, 754s, 713m, 655m, 614m, 499m.

2.2.6. [Co(mal)(L_1)(H_2O)] · 0.5MeOH (6)

Compound **6** was prepared in the same manner as for **3** from malonic acid (10.4 mg, 0.1 mmol), NaOH (8 mg, 0.2 mmol), $CoCl_2 \cdot 6H_2O$ (24 mg, 1 mmol) and L_1 (14.8 mg, 0.1 mmol). The compound was isolated as violet block crystals. Yield: 23 mg, 67%. Elemental analysis performed on crystals exposed to the atmosphere: *Anal*. Calc. for $C_{10.5}H_{14}CoN_4O_{5.5}$: C, 36.75; H, 4.11; N, 16.33. Found: C, 36.70; H, 4.06; N, 16.27%. IR data (KBr pellet, cm^{-1}): 3277br, 3127w, 1642w, 1566s, 1437m, 1394w, 1348m, 1288w, 1235m, 1161m, 1100m, 1035m, 940m, 848m, 760m, 715m, 659m, 618w, 575m.

2.2.7. [Co(pdc)(L_1)(H_2O)] (7)

Compound **7** was prepared similarly as for **3** using pyridine-2,6-dicarboxylic acid (16.7 mg, 0.1 mmol), NaOH (8 mg, 0.2 mmol), $CoCl_2 \cdot 6H_2O$ (24 mg, 0.1 mmol) and L_1 (14.8 mg, 0.1 mmol). Violet crystals were obtained by slow evaporation of the aqueous solution. Yield: 28 mg, 72%. *Anal*. Calc. for $C_{14}H_{13}CoN_5O_5$: C, 43.09; H, 3.36; N, 17.95. Found: C, 43.01; H, 3.29; N, 17.88%. IR (KBr pellet, cm^{-1}): 3118m, 2363w, 1632s, 1502m, 1417m, 1359m, 1280m, 1228m, 1176m, 1088m, 1038m, 936w, 911w, 846w, 817w, 766m, 721m, 690w, 666w, 619w.

2.3. X-ray crystallography

Single-crystal X-ray diffraction data for complexes **1**–**7** were collected at 298(2) K on a Siemens Smart/CCD area-detector diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å) by using an ω scan mode. Data collection and reduction were performed using the SMART and SAINT software [32]. The structures were solved by direct methods and the non-hydrogen atoms were subjected to anisotropic refinement by full-matrix least-squares on F_2 using the SHELXTXL package [33]. Hydrogen atom positions for all of the structures were calculated and allowed to ride on their respective C atoms with C–H distances of 0.93–0.97 Å and $U_{iso}(H) = -1.2U_{eq}(C)$. Hydrogen atoms bound to water molecules were located in the Fourier difference map and their distances were fixed. Further details of the structural analysis are summarized in Table 1. Selected bond lengths and angles for complexes **1**–**7** are listed in Table 2.

3. Results and discussion

3.1. Synthesis and general characterization

Complexes **1**–**7** were prepared in water, and they are insoluble in water and common organic solvents. Crystals

of **3**, **4**, **6** and **7** suitable for X-ray diffraction analysis were obtained by standing their aqueous solutions at room temperature, but crystals of complexes **1**, **2** and **5** were obtained by slow evaporation of their ammonia solutions. The elemental analysis data for the compounds are in good agreement with their formula.

The infrared spectra of **1**–**7** are consistent with their chemical formula as determined by elemental analysis and further confirmed by X-ray diffraction analysis. The very strong and broad features at approximately 3400–3200 cm^{-1} in their vibration spectra arise from O–H stretching frequencies of either coordinated or uncoordinated water molecules. Aromatic and imidazolyl ring stretching and bending are attributed to the medium intensity bands in the regions 1500–1630 cm^{-1} and 600–750 cm^{-1}, respectively. The intense peaks at ca. 1640 cm^{-1} are derived from the existence of C=O stretches of the carboxylates, and the bands at 1285 cm^{-1} show the presence of the C–O stretches.

3.2. Structural description

Compound **1**, of the formula $[Cu_2(ox)_2(L_1)_2(H_2O)_2]\cdot 4H_2O$, was obtained by reacting Cu^{2+}, oxalic acid and bis(*N*-imidazolyl)methane (L_1) in basic aqueous solution and was isolated as blue crystals. Compound **1** belongs to the triclinic $P\bar{1}$ space group. X-ray diffraction analysis showed that **1** is a discrete dinuclear complex, and the asymmetric unit consists of one Cu ion, one oxalate and one bis(*N*-imidazolyl)methane molecule. The value of τ is 0.21 and the coordination environment of the copper atoms is between the idealized square-pyramidal and trigonal-bipyramidal extremes [34]. As shown in Fig. 1a, the Cu ion adopts

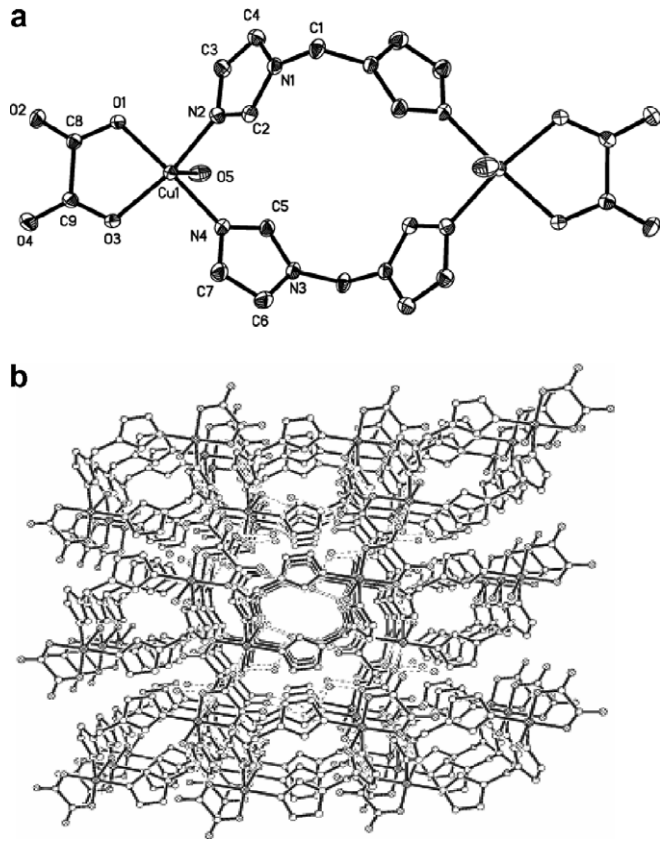

Fig. 1. (a) X-ray crystal structure of complex **1** with the atom numbering scheme. The thermal ellipsoids are drawn at 30% probability. (b) Three-dimensional network structure connected via hydrogen bonds.

a tetragonal pyramidal geometry and each copper atom is coordinated by two nitrogen atoms from two independent bis(*N*-imidazolyl)methane bridging ligands, two oxygen atoms from one oxalate anion in a chelating mode and one water molecule, completing its tetragonal pyramidal geometry with a N_2O_3 donor set. The Cu–O(water) bond distance, being 2.356(2) Å, is much longer than that of the Cu–O(carboxylate) bond distance (1.971(2) Å). The Cu–N distances of 1.999(2) and 1.978(2) Å are normal and are consistent with those of known Cu–imidazole complexes, which range from 1.876(13) to 2.049(8) Å [35]. The oxalate anion acts as a bis-unidentate ligand and forms a five-membered ring with the central metal ion, while two L_1 and two Cu atoms generate a 16-membered ring. The dimeric units are connected through strong multiple hydrogen bonds with water molecules, yielding a three-dimensional network structure, which is illustrated in Fig. 1b. The O–H···O distances range from 2.830 to 3.107 Å. The copper dimeric units are located in the channels built from the hydrogen bonding between the coordinated oxygen atoms and water molecules.

3.2.1. 1D polymeric ladder of $[Cu(pdc)(L_2)_{1.5}]\cdot 4H_2O$ (2)

Single crystals of **2** suitable for X-ray diffraction analysis were obtained by evaporating an ammonia solution of **2**. The central Cu(II) ion is hexacoordinated with a distorted octahedral geometry. Each Cu(II) ion is bonded equatorially to a pdc^{2-} (pdc^{2-} = pyridinedicarboxylate) and one nitrogen atom of a L_2 ligand (Fig. 2a). The pyridyl rings of pdc^{2-} and the imidazolyl ring are essentially co-planar. Two nitrogen atoms from two different 1,4-bis(*N*-imidazolyl)butane ligands fulfill the apical positions with Cu–N distances of 2.057(4) and 2.061(4) Å. The equatorial Cu–N bond does not show any significant difference to the axial Cu–N bonds, and the bond distances are similar to the values in the literature for other related Cu(II) complexes [36–38]. The two Cu–O bond distances,

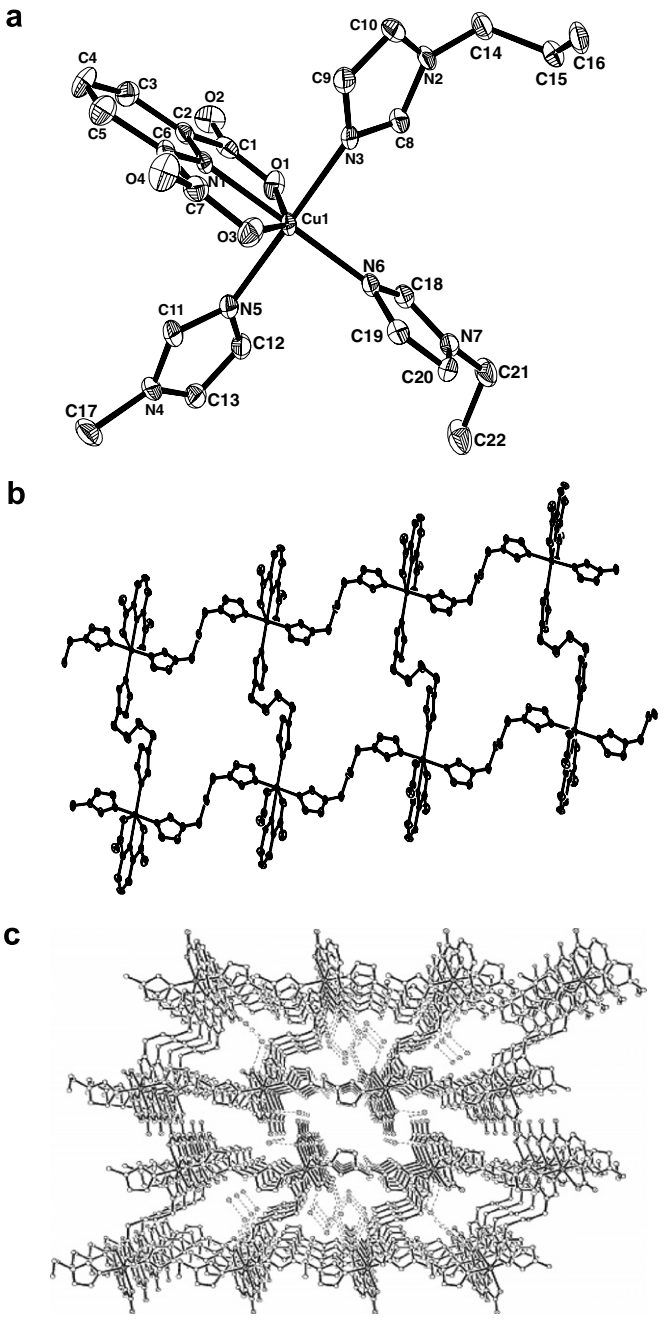

Fig. 2. (a) Local coordination environment of copper in polymer **2**. (b) Projection view of polymer **2** showing the one-dimensional ladder. (c) View of the 3D network structure based on the hydrogen bonds between the ladders and water molecules.

being 2.312(4) and 2.418(4) Å, are remarkably longer than normal Cu–O bonds for copper carboxylate complexes [25].

Each Cu ion is linked to three adjacent copper centers through three diimidazolyl ligands, extending into a one-dimensional ladder-like chain structure (Fig. 2b). Along the chains four L_2 ligands and four Cu cations form 36-membered square grids. The chains are built from repeated interconnection of the grids. Three lattice water molecules form pentagonal rings with two oxygen atoms of pdc^{2-} ligands via strong hydrogen bonds. The pentagonal rings are located in the channels constructed by the 36-membered rings. The water rings and the one-dimensional ladders are further connected by hydrogen bonds between water hydrogen atoms and the oxygen atoms of dicarboxylate groups with O–H···O distances ranging from 2.683(9) to 2.987(6) Å (Fig. 2c).

3.2.2. 1D polymeric hinged chains of $[M(L_1)_2(H_2O)_2]X\cdot nH_2O$ (3, M = Co, X = terephthalate; 4, M = Ni, X = isophthalate; 5, M = Cu, X = terephthalate)

The complexes of the general formula $[M(L_1)_2(H_2O)_2]X\cdot nH_2O$ (**3**, M = Co, X = terephthalate; **4**, M = Ni, X = isophthalate; **5**, M = Cu, X = terephthalate) were obtained by mixing the corresponding disodium dicarboxylate, metal salt and bis(*N*-imidazolyl)methane. The most common feature of the three compounds is that the dicarboxylate units are not coordinated to the central metals and act as counter anions. Although complexes **3**, **4** and **5** crystallize in different space groups, the structures of the cationic sections are essentially the same and thus only the structure of **3** is discussed in detail. The Co atom coordinates to four nitrogen atoms of four different bis(*N*-imidazolyl)methane molecules and two water molecules. The Co atom is in an octahedron environment (Fig. 3). Unlike compounds **1** and **2**, the terephthalate anion does not show any direct bonding interactions with the cobalt ion; it only acts as a counteranion. The Co–O_w distances, being 2.128(2) and 2.134(2) Å, are very close to those found for known cobalt complexes [39]. The Co–N distances (2.137(2), 2.140(2), and 2.143(2) Å) are not unusual and are well consistent with those observed for known compounds [39]. Adjacent Co ions are doubly bridged by two bis(*N*-imidazolyl)methane ligands and thus form infinite one-dimensional zigzag chains with a Co–Co separation of 8.960 Å.

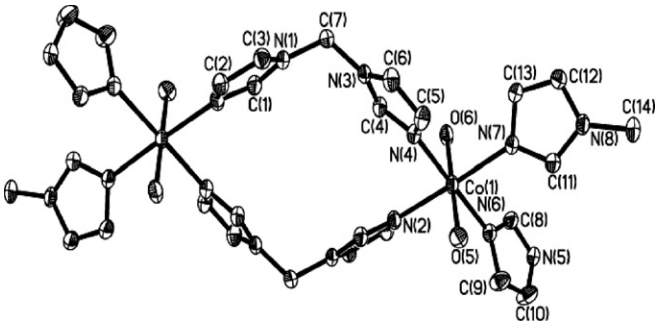

Fig. 3. X-ray crystal structure of the cationic section of complex **3** with the atomic numbering scheme. The uncoordinated anions and water molecules are omitted. The thermal ellipsoids are drawn at 30% probability.

The whole molecules are organized in a three-dimensional structure involving hydrogen bonds, both intercationic and between cations and terephthalate anions or water molecules. The O···O distances of the hydrogen bonding are observed to be in the range of 2.659(2)–2.775(3) Å for **3** and 2.644(2)–2.77(3) Å for **4**. The one-dimensional cationic chains arrange in a parallel way forming cationic layers, whereas the uncoordinated terephthalate anions and water molecules are connected into two-dimensional corrugated layers through strong hydrogen bonds. The two layers are alternatively stacked in an ABAB sequence and are intercalated with each other, as shown in Fig. 5a and b. Normally, aqueous hydrogen bonding to carboxylate oxygen atoms attracts water molecules causing a localized high density water clustering. It is interesting to note that in **3** and **4** free water molecules, coordinated water molecules and the anions form various polygonal oxygen rings, which link the coordinated water molecules and the chains through hydrogen bonds. The 2D sheets of dicarboxylate–water clusters consisting of p-$C_6H_4(CO_2^-)_2\cdot 4H_2O$ in **3** and m-$C_6H_4(CO_2^-)_2\cdot 5H_2O$ in **4** are depicted in Fig. 4a and b. Fig. 4a and b clearly shows that cyclic hexamer water clusters exist and display an ice-like chair conformation. These six-membered water rings hold the terephthalate or isophthalate ions together yielding supramolecular sheets in **3** and **4**. These hexamer water clusters have also been observed recently in a few inorganic and organic lattices [40]. Water clusters have been extensively studied both theoretically and experimentally [41]. A variety of water clusters $(H_2O)_n$ ($n = 2$–10) found in a number of crystal hosts, have been characterized and display different configurations. The hexamer water cluster is particularly interesting because this cluster can exhibit some of the properties of bulk water and may well provide an interesting model for the smallest piece of ice. How the size and symmetry of the anions influence the formation of water clusters in our cases have not been fully understood?

Although **5** consists of the same one-dimensional double chain structure as **3** and **4**, the chains extend in two directions (i.e. along the *a*- and *c*-axes), the chains in the *a*-axis direction are perpendicular to the chains in the *c*-axis direction, shown in Fig. 5c. The chains are connected to each other through multiple hydrogen bonds between tp anions and coordinated water molecules, resulting in a three-dimensional structure.

3.2.3. 2D network sheets of complexes $[Co(mal)(L_1)(H_2O)]\cdot 0.5MeOH$ (6)

The compound $[Co(mal)(L_1)(H_2O)]\cdot 0.5MeOH$ (**6**) was obtained from a basic aqueous solution of $CoCl_2$, malonic acid and bis(*N*-imidazolyl)methane. X-ray diffraction analysis revealed that the cobalt centers are interlocked

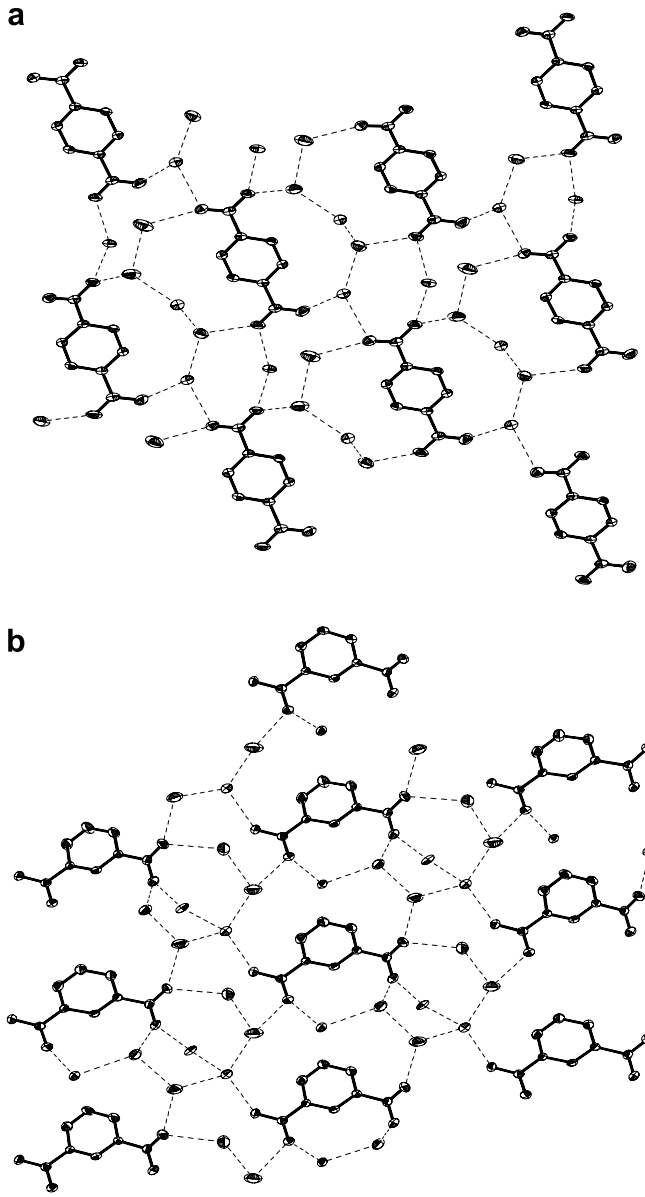

Fig. 4. Perspective view of the 2D corrugated sheets of hydrated dicarboxylates connected by hydrogen bonds. Metal ions and all carbon, nitrogen atoms other than the anions are omitted: (a) p-$C_6H_4(CO_2^-)_2 \cdot 4H_2O$ in **3**; (b) m-$C_6H_4(CO_2^-)_2 \cdot 5H_2O$ in **4**.

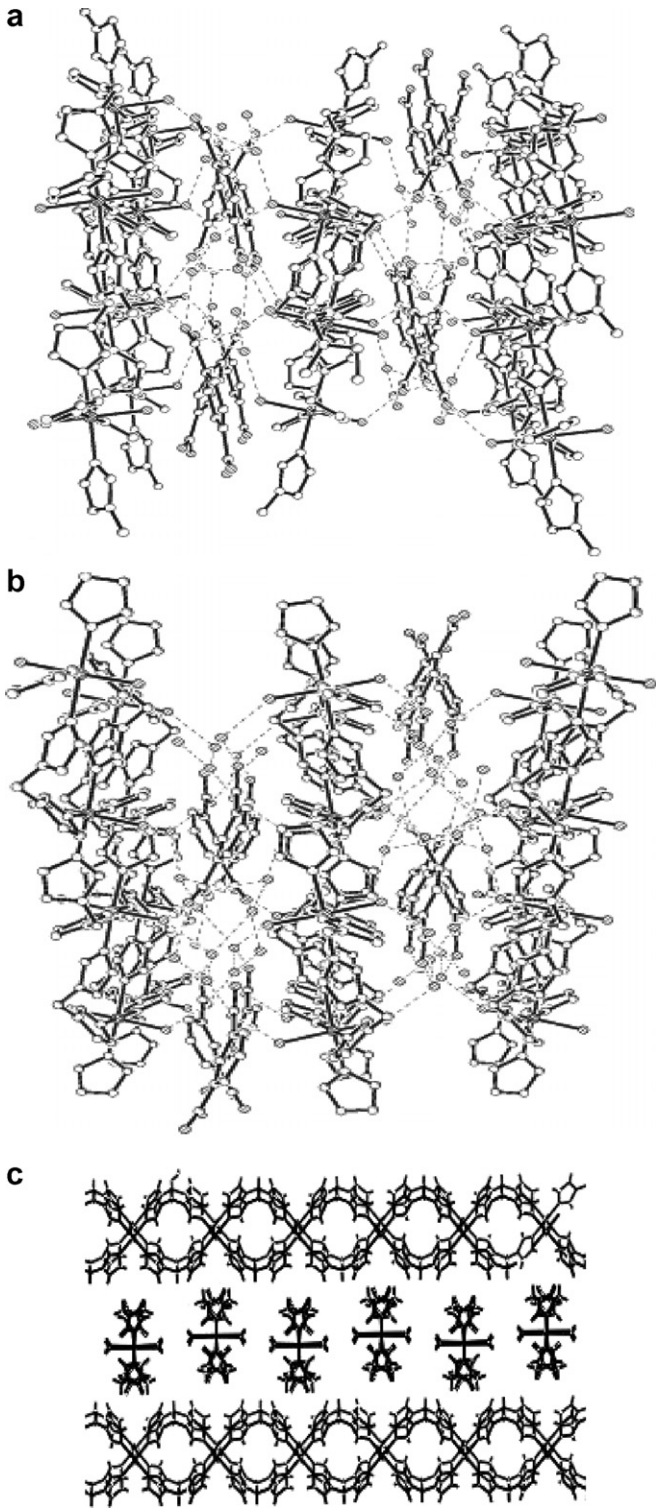

Fig. 5. (a) Space arrangement of intercalated cationic layers and anions layers in **3** (viewed along the c-axis). (b) Space arrangement of intercalated cationic layers and anions layers in **4** (viewed along the c-axis). (c) Chain arrangement of **5** (viewed along the a-axis).

by malonate ligands, giving an infinite two-dimensional network structure, as shown in Fig. 6b. The Co atom is six coordinated in a compressed octahedral environment. Two imidazolyl nitrogen donors coordinate to the center metal with Co–N distances of 2.118(4) and 2.131(3) Å. Another four sites are occupied by four oxygen atoms, one from a water molecule, others from carboxylate groups of two different malonate anions with Co–O distances ranging from 2.092(3) to 2.125(3) Å. The Co–O_w distance, being 2.093(3) Å, is slightly shorter. The malonate anion coordinates to one metal ion in a chelating form with two of the four oxygen atoms, and further bridges the second metal ion with one of the remaining two oxygen atoms (Fig. 6a). This coordinating mode has only been observed in a few examples [36]. Thus compound **6** may be viewed as an aggregate of the dimeric unit $[Co_2(mal)_2(L_1)_2]$ in which two Co centers are doubly bridged by two bis(N-imidazolyl)methane ligands. The dimeric units are

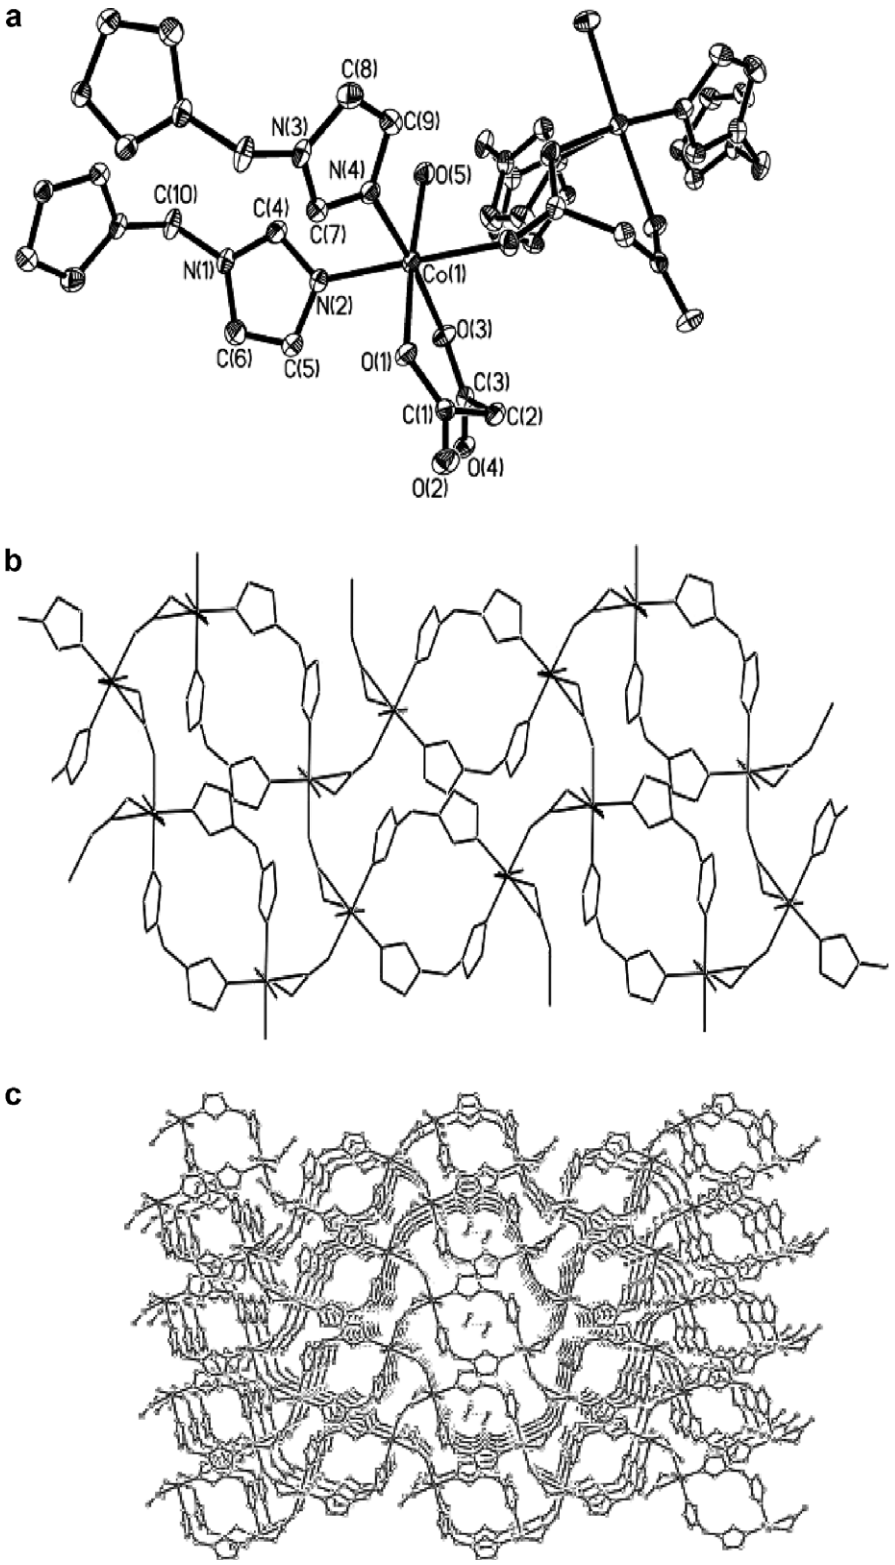

Fig. 6. (a) Structure of **6** showing the coordination environment of the metal atom with the atomic numbering scheme. (b) A segment of the 2D sheet. (c) Three-dimensional network structure showing the microchannels built by the parallel chains.

further held together via malonate anions in a μ_3 mode. This linkage leads to the construction of a two-dimensional sheet structure (Fig. 6b). Another oxygen atom O(2) forms a hydrogen bond with a crystal lattice water molecule with an O(2)···O(5w) distance of 2.712(4) Å.

The hydrogen atoms of the coordinated water and free water molecules are engaged in hydrogen bonding interactions with the oxygen atoms of the malonate anions, resulting in the formation of a three-dimensional channel structure, viewed down the *a*-axis as shown in Fig. 6c.

The short O···O contacts arising from hydrogen bonding are in the range 2.712(4)–2.985(8) Å.

3.2.4. 2D polymeric double sheet of [Co(pdc)(L_1)(H_2O)] (7)

The cobalt compound was prepared in the same manner as for the copper complex **2**. The structure of compound **7**, shown in Fig. 7a, is different from that observed for **6**. The structural analysis revealed that the coordination environment of the cobalt ion is a distorted octahedron surrounded by a 2,6-pyridinedicarboxylate and a water molecule in its equatorial positions, and the two axial positions are occupied by two imidazolyl rings. The Co–$N_{pyridyl}$ bond distance (2.060(3) Å) is shorter than that of Co–$N_{imidazolyl}$ (2.146(3) Å), and other bond distances are normal. The planar [Co(pdc)(H_2O)] units are linked to each other by bis(*N*-imidazolyl)methane, and this coordination mode generates a one-dimensional neutral polymeric chain structure.

The one-dimensional chains are arranged in a parallel fashion in the *ab*-plane. The adjacent chains interact with each other owing to the formation of hydrogen bonds between the coordinated waters. Such an arrangement generates an infinite two-dimensional double sheet structure in the *ab*-plane. These sheets stack into a layered structure as shown in Fig. 7b. The O3–H···$O3^i$ distance (symmetry

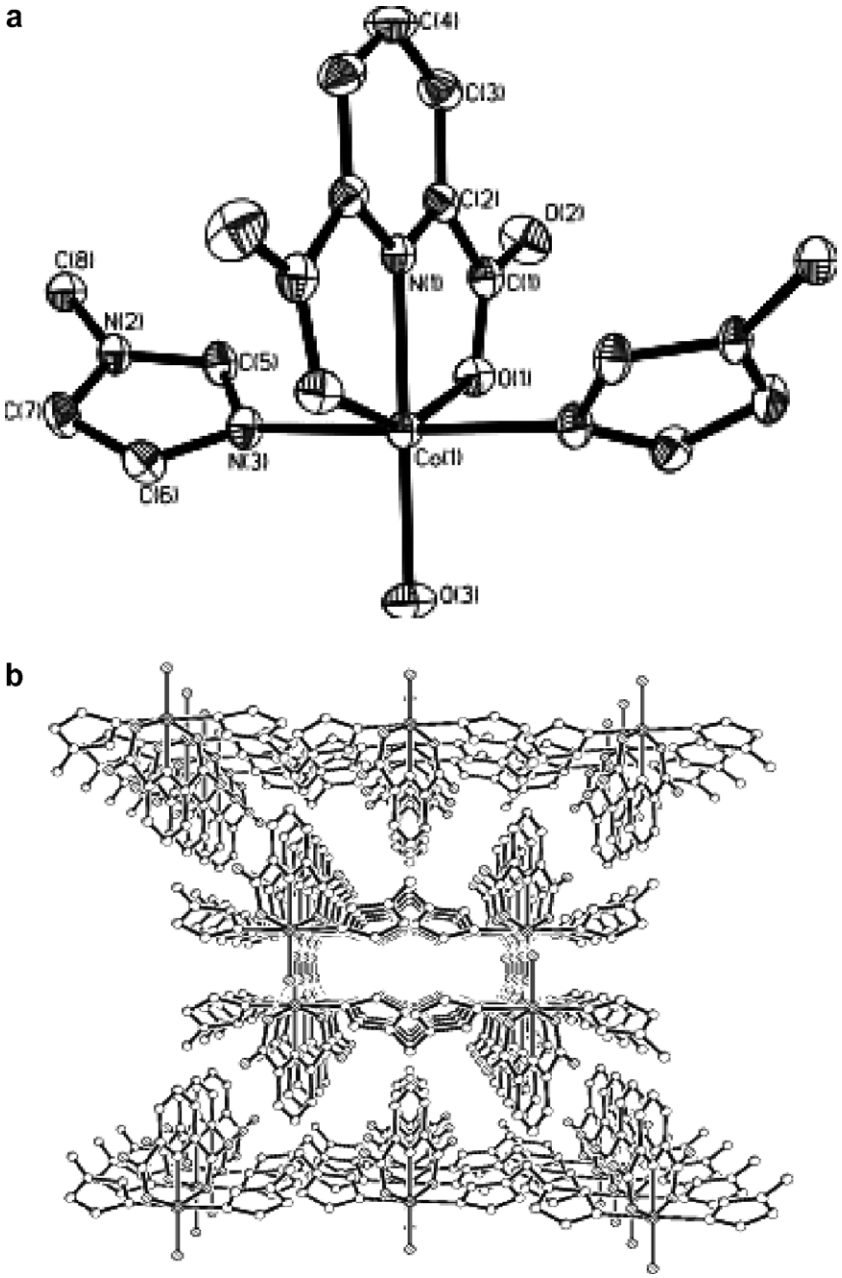

Fig. 7. (a) Local coordination environment of cobalt in polymer **7**. (b) The packing arrangement of the double sheet structure linked by hydrogen bonds between coordinated water molecules viewed down the *c*-axis.

code: i $x, -y+1, z+1/2$) is 2.723(3) Å with an almost linear geometry (169.5°). The intra-sheet Co···Co distance is 4.961 Å, illustrating that the chains are closely connected.

3.3. Thermal properties

The thermogravimetric analysis showed that the coordination polymers **2**–**5**, displaying a one-dimensional chain motif, and the dinuclear complex **1** normally begin to lose either their coordinated or uncoordinated water molecules at a relatively low temperature, ranging from 51 to 117 °C. Complex **1** is the least stable and decomposed at 179 °C, and the weight loss of 20.46% (calc. 20.92%) corresponds to the loss of one L_1 ligand in the temperature range of 179–192 °C. Higher temperature led to complete decomposition with the weight loss of 45.11% (calc. 45.79%) corresponding to one L_1 ligand and two oxalate anions in the range of 215–255 °C. The molecular structure of **2** began to collapse at 250 °C, and the weight loss of 48.56% in the range of 250–350 °C corresponds to the loss of L^2 (calc. 48.63%). Complex **3** begins its decomposition at 231 °C. The weight loss between 231 and 253 °C is attributed to the loss of one L_1ligand (obsd. 23.15%, calc. 23.59%), and finally at 350 °C it decomposed completely to yield metal oxide. Complex **4** began its decomposition at 303 °C, and the weight loss of 22.15% (calc. 22.94%) corresponds to the loss of one L_1 ligand in the range 303.9–309.9 °C. For complex **5**, the weight loss of 23.43% (calc. 23.75%) corresponds to the loss of two L_1 ligands in the range 202–235 °C, and another weight loss of 36.40% (calc. 36.91%) corresponds to the loss of two L_1 ligands and one tp anion in the range 287–295 °C.

In contrast to the one-dimensional chain compounds, complexes **6** and **7**, having two-dimensional layered structures, are much more stable. They began to lose their uncoordinated or coordinated water molecules at 162.1–196.5 °C for **6** and 209.1–243.2 °C for **7**. For **6**, the weight loss of 29.21% (calc. 29.72%) corresponds to the decomposition of one malonate ligand in the temperature range 242.3–295.5 °C, whereas **7** releases its L_1 ligand (obsd. 37.48%, calc. 37.93%) in the temperature range 310.3–380.7 °C. The above data clearly demonstrated that the 2D structures are more thermally stable.

4. Conclusion

A series of Cu(II), Ni(II) and Co(II) coordination polymers with different topologies have been synthesized and structurally characterized. The different coordination modes of the dicarboxylate anions, due to their different chain length, rigidity and diimidazolyl functionality, lead to a wide range of different coordination structures. The dicarboxylates can be coordinated or act as anions. The coordination polymers exhibit 1D single chain, ladder, 2D sheet and 3D network structures. The aliphatic and aromatic dicarboxylates can adopt chelating μ_2 bridging μ_2 and chelating-bridging μ_3 coordination modes, or act as uncoordinated counter anions. The central metal ions are coordinated in N_2O_4, N_4O_2, N_2O_3 and N_3O_3 fashions depending on the ancillary ligands. Both bis(*N*-imidazolyl)methane and 1,4-bis(*N*-imidazolyl)butane act as bidentate bridging ligands. The results illustrate that it is quite feasible to prepare various coordination polymers of diverse network structures by utilization of flexible dicarboxylates and diimidazolyl compounds as building blocks. The employment of flexible ligands does not inevitably yield 3D interpenetrated structures. The structural features observed within the seven polymers presented above tell that desirable functional materials of various structural motives can be achieved through the selection of suitable flexible ligands.

Abstract

The copper(II) polymer Cu(2-qic)Cl (2-qic = quinoline-2-carboxylate) was synthesized and then characterized by X-ray crystal structure determination, spectroscopic and magnetic studies. The crystal structure consists of copper(II) ions with two different chromophores: four-coordinated in a square-planar geometry and five-coordinated in an environment between square-pyramidal and trigonal-bipyramidal. The copper ions are bridged sequentially through the carboxylate groups in a *syn–anti* conformation, forming an infinite one-dimensional zigzag chain with two alternating non-equivalent copper(II) chromophores. The chloride atom acts as a single chloro-bridge link to adjacent chains, forming a ribbon type structure (1D). The variable-temperature (1.8–300 K) magnetic susceptibility data of the complex were interpreted with the dimer law using the molecular field approximation. The results obtained indicate a very weak ferromagnetic ($J_2 = 0.37\ cm^{-1}$) interchain interaction through the *syn–anti* carboxylate bridge. A relatively strong antiferromagnetic interaction, transmitted through the chloro-bridge with an exchange coupling of $J_1 = -57.0\ cm^{-1}$, dominates the magnetic properties of this complex. The magnitude and the nature of the exchange coupling are explained on the basis of the structural results.

1. Introduction

Structural and magnetic studies of binuclear and polynuclear complexes containing monoatomic and multidentate bridging ligands are of considerable interest from the standpoint of inorganic and bioinorganic chemistry [1–3]. Particularly interesting is the phenomenon of interaction between metal centers, which is important for the physics of magnetic materials. Much attention has been focused on the magneto-structural correlation and the exchange mechanism [4,5]. In particular, the coordination chemistry of copper(II) complexes containing carboxylates is interesting from structural and magnetic points of view. Copper(II) carboxylates are structurally a very diverse group of coordination compounds due to the various coordination modes of the carboxylate ligands. From a magnetic point of view, the range of magnetic behaviors as a function of different coordination modes was pointed out: from strongly coupled to moderate or weak antiferromagnetic compounds and even ferromagnetic ones [6]. It should be underlined that complexes containing *syn–anti* carboxylate bridges are still few and show unique magnetic properties [6–11].

Singly and doubly chloro-bridged copper(II) systems (singly chloro-bridged chains and doubly chloro-bridged dimers and chains) have become a very active subject of research in the last three decades. For such systems some theoretical analyses [12] and magneto-structural ideas have been presented [4,13,14]. However, no simple magneto-structural relationship has been established relating the value of the magnetic exchange constant J to the Cu–Cl–Cu bonding angle, Cu–Cl or Cu···Cu distances. This may be due to a large variation in structural features observed, together with the fact that chloride possesses both p and d orbitals which may participate in creating

doi:10.1016/j.poly.2007.02.013

an exchange pathway. In contrast to the above chloro-bridged Cu(II) compounds, dinuclear Cu(II) complexes involving only one chloride bridge are rare [15,16] and therefore are of special interest.

It is interesting to note that although some structural analyses of Cu(II) complexes with linear and near linear Cu–Cl–Cu bridging systems have been reported [15–17], only two such Cu(II) compounds, to the best of our knowledge, have been magnetically investigated and characterized so far [15,16].

In this work, we present a synthesis, the spectral and magnetic properties, and the X-ray single-crystal analysis of a new copper(II) compound with a quinoline-2-carboxylate ligand of the formula Cu(2-qic)Cl, where 2-qic = quinoline-2-carboxylate. This complex is an example of a polynuclear copper(II) compound based on *syn–anti* carboxylato-bridges and linear μ_2-chloro bridging motifs.

It is worth noting that recently we have determined the magnetic properties of a polynuclear copper(II) compound with pyridine-2-carboxylate, of the formula Cu(pyridine-2-carboxylate)Cl [6]. The crystal structure of the two-dimensional (2D) polymeric compound consists of a dinuclear $Cu_2(\mu\text{-}Cl)_2$ moiety interconnected with Cu_4 units containing single *syn–anti* carboxylate bridges. The copper ions within a given layer are coupled ferromagnetically.

From the synthetic and structural points of view, it is interesting that both these compounds (i.e. that with the picolinate [6] and the quinaldinate ligands) were obtained in an unusual oxidative P-dealkylation/dephosphorylation reaction. Unfortunately, in this reaction we have not succeeded in preparing crystals suitable for X-ray studies of Cu(quinoline-2-carboxylate)Cl. Therefore, here we describe the results of a structural and magnetic investigation of the Cu(2-qic)Cl compound obtained directly from quinaldinic acid. The results of the studies of the structural and magnetic properties are presented, and possible magneto-structural correlations are discussed.

2. Experimental

2.1. Reagents and physical measurements

Starting materials and solvents for the synthesis were obtained commercially and were used as received. The metal content was determined using a Carl-Zeiss-Jena atomic absorption spectrophotometer. Elemental analyses were carried out using a Perkin–Elmer elemental analyzer 2400CHN.

Infrared spectra (100–4000 cm^{-1}) were recorded on a Bruker IFS 113v spectrophotometer using KBr pellets, and solid-state electronic spectra (28 000–4000 cm^{-1}) were performed on a Cary 500 spectrophotometer.

Solid-state EPR spectra were recorded at room temperature and at 77 K on a Bruker ESP 300E spectrometer operating at X-band and equipped with a Bruker NMR gaussmeter ER 0.35 M and a Hewlett–Packard microwave frequency counter HP 5350B. The spectrum at 4.5 K was measured with an X-band radiopan SE/X 2543 spectrometer.

Magnetic measurements of a polycrystalline sample were carried out with a Quantum Design SQUID magnetometer (MPMSXL-5 type). The measurements were recorded at a magnetic field of 0.5 T over the temperature range 1.8–300 K. The correction for diamagnetism of the experimental susceptibility was based on subtracting the sample-holder signal and estimating the contribution χ_D from Pascal constants [18]. The effective magnetic moments were calculated from $\mu_{eff} = 2.83(\chi_M T)^{1/2}$, using a temperature-independent paramagnetism of 60×10^{-6} cm^3 mol^{-1} for Cu(II).

2.2. X-ray crystallography

Crystal data are given in Table 1, together with the refinement details. X-ray data were collected at low temperature using an Oxford Cryosystem device on an Xcalibur PX κ-axis diffractometer with graphite-monochromated Cu Kα radiation ($\lambda = 1.5418$ Å) and an Onyx CCD camera. The crystal was positioned at 85 mm from the CCD camera. Frames (1872) were measured at 1.0° intervals with a counting time of 60 s. Accurate cell parameters were determined and refined by a least-squares fit of 3600 strongest reflections. The data were corrected for Lorentz and polarization effects. An analytical absorption correction was also applied. Data reduction and analysis

Table 1
Crystal data and structure refinement for Cu(2-qic)Cl

Empirical formula	$C_{10}H_6NO_2ClCu$
Formula weight	271.15

Largest difference in peak/hole (e Å^{-3})	1.31/−0.604

were carried out with Oxford Diffraction (Poland) Sp. z o.o. programs. The structure was solved by direct methods (program SHELXS97 [19]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL97 [20] program. Non-hydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms were included from the geometry of molecules and $\Delta\rho$ maps. They were refined with isotropic displacement parameters as riding atoms.

2.3. Synthesis

$CuCl_2 \cdot 2H_2O$ (1.5 mmol) dissolved in ethanol (50 cm^3) was added to a solution of quinaldinic acid (1 mmol) in ethanol (50 cm^3). The resulting green solution was filtered and left to evaporate slowly at room temperature. Green monocrystals suitable for X-ray determination were collected after three weeks. This compound is insoluble in most common organic and inorganic solvents.

Anal. Calc. for $C_{10}H_6CuNO_2Cl$: C, 44.29; H, 2.23; N, 5.17; Cu, 23.43. Found: C, 44.32; H, 2.22; N, 5.45; Cu, 23.71%.

3. Results and discussion

3.1. Crystal structure

Crystallographic parameters are summarized in Table 1. Selected bond distances and angles are listed in Table 2.

A fragment of the structure of Cu(2-qic)Cl (2-qic = quinoline-2-carboxylate), showing the local coordination environment of the Cu(II) ions with the crystallographic numbering, is depicted in Fig. 1.

2-Qic acts as a didentate N,O-bonded chelate ligand, coordinating through the quinoline nitrogen and a carboxylate oxygen atom, forming a five-membered ring. The second carboxylate oxygen is involved in coordination to the copper ion of an adjacent molecule (Fig. 1). The crystal structure consists of copper(II) ions bridged sequentially through carboxylate groups in a *syn–anti* conformation, forming an infinite one-dimensional zigzag chain with

Symmetry transformations used to generate equivalent atoms: $A = -x, -y+1, -z+1$; $B = -x, y, -z+1/2$; $C = -x, y, -z+3/2$.

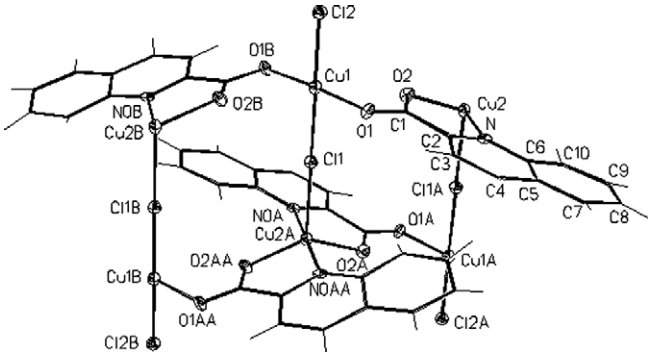

Fig. 1. Fragment of the structure of Cu(2-qic)Cl showing the local environment of the Cu(II) ions and the atomic numbering. Hydrogen atoms are omitted for clarity.

two alternating non-equivalent copper(II) chromophores. The Cu···Cu distance of 4.640(1) Å is in the near range of the reported values of ca. 5 Å observed for polyatomic bridges [21]. Chloride atoms link adjacent chains, forming a ribbon type structure (Fig. 2) extended along the *z*-axis (Cu···Cu distance of 4.860(3) Å). Parallel pyridine rings are stacked. The perpendicular distances between the parallel pyridine rings are 3.3 Å. The crystal packing is depicted in Fig. 3.

As mentioned above the copper(II) ions exhibit two different coordination polyhedra. The Cu(1) atom is in a nearly square-planar geometry, which is clearly demonstrated by the Cl(1)–Cu(1)–Cl(2) and O(1)–Cu(1)–O(1B) angles of 180° and 176.5(3)°, respectively. This geometry is formed by two chloride atoms, bridged Cl(1) and terminal Cl(2), and two carboxylate oxygens atoms, O(1) and O(1B), belonging to adjacent molecules (CuO_2Cl_2 chromophore). The Cu(1)–O(1) distance is 1.983(6) Å. The Cu(1)–Cl(1) and Cu(1)–Cl(2) distances of 2.349(4) and 2.232(4) Å, respectively, are different from each other. The Cu(1)–Cl(2) bond length is typical of a terminal Cu–Cl bond [22]. The geometry around Cu(2) involves a strongly distorted five-coordinate stereochemistry, intermediate between two ideal geometries: square-pyramidal and trigonal-bipyramidal (CuN_2O_2Cl chromophore). This is consistent with the calculation of the structural parameter $\tau = 0.64$ (τ is defined as $(\beta - \alpha)/60$, where β and α are the largest coordination angles). A regular trigonal-bipyramid (TBP) and square-based pyramid (SP) have τ values of 1 and 0, respectively [23]. In the trigonal-bipyramidal description of the environment around Cu(2), the basal plane is defined by the O(2), O(2C) and bridging Cl(1A) atoms, while the N and N(C) atoms occupy apical positions. The pseudotrigonal axis does not show too much distortion from linearity. The N–Cu(2)–N(C) angle is 178.2(4)°. However, the angles in the equatorial plane depart significantly from the theoretical 120° value, being 110.17(18)°, 110.17(18)° and 139.7(4)°. Therefore, the coordination geometry is best described as a distorted tetragonal-pyramid. In this model, the equatorial plane is composed of O(2), O(2C), N and N(C). The N–Cu(2)–N(C) and O(2)–Cu(2)–O(2C) angles

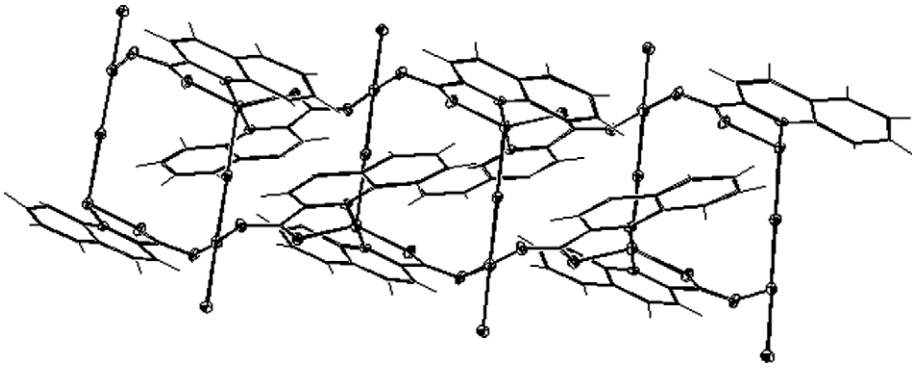

Fig. 2. View of the structure of Cu(2-qic)Cl along the crystallographic *z*-axis.

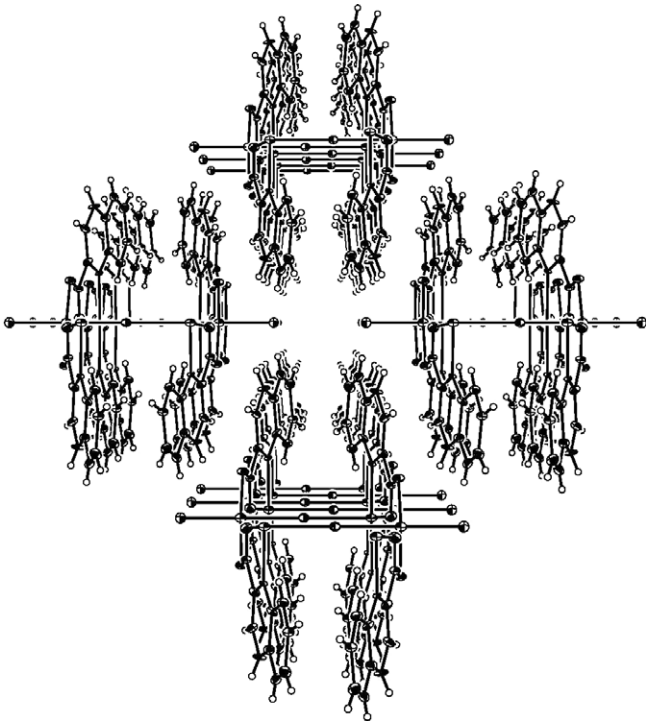

Fig. 3. Crystal packing of Cu(2-qic)Cl.

of the basal plane are 178.2(4)° and 139.7(4)°, respectively. Also, the observed bond distances are in better agreement with a tetragonal-pyramidal model involving long apical Cu(2)–Cl(1A) bonding of 2.513(4) Å. If the coordination of Cu(2A) is described in terms of a square-pyramidal geometry, the plane of Cu(1) is perpendicular to the equatorial plane of Cu(2A) (O_2N_2 set of donor atoms), i.e. the planes are approximately oriented at 90° to each other. This angle leads to a Cu(1)–Cl(1)–Cu(2A) bridging angle of 180°. The Cu(1)–Cl(1) bond distance [2.349(4) Å], is shorter than the Cu(2A)–Cl(1) bond length [2.513(4) Å], which is consistent with the lower coordination number for Cu(1). The Cu(2A)–Cl bond length [2.513(4) Å] is in the range observed for the few reported Cu(II) complexes with a linear μ_2-chloro-bridging motif [17].

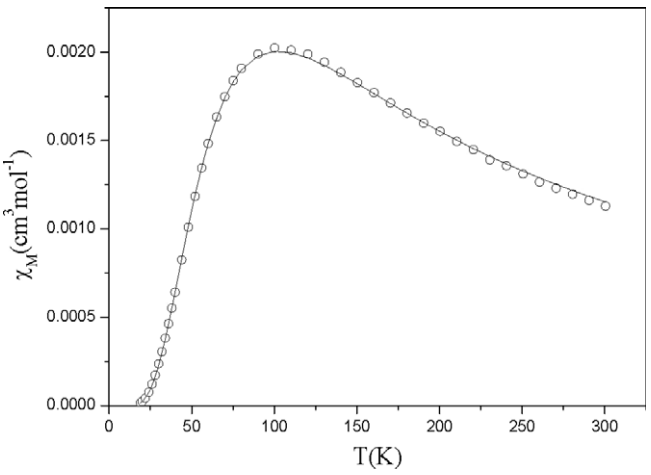
Regarding the carboxylate group, the Cu–O–C–O–Cu′ bridges are planar. Furthermore, the two C–O distances [1.264(10) and 1.252(10) Å] and the related Cu–O distances [1.983(6) and 1.976(5) Å] are nearly identical.

3.2. Spectroscopic properties

This compound shows strong carboxylate stretching frequencies ν_{as}(COO) and ν_s(COO) at 1600 and 1413 cm^{-1}, respectively, in the range characteristic of copper(II) carboxylate compounds [24,25]. The observed $\Delta\nu$ separation value of 187 cm^{-1} is in the range expected for a bridging carboxylate group. According to Nakamoto, $\Delta\nu$ values of ca. 180 cm^{-1} are generally associated with classical carboxylate bridges Cu–O–C–O–Cu [26]. The very strong bands at 290 and 184 cm^{-1} are tentatively assigned to Cu–Cl vibrations, suggesting the presence of terminal and bridging chlorides [27,28].

The ligand field spectrum shows poorly resolved broad-band envelopes with a shoulder at ca. 14.0×10^3 cm^{-1} and a band at 11.8×10^3 cm^{-1}. This broad envelope may be the result of the presence of two different copper chromophores [29].

The polycrystalline EPR spectrum reveals a very broad isotropic signal with *g* equal to 2.12 at 293, 77 and 4.2 K. This broad unresolved signal can be due to a narrowing



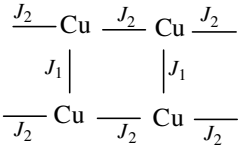


Fig. 4. Plot of the experimental χ_{Cu} (○) and calculated χ_{Cu} (—) *vs.* temperature for Cu(2-qic)Cl.

exchange, as well as to the fact that the compound contains two different copper sites. There are no signals concerning the $\Delta M_s = \pm 2$ transition.

3.3. Magnetic properties

The variable-temperature magnetic susceptibility data (1.8–300 K) illustrated in Fig. 4 show a broad maximum in χ_{Cu} near 90 K, which is consistent with strong antiferromagnetic coupling.

The crystal structure of Cu(2-qic)Cl suggests that two kinds of coupling parameters must be considered to interpret the magnetic properties, according to the scheme:

where J_1 and J_2 are the constants for exchange coupling via the mono-μ-chlorobridge in the dimeric unit and the carboxylate bridge in the chain, respectively. Experimental data from 300 down to 24 K have been fitted with the dimer law with a molecular field correction in order to account for interdimer interactions of the complex. Therefore, for two exchange coupled copper(II) ions the Bleaney–Bowers equation (1) was used with a molecular field correction (2) [30–32]:

$$\chi_{Cu} = \frac{Ng^2\beta^2}{3kT}[1 + 1/3\exp(-2J/kT)]^{-1} \quad (1)$$

$$\chi^{exp} = \frac{\chi_{Cu}}{1 - (2zJ'/Ng^2\mu_B^2)\chi_{Cu}} \quad (2)$$

where χ^{exp} is the measured magnetic susceptibility, $zJ' = z J_2$ is the interdimer exchange parameter, and z is the number of nearest neighbours. Within the frame of this approximation, with the interaction Hamiltonian $H = -J\widehat{S}_1 \cdot \widehat{S}_2$, the best-fit parameters obtained by least-squares fit through Eq. (2) are as follows: $J_1 = -57.0\ cm^{-1}$, $zJ_2 = 1.47\ cm^{-1}$ ($z = 4$), $g = 2.09$ with an R value of 1.61×10^{-6}, where R is the agreement factor defined as

$$R = \sqrt{\sum \frac{1}{(\chi_i^{exp})^2}(\chi_i^{exp} - \chi_i^{calc})^2 / \sum \frac{1}{(\chi_i^{exp})^2}}$$

A satisfactory match of the experimental data is obtained through this approach, as shown in Fig. 3. The fitted g value is lower than the g value of 2.12 obtained by EPR, but as the EPR spectrum gives a very broad unresolved signal, no accuracy can be given on that observed spectroscopic splitting factor value.

3.4. Magneto-structural correlations

Weak antiferromagnetic or ferromagnetic interactions are observed in these carboxylato bridged copper(II) complexes in which the carboxylate adopts the *syn–anti* conformation, as has been shown in the few well-characterized copper(II) complexes [6].

Examination of the magneto-structural data of well-characterized copper(II) complexes in which the carboxylate adopts the *syn–anti* conformation indicates that weak ferromagnetic or antiferromagnetic coupling depends on the structural features of the Cu–O–C–O–Cu′ bridge and the coordination geometry of the exchange-coupled copper ions. As indicated by the structural data, the geometry of the Cu(1) polyhedron is square-planar. In such a geometry, the ground state of the copper ion is adequately described by the $d(x^2 - y^2)$ orbital. Thus, the unpaired electron localized in the $d(x^2 - y^2)$ orbital is pointing along the Cu–O direction in the equatorial plane. However, the geometry of the Cu(2) polyhedron is intermediate between square-pyramidal and trigonal-bipyramidal. In this case, the orbital ground state of the copper ion should have a significant admixture of the $d(x^2 - y^2)$ and $d(z^2)$ orbitals. Because of low site symmetry of the Cu(2) ion between D_{3h} and C_{4v}, it is difficult to attribute the exchange interactions to a specific pathway. The low symmetry of the Cu(2) chromophore ($C_{4v} \leftrightarrow D_{3h}$) causes a weak delocalization of the magnetic orbital on the oxygen atom of the carboxylate bridge from the Cu(2) atom in contrast to the magnetic orbital on Cu(1) directly delocalized toward the 2p oxygen orbital of the COO bridge. For a *syn–anti* carboxylate bridged copper(II) ion with very low symmetries of the coordination environment of both copper ions ($\tau = 0.39$), a very weak ferromagnetic coupling ($J = 0.38\ cm^{-1}$) has been obtained by us before [6]. Finally, the weak ferromagnetic interaction through the *syn–anti* carboxylate bridge observed for our compounds is expected in the light of the above structural and electronic features.

In almost all mono-chloride bridged Cu(II) complexes reported so far, the copper coordination geometries observed are distorted square-pyramidal, and the cases in which the coordination environment of the Cu(II) ions is trigonal-bipyramidal or octahedral are quite rare [35]. The environment of the Cu(II) ions in the compound studied here shows different geometries, viz. one intermediate between square-pyramidal and trigonal-bipyramidal, and the other square-planar.

As mentioned earlier, Cu(II) complexes with a linear Cu–Cl–Cu bridging system are known, and in accordance with a qualitative explanation provided by the Goodenough–Kanamori rules [33] and the Anderson model [34] for the linear bridge, antiferromagnetic coupling is expected. Up until now, to the best our knowledge, only two Cu(II) compounds with a nearly (177.35°) [15] and a strictly [16] linear Cu–Cl–Cu bridge have been characterized structurally and magnetically. In these compounds, the Cu(II) ions have almost perfect square-pyramidal geometry (reflected by the τ parameter being <0.1), and the exchange pathway through the Cu–Cl–Cu chloride bridge involves a chloride ion in the axial position on both copper atoms. Because the magnetic orbital of the

copper(II) is mainly delocalized in the equatorial plane, a very weak spin density is expected on its axial position. In fact, very weak antiferromagnetic exchange couplings, with J values of $-1.30\ cm^{-1}$ [15] and $-0.86\ cm^{-1}$ [16], have been observed.

From a magnetic point of view, it is interesting that the antiferromagnetic exchange coupling in Cu(2-qic)Cl, transmitted by the bridging chloride ion with the value of $J = -52\ cm^{-1}$, is the strongest observed for chloro-bridged systems up to now. The exchange pathway in the linear Cu–Cl–Cu system in the studied compound involves an equatorial position on the Cu(1) (see structure). Because the magnetic orbital of the Cu(1) is located in the equatorial plane, in this case its spin density on the bridge is expected to be large. Owing to the fact that the Cu(1)–$Cl(1)_{eq}$ pathway in Cu(2-qic)Cl is more effective in allowing for spin delocalization than the Cu–Cl_{ax} pathway in the mono-chloro-bridged dimers of an axial(apical)–axial(apical) type cited above [15,16], an increase of the antiferromagnetic exchange transmitted through the bridging chloride ion in our compound is expected.

On the other hand, distortion from a square-pyramidal towards a trigonal-bipyramidal copper coordination geometry is expected to increase the spin density on the bridge, and calculation on a hypothetical mono-chloro-bridged copper(II) dimer have predicted an increase of the antiferromagnetic coupling as such a distortion proceeds [12]. Therefore, the distortion from the square-pyramidal to the trigonal-bipyramidal geometry (reflected by the τ parameter of 0.64) coordination environment of Cu(2) may play a significant role in the coupling. As a result of the distortion, an increase of the antiferromagnetic interaction in Cu(2-qic)Cl can be expected in comparison to the mono-chloro-bridged linear dimer with an almost perfect square-pyramidal geometry about the copper(II) cited above [16].

Finally, although more examples of complexes like Cu(2-qic)Cl with linear Cu–Cl–Cl bridges are needed for a meaningful magneto-structural correlation, on the basis of the observed influence of the parameter τ on the value of J for other chloro-bridged systems [13,14] we believe that the latter effect, i.e. the influence of the distortion towards trigonal-bipyramidal geometry on the value of the antiferromagnetic coupling in our compound, should be less important. In other words the τ parameter has a minor influence on the relatively superexchange interaction through the linear chloride bridge. However, mutual orientation of the equatorial planes of Cu(1) and Cu(2A) (see structure) causes that the Cu(1)–$Cl(1)_{eq}$ pathway in the linear Cu(1)–Cl(1)–Cu(2A) bridge is mainly responsible for the observed strength of the magnetic interaction.

One should also pay attention to the fact that the observed strength of the antiferromagnetic exchange through the linear chloro-bridge in our compound ($J = -57\ cm^{-1}$) is the strongest compared to those already published for chloro-bridged systems, in particular those with linear and close to linear chloro-bridges.

In summary, the electronic and structural features of the linear Cu–Cl–Cu bridge in Cu(2-qic)Cl mentioned above are favorable for the propagation of strong interactions, and hence a relatively strong antiferromagnetic coupling between the copper ions transmitted by the chloride bridging atom, despite the large Cu···Cu distance of 4.860(3) Å, is observed.

Abstract

Synthesis and structural characterization of distorted pentagonal bipyramidal Co(II), pseudo-octahedral Ni(II) and Cu(II) complexes of the type $[ML(NO_3)_2]$, {L = *N*-(2-pyridylethyl)pyridine-2-methylketimine} are reported. Characterization includes elemental analysis, spectral, magnetism, and X-ray crystallographic studies. In case of cobalt (**1**) both the nitrates coordinate in bidentate fashion resulting overall distorted pentagonal bipyramidal geometry. In nickel (**2**) and copper (**3**) complexes, bivalent metal ion is coordinated by the three nitrogen atoms of the tridentate **L** with two pyridine-N occupying *trans* positions and amongst the two nitrates one coordinates in a bidentate fashion while other adopts a monodentate fashion. All the complexes exhibit d–d transitions in the visible region. Complex **1** is high-spin in nature and the X-band EPR spectra of **1**, and **3** at room temperature and 77 K are reported.

1. Introduction

The coordination chemistry of Schiff base is vast since its first report [1–3]. The imine function in combination with other functions is useful for metal binding, as they can easily be derived from suitable carbonyl groups (aldehyde or ketone) and primary amines. Design and construction of molecular architectures and supramolecular macrocycles having imine as well as pyridyl groups are of considerable attention [4–13]. The coordination chemistry and tyrosinase activity of tridentate Schiff base ligand containing pyridine rings are reported [14–22]. Recently we have reported that one such a tridentate Schiff base containing pyridyl function, *N*-(2-pyridylmethyl)pyridine-2-methylketimine, readily converted to 4′-(2-pyridyl)-2,2′:6′,2″-terpyridine in the presence of $Cu(NO_3)_2 \cdot 3H_2O$ [13]. This prompted us to explore the metal chemistry of *N*-(2-pyridylethyl)pyridine-2-methylketimine. In this article, we report the synthesis, spectra, and structural studies of $[ML(NO_3)_2]$, where M = Co(II), Ni(II), Cu(II), and **L** = N-(2-pyridylethyl)pyridine-2-methylketimine.

2. Experimental

2.1. Instrumentation and methods

UV–Vis spectra were recorded in a Perkin–Elmer Lambda 25 spectrometer. A Perkin–Elmer Spectrum One spectrometer was used to record FT-IR spectrum in the range 4000–400 cm^{-1}. ^1H NMR spectrum was recorded on a Varian Mercury plus 400 MHz NMR Spectrometer. Elemental analysis was performed by a Perkin–Elmer Series II CHNS/O Analyzer 2400. The EPR spectra were recorded on a JEOL JES FA-200 X-band EPR spectrometer. $Co(NO_3)_2 \cdot 6H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$ were purchased from Merck India Ltd. and 2-acetylpyridine, 2-(2-aminoethyl)-pyridine from M/S Aldrich, USA.

All the chemicals and solvents were of reagent grade and were used as received without further purifications.

2.1.1. X-ray crystallography

X-ray crystallographic data were collected using Bruker SMART APEX-CCD diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å). The intensity data were corrected for Lorentz and polarization effects and empirical absorption correction was applied using SAINT program [23,24]. All the structures were solved by direct methods using SHELXS-97 [25]. Non-hydrogen atoms located from the difference Fourier maps were refined anisotropically by full-matrix least squares on F^2, using SHELXL-97 [25]. The hydrogen atoms were included in the calculated positions and refined isotropically using a riding model.

2.2. Syntheses

*N-(2-Pyridylethyl)pyridine-2-methylketimine (**L**).* To anhydrous $MgSO_4$ (2.5 g) suspended in 30 mL of CH_2Cl_2, 2-(2-aminoethyl)-pyridine (283 mg, 2.31 mmol) and 2-acetylpyridine (281 mg, 2.31 mmol) were added and heated at reflux for 1.5 h. The solution was then stirred at ambient temperature for another 3 h, filtered, washed with 2×10 mL portions of CH_2Cl_2 and the volatile components in the combined solution were removed by evaporation in vacuum. The crude product was obtained as yellowish oil, which is pure enough as inferred from the ^{1}H NMR spectrum and was used without further purification. Yield: 385 mg (74%). ^{1}H NMR (δ (*J*, Hz), $CDCl_3$): 2.73 (3H, s), 2.92 (2H, t, 6.4), 3.11 (2H, t, 6.6), 7.10 (1H, t, 5.8), 7.15 (1H, d, 7.6), 7.45 (1H, t, 6.6), 7.58 (1H, t, 7.4), 7.81 (1H, t, 8.4), 8.02 (1H, d, 8.0), 8.51 (1H, d, 4.0) and 8.66 (1H, d, 4.8). IR (neat, cm^{-1}): 1639 ($C{=}N_{im}$), 1590 ($C{=}N_{py}$).

*[Co**L**(NO$_3$)$_2$] (**1**).* To $Co(NO_3)_2 \cdot 6H_2O$ (168 mg, 0.58 mmol) dissolved in 50 mL of methanol, **L** (130 mg 0.58 mmol) was added with stirring and after 4 h, the reaction mixture was left to crystallize. Orange block-like crystals deposited were collected and washed with ice-cold methanol. Yield: 0.19 g (80%). IR (KBr, cm^{-1}): 1650 ($C{=}N_{im}$), 1602 ($C{=}N_{py}$). *Anal.* Calc. for $C_{14}H_{15}N_5O_6Co$: C, 41.15; H, 3.67; N, 17.15. Found: C, 41.26; H, 3.69; N, 17.34%.

*[Ni**L**(NO$_3$)$_2$] (**2**)* and *[Cu**L**(NO$_3$)$_2$] (**3**)* were prepared using the same procedure as **1**, in similar yields. For compound **2**: IR (KBr, cm^{-1}): 1645 ($C{=}N_{im}$), 1600 ($C{=}N_{py}$). *Anal.* Calc. for $C_{14}H_{15}N_5O_6Ni$: C, 41.17; H, 3.67; N, 17.16. Found: C, 41.39; H, 3.74; N, 17.44%. For compound **3**: IR (KBr, cm^{-1}): 1650 ($C{=}N_{im}$), 1602 ($C{=}N_{py}$). *Anal.* Calc. for $C_{14}H_{15}N_5O_6Cu$: C, 40.69; H, 3.63; N, 16.96. Found: C, 40.35; H, 3.71; N, 17.14%.

3. Results and discussion

3.1. Electronic spectra

In acetonitrile, **1**, **2**, and **3** exhibit d–d transitions in the visible region. The λ_{max} and their molar extinction coefficient values were obtained after fitting to a Gaussian are listed in Table 1. The complex **1** shows characteristic d–d transitions at 497 and 407 nm. Both **2** and **3** have been established to have a pseudo octahedral geometry by structural studies (*vide infra*). The $^3A_{2g} \rightarrow {}^3T_{2g}$ and $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ transitions in complex **2** appear near 920 and 568 nm, but $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ is not observed, may be it is obscured by the intra-ligand transitions in the higher energy region. The characteristic feature of **3** is, two d–d transitions at 640 and 370 nm. Since the distortion from the perfect octahedral symmetry is present, these can be, respectively, due to $d_{x^2-y^2} \rightarrow d_{z^2}$ and $d_{x^2-y^2} \rightarrow d_{xy}$ transitions. In all the three cases intra-ligand transitions occur in the 315–260 nm region and the molar extinction coefficient of these bands is higher than that observed for the free ligand.

3.2. Magnetism and EPR spectra

The room temperature magnetic moments (Table 1) of **1**, **2**, and **3** is in agreement with the presence of 3 (high-spin Co(II)), 2 and 1 unpaired electrons, respectively. In all the three cases $\mu_{eff} > \mu_{so}$ is consistent with more than half-filled configuration and the trend, $\mu_{S+L} > \mu_{eff} > \mu_{so}$, shows the existence of spin–orbit coupling [26–28]. The X-band (9.44 GHz) EPR data of all the complexes is given in Table 1. In the frozen glass **1** shows a broad single-line spectrum but is not observable at room temperature. At room tem-

perature, **3** in acetonitrile solution exhibits a four-line spectrum (A in Fig. 1), which is due to the presence of hyperfine splitting of the single-line spectrum. However at 77 K, an axial spectrum with splitting due to a slight rhombic symmetry (B in Fig. 1) is present and the trend $g_{zz} > g_{yy} > g_{xx}$ is observable. Hyperfine splitting of the g_{zz} signal is present. These features suggest that the unpaired electron is in the $d_{x^2-y^2}$ orbital [14,15,18,21].

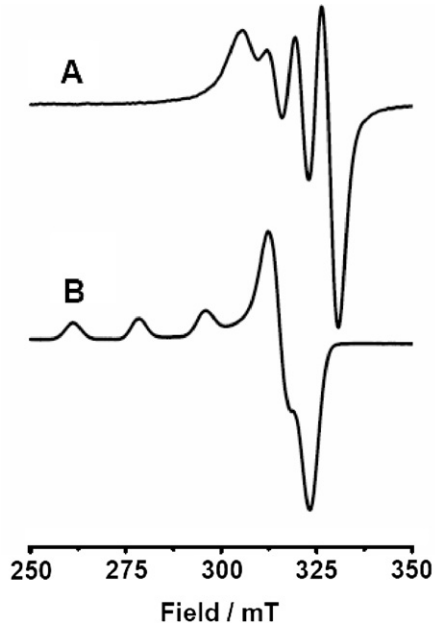

Fig. 1. EPR spectra of **3** in CH_3CN solution (A) at 293 K and in frozen glass (B).

3.3. Molecular structures

The molecular structures of **1**, **2**, and **3** were determined by X-ray crystallography. The crystallographic data and refinement parameters are summarized in Table 2 and selected bond parameters are listed in Table 3. A perspective view of **1** is shown in Fig. 2. The bivalent metal ion in each case, is coordinated by the three nitrogen atoms of the tridentate **L** with two pyridine-N spanning the *trans* positions. In **1** both the nitrates coordinate in a bidentate fashion and consequently the bivalent cobalt adopts distorted pentagonal bipyramidal geometry. The atoms O1, O2, O4, O5, N2 form the pentagonal plane and N1, N3 occupy the apical positions. In **2** and **3**, of the two nitrate ions, one binds in bidentate fashion and the other in a monodentate fashion, resulting in an overall pseudo-octahedral geometry at the metal center. The basal plane contains the O1, O2, O4, N2 and the apical positions are occupied by N1, N3.

The **L** binds the metal ion by a five-membered and a six-membered chelate ring. Five-membered chelate ring is nearly planar in **1**, **2** but deviate from planarity to have an envelope conformation in **3**. Six-membered ring is puckered in all the three complexes. The N1–M–N2 angle of the five-membered chelate ring is 78.2(2)°, 79.8(2)°, and 82.8(8)°, while N2–M–N3 of the six-membered ring is 93.1(2)°, 94.5(2)°, and 93.0(8)°, respectively, in **1**, **2**, and **3**. These angles are deviating significantly from the ideal value 90° due to the sizes of five-membered and the six-membered non-planer chelate rings. Average M–N lengths are shorter by 0.170(5) Å (**1**), 0.119(3) Å (**2**), 0.256(9) Å (**3**) than that of the M–O distances of the bidentate NO_3^-. Bidentate NO_3^- has a longer contact with Ni1 than when it

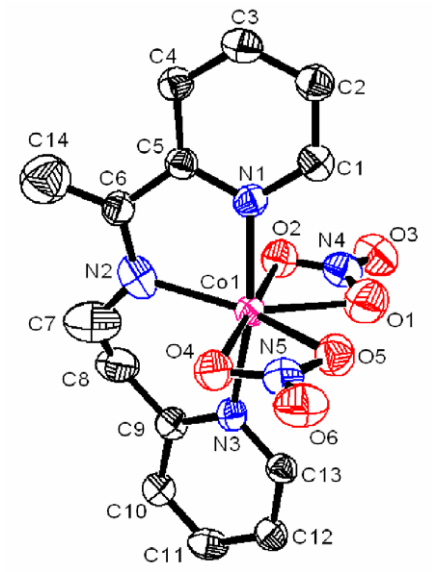

Fig. 2. ORTEP diagram of **1** (30% probability, hydrogens are omitted for clarity).

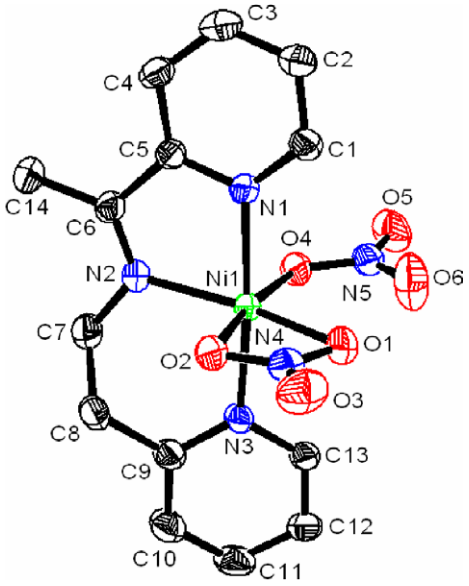

Fig. 3. ORTEP diagram of **2** (30% probability, hydrogens are omitted for clarity).

coordinates with one oxygen atom but it is shorter in case of **3**. In **1** the NO_3^- chelate bite angles are 52.8(2)° and 55.3(2)°, while in **2** and **3** it is 58.9(2)° and 45.8(4)°, respectively. A perspective view of **2** and **3** are shown in Figs. 3, and 4. In **3**, a long axial Cu1···O5 contact of 2.848(11) Å is present.

The M–N_{im} and M–N_{py} bond lengths follow the order Co > Ni > Cu and is consistent with the trend in the relative size of the bivalent ions. Notable is the parameters of the methylketimine function in complex **3**: N2–C6 and C6–C14 bonds in **3** are, respectively, longer and shorter than those observed in **1** and **2**. In **3**, the sum of the three angles subtended at N2 and C6 are, respectively, 355.7(16)° and 354.3(19)° and these values are very much closer to 360° in **1** and **2**.

A perspective view of molecular packing diagram of **1** shown in Fig. 5 indicates the presence of C3···O2, C3···O4, C11···O2, C11···O4, C13···O6, and C14···O5 donor-acceptor interactions. The molecular packing of **2** shows a transverse wave like pattern along the *b*-axis with a distance of around 18.91 Å between two crests. The intermolecular interactions C3···O4, C4···O4, C4···O5, and C12···O6, are present in this packing. In case of **3**, a layered sheet observed on viewing down the *b*-axis. Non-bonded intermolecular contacts C11···O5, C12···O6, C14···O4, C3···O5, C2···O3, C1···O3, and π–π interaction of 3.365(13) Å between C4···C10, are important factors responsible for layered stacking.

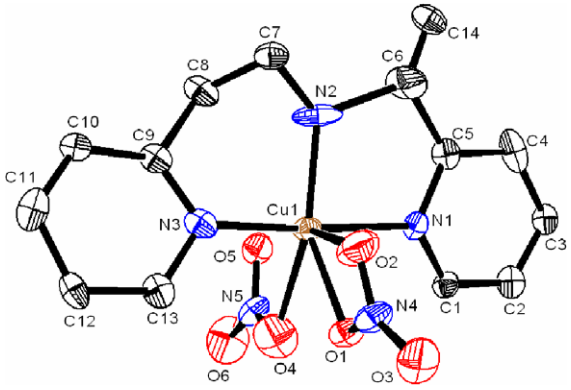

Fig. 4. ORTEP diagram of **3** (30% probability, hydrogens are omitted for clarity).

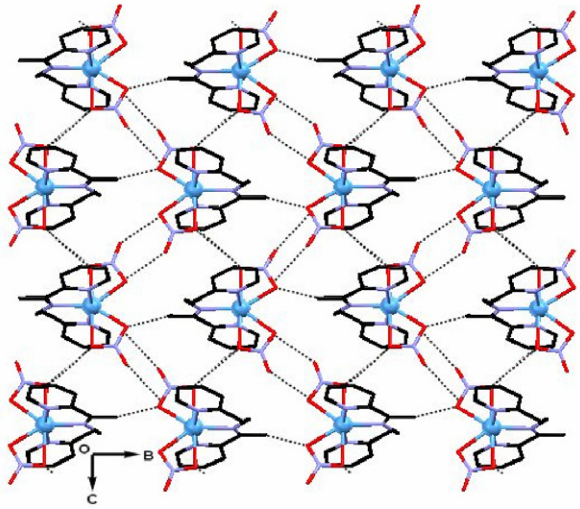

Fig. 5. Molecular packing of **1** viewing down the *a*-axis.

4. Conclusion

Cobalt (**1**) has overall distorted pentagonal bipyramidal geometry with N_3O_4 chromophore whereas nickel (**2**) and copper (**3**) complexes have pseudo-octahedral geometry with N_3O_3 chromophore. The $M–N_{im}$ and $M–N_{py}$ bond lengths follow the order Co > Ni > Cu. The X-band EPR spectra of **3** shows an isotropic spectrum splitted by hyperfine coupling at room temperature and an axial spectrum with splitting due to a slight rhombic symmetry at 77 K. The trend, $g_{zz} > g_{yy} > g_{xx}$ and hyperfine splitting of the g_{zz} signal are observed.

Abstract

Ni(II) complexes (**1**–**5**) of di-2-pyridyl ketone *N*(4)-phenylthiosemicarbazone (HL) have been synthesized and spectrochemically characterized. Elemental analyses revealed a $NiL_2 \cdot 2H_2O$ stoichiometry for compound **1**. However, the single crystals isolated revealed a composition $NiL_2 \cdot 0.5(H_2O)0.5(DMF)$. The compound crystallizes into a monoclinic lattice with the space group $P2_1/n$. Complexes **2**, **3** and **4** are observed to show a 1:1:1 ratio of metal:thiosemicarbazone:gegenion, with the general formula $NiLX \cdot yH_2O$ [X = NCS, $y = 2$ for **2**; X = Cl, $y = 3$ for **3** and X = N_3, $y = 4.5$ for **4**]. Compound **5** is a dimer with a metal:thiosemicarbazone:gegenion ratio of 2:2:1, with the formula $[Ni_2L_2(SO_4)] \cdot 4H_2O$.

Keywords: Di-2-pyridyl ketone; Thiosemicarbazone; Ni(II) complexes; Crystal structure

1. Introduction

Nickel species in various coordination environments are of interest to inorganic biochemists, for instance, some nickel complexes of thiosemicarbazone derivatives are observed to exhibit antitumour activity [1]. Some mono- and bis-chelated nickel complexes of di-2-pyridyl ketone derivatives of *S*-methyldithiocarbazate are observed to have antifungal and antibacterial properties [2]. Ni(II) complexes of substituted thiosemicarbazones [3,4] and their di-2-pyridyl ketone derivatives [5–7] have been previously reported. There are also reports on the magnetic behaviour of coordination complexes of nickel. For the past few years we have been under constant pursuit of the versatile coordination chemistry of di-2-pyridyl ketone thiosemicarbazones [7–10]. However, studies on the chemistry of nickel complexes of di-2-pyridyl ketone *N*(4)-substituted thiosemicarbazones are very rare, and here we report some new Ni(II) complexes of di-2-pyridyl ketone *N*(4)-phenylthiosemicarbazone.

2. Experimental

2.1. Materials

Di-2-pyridyl ketone (Fluka), $Ni(OAc)_2 \cdot H_2O$ (CDH), $NiClO_4$ (Fluka), $NiSO_4$ (Merck), $NiCl_2 \cdot 2H_2O$ (SD Fine), NaN_3(Reidel-De Haen) and KSCN (BDH) were used as received. The solvent used, ethyl alcohol was repeatedly distilled before use.

2.2. Physical measurements

Elemental analyses were carried out at the Sophisticated Analytical Instruments Facility, Kochi, India using a Vario-EL III CHNS. The magnetic susceptibility measurements were carried out in the polycrystalline state on a Vibrating Sample Magnetometer (VSM) at 5.0 kOe field strength at the Indian Institute of Technology, Roorkee, India. Infrared spectral measurements were done on an ABB Bomem

FTIR instrument using KBr pellets for spectra in the region 4000–500 cm^{-1}. The far IR spectra were recorded using polyethylene pellets in the 500–100 cm^{-1} region on a Nicolet Magna 550 FTIR instrument at the Regional Sophisticated Instrumentation Facility, Indian Institute of Technology, Bombay. An Ocean Optics SD 2000 Fiber Optic spectrometer was used to measure solid-state reflectance spectra in the range 200–900 nm. NMR spectra were recorded using a Bruker AMX 400 FT-NMR spectrometer using TMS as the internal standard at the Sophisticated Instruments Facility, Indian Institute of Science, Bangalore.

2.3. X-ray crystallography

Single crystal X-ray diffraction measurements were carried out on a Bruker Smart Apex CCD diffractometer equipped with a fine-focused sealed tube. The unit cell parameters were determined and the data collections were performed using graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. The data collected were reduced using the SAINT program [11] and the empirical absorption corrections were carried out using the SADABS program [12]. The trial structure was obtained by direct methods [13] using SHELXS-97, which revealed the position of all non-hydrogen atoms, and was refined by full-matrix least squares on F^2 (SHELXL-97) [14] and the graphics tool used was DIAMOND version 3.0 [15]. All non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were placed in calculated positions and refined as riding atoms.

2.4. Synthesis of the ligand

The ligand used is di-2-pyridyl ketone *N*(4)-phenylthiosemicarbazone, HL (Fig. 1). Preparation of the ligand was done as described previously [16].

2.5. Preparation of complexes

2.5.1. $NiL_2 \cdot 2H_2O$ (**1**)

A solution of $Ni(OAc)_2 \cdot H_2O$ (0.199 g, 1 mmol) in 10 ml of ethanol was added to an ethanolic solution of HL (0.333 g, 1 mmol) and refluxed for 4 h. The resulting brown product was washed with an ethanol–water mixture followed by ether and dried over P_4O_{10} *in vacuo*. Single crystals suitable for X-ray diffraction were grown at room temperature by slow evaporation of a 1:1:1 solution of the complex in methanol, chloroform and dimethylformamide. Colour: light brown, Yield: 0.36 g (67%), $\mu_{eff} = 2.98$ BM, Elemental *Anal.* Calc.: C, 56.04; H, 5.75; N, 18.15. Found: C, 55.83; H, 5.09; N, 17.71%.

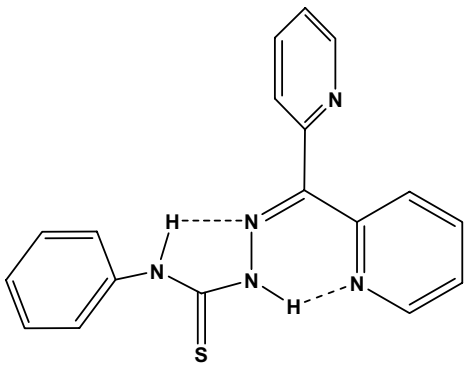

Fig. 1. Structure of compound HL.

2.5.2. $NiLNCS \cdot 2H_2O$ (**2**)

To an ethanolic solution of HL (0.333 g, 1 mmol), $Ni(OAc)_2 \cdot H_2O$ (0.199 g, 1 mmol) dissolved in ethanol (10 ml) was added, and the resulting mixture was refluxed for the preparation of compound **2**. After 15 min, an aqueous solution of KSCN (0.097 g, 1 mmol) was added to the solution followed by a further refluxing for three hours. The product that separated out was collected, washed with ether and dried *in vacuo*. Colour: dark brown, Yield: 0.49 g (77%), Elemental *Anal.* Calc.: C, 47.03; H, 3.74; N, 17.32. Found: C, 46.58; H, 3.79; N, 17.17%. ^{1}H NMR: δ (ppm) 8.70 (t, N5H); 8.05 (d, C1H); 7.65 (d, C11H); 7.25 (m, aromatic H).

2.5.3. $NiLCl \cdot 3H_2O$ (**3**)

A solution of $NiCl_2 \cdot 2H_2O$ (0.166 g, 1 mmol) in 10 ml of ethanol was added to an ethanolic solution of HL (0.333 g, 1 mmol), and the resulting mixture was refluxed for 4 h. The product that separated out was washed with ethanol followed by ether and dried over P_4O_{10} *in vacuo*. Colour: brown, Yield: 0.32 g (63%), Elemental *Anal.* Calc.: C, 44.98; H, 4.19; N, 14.57. Found: C, 44.85; H, 3.71; N, 13.92%. ^{1}H NMR: δ (ppm) 9.75 (s, N5H); 8.85 (d, C1H); 8.75 (d, C11H); 7.60 and 7.35 (m, aromatic H).

2.5.4. $NiLN_3 \cdot 4.5H_2O$ (**4**)

To an ethanolic solution of HL (0.333 g, 1 mmol), 1 mmol of $Ni(OAc)_2 \cdot H_2O$ (0.199 g) dissolved in ethanol (10 ml) was added and the resulting mixture was refluxed. An aqueous solution of NaN_3 (0.0651 g, 1 mmol) was then added to the solution followed by a further refluxing for three hours. The product that separated out was collected, washed with ether and dried *in vacuo*. Colour: light brown, Yield: 0.42 g (71%), $\mu_{eff} = 2.88$ BM, Elemental *Anal.* Calc.: C, 42.05; H, 4.51; N, 21.79. Found: C, 41.33; H, 3.60; N, 21.52%.

2.5.5. $[Ni_2L_2(SO_4)] \cdot 4H_2O$ (**5**)

HL (0.333 g, 1 mmol) was dissolved in ethanol (15 ml) and refluxed with a solution of $NiSO_4$ (0.223 g, 1 mmol) in 10 ml of water. A crystalline product separated out, which was filtered and washed with ether and dried over P_4O_{10} *in vacuo*. Colour: brown, Yield: 0.29 g (52%), $\mu_{eff} = 3.41$ BM, Elemental *Anal.* Calc.: C, 45.50; H, 3.82; N, 14.74. Found: C, 45.50; H, 3.77; N, 15.06%.

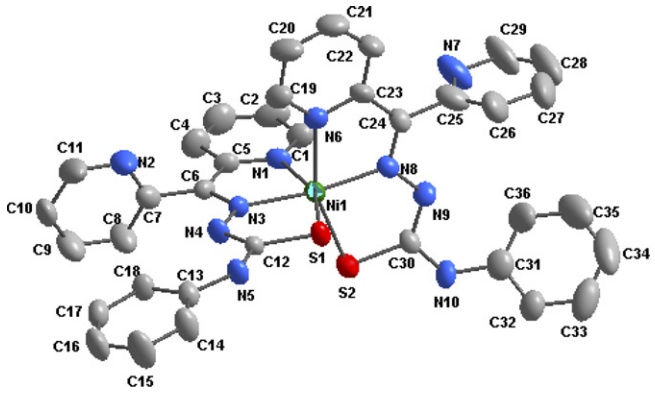
3. Results and discussion

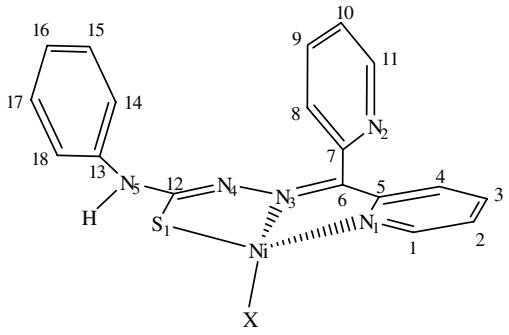
3.1. Synthesis of the compounds

Single crystals suitable for X-ray diffraction of compound **1** were grown at room temperature by slow evaporation of a 1:1:1 solution of the complex in methanol, chloroform and dimethylformamide. The elemental analyses revealed a $NiL_2 \cdot 2H_2O$ stoichiometry for compound **1**. However, the single crystals prepared from the compound revealed a composition incorporating one molecule each of water and DMF additionally in the lattice. The molecular structure of NiL_2 with the atom labelling scheme is given in Fig. 2. The tentative structures of compounds **2**, **3**, **4**, **5** and the ^1H NMR labelling scheme are provided in Fig. 3. Complexes **2**, **3** and **4** were observed to show a 1:1:1 ratio of metal:thiosemicarbazone:gegenion, with the general formula $NiLX \cdot yH_2O$ [X = NCS, $y = 2$ for **2**; X = Cl, $y = 3$ for **3** and X = N_3, $y = 4.5$ for **4**]. Compound **5** was revealed to be a dimer with a metal:thiosemicarbazone:gegenion ratio of 2:2:1, with the formula $[Ni_2L_2(SO_4)] \cdot 4H_2O$. Recently, we have reported a tetranuclear copper complex with four and five coordinated copper centers bridged through sulfate linkages, the structure of which was confirmed by single crystal X-ray diffraction [17]. Magnetic studies reveal the compounds **1**, **4** and **5** to be paramagnetic while compounds **2** and **3** are diamagnetic.

3.2. Crystal structure of $NiL_2 \cdot 0.5(H_2O)0.5(DMF)$

There are two crystallographically independent molecules in the asymmetric unit of $NiL_2 \cdot 0.5(H_2O)0.5(DMF)$. The compound crystallizes into a monoclinic lattice with the space group $P2_1/n$. The structural refinement parameters are given in Table 1 and the selected bond distances and bond angles are given in Table 2. The bonding parameters in the crystallographically independent molecules in the asymmetric lattice bear almost identical features. In addition to the two NiL_2 moieties, there are two solvent molecules, i.e., one molecule each of water and DMF in the lattice.





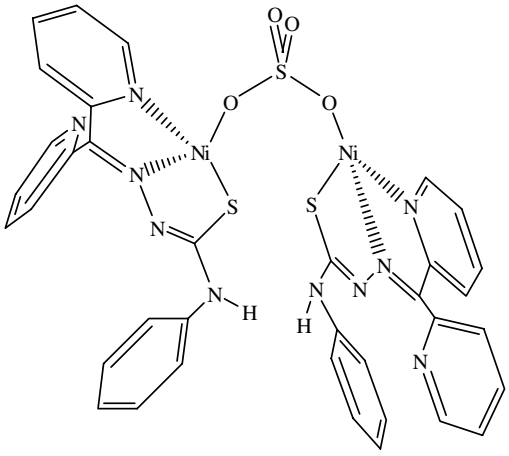


Fig. 2. Structure of NiL_2 showing the atom numbering scheme. The ellipsoids are shown with 50% probability and the hydrogen atoms, water and DMF are omitted for clarity.

(b) Compound **5**

Fig. 3. (a) Structures of compounds **2**, **3** and **4** with the NMR labelling scheme and (b) structure of compound **5**.

The bond distances and angles from the single crystal X-ray diffraction studies reveal that the independent units of the molecules exist in a distorted octahedral geometry around the metal center. There are two deprotonated ligand moieties of HL around each metal center and they are bonded through the azomethine nitrogen, pyridyl nitrogen and thiolate sulfur of each of the thiosemicarbazone moieties, thus effecting a six-coordinate environment about the metal center. In the present Ni(II) complex, the thiosemicarbazone moiety reveals an *ZZ* conformation with *cis* configurations about both the C6–N3 and N4–C12 bonds, contrary to the *ZE* conformation in the free ligand. The S1–C12–N4–N3 torsion angle value is 2.9(7)°, which reveals a *cis* nature of the thiocarbonyl S1 atom with the hydrazinic N3 atom. The two ligand moieties in the present compound are aligned almost perpendicular to each other, as revealed from the dihedral angle of 85.55(1)° of the C6/N3/N4/C12/N5/S1 plane with that of the C24/N8/N9/C30/N10/S2 plane. The distortion from an ideal octahedral stereochemistry is suggested by the values for the orthogonal bite angles N1–Ni1–N3 (77.62(18)°); S1– Ni1–N3

(79.99(13)°); N6–Ni1–N8 (77.65(18)°) and S2–Ni1–N8 (80.25(13)°). The maximum mean plane deviation of the equatorial plane consisting of N3, N6, N8, S2 and Ni1 is 0.0556(4) Å at N8 and the central Ni(II) atom is displaced out of this mean plane at a distance of −0.0423(4) Å. The two metal chelate rings in one of the thiosemicarbazone moieties, comprising of atoms Ni1, N1, C5, C6, N3, N4, C12 and S1, are found to be almost coplanar with rms values of 0.0196 (4) and 0.0203 (4) Å, respectively. It is interesting to note that the azomethine and thiolate bond distances are slightly increased in the complex, when compared to the corresponding values in the free ligand HL, and this supports coordination. A significant amount of metal-to-ligand π back bonding generates a delocalized conjugating effect along the metal–chelate rings which imparts partial single and double bond nature to the N4–C12 and N3–N4 hydrazinic bonds in the thiosemicarbazone moiety, owing to the extensive delocalization over the entire coordination framework.

Two independent molecules in the asymmetric unit constitute the repeating unit of the crystal packing in the unit cell. The sets of two molecules repeat one- dimensionally in the lattice. Intermolecular π–π interactions are observed at distances greater than 3.5 Å, and hence they contribute little towards the effective packing of the molecules in the lattice. However, some C–H···π interactions, which are rather short, appear significant. The list of intermolecular interactions is given in Table 3.

3.3. IR and electronic spectra

A broad band around 3500 cm^{-1} in the IR spectra of the complexes is assigned to the –OH stretching vibrations of lattice water. The azomethine stretching vibration is observed at 1592 cm^{-1} in the ligand HL. However, in the complex this band is shifted as the azomethine nitrogen is coordinated to the Ni(II) centre. In complex **3**, the coordinated azomethine band is observed as a strong combination band at 1641 cm^{-1}. In other complexes, it is shifted to the range 1562–1541 cm^{-1}. The stretching vibrations of the newly formed N4=C12 bond, due to coordination through deprotonation, appear as sharp bands in the region near 1585 cm^{-1}. The δ(CS) band observed at 806 cm^{-1} in the ligand is shifted to the region near 750 cm^{-1} in the complex due to the enolization of thiosemicarbazone moiety upon coordination. The IR spectrum of compound **2** shows a sharp band at 2095 cm^{-1} corresponding to the antisymmetric ν(NCS) vibrations. The δ(Ni–N_{NCS}) band at 498 cm^{-1} shows that the thiocyanate group is N-bonded to the nickel centre. Another band at 438 cm^{-1} is assigned to the ν(NiN) vibration and it supports the coordination of the imine nitrogen. A medium band at 384 cm^{-1} corresponds to the ν(NiS) vibration, con-

[A] No classic hydrogen bonds found.

firming the coordination of the thiolate sulfur. Coordination of the pyridyl nitrogen results in the ν(NiN) band appearing as a strong band with two splits at 291 and 281 cm^{-1}. In compound **3**, a sharp band at 397 cm^{-1} reveals the presence of a terminal chlorine in the complex. The IR spectrum of **4** reveals a sharp band at 2066 cm^{-1} corresponding to the asymmetric stretching vibrations of the coordinated azido group. The ν(Ni–N_3) band is observed at 395 cm^{-1} and a band at 457 cm^{-1} is assigned to the ν(NiN) vibrations, supporting the coordination through the imine nitrogen. In the sulfato complex **5**, the ν_1 and ν_2 vibrations, observed as weak bands at 979 and at 455 cm^{-1}, suggest the bridged bidentate nature of the sulfato anion in the complex. The ν_3 vibration is observed at 1050 cm^{-1}, while the ν_4 vibrations are observed near 615 and 510 cm^{-1}, similar to the corresponding values of other complexes where the sulfate anion exists in the bridged bidentate form [18]. The Ni–$N_{azomethine}$ and Ni–$S_{thiolate}$ stretching vibrations are observed at 418 and 385 cm^{-1}. The solid state electronic spectra of the complexes reveal that the $\pi \rightarrow \pi^*$ and the $n \rightarrow \pi^*$ transitions appear in regions near 280 and 300 nm respectively. The ligand to metal charge transfer transitions are observed either as a shoulder or as a broad band near 400 nm. Weak shoulders near 500 nm correspond to the d–d transitions [19]. Selected electronic spectral data are given in Table 4.

			462 b	637 sh

b = broad, s = strong, sh = shoulder.

3.4. Nuclear magnetic resonance studies

The numbering scheme used in the ^1H NMR spectra is shown in Fig. 3a. A sharp singlet at 14.55 ppm in the ^1H NMR spectrum of HL due to the proton on the N4 nitrogen is absent in the spectra of the complexes, which supports coordination of the thiosemicarbazone moiety in the thiolate form after enolization and deprotonation. The ^1H NMR spectrum of compound **2** reveals a triplet centred around 8.70 ppm, which does not reveal any coupling interactions in the ^1H–^1H COSY spectrum. Hence it can be assigned to the proton on the nitrogen atom N5 of the thiosemicarbazone moiety, the resonance due to which splits into a triplet by quadrupole splitting. It is interesting to note that the coordination through the pyridyl nitrogen is clearly evident in the NMR spectra. The resonances corresponding to the protons on carbons adjacent to the pyridyl nitrogen are observed at 8.05 and 7.65 ppm in the complex, which are shifted from the

corresponding values of 8.85 and 8.68 ppm in the ligand HL. Both resonances show correlation with the aromatic protons. A slight shift in the alpha proton resonance of the uncoordinated pyridyl nitrogen may be attributed to the absence of hydrogen bonding interactions in the complex, unlike in the ligand. The low intensity of the multiplets in the aromatic region may be attributed to the delocalization of electron density due to coordination in the complex. The ^{1}H NMR spectrum of compound **3** is also resolved in a similar fashion as that of compound **2**.

Abstract

The reactions between $Cd(OAc)_2$/$Cu(NO_3)_2$ and mixed ligands (2,3-pyrazinedicarboxylic acid (pzdc) and N-donor ligands) under different reaction conditions give the three title complexes **1**, **2** and **3**. There is a (4,8) net 2D network structure and a rectangular grid network structure in the cadmium complexes $[Cd(pzdc)(phen)]\cdot H_2O$ (**1**) and $Cd_2(pzdc)_2(4,4'\text{-bpy})(H_2O)_2$ (**2**), respectively. The complex $[Cu_4(pzdc)_4(phen)_2(H_2O)_4]\cdot 10H_2O$ (**3**) has a 1D zigzag chain structure. The influences of coordination modes of the pzdc ligand and N-donor ligands on the superstructural diversity have been discussed. Complexes **1** and **2** exhibit strong fluorescent emission bands in the solid state at room temperature. The EPR spectrum of **3** is typical for a square-pyramidal geometry of copper (II) ions.

Keywords: Supermolecular chemistry; Cadmium; Copper; Pyrazinedicarboxylic acid; Mixed ligands

1. Introduction

The design and construction of coordination polymers are of great interest due to their intriguing structural topologies [1–3]. In particular, polycarboxylate ligands have been shown to be good building blocks in the design of metal-organic materials with desired topologies owing to their rich coordination modes. For example, some complexes with pyridine-2,3-dicarboylate [4], 2,3-pyrazinedicarboxylic acid (pzdc) [5–16], 2,3,5,6-pyrazinetetracarboxylic acid, imidazoldicarboxylic acid [17,18] and polybenzenecarboxylate ligand [19,20] have been reported. Susumu Kitagawa's group selected $\{Cd(pzdc)_n\}$ as a layer, and a pillar ligand as a second ligand to obtain novel porous frameworks [9–11]. The coordination polymers constructed by polycarboxylate ligands and N-bonding ligand are also of great interest [21,22]. In order to understand the role of N-donor ligands as a second ligand, we report the syntheses and structures of three complexes containing $\{Cd(pzdc)_n\}$ with 1D or 2D structures and a N-donor ligand. The three title complexes are $[Cd(pzdc)(phen)]\cdot H_2O$ (**1**), $Cd_2(pzdc)_2(4,4'\text{-bpy})(H_2O)_2$ (**2**) and $[Cu_4(pzdc)_4(phen)_2(H_2O)_4]\cdot 10H_2O$ (**3**). The influences of the coordination modes of pzdc and the mixed ligands on the number of possible superstructures (i.e. discrete structures or 1D, 2D or 3D networks) have been studied.

2. Experimental

2.2. Syntheses of the complexes

2.2.1. [Cd(pzdc)(phen)] · H_2O (1)

$Cd(OAC)_2$ (0.1 mmol), 2,3-pyrazinedicarboxylic acid (0.1 mmol), phen (0.1 mmol) and H_2O (16 ml) in a molar ratio of 1:1:1:8888 were loaded into a 23 cm^3 Teflon-lined stainless-steel vessel, which was then sealed and placed in a programmable furnace. The resulting mixture was heated at 160 °C for 4 days and then cooled to room temperature. The colorless crystals of **1** were obtained with a 36% yield based on Cd. *Anal*. Calc. for $Cd_1C_{18}H_{12}N_4O_5$: C, 45.31; H, 2.52; N, 11.75. Found: C, 45.23; H, 2.59; N, 11.86%. FT-IR (KBr pellet, 4000–400 cm^{-1}): 3415 s, 1627 s, 1568 s, 1460 m, 1436 w, 1392 s, 1361 m, 1201 m, 1169 m, 1123 m, 1069 s, 896 m, 843 m, 780 w, 751 w, 668 s, 602 s, 541 s, 441 m.

2.2.2. $Cd_2(pzdc)_2(4,4'\text{-bpy})(H_2O)_2$ (2)

An aqueous solution of $Cd(OAC)_2$ (0.1 mmol) was added to an aqueous solution of 2,3-pyrazinedicarboxylic acid (0.1 mmol) and 4,4′-bpy (0.05 mmol), and the resulting mixture was stirred for 2 min, filtered immediately and left in air. After several days, colorless crystals of the title compound were obtained. Yield: ca. 28% based on Cd. *Anal*. Calc. for $Cd_2C_{22}H_{16}N_6O_{10}$: C, 35.24; H, 2.14; N, 11.21. Found: C, 35.32; H, 2.19; N, 11.16%.

2.2.3. $[Cu_4(pzdc)_4(phen)_2(H_2O)_4] \cdot 10H_2O$ (3)

The synthetic procedure is similar to that for compound **2**, using $Cu(NO_3)_2$ and phen instead of $Cd(OAC)_2$ and 4,4′-bpy. Blue crystals of **3** were obtained in two days. Yield: ca. 45% based on Cu. *Anal*. Calc. for $Cu_4C_{48}H_{52}N_{12}O_{30}$: C, 37.62; H, 3.40; N, 10.97. Found: C, 37.93; H, 3.42; N, 10.89%.

2.3. Physical measurements

IR absorption spectra (KBr pellets) were recorded on a Perkin–Elmer spectrum 2000 spectrophotometer. Elemental analyses were carried out on a Vario EL III. Fluorescent data were collected on an Edinburgh FL-FS920 TCSPC system. Thermal gravimetric analysis (TGA) was tested under nitrogen with a heating rate of 10 °C min^{-1} using a Perkin–Elmer TGA-7 Thermal Analysis system. EPR spectra were recorded at room temperature at X-band frequency with a Bruker EMX 10/12 automatic spectrometer.

2.4. Crystal structure determination

Crystals of the three title compounds of a suitable size were mounted on glass fibers. Intensity data were collected on a Rigaku RAPID Weissengberg IP diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) and the ω scan mode. The structures were solved by direct methods with SHELXS-97 [23] and refined by full-matrix least-squares calculations with SHELXL-97 [24]. All the non-hydrogen atoms in the three complexes were refined anisotropically, except for the oxygen atoms of crystal water molecules in **3** which were refined isotropically. Most of the hydrogen atoms in the three complexes were located in calculated positions or found from difference Fourier maps. Crystallographic data for **1**, **2** and **3** are listed in Table 1.

3. Results and discussion

3.1. Crystal structures

3.1.1. [Cd(pzdc)(phen)] · H_2O (1)

As shown in Fig. 1, the Cd1 atom in complex **1** is coordinated by three carboxyl oxygen atoms (O1, O4A and O3B) and one nitrogen atom N1 from the three surround-

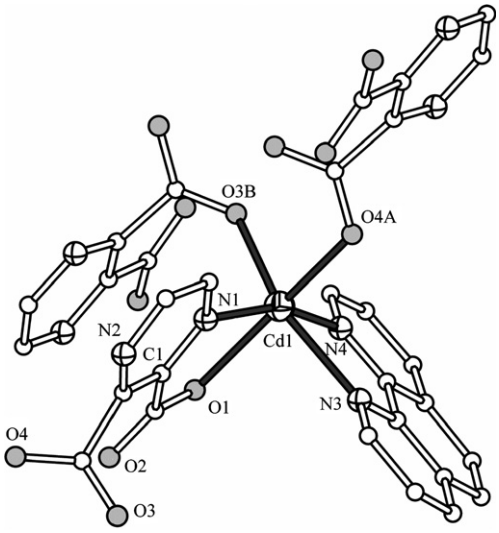

Fig. 1. The coordination environment of the cadmium atom in 1.

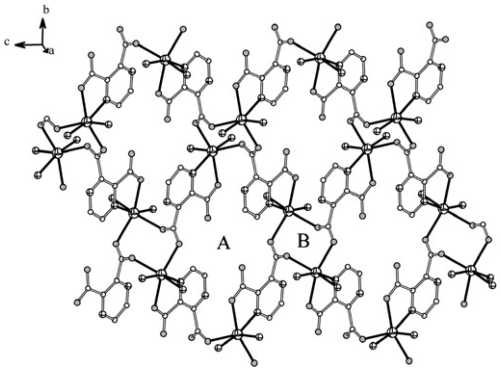
ing $pzdc^{2-}$ ligands (where symmetry codes A and B are $-x+1, y+1/2, -z+1/2$ and $x, -y+1/2, z-1/2$, respectively), and two nitrogen atoms (N3 and N4) from a terminal phen, forming a distorted octahedron. Each pzdc ligand in **1** is coordinated to three cadmium atoms through its three carboxyl oxygen donors and one nitrogen donor. The carboxyl group C5O1O2 coordinates to Cd through O1 atom in a monodentate fashion. Two oxygen atoms of the other carboxyl group C6O3O4 coordinate to other two Cd atoms.

Two Cd ions and four pzdc ligands form a basic binuclear unit $Cd_2(pzdc)_4(phen)_2$. The ring B of the binuclear unit $Cd_2(pzdc)_4(phen)_2$ is cyclic eight-membered $[Cd_2(-O_2C-)_2]$ ring with a Cd···Cd distance of 4.904(2) Å, and then four binuclear units are connected to each other by sharing the pzdc ligands to get a (4,8) net 2D network [25] along the *bc* plane, as shown in Fig. 2 and Scheme 1. There are two kinds of macrocyclic rings, the 16-member ring (ring A) and the 8-member ring (ring B), in the 2D network.

Selected bond lengths and angels are given in Table 2. The Cd–O(N) lengths range from 2.271 to 2.372 Å. The



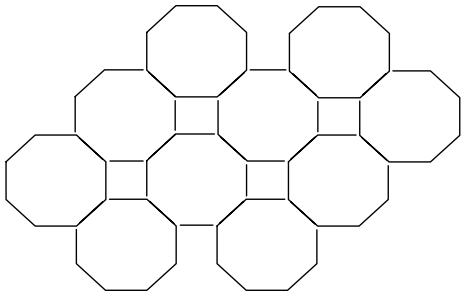


Fig. 2. (4,8) net 2D network in **1** with phen omitted for clarity.

Scheme 1. Schematic representation of the 2D 4.82 net.

Cd–O distances in the title complex are a little longer than the Cd–O bond distance in $[H_3O_2]_x[Cd(pzdc)_2]_x$ [6] (2.246) Å, and the Cd–N bond distances are almost the same as corresponding one in $[H_3O_2]_x[Cd(pzdc)_2]_x$ [6] (2.354 Å).

There are some intermolecular hydrogen bonds O(1W)–H(2WA)···O(2) and O(1W)–H(1WA)···O(4C) between the uncoordinated water molecules and the carboxyl oxygen atoms in the network. As illustrated in Fig. 3, these hydrogen bonds are in the hole of the network. The title complex **1** and the complex reported in [15] are allomorphic. The two complexes have the same chemical formula and the same molecular configuration, but they have different molecular packing. A comparison among the known complexes with the pzdc ligand and the three title complexes with the pzdc ligand is shown in Table 3.

3.1.2. $Cd_2(pzdc)_2(4,4'\text{-bpy})(H_2O)_2$ (**2**)

As shown in Fig. 4, the coordination geometry of the cadmium atom in complex **2** is a distorted octahedron with three carboxyl oxygen atoms (O1, O4A and O4B) and one nitrogen atom (N1) from three $pzdc^{2-}$ ligands (where symmetry codes A and B are $x, y+1, z$ and $-x, -y, -z$, respectively), one nitrogen atom (N3) from 4,4′-bpy and one oxygen atom (O1W) from a coordinated water molecule. Selected bond lengths and angels are listed in Table 4. The Cd–O and Cd–N bond lengths in **2** are in the range 2.293–2.378 Å and are similar to those in complex **1**.

Every pzdc ligand is coordinated to three cadmium atoms through two oxygen atoms from its two carboxylate groups and one nitrogen atom. The pzdc ligand adopts a chelate interaction to one cadmium atom and one μ_2-bridging oxygen atom to the other two cadmium atoms. The two Cd(II) ions are combined by the two μ_2-bridging oxygen atoms with a Cd···Cd interatomic distance of 3.76(3) Å, forming a basic binuclear structure unit $Cd_2(pzdc)_4$ with a Cd_2O_2 core. Two neighboring binuclear units are connected together through the bridging carboxylate groups to obtain a 1D double chain along the *b*-axis, as illustrated in Fig. 5.

The 1D chains are further connected by the bridging 4,4′-bpy to result in 2D networks (Fig. 6). There are intermolecular hydrogen bonds O(1W)–H(01B)···O(1C) and O(1W)–H(01B)···O(2C) between the O(1W)–H(01B) group in the coordinated water molecule and the carboxyl oxygen atom (see Table 4). As shown in Fig. 7 and Fig. S1,

of porous coordination polymers $\{[Cu_2(pzdc)_2(bpy)]\cdot G\}$ (where G are H_2O and benzene) [16]. An important structural phenomenon for the two complexes is that there is the existence of a pore structure in $\{[Cu_2(pzdc)_2(bpy)]\cdot G\}$ and the non-existence of a pore structure in $Cd_2(pzdc)_2(4,4'\text{-bpy})(H_2O)_2$, although the two complexes have the same 4,4′-bpy ligand. One of the reasons of this important structural phenomenon is the following structural fact. The coordination configuration of the metal atom and the coordination mode of the pzdc ligand in $\{[Cu_2(pzdc)_2(bpy)]\cdot G\}$ are quite different from that in the title complex $Cd_2(pzdc)_2(4,4'\text{-bpy})(H_2O)_2$ (**2**).

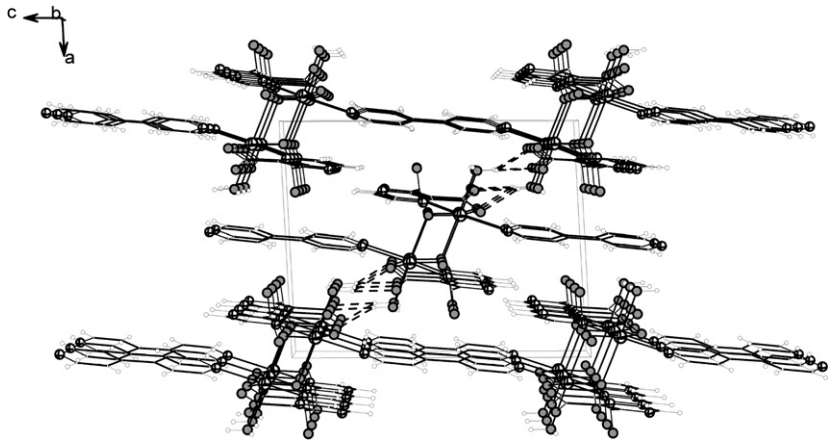

Fig. 7. The extended 3D network of complex **2** interconnected by hydrogen bonds between the layers.

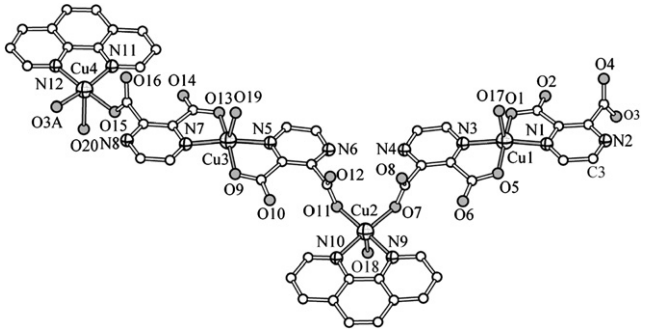

Fig. 8. Molecular structure of complex **3** with hydrogen atoms omitted for clarity.

3.1.3. $[Cu_4(pzdc)_4(phen)_2(H_2O)_4]\cdot 10H_2O$ (**3**)

As illustrated in Fig. 8 and Table 5, there are four crystallographically independent Cu centers in complex **3**. The four copper atoms in **3** have a distorted square-pyramidal geometry with CuN_2O_3 coordination, but all 1,10'-phen ligands are coordinated to Cu2 and Cu4 atoms only, not to Cu1 and Cu3 atoms. The Cu1 and Cu3 atoms are coordinated by two oxygen atoms and two nitrogen atoms from two pzdc ligands and one water oxygen atom. However, Cu2 and Cu4 atoms are coordinated by two oxygen atoms of two pzdc ligands, two nitrogen atoms of one terminal 1,10'-phen ligand and one water oxygen atom. The τ values

Symmetry codes. A: $x, y, z+1$.

of the pentacoordinated polyhedra are 0.03, 0.01, 0.03 and 0.08 for Cu1, Cu2, Cu3 and Cu4 atoms, respectively [26]. In the basal plane, the Cu–O and Cu–N bond distances are from 1.934(3) to 1.975(3) Å and from 1.983(3) to 2.033(3) Å, respectively. The Cu–O(water) bond distances in the axial position are in the range 2.182(4)–2.300(3) Å. These Cu–N and Cu–O bond distances are similar to the corresponding ones in known copper complexes [5].

Every pzdc ligand is coordinated to two neighboring copper atoms through its two carboxyl oxygen atoms and one nitrogen atom, i.e. the pzdc ligand adopts a chelate interaction to one copper atom and bonding through a single carboxylate oxygen to the other copper atom. Therefore, neighboring tetranuclear copper complex molecules are combined together by the bridging pzdc ligands to form a 1D covalently bonded chain along the *c*-axis (Fig. 9). The adjacent Cu–Cu distances are 7.936, 7.910, 7.990 and 7.943 Å.

3.1.4. The influence of the coordination modes of the pzdc ligand on the dimensions of the polymer

As shown in Scheme 2 and Table 3, there are 10 kinds of coordination modes of the six donor atoms of the pzdc ligand in known complexes and the three title complexes. The structures constructed between the pzdc ligands and the metal atoms for some coordination modes of the pzdc ligand are 1D and 2D. For example, supermolecular 1D and 2D structures are observed with coordination mode c. The type of the second ligand, such as 4,4′-bipy and dpyg, sometimes may increase the superstructural diversity. For example, the dimensions in the crystal structures increase from 1D to 2D and from 2D to 3D in the title complex **2** and the complex reported in reference [9], respectively. But for some other kinds of second ligand, its existence does not affect the dimensions of the crystal structure. Therefore, the selection of the second ligand plays an important role in the design of supermolecular structures.

Scheme 2. Coordination modes of 2,3-pyrazinedicarboxylic acid.

3.2. Elemental analysis and TGA measurement

The elemental analysis data for complexes **1**, **2** and **3** are consistent with the formulas $[Cd(pzdc)(phen)]\cdot H_2O$ (**1**), $Cd_2(pzdc)_2(4,4'\text{-bpy})(H_2O)_2$ (**2**) and $[Cu_4(pzdc)_4(phen)_2(H_2O)_4]\cdot 10H_2O$ (**3**). The TGA data of complex **1** indicate two obvious weight losses as shown in Fig. S2. The first weight loss starts at ca. 70–130 °C to give a total weight loss of 3.84%, corresponding to the loss of one guest H_2O molecule per formula unit. Then at ca. 300 °C

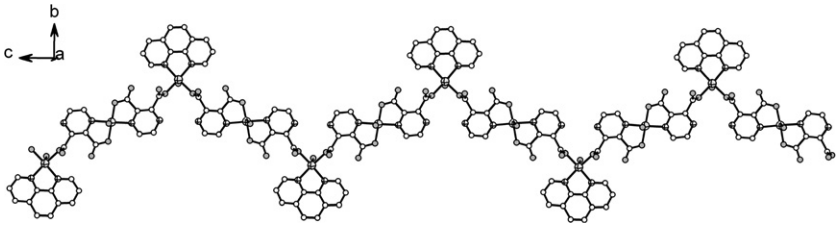

Fig. 9. 1D zigzag chain of complex **3** with hydrogen atoms omitted for clarity.

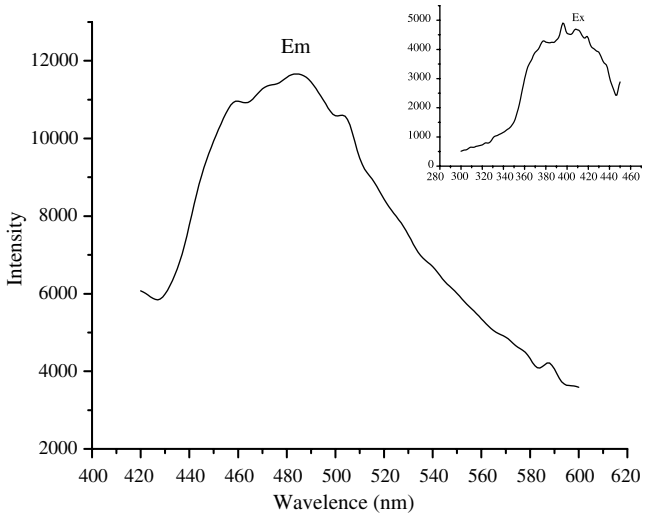

Fig. 10. Solid-state emission spectra of complex **1** at room temperature.

complex **1** undergoes degradation in essentially one step. Thermogravimetric analysis data of **3** shows three obvious weight losses (Fig. S3) starting at ca. 50–80 °C and 80–120 °C to give a total loss of 3.49% and 8.04%, corresponding to the loss of $10H_2O$ molecules per formula unit. At ca. 150 °C a total loss of 4.42% corresponds to the loss of $4H_2O$ molecules per formula unit, then at ca. 200 °C it undergoes degradation in essentially one step, which indicates that complex **3** is unstable. A similar behavior has been observed in several 2,3-pyrazinedicarboxylate complexes of the first transition series [6], which are all found to decompose into the corresponding metal oxides.

3.3. Spectroscopy and luminescent properties

The luminescent properties of the free ligand 2,3-pyrazinedicarboxylic acid, complex **1** and complex **2** were investigated in the solid state at room temperature. No luminescent properties were found for the free ligand, 2,3-pyrazinedicarboxylic acid. However, complex **1** gives an intense broad emission band from 440 nm to 550 nm with the maximum at 484 nm upon excitation at 396 nm, as shown in Fig. 10, and complex **2** gives an intense broad emission band from 470 nm to 650 nm with the maximum at 567 nm upon excitation at 400 nm, as shown in Fig. 11. The emission may be assigned to the ligand-to-metal-charge-transfer bands (LMCT).

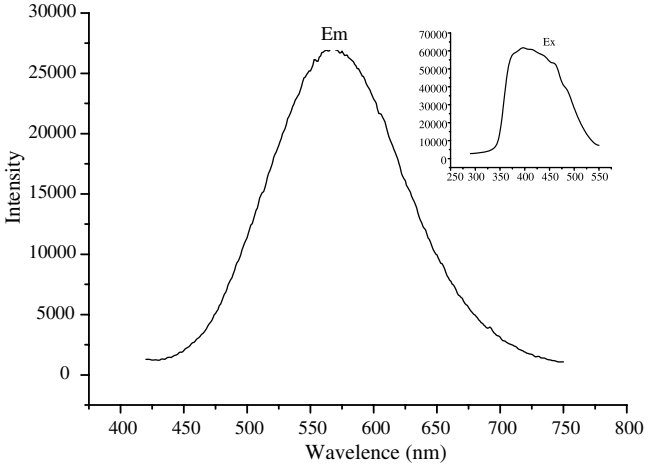

Fig. 11. Solid-state emission spectra of complex **2** at room temperature.

3.4. Magnetic study of complex 3

The EPR spectrum of complex **3** was measured at room temperature and is typical for a square-pyramidal geometry of the copper (II) ions, $g_{\parallel} = 2.43$ and $g_{\perp} = 2.10$ (average $g = 2.15$, in agreement to the value obtained by the susceptibility fit) according to the EPR measurements as shown in Fig. S4.

Abstract

The reaction of nickel and zinc chlorides and nitrates with the ligand *N*-(5,6-dihydro-4H-1,3-thiazin-2-yl)-2-aminobenzimidazole (BzTz) leads to the formation of the new complexes: $[NiCl_2(BzTz)_2]$ (**1**), $[Ni(NO_3)(BzTz)_2(H_2O)_3](NO_3)$ (**2**), $[ZnCl_2(BzTz)_2]$ (**3**) and $[Zn(NO_3)_2(BzTz)_2]$ (**4**). They have been characterized by spectroscopic methods (electronic, infrared and NMR) and magnetic susceptibility measurements. Additionally, the crystal structures of the complexes **1** and **3** have been determined by X-ray single-crystal diffraction. The ligand exhibits the *N*-benzimidazole coordination mode on interacting with the metal centers. The X-ray structure of the complexes **1** and **3** reveals a distorted tetrahedral coordination geometry around the metal center, with the metallic atoms coordinated to two chlorine atoms and two benzimidazole nitrogen atoms. These two complexes are isostructural, crystallizing in the monoclinic system and *Cc* space group. In complex **2** the geometry around the nickel atom could be described as a distorted octahedron whereas in case of complex **4** the zinc atom is in a distorted tetrahedral environment.

1. Introduction

Transition metal complexes with N-donor ligands are studied not only because of their interesting magnetic and spectral properties but also for their use as corrosion inhibitors for metals and alloys and for applications in the pharmaceutical industry for their potential antibacterial, antiviral and antitumor effects [1–3]. Moreover, metal complexes of biologically important ligands are sometimes more effective than the free ligand [1].

In this way, *N*-(5,6-dihydro-4H-1,3-thiazin-2-yl)-2-aminobenzimidazole (BzTz) is an organic compound containing important biological heterocycles that possesses potentially four nitrogen and one sulfur donor atom that can be coordinated to the central atoms in different coordination modes.

Thus, the benzimidazole moiety is structurally related to purina bases and is found in a variety of naturally occurring compounds, such as vitamin B_{12}. Benzimidazole derivatives exhibit a wide variety of pharmacological properties including antitumor activity [4] and inhibition of nucleic acid synthesis [5]. Transition metal complexes with 2-substituted benzimidazole ligands act as cytotoxic [6,7], antiviral [7] and antiamoebic agents [8].

Likewise, thiazine derivatives have also been reported as well known useful therapeutic agents [9–12] and have shown anticancer, antihistaminic, antibacterial, antidiabetic, anti-inflammatory and analgesic activities [13–21].

With regard to the different coordination modes of the BzTz ligand, we have previously reported [22] the characterization of this ligand and its cobalt(II) and cadmium(II)

doi:10.1016/j.poly.2007.02.016

complexes in which BzTz behaves as a monodentate ligand through the nitrogen atom of the benzimidazole ring. We now report the synthesis of four new nickel(II) and zinc(II) complexes with BzTz and their characterization by means of elemental and thermal analyses, IR, UV–Vis–NIR spectra, magnetic susceptibility measurements, proton and carbon nuclear magnetic resonance (^{1}H NMR and ^{13}C NMR) and moreover, in the cases of $[NiCl_2(BzTz)_2]$ (**1**) and $[ZnCl_2(BzTz)_2]$ (**3**) by X-ray diffraction. The evidence from these spectral and structural data suggests that in these new metal complexes, coordination through the *N*-benzimidazole is also observed.

2. Experimental

2.1. Preparation of *N*-(5,6-dihydro-4H-1,3-thiazin-2-yl)-2-aminobenzimidazole (BzTz)

The ligand was prepared by the reaction of 2-aminobenzimidazole and 3-chloropropylisothiocyanate in dry glyme following a previously described method [22,23]. ^{1}H NMR (DMSO): δ 7.48 (d, $J = 7.6$ Hz, 1H), 7.16 (d, $J = 7.6$ Hz, 1H), 7.02 (t, $J = 7.2$ Hz, 1H), 6.91 (t, $J = 7.6$ Hz, 1H), 6.80 (s, 2H), 3.88 (t, $J = 5.4$ Hz, 2H), 3.30 (t, $J = 6.0$ Hz, 2H), 1.92 (m, 2H); ^{13}C NMR (DMSO): δ 153.3, 145.8, 142.9, 131.8, 122.3, 118.9, 115.5, 110.8, 46.9, 26.9, 19.0. *Anal*. Calc. for $C_{11}H_{12}N_4S$: C, 56.87; H, 5.21; N, 24.12; S, 13.80. Found: C, 56.72; H, 5.24; N, 23.83; S, 14.05%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 208 (40210), 244 (22370), 279 (6755) [22].

2.2. Preparation of $[NiCl_2(BzTz)_2]$ (1)

$NiCl_2 \cdot 6H_2O$ (102 mg, 0.43 mmol) dissolved in methanol (1 mL) was added to a methanol solution (15 mL) of BzTz (100 mg, 0.43 mmol). The resulting dissolution was surrounded with ether using a liquid–vapour diffusion method to obtain blue crystals (80.7 mg, 31.6%). The crystals were filtrated, washed with cold ether and finally air-dried. *Anal*. Calc. for $C_{22}H_{24}Cl_2NiN_8S_2$: C, 44.51; H, 4.07; N, 18.88; S, 10.80. Found: C, 44.33; H, 4.32; N, 18.49; S, 10.51%.

2.3. Preparation of $[Ni(NO_3)(BzTz)_2(H_2O)_3](NO_3)$ (2)

This complex was prepared by reacting a methanol solution (1 mL) of $Ni(NO_3)_2 \cdot 6\,H_2O$ (125 mg, 0.43 mmol) with a methanol solution (15 mL) of BzTz (100 mg, 0.43 mmol). The blue precipitate (93.2 mg, 30.9%) that was obtained was filtered, washed with cold ether and air-dried several times. *Anal*. Calc. for $C_{22}H_{24}NiN_{10}O_6S_2 \cdot 3H_2O$: C, 37.78; H, 4.33; N, 20.02; S, 9.17. Found: C, 38.10; H, 4.12; N, 19.87; S, 9.07%.

2.4. Preparation of $[ZnCl_2(BzTz)_2]$ (3)

This complex was prepared by reacting a methanol solution (1 mL) of $ZnCl_2$ (59 mg, 0.43 mmol) with a methanol solution (15 mL) of BzTz (100 mg, 0.43 mmol), giving colourless crystals after slow evaporation of the solution at room temperature (87.0 mg, 67.3%). The crystals were filtrated and washed with cold ether and finally air-dried. ^{1}H NMR (DMSO): δ 7.51 (d, $J = 7.6$ Hz, 1H), 7.39 (s, 2H), 7.35 (d, $J = 7.6$ Hz, 1H), 7.09 (t, $J = 7.6$ Hz, 1H), 7.03 (t, $J = 7.8$ Hz, 1H), 3.91 (t, $J = 5.6$ Hz, 2H), 3.32 (t, $J = 5.8$ Hz, 2H), 1.94 (m, 2H); ^{13}C NMR (DMSO): δ 153.3, 144.8, 138.9, 130.7, 123.1, 120.8, 114.9, 111.0, 47.2, 27.0, 18.7. *Anal*. Calc. for $C_{22}H_{24}Cl_2ZnN_8S_2$: C, 43.97; H, 4.03; N, 18.65; S, 10.67. Found: C, 43.74; H, 4.18; N, 18.36; S, 10.29%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 208 (39618), 243 (22886), 280 (7387).

2.5. Preparation of $[Zn(NO_3)_2(BzTz)_2]$ (4)

$Zn(NO_3)_2 \cdot 6H_2O$ (128 mg, 0.43 mmol) was dissolved in methanol (1 mL) and added to a solution of BzTz (100 mg, 0.43 mmol) in methanol (15 mL). A colourless powder (106 mg, 36.2%) was obtained, which was filtered and washed with cold ether and air-dried several times. ^{1}H NMR (DMSO): δ 7.48 (d, $J = 8.0$ Hz, 1H), 7.21 (d, $J = 7.6$ Hz, 1H), 7.05 (t, $J = 7.6$ Hz, 1H), 6.94 (t, $J = 7.7$ Hz, 1H), 6.90 (s, 2H), 3.89 (t, $J = 5.6$ Hz, 2H), 3.30 (t, $J = 5.8$ Hz, 2H), 1.92 (m, 2H); ^{13}C NMR (DMSO): δ 153.3, 145.5, 141.7, 131.5, 122.5, 119.5, 115.7, 111.0, 47.0, 27.0, 18.9. *Anal*. Calc. for $C_{22}H_{25}ZnN_{10}O_6S_2 \cdot 1.5H_2O$: C, 38.80; H, 4.00; N, 20.56; S, 9.41. Found: C, 38.97; H, 3.67; N, 20.87; S, 9.28%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 207 (102005), 243 (43295), 281 (13831).

2.6. Instrumental procedures

The carbon, hydrogen, nitrogen and sulfur contents of the compounds were determined on a Leco CHNS-932 microanalyser. IR spectra were recorded on a Perkin–Elmer FT-IR 1720 spectrophotometer, from KBr pellets in the 4000–370 cm^{-1} range and on a Perkin–Elmer FT-IR 1700X spectrophotometer, from polyethylene pellets in the 500–150 cm^{-1} range. Solution electronic spectra of the ligand and the zinc complexes were measured on a Shimadzu UV-3101 PC using a 10 mm quartz cell. Solid state electronic spectra for the nickel complexes in the 200–1200 nm range were obtained from pellets of the samples, using a Shimadzu UV-3101 PC spectrophotometer and $BaSO_4$ as a reference. Magnetic susceptibility measurements were performed on polycrystalline samples using a magnetometer with a pendulum MANICS DSM8, equipped with a helium continuous-flow cryostat and an electromagnetometer DRUSCH EAF 16 UE. Data were corrected for temperature independent paramagnetism and diamagnetic contributions, which were estimated from the Pascal constants. ^{1}H (400 MHz) and ^{13}C NMR (100 MHz) spectra were recorded in DMSO on a Bruker AM 400 instrument using Me_4Si as a reference. A thermal study was carried out on a Mettler TA-3000 system, provided with a Mettler TG-50 thermobalance. The TG curve

[b] $R = \left\{ \sum \left[w\left(F_o^2 - F_c^2\right)^2 \right] / \sum \left[w\left(F_o^2\right)^2 \right] \right\}^{1/2}$.

[c] The goodness-of-fit (GOF) equals $\left\{ \sum \left[w\left(F_o^2 - F_c^2\right)^2 \right] / (N_{reflections} - N_{parameters}) \right\}^{1/2}$.

was obtained on heating a sample of the solid in a dynamic pure air atmosphere (200 mL min^{-1}) in the 30–200 °C temperature range with a heating rate of 10 °C min^{-1} and samples varying in weight from 9 to 15 mg.

2.7. Crystal structure determinations

The single crystals of **1** and **3** of suitable size were mounted in an Enraf Nonius CAD4 diffractometer equipped with graphite-monochromated Cu Kα radiation ($\lambda = 1.5418$ Å) and the intensity data were collected using the ω–2θ scan technique. Semiempirical absorption corrections were made based on psi-scan application using the WINGX [24] package. The structures were solved by direct methods and subsequent Fourier differences using the SHELXS-97 [25] program included in WINGX package [24] and refined by full-matrix least-squares on F^2 with the SHELXL-97 program [26]. All non-hydrogen atoms were refined with anisotropic displacement parameters, except atoms involved in disorder which were refined with isotropic displacement parameters. In the structure of the nickel complex, the two thiazine rings show a dynamic disorder affecting the C(2), C(2A), C(3), C(3A), N(1), N(1A), C(14) and C(14A) atoms. In the first ring, the value of the refined occupancies are 0.45(2) for C(2), C(3) and N(1), and 0.55(2) for C(2A), C(3A) and N(1A). Likewise, in the second one the occupancies are 0.52(2) for C(14) and 0.48(2) for C(14A). In the structure of the zinc complex, the two thiazine rings show a dynamic disorder affecting the C(3), C(3A), N(5), N(5A), C(13) and C(13A) atoms, the value of the refined occupancies being 0.58(3) for C(3), 0.42(3) for C(3A), 0.64(2) for N(5) and C(13), and 0.36(2) for N(5A) and C(13A). Hydrogen atoms attached to carbon and nitrogen atoms were positioned geometrically, with U_{iso} values derived from U_{eq} values of the corresponding carbon and nitrogen atoms. Details of the crystal parameters, data collection, structure determinations and refinement parameters for **1** and **3** are listed in Table 1.

3. Results and discussion

3.1. Thermal study

Since the elemental analyses of complexes **2** and **4** indicate that these compounds are hydrated, thermogravimetric dehydration studies has been performed in the 30–200 °C temperature range to determinate the nature of the water molecules involved in these complexes. TG–DTG curves for **2** and **4** are shown in Figs. 1 and 2, respectively.

The TG–DTG curve of **2** displays between 44 °C and 162 °C a first effect centered at 127 °C, that can be assigned to 2.7 waters molecules per mol of complex, with an associated mass loss of 6.87% of the initial sample ($-\Delta_{m\ exp} = 6.95\%$). This behaviour, in agreement with the IR data, suggests that this effect could be attributed to coordinated water molecules [27]. Nevertheless, in the TG–DTG curve of **4**, no effect is observed in the region 30–200 °C, therefore water molecules detected by chemical

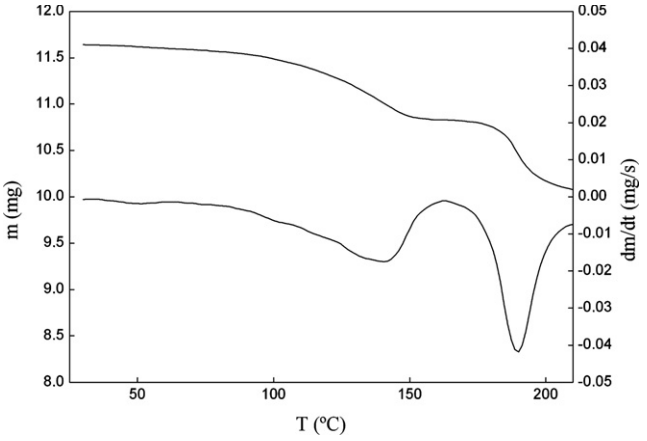

Fig. 1. TG–DTG curve for **2**.

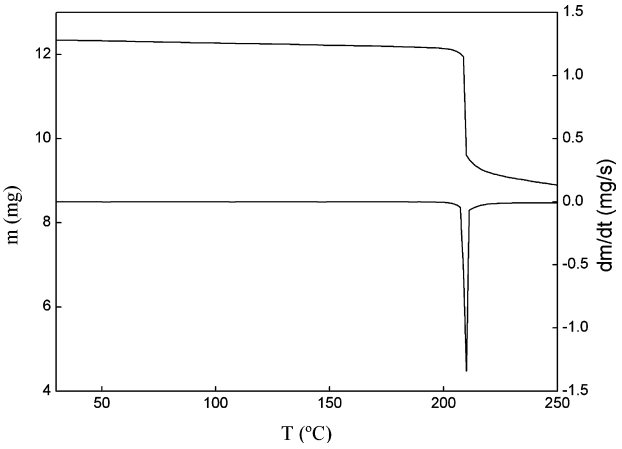

Fig. 2. TG–DTG curve for **4**.

analyses could be due to the humidity of sample, which do not form part of the compound.

3.2. Spectroscopic properties

The IR spectra of the complexes exhibit characteristic bands that emulate the features observed for the *N*-benzimidazole coordination mode in Co(II) and Cd(II) complexes with the BzTz ligand [22]. In general, for all complexes, the stretching vibrations of the benzimidazole ring are shifted to lower frequencies in relation to the free ligand, which is indicative of coordination through the benzimidazole nitrogen atom.

In addition, other bands due to nitrate ligands are registered at 727 and 700 cm^{-1} (ν_4), 1358 cm^{-1} (ν_3) and 1043 cm^{-1} (ν_1) for **2** and at 723, 713, 695 and 681 cm^{-1} (ν_4), 1385 cm^{-1} (ν_3), 820 cm^{-1} (ν_2) and 1021 and 1038 cm^{-1} (ν_1) for **4** [28]. It can be observed that there is splitting of the ν_4 band in both complexes, which suggests the presence of nitrate groups in some coordination mode. Likewise, the presence of bands at 1385, 1021 and 743 cm^{-1} for **2** indicates the existence of some nitrate groups.

Moreover, the IR spectra of complexes **2** and **4** were investigated to obtain evidence for ionic or coordinated nitrate groups, according to the method of Lever and coworkers [28–31]. The bands registered at 1770, 1749 and 1733 cm^{-1} for **2** are assigned to ($\nu_1 + \nu_4$) combination bands. The first one is assignable to combination band of an ionic nitrate group [28]. The splitting value ($\Delta = 16$ cm^{-1}) for the last two bands reveals the presence of one monodentate nitrate group, in agreement with Lever's criteria [28]. For **4**, the 1800–1700 cm^{-1} region only shows three bands at 1749 and 1733 cm^{-1} and at 1716 cm^{-1}, with a separation of 16 cm^{-1} for the first two bands and 17 cm^{-1} for the last two bands. These bands can be assigned to two monodentate nitrate groups [28].

These observations, together with those obtained by thermal and chemical analyses, have been further supported by the appearance of new bands at low frequencies, which can be assigned to M-ligand stretching vibration modes. Tentative assignments for the chloro complexes (**1**, **3**) and nitrate complexes (**2**, **4**) are listed in Table 2. The strong bands in the region 326–280 cm^{-1} are assigned to the ν(M–Cl) vibration [22,29,32–35] and the bands at 247–171 cm^{-1} can be tentatively attributed to ν(M–$N_{benzimidazole}$) vibrations [22,35,36]. In addition, the presence of a Ni–O_{water} bond in complex **3** is supported by the identification of a band due to ν(Ni–O_{water}) vibration at 300 cm^{-1} [37–39]. Finally, ν(M–ONO_2) vibrations [40–42] are registered in the spectra at 330–277 cm^{-1}.

Table 2
Far IR bands (cm^{-1}) with tentative assignments

Compound	ν(M–$N_{bencimidazole}$)	ν(M–Cl)	ν(M–O_{water})	ν(M–ONO_2)
1	247 m	326 s		
	226 m	280 s		
2	200 m		300 s	277 s
3	180 m	290 s		
	171 m	280 s		
4	203 m			330 m
	177 m			281 m

Abbreviations: (s) strong; (m) medium.

In the nickel(II) complex **1**, the electronic spectrum shows two intense bands at 380 nm (26 320 cm^{-1}) and 278 nm (35 970 cm^{-1}), which are assigned to a charge-transfer band and the $\pi \rightarrow \pi^*$ transitions of the organic ligand, respectively. Moreover, the spectrum exhibits an absorption band at 1008 nm (9920 cm^{-1}) with a shoulder at 822 nm (12 170 cm^{-1}) and an asymmetric band at 576 nm (17 360 cm^{-1}). These bands may be assigned to: $\nu_2[^3T_1(F) \rightarrow {}^3A_2(F)]$, $[^3T_1(F) \rightarrow {}^1E(G)]$ and $\nu_3[^3T_1(F) \rightarrow {}^3T_1(P)]$ transitions, respectively, in an idealized T_d symmetry. The position of the allowed d–d transitions permits the calculation of the ligand field parameters 10 Dq and *B*, using the following relationships [43]:

$$\nu_2[^3T_1(F) \rightarrow {}^3A_2(F)] = 1/2(30\ Dq - 15B) + 1/2[(10\ Dq + 15B)^2 - 12B \cdot 10\ Dq]^{1/2}$$

$$\nu_3[^3T_1(F) \rightarrow {}^3T_1(P)] = [(10\ Dq + 15B)^2 - 12B \cdot 10\ Dq]^{1/2}$$

The calculated values of the ligand field parameters 10 Dq = 5231 cm^{-1} and $B = 881$ cm^{-1} are consistent with those observed for several tetrahedral Ni(II) complexes [44].

The electronic spectrum of **2** shows a shape characteristic of octahedral complexes. The higher intensity band registered at 292 nm (34 250 cm^{-1}) can be assigned to the $\pi \rightarrow \pi^*$ transitions of the organic ligand. Also, the spectrum exhibits the presence of four absorption bands due to d–d transitions in an octahedral NiN_2O_4 crystal field [1020 nm (9800 cm^{-1}), 630 nm (15 870 cm^{-1}) with a shoulder at 802 nm (12 470 cm^{-1}) and a shoulder at 380 nm (26 320 cm^{-1})]. The four previous bands can be assigned to $\nu_1[^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)]$, $[^3A_{2g}(F) \rightarrow {}^1E_g(D)]$, $\nu_2[^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)]$ and $\nu_3[^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)]$, respectively. We have calculated the value of 10 Dq and the Racah interelectronic repulsion parameters using the following relationships [43]:

$$\nu_1[^3A_{2g}(F)\rightarrow{}^3T_{2g}(F)] = 10\ Dq$$

$$\nu_2[^3A_{2g}(F)\rightarrow{}^3T_{1g}(F)] = (1/2)(15B + 30\ Dq) - (1/2)[(15B - 10\ Dq)^2 + 12B\cdot 10\ Dq]^{1/2}$$

$$\nu_3[^3A_{2g}(F)\rightarrow{}^3T_{1g}(P)] = (1/2)(15B + 30\ Dq) + 1/2[(15B - 10\ Dq)^2 + 12B\cdot 10\ Dq]^{1/2}$$

The calculated values of the ligand field parameters $10\ Dq = 9800\ cm^{-1}$ and $B = 853\ cm^{-1}$ are consistent with the presence of the chromophore group $[Ni^{II}N_2O_4]$ [44,45].

In the ^1H NMR spectrum of **3**, the downfield shift of H-7 (δ 7.16 ppm in BzTz; 7.35 in the complex) and NH_2 (δ 6.80 ppm in BzTz; 7.39 in the complex) suggests an $M–N_{benzimidazole}$ coordination [46]. The trends in the shifts in the carbon-13 spectrum are less straightforward. However, in the ^{13}C NMR spectrum of **3** the higher field shift of the C-5 signal (δ 142.9 ppm in BzTz; 138.9 in the complex) is likewise attributable to coordination through the benzimidazole nitrogen atom. This fact is supported by the X-ray diffraction structure of $[ZnCl_2(BzTz)_2]$. In the ^1H NMR and ^{13}C NMR spectra of **4**, the signals do not show the downfield shifts normally observed, which could suggest the total dissociation of the complex in dmso-d_6 [47].

3.3. Magnetic measurements

The molar magnetic susceptibility for complexes **1** and **2** were corrected for diamagnetism and temperature-independent paramagnetism to provide the fully corrected magnetic moment at room temperature ($\mu = 3.4$ BM for **1**; $\mu = 3.2$ BM for **2**). These results suggest a tetrahedral geometry for **1** and an octahedral geometry for **2** [45,48].

3.4. Crystal structures of the complexes *1* and *3*

The molecular structure of **1** is shown in Fig. 3 together with the atomic numbering scheme. Selected bond lengths, angels and hydrogen-bonds parameters are given in Table 3.

The structure of compound **1** consists of discrete neutral monomeric units in which the environment around the metallic atom may be described as a distorted tetrahedral geometry. This distorted tetrahedral geometry about the metal is completed by two chlorine atoms [Ni–Cl(1) = 2.245(2) Å; Ni–Cl(2) = 2.232(3) Å] and two benzimidazole nitrogen atoms from two BzTz ligands [Ni–N(3) = 1.998(6) Å; Ni–N(7) = 1.997(6) Å]. The Ni–Cl

bond lengths are similar and are comparable to the calculated average value [2.230(30) Å] for 19 tetrahedral nickel(II) complexes with a $NiCl_2N_2$ chromophore group, obtained from CONQUEST software [49] from the Cambridge Structural Database (CSD, Version v5.28, November 2006) [50]. Likewise, the Ni–$N_{benzimidazole}$ bond distances are similar and comparable to the mean value [1.995(40) Å] calculated for 23 tetrahedral nickel(II) complexes. The ligand–metal–ligand bite angles differ from the ideal value of 109.5°, varying between 99.0(2)° [N(3)–Ni–N(7)] and 120.7(1)° [Cl(1)–Ni–Cl(2)].

The conformations and the puckering parameters calculated according to Cremer and Pople [51] for the thiazine rings of **1** are shown in Table 4.

The crystal structure of this complex presents intramolecular hydrogen-bonds in which nitrogen atoms N(1),

 Half-boat	$Q = 0.470$ Å $\theta = 120.0°$ $\phi = 56.6°$	−0.635 [C(14)]	C(15) = −0.077
 Half-chair	$Q = 0.291$ Å $\theta = 154.5°$ $\phi = -139.8°$	0.217 [C(12)] −0.208 [S(2)]	C(3A) = 0.112

N(1A) and N(5) act as acceptors of hydrogen, whereas nitrogen atoms of the amino groups N(4) and N(8) act as donors. A diagram showing these intramolecular hydrogen-bonds is given in Fig. 3.

Complex **3** is isostructural with **1** and with a Co(II) complex previously reported [22] (same crystal system, comparable cell dimensions, same space group and similar internal atomic coordinates). The formation of isomorphous and isostructural Co(II), Ni(II) and Zn(II) coordination compounds is common enough and occurs in particular with the coordination number 4, (pseudo)tetrahedral geometry [33,52–55] or with coordination number 6, (pseudo)octahedral geometry [53,56–62]. This phenomenon is favoured by the similarity of Zn(II), Ni(II) and high spin Co(II) ionic radii in these environments (0.74, 0.69 and 0.72 Å with coordination number 4; 0.88, 0.83 and 0.88 Å with coordination number 6, respectively) [63].

Fig. 4 shows the molecular structure of **3** and the atomic numbering system used. Selected bond lengths, angles and hydrogen-bond parameters are given in Table 3.

The tetrahedral environment of the zinc(II) ion is distorted, with the ligand–metal–ligand bite angles varying between 101.3(2)° [N(7)–Zn–N(3)] and 114.3(1)° [Cl(1)–Zn–Cl(2)]. This distortion is similar to that in **1** and $[CoCl_2(BzTz)_2]$ [22], this fact being indicated by the dihedral angles (88.4° for complex **1**, 87.8° for complex **3** and 87.2° for Co(II) complex).

The Zn–Cl and the Zn–N distances are comparable to the calculated average value [Zn–Cl = 2.222(25) Å; Zn–N = 2.051(34) Å] for 187 four-coordinated zinc(II) complexes with a $ZnCl_2N_2$ chromophore group in the CSD [49,50].

The conformations and the puckering parameters for the thiazine rings of **3** are shown in Table 5.

The crystal structure presents three intramolecular hydrogen-bonds as is shown in Fig. 4, in which the nitrogen atoms of the amino groups N(4) and N(8) act as donors of hydrogen, whereas nitrogen atoms N(1), N(5) and N(5A) act as acceptors.

4. Conclusion

In conclusion, four complexes bearing 2-aminobenzimidazole and thiazine have been synthesized. The coordination involved for the metal complexes is via *N*-benzimidazole. In the same way as that in the cadmium(II) and cobalt(II) complexes preliminary reported [22], it should be pointed out that BzTz acts as a monodentate ligand through the nitrogen atom of the benzimidazole ring probably due to the existence of an intramolecular hydrogen bond between the amine group and the thiazine nitrogen atom in the free ligand and the complexes. The formation of this metal–$N_{benzimidazole}$ bond results in an increase the N(3)–C(5) [or N(7)–C(16)] and N(3)–C(6) [or N(7)–C(17)] distances with respect to the structure of free BzTz.

The results of the present study clearly demonstrate the distorted tetrahedral coordination geometry for complexes **1** and **3**.

A study of all the characterization methods applied to compounds **2** and **4** suggests that these complexes could

be formulated as $[Ni(NO_3)(BzTz)_2(H_2O)_3](NO_3)$ and $[Zn(NO_3)_2(BzTz)_2]$, respectively. The geometry around the nickel atom could be described as a distorted octahedron whereas in case of the zinc atom as a distorted tetrahedron.

Abstract

Three di-Schiff-base ligands, *N*,*N*′-bis(salicylidene)-1,3-propanediamine (H_2Salpn), *N*,*N*′-bis(salicylidene)-1,3-pentanediamine (H_2Salpen) and *N*,*N*′-bis(salicylidine)-ethylenediamine (H_2Salen) react with $Ni(SCN)_2 \cdot 4H_2O$ in 2:3 molar ratios to form the complexes; mononuclear $[Ni(HSalpn)(NCS)(H_2O)] \cdot H_2O$ (**1a**), trinuclear $[\{Ni(Salpen)\}_2Ni(NCS)_2]$ (**2b**) and trinuclear $[\{Ni(Salen)\}_2Ni(NCS)_2]$ (**3**) respectively. All the complexes have been characterized by elemental analyses, IR and UV–VIS spectra, and room temperature magnetic susceptibility measurements. The structures of **1a** and **2b** have been confirmed by X-ray single crystal analysis. In complex **1a,** the Ni(II) atom is coordinated equatorially by the tetradentate, mononegative Schiff-base, HSalpn. Axial coordination of isothiocyanate group and a water molecule completes its octahedral geometry. The hydrogen atom attached to one of the oxygen atoms of the Schiff base is involved in a very strong hydrogen bond with a neighboring unit to form a centrosymmetric dimer. In **2b,** two square planar [Ni(Salpen)] units act as bidentate oxygen donor ligands to a central Ni(II) which is also coordinated by two mutually cis N-bonded thiocyanate ligands to complete its distorted octahedral geometry. Complex **3** possesses a similar structure to that of **2b**. A dehydrated form of **1a** and a hydrated form of **2b** have been obtained and characterized. The importance of electronic and steric factors in the variation of the structures is discussed.

Keywords: Nickel(II); Schiff base; Thiocyanate; Crystal structures; H-bonding

1. Introduction

The salen type di-Schiff base complexes of transition metals are one of the most exhaustively studied topic in coordination chemistry [1]. Their interest stems from the ease with which they can be synthesized, their versatility and wide range of complexing ability. They not only have played an important role in the development of modern coordination chemistry [2], but they can also be found at key points in the development of inorganic biochemistry [3], catalysis [4,5], magnetism, medical imaging [6] etc. Since nickel compounds are present in the active sites of urease and are used extensively in the design and construction of new magnetic materials, the study of nickel compounds is of great interest in various aspects of chemistry [7–9]. In general, the reaction of H_2Salen or related ligands with Ni(II) yields complexes in which the deprotonated, di-negative Schiff base acts as a tetradentate chelating ligand [10–21]. However, in some cases it has been found that the oxygen atoms of the Schiff base can bridge another metal ion to form multinuclear (homo- or heteronuclear) complexes [22–35]. In all the reported homonuclear nickel complexes, the oxygen atoms of two mononuclear units bridge a third Ni(II) to form a trinuclear entity and in all but one case, an additional bridging anionic ligand (e.g. acetate, nitrite etc.) was required to provide the required stability for the polynuclear structure [22–25]. Interestingly, most of the trinuclear complexes reported so far are of Salpn (Scheme 1) and contain the additional anion bridge. The geometry of all three Ni(II)

Scheme 1.

ions in those complexes is octahedral in a linear structure. To our knowledge, only one trinuclear complex has been reported incorporating Salen as the ligand and that does not have the additional anion bridge [26]. The molecule is bent and the geometry of the three Ni(II) is square planar-octahedral-square planar. On the other hand, a more flexible Schiff base *N*,*N*′-bis(salicylidene)-1,4-butanediamine shows an interesting conformational isomerism and different anion bridging behavior in its trinuclear complexes [23]. However, to have a clear idea about the steric and electronic factors that determine the structure and connectivity of such complexes, it is necessary to synthesis some more complexes.

Herein, we report the structural variation in the complexes of three di-Schiff base ligands, H_2Salpn, H_2Salpen and H_2Salen (Scheme 1) with Ni(II) thiocyanate. It is

observed that small differences in the diamine fragment can cause remarkable change in the composition and geometry of the complexes. A probable explanation for such difference in structures has also been provided.

2. Experimental

2.1. Materials

All the chemicals were of reagent grade and used without further purification. The three double-condensed Schiff-base ligands, *N*,*N*′–bis(salicylidene)-1,3-propanediamine (H_2Salpn), *N*,*N*′-bis(salicylidine)-1,3-pentanediamine (H_2Salpen) and *N*,*N*′-bis(salicylidine)-ethylenediamine (H_2Salen) have been synthesized in our laboratory by the methods described below.

2.2. Synthesis of the Schiff-base ligands (H_2Salpn, H_2Salpen and H_2Salen)

The three Schiff bases were prepared by standard methods [23,36,37]. Briefly, 10 mmol of salicylaldehyde (1.05 cm^3) were mixed with 5 mmol of the required amine, 1,3-propanediamine (0.420 cm^3), 1,3-pentanediamine (0.596 cm^3) and 1,2-ethanediamine (0.308 cm^3) for the ligands H_2Salpn, H_2Salpen and H_2Salen, respectively in methanol (10 cm^3). The resulting mixture were refluxed for an hour, filtered when hot and allowed to cool. The desired yellow precipitates were filtered off, washed with methanol and dried in a vacuum desiccator containing anhydrous $CaCl_2$.

2.2.1. Synthesis of [Ni(HSalpn)(NCS)(H_2O)] · H_2O (**1a**)

A solution of $Ni(SCN)_2 \cdot 4H_2O$ (1.84 g, 7.5 mmol) in methanol–water (9:1 v/v) mixture (10 cm^3) was added to a solution of H_2Salpn (1.4 g, 5 mmol) in methanol (10 cm^3) with constant stirring. The mixture was stirred for 1 h at room temperature and then filtered. The filtrate was left to stand overnight in air, when green X-ray quality single crystals appeared at the bottom of the vessel on slow evaporation of the solvent. The crystals were isolated, washed with methanol and dried in vacuum desiccator containing anhydrous $CaCl_2$. Yield: 1.52 g (70%). *Anal.* Calc. for $C_{18}H_{21}NiN_3O_4S$: C, 49.80; H, 4.88; N, 9.68; Ni, 13.52. Found: C, 49.52; H, 4.36; N, 9.57; Ni, 13.14%. $\lambda_{Max/nm}$ (solid, reflectance) 594 and 1042 nm; IR: ν(C=N), 1634 cm^{-1}, ν(SCN), 2094 cm^{-1}, ν(H_2O), 3328 cm^{-1}, $\mu_{eff} = 3.3$ BM.

2.2.2. Synthesis of [Ni(HSalpen)(NCS)] (**1b**)

Complex **1b** was produced as a dirty green compound by heating the complex **1a** at 140 °C for 15 mins. *Anal.* Calc. for:$C_{18}H_{17}NiN_3O_2S$: C, 51.95; H, 4.60; N, 10.10; Ni, 14.10. Found: C, 51.64; H, 4.42; N, 10.17; Ni, 14.01%. $\lambda_{Max/nm}$ (solid, reflectance) 595 and 1148 nm; IR: ν(C=N), 1611 cm^{-1}, ν(SCN), 2086 cm^{-1}, $\mu_{eff} = 3.0$ BM.

2.2.3. Synthesis of [{Ni(Salpen)(H_2O)$_2$}$_2$Ni(NCS)$_2$] · 2H_2O (**2a**)

A methanol solution of $Ni(SCN)_2 \cdot 4H_2O$ (1.84 g, 7.5 mmol) in methanol–water (9:1 v/v) mixture (10 cm^3) was added to a solution of H_2Salpen (1.54 g, 5 mmol) in methanol (10 cm^3) with constant stirring. A green precipitate appeared immediately. The mixture was stirred for 1 h at room temperature. The precipitate was filtered, washed with methanol and dried in air. Yield: 1.8 g. (70%). *Anal.* Calc. for $C_{40}H_{52}Ni_3N_6O_{10}S_2$: C, 47.24; H, 5.15; N, 8.26; Ni, 17.31. Found: C, 47.02; H, 5.11; N, 8.12; Ni, 17.17%. $\lambda_{Max/nm}$ (solid, reflectance), 595, 908 and 1175 nm; IR: ν(C=N), 1626 cm^{-1}, ν(SCN), 2098 cm^{-1}, ν(H_2O), 3401 cm^{-1}, $\mu_{eff} = 5.1$ BM per trinuclear unit.

2.2.4. Synthesis of [{Ni(Salpen)}$_2$Ni(NCS)$_2$] (**2b**)

The green precipitate of complex **2a** was dissolved in hot MeCN solution. The color of the solution changes from green to yellow during dissolution. On keeping the filtrate overnight in air, red block-shaped crystals of **2b**, suitable for X-ray analysis were obtained. Yield: 1.36g (60%). *Anal.* Calc. for $C_{40}H_{40}Ni_3N_6O_4S_2$: C, 52.85; H, 4.44; N, 9.25; Ni, 19.37. Found: C, 52.32; H, 4.36; N, 9.12; Ni, 19.48%. $\lambda_{Max/nm}$ (solid, reflectance) 490, 1182 and 1389 nm; IR: ν(C=N), 1610 cm^{-1}, ν(SCN), 2090 cm^{-1}, $\mu_{eff} = 3.3$ BM per trinuclear unit.

2.2.5. Synthesis of [{Ni(Salen)}$_2$Ni(NCS)$_2$] (**3**)

A solution of $Ni(SCN)_2 \cdot 4H_2O$ (1.84 g, 7.5 mmol) in methanol–water (9:1 v/v) mixture (10 cm^3) was added to a solution of H_2Salen (1.40 g, 5 mmol) in methanol (10 cm^3) with constant stirring. An immediate red precipitate appeared. The mixture was stirred for 1 h at room temperature. The solid was collected by filtration, washed with methanol and allowed to dry in air. The complex was only sparingly soluble in hot methanol and in DMF. However, suitable single crystals for X-ray analysis could not be grown. Yield: 1.65 g (80%). *Anal.* Calc. for $C_{34}H_{28}Ni_3N_6O_4S_2$: C, 49.51; H, 3.42; N, 10.19; Ni, 21.35. Found: C, 49.32; H, 3.26; N, 10.12; Ni, 20.37%. $\lambda_{Max/nm}$ (solid, reflectance), 510 800 and 1252 nm; IR: ν(C=N), 1627 cm^{-1}, ν(SCN), 2077 cm^{-1}, $\mu_{eff} = 3.2$ BM per trinuclear unit.

2.3. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer 240C elemental analyzer. The nickel content in all the complexes was estimated gravimetrically using DMG. IR spectra in KBr (4500–500 cm^{-1}) were recorded using a Perkin–Elmer RXI FT-IR spectrophotometer. Electronic spectra in acetonitrile (1500–350 nm) and in the solid state were recorded in a Hitachi U-3501spectrophotometer. The thermal analyses (TGA-DTA) were carried out on a Mettler Toledo TGA/DTA 851 thermal analyzer in a dynamic atmosphere of dinitrogen (flow rate: 30 $cm^3 min^{-1}$). The samples were heated in an alumina crucible at a rate of 10 °C min^{-1}.

The effective moments at room temperature were evaluated from magnetic susceptibility measurement with an EG and G PAR 155 vibrating-sample magnetometer.

2.4. Crystallographic studies

Intensity data were measured using the Oxford X-Calibur CCD System using Mo Kα radiation. The crystals were positioned at 50 mm from the CCD. 321 frames were measured with a counting time of 3 s. Data analyses were carried out with the CRYSALIS program [38] to give 5654, 11 524 independent reflections for **1a** and **2b** respectively. The structures were solved using direct methods with the SHELX97 program [39]. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. In **2b** a sulfur atom of a thiocyanate ligand was disordered over three positions each with occupancy of 0.333. Hydrogen atoms on water molecules and on O(11) were readily located in **1a** from a difference Fourier map. Absorption corrections were carried out using the ABSPACK program [40]. The structures were refined on F^2 using SHELX97 [39] to give wR 0.0569, 0.1253, wR_2 0.0825, 0.2445 for 3273, 4384 reflections with $I > 2\sigma(I)$. The relatively high R value of **2b** is due to the poor quality of the crystal. Despite our best efforts with a state-of-the-art CCD diffractometer we were unable to get a lower value. The data were collected (and refined) up to a theta angle of 60°; on refinement with a theta max of 50°, the R_1 is 0.0837 and wR_2 is 0.2225. We would like to use as much data as possible and so prefer to report the refinement using all data up to 60°. Details of crystallographic data and refinements of the complexes **1a** and **2b** are summarized in Table 1 while selected bond lengths and bond angles are presented in Tables 2 and 3 respectively. A list of H-bonds in the two complexes is given in Table 4.

3. Results and discussion

3.1. Synthesis of the complexes

We have synthesized three di-Schiff base ligands, H_2Salen, H_2Salpn, and H_2Salpen (Scheme 1) and allowed them to react separately with Ni(II) thiocyanate in 2:3 molar ratios. Although the ligands are very similar, the

composition and structure of the products are considerably different as shown in Scheme 1. H_2Salpn results a mononuclear complex, $[Ni(HSalpn)(NCS)(H_2O)]\cdot H_2O$ (**1a**) where Ni(II) is chelated by the mono-negative HSalpn. H_2Salpen produces initially a trinuclear complex $[\{Ni(Salpen)(H_2O)_2\}_2Ni(NCS)_2]\cdot 2H_2O$ (**2a**) in which the geometry around all three Ni(II) atoms is octahedral. **2a** on heating or crystallization from acetonitrile or even in contact with organic solvents e.g. dichloromethane loses the water molecules and transforms into the square planar–octahedral–square planar trinuclear complex, $[\{Ni(Salpen)\}_2Ni(NCS)_2]$ (**2b**). H_2Salen, on the other hand, yields immediately the 'square planar-octahedral-square planar' trinuclear complex $[\{Ni(Salen)\}_2Ni(NCS)_2]$ (**3**). Complexes, **1a** and **2b** have been characterized by single crystal X-ray analysis. We failed to obtain suitable single crystals for the other complexes and characterized them by elemental analyses, thermal analysis, room temperature magnetic moment measurement, IR and UV–VIS spectra.

3.2. Description of structures of *1a* and *2b*

3.2.1. Complex *1a*

The structure of **1a**, shown in Fig. 1, contains the metal in a six-coordinate, distorted octahedral environment in which O(11), N(19), N(23) and O(31) of the mono-negative Schiff base constitute the equatorial plane. The deviations of the four basal donor atoms from their mean plane are within ±0.015 Å. The Ni atom deviates from the mean plane by −0.0567(4) Å. The two axial positions are occupied by N(1) of a thiocyanate group and O(100) of a water molecule. The six-membered ring comprising the nickel, imine N atoms and three propylene C atoms adopts a chair conformation. The complex contains another non-coordinated water molecule and there is a strong hydrogen bond between the coordinated and uncoordinated two water molecules as shown in Fig. 1. A weaker H-bond is also formed between one of the hydrogen atoms of this uncoordinated water molecule (H4) and the N(1) atom of the coordinated isothiocyanate (Table 4). One interesting feature of this complex is that one of the oxygen atoms (O11) of the Schiff base is protonated which allows the charge on the complex to be balanced. The presence of H on O(11) is substantiated by the longer Ni(1)–O(11) bond distance of 2.039(3) Å compare to Ni(1)–O(31) bond distance of 2.025(2) Å. However, it should also be noted that the difference in bond distances is not remarkable and the Ni(1)–O(31) bond is rather long compare to that found in octahedral Ni(Salpn) type complex (2.017(2) Å) [13]. This can be explained by the involvement of this hydrogen (H11) in a very strong hydrogen bond with O(31) of another unit to form a centrosymmetric dimer as shown in Fig. 2. The symmetry related dimers are linked by weaker O100–H(2)···S(1) intermolecular hydrogen bonds to form a two dimensional layer structure as shown in Fig. 3. It is interesting to note that the same ligand has previously been reacted with nickel(II) thiocyanate adopting a different procedure [41] to form the complex, $[Ni(HSalpn)(NCS)(CH_3OH)]$ which is analogous to **1a**. The only difference is that the axially coordinated water of **1a** is replaced by a MeOH molecule. The bond angles and distances of the two compounds are very similar. However, the difference (0.040 Å) between two Ni–O (Schiff base) bond distances (2.054 and 2.014 Å) of that complex is slightly higher than that (0.014 Å) in **1a** probably due to the weaker H-bond that is formed involving the hydrogen atom attached to the Schiff base of that compound.

3.2.2. Complex *2b*

The structure of **2b** is a trinuclear compound as shown in Fig. 4 containing three independent nickel atoms. Ni(1) is six-coordinate with a distorted octahedral environment, while Ni(2) and Ni(3) are four-coordinate with a square planar environment. Each of the two

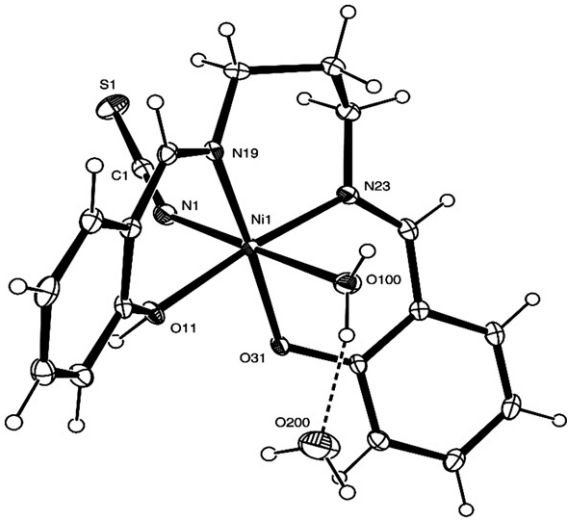

Fig. 1. Ortep-3 view of the complex **1a** with ellipsoids at 50% probability.

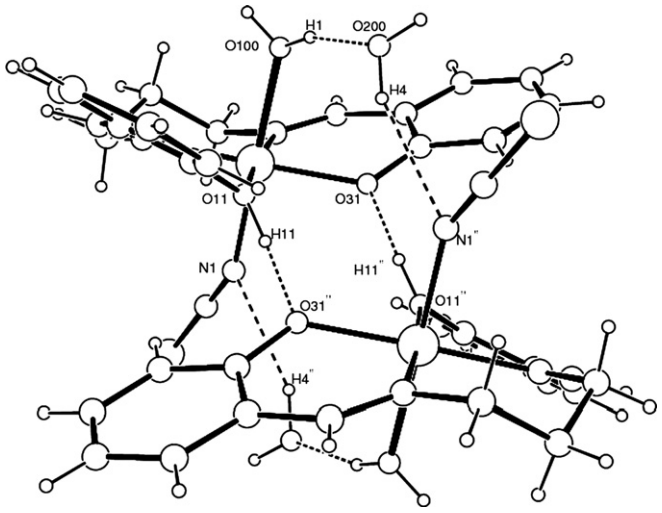

Fig. 2. Ortep-3 view of the dimeric unit c of **1a** with ellipsoids at 20% probability.

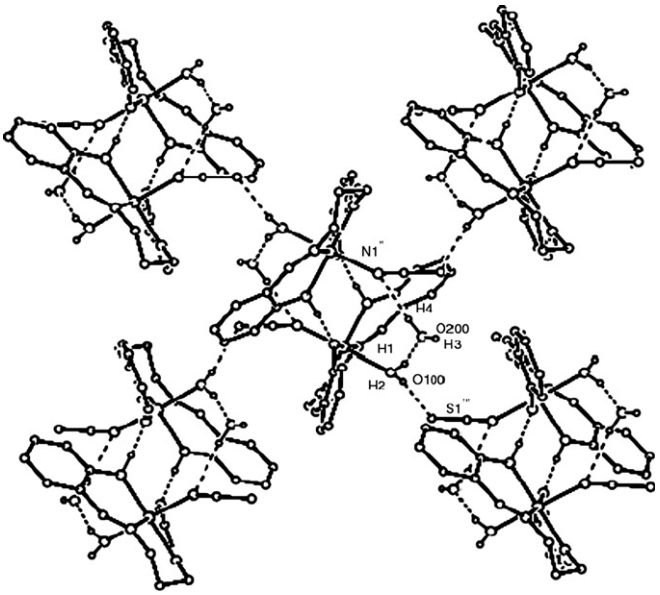

Fig. 3. Extended hydrogen-bonding network in complex **1a**.

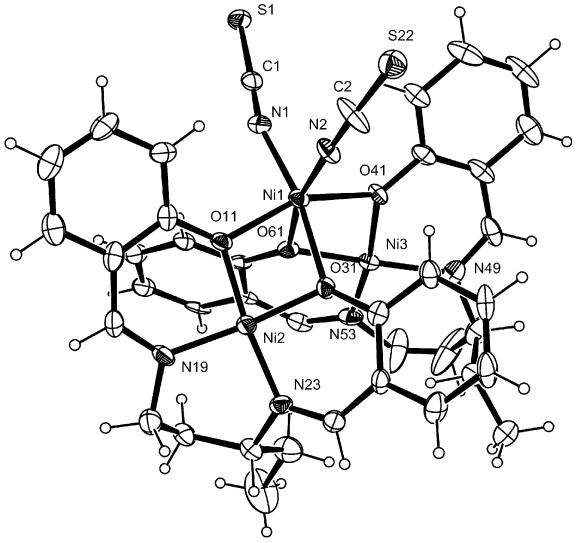

Fig. 4. ORTEP-3 view of the complex **2b** with ellipsoids at 25% probability.

terminal nickel atoms, Ni(2) and Ni(3) are coordinated by the two nitrogen atoms and two oxygen atoms of the deprotonated, chelating Schiff base ligand, H_2Salpen. The average trans angles are 172.8° and 168.2° for Ni(2) and Ni(3), respectively indicate that there is slight tetrahedral distortion from the ideal square planar geometry. The deviations of Ni(2) and Ni(3) from the respective mean planes passing through the coordinating atoms are 0.019(1) and −0.018(1) Å. The six-membered chelate rings containing the diamine fragment and nickel atom adopt boat and half-chair conformations for Ni(2) and Ni(3), respectively.

The four oxygen atoms of the two Ni(Salpen) moieties are also bonded to a third nickel atom Ni(1) forming the phenoxo bridged trinuclear complex. In addition Ni(1) is bonded to two mutually cis isothiocyanate ligands with Ni(1)–N(1) 2.016(9), Ni(1)–N(2) 2.009(9) Å to complete its distorted octahedral coordination. The small bite of Ni(Salpen) on coordinating to Ni(1) (average angle 70.8°) is the main cause of distortion from the ideal octahedron. The bond lengths, Ni(1)–O(11) 2.096(6), Ni(1)–O(31) 2.102(6) Å with the oxygen atoms bridging to Ni(2) and Ni(1)–O(41) 2.057(6) Å, Ni(1)–O(61) 2.137(6) Å with the oxygen atoms bridging to Ni(3) are significantly longer than Ni(2)–O and Ni(3)–O distances at 1.853(6), 1.859(6), 1.876(6), 1.878(6) Å. This difference is expected as in Ni(II) complexes, the bond distances in square planer geometry are usually less than that in octahedral geometry indicating that the axial coordination weakens the equatorial ligand field strength [12,13,15,41]. The Ni(2)–O and Ni(3)–O bonds are, however, slightly longer than those found in the mono-nuclear square planar Ni(Salpn) complex (1.845 Å) as a result of lower electron density of the oxygen upon bridging. A comparison of the structures of the similar complexes reveals an interesting feature – when trinuclear Ni(II) complexes are formed by both phenoxo- and anion bridges, the resulting complexes are linear in which the four phenoxo groups occupy a square plane (four meridional positions) of the central Ni(II) leaving its *trans* axial positions to be occupied by the bridging anions [22–25]. However in the case of complexes containing phenoxo bridges only (as is **2b**), the four oxygen atoms coordinate in facial manner to the central Ni(II) to result in a bent structure [26]. In **2b,** the Ni(2)–Ni(1)–Ni(3) angle is 87.88(5)° and the two Ni(Salpen) planes are disposed at a dihedral angle of 37.9°, compared to17.6° for the Ni(Salen) complex [26].

3.3. IR and UV–VIS spectra, thermal analysis and magnetic moment of the complexes

*3.3.1. Complexes **1a** and **1b***

The coordination mode of the thiocyanate anion to the transition metal is detected by the intense IR band due to (SCN) which occurs above 2000 cm^{-1}. The CN stretching frequency for N-bonded thiocyanate usually appears below 2100 cm^{-1} and that of S-bonded thiocyanate appears above 2100 cm^{-1} [42]. Complex **1a** shows a strong absorption band at 2094 cm^{-1} corroborating the presence of N-bonded thiocyanate group. It shows a strong and broad band, centering at 3328 cm^{-1} due to the presence of water molecule. Generally, stretching vibration for water appears above 3400 cm^{-1}. The shift of this band towards lower wave number and its broadness indicate the presence of strong hydrogen bonding as is substantiated by crystal structure. The band due to azomethine (C=N) appears at 1634 cm^{-1}. The magnetic moment ($\mu_{eff} = 3.3$ BM) and the appearance of two bands in the UV–VIS spectra of the complex corroborate its octahedral geometry. The highest energy d–d transition band is obscured by the CT band at that region.

The simultaneous TGA–DTA curves of complex **1a** reveal that upon heating it starts to lose water molecules at 90 °C and becomes dehydrated at ca. 150 °C in a single step. The observed weight loss (8.6%) corroborates the loss

of two water molecules (calc. 8.29%). Both the coordinated and crystallized water molecules are lost simultaneously as they are linked by strong hydrogen bonds. The dehydrated species (**1b**) is dirty-green in color and reabsorbs the two water molecules on keeping in open atmosphere for several days. It, however, does not absorb any organic solvent (e.g. methanol or acetonitrile) on keeping as suspension in these solvents. The magnetic moment of **1b** ($\mu_{eff} = 3.0$ BM) shows the presence of two unpaired electrons. Its electronic spectra indicate either penta-cordinated or hexa-coordinated geometry around Ni(II). The IR spectra of **1b** expectedly do not show any band due to water molecule. The (SCN) stretching vibration occurs nearly at the same wave number (2095 cm^{-1}) as in **1a** indicating no change of its coordination behavior on deaquation. Therefore, a penta-coordinated geometry around Ni(II) with an N-bonded thiocyanate is suggested for **1b**.

*3.3.2. Complexes **2a** and **2b***

The green compound **2a** is unstable and loses its water molecules on drying in a desiccator or in contact with organic solvents such as chloroform, dichloromethane etc. to transform into the red colored compound, **2b**. Therefore, an air dried sample of **2a** has been used for all physico-chemical studies. Complex **2a** shows a single absorption band at 2099 cm^{-1} due to the presence of coordinated isothiocyanate group. A strong and broad band around 3400 cm^{-1} indicates the presence of water molecules in it. The band due to azomethine appears at 1630 cm^{-1}. The magnetic moment ($\mu_{eff} = 5.1$ BM for trinuclear structure; 3.0 BM per Ni ion) and electronic spectra of the compound are typical of octahedral Ni(II) complexes. Therefore, a phenoxo bridged, trinuclear structure in which the two terminal Ni(II) have axially coordinated water molecules is suggested for it (Scheme 1). Upon heating, it starts to lose water molecules at ca. 40 °C and become anhydrous at ca. 110 °C. The observed weight loss (11.0%) corresponds to the presence of six molecules of water per trinuclear unit (calc.10.6%). The color of the species changes from green to red on dehydration. It does not reabsorb any water molecule on keeping in open atmosphere. The spectral and analytical results of the dehydratd species confirm that it is identical to compound **2b**.

The physico-chemical studies of **2b** corroborate its trinuclear structure as elucidated by X-ray analysis. The electronic spectra clearly show the presence of both octahedral and square planar Ni(II) in the compound. The magnetic moment ($\mu_{eff} = 3.3$ BM) corresponds to the presence of one paramagnetic octahedral Ni(II) per trinuclear unit. In IR spectra, stretching vibration band due to thiocyanate (SCN) and azomethine (C=N) appears at 2090 cm^{-1} and 1610 cm^{-1}, respectively and there is no band due to water around 3400 cm^{-1}.

*3.3.3. Complex **3***

The analytical, spectral and magnetic data of **3** indicate that it has similar composition and structure to that of **2b.** In IR spectra, no band due to water is found. The (SCN) and (C=N) bands appear at 2077 cm^{-1} and 1627 cm^{-1}, respectively. In the electronic spectra, peaks due to both square planar and octahedral Ni(II) appear and the magnetic moment indicates the presence of one paramagnetic Ni(II) with two unpaired electron per trinuclear unit.

3.4. Variation of structures with chain length and substitution in diamine fragment

The three Schiff bases that have been used here are very similar (Scheme 1). Salen forms a five membered chelate ring with the metal ion by the coordination of two nitrogen atoms. The diamine fragment in Salpn is 1,3-propanediamine and consequently a six membered ring is formed on chelation of the two nitrogen atoms of the Schiff base. Salpen forms a similar six-membered chelate ring but there is an ethyl substitution in one of the ring carbon atoms. On reaction with Ni(II) thiocyanate both Salen and Salpen form phenoxo bridged, square planar–octahedral–square planar trinuclear complexes (**3** and **2b**, respectively). The initial formation of trinuclear species with all three nickel atoms in octahedral environments (**2a**) with Salpen but not with Salen may be explained by their slight difference in ligand field strength. The steric hindrance due to the bulkier trimethylene group between the N atoms causes a weaker ligand field for the Schiff bases derived from 1,3-propanediamine and its derivative. As a result, water molecules can coordinate to Ni(II) axially as is found in **2a**. In fact, for this reason, all the Ni(II) complexes where Salen acts as a chelate are square planar [10–21] but complexes of Salpn type ligands can be square planar [12], penta- [15] or hexa-coordinate [13,41] species. It also explains the existence of several trinuclear Ni(II) complexes which are bridged both by phenoxo and an anionic ligand to form octahedral geometry around all three Ni(II) containing Salpn but not Salen as ligand [22–25].

The composition and structure of **1a**, on the other hand, is very different from the complexes that are usually formed by salen-type Schiff base ligands. The hydrogen atoms present in the –OH group of these types of Schiff bases are acidic in nature. Generally, when metal ion is added, the two oxygen atoms coordinate to the metal center and consequently their acidity is increased so much that these protons are lost readily and a complex with di-negative Schiff base is formed. Complex **1a** is an interesting exception in which the very uncommon mono-negative Schiff base is stabilized making the stoichiometry and structure of **1a** different from other related complexes. An explanation for the formation of this exceptional compound may be as follows:

The weak ligand field of Salpn as discussed above allows axial coordination of a thiocyanate and a water molecule (or methanol [41]). The proton bonded to one of the oxygen atoms is stabilized by the formation of a very strong H-bonded dimer (Fig. 2) The supramolecular two-dimensional H-bond structure involving the water molecules and thioyanate group (Fig. 3) also tilts the balance

in favor of the mononuclear complex containing the mononegative Schiff base over the trinuclear one. Salen does not allow the formation of such a complex as axial coordination to Ni(II) is unfavorable. The ethyl group present in the Salpen ligand probably prevents the formation of the H-bonding network and consequently the trinuclear complex is formed. The formation of phenoxo bridged trinuclear or H-bonded mononuclear compounds of Ni(II) is thus a delicate balance of electronic and steric effects of the Schiff base ligand as well as the capability of different donor and acceptor sites to form intermolecular hydrogen bonds to an adjacent coordinated ligand.

4. Conclusion

The present study shows that in Schiff base complexes of Ni(II), the environment at coordination center can be modified by changing the chain length or introducing substitution in carbon atom of the diamine. A minor difference in the subunit structure can bring about drastic change in molecular and crystal structure. The examples nicely illustrate the importance of steric and electronic properties for the fine tuning of composition and structure. Formation of **2a** demonstrates the importance of hydrogen bonding in the formation of unusual compounds.

Abstract

Two new bulky ligands, *N*-(1-adamantyl)-3,5-^{t}Bu$_2$-salicylaldimine (**1**), and *N*-(2-adamantyl)-3,5-^{t}Bu$_2$-salicylaldimine (**2**), and their copper bis-chelate complexes, **3** and **4**, have been prepared and their analytical, spectroscopic and magnetic properties, chemical and electrochemical redox reactivity are described. EPR and UV/Vis results [higher $g_{\|}/A_{\|}$, lower energy λ (nm)] for **3** and **4** suggest a distorted square planar geometry with a higher degree of distortion for **3** than for **4**. Chemical oxidation of **1**–**4** by ACN, on the basis of their EPR and UV/Vis spectra results in the formation of the free $\mathbf{1}^{\cdot+}$, $\mathbf{2}^{\cdot+}$ phenoxyl and Cu(II)-phenoxyl radicals complexes [$g = 2.0065$ ($\mathbf{3}^{\cdot+}$), 2.0099 ($\mathbf{4}^{\cdot+}$) and λ_{max} at *ca.* 430 and 720 nm]. Electrochemical studies have shown that the complexes possess ligand- and copper(II)-centered quasi-reversible and irreversible responses and the more distorted complex **3**, having the bulkier 1-adamantyl on the imine nitrogen, was reduced at a more negative potential than the less distorted complex **4**.

1. Introduction

There has been considerable interest in copper (II) salicylaldimine (SA) complexes, for example they have been studied as model compounds for biological dioxygen carriers [1], metalloenzymes [1b], oxidative coupling reactions of phenol compounds [2] or used as catalysts in catalytic reactions [3]. The ability of copper-containing enzymes such as tyrosinases and catechol oxidases to reversibly bind and activate molecular oxygen plays a vital role in biological oxidation catalyses [3]. The discovery of the Cu^{II}-phenoxyl radical in the active site of copper(II)-containing enzymes (galactose and glyoxal oxidases) [4] has stimulated the development of structural and functional model transition metal complexes with coordinated phenolate or phenol ligands which are used for the direct generation of coordinated or uncoordinated M^{II,III}-phenoxyl radical complexes [4–6]. Model complexes of this kind are important because they allow the definitive establishment of spectroscopic features of *coordinated versus uncoordinated* phenoxyl radicals and to understand their chemical reactivity.

Nevertheless, in simple systems such as bis-bidentate SA complexes there are still some stereochemical and conformational questions. For instance, it has been reported that tetrahedral distortion is enhanced in bis(*N*-alkyl-SA)copper(II) complexes as the bulkiness of the alkyl group increases and in parallel to this the reduction potential shifts to more positive values as the distortion from planarity of those complexes is enhanced [7]. However, in the analogous bis(*N*-cycloalkyl-naphthaldiminato)copper(II) complexes, the above trend is inversed [8].

In continuation of our early studies [9,10] on the chemistry and reactivity of metal complexes with salicylaldimines bearing sterically protected 2,6- or

3,5-^{t}Bu$_2$-substituted phenol arms, which enable them to produce stable phenoxyl radical complexes, we report herein the synthesis, spectroscopic characterization, as well as chemical oxidation and electrochemical behaviors of bis[*N*-(adamantly)-3,5-^{t}Bu$_2$-salicylaldiminato]Cu(II) complexes. The *N*-(1-adamantyl)-3,5-^{t}Bu$_2$-salicylaldimine (L_1H) and *N*-(2-adamantyl)-3,5-^{t}Bu$_2$-salicylaldimine (L_2H) ligands and their corresponding Cu(L_1)$_2$ and Cu(L_2)$_2$ bis(ligand) complexes are abbreviated as **X** (**X**=**1**, **2**, **3** and **4**, respectively).

2. Experimental

2.1. Measurements

The C, H, N elemental analyses were performed on a LECO CHNS-932 model analyzer by the microanalytical services of the Department of Chemistry at the University of Inonu. Electronic absorption spectra were recorded on a Shimadzu 1601 UV–Vis spectrophotometer in the range 1100–200 nm. IR spectra were recorded on a Perkin–Elmer FTIR spectrometer using KBr disks. ^{1}H NMR spectra were recorded on a Bruker Spectro spin Avance DPX-400 Ultra Shield Model NMR using TMS as an internal standard in $CDCl_3$. The room temperature (r.t.) magnetic susceptibility measurements were performed by using a Sherwood Scientific magnetic balance and the diamagnetic corrections were evaluated using Pascal's constants. ESR spectra were taken on a Varian E109 C X-band spectrometer. The field and frequency calibration were made using DPPH ($g = 2.0037$) powder.

Electrochemical measurements were recorded on a PC-controlled Eco Chemie-Autolab-12 potentiostat/galvanostat in nitrogen degassed solutions of *ca.* 10^{-3}–10^{-4} M of **X** containing 0.05 M Et_4NBF_4 as the supporting electrolyte. The potentiostat/galvanostat has an iR compensation option. Cyclic voltammetry were taken in a conventional three-electrode cell consisting of a Pt auxiliary electrode, an Ag/AgCl reference electrode and a 2 mm sized Pt disc working electrode. Prior to running the voltammograms, the solutions were purged with dry nitrogen for 3–4 min in order to remove dissolved oxygen. The potentials are referred to Ag/AgCl in the potential range +1.5 to −1.85 V.

2.2. Materials

All commercial chemicals and solvents were of spectroscopic and HPCL grade and were used without further purification. *N*,*N*-Dimethylformamide (DMF), dimethylsulfoxide (DMSO), acetonitrile (MeCN), chloroform, alcohols, 2,4-di-*tert*-butylphenol, $(NH_4)_2Ce(NO_3)_6$ (ACN), Et_4NBF_4, copper(II) acetate monohydrate, 1-adamantanamine, 2-adamantanamine hydrochloride were obtained from Aldrich Chemical Co, Inc. 3,5-^{t}Bu$_2$-salicylaldehyde was prepared as described in the literature [11]. The ligands and the copper(II) complexes were prepared by methods described elsewhere [10].

2.3. Preparation of the ligands and the complexes

N-(1-Adamantanyl)-3,5-^{t}Bu$_2$-salicylaldimine (**1**) and *N*-(2-adamantanyl)-3,5-^{t}Bu$_2$-salicylaldimine (**2**) were prepared using standard procedures involving the condensation of 3,5-^{t}Bu$_2$-salicylaldehyde with the appropriate 1-adamantanamine and 2-adamantanamine in refluxing ethanol in the presence of a catalytic amount of formic acid. The yellow products were recrystallized from methanol and air-dried. **1**: yield 65%, M.p. 140 °C. 3. Results and discussion

All of the SA ligands and complexes studied were prepared in good yields as yellow (**1**,**2**) and brown (**3**,**4**) crystalline solid products. Satisfactory elemental analyses were obtained for all of the compounds. Spectroscopic (IR and ^{1}H NMR) data for the ligands are consistent with the formulations of **1** and **2**. The ligands are soluble in MeOH, EtOH, MeCN, CH_2Cl_2 and $CHCl_3$, but the complexes are less soluble in solvents such as alcohols, MeCN and benzene; in addition complex **4** is very poorly soluble even in MeCN and DMSO.

3.1. IR, ^{1}H NMR and electronic spectra

Important IR absorption frequencies of **1**–**4**, along with their assignments, are given in Section 2. The IR spectra of **1** and **2** exhibit a broad absorption band at *ca.* 2660 cm^{-1} due to ν(OH) involved in intramolecular (O–H···N) H-bonding that disappears upon complexation. The ν(C=N) vibration (~1632 cm^{-1}) of **1** and **2** undergoes shifts to lower frequencies in the spectra of **3** and **4** (1608 and 1620 cm^{-1}), indicating coordination of the iminic nitrogen [12a]. The ^{1}H NMR spectral results obtained for **1** and **2** in $CDCl_3$, with their assignments, are given in Section 2. The ^{1}H NMR signals were assigned on the basis of their integral intensity, spin–spin coupling pattern and chemical shift values.

The electronic spectra of **1**–**4** and their oxidized intermediates recorded in ethanol, MeCN and $CHCl_3$ are presented in Table 1. The intraligand absorptions <400 nm are assigned to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions in the enoliminic tautomer. The low intensity band at *ca.* 416 nm is assigned to a $n \rightarrow \pi^*$ transition in the dipolar zwitterionic or ketoamine tautomeric structures of **1** and **2** (Table 1) [12b,12c]. Within the visible region, **3** and **4** manifest absorptions at *ca.* 525 and 800(sh) nm and 480 and 680(sh) in $CHCl_3$ and MeCN, respectively (Table 1). In each case, the higher energy transition is assigned to a phenolate-to-Cu(II) charge transfer transition, on the basis of comparisons with the UV/Vis spectra of other Cu(II)-phenolate complexes [6b]. The bands observed around 700 and 800 nm are assigned to d–d transitions in the pesudotetrahedral geometry [7b,7c].

3.2. EPR and magnetic properties of the complexes

The X-band EPR spectra of polycrystalline samples of both complexes **3** and **4** have been recorded in the temperature range from 300 K to 113 K, which clearly exhibit three and five resolved lines in the $g_{\|}(g_{zz})$ region, respectively, and one unresolved asymmetric pattern in $g_{\perp}(g_{xx}/g_{yy})$ region (Figs. 1 and 2). These facts suggest the absence of dipolar broadening and that spin exchange between adjacent molecules is not fast enough to average the A-anisotropy [13a]. When the temperature was decreased from 298 to 133 K, with a slight change in the line widths and g-factors ($g_{\|} = 2.286$, $A_{\|} = 112$ G, $\Delta H_{\|} = 56$ G at 298 K and $g_{\|} = 2.276$, $A_{\|} = 124$ G, $\Delta H_{\|} = 62$ G at 113 K for **3**), increases of the signal intensities by factors of about 2.6 and 2.2 for **3** and **4**, respectively, were detected. These behaviors are indicative of ferromagnetic type exchange interactions [14]. An antiferromagnetic exchange interaction would decrease the ESR intensity with a decrease of temperature. The appearance of five non-equally separated lines, which were detected as a broad peaks and overlapped shoulders in the $g_{\|}$ region of the powder ESR spectrum of **4** is not typical for mononuclear or binuclear Cu(II) complexes. In addition, the $CHCl_3$ solution spectrum of this sample at 300 and 193 K is typical for mononuclear copper(II) species. The reason of this anomaly is not apparent. It is thought that one reason of this behavior may be anisotropic spin relaxation effects in the crystal state. It is interesting that the powder spectrum of **4** exhibits appreciable line broadening at lower temperature and as a result of this, along with disappearance of the fifth line around 2960 G, the other $g_{\|}$ components become ill-defined at 113 K. Spin-Hamiltonian parameters g_{iso}, A_{iso}, $A_{\|}$ and $g_{\|}$, extracted from experimental spectra of polycrystalline, frozen glass and solution samples, are collected in Table 2. The spectra of **3** exhibits three well resolved lines of the four g_{zz} components in the temperature range 293 to 113 K, which is typical of a Cu(II) complex possessing a $(d_{x^2-y^2})^1$ or $(d_{xy})^1$ ground state ($S = 1/2$), with $g_{\|} > g_{\perp} > g_e$ [13b]. The appearance of five non-equally spaced line components in the $g_{\|}$ region in the solid-state spectrum of **4** is unusual for $S = 1/2$ Cu(II) systems and suggests the existence of magnetically non-equivalent copper(II) ions in the unit cell, having different g- and A-tensors

Table 1
Electronic spectral data for **1**–**4** and their oxidized intermediates

Compound	Solvent	Electronic spectra, λ (nm), ($\log\varepsilon$, M^{-1} cm^{-1}); absorbance (A)

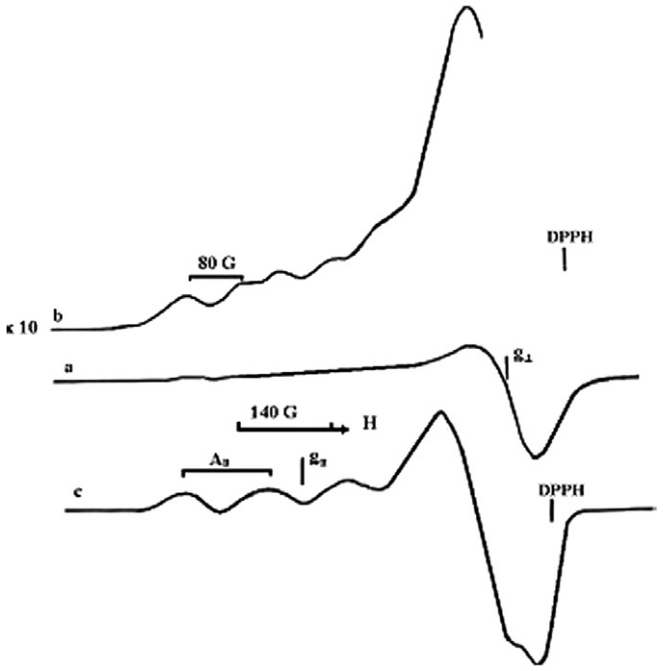

Fig. 1. The polycrystalline EPR spectra of **4** at 300 K (a and b) and **3** at 253 K.

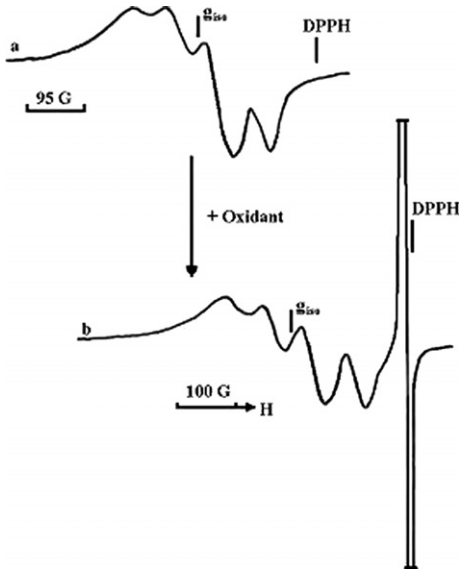

Fig. 2. (a) Solution EPR spectrum for **4** and (b) for the **4** + ACN system at 300 K in $CHCl_3$ solution.

($g_\parallel = 2.248$, $A_\parallel = 144$ G, $g_\parallel/A_\parallel = 166$ cm and $g_\parallel = 2.178$, $A_\parallel = 152$ G, $g_\parallel/A_\parallel = 154$ cm at 293 K). The $g_\parallel/A_\parallel$ ratio, which reflects the degree of the tetrahedral distortion from square-planar geometry in the Cu(II) complexes, for powder samples of **3** and **4** were found to be 208 cm and 162 cm (average) at 293 K, respectively, suggesting that the former complex is considerably more distorted than the latter in the solid state [15]. It should be noted that due to the overlapping of $g_\parallel$ components in the spectra of powder samples of **4** (Fig. 1b), a more accurate estimation of the $g_\parallel$ and $A_\parallel$ tensors is difficult. Thus the observed $g_\parallel > g_\perp > g_e$ and the $G = (g_\parallel - g_e)/(g_\perp - g_e)$ in the range 3–5 are consistent with a $(d_{x^2-y^2})$ or d_{xy} ground state having a small exchange coupling [13b]. Comparison of the $g_\parallel/A_\parallel$ values indicates that the degree of tetrahedral distortion in **3** is higher than that in **4**.

The X-band ESR spectra of **3** and **4** obtained in $CHCl_3$ solution at 300 and 173 K correspond to the common spectra for monomeric copper(II) complexes with the axial $g_\parallel > g_\perp > g_e$ trend, typical for copper(II) complexes with a $(d_{x^2-y^2})^1$ or $(d_{xy})^1$ ground state ($S = 1/2$), (Table 2). Their solution spectra do not display superhyperfine features from the nuclear spin of the coordinated nitrogen atoms (^{14}N; $I = 1$), not in the g_{xx}/g_{yy} region (173 K) or on the high field components of the r.t. spectra. According to the values of the $g_\parallel/A_\parallel$ ratio (Table 2), in $CHCl_3$ solution the tetrahedral distortion in **3** is significantly higher than that in **4**. The ratio of $g_\parallel/A_\parallel = 142$ cm, determined from the frozen glass spectrum of **4**, suggests that the CuN_2O_2 chromophore of this complex adopts a square-planar geometry in $CHCl_3$ solution. At the same time, the $g_\parallel/A_\parallel$ quotient for the solid state (220 cm) and solution (189 cm) spectra of **3** indicate that the tetrahedral geometry of this complex practically remains unchanged upon dissolution. It is necessary to note that for a four-coordinate copper(II) system, the $g_\parallel/A_\parallel$ ratio is a function not only of the tetrahedral distortion from the square-planar structure but also is dependent upon the nature and numbers of the atoms (for example, O_4, N_4, S_4, N_2O_2, N_2S_2, O_2S_2 and others) coordinated to copper(II) [14b,16].

The room temperature effective magnetic moments of **3** and **4** were found to be $1.66\mu_B$ and $1.83\mu_B$, respectively, which is reasonable compared to the theoretical spin-only value of $1.73\mu_B$ for $S = 1/2$ systems. Although the μ_B value of **4** is typical for square-planar or pseudo-tetrahedral mononuclear copper(II) complexes, the value for **3** is similar to those in magnetically dilute systems, in which the magnetic centers are separated by more than 8 Å [13b].

Table 2
ESR parameters for complexes **3** and **4**

Complex	Polycrystalline spectra				Solution ($CHCl_3$) spectra							
	$g_\parallel$	$g_\perp$	$A_\parallel$	G	g_{iso}	$g_\parallel$	$g_\perp$	A_{iso}	$A_\parallel$	$A_\perp$	$g_\parallel/A_\parallel$	G
3	2.286	2.084	118	3.47	2.127	2.275	2.054	66	130	23	186.9	5.27

	2.178	2.062	152	2.94								

3.3. Chemical oxidation of 1–4 with ACN

Our recent studies demonstrated that the chemical oxidation of bis[*N*-alkyl(aryl)-3,5-^{t}Bu$_2$-salicylaldiminato]copper(II) complexes by $(NH_4)_2[Ce(NO_3)_6]$ (ACN) in $CHCl_3$ was accompanied by a decrease of the intensity of their ESR spectra and the appearance of radical signals [9]. A similar EPR investigation of the oxidative behavior of **3** and **4** revealed that when they are treated with a 2–3 fold excess of ACN in $CHCl_3$ at r.t., along with a color change from dark brown to green, a decrease in intensity of their EPR spectra and appearance of new radical signals with $g = 2.0099$ and 2.0065, respectively, were observed (Fig. 2b). The observed g values are slightly greater than that observed for free phenoxyl radicals (~2.004–2.005) [17]. The decrease in the EPR signal intensity of the oxidized complexes probably results from magnetic coupling between a $S = 1/2$ Cu(II) center and a $S = 1/2$ coordinated radical ligand in Cu^{II}-·OPh radical species. Our suggestion, the generation of M-phenoxyl radical complexes, is supported by EPR, UV/Vis and X-ray evidences, which recently were reported for bis(*N*-aryl(alkyl)-3,5-^{t}Bu$_2$-salicylaldiminato)M(II) complexes where M = Cu(II), Co(II) and Pd(II), and other types of various metal complexes bearing di-*tert*-butyl protecting groups on the ligands [5,6,9].

The spectral changes for **X** + ACN systems were monitored by UV/Vis spectroscopy during the progress of the oxidation of **X** in $CHCl_3$. The oxidant is insoluble in $CHCl_3$ so the reaction system was heterogeneous and prior to each scanning, the solution of the sample was mixed with the oxidant by using a spatula for 5–6 s. Then the solution was transferred into a 1 cm quartz cuvette to measure the spectrum. When a 3–4 fold excess of ACN was added to the solutions of **3** and **4** in $CHCl_3$ at r.t., the dark brown solutions turned green with a decrease of the intensity of their original visible bands in the 480–800 nm region, and a new band at *ca.* 660–690 nm was detected (Fig. 3). After 2–3 scans, the initial bands

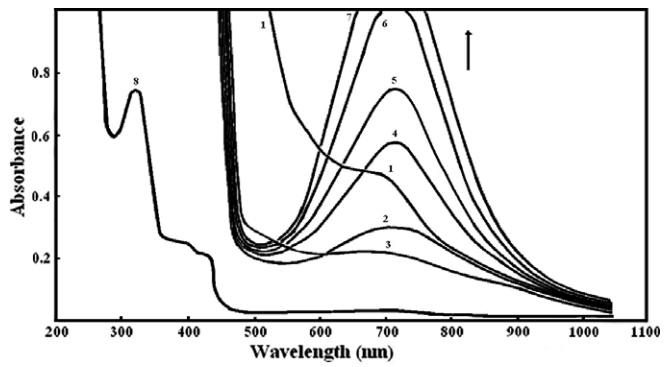

Fig. 3. The change in the absorbance of UV/Vis spectra of the **4** + ACN system in the time course (5 min) in $CHCl_3$ solution at r.t. and aerobic conditions. 1 – initial spectrum of **4** in $CHCl_3$; each spectrum from 2 to 7 is scanned after mixing the reaction mixture; 8 – is a scanned dilute solution of sample 7. The arrow indicates the direction of increasing absorbance.

in the region 480–800 nm completely disappeared and new maxima began to appear, whose intensities gradually increased after each mixing of the reaction system, and in parallel to this their λ_{max} value shifted to higher wavenumbers (Fig. 3 and Table 1). For example, as can be seen from Table 1, the λ_{max} (A) values of a new band for the **3** + ACN system after 10 repeated mixing and scanning, shifted from 660(0.27) to 710(0.81) nm, and then the spectrum reached a steady-state with no further change in position upon mixing. When the reaction mixtures are scanned without mixing over 30 min, a decrease in the absorbance of λ_{max} and a change in color from deep green to yellowish green were observed. Similar behavior also was observed for the **4**+ ACN system (Table 1).

It is interesting that the spectral features of the **X** + ACN systems in MeCN were different from those in $CHCl_3$. As soon as ACN and **X** were dissolved in MeCN, the oxidation of the ligands and their complexes was carried out with one and two equivalent molar amounts ACN. The results of these experiments show that on mixing equivalent molar amounts of the ligands and ACN in MeCN, the yellow color of the ligands simultaneously turns to deep green, and along with the disappearance of the original band at *ca.* 415 nm a new maximum peak appears at 712 and 721 nm for oxidized **1** and **2** (Table 1), respectively. Note that practically without any change in position, the intensity of both new bands decreased from 712 (1.1622) to 711 (0.2698) nm after 12 min and from 722 (0.5938) to 721 (0.3090) nm after 10 min, respectively, for the oxidized ligands **1** and **2** (Table 1). The green color of these oxidized systems after *ca.* 1 h gradually converted to brownish yellow, and then to light yellow after ~ 3 h. Similar behaviors also were observed in the oxidation of complexes **3** and **4**. For example, after addition of 1 or 2 equivalents of ACN to MeCN solutions **3** and **4**, a simultaneous change of the dark brown color to dark green with the disappearance of bands in the 480–800 nm region, and the appearance of a new maximum band at *ca.* 720 nm were observed (Table 1). On standing, the green color of this mixture gradually converts to brownish yellow. However, the rate of decrease in the peak absorbance for the oxidized complexes was significantly lower than that for the ligands. Note that the observed less intense band at *ca.* 720 nm and the strong absorption at *ca.* 430 nm detected in the spectra of the oxidized **X** compounds (Table 1) are characteristic for phenoxyl type radicals [6b,6d]. The absorption at *ca.* 430 nm is assigned to the $\pi \rightarrow \pi^*$ transition of the phenoxyl radical ligand, as ascribed in the UV/Vis spectra of several other Cu(II)- and Zn(II)-phenoxyl radical complexes. The detection of an identical band around 720 nm for the oxidized ligands and complexes confirm that the chemical oxidation occurs at the ligand centers of complexes **3** and **4**. These bands could arise from ligand based ($\pi \rightarrow \pi^*$ or $n \rightarrow \pi^*$) MLCT, LMCT or LLCT transitions [5c,5d,6d].

3.4. Electrochemistry

The electrochemical redox properties of **1**–**4** were investigated by cyclic voltammetry in potentials ranging from −1.5 to + 1.85 V vs. Ag/AgCl at 300 K under N_2 in MeCN, DMF and DMSO, containing Et_4NBF_4 (0.05 M) as the background electrolyte. Selected results are collected in Table 3. Typical cyclic voltammograms (CV) of the **1** and **2** ligands recorded in MeCN are presented in Fig. 4a and b. The i_{pc}/i_{pa} ratios are less than unity (0.4–0.7) and increase as the scan rate is increased. In the above potential range, the initial CV of **1** displays an oxidation peak at 1.12 V, with the reverse weak reduction curve at *ca.* 0.83 V and ill-defined cathodic shoulders at *ca.* −0.94 V (E_{pc}) and −0.31 V (E_{pa}). The initial CV of **2** in the same potential range exhibits quasi-reversible oxidation and reduction waves at $E_{1/2} + 1.02$ V and at $E_{1/2} - 0.69$ V, respectively. At the same time, CVs of the ligands recorded in the anodic potential range from 0.0 to 1.5 V exhibit very similar well defined quasi-reversible oxidation waves at $E^1_{1/2} + 1.02$ V for **1** and $E^2_{1/2} + 1.03$ V for **2** (Fig. 4a). In the case of the cathodic scan from 0.0 to −1.5 V for both **1** and **2** the identical quasi-reversible reduction waves at $E^1_{1/2} - 0.82$ V and $E^2_{1/2} - 0.78$ V, respectively, were detected (Fig. 4b). The observed quasi-reversible anodic oxidation waves were assigned to the phenolate/phenoxyl couple. The waves detected at a negative potential have been ascribed to the reduction of the imine group [18].

The CV of **3** recorded in the potential range from −1.5 to 1.5 V versus Ag/AgCl in DMSO solution shows two well defined oxidation processes, in the cathodic region at $E^1_{1/2} - 0.38$ V, which can be assigned to the Cu^I/Cu^{II} couple and a quasi-reversible anodic oxidation wave at $E^1_{1/2} + 0.26$ V assignable to a Cu(II)/Cu(III) or ligand centered one-electron oxidation. A poorly defined response at *ca.* $E_{1/2} + 1.03$ V is assigned to a ligand centered oxidation.

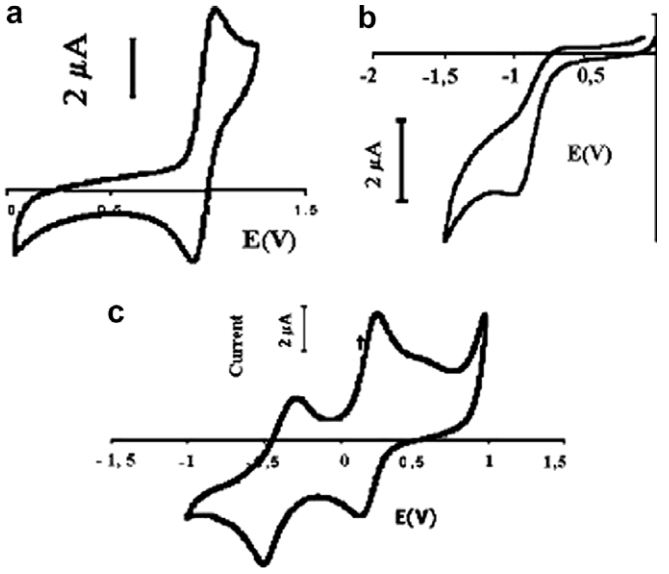

Fig. 4. Cyclic voltammograms of **1** (0.5 mM) in MeCN containing 0.05 M TEATFB at a scan rate of 0.1 V/s: (a) in the potential range 0.0 to + 1.25 V and (b) in the potential range −1.5 to 0.0 V; (c) CV of **3** (0.4 mM) in DMSO containing 0.1 M TETFB at a scan rate of 0.1 V/s. Working electrode Pt, counter electrode Pt wire, reference electrode Ag/AgCl were used in all experiments.

On the other hand, in MeCN solution for this complex only a quasi-reversible feature with $E_{pa}/E_{pc} = 1.43/1.36$ V was observed. A departure from the electrochemical reversibility is evident from the peak to peak separations, $\Delta E_p = E_{pa} - E_{pc}$ of 0.19 − 0.40 V, which are considerably greater than those expected for a reversible system (0.06 V), suggesting a quasi-reversible charge-transfer. In addition, the current relationship (i_{pa}/i_{pc}) is less than unity in each case. Similar ligand and metal centered redox responses with $E_{1/2}$ values of 0.24, 1.01, −0.88 V and an irreversible weak peak at $E_{pc} = -1.32$ V, were detected

[a] Irreversible shoulder.

for **3** in DMF (Table 3). The CV of **4** in the potential range from −1.5 to 1.5 V in DMF exhibits an anodic oxidation curve at *ca.* $E_{1/2} = 0.26$ V, $E_{pc} = -1.03$ V (with an associated broad anodic oxidation curve centered at the potential ~−0.71 V) and an irreversible weak peak at −1.31 V (Table 3). It is worth noting that the first reduction potential of the more distorted **3** ($E_{pc} = -1.12$ V) in DMF is more negative than that for the less distorted **4** ($E_{pc} = -1.03$ V), which is the inverse to the reported trend observed in a series of bis(*N*-alkyl-SA)copper(II) complexes, where it was found that the more distorted bis-chelate complexes are easier to reduce than their planar analogs [7a]. The CV of **4** in MeCN exhibits irreversible reductions at $E^1_{pc} = -1.35$ V and $E^2_{pc} = -0.73$ V and an oxidation curve at *ca.* 0.21 V. The wave at −1.35 V is assigned to the reduction of the free anionic ligand **2** [19]. On the other hand, on cathodic (from 0.0 to −1.5 V) and anodic (from 0.0 to 1.5 V) scans of **4** in MeCN no reduction and oxidation responses were detected.

Comparing the voltammetric data (E_{pc}) in DMF with those from the ESR ($A_{\|}$, $g_{\|}$), it is noticeable that for **3** and **4**, as the bulkiness of the adamantly group increases, the E_{pc} values become more negative. These observations are in good agreement with the results suggesting that the more negative the E_{pc} value, the more voluminous the alkyl substituent on the imine nitrogen, as reported by J.M. Fernandez-G and co-workers [8].

Abstract

The complex $[BuMeIm]_2[UCl_6]$ was characterized in the solid state and in a solution of $[BuMeIm][Tf_2N]$ room temperature ionic liquid using single-crystal XRD, EXAFS, visible absorption spectroscopy and NMR techniques.The structure of solid $[BuMeIm]_2[UCl_6]$ contains two crystallographically independent formula units (U(1) and U(2)).The U–Cl distances in UCl_6^{2-} anions range from 2.576(6) to 2.638(4) Å, the average values being 2.621(6) and 2.601(8) Å for U(1) and U(2), respectively.The $BuMeIm^+$ cations have four different conformations of C_4H_9 chains.The shortest distances between the centres of the five-member rings of the $BuMeIm^+$ cations and U atoms of $[UCl_6]^{2-}$ anions are in the range 5.53–4.90 Å.Single-crystal XRD data reveal the existence of a hydrogen bond between the most acidic H atom of the imidazolium ring (C2) and the chloride anion of the UCl_6^{2-} octahedron, with the shortest distance Cl···H(C2) equal to 2.57 Å.Quantitative EXAFS measurements indicate that the octahedral complex UCl_6^{2-}($R_{U-Cl} = 2.632(2)$ Å) is the predominant chemical form of U(IV) in $[BuMeIm][Tf_2N]$ solution.Visible absorption spectroscopy and ^1H NMR spectroscopy confirm the existence of hydrogen bonding between theUCl_6^{2-} anion and the acidic proton of the $BuMeIm^+$ cation in RTIL solution, similar to that in the solid state.

1. Introduction

The unique properties of water-stable room temperature ionic liquids (RTIL) create an opportunity to obtain fundamental data on actinide chemistry without interference from hydrolysis reactions [1,2]. These solvents also offer the possibility to develop new processes for the recovery and purification of actinides [2,3]. Most published studies on actinide behaviour in ionic liquids are focused on spectroscopic and electrochemical investigations of actinide(IV) hexachloro complexes, $AnCl_6^{2-}$ [4–6]. UV/VIS/NIR spectroscopic studies reveal that the complexes $AnCl_6^{2-}$, where An(IV) is U(IV), Np(IV) and Pu(IV), preserve their centrosymmetric octahedral environment in Tf_2N^- based hydrophobic ionic liquids, where Tf_2N^- is the bis(trifluoromethyl-sulfonyl)-imide anion. To obtain detailed information about the U(IV) coordination shell in RTIL solutions, EXAFS and ^1H NMR measurements of UCl_6^{2-} have been carried out for the first time in the hydrophobic ionic liquid [BuMeIm]-$[Tf_2N]$, where $BuMeIm^+$ is the 1-butyl-3-methyl-imidazo-

lium cation. The single-crystal structure of the complex $[BuMeIm]_2[UCl_6]$ is also reported.

2. Experimental

Complex $[BuMeIm]_2[UCl_6]$ was precipitated from U(IV) solution in concentrated HCl in the presence of a slight excess of [BuMeIm]Cl, as previously described [6a]. To obtain single crystals of $[BuMeIm]_2[UCl_6]$, the powder was recrystallized from a MeOH-MeCN (50/50) mixture under reduced pressure. It should be noted that the crystals available for single-crystal XRD study cannot be obtained from neat MeOH or MeCN. The solid complex $Cs_2[UCl_6]$, used in the EXAFS measurements as a reference, was precipitated by a well known procedure [4]. All U(IV) solids as well as their solutions were prepared and stored in an argon-filled dry box.

The ionic liquid was prepared by a metathesis reaction of [BuMeIm]Cl and HTf_2N in an aqueous medium. [BuMeIm]Cl was synthesized via quaternization of 1-methylimidazole by 1-chlorobutane and washed with ethyl acetate as recently described [1]. The initial chemicals (Aldrich, highest purity) were used in the synthesis without additional purification. To remove chloride ions and protonic impurities the as-prepared RTIL was washed with deionized water (18 MΩ cm) until a neutral pH was obtained. The control of chloride ions was performed by an $AgNO_3$ test. Organic impurities were removed from the RTIL with activated charcoal for 12 h, after which the mixture was passed through a column with small amounts of acidic alumina. ^{1}H NMR test revealed the absence (<1%) of residual reagents in the purified ionic liquid. The RTIL was dried overnight under reduced pressure (~5 mbar) at 70 °C. The water concentration in the dried RTIL was measured by coulometric Karl–Fisher titration and found to be equal to 0.008(2) M.

Single crystal ($0.3 \times 0.12 \times 0.04$ mm) X ray data were collected on a Nonius KappaCCD area detector diffractometer. The crystal was introduced into a Lindemann glass capillary. The lattice parameters were determined from ten images recorded with 1° ϕ-scans and later refined on all data. A hemisphere of the reciprocal space has been measured. The crystal-to-detector distance was fixed at 30 mm. The data were processed with the HKL package [7]. Absorption effects were empirically corrected with the program MULABS from PLATON [8]. The structure was solved by the heavy-atom method with SHELXS97 and subsequent difference Fourier-syntheses and refined by full-matrix least-squares on F^2 with SHELXL97 [9]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in idealized calculated positions and refined as riding atoms with displacement parameters equal to 1.2 (CH_2) or 1.5 (CH_3) times that of the attached carbon atom. Restrictions were imposed on the bond lengths and angles in all butyl groups. The structure was refined as a racemic twin with a Flack parameter between 0 and 1 [10]. It should be noted that refinement in the space group $P2_1$ is also appropriate. The molecular drawings were done with SHELXTL [11].

Uranium L_{III}-edge EXAFS spectra were collected at the Rossendorf Beamline at the ESRF (6.0 GeV, 200 mA) [12]. The measurements were carried out in transmission mode using argon-filled chambers at ambient temperature and pressure. The measurements were performed using a double crystal Si (1 1 1) monochromator. Data were collected in equidistant k-steps of 0.05 Å^{-1} across the EXAFS region. Six to ten scans were recorded for each sample and then averaged. A Y metal foil (first inflection point at 17038 eV) was used for energy calibration. The U L_{III} threshold energy, $E_{k=0}$, was defined as 17185 eV. EXAFS data were extracted from the raw absorption spectra by standard methods including a spline approximation for the atomic background using the program EXAFSPAK [13]. Theoretical phase and amplitude functions were calculated with FEFF 8.2 [14]. The scattering path and amplitude functions were calculated using the crystal structure of $[BuMeIm]_2[UCl_6]$ described here. The amplitude reduction factor, S_0^2, was defined as 1.0 in the FEFF calculation and fixed to that value in the data fits.

UV/Vis spectra were collected with a Shimadzu UV-3101 PC spectrophotometer using of 1 cm quartz cells sealed airtight by Teflon stoppers. The UV/Vis spectra of solids were obtained in NaCl pellets.

^{1}H NMR spectra were measured with Varian-INOVA 400 instrument in anhydrous CH_2Cl_2 solutions. The ^{1}H chemical shifts were externally referenced to d^6-benzene at 7.15 ppm.

3. Results and discussion

3.1. Single-crystal X-ray study

Crystal data for the structure of $[BuMeIm]_2[UCl_6]$ are given in Table 1. The structure of $[BuMeIm]_2[UCl_6]$ contains two crystallographically independent formula units,

Table 1
Crystallographic data of the $[BuMeIm]_2[UCl_6]$ complex

Chemical formula	$C_{16}H_{30}Cl_6N_4U$
Formula weight	729.17
Space group	$P2_1$ (No. 4)
a (Å)	10.2509(4)
b (Å)	9.5129(2)
c (Å)	27.4386(10)
β (°)	99.4712(14)
V (Å^3)	2639.22(15)
Z	4
D_{calc} (g cm^{-3})	1.835
T (°C)	−153(2)
λ (Å)	0.71073
μ (mm^{-1})	6.767
$R(F)$[a] ($I > 2\sigma(I)$)	0.0589
$wR(F^2)$[a] (all data)	0.1515

[a] $R(F) = \sum ||F_o| - |F_c|| / \sum |F_o|$; $wR(F^2) = \{\sum[w(F_o^2 - F_c^2)^2]/[\sum F_o^4]\}^{1/2}$.

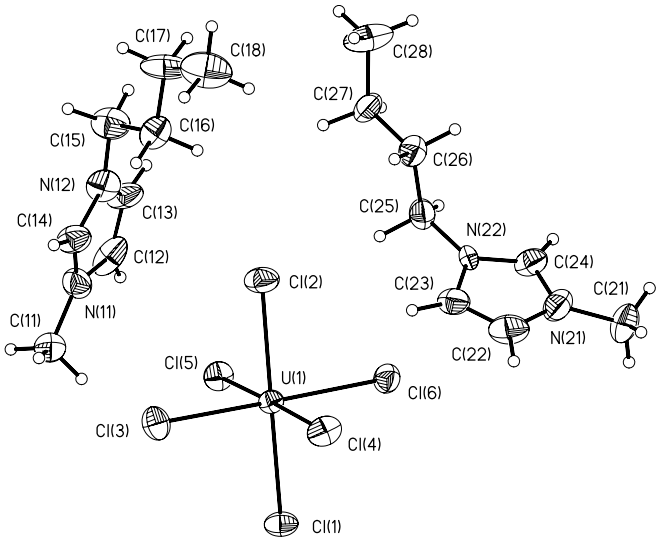

Fig. 1. A view of $[BuMeIm]_2[UCl_6]$, showing the atom-labelling scheme. Displacement ellipsoids are drawn at the 50% probability level and H atoms are represented by circles of arbitrary size. Only one crystallographically independent formula unit is shown.

Table 2
U–Cl bond lengths (Å) of the $[BuMeIm]_2[UCl_6]$ complex

U(1)–Cl(1)	2.625(4)
U(1)–Cl(2)	2.605(4)
U(1)–Cl(3)	2.620(4)
U(1)–Cl(4)	2.638(4)
U(1)–Cl(5)	2.606(3)
U(1)–Cl(6)	2.632(4)
U(2)–Cl(7)	2.620(5)
U(2)–Cl(8)	2.618(4)
U(2)–Cl(9)	2.603(5)
U(2)–Cl(10)	2.576(6)
U(2)–Cl(11)	2.587(5)
U(2)–Cl(12)	2.604(5)

one of them is shown in Fig. 1. Table 2 indicates that the U–Cl distances of the $[UCl_6]^{2-}$ anions range from 2.576(6) to 2.638(4) Å and the average values is 2.621(6) and 2.601(8) Å for U(1) and U(2), respectively. These values are close to each other and are in a good agreement with the average U–Cl distance for the Cs_2UCl_6 complex (2.62 Å) [15]. All bond lengths and torsion angles are presented in Supplementary material. Fig. 2 shows the packing of cations and anions in the unit cell.

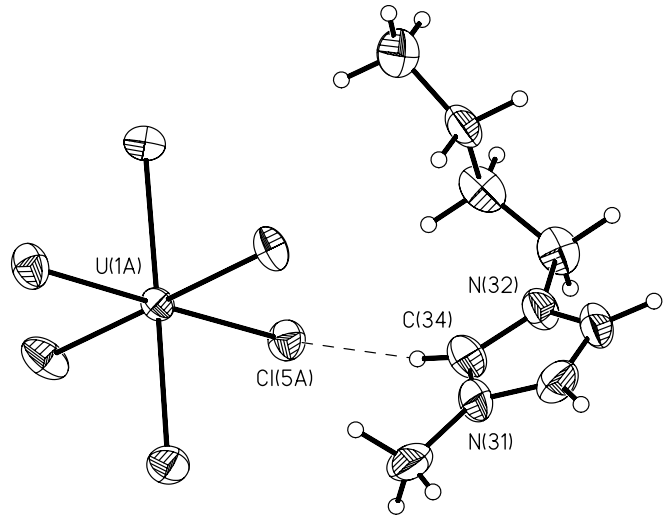

Fig. 3. A schematic view of the shortest H-bond in the $[BuMeIm]_2[UCl_6]$ structure.

The $BuMeIm^+$ cations have four different conformations of C_4H_9 chains and the shortest distances between the centres of the five-membered rings of $BuMeIm^+$ and the U atoms of $[UCl_6]^{2-}$ are 5.53, 5.39, 5.38 and 4.90 Å for the four crystallographically independent cations (see Supplementary material). For the shortest contact of 4.90 Å, the plane of the five-member ring of the cation is parallel to one face of UCl_6^{2-} octahedron. Single crystal XRD reveals the existence of a hydrogen bond between the most acidic H (C34) atom of the imidazolium ring and a chloride of UCl_6^{2-}, where the C34 atom of the structural nomenclature corresponds to the C2 atom between the nitrogen atoms of the imidazolium ring, as shown in Fig. 3. The Cl···H distance, equal to 2.57 Å, is close to the H-bond distance between Cl^- and H(C2) of [PrMeIm]Cl, where $PrMeIm^+$ is a propylmethylimidazolium cation [16]. It should be

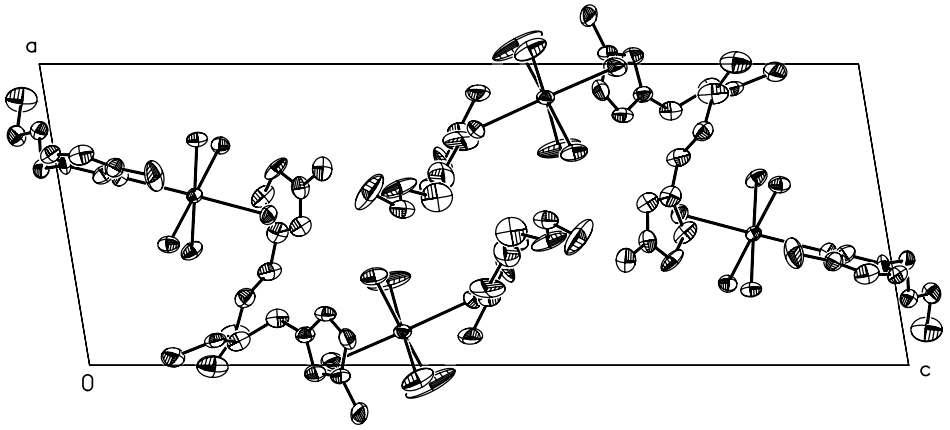

Fig. 2. Content of the unit cell of the $[BuMeIm]_2[UCl_6]$ structure.

Table 3
Geometry of some C–H···Cl bonds of $[BuMeIm]_2[UCl_6]$ and $[EtMeIm]_2[UCl_6]$ complexes in the crystalline state

Complex	C–H···Cl distances/Å	C–H···Cl angles/°
$[BuMeIm]_2[UCl_6]$ our data	C2–H···Cl : 2.57	C2–H···Cl : 128.57
$[EtMeIm]_2[UCl_6]$	C4–H···Cl : 2.74	C4–H···Cl : 132.83
Ref. [17]	C2–H···Cl : >2.96	No H-bonding

emphasized that only 3 Cl···H contacts from 10 with a distance less than 2.80 Å correspond to such a kind of interaction, and the mentioned contact of 2.57 Å is the shortest one. Very recently the existence of extremely weak hydrogen bonds was reported for the solid complex $[EtMeIm]_2[UCl_6]$, where $EtMeIm^+$ is 1-ethyl-3-methylimidazolium [17]. The geometries of some C–H···Cl contacts are shown in Table 3 for the complexes $[BuMeIm]_2[UCl_6]$ and $[EtMeIm]_2[UCl_6]$. The shortest distance for the low acidity hydrogen donor atom Cl···H(C4) (2.74 Å) of $[EtMeIm]_2[UCl_6]$ is significantly longer than the shortest distance Cl···H(C2) of $[BuMeIm]_2[UCl_6]$. Surprisingly, the most acidic hydrogen atom H(C2) is not involved in hydrogen bonding in the case of the $[EtMeIm]_2[UCl_6]$ complex, indicating that even a small modification in the structure of the 1,3-dialkylimidazolium cation may have a large effect on the hydrogen bonding in solids. The origin of such phenomenon could be related to differences in the packing of cations and anions in the unit cell for the studied complexes. However, additional study is needed to elucidate the effect of the side alkyl chain in 1,3-dialkylimidazolium rings on the hydrogen bonding with metal complexes in RTILs.

3.2. EXAFS study

EXAFS measurements were performed to investigate the coordination of U(IV) in a solution of [BuMeIm][Tf_2N]. Fig. 4a shows the U L_{III}-edge k^3 weighted EXAFS spectra and the corresponding Fourier transforms (Fig. 4b) for a solid powder of $[BuMeIm]_2[UCl_6]$ (IL-1), Cs_2UCl_6 (IL-2) and a 0.02 M solution of $[BuMeIm]_2[UCl_6]$ in [BuMeIm][Tf_2N] (IL-3). The structural parameters are presented in Table 4. The k^3-weighted EXAFS signal, $\chi(k)k^3$, shows a single sine-like oscillation without any beat node. This indicates clearly, that the first coordination shell consists only of a single type of backscatter. A quantitative analysis of sample IL-3 gives a Cl^- shell with a U–Cl bond distance very close to the reference samples and coordination numbers equal to 6, with a deviation in the typical range of 10–15%. Thus the EXAFS measurements confirm that the octahedral complex UCl_6^{2-} is the predominant chemical form of U(IV) in Tf_2N^- based hydrophobic ionic liquids.

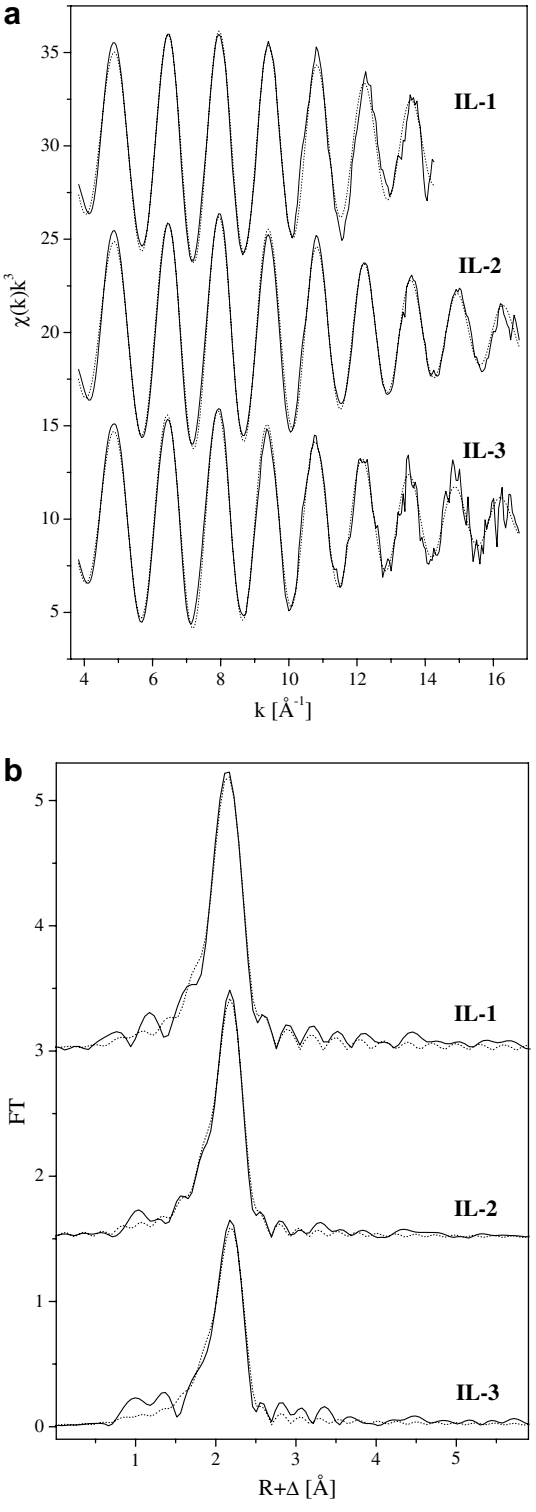

Fig. 4. U L_{III}-edge k^3 weighted EXAFS spectra (a) and the corresponding Fourier transforms (FT) (b) for a solid powder of $[BuMeIm]_2[UCl_6]$-(IL-1), Cs_2UCl_6, (IL-2) and 0.02 M solution of $[BuMeIm]_2[UCl_6]$ in [BuMeIm][Tf_2N] (IL-3).

3.3. Absorption spectroscopy

Fig. 5 shows the visible spectrum of $[BuMeIm]_2[UCl_6]$ in [BuMeIm][Tf_2N] solution and the spectra of solid $[BuMeIm]_2[UCl_6]$ and $Cs_2[UCl_6]$. Complex $Cs_2[UCl_6]$ exhibits two ro-vibronic bands at 593 and 601 nm. A third $f \rightarrow f$ electron transition band appears at 597 nm in the presence of the $BuMeIm^+$ cation in the solid state as well

Table 4
Structure parameters of $[BuMeIm]_2[UCl_6]$ obtained from EXAFS shell fit

Sample	Δk (Å^{-1})	N[a]	R[b] (Å)	σ^2 (Å^2)	ΔE (eV)	Fit error
IL-1	3.8–14.3	6.5	2.619(2)	0.0045	−1.1	0.35
IL-2	3.8–16.8	6.1	2.620(1)	0.0040	−1.2	0.17
IL-3	3.8–16.8	6.1	2.632(2)	0.0044	−0.3	0.28

[a] Errors in coordination numbers N are ±15%.

Il-1: $[BuMeIm]_2[UCl_6]$ in the solid state; IL-2: Cs_2UCl_6 in the solid state; IL-3: $[BuMeIm]_2[UCl_6]$ 0.02 M in $[BuMeIm][Tf_2N]$.

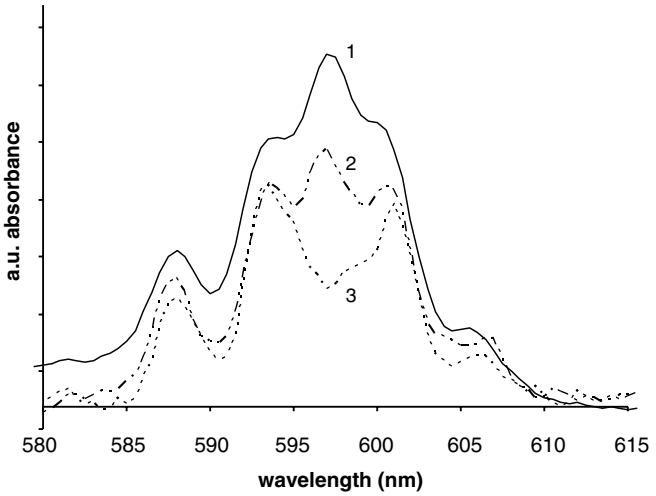

Fig. 5. Visible absorption spectra of $[BuMeIm]_2[UCl_6]$ in $[BuMeIm][Tf_2N]$ solution (1), solid $[BuMeIm]_2[UCl_6]$ (2) and solid $Cs_2[UCl_6]$ (3).

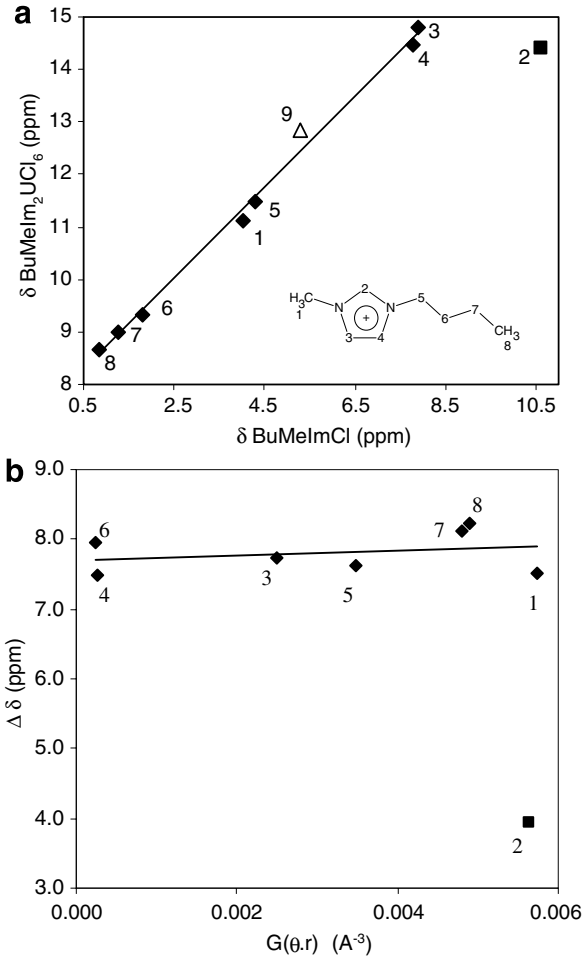

Fig. 6. (a) Relationship between the proton chemical shifts of $[BuMeIm]_2[UCl_6]$ and [BuMeIm]Cl in CH_2Cl_2, (Δ) CH_2Cl_2 protons. (b) Protons isotropic shifts, $\Delta\delta_I$, vs. the geometric factor $G(\theta_i, r_i)$ for $[BuMeIm]_2[UCl_6]$ in CH_2Cl_2.

as in RTIL solutions. It should be noted that only this difference can be clearly observed in the visible spectra of the studied complexes. Other ro-vibronic and $f \rightarrow f$ transitions are not sufficiently resolved to be correctly interpreted.

An absorption band at 597 nm was observed for UCl_6^{2-} in MeCN solutions in the presence of strong hydrogen-bond donors [18], indicating that the UCl_6^{2-} anion acts as a hydrogen bond acceptor. The slight distortion of the UCl_6^{2-} octahedral structure due to the hydrogen bonding causes the appearance of $f \rightarrow f$ electron transitions which are Lapport forbidden in the centrosymmetrical complexes. Thus the visible absorption spectra suggest the existence of hydrogen bonding in $[BuMeIm][Tf_2N]$ solutions of the UCl_6^{2-} complex.

3.4. NMR study

^{1}H NMR spectra were collected on [BuMeIm]Cl and $[BuMeIm]_2[UCl_6]$ in weakly solvating dichloromethane to avoid hydrogen bond dissociation. The observed isotropic shifts are widely displaced to low fields due to the uranium(IV) paramagnetism. Surprisingly, Fig. 6a reveals a linear relationship between the proton chemical shifts of [BuMeIm]Cl and $[BuMeIm]_2[UCl_6]$ for the overall protons, except for the acidic H(C2) proton. Obviously, the isotropic shifts essentially arise from a dipolar interaction between the UCl_6^{2-} anion and the $BuMeIm^+$ cation, and not from a covalent interaction. Even the proton chemical shift of the dichloromethane solvent lies on this linear relationship, which emphasizes that the paramagnetic shift mainly comes from a dipolar effect. Neglecting the contact shift and considering that the axial symmetry applies according to the $[BuMeIm]_2[UCl_6]$ single-crystal XRD results, the isotropic shift, $\Delta\delta_i$, can be expressed as [19]:

$$\Delta\delta_I = \delta_{U_i} - \delta_i = \frac{g^2\beta^2 S(S+1)}{3kT} \cdot \left(\frac{3\cos^2\theta_i - 1}{r_i^3}\right) = K \cdot G(\theta_i, r_i), \quad (1)$$

where δ_{U_i} and δ_i are the proton Hi chemical shift of the ionic liquid respectively with and without the UCl_6^{2-} complex. All the geometric parameters are collected in the $G(\theta_i, r_i)$ function whereas K is a fixed term for all nuclei in solution.

The EXAFS data indicate the strong similarity of the UCl_6^{2-} structure in solution and in the solid state.

Thus the geometric factors $G(\theta_i, r_i)$ for solutions can be computed from X-ray crystallographic data considering r_i, the distance in Å between the Hi proton and U(IV), and θ_i, the angle between r_i and the vector formed by the U and Cl atoms. The isotropic shifts versus $G(\theta_i, r_i)$ averaged for the overall protons of $[BuMeIm]_2[UCl_6]$ and [BuMeIm]Cl in $[BuMeIm][Tf_2N]$ are plotted in Fig. 6b. The K parameter is given by the 31.5 slope, indicating that a relationship exists between proton isotropic shifts and geometric factors, except for H(C2). Then short distance between H(C2) and U(IV) cannot explain this deviation and one can presume a contact contribution to the isotropic shift. Moreover, a large intercept value (roughly 7.7 ppm) for the overall protons (Fig. 6b) indicates that the relative shifts are induced by the complex formation. The diamagnetic contribution caused by the organization around the UCl_6^{2-} anion should be taken into account rather than the simple diamagnetic δ_I contribution of the free ionic liquid.

Assuming a 7.7 ppm diamagnetic shift and 0.177 ppm dipolar shift from the aforementioned calculations, one can estimate the contact interaction between the anion UCl_6^{2-} and the proton H(C2). Taking into account the $5f^2$ electronic configuration of U(IV), Eq. (1) gives the following expression of the contact shift:

$$\delta_C = \frac{A}{h}\langle S_z \rangle. \quad (2)$$

Eq. (2) yields a $\frac{A}{h}$ hyperfine coupling constant equal to 1.23 ppm. The average value of the component along the field of the electron spin magnetization of the uranium(IV), $\langle S_z \rangle$ is calculated using the published procedure [20] for the lanthanide Pr(III). The contact contribution found for the proton H(C2) of the $BuMeIm^+$ cation with UCl_6^{2-} species is small and of the same magnitude as those of CH_2 protons in the α position of the nitrogen in tetra *n*-alkylammonium cations [21]. It can be thus concluded that the anomalous H(C2) proton chemical shift in the $BuMeIm^+ \cdot UCl_6^{2-}$ ion pair is related to the hydrogen bonding. The proton chemical shifts demonstrate much higher sensitivity to hydrogen bonding that the electronic or EXAFS spectra.

4. Concluding remarks

In the solid state, the single-crystal XRD study of the $[BuMeIm]_2[UCl_6]$ complex shows the existence of two crystallographically independent formula units and four conformations of C_4H_9 chains in $BuMeIm^+$. The average U-Cl distances of the UCl_6^{2-} octahedral complex are equal to 2.621(6) and 2.601(8) Å for the units U(1) and U(2), respectively.

In $[BuMeIm][Tf_2N]$ solution, EXAFS quantitative measurements confirm that the octahedral complex UCl_6^{2-} is the predominant chemical form of U(IV). The average U–Cl distance in RTIL solution is equal to 2.632(2) Å, which is very close to that in the solid state.

Single-crystal XRD, visible absorption spectroscopy and ^1H NMR reveal the presence of H bonding between the chloride anion of UCl_6^{2-} and the most acidic proton H(C2) of the imidazolium ring, both in the solid state and in ionic liquid solution. In the solid state, the $Cl^{\cdots}H(C2)$ distance is 2.57 Å. An isotropic shift for the acidic H(C2) proton in the ^1H NMR spectrum of $[BuMeIm]_2[UCl_6]$ in CH_2Cl_2 solutions also clearly indicates hydrogen bonding.

Abstract

The synthesis, characterization and catalytic activity of a series of tetra-halo-dimethyl salen and di-halo-tetramethyl-salen ligands are reported in this paper: α,α′-dimethyl-Salen (dMeSalen) (**L**[1]); 3,3′,5,5′-tetrachloro-α,α′-dimethyl-Salen, (tCldMeSalen) (**L**[2]); 3,3′-dibromo-5,5′-dichloro-α,α′-dimethyl-Salen, (dCldBrdMeSalen) (**L**[3]); 3,3′,5,5′-tetrabromo-α,α′-dimethyl-Salen, (tBrdMeSalen) (**L**[4]); 3,3′,5,5′-tetraiodo-α,α′-dimethyl-salen, (tIdMeSalen) (**L**[5]); 3,3′-dichloro-5,5′,α,α′-tetramethyl-Salen (dCltMeSalen) (**L**[6]); 3,3′-dibromo-5,5′,α,α′-tetramethyl-Salen (dBrtMeSalen) (**L**[7]); and 3,3′-diiodo-5,5′,α,α′-tetramethyl-Salen (dItMeSalen) (**L**[8]) (Salen = bis(salicylaldehyde)ethylenediamine). Upon reaction with Co(II) ions, these ligands form complexes with square planar geometry that have been characterized by elemental analysis, cyclic voltammetry, UV–Vis, IR and EPR spectroscopies. In the presence of pyridine the obtained Co(II) complexes were found able to bind reversibly O_2, which was shown by EPR spectroscopy and cyclic voltammetry. They were also found able to catalyze the oxidation of 2,6-di-*tert*-butylphenol (DtBuP) (**9**) with formation of 2,6-di-*tert*-butyl-1,4-benzoquinone (DtBuQ) (**10**) and 2,6,2′,6′-tetra-*tert*-butyl-1,1′-diphenobenzoquinone (TtBuDQ) (**11**). These properties are first influenced by the coordination of pyridine in axial position of the Co(II) ion that causes an increase of the electronic density on the cobalt ion and as a consequence a decrease in the $E_{1/2}$ value and an increase of the reducing power of the Co(II) complex. It is noteworthy that, under those conditions the complexes also show a remarkable quasi-reversible behaviour. Second, complex properties are also influenced by the substituents (methyl and halogen) grafted on the aromatic ring and on the azomethynic groups. The donating methyl substituent on the azomethynic groups causes a decrease in the $E_{1/2}$ value, whereas the halogen substituents on the aromatic rings have two effects: a mesomeric donating effect that tends to lower the redox potential of the complex, and a steric effect that tends to decrease the conjugation of the ligand and then to increase the redox potential of the Co(II) complex. In pyridine, the steric effect predominates, which causes both an increase of the redox potential and a decrease of the selectivity of the oxidation of phenol **9**. As a result of all these effects, it then appears that the best catalysts to realize the selective oxidation of 2,6-di-*tert*-butyl-phenol (**9**) by O_2 are the Co complexes of ligands bearing CH_3 donating substituents, Co(dMeSalen) **1** ($2CH_3$ substituents), and Co-di-halo-tetra-methyl-salen complexes **6**, **7** and **8** ($4CH_3$ substituents), in the presence of pyridine.

1. Introduction

Transition metal complexes of Schiff bases are of paramount scientific interest, due to their multiple uses as biomimetic systems of enzymes involved in the transport, storage and activation of dioxygen [1–5]. First, some of such complexes are able to bind reversibly dioxygen, and can be used as simplified models in the study of the reversible binding of dioxygen by its natural transporters. In particular, the Co(II) ions form coordinative compounds with Schiff bases, with a square planar geometry, capable of

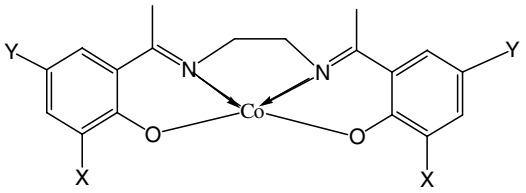

Fig. 1. General formula of the cobalt(II)–salen complexes (1–8) studied in this paper. 1, X = Y = H; 2, X = Y = Cl; 3, X = Br, Y = Cl; 4, X = Y = Br; 5, X = Y = I; 6, X = Cl, Y = CH_3; 7, X = Br, Y = CH_3; 8, X = I, Y = CH_3.

reversibly binding dioxygen [6–8]. Second, cobalt complexes can be used as catalysts in highly selective oxidation reactions using molecular oxygen as oxidant, and therefore can serve as models for oxygenases, peroxidases or mono- and dioxygenases. So, cobalt complexes of Schiff bases are able to catalyze the oxidation of phenols, alcohols, flavonoides, nitroalkanes, hydrazines or olefins [9–11]. Finally, more recently, Mn and Cr complexes of Schiff bases have been used as metal cofactors for the elaboration of artificial metalloenzymes used as new biocatalysts for selective oxidation reactions [1,12,13].

This study aims at obtaining new coordinative compounds with similar properties but with improved efficiency and selectivity. Therefore, the present paper describes the synthesis, characterization and catalytic activity of some tetra-halo-di-methyl-salen- [14] and some new di-halo-tetra-methyl-salen-cobalt complexes, which are presented in Fig. 1. The influence of halogens substituents (Cl, Br, I) grafted on the positions 3 and 5 of the aromatic rings and of the methyl substituent on the azomethyne bridge on the chemical properties was studied. The relationship between the electrochemical potential and the catalytic activity of these compounds was also studied.

2. Experimental

2.1. Materials and methods

Elemental analysis (C, H, N) was performed by the Service de Microanalyses at Gif-sur-Yvette, France. ^{1}H and ^{13}C NMR analysis were performed on a Bruker AM 250 or a Bruker AC 250 spectrometer, operating at 250 MHz. All spectra were obtained in $CDCl_3$ and chemical shifts calculated in ppm with respect to TMS ($\delta = 0$) or to the solvent residual peak ($\delta = 7.26$ for proton and 77.1 for carbon). UV–Vis spectra were recorded on DES device, operating with a SAFAS program. The FT-IR spectra were obtained on a Brucker IFS 66 apparatus in KBr pellets.

Cyclic voltammetry experiments were performed on a Digilab apparatus, in a glass cell incorporating a conventional three-electrode configuration using a vitreous carbon electrode ($A = 3.8$ mm^2) as working electrode, a saturated calomel electrode (SCE) as reference electrode and a platinum wire as auxiliary electrode. Cyclic voltammograms were recorded at 293 K, from 2 mM solutions of Co-complexes in DMF, under argon atmosphere, using lithium perchlorate as support electrolyte. Potentials are reported versus SCE, using the ferrocenium/ferrocene couple (Fc^+/Fc) as internal standard ($E_{Fc^+/Fc} = 0.466$ V, under these experimental conditions: scan rate = 0.1 V/s, concentration 2 mM).

EPR spectra were recorded in frozen DMF solution at 10 K, on a Brucker Elexis apparatus. To prepare the EPR samples, 1.2 mg of complex was dissolved in 2 mL of DMF previously degassed under argon, and 0.1 mL of pyridine (Py) was further added. Approximately, 0.3 mL of this solution was then transferred under argon via a syringe into the quartz EPR tube sealed with a septum. The tube was then frozen in liquid nitrogen, prior to analysis by EPR spectroscopy. Oxygenated samples of the Co complexes were obtained by bubbling dioxygen into the solution before freezing.

Magnetic susceptibility measurements were made on solid samples by a Quantum Desing model MPMS, SQUID. The measurements were calibrated using a recrystallized $HgCo(NCS)_4$ standard. The appropriate diamagnetic corrections were made.

ESMS (electrospray mass spectra) were recorded in a $MeOH/CH_2Cl_2$ (1/1, vol.) mixture on an Excalibrus device.

To assay the catalytic activity of the Co complexes, the oxidation of 2,6-di-*tert*-butyl-phenol (**9**) by dioxygen was realized in the presence of catalytic amounts of complex as previously described [14]. The reaction was performed at room temperature (21–22 °C) in a 100 mL round-bottomed flask sealed with a rubber septum. The flask was connected via a syringe needle to a gas burette. In a typical experiment, 2.5×10^{-2} mmol of complex (5% with respect to the substrate) were dissolved in 5 mL of dry DMF, degassed under argon. 2.5 mmol of pyridine and 103 mg (0.5 mmol) of **9** dissolved in 5 mL of DMF were subsequently added. Argon was then removed under vacuum, and the flask was refilled with dioxygen and connected to the burette. Stirring was started and dioxygen consumption was then monitored using the gas burette. After 24 h, the reaction was stopped and the products were separated by flash chromatography, using dichloromethane/heptane 1/1 (v/v) as eluent. After evaporation of the volatiles, the fractions were analyzed by ^{1}H NMR on a Bruker AM 250 and by gas-chromatography on a Fison 9000 GLC apparatus, respectively, which allowed determining the conversion and the yields of the products.

2.2. Preparation of the ligands and cobalt (II) complexes

2.2.1. Preparation of the halogeno derivatives of 2-hydroxyacetophenone

The 3,5-dichloro-2-hydroxyacetophenone and 2-hydroxy-5-methylacetophenone are commercially available. The bromo- and iodo-2-hydroxyacetophenone derivatives were obtained by bromination and iodination of 2-hydroxyacetophenone derivatives.

The 3-chloro-5-methyl-2-hydroxy-acetophenone was obtained by the Friedel–Crafts substitution of the corresponding 2-chloro-4-methylphenol with acetyl chloride [15]. CH_3COCl (1.25 g, 0.16 mol) was added, with stirring, to 2-chloro-4-methylphenol (2.19 g, 0.15 mol) at room temperature (r.t.). The mixture was heated (40 °C) until no gas evolved anymore and then $AlCl_3$ (2 g) was added slowly. The reaction mixture was heated at 180 °C for 30 min, cooled down at r.t. and then a mixture of HCl conc./H_2O (12 mL/50 mL) was added and the mixture was allowed to stand overnight. The resulting white crystals were filtered, washed with water and recrystallized from ethanol. The purity was checked by ^1H NMR and confirmed by elemental analysis. Melting point (M.p.) 88–89 °C; ^1H NMR ($CDCl_3$) δ (ppm): 11.70 (s, OH), 7.45 (s, 1 Har), 7.41 (s, Har), 2.65 (s, 3H, CH_3), 2.30 (s, 3H, CH_3).

2.2.2. Bromination [16]

2.2.2.1. 3,5-Dibromo-2-hydroxyacetophenone. A mixture of 2-hydroxyacetophenone (1.36 g, 0.01 mol) and pyridinium bromochromate (PBC) (5.16 g, 0.02mol) in glacial acetic acid (8–10 ml) was heated at 40 °C for 2 h. The reaction mixture turned green, and was heated until the reaction was completed (TLC). It was then poured into ice-cold water. The solid thus obtained was filtered, washed with water and recrystallized from aqueous ethanol. Its purity was checked by ^1H NMR and confirmed by elemental analysis. M.p. 105–107 °C; ^1H NMR ($CDCl_3$) δ (ppm): 2.66 (s, 3H, CH_3); 7.68–7.69 (d, 1H, ArCH); 7.73–7.74 (d, 1H, ArCH); 12.85 (s, 1H, OH).

2.2.2.2. 3-Bromo-5-chloro-2-hydroxyacetophenone. This was obtained by the same procedure from 5-chloro-2-hydroxyacetophenone and PBC. M.p. 112 °C, ^1H NMR ($CDCl_3$) δ (ppm): 2.66 (s, 3H, CH_3); 7.81–7.82 (d, 1H, ArCH); 7.85–7.86 (d, 1H, ArCH); 12.87 (s, 1H, OH).

2.2.2.3. 3-Bromo-5-methyl-2-hydroxy-acetophenone. This was obtained by bromination of 2-hydroxy-5-methylacetophenone. M.p. 86–88 °C, ^1H NMR ($CDCl_3$) δ (ppm): 12.75 (s, OH), 7.57 (s, 1 Har), 7.49 (s, 1 Har), 2.64 (s, 3H, CH_3), 2.31 (s, 3H, CH_3).

PBC (pyridinium bromochromate) was synthetized as follows. A solution of 20 g (0.2 mol) of chromium trioxide in water (25 ml) was cooled down to 0 °C. To this solution, 47% HBr (38 ml, 0.21 mol) was added slowly with constant stirring, the temperature being kept constant at 0 °C. Pyridine (16.3 ml, 0.2 mol) was then added over 15–20 min, to give a brown solid. The reaction mixture was chilled for 4–5 h. The dark brown crystals were then filtered and dried. The product was recrystallized from aqueous acetic acid (40:60 v/v) and its purity was checked by TLC and confirmed by elemental analysis and melting point 108 °C.

2.2.3. Iodination [17]

2.2.3.1. 3,5-Diiodo-2-hydroxyacetophenone. A suspension of 2-hydroxyacetophenone (1.36 g, 0.01 mol), excess HgO, (6.51 g, 0.03 mol) and excess iodine (7.63 g, 0.03 mol) in CH_2Cl_2 was stirred at r.t. for 20 h. The reaction was followed by TLC. The precipitate was removed by suction filtration. The filtrate was washed with 5% aq. $Na_2S_2O_3$ (20 ml) and water (30 ml), dried over $MgSO_4$, and evaporated to dryness. The residue was recrystallized from ethanol and its purity was checked by ^1H NMR and elemental analysis. Melting point 125–127 °C, ^1H NMR ($CDCl_3$) δ (ppm): 2.64 (s, 3H, CH_3); 7.98–7.99 (d, 1H, ArCH); 8.18–8.19 (d, 1H, ArCH); 13.09 (s, 1H, OH).

2.2.3.2. 3-Iodo-5-methyl-2-hydroxy-acetophenone. This was obtained by iodination 2-hydroxy-5-methyl acetophenone. Melting point (97–99 °C), ^1H NMR ($CDCl_3$) δ(ppm): 12.49 (s, OH), 7.72 (s,1 Har), 7.64 (s, 1 Har), 2.39 (s, 3H, CH_3), 1.92 (s, 3H, CH_3).

2.3. Preparation of the ligands

The ligands were obtained according to already described general methods, by the reaction between 3-X, 5-Y, 2-OH acetophenone (where X and Y are H, Cl, Br, I, CH_3), and ethylenediamine in a 2:1 molar ratio [18–20].

A solution of 2 equiv. 3-X, 5-Y, 2-OH acetophenone derivatives and 1 equiv. ethylenediamine, was stirred for 2–3 h in MeOH or EtOH at 40 °C. The ligands were recrystallized from MeOH or EtOH.

Bis(α-CH_3-salicylaldehyde)ethylenediimine ($\mathbf{L^1}$): To 2.72 g (0.02 mol) of 2-hydroxy acetophenone, dissolved in 30 mL MeOH at 40 °C, was added dropwise 0.6 g ethylenediimine dissolved in 8 ml MeOH. The reaction mixture was refluxed with stirring at 40 °C for 2 h and allowed to stand overnight at r.t. Then, the solid obtained was filtered, washed with water and MeOH, dried and recrystallized from methanol. A yellow solid was obtained, (91% yield). M.p. 202–203 °C, ^1H NMR ($CDCl_3$) δ (ppm): 2.84 (s, 6H, 2CH_3); 3.98 (s, 4H, 2CH_2); 6.76–7.54 (m, 8H, ArCH); 13.29 (s, 2H, OH). IR (cm^{-1}): 1610 ($\nu_{C=N}$), 1290 ($\delta_{Ar\text{-}OH}$), 1158 (ν_{C-N}), 1065 (ν_{C-O}). UV–Vis (λ [nm], logε[l/mol × cm]): 390 (2.96), 336 (3.10), 232 (2.47). Elemental *Anal.* Calc. for $C_{18}H_{20}N_2O_2$: Calc. C, 72.95; H, 6.80; N 9.45. Found: C, 72.78; H, 6.82; N, 9.39%.

The other ligands were prepared by same procedure.

2.4. Preparation of the cobalt complexes

The cobalt complexes were prepared as described in literature [21–23]. One equivalent of $Co(OAc)_2 \cdot 4H_2O$, dissolved in 5 mL of water, was added dropwise to a solution of 1 equiv. of ligand, dissolved in 25 mL of EtOH or MeOH, at 40 °C under argon. In the case of the less soluble ligands, (in EtOH or MeOH) 2 equiv. of NaOH were added. The complexes immediately started to precipitate. The mixture was further stirred at 40 °C for 1 h. After cooling down at room temperature, the solid was filtered and washed successively with water, ethanol–water (1/1, v/v) and absolute ethanol. After drying in vacuum, the cobalt complexes were isolated and analyzed.

Compound **1**: Yield: 65%. *Anal*. Calc. for $C_{18}H_{18}N_2O_2Co$ (353.3): C, 61.20; H, 5.14; N, 7.93. Found: C, 60.89; H, 5.15; N, 7.83%. $m/z = 352.3$. 3. Results and discussion

The 3,5-dihalo derivatives of 2-hydroxyacetophenone were obtained as described in Section 2.1, using already reported procedures for introducing halogen atoms into the aromatic ring by bromination or iodination of 2-hydroxyacetophenone [15–17]. The ligands were obtained from the reaction between 3X-, 5Y, 2OH-, acetophenone (where X and Y are Cl, Br, I) and ethylenediamine in a 2:1 molar ratio [18–20]. The cobalt(II) complexes were obtained by a general method from an aqueous solution

of $Co(OAc)_2 \cdot 4H_2O$ and solutions of ligands in EtOH, under argon [21–23]. The elemental analysis of all complexes was in agreement with a 1:1 metal:ligand ratio, which was also confirmed by ESMS spectroscopy.

After coordination of cobalt (II) to the tetradentate Schiff bases which contain four donor atoms, O, N, N, O, highly thermodynamically stable three-rings planar chelates were obtained. The compounds were isolated as powders that were not suitable for X-ray diffraction analysis. Until now further attempts to obtain crystals were not successful.

The oxygenated species were not isolated; they were obtained and studied "in situ" only.

3.1. ESMS spectra

Although, the ESMS spectra for neutral complexes are not always very accurate for the determination of molecular weights, because of chemical ionisation of these complexes [24], the obtained results can be used for confirmation of the structure. Our Co(II)-salen complexes were all analyzed by ESMS spectroscopy and their spectra all exhibited a peak at a m/z value corresponding to their molecular weight. For example, for the complex **3** a maximum molecular peak was obtained at $m/z = 578.9$ (Fig. 2a). Around this value, some other peaks were present that could be assigned to the molecular weight of the compounds with the various isotopes of the Cl and Br atoms. The peak at $m/z = 601.9$ was assigned to **3-Na**, and the other peaks around it corresponded to molecular weight of the compounds with the various isotopes of Cl and Br [25]. In the ESMS simulated spectra (Fig. 2b) a maximum peak at 578.8 was observed. In addition, other peaks around this value were observed, that corresponded to the molecular weight of the compounds with various isotopes of the Cl and Br atoms (see Fig. 2).

3.2. Infrared spectra

The IR spectra of the ligands and complexes (Section 2) all showed major bands around of 1605 cm^{-1} that can be assigned to $\nu_{C=N}$, and around 1560 cm^{-1} and 1500 cm^{-1} that can be assigned to ring vibrations. The band around 1280 cm^{-1} was assigned to the deformation of the Ar-OH outside the plane of the ArOH moiety, δ_{OH}, and the bands around 1230 $cm^{-1}$and 1050 cm^{-1} were assigned to ν_{C-N}, and ν_{C-O}, respectively [26,27], (see Fig. 3).

In the spectra of the cobalt (II) complexes, the bands corresponding to $\nu_{C=N}$, ring vibrations and ν_{C-N} and ν_{C-O} appeared to be shifted when compared to the corresponding bands in the spectra of the free ligands. In addition, the band characteristic of the deformation of the Ar-OH outside the plane of the ArOH moiety, $\delta_{Ar\text{-}OH}$, in the spectra of the free ligands was absent in the spectra

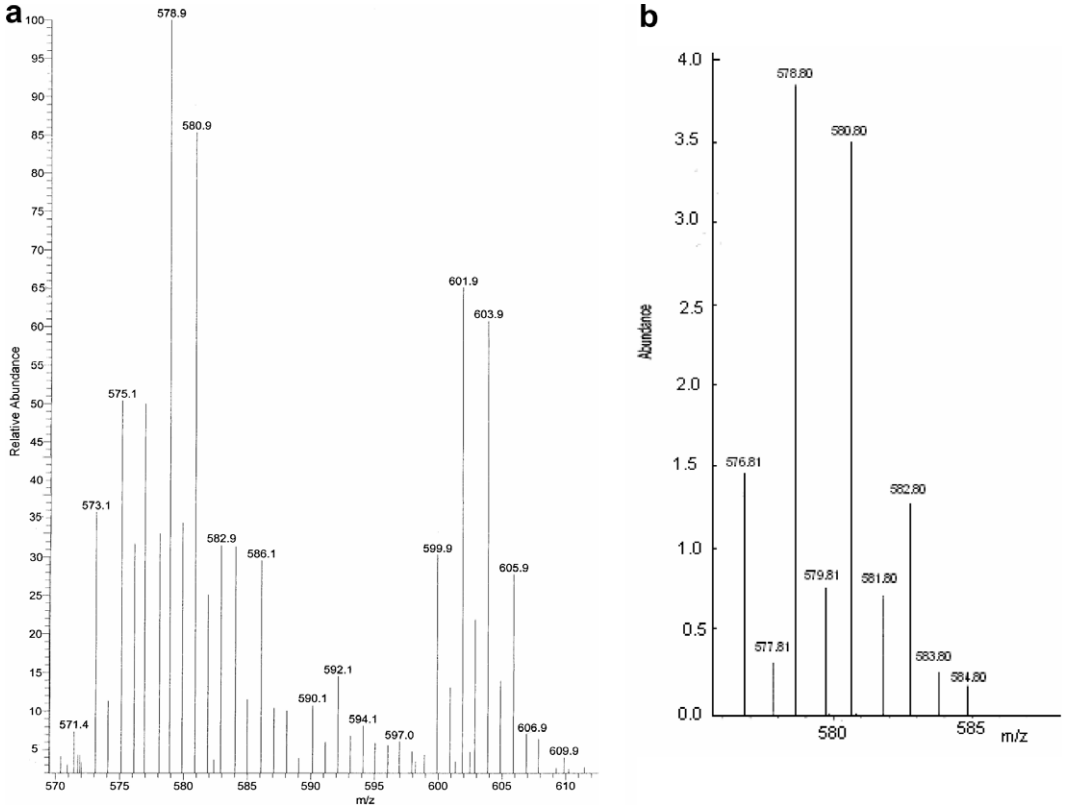

Fig. 2. ESMS spectrum of the complex **3**: (a) recorded; and (b) simulated.

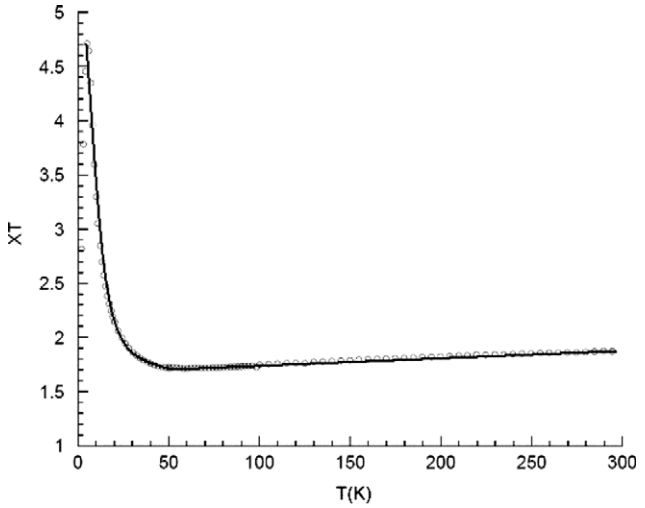

Fig. 3. Magnetic susceptibility of **7** collected at 1000 G plotted as χ_T vs. temperature (K).

of the Co(II) complexes, as a consequence of the involvement of the oxygen anion into a σ bond with the metal ion. The formation of cobalt–oxygen and cobalt–nitrogen σ bonds was proven by the appearance of some new absorption bands in the 400–690 cm^{-1} region of the spectra of the Co(II) complexes that could be assigned to ν_{Co-O} and ν_{Co-N} vibrations [28].

As a conclusion, the recorded IR spectra were in complete agreement with the formation of complexes by the coordination of Co(II) to the azomethyne nitrogen and to the phenolic oxygen atoms [28,29].

3.3. Electronic spectra

The electronic spectra of the free ligands in DMF showed two strong absorption bands in the UV–Vis region (316–432 nm) (Section 2), that could be attributed respectively to the π–π^* and n–π^* transitions. The free ligands also exhibited a UV band between 232 nm and 422 nm that attributed to the n–π^* and n–σ^* transitions [30,31]. In the spectra of the corresponding Co(II) complexes, the position and intensity of the bands characteristic of the ligand appeared to be modified with respect to those of the free ligand. In addition, these spectra also presented new bands (sometimes not well-defined) between 500 and 560 nm that were characteristic of the formed Co(II) complexes.

The bands located in the 404–438 nm region were attributed to the d–π^* charge-transfer transitions, which overlap with the π–π^* or n–π^* transitions of the ligands. The new band that appeared over 500 nm could be attributed to the d-d transitions of the divalent cobalt complexes [32,33]. These modifications in shifts and intensity for the absorption bands supported the coordination of the ligand to the central Co(II) ion.

A square planar geometry with four donor atoms (O, N, N, O) in the same plane was proposed for the complexes in the solid state. But, in solution, cobalt (II) complexes can coordinate 2 solvent molecules in axial positions, leading to a complex with an octahedral geometry. These solvent molecules can be replaced by coordinating amine bases such as pyridine, imidazole, etc. Accordingly, after addition of pyridine to DMF solutions of the Co(II) complexes, the [LCo(py)(DMF)] or [$LCo(Py)_2$] complexes were formation [34].

3.4. Magnetic measurement

The magnetic moment μ_{eff}, of the complex **7** was found to be 4.89 MB, at 295 K. This value is well within the reported range for high-spin octahedral cobalt (II) monomer complexes [31]. For the other complexes we appreciate similarly values. Variable-temperature magnetic susceptibility data (2–300 K) were collected for **7** in a 195 applied magnetic field of 1000 G (Fig. 4).

The susceptibility data turn over at 30 K, indicating the presence of a ferromagnetic exchange interaction.

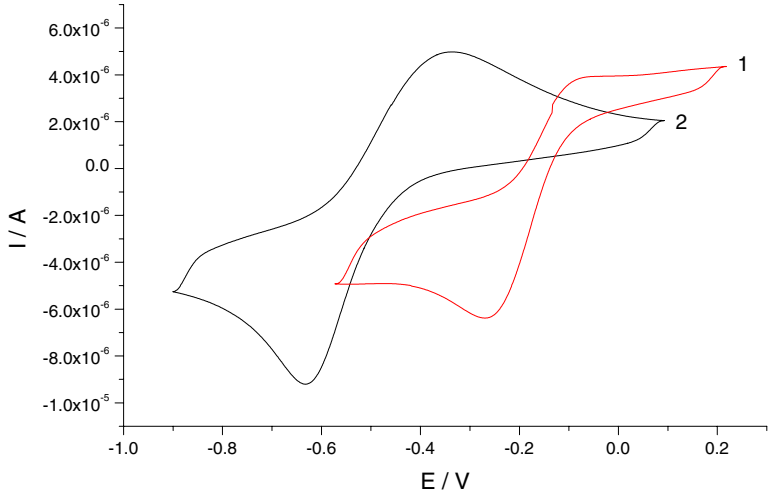

Fig. 4. Cyclic voltamogram for the complex **7**, $C_{CoL}=2\pm10^{-3}$ M, in DMF, scan rate = 0.1 V/s, vs. the saturated calomel electrode (SCE): (1) initial, under argon atmosphere, (2) after addition of pyridine, $c_{py}=0.2$ M.

3.5. Electrochemistry

The redox potential of the Co(II)/Co(III) couple is an important parameter for the catalytic activity of the Cobalt(II)-salen complexes in the oxidation of substrates by O_2. Its value is strongly influenced both by the nature of the axial ligand of the cobalt ion and by the structure of the ligand (Table 1).

All the cyclic voltammograms for the Co-salen complexes were recorded in the presence or not of 0.2 M pyridine. The corresponding anodic (E_{pa}), cathodic (E_{pc}) and half-wave ($E_{1/2}$) potentials, as well as the ΔE values measured for each Co(II) complex are reported in Table 1. In order to compare the half-wave ($E_{1/2}$) potentials values more easily to literature data, they are also reported to those of the ferrocenium/ferrocene (Fc^+/Fc) couple (i.e. $E'_{1/2}$) [35,36]. Examining the data showed in Table 1, one can observe that, in the absence of pyridine (lines 1–9) all the complexes have a non-reversible behavior, except the Co(salen) complex which presents a quasi-reversible behavior. The electrochemical data of the Co-complexes of substituted salens (lines 2–8) can be compared with those of the Co complex of non substituted salen (line 1). Substitution by a methyl group in the α-position of the ligand, in complex **1** causes a decrease of the $E_{1/2}$ value from –0.159 V for Co(salen) to −0.280 V (for complex **1**). This correlates with the donating effect of the methyl substituent which causes an increase of the reducing power of the Co-salen complexs. Surprisingly, substitution of the aromatic rings by halogen atoms leads to a further decrease of the $E_{1/2}$ value around 0.370 ± 0.010 V (lines 3–6) with almost no difference whatever the halogen substituent. Thus, these results cannot be explained by the electronegativity of the halogen substituents, which would have been expected to cause an increase in the $E_{1/2}$ value. It is then likely that, in this case, it is the donating mesomeric effect of the halogen atoms that is predominant and causes an increase in the reducing power of the Co-salen complexes.

Table 1
Electrochemical data for the cobalt(II)-salen complexes

Compounds	E_{pa} (V)	E_{pc} (V)	ΔE	$E_{1/2}$ (V)	$E'_{1/2}$ (V)

8, py	−0.312	−0.409	0.097	−0.361	0.106

$C_{CoL} = 2 \times 10^{-3}$ M; $c_{py} = 2 \times 10^{-1}$ M; scan rate 100 mV/s; E_{pa} and E_{pc} are the anodic and cathodic peak potentials, respectively. $\Delta E = E_{pa} - E_{pc}$ in 0.1 M $LiClO_4$ in DMF. $E_{1/2} = (E_{pa} + E_{pc})/2$. $E'_{1/2}$ is $E_{1/2}$ reported to the potential of the couple Fc^+/Fc, where Fc = ferrocene, $E_{Fc^+/Fc} = 0.466$ V.

As shown in Fig. 4 in the typical case of the complex **7**, addition of 0.2 M pyridine to the solution of Co-salen complex caused a large change in the shape of the cyclic voltammogram (Fig. 4, curve 2). In particular, it caused a severe decrease in the half-wave ($E_{1/2}$) potential from −0.134 V to −0.485 V (Table 1, compare line 8 and line 17).

Under those conditions, the decrease in ΔE was observed for all the complexes, leading to ΔE values between 0.161 V and 0.318 V (Table 1, lines 12–18) and their behaviour became quasi-reversible.

The decrease of the half-wave potential was due to the replacement of the axial solvent molecules by pyridine, which has a stronger basic character, enhancing electronic density on the Co(II) ion, and thus increasing its reducing power [37,38]. This effect, however, was not observed for all complexes, as in the case of the complexes **4** and **5** higher $E_{1/2}$ values were found in the presence of pyridine (resp. −0.283 V and −0.306 V, Table 1 lines 14 and 15) than without pyridine (resp. −0.374 V and −0.359 V, Table 1 lines 5 and 6). It is then likely that in these cases, in the presence of pyridine, steric hindrance, which diminishes the conjugation of the ligand ring, occurs.

EPR spectra of non-oxygenated and oxygenated cobalt(II) complexes were measured at 10 K as a frozen DMF solution, in the presence of excess pyridine. All the spectra were similar to those shown in Fig. 5 in the case of the complex **3.** In the absence of O_2, the spectrum of the complex **3** exhibits a signal centred around $g = 2$, characteristic of a low-spin Co(II) complex, with a rhombic distortion from ideal axial symmetry, with $g_1 = 2.08$, $g_2 \cong g_3 = 2.02$. The perpendicular component of the spectrum appears as a clearly identifiable 8 lines signal, corresponding to ^{59}Co ($I = 7/2$) hyperfine splitting (and $A = 9.4$ G) (Fig. 5a). In addition, in the presence of pyridine the eight-line signal corresponding to the parallel component g_3 is further split into three or five lines due to the coupling of the cobalt (II) centre with one or two axially coordinated pyridine nitrogen atoms [31,39].

In the presence of O_2, a new spectrum characteristic of **3**-$O_2$was obtained (Fig. 5b). It also exhibited a signal

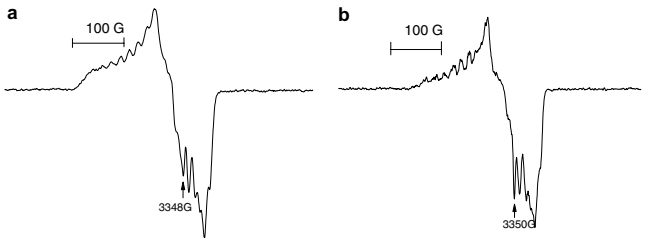

Fig. 5. EPR spectra of: (a) complex **3**, (b) adduct **3**-O_2, in DMF at 10 K, in the presence of excess pyridine.

centred around $g = 2$, characteristic of a Co(II) complex, with a rhombic distortion from ideal axial symmetry, with $g_1 = 2.03$, $g_2 \cong g_3 = 2.01$ The perpendicular component of the spectrum appeared as a clearly identifiable 8 lines signal (diminished as intensity, 3/1), corresponding to ^{59}Co ($I = 7/2$) hyperfine splitting ($A = 9.4$ G) (Fig. 5b). The formation of 1/1 complex **3**/O_2 adduct was thus EPR spectra confirmed [40].

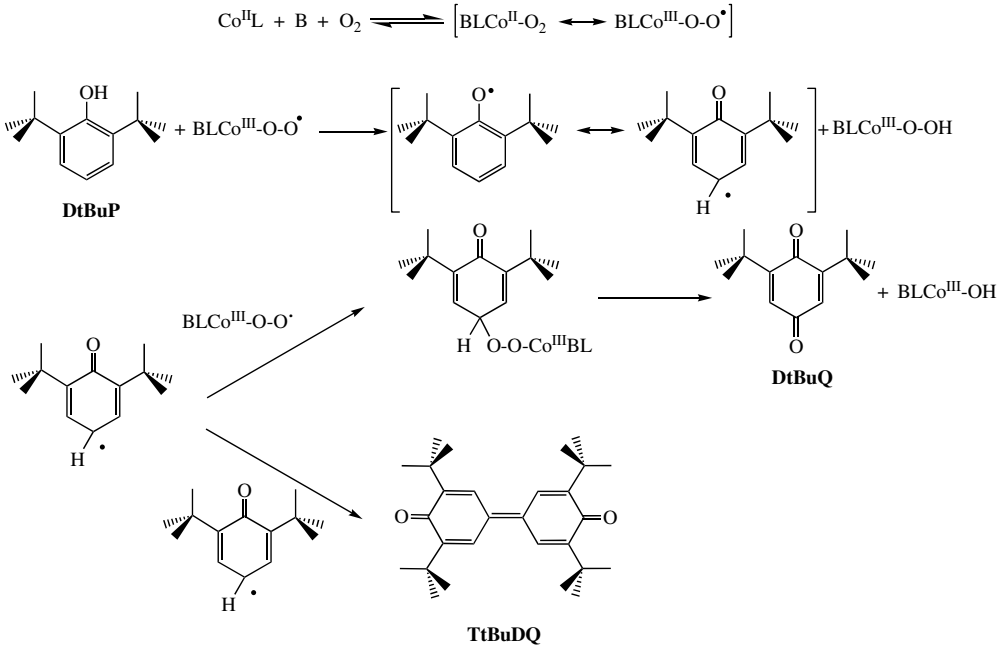
3.6. Catalytic activity

2,6-Di-*tert*-butylphenol (**9**), can easily be oxidized by molecular oxygen in the presence of metal complexes as catalysts to give mainly two products: 2,6-di-*tert*-butyl-1,4-benzoquinone (**10**) and 2,6,2′,6′-tetra-*tert*-butyl-1,1′-diphenobenzoquinone (**11**), respectively (Scheme 1) [41,42]. Their formation depends on the nature of the metallic ion present in the complex, which may influence their relative proportions.

Table 2 shows the yields and relative proportions of these two products, determined by ^1H NMR and GC as described in Section 2.1, when phenol **9**, 0.1 M in dry DMF was oxidized by O_2 in the presence of 0.5 M pyridine and 0.5×10^{-2} M (5% molar with respect to the substrate) Co-salen complex as catalyst. Increasing the catalyst/substrate ratio did not lead to any significant increase in the yield (1–2% at the most).

The presence of pyridine was crucial for the reaction, as in the absence of the pyridine, much lower yields were obtained (below 50%) and the reaction proved to be not selective with the formation of up to 60% of quinone **10**. Finally, kinetic studies indicated a second order reaction, par rapport a metallic complex.

Table 2
Reaction products of catalytic oxidation of the phenol **9** with Cobalt (II) complexes[a]



Compounds	Yield %[a]	**10** (%)	**11** (%)
1	97	98	2
2	95	91	9
3	94	87	13
4	89	64	36
5	90	71	29
6	100	94	6
7	100	96	4
8	100	97	0

[a] Error +/−0.5%.

From Table 2, it appears that the highest yield as well as the best selectivity in favor of the formation of **11** are obtained with the Co complexes of ligands bearing $2CH_3$ substituents, Co(dMeSalen) **1**, or 4 CH_3 substituents (Co-3,3′-dichloro-5,5′,α,α′-tetramethyl-Salen **6**; Co-3,3′-dibromo 5,5′,α,α′-tetramethyl-Salen **7**; and 3,3′-diiodo 5,5′,α,α′-tetramethyl-Salen **8**), as catalysts. Both the yield and mainly the selectivity decrease when the aryl rings of the salen ligand are substituted by halogen atoms, and in addition, a good correlation was found between the half-wave potential $E_{1/2}$ and both the yield of the reaction and the relative proportion of DtBuQ formed (Fig. 6).

From Fig. 5, it is clear that the lower was the value of the half-wave potential, the higher were the catalytic activity and the selectivity in favor of **10**.

To explain the formation of **10** or **11** it is necessary to consider the mechanism of the reaction, which has been thoroughly studied [43,44]. The main steps involved in this mechanism are described in Scheme 1.

Scheme 1. Reaction pathway for oxygenation of phenol **9** with molecular oxygen, in the presence of Co(II) complexes (B is axial base, this can be DMF or py molecule).

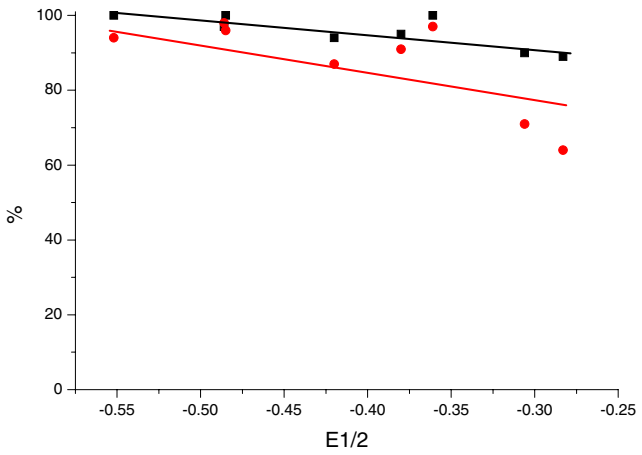


Fig. 6. Yield (%) and proportion of **10** formed as a function of the half wave potential.

In presence of pyridine, the first step of the mechanism involves the reversible formation of a Co–O_2 adduct. This was confirmed in our case not only by EPR spectroscopy, but also by cyclic voltammetry in the case of **7** (Fig. 7).

When molecular dioxygen is bubbled into a solution of the complex **7**, 2 mM in DMF, in the presence of pyridine (in excess, 10/1), its quasi-reversible voltammogram (Fig. 7(1)) is replaced by an irreversible one (Fig. 7(3)). Further, argon bubbling into the solution, led to the replacement of this voltammogram by a new quasi-reversible one (Fig. 7(2)), that was almost superimposible to that of the starting complex **7**. This was in agreement with the formation of a Co^{II}–O_2 adduct which could be reversed by bubbling argon into the solution.

This Co^{II}–O_2 is then able to perform the one electron-reduction of phenol **9** into a semi-quinone radical. The further, formation of the compounds **10** and **11** depends upon the evolution of this radical. Either it reacts with another Co^{II}–O_2 adduct to form a BLCo-O-O-DtBuP peroxo complex (**12**), that is then hydrolyzed to lead to the quinone **10**, or its dimerization, followed by an oxidation steep, lead to diphenoquinone **11** (Scheme 1) [40].

Since the kinetic studies have shown that the reaction was bimolecular, it is likely that the determining step of the process is the one electron reduction of phenol **9** into a semi-quinone radical by the Co(II)–O_2 adduct. It may then be expected that the best reactivity occur with the best reducing complex, i.e. the one that have the lowest half-wave potential. This is in agreement with our results, since the best yield (98%) was obtained with the Co-salen complexes having the lowest half-wave potential in the presence of pyridine (complex **1**), $E_{1/2} = -0.486$ V, (Table 1), and since a good correlation was observed between the yield of the reaction and $E_{1/2}$, the yield decreasing as $E_{1/2}$ increased (Fig. 6). In this case, the dimerization of this semi-quinone radical into **11** was the predominant reaction observed [45].

Concerning the selectivity of the reaction, the ratio between quinone **10** and diphenoquinone **11** is governed by the ability of semi-quinone radical to react with a Co^{II}–O_2 adduct to give the peroxo complex **12** which is further hydrolyzed into **10**. This reaction is disfavoured when the steric hindrance around the Co(II) ion is important. This is in agreement with our results, since the relative proportion of **10** formed decreases from 98% to about 65% when the aromatic rings of the dMeSalen ligands are substituted with bulky bromine and iodine atoms (Table 2). Since the ligands substituted by the more bulky atoms are also the ones that have the lowest reducing power, a good correlation is also observed between the $E_{1/2}$ value and the relative proportion of **10** formed (Fig. 6).

In the absence of pyridine, a lower yield was obtained because of the irreversible oxidation process of Co(II) to Co(III), which disfavoured the reaction of the semi-

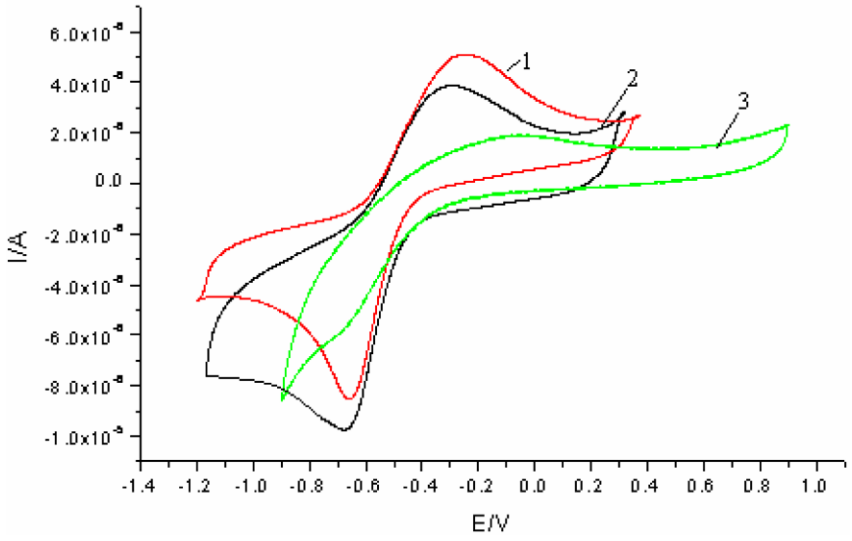

Fig. 7. Cyclic voltammograms for the complex **7**, $C_{CoL} = 2$ mM, in DMF; Scan rate = 100 mV/s: 1, initial, under Ar atmosphere; 2, after elimination of O_2 (Ar bubbling, under Ar atmosphere.); 3, in the presence of O_2.

quinone radical with Co^{II}–O_2 to lead to the peroxo complex **12** and then to quinone **10**.

4. Conclusion

Grafting of various halogen substituents on the aromatic ring and of a methyl substituent on the azomethynic group of Salen type ligands leads to the formation of some new ligands which form complexes with square planar geometry upon reaction with Co(II) ions. Such compounds are of interest for the reversible binding of dioxygen and for their catalytic activity in the oxidation reactions of substrates by O_2. These properties are first influenced the coordination of pyridine in axial position of the Co(II) ion causes an increase of the electronic density on the cobalt ion and as a consequence a decrease in the $E_{1/2}$ value and an increase of the reducing power of the Co(II) complex. It is noteworthy that, under those conditions the complexes also show a remarkable quasi-reversible behaviour. Second, complex properties are also influenced by the substituents (methyl and halogen) grafted on the aromatic ring and on the azomethynic group. The donating methyl substituent on the azomethynic group causes a decrease in the $E_{1/2}$ value, whereas the halogen substituents on the aromatic rings have two effects: a mesomeric donating effect that tends to lower the redox potential of the complex, and a steric effect that tends to decrease the conjugation of the ligand and then to increase the redox potential of the Co(II) complex. In pyridine, the steric effect predominates, which causes both an increase of the redox potential and a decrease of the selectivity of the oxidation of phenol **9**. As a result of all these effects, it then appears that the best complex to realize the selective oxidation of the phenol **9** by O_2, in the presence of pyridine, is complexes **6**, **7**, **8** and **1**.

Abstract

A series of ferrocenylacetylenylbiphenyl derivatives Fc-C≡C—R [R = C_6H_4—C_6H_5 (**1**), C_6H_4—C_6H_4—I (**2**), C_6H_4—C_6H_4—NO_2 (**3**), $C_6H_3(NO_2)$—C_6H_4I (**4**)] and Fc-C≡C—R′—C≡C—R″ [R″ = Fc, R′ = C_6H_4—C_6H_4 (**5**), $C_6H_3(NO_2)$—C_6H_4 (**6**); R″ = C_6H_5, R′ = C_6H_4—C_6H_4 (**7**)] were synthesized from FcC≡CH and biphenyl iodides by the Castro–Stephens and Sonogashira coupling reactions, in which compounds **1**, **2**, **3**, **4**, **6** and **7** are new. Seven new complexes [Fc-C≡C—R][$Co_2(CO)_6$] [R = C_6H_4—C_6H_5 (**8**), C_6H_4—C_6H_4—I (**9**), C_6H_4—C_6H_4—NO_2 (**10**), $C_6H_3(NO_2)$—C_6H_4I (**11**)] and [Fc-C≡C—R′—C≡C—R″] [$Co_2(CO)_6$]$_2$ [R″ = Fc, R′ = C_6H_4—C_6H_4 (**12**), $C_6H_3(NO_2)$—C_6H_4 (**13**); R″ = C_6H_5, R′ = C_6H_4—C_6H_4 (**14**)] were obtained by the reaction of the ligands Fc-C≡C—R and Fc-C≡C—R′—C≡C—R″ with $Co_2(CO)_8$, respectively. Compounds **1**–**7** and their complexes **8**–**14** have been characterized by element analysis and spectroscopy, as well as by X-ray diffraction for **1**, **4, 8, 9** and **11**. The electrochemical data of compounds **1–12** have been obtained by cyclic voltammetry.

Keywords: Ethynylferrocene; Coupling reaction; Biphenyl derivative; Cobalt carbonyl complex

1. Introduction

In recent years, the design of materials for application in molecular wires has focused on how to arrange organometallic redox-active centers to enhance the capability of transferring electrons along a conjugated molecular axis [1–3]. The diyne $Co_2(CO)_6$ complexes are probably better candidates and have displayed some electronic communication and interactions between redox-active centers [4–6]. A variety of ferrocenyl π-conjugated derivatives have been designed and synthesized by Castro–Stephens, Sonogashira and other coupling reactions [7–13] because these compounds can be used as an approach to construct linear donor-π-conjugated spacer-accepter assemblies. π-Conjugated compounds with aryl groups have largely been reported [14–16], but ferrocenylacetylenylbiphenyl derivatives are rare [17]. Here we describe the preparation and structural characterization of seven ferrocenylacetylenylbiphenyl derivatives Fc-C≡C—R [R = C_6H_4—C_6H_5 (**1**), C_6H_4—C_6H_4—I (**2**), C_6H_4—C_6H_4—NO_2 (**3**), $C_6H_3(NO_2)$—C_6H_4I (**4**)] and Fc-C≡C—R′—C≡C—R″ [R″ = Fc, R′ = C_6H_4—C_6H_4 (**5**), $C_6H_3(NO_2)$—C_6H_4 (**6**); R″ = C_6H_5, R′ = C_6H_4—C_6H_4 (**7**)], in which **1**, **2**, **3**, **4**, **6** and **7** are new compounds. Compound **1** was synthesized by the Castro–Stephens coupling reaction of Fc-C≡C—Cu and I—C_6H_4—C_6H_5, and compounds **2**–**4** were obtained by the Sonogashira coupling reaction of ethynylferrocene with the relevant iodobiphenyl derivatives, and compounds **5**–**7** were prepared by a second Sonogashira coupling reaction of ethynylferrocene with compounds **2** and **4**, or ethynylbenzene with compound **2**, respectively. Seven new cobalt carbonyl complexes [Fc-C≡C—R][$Co_2(CO)_6$] [R = C_6H_4—C_6H_5 (**8**), C_6H_4—C_6H_4—I (**9**), C_6H_4—C_6H_4—NO_2 (**10**),

$C_6H_3(NO_2)$—C_6H_4I (**11**)] and [Fc-C≡C—R′—C≡C—R″]-$[Co_2(CO)_6]_2$ [R″ = Fc, R′ = C_6H_4—C_6H_4 (**12**), $C_6H_3(NO_2)$—C_6H_4 (**13**); R″ = C_6H_5, R′ = C_6H_4—C_6H_4 (**14**)] have successfully been synthesized by using the reactivity of the alkyne bonds of compounds **1**–**7** with $Co_2(CO)_8$. The molecular and crystal structures of compounds **1**, **4** and complexes **8**, **9** and **11** have been determined by X-ray single crystal analysis. The electrochemical properties of compounds **5**, **6** and **12** reveal that no significant electronic communication between the two ferrocenyl units was observed.

2. Experimental

Published procedures or extensions thereof were used to synthesize the initial intermediates Fc-C≡CH, Fc-C≡CCu [8], $C_6H_5C_6H_4I$, IC_6H_4—C_6H_4I, IC_6H_4—$C_6H_4NO_2$, $IC_6H_3(NO_2)$—C_6H_4I [18,19]. Other chemicals were purchased and used as received.

Unless stated otherwise, all reactions and manipulations were carried out using standard Schlenk techniques under an atmosphere of inert gases. Solvents were purified, dried and distilled under a nitrogen atmosphere prior to use. Reactions were monitored by TLC. Chromatographic separations and purifications were performed on 200–300 mesh silica gel or neutral alumina.

IR spectra were recorded on a Nicolet FTIR spectrometer as KBr discs. Elemental analyses were carried out on an Elementar var III-type analyzer. ^1H and ^{13}C NMR spectra in $CDCl_3$ were recorded on an Inova 500FT-MHz spectrometer. The mass spectra were determined using a Polaris Q MS and a Micromass Autospec ultima- TOF instrument. The electrochemical properties were determined with a BAS 100A-type analyzer. Melting points were recorded using XT-4 melting point apparatus.

2.1. Synthesis of 4-ferrocenylacetylenylbiphenyl (*1*)

Fc-C≡CCu (304 mg, 1.12 mmol) and $C_6H_5C_6H_4I$ (313 mg, 1.12 mmol) were dissolved in 15 ml pyridine. The mixture solution was stirred for 8 h under reflux. The solvent of the resulting brown mixture was removed in vacuum. The residue was dissolved in a minimal amount of CH_2Cl_2. The filtrate was concentrated and subjected to chromatographic separation on a neutral alumina column (2 × 30 cm). Elution with hexane–benzene (10:1, v/v) afforded an orange band **1**. The yellow solid **1** was obtained by crystallizing from hexane–benzene. Yield, 46%. m.p. 149–151 °C. *Anal.* Calc. for $C_{24}H_{18}Fe$: C, 79.58; H, 5.01. Found: C, 78.92; H, 4.98%. IR (KBr disk): ν(C≡C) 2218 (m) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.26–7.62 (m, 9H, C_6H_4—C_6H_5), 4.28 (s, 5H, C_5H_5), 4.54 (s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 122.88, 126.95, 127.50, 128.83, 131.78, 140.33, 140.47 (C_6H_4—C_6H_5), 85.63, 89.08 (C≡C), 65.41, 68.93, 70.07, 71.47 (Cp). MS (EI, *m*/*z*, relative abundance): 362 (M^+, 100%).

2.2. Syntheses of ferrocenylacetylenylbiphenyl derivatives *2* and *5*

Ethynylferrocene (375 mg, 1.79 mmol) and 4,4′- diiodobiphenyl (501 mg, 1.79 mmol) were stirred in diisopropylamine (20 ml) with $Pd(PPh_3)_2Cl_2$ (30 mg, 0.04 mmol) and $Cu(OAc)_2$ (4 mg, 0.02 mmol) for 20 h under reflux. The solvent of the resulting orange mixture was removed in vacuum. The residue was dissolved in a minimal amount of CH_2Cl_2. The filtrate was concentrated and subjected to chromatographic separation on a neutral alumina column (2 × 30 cm). Elution with hexane–dichloromethane (4:1 for **2**; 2:1 for **5**, v/v) afforded a yellow band **2** and an orange band **5**. Yellow crystalline **2** was obtained by re-crystallizing from hexane–dichloromethane at −20 °C. Yield, 11%. m.p. 191 °C. *Anal.* Calc. for $C_{24}H_{17}FeI$: C, 59.05; H, 3.51. Found: C, 59.43; H, 3.54%. IR (KBr disk): ν(C≡C) 2197 (m) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.16–7.79 (m, 8H, C_6H_4—C_6H_4), 4.63 (s, 5H, C_5H_5), 4.95 (br s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 93.28, 123.39, 126.67, 128.76, 131.89, 137.92, 139.09, 139.96 (C_6H_4—C_6H_4), 85.47, 89.51 (C≡C), 65.33, 69.05, 70.13, 71.53 (Cp). MS (EI, *m*/*z*, relative abundance): 488 (M^+, 13%). Orange crystalline **5** was obtained by re-crystallizing from THF at room temperature. Yield, 34%. m.p. 233 °C (dec.). *Anal.* Calc. for $C_{36}H_{26}Fe_2$: C, 75.82; H, 4.60. Found: C, 75.07; H, 4.49%. IR (KBr disk): ν(C≡C) 2208 (m) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.48–7.70 (m, 8H, C_6H_4—C_6H_4), 4.42 (br s, 14H, C_5H_5, C_5H_4), 4.70 (br s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 123.14, 126.73, 131.83, 139.51 (C_6H_4—C_6H_4), 85.59, 89.38 (C≡C), 68.99, 70.10, 71.50 (Cp). MS (EI, *m*/*z*, relative abundance): 570 (M^+, 9%).

2.3. Syntheses of new compounds *3*, *4*, *6* and *7*

For the syntheses of the new compounds **3**, **4**, **6** and **7** see Table 1, the separation method being similar to that of compounds **1**, **2** and **5**. The chemical and spectroscopic characterization are as follows:

Compound **3**: *Anal.* Calc. for $C_{24}H_{17}FeNO_2$: C, 70.78; H, 4.21; N, 3.44. Found: C, 70.62; H, 4.14; N, 3.46%. IR (KBr disk): ν(C≡C) 2203 (m), ν_{asNO_2}1507 (s), ν_{sNO_2} 1341 (vs) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.26–8.32 (m, 8H, C_6H_4—C_6H_4), 4.40 (s, 5H, C_5H_5), 4.68 (br s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 124.18, 124.81, 127.22, 127.58, 132.05, 137.61, 146.82, 147.13 (C_6H_4—C_6H_4), 85.20, 90.62 (C≡C), 65.01, 69.20, 70.17, 71.61 (Cp). MS (EI, *m*/*z*, relative abundance): 407 (M^+, 100%).

Compound **4**: *Anal.* Calc. for $C_{24}H_{16}FeINO_2$: C, 54.03; H, 3.19; N, 2.63. Found: C, 53.93; H, 3.00; N, 2.66%. IR (KBr disk): ν(C≡C) 2208 (m), ν_{asNO_2}1527 (vs), ν_{sNO_2}1358 (s) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.04–7.92 (m, 7H, C_6H_3—C_6H_4), 4.33 (s, 5H, C_5H_5), 4.60 (br s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 94.48, 125.04, 126.71, 129.59, 131.63, 133.86, 134.70, 136.54, 137.88, 148.84 (C_6H_3—C_6H_4), 83.24, 92.54 (C≡C), 63.93, 69.53, 70.25,

Table 1
Syntheses of new compounds **3**, **4**, **6** and **7**

Reactants[a]	Catalyst[b]	Time (h)	Product	Yield (%)	m.p. (°C)
Ethynylferrocene and 4-nitro-4′-iodo-biphenyl	A	20	**3**	51	216–217
Ethynylferrocene and 2-nitro-4,4′-diiodo-biphenyl	A	19	**4**	31	157–158
			6	15	179–180
Ethynylbenzene and 4-iodo-4′-ferrocenylethynyl-biphenyl	B	16	**7**	69	240 (dec.)

[a] Mol ratio = 1:1 (for **3**, **4**, **6**), 1:2 (for **7**); solvent: diethylamine (for **3**, **4**, **6**), THF/diisopropylamine (V:V = 3:1, for **7**); reaction temperature: reflux (for **3**, **4**, **6**), 60 °C (for **7**).
[b] A: $Pd(PPh_3)_2Cl_2$/CuI (1:1, 2.4 mol%), B: $Pd(PPh_3)_2Cl_2/Cu(OAc)_2$ (1:1, 6 mol%).

71.78 (Cp). MS (EI, *m*/*z*, relative abundance): 533 (M^+, 16%).

Compound **6**: *Anal.* Calc. for $C_{36}H_{25}Fe_2NO_2$: C, 70.24; H, 4.06, N, 2.28. Found: C, 69.66; H, 4.11, N, 2.39%. IR (KBr disk): ν(C≡C) 2208 (m), ν_{asNO_2}1537 (vs), ν_{sNO_2}1358 (s) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.23–7.58 (m, 7H, C_6H_3—C_6H_4), 4.24 (s, 14H, C_5H_5, C_5H_4), 4.50 (s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 122.44, 123.25, 123.31, 126.81, 128.31, 128.37, 131.62, 131.86, 132.09, 139.39, 140.16 (C_6H_3—C_6H_4), 85.56, 89.25, 89.48, 92.30 (C≡C), 65.19, 68.90, 69.99, 71.45 (Cp). MS (EI, *m*/*z*, relative abundance): 615 (M^+, 43%).

Compound **7**: *Anal.* Calc. for $C_{32}H_{22}Fe$: C, 83.12; H, 4.76. Found: C, 83.70; H, 4.89%. IR (KBr disk): ν(C≡C) 2203 (m) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.26–7.96 (m, 13H, C_6H_4—C_6H_4, C_6H_5), 4.29 (br s, 5H, C_5H_5), 4.54 (br s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 124.30, 124.77, 126.69, 127.80, 131.69, 134.41, 134.60, 136.04, 149.02 (C_6H_4—C_6H_4, C_6H_5), 83.36, 85.26, 89.97, 92.34 (C≡C), 64.95, 69.35, 70.09, 71.66 (Cp). MS (EI, *m*/*z*, relative abundance): 462 (M^+, 100%).

2.4. Synthesis of complex [Fc-C≡C—C_6H_4—C_6H_5][$Co_2(CO)_6$] (**8**)

A benzene solution of equimolar amounts of compounds Fc-C≡C—C_6H_4—C_6H_5 (**1**) and $Co_2(CO)_8$ was stirred for 4 h at 20 °C. The solvent of the resulting black mixture was removed in vacuum. The residue was dissolved in a minimal amount of benzene and subjected to chromatographic separation on a silica gel column (1.2 × 30 cm). Elution with hexane–benzene (10:1) afforded a black band. Crystals of the complex [Fc-C≡C—C_6H_4—C_6H_5][$Co_2(CO)_6$] (**8**) were obtained by recrystallizing the black solid from hexane–dichloromethane at −20 °C. Complex **8**: Yield, 61%. m.p. 119–120 °C. *Anal.* Calc. for $C_{30}H_{18}Co_2FeO_6$: C, 55.59; H, 2.80. Found: C, 55.83; H, 3.19%. IR (KBr disk) ν(CO) 2085 (s), 2049 (vs), 2008 (vs) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.26–7.96 (m, 9H, C_6H_4—C_6H_5), 4.21 (s, 5H, C_5H_5), 4.44, 4.54 (2s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 199.45 (CO), 92.36, 126.96, 127.46, 127.57, 128.90, 137.66, 140.46, 140.85 (C_6H_4—C_6H_5), 85.26, 91.16 (C≡C), 69.36, 69.66, 70.10 (Cp). MS (FAB, relative abundance): 648 (M^+, 4%), 592 (M^+−2CO, 41%), 564 (M^+−3CO, 100%), 508 (M^+−5CO, 53%), 480 (M^+−6CO, 58%).

2.5. Syntheses of new complexes **9**, **10**, **11**, **12**, **13** and **14**

The syntheses of new complexes **9, 10, 11, 12, 13** and **14**, see Table 2, and the separation method is similar to that of complex **8.** The chemical and spectroscopic characterizations are as follows:

Complex **9**: *Anal.* Calc. for $C_{30}H_{17}Co_2FeIO_6$: C, 46.55; H, 2.31. Found: C, 46.52; H, 2.37%. IR (KBr disk) ν(CO) 2080 (s), 2044 (vs), 2008 (vs) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.17–7.88 (m, 8H, C_6H_4—C_6H_4), 4.12 (br s, 5H, C_5H_5), 4.37 (br s, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 199.38 (CO), 127.25, 130.24 (C_6H_4—C_6H_4), 85.20 (C≡C), 69.38, 69.66, 70.12 (Cp). MS (FAB, relative abundance): 718 (M^+−2CO, 9%), 690 (M^+−3CO, 58%), 662 (M^+−4CO, 24%), 634 (M^+−5CO, 14%), 606 (M^+−6CO, 18%).

Complex **10**: *Anal.* Calc. for $C_{30}H_{17}Co_2FeNO_8$: C, 51.96; H, 2.47; N, 2.02. Found: C, 52.06; H, 2.65; N, 2.16%. IR (KBr disk) ν(CO) 2077 (s), 2044 (vs), 2011 (vs) cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.24–8.33 (m, 8H, C_6H_4—C_6H_4), 4.19 (s, 5H, C_5H_5), 4.44, 4.50 (d, 4H, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 199.23 (CO), 124.28, 127.58, 127.82, 130.34, 137.92, 139.98, 146.83 (C_6H_4—C_6H_4), 85.02, 90.08 (C≡C), 69.50, 69.68, 70.12

Table 2
Syntheses of new complexes **9**, **10**, **11**, **12**, **13** and **14**

Reactants[a]	Temperature (°C)	Time (h)	Product	Yield (%)	m.p. (°C)
Fc-C≡C—C_6H_4—C_6H_4—I and $Co_2(CO)_8$	35	4	**9**	65	150 (dec.)

2.6. X-ray crystallography of compounds *1*, *4*, *8*, *9* and *11*

Black crystals of compounds **1**, **4**, **8**, **9** and **11** were mounted on a glass fibres. All measurements were made on Bruker SMART APEX CCD diffractometers with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. All data were collected at 20 °C using the ϕ and ω scan techniques. All structures were solved by direct methods and expanded using a Fourier technique [20]. An absorption correction based on SADABS was applied [21]. All non–hydrogen atoms were refined by full matrix least-squares on F^2. Hydrogen atoms were located and refined by a geometry method. The cell refinement, data collection and reduction were done by Bruker SMART and SAINT programs [22]. The solution and refinement of the structures were performed by SHELXSL97 [23].

3. Results and discussion

3.1. Syntheses and characterizations of the ferrocenylacetylenylbiphenyl derivatives and their complexes

The coupling reactions carried out in this work are summarized in Scheme 1. The addition reactions of the ligands Fc-C≡C—R and Fc-C≡C—R′—C≡C—R″ with $Co_2(CO)_8$ are summarized in Scheme 2. The complexes **8**, **9**, **10**, **11**, **12**, **13** and **14** were prepared by the addition reaction between the Co—Co bond of $Co_2(CO)_8$ and the C≡C triple bond of the ligands Fc-C≡C—R and Fc-C≡C—R′—C≡C—R″

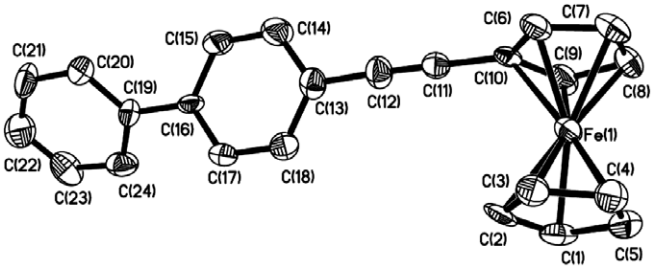

Fig. 1. Molecular structure of compound **1**.

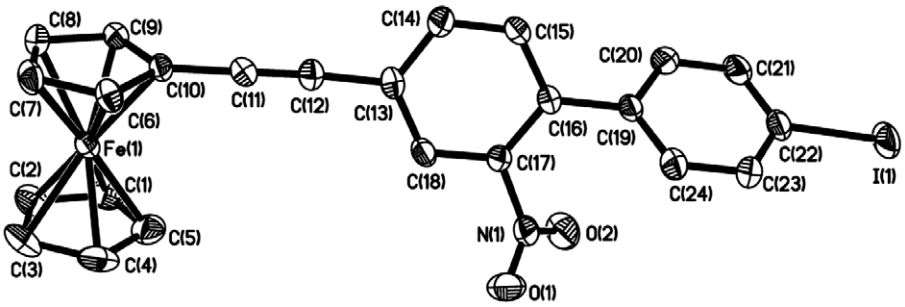

Fig. 2. Molecular structure of compound **4**.

with the mole ratios of $Co_2(CO)_8$ to ligand fixed at 1:1 and 1:2, respectively. The compounds are yellow for **1** and **2** and orange for **3**, **4**, **5**, **6** and **7**, and they are air-stable crystalline compounds which are slightly soluble in non-polar solvents such as hexane, and easily soluble in benzene and polar solvents such as dichloromethane. The complexes **8**–**14** are black crystals and their solubilities are similar to the corresponding ligands. The IR spectra (2077–2018 cm^{-1}) confirm that there are coordinated $Co_2(CO)_6$ species with C≡C triple bonds in complexes **8**–**14**. The compositions and structures of compounds **1**–**14** are further proved by the data of their element analyses, ^1H, ^{13}C NMR and MS.

3.2. Molecular structures of compounds *1, 4, 8, 9* and *11*

The molecular structures of compounds **1**, **4, 8, 9, 11** were determined by X-ray single crystal analysis. Crystal data and relevant structural parameters are enumerated in Table 3. The structures of compounds **1**, **4, 8, 9** and **11**, with the atom numbering scheme, are shown in Figs. 1–5, respectively, and selected bond lengths and angles are listed in Table 4.

The molecules of compounds **1**, **4**, **8**, **9** and **11** are constituted of a π-conjugated alkynyl system with terminal ferrocenyl and biphenyl or substituted biphenyl units, respectively. In **1** the bond distance C(11)–C(12) (1.183 Å) shows there is a carbon–carbon triple bond. The bond distances C(10)–C(11) (1.45 Å) and C(12)–C(13) (1.44 Å) are shorter than that of C(16)–C(19) (1.51 Å) as a result of stronger electron delocalization

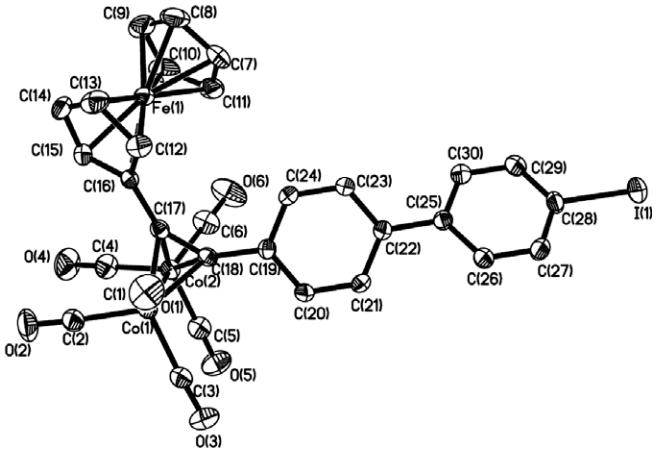

Fig. 4. Molecular structure of compound **9**.

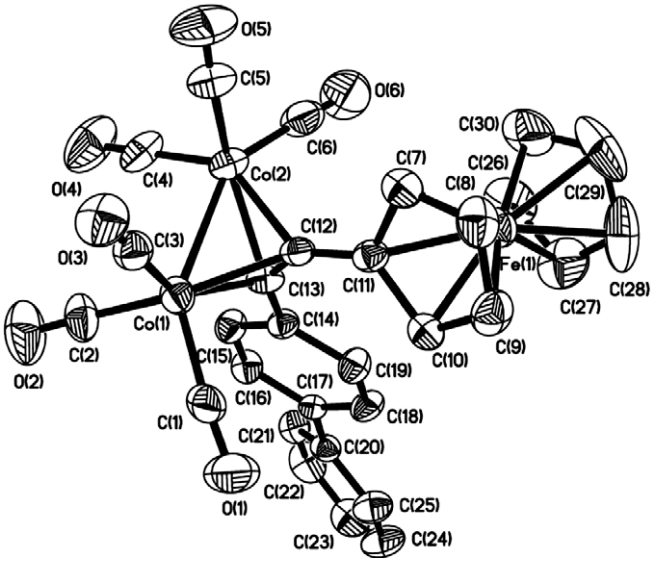

Fig. 3. Molecular structure of compound **8**.

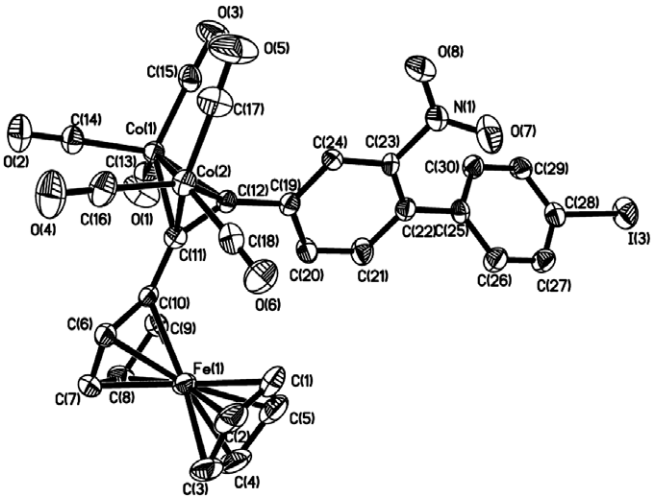

Fig. 5. Molecular structure of compound **11**.

between the C≡C bond (sp-C) and biphenyl (sp^2-C) or the C≡C bond (sp-C) and ferrocenyl group (sp^2-C) than that between two phenyl groups (two sp^2-C). The bond angle data in Table 2 demonstrate that the linear structure of compound **1** is altered to a non-linear structure in **8**, while the alkyne bond of **1** is coordinated to a $Co_2(CO)_6$ unit. The molecular structures of compounds **4** and **11** are similar to the structures of compounds **1** and **8**, respectively (see Figs. 2, 5 and 1, 3). The coordinated $Co_2(CO)_6$ units with the C≡C bond in complexes **8**, **9** and **11** are all approximately tetrahedral μ-alkyne dicobalt moieties. The alkyne bond adopts a typical μ_2–η^2 coordination fashion with the alkyne bond lying essentially perpendicular to the Co—Co bond in the C_2Co_2 unit. The average Co—Co bond distance (2.46 Å) is typical of classical alkyne dicobalt complexes. The average C—C bond length (1.34 Å) of the C_2Co_2 fragments shows a bond distance of the coordinated C≡C bond located in the scope of a C—C double bond. In complexes **8**, **9** and **11** the $Co_2(CO)_6$ units coordinated to the alkyne bond are in a trans configuration with the biphenyl and ferrocenyl groups, and the two terminal groups (biphenyl or substituted biphenyl and ferrocenyl groups) are orientated *cis* to each other (see Fig. 3–5).

In compounds **1**, **4**, **8**, **9** and **11**, the data of the dihedral angles (40.12° for **1**, 52.52° for **4**, 26.30° for **8**, 35.41° for **9** and 57.51° for **11**) between the two phenyl rings are different from each other, and have been affected by the substituted group on the biphenyl ring and the coordinated $Co_2(CO)_6$ unit with the alkyne. The dihedral angle between the two phenyl rings in **1** is smaller than that in **4** because of the effect of the substituted group (NO_2) on the phenyl ring. The data of the dihedral angles (1.97° for **1**, 0.88° for **4**, 4.01° for **8**, 5.58° for **9** and 2.97° for **11**) between the two Cp planes in compounds **1**, **4**, **8**, **9** and **11** reveal that the two Cp planes are nearly parallel in **4**, but are slightly deviated from parallel in **1**, **8**, **9** and **11**.

3.3. Electrochemical properties of compounds 1–12

The electrochemical properties of compounds **1**–**12** have been studied by cyclic voltammetry at 298 K in a standard three-electrode system with *n*-NBu_4ClO_4(TBAP) in CH_2Cl_2 solution as the supporting electrolyte. The results are given in Table 5.

For compounds **1**–**7** and complexes **8**, **10** and **12** the usual electrochemically quasi-reversible ferrocene (0/1+) peak couples and a one-electron redox process were observed (see Table 1), but for complexes **9** and **11** an irreversible redox process was observed. Only a pair of redox peaks appears, which reveals that there are no Fe–Fe interactions in the di-ferrocenyl compounds **5**, **6** and **12** through the conjugated biphenyl ethynyl bridges [17]. However, a redox behavior study of ethynyl-bridged ferrocenes, such as the Fc-$(C{\equiv}C)_2$-Fc ligand and its clusters, demonstrates two one-electron redox processes, which show there are Fe–Fe interactions [24]. The irreversible reduction peaks within range $E_{pc} = -0.55$ to -0.88 V in complexes **8**–**12** were regarded as the result of a reducing process on the $Co_2(CO)_6$ moieties. Although there are substituted electron-withdrawing groups on the biphenyl rings in compounds **2**, **3**, **4**, **6**, **9**, **10** and **11**, and the coordinated $Co_2(CO)_6$ units for complexes **8**–**12**, no significant variation of E^0 was observed.

4. Conclusion

Ferrocenylacetylenylbiphenyl and bisferrocenylacetylenyl-biphenyl derivatives could be synthesized by Sonogashira coupling and a second Sonogashira coupling reaction, respectively, and their cobalt coordinated complexes could be obtained by the addition reaction of $Co_2(CO)_6$ units to the alkyne bond. The molecular structures of complexes **8**, **9** and **11** show the $Co_2(CO)_6$ units coordinated to the alkyne bond are in a trans configuration with the terminal biphenyl derivatives and ferrocenyl groups. The data of dihedral angles reveal two phenyl rings of biphenyl derivatives in compounds **1**, **4**, **8**, **9** and **11** are deviated from parallel.

Abstract

The five-coordinate mixed-imido complex [Mo(N*t*-Bu)(NC_6F_5)(L)] (**1**) can be prepared in high yield via treatment of [Mo(N*t*-Bu)(NC_6F_5)(O*t*-Bu)$_2$] with LH_2, where LH_2 is 2,6-bis(2-hydroxy-2,2-diphenylethyl)pyridine. Contrastingly, the reaction of [Mo(N-Ad)(NC_6F_5)(O*t*-Bu)$_2$] (Ad = adamantyl, C_6H_{10}) with LH_2 gave [Mo(NAd)$_2$(L)] (**2**) via an imido-exchange reaction. Complex **2** can also be synthesised via treatment of in situ generated [Mo(NAd)$_2$(O*t*-Bu)$_2$] with LH_2; the latter method also results in trace amounts of the five-coordinate complex [MoCl(NAd)$_2$(L_{dehyd})] (**3**) (L_{dehyd} = 2-(2-hydroxy-2,2-diphenylethenyl)pyridine). The structures of **1**–**3** have been determined by X-ray crystallographic study. In each complex, the geometry at the metal is distorted trigonal bipyramidal with the pyridinediolate ligand adopting an 'aea' bonding arrangement in **1** and an 'eee' arrangement in **2**. The angle associated with the imido moiety also varies, with the greatest deviations found in **1** and **3**, indeed, the pentafluoroimido ligand in **1** has one of the largest deviations from linearity for an M–N–C angle recorded to-date [135.98(16)°]. This has been rationalised on the basis of an electronic effect rather than intramolecular steric interactions or crystal packing forces.

Keywords: Molybdenum; Imido; Crystal structures

1. Introduction

The organoimido function has featured heavily in coordination chemistry over the last three decades [1]. Interest in bis(imido) complexes of group VI in-particular continues, primarily because of their use as precursors to useful catalytic systems [2]. The vast majority of terminal organoimido (NR, R = alkyl or aryl) groups in the literature are sp-hybridised at nitrogen and hence triple-bond in nature (four electron donors). The softness of the M–N–C angle has been noted previously with angles in the range 180–150° considered linear (**I**) [3]. An additional linear form (**II**) with a formal M = N double bond has also been noted [4]. Contrastingly, there are few examples of bent imido groups (**III**), although a number of chelate species are known where the restricted imido bond angle is a function of the bite angle of the ligand [5]. In the case of **III**, the lone pair resides on the sp^2-hybridised nitrogen atom and the metal imido group can be described as possessing double-bond character (2 electron donor).

The earliest structurally characterised example [Mo(NPh)$_2$(S$_2$CNEt$_2$)$_2$], a 20 electron complex, was found to possess one bent [Mo–N–C = 139.4(4)°] and one linear [Mo–N–C = 169.4(4)°] imido group at −80 °C [6]; only slight differences were observed in a later room temperature study [7]. Interestingly, the related complexes [Mo(NAr)$_2$(S$_2$CNEt$_2$)$_2$] (Ar = 2-MeC$_6$H$_4$, 2,6-Me$_2$C$_6$H$_3$, 2,6-*i*-Pr$_2$C$_6$H$_3$ and 2,6-Cl$_2$C$_6$H$_3$) do not contain bent imido groups, leading to the conclusion that the bending of the imido ligand in this system is attributable to intramolecular steric interactions and/or crystal packing forces [7]. Examples of bent imido ligands for other metals (see Table 1) include the manganese complexes [Mn(N*t*-Bu)$_3$X] (X = Cl, OC(O)Me, OC$_6$F$_5$ and SC$_6$F$_5$) for which the Mn–N–C angles fall in the range 138.5(3)–144.6(3)° [8], and the rhenium(VII) complex {[Re(N*t*-Bu)$_2$(η^1-C$_5$H$_5$)]$_2$(μ- C$_5$H$_4$)(μ-O)} [9]. Recently, Odom et al. have carried out a statistical analysis of bis(imido) group VI complexes using data from the Cambridge Structural Data Base, and presented the data in terms of the sum of the imido angles [10]. The average sum of the imido angles was found to be 328° (standard deviation 8°), whilst it was also apparent that bending of the imido group was no more prevalent for 6-coordinate complexes than for 4- or 5-coordinate species.

In our previous studies on the 2,6-bis(2-hydroxy-2,2-diphenylethyl)pyridine (LH$_2$), **IV**, we have described the synthesis and X-ray crystal structure of the five-coordinate molybdenum (VI) compound [Mo(NAr)$_2$(L)], where Ar = N-2,6-*i*-Pr$_2$C$_6$H$_3$ [3]. In this case the pyridinediolate ligand adopts a *'facial'*, (eae) coordination mode[1] leaving one of the imido ligands to occupy an axial coordination site within the trigonal bipyramidal structure, the other imido group occupies an equatorial site. The structure of this complex revealed a severe bending of the equatorial imido ligand, [144.8(5)°] the axial imido group remaining essentially linear [164.7(4)°]. In order to help understand whether the bending was due to an electronic or steric effect, the related alkylidene complex was prepared and structurally characterised. Here, the alkylidene ligand was found to preferentially occupy the equatorial site and is of course necessarily bent due to the sp^2-hybridised alkylidene carbon centre. Indeed, it was thought likely that the alkylidene ligand would prefer the equatorial site since in that position there exists only one dπ metal orbital available for bonding to the π-ligand. Thus, the bending of the imido group in this environment may be attributed to an electronic explanation rather than due to steric effects or crystal packing forces. In extending this work, we wished to probe the effect of incorporating differing imido ligands, especially those with different electronic requirements, i.e. an electron-withdrawing substituent and an electron-releasing substituent within this 5-coordination geometry. Furthermore, would an imido ligand with a strong electron-withdrawing substituent show a preference for the equatorial site. We were also interested to compare the effect of *facial* (eae) coordination of the [O,N,O] ligand with *meridional* (eee) coordination, and the effect this might have on the imido ligand bonding.

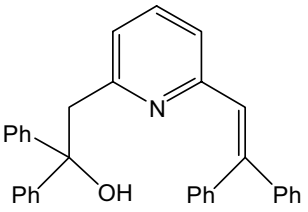
[c] Thought to be protonated.
[d] TTP = tetratolylporphyrin.



[1] We have opted not to use the terms *fac* and *mer* here, as IUPAC usually reserves such descriptions for hexa-coordinate centres.

In this paper, we report the successful synthesis and structural characterisation of two complexes [Mo(N*t*-Bu)(NC_6F_5)(L)] (**1**) and [Mo(NAd)$_2$(L)] (**2**), which possess the desired *facial* and *meridional* coordination geometries, respectively. The structure of the trace product [MoCl(-NAd)$_2$(L_{dehyd})] (**3**) is also reported.

Few other studies of the tridentate ligand L have been reported, examples include oxo, nitrido and imido complexes of osmium [20], the dioxo complexes of molybdenum reported by Holm [21], a titanium dichloride complex [$TiCl_2$L] [22] and the main-group complex [$SiMe_2$L] [23–25]. We have also recently reported the isodiazene complex [MoCl(O_3SCF_3)($NNPh_2$)L] which contains a *meridional* ligand [26].

LH_2 (IV)

LH_{dehyd} (V)

2. Results and discussion

Starting materials of the form [Mo(NR′)(NR″)Cl_2(dme)] (R′ = *t*-Bu, R″ = C_6F_5; R′ = Ad, R″ = C_6F_5) have been used previously for the synthesis of mixed-imido compounds [27]. The five-coordinate complex [Mo(N*t*-Bu)(NC_6F_5)(L)] (**1**) can be prepared in multigram quantities via treatment of [Mo(N*t*-Bu)(NC_6F_5)(O*t*-Bu)$_2$] (prepared in situ from [Mo(N*t*-Bu)(NC_6F_5)$_2Cl_2$(dme)] and LiO*t*-Bu) with LH_2.

Crystals of **1** suitable for an X-ray determination were grown from a saturated MeCN solution upon standing at room temperature. The molecular structure is shown in Fig. 1 and key bond lengths and angles are given in Table 2, crystal data are given in Table 3. The molecular structure is best described as a distorted trigonal pyramid with the pyridine of the diolate and the *tert*-butylimido groups occupying axial sites, i.e. an 'aea' set.

The 'aea' arrangement of the pyridinediolate (L) is similar to that observed in [Mo(NAr)$_2$L] (Ar = N-2,6-*i*-$Pr_2C_6H_3$)[2] and [OsNCl(L)] [20]. The structural parameters associated with the two imido groups in **1** reflect their differing electronic properties. The result is one linear *tert*-butylimido ligand [Mo(1)–N(1) = 1.7228(19) Å, Mo(1)–N(1)–C(1) = 173.52(18)°] and one bent pentafluorophenylimido group [Mo(1)–N(2) = 1.8074(19) Å, Mo(1)–N(2)–C(5) = 135.98(16)°]; a feature attributed to the more electron-releasing nature of the *tert*-butylimido ligand. In the bent ligand, there is also a diminished metal-nitrogen π contribution due to the presence of π-bonding between the nitrogen and the *ipso*-carbon of the phenyl ring as evidenced by the short C(5)–N(2) distance [1.379(3) Å cf. 1.449(3) Å for C(1)–N(1)]. Table 1 contains literature examples of 'bent' imido groups and reveals that for complex **1** the imido group has one of the greatest deviations from linearity observed to-date. The sum of the imido angles for **1** = ca. 309.5(°), which is very close to that observed for [Mo(NPh)$_2$(S_2CNEt_2)$_2$] [309°] – which is the lowest 'sum' in the literature.

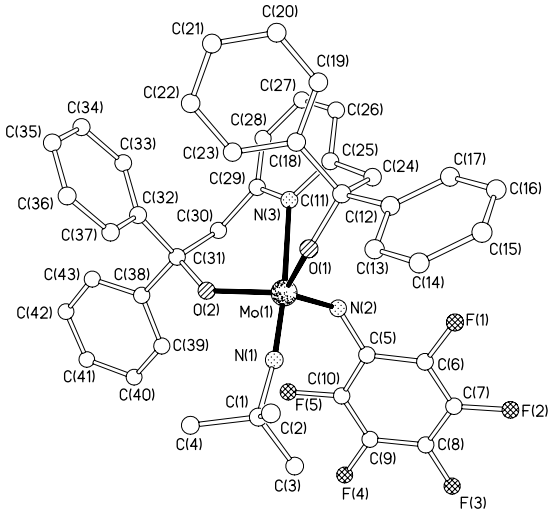


Fig. 1. The molecular structure of **1** with H-atoms omitted.

The five-coordinate complex [Mo(NAd)$_2$(L)] (**2**) can be prepared via treatment of [Mo(NAd)(NC_6F_5)(O*t*-Bu)$_2$] (prepared in situ from [Mo(NAd)(NC_6F_5)Cl_2(dme)] and LiO*t*-Bu) with LH_2 in refluxing toluene. The production of complex **2** at elevated temperatures indicates that under these conditions imido-ligand exchange occurs. Similar imido ligand exchange has been observed for the four-coordinate complexes [MoX_2(O*t*-Bu)$_2$] (X = O or NR), the tetratungstate [W_4(N*t*-Bu)$_4O_4Cl_{10}$]$^{2-}$ and more recently for the *tert*-butylimido titanium complex [Ti(N*t*-Bu)Cl_2(py)$_2$] [28–30]. It is also noteworthy that the bis(imido) complexes [Mo(NR)$_2Cl_2$(dme)] (R = *t*-Bu, 2,6-C_6H_3-*i*-Pr_2) and [Mo(NAr)$_2$(O*t*-Bu)$_2$] undergo metathesis with the imines PhN = CH(*t*-Bu) or (*n*-Pr)N = CHPh [31]. Crystals of **2** · MeCN suitable for an X-ray determination were obtained from a saturated MeCN solution upon prolonged standing at ambient temperature. The molecular structure is shown in Fig. 2a and b; key bond lengths and angles

are given in Table 4 and crystal data appear in Table 3. Each molecule of **2** crystallises with a molecule of MeCN. The molecular structure is best described as a distorted trigonal pyramid with the pyridine of the diolate and the two imido groups in equatorial positions, i.e. 'eee' ligated L.

The ^{1}H NMR spectrum of **1** reveals an *AB* quartet at 3.86 ppm for the ligand backbone methylene units consistent with the diastereotopic proton environments in the 'aea' coordinated ligand. Contrastingly the room temperature ^{1}H NMR spectrum of **2** reveals a broadened singlet consistent with the 'eee' coordination geometry.

Meridional arrangements for L have been observed previously in the 6-coordinate complexes $[Mo(O)_2(L)(Me_2SO)]$ and $[Os(O)_2(L)(H_2N\textit{t}\text{-Bu})]$ [20,21]. In **2**, a non-crystallographic 2-fold-axis bisects the N(1)–Mo–N(2) angle between the imido groups and passes along the Mo–N(3) bond of the pyridinediolate. The bond parameters associated with the equatorial imido ligands are of particular interest to us here. The Mo–N distances are similar, viz Mo–N(1) = 1.710(5), Mo–N(2) = 1.727(4) Å, whereas the angles at the imido nitrogens are quite different, 168.8(4)° and 159.6(4)° (sum of angles = 328.4°), however, both imido ligands are still considered to be 'linear'.

Reaction of $[Mo(NAd)_2(O\textit{t}\text{-Bu})_2]$ (prepared in situ from $[Mo(NAd)_2Cl_2(dme)]$ and Li*O*t-Bu) with LH_2 led to complex **2** together with trace amounts of yellow plate-like crystals, which were shown by X-ray diffraction to be the complex $[MoCl(NAd)_2(LH_{dehyd})]$ (**3**), where LH_{dehyd} is the partially dehydrated ligand **V**. The structure of **3** is shown in Fig. 3, with selected bond lengths and angles given in Table 5. There is approximate trigonal bipyramidal geometry at the metal centre, with the pyridine of the chelate and two imido ligands equatorial. As in **1**, the two imido ligands are quite different: Mo(1)–N(3) 1.724(3) Å/Mo(1)–N(3)–C(44) 170.9(3)° versus Mo(1)–N(2) 1.745(3) Å/Mo(1)–N(2)–C(34) 148.6(3)°; the latter is now in the range associated with bent imido groups (sum of angles = 319.5°). This bending could arise as a consequence of steric interactions with the pendant alkenyl arm of the chelate ligand. Pyridinediols have previously been found to act as HCl receptors, and the structure of the partially dehydrated ligand **V** · HCl (i.e., the HCl adduct of LH_{dehyd}) was shown to contain a Cl^- ion hydrogen-bonded to a protonated pyridine nitrogen atom. Interestingly, in order to achieve complete dehydration, neat H_3PO_4 had to be used at elevated temperatures [32].

3. Summary

We have described the synthesis and characterisation of two bis(imido)molybdenum complexes that differ in the coordination geometry of a tridentate [O,N,O] ligand: one of the complexes also has two electronically differing imido substituents. In this case the imido ligands with an electron-releasing tertiary-butyl substituent occupies the axial site within the trigonal bipyrimidal coordination

geometry, the electron-withdrawing pentafluorophenyl imido group, the equatorial site. This would appear to be a favourable arrangement allowing the tertiary-butylimido group to maximise its π-donor group capacity through the formation of two π bonds. In the equatorial position, there is only a single dπ metal orbital available to overlap with the imido nitrogen π orbital thereby restricting the imido group to a single π-bond. A consequence of this is a formally sp^2-hybridised nitrogen and an accordingly bent imido ligand. The structure of **2** lends further support to the observation that for electronically similar imido groups in identical coordination environments, especially when placed in direct competition for the available metal dπ orbitals, an imido bend angle in the range 150–180° is anticipated. The M–N–C angle then appears to be dictated by intramolecular steric effects and crystal packing forces, a consequence of a relatively shallow potential energy well for M–N–C bending when the two imido groups are in chemically equivalent sites and therefore in direct competition for the available metal π-orbitals.

4. Experimental

4.1. General

All manipulations were carried out under an atmosphere of nitrogen using standard Schlenk and cannula techniques or in a conventional nitrogen-filled glove-box. Solvents were refluxed over an appropriate drying agent, and distilled and degassed prior to use. Elemental analyses were performed by the microanalytical services of the Department of Chemistry at Durham and of Imperial College. NMR spectra were recorded on a Varian VXR 400S spectrometer at 400.0 MHz (^{1}H), and 376.3 MHz (^{19}F) at 298 K; chemical shifts are referenced to the residual protio

impurity of the deuterated solvent; IR spectra (nujol mulls, CsI windows), Perkin–Elmer 577 and 457 grating spectrophotometers. [Mo(N*t*-Bu)(NC_6F_5)Cl_2(dme)], [Mo(NAd)(NC_6F_5)Cl_2(dme)], [Mo(NAd)$_2Cl_2$(dme)] and LH_2 were prepared by the literature methods [27,21]. All other chemicals were obtained commercially and used as received unless stated otherwise.

4.2. Preparation of [Mo(Nt-Bu)(NC_6F_5)L] (1)

To [Mo(N*t*-Bu)(NC_6F_5)(O*t*-Bu)$_2$] [prepared in situ from [Mo(N*t*-Bu)(NC_6F_5)Cl_2(dme)] (1.50 g, 2.98 mmol) and LiO*t*-Bu (0.48 g, 6.00 mmol)] in ca. 50 cm^3 diethyl ether was added LH_2 (1.37 g, 2.91 mmol). After stirring for 5–10 min, the volatiles were removed in vacuo. Toluene (ca. 40 cm^3) was added and the system was refluxed for 12 h. On cooling, volatiles were removed in vacuo and the residue was extracted with hot MeCN (40 cm^3). On standing at room temperature large yellow prisms of **1** formed. Yield: 1.90 g, 80%. *Anal.* Calc. for $MoF_5O_2N_3C_{43}H_{36}$ requires C, 63.2; H, 4.4; N, 5.1. Found: C, 63.4; H, 4.4; N, 5.0%. IR: 1600w, 1575w, 1494m, 1343m, 1312m, 1292m, 1261s, 1239m, 1211m, 1189m, 1093s, 1060s, 1023s, 977m, 960m, 947m, 916m, 892m, 875m, 801s, 770m, 753m, 733m, 724m, 701m, 658w, 638w, 619w, 607w, 600w, 592w, 565w, 512w, 497w, 484w, 452w, 427w, 417w, 404w. ^{1}H NMR ($CDCl_3$): δ 7.46–6.74 (several m, 23H, aryl*H*), 3.86 (ABq, 4H, CH_2), 1.12 (s, 9H, C(CH_3)$_3$). ^{19}F NMR ($CDCl_3$): δ −152.00 (m, 2F, *o*-F), −165.36 (tm,* 2F, $^3J_{FF}$ 18 Hz, $^4J_{FF}$ 3Hz, *m*-F), −167.44 (m, 1F, *p*-F). * triplet of multiplets.

4.3. Preparation of [Mo(NAd)$_2$L] (2)

As for **1**, using [Mo(NAd)(NC_6F_5)Cl_2(dme)] (2.00 g, 3.42 mmol) and LiO*t*-Bu (0.54 g, 6.75 mmol) and LH_2 (1.60 g, 3.39 mmol) affording **2** · MeCN as golden-yellow prisms. Yield: 1.37 g, 89%. *Anal.* Calc. for $MoO_2N_3C_{53}H_{55} \cdot CH_3CN$ (sample dried for 12 h in vacuo) requires C, 73.2; H, 6.5; N, 6.2. Found: C, 73.7; H, 6.5; N, 6.1%. IR: 2359m, 2342m, 1737w, 1705w, 1654w, 1602w, 1580w, 1560w, 1500s, 1308w, 1242m, 1182w, 1119w, 1096w, 1062m, 1044s, 1027s, 984w, 963w, 924w, 890w, 812w, 784m, 752w, 701s, 606s. ^{1}H NMR (Acetone-d_6) δ: 7.65–7.16 (several m, 23H, aryl*H*), 4.08 (bs, 4H, CH_2), 1.98 (m, 6H, C*H*ad), 1.57 (m, 12H, CH_2ad), 1.56 (m, 12H, CH_2ad).

4.4. Preparation of [MoCl(NAd)$_2$(L_{dehyd})] (3)

As for **1**, but using [Mo(NAd)$_2Cl_2$(dme)] (0.93 g, 1.69 mmol) and LiO*t*-Bu (0.26 g, 3.25 mmol) with LH_2 (0.80 g, 1.70 mmol) affording on recrystallisation from hot acetonitrile **2** (0.61 g, 80%) and **3** (0.11 g, 15% based on Mo). For **3**, *Anal.* Calc. for $MoClON_2C_{43}H_{40}$ requires C, 70.5; H, 5.5; N, 3.8. Found: C, 69.4; H, 5.7; N, 3.8%. IR: 2359m, 2325m, 1654w, 1603m, 1568w, 1491m, 1302w, 1267w, 1233m, 1181w, 1122m, 1095m, 1053s, 1027m, 950m, 907w, 821w, 779m, 735w, 701s, 666s, 598s. ^{1}H NMR (CD_3CN) δ: 7.83–7.01 (several m, 23H, aryl*H*), 6.50 (d, 1H, C*H*), 4.09 (bs, 2H, CH_2), 1.97 (m, 18H, Ad*H*), 1.65 (m, 12H, Ad*H*).

4.5. X-ray crystallography

Crystallographic data and details of the data collection procedures and structure refinement for structures **1**, **2** and **3** are presented in Table 3.

Data for **1** and **3** were collected on a Bruker AXS SMART 1K CCD area detector diffractometer using graphite monochromated Mo Kα radiation (λ = 0.71073 Å) and narrow frames (0.3° in ω). Corrections were applied for Lorentz-polarisation effects and semi-empirically for absorption based on symmetry equivalent and repeated data. Programs used were Bruker AXS SMART (machine control) and SAINT (frame integration) [33]. Data for **2** were collected on a Stoe-Siemens diffractometer with ω/θ scans and on-line profile fitting [34] with all machine-control calculations performed using Stoe DIF4 software and with graphite monochromated Cu Kα radiation (λ = 1.54184 Å). Corrections were applied for Lorentz-polarisation effects and semi-empirically for absorption using Ψ-scans. The structures were solved by direct methods for **1** and **3**, (Patterson synthesis for **2)** and refined by full-matrix least-squares on all data using F^2 values. All non-H atoms were refined anisotropically, H atoms, initially located in difference maps, were included using a riding model with U_{iso} equal to 1.2 times that of the carrier atom (1.5 times for methyl H). The program SHELXTL [35] was used for crystal structure solution and refinement and molecular graphics.

5. Supplementary material

CCDC 147054, 147055 and 147056 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Synthesis and characterization of some dimethylsilicon(IV) complexes with internally functionalized oximes: Crystal and molecular structure of $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$. Formation of mesoporous materials by the hydrolytic study of $[Me_2Si\{ON{=}C(CH_3)C_4H_3O\text{-}2\}_2]$ in the presence of $Al(OPr^i)_3$

Abstract

Reactions of Me_2SiCl_2 in a 1:2 molar ratio with internally functionalized oximes in the presence of Et_3N in anhydrous benzene afford compounds of the type $[Me_2Si\{ON{=}C(R)Ar\}_2]$ {where R = Me, Ar = 2-C_5H_4N (**1**), 2-C_4H_3O (**2**), 2-C_4H_3S (**3**); R = H, Ar = 2-C_5H_4N (**4**), 2-C_4H_3O (**5**), 2-C_4H_3S (**6**)}. Molecular weight measurements of all these derivatives in freezing benzene and the FAB mass spectral studies of **1** and **6** indicate that these complexes are monomeric. The ^1H and $^{13}C\{^1H\}$ NMR spectra suggest that the oximate moieties are monofunctional monodentate in solution. $^{29}Si\{^1H\}$ NMR signals appear in the region expected for tetra-coordinated dimethyl silicon atoms. Single crystal X-ray diffraction analysis of $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$ (**5**) confirms the presence of a distorted tetrahedron as the immediate environment around silicon. Secondary weak β-donor bonding is also observed in the solid state, indicating that silicon is in the (4+2) coordination state. The TGA curve of $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$ shows the high thermal stability and volatile nature of the complex. A comparison of hydrolytic studies of a mixture of $[Me_2Si\{ON{=}C(CH_3)C_4H_3O\text{-}2\}_2]$ and $Al(OPr^i)_3$ in a 1:2 molar ratio with those of pure $Al(OPr^i)_3$ under similar conditions by the sol–gel technique suggests the formation of a silicon embedded amorphous powder **7** and γ-alumina **8**, respectively. The variation in specific surface area, total pore volume and pore size indicate formation of mesoporous materials.

Keywords: Functionalized oximes; β-Donor interactions; (4+2) Coordination; γ-Alumina

1. Introduction

Modified mesoporous silica materials are receiving special attention [1], because of their variety of applications in adsorption [2], separation [3], catalysis [4], environmental degradation processes [5], drug delivery [6] and electronic devices [7]. The syntheses of these materials require suitable tailor-made precursors, such as organosilicon complexes containing SiON units [8,9].

Recently, we have reported that the η^2 coordination mode, which is the interaction of a β-positioned donor atom with the central acceptor atom, is favored in complexes of transition metals containing functionalized oximes [10], as demonstrated by V–N = 1.980(4) Å in $[VOCl\{ON{=}C(CH_3)C_4H_3S\text{-}2\}_2]\cdot CH_3OH$ compared to V–ON = 1.925(4) Å [10i] and Zr–N = 2.239(2) Å in $(acac)_2Zr\{ON{=}C(CH_3)C_4H_3O\text{-}2\}_2$ compared to Zr–ON = 2.109(10) Å [10d].

$[Me_2Si\{ON{=}C(H)C_4H_3S\text{-}2\}_2]$ (**6**)	Viscous	46.12 (46.42)	4.41 (4.55)	8.97 (9.02)	9.00 (9.05)	311 (310.5)

However, no such studies on the β-donor capability of functionalized oximes in their silicon derivatives have been undertaken. Therefore, we report herein the synthesis of some dimethylsilicon(IV) complexes with internally functionalized oximes along with the single crystal X-ray diffraction structure of $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$, which demonstrates the existence of β-bonding with [4+2] coordination around silicon. Thermal analysis of the same derivative as well as formation of mesoporous materials by the hydrolytic study of $[Me_2Si\{ON{=}C(CH_3)C_4H_3O\text{-}2\}_2]$ in the presence of $Al(OPr^i)_3$ has also been reported.

2. Experimental

All manipulations (except hydrolysis) were carried out under strictly anhydrous conditions. The solvents and reagents were dried and purified prior to use by conventional methods [11]. Appropriate precautions were taken in handling hazardous chemicals and solvents such as benzene. Dichlorodimethylsilane was used as supplied (Merck). Oximes were prepared by conventional methods [10c,12]. Silicon was estimated gravimetrically as SiO_2 [11]. IR spectra (4000–400 cm^{-1}) were recorded as Nujol mulls between CsI plates or as dry KBr pellets on a Shimadzu FTIR 8400 spectrometer. NMR [^1H, $^{13}C\{^1H\}$ and $^{29}Si\{^1H\}$] data were collected on a JEOL FX 300 FT NMR spectrometer in $CDCl_3$ solutions at 300.4, 75.45 and 59.60 MHz frequencies for ^1H, $^{13}C\{^1H\}$ and $^{29}Si\{^1H\}$ NMR, respectively, using TMS as an internal standard. FAB mass spectra were obtained on a JEOL SX 102/DA-6000 mass spectrometer using *m*-nitrobenzyl-alcohol matrix. Molecular weight measurements were carried out by determining the depressions in freezing point of anhydrous benzene using a Beckmann's Thermometer [Einstellthermometer *n*-Bek] fitted in a glass assembly (supplied by JSGW, India). XRD patterns were obtained on a Phillips-1840 diffractometer using a Fe source at $\lambda = 1.937$ Å. Microanalyses were carried out on a Heracus Carlo Erba 1108 analyzer. Thermogravimetric analysis was performed on Mettler Toledo Star SW 701 with a heating rate of 25–650/10 °C.

2.1. Preparation of $[Me_2Si\{ON{=}C(CH_3)C_5H_4N\text{-}2\}_2]$ (*1*)

A benzene solution of 2-acetyl pyridyl oxime (2.24 g, 16.45 mmol) and triethyl amine (1.68 g, 16.60 mmol) was added dropwise to a stirred ice-cooled benzene solution of dichlorodimethylsilane (1.06 g, 8.21 mmol). The mixture was stirred for 1 h and then refluxed for 5 h. The triethylaminehydrochloride [2.24 g, 16.27 mmol] formed was filtered off and the filtrate was concentrated in vacuo to give a pink liquid [2.65 g, 98.5% yield], which solidified on standing for a few days.

All other dimethylsilicon(IV) derivatives were prepared by a similar route. Their physical and analytical data are summarized in Table 1.

2.2. X-ray diffraction analysis

A colorless block crystal of $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$ (**5**) was covered in Paratone-N and placed rapidly into the cold N_2 stream of a Kryo-Flex low temperature device.

$[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$ (**5**)	1607 (s)	823 (vs)	962 (vs)
$[Me_2Si\{ON{=}C(H)C_4H_3S\text{-}2\}_2]$ (**6**)	1613 (s)	805 (vs)	985 (vs)

The data were collected on a Bruker APEX CCD diffractometer using a graphite monochromator with Mo Kα radiation ($\lambda = 0.71073$ Å). A hemisphere of data was collected using a counting time of 20 s per frame. The data were collected at −100 °C. Details of crystal data, data collection and structure refinement are listed in Table 2. Data reduction were performed using the SAINT software [13] and the data were corrected for Lorentz, polarization and absorption effects using the SAINT and SADABS programs [14]. The structure was solved by direct methods using SIR 92 [15] and was refined using the WINGX version [16] of SHELX-97 [17]. All of the non-hydrogen atoms were treated anisotropically. Hydrogen atoms were located in the difference map and refined isotropically. The final cycle of full-matrix least squares refinement was based on 1654 observed reflections (1415 for $F^2 > 4\sigma(F^2)$) and 115 variable

parameters and converged (largest parameter shift was 0.001 times its esd).

2.3. Hydrolytic studies: preparation of mesoporous materials 7 and 8 by the hydrolysis of a mixture of $[Me_2Si\{ON{=}C(CH_3)C_4H_3O\text{-}2\}_2]$ and $Al(OPr^i)_3$ in a 1:2 molar ratio and of pure $Al(OPr^i)_3$ by the sol–gel technique

$[Me_2Si\{ON{=}C(CH_3)C_4H_3O\text{-}2\}_2]$ (1.08 g, 3.52 mmol) and $Al(OPr^i)_3$ (1.44 g, 7.05 mmol) were dissolved in toluene and refluxed for about 6 h. The clear solution was dried in vacuo to give a brownish viscous liquid [$^{29}Si\{^1H\}$ NMR in $CDCl_3$ {δ ppm}: 5.1 and −17.4]. This was re-dissolved in dry isopropanol. To this clear solution a drop of water was added and the mixture was stirred for 1 h. Gel formation occurred immediately. A few more drops of water were added and the mixture was stirred for about 24 h. The whole mixture was dried at 100 °C in a preheated oven, to give a brown powder, which was washed thoroughly with an acetone–hexane mixture. This powder was sintered at 900 °C for about 1 h to yield **7**.

Using a similar procedure on pure $Al(OPr^i)_3$ dissolved in dry isopropanol, sample **8** was obtained.

3. Results and discussion

3.1. Preparation

Metathetical reactions of Me_2SiCl_2 with internally functionalized oximes in a 1:2 stoichiometry in the presence of triethylamine afford compounds of the type $[Me_2Si\{ON{=}C(R)Ar\}_2]$ in quantitative yield as depicted below:

$$Me_2SiCl_2 + 2HON{=}C(R)Ar + 2Et_3N \xrightarrow{\text{benzene}} \underset{(\mathbf{1}-\mathbf{6})}{[Me_2Si\{ON{=}C(R)Ar\}_2]} + 2Et_3N.HCl\downarrow$$

where R = Me or H and Ar = 2-C_5H_4N, 2-C_4H_3O or 2-C_4H_3S.

With the exception of complex **1**, a pink liquid which slowly solidifies on standing, all other derivatives are brown yellow solids or liquids that are highly soluble in common organic solvents. Molecular weight measurements in freezing benzene, along with the FAB mass spectral studies of two of the derivatives **1** and **6**, indicate the monomeric nature of all these complexes (Table 3).

Elemental analysis correspond to the expected formulae (Table 1).

3.2. IR spectra

The IR spectra of all these derivatives were interpreted by comparison with the spectra of the free oximes and related derivatives [8i,10c]. Some important absorption bands are given in Table 4. The absence of vibrations attributable to the hydroxyl group of the oximes (in the region 3200–3400 cm^{-1}) in all these derivatives and the presence of a new strong intensity vibration in the region 805–850 cm^{-1} (assigned to νSi–O) indicate the deprotonation of the oxime and concomitant bond formation with silicon. Absorptions in the region 929–985 cm^{-1} and 710–750 cm^{-1} have been assigned to ν(N–O) and ν(Si–C), respectively. The ν(C=N) absorption appeared at slightly lower wave numbers (a shift of 14–38 cm^{-1}) in comparison to the free oximes.

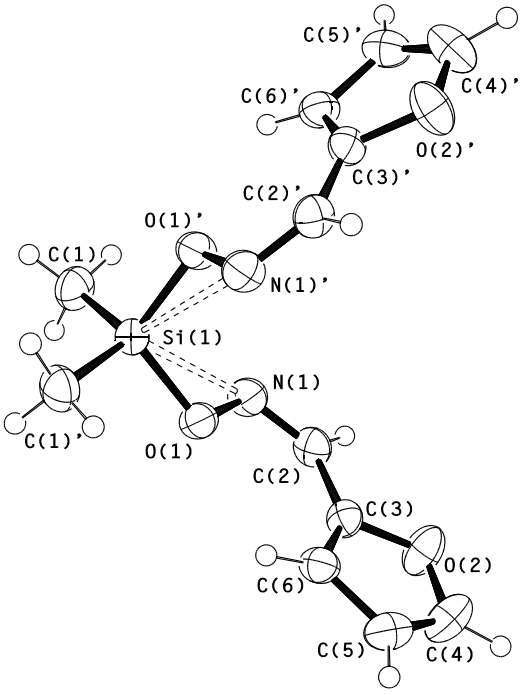

Fig. 1. ORTEP plot of $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$. The non-hydrogen atoms are drawn with 50% probability ellipsoids.

3.3. NMR spectra

The ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra of the complexes were interpreted by comparing them with those of the free oximes (Table 5) [10a,10c]. The hydroxyl proton resonances of the free oximes (δ 8.58–9.23 ppm) were absent in the ^{1}H NMR spectra of all these complexes indicating again the deprotonation of the oximes and their bond formation with silicon. There were no significant shifts in the hetero aryl ring proton/carbon resonances in the $^{1}H/^{13}C\{^{1}H\}$ NMR spectra, as is to be expected if the heteroatom of the ring is not taking part in coordination with the central silicon atom. The position of the C=N carbon resonance of the ligand moiety is almost unchanged in the $^{13}C\{^{1}H\}$ NMR spectra suggesting that the oximate moiety in these complexes in solution is probably monofunctional monodentate.

Only a single absorption signal is observed in the region δ 13.1–15.4 ppm in the $^{29}Si\{^{1}H\}$ NMR spectra of all these derivatives, which falls within the expected range for a tetra-coordinated dimethyl silicon atom [18].

3.4. X-ray diffraction analysis

The molecule $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$ (**5**) crystallizes in the space group *C*2/*c*. Distances and bond angles are given in Table 6 and the molecule is displayed as an ORTEP diagram in Fig. 1. The immediate environment around silicon is distorted tetrahedral with the C(1)–Si(1)–C(1)′ angle of 117.1(1)° being considerably larger than that of O(1)–Si(1)–O(1)′ (108.80(9)°). Two of the O(1)–Si(1)–C(1) angles are considerably smaller (102.84(7)°) than the other two 112.66(8)°). This degree of distortion is relatively unusual for the Me_2SiO_2 moiety unless there are clear restraints.

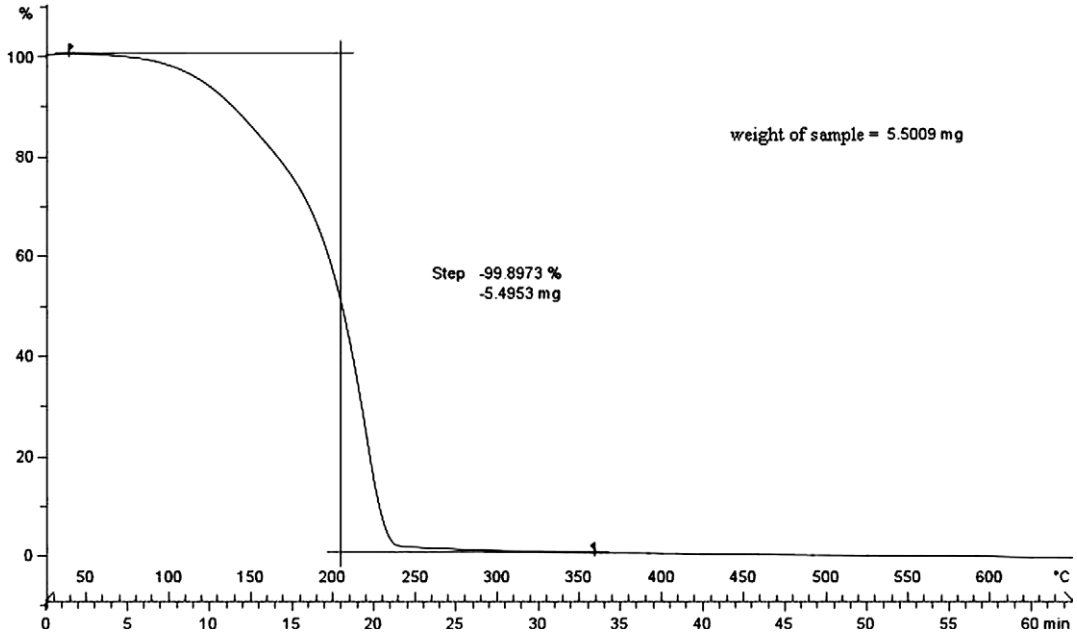

Fig. 2. TGA curve (weight % vs. temperature °C) of $[Me_2Si\{ON{=}C(H)C_4H_3O\text{-}2\}_2]$ (**5**).

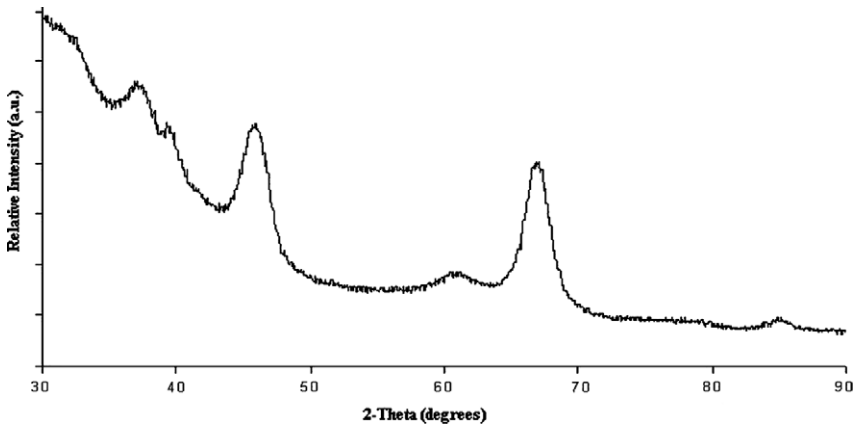

Fig. 3a. XRD of **8**.

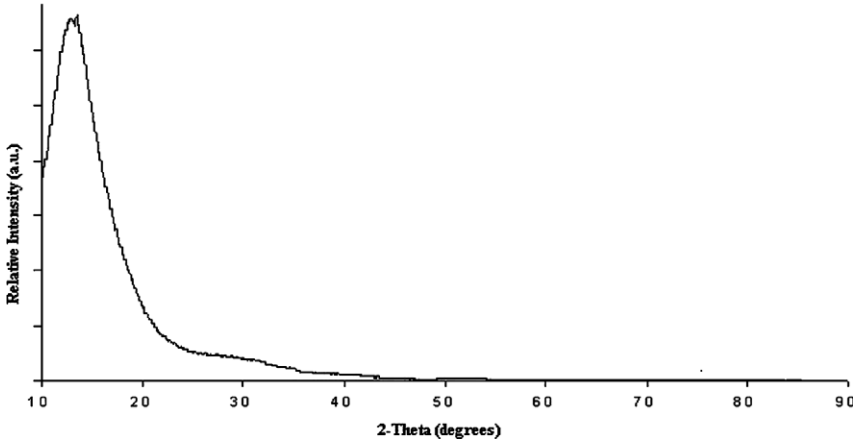

Fig. 3b. XRD of **7**.

The Si–O–N bond angle of 111.48(9)° and Si–N bond distance of 2.554(1) Å are of particular interest. It has been proposed that when the value of the Si–O–N bond angle is less than 116° it is reasonable to assume a degree of Si–N interaction in SiON compounds [8f]. Further, the bond distance of 2.554(1) Å is less than the sum of Bartell's one-angle radii of 2.69 Å for Si and N [8a]. Thus the description of this molecule as containing weak β-donor SiON bonds, resulting in (4 + 2) coordination [8g], is justified.

3.5. Thermogravimetric analysis

A thermogravimetric experiment was performed on complex **5** with the heating rate 25–650/10 °C. A great weight loss (~99.9%) step in the TGA curve (Fig. 2) reveals the thermal stability and volatility of the compound.

3.6. Crystallinity, surface area, pore volume and average pore size of mesoporous materials 7 and 8

The crystallinity of the materials was studied by X-ray diffraction, which exclusively showed the formation of γ-alumina for sample **8** (Fig. 3a). The XRD pattern of sample **7** indicated its amorphous nature (Fig. 3b). The nitrogen adsorption–desorption isotherms for samples **7** and **8** are shown in Fig. 4. The variations in specific surface area, total pore volume and average pore size samples are presented in Table 7. The isotherm of sample **8** shows a hysteresis loop, suggesting that the alumina under study is basically mesoporous with a pore size of 11.1 nm and a high surface area of 216.5 m^2/g. Similarly, sample **7** also has a relative high surface area of 192.3 m^2/g, but with a small pore volume of 0.13 cm^3/g. The TEM image of the mesoporous aluminum oxide is shown in Fig. 5. There is

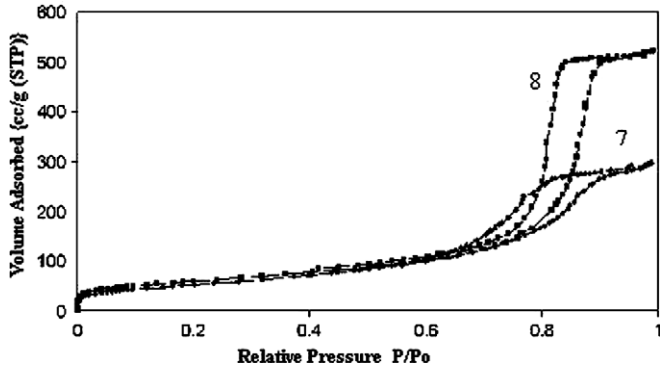

Fig. 4. Nitrogen adsorption–desorption isotherms of **7** and **8**.

Abstract

The magnetic interactions in a new series of isostructural imino nitroxide radical lanthanide(III) complexes, $[Ln(hfac)_3(IM2py)]$ (Ln = Gd–Yb: IM2py = 2-(2′-pyridyl)-4,5-dihydro-4,4,5,5-tetramethyl-1H-imidazoline-1-oxy; hfac = 1,1,1,5,5,5-hexafluoro-2,4-pentanedione), are examined by considering the intrinsic paramagnetic contribution of the Ln(III) ion from the corresponding $[Ln(hfac)_3(pybzim)]$ with a diamagnetic pybzim(2-(2-pyridyl)benzimidazole) ligand; the Ln(III)–IM2py interaction being antiferromagnetic for the $4f^7$ to $4f^{13}$ Ln(III) complexes and negligibly small for the other complexes. This series is the first example reverse to the previous cases for the series of Ln–Cu or Ln–aminoxyl(NIT) radical (4,5-dihydro-4,4,5,5-tetramethyl-1H-imidazoline-3-oxide-1-oxy) complexes, other than only a few examples of semiquinone Ln complexes. This reverse nature of the magnetic interaction, as compared with the NIT complexes, validates the empirical approach by O. Kahn et al. [Inorg. Chem. 38 (1999) 3692; J. Am. Chem. Soc. 122 (2000) 3413] in the spin-coupled systems for a series of Ln(III) complexes.

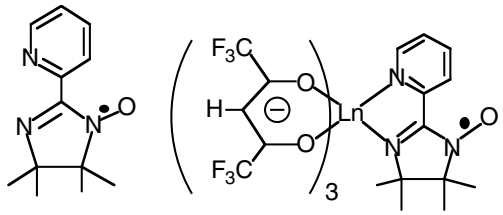
Keywords: Imino nitroxide radical; Lanthanide complexes; Magnetic properties



1. Introduction

Following a number of previous investigations of nitroxide radical complexes, aiming to construct molecular-based magnetic materials in terms of the so-called radical approach [1], we have recently studied the magneto-optical properties for lanthanide complexes with an imino nitroxide radical (IM2py = 2-(2′-pyridyl)-4,5-dihydro-4,4,5,5-tetramethyl-1H-imidazoline-1-oxy; Chart 1, left), $[Ln(hfac)_3(IM2py)]$ (Chart 1, right) [2], as well as those for transition metal complexes with nitronyl and imino nitroxide radical(s), in order to reveal the rational relationship of the optical properties with the magnetic interaction [3–6]. In our case [2a], the Gd(III) IM2py complex was found to give an antiferromagnetic interaction. This is one of a few recently described exceptions [7–9] for an antiferromagnetic interaction in nitronyl nitroxide radical (NIT2py = 2-(2′-pyridyl)-4,5-dihydro-4, 4,5,5-tetramethyl-1H -imidazoline-3-oxide-1-oxy) Gd(III) complexes, in contrast to the claim that the intramolecular Gd(III)–radical magnetic interaction was intrinsically ferromagnetic [10].

As for the nature of the magnetic interactions in Ln–radical complexes, except the isotropic Gd(III) complexes, there is little information partly, owing to the orbital contribution arising from the ground state splitting into Stark sublevels from the $^{2S+1}L_J$ spectroscopic energy terms due to the crystal field perturbation, or the violation of the Curie law corresponding to a depopulation of the sublevels. In order to overcome this difficulty for the Ln(III) ions, Kahn et al. have proposed an empirical approach to obtain greater insight into the nature of the magnetic interactions, where conclusive information on the ferro- or antiferromagnetic nature of the Ln–radical or Ln–Cu(II) interaction in the Ln–radical [10] or Ln–Cu(II) complexes [11] was given by comparing the magnetic characteristics with those of the corresponding Ln–non-radical or

IM2py **[Ln(hfac)$_3$(IM2py)]**

Chart 1. IM2py and the lanthanide-radical complex, [Ln(hfac)$_3$(IM2py)].

Ln–Zn(II) complexes through isostructurality in a series of lanthanide complexes. This approach has been applied to another type of Ln–Cu(II) or Ni(II) [12] and Ln–Fe(III) complexes [13]. Recently, this was analytically confirmed for Dy and Ho NIT radical complexes by qualitative and quantitative approaches [14]. For the Kahn's case, however, there are intraligand magnetic interactions between two nitronyl nitroxide radical ligands in addition to the two intramolecular magnetic interactions between Ln and the nitronyl nitroxide in the Ln complexes. Moreover, the validity of this approach could be confirmed by applying it to the opposite antiferromagnetic case for the Gd complexes. A few years ago, semiquinone Gd(III) complexes were found to display antiferromagnetic interactions [15–17] and the Kahn's approach was testified [16]. One of the appropriate candidates for the nitroxide complexes could be our recently synthesized mono(IM2py)Gd complex, in which the magnetic interaction is antiferromagnetic, showing a reverse case to the nitronyl nitroxide radical Gd complexes [2a]. The magnetic study for a series of lanthanide imino nitroxide radical complexes other than the Gd complex is expected to gain more unambiguous information concerning the magnetic interaction in comparison with the semiquinone radical complexes [16]. Recently, these aspects concerning lanthanide ions in molecular exchange coupled systems were reviewed [17].

In this paper, the nature of the magnetic interaction in Ln–imino nitroxide radical complexes from Nd to Yb are examined by comparing the magnetic character of the Ln–radical complexes, [Ln(hfac)$_3$(IM2py)] with the corresponding Ln–non-radical 2-(2-pyridyl)benzimidazole(pybzim) complexes, [Ln(hfac)$_3$(pybzim)].

2. Experimental

2.1. Synthesis

The [Ln(hfac)$_3$(IM2py)] (Ln = Nd–Lu) complexes were obtained according to the procedures described [2a]. 2-(2-Pyridyl)benzimidazole(pybzim), which was purchased from Aldrich, was reagent grade and used without purification. [Ln(hfac)$_3$(pybzim)] complexes were prepared by a similar procedure with use of pybzim instead of IM2py. These complexes gave satisfactory elemental analyses (Table 1).

Table 1
Elemental analysis for [Ln(hfac)$_3$(pybzim)]

Ln	C%	H%	N%
	Found (calc.)	Found (calc.)	Found (calc.)

Magnetic susceptibility data were collected at 2000 Oe between 2 and 300 K using a SQUID susceptometer (MPMS-5S, Quantum Design). Pascal's constants were used to determine the constituent atoms diamagnetism.

2.2. X-ray structural analysis

Colorless crystals of [Gd(hfac)$_3$(pybzim)] suitable for X-ray crystal analyses were obtained by slowly evaporating a solution of the complex in a mixture of dichloromethane and *n*-heptane. A crystal was mounted on a glass fibre. The X-ray intensities were measured at 23 °C with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) on a Rigaku AFC-5R or four-circle diffractometer using the ω–2θ scan technique. Final lattice constants were determined by least-squares refinements of the orientation angles of 25 centered reflections in the range $25° < 2\theta < 30°$. Three standard reflections were monitored every 150 reflections and showed no serious decomposition. ($|F_0|/(|F_0|)_{initial} > 99\%$). The intensities collected for $(-h, +k, \pm l)$ octants at $2\theta \leqslant 60°$ were corrected for Lorentz-polarization effects, and absorption corrections were made by the Gauss numerical integration method [18]. The structure could be solved reasonably by using the direct method (SHELXS-97 [19a]) and refined by the SHELXL-97 program [19b]. The positions of hydrogen atoms were fixed at calculated positions and only their isotropic displacement parameters were refined. All calculations were carried out by Crystal Structure software [20].

3. Results and discussion

3.1. Crystallographic studies of the non-radical complex [Gd(hfac)$_3$(pybzim)]

[Gd(hfac)$_3$(pybzim)] forms colorless crystals with the space group $P2_1/n$ by recrystallization from dichloromethane–*n*-heptane solution. The molecular structure of [Gd(hfac)$_3$(pybzim)] is illustrated in Fig. 1 and the crystallographic data are shown in Table 2. The Gd atom of [Gd(hfac)$_3$(pybzim)] is eight-coordinated with three didentate hfac ligands and one didentate pybzim ligand. Selected

bond lengths and angles of [Gd(hfac)$_3$(pybzim)] are summarized in Table 3. The range of the Gd–O bond lengths, from 2.335 to 2.430 Å, is close to that (2.315–2.420 Å) for [Gd(hfac)$_3$(IM2py)] [2a]. The average bond length (2.547 Å) of Gd–N is similar to that (2.550 Å) of [Gd(hfac)$_3$-(IM2py)] [2a]. The interplane distance between the pybzim planes in the adjacent molecules is ca. 3.60 Å, indicating negligibly small intermolecular interactions.

An examination by the semi-quantitative method of polytopal analysis [21] suggests that the N_2O_6 eight coordinate geometry around the Gd atom in [Gd(hfac)$_3$(pybzim)] is intermediate between a square antiprism and a square-bicapped trigonal prism, being isostructural to [Gd(hfac)$_3$-(IM2py)].

In view of the similarity in geometrical structure between [Ln(hfac)$_3$(IM2py)] and [Ln(hfac)$_3$(pybzim)], the crystal field effects of these complexes are similar to each other.

3.2. Magnetic properties

In order to manifest the unambiguous interaction, the contribution to $\chi_M{}^{Ln}T$(IM2py) for the Ln–IM2py complexes due to the thermally depopulated Stark sublevels of Ln(III) is deducted from $\chi_M{}^{Ln}T$(pybzim) for the Ln–pybzim complexes. The temperature dependence in direct conjunction with the local contribution of the crystal field in the Ln(III) ion can be given by the isostructural Ln(III) complexes with analogous diamagnetic ligands. The requirement for this approach is that there is the same crystal field in the non-radical complex as that in the radical complex. This may be fulfilled in view of the similar coordination geometry around the metal ion between the diamagnetic pybzim complexes and the radical IM2py ones.

Taking into consideration the isostructurality of the coordination geometry of [Ln(hfac)$_3$(IM2py)] for Sm, Gd, Dy, Er and Yb, as previously reported [2a], it is plausible that the corresponding Nd and Tb complexes may have the same crystal structure. Thus, the present series of Ln(III) complexes gives only the intramolecular magnetic interaction.

3.2.1. Gd ($4f^7$) compounds

According to the temperature dependence of the magnetic susceptibilities for [Gd(hfac)$_3$(IM2py)] [2a], the magnetic interaction between the Gd(III) ion and the IM2py radical is found to be antiferromagnetic ($J = -3.00$ cm^{-1}). This is confirmed for the analogous IMBzImH(2,3-bis(hydroxylamino)-2,3-dimethyl-butane-2-(2-benzyimdazolyl)-4,4,5,5-tetramethylimidazoline-1-oxide) complex, as well as the IM2py complex by Lescop et al. [9b].

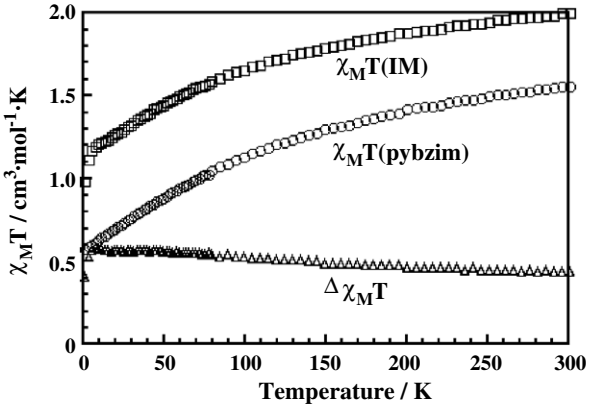

Fig. 2. Temperature dependence of $\chi_M T$(IM) (□), $\chi_M T$(pybzim) (○) and $\Delta\chi_M T$ (△) for Nd(III) complexes.

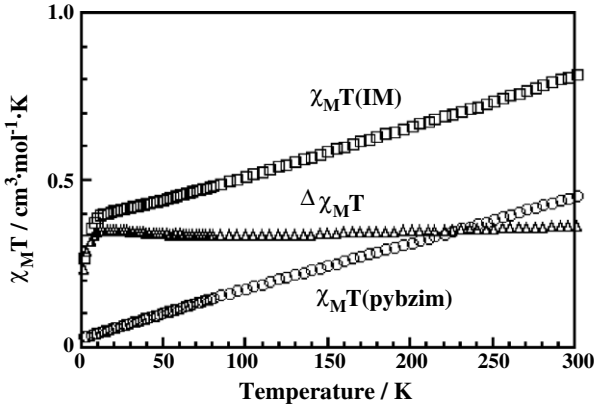

Fig. 3. Temperature dependence of $\chi_M T$(IM) (□), $\chi_M T$(pybzim) (○) and $\Delta\chi_M T$ (△) for Sm(III) complexes.

3.2.2. Nd ($4f^4$) and Sm ($4f^5$) compounds

The temperature dependence of the magnetic susceptibility of [Nd(hfac)$_3$(IM2py)] is shown as a product of the magnetic susceptibility and temperature, ${\chi_M}^{Nd}T$, versus the temperature T plot in Fig. 2. At 300 K, ${\chi_M}^{Nd}T$(IM) is equal to 2.00 cm^3 K mol^{-1}, close to the sum of the calculated values for the uncorrelated $\chi_M T$ of the Nd(III) ion and IM2py. On the other hand, the ${\chi_M}^{Nd}T$(pybzim) versus T plots of [Nd(hfac)$_3$(pybzim)] does not follow the Curie law (Fig. 2). Similarly as for the IM2py complex, the ${\chi_M}^{Nd}T$(pybzim) value decreases on lowering the temperature. Since the first $^4I_{11/2}$ excited state of the free Nd(III) ion is located at ca. 2000 cm^{-1} above the ground $^4I_{9/2}$ state, the excited $^4I_{11/2}$ state is expected to be completely depopulated at room temperature. The deviation of the magnetic behavior with respect to the Curie law results from the crystal field by which the $^4I_{9/2}$ free-ion ground state is split into five Kramers doublets (Stark sublevels). The Kramers doublets are almost equally populated at 300 K, but on lowering the temperature they are progressively depopulated until the lowest Kramers doublet is completely populated. This results in the decreases in $\chi_M T$. At 300 K, the difference value ($\Delta{\chi_M}^{Nd}T = {\chi_M}^{Nd}T$(IM) − ${\chi_M}^{Nd}T$(pybzim)) is 0.44 cm^3 K mol^{-1}, close to the expected value for an uncorrelated $S = 1/2$ spin for IM2py, as shown in Fig. 2. The $\Delta{\chi_M}^{Nd}T$ values gradually increase on lowering the temperature to 10 K. However, the variation of $\Delta{\chi_M}^{Nd}T$ values is too small to yield a conclusive result. Since our recent low temperature magnetic circular dichroism measurement of the 4f–4f transition at 4 K demonstrates little difference in the pattern between [Nd(hfac)$_3$(IM2py)] and [Nd(hfac)$_3$(bpy)](non-radical ligand bpy = 2,2′-bipyridine) [22], the small variation may be responsible for the difference of the ground state splitting by the crystal field between [Nd(hfac)$_3$(IM2py)] and [Nd(hfac)$_3$(pybzim)], but not for the small ferromagnetic interaction between the Nd(III) and IM2py radical ligand.

The situation for the Sm complex is more complex than that for the Nd complex, though their magnetic behavior is similar to each other. The temperature dependences of ${\chi_M}^{Sm}T$(IM), ${\chi_M}^{Sm}T$(pybzim) and $\Delta{\chi_M}^{Sm}T$ are shown in Fig. 3. Since the spin–orbit coupling parameter in the Sm(III) ion is of the order of 200 cm^{-1}, the first excited state $^6H_{7/2}$ can be populated at room temperature. Thus in the lower temperature range, the decrease of the $\chi_M T$ value results from both the multiplet splitting and Stark splitting. At 300 K, the ${\chi_M}^{Sm}T$(IM) and ${\chi_M}^{Sm}T$(pybzim) values are 0.82 and 0.45 cm^3 K mol^{-1}, respectively. These values are slightly larger than the expected values of ${\chi_M}^{Sm}T$(IM) and ${\chi_M}^{Sm}T$(pybzim). This deviation from the theoretical values may be responsible for the crystal field effect. The difference value $\Delta{\chi_M}^{Sm}T$ (0.37 cm^3 K mol^{-1}) is close to the expected value for an uncorrelated $S = 1/2$ spin for IM2py at 300 K, and is almost constant above 100 K. The profile with a gradual increase of $\Delta{\chi_M}^{Sm}T$ below 100 K results from the ground state splitting by the crystal field, but not necessarily from the ferromagnetic interaction.

3.2.3. Tb ($4f^8$) to Yb ($4f^{13}$) complexes

$\chi_M T$(IM) for a series of [Ln(hfac)$_3$(IM2py)] complexes (Ln = Tb–Yb) (Fig. S1) decreases on lowering the temperature. For the Yb complex, ${\chi_M}^{Yb}T$ (IM) (2.71 cm^3 K mol^{-1}) at 300 K is close to the sum of the expected $\chi_M T$ values for uncorrelated Yb(III) and IM2py spin, and decreases to attain 2.50 cm^3 K mol^{-1} at 2 K. The ${\chi_M}^{Yb}T$(pybzim) value for the pybzim complex also decreases on lowering the temperature (Fig. 4). Though the first excited $^2F_{5/2}$ state of Yb(III) ion can be fully depopulated, the contribution arising from the thermal depopulation of the Stark sublevels is relatively large. However, the decreasing slope of ${\chi_M}^{Yb}T$ (pybzim) is more gradual than that of [Yb(hfac)$_3$(IM2py)], and ${\chi_M}^{Yb}T$ (pybzim) is 1.41 cm^3 K mol^{-1} at 2 K, which is larger than ${\chi_M}^{Yb}T$ (IM). The difference value $\Delta{\chi_M}^{Yb}T$ gradually decreases on lowering the temperature. The profile of $\Delta{\chi_M}^{Yb}T$ also shows different behavior from that of the Nd(III) or Sm(III) complexes (Fig. 4). The variation of $\Delta{\chi_M}^{Yb}T$ is relatively large compared with that of the Nd

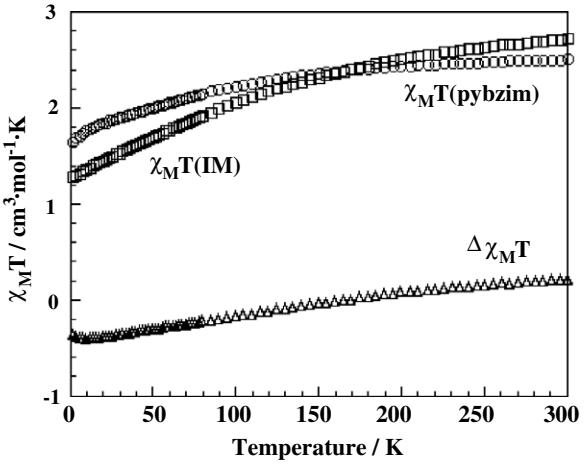

Fig. 4. Temperature dependence of χ_MT(IM) (□), χ_MT(pybzim) (○) and $\Delta\chi_M$T (△) for Yb(III) complexes.

or Sm complexes. Therefore, it is likely that the interaction between the Yb(III) ion and IM2py is antiferromagnetic.

The Tb(III) complexes give more remarkable behavior (Fig. 5). The $\chi_M{}^{Tb}T$(pybzim) value is 11.6 cm^3 K mol^{-1} at 300 K, which is close to the theoretical value of the Tb(III) free ion. At lower temperatures, the values gradually increase to attain 11.8 cm^3 K mol^{-1} at around 50 K. The larger $\chi_M{}^{Tb}T$(pybzim) value at lower temperature is attributed to the contribution of the thermal population in the ground $^7F_6$ state for Tb(III) in contrast to Eu(III) with the non-magnetic $^7F_0$ state (vide infra). On the other hand, the $\chi_M{}^{Tb}T$ (IM2py) value is 12.6 cm^3 K mol^{-1} at 300 K and then the gradual decreases are observed as the temperature is lowered. The temperature dependent $\Delta\chi_M{}^{Tb}T$ also tends to decrease at lower temperatures (Fig. 5). This apparently indicates that the magnetic interaction between the Tb(III) ion and IM2py is antiferromagnetic.

The Dy ($4f^9$), Ho ($4f^{10}$) and Er ($4f^{11}$) complexes exhibit higher $\chi_M{}^{Ln}T$ (pybzim) than $\chi_M{}^{Ln}T$ (IM2py) or a decrease of $\Delta\chi_M{}^{Ln}T$ (IM2py) at lower temperatures (Figs. S2–S4), but for the Tm complex, $\Delta\chi_M{}^{Tm}T$ (IM2py) increase on lowering the temperature (Fig. S5). Thus the magnetic interaction in the Ln–IM2py complexes with more than seven 4f electrons is antiferromagnetic, except for Tm whose magnetic properties could not be definitely determined.

3.2.4. Eu ($4f^6$) compound

As shown in Fig. 6, both $\chi_M{}^{Eu}T$(IM2py) and $\chi_M{}^{Eu}T$-(pybzim) decrease with a lowering of temperature, similar to the magnetic behaviors of the Tb–Yb complexes. The profile of $\Delta\chi_M{}^{Eu}T$ shows a decrease at lower temperatures, but the magnetic interaction between the Eu(III) ion and IM2py is not necessarily considered to be antiferromagnetic, as in the case of the other Ln–IM2py complexes, since the lowest level in the ground state of Eu(III) is non-magnetic ($^7F_0$). It is found that the $\chi_M{}^{Eu}T$(IM) value of [Eu(hfac)$_3$(IM2py)] is close to that of the isolated unpaired spin of IM2py at low temperature, as shown in Fig. 6. According to the theoretical model for the non-magnetic ground state, having no Stark sublevel in Eu(III) [23], the magnetic properties of [Eu(hfac)$_3$(IM2py)] can be estimated in terms of the temperature dependent magnetic behavior of [Eu(hfac)$_3$(pybzim)]. For the uncorrelated spin system of [Eu(hfac)$_3$(IM2py)], the $\chi_M{}^{Eu}T$(IM) value is expressed as $\chi_M{}^{Eu}T(\mathrm{IM}) = \chi_M{}^{Eu}T(\mathrm{pybzim}) + \chi_M T(\mathrm{IM2py})$. At 2 K, the observed $\chi_M T$ value is similar to the theoretical value of the $S = 1/2$ unpaired spin in IM2py. This confirms no intermolecular magnetic interaction as well as no intramolecular interaction in the Eu–IM2py complex. This is somewhat different from the magnetic behavior in [Eu(NO$_3$)$_3$(NITtrz)$_2$] at lower temperature, which is responsible for the intraligand (NIT–NIT) antiferromagnetic interaction [10a]. At higher temperatures, the $\chi_M{}^{Eu}T$ (IM) values are larger than the sum of the uncorrelated values for the system ($\chi_M{}^{Eu}T$(pybzim) + $\chi_M T$(IM2py)), or $\Delta\chi_M{}^{Eu}T$ increases with increasing temperature. This increase may be responsible for the difference in crystal

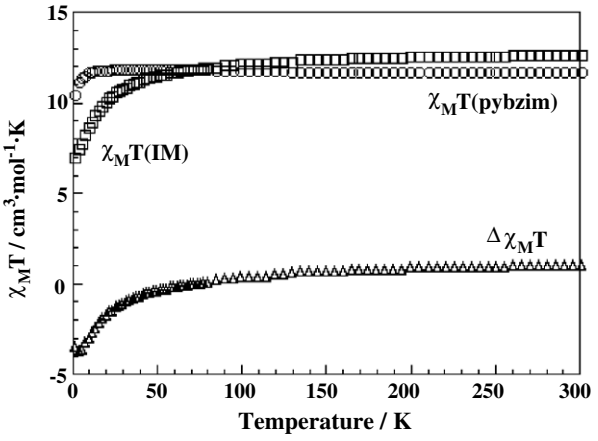

Fig. 5. Temperature dependence of χ_MT(IM) (□), χ_MT(pybzim) (○) and $\Delta\chi_M$T (△) for Tb(III) complexes.

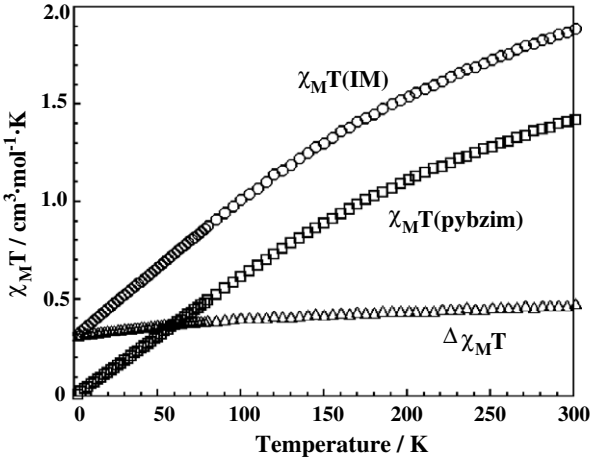

Fig. 6. Temperature dependence of χ_MT(IM) (□), χ_MT(pybzim) (○) and $\Delta\chi_M$T (△)for Eu(III) complexes.

Table 4
Nature of the magnetic interaction between Ln(III) ions and some radical ligands

Ln(III)	Nd	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	Ref.
Aminoxyl	AF	AF	ND	F	F	F	F	ND	ND	ND	[10a]
Semiquinone	ND	ND	ND	AF	ND	ND	AF	ND	ND	F	[15c]
IM2py	ND	ND	ND	AF	AF	AF	AF	AF	ND	AF	this work

AF = antiferromagnetic; F = ferromagnetic; ND = not determined.

field between the IM2py and pybzim complexes, but not for the ferromagnetic interaction between an IM2py radical and the excited $^7F_1$ state in Eu which is populated at higher temperature at the expense of the depopulation of the non-magnetic ground $^7F_0$ state.

In summary, from the temperature dependence of $\Delta\chi_M{}^{Ln}T$ in a series of [Ln(hfac)$_3$(IM2py)] complexes, the Ln–IM2py interaction is antiferromagnetic for the Ln complexes with more than seven 4f electrons, from Tb to Yb, except Tm. This is exactly the reverse behavior to that found for the Ln–NIT complexes with more than seven 4f electrons [10] as summarized in Table 4. Thus, Kahn's approach is also applicable to the present Ln–IM2py complexes. However, for the Ln–IM2py complexes with less than seven 4f electrons (Ln = Nd, Sm and Eu), the magnetic interaction seems to be negligibly small as compared with the difference in crystal field between the pybzim and IM2py complexes.

4. Conclusion

The simpler two spin system of the mono(IM2py) Ln complexes rather than the three spin systems of the bis (NIT type) radical Ln complexes provides more reliable elucidation of the nature of the magnetic interaction in a series of paramagnetic Ln(III) complexes with a radical ligand, without involving interligand nitroxide radicals interactions which were estimated to be comparable to the intramolecular Ln–NIT interaction in the latter case [10a]. This is the first series for a reverse case to the nature of the magnetic interaction for the aminoxyl radical complexes with more than seven 4f electrons, whereas the semiquinone Ln complexes show only few examples for such a reverse case [15c], as shown in Table 4. It is noted that the chelate ring of IM2py in the IM2py complexes is planar, in common with that of the semiquinone ligands in the semiquinone Ln(III) complexes, and in contrast to the NIT2py complexes with non-planar rings. Such a difference in planarity of the chelate rings may result in the reverse magnetic behavior between the IM2py and NIT2py radical complexes, which were discussed for the IM2py and IM2imH Gd(III) complexes in relation to the orbital orthogonality between the 5d orbitals of Gd and SOMOπ^* orbital of the IM radical [2a,2c], in analogy to the case of IM2py and NIT2py Ni(II) complexes [4]. This notion may give some hint in revealing the nature of the magnetic interaction in radical lanthanide(III) complexes.

Appendix A. Supplementary material

CCDC 627506 contains the supplementary crystallographic data for [Gd(hfac)$_3$(pybzim)] in CIF format. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. The temperature dependence of the experimental χ_MT values of [Ln(hfac)$_3$(IM2py)] (Ln = Tb–Yb) (Fig. S1), χ_MT(IM), χ_MT(pybzim) and $\Delta\chi_M$T of Dy(III), Ho(III), Er(III) and Tm(III) complexes (Fig. S2-S5) are available free of charge via the Internet. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.02.024.

Abstract

The one-dimensional linear polymer W–Se–Ag compound $\{[Et_4N][(\mu\text{-}WSe_4)Ag]\}_n$ (**1**) was obtained from the reaction of $[Et_4N]_2[WSe_4]$ and $AgNO_3$ in a mixed solvent, MeCN/DMF (1:10). Treatment of a solution of **1** in Me_2SO with $Ln(NO_3)_3 \cdot 6H_2O$ resulted in the formation of a helical chain polymer compound $\{[Ln(Me_2SO)_8][(\mu_3\text{-}WSe_4)_3Ag_3]\}_n$ (Ln = Pr **2**, Er **3**). The solid-state structures of the three polymer compounds **1**, **2**, and **3** have been established by X-ray crystallography. The third-order non-linear optical properties of the linear polymer compound **1** were determined by *z*-scan techniques with 7 ns pulses at 532 nm.
